THE REGULARITIES OF FORMING AND MODELLING THE MICROSTRUCTURE AT THE EARLY STAGES OF CEMENT STONE HARDENING

Alexander V. USHEROV-MARSHAK, Victor P. SOPOV, State technical University of Building and Architecture, Kharkov, Ukraine, Valery I. KONDRASCHENKO, State Academy of railway transport, Kharkov, Ukraine

ABSTRACT The structure of cement stone has been classified in consideration of physical-chemical interaction of solid, liquid and gaseous phases. There has been done analysis by the method of thermoporometry, and regularities of microstructure development under the hardening of cement and its minerals were found. The model of the formation of cement stone structure has been computerised along with the graphical, stage-by-stage representation of the results of modelling.

KEY-WORDS: Calorimetry, Pore structure, Porosity, Structure, Temperature, Thermodynamics.

INTRODUCTION

Formation of the structure of a typical capillary-porous material (that of cement stone) takes place in the process of the complex interaction of hydration of solid, liquid and gaseous phases. It is, therefore, difficult to estimate the microstructure quantitatively. The availability of the very quantitative characteristics is principal for analysis of the properties of materials based on cement.

STRUCTURE OF CEMENT STONE.

The complication of the process of binding materials hydration, instability of a hardening system and continuous changing of phase constitution present difficulties in the studying of the structure and those of the process of its formation. The formation of the structure under the hardening of the cement paste is the process of development of polydispersed and polymineral systems. The true concept of it is based on the geometrical structure evolution and conversion of phases in hardening cement. Classification of the cement stone structure presumes the presence of several levels of the latter. This is conditioned by shapes and sizes of particles, their state of aggregation as well as by their location. Solid and liquid phases and porosity can be considered as the basic elements of the structure. As a result of analysis of the data given by literature, the classification of the structure of cement stone has been proposed (Fig 1). It emphasizes two structural levels: microstructure - the one of colloidal size (less than 10^{-7} m), and macrostructure (greater than 10^{-7} m). The increase of the number of molecules on the interphase surface and, consequently, the excess of free energy are characteristic for the first level. This influences significantly the changes in the properties of the cement stone. The size of cement hydrates belongs to this level. The structure of the products of hydration has not been well-explained. The reason for that is morphological variety of hydratied species and the many factors which influence formation of the structure. Development of the notion of the cement stone structure is due to the modelling (Garboczi and Bentz, 1991, van Breugel, 1992), when liquid phase and porosity have been considered as primary factors.

Methodologies including different impacts upon experimental material (pressure, dehydration-saturation, etc) are used for research of porosity of cement stone within a wide range of pores sizes. The method of thermoporometry (Brun et al., 1973, Usherov-Marshak and Sopov, 1994) is based upon the thermodynamical estimation of phase transitions of porous water under process of freezing

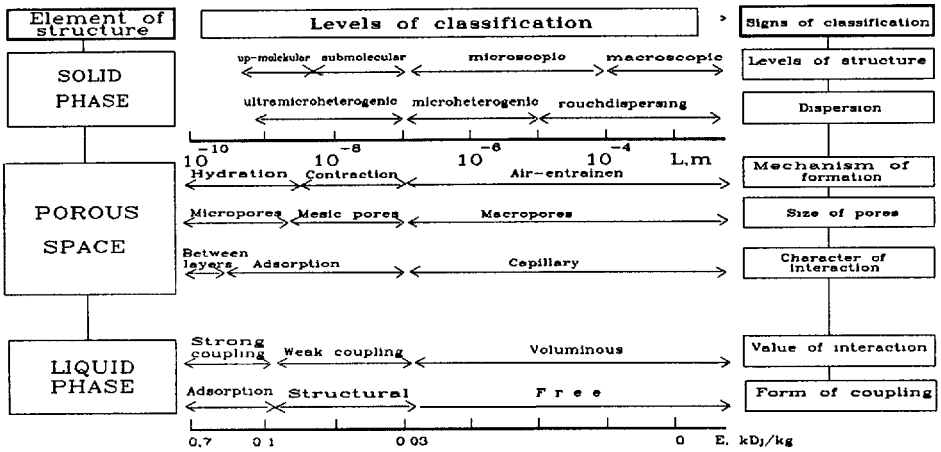

Figure 1 Classification of the cement stone structure.

of cement stone and, therefore, exludes coercive errors. The thermodynamically allowable transition from overcooled liquid to a crystal becomes possible only when a nucleus of the size greater then r_{cr} has been formed. The nucleus in porous materials can not reach its critical size under $t_0=0^0C$. It is originated in pores of the size corresponding to that of the critical nucleus under temperature t less than t_0. The temperature of crystallization and radius of pore are related by the equation:

$$\frac{1}{r} = \frac{1}{2\gamma}\int_{T_0}^{T}\frac{\Delta S}{V_l}dT, \qquad [1]$$

where: γ- free surface energy at the boundary between solid and liquid phases; V_1- molar volume of porous water; ΔS- changes of the entropy of crystallization; T- temperature of crystallization. Temperature of crystallization has been taken by the method of Differential Scanning Calorimetry. The cement stone samples of 10-50 mg of mass have been placed in alluminium air-tight capsules. The process of their cooling took place with the rate of 0.5 ^{0}C/min within the temperature range of +20...-60 ^{0}C. Liquid nitrogen was used as the cooling agent. A typical DSC plot is shown in Fig.2.

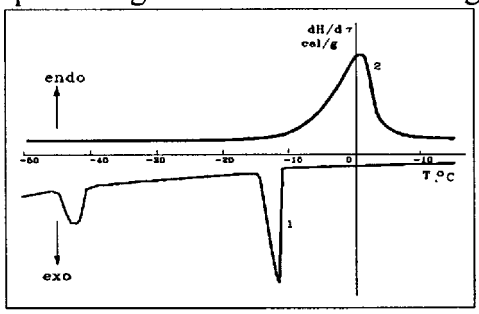

Figure 2 Typical DSC-curve of freezing 1 and thawing 2 for cement stone

TRICALCIUM SILICATE

Formation of the porous structure during the process of hardening of tricalcium silicate is conditioned by the originating and growth of amorphous calcium hydrosilicates of CSH- type. At the early stages, the number of hydrated phases is not substential. Calcium hydrosilicates grow among the particles of C_3S in the form of long fibres, together with thin plates of calcium hydroxide.The fibres of the hydrosilicates create space links. At this stage, an area of distribution of micropores by size from 7 to 12 nm is observed. New hydrates are continuously formed in micropores filled with water, so that the volume and size of pores decrease. The presence of two areas is noted on the second day: distribution of micropores by size is ranged from 2 to 2,5 nm in the first one, that in the

other is from 5,2 to 7,5 nm (Fig 3). Changes of micropores cause the decrease of size of hydrated phases located within. According to Locher and Richartz (1976) fibres of calcium hydrosilicates are on the first day 5-10 nm long with diametre of 0,1 - 0,2 nm. The size of the inner pores of fibrous hydrosilicates is approximately 2-2,5 nm. Primary calcium hydrosilicates are encrusted with the new ones and calcium hydroxides. Integrated microporosity of the hardening tricalcium silicate decreases from 0,21cm^3/g (Fig 3) - on the first day, to 0,043cm^3/g - on the 48th day. The most intensive changes of microporosity are observed during the first seven days. The volume of micropores decreases twice if compared to the specimen which was hardening in one day. During later terms - up to 48 days - changes in the micropores volume are insignificant.

ALUMINATE PHASE

Formation of microporosity of hydroaluminate and hydrosulphoaluminate phases differs substantially in character from that of calcium hydrosilicates. Their structure is conditioned cheifly by mutual location and size of the crystalls of the stable C_3AH_6. Microporosity of the hardening C_3A is characterised by the presence of an area of micropores ranged from 4 to 17 nm. Location and boundaries of microporosity are changing in the process of hydration. The total volume of micropores is decreasing from 0,56 cm^3/g (Fig 3) to 0,06 cm^3/g within 7 days. The main change is taking place during the first day. The following changes of the volume are caused by transformation of hexangonal hydroaluminates of C_4AH_{13} - type to cubical C_4AH_6. The change of the total volume of micropores C_4AF from 0,61 cm^3/g to 0,1 cm^3/g is obvious. Two areas of micropores in the interval of 9,5-17 nm are formed at the early stages. Later on they come closer and the interval of distribution of micropores narrows to 8 - 12 nm (Fig 3).

CEMENT STONE

Formation of the structure of cement stone is obviously more complicated because of development and interaction of hydroaluminate and hydrosilicate phases. Microporosity of cement stone was studied for three kinds of cement of different compositions. The results of the studying are presented by Fig.3.

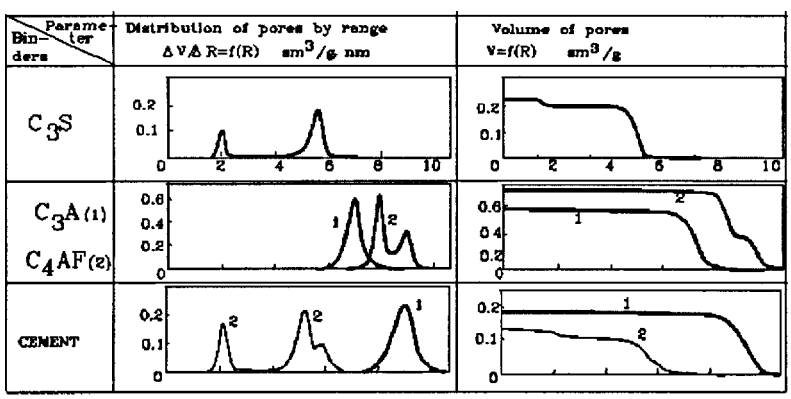

Figure 3 Microporosity of cement stone

Variations in the character of microporosity have been found (Fig.3). An area of distribution of range from 7 to 13,7 nm is observed when the presence of aluminate phase increases. Its width and location change as the process of hydration goes on. At the beginning, it is located in the range from 10-13,7 nm. By the end of the first day, its shifting to the area of range from 7,3 to 9,3 nm is observed. The total volume of micropores decreases three times. Two areas of distribution of micropores by size ranged between 2-10 nm are observed when the presence of aluminates decreases

and that of silicates increases. Cement stone of the increased content of β-C_2S (up to 30%) has an area of distribution of micropores ranged between 12-14,5 nm. Changes in the size of micropores during hydration are caused by the changes of morphology of new products. At the early stages - up to the end of the first day, the area of distribution of micropores is conditioned by aluminated phases. Development of microporosity is probably connected to destruction of the primary hydrosulphoaluminated carcass, to the process of origin and growth of smaller hydrosilicate phases which, in their turn form pores of smaller size (Usherov-Marshak and Sopov, 1995). The total volume of the micropores increases almost two times under the nonsignificant growth of aluminates content: of C_3A - up to 2,5% and of C_4AF - up to 2%. The decrease of pores size is conditioned by the acceleration of the processes of hydration of cement under the growth of content of aluminates. The structure of cement stone (Fig 3) represents hydrosilicate gel (pores size - 2- 4 nm) and phases of hydroaluminates, hydrosulfoaluminates, calcium hydroxides (pores size - 6-8 nm).

MODELLING OF STRUCTURE

The primary structure is represented by particles of irregular shape which are located randomly on a plate of unit thickness. Formation of the structure is conditioned by the changes of the size of each particle. The rate of changes in the particles size is computed by data of thermokinetic analysis. The basic elements of the structure are particles of cement which have not reacted, CSH-, AFm- and CH-phases and porous space of two types of pores. Interparticle porosity is estimated by the model. Porosity of CSH is determined by thermoporometry. Formal equations of particles size changings are set by structure-imitating analysis. The quantitative characteristics (size, volume, shape of pores, number of contacts, etc.) of the cement stone structure have been determined. The modelling data correlate with that done by Jennings and Tennis (1994). Modelling of the process of hardening of cement stone verified the validity of kinetic schemes of changings of crystalline and amorphous structures of hydrates.

CHARACTERISTICS OF C-S-H GELS

Michael GRUTZECK, Judith LaROSA-THOMPSON and Stephen KWAN, Materials Research Laboratory, The Pennsylvania State University, University Park, PA 16802 U.S.A.

ABSTRACT Data are presented which reinforce a two phase model for the structure of calcium silicate hydrate (C-S-H). Recent ^{29}Si MAS NMR data on the nature and number of silicon's nearest neighbors in a variety of C-S-Hs suggests that 1.4nm tobermorite is a suitable model phase for C-S-H having C/S ratios ranging from 0.6 to 1.0, but not for the C-S-H normally associated with hydrated cement and concrete (C/S≥1.1). These C-S-Hs are better described as Ca-deficient derivatives of a sorosilicate-like phase having the general formula $Ca_4Si_2O_7.(OH)_2 \cdot xH_2O$.

Key-Words: CSH, C-S-H, Hydration, Structure, Nuclear Magnetic Resonance

INTRODUCTION

Calcium silicate hydrate (C-S-H) is an ill defined, cryptocrystalline material which, for want of a better descriptor, is often described as having gel-like characteristics. C-S-H develops as a function of time as anhydrous clinker phases found in portland cement react with water to form a characteristic network of interlocking plates and foils. Because of its gel-like character, the crystal chemical structure of C-S-H is not yet fully understood. Nevertheless, as a binder and matrix phase present in cementitious materials such as grouts, mortars and concrete, C-S-H has literally become the foundation of modern civilization. Portland cement is a readily available, rather inexpensive building material, which is adaptable for use under a wide variety of weather conditions and is relatively free of problems once placed in service. When the anhydrous clinker phases are mixed with water, the resulting slurry transforms into a solid. Although the physical and mechanical properties of cementitious materials are well documented, questions concerning the chemistry and potential chemical interactions of C-S-H with its environment (durability) still remain to be answered. If the structural model for C-S-H and its chemical performance were better understood, there is a strong possibility that long term performance could be increased and that the practice of over designing concrete structures for safety purposes might be better quantified.

The literature speaks of C-S-H as a single phase akin to a solid solution having a structure similar to tobermorite in which a fully occupied layer of CaO molecules are sandwiched between layers of silicate dreirketten. As the C/S ratio of the C-S-H increases from 0.6 to 1.7, it has been suggested that additional Ca ions are accommodated in the interlayers between small bits of randomly oriented layers of tobermorite-like material. An HOH molecule is replaced by CaO along an edge of a bridging tetrahedron for every incremental increase in C/S ratio. When fully loaded with Ca in interlayer positions (C/S≈1), it is then suggested that individual bridging tetrahedra are removed from the dreirketten, which has the effect of increasing the C/S ratio. The two most widely accepted models for single phase C-S-H have been promoted by Taylor (1990) and more recently Richardson and Groves (1992). In terms of substitution theory the models are related, but Taylor goes a bit further and also suggests that the single phase C-S-Hs seen in cementitious materials may actually be comprised of a mixture of nanosized bits of two different structures, structures possibly related to tobermorite and jennite. Unfortunately, at least in terms of recent ^{29}Si MAS NMR data for these mineral analogues, neither structure contains dimer. Both are made up of layers of dreirketten, and thus they can not be used to account for the extensive amount of dimer present in most C-S-Hs. Because of these inconsistencies, it is proposed that C-S-H is actually better described by a two phase model which embraces the idea of two atomic level structures rather than one.

Studies by Stein (1972), Stade and Wieker (1980), Stade (1980), Ramachandran and Grutzeck (1993), Grutzeck et al. (1989), Kwan et al. (1996) and others have suggested that two C-S-H phases rather than one might actually exist. Recent fixed pH studies in the system $CaO\text{-}SiO_2\text{-}H_2O$ and more recently $CaO\text{-}Al_2O_3\text{-}SiO_2\text{-}H_2O$ (Kwan and Grutzeck, 1994) coupled with morphologic investigations show that there is a distinct and sharp boundary occurring at a

CaO/SiO_2 ratio of ~1.0. If one goes through the exercise of recalculating Flint and Wells' (1934) and Roller and Ervin's (1940) data as a function of pH, these too suggest a discontinuous change at about C/S = 1. The observed discontinuities indicate that two distinct phases are present (invariant situation) and as one moves through the composition range represented by the discontinuity one C-S-H phase is replaced by another, the latter having a lower free energy of formation. Fig 1a represents a schematic representation of the phase relations in the system CaO-Al_2O_3-SiO_2-H_2O containing a single C-S-H. In constructing this figure, the compositions of the hydrated phases have been projected onto the anhydrous base of the system. Fig 1b represents the same system but it contains two C-S-Hs instead of one. Note that the figures are not that different in appearance because, the only significant change was to increase the number of C-S-H phases to two and add an invariant triangle between them.

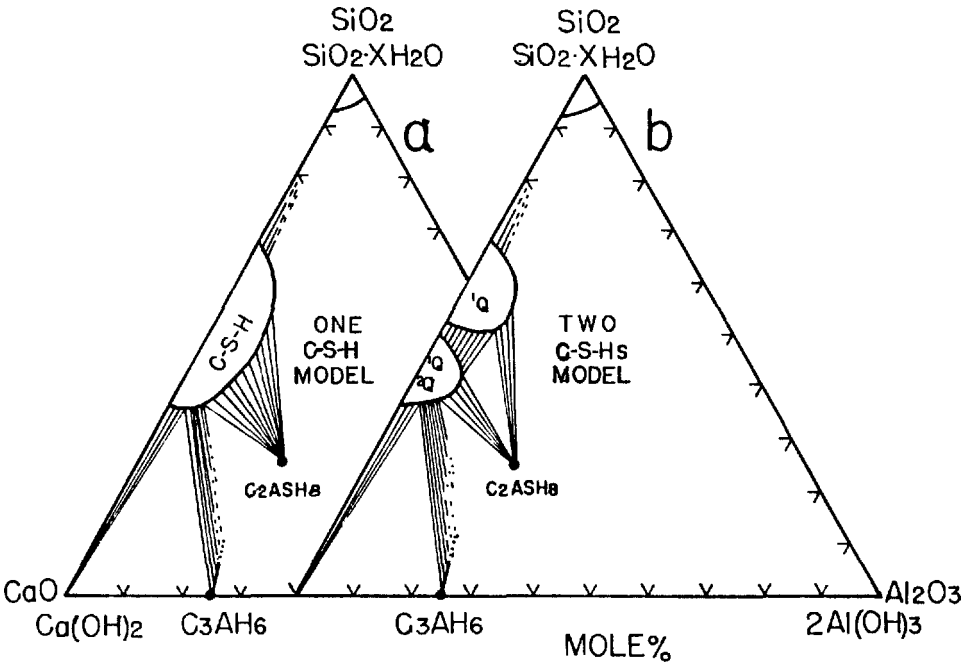

Figure 1 Schematic phase diagrams for the system CaO-Al_2O_3-SiO_2-H_2O showing the extent of a single C-S-H phase field (view a) and two C-S-H phase fields (view b).

The two C-S-H concept which is the topic of the current paper was an outgrowth of recent ^{29}Si MAS NMR data for C-S-H precipitated from lime silica slurries. The spectra given in Fig 2 are typical of the C-S-Hs studied. They represent data for 3 samples taken from either side of the proposed invariancy. Some data have been reported previously (Kwan et al., 1994) and four are taken from Kwan's Ph.D. thesis (1995). The spectra are for C-S-H samples containing 10 wt.% Al_2O_3 and reported upon later in the text. The spectra from either side of the discontinuity suggest that something out of the ordinary happens as one moves across the C/S 1.0 to 1.1 ratio of compositions. There is a noticeable jump in the Q^1/Q^2 ratio as one moves from the silica-rich group of three identified as 23-57.5, -52.5, and -50, to the calcium-rich group of three identified as 23-40,-35,-30.[1] A similar discontinuity is also reflected in the data of Cong and Kirkpatrick (1996). For discussion purposes, these data have been plotted as a compendium of ^{29}Si MAS NMR spectral data for C-S-H as a function of their Q^1/Q^2 ratios in Fig 3. Data points falling in the C/S range of 1.0 to 1.1 (stippled area) have been plotted, but not included in calculations of the best fitting straight lines representing the points. These points have been omitted because they fall within the invariancy and are thus a combination of both C-S-H phases. In toto, the data suggest the presence of a discontinuity occurring over the C/S ratio of 1.0 to 1.1.

[1]Throughout the paper a series of mind experiments are carried out in which Ca is gradually added to or subtracted from the structure. The experiments are akin to visualizing the structural consequences of a small change in composition, a change that in the thermodynamic sense does not change the state of equilibrium.

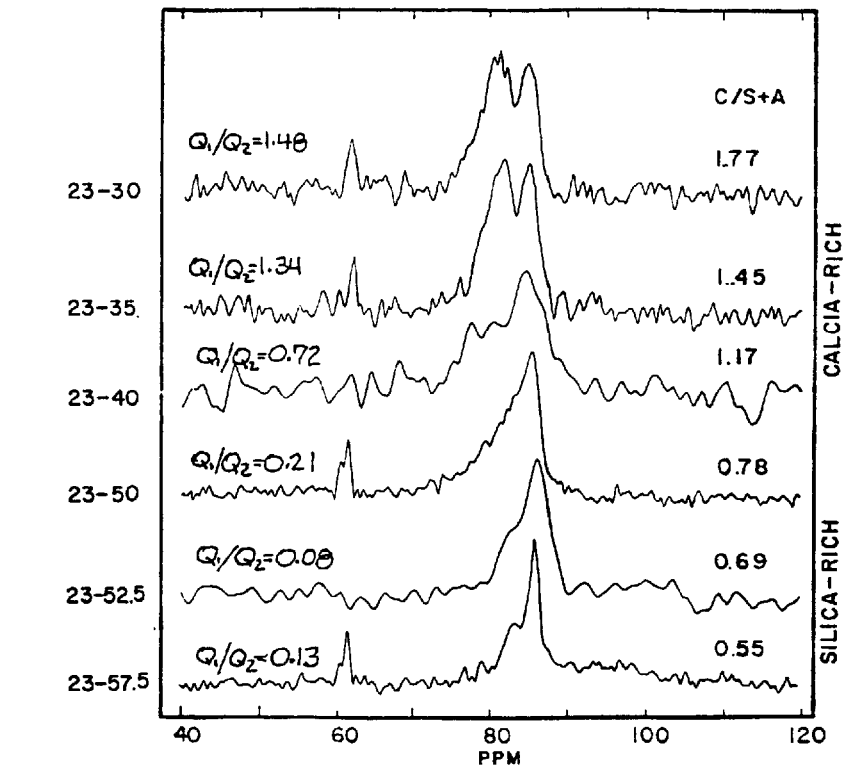

Figure 2 MAS NMR data for 6 mixtures highlighted in Fig. 3. Q^1/Q^2 ratios for each spectrum were calculated and are plotted beside their respective spectra.

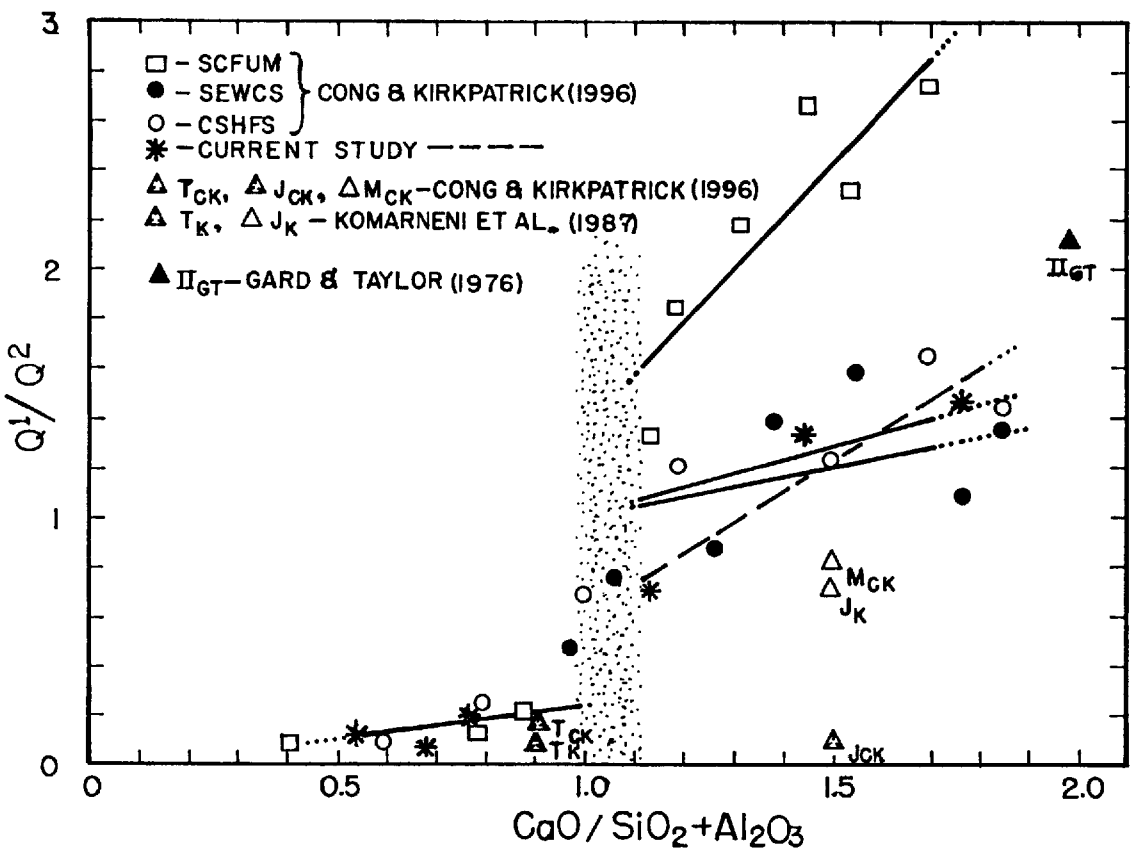

Figure 3 Plot of Q^1/Q^2 ratios for various C-S-H and related samples. Compared to Cong and Kirkpatrick's short term lime-silica data (SCFUM), the plot for our Ca-rich samples is offset to lower Q^1/Q^2 values. Our data are more in keeping with their dicalcium silicate data. Apparently lime-silica samples take longer to equilibrate than dicalcium silicate containing samples.

EXPERIMENTAL METHOD

The purpose of the current paper was to provide confirmatory data for the two phase model, to show that a discontinuity does in fact exist in the systems under study and thus strengthen the two C-S-H theory. It was hypothesized that if two C-S-Hs do exist, they should have distinctly different properties and that the properties should fit the proposed model. Ramachandran and Grutzeck (1993) demonstrated that C-S-H had different dissolution behavior and different morphologies depending on which side of the observed invariancy in the lime-silica systems they took their samples. MAS NMR data also reflect the presence of a discontinuity (Grutzeck et al., 1989). Results for X-ray, TGA, BET surface area, and SEM measurements for the same C-S-H samples used to gather the original ^{29}Si MAS NMR C-S-H data plotted in Fig 2 are reported upon in this paper. The samples were prepared from suspensions of lime, colloidal silica and highly reactive alumina. After mixing with freshly boiled deionized water the samples were sealed in HDPE bottles, placed on a shaking table where they have received continuous room temperature agitation (60cpm) for 8 years. The samples span the C/(S+A) molar range 0.6 to 1.8. Samples were separated from solution via centrifuging followed by freeze drying prior to examination.

RESULTS

X-ray

X-ray data are given in Fig 4. Two aluminate phases were found in two mixtures (23-35 and 23-30). See Figure 4a. One is of the AFm type, most likely containing carbonate, the other is hydrogarnet. The C-S-H which is present in both groups is poorly crystalline as reflected by the presence of 4-5 peaks. In addition, all samples have a characteristic peak(s) in the 1.4nm region. See Fig 4b. These spectra are partial scans of the low angle peaks (3-10°2θ) of the C-S-Hs taken at 1/2 degree 2θ/minute. The 23-40, -35 and -30 samples have a hint of a bimodal distribution which changes with composition as Ca is added to C-S-H.

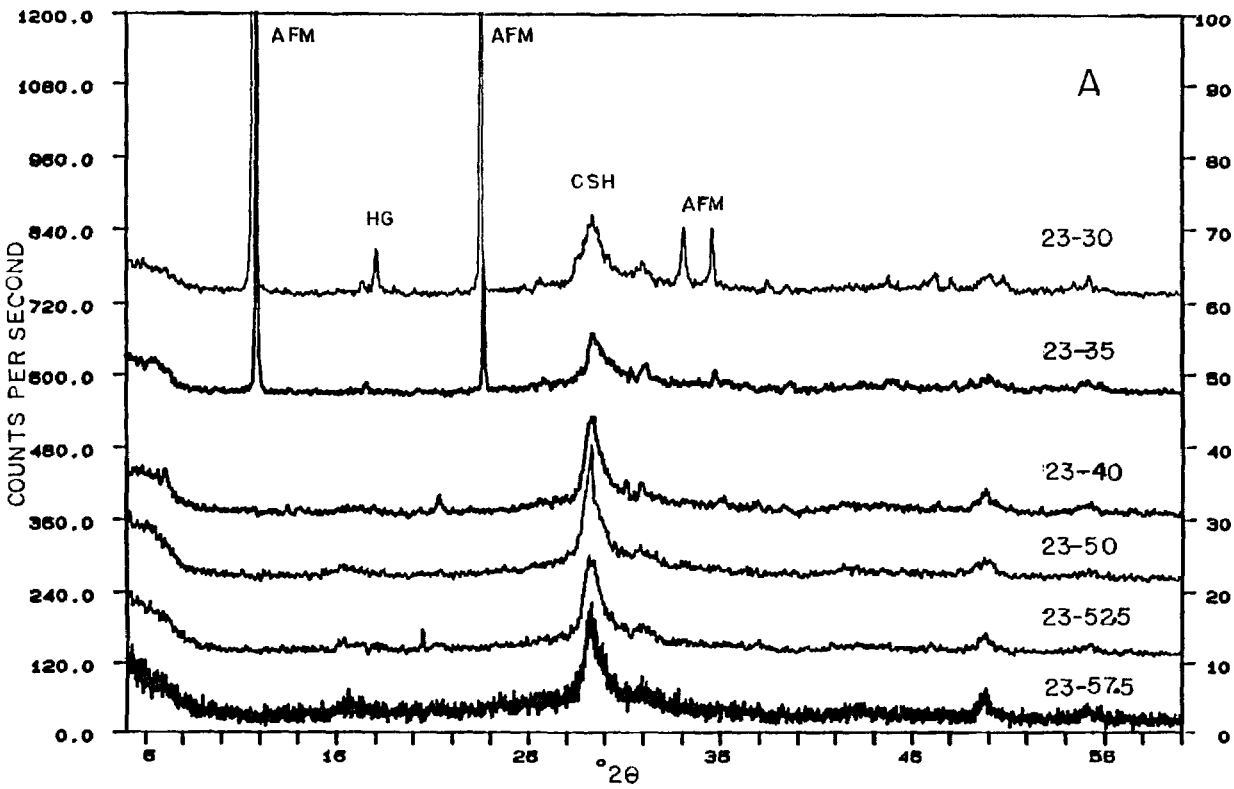

Table 1. Values of bimodal peaks present in lime-rich C-S-H X-ray patterns.

Mixtures	C/S	d-spacing (nm)
23-40	1.17	1.66, 1.32
23-35	1.45	1.49, 1.26
23-30	1.77	1.40, 1.26

On the other hand, the silica rich C-S-Hs have a single broad peak centered about 6.3°2θ which is equivalent to 1.4nm. The broad peak gradually decreases in height as more silica is added to the C-S-H. The 23-57.5 pattern has just a trace of the 1.4nm peak, suggesting that we are approaching its limit of stability. Overall, the consistency of all of the patterns (Figs 4a &b) indicates that the long range order of all the C-S-Hs is similar, which in turn suggests that the presence of dreirketten must somehow be preserved even in the very lime rich material. The single 1.4nm peak in the silica-rich samples reinforces the tobermorite-derivative model for these phases, but the bimodal distribution of the more lime rich material suggests that a different structure exists, a structure containing dimeric silicate intermixed with dreirketten which has a spacing close to that of tobermorite.

TGA

TGA data for the same samples are given in Fig 5. View 5a represents the original data collected in flowing air with a 10°C/min heating rate. Our interpretation of the behavior of samples 23-35 and 23-30 is that they contained some type of AFm phase and thus lost some water in the 200-400°C range. Of the 2, the 23-30 sample lost more water, which is consistent with the larger amount of AFM seen in the X-ray diffraction pattern. The presence of AFM was unexpected. However, by taking the remaining four curves as a model (each is rather smooth with a major weight loss up to 200°C followed by a less intense loss that gradually lessens up to 1000°C) one can then assume that the 200-400°C loss observed in 23-35 and -30 is due to AFM and thus it should be possible to sketch AFM-free equivalents of 23-35 and -30. In effect we have connected the initial and final parts of these 2 curves to produce the curves given in Fig 5b. The latter were used to calculate total weight loss at 1000°C for each C-S-H phase (see Table 2).

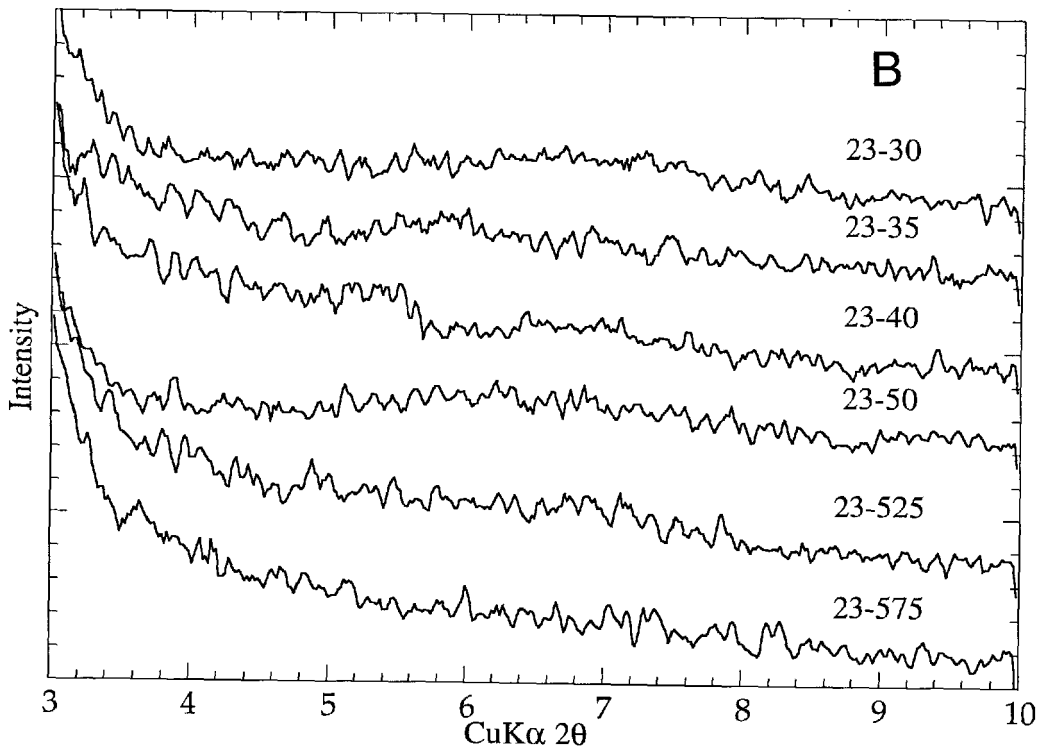

Figure 4 X-ray diffraction patterns of the 6 mixtures studied. View (a) = full pattern. View (b) = 3-10° 2θ.

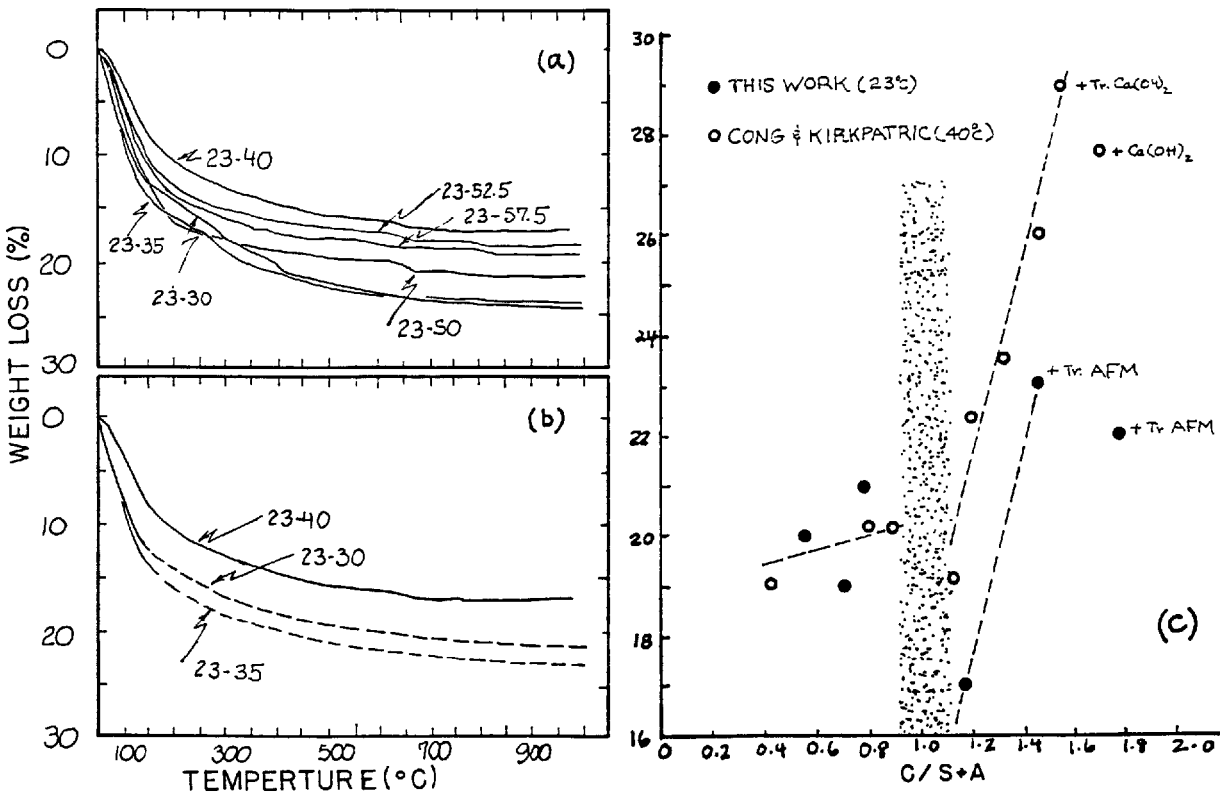

Figure 5 TGA data for the 6 mixtures studied. View (a) = raw data. View (b) = treated data. View (c) = plot of 1000°C weight loss versus C/(S+A).

Table 2. TGA weight loss of freeze dried samples at 1000°C

GROUP ONE (Si-rich)				GROUP TWO (Ca-rich)		
Mixture	C/(S+A)	wt.%		Mixture	C/(S+A)	wt.%
23-57.5	0.55	20		23-40	1.17	17
23-52.5	0.69	19		23-35	1.45	23
23-50	0.78	21		23-30	1.77	22

Plotting these data as well as those of Cong and Kirkpatrick (1996) as a function of C/S+A ratio (Fig 5c) one gets the impression that water content varies differently in the two groups. In the silica-rich C-S-Hs the water loss remains reasonably constant at 20wt.%±1. This would imply that the level of combined water in the C-S-H as C/S+A ratio varies from 0.6 to 1.0 is reasonably constant. As CaO enters interlayer sites, it is does so by displacing the equivalent one molecule of water. On the other hand, in the lime-rich C-S-Hs the water content seems to rise with increasing Ca content. This is reasonable behavior for the proposed Ca-deficient sorosilicate structure. As more Ca returns to the structure the dreirketten layers which had formed revert back to dimers and in doing so incorporate three additional water molecules for each Ca ion. Because dimer formation is linked to Ca^{2+} uptake as C/S increases from 1.1 to 1.7, the positive slope of the curve is justifiable. Note that Cong and Kirkpatrick's data mirror the same behavior as our data. In any case, the lime rich C-S-H contains more water than its silica rich counterpart. This has been observed in slurry systems produced with identical w/s ratios where samples of C-S-H >1.1 have formed "dry" powders whereas C-S-Hs having C/S ratios <1.0 have remained slurries.

BET Surface area

BET surface area data were collected on the identical freeze dried samples. The values for the six samples are listed in Table 3. Units are in square meters/gram.

Table 3. Surface area of freeze dried C-S-H samples.

GROUP ONE				GROUP TWO		
Mixture	C/(S+A)	m^2/g		Mixture	C/(S+A)	m^2/g
23-57.5	0.55	270		23-40	1.17	97
23-52.5	0.69	190		23-35	1.45	40
23-50	0.78	134		23-30	1.77	62

A plot of the data is given in Fig 6. Here more than anywhere else is the structural division between the two C-S-H phases most easily seen. The two straight lines intercept at C/S ~0.9, which is in keeping with the suggested location of the invariancy between the two C-S-H structures. There is however more scatter in the calcia-rich samples. Repeat measurements show that the value of 23-35 is always much lower than its neighbors. The cause of the low reading is not understood, but it may be more than coincidental that its C/S+A ratio is close to 1.5.

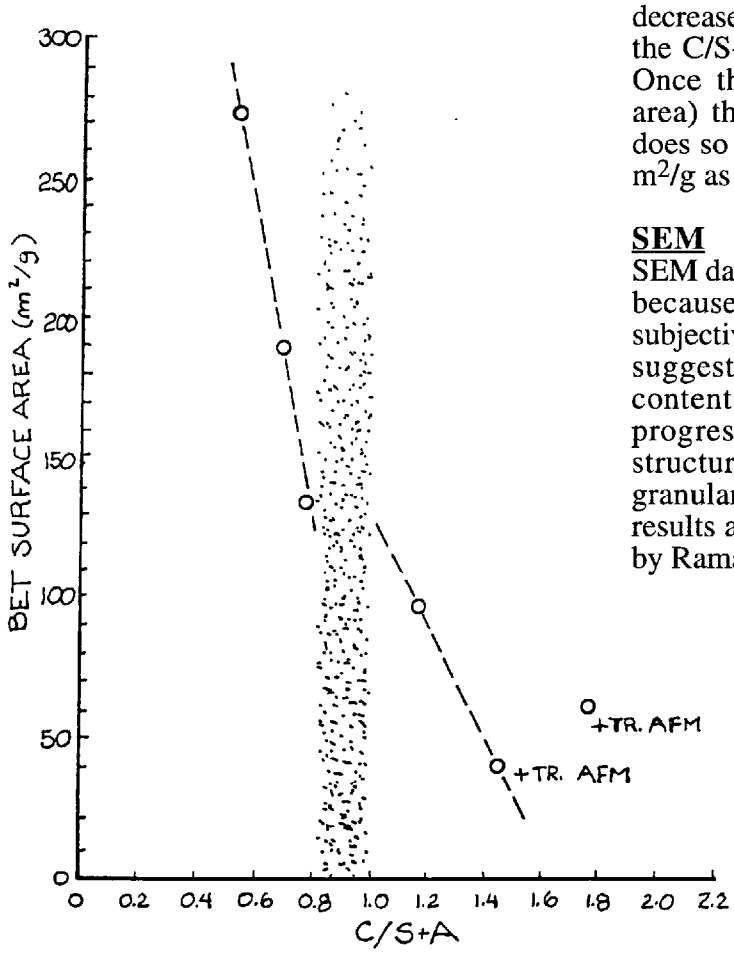

Figure 6. BET surface area of 6 C-S-H samples studied.

The surface area of the silica-rich C-S-Hs decreases almost 2 fold (270 to 130 m^2/g) as the C/S+A ratio increases from 0.6 to 2.0. Once the invariancy is crossed (stippled area) the surface area still decreases, but does so at a much lower rate, e.g. 100 to 50 m^2/g as C/(S+A) varies from 1.3 to 2.0.

SEM

SEM data are not as conclusive as other data because their interpretation can be quite subjective. Yet there seems to be a trend that suggests that, with increasing calcium content, the morphology of the C-S-H progresses from a very open foil-like structure to one which is denser, more granular, and more clustered looking. The results are similar to those noted previously by Ramachandran and Grutzeck (1987).

DISCUSSION

Apparently there are two C-S-Hs in the systems studied. This fact was suggested by an abrupt change in atomic level structure and chemistry of the coexisting solution phase. It was theorized that this discontinuity would also be reflected in other measured properties. Fortunately it has, but the picture is not yet entirely clear. Nevertheless, on the whole the experiment was a success. A discontinuous change first detected in ^{29}Si MAS NMR data was observed to occur in other properties as well. Using these findings, it is now possible to propose models for the two C-S-Hs described in this paper.

Silica-rich C-S-H

The high silica C-S-Hs reported in Fig 3 had C/S ratios ranging from 0.6 to 1.0. It is generally agreed that these C-S-Hs are tobermorite-derivatives probably consisting of layers of dreirketten with Ca^{2+} ions occupying more and more of the interlayer positions as C/S ratio increases from 0.6 to 1.0. This model is consistent with the current data and is essentially the same as other models in the literature. The Q^1/Q^2 ratios of the C-S-Hs are nearly constant (0.15 ± 0.05) as is the combined water content over this range of composition. The surface areas are extremely high and because there is no Q^3 present that can be attributed to C-S-H, these values suggest a lack of cross bonding between the interlayer silicate ions.

Calcia-rich C-S-H

At C/S $\geq$ 1.1 the C-S-H structure that forms has a Q^1/Q^2 ratio in the vicinity of 1 to 1.5 depending upon whether or not the system contained calcium silicate or lime, respectively (see Fig 3). This implies that the structure is radically different--now containing approximately 50% dimer and 50% dreirketten. Because jennite as well as tobermorite are composed of dreirketten chains (see plotted points from Komarneni et al., 1987, Cong and Kirkpatrick, 1996), where are the dimers coming from? One can shorten the chains only so much, but even a chain of 5 would have a Q^1/Q^2 ratio of 0.67. It is hard to fathom a complete disintegration of the tobermorite chain into one consisting mainly of dimers ($Q^1/Q^2 = \infty$), especially in light of TMS data which suggests the average chain length is around 8 (Taylor, 1990). The sorosilicate-derivative model we are proposing better accommodates ^{29}Si MAS NMR data as well as the data presented above. It is conceivable that amorphous gel-like precursors having sorosilicate structures similar to cuspidine [$Ca_4Si_2O_7(OH,F)_2 \cdot H_2O$] and lawsonite [$CaAl_2Si_2O_7(OH)_2 \cdot H_2O$] could form in cements. For example, if one replaces the fluoride ions in cuspidine with hydroxyl groups (which have identical sizes) one gets [$Ca_4Si_2O_7(OH)_2 \cdot H_2O$]. If one starts with lawsonite and replaces all of the aluminum ions in the octahedrally coordinated (AlOOH) layers with calcium, one also gets [$Ca_4Si_2O_7(OH)_2 \cdot H_2O$].

Sorosilicates normally contain dimers that are arranged in columns that radiate outward from a central octahedrally coordinated AlOOH/CaO layer with additional molecules of calcium hydroxide and H_2O occupying holes in the diametric portion of the structure (Liebau, 1985). In the calcium sorosilicate analogue we are proposing, we believe the dimers have three different orientations: parallel to, and at 30° and 120° angles to the central CaO layer forming a highly distorted diametric layer containing additional calcium ions. See Fig 7a for a schematic representation of the C/S=1.17 C-S-H end-member. Note that there are "holes" in the structure which can accommodate additional water and/or $Ca(OH)_2$ molecules. This arrangement is not inconsistent with Viehland et al., (1996) TEM data. The "secondary ring" (in their Figure 2a) is discontinuous, has a hexagonal/trigonal symmetry and a periodicity of ~0.18nm, which could be the repeat distance and spatial orientation of the $[Si_2O_7]^{-6}$ groups in the proposed sorosilicate structure.

By removing the molecular $Ca(OH)_2$ from the sorosilicate structure and replacing it with HOH, a predominantly Q^2 C-S-H with a C/S=1.5 can be obtained. Beyond that point continued removal of calcium down to C/S=1.1 causes the structure to become highly calcium deficient and as a result some of the dimeric layers between adjacent CaO layers are prone to collapse and convert to dreirketten; the sorosilicate has essentially "unzipped" to alleviate some of the instability and formed a tobermorite-like interlayer as depicted in Fig 7b.

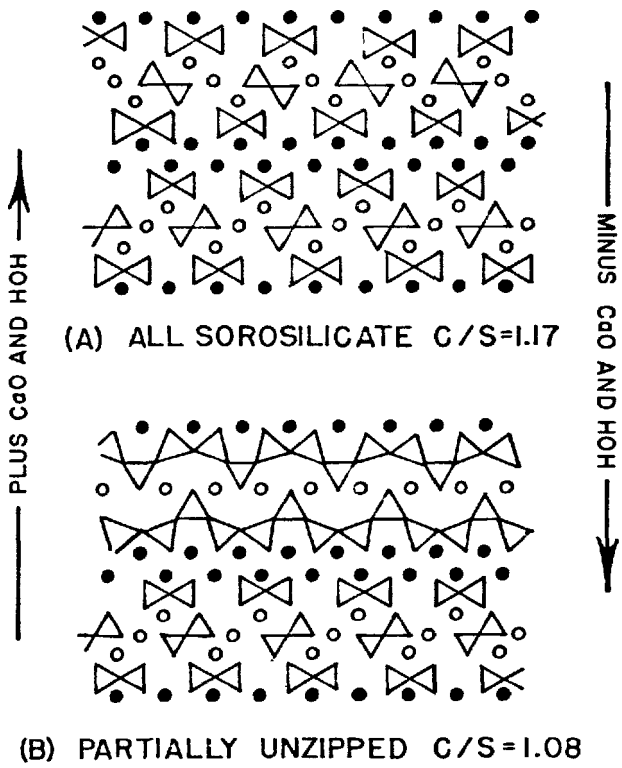

Figure 7. C-S-H structures. View (a) = sorosilicate C/S = 1.17. View (b) = partially converted sorosilicate C/S = 1.08.

The proposed sorosilicate structure would be extremely unstable under ambient conditions and thus constantly "teetering" on the verge of collapse. This would explain its extreme sensitivity to temperature and starting material composition. This sensitivity is clearly documented by Stade and Weiker's (1980) and Stade's (1980) work in which they demonstrate the existence of a completely dimeric C-S-H at 0°C. This preparation could be dried at -10°C, but it tended to "unzip" more and more as it was held at room temperature. They also found that the Q^1/Q^2 ratio of their calcia-rich C/S (1.1-1.7) C-S-H decreased with increasing temperature. Once again, the compositional variation exhibited by their di,poly C-S-H could be better explained in terms of a sorosilicate model rather than a tobermorite model.

In addition, a sorosilicate-derivative structure for C/S≥1.1 to 1.7 C-S-H seems to resemble Gard and Taylor's (1976) C-S-H (II) structure more so than a tobermorite in as much as it contained 68% dimer and 32% chains. See Fig 3. A sorosilicate-derived C-S-H also resembles Carpenter et al.'s first anionic structure for jennite (1966). Although they first suggested that jennite could contain $3[SiO_3]_n$ and Si_2O_7 units, in a subsequent paper (1977) Gard and Taylor suggest that jennite contains only dreirketten. If one plots Cong and Kirkpatrick's jennite on Fig 3 it would look very much like it falls on an metastable extension of the tobermorite-like C-S-H curve on the left side of the figure. What is even more interesting, however, are the locations of the points representing the stated Q^1/Q^2 ratios for Komarneni et al.'s jennite spectrum and Cong and Kirkpatrick's metastable intermediate phases. If one plots these, they are clearly more sorosilicate-like than tobermorite-like.

CONCLUSIONS

It is concluded that the observed discontinuous offset in the measured physical properties of C-S-H reflects a phase change in which C-S-H changes from a tobermorite-like structure to a sorosilicate-like structure. The latter structure is highly unstable (favoring low temperatures and high C/S ratios) and thus very sensitive to changes in composition and curing conditions. As both thermal and compositional instability increase, the dimers in the sorosilicate-like C-S-H will occasionally convert to "islands" of dreirketten similar to those shown by Viehland et al. (1996). Because C-S-H is normally heterogeneous, the phase change may often occur in what one may think is a random fashion. But there is a delicate balance between the two structures and either one can convert to the other based upon localized conditions. Given the instability of the sorosilicate structure, it now becomes rather easy to model the behavior of C/S≥1.1 C-S-H without invoking a tobermorite-derived structure (i.e. jennite).

THE STRUCTURE OF C-S-H IN HARDENED SLAG CEMENT PASTES

Ian G. RICHARDSON
CEMU, Department of Civil Engineering, University of Leeds, Leeds LS2 9JT, U.K.

ABSTRACT The C-S-H gels present in hardened pastes of alkali-activated blast-furnace slags of varying composition and of both water- and alkali-activated white Portland cement / slag blends have been characterised by solid-state ^{29}Si NMR spectroscopy and analytical TEM. All of the C-S-H gels, whatever their chemical composition or degree of structural order, have aluminium substituting for silicon only in the central tetrahedron of pentameric silicate chains. The results strengthen confidence in dreierkette-based models for the structure of C-S-H.

Key-words: C-S-H; Structure; NMR; TEM, Blastfurnace slag

INTRODUCTION

The Al/Ca ratio of the calcium silicate hydrate (C-S-H) gels in ordinary Portland cement (OPC)/blast-furnace slag blends increases linearly with increasing Si/Ca ratio (Richardson and Groves, 1992a, 1993a). This has been interpreted in terms of a model for the C-S-H gel structure in which the mean silicate chain length increases as the Si/Ca ratio increases, with Al substituting for Si at bridging sites of a 'dreierkette' chain structure (Richardson and Groves, 1992b, 1993b). The model may be represented as formula 1,

$$\left\{Ca_{2n}H_w\left(Si_{1-a}R_a^{[4]}\right)_{(3n-1)}O_{(9n-2)}\right\}\cdot I^{c+}_{\frac{a}{c}(3n-1)}\cdot(OH)_{w+n(y-2)}\cdot Ca_{\frac{n.y}{2}}\cdot mH_2O \qquad [1]$$

where if $0\leq y\leq 2$ then $n(2\text{-}y)\leq w\leq 2n$, if $2\leq y\leq 4$ then $0\leq w\leq 2n$, and if $4\leq y\leq 6$ then $0\leq w\leq n(6\text{-}y)$. The model is based on a tobermorite-like core (that part of formula 1 contained within the braces) and consists of a highly disordered layer structure comprising finite silicate chains of average length $3n$-1. In immature cement pastes dimer is the most abundant silicate species (n=1). These are linked during polymerization by bridging tetrahedra to form pentamer (n=2) and higher polymers. $R^{[4]}$ is a trivalent cation, mainly Al^{3+}, in tetrahedral co-ordination and I^{c+} is an interlayer ion, either a monovalent alkali cation or Ca^{2+}, charge-balancing the R^{3+} substitution for Si^{4+}. Aluminium is assumed to only substitute for Si in the bridging tetrahedra of the dreierkette structure; since there are n-1 bridging sites,

$$0\leq a\leq\frac{n-1}{3n-1}$$

The model can be interpreted in terms of either of the two most common approaches to the structure of C-S-H, namely as a mixture of structural units based on the minerals jennite and 1.4nm-tobermorite (Taylor, 1986) or as tobermorite-based units in 'solid-solution' with $Ca(OH)_2$ (Greenberg et al. (1960,1965), Fujii and Kondo (1983), Kantro et al. (1962), Birchall and Thomas (1984)). This is most simply demonstrated for dimeric C-S-H: if we consider the model as a mixture of structural units based on jennite and tobermorite, then with w=n and y=1 we get,

$$\left[Ca_2HSi_2O_7\right]\cdot\tfrac{1}{2}Ca\cdot mH_2O$$ i.e. Taylor's tobermorite-based dimer, Ca/Si = 1.25,

or with w=n and y=5 we get,

$\left[Ca_4HSi_2O_7(OH)_4\right]\cdot\frac{1}{2}Ca\cdot mH_2O$ i.e. Taylor's jennite-based dimer, Ca/Si = 2.25.

From the tobermorite/$Ca(OH)_2$ viewpoint it is better to represent the model by formula 2,

$$Ca_XH_{(6n-2X)}\left(Si_{1-a}R_a^{[4]}\right)_{(3n-1)}O_{(9n-2)}\cdot I^{c+}_{\frac{a}{c}(3n-1)}\cdot zCa(OH)_2\cdot mH_2O \qquad [2]$$

where, $X=\frac{1}{2}(6n-w)$; $z=\frac{1}{2}\left(w+n\left(y-2\right)\right)$. When n=1 (i.e. dimer), formula 2 reduces to that used by Glasser et al. (1986) to describe the C-S-H predominant in young OPC pastes:

$$Ca_XH_{(6-2X)}Si_2O_7\cdot zCa(OH)_2\cdot mH_2O$$

The model successfully links the chemical composition and silicate anion structure of low Ca/Si ratio C-S-H phases (Richardson and Groves, 1992b) and is supported by Richardson et al.'s determination of the location of Al in semi-crystalline substituted C-S-H gels (Brydson et al., 1993, Richardson et al., 1993, 1994). These were formed by the reaction of a slag (SC in Table 1) and a synthetic slag-glass (AG) with 5*M* KOH solution. The single-pulse ^{29}Si and ^{1}H-^{29}Si cross-polarization (CP) magic-angle spinning (MAS) NMR spectra for these gels gave conclusive evidence that Al only substitutes for Si in the central tetrahedron of pentameric linear chains. Since there were no $Q_1(1Al)$* units on the ^{29}Si CP MAS NMR spectra Al could - assuming no chain terminating Al - only be substituted for Si in bridging tetrahedra. There were no chain terminating Al as this would have produced higher Al/Si ratios derived from NMR than from analytical transmission electron microscopy (TEM) which gives unambiguous compositions. This paper presents new data for slags of varying chemical composition and data for both water- and alkali-activated Portland cement / slag blends (Richardson and Groves, 1997).

EXPERIMENTAL

Results are reported for six commercial blast-furnace slags (supplied by Frodingham Cement Company and the AEA Technology Harwell Laboratory) with different chemical and mineralogical compositions and for one synthetic slag glass (AG). Powder X-ray diffraction showed that slags SC, HG and VL were >95% glassy whilst slags SM, PT and CP had varying amounts of merwinite and/or melilite. Chemical data for the glassy phase present in the slags and fineness data are given in Table 1. These data are given in greater detail elsewhere (Richardson et al., 1997). The cement used in the blends was a white Portland cement (WPC) from the Aalborg company (Bogue composition: 65% C_3S, 22% C_2S, 4% C_3A, 1% C_4AF). A white Portland cement was used because of its low Fe content; the presence of paramagnetic ions causes peak broadening in NMR. The commercial slags were activated with KOH solution (S/S=0.4) and blends of 1/9 and 1/1 WPC / VL slag with water (W/S=0.4) or 5*M* KOH solution (S/S=0.5). Freshly ground samples were used for X-ray diffraction and NMR.

---

* ^{29}Si MAS NMR can provide quantitative information on the fractions of silicon present in different tetrahedral environments, Q_n ($0 \le n \le 4$), where Q is a silicate tetrahedron and n is the number of oxygens which bridge to adjacent tetrahedra. Increased polymerization of the Q_n building units causes characteristic up-field chemical shifts. In aluminosilicates the shifts are further influenced by the replacement of Si by Al. There are 15 possible $Q_n(mAl)$ structural units where Q is a silicate tetrahedron connected via oxygen bridges to m Al and n-m other Si atoms, with n=0 to 4 and m=0 to n.

Table 1. Glass composition (determined by wavelength dispersive X-ray analysis) and fineness data. n and x_0 represent the particle size distribution (Rosin-Rammler constants): n is a measure of breadth of distribution (higher n → narrower); x_0 is a measure of average size (36.8% of particles are > x_0 μm).

Median	16.9	12.2	89.3	11.7	9.7	14.0	20.6	13.8	27.1

Details of TEM sample preparation and analysis are given elsewhere (Groves et al. (1986), Richardson and Groves (1992a)). Specimens for NMR spectroscopy were ground to a powder and packed into zirconia rotors. The single-pulse ^{29}Si spectra for slags HG, SM, PT and CP were acquired using a Bruker MSL-400 spectrometer (magnetic field 9.4 T; operating frequency of 79.49 MHz for ^{29}Si). All other single-pulse ^{29}Si and ^{1}H-^{29}Si cross polarization (CP) spectra were acquired using a Bruker MSL-200 spectrometer (magnetic field 4.7 T; operating frequencies of 200.13 MHz for ^{1}H and 39.76 MHz for ^{29}Si). The single pulse spectra were acquired over 4000→42000 scans using flip angles (30→45°) and pulse recycle delays (2→20s) sufficient to minimize saturation effects. For CP, the Hartmann-Hahn condition was set using kaolinite (Rocha and Klinowski, 1990). ^{29}Si chemical shifts are given relative to tetramethylsilane (TMS) at 0 ppm, with kaolinite used as an external standard at -91.2 ppm. All spectra were apodized with 10 Hz of exponential line broadening and zero filled to 8192 points prior to Fourier transformation. The spectra were iteratively fitted to voigt line shapes using the software Igor (WaveMetrics, 1992&1996) with additional macros written by Brough (1993). The full procedure is outlined in Richardson and Groves (1997).

RESULTS AND DISCUSSION

Hydration products and microstructure

The microstructural features and hydration products present in all of the systems studied can be classified as either 'outer', forming within the boundaries of the original anhydrous grains - whether cement or slag - or 'inner', forming in the originally water- or solution-filled spaces. The microstructures of the water-activated WPC / VL slag blends are similar to those of the OPC / SC slag pastes described previously by Richardson and Groves (1992a,1993a). The main 'outer' hydration products are C-S-H and AFm with $Ca(OH)_2$ present in the blends. The $Ca(OH)_2$ in the water-activated blends generally occurs as large plates but in the KOH-activated pastes it is largely microcrystalline, being intimately mixed on a nanometer scale with layers of C-S-H; this is illustrated in Richardson and Groves (1997). The C-S-H is generally nearly amorphous but it is semi-crystalline in some of the KOH-activated systems giving electron diffraction patterns similar to the example for the SC slag / KOH paste in Richardson et al. (1994). Whatever its degree of structural order, C-S-H is present in all of the systems as two morphologically distinct forms: inner product (Ip) and outer product (Op). This is illustrated in Fig 1. Ip can be considered to be an intimate mixture of C-S-H and a Mg,Al hydroxide type phase.

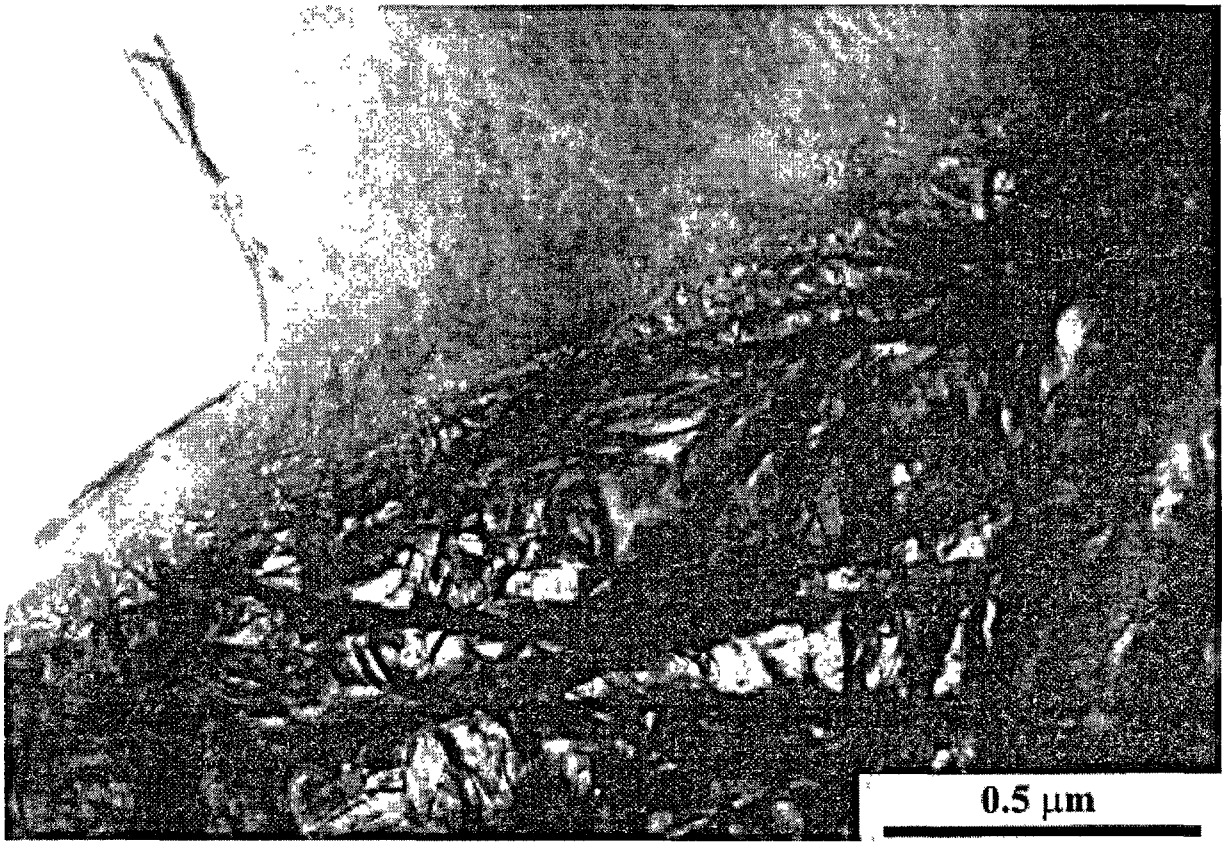

Figure 1. Transmission electron micrograph showing examples of fine-textured Ip (top) and foil-like Op C-S-H.

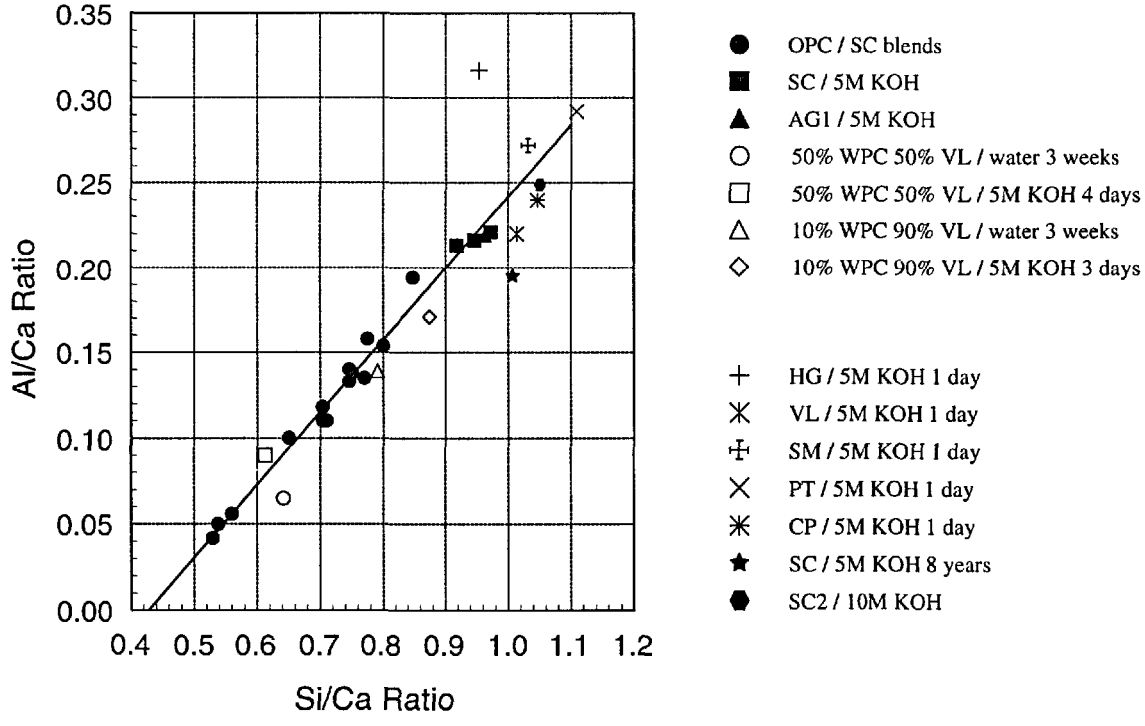

Figure 2. Al/Ca v Si/Ca for Op C-S-H gels in a range of slag-containing hardened cement pastes. Each point corresponds to a mean value of 20→50 analyses which are unambiguously of Op C-S-H.

Chemical composition of the C-S-H gels

Fig 2 is a plot of Al/Ca ratio against Si/Ca ratio for Op C-S-H gels present in a range of slag-containing hardened cement pastes: the Al/Ca ratio increases linearly with increasing Si/Ca ratio. The figure incorporates some earlier data of Richardson and Groves' (1992a,1993a,1994) for a range of OPC / slag blends (SC slag; hydrated at 20°C for 14 months (W/C=0.4) (●)), some slag / KOH pastes made with the same slag (■), and a synthetic slag / KOH paste (▲). The compositional trend line is derived from these data. The compositions of the Op C-S-H gels present in the WPC / VL slag blends (open symbols) are similar to those in the OPC / SC slag blends despite having different Portland cements and different blast-furnace slags. The C-S-H gels in all but one of the other KOH-activated slags fall on the same compositional trend line, suggesting an almost universal compositional relationship for the C-S-H phases present in slag-containing hardened cement systems. The HG slag has a very high aluminium content (Table 1) and this is reflected in the composition of the C-S-H present in the HG slag-KOH paste. Although its composition is off the trend line, the compositional and structural data are still consistent with formula 1.

Aluminosilicate anion structure

Fig 3 (top) shows the single-pulse ^{29}Si NMR spectrum for the PT slag-KOH paste which has particularly well-resolved peaks: the broad Q_0 peak at -73.0 ppm corresponds to unreacted slag and the three sharp hydrate peaks at -78.9, -82.0, and -85.2 to Q_1, $Q_2(1Al)$, and Q_2 respectively. Deconvolution of the spectrum (bottom) allows calculation of the mean Al/Si ratio of the C-S-H in the paste - i.e. in both the Op and Ip - and of the mean aluminosilicate chain length (MCL); the results are reported in Table 2. Fig 4 shows the single-pulse ^{29}Si NMR spectra for the water- (top) and KOH-activated 1/1 WPC / VL slag blend. The Q_0 peaks correspond to both unreacted slag and belite (the sharp component); it is assumed that all of the alite has reacted. Although the water-activated spectrum appears to have three hydrate peaks, Q_1, $Q_2(1Al)$, and Q_2, they are not well-resolved and so the results from deconvoluting the KOH-spectrum, where the hydrate peaks are very clearly defined, were used to aid in its deconvolution. This process, which was also done for the 9/1 blends, is discussed in greater detail in Richardson and Groves (1997). The compositional results are summarised in Table 2 and on Fig 5. The MCL of the C-S-H present in these systems increases with age but the chemical composition does not change very much; this is illustrated in Fig 6 for the VL slag / KOH system. It can be seen from Fig 5 that the compositions derived from the deconvolution of the NMR spectra are in excellent agreement with those from TEM. The assumptions that there are no chain-terminating Al, and that Al only substitutes for Si at tetrahedral bridging sites, would seem therefore to be well-founded. Al substitution in non-bridging sites would require the presence of $Q_1(1Al)$ units. The ^{29}Si chemical shift expected for $Q_1(1Al)$ units is ≈-75ppm; such peaks are not present on the ^{1}H-^{29}Si CP spectra - an example is given in Fig 7 - so it can be concluded that Al replaces Si only in the bridging sites of a dreierkette structure. The absence of $Q_1(1Al)$ units also supports the view that the higher polymers are formed by the linking of dimeric silicate units by silicate or aluminate monomers; there can be no aluminate-containing dimers. The number of occupied bridging sites that are occupied by Al and not Si is high in all cases of KOH-activation: 81, 86, 91, 72, and 83% for the C-S-H gels in Figs 3, 8, 9, and in the WPC / VL slag 1/1 and 1/9 blends respectively. Water-activation of the blends produces only ¾ as much Al substitution as does KOH.

Table 2. Composition of C-S-H in the pastes as determined by TEM and NMR. WPC / VL slag 1/1 and 1/9 blends activated with water (1W and 9W) or 5*M* KOH solution (1K and 9K); temperature (°C) of hydration and age as indicated. HT= hydrotalcite-type phase; N/Q = not quantitative; % hyd = % slag hydrated; MCL = mean linear aluminosilicate chain length.

CONCLUSIONS

The C-S-H gels present in hardened pastes of alkali-activated blast-furnace slags of varying composition and of both water- and alkali-activated white Portland cement / slag blends - whatever their chemical composition or degree of structural order - all have aluminium substituting for silicon only in the central tetrahedron of pentameric silicate chains. The results give considerable confidence in models for the structure of C-S-H based on broken dreierkette chains with Al substituting for Si at 'bridging' sites only.

ABSTRACT Hydration of cement paste causes a certain amount of chemical shrinkage. A distinction is made between chemical shrinkage and external or autogenous shrinkage. This paper discusses different measuring methods for the chemical and external shrinkage, their negative effects on the measured results and how the rotation method and the handling procedures of the samples were developed to overcome these problems.

Key-words: chemical shrinkage, autogenous shrinkage, hydration, structure.

INTRODUCTION

Shrinkage of a cement paste can be defined as a decrease in volume caused by a certain loss of water volume. This loss of water volume can be caused by physical or/and by chemical reasons. The physical processes which have an effect on the shrinkage can be easily recognized. Sedimentation of the solid particles and absorption by porous substances are two of them. Plastic shrinkage can occur when the water evaporates at the surface or is sucked up by dry cement paste below. Drying shrinkage occurs through evaporation when the hardened cement paste is stored in unsaturated air. A part of this shrinkage is irreversible and should be distinguished from the reversible part. If sufficient attention is given during the hardening period, most part of the shrinkage caused by physical reasons can be avoided.

However, even when there is no moisture movement possible to or from the cement paste autogenous shrinkage occurs. This external volume change is also called external chemical shrinkage. It is part a consequence of the chemical shrinkage. The chemical shrinkage during the hydration is caused by the smaller volume of reaction products compared to reactants. It may be calculated by assigning the total volume reduction to the water taking part in the hydration, with the value of 25.4 % reduction per cm^3 chemically bound water. The result is the rule of thumb, that chemical shrinkage at 100% hydration is about 6.00 ml/100g cement (Powers T.C. and Brownyard T.L.,1948, in Lea F.M.,1970). Autogenous shrinkage, a small volume change by itself, can cause cracks or may act as an initiator of processes. As a consequence, chemical shrinkage of the cement paste may influence the durability of concrete, particularly for low w/c-ratio concrete. It is therfore of importance to have reliable methods to measure the amount of autogenous shrinkage of cement pastes as a function of their composition, fineness, w/c etc., from as early as possible. It will be shown that the amount of autogenous shrinkage of a cement paste is very dependent on the adopted measuring procedure. A discussion of the effects of measuring procedures on the results is made, and a rotation method is presented to overcome most of the unwanted effects. The amount of autogenous and chemical shrinkage of cement pastes was measured for pastes in the w/c range 0.30 to 0.50 over a period of 48 hours. This paper only deals with the measuring methods. The shrinkage values as a function of w/c are discussed earlier (Justnes et al, 1996).

MATERIALS

All tests were performed with two commercially available Norwegian portland cements: Cement 1 with a setting time of 142-204 minutes, and Cement 2 with a setting time of 87-134 minutes. The cement characteristics were for Cement 1; 20.92% SiO_2, 4.60% Al_2O_3, 3.54% Fe_2O_3, 63.44% CaO, 3.06% SO_3, 1.80% MgO, 0.88% K_2O, 0.36% Na_2O, 0.94% Alkalis and fineness (Blaine) 358 m^2/kg, and for Cement 2; 20.84% SiO_2, 5.04% Al_2O_3, 3.30% Fe_2O_3, 63.61% CaO, 2.70% SO_3, 1.06% Alkalis and fineness (Blaine) 361 m^2/kg. Potential minerals according to Bogue calculations were for Cement 1; 19% C_2S, 55% C_3S, 6.2% C_3A and 10.8% C_4AF, and for Cement 2; 24.4% C_2S, 46.9% C_3S, 7.80% C_3A and 10.0% C_4AF. Distilled water was used in the experiments.

EXPERIMENTAL METHODS FOR CHEMICAL SHRINKAGE MEASUREMENTS

Chemical shrinkage

The addition of water to a cement results in hydration reactions. The hydration products will gradually fill the originally water filled spaces between the cement particles, resulting in reduced porosity. There are three main measuring techniques: 1) **Dilatometry.** The cement slurry is water saturated in a receptacle. A pipette reaches into the water in the receptacle and the total chemical shrinkage is measured by the change in water level in the pipette. 2) **Gravimetry.** This method is based on the principle of Archimedes. The cement paste is put in a container with flexible membrane together with an excess of water. The change in buoyance force of the sealed sample gives the total chemical shrinkage in time. 3) **Pycnometry.** The hydrating cement paste undergoes a volume decrease. The water level is kept constant by the addition of water. The change of weight measures the total chemical shrinkage.

In our experiments the total chemical shrinkage is determined by the dilatometry method. The cement paste was put into three 50ml Erlenmeyer flasks, forming a ± 10 mm thick layer. After weighting the samples, the Erlenmeyers were filled with distilled water. A rubber stopper closed the Erlenmeyer. A pipette was put through the stopper into the Erlenmeyer. This pipette was filled with water. On top of the water level an few drops of paraffin oil prevented evaporation which would disturbe the measurements. The Erlenmeyers were kept in a water filled bath at 20°C ± 1°C, Fig 1.

Autogenous (external) shrinkage

When water is added to the cement, hydration of the cement starts. The reaction products grow into the pores and build a structure between the cement particles. Initially, the chemical shrinkage is identical to the external shrinkage since the paste is fluid, but when a skeleton structure is formed the chemical shrinkage results in empty pores, and the external shrinkage becomes much smaller than the chemical shrinkage. The measurements of the external shrinkage of sealed specimens can be done using an unidimensional dilatometer method or using a volumetric dilatometer method.

1. Unidimensional dilatometer

By using a unidimensional dilatometer the distance variation between two studs which are fixed to a testbar, is followed (Fulton, 1963, and Baron, 1968, in Buil M. and Baron J., 1980). However, in the period that the cement paste has not yet set, it behaves liquidlike, and the deformation will mainly take place vertically. Hence, linear measurements are not reliable before setting.

2. Volumetric dilatometers

Measurements by volumetric dilatometry can be executed in various ways.

- The paste is put in a rubber balloon. This balloon acts as a barrier between the cement paste and a mercury column. The external shrinkage is given by the movement of the mercury which follows

the external shrinkage of the sample (Edmeades et al., 1966, in Setter N. and Roy D.M., 1978).

- Also common is to put the sealed sample in a water filled vessel which is connected to a beaker. Due to contraction of the cement paste, water migrates from the beaker to the vessel. By measuring the weight change of the beaker, the external shrinkage can be determined.
- Another method to determine the external chemical shrinkage is based on Archimedes' principle: external shrinkage of the sealed specimen leads to a decrease of the buoyance force and consequently an increase in weight is measured.

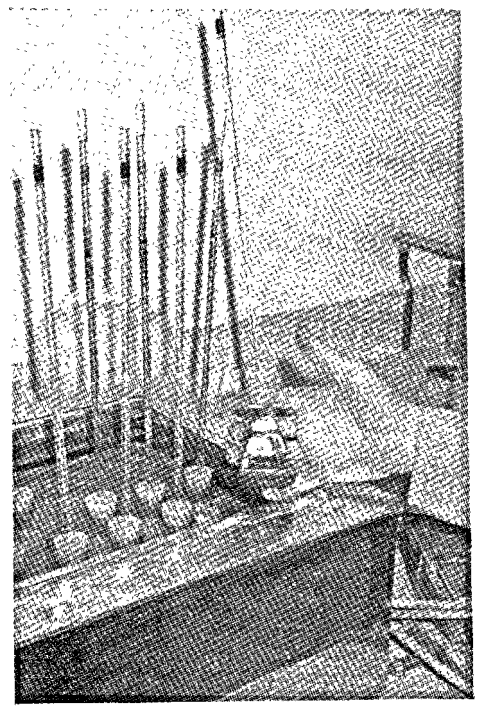

Figure 1 Equipment to determine total chemical shrinkage

In our experiments the Archimedes principle was used. Three parallel elastic rubber bags (condoms) were filled with cement paste. The rubber bags were closed by twisting the end and tying it with a thin copper wire. To be sure that the sample was sealed from the environment silicon glue was applied into the open end. The samples were kept in a water filled bath at a constant temperature of 20°C ± 1°C. One hour after water-cement contact, the weight measurements started.

BLEEDING EFFECT

The settlement of solids in a fresh, plastic paste is followed by the formation of a water layer at the paste surface known as "bleeding". Fig 2 shows that bleeding has an enormous effect on the measurements of autogenous shrinkage. The total chemical shrinkage vs time curve of Cement 2 paste with w/c = 0.50 is compared with the external chemical shrinkage curve of the same paste without and with rotation prior to setting. The external chemical shrinkage curve follows more or less the total chemical shrinkage curve within the observation time of 48 h, while the external chemical shrinkage curve for the rotated specimens flattens out at about 7 h as expected (i.e. a strong enough hydration network has been formed that can resist the contracting forces). The behavior of the static samples is caused by the "bleeding" water (can be seen through the transparent condom) formed by the segregation of the paste: After the skeleton of interconnecting hydration products is strong enough to resist the contracting forces created by the chemical shrinkage, the under pressure set up by the contraction pores will suck the bleeding water into the paste and the volume decrease (directly proportional to the volume of contraction pores) will erroneously be

interpreted as external chemical shrinkage. A secondary, false flattening out level will be registered when the imbibition of the bleeding water is complete.Therefore, in order to get correct results of the amount of external shrinkage, a new method had to be developed to avoid the bleeding effect.

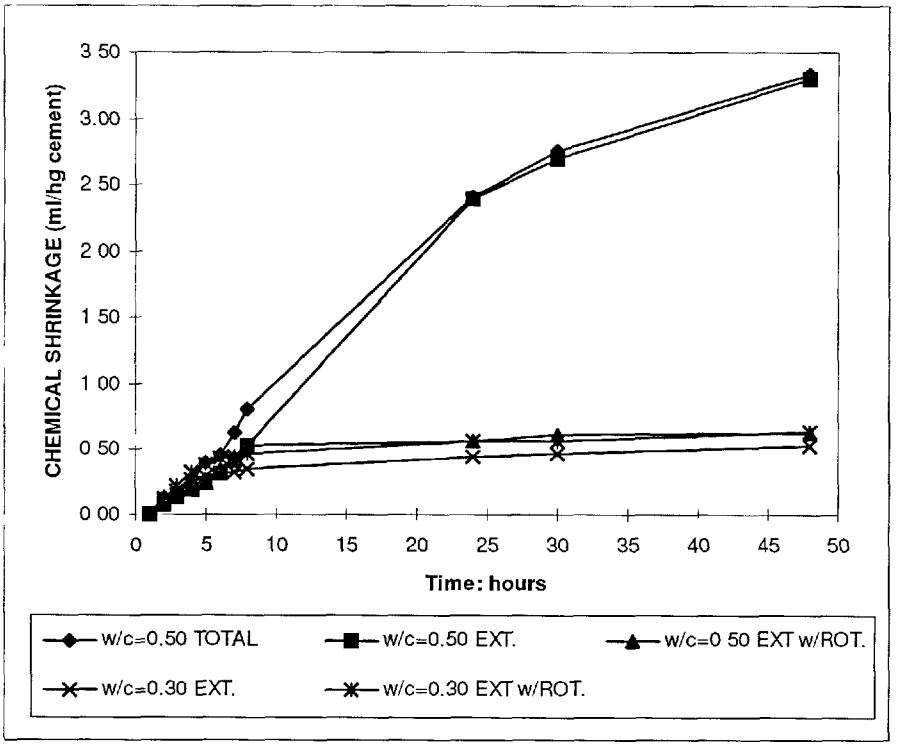

Figure 2 Comparison of total chemical shrinkage and external chemical shrinkage for static and rotated Cement 2 pastes.

In the beginning, the samples were turned around by hand every quarter of an hour. This experiment was done with 3 parallels of Cement 1 and a w/c ratio of 0.40. As can be seen in Fig 3 the shrinkage curves of the paste flattened out after about 10 hours if the samples were rotated by hand, but when the samples were not rotated (static test) there was still some bleeding water present after 48 hours, as demonstrated by the higher rate of shrinkage. Moreover the external shrinkage dropped with 60% (from 3.19 cm^3/ 100 g cement to 1.23 cm^3/ 100 g cement).

The first success at rotating the samples by hand had strenghened the idea to develop a system that would rotate the samples continuously. The rotating system consisted of an ordinary rotating table which was modified to function under water (Fig 4). This was done by a chain transfer between the motor and the rolling bars which were placed under water. A problem which occurred when using the rotating system was damage to the rubber bags when they were lying on the rolling bars. Because the form of the samples was not symmetric the samples moved to the outside of the rolling bars and were damaged by the gear or by the chain. A hole in the rubber would disturb the measurements because water from the bath would be sucked into the sample and the weight would increase. To avoid this problem the samples were put into a stiff plastic tube. This tube could withstand the friction and torsion forces which arise at rotation and which act on the sample. The extra advantage of using the tube is that the building up of the network of the cement paste will not be disturbed when the sample is manipulated for weighing.

But now another problem arised. The rubber bags were slided into the tubes in the air, above water. Once the tubes were filled, they had to be transported to the rotating system. A lot of air bubbles were hanging on the tube and some were located between the rubber bag and the tube. It was impossible to remove all the air bubbles without damaging the rubber bag. These air bubbles had a negative effect on the measurements, because the amount of air bubbles was not the same at the different measurements. To avoid this problem the samples were slipped into the tube just above the water surface, whilst the tube was always kept under the water surface. By filling the tubes in this way, the air bubbles were avoided. When the samples needed to be weighed they were transported from the rotating bath to the weighing bath in a big glass container to be sure that no air bubbles were trapped and could influence the measurements. The weighing had to be done in a separate water bath because the turbulence of the rotating system and of the stirrer, which assured an equal temperature in the water bath, disturbed the stability of the weight too much.

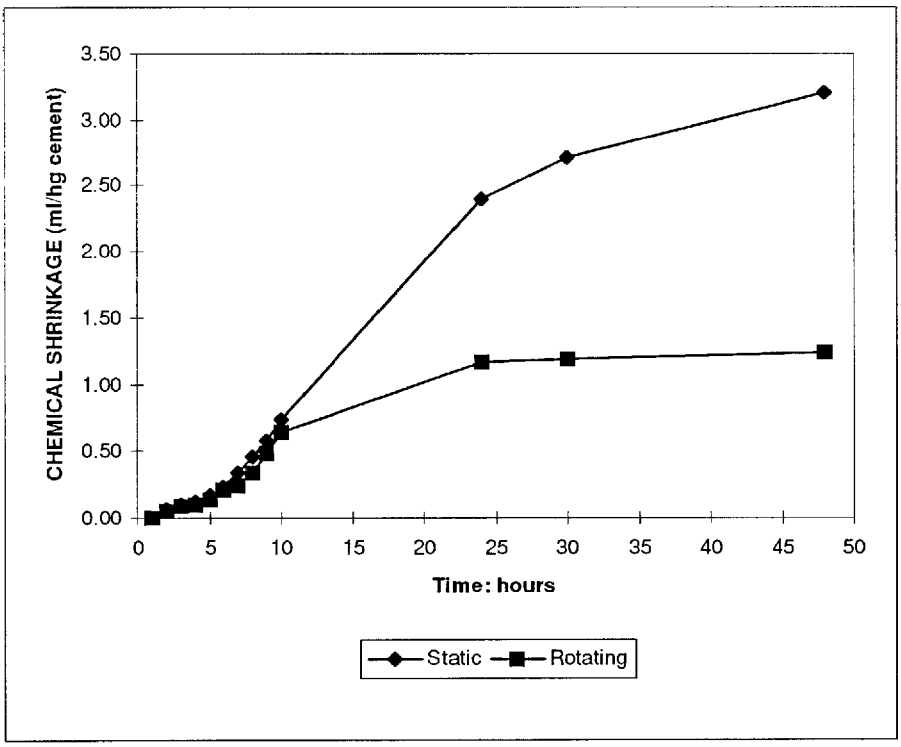

Figure 3 Average values of external chemical shrinkage of samples in static and hand rotated test. Cement 1, w/c = 0,40.

After the measurements the rubber bag was wiped dry and was stripped from the paste. The amount of cement paste had to be determined from the difference in weight of the paste + rubber bag + tube + silicone glue + copper wire and the weight of the tube + rubber bag + silicone glue + copper wire. The external shrinkage is calculated as the average value of three parallel samples and is given in ml/100 g cement.

RESULTS AND DISCUSSION

When the samples were rotated, bleeding water on top of the sample could be prevented even when the w/c ratio was 0.50. In Table 1 a comparison is made between the measured values of external chemical shrinkage of rotated and non-rotated samples.

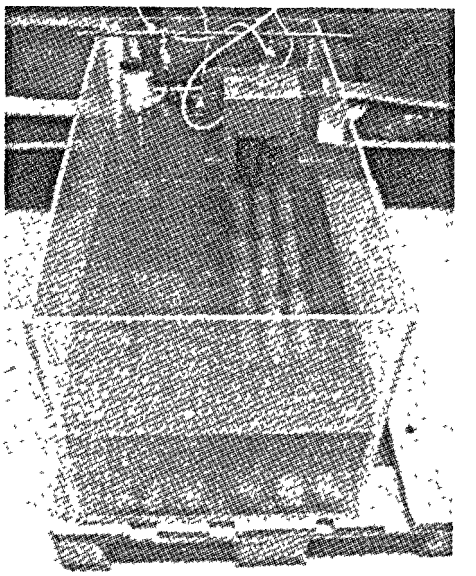

Figure 4 Water bath with automatic rotating system. 9 samples are being rotated.

Table 1 Results of the external chemical shrinkage after 48 hours of rotated and static samples (cm^3/ 100 g cement)

		w/c ratio				
Cement type	**procedure**	**0.30**	**0.35**	**0.40**	**0.45**	**0.50**
Cement 2	non-rotated	0.53	0.71	1.79	3.41	3.21
	rotated	0.50	0.68	0.61	0.64	0.63

The difference between the measured external chemical shrinkage of rotated and non-rotated samples becomes larger as w/c increases. This is evidently caused by the bleeding water that is present on top of the non-rotated samples. The greater the w/c ratio, the greater the amount of bleeding water. This could easily been observed through the transparant rubber bag. At a w/c ratio of 0.30 and 0.35 there is just a small difference of 0.03 cm^3/ 100 g cement between the rotated and non-rotated sample. This difference might be caused by manipulating the samples by hand for weighing when the paste had not yet set. This conclusion came after the observation of clear finger prints in the hardened samples. As mentioned earlier the handling of the rotated samples was easier because they were put in a hard plastic tube.

The shrinkage "flattening out" level for the rotated samples does not depend on the w/c-ratio (Fig. 3) in contrast to the static test (Fig. 2). This implies that the degree of hydration, which is proportional to the chemical shrinkage at the knee point, needed to produce a rigid skeleton allowing empty pores to form, is independent of the w/c-ratio. This is somewhat surprising, since the average distance to be 'bridged' by hydration products to produce a skeleton increases strongly with increasing w/c-ratio. Possibly the greater friction, and hence more energetic mixing, of low w/c-ratio pastes produces a less flocculated structure than for high w/c-ratio pastes. Thus, the skeleton of the two is formed at the same degree of hydration, but the bridging for low w/c-ratio is primarily particle-to-particle, while in high w/c-ratio the bridges are between flocs.

In order to get a better understanding of the different shrinkage behaviour of the rotated and non-rotated samples an electron microscope examination of a hardened sample of each type was done. Cement 2, w/c ratio 0.45, was used in the examination. Two small pieces were taken from each sample for the examination: one at the outside of the sample and one in the centre. The small pieces were dried and a graphite layer was deposited over the pieces on fracture surfaces.

The piece that was taken on the edge of the rotated sample which consisted of some layers that could be recognized bacause of their different colour. Alternatively bright and grey layers could be distinguished (Fig 5).

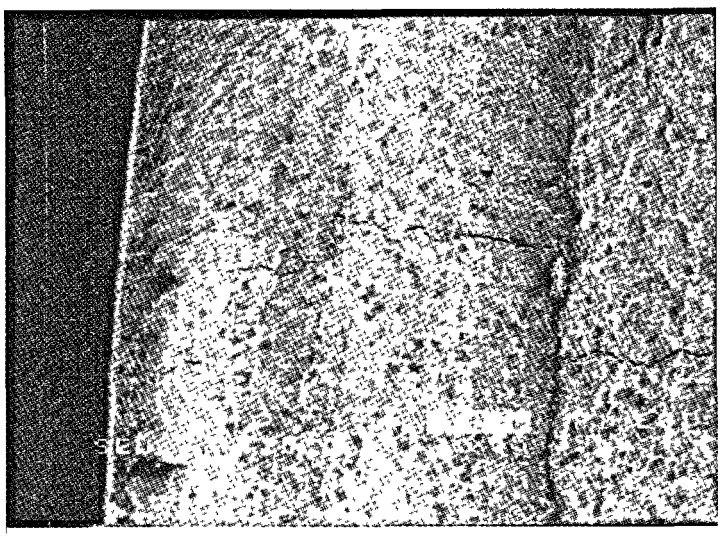

Figure 5 Cement 2, w/c = 0.45, layered structure at outside of rotated sample. Layer thickness about 0.3 mm.

The bright layer is probably rich in $Ca(OH)_2$ which is precipitated out of the water solution while the grey layers are mainly CSH-gel. This can indicate that at the edge of the samples ,when the paste is not set, some layers are rotating over each other divided by a small water layer. This layered structure was not found in the non-rotated sample.

The microstructure of the rotated sample seemed to have a less dense structure than the non-rotated sample. This confirms the observations that when bleeding water is present, the real w/c ratio is decreased and a denser structure will be formed. During the experiments a lot of bleeding water was present on top of the non-rotated sample. The microstructure of the rotated sample was a mix of plates, needles and pores, whereas the microstructure of the non-rotated sample contained more plates, less needles and less pores. Further research has to be carried out to determine the nature of the elements of the microstructure, as well as to check if the microstructure of the rotated cement paste still represents the structure of the corresponding cement paste in concrete or mortar.

A continuous external shrinkage measurement has been done to get an idea about the influence of the weighing manipulations during the normal procedure on the results. The measurement was done using a continuous registration of the buoyance force in a static balloon test. At a w/c ratio 0.40 the value of the external chemical shrinkage increased by more than 25 % due to the weighing manipulations, compared to the continuous measurement without manipulations. This observation again stresses the importance of the careful experimental handling procedure on the results of autogenous shrinkage measurements.

CONCLUSIONS

External chemical shrinkage values of hydrating cement pastes are highly dependent on the measuring procedure. This paper compares the usual balloon method under static and rotating conditions. The static method is unable to deal with the influence of bleeding at medium and high w/c ratios. The rotation method avoids bleeding of the cement pastes, and keeps the pastes at the desired w/c ratio. Thus, we believe that the rotating method is the best to obtain a "true" autogenous shrinkage curve, and in particular to establish the "knee" where the autogenous shrinkage curve "flattens out" and deviates from the chemical shrinkage curve, indicating that a skeleton is formed by the hydration allowing empty pores to form. We furthermore believe that this knee represents the transition from liquidlike to solidlike behavior in the paste, and that the crack sensitivity is very high during this transition when the skeleton has very low strength. It should be added that any physical manipulation during the experiment appears to influence the results, and of course the rotation itself represents a manipulation.

The present results illustrate quite clearly that the often used method to measure autogenous shrinkage linearly in a horizontal direction is a very questionable procedure.

ACKNOWLEDGEMENT

The study is partly a result of the collaboration between Katholieke Universiteit Leuven (Belgium) and Norwegian University of Science and Technology in Trondheim (Norway) within the framework of the european student exchange programme ERASMUS.

AUTOGENEOUS SHRINKAGE OF CEMENT PASTE DURING HYDRATION

Toshiyuki TAKAHASHI, Hideki NAKATA and Kozaburo YOSHIDA, R & D Department, Constructing Materials Division, Ube Industries, Ltd., Ube,Yamaguchi, Japan
Seishi GOTO, Department of Advanced Materials Science and Engineering, Yamaguchi University, Ube, Yamaguchi, Japan

ABSTRACT Autogeneous shrinkage of cement pastes with W/C=0.30 for low heat cements and ordinary portland cement has been measured. The development of shrinkage can be divided into 3 stages, that is (1) first shrinkage, (2) no shrinkage or expansion and (3) second shrinkage. The first shrinkage ended when the rigid structure was formed in each cement paste. The second shrinkage initiated when gypsum was consumed. It was suggested that second shrinkage initiated with reaction and/or recrystallization of ettringite.

Key-words : Autogeneous shrinkage, Chemical shrinkage, Hydration, Ettringite

INTRODUCTION

It is well known that the absolute volume of hydrates formed is less than the sum of the volumes of cement hydrated and water consumed. This phenomenon is called " Chemical shrinkage" or " Hardening shrinkage" (White, 1928). If the specimen is not in communication with an external water source, after the rigid structure has formed, chemical shrinkage causes the development of a gaseous volume, empty space, in the pore initially saturated with water. This phenomenon is called "Self desiccation" .

Autogeneous shrinkage is a macroscopic reduction in the volume of paste, which has kept in the condition of constant temperature, no moisture migration, no carbonation and so on (Davis, 1940). A recent study (Tazawa and Miyazawa et.al., 1991) has revealed that the amount of autogeneous shrinkage, in contrast to drying shrinkage, increases with a decrease in the water-cement ratio (w/c) and with densifying of the microstructure of cement. It becomes more significant when higher strength is required for concrete. There are many reports discussing the influence of the kind of cement and the mix proportion of concrete on autogeneous shrinkage(Tazawa and Miyazawa, 1994), but very few that have discussed the behavior of autogeneous shrinkage with the course of hydration of cement.

The purpose of this study is to understand the relationship between the behavior of autogeneous shrinkage and that of the hydration of cement. Autogeneous shrinkage of the cement pastes prepared with low heat cements and ordinary portland cement with w/c=0.30 was measured by a newly prepared apparatus which is able to measure the shrinkage from an early stage to a later stage of hydration.

EXPERIMENTAL PROCEDURE

In this experiment, an ordinary portland cement (OPC) and a low heat cements such as a moderate heat portland cement (MHC), a low heat portland cement (LHC) and a low heat portland cement based blastfurnace slag cement (LSC) were used. Synthesized alite was also used to investigate the effect of aluminate on the autogeneous shrinkage. Alite was prepared by Yamaguchi's method and 2% of gypsum was added to alite. Chemical composition and specific surface areas (Blaine) were shown in Table 1. Slag content in LSC was 60% in weight.

Cement pastes were prepared according to JIS R 5201. Water-cement ratio (w/c) was 0.30 for the measurement of autogeneous shrinkage and analysis of hydration process, and 0.40 for the measurement of chemical shrinkage. Setting time of cement was measured with w/c=0.30 according to JIS R 5201. The penetration time was also measured by using a needle loaded with 3000g.

Table 1 Fineness and chemical composition of cement, alite and slag used

Type	Braine (cm2/g)	Chemical composition (%)										Mineral composition(%)

Measurement of autogeneous shrinkage

An apparatus for the measurement of autogeneous shrinkage strain of cement paste was made for this study. This apparatus can measure the change in length from an early stage of hydration(Takahashi et.al., 1996). The apparatus is shown in Fig. 1. We considered that vertical volume change by bleeding almost finished at initial setting time, and measured horizontal change in length, which is caused by the hydration of cement, after initial setting time. The change in length from initial setting time to 2 days was determined by measuring the displacement of gauge plugs attached to a specimen with non-contact type displacement sensors shown in Fig. 1 (a). A specimen was wrapped with a polyethylene film to reduce an adhesion force between specimen and mold, and to prevent water evaporation from the specimen. The hardened paste cured for 2 days was demolded from the apparatus shown in Fig. 1 (a), and wrapped with a polyethylene film and an aluminium film. Then the specimen was put on an apparatus shown in Fig. 1 (b) to measure the change in length after 2 days. These measurements were carried out at 20 ± 3℃. The strain of autogeneous shrinkage measured with this apparatus was a good reproducibility within ± 30 μ (3 σ) on repeated runs. The obtained value was not corrected by the thermal expansion coefficient because of little rise in temperature inside the specimens.

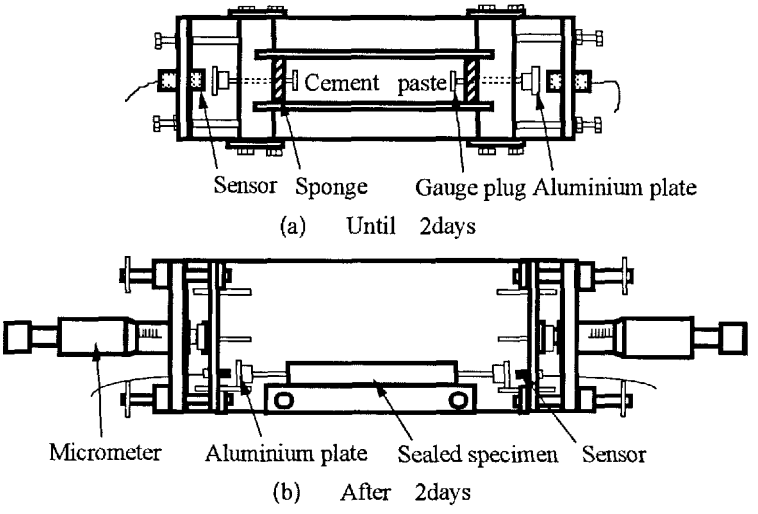

Figure 1 Apparatus for measurement of autogeneous shrinkage (Top view)

Measurement of chemical shrinkage

The chemical shrinkage was measured by Tazawa's method (Kasai and Tazawa, 1988) where a cement paste was placed in an Erlenmeyer flask with a depth of about 10mm and water was added on the top of the paste. The volume change of cement plus water was measured with a pipette mounted on the top of the water. The flask was immersed in a water bath controlled at 20 ± 3℃.

Analysis of hydration process

Cement paste for the analysis of hydration ratio was molded in a plastic container (ϕ 20mm × 40mm) and the sealed container was cured at 20 ± 3℃. The cured samples were crushed under 5mm and washed by acetone to stop the hydration.

For X-ray diffraction (XRD) analysis, the crushed samples were ground under 88 μ m. The ground samples were mixed with internal standard material (CaF_2) and dried at 11%RH under nitrogen atmosphere. A Rigaku X-ray diffractometer system (RU 200B, 50kV, 180mA) was used for XRD analysis. The XRD data was collected by step scanning (stepped width : 0.02deg, fixed time : 10sec).

The relative intensity of hydrates to that of internal standard material was determined where the ranges of scanning 2 θ (Cu K α ,deg) for gypsum, ettringite, monosulfate and CaF_2 were from 11.2 to 11.8 degree, from 8.7 to 9.4 degree, from 9.5 to 10.3 degree, and from 28.0 to 28.5 degree, respectively.

For transmission electron microscopy (TEM), the crushed samples were D-dried and then polished by dimpling and ion-thinning. A Nihondenshi TEM system (JEM-2010) was used for the observation of samples.

RESULTS AND DISCUSSIONS

Autogeneous shrinkage of cement pastes

The changes in length of pastes for OPC, MHC, LHC and LSC were shown in Fig. 2. For OPC, MHC and LHC pastes, two types of turning points appeared on the strain-time curve at the early stage of hydration. The initial shrinkage stopped at the first turning point (black arrow) and started again after the second turning point (white arrow). The times of these turning points for OPC were shorter than those of MHC and LHC. Cement pastes for MHC and LHC expanded during the first turning point and the second turning point. The

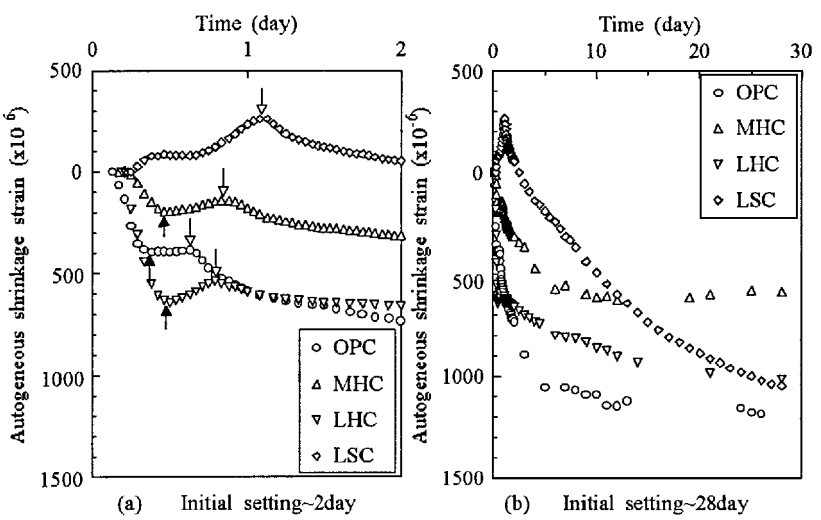

Figure 2 Autogeneous shrinkage of cement paste (W/C=0.30)

there were no autogeneous shrinkage during the first turning point and the second turning point. The slopes of curves for LSC and OPC paste after the second turning point were larger than that of MHC and LHC paste. These results suggested that the mechanism of autogeneous shrinkage could not be explained directly by chemical shrinkage.

The relationship between autogeneous shrinkage and the setting of cement

The development of autogeneous shrinkage could be divided into 3 stages, that is (1) the first stage with first shrinkage (before the first turning point) , (2) the 2nd stage with no shrinkage or expansion (between the first turning point and the second turning point) and (3) the 3rd stage with the second shrinkage (after the second turning point).

We investigated the reason why first shrinkage terminated in spite of progressive chemical shrinkage. Fig. 5 shows the relationship between the time of the first turning point (t_1) and the final setting time (t_s) of cement. Time (t_1) had a good correlation with the final setting time, but these times did not correspond to each other.

Fig. 6 shows the relationship between time (t_1) and the penetration time (t_p) of a 3000g loaded needle into paste. Time of t_1 and t_p for OPC, MHC and LHC pastes also had a good correlation of linearity, and corresponded to each other. These results show that first shrinkage ended when a rigid structures were formed in cement pastes. The shrinkage, is a result of the balance of contracting force and rigidity of paste. So, at the first turning point, the rigidity might overcome the force of contraction. The development of empty space in paste, that is self-desiccation, should start at the first turning point.

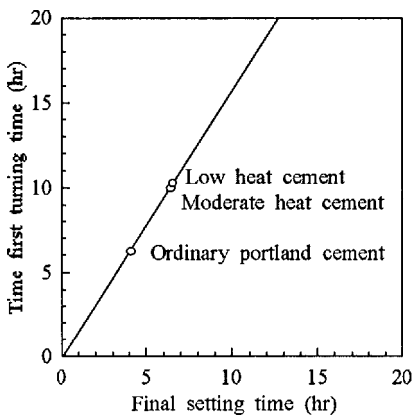

Figure 5 Relationship between setting time and time to first turning point

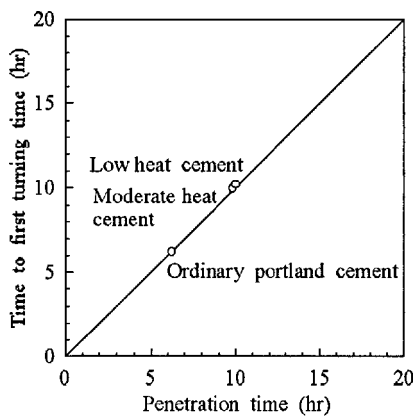

Figure 6 Relation between penetration time and time to first turning point

The influence of reaction of aluminate on autogeneous shrinkage

The influence of hydration of aluminate on autogeneous shrinkage was investigated to clarify the reason why the second stage (no shrinkage or expansion) terminated. Fig. 7 shows the result of XRD analysis for OPC, LHC and LSC paste. Gypsum was consumed at the second turning point in all cements paste. The amount of ettringite increased until the second turning point occurred and decreased after that, especially in LSC paste. There was little amount of monosulfate before the second turning point in all cement pastes. For LSC paste only, the amount of monosulfate increased with curing time after the second turning point .

TEM photographs of cement paste cured for the time of the second turning point (t_2) and for the time of t_2 plus 24 hrs are shown in Fig. 8. At the second turning point, prismatic crystals of ettringite elongated from the surface of cement particles. Some crystals made

magnitude of shrinkage strains at the first turning point were in the order of LHC, OPC and MHC, but the shrinkage strain after the second turning point for OPC paste was larger than that of LHC and MHC. The cement paste of LSC cement paste showed no shrinkage after the initial setting, but expanded greatly up to about 26 hrs. The shrinkage for LSC paste after the second turning point was largest of all.

The relationship between autogeneous shrinkage and chemical shrinkage of cement pastes

Fig. 3 shows the change in volume by chemical shrinkage. The turning points such as appeared in the curve of autogeneous shrinkage were not recognized in the chemical shrinkage curve. The changes in volume by chemical shrinkage were less in the order of OPC, MHC, LSC and LHC pastes.

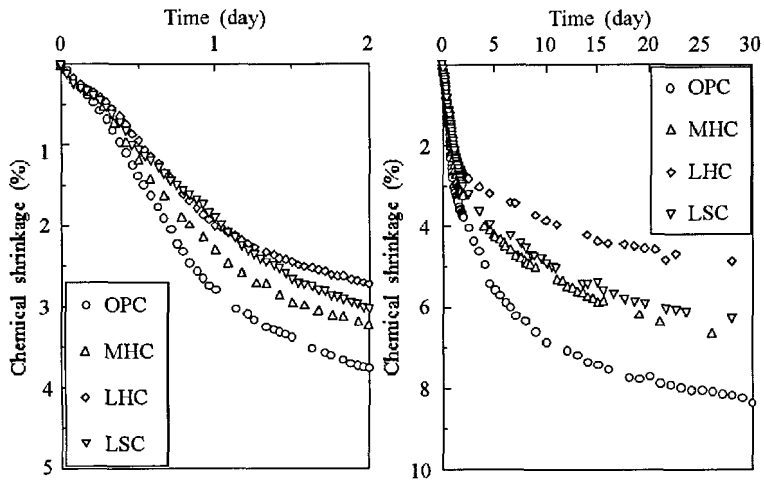

Figure 3 Chemical shrinkage of cement paste (W/C=0.40)

Fig. 4 shows the relationship between autogeneous shrinkage and chemical shrinkage. The turning points were recognized in these relationships. The time at which turning points appeared corresponds to that of the autogeneous shrinkage curve. The slope of curves differed with curing time and kinds of cement. In spite of progressive chemical shrinkage,

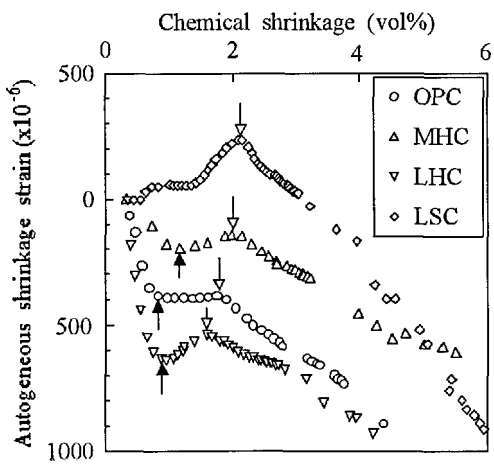

Figure 4 Relationship between chemical shrinkage and autogeneous shrinkage

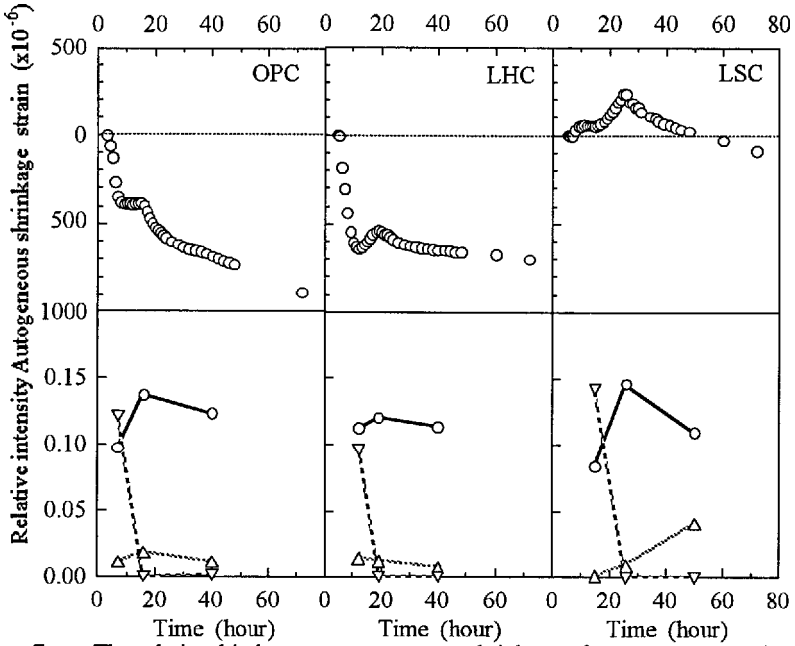

Figure 7 The relationship between autogeneous shrinkage of cement pastes and amount of calcium aluminate hydrate and gypsum
(○:Ettringite,△:Monosulfate,▽:Gypsum)

contact with other cement particles. The amount and crystal size of ettringite was larger for OPC and LSC paste. This is agreed with the result of XRD analysis. At t_2 plus 24 hrs, the number of ettringite crystals elongated from cement particles decreased and large crystals were observed between cement particles. These large crystals were identified as ettringite and monosulfate by element analysis. Plate crystals of monosulfate was rarely observed in the case of OPC and LHC, and more observed in the case of LSC.

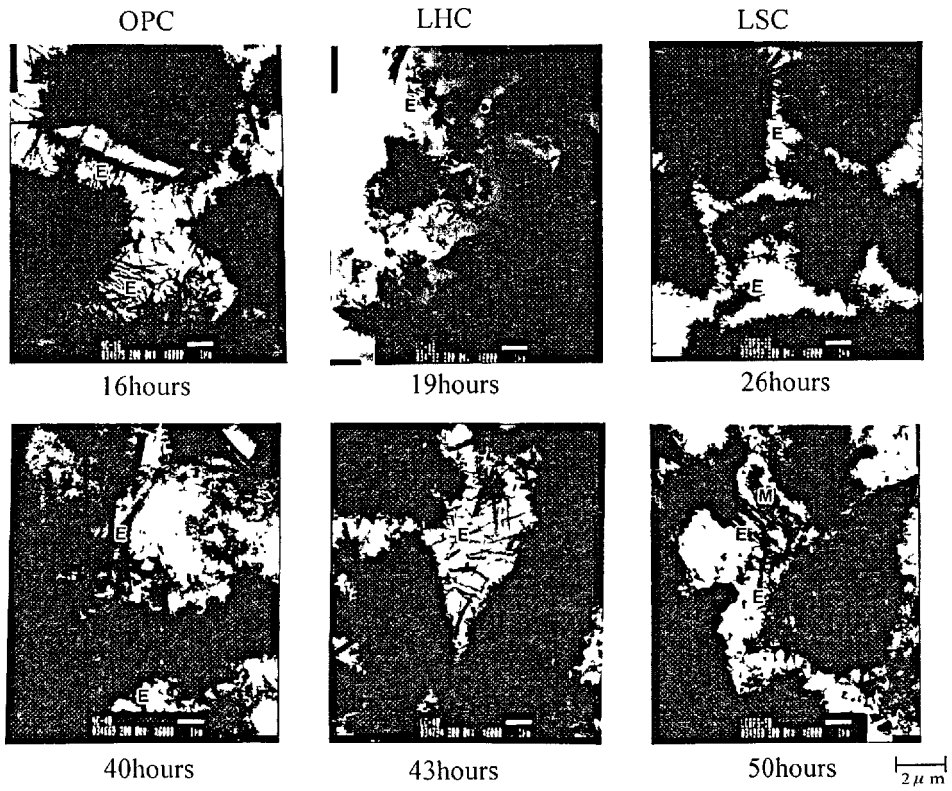

Figure 8 Transmission electron micrographs of cement pastes (W/C=0.30)
(E: Ettringite, M: Monosulfate)

Fig. 9 shows the change in length by autogeneous shrinkage of alite paste which contains no aluminate phase . Both the first and the second turning points were recognized in the curve , but the second turning point occurred at longer hydration times (about 2 days) than OPC, LHC and LSC.

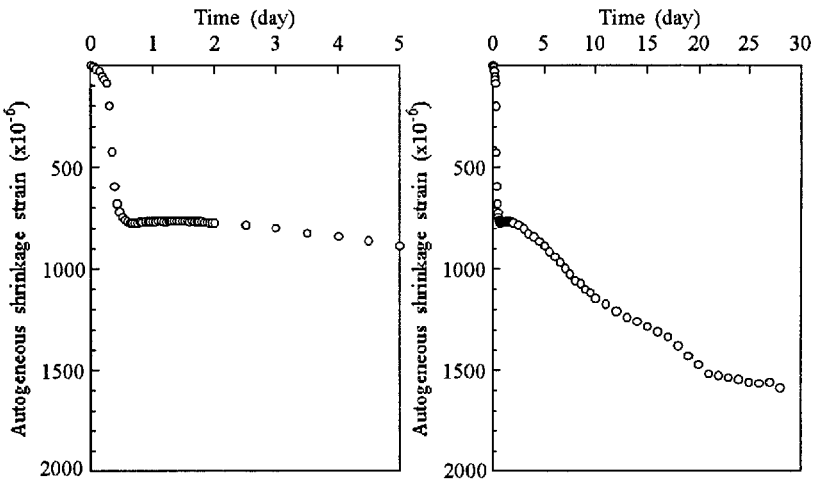

Figure 9 Autogeneous shrinkage of alite paste (W/C=0.30)

The following mechanism of autogeneous shrinkage at an early stage of hydration is suggested.

(1) first shrinkage ($\sim t_1$) in the 1st stage of autogeneous shrinkage

Autogeneous shrinkage is mainly caused by chemical shrinkage. The void produced by chemical shrinkage may be closed by vacuum pressure inside the void. The first shrinkage ends when a rigid structure is formed by progressive hydration.

(2) no shrinkage or expansion ($t_1 \sim t_2$) in the 2nd stage of autogeneous shrinkage

Ettringite is produced by the reaction between the aluminate phase and gypsum in cement. Prismatic crystals of ettringite elongate from the surface of cement particles. Some crystals make contact with other cement particles. Cement paste in which elastic modulus is low, expands by the formation of ettringite. The reason why no expansion occurs for OPC paste is probably attributed to the rigid structure made by large amounts of C-S-H produced by the reaction of alite.

(3) second turning point (t_2)

The consumption of gypsum results in the termination of ettringite formation. The time at which second turning point appears is often consistent with the time at which the third peak appeared in calorimetric curve of cement, e.g., 16 hrs for OPC and 26 hrs for LSC(Yoshida,1993).

(4) second shrinkage ($t_2 \sim$) in the 3rd stage of autogeneous shrinkage

Ettringite becomes unstable when the gypsum in cement paste has been consumed. XRD analysis and TEM observation shows that small crystals of ettringite elongated from cement particles are recrystallized to form large crystals in the space between cement particles at the 3rd stage of autogeneous shrinkage, and conversion from ettringite to monosulfate occurs, especially for LSC paste. Gartner and Gaidis(1991) assumed that solubility of ettringite crystal growing outside a C-S-H shell is sufficiently high to allow recrystallization of the previously existing small crystals into larger, more well-formed crystals. It is suggested that second shrinkage of cement, having an aluminate phase initiates with dissolution of ettringite crystals, which contributed to expansion, by recrystallization and conversion.

The recent study by Hirao and Uchikawa et. al.(1996) mentioned that self desiccation of ordinary portland cement and blastfurnace slag cement pastes prepared with W/C ratio of 0.25 occurs at about 2 days of hydration. It is therefore suggested that autogeneous shrinkage of ordinary portland cement and blastfurnace slag cement pastes after about 2 days of hydration is caused by capillary tension in meniscus which is formed by self desiccation.

The reason why second shrinkage initiated before 2 days during which capillary tension is small is attributed to rapid dissolution of ettringite crystals as described previously. The fact that second shrinkage for alite paste, which contains no ettringite, initiates after 2 days may support accelerated shrinkage by recrystallization and conversion of ettringite.

CONCLUSIONS

Autogeneous shrinkage of cement paste with W/C ratio of 0.30 has been measured. The cement paste was prepared with low heat cements and ordinary portland cement. An apparatus for measurement of autogeneous shrinkage strain of cement paste was made in this study. This apparatus can measure the change in length from early stage of hydration. The development of shrinkage can be divided into 3 stages, that is (1) the first stage with first shrinkage (before the first turning point) , (2) the 2nd stage with no shrinkage or expansion (between the first turning point and the second turning point) and (3) the 3rd stage with the second shrinkage (after the second turning point). These stages were not recognized in chemical shrinkage of cement pastes. The first stages of shrinkage ended when a rigid structure was formed in each cement paste. At the second stage, low heat cement pastes expanded, while ordinary portland cement paste did not expand. This expansion seemed to be attributed to the formation of ettringite. The 3rd stage of second shrinkage initiated when gypsum was consumed. It was suggested that second shrinkage initiated with reaction and/or recrystallization of ettringite.

INFLUENCE OF CEMENT COMPOSITION ON AUTOGENOUS SHRINKAGE OF CONCRETE

Ei-ichi TAZAWA, Department of Civil Engineering, Hiroshima University, Japan
Shingo MIYAZAWA, Department of Civil Eng., Ashikaga Institute of Technology, Japan

ABSTRACT Autogenous shrinkage was observed with cement paste and concrete with different types of cement, with different water to cement ratio and volume concentration of aggregate. It was proved that autogenous shrinkage was strongly dependent upon the content of C_3A and C_4AF, that the effect of volume concentration of aggregate could be estimated from an existing composite model. A practical equation for estimating autogenous shrinkage of concrete was proposed as the function of time elapsed, the type of cement and water to cement ratio.

Key-words: Autogenous shrinkage, volume change, composition, water-to-cement ratio

INTRODUCTION

Autogenous shrinkage of concrete, which was defined by Davis(1940) , is a macroscopic volume reduction caused by hydration of cement. It has recently been demonstrated that autogenous shrinkage is considerably large for high-strength concrete and it should be considered in the design of concrete structures, especially in the control of cracking(Paillere, 1989 and Tazawa, 1996). It was reported by Tazawa(1992) that autogenous shrinkage was considerably influenced by the type of cement, but the relationship between autogenous shrinkage and cement composition has not been quantitatively understood.

Studies on the prediction of autogenous shrinkage of concrete have recently been done by some researchers. A prediction model, which was a function of compressive strength of concrete was proposed by Roy(1996). However, a model which includes the effect of cement type has not been obtained yet.

EXPERIMENTAL PROCEDURES

For cement paste, two series of experiments were conducted; w/c=0.30 in series 1, w/c=0.23 and 0.40 in series 2. In order to study the effect of cement composition on autogenous shrinkage, number of cements with various composition were used. Physical properties and chemical composition of cements used in the experiments for cement paste are shown in Table 1. Mineral compositions of these cements calculated form Bogue's equations are shown in Table 2. Cement L1, L2, L4 and L5 are low heat cement with high C_2S content ranging from 56.3% to 74.1%. Cement N, M, H, S, W and O are commercial cements in Japan which contain some mineral powder up to 5% by weight. N0 is pure Portland cement. Cement N2, N3 and N4 have different fineness, which were prepared by milling cement N1.

For experiments for concrete, ordinary Portland cement, moderate heat cement and low heat cement with high C_2S content were used. Water to cement ratio was varied from 0.20 to 0.56. In some cases, volume concentration of aggregate was varied from 0 (cement paste) to 0.60.

Autogenous shrinkage was measured as horizontal length change of sealed cement paste and concrete beam specimens in a room at 20 ℃. For the first 24 hours after casting, measurement was done with mixtures in the mold by dial gauges(Fig 1). In order to eliminate the restraint by the mold, foamed styrol mold was used for cement paste, and Teflon plate 1 mm in thickness was

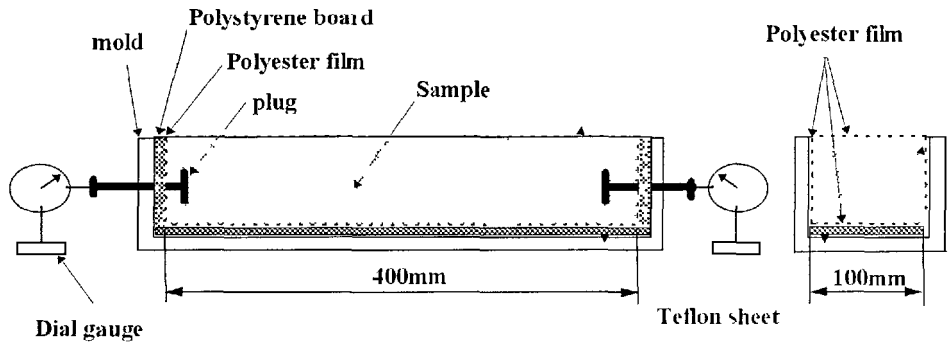

Figure 1 Measurement of autogenous shrinkage of concrete during first 24 hours

put on the bottom of steel mold for concrete In order to consider cracking, it is convenient to exclude volume change of fresh concrete, so the measurement was started at time of initial setting which was determined by Japanese Industrial Standard(JIS R 5201) for cement paste and JIS A 6204 for concrete During the first day, temperature of specimens rose due to hydration Therefore, thermal expansion was excluded from the measured strain on the assumption that thermal expansion coefficient of cement paste and concrete were $20\times10^{-6}/℃$ and $10\times10^{-6}/℃$ respectively.

After specimens were demolded at the age of 24 hours, the specimens were sealed with aluminum tape in order to prevent from evaporation, and length change was measured at specified ages The specimens were $40\times40\times160$mm beam for cement paste, and $100\times100\times400$mm for concrete.

RESULTS AND DISCUSSIONS

Autogenous Shrinkage of Cement Paste

Autogenous shrinkage of cement paste with various types of cement is shown in Fig 2. Autogenous shrinkage dose not reach the ultimate value even after two years from casting. Compared to normal Portland cement(N), autogenous shrinkage is larger for high-early strength cement(H) at early age, and it is lower for moderate heat cement(M). Autogenous shrinkage is very low for low heat cement with high C_2S content(L)

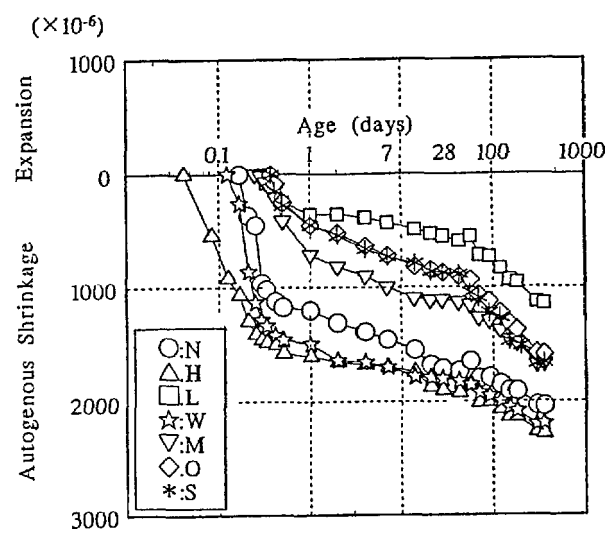

Figure 2 Autogenous shrinkage of cement paste (w/c=0 23)

Autogenous shrinkage is strongly dependent upon the type of cement. This may be due to the different composition of cement It is assumed that autogenous shrinkage strain of cement paste depends on the hydration of each mineral

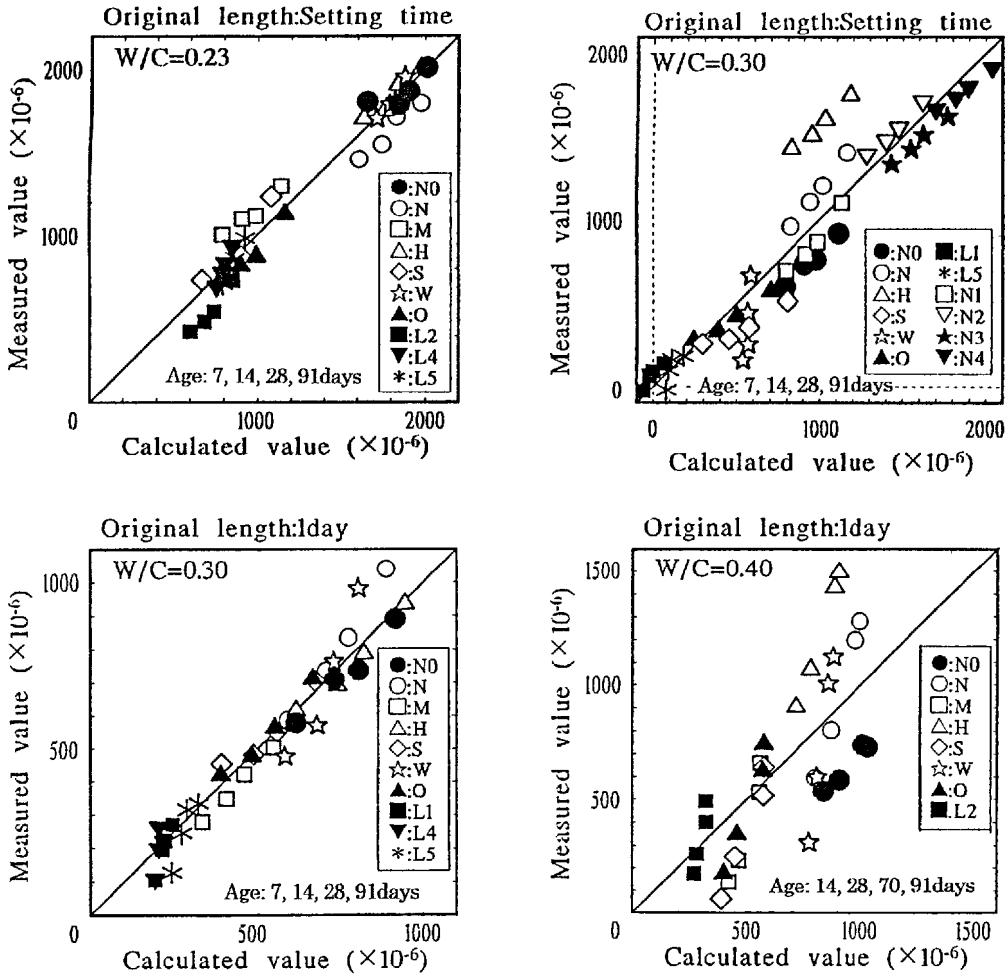

Figure 3 Relation between calculated and observed autogenous shrinkage of cement paste

compound and that it is equal to the sum of the strains due to these hydrations. Then, it is assumed that autogenous shrinkage of cement paste can be described by the next equation.

$$\varepsilon_p(t) = \mathbf{a}\cdot\alpha_{C3S}(t)\cdot(C_3S\%)+\mathbf{b}\cdot\alpha_{C2S}(t)\cdot(C_2S\%)+\mathbf{c}\cdot\alpha_{C3A}(t)\cdot(C_3A\%) +\mathbf{d}\cdot\alpha_{C4AF}(t)\cdot(C_4AF\%)+\mathbf{e}\cdot(\text{Blaine})+\mathbf{f} \quad [1]$$

where

$\varepsilon_p(t)$ is autogenous shrinkage of cement paste ($\times 10^{-6}$)
$\alpha_i(t)$ is hydration ratio of compound i (%)
t is age of concrete
(i %) is content of compound i (%)
i is mineral compound
(Blaine) is Blaine fineness of cement (cm^2/g)
a, **b**, **c**, **d**, **e** and **f** are constants

The constants **a**, **b**, **c**, **d**, **e** and **f**, which are dependent on water to cement ratio, are obtained by the least square analysis with observed autogenous shrinkage. In the calculation, mineral

composition shown in Table 2 and the hydration ratio shown in Table 3, which is obtained from data by Copeland(1960), are used. The values of α i(t) at the time of initial setting are assumed to be zero in the calculations.

The relations between observed values and the calculated ones from Eq 1, which are corresponding to ages of 7, 14, 28, 70 and 91 days, are shown in Fig 3. It can be seen that autogenous shrinkage of cement paste can be estimated by the proposed method. As shown in Fig 4, the absolute values of coefficients for C_3A and C_4AF are larger than those for C_2S and C_3S by one or two orders. This suggests that autogenous shrinkage depends on the hydrations of C_3A and C_4AF and it increases with increasing these compounds. When the original length is taken at initial setting time, **e**=0.195 and **f**=-960 for w/c=0.23, and **e**=0.224 and **f**=-1610 for w/c=0.30, which means autogenous shrinkage increases with fineness of cement. As the influence of fineness is not observed after 24 hours, **e** and **f** are taken to be zero when the original length is taken at 24 hours.

Table 3 Hydration ratio of cement compounds(%)

C_2S	0	10	38	53	65	82
C_3A	0	64	87	91	93	96
C_4AF	0	29	58	67	74	86

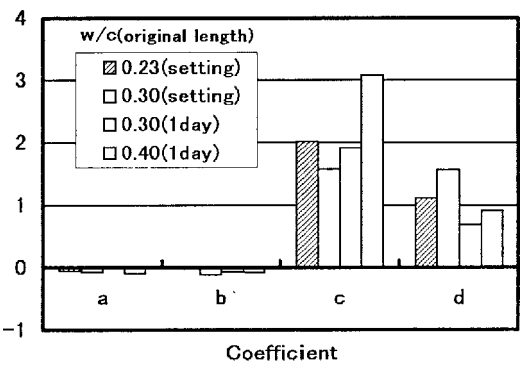

Figure 4 Coefficients in Eq 1

Influence of volume concentration of aggregate

Autogenous shrinkage of concrete occurs in cement paste phase. So autogenous shrinkage of concrete is less than that of cement paste itself because of the presence of aggregate particles. It is assumed that concrete can be expressed by a two-phase model, where aggregate particles are dispersing in cement paste matrix as inclusions. Hobbs' model(Hobbs, 1974), Eq 2, which was proposed for estimating drying shrinkage of concrete, is used to evaluate the effect of aggregate on autogenous shrinkage.

$$\varepsilon_c/\varepsilon_p = \frac{(1-V_a)(K_a/K_p+1)}{1+K_a/K_p+V_a(K_a/K_p-1)} \qquad [2]$$

where

ε_c is autogenous shrinkage of concrete

ε_p is autogenous shrinkage of cement paste

V_a is volume concentration of aggregate

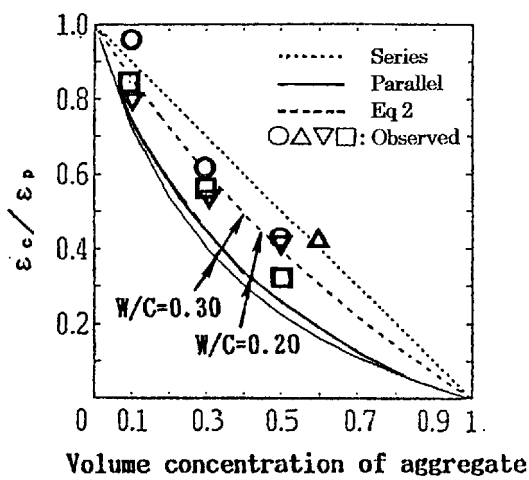

Figure 5 Effect of volume concentration of aggregate on autogenous shrinkage

K_p is bulk modulus of elasticity of cement paste

K_a is bulk modulus of elasticity of aggregate

$K = E / 3(1-2\upsilon)$, υ is Poisson's ratio, E is modulus of elasticity

Autogenous shrinkage observed for mortar and concrete after age of 24 hours is shown in Fig 5, with estimated curves given by Eq 2, parallel and series models. In the calculations, the values of K_a and K_p determined by experiments(Tazawa, 1992) are used. Estimation by Hobbs' model gives good agreement with the observed values. Therefore, the reason why autogenous shrinkage decreases with increasing aggregate volume concentration can be explained both by reduction in cement paste content and by the elastic deformation of aggregate particles.

Predicting model for autogenous shrinkage of concrete

Autogenous shrinkage increases with decreasing water to cement ratio, as shown in Fig 6. Therefore, water to cement ratio is taken as a main valuable in the predicting model of autogenous shrinkage. In order to take account the effect of cement type, a coefficient γ is introduced. Then the model for concrete with a normal volume concentration of aggregate is as follows.

$$\varepsilon_c(t) = \gamma \ \varepsilon_{c0} \ \beta(t) \qquad [3]$$

where

$\varepsilon_c(t)$ is autogenous shrinkage of concrete at age t

γ is a coefficient to describe the effect of cement type (γ =1.0 for ordinary Portland cement)

ε_{c0} is the ultimate autogenous shrinkage(Eqs 4 and 5)

$\beta(t)$ is a coefficient to describe the development of autogenous shrinkage with time(Eq 6)

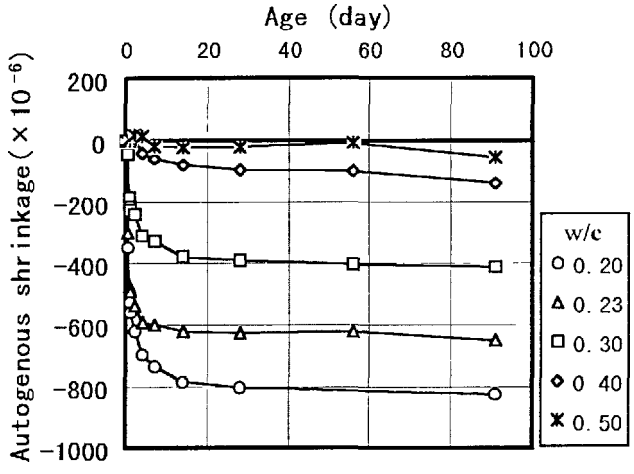

Figure 6 Influence of w/c on autogenous shrinkage (Ordinary Portland cement)

The ultimate autogenous shrinkage ε_{c0} and the development of autogenous shrinkage with time $\beta(t)$ are given by the next empirical equations Eqs 4, 5 and 6, which are obtained by the approximation of observed values.

0 2≦w/c<0.5:

$$\varepsilon_{c0} = 3070\exp\{-7.2(w/c)\} \times 10^{-6} \qquad [4]$$

0.5≦w/c:

$$\varepsilon_{c0} = 80 \times 10^{-6} \qquad [5]$$

Table 4 Coefficients a and b in Eq 6

w/c	a	b
0.20	1.2	0.4
0.23	1.5	0.4
0.30	0.6	0.5
0.40	0.1	0.7
more than 0.50	0 03	0.8

$$\beta(t)=[1-\exp\{-a(t-t_0)^b\}] \qquad [6]$$

where

w/c is water to cement ratio
a and **b** are constants
t is age in day
t_0 is initial setting time in day

Development of autogenous shrinkage with time, β (t), describes the shrinkage after initial setting time t_0. The rate of autogenous shrinkage at early ages increases with decreasing water to cement ratio. Autogenous shrinkage reaches the ultimate value at earlier ages, as water to cement ratio is lower. Therefore, the coefficients **a** and **b** in Eq 6 are strongly dependent upon water to cement ratio. Coefficients **a** and **b** obtained from observed values are shown in Table 4. Fig 7 shows the relationship between observed $\varepsilon_e(t)/\varepsilon_{e0}$ and calculated one from Eq 6. Relationship between observed and calculated autogenous shrinkage at 91 days is shown in Fig 8. The calculated values in these figures have a good agreement with the observed ones.

The prediction model for autogenous shrinkage (Eq 3) is valid for concretes with water to cement ratio ranging from 0.2 to 0.56, and with volume concentration of aggregate ranging from 0.55 to 0.65, at an environmental temperature 20℃. It should be noted that autogenous shrinkage calculated from Eq 3 is the strain after time of initial setting t_0, and that the exact value of t_0 is necessary to make an accurate estimation for concrete with low water to cement ratio.

Autogenous shrinkage with different type of cement are shown in Fig 9. As is shown in the experiments for cement paste, concretes with moderate heat cement(M) and low heat cement(L) show lower autogenous shrinkage than concrete with ordinary Portland cement(N). By using γ in Table 5, autogenous shrinkage of concrete with different type of cement can be calculated from Eq 3.

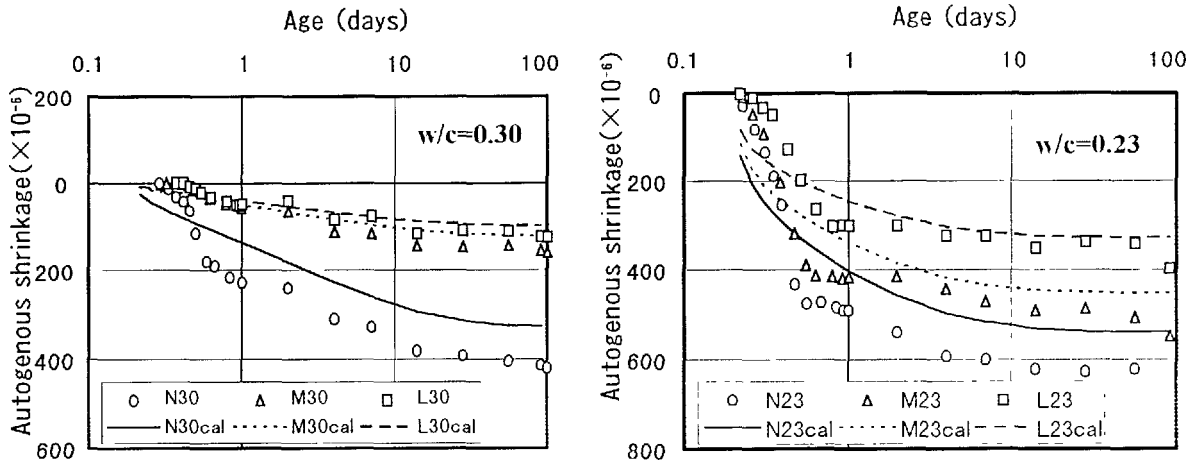

Figure 9 Autogenous shrinkage of concrete with different type of cement

CONCLUSIONS

In this study, influence of cement composition on autogenous shrinkage of concrete was investigated, and the following conclusions were obtained.

1. Autogenous shrinkage of cement paste at a certain age can be estimated by the mineral composition and the hydration ratio of each compound. Autogenous shrinkage increases with increasing C_3A and C_4AF content.
2. Influence of aggregate volume concentration on autogenous shrinkage can be estimated by an existing composite model.
3. Autogenous shrinkage of concrete with different type of cement and various water to cement ratio can be calculated from the proposed equation Eq 3.

CHEMICAL SHRINKAGE AS INDICATOR FOR HYDRAULIC BOND STRENGTH

Peter PAULINI, Institute for Building Materials and Material Testing, University of Innsbruck, Austria

ABSTRACT Hardening processes like cement hydration are exothermic and supply a bonding energy to the reacting system. Bonding forces cause a densification of the material which can be measured as chemical shrinkage. The strain work supplied to the material is described by using the bulk modulus and is applied to a strength model for hydraulic bond materials. Material tensile strength is defined with half of the strain work. The influence of porosity is considered by a linear strength reducing function.

Key-words: Chemical shrinkage, Volume change, Bound water, Porosity, Strength development

INTRODUCTION

Volume shrinkage is a natural phenomenon accompanying all hardening processes. It expresses the dominance of Coulomb attractive potentials over electrostatic repulsive potentials during the chemical reaction. The result of a hardening reaction is a material densification which can be measured as a volume loss. Therefore, volumetric measurements of cement hydration have been used for a long time together with calorimetric kinetic data to follow hydration developement.

Since the early measurements of Le Chatelier (1904) many other authors have used volumetric procedures to record the kinetics of cement hydration (Czernin (1956), de Haas et al (1975), Geiker and Knudsen (1982), Raffle (1984)). Compared with calorimetric methods, volumetric measures are possible over much longer periods. Accurate results can now be obtained with strain gauges and electronic scales applying dipping and weighing methods (Paulini, 1992a).

Chemical volume changes have direct physical significance for describing material strength. A volume strain work is supplied to the material during a hydraulic hardening reaction which must be overcome by a mechanical force. Attempts to define hydraulic bond energy by means of chemical shrinkage volume are described by Paulini (1992a,b).

CHEMICAL SHRINKAGE VOLUME AND KINETICS OF CEMENT REACTIONS

Chemical shrinkage volume of cement hydration is in a range of 55-69 cm^3/kg. It can be measured or can be calculated from stoichiometry of cement phase reactions. With mass fractions of cement phases the ultimate chemical shrinkage volume $V_{cs,u}$ becomes (Paulini, 1992a)

$$V_{cs,u} = -(53.2\cdot[C_3S] + 40.0\cdot[C_2S] + 178.5\cdot[C_3A] + 111.3\cdot[C_4AF]) \qquad [cm^3/\ kg\ Cement] \qquad [1]$$

In Table 1 some values are given for ASTM type cements which are reached after full hydration. They can be used to define the degree of hydration α according to Eq 2.

$$\alpha(t) = \frac{V_{cs}(t)}{V_{cs,u}} \qquad [2]$$

Fig.1 shows some kinetic plots of pure cement phases where chemical shrinkage has been measured by hydrostatic weighing. Reactions occurred isothermally at 20°C and with a water/solid ratio of 0.40 (Paulini, 1988). Negative volume changes are drawn with a positive sign in order to receive

conventional kinetic plots.

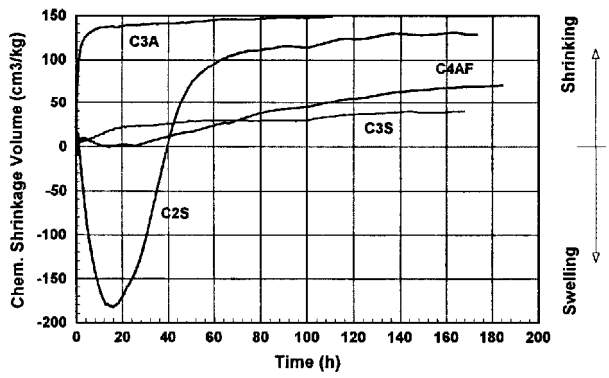

Fig. 1, Measured pure cement phase shrinkage volumes, T=20 °C, w/s=0,40

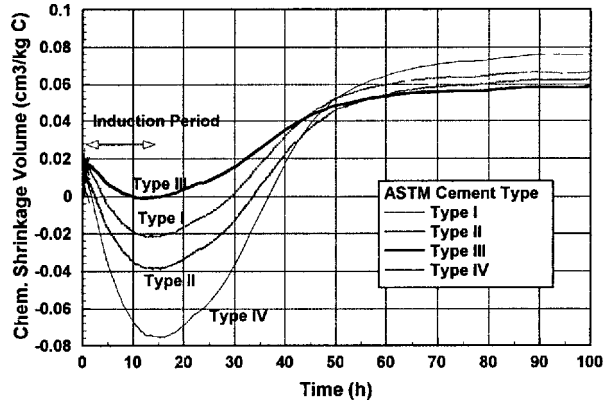

Fig. 2, Calculated shrinkage volumes for ASTM cement types

Table 1 Mean mass fractions of ASTM type cements and calculated chemical shrinkage volume and water demand factor

ASTM Cement	C_3S %-M	C_2S %-M	C_3A %-M	C_4AF %-M	Total %-M	$V_{cs,u}$ cm³/kg	$F_{wv,u}$ %-V
Type I	49	25	12	8	94	60.5	82.5
Type II	46	29	6	12	93	60.8	81.9
Type III	56	15	12	8	91	66.9	82.7
Type IV	30	46	5	13	94	57.7	81.2

Except for C_2S chemical shrinkage volumes of cement phases tend towards the ultimate values of Eq 1. In C_2S at the beginning a significant swelling occurs which changes after about 18 hours into a volume shrinkage. High Le Chatelier expansions are known for C_2S rich belite cements (Chatterjee, 1996). Fig.2 shows ASTM type cement reactions calculated as linear combinations from the kinetics of pure cement phases with the mass fractions in Table 1. Despite the fact that a linear combination of cement phase reactions may not be absolutely valid for a cement reaction and that variations of measured cement phase kinetics exist depending on burning conditions, the following conclusions can be drawn from Fig.2:

- the initial phase of cement hydration is characterised by the opposed reaction behaviour of C_3A and C_3S on the one side and C_2S on the other side
- growing fractions of C_2S lead to a dominance of early swelling in cement reaction
- the initial dormant period of setting is obviously defined by the swelling time of the cement reaction

An initial swelling behaviour has been found with blended cements (BFC, FAC), sulphate resistant cements (SRPC) and by addition of silica fumes. The use of concrete admixtures like retarders and plastizicers can also force an initial swelling (Paulini, 1990).

A stoichiometric calculation of ultimate shrinkage volume according to Eq 1 cannot be made for blended cements because the assumption of pure cement phase reactions does not hold. For such cements with an initial swelling period the ultimate chemical shrinkage $V_{cs,u}$ has to be extrapolated from long term measurements of shrinkage volume. A kinetic model based on chemical shrinkage volume has been presented by Paulini (1994).

The kinetic model assumes that volume changes occur basically during both the phase transitions of cement hydration. A first order serial reaction is taken to be

$$A \xrightarrow{k_x} X \xrightarrow{k_z} Z \qquad [3]$$

with constant reaction rates k_x and k_z. Reactant A is regarded as a solid mass of cement, the intermediate product X as solution product in pore water and the final product Z again as solid bound CSH-gel. The first phase transition solid-fluid $A \Longrightarrow X$ causes a volume gain while the crystallisation step fluid-solid $X \Longrightarrow Z$ leads to shrinkage. As a result of increased bond energies a shrinkage volume $V_{cs,u}$ remains in the final product Z (Eq 1). The solution of differential Eq 3 shows an interesting context for the total reaction rate (Eq 4)

$$\frac{dZ(t)}{dt} = k_z \cdot X(t) \qquad [4]$$

The solution product $X(t)$ becomes the dominant quantity for the total reaction rate. The function $Z(t)$ behaves steady convergent towards 1 and is defined as the degree of hydration α. Chemical shrinkage volume $V_{cs}(t)$ is expressed by the solutions $X(t)$ and $Z(t)$ of differential Eq 3

$$V_{cs}(t) = V_{cs,u} \cdot [Z(t) - X(t)] \qquad [5]$$

HYDRAULIC BOND ENERGIES AND STRAIN WORK

Chemical reaction energies set free in a system can be described with the internal energy U of the system

$$\Delta U = \Delta Q + \Delta W = \Delta(c \cdot T) + \Delta(p \cdot V) \qquad [6]$$

Under the pressure term p we understand for reactions in fluids and solids the internal bonding forces p_B between particles. These forces result from changes of energy potentials and lead to volume changes. The change of internal energy dU_R of a chemical reaction becomes

$$dU_R = dQ_R + dW_B \qquad [7]$$

Exothermic hardening of cement hydration supplies a positive heat of reaction dQ_R as well as a positive bonding energy dW_B to the system. According to the general understanding the total change of internal energy is positive ($dU_R > 0$).

In considering only the reacting system the exothermic heat of reaction dQ_R is regarded as an excess energy which is released from the system. This dissipative energy flux means an energy loss for the system. Instead, a positive bonding energy dW_B is supplied to the system. The first law of thermodynamics also holds true for the reacting system in the form $dU_R = 0$. Therefore, energy changes of chemical reactions are energies working in opposing directions according to Eq 8 (Paulini, 1988).

$$dW_B = -dQ_R \qquad (8)$$

This opposing behaviour of chemical reactions is known as the *Le Chatelier* principle. Dissolving reactions with negative bonding energies occur endothermically while exothermic reactions are hardening or densification processes. It is obvious from Eq 8 that volumetric as well as calorimetric reaction measurements will lead to the same kinetic rates. In Fig. 3 kinetic data of differential calorimetric (Wieker, 1995) and shrinkage volume measurements are shown for a cement reaction at 20 °C. Both methods result in very similar kinetic rates.

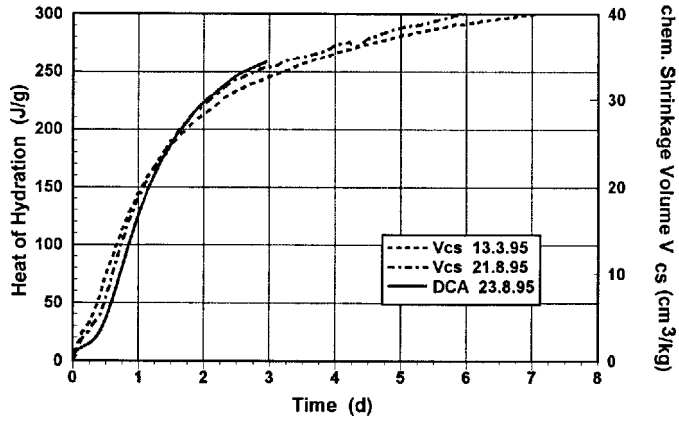

Fig.3, Cement reaction data, chemical shrinkage volume and heat of hydration, T=20 °C

Bonding forces p_B can be expressed by the bulk modulus K and relative volume changes e (Eq 9). The bonding energy W_B of the reacting material is obtained by Eq 10

$$p_B = -K \cdot \frac{\Delta V}{V} = -K \cdot e \qquad [9]$$

$$W_B = p_B \cdot V = -K \cdot \Delta V = -K \cdot e \cdot V \qquad [10]$$

Relative volume changes e can be calculated stoichiometrically for hydration of pure cement phases or can be measured (Paulini 1988, 1992a). It is more difficult to determine their bulk moduli K. Verbeck and Helmuth (1968) mention for cement values of K=54.5 GPa and E=74.5 GPa. Using these data, bulk moduli of CSH-gel were calculated with a composite model (Paulini and Gratl, 1995) applied to the water fraction of full hydration. Bulk moduli and bond energy of cement phases calculated with Eq 10 are shown in Table 2.

Table 2 Calculation of bond energy and strain work resulting from hydration of cement phases

Cement Phase	Heat of Hydration Q_R	rel.Volume Change e=Vs/Va	Density of CSH	Solid Mass Fraction	Water Content	calc.Bulk Modulus CSH-Gel	Hydration Strain Energy W_{IIT}	Hydration Bond Energy W_B	Ratio Q_R/W_B
	J/g	%-V	g/cm3	%-M	%-V	MPa	J/g	J/g	
C3S	490	-9.56%	2.457	80.86%	42.60%	23340	53.7	1123.3	0.44
C2S	222	-7.78%	2.549	82.70%	40.74%	24060	34.5	888.1	0.25
C3A	1373	-24.32%	2.520	71.43%	54.59%	19780	325.0	2672.6	0.51
C4AF	465	-17.78%	2.648	77.88%	48.86%	21620	165.7	1864.1	0.25

For all cement phases the ratio of heat of hydration to bond energy is smaller than 1 ($Q_R/W_B<1$). It is particularly low for slow reacting phases C_2S and C_4AF for which long term calorimetric measurements are inaccurate. More precise calculations of bond energies would have to be based on measured bulk moduli.

A positive bond energy W_B corresponds with a densification work, which results in a volume loss . According to a theory given by Paulini (1988,1992a,b), only the irreversible part of strain energy is responsible for material strengthening. The total work done during the irreversible chemical reaction from initial state 0 to final state 1 along the adiabate 0-2-1 (Fig. 4) is

$$\Delta W = (p_1 - p_0) \cdot (V_1 - V_0) = \Delta p_B \cdot \Delta V \qquad [11]$$

Assuming a possible reversible path between initial and final state, the irreversible strain work ΔW_{irr} remaining in the material becomes

$$\Delta W_{irr} = \Delta W - \Delta W_{rev} \qquad [12]$$

The reversible strain work ΔW_{rev} is obtained by integration over the volume changes V_s (chemical shrinkage volume)

$$\Delta W_{rev} = \int_0^{V_s} p_B \cdot dV = - V \cdot \int_0^{e} K \cdot e \; de = - \frac{K}{2} \cdot e^2 \cdot V \qquad [13]$$

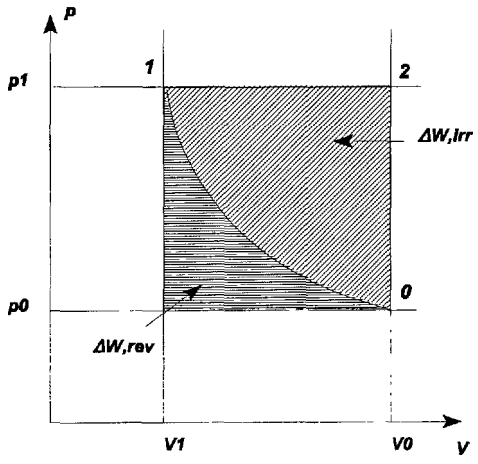

Fig.4, Strain work of an irreversible process from state 0 to 1

With Eqs 11, 9 and 13 the irreversible strain work ΔW_{irr} is obtained with the same expression as the reversible work

$$\Delta W_{irr} = - \frac{K \cdot e^2}{2} \cdot V \qquad [14]$$

Material tensile strength is considered as an all round stress, whose mechanical strain work is opposed directed to the irreversible strain work of the chemical reaction. The failure state is characterized by an equivalence of failure energy and resisting energy. Therefore, tensile strength f_t is defined by half of the supplied irreversible strain work (Eq 15).

$$f_t = - \frac{K \cdot e^2}{4} \qquad [15]$$

Integration of Eq 13 assumes a constant bulk modulus during the chemical reaction. Bulk moduli of concrete change from initially 3-6 GPa to finally over 20 GPa during cement hydration. Exact values depend to a large extent on the stiffness of aggregates. Nevertheless, Eq 15 remains valid if we consider the final values for K and e and if we count the reaction from an initial state without any bond pressure. To prove this, consider the total differential of bond pressure p_B (Eq 16)

$$dp_B = - (K \cdot de + e \cdot dK) \qquad [16]$$

An integration from initial state 0 to the state defined by the degree of hydration α leads to

$$p_B(\alpha) = - \int_0^{\alpha} \left(K \cdot \frac{de}{d\alpha} + e \cdot \frac{dK}{d\alpha}\right) d\alpha \qquad [17]$$

By partial integration of Eq 17 we obtain the bond pressure p_B

$$p_B(\alpha) = -[K(\alpha) \cdot e(\alpha)]_0^{\alpha} + p_{B0} = -K(\alpha) \cdot e(\alpha) + p_{B0} \qquad [18]$$

For engineering practice, the initial state 0 is considered to be the state when water is added to the mix, where an initial bond pressure p_{B0} can be neglected. Then, bond pressure $p_B(\alpha)$ is only dependent on bulk modulus $K(\alpha)$ and on the relative volume change $e(\alpha)$. The description of a hydration dependent tensile strength according to Eq 15 needs a formation function for the bulk modulus $K(\alpha)$. Such a stiffness model for concrete has been proposed by Paulini and Gratl (1995).

INFLUENCE OF CAPILLAR POROSITY

The dominant influence of porosity to strength properties is well known to concrete technologists through the wc-ratio. The same amount of cement C leads to the same shrinkage volume $Vs(\alpha)$

$$V_s(\alpha) = C \cdot V_{cs,u} \cdot \alpha \qquad [19]$$

but will result in different concrete strength depending on the wc-ratio. The most important factor is the strength development in cement paste. In this model a strength f_0 for cement paste with zero porosity is calculated and then reduced by a function considering the capillar porosity $P(\alpha,wc)$. In the literature different theories are known to reduce a strength depending on the porosity of a material. For cement pastes the linear model of Hasselmann has been found to hold true (Rößler and Odler, 1985). Accordingly, strength $f(P)$ is reduced by porosity P (Eq 20)

$$f(P) = f_0 \cdot \left(1 - \frac{P}{P_0}\right) \qquad [20]$$

Therein, P_0 is the maximum porosity where zero material strength occurs. Porosity of cement paste as a function of the degree of hydration and the wc-ratio is given in Eq 21

$$P(\alpha,wc) = \frac{v_{wc} - \alpha \cdot F_{wv}}{1 + v_{wc}} \qquad [21]$$

$$v_{wc}(wc) = \frac{V_w}{V_c} = wc \cdot \frac{\rho_c}{\rho_w} \qquad [22]$$

The constant v_{wc} represents the volume ratio of mix water to cement in the fresh mix (Eq 22). The volumetric water demand factor F_{wv} (Paulini, 1992a) is the ratio of chemical bond water V_{cw} to the binder solid volume V_s can also be calculated stoichiometrically (Eq 23) and is given for different cement types in Table 1.

$$F_{wv} = 0.7422 \cdot [C_3S] + 0.6874 \cdot [C_2S] + 1.2023 \cdot [C_3A] + 1.3754 \cdot [C_4AF] \qquad [23]$$

Fig. 5 shows porosities of cement paste over wc-ratio for limiting degrees of hydration α=0 and α=1. Zero strength porosity P_0 of Eq 20 is taken to be $P(0,wc)$ for α=0 according to Eq 21. The strength reducing function $(1-P/P_0)$ has a shape as shown for the degree of hydration α=1 in Fig.5.

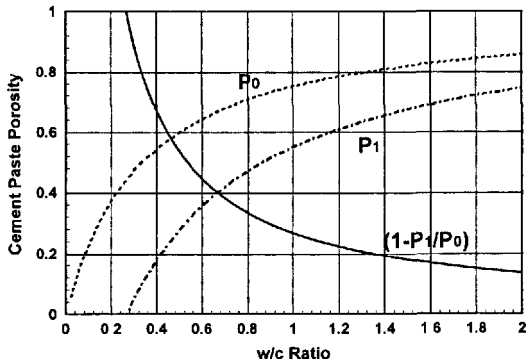

Fig.5, Limiting porosities in hydrated cement paste and strength reducing function

Hydrostatic tensile strength for zero porosity f_{t0} is calculated from Eq 15. With the cement content C_p of cement paste

$$C_p = \frac{\rho_c}{v_{wc}(wc) + 1} \qquad [24]$$

the relative volume change e in cement paste becomes Eq 25

$$e\ (\alpha,wc) = C_p \cdot V_{cs,u} \cdot \alpha \qquad [25]$$

Uniform tensile strength f_{ct} of a concrete mix with a cement content C_{con} is obtained with Eq 15 to

$$f_{ct}(\alpha,wc) = -\ e(\alpha,wc)^2 \cdot \frac{K(\alpha)}{4} \cdot \frac{C_{con}}{C_p} \cdot \left(1 - \frac{P(\alpha,wc)}{P(0,wc)}\right) \qquad [26]$$

Fig. 6 shows some model results of concrete tensile strength for different degrees of hydration calculated with Eq 26. A mix content of 300 kg/m^3 cement and an ultimate shrinkage volume of $V_{cs,u}$ = 60 cm^3/kg have been assumed. Bulk modulus has been calculated with Eq 27 and constants of K_0=5 GPa, B=3.5, C=0.4 and D=2 (Fig. 7)

$$K(\alpha) = K_0 \cdot (1 + B\cdot\alpha + D\cdot\alpha^C\cdot(1-\alpha)) \qquad [27]$$

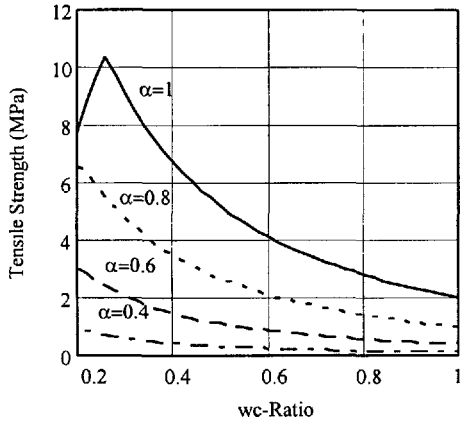

Fig. 6, Concrete tensile strength, model results, C_{con}=300 kg/m^3

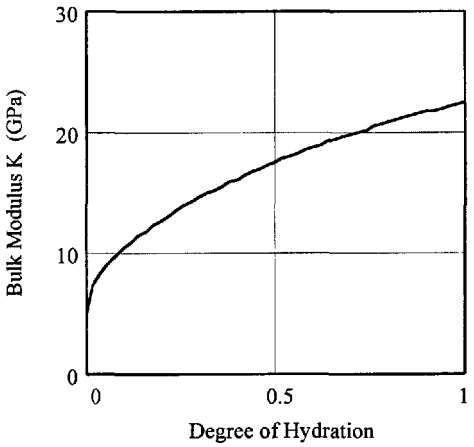

Fig. 7, Bulk modulus K(α)

Results obtained by Eq 26 are in normal strength ranges for concrete and exhibit the known dependence on the wc-ratio. Notice also the strength limiting behaviour for low wc-ratios and high degrees of hydration, resulting from incomplete hydration. Fig. 8 shows a similar calculation for different cement contents at a degree of hydration α=0.9 .

This strength model does not describe the relationship between tensile and compressive strength. Such a model must contain a description of internal material friction and is not yet finished.

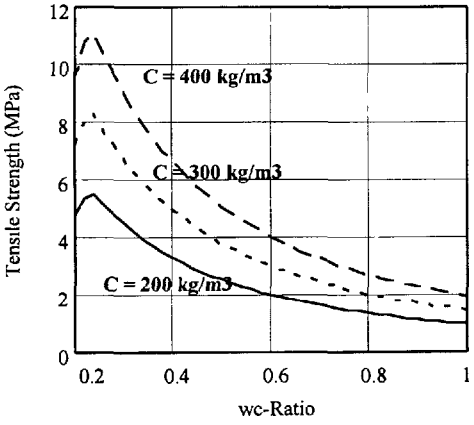

Fig. 8, Concrete tensile strength, model results, degree of hydration α=0.9

CONCLUSION

Exothermic hydration of cement is accompanied by a chemical shrinkage. Internal volume changes of cement hydration are very much dependent on the cement type especially during the initial reaction period. During early cement hydration a swelling behaviour can dominate over volume shrinkage. The swelling period is strongly influenced by the percentage of C_2S. The induction period of setting is defined by the swelling time.

Internal volume changes during a chemical reaction are generally not considered in physics. In this article an attempt is made to express bonding forces of a chemical reaction in terms of volume changes and bulk modulus. Heat of reaction and bond energy are considered as oppositely acting energies according to the principle of *Le Chatelier*. Bonding forces lead to a material densification and supply a strain work to the material. The uniform tensile strength resulting from chemical reaction is defined with half of the supplied strain work. A strength model based on chemical shrinkage volume is introduced for cement paste. The influence of porosity has been considered according to the linear Hasselmann theory. A few results prove the model to be applicable to the tensile strength of concrete.

LONG-TERM SHRINKAGE OF HIGH-PERFORMANCE CONCRETE, HPC

Bertil PERSSON, Lund Institute of Technology, University of Lund, Division of Building Materials, Lund, Sweden

ABSTRACT In this article an extensive experimental and numerical study of shrinkage in HPC is outlined. For this purpose cylinders of eight qualities of concrete were studied. Parallel studies of autogenous, carbonation and drying shrinkage, hydration, internal relative humidity and strength were carried out. Previous research in the field is summed up. Finally the article presents the mechanisms of shrinkage in HPC by modelling correlations to the composition of the concrete and the physical properties. The project was carried out between the years 1992 and 1996.

Keywords: Autogenous shrinkage, Carbonation, Pozzolanic, Relative humidity, Self-desiccation.

GENERAL

Autogenous shrinkage caused by the self-desiccation in HPC with low water-cement ratio, w/c, has been pointed out by Persson (1997). Autogenous shrinkage as such is not a new phenomenon, but may be the driving force is self-desiccation. When the internal relative humidity decreases substantially the depression in the pore water also decreases, which causes compression in the aggregate and the cement paste (Persson, 1996) and self-stress in HPC.

PREVIOUS RESEARCH ON SHRINKAGE OF HPC

Roy and Larrard (1993) studied shrinkage of both HPC and normal concrete at different w/c, and also with different amounts of silica fume. They found that the autogenous shrinkage increased at lower w/c. At w/c $\approx$ 0.3 the autogenous shrinkage after 400 days was about 250 μm/m. However, they observed the total shrinkage (sorption shrinkage and autogenous shrinkage) to be larger at higher w/c; for example about 600 μm/m at w/c $\approx$ 0.6. Fig 1 shows the results of shrinkage versus w/c with different amounts of silica fume (Roy and Larrard, 1993). The specimens were 1 m long and 0.16 m in diameter. The following conclusions were drawn:

1) The autogenous shrinkage increased with decreasing w/c.
2) The autogenous shrinkage increased when the concrete contained silica fume.
3) The total shrinkage and the sorption shrinkage increased with increasing w/c.

Other French experiments were carried out on 0.12 m diameter cylinders with a length of 0.24 m (Sicard, 1993). In this case the water moisture losses were 1% by the weight of the concrete per year. The measurements of shrinkage started at an age of 1.2 days. In Fig 2 the result of the autogenous shrinkage is shown versus time. The following conclusions were drawn:

1) The autogenous shrinkage increased with decreasing w/c.
2) The autogenous shrinkage was larger with limestone aggregate than with sandstone.
3) The autogenous shrinkage was larger in a concrete with silica fume than without silica fume.

Tazawa and Miyazawa (1993) studied shrinkage at very early ages by cast-in strain gauges. The specimen was 0.1 x 0.1 x 1.2 m. The concrete was cast in vinyl polymer plastic moulds allowing for movements of the concrete at early ages. The measurements started at $\approx$ 0.2 days' age. Fig 3 shows the shrinkage versus time at different w/c. The shrinkage increased with lower w/c and higher content of silica. The difference between autogenous and drying shrinkage was small.

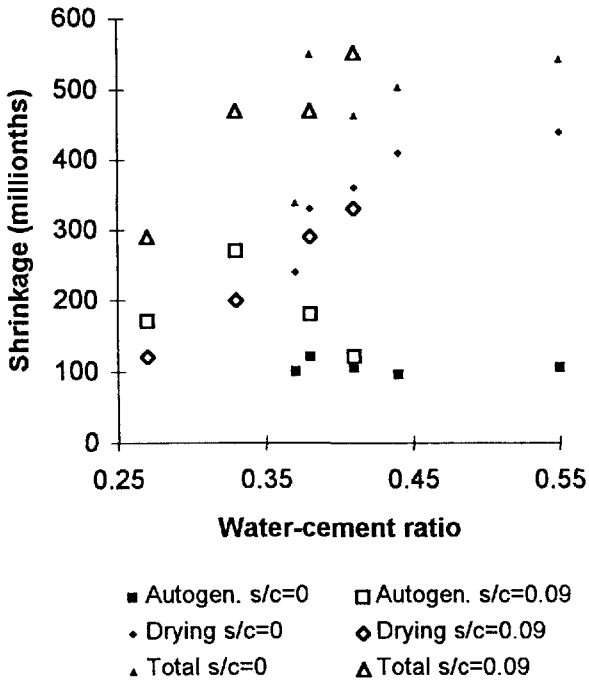

Figure 1 Shrinkage versus w/c with different amounts of silica fume (Roy and Larrard, 1993).

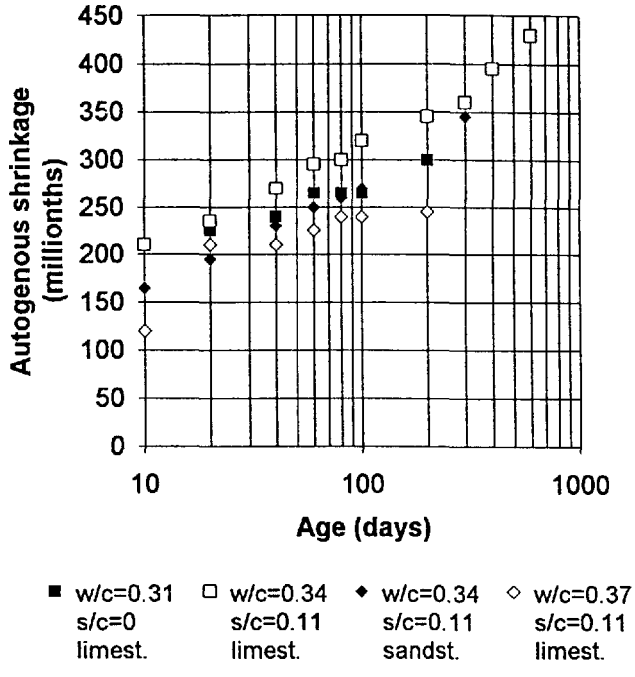

Figure 2 Autogenous shrinkage versus time, (Sicard, 1993). c = cement; s = silica fume.

EXPERIMENTAL METHOD

A total of 52 specimens for studies of autogenous shrinkage and 26 for studies of drying shrinkage were cast from 78 different concrete batches with compositions given in Table 1.

After demoulding and insulation by 2 mm butyl rubber clothing (in case of studies of autogenous shrinkage), 6 stainless steel screws were fixed into cast-in items in the cylinder. Measurements were taken on three sides of the cylinder on a length of 250 mm within 1 h of demoulding (Bazant and Carol, 1993). After cooling the specimen was placed in a 20 °C climate chamber with a relative humidity, RH = 55%. The measuring was performed by mechanical devices.

SOURCES OF ERROR

In spite of all the careful precautions some faults existed causing unforeseen weight losses. The specimens were continuously weighed to detect this loss. Possible absorption of water in the butyl rubber insulation would affect the total weight of the specimen. Effects of hydration heat in particular were avoided by obtaining the first measurement at 20 °C. A thermocouple was cast in the specimen and the temperature was followed. The different materials of the mix design were carefully weighed to avoid variations. However, the moisture of the gravel (normally 4%) had to be calibrated after the batching as well, which may cause alteration in the mixed proportions.

RESULTS FROM PRESENT STUDY

In Fig 4 a summary of the shrinkage of concrete 6 is given versus age. Fig 5 shows the relative loss of weight (the ratio of weight loss, w_e, to the mixing water, w) versus time. Fig 6 shows the shrinkage versus the relative loss of weight. Symbols in use in Figs 4, 5 and 6:

6...	denotes the concrete type
....02	denotes a batch of the same type of concrete
c	denotes the content of cement (kg/m^3)
s	denotes the content of silica fume (kg/m^3)
w	denotes the mixing water of the concrete (kg/m^3)
w_e	denotes the evaporated water or the absorbed carbon dioxide (kg/m^3)
.B..	denotes autogenous shrinkage
.D..	denotes drying shrinkage (RH= 55%)

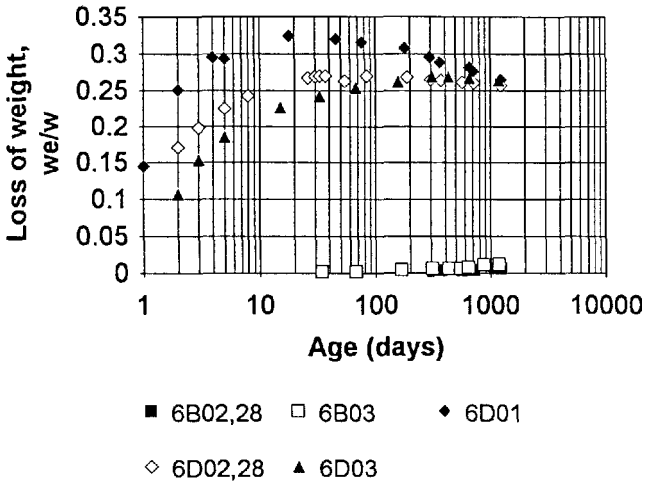

Figure 5 Loss of weight versus concrete age.

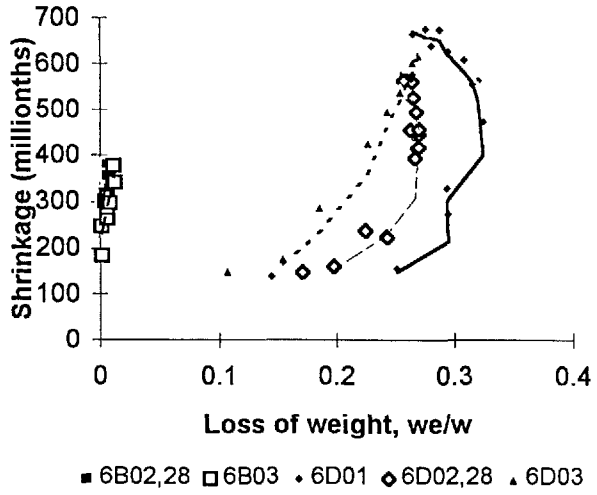

Figure 6 Shrinkage versus loss of weight.

ACCURACY

All results of shrinkage studies and weighing were presented in the same way as in Figs 4, 5 and 6. After about 1 months' age carbonation affected the weight of the drying specimens at w/c > 0.30, which caused a combination of drying and carbonation shrinkage. At low w/c = 0.25 no increase of the weight was observed within the period of measurement. Absorption of water in the butyl rubber insulation existed at a high relative humidity only. Three rubber insulation tubes were first placed in an ambient relative humidity, RH = 40%. After one week they were weighed and placed in RH = 55%. No change of weight was observed at RH = 55%. At RH = 95% the weight increased slightly but was hardly detectable, that is 0.1 g of increased weight. Since the specimen originally contained 120 g of mixing water the absorption was negligible.

A thermocouple was cast in the specimen and the temperature was followed as the first measurement was performed. The maximum faults would then have been $4 \cdot 8 \cdot 10^{-6} = 32$ μm/m, assuming the same effect of temperature on HPCs like on normal concrete. The temperature was followed as the first measurement was performed (± 1 °C of difference to 20 °C reducing the observed fault to ≈ 16 μm/m). The variations in the mixed design were normally very small, much less than stipulated w/c ± 0.01. Only for concrete 6 was a slightly larger difference observed; w/c≈ 0.285 instead of w/c = 0.30. Finally, the mechanical devices (Huggenberger and Proceq) were continuously calibrated with an INVAR rod and with a Mitutoyo micrometer. The reading of the device was within 0.005 mm, which was comparable to a maximum fault of 20 μm/m (the length of the device: 250 mm). The total fault of a temperature difference of ± 1°C and the fault of the mechanical device was fairly large i.e. ≈ 16 + 10 ≈ ± 25 μm/m.

ANALYSIS

Autogenous shrinkage

From a previous work on basic creep of HPC (Persson, 1995) it was observed that the loss of weight for 14 cylinders used in the long-term creep studied was less than 0.7 g per specimen over a period of at least 1 year. (A 0.7 g loss of weight equals to we/w= 0.006.) However, in the present study the joint between the side of the cylinder and the end rubber clothing did not perform perfectly, which may have increased the loss of moisture. Fig 6 show that very small loss of weight may affect the measured shrinkage. Linear regressions were performed to obtain the measured shrinkage at no loss of weight (autogenous shrinkage). In Fig 7 the autogenous shrinkage is given versus the w/c. The type and amount of silica fume affected the measured autogenous shrinkage, Fig 8, which has also been observed by others (Mejlhede Jensen, 1993).

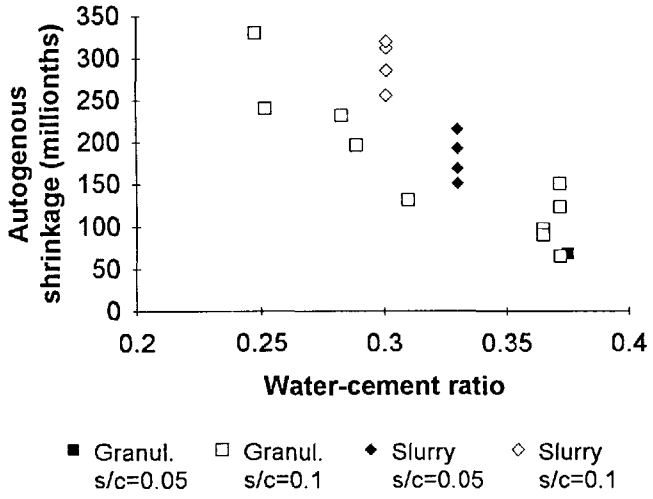

Figure 7 Autogenous shrinkage versus w/c. The concrete type is given.

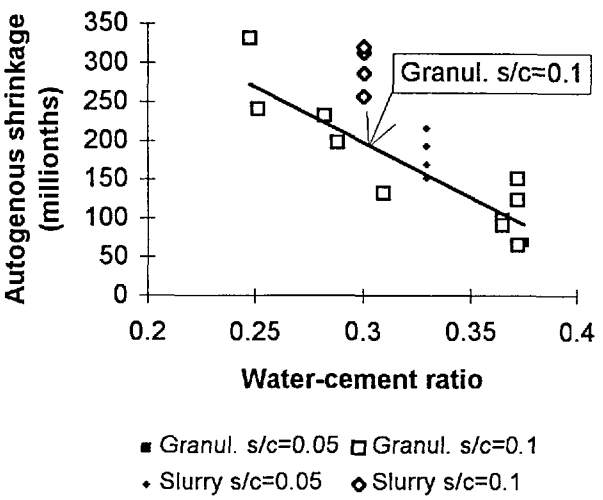

Figure 8 Autogenous shrinkage versus w/c. The type and amount of silica fume is indicated.

In Fig 9 the autogenous shrinkage is given versus the internal relative humidity. The autogenous shrinkage was affected by the type and amount of silica fume, Fig 10. (The internal relative humidity was obtained in the experiments). Silica fume slurry reacted more rapidly with the calcium hydroxide which caused a larger shrinkage. The following correlations were obtained to describe the autogenous shrinkage, ε_B (mm/m):

$$\varepsilon_B = k_s \cdot k_5 \cdot 0.624 \cdot [1 - 2.27 \cdot (w/c)] \quad [1]$$

$$\varepsilon_B = k_{s\varnothing} \cdot 1.75 \cdot (1 - 1.13 \cdot \varnothing) \quad [2]$$

k_s	= 1.5 for silica fume slurry; k_s = 1 for granulated silica fume
$k_{s\varnothing}$	= 1.3 for silica fume slurry; k_s = 1 for granulated silica fume
k_5	= 0.78 for 5% silica fume; k_5 = 1 for 1% silica fume
w/c	denotes the w/c $\{0.2 < w/c < 0.4\}$
$\varnothing$	denotes the internal relative humidity $\{0.7 < \varnothing < 0.9\}$

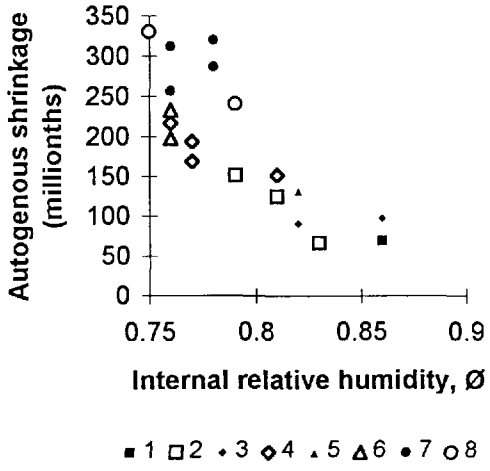

Figure 9 Autogenous shrinkage versus the internal relative humidity. Type of concrete.

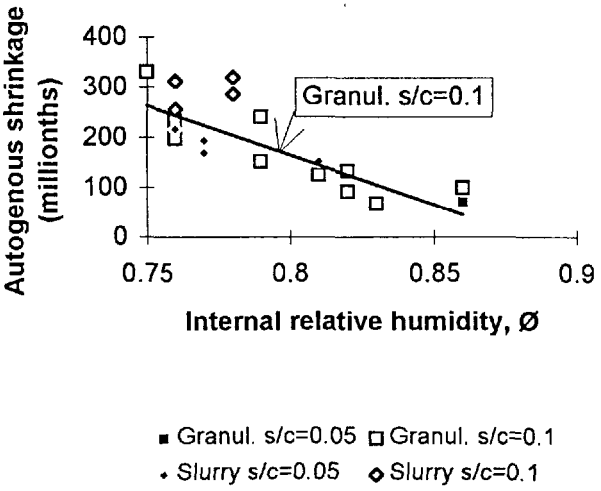

Figure 10 Autogenous shrinkage versus the internal relative humidity. Type of silica fume.

Drying shrinkage of mature concrete

Small loss of weight was observed of the sealed specimens of reasons mentioned above. Table 2 shows the loss of weight recorded during a period of at least 3 years from a 1.8 kg concrete specimen. Small loss of weight over a long period gave a good simulation of the shrinkage of a large specimen of mature concrete. The relationship between the relative loss of weight, i.e. the ratio of evaporated water to the mixing water made the study non-dimensional. Fig 11 shows the specific shrinkage versus the ratio of evaporated water to the mixing water, w_e/w:

$$\varepsilon_D = k_{sD} \cdot 20 \cdot [1.1 \cdot (w_e/w) - (w_e/c)] \qquad \{0 < w_e/w < 0.03\} \qquad [3]$$

c	denotes the cement content of the concrete (kg/m^3)
k_{sD}	= 0.4 for concrete with silica fume slurry; k_{sD} = 1 for granulated silica fume
w	denotes the mixing water of the concrete (kg/m^3)
w_e	denotes the evaporated water from the concrete (kg/m^3) $\{0 < w_e/w < 0.03\}$
ε_D	denotes the specific shrinkage related to the evaporated water (per mil)

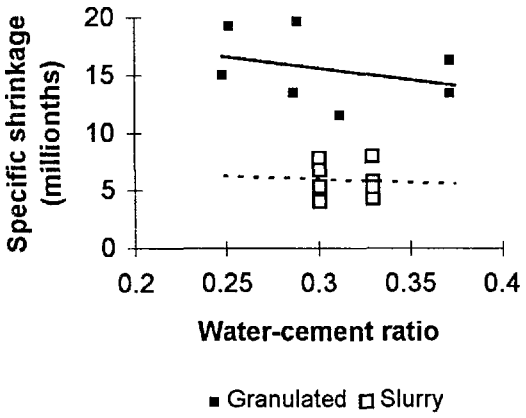

Figure 11 Specific shrinkage versus w/c.

Drying shrinkage of young concrete

The internal relative humidity, Ø, of the cylinder used for the measurements of shrinkage was obtained in the experiments. Between 5 and 28 days' age Ø became less than 0.70, which ceased the effect of hydration and thus the autogenous shrinkage in the specimens. However, at 28 days' age, Ø of the specimen was still about 5% larger than the ambient relative humidity. However, due to carbonation of the calcium hydroxide of the concrete, the loss of weight ceased at an age of the concrete that was dependent on w/c as shown in Fig 12. [The water in the calcium hydroxide (molecule weight 74) was replaced by the carbon dioxide (molecule weight 100)]. When sufficient silica fume was available in the concrete all the calcium hydroxide was consumed by the pozzolanic reaction according to Eq 4. In normal concrete about 16% silica fume is required to consume all the calcium hydroxide (Peterson, 1976):

$$3\ Ca(OH)_2 + 2\ SiO_2 = 3\ CaO.2\ SiO_2.3\ H_2O \qquad [4]$$

At lower w/c the required amount of silica fume, s_{rq}, to consume all the water in the calcium hydroxide became smaller (Powers & Brownyard, 1946-1948; Peterson, 1976):

$$s_{rq} \approx [(w/c)/0.39] \cdot 0.16 \approx 0.4 \cdot (w/c) \qquad [5]$$

According to Eq 5 carbonation does not occur at w/c = 0.25 and s/c = 0.10. This was confirmed by the experiments as shown in Fig 12. At w/c = 0.3 some of the concretes did not carbonate, which indicated the required amount of silica fume to be slightly lower than estimated in Eq 5. Eq 6 was evaluated for the age at carbonation of HPC with 10% silica fume, t_{ca} (days):

$$t_{ca} = 0.142 \cdot (w/c)^{-6.42} \qquad \{0.3 < w/c < 0.4\} \qquad [6]$$

For concretes with w/c < 0.3, when carbonation did not occur, the drying shrinkage, ε_{D1}, was correlated to the loss of weight by Eq 7 (μm/m):

$$\varepsilon_{D1} = 1600 \cdot [(w/c) - 0.22] \cdot e^{63 \cdot [0.42 \cdot (we/w) - (we/c)]} \qquad \{0 < w_e/w < 0.30\} \qquad [7]$$

c	denotes the cement content of the concrete (kg/m^3)
w	denotes the mixing water of the concrete (kg/m^3) {0.25< w/c<0.30}
w_e	denotes the evaporated water from the concrete (kg/m^3) {0< w_e/w<0.30}
ε_{D1}	denotes the specific shrinkage related to the evaporated water (μm/m)

However, for w/c > 0.3 the carbonation took place simultaneously with the drying of moisture In this case the shrinkage was correlated to time, which made Eq 8 dependent on the size of the specimen. (Eq 7 was non-dimensional.) The time of drying shrinkage was set according to Eq 6. Fig 13 shows the rate of shrinkage. The following equation was obtained [(mm/m)/day]:

$$\delta\varepsilon_{D2}/\delta t = k_s \cdot [5.65 \cdot (w/c)^2 - 3.28 \cdot (w/c) + 0.556]/t \qquad [8]$$

k_s	=0.85 for concretes with silica fume slurry; k_s= 1 otherwise
t	denotes the age (days)
$\delta\varepsilon_{D2}/\delta t$	denotes the rate of shrinkage [(mm/m) /day] (diameter: 55 mm; length: 300 mm)

Eq 8 indicates that the rate of drying was lower for concrete with silica fume slurry than for concrete with granulated silica fume, which seemed logical due to the autogenous shrinkage.

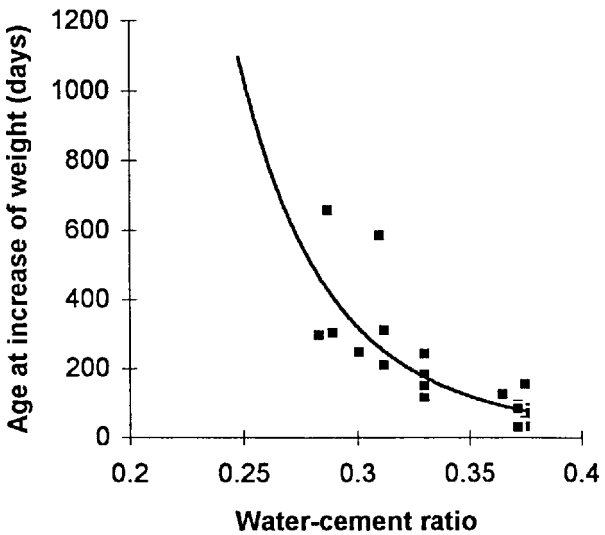

Figure 12 Age at increase of weight due to carbonation versus the w/c.

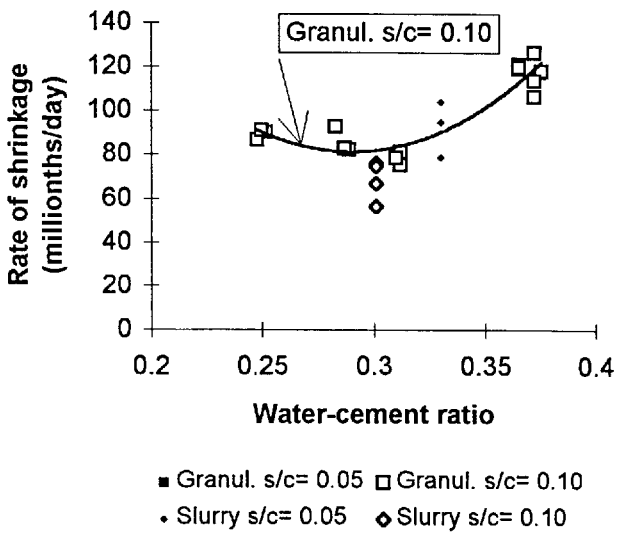

Figure 13 Rate of drying shrinkage versus the w/c. Type of silica fume is indicated.

Carbonation of mature concrete

At an age as described in Eq 6 the specimens began to carbonate, which was recorded by weighing. Once the carbonation started, no decline of the internal relative humidity occurred. Fig 6 shows the carbonation shrinkage versus the loss of weight. Fig 14 shows the carbonation rate versus w/c. The carbonation rate, $\delta(w_c/w)/\delta t$, was related to the mixing water, w [(kg/kg)/day]:

$$\delta(w_c/w)/\delta t = 0.25\ (w/c-0.25)/t \qquad \{0.25< w/c<0.40\} \qquad [9]$$

t denotes the age (days)
w_c denotes carbonated weight (kg/m^3) $\{0.2< w_c/w<0.35\}$

Eq 9 confirmed the previous results in Eqs 5 and 6 namely that no carbonation occurred in a concrete with 10% silica fume and a water-cement ratio less than 0.25.

Total shrinkage

From Fig 15 the shrinkage after at least 3 years (4 years for concretes 4 and 7) was correlated:

$$\varepsilon = k \cdot 34 \cdot [(w/c)^2 - 0.68 \cdot (w/c) + 0.13] \qquad [10]$$

$$\varepsilon_B = k_B \cdot 1.5 \cdot [0.43 - (w/c)] \qquad [11]$$

$$\varepsilon_C = 0.85 \cdot [(w/c) - 0.25] \qquad [12]$$

$$\varepsilon_D = 33 \cdot [(w/c)^2 - 0.65 \cdot (w/c) + 0.11] \qquad [13]$$

k =1.1 for 10% silica fume slurry; k=1 for 10 % granulated silica fume or 5% slurry
k_B =1.5 for 10% silica fume slurry; k_B=1 for 10 % granulated silica fume or 5% slurry
ε, ε_B, ε_C, ε_D denote total, basic (autogenous), carbonation, drying respectively (mm/m)

Comparison with other results

Table 2 shows a comparison with results according to other studies of the estimated shrinkage.

Table 2 A comparison of results of the estimated shrinkage (μm/m) for w/c= 0.3 and s/c= 0.1.

Study	le Roy and Larrard (1993)	Sicard (1993)	Tazawa and Miyazawa (1993)	Persson (1995A)	Persson (1995A)	Present study	Present study
Silica fume	Granulated	Granul.	Granulated	Granul.	Slurry	Granul.	Slurry
Age (days)	400	600	40	1000	1000	1200	1500
Autogenous	220	430	200	320	380	195	295

Carbonation	-	-	-	-	-	45	30
Total	380	-	400	-	-	540	610

CONCLUSIONS

The following conclusions were drawn from the experiments after studies for at least 3 years:

1) The autogenous shrinkage was dependent on the age, w/c and type and content of silica fume.
2) The autogenous shrinkage of HPC was related to the decline of internal relative humidity.
3) Estimations of drying shrinkage of mature HPC were made related to the evaporated water.
4) The conditions for carbonation of HPC were settled related to w/c and content of silica fume.
5) The age at start of the carbonation of HPC was related to w/c.

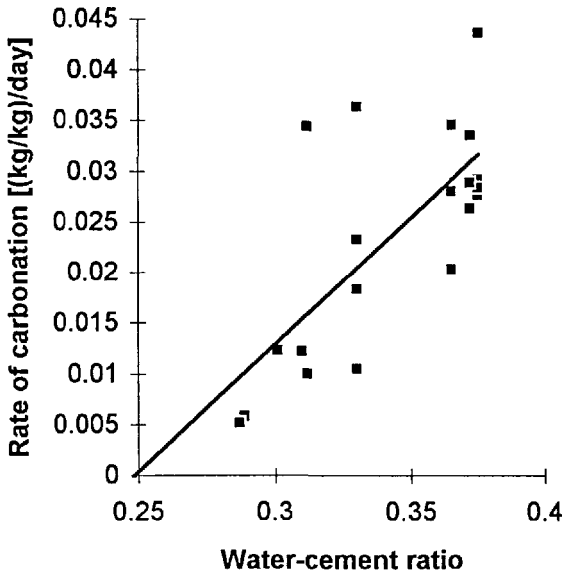

Figure 14 Rate of carbonation versus w/c.

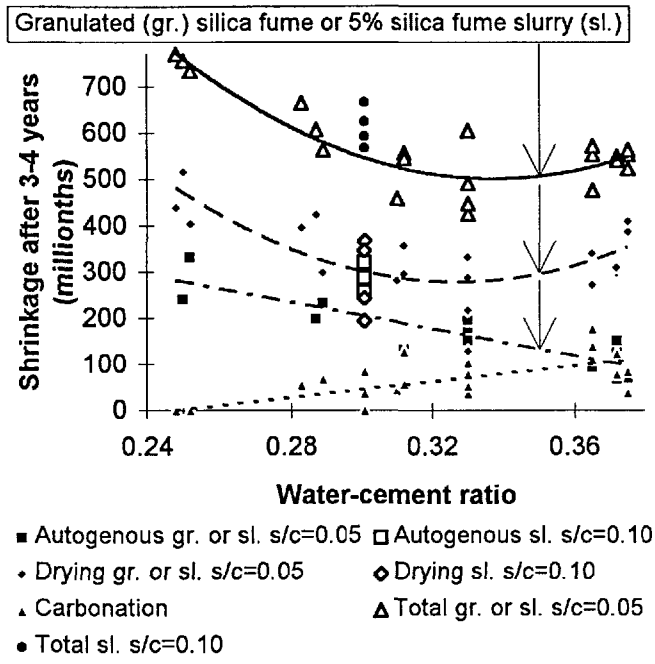

Figure 15 Type of shrinkage versus w/c.

6) The drying shrinkage of young HPC was related to the age and to the loss of weight.
7) The carbonation rate of HPC was related to age and w/c by a logarithmic relationship.
8) The total shrinkage after 3-4 years was related to age, w/c and type and content of silica fume.

ACKNOWLEDGEMENT

The study was financed by a Norwegian-Swedish consortium (Cementa, Elkem, Euroc Beton, NCC Bygg, SKANSKA, Strängbetong, BFR, NUTEK) which hereby is gratefully acknowledged.

INVESTIGATIONS ON SHRINKAGE COMPENSATED AND EXPANSIVE REPAIR MORTARS AND GENERAL BEHAVIOUR TO TYPICAL INFLUENCES

M. DEGENKOLB and D. KNÖFEL, Universität-GH Siegen, Labor für Bau- und Werkstoffchemie, Siegen, Germany

ABSTRACT Lime-based binders and mortars rich in blastfurnace slag were modified with expansion compounds on the basis of calcium aluminate, calcium aluminate sulphate and meta-kaolin in combination with gypsum. Compounds on the basis of CA and CAS show the quickest expansion. Meta-kaolin addition gives low swelling effects and causes a slower reaction. Generally, the course of expansion succumbs a strong interaction with chemical admixtures. The addition of slag improves the controllability of expansive systems, independently of the binder.

Key-words: Additives, Blastfurnace Slag, Ettringite, Expansion, Lime

INTRODUCTION

As repair mortars for masonry two basic binder systems have been developed: Lime-based mortars blended with blastfurnace slag and sulphate activated slag mortars (Trautmann, 1990). For the restoration of masonry, lime-based mortars offer a favourable distortability and water vapour permeability. The first problem encountered is the strong initial shrinkage of lime-based mortars. These negative volume changes affect for example the bonding properties of repair mortars. Expansive additives, well known from the expansive cement technology (Kurdowski, 1980), enables us to compensate this initial shrinkage and to produce low swelling mortars. Sulphate activated slag mortars own a high sulphate resistance and offer good conditions for expansion by controlled ettringite formation (Henkel, 1994). By use of expansive compounds affecting initial swelling phenomena, the bonding properties of joint mortars can be improved.

PROGRAM

The following binders were used:

- lime hydrate with low hydraulic contents
- lime hydrate with slag sand (75 % lime + 25 % slag sand by weight) and
- slag sand/gypsum/cement (85 % slag sand + 10 % gypsum + 5 % portland cement by weight).

As expansion compounds

- calcium aluminate cement/gypsum (CA-1/gypsum and CA-2/gypsun)
- meta-kaolin/gypsum (MK/gypsum)
- calcium aluminate sulphate/gypsum (CAS/gypsum)

were added to the various binders.

The analyses of the raw materials used are established in table 1; the composition of expansive compounds is shown in table 2. The binder/aggregate value is 1:4 in parts by weight for all mixtures. As test samples, mortars prisms 40 mm x 40 mm x 160 mm were produced, as well as small prisms made of binder paste with the dimensions 15 mm x 15 mm x 60 mm. The

consistency of the mortar mixtures was adjusted to a slump of 15 cm ± 0,5 cm, the binder pastes were produced with a water/binder ratio of 0,5.
The following investigations were carried out, according to Knöfel and Schubert, 1993:

- determination of length change on hardened test samples
- expansion immediately after production using a special measuring mould
- determination of setting time
- strength development and modulus of elasticity
- variation of storage conditions (conditions are mentioned in table 4)
- freeze/thaw-cycles
- liability to efflorescence
- x-ray diffraction
- scanning electron microscopy
- application of testing fields

RESULTS

Lime-Based Mortars

Lime-based mortars exhibit a strong initial shrinkage. The expansive potential of the expansive additives is consumed for the compensation of this early shrinkage. Figure 1 shows the compensation of the initial shrinkage by increasing addition of expansion compound. More than 20 % addition provides actual expansion. The figure clarifies the typical length change of lime based binders; the main part of the shrinkage process happens during the first days.
By comparison of the different expansion additives used - meta-kaolin, calcium-aluminate-sulphate and calcium aluminate cements in combination with gypsum - the following differences relating to their mode of working have been determined and the results are mentioned in table 3.
The addition of meta-kaolin provides low expansion and the reaction proceeds slowly. To accelerate the expansion process, microsilica and nanosilica were added. This results in higher expansion, so that it is possible to compensate the strong shrinkage and to produce low swelling mortars up to an expansion of 0,5 mm/m. The addition of pure calcium aluminate sulphate (CAS) affects strong expansion and it takes a rapid course. The setting and hardening of lime-based mortars were accelerated. By addition of aluminous cements a quick and strong expansion can be reached.

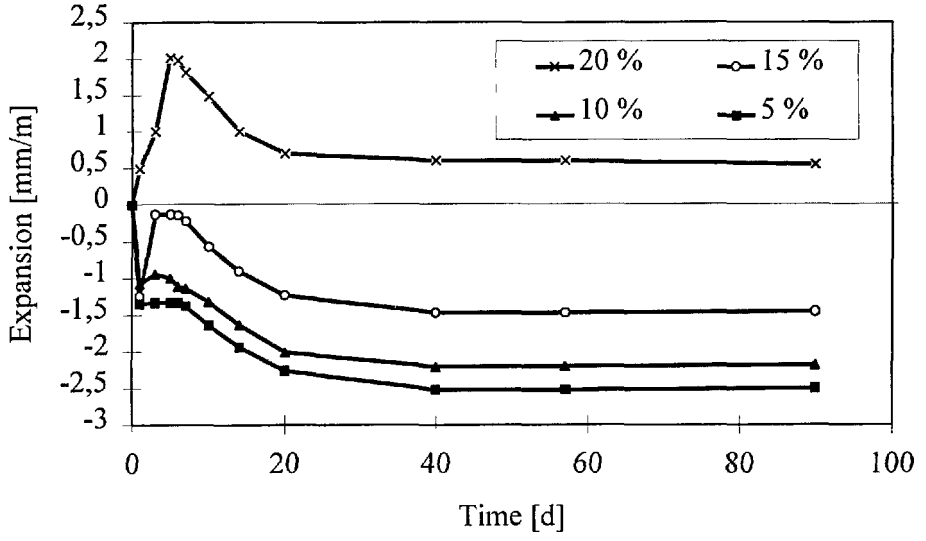

Figure 1 Length change of lime-based mortars, increasing addition (% by binder-weight) of expansive compound CA-1/Gypsum
Storage conditions 7 days 20/95 (20° C/95 % relative humidity), subsequently 23/50 (23° C/50 % r.h.)

After the end of the expansion period, lime-based mortars shrink to the same extent as unmodified binders. Normally, this is the usual behaviour of all expansion mortars, so that the term "shrinkage free" mortars is not correct strictly speaking.

Table 3 Comparison of different expansion compounds in different binder systems

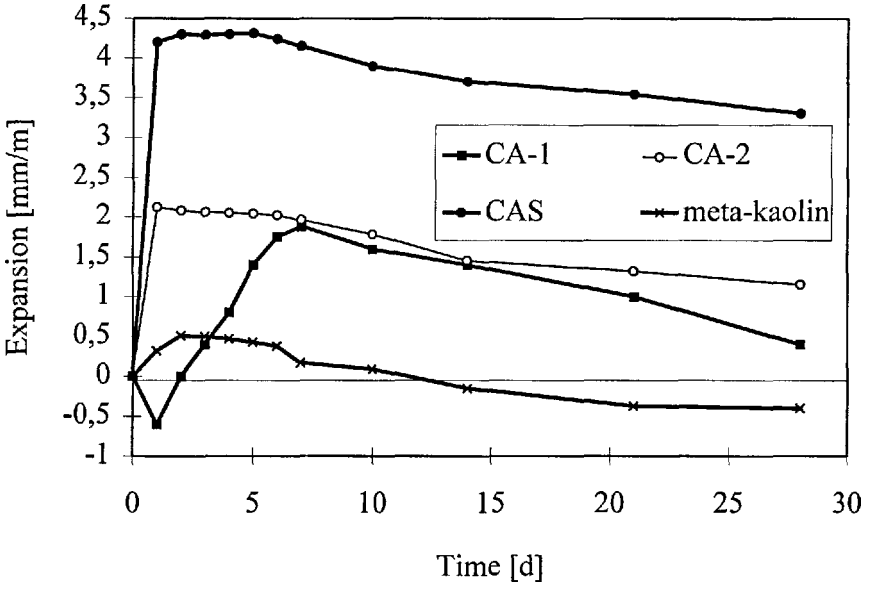

Figure 2 Lime/slag-mortars with different expansive compounds. Storage conditions 7 days 20/95, subsequently 23/50

Slag-Based Mortars

Unmodified mortars on the basis of sulphate activated blastfurnace slag don't succumb the initial shrinkage of lime mortars mentioned above. The hardening process is characterised by a low swelling period (0,2-0,3 mm/m) during the first days. The following shrinkage period takes a very slow course up to 90 days after production. Slag-based mortars offer excellent conditions for the modification with expansive additives, because the main hydration phases are AFt-phases like ettringite. By manipulation of quantity, speed or morphology of the ettringite formation a controlled expansion can be reached. Generally the addition of the expansive compounds affects

lower expansion values than in the lime-based mortars (see table 3). The reasons are the low $Ca(OH)_2$-content and accordingly lower pH-values.
A stronger expansion can be reached by adding $Ca(OH)_2$ to the slag-sulphate system. However, the excellent volume stability and the controllability of slag-mortars are impaired by adding $Ca(OH)_2$.
The addition of meta-kaolin affects low swelling phenomena. The further shrinkage doesn't differ from the normal shrinkage behaviour. Adding CAS/gypsum to slag-based mortars without an additional $Ca(OH)_2$-additive, low swelling effects are determined. By adding $Ca(OH)_2$ strong expansion is reached, but the controllability decreases.

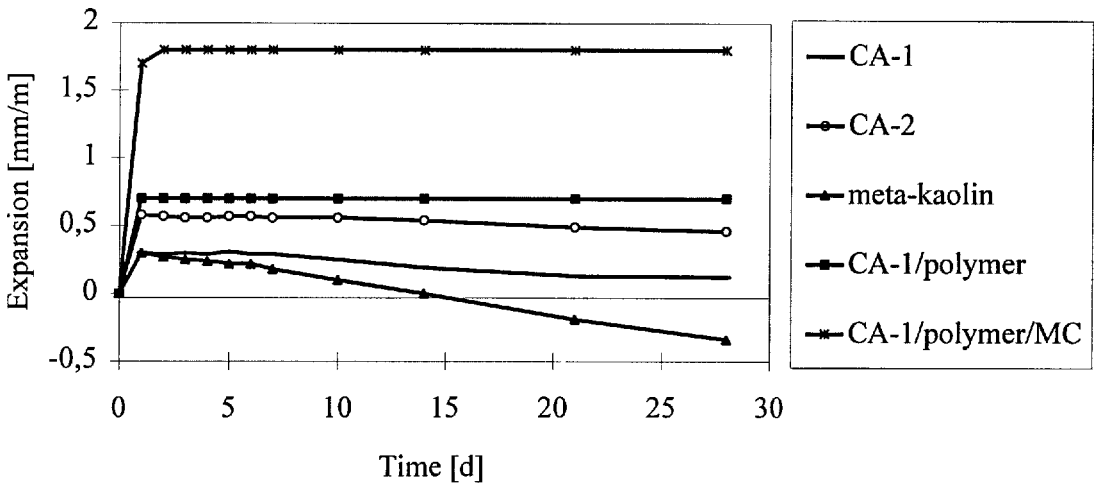

Figure 3 Sulphate activated slag mortars modified with various expansive compounds. Storage conditions 20/95, subsequently 23/50

The addition of CA-cements with varying Al_2O_3-contents in combination with gypsum enables the production of low and strong expansive mortars, which possess a long term shrinkage compensation due to a slow consumption of the sulphate compound (see figure 3).

Influence of storage conditions

The samples tested were stored until the 7th day after production in climate 20/95 (20 °C/95 % rel. air humidity). Thereafter, they were subjected to four different storage conditions until the testing date, temperature and air humidity being varied. Additionally one set of the samples was stored under water at 8° C immediately after production. The storage conditions are mentioned in table 4.

Table 4 Storage conditions

Storage	Temperature	Humidity	Weathering
	[° C]	[% relative humidity]	
wet (20/95)	20	95	-
dry (23/50)	23	50	-
CO_2	20	65-75	1 Vol.-% CO_2
under water	8	under water	-

The different storage conditions indicate the potential and the limits of practical applications of expansive mortars. The time progress and the ending of expansion is shown by a storage in wet climate with a humidity of 95 %; that means that for practical application the expansion of the mortars should be terminated during the first 7 days after production. The following change of storage to a temperature of 8° C under water shows remaining expansive compounds, that means, that undesired swelling phenomena after the 7th day of hydration can be detected. The "dry" storage in a climate of 23/50 shows the maximum of shrinkage. The weathering with 1 % carbon dioxide by volume indicates the resistance of the ettringite produced to carbonation. The additional storage in water at 8° C immediately after production determines the total potential of expansion at extreme conditions.

Generally the addition of blastfurnace slag has positive effects on the expansion behaviour of the mortars, which is expressed by quicker hardening, earlier expansion and easier controllability. Furthermore expansion is terminated after 7 days and during the following storage under water at a temperature of 8° C, no further expansion phenomena are observed - whereas, using pure lime mortars without slag addition, expansion may occur longer than 7 days. The slag can take over a regulating buffer function within the expansive system. The development of expansive mortars turned out to be complex using pure lime hydrate as binder.

By a storage in alternating wet/dry-cycles, liability of efflorescence and volume stability were detected. E.g., mortars containing expansion compounds with a CA-1/gypsum-ratio < 1 show damaging phenomena during the wet/dry-changing.

Further, the resistance to freeze/thaw-changing was tested. All samples remained without damaging after 45 cycles of freeze (-20° C, for 3 hours), thaw (+20° C for 3 hours) and respectively 1 hour of cooling and heating.

The behaviour of the mortars developed to natural weathering was tested by application on test fields as repair mortars on historic brickwork constructions in the north of Germany.

Main results of the storage variations:

- good controllability due to the presence of blastfurnace slag
- sulphate activated slag mortars are hardly influenced by changing of storage conditions
- critical sulphate contents are detected by wet/dry-cycles in climate 23/50
- during freeze/thaw-changing no damages were observed
- ettringite phase produced is being destroyed during CO_2-weathering, which has been determined by X-ray-diffraction

Influence of water/binder-ratio

With regard to practical application, the influence of mixing water on the course of expansion is an important parameter influencing length change. The following example shows this influence by use of a typical expansion mortar on the basis of a lime/slag-binder and addition of 25 % CA-2/gypsum by weight. The samples were stored in a climate of 20/95 and the water/binder-ratio was varied. The different ratios and mixing water contents are shown in figure 4. The increasing water content affects a linear decrease of expansion in the expansive mortar.

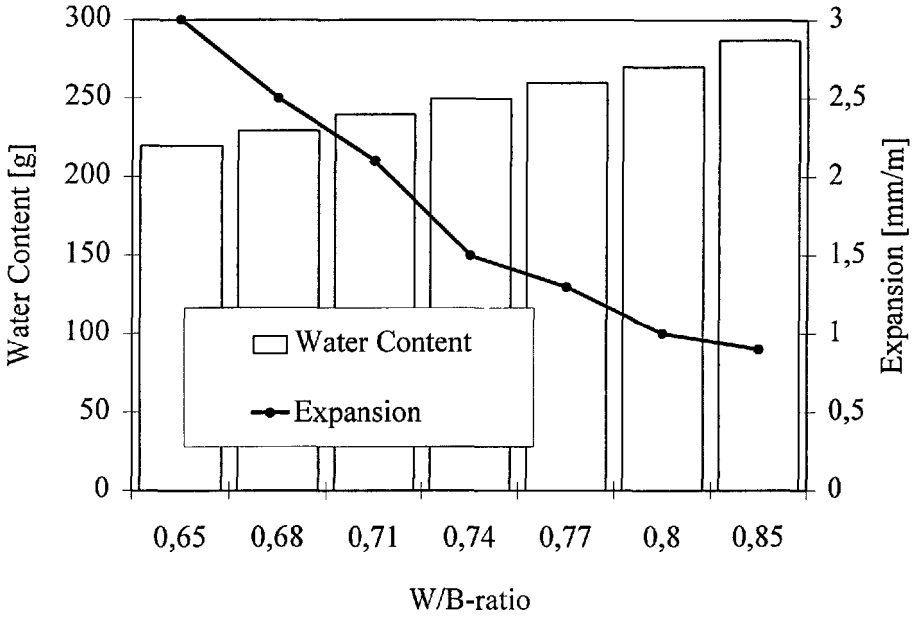

Figure 4 Influence of water content on expansion in lime/slag-mortars with 25 % expansive compound CA-2/gypsum

Influence of binder:aggregate-ratio

According to the variation of water/binder-ratio, the influence of the ratio of binder:aggregate (B/A-ratio) was investigated. By use of a standard expansive mortar (lime/slag-binder with 25 % CA-2/gypsum the binder:aggregate ratio was altered. Comparing the ratios 1:3, 1:4 and 1:5 the course of expansion differs decisively. The standard B/A-ratio 1:4 posses swelling effects of 2,5 mm/m. By increasing the ratio up to 1:5 the expansion is being reduced to 0,5 mm/m. On the other hand, using a B/A-ratio of 1:3 expansion remains on the same values of 2,5 mm/m.

Influence of fineness

The influence of fineness of expansive compounds was studied. The standard expansive compound CA-2/gypsum was added to ordinary portland cement by using a fineness of expansive compound of 4000 and 8000 cm^2/g (Blaine). The course of expansion was observed during a storage in 20/95 and at 8°C under water. Both storage conditions indicate no significant differences between the different grinding levels. Of course, technically used expansive cements basing on $C_4A_3\bar{s}$ show strong influences on fineness. However, the mortar compositions used in this investigation content amounts of expansive compound up to 25 % by weight related to binder. That means 5 % by weight related to the mortar, so that the influence of the specific surface of expansive additives on the course of expansion is quite low.

Influence of additives

Various chemical admixtures were added to the expansion systems, e.g. different types of polymers, air-entraining agents, accelerators or methyl-cellulose (see table 3). Polymers,

especially in the case of slag-based mortars, influence decisively the expansion. However, the effect of the polymer added depends on the type of polymer and on the binder used. Concerning the present treatise, the following effects of polymer addition occur:

- decreasing of expansion in lime-based mortars
- increasing and accelerating of expansion in slag-based mortars
- no influence on expansion by polymer addition in slag-based mortars

E.g., in the case of a slag based mortar with expansion compound CA-1/gypsum, the expansion increases by addition of 5 % polymer on the basis of vinyl acetate from 0,2 to 0,7 mm/m (see figure 3). An extra addition of MC, which is used to improve the water retentivity of slag-based mortars, accelerates and increases the expansion in this system to 1,8 mm/m.
By choosing the type of polymer, the course of expansion can be directed.
The mechanisms of the different admixtures influencing expansion are complex, consisting e.g. change of pH-value, change of setting and/or hardening during the first days after mortar production.

CONCLUSIONS

To reach a quick expansion process during the first 3 days after production, combined with a good controllability, availability and handling, calcium aluminate cements in combination with gypsum were preferred.
For the production of shrinkage compensated or low expansive mortars on the basis of lime, the blending with blastfurnace slag turned out to be a secure way to reach a good controllability of expansion.
Sulphate activated slag-mortars show a quick expansion during the first 3 days and subsequently a long lasting volume stability. Furthermore, the influence of different storage conditions, alteration of temperature and moisture on the course of expansion is quiet low.
Variation of storage conditions, especially the storage at low temperatures under wet conditions, indicates the mixing limits of expansive mortars.
The course of expansion is decisively influenced by technological and chemical parameters as e.g. water content, binder:aggregate ratio, setting time or additives. That means, that a reliable workmanship of expansive mortars must be guaranteed. Furthermore, it has to be kept in mind, that every change in mortar formula affects the expansion process.

Mechanical Property/Microstructure Relationships in a Mortar Fabricated in a Microgravity Environment

Richard FIRST Master Builders, Inc., Cleveland, Ohio, USA
Andre' WALLISER Master Builders Technologies (Schweiz) AG Zurich, Switzerland

ABSTRACT The purpose of this study was to examine the effects of microgravity on the microstructure/property development of a portland cement mortar; in particular, compressive strength and wedge-splitting experiments were performed. The results indicated a 30% increase in compressive strength and better performance under tensile load for the microgravity mortar than for the control mortar. These mechanical property data are correlated with the micro-structural differences observed between the two mortar specimens.

Key-words: microgravity, strain softening, wedge splitting, fracture mechanics, microstructure

INTRODUCTION

It has been thoroughly documented in the literature and is well accepted that changing the microstructure of a material can lead to changes or differences in physical properties and/or materials performance (Melton, 1975; Park and Snyder, 1995) . Portland cement-based mortar and concrete are no exception. It is well known that pozzolanic mineral admixtures (i.e. pulverized fly ash, ground granulated blast-furnace slag and silica fume) lead to microstructural changes in the interfacial transition zone (ITZ) which correspondingly lead to enhanced physical properties of the composite material (Faran, 1956; Scrivener and Pratt, 1996; Mindess, 1988; Bentur and Odler, 1996). As such, it is plausible that other changes in the microstructure of these materials could also lead to enhanced properties and/or performance.

Master Builders, Inc. designed an experiment for flight in the NASA space shuttle program in order to study the effect of microgravity on a Portland cement mortar (First *et. al.*, 1995 and Miller, *et. al.*, 1995). A 50:50 (by weight) mixture of a type I (U.S.) Portland cement and ASTM C-109 silica sand were mixed at a water/cement ratio of 0.40; a water-reducing admixture was also used in the mix design. The mortar was mixed once the shuttle was in a microgravity environment. The mortar hardened within the mixing chamber and cured for 12 days under microgravity conditions. Upon return to earth, the hardened mortar was removed for analysis. A second mortar was mixed at the Master Builders Headquarters in Cleveland, Ohio, USA, under the same controlled conditions except, in this case, a normal 1-g gravity environment.

Among the analyses performed on these materials, optical and scanning electron microscopy (SEM) were used to examine the macro/microstructure of the samples. BET and mercury intrusion porosimetry (MIP) were also used to examine the pore size distribution in the samples. In addition, the compressive strength of several samples taken from each of the materials was measured. Wedge-splitting experiments were also performed to assess the fracture behavior of these samples, as well as obtain the fracture energy/toughness of the materials. From these data, it is also possible to extract tensile strength information. These results are the topic of this paper and will be correlated with microstructural features of the materials.

OVERVIEW OF MICROSTRUCTURAL OBSERVATIONS

Upon removal from the mixing canister, the shuttle sample was observed to exhibit color variations along its central axis. Upon further investigation, it was apparent that these variations

were brought about by a combination of the failed false bottom mechanism and the unaccounted for 3-g force the experiment sustained during the shuttle lift-off. The 3-g force led to a packing of the dry materials on one side of the canister during lift-off. Because the false bottom did not actuate during the mixing procedure, there was no driving force for the material in the bottom portion of the canister to be mixed. As such, the material hydrated, but did not become part of a homogeneous mixture with the mortar in the rest of the canister. This material exhibited a lower water/cement ratio than the mortar in the rest of the mixing canister. This difference in water/cement ratio accounted for the bulk color variation in the sample. Also, the void space appeared to be concentrated at the surface of the hardened mortar sample and was helically shaped.

Optical microscopy

For reflected light optical microscopy investigation, a polished cross-sectional surface from each sample was examined. Both of the samples appeared fairly homogeneous and well-mixed. Porosity was evident in the control sample, while none was found in the microgravity sample. The overall water/cement ratio appeared lower in the control sample than in the microgravity sample. Slight, local variations in the water/cement ratio were observed throughout the cross-sectional surfaces of both samples. Perhaps the most significant difference here between the two samples was the presence of what the authors term "mixing folds" in the microgravity sample (Figure 1). It is thought that, as the mortar gained consistency, the material was able to fold onto itself. In the absence of gravity, as no driving force for settling occurs, the material may harden in place, with these folds or seams left in-tact. An appropriate analogy to this would be the folding of pizza dough onto itself. As this occurs, a seam is created where the two halves meet.

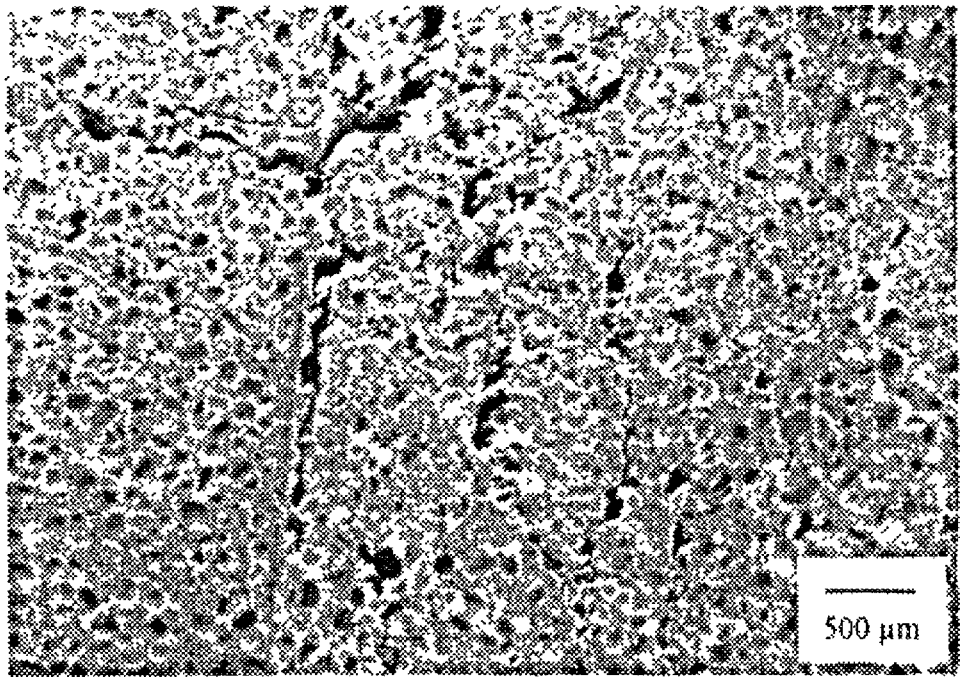

Figure 1 Normal-incidence, reflected light optical photomicrograph showing the "mixing folds" present in the microgravity sample microstructure.

The possibility that these features were merely cracks was discounted because of both the appearance of the features in cross section, as well as the fact the significant forces could not readily cause the features to propagate as crack would.

Thin-section and SEM analysis

The samples were also analyzed with transmitted light optical microscopy and SEM. The thin section optical microscopy work indicated the hydration (gel) products were more abundant in the microgravity mortar and that the $Ca(OH)_2$ crystals appears much larger (i.e. on the order of 2-3 times) in the control sample. SEM analysis on fresh fracture surfaces confirmed the above-mentioned observations. Furthermore, an abundance of ettringite crystals were observed in the microgravity mortar; whereas, no ettringite was observed in the control mortar. Also, there appeared to be no capillary pore space on any of the examined fracture surfaces from the control sample; whereas, the microgravity mortar contained many capillary pores, as evident by the plentiful amount of ettringite observed.

EXPERIMENTAL SYSTEM DESCRIPTION

Fracture tests carried out in an Environmental Scanning Electron Microscope allow us to observe the development of the fracture process zone and crack propagation under increasing load. The specimen chamber of the microscope is operated with a controlled environment (2-3 Torr, 25°C), while the optical column is kept under high vacuum.

Wedge splitting tests were conducted using a special in-situ testing machine developed at the Swiss Federal Institute of Technology, which was mounted on a coordinate table in order to control the position of observation. The test device consists of a stiff frame to support the specimen, as well as the loading wedge (wedge angle = 15°), a strain gauge and a load cell. The load was applied by means of this wedge, which allows fracture of the specimens under wedge displacement. Loading and unloading of the specimen was carried out by remote control. The position of the specimen is kept approximately constant via a contrarotating system. The splitting force and displacement were continuously recorded during testing.

The specimens were cut with a precision diamond saw from cores which were taken from the center of the space shuttle and control samples. Reference and space mortar specimens were further prepared by drilling holes for the load support and by cutting the notch with a diamond wire saw. As the drilling phase of the specimen preparation was too risky for the sample integrity, a piece of polymer concrete was glued on the top of the mortar (see Figure 2). Preliminary testing indicated that the polymer concrete pieces on the mortar specimens had no influence on their fracture behavior. A video recorder was also connected to the ESEM in order to follow, in full, the crack apparition and the crack opening pattern. For each specimen a scan over the surface was carried out in order to locate voids or macro defects before applying the load.

The fracture surfaces created during the wedge-splitting experiments were examined using SEM; the fracture surfaces were coated with gold to prevent charging.

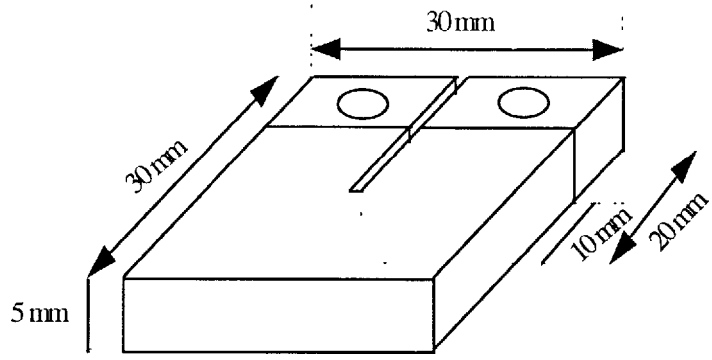

Figure 2 Schematic of wedge splitting sample tested *in-situ* using the environmental scanning electron microscope.

FRACTURE MECHANICS MODEL

Numerous fracture mechanics models have been presented for concrete (Elfgren, 1989). The two most prominent models are linear elastic fracture mechanics (LEFM) models and fracture energy models; only the fracture energy model will be discussed here. Fracture energy models are based on the concept that fracture energy is consumed for crack formation by the creation of two new surfaces. The material parameters for fracture energy models are: the specific fracture energy, G_f, the splitting force, F_{sp}, the crack mouth opening displacement, CMOD, and the softening diagram, which describes the relationship between the stress and the width of the fracture process zone by means of fitting graphical parameters from the fracture energy model with the experimental data.

The tensile softening diagram of concrete cannot be directly determined from fracture mechanics experiments other than uniaxial tensile tests. Roelfstra and Wittmann proposed a method (Roelfstra and Wittmann, 1985) to evaluate a bilinear softening diagram from the experimentally obtained force vs. displacement curve by means of a data fit. Their method is based on the Fictitious Crack Model (Hillerborg, Modeer and Peterson, 1976). In the above-mentioned method, the wedge splitting test is simulated by finite element analysis and the calculated force vs. deformation curve is compared to the experimental curve. The parameters of the input softening diagram are optimized until a good agreement between the calculated and experimental curves is obtained. The softening diagram leading to this result is considered to be the tensile softening diagram of the tested concrete/mortar.

A schematic representation of a tensile softening diagram is given in Figure 3. Here, the experimentally measured maximum splitting force is used to calculate the tensile force. The tensile strength of the material is calculated by the model. The other important parameters are denoted w_1 and w_2. w_1 denotes the softening point (displacement, CMOD) in the bilinear model and w_2 is the CMOD at the end of the wedge splitting test--that CMOD under a null load. These model parameters are adjusted to fit the experimental data and represent, in essence, a strain at a certain load.

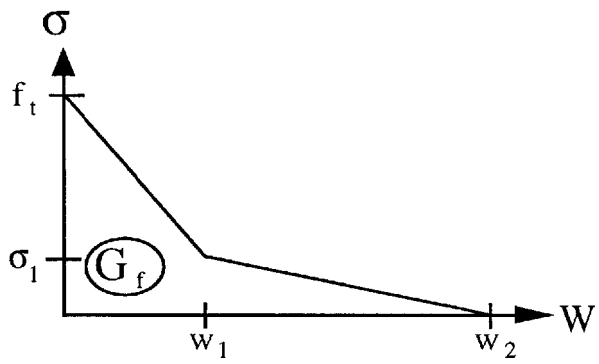

Figure 3 Schematic of the Bilinear Softening diagram used to calculate tensile parameters from the results of the wedge splitting experiments.

RESULTS

Porosity

The pore system was analyzed using Archimedes density (ASTM C-642), BET nitrogen absorption and mercury intrusion porosimetry (MIP). The ASTM C-642, BET nitrogen absorption and MIP data are summarized in Table 1 below:

Table 1 Summary of ASTM C-642 bulk specific gravity data

Technique	Property	Microgravity Mortar	Control Mortar
ASTM C-642	Bulk specific gravity	1.93	1.87
	Permeable voids (water)	24.5%	25.8%
BET nitrogen absorption	surface area	14 m^2/g	6 m^2/g
MIP	average porosity	18%	22%
	average pore diameter	0.020 μm	0.028 μm

Mechanical testing - compressive strength

The compressive strength measurement was performed on a single 25 x 25 x 25 mm cube taken from each sample at an age of 40 days. The compressive strength for the shuttle and control samples were 52 and 39 MPa, respectively. The compressive strengths were reevaluated at an age of 14 months by testing three (3) 10 x 10 x 10 mm cubes from each of the shuttle and control samples. The average compressive strengths for the shuttle and control samples at this age were 96.5 and 74.4 MPa, respectively.

Fracture mechanics - wedge splitting tests

Splitting force (F_{sp}), crack mouth opening displacement (CMOD) and elapsed time were simultaneously recorded. These data enable plots as shown in Figures 4,5. The F_{sp} vs. CMOD curve allows the calculation of the specific fracture energy, which is given by the area under curve. This specific fracture energy is then divided by the projected ligament area to obtain G_f.

The F_{sp} vs. time curve (Fig. 5) provides information regarding the stability of the performed test (i.e. if no sudden drop is observed on the recorded force, it can be said that cracking is occurring in a stable manner, Figure 4).

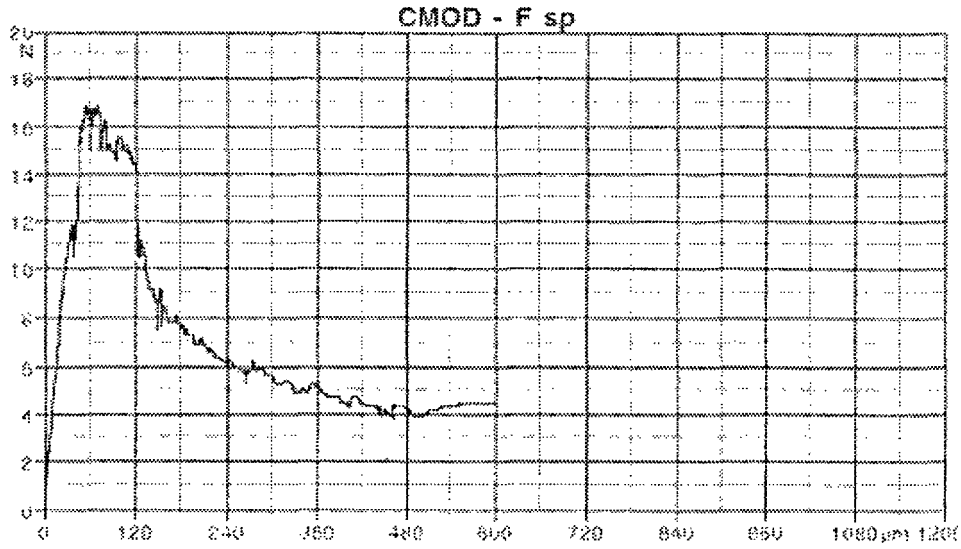

Figure 4 Experimental Splitting Force vs. CMOD Curve Obtained From the *In-Situ* Test.

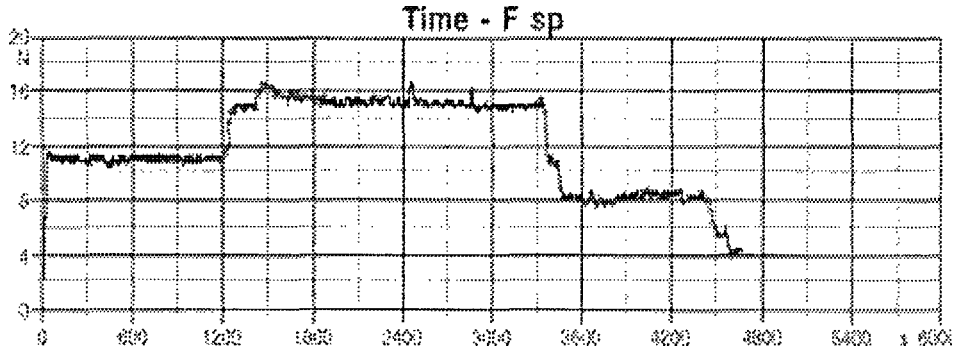

Figure 5 Experimental Splitting Force vs. Time Curve Obtained From the *In-Situ* Test.

Wedge splitting tests were conducted on four samples from each of the microgravity and control mortars. These data are summarized below in Table 2.

Table 2 Mean values based on four WST experiments

	Fspma (N)	G_f (N.m^{-1})	F_t (N.mm^2)	σ_1 (N.mm^2)	w_1 (mm)	w_2 (mm)
Microgravity mortar	15.6	79.5	2.86	0.33	0.029	0.272
Control mortar	15.7	77.3	2.52	0.31	0.047	0.356

DISCUSSION

In comparing the data produced in the present study, several significant differences in mechanical/physical properties are evident. Considering the pore size/distribution data, all of the results support the notion of the microgravity mortar sample exhibiting slightly less total porosity as well as a finer average pore diameter. The complete set of MIP data (not included here) also shows the pore size distribution for the microgravity mortar to be skewed toward the finer pore sizes (i.e. those pores in the 0.003-0.05 μm range. While there is much speculation regarding the accuracy with which these techniques define the actual pore size distribution, the data gathered in this investigation all support the implication that there exist a larger number of finer-sized pores

in the microgravity mortar than in the control mortar. The Archimedes data can be correlated with the original microscopical porosity determination, where it was found that the control mortar contained on the order of 5+% air voids; whereas, the microgravity mortar contained almost no optically observable pores. This could account for the 4% difference in average porosity as determined by ASTM C-642.

Considering both sets of compressive strength data, a 29.7% greater compressive strength average value was measured on microgravity mortar at an age of 14 months, which confirms the first compressive strength measurements of 52 MPa and 39 MPa (a difference of 33%) for the microgravity and control mortars, respectively, at an age of 82 days.

The experimentally obtained data from the in-situ wedge splitting tests were not markedly different for the two materials studied. Moreover, the in-situ observation of the propagating crack paths in all of the samples examined did not show a marked difference in the cracking behavior between the microgravity and control mortars. What is noteworthy are the data obtained from the strain softening diagram model. The computed tensile strength, f_t, was found to be ~13.5% higher for the microgravity mortar. Perhaps even more significant are the computed crack widths, w_1 and w_2, corresponding to σ_1 and a null stress at the end of the wedge splitting test. While the values of σ_1 are comparable for both sets of data, the computed crack widths are significantly different. The average crack width for the microgravity mortar at the same σ_1 is approximately 40% less than that computed for the control mortar. Moreover, at the end of the wedge splitting test, when there is a null load, the crack width in the microgravity mortar was ~24% less than that in the control sample. All of the above-mentioned modeled data from the strain softening diagram support the notion that the microgravity mortar exhibited better tensile properties than those of the control mortar. It should be noted again that this statement is inferred from the parameters of the fracture energy model/strain softening diagram and were not explicitly borne out in the experimentally obtained wedge splitting test data.

The microstructural features observed microscopically in previous investigations as well as those observed/measured in the present study support the mechanical property findings discussed above. The results of the compressive strength evaluation and the strain softening diagram obtained from the fracture mechanics experiments both indicate the microgravity mortar to have better overall mechanical properties that the control mortar. The porosity and pore size distributions of the two samples are somewhat different, as evidenced above by the BET, MIP, Archimedes density and SEM/image analysis results. All of the above-mentioned data indicate the microgravity mortar exhibited less total porosity and a finer average pore size. The MIP data specifically indicated the microgravity mortar contained more pores in the size range of 3-50 nm than did the control mortar. Furthermore, the microgravity mortar was found to contain almost no"macroscopic" porosity, as evidence by the optical microscopy analysis performed previously. The correlation between pore size distribution and compressive strength has been documented in the literature (Roelfstra and Wittman, 1985). It has been experimentally determined that a finer pore size distribution directly correlates with higher compressive strength--all other factors (including total porosity) being equal. Furthermore, a material having less total porosity may also have a lower compressive strength if it contains more larger-sized pores. Although the actual specific porosity size ranges which pertain to the above-mentioned relationships may be debatable, the general correlation likely exists within the present investigation. Moreover, the presence of a greater number of larger pores may serve to act as stress distributors during

fracture. The computed 13.5% greater tensile strength, f_t, for the microgravity mortar is evidence of this.

The previous SEM/thin-section optical microscopy analyses both concluded a significant difference in the $Ca(OH)_2$ crystals present in the two mortar samples; both studies documented a much larger average crystal size for $Ca(OH)_2$ present in the control mortar as well as more intergrowth of the crystals. As $Ca(OH)_2$ precipitates in pore space and at aggregate surfaces, its presence can typically be associated with areas or zones of weakness within the mortar. Furthermore, it is often the case in other materials systems that a finer grain size and/or a finer crystallite size also leads to an increase in physical properties. As such, it is plausible that these significant differences in $Ca(OH)_2$ crystal features may account, in part, for the lower compressive strength and modeled lesser tensile properties.

SUMMARY

Wedge splitting experiments were conducted on mortar mixed in a microgravity environment onboard a 1995 space shuttle mission using an in-situ device (in an ESEM) to facilitate observation of the crack propagation simultaneously with data gathering. The experimentally obtained fracture mechanics quantities and the observed crack behavior were not markedly different between the microgravity and control mortar samples; however, the modeled parameters obtained from the strain softening diagram indicate the microgravity mortar exhibits better tensile properties than that of the control sample. Indeed, the ~30% higher compressive strength for the microgravity mortar also indicates the microgravity mortar to exhibit better mechanical properties. Pore size distribution studies and microscopical analyses both provide useful information concerning the microstructure which appear to support the mechanical property findings.

Although not comprehensive, the intent of this article is to summarize the current status of the analyses performed on mortar samples mixed onboard the space shuttle in a microgravity environment. Although the results of the fracture mechanics model postulate better tensile behavior for the microgravity mortar, further investigation in this area as well as further SEM fractography of the wedge-split surfaces may help better define the actual role of microgravity in these experiments.

HARDENING OF CEMENTS, POLARIZED IN ELECTRIC FIELD

V.A. MATVIYENKO, N.M. ZAITCHENKO, Donbass State Academy of Civil Engineering and Architecture, Makeyevka, Ukraine

ABSTRACT The high-electric polarization of cement in the systems "solid-gas" and "solid-liquid" increases its hydrate activity as a result of surface and volume charging. Intensification of the condensed and crystallized stage of structure formation and increase of strength, modifying of microstructure of the hydration products, rebuilding of the cement paste's pore space are the peculiarities of the hardening processes of polarized cements.

Key-words: activation, hardening, heat evolution, strength development, structure

INTRODUCTION

Active centres in the cement structure play an important role in its hydration capacity. Electric polarization of cement in the system "solid - gas" is one of the ways of creating and exciting these active centres, which results in volume charging of dispersed particles. High electric polarization of cement pastes (systems "solid - liquid") thanks to low-voltage electric field doesn't cause volume charging in the conducting dispersed phase, but exciting of the surface of active centres according to electroadsorbtive mechanism and polarization of the double electric layer. Indicated phenomenons reduce the chemical bonds in cement, strengthen interphase and interparticle interactions during the hydration. Stimulation of hardening processes results in the creation of new non-equilibrium conditions in the system, which intencificate an increase of strength. So, electric polarization of cement systems allows to improve the physical-mechanical properties of the cement paste as a result of both increase of cement's degree of hydration (increase of concentration of active centres and speed of interphase diffusive processes), and modification of its structure (strengthening of interparticle interactions during the polarization of double electrical layer). Power consumptions for realization of polarization of cements are minimum, because density of electric current is limited for elimination of heat effects.

METHODS AND EQUIPMENT

Alumina, portland cements, cement pastes and concrete mixes have been examined by polarization. Electrodes from the constant current-source (5-25 kV) were placed in such a way that one of them had the contact with processing material, another (with opposite polarity) was isolated with high-resistance insulation for limiting of current density (less than 0.1 A/m^2). Duration of the exposition in electric field for the initial cements was 0.5-2 min and 2-30 min for the cement pastes. The hardening processes of cements were examined with the help of the methods heat of hydration, elastic properties of cement paste and plastometry. The hydration products were identificated by Infra Red Spectroscopy (IRS), DTA, X-ray examinations, electronic microscopy. Differential porosity of the cement stone was determined by a hydrodynamic method.

RESULTS AND DISCUSSION

It was established, that polarization of cements in the system "solid - gas" must be provided at intensity of electric field $(3\text{-}5)*10^5$ V/m during 2-3 min. Besides, portland cement must have contact with negative polarity electrode, but alumina cement with positive one. That is because of the different basicity of the minerals in the above-mentioned cements. As for the systems "solid - liquid" (e.g. cement pastes, building motars and concrete mixes) it is necessary to take into account the possibility of polarity change of the integrated charge of dispersed particles surface on the opposite one during hydration as a result of hydrate products

formation or adsorbtion of surface-active substances from dispersed environment also. Thus, while concrete mixes based on portland cement have an integrated negative charge prior to the setting at the given period of time this requires submission of the negative potential from an external source of high voltage on the contact electrode. When the setting has begun it is necessary to exchange the poles of electrodes in connection with the formation of highly dispersed hydrate of calcium oxide and calcium aluminate with the positive sign of the surface charge. Besides, concrete mixes on portland cement with additives of calcium or sodium nitrates, as well as containing lignosulphanates should be activated in the electric field of positive polarity. Cements preserve activated condition for a long-time period of curing after electroworking. It is described by the dependence of kinetics of heat evolution during hydration of polarized cement (Fig 1).

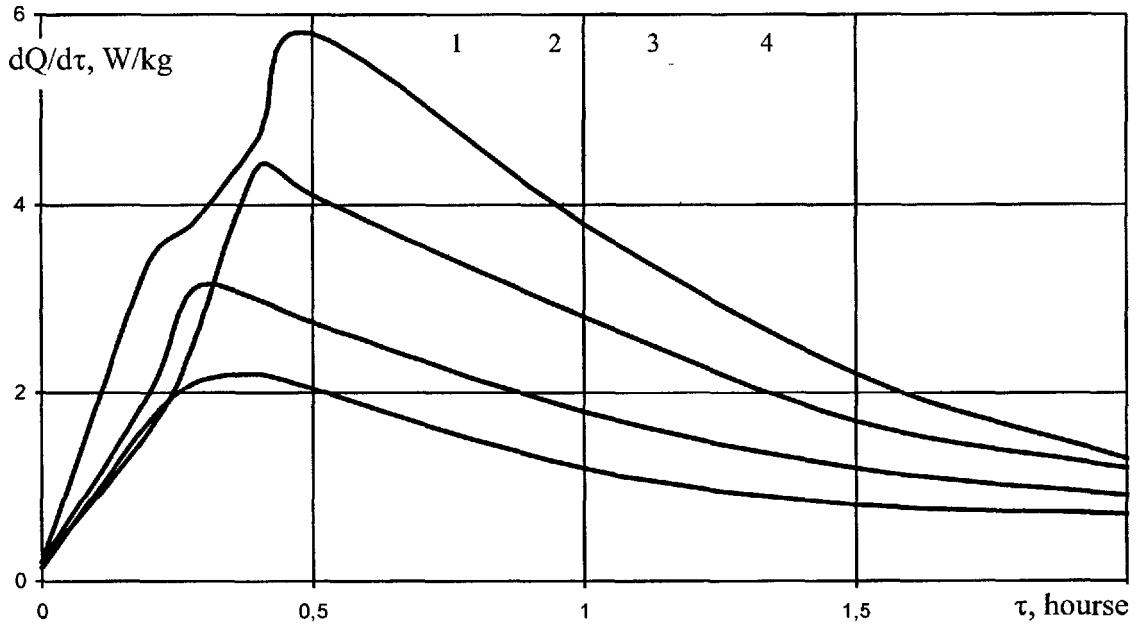

Figure 1 Kinetics of heat evolution during hydration of portland cement, activated in electric field of negative polarity.
1 - control cement; 2, 3, 4 - electric activation with voltage 3, 8 and 12 kV.

Intensive development of condensed and crystallized structure and growth of durability is explained by the acceleration of cement hydration on the early stages of hardening (Fig 2). By using a set of methods (X-ray diffraction analysis, IR spectroscopy and differential thermal analysis) to investigate the polarization-activated specimens, we determined high degrees of conversion of alite and polymerization of calcium silicate hydrates modified by sulfate ions and the content and stability of ettringite. We also noted an increase of the content of water belonging to hydrous aluminate components removable in the range 140-180 ^{0}C.

The polarization effectiveness is affected by electric-potential parameters and the structure of the electric double layer of the concentrated disperse system, which depends on many factors, namely the mineralogical and chemical composition of the binder, its particle-size distribution, the presence of additives, the solid-phase concentration, the temperature and hardening time of the system, etc. Electric voltage and current density are the main parameters of electroworking during the polarization of the cement-water systems (Fig 3).

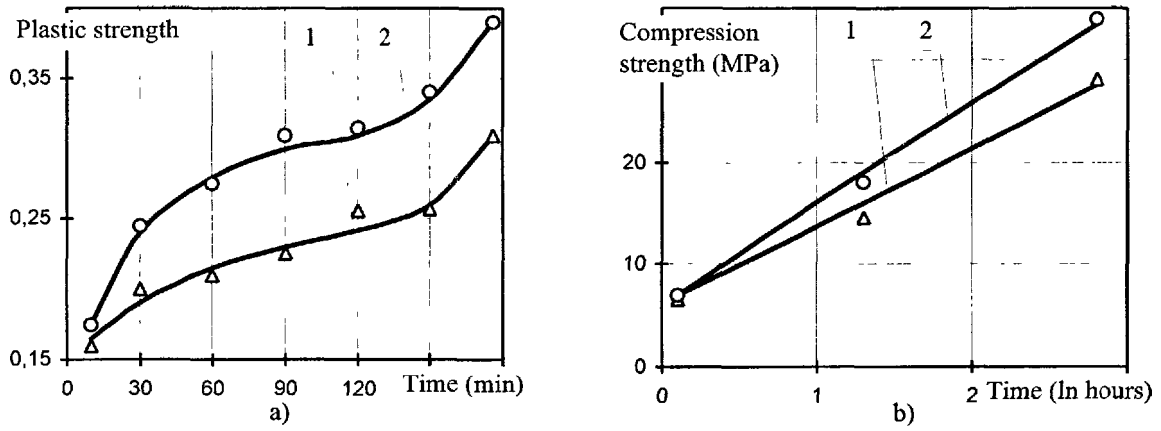

Figure 2 Increase of plastic strength t=20°C (a) and compression strength (b) during the hardening (t=85°C)of control (1) and polarized (2) cements.

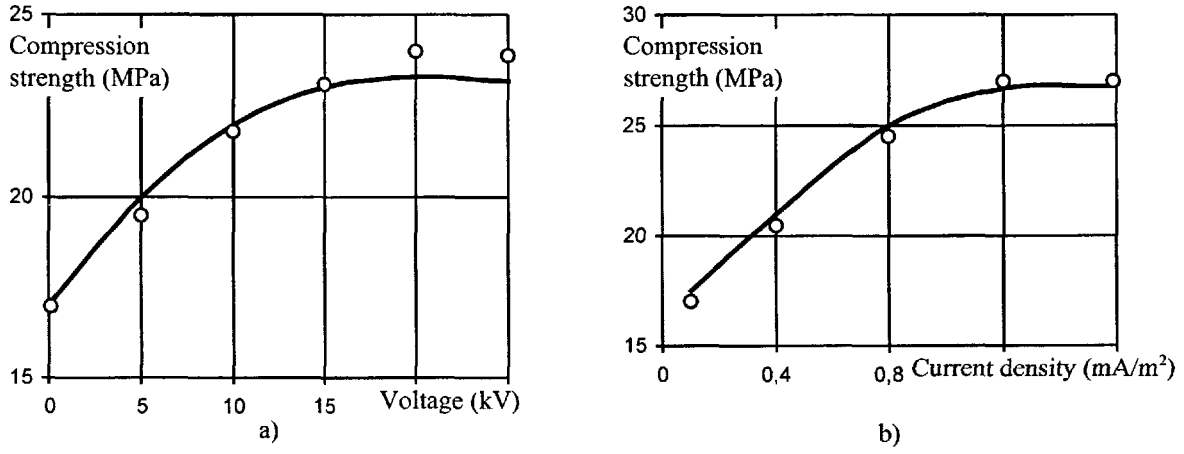

Figure 3 Dependence of concrete strength from the size of voltage (a) and current dencity (b)
during polarization of fine-grained concrete mix (at the age of 28).

An analysis of the relations σ=f(φpol) (a) and σ=f(Ipol/S) (b) shows that with increasing polarization potential and current dencity the strength of concrete increases. These relations are nonlinear, and in the high-potential range 20...25 kV (current density - 1.2...1.6 mA/m^2) they are flattening out. Investigations of structural characteristics of the cement paste and concretes on the base of polarized cements and cement-water systems indicate their common differences from control (non-activated) series. Their principal peculiarities are as follows:
- increase of the cement degree hydration by 15...30%;
- formation of small-crystalline structure of ettringite and portlandite;
- reduction of common porosity by 35...40% and redistribution of differential porosity: reduction of the quantity of pores with radius more than 10^3 nm and increase of the quantity of pores with radius less than 10^2 nm.

For the practical using of electric polarization different technological solutions have been developed. The developed ways of electrical processing of concrete mixes have comparable parameters of durability and energy costs (Table 1).

Table1 Technical characteristics of the activation posts of concrete mixes

Methods of electric activation	Technical characteristics of activation devices				
	electrical voltage, kV	duration of activation, min	specific energy costs, whr/m^3	relative increase of concrete strength,%	increase of strength on the unit of energy costs, %/whr
1.On the stage of concrete mix making	2.5...3	2...3	20...40	20...25	1...0.5
2.Before vibration seal of concrete mix in the curing bunker	15...20	2...3	50	20...50	0.4...1
3.Together with vibration seal	3...7	2...5	1.5...2	20...40	10...20
4.Curing products before heat treatment	15...20	15...120	150...200	15...25	0.1...0.2

CONCLUSION

As a result of modifying the cement paste microstructure by electrical polarization, mechanical (compression and tensile strength) and physical (frost resistance, deformations at drying shrinkage) properties improve. The specific power consumptions for the electroworking of cement or concrete mix do not exceed 50 whr/m^3 of concrete. Note that the polarity of external field must coinside with the sign of integral charge of solid phase surface and its voltage be within the limits of 15-20 kV and current density comes to 0.8-1.2 mA/m^2. The advantages of electric activation in concrete technology consist in hardening rate increase, strength increase, as well as in thermal treatment period reduction (1-5 hours) or cement saving (15-20%).

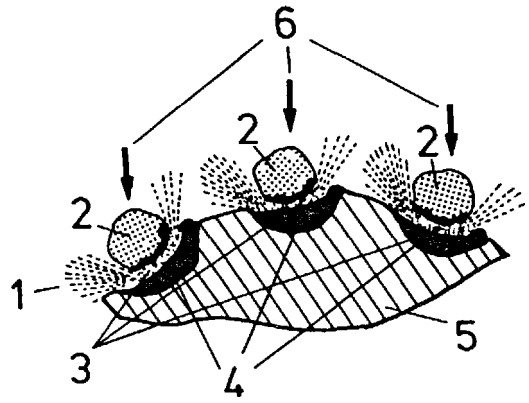
ADVANCED MODIFICATION TECHNOLOGIES OF THE PORTLAND CEMENT BASED BINDERS FOR DIFFERENT HIGH PERFORMANCE APPLICATIONS

Vladimir RONIN, Jan-Erik JONASSON and Hans HEDLUND, Luleå University of Technology, Sweden

ABSTRACT Portland cement-based binders with high performance properties regarding low clinker content, improved environmental parameters of production cycle, and higher durability can be produced with use of recently developed technology of Energetically Modification of Cement (EMC). Experimental results concerning EMC-cements containing up to 50% of quartz microfiller and application of the maturity concept for some EMC-concretes are presented.

KEY WORDS Degree of hydration, heat evolution, pozzolana, strength development



INTRODUCTION AND GENERAL ASPECTS

Solid-to-solid phase mechanical interactions of different levels of intensity in general terms gives significant influence on the interacted surfaces from the viewpoint of structural transformations and modification of surface properties known as mechano-chemical modification or activation, which plays an important role in a lot of technological processes. Milling equipments of different type should be considered as effective means for realisation of such processes, due to the wide range of mechanical force field parameters that could be created.

According to the latest experimental and theoretical data the mechanical (mechano-chemical) activation takes place when i) the particle size is lower than the size related to the though-brittle transition zone, and ii) the activated stress should exceed the yield stress of the powdery material, which depends on the dimension of the particle (Boldyrev et al, 1994 and Schönert, 1982 and 1990)The consequent significant increase in chemical reactivity (enthalpy gain) under mechanical action mainly associated with structural defects, irregularities and disturbances of the material, and with release of energy with following plastic alteration or degradation of the body. The main physical principals of the point stress generation, plastic deformation, temperature history in the areas of impact and friction of the solid phase, and movement of dislocations are discussed by Heinicke(1984)

Recently, it was discovered (Ronin et al, 1994 and 1995 and Jonasson et al, 1996) that considerable impact on the degree of activation of the Portland cement-type minerals can be achieved by a combined usage of cement grains and a superfine micro-filler, e.g. silica fume, in powdery form in a vibration mill with optimized mode of operation. Super high specific surface of this type of micro-filler (about 20 m^2/g, BET) and its much lower density in comparison with OPC provides a complete cover, in adsorbed form, of the surface of the commercially produced cements (specific surface about 1.8 m^2/g, BET), when introduced in the amount from 3 to 5% by weight of the cement. In this case the micro-filler starts to act as an additional component between the Portland cement particles and the grinding media of the mill, which transforms the flux of the kinetic energy of the vibrating grinding media preventing intensive grinding of the cement particles and creating surface zones with high concentration of micro-defects, see **Fig 1.**

An important feature of this stage of the process is a creation of the stress-strain conditions for partial disintegration of silica fume particles from agglomerated form with average size of 100 to 1000 nm to sub-micro level with size of 25 to 75 nm, which have been conformed by electron microscopy observations, see **Fig 2**, and corresponds to experimental results discussed by Lajnef

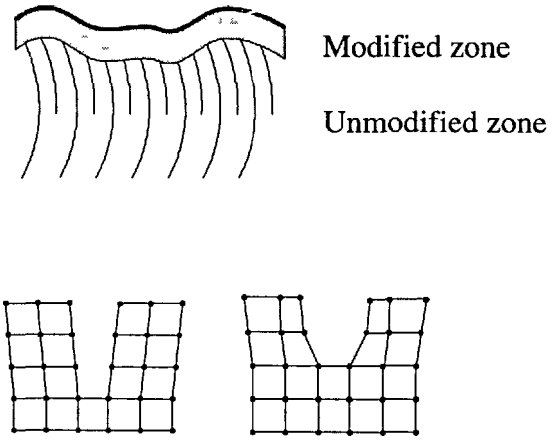


Figure 1 a) Hypothetical picture of the high intensive interaction of silica fume grains and Portland cement particles in the vibration mill. 1=exo-emission;2=initial silica fume grain; 3=newly developed sub-micro silica particles; 4=zones with distorted structure; 5=cement particles; 6=direction of impulses from the vibration grinding media.

b) Scheme of the surface of modified Portland cement particles deformation of mineral crystal lattice due to modification.

et al (1993). This means that the surface of cement particles, subjected to extremely intensive treatment (impact, shear, attrition) from vibrating media through sub-micro-metric silica particles, will also unclude some embedments of these particles in the surface layers of the Portland cement grains. As a result a significant increase of the surface energy of Portland cement minerals takes place, see **Fig 3**, and the obtained binder was called Energetically Modified Cement (EMC). The EMC-cements are characterised by increased rate of hardening, reduced porosity, increased rate of pozzolanic reaction and hydration of alite-component of cement, see **Figs 4, 5 and 6**, correspondingly.

EMC-BINDERS COMPRISING MICRO-FILLERS

Additional advantage of the EMC-cements is a significantly improved binding capacity (ability to produce a concretes of equal strength with reduced binder content) (Jonasson and Ronin, 1995a and 1995b). This gives a possibility to produce EMC-binders with low and super-low clinker content. The strength development has been measured for EN-mortars with standardized mixing proportions as well as for concretes produced with different amount of OPC and quartz microfiller. The microfiller had a SiO_2 content of 86%. The fraction before modification was 0 - 2 mm, and the fineness after modification was about 130 m^2/kg).

Tables 1, 2 and 3 represent clinker composition and strength development for the EN-mortar and concretes with binder (including modified microfiller) contents from 270 to 350 kg/m^3.

Table 1 Clinker composition of the binder types used.

Type of binder	Amount of microfiller, %	Clinker minerals, %			
		C_3S	C_2S	C_3A	C_4AF
OPC	0	59.0	13.0	8.0	7.0
EMC-20	20	47.2	10.4	6.4	5.6
EMC-30	30	41.3	9.1	5.6	4.9
ENC-50	50	29.5	6.5	4.0	3.5

Table 2 Compressive strength development of EN-mortars (max. aggregate size = 5 mm) with EMC-binders.

Type of binder composition	Compressive strength, MPa for the ages					Strength classification of the binder
	1 d	2 d	3 d	7 d	28 d	
OPC	16.5	21.6	36.1	43.1	54.2	CEM I 52.5
EMC-20	16.0	20.7	32.3	39.8	53.0	CEM 52.5
EMC-30	13.6	16.3	29.9	37.6	43.7	CEM 42.5
EMC-50	10.1	12.4	24.8	28.8	35.5	CEM 32.5R

Table 3 Compressive strength development of the concretes (max. aggregate size = 32 mm) with the binder EMC-50 cured at 20 °C. All mixtures had a slump of about 50 mm.

Concrete No.	Binder-to-Cement content ratio $(kg/m^3)/(kg/m^3)$	w_o/B	Compressive strength, MPa for the ages					Class of concrete
			1 d	2 d	3 d	7 d	28 d	
1	270/270 (ref. OPC)	0.58	9.9	14.8	15.8	21.1	28.6	K25
2	270/135	0.58	9.8	14.3	16.6	20.8	28.5	K25
3	300/150	0.56	10.4	14.9	17.6	22.4	33.2	K30
4	320/160	0.50	13.1	18.6	21.0	26.8	38.1	K35
5	350/175	0.47	13.9	19.4	22.3	30.1	42.8	K40

The gradual reduction of the clinker content and increase of the amount of microfiller (see **Table 1**) have very positive influence on i) sulphate resistance of the binder due to reduction of the C_3A content, ii) heat liberation and, most likely, the thermocrack generation mainly due to reduced amounts of C_3S and C_3A, iii) increased corrosion resistance of the reinforcement due to lower alkali content, and iv) environmental conditions of Portland cement production due to significant reduction of CO_2, SO_2 and NO_x emmisions.

Analysis of strength parameters of the EN-mortars containing different amounts of microfiller and the concretes with the binder EMC-50 (see **Tables 2 and 3**) clearly demonstrates the strong influence of the mechanochemical modification of blended binders on the strength development and ultimate 28-days strength. Especially, it is pronounced for the concretes (**Table 3**), where the substitution of half the clinker with microfiller has practically no significant influence on the strength gain for the whole range of studied cement contents. According to ENV-197 the EMC-binders containing microfiller are equivalent to the strength level from CEM 52.5 to CEM 32.5R depending on microfiller content (**Table 2**).

APPLICATION OF THE MATURITY CONCEPT FOR EMC-CONCRETES

Basic equations

The expending demands of the modern building practice require complex and flexible concrete technologies which can be adjusted and used for such purposes like assessing of stripping times and loading capacities at varying climate conditions and also comprehensive computer-based material simulations. The main purpose of the present investigation is to study whether the standard procedure to do calculations of temperature, maturity and strength development (Jonasson, 1994, Ekerfors, 1995 and Hedlund, 1996) can be applied to the EMC concretes. The concept used is based on an intrinsic parameter called equivalent time of hardening, t_{equ}, defined by

$$t_{equ} = \int \beta_T \, dt \qquad [1]$$

$$\text{with} \quad \beta_T = \begin{cases} \exp(\theta \cdot (1/293 - 1/(T+273)) & \text{when } T > -10\,^{\circ}\text{C} \\ 0 & \text{when } T \le -10\,^{\circ}\text{C} \end{cases} \qquad [2]$$

$$\text{and} \quad \theta = \theta_{ref} \cdot \left(\frac{30}{T+10}\right)^{\kappa_3} \quad [\text{K}] \qquad [3]$$

All notations and equation parameters in this chapter are in detail described and explained by Jonasson (1994), Ekerfors (1995) and Hedlund (1996). The compressive strength at a certain time is described by a fraction expressed in per mille of the 28 days strength by

$$f_{cc} = \frac{\eta}{1000} \cdot f_{28} \qquad \text{for } 4h \le t_{equ} \le 672h \qquad [4]$$

$$\text{and} \quad f_{cc} = 0 \text{ for } t_{equ} < 4h \qquad \text{and} \qquad f_{cc} = f_{28} \text{ for } t_{equ} > 672h = 28d\,. \qquad [5]$$

The strength development of **Eq 4** is given as a series of linear splines between a prechosen set of equivalent times of hardening according to

$$t_{equ} = [4h \quad 6h \quad 8h \quad 12h \quad 18h \quad 24h \quad 72h \quad 168h \quad 672h] \qquad [6]$$

$$\eta = [0 \quad \eta_2 \quad \eta_3 \quad \eta_4 \quad \eta_5 \quad \eta_6 \quad \eta_7 \quad \eta_8 \quad 1000] \qquad [7]$$

The use of **Eq 7** means that seven individual numbers per mixture, η_2 - η_8, are needed.

The heat of hydration is described in the following way

$$W = W_u \cdot \alpha^* \cdot B \qquad [J/m^3] \qquad [8]$$

$$\text{with} \quad \alpha^* = \exp\left(-\lambda_1 \cdot \left[\ln(1 + t_{equ} / t_1)\right]^{-\kappa_1}\right) \qquad [9]$$

The last parameter to be known for a specific mixture is the heat capacity per volume for the concrete mix, $\rho \cdot c$, which here is set to

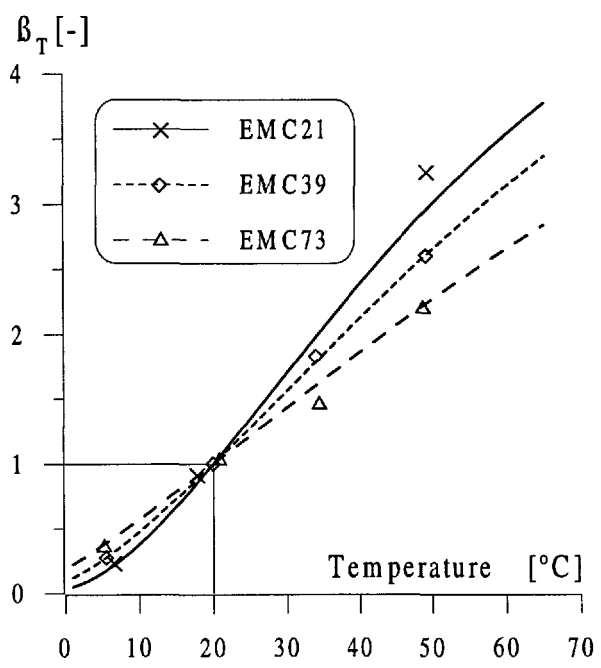
$$\rho \cdot c = 2.35 \cdot 10^6 \quad [J/m^3] \qquad [10]$$

The use of exactly **Eqs 1 - 10** is necessary in calculations, as the applications must be done in the same way as the underlying evaluation.

Examined EMC concretes

Five recipes with EMC binders have been studied with respect to **Eqs 1 - 10**. The main mix parameters and the 28 days compressive strength are given in **Table 4**. The remaining parameters in accordance with **Eqs 3 - 9** are given in **Table 5.**

Table 4 Mix parameters and 28 days strength for studied EMC concretes. Maximum aggregate size is 16 mm.



Designation	Type of binder	w/B	B [kg/m^3]	f_{28} [MPa]
EMC21	EMC510*	0.21	528	166
EMC39	EMC510*	0.39	331	108
EMC58	EMC500**	0.58	303	55

EMC73	EMC500**	0.73	180	42

Notes:
*) EMC510=94%OPC+ 5% SF+ 1% superpl.
**) EMC500=95%OPC+ 5% SF

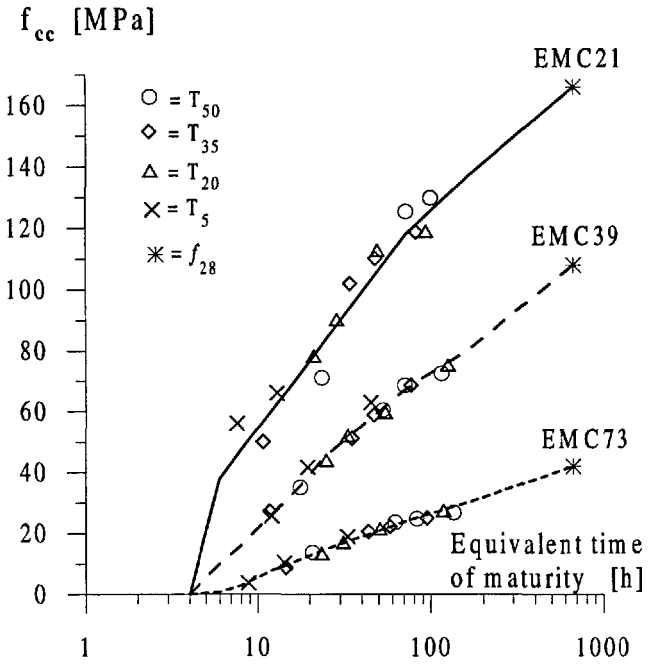

Table 5 Parameters to the use of **Eqs 3-9** for the recipes presented in **Table 4**.

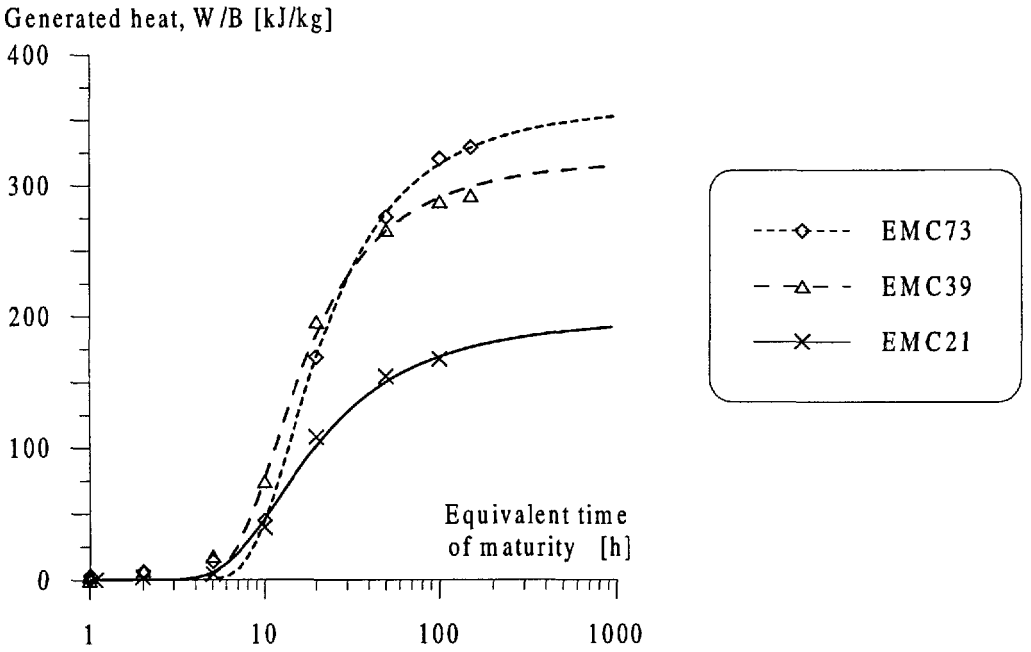
Denotation	**Eq 3**		**Eq 7**							**Eqs 8 and 9**			
	θ_{ref} [K]	κ_3	η_2	η_3	η_4	η_5	η_6	η_7	η_8	W_u [kJ/kg]	λ_1	t_1 [h]	κ_1
EMC21	5920	0.769	228	285	361	440	498	711	828	218	1.90	4.84	1.95
EMC39	3750	0.535	93	148	241	335	414	625	747	324	0.7	9.7	2.1
EMC58	4580	0.783	0	69	161	264	367	594	734	345	0.68	10.0	2.14
EMC65	4320	0.829	19	74	194	309	404	622	777	365	1.96	4.92	2.53
EMC73	4790	0.636	17	68	182	278	347	572	772	365	2.41	5.36	2.59



The description of the properties according to the parameters given here in comparison with the underlying test results are given in **Fig 7** for concrete mixes EMC21, EMC39 and EMC73, respectively. The scatter of test data and the agreement in accordance with the use of **Eqs 1 - 10** for EMC concretes are of the same nature as for the use of non-modified cement (Jonasson, 1994, Ekerfors, 1995 and Hedlund, 1996). One consequence is that calculation of the temperature field and assessments of strengths in hardening concrete for different applications can also for EMC concretes be made by the use of existing computer programs like for instance the Hett2DL program (Jonasson and Stelmarczyk, 1997).

a) Temperature sensitivity (**Eq 2**)

b) Strength development (**Eq 4**)

c) Liberated heat of hydration (**Eq 8**)

Figure 7 Comparison between evaluated properties (solid, long-dashed and short-dashed lines) and measured data (individual symbols) for three EMC concretes. Evaluated numbers are presented in **Tables 4 and 5**, and the basic relations are in accordance with **Eqs 1 - 10**. The indices (i for different T_i) in subfigure b) means curing temperature at level 5, 20, 35 and 50 °C, respectively.

CONCLUSIONS

- According to ENV-197 the EMC binders correspond to strength levels from CEM 52.5 to CEM 32.5 depending on the microfiller content. This shows that the use of a vibration mill as a EMC-processor is an effective way to produce EMC-cements containing quartz as a microfiller (SiO_2 content about 86%) with substitution ratio of the Portland clinker up to 50 %.
- The use of an ordinary maturity concept to describe the hardening process, the liberated hydration heat and the strength development has been shown to work equally well for EMC concretes as for the use of non-modified cements. This means that existing computer programs can be used in analysing early age behaviour even for EMC concretes.

HYDRATION OF PORTLAND CEMENT: THE EFFECTS OF CURING CONDITIONS

Dale P. BENTZ, Kenneth A. SNYDER and Paul E. STUTZMAN, National Institute of Standards and Technology, Gaithersburg, MD 20899-0001 USA

ABSTRACT In this paper, experimental and computer modelling studies of the effects of curing on hydration are presented. Degree of hydration has been quantified for saturated, sealed, and 90% relative humidity ambient environments, all at 25 °C. For both the saturated and the sealed curing conditions, experimental results for degree of hydration and scanning electron microscopy images are compared to those generated using the NIST cement paste microstructural model. Implications for the field curing of concrete are also addressed.

Key-words: Curing, Hydration, Modelling, Scanning Electron Microscopy, Simulation.

INTRODUCTION

Proper curing of concrete is paramount for obtaining optimum performance from a given set of mixture proportions. For high-performance concretes, curing becomes even more important, due to the typically lower water-to-cement (w/c) ratios and the increased propensity for early age cracking due to thermal and self-desiccation stresses (Henrichsen and Laugesen, 1995). Besides the water which is removed due to exposure to an ambient environment, additional empty capillary porosity is created within the cement paste component of the concrete due to the chemical shrinkage that accompanies the cement hydration reactions, quantified many years ago by Powers (Powers, 1935), but also the subject of much recent research (Geiker, 1983, Hua *et al.*, 1995, Tazawa *et al.*, 1995, and Justnes *et al.*, 1996).

The creation of empty capillary pore space has two major effects on the evolving cement paste system. First, the resultant capillary pressures induce shrinkage stresses within the cement paste microstructure, causing a measurable external physical shrinkage (Hua *et al.*, 1995 and Justnes *et al.*, 1996). The magnitude of these stresses (at relative humidities where some of the capillary pore space is still filled with water) will be influenced by the relative humidity (RH), in the following manner. The Kelvin-Laplace equation can be used to relate the relative humidity to the capillary condensation process:

$$\ln(\frac{\mathbf{RH}}{\mathbf{100}}) = -\frac{K\gamma V_m}{RT} \quad [1]$$

where γ is surface tension, V_m is the molar volume of water, R is the universal gas constant (8.314 J/(mol· K)), T is absolute temperature, and K is the average curvature of the surface of the condensed water (equivalent to $2/r$ for a spherical droplet where r is the radius of the droplet/pore). Thus, at a given RH, water will condense in all pores of curvature greater than or equal to K (pore radius less than or equal to r). The induced capillary pressure, $\sigma_{\text{capillary}}$, is then given:

$$\sigma_{\text{capillary}} = K\gamma = -\frac{\ln(\frac{\mathbf{RH}}{\mathbf{100}})RT}{V_m}. \quad [2]$$

According to Eq 2, the induced capillary pressure is directly proportional to ln(**RH**). The measured shrinkage should be a function of this capillary pressure and the moisture con-

tent (saturation) of the concrete (Mackenzie, 1950 and Bentz *et al.*, 1996). Indeed, field measurements have shown that both moisture content and measured concrete shrinkage are proportional to variations in ambient RH (Granger *et al.*, 1994). In the case of hydration under sealed conditions, the autogenous shrinkage stresses will be influenced by the internal RH reduction due to the chemical shrinkage. As first quantified in 1940 (Gause and Tucker, 1940), this RH reduction can be quite substantial, with RH values as low as 70% measured for low w/c (< 0.3) ratio cement paste and concrete systems (Mjornell, 1994 and Persson, 1996). According to Eq 2, the induced capillary pressures will be seven times greater in a system with an RH of 70% vs. one with an RH of 95%, which may be one reason why high-performance concretes are often more susceptible to early age cracking.

The second effect of the creation of empty capillary pores will be a change in the hydration kinetics for the cement paste (Powers, 1947 and Molina, 1992). Because cement hydration reactions generally proceed by a dissolution/precipitation mechanism, the empty pore space created due to drying or self-desiccation is no longer available to be filled with hydration products, so that the hydration will slow down and effectively terminate at a lower degree of hydration than that which could be achieved under saturated conditions. The remainder of this paper will focus on this latter effect, using a combination of experimental and computer modelling techniques to quantify the effects of curing conditions on the measured degree of hydration of a series of cement pastes.

EXPERIMENTAL PROCEDURES

Saturated and Sealed Specimens

Details for the two ASTM Type I portland cements used in this study, Cements 115 and 116 issued by the Cement and Concrete Reference Laboratory, can be found elsewhere (Bentz, 1997). In all cases, the cement and the necessary mixing water, w/c=0.3 or 0.4, were conditioned at 25 °C overnight and then mixed together by hand in a sealed plastic bag for two to three minutes. For hydration under saturated and sealed conditions, samples on the order of ten grams were stored in capped plastic vials at 25 °C until measuring the non-evaporable water content, typically after ages of 1, 3, 7, 14, 28, 56, and 90 days. For the saturated samples, approximately 1 mL of water was added on top of the cement paste to maintain saturation. Non-evaporable water was quantified as the weight loss between 105 °C and 950 °C, corrected for the loss on ignition for the dry cement powder. These values were converted to degrees of hydration based on measurements performed on fully hydrated specimens (w/c=3.0, continuously ground in a jar mill for 28 days), which yielded values of 0.226 and 0.235 g H_2O/g cement for Cements 115 and 116, respectively. For Cement 115, two samples, one saturated and one sealed hydration, were removed after 94 days curing and prepared for viewing in the scanning electron microscope (SEM).

Curing Under 90% RH

The companion controlled relative humidity experiments were performed using Cement 116. The paste samples were mixed in a sealed plastic bag for 5 minutes. The specimen holders consisted of two 1.6 mm-thick sheets of hydrophobic polytetrafluoroethylene (PTFE) cut to 127 mm $\times$152 mm. One of the sheets had been punched with twenty three 25 mm-diameter holes, and the two sheets were adhered together using a silicone sealant. The mixed cement paste was spread over the 25 mm holes, filling them to form discs of uniform thickness. The fresh specimens were then placed in a 25°C, 100% RH environment.

To assess the combined effects of RH and time on the hydration of cement paste, the specimens were stored at 100% RH for 6 and 12 hours, and 3 and 7 days before being placed into an environment of 25°C and 90% RH. Here, the specimens were maintained in an atmosphere free of CO_2, to avoid carbonation effects, achieved by using an overpressure of pure nitrogen. Prior to entering the 90% RH environment, the two sheets were pried apart, exposing both sides of the hardened specimens (the sheets for the 0.3 w/c pastes were pried apart after 24 hours, or sooner as required). Periodically, the degree of hydration was determined by measurement of the non-evaporable water content, as described above, from a sample consisting of two paste discs.

Computer Simulations

In addition to the experimental studies, computer simulations were performed using the NIST cement paste microstructural model (Bentz, 1997). For each of the two cements, initial 3-D cement particle images were created for w/c=0.3 and w/c=0.4, and then "computationally hydrated" under saturated and sealed conditions. In the case of sealed (self-desiccating) conditions, the computer model creates empty pore space as the hydration occurs to account directly for the chemical shrinkage. A previous calibration of model cycles to real time (Bentz, 1997) was then applied to create model degree of hydration vs. time curves to compare to the experimental counterparts. In addition, two-dimensional slices from the "fully hydrated" three-dimensional computer model microstructures were created to compare to the SEM images for the two curing conditions for Cement 115 with w/c=0.3.

RESULTS

Saturated and Sealed Specimens

Figure 1 shows a comparison of degree of hydration achieved under saturated and sealed conditions for the two cements studied, with w/c=0.3. In both cases, the sealed conditions are observed to reduce the achieved hydration, particularly at times exceeding 7 days (168 hours). At early times, the newly created empty porosity (from the chemical shrinkage) has only a minor effect on the hydration kinetics as a significant volume fraction of water-filled capillary pore space still exists. For a w/c=0.3 system, initially, about one half of the volume is filled with water. However, as more and more water is consumed by the hydration reactions, the fraction of empty pore space relative to that which is water-filled becomes significant, and a substantial reduction in the hydration rate is observed. The predicted results based on the NIST cement paste microstructural model are seen to closely follow the experimental values, particularly for Cement 115. Thus, it appears that the model is able to account successfully for the effects of self-dessication on hydration kinetics and may be useful as a predictive tool for anticipating the effects of different curing regimens on achievable hydration and physical properties, as the model has already been applied to predicting 7 and 28-day compressive strengths from 3-day values (Bentz, 1997).

It should also be noted that simulations performed for w/c=0.4 for the two cements have indicated much smaller differences in the hydration kinetics for saturated and sealed conditions. For Cement 115, the "final" achieved degrees of hydration after 5000 cycles of the hydration model were 0.88 and 0.83 for the saturated and sealed conditions, respectively. The corresponding values for Cement 116 were 0.90 and 0.85. In addition, the differences to be expected after 28 days of curing, for example, were less than for the w/c=0.3 systems (on the order of 0.01 for Cement 115 and 0.03 for Cement 116). Thus, the effects of sealed curing become more prominent at lower w/c (< 0.4) ratios.

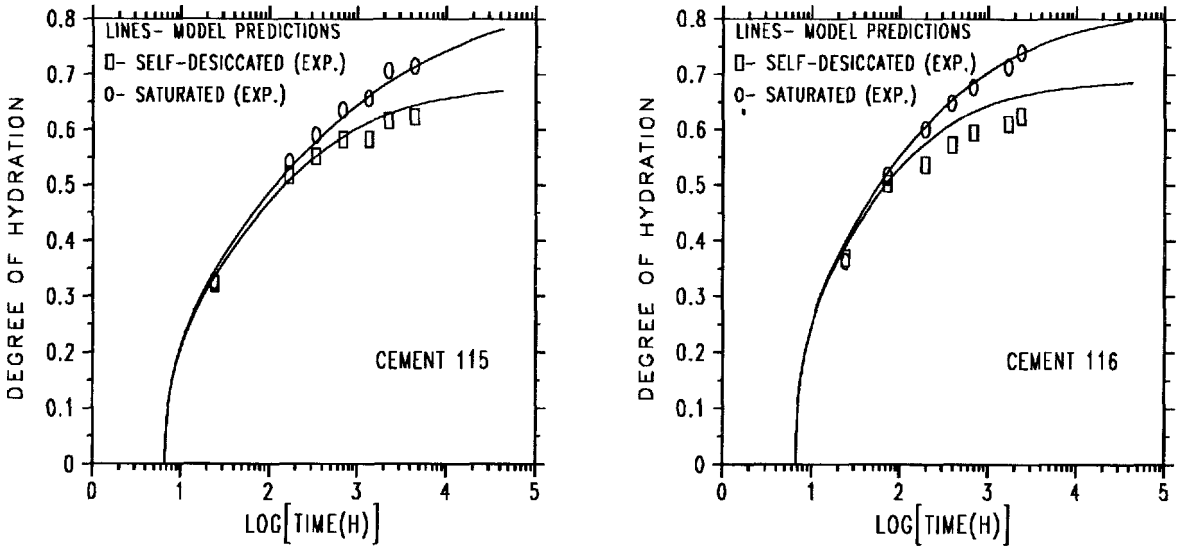

Figure 1: Comparison of saturated and sealed (self-dessicated) hydration for Cements 115 and 116 with w/c=0.3.

Microstructure

The model can be further validated against experiment by comparing SEM micrographs of real sample microstructures to two-dimensional images from the 3-D model. Figures 2 and 3 provide a comparison at similar scales for Cement 115. The two most distinguishing features between the sealed and saturated specimens are the amount and size of the unhydrated cement grains and the amount and size of the observable capillary pores. One can clearly observe that there are more and larger unhydrated cement grains in the sealed specimens (particularly in terms of the alite grains which are surrounded by a dense layer of calcium silcate hydrate gel), in agreement with their measured lower degrees of hydration. Based on quantitative SEM measurements of the unhydrated cement area fractions, after 94 days, the saturated sample has achieved a degree of hydration of 0.79 ± 0.03 while the sealed sample has only achieved a value of 0.66 ± 0.04, based on the averages from eleven fields of view (1024 pixels $\times$800 pixels, 0.25 μm/pixel) for each sample, and expressed with an uncertainty of one standard deviation. By constrast, the corresponding degrees of hydration for the two model systems shown are 0.80 and 0.69, respectively. In addition, due to the emptying of the capillary pores during chemical shrinkage, many relatively large pores remain in the sealed specimens. Once again, the effects observed in the real specimens are quite accurately duplicated by the model, as the real and model images exhibit many similar features.

Curing Under 90% RH

The results for the effect of the 90% RH environment on cement paste hydration are given in Fig 4. For the case of w/c=0.4, the 6 hour, 12 hour, and 3 day specimens show an effect due to hydration at 90% RH, while the 7 day specimen, over the first 28 days, does not appear to be affected by the change in environment. The data for the 0.3 w/c paste are similar, with the exception that the 3 day specimen also appears to be relatively unaffected by the change in environment.

These data, coupled with an understanding of the percolation of the capillary pore space, lead to a possible explanation for these effects. As the paste hydrates, the capillary porosity, and the characteristic capillary pore size, decrease. When the capillary porosity has been

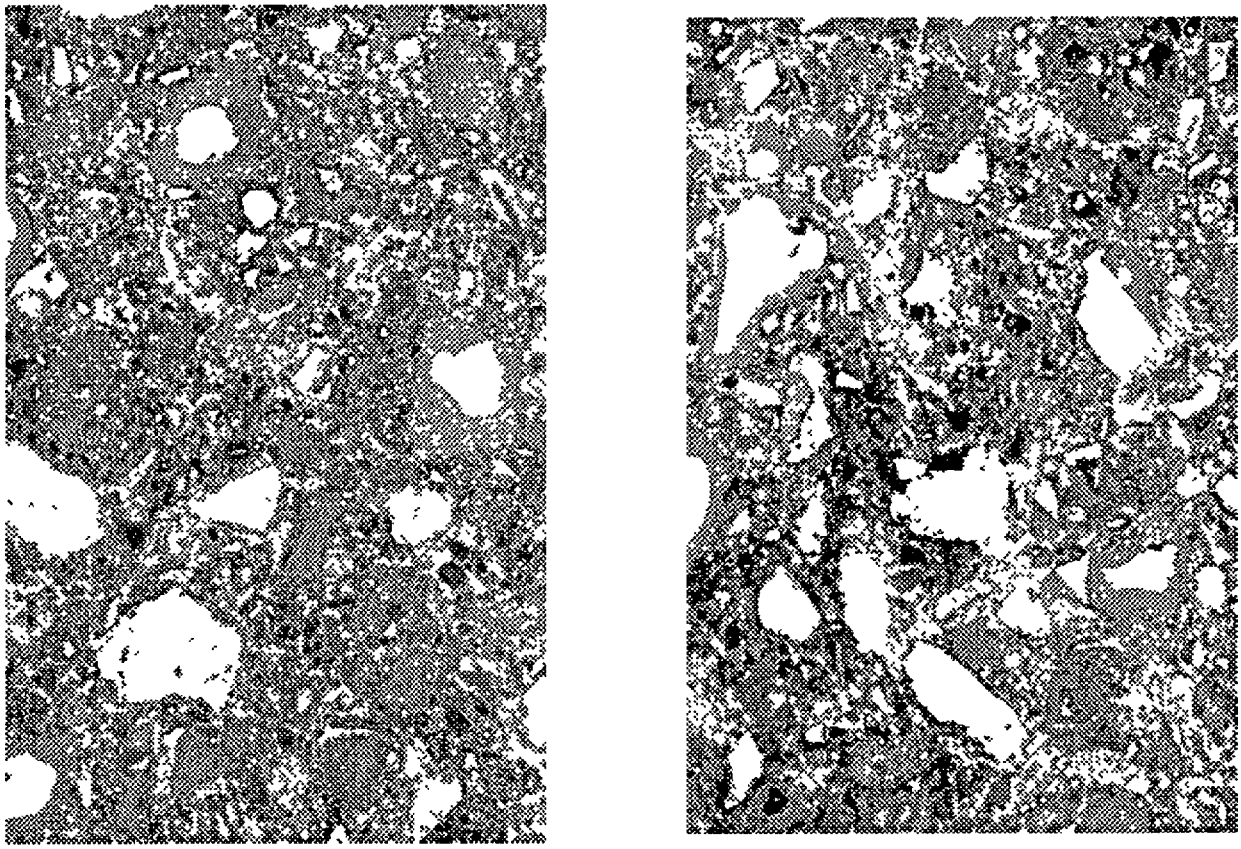

Figure 2: Comparison of real SEM images for saturated (left) and sealed (right) hydration for Cement 115 with w/c=0.3. Unhydrated cement is white, porosity is black, calcium hydroxide is light grey, and calcium silicate hydrate gel and other hydration products are dark grey. Areas imaged are approximately 128 μm $\times$190 μm.

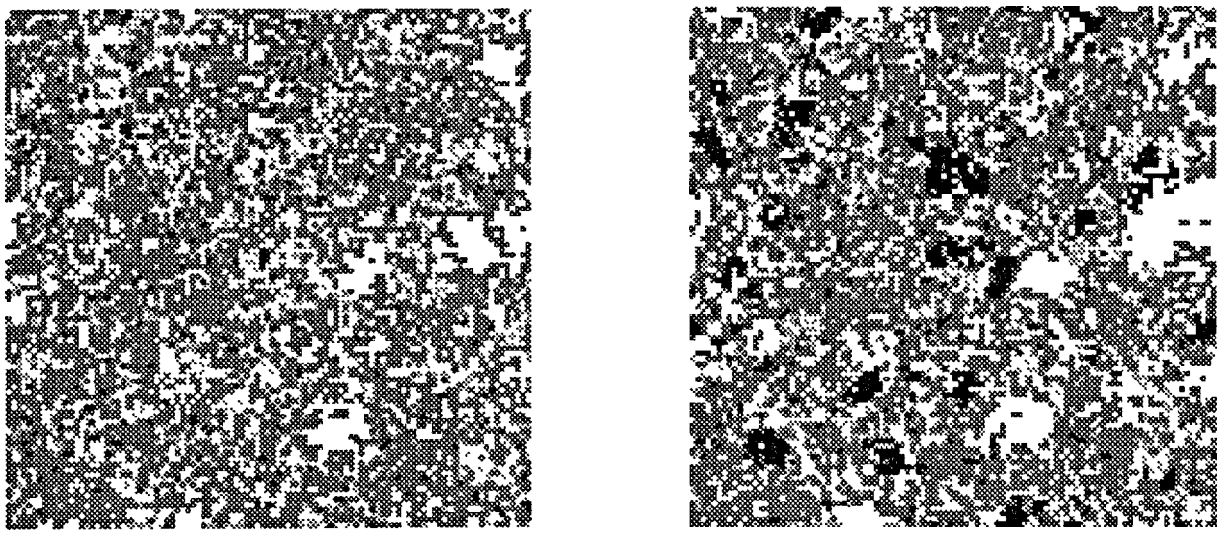

Figure 3: Comparison of model images for saturated (left) and sealed (right) hydration for Cement 115 with w/c=0.3. Greyscale assignments are the same as those given above for the real images. Areas represented by the images are 100 μm $\times$100 μm.

reduced to approximately 0.20, the capillary pore space is no longer interconnected throughout the paste (Powers *et al.*, 1959, and Bentz and Garboczi, 1991). When this occurs, vapor and moisture transport is restricted by the gel pore space, greatly reducing the transport coefficients. These gel pores, due to their small size (< 10 nm in diameter), will remain water-filled at RH values down to about 50% (Baroghel-Bouny, 1994). Any capillary pores connected to the exterior environment only via a path containing gel pores will also remain water-filled at RH > 50%. Thus, when the capillary pore space is no longer percolated, the moisture is, in effect, trapped inside the specimen, and if the specimen is placed in an environment at less than 100% RH, but greater than 50% RH, the specimen continues to hydrate. The estimated degrees of hydration needed to achieve a capillary porosity of 20% are 0.63 and 0.43 for the 0.4 and the 0.3 w/c pastes, respectively, as illustrated by the horizontal dotted lines in Fig 4.

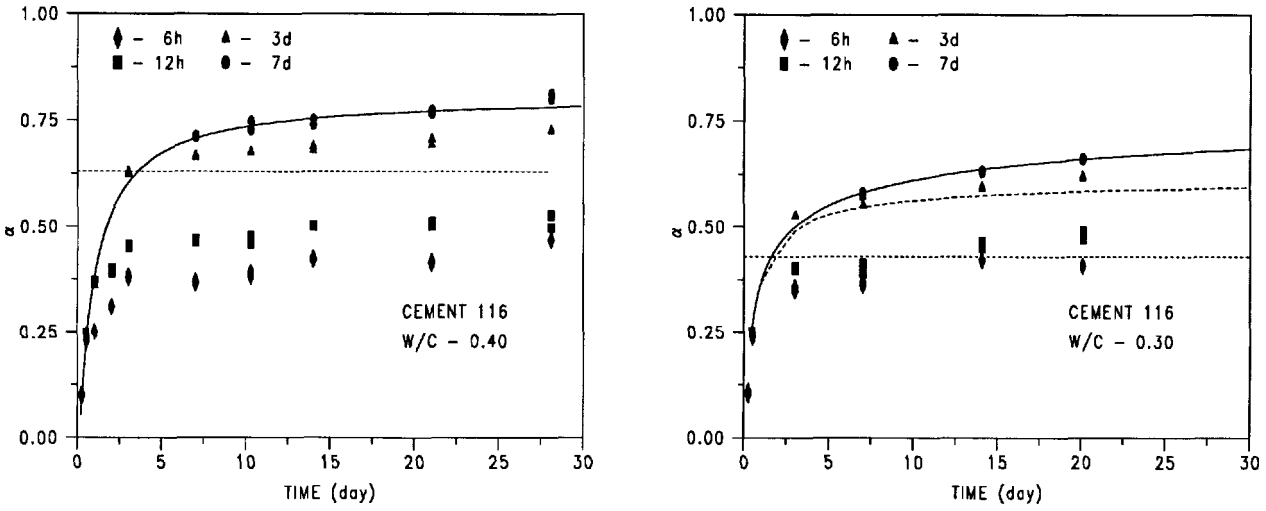

Figure 4: Effect of a 90% RH environment on the degree of hydration (α) for 0.4 and 0.3 w/c cement pastes after curing in 100% RH for 6 and 12 hours, and 3 and 7 days. The solid line indicates continuous hydration at 100% RH, the horizontal dotted line indicates the degree of hydration at which the paste achieves 20% capillary porosity, and the dashed line indicates hydration under sealed conditions for w/c=0.3.

For the w/c=0.3 data, while the 7-day data appear to directly track the saturated condition hydration data, the 3-day data fall slightly below this curve. This might be expected, since after 3 days exposure to 100% RH, the 3-day specimen is then exposed to 90% RH, where even if the capillary porosity has depercolated so that no water is removed, the hydration is continuing under sealed, as opposed to saturated, conditions. As hydration slowly continues beyond 3 days, this will lead to the creation of some empty capillary pores in the specimen due to the chemical shrinkage. Thus, the measured degrees of hydration are seen to fall between the curves for hydration under totally saturated and totally sealed conditions. Conversely, for w/c=0.4, where the saturated and sealed curves will nearly overlap (according to the computer model results discussed earlier), the 3-day system is not able to achieve the performance of a sealed environment. In this case, 7 days of curing are required to equal the performance of a sealed system.

In terms of practical implications, it may be important to realize that when the capillary

porosity depercolates, not only is it more difficult to remove water from the capillary pores in the specimen, but it is also more difficult to maintain saturation of the specimen via an external source of water. This effect has been observed during chemical shrinkage measurements on low w/c ratio cement pastes, where hydration as quantified by chemical shrinkage eventually falls below that measured by non-evaporable water content, as water can no longer be drawn into the specimen at a rate fast enough to maintain saturation (Powers, 1947, Geiker, 1983, and Bentz, 1997). This would imply that extended moist curing would be of limited benefit. However, moist curing during the first two to three days of hydration may be extremely important in maintaining internal saturated conditions to promote hydration, until depercolation of the capillary porosity is achieved. The situation will be even more complex in a concrete than in the cement paste specimens used in this study, due to the presence of the higher porosity interfacial transition zones surrounding each aggregate (Scrivener and Gartner, 1988). It is possible that when the capillary porosity depercolates in the "bulk" paste regions of the concrete, it may still remain interconnected in the interfacial zone paste regions (Winslow *et al.*, 1994 and Scrivener and Nemati, 1996). In this case, prolonged moist curing might be more valuable for a concrete than it would be for a cement paste specimen; more experimental measurements will be necessary to quantify the magnitude of this effect.

CONCLUSIONS

It has been shown that curing environments can have a significant effect on cement hydration kinetics. Even exposure to a 90% RH environment, after 6 or 12 hours of curing at 100% RH, can effectively terminate the hydration process as all remaining capillary water is removed from the specimen. While curing under sealed conditions may be adequate for systems with w/c ratios greater than 0.4, for lower w/c ratios, a significant reduction in the achieved degree of hydration has been observed. The best curing practice, similar to that originally suggested by Powers (Powers, 1947), may be to maintain surface saturated conditions until the capillary porosity depercolates, which will occur at different curing ages for different w/c ratios, and then seal the surface to prevent any moisture loss. The NIST cement paste hydration and microstructural model has provided valuable insights into the effects of sealed conditions and the resultant chemical shrinkage on hydration kinetics and microstructure.

IDENTIFICATION OF CAUSES OF LUMPS FORMATION IN INDUSTRIAL CEMENTS

Everaldo MARCIANO Jr., Sérgio Luiz CENTURIONE and Vagner MARINGOLO, Brazilian Association of Portland Cement, São Paulo - Brazil

ABSTRACT Portland cement is packed in papers bags prepared in such a way as to preserve the integrity of the hydraulic binder. Even by controlling the amount of alkali sulphates, monitoring grinding temperature and moisture, and storage in big silos, formation of lumps in cement bags or in bulk cement, whose causes are not directly related to pre-hydration of the cement, is likely to be observed. This phenomenon has been investigated on two cement samples of a Brazilian plant and compared with a non-problematic cement taken as reference.

Key-words: lumps, moisture, prehydration, packsetting

INTRODUCTION

The occurrence of alkali sulphates in portland clinker (Dreizler, 1986; Sprung, 1978; Kuhlmann et al, 1980), prehydration (due or not to gypsum dehydration) of cement inside the mill or silo (Hallick, 1980; Rott, 1987), fineness and electrostatic forces among particles after grinding (Thuler et al, 1988; Richartz, 1973), off-site vibrations, weight pressure on inadequately stored packs (ABCP, 1978) are some of numerous hypotheses that have been raised to explain the relatively common worldwide formation of lumps in packed and silo-stored cements.

In this work any causes, whether conventional or not, that might be acting on packsetting process occurring in cements produced by a Brazilian plant have been investigated.

METHODOLOGY

Samples

Three cement samples were chosen for experiment and analysis, two of them presenting lumps (A and B) and one pristine (R) which was taken as reference (Table 1).

Table 1 Characteristics of cement samples

Sample	Contents (%)			
	Clinker	Filler	Blast Furnace Slag	Gypsum [4]
A [1]	92	4	-	5
B [2]	86	10	-	3
R [3]	76	9	11	4

[1] High early strength cement, with little packsetting problems
[2] Cement with limestone filler with high incidence of lumps
[3] Reference cement, without occurrence lumps
[4] Calculated from chemical analysis

Experimental Work

All the three samples were packed in 7cm x 11cm x 2.8cm minibags (Kihara and Monteiro, 1993) in order to accelerate the cements hydration process. The minibags were further stored under laboratory conditions of temperature T = (23±1)°C and relative humidity = (68±1)%. After 7-, 14- and 21-day storage the samples were sieved (sieve #120) and thermodifferential-thermogravimetric and X-ray diffratometric analyses were carried out.

Sieving
Table 2 lists sieving residues of the three samples.

Table 2 Sieving residues

Sample	Residue >125μm		
	7 days	14 days	21 days
A	2.6	28.3	43.7
B	4.7	29.0	59.8
C	3.7	20.2	29.6

Results show that, under the same storing conditions, cements A and especially B tend to packset faster than R. This fact indicate that formation of lumps is not exclusively due to storage at the cement plant but also to some other distinct characteristic of the cement favoring the early packsetting.

Thermodifferential-Thermogravimetric (TD-TG) Analysis
The samples of the stored minibags and the here called *in-natura* samples, *i.e.* correspondent cements not exposed to laboratory storing conditions, were analysed for TD-TG. Figs 1 and 2 show the evolution of W_k (combined water) values (Theisen and Johansen, 1975) and calcite contents, respectively.

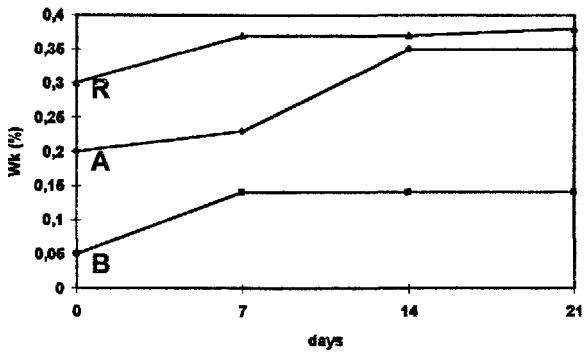

Figure 1 - Evolution of W_K values as function of storing time, under laboratory conditions

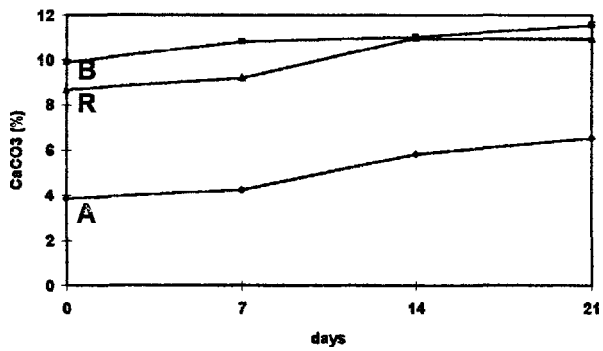

Figure 2 - Evolution of $CaCO_3$ contents as a function of storing time, under laboratory conditions

Smaller W_K values shown for samples A and B which have higher tendency to packset, as compared to sample R, allow us to affirm that lumps are being formed in those cements independently of significant prehydration of clinker components.

As for $CaCO_3$ contents, all the three samples went through a clear carbonation process.

X-Ray Diffratometry (XRD)
Residues from salicylic acid solution of laboratory-stored samples and the *in-natura* samples were also analysed for XRD. This analytical method was later on used to evaluate formation of hydration products and/or alkali sulphates in the samples. The minerals that make up the three samples are listed in Table 3.

Table 3 Samples mineral composition

Mineral component	Chemical composition	Sample		
		A	B	R
Alite+ Belite	$(Ca_3SiO_5) + (Ca_2SiO_4)$	*****	*****	*****
C_4AF	$Ca_4Al_2Fe_2O_{10}$	**	**	**
C_3A	$Ca_3Al_2O_6$	**	**	*
Calcite	$CaCO_3$	**	***	***
Gypsum	$CaSO_4.2H_2O$	8	*	*
Bassanite	$CaSO_4.½H_2O$	*	*	*
Quartz	SiO_2	tr	tr	tr
Syngenite	$K_2Ca(SO_4)_2.H_2O$	*	tr	*
Arcanite	K_2SO_4	tr	-	-
Ettingite	$Ca_6Al_2(OH)_{12}(SO_4)_3.26H_2O$	-	-	-

Note: * expresses comparatively a semiquantitative proportion of mineral phases according to diffraction peak intensity; tr = traces; - = not detected

The diffraction peaks comparatively shows that sample B has the lowest syngenite content in spite of its highest tendency to packsetting.

Along the laboratory storing process, no evidence of ettringite formation was found and incidence of syngenite was the same in the three samples.

CONCLUSION

The tendency to packsetting observed at the plant on samples A and especially B was evidenced in the laboratory tests through formation of lumps in minibags filled with these cements and stored for periods of 7, 14 and 21 days under laboratory conditions of temperature and relative humidity.

Cements A and B presented low prehydration, as compared to sample R, taken as reference for not showing packsetting problems. This evidence is indicative of lumps formation in those cements even at low W_K values what suggests that influence of prehydration was of little significance on this process.

A higher syngenite content was found in sample R followed by sample A and, in much smaller proportion, B. This curious fact indicates how little expressively alkali sulphates acted as packsetting agents on the cements analysed, especially sample B.

As to physical characteristics, very fine cement A (specific surface = $450 m^2.kg^{-1}$) presented less critical packsetting problems than coarser cement B (specific surface = $360 m^2.kg^{-1}$).

Based on data obtained, the evidences lead to the conclusion that formation of lumps in cement B and less intensively in cement A was actually due to their low W_K value, what for some physical-chemical reason makes the cement adsorb water. The reason for this adsorption must be related to grinding conditions, not only operational parameters but also the additive's nature and content.

From one point of view, W_K values higher than 0.35% in cements may affect negatively the mechanical strength performance of these cements (Theisen and Johansen, 1975), from another point, however, low values, normally lower than 0.10% may favour their susceptibility to

packsetting even under low humidity conditions. In case of high early-strength cements (sample A), W_K value was a little higher (0.20%), but its higher fineness must have contributed to its precocious lumps formation. In fact, the packsetting problems have been become more serious after water content in the mill was reduced.

KEY-WORD INDEX

A
Accelerated test; 3iii033
Accelerators; 3ii103, 3iii005, 3iii012, 3iii014, 3iii022, 3iii027, 3iii032,
Acid attack; 3ii109, 4iv002, 4iv021, 4iv038, 4iv039, 4iv040
Activation; 1i006, 2ii016, 2ii045, 2ii062, 2ii076, 3ii083, 3ii092, 3ii094, 3ii098, 3ii099, 3ii100, 3ii103, 3ii104, 3ii113, 3ii114, 3iii028, 4iv047
Activation energy; 1i053
Activity coefficient; 4iv083
Additives; 1i009, 1i020, 1i035, 2ii003, 2ii009, 2ii045, 2ii074, 3ii116, 3iii017, 3iii032
Adiabatic temperature rise; 4iv072
Admixtures; 2ii012, 2ii034, 2ii036, 2ii047, 3ii087, 3ii095, 3ii097, 3iii001, 3iii002, 3iii004, 3iii009, 3iii018, 3iii019, 3iii023, 3iii024, 3iii025, 3iii026, 3iii029, 3iii030, 3iii031, 3v015, 4iv004
Adsorption; 2ii001, 3iii002, 4iv077
AFm phase; 2ii032, 3iii032, 3ii089, 4iv034, 4iv061
AFt phase; 1i060, 4iv034, 4iv041, 4iv059
Aggregate; 2ii015, 3v024, 4iv053, 4iv057
Air entraining; 4iv031, 4iv057
Air pollution; 4iv002
Alinite; 2ii030, 3ii118
Alite; 1i006, 1i015, 1i041, 1i050, 2ii040, 2ii042, 2ii056, 3ii107, 3ii117, 3iii005, 3iii031
Alkali; 1i002, 1i012, 1i028, 1i035, 1i049, 2ii012, 2ii065, 3ii083, 3ii098, 3ii100, 3ii103, 3ii113, 3ii114, 3ii117, 3iii025, 4iv003, 4iv028, 4iv055, 4iv066
Alkali aggregate reaction; 3iii033, 3v022, 4iv048
Alkali silica reaction; 4iv047, 4iv049, 4iv065, 4iv074
Alkali silicate solutions; 4iv049, 4iv065
Alkaline cement; 4iv046
Alumina; 2ii027, 2ii026, 3iii010
Aluminate phase; 1i001, 1i022, 1i051, 1i056, 2ii041, 2ii060, 3iii010, 3iii015, 4iv027, 4iv034, 4iv066
Aluminoferrite; 1i004, 1i005, 1i055, 2ii031
Aluminosilicate; 1i024, 4iv046
Anhydrite; 1i032, 2ii011, 2ii022, 2ii029, 3ii092, 4iv059
Aragonite; 1i042
Arc furnace dust; 4iv042
Asbestos; 1i027
Ash; 3ii080
Autoclavation; 3ii120, 4iv054
Autoclave soundness; 1i023
Autogeneous shrinkage; 2ii069, 2ii070, 2ii071, 2ii073

B
Backscattered electron image; 2ii014, 4iv061
Bacterial attack; 4iv038, 4iv039
Bamboo dust; 1i019

Barite; 1i036
Barium phases; 1i058
Belite; 1i006, 1i015, 1i018, 1i041, 1i052, 2ii007, 2ii040, 2ii045, 2ii056, 3v009
Belite cement; 1i036
Binder; 1i059, 2ii047, 2ii054, 3ii080, 3ii101, 3iii021, 4iv057
Blastfurnace slag; 2ii068, 2ii074, 3ii082, 3ii093, 3ii095, 3ii096, 3ii098, 3ii099, 3ii101, 3ii102, 3ii103, 3ii104, 3ii115, 3ii122, 3iii009, 3iii017, 4iv001, 4iv005, 4iv009, 4iv015, 4iv035, 4iv040, 4iv063
Blended cement; 1i020, 3ii089, 3ii091, 3ii111, 3ii114, 3ii115, 3ii121, 3v026, 4iv004, 4iv017, 4iv020, 4iv052,
Bogue calculation; 1i039, 3v007, 3v009
Borax; 1i036
Bottom ash; 3ii090
Bound water; 2ii072, 3iii019, 3v019
Brick; 3ii080
Brownmillerite; 1i022, 2ii029, 2ii032,
Burnability of raw mixes; 1i021, 1i030, 1i031, 1i034, 1i040, 1i041, 1i045, 1i048, 1i054
Burning conditions of clinker; 1i018, 1i023

C
Calcium carbonate; 1i042
Calcium aluminate; 2ii022, 2ii025, 2ii050, 3iii022, 3v005
Calcium aluminate cement; 2ii024, 2ii026, 2ii027, 2ii028, 3iii007, 3v018, 4iv003, 4iv025, 4iv026
Calcium aluminate sulphate; 2ii010, 4iv068
Calcium aluminozincates, 1i059
Calcium hydroxide; 2ii049, 2ii059, 3ii082, 3ii106, 3ii107, 3ii108, 3ii112, 3iii031, 3v019, 4iv067
Calcium fluoride; 1i032, 2ii042
Calcium langbeinite; 2ii011
Calcium nitrate; 3iii012
Calcium phosphate; 1i036
Calcium phosphate cement; 2ii063
Calcium silicate; 1i035, 1i055, 2ii055, 2ii050, 2ii062, 4iv054
Calcium sulphate; 1i012
Calorimetry; 2ii021, 2ii025, 2ii041, 2ii066, 3iii032, 3v016, 3v017, 4iv042
Capillary; 2ii048
Carbon dioxide; 1i024, 2ii032, 4iv010
Carbonation; 2ii073, 4iv003, 4iv004, 4iv005, 4iv006, 4iv010, 4iv017, 4iv026, 4iv035, 4iv048, 4iv070, 4iv084
Case studies; 4iv002
Cement; 3ii092
Cement hydration equation; 2ii061, 4iv052
Characterization; 1i008, 2ii062, 3ii088, 3v011, 3v020 3v023, 3v026, 4iv019
Chemical analyis; 3v012
Chemical attack; 4iv015, 4iv026, 4iv028, 4iv031
Chemical prestressing; 3iii016

Chemical shrinkage; 2ii069, 2ii070, 2ii072
Chloride; 1i002, 1i012, 2ii030, 3ii118, 4iv006, 4iv015, 4iv027, 4iv078, 4iv080, 4iv081, 4iv082, 4iv083
Chloride Binding; 4iv016, 4iv069, 4iv070, 4iv078
Classification; 4iv046
Clay; 2ii020
Clinker; 1i048, 1i058
Clinker composition; 1i028, 4iv036
Clinker formation; 1i004, 1i006, 1i008, 1i010, 1i011, 1i026, 1i031, 1i037, 1i043, 1i044, 1i046, 1i049, 1i054, 2ii006, 3ii118
Cluster; 1i003
Coal; 1i047, 3ii090
Composite cements; 1i009, 2ii016, 2ii034, 3ii122
Composition; 2ii007, 2ii071, 3v004, 3v011, 3v026, 4iv007, 4iv023, 4iv060
Concrete; 2ii035, 3ii108, 3iii024, 3iii029, 3v021, 3v022, 4iv025, 4iv035, 4iv073
Cooling of clinker; 3v005
Corrosion; 2ii006, 4iv014, 4iv020, 4iv023, 4iv027, 4iv028, 4iv030, 4iv038, 4iv039, 4iv071, 4iv082, 4iv084
Creep; 4iv018
Cross-linking; 3iii011
Crystal; 2ii015
Crystal size; 1i051, 3iii031
Crystal structure; 1i055, 2ii048
Crystallisation pressure; 4iv049
Crystallography; 2ii054
CSH; 2ii044, 2ii047, 2ii053, 2ii055, 2ii059, 2ii064, 2ii067, 2ii068, 3ii082, 3ii093, 3ii121, 3v001, 3v003, 4iv016, 4iv041, 4iv043, 4iv061, 4iv074, 4iv076
Curing; 2ii037, 2ii078, 3ii091, 4iv055, 4iv059, 4iv067

D

Deformation; 4iv021, 4iv058
Degree of hydration; 2ii051, 2ii053, 2ii062, 2ii077, 3v019, 4iv016
De-icing salts; 4iv006, 4iv035
Delayed ettringite formation; 4iv059, 4iv061, 4iv062, 4iv063, 4iv064
Delayed expansion; 3iii016
Design life; 4iv071
Dicalcium silicate; 1i017, 1i053
Differential thermal analysis; 2ii041, 4iv031
Diffusion; 2ii046, 3ii084, 3ii098, 4iv010, 4iv015, 4iv016, 4iv056, 4iv080, 4iv081
Diffusivity; 4iv008, 4iv009
Dilation; 4iv033
Dispersion; 2ii005
Disposal; 1i027
Dopant; 1i053
Drying; 3iii018, 3v018, 4iv011, 4iv077, 4iv079
Durability; 2ii011, 3ii095, 3iii024, 3v022, 4iv004, 4iv007, 4iv022, 4iv023, 4iv026, 4iv029, 4iv030, 4iv037, 4iv040, 4iv046, 4iv048, 4iv062, 4iv065, 4iv070, 4iv075, 4iv082

E
Economy; 1i036, 3ii114
Ecology; 1i043
Electron microscopy; 1i060
Electron spectroscopy for chemical analyses (ESCA); 2ii044
Electrical conductivity; 4iv011
Electrical impedance; 3ii112
Electrical properties; 4iv079
Electrical resistivity; 3v021
Energy; 2ii046
Environment; 1i003, 3ii093
Equilibria; 2ii057, 2ii058
Ettringite; 1i025, 2ii006, 2ii010, 2ii017, 2ii029, 2ii031 2ii056, 2ii070, 2ii074, 3iii022, 4iv012, 4iv018, 4iv031, 4iv060, 4iv062, 4iv065
Evaporable water; 3v019
Expansion; 2ii006, 2ii074, 3iii017, 3v022, 4iv057, 4iv060, 4iv062, 4iv064
Expansive cement; 1i001, 2ii010
Extraction methods; 3v020

F
False set; 3iii013
Ferrite phase; 1i008, 1i015, 1i060, 3iii005, 3v003
Ferroaluminate; 4iv029
Filler; 1i020, 2ii002, 2ii020, 3ii081, 4iv056
Fineness; 1i007, 2ii001, 2ii002, 2ii018, 2ii043, 2ii060, 3ii088, 3v008, 4iv060
Fingerprinting; 3v010, 3v011
Fire; 4iv073
Fire damage; 4iv067
Flow; 2ii017, 3v024
Flue gas desuphurisation product; 3ii090
Fluidity; 2ii001, 2ii002, 2ii012
Fluoride phases; 2ii043, 3v002
Fly ash; 3ii081, 3ii082, 3ii083, 3ii084, 3ii085, 3ii086, 3ii087, 3ii088, 3ii089, 3ii090, 3ii110, 3ii115, 3ii116, 3ii122, 3v006, 3v020, 3v021, 4iv004, 4iv009, 4iv012, 4iv019, 4iv020, 4iv023, 4iv058, 4iv077
Fracture mechanics; 2ii075
Free lime; 1i016, 1i045, 2ii049, 4iv036
Freeze-thaw damage; 2ii016, 3iii019, 4iv034, 4iv035
Freezing; 4iv033
Friedel's salt; 4iv027, 4iv080
Fuels for clinker making; 1i013, 1i019

G
Gel; 3ii105, 3iii007, 3iii022, 4iv074
Glass; 1i046, 1i051, 3ii088, 3ii119, 4iv030, 4iv055
Grinding aids; 2ii020, 3v014
Grinding technology; 1i009, 1i040

Ground silica; 3ii120
Grout; 2ii005
Gypsum; 2ii040, 2ii044, 2ii060, 3ii093, 3ii115, 3iii025, 3v008, 3v023, 4iv017

H
Hardening; 2ii008, 2ii034, 2ii039, 2ii047, 2ii052, 2ii054, 2ii076, 3ii112, 3v016, 4iv071
Heat capacity; 4iv033
Heat evolution; 2ii021, 2ii035, 2ii051, 2ii076, 2ii077, 3ii102, 3ii105, 3iii029, 3v016, 4iv042, 4iv072
Heavy metals; 1i043, 2ii014, 3v010, 3v013, 4iv041, 4iv043
High alumina cement; 2ii023, 2ii033, 3iii010, 3ii096, 4iv013, 4iv027, 4iv038
High performance; 2ii035, 2ii038, 3ii108, 3v006, 3v021
High strength; 2ii037, 3ii120
High sulphate clinker; 2ii011
High temperature; 3ii111, 3iii020, 4iv067
Humidity; 4iv011, 4iv079
Hydration; 1i022, 1i057, 1i059, 2ii004, 2ii006, 2ii008, 2ii007, 2ii012, 2ii013, 2ii015, 2ii019, 2ii021, 2ii022, 2ii023, 2ii024, 2ii025, 2ii026, 2ii028, 2ii029, 2ii030, 2ii031, 2ii033, 2ii035, 2ii036, 2ii039, 2ii040, 2ii041, 2ii042, 2ii043, 2ii044, 2ii046, 2ii047, 2ii050, 2ii052, 2ii055, 2ii057, 2ii058, 2ii061, 2ii067, 2ii069, 2ii070, 2ii078, 3ii089, 3ii094, 3ii097, 3ii099, 3ii100, 3ii101, 3ii102, 3ii107, 3ii116, 3ii118, 3ii119, 3iii008, 3iii014, 3iii015, 3iii019, 3iii025, 3v006, 3v016, 3v018, 4iv072, 4iv071
Hydrothermal synthesis; 1i017

I
Identification; 3v010
Image analysis; 4iv084
Immobilization; 2ii014, 2ii016, 2ii052, 4iv043, 4iv045
impact prediction; 1i003
Impact evaluation; 1i003
Induction period; 2ii019, 2ii055
Infra red absorption spectra; 3ii104
Inhibitor; 3iii033
Interfacial zone; 4iv050, 4iv051, 4iv053, 4iv056, 4iv084
Interground cements; 1i013, 3v026
Interstitials; 2ii007
Ion exchange resin; 4iv045
Ionic assocoiation, 4iv083
Ions; 2ii036, 2ii046, 2ii065, 3iii012, 3iii013, 4iv075, 4iv079
Iron mud; 1i021
Isomorphism; 1i059

K
Kinetics; 1i005, 1i035, 1i044, 1i052, 2ii019, 2ii023, 2ii028, 2ii043, 2ii055, 3ii098, 3iii008, 4iv076

L
Latex; 3iii008
Leaching; 2ii014, 4iv012, 4iv041, 4iv043, 4iv045
Light microscopy; 3iii031, 3v007
Lignosulphonates; 2ii004, 3iii013, 3iii021
Lime; 2ii049, 2ii074, 3ii084, 3iii005, 4iv010
Limestone; 1i047, 1i048, 2ii022, 4iv018
Long age; 2ii016, 4iv050
Low energy; 1i034, 2ii045
Low temperature; 1i018, 1i029, 1i037, 2ii009, 2ii013, 2ii038, 3iii014, 3v017
Lumos; 2ii079

M
Magnesium chloride; 4iv022
Magnesium sulphate; 4iv022
Magnesium oxide; 1i023, 2ii064, 3v012
Magnesium phases; 1i057
Mass spectroscopy; 3v014
Maturity; 3ii111
Macro Defect Free; 3iii010, 3iii011, 4iv013
Mechanical properties; 3v025
Mechanism; 1i046, 2ii025, 2ii026, 2ii035, 2ii050, 2ii057, 2ii058, 3ii100, 3iii003, 3iii006, 3iii012, 3iii025,, 3v014, 4iv074
Melt; 1i008, 1i011, 1i012, 1i014, 1i029, 1i046, 3v005
Mercury Intrusion Porosimetry; 3ii104
Metakaolin; 3ii113, 3ii114, 4iv011
Method; 2ii021, 3v011, 3v013, 3v016, 3v018, 3v022, 3v023, 4iv081
Microcrack; 4iv021
Microgravity; 2ii075
Microscopy; 1i029, 1i030, 1i039, 1i051, 1i052
Microstructure 1i038, 1i039, 1i047, 1i049, 1i052, 2ii008, 2ii014, 2ii018, 2ii037, 2ii064, 2ii075, 3ii091, 3ii095, 3ii096, 3ii099, 3iii014, 4iv005, 4iv015, 4iv025, 4iv037, 4iv047, 4iv050, 4iv051, 4iv053, 4iv055, 4iv068, 4iv084
Mineralisers in clinker making; 1i028, 1i030, 1i031, 1i033, 1i034, 1i037, 1i050, 3v002
Mineralogy; 1i046, 3ii087, 3ii105
Mineral phase; 1i015, 2ii009, 2ii015, 4iv028
Mixing procedure; 3ii120
Mobility; 2ii065, 4iv083
Modelling; 1i038, 1i044, 1i045, 2ii048, 2ii052, 2ii078, 3ii085, 3ii084, 3iii013, 3v004, 4iv005, 4iv070, 4iv071, 4iv073, 4iv078
Modified cement; 2ii004, 2ii020, 3ii085, 3ii097, 3ii104, 3iii021, 3iii023
Moisture; 2ii079, 3iii011,3v004, 4iv010, 4iv013, 4iv062
Molybdic compounds; 1i054, 1i055
Monosulphate; 2ii056
Mortar; 4iv033

N
Naphtalene Formaldehyde Sulphonate; 3iii003, 3iii009, 3iii030
Nitrate attack; 4iv002
Nodulization in clinker formation; 1i007
Non-equilibrium burning; 1i011
Nuclear Magnetic Resonance; 1i024, 2ii028, 2ii056, 2ii067, 2ii068, 3iii007, 3v001, 3v002, 3v003, 3v004, 3v005, 3v006

O
Oilwell cement; 2ii013, 3iii014
Organic; 3v015
Osmotic pressure; 4iv049

P
Packsetting; 2ii079
Particle size distribution; 1i009, 2ii018, 2ii053, 3ii110, 3v024
Pattern recognitin; 3v010
Penetration; 2ii005, 2ii038, 3ii109, 4iv080
Performance; 4iv073
Permeability; 4iv008, 4iv075
Petroleum coke; 3ii090
pH; 4iv065
Phase composition; 3ii091
Phase diagram; 1i050, 1i052, 2ii024, 2ii057, 2ii058, 4iv066, 4iv074,
Phase transition; 4iv033
Phase transformation; 4iv034
Phosphate; 4iv057
Physical properties; 3v025
Plasticizers; 2ii020
Polymer; 3iii008, 3iii009, 3iii010, 3iii027, 4iv013
Polymorphs; 1i053
Pore size distribution; 4iv077
Pore solution; 2ii036, 3iii003, 3iii013, 3iii022, 3ii091, 4iv040, 4iv069
Pore structure; 2ii037, 2ii066, 3ii111, 3iii009, 3iii018, 3v017, 4iv001, 4iv005, 4iv080
Porosity; 2ii036, 2ii048, 2ii066, 2ii072, 3ii085, 3ii119, 3iii023, 3v017, 4iv006, 4iv007, 4iv008, 4iv013, 4iv017, 4iv024, 4iv040, 4iv048, 4iv054, 4iv078
Portland cement; 3ii107, 3iii006, 3v025, 4iv012
Potentiometry; 4iv083
Powder; 2ii002
Pozzolana; 1i020, 2ii073, 2ii077, 3ii106, 3ii107, 3ii108, 3ii112, 3ii115, 3ii117, 3ii123, 3ii124, 3v001
Pozzolanic cement; 4iv036
Pozzolanic reaction; 3v006
Pozzolanic reactivity; 3ii088
Pre-calciners for clinker making; 1i028
Prehydration; 2ii079
Process parametres; 1i047

Q
Qualitative; 1i004, 3v010, 3v011, 3v015
Quantitative; 1i039, 1i056, 3v007, 3v012, 3v013, 3v015, 3v020
Quartz; 1i048

R
Rapid hardening cement; 2ii017
Rate equations; 1i044
Reaction products; 4iv049
Reactivity; 1i016, 1i018, 1i047, 1i060, 2ii049, 2ii050, 3ii082, 3ii109, 3ii110, 3v020, 4iv016, 4iv050
Refractory; 2ii027, 4iv053, 4iv057
Relative humidity; 2ii073
Residual silica; 4iv049
Retarders; 3iii007, 3iii020, 3iii032
Rheology; 2ii003, 2ii004, 2ii011, 3iii003, 3iii027
Rice husk; 1i019
Rice Husk Ash; 3ii108, 3ii109, 3ii110
Rietveld analysis; 1i039, 1i056, 3v007
Roller compaction; 3ii086
Rotary kiln; 1i007, 1i019

S
Salt scaling; 4iv001
Scanning Electron Microscopy; 1i002, 2ii078, 3ii083, 3ii120, 3iii008, 3v019, 4iv037, 4iv064
Sea water; 4iv025
Secondary ettringite formation; 4iv065
Self deccication; 2ii073
Setting; 1i038, 2ii019, 2ii039, 2ii053, 2ii063, 3ii101, 3ii112, 3iii006, 3iii012, 3iii023, 3iii026, 3v008
Sewage; 3ii123, 3ii124, 4iv038, 4iv039
Shotcreting; 3iii027
Shrinkage; 1i032, 3iii018, 4iv036, 4iv056
Silica; 3ii080
Silica colloid; 3ii106
Silica fume; 2ii037, 3ii105, 3ii106, 3ii110, 3ii116, 3ii120, 3v001, 4iv014, 4iv069
Silica modulus; 1i035
Silicate; 2ii060, 3iii027, 4iv065
Simulation; 2ii078, 3iii001
Sintering; 1i005, 1i007, 1i022, 1i032
Slag; 1i020, 3ii080, 3ii092, 3ii094, 3ii097, 3ii100, 4iv050, 4iv051, 4iv058
Slump loss; 3iii003, 3iii020
Sodium chloride; 4iv022
Solid solution; 1i014, 1i023, 1i057, 2ii059, 1i060, 3v009
Solid state reactions; 1i042
Solidification; 4iv042
soluble glass; 2ii033

Sorption isotherms; 4iv077
Specific surface; 3iii028
Spectrophotometry; 3v012
Stability; 4iv065
Stabilization; 1i016, 2ii045, 4iv041
Standards; 3v025
Steam curing; 3ii102, 4iv036, 4iv063
Steel; 4iv014, 4iv082
Steric repulsive force; 3iii001
Strain softening; 2ii075
Strength; 1i048, 1i058, 3ii109, 4iv057
Strength development; 1i029, 1i038, 1i041, 2ii007, 2ii017, 2ii018, 2ii033, 2ii051, 2ii053, 2ii054, 2ii060, 2ii063, 2ii072, 2ii076, 2ii077, 3ii085, 3ii089, 3ii097, 3ii111, 3ii117, 3ii119, 3ii121, 3iii004, 3iii026, 3iii028, 3iii029, 3v024, 4iv024, 4iv052, 4iv054, 4iv055, 4iv056, 4iv058, 4iv063
Strength retrogression; 4iv019
Stress; 4iv049
Structure; 1i005, 1i014, 1i056, 2ii054, 2ii066, 2ii067, 2ii068, 2ii069, 2ii076, 4iv007, 4iv025, 4iv042, 4iv043, 4iv075
Sucrose; 3iii006
Sulphate; 1i049, 2ii012
Sulphate attack; 4iv002, 4iv018, 4iv020, 4iv021, 4iv024, 4iv057, 4iv059
Sulphate resistance; 3iii004, 3iii015, 4iv017, 4iv019, 4iv023
Sulphoaluminate; 1i001, 1i025, 2ii029, 3iii026, 3v009, 4iv029, 4iv030, 4iv068
Sulphoaluminoferrite; 1i014
Superplasticizers; 2ii002, 2ii004, 3iii001, 3iii002, 3iii019, 3iii020, 3iii021, 3iii030, 4iv001
Support; 2ii015
Synthesis; 1i015, 1i024, 1i033, 2ii064, 3ii113

T

Temperature; 1i005, 1i007, 1i008, 1i012, 2ii021, 2ii023, 2ii026, 2ii043, 2ii066, 3iii002, 3iii029, 3v001, 4iv047, 4iv060, 4iv068, 4iv069
Terminology; 4iv046
Texture; 1i048
Thawing; 4iv033
Thermal stress; 4iv072
Thermal treatment; 1i027
Thermodynamics; 1i042, 2ii024, 2ii057, 2ii058, 2ii059, 2ii062, 2ii066, 4iv039, 4iv066
Thermogravimetry; 2ii049, 3ii105, 3iii011 4iv003, 4iv037
Thermoporosimetry; 3v017
Tobermorite; 2ii064, 2ii065, 3v003
Trace components; 1i021
Transmission Electron Microscopy; 2ii068
Tricalcium silicate; 1i049 2ii041, 2ii044

U

Unreacted core model; 2ii051

V
Vibration; 2ii017
Viscosity; 1i014, 1i032, 2ii001, 2ii003, 2ii005
Void spacing factor; 3v024
Volume change; 2ii009, 2ii039, 2ii071, 2ii072, 4iv031

W
Waste disposal; 4iv012
Waste material utilization; 1i010, 1i019, 1i022, 1i025, 1i026, 1i027, 1i033, 2ii052, 3ii081, 3ii093, 3ii101, 3ii116, 3ii118, 3ii119, 3ii121, 3ii123, 3ii124, 3v003, 3v013, 4iv014, 4iv024
Water; 4iv075
Water sorption; 4iv008
Water suction; 4iv008, 4iv011, 4iv078
Water-to-cement ratio; 2ii071
Waterglass; 3ii092
Wedge splitting; 2ii075
White Portland Cement; 3iii004
Workability; 2ii011, 3iii029

X
X-ray Diffraction Analysis; 1i051, 1i016, 2ii041, 3iii028, 3ii087, 3ii114, 3v008, 4iv003
X-ray Fluorescense Analysis; 3v011
X-ray Powder Diffraction; 1i002, 1i010, 1i056, 2ii065, 4iv018

Z
Zeolites; 1i020, 1i024, 4iv028, 4iv045, 4iv046
Zeta potential; 3iii001, 3iii002

II PORTLAND, BLENDED AND SPECIAL CEMENTS

II.F Effect of blends or additions of combustion ash, slag, silica fume or rice husk ash

S. Pavlenko, M. Shmelkov: "Cementless Binder and Silica Brick Based on it", 3ii080, 5 pp

M.V. Kougiya, L.S. Fraiman: "Hollow Microspheres of Ash and Binding, Compositions based on them", 3ii081, 4 pp

R. Härdtl: "The Pozzolanic Reaction of Fly Ash in Combination with Different Types of Cement", 3ii082, 8 pp

A. Katz: "Fly Ash Blended Cement Activated by a Strong Base", 3ii083, 4 pp

S. Jalali: "Modelling the Overall Rate of Reaction in Lime-Fly Ash Systems", 3ii084, 4 pp

D.M, Krizan, C.E.S. Tango, V.A. Quarcioni, Y. Kihara: "A Study on Time Behaviour of Fly-Ash Blended Cement Products", 3ii085, 8 pp

I. Papayianni: "Cooperation of Cement-Fly Ash System in High Paste Roller Compacted Concrete (RCC)", 3ii086, 4 pp

S. Dietz, K. Miskiewicz, M. Schmidt: "Properties of Cement Containing German Lignite Fly Ashes", 3ii087, 10 pp

S. H. Lee, E. Sakai, M. Daimon: "Characterization of Fly Ashes Directly Collected from Electrostatic Precipitator", 3ii088, 8 pp

M. Gawlicki, A. Łagosz, J. Małolepszy: "Utilization of Fly Ashes Containing Calcium Sulfite in Cement Production", 3ii089, 4 pp

S.L. Sarkar, J.R. Prusinski: "Microstructural Characterics of By-products of Petroleum Coke Blended Coal Combustion", 3ii090, 4 pp

E. E. Lachowski, F.P. Glasser, A. Kindness, K. Luke: "Compositional Development (Solid and Aqueous Phase) in Aged Slag and Fly Ash Blended Cement Pastes", 3ii091, 8 pp

S.N. Ghosh, D.M. Joshi, S. Chanda, H. Vaishnav: "Studies on Activation of Slag Cement", 3ii092, 4 pp

S. Manjit: "Effect of Blended Gypsum on the Properties of Portland Cement and Portland Slag Cement", 3ii093, 4 pp

K.M. Sharma, P.S. Sharma, D. Yadav, S.C. Ahluwalia: "Hydration Characteristics of Steel Slag in Ordinary Portland Cement Blends", 3ii094, 4 pp

W. Brylicki: "Modification of Alkali Activated Slag Pastes by Use of Mineral Admixtures", 3ii095, 4 pp

Mª.L. Romero, Mª.T. Blanco-Varela, A. Palomo, F. Puertas, T. Vasquez: "Activation of Blast Furnace Slag/High Alumina Cement Pastes: Mechanical and Microstructural Evolution", 3ii096, 8 pp

W. Roszczynialski: "Influence of Silico-Manganic Slag Additives on Cement Hydration and Properties",
3ii097, 4 pp

A. Fernandez-Jimenez, F. Puertas: "Kinetic Study of Alkali-Activated Blast Furnace Slag", 3ii098, 4 pp

C. Shi: "Early Hydration and Microstructure Development of Alkali-Activated Slag Cement Pastes", 3ii099, 8 pp

W. Jiang, M.R. Silsbee, D.M. Roy: "Alkali Activation Reaction Mechanism and its Influences on Microstructure of Slag Cement", 3ii100, 9 pp

M. Radenkova-Yaneva, S. Dimitrova: "Influence of Spent Blast Furnace Slag on the Properties of Cement Systems", 3ii101, 4 pp

A.F. Battagin, G. Camarini, M.A. Cincotto: "A Study of Early Hydration of Slag Cement Pastes Subjected to Thermal Curing", 3ii102, 4 pp

E. Marciano Jr., A.F. Battagin: "The Influence of Alkali Activator on the Early Hydration and Performance of Portland Blast Furnace Slag Cement", 3ii103, 4 pp

H. R. Kota, V. Ronin, E. Forssberg: "High Performance Energetically Modified Portland Blast-Furnace Slag Cements", 3ii104, 9 pp

B. Meng, P. Schiessl: "The Reaction of Silica Fume at Early Ages", 3ii105, 8 pp

S. Chandra, H. Bergqvist: "Interaction of Silica Colloid with Portland Cement", 3ii106, 6 pp

K. Asaga, H. Kuga, S. Takahashi, E. Sakai, M. Daimon: "Effect of Pozzolanic Additives in the Portland Cement on the Hydration Rate of Alite", 3ii107, 8 pp

L.K. Lin, C.L. Hwang: "The Characteristics and Hydration Mechanism of RHA Cement Paste", 3ii108, 4 pp

S. Sugita, Q.Yu, M. Shoya, Y. Tsukinaga, Y. Isojima: "On the Semi-Industrial Poduction of Highly Reactive Rice Husk Ash and Its Effect on Cement and Concrete Properties",
3ii109, 9 pp

G. C. Isaia: "Synergic Action of Fly Ash in Ternary Mixtures with Microsilica and Rice Husk Ash", 3ii110, 8 pp

Y. Xi, B.E. Scheetz: "Compressive Strength and Pore Structure of Slag-Silica Fume Cement Cured at 38-175°C", 3ii111, 4 pp

W.J. McCarter, H. Ezirim: "Characterising Reactivity of Alkali-Activated Pozzolans", 3ii112, 4 pp

M.L. Granizo, Mª.T. Blanco-Varela, F. Puertas, A. Palomo: "Alkaline Activation of Metakaolin: Influence of Synthesis Parametres", 3ii113, 8 pp

J.N. Liu, M.R. Silsbee, D.M. Roy: "Strength and Hydration of an Activated Alumino-Silicate Material", 3ii114, 6 pp

N.B. Singh, K.N. Bhattacharjee, A.K. Shukla: "Hydration of Portland Cement Blends in Presence of Bag House Dust from Calcium Carbide Furnace", 3ii115, 4 pp

V. Lilkov, O.E. Petrov: "Hydration of Cement Mixed with 'Pozzolit' Mineral Additive", 3ii116, 7 pp

R.F. Runova, V.S. Melentyeva, J.I. Ustimenko: "Peculiarities of Ukrainian Pozzolana Cements", 3ii117, 4 pp

Y. Takuma, Y. Tsuchida, S. Uchida: "Characteristics and Hydration of Cement Produced from Ash from Incinerated Urban Garbage", 3ii118, 8 pp

S. Sugita, Q.Yu, M. Shoya, Y. Tsukinaga, Y. Isojima: "The Effect of Waste Glass Powder on the Properties and Pore Structure of Normal Portland Cement Hydrates", 3ii119, 8 pp

F. Van Rickstal, D. Van Gemert, P. Parmentier, K. Vanbelle: "Addition of Ultra Fine Ground Sand for the Production of High Strength Autoclaved Mortars", 3ii120, 8 pp

T. Nishikawa, S. Ito: "Fracture Mechanics and Microstructure of Blended Cement Paste", 3ii121, 7 pp

X. Zhang, K. Wu, J. Han: "Research on a New Type of Composite Cement", 3ii122, 4 pp

G. Morales: "Utilization of Sewage Sludge as a Raw Material for Production of Pozzolanic Material", 3ii123, 5 pp

A. H. Abedel-Reheem, M.A. Shater, I. G. Al-Alm Rashed, A.N. El-Afify: "Utilization of Stored Cement. Part II: The Blending of Stored Cement by Fresh Cement", 3ii124, 4 pp

III UTILISATION OF ADMIXTURES; WATER REDUCERS, AIR ENTRAINERS, ACCELERATORS, RETARDERS AND POLYMERS

III.A Mechanisms; admixture chemical ↔ cement interaction

H. Uchikawa, S. Hanehara, D. Sawaki: "Effect of Electrostatic and Steric Repulsive Force of Organic Admixture on the Dispersion of Cement Particles in Fresh Cement Paste", 3iii001, 8 pp

R. Flatt, Y.F. Houst, P. Bowen, H. Hofmann, J. Widmer, U. Sulser, U. Mäder, T.A. Bürge: "Adsorption of Superplasticizers on Model Powders: Temperature Dependence, Effect of Zeta-potential and Role of Chemical Structure", 3iii002, 8 pp

U. Costa, F. Corazza, P. Colombet, V. Fernon, A. Vichet: "Mechanisms of Cement - Admixture Interaction", 3iii003, 12 pp

CEMENTLESS BINDER AND SILICA BRICK BASED ON IT

Stanislav PAVLENKO, SSAMM, Novokuznetsk, Russia
Michail SHMELKOV, SSAMM, Novokuznetsk, Russia

ABSTRACT A cementless binder based on high-calcium ash from brown coals of the Irsha-Borodinsky deposit has been developed by the SSAMM. High-calcium ash was previously ground to the fineness of 4500 to 4800 cm^2/g, and 10 to 15 percent silica fume was introduced into it. Hot water (60 to 80 degrees) was used for mixing. As a result, the binder obtained had a compressive strength of 20 to 35 MPa. Cohesion of the binder was improved by binding free lime (8 to 15%) with microsilica and by more complete hydration of the blended cement binder achieved through grinding and hot water treatment.

KEYWORDS: High-Calcium Ash, Cementless Binder, Ash-Slag-Silica Brick.

INTRODUCTION

The objective of this work was to develop a cementless binder based on high-calcium fly ash from the Abakanskaya thermal power plant and the technology of the production of a silica brick on the basis of this binder using slag sand from the same thermal power plant as an aggregate and silica fume as an admixture. Expensive materials such as lime, sand and cement were not required. Besides, the production of this brick would contribute to the solution of the environmental problem and satisfy the great need of the thermal power plant in concrete and brick. Technology of the production of non-autoclave ash-slag-silica brick, which uses an ash-slag blend as a binder and does not contain any lime or sand, has been developed.
The difficulty is that, so far, state standards for use of high-calcium ashes derived from brown coals of the Kansko-Achinsky deposit in various types of concretes and structural materials have not been developed. There are only specifications 34-70.10898-88 (1988) developed by several institutes.

MATERIALS

Fly ash

The ash from the Abakanskaya thermal power plant is produced by burning powdered brown coals of the Irsha-Borodinsky deposit. It is collected by electric filters and then delivered to landfills by water, binding properties of ash being-lost. Average grading fractions of the ash from all electric filters were taken for the investigation.
Physical properties of ashes from the Kansko-Achinsky deposit are standardised by two indices (1988), i.e., specific surface and residue on sieve No 008. They were determined in accordance with the State Standard 310.02-76 (1976 a) and 310.3-76 (1976 b). The data are given in Table 1.

Table 1 Physical Properties of Fly Ash

Indices	Standards		Data from Investigation
	First Grade	Second Grade	
Specific Surface, no less cm^2/g	2800	2000	2358
Residue on Sieve No 008, no more, %	12	15	7.5

As can be seen from Table 1, the ash is of the second grade due to its specific surface. To improve the ash grade, its physical properties, chemical activity and, consequently, to eliminate

spreading of concrete, the ash should be ground. Chemical analysis of the ash was made in accordance with the state Standard 5382-91 (1991). The data of the analysis are given in Table 2.

Table 2 Chemical Analysis of Ash

Oxides	Contents,%
Silicon dioxide (SiO_2) total	39.45
including SiO_2 free	24.2
Calcium oxide (CaO) total	31.20
including CaO free	8.96
Magnesium oxide (MgO)	6.31
Aluminium oxide (Al_2O_3)	7.11
Ferrous oxide (FeO)	0.87
Ferric oxide (Fe_2O_3)	9.92
Manganese oxide (MnO)	0.18
Sulphur trioxide (SO_3)	0.86
Titanium oxide (TiO_2)	0.9
Sodium oxide (Na_2O)	0.4
Potassium oxide (K_2O)	0.7
Loss on Ignition	1.85

Table 3 gives specifications for high-calcium ashes.

Table 3 Specifications For Ashes

Indices	Standards	
	First Grade	Second Grade
1. Coefficient of Quality (Q) $Q=(CaO+Al_2O_3+MgO)/SiO_2$	1.2	1.0
2. Contents, %		
2.1 Free Calcium oxide, CaO no more	6.0	9.0
2.2 Magnesium oxide, no more	3.0	7.0
2.3 Sulphur trioxide, no more	5.0	5.0
2.4 Loss of Ignition	3.0	5.0

Due to its coefficient of quality (Ignatova, 1990), the ash investigated is of the second grade (1.13) but it has good binding properties (Q>1). The high contents of free silica, free calcium oxide (8.96%) and magnesium (6.31%) increase the binding properties of the ash after its grinding and heat treatment. The ash investigated has a very low sulphur trioxide content (0.85%), and a loss on ignition is negligible (1.85%).

Slag sand

Slag from the Abakanskaya thermal power plant was ground to a sand with a particle size of 0 to 5 mm. Chemical analysis of the slag sand was performed in accordance with the State Standard 26644-85 (1985). The data on chemical analysis are given in Table 4.

The losses of the slag mass on determining the silicate and ferriferous decompositions were 6.38 to 6.7% and 4.46 to 4.6%, respectively. These meet the State Standard, requirements (no more than 8 and 5%) for use in concretes and brick.

Table 4 Chemical Analysis of Slag Sand

Oxides	Quantities,%	
	Standard	In Fact
Silicon dioxide (SiO_2) total	Non-standardised	56.47
including free SiO_2	Non-standardised	15.57
Calcium oxide (CaO) total	Non-standardised	29.92
including free CaO	no more than 1%	-
Magnesium oxide (MgO)	Non-standardised	3.50
Aluminium oxide (Al_2O_3)	Non-standardised	8.16
Ferrous oxide ($FeO+Fe_2O_3$)	Non-standardised	9.63
Manganese oxide (MnO)	Non-standardised	0.17
Phosphorus oxide (P_2O_5)	Non-standardised	0.05
Sulphur trioxide (SO_3)	no more than 3%	0.011
Loss on Ignition	no more than 3%	-

TECHNOLOGY OF THE PRODUCTION OF NON-AUTOCLAVE ASH-SLAG-SILICA BRICK

Mixture Proportions

To determine the optimum mixture proportions for the ash-slag-silica mixture, the following series of tests were carried out:

1. The influence of an ash-to-slag ratio on the strength of the ash concrete was determined (Fig.1). The mixing water had a room temperature (+18 °C). As can be seen from Fig. 1, the a/w = 4:1 gave the best results.

2. The effect of the temperature of mixing water on the strength of the ash concrete was determined (Fig. 2). The best results were obtained with the temperature of mixing water of 60 to 80 °C.

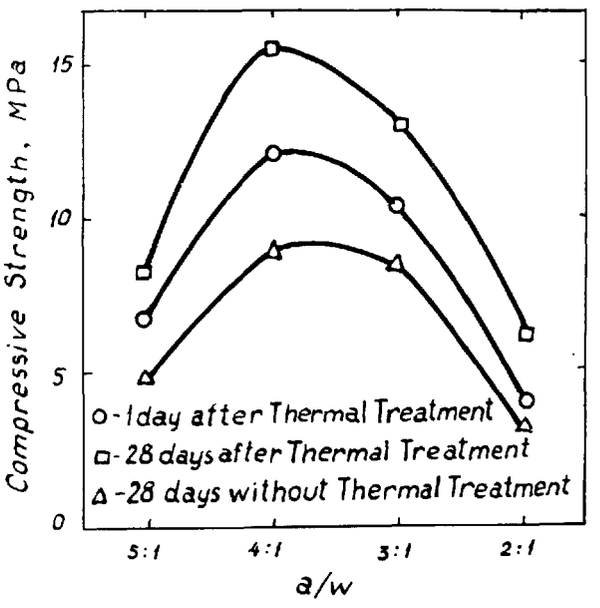

Figure 1 Strength of Ash Concrete Versus Ash-to-Water Ratio

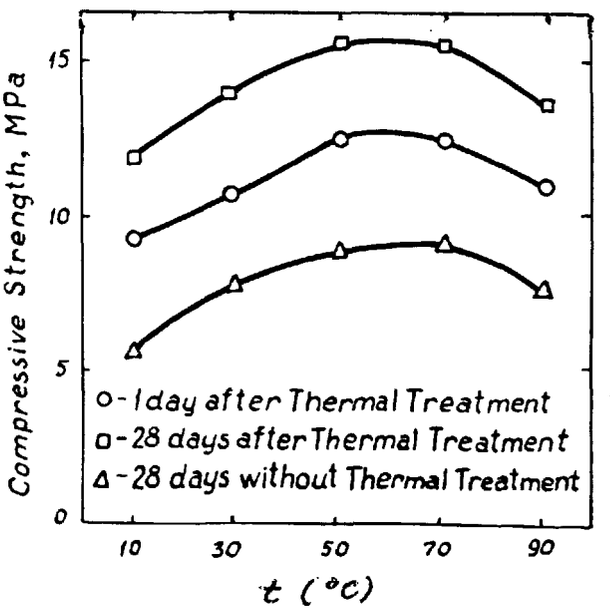

Figure 2 Strength of Ash Concrete Versus Water Temperature

3. The optimum amount of silica fume was determined. Table 5 shows the proportioning of the cementless concrete mixtures.

Table 5 Mixture Proportions and Properties of Fresh Concrete

Ingredients, kg/m^3			Slump, cm	Average Density kg/m^3	Compressive Strength, MPa
Fly Ash	Silica Fume	Water			
1540	- (0%)	420	4.6	1860	12.5
1460	73 (5%)	440	5.0	1885	13.8
1390	139 (10%)	400	4.0	1835	15.6
1237	186 (15%)	390	4.5	1750	15.2
1138	228 (20%)	380	4.8	1670	12.1

As can be seen from Table 5, the best results were obtained with 10 to 15% silica fume. The optimization of mixture proportions and technological parameters such as schedule of curing, temperature of mixing water etc, were performed using the mathematical method of the experimental planning (Voznesensky, 1972). The optimum mixture proportions of the ash-slag-silica mixture for the production of bricks were as follows:
High-Calcium Ash - 650-750 kg
Silica Fume - 70-80 kg
Slag Sand - 1000-1100 kg
Water - 180-210 kg
Superplasticizer - 0.7-2 kg (0.1-0.3% by weight of a binder)

Technology

The high-calcium ash collected by electric filters was ground in ball-tube mills to 4000 cm^2/g fineness which destroyed the glossy cover of the ash and sharply increased the degree of its hydration as well as accelerated the interaction of free calcium oxide and amorphous microsilica. This process was studied previously (Pavlenko, 1994).
The molten slag produced by the thermal power plant was granulated by water and ground to a particle size of 0 to 5 mm in roller crushers. The ash-slag-silica blend was mixed in a fixed-drum concrete mixer using hot water and at 12% humidity of the mixture. Brick was produced by the method of dri-pressing (P=20-25 MPa) and then cured in steam-curing chambers at 95 to 100 °C using a 3+10+3h cycle. The introduction of a high-molecular S-3 superplasticizer into the mixture (0.1 to 0.3% by weight of the ash) significantly improved its workability and increased the strength and durability of the brick. The variation of the free CaO content from 5 to 15% did not significantly affect the strength of the non-autoclave ash - slag- silica brick.

CONCLUSIONS

1. Non-autoclave slag-ash-silica brick having the compressive strength of 12.5 to 15 MPa, the average density of 1900 - 1950 kg/m^3 and frost resistance of 50 to 75 cycle has been produced. The brick meets the requirements of the State Standard 379-79 "Silica brick. Specifications".
2. The production cost of this brick is 35 to 40% lower than that of an ordinary autoclave silica brick.
3. The production of the ash-slag-silica brick directly at the Abakanskaya thermal power plant permitted to solve the problem of utilisation of by-products, to use steam and electrical energy of the plant.

HOLLOW MICROSPHERES OF ASH AND BINDING COMPOSITIONS BASED ON THEM

Marina V. KOUGIYA, Giprocement, Phys.-Chem. Studies Lab., St. Petersburg, Russia
Lev S. FRAIMAN, Giprocement, Process Engineering Lab., St. Petersburg, Russia

ABSTRACT The properties of and possibilities for utilizing hollow microspheres, one of ash dump species formed when burning coals and oil shales, are described.

KEY-WORDS: Waste material utilization, Filler, Fly ash.

INTRODUCTION

Aluminosilicate hollow microspheres of coal ash have been studied by Raask (1968) and Redlov (1974). Kizilstein et al (1987) have investigated ash microspheres from burning coals of Russia. The hollow inorganic microspheres are an ideal filler and are used in many industry branches (Aslanova, 1981; Manual, 1981). Goberis et al (1990) have developed a heat-resistant concrete on a basis of hollow microspheres. Lalov et al (1990) have presented data of obtaining and utilizing hollow microspheres.

EXPERIMENTAL

For studies use was made of specimens of ash products obtained at the heat-and-power station of the town of Angarsk (the Irkutsk region) where the mix of coals of coalfields of the East Siberia was burnt. Ash products generated at the heat-and-power station of the town of Narva when burning oil shales in boiler furnaces have been also studied. Averaged samples of ash products and the most light weight fraction representing a foam material floating at the surface of the ash pond were taken. The chemical composition of samples is given in Table 1, their physical characteristics are listed in Table 2. Microscopic and X-ray phase analyses of all four samples have been performed. The X-ray phase analyses were done with the help of ДРОН-3 device. The grain size distribution of the samples was determined using the Analyzette-22 Sedimentograph of FritschGmbH.

Table 1 Chemical composition of hollow microspheres fractions and averaged samples of coal and oil shale ashes.

№	Specimen	Oxide content, %							
		LOI	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	K_2O
1	Averaged coal ash sample	3.61	52.92	23.82	6.66	8.92	2.19	3.19	1.77
2	Fraction of hollow microspheres of coal ash	0.95	58.50	30.93	3.65	3.15	2.03	-	1.80
3	Averaged oil shale ash sample	-	28.06	7.64	5.00	48.85	3.74	3.74	2.61
4	Fraction of hollow microspheres of oil shale ash	42.26	2.08	0.75	0.23	52.54	0.19	1.18	0.37

Table 2 Physical characteristics of hollow microspheres and averaged samples of coal and oil shale ashes.

№	Specimen	Apparent density, kg/cu.m	Bulk density, kg/cu.m	Glass density, kg/cu.m	Microsphere wall thickness μm	Melting temperature	
						t_B, °C	t_C, °C
1	Averaged coal ash sample	2600	960	2500	-	1320	1400
2	Fraction of hollow microspheres of coal ash	540	290	2500	5 - 10	1400	1480
3	Averaged oil shale ash sample	2450	800	2650	-	1330	1360
4	Fraction of hollow microspheres of oil shale ash	485	232	-	0 - 5	-	-

Besides, binding compositions with the use of fractions of hollow microspheres of coal ashes were prepared. For test specimen preparation the components were ground up to the proper size, but for fraction of hollow microspheres, weighed out in necessary ratios and mixed. On addition of the required water amount and mixing the paste prepared was placed into the forms and compacted. After one-day storing under moist conditions the paste was unmolded, and the further specimen hardening ran under several conditions simulating the actual conditions of lining works, wherever possible. Table 3 gives the results for specimens which were hardened under the following conditions: 7 days of air-moist storing and 3 days at temperature of 110°C. The microspheres ratio was 10%. The specimens were prepared with the use of alumina and portland cement. Crashed chamotte brick in fraction of 3-7 mm and 1-3 mm served as a coarse aggregate.

Table 3 Strength and thermal characteristics of binding compositions.

Specimen No	Specimen Name	Compressive strength, MPa			Shrinkage after heating at 1200°C	Refractoriness, °C
		upon 7 days of air-moist storing + 3 days at 110°C	on heating at			
			800°C	1200°C		
1	Fraction of hollow microspheres: alumina cement=0.32	39.6	35.4	50.3	1.2	above 1500
2	Fraction of hollow microspheres: portland cement=0.24	22.6	15.0	30.7	1.2	above 1300

DISCUSSION OF RESULTS

Peculiarity of the chemical composition and properties of hollow microspheres was noted. For specimens of coal ash this was in the higher SiO_2 and Al_2O_3 content and in the lower Fe_2O_3 and CaO content for hollow microspheres fractions as compared with the averaged sample which was an indication of the aluminosilicate composition of material. The same was observed by Raask (1968), Redlov (1974) and Kizilstein et al (1987). The microscope study showed that rounded particles were made up of glass the refraction index of which is characteristics of glasses of mullite composition, a fine-grained crystallization of mullite was found at the surface. The rounded particles floated up in immersion oils which pointed to the low density and was supported by experiments (Table 2). The main element of the diffraction pattern for the specimen of hollow microspheres of coal ashes was a wide diffuse maximum over an interval of angles $2\Theta = 8 - 20^0$ characteristic of highly disordered and glassy phases. The diffraction peaks of mullite and quartz were noted at its descending branch. The main size of globules for the hollow microsphere fraction was 80-120 μm. The enrichment of samples with a fraction of hollow microspheres improved their refractoriness.

For the specimens of the oil shale ash the CaO and LOI content of the hollow microspheres fractions increased, and the SiO_2, Al_2O_3 and Fe_2O_3 contents decreased. The composition of this fraction is closely approximating the calcium carbonate composition. This was confirmed by the X-ray analysis. At the X-ray diffraction photograph there were seen reflexes of calcite. The specimen heating up to 950^0C provided support to the fact that the bulk of it was made up of calcite since at the X-ray diffraction photograph of the product after the thermal treatment there detected only CaO reflections and SiO_2 relics. The main size of globules was 150-250 μm. In this case the suggestion has been made that in consequence of the high CaO content of gas because of its high concentration in the initial fuel (the Baltic oil shales) the secondary calcium carbonate was deposited in large quantities on the thin aluminosilicate walls of the microspheres. The carbonate composition of the hollow oil shale ash microspheres was observed by Goberis (1990). This kind of material was characterized by the least density. The strength of the specimens was moderate.

From the data of Table 3 it may be concluded that binding compositions with microspheres on alumina and portland cement met the requirements of the Russian standards for heat-resistant concretes both in regard to the initial strength and upon heating at 800^0C, in respect of shrinkage at 1200^0C and refractoriness.

CONCLUSIONS

The studies conducted showed the peculiarity of hollow microspheres fractions in comparison with averaged samples of ash products as to chemical and mineral compositions, density characteristics and thermal properties. Ligtweight heat-resistant concretes for lining works can be prepared with the use of hollow microspheres. The hollow microspheres of the oil shale ash are promising as adsorbents or as filling material forming the heat-insulating layer and so on.

THE POZZOLANIC REACTION OF FLY ASH IN CONNECTION WITH DIFFERENT TYPES OF CEMENT

Reiner HÄRDTL, Heidelberger Zement AG, Department for Research, Development and Consulting in Leimen, Germany

ABSTRACT Investigations into the chemico-mineral structure of hardened cement paste in mortars were conducted to examine the pozzolanic reaction of fly ash. Especially in this context, the interaction between fly ash and different types of cement (portland-slag cement, blast-furnace slag cement, portland-limestone cement) was investigated. The beginning and development of the fly ash reaction depend, to an extreme extent, on the content of clinker and slag in the cement. The higher the portion of slag in the cement, the slower the fly ash reaction. The main reason is the lower $Ca(OH)_2$ content available. In the initial phase of the pozzolanic reaction the strength contribution of the fly ash is higher than later on, resulting from the bond of the fly ash particles into the matrix of the hardened cement paste.

Key-words: Fly ash, Reactivity, Blastfurnace slag, Calcium hydroxide, CSH

INTRODUCTION

Concrete is not any longer only a simple three-component-system consisting of cement, water and aggregates. The choice of different cement types and various additives makes concrete a complex multi-component-system. From a technological and economic point of view, the selective use of mineral additives (e.g. slag, fly ash, limestone filler) during the production of cement and concrete allows a very flexible control of concrete properties depending on the specific application.

The trend in the past few years has been to combine the application of these materials. However, it is necessary to gather as much information as possible about the reaction mechanisms of the individual components in order to take optimum advantage of the effects of such combinations. Here, the interaction between the components is of special interest. For basic technological research, it is of minor importance whether the substances are applied as additives blended to cement or as additions to the concrete. This report takes a closer look at the development of the pozzolanic reaction of fly ash in connection with different types of cement (portland-slag cement, blast-furnace slag cement, portland-limestone cement).

EXAMINATIONS

Table 1 gives a general survey of the cements examined. For comparison, portland cements were also included in the investigations. All cements meet the requirements of ENV 197-1. A low-calcium fly ash conforming to EN 450 "Fly ash for concrete" and produced in a dry-bottom furnace was used (its properties are equivalent to ASTM Class F fly ash).This type of fly ash has a specific surface of 379 m^2/kg retaining 16.5 wt.% residue after passing a 40-µm-sieve. The amount of glass is approximately 80 wt.% and the loss of ignition is 1.7 wt.%.

First, standard mortars according to EN 196-1:1994 were produced. 20 wt.% of the cement was replaced by the same weight of fly ash (f/c=0.25). The ratio w/(c+f) = 0.60 was held constant for all mixes.

The mortars were demoulded after 24 hours and the samples were stored in water (20°C) until testing. For more detailed information on the composition of the substances used and the conduction of tests are documented in preceding publications (Härdtl, 1992 and Härdtl,1995).

$Ca(OH)_2$ CONSUMPTION DURING POZZOLANIC REACTION

Apart from its physical and rheological effect, fly ash is mainly applied in concrete for its pozzolanic reaction. The main feature of the pozzolanic reaction of fly ash is the consumption of $Ca(OH)_2$. $Ca(OH)_2$ is formed during the hydration of the portland cement clinker. In the course of the pozzolanic reaction, the glassy siliceous parts of the fly ash react with the free $Ca(OH)_2$ in the hardened cement paste, in the course of which new CSH phases are formed. The amount of $Ca(OH)_2$ in the hardened cement paste is reduced by this reaction. The amount of $Ca(OH)_2$ thus consumed is a significant parameter for describing the development of pozzolanic fly ash reaction.

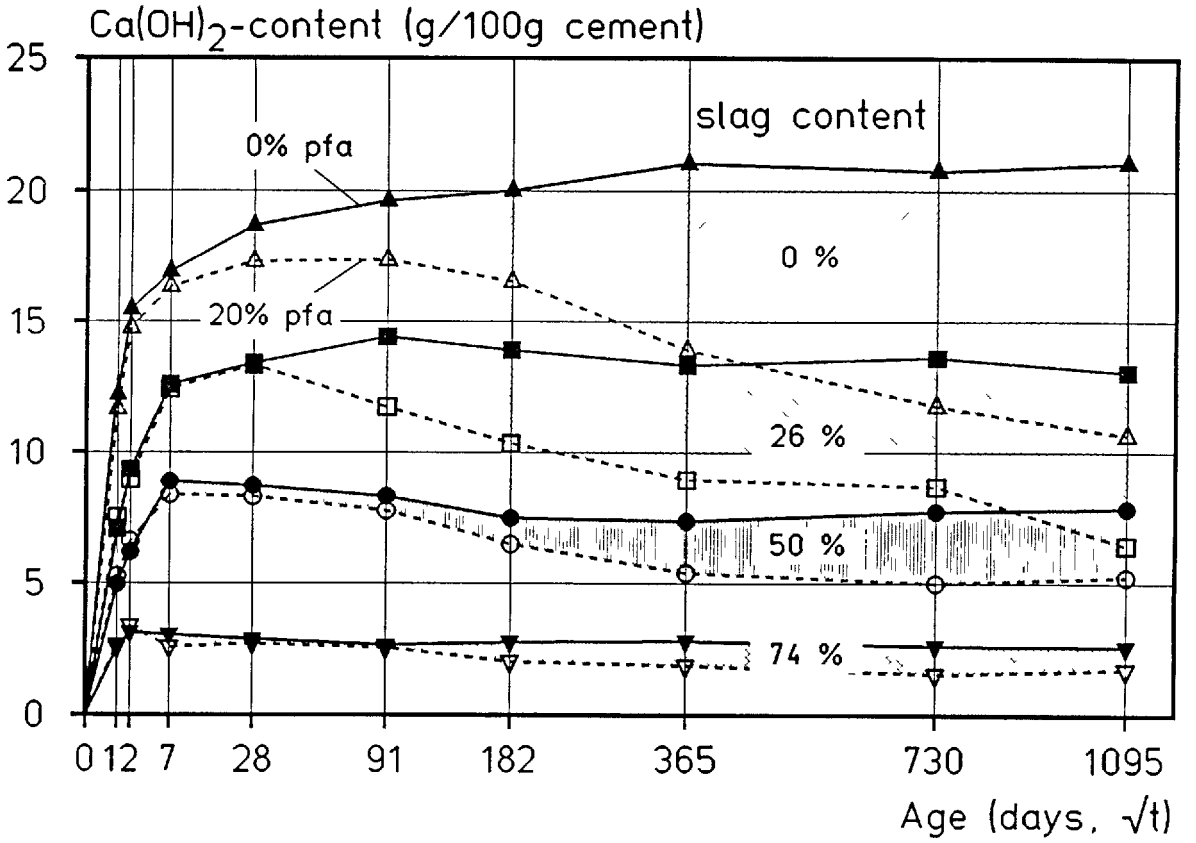

Figure 1 Development of $Ca(OH)_2$ content in mixes with different types of cement (mortar, w/(c+f) = 0.60; water curing)

In Figure 1 the development of the $Ca(OH)_2$ content for mixtures with 20 wt.% fly ash is contrasted to the corresponding reference mixes without fly ash. The amount of free $Ca(OH)_2$ in hardened cement paste was analysed by means of the Franke extraction method. This procedure not only determines CaO in free $Ca(OH)_2$, but also CaO components of other hydration products are extracted (Ramachandran, 1979; Shebl et al.,1983). By correcting the measured values by a factor of 0.85, these results correlated well to those obtained by thermogavimetrical analysis for all mixes.

The hatched areas show the reduction in $Ca(OH)_2$ by means of the fly ash reaction. Portland cement (C2) shows a slight consumption of $Ca(OH)_2$ at the early age of 7 days, indicating the start of the pozzolanic reaction. Increasing the amount of slag in cements causes the initial consumption of $Ca(OH)_2$ and thus the start of the fly ash reaction to occur at a later stage. Portland-slag cement (C5) containing 25 wt.% slag shows this reaction after 7 to 28 days, blast-furnace slag cement containing 50 wt.% slag (C6) after 28 to 91 days. After this period the $Ca(OH)_2$ consumption increases together with the reaction time, but it is still lower than the consumption occurring in portland cement. Given an extremely large amount of slag (C8), the cement generally reveals only a minor pozzolanic reaction of the fly ash.

The reduced pozzolanic reaction in connection with blast-furnace slag cements is caused by several factors. On the one hand, the alkalinity of the pore solution is slightly lower so that the glassy parts of the fly ash react at a lower rate. Furthermore, there is much less $Ca(OH)_2$ available as a reaction partner, which seems to be the main factor. Finally, the diffusion-related processes required for the pozzolanic reaction are hindered by the pore structure which becomes even denser as the amount of slag is increased.

This also explains why a pozzolanic fly ash reaction takes place at a slightly higher rate when the water-cement ratio is higher than when it is lower.

DEGREE OF FLY ASH REACTION

The determination of the cement hydration degree is relatively easy, e.g. by means of the amount of chemically bound water or by means of other parameters. With regard to fly ashes it is not possible to draw direct conclusions from the amount of $Ca(OH)_2$ consumed by pozzolanic reaction in proportion to the amount of reacted fly ash. Here, the amount of $Ca(OH)_2$ usually transformed during the development of the complete fly ash reaction must be known. Theoretical considerations based on simplified conditions for the chemico-mineral composition of the fly ash and the stoichiometry of the reaction products lead to the assumption that 1.0 g of completely reacted fly ash binds about 0.83 $Ca(OH)_2$ (Helmuth, 1987). Selected tests carried out so far show results of between 0.5 and 0.7 $Ca(OH)_2$ per 1 g reacted fly ash (Dalziel and Gutteridge 1986, Mohan and Taylor 1981, Taylor et al. 1985).

These investigations revealed a tendency of fly ash to bind a slightly decreasing amount of lime as the reaction time proceeded. There have also been, however, observations to the opposite effect (Dalziel and Gutteridge 1986). For the purpose of simplification, a constant lime consumption of 0.65 g $Ca(OH)_2$ per 1 g reacted fly ash is assumed independent of the reaction time, a ratio established during a number of experiments by the author. Yet these tests have only been carried out on the basis of portland cements so far.

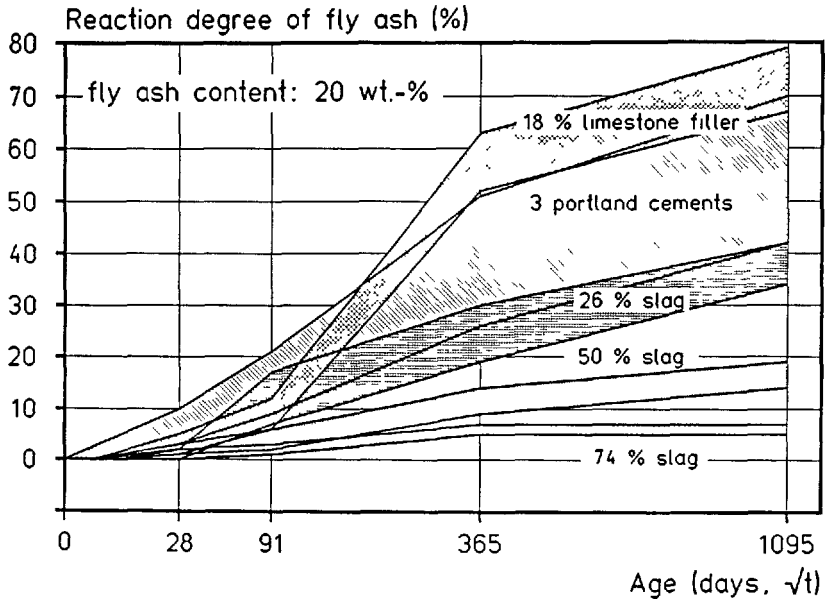

Figure 2 Degree of fly ash reaction dependent on the type of cement

Figure 2 shows the development of the degrees of fly ash reaction thus determined. With portland cements the degree of fly ash reaction at the age of 28 days is hardly more than 10 %, after 91 days slightly over 20%. Given sufficient moisture, the fly ash continues to react as the age of the cements increases. Consequently, the percentage of reacted fly ash after three years is between 40 and 70 %.

The increase in the amount of slag leads to a related decrease in values. Even after an extremely long reaction time, the degree of reaction is lower here. The degree of fly ash reaction with the extremely high slag portion of 74 wt.% is below 10%. In this context, it has to be verified if the assumed lime consumption of 0.65 $Ca(OH)_2$ per 1.0 g reacted fly ash can also be transferred to cements containing slag. Tests for orientation purposes indicate that the lime consumption of the fly ash is lower in these cements, leading to an effectively higher degree of fly ash reaction, as shown here. Further research is necessary to clarify the behaviour in slag cements.

The highest degree of reaction was observed for portland-limestone cement, where a degree of nearly 80% was reached after three years. In order to be able to generalise this result, further examinations have to be carried out. This can be an indication, however, that despite the reduced amount of clinker in the cement, enough $Ca(OH)_2$ is available for a complete pozzolanic fly ash reaction to take place.

CSH PHASES PRODUCED BY POZZOLANIC REACTION

As in the case of cement hydration, the pozzolanic reaction generates gel-like calcium silicate hydrate phases, abbreviated as 'CSH phases'. They are the main mineral phases in the hardened cement paste which determine the application properties of a concrete.

The absolute quantity of CSH phases, their stoichiometry and morphology influence, to a large extent, the pore system and the bond between the separate phases. In this publication, all hydrate phases that are not found in the hardened cement paste in form of unhydrated cement, unreacted fly ash, or $Ca(OH)_2$ are designated as CSH phases.

The investigations below were conducted to find out to what extent the pozzolanic degree of fly ash reaction has influence on the formation of CSH phases. For this purpose, the amount of CSH phases formed during the pozzolanic reaction was examined in relation to the specific amount of reacted fly ash (Fig. 3).

The amount of CSH phases formed during the pozzolanic fly ash reaction increases as the amount of reacted fly ash increases. This can be especially well observed in portland cements and portland-limestone cement. Considering the range of results there is an approximately linear relation between these two variables independent of the amount of fly ash. This can also be observed in blast-furnace slag cements, yet due to the reduced degrees of the fly ash reaction only in the lower region.

Proceeding from the above mentioned assumptions, about 1.5 g (± 0.5 g) CSH phases are formed per 1.0 g of reacted fly ash on average. On the basis of the same calculation methods, the hydration of portland cement leads to the formation of about 1.0 g CSH phases per gram hydrated cement. This deviation can be accounted to the fact that during hydration the lime and silicate portions are contained in the clinker, and only water needs to be integrated, forming not only CSH phases, but also $Ca(OH)_2$. During the pozzolanic reaction only the silicate portion is derived from the reacting substance (from the fly ash). The lime and water portion both come from $Ca(OH)_2$. This is why, relating to the amount of reacting fly ash, more CSH phases are formed here than during the cement hydration. This is also one reason why blast-furnace slag cements have a higher amount of CSH than portland cements, given the same hydration degree or age.

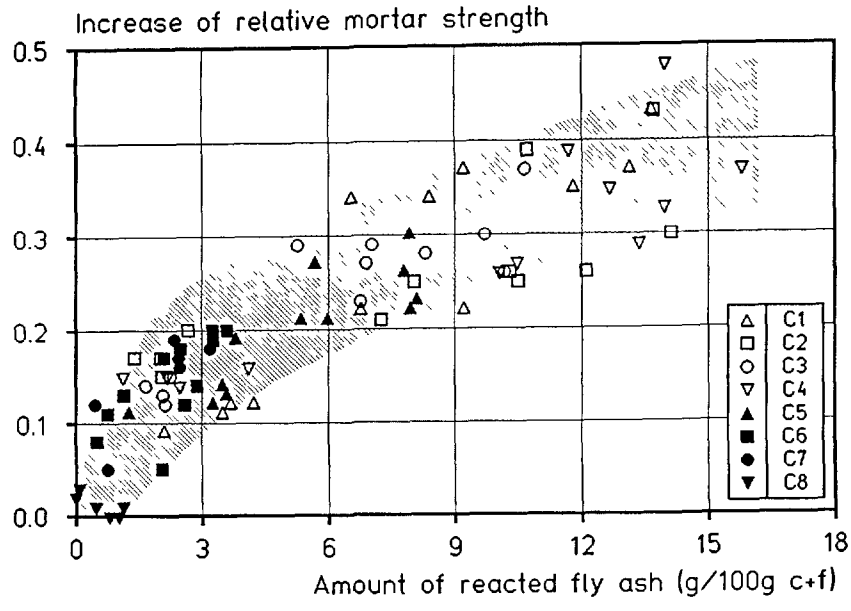

Figure 3 CSH phases formed during pozzolanic reaction dependent on the amount of reacted fly ash (mortar, w/(c+f) = 0.60, f/c = 0.25 and 0.50)

RELATIONSHIP BETWEEN DEGREE OF FLY ASH REACTION AND STRENGTH

The method of determining the course of fly ash reaction described in this report demands much work and effort. Thus, this procedure is not suitable as a standard test method for ordinary laboratories. The procedure usually used is the testing of the compressive strength. As to the cement hydration, a direct linear relationship between hydration degree and compressive strength is generally recognised and accepted. In order to determine fly ash efficiency, an activity index (relative strength) is usually established as a quotient of a mortar or concrete containing fly ash and a corresponding reference mixture without fly ash. Based on the well-known interaction in cements, it is assumed that the development of the fly ash reaction is reflected proportionally in strength development. It has not been verified so far, however, if this relation can be transferred to fly ashes as well.

The relationship between pozzolanic reaction and improvement in strength is shown in Figure 4. Here, the strength contribution of the fly ash is characterised by the increase of relative compressive strength. This contribution is derived from the difference to the relative compressive strength at the age of 28 days. At this stage, relative strength is not significantly influenced by the cement hydration any longer.

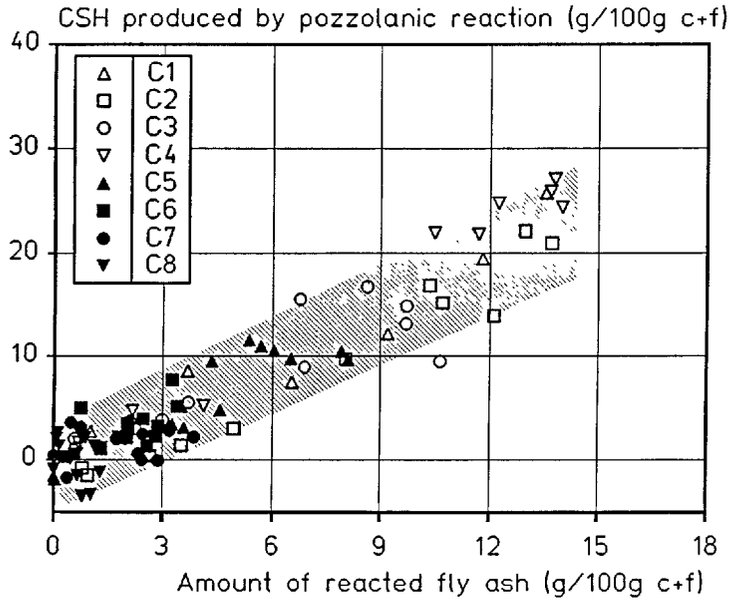

Figure 4 Increase of relative compressive strength dependent on the amount of reacted fly ash

The increase of relative compressive strength of mortar grows as the amount of reacted fly ash increases. This growth is somewhat more striking with lesser degrees of fly ash reaction than with higher amounts of reacted fly ash. This means, however, that the initial chemical reaction of the fly ash contributes more to the strength than the pozzolanic reaction at a higher age.

The fact that a higher strength contribution can be observed despite the smaller amounts of reacted fly ash can probably be accounted to the formation of a shell of CSH phases on the surface of the fly ash particles quite soon after the pozzolanic reaction has started (Pietersen 1993, Rodger and Groves 1988). This reaction shell generates a bond between fly ash particles and surrounding hardened cement paste. This integration of the fly ash into the matrix at this early stage causes a somewhat higher strength increase than the formation of additional CSH phases in the hardened cement paste itself.

CONCLUSIONS

Information gained about the variations of the chemico-mineral structure of hardened cement paste contained in cement mortars made it possible to observe the development of the pozzolanic reaction of fly ash in combination with different types of cement. Here, especially cements containing different amounts of slag were taken into consideration.

In the first 28 days the degree of the fly ash reaction is very low, that is below 10 %. The main pozzolanic reaction of the fly ash occurs only in an advanced age of the cement. A further progression can be expected far beyond the time period examined (3 years). As the amount of slag grows, the course of the fly ash reaction decreases. This can mainly be accounted to the fact that less $Ca(OH)_2$, the reaction partner for the fly ash, is available. Deviations in the alkalinity of the pore solution are of minor importance.

The investigations carried out did not produce any evidence on whether the hydration of slag is influenced by the application of fly ash or not.

The amount of CSH phases, most important in terms of strength and pore structure, increases proportionally to the degree of pozzolanic reaction. On the other hand, a non-linear relationship between improvement of strength and pozzolanic reaction was observed. In the first stage of the pozzolanic reaction, the fly ash particles are integrated into the hardened cement paste by reaction products on their surface. As a result, strength is improved to a larger extent at early ages than later on, when pozzolanic reaction only leads, so to speak, to 'pore filling' with a lesser gain in strength.

FLY-ASH BLENDED CEMENT ACTIVATED BY A STRONG BASE

Amnon KATZ, National Building Research Institute, Department of Civil Engineering, Technion, Haifa 32000, Israel

ABSTRACT The activation mechanism of fly ash in a basic environment was studied as a means to improve the reactivity of fly ash in blended cements. Experimental program included activation of fly ash by a strong base (NaOH) at different concentrations and water to fly ash ratio. Testing program included compressive tests, Scanning Electron Microscopy (SEM) and Mercury Intrusion Porosimetry (MIP).

Key-words: Fly ash, Alkali, Activation, Scanning Electron Microscopy

INTRODUCTION

Coal fly-ash from power plant is widely used as an additive or as partial replacement of cement (Helmuth, 1987) and its pozzolanic properties are known since Roman time. An increased interest in the activation of fly-ash came up lately (Roy and Silsbee, 1992, Larosa et al., 1992a,b and Brough et al., 1995). The motivation to these works came mainly from disposal of nuclear waste which is frequently of high alkalinity. Solidification of this waste in a cementitious material is one of the proposed methods for disposal of this material.

Studies done lately on the solidification of Low Level Waste (LLW) showed a high degree of reactivity of the fly-ash particles induced by the high alkalinity of the waste solution (Katz et al., 1995, 1996), when the process was performed at a relatively high water to binder (cementitious materials) ratio of 1.0 and at a curing temperature of approximately 90°C. Such temperature may develop adiabatically when solidifying wastes in large volumes (Lokken, 1991) though higher temperatures were used by others (Jiang et al., 1993) for better activation of fly-ash in the process.

In the studies by Larosa et al. (1992a,b) and Katz et al. (1995) a development of various types of zeolites and a relatively high compressive strength was reported when cement blended with flay ash had activated by a strong base at relatively low temperature (up to 90°C). The activating solution was a pure NaOH solution or a high alkalinity LLW solution. water glass ($Na_2O{\cdot}SiO_2$) is also common in works dealing with activation of blast furnace slag (Wang and Scrivener, 1995).

In this study the activation mechanism of fly-ash by highly alkaline solution was investigated, mainly the development of mechanical properties under different conditions and the microstructure of these systems.

EXPERIMENTAL

Fly-ash from local power plant was tested. The mineral composition of the fly-ash is presented in Table 1. All batches were of 250 gr. of d.i. water. The amount of NaOH and fly-ash was determined according to the experimental program shown in Table 2. Mixing was performed using a small Hobart mixer at a low speed. The mix was cast into a 25x25x25mm mold, sealed and stored in an oven in 90°C. After the mix had hardened sufficiently (usually one day) it was demolded and stored back in the oven in a sealed container, where a high humidity was maintained constantly.

Table 1: Mineral composition of the fly-ash (% by weight)

SiO_2	Al_2O_3	Fe_2O_3	CaO	TiO_2	K_2O	P_2O_5
55.1	26.1	9.3	3.1	1.3	1.9	0.4

The testing program was divided into two parts: *i.* studying the effect of NaOH concentration, *ii.* studying the effect of water/fly-ash (w/FA) ratio.

Four Sodium hydroxide concentrations were tested in the first part of the experimental program: 1M, 2M, 3M and 4M. Water to fly-ash ratio was 0.8 for all the mixes. Compressive strength was tested at the age of 7 days after curing at 90°C. According to the results it was decided to test the effect of water/fly-ash ratio on the 4M solution only. Three water/fly-ash ratios were tested: 0.4, 0.8 and 10. Due to technical difficulties the latter was tested in 80°C only. Summary of the testing program can be found in Table 2.

The fractured surface of all the specimens was observed by a Scanning Electron Microscope (SEM). Pore size distribution and compressive strength was tested for the low water/fly-ash mixes (0.4 and 0.8).

Table 2: Summary of the testing program.

water/FA ratio	NaOH concentration	Water (gr.)	NaOH (gr.)	Fly-ash (gr.)	Curing temperature (°C)
10.0	4M	10	4	1	80
0.8	4M	250	40	312	90
	3M	250	30	312	90
	2M	250	20	312	90
	1M	250	10	312	90
0.4	4M	250	40	325	90

RESULTS AND DISCUSSION

Effect of solution concentration

The effect of solution concentration on the compressive strength at the age of 7 days can be seen in Fig. 1. It can be seen that for the same water to fly-ash ratio and curing temperature the compressive strength increases as the concentration of the solution increases. The mixes of 4M exhibited good mechanical properties and a compressive strength of 6.1 MPa was obtained after 7 days, close to the compressive strength of a cement paste at the same age and water/ cement ratio. For the low concentration of 1M the specimens could hardly be demolded after 4 days of curing at 90°C and the compressive strength after 7 days was very low (0.2 MPa).

Other solution concentrations of 2M and 3M exhibited compressive strength values in between the 1M and 4M mixes (see Fig. 1) which indicates that the degree of reactivity increases as the NaOH concentration increases. Interesting to note that lowering the water/fly-ash ratio did not revealed a higher compressive strength as expected, but a lower compressive strength has observed as shown in Fig. 1 (6.1 and 4.9 MPa for the high and low w/FA ratios, respectively). A different microstructure was also seen by the SEM as will be discussed in the following.

Various modes of activation of the fly-ash were seen under the microscope. Fly-ash particles, as received from the power plant, seem round and smooth or appear as a cluster of particles. Fly-ash particles reacted by 1M solution of NaOH look similar to the unreacted fly-ash and only slight etching could be seen on the surface of the fly-ash reacted with 2M solution. An extensive etching was seen on the surface of the fly-ash reacted by 3M solution (see Fig. 2) and

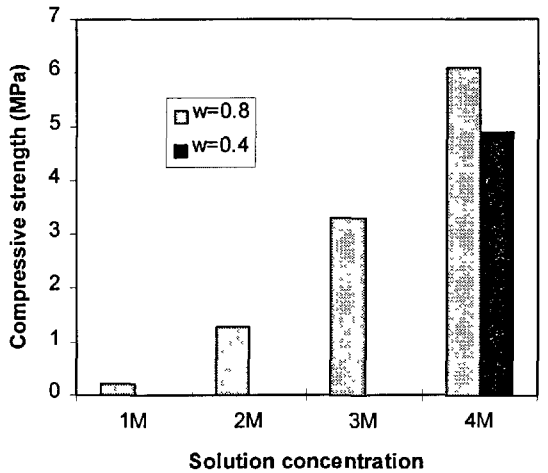

Figure 3: Effect of solution concentration on the compressive strength at the age of 7 days.

it seems as if most of the glassy phase was dissolved from the fly-ash, exposing the skeleton of the mullite crystals.

The fly-ash reacted by the 4M solution exhibited a different microstructure as seen in Fig. 3. A continuous matrix is seen between the particles and the material seems to be less porous. Higher magnifications showed needle like crystals between the fly-ash particles in the 3M system while cubic like crystals were seen on the surface of the particles of the 4M solution and non of needle like crystals were seen. Similar phenomenon of changes in the hydration products as the concentration of the activating solution increases was seen in the work of Katz et al. (1995) where Na-P1 (gismondine) was favored at one concentration and sodalite was favored at higher concentrations.

Effect of water/FA ratio

In addition to the change in the compressive strength discussed earlier, the microstructure as observed under the SEM was different when the water/fly-ash was lowered from 0.8 to 0.4 or increased to 10 as can be seen in Figs. 4 and 5, respectively. When lowering the water/fly-ash ratio the fly-ash particles seems to be separated form each other and no continuous matrix could be seen. The material over the particles of the w/FA of 0.8 seems more cubic while that of the 0.4 seems more plate like.

At the high w/FA ratio a different microstructure was formed as can be seen in Fig. 5. It seems as if an extensive etching took place, removing part of the glassy phase form the surface, while at the same time, sedimentation of another phase on the surface took place.

MIP tests on the samples showed that a threshold exist at a relatively large pore size in the range of 1-10μm. Changes in the solution concentration or w/FA ratio took place in this range accompanied by a reduction in the total porosity when lowering the w/FA ratio.

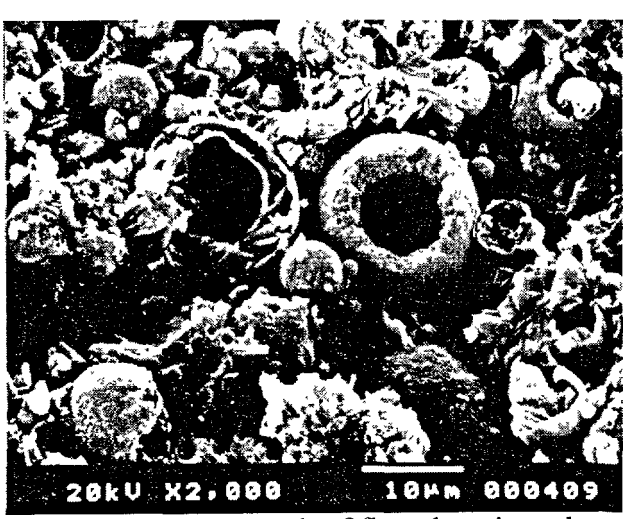

Figure 2: Micrograph of fly-ash activated by 3M of NaOH, water/fly-ash=0.8.

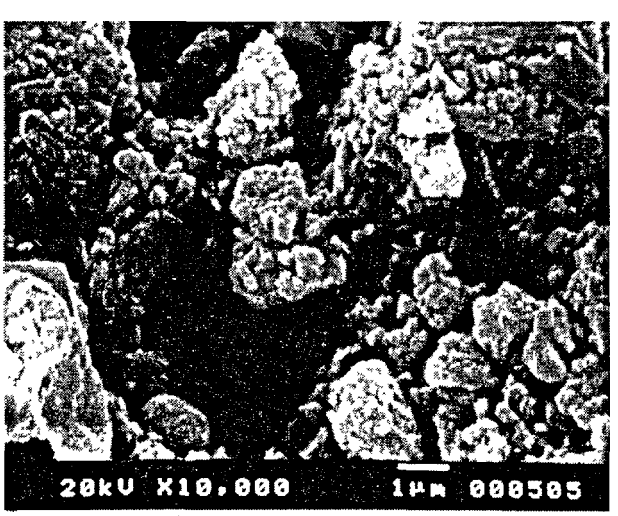

Figure 3: Micrograph of fly-ash activated by 4M of NaOH, water/fly-ash=0.8.

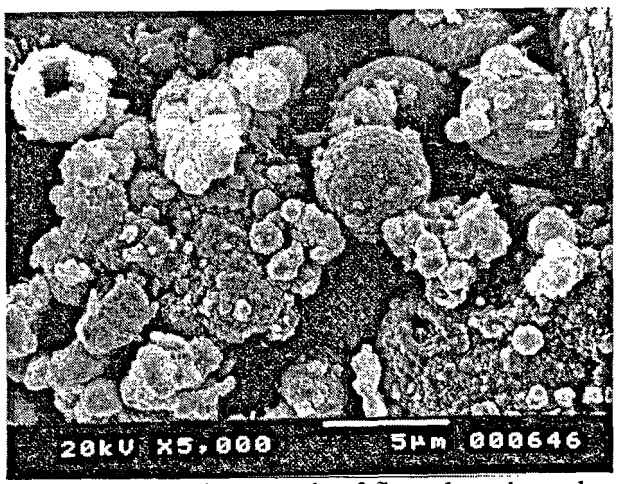

Figure 4: Micrograph of fly-ash activated by 4M of NaOH, water/fly-ash=0.4.

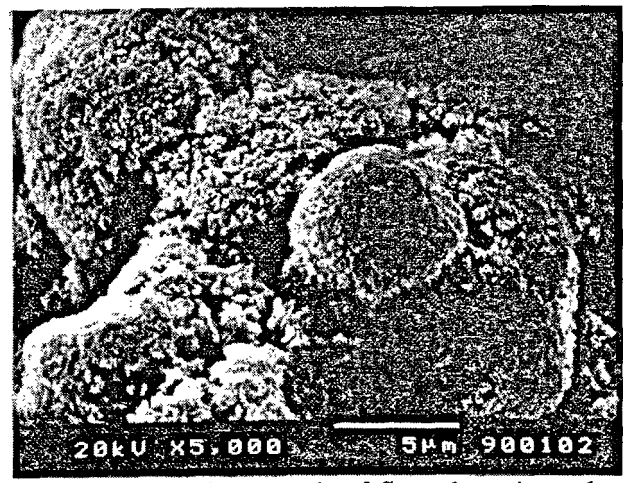

Figure 5: Micrograph of fly-ash activated by 4M of NaOH, water/fly-ash=10.

CONCLUSION

1. Increasing the concentration of the activating solution (NaOH) increased the compressive strength developed in a solution-fly ash system, indicating a higher reactivity. However, lowering the water/fly-ash ratio from 0.8 to 0.4 lowered the compressive strength.
2. SEM observations showed different microstructure of the systems affected by solution concentration and w/FA ratio. The differences were mainly in the etching manner and the type of crystals formed.
3. MIP showed that the changes in the pore size was mainly in the range of 1-10µm for the various systems.

MODELLING THE OVERALL RATE OF REACTION IN LIME-FLY ASH SYSTEMS

Said JALALI, Universidade do Minho, Civil Engineering Department, Guimarães, Portugal

ABSTRACT Fly ash is the most widely used artificial pozzolan in concrete. It reacts with calcium hydroxide forming cementitious materials which enhance the strength and durability of concrete. A theoretical model for predicting the overall rate of reaction in lime-fly ash systems, based on nucleation, diffusional growth and the overlap of the growth centres is presented. Results from Differential Scanning Calorimetry (DSC) tests are used to evaluate the validity of the model.

Key-words: Modelling, Fly Ash, Lime, Diffusion

INTRODUCTION

Fly ash reacts with lime at ordinary temperatures in the presence of water, and cementitious materials are produced that are similar to the hydration products of ordinary Portland cement. Reactions which take place on the surface of fly ash are complex because of the complex chemical composition of fly ash particles. Furthermore, one reaction product may well influence the formation of others. Taking the individual reactions into account would make a model complex and thus impractical to use. Therefore, the cementitious materials are regarded as a single product and the aim is to estimate the overall rate of its formation.

Based on principles of nucleation and growth the mechanism of formation of cementitious material can be described in terms of the formation of small stable regions of product, i.e. nuclei. The growth of one centre, considered here to be diffusion controlled, will continue until it is limited by running into a nearby growing centre, i.e. impingement occurs. This type of impingement will physically inhibit the growth of the new phase in one direction (Christian, 1975). The process will continue until all directions of growth are blocked to all centres. A 'soft' type of impingement can also be visualised when gradual exhaustion of available reactants or when gradual 'soft' impingement of interweaving fibrils occur (Double, 1978). Hence, the proposed model considers nucleation and growth of the centres and their subsequent impingement on each other.

It can be seen that the morphology of the new phase plays an important role in the overall rate of the formation of cementitious materials. Scanning and transmission electron microscope provide direct means for observation of the morphology of the new phases. It is noticed (Jalali, 1991) that the new phase covers first the surface of the fly ash particles, which can be approximated to a two dimensional nucleation and growth. The second stage, which occurs apparently after the surface of fly ash particles are covered with the new phase, is the formation and growth of needle-like fibrous material. This can be assumed to be either one dimensional growth, if the radius of the needle is considered constant, or three dimensional if the radius of the fibres is also increased with time.

A conceptual model based on progressive nucleation is suggested and the equations governing the one, two and three dimensional diffusional growth of nuclei and their impingement are derived in the next section. A general form of these equations is suggested to predict the overall rate of reaction in lime-fly ash systems.

DERIVATION OF EQUATIONS FOR OVERALL RATE OF REACTION

The conceptual model, that will be published elsewhere, is based on the analysis of images obtained by SEM and TEM (Jalali, 1991). It is suggested that the cementitious material is formed by progressive nucleation, similar to what happens with the formation and growth of the new branches and twigs of trees. In such cases nuclei are formed gradually and growth occurs continuously.

Assuming a diffusional controlled growth process, the size of a transformed region in any direction is proportional to square root of time. Considering an isotropic growth rate constant k the area covered will have a circular shape with a radius proportional to $k(t)^{1/2}$. If a centre is formed at time u ($0<u<t$), at time t it will have an age equal to (t-u) and the radius will be given by $k(t-u)^{1/2}$. The contribution of one such centre to the total area will be $\pi r^2 = \pi k^2(t-u)$.

According to the general nucleation equation (Abyaneh, 1981 and Bewick, 1962), for progressive nucleation at preferred sites, when the product of A't remains small during the process, the number of nuclei (N) at a time t is given by

$$N = N_o A' t \qquad [1]$$

where N_o is the total sites available per unit area and A' is the rate of conversion of one site into a nucleus. In time δu the number of nuclei formed are $\delta N = N_o A' \delta u$. Thus the growth area in the absence of impingement, i.e. extended area (S_{ext}), of new material formed in the time interval between 0 and t will be

$$S_{ext} = \int \pi k^2 (t-u) A' N_o \delta u \qquad [2]$$

Considering that N_o, A' and k are constants, the integration yields

$$S_{ext} = (\tfrac{1}{2}) \pi k^2 N_o t^2 \qquad [3]$$

The actual area of growing centres (S) using Avrami's postulate (Avrami, 1939, 1940 and 1941) for overlap will be

$$S = S_{max} [1 - \exp[- (\tfrac{1}{2}) \pi k^2 N_o t^2] \qquad [4]$$

where S_{max} is the total area the new material can cover. For one dimensional growth, when A' is small, it can be shown that the volume of the new phase will be

$$V = V_{max} \{ 1 - \exp [- (\tfrac{2}{3}) \pi r^2 k' N' t^{3/2}] \} \qquad [5]$$

where N' is the number of sites available, r is the radius of the needle like material and k' is the growth constant for one dimensional growth. Likewise for three dimensional growth Eq 5 will become

$$V = V_{max} \{ 1 - \exp [- (\tfrac{2}{5}) \pi k"^3 N" t^{5/2}] \} \qquad [6]$$

It is suggested that Eqs 4-6 be represented in the following general form

$$V = V_{max} \{ 1 - \exp [- K t^n] \} \quad [7]$$

Eq 7 is suggested for prediction of the overall rate of reaction in lime-fly ash systems. Parameter K is the rate constant for growth and its temperature dependence can be shown by an Arrhenius equation. Parameter n, on the other hand, indicates the dominant morphology of the products. A value of 3/2 indicates a one dimensional growth while a value of 2 indicates a two dimensional growth and 5/2 indicates a three dimensional growth.

EVALUATION OF THE MODEL PROPOSED

In order to evaluate the validity of the proposed model Differential Scanning Calorimetry (DSC) tests were performed on lime fly ash mixtures at constant temperatures of 65, 75, 85 and 95 °C. In this mode, DSC tests provide the rate of heat flow while the reaction takes place, the integration of which indicates the degree of reaction at any given time.

The integral of the rate of heat flows obtained from DSC tests were used for evaluating the validity of Eq 7. A non-linear regression analysis was used to estimate the values of parameters K and n. Table 1 shows the values for these parameters as well as the sum of squared errors (SSE) estimated. Figs 1-4 show the DSC test results and the predicted values using Eq 7. It can be seen that the proposed model explains well the data.

Table 1. Parameters obtained using Eq 9 and DSC test results

Temperature (°C)	V_{max}	K	n	SSE
65	17.11	2.325E-6	2.328	0.35
75	18.73	4.348E-7	2.588	0.28
85	35.63	1.862E-6	2.548	3.65
95	33.96	8.228E-6	2.466	22.9

CONCLUSIONS

It can concluded that the proposed model explains the data from the DSC tests well and hence is able to predict the amount of reaction products at any given time. It can also be seen that the values of n are close to 2.5, which indicates that the nucleation and growth in the present case are predominantly three dimensional. Furthermore, it is seen that, except for the 65 °C, parameter K increases with temperature, which confirms the assumption of the diffusional growth of the reaction products.

ABSTRACT
Aiming to verify fly-ash addition influence on Portland cement paste, mortar and concrete, tests for compressive and tensile strength, porosity, chemical analysis of paste pore extracted solution, DTA and TGA were conducted at ages 7, 28, 63, 91 or 182 days. Proposed methods for accessing porosity by squeezing specimens at high compressive stress level and by acetone impregnation were compared with ASTM and Hg porosity with promising results. Good porosity/strength correlations were found, and a previous strength/time mathematical model always verified for cement without fly-ash was adjusted with success, in order to establish limit strengths or strength reserves for infinite ages, related with potential compaction and durability.

Key-words: Fly ash, modified cement, porosity, strength development, modelling

INTRODUCTION
This paper is a product of a co-operation program between IPT - Technological Research Institute (Brazil) and IMS Institute for Materials of Serbia (Yugoslavia) concerning laboratorial works developed in São Paulo, Brazil. The study was done with collaboration of Portland Cement Brazilian Association (ABCP) and participation of São Paulo University Polytechnic School (EPUSP).

The objective was to study Portland cement with fly ash addition. This subject is important for both countries since fly ash addition is an available and interesting common way to save energy in the manufacturing of cement for construction. Time evolution of paste, mortar and concrete properties was considered an adequate first approach of this subject, and Brazilian materials which characteristics are supposed acceptable for representing typical world-wide materials were used. The study is divided in characterisation of employed materials, study on paste, mortar and concrete, and conclusions.

CHARACTERISATION OF EMPLOYED MATERIALS
Brazilian Portland Cement CP V - ARI type (High Early Strength), with Standard strength 50.7 MPa at 28 days and Blaine Fineness 495 m^2/kg, was used. Pozzolan was a ground fly ash from Tubarão Coal Power Station, Santa Catarina State, Brazil, with Blaine Fineness 445 m^2/kg and Pozzolanicity Index with Lime 7.0 MPa. River sand with maximum grain size 2.4 mm was used as fine aggregate and crushed granite 9.5 mm maximum grain size as coarse. Potable water of São Paulo supply was used.

STUDY ON PASTE, MORTAR AND CONCRETE
Paste Study
Pastes with 0.6 water/binder weight proportion, pozzolan/binder amounts 0%, 35% and 55% were cured in moist conditions and standard ordinary temperature. Study was performed at 7, 28, 63, 91 and 182 days ages on cylinders 20 mm diameter x 40 mm height (compressive strength, acetone impregnation, modified ASTM voids by boiling water method, DTA, TGA) or 40 mm

diameter 80 mm height (squeezing for accessing porosity and pore solution extraction), or on prisms 40 x 40 x 160 mm^3 (ISO flexural tensile strength). Paste cylinders were cut with the shape of 4 or 5 coins (height 5 mm) for acetone impregnation.

Squeezing of specimens was performed with a special device in which specimen is highly confined, keeping a constant diameter, to compressive stress level 477 MPa, sufficient to destroy paste structure, deform specimen proportionally to voids volume, and expel pore water, collected for chemical analysis (OH^- by titration and Na^+, Ca^{2+} and K^+ by atomic absorption). Figs 1 to 5 present relations between paste's properties.

Acetone impregnation was made for interrupting hydration and obtaining a voids index by the following procedure: 1) Transversal diamond cutting obtaining at least 4 coins, 2) obtaining the Natural Weight of the coins, 3) vacuum (640+5 mmHg) of 1 hour for drying partially the water, 4) first immersion of the coins in acetone inside a closed glass, making vacuum during 10 min, 5) with the coins inside acetone, left liquid in atmospheric pressure 20 min (first impregnation), 6) submission of the coins to 2 hours of vacuum for drying the acetone and water, 7) obtaining "Weight after first Immersion and Vacuum", 8) second immersion of coins in acetone inside a closed glass, vacuum during 10 min, 9) with the coins inside acetone, left liquid in atmospheric pressure 20 min (2nd. impregnation), 10) obtaining "Weight after second Immersion" (W_s), 11) submission of the coins to 30 min of vacuum for drying the acetone, 12) obtaining "weight of the dry sample" (W_d), 13) immersion of coins in acetone for storage with interrupted hydration.

Calculations were made following the formula:

$$V_i = (100(W_s - W_d)/D_a)/(W_d/D_d) \quad [1]$$

where: V_i = Voids Index by acetone impregnation (%); D_a = Density of acetone (g/cm^3); D_d = ASTM bulk specific gravity of corresponding dry specimen (g/cm^3).

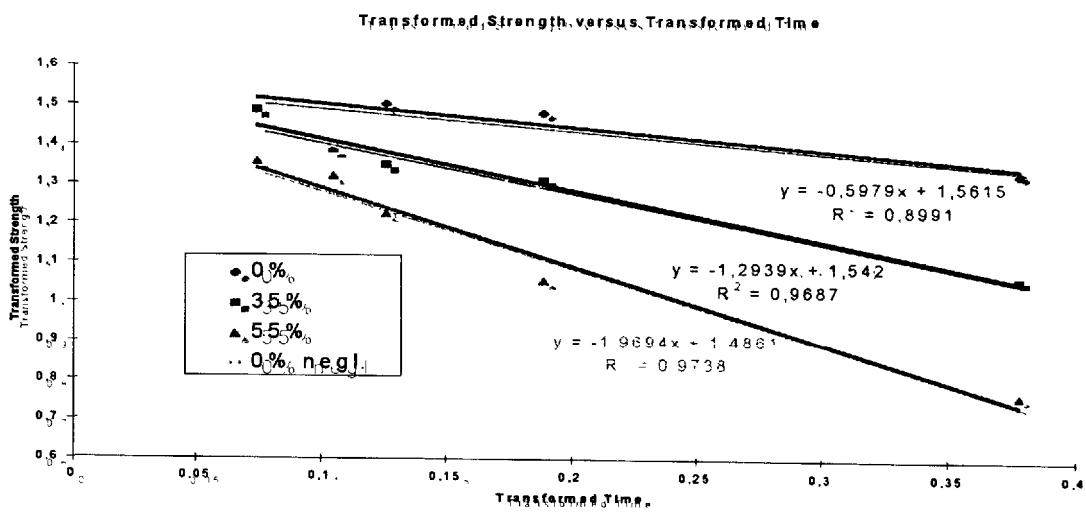

Figure 1: Transformed Strength versus Transformed Time for pastes. Acceptable linearisations, as proposed in a previous work (Tango, 1992) was obtained using $\log f_t$ instead of f_t (compressive strength in MPa) and $t^{-0,5}$ instead of t (time in days).

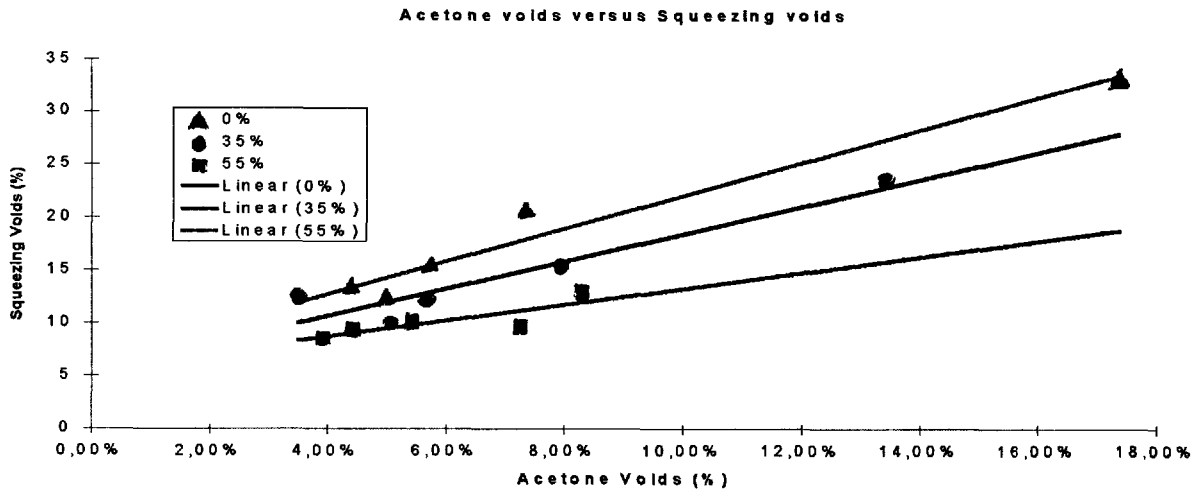

Figure 2. Acetone Voids versus Squeezing Voids for Pastes. There is influence of pozzolan amount in the correlation between these properties. Probably the method for acetone voids would be improved varying the time of acetone impregnation to obtain, for instance, constant weight and not using constant time.

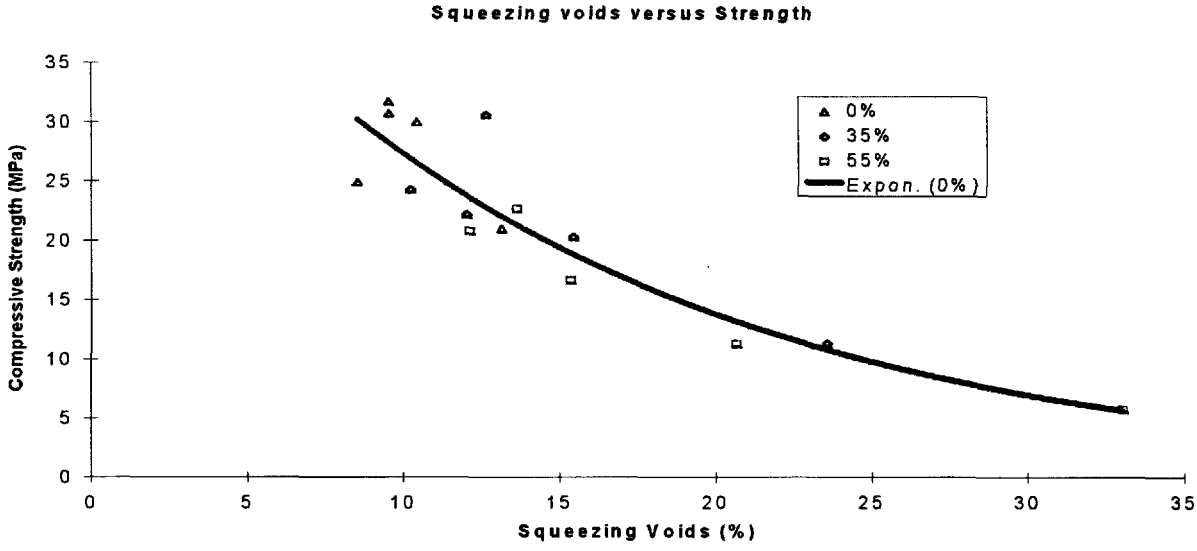

Figure 3. Squeezing Voids versus Strength for Pastes. A good correlation indicates Squeezing Voids as a good index for Compressive Strength, practically without influence of different pozzolan amounts.

Study on Mortar

Pozzolan amounts 0 %, 35 %, 55 % and fine aggregate/binder 1,00:2,00; 1,00:3,00; 1,00:4,00 were used. Ages were 7, 28, 63 (except for flexural strength test), 91 and 182 (except for flexural strength test) days. Thus, the number of different conditions for the mortar study was 45, except for flexural tests, which were 27. The amount or water of each mix proportion of mortar was determined by tentative, aiming a Brazilian flow table consistency ABNT MB-1 index of 210+10mm. Prismatic 40mm x 40mm x 160mm specimens were poured following ISO EN 196/1 for flexural strength and cylindrical specimens 50 mm (diameter) x 100 mm (height) were poured following Brazilian Standard ABNT MB-1 (modified from standard sand fixed aggregate

test to variable fine aggregate) for the rest of the tests. All specimens were cured following ABNT MB-1 procedure (submerged specimens in water with controlled pH and temperature).

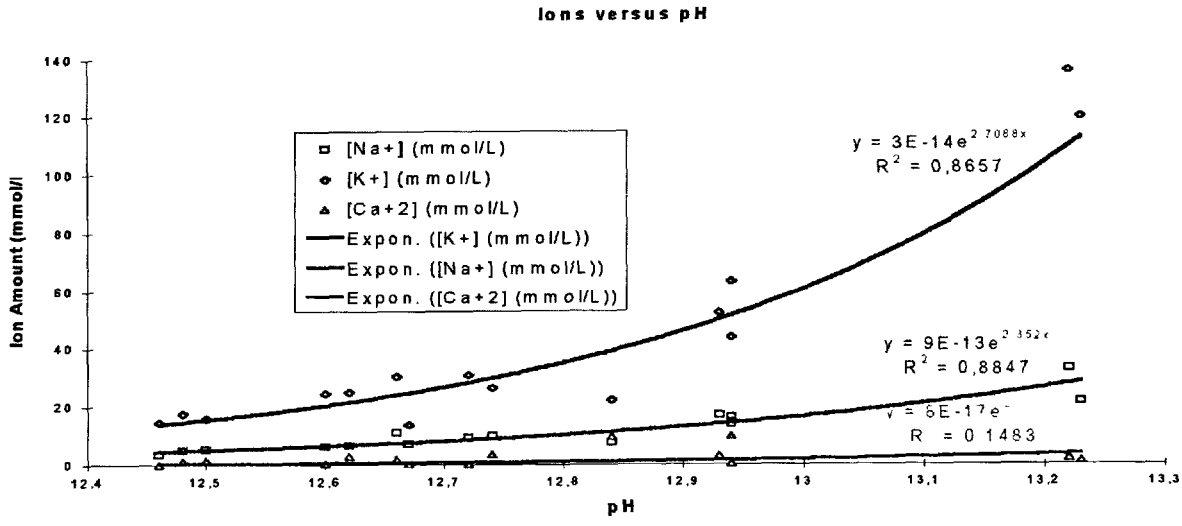

Figure 4. Ion molar concentrations versus pH_i for Pastes. Good correlation's between ions amounts (except Ca) and pH. The main influence on pH is not Calcium, but Potassium and Sodium ions.

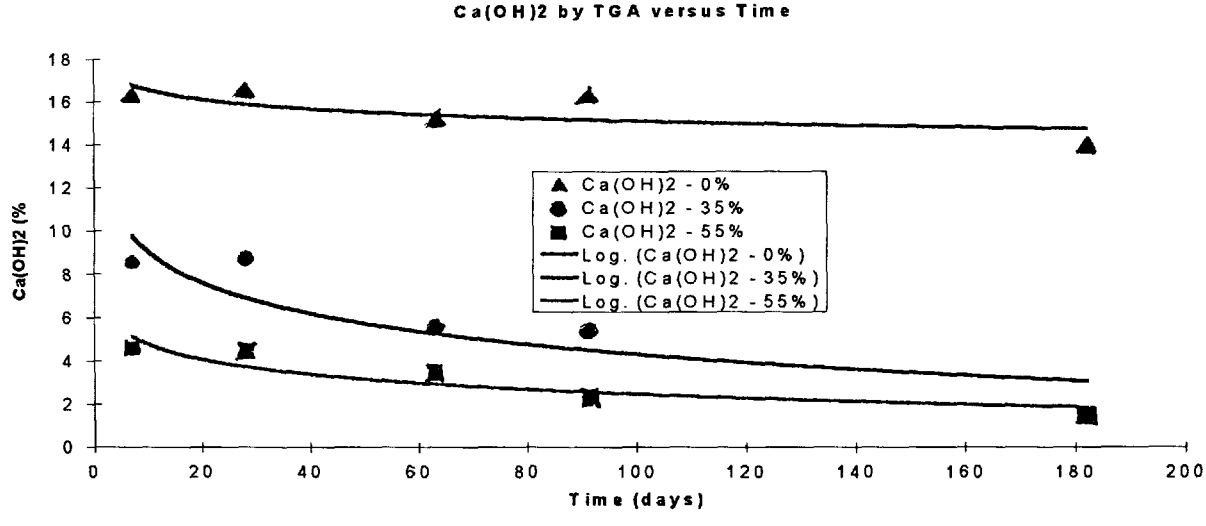

Figure 5. $Ca(0H)_2$ versus Time for Pastes. Expected behavior. Decreasing for cements with pozzolan and very slowly decreasing or practically constant for cements without it. According qualitatively to determinations of Ca Ion in pore solution extract.

Compressive strength tests were conducted following ABNT MB-1 procedure. The cylinders for hydration interruption and porosity by acetone impregnation were submitted to the same procedures and calculations for mortar disks as done for paste coins. The ASTM water boiling method C 642 originally used for concrete was adapted for mortars by the use of a balance with sufficient precision (0,5g division) for weighing parts of cylindrical 5-cm diameter x 10-cm height specimens. Only one specimen for each condition was tested.

A previous mathematical model (Tango, 1992) was aimed to adjust between the *dependent* variable *compressive strength* and *independent* variables *water/binder ratio* and *time*. The proposed model was:

$$f_c = A / (B^x \cdot D^{x/\sqrt{j}} \cdot E^{1/\sqrt{j}}) \quad [2]$$

where; f_c = compressive strength, x = water/binder ratio by weight, j = age of curing and A, B, D and E are constants. Eq 2 can be transformed to the linear form:

$$\text{Log } f_c = \log A - x \cdot \text{Log } B - (x/\sqrt{j}) \cdot \text{Log } D - (1/\sqrt{j}) \cdot \text{Log } E \quad [3]$$

which can be adjusted by linear correlation's algorithm available in microcomputer program Excel for Windows 95, using, as dependent variable, log f_c, and as independent variables, x, $x/\sqrt{j}$ and $1/\sqrt{j}$. Table 1 shows the values for the obtained constants and determination coefficients for each condition of this study on mortars.

Table 1. Compressive Strength Mathematical Model Constants for Mortars*

Pozzolan amount (%)	Log A	Log B	Log D	Log E	R^2**

35	2.2734	1.0089	0.7661	0.5851	0.9961
55	2.2743	1.1093	1.0784	0.8582	0.9862

*Strength in MPa, Water/Binder Ratio adimensional (weight/weight), Age in days in Eqs 2 or 3.
**R^2 = determination coefficient.

Figs 6 to 8 show relations between mortar properties with comments.

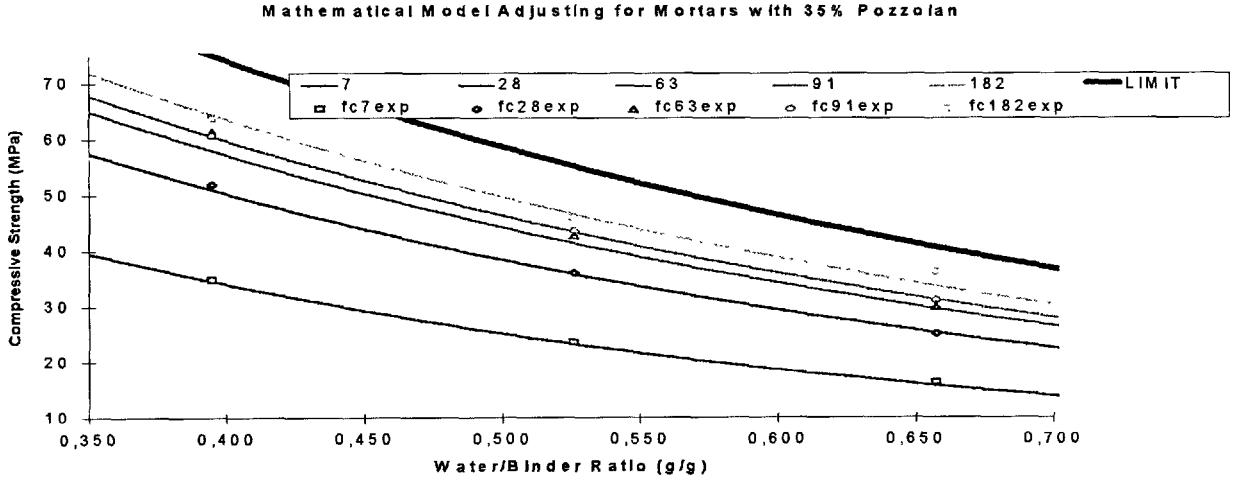

Figure 6. Generalization of Abrams' Law in the Time .for Mortars with 35% pozzolan binder. LIMIT means the theoretical curve inferred for infinite age. The mathematical model and its inferred constants are shown in Table 1 and Eq 3.

Study on Concrete

Concrete was made with a low maximum size coarse aggregate and can be classified as a plastic (not fluid) grout with Abrams' Slump Cone Consistency Index between (100±20) mm. Cement/Binder weight proportions 1/3.5; 1/5.0 and 1/6.5 were used. Dry mortar/Dry Concrete weight proportions were optimized for each pozzolan proportion by tentative method and maintained constant for the three Cement/Binder proportions. One-way cylindrical molds using PVC commercial tubes with polyethylene sheets fixed to the bottoms with a strong adhesive tape with 75 mm in nominal diameter and approximately 150 mm in height were used for the main part of the specimens. Exclusively for age 91 days, pozzolan proportion 0% (all aggregate proportions), and pozzolan proportion 35% (only 1/3.5 binder/aggregate proportion), eight

available metallic molds of the same nominal dimensions were used. Two specimens by condition of test were poured, remained 24 h in laboratory conditions covered by polyethylene sheets before demolding, and were cured in moist chamber (relative humidity over 95% and temperature between 24 $\pm$ 2 ^{0}C), following Brazilian ABNT method MB-2. Compressive tests were made following Brazilian ABNT method MB-3. Cylinders for hydration interruption and acetone voids index were submitted to the same procedures and calculations for paste, except for using slices of 10 mm instead of 5 mm. There was a procedure modification for 91 ages: the specimens were submerged into acetone at date of test for interrupting hydration, and after a few days as laboratory's schedule permitted, the test was normally carried. ASTM water boiling method C 642 was used in the remaining parts of specimens cut for acetone impregnation. As it was done for mortars, constants for eqs. 2 and 3 were inferred. See Table 2 and Figs. 9 and 10 with main results.

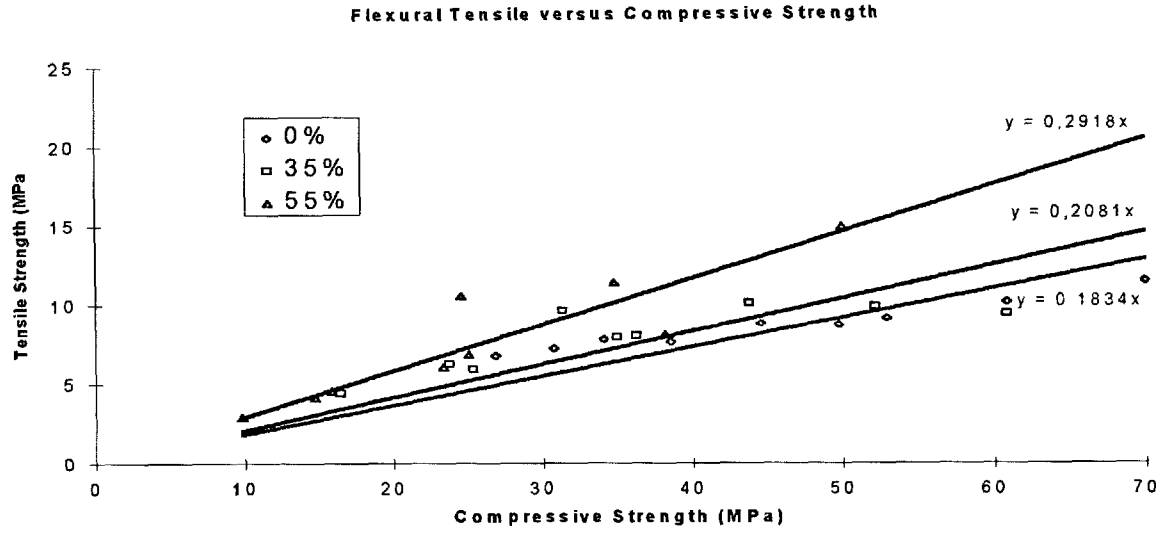

Figure 7. Tensile Strength versus Compressive Strength for Mortars. There is influence of pozzolan amount in the ratio between tensile and compressive strength. Binders with higher amounts of pozzolan reach higher ratios.

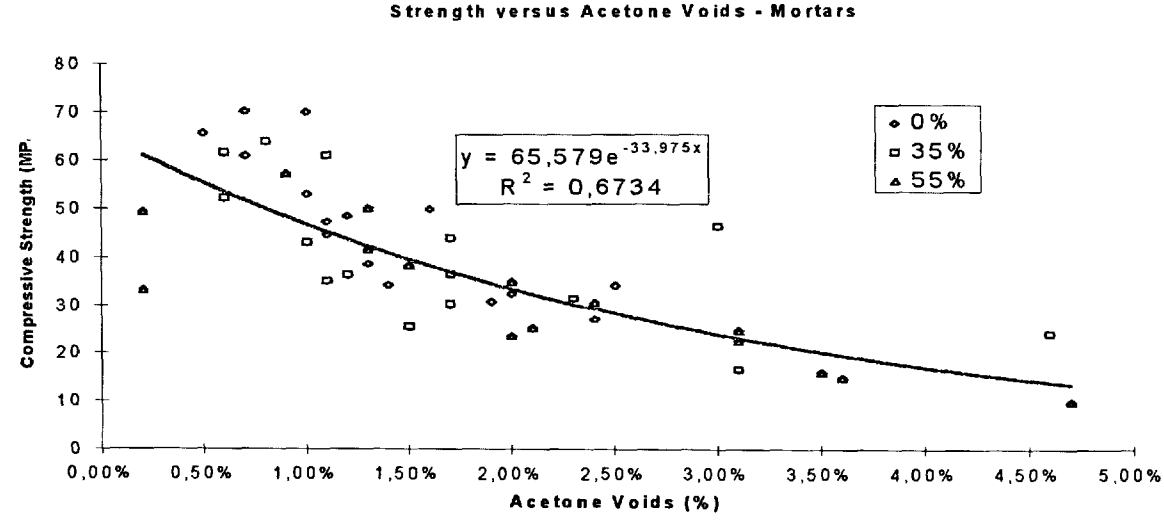

Figure 8. Compressive Strength versus Acetone Voids for Mortars. A not so good but the best correlation coefficient between strength and a voids index for mortars in this experience is shown in this figure, confirming paste's results. There is a very little influence of pozzolan amount but it appears negligible compared to the dispersion.

Table 2. Compressive Strength Mathematical Model Constants for Concretes*

Pozzolan amount (%)	Log A	Log B	Log D	Log E	R^2**
0	2.372	0.0915	1.1997	0.3484	0.9842
35	1.9947	0.6014	0.5752	0.5004	0.8814
55	2.0583	0.4646	0.7088	1.0136	0.9669

*Strength in MPa, Water/Binder Ratio adimensional (weight/weight), Age in days in Eqs 2 or 3.
**R^2 = determination coefficient.

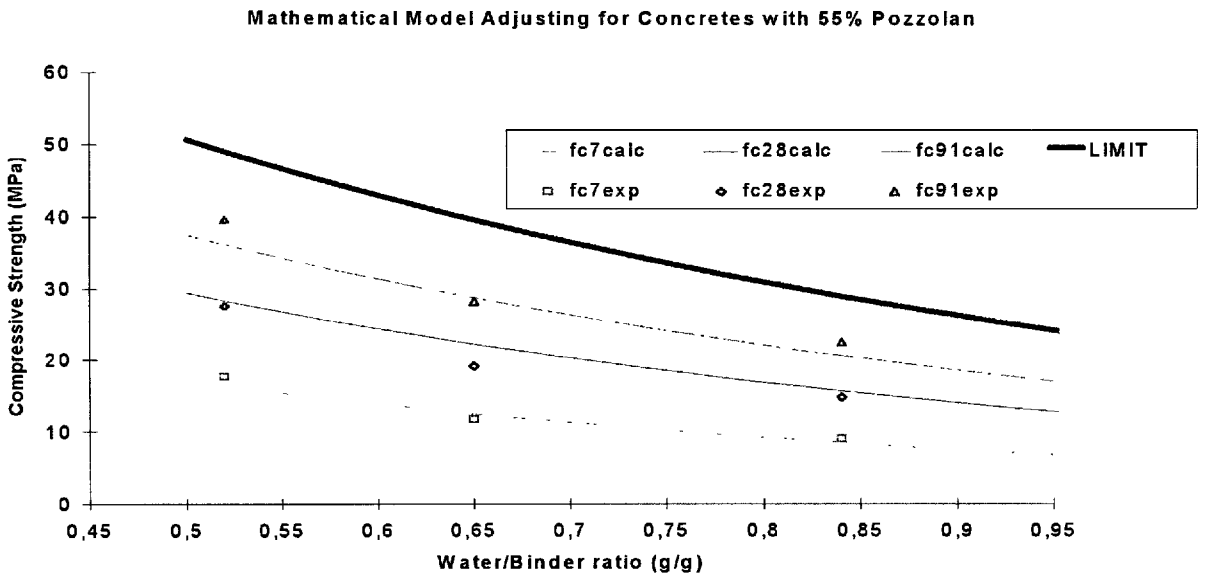

Figure 9. Generalization of Abrams' Law in the Time for Concretes with 55% pozzolan binder. LIMIT means the theoretical curve inferred for infinite age. Constants for the model are found in Table 2.

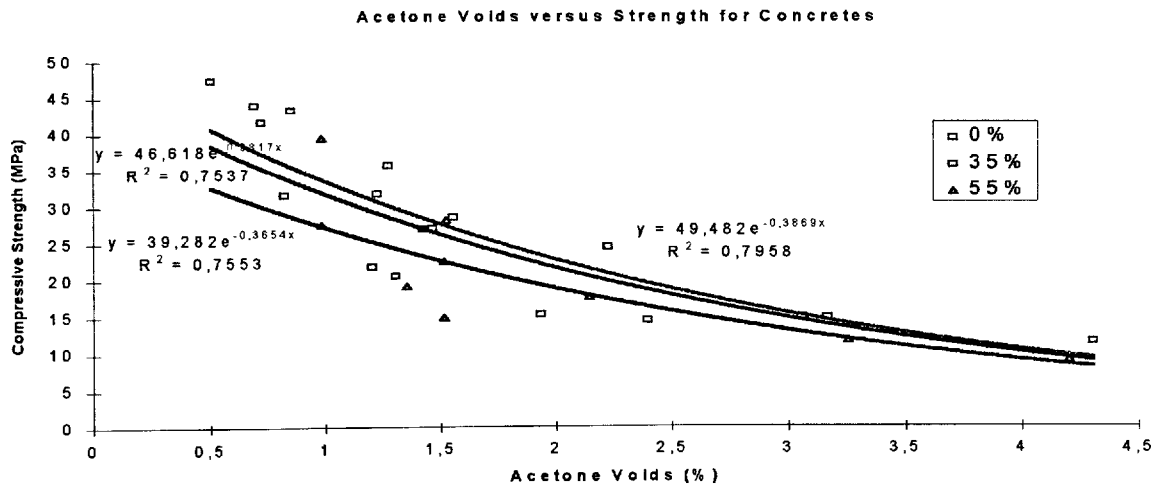

Figure 10. Compressive Strength versus Acetone Voids for Concretes. Relatively good determination coefficients and small influence of pozzolan amount on the curves' position.

CONCLUSIONS

In general, paste, mortar and concrete results agree qualitatively concerning compressive strength and porosity: binders without pozzolan reached higher strengths and higher speeds of developing strengths, with the inverted effect concerning decreasing of total pore volume.

Mathematical models for compressive strength as a function of water/binder ratio and age, proposed by equations 2 and 3, seems to be adequate for concrete or mortar both without or with pozzolan. These model permits to predict, for 35% and 55% pozzolan amounts in the binder, a theoretical limit strength, related to potential durability, which is lower than the corresponding for 0% pozzolan binder, for low water/binder ratios, and higher than the same, for high water/binder ratios. Keeping constant water/binder ratios, it is reasonably possible to linearize the curve strength versus time transforming the coordinates strength as logarithm of strength and age as inverse of age square root. This was confirmed for pastes, mortars and concretes with or without pozzolan.

For concretes, mortars and pastes it was found that acetone voids index is a good indicator of strength and probably of aggressive agents' accessibility. For pastes, the best index for compressive strength was squeezing voids, followed by acetone voids, modified ASTM boiling method voids and Hg intrusion voids. The ASTM method for voids index and its adaptations for mortars and pastes seem not to be adequate for low curing ages, probably because of leaching effect on soluble hydration products. Hg intrusion voids did not present good correlation with pastes' strength. Maybe paste structure destruction would have happened. It is recommended to research correlations between strength and various diameters cumulative pore volume amounts. It seems that acetone method gives better porosity indexes than ASTM and Hg intrusion total porosity, in spite of non realistic voids estimated percentages. The method for acetone impregnation must be improved reviewing the impregnation times in order to assure more complete pores' impregnation by acetone, giving more realistic estimated voids percentages. The method for squeezing voids in pastes must be improved by reviewing the maximum load in order to assure a more complete destruction of different binders' paste structures. Probably a not constant but a variable final load, in which it is noted a negligible displacement between compression machine plates, would assure the maximum paste structure destruction, giving more representative voids indexes as a consequence.

For the different pozzolan amounts in the binder, the relative tensile strength's development along time was different than the compressive strengths in mortars. Mortars with 55% of pozzolan exhibited a marked trend for higher tensile strengths at higher ages. Also in mortars, the ratio between tensile and compressive strength tended to be higher when the pozzolan amount increased.

Chemical analysis of paste extracted pore solution indicated that pH is very much more influenced by sodium and potassium ions than by calcium ions at the researched ages. As expected, decreasing of Ca ion with time was very marked in pastes with pozzolan, while not in pastes without pozzolan, and this was confirmed by $Ca(OH)_2$ amount obtained by TGA analysis. It is expected to continue this study not only by determinations on stopped hydration mortars and concretes stored in IPT Materials Chemistry Laboratory, but also by more discussions of results presented in this report, because of a presumable high number of non explored possibilities.

COOPERATION OF CEMENT-FLY ASH SYSTEM IN HIGH PASTE ROLLED COMPACTED CONCRETE (RCC)

Ioanna PAPAYIANNI, Aristotle University of Thessaloniki, Greece

ABSTRACT The use of cement - fly ash system (C/F) in RCC has started almost at the same time with the development of RCC. The effectiveness of it depends mainly on the type of fly ash. Low heat generation, slow strength development, low modulus of elasticity are the main advantages of C/F in mass concrete. The performance of C/F system with a high calcium fly ash was systematically studied during the construction of Platanovryssi RCC dam in Greece. Some of the results are presented here.

Key words: **Cement, high-calcium fly ash, cooperation, roller compacted concrete**

INTRODUCTION Mass concrete construction proved an unsuccessful field of application for the cement, a high energy enclosing material. Since the early 1970s (Dustan 1981) different types of mass concrete have been tried in gravity dams such as the rollcrete (cement content 110-200 Kg/m^3), the econocrete (cement content 120 Kg/m^3) and the high paste roller compacted concrete (RCC) in which large amounts of fly ashes contribute to cementitious phase. The proportioning of cement-fly ash system (C/F) depends basically on the tensile strength requirements of the RCC. The impact of fly ash inclusion on the properties of mortars and concretes (Malhotra and Mehta 1996) is closely related to its composition and origin (Low calcium fly ash from bituminous coal and high calcium from lignite coals). The combination of cement and fly ash, a high and a low potential material, constitutes a very clever system in which the by-product, fly ash, is upgraded. The fact, that 94 RCC dams (Dunstan 1994) all over the world have been constructed incorporating high content fly ash cementitious phase indicates that C/F system works quite satisfactory irrespective of variations in fly ash composition. This does not mean that fly ashes may exceed their own capacity for hardening. They need like provitamins activators and suitable climate to compensate for cement.

THE BEHAVIOR OF C/F IN HIGH PASTE RCC

One of the most characteristic cases of C/F system performance is the Platanovryssi RCC dam in Greece, the highest in Europe. It is being constructed with a paste consisting of 82% high lime fly ash and 18% portland cement I 42.5. The calcareous fly ash has been treated in a milling plant in order the free lime (CaOf) be reduced below 3% (Table 1).

Table 1. Chemical composition of cement, fly ash and cement/fly ash (C/F) system

Oxides	Cement I 42.5 (%)	Fly ash in oxides	C/F = 50/225 C+F = 275 kgr
SiO_2	19.80	33 - 88	32.65
Al_2O_3	4.65	16 - 18.5	14.91
Fe_2O_3	1.60	6 - 7.5	6.01
CaO	66.0	24.5 - 26.5	32
CaO_{Free}	-	1.96 - 2.17	1.60 - 1.77
MgO	2.62	2.05 - 3.5	2.15 - 3.33
SO_3	2.80	4.5 - 6.0	4.19 - 5.41
Insoluble residue	0.40	12.5 - 25.2	10.29 - 20.68
Loss of ignition	2.60	3.5 - 4.5	3.3 - 4.15

In the cementitious system there is an excess in $Ca(OH)_2$ and sulfates (SO_3), (Table 1), that implies unsuitability. However the main requirements of RCC for high VeBe density, low heat generation, slow strength development and as possible high deformability are fulfilled. Although for the low calcium C/F system the water demand in fresh RCC decreases up to 25% for the high calcium fly ashes, in RCC mixtures of the same VeBe time, the W/C+F increases with the content of fly ash (Papayianni 1992). This is also obvious in water demand of normal consistency pastes (Table 2). The retarding effect of the system on the setting and the low heat of hydration (Table 3) are very advantageous for RCC. It is worth mentioning that the heat of hydration of this fly ash should always be determined and varies with its reactivity. The slow rate of strength development (compressive and flexural) and the relatively low values of static modulus of elasticity are shown in Table 4 for mortars and in Table 5 for RCC.

DURABILITY ASPECTS

Durability of RCC structures is governed by permeability which is affected by the achieved compactability (VeBe density), the bonding between successive layers and time dependent deformations due to drying shrinkage or thermal movement. A number of reports (Dunstan 1994) have shown that in high fly ash RCC higher than theoretical densities and very good bonding have been succeeded in the field. Very good volume stability of Platanovryssi RCC, was found after monitoring it for over a year (Papayianni 1992). The delayed ettringite formation due to the high sulfate content of C/F system is a question of great

concern. It was estimated that for 6% SO_3 in fly ash an amount up to 15% of ettringite could be formed. Ettringite is easily detected in X-ray diagrams of hardened RCC (Fig. 1). It seems that its gradual formation is unevitable. Needle crystals of ettringite are observed microscopically in the pores of RCC (Fig. 2). However the Dugan test applied in a number of cores taken from RCC did not show significant dilation. That leads to the thought that stresses developed are successfully balanced by existing restrainment in RCC mass. The crystal form of ettringite, in which less water is absorbed and less swelling is created is in favor of that stress balance (Mehta, 1973).

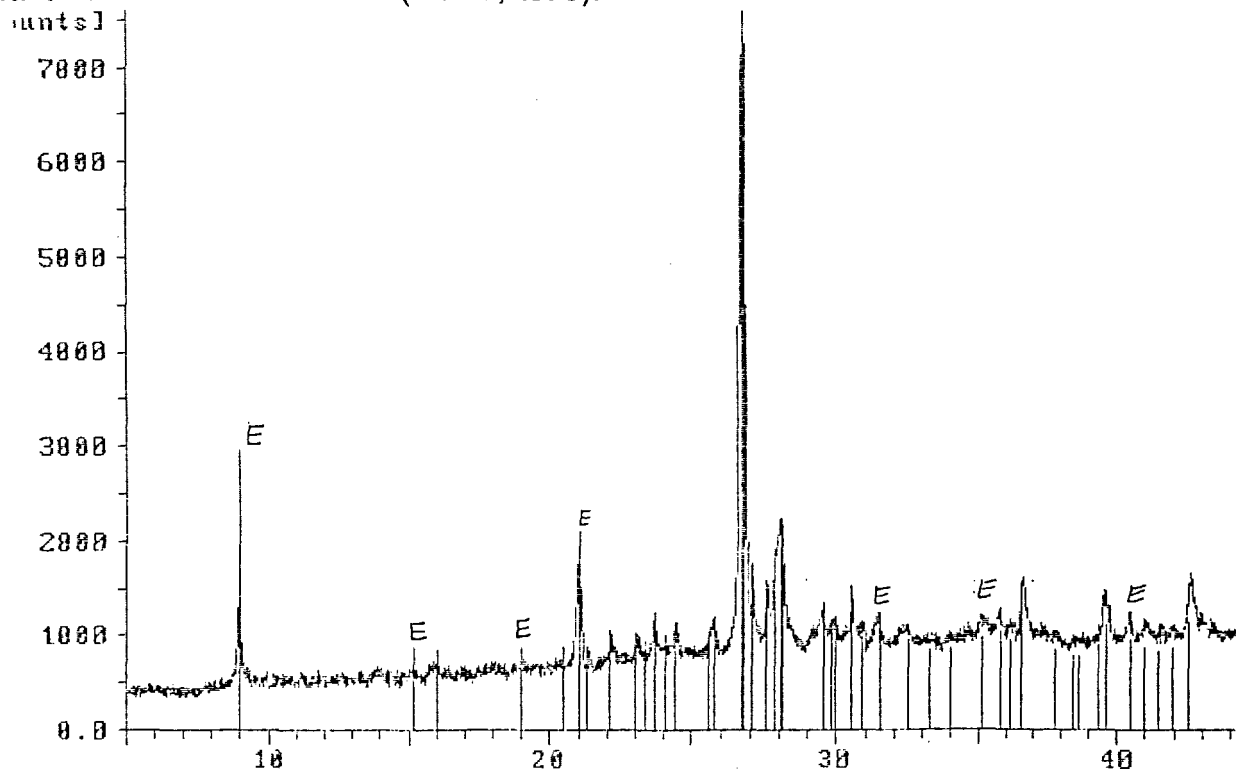

Figure 1. X-ray diagram of paste taken from RCC Sulfate content 13,5% E= Ettringite

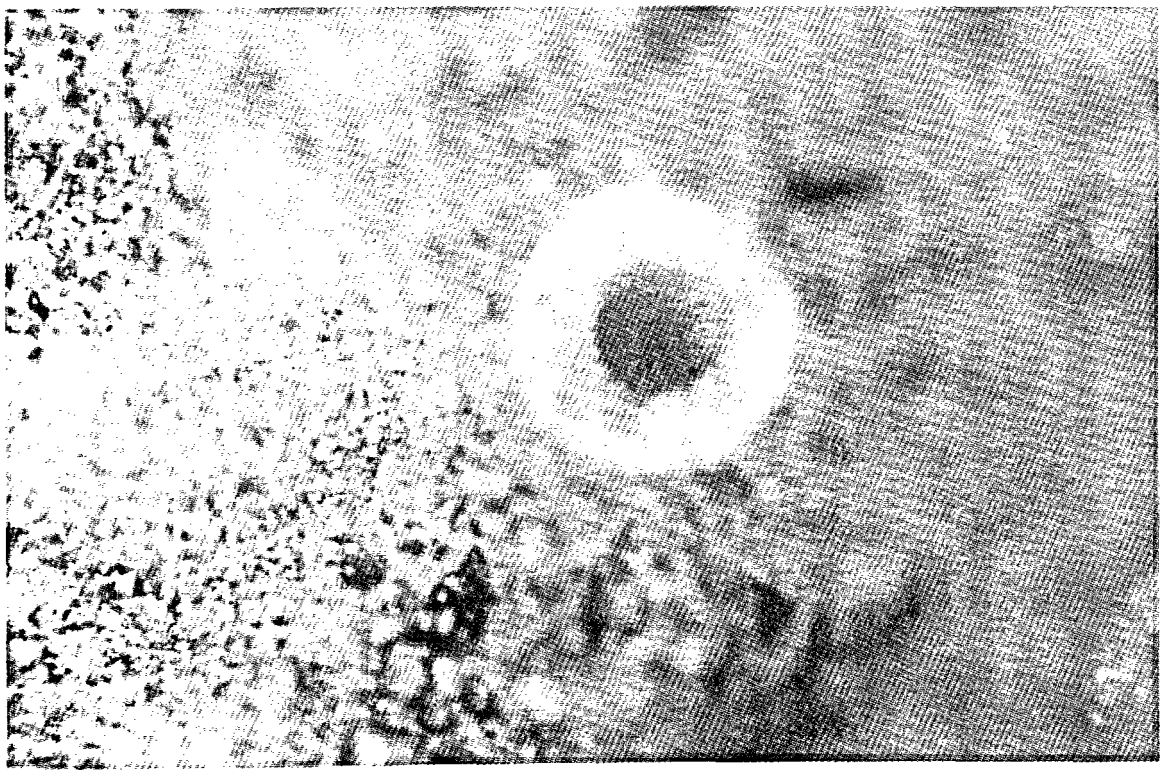

Figure 2. Ettringite crystals in pores of RCC

CONCLUSIONS

In C/F cementitious systems, the fly ash changes into an added value material by which the economy and the ecological profile of large projects are significantly improved. The proportion of fly ash in C/F system should be determined after trial mixes, taking into account the strength and elasticity requirements of the structure. The successful application of C/F high paste RCC in road construction could open new field in cement market in many countries. The good cooperation of cement fly ash system is a challenge for developing new blended type cement suitable for low strength concrete products.

PROPERTIES OF CEMENT CONTAINING GERMAN LIGNITE FLY ASHES

Stefan DIETZ, University of Heidelberg, Germany
Krzysztof MISKIEWICZ, RWE-Gesellschaft für F und E mbH, Wesseling, Germany
Michael SCHMIDT, Heidelberger Zement AG, Leimen, Germany

ABSTRACT Lignite fly ash was tested as partial cement replacement on its properties and suitability. Lignite fly ashes represent a mixture of different binding type particles, whereas each fly ash possesses a specific reactivity. The fly ash-cement mixes showed strength contributions connected to the hydraulic activity of the fly ash. The fly ash-cement mixes had a good stability of volume and low expansion rates. Negative effects on the fly ash-cement-properties due to fly ash addition couldn't be observed with up to 10-15 % by mass fly ash content in most of the mixes.

Key-words: Fly ash, Admixture, Mineralogy, X-ray Diffraction Analysis

INTRODUCTION

In Germany about 180 million tonnes per year of lignite are fired for electricity supply. During the firing process about 10.9 million tonnes of fly ash are produced, of which 0.8-1.4 million tonnes are free for utilization.Today in Germany fly ashes from lignite fired power plants are mostly used to refill open pits in a mixture with FGD-process water.

In the last few years many projects were run by energy suppliers and building material producers about the properties, qualification and utilization options of lignite fly ashes. One of these projects was the „Utilization of Filter Ash from Coal Power Plants in the Federal Republic of Germany" cooperative research project („Ash Recovery", duration 1991-1995, over 30 different single projects) which was coordinated and financed with different shares by RWE AG, RWE Energie AG, VEAG, Rheinbraun AG, LAUBAG, NUKEM GmbH and RWE Entsorgungs AG. The investigation of fly ashes as a cement additive in blended cements was one of these projects carried out by the RWE-Gesellschaft für Forschung und Entwicklung mbH in cooperation with the Heidelberger Zement AG.

Several tests according to DIN-EN or other well-known testing methods for durability, carbonation, sulphate- or freeze-thaw-resistance were carried out, besides several mineralogical investigations.

PROPERTIES OF FLY ASH AND CEMENT

Chemical composition and physical properties

For the test programme fly ashes from two power plants in the main lignite mining regions in Germany, the Rhine region and the Lusatian region, were choosen. To ensure a representative composition of the fly ash 238 samples were taken from each power plant. The composition of the investigated fly ashes is close to the mean value of the fly ash samples tested. Table 1 shows the chemical composition and physical properties of the used fly ashes. BFA R represents a calcareous fly ash deriving from firing of lignite of the Rhine lignite mining region, BFA L a silica-rich fly ash from the Lusatian lignite mining region. BFA R is finer grained and has a higher specific surface (Blaine) than BFA L. BFA R can be described as a reactive latent-hydraulic fly ash, BFA L as a pozzolanic fly ash. As reference and mixing cement 2 Portland cements of a different strength class, PZ 45 F (CEM I 42,5 R) and PZ 35 F (CEM I 32,5 R) from the Heidelberger Zement AG were selected (Table 2).

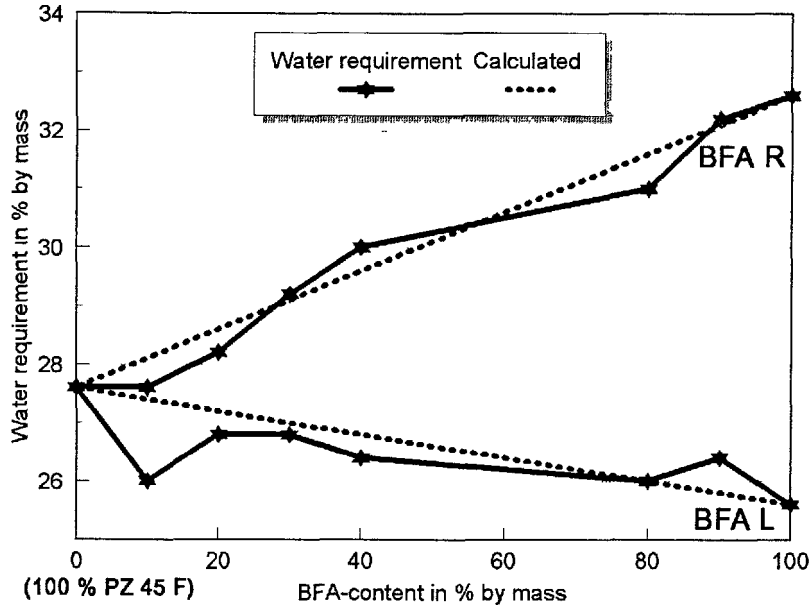
PROPERTIES OF FRESH FLY ASH-CEMENT-MIXES

The following presentation of results is concentrated on mixtures with PZ 45 F. The same investigations were undertaken with PZ 35 F as well. The results are summerized in Table 3.

The indication of the raw material and fly ash-cement mixtures is as follows:

BFA L: Lignite fly ash from the **L**usatian lignite mining region
BFA R: Lignite fly ash from the **R**henish lignite mining region
PZ 45 F: Portland cement, strength class 45 N/mm² according to DIN 1164 (CEM I 42,5 R according to ENV 197)

Fly ash-cement-mixes (examples):



R 30-45 30 %(m/m) BFA R; 70 %(m/m) PZ 45 F

Water requirement

The water requirement, tested according EN 196 part 3, decreased cement was substituted by BFA L and increased with BFA R. Many parameters of BFA R like the higher surface area, the higher fineness, lower bulk density and the higher CaO-content compared to BFA L result in the different behaviour of the fly ash-cement-mixes. The water requirement of BFA R and of the fly ash-cement-mixes correlate with the calculated value (linear relation between water requirement

of OPC (27.6%) and water requirement of fly ashes (BFA R: 32.6%; BFA L: 25.6%)). BFA L-cement mixes show a minimum water requirement with 10 % by mass fly ash content but the same tendency as the calculated values (Fig 1).

Figure 1 Comparison of measured and calculated water requirement of BFA-PZ 45 F-pastes

Setting time

The setting, determined according to EN 196, part 3, was generally accelerated with increasing amounts of BFA R and retarded by fly ash BFA L. The setting periods of all fly ash-cement-mixes range in the time period required in EN 196 part 3, setting starts not earlier than 1 hour after water addition and ends not later than 12 hours.

Flow table test

The flow diameter, determined according to DIN 1060, was decreased with increasing amounts of fly ash. BFA R-cement mortars had a stiffer consistence than the mixes with the same content of BFA L.

PROPERTIES OF HARDENED FLY ASH-CEMENT-MIXES

The hardened fly ash-cement mixes were tested as mortar bars (4x4x16 cm) manufactured according to EN 196 part 1. The Freeze-Thaw-resistance was tested on 10 cm concrete cubes.

Expansion

The mortar bars were stored according to DIN 52450 under water at 20°C. The expansion rates of the fly ash-cement mortar bars are mostly below 1 mm/m after 700 days. Only with a BFA R content of 90 % by mass the rates summed up to 3 mm/m (Fig 2). After 90 days of hardening the expansion rates remain constant, that means no delayed expansion reaction occurs due to fly ash-reactions. The expansion rates of BFA L-cement-mixes didn't exceed 1 mm/m with up to 90 % by mass fly ash content after 700 days.

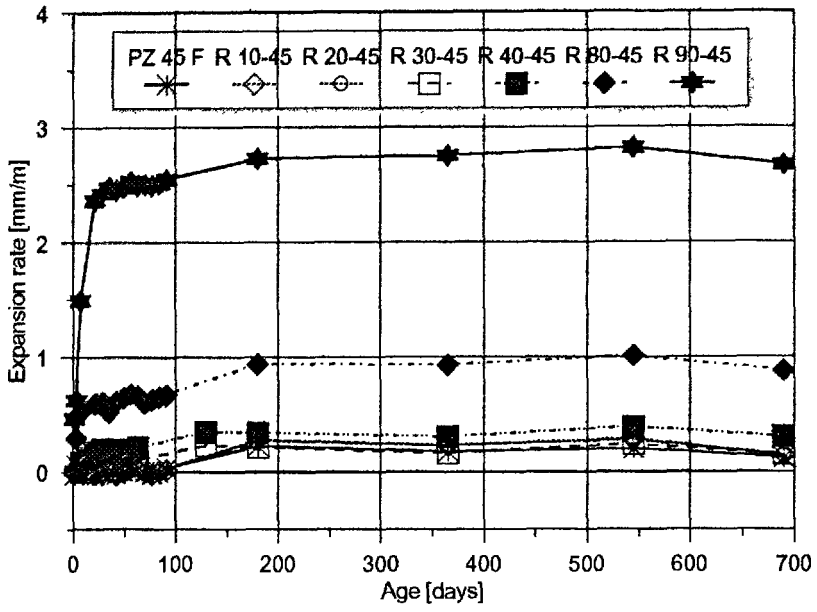


Figure 2 Expansion rates of BFA R-PZ 45 F-mixes depending on curing time (under water, 20°C)

Compressive strength

The compressive strength was determined according to DIN EN 196 part 1. Fly ash cement mixes with 10 % by mass fly ash content reached more than 90 % of the compressive strength of the reference cement mix at all ages. A strength contribution of the fly ash could be observed even for higher fly ash additions in most of the fly ash-cement mixes. The calcareous fly ash shows early strength contributions at 2 days because of their latent-hydraulic character, the silica-rich fly ash has a pozzolanic character, with increasing strength at higher ages (Fig 3).

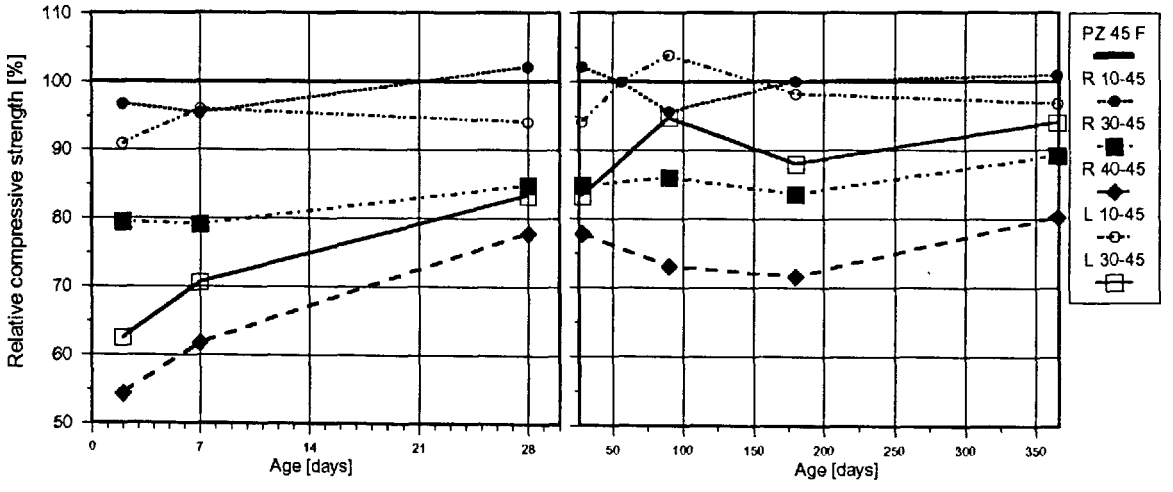

Figure 3 Compressive strength development of fly ash-cement-mortar bars related to reference mortar

Carbonation

After 2 days curing in 90 % rel. humidity, the mortar bars were stored in 20°C and 65 % rel. humidity. The short humid precuring represents very severe conditions.

Increasing carbonation depths could be observed with increasing fly ash contents (Fig 4). The carbonation depths of fly-ash-cement mortar bars with 10 % by mass fly ash content are in the range of the reference cement.

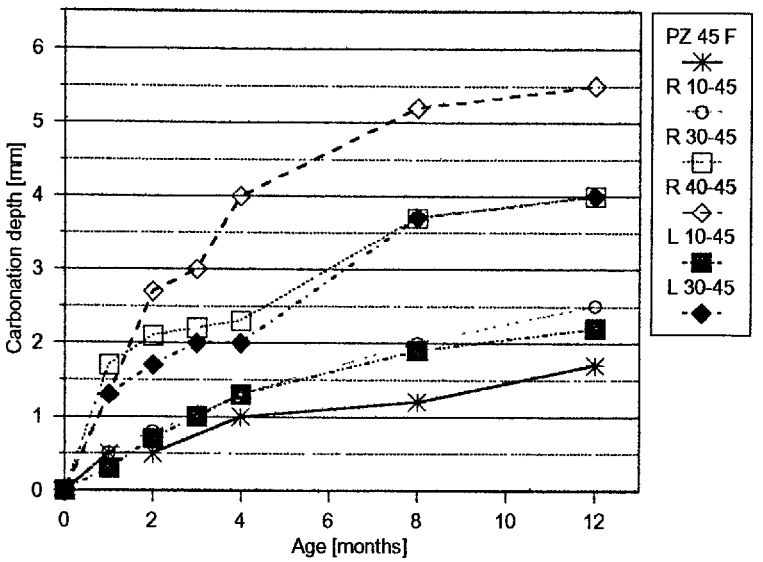

Figure 4 · Carbonation depth of BFA-PZ 45 F-mortar bars as a function of age

There was no difference between the two fly ashes concerning carbonation depth. Other test series with a longer wet curing of the mortar bars of 7 and 28 days under water before measurements started resulted in reduced carbonation depth.

The carbonation depth correlates with the compressive strength. The carbonation depth increases with decreasing compressive strength, that means the main influence factor on the carbonation is the compressive strength. Secondary the $Ca(OH)_2$-binding of latent-hydraulic and pozzolanic components e.g. Ca-Al-glass phases could reduce the alkaline potential in the fly ash cement mixes and lead to higher carbonation depths.

Freeze-Thaw-resistance of concrete

After defined Freeze-Thaw-cycles the concrete cubes were weighed according to the cube-method[1]. The decrease in weight is caused by scaling due to frost attack.

The Freeze-Thaw-resistance test showed an increasing scaling with increasing fly ash content (Fig 5). Concretes with BFA L-cement mixtures had a high freeze-thaw resistance up to 30 % fly ash content by mass and concretes with BFA R-cement-mixtures up to 10 % fly ash content (scaling of up to 5 % by mass is considered for good freeze-thaw-resistance).

Concretes with BFA R-cement-mixes showed significantly higher scaling than those with BFA L. As the concrete cubes were produced with a constant water content, the fresh concretes with BFA R had a stiffer consistency. Nevertheless the concretes containing fly ash had a higher raw density compared to the PZ 45 F concretes. Further investigation didn't show any relation between fly ash particles e.g. porous carbon particles and the decrease in Freeze-Thaw-resistance of fly ash containing concretes. From other investigation it was concluded that a reduction of compaction pores due to fly ash addition could lead to a higher scaling. Until there are no further

[1] Bunke N.: Prüfung von Beton, Empfehlungen und Hinweise als Ergänzung zu DIN 1048 - Heft 422, Beuth-Verlag,, p. 30-31 (1990)

information on the pore structure and distribution in cement paste future investigations are necessary.

More tests should be made with concretes of comparable workability and compressive strength to determine the influence of fly ash on the Freeze-Thaw-resistance. Air entraining agents can improve the Freeze-Thaw-resistance of concretes with higher fly ash contents.

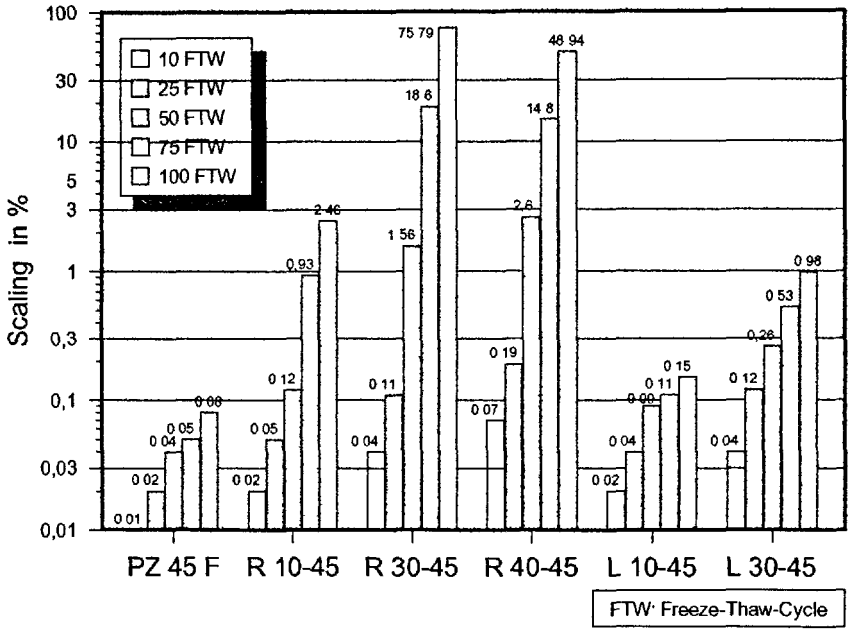

Figure 5 Scaling of BFA R-PZ 45 F containing concrete cubes due to frost-attack depending on the number of Freeze-Thaw-cycles

MINERALOGICAL INVESTIGATIONS

In addition to the mortar and concrete tests to determine macroscopic effects of fly ashes on cement properties, the mineralogical tests should show the effects on the microstructure as well as differences in the hydration reaction due to fly ash addition.

X-ray diffraction (XRD)

An important question for the durability of fly ash-cement mixes is the reactivity of free lime. In-situ XRD which allows the continous measurement of pastes during the early hydration (measurement starts 2 minutes after water addition) showed the nearly complete reaction of CaO forming $Ca(OH)_2$ within the first two hours of hydration. It can be concluded that there will be no expansion due to CaO-hydration in corresponding fly ash-cement mixes (Fig 6).

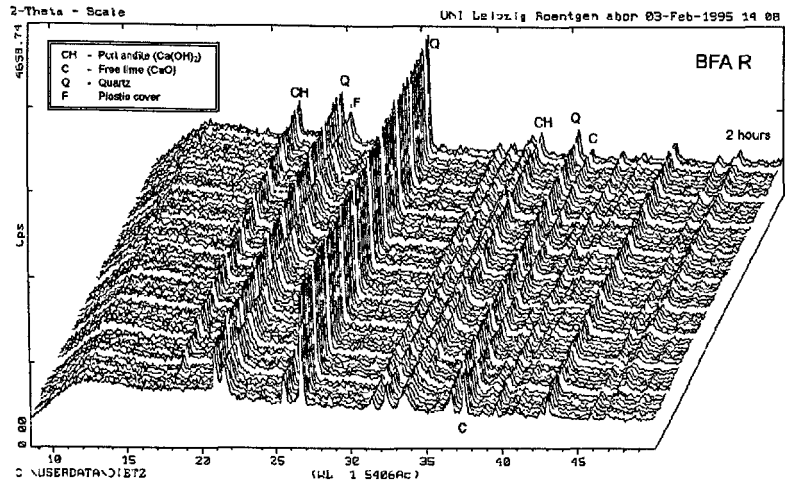

Figure 6 In-situ X-ray diffractogram of an BFA R-paste during the first 2 hours of hydration

Normal X-ray diffraction on fly ash-cement mix samples, hydration stopped with isopropanol and dried in a vacuum-dryer after certain hydration times showed a slightly higher Ettringite-concentration until 28 days of hydration in BFA R-cement mixes than in the cement-mixes.

Dynamic Scanning Calorimetrie (DSC)

The DSC showed the high reactivity of the fly ashes (Fig 7).

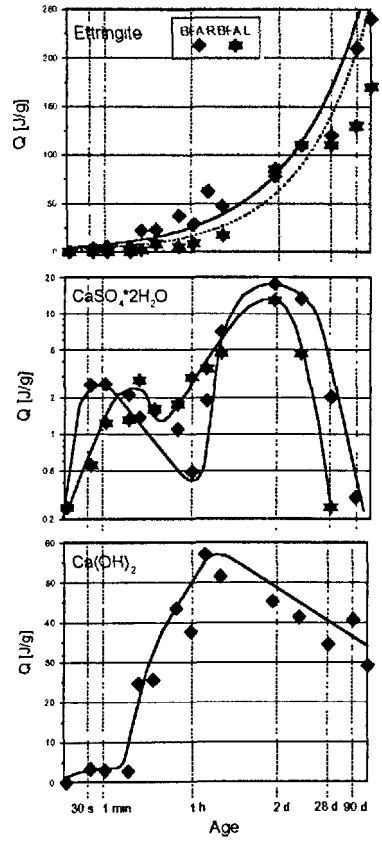

Figure 7 Quantitative DSC-determination of Ettringite, gypsum and portlandite during hydration

Ettringite was formed after the first minutes with increasing amounts during hydration. Anhydrite is highly soluble. Gypsum was formed in cycles depending on the saturation of the pore solution. Free CaO was hydrated very quickly so that $Ca(OH)_2$ could be formed in BFA R, with decreasing amounts due to the formation of Ettringite and other CSH-phases.

Scanning electron microscope (SEM)

For the SEM-investigations the samples, stopped with Isopropanol and dried, were coated with platinum. No major differences in the microstructure between the reference cement samples and the fly ash-cement-mixes could be observed. Fig 8 shows a reacting glass sphere (B) coated by a reaction cover (A). Fig 9 shows a pore filled with Ettringite and hexagonal Portlandite ($Ca(OH)_2$)crystals.

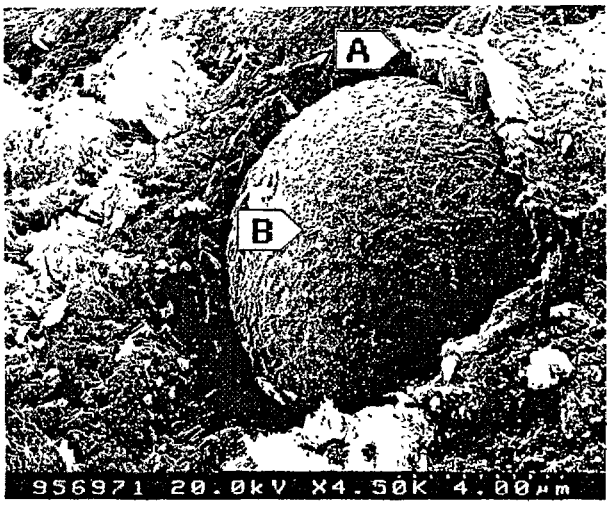

Fig 8 Reacting glass sphere of BFA R in a R 30-45-paste after 180 days of hydration

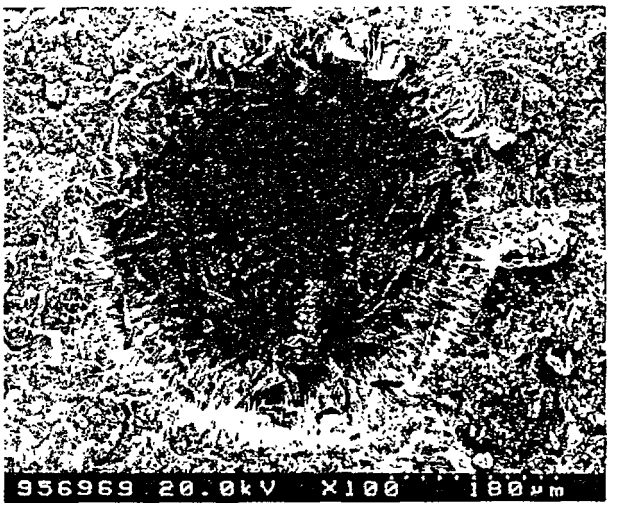

Fig 9 Ettringite and Portlandite in a pore of a R 30-45-paste after 180 days

DISCUSSION AND CONCLUSIONS

The investigation showed, that fly ashes are a reactive component in the fly ash-cement system. Early strength contributions even at early ages of hydration showed the high reactivity of the calcareous BFA R. The silica-rich BFA L reacts like a pozzolan with a „delution effect" due to low reactivity at the beginning of the hydration and a continous strength contribution with increasing hydration time.

The strength contribution of the fly ash in cement mixes could be observed for most of the mixes up to 40% by mass fly ash content.

Volume stability due to expansion-reactions is ensured with both fly ash types up to at least 40 % by mass fly ash content. Unsoundness couldn't be observed. The free lime in the calcareous fly ash BFA R is highly reactive and hydrates nearly completely after 2 hours of hydration.

The carbonation is increased with increasing fly ash content, no matter which type of fly ash is used. Reasons could be differences in pore structure and distribution and pozzolanic reactions of fly ash particles that lead to a decrease in the $Ca(OH)_2$-concentration. An extended curing time of the samples can decrease the carbonation depth of fly ash-cement-mixes. However extended wet curing is hard to realize in civil engineering.

OPC: Ordinary Portland cement

* higher fly ash amounts were not tested

n.d. : not detected

- : the given value was not reached resp. fly ash contents < 10 % by mass were not tested

Freeze-thaw-resistance of fly ash containing concrete cubes decreases with increasing fly ash content. The reason for that phenomena could be an increasing capillary porosity and a reduction of air pores.

Table 3 shows the maximum contents of fly ash in fly-ash-cement-mixes which didn't show any negative effect on the cement and concrete properties.

The mineralogical investigations showed that lignite fly ashes represent a system of puzzolanic (Si-rich glassphases), latent hydraulic constituents (Al-Ca-rich glassphases) and CaO- and SO_3-suppliers. The reactivity of the fly ash and their influence on binding systems depends on the quantity of each category in the fly ash (Fig 10).

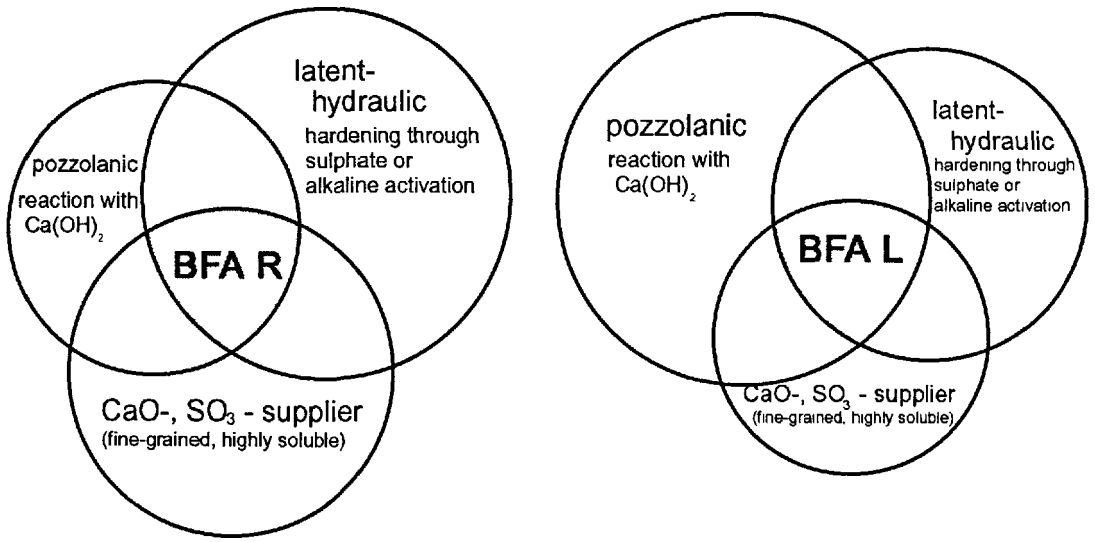

Figure 10 The binding character of the fly ashes as a combination of the three principle binding types

The differences in hydration of Portland cement compared to fly ash containing cement were very little. A slightly higher Ettringite concentration in BFA R-cement mixes could be observed without having any effect on the volume stability.

Finally it has to be pointed out that a fly ash content of at least 10-15 % by mass showed no negative effect on the properties of most of the fly ash-cement-mixes. Further investigation should be made on the effects of fly ash on the carbonation and the Freeze-Thaw-resistance of concrete.

CHARACTERIZATION OF FLY ASHES DIRECTLY COLLECTED FROM ELECTROSRATIC PRECIPITATOR

Seung Heun LEE, Kunsan Nat l. Univ., Kunsan, Korea
Etuo SAKAI, Masaki DAIMON, Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT The test results show that fly ashes obtained from the hopper at the furthest point from the combustion boiler tend to have a finer particle size, larger density, lower carbon content and higher glass content. When the boiler is operated in full load running(600MW) in comparison with half load running (300MW) the glass content increases but the Blain specific surface area and carbon content decreases. And the fly ashes show that pozzolanic reactivity at 40℃ is related to the fineness. But the glass content has no significant influence on reactivity. there is a negative correlation between the apparent viscosity of cement paste with fly ashes and carbon content at addition of 1.6% superplasticizer.

Key-words: Characterization, Fly ash, Fineness, Pozzolanic reactivity, Glass content

INTRODUCTION

In coal-fired power plant, coal ashes passing through boiler are negatively charged by corona discharge in electostatic precipiator(ESP) system and attach to collection electrode and fall into hopper by rappers. ESP system has many collected fields in the direction of flue gases and hopper is installed in each collected field. In most coal-fired power plants, fly ashes collected from each hopper in ESP are transported to one line and stored in silo and the necessary amount is supplied to classifier. The supplied fly ashes are divided into coarse and fine particles by classifier to be stored in silo. However, since the properties of the fly ashes collected from each hopper in ESP system change as the farther the collected field gets from boiler the larger the Blaine specific surface area gets(Hemming and Berry, 1988), the hopper itself in ESP system is expected to have the effect of classifying fly ashes.

Based on the above background, this research investigated physical and chemical properties of fly ashes collected from hoppers in ESP system when boiler was operated either in full load running(600MW) and in half load running(300MW). Also the effect of the properties of such fly ashes on the apparent viscosity of paste following the reactivity with $Ca(OH)_2$ and the addition of superplasticizer has been examined.

EXPERIMENTAL METHODS

Materials

Fly ashes of six kinds collected per each load and hopper were used, when load of boiler in the capacity of 600MW in power plant was operated in 600MW and 300MW(at night), and when the locations of hoppers attached to ESP system were named 1st, 2nd and 3rd field in the moving direction of gases. $Ca(OH)_2$ of first grade reagent in evaluation of reactivity, and ordinary portland cement(Blaine specific surface area: 3560㎠/g, specific gravity: 3.15) and polycarboxylic acid superplasticizer in measurement of apparent viscosity were used.

Measurement of physical and chemical properties of fly ashes

Chemical properties of fly ashes, such as chemical composition, mineral composition, carbon content, loss on ignition and the adsorption amount of methylene blue(MB) were measured. And also physical properties, such as Blaine specific surface area, particle size distribution, residue on 45 μm sieve and specific gravity were measured. Mineralogical compositions of

fly ashes was obtained with powder X-ray diffraction analysis by the use of internal standard method.

Measurement of the amount of reacted $Ca(OH)_2$

After fly ashes and $Ca(OH)_2$ were mixed by the mole ratio of Ca/(Si+Al)=1 and water/powder was mixed with the mixture by weight fraction of 0.6, it was reacted in incubator of 40℃ for 3, 7, 28 and 56 days. The sample reacted for a certain period of time was deposited in acetone for 1 day and dried at 110℃ for 24 hours. The product was identified by powder X-ray diffraction analysis and the amount of unreacted $Ca(OH)_2$ was obtained from atmosphere of N_2 gas by TG-DTA. Reacted $Ca(OH)_2$ was obtained from the value and loss on ignition.

Measurement of apparent viscosity

Fly ashes were mixed by 20% of volume fraction in ordinary portland cement, and polycarboxylic acid plasticizer was added up to 2.0%. And then water/powder was mixed with the mixture by volume fraction of 0.6. This paste was made rise and fall between shear stress 0Pa and 200Pa at 20℃ by the use of viscometer, and the apparent viscosity at 200Pa was measured.

RESULTS AND DISCUSSION

Fineness of fly ashes

Table 1 shows the physical properties of fly ashes. It represents that as going from the 1st field to the 3rd one regardless of the load of boiler, the Blaine specific surface area of fly ashes increases and showes the value of 7,000cm^2/g or more in the 3rd field. The mean particle size of fly ashes was more than 30 μm in the 1st field but was 6.9 μm in the 3rd one. Most of fly ashes that obtained the 3rd field passed through 45 μm sieve. As the particle size distribution of fly ashes is shown in Fig 1, fly ashes going from the 1st field to the 3rd one, maximum particle size becomes smaller and the range of particle size distribution gets narrower and fly ashes in the 1st field represent multiple distribution with two maximum frequency diameters but, fly ashes in the 3rd one show normal distribution. In view of the differences in fineness by the load of boiler, the fineness was slightly better in half load running of 300MW than in full load running of 600MW. The presumed reason why it is so is because, in half load running of 300MW the amount of coal put into boiler has decreased to half in comparison with 600MW and thus cohesion by collision between pulverized coals at the time of combustion has decreased.

Table 1 Physical properties of fly ashes.

fly ash	load(MW)	collected position	specific gravity	Blaine specific surface area(cm^2/g)	residue on 45 μm sieve(%)	mean particle size(μm)

A-2	600	2nd field	2.22	4180	3.8	18.6
A-3	600	3rd field	2.42	7360	1.7	6.9
A'-1	300	1st field	2.08	3580	16.6	30.4
A'-2	300	2nd field	2.23	4980	3.2	15.6
A'-3	300	3rd field	2.40	7920	0.2	6.9

Carbon content, loss on ignition and adsorption amount of methylene blue

carbon content, loss on ignition and adsorption amount of methylene blue are items used in evaluation of the amount of unburned carbon among fly ashes, as represented in table 2.

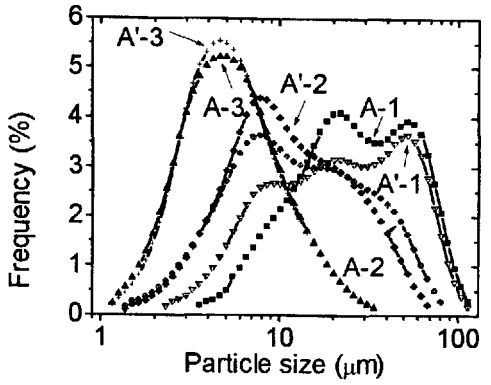

Fig. 1 Particle size distribution curves for fly ash

Carbon content and loss on ignition had overall low values in the range of 0.3-1.5% and 1.1-2.1%. carbon content was least in fly ashes of the 3rd field with least mean particle size but, loss on ignition did not show any such relation. Fly ashes collected from one and the same place had less total carbon and loss on ignition in full load running of 600MW than in half load running of 300MW. This may be because the combustion state is stable in full load running of 600MW appropriate to the capacity of boiler. As it was reported that adsorption amount of methylene blue, the blue coloring matter was linked to the adsorption amount of air-entraining agent on unburned carbon.(Tanosaki et al., 1995) However, in this experiment the correlation between the adsorption amount of methylene blue and carbon content, loss on ignition was not shown because the carbon content of fly ashes was small. But A'-1 and A'-2 with the most carbon content had more loss on ignition and adsorption amount of methyl blue.

Table 2 Ccarbon content and loss on ignition of fly ashes and adsorption amount of methylene blue(MB) on fly ashes.

fly ash	carbon content(%)	loss on ignition(%)	adsorption amount of MB(mg/g)

Chemical and mineral characteristics of fly ashes

Table 3 represents the chemical compositions of fly ashes. It represents a typical composition of bituminous coal ashes as analytical SiO_2 and Al_2O_3 was more than 85% and analytical CaO had low value of 2.0-2.3%. In view of chemical composition of fly ashes depending on the place of collection, fly ashes going from the 1st field to the 3rd one, analytical SiO_2 decreased by 3.5% in full load running of 600MW and 2.5% in half load running of 300MW. But analytical Al_2O_3 increased to 1.6% and 1.5% in each running. The total amount of Fe_2O_3, alkali and alkali earth oxide which lower the melting temperature of coal ashes was about 10% and increased slightly as going from the 1st field to the 3rd one. There was little difference in chemical composition by load change of boiler. Fig 2 shows the results of X-ray diffraction of fly ashes. Major crystalline phase was mullite and α-quartz and minor crystalline phase was magnetite and hematite regardless of the place of collection and the load of boiler. Ca-containing phase could not be identified in X-ray diffraction analysis. As mentioned above, this may be because fly ashes used in this experiment had low value of 2.3% or less in the analytical CaO content and most acted as modifiers in glass formation.(McCrthy et al., 1988)

Table 3 Chemical analysis of fly ash(wt%).

fly ash	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	TiO_2	Na_2O	K_2O	C

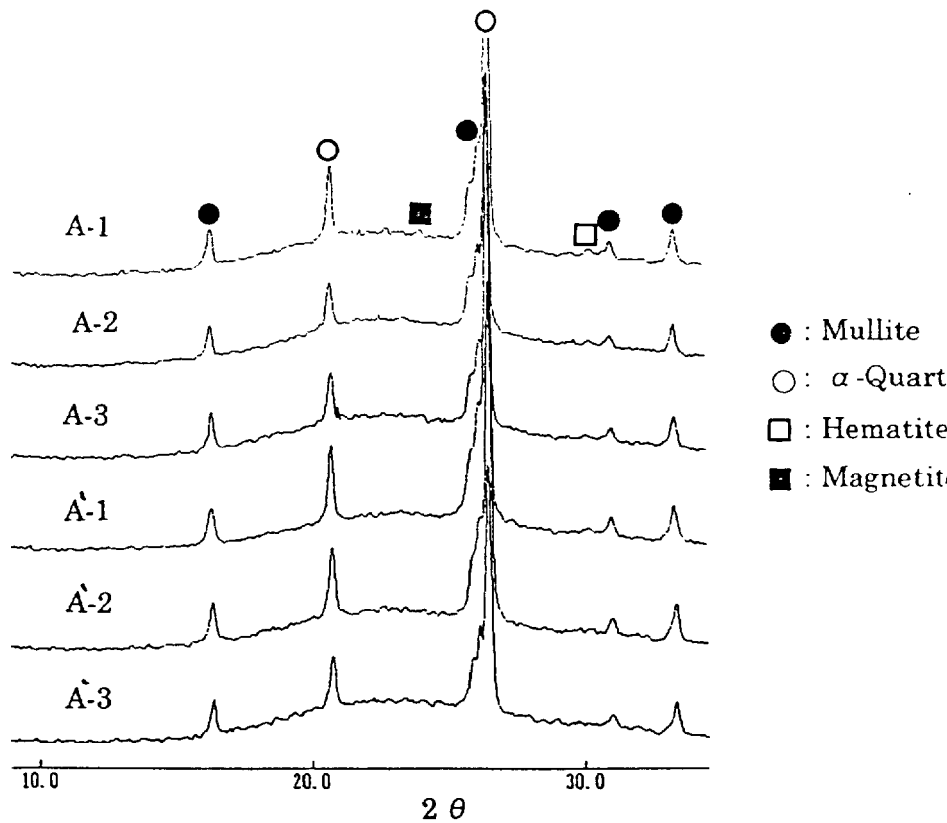

Figure 2 X-ray diffractograms of fractionated fly ashes.

As in Fig 2, fly ashes contain a considerable amount of glass phase as noncrystalline phase and thus a series of halo attributing to glass phase appears. This halo means long range order is lost. When the modifiers, alkali and alkali earth oxide enter random network structure, they break it and nonbridging oxygen is created, which in turn leads to discontinuous structure, and if the amount of modifiers increases, the structure becomes all the more discontinuous (Hemming and Berry, 1988,) and the maximum peak position of halo moves to high angle.(Diaond, et al., 1983) The maximum peak position of halo by X-ray diffraction represents the value approximate to 2θ =23.3 regardless of the kinds of fly ashes and may be considered to have a basically similar glass structure. Table 4 is mineral composition quantified by powder X-ray diffraction. Mullite, α -quartz, magnetite and hematite were obtained directly by internal standard method.(Alexander and Klug, 1948, Roode et al., 1987) SO_3 content was calculated on the assumption that they exist in the form of $CaSO_4$. The glass content deducted crystalline phase and loss on ignition from the total. The glass content had the value in the range of 65.9-76.8% and increased as going from the 1st field to the 3rd one. The amount of increase

was 6.2% in 600MW and 8.2% in 300MW. In other words, the finer the particles, the more the glass content has. The degree of glass content depends on the rate of quenching. If the rate of quenching is high, precipitation of crystalline phase is prohibited and the glass content is increase.(Freiman and Hench, 1969)

Table 4 Mineralogical compositions of fly ashes(wt%)

fly ash	α-quartz	mullite	hematite	magnetite	anhydrite	glass

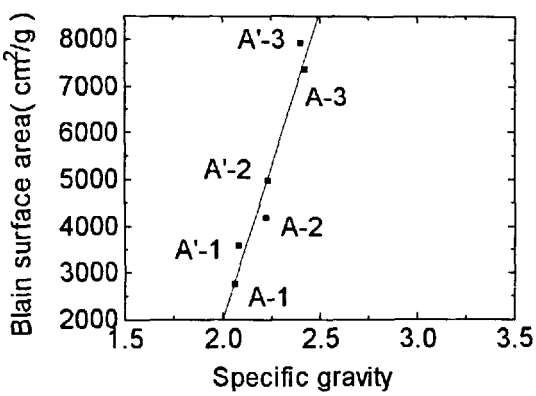

Figure 3 The relationship between Blaine specific surface area and specific gravity

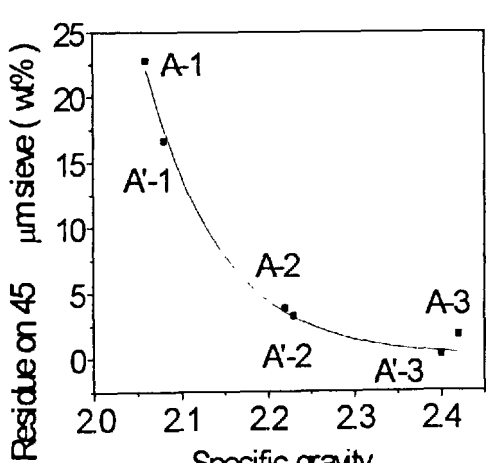

Figure 4 The relationship between specific gravity and residue on 45μm sieve

Ash particles are migrated by gases such as CO_2 , H_2 O generated in combustion and exit from the boiler. As the minimum fluidizing velocities of particles rely largely on particle diameter rather than density, small particles have high velocities of minimum fluidizing.(Kunii and Levenspiel, 1990) Accordingly fine particles have high rate of quenching. Fly ashes in the 3rd field composed of fine particles contain much glass content. The glass content in 600MW is larger than in 300MW. This may be attributed to the instability of combustion state following the load decrease of boiler. On the assumption that crystallines had stoichiometric composition, the chemical composition of fly ashes with deducted composition of crystallines was made the chemical composition of glass. The chemical compositions of glasses were mainly composed of SiO_2(63.3-67.6%) and Al_2O_3(18.9-22.6%) which can form a network structure and the modifier content was less than 10%. , the mole ratio of glass Al/(Si+Al) increases from 0.26 to 0.30 as going from the 1st field to the 3rd one, regardless of running conditions.

Specific gravity of fly ashes

As listed in Table 1, the specific gravity which is 2.06-2.42 takes the form of hollow spheres having a lower value than the theoretical value of mineral compositions. Fly ashes collected from one and the same location had similar values regardless of the load of boiler, and their increased as going from the 1st field to the 3rd one. The gravity of fly ashes is expected to decrease from the standpoint of the mass proportions of the mineral components because the finer the particles, the more likely the glass content of low gravity will increase. However, as this conflicts with the results of experiment, the mineralogical compositions may not greatly affect the specific gravity. In view of the relation between carbon content and specific gravity, carbon content are less than 1% and specific gravity and carbon content do not have any correlation, and thus gravity may not be affected by porous particles such as charcoal. Fine flyes ash may have thick shell wall because the finer the particles, the more the glass content has. However, in comparison, the fly ashes in the 3rd field of 300MW had 2.5% less glass content but bigger specific gravity than those in the 2nd of 600MW. Therefore, the shell wall thickness of fly ashes may not greatly affect the specific gravity. In hollow fly ashes, the finer the particles, the more likely the volume of closed pores will decrease. Fig 3 and Fig 4 show the relation between specific gravity and fineness. Specific gravity and Blaine specific surface area represent a good direct relation and an exponential correlation with residue on 45 μm sieve is shown. Therefore, the factors greatly affecting specific gravity may be the content of closed pores.

The tone of colors of fly ashes

The overall tones of fly ashes are bright gray. The brightness increases as going from the 1st field to the 3rd one. In other words, fly ashes collected from one and the same location represented the same tone of color regardless of the load of boiler. The color of fly ash is reported to depend on the amount of Fe_2O_3 (red) and unburned carbon(black).(Tanosaki et al. 1995) However, in this experiment such trend did not show. Moreover, Fe_2O_3 content had a similar value of 4.2-4.8% and carbon content had a low value of 0.3-1.5% A-1 and A'-1 with most differences in Fe_2O_3 and carbon content among all fly ashes represented the same tone of color. Presumably, in fly ashes produced from the same coal, the smaller the size of particles (glass content), the brighter they become.

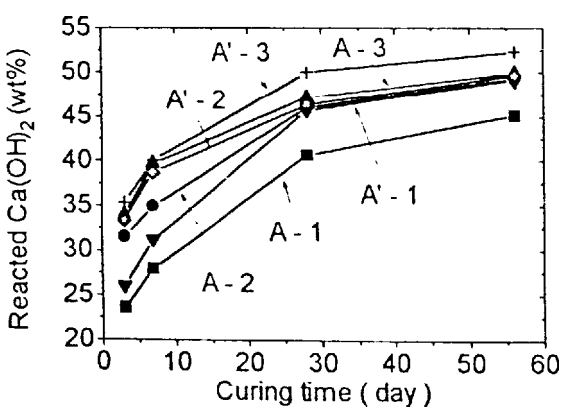

Figure 5 Amount of reacted $Ca(OH)_2$ with curing time at 40 C.

Reactivity with $Ca(OH)_2$

Fig 5 shows the relation between the aging time for fly ashes at 40℃ and the amount of reactivity with $Ca(OH)_2$. The longer the aging time, the more the amount of reactivity with $Ca(OH)_2$ increased and after 28 days there was virtually no change. The amount of reactivity of fly ashes with $Ca(OH)_2$ increased as going from the 1st field to the 3rd one, and fly ashes collected from one and the same location had slightly better reactivity with $Ca(OH)_2$ in load 300MW than

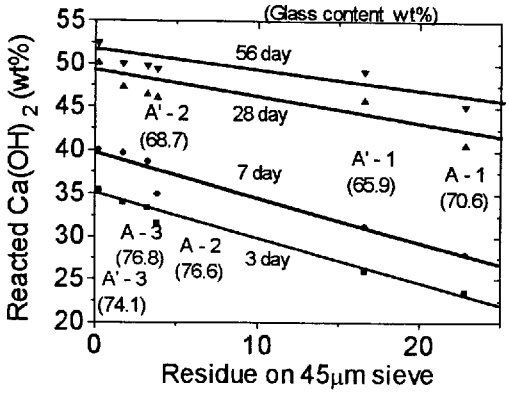

Figure 6 The relationship between reacted $Ca(OH)_2$ and residue on 45μm sieve

in 600MW. As a result of powder X-ray diffraction analysis, reacted products showed small amount of $CaSO_4 \cdot 2H_2O$ and C-S-H. Factors of fly ashes affecting the reactivity at 40℃ may include fineness and glass content. Fig 6 represents the relation between residue on 45 μm sieve and the amount of reacted $Ca(OH)_2$. A direct correlation between residue on 45 μm sieve of fly ashes and the amount of reacted $Ca(OH)_2$ was shown regardless of running conditions and the location of collection. In other words, as the residue on 45 μm sieve decreased, the amount of reacted $Ca(OH)_2$ increased and as aging time increased, the width of increase(tilt of direct line) decreased. Fig 6 did not show the correlation between glass content and the amount of reacted $Ca(OH)_2$. In conventional report(Sakurai et al., 1964), the more the glass content, the better the pozzolanic reactivity is in fly ashes where glass and crystallines are mixed. However, as the fly ashes used in this experiment had large difference in fineness, it might have been hard to show any effect of glass content.

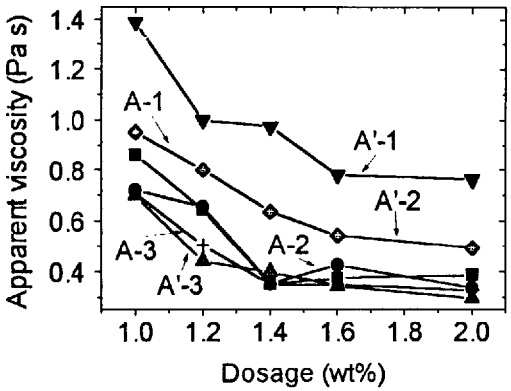

Figure 7 The influence of dosage of superplasticizer on the apparent viscosity of paste with fly ash.

Evaluation of apparent viscosity

Fig 7 shows the relation between the apparent viscosity of cement paste with 20vol% of fly ashes and the addition of superplasticizer. Up to 1.6% of superplasticizer, the apparent viscosity of paste decreased regardless of the kinds of fly ashes and in more admixture there was no change. This may be because the amount of admixture adsorbed on particles reached saturation around 1.6wt% of superplasticizer. The apparent viscosity is represented as $\eta = \tau / \gamma$ (τ : shear stress, γ : shear velocity) and counteracts to the reverse value of shear velocity generated under certain shear stress. From the standpoint of fluidity, the evaluation by $1/\eta$, the shear velocity itself is important rather than η counteracting to the reverse value of shear velocity. Fig 8 represents the relation between carbon content and the reverse value of apparent viscosity in 1.6% where the addition of admixture is saturated. The value $1/\eta$ linearly decreases as the carbon content increases.

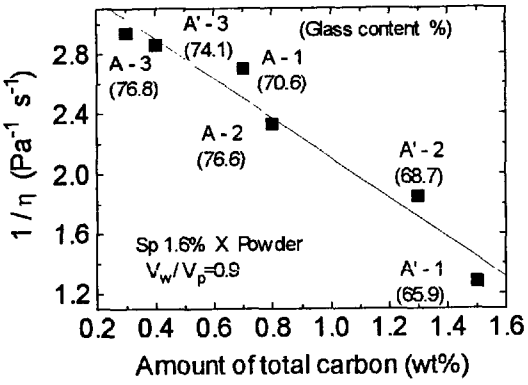

Figure 8 The relationship between amount of total carbon and 1 / η of pastes (η: Apparent viscosity)

CONCLUSION

The results obtained in this experiment can be arranged as follows.

1) Regardless of running conditions, the collected fly ashes increased in fineness, specific gravity and glass content as going from the 1st field to the 3rd one, but SiO_2 was decreased.

2) When the boiler is operated in full load running(600MW) in comparison with half load running(300MW) the glass content was increased, but the Blaine specific surface area and carbon content were decreased.

3) The reactivity of fly ashes at 40℃ with $Ca(OH)_2$ was more affected by fineness than by glass content.

4) In cement paste of 20vol% of fly ashes, the apparent viscosity represented constant value in 1.6% of superplasticizer, and at this time there was a linear correlation between carbon content and fluidity.

UTILIZATION OF FLY ASHES CONTAINING CALCIUM SULPHITE IN CEMENT PRODUCTION

Marek GAWLICKI, Artur ŁAGOSZ and Jan MAŁOLEPSZY, University of Mining and Metallurgy, Cracow, Poland

ABSTRACT The research has been carried out on blended Portland cements containing fly ash and mixed gypsum and $CaSO_3 \cdot 0.5H_2O$ with different $CaSO_4/CaSO_3$ molar ratios. It was found that the fly ash cements containing calcium sulphite together with gypsum (molar ratio of $CaSO_4/CaSO_3 > 1$) gave a slightly slower setting. The increase of the amount of $CaSO_3 \cdot 0.5H_2O$ (molar ratio of $CaSO_4/CaSO_3 < 1$) results in a slow setting of cement mortars. It was also found that fly ash cements containing $CaSO_3 \cdot 0.5H_2O$ exhibit lower strengths.

Key-words: AFm phase, blended cement, fly ash, hydration, strength development.

INTRODUCTION

The desulphurization of non-dedusted flue gases in industrial fittings in which solid fuels are burned is carried out in a relatively low temperature. SO_2 sorbent and desulphurization produts do not react with the components of fly ash. The wastes acquired in the process are a mixture of fly ash, unreacted sorbent and calcium sulphates and $CaSO_3 \cdot 0.5H_2O$. The degree of hydration of calcium sulphates and the proportion of $CaSO_4/CaSO_3$ in the waste varies in quite a broad range and depends on the conditions in which desulphurization is conducted, as well as the conditions and time of waste storage. After some time both $CaSO_4$, $CaSO_4 \cdot 0.5H_2O$ and calcium sulphite change into gypsum (Grzeszczyk, 1995).

The present experiences in the utilization of ash sulphate/sulphite in building material industry are scarce. In Poland there has been an attempt in the production of pulverized fuel ash cellular concrete (Małolepszy et al., 1991). The majority of chemical components present in ash sulphate/sulphite wastes is active in a cement - water system and can influence the properties of hardening of cement pastes. It seems that a remarkable portion of these wastes can be utilized in the production of blended cements in which the wastes would play a double role: of a pozzolanic agent and of a regulator of setting time for cement. Such utilization is conditioned by the ability to perceive the role of particular waste components in the process of paste setting and the increase of strength in cement mortars. The functioning of those waste components seems to have synergic effects. Although the influence of calcium sulphate and calcium carbonate on cement hydration is widely known, the role of calcium sulphite in this process has been a subject of few publications. Their authors agree that $CaSO_3 \cdot 0.5H_2O$ in cement - water system gives AF_m phase but the authors describe them by means of different formulas: $3CaO \cdot Al_2O_3 \cdot CaSO_3 \cdot 8H_2O$ (Bloss and Odler, 1982) or $3CaO \cdot Al_2O_3 \cdot CaSO_3 \cdot 12H_2O$ (Yasue et al., 1981).

EXPERIMENTAL

The research has covered the determination of principal properties of blended cements containing fly ash with different amounts of $CaSO_4 \cdot 2H_2O$ and $CaSO_3 \cdot 0.5H_2O$. Those cements have been treated as model systems which allowed to determine the influence of calcium sulphite on the hydration of blended cements. Also, a series of analyses of reaction products in $3CaO \cdot Al_2O_3 - CaSO_3 - H_2O$ system have been carried out. Ordinary Portland clinkier (OPC) and fly ash (FA) acquired in a bituminous coal-fired power plant have been used in the preparation of blended cement samples. Chemical components of OPC and FA are presented in Table 1. Phase components of OPC were the following: C_3S - 58%, C_2S -18%, C_3A - 12 %, $C_2(A,F)$ -

- 8% and free CaO - 0.7%. The basic mineral components of fly ash were: quartz, glassy phase and mullite. Fly ash has also contained a limited amount of non-burned coal, hematite, magnetite, calcium sulphate and free CaO.

Table 1 Chemical composition of starting materials.

Compound	Composition [wt. %]	
	OPC	FA
LOI	0.15	2.21
CaO	66.06	4.86
SiO_2	21.48	51.43
Al_2O_3	6.12	25.21
Fe_2O_3	2.63	8.35
SO_3	0.19	0.52
MgO	1,46	3.06
K_2O	1.05	2.84
Na_2O	0.16	1.01

Portland clinker (85%) and fly ash (15%) were initially pulverized in a laboratory ball mill. Then gypsum or $CaSO_3 \cdot 0.5H_2O$ or the combination of these phases was added in the proportions presented in Table 2 in such amount that the total content of $CaSO_4/CaSO_3$ calculated as SO_3 amounted to 3% of total weight of every cement. The material was pulverized again until the acquisition of the cement with the specific surface equaling 320 ± 5 m^2/kg as measured by Blaine method. Calcium sulphate was added into cements as gypsum in its natural form ($CaSO_4 \cdot 2H_2O$ > 98%) and calcium sulphite - in the form of synthetic $CaSO_3 \cdot 0.5H_2O$.

Table 2 Molar ratio of SO_4^{2-}/SO_3^{2-} in blended cements.

Symbol of cement	Molar ratio of SO_4^{2-}/SO_3^{2-}	Symbol of cement	Molar ratio of SO_4^{2-}/SO_3^{2-}
BC-0	only SO_4^{2-}	BC-3	1:1
BC-1	4:1	BC-4	1:2
BC-2	2:1	BC-5	only SO_3^{2-}

Initial and final setting times (Vicat method) were determined in the pastes prepared from the above described cements. The analysis of compressive and flexural strength of mortars at w/c ratio = 0.5 was carried out on 4 x 4 x 16 cm samples kept in the water which temperature was 18 ± 2° C. The strengths of those mortars were determined after one day and after 3, 7, 28 i 90 days.

In order to explain what products are created in the reactions in $3CaO \cdot Al_2O_3 - CaSO_3 - H_2O$ system, two mixtures at molar ratios $3CaO \cdot Al_2O_3/CaSO_3$ equalling respectively 1:3 and 1:1 have been prepared. Tricalcium aluminate and $CaSO_3 \cdot 0.5H_2O$ were pulverized until the size of grains was smaller than 20 μm. The hydration of those mixtures was carried out in a normal temperature at a liquid to solid ratio equalling 1.0. Phase components of the samples were determined by an X-ray method in the range of the angles 5 - 40° $2\Theta CuK_\alpha$. DTA/TG and SEM/EDS studies were also performed.

RESULTS AND DISCUSSION

The resuts of the determination of BC paste setting time is shown is Table 3, and the determination of compressive and flexural strengths of mortars in Tables 4 and 5. The figures in parentheses include relative strengths (percentage of BC-0 cement strength).

Table 3 Setting time of BC pastes.

Symbol of cement	Normal consistency of pastes [w/c]	Setting time of cement pastes	
		Initial setting [h-min.]	Final setting [h-min.]

Table 5 Flexural strength of BC mortars.

Symbol of cement	Flexural strength of cement mortars [MPa]				
	1 day	3 days	7 days	28 days	90 days
BC-0	4.3 (100)	5.9 (100)	7.2 (100)	8.4 (100)	9.2 (100)
BC-1	3.7 (86)	5.7 (97)	7.3 (101)	8.0 (95)	9.2 (100)
BC-2	3.2 (74)	5.2 (88)	6.4 (89)	8.7 (103)	9.4 (102)
BC-3	2.9 (67)	5.0 (85)	6.1 (89)	8.7 (103)	9.4 (102)
BC-4	2.6 (60)	4.6 (78)	6.0 (83)	8.1 (96)	8.9 (97)
BC-5	2.2 (51)	4.2 (71)	5.9 (82)	7.9 (94)	9.0 (98)

The XRD studies proved that in the process of chemical reactions between $3CaO \cdot Al_2O_3$ and calcium sulphite in the water environment, irrespective of the molar ratios of substrata, $3CaO \cdot Al_2O_3 \cdot CaSO_3 \cdot xH_2O$ phase is created. The attempt to determine an exact amount of water by means of DTA/TG turned out to be imprecise. The SEM/EDS studies showed that

$3CaO \cdot Al_2O_3 \cdot CaSO_3 \cdot xH_2O$ crystals created in a normal temperature are small and even after 28 days do not exceed 3 μm.

It seems that the differences in the setting time of BC pastes (Table 3) and the rate of increase in compressive and flexural strengths in cement mortars with different molar $CaSO_4/CaSO_3$ ratios (Tables 4 and 5) are probably the result of the fact that the $CaSO_3 \cdot 0.5H_2O$ dissolution is over 50 times smaller in comparison with $CaSO_4 \cdot 2H_2O$ dissolution and the fact that the gypsum in the cement - water system creates initially ettringite which quickly turns into monosulphate, and calcium sulphite creates only one phase - $3CaO \cdot Al_2O_3 \cdot CaSO_3 \cdot xH_2O$ (Bloss and Odler, 1982). In the cements containing enough $CaSO_4 \cdot 2H_2O$ (molar ratio of $CaSO_4/CaSO_3 > 1$), the setting of BC pastes is carried out in a typical way, but the layer of ettringite created on the grains of tricalcium aluminate is "insulated" by the tiny $3CaO \cdot Al_2O_3 \cdot CaSO_3 \cdot xH_2O$ crystals. Such layer prevents the hydration of $3CaO \cdot Al_2O_3$ for a period of time longer than the layer of "pure" ettringite. This causes that BC mortars containing gypsum together with calcium sulphite set slower than BC mortars containing only gypsum. The higher the amount of $CaSO_3 \cdot 0.5H_2O$ in relation to gypsum (BC-1, BC-2 and BC-3), the longer the setting time for BC mortars. The addition of too big an amount of $CaSO_3 \cdot 0.5H_2O$ in relation to gypsum causes the opposite process - the setting time for BC mortars is shorter. The reason for quick setting of BC mortars containing relatively small amounts of gypsum or containing no gypsum but only $CaSO_3 \cdot 0.5H_2O$ lies in the slow process of dissolution of $CaSO_3 \cdot 0.5H_2O$. It causes the creation of $3CaO \cdot Al_2O_3 \cdot CaSO_3 \cdot xH_2O$ in the amount not sufficient to delay the hydration of $3CaO \cdot Al_2O_3$ for a required period of time. The increase of the setting time for BC mortars influences mechanic properties of cement mortars. It causes the decrease of compressive and flexural strengths in the first day of hardening. The lower $CaSO_4/CaSO_3$ molar ratio in blended cement is, the higher a relative decrease of strengths of all BC mortars is. Within 3 - 7 days cement mortars, in which molar ratio of $CaSO_4/CaSO_3 > 1$, reach the strengths which are similar to the strengths of BC-0 cement mortars. In BC-4 and BC-5 ($CaSO_4/CaSO_3 < 1$) cement mortrars the decrease of strengths was greater. Those mortars had the strength similar to BC-0 mortars after 90 days.

CONCLUSIONS

Calcium sulphite is chemically active in the cement - water system and in the mixture with gypsum (molar ratio of $CaSO_4/CaSO_3 > 1$) can be used as a setting time regulator for blended cements containing fly ash.

The presence of $CaSO_3 \cdot 0.5H_2O$ in blended cements (molar ratio of $CaSO_4/CaSO_3 > 1$) prolongs the setting time of BC pastes and decreases compressive and flexural strengths of BC mortars in an initial period of their hardening.

Blended cements which contain a lot more calcium sulphite than gypsum set faster than cements containing only $CaSO_4 \cdot 2H_2O$. However, those cements have lower compressive and flexural strengths..

MICROSTRUCTURAL CHARACTERISTICS OF BY-PRODUCTS OF PETROLEUM COKE BLENDED COAL COMBUSTION

Shondeep L. SARKAR, Sarkar & Associates, Inc., Houston, Texas, USA
Jan Richard PRUSINSKI, Portland Cement Association, Sugar Land, Texas, USA

ABSTRACT: Three by-products, namely fly ash (FA), bottom ash (BA) and flue gas desulfurization product (FGDP) from an experimental burn using a fuel mixture of 90% coal + 10% petroleum coke (PC) at a power plant in Texas, USA, were characterized microstructurally. The results demonstrate differences in particle size, sulfate and unburnt fuel contents. No significant difference in glass content was noted. The minerals produced were nearly the same, but their proportions varied. The coal + PC fuel blend imposed restrictions by way of sulfate content and unburnt fuel particles in the FA.

Key-words: Fly ash, bottom ash, flue gas desulfurization product, coal, petroleum coke

INTRODUCTION

An experiment to burn petroleum coke (PC) as a partial replacement for subbituminous Wyoming coal was initiated at a Texas power plant generating 2400 MW of electricity from four coal-fired units.

Higher calorific value of PC reduces energy cost. Additionally, its higher burning efficiency produces lesser amount of ash. Nonetheless, the higher sulfur content of PC is a major constraint for burning it without proper gas entrapment facilities. To meet the U.S. Environmental Protection Agency's regulation concerning maximum SO_2 emission, 10% PC by weight of total fuel was calculated as the permissible replacement value.

After a trial combustion using this fuel mixture, the three by-products, namely FA, BA, and FGDP that were collected for laboratory analyses, were compared with the three corresponding by-products of conventional coal combustion from the same power plant. The identifiable mineralogical, chemical, and microstructural differences that arise from this change in fuel are reported.

The chemical analysis results show that Class C FA with CaO >20% is produced. A conspicuous increase in its SO_3 level occurs with coal + PC combustion, but not in the corresponding BA. The LOI also increases noticeably in the FA and BA, indicating the presence of more unburnt fuel. The Al_2O_3 and SiO_2 contents do not change as a result of blended fuel. A decrease of nearly 1% Fe_2O_3 in both FA and BA when coal + PC is used is noteworthy. Higher LOI of the BAs suggests a concentration of unburnt carbon in this by-product, whereas it represents carbonate and loss of SO_2 in the FGDP when ignited. As expected, the FGDPs are mainly constituted of Ca and SO_3 (with minor variations) and very small amounts (<1.0%) of other oxides.

Bulk chemical analyses (Table 1) also supports this trend. Despite a lower amount of total SO_3 in FGDP of coal + PC combustion, its soluble form of SO_3 is higher, suggesting the possible presence

of more bassanite ($CaSO_4 \cdot 1/2H_2O$). Soluble Na is mostly concentrated in the FA. Though the total Na_2O in FGDPs is low, it is mostly in the soluble form. The mineralogical compositions of these by-products determined from XRDA are summarized in Table 3.

RESULTS

Table 1: Chemical analysis of coal and coal + petroleum coke combustion by-products (weight percent)

BP*	Fuel Type	SiO_2	Al_2O_3	CaO	K_2O	Na_2O	SO_3	Fe_2O_3	TiO_2	LOI
FA	Coal (C)	31.0	19.3	27.5	0.3	2.1	1.8	7.3	1.7	0.2
	C + PC	31.3	18.8	24.4	0.4	1.8	3.0	6.6	1.5	3.9
BA	Coal (C)	36.2	16.9	20.9	0.3	1.4	1.0	8.5	1.3	7.7
	C + PC	37.0	16.8	19.6	0.3	1.2	1.1	7.0	1.3	10.0
FGDP	Coal (C)	0.4	0.1	41.2	0.02	0.01	52.6	0.3	.01	8.9
	C + PC	0.8	0.4	42.8	0.05	0.02	45.4	0.3	.02	8.5

* BP - By-product

Table 2: Chemical analysis of soluble analytes (mg/L)

BP	Fuel	Ca	K	Na	SO_4
FA	Coal (C)	60.0	9.3	97.0	36.0
	C + PC	240.0	8.4	86.0	660
BA	Coal (C)	280.0	0.7	13.0	480.0
	C + PC	120.0	1.3	8.0	250.0
FGDP	Coal (C)	700.0	2.6	33.0	1480.0
	C + PC	810.0	1.6	36.0	1710.0

Soluble Ca and SO_3 ions in the three by-products of coal combustion follow the order:
FGDP >> BA >> FA (Table 2)

This trend, however, changes slightly in the case of coal + PC combustion to:
FGDP >>> FA > BA

Table 3: Mineralogical composition of by-products

Fuel	FA	BA	FGDP
Coal (C)	Quartz, anhydrite, merwinite, periclase, free lime	Quartz, graphite, calcite, anorthite, gehlenite	Hannebachite, bassanite, calcite
C + PC	Quartz, anhydrite, merwinite, periclase, free lime, magnetite	Quartz, graphite, calcite, anorthite, gehlenite	Hannebachite, bassanite, calcite

Though the glass content of the FAs did not appear to change with change in fuel type, the characteristic hump in the XRD pattern of BA for coal + PC combustion was higher. The mineral types did not change except for possible magnetite formation in the coal + PC fired FA. The contents, however, vary due to the change in fuel (Table 3).

Table 4: Thermal analysis of FGD products

Fuel	Peak 1		Peak 2		Peak 3	
	Temp.	Wt. Loss	Temp.	Wt. Loss	Temp.	Wt. Loss
	°C	%	°C	%	°C	%
Coal	140	3.82	390	1.93	740	1.54
Coal + PC	100	0.70	385	4.40	750	5.72

From thermal analyses (Table 4) it is postulated that slightly different forms of $CaSO_4$ hydrate are formed, represented by a difference in the first endotherm positions (100°-140°C). Hannebachite ($CaSO_3 \cdot 1/2\ H_2O$) and $CaCO_3$ exhibit greater weight loss at 385°C and 750°C respectively for coal + PC combustion. In the chemical analysis, however, there is negligible difference in ignition loss. From scanning electron microscopy, the FA particles of coal + PC combustion were observed to be more textured. Fused glass particles and unburnt fuel were clearly identified in the corresponding BA. The FGDPs were composed of two types of mineral, one which is highly geometric (prismatic, euhedral, thin platy), and the other occurs as lumps. No difference in their compositions could be established from microprobe analysis. The strong preferred orientation of bassanite suggests that the platy crystals are basanite, whereas the lumps represent hannebachite.

The particles in the coal + PC-fired FA are finer; in the corresponding BA only 30% particles are

finer than 10 μm versus 61% in the coal-fired one. The general particle size distribution pattern can be represented as: BA >> FA > FGDP

DISCUSSION

The FA produced from coal + PC combustion apparently is formed either under a hotter burning zone or under a cleaner and sharper flame resulting in smaller size of particles (Sarkar and Bonen, 1993). The larger hump in the XRD pattern of its BA can be attributed to higher amorphous phase; presence of unburnt coal, however, cannot be ruled out in view of its notably higher LOI. The higher calorific value of PC sets up a new crystallization regime. Not only does this affect the particle size, but also the amount of glass phase formation. Coal + PC combustion produces distinctly higher amount of sulfate due to less efficient heat transfer. Mullite was conspicuously absent in these ashes. According to McCarthy et al. (1988), low Al_2O_3 (10-15%) leads to the formation of other minerals. In the BAs investigated, gehlenite and anorthite were identified although, the Al_2O_3 content was slightly higher (16.8%). Gehlenite was also reported by Diamond, (1981).

Expansion and fracturing of $CaCO_3$ occurs in the scrubber during FGD sulfatization. Hannebachite is the first mineral to crystallize. Partial oxidation of this sulfite mineral converts it to the bassanite form of sulfate as observed in these FGDPs, whereas gypsum is formed from more complete oxidation. No gypsum was identified in either of the FGDPs.

The unburnt fuel particles in FA and BA from coal + PC combustion may be due to more rapid temperature rise of the higher calorific value PC, suggesting an incompatibility of conjunctive burning of these fuels; it is important to stabilize the calorific value when using fuels with varying heat generating capacity, and it is also necessary to control the balance of fuel streams.

From this study it appears that FA produced from this blend of coal + PC combustion will impose serious restrictions on its use in concrete because of its higher sulfate content and unburnt fuel particles; the latter is expected to increase the demand for air entraining agent when incorporated in concrete mixture.

CONCLUSIONS

The three by-products of coal + petroleum coke combustion, namely FA, BA and FGDP show differences in terms of particle size and unburnt fuel particles from those of conventional coal firing. Distinctly higher amounts of total and soluble sulfate in FA from this blended fuel combustion can impose restrictions concerning its use in concrete. The presence of unburnt fuel can be related to incompatibility in the blend, whose calorific value needs to be stabilized, in addition to controlling the balance of fuel streams.

ABSTRACT A comprehensive compositional and microstructural examination has been made of cements, blended with fly ash (class 'F') and blast furnace slag, cured for 6 years. The evolution of the phase assemblage is continuing; some unreacted slag and fly ash remain. The reactivity of fly ash particles is particularly variable, ranging from completely unreacted to almost totally consumed. Pore fluid compositions were determined on solutions following extraction under high pressure.

Key-words: Blended cement, curing, microstructure, phase composition, pore solution

INTRODUCTION

Pozzolanic materials such as blast furnace slag and fly ash have been used as cement admixtures for many years. The composite matrix is dynamic in that there is continual change in the mineralogy, microstructure and aqueous phase chemistry with time. It is assumed that eventually the cement matrix will approach a steady-state in terms of the solid and aqueous chemistry. Studies to date have normally been carried out on laboratory samples aged up to 2 years (Taylor, 1990) or on aged specimens with undefined history (Thomas et al., 1992). Uncertainty exists concerning the impact of complete or nearly complete reaction on internal properties. Accelerated curing at temperatures in the range of 40-60°C have also been considered (Luke & Glasser, 1988) to accelerate reaction, though there has been question as to the relevance of elevated temperature cure to the steady-state attained at ambient temperature.

The present study reports the solid and aqueous chemistry of OPC and OPC blended pastes cured under controlled conditions for 6 years, at ~25°C, by which age it was assumed that most of the pozzolanic reaction would have taken place. Results have previously been reported for the same blends cured up to 2 years (Luke & Glasser, 1988, 1988a). The data generated can also be used to verify and develop models and to obtain a base-line from which the effect of environmental exchanges can be addressed.

EXPERIMENTAL

The ordinary portland cement (OPC) used in all preparations conformed to BS 12 specification and is comparable to that of an ASTM Type 1. Blending agents consisted of two commercially available class F fly ashes (FA) and one slag (BFS). The FA's were obtained from the British base-load power stations, Eggborough and Longannet. Their crystalline mineral content, as determined by X-ray diffraction and optical microscopy, included quartz, mullite, spinel close to magnetite and unburnt carbon. The BFS was supplied by Clyde Cement Ltd., and had a glass content of ~ 97% as shown by petrographic examination. Chemical and physical data for the raw materials have previously been reported (Luke & Glasser, 1988).

Cylinders of OPC and OPC blends, in the proportion of 30% admixture / 70% OPC (wt), were prepared as described previously (Luke & Glasser, 1988a) and stored at ~25°C and 100% RH. A 2g section from each cylinder was taken prior to pore fluid extraction, quenched in acetone to stop hydration, and oven-dried at 60°C. These sections were then subjected to solid phase analyses. Analytical electron microscopy (AEM) was carried out on argon-beam thinned sections using a JEOL 2000X EX Temscan electron microscope with LINK AN 1085/S analytical system. X-ray data were obtained using a Rigaku DMAXB diffractometer with $CuK\alpha$ radiation and Ni-filter. A sample of each section, not quenched in acetone, was analysed for $Ca(OH)_2$ content by thermogravimetry using a Seiko 320 SSC 5200 DTA-TGA thermoanalyser.

Pore fluid, ~5 ml, was extracted from the cylinders by a technique modified from that developed by Longuet et al. (1973). Mg and Ca contents were determined by atomic absorption spectroscopy while Na and K were determined by atomic emission spectroscopy using a Pye Unicam SP9 spectrophotometer. SO_4^{2-} content was obtained using a Dionex 2010i anion chromatograph. Spectrophotometric methods, using catechol violet (Dougan & Wilson, 1974) and molybdenum blue (Ramachandran & Gupta, 1985) reagents, were used to determine the Al and Si contents respectively. Total OH^- content was measured by titration with dilute HCl.

RESULTS

Solid Phase

SEM micrographs typical of the 6yr hydrated cement are shown in Fig 1 while those of the blended systems are shown in Figs. 2-4. Morphologies of the hydrated products in the neat cement paste are characteristic of those reported at earlier ages (Luke & Glasser, 1987). Fig 1a shows a somewhat open structure as expected for a W/S of 0.6, with CH platelets of variable dimensions well distributed throughout the specimen,. The C-S-H appears to be present principally in fibrous form, Fig 1b. In the case of the FA blended pastes the overall morphology is somewhat different. Less CH is present and the C-S-H is less well defined. Fig 2a shows the relict of an Eggborough FA particle; the outer section was determined to be of a mullite composition while the inner section was composed of a mixture of C-S-H, CH and fine needles of ettringite. A high percentage of almost totally unreacted particles were also observed of which Fig 2b is typical. The Longannet FA tended to have somewhat different morphological characteristics in comparison with the Eggborough FA, as seen in Fig 3a. The large micropores of the FA tend to become more evident on hydration and were a common feature in the Longannet FA blend. The structure remaining between the pores appeared to be composed of mullite crystals. In this case more of the FA particles seemed to have reacted although in many cases not completely, Fig 3b. The central particle in Fig 3b shows a reaction rim surrounding a central core; however the space between the rim and the core was atypical. The morphology of the slag blend, Fig 4, also differed considerably from that of the neat cement. Fig 4a shows formation of a more dense microstructure in which CH crystals are less well defined and unreacted slag grains persist as illustrated in Fig 4b.

Figs 5-7 are of argon-milled specimens of the pastes; numbers indicate areas selected for individual spot analysis. Characteristically, OPC cement pastes have C/S ratios in the range of 1.7-2.0 whereas in the present study ratios of up to 5 were observed This suggests that the some of the C-S-H analysed in Figs 5a and b (neat OPC) had embedded CH. Fig 8 shows a plot of Al/Ca ratio against Si/Ca. Ca-rich phases, Si/Ca~0.01, due undoubtedly to CH or calcite were also observed but were omitted from Fig 8 due to scaling factors. The fibrous phases in Fig 5a

and b at points 5 and 4 respectively, are of similar composition. Point 5 has a composition (based on hypothetical oxides and ignoring the presence of water or hydroxyl) of $Ca_{6.00}Si_{1.60}Al_{1.58}S_{1.59}Mg_{0.01}Fe_{0.01}O_{17}$ and is somewhat richer in Si and S and lower in Al compared

to point 4 which has a composition of $Ca_{6.00}Si_{1.41}Al_{2.35}S_{0.77}Mg_{0.01}Fe_{0.05}K_{0.03}Ti_{0.01}O_{15}$. It is believed that this fibrous phase, indicated in Fig 8 by the region E/T, is an ettringite/thaumasite solid solution. The phase rich in both Al and Ca as evidenced from Fig 8 and which corresponds to the lath-like crystals, 5, Fig 5b, has an atomic ratio Ca:Al:Si of 2:2:1, i.e. it is probably C_2ASH_8. Small fibrous particles, 6, situated adjacent to these lath-like crystals, had a similar composition though their Si content was much higher and are believed to be a mixture of C_2ASH_8 and C-S-H. Unreacted ferrite was also observed in the paste.

Figs 6a-d are representative of the FA blend. Analysis of the unreacted particles of Longannet FA, Fig 6a, b, shows it to be a mullite FA, whereas the Eggborough FA, Fig 6c, d, is primarily calcium-aluminium silicate having mean Si/Ca=0.34 and Al/Si=0.85. The C-S-H observed in the proximity of the Longannet FA, Fig 6a, has Si/Ca ratios of 0.83 -1.0 and is similar to that previously reported for C-S-H close to FA in a 10 year old mortar (Sato & Furuhashi, 1982). This is illustrated in Fig 9 where elemental ratios, Al/Ca versus Si/Ca are plotted. In general, Si/Ca ratios of the C-S-H from the hydrated cement lie between 0.56 to 0.67 while the Al/Ca is approximately 0.13 which is consistent with the results of Harrisson et al. (1986) for a 91 day old cement paste, with 28% FA and w/s=0.5. Interestingly in Fig 6b there appears to be no FA reaction product between the FA mullite crystals and the C-S-H. Fig 6c clearly shows reaction rims of FA hydration product, points 2, 3, 4 and 10. Elemental analysis gives a mean Si/Ca ratio of 0.34 and Al/Ca of around 0.30. The Si/Ca is lower than reported in the literature and could be due to inclusion of CH. Points 4 and 5, Fig 6a and points 1,2 and 6 Fig 6b have Al/Ca > 5.0 and are omitted from Fig 9 due to scaling factors. The elemental analyses of these points are consistent with mullite. Points 1, 2 and 3 in Fig 6d are Fe-rich: point 4 is a mixture of CH and C-S-H.

Fig 7 is a typical section of hydrated slag cement. Points 1 and 6 are representative of the internal composition of what appears to be completely hydrated slag grains. Oxide ratios (normalised to 10 oxygens for convenience) are $Ca_{2.61}Si_{1.16}Al_{1.44}Mg_{2.59}S_{0.05}K_{0.03}Ti_{0.04}Fe_{0.05}O_{10}$ and $Ca_{0.73}Si_{0.56}Al_{2.60}Mg_{3.98}S_{0.03}K_{0.12}Ti_{0.01}Fe_{0.03}O_{10}$, respectively, which are consistent with mixtures of C-S-H and hydrotalcite (Luke & Glasser, 1987a). The relict remaining in the hydrated slag particle, defined by point 5, is rich in both Ti and Fe and has the composition $Ca_{3.24}Si_{1.32}Al_{1.35}Mg_{0.54}S_{0.07}K_{0.01}Ti_{0.57}Fe_{0.14}O_{10}$. The large lath-like crystals at point 7 are ettringite, low in Si, unlike the high-Si thaumasite-like phase found in the neat OPC paste. Points 2, 3, 4 and 8 are indicative of C-S-H from cement paste between slag particles and have C/S of 1.82, 1.77, 1.68 and 1.66, respectively. Points 1-8 are illustrated in Fig 10 in terms of the Al/Ca ratio versus Si/Ca ratio. Si/Ca ratios of the slag relicts are considerably lower than the 0.62 value given by Harrisson et al. (1986) for blended pastes hydrated at 6 and 14 months.

XRD data for more crystalline components of the OPC and blended cement pastes are given in Table 1. Ettringite and AFm were observed in substantial amounts in both OPC and FA. XRD of the slag cement indicated only AFm while AEM also suggests the presence of trace amounts of ettringite. Hydrotalcite was clearly evident in the slag paste and was also observed but to a lesser extent in the FA blends. Mullite and quartz associated with FA particles were also detected. $Ca(OH)_2$ was observed in all pastes but was most prevalent in the neat OPC paste. This is further confirmed by the thermogravimetric analysis, Table 2, which shows the OPC to contain 32 wt% $Ca(OH)_2$ in comparison to ~11wt% in the FA blends and 19 wt% in the slag blend with $Ca(OH)_2$ content corrected for calcium present as $CaCO_3$.

Table 1 Phases observed by XRD in OPC and OPC-blended cements

Paste	C-S-H	AFt	AFm	Hydr	$Ca(OH)_2$	Calc	Vat	Mul	Qtz
OPC	+	++	++		+++	+			
OPC/Eggb	+	+	+	+	+	++		+	+

OPC/Slag	++		++	++	++	+			

Calc=calcite, Vat=vaterite, Mul=mullite, Qtz=quartz + trace ++ minor +++ major

All samples showed some degree of carbonation, primarily as calcite, though the OPC Longannet blend also contained some vaterite. Unidentified peaks of weak intensity with d-spacings at 4.40, 2.27, 1.67 and 1.63 (Å) were observed in XRD of both OPC and OPC blended pastes and were most prevalent in the OPC paste.

OPC/	120	233	1.23	6.15	2.33	4.6	0.037	13.4
Eggborough	*77*	*175*	*0.47*	*2.11*	*1.1*			*13.3*
OPC/Slag	106	181	0.77	2.83	0.92	0.59	<0.02	13.3
	69	*125*	*0.99*	*0.67*	*<0.3*			*13.2*

intervening four year period, most noticeably in the neat OPC paste where there is a 85% increase in Na^+ and 193% increase in K^+. The OPC blends show a significantly lower increase, averaging 52% in Na^+ and ranging from 13 - 45 % in K^+. $SO4^{2-}$ concentrations are also notably higher in the 6 year old pastes with an increase of approximately 13% in the OPC paste and around 144-320% in the OPC blends. Aluminium concentrations also significantly increased though absolute concentrations remained low. Ca^{2+} concentrations increased in the OPC and OPC slag blends but decreased in the OPC FA blends which undoubtedly relates to the availability of $Ca(OH)_2$. pH in all cases was relatively constant between 2 and 6 years.

Pore fluid data for the 6 year old paste were run through the program MINEQL to give an indication on which solid phases are solubility-limiting for the components of the aqueous phases. Data are presented in Table 4 where a log saturation index (I) close to zero indicates close to saturation, <0 undersaturation and >0 oversaturation. Ca^{2+} solubility, as expected, is 'controlled' primarily by $Ca(OH)_2$ as it is the most soluble calcium-containing phase in all pastes. Sulphate solubility is not apparently limited by either gypsum, since the I values are all significantly negative, or AFt, where the high positive values indicate considerable supersaturation, in which case, AFt should precipitate spontaneously. This suggests some other phase(s) may be responsible for the observed sulphate solubility. The I values for C_3AH_6 indicate this could be the solubility "controlling" phase for aluminium but the notable absence of C_3AH_6 in both the XRD and SEM studies suggest this is questionable: clearly it is not $Al(OH)_3$. High positive I

Table 4. Log saturation indices (I) for pore fluids in Table 3, calculated by MINEQL with upgraded NEA/EIR database.

Cement	CH	AH_3	MH	CS	Si gel	C_3AH_6	AFt
OPC	+0.15	-	+3.0	-3.1	-	-	-
OPC/Longannet	-0.33	-1.8	+3.3	-1.6	-2.1	-0.32	+4.7
OPC/Eggborough	+0.01	-1.6	+3.4	-2.1	-2.8	+1.1	+4.9
OPC/Slag	-0.28	-1.9	+3.0	-2.5	-3.5	-0.43	+1.9

values for $Mg(OH)_2$ indicate that the pore fluids are supersaturated with respect to this phase: Mg contents should be < 0.001mM, the solubility product of $Mg(OH)_2$. Hydrotalcite which is known to exist in OPC pastes (Luke & Glasser, 1987a, Roger & Groves, 1989) is most likely the solubility "contolling" phase for Mg: solubilities for hydrotalcite were, however, not determined. Aqueous Si solubility would appear not to be determined by C-S-H gel, according to the high negative I values obtained. There are, however, substantial differences in the solubilities of pure C-S-H systems compared to 'real' pore solutions (Atkins et al. 1993).

DISCUSSION

Hydration of OPC and OPC blends is an evolving process controlled by both aqueous and solid phase chemistry. Processes such as a decrease in pore solution volume as hydration proceeds and liberation of alkalis from anhydrous cement grains, FA and slag, for which there is no distinct solubility limit are continuous. Other ionic species ultimately approach a 'steady state' equilibrium dependent on the rate of dissolution and precipitation of phases. Since the rate of dissolution of OPC and blending materials differs markedly, so does the time scale to approach the 'steady state' equilibrium. The present data suggest that for both OPC and OPC-FA blends the time to steady state exceeds 6 years. The microstructures of the pastes at 6 years still show the influence of the original fly ash microstructures.

It has been well established that the use of FA and slag can significantly reduce or eliminate the expansion due to alkali-aggregate reaction. However the evidence regarding the efficiency of the FA or slag in suppressing alkali-aggregate reaction is conflicting and it has proved difficult to produce a consensus on guidelines for their use. Inasmuch as the blending materials used in this study were typical, it is not difficult to understand this conflict. It is well known that slag hydration differs from that of FA (Luke & Glasser, 1987a) but the FA's themselves show considerable variation. SEM indicates a higher degree of reaction in the Longannet FA compared to Eggborough FA though $Ca(OH)_2$ contents are equivalent. The $Ca(OH)_2$ content of the Longannet FA at 6 years is similar to that for 2 years. This suggests that the pozzolanic reaction had ceased at around 2 years. Eggborough FA on the other hand shows a 35% decrease in $Ca(OH)_2$ between 2 to 6 years representing a considerable degree of ongoing reaction.

At 6 years, the aqueous alkali concentrations of the pozzolan blends was much reduced compared to the neat cement, even though aqueous alkali concentration had been increasing from 2 years. Although total alkali was lower, it should be noted that the Na^+ concentration was higher than in the neat cement for both the Eggborough and slag blends. The pH of the solution remains relatively constant and it may be assumed that the partitioning of the alkalis, their release characteristics from the solid phase and the alkali pore solution composition are the more important parameters in the beneficial though often unpredictable properties of blended cements. The concentration of alkalis in the OPC paste shows a substantial increase from 2 to 6 years and suggests continued hydration with release of alkalis from the remaining cement grains and associated decrease in the volume of pore solution upon the formation of hydration products: this differs, however, with data reported by Atkins et al. (1993), where no substantial difference was observed in the aqueous phase of OPC pastes hydrated from 90 days to 10 years.

STUDIES ON ACTIVATION OF SLAG CEMENT

S. N. GHOSH, D. M. JOSHI, S. CHANDA and H. VAISHNAV
Gujarat Ambuja Cements Ltd., Ambujanagar
362715 Kodinar, Gujarat, India.

ABSTRACT An investigation on the feasibility of activating normal slag cement blend with alkali in the form of sodium silicate (waterglass) has been reported. In this multiple activators system, reasonable degree of improvement in early compressive strength development and reduction in setting time have been observed.

Key-words: Activation, Slag, Waterglass, Anhydrite, Cement.

INTRODUCTION

The production of slag cement in India is increasing but the use is limited to areas in the Eastern region of the country. The difficulty in acceptability of slag cement is mainly due to slow setting and lower early strength development compared to Ordinary Portland Cement (OPC). A market survey of slag cement showed the average compressive strenths are 11.86 (1d), 25.20 (3d) 37.94 (7d) and 53.04 MPa (28d) and average initial and final setting times are 165 min. (initial) to 220 min. (final). We conducted a detailed laboratory study on a steel plant slag and found that with the addition of alkali activator, improvement in properties can be achieved. For general acceptability all experiments were carried out on slag cement of conventional composition range and the present report is made out of these experiments.

EXPERIMENT

Materials

Granulated blast furnace slag (GBFS) was obtained from a steel plant in India. The chemical analysis is given in Table 1. The glass content of the slag is 96% as determined by optical microscopy. The basicity of the slag is 1.03 using (CaO + MgO + 1/3 Al2O3) / (SiO2 + 2/3 Al2O3). Cement clinker was obtained from our plant. The chemical composition is given in Table 1. Mineral gypsum or marine gypsum (Gyp) (after washing) was used along with anhydrite (gypsum heated to 150 deg.C for 3 hrs. in oven) in certain cases and marked as AG in the graph. Waterglass (WG) in solution of silicate modulus 3 was used. The chemical composition of the waterglass is SiO2 = 21.61%, Na2O = 7.20%, and its pH = 11.7.

Preparation and Testing

Compositions similar to normal slag cement i.e. slag, clinker & gypsum were used as base materials for making different batches. The percentage of slag was kept at 55, 65, 75 & 85. The water glass added in solution during grinding in a ball mill. (Gypsum and anhydrite were used at constant percentage). Preparation of batches (co-grinding) each about 6 kg. was made and the fineness (Blaine) was maintained around 400 m2/kg.

Normal consistency, setting time and mortar cubes (7.06 cm) were obtained as per IS-455 -1976. Autoclave Le-Chatelier tests were performed as per the above standard. The mortar cubes were cured in 100% RH at 27 +/- 1 deg. C for 24 hrs. and subsequently cured in water at the same temperature. Microscopic examinations (model Optiphot, Nikon) of hydrated slag cement samples (in powder mount, immersed in a liquid of suitable RI) were carried out after arresting hydration of the material. Particle size analysis of samples was done using Malvern Laser Beam

apparatus (Mastersizer-X model). X-ray diffraction (Rigaku D-Max 2000) and DTA (Rigaku Themoflex) studies of hydrated samples were undertaken.

Table 1 Chemical analysis of components.

OXIDE	CLINKER	SLAG	GYPSUM	OXIDE	CLINKER	SLAG	GYPSUM
SiO2	21.30	33.37	7.62	SO3	0.36	Tr.	40.71
Al2O3	5.64	19.62	0.68	Cl	0.003	-	0.57
Fe2O3	4.22	2.16		P2O5	0.14	-	-
CaO	65.30	33.64	28.90	MnO	-	0.76	-
MgO	1.62	9.60	Tr.	TiO2	0.50	-	-
K2O	0.42	1.00	0.22	IR	-	0.33	7.80
Na2O	0.21	0.20	0.36	LOI	-	-	21.88

RESULTS AND DISCUSSION

The addition of waterglass could lead to substantial gain in 1d and 3d compressive strength besides reduction in setting time. The increase was 91 to 42% (1d), 23 to 16% (3d) and marginally higher at 7d and 28d for 55 to 85% slag content. Fig 1 represents the increase of compressive strength of a 55% slag cement with different activators. The reduction in setting time (initial & final) was around 60 minutes.

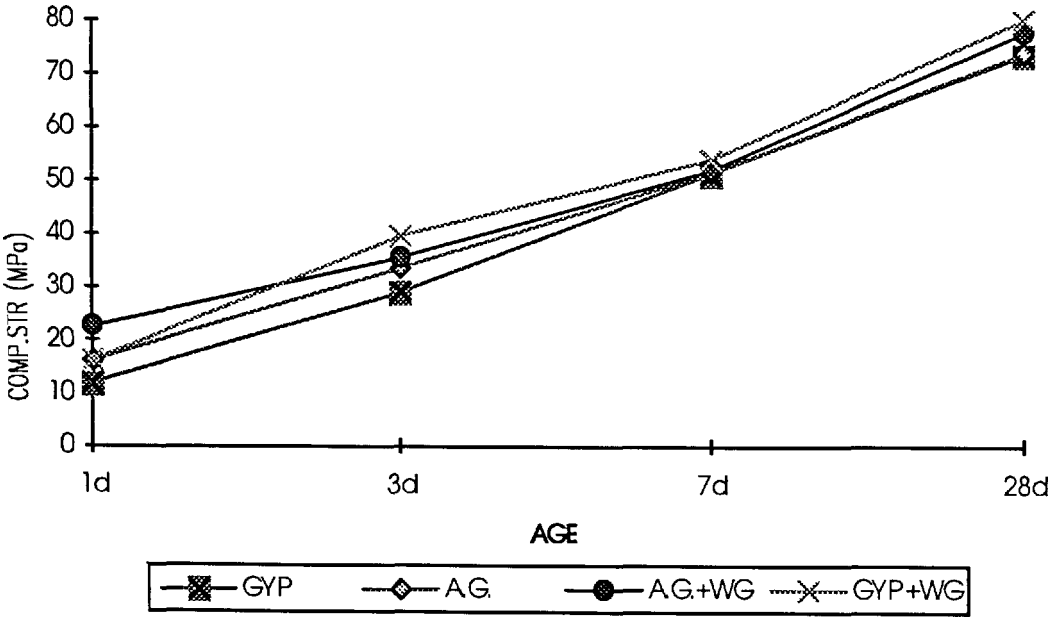

Figure 1 Effect of different activators on compressive strength.

In spite of the added alkali for activation of slag, compressive strength development above 65% slag containing batch, especially after 7d of hydration slowed down (Fig 2). This follows the pattern of normal slag cement hydration. Optical microscopy observation (X 400) of hydrated slag cement shows reacted slag pieces along the 'rims' in the initial stage of hydration i.e. even at 1d and later the surfaces of slag pieces were covered with this material (Fig 3). Similar observations of reacted rim of slag pieces had been reported earlier by Wilding and Mc Hugh (1986) and Richardson et al (1994). Formation of hydrotalcite type phase was indicated.

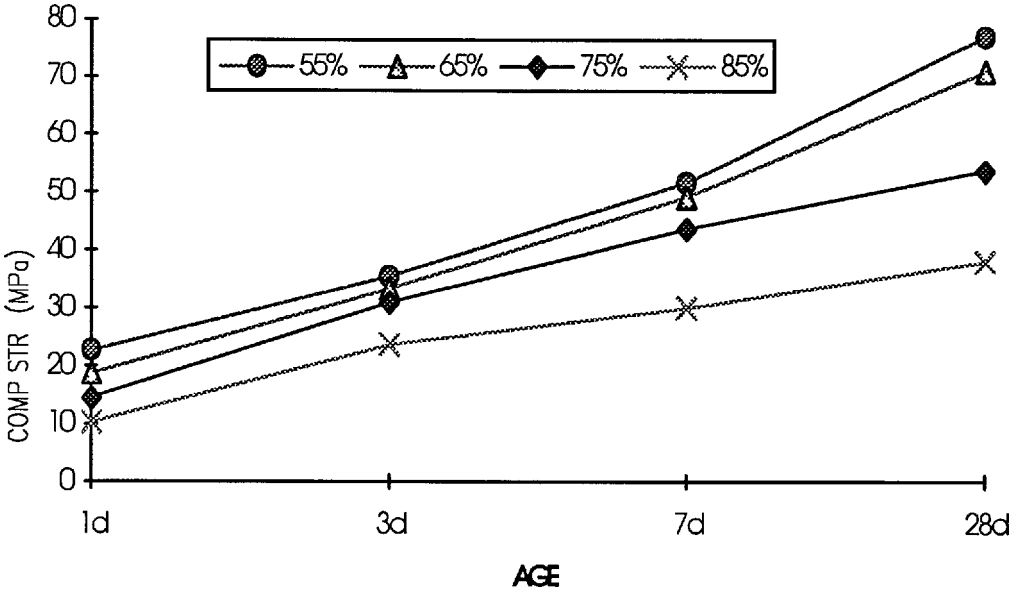

Figure 2 Compressive strength development with different percentage of slag addition.

There has been lot of research activity in the area of alkali activated slag in the Far East and in Europe. Wang et al (1994) reported the factors affecting the strength of alkali activated slag and recently Wang and Scrivener (1995) indicated presence of C-S-H(1), hydrotalcite and AFm type phases in NaOH/waterglass activated slag. The presence of C-S-H (82 deg.C, 112 deg.C), AFm type phase (150-200 deg.C), hydrotalcite type phase (384 deg.C), Ca(OH)2 (472 deg.C) can be identified by the DTA (Fig. 4) on the basis of hydrated OPC and alkali activated slag (Wang & Scrivener, 1995).

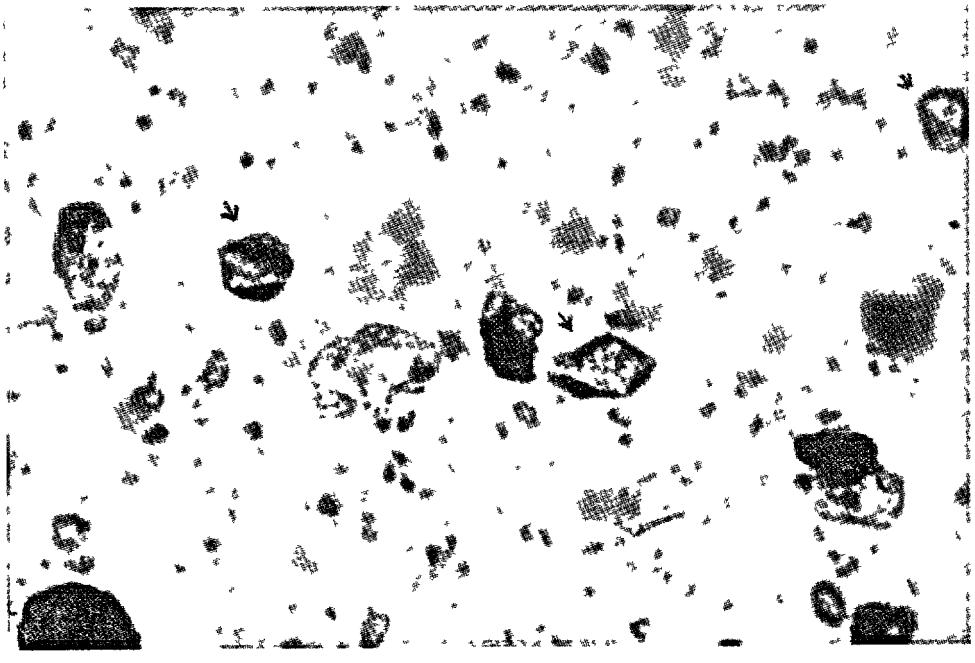

Figure 3 1d hydrated slag cement sample (x 400) - reacted slag (↑)

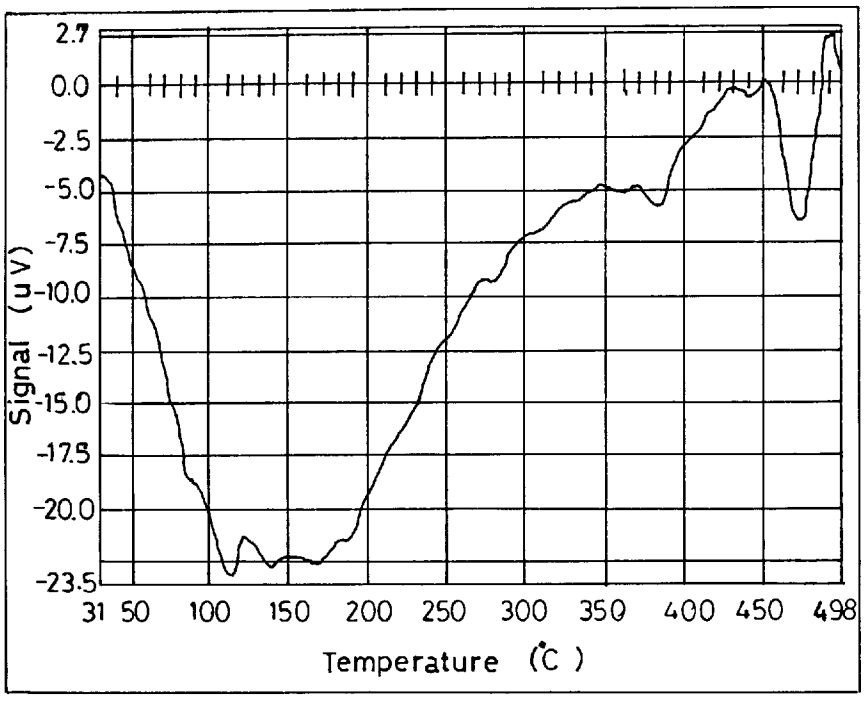

Figure 4 DTA patterns of activated slag cement (1d hydrated).

We carried out the detailed testing of one batch of our cement through our Concrete testing laboratory. Initial results appear satisfactory with respect to strength gain, workability, etc. In our system the content of alkali has been kept around 0.9 Na equ. Gifford and Gillott (1996) observed that increased alkali content for the activated BF slag cement concrete leads to a higher rate of consumption of reactive silica in the aggregates during the early stages of hydration. Hakkinen (1993) observed that with the increase of OPC content the number of micro cracks decreased in this type of cement.

EFFECT OF BLENDED GYPSUM ON THE PROPERTIES OF PORTLAND CEMENT AND PORTLAND SLAG CEMENT

Singh MANJIT, Central Building Research Institute
Roorkee - 247 667 (India)

ABSTRACT The effect of unprocessed phospho and fluorogypsum both independently and in combination with natural gypsum on various properties of portland and portland slag cement was studied. The adverse effect of P_2O_5 and F impurities in phosphogypsum and those of fluorogypsum was offset by blending the natural gypsum with the by-product gypsum. The properties of cements conformed to the requirements of cement produced with natural gypsum. As compared to phospho and fluorogypsum the power consumption for grinding cement was reduced on using the blended gypsum.

KEY-WORDS : Blast furnace slag; CSH; gypsum; environment; waste.

INTRODUCTION

Large quantities of by-product gypsum are produced by the chemical industry which are currently disposed off by dumping into rivers, pond or onto waste land. Due to increasing concern about environmental pollution, it is essential to utilize these wastes as building material. Attempts have been made by Olmez and Erden (1989), Tabikh and Miller (1971) and Singh (1988) to use phospho and fluorogypsum (by-products of phosphoric acid and hydrofluoric acid industries) in the manufacture of cement. The impurities of P_2O_5, F, organic matter, alkalies present in the gypsum adversely affect the setting and hardening of cement (Singh, 1987). The effect of unprocessed phospho- and fluorogypsum was studied on the properties of portland cement and portland slag cement with and without natural gypsum. The natural gypsum was blended with the by-product gypsum to reduce the bad effect of obnoxious impurities of P_2O_5 & F present in the waste material. The role of blended gypsum vis-a-vis by-product gypsum on the grindability properties of cements was examined. The results of these findings are discussed in the paper.

RAW MATERIALS

The phosphogypsum (P_2O_5 0.42%, F 1.12%, $CaSO_4.2H_2O$ 96.75%, fluorogypsum (CaF_2 1.5%, $CaSO_4$. 93.5%, pH 5.0), cement clinker (SiO_2 24.19%, Al_2O_3 + Fe_2O_3 7.9%, CaO 64.04%, MgO 3.34%, SO_3 0.31% and loss on ignition 0.70%), granulated blast furnace slag (SiO_2 35.85%, Al_2O_3 + $Fe_2O_3$19.12%, MnO 0.63%, CaO 39.62%, MgO 4.09%, SO_3 0.13% and Sulphur 0.54%, glass 98.0%) and natural gypsum (SiO_2 8.80% Al_2O_3+ Fe_2O_3 0.66%, CaO 30.25%, MgO 0.10%, SO_3 39.60%, $CaSO_4.2H_2O$ 85.14%) were used to prepare the ordinary portland cement (OPC) and portland slag cement (PSC) respectively.

EXPERIMENTAL

Preparation and Testing of Cement

The ordinary Portland Cement (OPC) was produced by intergrinding cement clinker with unprocessed phosphogypsum (UPPG) and fluorogypsum (F.G.) with and without natural gypsum (N.G.) at 2.0% SO_3 content. The cement mixes were ground to a fineness between 317 and 421 m^2/kg (Blaine). The cements produced were tested for consistency, setting time and compressve strength as per relevant Indian Standards. The grindability of the cement samples was studied as per Bond's grindability test (Kannewurf, 1957).

RESULTS AND DISCUSSION

The physical properties of OPC and PSC reported in Table 1 show that setting time prolonged while the compressive strength reduced (Figures 1 and 2). However, on addition of blended gypsum

	60 40	0.82	23.90	400	58.22

(UPPG/FG + natural gypsum), the setting time accelerated and the strength improved considerably (Figures 1 and 2). This may be ascribed to the dilution of impurities with the addition of natural gypsum. It is interesting to note that strength development of cement mortars were not affected by the impurities of fluoride of fluorogypsum, because most of the water soluble fluoride originate from fluoric acid, hence fluorogypsum does not so markedly retard the hydration of cement as the water soluble fluoride of phosphogypsum. The retardation is due to formation of silica gel or CSH (Na_2SiF_6 + $Ca(OH)_2 \longrightarrow CaF_2$ + C-S-H + NaOH) on the surface of cement grains. The power consumption for grinding cements (OPC & PSC) (Table 2) with fluorogypsum was mitigated on blending it with natural gypsum and found comparable to the values attained with natural gypsum.The presence of clay matter in natural gypsum apparently reduce the time of grinding thus, effecting power consumption.

HYDRATION CHARACTERISTICS OF STEEL SLAG IN ORDINARY PORTLAND CEMENT BLENDS

K. M. SHARMA, P. S. SHARMA and D. YADAV
National Council for Cement and Building Materials, New Delhi.
S. C. AHLUWALIA, OCL (India) Ltd., New Delhi, INDIA

ABSTRACT In view of the interest in the use of steel slag as a blending material for the manufacture of portland slag cement (PSC), investigations were carried out to explore the potentials of its use a reactive component by thermally activating it. Hydration of blends of air cooled steel slag and laboratory granulated steel slag with OPC over a period of six months under ambient and hydrothermal conditions have been studied and results reported.

Key-words : Activation, Hydration, Steel slag.

INTRODUCTION

Integrated steel plants produce two major slag wastes; blast furnace slag and steel making slag, more commonly known as steel slag. In India, presently about 1.8 million tonnes of steel slag is generated per year and an estimated 12 million tonnes of steel slag is accumulated. With the expansion of steel industry the volume of steel slag is likely to increase many times over creating a potential for a serious environmental problem and the requirement for a disposal site. The properties and use of blast furnace slag for making blended cements are widely known. A comparative evaluation with blast furnace slag indicates vital differences in terms of chemical, mineralogical and physical characteristics of the two slags. In view of the interest in the use of steel slag as a blending material for the manufacture of portland slag cement, investigations were carried out to explore the potential of its use as a reactive component by thermally activating it. Hydration characteristics of air cooled steel slag and the laboratory granulated steel slag have been studied and the results are presented in this paper.

EXPERIMENTAL

Steel slag, granulated blast furnace slag (GBF Slag), portland cement clinker and gypsum samples were obtained from the major steel and cement plants respectively and used for the preparation of cement blends. The elemental analysis of the raw materials are given in Table 1. Mineralogical characteristics of the raw materials were determined by X-ray diffraction and optical microscopic techniques.

TABLE 1 : Elemental Analysis of Raw Materials

S. No.	Sample Details	LOI/GOI*	Constituent (Percent) SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	Na_2O	K_2O
1.	Clinker	1.68	21.65	4.00	5.55	63.46	2.08	0.73	0.86
2.	Steel Slag	2.32	14.21	24.40	4.17	44.32	10.32	0.08	0.07
3.	GBF Slag	0.65	33.41	0.89	20.05	34.24	8.86	0.16	0.82
4.	Gypsum	14.22	18.55	0.83	1.40	23.83	0.97	-	-

Gypsum sample contains 34.95 % SO_3; purity works out to 75%
Clinker contains 0.27% CaO_f, Steel Slag contains 1.00 % TiO_2

*GOI = Gain on ignition

Activation of Steel Slag

Steel slag sample was melted in laboratory furnace at 1400°C and the molten slag was poured in water to granulate it (Sharma et al., 1992). The granulated slag so obtained was dried and ground to fineness of 400 m^2/kg and used for making blends with OPC.

Hydration Studies

The blends prepared air cooled with steel slag, granulated steel slag and granulated blast furnace slag were hydrated upto 180 days. The hydration was arrested by treating the hydrated samples with acetone and drying under vacuum. XRD and SEM techniques were employed for characterising hydration products.

Performance Studies

Blends of OPC-Steel slag, OPC- laboratory granulated steel slag and OPC-granulated blast furnace slag were prepared along with a control OPC sample maintaining the fineness level of all the samples at 350 m^2/kg Blaine. The performance characteristics of all the samples were determined as per the relevant Indian Standard and the data is presented in Table 2.

Table 2 : Performance cement blends prepared from air cooled and laboratory granulated steel slag and blast furnace slag (Fineness 350 m^2/kg Blain)

Sample No.	Composition %			w/c	Setting Time (min)		Compressive Strength (N/mm^2)

* Laboratory granulated steel slag

RESULTS AND DISCUSSIONS

Evaluation of Raw Materials

The OPC clinker used in the present investigation contained 49.65 % C_3S, 24.61 % C_2S and had only 0.27 percent free lime.

The elemental analysis of granulated blast furnace slag indicates the presence of 34.24 and 33.41 percent of CaO and SiO_2 respectively. The sample also has 20.05 % Al_2O_3 and 8.86 % MgO. The optical microscopic analysis has indicated 92 % glass content in the sample. The elemental analysis of steel slag indicates the presence of 44.32 and 24.40 percent CaO and Fe_2O_3 respectively. Apart from CaO and Fe_2O_3 the sample also contains 14.21, 10.23 percent SiO_2 and MgO respectively. Optical microscopy has indicated the presence of only 34 % glass content in the air cooled steel slag.

Evaluation of elemental analysis data presented in Table 1 indicates that both the slags fulfill the chemical requirements laid down in Indian Standard Specification IS:12089-1987 for the slag to be used for the manufacture of portland slag cement.

However, steel slag does not fulfill the requirement of the glass content laid down in Indian Standard Specification. An attempt was therefore made to granulate steel slag in the laboratory by heating it to 1400^{O}C and quenching in water. The results indicate an increase in glass content from 34 to 60 percent. These results are confirmed by X-ray diffraction analysis which shows higher amorphous material in laboratory granulated steel slag. The diffractograms are presented in Fig. 1.

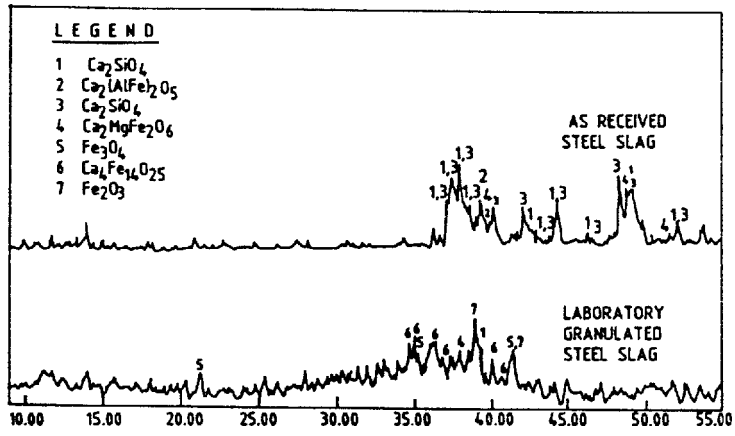

FIG. 1 : XRD OF AIR COOLED AND GRANULATED STEEL SLAG

Hydration Characteristics

The results of hydration studies indicate that the hydration of OPC starts immediately both in PSC-1 and PSC-2 prepared from air-cooled steel slag and laboratory granulated steel slag respectively. Presence of low quantities of $Ca(OH)_2$ and unhydrated ß-C_2S in blend prepared with laboratory granulated steel slag indicate faster hydration in it compared to the blend prepared with air cooled steel slag (Sharma et al., 1995). The diffractograms are presented in Fig.2.Scanning electron micrographs of hydrated samples of PSC-1 and PSC-2 under ambient conditions at 90 and 180 days have been presented in Plates 1 and 2. The results have shown the presence of unhydrated ß-C_2S upto 90 days and $Ca(OH)_2$ even upto 180 days alongwith C-S-H and other hydration products in PSC-1 where as in blend prepared with laboratory granulated steel slag (PSC-2) presence of cloud of C-S-H was noticed along with other hydration products as such as calcium aluminate hydrate etc. At 180 days hydration no $Ca(OH)_2$ was observed. Results indicate a higher degree of hydration for blend prepared with laboratory granulated steel slag. Performance studies of the blends (Table 2) confirm these findings. Autoclaved products however, were same: tobermorite, portlandite and α-quartz in both the cases. ß-C_2S was also fully hydrated under autoclaving condition.

180 days

PLATE 2 : Hydrated PSC-2

CONCLUSION

1. Air cooled steel slag contains only 34 % glass content and shows poor hydraulicity. Steel slag granulated in the laboratory showed considerable improvement in glass content and the hydraulicity.
2. Results of hydration studies conducted at ambient temperature upto 180 days indicated much better and faster hydration for blend prepared from laboratory granulated steel slag. The findings have been confirmed by the performance data.

MODIFICATION OF ALKALI ACTIVATED SLAG PASTES BY USE OF MINERAL ADMIXTURES

Witold BRYLICKI, University of Mining and Metallurgy, Kraków, Poland

ABSTRACT The pastes produced from the ground, granulated blast furnace slag, activated with 5 % Na_2CO_3 additive and containing different mineral admixtures, such as ground portland cement clinker, portland cement, converter slag, bentonite clay and natural zeolite were studied at varying w/c ratio and curing conditions. The physical and mechanical properties of pastes were investigated as well as their phase composition, microstructure and porosity.

Key - words : admixtures, blastfurnace slag, durability, microstructure.

INTRODUCTION

The alkali activated slag binders show several good practical properties; particularly high corrosion resistance should be underlined. As a result of long term studies, these materials have been applied for many purposes; among them the injection - sealing works are particularly interesting (Brylicki, Malolepszy, Stryczek 1992, 1993, 1994). Mineral admixtures can succesfully improve the parameters of alkali activated slag paste - the results of investigations are the subject of presented work.

EXPERIMENTAL

Materials

The alkali activated slag binders were produced from the ground granulated blast furnace slag and 5 % Na_2CO_3 activator, 5 - 10 wt. % of the following admixtures were also used : ground portland cement clinker, portland cement class 45, ground converter slag, bentonite clay and natural zeolite. The pastes were cured in the following three ways : stored in standard conditions, at temperature 18 ± 2° C, RH > 90 %; heated at ambient pressure within 2 - 6 - 2 h cycle (max. 80° C); autoclaved at 180° C within 1 - 4 - 1 h cycle.

Methods

The following properties of slag - alkaline binders were studied : water demand, setting time, rheology, flexural and compressing strength, linear dimension changes using standarized procedures. The phase composition and microstructure were characterized by XRD, SEM and EDS as well as by porosimetry.

Results

The composition of pastes with admixtures are given in Table 1 together with the water demand (as w/c at standard consistency) and setting data. The fluidity, rheology and strength was measured on pastes of consistency used in sealing - injection works. The fluidity was evaluated by conus test, the relative viscosity was measured by Ford cup No 4 and rheology - by rotating viscosimeter Fann V - G 355. The results are shown in Table 2 and 3. The sample numbers correspond to the compositions given in Table 1. The linear dimension changes of 40x40x160 mm bars were measured in the Graf - Kaufman apparatus. The bars were produced from pastes of standard consistency. The results are presented in Table 4.

Table 1. Water demand and setting characteristics of slag - alkaline pastes with admixtures

Sample No	Compositttion of paste (in wt. %)	w/c at standard consistency	Initial setting [min.]	Final setting [min.]
1	95% bfs + 5% Na_2CO_3	0.29	155	320
2	85% bfs + 5% Na_2CO_3 + 10% PC cl	0.28	20	58
3	85% bfs + 5% Na_2CO_3 + 10% PC45	0.30	25	70
4	90% bfs + 5% Na_2CO_3 + 5% conv	0.26	65	169
5	85% bfs + 5% Na_2CO_3 + 10% bent	0.33	54	232
6	85% bfs + 5% Na_2CO_3 + 10% zeol	0.30	47	140

* following abbreviations are used : bfs - blast furnace slag; PC cl - portland cement clinker; PC 45 - portland cement class 45; conv - converter slag; bent - bentonite clay; zeol - natural zeolite.

5	+ 0.22	+ 0.24	+ 0.65	+ 0.78

The phase composition studies by XRD method on standard, 28 days cured samples revealed the presence of near amorphous C - S - H, calcite and calcium carboaluminate $C_3A\ CaCO_3\ 12H_2O$. In the 6 months stored samples the hydrogarnets were detected with varying Si/Al ratio as well as zeolites, such as thomsonite $CaNa_2\ [Al_5\ Si_5\ O_{20}]\ 12H_2O$ and natrolite $Na_2Al_2Si_3O_{10}\ 2H_2O$. The low pressure steam curing did not change the phase composition. In the autoclaved samples the better crystalized calcium silicate hydrates appeared (1.13 nm tobermorite). In Figure 1,2 the SEM micrographs and EDS plots of hydrogarnets and sodium - calcium zeolites are shown. These zeolites are modified by the presence of Mg^{2+} and K^+ ions being the components of pastes.

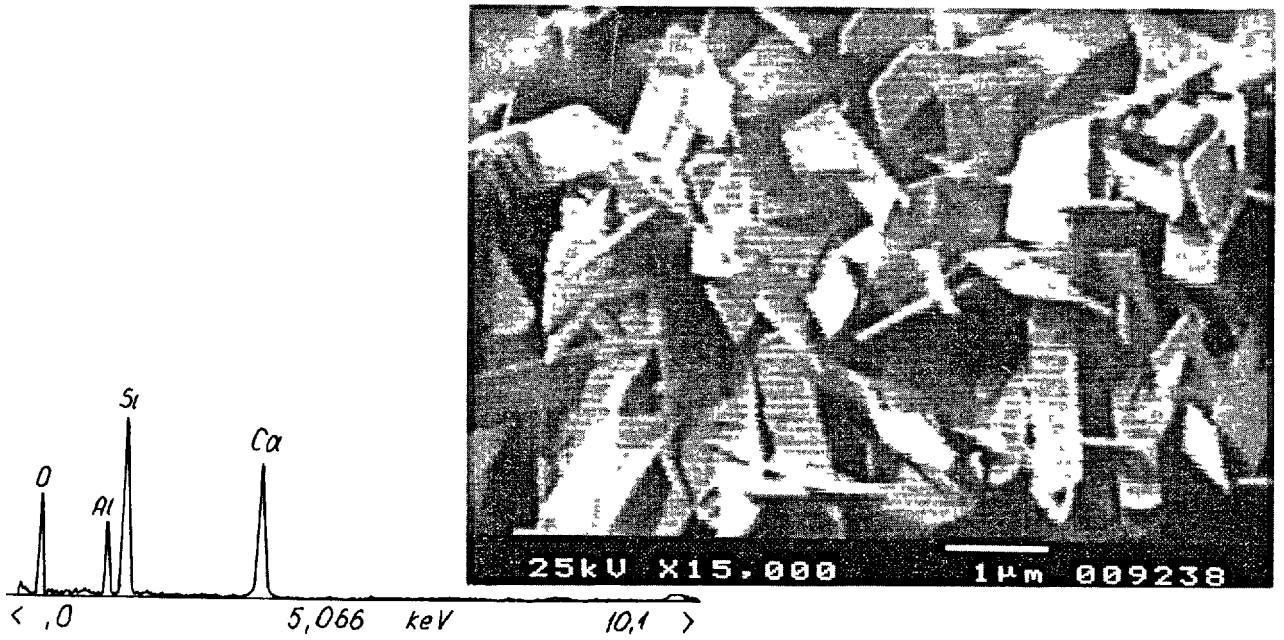

Fig.1. SEM : slag - alkaline paste with zeolite after autoclaving, the hydrogarnets crystals rich in Al are visible; EDS of hydrogarnets.

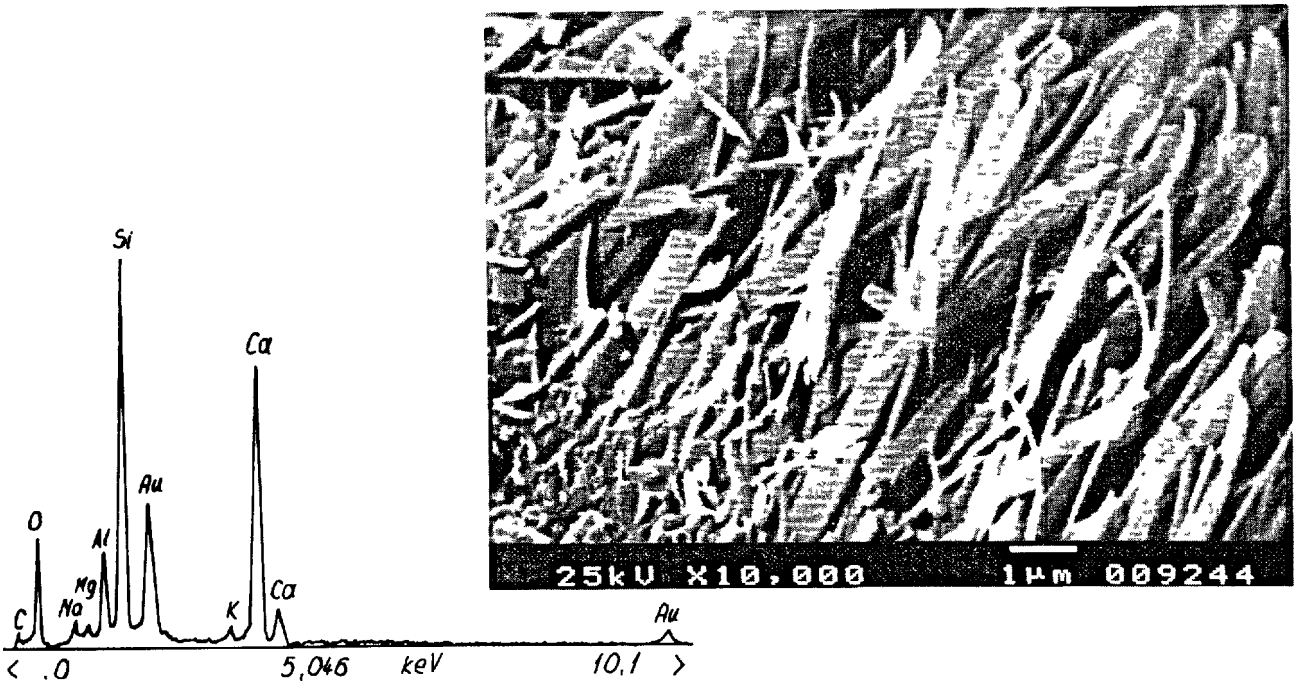

Fig.2. SEM : slag - alkaline paste with zeolite after autoclaving, the alongated zeolite crystals are visible; EDS of zeolite.

The results of porosity measurements are presented in Figures 3 and 4.

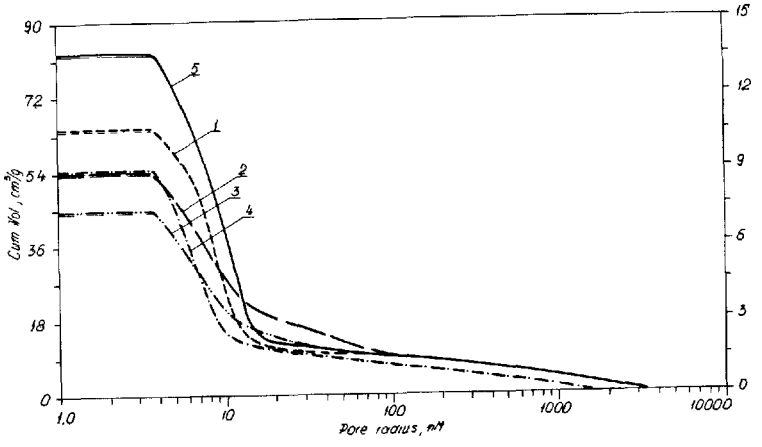

Fig.3. Porosity of hardened slag alkaline pastes 1 - 5 cured 6 months at standard conditions

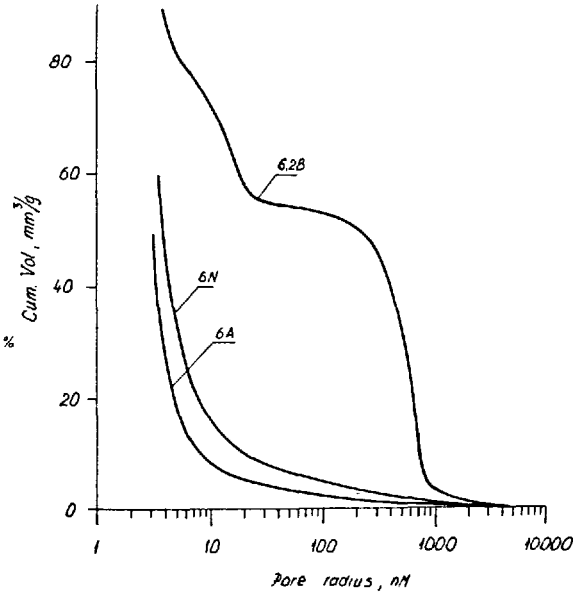

Fig.4. Porosity of hardened slag alkaline pastes admixtures with zeolite cured at standard conditions (sample 6,28) heated (6N) and autoclaved (6A).

CONCLUSIONS

1. Mineral admixtures improve substantially the properties of fresh and hardened slag - alkaline paste. This fact is of special, practical importance.

2. In the presence of mineral admixtures the water demand of slag - alkaline pastes does not change generally, setting time is significantly reduced, as well as shrinkage. In the presence of bentonite clay the expansion occurs.

3. Slag - alkaline pastes with mineral admixtures show very good flowability and rheology at w/c >0,45; simultaneously fairly good strength is maintained. From rheological point of view they correspond to the Casson's liquids.

4. Mineral admixtures do not alter significantly the phase composition but strongly affect the microstructure of hydrogarnets and zeolites.

5. Portland cement, clinker, converter slag bring about the reduction of total porosity and sealing of slag - alkaline pastes. Bentonite clay causes the porosity increase due to expansion.

Thermal treatment of pastes results in total porosity decrease with a significant change of pore structure.

ACTIVATION OF BLAST FURNACE SLAG/HIGH ALUMINA CEMENT PASTES: MECHANICAL AND MICROSTRUCTURAL EVOLUTION

Mª Luisa ROMERO, Mª Teresa BLANCO-VARELA, Angel PALOMO, Francisca PUERTAS and Tomás VÁZQUEZ, Instituto Eduardo Torroja (CSIC), Spain.

ABSTRACT This study focuses the evolution of phases and the mechanical-resistant behaviour of high alumina cement (H.A.C.) mixed with granulated blast furnace slags (GBFS) and Na_2CO_3 2N as activator at 5 and 40ºC. Among other effects, the activator inhibits formation of C_2ASH_8 (at low temperature), induces carboaluminates formation and favours strengths.

Key-words: High alumina cements, Blastfurnace slag, microstructure.

INTRODUCTION

The hydration of high alumina cement (H.A.C.) mixed with slags produces different phases from those obtained by separate. The formation of hydrated gehlenite (C_2ASH_8) is of great interest, since it can result in a major phase (Fentiman et al., 1990)

The purpose of this work is to study the development of strengths, at different ages, in samples of high alumina cement with addition of slags in different proportions, and activator solution (dissolution of Na_2CO_3, 2N), and how the temperature affects their composition.

EXPERIMENTAL

Two types of hydration samples were prepared:
- High alumina cement + slags + standard solution (H_2O)
- High alumina cement + slags + activation solution (Na_2CO_3, 2N)

with three different mixtures:

A= 80% of high alumina cement + 20% of slags
B= 50% " " + 50% "
C= 20% " " + 80% "

The specific surface of the high alumina cement was 3.021 cm^2/gr, and that of the slag was 4.337 cm^2/gr. In Table 1 the chemical analysis of both samples is shown.

Table 1 Chemical Composition of High alumina cement and Slag

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	H_2O comb.	S^{2-}
H.A.C	2.85	42.47	15.31	40.49	-	-	-	-
Slag	36.88	11.70	0.49	41.87	8.71	-	0.31	0.94

After drying at 100º C and homogenizing the mixtures, they were hydrated with distilled and deionized water and with a solution of Na_2CO_3 2N. Solution/powder ratio was 0.4.

All hydrated samples were stored in saturation chambers (100% RH) and kept at two different temperatures : 5ºC and 40ºC.

Samples were removed after 3, 7, 28 and 90 days. The process of hydration was interrupted in each case by "freezing" the sample with acetone and ethanol, and they were vacuum filtered. The pastes obtained were analyzed through XRD and FTIR.

Flexural strengths were determined at 28 and 90 days in two series of 1x1x6 cm prisms, one mixed with water, others with the alkaline solution. Samples were kept at 5ºC and 40ºC at 100% RH chambers. Samples were stripped off moulds 24 hours later and put again into their corresponding humidifying chambers, at the two chosen temperatures. Moreover, microstructural studies by SEM and EDAX were carried out on samples.

RESULTS AND DISCUSSION

Hydrated samples without activator, cured at 5ºC

In Table 2, results obtained by XRD are shown. At 3 and 7 days the major phase was CAH_{10}. In A samples (20% of slag) the most part of the anhydrous phases did not react during this period.

Table 2 XRD results of samples without activator (5°C).

+ : Abundant. o : Little, trace.
* : Moderate. - : None.

B Samples (with 50% slag) also showed hydrated gehlenite that became the major hydrated phase after 28 days, which agrees with Fentiman et al.(1990) and with Richardson et al. (1990). In the C samples (with 80% of slag), this was already a major phase at 7 days of hydration.The amount CAH_{10} in all samples decreased as slag amount was higher in the sample; that is, it showed a reciprocal evolution to this of the hydrated gehlenite. Thus, with 80% of slag, after 28 days hydration, samples were free of CAH_{10}.

IR absorption bands, typical of C_2ASH_8, used to be partly overlapped by those of aluminates and by those of the slag; however, in the IR spectra of the samples (Fig. 1) their presence could be clearly observed at 1130cm^{-1}. In samples with 80% of slag and 90 days of hydration, they gave broad, blurry bands in the region of OH stretching (3200-3600cm^{-1}) supposedly caused by the presence of amorphous (gel type) or poorly crystallized hydrates. A study by means of SEM and EDAX was carried out in samples with 80% of slag, at 28 and 90 days, in order to identify the hydrated gehlenite and the amorphous phase already detected through IR. Grains of slag are surrounded by plate-like hydration products growing perpendicular to their surface (Fig. 2). This product is hydrated gehlenite, as it was observed by EDAX analysis. Moreover, the presence of an amorphous phase surrounding the slag could be observed (Fig. 3), whose analysis through EDAX indicated that its composition did not correspond to any known hydrate and it also extended beyond from C-S-H gel phases or alumina gel. This amorphous phase detected through IR and observed through SEM, could

probably be a mixtureof C-S-H gel and other aluminum-rich gels, and even hydrated phase gels that did not have crystallized yet.

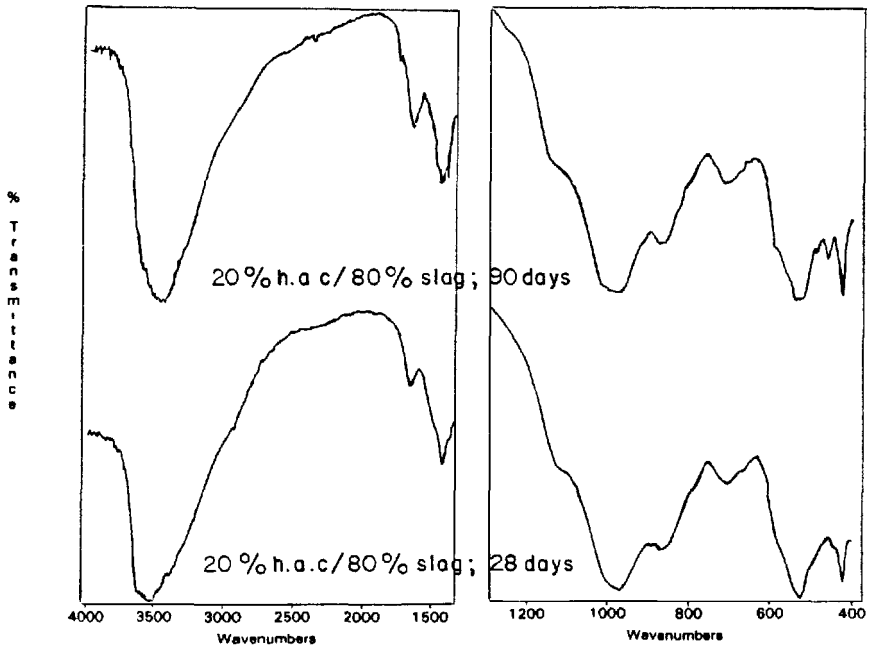

Fig.1. IR spectra of samples with 20% H.A.C. and 80% of slag

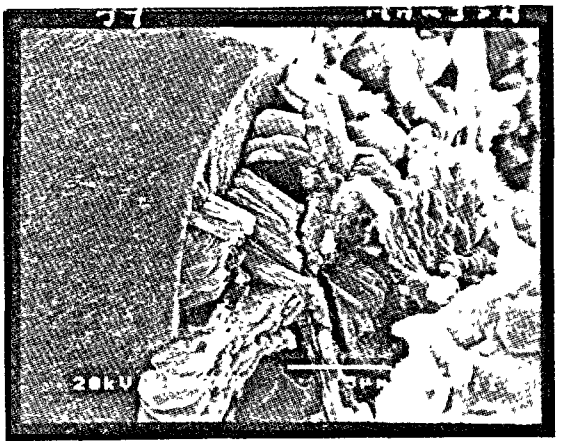

Fig. 2. Hydration products growing suround to slag grains.

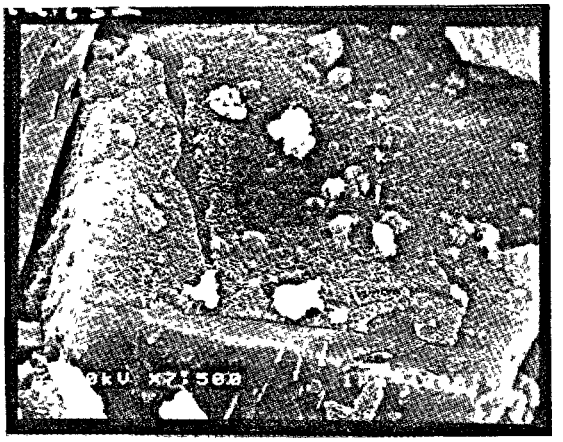

Fig. 3. Amorphous phase unknown

The formation of these gel type phases in reaction products of aluminous/slags mixtures has been proved by several researchers (Edmonds et al., 1989; Majumdar et al., 1989).
Flexural strength tests (Fig. 4) showed that at 28 days hydration, the paste with the highest strength (without act., at 5°C) was the one with 50% of slag. With 20% and 80% of slag, strengths at 28 days were lower but they increased with time. No doubt that initial low strengths in samples with higher content of slag were due to the low hydration rate of slags.
These results indicate that at low temperatures, and at 90 days, the reaction of the CAH_{10} with the slag silicates results in a diminish of strengths.

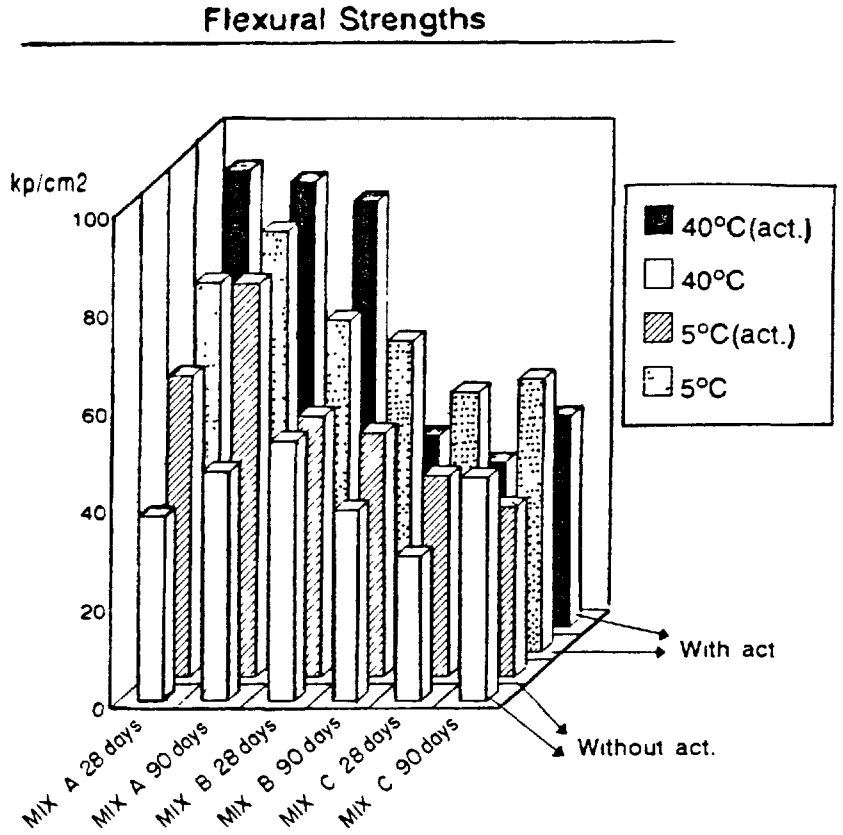

Fig. 4. Flexural strengths of specimens at 5 and 40°C with and without activator.

Hydrated samples with activator, cured at 5°C

Cement pastes hydrated with activator solution and kept at 5°C gave diffractograms which indicated, in all cases, the presence of CAH_{10} which decreased when the slag increased (Table 3). This hexagonal hydrate remains practically constant with time when the amount of slag was 20% and contained a small amount of monocarboaluminates (C_4AcH_{11}). When the amount of slag increased in the mixture, the CAH_{10} decreased with time, in the same proportion as C_4AcH_{11}. In the case of samples with 80% of slag, the amount of C_4AcH_{11} was negligible, but the increase of calcite was considerable.

Table 3 XRD results of samples with activator (5°C).

AGE (DAYS)	CA			CAH_{10}			C_4AcH_{11}			$CaCO_3$			F F		
	A	B	C	A	B	C	A	B	C	A	B	C	A	B	C
3	+	+	-	+	+	*	-	-	-	-	-	+	+	-	-
7	+	+	-	+	o	*	o	o	-	-	-	+	+	-	-
28	+	+	-	+	+	o	o	o	-	-	-	+	*	-	-
90	+	+	-	+	*	o	o	o	-	-	-	+	*	-	-

+ : Abundant. o : Little, trace.
* : Moderate. - : None.

Such results indicate that the activator induces carboaluminates formation, and prevents the C_2ASH_8 formation when there is a moderate amount of slag. When the amount of slag is high, $CaCO_3$ develops because the reaction of Na_2CO_3 from the activator with the Ca^{2+} of the slag released into solution.

Even though the presence of aluminum hydroxides was not detected through XRD, in the IR spectra corresponding to the samples with 20% and 50% of slag (Fig. 5), absorption bands at 3620-3525-3394-3376, 1024 and 970 cm^{-1}, which are characteristic of AH_3 (gibbsite), were clearly visible. The intensity of these bands in spectra is lower in older samples.

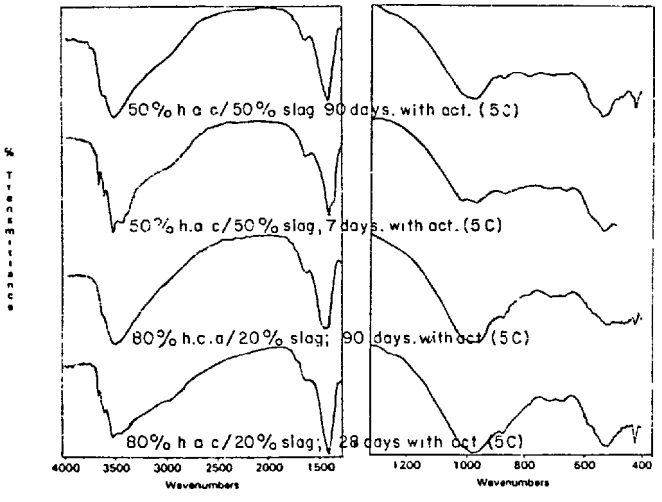

Fig.5 IR spectra of samples with act. (5°C)

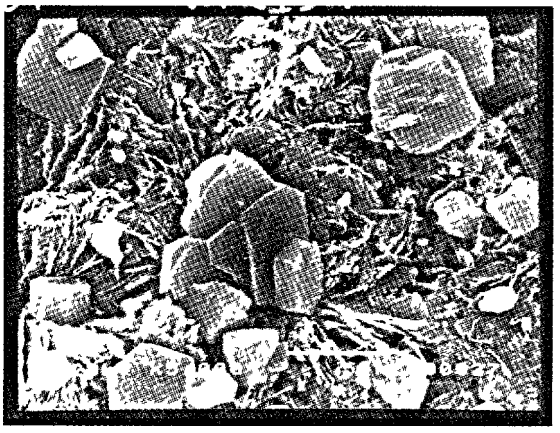

Fig.6 Crystal of CAH_{10}

This interpretation is verified by SEM studies carried out on these samples, where crystals of about 2 - 5 microns could be seen, and whose analysis by EDAX indicated that those were crystals containing almost exclusively aluminum (Fig. 6). Also, hexagonal crystals corresponding to CAH_{10} were seen.

The strenght of these samples made with addition of activating solution, were highly superior to those mixed only with water, which lead us think that the formation of carboaluminates confers these high, probably non-permanent, strenghts. The only exception is the 90 days hydration sample with the higher proportion of slag; this was precisely the case where no carboaluminates were detected, only calcite and the hexagonal hydrate.

The highest strengths were obtained when the proportion of slag was 20%.

Hydrated samples without activator, cured at 40%

XRD data (Table 4) indicates a logical absence of hexagonal hydrates. Diffraction lines, characteristic of cubic hydrate (C_3AH_6) and of hydrated gehlenite (C_2ASH_8) appeared instead.

Table 4 XRD results of samples without activator (40°C).

AGE (DAYS)	C_3AH_6			C_2ASH_8			$Al(OH)_3$			C_4AcH_{11}			F F		
	A	B	C	A	B	C	A	B	C	A	B	C	A	B	C
3	+	+	-	o	+	+	o	-	-	-	-	o	-	*	*
7	+	+	-	o	+	+	o	-	-	-	-	o	-	*	*
28	+	+	-	o	+	+	o	-	-	-	-	o	-	o	*
90	+	+	-	o	+	+	o	-	-	-	-	o	-	o	*

+ : Abundant. o : Little, trace.
* : Moderate. - : None.

The cubic hydrate was most abundant at early ages when the slag proportion was 20%; but it diminished when the proportion of slag increased, and was absent when slag amount reached 80%. Instead, C_2ASH_8 started to be noticeable in growing amounts.
These data indicated that slags, depending on their proportion in the mixture, prevent the formation of cubic hydrate, total or partially, because of the formation of hydrated gehlenite. The characteristic lines of AH_3 were only present in samples with 20% slag. Through IR (Fig. 7), spectra of samples with 50% and 80% slag, the broadening of absorption bands could be noticed, particularly in 3400-3600 cm^{-1}, presumably caused by hydrated amorphous compounds.

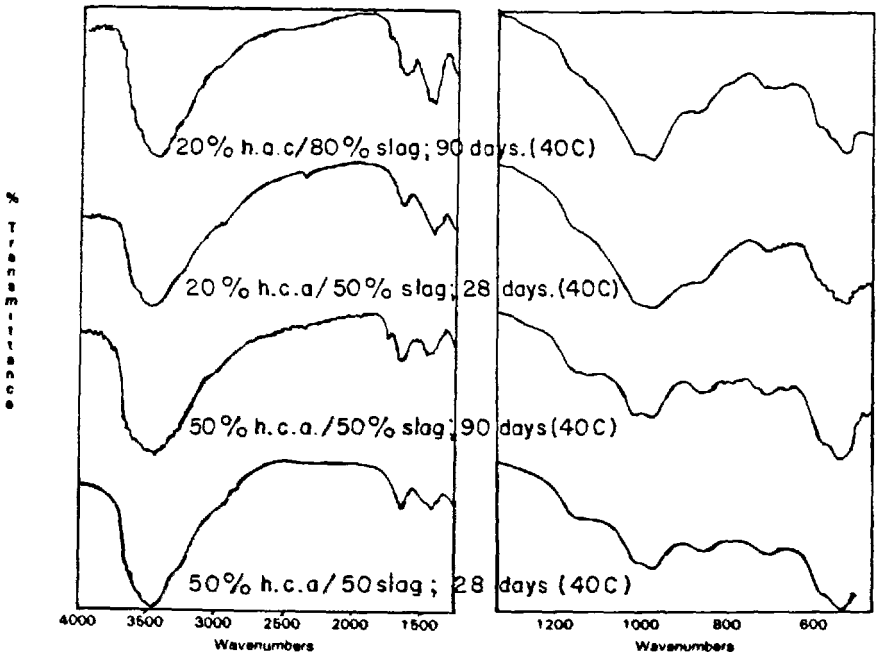

Fig.7. IR spectra of samples at 40°C

Therefore it is asssumed that absence of AH_3 bands is due to the fact that hydrated gehlenite does not only form from the reaction of hexagonal hydrates with the silica of the slag, but also

from aluminum hydroxide. Fetiman et al, (1990) support this hypothesis.
The evolution of the strength of these samples (Fig.4) indicates that a higher temperature favours a fast acquisition of mechanic strengths, at least along the ages studied in this work.

Hydrated samples with activator, cured at 40° C

Phases with silica incorporated in their structures were abundant in these samples as a consequence of a reaction of the cubic hydrates of the H.C.A. with the solubilized silica of the slag, which was favoured by rising temperatures.
The XRD of samples with 20% slag (Table 5) showed the simultaneous presence of C_3AH_6, katoite (hydrogarnet which formula is close to C_3ASH_4), and AH_3. This proportion (especially in the case of the katoite) increased with time. A small amount of hydrated gehlenite, was also observed. The katoite could be detected through IR because of the characteristic bands of the C_3AH_6; particularly, the intense sharp band of free OH, in 3663 cm^{-1}, diminished considerably and it is shifted to 3645 cm^{-1} (Fig. 8).

Table 5 XRD results of samples with activator (40°C).

90	+	-	-	o	o	-	+	-	-	o	o	-	+	-	-	-	-	+	*	o	-

\+ : Abundant. o : Little, trace.
* : Moderate. - : None

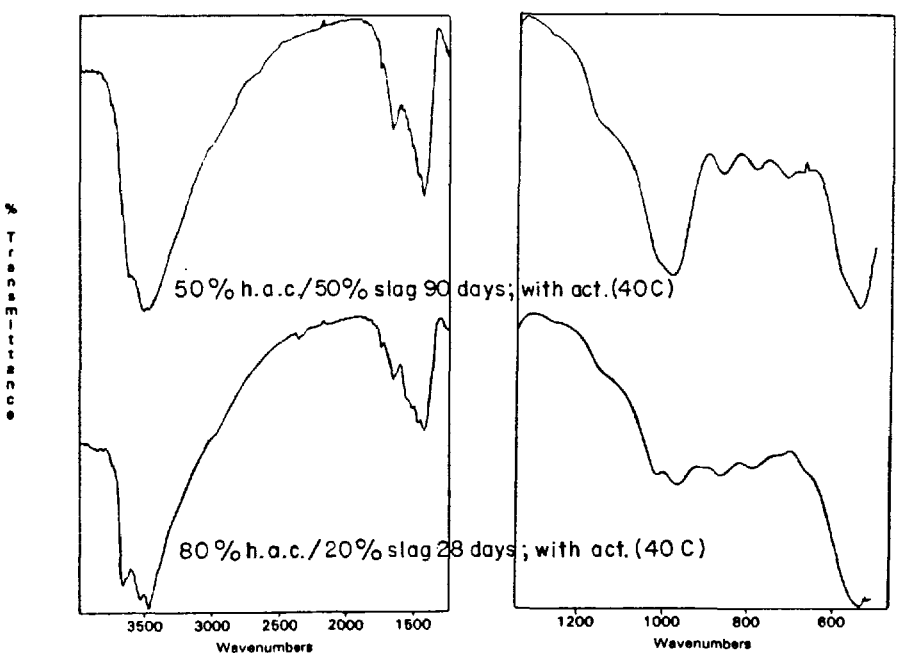

Fig. 8. IR spectra of samples with act. (40°C)

Samples with 50% slag had hydrated gehlenite as the only crystalline hydrate. The only crystalline compound in samples with 80% slag was calcite.

Bands with low definition, associated with gel type phases could be seen through IR (Fig. 8).
The presence of activator in samples cured at 40ºC favours the development of mechanical strengths (with 20% and 50% of slag) (see Fig. 4), while when 80% is added, the strength is decreased due to the scarcely reactive to the ages studied.

CONCLUSIONS

On samples cured at 5ºC

- Hydrated gehlenite (C_2ASH_8) is the major stable crystalline product which develops at low temperature in H.C.A. mixtures with a high proportion of slag, and hydrated with water. Its formation is mostly triggered by the reaction of the CAH_{10} and the dissolved silica from the slag. Amorphous phases, probably mixtures of C-S-H gel and other gels rich in aluminum, also appear.
- The activator prevents C_2ASH_8 formation. It also induces carboaluminates formation when amounts of slag are moderate. When the content of slag is very high, $CaCO_3$ appears due to the reaction of the activator with the Ca^{2+} of the slag, that is found in the solution.
- In samples manufactured with activator solution the resistances are higher than in samples mixed only with water. This indicates that formation of carboaluminates confers higher resistances which, in another hand, might not be permanent.

On samples cured at 40ºC

- The rise of temperature favours a fast strength increase.
- The slags, depending on their proportion in the mix, prevent total or partially the formation of cubic hydrates because of the formation of hydrated gehlenite, that, in another hand, is not only formed from the reaction of the hexagonal hydrates with the silica of the slag, but the aluminum hydroxide also influences its formation.
- The presence of activator in samples cured at 40ºC favours the obtention of mechanic resistances (with 20 and 50% of slag) while its effect is negative on those with 80%, due to their limited reactive character at the ages studied.

INFLUENCE OF SILICO-MANGANIC SLAG ADDITIVES ON CEMENT HYDRATION AND PROPERTIES

Wojciech Roszczynialski, University of Mining and Metallurgy, Kraków, Poland

ABSTRACT Si-Mn slag is the mixture of different minerals with the akermanite as a predominant phase. In the granulation process almost all the Si-Mn slag transforms into the glassy substance. The investigation of the Si-Mn slag additives, from 1.5 to 15 %, on the standard properties of cement have been carried out. The effect of 15 % Si-Mn slag admixture on cement hydration was additionally studied by XRD and DTA methods. The results thus obtained prove the possibility of Si-Mn slag utilisation as cement admixture.

Key-words: admixtures, slag, modified cement, hydration, strength development.

INTRODUCTION

The silico-manganic slag (Si-Mn slag) is delivered as a by-product in the ferro-silico-manganese metallurgy. This slag has been used as cement admixture for a long time (Znaczko - Jaworski 1951), because of the similarity of chemical and phase composition to that for the blast furnace slag. However, the opinions about this material, as a component of cements, are not equivocal. The Si-Mn slags show much higher MnO content than the blast furnace ones. The effect of this component on the activity of slag and cement properties has not been understood until now. Generally, MnO is treated as an activity reducing agent (Smolczyk 1980). Among the numerous formulas, giving the factors of slag quality characterisation, the three following ones include the MnO component:

$$F_1 = \frac{CaO + 0.5MgO + Al_2O_3 + CaS}{SiO_2 + MnO}$$

$$F_2 = \frac{CaO + 0.5MgO + Al_2O_3}{SiO_2 + FeO + (MnO)^2}$$

$$F_3 = \frac{CaO + MgO + Al_2O_3 + BaO}{SiO_2 + MnO}$$

In all these indexes, MnO occurs in denominator; it means that MnO acts as an activity reducing component. On the other side, the applicability of slags as cement admixtures is determined not only on the basis of modulus, calculated from chemical composition but also by the structural disorder (Satarin 1974). MnO can favourize the formation of microheterogenity in the slag structure, as it would result from many experiments, in which the full applicability of slags with higher MnO content (5-20 %) was found (Datta and Lahiri 1972; Vylkova and Dagandzhieva 1974; Taneja et al. 1980; Roszczynialski et al. 1995).

EXPERIMENTAL

Materials

The crude Si-Mn slag from metallurgical plant was used in the studies. This slag was also granulated in laboratory. The granulated blast furnace slag was taken as reference. The chemical composition of slags is given in Table 1. In Figure 1 the XRD patterns of crude and granulated Si-Mn slags are plotted.

Table 1 Chemical composition of slags.

Component	Percentage (in weight %) in		
	crude Si-Mn slag	granulated Si-Mn slag	granulated blast furnace slag
SiO_2	42,5	42,4	39,2
Al_2O_3	7,0	7,0	8,3
Fe_2O_3	0,5	0,4	0,6
CaO	22,8	23,8	42,5
MgO	6,8	6,5	7,7
SO_3	0,1	0,1	1,1
MnO	8,5	8,9	0,2

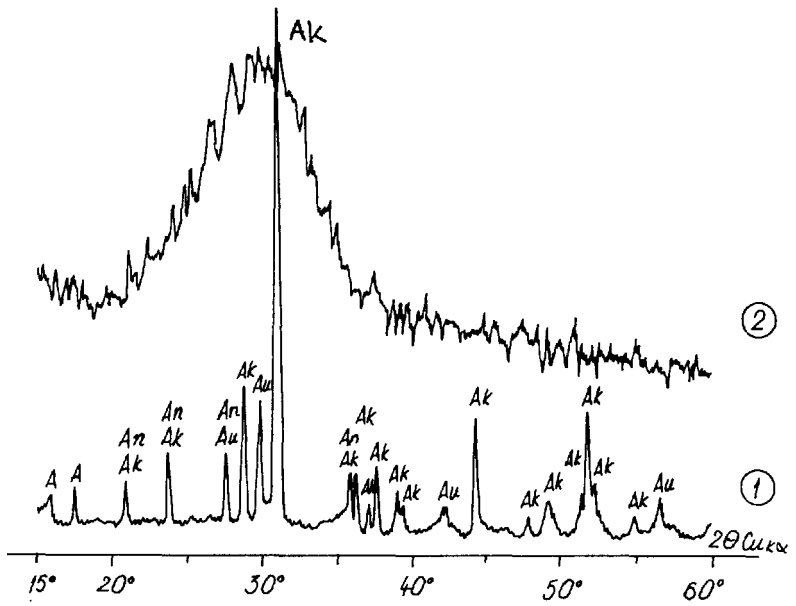

Figure 1 XRD pattern of crude and granulated Si-Mn slag (① crude Si-Mn slag, ② granulated Si-Mn slag, Ak - akermanite, Au - augite, An - anorthoclase).

Taking into account only the chemical compositions of slags and resulting values of modulus, one could presume much lower activity of Si-Mn slag as compared to the blast furnace slag (lower CaO and higher MnO content in Si-Mn slag). However, the XRD revealed the predominant occurrence of akermanite in crystalline Si-Mn material. This phase is of particular meaning as an active component of slags. Due the granulation process, practically all the crystalline phases transform into the microcrystalline or vitreous ones.

Cements with Si-Mn slag admixture

These cements were produced by grinding of portland cement clinker with Si-Mn slag in crude form or laboratory granulated and gypsum. The Si-Mn slag content was in the range of 1.5 to 15 % by weight of cement. The cement were ground to the Blaine specific surface about 300 m^2/kg. The two reference cements: portland cement without admixture and cement with 15 % blast furnace slag were prepared as references.

The cements thus produced were subjected to the standard tests in order to determine water demand, setting time, volume changes and strength. The reduction of water to attain the standard consistency was found for the Si-Mn slag containing cements. This reduction was in the range 1 - 12 %, depending on the slag content. Time of setting and volume changes were generally not affected by the presence of admixture. The results of compressive strength tests after 1, 3, 7 and 28 days curing are given in Table 2.

Table 2 Compressive strength of cements.

Admixture to cement	Compressive strength in MPa at age			
	1 day	3 days	7 days	28 days
-	8,6	20,0	29,3	41,1
1.5 % crude Si-Mn slag	8,1	19,1	28,9	39,9
1.5 % granulated Si-Mn slag	8,1	19,4	29,1	40,8
3 % crude Si-Mn slag	7,9	19,6	30,5	40,7
3 % granulated Si-Mn slag	8,2	19,8	30,4	41,8
5 % crude Si-Mn slag	7,7	19,2	29,6	38,1
5 % granulated Si-Mn slag	8,0	18,8	29,9	42,5
15 % crude Si-Mn slag	6,0	16,1	24,7	37,6
15 % granulated Si-Mn slag	6,8	17,2	26,8	39,2
15 % granulated blast furnace slag	6,0	16,4	25,6	36,8

Hydrated cements with 15 % granulated Si-Mn slag admixture and reference sample without admixture were subjected to the XRD and DTA measurements. The pastes were cured for 5, 10, 24, 72 hours and 28 days respectively. The acceleration of cement clinker minerals hydration in the presence of Si-Mn slag was observed after 10 hours from the beginning. The admixture plays a role of nucleating agent, thus facilitating the alite decomposition and calcium hydroxide crystallisation as one can notice from DTA results (see Figure 2). The admixture itself takes a part in the hydration products formation. Despite of 15 % clinker minerals content lowering the $Ca(OH_2)$ content between 10 and 72 hours is almost the same as for paste without admixture. After 28 days (see Figure 2) the $Ca(OH_2)$ content in the 15 % Si-Mn slag containing sample is about 10 % lower than in the reference one. It would result from the calcium ions consumption by active slag components. The accelerating effect of Si-Mn slag on cement hydration is additionally illustrated by XRD patterns of 28 days hydrated samples. In Figure 3, it is clearly seen, that the alite peak intensities are reduced more than it would result from only the "dilution" of cement with 15 % slag.

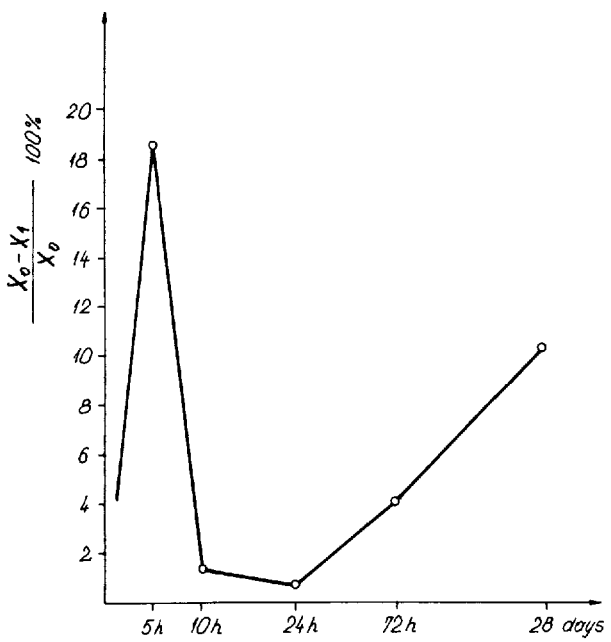

Figure 2 $Ca(OH_2)$ content evaluation in 28 days hydrating cement pastes calculated from TG measurements (X_0 - $Ca(OH_2)$ in paste without admixture; X_1 - $CA(OH_2)$ in paste with Si-Mn slag).

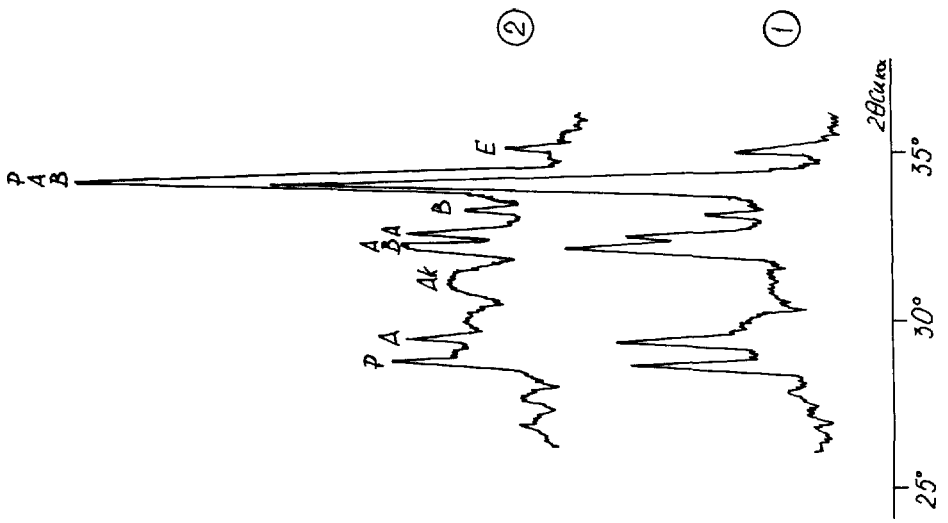

Figure 3 XRD patterns of pastes after 28 days hydration (① cement without admixture ② cement with 15 % granulated Si-Mn slag, A-alite, B-belite, P-portlandite, Ak-akermanite, E-ettringite).

CONCLUSIONS (SUMMARY)

From the data thus presented it results that the Si-Mn slag, added as 8-10 % of cement, is an active admixture. 1.5 - 15 % slag content can, of course, reduce the early strength (1-3 days), but at 28 days the strength values are similar to those for reference cements. The best results have been achieved at 5 % slag admixture. The granulated Si-Mn slag gives better parameters of cement, but the differences, as compared to the crude slag, are not significant. The results for Si-Mn slag are good as compared to those for the granulated blast furnace slag.

The good results achieved at Si-Mn slag admixtures can be explained as follows:

- Si-Mn slags reveal high content of active component, such as akermanite or akermanite glassy phase;
- Si-Mn slag acts as a modifying agent in clinker minerals (particularly alite) hydration.

KINETIC STUDY OF ALKALI-ACTIVATED BLAST FURNACE SLAG

Ana FERNANDEZ-JIMENEZ. Instituto Eduardo Torroja (CSIC), Spain.
Francisca PUERTAS. Instituto Eduardo Torroja (CSIC), Spain.

ABSTRACT The alkaline activation process of granulated blast furnace slag (GBFS) has been studied. Activation degree (α) was determined from the data obtained by isothermal conduction calorimetry. The variables considered on the test were: temperature (25-60°C) and concentration of alkaline activator (Na_2O, 3-5% wt). For values of $\alpha \geq 0.5$ the process is controlled by diffusion. The equations that explain these kinetics are those of Jander (D_3, diffusion in sphere) and Ginstling-Brounshtein (D_4, surface diffusion).

Key-words: Alkali, Activation, Blastfurnace slag, Kinetic, Diffusion.

INTRODUCTION

The alkaline activation of granulated blast furnace slag (GBFS) leads to a cement material with low energy cost, high strength and good durability compared to portland cements (Glukhosky, 1980; Krivenko, 1992; Kutti, 1992; Wang, 1995). Nevertheless, the kinetic of the reactions has been little studied (Zhou, 1993). The objective of this work has been the determination of kinetic equations that explain the reaction processes of the slag with an alkaline activator. The activator solution was a mixture of water-glass and NaOH. The variables of the process were temperature (25, 35, 45, 60°C) of reaction and the concentration of Na_2O in activator solution (3, 4, 5% in weight).

EXPERIMENTAL

In Table 1 the chemical analysis of the GBFS from Avilés (Asturias, SPAIN) is shown.

Table 1 Chemical composition (% wt.) of the granulated blast furnace slag.

H_2O Comb	CO_2	*IR	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	**F	Blaine
0.10	1.23	0.14	36.10	11.22	0.49	42.80	8.40	0.0	1.72	440 m^2/kg

* IR= Insolubility Residue
**F= Hydraulic Index ($F=(CaO+MgO+Al_2O_3)/SiO_2$)

The activator solution was prepared with a mixture of commercial "water-glass" (SiO_2 =18.01%; Na_2O=8.53%) and NaOH. SiO_2/Na_2O ratio was maintained constant and equal to 1.5. The concentration of Na_2O was varied: 3, 4 and 5% wt respect to the weight of slag.

The degree of reaction (α), was determined according to the methodology of Stutter (1995), where $\alpha=Q(t)/Qmax$, (Q(t)= heat as a function of time; Qmax= total heat in kJ/kg). The mixtures were prepared to a constant ratio alkaline activator solution/slag = 0.4. The reaction temperatures were varied from 25 to 60°C and the time of reaction was constant and fixed at 45 hours.

RESULTS AND DISCUSSION

Figs. 1, 2 and 3 show heat evolution curves (kJ/kg) versus reaction time, for the different concentrations of activator solution and test temperatures. Figs. 4, 5 and 6 show the degree of reaction (α) versus time.

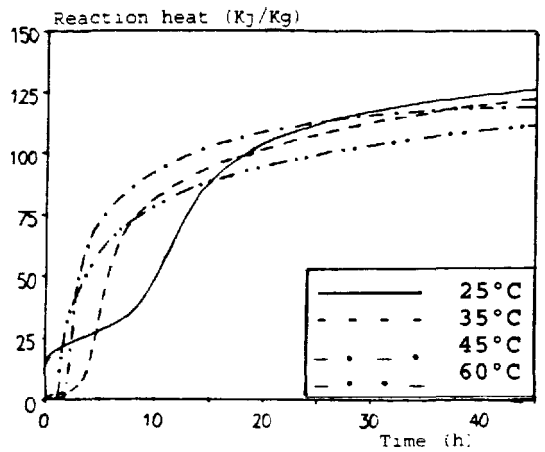

Fig 1 Reaction heat, 3% of Na_2O

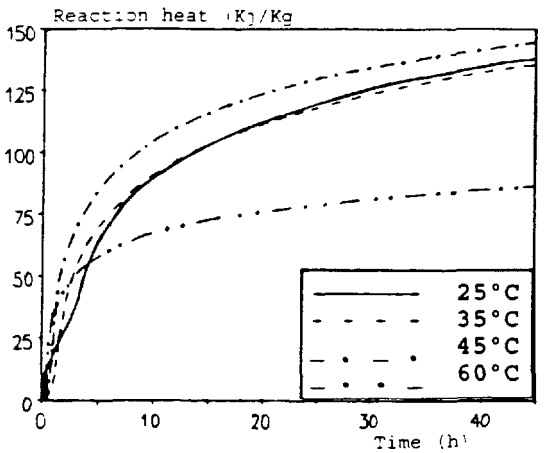

Fig 2 Reaction heat, 4% of Na_2O

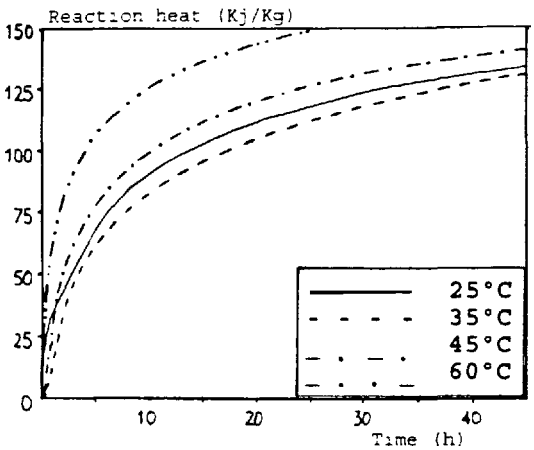

Fig 3 Reaction Heat, 5% of Na_2O

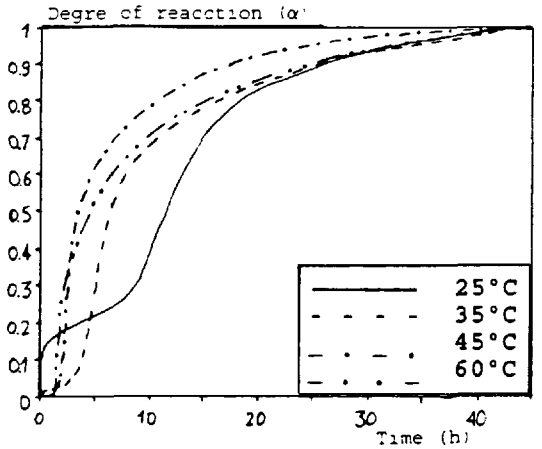

Fig 4 Degree of reaction, 3% of Na_2O

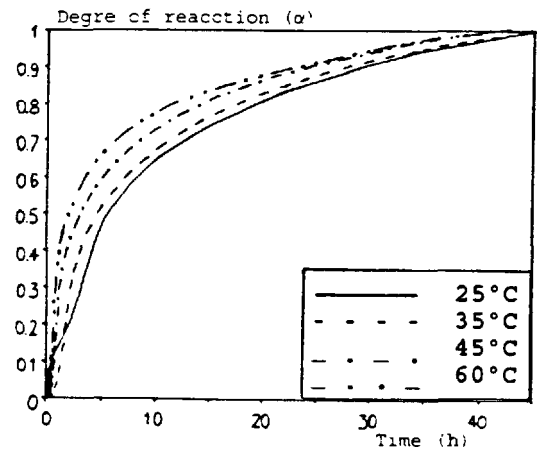

Fig 5 Degree of reaction, 4% of Na_2O

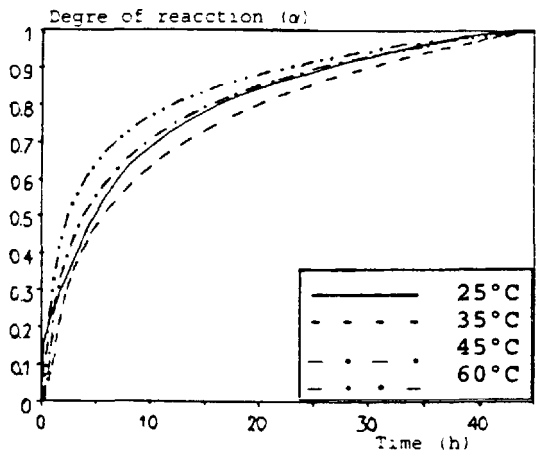

Fig 6 Degree of reaction, 5% of Na_2O

The kinetic of the process was studied through two complementary methods:

a) Mori and Minegishi method (1968). This method is based on determining the value of N on the Eq.1:

$$(1-(1-\alpha)^{1/3})^N = Kt \qquad [1]$$

Where α= degree of reaction; K = rate constant; t = reaction time; N is the value which is variable according to the reaction type. In the present case representing the $\log(1-(1-\alpha)^{1/3})$ versus the log(t), only two straight lines were obtained. These lines correspond to the periods of acceleration-deceleration and decay (dissolution and induction stages are so rapid that it is difficult to distinguish them).

The first straight line shows values of N less than 1 indicating that the reaction is autocatalytic, and the products that are being formed coat the slag grains without affecting the process of reaction. In Table 2 the values of N for the period of decay (second straight line) are shown, theses values are obtained for values of $\alpha \geq 0.5$.

Table 2 Values of N for Eq 1 (for $\alpha \geq 0.5$).

Na_2O (% weight)	Temperature (°C)			
	25	35	45	60
3	1.40	1.82	1.80	1.90
4	1.80	1.96	2.10	2.70
5	1.90	1.69	1.95	2.40

This process is phase boundary controlled when N=1. For N=2 it is controlled by pure diffusion, but for N>2 it is controlled by diffusion but the products formed around the slag grains are more dense and the diffusion rate decrease.

From the results of Table 2 it can be deduced that when the temperature of reaction increases the values of N increases too. Except for the samples with 3% Na_2O at 25°C at the time of test, N values are close to 2. It means that the process is controlled by diffusion.

b) Sharp method (1966). In this method the equations are expressed in the form $F(\alpha) = A(t/t_{0.5})$, where $t_{0.5}$ is the time for 50% reaction and A is a calculable constant depending on the form of F(x). With this methodology our values are fitted to the following equations:

The equation of Jander:

$$D_3 = (1-(1-\alpha)^{1/3})^2 = (k/r^2)t = 0.0426(t/t_{0.5}) \qquad [2]$$

This equation indicates that reaction is controlled by three-dimensional diffusion, in a sphere.

The equation of Ginstling-Brounshtein

$$D_4 = (1-2\alpha/3) - (1-\alpha)^{2/3} = (k/r^2)t = 0.0367(t/t_{0.5}) \qquad [3]$$

This equations indicates that reaction is controlled by diffusion starting on the exterior of a spherical particle of radius r, and the difference between the volume of the reaction product and that of the initial material is unity. Table 3 shows the equation followed in each activation process.

Table 3 Equations obtained according to Sharp method.

Na_2O (% in weight)	Temperature (°C)			
	25	35	45	60
3	--	D_4	D_3, D_4	D_3, D_4
4	D_4	D_3, D_4	D_3, D_4	D_3
5	D_4	D_4	D_3	D_3

These results confirm that for $\alpha \geq 0.5$ the alkaline activation of slags follows a diffusion kinetic (D_3 and D_4). But the kinetic equations vary depending on the temperature and the concentration of activator. The equation of Ginstling-Brounshtein (D_4) explain better the process at low temperature and concentration of activator. The equation of Jander (D_3) is more correct for high temperature and concentration of activator. In the same samples it was not possible to establish one of the equations.

The kinetic process depends mainly on the nature and the thickness of the hydration product around the slag grain. The temperature of reaction and activator concentration modify the nature and thickness of the diffusion barrier and this explain the change observed from D_4 to D_3.

CONCLUSION

The two methods applied are concordant. For values of $\alpha \geq 0.5$, kinetic equations controlling the alkaline activation slag are those of the diffusion (D_3 and D_4). When the temperature and concentration of activator increase the value of N increases too, and the kinetic equations change from D_4 to D_3.

ACKNOWLEDGMENTS

The authors of the present work wish to thank to DGICYT for funding this research through Program PB94-0048 which was necessary to the realization of the present study.

EARLY HYDRATION AND MICROSTRUCTURE DEVELOPMENT OF ALKALI-ACTIVATED SLAG CEMENT PASTES

Caijun **SHI,** Water Technology International Corporation, Burlington, Ontario, Canada

ABSTRACT The early hydration and microstructure development of NaOH-, Na_2CO_3- and Na_2SiO_3-activated slag pastes were examined using calorimetry, scanning electron microscopy and X-ray diffractromery. The nature of activators played a crucial role during the hydration and microstructure development of alkali-activated slag pastes. C-S-H was the main hydration product regardless of activators, while minor phases varied with activators - C_4AH_{13} and C_2ASH_8 appeared in NaOH-, $C_3A.CaCO_3.12H_2O$ in Na_2CO_3- and C_4AH_{13} in Na_2SiO_3-activated slag pastes.

Key-words: Activation, Blastfurnace slag, Hydration, Microstructure

INTRODUCTION

Numerous studies have reported properties of alkali-activated slag cement and concrete [Gluhovsky, 1980; Shi et al 1992, Talling and Brandstetr, 1989]. Since the characteristics of slag vary from source to source, slags from different sources may be sensitive to different activators. Shi and Day [1996] have explained the selectivity of activators for the activation of slags from the aspect of hydration chemistry. However, very limited amount of work has been done on the hydration and microstructure development of alkali-activated slag pastes [Shi and Day, 1995, 1996; Wang and Scrivener, 1995]. An understanding of hydration characteristics and microstructure development will be beneficial to the explanation of the property development of hardened cement pastes and concrete, and to facilitate practical applications. The purpose of this work is to examine early hydration and microstructure development of NaOH-, Na_2CO_3- and Na_2SiO_3-activated slag.

EXPERIMENTATION

Raw Materials

A ground pelletized Canadian blast furnace slag was investigated. The characteristics of the slag have been reported previously [Shi & Day, 1995]. Chemical reagents NaOH, Na_2CO_3 and $Na_2SiO_3.9H_2O$ were used as alkaline activators. These activators were dissolved in mixing water first and then added at the dosage of 4% Na_2O by the mass of slag.

Measurement of Heat of Hydration

The heat of hydration of alkali-activated slag was measured at a constant temperature of 25±1°C using a Seebeck Isothermal Conduction Calorimeter. The sample container with 14 g of the slag sample and a syringe with the activator solution were heated to the testing temperature prior to mixing. A water-to-slag ratio of 0.45 was used. When thermal equilibrium was achieved, the slag and the activator solution were mixed by injecting the solution into the slag. The heat evolution was recorded by a computer as a voltage and then converted to kJ/kg.h through a calibration test. The calibration base line was established by recording the heat evolution of a mixture of water and ground quartz with the same water-to-solid ratio.

Scanning Electron Microscope (SEM) Observation

Pastes with the same mixing proportions as for calorimetry test were cast to SEM sample stubs directly and cured in a CO_2-free moisture desiccator. The samples were freeze-dried before SEM observations.

At testing ages, one sample from each batch was taken from the desiccator to cut the exposed surface, then, together with the sample stubs, placed in a bath of liquid nitrogen. After 3-5 minutes in the bath, these specimens were vacuumed for 24 hours to remove all free water. A Cambridge stereoscan 150 Scanning Electron Microscope was used to observe the morphology of raw materials and the microstructure of pastes.

X-Ray Diffraction (XRD) Analysis

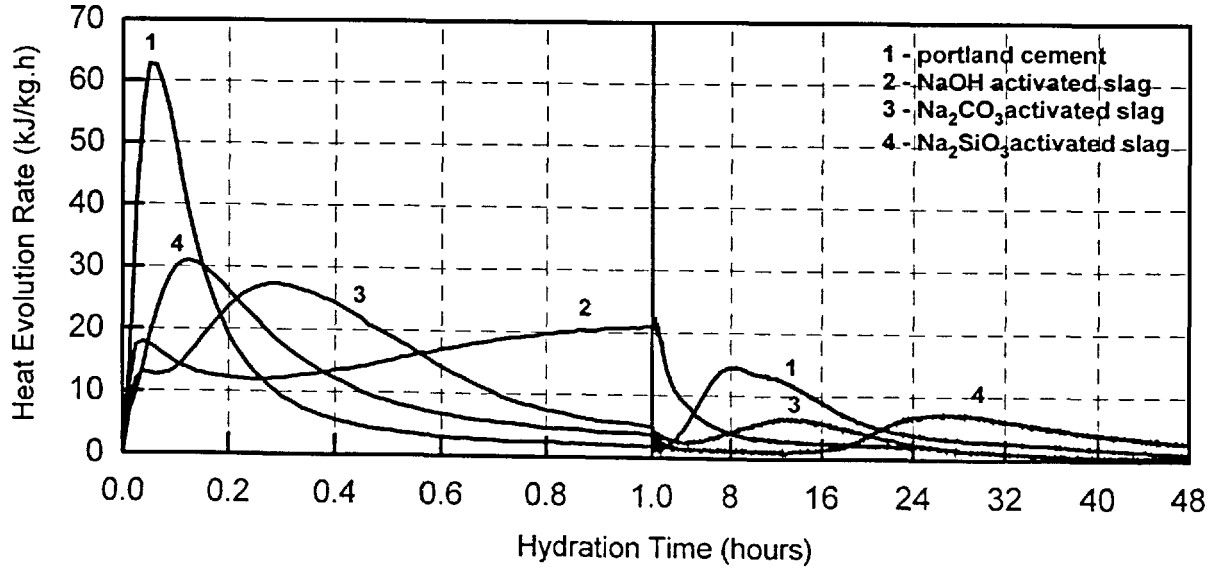
For XRD examination, the pastes were cast into small plastic bottles and then cured in a CO_2-free moisture desiccator. At testing ages, one specimen from each batch was taken out from the desiccator and was ground in 2-propanol to arrest the further hydration. A Philips PW 1139 Diffractometer was used to perform the tests at a scanning rate of 2.10°/minute from 5 to 75° (2θ).

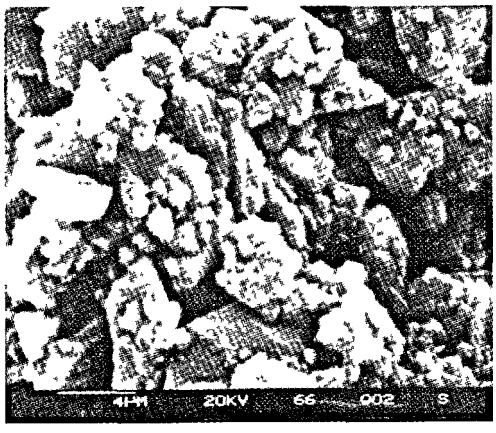
EXPERIMENTAL RESULTS

Heat of Hydration

It is well known that the hydration of portland cement can be classified into five periods based on the heat evolution curves: (I) initial (pre-induction) period; (II) induction period; (III) acceleration (post-induction) period; (IV) deceleration period; and (V) diffusion period. Heat evolution curves of alkali-activated slag in Fig.1 indicated that the classification was also suitable for the description of the hydration of alkali-activated slag.

Alkali-activated slag showed much lower initial heat evolution peaks than portland cement. The heat evolution features of alkali-activated slag varied with activators. NaOH-activated slag showed the lowest initial heat evolution peak, a negligible induction period and the highest accelerated hydration peak. Na_2CO_3-activated slag exhibited two obvious heat evolution peaks before the appearance of a induction period of 5 hours. Na_2SiO_3-activated slag also showed two heat evolution peaks before the very lengthy induction period, which lasted approximately 17 hours. However, the first peak was not so evident to be observed. Both Na_2CO_3- and Na_2SiO_3-activated slag pastes showed lower accelerated hydration peaks that the portland cement.





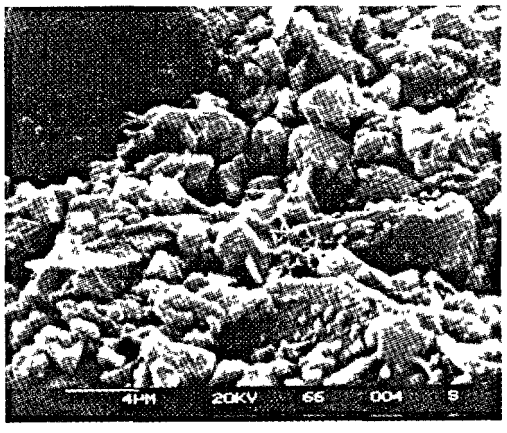


Figure 1 Heat Evolution Rates of Portland and Alkali-Activated Slag Cements

Microstructure Development

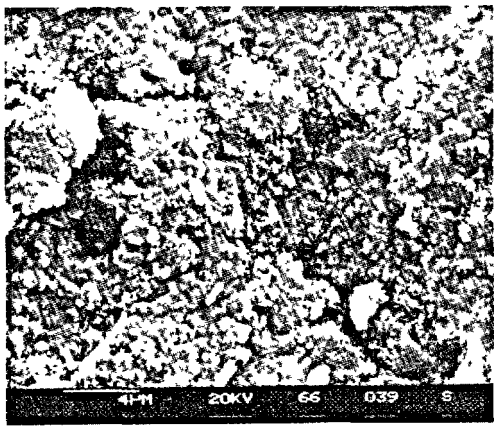

Fig.2 shows microstructure development of NaOH-activated slag pastes from 20 minutes to 3 days. At 20 minutes, it appeared that the surface of all slags particles were etched and coagulated products precipitated at some locations, as shown in Fig. 2-a. As time proceeded to 2 hours, most voids between slag particles were filled by coagulated products. Hexagonal plates, which were embedded in the coagulated products, appeared (Fig.2-b). However, the configuration of slag particles could still be identified. At 1 day, an uniform hardened structure was observed on fracture surface. At this time, although structure looked loose (Fig.2-c), it was impossible to identify the configuration of slag particles. Features of hydration products could only be notified in air voids. At 3 days, fracture surface of the activated slag paste appeared to be similar to but denser than that at 1 day. Features of hydration products in air voids are shown in Fig.2-d. In addition to coagulated particles, some hexagonal plates were also observed.

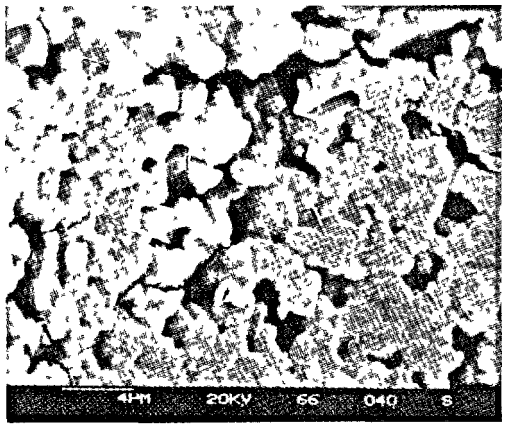
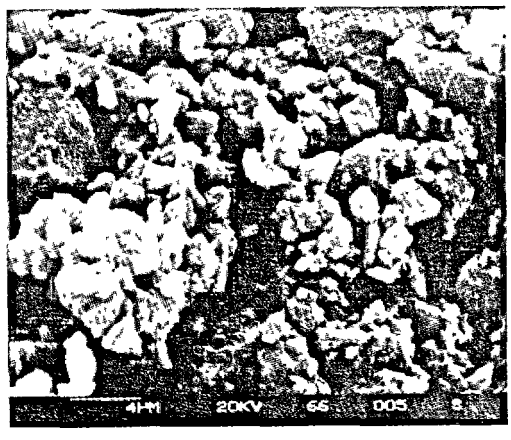
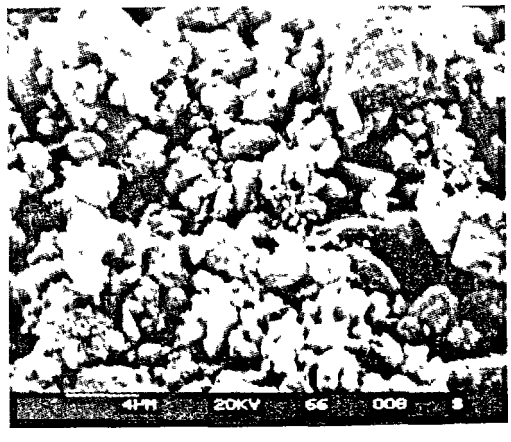


(a) at 20 minutes

(b) at 2 hours



(c) at 1 day



(d) at 3 days

Figure 2 Microstructure Development of NaOH-Activated Slag Pastes

Microstructure development of Na_2CO_3-activated slag pastes is shown in Fig.3. At 20 minutes, most slag particles were intact except for precipitated gel-like products on some slag particles (Fig.3-a). At 2 hours, all slag particles were etched and more gel-like products filled voids between slag particles (Fig.3-b). As time proceeded to 1 day, a foil-like product was observed, which had really different morphology from that either at early ages or in NaOH-activated slag. The foil-like product most spaces between slag particles (Fig.3-c). The configuration of slag particles was only identified at occasional locations. At 3 days, the fracture surface of hardened pastes showed a dense structure and the morphology of products could only be identified in voids (Fig.3-d). No well crystallized products were observed up to 3 days.

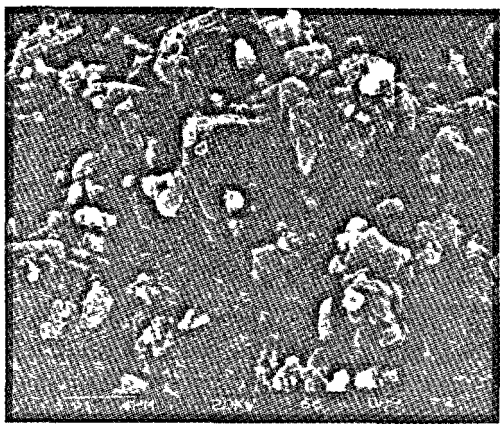
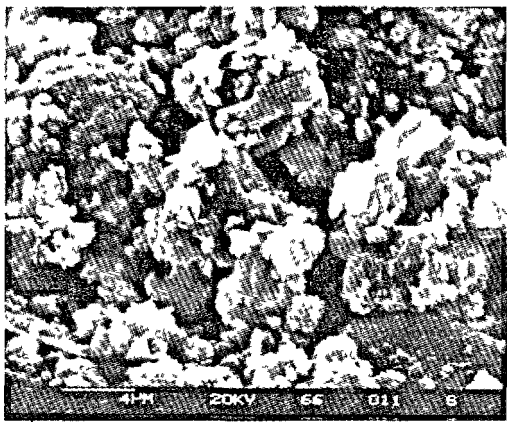
(b) at 2 hours



(c) at 1 day



(d) at 3 days

Figure 3 Microstructure Development of Na_2CO_3-Activated Slag Pastes

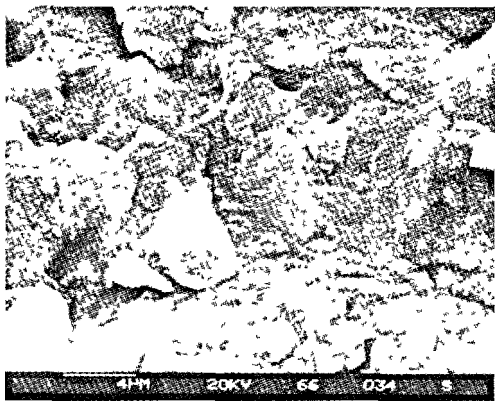


Fig.4 shows the microstructure development of Na_2SiO_3-activated slag pastes. During the first two hours, the microstructure characteristics of Na_2SiO_3-activated slag pastes (Fig.4-a and 4-b) were very similar to those of Na_2CO_3-activated slag pastes. However, at 1 day, most slag particles were covered by a layer of coagulated products but still separated. The morphology of C-S-H was very similar to that observed at 2 hours. The SEM picture is not presented here due to the poor quality picture. At 3 days, the fracture surface appeared to be denser that that of Na_2CO_3-activated slag pastes.

(a) at 20 minutes

(b) at 2 hours

(c) at 3 days

Figure 4 Microstructure Development of Na_2SiO_3-Activated Slag Pastes

Hydration Products

Hydration products of alkali-activated slag pastes were analyzed by XRD since 20 minutes of hydration. The XRD patterns of alkali-activated slag pastes at 1 day are shown in Fig.5. Combining with the SEM observations, it could be concluded that the main hydration product of all three alkali-slag cement pastes was C-S-H gel, but minor products varied with type of activator: C_4AH_{13} and C_2ASH_8 in NaOH-activated, $C_3A.CaCO_3.12H_2O$ in Na_2CO_3-activated and C_4AH_{13} in Na_2SiO_3-activated slag pastes.

DISCUSSIONS

(a) in NaOH Solution

NaOH solution has a high concentration of OH^-, the Ca-O, Si-O and Al-O bonds on the surface of the glassy slag break under the polarization effect of OH^- [Teoreanu, 1991]. These dissolved species exist in water in the form of Ca^{2+}, $[H_2SiO_4]^{2-}$, $[H_3SiO_4]^-$ and $[H_4AlO_4]^-$. Since the Ca-O bond is much weaker than Si-O and Al-O bonds, the concentration of Ca^{2+} in the solution is much higher than $[H_2SiO_4]^{2-}$, $[H_3SiO_4]^-$ and $[H_4AlO_4]^-$, and a Si-Al-rich layer forms quickly on the

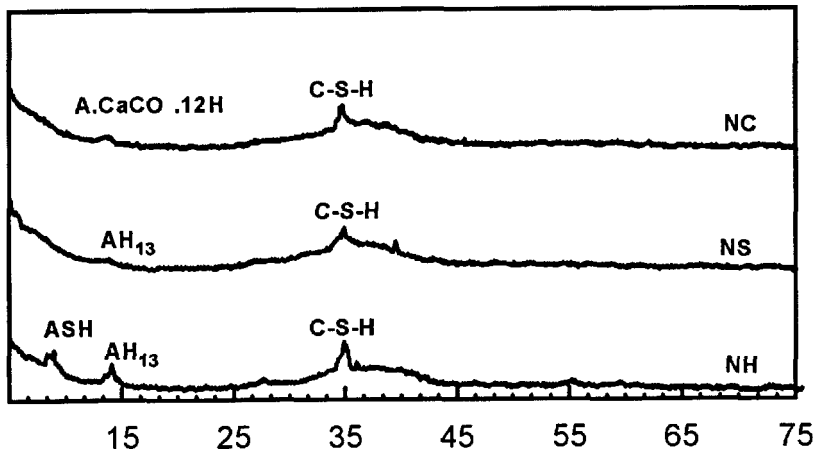

Figure 5 XRD Patterns of Alkali-slag Cement Pastes Hydrated For One Day at 23°C

Table 2 pH of Activator Solutions and Solubility Product of Relevant Ca-Compounds

Activator Solution	Measured pH	Ca-Compound	Solubility Product	Reference
NaOH	13.87	$Ca(OH)_2$	$5.5x10^{-6}$	[Yin, 1985]
Na_2CO_3	12.17	$CaCO_3$	$2.8x10^{-10}$	[Yin, 1985]
Na_3SiO_3	12.89	C-S-H*	$1.0x10^{-24\ to\ -14}$	[Glasser et al, 1987]

* the lower the C/S ratio of C-S-H, the higher the solubility product is.

surface of slag [Rajaokarivony-Andriambolona et al, 1990]. Table 2 lists these Ca-compounds associated with the anions or anion groups of alkaline activators investigated. Since $Ca(OH)_2$ has a much higher solubility than C-S-H, C-A-H and C-A-S-H, $Ca(OH)_2$ cannot precipitate from the solution. While C-S-H, C_4AH_{13} and C_2ASH_8 precipitates through the solution onto the surface of slag particles when concentration of Ca^{2+}, $[SiO_4]^{4-}$ and $[Al(OH)_4)]^-$ reach certain critical values. Thus, the initial peak was attributed to the wetting and dissolution of slag grains, adsorption of some ions onto the surface of slag grains and the formation of these products. 20 minutes of hydration correspond to the induction period on the heat evolution peak. At that time, all slag particles were etched, the gel-like product belong to C-S-H and some other products. Hexagonal hydration products can not be identified under SEM since they grow first as poorly crystallized compounds [Jawed et al, 1983].

The high concentration of OH^- enables OH^- to penetrate the precipitated layer of hydration products and to initiate the accelerated hydration of slag quickly. Thus, NaOH-activated slag does not show a noticeable induction period on the heat evolution curve. At time proceeds to 2 hours, it corresponds to the top of the accelerated hydration peak. Well crystallized hexagonal plates can be observed and C-S-H gel interlocks each other. Slag continues hydration and C-S-H fills most voids at 1 day.

(b) in Na_2CO_3 Solution

Two peaks are well identified during the initial hydration period on the heat evolution curve of Na_2CO_3-activated slag. Since the pH of Na_2CO_3 solution is significantly lower than that of NaOH solution (Table 2), the first peak corresponds to the wetting and dissolution of slag grains and adsorption of some ions onto the surface of slag grains, as stated above. Ca-O bonds at some active

centres on the surface of the glassy slag break first under the polarization effect of OH^-. The high concentration of $[CO_3]^{2-}$ in the solution results in the formation of poorly crystallized $CaCO_3$, which causes the second heat evolution (Fig.1). 20 minutes corresponds to the top of the second peak. the surface of most slag particles is intact at that time, and very limited amount of gel-like product, which is most likely $CaCO_3$, precipitates on the surface of slag particles (Fig.3-a).

The precipitation of $CaCO_3$ and low pH of the solution result in a lengthy induction period. After 2 hours of hydration, which corresponds to the middle of the induction period, the surface of most slag particles is etched and more gel-like product precipitates (3-b). Some gel-like product may belong to C-S-H in addition to $CaCO_3$ As OH^- continues attacking the surface of the slag particles, an accelerated hydration happen and more hydration products form. At one day, foil-like C-S-H fills most void space between slag particles and no other product can be observed (Fig.3-c). The difference in the morphology of C-S-H between NaOH- and Na_2CO_3-activated slag may be attributed to the difference in the pH of pore solution. While XRD analysis indicates the presence of $C_3A.CaCO_3.12H_2O$, instead of C_4AH_{13} and C_2ASH_8. $C_3A.CaCO_3.12H_2O$ can not be observed probably due to its limited amount.

(c) in Na_2SiO_3 Solution

Na_2SiO_3-activated slag exhibits two heat evolution peaks during the initial hydration period as Na_2CO_3-activated slag. However, the first peak of Na_2SiO_3-activated slag appears smaller and earlier than that of Na_2CO_3-activated slag. The first tiny peak corresponds to the wetting and dissolution of slag grains and adsorption of some ions onto the surface of slag grains, and the second peak to the formation of primary C-S-H [Shi and Li, 1989]. The difference in the heat evolution features between Na_2SiO_3-activated and Na_2CO_3-activated slag may be explained by the higher pH of Na_2SiO_3 solution than that of Na_2CO_3, and lower solubility of C-S-H than that of $CaCO_3$. By comparing the microstructure of between Na_2SiO_3-activated and Na_2CO_3-activated slag pastes at 20 minutes (Figs.3-a and 4-a)and 2 hours (Figs. 3-b and 4-b), they appear to be very similar but slight difference in the morphology of hydration product. While C-S-H and $CaCO_3$ exist in Na_2CO_3-activated slag and only C-S-H in Na_2SiO_3-activated slag pastes at these times.

The precipitation of the primary C-S-H results in a very long induction period. One day is almost on the top of the accelerated hydration peak of Na_2SiO_3-activated slag. Foil-like C-S-H fill most void spaces between slag particles at one day. C_4AH_{13} can be identified by XRD but not observed under SEM probably due to limited quantity. As time proceeds to 3 days, a very dense structure is observed.

CONCLUSIONS

1. In this study, it was found that the heat evolution peak of alkali-activated slag before the appearance of induction period was much smaller than that of portland cement. The heat evolution features of alkali-activated slag depended on the nature of activators. NaOH-activated alkali-slag cement showed the lowest initial heat evolution peak, but a negligible induction period and the highest accelerated hydration peak. Na_2CO_3-activated slag exhibited two obvious heat evolution peaks before the appearance of a induction period of 5 hours. Na_2SiO_3-activated slag also had two heat evolution peaks before the very lengthy induction period, which lasted 17 hours. However, the first peak was too small to be obviously observed.

2. The microstructure development of alkali-activated slag pastes was very consistent with the heat evolution characteristics. More hydration products were observed in NaOH-activated slag pastes and less in Na_2SiO_3-activated slag pastes. As time proceeded, more and more hydration products formed in Na_2SiO_3-activated slag pastes. Na_2SiO_3-activated slag pastes showed the densest structure at 3 days.

3. The main hydration product of the three alkali-activated slag pastes was C-S-H, but the minor products varied with activators: C_4AH_{13} and C_2ASH_8 in NaOH-activated, $C_3A.CaCO_3.12H_2O$ in Na_2CO_3-activated and C_4AH_{13} in Na_2SiO3-activated alkali-slag cements.

ALKALI ACTIVATION REACTION MECHANISM AND ITS INFLUENCES ON MICROSTRUCTURE OF SLAG CEMENT

Weimin JIANG, Michael R. SILSBEE and Della M. ROY, Materials Research Laboratory, The Pennsylvania State University, University Park, PA 16802, USA.

ABSTRACT This research constitutes a fundamental investigation of the reaction mechanisms in alkali activated granulated blast-furnace slag, and their influences on microstructure of slag cement. The microstructure of these materials was analyzed by SEM and ESEM. Also ^{29}Si MAS-NMR was performed to characterize the amorphous phase in these systems. A set of ordinary portland cement paste samples served as a control. Results of XRD, TGA, calorimeter, pore solution and Vicat penetration profiles were also reported.

Keywords: activation, alkali, hydration, mechanism, slag.

INTRODUCTION

This study is a part of research which deals with the microstructure and properties of alkali activated cementitious materials (AAC), the reaction mechanisms of which are still not properly understood, and remain one of the most difficult topics in the study of AAC. This is due to a number of theoretical and experimental problems encountered in the correct assessment of activation courses. Nevertheless it is understood that with the compositions studied the activation phenomenon is due to the attack of OH^- ions on the SiO_2 or Al_2O_3-SiO_2 bonds resulting in increased hydration rates. The primary focus of this study is on activation mechanisms, not only because knowledge of the mechanisms is essential to understanding activation processes but also because theories about activation mechanisms can explain diverse chemical phenomena in terms of a relatively small number of general principles.

This study also tried to emphasize the experimental evidence upon which mechanistic ideas are built and to point out areas of uncertainty and controversy where more work still needs to be done. The microstructural observations and properties test results presented in recent literature try to rationalize the factors which govern the course of alkali activation (Richardson *et al.*, 1993; Wang *et al.*, 1994; Wu *et al.*, 1990; Hong *et al.*, 1993; Shi and Day, 1995 and 1996; Roy and Silsbee, 1994, Krivenko, 1994; and Roy 1995). It is suggested by some researchers that R^+ (alkali) ions play a catalytic role in the early stages of hydration in a process involving interchange with Ca^{2+} cations, then in the later stage they are combined into the structure to form zeolite-like phases. Others believe that the alkaline cations may only have an effect of balancing and maintaining OH^- anions. Some controversy has been evoked over the identification of hydration products. Roy *et al.* (1992) reported their result, suggesting the reaction products were mainly varieties of C-S-H, $(C, M)_4AH_{13}$, and minor amounts of $Ca(OH)_2$ and C_2ASH_8 (strätlingite). Wang and Scrivener (1994) suggested that no zeolitic hydrates or other crystalline phase containing alkali cations or mica groups such as nepheline, natrolite, analcite, paragonite or gismondite could be identified in the pastes of slag activated with NaOH. Also there appears to be no convincing evidence for existence of a true solid solution $(M,C)_4AH_{14}$.

EXPERIMENTAL

The starting materials are granulated blast-furnace slag, and alkali activator expressed as R_2O. Some recent experiments reported were focused on pure slag activated with 4 or 5M NaOH (or KOH) at w/c = 0.4 (Richardson *et al.*, 1993; Wang *et al.*, 1994; and Wang and Scrivener, 1994). Ordinary Portland cement (OPC) was used as control. The chemical compositions of the OPC, and slag used in the current study have been reported in an earlier paper (Roy and Jiang, 1994). Formulations selected in this work are shown in Table 1. Two series (paste and mortar) were made. The specimens were cured under 98% relative humidity at 25°C. Hardened AAC paste hydration products from one hour to 16 months old were examined by means of x-ray diffraction (XRD). The morphologies of hydrates were observed by ESEM.

Table 1 Mixture proportions (by weight)

Paste	Mortar
Slag 100% + 5M NaOH or KOH solution at w/c= 0.4 casting in ø31.75 mm x 38.10 mm cylinders Control OPC (type I cement) + deionized water at w/c = 0.4	Slag:Sand (C 109 ASTM) : 1.0:2.25 (1) adding 5M NaOH or KOH solution w/c = 0.46 (2) adding sodium silicate solution (16.31 wt % SiO_2; 10.87 wt% Na_2O; 72.82% H_2O) at w/c = 0.46 casting 2 in. cubes or ASTM C490 prisms

Test Methods

NMR—^{29}Si NMR Spectra were recorded using a JEOL FX-90 instrument with a multinuclear probe covering the range 2.8-36.2 MHz.

DTA—Differential thermal analysis of materials was performed on a Perkin Elmer System 7/4 with a DTA 1700 unit. In all cases the heating rate was either 10 or 20°C/min and Pt/Pt 10 Rh thermocouples were used.

Isothermal conduction calorimeter—A thermostatically controlled Haake F3 water circulator with heating and cooling equipment was used in conjunction with a Thermonetics Corporation calorimeter. In each case 3 g of powder was placed in metal container, then 1.5 g of water was added. Setting time—was measure by Vicat needle (ASTM C191).

Pore solution—Samples of the aqueous phase in contact with alkali activated cement pastes were obtained by expression of the pore solution from hardened cement pastes under high pressures of 500 MPa at ages ranging from 15 minutes to 90 days.

Shrinkage—the length changes of the prisms were recorded as function of time. The preparation of mortar bar is in accordance with the requirements of ASTM C 490 (25/25/300mm). The stainless steel gage stud was used in each end. After mold has been filled, place the mold immediately in the moist cabinet. The specimens remain in the molds for 24 hours. Then the prisms are removed from the molds and measured for initial length. Following measurements are made at later ages as required, while specimens are stored in the air at temp. 30°C rh: 70%.

XRD—were performed on a Scintag Automated x-ray diffractometer (CuKα radiation, λ=1.540598Å) interfaced with a microVAX computer.

RESULT AND DISCUSSION

Hydration products

Fig. 1 is the XRD spectrum of a pure slag paste mixed with 5M NaOH after 2 days of curing. The main phases are C-S-H (JCPDS file No. 33-306), calcium carbonate (JCPDS file No. 5-586) and hydrotalcite. Although the intensity of those peaks increased with increasing cure time, the main peaks were formed after 2 days. These results suggest that the low-basic calcium silicate hydrate related to tobermorite is the major silicate hydration products of AAC. The hydrotalcite-type phase found is similar to formula $Mg_6Al_2CO_3(OH)_{16}{\cdot}4H_2O$ (JCPDS file No. 41-1428).

NMR—Schilling, *et al.* (1994) used the ^{29}Si NMR on NaOH-activated blast-furnace slag in order to better characterize the amorphous and poorly crystalline phases which occur in this system. The unreacted glass has a mainly dimeric silicate structure represented by a broad ^{29}Si

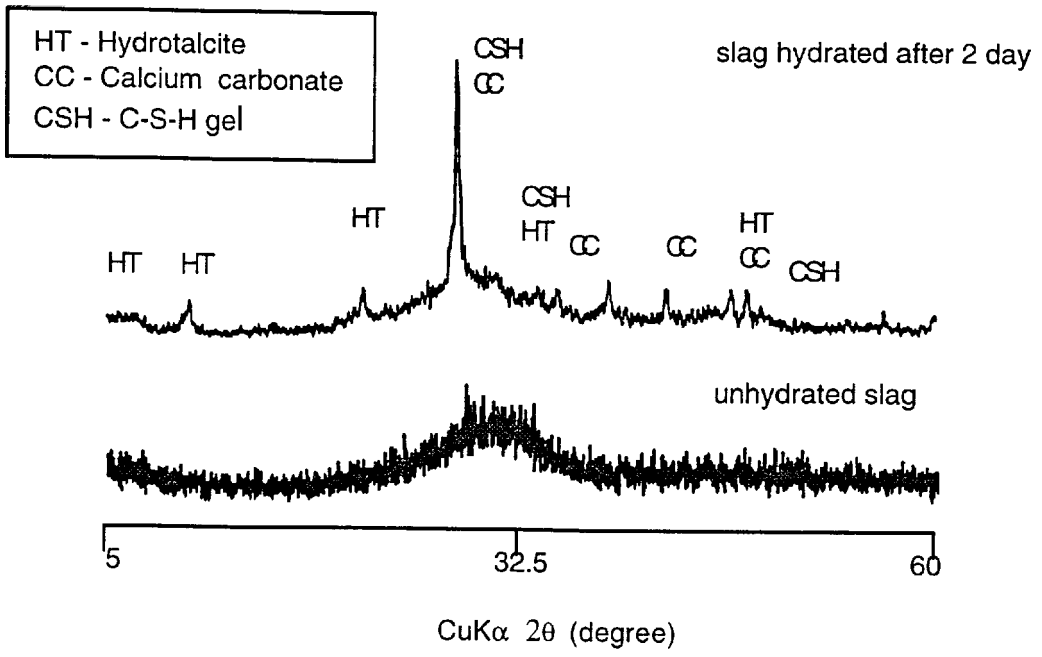

Figure 1 XRD patterns of slag pastes activated with 5M NaOH solution at w/c = 0.4 after 2 days hydration

peak centered at -74.5 ppm [Q^1], with aluminum present exclusively in tetrahedral coordination. ^{29}Si results indicate rapid initial consumption of glass, with roughly a third of the glass reacting within the first day and another third consumed over the following 27 days. Pietersen, *et al.* (1994) observed blended cement with 70% slag has a chemical shift to -73 ppm. Richardson *et al.* (1993) combined the solid-state ^{29}Si and ^{27}Al magic angle spinning NMR spectroscopy with electron energy loss spectroscopy (EELS) carried out in the transmission electron microscope to determine the location of Al substituting in a semicrystalline C-S-H gel present in a hydrated synthetic slag glass. Our ^{29}Si MAS NMR results (Fig. 2) show that unhydrated slag has peaks at -73.0 and -75.2 ppm. The hydrated KOH activated cement yields a peak near -78.3 ppm. After hydration, a shift is seen to a more shielded (more negative) position and the peak is much narrower, indicating a greater degree of short-range order. Two general observations can be immediately made from these ^{29}Si patterns. First, that the degree of structural modification around the Si nuclei during hydration is not great, as reflected by the minor shift in peak position. Second, extensive reaction is observed, with the broad glass peak greatly reduced in the pattern of the reacted materials. The result is similar to that reported by Schilling et al. (1994).

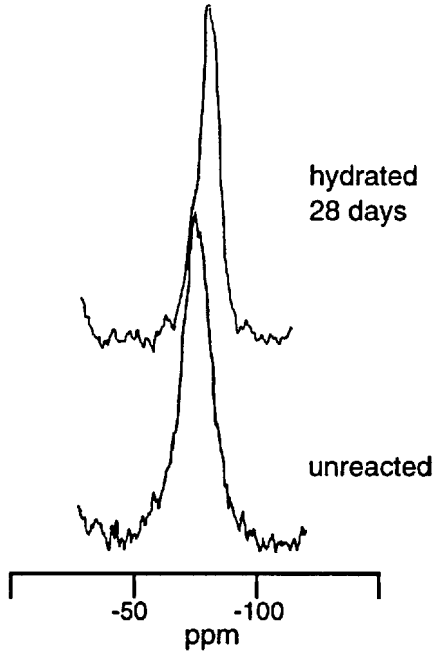

Figure 2 ^{29}Si MAS NMR spectra of slag with 5M KOH at w/c=0.4.

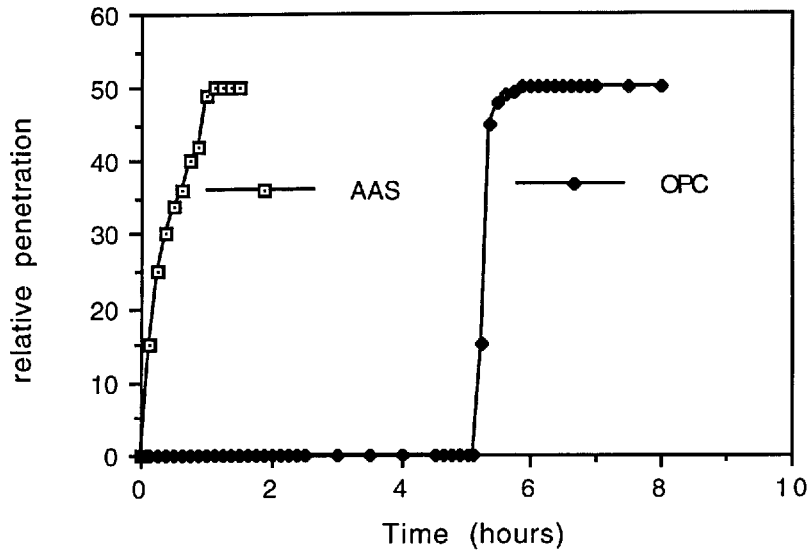

Figure 3 The Vicat penetration profiles for slag with 5M NaOH at w/c=0.4 compared with OPC at 25°C.

Setting time and DTA

The Vicat penetration profiles for AAC with different dosages of NaOH at 25°C shown in Fig. 3. The setting time for AAS is faster than OPC. Cheng and Sarkar (1994) also reported similar observations. The fast setting reaction may be described by dissolution and precipitation mechanisms during the early stages of reaction.

Fig. 4 shows a typical the DTA curve for slag paste activated with NaOH. In the pattern the endothermic peak at 130-150 °C is due to C-S-H(I), and the shoulder at 200-220 °C, superimposed on the right side of the main peak, indicates the presence of an AFm-type phase. The presence of the peak at 460-480 °C can be attributed to the hydrotalcite-type phase, corresponding to release structural water and CO_2.

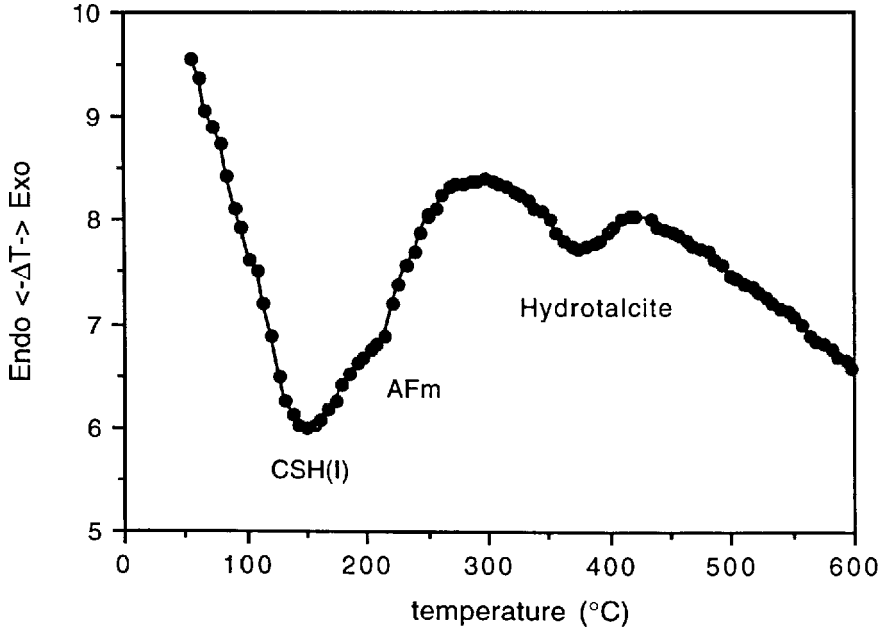

Figure 4 DTA pattern of slag activated 5M NaOH

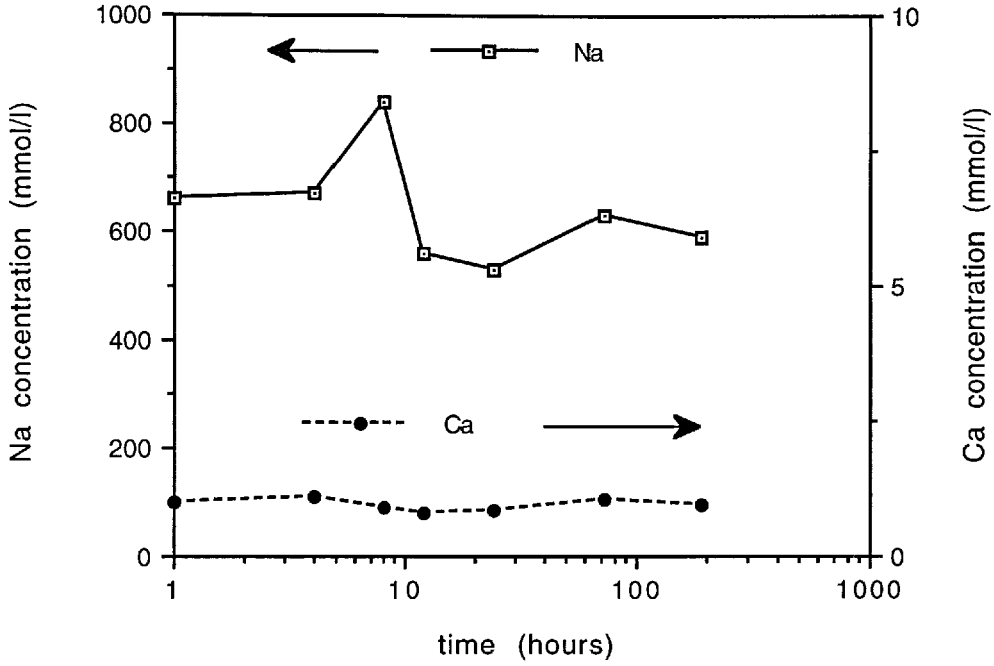

Figure 5 Pore solution composition of slag under activation by 2.5M NaOH at w/c = 0.4

Pore solution and hydration heat

Fig. 5 shows the pore solution compositionof slag under activation by 2.5M NaOH at w/c = 0.4. Condon (1992) showed that content of Na^+ in the pore solution of NaOH activated slag decreased by about 10% in 7 days. The content of Ca^{2+} was keeping unchange. Fig. 6 shows calorimetric curves of heat evolution as function of time for 5M KOH activated slag at w/c = 0.4 compared with OPC during first 24 hours of hydration. The increased reaction rates observed at early time is consistent with the increased rate of setting shown in Fig. 3.

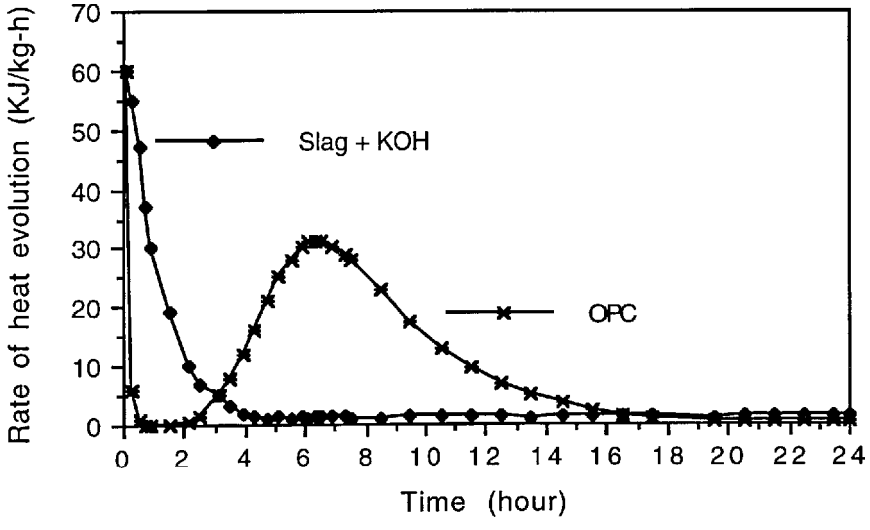

Figure 6 Calorimetric curves showing the heat evolution as function of time for 5M KOH activated slag at w/c = 0.4 compared with OPC during first 24 hours of hydration.

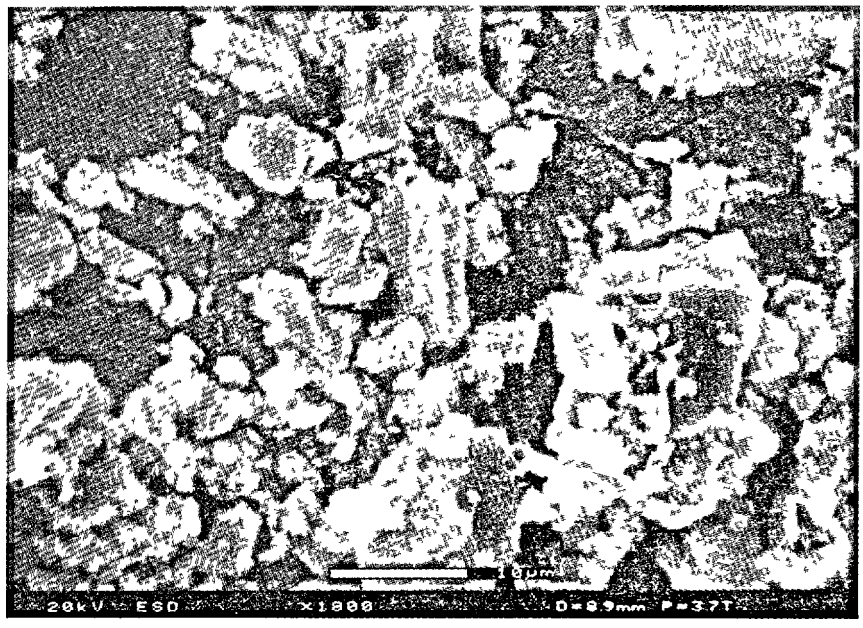

Figure 7 ESEM of 1g slag + 200 mL water after 24 hours.

ESEM

From direct observation of unconstrained samples under controlled humidity conditions, Fig. 7 shows that the slag particles remain relatively unhydrated 24 hour after adding deionized water. Fig. 8 in contrast shows that 1g slag added to 200 ml 5M NaOH solution after 24 hours, with gel-like reaction products.

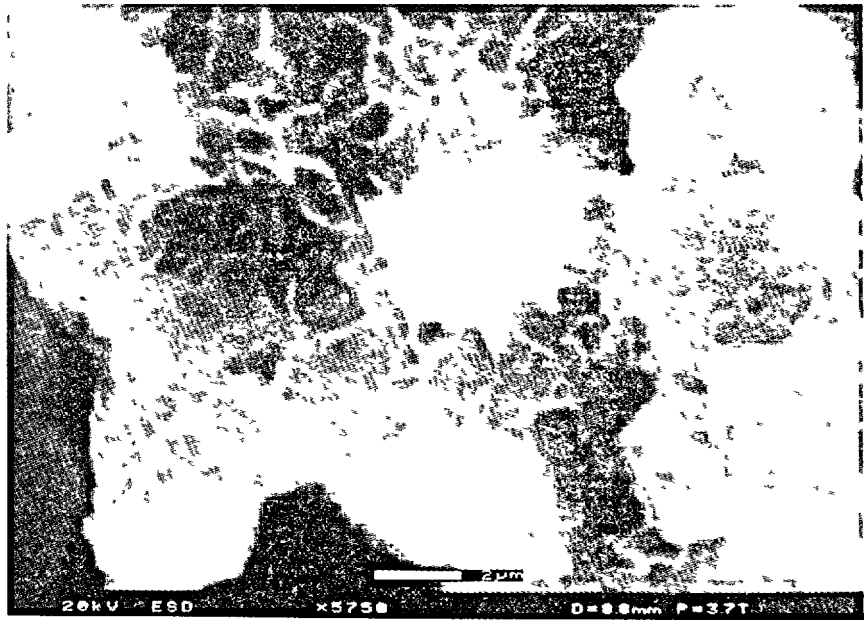

Figure 8 ESEM of 1g slag + 200 ml 5M NaOH solution after 24 hours.

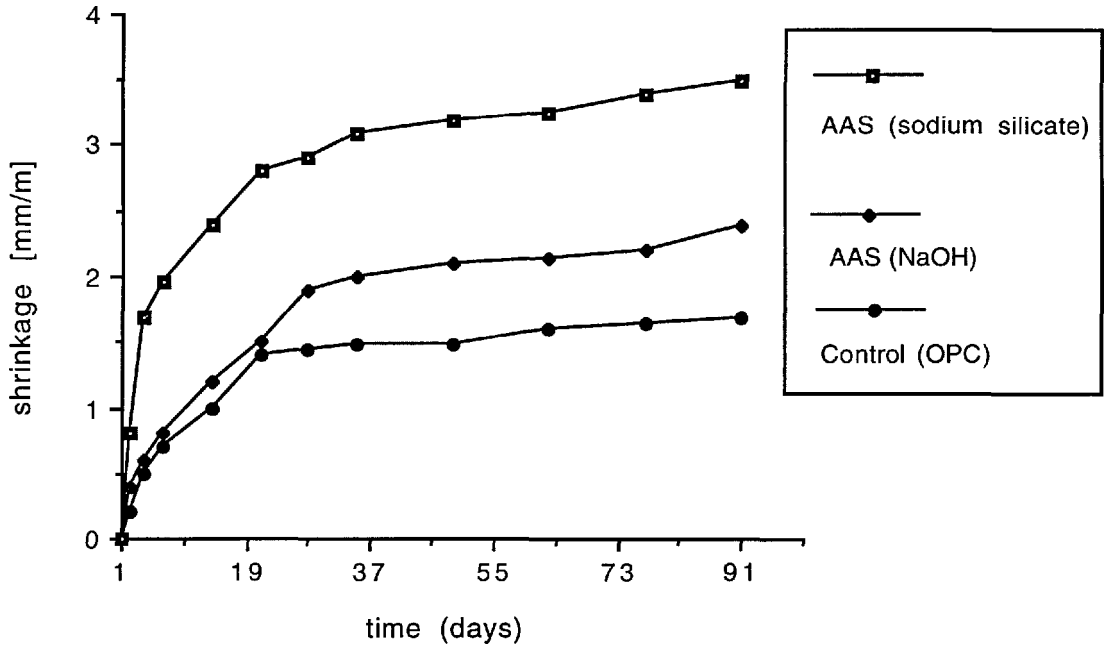

Figure 9 Shrinkage of slag mortar exposed in the air (rh: 70%, temp.: 30°C) at one day as reference state.

Shrinkage

Shrinkage is common measure of rate of a cementitious reaction. It also is used to investigate the stability of mature cement hydration products. The shrinkage of AAS mortars at rh 70% are shown in Fig. 9 in comparison with the control OPC. The shrinkage of slag paste and mortar involves different mechanisms, and is controlled by a number of factors that operate in various parts of the microstructure and at various length scales. The dimensional change due to drying is heterogeneous and each size range is controlled by its own mechanism. Some previous investigation reported that when waterglass was used, the strength is high (Wang et al. 1994), but those based on waterglass solution often undergo greater drying shrinkage due to the formation of silica or silica rich gel during hydration. Silica-rich gel has high water content and may dry with water loss. Drying shrinkage may result in microcracks.

Mechanisms

Activation mechanisms — The primary reaction is an attack on the SiO_2 or Al_2O_3-SiO_2 framework by OH^- ions. It may be postulated that the alkali activation effect could be described as a chemical acceleration of a more conventional pozzolanic reaction. In cementitious composites containing pozzolans the ratio [S+A]/C is high in comparison to conventional cements. Taylor (1990) stated that "the products formed in situ from the pozzolanic material are likely to reflect its composition and the situation in which SiO_2 and Al_2O_3 are readily available compared with CaO". Since slag differs sharply from portland cement in chemistry, it is not surprising that the properties of hardened pastes containing pure slag under alkali activation condition differs from those of cement. The effect of ordinary portland cement were excluded in this research. Perhaps the most common activator used for slag hydration is portland cement. The mechanism of anion removal ensures that even salts which have near-neutral aqueous solution often are able to activate slags.

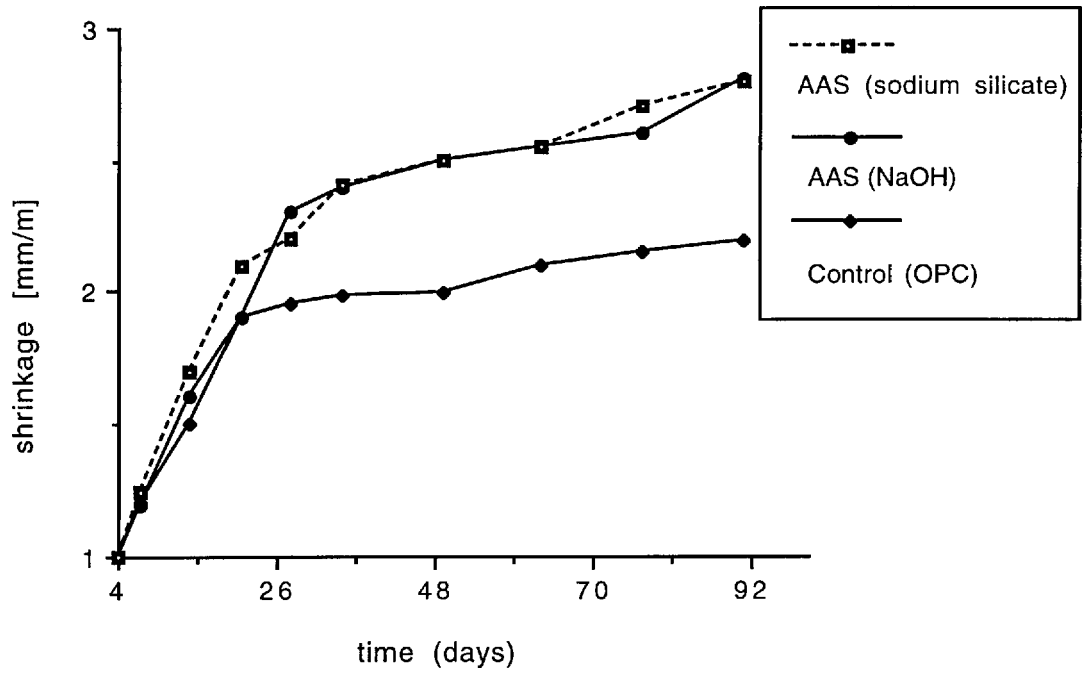

Figure 10 Shrinkage of slag mortar exposed in the air (rh: 70%, temp.: 30°C) at 4 days as reference state.

CONCLUSION

The results of this study show:

- From results of XRD and DTA, at room temperature the most possible hydrated products of alkali activated slag are CSH gel and a hydrotalcite-type phase.
- The results of NMR show that the degree of structural modification around the Si nuclei during hydration is not great, as reflected by the minor shift in peak position and also indicating a greater degree of short-range order.
- Calorimetric results show that a strong initial hydration peak appears. So it may that concluded the alkali (hydroxyl) acts strongly on slag at an early stage of hydration. The setting time is short. The fast setting reaction may be described by a dissolution and precipitation mechanisms during the early stages of reaction.
- ESEM revealed a gel-type reaction product observed after slag is reacted with NaOH for one day, showing the secondary fibrillar development of gel around the slag particles.
- Alkali activated pure slag showed larger shrinkage than those of OPC, when waterglass was used, the amount of shrinkage increased, showing increased reaction.
- The activation mechanisms proposed is that the primary reaction is an attack on the SiO_2 or Al_2O_3-SiO_2 framework by OH^- ions. However more direct experimental evidence still needs to be provided for understanding details.

Due to its rapid hardening and high ultimate strength, AAC have important applications; however, additional research is important to fully understand both "pure" and more complex alkali-activated cements

INFLUENCE OF SPENT BLAST FURNACE SLAGS ON THE PROPERTIES OF CEMENT SYSTEMS

Magdelinka RADENKOVA-YANEVA, Sonya DIMITROVA, University for Architecture, Civil Engineering and Geodesy, Sofia, Bulgaria

ABSTRACT The paper presented deals with the application of spent blast furnace slag sorbents used for waste water cleaning from heavy metal ions. The influence of the type of the ions and the quantity of the spent sorbent on the properties of cement pastes are investigated. It is shown that the structure formation in cement systems and the strength properties of the cement stone are a result of the mutual action of the slag, which has lost its activity during the cleaning process, and ions Cr^{3+} and Zn^{2+}, incorporated in the slag. A possibility for application of useless spent blast furnace slag sorbents in the civil engineering practice is found out and materials saving and environment protection are achieved simultaneously.

Key words: binder, blast furnace slag, hydration, setting, waste material utilization.

INTRODUCTION

The sorption method is one of the most effective methods for drawing out heavy metal ions from waste waters, especially in the case of using cheap and accessible raw materials. In our previous investigations (Dimitrova, 1995; 1996) the sorption activity of blast furnace slag to the Cr^{3+}, Cu^{2+}, Ni^{2+}, Zn^{2+} - ions is established. Preliminarily conducted studies with the spent sorbent show that it is not an occasional case for environment pollution and can be disposed of or used additionally.

Recently a manner of inertization of wastes, containing heavy metals, is found (Malone, 1989; Conner, 1990; Rossetti et al, 1995). Different matrixes are used, including binders on the base of cement (Venkobachar et al, 1995). But more attention is paid there to the method for inertization of wastes while their influence on the hydration of binders is studied in a small scale.

It is known that the addition of inorganic salts in cement systems influences their hydration and properties (Ratinov, 1973; Babatschev, 1976). The possibility for application of blast furnace slag for production of slag cements and slag portland cements due to the hydraulic activity of the slag is ascertained (Ners, 1964). The possibility for additional use of slag applied for waste water cleaning and thus containing heavy metals ions is not still studied

The present study aims to establish the influence of the blast furnace slag sorbent on the physico-chemical and physico-mechanical properties of cement systems.

MATERIALS AND EXPERIMENTAL METHODS

The investigation is conducted using an ordinary portland cement type I (ENV 197-1). Blast furnace slag used as a sorbent has the following chemical composition (% by weight): SiO_2 - 36.0; CaO - 41.6; MgO - 2.7; MnO - 2.5; Al_2O_3 - 8.7; BaO - 3.0. The data from blast furnace slag studies (Dimitrova, 1995) show that it is a mixture of complex crystal calcium hydroaluminates, calcium silicates and oxides with sorption properties. The investigations are performed with ground blast furnace slag with a size of the grains below 0.25 mm ($d < 0{,}25$ mm) after its using as a sorbent for the cleaning of waste waters containing Cr^{3+}

and Zn^{2+} ions in dynamic condition. The spent sorbent contains approximately 1 % metal ions and is added in cement systems as a dry material.

From the cement and the spent sorbent, mixtures of binders are prepared. Their composition is shown in Table 1 and Table 2. The sorbent is added in quantities 5, 10, 15 and 20 % by the weight of the binder. From binders, pastes are prepared and using Vicat method (EN 196) the setting time is determined. The time for structure formation is reported from the curves of the shear strength change versus time of hydration.

Table 1 Setting time and time for structure formation for the pastes containing spent blast furnace slag sorbents

Binder			Setting time		Time for structure formation
Designation	Type	Spent slag, %	initial	final	
			hour - min.		hour - min.

The mechanical tests are performed using pastes with equal consistency. From the pastes samples prisms 2x2x8 cm are prepared. At a relevant age flexural and compressive strengths are determined.

RESULTS AND DISCUSSIONS

The data from the investigation performed are shown in Tables 1 and 2. The control in the mechanical testing is a pure portland cement without addition of slag (Table 2, composition A). For the other tests, characterizing setting and hardening, the control samples are of cement with a corresponding quantity of freshly ground slag (without heavy metal ions) (table 1, compositions A). The properties of the systems studied depend on the quantity of the spent blast furnace slag sorbent and the type of the contained in the slag metal ions. The spent sorbent, used in our investigations, has been in a prolonged contact with water during waste water cleaning. The appreciable finess of the material ($d < 0.25$ mm) and its peculiar composition determine some interaction with water (Dimitrova, 1995). That is why the spent blast furnace slag has a lower activity in comparison with the freshly ground slag. Metal ions, sorbed onto the surface of the slag grains, also influence the hydration process and on the properties of the hydrated systems.

The mixtures with addition of spent blast furnace slag have a retarded setting time and a prolonged time for structure formation (t_{sf}) (table 1, compositions B and C). This is explained with the kind of the ions sorbed on the surface of the slag grains and with the reduced quantity of the active component in the binders. The results received show, that the behavior of mixtures with two kinds of ions (Zn^{2+} and Cr^{3+}) is different. The retardation of structure formation (higher values for t_{sf}) is considerably higher for compositions containing Zn^{2+} ions (Table 1, samples B). In this case the retarding effect of heavy metal ions (Zn^{2+}) is summed with the generally lowered activity of the binders (the influences are unidirectional). For compositions containing Cr^{3+} (Table 1, samples C) the effect of the lower activity of the sorbent is summed with the accelerating action of the chromium ions, and the latter are predominant. The accelerating action of Cr^{3+} ions is sufficient to neutralize almost completely the effect of the lowered activity of the spent slag in the investigated compositions. The results received conform well to the literature data (Ratinov, 1973; Babatschev, 1976).

The flexural and compressive strengths of the mixtures studied are lower in comparison with those of the control (Table 2, sample A). These differences are greater in the later stage of investigation (29 and 90 days). The lowering of the strength properties is in accordance with the composition of the studied systems. The quantities of metal ions added to the binders with spent sorbents are not very high and their action is revealed in the early stages of hardening. The above mentioned can explain the almost equal flexural and compressive strengths at the age of 7 days for all the investigated compositions. The results obtained allow to propose the spent blast furnace slag for use as a component of cement systems where high strength properties are not required. The combination between retarded setting and enough strength could be suitable in special cases in civil engineering practice - the producing of "wash" concretes, decorative concrete products and others.

CONCLUSION

The investigations conducted and the results received show that the used spent blast furnace slag sorbent, containing metal ions (Zn^{2+} and Cr^{3+}), influences the hydration, the structure formation and the mechanical properties of the cement systems. The retarded time for setting and hardening and the sufficient strengths of the hardened cement systems enable us to recommend their use in specific cases in the civil engineering practice. The adding of spent blast furnace slag sorbent in cement systems results in the lowering of cement consumption and contributes to additional environment protection - the waste product from water cleaning is used and the area for its disposal is reduced.

A STUDY OF EARLY HYDRATION OF SLAG CEMENT PASTES SUBJECTED TO THERMAL CURING

Arnaldo Forti BATTAGIN, Brazilian Association of Portland Cement, São Paulo, Brazil
Gladis CAMARINI, State University of Campinas, Brazil
Maria Alba CINCOTTO, State University of São Paulo, Brazil

ABSTRACT A conduction calorimeter and DTA/TGA techniques were used to monitor hydration kinetics of mixtures of ordinary portland cement and granulated blast-furnace slag. It was found that at 23°C cement and slag have maximum hydration rates at different period. At 60°C only one peak occurs after a smaller period of hydration. Slag shows better behaviour under thermal curing than clinker and acceleration of slag hydration is confirmed by thermogravimetry and compressive strength results.

Key-words: blastfurnace-slag, heat evolution, hydration, steam curing

INTRODUCTION

Steam curing is a very useful technique employed in precast concrete with the aim of accelerating the concrete demolding. Cements at low hydration rate as the slag cements are known for a good behaviour under thermal curing.An attempt is made to explain the hydration characteristics of slag cements under thermal curing (60°C) in comparison to the same cements under normal curing (23°C).

EXPERIMENTAL PROCEDURE

The influence of curing temperature on hydration of slag cements were studied on mixtures of ordinary portland cement (OPC) and granulated blast-furnace slag (GBFS) representative of industrial production in Brazil. Proportions of OPC/GBFS were 100/0, 65/35, 50/50 and 30/70.

These mixtures were submitted to an isothermal conduction calorimeter (JAF model), w/c = 0.4, at both 23°C and 60°C and hydration products were analysed by DTA/TGA techniques. Mortar compressive strengths were determined according to the Brazilian method (NBR 7215) by using cylindrical test specimens Ø50 x 100mm height in proportion 1:3 (cement:sand), cured at 23°C, w/c = 0.48 and at 60°C according to a thermal cycle detailed in Camarini et al (1996).

Table 1 Characteristics of starting materials and mixtures

% mass	SiO_2	$A\ell_2O_3$	Fe_2O_3	CaO	MgO	SO_3	K_2O	Na_2O	LOI	IR
OPC	18.51	4.32	4.08	60.14	5.98	3.15	0.56	0.12	1.32	0.19
GBFS	33.25	11.29	0.53	44.93	6.28	1.60	0.36	0.19	-	-

	OPC	65/35 MIX	50/50 MIX	30/70 MIX	GBFS
Initial setting time (h:min) (Vicat test)	2:30	4:00	5:00	5:15	-
Specif surface area ($m^2.kg^{-1}$)	324	380	395	440	500

RESULTS AND CONCLUSIONS

Compressive Strength

Table 2 shows the mortar compressive strength results. RIC values were obtained just after an isothermal cycle of 9h at 60°C plus periods of both temperatures increasing and decreasing and setting time as schematized in Figure 1. RIC is abbreviation of "strength just after cycle", in portuguese.

Table 2 Mortar Compressive Strength (MPa) Camarini (1995)

Curing Temperature (°C)	Age (days)	OPC	65/35 Mix	50/50 Mix	30/70 Mix
60	RIC	21.2	22.3	22.9	22.2
23	2	21.9	14.1	11.3	9.0
	28	42.0	45.4	51.3	48.5
	90	44.4	49.0	62.9	50.0
60/23 (*)	2	30.0	28.4	26.8	26.4
	28	39.9	50.1	48.9	53.0

(*) thermal cycle at 60°C plus normal curing

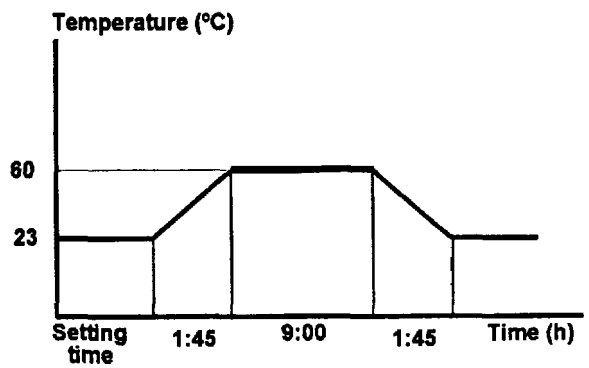

Figure 1 Thermal cycle characteristics

From Table 2 we can conclude that at early ages under normal curing, the higher the cement replacement by slag, the lower is the compressive strength. Slag hydration rate is lower than that of clinker and this fact can explain the strength reduction of mixtures when compared to the control. At 28 days and 90 days the highest values are found for 50% replacement. In this case, 50% seems to be the optimum content of slag and this proportion depends on the physical and chemical characteristics of both clinker and slag. Compressive strength values after initial 60°C cycle are almost the same for all mixtures moreover, these values are similar to the OPC specimens at 2 days under normal curing. The early strength gain of mixtures under thermal curing when compared to the same mixtures under normal curing is higher for higher the cement replacement by slag.

Heat of hydration

Figure 2 and Table 3 show the heat evolution rate. At 23°C, clinker and slag have maximum hydration rates at different time, represented by two peaks of heat evolution. One peak from 10:30h to 11:40h is due to clinker fraction and the other from 16:00 to 19:00h is due to slag hydration. At 60°C, only one peak occurs after a period between 3:25h and 4:30h, showing the acceleration of both clinker and slag hydration.

At 23°C, first peak of 50/50 and 65/35 mixtures is slightly retarded when it is compared to OPC but at 60°C it is slightly accelerated. However, kinetics of reaction of clinker and slag seems to be independent at 23°C as we can conclude from the experimental measures and calculated values presented in Table 4.

Table 4 Experimental and calculated values of heat liberation at 23°C

Mixtures	Peak of Heat (W/kg)		Total Heat Liberated After 48h		
			Experimental (J/g)	Contribution of Slag (Calculated)	
	Experimental	Calculated		J per gram of cement	J per gram of slag
OPC	3.34	3.34	239	-	-
65/35	2.12	2.17	180	25	70
50/50	1.66	1.67	152	32.5	65
30/70	0.99	1.00	114	42.3	60

DTA/TGA Results

In Figures 3 and 4 are presented thermograms of all mixtures cured at 23°C and 60°C, respectively. They exhibit an intense endothermic peak between 60°C and 100°C due to the loss of the free water. Another endothermic peak appears at 460°C and is due to $Ca(OH)_2$ decomposition. The lower the intensity of this peak, the higher is the contents of slag in the mix. In fact, increased amounts of $Ca(OH)_2$ are found at lower contents of slag, as we can conclude from the loss of mass values for the temperature interval of 440-500°C, shown in Table 5. These effects are indicative of the consumption of $Ca(OH)_2$ by the slag, mainly for the pastes cured at 60°C. Another endothermic peak of smaller magnitude also appears at 170°C in the pastes cured at 60°C and it is supposed to be due to hydrated aluminous phases. Sometimes an exothermal

peak is also found at 230°C probably due to the calorimeter oil contamination. From Table 5 we can also conclude that the contents of non evaporable water of mixtures cured at 60°C compared to those of the same mixtures cured at 23°C are higher, the higher the slag proportion.

THE INFLUENCE OF ALKALI ACTIVATOR ON THE EARLY HYDRATION AND PERFORMANCE OF PORTLAND BLAST FURNACE SLAG CEMENT

Everaldo, MARCIANO JR.
Arnaldo Forti BATTAGIN, Brazilian Association of Portland Cement, São Paulo, Brazil

ABSTRACT This paper shows the best behaviour of Na_2SO_4 among other activators of portland blast furnace slag cement. Sodium silicate, extensively used in alkali activated slag, has a poorer performance than Na_2SO_4 in the presence of $Ca(OH)_2$. Depending on the characteristics of cement and activator, Na_2SO_4 can increase the early strength gain of blast furnace slag cements without significantly affecting long term compressive strength. A use of sodium sulfate - rich waste could be an environmental solution for waste disposal but further studies will be necessary.

Key-words: accelerators, activation, alkali, blastfurnace slag.

INTRODUCTION

Many publications have dealt with the role of chemical activators, mainly sodium silicates (water glass) on the slag hydration (Shao-Dong Wang et al, 1995). There is a general agreement about the good behaviour of these compounds as slag activators on so-called alkali-activated slag cements (AAS) but less work has been done about the study of alkaline activation of slag in portland cement.

In order to evaluate the most suitable slag activator we carried out preliminary tests based on compressive strength. Two blast furnace slag cement (BFSC) samples representative of industrial production in Brazil were chosen. Cements selected have different mechanical performance according to the Brazilian method by using 50 x 100mm cylindrical test specimens in proportion 1:3 (cement:sand), water cured at 23°C, w/c = 0.48. Both granulated blast furnace slag are basic, refractive index 1.65 and 95% vitrified. Mixes of 99% cement and 1% of six different chemical agents (Reagent Grade) were used with the aim of improving the early strength gain. Results are shown on Table 1.

Table 1 - Effects of different slag activators

Cement	Activator	Compressive Strength (MPa)			
		1 day	3 days	7 days	28 days
A	None	5.1	17.4	35.3	59.1
	K_2SO_4	8.1	21.2	35.2	49.8
	NaOH	7.2	15.7	23.0	33.8
	Na_2CO_3	6.9	17.3	26.7	37.4
	$A\ell_2(SO_4)_3$	5.5	18.3	32.3	52.1
	Na_2SO_4	8.6	21.0	32.7	47.1
	$NaSiO_3.nH_2O$	5.5	16.1	27.9	46.2
B	None	4.3	13.1	20.0	32.8
	K_2SO_4	7.2	15.7	22.4	34.7
	NaOH	6.5	14.1	19.1	29.5
	Na_2CO_3	5.6	14.1	18.7	30.6
	$A\ell_2(SO_4)_3$	4.0	13.0	21.3	36.0
	Na_2SO_4	7.6	16.1	22.5	33.8
	$NaSiO_3.nH_2O$	4.7	13.2	20.1	32.0

Based on the preliminary results it was decided to detail the investigation of the Na_2SO_4 activator, although Jawed and Skalny (1983) have shown it decrease the cement strength at long term age. Sodium silicate had a poorer and unexpected behaviour compared to those reported in literature for slag alone.

ACTIVATION WITH Na_2SO_4 (REAGENT GRADE)

Mixtures of BFSC and Na_2SO_4 at proportions in mass of BFSC/Na_2SO_4 of 100/0, 99.5/0.5, 99/1 and 98/2 were made. Compressive strengths were determined at 1, 3, 7, 28, 60 and 91 days and a conduction calorimeter was used to monitor hydration kinetics. Table 2 shows the results obtained as well as additional characteristics of materials.

Table 2 - Mechanical and Rheologycal Results

Cement	Na_2SO_4 (%)	Compressive Strength (MPa)						Setting Time (Vicat Test)		Soundness Le Chatelier
		1 day	3 days	7 days	28 days	60 days	91 days	Initial (h:min)	Final (h:min)	(mm)
A	0 (reference)	5.1	17.4	35.3	59.1	60.7	68.6	3:55	5:35	0
(58% slag , 5%	0.5	7.1	20.5	34.1	51.5	54.8	57.3	3:45	5:15	0.5
limestone and 419$m^2.kg^{-1}$	1.0	8.6	21.0	32.7	47.1	50.4	54.8	2:55	4:15	0
Blaine surface area)	2.0	10.7	21.9	29.5	39.9	44.3	46.5	2:35	4:15	0
B	0 (reference)	4.3	13.1	20.0	32.8	39.9	43.1	3:25	4:55	0
(44% slag, no	0.5	5.6	14.4	20.7	32.1	38.4	42.9	3:05	4:05	0
limestone and 342$m^2.kg^{-1}$	1.0	7.6	16.1	22.5	33.8	36.0	38.8	3:10	4:20	0
Blaine surface area)	2.0	8.5	17.0	22.0	33.1	37.1	39.5	2:40	4:00	0.5

From Table 2 we can conclude that at early ages (1 and 3 days) the higher the Na_2SO_4 content, the higher the compressive strength for both samples.For cement A, at 7 days and beyond, there is a remarkable decrease of strength with the increasing quantities of Na_2SO_4. It can be seen that strength values can reach only 68% of the reference at 91 days with 2% Na_2SO_4. However, a different behaviour was found for sample B showing smaller loss of strength. In fact, at 91 days a value of 90% of reference for 1% Na_2SO_4 was observed.

Tables 3 and 4 summarize the results of heat of hydration up to 72 hours, taking into account that the peak due to the first minutes of hydration was undetected due to operational conditions.

Table 3 - Heat Peak Evolution

Cement	Na_2SO_4 (%)	Heat peaks at 23°C (W/g)		Time (h:min)	
		First	Second	First	Second
A	0	2.32	-	12:25	-
	0.5	2.40	-	12:30	-
	1.0	2.42	-	12:15	-
	2.0	2.43	-	11:00	-
B	0	1.58	1.89	8:40	15:50
	0.5	1.69	1.78	8:30	17:00
	1.0	1.77	1.77	7:10	14:50
	2.0	1.73	1.74	8:20	15:20

Table 4 - Total heat liberation up to 72h

Sample	Na_2SO_4 (%)	Total heat liberated after (hour) (J/g)												
		2	4	6	8	12	16	20	24	30	40	50	60	72
A	0	1	4	12	22	50	76	91	103	118	139	156	169	182
	0.5	1	5	14	26	56	88	106	119	134	154	169	183	196
	1.0	1	5	13	26	57	90	111	125	140	159	173	184	193
	2.0	2	6	17	32	66	96	117	132	147	165	178	187	194
B	0	2	8	18	29	51	76	97	108	121	137	149	159	168
	0.5	2	9	19	31	55	80	104	120	135	152	164	174	184
	1.0	3	12	24	37	61	87	110	126	141	158	170	181	191
	2.0	2	9	20	32	56	81	105	123	139	156	169	180	190

From Table 3 we can conclude that first peak of 99/1 and 98/2 mixes is slightly accelerated compared to reference for both sample. The same phenomenon is found for the second peak of heat for sample B. First peak is supposed to be due to clinker fraction hydration and second peak is attributed to slag hydration. However, sample A exhibits only one peak. These atypical results indicate that, in this case, maximum hydration rate of both clinker and slag are simultaneous. Acceleration of both clinker and slag fraction by using Na_2SO_4 as activator is confirmed by results of total heat liberation listed on Table 4.

ACTIVATION WITH SODIUM SULFATE WASTE

The use of an activator is usually expensive and may impair its use in practice. Aiming the reduction of the costs and trying to find an environmental solution for waste disposal an attempt was made concerning the use of a waste as activator. So we replaced the Na_2SO_4 (Reagent Grade) by a glass - industry waste rich in this component (27.1% SO_3 and 47.5% Na_2O). Similar tests to those of compressive strength shown in Table 2 were carried out. Preliminary results are listed on Table 5.

Table 5 - Results of sodium sulfate waste as an activator

Cement	Waste Content (%)	Compressive Strength (MPa)			
		1 day	3 days	7 days	28 days
1	0	5.1	17.4	35.3	59.1
	0.5	3.0	16.0	30.9	55.5
	1.0	2.4	16.3	30.6	50.5
	2.0	1.1	16.7	28.5	43.8
2	0	4.3	13.1	20.0	32.8
	0.5	3.7	10.8	17.3	28.9
	1.0	5.1	13.2	18.6	29.5
	2.0	1.1	10.0	15.3	26.1

In spite of bad results for cement 1, the use of waste brought up some advantages to cement 2, mainly with 1% Na_2SO_4. This fact stimulates further studies to a better understanding of the behaviour of waste activated cement as a contribution for waste elimination.

DISCUSSION AND CONCLUSION

- Sodium silicate is the most used activator for alkali activated slag but its behaviour was not good in presence of $Ca(OH)_2$ liberated from clinker hydration.

- At 1% levels, Na_2SO_4 seems to be the most suitable activator among those used in this study.
- Unique heat peak found in cement 1 is probably not due to influence of activator because it also occurs in reference sample. In this case a higher specific surface area of slag and a poorer reactivity of clinker compared to sample 2 accelerated slag hydration and retarded clinker hydration.
- Compared to cement 1, cement 2 presented a higher heat liberation at first 12 hours probably due to its lower slag content in spite of being coarser than sample 1. At 24h and beyond (72 h) heat liberation was higher for sample 1. Results are in agreement with compressive strength results. Setting time is accelerated with the increase of Na_2SO_4 contents and unsoundness due to its use was not detected.
- At 1 and 3 days the behaviour of both samples activated with Na_2SO_4 was similar, with a strength gain of aproximately 100% and 25-30% respectively for 2% Na_2SO_4. However, a different behaviour was found after 7 days, with a harmful influence of Na_2SO_4 on the cement of better performance (sample 1). On the other hand, long term strength was little affected in cement of worse performance.
- Optimum contents of Na_2SO_4 depends on characteristics of both cement and activator and further studies will be necessary for supplementary consideration about the potential use of sodium sulfate-rich waste as activator.

HIGH PERFORMANCE ENERGETICALLY MODIFIED PORTLAND BLAST-FURNACE CEMENTS

Hanumantha Rao KOTA[1], Vladimir RONIN[2] and Eric FORSSBERG[1]
[1]Division of Mineral Processing, [2]Division of Structural Engineering, Luleå University of Technology, S-971 87 Luleå, Sweden

ABSTRACT The mechano-chemical treatment in the milling equipment with vibrating grinding media of Portland cement-blast furnace slag blends has considerable impact on strength development, especially in the early-ages. The high shear/attrition treatment of solids increases the pozzolanic activity of microsilica by its disintegration and dispersion, increases the rate of hydration reactions due to the increase in surface free energy and increases the hydraulic activity of blast-furnace slag.

INTRODUCTION

A new mechano-chemical activation method has been developed at Luleå University of Technology during the last years (Jonasson and Ronin, 1993; Ronin and Häggström, 1994), in which the ordinary Portland cement (OPC) in combination with silica fume is treated in a vibrating mill. The high shear/attrition environment is thought to have led an increased irregularities of the surface structure of the blends thereby increasing the surface electrostatic field and creating a new binder surface by coating silica fume on the cement particles. This newly obtained binder is called Energetically Modified Cement (EMC) and is found to have an extremely high chemical reactivity when compared to the reference blend of OPC and silica fume. The cement pastes and mortars obtained with the use of EMC show a pronounced increase of pozzolanic reaction rate with corresponding increase of C-S-H-gel amount and a significant decrease of the paste porosity, thereby the strength parameters at early ages and after prolonged curing times have greatly improved.

The EMC method is found to be effective for the development of high performance concretes with low-heat liberation. Compositions of the binders with various amounts of ordinary Portland cement, ground blast furnace slag and 5% of silica fume are investigated in order to understand the mechanisms underlying the improved properties of binding materials by the mechano-chemical activation method in a vibrating grinding mill. This paper describes the results of the efficiency of EMC method through particles characterisation, FT-IR studies, porosity of the pastes and strength development of the mortars at different stages of curing, while using the materials before and after the activation process.

EXPERIMENTAL

Materials

The ordinary Portland cement produced by Cementa AB, Sweden was used in this work. The condensed silica fume produced by Elkem A/S, Norway as a puzzolanic additive and the ground blast-furnace slag (MERIT 5000) manufactured by SSAB, Sweden as an admixture were used in the experiments. The chemical composition of the materials, according to the manufacturers, are given in Table 1.

Table 1. Chemical composition of the materials.

Oxide	OPC (wt%)	Silica fume (wt%)	Blast-furnace slag (wt%)
SiO_2	19.80	96.00	34.03
Al_2O_3	4.23	0.30	11.51
Fe_2O_3	2.21	0.20	0.42
CaO	63.00	0.95	35.46
MgO	3.43	0.30	13.54
SO_3	3.23	0.10	3.44
K_2O	1.28	0.30	0.56
Na_2O	0.27	0.20	0.54
MnO			0.44
TiO_2			1.90
Surface area, m^2g^{-1}	0.368 (Blaine) 1.830 (BET)	19.74 (BET)	1.21 (BET)

The following blends were investigated and referred in the text as 1 to 4:

1. 30% Ordinary Portland cement + 5% silica fume + 65% blast-furnace slag
2. 20% Ordinary Portland cement + 5% silica fume + 75% blast-furnace slag
3. 10% Ordinary Portland cement + 5% silica fume + 85% blast-furnace slag
4. 0% Ordinary Portland cement + 5% silica fume + 95% blast-furnace slag

Methods of investigation

The mechanical modification of the above mentioned blend mixtures was carried out in Humboldt Palla 20U vibrating mill. The blends of 2 kg material was subjected to milling ea time with porcelin cylindrical grinding media. Each blend was milled for three different perio (i.e., 5, 15 and 30 min) and the products before and after milling were used for the followi investigations:

Particles characterization

The particle size distribution was determined by Sedigraph (Micromeritics, model 5100) wh using Sedisperse A12 particle dispersion liquid. The particles in the suspension were dispers in a ultrasonic bath for about 30 seconds prior to the measurement. The specific surface areas the samples were determined by BET method (Micromeritics, flow sorb II 2300) using nitrog gas adsorbate.

FT-Infrared measurements

The spectra of the samples were recorded using a Perkin Elmer 1720X infrared Fouri transform spectrometer with diffuse reflectance attachment. The samples for diffuse reflectan were prepared by dispersing 25 mg of the sample in 200 mg of KBr. Typical measurement ti for recording the spectra was 2.4 min (32 scans) at a resolution of 4 cm^{-1}.

Porosity measurements

Porosity measurements were made by mercury porosimetry (Micromeritics, pore sizer 930 Cylindrical mortar specimens measuring 25 x 55 mm were produced with the water-binder ra of 0.25. For each blend, three specimens were prepared in a polyethylene container and th were heated at 105°C overnight after allowing a curing time of 7, 14 and 28 days respectively, order to stop the hydration process. Pore-size distributions were obtained at various times intruding mercury into the dried specimens at pressures up to 25 000 psi.

Mechanical strength properties

The mechanical strength tests, i.e., the compressive and bending strengths development, were performed on the mortar specimens containing 1 part by weight of binder of different composition and 3 parts by weight of EN standard sand. The water to binder ratio was maintained constant at 0.40. The mortars were mixed at room temperature of about 20°C in Horbart mixer for 3 min and cast in 40x40x160 mm steel moulds. After casting, the samples were compacted on the laboratory vibrating table for about 40 seconds. The density of the compacted mortars were 2250 to 2320 kg m^{-3}. The samples were sealed in plastic foil and put in curing chamber at 20°C for 24 hours. After one day curing, the samples were transfered to a thermostated water bath for the rest period of curing. The temperature was maintained constant at 20°C. Samples of each mortar were removed from moulds and tested for uniaxial compression and three-point bending for 1, 3, 7 and 28 days. Testing was done on the hydraulic press 506/200/10 DM1 (Germany). Loading speed rate was 2.4 kN/sec for compression and 0.5 kN/sec for bending. An average data of nine test results was presented.

RESULTS AND DISCUSSION

Particles characterization

Portland cement and slag materials consist rather broad size distributions extending from 2 to 40 μm size. The slag (d_{50} = 12.14 μm) is finer than Portland cement (d_{50} = 15.66 μm) but the BET surface area of the cement is found to be bigger (1.83 m^2g^{-1}) than slag (1.21 m^2g^{-1}). The results indicate the porous nature of cement grain when compared to the slag particle. The specific surface area of silica fume is determined to be 19.74 m^2g^{-1}.

The particle size distributions of the blends 1 to 4 after mechanical treatment at different time intervals have been summarized in Table 2. The vibration milling reduced the average particle size to 30-40% and increased the specific surface area to 10-20% at 30 min activation time. When the quantity of cement is proportionately decreased in the blends with an increase in the finer slag amount, the effect of treatment on decreasing the particle size is not that significant.

In vibration milling, the particles experience greater attrition/shear forces than impact forces, thereby the surfaces of the particles will become smoother leading to the shape of the particles close to sphere. The fluidity of the cement could be improved by bringing the shape of the particle close to sphere since the thickness of the free water film that exists between the particles increases with the increase of smoothness of surface (Uchikawa, 1994). High-strength concrete demands low water/cement ratio and at low water content, the particles will be closer in contact with each other and the viscosity is reduced. Thus, one of the beneficial effect of the present mechanical treatment is the improvement of the fluidity of cement paste at lower water contact by making the particles close to sphere.

The dosage of silica fume is an important parameter influencing the compressive strength of silica fume concrete. An optimum dosage is reported to vary in between 7 and 10 wt% of the total blend (Malhotra et al., 1992). Based on the specific surface area of cement and slag materials, the amount of 5 wt% silica fume used, is calculated to cover more than 86% fraction of the total surface area of matrix materials in any of the blends.

FT-Infrared studies

The diffuse reflectance spectra of ordinary Portland cement (OPC), blast-furnace slag (BFS) and silica fume (SF) are presented in Fig 1. The spectrum of silica fume shows the strongest absorbance bands at 1122, 805 and 480 cm^{-1}, characteristic of silica gel where the four-coordinated silica absorbs at 1094, 800 and 470 cm^{-1} (Moenke, 1974). The silica gel nature can also be seen by the band at 3625 cm^{-1} due to OH stretching of SiOH, and the H-O-H bending vibration near 1630 cm^{-1}.

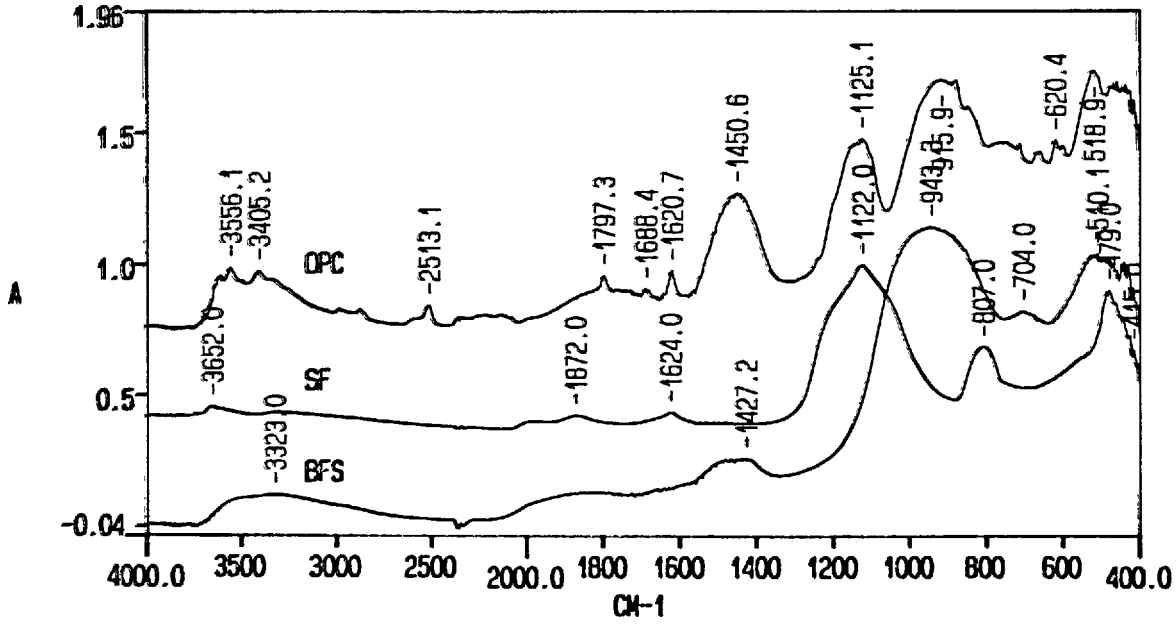

Figure 1 Diffuse reflectance spectra of ordinary Portland cement (OPC), silica fume (SF) and blast-furnace slag (BFS).

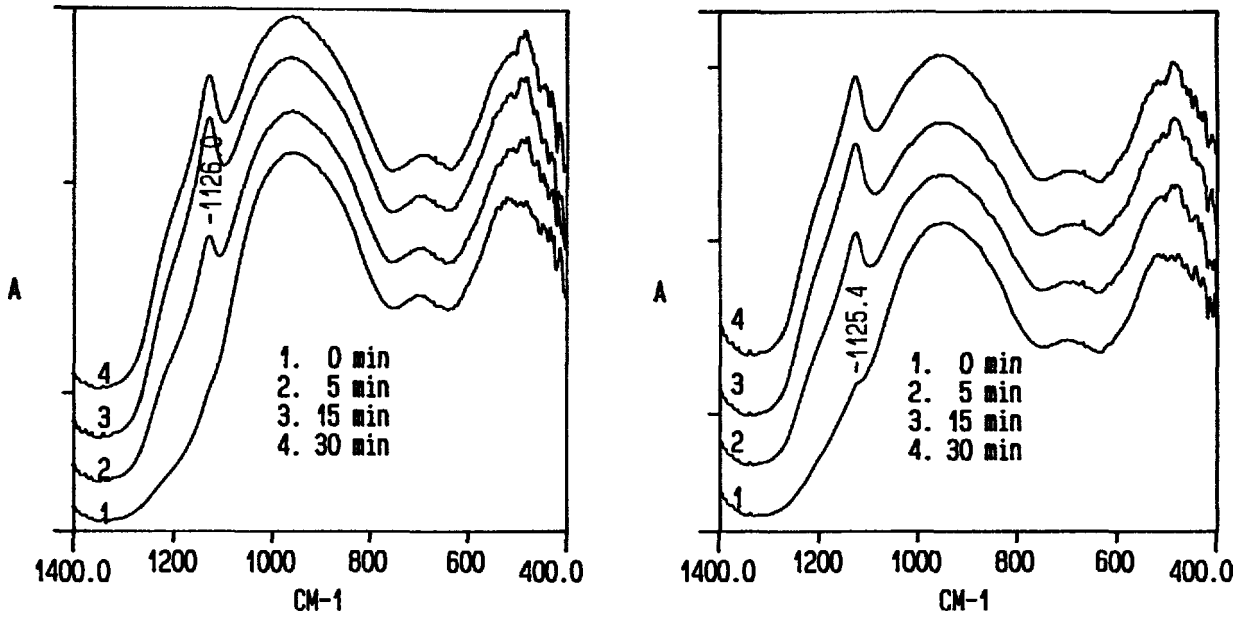

Figure 2 Diffuse reflectance spectra of the blends 2 (right) and 4 (left) before and after activation at different time intervals.

The spectrum of blast-furnace slag shows entirely different absorbance features than Portland cement, although the materials differ only in the ratio of chemical composition of the SiO_2, Al_2O_3, CaO and MgO. The main difference being that the CaO content is less in slag but with a proportionate increase in SiO_2, Al_2O_3 and MgO amounts. Since the materials consist of different mineralogical compositions, the different absorbance pattern is obviously expected. The antisymmetric Si-O-Si stretching band at 1125 cm^{-1} in the case of cement is shifted in slag with a broad high intensity band centering around 950 cm^{-1} due to its increased alumina content (Moenke, 1974). This low-frequency shift arises from the increasing contribution made by Si-O-Al linkages at the expense of Si-O-Si. The surface hydroxyl groups or the structural hydroxyl groups that present in gypsum component of cement can be seen from the OH stretch modes at 3610, 3556 and 3405 cm^{-1}, and from the H-O-H bending modes at 1687 and 1620 cm^{-1} in the spectrum of cement.

The spectral features of the blend containing only cement and silica fume are found to be exactly the same before and after vibration milling. However, the intensity of the band due to Si-O stretching vibration at 1127 cm^{-1} is seen to increase after the modification process. The beneficial effect of microsilica on the strength properties of concrete was reported by several authors, only when it is well dispersed in a concrete mixture. The efficient dispersion of microsilica can be noticed from the spectra of the blends in the presence (20 wt%) and absence of the cement component. These spectra before and after activation in vibration milling at different time intervals are presented in Fig 2. The spectrum of slag and silica fume mixture before activation show no absorbance bands characteristic of silica fume, but after the activation process, a sharp band characteristic of Si-O stretching vibration at 1127 cm^{-1} can be seen. It is worthwhile to point out here that the 0 min spectrum corresponds to the mixture before modification, but thoroughly homogenized in a rotating drum prior to recording the spectrum. With increasing time of activation process, the intensity of the band at 1127 cm^{-1} increases and also the silica fume characteristic band at 482 cm^{-1} became more predominant. The increase in the intensity of silica fume bands after vibration milling is obviously due to the increase in the

surface area of silica fume by deagglomeration and its dispersion. Thus, the intensity of the peak at 1127 cm^{-1} could be used as a measure of microsilica dispersion in the blend and the optimum time of activation process would equal to the intensity where it could no longer increase with increasing time of vibration milling.

Pore size distribution

The pore size distribution curves for the pastes made from the blends 2 and 4, before and after activation, are presented in Fig 3 for 7, 14 and 28 days curing age. In the case of cement-slag blend samples prepared from the blend 2, the unactivated samples have coarser pore sizes than activated samples at any of the curing age from 7 to 28 days. A discontinuity in the pore structure can be seen from the shape of the curves and with increasing curing age from 7 to 28 days, this disruption shifts to a lower pore size. The change in slope of these curves with age shows that large changes occur up to 28 days. These changes have been reported to take place with slag blends due to the silica fume reaction with $Ca(OH)_2$ (Cheng-yi and Feldman, 1985a).

A significant change in pore size distributions is observed with the pastes containing only slag and silica fume. The unactivated samples contain very large pores ranging from 0.37 to 10 μm and the distribution curves at 7 and 14 days are found to be the same. The activated samples after 7 days not only produced smaller pores but also fall within the narrow size range of 0.02 to 0.04 μm. This range is shifted to lower size end with increasing age and at 28 days, nearly 90% of the pores have sizes in between 0.01 and 0.02 μm. For the unactivated sample, there is a sudden change at 28 days and 70% of the pores are in between 0.02 and 0.03 μm size. The results show an increase in the hydraulic activity of slag pastes by the applied activation process.

The activation process in vibration milling has greater influence on the pore size distribution either for cement pastes or cement-slag blends or slag pastes. The pore sizes are always found to be more coarser for unactivated sample at any curing age in comparision to the activated sample. During the early stages of Portland cement hydration reactions, the C-S-H gel on the surface of cement particles and $Ca(OH)_2$ are formed (Cheng-yi and Feldman, 1985b). Silica fume is thought to accelarate hydration reactions by providing nucleation sites for $Ca(OH)_2$ within minutes after reaction commences, and also by reacting with the $Ca(OH)_2$ by pozzolanic reaction. The activation method allows the dispersion of microsilica around the cement grains and filling of the spaces between the cement grains to participate microsilica in pozzolanic reaction evenly in the entire matrix and thereby causing more refined capillary pore system. The development of smaller pores within 7 days shows that coagulation and bonding of C-S-H are considerably progressed in the case of activated samples.

Mechanical strength properties

The compressive and bending strengths of binders at various compositions of Portland cement, blast-furnace slag and silica fume (blends 1-4) for non-activated and activated samples as a function of curing age are presented in Fig 4. For the reference cement mortar not containing slag, the compressive strengths at 1, 3, 7 and 28 days are determined to be 24, 42.2, 49.5 and 62.6 MPa respectively. The strength is seen to decrease with decreasing cement composition during early days, but after 7 days, comparable strength has been developed with 30% cement component for the non-activated samples. After 28 days, the strength of the reference cement mortar is 62.6 MPa and the corresponding strengths for blends at 70 and 80% cement replacement are 57.23 and 51.71 MPa. For activated sample, a strength of 56.24 MPa has developed as early as 7 days for the 70% cement replacement sample and after 28 days, higher

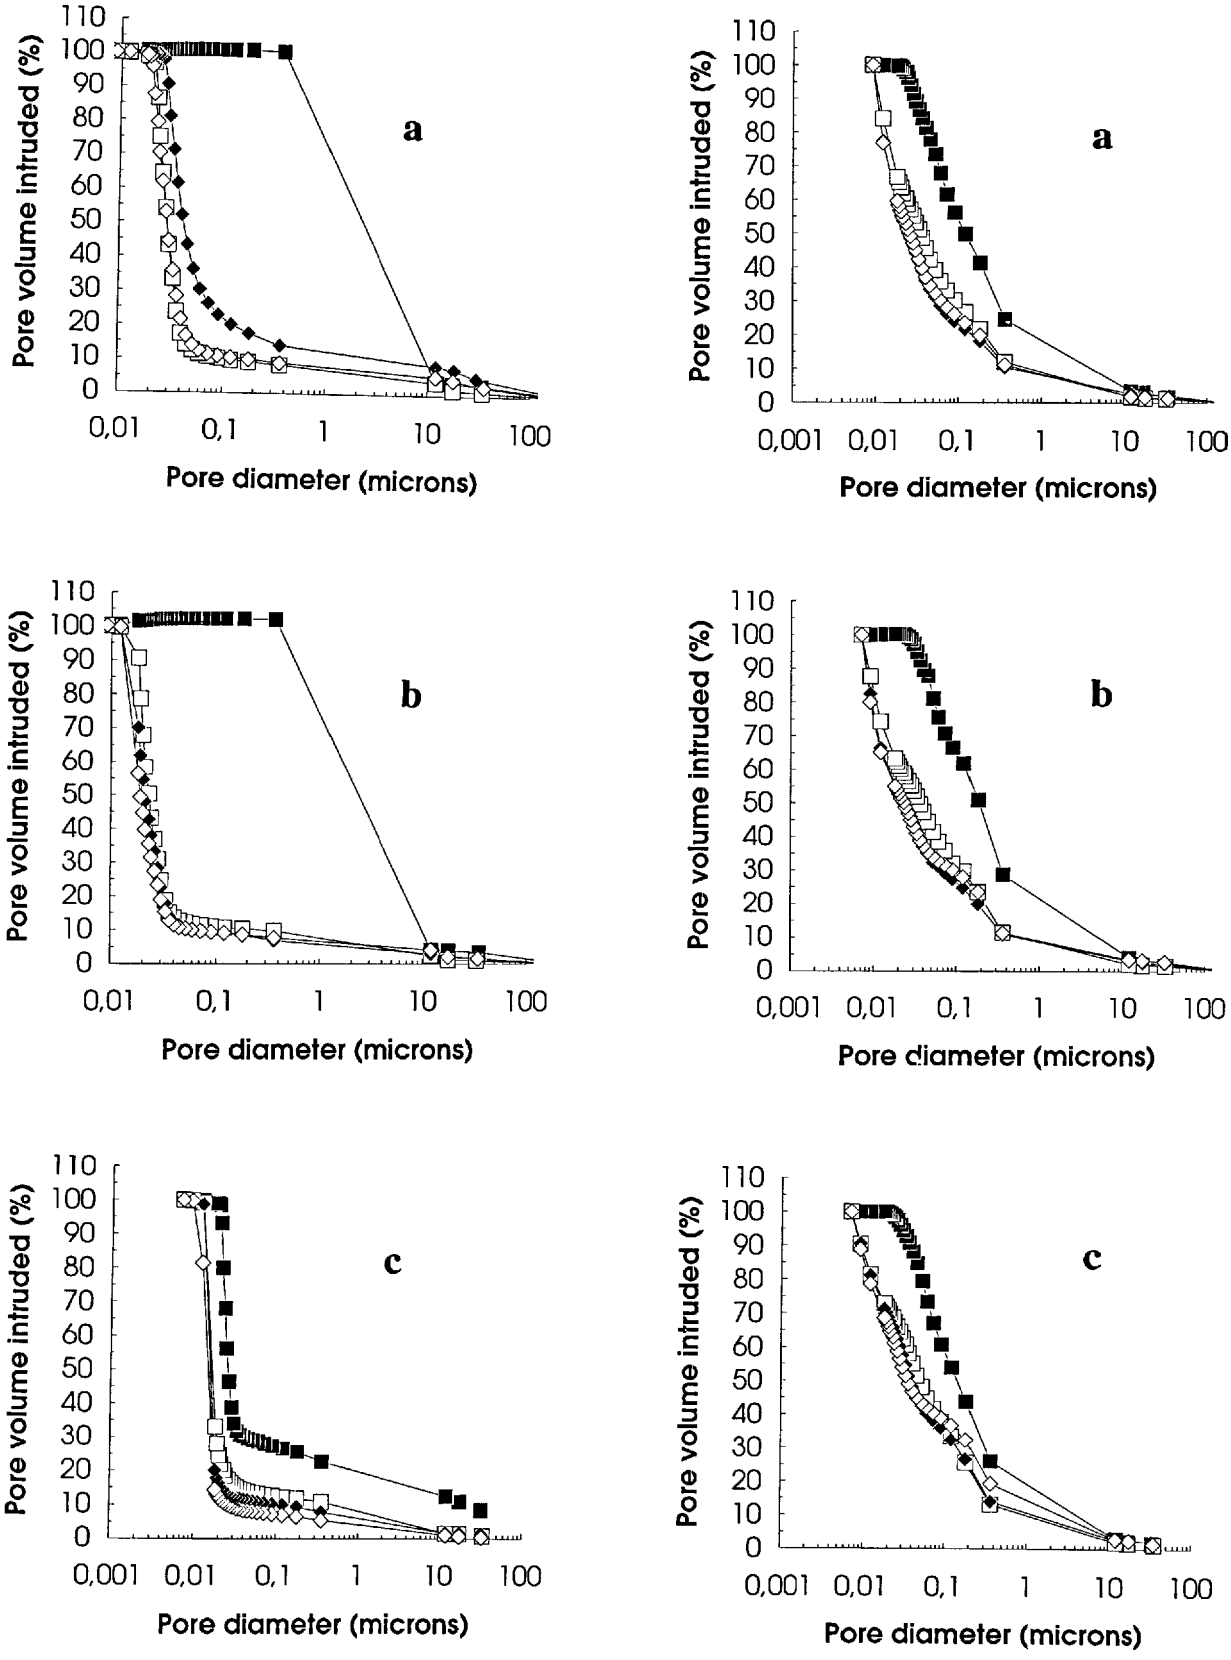

Figure 3 The pore size distribution of the pastes prepared from the blends 2 (right) and 4 (left) before and after modification at different time intervals and curing age. (a) 7 days (b) 14 days (c) 28 days; (■) 0 min (□) 5 min (♦) 15 min (◊) 30 min .

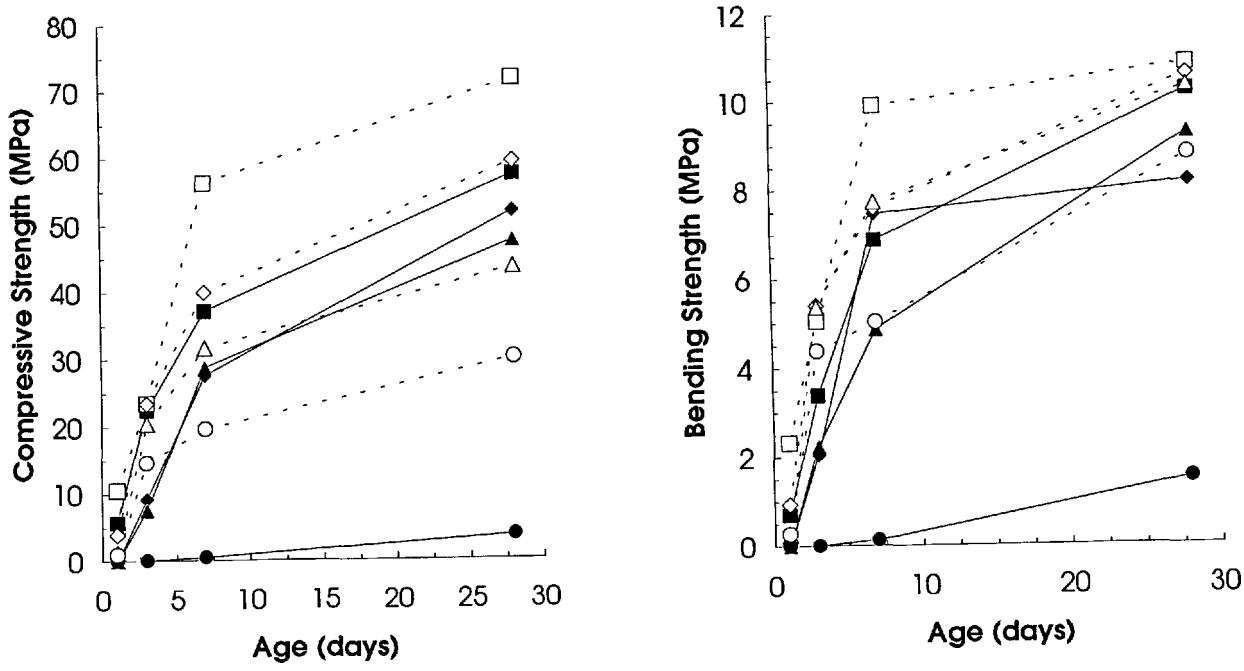

Figure 4 Compressive and bending strength results of the mortars prepared from the blends 1 (□), 2 (◊), 3 (Δ) and 4 (O) before and after modification. The dark symbols with lines represents the results before modification.

strength (71.62 MPa) than the reference cement mortar has been developed. It is especially important to note the strength development of blend 4, which do not contain OPC. The non-modified binder shows no strength up to 7 days of hardening and very low compressive strength of 3.6 MPa after 28 days. The corresponding compressive strengths for the modified binder are about 14 and 30 MPa after 3 and 28 days respectively, which directly reflects the increase of hydraulic activity of the slag. In the early age of hardening (1-3 days), the average strengths of the activated samples are three times higher in comparision to the non-activated samples. The increase in bending strengths for the activated samples are similar to that of the compressive strength results.

The strength increase of the hardened mortar leads to increased strength of the concrete. The strength of the mortar is closely related to the porosity and the first measure for increasing the strength is to reduce the porosity. The volume of gel pores in high- and ultra high-strength concretes is smaller than in ordinary concrete, though the combined water is higher. The mortars made from activated samples show smaller pores and hence the observed higher strength properties. The reduced amount, crystal size and crystallinity of $Ca(OH)_2$ could also increase the strength and the efficient dispersion of microsilica in matrix materials caused by the activation process would allow the pozzolanic reaction to take place at all calcium hydroxide crystal sites, thereby complete depletion of $Ca(OH)_2$ in the mortar may occur.

CONCLUSIONS

The activation of concrete blends in a vibration mill has the following beneficial effects:

(1) The hydraulic activity of blast furnace slag increases due to the increase in surface free energy and activity by the attrition and shear forces that experience in vibration milling.

(2) The rate of hydration reactions increases due to the increase in surface free energy of the particles. The increase in surface free energy allows faster dissolution of chemical species into

pore solution, which in turn, causes early $Ca(OH)_2$ and C-S-H formation, and thus an early strength development.
(3) The pozzolanic activity of silica fume increases due to its disintegration and thorough dispersion into the spaces between cement grains. The dispersion of microsilica allows the pozzolanic reaction to take place at all crystal nuclei sites of calcium hydroxide, leading to the depletion $Ca(OH)_2$ in the early curing ages and thus an early strength development.

THE REACTION OF SILICA FUME AT EARLY AGES

Birgit MENG, Peter SCHIESSL, Institute for Building Materials Research (ibac),
University of Technology, Aachen, Germany

ABSTRACT Investigations on the reaction mechanisms of silica fume in combination with cement were carried out. The results (rate of hydration heat, evolution of $Ca(OH)_2$ and bound water content) showed that the intense action of silica fume varies distinctly, depending on the type of cement. Principally, gel phases that are rich in water are formed at first and then later undergo phase transitions, expelling water.

Key-words: silica fume, mineralogy, heat evolution, thermogravimetry, gel

INTRODUCTION

The positive influence of pozzolanic additions on the properties of concrete is well known from research and practice. The long term effects have been studied extensively while only a few investigations on processes at early ages (the first 3 days) exist. The known increase in early strength shows that the silica fume reaction starts at very early ages. On the other hand, effects like an increased early shrinkage resulting in microcracking have been reported, when silica fume is added (Alfes, 1992, Al-Sugair, 1995, Cohen, 1990).

An addition of pozzolan affects the hydration mechanisms of the cement and possibly already leads to pozzolanic reactions at early ages. Some aspects of the reaction kinetics in combination with Portland cement (CEM I) are well understood by various investigations, but the more complicated mechanisms in combination with slag cement (CEM III/A) are widely unkown.

The investigations described in this paper were part of a research project dealing with the reaction mechanisms of fly ash and silica fume in cementitious materials (Schießl and Meng, 1996). Focusing on the reaction mechanisms affected by silica fume addition some results of practical interest, especially concerning the mineralogical phase evolution and the time-dependent progress of the reactions, will be discussed.

MATERIALS AND METHODS

The reaction behaviour of silica fume was investigated in combination with 2 different types of cement (CEM I 32,5 R and CEM III/A 32,5). All the tests were carried out on hardened cement paste specimens with a w/b value (b = total binder content = cement + silica fume = c + s) of 0.50. Silica fume was employed at an extremely high dosage in comparison with practical conditions (25 % by mass in relation to the total binder content), to enable clear identification of the influences on the reaction mechanisms in the hardened cement paste.

Measurement of hydration heat evolution

The tests were carried out according to the semi-adiabatic method (DIN prEN 196 - 9 : 1994). This method enables continuous tracing of the reaction processes which take place in the mortar or concrete at a young age (< 3 days). Evaluation of the results covered determination of the evolution of temperature and hydration heat as a function of time. To enable mathematical determination of the heat loss, cooling curves were measured on all specimens in an older state,

whereby the same test set-up was maintained throughout. With the aid of a maturity formula (Eq. 1), the time at which a certain heat of hydration was released was converted into the *reference time* at 20 °C. This is necessary because the course of hydration is accelerated by heat: at 35 °C, the reaction already takes place twice as quickly as at 20 °C. Consequently, quantitative comparison of the evolution of the heat of hydration of different specimens can only be achieved when the obtained results are converted back into constant temperature conditions (20 °C) by means of the reference time, (CEB, 1992).

$$\frac{v(T)}{v(20)} = \exp\left[\frac{E}{R}\left(\frac{1}{293} - \frac{1}{273+T}\right)\right] \qquad [1]$$

v = rate of reaction, T = temperature in °C,
E = activation energy (33500 J/mol) R = gas constant (8.314 J/mol).

For the purposes of assessment, the released heat of hydration was considered as a function of the reference time. These results show whether and in what manner changes result from replacing part of the cement with pozzolanas.

Measurement of $Ca(OH)_2$ and bound water content

At the time of testing, hydration of the cement was stopped by placing the cement in methanol. The specimen was subsequently dried at 105 °C and pulverised, prior to undergoing thermogravimetric (TG) examination. The analysis programme covered a temperature range from 30 to 894 °C. Fig. 1 shows the absolute weight losses (TG) and the appurtenant differential representation (DTG) over the entire temperature range, by reference to one representative cement paste specimen. The change in weight (TG) here represents a specific change in relation to the originally determined weight of the specimen concerned.

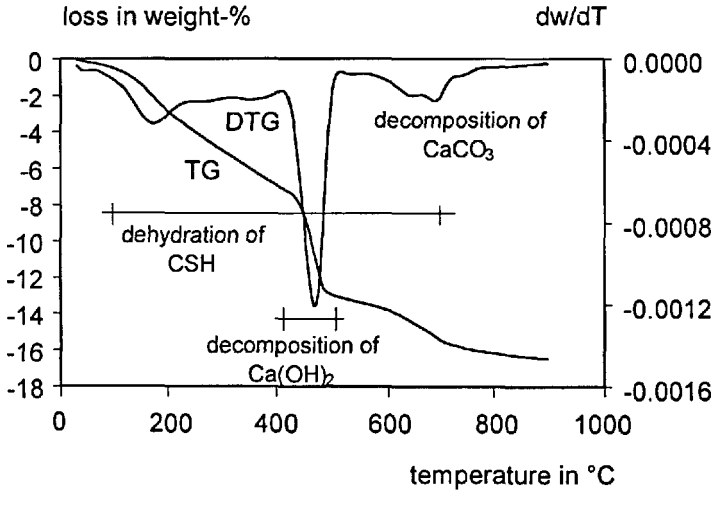

Figure 1:TG-Analysis of hardened cement paste (100 % CEM I 32,5 R, age: 28 days)

The hardened cement paste consists primarily of compounds containing hydration water, together with a small fraction of inorganic compounds containing carbonates. The most important compounds, the calcium silicate hydrates and calcium aluminate hydrates, occur in cement paste in a large number of composition variants, the decomposition reactions of which overlap. This makes quantitative evaluation more difficult, i.e. it is not possible to specify exact temperature ranges for the decomposition ranges.

The decomposition reactions can be explained by reference to Fig. 1. In the temperature range from around 100 to 750 °C, the CSH phases dehydrate relatively continuously. Between

approximately 400 and 500 °C, the water is removed from the $Ca(OH)_2$ in accordance with Eq. 2. $CaCO_3$ decomposes at a temperature of around 700 °C (separation of the CO_2).

$$Ca(OH)_2 \xrightarrow{\Delta T} CaO + H_2O \qquad [2]$$

The decomposition peak of the $Ca(OH)_2$ appears relatively sharp in comparison to the continuous decomposition of the CSH phases. According to Marsh (1984), during evaluation the $Ca(OH)_2$ content can be calculated from the TG curve by taking into account the CSH phases before and after the $Ca(OH)_2$ peak and, indirectly (via interpolation), during the $Ca(OH)_2$ peak. The $Ca(OH)_2$ content of the hardened cement paste specimen is obtained in accordance with Eq. 3.

$$Ca(OH)_2 = \frac{4.113 \cdot \Delta w}{w_{894\,°C}} \cdot 100 \quad \text{in weigth-\%} \qquad [3]$$

Δw = weight loss due to decomposition of $Ca(OH)_2$ in mg according to (Marsh, 1984); calculated from the TG curve (e. g. Fig. 1)

$w_{894\,°C}$ = weight of specimen at 894°C (final temperature of analysis) in mg.

As $Ca(OH)_2$ is consumed and CSH phases are formed in the course of the pozzolanic reaction, conclusions on the course of the pozzolanic reaction can be drawn from the results of the thermogravimetric investigation. The consumption of $Ca(OH)_2$ can be determined directly in comparison with a reference mixture. The formation of CSH phases can be determined only indirectly, via the bound water. By subtracting the water content of the $Ca(OH)_2$ from the directly measured total bound water (weight loss in the temperature range from 30 to 600 °C), the fraction of CSH phases can be deduced from the residual water, subject to several approximate assumptions. By way of approximation, the residual water is regarded as CSH water (i.e. water bound in the CSH phases), although it also contains the water bound in calcium aluminate hydrates and sulphate phases. The time-dependent development of the so-called CSH water fractions can only provide direct information on the development of the CSH phase fractions when the stoichiometry of the CSH phases remains constant.

RESULTS AND DISCUSSION

Heat of Hydration

The object of the investigations on the evolution of the heat of hydration was to establish at what point in time and to what extent silica fume influences the reactions in the cement paste. Differing, sometimes contradictory information, can be found in the relevant literature with regard to the extent and timing of silica fume's contribution to the evolution of hydration heat.

Contrary to the results specified in the relevant literature (Cheng-Yi, 1985, Meland, 1983), the test results presented in Figs. 2a and 2c demonstrate that the addition of silica fume does not inevitably reduce the specific release of heat in relation to the total binder mass (cement + silica fume). At a very young age (< 24 h) in particular, the heat evolution of the two types of cement is even markedly increased. In the medium term mixes of silica fume with CEM I release nearly the same quantity of heat as the pure cement. In the case of CEM III/A the hydration heat in the medium term is increasingly reduced by the addition of silica fume.

The specific heat evolution in relation to the cement mass is always greater when silica fume is added. Figs. 2a and 2c show that this applies not only in combination with CEM I, but also with CEM III/A. This contribution of the silica fume to the evolution of heat indicates that a pozzolanic reaction already occurs in the early phase. However, this effect cannot be separated beyond doubt from a possible promotion of cement hydration as a result of the addition of silica fume (higher level of hydration due to effect of nucleation substrate and inevitably higher w/c at constant w/b).

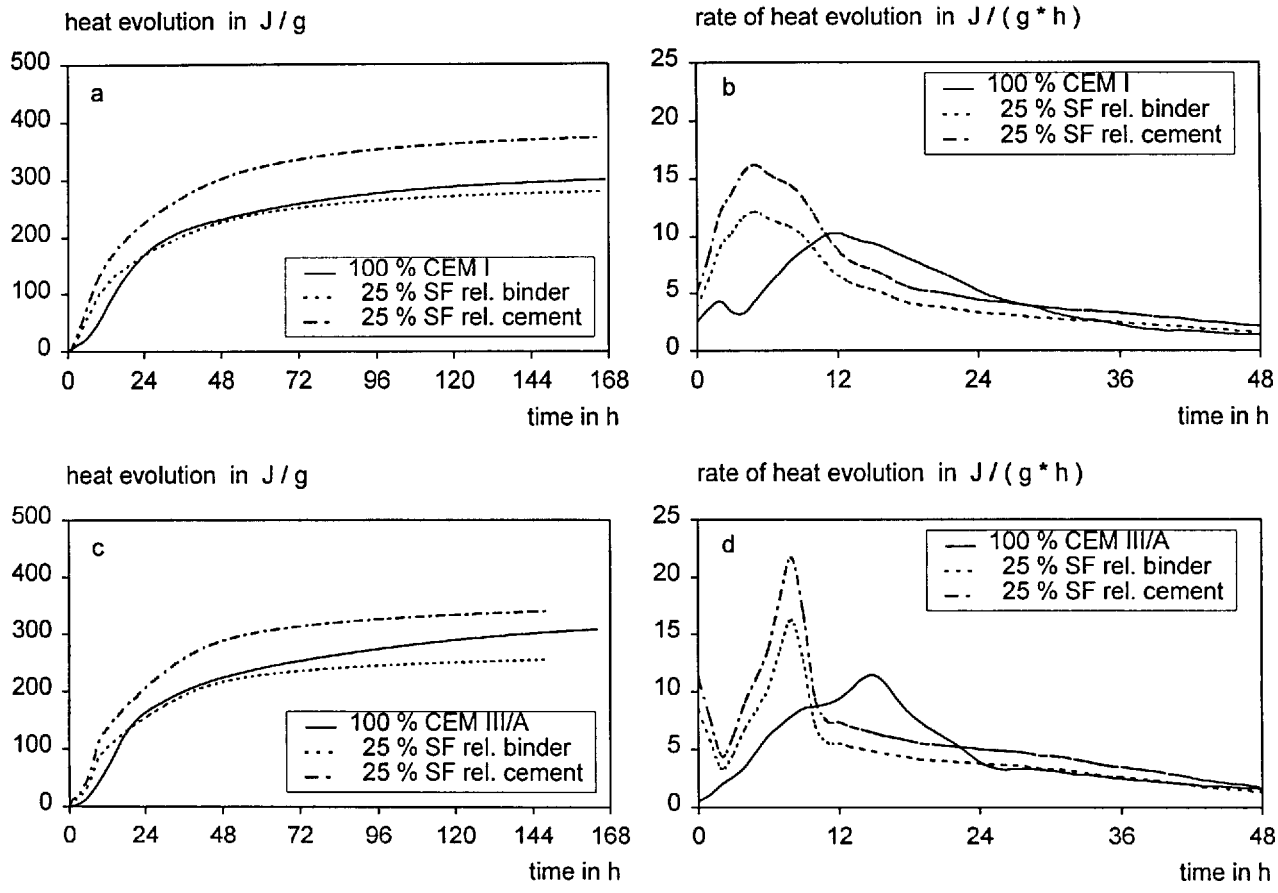

Figure 2: Heat evolution with and without silica fume

Different authors hold different views as to the influence of silica fume on the time at which the evolution of heat begins. It is generally assumed that the influence is only minor. There appears to be a general tendency for the onset of the evolution process to occur at an earlier point in time. The courses of evolution of hydration heat presented in Figs. 2a to 2d show that the evolution of heat commences substantially earlier when silica fume is added, in combination with both CEM I and CEM III/A. The maximum for the evolution of hydration heat also occurs markedly earlier. This is why the levels of hydration heat developed at an age of 12 hours are, in both cases, higher for the mixes containing silica fume than in the reference mixes without silica fume content. On the basis of these results alone, it is not possible to distinguish whether the strong evolution of heat is caused by the pozzolanic reaction, by other reactions of the silica fume (e.g. gel formation), by the promotion of cement hydration or by a combination of these three different processes.

The results do essentially show that the influence of the silica fume on the maximum rate of evolution of hydration heat is more pronounced with the employed CEM III/A than with the CEM I. The total quantity of heat released, on the other hand, is particularly high with CEM I: here, the reaction of the silica fume develops a quantity of heat which virtually corresponds tc the heat of hydration of the pure cement.

Reaction Products

Figs. 3 and 4 compare the $Ca(OH)_2$ and CSH water contents of mixes with and without silica fume at ages of 12, 24 and 48 hours. Both for the CEM I and CEM III/A mixes it can be seen that the $Ca(OH)_2$ contents of the specimens containing silica fume are significantly lower than those of the reference mixes without silica fume at all the investigated times. The reverse applies with regard to the so-called "CSH water" content. Conclusions regarding the pozzolanic reaction can be drawn from the consumption of $Ca(OH)_2$ and the bound CSH water.

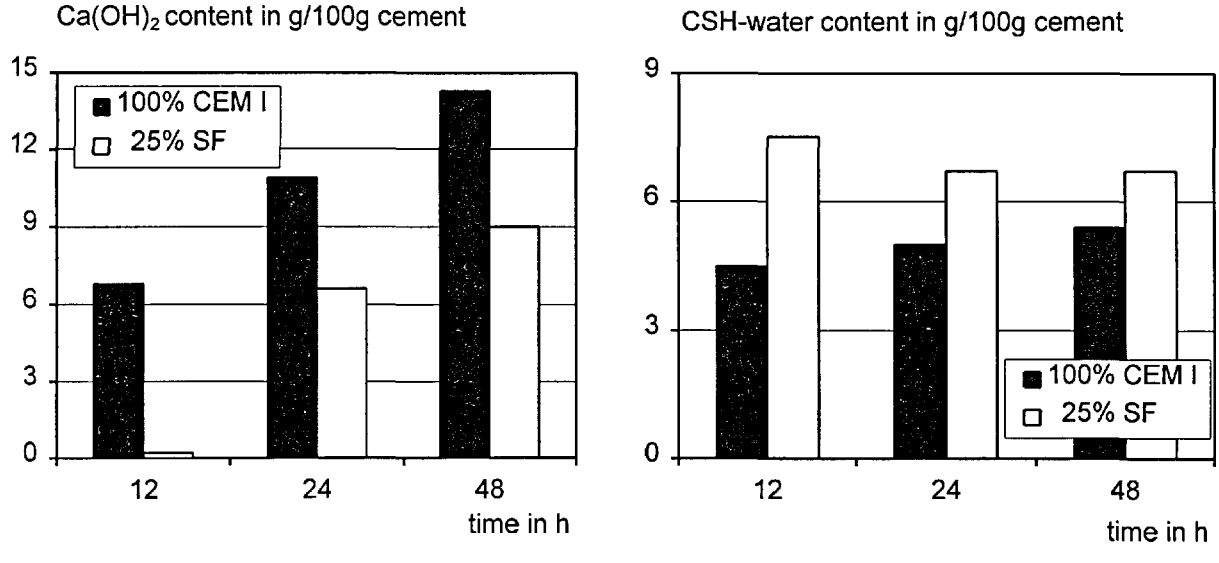

Figure 3: Influence of silica fume on $Ca(OH)_2$ and CSH-water contents for mixes with CEM I

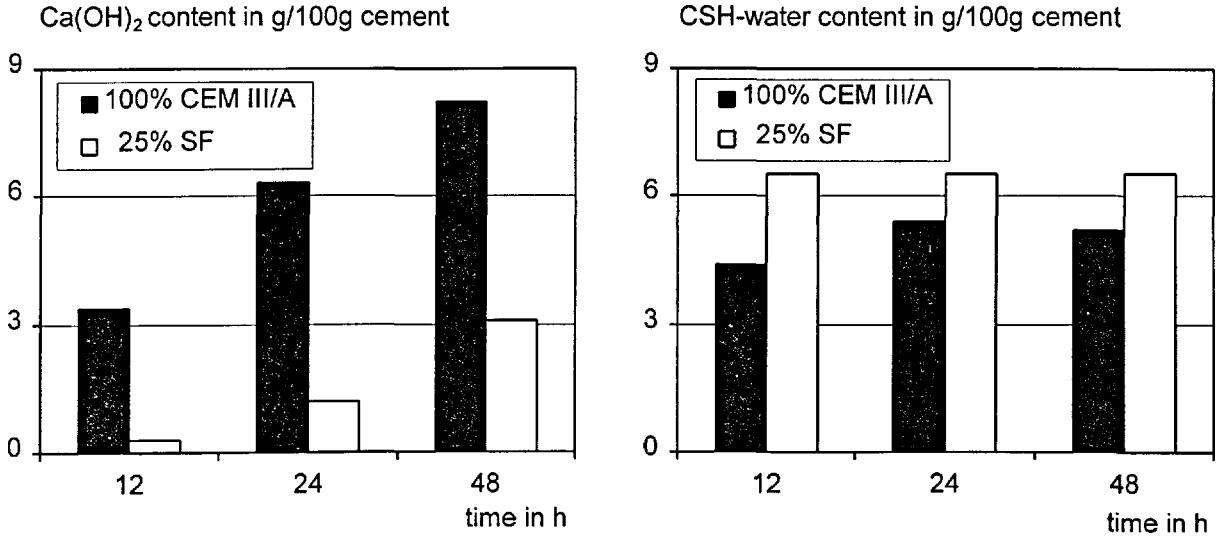

Figure 4:Influence of silica fume on $Ca(OH)_2$ and CSH-water contents for mixes with CEM III/A

It is notable that the mixes with silica fume contain only very minimal quantities of $Ca(OH)_2$ after 12 hours, while the reference mixes without silica fume already reveal a high level of $Ca(OH)_2$ content. The possibility of a delay in the cement hydration process can be excluded, as measurement of the heat of hydration rather revealed an accelerating effect (see Fig. 2). It would appear justified to assume that the quantity of $Ca(OH)_2$ corresponding to the difference involved here has already been consumed as a result of a very early reaction of the silica fume. Fig. 5 shows the differences in the $Ca(OH)_2$ content and in the CSH water content between the specimens with and without silica fume. If the difference between the $Ca(OH)_2$ content of the mixes containing silica fume and the mixes without silica fume is interpreted as the $Ca(OH)_2$ consumed by a pozzolanic reaction, in the case of the Portland cement this results in the paradox that the "$CaOH)_2$ consumption" is higher after 12 hours than after 24 hours. This can only be the case if the consumption of $Ca(OH)_2$ in the period between 12 and 24 hours is overcompensated by the new formation of $Ca(OH)_2$ (possibly accelerated cement hydration by the effect of silica fume as a nucleation substrate).

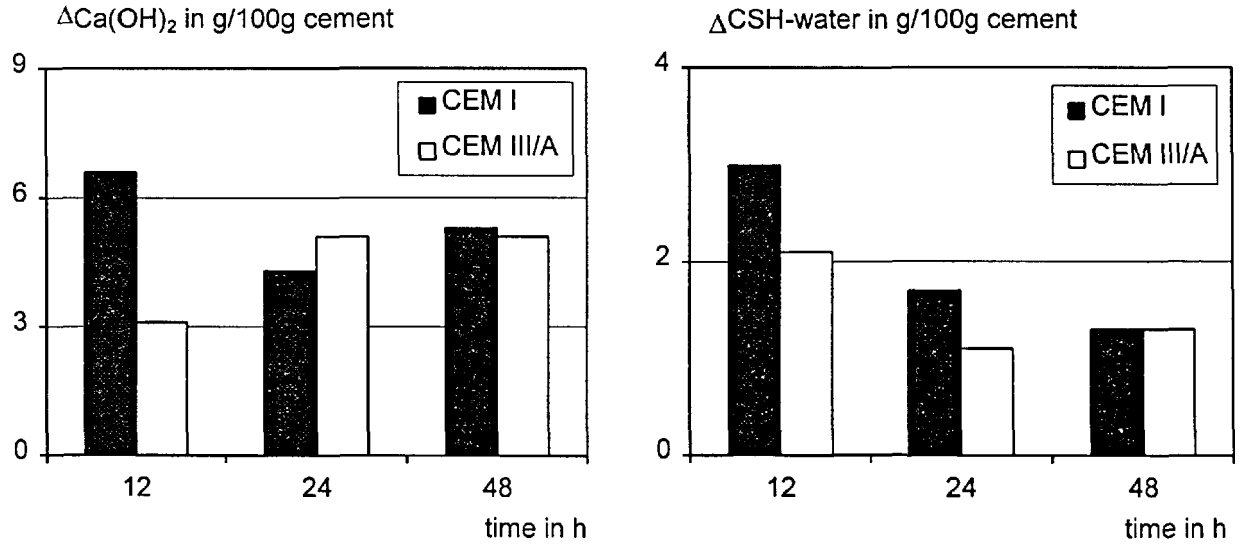

Figure 5: Influence of silica fume on $Ca(OH)_2$ and CSH-water contents (differences between the mixes with and without silica fume)

The course of development of the differences between the CSH contents of the mixes with and without silica fume, which is also presented in Fig. 5, supports the theory that a pozzolanic reaction already takes place at this stage. In all cases, the CSH water content of the mixes containing silica fume is greater than that of the mixes without silica fume. The blends containing silica fume reveal a higher surplus CSH water content after 12 hours than after 24 hours. This can only mean that primarily water-rich hydrate phases are formed, which release part of their water content again within several hours. Such dehydration is to be found with water-rich silica gels. It is possible that this dehydration may also take place with water-rich CSH gels.

This result is supported by different reports documented in literature. Specific examinations of the reaction products of silica fume in the early phase showed even when sufficient $Ca(OH)_2$ is available, CSH phases do not develop directly. Instead, a gel with high water content and low lime content is first of all formed (Grutzeck et al, 1983). This gel formation begins in the very first minutes after mixing. In turn, the gel then reacts to form CSH phases. This reaction takes

place predominantly with $Ca(OH)_2$, but it may also occur with CSH phases containing higher levels of lime from the cement hydration process (Wu and Young, 1984).

When silica fume binds large quantities of water in water-rich gel in the early phase, this water is interpreted (evaluating the TG curves) as a constituent of the so-called CSH water, with no possibility of differentiation. The dehydration characteristics of the thermogravimetry do not reveal any characteristic differences for the various investigated ages (12, 24, 48 hours). With this method, it is not possible to clarify whether a CSH gel or a silica gel (or both) forms.

At the age of 24 and 48 hours the results can be interpreted more clearly, after initially formed water-rich gel phases have released part of their water. A substantial quantity of $Ca(OH)_2$, of approximately the same magnitude in both cases, had already been consumed in both types of cement. This is accompanied by a higher CSH water content in the mixes containing silica fume, which supports the assumption that pozzolanic reactions are already taking place here.

SUMMARY

On the basis of the discussed results regarding the evolution of hydration heat and phase evolution, it was possible to determine the following influences of silica fume on the processes in the early phases of cement hardening:

- Replacing cement with silica fume does not inevitably lower the total quantity of hydration heat (in relation to the total binder mass) released in the early phase. An evident lowering is to be observed in combination with CEM III/A only, while in combination with CEM I nearly the same quantity of heat is produced as with the pure cement.
- When the quantity of heat developed in the early phase is considered in relation to the cement content, a substantial contribution of the silica fume to the evolution of hydration heat is to be observed with both types of cement. This is to be regarded as an indication that pozzolanic reactions already take place in the early phase of hydration. Without additional experiments, however, such effects cannot be clearly differentiated from a possible increase in the evolution of hydration heat as a result of an acceleration in clinker hydration (effect of nucleation substrate and higher w/c value).
- The course of phase evolution also indicates an early onset of the pozzolanic reaction. This is substantiated both by the consumption of $Ca(OH)_2$ and by the formation of additional CSH phases with regard to the reference mixes without pozzolanas. In the mixes containing silica fume, this formation process occurred very early, irrespective of the type of cement.
- The point in time at which the maximum level of hydration heat development occurs is brought forward by silica fume. The maximum is more pronounced than in the cement paste without silica fume. The latter effect is particularly pronounced in the employed CEM III/A.
- When silica fume is added, there are indications of other involved reactions, such as the primary formation of water-rich gels (CSH gel or silica gel). Thermogravimetry is unable to differentiate the bound water which results from these reactions and from the pozzolanic reactions, which consequently makes interpretation more difficult. This high level of water binding occurs primarily during the solidification phase of < 24 hours.

It can be deduced from these results that pozzolanic reactions occur with silica fume at an early age. Pozzolanic reactions are not the only reactions which take place, however: Water-rich gel phases develop very quickly within the first 12 hours, and these are accompanied by a high rate of evolution of hydration heat. These gel phases relatively quickly release a large proportion of

their water once again (stage between 12 and 24 hours). This phase transition could serve as a plausible explanation for the early shrinkage and the frequent ultrafine microcracking systems which are to be found in concretes containing a high level of silica fume.

INTERACTION OF SILICA COLLOID WITH PORTLAND CEMENT

CHANDRA,S*, BERGQVIST,H**
* Chalmers University of Technology, Götebrog, Sweden
** Eka Chemicals AB, Bohus, Sweden

ABSTRACT
Interaction of silica colloids with cement have been studied with the help of XRD and thermogravimetric analysis. It is shown that the reactivity of silica colloid with calcium hydroxide is much faster in comparison with the condensed silica fume. Small amount of colloidal silica is sufficient to produce the same pozzolanic effect as with the addition of higher doses of condensed silica fume at early ages.

Keywords: Calcium hydroxide, Silica fume, Interaction, Pozzolanic reaction, Silica Colloid.

INTRODUCTION
Silica fume is an industrial by product from ferro-silicium alloys producing units, and hence its availability is limited. Silica fume gives dark color to the concrete which is due to the unburnt coal contained in it, and is an aesthetical problem. However, specially treated silica fumes are available, but they are expensive. Besides this, being an industrial by-product homogeneity of the product can vary. This uncertainty in the quality can be overcome by using silica colloids which are man made in chemicals manufacturing companies. This makes its easy access worldwide. Special silica colloids have been developed by Eka Nobel AB, Sweden for use in cement mortars and concrete. These are tested in mortars and concretes at the Division of Concrete Structure, Chalmers University of Technology; Göteborg, Sweden. Interaction of condensed silica fume calcium hydroxide has been studied by many researchers (Buck et al, 1981, Costa and Massaza, 1983, Grutzeck et al, 1983). Interaction of silica colloid with portland cement during hydration is studied and comparison is made with condensed silica fume.

Silica Colloid
The silica colloids specially developed are stabilized for use in mortars and concrete. It is the aqueous silicic acid suspension which contains silicic acid particles expressed as silica, in an amount in the range from about 8% to 60% silica by weight of solution. The specific surface area of the particles is in the range of about 50 m^2/g to a 1000 m^2/g, but preferably in the range from about 50 m^2/g to about 200 m^2/g. Generally, the aqueous silicic suspension employed includes silicic acid particles which have a wide particle size distribution with particles ranging from 5 to 200 nanometers. Preliminary tests have been done with silica colloids having specific surface area ranging between 80 to 500 m^2/g. Some of the results are reported here. It was found that the silica colloid with specific surface area of 80 m^2/g behaved reasonably well. It was used therefore in further investigations.

MATERIALS AND METHODS
Standard Portland cement, supplied by Cementa AB, Slite.
Condensed silica fume (**SF**) was supplied by ELKEM, Norway. It has specific surface area of 20 m^2/g. It is in the dry powder form.

Colloidal silica (**KF**); was supplied by Eka Chemicals AB, Bohus, Sweden. It has specific surface area of 80 m^2/g.

Calcium silicates which are major constituents of Portland cement reacts with water and produce calcium hydroxide. Calcium hydroxide thus produced interacts with silica from condensed silica fume and silica colloid. This interaction is studied here. Portland cement, condensed silica fume/silica colloid and water have been mixed at the constant water to binder ratio. Total binder (portland cement + SF/KF) has also been kept constant. The mixes are shown in Table 1. The samples have been sealed in plastic beakers and were put with their lock on in water to avoid leakage to air and subsequent carbonation. These samples were used for XRD and thermogravimetric analysis.

X-ray Diffraction Analysis

The samples prepared have been analyzed after 1, 7, 28 and 48 days by X-ray diffractometry. The amount of calcium hydroxide detected at a particular time is calculated with respect to their intensities in cps (count per second). The results are summarized in Figure 1. Figure 2 shows the presence of calcium silicates at particular times. Calcium hydroxide (reflection at $2\theta = 18.10°$) decreases both with the addition of condensed silica fume as well as with silica colloid (Figure 1). The amount of calcium hydroxide is less in all the samples except with 4% SF, compared with the reference samples i.e without the addition of silica. This tendency is not very much pronounced with 4% SF even at the later stage. Whereas with the addition of 8 and 16% SF there is not much difference after one day but later on substantial decrease in the amount of calcium hydroxide is noted. In the case of silica colloid the amount of calcium hydroxide is significantly low compared to the other samples already after 1 day. 4% KF consumed 60% more calcium hydroxide after 7 days than 4% SF. It suggests that the silica colloid has reacted more and thus has consumed more calcium hydroxide. 8% and 16%
SF have shown more reaction than 4% KF assessed from the lower amount of calcium hydroxide presence, but have reacted less than 8% KF which has shown the lowest amount of calcium hydroxide at all ages. Consequently rate of reaction was highest for 8% KF.

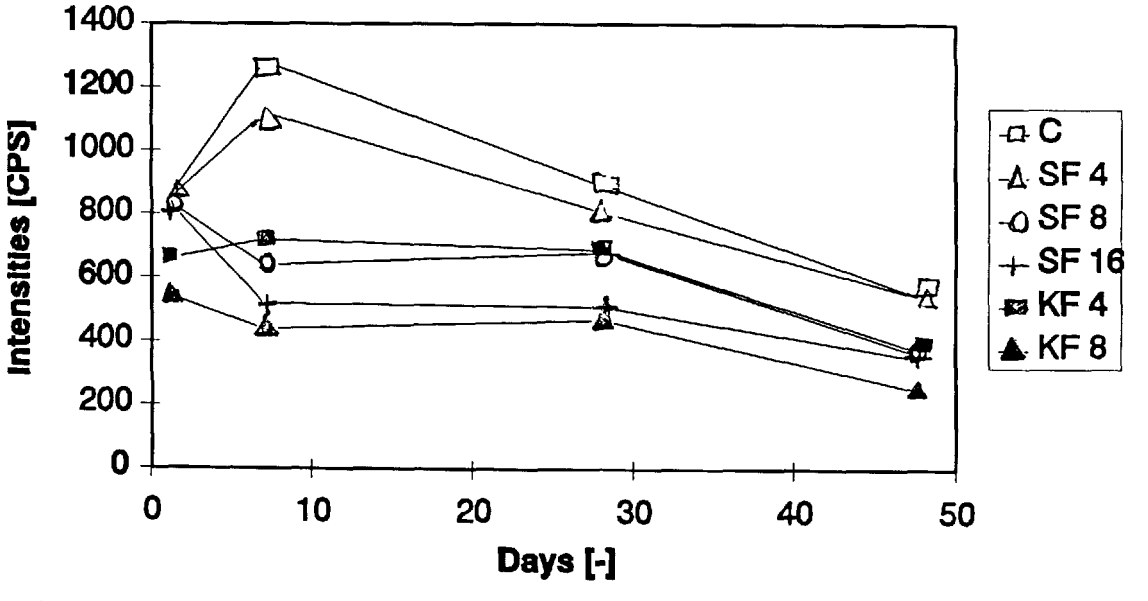

Figure.1, Quantity of calcium hydroxide calculated as counts per second (cps at $2\Theta = 18.10°$) at different curing times.

With increase in the reaction with calcium hydroxide and silica, more calcium silicate hydrate is produced in the early stage, which subsequently provides strength to the mortar. It may lead to higher early strength with the addition of silica colloid compared to the addition of condensed silica fume. On the other hand the content of di-calcium silicate (C_2S) and tri- calcium silicate

(C_3S) are a slightly higher in the case of 8% colloidal silica addition. It is speculated that the higher dose of silica colloid causes gelling, and some of the cement
particles become encapsulated and hydrate slower. It suggests that the higher dosages of silica colloid is difficult to mix. The limit seems to be 4-5% silica calculated on its solid weight in the dispersion to the weight of cement. Because of its high specific surface area very small amount of silica colloid is able to provide the same effect as with the addition of higher dosages of condensed silica fume at early ages.

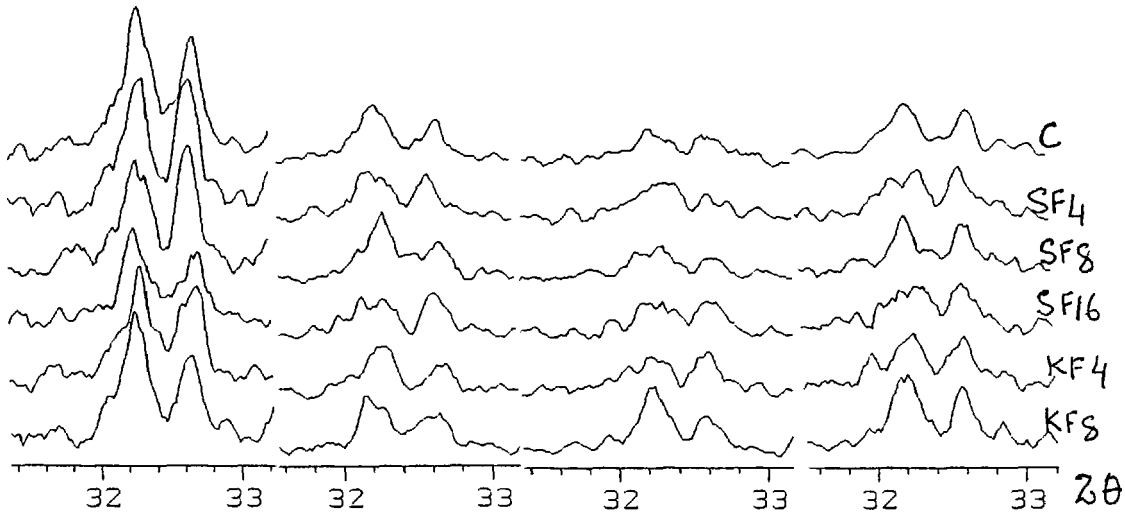

Figure 2, XRD of calcium silicate at different times a) 1 day, 148.92 cps, b) 7 days 280.98 cps, c) 28 days 280.98 cps, d) 48 days, 198.69 cps.

Thermogravimetric Analysis

The cement paste samples with the condensed silica fume and silica colloid addition (Table 1) have been analyzed by thermogravimetric method. The weight loss between 105-400°C have been calculated as non evoperable water to the weight of cement have been calculated. Weight loss between 400-500°C is on the otherhand considered mainly due to the loss of water from calcium hydroxide and is calculated as calcium hydroxide in percent to cement weight. Similar method have been used by Costa and Massaza (1983) for determining calcium hydroxide. The results are shown in the Figures 3 and 4 respectively.

Fig. 3 shows that the non evoperable water is higher in the case of 4 and 8% KF compare to the equal amounts of SF after one day. This tendency continues upto 7 days when its becomes on the same level. After 7 days the non evoperable water does not increase in the same proportion as in the case of SF and the reference sample. It means that there is less physically combined water and more chemically combined water, which suggests that the silica colloid has reacted more compare to the SF upto 7 days. After 7 days the reaction with SF becomes more progressive.

Water of calcium hydroxide is very low at 7 days with silica colloid addition (4% KF and 8% KF, Fig.4) compared to those made with silica fume addition. It shows that the reactivity of silica colloid to calcium hydroxide is much higher at early age compared with condensed silica fume. This confirms the measurements of the non evoperable water. Same tendency has been shown upto 28 days both with 4 as well as 8% addition. After which 8% addition continued to

show higher reactivity compared with 4% silica colloid addition upto 48 days.

Table 1., Mix proportions for X-ray diffraction and thermogravimetric analysis, number represents weight units.

No.	Description of Mix
1	Cement 100 + Water 35
2	Cement 96 + SF 4 + Water 35
3	Cement 92 + SF 8 + Water 35
4	Cement 84 + SF 16 + Water 35
5	Cement 96 + KF 4(Soln.8) + Water 31(4 water from KF solution).
6	Cement 92 + KF 8(Soln.16) + Water 27(8 water from KF solution).

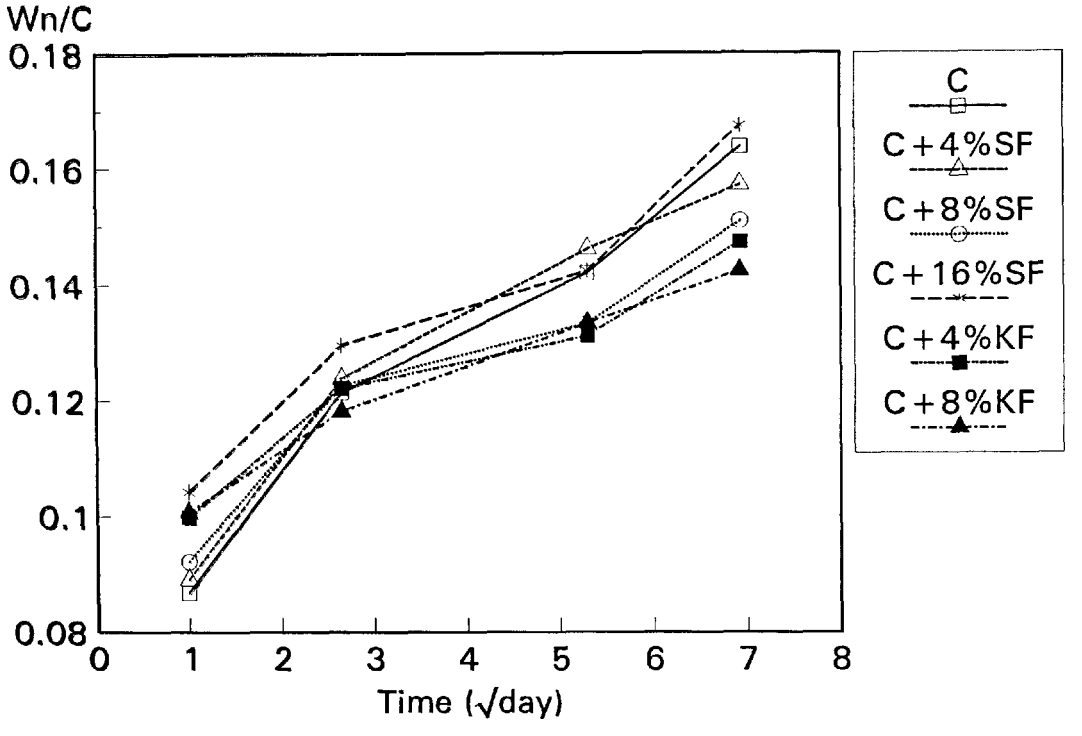

Figure 3, Weight loss between 105-400°C to the weight of cement with respect to curing time.

Thermogravimetric analysis results have shown low calcium hydroxide at 7 days both with the addition of 4 as well as 8% addition of silica colloid compare with the silica fume addition, suggesting more interaction with silica colloid than with condensed silica fume. Whereas XRD analysis has shown that the calcium hydroxide lies between 4% KF and 8% KF at 7 days. It shows that reaction with 8% SF and 16% SF at 7 days is more than 4% KF and less than 8% KF with calcium hydroxide, which is not in agreement with the thermogravimtric results. It may be due to the formation of silica rich layer around some of the cement particles with 8 and 16% condensed silica fume addition, causing hindrance in hydration, and thus resulting in less calcium hydroxide formation. This lower amount is subsequently interpreted

as due to the interaction with silica fume. Gel like layer formation is described by Grutzeck et al (1983).

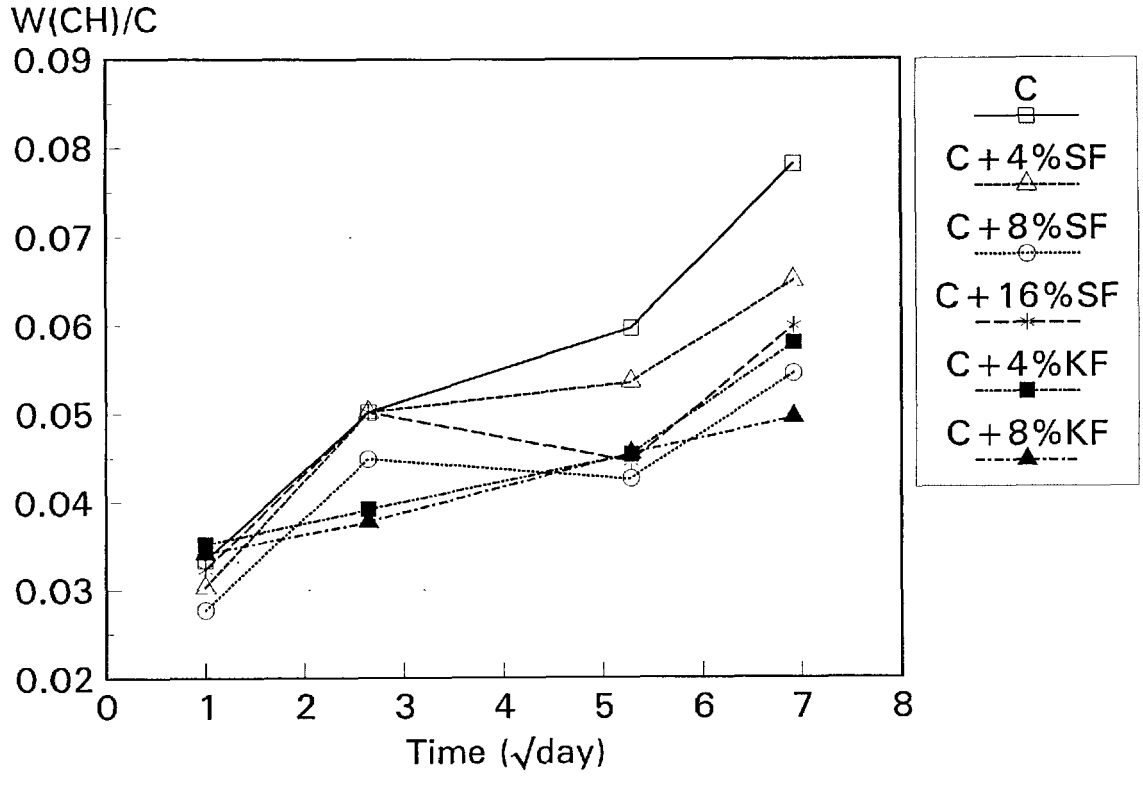

Figure 4, Weight loss between 400-500°C to the weight of cement with respect to curing time.

It clearly shows that there is more interaction of silica colloid with calcium hydroxide in comparison to condensed silica fume especially at early age. Similar observations have been made by Young et al (1984) during their study on the influence of colloidal silica on tri-calcium silicate hydration. One of the main reason of this is attributed to the fine particle size of silica colloid. Another factor involved may be that the silica colloid unlike condensed silica fume is in fine dispersion form which enables its quick access to the calcium hydroxide formed during portland cement hydration.

CONCLUSIONS

Tests performed reveal that the colloidal silica reacts with calcium hydroxide produced during the hydration of portland cement much faster than in the case of condensed silica fumes specially at early age. This may lead to the development of high early strength in mortar and concrete with its addition.

Small amount of silica colloid shows similar pozzolanic effect as with the higher doses of silica fume at early ages. This effect is attributed to the finer particle size of silica colloid.

EFFECT OF POZZOLANIC ADDITIVES IN THE PORTLAND CEMENT ON THE HYDRATION RATE OF ALITE

Kiyoshi ASAGA, Teikyo University of Science and Technology
Hiroshi KUGA, Teikyo University of Science and Technology
Shigeru TAKAHASHI, Cement Association of Japan
Etsuo SAKAI, Tokyo Institute of technology
Masaki DAIMON, Tokyo Institute of technology

ABSTRACT Pastes of portland cement with pozzolanic additive in the water/solid ratio of 0.3–0.5 were hydrated at 20℃. The hydration percentage of alite was measured by means of quantitative X–ray analysis. It was observed that the standard deviation of reaction percentage of alite was about 1%. The hydration rate of alite in the portland cement is almost independent of water/solid ratio at initial stage, and reaction percentage in later stage is strongly affected by the water/solid ratio. Each pozzolan accelerates the hydration rate of alite.

Key–words Portland cement, Alite, Hydration, Pozzolana, Calcium hydroxide

INTRODUCTION

The hydration rate of portland cement is significantly affected by the water/cement ratio and pozzolanic additives. There are many studies on the effects of the water/cement ratio or pozzolanic additives on the hydration of portland cement (COPELAND,1968, UCHIKAWA,1986, TAYLOR,1990, MASSAZZA,1992). The hydration percentage of each compound is usually measured by means of quantitative analysis of XRD. But it is very difficult to get a sufficient accuracy. Then, there are little data of hydration percentage of cement compounds in the blended cement in spite of fundamental data of a mass concrete or high strength development concrete. To discuss the effect of pozzolanic additives on the hydration ratio of cement compounds, it is necessary to get a sufficient accuracy of XRD analysis. The authors discussed the method of measurement of hydration percentage of each compound by means of quantitative XRD analysis in their previous studies (ISHIZAKI,1988a, ASAGA,1992). The purpose of this study is to get more accuracy of measurement, and discuss the effect of water/solid ratio and pozzolanic additives on the hydration rate of cement compounds and hydration products by analyzing the precise hydration percentage of cement compounds.

The accuracy of the reaction rate of alite was improved, but was not improved for reaction ratio of belite and aluminate phase. The effect of water/solid ratio and pozzolanic additives on the hydration rate of alite in the blended cement are discussed in this studies.

EXPERIMENTAL PROCEDURES

SAMPLES

Ordinary portland cement used in the experiments was prepared by cement association of Japan, which did not include any pozzolan or filler particles. Chemical composition and physical test results of the ordinary portland cement are listed in Table 1. From the calculation of Bogue equation, there is 60% C_3S, 16% C_2S, 9% C_3A and 8% C_4AF in this portland cement. Specific gravity, Specific surface area and chemical compositions of used fly ash, blastfurnace slag and silica fume are listed in Table 2. Portland cement (PC) and the 3 types of blended cement were prepared by mixing the portland cement and pozzolan such as 80wt% of portland cement and 20wt% of fly ash (PF), 50wt% of portland cement and 50wt% of slag (PB) and 90wt% of portland cement and 10wt% of silica fume (PS).

Cement paste prepared with water to solid (W/S) ratio of 0.30, 0.40 and 0.50 was sealed in a test tube, and then cured in a incubator at 20℃ for 1, 3, 7 and 28 days, respectively. Hydration

was stopped by acetone and dried at 110℃ for 24 hours. In the case of preparation of paste with W/S=0.30, 0.6wt% of naphthalene–formaline condensates was added as the superplasticizer.

MEASUREMENT AND ANALYSIS OF HYDRATION

Ignition loss of hydrated samples was measured by burning at 1000℃ for 1 hour. Amount of $Ca(OH)_2$ was measured by means of differential scanning calorimetry (DSC). Hydration ratio of each compound was measured using XRD. For XRD analysis, 10% of corundum was added as internal standard. Measurement was carried out after drying at 200℃ for 24 hours in order to dehydrate the AFm phase. This treatment was necessary to avoid to overlap between the peaks of AFt and belite. The condition of measurement was as follows. Target: Cu, 40kV, 150mA, 1 step: 0.02 deg./5 sec. More than eight measurements on each sample were carried out to avoid the statistical error and preferred orientation factor of minerals. Hydration ratio was calculated from the integrated intensity of selected peaks by means of pattern fitting calculation program using modified Lorentz function (ISHIZAKI, 1988b).

RESULTS AND DISCUSSION

Figure 1 shows the effect of water/solid ratio on the reaction ratio of alite in the samples of portland cement (PC). The standard deviation of reaction percentage of alite was about 1% in this study, which was smaller than that of previous study (ASAGA,1992). In the case of the samples with W/S=W/C=0.4 and 0.5, hydration of alite proceeded up to 28 days curing, but in the case of 0.3, it was very slow after 3 days curing. The reaction percentage of alite in the sample cured for 1 and 3 days was about 53% and 67% respectively, which was not affected by the water/solid ratio. But after 3 days curing, it was strongly affected by the water/solid ratio. The hydration rate of alite in the sample with W/S=0.3 decreased with curing time and then less than 75% of alite reacted at 28 day curing. On the other hand, it did not so decrease in the sample with W/S=0.4 and 0.5, the reaction percentage of alite at 28 days curing was about 90% and 92%, respectively. These results were in good agreement with the previous studies (ASAGA,1992).

From these results, it was considered that the amounts of water was sufficiently supplied to maintain the hydration of the cement until about 70% of alite reacted. In this range, hydration rate of alite in the cement did not depend on the amount of water/solid ratio. In the case of W/S=0.3, either supply of water or space for precipitation of hydrates was short to maintain the hydration, and then the ratio of hydration decreased remarkably after 70% of alite reacted.

Figure 2 shows the effect of water/solid ratio on the reaction ratio of alite in the samples with fly ash (PF). The reaction percentage of alite at 1 day curing was about 57%, which was almost same amount the samples with different water/solid ratio, and slightly greater than that of PC. It changed with water/solid ratio after 3 days curing. The hydration rate of alite in the

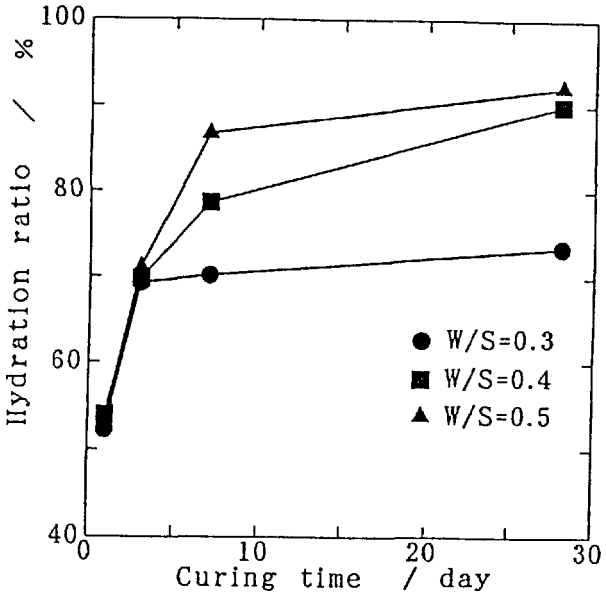

Fig.1 Effect of water/solid ratio on the reaction ratio of alite. sample: PC

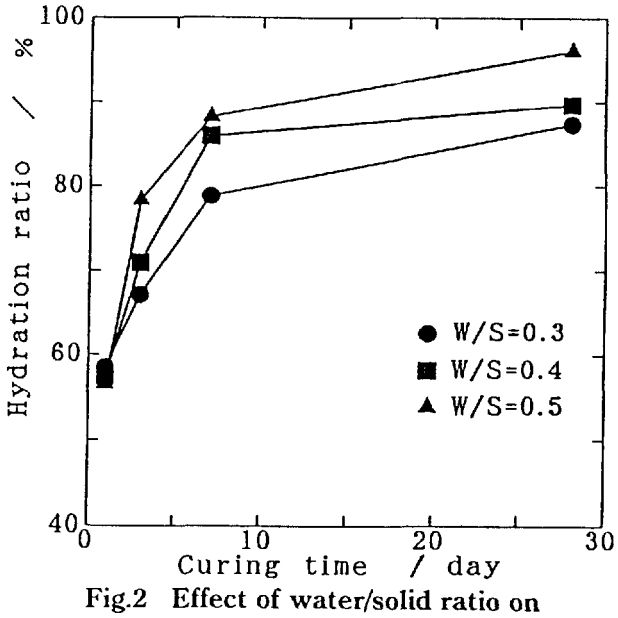

Fig.2 Effect of water/solid ratio on the reaction ratio of alite. sample: PF

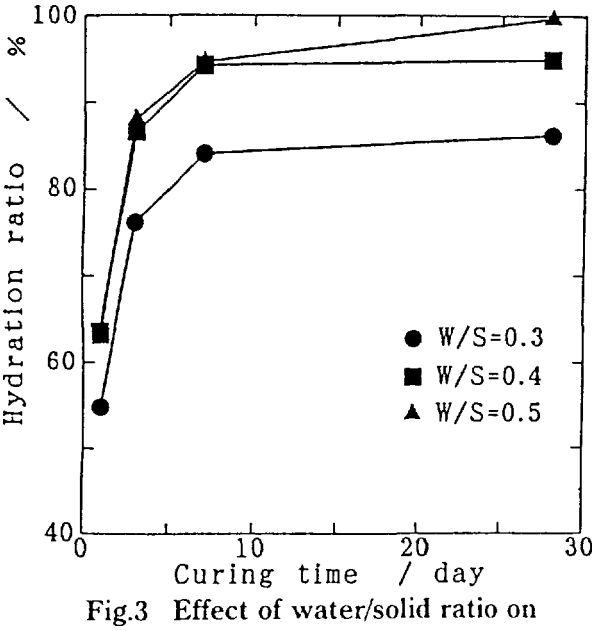

Fig.3 Effect of water/solid ratio on the reaction ratio of alite. sample: PB

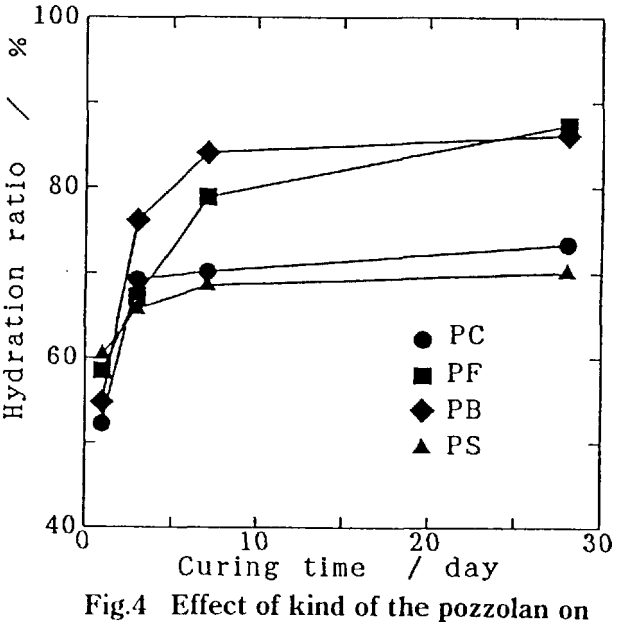

Fig.4 Effect of kind of the pozzolan on the reaction ratio of alite W/S=0.3.

sample with W/S=0.3 did not so much decreased with curing time compared to PC, and then about 87% of alite reacted at 28 day curing. In the case of W/S=0.4 and 0.5, the reaction percentage of alite at 28 days curing was about 90% and 96%, respectively.

Figure 3 shows the effect of water/solid ratio on the reaction ratio of alite in the samples with slag (PB). The hydration rate of alite in all of the samples was larger than that of PC. In the case of W/S=0.4 and 0.5, the reaction percentage of alite at 1 days curing was about 63% and 64%, respectively, which was about 10% larger than that of PC. But in the case with W/S=0.3, it was about 55%, which was slightly larger than that of PC. The hydration of alite continued with curing time, and then about 86% of alite was reacted at 28 day curing in the sample with W/S=0.3. In the case of W/S=0.4 and 0.5, almost of alite reacted, the reaction percentage of alite at 28 days curing was about 94% and about 99%, respectively.

Figure 4 shows the effect of kind of the pozzolan on the reaction ratio of alite in the samples

with W/S=0.3. At the 1 day curing, the reaction percentage of alite with pozzolan was larger than that of PC. In the case with silica fume, the reaction percentage of alite was largest at 1 day curing, but the hydration rate decreased with curing time and then less than 70% of alite reacted at 28 day curing, which was smaller than that of PC. On the other hand, it did not so much decrease in the sample with fly ash or slag, the reaction percentage of alite at 28 days was larger than that of PC.

The water/portland cement ratio (W/C) is different among the samples with the same water/solid ratio, because the amount of addition is different in the each pozzolanic materials. If the water/solid ratio (W/S)=0.3 is estimated in water/portland cement ratio (W/C), W/C is 0.375 in the case of PF, W/C is 0.6 in the case of PB, W/C is 0.33 in the case of PS. But the difference of the hydration percentage of alite among the samples within 3 days curing did not considered to the effect of water/solid ratio, because the reaction percentage of alite in the PC was not affected by the water/solid ratio within 3 days curing. The differences was considered to the effect of pozzolanic reaction.

The each pozzolan affected the reaction (UCHIKAWA,1986, MASSAZZA,1992). It is well known that silica fume accelerate the reaction of alite resulting the pozzolanic reaction (HUANG, 1985). In this study, it is clarified that the 10% of addition of silica fume accelerate the reaction of alite about 8% at 1 day curing. The microstructure changes by pozzolanic reaction resulted in the decrease of the reaction of alite at the later stage.

Figures 5 and 6 show the effect of kind of the pozzolan on the reaction ratio of alite in the samples with W/S=0.4 and 0.5, respectively. Within the 28 days curing, the reaction percentage of alite with pozzolan was larger than that of PC. Slag accelerated the alite reaction more than fly ash. In the both case of PF and PB, the hydration percentage did not change with W/S within the 7 days of curing. After 7 days curing, the reaction continued in the samples with 0.5, but slowed down in the samples with 0.4.

Water/portland cement ratio (W/C) is 0.5 (PF), 0.8 (PB) as W/S=0.4. and is 0.625 (PF), 1.0 (PB) as W/S=0.5, respectively. It is considered that the sufficient amount of water is existed in all the system. The acceleration of the hydration of alite did not result of the large water/solid

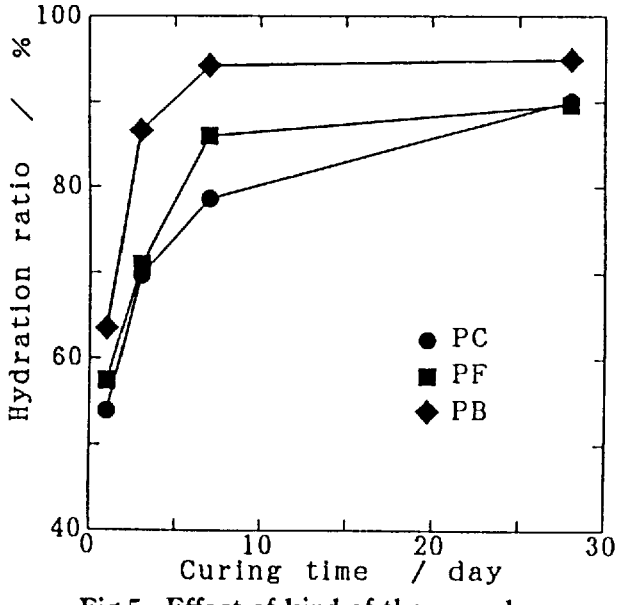

Fig.5 Effect of kind of the pozzolan on the reaction ratio of alite W/S=0.4.

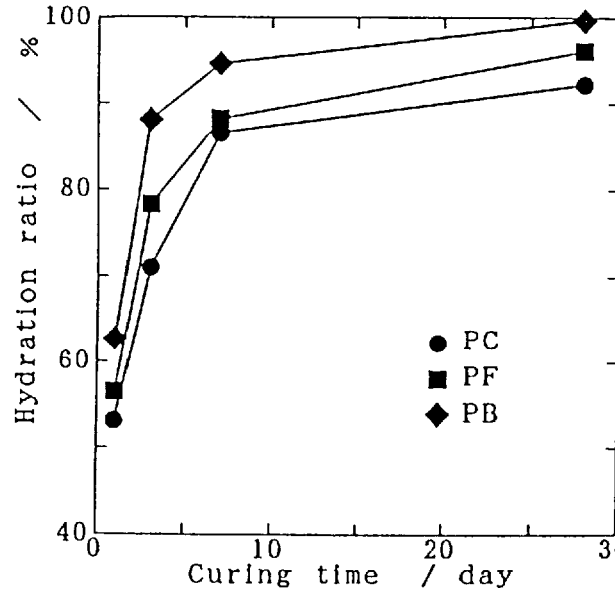

Fig.6 Effect of kind of the pozzolan on the reaction ratio of alite W/S=0.5.

ratio, because the reaction percentage of alite was the same value between W/S=0.4 and 0.5 within the 7 days curing. In the later stage, the retardation of the reaction in the case of W/S=0.4 was not due to the shortage of water but change of microstructure.

Figures 7–9 show the effect of water/solid ratio on the loss on ignition in the samples of PC, PF and PB, respectively. Figure 10 shows the effect of kind of the pozzolan on the loss on ignition in the samples with W/S=0.3. The each value was shown by the ignited base. In the case of PC , PF and PS, the loss on ignition increased with curing time almost the same manner of the hydration of alite. But in the case of PB, it increased much after 3 days curing compared to the reaction ratio of alite. It suggested the pozzolanic reaction of slag was much larger than that of fly ash.

In the case of W/S=0.5, the weight loss at 28 days curing of PC was about 25%, and the weight loss between 50℃ and 110℃ was about 13% of the initial solid, which was measured from sample weights dried at 50 ℃ for 24 hours and dried at 110 ℃ for 24 hours. About 12% of

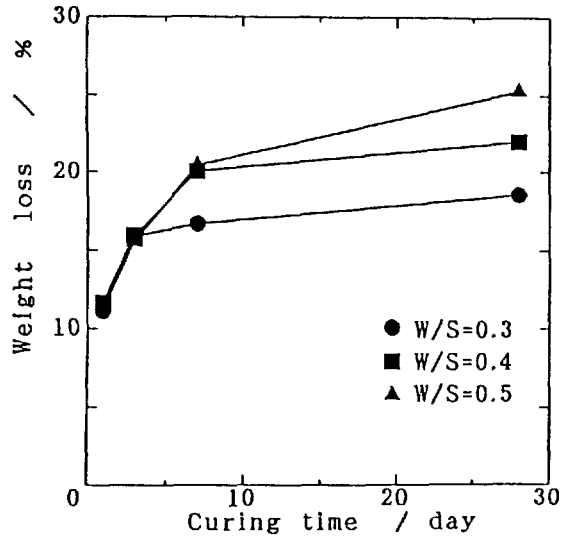

Fig.7 Effect of water/solid ratio on the loss on ignition samples: PC

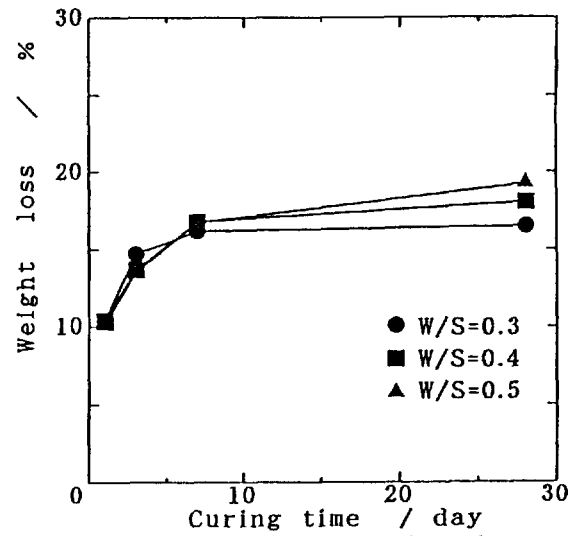

Fig.8 Effect of water/solid ratio on the loss on ignition samples: PF

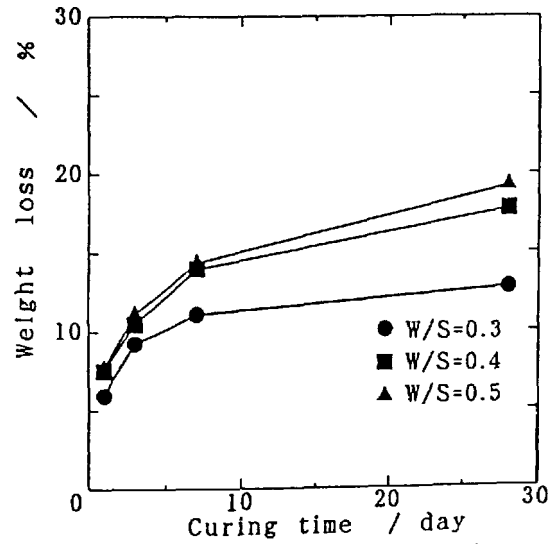

Fig.9 Effect of water/solid ratio on the loss on ignition samples: PB

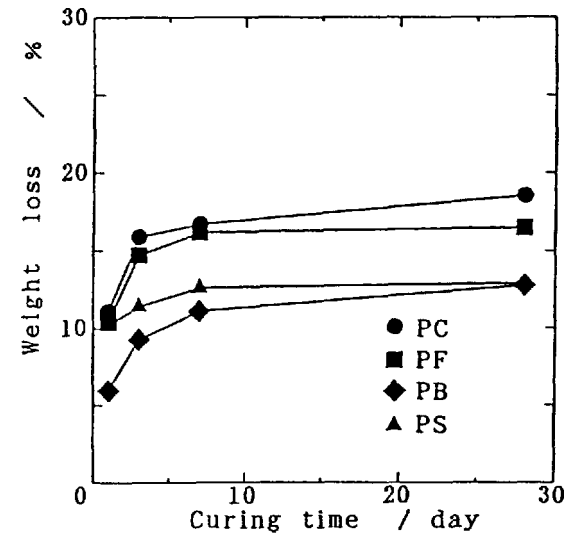

Fig.10 Effect of kind of the pozzolan on the loss on ignition W/S=0.3.

free water existed in the system at 28 days curing, In the case of W/S=0.3, the value of weight loss at 3 days curing of PC was about 16%, and the weight loss between 50℃−110℃ was about 7%. Less than 7% of free water existed in the system at 3 days curing, and same way, less than 3% of free water at 28 days curing. It is considered that the free water is too little to maintain the hydration in the sample of W/S=0.3 after 28 days curing.

Figures.11−13 show the effect of water/solid ratio on the amount of $Ca(OH)_2$ in the samples of PC, PF and PB respectively. Figure 14 shows the effect of kind of the pozzolan on the amount of $Ca(OH)_2$ in the samples with W/S=0.3. In the case of PC, the amount of $Ca(OH)_2$ increase with time as almost the same manner of the hydration of alite. But the values of W/S=0.3 were too small compared to the reaction ratio of alite. The shape of endothermic curve by decomposition of $Ca(OH)_2$ was observed slightly different from the sample with 0.4 or 0.5 in the measurement of DSC. The same phenomena were observed in the sample with pozzolan only at W/S=0.3. The superplasticizer might have affected the measurement, but, it was not clear that

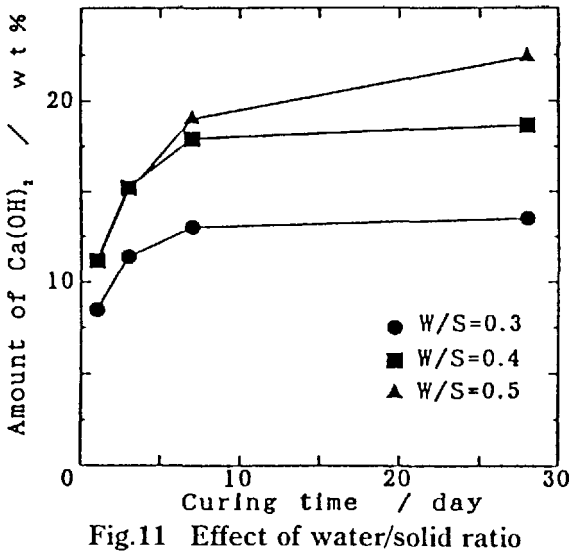

Fig.11 Effect of water/solid ratio on the amount of $Ca(OH)_2$ samples : PC

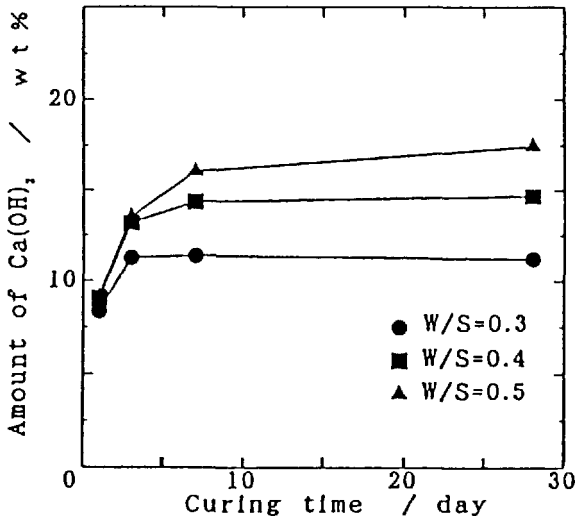

Fig.12 Effect of water/solid ratio on the amount of $Ca(OH)_2$ samples : PF

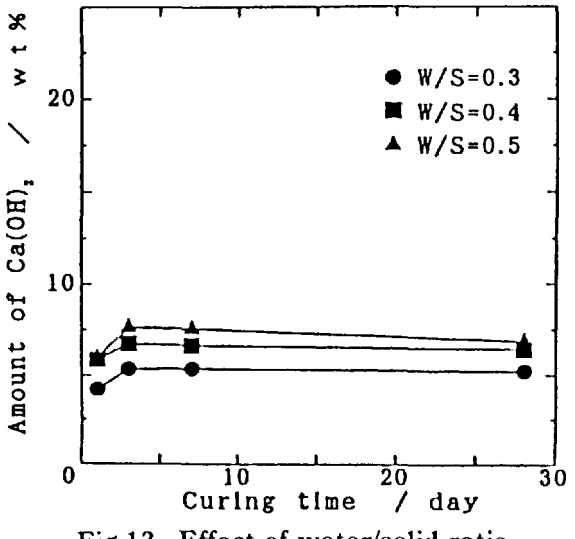

Fig.13 Effect of water/solid ratio on the amount of $Ca(OH)_2$ samples : PB

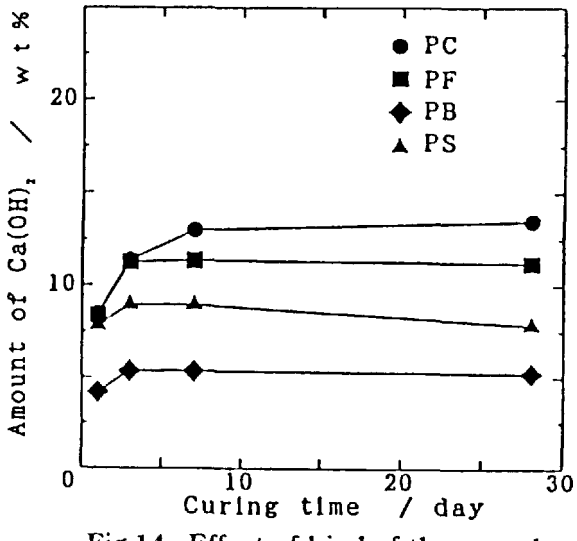

Fig.14 Effect of kind of the pozzolan on the amount of $Ca(OH)_2$ W/S=0.3.

the superplasticizer affected the formation of $Ca(OH)_2$ during the hydration or the only accuracy of the measurement.

In the case of PF, $Ca(OH)_2$ did not decreased within the 28 days curing, but $Ca(OH)_2$ decreased after 3 days curing in the samples of PB and PS.

The ignition loss and amount of $Ca(OH)_2$ of blended cement was smaller than that of PC within 28 days curing. Of course, these values depend on the content of portland cement, to compare the relation each others, the values need to change to per portland cement.

Figures 15 and 16 show the loss on ignition and amount of $Ca(OH)_2$ per portland cement respectively. In the case of W/S=0.4 and 0.5, loss on ignition of PB was remarkably larger than

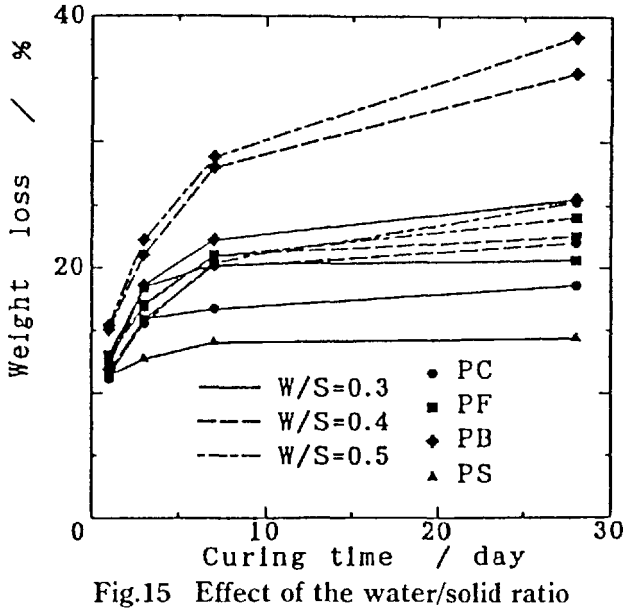

Fig.15 Effect of the water/solid ratio and kind of the pozzolan on the loss on ignition per cement

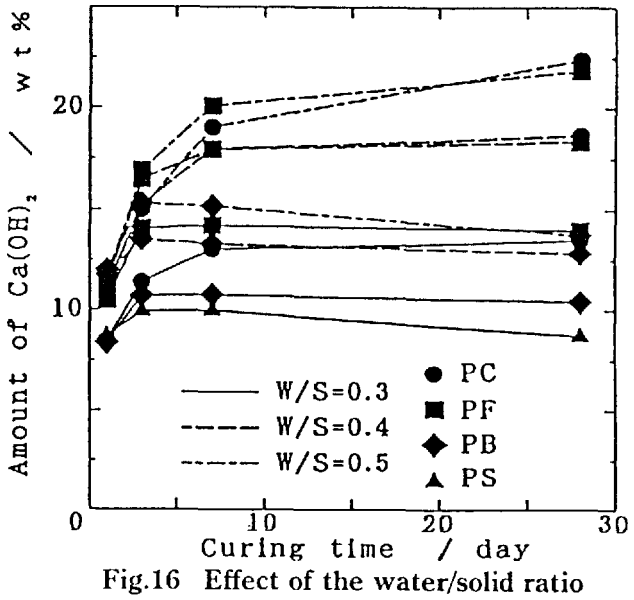

Fig.16 Effect of the water/solid ratio and kind of the pozzolan on the amounts of $Ca(OH)_2$ per cement

that of PC. On the other hand, it was not so much different between PB and PC. In the case of W/S=0.3, it was smaller in the sample of PS than that of the others.

The amount of $Ca(OH)_2$ in the PF samples was slightly large at early curing time, but at later stage it was not so much different from the sample of PC. It suggested that alite reacted more at early time, but fly ash reacted little within the 28 days curing. In the case of PB and PS,the amount of $Ca(OH)_2$ was remarkably less that of PC. Slag and silica fume considered to react from the early stage.

Figure 17 shows relation between the amount of $Ca(OH)_2$ and hydration ratio of alite in this experiments. In the case of W/S=0.3, the amount of $Ca(OH)_2$ is too small, it is discussed without the case of W/S=0.3. In the samples of PC and PS, the amount of $Ca(OH)_2$ increased almost proportionally

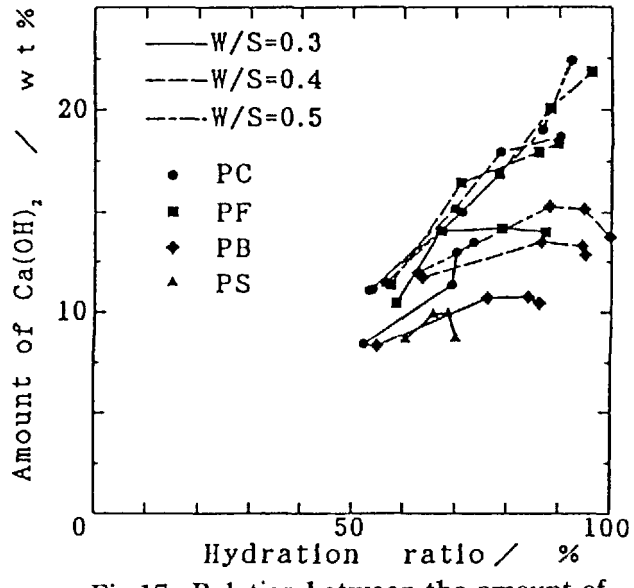

Fig.17 Relation between the amount of $Ca(OH)_2$ and hydration ratio of alite in the samples

with hydration ratio of alite, and it appears almost on the same line. In the samples of PB the amount of $Ca(OH)_2$ was remarkably below the line.

The mineral composition is assumed to the Bogue equation, the following experimental equation between the amount of $Ca(OH)_2$ and the amount of reacted alite was obtain from the sample PC and PB.

$$Y=1.15X$$

where, Y is the amount of $Ca(OH)_2$ shown as mole, X is the reacted alite shown as mole. The C/S ratio of C–S–H calculated was 1.85. It is the same result with the previous data (ASAGA,1992). In the case with fly ash, C/S ratio of C–S–H did not change remarkably within the 28 days curing.

It is pointed out that the mineral compositions are different from those obtained from Bogue equation and actual content of alite is larger than that from Bogue equation (YAMAGUCHI,1968, TAYLOR,1990). In the case, the C/S ratio of C–S–H might be larger than 1.85.

The value of C/S ratio of C–S–H produced from PB was not calculated because of the unknown of the hydration ratio of slag. The more studies will be needed to clarify the reaction of cement and pozzolanic additives, especially the improvement of the accuracy of analysis of the hydration rate of belite and aluminate.

CONCLUSIONS

(1) The hydration percentage of alite in the portland cement with the pozzolans was measured by XRD. It was observed that the standard deviation of reaction percentage of alite was about 1% .

(2) The hydration rate of alite in the portland cement is almost independent of the water/cement ratio at initial stage, and reaction percentage in later stage is strongly affected by the water/cement ratio.

(3) Fly ash accelerates the hydration rate of alite especially at initial stage, but fly ash reacts little at the initial stage.

(4) Slag accelerates remarkably the hydration rate of alite.

(5) Silica fume accelerates the hydration rate of alite especially at initial stage, but retards later.

CHARACTERISTICS AND HYDRATION MECHANISM OF RHA CEMENT PASTE

Lee K. LIN, National Taipei Institute of Technology, Taipei, Taiwan, ROC.
Chao L. HWANG, National Taiwan Institute of Technology, Taipei, Taiwan.

ABSTRACT Rice husk ash (RHA) produced by controlled incineration is a reactive pozzolan. Test results indicated active RHA are useful for making good concretes. Forming C-S-H gel by silicon ion from RHA with calcium hydroxide (CH) seemed to be one important hydration mechanism. Such hydration mechanism can be used for the R&D of high performance concrete (HPC) with solid waste.

Key words: Rice Husk Ash, Pozzolan, Calcium hydroxide, High performance concrete

INTRODUCTION

In each year, there are about 1.6 million tons of rice husk (RH) produced in the world (Lin, 1989). The treatment of RH has occurred as a severe waste problem due to such material is hard to disintegrate, so how to consume rice husk ash (RHA) effectively should be a significant study (Hwang, et al., 1990).

REVIEW ON R&D OF RHA

The beginning of burning RH into RHA and application as binding material was shown on the record of 1924 (Beagle, 1978). During 1950's RHA was only used in low-value applications (Mehta, 1986). Recent researches on the application of RHA as a supplementary cementing material in portland cement concrete have been made (Al-Khalf and Yousif, 1984, James and Subba, 1986, Boateng and Skeete, 1990, Hwang and Wu, 1989). However, the application is still limited.

RESEARCH PLAN

Acquired RH are treated by burning with Nabertherm furnace. The maximum heating temperature is about 1200°C. The process of heating in this research was maintained at heating rate of 5 °C/sec up to 700°C for 4 hours, and then naturally cooled down. The properties and characteristics of RHA and type I cement are shown in Table 1 (G represents "ground", UG represents "unground"). Cement paste and mortar specimens with W/B of 0.35, 0.47 and 0.59, and with 0, 10, 20 and 30 % RHA of cement, respectively, were studied.

Table 1. Properties of 700°C RHA and Cement

	Item		RHA	Cement
Chemical Ingredients	SiO_2		92.15	20.69
	Al_2O_3		-	6.04

		final	-	5 : 30

RHA PROPERTIES AND HYDRATION BEHAVIOR

After burning up to 700°C, the properties of RHA are shown in Table 2.

Table 2. Basic properties of 700°C RHA

Item		Test result	Test method
Appearance color		light pink	visual observation
Weight loss ratio		86.0%(AD); 83.8%(OD)	average of 10 tests
Main ingredient		SiO_2	chemical analysis
Overall unit weight (kg/cm^3)	G	0.29(loose); 0.45(dense)	average of 6 test
	UG	0.14(loose); 0.20(dense)	
true specific gravity		2.22(G); 2.04(UG)	average of 2 tests
Microstructure		dense, straight crystal row	SEM
Pore structure		590 Å of average pore size	MIP

The appearance color of RHA is pink. Residual ash mainly contains SiO_2. Weight loss from combustion is over 80%. The overall unit weight of ground RHA is more than two times of unground RHA and with about 10% higher in density. Pore diameter lies within the range of 590 Å. Figure 1 illustrates the hydration behavior of cement paste with or without RHA. The first peak of heat evolution curve has dropped a lot as the addition of RHA to replace part of cement. This is caused by the large water absorption of RHA at an early stage, and then inadequate water contacts with the cement grain. The zeta-potential of RHA is -20~-30 mV, that is quite active to repeal water. As small amount of RHA may shorten setting time, however large amount may have worse effect on workability due to rough surface and light weight features. Proper use of RHA can obtain better properties, and is believed to help producing with high flowability HPC. On the 7th day, the C-S-H gel has partial growth only; and the

product on the RHA grain surface is not significant. On the 28th day, the C-S-H gel is observed with large formation which is connected with RHA grain as a continuous structure; pores are rapidly decreased; part of needle ettringite and calcium hydroxide (CH) laminar crystal are randomly heaped on the boundary, and therefore the strength is fully developed.

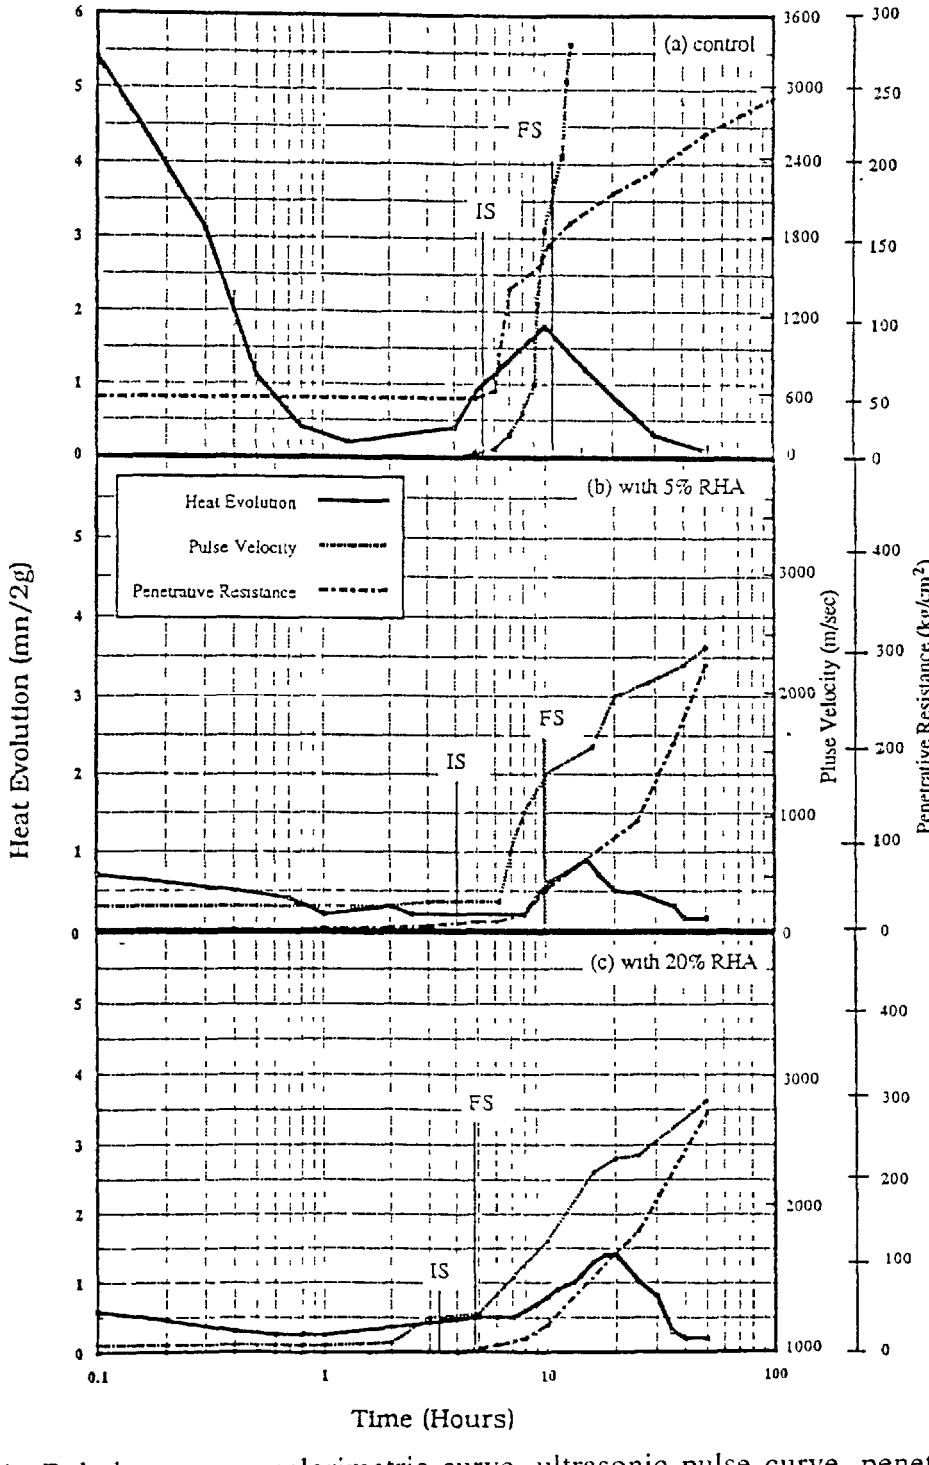

Figure 1 Relation among calorimetric curve, ultrasonic pulse curve, penetrative resistance curve and setting time (W/B=0.47). IS and FS are initial and final set, respectively.

HYDRATION MECHANISM MODEL OF RHA CEMENT

The addition of water with cement will react in the similar way with or without RHA. The water absorbed in the porous silica structure is released and aids the quick reaction of Ca^{++} with silica ion from RHA. Because the amount of hydrate in unit volume is increasing, the pore is decreased, so whole structure gets denser. Moisture is diffused for dissolving CH, therefore Ca^{++} has reacted with Si ion of RHA to form C-S-H gel. Such phenomenon is repeating over and over, so the strength is developed by the increasing age. The crystal is growing in accordance with the increasing of action energy and forms a continuous gel matrix finally.

CONCLUSION

Proper burning of RHA will have porous feature that will be highly active. The hydration mechanism of RHA paste is through silicon ion resolved and bound with CH to form loosen gel. In the future, large quantity of RHA in high quality can be produced in many rice-growing countries and could be effectively applied in HPC.

ON THE SEMI-INDUSTRIAL PRODUCTION OF HIGHLY REACTIVE RICE HUSK ASH AND ITS EFFECT ON CEMENT AND CONCRETE PROPERTIES

Shuichi SUGITA, Qijun YU*, Masami SHOYA, Yoichi TSUKINAGA and Yasuo ISOJIMA
Hachinohe Institute of Technology, 88-1, Myo, Hachinohe, 031, Japan
*Institute of Materials, Wuhan University of Technology, China

ABSTRACT Based on the further investigation on the relation between the pozzolanic activity of rice husk ash (RHA) and its burning, grinding processes, the authors proposed a method for the semi-industrial production of highly reactive RHA. It was found the burning and grinding conditions were the key to get active RHA. With the addition of the RHA obtained in the semi-industrial furnace to cement not only the strength of cement was increased but also the resistance of concrete to 2% HCl solution attack, Cl^- penetration and carbonation was improved greatly.

Key words: Acid attack, Penetration, Reactivity, Rice Husk Ash and Strength

INTRODUCTION

Just as the wide application of blast-furnace slag, fly ash and silica fume the possible utilization of rice husk ash (RHA) in concrete has received much attention since the end of 1970s and many positive results have been obtained (Mehta, 1977 and 1986, Karasudhi, 1979, Khan, 1985, Sugita, 1992 and 1996, Mazlum, 1992, and Inoue, 1996). RHA mainly contains 90-95% SiO_2 and 1−5% carbon residue, which is similar to silica fume in SiO_2 content but the SiO_2 in it can be in amorphous or crystalline form according to the manner in which it is burned. When over-burning occurs the amorphous SiO_2 will be changed to cristobalite, quartz and tridymite (Ibrabim and Helmy, 1981, James and Rao, 1986), and when it is burnt at low temperatures much carbon will exist in the product. In either case the pozzolanic activity of RHA will be decreased greatly. Although RHA of high quality has been obtained by many researchers in laboratories because the burning temperatures and cooling conditions can be well controlled at what as desired, yet it is difficult to get active and homogeneous RHA in an industrial scale. In an ordinary furnace for producing RHA in large quantities there always exists a heterogeneous temperature distribution due to the self-burning of rice husk and the heat loss from the surface of the burning rice husk, so the quality of RHA, sampled from the same furnace but at different parts or even at the same part but at different time, is often varied considerably. Now how to realize the production of active RHA with homogeneous quality in an industrial scale, in our opinion, becomes the key to the transformation of the study of RHA in laboratory to its industrial application, which is also the practical and final purpose of the research on RHA. As little detailed information on the above exists, the following work was therefore undertaken: 1) effect of burning temperature and grinding condition on the pozzolanic activity of RHA, 2) design of the furnace for producing RHA in large quantities and 3) the property of the RHA burnt in our semi-industrial furnace and its effect on the characteristics such as strength, resistance to acid attack, carbonation and penetration of portland cement mortar and concrete.

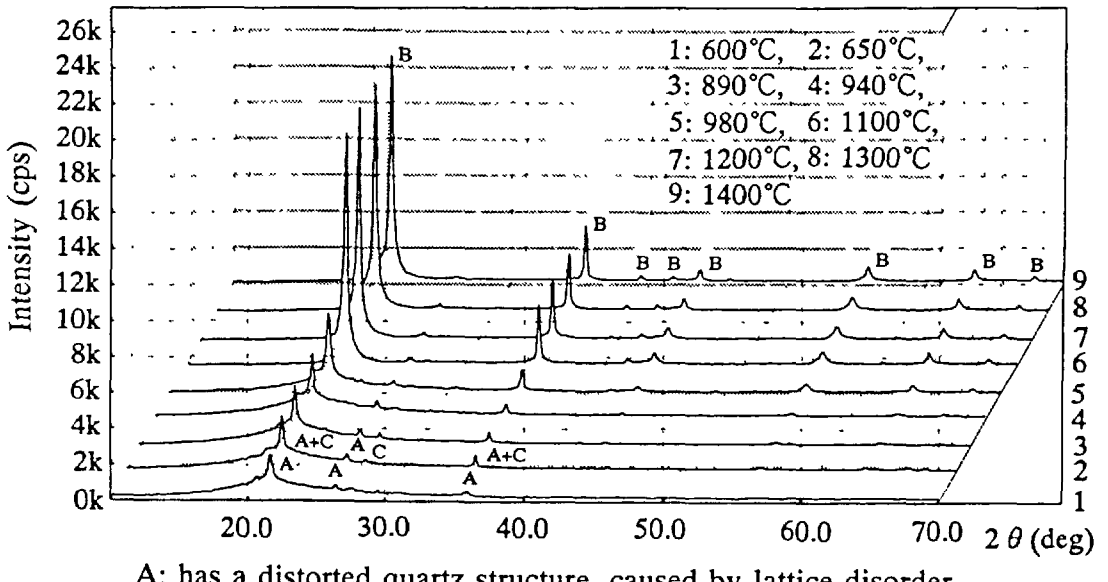
RAW MATERIALS

The used RHA was obtained by burning rice husk in an electric furnace or in the semi-industrial furnace designed by us. The cement and aggregates were: 1) Sumitomo ordinary portland cement, OPC for short, 2)Toyoura standard sand for preparing mortar specimens and 3) crushed stone with the nominal maximum size of 25 mm and river sand as the coarse and fine aggregate of concrete specimens (Table 1). In order to control the flow value of mortars with different RHA addition within 190−210 mm water reducer NL-1450 (highly polymarized aromatic sulphosalt) was adopted and for regulating the air volume and slump of various fresh concrete to about 5% and 12 cm both NL-1450 and air-entraining admixture (vinsol resin) were used.

Table 1 Properties of the aggregates used in this experiment

Sample	Specific gravity	F.M.*	Water absorption (%)	Solid volume (%)
Toyoura sand	2.65	0.96	0.78	57.0
River sand	2.66	2.46	1.26	66.2
Crushed stone	2.72	6.99	0.28	57.9

* F.M.--fineness modulus



EXPERIMENTAL AND RESULTS

Evaluation of the pozzolanicity of RHA

An exact evaluation of the pozzolanicity of any natural or artificial pozzolans should be based on the result of strength tests, but in which at least 28 days will be taken. We found the method for rapid evaluation of pozzolanic activity of natural products by conductivity measurement, proposed by Luxan et al. (1989), was also available to estimate the pozzolanic activity of RHA (Sugita, et al., 1992). The analysis procedures are mainly described as follows: 1) to measure the electrical conductivity of a saturated $Ca(OH)_2$ solution (E_0) of 40 ± 1°C, 2) to add 5.00g of the material to be tested to 200 ml of the $Ca(OH)_2$ solution and stir the solution continuously, 3) to read the electrical conductivity of the solution (E_1) after it is mixed with the material for 120 seconds, and 4) by subtracting E_1 from E_0 the change in conductivity of the solution is therefore obtained. The larger the change in electrical conductivity, the more active the tested material. In present work this method was also used.

Effect of burning temperature on the silica form in RHA and its activity

The effect of burning temperatures on the silica form in the RHA which was burnt in an electric furnace at 600°C, was investigated by high temperature XRD at a heating rate of 10°C / min (Fig 1). Fig 2 shows the change in conductivity of the $Ca(OH)_2$ solution after added with the RHA burned at different temperatures.

A: has a distorted quartz structure, caused by lattice disorder,
B: β - tridymite, C: β - quartz

Figure 1 XRD patterns of RHA at different temperatures

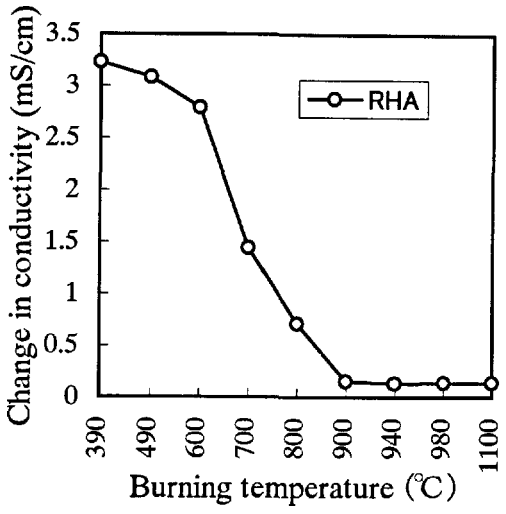


Figure 2 Relation between the change in conductivity and the heating temperature of RHA

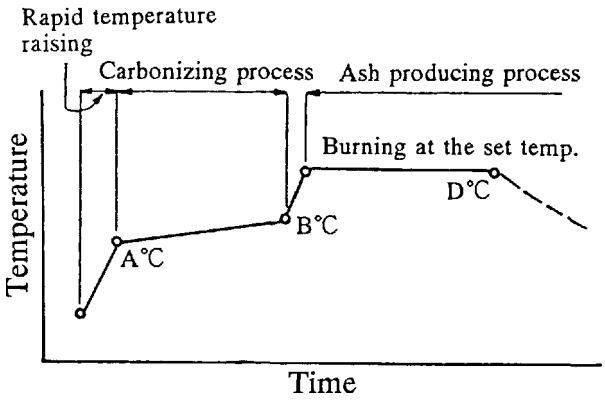

Figure 3 Schematic diagram of the "two step burning method"

Design of the furnace for producing highly active RHA

Based on the relation of the pozzolanicity of RHA with its burning processes and burning temperatures a new way to get highly active RHA, i.e. "two step burning method", has been proposed by the authors (Fig 3), the furnaces in respect to the method are shown in Figs 4 and 5 respectively. The "two step burning method" means that the whole process of burning RHA should be divided into two steps: one is to drive off the organic materials and water in the husk and carbonize the husk at a relatively low temperature under a reducing atmosphere, the other is to burn the carbonized husk to ashes at a proper temperature in a given time. Experiments showed the atmosphere and temperature at which the two processes occur and the time taken for each process were very important to the pozzolanicity of the final product (Sugita, 1996).

According to Luxan et al. (1989) the RHA produced by the furnace of either continuous system or batch system was very active: the change in conductivity of the saturated $Ca(OH)_2$ solution

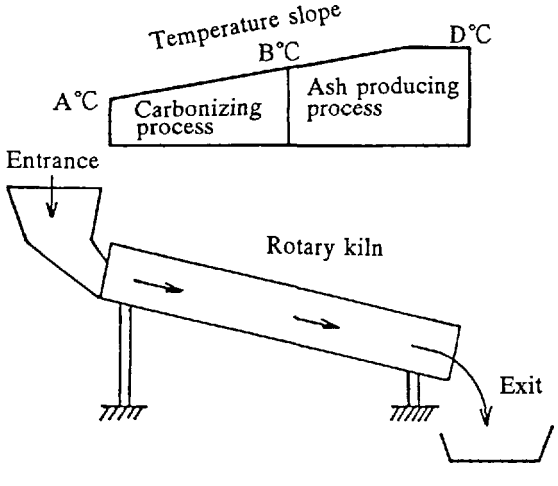

Figure 4 Continuous RHA production system with a rotary kiln

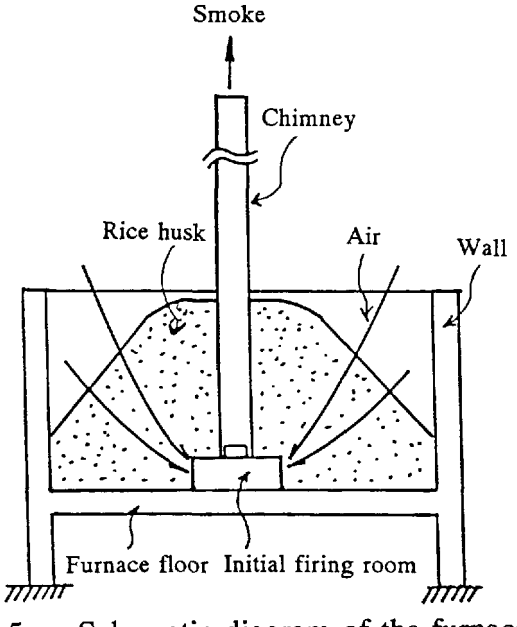

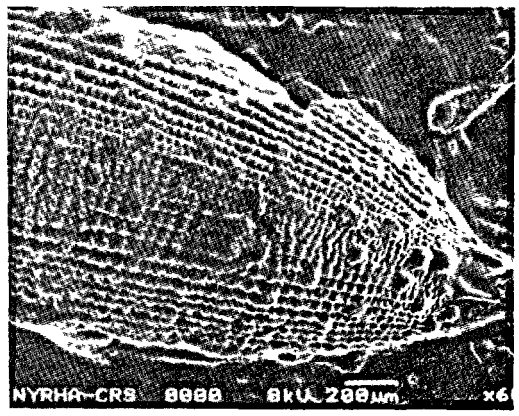

Figure 5 Schematic diagram of the furnace of batch production system

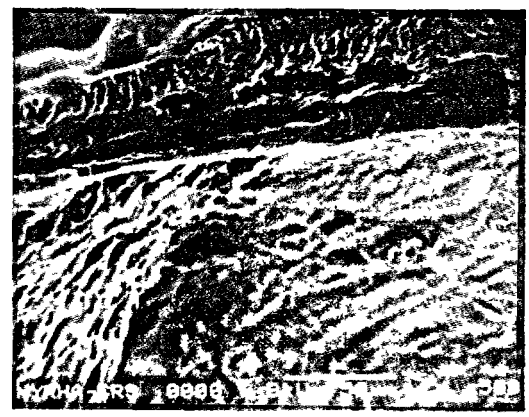

added with the RHA produced by the rotary kiln (Fig 4) and by the furnace as shown in Fig 5, called semi-industrial or batch furnace, was about 6.3 mS/cm and 2.4－3.0 mS/cm respectively. As small temperature difference yet exists in the batch furnace, now innovation upon it is being undertaken. With the addition of the RHA either from the kiln or from the furnace to cement the strength of concrete could be greatly enhanced (Sugita, 1996).

The effect of grinding on the pozzolanicity of RHA

Fig 6 are the SEM images of the corase and ground RHA burnt in the batch furnace. From Fig 6-b it can be found the corase RHA has a porous inner wall. In the presence of grinding agent (J=250) RHA can be finely ground to an average diameter of 15.4 μ m (Fig 6-c) with a high change in conductivity and a large N_2 specific surface (Fig 7), otherwise its specific surface and the change in conductivity are gradually decreased with grinding time, coherently large particles remain in the final product (Fig 6-d and Fig 7). Fig 8 shows the variation of the pore distribution of RHA with its grinding time.

(b) the inner wall of the coarse RHA, 500×

(c) ground RHA with added grinding agent, 250×

(d) ground RHA without added grinding agent, 250×

Figure 6 SEM images of the coarse and ground RHA burnt in the batch furnace

Strength of RHA blended mortar and concrete

In the following experiments all the used RHA was from the batch furnace and ground in a ball mill for 60 min. with 0.025% grinding agent addition (J=250). It contains 91.2% SiO_2 and 1.48% residual C, with N_2 specific surface of 50 m^2/g, change in conductivity of 3.00 mS/cm and specific gravity of 2.17, and the silica in it is mainly in amorphous form.

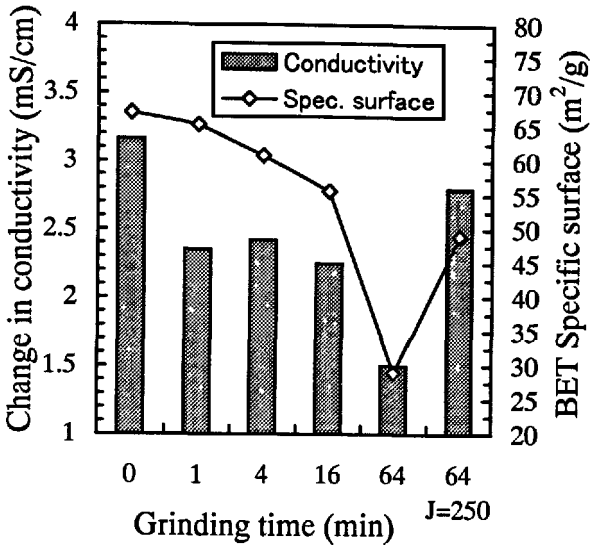

Figure 7 Variation in conductivity and specific surface of RHA vs grinding time

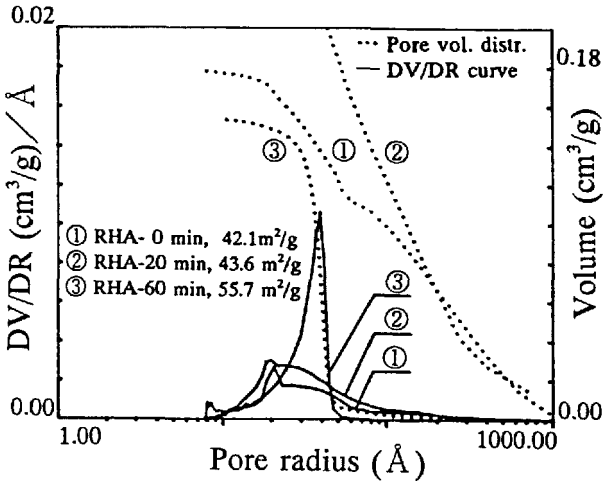

Figure 8 The effect of grinding on the pore distribution and cumulative pore volume of RHA

With adding 5%, 10%, and 15% of this RHA to OPC, mortar specimens of 40×40×160 mm were made at: 1) water cement ratios of 45%, 55%, and 65%, 2) sand cement ratio of 1.5 for the mortar at w/c = 45%, 1.8 for the mortar at w/c = 55%, and 2.0 for the mortar at w/c = 65%, and 3) flow values of 190−210 mm. Fig 9 shows their compressive strength variations relative to the control samples of OPC at 7d, 28d and 91d. According to JIS A 1132 concrete specimens of ϕ 100×200 mm were prepared at: 1) RHA blending ratios of 0%, 10%, 20%, 30%, and 50%,

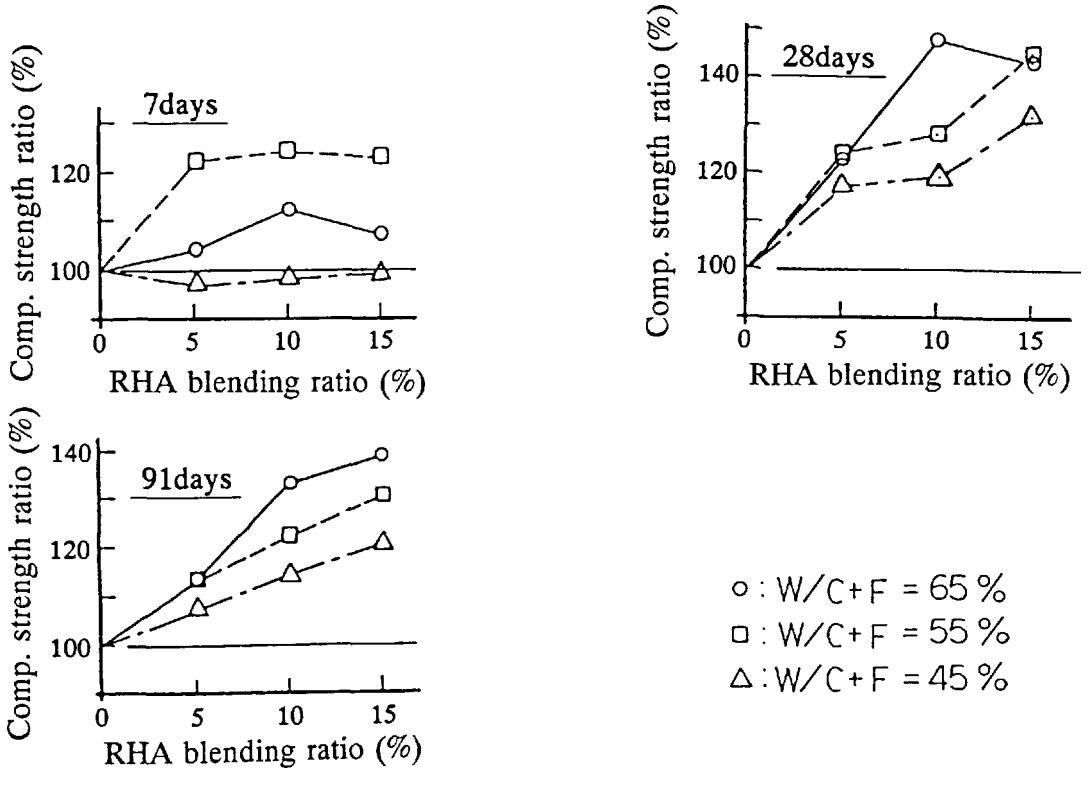

Figure 9 Relative compressive strength of RHA blended mortar vs RHA addition

2) water cement ratios of 70%, 75%, and 80%, and 3) slump of 12±1 cm and air volume of 5±1%. The relative compressive strength of the specimens is shown in Fig 10.

Resistance of RHA blended concrete to carbonation and to the attack by 2% HCl solution

As same as the above concrete cylinders of ϕ 100×200 mm were made at a water cement ratio of 75% and with 0%, 10%, and 30% RHA addition. After curing in water for 28 days the cylinders were dried at 60±2°C for 24 hrs, then dried at 20±2°C in the air of R.H.<40% for one week. Subsequently 3 slices of ϕ 100×50 mm were taken out from the middle portion of each of the cylinders. Finally the slices, with their top and bottom surfaces being tightly sealed with epoxy but with their outside surfaces being exposed, were cured in an accelerated carbonation chamber in which the conditions of 30°C, 60% R.H. and 5% CO_2 were set. Average carbonation depth was measured by a computer coordinating area-curvimeter at the ages of 2, 4 and 8 weeks using 1% phenolphthalein to distinguish carbonated portion from uncarbonated one. The result is as shown as Fig 11. In another aspect, some of the dried concrete cylinders were respectively immmersed to 2% HCl solution and water after their top and bottom surfaces were sealed with paraffin wax. Fig 12 and Fig 13 show their compressive strength and mass variations by percentage compared with the mass before cured in the HCl solution.

Resistance of RHA blended concrete to Cl^- penetration

The concrete cylinders of ϕ 100×200 mm with RHA blending ratios of 0%, 10%, and 30% were prepared at water cement ratios of 65% and 75%. After curing in water for 28 days they were cut to two parts of ϕ 100×100 mm and dried at 20±1°C in the air of 60% R.H. for one week. Afterwards they were immersed into 13% NaCl solution at 20°C for one week and then dried at the same condition for one week. After six immersion-drying recycles the average penetration depth of Cl^- was determined with the area-curvimeter by spraying 0.1% fluorescein sodium solution and 2% $AgNO_3$ solution on the freshly exposed surface, obtained by cutting the specimen along the direction of its diameter, to display the Cl^- penetrating region, the results are shown in Fig 14.

DISCUSSIONS

Fig 1 shows that with the increment of temperature the diffraction intensity of SiO_2 crystal is gradually increased. At 600°C the RHA is mainly consisted of amorphous SiO_2 (d = 4.04Å, JCPDS Card: 29-0085) and there is only a small amount of phase A in it. From 650°C β-quartz appears but disappears at 940°C. After 980°C the diffraction intensity of crystalline SiO_2 becomes

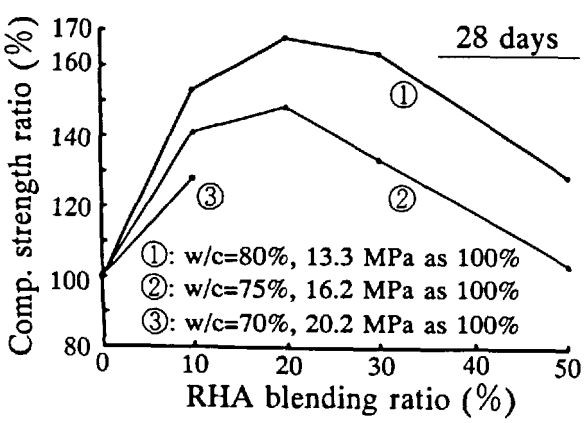

Figure 10 Relative comp. strength of RHA blended concrete vs RHA addition

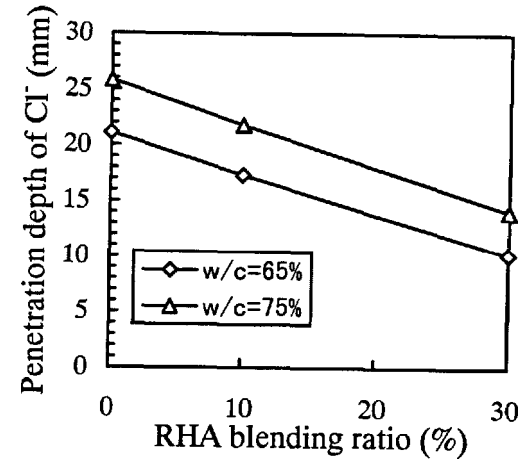

Figure 14 Penetration depth of Cl^- in concrete vs RHA blending ratios

much stronger than those of before and the peak of d = 4.04 Å disappears, which shows all the amorphous SiO_2 has been changed to crystalline SiO_2— a mixture of β-tridymite and phase A in which the former is the main constituent. As the result of the transformation of amorphous SiO_2 to crystalline SiO_2 the change in conductivity is decreased, especially there is an evident reduction of the change in conductivity between 600°C and 900°C (Fig 2). After 900°C the RHA will not behave any pozzolanic activity as the change in conductivity is less than 0.4 mS/cm (Luxan et al., 1989). On another hand if RHA is burnt at low temperatures, for instance below 500°C, much unburnt carbon will remain in it, which also leads it to have poor pozzolanic activity and have a negative influence on the long term properties of concrete. Hence after carbonizing process (Fig 3) it is suggested to controll the final burning temperature of RHA at about 600°C.

In the presence of much carbon in RHA, e.g. more than 4—5%, the change in conductivity of the saturated $Ca(OH)_2$ solution after adding the RHA to it can not give an exact evaluation of the pozzolanicity of the RHA as the carbon is active and can also cause a large change in

conductivity of the solution by physisorption and chemisorption.

It was observed even though RHA was appropriately burnt it was also inactive when it was inappropriately or over ground (Sugita, 1996). The reason for this is the secondary agglomeration occurred among the finely ground RHA particles caused by van der Waals attraction and the giant supersurface energy they have. The less the specific surface of the ground RHA, the poorer the pozzolanicity of it. In the presence of grinding agent (J=250) the specific surface of RHA is increased with grinding time (Fig 8). Therefore, in our opinion, in order to get active ground RHA grinding agent, for instance the by-product in the production of di-ethylene glycol, should be used in its grinding process.

From Fig 8 it can be also found the specific pore volume of coarse RHA is as much as 0.16 cm^3/g and the pores in it is mainly distributed in the region of 20 − 400 Å with an average radius of 123 Å. With a so large number of mesopores RHA has a characteristics of high water absorption (Inoue and Hara, 1996), which may directly worsen the workability of concrete. Before we tried to use unground RHA to cast concrete specimens but finally failed because the mix was too dry, but this phenomenon could be eliminated by grinding the RHA for a definite time in the presence of grinding agent (Sugita, 1996). Fig 8 shows the distribution of the pores in ground RHA is narrowed to the range of 20 − 50 Å with an average radius of 40 Å, at the same time its specific pore volume is decreased to 0.13 cm^3/g. As its pore volume and pore size are both decreased its ability of water absorption is certainly reduced as well. Therefore an appropriate grinding of RHA is not only advantageous to the enhancement of its pozzolanic activity but also to the improvement of the workability of RHA blended concrete.

With blending RHA with OPC at ratios of 5%, 10%, and 15%, the compressive strength of mortar at different ages are all increased. The more the added RHA the higher the strength of mortar, especially at 28d and 91d the RHA blended mortars show a higher strength increase than that of OPC mortars (Fig 9).

Fig 10 indicates that with an appropriate addition of RHA to OPC, for instance 20% by weight, the 28d compressive strength of concrete with different w/c is enhanced by more than 25%, in particular the strength of the concrete with a w/c of 80% is increased by as much as 65% compared with the control concrete.

From Fig 9 and Fig 10 it can be found that the higher the water cement ratio, the bigger the strength increase of either the mortar or concrete blended with RHA. This is possibly attributed to the reduction of effective water cement ratio in the mortar or concrete blended with RHA as free water has been absorbed by the added RHA and kept in its mesopores.

Regarding the strength increase mechanism of RHA blended concrete, the following results have been obtained: 1) at a definite age cement hydration degree is improved by the added RHA, 2) due to the reaction of the active SiO_2 in RHA with $Ca(OH)_2$ in the hydrates both the size and the amount of portlandite in RHA blended concrete is decreased, but the amount of C − S − H gel in it is increased and 3) with the addition of RHA the average pore size of concrete is reduced, especially the portion of pores greater than 200 Å in radius is evidently decreased instead of the increase of the amount of small pores.

With higher strength and smaller pores than reference concrete the resistance of RHA blended concrete to carbonation, to acid attack, and to Cl^- penetration is certainly improved (Figs 11, 12, 13 and 14).

Having the characteristics of continuous operation and a well controlled burning temperature the rotary kiln shown in Fig 4 can produce much more active RHA than the batch furnace (Fig 5) does. But the latter has the advantages of low investment and low production cost, and if it is operated in a proper manner active RHA can be obtained.

CONCLUSIONS

1. By using "two step burning method" proposed by the authors, RHA of high quality can be obtained with either the rotary kiln or the batch furnace when the burning conditions in them are well controlled.
2. The burning temperature of RHA has a great influence on the pozzolanicity of RHA. At the temperatures higher than 600°C the amorphous SiO_2 in RHA will be transformed to crystalline SiO_2, at the same time its activity is decreased greatly. At the temperatures below 500°C the quality of RHA is also poor due to the presence of much unburnt carbon in it.
3. RHA has a mesoporous structure with large N_2 specific surface. To prevent the secondary agglomeration among its finely ground particles, which will result in the decrease of its reactivity, grinding agent should be used in its grinding process.
4. With the addition of the ground RHA which was burnt in the batch furnace to ordinary portland cement not only the strength of cement was increased but also the resistance of concrete to the attack by 2% HCl solution, to carbonation and to Cl^- penetration was improved greatly. The higher the water cement ratio the bigger the strength increase of the RHA blended mortar and concrete respective to the control samples.

SYNERGIC ACTION OF FLY ASH IN TERNARY MIXTURES WITH SILICA FUME AND RICE HUSK ASH

Geraldo Cechella ISAIA, Federal University of Santa Maria, Santa Maria, RS, Brazil

ABSTRACT This paper presents the pozzolanic and physical effects of fly ash in addition with silica fume and rice husk ash, on substitution levels of cement ranging from 10 to 50%, by weight. The ternary mixtures with fly ashes showed synergic effects when the data was correlated with the remaining calcium hydroxide or unitary compression strength. It follows that when the fly ash was added to silica fume or rice husk ash, the performance of the reactivity depended on the amount of pozzolans in the mixture, besides the size of the grains less than 5 μm.

KEY-WORDS: fly ash, rice husk ash, silica fume, reactivity, particle size distribution

INTRODUCTION

The addition of pozzolans to Portland cement has the purpose to improve the concrete microstructure. According to Mehta and Aïtcin (1990), the small particles of pozzolans are less reactive than Portland cement and, when dispersed in the paste, they generate numberless nucleation sites for the precipitation of hydration products. Therefore, this turns the paste more homogeneous and dense in respect to fine pores distribution. In addition, through physical effect, the smallest grains bring on better packing with cement and decrease the wall effect at the transition zone. In consequence, there is reinforcement of this weaker zone due the higher adherence between paste and aggregate, increasing the concrete properties. Thus, the pozzolanic effect upon the cement paste performance depends on both the pozzolanic reactions as well as the filler effect of the small particles. Goldman and Bentur (1993) concluded that concrete strength increases when silica fume is added, due to the microfiller effect through the thickness of the transition zone, and this effect is even more relevant than the pozzolanic action.

The incorporation of fly ash or rice husk ash fine particles to the cement paste, even if not fully pozzolanic, as shown by Mehta (1987), causes the segmentation of large pores and increases the amount of the nucleation sites for the hydration products precipitation, accelerating the reactions and forming smaller calcium hydroxide crystals. The chemical action via pozzolanic reactions enhance the physical action, segmenting the pores in higher level and refining the CH grains, in extent the age increases. Research made by Berry et al. (1994) in CANMET, Canada, also followed that the particles of fly ash particles that are not completely hydrated are able to fill the voids, increase the denseness of the paste, and the result is more relevant if the amount of fly ash contained in the paste is higher.

Within this purpose, this paper investigates the fly ash action in ternary mixtures with silica fume or rice husk ash, through pozzolanic activity test, remaining CH, non-evaporable water and unitary axial compression strength. The results indicated that the fly ash presented synergic effect in the ternary mixtures, and this action was connected with the total pozzolans quantity of each mix, as well as the contents of the grains size smaller than 5 micrometers.

EXPERIMENTAL

A high early Portland cement (NBR 5733) was used and the fly ash came from Petrochemical Pole (Triunfo, RS) ground in laboratory for an hour and sieved in a #0.3 mm mesh sieve. A non-densificated silica fume was provided by a national supplier. The rice husk ash was constituted with 50%, by weight, burnt in a brick furnace factory, without temperature control, and

50% burnt in laboratory furnace at 650°C. The two parts were ground together for one hour and sieved in a #0,3 mm mesh sieve. Table 1 shows the physical and chemical characteristics of Portland cement and pozzolans. Figure 1 presents pozzolans XRD with quartz and mullite as crystalline phases in fly ash, and quartz and cristoballite in rice husk ash. Natural sand with FM = 2.83, Dmax = 4.8 mm, a basaltic coarse aggregate with FM = 6.97 and Dmax = 19 mm were used. The superplasticizer admixture was a ASTM C 494 Type F, with 1.18 kg/dm^3 density, 32.5% solid content and pH = 7.68.

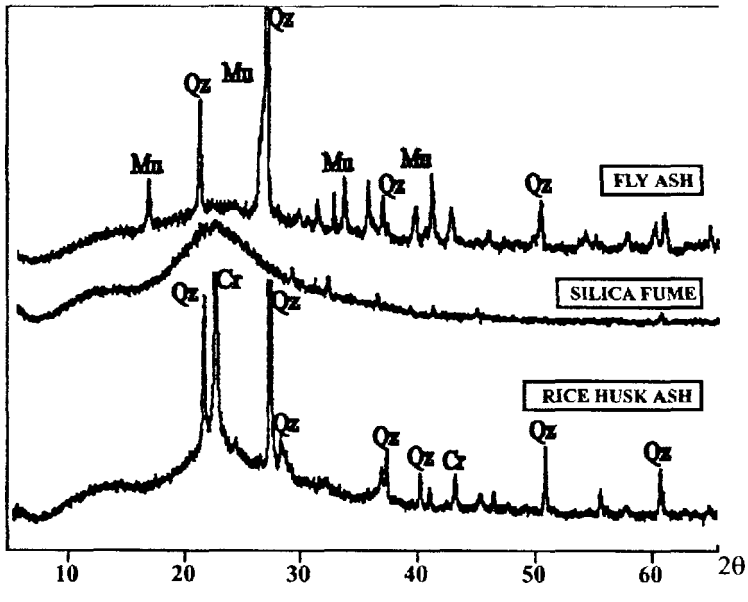

Figure 1 Pozzolans X-ray diffractogram

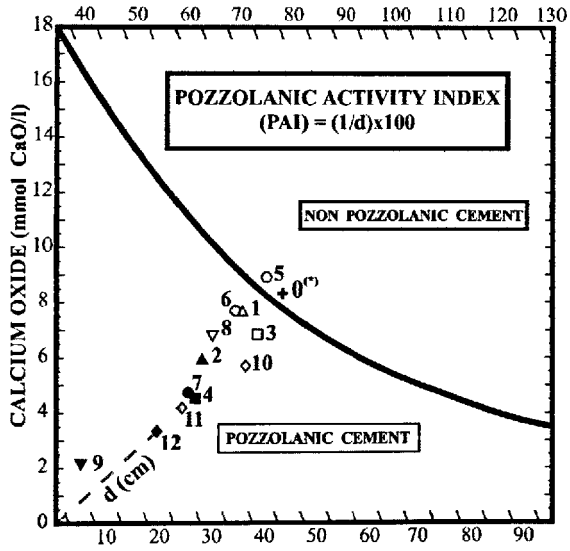
The concrete mixes were proportioned with 0.4 water-binder ratio, with the following amounts of pozzolans in the mixtures, by weight, with normal (N) and high (H) contents: i) ***binary mixtures***: fly ash (F) = 25 and 50%; silica fume (S) = 10 and 20%; rice husk ash (R) = 10, 20 and 30%; ii) ***ternary mixtures***: (F+S) = (15+10) and (30+20)%; (F+R) = (15+10), (30+20) and (20+30)%. A total of 13 binary and ternary mixtures were investigated. The following tests were

made: **a)** pozzolanic activity with pozzolanic PC, Fratini test (NBR 5753); **b)** non-evaporable water content, by mass difference between 105 and 550°C. In despite of this test not be a precise indicator, Sellevold and Justnes (1993) attest that this test provides adequate results to indicate the variations of the paste hydration degree; **c)** remaining CH (NBR 5748) and **d)** uniaxial compressive strength, NBR 5738, with 10x20 cm specimens.

TESTS RESULTS

Figure 2 and Table 2 show the results of the pozzolanic activity test (Fratini test). A Pozzolanic Activity Index (PAI) was calculated, representing the inverse of the distance (d), in cm, that separates each graphical point from the origin of the coordinates, multiplied by 100. Greater this index, higher was the pozzolanic activity, because the graphical points placed closer to origin means more consumption of CH and less total alkalinity. The PAI was higher to the fly ash ternary mixtures, with high total contents of pozzolans, followed by the mixtures with normal contents. It was established by this test that fly ash mixed with silica fume or rice husk ash increased the pozzolanic activity, in comparison with the binary mixtures, and it was more elevated as more elevated was the total amount of pozzolans in the mixture.



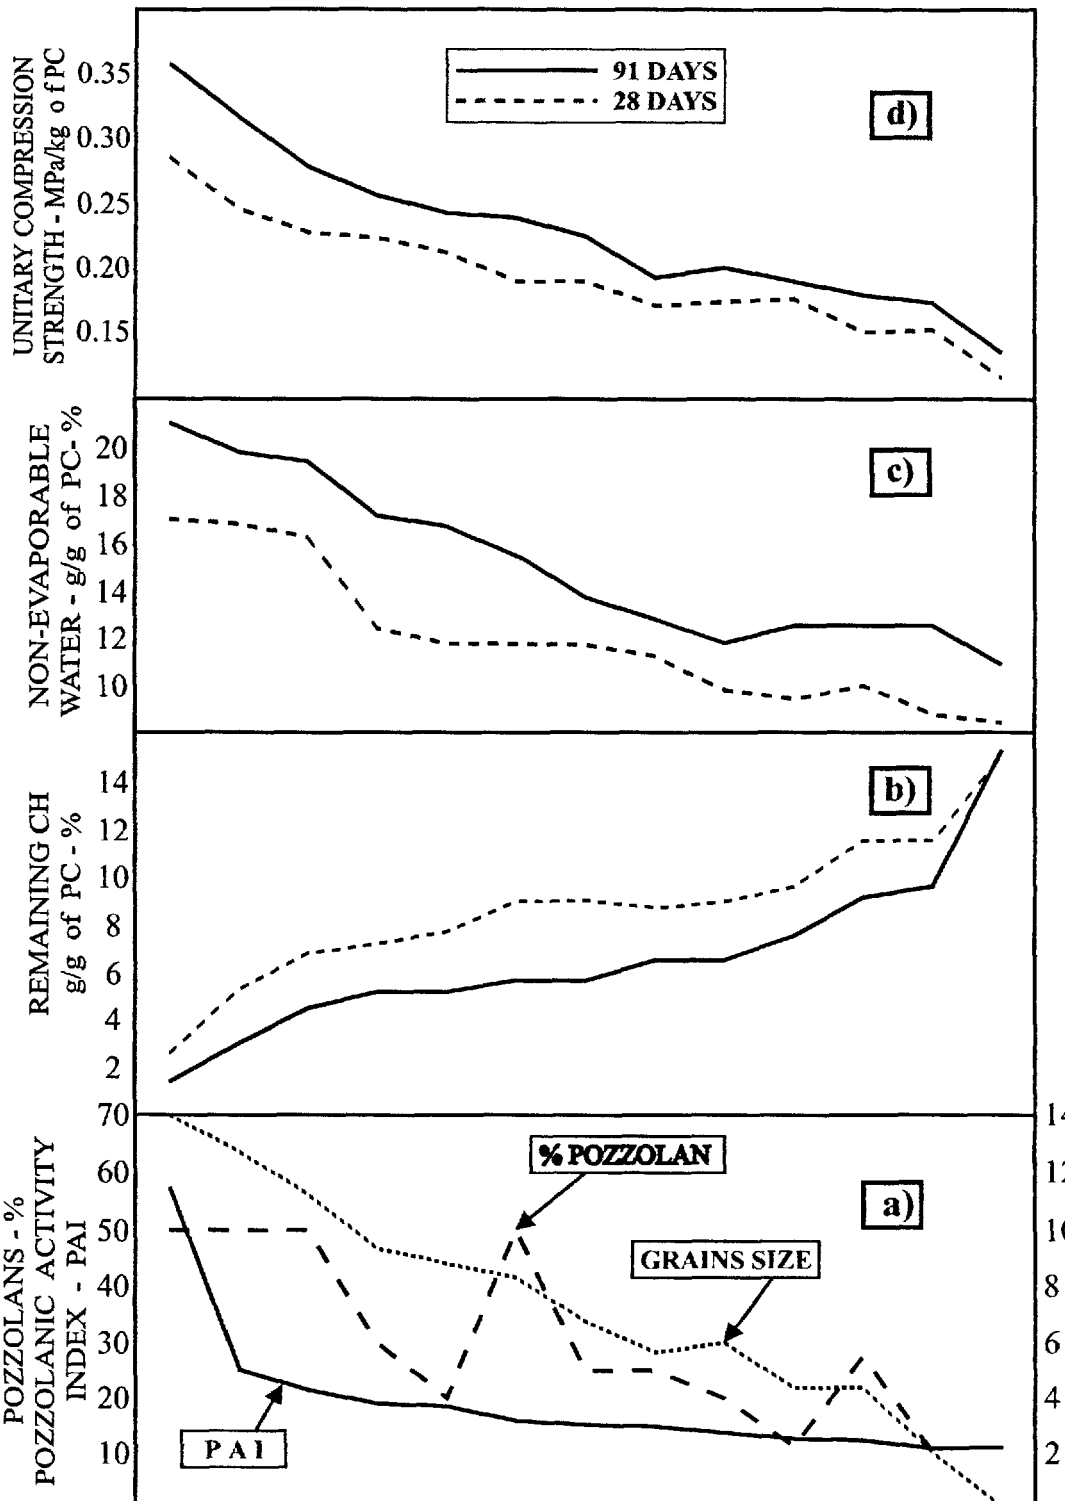


Table 2 Pozzolanic activity with cement

Figure 2 Pozzolanic activity (Fratini test)

Figure 3 presents the results for the remaining CH, non-evaporable water and unitary axial compression strength located according to the decrescent sequence of the pozzolanic activity indexes. Segment a) shows the PAI, as well as the grains size contents smaller than 5 μm and the pozzolans quantity of each mixture, showing similar decreasing behavior with PAI, except for 25 and 50% fly ashes binary mixes. The segments b), c) and d) of Figure 3 show, respectively, the contents of the remaining CH, non-evaporable water and unitary axial compression strength. This figure shows that: **a)** the experimental mixtures arranged decreasingly related to pozzolanic activity, practically followed the same disposition of the pozzolans quantity, except for the fly ashes binary mixtures, likewise higher the pozzolans content was, more elevated was the PAI; **b)** the contents of pozzolans grains smaller than 5 μm strictly followed the same PAI sequence; **c)** to higher reactivities corresponded smaller remaining CH contents; **d)** the non-evaporable water and unitary compression strength decreased in the same sequence of PAI.

DISCUSSION

The results show that concrete blended performances depended not only on the mineralogical composition or fineness, but also on the pozzolans quantity of each mixture, as well as the eventual aggregation with another pozzolan. Figure 4 shows that, as the content of the pozzolans increased in the mixture, the PAI and the unitary strength increased their performances too, that was higher to the ternary mixtures than to the binary ones.

The data make evident that, together the chemical activity, the physical parameters represented by the quantity of pozzolans and fine fraction of the grains also exercised influence upon the reactivity. Thus, it is possible to perceive the importance of small grains in this context, as shown by Scrivener (1989), when said that grains smaller than 5 μm react immediately while the bigger particles take more time to start the reaction. Besides the chemical action linked with the active grains size, the physical aspects concerned with the non-reactive grains are also important to the microstructure of the hydrated paste, with regard to packing, nucleation, microaggregate effects, etc. In a previous work Mehta (1985) pointed out that, besides the calcium content, the granulometric distribution of the pozzolans particles is an important parameter that governs the reactivity. In his experiment with fly ash, the reactivity was directly proportional to the particles contents smaller than 10 μm and inversely proportional to the particles amount bigger than 45 μm. The results of the present research is a claim fortified by the facts shown by the latter authors, as it is seen in Figure 5 where it is demonstrated the high statistical correlation obtained by regressions between the content of grains smaller than 5 μm and the contents of the remaining CH (r^2 = 94%) and the unitary axial compression strength (r^2 = 98%). The latter variable also had good correlation with the PAI as shown in Figure 6, based on complementary data of this research presented by Isaia (1995). The linear correlation is strong as from 28 days, when more than 72% of unitary strength variation is explained by the PAI. In earlier ages the coefficients r^2 are lower because, by that time, the pozzolanic reactions resulting from the CH consumption, only take place at older ages. It becomes evident, by the data submitted for consideration, that the reactivity matter it is not only linked with the crystalline or amorphous phases, as showed by XRD in Figure 1, but also to the quantity of pozzolans and the content of fine particles that may act synergicly, by physical effect, together with the pozzolanic reactions.

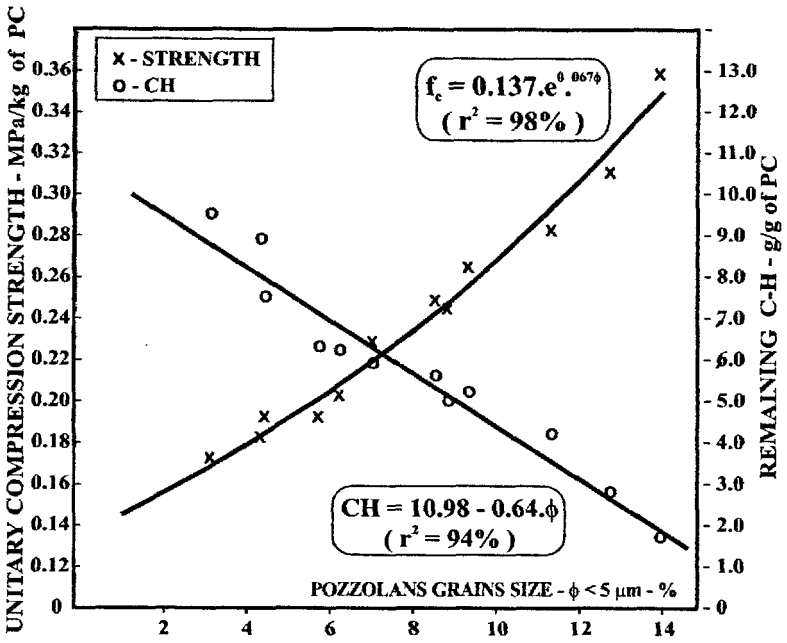

Figure 5 Correlation between $\phi < 5$ μm, unitary strength and remaining CH

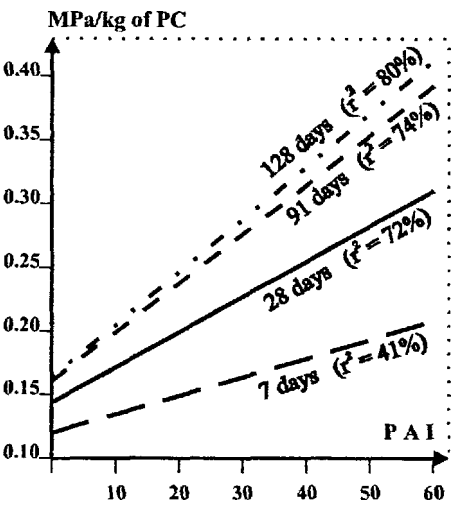

Figure 6 Correlation between PAI and MPa/kg

SYNERGIC EFFECT

It is possible to calculate the increment of the properties studied, like pozzolanic activity index and unitary strength, taking the Portland cement mix as reference. The increase of the pozzolanic activity due to the combined use of fly ash with silica fume or rice husk ash, is called **synergic effect** of the former pozzolan over the two latter ones, therefore, it can be shown by the formula: $P = (I_p/I_r).100$. P means the performance increment of a pozzolan with a given property, I_p and I_r show the increment of the considered property, respectively between the concrete with pozzolan and the reference mix. The synergic effect (SE) can be calculated by:

$$SE = P_{(FA + poz)} - (P_{FA} + P_{poz}) \qquad [1]$$

where $P_{(FA + poz)}$ represents the increment of the considered property of the fly ash ternary mixture with silica fume or rice husk ash; P_{FA} of the fly ash and P_{poz} of the silica fume or rice husk ash in binary mixtures. The influence of fly ash on the increment of the pozzolanic activity and unitary strength is shown in Table 3 and Figure 7. If had had only superposition of the effects when two pozzolans were mixed, the increase of the pozzolanic activity or unitary strength would be the arithmetic sum of the increments in the binary mixtures. In the case of PAI, the increase of the series SN and SH with 10 and 20% of silica fume was 15.8 and 71.1%, respectively. The increments for 15% (calculated by extrapolation) and 30% (calculated by interpolation) of fly ash series FN and FH were 8.9 and 21.4%, respectively, resulting in 24.7% to FSN (15+10 % of FA+SF) and 92.5% to FSH (30+20% of FA+SF) series. However, by the Fratini test, these two ternary series presented PAI increments of 33.3 and 415.8%, respectively, according to the sample of the Portland cement reference concrete. Therefore, there was an additional increase of 33.3 - 23.7 = 8.6% to the FSN and 415.8 - 92.5 = 323.3% to the FSH series, both called synergic effect of the fly ash on the two pozzolanic systems. The same calculations are valid to the increments of ternary mixtures of RHA in the FRN and FRH series, as well as to the unitary strength.

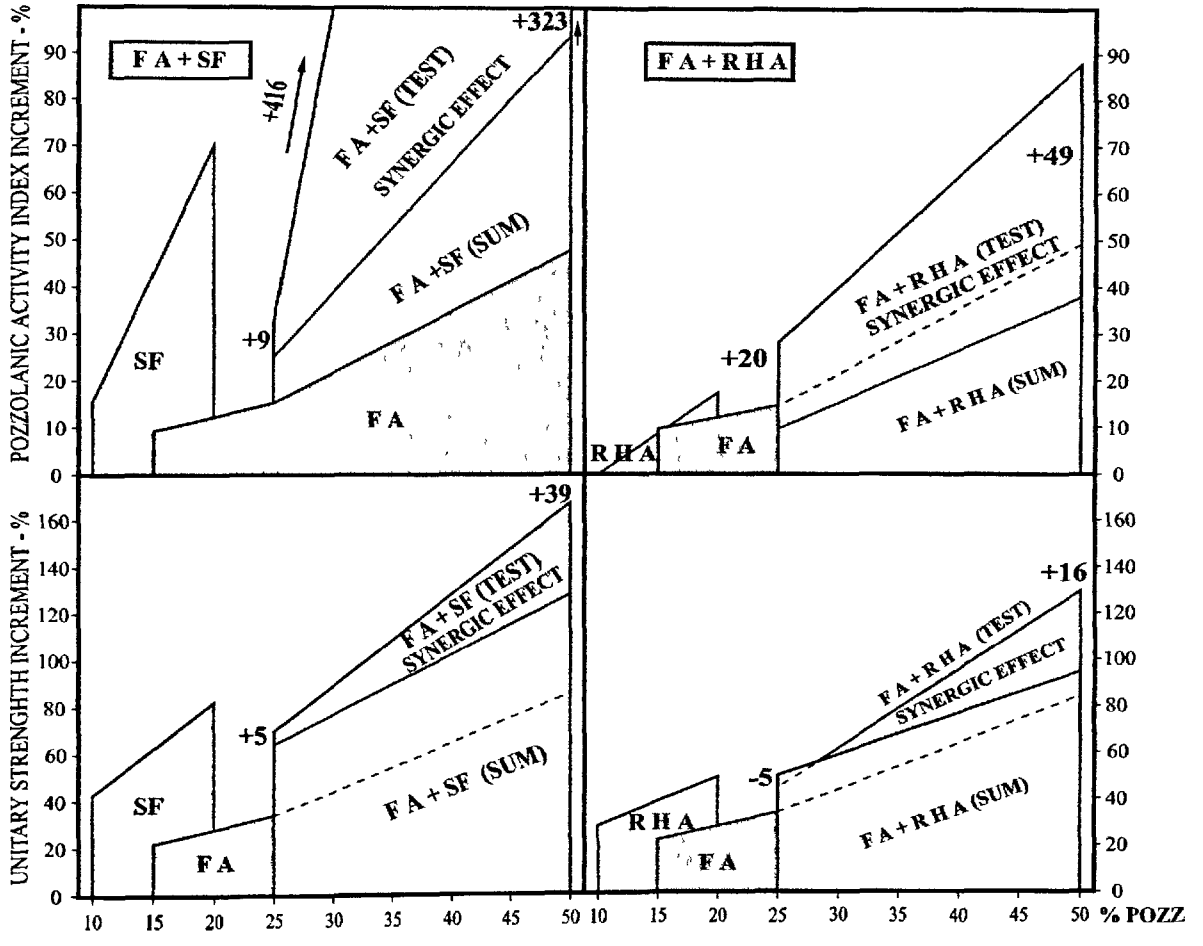

Figure 7 Synergic effect of fly ash on the silica fume and rice husk ash mixtures in the pozzolanic activity index and unitary axial compression strength at 91 days (w/b = 0.4).

The fly ash synergic effect could be explained by the higher physical action rather than the chemical one. Such behavior would be linked by the greater deflocculation of the cement grains provided by the fly ash, than to the silica fume or rice husk ash particles, increasing the surface of the cement grains in contact with free water, that would be more available by the

plasticizing effect of the fly ash, enhanced by its eletrocinetic potential (zeta potential). These mechanisms would propitiate more nucleation sites to start the reactions, and the final result would be an enlargement of the hydration reactions, consequently, higher CH consumption, pozzolanic activity and, finally, unitary compression strength gain. Similar performances were showed by Isaia (1996) to others properties related to concrete durability as chloride and water penetration, Cl^-/OH^- relationship and carbonation, with the same mixtures of this experiment.

CONCLUSIONS

It follows that the performance of pozzolans, in relation to chemical reactivity or mechanical strength, is not only a matter of crystalline or amorphous state but overall, the association with other pozzolans as the mixture of fly ash with silica fume or rice husk ash. The results presented in this research make evident that the fly ash added to the ternary mixtures presented a multiplier effect when associated to high total volumes of pozzolans, enhancing the idea that reactivity depends on the mineral addition quantity. The parameters tested as grains size content smaller than 5 μm, remaining CH, non-evaporable water and unitary axial compression strength reinforce the later conclusions. It was established that the synergic effect depended on physical action of the fly ash that, as well as the plasticizing admixtures, producing more deflocculation of the cement grains, and enabling higher quantity of sites to the hydration products nucleation. Thus, the resulting chemical effect was enhanced by physical action, and the general concrete performance was improved by means of grain and pore size refinement.

COMPRESSIVE STRENGTH DEVELOPMENT AND PORE STRUCTURE OF SLAG - SILICA FUME CEMENT CURED AT 38 -175 °C

Yaozhong XI, China Building Materials Academy, Beijing 100024, P. R. China
Barry E. SCHEETZ, Materials Research Laboratory, The Pennsylvania State University, PA, USA

ABSTRACT A PC-slag-silica fume cement paste was processed at 38 -175 °C for 1- 48 hours. The plots of f (compressive strength) - d (curing time) and f - t (curing temperature) translation are given. The cost effective d is 10 hours and the cost effective t is 90 °C. The regression analysis shows the logarithmic correlation of f - d at a certain t and of f - t at a certain d. The maturity equation is useful within certain ranges of t and d to predict an approximate strength. The strength-porosity data show the linear correlation of strength with porosity.

Key-words: blended cement; high temperature; maturity; pore structure; strength development

INTRODUCTION

Hooton (1980) reported the compressive strength of a pelletized slag cement and mortar with addition of 20-40% silica flour cured at 185°C for 4h, but recently the number of papers on the strength development and pore structure for a slag-silica fume cement (SS) at elevated temperatures and pressures is very limited. In engineering practice and production of prefabricated components it is very useful to be able to predict an approximate strength based on curing time and temperature, which are the two most important environmental factors determining strength gain. There have been simple and sophisticated ways to do this. In this paper the strength development and pore structures were tested for a slag-silica fume cement (weight percentage: PC 32.5%, slag 60.5%, SF 7%) cured at elevated temperatures. The strength data were processed using a computer software to establish strength expressions and correlation coefficients. The maturity (curing time × curing temperature) was calculated to determine whether the relationship of strength-logarithm of maturity is linear. In the last section critical pore radii and total porosities related to their compressive strengths are plotted and their correlation is discussed.

EXPERIMENTAL

ASTM Type-I portland cement of Ash Grove (PC), slag of Koch Minerals (ggbfs), silica fume of Elkem (SF) and superplasticizer Mighty-150 of Boremco Specialty Chemicals were used. The formulation of the neat paste: PC 100, ggbfs 186, SF 21.5, water 98.4, Might-150 4.7 (to control a flow of 110 ± 5). The superplasticizer was first mixed with water in the bowl of a paddle-mixer, then the raw materials were added and mixed for 1.5 min. The neat paste was placed in a 50× 50×50 mm mold and tamped with a 13×25×150 mm hard wood tamper. The molding plus precuring lasted nearly one hour. The molds with fresh paste were put into containers at 38, 60, 90, 125 and 175°C for 1, 10, 24 and 48 hours. The 38, 60 and 90°C containers accommodated saturated steam of atmospheric pressure. The 125 and 175°C curings were in a Chandler duplex curing chamber filled with water and kept at 1 ± 0.1 MPa (gauge pressure). The heating time was 1.5 h and the cooling was more than 1.5 h. The cooled cubes were tested for compressive strength. A Quantachrome scanning mercury porosimeter was used for pore data measuring. The samples with particle size < 6 mm were crushed from fragments of tested cubes and freeze-dried. The maximum intrusion pressure was 374 MPa, the canning rate 4, assuming a wetting angle of 140°.

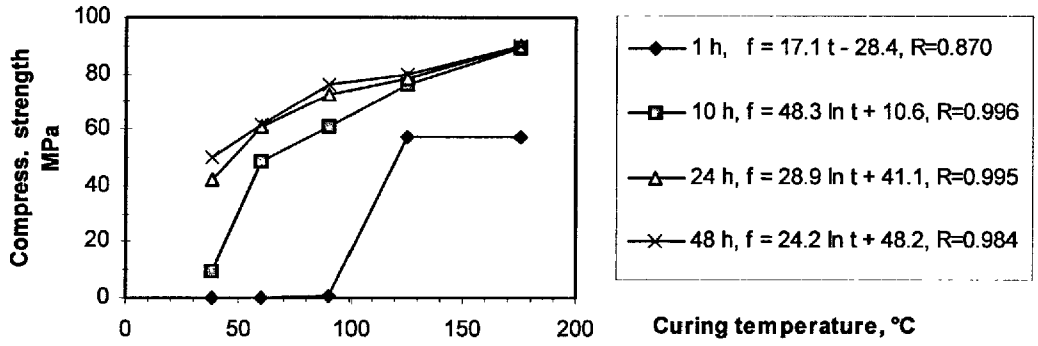

Fig.1A . Strength (f) ~ temperature (t)

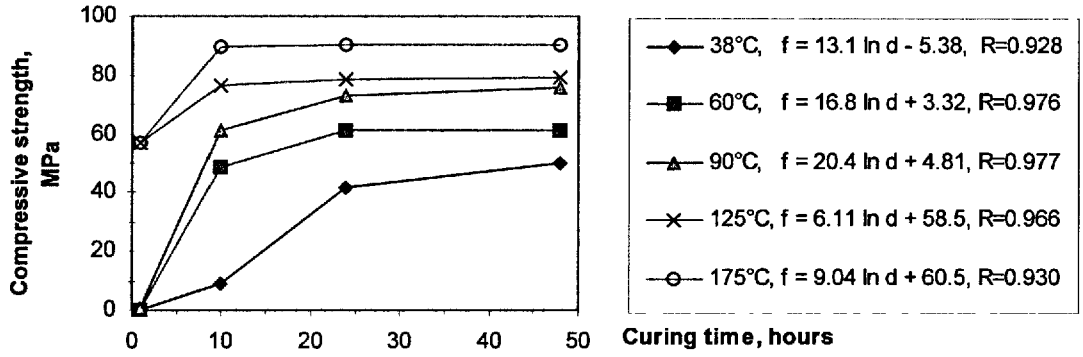

Fig.1B. Strength (f) ~ curing duraton (d)

LOGARITHMIC RELATIONSHIP OF f WITH t OR d

According to Fig. 1, for reaching a strength of 50 MPa, the following curing regimes can be chosen: 48 h at 38°C, 10 h at 60-90°C, and the quickest, one hour or less at or above 125°C. Fig.1A shows that the strength for 48 h curing is almost equal to that of 24h curing except at 38°C, i.e. a curing time longer than 24 h should not be selected. In Fig.1, regression equations and correlation coefficients are given to all the curves, indicating all curves are logarithmic except for 1 h curve since the paste had no strength after 1 h curing at 38°C and at 60°C. The 10 h curve in Fig.1A has the highest slope 48.3, suggesting the most effective curing time 10 h; the 90°C curve in Fig.1B has the highest slope 20.4, indicating the most effective curing temperature 90°C. The logarithmic relationship between strength - curing time and strength - curing temperature can be seen in other cement systems, e.g. in slurries of G class oil well cement plus silica flour and/or silica fume cured at 20°C 100% R. H. and 230°C 2.75 MPa (Grabowski et al, 1989a, 1989b), and in pastes of each of the four components for cement clinker (Bogue, 1934).

STRENGTH-MATURITY RELATIONSHIP

The early works by Nurse (1949, 1951) and Saul (1951) reported the maturity equation $M = \Sigma(T-T_0)\Delta t$, where T is the temperature of a concrete for the duration of Δt and T_0 is the datum temperature below which the concrete will not gain strength. T_0 has been defined by many researchers and ranges from 10 - 14°F for most concretes. Bergström (1953) accepted -10°C (14°F) as the datum temperature and gave the equation $M = \Sigma a_t (t + 10)$, where a_t is the duration at the temperature of t in degrees centigrade. Plowman (1956) found the relationship of strength with logarithm of maturity to be linear: $f = a \lg M + b$ ($\lg M$ is common logarithm). The maturity equation had been widely used, but later disagreements have been reported (Volz et al, 1981; Carino et al, 1983a and 1983b). Volz et al (1981) monitored the real temperature variation of a concrete cured at -1 , 21 and 43 °C by thermocouples to calculate maturity. They found that the

equation does not properly account for the effect of temperature occurring within about seven hours after placement on later strength. Kee (1971) suggested another strength-maturity relation—hyperbolic equation: S = M / (1/A + M/Su), where S = strength, M = maturity, Su = limiting strength as maturity tends to infinity and A = initial slope of the strength-maturity curve. Carino et al (1983a, 1983b) confirmed the equation is a good approximation for the actual strength - maturity relation.

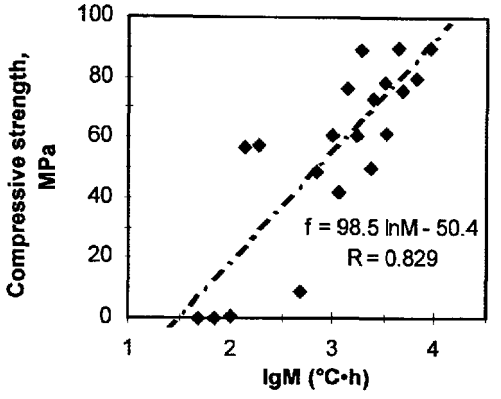

Fig. 2A. Strength (f) ~ all lg M(°C•h)

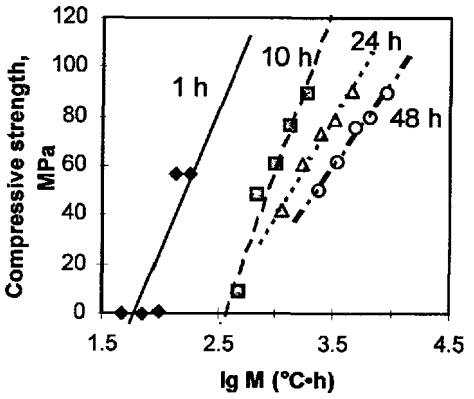

Fig. 2B.Strength(f)~grouped lgM(°C•h)

The maturities here are calculated for the SS paste (Table 1), neglecting molding and cooling periods from practical viewpoint of convenience. If all the strength - maturity data are plotted together, the linear relationship is not good (Fig.2A, R=0.829); if the data are group-plotted under 1, 10, 24 and 48 h, the linear correlation is satisfactory except for one hour " early" curing (Fig.2B). The correlation coefficients for lines of 10, 24 and 48 h are 0.975, 0.989 and 0.992 (Table 1), which is the situation similar to Fig.1A described in the previous section. Therefore the maturity equation is still a good approximate expression within certain range of time and temperature for a given concrete. However, the equation is inaccurate for a concrete with extensive or multiple curing history of time, temperature and pressure.

Table 1 Relationship of compressive strength (MPa in brackets) with lg M (°C • h)

	38°C	60°C	90°C	125°C	175°C	Regress. equatn	R
1 h	1.68 (0)	1.85 (0)	2.00 (0.7)	2.13(56.9)	2.27(57.1)	f = 115M - 205	0.851
10 h	2.68 (9.1)	2.85(48.5)	3.00(60.8)	3.13(76.1)	3.27(89.4)	f = 130M - 332	0.975
24 h	3.06(41.7)	3.23(60.8)	3.38(72.8)	3.51(78.6)	3.65(90.1)	f = 79.2M - 198	0.989
48 h	3.36(50.2)	3.53(61.4)	3.68(75.9)	3.81(79.4)	3.95(90.0)	f = 67.3M - 175	0.992

STRENGTH versus CRITICAL PORE RADIUS AND POROSITY

The mercury intrusion porosimetry provides a useful means for comparison of pore structures of hardened cement pastes (hcp), but it is not possible to obtain an actual pore size distribution of hcp because of its sensitivity to stresses introduced by sample pretreatment, resulting in pore coarsening (Moukwa et al 1988, Feldman et al 1991). The critical pore radii (r) and total porosities (p) of the hardened SS neat paste related to their compressive strengths are plotted in Fig.3. The paste has smaller critical pore radii down to 2 nm and lower porosities down to 14% than the hardened portland cement paste (typically, r~ 20 nm, p ~30% for 28 days curing at room temperature). Fig.3A shows an approximate linear relationship between f and p. This supports the finding by Watson (1981) that the compressive strengths of autoclaved aerated concretes with porosities 0.48-0.78 and portland cement pastes with porosities 0.26-0.45 is linearly related to the solid/pore volume ratio determined by helium pycnometry. Fig.3B shows

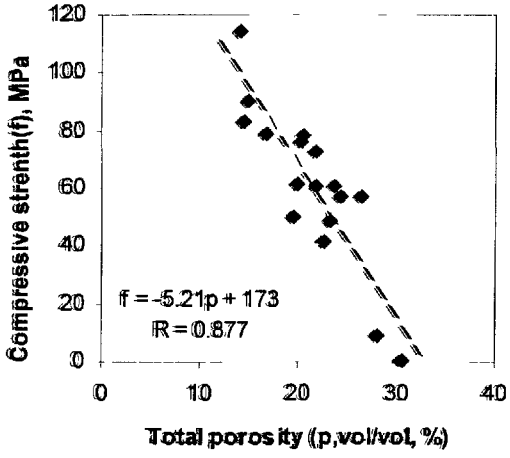

Fig.3A. Strength(f)~total porosity(p)

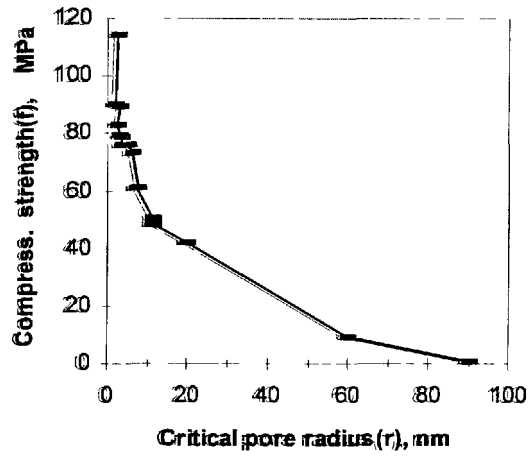

Fig.3B. Strength (f)~criti. pore radius(r)

that the critical pore radii of the SS paste having a strength greater than 79 MPa approach a constant value about 2.5 nm, possibly indicating that critical radii of dense pastes like SS pastes would not change much after reaching a certain small value. Jiang et al (1989) reported that the volume of small pores (radius 37-50 nm) for the 1:3 mortar of a slag cement composed of 20% clinker and 80% slag remains constant. Another explanation may be that the mercury intrusion method does not apply to a dense paste with critical pore radius $\leq$ 3 nm. Feldman (1987) indicated that cement pastes with SF contain discontinuous pores and mercury does not enter all the micropores.

CHARACTERISING REACTIVITY OF ALKALI-ACTIVATED POZZOLANS

W John McCARTER, Heriot-Watt University, Edinburgh, Scotland, UK.
Hubert EZIRIM, Heriot-Watt University, Edinburgh, Scotland, UK.

ABSTRACT The work detailed investigates the reactivity of replacement materials by direct activation with calcium hydroxide (CH) at ambient temperatures. Electrical impedance techniques are employed as a non-invasive method for investigating the pozzolanic reaction. Test results show that such a technique can be used to monitor the hydration process thereby following the stages of hydration and rate of chemical activity of replacement materials when blended with CH.
Key-words: Pozzolan; Calcium Hydroxide; Setting; Hardening; Electrical Impedance.

INTRODUCTION

Methods for quantifying pozzolanicity are varied including measurements on strength and lime consumption e.g. Chapelle test (Kostuch et al 1993). Regarding the latter, such a test gives no information on the rate of reaction at ambient temperatures. Electrical impedance methods have proved useful in monitoring and elucidating the early hydration characteristics of ordinary Portland cement (OPC) i.e. initial 24-hours (McCarter and Afshar, 1988; McCarter and Garvin 1989). It is over this period that the cement paste changes from a fluid to rigid state and results in significant changes in its electrical response. In a similar fashion, electrical resistance measurements have been made on pozzolans activated with solid CH and then subjected to elevated temperature (70°C) curing (Tashiro et al, 1994). In this instance, when used in conjunction with XRD studies, the electrical resistance of pozzolanic material measured at 72-hours was shown to correlate well with its CH consumption - a high resistance correlated with low CH consumption, whereas low resistance was indicative of high CH consumption.

A unified testing procedure is required for pozzolanic materials and electrical methods could offer a viable alternative for assessing setting and hardening; optimising CH content, or as a method for monitoring pozzolanic activity of natural materials (Luxan et al, 1989).

EXPERIMENTAL

Commercially available replacement materials were used in the current experimental programme and comprised pulverised fuel ash (PFA); ground granulated blast-furnace slag (GGBS) and metakaolin (MK). Materials were blended with reagent grade calcium hydroxide (CH) and mixed with sufficient water to obtain pastes of similar consistency. The mixes studied are summarised in Table 1; for comparative purposes, tests on plain OPC pastes were also undertaken.

Pastes were mixed in a planetary motion mixer and compacted into plexiglass *cube-type* cells with the contained sample being 50x50x45mm. Opposite walls of each cell had 50x50mm stainless-steel plate-electrodes. Four samples were tested for each of the mixes in Table 1. Leads from all four samples were connected to a multiplexing unit which, itself, was connected to an impedance analyser. A thermistor was embedded in one of the four replicate samples to monitor internal temperature changes. The complete monitoring system was controlled through a PC (486/66), with all tests carried out in a temperature controlled laboratory (22°C).

Table 1: Summary of materials and mix ratios.

Binder	Binder : CH ratio	ater : (Binder + CH) ratio
OPC	binder only	0.270:1
GGBS*	4:1	0.425:1
PFA	4:1	0.460:1
MK	4:1	1.000:1

* GGBS is more aptly termed a latent hydraulic binder

As the electrical response is frequency dependent (McCarter and Afshar, 1988), impedance measurements were recorded at up to 14 spot frequencies within the range 100Hz-100kHz. Both the in-phase (i.e. resistive) **and** quadrature (i.e. capacitive) components of the sample impedance were recorded at each spot frequency at 10 minute intervals over the test period, which extended over 55 hours in some instances.

RESULTS AND DISCUSSION

Since the geometry of the test cells (and hence samples) was fixed, the values of capacitance and conductance for the various binders can be compared and does not necessitate conversion of the results to conductivity and dielectric constant. In addition, results are presented in the form of *normalised* conductance and capacitance whereby the data recorded at time, t, after the start of the test (denoted G_t and C_t respectively) are divided by the respective conductance and capacitance value at time t = 0 (denoted G_o and C_o). The initial values of G_o and C_o and presented in Table 2.

Table 2: C_o and G_o values and frequency at which data are presented.

Binder	G_o $x10^{-3}$ (Siemens)	C_o $x10^{-9}$ (Farads)	Frequency (kHz)
OPC	72.7	1.55	30
GGBS	17.5	139	0.4
PFA	34.0	80.3	10
MK	21.0	59.5	1

The temporal change in normalised conductance and capacitance is displayed in Figures 1 and 2 respectively, for clarity only every 20^{th} data marker is identified on these curves. Although data were recorded at a number of spot frequencies, for the current work, only those measurements at what is considered as the optimum response frequency are presented (this frequency is presented in Table 2). It should be emphasised that as far as absolute values are concerned, no direct comparison can be made between the various pastes as this parameter is frequency dependent (McCarter and Afshar, 1988) - as is conductance, although to a lesser extent.

General

The Portland cement response in Figures 1 and 2 is in agreement with published data (McCarter and Afshar, 1988; Christensen et al 1994). It is interesting to note that the overall trend in the electrical response of the alkali-activated pozzolanic materials is similar to the Portland cement paste, although the duration and prominence of specific features vary between the materials tested.

Figure 1: Normalised Conductance Response

As far as OPC is concerned, the conductance increases over the initial 30 minutes as the ionic concentration increases within the aqueous phase. For the GGBS, PFA and MK there is no discernible increase in conductivity over this time, indeed conductivity values reduce almost immediately after the start of the test.

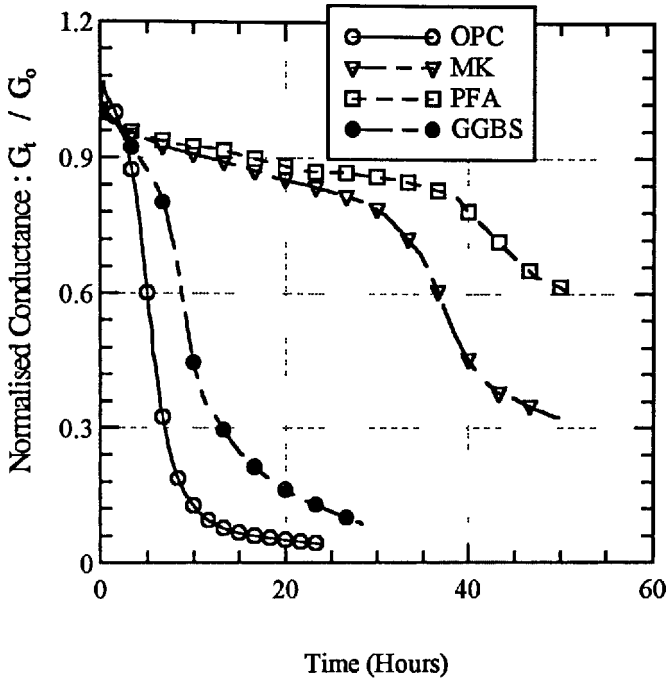

Figure 1: Change in normalised conductance over test period.

The conductivity for the pozzolanic materials decreases before undergoing a more rapid reduction, marking the end of the induction period. The more rapid decrease in conductance varies from approximately 8 hours for the GGBS; 32 hours for the MK to 38 hours for the PFA. This would signify an increase in rigidity, or setting, of the CH activated binder and the formation of an interconnected pore network. The rate of decrease over the setting period is in the order GGBS>MK>PFA. This result is not surprising as GGBS has a high lime content in its own right (≈ 41% for the material used).

After the setting period, the conductivity curves for GGBS and MK undergo a reduction in rate of change - at approximately 12 hours and 40 hours, respectively. This delineates the end of the acceleratory period and the beginning of the slower hardening process. This feature is not identified on the PFA curve as it lies outwith the 55 hour test period.

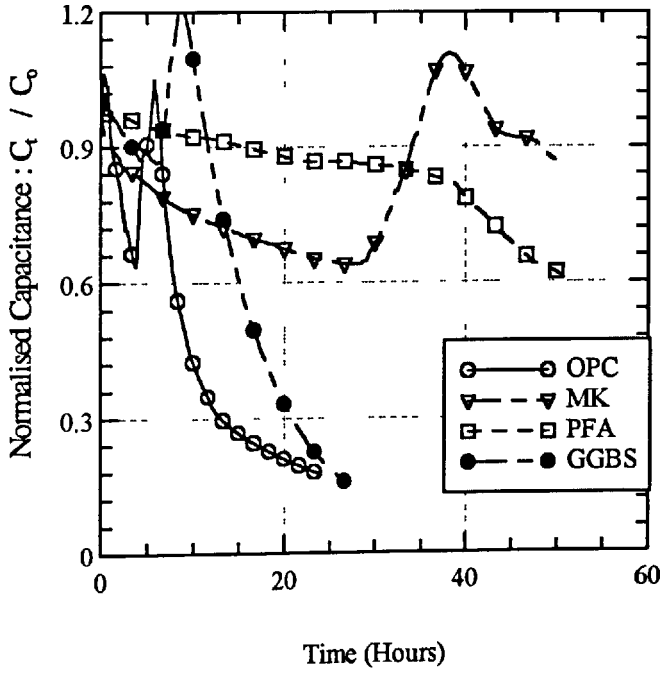

Figure 2: Change in normalised capacitance over test period.

Figure 2: Normalised Capacitance Response

For the most part the normalised capacitance almost mirrors conductance - an initial rapid decrease leading into a period of reduced chemical activity. The most interesting aspect of the capacitance response is just prior to the acceleratory period where a transient peak occurs.

Capacitance can be regarded as a movement or oscillation of charge in a applied electrical field. For example,

charges in the aqueous phase can move along the applied field and then get blocked at interfaces or boundaries within the system. Such charges take no part in the conduction process but manifests itself as a capacitive effect.

The increase in capacitance just prior to setting could be as a result of a phase change or transformation. The growth of fibrous gel layers from the grain surface could introduce thin blocking layers thereby enhancing capacitance in a transient way. The theory of *dielectric amplification* could be invoked to account for such behaviour (Christensen et al, 1994). After the peak in capacitance, solidification (thereby restricting charge movement) and irrotational binding of charges within the system results in the rapid reduction in capacitance values. The peak in capacitance is not observed in the PFA response and could be as a result of a lime deficient environment and hence much slower rate of gel formation.

Internal Temperature

Although not presented graphically, for OPC, setting is accompanied by liberation of heat with the internal temperature of the sample increasing to 30°C at approximately 10 hours. The internal temperature for all the pozzolanic materials fluctuated between 22±0.5°C in a gradual manner, representing no more than minor changes in laboratory temperature.

CONCLUDING COMMENT

Electrical impedance, when measured in terms of conductance and capacitance, has proved to be an effective testing technique for following the hydration of alkali-activated pozzolanic materials. The electrical response (the capacitance in particular) indicated a number of stages during early hydration and comparisons can be made with OPC in this respect.

ALKALINE ACTIVATION OF METAKAOLIN: INFLUENCE OF SYNTHESIS PARAMETERS

M.L. GRANIZO, Instituto Eduardo Torroja (CSIC), Spain
M.T. BLANCO-VARELA, Instituto Eduardo Torroja (CSIC), Spain
F. PUERTAS, Instituto Eduardo Torroja (CSIC), Spain
A. PALOMO, Instituto Eduardo Torroja (CSIC), Spain

ABSTRACT Alkaline activation of metakaolin to produce inorganic polymers with high mechanical strengths has been studied. Two different metakaolins have been activated at 85°C during 2 hours. Four concentrations of NaOH solutions (5, 12, 15 and 18 M) were used as activator. Some metakaolin/liquid ratios were tested. A complete characterization of the products obtained was carried out. Flexural strengths were found to be between 2 and 16 MPa. Correlations among mechanical strength of specimens, activator concentration and metakaolin/liquid ratio have been found.

Key-words: Synthesis, Metakaolin, Alkali, Activation

INTRODUCTION

Metakaolin based cements result from an inorganic polycondensation reaction that occurs when metakaolin is activated by alkaline hydroxide solutions. These cements rapidly harden at temperatures below 100°C and provide high mechanical strengths. Both kaolin and metakaolin can be activated by alkaline hydroxides to give the inorganic polymer. The starting aluminosilicate and the different synthesis parameters directly influence the characteristics and properties of this polymer.

The synthesis of these binders can be compared to zeolite synthesis. The resulting binder network consists of SiO_4 and AlO_4 tetrahedra linked alternately by sharing all the oxygens where the alkaline cations from the activator solution are present in the structure balancing the negative charge of IV- coordinated Al. So, the structure of metakaolin cements can be also related to the structure of some zeolites. However, while in zeolite synthesis, to favour crystallization, an excess of liquid (activator dissolution) is used and the synthesised product can be separated through filtering, in metakaolin cements, a minimum of activator solution is desirable to obtain a paste with suitable workability. Thus, zeolites are very crystalline materials whereas metakaolin cements are almost amorphous. In the literature, there are some studies about alkaline activated metakaolin in which the influence of parameters such as temperature, curing time, reagents mix order, etc. have been studied (Palomo and Glasser, 1992, and Madani et al., 1990). Some composition limits to obtain optimum alkaline cements with high mechanical strength have been proposed, and the following ranges have been indicated: M_2O/SiO_2, 0.2 to 0.8; SiO_2/Al_2O_3, 3.3 to 4.5; H_2O/M_2O, 10 to 25; M_2O/Al_2O_3, 0.8 to 1.6 (Davidovits, 1985). Also, microstructural and mechanical characterisation studies of the obtained cements are found (Palomo et al., 1992). However, no references have been found about the influence of alkaline hydroxides solutions on final product properties. The influence of the starting kaolin characteristics on cement properties and its mechanical behaviour have not been studied.

The aim of this work is to study the influence of these parameters on the flexural strengths of metakaolin binders. For this purpose, two different metakaolins have been activated at 85°C during 2 hours. Four concentrations of NaOH solution (5, 12, 15 and 18 M) were used. Some metakaolin/liquid ratios were tested.

EXPERIMENTAL

Specimens of 1x1x6 cm were synthesised mixing MK1 and MK2 with 5M, 12M, 15M and 18M NaOH solutions and variable MK/liquid ratios. Specimens were cured during 2 hours at 85 ± 2°C. Then, the specimens were mechanically tested.

Rheological behaviour of MK1 and MK2 is very different (mainly due to their different fineness) so, MK1 specimens were mixed with 45-50 and 60 ml of solution by each 70 g of MK whereas those of MK2 were mixed with 20, 25, 30 and 35 ml of NaOH solution by each 70 g of MK. Specimens porosity was determined through mercury porosimetry.

The insoluble residue (I.R.) in acid of each paste was determined. The grounded sample is treated with cold diluted hydrochloric acid (1:10) and then with a 5% Na_2CO_3 solution. After this treatment the sample is calcined at 1000°C and the insoluble residue is calculated.

Soluble sodium was determined according to the following methodology: 3g of grounded sample dried in vacuum until constant weight are mixed with 200ml of deionized water, and stirred (magnetic agitation) during 3 hours. After this time, it is filtered and washed. The resultant liquid is taken to 500ml and Na^+ measured by ionic chromatography.

RESULTS

In a previous work (Granizo et al., 1996), a complete characterization of the two kaolins and their respective metakaolins was carried out (chemical and mineralogical composition, thermal behaviour, specific surface, particle size distribution, etc.).

Flexural strengths and insoluble residues of specimens elaborated with MK1 and MK2 mixed with different volumes of 5, 12, 15 and 18M NaOH are shown in Table I.

According to the results, 5M concentration is not enough to provoke reaction in the test duration. Specimens have no strength and this indicates that a higher solution concentration is required to provide reaction in the test time.

Regression analysis of flexural strength data of MK1 and MK2 is carried out in order to quantify the influence of the parameters (NaOH concentration and ml of dissolution in the mixes) on flexural strengths. Eqs 1 and 2 show the influence of NaOH solution concentration and the volume of NaOH solution on flexural strengths of the specimens with MK1 and MK2, respectively.

$$\text{F. Strength} = 124.73 - 1.5033\ \text{liquid (ml)} - 0.9575\ [\text{NaOH}] \quad (\text{R-SQ.} = 0.7560) \qquad [1]$$

$$\text{F. Strength} = 204.59 - 5.1317\ \text{liquid (ml)} + 1.9258\ [\text{NaOH}] \quad (\text{R-SQ.} = 0.8060) \qquad [2]$$

According to both equations, the sign of the coefficient affecting liquid amount (ml) is negative in both cases and as liquid amount increases, flexural strengths decrease. The sign of the coefficient affecting NaOH concentration is opposite in the two kaolins. Flexural strengths increase as NaOH concentration increases in MK2 while they decrease when NaOH concentration increases for MK1.

Table 1. Flexural strengths and insoluble residues of the compositions studied.

I.R. data can be taken as a measurement of reaction degree, because both metakaolins are very insoluble in acid medium while the polymers obtained are soluble in such medium. Thus, in the case of MK1, its reaction degree is already almost total for 12M concentration and the lowest liquid, varying little when these parameters increase. In the case of MK2, I.R. decreases, this means that reaction degree increases when the two parameters studied increase. Equation relating reaction degree of MK2, with NaOH concentration and liquid amount is the following:

I.R. = 90.3191 - 1.395 liquid ml - 1.4475 [NaOH] (R-SQ. = 0.8085) [3]

Soluble Na_2O content

Na_2O solubility tests were carried out through ionic chromatography in order to quantify the Na_2O percentage that remains in the product structure after water treatment. Results are shown in Table 2.

Table 2. Results of Na_2O solubility tests

* %Na_2O expressed with respect to the initial Na_2O.

These results indicate that soluble Na_2O increases as the Na_2O initial dosage increases. Hence, in MK1 compositions, where initial Na_2O amount is higher, there is a considerable increase in soluble Na_2O amount with respect to MK2 compositions. Thus, soluble Na_2O increases exponentially with the initial Na_2O amount dosage according to the following equation:

$$\text{Soluble \% } Na_2O = 0.097 \exp [(\text{\% initial } Na_2O)/4.1890] \qquad (\text{R-SQ.} = 0.9674) \qquad [4]$$

Hg porosimetry

Mercury porosimetry tests were carried out on dried specimens. Results are shown in Table 3. These results show that total porosity percentage is higher in samples obtained with MK1 than that of those made with MK2.

Table 3. Results of mercury porosimetry

	% TOTAL POROSITY (AREA)	% TOTAL POROSITY (VOLUME)	AVERAGE PORE DIAMETER (μm)

TD8B	16.08	36.99	0.0899
TD8M	19.03	43.28	0.1302

The behaviour of both metakaolins is different, and a high relation between porosity of MK2 specimens with respect to NaOH concentration and amount of liquid is found. The equation governing this behaviour is the following:

$$\text{Porosity} = 7.6955 + 0.5622 \text{ liquid ml} - 0.3076 [\text{NaOH}] \qquad (\text{R-SQ.} = 0.9787) \qquad [5]$$

With respect to MK1 specimens, an increase in total porosity percentage is observed when liquid amount and NaOH concentration increase.

An exponential relationship between porosity and flexural strength of both MK specimens is found; strength increases as porosity decreases according to the following equation:

$$R = 565.25 \exp [(- \%\text{porosity})/9.8590] \qquad (\text{R-SQ.} = 0.9491) \qquad [6]$$

DISCUSSION

The starting kaolins present a similar chemical composition and they are mainly constituted by kaolinite with minor proportions of quartz (approximately 10%), also similar in both cases. K2 kaolin has also a minor proportion of anatase and pyrophyllite. The main difference between these kaolins is in their crystallinity index that is higher in the case of K1 and in their specific surface, also higher in K1.

Dehydroxilation of both kaolins by thermal treatment at 750°C during 24 hours leads to kaolinite structure destruction with metakaolin production. In this process, a decrease of specific surface is produced, being MK1 specific surface higher than MK2 one.

The behaviour of these metakaolins when they are alkaline activated is very different from the point of view of rheology, mechanical properties, etc.

Reaction degree reached by MK1 samples is practically constant and very high (of about 90%) in all the experiments, if the quartz proportion of the starting kaolin (close to 10%) is taken into account. Sodium fixing capacity in the final product is of about 11% with respect of the weight of such product and it remains almost constant in all the experiments.

On the other hand, specimens with MK1 have high porosity values. The porosity increases as activator solution concentration and volume increase.

Mechanical behaviour of specimens elaborated with MK1, described by Eq 1, can be justified if test conditions and measurements of porosity, fixed sodium and insoluble residue are taken into account.

Because of the high specific surface of MK1, the activator solution amount necessary to elaborate specimens is also high (45-60 ml /70g MK). This leads to a high Na_2O amount per gramme of MK in these samples and, thus, a practically complete reaction at the most soft test conditions is reached. When increasing the values of synthesis parameters ([NaOH], activator

liquid volume,) reaction degree and sodium fixing capacity (Na remains free in specimens) does not increase further, but, however, an increase in porosity is produced. As a consequence, specimens mechanical strengths decrease when solution volume and activator solution concentration are increased as it is described by Eq 1.

On the other hand, mechanical behaviour of specimens elaborated with MK2 and described by Eq [2] is also justified analyzing the results of insoluble residue determination, sodium fixed and specimens porosity as well as the conditions of the experiments.

So, the lower specific surface of MK2, permits the utilization of lower solution volumes (20-35 ml/70 g MK) in specimens mixing. This means that, in some of the experiments, sodium amount is not enough to provide a complete reaction degree and, thus, sodium fixed in the structure is not maximum. The sodium fixing capacity in MK2 specimens increases as initial $\%Na_2O$ increases and the maximum is of about 11-12% (expressed as Na_2O percentage).

The maximum reaction degree would be higher than 90% if minor compounds in the MK2 (quartz, anatase, pyrophillite) are taken into account.

However, an increase in reaction degree does not always involve higher mechanical strengths, but, as it is described by Eq 3, reaction degree increases as dosage of Na_2O increases , by mean of increasing NaOH concentration or by increasing activator solution volume. However, mechanical strengths (oppositely to porosity) increase as activator solution concentration increases, but they decrease when liquid/solid ratio increases.

Hence, higher strengths in specimens with MK2 will be obtained when porosity is lower, this is, when NaOH concentration is the highest and activator solution volume the lowest. In any case, mechanical strengths of specimens with MK1 are lower than those of MK2, but important values are reached if the high porosity of these samples is taken into account. Further investigations must be carried out in order to improve rheology and decrease liquid/solid ratio that will be translated in a porosity decrease and an improvement of mechanical strengths.

CONCLUSIONS

Metakaolin alkaline activation in hydrothermal conditions (85°C, 2h) leads to high strength cementitious materials. The synthesis parameters studied (activator solution concentration and the liquid amount of this activator) as well as the characteristics of the starting metakaolin have a decisive influence on the mechanical properties of the cements obtained.

Metakaolins specific surface condition their rheological behaviour and, subsequently, their mechanical strengths.

Metakaolins with a high specific surface need high liquid/solid ratios for their mixing. This leads to higher porosities and, thus, lower strengths of the specimens. Activator solution concentration necessary to obtain optimum strengths depends on metakaolin reactivity. So, in metakaolins with high specific surface (more reactive), more diluted solutions can be used in order to obtain reaction degrees similar to those obtained with metakaolins with lower specific

surface in the same hydrothermal conditions. To obtain the higher strengths the minimum activator solution amount providing reaction degrees higher than 90% must be used (in the curing conditions described above).

Later increases of activator solution concentration produce porosity increase and leave soluble alkaline hydroxides unreacted. All this leads to a strength decrease.

Materials obtained by metakaolin alkaline activation are extremely porous materials and their pore size is of about 0.1 μm.

An enhancement of pastes rheology would lead to higher mechanical strengths. Sodium fixing capacity in the polymer is of about 11% (expressed as Na_2O percentage).

STRENGTH AND HYDRATION OF AN ACTIVATED ALUMINO-SILICATE MATERIAL

J.N. LIU, M.R. SILSBEE and D.M. ROY, Materials Research Laboratory, Pennsylvania State University, University Park, PA 168021 USA

ABSTRACT This paper presents the results of a study of the behavior of an activated alumino-silicate material (metakaolin). The use of portland cement, $Ca(OH)_2$, gypsum and water soluble silicate ($Na_2O{\cdot}nSiO_2$) as activators of metakaolin were investigated. Compressive strength measurements along with X-ray diffraction studies were used to track hydration occurring in the system. The results of the study show that metakaolin has the potential to act as a supplementary cementitious material when the right combination of activators are employed to provide a suitable environment for hydration. In order to hydrate metakaolin, additional $Ca(OH)_2$ is required in order to form calcium silicate hydrate (CSH). Although, gypsum by itself cannot activate metakaolin, combinations of gypsum and $Ca(OH)_2$ or portland cement show promise as activators for metakaolin. Gypsum that consumes $Ca(OH)_2$ to form calcium aluminum sulfate hydroxide reduces $Ca(OH)_2$ significantly in the reaction product of a mixture of cement and metakaolin.

Keywords: activation, alkali, blended cement, economy, metakaolin, X-ray Diffraction Analysis

INTRODUCTION

It is well known that metakaolin has considerable potential for use as a cementitious material when mixed with calcium hydroxide. Metakaolin is kaolinite that has been calcined at a temperature in the range from 650-850°C (He et al., 1995; Murat and Comel, 1983). At this temperature range the interlayer water and hydroxyl in kaolinite is lost but the original network of a combination of SiO_4 tetrahedra and AlO_6 octrahedra or irregular polyhedra remain. During hydration the network first is attacked and bonds are broken by hydroxyl ions then new hydrates including CSH and other aluminate containing hydrates, such as C_2ASH_8, C_4AH_{13} and possibly zeolite precursors when alkalis are present are formed.

Calcium hydroxide is a very effective activator for metakaolin. For optimum strength development, 25% calcium hydroxide is needed (3). Metakaolin can be used to react with and eliminate calcium hydroxide in portland cement (4) in much the same manner as does silica fume. This is desirable since the excess calcium hydroxide forms as relatively soluble crystals that contribute much less to strength development and may cause durability problems (5). Using this approach some researchers have attempted to minimize calcium hydroxide formation in glass fiber reinforced cement composites by adding metakaolin to the composite (6).

The current study focuses on: 1) using combinations of calcium hydroxide and gypsum as activators; and 2) the characterizing the reduction of calcium hydroxide in cement matrixes with various metakaolin contents.

EXPERIMENTAL

Materials

Both Type III portland cement (PC) and metakaolin (MK) are commercial products and their chemical analysis are given in Table 1.

Table 1. Chemical Analysis of Type III Cement and Metakaolin

	SiO_2	Al_2O_3	TiO_2	Fe_2O_3	MgO	MnO	CaO	Na_2O	K_2O	P_2O_5	SO_3	L.O.I.
PC	20.2	2.32	0.11	4.47	3.54	0.05	63.9	0.12	0.49	0.21	3.0	0.85
MK	51.91	39.68	0.54	0.93	0.16		0.16	0.60	0.60			0.23

The $Ca(OH)_2$ and $Na_2O{\cdot}nSiO_2$ (Pine PQ Corporation) n=3.2] are chemical agents with 99.99% purity. Superplasticizer (Mighty 150, Boremco) is a dark brown solution containing 56% solid.

Mixture Proportions

Metakaolin (MK) was mixed with 0, 25, 50, and 65% Type III portland cement by weight respectively. Calcium hydroxide and gypsum dosages were 0, 5, and 10%. To maintain workability in the cementitious pastes, the water to solid ratios (W/S) and dosage of superplasticizer were adjusted from 0.45 to 0.65 and 1 to 3% respectively. The fluidity of the pastes was controlled within 150 - 175 mm flow by the use of a flow table. The mixture proportions are listed in Table 2.

Table 2. Mixture Proportions

No.	cement	MK	$Ca(OH)_2$	gypsum	SP	W/S	note
MK50-0	50%	50%			3%	0.45	
MK50-1	45%	45%	10%		3%	0.45	
MK50-2	45%	45%		10%	3%	0.45	
MK50-3	45%	45%	5%	5%	3%	0.45	
MK65-1	25%	65%	5%	5%	3%	0.60	
MK65-2	25%	65%	10%		3%	0.60	
MK65-3	25%	65%	5%			0.60	$Na_2O{\cdot}nSiO_2$ 5%
MK100-1		65%	35%		3%	0.65	
MK100-2		65%	25%	10%	3%	0.65	
MK20	75%	20%		5%	1%	0.45	
MK0	100					0.45	

Specimens and samples preparation

The solid materials were dry mixed in a paddle style mixer for 1 minute before the water was added; after the water was added, mixing continued for three minutes. The pastes were cast into 25 x 50 mm cylinder molds. After casting, all specimens were put into a curing chamber at 38 ± 2°C and 100% relative humidity for 24 hrs before being demolded for further curing.

On the test day the cylinders were cut into 25 x 25 mm specimens using a diamond saw and the bearing surfaces polished before the compressive strength tests were conducted. Samples of the broken specimens were ground to less than 100 μm and characterized by powder XRD using a Scintag diffractometer (Scintag, Sunny Vale, CA), with Cu Kα radiation.

RESULTS AND DISCUSSION

Compressive strength

The compressive strength development of hardened mixtures of cement and metakaolin is illustrated in Fig. 1.

In mixture MK50-0, the only activation is from the $Ca(OH)_2$ released from the cement during its hydration. A typical portland cement will produce about 20% $Ca(OH)_2$ or 10% in the mixture MK50-0. The 28 day strength of MK50-0 is 59.13 MPa. The strength of MK50-1 was higher than MK50-0 after 7 days curing since 10% $Ca(OH)_2$ was added. When the $Ca(OH)_2$ was replaced with 10% gypsum, (MK50-2) higher 7- and 14-day strengths than both MK50-0 and MK50-1, and equal 28-day strength as MK50-1, resulted. In mixture MK50-3, gypsum and $Ca(OH)_2$ (5% each) were added in combination. This combination of activators worked very well. The strength (78.38 MPa, 28 day) of MK50-3 is obviously higher than the others at both early and later age. When gypsum and $Ca(OH)_2$ were used the 28-day strengths of the mixture containing only 45% cement was nearly 85% of the pure cement paste.

Fig. 2 shows the effect of combined activators in mixtures with lower or zero cement contents. The strengths of MK65-1 and MK65-3 were improved compared with MK65-2. Soluble silicates ($Na_2O{\cdot}nSiO_2$) have been used to activate other pozzolanic materials, such as slag and fly-ash. It is very interesting that the combination of $Ca(OH)_2$ and soluble silicate resulted in MK65-3 having a lower early strength and significant strength increase at later ages.

In the mixtures which contained no cement, although the combined activators showed improved early strengths at 3, 7 and 14 days, the strengths decreased slightly after 14 days compared to the control.

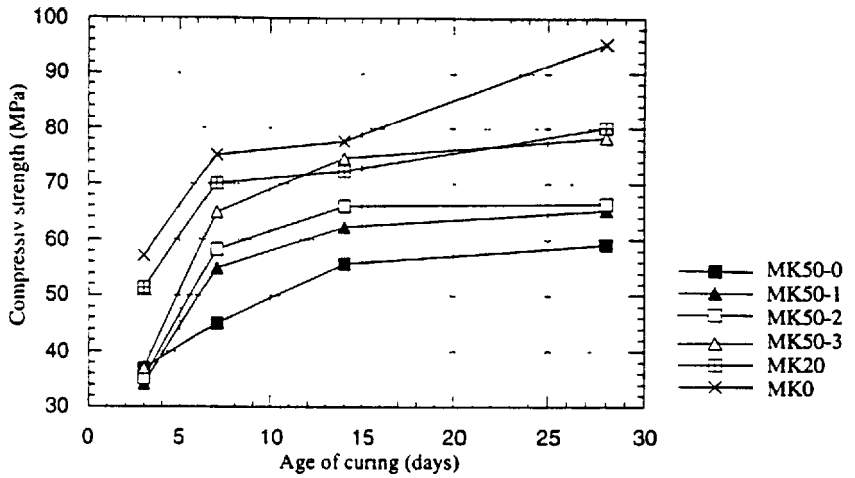

Fig. 1. Compressive strengths of metakaolin mixtures with high cement content

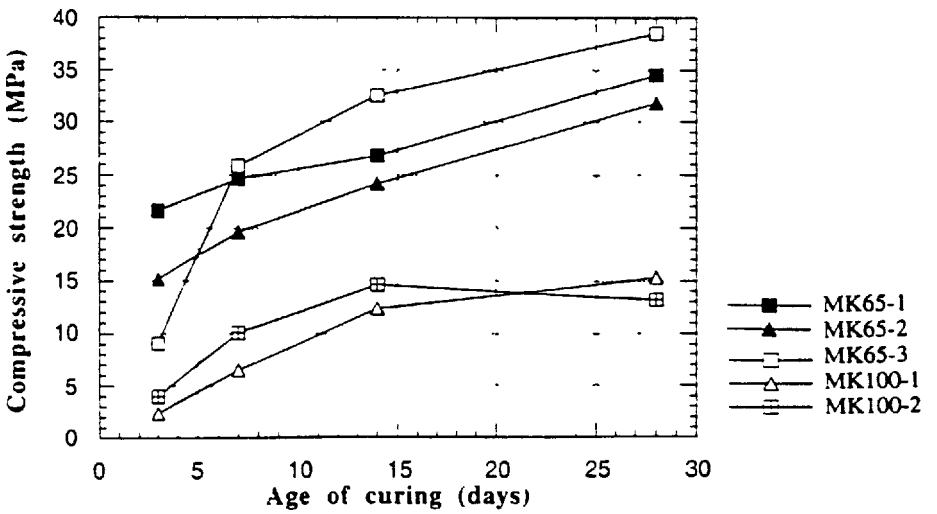

Fig. 2. Compressive strength of metakaolin mixtures with low cement content

Hydration of mixes

Fig. 3 shows the X-ray patterns gathered from samples of 50% metakaolin-50% portland cement paste (MK50-0) at various ages: The following observations can be made: 1) at all ages there was less $Ca(OH)_2$ than normally observed in portland cement pastes;

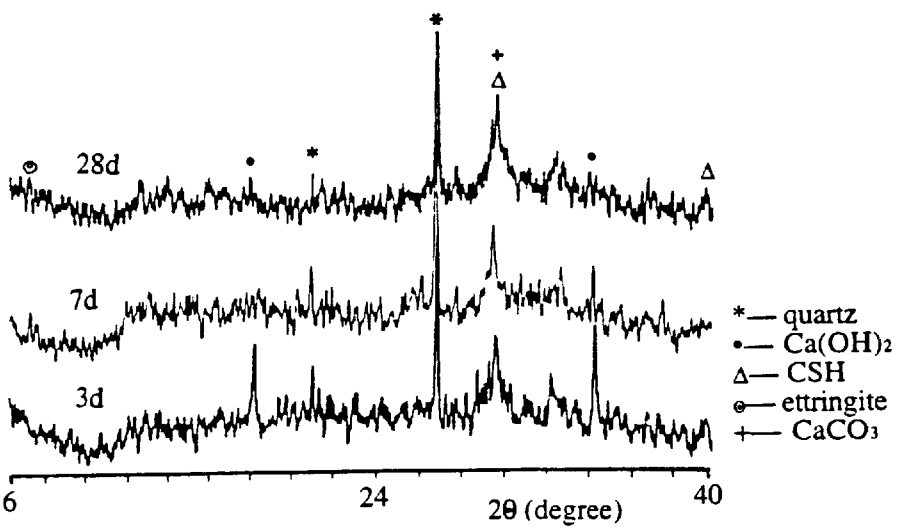

Fig. 3. The X-ray patterns of mixture MK50-0 (PC 50%, MK 50%)

2) there were several sharp peaks of quartz that was introduced as an impurity in the metakaolin and reacted very slowly; 3) $CaCO_3$ formed as the samples were exposed to the atmosphere.

Fig. 4 shows that metakaolin consumes $Ca(OH)_2$ during the hydration of MK50-1 (PC 45%, MK 45%, CH 10%). However, the metakaolin had not consumed all the $Ca(OH)_2$ at 28 days as evidenced by the peaks of $Ca(OH)_2$ that can be identified easily in the X-ray patterns of both MK50-0 and MK50-1.

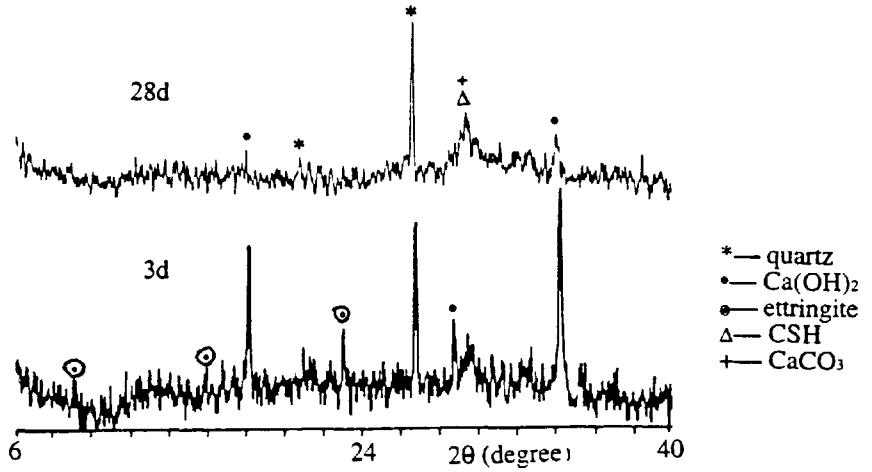

Fig. 4. The X-ray patterns of mixture MK50-1 (PC 45%, MK 45%, CH 10%)

When gypsum was added (MK50-3), very interesting results were obtained not only during strength development but also in the X-ray patterns (Fig. 5).

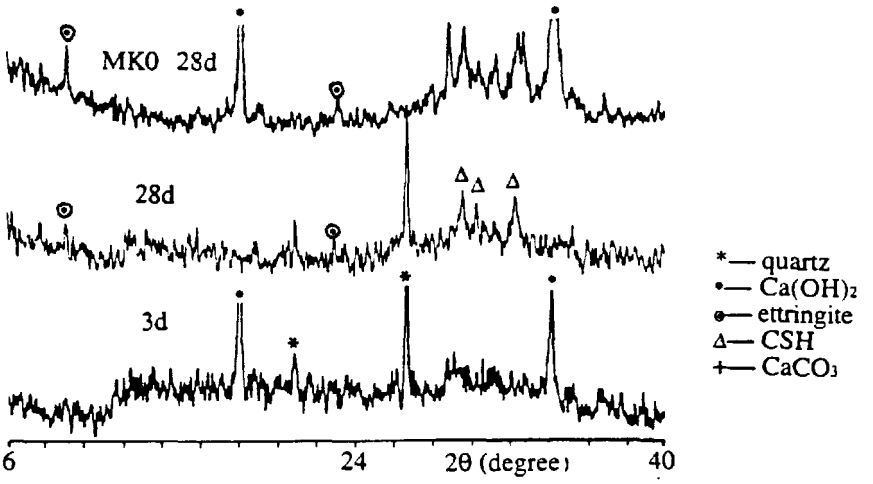

Fig. 5. The X-ray patterns of mixture MK50-3 (PC45%, MK45%, CH5%, gypsum 5%)

No $Ca(OH)_2$ peaks can be detected at age of 28 days. It indicated that $Ca(OH)_2$ was totally combined with gypsum and metakaolin to form calcium aluminum sulfate hydroxide hydrate (ettringite) and other hydrates. From Fig. 5 it also can be seen that the CSH peaks in MK50-3 were more like thatof pure cement paste than other mixtures and the quantity of ettringite was similar to that of cement paste at 28 days.

Fig. 6 shows X-ray patterns of mixtures MK65-1 and MK65-2 that are based on a 25% cement content. The peaks of ettringite were clearly found in both mixes, but more ettringite was in MK65-1 since 5% gypsum was added to the mixture. The peaks of $Ca(OH)_2$ did not appear in the mixture MK65-1 but can be observed in MK65-2 in which there was no gypsum added.

Mixtures MK100-1 and MK100-2 contained 35% $Ca(OH)_2$ or 25% $Ca(OH)_2$ and 10% gypsum respectively (no cement). At an early stage of hydration of MK100-2 (see Fig. 7), there were very sharp peaks of gypsum and $Ca(OH)_2$ present in the X-ray pattern. Ettringite

can not be identified from X-ray patterns at the age of 3 days. This means that the hydration processes occurring in this mixture was very slow. At the age of 14 days the peaks of ettringite were very clear and the peaks of gypsum were noticeably smaller than at 3 days. This phenomenon indicates that metakaolin, even when activated by $Ca(OH)_2$ and gypsum, has a very low hydration rate at early ages and then gradually accelerates. In contrast the X-ray pattern of MK100-1 at 28 days shows no peaks for ettringite or gypsum (as might be expected), the only evidence of hydration being a very broad peak indicative of CSH and the relatively low intensity observed for $Ca(OH)_2$.

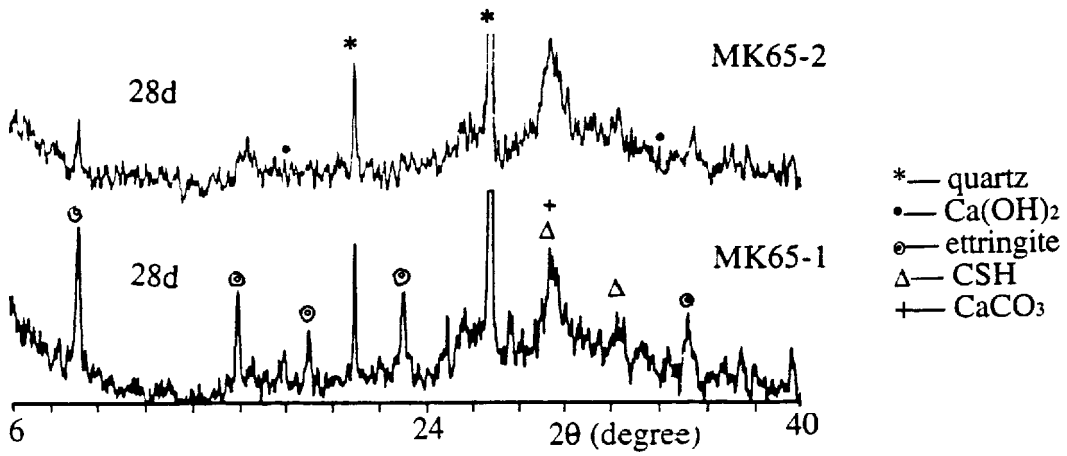

Fig. 6 The X-ray patterns of mixture MK65-1 and MK65-2

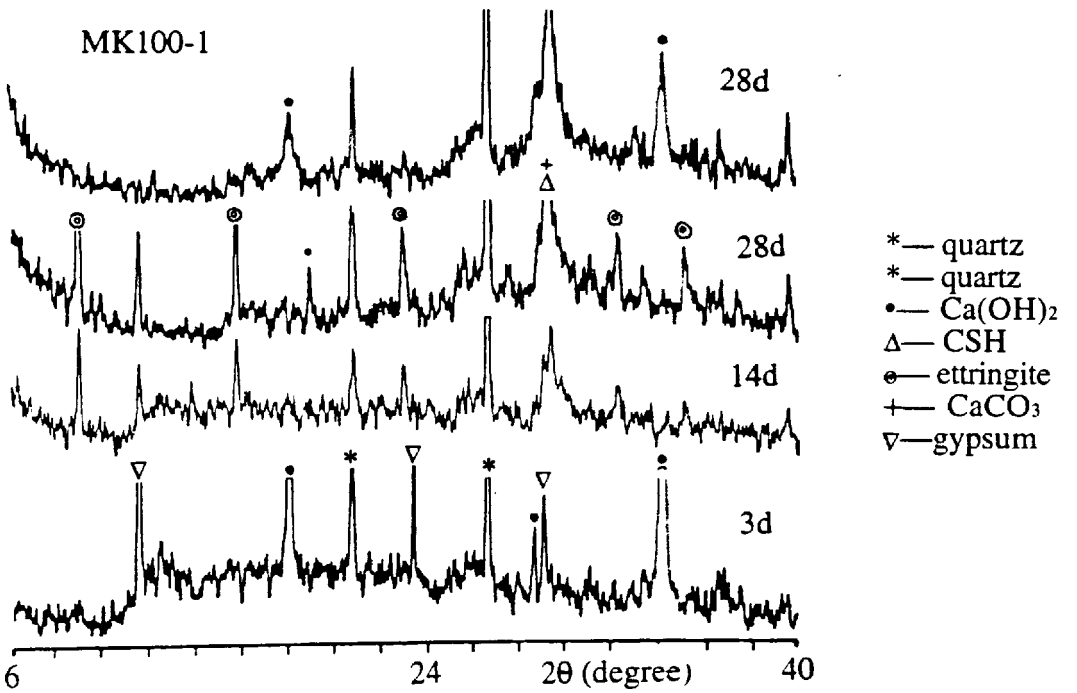

Fig. 7. The X-ray patterns of mixtures MK100-1 and MK100-2

DISCUSSION

The results above have shown that combinations of activators with metakaolin resulted in higher early and later strengths. The increase of early strength is mainly the result of the formation of ettringite. Ettringite is one of most easily formed crystalline phases found during cement hydration when Ca^{+2}, Al^{+3} and SO_4^{-2} are available at same time. It can be easily detected in a few hours, even in less than an hour, after cement is mixed with water. Ettringite that is formed quickly at early age of hydration builds up a skeleton in the fresh cementitious matrix and contributes to the early strength. The X-ray patterns indicated that Al^{+3} ions in the mixture at the beginning of hydration were from the C_3A in the cement not from the metakaolin. After three days, as the network was attacked by both hydroxyl and sulfate ions,

Al^{+3} ions dissolved gradually. The formation of ettringite consumed Al^{+3} ions from metakaolin and accelerated the dissolution reaction.

The average C/S ratio of CSH is about 1.5-1.7. If all the SiO_2 in the metakaolin was consumed by the formation of CSH (100% hydration), one mole of metakaolin would consume 3.0-3.4 moles of $Ca(OH)_2$. Based on silica alone metakaolin can theoretically consume an amount of $Ca(OH)_2$ equal to its weight. In fact calcium aluminum hydrates will also consume $Ca(OH)_2$ during their formation. In the short term metakaolin consumes less $Ca(OH)_2$ than the theoretical quantity since the hydration process is a slow one. The potential of using metakaolin to react with $Ca(OH)_2$ in blended cement pastes and form CSH has been demonstrated.. Gypsum when added to the mixture of cement and metakaolin resulted in higher composite strengths and also lower $Ca(OH)_2$ contents.

CONCLUSIONS

1) Although gypsum does not perform well as an activator by itself the combination of gypsum and portland cement or $Ca(OH)_2$ was effective in activating metakaolin.
2) Gypsum added to mixtures of cement and metakaolin results in not only an improvement in the strength of the mixtures but also lower $Ca(OH)_2$ contents.
3) Initially the rate of hydration of metakaolin is very slow, however, after 3 days the hydration begins to accelerate.

HYDRATION OF PORTLAND CEMENT BLENDS IN PRESENCE OF BAG HOUSE DUST FROM CALCIUM CARBIDE FURNACE

N.B. SINGH, K.N. BHATTACHARJEE and A.K. SHUKLA
Department of Chemistry, Gorakhpur University
Gorakhpur 273 009, India

ABSTRACT Hydrations of ternary and quarternary blends made from portland cement clinker, bag house dust, granulated blast furnace slag and gypsum were studied. It is found that in presence of an appropriate amount of bag house dust and gypsum, the deficiencies of slag cements can be removed and slags can be used in higher doses without diluting the quality.

Key-Words : Blast furnace Slag, Blended Cement, Fly Ash, Gypsum, Pozzolana

INTRODUCTION

In recent years considerable amount of work has been done on blended cements: Uchikawa (1986), Narang et al (1992), Chatterjee (1992), Singh et al (1995). Most of the blended cements presently commercialised are binary blends with either granulated blast furnace slag or pozzolans like fly ash, calcined clay or natural pozzolana. Multiblend systems with three or more components are gaining grounds in many countries. In this investigation the hydration characteristics of various ternary and quarternary cement systems have been studied in the presence of highly reactive calcareous particulate matter from the bag house of a calcium carbide furnace.

EXPERIMENTAL

Materials

Bag house dust (BHD) was procured from a specially designed calcium carbide furnace of M/S Bhutan Carbide and Chemicals Ltd. Pasakha, Bhutan. Portland cement clinker (PCC) was procured from a shaft kiln plant near Kanpur. Gypsum was procured from RSMDC Rajshthan. Granulated blast furnace slag was obtained from Indian Iron and Steel Co. Ltd. Burnpur. The chemical composition of the materials are given in Table 1.

Table1. Chemical composition of materials (Wt %)

Materilas	LOI	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Others
PCC	1.1	20.2	6.5	4.6	63.5	3.6	CaO=2.5
BHD	21.6	12.8	6.8	2.8	48.5	2.8	alk., sulphates-traces
GBFS	0.3	34.8	21.0	1.0	34.5	7.6	Sulphite = 0.5
Gypsum (Mineral)	13.6	10.3	5.6	1.1	28.8	1.2	SO_3 = 39.0

Methods

Blends of composition given in Table 2 were prepared in the laboratory.

Table 2. Composion of blends (wt%) with symbols

PCC	BHD	GBFS	Gypsum	Symbol
5	10	85		A
5	15	80		B
10	20	70		C
15	15	70		D
20	20	60		E
25	15	60		F
15	5	80		G
25	5	70		H
10	10	80		I
20	10	70		J
10	20	65	5	K
10	20	60	10	L

All physical testings were done in accordance with test methods prescribed in Indian Standard specifications IS 4031:1988 (Methods of physical tests for hydraulic cement) and chemical testing was done as per IS 4032:1985 (Methods of chemical analysis of hydraulic cement). Hydrations of cements (w/c=0.5) were allowed to continue for different intervals of time and were stopped with iso propyl alcohol and ether. Free lime and non-evaporable water contents were determined. Powder X-ray diffraction patterns of slected samples were recorded. M-15 concrete moulds were casted for few blended cements by taking one part cement, 2 parts sand and 4 parts aggregate. Compressive strengths were determined on a 150 x 150 x 150 mm^3 cube after 7 days. Some cement mortar cube samples were autoclaved after one day curing to assess the long term durability of the nonconventional blends.

RESULTS AND DISCUSSION

Results of physical testing and hydration studies are given in Tables 3 and 4. From Table 3 it is inferred that in absence of gypsum, with the increase of BHD, the setting time is shortened. This may be due to highly reactive calcium aluminate in BHD which tend to bring flash setting characteristics. Further the initial strengths are improved with BHD. This indicates that in addition to higher hydraulic activity of BHD, it might also act as a filler in the cement matrix due to high fineness. Addition of gypsum to the ternary blends reduces water demand and delays both initial and final setting characteristics. This might be due to the formation of ettringite which envelopes the grains of calcium aluminates initially and tends to reduce its flash setting characteristics. Blend L shows very high strength at 7 and 28 days indicating the formation of calcium sulphoaluminate hydrates. Such blends are expected to show high sulphate resistance.

From Table 4 it is seen that non evaporable water contents increase with hydration time but there is no correlation with the blends. The free lime values in all the blends increase upto 7 days and then there is a decrease at 28 days of hydration indicating pozzolanic activity of GBFS.

J	28.5	30	100	13.0	22.0	27.4	33.0	-
K	25.3	90	135	14.6	30.0	32.2	39.6	10.2
L	24.0	65	90	9.0	30.6	39.8	50.0	10.8

Table 4. Hydration studies of blends (w/c=0.5), Temp. 28°C

Blends	Free lime (%)				Wn (%)			
	1D	3D	7D	28D	1D	3D	7D	28D
G	4.2	7.0	7.8	4.1	6.5	11.8	14.9	15.9
H	3.8	5.2	5.8	3.1	10.3	13.3	16.6	19.8
I	4.5	6.5	7.5	4.3	7.8	9.5	14.8	16.2
J	4.0	5.8	6.2	3.5	9.7	12.7	15.2	17.5

Conclusion

Proper proportions of PCC, BHD, GBFS and Gypsum in the blended cement made it much better cement as compared to OPC and at the same time deficiencies of the slag cements are eliminated. In presence of suitable amounts of BHD and Gypsum, higher percentage of Indian GBFS (70%) can be used for making the slage cements without detoriating the quality of cement. BHD

activates GBFS and presence of gypsum form sulphoaluminate hydrates which makes significant contribution towards strength development.

HYDRATION OF CEMENT MIXED WITH "POZZOLIT" MINERAL ADDITIVE

Vili **LILKOV**, University of Mining and Geology, Sofia, Bulgaria
Ognyan E.**PETROV**, Centr. Lab. of Mineralogy and Crystallography, Sofia, Bulgaria

ABSTRACT Results from studies on the hydration process of cements mixed with fly ash, silica fume or a combination of both, called Pozzolit, are presented. The active role of the Pozzolit additive was revealed by DTA, XRD and IRS analyses. The effect of the additive is expressed in increased total amount of hydration products and decreased portlandite content.

Key-words: additives, fly ash, hydration, silica fume, waste material utilization

INTRODUCTION

The incorporation of silica fume-fly ash blend in the form of an additive in cement compositions results in decreased corrosion and permeability and increased strength of cement stone (Mehta and Gjørv., 1982; Matkovic et al., 1990; Stoichkov et al., 1994). The individual effect of fly ash and silica fume on cement hydration have been thoroughly studied (Ogawa et al., 1980; Marsh and Day, 1988; Fraay et al., 1989; Roy, 1989) and no substantial controversy regarding the mechanism of their action has been found. The hydration of cement in the presence of silica fume-fly ash blend has not been well described till now. The present work considers the results from studies on the hydration process of cement containing silica fume and low-calcium fly ash.

MATERIALS AND METHODS

Portland cement, PC 45, was tested. The silica fume (SF) is a by-product from the ferro-silicon steel production. The fly ash (FA) is a low-calcium one, class F. The blend of the two additives called Pozzolit (Pz) (Stoichkov et al., 1994) is prepared from equal quantities of fly ash and silica fume, and has a density of about 610 kg/m^3. The specific surface of SF, FA, and Pz determined by the BET-method is 19.2, 2.83, and 8.9 m^2/g, respectively. Four cements were studied - without additives (#1) and with addition of SF(#2), FA(#3), and Pz(#4) in amounts of 10% of the initial cement mass. The cement pastes (water/solid ratio of 0.33) were cured in plastic containers at a temperature of 20(±2)°C. The hydration was stopped at the respective time by consecutive soaking in acetone and ether and the samples were subsequently dried at 105°C for 3 hours in vacuum. The DTA studies were carried out on a MOM-3427 derivatograph (Hungary) at a heating rate of 10°C/min in the range 20 - 1000°C. The test samples were of equal mass of 200 mg each. The amount of non-evaporable water (the mass loss in the temperature interval 105 - 1000°C) was the estimate for the quantity of the hydration products in the cement pastes. The quantity of water released during portlandite dehydration, termed CH-water, was determined in the temperature range 460 - 520°C. The IR spectroscopic test was performed by IR spectrometer "Specord 75 IR" (Germany) in the frequency range 400 - 4000 cm^{-1}. The samples (1 mg mass and 0.5 mm thickness) were mixed with 300 mg KBr. The powder X-ray diffraction (XRD) phase analyses of the cement samples were performed on a DRON 3M diffractometer (Russia) with Ni-filtered Cu-α radiation. The patterns were recorded in the range 10-55° 2Θ. Before the XRD measurements the samples were dried, ground and pressed in standard sample holders.

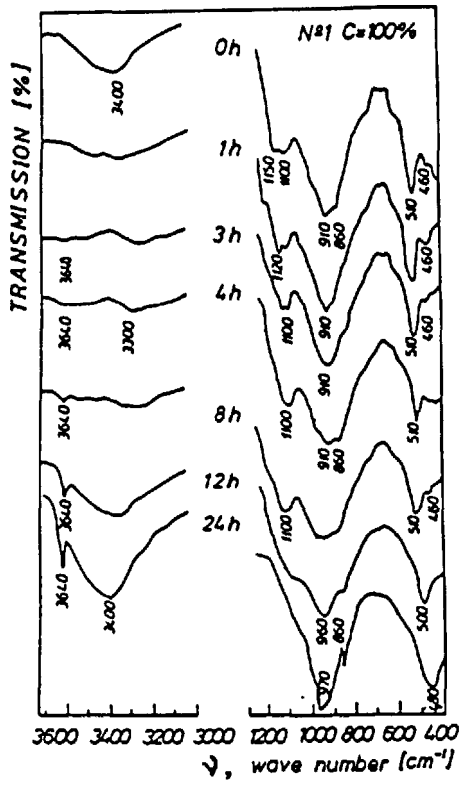

Fig.1 IR spectrum of plain cement paste

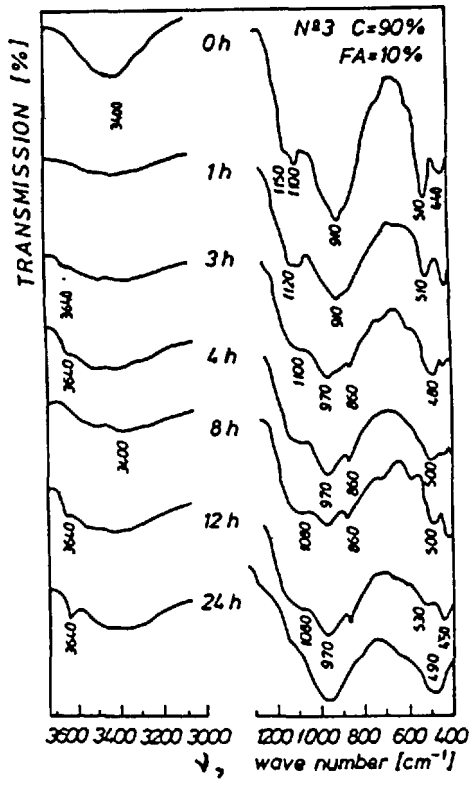

Fig.2 IR spectrum of FA-containing cement paste

RESULTS AND DISCUSSION

The IR spectra of all non-hydrated cements (0 h) (Figs. 1-4) contain the bands of the basic clinker minerals: alite - ν=460 and 910 cm^{-1}; belite - ν=510 and 860 cm^{-1} and gypsum-ν=465, 805, and 1100 cm^{-1}. The main changes in the plain cement spectrum in the first hours of hydration (Fig.1) are expressed in a decreased intensity of the gypsum and alite bands and emerging of the band characteristic for portlandite (ν=3640 cm^{-1}). The C-S-H band at ν=960-970 cm^{-1} gradually formed after the 4th hour. Parallelly, the intensity of the portlandite band increased and after the 8th hour the sulphoaluminate band with maximum at ν =3400 cm^{-1} was formed. The IR-spectra of FA-containing cement (Fig.2) repeat the above regularities for the plain paste, the only difference being that the band of C-S-H was formed earlier (between the 1st and 3rd hour of hydration)while the bands of portlandite and ettringite were not so clearly expressed. All the bands of the main hydration products (Fig.2) are broader than those in the plain cement which is, probably, due to the presence of distorted Si-tetrahedra in the fly ash portion causing variable frequency. The spectra in Figs.3 and 4 of SF- and Pz-containing cements show that SF participates actively in the hydration process from the first hour after the contact with water-the characteristic bands of amorphous silica at ν=1100 cm^{-1} fade with time, the spectral bands of C-S-H being formed at the same time (after 1 hour for Pz-containing paste and about the 4th hour for the SF-containing one). The SiO_2 band of cement #2 is preserved indicating that part of silica had not reacted and remained for further reaction in the later stages of hydration. The same band was not observed in paste #4 after the 8th hour, which was expected in respect to the lower SF quantity in it. The earlier formation of the C-S-H band in the spectrum of cement #4 is related to the easier C-S-H formation at lower SF-concentrations. The portlandite band is not displayed in the last two figures, probably, because of its small amount in both pastes and the screening effect of the ettringite band which is better shaped in the Pz-containing paste.

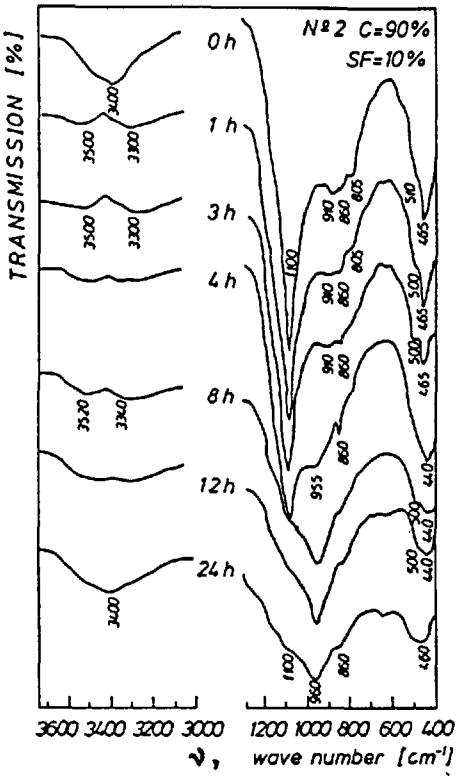

Fig.3 IR spectrum of SF-containing cement paste

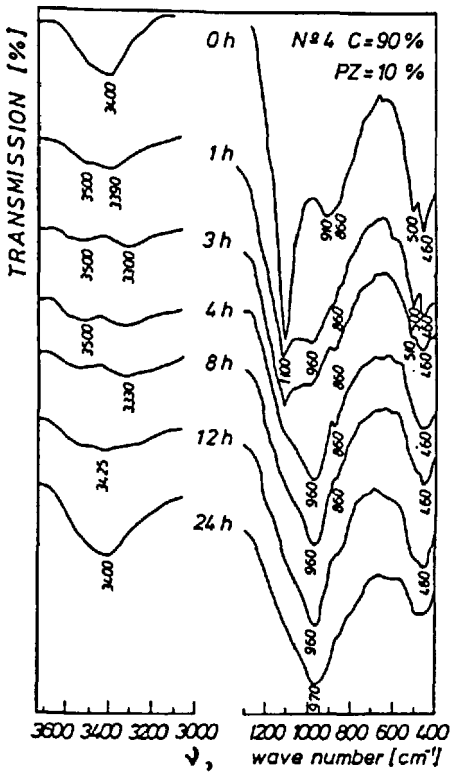

Fig.4 IR spectrum of Pz-containing cement paste

Summarized diffraction patterns of cement pastes (##1-4) showing the phase changes in the first 24 hours of hydration are given in Fig. 5. The lowest pattern in each case is of cement before hydration start. In the plain cement paste the portlandite (CH) formation is found to start around the 3-4th hour with gradual increasing crystallization followed up to the 24th hour. The most intense diffraction peak of CH (d=4.90 Å) in the pattern of FA-containing paste first was detected after the 6th hour then followed by a gradual intensity increase. For the case of SF-containing paste the formation of CH was obstructed up to the 12th hour (except a very small intensity trace at the 6th hour). Between the 12th and 24th hour the CH-content in this sample rapidly increased. For the cement paste with Pozzolit the crystallization of CH with time very much resembles that of cement #2 - up to the 12th hour of hydration no portlandite was detected.

DTA data showing the changes in the total amount of the newly formed hydrates in cement pastes during the first 24 hours of hydration are shown in Fig.6a. The amount of the hydration products for 1g cement in the pastes with SF and Pz is higher than the corresponding amount in the plain cement and FA-containing pastes. The CH-water content in the SF- and Pz-containing pastes till the 6th hour of hydration is in the range of the accuracy of the method - about 1.5 mg per gram cement, and it increases sharply after this age for both pastes (Fig.6b). After 1 hour of hydration the CH-quantity in the FA-containing pastes and in the plain cement paste is the same, rising more rapidly in consequence for the additive-free paste. The difference between the non evaporable water content and the CH-water, called H-water, is a measure for the hydrosilicate and hydroaluminate quantity in the cement pastes. Fig.7 shows the changes in the difference between the H- ($H-H_o$) and CH-water content ($CH-CH_o$) for the pastes with additives on one hand and for a plain paste on the other. The periods of accelerated hydration product formation and the period of relatively delayed hydration process in the additive containing pastes due to the specific effect of the additives are clearly observed from the curves.

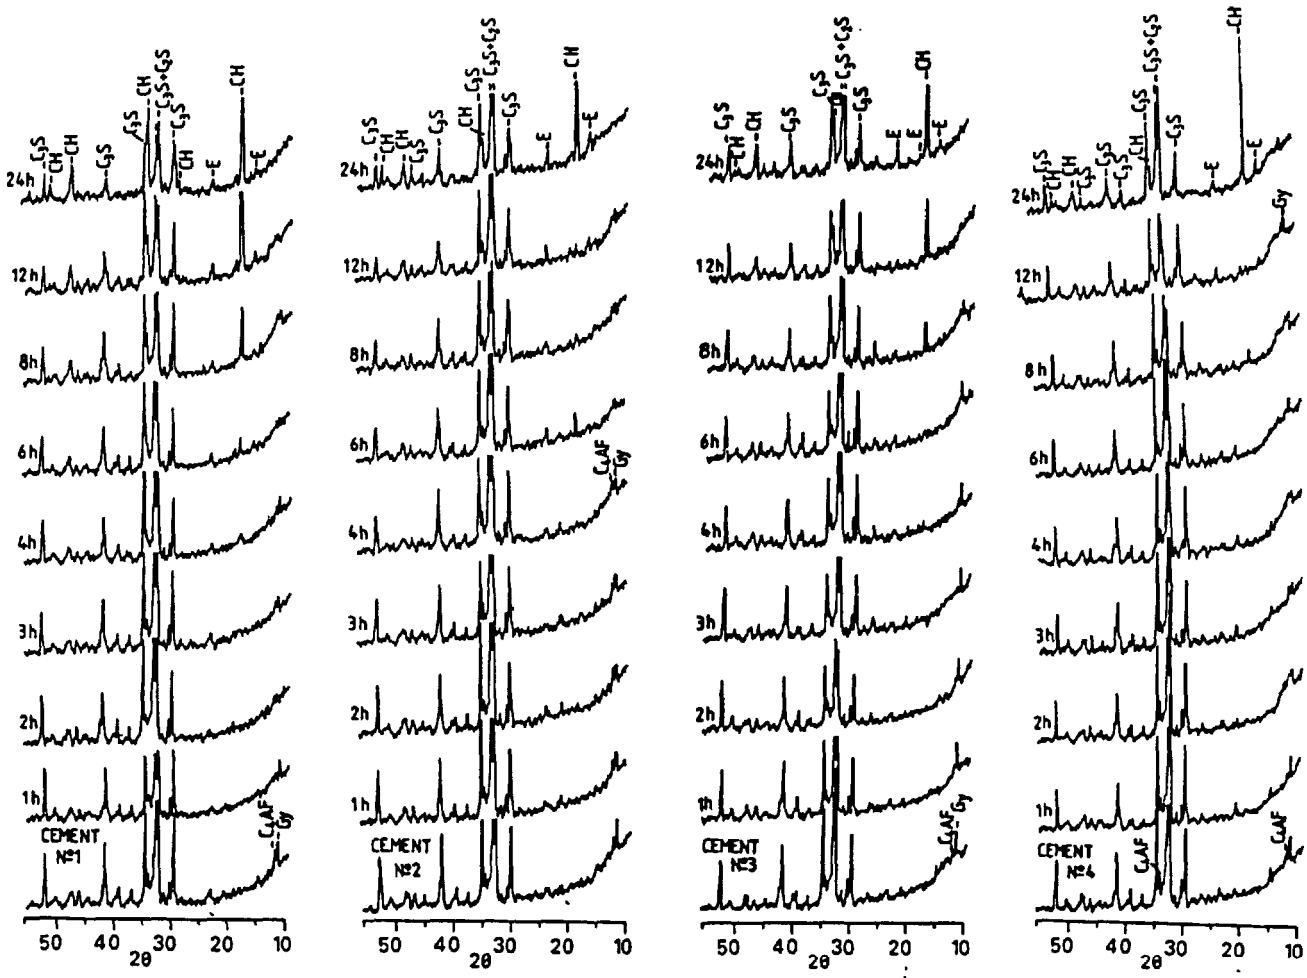

Fig.5 XRD patterns of plain cement paste (#1); with SF (#2), FA (#3) and Pz(#4)

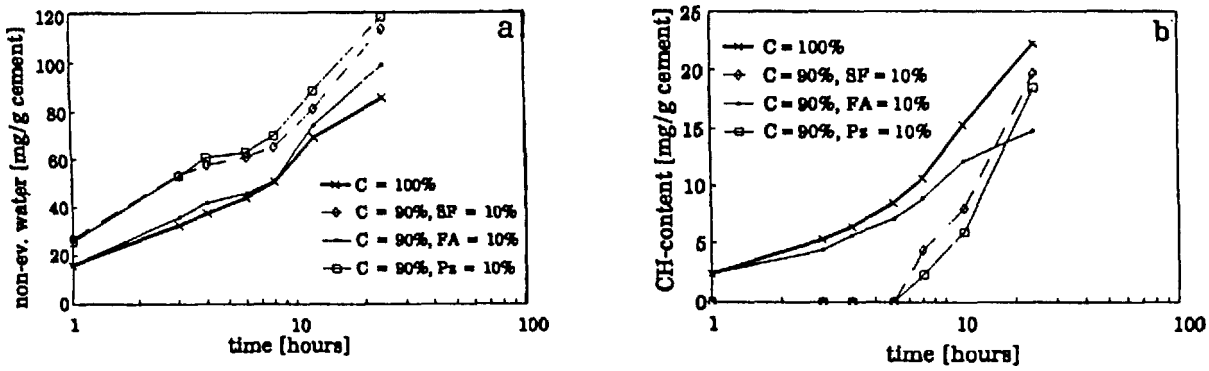

Fig.6 Changes in the amount of hydration products (a) and portlandite (b) in the cement pastes

The DTA, IRS, and XRD results prove that the manifestation of the chemical nature of the fly ash is negligible till the 24th hour of hydration and its effect can be considered rather as a physical one - the fly ash surface favours the nucleation mechanism of the hydration products. The SF particles participate actively in the hydration process of cement during the first 8 hours. They bind entirely the calcium ions in the solution and for this the amount of portlandite is very low. The absence of free calcium ions in the solution stimulates the dissolution of cement particles, the latter being gradually

covered by SF particles and hydrosilicate gel forming a diffuse layer which hampers their contact with water and slows down the dissolution rate. This period has a longer duration in the SF containing paste because of the high density of the SF particles around the cement grains. SF, FA particles, and complexes of FA-particles surrounded by SF ones exist separately in the Pz-containing paste. The lower SF-concentration and the last two types of aggregations make the diffusion layers around the cement grains in the Pz-containing paste more permeable for the water molecules. This is most probably the reason for the shorter period of retardation of the hydration rate in comparison with the SF-containing paste. Hydration is accelerated after the 8th hour due to breaking apart of the gel covers.

Table 1 presents results of determined CH-water contents from the 1st to 360th day of hydration. In cement pastes with mineral additives at all ages it is lower than in the plain paste. The CH-water content of SF- and Pz-containing cement pastes increases till the 28th and 90th day respectively, its decrease with time being clearly observed subsequently. The CH-content in FA-containing paste is low till the 28th day, then weakly increases and remains practically constant.

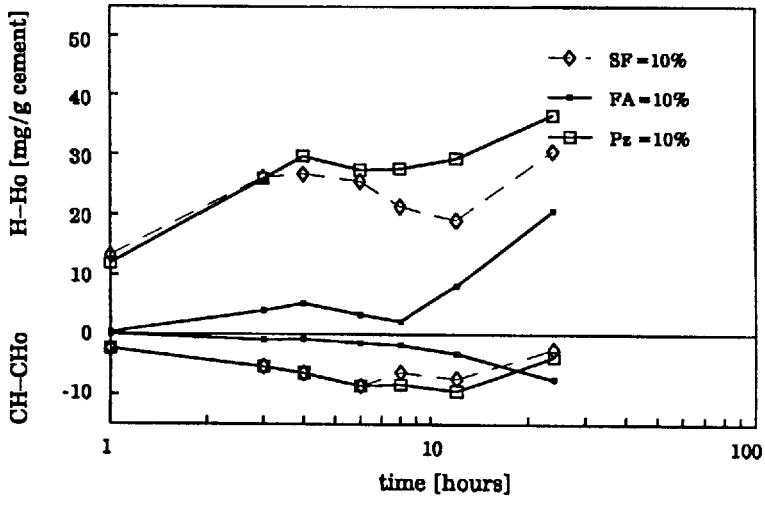

Fig.7 Differences between H- and CH- water contents in cement pastes with and without additives.

TABLE 1 CH-water content (mg/g cement) for age of hydration (days)

Cem. paste	Age	1	2	3	7	28	90	180	360
#1		22.2	28.7	31.0	36.6	39.9	43.2	41.9	42.6
#2		19.7	22.2	27.2	32.1	34.4	32.1	29.6	28.7
#3		14.8	19.7	22.2	25.9	30.7	33.7	34.4	35.0
#4		18.5	24.6	26.0	28.7	32.1	34.4	30.7	29.6

TABLE 2 H-water content (mg/g cement) for age of hydration (days)

Cem. paste	Age	1	2	3	7	28	90	180	360
#1		63.2	66.7	73.2	92.5	130.8	224.2	230.8	234.7
#2		93.7	119.4	121.8	152.7	177.3	273.8	278.3	280.0
#3		83.9	103.4	108.3	145.3	203.2	261.9	266.1	267.6
#4		99.7	118.2	121.8	164.0	195.8	263.6	270.4	273.4

The H-water content is growing with time for all tested specimens and at each age it is higher in the pastes with additives (Table 2). The hydrosilicate and hydroaluminate content in the Pz-containing cement paste is higher than in the SF-containing one till the 28th day of hydration, then this relation turning to be opposite till the 360th day. The paste with FA has the lowest H-water content among all additive containing pastes except for the age of 28 days.

The CH/H water content ratio was chosen as a criterion for the relation between the processes leading to portlandite formation on one hand and hydrosilicate and hydroaluminate formation on the other (Fig.8). The ratio of the plain cement paste is higher than the ratio in all other pastes at all investigated ages of hydration which is an evidence for the pozzolanic activity of the additives. A clearly expressed diminution of this parameter is observed between the 3rd and 90th day of hydration for all studied cements, the values being very slightly decreased till the 180th day reaching a constant value subsequently. The only exception is the FA-containing cement paste, where the equilibrium between CH- and H-water content is achieved as early as the 90th day of hydration. The maximum of this ratio is observed at the age of 3 days for cement with additive and at the age of 2 days for plain cement. The CH/H ratio for SF-containing paste is higher than the ratio of FA- and Pz-containing pastes (except for the 2nd day) till the 28th day and the relation turning to be opposite later on.

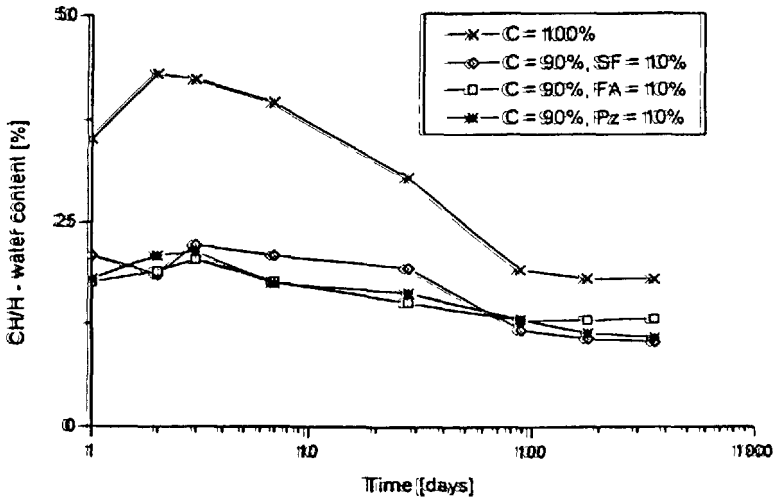

Fig.8 Changes of CH/H ratio

CONCLUSIONS

1. The effect of Pz mineral additive on the early hydration of cement is expressed in increased total amount of hydration products and in a decreased amount of calcium hydroxide.
2. The conditions of early hydration in the Pz-containing paste are more favourably in comparison with these of the SF-containing one where a part of the SF particles remains closed between the forming hydrates on the cement grain surface and do not actively participate in the cement hydration during the first 24 hours.
3. In the cement pastes with additive after the 3rd day the portlandite consumption prevails, although its total quantity continues to grow as a result of the proceeding hydration.
4. During the first days the effect of silica fume is in acceleration of the clinker minerals hydration and in consumption of portlandite in the cement paste. After the 28th day SF mainly bounds portlandite in insoluble hydrosilicates. Fly ash is not so active with respect to portlandite consumption till the 7th day of hydration but is

activated in the time between the 7th and the 90th day when the pozzolanic reactions of FA are dominant.

5. The effect of Pozzolit depends on the SF component during the first 7 days which is expressed in acceleration of cement hydration and binding of portlandite. The main processes in the Pz-containing paste later on depend in the FA-component.

PECULIARITIES OF UKRAINIAN POZZOLANA CEMENTS

Raisa RUNOVA, Kiev State Technical University of Construction and Architecture, Kiev, Ukraine
Juriy USTIMENKO, "Horda Ltd.", Kiev, Ukraine
Victoria MELENTYEVA, Joint Stock Company "Podol'skiy tsement", Kamenets-Podolskiy, Ukraine

ABSTRACT Technical characteristics of cements made from clinkers produced by the plants situated in southern, central and western regions of Ukraine and natural pozzolana in a form of reactive silica (up to 55%), glassy rock (up to 70%) are given. The peculiarities of composition and structure of pozzolanas as well as their influence on properties of the cements are demonstrated. Technologies permitting to produce a concrete with a strength 1.5 times exceeding that of portland cement and frost resistance up to 900 cycles have been developed.

KEY-WORDS: alite, alkali, pozzolana, strength development.

INTRODUCTION

National standard of Ukraine and ENV-197-I prescribe the use of pozzolanic additives of different types and in different quantities in 4 from 5 types of cements. The advantages of Portland pozzolana cements is known to be caused by technical and economical reasons. In Ukraine with its well developed cement industry a problem of how to provide a competitiveness of cements on world and domestic markets may be solved successfully due to blended cements. As it follows from the reports (Narang, 1992; Sersale, 1992), the development of researches in the field of pozzolana cements is attributed, first of all, to possibility of utilisation of such industrial wastes as fly ashes and slags.This made attention to investigations of the compositions containing natural pozzolanas weaker. Undoubtedly, the use of natural pozzolanas is reasonable when properties of the obtained cements are equal to those of clinker cements or exceed them. The content of reactive silica may be considered as a determining requirement to quality of pozzolanas (even though this condition can not be easily provided)(Glasser et al, 1988). The modification of pozzolana cements properties is possible due to chemical additives in a form, first of all, of easily soluble salts (Tokemoto and Uchikawa, 1980). Simultaneously, other chemical and technological advantages can be achieved while using naturally occurring pozzolanas. This comes, first of all, from the researches on structure formation of alkaline cements which simulate the processes occurring in nature and new formations are represented by analogues to rock-forming minerals (Glukhovsky, 1957, 1971). The present study was dedicated at comparing the influence of natural pozzolanas on properties of the blended cements composed of clinkers manufactured by the main Ukrainian cements producers.

EXPERIMENTAL DETAILS

Used in the experiments were portland cement clinkers from 5 Ukrainian leading cement producers. Table 1 shows mineralogical composition of the clinkers.

Used as a pozzolanic additive was a reactive naturally occurring amorphous silica taken from deposits of western regions and perlite from the Carpethian Mountains (Table 2), a characteristic feature of natural silica composition was the presence, besides amorphous silica, of the increased content of quartz (up to 20%) as well as clay minerals and calcite. Perlite is itself a homogenous glassy mass consisting in chemical composition mainly of silica, alumina, and great quantities of alkalis.

Table 1 Mineralogical composition of the clinkers

Producer	Code	Content of minerals, %			
		C_3S	C_2S	C_3A	C_4AF
Open Joint Stock Company "Nikolaevtsement"	I	63.52	15.12	5.20	13.01

Joint Stock Company "Podol'skiy tsement"	III	55.82	17.13	9.38	13.44
Open Joint Stock Company"KTSGK",Krivoy Rog	IV	59.29	19.54	6.83	11.49
Open Joint Stock Company "Baltsement"	V	66.55	12.94	5.64	13.13

Table2 Chemical composition of pozzalanic constituent of the cements

Rock	Chemical composition, mass %					
	SiO_2	Al_2O_3	CaO	MgO	Fe_2O_3	R_2O
Natural silica	68.3	9.2	12.5	1.2	2.9	0.6
Perlite	73.0	16.4	2.5	0.9	1.9	6.6

The blended cements were made by grinding a clinker and pozzolana in certain ratios to produce a specific surface of 500-550m^2/kg was reached. The content of gypsum in all formulations was taken 5 %. When use was made of perlite a complex additive containing sodium sulfate in a quantity of 3 % by cement mass was introduced with a mixing water. The samples were prepared and tested under procedure specified in the USSR Standards 310.I-3-76 and 310.4-81. Strength development of the cement was observed while hardening in standard conditions and after steam curing (3+6+3 hrs, T=85^{0}C). Physico-chemical investigations were held with the use of XRD and DTA methods.

RESULTS AND DISCUSSION

High content of alite in clinkers of all the Ukrainian cement producers allowed to assume a possibility of introduction of pozzolana in rather great quantities. However, the results (Table 3) turned out to be unadequate, namely: the presence of 25% natural silica decreased the cement activity by 21-35 % .The cements with a higher content of alite ("Volyn", "Baltsement") demonstrated the higher strength both in 3 days and 28 days age. The cements from the Zdolbunov Plant demonstrated the strength of brand M400 if replacing 30 % clinker with natural silica. The cements with high content of alite demonstrated good results after steam curing. So, the cements from the Balakleya Plant, even with an additive of 55 % natural silica reached after steam curing 60 % of standard strength of additive-free cement.

The technological properties of the cement containing natural silica vary considerably. The initial and final setting times of all reference additive-free cements were found to be within 2hr.-40 min.-3 hr.-15 min. and 4hr.-00 min.- 4 hr.-30 min., respectively. The increase in pozzolana content in all commercially produced clinkers was accompanied by a shortening of the initial and final setting times to 1hr.-10 min.-1 hr.-30 min. and 4 hr.10 min.- 7hr.30 min., respectively, depending upon variations in mineralogy of clinkers. All the cements with a content of the natural silica within 30 % showed good results when tested for frost resistance (up to 50 cycles). Physico-chemical studies proved that in the cements containing the natural silica a free lime was absent, calcium hydrosilicates were found in a low-basicity form, and quartz present in the natural silica remained in an unbound state (Figure 1).

NOTE: R* -standard strength (in 28 days- age); R **- strength of steam cured cements.

The main reason of not satisfactory activity of the blended cements containing natural silica may be attributed to a presence of the quartz. The results differ greatly when use is made of a glassy aluminosilicate rock: a share of clinker may be decreased greatly (to 30 %) without decline of cement activity and by 1 year- age the cement strength reached 80 MPa. Of interest is the fact that even for these cements the best results were obtained with the clinker produced by the "Baltsement" Plant However, for all other Ukrainian clinkers, if using 50 % pozzolana, the activity corresponding to that of "pure" clinker cement may be provided. It is of importance because the plants in the western part of Ukraine are situated very close to sources of perlite.Worthy of particular mention is the fact that the use of a complex additive affects the initial and final setting times: 0 hr.-30 min.- 0 hr-.45 min. and 2 hr.-50 min.- 3 hr.-30 min., respectively.

The peculiarities of a perlite structure and large content of alkalis determined a different mechanism of strength development (Runova and Fundi, 1991). The alkaline hydroalumino-silicate of calcium analogous to natural hydronepheline were found to occur along with hydrosilicates of calcium. These alkaline hydroaluminosilicates create a main volume of new formations in a form of a gel phase. Nature of the gel, its increased density as well as capability to slow crystallization were found the main reason of good performance of the pozzolana cements.

CONCLUSIONS

The Ukrainian clinkers may be referred to a class of high alite cement and may be considered potential for manufacturing blended cements allowing to decrease a share of clinker to 30 % without corresponding decline of activity of the initial clinker cement. The peculiarities of composition and structure of natural reactive mineral additives determine a rather wide range of technical properties of the pozzolana cements such as activity in a 28 days-age varying from 40 to 70 MPa. The use of alkaline-alkali earth binder systems modified with glassy rocks and involvement of alkalis present in them in structure-forming processes may be considered as an advanced direction in manufacturing high performance pozzolana cements (high atmosphere-and frost resistance resulted in long-term durability).

CHARACTERISTICS AND HYDRATION OF CEMENT PRODUCED FROM ASH FROM INCINERATED URBAN GARBAGE

Yasuhisa TAKUMA, Yoshiaki TSUCHIDA and Shun-ichiro UCHIDA, Chichibu Onoda Cement Corporation, Japan

ABSTRACT Three types of cement containing alinite or calcium chloroaluminate were produced from ash taken from incinerated urban garbage, and the characteristics of the clinkers and the hydration properties were investigated. Alinite turned to alite at about 1350℃, while calcium chloroaluminate remained stable at 900-1400℃. Each type of cement showed its own peculiar hydration characteristic and the microstructure of hardened body. Cement containing calcium chloroaluminate showed rapid setting and hardening property.

Key-words: Alinite, Chloride, Clinker formation, Hydration, Waste material utilization

INTRODUCTION

In Japan, urban refuse the main waste product of domestic life is rising owing to industrial development and the drift of population into cities. It is now becoming necessary to find practical applications that treat ash from incinerated urban garbage as a resource. Ash from incinerated urban garbage contains remarkable amounts of chlorine, primarily from plastics such as vinyl chloride and cooking salt, in addition to SiO_2, Al_2O_3, Fe_2O_3 and CaO, which are indispensable elements for producing Portland cement. Consequently, the ash cannot be used as a raw material for Portland cement as it is, although it can find practical application as a raw material for a special cement containing hydraulic materials such as alinite or calcium chloroaluminate ($C_{11}A_7 \cdot CaCl_2$). Cement containing alinite was examined as a potential energy-saving cement, since it could be burnt at lower temperatures, and was produced from steel refinery waste (Pradip et al, 1990). Several studies about the cement containing calcium chlorosilicate and calcium chloroaluminate were reported mainly from the environmental point of view, in Japan (Uchikawa; 1992, 1994a and 1994b, Uchikawa et al; 1995 and 1996).

In this study, three kinds of cement, each containing a quantity of alinite, $C_{11}A_7 \cdot CaCl_2$, belite (C_2S) and alite (C_3S), were produced from ash that was taken from incinerated urban garbage and other raw materials. The authors investigated the characteristics of the clinkers burnt under appropriate conditions, the hydration reactions and the physical properties of each cement produced.

EXPERIMENTAL

Raw material and cement preparation

Table 1 shows the target mineral composition of the clinkers, and the chemical composition of the raw meal of the three types of cement and the ash from incinerated urban garbage used as a raw material. The chemical compositions of ash from incinerators fluctuate with the season and the location where it was produced. Industrial grade $CaCO_3$, SiO_2, Al_2O_3, Fe_2O_3, $MgCO_3$ and $CaCl_2$ were used as raw materials for producing the cement clinkers, in addition to the incinerated ash. Since chlorine was vaporized in combination with alkali metals in the raw meal, the amount of chlorine, that was slightly more than the equivalent amount of alkali content, was added to the theoretical value.

Raw meal was burnt at between 900℃ and 1400℃ for 30 minutes in an electric furnace in order to determine the temperature range for the stable formation for each clinker mineral. Based on these results, clinkers were burnt at the most suitable temperature in a small rotary kiln which had a device to trap toxic gases such as hydrogen-chloride or dioxin. Three types of cement were manufactured from the clinkers : EC-1 clinker was ground with a 3% gypsum component as SO_3; EC-2 and EC-3 clinkers were ground alone, and mixed with anhydrite (II-$CaSO_4$) powder, the amount of which made the SO_3/Al_2O_3 molar ratio in the cement 1.0. Blaine's specific surface area of each ground powder was about 350m^2/kg.

Investigation of clinker characteristics, hydration and physical properties

Quantitative analysis of trace elements of cement clinkers was performed using X-ray Fluorescence Spectrometry. The observation of back scattered electron image and analysis of composition for each clinker mineral were performed using Electron Probe Micro-Analyzer (EPMA), for the polished surface of each clinker.

The heat evolution in hydration of cement with a water-cement ratio (W/C) of 1.0 was measured using a conduction calorimeter. The pastes of these three types of cement were prepared with W/C=0.5 and were cured in water at 20 ℃. After the determined curing time, the pastes were cut to cubes of about 5 mm in size, washed several times with acetone and then dried under conditions of 11% relative humidity or D-dry. For these specimens, the measurement of combined water by ignition, and the identification and quantitative analysis of hydration products were performed by X-ray Diffraction (XRD) and Differential Scanning Calorimetry. For D-dried specimens, fracture surfaces and polished surfaces were observed using Field Emission Scanning Electron Microscope (FE-SEM) and EPMA, respectively. The setting time and compressive strength of each kind of cement were measured using a Japanese Industrial Standard (JIS) mortar, in which the W/C=0.65 and sand cement ratio (S/C) was 2.

RESULTS AND DISCUSSION

Clinker formation

Figure 1 shows the typical mineralogical phase-temperature relationships during the formation of the three types of cement clinkers, which were drawn up based on the results of XRD measurement of the clinkers burnt in an electric furnace. Alinite was not observed at 900℃, but was noted at 1000℃, despite the report by Agarwal et al (1986) that the formation of alinite became remarkable at about 900℃. As the temperature rose, the alinite increased, with a fall in C_2S and free lime, and began to change to C_3S, losing chlorine from about 1350℃ (EC-1 and EC-2) (Uchikawa, 1992 and Uchikawa et al, 1995). $C_{11}A_7 \cdot CaCl_2$ existed at a constant amount over a range of 900℃ to 1400℃, and the formation of tricalcium aluminate (C_3A)

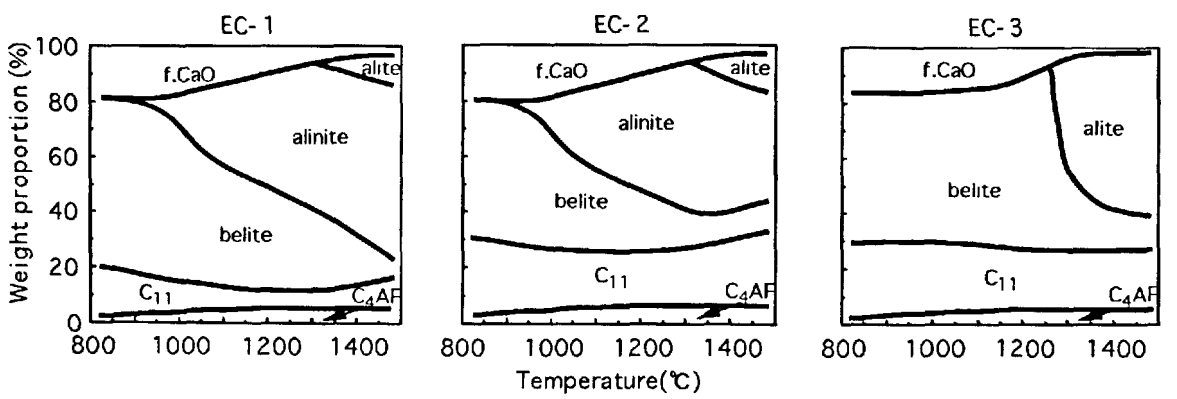

Figure 1. Schematic diagrams showing variations in typical contents of phases during the formation of prepared cement clinkers (C_{11}:$C_{11}A_7 \cdot CaCl_2$).

was not observed (EC-2 and EC-3). It is thought that at higher temperatures, $C_{11}A_7 \cdot CaCl_2$ is more stable (Sango et al, 1991) than $C_{11}A_7 \cdot CaF_2$ which declines rapidly and changes to C_3A from about 1380℃ (Uchikawa et al, 1983). In EC-3 clinkers, alinite did not appear prior to the formation of C_3S, it seems because $C_{11}A_7 \cdot CaCl_2$ was formed at still lower temperature range, consuming most of the chlorine and MgO, the contents of which in raw meal were small. On the basis of these results, EC-1, EC-2 and EC-3 clinkers were burnt in a rotary kiln at 1290℃, 1330℃ and 1360℃, respectively.

Clinker characteristics

Trace elements in clinkers

Table 2 shows the MgO, SO_3, Na_2O, K_2O and chlorine content in each clinker burnt in a rotary kiln. The amounts of alkalies and chlorine decreased remarkably, compared to those in raw meal (Table 1), because chlorine and alkalies combined and were vaporized. Measured chlorine content in EC-3 clinker was lower than the theoretical value, although the excess chlorine was added as a raw material.

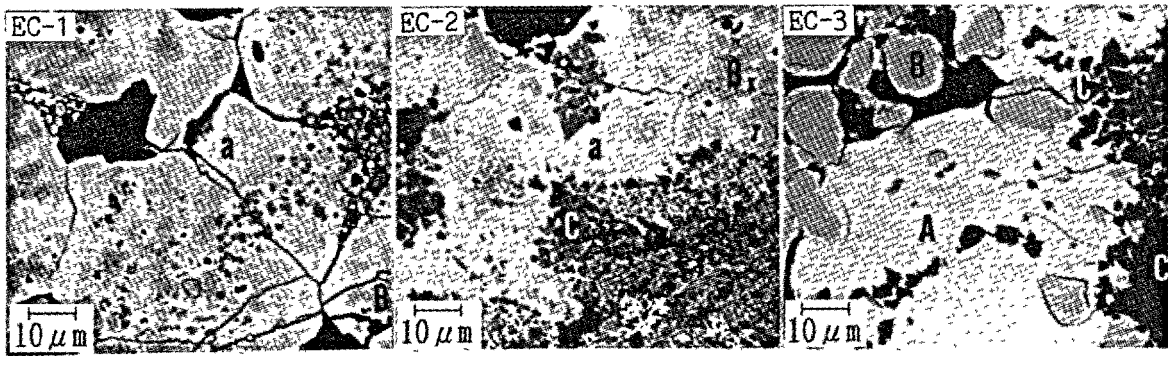

Table 2. Result of chemical analysis of clinkers (trace elements).

Sample	Chemical composition(%) MgO	SO_3	Na_2O	K_2O	Cl	Cl*
EC-1	3.1	0.50	0.0	0.0	4.0	2.9
EC-2	1.9	0.28	0.0	0.0	4.2	3.4
EC-3	1.3	0.16	0.0	0.0	1.0	1.2

Cl : Calculated value from target mineral composition

Crystalline state of clinker minerals

Figure 2 shows the typical back-scattered electron images of polished surface of each clinker observed by EPMA. In the EC-1 clinker, alinite crystal is observed to be 15-40 μm in size, to be irregular shape and to include C_2S clusters. Alinite grains are supposed to have grown in contact with each other, because of the rapid burning reaction. C_2S grain is several μm in size, and has an elliptical cross section. Calcium alumino-ferrite phase (C_4AF) is needle-shaped and appears in minute quantities. In the EC-2 clinker, the C_2S grain is slightly larger than that in the EC-1 clinker, because the burning temperature was higher than that of the EC-1 clinker, and $C_{11}A_7 \cdot CaCl_2$ forms clusters which consist of small grains of 2-3 μm in size. In EC-3 clinker, C_3S grains grew to 10-20 μm in size, and to hexagonal plates in shape. C_2S and $C_{11}A_7 \cdot CaCl_2$ grains also grew larger. It is suggested that C_3S grains are large enough, considering the burning temperature of 1360℃, owing to the mineralizing effect of the chlorine.

a:Alinite , C:$C_{11}A_7 \cdot CaCl_2$, A:C_3S , B:C_2S , F:C_4AF

Figure 2. Back-scattered electron images of burnt cement clinkers.

Chemical composition of clinker mineral

Table 3 shows the chemical composition of the principal minerals in each clinker, observed by EPMA. In alinite, the chlorine content was 4.2%, which conformed to the theoretical value (4.2%) calculated using the chemical formula. The amount of MgO was 3.2% (EC-1) and 3.5% (EC-2), which were closer to Lampe et al's (1986) theoretical value (3.7%) than to Bikbaou's (1986) value (2.3%).

In $C_{11}A_7 \cdot CaCl_2$, The chlorine content was 5.5% (EC-2) and 4.7% (EC-3), close to the theoretical value of 4.9%, and it is thought that the amount of chlorine fell as the burning temperature rose. Although it is generally reported that the $C_{11}A_7 \cdot CaX_2$ compound is apt to make solid solution with $C_{12}A_7$ or $C_{11}A_7 \cdot Ca(OH)_2$, and the X_2 content in $C_{11}A_7 \cdot CaX_2$ is smaller than the theoretical value, the results of this study suggest that $C_{11}A_7 \cdot CaCl_2$ in the EC-2 clinker has excess chlorine. This is because an excess amount of the chlorine was compounded to a raw meal, with the vaporization of the chlorine combining with alkalies taken into account.

C_2S has little chlorine and MgO. C_3S, the structure of which is similar to that of alinite, has little chlorine and has 1.2% composed of MgO, similar to the MgO component in C_3S in the OPC clinker. These results reconfirm that MgO as well as chlorine are, generally speaking, indispensable constituents in the formation of alinite.

Table 3. Chemical compositions of principal minerals in clinkers observed by EPMA.

Hydration reaction

Heat evolution by hydration

Figure 3 shows the heat evolution rate curves and the cumulative heat evolution amount curves of three types of cement. In the case of EC-1, the initial heat evolution rate was lower than that in the other two, because the $C_{11}A_7 \cdot CaCl_2$ content in EC-1 was considerably small. In the case of EC-2, the initial heat evolution rate and the cumulative heat evolution amount up to one hour were larger than those observed in EC-3. In the case of EC-3, a small peak of heat evolution rate, owing to the formation of ettringite, appeared after the first peak. These results suggest a difference in hydraulic activity between $C_{11}A_7 \cdot CaCl_2$ in EC-2 and $C_{11}A_7 \cdot CaCl_2$ in EC-3.

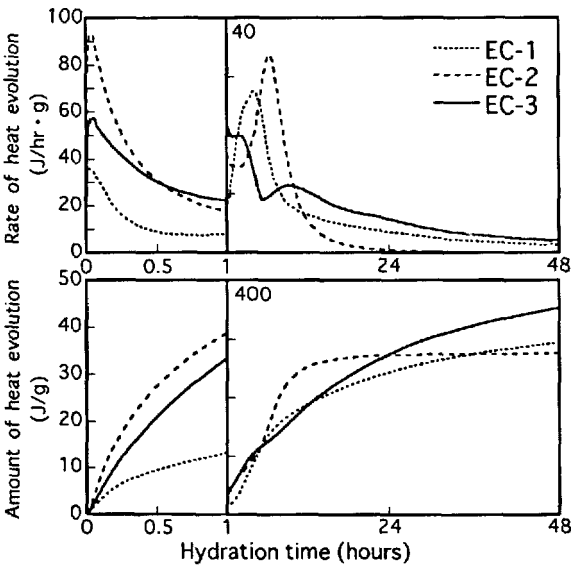

Figure 3. Heat evolution curves in hydration of cement pastes.

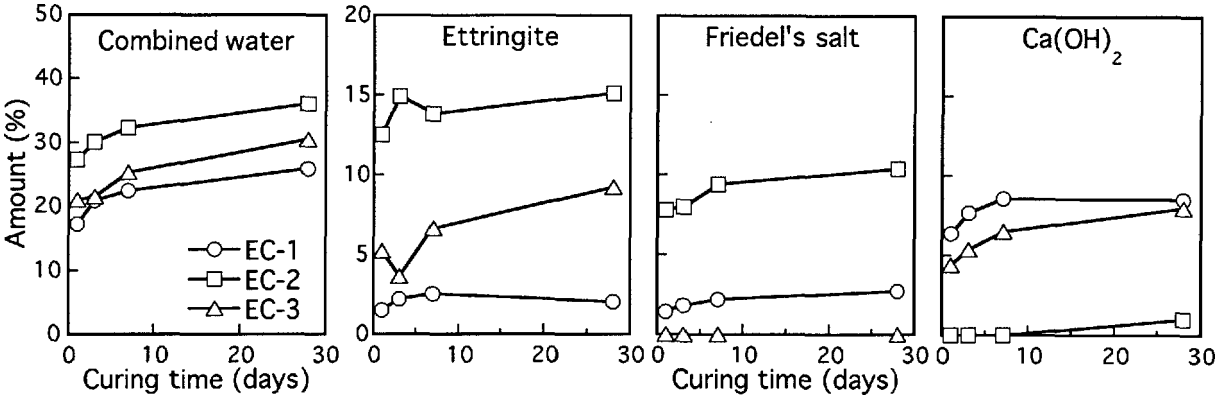
The second peaks of heat evolution rate of alinite in EC-1 and EC-2, and the third peak of C_3S in EC-3 appeared at 5-6 hrs, 7-8 hrs and 9-10 hrs, respectively. These results suggested that alinite was more active in hydration than C_3S. It is thought that the periods, in which alinite actively hydrates, differ depending on the concentration of Ca^{2+} in liquid phases (Uchikawa et al, 1985), between in EC-1 and in EC-2. The concentration of Ca^{2+} in liquid phase of EC-2 are

supposed to be considerably low, owing to the formation of ettringite or Friedel's salt caused by the active hydration of $C_{11}A_7 \cdot CaCl_2$. The cumulative heat evolution amount of EC-3 exceeded that of EC-2 after 24 hours, because of the hydration of C_3S, which was not abrupt but steady.

Amount of combined water and hydration products

Figure 4 shows the amounts of combined water and hydration products of each cement, depending on curing time. Three types of cement show distinct amounts of combined water and of hydration products. EC-1 formed $Ca(OH)_2$ and Friedel's salt, as well as the smallest amount of combined water and ettringite among the three types of cement. EC-2 formed a large amount of ettringite and Friedel's salt during the initial stage of hydration, but $Ca(OH)_2$ was not formed until seven days, since $Ca(OH)_2$ was consumed when ettringite and Friedel's salt were actively formed from alinite, $C_{11}A_7 \cdot CaCl_2$ and $CaSO_4$. EC-3 formed a medium amount of ettringite and $Ca(OH)_2$, and very small amount of Friedel's salt.

In case of the cement containing alinite (EC-1 and EC-2), the amount of combined water increased in proportion to the $C_{11}A_7 \cdot CaCl_2$ content, and $C_{11}A_7 \cdot CaCl_2$ formed Friedel's salt as well as ettringite (Uchikawa et al, 1995). In the case of the cement containing C_3S (EC-3), $C_{11}A_7 \cdot CaCl_2$ formed little Friedel's salt, and smaller amount of ettringite and combined water compared to the $C_{11}A_7 \cdot CaCl_2$ content. It is considered not only that the hydraulic activity of $C_{11}A_7 \cdot CaCl_2$ is depending on the crystal growth during the burning process, but also that the chloride ions, which remain excessively in the clinker and are released from alinite, promote the diffusion of water into $C_{11}A_7 \cdot CaCl_2$ (Kondo et al, 1977).



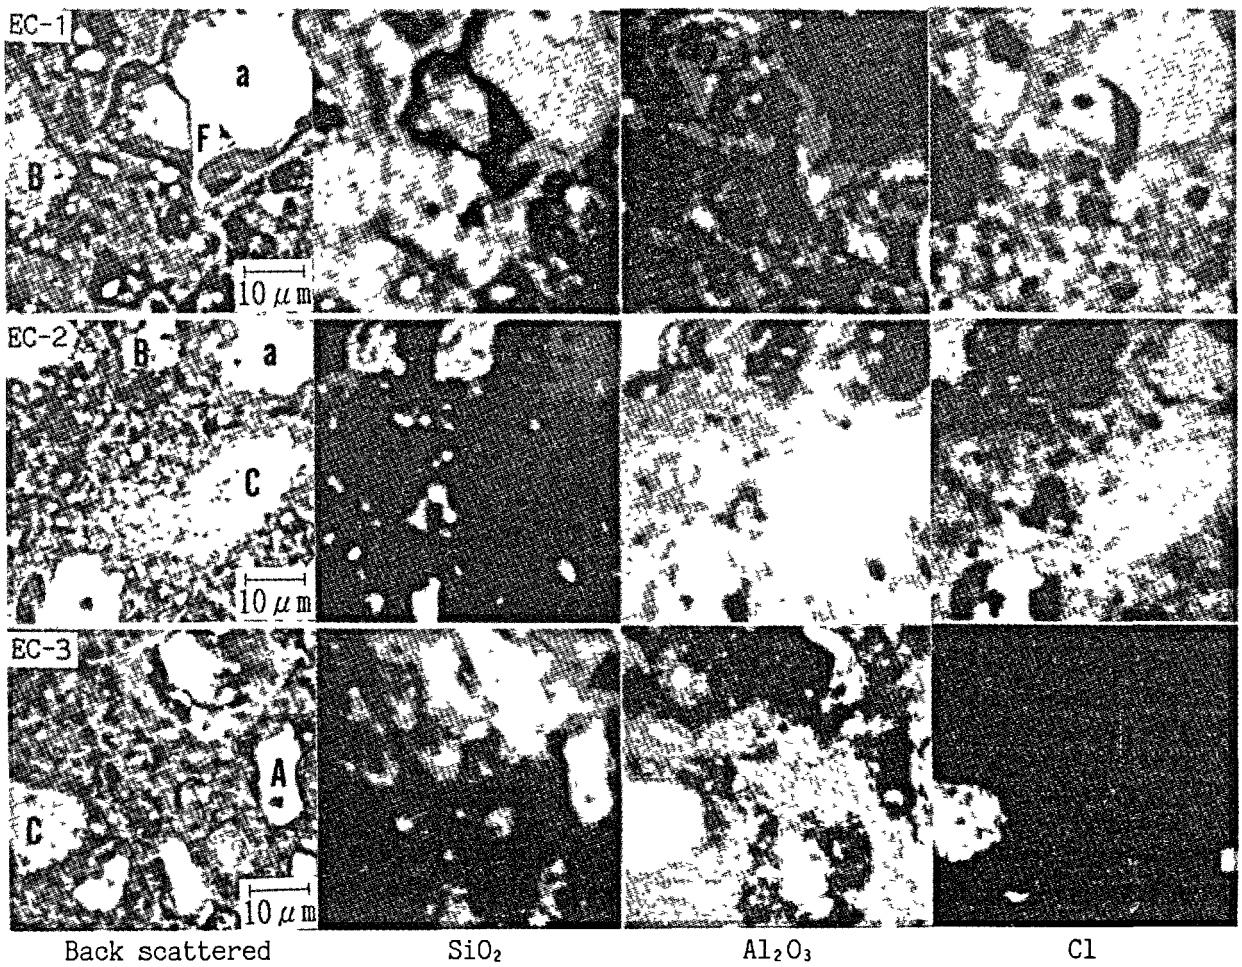


Figure 4. Change in the amounts of combined water and hydration products in cement pastes with curing time.

Microstructure of hardened cement pastes

Figure 5 shows the back-scattered electron images and the concentration mapping of each element of the polished surfaces of hardened cement pastes (seven days) observed by EPMA. In case of EC-1 and EC-2, the chlorine distributed to almost the entire hydrates. SiO_2 distributed to the hydrates more remarkably in the case of EC-1, while Al_2O_3 distributed to the hydrates more remarkably in the case of EC-2, than that in the case of the other, respectively. It is suggested that the chlorine exists not only in the Friedel's salt, but also in the ettringite and C-S-H. In the case of EC-3, the distribution of Al_2O_3 and chlorine are inferior to that in the case of EC-2, which supports the result that the degree of hydration of $C_{11}A_7 \cdot CaCl_2$ in EC-3 is considerably lower than that in EC-2. The amounts of the chloride ions, dissolved into the solution from the cement pastes hydrated in suspension, are 40%, 10% and 10% of the chlorine content in the cement of EC-1, EC-2 and EC-3, respectively. These results suggest that the chlorine is adsorbed to C-S-H, while the chlorine is chemically combined into ettringite and Friedel's salt.

SiO_2	100.0	60.0	45.0	30.0	20.0	15.0	10.0	5.0	0.0
Al_2O_3	50.0	30.0	20.0	15.0	10.0	5.0	2.0	1.0	0.0
Cl	20.0	10.0	7.0	5.0	3.0	2.0	1.0	0.5	0.0

Figure 5. Back-scattered electron images and concentrations of three kind of elements on polished surfaces of hardened cement pastes.

Figure 6 shows the FE-SEM photographs of the fracture surface of each cement paste (seven days). In the case of EC-1, a needle-shaped ettringite, Friedel's salt in the shape of hexagonal plates and $Ca(OH)_2$ in the shape of layers are observed, in addition to large amount of calcium silicate hydrate gel (C-S-H). The C-S-H is more net-shaped (type II) than needle-shaped (type I). It is generally suggested that net-shaped C-S-H is formed when C_3S and C_2S are cured in heat (Diamond, 1976), and it is considered that alinite formed a net-shaped C-S-H, because alinite hydrated actively. On the other hand, EC-2 and EC-3 formed ettringite in the shapes of needles and pillars in large amounts. Friedel's salt in the shape of hexagonal plates was formed inside the ettringite in the case of EC-2, and C-S-H in the shape of small spheres (type III) filled the gaps in the both cases.

Physical properties

The setting time and compressive strength of the JIS mortar of each cement are shown in Table 4 and Figure 7, respectively. The setting property of EC-1 is earlier than that of Portland cement, owing to the hydration of alinite and $C_{11}A_7 \cdot CaCl_2$. The setting properties of EC-2 and EC-3 show rapid hardening because they contain more than 20% of $C_{11}A_7 \cdot CaCl_2$, which actively hydrates in the initial stage. It is necessary to add 0.5-1.0% retarder, such as citric acid, in order to use EC-2 and EC-3 practically (Uchikawa et al; 1995 and 1996).

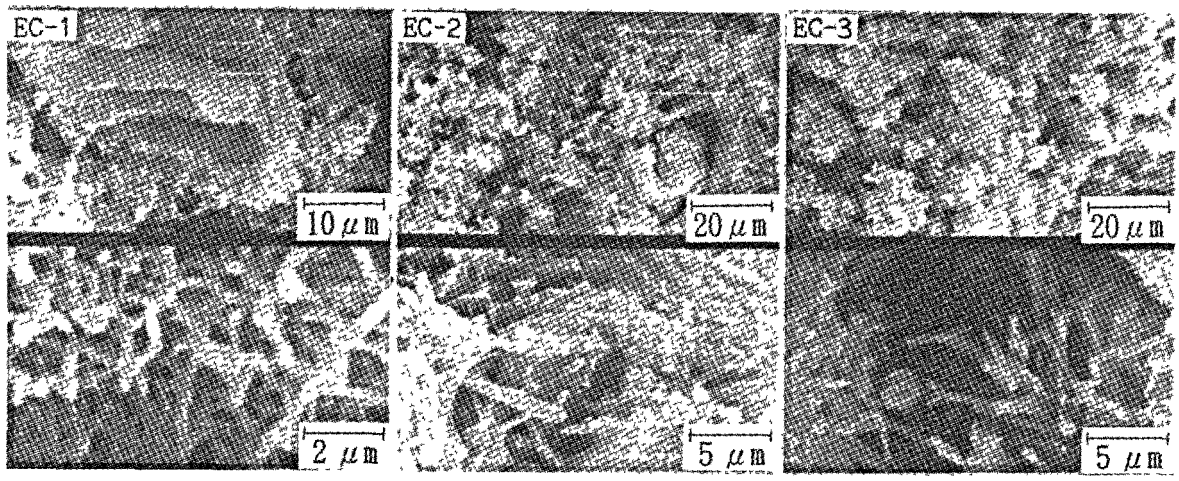

Figure 6. FE-SEM photographs of fracture surfaces of hardened cement pastes.

The strengths of EC-2 and EC-3 (three days and seven days) are significantly higher than those of EC-1, but are not as high as that of high early strength cement. The inferiority of the development of the strength of EC-1 is suggested to be owing to the lower degree of hydration and the greater amount of coarse pores. The strength of the three kinds of cement at 28 days were slightly lower than that of OPC. It is thought that the development of the strength of EC-2 containing alinite phase is smaller than that of EC-3 after seven days, as alinite encourage to form the Friedel's salts in the shape of hexagonal plates, which bring the coarse pores 0.2-1.0 μm in size. In the case of EC-3, these coarse pores remarkably decreased by 28 days.

Table 4. JIS mortar setting times.

Sample	Setting time (h:m) Initial	Final
EC-1	2:15	4:20
EC-2	0:37	1:04
EC-3	0:40	1:24

W/C=0.65, S/C=2

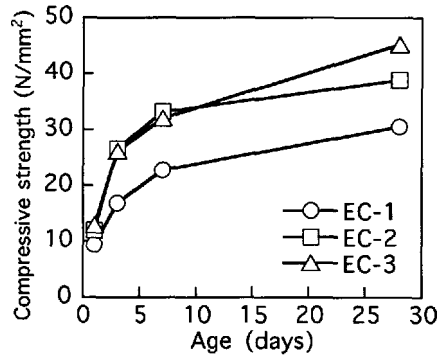

Figure 7. Development of compressive strength of each cement.

CONCLUSION

Three types of cement were produced from ash from incinerated urban garbage, and the characteristics of clinkers, hydration properties and the physical properties of each kind of cement were investigated. The following conclusions were obtained.

(1) Alinite was formed at about 1000℃ and began transforming to C_3S at about 1350℃ with the release of chlorine, although $C_{11}A_7 \cdot CaCl_2$ existed with stability at 900-1400℃. In the case of EC-3, alinite was not formed at lower temperature because chlorine in raw meal was largely consumed by the formation of $C_{11}A_7 \cdot CaCl_2$ at still lower temperatures.
(2) An almost stoichiometric chlorine component was included in alinite and $C_{11}A_7 \cdot CaCl_2$, but C_3S and C_2S had very little chlorine in any cement clinker.
(3) In the cement containing alinite, ettringite and Friedel's salt are formed with the hydration of $C_{11}A_7 \cdot CaCl_2$, and C-S-H and $Ca(OH)_2$ are formed with the hydration of alinite. The

amount of Friedel's salt increases and that of $Ca(OH)_2$ decreases in proportion to the $C_{11}A_7 \cdot CaCl_2$ content.
(4) The cement containing C_3S (EC-3) formed little Friedel's salt, and $C_{11}A_7 \cdot CaCl_2$ in that cement showed a lower hydraulic rate.
(5) The setting property of EC-1 is earlier than that of Portland cement, while those of EC-2 and EC-3 show rapid hardening because these cements contain more than 20% $C_{11}A_7 \cdot CaCl_2$. It is necessary to add 0.5-1.0% retarder, such as hydroxy-carboxylic acid, in order to use them.
(6) As a whole, the initial strengths of three kinds of cement are rapid hardening type, but the long term strengths of them are slightly lower than those of OPC. The developments of strengths are explained by hydraulic reactivity of the cement and the porous structure of hardened body.

THE EFFECT OF WASTE GLASS POWDER ON THE PROPERTIES AND PORE STRUCTURE OF ORDINARY PORTLAND CEMENT HYDRATES

Shuichi SUGITA, Qijun YU, Masami SHOYA, Yoichi TSUKINAGA and Yasuo ISOJIMA
Hachinohe Institute of Technology, 88-1, Myo, Hachinohe, 031, Japan

ABSTRACT Trials of using glass powder (GP) as admixture of cement under normal curing conditions have been made. With the addition of GP the strength of cement was decreased. After GP was ground for one more hour, nominated to NGP, it behaved differently on the properties of cement: 1) cement strength was increased, 2) porosity and average pore radius of mortars were reduced and 3) hydration degree of cement were enhanced. Moreover when 0.5% NaOH was introduced to NGP blended cements their strength and hydration were further developed.

Key-words: Glass, Hydration, Porosity, Strength development and Waste material utilization

INTRODUCTION

Now more and more waste such as blast-furnace slag, silica fume, fly ash and rice husk ash have been utilized as pozzolanic material in cement and concrete production (Mehta, 1983). With this not only the production cost is reduced but also the properties of concrete such as workability and strength can be changed so as to meet the various necessities of practical projects, and another benefit of this, possibly the most important one, is that the pollution by solid waste in now increasingly and seriously polluted world is decreased. Waste glass can be found everywhere, except the recycle of some glass bottles how to economically treat or reuse it is a practical problem ahead of us. The change in electrical conductivity of the saturated $Ca(OH)_2$ solution doped with the GP used in this experiment was determined to be -0.02 mS/cm but that added with one kind of silica fume (SF for short) was as high as 1.65 mS/cm. According to the evaluation standard for pozzolanic activity proposed by M.P. Luxan et al.(1989) GP did not exhibit any pozzolanic activity while the silica fume was very active. The difference of pozzolanic activity between GP and SF was also confirmed by mortar strength tests. With the increment of GP to ordinary portland cement (OPC) the final setting of cement was prolonged and cement strength was gradually decreased. Both GP and SF are amorphous and contain much silicon oxide (Fig 1 and Table 1) why they behave so much differently in pozzolanic activity? Can we utilize GP as an effective admixture of cement under normal curing conditions as we conducted on silica fume and rice husk ash (Sugita et al., 1992) and how can we improve the properties of GP blended cement? It is the focus of our attention. Fortunately it was found that with different fineness the glass powder did show different effects on the properties and pore structure of OPC hydrates. After GP was further ground for one hour in an effective ball mill, namely NGP, it was observed that the strength of NGP blended cement mortars was increased compared with that of GP blended cement. Moreover when 0.5% NaOH was introduced to NGP blended cement its hydration was accelerated and strength was further increased as well. This work is only a preliminary study on the utilization of waste glass but it does give us a hint, i.e. just as blast-furnace slag, fly ash and silica fume in the future waste glass can also be reused in the field of cement and concrete after more and further effort.

EXPERIMENTAL AND RESULTS

Raw material and mix proportions

Exhausted drink bottles were cleaned and dried, then ground in a vibration ball mill for one hour or two hours, the Blaine specific surface area and average particle size of the two products were respectively responding to 416 m^2/kg, 40 μ m (GP) and 656 m^2/kg, 8 μ m (NGP). Fig 2 are the SEM images of them. Sumitomo ordinary portland cement (OPC) was used as control sample

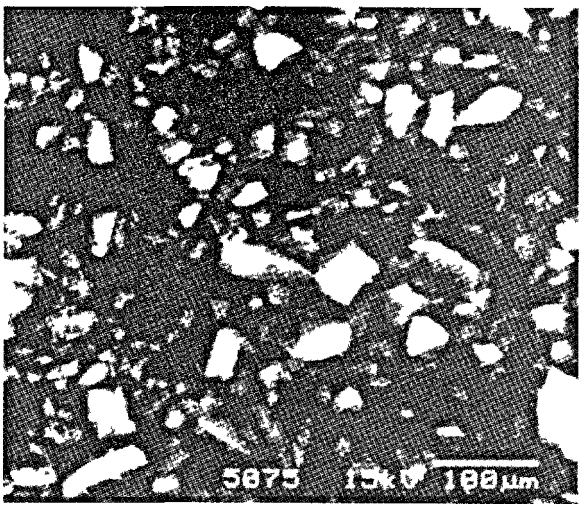
Glass	71.6	0.01	0.67	9.25	3.52	1.11	0.19	0.04	Tr.	0.00
SF	94.6	0.01	Tr.	Tr.	1.16	1.36	0.09	0.01	—	2.50

and Toyoura standard sand as fine aggregate in this experiment. The chemical composition of the glass and the mechanical properties of OPC are respectively shown in Table 1 and 2. GP and NGP blended cement were prepared by mixing x% GP or NGP with (100-x)% OPC by weight, where x=5, 10, 15 and 20 for GP blended cement (GP_1, GP_2, GP_3 and GP_4) and x=5, 10 for NGP blended cement (NGP_1 and NGP_2). In addition, 0.5% NaOH by weight was respectively incorporated into the cements added with 5% and 10% NGP, nominated to NGP_3 and NGP_4.

Electrical conductivity of GP, NGP and SF



A rapid evaluation of pozzolanic activity of natural products by electrical conductivity measurement was proposed by Luxan et al. (1989), which was proved to be also very effective and convenient in the evaluation of pozzolanic activity of rice husk ash and silica fume (Sugita et al., 1992, and Sugita et al., 1993). In this experiment two kinds of solution were adopted, one was saturated $Ca(OH)_2$ solution and the other was 0.5% NaOH solution. The analysis procedures of electrical conductivity are mainly described as follows: 1) the electrical conductivity of 200 ml of the $Ca(OH)_2$ solution or the NaOH solution at 40 ± 1°C (E_0) is measured at first, 2) 5.00g of the material to be tested is added to the solution and the solution is kept under constant stirring, 3) the electrical conductivity of the solution incorporated with the material (E_1) is taken over 120 seconds, and 4) by subtracting E_1 from E_0 the change in conductivity of the solution is therefore obtained. Table 3 shows the standard for the evaluation of pozzolancity by conductivity measurement (Luxan et al., 1989) and the electrical conductivity variation of the solution doped with GP or NGP or SF.

Normal consistency, setting time and strength of GP or NGP blended cement

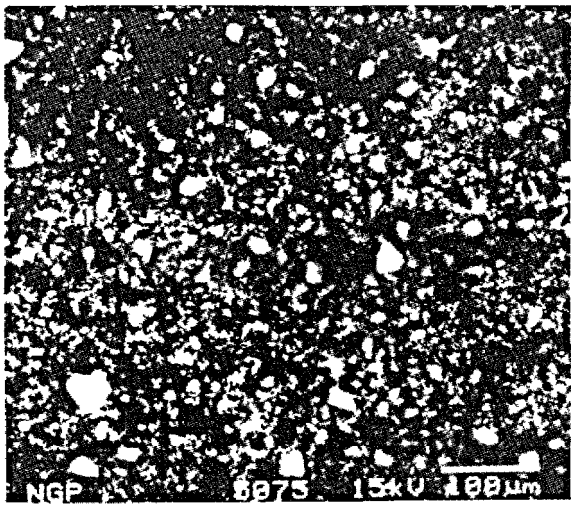


Table 2 gives the effect of GP addition on the the normal consistency and setting time of cement. The $40\times40\times160$ mm strength specimens, which were made at a water binder ratio of 0.65 and sand binder ratio of 2.0, were cured at 20 ± 1°C in the air of R. H.>90% for one day after casting, then demoulded. Subsequently, the specimens were cured in water at 20 ± 1°C for 3d, 7d and 28d respectively. The strength of the tested mortars are shown in Table 2 and 4.

Good pozzolancity	larger than 1.2	NGP	-0.04	0.55

Non-evaporable water in the pastes

Pastes of OPC, GP and NGP blended cement were prepared at a water binder ratio of 0.65, then they were tightly sealed in glass bottle and cured in water at 20±1°C to 7d and 28d. The method for determining non-evaporable water in the pastes is shown in Eq 1 (Czernin, 1964) and the result is listed in Table 5.

$$W_c = \{(W_d - W_i)/W_d\} \times 100\% - W_o \quad [1]$$

where W_c is the amount of non-evaporable water of paste (%), W_d is the weight of the ground paste after dried at 105°C for one hour, W_i is the weight of the paste after calcined at 1000°C to constant weight and W_o is the ignition loss by weight percentage of the respective cement.

Pore size and pore volume distribution of cement mortars

After strength test the mortar specimens were carefully crushed and dried at 40°C in a vacuum drier for 48 hours, from which particles around 3×3×3 mm in size were selected for determining pore size and pore volume distribution with PASCAL 140 and 240 Porosimeter. The pressure of mercury intrusion was from 0.1 to 200 MPa and mercury penetration speed, in the both procedures of pressure increase and decrease, was all controlled at 4p. The results are respectively shown in Table 6 and Fig 3.

The change in electrical conductivity of the saturated $Ca(OH)_2$ solution after adding GP or NGP to it was respectively equal to -0.02 mS/cm and -0.04 mS/cm, which showed that both of them would not have any pozzolanic activity according to Luxan, et al. (1989). But in our opinions the minus variation in electrical conductivity of the $Ca(OH)_2$ solution with GP or NGP may result in the rapid dissolution of partial CaO or other dissoluble oxides contained in them into the solution. The same phenomenon occurred for rich calcium fly-ash in the test conducted by us before. So only by this test it is yet difficult and not enough to give a precise estimation of the pozzolanicity of GP and NGP.

Table 2 indicates that with the addition of GP to NPC, from 5% to 20% by weight, the final setting of cement is prolonged, the flowability of mortar increased and the strength of cement decreased, only the initial setting of cement is kept unchanged. The more the added GP, the bigger the loss of the strength. In another hand SF, with a variation in electrical conductivity of 1.65 mS/cm, showed high pozzolanic activity and was proved able to greatly improve the strength of NPC (Sugita et al., 1992). Both GP and SF were rich in amorphous silicon oxide why GP exerted an adverse effect to SF on the properties of cement? It is known that silica fume is a by-product condensed in gas in the production of silicon or silicon alloys. The SF used here consisted mainly of spherical glass particles with an average diameter of 1500 Å and had

a N_2 specific surface area (BET method) of 24.06 m^2/g, while the N_2 specific surface area of GP which had an average particle size as high as 40 μ m was only 0.85 m^2/g. So in our opinions the main reason for the difference between the pozzolanic reactivity of GP and SF is that they have much different fineness and surperficial state, both of which are directly related to the reactivity of any material. So one possible way of improving the strength of GP blended cement is to increase the fineness of GP. This supposition has been proved true by experiments. NGP, which was obtained by grinding GP for one more hour, did show a higher conductivity variation in 0.5% NaOH solution than that of GP (Table 3), and Table 4 indicates with its addition both the compressive and flexural strength of cement mortars are increased compared with those of GP blended cement and at 28 days they come close to those of OPC. Even though at a same mix proportion the flow value of NGP blended cement mortar was higher than that of OPC and GP blended cement the phenomenon of bleeding has not been found.

Influence of NaOH addition on the strength of NGP blended cement

The stimulating effect of NaOH on the activity of slag and fly ash and other pozzolans as well has been observed by many other researchers. In this experiment the same phenomenon also occurred, that is after the addition of 0.5% NaOH to NGP blended cement its strength was improved and even became greater than that of NPC. Table 5, 6 and Fig 3 (b, c and d) give the direct reasons for the strength increment as follows: 1) non-evaporable water in the pastes of NGP_3 or NGP_4 at 7d and 28d are both enhanced compared with those in NPC pastes and 2) pore

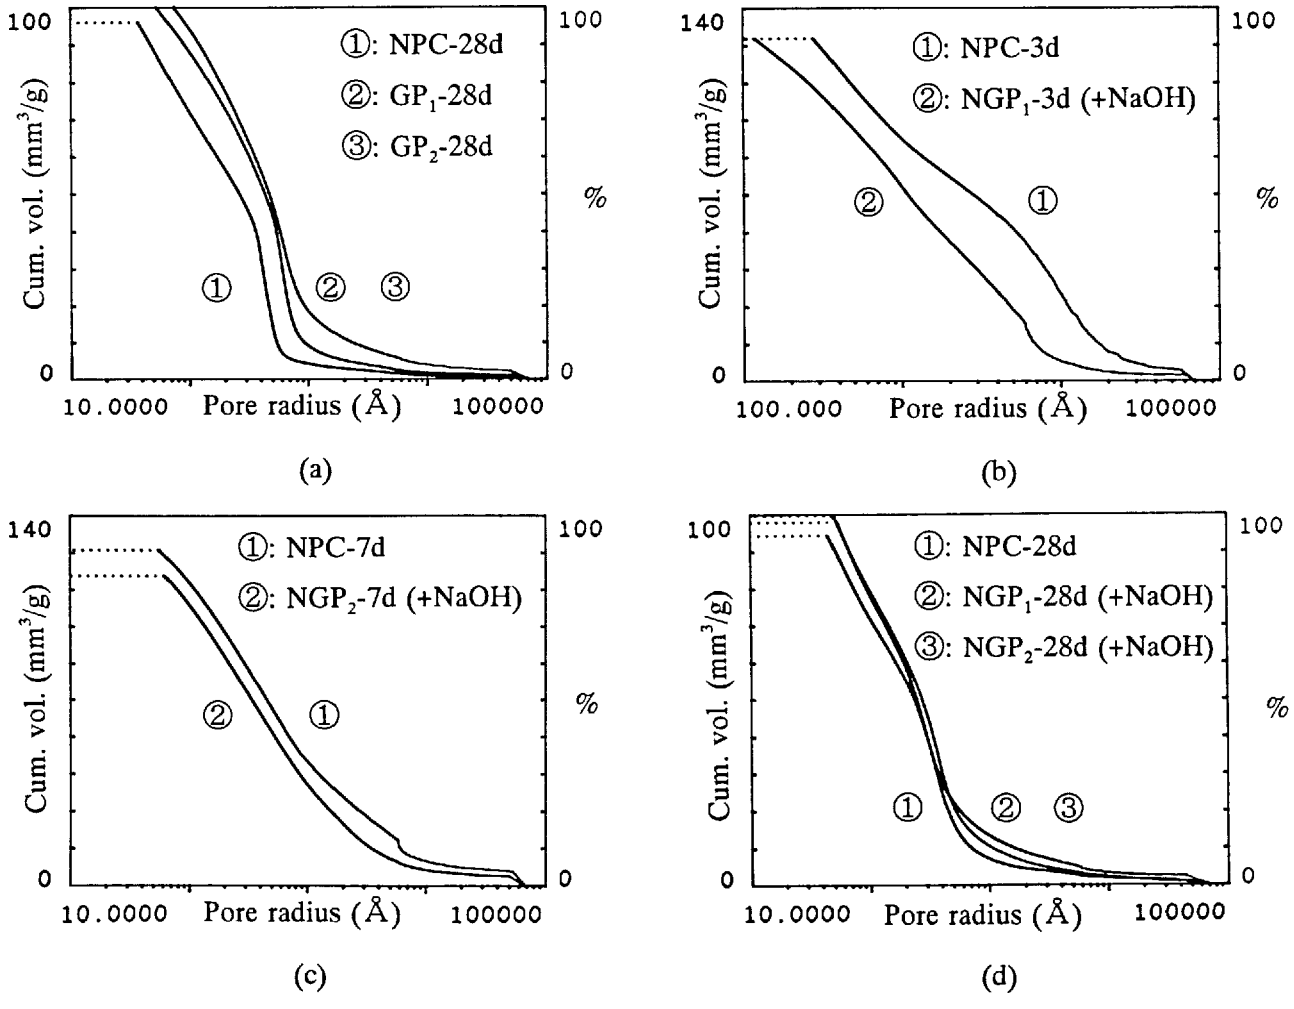

Figure 3 Pore size distribution of the tested mortars

size of their mortars at different ages are all reduced, in particular at 3d age the average pore radius of NGP_3 mortar shows a remarkable decrease in respect to that of NPC mortar.

Under the normal alkalinity produced by portland cement hydrates the potential activity possessed by glass powder could not be activated, therefore with the addition of either GP or NGP to OPC cement strength was gradually decreased. But in the presence of NaOH the dissolution of amorphous silica in the glass into the liquid phase of hydrating cement could be accelerated greatly, which possibly resulted from: 1) the activation of the surface of glass particles by the etching and damaging effect of alkali ions and 2) the early failure of Si-O network under the strong alkalinity circumstance produced by the added NaOH. As the result of this the silica in glass could react with $Ca(OH)_2$ in cement hydrates resulting in forming more C-S-H gel in the hydrates and accelerating the hydration of cement. So after adding NaOH to NGP blended cement the non-evaporable water in the hydrated pastes was enhanced and the pore structure of mortar was improved in favour of strength development, leading the strength of NGP blended cement to be increased finally.

In addition, Table 3 shows the change in electrical conductivity of the 0.5% NaOH solution added with glass powder was positive and increased with the fineness of glass powder, which also indicated that NaOH had a stimulating effect on the reactivity of glass powder.

Mechanism of the strength development of the cement blended with GP or NGP

Under a same hydration condition the strength of cement is closely related with the pore struture and hydration degree of its hydrate. Generally speaking the hydration degree of cement can be evaluated by the amount of non-evaporable water existing in its hydrate. Table 5 shows with the addition of GP to OPC the non-evaporable water in the paste, hydrated both for 7d and 28d, is increased. But from Table 6 and Fig 3-a it can be found the average pore radius and total cumulative pore volume of the mortars at 28d are adversely increased, especially the relative volume of mesopores (<500 Å in radius) is reduced by about 20% instead of the increment of the pores, ranged from 500 to 1000 Å in radius, by about 20%. Here the enlargement of pore size and total pore volume may plays the leading effect on the strength development, so cement strength is gradually decreased with the increased addition of GP.

NGP, with an average size of 8 μ m and a smooth surface, had a larger specific surface area than GP and NPC did. In both periods of specimen casting and cement hydration it probably played a dispersing role. With its addition to OPC instead of GP, at first compact specimens could be obtained by the increase of mortar flowability, in another aspect the hydration of cement was developed by improving the contact of cement particles with water. As the result of these the non-evaporable water in its paste was increased compared with that in GP cement paste, coherently the average pore radius and total pore volume of mortar were decreased, and particularly the volume proportion of the pores, greater than 500 Å in radius, was decreased evidently (Table 6), which certainly led the strength of NGP blended cement to be increased.

Now it is also difficult to say whether NGP has a high pozzolanicity or not as the strength of NGP blended cement is still inferior to that of OPC, there is also short of enough comparison data. But as far as the effect of NGP and GP on the properties of OPC it might be convinced that NGP is more active than GP. The influence of the fineness of glass powder on the hydration and strength properties of cement, and the effect of NaOH on the activity of glass powder should be investigated deeply in the future from the chemical or/and physical reaction of the finely ground glass with cement hydrates, and from the structure variation of both fresh and hardened cement paste and mortar after the addition of glass powder.

CONCLUSIONS

1. With the addition of glass powder to OPC the final setting of cement was prolonged and the strength was decreased.
2. The direct reason for the difference of pozzolanicity between silica fume and the glass powder used in this experiment was that they had much different specific surface areas. It was possible to improve the reactivity of glass powder by finely grinding it. The finer the glass powder, the higher the strength of glass powder blended cement. The increase of cement strength with the fineness of glass powder was mainly attributed to the improvement of cement hydration and the formation of compact structure of mortar.
3. After 0.5% NaOH was introduced to fine ground glass powder (NGP) blended cement its strength was further increased and became to greater than that of normal portland cement. The reason for this was the reactivity of NGP, which had a large specific surface area, was activated by the added NaOH and the pore size of mortar at different ages was decreased as well.

Petra PARMENTIER, K.U.Leuven, Belgium
Kris VANBELLE, K.U.Leuven, Belgium

ABSTRACT In concrete and in mortars, especially the weaker interfacial zones are determining the tensile and bending strength. To condense this interfacial zone, very fine ground sand, whose granularity is comparable to the one of cement, was added to the mix. By autoclaving the mortars, bending strength could be doubled from about 5 MPa to 10 MPa. The compositions were adjusted to a CaO/SiO_2 ratio of one, which is commonly known as the optimum, by adding silica fume. SEM- analysis showed that the interfacial zone of the autoclaved mortars became very dense and indicated reactivity of the ground sand.

INTRODUCTION

For several years the Reyntjens Laboratory of the Civil Engineering Department of K.U.Leuven, has been involved in a research program about cement tiles. In this research program knowledge was built up about non standard curing cycles, i.e. autoclaving and steaming. Recently we focussed on the production of a mortar for the fabrication of small building components. The bending strength of these mortars should increase up to 15 to 20 MPa, to be competitive with ceramics.

Since in concrete and mortars the weaker interfacial zones are determining the strength, ultra fine ground silica sand, known as quartz flour, showing a granularity comparable to the one of cement (Fig 1), was added to the mix. Comparisons were made between the fine mixes and the coarser mixes regarding mechanical strength and shrinkage. For the mechanical testing of bending strength and compressive strength and also for the measurement of the shrinkage, standard mortar prisms (40 mm x 40 mm x 160 mm) are made, the strength is determined according to NBN B12-208. The E-dyn is calculated measuring the velocity of the sound through the samples according to NBN B15-229. The last part of this paper deals with the SEM analysis of the mortars, especially of the interfacial zone.

MATERIALS AND METHODS

Composition

Fig 1 shows the sieve curves of the M300, M2 and M32 sands, with the OP cement class 42.5 R. All three are nearly pure silica sands (> 99% SiO_2), which makes them very homogeneous, strong and hard. The shape of the M300 is very angular and irregular since it is ground quartz, providing good mechanical anchoring in the cement paste. Because of the very fine aggregates, a superplasticizer is absolutely necessary to obtain workability with an acceptable W/C ratio. Rheobuild 716 is used, a superplasticiser from the sulfonated naphthalene family. Without this superplasticizer, the W/C ratio would be too high to obtain a strong mortar. The silica fumes were added as a slurry.

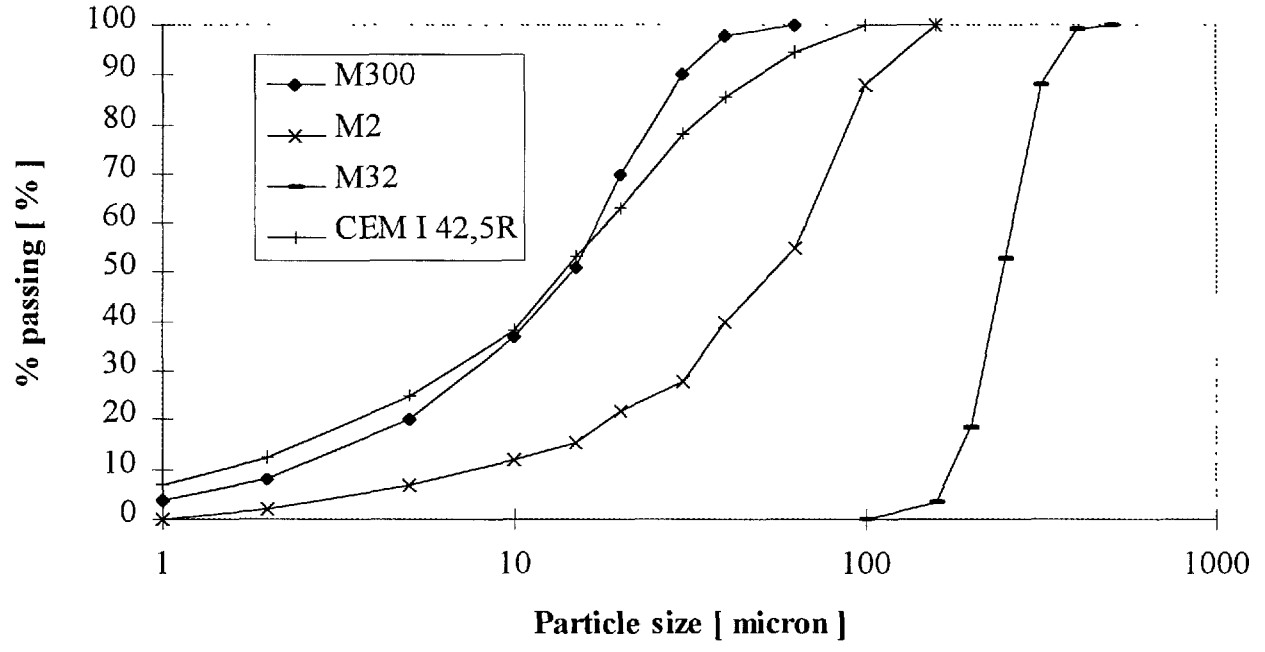

Figure 1 Sieve curves of the used sands and cement

The optimal mix was forced to meet the following requirements:
C/S ratio = 1, known as the optimum for steaming and autoclaving, taking into account the reactive silica and calcium in silica fume and cement
Cement/inert material = 1/3
Granularity of the mix fits close to the optimal granularity according to Bolomey's formula:
$y = A + (100 - A)\sqrt{d/D}$, where y = percentage passing, A = constant (= 10), d = sieve opening and D = max particle size.

The mix proportions for the above requirements are obtained with a least square solution for the granularity meeting the above boundary conditions:
M300 = 190 g, M2 = 1160 g, Silica Fume=142 g and CEM I 42.5 R = 308 g.

The initial W/C ratio for this mix to provide the necessary workability, equals 0.75. It will be explained further on how this W/C ratio was decreased by changing the mixing procedure without decreasing the workability. To be able to determine the influence of the amount of ultra fine ground sand, small variations in the content of M300 are used. In the same program several mixes containing the coarser M32 sand were tested, although these coarser mortar might not be suitable for certain building components.

Mixing procedure

In the first stage the mixing procedure of the Belgian code NBN B 12-108 was used. This means: mixing of silica fume slurry, water and superplasticiser for 5", adding the cement and mixing slowly for 30", adding the sand while slowly mixing in 30" and then switch to the high speed for another 30", stop mixing and scratch off the sides of the recipient, cover the recipient and wait for 1'30". Hereafter, mix for another 1' at high speed. The W/C ratio was adapted to 0.75 at which the flow of the mortar became 1.25.

Curing Cycles

In addition to the reference curing for 28 days at 60% R.H. and 20 °C, the mortars were steamed and autoclaved. Fig 2 shows both curing cycles. The temperature rising rate for the steaming is 18°C/hour, the isothermal period at 80°C lasts 20 hours. Thereafter the system is cooled by unforced heat exchange with the environment, since the autoclave, where the steaming and autoclaving are carried out, has no cooling abilities. From our experience, 180°C for the isothermal period is optimal for autoclaving. This isothermal period lasts only 5 hours, the rising rate to this temperature is 80°C/hour. The short isothermal period makes the curing cycle to obtain final strength very short, enabling a significantly shorter production period.

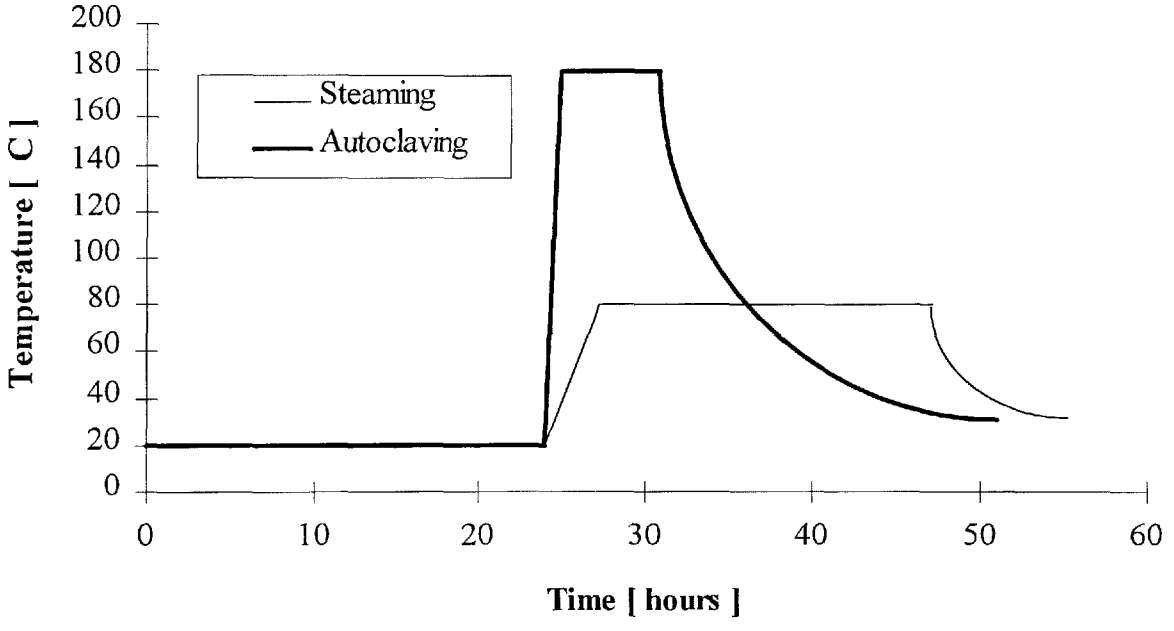

Figure 2 Temperature vs Time plot of autoclave and steam cycle

Initial Results

Although the W/C ratio was still too high, the results of the mechanical tests were promising, especially for the autoclaved samples. It appeared to be impossible to obtain the desired strength without autoclaving the mortars: steamed samples are significantly better than the reference cured ones concerning the shrinkage, but show no increased strength. The autoclaved samples perform very well for the mechanical strength and also for the final shrinkage. Table 1 lists the different mixes and their bending strength, compressive strength after 28 days and the E-dyn. The mortars are named after their composition: i.e. 36-64-00 means 36 % of the inert material = M300, 64 % = M2, 0 % = M32. As mentioned above, the W/C ratio of the mortars containing no M32 is 0.75, whereas the W/C for the mortars containing M32 is 0.65.

MODIFICATIONS AFTER FIRST RESULTS

Addition of SP in repeated doses decreases W/C ratio with 15 %.

The effect of the addition of ultra fine ground sand to increase the strength, is partly counteracted by the necessity to increase the W/C ratio up to 0.75. Adding more SP was no valid option, since the % of SP was already high (3.33 %). Addition in repeated doses of the same amount of SP could reduce the W/C ratio with 15 % down to 0.65 for the same workability. The mixing procedure to reduce the W/C ratio consists in the following steps: mixing the cement, the SF slurry and 3/4 of the water slowly for 1'; scratch off the recipient, mix for 1'30" at high speed; addition of half the

remaining water and half the SP, mixing for 3'; addition of the remaining water and SP and mixing for another 3'; add the sand in about 1'; after that, mix at high speed for 3' minutes. This mixing procedure takes about 15 minutes, but it seems to be the only way to reduce the W/C ratio with the materials and admixtures used.

The porosity after hardening will decrease because of the lower W/C ratio, the transition zone is still denser and so mechanical performance and drying shrinkage improves. **Table 2** lists the results of the mechanical tests for the mortars with the reduced W/C ratio.

Additional baking after autoclaving

Ohama (1991) indicated that additional baking immediately after autoclaving could increase the mechanical strength of the mortars. When the isothermal period of five hours is over, to pressure is released and the samples are put in a drying oven at 200°C and atmospheric pressure for 24 hours. Shrinkage was not checked and only one series of samples was produced this way. Since the average bending strength of these samples was up to 13.7 MPa and 14.7 MPa (Table 3), this curing procedure will be subject for investigation in a next program.

CORRELATION BETWEEN MECHANICAL STRENGTH AND E-dyn.

The research program provided a large amount of data from the different compositions and the different curing cycles. In this section, although somewhat separated from the rest of the paper, the correlation between the mechanical strength and the E-dyn is discussed. Fig 3 shows the correlation between the compressive strength and the E-dyn for each curing cycle. The correlation is good for the autoclaved samples, acceptable for the reference cured samples and poor for the steamed ones. The overall correlation of all samples, no matter what curing cycle, is 0.56. It is remarkable that the slopes of the steamed samples and the reference cured samples are nearly the same whereas the slope of the autoclaved sample is almost the double of that, probably caused by a different microstructure.

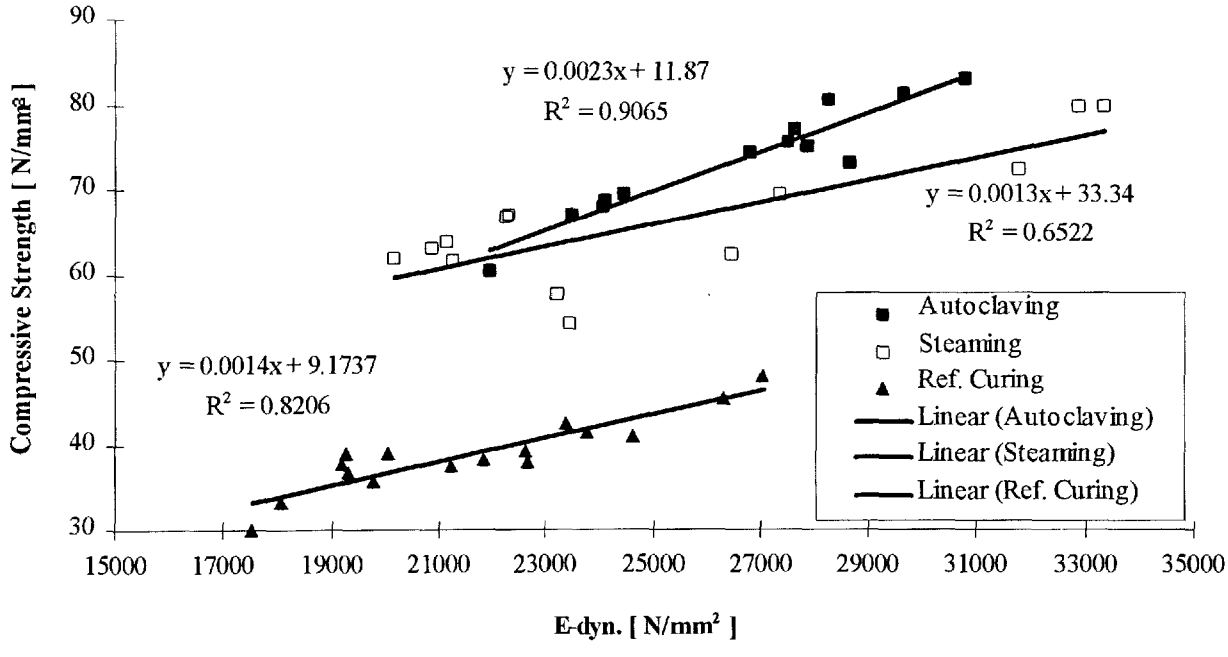

Figure 3 Correlation between compressive strength and E-dyn.

The correlation between the bending strength and the E-dyn. (Fig 4) is very poor. The overall correlation is only 0.19, meaning that there is no correlation at all. For the individual curing cycles, the correlation is a little better, but still very poor. It is worth investigating why the correlation forthe compressive strength is acceptable or even good and why this is not the case for the bending strength. Microcracking might be the reason for this fenomenon.

SCANNING ELECTRON MICROSCOPY FOR MICROSTRUCTURE ANALYSIS

General discussion of the SEM analysis

From the above results it is obvious that the production of high strength mortars without addition of polymers is impossible when reference or steam curing is applied. Only the autoclaved samples reach the desired strength and low shrinkage. SEM-analysis of the microstructure shows a big

difference in microstructure between reference cured and steamed samples on one hand and autoclaved samples on the other hand

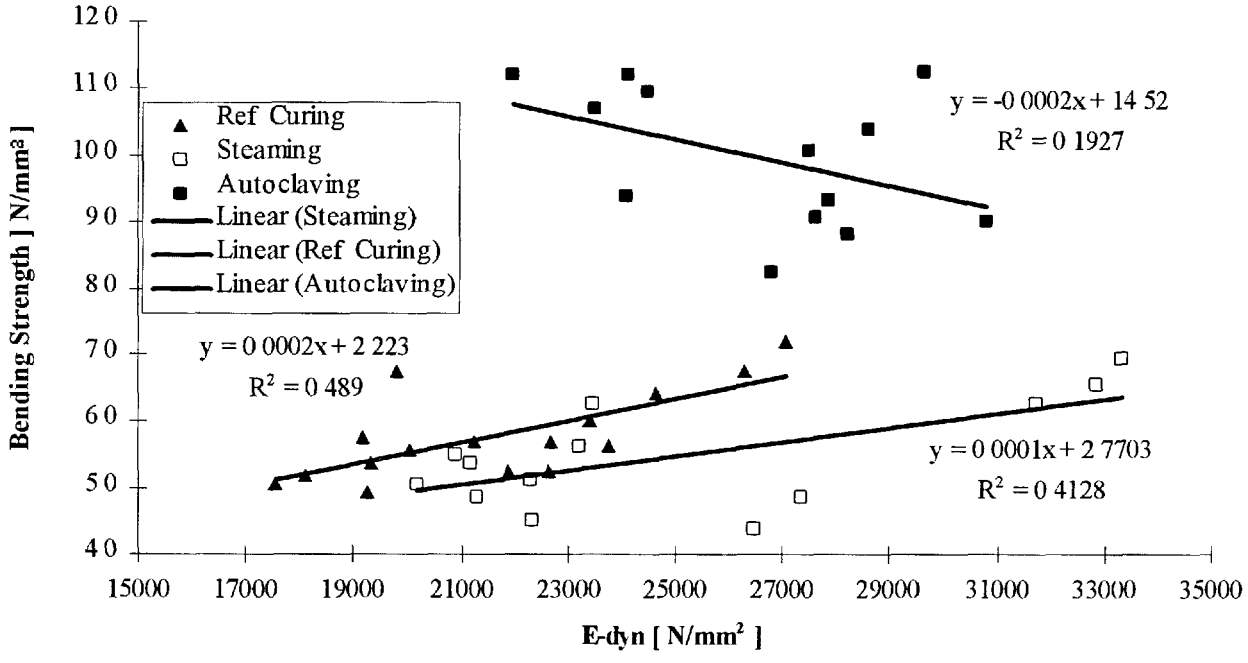

Figure 4 Correlation between bending strength and E-dyn

All reference samples show empty layers around sand grains (Fig 5) The big amount of water causes a thin water layer around every grain In case of a sand grain this water will not react and after evaporation an open layer between cement paste matrix and granulate is developed The same phenomenon can be seen in case of the reduced W/C ratio Although smaller there still exists an open space around each sand grain This interfacial zone will be the favorite place for cracks to develop due to shrinkage or mechanical load Cracks propagate around the sand grains via this interfacial zone (Fig 5) and do not pass through the grains

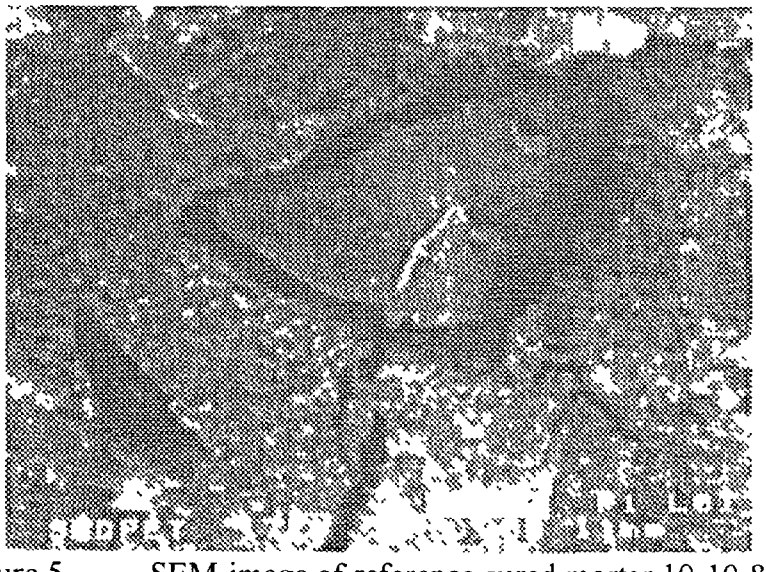

Figure 5 SEM-image of reference cured mortar 10-10-80

To analyze the hydration products, XRD-analysis is carried out, especially on the interfacial zone The reference cured samples have especially CH and $C_3S_2H_3$ crystals that have an open and amorphous structure With the addition of SF, the CH crystals are consumed by the reactive SiO_2 Autoclaved samples do not show any big CH-crystals that are well visible and detectable by XRD in case of the reference cured samples without silica fumes

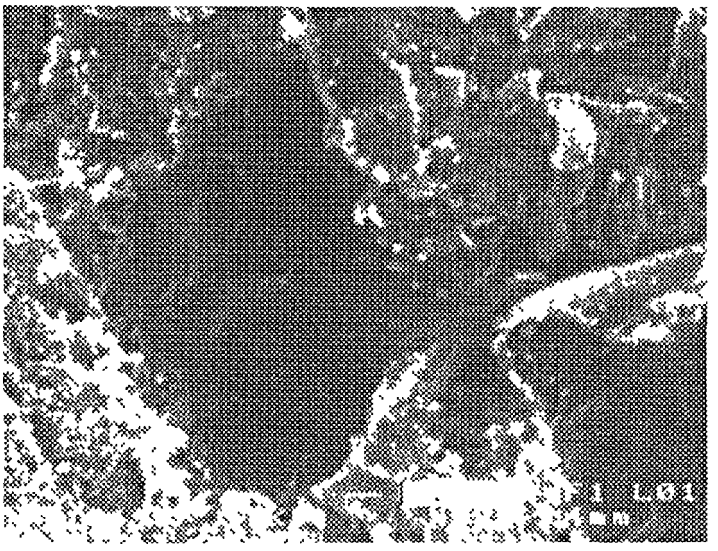

Figure 6 SEM-image of autoclaved mortar 10-30-60

Autoclaved samples (Fig 6) have a much denser structure The cement paste is much denser and the paste fits well to the sand grains. There is hardly any interfacial zone The open space between paste and grain has disappeared completely XRD-analysis indicates that the weak hydration products of the reference cured samples, CH and $C_3S_2H_3$, are less present and that the formation of tobermorite took place to form a dense and strong paste The hydration at higher temperature produces different hydration products and makes the interfacial zone more dense because of the high kinetic energy and hence the higher mobility of the hydration products Regularly cracks passing through the sand grains were found, whereas they passed through the transition zone in case of reference curing At last almost no cracks due to shrinkage occurred in the autoclaved samples, explaining the very low shrinkage values of the autoclaved samples

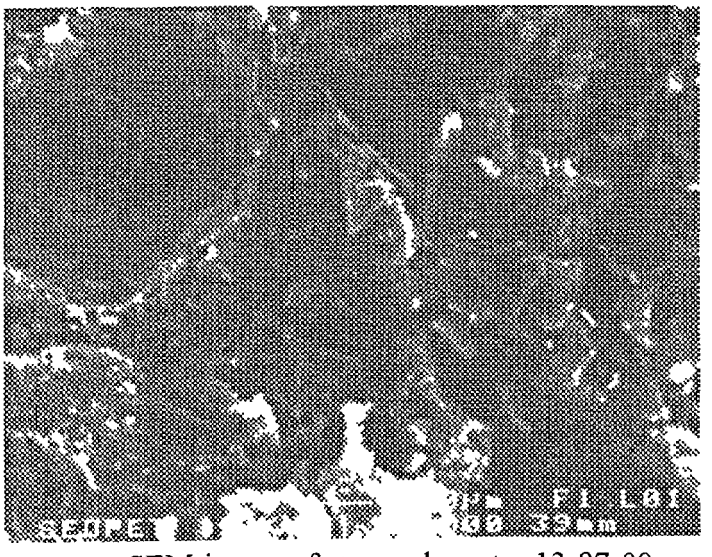

Figure 7 SEM-image of steamed mortar 13-87-00

The steamed samples (Fig. 7) are situated between the reference cured samples and the autoclaved samples. They show a finer microstructure, a denser transition zone than the reference cured samples, but do not perform as well as the autoclaved samples.

Was there any reaction between the ground quartz and the cement?

By analyzing the autoclaved samples with the fine ground quartz M300 a very good adhesion of the paste to the grains was detected. Cracks did not pass through the zone adjacent to the grain, but passed through the grain or passed by a little further away from the silica grains. We assume that the fine ground silica sand participates in the chemical reaction and is a little affected by the hydration forming an irregular surface where the hydration products are chemically and mechanically anchored at the grain. This makes the transition zone very strong and explains the good performance of this mortar. However, we were not able to find an increased amount of soluble SiO_2 in the mortar, to proove the assumption of reactive ground sand.

CONCLUSIONS

The aim of this research program was to check the possibilities of composing a high strength mortar for the production of prefabricated building components. When applying a cement mortar without polymer admixtures, autoclaving seems to be a necessity to obtain the desired 15 to 20 MPA bending strength. Actually, autoclaving doubles the mortars bending strength up to 11 MPa. Additional baking gives a bending strength up to 13.7 and 14.7 MPA.

The 28 days shrinkage values of the autoclaved mortars are very low with an average of 0.015 %. SEM-analysis provided the explanation for the good performances of the autoclaved mortars. A dense microstructure and different hydration products give a good adhesion between grains and paste. The low shrinkage and the absence of shrinkage cracks are confirmed by the SEM-analysis. XRD shows that the hydration products of the autoclaved samples are tobermorite. The amount of the weaker portlandite and $C_3S_2H_3$ have significantly decreased. Although it could not be confirmed by chemical analysis, there are some evidences that the very fine ground sand has taken part in the reaction. This can explain why the transition zone is strong enough to prevent cracks to pass through.

FRACTURE MECHANICS AND MICROSTRUCTURE OF BLENDED CEMENT PASTE

Tadahiro NISHIKAWA and Suketoshi ITO, Nagoya Institute of Technology, Nagoya, Japan

ABSTRACT Hardened cement pastes (HCP) were prepared with ordinary portland cement containing fine powder. Their fracture energy and strength were measured in relation to microstructure and hydrates formed. Effect of particle dispersion in cement matrix on the fracture mechanics was discussed with blended content, characteristics of powder, particle size or curing time. Bending strength for HCP was closely related to its fracture energy and critical crack length at fracture.

Key-words: Blended cement, CSH, Strength development, Waste material utilization

INTRODUCTION

Utilization of powder materials is necessary for enhancement of multiple functional properties for hardened cement paste(HCP). In particular, it is hoped to use waste materials or by-products in the development of chemical or mechanical properties. Blast furnace slag or silica fume is already used and results in lowering the heat evolution and developing the long-term strength. These inorganic materials are mainly prepared as a ground fine powder. Therefore, mechanical properties of blended HCP must be discussed in relation to the hydraulic properties and interaction of blended powder. Beaudoin et al (1985) already reviewed the factors influencing strength of porous cement systems, and took up the fracture energy together with the bending and compressive strength for mechanical properties. Fracture energy corresponds to the fracture toughness, which is an index of the resistance to crack propagation. Fracture energy is also important to evaluate the durability of HCP. However, it is difficult to measure the fracture energy for HCP or concrete, because of the preparation of large specimen having sharp and stable crack. Simultaneous development of bending strength and fracture toughness is required besides that of compressive strength. The HCP was prepared with ordinary portland cement containing fine non-reactive or reactive powder. The fracture mechanics and microstructure of blended HCP were investigated after curing at room temperature. The fracture energy of HCP was measured exactly by using compact tension specimen. Critical crack length, which controlled the strength and toughness for HCP, was estimated using Griffith (1920) equation. Optimum content or particle size of blended powder for durability and strength is also discussed.

METHODS AND MATERIALS

Mixing ratio and curing condition of HCP

The HCP was prepared with ordinary portland cement (Dai-ichi Cement Co.,Ltd.) and isotropic graphite (IG-11 Toyo Tanso Co.,Ltd.), good quality sand (Toyoura Standard Sand), glass waste or blast furnace slag (Dai-ich Cement Co.,Ltd.). Each additive powder, having Blaine of approx. 3000 ~ 4000 cm^2/g, average particle size of 20 μm, was replaced with cement up to 40 wt% (Nishikawa et al, 1995). For slag addition, gypsum of 5 wt% was added to promote hydration of slag. All components were added to distilled water containing a water reducer of 1 wt%, keeping a constant flow value in the water/solid ratio range of 0.28 to 0.32. The water/solid ratio increased with increase of additive powder content. Rectangular specimens 2x2x10 cm^3 were cast and cured in moist air above 1 month.

Hydrates and microstructure

Identification and quantitative analysis of hydrates were performed by XRD and DTA-TG analysis. The Ca/Si molar ratio of C-S-H was estimated by EDX after separation of hydrates with heavy liquid. The procedure for analysis (Nishikawa et al, 1994) is shown schematically in **Fig 1** . Microstructure of blended HCP was observed using SEM together with EDX near the propagated crack in HCP. The AFm and AFt phasaes were separated with ethylene glycol (Uchikawa et al, 1974).

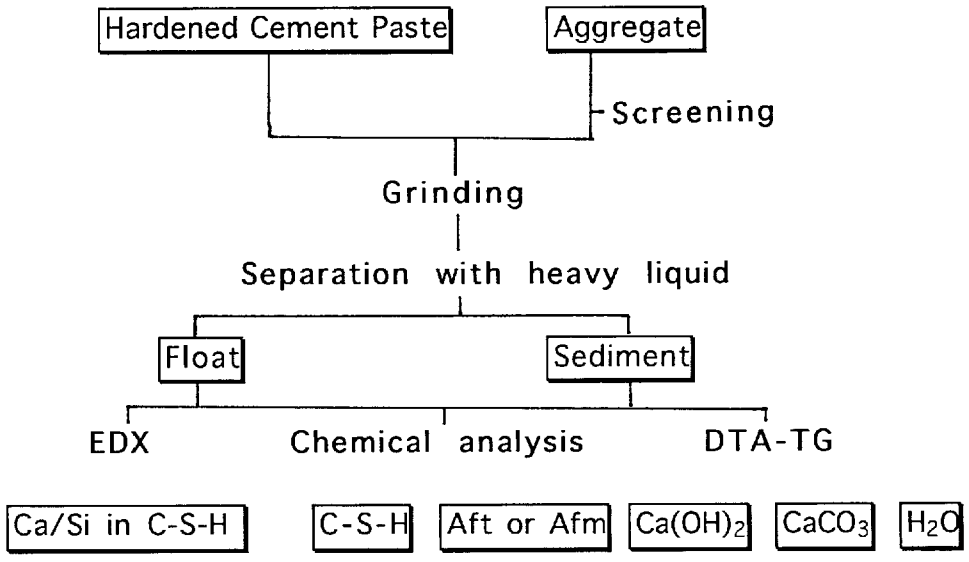

Figure 1 Procedure for analysis of C-S-H and other hydrates

Mechanical properties of HCP

Bending strength was estimated in the ten rectangular specimens by a three-point loading. The lower span width was 8 cm and cross head speed was 0.1 mm/min. Weibull's modulus of specimen for any mixed ratio was above 10, which showed a slight deviation in strength. The tensile strength of HCP was calculated from their bending strength and the Weibull's modulus (Davies, 1973). Compressive strength was measured at the contact area of 2x2 cm^2 after bending test. Ten specimens for each mixed ratio were used for the test. After the compressive test, cone-shaped scraps were observed at the upper and lower parts of specimens due to the fracture of only shear stress.

Fracture energy of HCP using compact tension specimen

A uniaxial tensile test was performed using compact tension specimen, which was cast according to ASTM E399/83, as shown in **Fig 2**. The crack mouth displacement (CMD) was measured by a strain gage on a bronze semicircular plate. The load-displacement (P-u) curve was measured by repetition of load and unload with a cross head speed 0.1 mm/min. The total fracture energy was calculated from the total area of P-u curve divided by double the

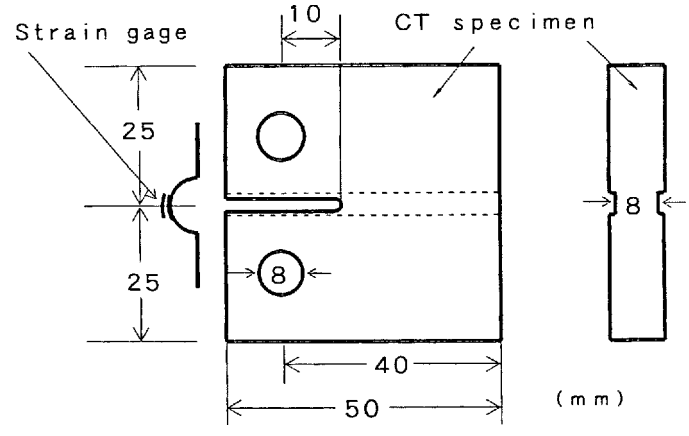

Figure 2 Compact tension specimen

fracture surface area. The obtained P-u curve showed the quasi-brittle fracture. Therefore, elastic fracture energy was obtained by shifting the irreversible residual displacement to the origin. The difference of above two kind of energy corresponds to the plastic energy dissipation (Sakai et al, 1986), which shows the plastic behavior of HCP.

RESULTS AND DISCUSSION

Formed hydrates and microstructure

In HCP subjected to load, the fracture origin and propagated cracks were observed mainly in the formed hydrates, calcium hydroxide and C-S-H. A few cracks propagated around unreacted mixed powder during early hydration. Therefore, fracture behavior mainly depended on the hydrates of HCP. The Ca/Si molar ratio of C-S-H in blended HCP, which was cured for 3 months, are shown in **Fig 3**. The C-S-H formed with unreacted graphite was approximately 2 to 3, which was normal ratio and similar to that in monolithic HCP. The amount of calcium hydroxide was in proportion to the initial amount of ordinary portland cement. Therefore, graphite powder did not participate in the hydration of cement or the formation of the hydrates. In the HCP with glass powder, the decrease in Ca/Si molar ratio was observed due to the sodium and soluble silicate ions dissolved from glass. A similar low-lime C-S-H was observed in HCP mixed with blast furnace slag or alkaline solution (Suzuki et al, 1986). The formation of calcium carbonate was also detected, which was explained by an increase in pH in the pore solution due to the alkaline ions dissolved. Glass or slag particles were not remarkably reduced in size even after 6 months, as shown in **Fig 4**.

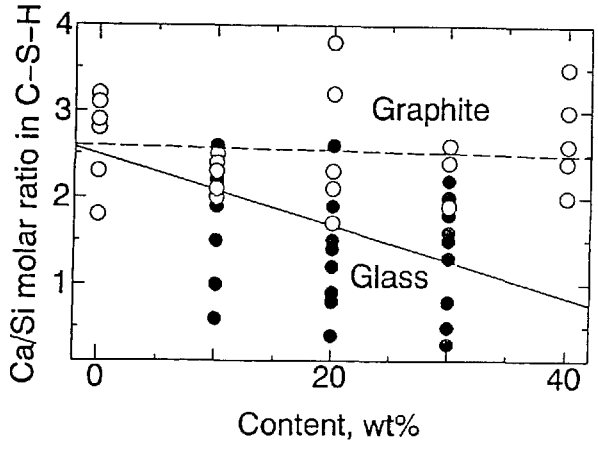

Figure 3 Ca/Si molar ratio of formed C-S-H

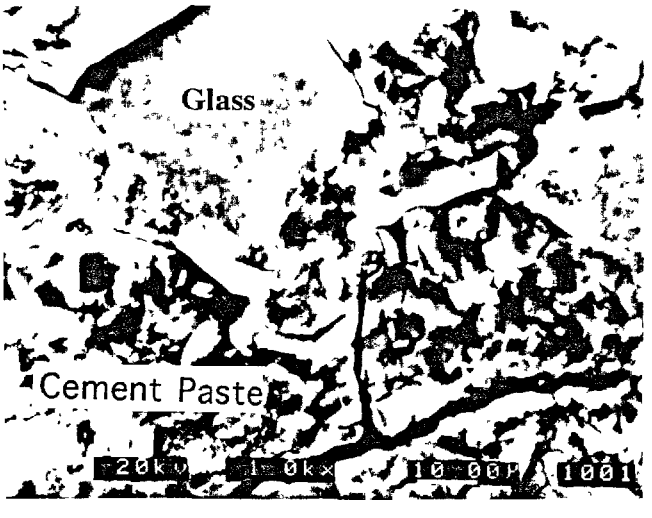

Figure 4 SEM photograph of HCP with glass cured for 6 months

Effect of mixed content on fracture behavior

Resistance to the propagation of a crack for cement based materials consists in a stress relaxation at the front of the crack and a crack shielding effect behind the crack tip, proposed by Cotterell et al (1987) and Jennings (1988). In this experiment, microcracks, which were mainly capillary pores in the cement paste, were observed in front of the propagated crack. The unhydrated cement and addition particles brought a refraction in the crack or grain bridging. This behavior was directly reflected in the fracture energy. Total fracture energy γ_{WOF}, elastic fracture energy γ_e and plastic energy dissipation γ_p were calculated from the P-u curves and shown schematically in **Fig 5** for blended content. Graphite does not react

with cement paste, only the dispersion effect of powder in cement paste can be discussed. In the HCP containing graphite, the hydration mechanism and Ca/Si molar ratio in C-S-H were similar to those for the monolithic HCP. The elastic fracture energy γ_e, according to the linear fracture mechanics, increased with blended content and depended solely on the crack refraction around the graphite particles (Hillemeier et al, 1977). However, bending and compressive strength were not developed by blending graphite. It was mainly due to the weak cementitious property between graphite particles and cement hydrates. The dispersion effect of the unreacted particles was not exhibited on the instantaneous fracture, that was bending or compressive strength. However, this effect increased slightly the fracture toughness, considering large total fracture energy.

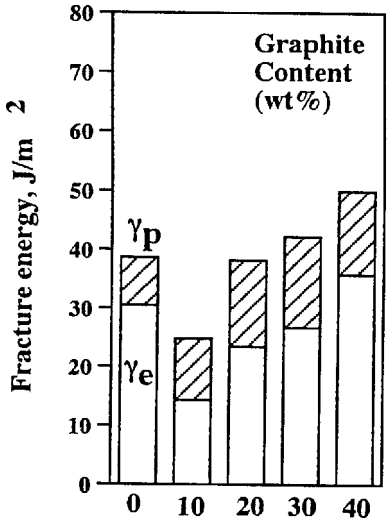

Figure 5 Fracture energy for HCP with graphite powder

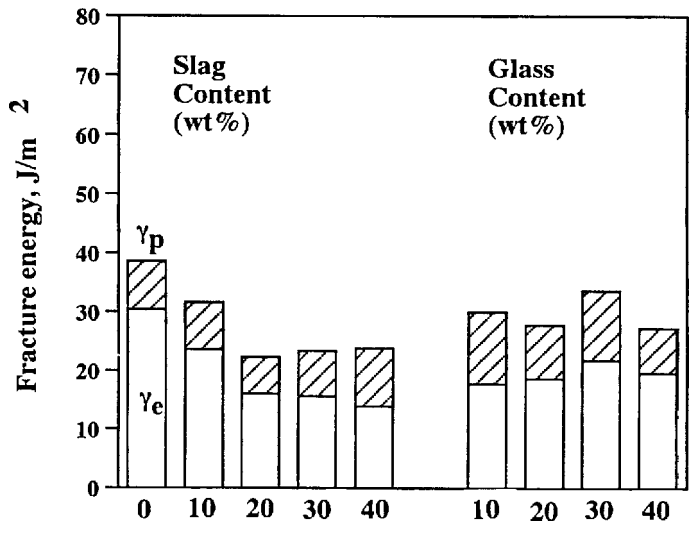

Figure 6 Fracture enegy for HCP with glass or slag powder

Effect of kind of powder on fracture behavior

Fracture energy of HCP containing reactive powder, glass powder or blast furnace slag, are shown in **Fig 6**. In the HCP containing glass powder, which reacted with cement in the same manner as blast furnace slag, a low γ_e was observed independent of mixed content. The lower Ca/Si molar ratio in C-S-H resulted in changes of the morphology and microstructure of C-S-H. Suzuki et al (1988) synthesized the various Ca/Si molar ratio of C-S-H by sol-gel method. The low-lime C-S-H had ill-crystalline phase and spherical shape, similar to silica gel. These chemical and crystalline change of C-S-H decreased the resistance to crack propagation. The friction among projected particles and grain bridging at the fracture surface are also important in discussing fracture behavior in HCP. High plastic energy dissipation γ_p was observed independent of kind of addition. Large unreacted particles remaining in HCP, independent of kind of powder, promote resistance to crack propagation to exhibit plastic behavior after the maximum load point in the P-u curve. Higher bending and compressive strength but lower fracture toughness were observed in HCP containing reactive powder due to the cementitious strength than those in HCP containing non-reactive powder. The formation of dense hydrates and a few large cracks at interface of powder can not disperse or consume the fracture energy of crack propagation at the crack tip.

Effect of curing time on fracture behavior

Fracture energy in HCP containing glass powder with curing time is shown in **Fig 7**. Elastic fracture energy γ_e in HCP containing glass powder showed double as much as that in monolithic HCP cured for1 month. The γ_e in HCP containing glass powder decreased with curing time, but that in monolithic HCP increased. The Ca/Si molar ratio in HCP did not change remarkably independent of curing time (Nishikawa et al, 1994). The formation of lower Ca/Si molar ratio C-S-H or calcium hydroxide with different morphology, and change of cement strength with time must be considered. However, total fracture energy did not decrease due to the increase of plastic energy dissipation. Therefore, fracture toughness did not drastically decrease with curing time, maintaining the high bending and compressive strength.

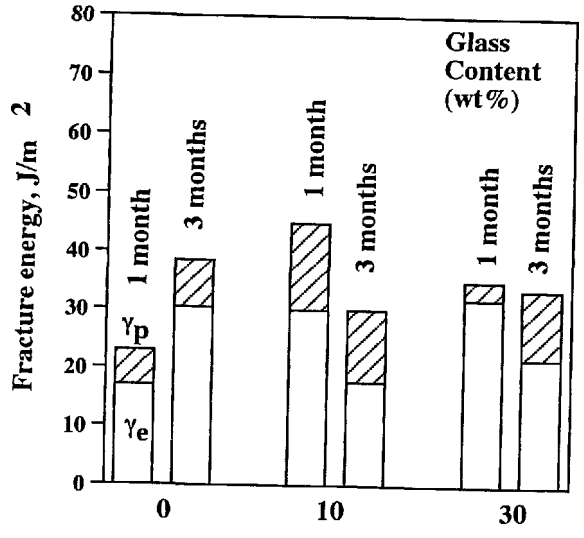

Figure 7 Fracture energy for blended HCP with curing time

Effect of particle size on fracture behavior

Fracture enegy in HCP containing large glass powder and sand (average particle size of 200 μm) after curing of 1 or 6 months were shown in **Fig 8**. Large particles in the cement matrix increased the fracture energy or fracture toughness at early hydration, but decreased the bending strength. In particular, thios increase of fracture energy was observed for HCP with

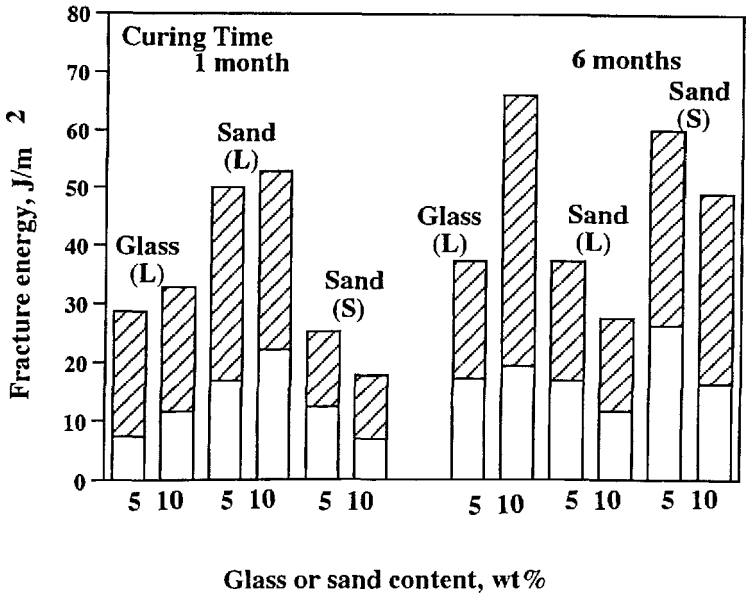

Figure 8 Fracture energy for blended HCP with particle size of powder

good quality sand. The large critical crack might grow along the interface between particle and cement paste. These cracks obstruct the propagation of main crack. After enough curing time, bending strength increased with slight decrease of fracture energy. While, for the HCP with reactive glass powder, this fracture behavior was not remarkable. Hydration of cement was promoted by the alkaline ions dissolved. The crack length grown along the interface might be small. These cracks do not become fracture origin.

Relationship between mechanical properties and fracture energy

For discussing the mechanical properties of HCP by fracture mechanics, tensile strength has been employed. Calculated tensile strength in HCP is shown in **Fig 9**, with their fracture energy. In Fig 9, the experimental data in HCP cured for 1 months are shown as square marks. Circle marks correspond to the HCP cured above 3 months. Closed and opened marks are the HCP with reactive powder and with non-reactive powder, respectively.

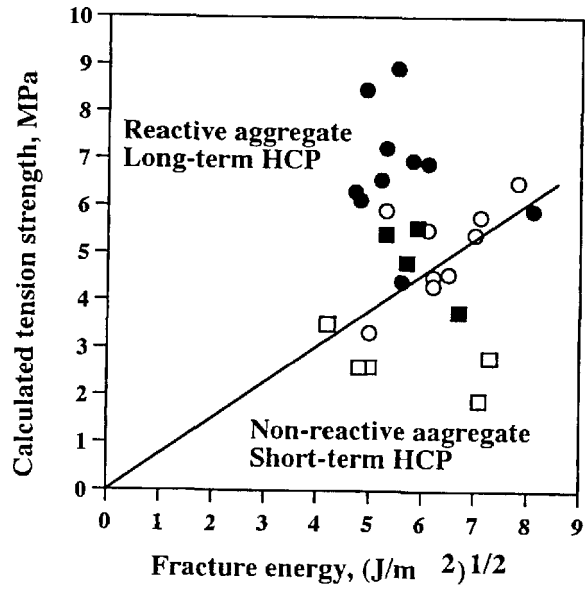

Figure 9 Calculated tensile strength for HCP with their fracture energy

Fracture in bending test is classified to mode I by fracture mechanics. Therefore, the tensile strength calculated from bending strength and fracture energy are formularized as Griffith equation, $\sigma_f=(\gamma_{WOF}E/\pi c)^{1/2}$. Here, σ_f is fracture strength, which corresponded to calculated tensile strength in this experiment. The E is Young's modulus and c is critical crack length at fracture. Fracturetoughness was in propotion to $(\gamma_{WOF})^{1/2}$. The linear relationship between σ_f and $(\gamma_{WOF})^{1/2}$ was observed in HCP containing graphite or in monolithic HCP. The similar relationship was also observed in HCP, which contained reactive powder cured for 1 month. If Young's modulus of HCP is constant independent of blended content and curing time (Glucklich et al., 1975), the slope in Fig 9 shows the critical crack length at fracture. The gentle slope corresponds to the large crack length. In particular, the existence of large crack was estimated for the HCP with large sand, curing for only 1 month. Large initial crack grew unstable along the interface between large sand particle and cement paste, which was proposed by Wittmann (1981). Adsorbed water on powder might also accelerate the peeling of hydrates. The critical crack length became small with curing time for HCP containing reactive powder. For HCP cured long time, the microcracks or capillary pore in C-S-H is considered to be fracture origin instead of interface of powder. Chemical and morphological difference of C-S-H formed in HCP has effect on the size of microcrack, which will become fracture origin. Compressive strength was important as structural materials. However, fracture in compressive test is classified to mode II (Davies,1987). Compressive strength could not be estimated from

the fracture energy, but a slight difference related to reactive and non-reactive powder was observed. For this fracture, frictional coefficient at fracture surface was considered besides the shear stress. The former may have relation to size and cementitious properties of powder.

CONCLUSIONS

Various powder materials have been blended up to 40 wt%, to improve its mechanical and chemical properties of hardened cement pastes (HCP). Fracture energy and bending strength of HCP were measured and discussed in relation to microstructure and hydrates formed. An improvement in fracture toughness and plastic fracture behavior were observed for HCP having non-reacted powder. Reactive powder, blastfurnace slag or glass waste, decreased the Ca/Si molar ratio of C-S-H to decrease fracture toughness. The critical crack length at fracture in HCP could be estimated from their bending strength and fracture energy.

RESEARCH ON A NEW TYPE OF COMPOSITE CEMENT

ZHANG Xiong, WU Keru, HAN Jihong, State Key Laboratory of Concrete Materials Research, Tongji University, Shanghai, China

ABSTRACT The paper deals with the preparing technique of a new type of low energy -consumption composite cement by mixing fly ash and blastfurnance slag with composite activator and then grinding. The physical and mechanical properties of the composite cement meet the requirements of 525# quality grading (GB). Low hydration heat, micro -expansion and high long-term strength are its virtues . Concrete with high strength and excellent durability can be prepared by using it.

Key-words : Composite cement , Blast-furnace slag , Fly ash

INTRODUCTION

Fly ash and slag are different kinds of active blends with different hydration mechanism and rate. Compared with those prepared by single blend, the cementing materials prepared by mixing fly ash and slag with suitable activation exhibits "blends composite effect". Thus the composite cement with both fly ash and slag can be prepared.

EXPERIMENTS

The chemical composition of fly ash , slag and composite activator are listed in Table 1. The samples' fineness is controlled in the range of 360-380 m^2/kg and the proportion of samples Xn (n=0, 1, 2 . . 8) are shown in Table 2.

Table 1 Chemical Compositions of Raw Materials

Raw materials	Chemical composition (%)						
	Fe_2O_3	Al_2O_3	CaO	MgO	SiO_2	SO_3	Loss
Fly ash	6.24	30.36	3.25	0.16	47.07	—	8.65
Blastfunace slag	1.96	13.8	40.11	8.02	32.04	—	—
Composite activator	2.10	13.34	21.74	0.63	32.20	26.23	7.49

The physical and mechanical properties of the composite cement X4 such as compressive strength, setting time, soundness, fineness and expansion are tested. Strength, freeze resistance and carbonization of concrete prepared by using X4 are determined. Mix propotion of the concrete is as follows :

Cement (X4) :	Sand (Mx=2.8):	Gravel (5-25mm):	Water	Slump (cm)
1	1.46	2.97	0.48	13

Hydration heat evolution rate of X4 is measured by hydration heat of calorimeter. The hydration products and morphology are observed by SEM, XRD and DTA etc. The hydration degree of various ages is measured by water of combination test.

Table 2 Proportion and strength of samples

sample	Proportion (%)			Compresive strength (MPa)		
	Slag	Fly ash	Activator	3d	7d	28d
X0	75	0	25	22.6	33.3	56.8
X1	60	15	25	18.5	31.5	56.0
X3	45	30	25	18.1	31.1	66.0
X4	40	35	25	19.7	33.9	67.2
X5	30	45	25	17.0	24.0	60.7
X6	25	50	25	15.7	21.4	55.0
X7	15	60	25	16.0	22.4	56.o
X8	0	70	25	12.4	12.8	25.0

RESULTS AND DISCUSSIONS

The composite effect of fly ash and slag

The proportion between fly ash and slag is selected as main technical parameters of the composite cement. Table 2 shows the compressive strengthes of 3d, 7d and 28d of samples Xn (n=0, 1, 2. . 8) in different proportion of fly ash and slag. It indicates that the hydraulic activity of slag is higher than that of fly ash. Cement with single blend of fly ash has lower compressive strength at all ages. But with the increasing of slag content the strengthes of various ages are increased obviously. When the ratio between slag and fly ash (slag / fly ash) is in 1- 2. 5 the compressive strength of the composite cement reaches maximum . If the ratio exceeds 1% till only single slag the strengths of 3d and 7d changes a little but those of 28d drop markedly and generally 10 MPa lower than those in the optimum range. Thus the optimum proportion between fly ash and slag of composite cement is in the range of 1-2. 5. Within this range there exists a "blends composite effect".

Properties of the Cement and Concrete

The physical and mechanical properties of composite cement X4 are listed in Tables 3 and 4. Table 3 shows that composite cement possesses fine physical and mechanical properties . The strength develops slowly in early period but later increases rapidly and keeps on developing in long-term. Compared with 28d strength of 69.4 MPa , 3d, 7d and 14d separately reach to 13.4% 38.8% and 70.5% . Meanwhile flexural strength is also high with 9.9 MPa of 28d and expansive property is small and stable with expansion ratio of 28d nearly the same as that of 90d (Table 4). The physical and mechanical properties of concrete made from the composite cement are tested and showed in Tables 5 and 6.

Table 3 Physical and Mechanical Properties of the Composite Cement

Soundness Setting time (Ini. / Fin. Consistancy (%)	qualified 1: 31 / 3: 53 28.25					
Strength (MPa)	3d	7d	14d	21d	28d	180d
Flexural strength Compressive strength	1.6 9.3	4.7 26.9	6.9 48.9	8.4 57.0	9.9 69.4	10.4 74.5

Table 4 . Data of Expansion Ratio of Composite Cement

Sample	Expansion ratio (%)							Remark
X4	1d	2d	4d	7d	14d	28d	90d	specimen size 3x3x28 cm cement/sand=1/3
	0.014	0.039	0.046	0.042	0.046	0.046	0.045	

Table 5 Mechanical Properties of Concrete made from the Composite Cement

Compressive strength (MPa)	53.4
Tension splitting strength (MPa)	3.88
Flexural strength (MPa):	6.62

Table 6 Durability of the Concrete

Sample	Freezing resistance		Depth of carbonization (mm)				Impermeability
	loss of wt	Loss of Rc	3d	7d	14d	28d	(MPa)
X4	1.5 %	14.3 %	4.5	6.0	6.7	7.5	> 1.1

It can be seen that the composite cement can be used to prepare concrete with stength higher than 50 MPa and with all other mechnical properties nearly the same as the ordinary concrete of equivalent strength grading (Table 5). In the eye of durability (Table 5), the concrete with composite cement has satisfactory impermeability and freezing resistance but lower carbonization resistance, which can also meet the demands of construction engineering.

Hydration of Composite Cement

The curve of hydration heat evolution of the composite cement demonstrates that the

early hydration rate of composite cement is relatively low and the hydration heat at 1d is 144.6 J/g. The result of bond water (Table 7) shows that hydration degree of the cement of 3d is only 29.3% but that of 7d increases rapidly to 45.8% and that of 28d comes to 48.9% accounting for its strength development trend above-mentioned .

Table 7 Data of Bond Water and Hydration Degree

Sample	Bond water (%)					Hydration degree (%)			
	1d	3d	7d	28d	fully hydrated	1d	3d	7d	28d
X4	2.9	4.6	7.2	7.7	15.7	18.7	29.3	45.8	48.9

XRD diagrams of the composite cement at various ages indicate that hydration products in early period are AFt and $Al(OH)_3$. No characteristic peak of $Ca(OH)_2$ could be found in in XRD diagrams and DTA curve. The hydration process of the composite cement could be summarized as follows : shortly after composite cement mixed with water, Ca^{2+} dissolves quickly from the composite activator into water, forming the base liquid phase, and then dissolve SO_4^{2-}, Al^{3+} and Si^{4+} in proper order . When the concentrations of Si^{4+}, Al^{3+} and Ca^{2+} exceed the solubility of AFt, needle like AFt are deposited from the liquid phase. Then slag and fly ash commence hydrating in the base medium and sulphate, forming C-S-H gel and AFt. In the initial hydration process, the hydration activity of slag is much bigger than fly ash and the essential Ca^{2+} for forming AFT and C-S-H are offered mainly by slag but not by fly ash or activator, which contain fewer Ca^{2+}, so the early hydration products are mainly formed by slag while fly ash takes only micro-filler effect. Because of the lower hydration degree of slag , the amount of AFt and C-S-H are limited and the early strength is low. On the other hand, with more Al^{3+} and Si^{4-} dissolving from activitor into liquid phase , more $Al(OH)_3$ gel of high activity can be formed. Because of filling in the frame of cement paste, they can with the help of dissolving SO_4^{2-} stimulate the release of Ca^{2+} from slag, decrease the stability of slag glass network and improve the hydration degree of slag up to 45% at 7d. Moreover the hydration activity of fly ash is also increased, its hydration products intensify the density of the interface of fly ash and cement paste, leading to the densification of cement paste. So the later strength of composite cement is increased remarkablly.

CONCLUSIONS

1. The composite cements of GB525# grade could be prepared by mixing fly ash and slag with composite activator, which have fine physical and mechanical properties. The main technical parameter is slag/fly ash = 1 - 2.5 .

2. The composite cement has the properties of low hydration heat, micro- expansion and high later strength, Concrete with high strength and excellent durability is able to be prepared by using the composite cement. The results of microstructure experiments show that the main hydration products are AFt, hydrated calcium alminate, C- S- H and $Al(OH)_3$ gels.

UTILIZATION OF SEWAGE SLUDGE AS A RAW MATERIAL FOR PRODUCTION OF POZZOLANIC MATERIAL

Gilson Morales, PhD
Civil Engineer and Professor
STATE UNIVERSITY OF LONDRINA
University Campus - CTU - Department of Civil Construction
86051-990 LONDRINA / PARANÁ / BRAZIL

ABSTRACT

The sewage sludge is a residue deriving from the aerobic or anaerobic digestion in the purification plants. The utilization of this sewage sludge is restricted and, in many cities, it's simply cast on the solo as a sanitary embankment or as an organic fertilizer for agriculture. Meantime, these utilizations aren't very interesting for large cities because the large distances to the utilization place. In function of its chemical composition it's advisable to study the possibility of its utilization for production of pozzolanic material through the calcination process.

First of all, the sewage sludge needs to be dried, by centrifugation or other similar mechanism, then it's calcined under oxidant atmosphere about 750°C. After the calcination the ashes are grounded until the specific surface area about 800 m^2/kg. Their pozzolanic activity is determined by consumption of lime measured in milligrame for gramme of pozzolanic material.

It was verified that the sewage sludge presents pozzolanic activity when calcined above 500°C. The tests show that the ideal temperature for calcination is about 750°C and that garantees the adequate treatment of the present montmorillonite in this material, avoiding the possibility of expansion in the concrete. The sewage sludge presents pics of quartz and absence of diffuse band in the X-Ray Diagram, before and after the calcination. It shows the inexistence of the glass-phase or amorphous silica in this material. It shows that the pozzolanic activity is due of the montmorillonite presence. The ratios of ashes additionned in the concrete were: 15, 25 and 35% by weight of cement Portland and it was verified significant results on the compressive strenght and on the resistance of chlorides and sulphates attack. The fixation rate of lime by Modified Capelle Essay was about 600 mg/g of pozzolanic material showing an excellent performance of these ashes like pozzolana.

1. INTRODUCTION

The purification of the sewage sludge in the purification plants produces a lot of volum of solid residue which is simply cast on the peripheric cities places. This shows that it's urgent to meet a solution for this problem and we think that we have an excellent raw material for production of pozzolanic material in function of the chemical composition of the sewage sludge.

2. GENERAL CONSIDERATIONS

2.1. Calcination Process

The mineral clays need to be calcinated for to present satisfactories pozzolanic properties. However, the experience has showed that some calcinated clays present an excellent performance like pozzolanic materials.

2.2. Grinding Process

The specific surface area is very important for a good performance of the pozzolanic materials because they offer an appropriate place for the precipitation of the hydrated compounds of the paste of cement.

In first moment the specific surface area is fundamental to the pozzolanic activity and after others factors, like the presence of reactive silica and aluminium.

2.3. Pozzolanic Activity

With respect to the performance of the ashes like pozzolanic materials, the experience shows that its small particles present the maximization of the appropriate places for the precipitation of the hydrated compounds of the paste.
The development of the hydration of the cement results in the augmentation of the C - S - H and as a result of the presence of the pozzolanic materials, between others results, is the elevation of the mechanic resistance.

As more lime will be liberate for the paste, more C - S - H will be maden. Summarizing these comments, this consumption of lime by the pozzolanic materials characterize their pozzolanic activity.

2.4. The Sewage Sludge

The sewage sludge is a solid residue from the purification process of the sanitary sewer after the separation of the solid and liquid phases and still after the aerobic or anaerobic digestion of the solid fraction.

3. PRODUCTION METHODOLOGY

3.1. Drying Process

The usual drying process utilized in Brazil is the deposition of the sewage sludge in plane surfaces denominade "drying beds" whish have been an option that demand a minimum of investment costs. The "drying bed" is a very large basin with a small profoundity and having a permeable surface. The sewage sludge humidity is generally about 70 to 75%. It shows that is possible to calcine the sewage sludge immediately after its remotion of the "drying bed".

3.2 Thermic Activation

The sewage sludge is calcined under oxidant atmosphere and in temperature about 750°C because this temperature possibilitates the occurrence of the structural disorder in the crystalline structure of the material calcined. It was verified that the loss ignition is constant up to 600°C.
The samples were calcined staying in the furnace about three differents residence times. The effect of the residence time about the reduction of the original mass is showed in Table 1.

TEMPERATURE OF CALCINATION	MASS REDUCTION (%) RESIDENCE TIME (minutes)		
(°C)	30	60	90
600	17,62	20,31	20,55
650	19,18	21,39	23,56
680	17,79	21,60	22,43
730	18,48	19,18	18,95
790	20,09	21,61	21,68
980	23,21	22,34	22,01

TABLE 1 . Effect of the residence time in the reduction of the original mass of sewage sludge.

3.3. Mechanic Activation

The mechanic activation of the calcined sewage sludge by grinding promoves the mineralogical species separation and the elevation of the specific surface area about 800 m^2/kg.
The grinding systems more utilized were the ball mills and the disc mills.

4. SEWAGE SLUDGE ASHES

4.1. Physical and Chemical Analysis

The ashes presented specific mass by Blaine Test about 2,78 g/cm^3 and aparent mass about 0,75 g/cm^3. Table 2 shows the results of the chemical analysis of the ashes obtained from the calcination of the sewage sludge.

COMPOUNDS	PRESENCE IN %
SiO_2	41,20
Fe_2O_3	15,00
Al_2O_3	22,70
CaO	4,92
MgO	2,42
Na_2O	0,05
K_2O	0,28
SO_3	0,99
S^{2-}	0,35
Loss ignition	12,50
Equivalent alcaline (in Na_2O) (*)	0,23

(*) = % Na_2O + 0,658 (% K_2O)

TABLE 2. Chemical Analysis of the Ashes from Calcined Sewage Sludge

4.2. Diferential Thermic Analysis (DTA)

It was verified a very big endothermic peak at about 110°C possibily from the dehydration of the sodic montmorillonite. The DTA Diagram shows an endothermic peak at about 150°C from the dehydration. It was verified an exothermic peak at about 250 to 300°C possibily from the combustion of the organic material. It was verified an exothermic peak at about 300°C from the occurrence of organic material. At about 480°C it was verified an exothermic peak from the presence of sulfid or carbon. The occurrence of endothermic peaks at about 500 and 750°C amplify the possibility of the presence of montmorillonite. At about 550°C it was verified an endothermic peak from the loss of hydroxiles of the smectite. It was refused the possibilitiy of the occurrence of caulinite because in the Diagram of X-Ray Diffraction it was absent its maximum peak, (d=1,48). At about 750°C it was verified an exothermic peak from the graphite and at about 990°C it was verified an exothermic peak possibily from the recrystallization of the microscopical structure.

4.3. Thermogravimetry

The thermogravimetry analysis of the sewage sludge shows a very considerable loss of mass at about 270°C and a total loss of mass was verified at about 700°C.

4.4. Pozzolanic Activity Analysis

The minimum fixation rate of the lime by the pozzolanic material is 300 mg/g of pozzolanic material. For this analysis It was adopted the "Modified Chapelle Essay" which verified the consumption rate of lime by the pozzolanic material. Table 3 shows the results from these tests.

TEMPERATURE OF CALCINATION (°C)	CALCINATION TIME (horas)	SAMPLE	RESULTS MODIFIED CHAPELLE (mgCaO/g)
600	1:00	01	657,32
	2:00	02	685,32
700	1:00	03	732,92
	2:00	04	655,92
800	1:00	05	710,52
	2:00	06	685,32

TABLE 3. Results of Modified Chapelle Tests with Ashes from Calcined Sewage Sludge

4.5. X-Ray Diffraction

The results of the X-Ray Diffraction obtained with samples of ashes for about two years show a constancy in the diagrams which had the same pics. It shows a constant mineralogical composition and it was verified that the more evident pics present are from the quartz. The most important aspects verified in these tests were the absence of diffuse band on the X-Ray Diagram, before and after the calcination, showing that don't exist the glass-phase, or amorphous silica, in these ashes. The peaks at d=7, d=10 and d=12 Å are correspondent to clays and they disappear after the treatment for destruction of organic material and carbonate, probabily in function of the acid pH verified when is eliminated the carbonates. The disappearance of the clays peaks after the destruction of the organic material with H_2O_2 shows that is an organic mineral complex, probabily with the presence of montmorillonite. It justify the occurrence of pozzolanic activity althrough the absence of the amorphous silica.

4.6. Eletronic Microscopy

The sewage sludge calcined about 600°C during two hours shows, with amplifying of 3.000 times, two areas with different compositions: one presenting hexagonal plates with occurrence of calcium and potassium and other presenting spheric grains. With amplifying about 7.000 times it was verified very big hexagonal plates with occurrence of potassium from muscovite mica. It was still detected split plan that can be from the montmorillonite and a very porose structure.

5. CONCLUSIONS

The ash obtained presents a good performance like pozzolana and the results show that the process is technically viable. The cost of production equivale to the cost of the calcination of clays. The ratios of ashes additionned in the concrete were: 15, 25 and 35%about the cement weight and it was verified significant results in the compressive strenght and a good performance in presence of chlorides and sulphates attacks.
An important remark is the possibility to reduce the cost of production utilizing the own sewage sludge like a combustible because its high calorific power is about 3.000 kcal.
The next step will be a work to study the performance of ashes from calcined sewage sludge containning elevated levels of heavy metals.

UTILIZATION OF STORED CEMENT, PART II: THE BLENDING OF STORED CEMENT BY FRESH CEMENT

ABEDEL-REHEEM. A . H , SHATER. M.A, AL-ALM RASHED.I.,GAR, EL-AFIFY.A.N

ABSTRACT: A suitable method, has been studed to improve the strength of stored cement, which may lose a percent of its strength during storage. This method includes the replacement of a part of stored cement by fresh cement. As the replacement ratio by fresh cement increases the strength of the stored cement is improved. The percent of improvement depends mainly on the storage conditions and on the age of storage.
Key words: Wast cement utilization,Strength fit, Reactivity,Long age of storage, Economy,

INRTODUCTION:

During the storage of cement, the storage conditions may cause the cement properties to deteriorate as the age of storage increses. The scope of this work is to find a suitable method to utilize stored cement. Prehydration may take place during cement storage. And as a result syngenite and ettrigite are formed, these products may cause false set and strength decline (El-Afify, 1994, Hunsen, 1954, and Hogan, 1981). So, it is required to reduce the effect of thses products on the strength development. The blending of cement with any material has a cementitious properties may reduce the effect of the prehydration products. ACI, (225R-91) reported that, the over all chemistry of blended cement is similar to that of portland cement. The blending ingredients contain the same major elements as portland cement, i,e. calium, granulated blast furnace slag, fly ashes and natural pozzolans. Many works have been carried out to use fly ash and slags as ingredient in blended cement for economy and to improve the strength of the concrete used for a certain application, such as the work of Hogan, and Meusel (1981). So, the method used in this work depends on the blending of stored cement by fresh cement to improve its strength (El-Afify 1994).

EXPERIMENTAL WORK

CASES OF STORAGE

a- Case I: The cement bags were stored inside the laboratory, they were placed over a woden base and covered with a tent cover. The average temperature inside the laboratory was 25°C. This case represents good storage conditions in the Egyptian sites.
b- Case II: The cement bags were placed in the open air over a wooden base without any cover. The cement bags were exposed directly to high humidity (rains and water vapour) and temperature.
The maximum temperature was about 40°C during summer. While the minimum was about 5°C in winter. This case represents bad storage conditions in the Egyptian sites.

STORES CEMENT SAMPLES

Storage compared in Table 1 includes the ages of storage that will be tested for both cases of with specification limit and the original values of the fresh cement. The method of maximum density of aggregate was used to design the proportions of concrete mix tested in this investigation. The mix proportions are (1:4.1:1.44) of cement: gravel: sand and w/c = 0.45

EXPERIMENTAL PROGRAM

The work is mainly designed to study the effect of blending the stored cement by fresh cement on the compressive strength. The study included samples from the two cases of storage (I,II). The program is mainly divided for two parts, the first part includes the tests of mortar specimens after 3,7 and 28 days. The second part includes the tests of concrete specimens after 7 and 28 days. The ratios of this work are chosen from 15% to 60% cover a wide range of study, and also to achieve the best utilization of stored cement.

RESULTS

THE COMPRESSIVE STRENGTH OF MORTAR

a-Case I

1- The results of 6 months stored cement indicate that the compressive strength after 3 and 7 days are nearly identical with that of fresh cement, about 98% from the original value, at a replacement ratio 60%. The results of the strength after 28 days show that, the percent of increase in the strength is less than that after 7 days. This result is acceptable, because the prehydration products may affect the strangth after 28 days more than that after 7 days.

2- The results of 8 and 10 months storage indicate that, the percent of increase in the strength after 7 days is more than that after 3 days. This result may be attributed to the effect of blending by fresh cement, which may increase the rate of hydration after 7 days more than that after 3 days. On the other hand, the percent of increase in the strength after 28 days is less than that at early after 28 days for 10 months is less than that of 6 months. So, it can be stated that, as the age of storage increases the formation of the prehydration products may reduct the effect of blending by fresh cement on the strength development after 28 days.

b- Case II

1- The results of 2 months storage, to some extent, give the same behavior of case I (6 months). But the effect of the prehydration products on the strength after 28 days is more than that on case I.

2- The results of 4 and 6 months storage indicate that the percent of increase in the strength after 28 days is considerably lower compared with that of case I (8 & 10 months). So, it can be seen that, for the cement which stored in bad storage conditions the formation of the prehydation products reduces the effect of blending by fresh cement after a short period of storage. Also, these result may give a restriction on the use of this method to utilize stored cement in bad storage conditions.

For all the tested samples, it can be seen that, the increase in the strength of mortar at 15 % replacement ranges between 5% -10%. While at 60% replacement, the increase in the strength ranges between 15% - 20%. Also, it can be seen that, a high percentage of increase in the strength is achieved at 15% replacement.

From the previous analysis of the results, it can be concluded that, if the cement does not loose a great percent of its properties during storage, a low replacement ratio (such as 15%) may be sufficient to gain most of its original strength. While cement which lost a great percent of its strength during storage, high ratios of replacements (such as 50%) may ensure that the blending with fresh cement will achieve safe and effective increase in the strength of stored cement.

THE COMPRESSIVE STRENGTH OF CONCRETE

The results of the tests show a significant increase in the strength as the replacement ratio by fresh cement increases. The results of both the two cases of storage can be indicated as following:

a- Case I

The resu;ts tend to have the same behavior of mortar after 7 days. In addition, an important note can be observed, the great value of the increase in the stength is achieved at 15% replacement, then a little change can be found between 15% and 60% replacement. This result may be attributed to the effect of the aggregate content on the concrete mix propertes (singh,1958). So, the aggregate content may reduce the effect of prehydration products on the strength of the concrete mix. And. the percent of increase in the strength after 28 days is more than or nearly equal to that after 7 days.

b- Case II

After 2 and 4 months of storage, most of the increase in the strength is attaind at 30% replacement. Then, a little change can be found between 30% and 60%. The percent of increase in the strength after 28 days is less than or nearly equal to that after 7 days.

For both the two cases (I,II), the percent of increase in the strength of concrete is greater than that of mortar after 28 days. This result may be attributed to, as discussed before, the effect of the aggregate content on the concrete mix properties.

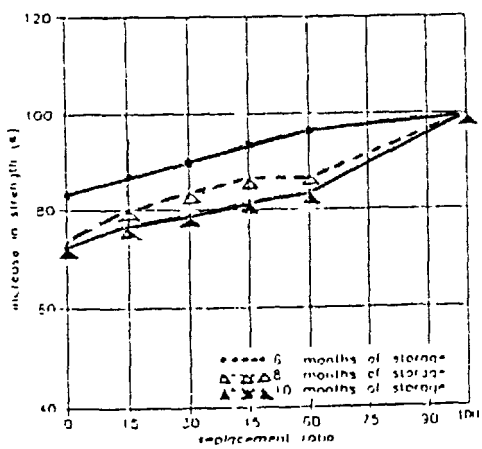

Fig (1) The percent of increase in the strength of 7 days due to blend- concrete (case I) after ing by fresh cement

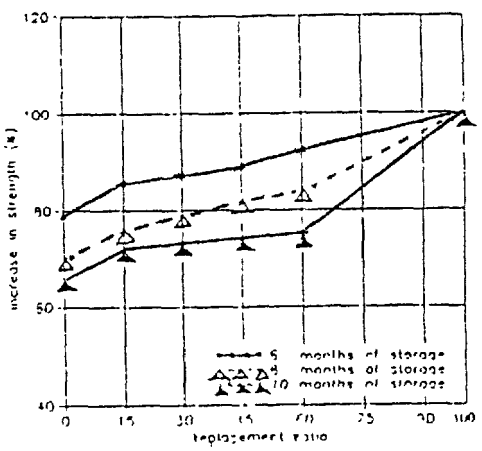

Fig (2) The percent of increase in the strength of concrete (case I) after 28 days due to blend- ing by fresh cement

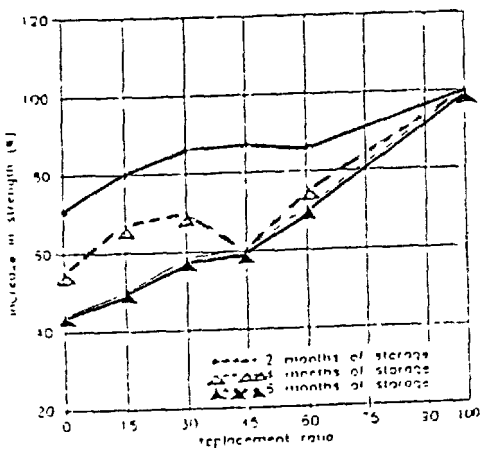

Fig (3) The percent of increase in the strength of mortar (case II) after 3 days due to blending by fresh cement

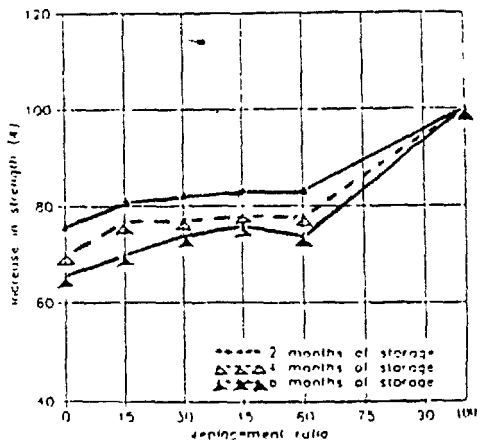

Fig (4) The percent of increase in the strength of concrete (case II) after 28 days due to blending by fresh cement

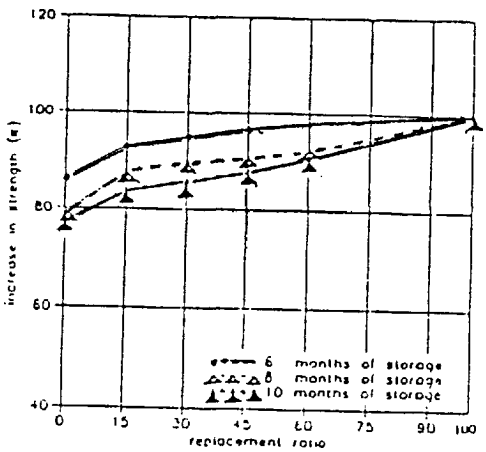

Fig (5) The percent of increase in the strength of concrete (case I) after 28 days due to blending by fresh cement

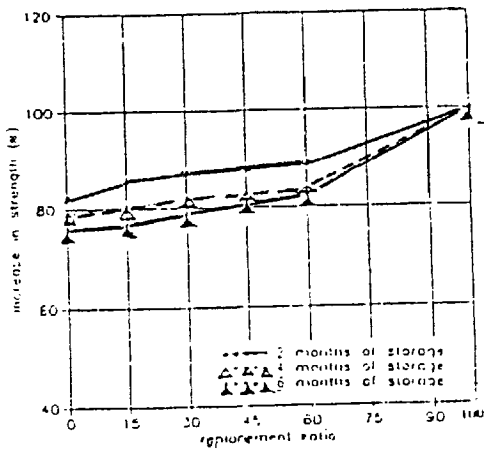

Fig (6) The percent of increase in the strength of concrete (case II) after 28 days due to blending by fresh cement

CONCLUSION

From the previous test results and discussions, the main conclusions can be summarizes as following:

1- The cement which is stored in good storage conditions and still within the specification limits, the blending by fresh cement may be sufficient to gain most of its original strength by blending with fresh cement.
2- The cement which is going to be out of specification and beyond, 50% replacement may ensure the effect of blending by fresh cement on the strength development. Also, the replacement retio by fresh cement must not be less than 30%.
3- In case of mortar, the results of blending stored cement by fresh cement showed that, the replacement ratio by 15% fresh cement may achieve an increase in the strength about (5-10%) of the original strength. while the replacement ratios between (45%-60%) an increase in the strength about (15%-20%) of that of the original strength.
4- In case of concrete, the results of blending by fresh cement showed that a great percent of the increase in the strength is achieved at 15% replacement. Then, a little change can be found between 15% and 60% replacements.

EFFECT OF ELECTROSTATIC AND STERIC REPULSIVE FORCE OF ORGANIC ADMIXTURE ON THE DISPERSION OF CEMENT PARTICLES IN FRESH CEMENT PASTE

Hiroshi UCHIKAWA, Shunsuke HANEHARA and Daisuke SAWAKI, Chichibu Onoda Cement Corporation, Japan

ABSTRACT The authors proved for the first time that the existence of steric repulsive force acting on the surface of cement particles adsorbing the organic admixture by measuring the interactive force between surface of cement clinker adsorbing the admixture with an atomic force microscope and measuring the zeta potential of fresh cement paste under actual water to cement ratio by electrokinetic sonic amplitude method. It is also clarified that the rate of contribution of electrostatic and steric repulsive force to the dispersion of cement and hydrated cement particles differs by the kind of organic admixture.

Key-words: Admixture, Superplasticizer, Simulation, Zeta potential, Steric Repulsive Force

INTRODUCTION

The improved fluidity of concrete by adding the organic admixture is considered mainly caused by the dispersion of solid particles by the electrostatic repulsive force due to the increase of the surface potential caused by the admixture adsorbed to the surface of solid particles and by the steric repulsive force based on the interaction between the adsorption layers of admixture (Uchikawa, 1994). The electrostatic repulsive force has been proved by measuring the zeta potential of diluted suspension of cement, while the steric repulsive force is at present only estimated from the current knowledge of surface and organic chemistries and the existence of the steric repulsive force has never been evidenced by experimental determination.

This paper studies the relationship between the electrostatic and steric repulsive forces aiming at acquisition of the basic data for the material design and appropriate application of the organic admixture by proving the existence of the steric repulsive force in the dispersion of solid particles in concrete prepared by adding the organic admixture, and determining the contribution of it according to the types of admixture, and relationship of the contribution with the physical properties.

INTERACTIVE FORCE BETWEEN CEMENT PARTICLES COEXISTING WITH ORGANIC ADMIXTURE

The fluidity of concrete is strongly affected by that of cement paste, which correlates with the repulsive force between the cement particles. The force acting between the cement particles comprises van der Waals force (F_A) and the electrostatic repulsive force (F_{RE}) generated by the electric charge on the surface of particles. It is considered, however, that adding the organic admixture to the cement paste, in addition to those forces, the electrostatic repulsive force is increased by the organic admixture adsorbed to the surface of the cement particles and the steric repulsive force (F_{RS}) is generated from the osmotic pressure for relieving the local increase of density caused by overlapping of the adsorption layers of admixture. According to this idea, the force acting between the cement particles (F) in the coexistence of the organic admixture is represented as follows:

$$F = F_A + F_{RE} + F_{RS} \quad [1]$$

It is known that the force acting between the cement particles depends upon the distance between them, which is related to the interactive energy as illustrated in Fig 1 (Verwey et al., 1948).

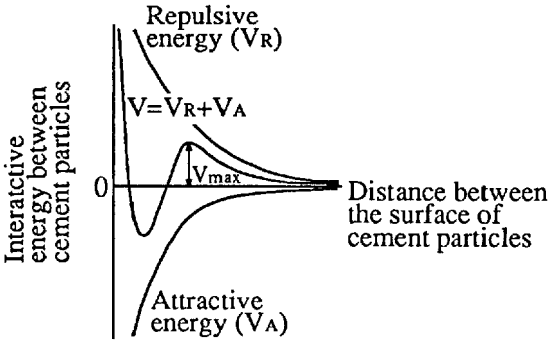

Figure 1 Relationship between distance and interactive energy of cement particles

Let the maximum repulsive energy on the potential

curve equal to Vmax, minimum Vmax required for keeping dispersion is considered to be 15kT (Verwey et al., 1948).

Since the working region of van der Waals force is within 1 nm from the surface of particles (Israelachvili, 1985) and the magnitude of it is approximately 0.5 nN (Israelachvili, 1985) assuming that the diameter of a cement particle is 2μm, it is negligible small compared with the force corresponding to Vmax and the compensated interactive force described later.

SELECTION OF MEASURING METHODS

Force acting between surfaces

Although Surface Force Apparatus (SFA) (Israelachvili et al., 1978) is applicable to measure the interactive force of solid sample, the sample must be transparent and the surfaces of them must be smooth at the molecular level. The sample applied to the method is, therefore, limited to a few kinds of solid.

The atomic force microscope (AFM) is used for measuring very little force acting between the sample and the probe brought close to it to approximately 1 nm (Uchikawa, 1992). The distance between the probe and the sample can be controlled at the accuracy of 0.05 nm with a piezo-electric element. The displacement of a cantilever caused by the force acting between the surfaces is determined at an accuracy of 0.1 nm at least by measuring the intensity of laser beams reflected from the back side of the lever with a position-sensitive photo-detector. The force acting between the surfaces is calculated by multiplying the displacement of cantilever by the spring constant of the lever and the lower limit of the measurement is 10^{-3} nN.

In this study, therefore, AFM was used for measuring the force acting between the solid surfaces since AFM is more easily operated than SFA and does not require so much smooth surface of the sample as that of SFA because the measuring region is as small as an order of μm^2 as well as can use an opaque sample though the measurements of the distance in the curve of the distance between the surfaces versus the force acting between the surfaces (F-D curve) with AFM are not so accurate as those with SFA.

Zeta potential

As mentioned before, one of the dispersion force of cement particles in fresh cement paste is the electrostatic repulsive force which is related to the surface potential of cement particle. Since the surface potential (ϕ_0) of bare particles and the Stern potential (ϕ_s) outside of the Stern layer cannot be measured, the potential on the slipping surface or zeta potential is substituted for the surface potential of the solid in solid-liquid suspension (Fig 2).

The electrophoretic method which has been used so far as a measuring method of zeta potential requires diluted concentration of particles in suspension because the migration speed of dispersed particles to which voltage is applied is directly observed. The streaming potential method is not only unsuitable for practical cement paste with a W/C of 0.5 or less because it requires the concentration of particles of 1vol% or less but also it has shortcomings including poor reproducibility and low accuracy. The zeta potential measured with conventional methods does not necessarily correspond to the fluidities of cement paste and concrete (Massazza et al., 1982).

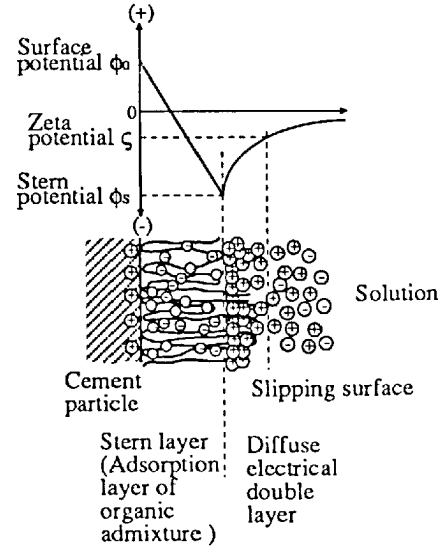

Figure 2 Schematic explanation of interfacial electrical double layer formed on the cement particle adsorbing organic admixture

In this study, therefore, the electrokinetic sonic amplitude method (Babchin et al., 1989) which has recently been developed for measuring zeta potential of cement paste with a practical W/C

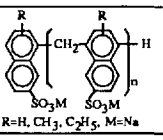
as low as 0.3 is used. This method is applied to the measurement of zeta potential in such a way that the electrokinetic sonic amplitude (ESA) value caused by the particles moving between both electrodes by applying alternating voltage with higher frequency than 1 MHz to the charged particles is measured, and calculated according to the following formulas representing the relationship of ESA with dynamic mobility (μd) and zeta potential (ζ) of particle:

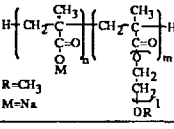
$$ESA = C \cdot V \cdot (\Delta \rho / \rho) \cdot \mu d \cdot (Zs / Zs + Zg) \quad [2] \qquad \mu d = \varepsilon \zeta G(\alpha) / \eta \quad [3]$$

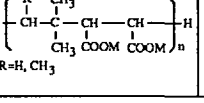
where C = apparatus constant, V = volume fraction of particles, $\Delta \rho$ = difference of density between particle and disperse medium, ρ = density of disperse medium, Zs = acoustic impedance of solution, Zg = acoustic impedance of glass rod, ε = permitttivity of disperse medium, η = viscosity of disperse medium, and $G(\alpha)$ = correction term of inertia force.

SAMPLE AND EXPERIMENTAL METHOD

Cement and admixture







Normal portland cement shown in Table 1 was used. Polished surfaces of cement clinker produced at the time when the cement shown in Table 1 was manufactured were used for measuring the force acting between the surfaces of cement particles.

Three types of organic admixtures in total - a type of sulfonate based- and two types of polycarbonate based-admixtures - were used. Assuming that polycarbonate based-admixture, PC-A, has 40 branches of ethylene oxide in a molecule, it is inferred from the bond length of C-C and mean molecular weight that the lengths of the main chain and side chain will be approximately 30 and 20 nm, respectively. It is also inferred from the mean degree of condensation of 256 obtained from the mean molecular weight and the length of C-C bond of polycarbonate based-admixture, PC-B, that the molecular length of it will be approximately 154 nm. Ten percent (10%)-aqueous solutions of NS, PC-A and PC-B and 10^{-2} mol/l-aqueous solution of sodium sulfate similar to the concentration of ion in the liquid phase of cement paste were used as admixture or immersing solution.

Table 1 Character of normal portland cement

Chemical composition (%)								Free lime (%)	Blaine specific surface area (cm^2/g)
SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	Na_2O	K_2O		
22.1	5.3	3.1	65.2	1.2	2.1	0.43	0.23	0.5	3,350

Table 2 Character of organic admixture

Kind	Main component	Structural formula of main component	Solid content (%)	Mean molecular weight	Sodium content (mol/l)
NS	Condensate of β-naphthalene sulfonate with formalin	 R=H, CH_3, C_2H_5, M=Na	41	1400	1.3
PC-A	Copolymer of acrylic acid with acrylic ester	 R=CH_3 M=Na	30	88000	0.8
PC-B	Copolymer of olefin with maleic acid	 R=H, CH_3	34	59000	3.0

The characters of the organic admixtures used for the experiment are listed in Table 2.

Analysis of admixture

Solid content, mean molecular weight and sodium content were determined according to the procedures described in the previous paper (Uchikawa et al., 1996). The solid content was determined from the weight after drying the liquid admixture sample for an hour at 110°C. The mean molecular weight was determined by gel permeation chromatography. The sodium content was determined by high-frequency inductively coupled plasma emission spectrometry.

Measurement of force acting between surfaces of cement particles adsorbing admixture

Force acting between the surfaces of cement particles adsorbing the admixture was measured by immersing a polished surface of cement clinker sample or a silicon wafer in the admixture solution and determining the F-Dcurve of the adsorption surface of the admixture with the AFM.

Auto Probe CP manufactured by Nikon/Park Scientific Instruments Co. was used as the AFM which uses a quadrangular silicon nitride probe of approximately 100nm base length and a cantilever with the spring constant of 0.05 N/m. The dimensions of the polished sample of cement clinker are 5mm x 5 mm x 3 mm and the surface is finished with aluminum oxide of 0.05μm in diameter. The silicon wafer covered with silicon dioxide (SiO_2) supplied by Nikon was used. Prior to the measurement, the surface of the sample was washed by UV ozone cleaning to remove the contaminants including organic matter. The surface was carefully washed until it was evenly wetted by water. The working range and speed of the cantilever were zero to 750 nm and 1500 nm/sec, respectively.

Measurement of zeta potential of the surface of cement particle adsorbing admixture

Cement paste with the W/C of 0.3 was prepared by adding the admixture to it so as to make the weight ratio of the solid content of admixture to cement 0.6%. The zeta potential of the cement paste was determined with an electrokinetic sonic amplitude type zeta potential measuring apparatus (AcoustoSizer made by MATEC APPLIED SCIENCES Co.) five minutes after adding the mixing water.

Measurement of flow of cement paste

The value of flow of the same cement paste as used for measuring zeta potential was measured with the flow cone for mortar test specified by JIS R 5201 five minutes after the addition of water. The flow cone is 70mm in top diameter, 100 mm in bottom diameter and 60 mm high.

RESULTS AND DISCUSSION

Force acting between surfaces

A F-D curve of silicon wafer surface immersed in 10% aqueous solution of naphthalenesulfonate based-admixture (NS) is illustrated in Fig 3. The probe was brought close to the surface of sample at the speed of 1,500 nm/sec. The moving distance of the probe from the starting point and the interactive force calculated from the deflection of the cantilever are put on the X- and Y-axes, respectively. The point S at which the interactive force begins linearly increasing shows the point where the probe is brought into contact with the surface of sample. The force acting between the solid surfaces is determined as the difference of the interactive force between points S and P, and the range of the interactive force acting is determined from the moving time of probe. Fig 3 reveals that there is a difference between the F-D curve of the probe approaching the sample and that of the probe going away from it. In this study, however, the force acting between the surfaces was evaluated using the former force curve.

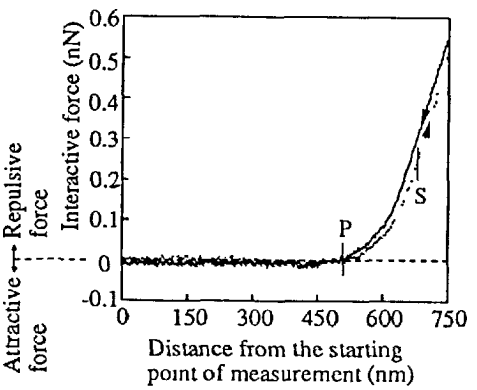


Figure 3 Interactive force-distance curve of silicon wafer surface immersed in the 10% solution of NS measured by AFM

The left side figure of Fig 4 is a figure drawn anew by transferring the point S in Fig 3 showing the actual measurements to the point of origin of distance. Since that figure is convenient for understanding the change of the interactive force perpendicular to the surface of cement particle, F-D curve will be illustrated such as this hereafter.

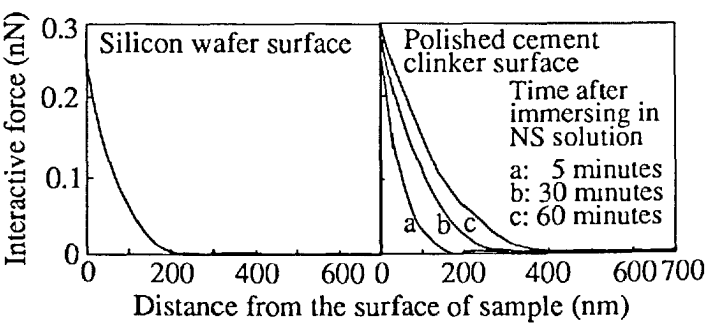

Figure 4 Influence of the time elapsed after immersing the cement clinker sample in organic admixture solution on the force-distance curve of it measured by AFM

The relationship between the distance of the probe from the surface of the

adsorption layer of admixture and the interactive force on the polished surface of cement clinker immersed in a 10%-NS aqueous solution is illustrated in the figure on the right side of Fig 4. The F-D curve varied according to the passage of time from the immersion in the aqueous solution of admixture. Maybe this is because the distance between the probe and the polished surface of clinker varied with time by the dissolution of component elements and the deposition of hydrates on the surface. It is, therefore, important to choose the measuring time in such a highly accurate study of a material progressing reaction during the measurement as this particular case. The F-D curve obtained in five minutes after the immersion was not so different from that of silicon wafer.

The relationships between the distances from the surfaces of the adsorption layer of admixtures determined from the F-D curves obtained in five minutes after immersing the polished surface of cement clinker in various organic admixtures and the interactive force are illustrated in Fig 5. The repulsive force on the polished surface of cement clinker immersed in pure water was 0.004 nN, while the maximum repulsive forces on the polished surface of cement clinker immersed in such aqueous solutions of admixtures as NS, PC-A and PC-B were 0.24, 0.60 and 0.19 nN, respectively. The distance beginning to work the repulsive force increased with increasing the repulsive force given from the admixture. It was approximately 10 nm for pure water, while approximately 160, 560 and 120 nm for the NS, PC-A and PC-B aqueous solutions, respectively. The interactive force logarithmically fell off in inverse proportion to the distance from the surface of the adsorption layer of admixture.

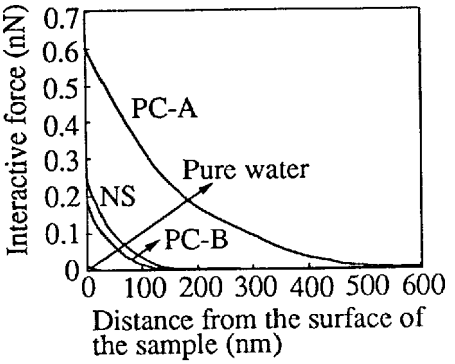

Figure 5 Relationship between interactive force and distance of polished cement clinker immersed in pure water and the 10% solutions of organic admixtures measured by AFM

Zeta potential of cement particle in fresh cement paste

The result of measurements of zeta potential of cement particle in fresh cement pastes with the W/C of 0.3 prepared by adding and without adding the organic admixture are listed in Table 3.

NS contains 64 mmol/l of SO_4^{2-} (Uchikawa et al., 1996) which is dissociated into anions. The zeta potential of cement particle in fresh cement paste prepared by adding NS was high. The PC-A contains as little as approximately 3% of carboxyl group and the hydrophobic group may enclose carboxyl group dissociated, so the zeta potential of cement particle in fresh cement paste prepared by adding PC-A was low. Meanwhile PC-B contains as high as approximately 60% of carboxyl group according to the calculation based on the molecular structure and maleic acid as a component is easily dissociated, therefore the zeta potential of cement particle in fresh cement paste prepared by adding PC-B was high.

In this experiment, even the zeta potential of well-dispersed cement particles in the fresh cement paste containing NS was -10mV. Maybe this is because the zeta potential is higher (lower in absolute value) than the surface potential.

Table 3 Zeta potential of cement particle in fresh cement paste prepared by adding organic admixtures measured by electrokinetic sonic amplitude method

Admixture	Zeta potential (mV)
NS	-11.0
PC-A	-1.5
PC-B	-9.1
No added	-1.8

Conversion of measured zeta potential to electrostatic repulsive force

It is necessary to convert electric potential to force for determining the electrostatic repulsive force from the measurements of zeta potential of cement particles in fresh cement paste. To the relationship in two spherical particles between the surface charge density (σ), Debye parameter (κ) and the electrostatic repulsive force (F), the following formula applies (Li et al., 1993):

$$F = [(2\pi\sigma^2 R)/(\varepsilon_r \varepsilon_0 \kappa)] \exp(-\kappa D) \quad [4]$$

where R = radius of spherical particle, ε_r = relative permittivity of water, ε_0 = vacuum permittivity, and D = distance between surfaces of particles.

The reciprocal number of Debye parameter (κ^{-1}) represents the thickness of an electric double layer. The following relationship exists between the concentration of electrolyte and κ^{-1}:

$$\kappa^{-1} = 0.304/C^{1/2} \quad [5]$$

where C= concentration of electrolyte. Since the concentration of electrolyte in the liquid phase of fresh cement paste is approximately 0.1mol/l, the thickness of diffuse electric double layer formed on the surface of cement particle adsorbing the admixture will be approximately 1 nm.

The surface charge density of the cement particle in cement paste can be calculated using the zeta potential instead of the surface potential from the following formula:

$$\sigma = (8n\,\varepsilon_r\,\varepsilon_0\,kT)^{1/2} \sinh (Ze\,\phi_0/2kT) \quad [6]$$

where n = concentration of electrolyte, k = Boltzmann constant, T = absolute temperature, Z = ionic charge number, e = elementary electric charge, and ϕ_0 = surface potential.

Values 1μm, 78.3 and 8.854 x 10^{-12} C^2/J m were used as the radius of cement particle, the relative permittivity of pure water and vacuum permittivity, respectively. Although the thickness of the adsorption layer of admixture corresponding to the Stern layer varies according to the types and concentrations of admixture (Uchikawa et al., 1992), 100 nm was used as the mean value of it in this study.

Taking the concentration of electrolyte as 0.1 mol/l, the temperature as 20°C, the ionic charge number as 1 and the elementary electric charge as 1.602 x 10^{-19}C, the electrostatic repulsive force of -15 mV equivalent to the minimum value of Vmax (=15kT) required for keeping the dispersion of cement particles 2μm in diameter in fresh cement paste is approximately 10 nN at the distance between the particles of 1 nm.

Factors affecting fluidity of fresh cement paste

The results of measurements of flow of cement paste with the W/C of 0.3 prepared with and without adding the organic admixture are illustrated in Table 4. The table reveals that the flow value is sharply increased by the addition of the admixture in such a manner that the fluidity is particularly much increased by adding PC-A, but the flow value is less increased by adding PC-B than by adding NS.

Table 4 Flow of fresh cement paste prepared by adding organic admixtures

Admixture	Flow (mm)
NS	248
PC-A	476
PC-B	182
No added	113

The relationship between the measured value of force acting between the polished surfaces of cement clinker immersed in an aqueous solution of organic admixture and the flow of fresh cement paste, and that between the zeta potential of the cement particle in cement paste containing the admixture and the flow of fresh cement paste are illustrated in Fig 6. The force acting between the surfaces are linearly related to the flow of fresh cement paste independently of what types of admixture is added and whether the admixture is added or not. The flow value increased with increasing the force acting between the surfaces. Meanwhile, the zeta potential is not necessarily linearly related to the fresh cement paste flow, especially the relation was remarkably separated from the linear relation by adding PC-A. This suggests that force other than the zeta

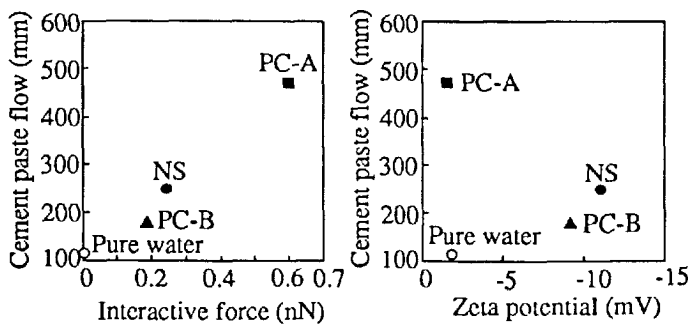

Figure 6 Relathionships between fresh cement paste flow and interactive force, and zeta potential

potential or electrostatic repulsive force contributes to the dispersion of cement particles, namely, the fluidity of fresh cement paste containing PC-A.

Effects of electrostatic and steric repulsive forces on fluidity

The steric repulsive force is considered to be one of the most important forces contributing to the fluidity of cement paste. The value of it can be calculated by subtracting the electrostatic repulsive force converted from the zeta potential measured according to the method described before from the force acting between the surfaces of cement particles in cement paste. Since no steric repulsive force acts in fresh cement paste without admixture, the electrostatic repulsive force converted from the zeta potential of it should be equal to the repulsive force measured with the AFM. The former value is, however, 1.5 nN, while the latter value is 0.004 nN. The former is, therefore, 375 times as much as the latter.

The repulsive force measured with the AFM is the force acting between the probe and the solid surface and the tip of probe is quadrangular with a side of 100 nm. Since the interactive force is proportional to the area, assuming that the tip of probe is a cement particle 2 μm in diameter, it will be 400 times [(2000 nm/100 nm)^2] as much as the force acting between the probe and the solid (cement clinker), which is nearly equal to the above-mentioned value of 375 times.

The relationship between the compensated interactive force of the surface of the adsorption layer of admixture on polished surface of cement clinker opposite to the cement particle 2 μm in diameter obtained by multiplying the value measured with the AFM by 400 and the distance is illustrated in **Fig 7**. A curve drawn by plotting the electrostatic repulsive force converted from the measured value of zeta potential versus the distance is illustrated together in the figure.

Fig 7 reveals that though the electrostatic repulsive force contributing to the dispersion of cement particles in fresh cement paste without admixture is extremely small and the working region is also narrow, the force acting on the surface of cement particle is increased by adding the admixture. The steric repulsive force predominates in the large repulsive force acting between the cement particles in fresh cement paste containing PC-A. Meanwhile, the steric repulsive force contributes only to the regions in the vicinity of cement particles in fresh cement paste containing PC-B and NS, but it disappears in the region exceeding 90 nm from cement particle and accordingly the mean contributions in the former and latter cases to total repulsive force are estimated to be 30 and 20%, respectively. Maybe this is because each molecule of PC-A with a long straight chain and side chains branched from it is adsorbed overlapping each other to the surface of cement particles and the adsorption layer containing many high-density regions are formed, thereby generating large steric repulsive force.

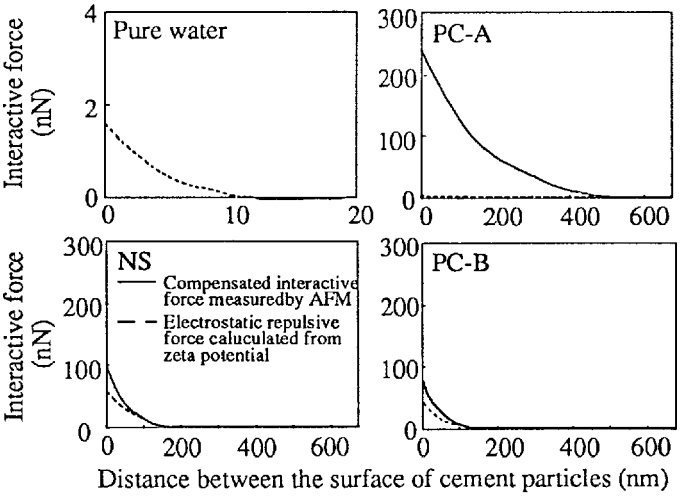

Figure 7 The rate of contribution of electrostatic repulsive force to total repulsive force

The results mentioned above prove for the first time that the steric repulsive force of the organic admixture, which has been a matter of speculation, acts on the dispersion of cement particles, and that the magnitude of the steric repulsive force is closely related to the molecular structure of the admixture. Most of the action dispersing the particles is attributed to the steric repulsive force in fresh cement paste containing a polycarbonate based-admixture mainly composed of acrylic acid-acrylic acid ester copolymer.

CONCLUSIONS

The conclusions obtained by investigating the function dispersing the particles of cement in concrete by the organic admixture are as follows:

(1) The force acting the polished surface of cement clinker adsorbing the admixture can be measured with good reproduciblity as a function of the distance from the adsorption surface of admixture with the atomic force microscope. The zeta potential of cement particles in fresh cement paste with low W/C can be reliably determined by measuring the magnitude of a pressure wave or an electrokinetic sonic amplitude value caused by the dynamic mobility of cement particles to which high-frequency alternating voltage is applied.

(2) Although the fluidity of fresh cement paste containing the organic admixture correlates with the repulsive force of cement particles, there is no constant relationship between the fluidity and the zeta potential. This suggests that force other than the electrostatic repulsive force acts on the dispersion of cement particles.

(3) Considering that van der Waals force is negligible small attractive force, it has been proved for the first time in this study that the cement particles adsorbing the organic admixture have the steric repulsive force besides electrostatic repulsive force by determining the difference between the compensated interactive force obtained from measured value of force acting between the surfaces and the force converted from the measured value of zeta potential.

(4) The repulsive force of the cement particles in fresh cement paste is increased by adding the organic admixture and the magnitude and working region of it depend upon the types of the admixture. The action dispersing the particles of a polycarbonate based-admixture mainly composed of an acrylic acid-acrylic acid ester copolymer is mainly attributed to the steric repulsive force, while that of naphthalene sulfonate based-admixture is attributed considerable part to the electrostatic repulsive force.

(5) The reason why steric repulsive force contributes predominantly to the dispersion of cement and cement hydrate particles in the addition of admixture composed of acrylic acid - acrylic acid ester is considered to be attributed to its molecular structure with a long straight chain of carbon atoms and the side chains branched from it. It forms an adsorption layer containing many high-density regions overlapping each other to the surface of cement particles. Less content of carboxyl group with electric charge ionized in water and the enclosure of carboxyl group with electric charge by hydrophobic groups may also be responsible to reduce the contribution of electrostatic repulsive force for the dispersion of particles.

ADSORPTION OF SUPERPLASTICIZERS ON MODEL POWDERS: TEMPERATURE DEPENDENCE, EFFECT ON ZETA POTENTIAL AND ROLE OF CHEMICAL STRUCTURE.

Robert J. FLATT, Yves F. HOUST, Paul BOWEN, Heinrich HOFMANN, EPFL - Powder Technology Laboratory, Lausanne, Switzerland

ABSTRACT It has been shown that the adsorption of superplasticizers on MgO and $Mg(OH)_2$, at pH 12.1 and 11.3 respectively, can strongly vary with temperature according to the chemical nature of the superplasticizer. MgO and $Mg(OH)_2$ were chosen as model powders because their surfaces and zeta potentials are similar to cement. The two polymers studied, of similar molar mass, contain the same ionic groups but have different charge spacing. The influence of this structural difference on adsorption and zeta potential was studied.

Key-words: Admixtures, Adsorption, Superplasticizers, Temperature, Zeta Potential.

INTRODUCTION

In the early 1960's, the first synthetic, high performance water reducing admixtures for concrete were developed. These admixtures were based on sulfonated naphthalene-formaldehyde, and, some years later, melamine formaldehyde polycondensates. In the eighties and nineties, new types of polymers, which form the chemical basis of a novel class of high range water reducers (HRWR), also called superplasticizers, were introduced. At present mainly three types of anionic polymers (anionic polyelectrolytes) are used in modern superplasticizers: Sulfonated Naphthalene-Formaldehyde-Polycondensates (SFNC), Polycarboxylic Acid Polymers (PCA) and Polycarboxylic Ester-polymers (PCE).
Such admixtures are today a valuable help in the production of high performance concrete exhibiting high flow and excellent workability which develope high density and durability on setting.
The effect that these polymers induce in cement suspensions, which permits high water reduction for the same workability, is linked to a change in interparticle forces [Horn (1990), Israelachvili (1992)]. However, the exact way in which these polymers modify interparticle forces in cement suspensions, whether it is by electrostatic, steric or entropic effects or a combination of these, is still a debated matter [Aïtcin et al (1994), Jolicoeur et al (1994)].
Our research aims to get new and additional information and knowledge about the mechanisms of the interaction of structurally different water-soluble polymers which are used or could be used as HRWRs. In this paper, we present results concerning the adsorption, at different temperatures, of a PCA and a PCE on model powders which bear many physical similarities to cement phases. We also look at the change in surface charge which these polymers induce on these model powders.

STRATEGY

When studying the effect of polymers on interparticle forces, it is important to know whether they adsorb on surfaces, and if so to what extent.
Because cement hydrates and its surface therefore changes with time, adsorption of HRWRs is commonly studied on inert model powders [Jolicoeur et al (1994), Nkinamubanzi (1994), Chapuis (1990), Pierre et al (1988), Girod et al (1988), Daimon and Roy (1978)]. This is believed to provide information on the initial steps of the interaction between HRWRs and cement. Such studies, carried out by Nkinamubanzi (1994) and Pierre et al (1988) have shown for instance that the adsorption of PNS on TiO_2 is strongly dependent on the pH of the suspension. At pH 3, where TiO_2 bears a strong positive surface charge, the adsorption is maximum, while it becomes non-existent in the alkaline region where the surface charge of TiO_2 is negative. From this example, we see that electrostatic interactions between a HRWR and a surface can be a determining factor for its adsorption.

The model powder must therefore have both a zeta potential and a pH similar to that of a cement suspension if we intend to relate adsorption on the model powder to that on Portland cement. Nägele (1985) found this potential to be positive by a couple mV. On the other hand, the behavior of a polymer in aqueous solution and its action at the interface of a solid is determined by specific structural characteristics of the solvated macromolecules. These characteristics, apart from depending on the polymer structure (electric charge, number, type, distribution and spacing of the functional side-groups), are strongly influenced by the solution pH.
This brings a second condition for adsorption experiments. It is to have a pH similar to that of cement (about 12.5). This can be quite a problematic condition, since at such a pH most powders have a negative surface charge. To the best of our knowledge, no adsorption experiments have so far been carried at pH 12 with model powders positively charged under those conditions.
In this study, the powders used are MgO dead burnt and $Mg(OH)_2$. Suspensions of MgO at pH 12 had positively charged surfaces since its Isoelectric Point (IEP) is at pH 12.4 [Parks (1964)]. $Mg(OH)_2$ is expected to have an IEP at pH 12 [Parks (1964)], therefore we used suspensions at pH 11.3 to obtain slightly positively charged surfaces. The small pH difference is not expected to alter results significantly. Another major interest for these powders is their chemical similarity to the major cement phases C_3S, C_2S and C_3A. The Mg-O bond is much stronger than the Ca-O bond because of the smaller size of Mg (it is above Ca in the periodic table). By dead burning, the reactivity of this powder is further decreased, making it almost insoluble.
The polymers used in this study (a PCA and a PCE) have the same ionic groups (carboxylate and sulfonate). However, the spacing of these groups is larger in the PCE, due to the inclusion of polyethylene glycol-ester (PEG-ester). This structural difference should allow us to get information concerning the importance of electrostatic interactions in the adsorption of such HRWRs.

EXPERIMENTAL

Powders

MgO dead burnt and $Mg(OH)_2$ from Martin Marietta Magnesia Specialties Inc. (type: P-98 and MH-10 respectively; Baltimore, USA) were carefully sampled. Half the MgO was sieved. The fraction below 50 µm, sampled with a spinning riffler, was used in our experiments.
The particle size was determined by laser diffraction (Malvern Mastersizer; Malvern, GB). The BET specific surface was determined by adsorption of N_2 (Micromeritics Gemini III 2375; Norcross, USA). XRD showed the $Mg(OH)_2$ contained a small amount of MgO, possibly formed at the surface by excess drying during the production. secondary phases were not observed in the MgO. Other powder characteristics are given in Table 1.

Table 1: Powder characteristics

	$Mg(OH)_2$	MgO
Specific Surface Area	11.8 ± 0.1 m^2 g^{-1}	0.77 ± 0.03 m^2 g^{-1}
Median Volume Diameter	10.5 ± 0.2 µm	15.0 ± 0.5 µm

Polymers

The polymers used for this study are laboratory test products produced by Sika A.G. (Zürich, Switzerland). Information as to their composition is given in Table 2.

Table 2: Characteristics of the polymers used.

	PCA	PCE
Chemical type	Na-polycarboxylate-polysulfonate	Na-polycarboxylate-polysulfonate, PEG-ester containing
Number Average Molar Mass	11'500 ± 2'000 g mol^{-1}	9'500 ± 1'500 g mol^{-1}

Adsorption

Adsorption measurements were performed on suspensions of 10 g of MgO or 5 g of $Mg(OH)_2$ in 20 ml NaOH 0.01M (pH 12 ± 0.1), previously thermostated in rotary bath at 200 rpm (different masses were taken to achieve similar volume fractions). The superplasticizers were added as concentrated aqueous solutions with a microdispenser. This makes dilution minimal and avoids possible hydrolysis due to a long exposure in an alkaline solution). After 30 min in the rotary bath, the suspensions were centrifuged for 5 min at 3'000 rpm. Five ml of the supernatant, buffered with 25 µl of CH_3COOH (30% V/V), were filtered at 0.45 µm through a filter mounted on a dispensable syringe. The first 2 ml were discarded and the rest was analyzed by reverse phase chromatography with an HPLC from Waters (mod. Alliance; Milford, U.S.A.) equipped with a diode array detector. The calibration standards, which apart from containing no powder and not being centrifuged, were submitted to the same treatment.

Zeta potential

Zeta potential was measured at 23-25° C by acoustophoresis (Penkem, system 7000; Bedford Hills, U.S.A.). Potentials were calculated from measured data using the method proposed by PenKem (Marlow et al 1988). The suspensions were prepared by dispersing 20 g of powder in 300 ml NaOH 0.01M under vigorous agitation and sonification for 15 min (150 W, 20 kHz). Prior to measuring, they were degassed for 5 min (≈20 torr). A slight vacuum was maintained in the measuring cell to avoid bubble formation which attenuates the signal. The superplasticizers were progressively added as concentrated aqueous solutions with a microdispenser.

RESULTS

Stability of powders

The pH of $Mg(OH)_2$ suspensions decreased from pH 12 to pH 11.3. This may be a result from the dissolution and/or precipitation of impurities not detected by XRD. Further pH decrease is hindered by the equilibrium:

$$MgOH^+ + OH^- \rightleftharpoons Mg(OH)_2$$

The suspensions containing dead burnt MgO however remained at pH 12, indicating this powder to be essentially non reactive.

Adsorption

The adsorption isotherms on MgO at 25, 32 and 40 °C for superplasticizers PCA and PCE are reported in Figs 1 and 2 respectively. These figures show that the adsorption of the PCE increases sharply with temperature, while adsorption of the PCA is uneffected by it. Figures 3 and 4 give the adsorption isotherms of the same polymers on $Mg(OH)_2$. In this case, neither polymer is effected by temperature.

The fact that on both powders adsorption of the PCA is not effected by temperature can be assumed to be due to a large adsorption enthalpy ΔH_{ads}. Indeed, over small temperature ranges, both enthalpy ΔH_{ads} and entropy ΔS_{ads} can be regarded as constant and the adsorption free energy ΔG_{ads} is therefore mainly effected by the $-T\Delta S_{ads}$ term, as $\Delta G_{ads} = \Delta H_{ads} - T\Delta S_{ads}$.

Understanding the behavior of the PCE is a more challenging task. However, we can gain some insight using similar considerations regarding its adsorption free energy. The PCE polymer is

similar to the PCA but has ionic groups which are further apart, due to the insertion in this polymer of PEG-ester segments which act as charge spacers. This anionic polymer will therefore have weaker electrostatic interactions with the positively charged surface and consequently a smaller heat of adsorption ΔH_{ads} than the PCA. Although this could explain a temperature dependent adsorption, it does not account for an increase as a function of temperature. Indeed, because of the decrease in configuration entropy linked with adsorption ΔS_{ads} is expected to be positive and adsorption to decrease with temperature. However, it could be that the PCE polymer would remain on the surface but be linked to it by less anchor points. This would then allow larger amounts of polymers to adsorb on the surface. Over a larger temperature range, these polymers would be expected to desorb. The reason why adsorption remains unchanged with temperature on the $Mg(OH)_2$ could be due to a larger ΔH_{ads} interaction with this powder.

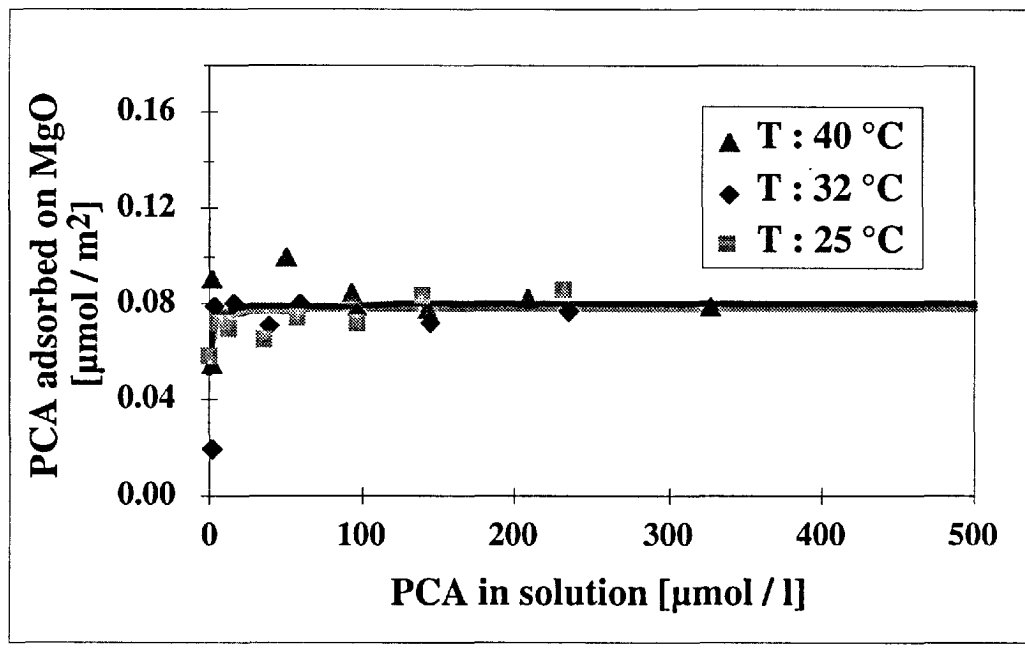

Figure 1 Adsorption isotherms of PCA on magnesium oxide at 25, 32 and 40°C.

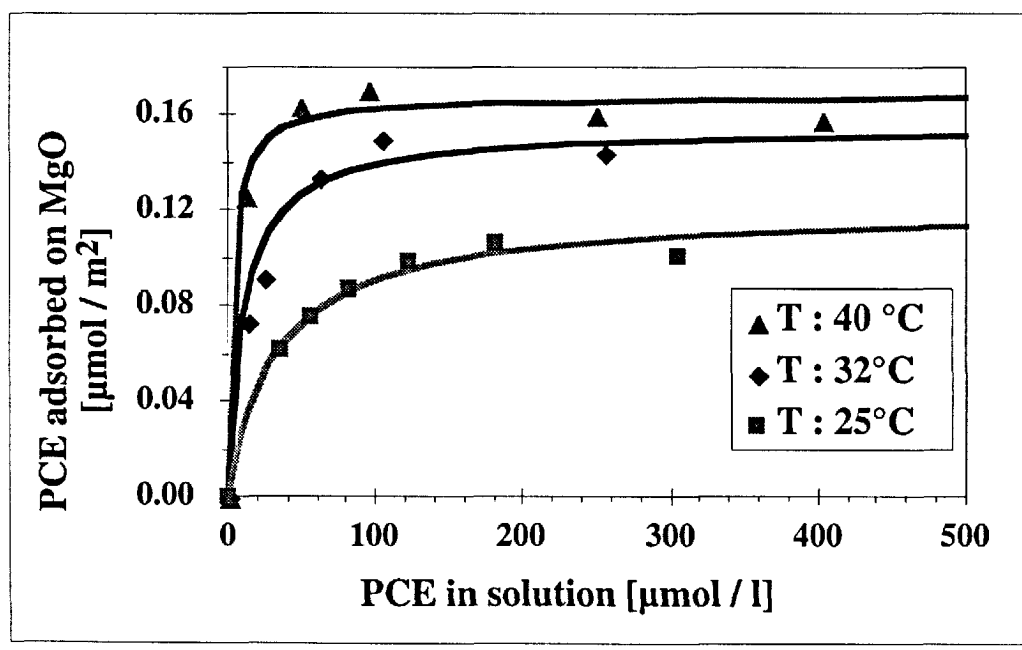

Figure 2 Adsorption isotherms of PCE on magnesium oxide at 25, 32 and 40°C.

Another possible consequence of the PCE having a smaller ΔG_{ads} than the PCA, would be to allow competitive adsorption of hydroxyl groups OH^-. These would be more easily desorbed by rises in temperature, allowing a higher surface coverage, especially on MgO. Adsorption on the $Mg(OH)_2$ might not be influenced by temperature because of the pH difference (12 and 11.3), which corresponds to a five fold concentration difference in OH^-.
On the other hand, it is known that PEO polymers, which are similar to our PCE, have increased polymer-polymer interactions with temperature rises over similar ranges (Claesson et al. 1986). This might lead to multiple layer adsorption (Klein 1997) on the MgO. This may not occur on the $Mg(OH)_2$ either because of different surface interactions, the pH difference or a larger porosity. We can point out that the interaction energy increase between PEO polymers is believed to be linked to the loss of a solvation layer (Israelachvili 1996). This in turn would lead to smaller surface occupation of the adsorbed polymers and would allow increased adsorption.

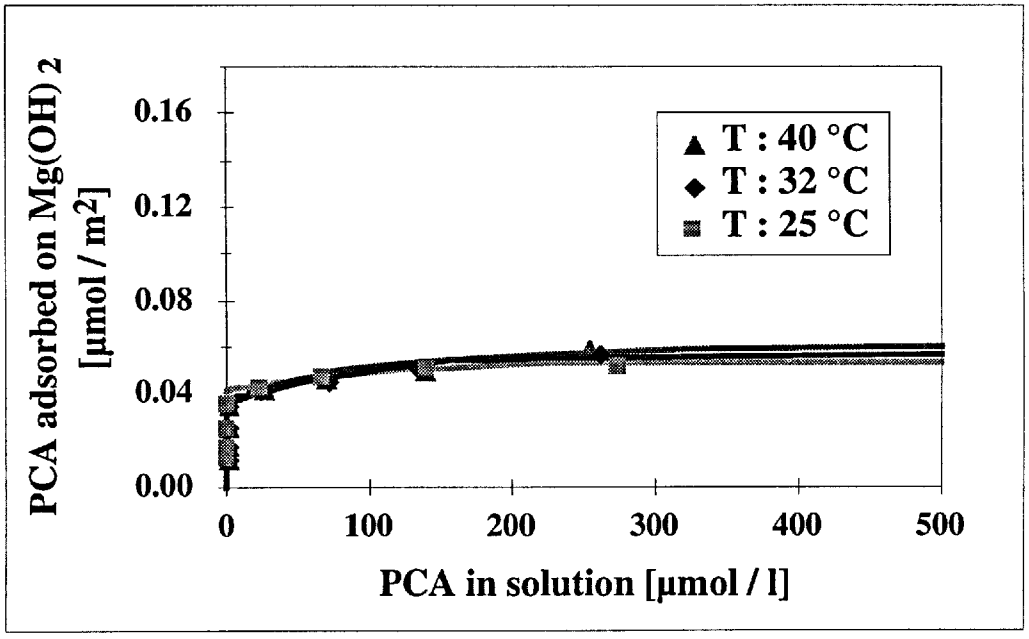

Figure 3 Adsorption isotherms of PCA on magnesium hydroxide at 25, 32 and 40°C.

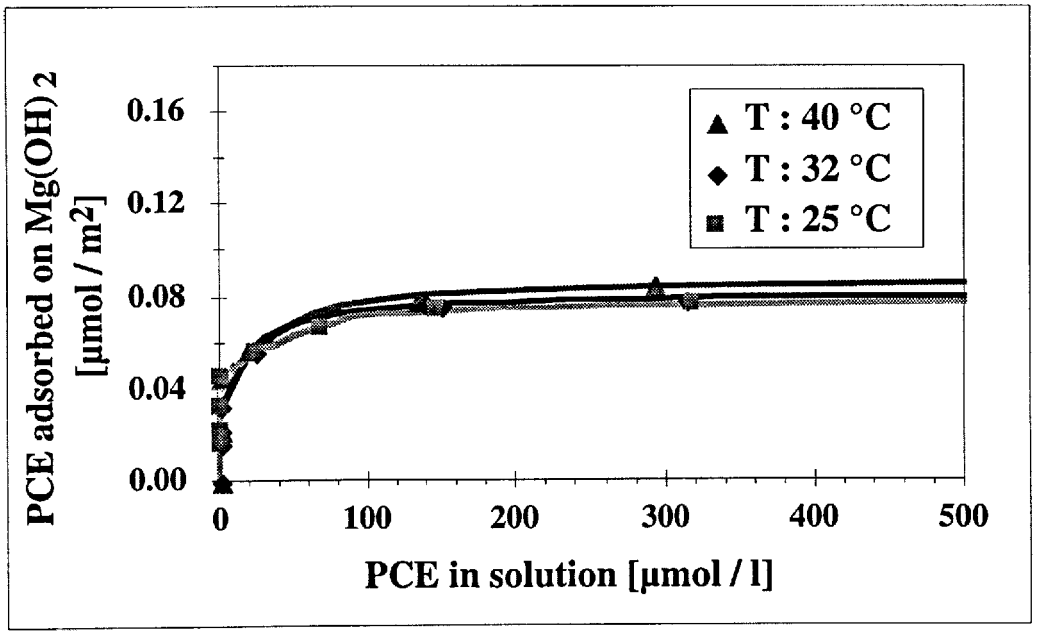

Figure 4 Adsorption isotherms of PCE on magnesium hydroxide at 25, 32 and 40°C.

Zeta potential

In Figs 5 and 6, we have reported the change in zeta potential (related to the surface charge) that the PCA and the PCE induce on MgO and $Mg(OH)_2$ respectively. In both cases, the PCA induces a larger negative zeta potential. This means that the larger adsorption of the PCE is not sufficient to overbalance the greater charge of the PCA. It is possible to compare absolute molar concentrations of these polymers because they have similar molar mass and similar mass distributions.

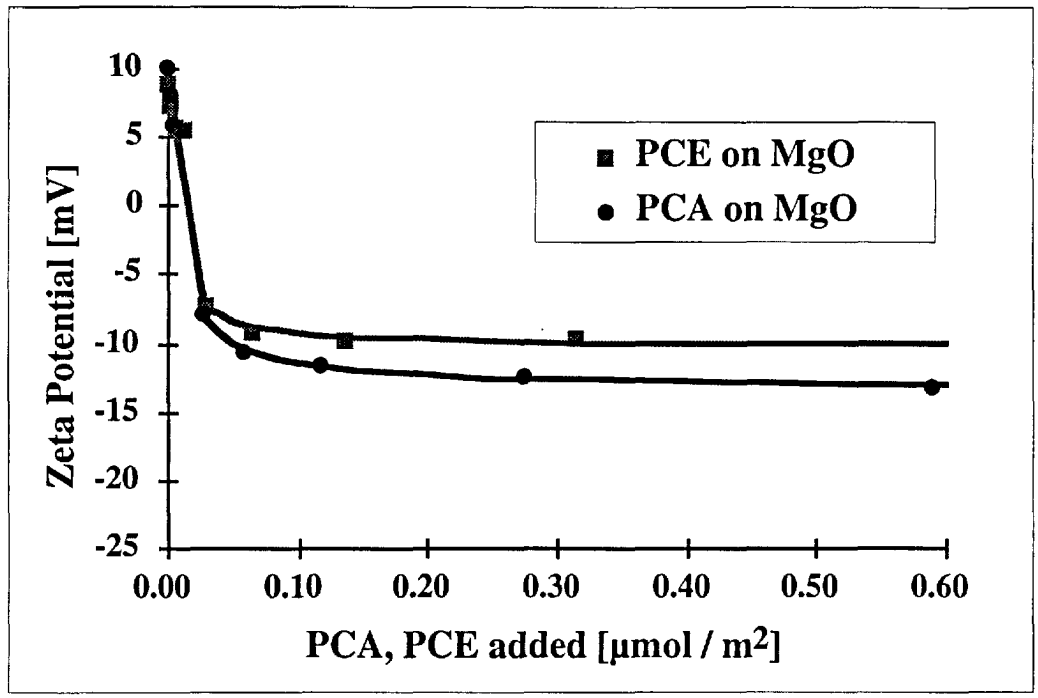

Figure 5 Zeta potential measured on magnesium oxide. The amount of superplasticizer added is given with respect to the surface of the powder in the suspension.

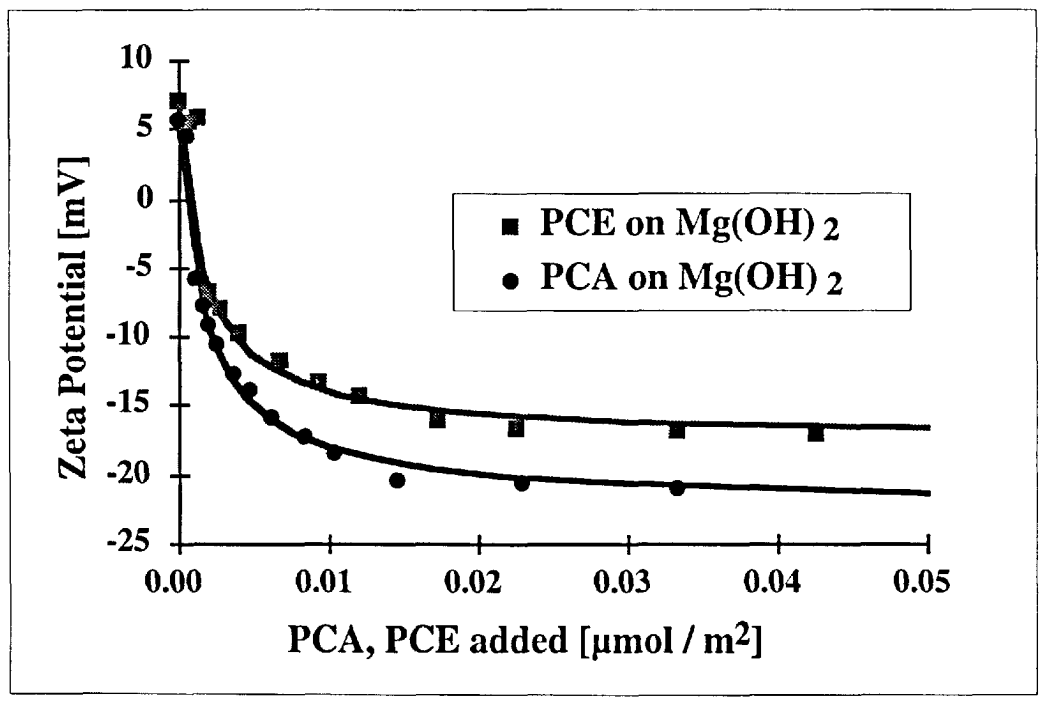

Figure 6 Zeta potential measured on magnesium hydroxide. The amount of superplasticizer added is given with respect to the surface of the powder in the suspension.

We also see especially in Fig 6, that the adsorption continues after the surface has acquired a negative charge. This might be due to either a non electrostatic interaction involved in the adsorption process, or to an inhomogeneity in the surface charge distribution. Hoogeveen et al (1996) in their study of the adsorption of cationic polyelectrolytes on oxides (TiO_2 and SiO_2) find the latter possibility the most likely in explaining a similar result with TiO_2.

CONCLUSIONS

The adsorption of the PCA polymer (a polycarboxylate, polysulfonate) on MgO does not depend on temperature, while it does for the PCE polymer (a polycarboxylate, polysulfonate, polyethylene glycol-ester containing). This may result from the PCA having a stronger interaction with the MgO surface, due to its larger number of ionic groups. On the $Mg(OH)_2$ no temperature dependence is observed. This can be due to the differences between the surfaces of both powders. More PCE than PCA can be adsorbed on either surface. However, the extra amount of adsorbed PCE is not sufficient to induce a larger negative zeta potential than the PCA.

When considering the dispersion effect of these polymers, we must therefore expect that the electrostatic effect of the PCA will be greater than for the PCE. However, due to its greater adsorption, the PCE will probably have a more important effect through steric repulsion or by entropic exclusion.

Rheological measurements must now be carried out to determine which of these polymers is the most efficient water reducer. From such measurements and with the above conclusions it may be possible to find out which effect is the most important. This knowledge will be an important help in the design and production of new even more efficient superplasticizers.

The strong temperature dependence for the adsorption of the PCE has shown that this factor could be a dominant issue concerning the use of some superplasticizers. Consequences on the rheology have still to be studied.

ACKNOWLEDGMENTS

This research was made in the frame of the EUREKA Project 1363 ICHRWR and received financial support from the Swiss Commission for Technology and Innovation (CTI) which is gratefully acknowledged. R. Oesch is thanked for having performed BET measurements of the specific surface of the powders used.

MECHANISMS OF CEMENT - ADMIXTURE INTERACTION

Umberto COSTA, Fabio CORAZZA, CTG Italcementi Group, Bergamo, Italy
Pierre COLOMBET, Valérie FERNON, Angélique VICHOT, CTG Italcementi Group, Guervillle, France

ABSTRACT Beside having physical effects which modify the bonds between the particles and therefore the rheology of cementitious mixes, some admixtures can act on the chemical processes of hydration and particularly on the nucleation and growth of crystals. When these interactions occur, final user describe the premature formation of chemical and physical bonds in the mixes as an inconvenience which is termed as "cement-admixture incompatibility" or "early thickening" of concrete. Such a too early loss of workability may have different origins. This paper is aimed at describing the basic mechanism of cement-admixtures interaction by considering the investigations of cases of practical interest.

KEY-WORDS: Mechanism, Naphthalene Formaldehyde Sulfonate, Pore solution, Rheology, Slump loss.

INTRODUCTION

The rheological behaviour of cementitious mixes depends on a number of chemical and physical factors, including the historic trend of the shear stresses occurring during preparation, haulage and casting operations (Bombled and Kalvenes, 1967; Locher et al., 1980; Massazza and Costa., 1982; Tattersall and Banfil, 1983; Costa and Massazza, 1986). Some admixtures have physical effects which modify the bonds between particles and can act on the chemical processes of hydration and particularly on the nucleation and growth of crystals. When these interactions occur, final user describe the premature formation of chemical bonds in the mixes as an inconvenience which is termed as "cement-admixture incompatibility" or "early thickening" of concrete. Such a too early loss of workability may have different origins that this paper is aimed at describing on the basis of studies carried out on some cases of practical interest.

RHEOLOGICAL BEHAVIOUR OF CONCRETE

Normal Workability Loss

The normal course of the chemical reactions occurring in the cement paste causes the progressive time-related increase in the yield value. Hydration has an evident effect in that it produces an increasing number of so-called "welding points" between the cement grains which constitute the very essence of setting and hardening. The chemical reactions occurring during the first phase of hydration (the dormant period) are the following:
- Formation of ettringite, whose nucleation starting from solution ions is the slow phase of the mechanism;
- C-S-H formation.

The natural loss of workability is therefore found in all cements, also when C_3A fails to be present, as is the case of pure C_3S, due to the formation of C-S-H bridges between the granules. This process is influenced by the mean distance between the particles which depends on the fineness and particle size distribution of the cement as well as on the water/cement ratio

(Blombed and Kalvenes, 1967). According to their different nature, admixtures can variously affect the natural loss of workability. Retarding agents, by slackening the chemical process, reduce the workability loss at a constant w/c ratio. Accelerating agents perform completely the opposite. Plasticizing and superplasticizing admixtures used as water reducing agents tend to accelerate the natural yield threshold increase as a consequence of a reduced w/c ratio.

The chemical processes related to the rheological behaviour have been investigated through isothermal calorimetry. The calorimetric curve of a portland cement, illustrated in Fig. 1, shows a first intense peak during the mixing period with ettringite being the prevailing product. The rate of reaction is subsequently slackened off (dormant period). After 2 hours, setting reactions make the rate increase again (second thermal peak). The speed is then reduced as soon as the hydrated layers surrounding the cement grains have become sufficiently thick (approximately 25 μm at 20°C) to slow down water and ion diffusion.

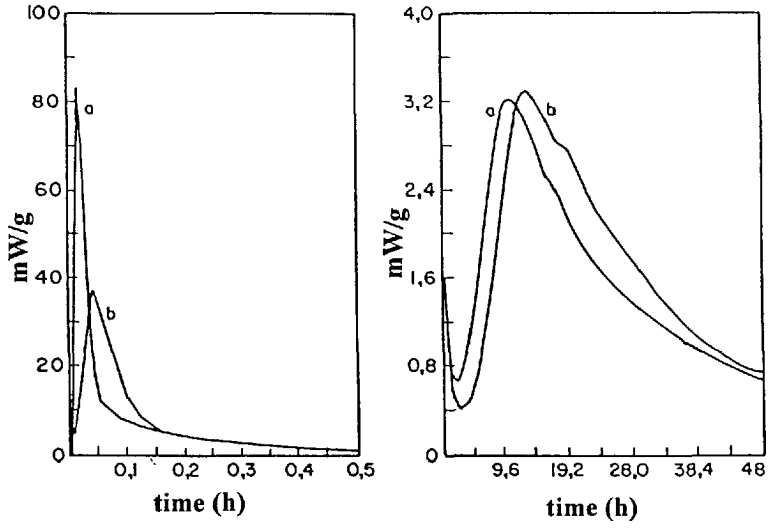

Figure 1 Calorimetric curves obtained on cement pastes: a) cement as received; b) cement with a 0,5% addition of Na-PNS

In the presence of superplasticizer the first thermal peak has lower intensity but the thermal flux is higher for a longer duration. In this case the admixture emphasises the retarding action of the calcium sulfate at the mixing period. The peak corresponding to the setting and hardening phases is not modified by the presence of the admixture. These results demonstrate that the intensification of workability loss caused by superplasticizer is principally linked to the reduction of the w/c ratio and not to particular interactions on hydration process.

Anomalous workability loss

In some cases concrete can show an anomalous trend of the rheology. The phenomena occurring in this case can be false or rapid setting.

False setting

False setting occurs when the rapid dissolution of hemihydrate produces a supersaturated solution from which gypsum crystals are formed, as in the case of the plaster of Paris. Bombled and Kalvenes (1967) determined the progress of the yield threshold in a paste affected by false setting and indicated also that the phenomenon is destined to disappear after remixing. False setting is not easily detectable in ready-mixed concrete on account of the large amount of energy

employed during mixing operations at the ready mix concrete plant. Admixtures containing strong electrolytes accelerate not only cement setting but also gypsum precipitation, which intensifies false setting. Weak electrolytes and most organic molecules with a retarding effect delay or inhibit the phenomenon inasmuch as they hinder nucleation of gypsum crystals and prevent these from precipitating.

Rapid setting

In less frequent cases of a too low gypsum content in cement, the retarding mechanism of C_3A by ettringite formation performs wrongly. Rapid setting is found to occur when the sulfate concentration gradient at the C_3A/solution interface is too small to inhibit the formation of hexagonal hydrates. The layer of aluminate hydrates covering the surfaces of C_3A contributes to stiffening the paste.

The size of hydrates thus formed, close to that of gels, is such that bonds cannot be broken by such typical mechanical actions as mixing or vibration. In the event that gypsum is not particularly underdosed, the situation is not so clear as that described above. In this case, however, a permanent increase in the yield value defined as "thickening" is found to occur.

The effects of the content and crystalline form of C_3A as well as the solubilisation rate of the mineralogical forms of gypsum have been covered exhaustively in literature (Locher et al., 1980). Fig. 2 shows the trend of the yield value of a cement paste as a function of the gypsum content and highlights the variable intensity of rapid setting.

Attenuated rapid setting (curve 5) manifests itself with a rapid increase in the yield value between 10 and 70 minutes.

Paradoxically, real set is delayed by the rapid one: in fact, the initial set is shifted from 100 to 500 minutes on account of the chemical effect of aluminate ions on the nucleation of portlandite. Also, the phenomenon of attenuated rapid setting is evidenced by conduction calorimetry (Fig. 3). An additional thermal peak, which is not observed in a normal cement, appears between 3 and 10 minutes due to the formation of aluminate hydrates.

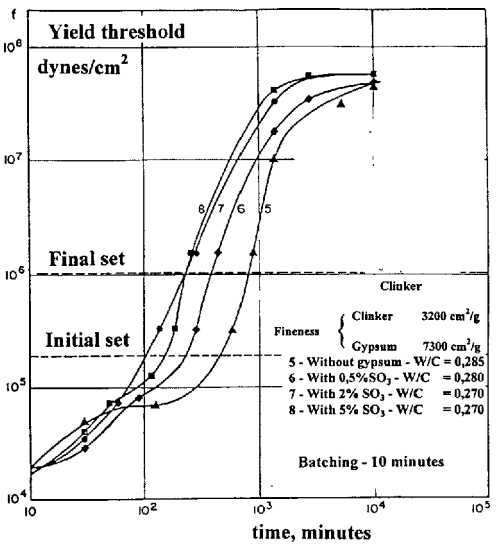

Figure 2 Attenuated rapid set: effect of gypsum addition (Bombled et al., 1967)

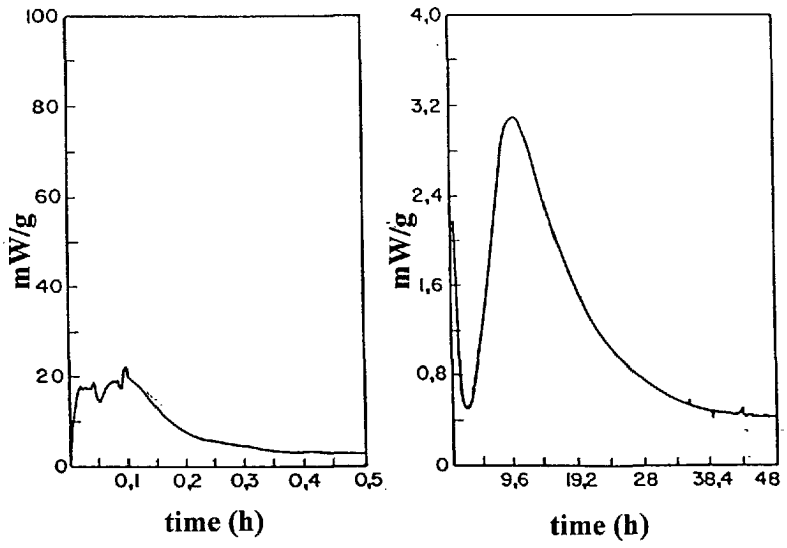

Figure 3 Calorimetric curve of a cement paste affected by an attenuated rapid set

As regards the influence of admixtures, a typical effect of attenuated rapid setting is sometimes found when using superplasticizers. Paste thickening becomes evident when the superplasticizers disturb the regulating mechanism of gypsum on C_3A hydration. With reference to set regulation mechanisms in the presence of superplasticizers, these items are considered in this study:

- The effect on the gypsum solubility
- The effect on ettringite nucleation
- The complex formation between superplasticizer and aluminate hydrates
- The modification of ionic equilibria of interstitial solutions.

POLYNAPHTHALENESULFONATE (PNS) - CEMENT INTERACTION

Materials

Cements - Five portland cements (A, B, C, D, E) were studied. Fineness, setting times, specific gravity and chemical analysis of those cements are given in Table 1.

Superplasticizers - The admixtures were sodium or calcium salts (Na-PNS, Ca-PNS) of a polydispersed naphthalene formaldehyde sulfonic acid. Two other sulfonates have also been tested, namely a sodium salt of β-naphthalene sulfonic acid (2NSA) and a disodium salt of 1,5-naphthalenedisulfonic acid (15NDS), both of which had been previously studied as far as the interaction with calcium aluminate hydrates is concerned (Fernon, 1994).

Calcium sulfates - The gypsum was an industrial set regulator (73% gypsum + 16% anhydrite + 11% impurities). Various other calcium sulfates containing various amounts of hemihydrate and anydrite (Table 2) were obtained from this set regulator via thermal treatments. Interaction between Ca sulfates and PNS was studied using a saturated lime solution to simulate the conditions of a cement paste. The water/solid ratio was 10, thus yielding a mixure with a consistency similar to that of a paste and the PNS concentration was 21.33 $g.l^{-1}$.

Hydrates preparation - Pristine calcium aluminate hydrate (C_4AH_X) was prepared by reacting a small excess of a saturated $Ca(OH)_2$ solution ($[Ca^{2+}] = 21.45$ mM) with an aqueous solution of $NaAlO_2$ ($[AlO_2^{-1}] \approx 6.5$ mM). Coprecipitation products of calcium aluminate hydrate and PNS were obtained following the same procedure. PNS was first dissolved in the saturated $Ca(OH)_2$ solution together with various amounts of K_2SO_4. All the syntheses were perfomed using a continuous batch reactor with a sufficient residence time (an hour) to allow the equilibrium to be reached. After precipitation, the suspension was filtered. The solid phase was dried under vacuum at 80-100°C and stored in a CO_2 and H_2O- free atmosphere prior to characterization.

Methods

Solid products characterization - The structure of the precipitated solids was determined using X-ray diffraction, scanning electron microscopy and transmission electron microscopy.

Fluid pore analysis - PNS concentration was measured by UV spectrophotometry at the characteristic peak absorbance wavelength of 290 nm. Filtrate composition (SO_4^{2-}, Cl^-, Ca^{2+}, Na^+, K^+) was determined by capillary-ion analysis, ion chromatography and atomic absorption spectrophotometry along with its pH. The pore fluid was removed from fresh pastes by filtration and from mortars using a pressing-machine equipped with an adapted mold.

Mortar and pastes rheology - The flow behavior of mortars was studied using a flow table meeting ASTM specification C-230 (cement A, B and C), and a Fann rotation rheometer for pastes (cement D and E). The mortar flow was measured after 15 drops. All the tests were perfomed at 20°C and 75% RH. For pastes, yield value was estimated by measuring stress at various strain rates and extrapolating the stress at zero strain rate.

Results

Organomineral Compounds Formation

In the absence of sulfate anions

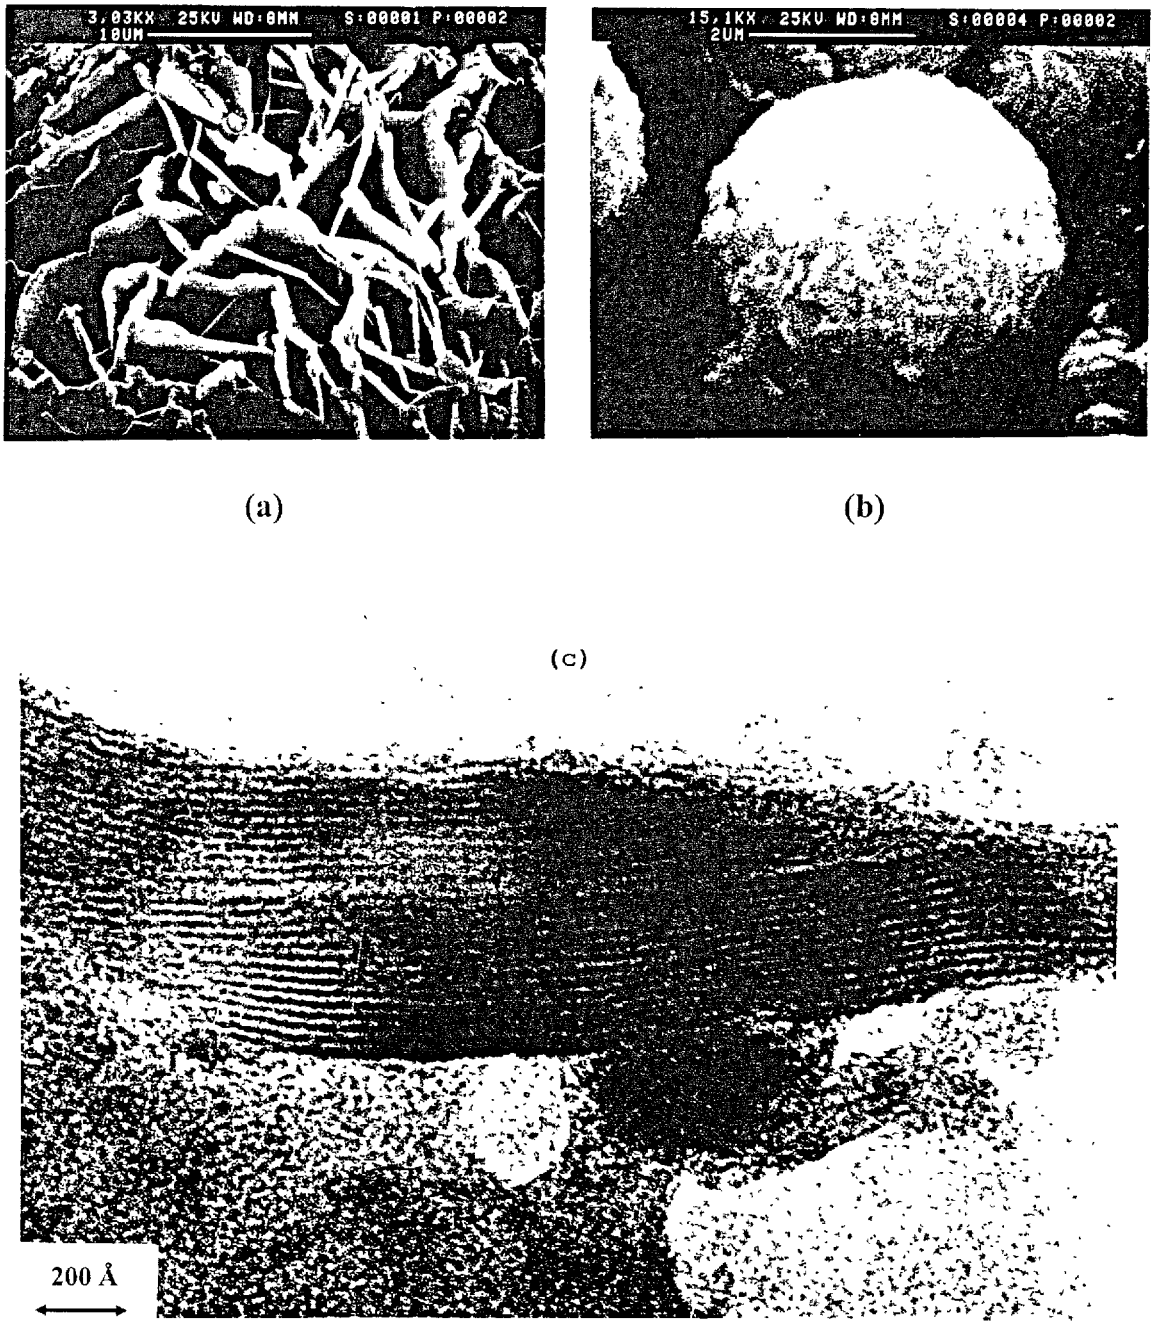
The elemental composition of the co-precipitated products is given in Table 3. They can all be considered as organomineral compounds, since they appear, at the scale of the SEM and TEM observations (Fig. 4), as homogeneously constituted of organic molecules or polymers intimately bound to a mineral skeleton made of calcium aluminate hydrate. In all cases, the Ca/Al molar ratio as measured using elemental analysis is not far from 2, suggesting the existence of $[Ca_2Al(OH)_6]^+$ units which are the principal layers from which C_4AH_X is built up (Hanic et al., 1989). From Table 3, it may be seen that the shorter the length of the polymer, the closer to 2 is the Ca/Al molar ratio which indicates a better ordered structural organization of the constitutive elements.

Table 3 Elemental composition of the organomineral compounds obtained by co-precipitation

Sulfonate precursor	Initial sulfonate concentrat. (gl^{-1})	Ca/S Initial molar ratio	% C	% S	% H	% Ca	% Al	Ca/Al molar ratio	Ca/SO_3 molar ratio	% organic part
none	-	-	3.8	-	3.1	9.9	24.7	1.7	-	
2NSA	2.5	2.00	25.6	6.6	3.9	16.4	5.7	1.9	2.0	42
15NDS	1.8	2.00	12.5	6.0	2.4	21.2	8.1	1.8	2.8	24
Na-PNS	2.0	2.60	31.1	6.5	4.1	13.6	3.9	2.4	1.7	57
Na-PNS	4.7	0.56	35.7	7.9	4 1	11.4	3.1	2.5	1.2	75
Na-PNS	10.0	0.26	35.0	7.8	4.1	11.1	3.2	2.3	1.1	75
Ca-PNS	2.7	1.95	28.9	7.0	3.7	14.2	4.3	2.2	1.6	80

This is confirmed by the XRD study which shows that the diffraction peaks become narrower. As the system becomes disordered both with increasing sulfonate molecular weight and initial concentration, the Ca/SO_3 molar ratio (SO_3 being the sulfonate group of the oligomers or polymers) decreases from ca. 2 to ca. 1. Simultaneously, the organic part amount increases from ca. 30% to ca. 75%. From these considerations, two formulae can be proposed. For the oligomers (2NSA and 15NDS), the organomineral compound can be described using the formula $< [Ca_4Al_2(OH)_{12}]^{2+}$, $2SO_3^-$, $nH_2O >$, whereas for the polydispersed high molecular

weight sulfonates it is described using $< [Ca_4Al_2(OH)_{12}]^{2+}$, $2SO_3^-$, x/2 Ca^{2+}, xSO_3^- $nH_2O >$. Also, the lamellar aspect of the organomineral compounds is confirmed by TEM showing well defined 002 lattice fringes (Fig. 4c).



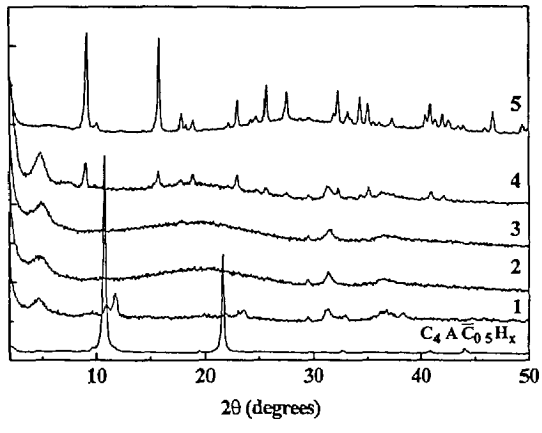


Figure 4 SEM Micrographs of the synthesized organomineral compounds obtained with 2NSA (a) and PNS (b); TEM micrograph of the 2NSA organomineral compound showing 002 lattice fringes (c)

In the presence of sulfate

When sulfate anions are present in the solution (this study is restricted to the case of Na-PNS), both ettringite and the organomineral compound are shown to be formed. Their proportions

depend on the initial SO_3^{-}/SO_4^{2-} molar ratio (Fig. 5). As this ratio decreases, the amount of ettringite increases. Interestingly, the morphology of ettringite in the presence of PNS is observed to be different from the one typically observed in cement pastes. Instead of long needles with an hexagonal section, small crystallites have grown. PNS may hence be suggested as acting as an inhibitor of crystal growth as previously stated by Luke and Aitcin, 1990.

1 - $[SO_4^{2-}] = 0$ g l^{-1} and low initial $[SO_3^{-}]$ concentration
2 - $[SO_4^{2-}] = 0$ g l^{-1} and high initial $[SO_3^{-}]$ concentration
3 - 7.2 ≤ initial SO_3^{-} / SO_4^{2-} molar ratio
4 - 2.88 ≤ initial SO_3^{-} / SO_4^{2-} molar ratio ≤ 4.11
5 - 0 < initial SO_3^{-} / SO_4^{2-} molar ratio < 2.88

Figure 5 XRD patterns (λ_{Cu} = 1.54051 Å) of the organomineral compounds obtained from Na-PNS in the presence of K_2SO_4

PNS/sulfate interaction

The results of the analysis of the sulfates and PNS in the lime saturated solution as a function of time are shown in Fig. 6.

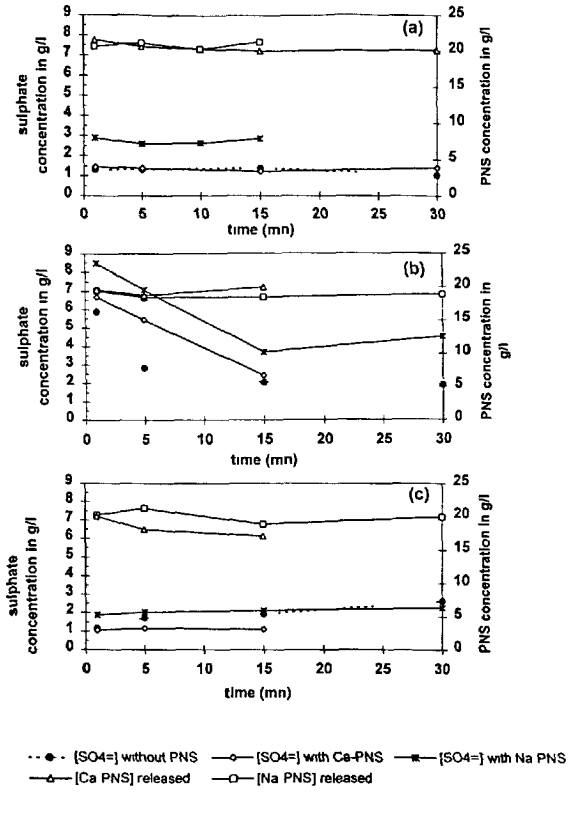

Figure 6 Effect of PNS-counter ions on the dissolution of set regulators of different nature: sample 1 (a), sample 2 (b) and sample 3 (c) (see Table 2)

It is clearly observed that Na-PNS greatly enhances the solubility of set regulators rich in gypsum or in hemihydrate, in agreement with the results obtained by Jolicoeur et al. (1994) for the same type of superplasticizer with Na as the counter ion, and only slightly that of anhydrite. To the contrary, Ca-PNS does not affect their solubilities except for anhydrite for which a decrease is evidenced. On the other hand, both Na- and Ca-PNS delay the gypsum precipitation subsequent to hemihydrate dissolution (15 minutes as compared to 5 minutes without superplasticizer). The important effect of Na-PNS on the gypsum and hemihydrate solubilities can be explained considering that ionized sulfonate groups in an alkaline medium are able to complex the free calcium ions present in the solution, increasing the dissolution of calcium sulfate due to an equilibrium shift.

The fact that the gypsum and hemihydrate solubilities in the presence of Ca-PNS are unchanged, as previously observed by Dodson and Hayden in the case of Ca-lignosulfonate (Dodson and Hayden, 1980), corroborates the hypothesis that calcium complexation by Na-PNS is actually at the origin of the solubility enhancement.

Pore fluid solution and rheology

As shown in Fig. 7 the plain pastes and mortars exhibit only a slight decrease of flow as a function of time (normal slump loss). This loss of fluidity is higher in the presence of the superplasticizer, except for cement E for which the yield value is practically zero. Cement A has a behavior markedly distinct from that of the other cements since the flow decrease from 5 to 15 minutes is much larger. As a matter of fact, cement A mortar is no longer workable after ca. 30 minutes, which leads us to consider that this cement exhibits early stiffening as it is superplasticized.

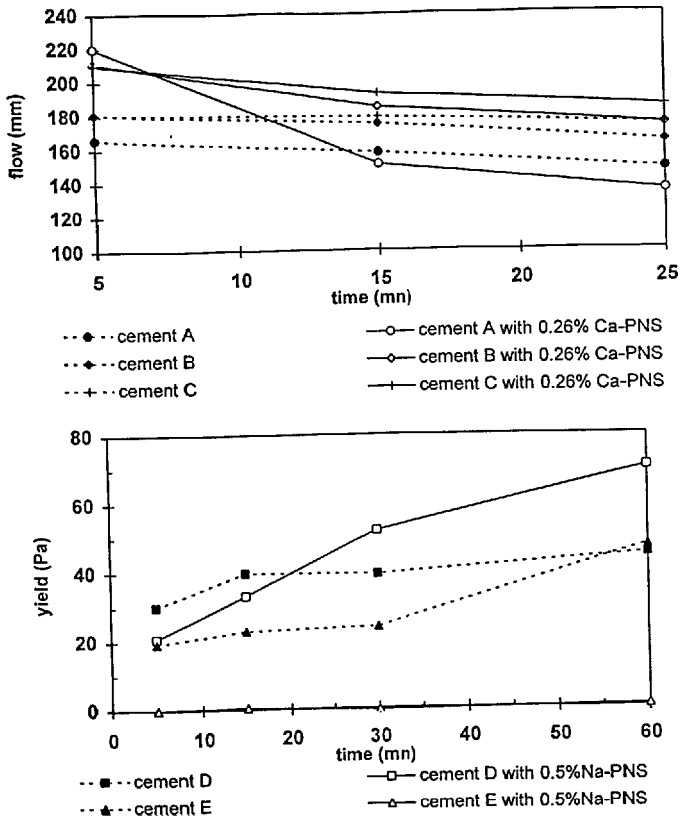

Figure 7 Rheological behaviour of the studied cements

As it can be seen from Tables 4 and 5, the peculiar behavior of cement A with respect to that of the others is also reflected in the chemistry of the pore fluid solution, as regards the sulfate concentration. That is to say, the above discussed stiffening for cement A is accompanied by an important increase in the sulfate concentration, which is not observed for cements B-E. For cement A specifically, the sulfate concentrations are 3.7, 5.9 and 7.0 $g.l^{-1}$ for initial PNS concentrations equal to 0, 5.4 and 14.8, respectively whereas they remain fairly constant and equal to 3.5 ± 0.5 (mortars, cements B and C) or 14 ± 1 (paste, cement D) or 6 ± 1 $g.l^{-1}$ (paste, cement E) i.e. dependent on the water/cement ratio (differing for mortars or pastes) and composition of the cement, but not on the absence or presence of superplasticizer. Note that for all the studied cements, including cement A, the concentrations of the other ions remain unchanged, within experimental accuracy, as the superplasticizer is added to the mixes, with reference to the concentrations measured in the absence of superplasticizer. On the other hand, whatever the flow behavior may be, about 80% of the PNS initial amount is observed to be consumed within 15 minutes.

DISCUSSION

The basic interactions of PNS with aluminate hydrates, calcium sulfate and pore solution can justify the different rheological behavior shown by the cements studied. It can be stated that the ability of C_3A hydration products to absorb PNS (yielding organomineral compounds of the type described earlier) prevents any positive effects of the admixture on the normal workability loss observed for cements B, C and D. The cement E has not an evident workability loss but

this cement is very easy to fluidify by PNS and that can be ascribed to peculiar minerological composition characterized by the absence of C_3A.

Table 5 Ionic concentration ($g.l^{-1}$) evolution of the pore fluid solution of pastes during hydration. The contribution from Na_2SO_4 present in PNS has been substracted.

	30	0.8	5.8	0.9	2.2	3.5
	60	0.8	6.3	1.0	2.1	4.6

The cement A exhibits en abnormal early stiffening in spite of having chemical and minerological composition similar to that of cements B, C. It is important to note that the early stiffening of cement A can neither be related neither to false setting nor to attenuated rapid setting, otherwise the flow loss would have been observed in the absence of PNS.

The sulfate excess found in the pore solution of mortar of cement A in the presence of Ca-PNS cannot be attributed to an enhancement of the solubility of the set regulator (via e.g. calcium complexation), as it could have been inferred for Na-PNS taking into account the results presented in Fig. 6. Alternatively, it cannot be accounted for by assuming simply the formation of an organomineral compound, resulting from co-precipitation of PNS and C_4AH_X, because this cement has shown an absorption rate of PNS similar to that of the other cements. The only way to explain the observed phenomenon for cement A (early stiffening and excess of sulfates) hence turns out to invoke the insufficient supply of calcium and aluminate ions from aluminate phases ($C_3A + C_4AF$) to yield ettringite, due to a strong reduction of their reactivity to gypsum in the presence of PNS. The supply would however be sufficient in the absence of superplasticizer.

CONCLUSION

The previous studies dealing with early stiffening as a case of cement-admixture incompatibility evidence the fact that such a peculiar rheological behavior may be accounted for assuming that the presence of e.g. PNS leads to an insufficient supply of dissolved calcium sulfate to form ettringite (Jolicoeur et al., 1994; Dodson and Hayden, 1980; Tagnit-Hamou and Aitcin, 1993). This study does not confirm this hypothesis because the phenomenon appears to be related to an excess of dissolved calcium sulfate. Also in this case, the normal progress of hydration is not regular because no ettringite is formed. This statement corroborates the conclusion recently drawn by Bonen and Sarkar, 1995 stating that the higher the ionic strength (stemming from a higher ionic concentration), the faster the slump loss.

ABSTRACT The effect of two chemical admixtures (superplastizisers) on a normal white cement (16% C_3A) and on a mineralized cement (5% C_3A) has been studied. One of the admixtures is based on sulphonated naphthalene formaldehyde and the other on sulphonated melamine formaldehyde. Variations on setting times, on rheological properties as well as variations on mechanical strengths of mortars of both cements have been established.

Key words: Admixtures, White Portland Cement, Sulphate resistence, Strength development.

INTRODUCTION

Blanco-Varela et al (1981), Giménez et al (1991) described the procedure for obtaining new cements, using ordinary raw mixes partially substituted by fluorine and sulphates. One of the most interesting compositional characteristics of these cements are they contain a **new liquid phase** (Blanco-Varela et al., 1986) with low aluminate proportion.

The temperature of formation of the mentioned liquid phase is 1180°C and its approximated composition is :

CaO = 54%wt
Al_2O_3 = 4%wt
Fe_2O_3 = 3%wt
SiO_2 = 11%wt
CaF_2 = 4%wt
$CaSO_4$ = 24%wt

The validity of the mentioned melt for production of clinkers of low energy cost was verified in laboratory as well as in various Spanish cement factories.

The mineraliser pair F^- and SO_4^{2-} decreases alite stabilisation temperature, placing it at 1050°C.

As a function of the clinker desired (grey or white; or the same with little liquid phase that are more difficult to get), a suitable amount of mineralisers will be necessary.

As a consequence, this process provides clinkering with any type of raw mix and low energy cost, being its action more decisive in the so-called "very hard burning".

Most of the characteristics of the new raw mixes are similar to those of the traditional ones. So, the proportion of hydraulic calcium silicates (alite and belite) remains similar or even increased in the mineralised cement; however, mineralogical composition of the new cement is different

to that of the normal cement with respect to interstitial clinker phase, because aluminates and ferrites may be substituted, even totally by the phase called **fluorellesteadite** (Fell.) : $Ca_{10}(SiO_4)_3(SO_4)_3F_2$.

In these cases, because of the low aluminate content (as in the case of sea-water and sulphate resistant cements SR-MR of spanish standard UNE 80.305 and type V of ASTM), and with respect to normal white cements, they lead to longer setting times and lower mechanical strengths at early ages, although at longer times, the strengths are higher. There are little differences in microstructural developments in the pastes obtained from the two cements; with except of a considerably lower ettringite content in the case of the mineralised cement. Fluorellesteadite, an extremely stable phase, remains unaltered with cement hydration.

Other advantages of the new cements, with respect to that obtained according to the traditional process are:

- Decrease in environmental pollution caused by dust emission.
- Increase in specific clinker production
- Better performance in cement mills
- Low hydration heat
- Better strengths at long ages.

The effect of additions on mineralised cements have not been verified. The different nature of the liquid phase of said cements it is supposed to influence the effect of the chemicals when compared to the normal cement. At least, with respect to rheological characteristics, setting time and early age strengths.

The aim of the present work is to verify the effect of two commercial superplasticizers (hyperplasticising admixture) of general use, on a SR-MR white mineralised cement. One of the admixtures used is of sulphonated melamine formaldehyde type (S.M.F.) and the other is based on sulphonated naphthalene formaldehyde (S.N.F.).

EXPERIMENTAL

The normal clinker used in this work has been obtained in a spanish factory of white cement. The mineralised white clinker used has been obtained in the same factory, but modifying the raw mix with the mineraliser pair $CaF_2/CaSO_4$. The mineralised cement was obtained from this clinker, but after a period of time which generated on it to a partial meteorization.
The characteristics of the superplastizicers utilised are the following:

SNF: S.g. (specific gravity) = 1.21 g/cc
solid content = 40%
pH = 7.1± 0.5

SMF: S.g.= 1.24 g/cc
solid content = 40%
pH = 12 ±0.5.

The chemicals were used in proportion 1% in weight of the cement and they were added to mixing water. The settings has been carried out on pure paste by Vicat needle and workability

loss is measured with a mini-slump using mortars (1:3), and measuring the flow after 60 minutes rest.

To make the mechanical strength tests comparable in all cases, 1:3 mortars have been obtained at constat flow. This is, varying the european standard E.N. 197.1 that recommends that water remains constant (w/c = 0.5).
Compressive strengths have been tested at 1, 3, 7 and 28 days. Cements characteristics have been proved with and without the admixtures.

RESULTS AND DISCUSSION

The general characteristics of the clinkers which were the base for the cements studied are given in Tables 1 and 2, respectively.

Obviously, Bogue formulas and moduli cannot be applied to the case of mineralised clinker. For example, fluorellesteadite formation means to fixed certain proportions of Si and Ca that will not be integrated in phases hydraulically active. In this case modified Bogue formulas and LSF moduli are applied. Anyway, for their relative value, they are given in Table 2.

TABLE 1 CHEMICAL ANALYSIS OF THE INDUSTRIAL WHITE CLINKERS (% wt)

CLINKER	L O I	F LIME	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	F^-	SO_3	K_2O	Na_2O	$(SO_3)s$ (*)	$(K_2O)s$	$(Na_2O)s$
NORMAL	0,50	0,63	23,1	6,2	0,28	67,8	0,83	0,24	0,89	0,14	0,05	0,31	0,02	0,01
MINERAL	0,90	0,84	23,8	2,3	0,27	68,0	0,48	0,85	3,5	0 12	0,04	0,65	0,01	0,01

(*) $(SO_3)s$-$(K_2O)s$-$(Na_2O)s$ - Water soluble

TABLE 2 RATIOS AND MAIN CLINKER PHASES

CLINKER	L S F	S/A+F	A/F	C_3S	C_2S	C_3A	C_4AF	FeII
NORMAL	92,4	3,6	22,1	55	25	16	0,85	--
MINERAL	93	9,3	8,5	66,7	10,5	5,6	0,85	14

The major difference between both clinkers is the moderate value of SO_3 (0.89%) and the high value of Al_2O_3 (6.2%) in the normal cement and the high SO_3 value (3.5%) and low Al_2O_3 value (2.3%) in the mineralised cement. C_3A content is of 16% in the first case and of about 5% in the second case. In spite of the different SO_3 proportion, water soluble sulphates are low in both cases. Likewise, both clinkers are "low -alkali". C_3S and C_2S sum is similar in both cases. Of course the mineralised clinnker contains the new phase Fluorellestadite.

After clinkers grinding in laboratory in the same conditions, normal clinker (with high C_3A content) gives higher initial strengths, having the mineralised clinker higher values at 7 days (Table 3).

TABLE 3 PHYSICAL CHARACTERISTICS OF THE INDUSTRIAL WHITE CLINKERS

CLINKER	WHITENESS	BLAINE	COMPRESSIVE STRENGTH (E N 1971)(N/mm²)			
			1 DAY	2 DAYS	7 DAYS	28 DAYS
NORMAL	83	3 900	18	33	57	67
MINERALIZED	83	3 900	12	27	58	75

The fineness and whiteness indexes are similar in both clinkers. The cements used in the present study were obtained from former clinkers, but, as it has been said, the mineralised cement was manufactured from a slightly meteorised clinker, which has negatively influenced strength development, mainly at early ages. This fact was thought would show better the admixture effect and by this reason, the use of this cement was considered suitable for this study. That effect shows why L.O.I. values (2,5%) and F. Lime values (1.0%) in the cement (Table 4), are higher than those of the clinker, showed in Table 1.

Optimum gypsum amount for normal cement is of 5% and it is of 2% in the mineralised cement.

TABLE 4 CHEMICAL ANALYSIS (%wt) OF HITE CEMENTS USED

CEMENT	L O I	F LIME	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	F^-	SO_3	K_2O	Na_2O	$(SO_3)s$	K_2Os	Na_2Os

MINERAL	2,4	1,0	22,9	2,2	0,26	66,2	0,46	0,82	5,1	0 12	0,04	1,8	0,01	0,01

Setting times and rheological characteristics.

The effect of admixtures on setting time depends on cement type. The parameters with major influence are: fineness, alkalis, different sulphate forms and C_3A content.

In the cements here studied, fineness differences are inexistent; SO_3 soluble content is similar (approx. 2%) and alkaline sulphates are very low, hence, their influence on setting times is negligible. The most notable difference between both cements is the corresponding C_3A content.

Soluble SO_3 to C_3A ratio is 0.14 in the normal clinker an 0.36 in the mineralised clinker. So in the latter, C_3A hydration is blocked before - ettringite formation rate is higher- than in cement with higher C_3A content. This is, setting duration is longer than in normal cement.
The C_3A that has not reacted with sulphates, adsorb the admixtures acting these as regulators: as a consequence, setting duration is longer.

In the case of mineralised cement, admixtures shorten setting duration because they inhibit the sulphate reaction. Setting times of both cements after admixtures addition are similar and they correspond to normal values (Table 5).

TABLE 5 TIME OF SETTING (PASTE)

CEMENT	BLAINE	% ADM	I. SET	F. SET	% ADM	I. SET	F. SET	% ADM	I. SET	F. SET
NORMAL	3730	0	199'	159'	1% S.N.F.	174'	219'	1% S.N.F.	139'	179'
MINERAL	3690	0	169'	264'	1% S.M.F.	134'	234'	1% S.M.F.	139'	214'

Sometimes, admixtures fluidifying action is short and the time necessary for a determined work is not maintained. In Table 6, mini-slump loss is shown for both cements after 60 minutes rest.

TABLE 6 EFFECT OF TIME ON THE FLOW (MORTAR)

CEMENT	%ADMIXT.	w/c	FLOW 1'	FLOW 60'	%ADMIXT.	w/c	FLOW 1'	FLOW 60'	%ADMIXT.	w/c	FLOW 1'	FLOW 60'
NORMAL	0	0,578	110±5	32	1%S.N.F.	0,511	110±5	47	1%S.M.F.	0,518	110±5	36
MINERAL.	0	0,544	110±5	31	1%S.N.F.	0,453	110±5	15	1%S.M.F.	0,436	110±5	57

The same behaviour is observed in both cements when they have no admixture. Superplasticizing SNF addition enhances workability in normal cement, whereas SMF enhances that of the mineralised cement.

Mechanical strengths

In order to make comparable the tests, mortars were obtained at constant flow of 110±5, varying water proportion. Water content of specimens done with mineralised cement was always lower than in the case of mortars done with C_3A high content cement (Table 7). This also happens in mortars with admixture.

TABLE 7 COMPRESSIVE STRENGTH E.N. 1971 MODIFIED. - c/s = 1/3 W/C = VARIABLE; FLOW=k=110 ± 5

CEMENT	%ADMIXTURE	W/c	1 DAY %	3 DAYS %	7 DAYS %	28 DAYS %
NORMAL	0	0,578	100%	100%	100%	100%
MINERAL	0	0,544	69%	74%	76%	92%
NORMAL	1% S.N.F.	0,511	146%	126%	122%	117%
MINERAL	1% S.N.F.	0,453	114%	114%	113%	120%
NORMAL	1% S.M.F.	0,518	144%	120%	110%	98%
MINERAL	1% S.M.F.	0,436	132%	116%	116%	121%

In the same Table 7, values of compressive strength (in percentage) are shown, given at 100% value to results obtained with normal cement; it is observed that specimens elaborated with mineralised cement, with low C_3A content, present lower strengths at early ages than normal cement. Particularly, at 24 hours, they are 60% of those. Values are similar at longer ages.

In specimens elaborated with normal cement and SNF admixture, strengths are higher to those obtained with SMF, being generally more acute the strengths increase at early ages (146% with SNF at 24 h) than at long ages (98%, at 28 days with SMF).

Oppositely, with the mineralised cement, the highest strengths are reached with SMF admixture.

In general, the response of mineralised cement is very good with both admixtures, reaching percentage increases with respect to those of the cement without admixtures higher than those of the normal cement, specially at early ages, which was the weaker aspect of this cement (Table 8).

TABLE 8 EFFECT OF CHEMICAL ADMIXTURES ON COMPRESSIVE STRENGTH (CEMENT MINERALIZED)

% ADMIXTURE	w/c	1 DAY %	3 DAYS %	7 DAYS %	28 DAYS %
0	0,544	100	100	100	100%
1% SNF	0,453	165	154	150	131
1% SMF	0,436	192	158	153	132

SUMMARY AND CONCLUSIONS

The difficult burnability of the white clinker with low C_3A content is highly enhanced with the adequate dosage of the raw mix with the mineraliser pair gypsum-fluorite, saving more than 10% of the clinkering energy. Besides, a lower consumption in Kwh/T in the mills is reached because of an easier clinker grinding.

The cements elaborated with this clinker are resistant to aggressive agents (gypsum and sea water), although, as a consequence, setting time and strengths at early ages are somehow altered. They are lower than those corresponding to cements with high and moderate C_3A contents. The addition of superplastizicing admixtures based on SNF and SMF to the mineralised cement shortens setting time and considerable increases strengths, specially at early ages.

With SMF, flow is maintained for a longer time. Hence, with mineralised cement, concretes with equal or better rheological behaviours than those of white concrete of high resistance can be manufactured with the advantage that they will be resistant to aggressive agents (sulphates and sea water).

ABSTRACT This study deals with the relation of cement characters to the effects of triisopropanolamine (TIPA) as an accelerator of hydration and strength development. TIPA enhanced the 28 day mortar strength development of the cement with ferrite phase. The content of alite and the fineness of cement were also concerned with the effects of TIPA; i.e., the increased degree of the strength development with TIPA became high with increasing the former and decreasing the latter. TIPA was further valuable for the cements containing high amounts of limestone and gypsum (SO_3) because of their reaction with ferrite phase during hydration.

Key-words: Accelerators, Alite, Ferrite phase, Lime, Gypsum

INTRODUCTION

Organic agents give a significant influence on the hydration of portland cement (Suzuki et al. 1959, Ramachandran 1976). E. Gartner et al. (1993a) have clarified that TIPA accelerates the hydration of ferrite phase as a result of increasing the solubility of ferric hydroxide which is produced by the hydration of ferrite phase and inhibits the subsequent hydration. Further, TIPA enhances the strength development of cement mortar because its effect on ferrite hydration leads to the promotion of the hydration of silicate phases which form a cement grain with ferrite phase.

The present study deals with the influence of cement characters such as mineral composition of the clinker used, fineness, amount of added limestone and SO_3 content on the strength enhancement of cement mortar with the addition of TIPA.

MATERIALS

Three types of cement clinkers N, L and W, of which mineral compositions are different as shown in Table 1, were ground with gypsum in a ball mill to a given blaine specific surface area. Limestone (Calcite) with the chemical composition shown in Table 2 was separately ground to blaine specific surface area of 392m²/kg. The characters of the prepared cements are listed in Table 3. TIPA used is a reagent with a purity of more than 95%.

EXPERIMENTAL

Determination of compressive strength

The compressive strength of cement mortar after 3, 7 and 28 days was determined in accordance with JIS R 5201. Since TIPA is solid at room temperature, it was previously dissolved in the mixing water. The amount of TIPA added was 0.01wt% of the cement.

Observation of alite and belite crystals in cement

Microscopic observations have been made to examine the cement grains consisting of alite and belite crystals.

Identification of hydration products and determination of the hydration degrees of cement constituent minerals

The cements with blaine specific surface area of 325m^2/kg prepared from clinker N with and without limestone admixture were mixed with water at the W/C ratio of 0.4. The cement pastes were kept in small sealed glass jars at 20℃ for 3 and 28 days. TIPA was added in the same manner as in the compressive strength test. Hydration was stopped by grinding with acetone. It was then dried in a nitrogen atmosphere of 15% R.H. for 3 hours.

Using the prepared samples, the crystalline hydration products were identified with powder X-ray diffractometry. The X-ray diffractometer with CuKα radiation (40kV 150mA) was used at a scan rate of 5° 2θ/min. The DS, SS and RS are 1°, 1° and 0.15mm, respectively.

The degrees of hydration of alite, ferrite phase and limestone after 28 days were also determined. The measuring conditions of the X-ray diffractometer are the same as above except for carrying out the step scanning with each 2θ step 0.02° and fixed time 8 seconds. α-Al_2O_3 was used as the internal standard. According to Ishizaki et al. (1988) and Asaga (1995) the peaks used were 0 4 0,14 2 4 (d=1.76Å, 1.77Å) of alite, 0 2 0 (d=7.27Å) of ferrite phase, 1 0 4 (d=3.04Å) of limestone (Calcite) and 0 2 4 (d=1.74Å) of α-Al_2O_3.

RESULTS AND DISCUSSION

Fig. 1 shows the relation of the mineral composition and blaine specific surface area with the strength enhancement by TIPA. The compressive strength of mortar with the cement W*, which contains almost no ferrite phase, was not enhanced by TIPA. This indicates that the effect of TIPA as an accelerator of the ferrite phase hydration (Gartner and Myers1993a) is definitely concerned with the strength enhancement. However, a large difference in the above effect by TIPA was obtained even between the cements N and L in which the amount of ferrite phase was nearly equal; the ratio of the mortar strength with TIPA to that without it was obviously high in the cement N. The decrease in blaine specific surface area increased the difference. These are explained by taking into account the differences in the ratio of silicate phases (alite and belite) and in their grindability. Of four main minerals in clinker, belite shows the strongest resistance to fracture (Hornain and Regourd 1980), so that fractures are apt to occur along the crystal grain boundary of belite during clinker grinding (Maki et al. 1993b). In contrast, the high grindability of alite causes fractures to penetrate into the alite crystal, leading to the existence of alite as a

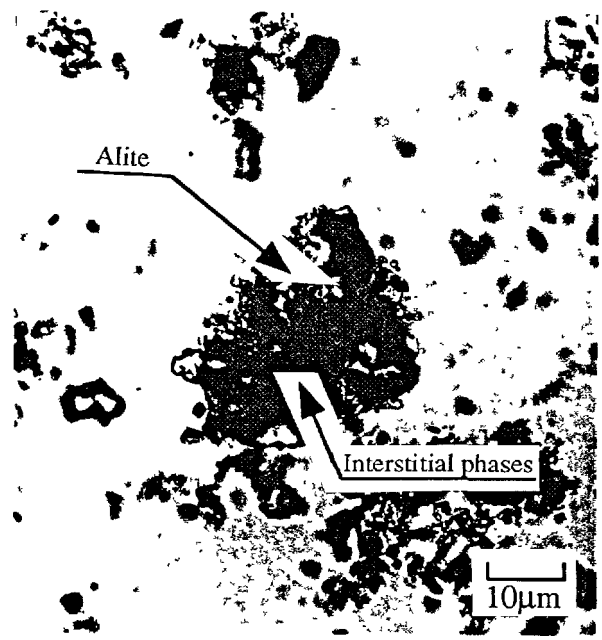

Fig. 2 Alite crystal coexisting with interstitial phases in a cement grain.

* Cement W (N and L) ; Cement prepared from clinker W (N and L)

polymineralic grain after grinding. According to our microscopic observations, belite in cement mostly existed as a single grain though some coarse clusters of belite in the fraction over 30μm in diameter were observed. Meanwhile, as shown in Fig. 2, alite frequently coexisted with interstitial phases including ferrite phase in a grain. Gartner et al. (1993a) suggested that in a polymineralic grain the accelerated hydration of ferrite phase by TIPA will expose surfaces of the adjacent silicate phases and consequently accelerate the hydration of them. The difference in strength enhancement of mortar by TIPA between the cements N and L is considered to be caused by the difference in the proportion of polymineralic grain; i.e., the cement N, which is abundant in alite, includes a high amount of polymineralic grains, resulting in a high strength enhancement by TIPA. It was easily understood that the decrease in blaine specific surface area increases the polymineralic grains and the strength enhancement by TIPA. In conjunction with belite content it took a longer time for grinding the clinker L to a given fineness compared to the other clinkers and thus fine single grains of alite were easily observed in the cement L. This is presumably one of the reasons why the strength enhancement by TIPA is limited in the cement L.

Fig. 3 shows the relationship between the limestone content in cement and the strength enhancement of mortar by TIPA. The strengths of mortar after 3 and 7 days were almost constant regardless of the limestone content and the addition of TIPA. On the other hand, the 28 day strength decreased to a considerable extent with the increase in the limestone content but the addition of TIPA depressed the decrease; i.e., the effect of TIPA was enlarged with the increase in limestone admixture.

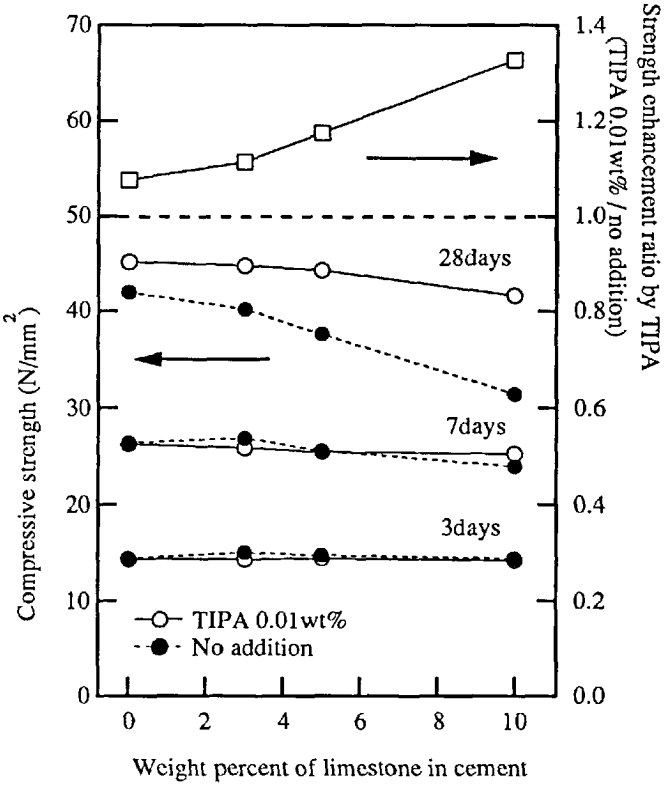

Fig. 3 Relationship between the limestone content in cement and the strength enhancement of mortar by TIPA. (Clinker: N, Blaine specific surface area: 325m^2/kg , SO_3: 2.0%)

Fig. 4 illustrates the X-ray diffraction patterns of cement hydrated for 3 and 28 days. The crystalline hydration product after 3 days was only ettringite, independent of the addition of TIPA and limestone and moreover, estimating from the peak height, no difference in quantity was confirmed. Gypsum in cement has already been consumed. These facts indicate that TIPA and limestone are not thoroughly concerned with the formation of such hydration products and the reaction in Eq. 1 preferentially proceeds. Because the solid solubility of Fe_2O_3 into hydrates is limited (Fukuhara et al. 1981) it is actually deposited as iron hydroxide in the same way as formulas in Eqs 2 and 3.

$$C_3A,\ C_4AF + 3CaSO_4 \cdot 2H_2O + 26H_2O \rightarrow C_3(A,\ F) \cdot 3CaSO_4 \cdot 32H_2O \quad [1]$$

This result is consistent with the experimental fact in Fig. 3 that the addition of TIPA, regardless of the limestone content, gives little effect on the initial strength of the mortar.

Meanwhile, the hydration products after 28 days remarkably varied in each cement. The ettringite changed to monosulfoaluminate hydrate in the cement without limestone and TIPA accelerated the change. No monosulfoaluminate hydrate was produced in the cement with limestone but calcium carboaluminate hydrates, which increase in amount with the addition of TIPA, were substitutionally produced. These indicate that TIPA and limestone definitely participate in the later stage of cement hydration and the acceleration of ferrite hydration with TIPA promotes the reactions in Eqs 2 and 3.

$$C_3(A,F) \cdot 3CaSO_4 \cdot 32H_2O + 2C_3A,\ C_4AF + 4H_2O \rightarrow 3C_3(A,\ F) \cdot CaSO_4 \cdot 12H_2O \quad [2]$$

$$C_3A,\ C_4AF + 3CaCO_3 + nH_2O \rightarrow C_{3.5}(A,\ F) \cdot 1/2CaCO_3 \cdot 12H_2O,\ C_3(A,\ F) \cdot CaCO_3 \cdot 11H_2O \quad [3]$$

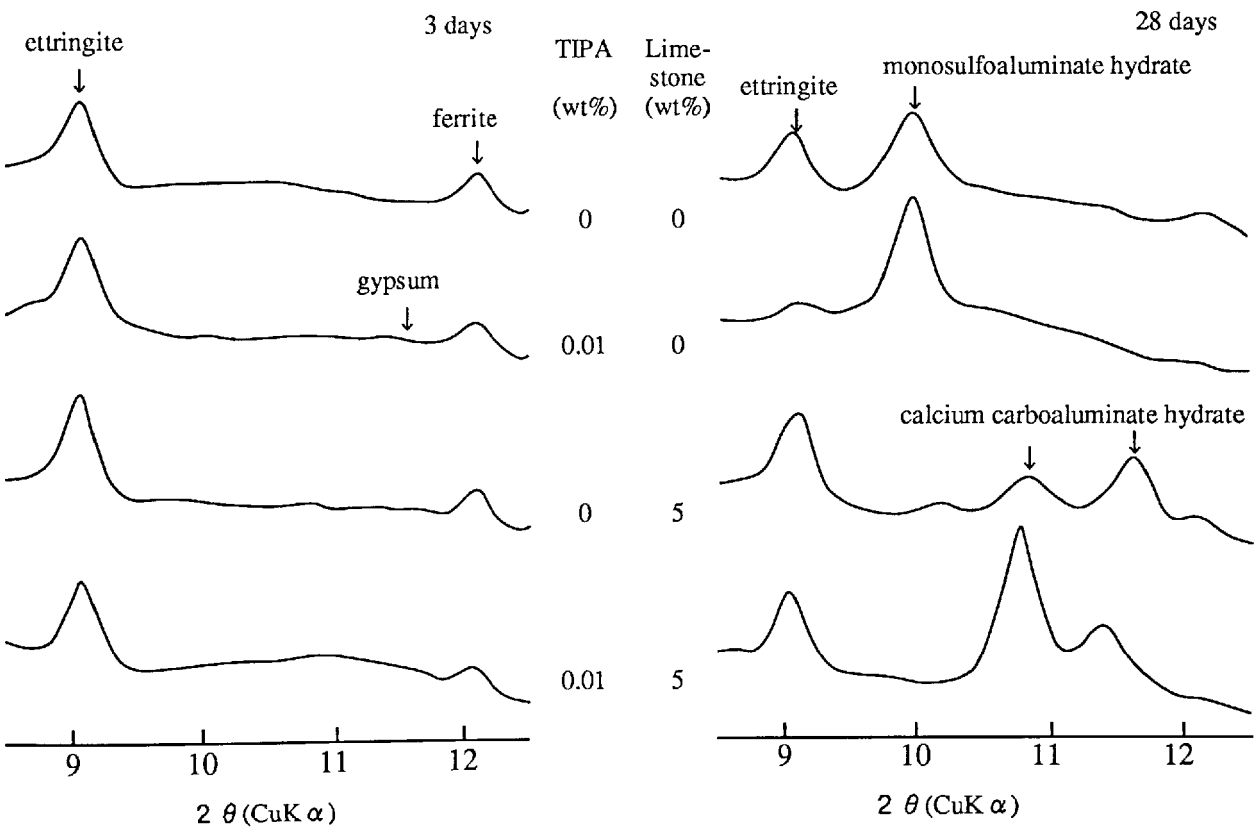

Fig. 4 X-ray diffraction patterns of cement hydrated for 3 and 28 days.
(Clinker: N, Blaine specific surface area: 325m^2/kg , SO_3: 2.0%)

Table 4 shows the hydration degree of cement constituent minerals after 28 days. As suggested from the variation in hydration products, the hydration degree of ferrite phase and limestone were evidently increased with the addition of TIPA. The hydration of alite was also promoted. The promotion of the hydration of limestone in addition to those of ferrite phase and alite is considered to be concerned with the experimental fact shown in Fig. 3 that the strength enhancement by TIPA increased with increasing limestone content in cement.

Table 4 Hydration degrees of cement constituent minerals after 28days.
(Clinker : N , Blaine specific surface area : 3250cm^2/g)

Limestone	TIPA	Hydration degrees (%)		
		C_3S	C_4AF	Limestone
—	—	79	40	—
	0.01wt%	86	73	—
5wt%		82	37	18
	0.01wt%	91	80	39

The strength enhancement by TIPA, as shown in Fig. 5(a), varied with SO_3 content in cement without limestone. The mortar strength after 28 days, when TIPA was not added, increased with decreasing SO_3 content in the range from 1.0% to 3.0%, while that was a maximum at the SO_3 content of 2.0% when TIPA was added. Accordingly, the strength enhancement ratio by adding TIPA was increased with SO_3 content. Khus (1959) confirmed that the optimum SO_3 content to obtain a maximum strength increases with increasing the amounts of interstitial phases such as the aluminate

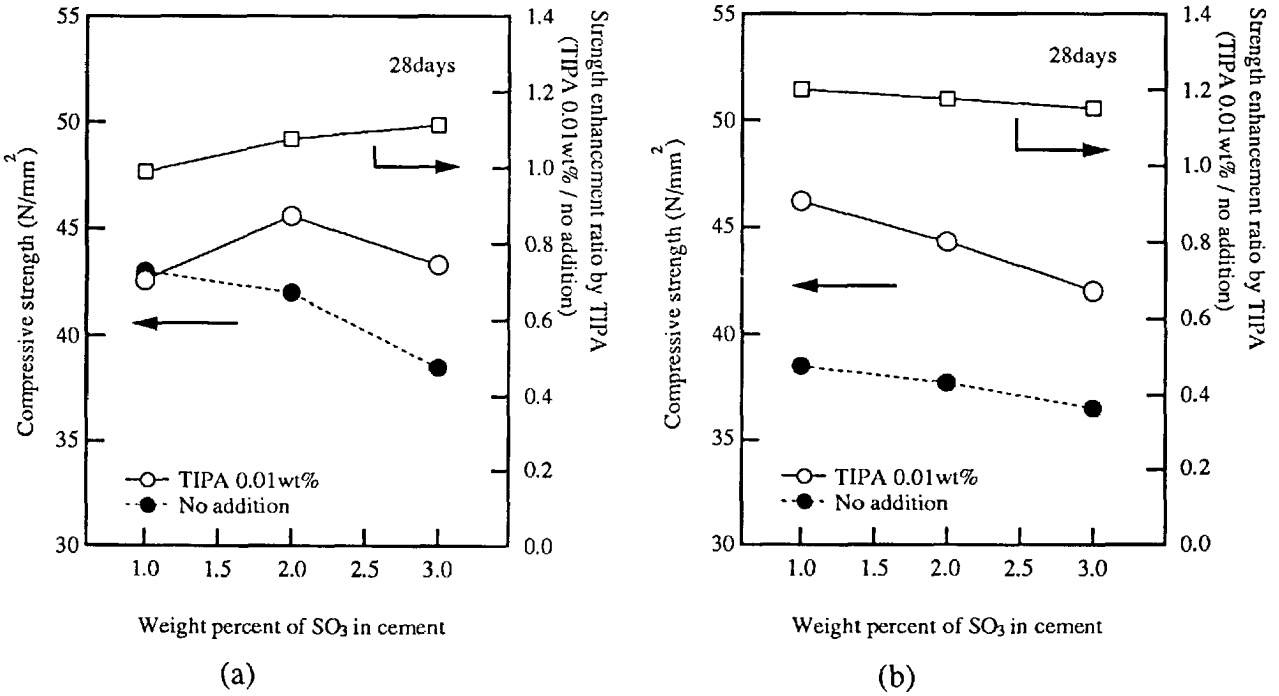

Fig. 5 Relationship between SO_3 content in cement and increase in the strength development with TIPA.
(a): Cement without limestone (b): Cement with 5wt% limestone (Clinker: N, Blaine specific surface area: 325m^2/kg)

and ferrite phase. Postulating that the acceleration of the ferrite hydration by TIPA is equivalent to the increase in the interstitial phases in cement, it can be explained that the optimum SO_3 content became high by adding TIPA. However, in case of the cement with limestone shown in Fig. 5(b), since limestone presumably compensates for the shortage of SO_3 (Bensted 1983), the 28 day strength monotonously decreased with SO_3 content even when TIPA was added, and so the difference in the strength enhancement ratio by TIPA with SO_3 content was not apparent. The increase in the hydration degree of limestone with decreasing SO_3 content, as shown in Fig. 6, supports this.

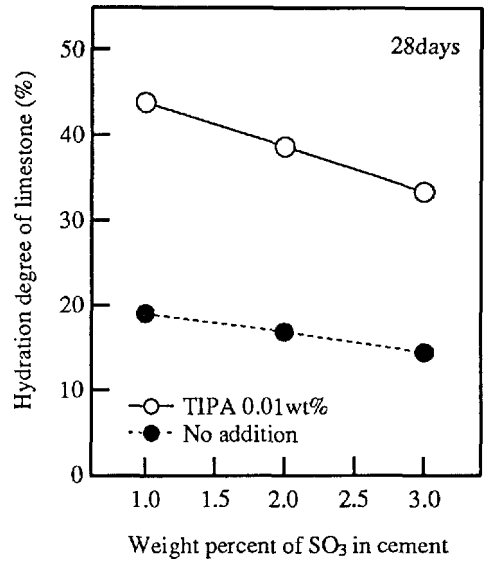

Fig. 6 Relationship between SO_3 content in cement and hydration degrees of limestone. (Clinker: N, Blaine specific surface area: 325m^2/kg, Limestone: 5wt%)

CONCLUSIONS

(1) The strength enhancement of cement mortar by TIPA depends on the quantity of ferrite phase. No effect was obtained on the cement prepared from the clinker without ferrite phase.
(2) Alite content and fineness of cement were also related to the above effect. An increase in the former and a decrease in the latter intensified it. These were understood by taking into account the grain properties of alite and belite in cement.
(3) When cement includes limestone admixture, the strength enhancement ratio with the addition of TIPA after 28 days became high because of the promotion of the limestone reaction in addition to that of ferrite and alite hydration.
(4) The promotion of ferrite hydration by adding TIPA increased the optimum SO_3 content in cement concerning the 28 day strength development. Limestone admixture depressed the increase.

INFLUENCE OF SUCROSE ON THE SETTING OF PORTLAND CEMENT

Peiming WANG, Jianguo WU, Tongji University, Shanghai, China

ABSTRACT The setting of portland cement in the presence of sucrose was studied.The amount of sucrose varied between 0.03% and 4.00% on the weight of cement.There exists a critical addition amount of sucrose to the maximal setting time.Sucrose as a retarder becomes a accelerator when its adding exceeds a given amount. The mechanism of regulation set of sucrose was discussed from the results of QXDA and SEM of hydrates and analysis of pore solution of cement paste. The influence of sucrose on setting is, most probably,dependent on the quantity of AFt crystals formed.

Key-words: cement; setting; sucrose; mechanism

INTRODUCTION

Sucrose is an effective set-retarding admixture for cement. Different addition methods, direct and delayed, result in different effect on set (Ludwig and Urrutia, 1989 ;Wang,1995). There have been theories of the set-retardation mechanism of sucrose. Those are adsorption of sucrose on the surfaces of hydrates(Thomas and Birchall 1983; Young, 1972)and inhibition of nucleation and growth of calcium hydroxide (Banfill and Saunders, 1986). However, these theories were deduced from results with a small dosage of sucrose, and through which, one can not explain the set-accelerating effect of surcrose. In this paper, we try to approach the set-regulation mechanism of sucrose on different exprimental data.

EXPERIMENTAL

525 II portland cement with 1.84% SO_3 was used to make cement pastes without and with sucrose of a w/c ratio varied with the standard consistancy,then they were cured under 20 °C. Setting times were measured using a Vicat needle.For determination of ion concentrations in pore solution of paste, the aqueous phase was extracted and analysed with a frame photometer for K^+ and Na^+ and with EDTA titration for $Ca^{2+}$and Al^{3+} after a given time. For SEM, after 40 d curing, the samples were immered in absolute alcohol for 24 h and dried under 40 °C for 48 h to stop their hydration. For the quantitative x-ray diffraction analysis, at the initial and final setting times, the samples immered with absolute alcohol were ground into fine powder and dried under 40 °C .

RESULTS AND DISCUSSION

Setting time

Fig 1 shows the setting times of the cement pastes with standard consistancy. We (Wang,1995) difined the addition amount at which the final setting time reaches maximal as the critical addition amount . In this experiment the critical addition amount lies in about 0.1%, the responding setting times are 7.4 h (initial) and 12 h (final), which agrees with our former results (Wang,1995) absolutely. When the content of sucrose is below the critical addition amount, the setting times increase with the adding; when the amount of sucrose exceeds the critical amount, setting times decrease with the adding, even become more shorter than that of the cement paste without sucrose, e.g. addition more than 0.4% makes the setting time less than 1 h. Sucrose can not only retard but also accelerate setting of portland cement, it deponds on the content of sucrose when the cement component is not considered.

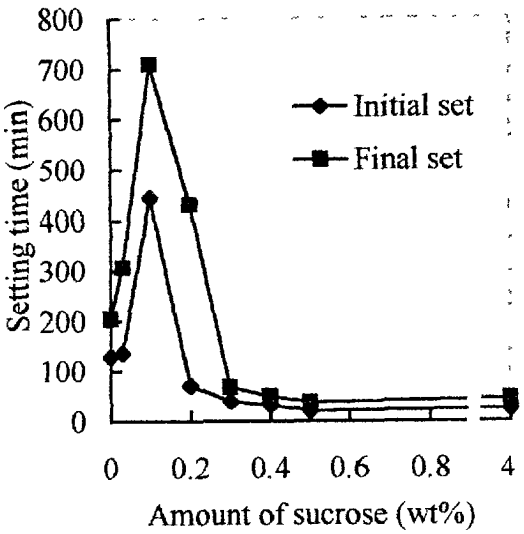

Fig 1 Change of setting times with amount of sucrose

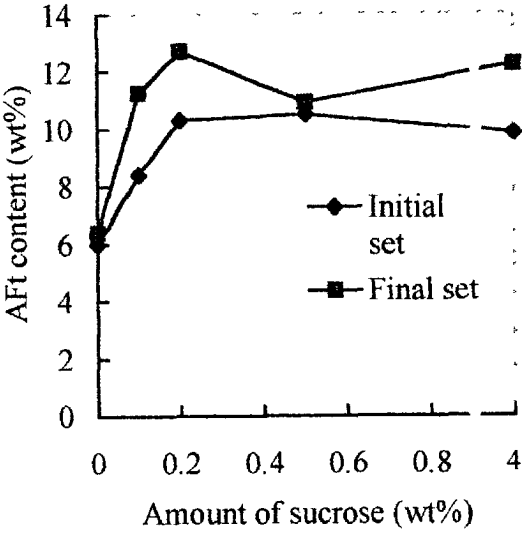

Fig 2 Change of AFt content with amount of sucrose

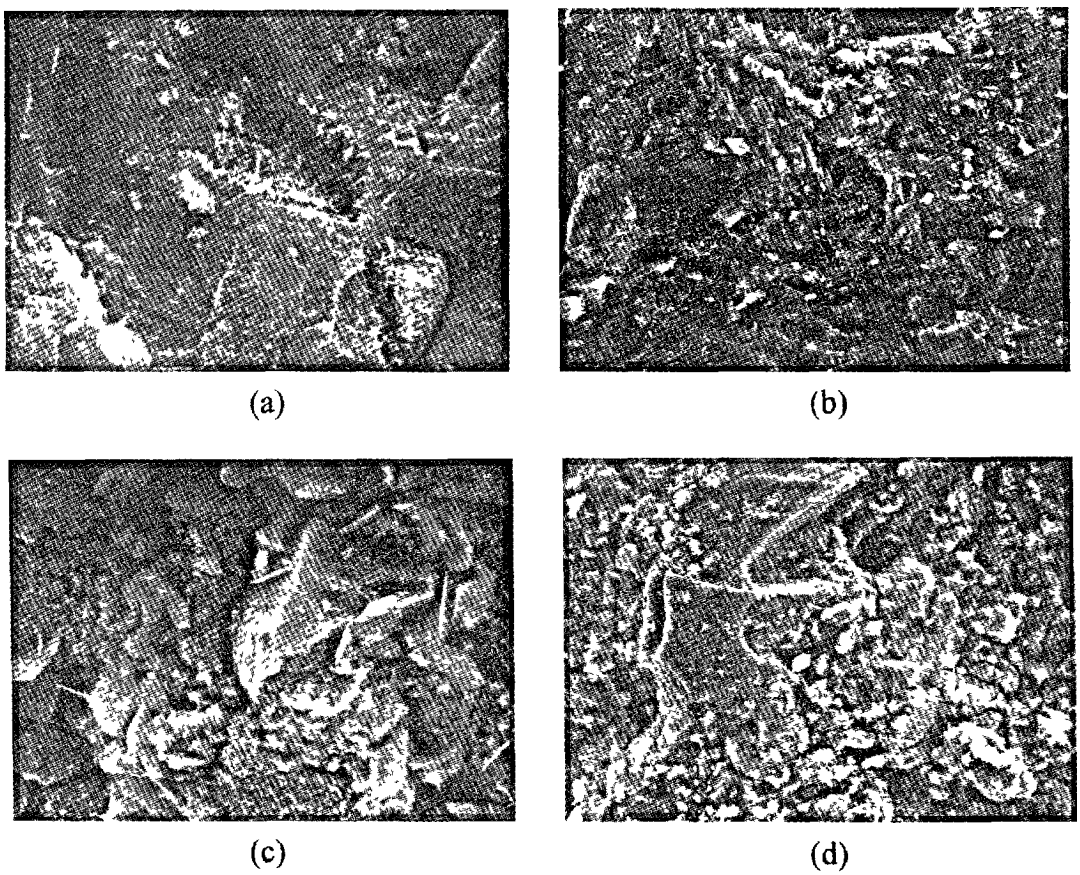

Fig 3 Morphologies of cement pastes with sucrose (a) 0%; (b) 0.2%; (c) 0.5%; (d) 4.0% 1000X

Hydrates

Fig 2 shows that the AFt contents obtained by QXDA,which increases with amount of sucrose at both initial and final setting times. This means that sucrose accelerates the formation of AFt crystals. Fig 3 gives morphologies of cement pastes by SEM. With pastes of more sucrose, the silicate phases yet maintain a distinct outline after 40 d (Fig 3(c) and (d)),the mittel phases have

hydrolysed and retain a cavity. This proves the inhibition action of sucrose on the hydration of silicate phases.

Ion concentrations

Fig 4 shows concentrations of K^+, Na^+, Ca^{2+} and Al^{3+} in pore solution of the cement pastes. It is evident that the concentrations of these ions vary with the amount of sucrose significantly. The K^+, Na^+ and Al^{3+} concertrations increase in line with the rise of sucrose almost at all curing times. The Ca^{2+} ions,however,decrease with the adding of sucrose, except at 0.2%, at early age. With the curing times the Ca^{2+} ions fall at almost all dosages, except 0.03%.The decrease of Ca^{2+} concertrations at early age is due to the inhibition of C_3S hydration, at late age to the complexing with sucrose. The increase of K^+, Na^+ and Al^{3+} proves a fact that the sucrose accelerates the hydrolyse of C_3A,because K_2O and Na_2O existed in C_3A phase of portland clinker,mainly.

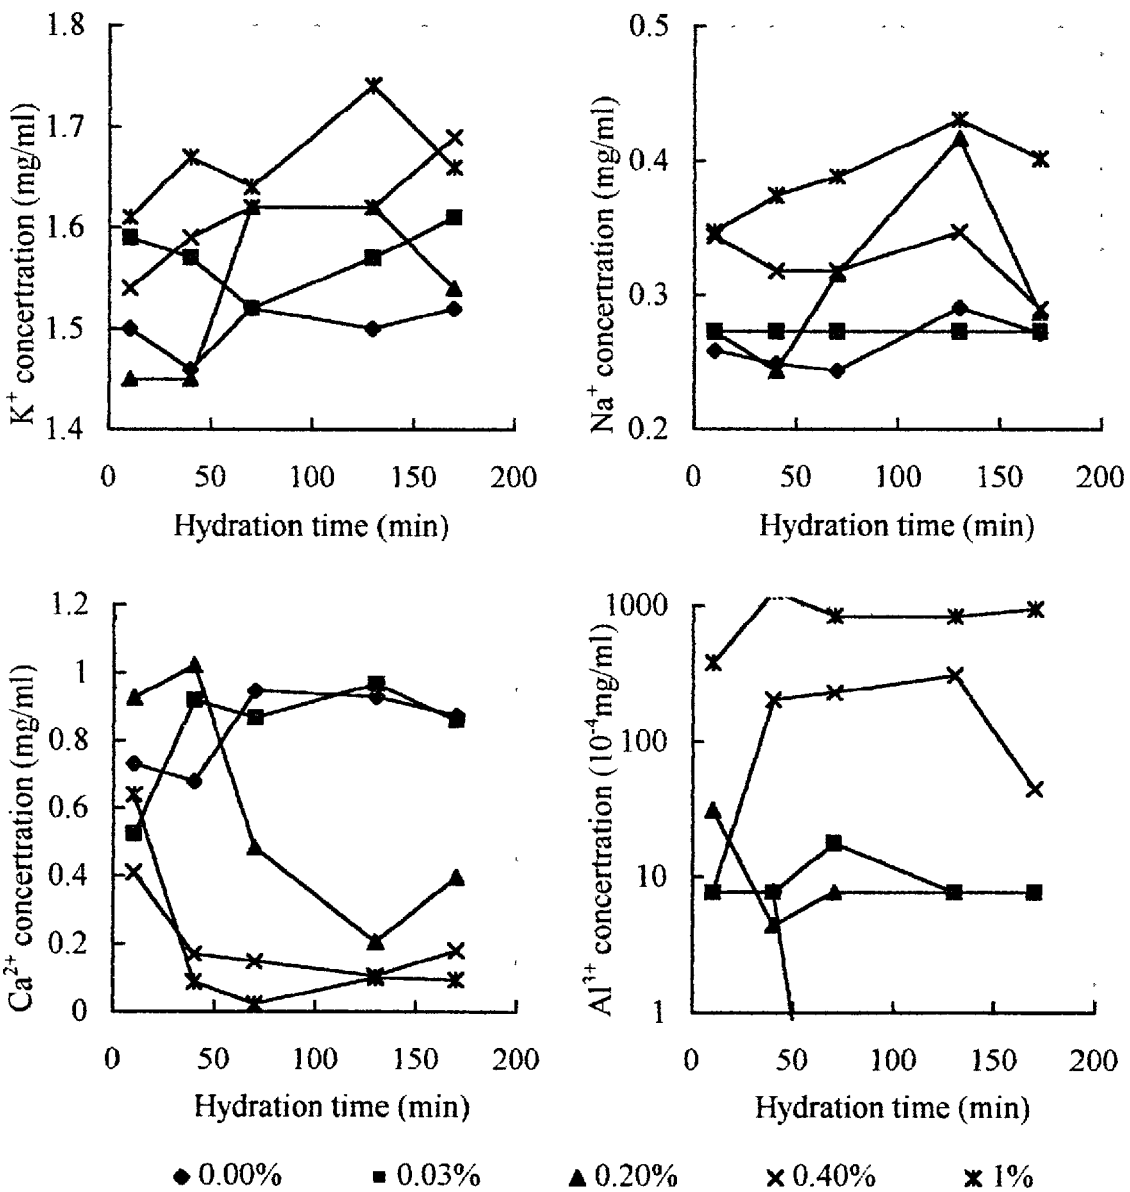

Fig.4 Change of ion concentrations in pore solution of the cement pastes with hydration time

Set-regulation mechanism

When sucrose comes to contact with Ca^{2+} ions, they react to form a spherical complex. The latter adsorbs the $Al(OH)_3$,forming $C_3A{\cdot}CH{\cdot}H_{31}$. This could be proved from our expremental results. The content of AFt determined by QXDA is more than that which form only from SO_3. The cement used here contains 1.84% SO_3 and the specimen with more than 0.2% sucrose for QXDA has 5% chemically bond water on average at final set according our determations. Corresponingly, those specimen possess 1.75% SO_3,which form at most 9.15% $C_3A{\cdot}3CS{\cdot}H_{32}$ on weight of specimen. The amount is far less than that of AFt determined by QXDA,12%, this means that there were other ions statt SO_3 to form AFt. These should be Ca^{2+} and OH^-, their content falls with the hydration time, rapidlier with more sucrose than without or with less sucrose. From this fact we can assume that large amount of AFt crystals, including $C_3A{\cdot}3CH{\cdot}H_{31}$ and $C_3A{\cdot}3CS{\cdot}H_{32}$, first form. So a large amount of water is consumed,the cement paste becomes thicker rapidly. In addition, AFt crystals having interlocking function make the setting time shortened. Therefore, in this case,AFt crystals play a crucial role in the setting of cement paste.

In the case of low dosage of sucrose, no complex forms. The $C_3A{\cdot}3CS{\cdot}H_{32}$ is formed rather than $C_3A{\cdot}3CH{\cdot}H_{31}$. The total AFt crystals are less in amount. Their interlocking is not enough to make the cement paste set, so that the setting time is prolonged. The paste does not set until more silicate hydrates form.

In addition, K^+ and Na^+ concentrations of the cement pastes with more sucrose are higher than those with less sucrose. These ions can precipitate syngenite $K_2Ca(SO_4)_2{\cdot}H_2O$ and arcanite K_2SO_4 which show platt-form or cylinder-form and may contribute to the setting.Besides,due to the removal of $CaSO_4$ from the system,AFm and AFm-CH solid solution are formed.This can cause rapid set.

It is seen that, in the presence of sucrose, abnormal setting occurs and is dominated by the quantity of AFt crystals formed. This supports Chen and Odler(1992) strongly, who reported that normal setting of portland cement appears to be controlled mainly by the amount of CSH, abnormal setting is associated with the formation of AFt and AFm.

A NMR STUDY OF GELS FORMED DURING THE HYDRATION OF CALCIUM ALUMINATE CEMENTS IN THE PRESENCE OF CITRATE OR GLUCONATE

Angelika RETTEL, Denis DAMIDOT, LAFARGE Laboratoire Central de Recherche, St-Quentin Fallavier, France
Dirk MÜLLER, Wolfgang GESSNER, Institut für Angewandte Chemie Berlin-Adlershof, Berlin, Germany

ABSTRACT At 20°C, high concentrations of trisodium citrate and sodium gluconate can induce a massive formation of gels that contain citrate or gluconate and calcium and aluminate. The formation of the gel can be simulated by adding sodium gluconate or sodium citrate solutions to a metastable solution obtained by the filtration of a Fondu cement suspension. The gels synthesised by this method, have been studied by ^{13}C and ^{27}Al NMR. These gels consist in finely combined mixtures of either calcium di-gluconate or tricalcium di-citrate, with CAH_{10} and may be with the corresponding AFm phase.

Key-words: Calcium aluminate cement, Retarders, Nuclear magnetic resonance, Gel.

INTRODUCTION

Sodium gluconate and trisodium citrate, are often used with calcium aluminate cements in order to improve the rheological properties of the paste at the beginning of hydration. These organic salts and their derivatives are known retarders of calcium aluminate cements (Tsuyuki, 1981, Rodger, 1984, Currell, 1987, Sharp, 1990, Damidot, 1996). Thus it appears to be surprising that high concentrations of these salts can induce a degradation of the rheological properties of Fondu cement pastes during the initial period of the hydration. The shear-stress measurements with a rotating coaxial cylinder on a paste after 18 minutes of hydration show a strong increase with the retarder content (Fig. 1)

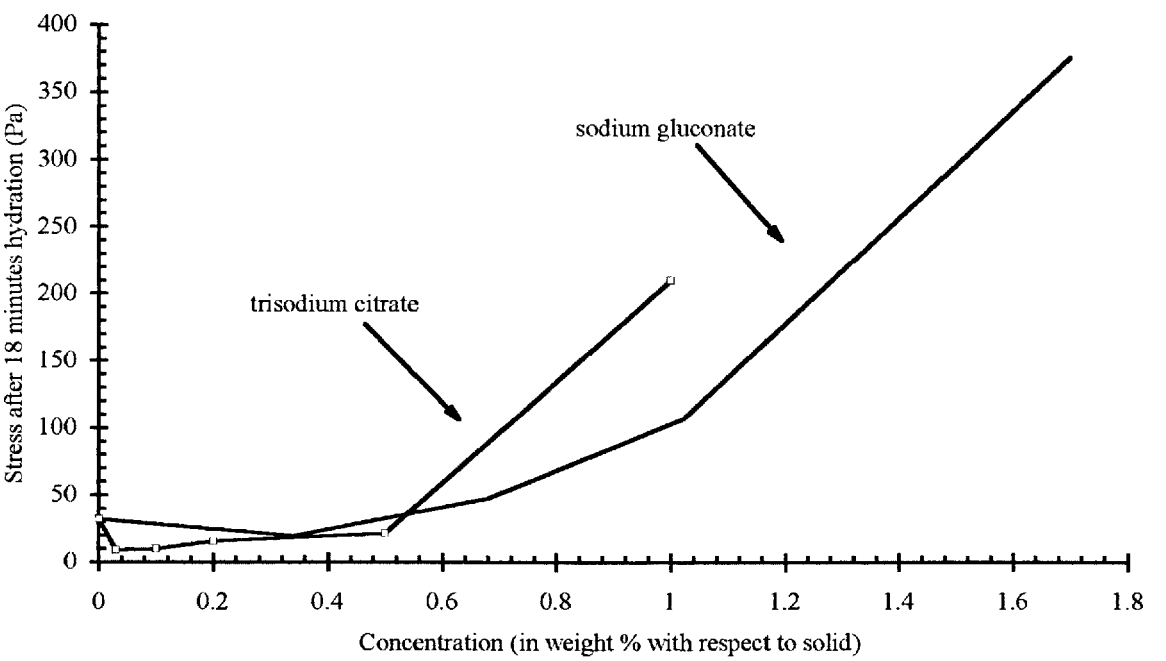

Fig 1. Shear-stress of Fondu cement paste (W/C=0.3) after 18 minutes hydration, in sodium gluconate and trisodium citrate solutions of increasing concentrations at 20°C

If the paste is mixed again after 30 minutes hydration, the structure of the paste is destroyed and the stress returns to the usually low value that characterises the beginning of hydration. Then the stress increases slowly as hydration proceeds. The aim of this study was to understand the mechanism of action of high concentrations of trisodium citrate or sodium gluconate on the hydration of the Fondu cement.

EXPERIMENTAL

The cement used in this study was a commercial Lafarge Ciment Fondu which contains mainly CA along with small quantities of $C_{12}A_7$, C_4AF and C_2S. Sodium gluconate and trisodium citrate were AnalaR grade reagents that were dissolved in distilled water prior to mixing with Fondu cement. The hydration was followed in stirred suspension in order to be able to study the aqueous phase more easily (W/C=10). Sodium, calcium and aluminium concentrations were determined by ICP. Citrate and gluconate were analysed by liquid chromatography. The NMR spectra were recorded on a Bruker solid-state NMR spectrometer running at 9.4 T. The corresponding resonance frequencies for ^{13}C were 100.6 MHz and for ^{27}Al 104.2 MHz, respectively. Additional ^{13}C MAS NMR spectra were recorded on a Varian Unity-plus 300 NMR spectrometer at 76 MHz. For line-narrowing magic-angle spinning (MAS) technique was applied using a double bearing 4 mm MAS probe. Spinning rates of 10 kHz were used. Up to 22000 scans with recycle delays of 6 s were accumulated in the case of the ^{13}C MAS NMR spectra of the treated cement gels. For the ^{27}Al MAS NMR spectra 100 scans with a recycle delay of 6 s were sufficient. Excitation pulses of 1 μs were applied. The chemical shifts refer to TMS and an aqueous solution of $AlCl_3$, respectively.

RESULTS

The aqueous phase composition was analysed during the hydration of Fondu in presence of 10mmol/l of sodium gluconate (Fig. 2). During the beginning of Fondu cement hydration, a decrease in gluconate ions and an increase in calcium and aluminate ions are observed.

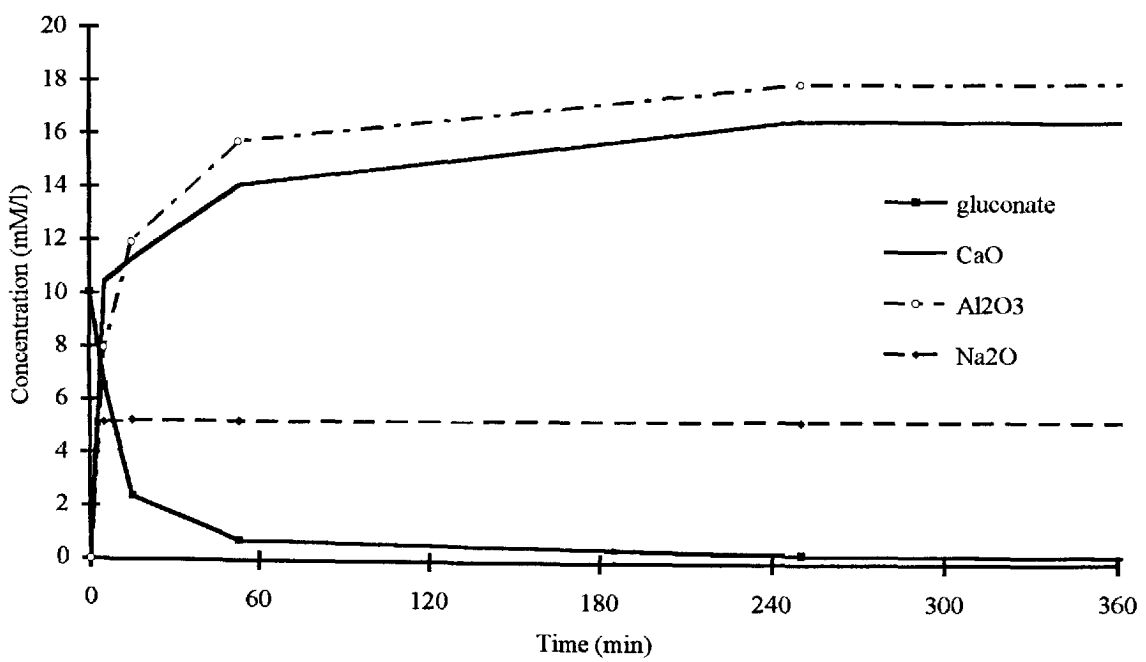

Fig. 2. Aqueous phase composition for Fondu cement hydrated in 10mmol/l sodium gluconate solution at 20°C and W/C=10

Experiments with C_3A, instead of Fondu cement, also indicated the gluconate ions are consumed (Casu, 1980). The sodium concentration remained constant at 10mmol/l. At first, there is a higher concentration of Ca^{2+} (expressed as CaO) than of $Al(OH)_4^-$ (expressed as Al_2O_3). After 15 minutes of hydration an inversion of these concentrations is also observed: the C/A ratio of the aqueous phase is higher than 1 during the first 15 minutes and then it stays close to 0.9. This effect is expected to be linked to the consumption of gluconate ions: as gluconate ions are consumed, they are replaced by OH^- ions in solution to keep the electrical balance of the aqueous phase. This mechanism could be explained by several chemical reactions; OH^- could come from the cement dissolution or the formation of AH_3 as described in the following chemical equation:

$Ca^{2+} + 2Al(OH)_4^- + 2[OH\text{-}CH_2[CH(OH)]_4COO.Na] \Rightarrow [OH\text{-}CH2[CH(OH)]_4COO]_2.Ca + Al(OH)_3 + 2Na^+ + 2OH^-$

Thus the calcium concentration is reduced by the common ion effect with sodium ions as it is observed when Fondu cement is hydrated in NaOH solution. The C/A molar ratio of the aqueous phase of Fondu cement hydrated in 10mmol/l NaOH is 0.86 at the beginning of the hydration.

If calcium and aluminate concentrations are compared between Fondu cement hydrated in water and in 10mmol/l sodium gluconate, it is obvious that the rate of increase of the concentration of these ions is less in the presence of gluconate ions (Fig. 3). Sodium ions did not reduce the rate of dissolution of Cement Fondu. Thus gluconate ions act on the surface of the dissolving solids either by an absorption process on cement Fondu and/or by the precipitation of solids that contain gluconate.

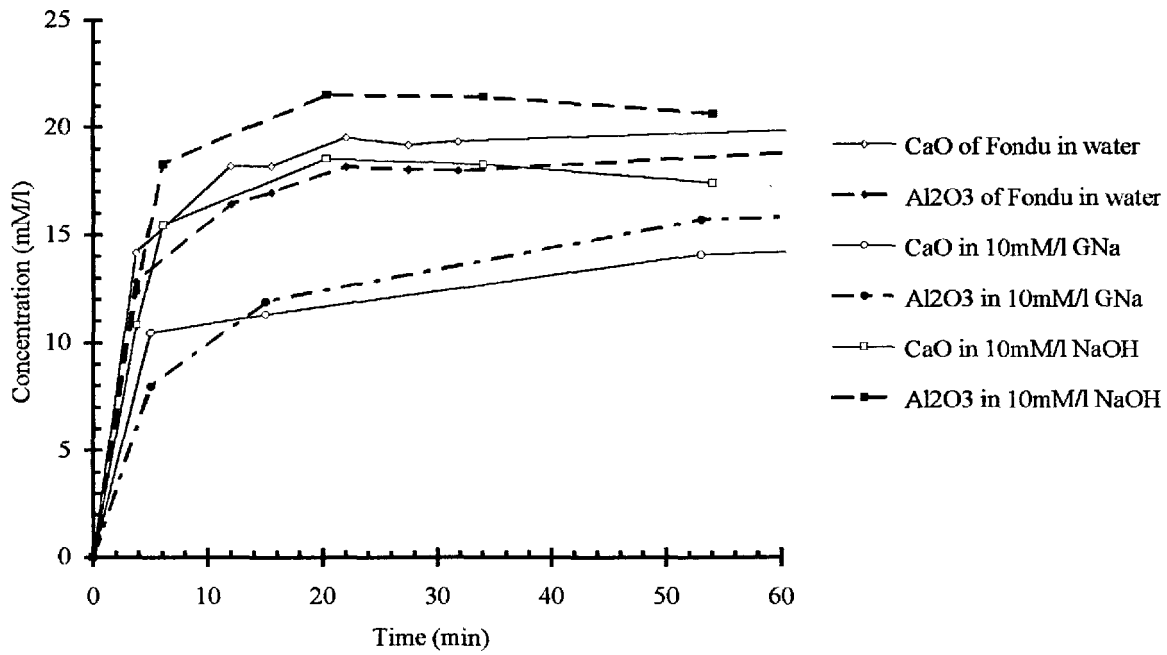

Fig. 3. CaO and Al_2O_3 concentrations in the aqueous phase during Fondu cement hydration in water, 10mmol/l sodium gluconate and 10mmol/l NaOH solution at 20°C and W/C=10

In order to investigate the possibility of the precipitation of solids, some specific experiments were carried out on a Fondu suspension filtered after 20 minutes hydration. 2ml of 41 or 205 or 410mmol/l sodium gluconate solutions were added to 80ml of clear filtrate in order to obtain 1, 5 or 10mmol/l sodium gluconate concentrations. A white precipitate appeared as soon as the sodium gluconate was added. The solid was recovered after one hour and dried with an acetone ether washing. The aqueous phase was also analysed (Table 1) and thus the global composition of the precipitated solid could be calculated: $C_{4.38}A_{3.91}Glu$ (1mmol/l), $C_{2.11}A_{1.45}Glu$ (5mmol/l) and

$C_{1.60}A_{1.03}Glu$ (10mmol/l). Higher gluconate concentrations lead to higher gluconate content in the solid compared to C and A. The solids appeared to be amorphous by XRD. NMR experiments were carried out on the solid precipitated in the presence of 10mmol/l sodium gluconate. ^{13}C MAS NMR showed some broad bands indicating a gel structure (Fig. 4). The three main bands can be assigned with the help of sodium gluconate and calcium di-gluconate NMR spectra (Figs. 5-6).

Table 1. Concentrations in the aqueous phase

	[Ca] mmol/l	[Al_2O_3] mmol/l	[Gluconate] mmol/l	[Na] mmol/l
initial filtrate	18.90	16.80	0.00	0.00
1mmol/l GNa added	16.84	14.96	0.53	1.00
5mmol/l GNa added	10.09	10.75	0.84	5.00
10mmol/l GNa added	5.63	8.28	1.72	10.00
	Δ[Ca]	Δ[Al_2O_3]	Δ[Gluconate]	Δ[Na]
1mmol/l GNa added	2.06	1.84	0.47	0.00
5mmol/l GNa added	8.81	6.05	4.16	0.00
10mmol/l GNa added	13.27	8.52	8.28	0.00

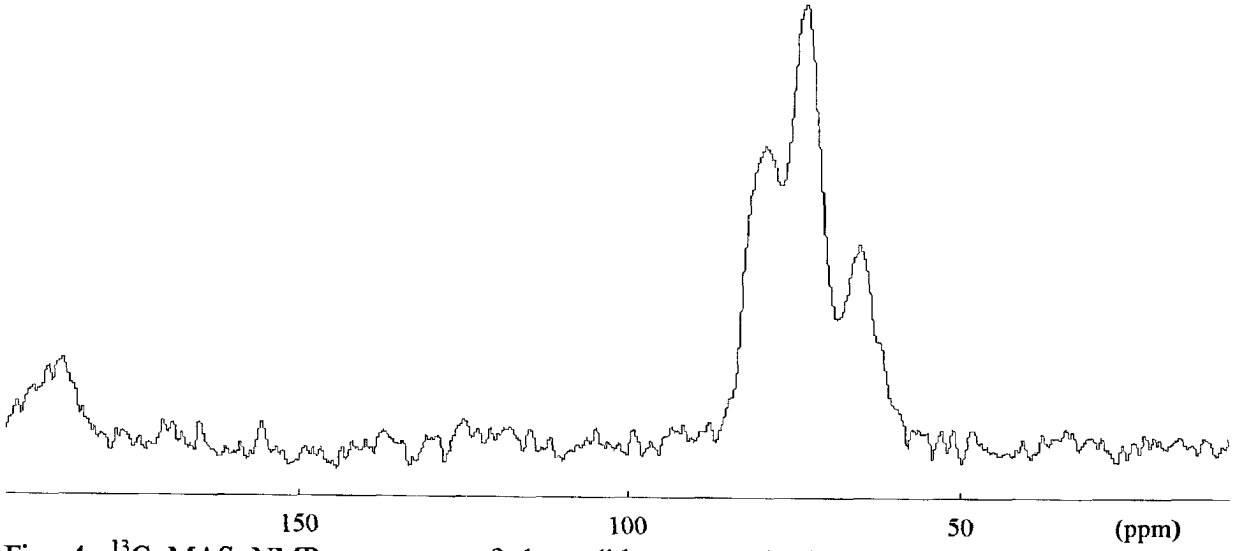

Fig. 4. ^{13}C MAS NMR spectrum of the solid recovered after adding 10mmol/l of sodium gluconate to a solution that contains 18.9 mmol/l CaO and 16.8mmol/l Al_2O_3.

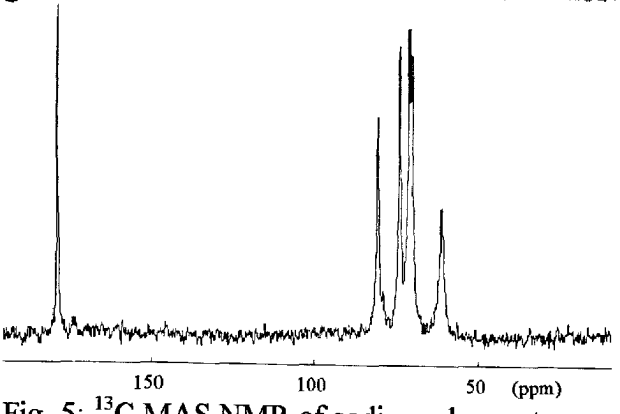

Fig. 5: ^{13}C MAS NMR of sodium gluconate

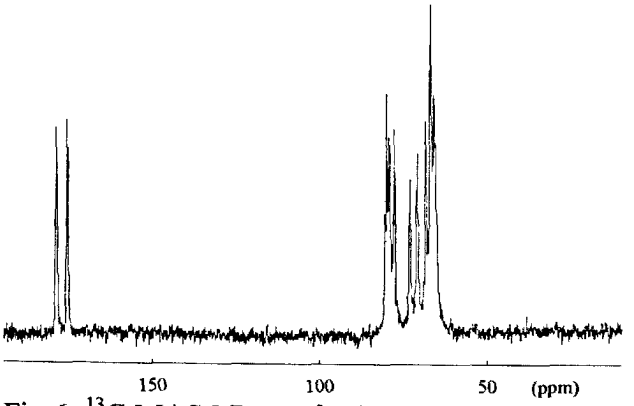

Fig 6. ^{13}C MAS NMR of calcium di-gluconate

The band at 185ppm corresponds to the signal of the carboxyl group. The signal at 65ppm is due to the other end group. The four carbon atoms of the middle chain give the bands in the region

between 70 and 80ppm. It can be noted that for calcium di-gluconate, the bands are more numerous than for sodium gluconate as the two gluconates do not occupy equivalent sites in the structure: two bands for the carboxyl groups exist. The ^{27}Al MAS NMR spectrum that is shown in Fig. 7, exhibits a strong signal representative of Al VI and a shoulder that may be induced by Al contained in a gel structure. Due to the width of the band, it is not possible to assign this peak to alumina gel, CAH_{10} or C_2AH_8 (Müller, 1992) or even an AFm phase.

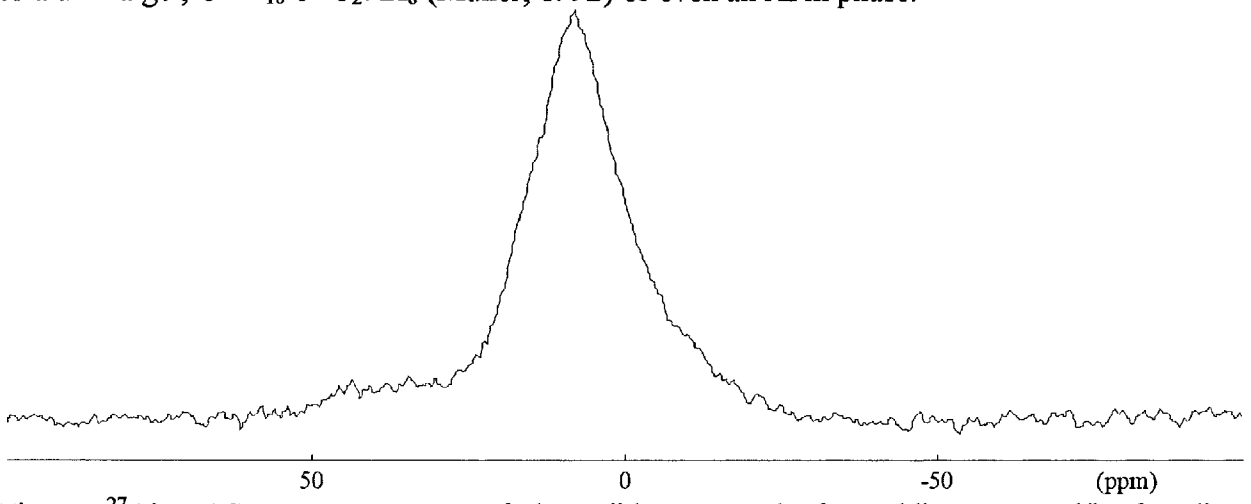

Fig. 7. ^{27}Al MAS NMR spectrum of the solid recovered after adding 10mmol/l of sodium gluconate to a solution that contains 18.9 mmol/l CaO and 16.8mmol/l Al_2O_3.

Similar experiments were carried out with trisodium citrate. First the composition of the aqueous phase was followed for Fondu cement hydrated in the presence of 1.7mmol/l trisodium citrate (Fig. 8). The citrate ions are consumed during the first 30 minutes which is a relatively long time compared to the initial citrate concentration. Rodger (Rodger, 1984) also reported that citrate ions were consumed in paste experiments.

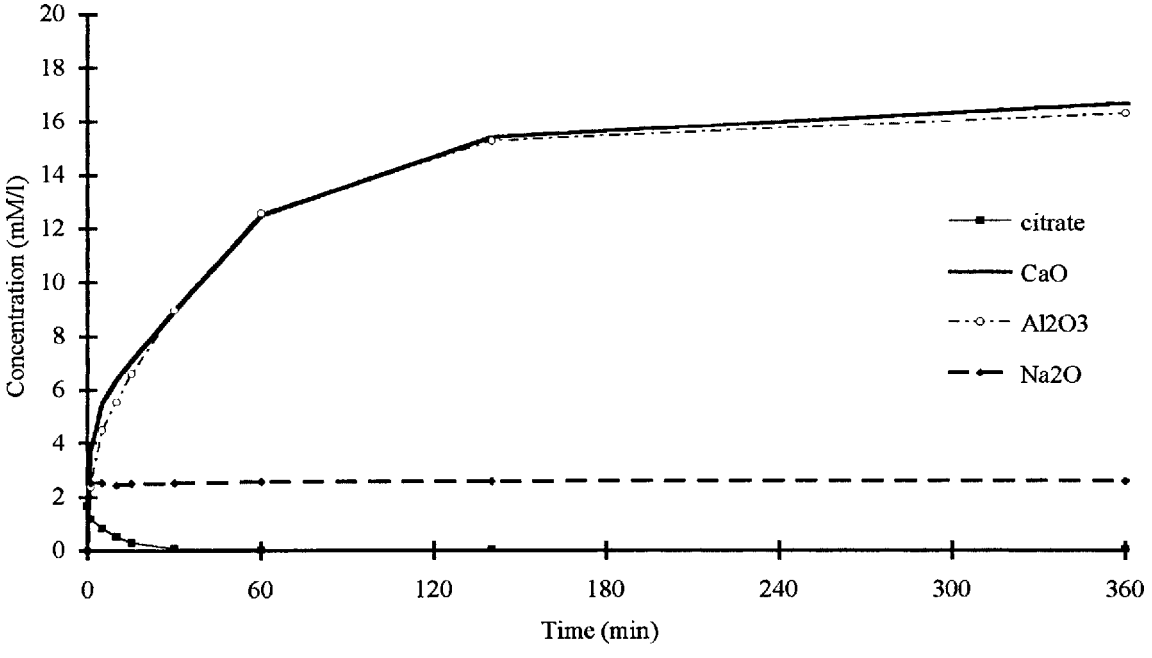

Fig. 8. Aqueous phase composition for Fondu cement hydrated in 1.7mmol/l trisodium citrate solution at 20°C and W/C=10

In order to study the possible precipitation of solids, 2ml of a 205mmol/l trisodium citrate solution were added to 80ml of filtrate containing 18.9 mmol/l CaO and 16.8mmol/l Al_2O_3. As with sodium gluconate, a white precipitate appeared as soon as the sodium citrate was added. The solid recovered after one hour was also amorphous by XRD. ^{13}C MAS NMR spectrum of the solid is presented on Fig 9. This spectrum contains three main broad bands that can be attributed by comparison with the chemical shifts of trisodium citrate and tricalcium di-citrate (Figs. 10-11). The carboxyl groups induce a band at 181ppm. The band at 47ppm corresponds to the two CH_2 groups and the signal at 76ppm is due to the carbon linked to OH. The ^{27}Al MAS NMR spectrum is very similar to the spectrum obtained with sodium gluconate (Fig. 12); an important broad band is observed in the Al VI region and also a small shoulder is found between 25 and 50ppm.

DISCUSSION

In a sodium gluconate or a trisodium citrate solution, gluconate and citrate ions are completely dissociated: Cit^{3-} and Glu^{-}. As soon as cement hydrates, calcium, aluminate and OH- ions are introduced in the solution and can interact with citrate and gluconate ions. The pH is immediately higher than 11, and complexes with aluminium and citrate or gluconate ions do not exist (Motekaitis, 1984): $Al(OH)_4^-$ is the only aluminium containing species. On the contrary there can be aqueous complexes between calcium ions and gluconate or citrate ions (Amico, 1982). However the concentration of these complexes in solution is rapidly limited by the low solubility of $Ca_3(C_6H_5O_7)_2.4H_2O$ and of $Ca(C_6H_{11}O_7)_2$.

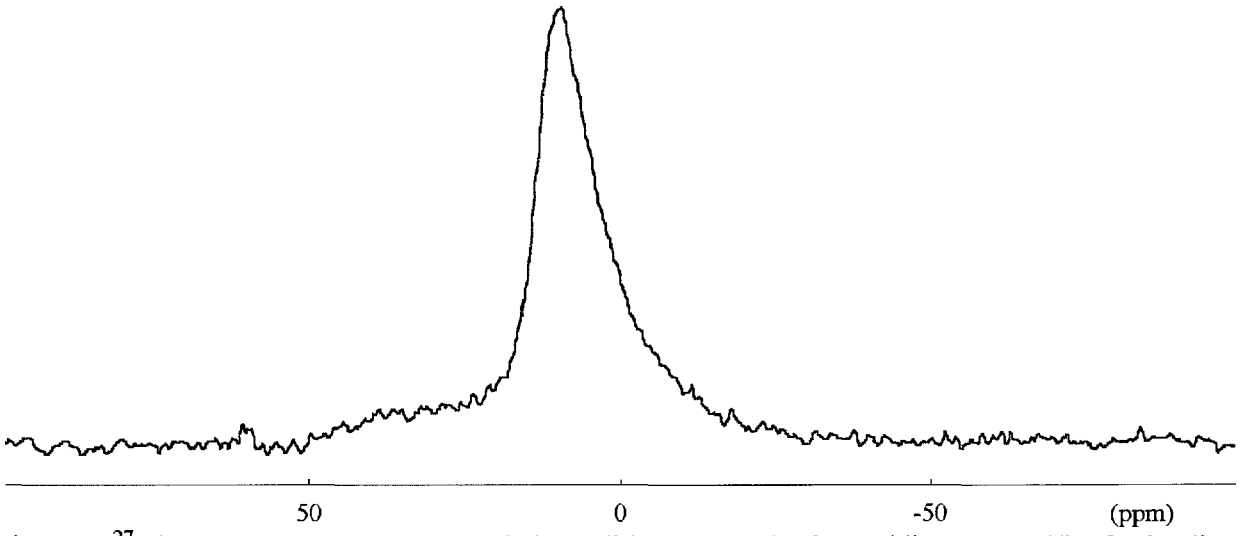

Fig. 12. ^{27}Al MAS NMR spectrum of the solid recovered after adding 5mmol/l of trisodium citrate to a solution that contains 18.9 mmol/l CaO and 16.8mmol/l Al_2O_3.

Experiments reported in the literature done with C_3A instead of Fondu cement, can give supplementary information. The hydration of C_3A in the presence of citric acid (Poellmann, 1990) indicates that a gel of citrate is formed at first. This gel that covers C_3A grains could be composed of $Ca_3(C_6H_5O_7)_2.4H_2O$ and AH_3. Then $Ca_3(C_6H_5O_7)_2.4H_2O$ would react further with C_3A in order to form an AFm phase having a composition close to $C_3A.0.33Ca_3(C_6H_5O_7)_2.nH_2O$ (AFm-Cit).

Casu et *al.* (Casu, 1980) indicate that aqueous complexes are formed during C_3A hydration in the presence of sodium gluconate. Then the complex precipitates on the surface of C_3A grains and should reduce the dissolution rate of C_3A. These authors suggested that aluminium is essential to rapidly form the complexes in which all hydroxyl groups of the gluconate are involved.

In our experiments (Table 1), aluminate ions are also consumed during the formation of the gel, thus the gel may be a coprecipitate of badly crystallised $Ca_3(C_6H_5O_7)_2.4H_2O$ or of $Ca(C_6H_{11}O_7)_2$ and an amorphous aluminium containing phase, which could be an alumina gel (AH_3), CAH_{10}, or an AFm phase; the AFm containing gluconate ions could be written as $C_3A.0.5[Ca(C_6H_{11}O_7)_2].0.5[Ca(OH)_2].xH_2O$ (AFm-Glu). The presence of citrate ions delay the nucleation and growth process of AH_3 (Van Straten, 1985) and a similar behaviour was found for gluconate ions (Rossiter, 1996). Thus it is not likely that the gel could contain AH_3. Moreover if AH_3 would be formed, the induction period should be accelerated (Damidot, 1996), instead of being retarded as found experimentally. AFm phases, AFm-Glu or AFm-Cit, which are generally well crystallised are not detected by XRD. On the other hand CAH_{10} is often badly crystallised and thus may not be observed by XRD.

Taking into account all the previous remarks, we can hypothesise that the solid formed could be a badly crystallised mixture of $Ca_3(C_6H_5O_7)_2.4H_2O$ or of $Ca(C_6H_{11}O_7)_2$ and of CAH_{10}. However, a gel-like structure containing randomly Ca, Al and gluconate could not be ruled out with our results: Sugama *et al.* (Sugama, 1989) indicate that electrostatic bonds formed by charge transfer from the Al as an electron donor to the electron accepting oxygen portion of COOH and C=O, exist, concomitantly with chemical bond between Ca and COOH.

CONCLUSION

Gluconate or citrate ions concentration decreases rapidly during the hydration of Fondu cement. This is a consequence of the precipitation of the aqueous gluconate or citrate complexes as soon as their concentrations reach a sufficient value. The precipitate covers the surface of the grains of Fondu cement and induces a decrease in the dissolution rate of the cement. If the concentration

of gluconate or citrate is high, the precipitate can create a thick gelatinous layer around the grains but also can form isolated gels. These gels are believed to be responsible for the bad rheological properties reported in Fig. 1 of the introduction. On the other hand, low concentrations of these organic salts, just form a thin layer around cement grains and give better rheological properties as the hydration rate is reduced.

It is not easy to determine the structure of the gels that are formed. It appears that the gluconate and citrate structures persist in the gels with some differences that are induced by different environments. Aluminium is octahedrally coordinated in the gel but the chemical shift does not allow us to determine accurately the solids that contain Al. Chemical analysis of the gel also indicates that calcium is present. It is believed that at 20°C, these gels are finely combined mixtures of either calcium di-gluconate or tricalcium di-citrate with CAH_{10} and may be with the corresponding AFm phase: $C_3A.0.5[Ca(C_6H_{11}O_7)_2].0.5[Ca(OH)_2].xH_2O$ and $C_3A.0.33$ $Ca_3(C_6H_5O_7)_2.nH_2O$ respectively. Note that CAH_{10} is not stable for temperatures higher than 30°C and that the aluminium containing phase could differ at these temperatures.

THE INFLUENCE OF ACRYLIC POLYMER LATEX ADDITIONS ON THE HYDRATION KINETICS OF OPC AND C_3S

Simon P. DENNINGTON, Borvi AS, Sarpsborg, Norway
James W. GOODWIN, University of Bristol, Bristol, UK BS8 1TS
Dudley W. THOMPSON, University of Bristol, Bristol, UK BS8 1TS

ABSTRACT The effect of additions of acrylic polymer dispersions (latexes) on the hydration of OPC and synthetic C_3S has been studied by conduction calorimetry. Scanning electron microscopy showed that carboxylated polymer particles adsorb on OPC and C_3S, and to an even greater degree on C_3A. These latexes produced markedly different hydration exotherms compared to non-carboxylated particles, which do not adsorb. Two different mechanisms appear to be involved.

Key-words: Polymer, Latex, Hydration, Kinetics, SEM

INTRODUCTION

Ordinary Portland Cement (OPC) is a complex mixture of inorganic mineral phases which shows characteristic hydration kinetics (Double, 1983). The hydration exotherm can be divided into an immediate and vigorous evolution of heat followed by a prolonged and less intense main exotherm after an intervening quiescent period (the induction period). Tricalcium silicate (C_3S) is the major hydraulic component of OPC and its hydration exotherm shows the same essential features as that of OPC (Tadros, 1976). For this reason it is often taken as a model compound for hydration studies. Possible reasons for the induction period are the subject of much debate (Grutzek, 1987)(Fierens, 1976)(Odler, 1979). Many water-soluble additives modify the hydration kinetics of C_3S and OPC (Ramachandran, 1987). Dispersions of sub-micron sized polymer particles (or latexes) can also effect the course of hydration. Many studies have been reported on latex additives (Kuhlmann, 1990)(Ohama, 1987)(Lavelle, 1988) but the precise nature of the polymer and any incidental components of the latex (surfactants, salts) are seldom reported. Well-characterised acrylic latexes of varying compositions using the same stabilising system and having similar particle size distributions were synthesised for use in this study.

MATERIALS

Polymer latexes

The latexes were polymerised at a solid content of 50% using a standard pre-emulsion technique as described elsewhere (Justnes, 1988). The monomers used were methyl methacrylate (MMA), butyl acrylate (BA) and methacrylic acid (MAA). Polymer compositions and calculated glass transition temperatures (T_g) are given in table 1. The stabilising system consisted of 2 parts active material (by weight of monomer) of each of two surfactants, the sodium salt of nonyl phenol ether sulphate (9 moles ethylene oxide) and nonyl phenol ethoxylate (40 moles ethylene oxide).

Particle sizes were measured with a Leeds and Northrup Microtrac Ultrafine Particle Analyzer. Excluding two of the latexes, all the particle size distributions were highly monodisperse with the overall mean particle diameter 176 ± 3 nm. The exceptions were compositions a1 (100% BA, 223 nm) and c5 (80/0/20 MMA/BA/MAA, broad, polydisperse). The pH of the finished latexes was between 3.0 and 3.5. The latexes were used as prepared in some hydration experiments, while for others the polymerisation surfactants and ionic impurities were removed by extensive dialysis against distilled water.

Table 1 Polymer compositions. T_g calculated according to eq.1 in Anwari (1992)

	Composition	Calc. T_g		Composition	Calc. T_g
Ref:	MMA/BA	°C	Ref:	MMA/BA/MAA	°C
a1	0/100	-56	c1	0/80/20	-34
a2	20/80	-36	c2	20/60/20	-9
a3	40/60	-11	c3	40/40/20	21
a4	60/40	18	c4	60/20/20	60
a5	80/20	56	c5	80/0/20	110
a6	100/0	105	-	-	-

Ordinary Portland Cement

The OPC used was P-30, produced by Norcem, Norway, and had the following composition:

$C_3S = 54\%$ $C_2S = 17\%$ $C_3A = 7\%$ $C_4AF = 11\%$ Other = 11%

Tricalcium silicate

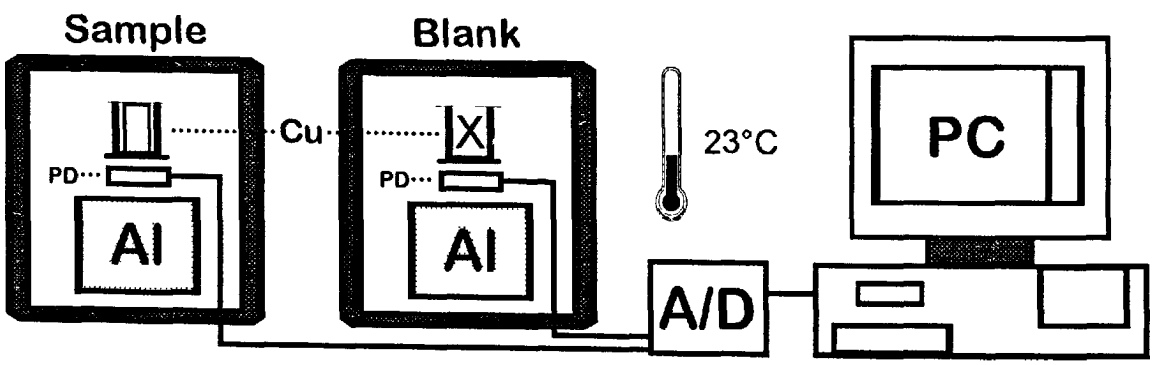
Synthetic C_3S was prepared by firing a stoichiometric mix of calcium hydroxide and silica at 1500°C followed by grinding and pelletizing before re-firing. The free lime, measured by the modified Franke method (Pressler, 1961), stabilised at 6% and was not reduced by re-firing.

Tricalcium aluminate

The sample of pure C_3A for microscopy was synthesised by Dr. G. Nickless (Univ. of Bristol).

CALORIMETRY

The conduction calorimeter used was based on a design by Dr. C. J. Wormald (Univ. of Bristol), shown diagramatically in Fig 2. Heat from the sample is conducted to the heat sink via a Peltier semi-conductor device, thus generating a voltage. The voltage output from the calorimeter was fed to an IBM PC fitted with a 20-bit analog to digital converter. The output from an identical blank calorimeter was simultaneously recorded and subtracted from the sample signal,providing a perfectly flat baseline. The data was stored on disc for subsequent calculation and analysis.



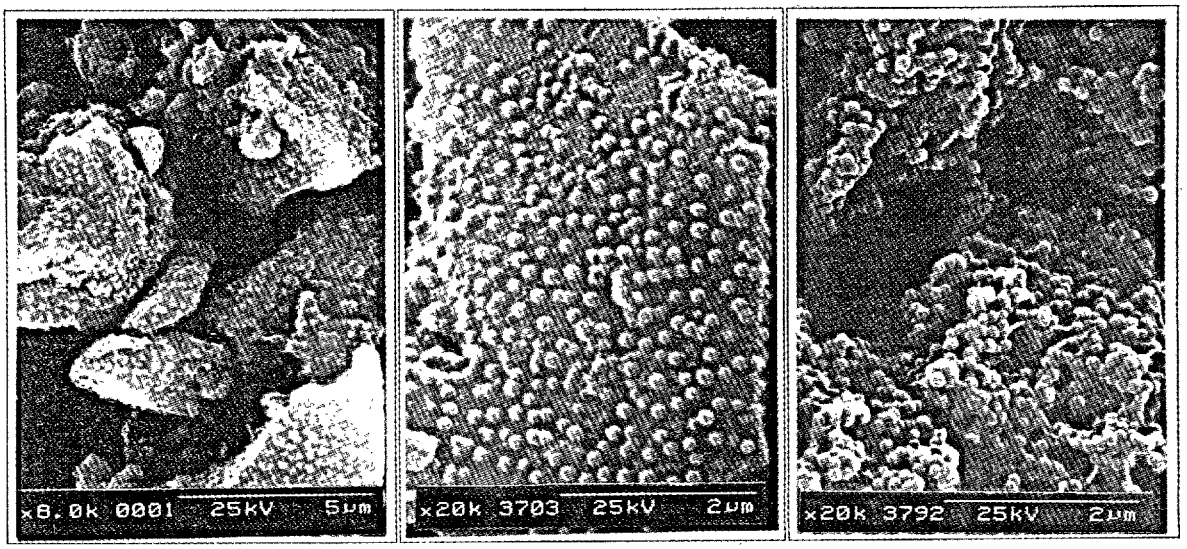


Figure 1 Diagram of conduction calorimeter.
PD = Peltier Device, Al = Aluminium heat-sink, Cu = Copper sample holder

Hydrations were carried out with the calorimeter placed in a temperature controlled room, at 23±1°C unless otherwise stated. The w/c ratio was 0.40 in all cases; polymer was taken in addition to the water and cement components and the amount is quoted as percent of cement weight (10g) or C_3S weight (5g) used. The calorimeter was calibrated electrothermally.

RESULTS

Scanning electron microscopy

Samples of cement minerals were affixed to grids and suspended upside down in dilute polymer latexes. Examination by SEM showed that not even the softest polymers formed films. The non-carboxylated polymer particles did not attach to OPC, C_3S, or C_3A. By contrast the 20%-MAA polymer particles did adsorb rapidly (in ≤1 minute). The coverage on OPC and C_3S was similar - a moderate, evenly spaced, covering of particles - while very much greater coverage was observed on C_3A, with the particles clustered in dense layers (see Fig 2):

a) OPC b) C_3S c) C_3A

Figure 2 Adsorption of latex c4 particles on cement mineral phases by SEM

Calorimetry

The exotherm from hydrating OPC was extremely reproducible. Fig 3 shows traces from four runs superimposed, and they all coincide closely:

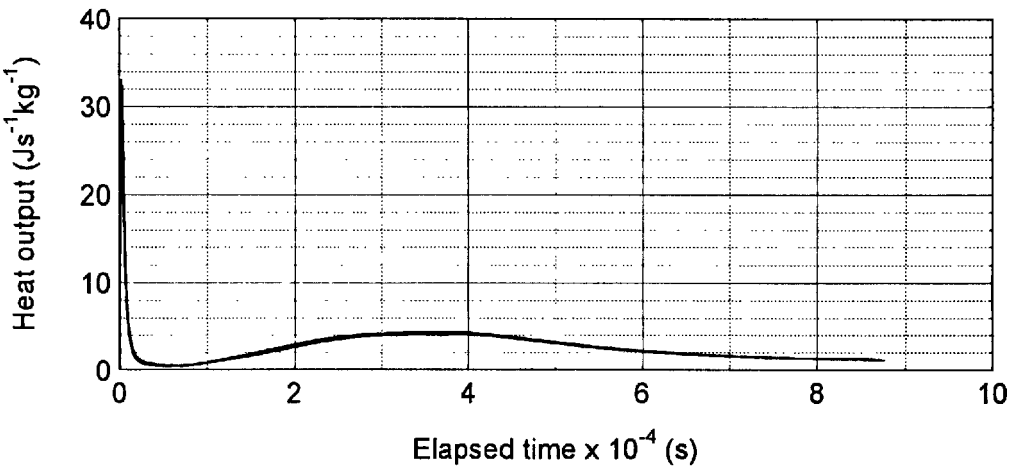

Figure 3 Linear plot of four superimposed standard OPC hydration exotherms

In Fig 4 the average of these four traces is shown plotted on log-log axes. This form of presentation allows comparison of hydrations lasting from a few minutes to several days, and is preferred in this work. Fig 5 shows the very slight retardation produced by the surfactants used.

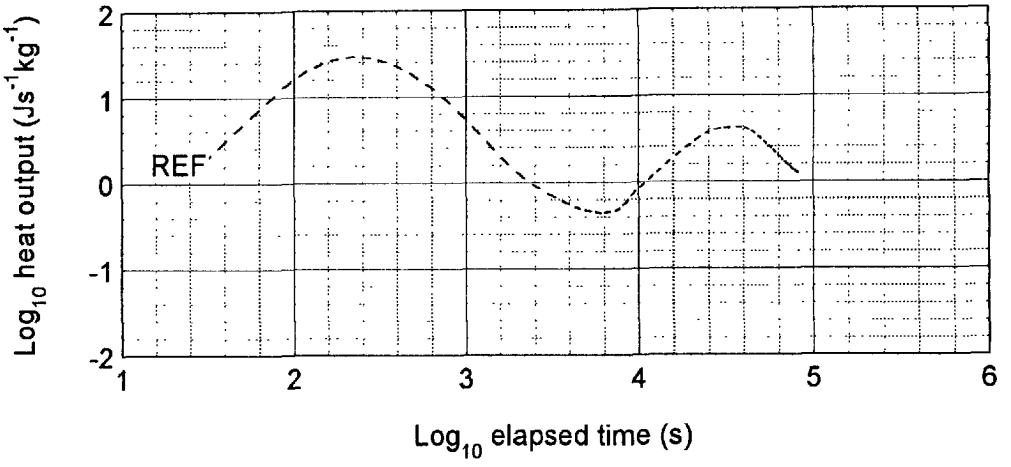

Figure 4 Log-log plot of standard OPC hydration exotherm (average of four traces)

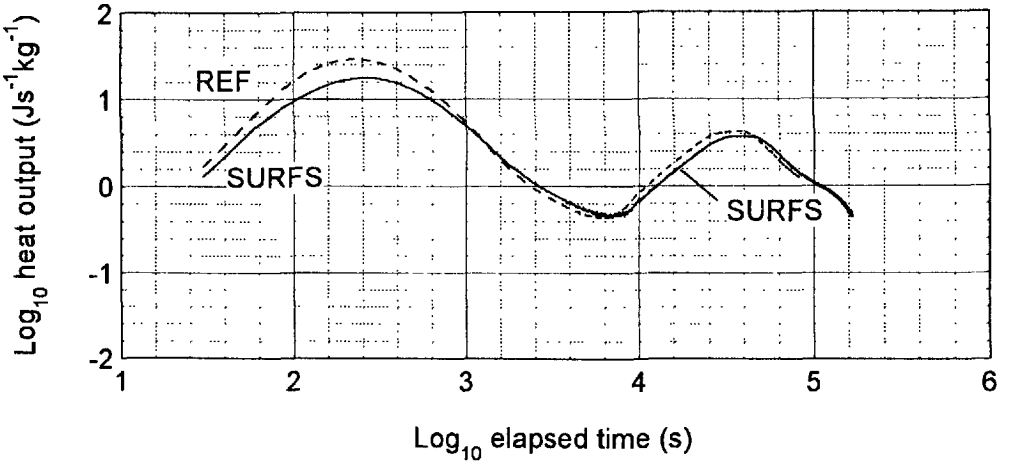

Figure 5 OPC hydration in a 2% solution with respect to each polymerisation surfactant

Hydration of OPC with the addition of the uncarboxylated latexes (a1-a6) as prepared (i.e. containing surfactants) showed a corresponding slight retardation combined with a progressive reduction in peak height of the main exotherm that depended on the composition of the polymer:

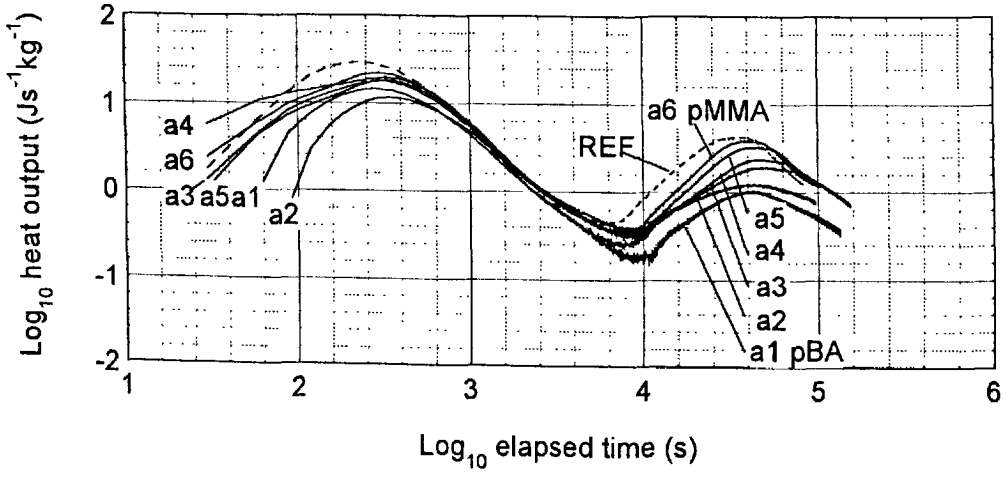

Figure 6 OPC hydration with BA/MMA copolymer latexes at P/C = 0.10

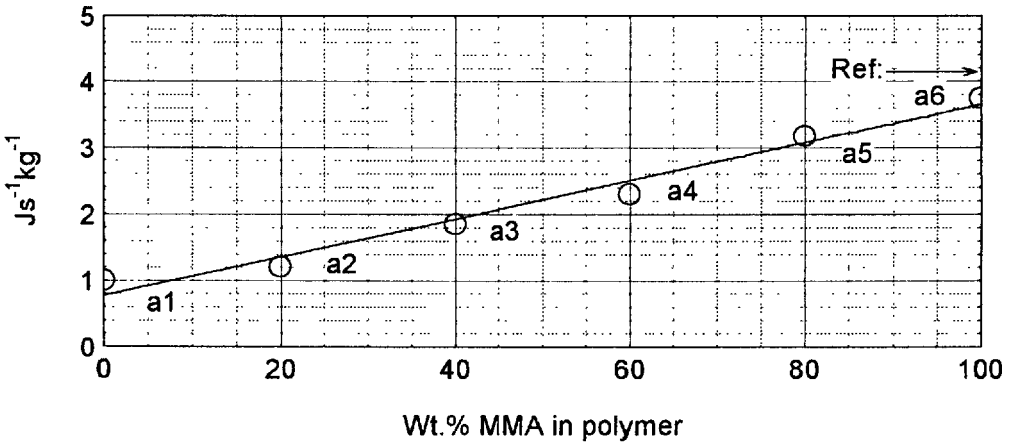

Figure 7 Peak height after 12 hours for OPC hydration with BA/MMA latexes

The slight reduction in peak height compared to the reference even with latex a6 (100% MMA) can be attributed to the presence of the surfactants. This was confirmed by hydrating OPC with the dialysed latex, when the trace coincided with the reference with no polymer. As these MMA homopolymer particles are hard (the glass transition temperature, T_g, of p-MMA is 105°C) and lacking chemical functionality, they may be considered simply as inert filler. Therefore they would not be expected to have a significant effect on the course of the hydration exotherm. However, softening the polymer particles by introducing the comonomer BA (T_g -56°C) did lead to a progressive reduction in the maximum vigour of the main exotherm, as shown by Fig 7. As BA is similarly without chemical functionality this effect can be attributed to the increasing softness of the polymer particles. In the high ionic strength aqueous environment produced during hydration of OPC the colloidal latex particles will become destabilised and tend to flocculate. The softer they are, the more strongly they will adhere to each other and form continuous networks of coagulum that restrict the diffusion of water-soluble species. This would account for the observed reduction in exotherm intensity without an accompanying delay in its occurrence.

The presence of carboxylated latexes in hydrating OPC systems resulted in a significant increase in the length of the induction period and also a marked reduction in the rate of heat evolution during the main hydration exotherm (Fig 8). These effects were found to increase with decreasing BA content of the polymer and also with increasing amount of polymer additive (Fig 9):

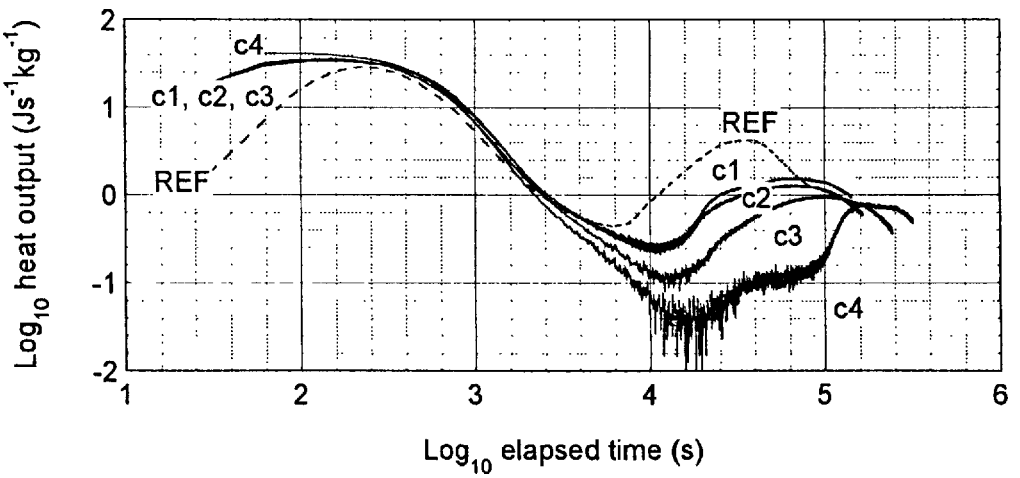

Figure 8 OPC hydration with undialysed 20%-MAA latexes at P/C = 0.10

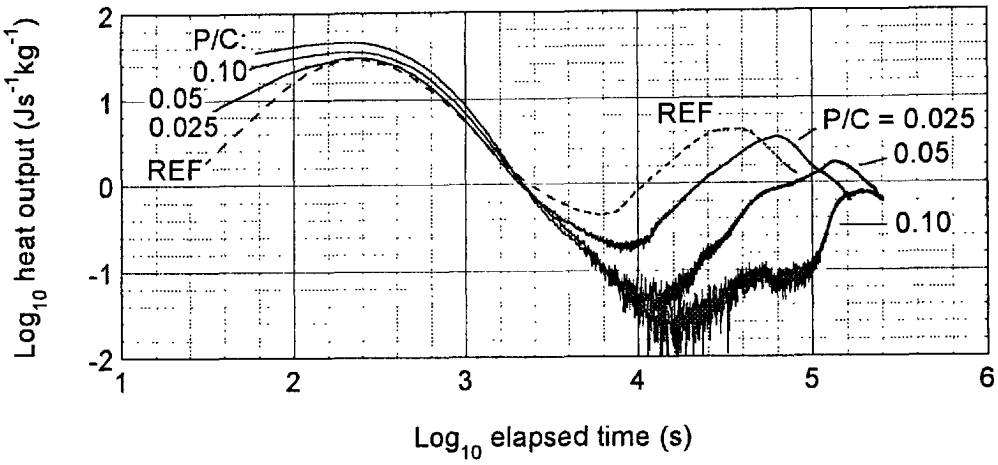

Figure 9 OPC hydration exotherm with varying amounts of dialysed latex c4

A dialysed sample of latex (c4) was centrifuged to remove the polymer particles and hydration carried out using the clear serum obtained. This had no retarding effect on the exotherm at all, so the inhibition produced by the carboxylated latexes must be due to the presence of the polymer particles themselves, rather than to any material remaining in the aqueous phase after dialysis.

Hydration of synthetic C_3S in the presence of the carboxylated latexes gave very similar results to those with OPC, indicating that this compound is a satisfactory model for investigating hydration:

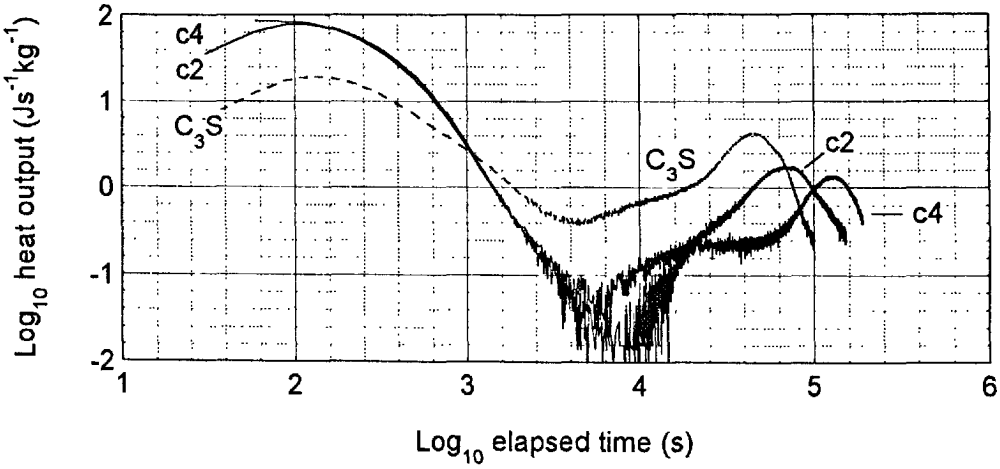

Figure 10 C_3S hydration with dialysed carboxylated latexes at P/C = 0.10

A sample of poly(methacrylic acid), p-MAA, of molecular weight ca. 80,000 was prepared. Hydration of OPC in a 0.1 M solution of this polyelectrolyte produced severe retardation of the main exotherm, even greater than that observed with polymer c4 (Fig 11). Monomeric methacrylic acid (MAA) produced only a slight reduction in the intensity of the main exotherm, with no significant retardation. The difference may be explained by the fact that calcium methacrylate is water-soluble, while the calcium salt of poly(methacrylic acid) is insoluble. Addition of p-MAA solution will therefore cause an insoluble precipitate of the polymeric calcium salt to form instantaneously around cement or C_3S grains, smothering their surfaces.

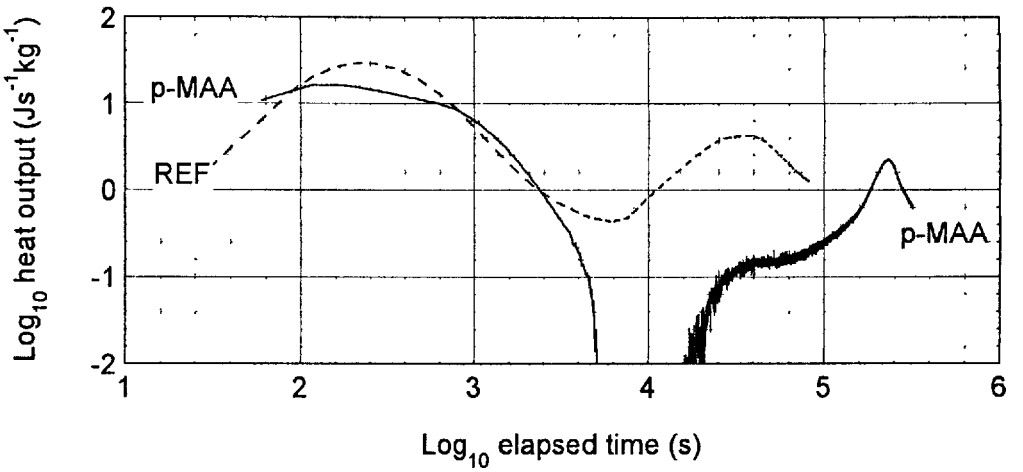

Figure 11 OPC hydration in 0.1 M poly(methacrylic acid) solution

The possibility that a methacrylic acid rich, water-soluble, polymer phase is present in the carboxylated latexes, and which could be responsible for their observed retardation, must therefore be considered. The extensive dialysis the latexes were subject to (at pH 3 as prepared) should have removed any free oligomers from the water phase; this was confirmed by the result of centrifuging the dialysed carboxylated latexes c2 and c4 and carrying out OPC hydration in the resulting clear supernatant fluids. No difference from the reference hydration in water was found, indicating a total absence of interfering oligomers.

One remaining possibility is that if any such carboxylated oligomers were present they would only be released at high pH, such as encountered in hydrating OPC. The carboxylated particles were found not to swell at all in saturated calcium hydroxide solution, although they do swell greatly when neutralised with sodium or ammonium hydroxide solutions (to three times their original diameter at pH 12). The lack of swelling with calcium hydroxide is undoubtedly due to ionic crosslinking of the polymer chains by divalent calcium ions which prevents their expansion (Han, 1991). This makes it unlikely that carboxylated oligomers would be able to escape from the particles in this case, even assuming they were not immediately precipitated by calcium ions. The interaction of calcium hydroxide and polymer latexes has been discussed by Chandra and Flodin (Chandra, 1989).

CONCLUSIONS

The addition of polymer latexes to hydrating OPC or C_3S affects the main hydration exotherm. Non-functionalised copolymer particles consisting only of methyl methacrylate and butyl acrylate were shown by SEM examination not to adsorb on OPC, C_3S, or C_3A. Nevertheless, these latexes reduced the intensity of the main exotherm but did not significantly delay its occurrence. The effect varied with T_g of the copolymer and is ascribed to the increasing tendency of the softer polymer particles to coagulate on flocculation, resulting in physically hindered diffusion of ionic species through the paste.

Polymer particles containing copolymerised methacrylic acid (at 20% by weight) showed much stronger effects and delayed the appearance of the main exotherm peak for many hours (or days). SEM observations showed that these carboxylated polymers adsorb rapidly onto OPC or C_3S grains, and to an even greater extent on to C_3A surfaces. However, as C_3S and OPC hydrations responded similarly to the presence of polymer, the retardation is unlikely to be associated with

the modification of the C_3A phase. The effect depended on the amount of polymer latex added, and was similar in form to that produced by hydrating in a solution of poly(methacrylic acid), which forms an insoluble precipitate on neutralising with calcium hydroxide, resulting in a strongly retarded exotherm. No water-soluble species were detected in the latexes dialysed as prepared, indicating that the retardation observed is due to the polymer particles themselves. Possible reasons for this are the subject of ongoing research.

HYDRATION BEHAVIOR OF CONVERTER SLAG ADMIXED WITH POLYMER CEMENT

Naomitsu TSUYUKI, Hyunkuk CHOI, Kazuhiro SEKI and Makoto HATANO
College of Science and Technology, Nihon University, Funabashi, Japan

ABSTRACT Hydration of portland cement - dephosphorized slag with reduced free lime - gypsum - SBR system is investigated. Hydration mechanism is studied with the help of XRD, SEM and calorimetry and the strength of hardened mortar is discussed in terms of pore structure. Effect of hydration mechanism on the strength development is discussed.

Key-words: Admixtures, Blastfurnace slag, Naphtalene Formaldehyde Sulphonate, Polymer, Pore Structure

INTRODUCTION

Method to utilize converter slag as a construction material has not been established so far. The authors proposed a method to utilize dephosphorized slag (Choi et al, 1993), the major components of which are di-calcium silicate (ß-C_2S) and fluoroapatite ($Ca_5F(PO_4)_3$), for construction materials by reducing free lime (CaO) present in it. It is well known that the component of human bone and tooth is hydroxyapatite ($Ca_5OH(PO_4)_3$) and what is included in the dephosphorized slag is a component in which OH of hydroxyapatite is substituted by F. This component can greatly contribute to bending strength of concrete as an admixture (Choi et al, 1995).

This paper will deal with a cement composite materials of high bending strength using dephosphorized slag with a high-range AE water-reducing agent and styrene-butadiene rubber (SBR) latex. The hydration mechanism is also discussed.

EXPERIMENTS

Materials used

The dephosphorized slag is a by-product of steel manufacture, whereby iron components were magnetically separated and crushed so as to pass through 75 µm sieve. The chemical components are shown in Table1. The dephosphorized slag was further burnt at 500 °C for 2 hours to reduce free lime less than 0.065% (Choi et al, 1993). The improved dephosphorized slag defined as to have free lime less than 1 %, hereinafter referred to as IDS, is used for the following experiments. The X-ray diffraction pattern of IDS is shown in Fig. 1, where the main minerals can be identified as ß-C_2S and $Ca_5F(PO_4)_3$. The total mineral components calculated from Table.1 is shown in Table. 2.

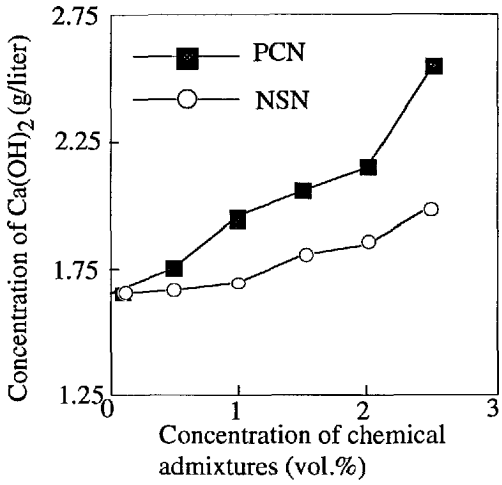

Fig.2 Solubility of $Ca(OH)_2$ vs. concentration of chemical admixtures

Testing methods

Since the SBR contains a high-range AE water-reducing agent which may affect the hydration of cement, reactivity with $Ca(OH)_2$ which may be released from portland cement and the IDS has been examined.

(1) Solubility of $Ca(OH)_2$ in chemical admixtures of naphthalene sulfonate (NSN) and polycarboxylate (PCN) was obtained by measuring the concentration of Ca^{2+} in the filtrate of well - stirred solution of over dispersed $Ca(OH)_2$ and 0 to 2.5 mass % of NSN and PCN. XRD of residue after chemisorption of NSN and PCN on $Ca(OH)_2$ was made and compared to that of gypsum ($CaSO_4 \cdot 2H_2O$).

(2) Hydration products of mixtures of portland cement, IDS and SBR (0 to 2.5 mass %) were identified by XRD and observed by scanning electron microscope (SEM). The same analysis was adopted when gypsum ($CaSO_4 \cdot 2H_2O$) is added.

(3) Total pore volume, specific surface area, mean pore diameter, total porosity, compressive strength and bending strength of the hardened material were measured.

RESULTS AND DISCUSSION

Solubility of calcium hydroxide in the high-range AE water-reducing agent solutions

Solubility of $Ca(OH)_2$ in the high-range AE water-reducing agent (NSN, PCN) solutions of 0 to 2.5 mass % was measured and expressed in terms of concentration of $Ca(OH)_2$ in Fig.2.
It is shown that the solubility of $Ca(OH)_2$ is higher in PCN solution than in NSN solution, and is always higher than 1.60 g/liter. This may be attributed to formation of a soluble complex at terminal groups and to chemisorption. XRD measurements of insoluble solid phase of $Ca(OH)_2$ and $CaSO_4 \cdot 2H_2O$ are given in Table. 3 where the diffraction intensity of $Ca(OH)_2$ at d=2.46 and $CaSO_4 \cdot 2H_2O$ at d=4.29 was normalized in 100. Table 3 shows that $Ca(OH)_2$ is likely to be a gel-like structure in the $Ca(OH)_2$ - NSN and $Ca(OH)_2$ - PCN system as seen in the depression of XRD intensity, while crystallinity is normal in the SBR system which contains no surfactant and in gypsum system. This characteristics may be dependent on the pH value of solutions.

Crystallinity of IDS

The crystallinity of IDS is substantially poor as shown in Fig.1 due to its glassy structure. The chemical composition implies the presence of a glass of the system of CaO - Al_2O_3 - CaF_2 or system of CaO - Al_2O_3 - SiO_2 (Tsuyuki et al, 1995), whereby the rapid formation of ettringite can be seen at hydration in the presence of gypsum. The exothermal rate of hydration of IDS in the presence of gypsum is shown in Fig.3. where the first exothermal peak reflecting the rapid formation of ettringite is recorded earlier than that without gypsum.

Hydration products in the hardened material

Hydration products of portland cement - IDS - gypsum - SBR system at the age of 28 days were identified by XRD. Since the crystallinity of IDS itself is poor and has much glass phase, the XRD shows low intensity when IDS is admixed. The major crystal components are ettringite and C-S-H group, and unreacted gypsum cannot be detected as it may react with CaO Al_2O_3 - CaF_2 glass phase to form ettringite. No substantial influence due to addition of SBR was detected.

Pore size distribution of the hydration products

Pore size distribution of the hardened mortar specimen at the age of 6 months measured by mercury porosimetry (Simazu Auto-pore 9220) is shown in Table. 4. Total pore volume and total porosity become smaller in the system OPC - IDS than in OPC, however in the presence of SBR, addition of 5 and 15 mass % of SBR resulted respectively larger and smaller pore volume than that of OPC. This may be attributed to the water reducing effect due to bleeding at mixing in the presence of larger

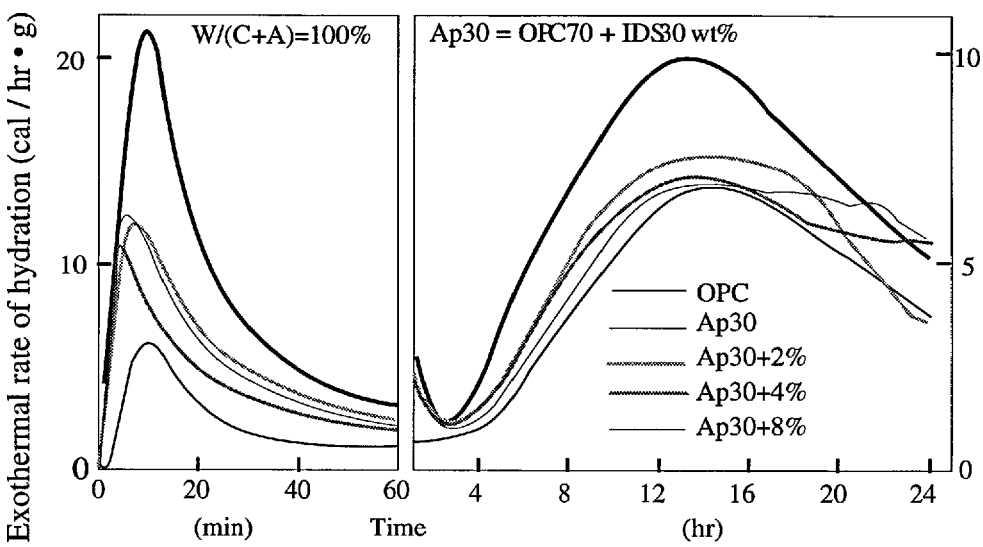

Fig.3 Exothermal rate of hydration of OPC-IDS-$CaSO_4$•$2H_2O$ system

Table 4 Pore structure (diameter below 30 μm)

Specimen	Total pore volume (cc / g)	Specific surface area (m^2 / g)	Mean pore diameter (μm)	Total porosity (%)
OPC	0.098	36.66	0.011	18.7
OPC+IDS	0.079	34.11	0.009	16.1
OPC+IDS+SBR5%	0.172	42.28	0.016	27.8
OPC+IDS+SBR15%	0.090	25.81	0.014	17.2
OPC+IDS+CaSO4·2H2O	0.088	32.62	0.011	17.3
OPC+IDS+CaSO4·2H2O+SBR5%	0.166	35.78	0.019	28.2
OPC+IDS+CaSO4·2H2O+SBR15%	0.101	30.77	0.013	18.8

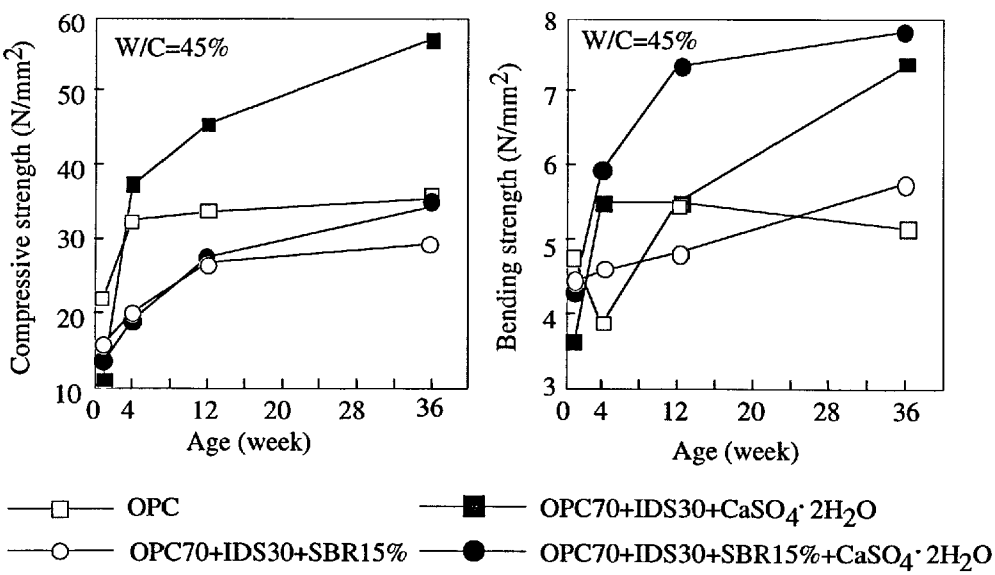

Fig. 4 Strength of hardened mortar

amount of SBR. Addition of gypsum also resulted in a dense structure with smaller pore volume thanks to the formation of ettringite.

Strength of the hydration products

Compressive strength and bending strength of mortar made of portland cement, IDS of 30 inner %, SBR, gypsum and standard fine aggregate are shown in Fig.4. Improvement of strength can be obtained by adding gypsum and SBR for 15 mass %.

Hydration mechanisms of IDS blended cement

IDS contains ß-C2S and $Ca_5F(PO_4)_3$. The former may contribute to the long term development of strength while the latter may play a role in fixing free lime in IDS as an apatite group, whereby major hydration products are C-S-H group and ettringite. With addition of SBR, the surfactant in the SBR forms a complex Ca^{2+} originated from the powder materials and the surface of the hydration products may be covered by the gel. In the presence of gypsum, pore volume may be reduced where interparticle pore space may be filled with SBR as schematically shown in Fig. 5.

CONCLUSIONS

A cement composite material with a high bending strength has been developed by blending the improved dephosphorized slag. The major findings are as follows.

(1) The surfactant in the SBR forms a complex in the $Ca(OH)_2$ - NSN and $Ca(OH)_2$ - PCN system and the surface of the hydration products may be covered by the gel.

(2) Development of strength of cement - IDS mortar with SBR and gypsum is greater than that without gypsum thanks to the formation of ettringite form the glass phase in IDS.

(3) Pore structure of a mortar admixed with SBR for 15 mass % shows more dense structure than that with 5 mass % due to the bleeding effect.

ABSTRACT High alumina cement based high flexural strength polymer composite developed recently is investigated in this paper to understand interactions of polymer and cement. This innovation raised a concept that making a high strength cement paste including no water, but utilizing generated water by phenol resin precursor during heat curing to hydrate the surface of cement particles. The authors discuss the role of calcium aluminates to make a strong organic-inorganic three-dimensional network, which gives high flexural strength higher than 120 MPa.

Key-words: Alumina, Aluminate phase, High alumina cements, Macro Defect Free, Polymer

INTRODUCTION

High alumina cement (HAC) consists chiefly of calcium aluminates, though not tricalcium aluminate, but alumina compounds relatively poor in lime. Depending on the lime content of the raw mixture, high alumina cement consists mainly either of monocalcium aluminate ($CaO.Al_2O_3$), or of a compound poorer in lime, with the formula of $CaO.2Al_2O_3$ or of an aluminate richer in lime, $12CaO.7Al_2O_3$(Czernin, 1980). The strength losses due to "conversion" of hydration products to which high alumina cement concrete is subject have led to the use of this cement for load bearing structures being banned, in Japan and in some other countries. However, innovation of high flexural strength Macro Defect Free (MDF) cement have renewed the use of high alumina cement for high flexural strength polymer cement composites. Although many hydraulic cement/water soluble polymer combinations could be used to make MDF cement composites, high alumina cement /polyvinyl alcohol (PVA)/water system has attracted much attention because of superior mechanical properties (Birchall et. al.; 1983). Several authors studied the role of calcium aluminates in making strong HAC/PVA Macro Defect Free cement and proposed chemical interaction mechanisms between calcium aluminates and PVA; Rodger et. al.(1985), Edmonds and Majumdar (1989), Popoola et. al.(1991).

In contrast to high alumina cement /polyvinyl alcohol (PVA)/water system, we discuss recently developed high alumina cement/phenol resin/alcohol system in this paper. This new composite is made by combining high alumina cement, alcohol soluble phenol resin precursor, a little amount of N-methoxymethyl 6-nylon and glycerol under high shear mixing to produce viscoelastic cement paste through a twin roll mill (Kobayashi et.al.; 1992, 1993). This innovation raised a concept that making a high strength cement paste including no water, but utilizing generated water by phenol precursor during heat curing to hydrate the surface of cement particles. The highest mechanical and durability properties are only achieved by composite made with resole-type alcohol soluble phenol resin precursor and high alumina cement. The strength loss after immersion in water at 20°C and after outdoor exposure for one year is only 9% and 6%,

respectively, and the elastic modulus remains almost unchanged. Linear expansion and weight increase of high alumina cement - phenol resin composite are 0.12% and 0.82%, respectively, after immersion in water at 20°C (Pushpalal et. al., 1997a). Within several mineralogical components present in the high alumina cement, phases with higher Al^{3+} concentration and the higher hydraulic property were the best in performances. The evidence of possible calcium aluminate - resin interaction has been experimentally found in processing, during curing and in the final product. We discuss here the efficacy of calcium aluminate to interact with phenol resin, based on the observations in processing, experimental data of differential scanning calorimetry and electron probe microanalysis.

MATERIALS

Particulate Fillers

Two types of commercially available high alumina cements (Secar 71 and 51); ordinary Portland cement (OPC); synthesized $CaO.2Al_2O_3$ (CA_2), $12CaO.7Al_2O_3$ ($C_{12}A_7$) and $CaO.6Al_2O_3$ (CA_6); calcined alumina, $Al(OH)_3$, $Ga(OH)_3$, CaO, $Ca(OH)_2$ were used in this study as particulate fillers. The chemical compositions and physical properties of the cements are listed in Table 1.

Table 1. Chemical compositions and physical properties of the cements

Type of cement	Chemical composition (wt%)							Blaine's specific surface area (cm^2/g)
	Al_2O_3	CaO	SiO_2	TiO_2	Fe_2O_3	MgO	SO_3	
Secar 71	70.22	28.30	0.27	0.26	0.15	0.14	0.03	4010
Secar 51	53.75	36.52	4.22	2.52	0.74	0.39	0.01	4017
OPC	5.30	63.40	21.40	0.26	3.10	1.00	2.0	3260

Calcium aluminates (CA_2, $C_{12}A_7$,CA_6) were prepared in our laboratory by reacting appropriate molar amounts of $CaCO_3$ and Al_2O_3 powders. These materials were thoroughly mixed in a mechanical agate mortar, and fired for 5h at 1350°C-1500°C in a electric furnace in air. Pellets were refired for 5h at 1350°C-1500°C with intermediate crushing, until finally producing the intended calcium aluminate, with no other substances remaining.

Organic Components

Methanol soluble resole-type phenol resin precursors have been shown to have the best results among the several formaldehyde resins. The nature of the hydroxyl group in the phenol moiety seems to be the leading factor that controls the resultant strength. The resole type phenol resin precursor used in the present experiments has the following physical and chemical properties.

Viscosity (25°C)	340 cps
Specific gravity (25°C)	1.09
Nonvolatile matter (135°C)	61.3%
Gel time (150°C)	3.8 (min.)
M_w	6319

N-methoxymethyl 6-nylon was incorporated to modify the phenol resin and to develop the rubbery consistency of the paste. N-methoxymethyl 6-nylon remarkably improves viscoelastic properties of the cement paste and processing details have been given elsewhere (Pushpalal, 1997b). Glycerol was used as a plasticizer.

FORMULATION AND PROCESSING

Formulation

Mix proportions are categorized into two main groups as shown in Table 2.

Table 2. Mix proportions

Mix type	Resin+ Methanol+ modifier/ Solid (%)	Mix proportions (parts by weight)						
		Solid substances			Resin	Methanol	Modifier	Plasticizer
		HAC	Al_2O_3	$Al(OH)_3$				
Standard	23	100			13.06	8.24	1.70	2.30
Comparison	23		66	40	13.06	8.24	1.70	2.30

High alumina cements, OPC and calcium aluminates (CA_2,$C_{12}A_7$,CA_6) were proportioned according to "standard" mix proportion, disregard of slight differences of their specific gravities. The mix proportion called "comparison" is used in this study to compare the properties of cement-based composites with non cement-based composites. All non cement-based mixtures (calcined alumina, $Al(OH)_3$, $Ga(OH)_3$, CaO, $Ca(OH)_2$) were designed considering differences of specific gravities; i.e. total particulates in non cement-based mixtures is equal in volume to particulates in "standard" mix proportion.

Processing

The paste containing organic/inorganic compounds was prepared by mixing inorganic compounds, the modified methanol solution of phenol resin precursor and plasticizer in a kneader-style mixer. The general method of roll milling is nearly equal to the MDF technology, except in its attempt to cool the rolls to minimize rising temperature (Young, 1991). When the paste is mixed in the roll, temperature rises due to the work of the rollers and the viscosity of the paste also rises to become moderately hard. Then the paste is condensed into a thin layer and twined around the faster roller. This sheet is scraped away, folded and re-rolled several times until it becomes a homogeneous sheet. The resulting mass is allowed to cure at 200°C for 18 h. If the sheet is further densified by pressing (6 MPa at 80°C) after the calendering, considerable increment in final strength can be obtained. To ensure the highest strength, it is necessary to elevate the temperature slowly and keep it at 65°C or above for more than 30 minutes under pressure. The heat pressing step can be skipped if necessary, depending on property requirements.

RESULTS AND DISCUSSION

Interaction During Processing

The ability to make a sheet through a twin roll mill is highly dependent on the base powder used. All hydraulic cements perform considerably well in the roll milling process regardless of the main mineralogical component contained. Young and Berg (1992) concluded that a controlled cross-linking action is needed to develop the rubbery characteristics which are suitable for roll-milling;

we also observed the same tendency. Table 3 shows processing characteristics of cements, pure calcium aluminates, metal oxides and hydroxides with the addition of phenol resin precursor.

Table 3. Processing characteristics of several inorganic powders with the addition of phenol resin precursor

Type of powder		Forming ability
High alumina cements	Secar 71	Good
	Secar 51	Good
Ordinary Portland cement		Fair
Calcium aluminates	CA_2	Poor
	$C_{12}A_7$	Fair
	CA_6	Very poor
$Al(OH)_3$		Good
$Ga(OH)_3$		Good
$Ca(OH)_2$		Immediately hardened
Al_2O_3		Did not harden
CaO		Immediately hardened
$Al(OH)_3/Al_2O_3$ ("comparison")		Fair

High alumina cement showed good processing characteristics among all the powders tested. When OPC and $C_{12}A_7$ are used, roll milling is difficult because of rapid hardening during the milling. CA_2 and CA_6 were poor in combining during roll milling, hence stiffness of the sheet is low and difficult to handle. Our experiments showed that the cement can be replaced by inert fillers for up to 50% of the volume but higher than 50% influences negatively on processing; i.e. sheet-making is unsuccesful. However, complete replacement of the cement by Group III (Periodic Table) hydroxides provided good processing characteristics but was of lower strength. The paste consisting of calcined alumina and resin did not combine properly in roll milling, sheet making ability is poor, like with calcium hexaluminate.

The paste of calcium oxide and resin underwent a highly exothermic reaction shortly after mixing in the twin roll mill and hardened rapidly, thus sheet forming became impossible. Calcium hydroxide also showed the same features as calcium oxide. The different behavior of calcium and aluminum can be explained by their ionization potentials. Oxidation potentials of calcium and aluminum are +2.87 and +1.66 volts, respectively [Dean, 1979], thus calcium should have a higher oxidation tendency in the phenol resin system. Moreover, hardened calcium oxide or hydroxide dough can be softened by dipping it in acetic acid, thus occurrence of ionic-type interaction (rapid and reversible) is confirmed. It is reasonably expected that such an ionic reaction also occurs between phenol resin and cement phases in the cement to a certain extent; the ionic-type reaction corresponds to the development of a rubbery consistency which is essential for making a good sheet. This idea has been confirmed by the different processing characteristics showed by different calcium aluminates; i.e. highly reactive Ca ion rich phases ($C_{12}A_7$) hardened rapidly, while the low reactive (CA_6) phases combined poorly in roll milling.

Interaction During Heat Curing

Hardening of the phenol resin cement sheet occurs with a polycondensation reaction of phenol resin to form a three dimensional crosslinking structure between 130°C -170°C; in this temperature range water is released from the phenol resin. Fig. 1 shows the development of flexural strength of the composite during various stages of thermal curing. The flexural strength was measured on the specimens kept at each temperature level for 2 hours and with the temperature elevating rate at 20°C/hr. The strength of a standard specimen was compared with a non-cement based composite made according to mix proportion "comparison". The standard specimen showed a significant strength increment in between 140°C and 160°C.

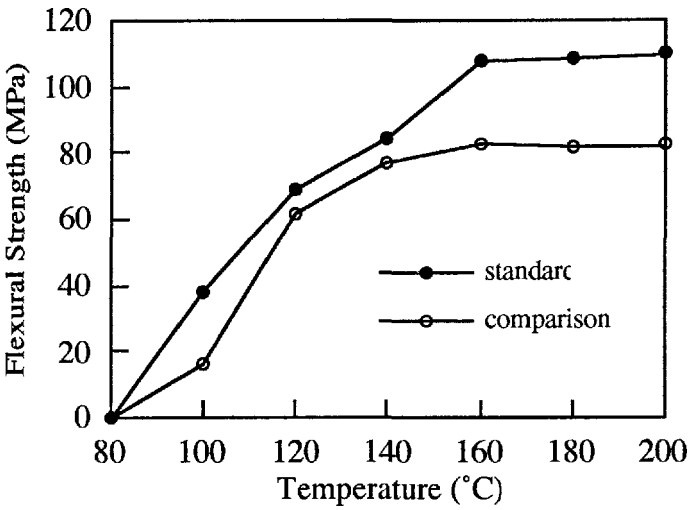

Fig. 1. Development of flexural strength of the composite during various stages of the thermal curing.

Hasegawa and coauthors (1995) have investigated the thermal behavior of phenol resin and several powder/phenol resin mixtures by Differential Scanning Calorimetry. The resole type phenol resin precursor shows sharp endothermic peak around 162°C, that certainly corresponds to the cross-linking formation accompanied with releasing the water molecules. The addition of HAC or CA to phenol resin precursor converts that endothermic peak to broad exothermic peak, while inert fillers (Al_2O_3 and SiO_2) do not show any response.

Strength Dependence on Base Powder

Table 4 shows flexural strengths and bending modulus results of specimens made with several inorganic powders. Mechanical properties are heavily dependent on the method of processing. Two processing routes were followed; one was calendering/heat curing (Route 1) and the other was calendering/heat press/heat curing (Route 2).

Secar 51 has recorded highest flexural strength among all the inorganic powders tested. With regard to the strength results of processing Route 1 of Table 4, Secar 71 gave slightly lower strength than Secar 51. To understand the reason of different behavior, mineralogy of both cements were analyzed by the X-ray diffractometer. Fig. 2 shows the X-ray profiles of Secar 51 and Secar 71 cements. Secar 71 contained more CA_2 than Secar 51. Moreover, pure CA_2 gave lower strength than Secar 51 cement, thus it is logical to conclude that slightly lower strength of Secar 71 is due to the lack of calcium monoaluminate. Neither phases like $C_{12}A_7$ which has higher hydraulic properties, nor CA_6 which is richer in Al^{3+} ions directly affects the strength

development. Moreover, the "comparison" formulation with non-cement powders shows moderate strength when processed by Route 1, however, further strength improvement by heat pressing was not possible. Pushpalal et. al. (1995) have shown that porosity and pore size of the specimens made by the same mix proportion was lower than that of the "standard," still, strength was lower than the "standard." Thus it can be inferred that both the hydraulic property, and a high concentration of aluminum ions in the base powder are essential for high strength and durability. In addition, OPC shows lowest strength in both processing routes regardless of its fair processability through the roll mill. Thus it can be inferred that aluminum ion plays a more essential role during heat curing than calcium ion, which enables it to produce a high strength and water resistant composite.

Table 4. Flexural strengths and bending modulus of specimens made with different inorganic powders.

Type of powder	Calendering/heat curing (Route 1)		Calendering/heat press/heat curing (Route 2)	
	Strength (MPa)	Modulus (GPa)	Strength (MPa)	Modulus (GPa)
Secar 51	134	29.57	198	39.08

Electron Probe Microanalysis

Samples of high alumina cement-phenol resin composite were investigated with an Electron Probe Microanalyzer. Wave Dispersive Spectrometer (WDS) in the electron microscope was used to quantify calcium and aluminum. Fig. 3 shows a back scattered electron image of a CA grain surrounded by the polymer matrix and an overlaid graph of the A/C ratio versus distance from the interface. A/C ratios were measured along the line of analysis at the distances indicated by bold circles. The A/C ratio of the center of the particle is 1.5 and decreases as it approaches the interface, where the ratio was found to be 1.36. In addition, certain amounts of calcium and aluminum were also traced in the polymer matrix.

Edmonds and Majumdar (1989) have suggested on the HAC/PVA system that the polymers (PVA) complex more readily with aluminum than with calcium ions to result in the removal of aluminum ions from the grain surfaces and the formation of a calcium-rich perimeter. Moreover, according to their suggestion, the calcium-rich hydration shells around CA and CA_2 grains suggest that the hydration involves first the removal of aluminum ions from the grain surfaces, followed later by the calcium ions. Thus we prefer to suggest that the aluminum-poor perimeter found by EPMA is due to the hydration which occurred by utilizing released water from the resin during the methylene bridge formation reaction. However, we have not detected any hydration products by Electron Probe Microanalysis.

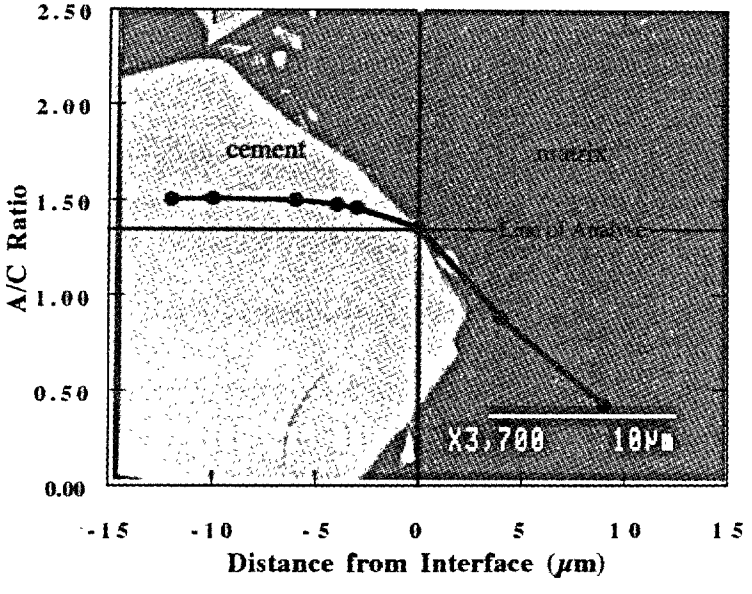

Fig. 3. Back scattered electron image of a CA grain surrounded by the polymer matrix and an overlaid graph of the A/C ratio versus the distance from the interface.

CONCLUSIONS

It is clear from the above results that calcium aluminates and resole type phenol resin precursor interact with each other through the whole process, beginning from the twin roll milling up to the final product to make it a stronger material. The authors prefer the mechanism in which the phenol resin complexes with Ca^{2+} ions through an ionic cross-linking reaction during the roll milling and

then with Al^{3+} ions through a chemical cross-linking reaction during heat curing. The schematic representation of crosslinking reaction is presented elsewhere (Pushpalal et. al., 1997c)

Acknowledgments

The authors wish to thank Mr. Tokuhiko Shirasaka and Mr. Takayoshi Okamura (Central Research Laboratory, Chichibu Onoda Cement Corporation) for their assistance on chemical analyses and useful discussions. The support of Dr. Bruno Espinosa, Mr. Vincent Mages and Mr. Arnaud Boussemart of Lafarge Aluminates, by providing samples and information to prepare this paper is appreciated.

MDF-RELATED SYSTEMS BASED ON SULFOBELITIC CLINKER / HYDROXYPROPYLMETHYL CELLULOSE / POLYPHOSPHATE GLASS COMPOSITIONS.

Milan DRABIK, Lubica GALIKOVA, Frantisek HANIC , Institute of Inorganic Chemistry, Slovak Academy of Sciences, 842 36 Bratislava, Slovak Republic
Robert C.T. SLADE , Department of Chemistry, University of Exeter, Exeter EX4 4QD, United Kingdom

ABSTRACT Model MDFs have been fabricated using (1) low-energy sulfobelitic clinkers (C_4AF and $C_4A_3\bar{S}$, with 25 % β–C_2S) or (2) sulfobelitic plant cement, with hpmc or polyphosphate glass as polymer component. Atomic level cross-links are demonstrated by nuclear (NMR and Mössbauer) spectroscopies and thermal analysis. The moisture resistance of these models is similar to that for PC-based MDFs. The use of polyphosphate glass enhances moisture resistance.

Key-words : Cross-linking , Macro Defect Free , Moisture , Thermogravimetry .

INTRODUCTION

A range of different clinker/polymer combinations have been said to have potential as regards formation of MDF materials. In an early patent in this field Birchall et al. (1988) outlined the use of aluminous, Portland (PC) and sulfate clinkers, and a wide range of water-soluble carbonaceous polymers. Studies comparing the properties of MDFs with hydraulic cements have attributed the improved mechanical characteristics to the partial filling of the pore structure by polymer gel and to the adhesive action of polymer, linking fibrils of hydrated cement. Several models involving atomic-level cross-linkages have been postulated (Rodger,1985; Edmonds,1989; Desai,1992) as explanations of the chemical origin of the exceptional properties of MDFs fabricated from aluminous cements and polyvinylalcohol-acetate (PVA/Ac). These models are complementary and evidently provide a realistic chemical view of the reactions occurring. Principles governing the chemistry and its transfer to bulk properties of PC-based MDFs have resulted from the studies of Roy's group, which performed MDF-related studies of Portland cement and polyacrylamide (Roy, 1992). More recently, Ma and Brown (1992, 1994) reported the use of polyphosphates (poly-P) in some model systems. We have reported MDF-processibility of particular components/phases arising in potential sulfobelitic clinkers in combination with hydroxypropylmethyl cellulose (hpmc) and polyphosphates (poly-P) (Drabik,1994a,b, 1995). The results have pointed to (i) the involvement of *Al, Fe, P* and *C* atoms in cross-links within amorphous AFm-like reaction products/intergranular gel, and (ii) the influence of that chemistry on porosity, a. c. electrical impedance and microstructure.

An exceptionally important task (for both scientists and technologists) is the control of moisture resistance of MDFs. The incompleteness of conversion of clinkers is obvious at the given w/s ratios, and this incompleteness exerts a negative effect - low (or undefined)

moisture resistance. Studies on the moisture resistance of MDFs are not uniform in their results. Igarashi (1992) differentiates effects of moisture below and above a relative humidity of 65%; the lower humidity environment does not deteriorate MDF material, whilst the upper does. That study was performed on PC-based MDFs. Results have also been presented for aluminous MDFs (Lewis,1994); moisture resistance was believed to be high. Percolative principles controlling the kinetics of degradation by moisture have been generally discussed by Chu and Robertson (1994), but the effects are not satisfactorily defined for MDFs. There are two contradictory tendencies evident in the results of these early studies: low percolation results in high moisture resistance (Lewis,1994; Chu,1994), but decomposition of PVA/Ac occurs in concretes and mortars (Zivica,1965) and especially in MDFs (Birchall,1988; Edmonds,1989; Rodger,1985).

The aim of present study was to investigate the MDF-related properties of model systems of the type sulfobelitic clinker / hydroxypropylmethyl cellulose (hpmc) / polyphosphate glass (poly-P). Particular interests are the processibility and cross-linking during MDF fabrication, and also the moisture resistance of the MDF models. Clinkers originating both from laboratory synthesis and from a cement plant have been investigated.

EXPERIMENTAL

Clinkers, cements and preparation of MDF probes

Laboratory clinker phases (C_4AF, $C_4A_3\bar{S}$) and physical mixtures of these (1:1, 1:2, 2:1) were prepared by reactions of chemical grade compounds at 1250 °C, as reported elsewhere (Drabik, 1994a). More complex sulfobelitic clinkers (in which the individual clinker phases were present along with C_2S, belite, 25 % by mass) were synthesized at 1250 °C (Drabik, 1994c). Low-energy sulfobelitic plant cements were produced at 1240 - 1270 °C in standard medium size rotary kilns (Cimus, Romania).

Processing to obtain model MDF materials was as follows : (i) Dry pre-mixing of clinker phases (or mixtures of clinker phases, or cement) with hpmc (5 % of total mass). (ii) Addition of water to give w/s = 0.2, or addition of an aqueous solution of sodium polyphosphate to incorporate 5 % (by mass) of poly-P and give w/s = 0.2 (s includes clinker and mass equivalent of the dissolved poly-P). (iii) Twin-rolling until the mixture reaches the consistency of dense dough (up to 5 min). (iv) Static 5 MPa pressure in a pellet die (diameter 10 mm) applied for intervals ranging from 30 minutes to 6 hours. (v) Chemical reactions kinetically frozen by air drying at 50 °C. Hydroxypropylmethyl cellulose (Aldrich) was p.a. purity, viscosity of 2 % aqueous solution 80 - 120 centiPoise. Sodium polyphosphate glass (Budit 9, approximate stoichiometry of a tetraphosphate) samples were supplied by Chemische Fabrik R.A. Oetker (Budenheim, Germany).

Methods of the treatment of MDF probes

For each model MDF composition 2 - 4 separate MDF disk samples were synthesized and investigated. In spectroscopic examination (multinuclear ^{27}Al, ^{13}C, ^{31}P high resolution MAS NMR, ^{57}Fe Mössbauer) and thermal analyses, ground samples were studied. ^{57}Fe Mössbauer spectra were recorded at -196 °C ($N_2(l)$) using a standard constant acceleration spectrometer and cryostat. Simultaneous TG and DTA were conducted on a T.A.I. sdt 2960 instrument (from ambient temperature to 1000 °C, 10-20 mg, 10 °C min^{-1}, in air).

MAS NMR spectra were recorded at ambient temperature using a Varian Unity 300 spectrometer. ^{27}Al (78.15 MHz) spectra were recorded with spin rates ~ 12 kHz. Short (1 μs) pulses were employed, a small background arising from the Doty probe was subtracted, and spectra were referenced to $Al(H_2O)_6^{3+}$ *(aq)*. ^{13}C (75.4 MHz) and ^{31}P (121.4 MHz) spectra were recorded with sample spinning rates 4.0 - 4.5 kHz, and were referenced to TMS (^{13}C) and concentrated (85%) H_3PO_4 (^{31}P). ^{13}C spectra were recorded with cross-polarization (^{1}H - ^{13}C), and ^{31}P spectra were recorded with gated decoupling.

In impedance studies the faces of an MDF disk were coated with conductive silver paint (Acheson Electrodag 915) and copper disks were then attached using the silver paint as adhesive. Pellets were equilibrated in a desiccator over saturated $NaHSO_4(aq)$ (relative humidity RH = 52 % at ambient temperature).

The moisture resistance of model MDFs was investigated at two different relative humidities (RH); mass increases of samples kept in the environments RH = 52% (above saturated $NaHSO_4(aq)$) and RH = 100% (above deionised water) were followed as a function of time. Sample changes after equilibration at those RHs were evaluated thermoanalytically.

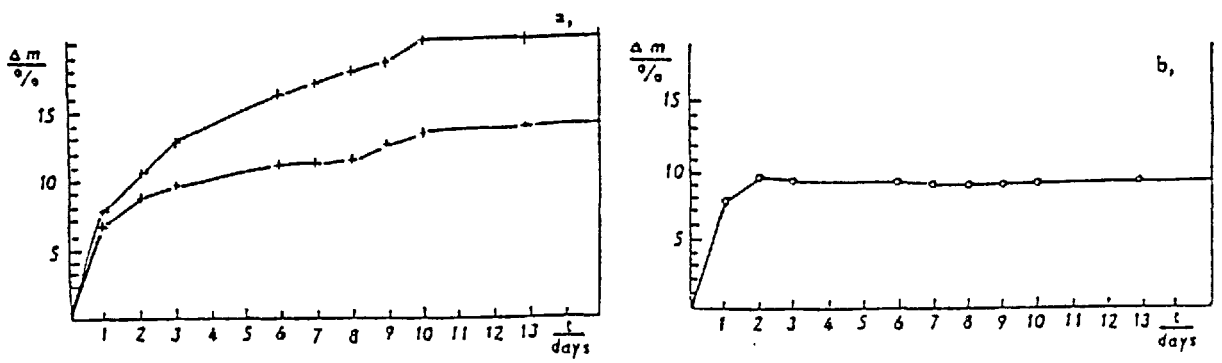

Figure 1 Δm = f (t), for MDFs formed from sulfobelitic clinker: (a) with hpmc and stored at RH = 100% (upper trace MDF pressing 1h, lower trace 6h), (b) with poly-P and stored at RH = 100% (independent of pressing time)

RESULTS AND DISCUSSION

Very good processibility is achieved across the whole composition range, with twin-rolling being an unavoidable step if proper dough consistency is to be achieved. Application of pressure for any interval between 30 min to 6 h results in well shaped test pieces, frequently with a semi-gloss surface. The test pieces do not all behave similarly under moisture-resistance testing (see later also). As regards the degree of atomic level cross-linking interactions and consequent moisture resistance, for MDFs made with hpmc as sole polymer a lengthy (5 - 6 h) pressing is preferable, whereas for systems with poly-P alone a shorter pressing (1 h) is sufficient.

Atomic level changes due to MDF fabrication procedures were monitored by nuclear (NMR and Mössbauer) spectroscopies and thermal analysis. Values of chemical (NMR) and isomer (Mössbauer) shifts of probe nuclei and assigned cross-linking interactions are summarized in Table 1. Indicative TG intervals and DTA events of MDF test pieces, both before and after moisture-resistance testing, are given in Table 2.

Table 1 Chemical shifts in MAS NMR (^{27}Al, ^{13}C, ^{31}P) and isomer shifts in Mössbauer (^{57}Fe) spectra, together with relevant local structures in (**a**) polymer-free systems, (**b**) MDF test pieces (cross-links in ***bold*** type) and (**c**) pure polymers.

	a	**b**	**c**
^{27}Al	δ = 13.4 *Al(6) - OH*	δ = 9.4 ***Al(6) - OX***	-

^{31}P	-	δ = - 5.1 ***P(4) - O - Me***	δ = 1.7, - 15.7 $P(4)_t$ - O $P(4)_b$ - O

Note : ^{29}Si m.a.s.-n.m.r. spectra revealed Q(0) of C_2S only, under all reaction conditions.

The resulting picture is fully in line with the accepted hydration kinetics of individual clinker phases ; $C_4A_3\bar{S}$ (containing *Al*) ~ C_4AF (containing *Al* and *Fe*) >> C_2S (containing *Si*). Cross-links are formed by *Al* and *Fe* originating in more reactive clinker phases. The results on *P* atom incorporation within the cross-links provide further evidence of the increasing value of the phosphate compounds in various branches of cementitious/ceramic materials, *cf.* Ma and Brown (1992, 1994), Connaway-Wagner (1991). ^{31}P MAS NMR spectra clearly show extensive chemical reaction and formation of *Al/Fe - O - P* cross-links during MDF procedures (Drabik,1995), and thus the attempt to use poly-P in this class of chemically bonded ceramics is very promising.

Thermal analysis of MDFs before and after moisture attack provides further useful information. Two (for models with hpmc alone) or three (for models with poly-P alone) steps of weight loss are seen in TG traces. When comparing these results with thermal events for polymer-free AFm hydrates (Nishikawa,1992) and for polymers alone, model MDFs have systematically higher decomposition temperatures, this being consequent on cross-links and clusters of those when polymers are incorporated. A significant exotherm at 300 °C in DTA traces of samples with hpmc indicates structural change of the carbonaceous network during the breakdown of cross-links containing *C* atoms. Mass loss between 500 - 700 °C in samples with poly-P alone is connected with chemical transformation of cross-links where the *P* atom is present. An additional mass loss and exotherm is seen for samples equilibrated at RH = 100 % (Fig. 2). These features coincide with literature reports for portlandite ($Ca(OH)_2$) dehydroxylation, and demonstrate the formation of secondary

portlandite at high relative humidities. Similar results were obtained for MDFs made with low-energy plant cement.

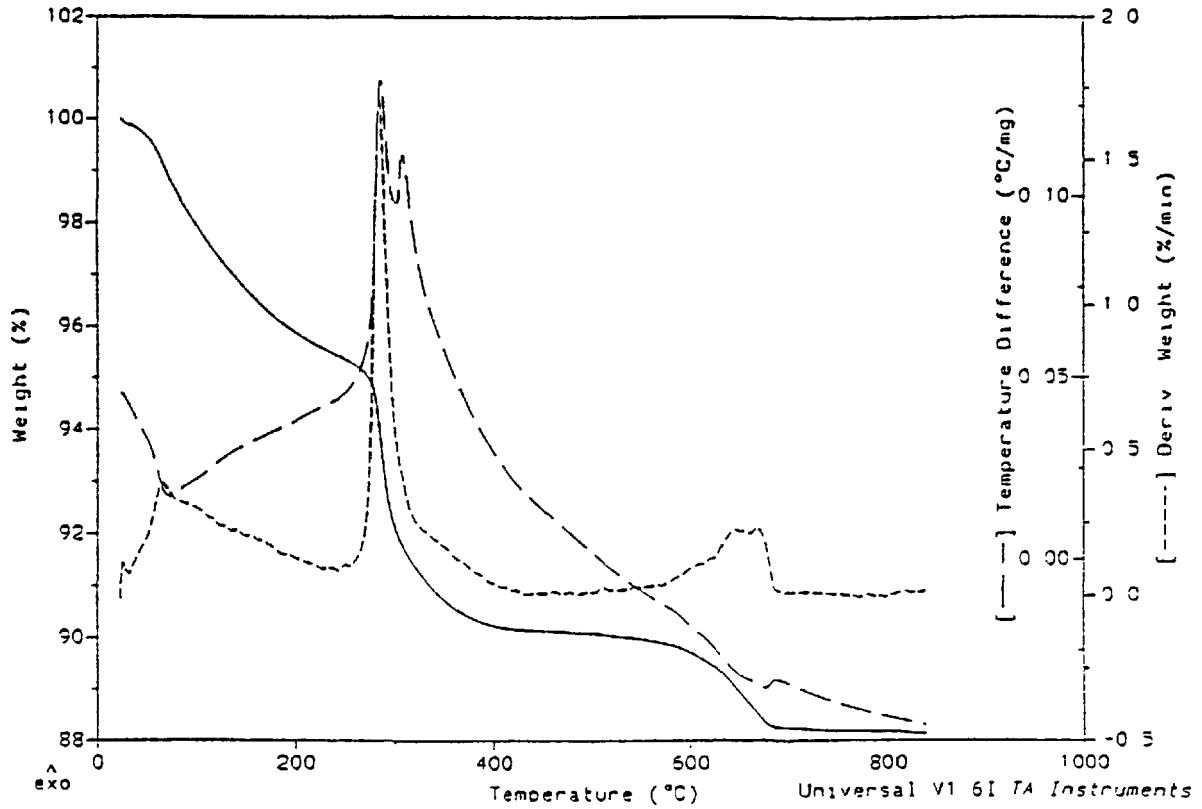

Figure 2 TG, DTG and DTA traces for the model MDF synthesized from sulfobelitic clinker + hpmc and after equilibration at RH = 100%.

Table 2 TG intervals (°C) and DTA events (°C) for model MDFs and those equilibrated at RH = 52 and 100 %.

polymer	RH = 52 %				RH = 100 %

* feature due to portlandite

We have recently (Drabik, 1996a) given a diagrammatic representation of the formation of *Al/Fe - O - C/P* cross-links in this MDF system. The detailed atomic-level model accounts for next nearest neighbor interactions as detected by nuclear spectroscopies. Several features of that model are related to the principles governing the chemistry of aluminous MDFs (Rodger,1985; Edmonds,1989; Desai,1992). The schematic outline of clusters in the cross-linking section of the local structure of sulfobelitic MDFs has been very valuable in the consideration of moisture resistance and conductivities (Drabik, 1996b) in that system. Impedance spectra are typical of electronically-insulating materials functioning as solid electrolytes, with conductivity values depending on polymer component as well as the temperature of the measurement. Conductivity differences between the various model MDFs arise from the atomic level details of the pore-filling by AFm-like intergranular gel, different polymers giving chemically different gels. Conductivities vary only slightly with "MDF reaction time".

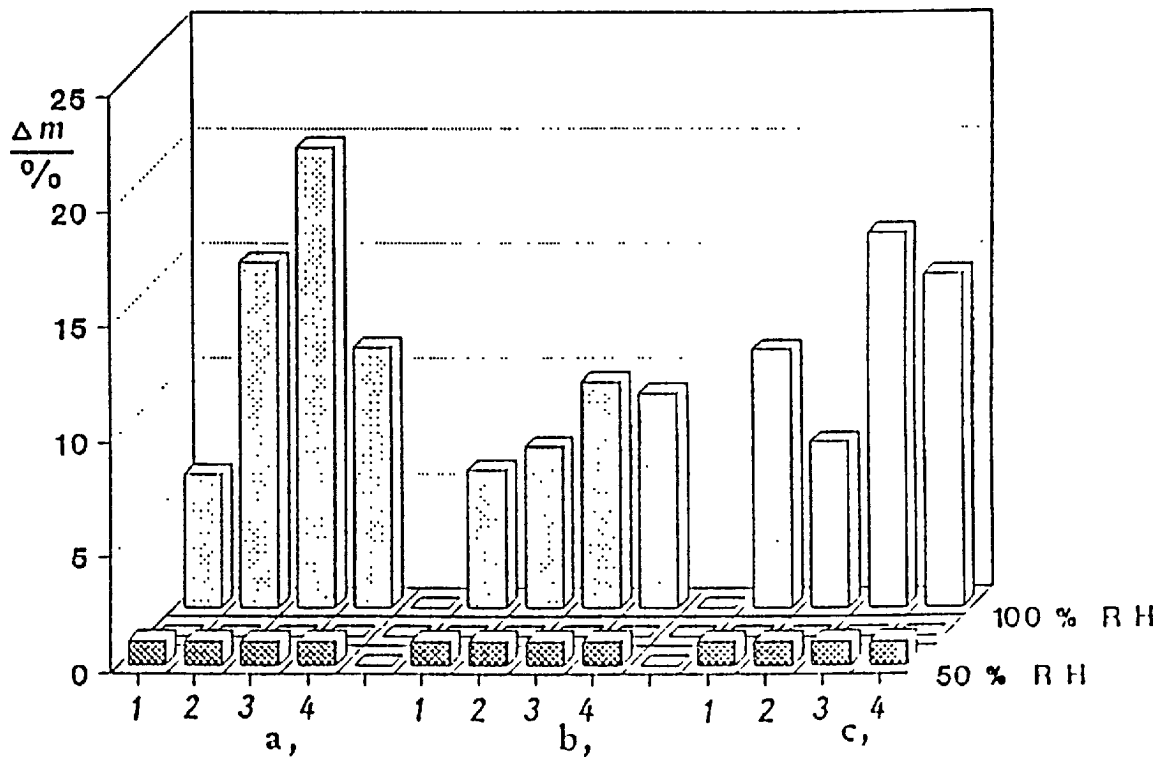

Figure 3 Mass increases of model MDFs after equilibration at RH = 52% and 100%. Polymer additions: (a) hpmc, (b) poly-P, (c) hpmc + poly-P. Clinker compositions: (1) $C_4A_3\bar{S}$ + C_4AF, (2)-(3) sulfobelitic laboratory clinkers, (4) Cimus sulfobelitic low-energy cement.

Mass increases of test pieces stored in moist atmospheres show that the behavior of MDFs within sulfobelitic clinker/hpmc/poly-P is similar to that of PC-based MDFs (Igarashi, 1992). In the current study, the moisture resistance is controlled by percolation through the AFm-like intergranular mass, in which clusters of cross-links hinder percolation for RH $\leq$ 52 %.

Those clusters are, however, attacked at higher relative humidity; an atmosphere with RH = 100 % exerts a fatal influence, degrading the surface of test pieces and leading to secondary portlandite (overall mass increase ~ 10 %, Figs. 1 and 3). Test pieces made with poly-P (Figs. 1b, 3b) appear more moisture resistant, with a lower mass increase and a mass plateau (equilibration) being achieved after 3 days (independent of MDF pressing time). For samples made with hpmc, the duration of pressing during fabrication is crucially important: the upper trace in Fig. 1a is for a sample fabricated with 1h pressing, the lower trace (with lower mass increase) is for 6h. Closely similar results were obtained for MDFs made with the low-energy plant cement (clinker No. 4 in Fig. 3). Percolation of MDFs by water and consequent surface corrosion by formation of $Ca(OH)_2$ (see above) clearly have technological consequences, and reinforce the need for very thorough improvement / impregnation of this type of material.

The results of this study demonstrate, as in simpler model systems related to sulfobelite-based MDFs (Drabik, 1994a,b, 1995), a link between the atomic level chemical interactions and bulk properties for a complex clinker mixture. We obtained similar results (in terms of moisture resistance and thermal events) with the low-energy plant cements. MDF processing leads to formation of *Al/Fe - O - C/P* cross-links; these represent the particular chemical bonds [generally postulated to be necessary in chemically bonded ceramics (Tan,1987)] and add the atomic scale viewpoint to the rheological knowledge of MDF materials. Cross-links are transferred into the bulk and affect the properties of the MDF test pieces. Control of the details of this synergism will improve the technologically important properties of such systems in the future. The system sulfobelite clinker / hydroxypropylmethyl cellulose / polyphosphate glass (especially compositions with polyphosphates incorporated) should be considered as an alternative to high alumina MDFs (Birchall,1988; Edmonds,1989; Rodger, 1985; Desai,1992; Young,1996) and PC-based MDFs (Igarashi,1992; Roy,1992; Ma,1992, 1994; Ohama,1996), when exploring the potential range of MDF materials.

CONCLUSIONS

1. The system studied exhibits a suitable processibility during MDF fabrication. Inorganic polymer (poly-P) reacts extensively to give cross-linking bonds to atoms originating in the clinker. Atomic level studies have demonstrated the AFm-like composition of hydrated intergranular mass.

2. Both nuclear spectroscopies and thermal analysis demonstrate the presence and rôle of *Al/Fe - O - C/P* cross-links. An increase of decomposition temperatures in MDFs is assigned to the existence of clusters of cross-links, which will be crucial in affecting thermal stability and bulk properties.

3. Moisture resistance is similar to that reported for PC-based MDFs, and is controlled by percolation of the AFm-like intergranular mass. The resistance is sufficient at RH $\leq$ 52%, but surface corrosion (portlandite formation) occurs at RH = 100%.

4. This study demonstrates the potential of low energy clinkers and cements for the MDF process. Further developments (*e.g.* use of the enhanced moisture resistance of systems containing poly-P, full evaluation of mechanical properties) are necessary if these compositions are to find technological application.

ACKNOWLEDGEMENTS

This research is funded by the Slovak Grant Agency for Science (VEGA 2070 project) and by the R&D Directorate of EC (as the part of Copernicus project ERB CIPA CT 94 0105). Low energy plant cements were produced by Cimus (Romania) within the Copernicus project. Part of the study was carried out under a collaborative agreement linking the University of Exeter and the Institute of Inorganic Chemistry (SASci, Bratislava). We thank the Royal Society and the British Council for the funds in support of that collaborative agreement. We thank the EPSRC National Solid State NMR service (Durham, UK) for recording MAS NMR spectra.

THE MECHANISM OF CALCIUM NITRATE AS SET ACCELERATOR FOR CEMENT

Harald JUSTNES, SINTEF Civil and Environmental Engineering, Cement and Concrete, N-7034 Trondheim, Norway
Erik C. NYGAARD, Norsk Hydro A.S., R&D, N-3901 Porsgrunn, Norway

ABSTRACT Technical quality calcium nitrate (CN) is widely used as set accelerator for Portland cements and concrete. However, its efficiency may vary strongly with the cement type. In order to find the reason for this, a thorough analysis of the water in cement pastes from mixing to past setting was undertaken with respect to the ions; Ca^{2+}, SO_4^{2-}, OH^-, NO_3^-, NO_2^-, K^+ and Na^+, together with the elements Al, Si and Fe. Two extreme cases was investigated; one Portland cement with setting virtually unaffected by CN and another very much accelerated by CN. The difference was due to the high content of alkali sulphate of the former, precipitating active calcium as gypsum. A negative linear correlation between setting efficiency and increasing alkalies in the initial water phase of paste was found based on 9 different Portland cements.

Key-words: Accelerator, calcium nitrate, ions, mechanism, pore water, setting

INTRODUCTION

Technical calcium nitrate (CN) has been used for some time as set accelerator for Portland cements and concrete. However, in several studies (Justnes, 1993; Justnes and Nygaard, 1993, 1995, 1996a and 1996b) the efficiency of CN as set accelerator has been found to vary strongly with the cement type. In order to find the reason for this, and possibly the mechanism of CN as set accelerator for cement, a thorough analysis of the water in cement pastes from mixing to past setting was undertaken with respect to a number of ions.

The Vicat-needle setting profiles of the two extreme cases investigated; P30 cement virtually unaffected by CN and HS65 cement which is very much accelerated by CN, are previously published by Justnes and Nygaard (1995).

EXPERIMENTAL

Components

Technical quality calcium nitrate (CN) may in general be written as $xNH_4NO_3 \cdot yCa(NO_3)_2 \cdot zH_2O$. The CN used in the present work had x = 0.092, y = 0.500 and z = 0.826, or in other words 19.00 % Ca^{2+}, 1.57 % NH_4^+, 64.68 % NO_3^- and 14.10 % H_2O. The nitrite (NO_2^-) content was below the detection level (= 0) and the pH of a CN solution was ≈7. The technical quality CN was delivered by Norsk Hydro A/S, Porsgrunn, Norway.

The technical quality calcium nitrate (1.55 % CN by weight of cement) was added to cement pastes (distilled water-to-cement ratio 0.55) based on two different cements; ASTM type I (ordinary Portland cement = P30) and ASTM type II (moderate sulphate resistant = HS65). The contents (%) of CaO (C), SiO_2 (S), Fe_2O_3 (F), Al_2O_3 (A), SO_3 (S), MgO (M), Na_2O (N), K_2O (K) and free lime were 63.56&64.32, 20.31&22.13, 3.52&3.39, 5.02&4.05, 2.88&3.07, 2.34&1.03, 0.39&0.23, 1.18&0.42 and 1.87&?, while the specific surfaces (Blaine) were 290&418 m^2/kg for the P30&HS65 cements, respectively. The Bogue calculation based on the analyses resulted in a potential mineral content (%) of C_3S (alite), C_2S (belite), C_4AF (ferrite) and C_3A (aluminate) of 57&53, 15&24, 10.7&10.3 and 7.4&5.0 for P30&HS65, respectively. The cements and their analyses were all obtained from Norcem A/S, Brevik, Norway.

Methods

Water analyses

Each of the two cement pastes with w/c = 0.55 was made as one mix and distributed in plastic cups after two minutes manual mixing. At each of the termins 10, 30, 60, 120 and 480 minutes the "gelled" cement pastes was rapidly stirred and poured onto a black bond filter paper on a Büchner funnel attached to a "water pump" through a Erlenmeyer flask. The fluid filtrate was poured through a blue bond filter into small plastic bottles before they were sent for ion analyses performed by Norsk Hydro A/S, Porsgrunn, Norway.

The filtrates were diluted with doubly distilled and de-ionized water before they were analysed by ICP-AES (Atomic Emission Spectroscopy) with respect to the following elements; Ca, K, Na, Si, Al, Fe and S. The content of nitrate (NO_3^-) and nitrite (NO_2^-) ions were determined by DIONEX ion chromatography. The hydroxyl (OH^-) concentration was measured by a pH meter directly on the filtrate.

Cement interstitials

The cement silicates, C_3S and C_2S, of the cements were removed by the following extraction procedure: 1) 5 g pre-dried (300°C) cement was dispersed in 150 ml water-free methanol. 2) 15 g dry maleic acid was added, followed by stirring for 10 minutes. 3) The filtrate was washed with methanol and dried at 60°C. The filtrate then contain the clinker interstitials (C_4AF, C_3A and alkali sulphates) + added gypsum.

The X-ray diffractograms of the filtrates from the P30 and HS65 cements were recorded by a diffractometer after an internal reference consisting of 10 % anatas (TiO_2) was interground. Cu K_α-radiation with wavelength λ = 1.5418 Å and a Ni-filter were used.

RESULTS AND DISCUSSION

The ion concentrations (mM) for Ca^{2+}, SO_4^{2-}, OH^-, NO_3^-/NO_2^-, K^+ and Na^+, together with the elements Al and Si (potential complex ions), in the paste fluids are listed as a function of time in Tables 1, 2, 3, 4, 5, 6, 7 and 8, respectively, while the concentration vs time profiles for calcium and sulphate are plotted in Figs 1 and 2, respectively. The content of iron is negligible since it at all times was < 1 mg Fe/l. The uncertainty in the ion analyses is estimated to ±10%.

Table 1 The calcium concentration (mmol/l = mM) in the fluids of P30 and HS65 cement pastes with 0.00 and 1.55 % CN as a function of time (min) from mixing.

Time (min)	P30, 0.00 % CN	P30, 1.55 % CN	HS65, 0.00 % CN	HS65, 1.55 % CN
10	14.4 mM Ca^{2+}	23.0 mM Ca^{2+}	18.5 mM Ca^{2+}	90.1 mM Ca^{2+}
30	16.1 mM Ca^{2+}	23.5 mM Ca^{2+}	20.0 mM Ca^{2+}	86.8 mM Ca^{2+}
60	16.2 mM Ca^{2+}	23.2 mM Ca^{2+}	20.7 mM Ca^{2+}	80.8 mM Ca^{2+}
120	17.5 mM Ca^{2+}	23.7 mM Ca^{2+}	20.5 mM Ca^{2+}	73.4 mM Ca^{2+}
480	12.5 mM Ca^{2+}	17.7 mM Ca^{2+}	15.5 mM Ca^{2+}	51.7 mM Ca^{2+}

480	10.5 mM Si	10.2 mM Si	3.6 mM Si	0.0 mM Si

In order to control that all ions in the aqueous phase of the cement pastes in the present investigation are accounted for, the sum of positive and negative charges are listed in Table 9. Note that since OH^- is measured by pH-meter, the charge pr Al is -1 due to the complex $Al(OH)_4^-$, while the charge pr silicon is assumed to be -1. If the hydroxyl concentration was determined by titration, the Al and Si charge should be +3 and +4, respectively, due to the decomposition of the complex hydroxy ions. With the exception of one fluid (from HS65 without CN after 480 minutes), the difference between the sum of charges is within the accuracy of ion determination (±10%). The accuracy of the pH determination is assumed to be ±0.1 unit, which correspond to an accuracy in OH^- concentration of ±25%. The "error" in the one low sum of negative charge seems to be a too low hydroxyl concentration.

Table 9 The sum of positive (Σ_+) and negative (Σ_-) charges (Σ_+/Σ_-) for the ions (mM) in the fluids of P30 and HS65 cement pastes with 0.00 and 1.55 % CN as a function of time (min) from mixing.

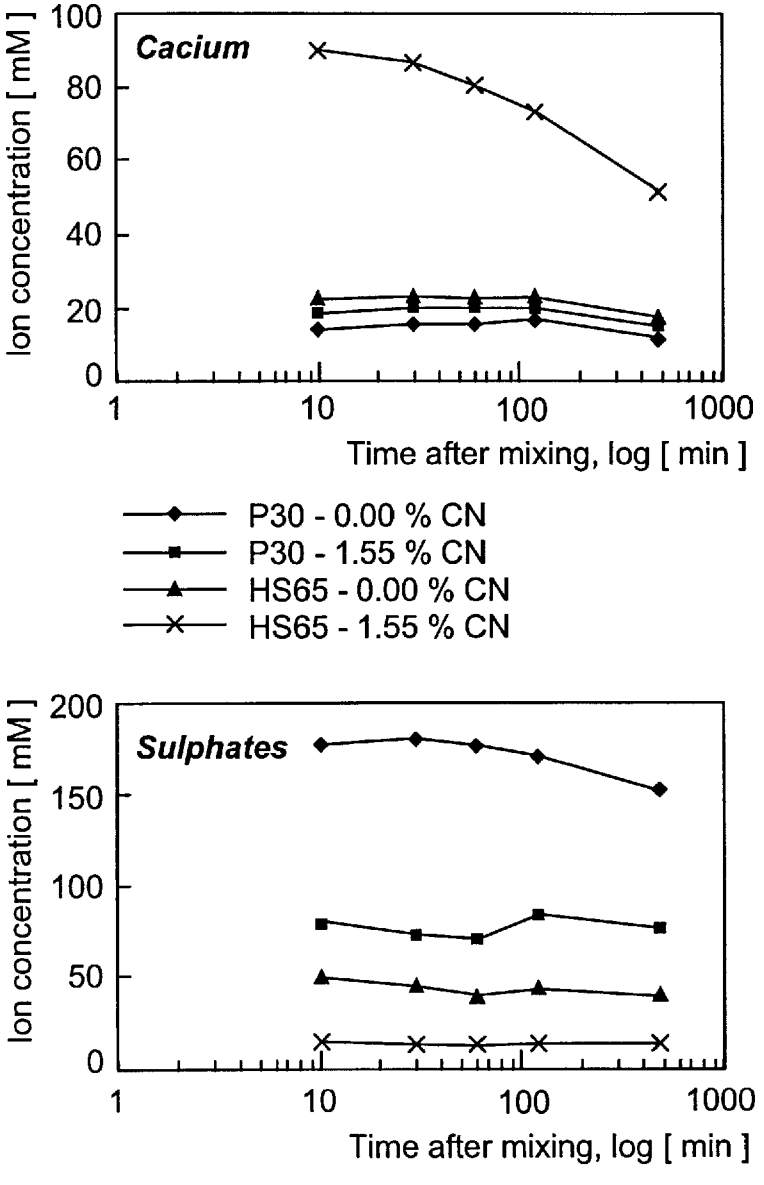

Fig. 1 The calcium (upper) and sulphate (lower) concentration as a function of time from mixing in the water of cement pastes.

For both cement pastes (w/c = 0.55), the most noticeable change when 1.55 % CN of the cement weight is added (except for the increase in nitrate concentration), is that the calcium concentration increases (see Table 1 and Fig 1) and the sulphate concentration decreases (see Table 2 and Fig 1). In addition, the hydroxyl concentration (see Table 3) is decreased in order to maintain the solubility product of calcium hydroxide.

The reason why the concentration of sulphates in the fluid of P30 is much higher than in HS65 paste, is the higher content of alkali sulphates (may also be seen from the potassium and sodium concentrations in Tables 5 and 6, respectively). Alkali sulphates may be detected by XRD of the residue after the extraction procedure enriching the interstitials if present. Alkali sulphates appear usually as the mineral Aphthitalite, $K_3Na(SO_4)_2$ (cement chemist's short hand notation; $K_3N\bar{S}_4$).

Aphthitalite is an excellent example of the solid solution phenomena, and the formula may be written $KK_{3-x}Na_x(SO_4)_2$, where x may vary from 1 to 3 without disturbing the crystal structure. The lattice distances for the two strongest reflections with hexagonal indices <110> & <102> will be 2.839 & 2.940, 2.804 & 2.889 and 2.778 & 2.841 Å for x = 1 (ASTM card 20-928), 2 (ASTM card 20-927) and 2.66 (ASTM card 20-926), respectively. The position of reflections (i.e. the unit cell axes) changes linearly with the composition according to Vegard's law of solid solution. For Aphthitalite, the linear correlation for the <110> reflection is $x = -27.319 \cdot d_{<110>} + 78.570$ and $x = -16.967 \cdot d_{<102>} + 50.921$ for the <102> reflection. The Portland cement P30 ("Standard" clinker) contain Aphthitalite with $d_{<110>}/d_{<102>} = 2.8355/2.9330$ Å, while the XRD of the interstitial residue from HS65 cement ("High strength" clinker) only shows weak indications of these reflections (see Fig 3 for reflections marked "A"). The observed lattice distances give x = 1.13±0.04 in the formula $KK_{3-x}Na_x(SO_4)_2$ for the P30 Portland cement.

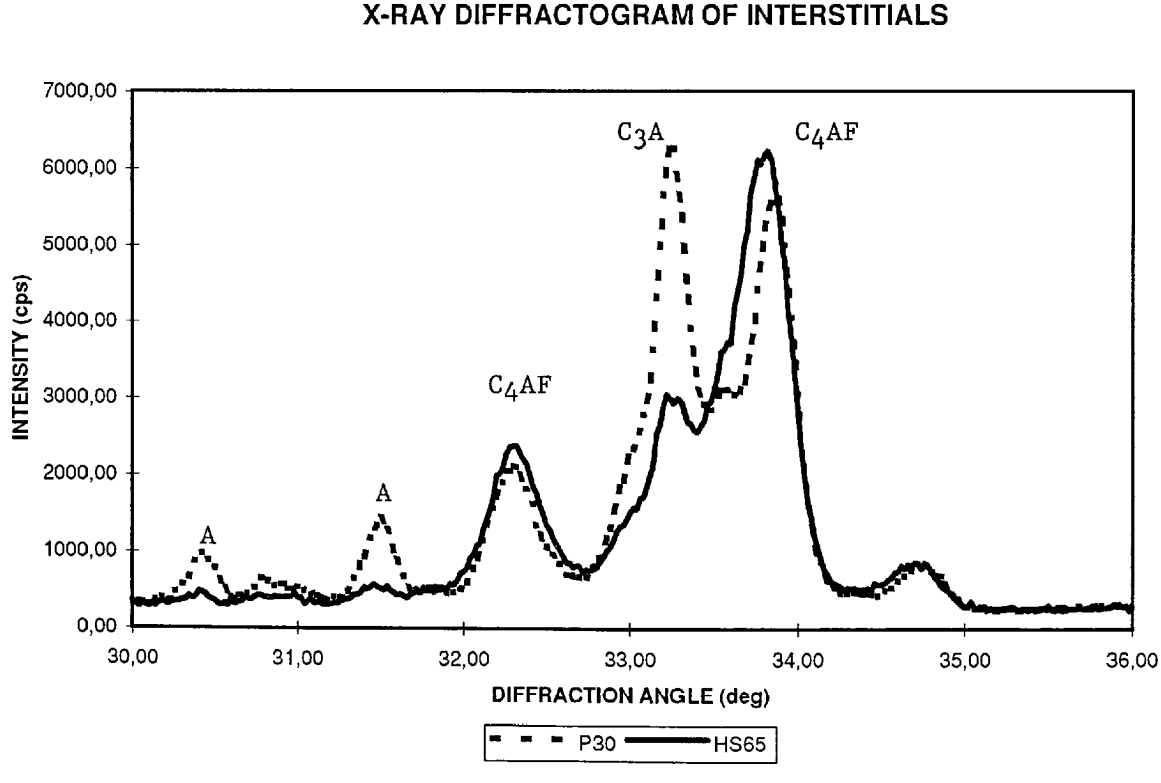

Figure 2 X-ray diffractogramme of the extracted interstitial phases from clinkers of P30 and HS65 Portland cements. The two reflections of the mineral Aphthitalite, $K_3Na(SO_4)_2$, are marked with an "A".

The alkali content of the cement paste fluids is not affected by CN additions (Tables 6 and 7). The K/Na ratio is about 3.5 for P30 and about 4 for HS65. In particular potassium may occur in other phases like syngenite and solid solution in belite (ß-C_2S). Assuming ideal composition of Aphthitalite (K/N=3), 100 mM Na^+ and w/c = 0.55 corresponds to 1.82 % $K_3N\bar{S}_4$ of the cement weight.

Justnes and Nygaard (1995, 1996a and 1996b) found a linear correlation between the belite content of different cements and the set accelerating efficiency of CN. Since belite is a slowly reacting mineral, it was concluded that this must be due to an indirect effect. This may now be understandable since belite can incorporate a portion of the total alkalies in its structure and consequently prevent them from taking part in the early fluid chemistry. Hence, for a series of cements with about equal total alkali content and increasing belite content, it is expected that the set accelerating efficiency of CN will increase. On the other hand, El Didamony et al (1996) investigated the influence of calcium acetate, chloride and nitrate on belite hydration. They found that after 1 day (first data point), the chemical bound water was increased 6 times when 2 % $Ca(NO_3)_2$ was mixed in the water, while 2 % $Ca(CH_3COO)_2$ and 2 % $CaCl_2$ only increased the 1 day chemical bound water by 30 % compared with the reference. Thus, a special influence of CN on β-C_2S can not be excluded.

When the alkali content (eqvivalent Na_2O) in the fluid of cement paste (w/c = 0.55) 20 minutes after mixing for 4 (of 5) Norwegian and 5 French portland cements investigated by Justnes and Nygaard (1995 and 1996a) is plotted against the reduction in setting time (i.e. measure of efficiency for set accelerator since the setting time without accelerator may vary widely for the cements) when 1.55 % CN is dissolved in the mixing water, a negative linear correlation with regression factor r^2 = 0.8196 is obtained as shown in Fig 3. This correlation supports the idea that the content of initially soluble alkalies (e.g. aphthitalite) is the most important characteristic of the cement influencing the efficiency of CN as set accelerator.

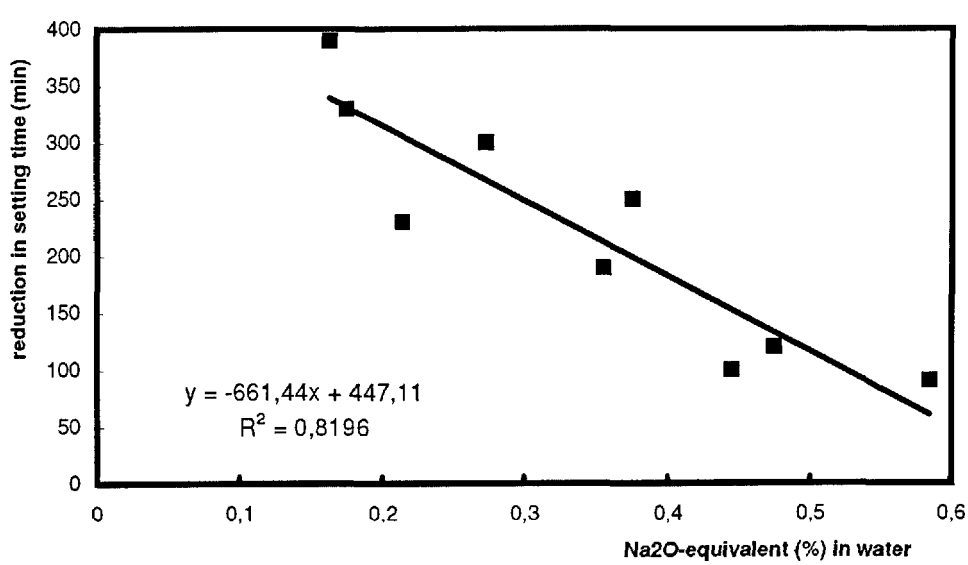

Figure 4 The reduction in setting time for portland cement pastes when 1.5 % calcium nitrate is added vs the alkali content of the liquid phase 20 minutes after mixing.

CONCLUSION

The mechanism for accelerated setting of cement by calcium nitrate (CN) is two-fold; 1) an increased calcium concentration lead to a faster super-saturation of the fluid with respect to calcium hydroxide, $Ca(OH)_2$, and thereby shorter time to initial crystallization and renewal of alite hydration, and 2) a lower sulphate concentration will lead to slower/less formation of ettringite which will shorten the onset of the aluminate, C_3A, hydration.

The reason why P30 is not accelerated by CN, is that P30 contain much more of the mineral Aphthitalite, $K_3Na(SO_4)_2$ from the clinker process, which will lead to a high sulphate concentration in the fluid. When CN is added, much of the calcium precipitates as sparingly soluble gypsum. Even when 1.55 % CN is added to the P30 paste, the sulphate concentration in the fluid is higher than in the water of HS65 paste without CN. The calcium concentration in the fluid of P30 with 1.55 % CN is only slightly higher than for HS65 without CN, while the Ca^{2+} concentration in the water of HS65 paste is increased with about 4 times when 1.55 % CN is added.

Generally speaking, the set accelerator calcium nitrate will be most effective for Portland cements high in belite and low in alkalies.

EFFECTS OF CEMENT/ADMIXTURE INTERACTIONS ON THE EARLY STIFFENING TENDENCIES OF PORTLAND CEMENT PASTE

S.A. FARRINGTON and D. CONSTANTINER, Master Builders, Inc., Cleveland, Ohio, USA

ABSTRACT The goal of this study was to correlate changes in pore solution composition with changes in workability of cement pastes. Two mechanisms of false set were investigated. Pore solution compositions were found to be significantly different for G-type and lignosulfonate-type false set. Experimental equilibrium constants and saturation indices were calculated with the Pitzer ion-interaction model. This approach indicates that G-type false set is related to gypsum precipitation, but does not indicate the mechanism of lignosulfonate-type false set.

Key-words: False set, Ions, Pore solution, Lignosulfonates, Modeling

INTRODUCTION

Early stiffening of Portland cement materials, known as false set, can occur under a variety of circumstances. The effect is traditionally attributed to the rehydration of calcium sulfate hemihydrate upon addition of mixing water to form The acicular gypsum crystals which interlock (Taylor, 1990). The presence of dehydrated sulfate phases other than gypsum in the cement powder is often due to improper final grinding or high temperature storage. This type of early workability loss has been referred to as G-type false set (Murakami, 1957).

In some cases, the addition of dispersing agents based on salts of lignosulfonic acid has been known to induce early workability loss in cement-based materials. This has been linked to the formation of increased levels of ettringite at early ages (Kalousek, 1974). Recent experience in our laboratory has shown that this effect does not occur with other dispersant chemistries (e.g. sulfonated naphthalenes) and therefore can not be attributed to a water reduction effect. This type of early workability loss will be referred to as lignosulfonate-type false set.

There exists very limited pore solution concentration data for false-setting cement systems (Kawada, 1966), and none was found for false-setting cement and lignosulfonate combinations. This study attempts to improve the understanding of false set mechanisms by examining the ionic concentrations in pore solutions of cement pastes at very early ages. In addition, it explores the possibility of explaining the mechanisms in cement paste through the chemistry of the pore solution. This has been carried out for cement paste with and without lignosulfonate.

EXPERIMENTAL

PORTLAND CEMENTS AND ADMIXTURES

The cement was a Type I Portland cement with the following oxide analysis: SiO_2=22.13%, Al_2O_3=4.50%, Fe_2O_3=2.99%, CaO=63.66%, MgO=2.12%, SO_3=2.68%, K_2O=0.80%, Na_2O=0.11%, Na_2O equiv.=0.64%, free CaO=0.50%, and LOI=1.16%. Blaine fineness was measured as 343 m^2/kg. Suggested Bogue potential phase composition: C_3S=48.8%, C_2S=26.6%, C_3A=6.9%, and C_4AF=9.1%. Suggested modified Bogue potential phase composition (Taylor, 1989): C_3S=62.8%, C_2S=17.8%, C_3A=4.0%, and C_4AF=10.2%.

X-ray powder diffraction analysis of this cement, following selective dissolution of the silicate phases by methanol/salicylic acid extraction, indicated that gypsum was the primary calcium

sulfate phase present in the normal cement. A portion of this cement was heat-treated for 16 hours at 160°C to induce G-type false setting behavior, and will be referred to as heated cement. X-ray powder diffraction analysis of the heated cement after methanol/salicylic acid extraction indicated that nearly all of the gypsum was dehydrated to calcium sulfate hemihydrate. Completely dehydrated calcium sulfate was not found.

Two commercially available lignosulfonate additives were used to induce lignosulfonate-type false set. These can be found in many water reducing admixtures for concrete. An analysis of these additives is displayed in Table 1.

Table 1 Chemical analysis of the lignosulfonate additives used in this study

	Calcium lignosulfonate	Sodium lignosulfonate
Reducing sugars	2.85%	4.21%
Sodium	0.96%	4.76%
Calcium	4.64%	1.92%

EXPERIMENTAL PROCEDURES AND RESULTS

The aim of this study was to correlate early age workability of cement paste with the chemistry of its pore solution. Six cement pastes mixes were prepared as shown in Table 2. For each of the mixes studied, workability was measured and pore solutions were collected over time. A detailed schematic of the experiment is shown in Fig 1. All experiments were carried out in the laboratory at approximately 20°C.

Table 2 Mix preparation data for the cement pastes

Cement	Mix	Additive (by weight of cement)	Paste w/c
	1	none	0.28
Normal	2	0.2% calcium lignosulfonate	0.26

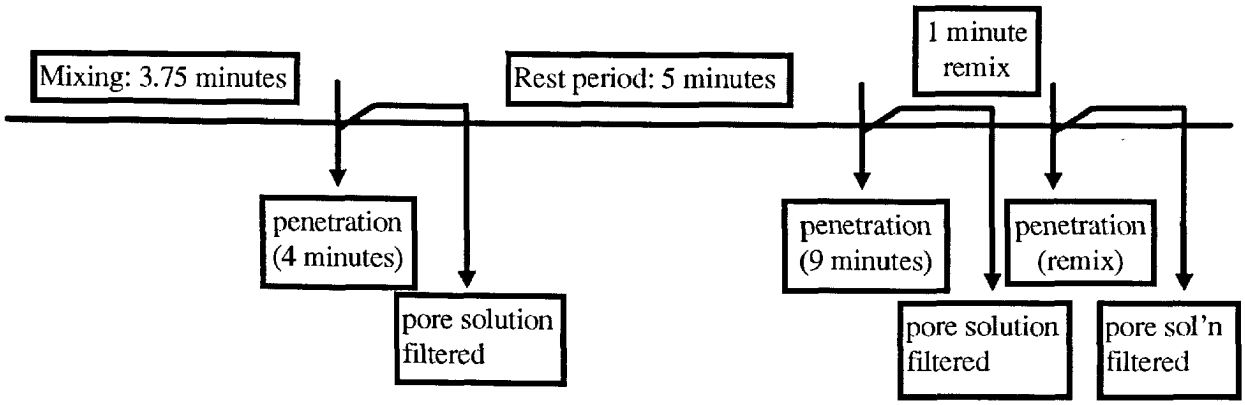

Figure 1 Experimental methodology

The mix procedure which evaluated the early stiffening of paste is outlined in Test Method C-451 (ASTM, 1991), in which workability is evaluated by penetration of a weighted plunger. The pore

solution was separated from the paste by pressure filtration through a polyethersulfone membrane with 0.8 μm opening. Details of the filtration apparatus are described elsewhere (Ong, 1993). The pressure-filtered pore solutions were analyzed for the following ions: OH^-, SO_4^{2-}, Na^+, K^+, Ca^{2+}, Al^{3+}, Mg^{2+}, Fe^{3+}, and SiO_4^{4-}. Hydroxide ion concentration was measured by titration with HCl and a methyl red indicator. Sulfate ion concentration was measured by ion chromatography. The remaining ionic concentrations were measured by inductively-coupled plasma (ICP) spectroscopy.

Early Stiffening Results

The results of the early stiffening measurements are shown in Figs 2 and 3. Fig 2 shows that the normal cement paste stiffened slightly after the rest period. Upon remixing, most of the workability was recovered. This pattern was present in all of the pastes studied, however, the degree of stiffening that occurred during the rest period and the subsequent increase in workability after remixing varied. False set is defined by significant stiffening during the rest period followed by workability increase after remixing. Based on this definition, the normal cement pastes experienced false setting only when lignosulfonates were added, i.e. lignosulfonate-type false set (Mixes 2 and 3). Although not reported here, studies on mortars (using the same cements and additives) followed similar stiffening trends.

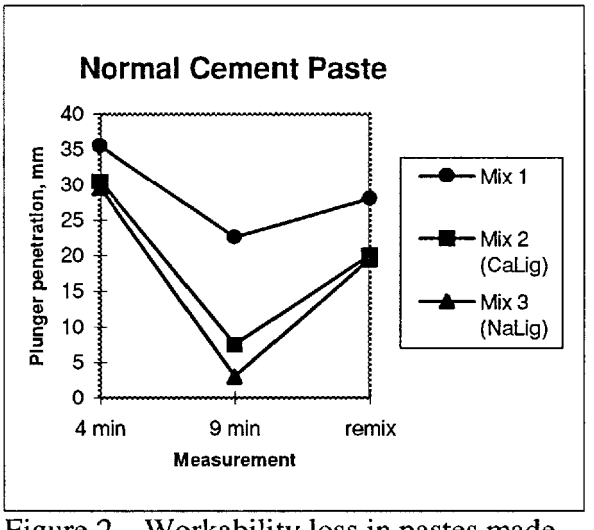

Figure 2 Workability loss in pastes made with normal cement

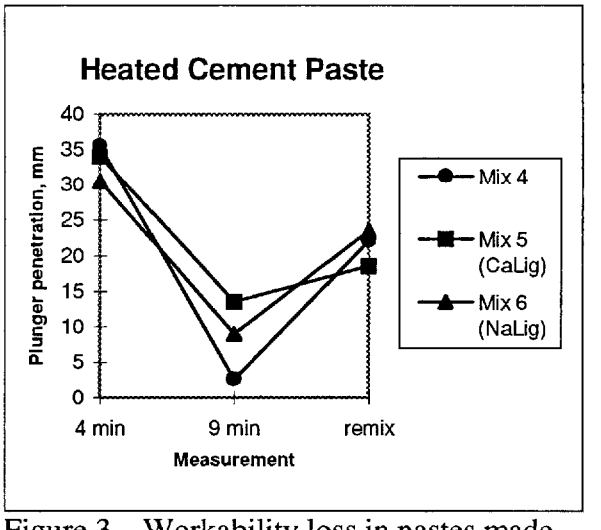

Figure 3 Workability loss in pastes made with heated cement

It can be seen from Mixes 1 and 4 that heating the cement produced a paste with definitive false setting tendencies. However, the addition of lignosulfonate to the pastes containing the heated cement resulted in a reduction of the early stiffening behavior relative to the paste without additive, although the pastes with lignosulfonate (Mixes 5 and 6) are also false-setting.

Pore Solution Results

The results of all pore solution analyses are included in Tables 3 for the highly concentrated ions and Table 4 for the ions of lower concentration. The net charge balance (summation of normality of all cations and anions) for all ions in each solution is also included in Table 4.

It can be seen that the pore solutions contain mainly Ca^{2+}, K^+, Na^+, OH^-, and SO_4^{2-}, with the concentrations of other ions being more than an order of magnitude lower. Early age concentrations reported elsewhere (Gartner, 1985) are in good agreement with these results. The

charge imbalances are significant in some cases and are attributed to experimental error. This paper addresses the highly concentrated ions in the pore solutions (Table 4), the other concentrations are included only for completeness.

Comparing all pore solution ion concentrations, it can be seen that heating the cement resulted in a large increase in $[Ca^{2+}]$, a large decrease in $[K^{+}]$, a large decrease in $[OH^{-}]$, and a decrease in $[SO_4^{2-}]$. Of additional note is that the ratio of $[K^{+}]/[Na^{+}]$ from the cement analysis was on the order of 5:1. This ratio appears to hold in Mixes 1 and 2, and falls to 4:1 in Mix 3, likely due to additional Na^{+} from the lignosulfonate. In Mixes 4 and 5, the ratio is on the order of 4:1, which falls closer to 3:1 in Mix 6, likely a result of sodium lignosulfonate addition.

Solid-Phase Saturation Indices

In addition to simple comparisons of ionic concentrations in solution, the pore solution data was used to assess the state of the pore solution with respect to the solid phases present. This is accomplished by calculating saturation indices from ionic activities for expected solid phases. The Pitzer ion-interaction approach (Pitzer, 1991) for calculating activities of ions in solution has been successfully applied by geochemists to determine the solubility of minerals in solutions of very high ionic strength. This method has been applied to cement pore solutions for the same purpose (Reardon, 1990, Duchesne, 1995). In this study, the ionic concentration data from Table

3 was used to calculate activity coefficients based on the Pitzer model using the software package PHRQPITZ (Plummer, 1988), with one exception: the software requires pH values instead of [OH^-]. An iterative approach was followed to find the correct pH input value, to find a match between the measured and calculated [OH^-]. The software converted concentration to units of molality for calculation of activity coefficients. The calculated activity coefficients and water activity are presented in Table A1 in the appendix. The input temperature used for all calculations was 20°C.

The tabulated ionic activities were used to calculate experimental equilibrium constants, i.e. ion activity products (IAP_{20}), for the following solids: $Ca(OH)_2$, $CaSO_4$, $CaSO_4 \cdot 0.5H_2O$, $CaSO_4 \cdot 2H_2O$, $K_2Ca(SO_4)_2 \cdot H_2O$, K_2SO_4, and $Na_2SO_4 \cdot 10H_2O$. The saturation index of each solid (log $IAP_{20}/K_{sp,20}$) was determined using values of the solubility product constant ($K_{sp,20}$) included in the software which are internally consistent. Since the $K_{sp,20}$ for $CaSO_4 \cdot 0.5H_2O$ is not included in the software, and to further maintain internal consistency of the data, it was necessary to input published solubility data (Linke, 1965) into PHRQPITZ and use the calculated IAP_{20} as the $K_{sp,20}$. The saturation indices and reference $K_{sp,20}$ values appear in Table 5. With respect to each solid phase, positive saturation index values indicate that the solution is oversaturated, negative values indicate undersaturation, and values close to zero indicate equilibrium. K_2SO_4, and $Na_2SO_4 \cdot 10H_2O$ were significantly undersaturated and are not tabulated.

Another study (Gartner, 1985), not concerned with false set, which examined saturation indices for $Ca(OH)_2$, $CaSO_4 \cdot 2H_2O$, and $K_2Ca(SO_4)_2 \cdot H_2O$ in pore solutions at early ages showed relatively close agreement with saturation indices measured for $CaSO_4 \cdot 2H_2O$ in Mix 1 of this study. However, the saturation indices measured for $Ca(OH)_2$ and $K_2Ca(SO_4)_2 \cdot H_2O$ in Mix 1 of this study indicate significant oversaturation while those previously reported indicated undersaturation or slight oversaturation (saturation index ~ 0.1).

DISCUSSION

The saturation index calculations for the normal cement without admixtures (Mix 1) indicates two things: that the solutions were oversaturated with respect to $Ca(OH)_2$, $CaSO_4 \cdot 2H_2O$, and $K_2Ca(SO_4)_2 \cdot H_2O$, and undersaturated with respect to $CaSO_4$ and $CaSO_4 \cdot 0.5H_2O$. This is in agreement with the X-ray powder diffraction analysis for this cement which indicated the presence of gypsum and the absence of calcium sulfate hemihydrate and anhydrite. Similar saturation states are shown for all solid phases in the normal cement pastes containing lignosulfonates, regardless of their false-setting tendencies. This indicates that the explanation for lignosulfonate-type false set does not appear to be found in the saturation state of the solution.

Using pore solution experiments, a particular case of false-setting cements has been related to the solubility product of $Ca(OH)_2$ (Kawada, 1965 and 1966). The saturation indices for $Ca(OH)_2$ were reported to be on the order of 0.5-0.7 for the normal cement and 0.2-0.4 for the false-setting cement, concluding that false set occurred when the saturation index for $Ca(OH)_2$ was in the range of 0.3-0.37. It must be noted that solubility products were calculated using activity coefficients based on Debye-Hückel theory in a range of ionic strength (>0.1M) where such an approach is questionable. Such trends in the saturation index for $Ca(OH)_2$ were not seen in this study.

The saturation index calculations for the heated cement show significant differences. First, the solutions are oversaturated with respect to $Ca(OH)_2$ and all of the calcium sulfate phases. This is in partial agreement with the X-ray diffraction analysis which indicated the presence of gypsum and hemihydrate and the absence of $CaSO_4$. Although $CaSO_4$ was not detected, the saturation state suggests that it should be present. Second, the saturation index for gypsum is on the order of four times higher than in the normal cement case. Finally, the saturation index for syngenite is also higher than in the normal cement case. Based on this data, the early stiffening of the heated cement paste appears to be a result of the precipitation of sulfate phases, most likely gypsum. This is the expected definition of G-type false set.

Role of Ettringite in Early Stiffening

An attempt was made to determine the role of ettringite in the early stiffening primarily because previous work (Kalousek, 1974) suggested that ettringite precipitation is the cause of early stiffening in pastes containing lignosulfonates. In addition, the calculated saturation indices provide no clear explanation of lignosulfonate-type false set. It was not possible to directly determine saturation indices for ettringite because the aluminum concentrations in solution fell below the detection level of the ICP (after an initial dilution of the pore solution) and PHRQPITZ does not include parameters for interactions involving aluminum species. Therefore, the measured data was used to calculate the aluminum activity required for equilibrium with solid ettringite. This activity is calculated for the $Al(OH)_4^-$ species since most of the aluminum should be ionized to this state. This calculation used a $K_{sp,20}$ for ettringite which was determined using the Pitzer equations as 1.23E-45 (Warren, 1994). The results of the aluminum hydroxide activities calculations are listed in Table 6.

The values of these $Al(OH)_4^-$ activities are extremely low when compared to the concentrations of the trace ions measured, such as Fe^{3+}. Since the activity coefficients for $Al(OH)_4^-$ are likely to be in the neighborhood of those in Table A1, it is likely that all of the pore solutions are oversaturated with respect to solid ettringite. The difference (greater than an order of magnitude)

between the $Al(OH)_4^-$ activities in the normal and heated cement pore solutions are significant but are unlikely to have an effect on this saturation state.

There are some difficulties with the pore solution approach. First, during early hydration, a single pore solution provides only a snapshot of a dynamic process. Some solid phases are dissolving while others simultaneously precipitate. The kinetics of each process strongly influence the chemical composition of the pore solution, with the solution acting merely as a transfer medium in some cases. Therefore, observations based on ion concentrations may be difficult to interpret correctly. Second, there is uncertainty in the degree of oversaturation necessary for solids to precipitate, such that conclusions may not be drawn from saturation indices with certainty. Finally, if solids precipitate in a pore solution containing a water-reducing additive, the result may be an adsorption of the admixture and a corresponding drop in dispersing effectiveness, i.e. stiffening.

CONCLUSIONS

1. G-type false set, most likely caused by precipitation of gypsum, was confirmed by saturation states determined with an ion-interaction model.

2. Differences in saturation states observed with G-type false set and lignosulfonate-type false set cases indicate that the mechanisms are different.

3. The chemistry of the pore solution is significantly different when early stiffening of cement paste arises from lignosulfonate addition rather than the presence of dehydrated forms of gypsum in the cement.

4. Lignosulfonate additions can aggravate the early stiffening tendencies of cement.

5. Lignosulfonate-type false set can not be explained solely by examining the pore solution chemistry.

EFFECT OF SODIUM ALUMINATE ON CLASS G OILWELL CEMENT HYDRATION AT LOW AND AMBIENT TEMPERATURES

Jasbir S. LOTA, Birchall Centre for Inorganic Chemistry and Materials Science, Department of Chemistry, Keele University, Keele, Staffordshire ST5 5BG, U.K.
John BENSTED, Birchall Centre for Inorganic Chemistry and Materials Science, Department of Chemistry, Keele University, Keele, Staffordshire ST5 5BG, U.K.
Peter L. PRATT (the late), Department of Materials, Imperial College of Science Technology and Medicine, Department of Materials, Prince Consort Road, London SW7 2BP, U.K.

ABSTRACT Sodium aluminate accelerates Class G oilwell cement hydration in a different way from other accelerating admixtures by not forming a hydration shell boundary around the cement grains. This causes the hydration to be rapid and more uncontrolled in comparison. More ettringite (AFt phase) is formed at 5°C than at 20°C, unlike for CSH. Significant morphological differences are found at these two temperatures.

Key-words oilwell cement, accelerators, hydration, microstructure, low temperature

INTRODUCTION

Oilwell cements are used in the oil industry both in exploration and in the production of oil and gas. Their primary use is to seal the annular space between the walls of a bore hole and the steel casing that lines the well (Bensted, 1987). Normally in oil- and gas-well cementing, the temperatures are mostly above ambient and pressures above atmospheric, often considerably so, which necessitates the use of retarders in the cement slurries to produce workable thickening or setting times. However, during the casing cementing of well sections at or near the surface under cold conditions, where the temperatures may be as low as around 0-5°C, typically in Arctic regions and in the Northern North Sea, the cement hydration reactions are slowed down and "accelerating" admixtures are used to promote hydration and give a successful cementing job. The work presented here was part of a research programme (Lota, 1994) in which other accelerating admixtures were used in addition to sodium aluminate ($NaAlO_2$). A greater understanding of the effect of low temperature and of accelerating admixtures upon the developing cement microstructure and properties should lead to improved and more efficient cementing of wells.

EXPERIMENTAL METHODS AND TECHNIQUES

The cement was supplied by Blue Circle Industries with a potential phase composition (Bogue %) of C_3S-56.6, C_2S-19.3, C_3A-1.5 and C_4AF-15.9. The $NaAlO_2$ was supplied by Fosroc Technology, U.K. Cement paste specimens were prepared using molar concentrations (0, 0.1, 0.3, 0.5 and 1.0M) of $NaAlO_2$ with distilled water and a water-to-cement ratio of 0.44 as recommended by the American Petroleum Institute (1995).

For examination by scanning electron microscopy (SEM), thermal analysis (differential thermal analysis (DTA) and thermogravimetry (TG)), infrared (IR) spectroscopy and x-ray powder diffractometry (XRD), cylindrical specimens, 11 mm diameter and 35 mm height, were cast after mixing in a Waring blender for three minutes and subsequently cured in water baths maintained at either 5°C and 20°C. Prior to casting at 5°C the cement and mix water were chilled at 8°C for 1 day.

At appropriate curing times the specimens were frozen in a slurry of solid carbon dioxide and ethanol mixture and then freeze-dried under vacuum. A JEOL-35CF scanning electron microscope was used to examine fracture surfaces. A solid state backscattered electron (BSE) detector linked to a Kontron SEM image processing system was used to obtain images from polished surfaces cut from the cement pastes after freeze drying.

The heat evolution from freshly prepared samples was measured using an isothermal conduction calorimeter supplied by Wexham Developments Limited (Forrester, 1970). Compressive strength measurements were obtained by crushing ten 12.7 mm side cubes, in an Instron testing machine, which had been cured at either 5°C or 20°C for a specified time.

RESULTS AND DISCUSSION

The heat evolution curves of the cement with additions of $NaAlO_2$ at 5°C or 20°C are shown in Figures 1 and 2 respectively. The concentration key in Figure 1 also applies to Figure 2.

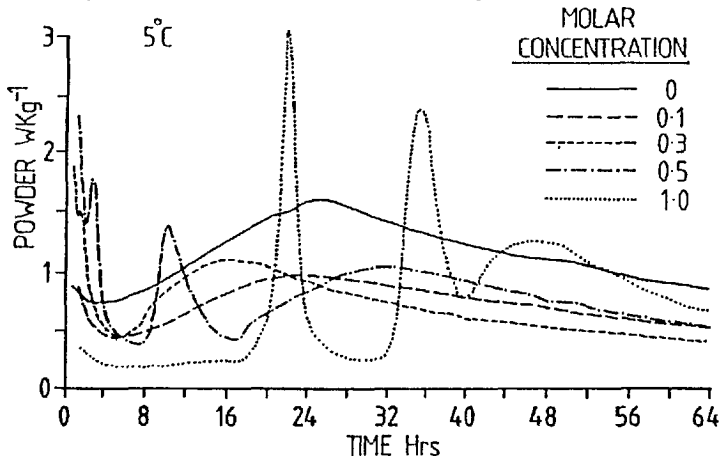

Figure 1. Heat evolution of cement paste hydrated with addition of $NaAlO_2$ at 5°C.

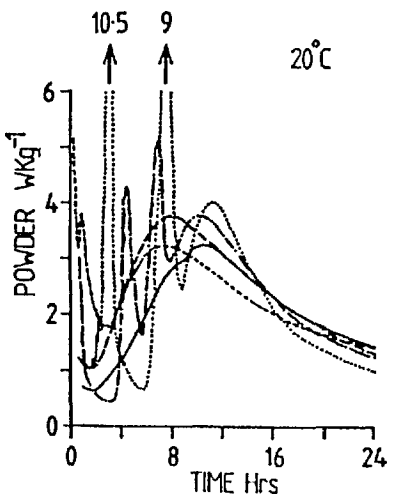

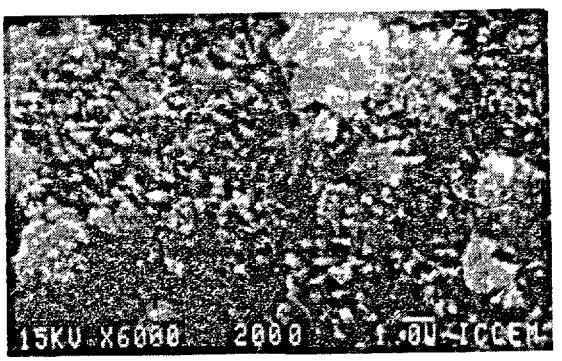

Figure 2. Heat evolution of cement paste hydrated with addition of $NaAlO_2$ at 20°C.

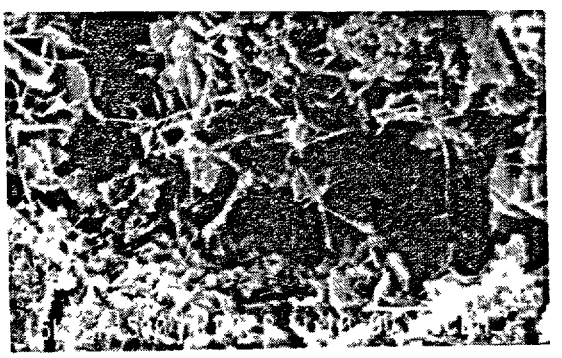
In addition to the peaks produced by the control paste, with increasing addition of $NaAlO_2$ two supplementary peaks appear at both temperatures during the "induction period". These supplementary peaks increase in intensity as the dosage is raised. At 5°C, 0.1M and 0.3M additions advance the main heat peak due to the alite phase hydration, whereas the 0.5M and 1.0M addition retard this peak significantly. At 20°C only the 1.0M addition retards the onset of the alite peak. Clearly, from these curves it can be deduced that the normal or "expected" cement hydration processes are not occurring with $NaAlO_2$ present.



Typical fracture surfaces and BSE images of the control paste and paste with 1.0M addition of $NaAlO_2$ that had been hydrated for 1 day at 20°C are shown in Figure 3. The fracture surfaces and BSE images of the control paste are typical of those hydrating Portland cement where CSH (calcium silicate hydrate) covers the cement grain surfaces and, amongst these, AFt phase

(ettringite) rods and calcium hydroxide (CH) are seen (Taylor, 1990). This is in contrast to the fracture surface of the paste containing $NaAlO_2$, which shows little evidence of CSH on the surfaces of the hydrating cement grains. Furthermore, there are thin and elongated rod-like crystals, probably AFt phase and an abundance of well defined hexagonal platelets of AFm/CAH (calcium aluminate hydrates) phases similar to those reported by Breval (1976). The surrounding CSH has an unrecognisable morphology, which appears to be ill-defined and not distributed throughout the paste thus creating large regions of porosity.

$NaAlO_2$ 1d 20°C, Fracture Surface

Control 1d 20°C, BSE image

$NaAlO_2$ 1d 20°C, BSE image

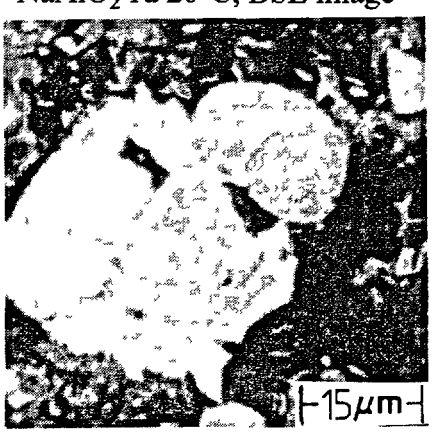

Figure 3. Fracture and BSE images of paste with/without 1.0M $NaAlO_2$ addition at 1d & 20°C.

The BSE images also show marked differences. In the control paste all the hydrating cement grains have hydration product shells, some forming hollow shells, and calcium hydroxide is clearly present. In comparison with the $NaAlO_2$-containing paste, there is no sign of a hydration product layer around any of the cement grains; clusters of CH are not clearly seen and the alite phase shows preferential signs of dissolution. It appears as if the presence of sodium and aluminate ions have interfered with the development of the CSH around the cement grains and consequently the mix water has had more opportunity to reach the anhydrous cement grains. As a result of this erratic process, there is much porosity within the paste.

The first supplementary peak in the heat evolution curves could be due to the formation of CAH in which the source of calcium ions come from the hydrating calcium silicate phases and the aluminate from the admixture. The removal of calcium ions from the developing hydration shell will prevent its forming similar to the manner in which EDTA (ethylenediaminetetraacetic acid) and sugars function (Thomas and Double, 1981 and Birchall and Thomas, 1984). Lack of

availability of calcium ions will have an influence on the Ca/Si ratio of the CSH and consequently upon the properties of the paste in its wet, set and hardened states.

With the absence of a hydration product shell enveloping the hydrating cement grain and easy access of the mix water to the anhydrous cement, there would be rapid dissolution of the aluminate phase. These aluminate ions from the dissolution of the aluminate and the ferrite phases will react further with calcium ions from the dissolution of the calcium silicate phases (especially alite) to form calcium aluminate hydrates. There are relatively smaller quantities of AFt phase in the $NaAlO_2$-containing paste probably because the high alkalinity of the mix water and the early surge of calcium ions in the aqueous phase would decrease the solubility of gypsum simply due to the common-ion-effect. It is probable (Iler, 1955) that when aluminium is co-ordinated with four oxygens in a silicate structure, an Al atom essentially replaces a Si atom giving a negative charge at the site on the aluminosiloxane structure, so that here:

$$3\,(\text{-O})_3\text{Si-OH} \;+\; \text{Al(OH)}_4^- \longrightarrow [(\text{-O})_3\text{Si-O}]_2\text{Al(OH)(O-Si-O-)}^- \;+\; 3\text{H}_2\text{O}$$

In this way, the structure of the CSH is disrupted and hence explains the absence of a hydration product layer completely covering the hydrating cement grain surface. This means that the mix water is not hindered in coming into contact with the anhydrous cement grain surface. Eventually, the remaining cement grains will begin to hydrate in the "normal" manner as the quantity of aluminate ions from the admixture diminish, provided that there is ample free water. This effect is seen by the emergence of the acceleratory peak due to the alite phase hydration. It appears that several processes are taking place simultaneously.

The CH of the paste measured by TG is shown in Table 1 and the measured non-evaporable water (loss-on-ignition, LOI) content of the paste is shown in Table 2.

Table 1. Volume % CH in the paste hydrated at 5°C and 20°C with and without $NaAlO_2$

3 Hours	1.13	0	0.61	0.70	3.26	3.69
6 Hours	1.19	0	1.47	1.18	1.10	0.62
12 Hours	2.42	1.67	0.74	3.93	4.02	3.20
1 Day	5.30	4.74	0.25	5.43	5.69	2.51
28 Days	9.01	12.28	8.34	10.99	10.21	4.24

Table 2. Non-evaporable water expressed as % weight loss referred to the ignited cement at 1000°C the paste hydrated at 5°C and 20°C with and without $NaAlO_2$

	5°C			20°C		
	Molar Addition of $NaAlO_2$					
Hydration Time	**Control**	**0.3M**	**1.0M**	**Control**	**0.3M**	**1.0M**
3 Hours	3.27	4.91	6.08	2.35	10.51	11.27
6 Hours	4.42	4.98	6.71	3.32	5.81	7.56
12 Hours	5.99	7.19	7.54	8.50	9.89	11.06
1 Day	7.47	12.58	6.91	8.99	12.17	10.78
28 Days	17.05	18.07	17.70	16.87	17.14	11.06

The LOI shows a pattern broadly similar to the CH content of the paste in Table 1. At 5°C, with 1.0M addition, the amount of CH that is formed up to 1 day is erratic. Beyond 1 day hydration the 0.3M addition produces the greatest amount of CH. At 20°C, with 0.3M and 1.0M addition there appears to be much more CH at 3 hours than in the control. The 1.0M addition does not significantly influence the formation of CH after 12 hours hydration and the quantity of CH remains low at least up to 28 days.

IR spectra of the control paste hydrated from 15 minutes to 1 year and the paste with 1.0M $NaAlO_2$ addition hydrated from 15 minutes to 28 days are shown in Figure 4.

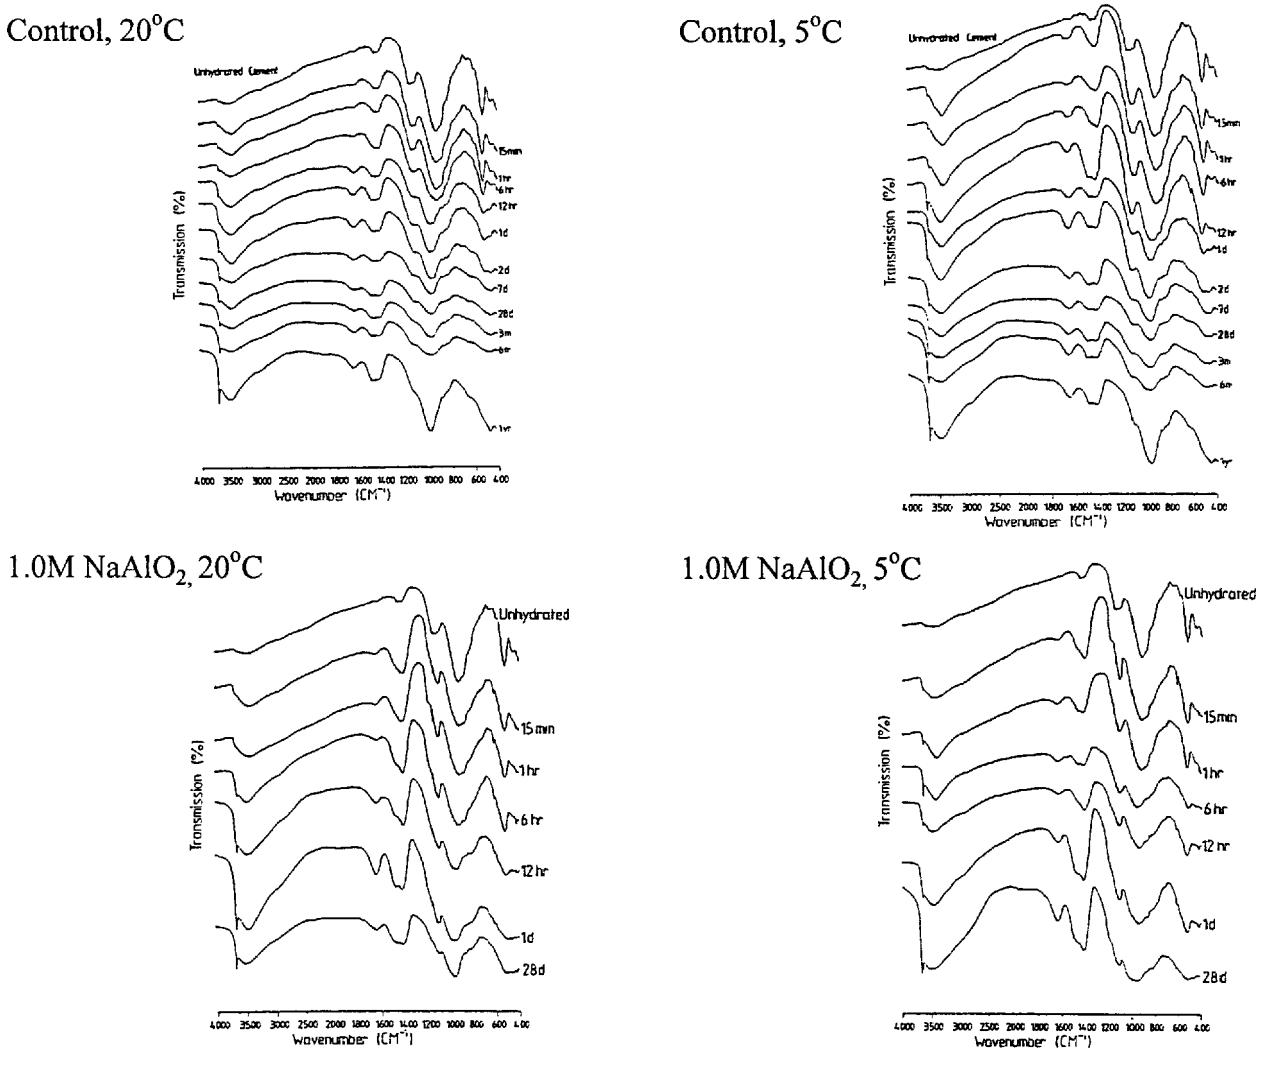

Figure 4. IR spectra of paste with/without 1.0M additions of $NaAlO_2$ hydrated at 5°C and 20°C.

The main differences in the paste hydrated at 5°C compared to that at 20°C are that greater quantities of AFt phase are formed up to 12 hours as indicated by the shape and sharpness of the water wavebands at 1600-1650 cm^{-1} and 3100-3500 cm^{-1}. The AFt phase is present from early ages (15 minutes) and persists up to 1 year. TG implies that greater amounts of water are retained within the paste when it is cured at 5°C than at 20°C. This may be due to the increased amount of AFt phase which incorporates a potential of 32 water molecules in its structure. At ages greater than 3 months AFm (monosulphate) phase is formed, as shown by the broadening of the water wavebands above 3000 cm^{-1}. The IR spectra of the paste hydrated with 1.0M

addition of $NaAlO_2$ at 20°C are similar to those of the control paste hydrated at 20°C and similar comments apply. The only exception is that the sulphate wavebands at 1000-1145 cm^{-1} remain much clearer up to 28 days. This may be as a consequence of the effect of the $NaAlO_2$ upon the hydration of the cement as discussed earlier.

The main difference between the XRD traces of the control paste hydrated at 20°C and at 5°C is that AFt phase at 20°C is detected from 28 days and at 1 year. In contrast, at 5°C AFt phase is present at all ages from 6 hours to 1 year hydration. The presence of AFt phase also is seen to persist in a sulphate resisting Portland cement (Gollop and Taylor, 1994) and may by due to the chemical composition of the ferrite phase being different from ordinary Portland cement (Lota et al, 1995) and hence more reactive. Furthermore, in the XRD traces there are small peaks or shoulders probably due to hydrogarnet phase. This phase is not normally observed in a Portland cement (Taylor, 1990). XRD traces of the paste with additions of $NaAlO_2$ at 5°C and 20°C are shown in Figure 5.

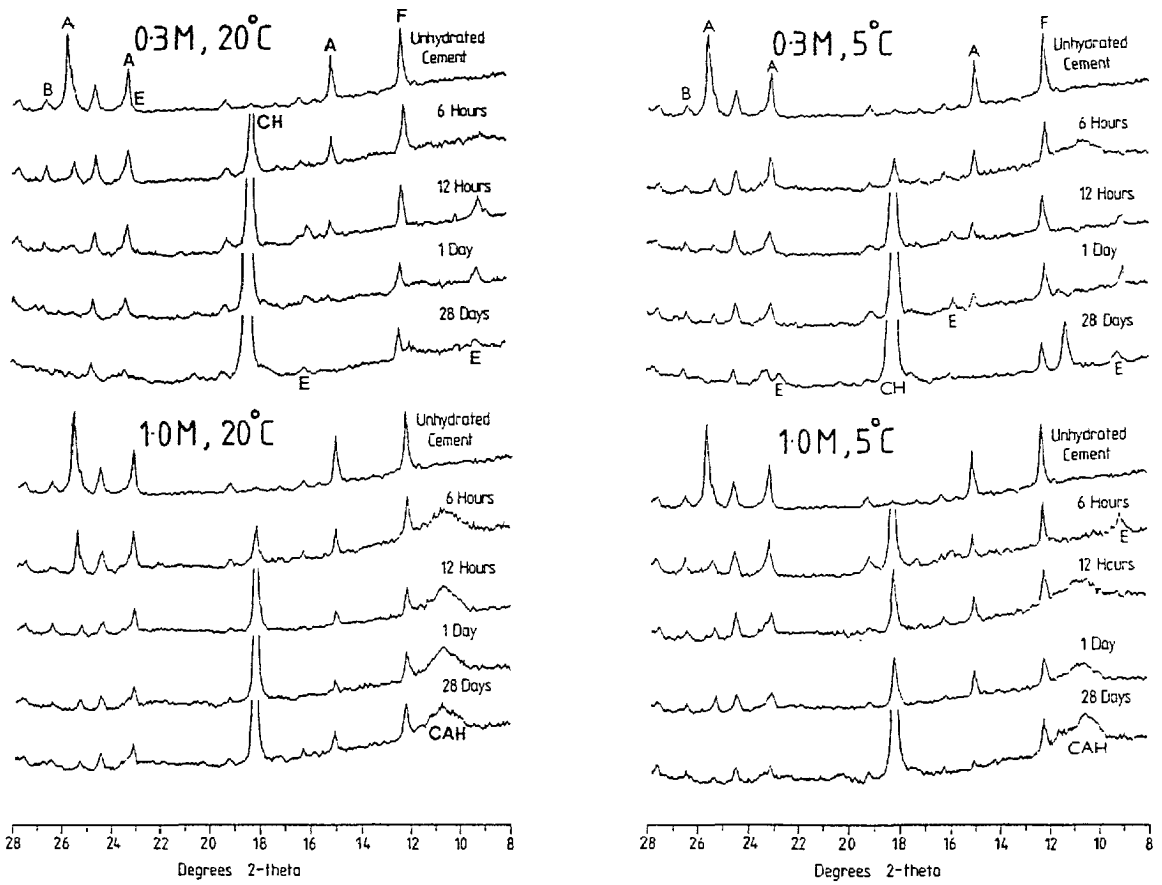

Figure 5. XRD traces of paste hydrated with additions of $NaAlO_2$ hydrated at 5°C and 20°C.

At 20°C, the 0.3M addition reveals AFt phase (9.28 and 15.95°2θ) at 12 hours; at 1 and 28 days its intensity decreases. The CH peak at 18.05°2θ becomes more intense as the paste ages. This indicates the continuing hydration of the calcium silicate phases. In contrast with the 1.0M addition, from 6 hours to 28 days hydration, a broad band is centred at 10.60°2θ suggesting the presence of AFm phase, $C_4(A,F)H_{13}$. The CH peak here is stunted at respective ages to that of the paste hydrated at 5°C and may be due to Ca^{2+} and OH^- ions being consumed to form CAH. At 5°C, with 0.3M addition a similar situation occurs to that at 20°C. However, at 6 hours CAH

is detected and there is the appearance of a sharp peak at 11.21°2θ possibly due to $C_4(A,F)H_{13}$ or other AFm phases. With 1.0M addition, AFt phase is detected at 6 hours and at later ages CAH is present. The intensity of the CH peak varies. This may be due to the consumption of Ca^{2+} and OH^- ions for the formation of CAH. These observations by XRD complement the SEM, TG and IR data. More AFt is formed at 5°C than at 20°C unlike for CSH, apparently because the slowness of CSH formation at 5°C means that there is much less competition for space, water and SO_4^{2-} ions here.

It is not known as to what the exact nature of the CSH in the paste with $NaAlO_2$ is and it may have Fe^{2+}, Al^{3+}, plus SO_4^{2-} from gypsum incorporated in its structure. The mode of action of $NaAlO_2$ in altering the paste hydration is depicted diagrammatically in Figure 6.

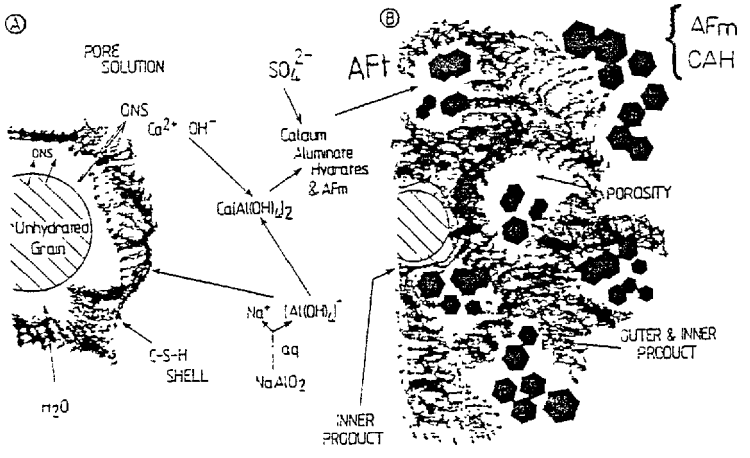

Figure 6. Development of cement microstructure of cement paste in the presence of $NaAlO_2$.

$NaAlO_2$ upon dissolution in water (initial pH 7.6) hydrolyses with release of OH^- ions to give higher pH values, viz. 11.0 for 0.1M and 12.7 for 1.0M solutions after 8 hours. Such release of OH^- ions and dissolution of aluminate in the aqueous phase would facilitate accelerated hydration of all the major cement phases, giving more CSH, CH (less crystalline) and aluminate hydrates including AFt at early ages. Due to rapid competition for space between the rapidly hydrating phases, overall hydration is not well controlled and "normal" hydrate formation suffers some disruption. This is typified by observations that a complete hydration product layer does not surround the hydrating cement grains and also that, since increased ferrite hydration will further raise silicate hydraulicity, the two characteristic supplementary conduction calorimetry peaks can be tentatively assigned as C_3A_{aq} from $NaAlO_2$ and C_3A_{aq} from ferrite phase.

Fracture surfaces and BSE images reveal that a distinct hydration product shell is not clearly discernible (see B in Figure 6). The consequence of this ill-developed shell boundary is that the AFm phase forms randomly and is not confined to the inner regions of the hydration shell. This is in complete contrast to the control paste where AFm phase only occurs within the intact hydration shell boundary and not in the aqueous/pore solution. The hydration shell appears to have become part of the surrounding CSH and no longer acts as a suitable barrier between the aqueous solution and the unhydrated cement core, thus exposing a greater surface area of unhydrated cement phases to the mix water. This results in an inhomogeneous hydration causing the paste to prematurely set by increasing the rate of hydration locally.

CONCLUSIONS

The hydration of the oilwell cement with additions of $NaAlO_2$ at 20°C and 5°C is different from that of the control paste. Rate of heat evolution curves show the emergence of supplementary peaks in addition to the typical peaks expected from the control paste with addition of $NaAlO_2$. This implies that different hydration processes are taking place in the paste with addition of $NaAlO_2$ as compared to the control paste. There is no well defined hydration product boundary around the hydrating cement grains and there are regions in the paste with preferential dissolution of the cement phases. $NaAlO_2$ appears to accelerate early hydration by not allowing formation of a hydration shell which completely surrounds the cement grain. Consequently, the lack of a hydration shell causes the hydration to be rapid and uncontrolled. It appears that $NaAlO_2$ accelerates the early hydration of the cement to such an extent that further hydration is stifled. AFt phase formation is erratic, but appear to be greater at 5°C than at 20°C, presumably because CSH formation is lower and there is thus less competition for space, water and sulphate ions, the majority of which end up in the CSH. Morphologies of the hydration products at 5°C and 20°C reveal significant differences. Such behaviour with $NaAlO_2$ is different for calcium chloride and calcium formate (Lota, 1994) and demonstrates that there is no universal mechanism for cement hydration.

INFLUENCE OF $BaCO_3$ ON THE HYDRATION OF C_3A

George DUMITRU, Universidad Craiova, Targu-Jiu, Romanie

ABSTRACT When gypsum is not present in the reaction, $BaCO_3$ retards the C_3A hydration. The mineral composition of the hydration products presents a specific peculiarity which is the formation of a hemicarboaluminate like $C_8A_2cH_{24}$[1] having 6 %wt of Ba in its composition. When gypsum is present $BaCO_3$ accelerates the hydration reaction of C_3A. Ettringite formation is inhibited.

Key-words: Aluminate phase, hydration, sulphate resistance.

INTRODUCTION

The utilisation of natural minerals as inexpensive substitution materials for cement manufacturing is a valid choice to get energy savings. Some authors have studied the influence of limestone, dolomite or magnesium carbonate additions on the behaviour and properties of cements, mortars and concretes (Ramachandran, 1986), (Negro et al, 1986), (Vernet, 1986), (Massazza et al, 1992). The role played by that limestone addition consists in a slight delay of hydration reactions of aluminate phases and the formation of carboaluminates of various nature. Limestone filler addition to cements is col ndards.
In some countr kia, Austria, England, Russia and those of other continents as Namibia, USA, Canada and China, have important witherite ($BaCO_3$) geological quarries. The aim of the present work is to know $BaCO_3$ influence on C_3A hydration process, in gypsum presence and absence.

EXPERIMENTAL

Tables 1 and 2 show the different mixes prepared, likewise water/solid ratios used for their preparation.

(*) $Ca(OH)_2$ saturated dissolution

The hydration of pastes obtained was stopped at different ages (1h, 3h, 24h, 3 days and 7 days) with acetone-ethanol. Resulting samples were analysed by XRD. On some pastes, SEM/EDX microstructural analyses were carried out.

RESULTS AND DISCUSSION

Reactions in gypsum absence

Table 3 shows the results obtained when analysing the pastes through XRD.

$BaCO_3$ delays C_3A hydration reaction as well as $CaCO_3$ does (Ramachandran, 1986). $BaCO_3$ delays C_3AH_6 formation, stabilising hexagonal hydrated calcium aluminates (C_2AH_8) and favouring the formation of C_4AcH_{11} and $C_8A_2cH_{24}$ type carboaluminates. $Ca(OH)_2$ presence in mix water inhibits C_3AH_6 formation until the ages studied.

C_2AH_8 is a metastable specie (Damidot and Glasser, 1994) in CaO-Al_2O_3-CO_3-H_2O system. The excess of $BaCO_3$, supposing that it acts similar to $CaCO_3$, would react with C_2AH_8 to form hydrated calcium-barium carboaluminates.

The hemicarboaluminate $C_8A_2cH_{24}$ is an stable specie until CO_2/Al_2O_3 ratios close to 0.8 (Fisher and Kuzel, 1982). In Fig.1, the microstructural aspect of this carboaluminate is shown. It presents a morphology of hexagonal plates. EDX analysis on these plates shows Ba presence (in proportion close to 6% wt.) in the hydrate composition.

Reactions in gypsum presence

In Table 4, results obtained analysing the pastes by XRD are shown. From these results, it is deduced that $BaCO_3$ presence accelerates C_3A hydration reaction.

In samples with $BaCO_3$ (F and F_1) ettringite formation is inhibited and high amounts of $BaSO_4$ are formed. In these samples, the presence of hydrated calcium carboaluminates is also detected.

In $CaO-Al_2O_3-CaSO_4-CaCO_3-H_2O$ system, ettringite is the stable phase when $[SO_4]$ concentrations are between 1.52 x 10^{-2} mol/Kg and 7.60 x 10^{-1} and for carbonate concentrations inferior to 8.39 x 10^{-6} mol/kg (Damidot and Glasser, 1995). In this concentration range, ettringite becomes compatible with all phases present in the system. From data obtained in this work, $BaCO_3$ amount added is enough to react with all the gypsum and form $BaSO_4$, highly insoluble salt. This makes very low the SO_4^{2-} level in solution and ettringite cannot be formed.

$Ca(OH)_2$ presence in mix water accelerates ettringite formation rate (E and E_1 samples comparison). However, the presence of saturated solution of calcium hydroxide does not seem to induce alterations in mineralogical composition of pastes (from samples with $BaCO_3$).

CONCLUSIONS

1.- $BaCO_3$ delays C_3A hydration reaction, as well as $CaCO_3$ does.

2.- When C_3A hydration occurs in $BaCO_3$ presence, hydrated calcium carboaluminates are formed. Hemicarboaluminate $C_8A_2cH_{24}$ contains Ba in proportion close to 6 %wt.

3.- $BaCO_3$ accelerates C_3A hydration reaction in gypsum presence. Ettringite formation is inhibited and high amounts of $BaSO_4$ precipitates. The main hydration product of these pastes is a C_4AcH_{11} type carboaluminate.

4.- From results obtained, $BaCO_3$ addition is proposed to those cements and concretes exposed to sulphate attack. $BaCO_3$ would act as a reserve for the fixing of sulphates coming from the external medium.

ABSTRACT The mechanism of delayed expansion for improving self—stressing level of the confined expansion concrete are studied, exemplifying the chemically prestressed concrete. The results show that the self—stressing level can be more than 21 MPa. The bearing capacity of chemically prestressed concrete filled steel tube is compared with that of ordinary concrete filled steel tube at different curing ages. Finally, QXDA, DSC and SEM data are presented to interpret the mechanism.

Key—words: delayed expansion; chemically prestressed concrete filled steel tube

INTRODUCTION

It is known that concrete has a very small elastic modulus, typical brittleness, low tensile strength. Researchers have tried to achieve the most favourable triaxial stress state by exerting confining binding factors on concrete in order to eliminate the inherent defects of concrete. The typical examples for application are the traditional concrete filled steel tube and high strength concrete filled steel tube.

Generally, the prestress can be exerted by mechanical and chemical methods. The former has good effects, but the process is too complicated and expensive. The latter is to make concrete obtain self—stress by adding expansive agent. According to former Soviet's method of stress correction, only when the self—stress reaches 20 MPa can it have the similar effect to mechanical prestress. Although the total expansive energy stored in expansion components is high and the process of self—stress is simpler than that of mechanical prestress, the self—stress is below 10 MPa for a long time, so the application of self—stressing concrete has been limited to low self—stressing members (Wu, 1990). The loss of lots of expansive energy is the essential cause to affect the improvement of self—stressing level in the traditional expansion mode. In view of this, a new mechanism of delayed expansion is proposed in this paper, exemplified by chemically prestressed concrete filled steel tube.

DELAYED EXPANSION MECHANISM AND TEST

Traditional expansion mechanism and mode

With the confined expansion concrete type ettringite, the major expansive source is ettringite phase (AFt) whose formation requires 45. 94% bound water. The mode of the traditional expansion is illustrated in Fig 1. It is obvious that a great amount of expansion occurs in the early stage and the confined expansion ratio reaches the maximum at 14 days, some at 7 days (Wu, 1990). When cured in air concrete will contract and become steady. When AFt phase grows, the strength structure of concrete undergoes a changing process of formation, plastic state, half—plastic state and elastic state. It is found that, under the curing condition of both enough water supply and moist air or water curing, a

* Project Supported by National Nature Science Foundation of China

large amount of AFt has formed when the strength structure is still in the plastic and half—plastic state,and expansion developes faster than strength. So along the expansion energy is absorbed by its working on the condensable strength structure,lots of expansion energy is consumed invalidly. In another aspect,the excessive water supply will increase the porosity of concrete and the size of pores,which influence the development of the elastic strength structure,lengthen the condensable process of the plastic and half—plastic stage,and increase the loss of expansion energy. In the past,the expansion mode above was widely used in the confined expansion concrete,where a large quantity of expansion produced before the formation of the elastic strength structure. Therefore,the self—stress did not exceed 10MPa on an average. This means that it is important to reform the traditional expansion mode for improving the self—stressing level.

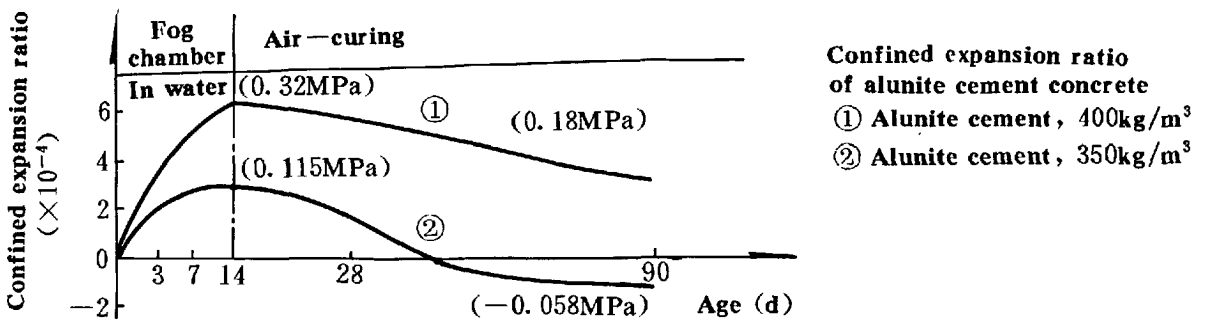

Fig 1 confined expansion ratio of alunite cement concrete

Delayed expansion mechanism and mode

The ettringite phase in the hardened cement paste will result in expansions which transform into self—stress,either because of the increase in volume of solid phase during the course of crystal growth,or because of the ion swelling by absorbing water only after the silicate phases have hydrated and the cement paste has a certain degree of strength. That is,the amount and rate of effective expansion depend on the amount and rate of the effective AFt formed after the formation of elastic strength structure. Therefore,the way to improve the self—stressing level of the confined expansion concrete is,in one hand,to improve its strength,especially the early strength,in the other hand,to restrict its expansive amount in the early age properly,so that the development of expansion and the improvement of strength as restricting factor can coordinate each other.

According to the analysis above,a new delayed expansion mechanism and mode are proposed in this paper. That is to allow maximal expansion of the confined expansion concrete to take place after the formation of the elastic strength structure. The quantity of AFt formation is restricted until the elastic strength structure of concrete founds,in order to reduce the invalid expansion energy as far as possible and to store the effective expansion energy as much as possible. The corresponding expansion mode is that the confined expansion ratio is restricted in the early age,rises up greatly in the middle age,and then goes down slightly and becomes steady in steps.

In order to reduce the expansion energy used for compacting concrete itself as far as possible,and to make more effective expansion energy form a strong active restricting force needed by high self—stress,the confined expansion concrete should possess the least porosity and the best strength in paste.

Physical and mechanical test of delayed expansion mechanism

The restricting condition of the specimen was offered by a steel tube of Φ88. 5mm×4mm ×164mm. The concrete core was mixed with 525 OPC, sand, gravel and water of 1 : 0. 46 : 1. 57 : 0. 4 proportion. Alunite expanding agent of low expansion and special water reducer were added. A combined temperature compensating strain gauge was embedded horizontally on the middle section of the concrete core, to test the variation of the confined expansion ratio of the concrete core in radial direction at different ages continually. The compressive strength of concrete at different ages was tested by six groups of 10mm ×10mm×10mm cubic specimen. The correspondent elastic modulus was obtained from the relation between the strength and the elastic modulus according to the concrete structure designing standard of China (GBJ10—89). The results are shown in Fig 2.

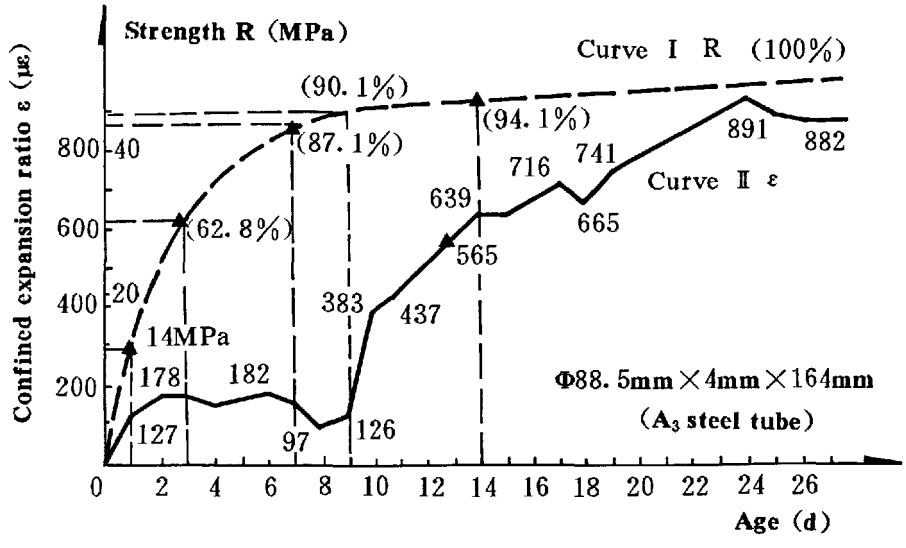

Fig 2 Mode of delayed expansion

It is shown that the strength of concrete reaches 14 MPa at age of 1 day when the self—stress has grown (curve I). In the early age (1～9 days) a low and flat area appears, which shows that the early expansion is restricted (curve Ⅱ). The strength of concrete at 9 days has increased quickly to 90. 1% of R28, and then the curve of the confined expansion ratio goes up rapidly, which shows that the confined expansive amount increases speedily and that there is a good coordination among the restricting factors, expansion and strength development. At age of 17 days, the confined expansion ratio is 716 με and the corresponding self—stressing level exceeds 21 MPa due to the delayed expansion (Gu, 1995).

Phase determination by QXDA, DSC and SEM

Two groups of cement pastes with same w/c ratio were made. For group A the condition of necessary mixing water was simulated, for group B the curing condition of keeping enough water supply. At the given ages, the content of AFt was determined by the quantitative X—ray diffraction analysis (QXDA). Whether the specimen contains the AFm was determined by the differential scanning calorimetry (DSC). The existing form of AFt and AFm on the pore wall of the sample section was observed by the scanning electron microscopy (SEM). The results are shown in Table 1 and Fig 3.

In the initial phase of hydration, the formation of AFt in group A is restricted, and then accelerated with the age. This is consistent with the development curve of concrete

strength with that of the confined expansion ratio. In addition, the formation of AFt is restricted before the formation of the elastic strength structure of concrete, while a certain amount of AFt crystals still grows after the foundation of the elastic strength structure, which indicates that the reduction of the invalid expansion energy in the early stage results in the later increase of the effective expansion energy stored in concrete, becoming the source of improving the self—stressing level.

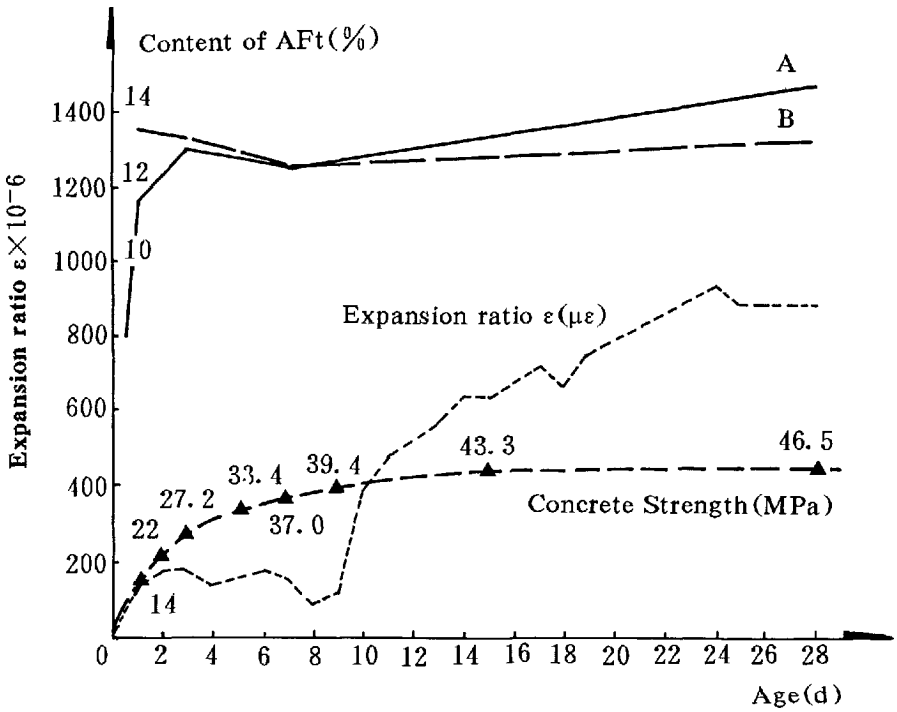

Fig 3 Curve of expansion, AFt formation and strength via ages

With group B, the amount of AFt reaches the maximum at 1 day, and then goes down slowly. It reflects that all AFt was formed during the stage when the strength structure is in the plastic and half—plastic state. Therefore, the invalid expansion energy at the early age is so big that the amount of the AFt can not increase after the elastic strength structure of concrete has formed. This essentially affects the magnitude of the later expansion energy and reduces the self—stressing level. If the amount of the mixing water is raised according to the traditional expansion mode, the formation of AFt will increase and the invalid expansion energy will increase in the early stage too, respondingly. Hence, it is difficult to improve the self—stressing level of the confined concrete made according to the traditional expansion mode.

It can be seen from the results of the SEM observation that only AFt crystals exist on the pore wall of the section of group A, while both AFt and AFm on that of group B.

The observation and analysis above prove that the mechanism of the delayed expansion is feasible, and that the corresponding mode is the only way to achieve the high self—stressing level of the confined expansion concrete.

Law of restricting concrete developing the high self—stress by delayed expansion

The self—stressing level of the confined expansion concrete is a measure of effective expansion energy stored in the expansion concrete under the confined conditions. Take the

example of the expansion concrete confined by steel tube into account. First, the expansion energy acts on the elastic strength structure of concrete, extruding the strength structure. The work can be transformed into the elastic recovering deformation energy of the elastic strength structure and be stored in concrete, when strength structure reaches a certain degree of strength (about 9.8 MPa), that is, when the structure changes from the plastic, half—plastic state to the elastic state. This will make concrete bear compression and become compact, compensating the microstructure defects of concrete itself. At the same time, the expansion energy acts on the steel tube and is transformed into its elastic recovering deformation energy, storing in the steel tube and acting on the concrete. Thus the concrete will be pressed further. Abiding by the delayed expansion mode, the expansion, the strength development of concrete and restricting factors can be coordinated, so that the process of storing energy above is accomplished effectively and the high self—stressing level is achieved.

The test proves that, when the inner expansive force acts on the steel tube, the stress relation on the inner and outer wall of the steel tube accords with the equation as follows:

Table 1 Phase determination by QXDA, DSC and SEM

Sample number		Content of AFt determined by QXDA, %	Existence of AFm tested by DSC	Existence of AFt and AFm observed by SEM *
Group A	C6h	8.1	none	AFt
	C1d	11.6	little	AFt
	C3d	13.0	little	AFt
	C7d	12.5	little	AFt
	C28d	14.6	little	AFt
Group B	W1d	13.5	none	AFt
	W3d	13.3	little	AFt+AFm
	W7d	12.6	little	AFt+AFm
	W28d	13.2	little	AFt+AFm

* Observed results on the pore wall of the sample section

$$P=\frac{2t\sigma_0}{D-t}=\frac{2TE\varepsilon_\theta}{D-t} \qquad [1]$$

Where P is radial expansive pressure (MPa); t is wall thickness of steel tube (mm); σ_0 is circular stress of steel tube (MPa); ε_θ is its circular strain; D is outside diametre of steel tube (mm); E is elastic modulus.

Therefore, given the circular strain of outer wall of steel tube measured by a resistance strain gauge, self—stress for extruding steel tube can be calculated from Eq[1]. In addition, using the embedded temperature compensating strain gauge, the confined expansion rate is measured directly continuously. Then total self—stress of concrete core is obtained by multiplying the measured strain and the elastic modulus according to its strength. The curve of confined expansion ratio via ages is shown in Fig 4. Considering the yielding of steel tube, we decrease the quantity of alunite expansive agent. Here we call the composite material as chemically prestressed concrete filled steel tube because its self—stressing level has the similar effect to mechanical prestress.

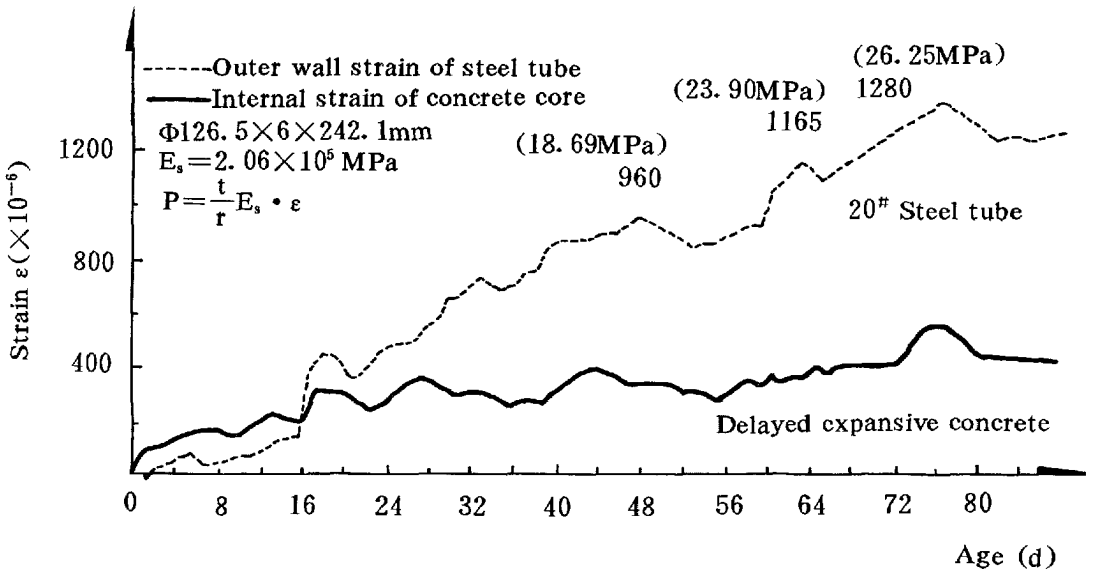

Fig 4 Curve of strain of chemically prestressed concrete filled steel tube via ages

Table 2 Self—stress value of concrete core at different ages

Classification	Age(d)			
	3	9	14	28
Internal strain of concrete ($x10^{-6}$)	97	136	190	344
Outer wall strain of steel tube ($x10^{-6}$)	26	66	133	582
Total self—stress of concrete core produced from effective expansion energy (MPa)	2.84	4.32	6.56	12.5
Self—stress for expanded steel tube (MPa) (fraction to total self—stress, %)	0.53 (18.7)	1.35 (31.2)	2.73 (41.6)	11.9 (95.2)
Self—stress for compacting concrete (MPa) (fraction to total self—stress, %)	2.31 (81.3)	2.97 (68.8)	3.83 (58.4)	0.6 (4.8)

It can be seen from Fig 4 that the curve of internal confined expansion ratio of concrete is above that of outer wall strain of steel tube before the two curves cross. It demonstrates that lower strength and elastic modulus make concrete core consolidate further. On the other side, the majority of expansion is restrained, the effective expansion energy produced is small and acts mainly on compacting concrete core itself. Furthermore, the elastic strength structure is developed gradually, and the expansion energy transmitted to steel tube is very small. As a result, it turns out that the internal strain of concrete is larger than outer wall strain of steel tube. After the two curves cross, a large amount of expansion occurs with the increasing of the consolidibility of concrete core and improving of the concrete strength structure. Therefore, more effective expansion energy is transformed into elastic deformation energy through the strength structure and then acts on steel tube while that used for self—compacting decreases. Meanwhile, the outer wall strain of steel tube increases rapidly. The increase of the internal strain of concrete is

slower than the outer wall strain of steel tube,but the self—stress of concrete grows still faster because its elastic modulus increases accordingly.

Table 2 shows the results calculated from the experimental data which fits the tendency of the strain curve,the total self—stress of concrete at 28 days is near the confining force of steel tube. In addition,the maximal self—stressing value more than 21 MPa occurs not at 28 days.

Table 3 Mechanical properties of chemically prestressed concrete filled steel tube

Specimen number	Ultimate elastic load (kN)	Ultimate yield load (kN)	Increase of ultimate elastic load (%)	Increase of ultimate elastic yield (%)
A_{21}	900	1100	73	29
A_{22}	900	1164	73	37
A_{23}	914	1200	76	41
A_{24}	890	1100	71	29
A_{25}	870	1010	67	19
A_{20}	520	850	0	0

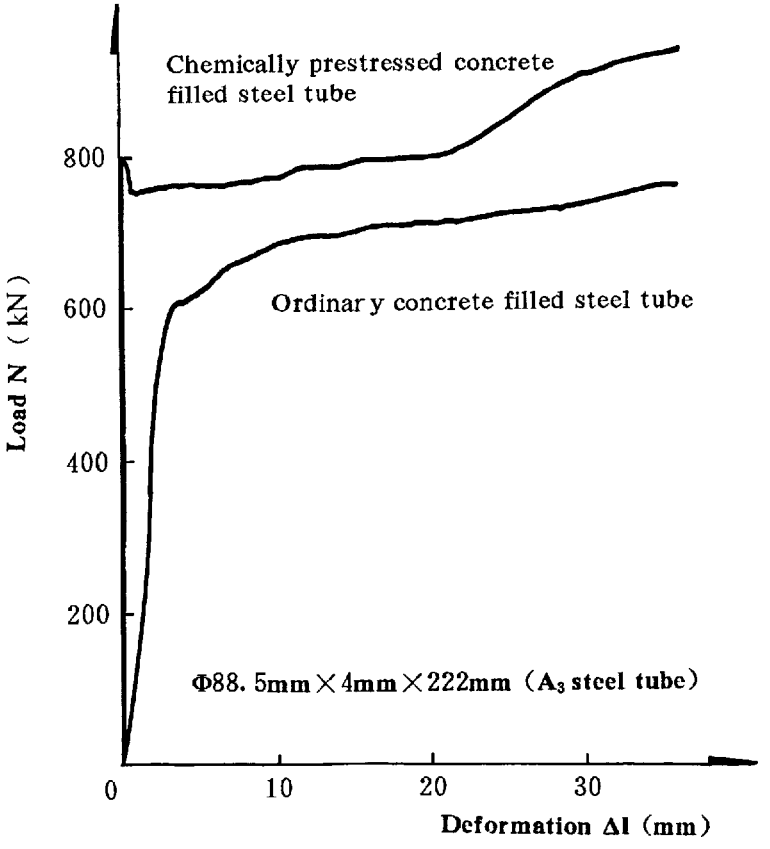

Fig 5 Curve of load—deformation of chemically prestressed concrete and ordinary concrete filled steel tube

Axial compressive test of chemically prestressed concrete filled steel tube

Table 3 gives the test results on the mechanical properties of delayed expansion on chemically prestressed concrete filled steel tube with 5 different dosages of expansive agent. Here a steel tube of Φ126. 5mm×6mm×241. 8mm (20#), was used as limiting condition. Of the specimen numbers, A_{20} is for the ordinary concrete filled steel tube. Compared to that, the property of chemically prestressed concrete filled steel tube at 28 days is a lot better.

Fig 5 shows the curve of load—deformation for chemically prestressed concrete filled steel tube and corresponding ordinary concrete filled steel tube at 60 days prepared by a same kind of cement. Strengthened under high self—stressing level, the chemically prestressed concrete filled steel tube has turned into strengthened elastic—plastic body with typical behavior of triaxial stress concrete of large bearing capacity and small deformation.

CONCLUSION

The mechanism of delayed expansion presented in this paper believes that the high self—stressing level can be obtained only when a large amount of expansion occurs after the establishment of elastic strength structure of concrete. It is proved that the mechanism can be not only put into practice, but also applied to all kinks of confined expansive concretes and make them as high self—stressing materials. Meanwhile, the matching between limiting conditions and maximal expansion should be taken into account in application.

The self—stress value of concrete core of chemically prestressed concrete filled steel tube, which is prepared by applying the mechanism of delayed expansion, is more than 21 MPa and its self—stressing level effects similarly as mechanical prestress. Compared to the corresponding ordinary concrete filled steel tube, the chemically prestressed concretes with 5 different dosages of the expansive agent used here at 28 days increase 72% of ultimate elastic load capacity and 31% of ultimate yield load capacity on an average.

The mode of delayed expansion can restrain the growth of AFt crystals before the establishment of elastic strength structure of concrete. According to this mode, the time and rate of AFt formation and the development of concrete strength can match each other, which allow to produce a large amount of effective expansion energy and then lead to high self—stressing level.

EXPANSIVE BEHAVIOR OF SLAG CEMENT WITH EXPANSIVE ADDITIVES

Atsumu ISHIDA, Minoru MORIOKA, Toshio MIHARA and Hirotoshi HAGIWARA
Cement & Special Cement Additive Laboratory, Denki Kagaku Kogyo Co., Ltd., Japan

ABSTRACT Expansive behavior of slag cement with expansive additives was investigated. Length change of slag cement with a new expansive additive was about three times larger than that with conventional type-K or type-O additive. Heat evolution curve of slag cement altered with the additives, which seemed to be reflecting the change of reaction behavior between slag and additives. Formation and morphology of calcium hydroxide and conversion rate of ettringite to monosulphate differed depending on the kinds of additives, suggesting that different expansive behavior took place.

Key-words: Additives, Expansion, Blastfurnace slag,

INTRODUCTION

Recently, the preservation of natural environment is strongly advocated, and is an important matter in the staple industries. In cement industry, a blended cement is one of the answer to the above statement. Blended cements are concerned with utilization of industrial wastes and reduction of CO_2 gas generated by the burning process of cement clinker, eventually decreasing overall energy consumption. Blastfurnace slag (BFS hereafter), pulverized fuel ash and microsilica, which are classified into pozzolanic materials, are well-known inorganic materials used in blended cements. In Japan, the amount of blended cements has increased up to 20% of total cement production in recent years.

With increasing use of blended cements, various additives, such as accelerators, water reducers and superplasticizers are applied to blended cements. An expansive additive is one of the widely known additive and is used to compensate a shrinkage of concrete or to produce self-stressing concrete. Two types of expansive additives are now placed on the market in Japan. One is type-K (ACI 223R-90, 1992) which contains hauyne as an essential ingredient, and the other is type-O (Neville, 1994) with free lime as an expansive ingredient. As ettringite and calcium hydroxide (CH hereafter) are considered to be the major expansive ingredients, their formation and morphology are important factors in producing expansion. At present, stress generated by the crystal growth or by swelling of colloidal form of the expansive ingredients are the most widely accepted mechanism for expansive behavior.

In applying expansive additives to blended cements, however, it has been pointed out that conventional expansive additives reduce their expansive activity when combined with blended cements (Tsuji et al, 1979, Mehta, 1995 and Min et al, 1995). Under such circumstances, present authors have developed a new expansive additive consisting of hauyne, anhydrite and high content of free lime, with improved expansive activity when applied to blended cements (Ishida et al, 1996).

In this paper, expansive properties of the new additive are reported compared with those of conventional type-K and type-O additives. As main expansive ingredients are CH and ettringite, studies of hydrates are focused on these two components.

EXPERIMENTAL

Materials

Commercially available BFS and ordinary Portland cement (OPC hereafter) were mixed by four

to six by weight to prepare slag cement (BFSC for blastfurnace slag cement, hereafter) used in the experiments. Three kinds of expansive additives, (A) new product, (B) type-K and (C) type-O were employed in the experiments. Their chemical composition and physical properties are shown in Table 1, along with OPC and BFS. In preparing mortar, ISO standard sand was used as an aggregate.

Table 1 Chemical composition and physical properties of expansive additives (A, B, C), ordinary Portland cement (OPC) and blastfurnace slag (BFS).

	ig-loss	SiO_2	Al_2O_3	CaO	SO_3	f-CaO	blaine (cm^2/g)	density (g/cm^3)

A; new product, B; type-K, C; type-O

Preparation of specimens

Specimens were made of mortar and paste, with water/cement ratio of 50%, and as for mortar, cement/sand ratio was 1/2. BFSC or OPC was replaced by expansive additives. Replacement ratio was set to 8 or 10 wt% in mortar, and 10 wt% in paste. Specimens of mortar were cast in 4x4x16 cm and cured under condition of 20°C and 80% RH for the first 24 hours, and then in water of 20°C for the next six days, and finally at 20°C and 60% RH. Each set of mortar consisted of three specimens. Pastes were stored and cured in closed vessels at 20°C.

Evaluation

Compressive strength and expansive behavior of mortar were measured for different period of curing time from one day to 28 days, according to JIS R 5201 and JIS A6202, respectively.
The following procedure was employed to study paste specimens hydrated for different period of curing time. The paste specimens were crushed and lightly ground in a porcelain mortar with excess acetone in order to stop the process of hydration. The resulting suspensions were filtered and dried at 40°C for one day. In succession, X-ray diffraction (XRD) method and differential scanning calorimetry (DSC) were conducted to evaluate the hydrates, such as CH, ettringite and monosulphate. Microstructure of paste specimens was observed by scanning electron microscopy (SEM), and pore size distribution was measured by mercury intrusion porosimeter. Additionally, heat evolution curve of pastes was measured by conduction calorimeter.

RESULTS AND DISCUSSION

Expansive behavior

Figure 1 shows the length change of mortar with different expansive additives as a function of age. 10 wt% of BFSC or OPC was replaced by each expansive additives. As shown in the figure, length change of mortar with additive-A is about three times larger than that with additive-B or -C in both cements. Comparing the two cements, length change of mortar with BFSC is lower than that with OPC, except for mortar with additive-C which shows nearly the same length change for both cements. In mortar with additive-A, large difference of length change was observed from age of one day to two days in the two cements.

The reason for low expansive activity due to replacement of OPC by BFS may be considered as follows. As the major expansive ingredients are considered to be ettringite and CH, two reasons are considered. One is the acceleration of conversion of ettringite to monosulphate due to the existence of BFS. The other is the reduction of CH formation. Concerning CH formation, BFS will decrease the concentration of OH^- ions in the pore solutions, as is generally accepted, thus lowering the supersaturation of pore solution of cement paste with respect to CH and partly inhibiting in-situ formation of CH crystals (Min et al, 1995). The experimental results are shown and discussed later concerning the two expansive ingredients.

Some papers have discussed " autogenous shrinkage", that BFSC paste shows larger autogenous shrinkage than OPC paste (Tazawa and Miyazawa, 1992 and Tazawa, 1994). In this study, the influence of autogenous shrinkage on expansive behavior is not unambiguous, and further investigation should be undertaken to clarify the relationship between the mechanisms of autogenous shrinkage and expansive behavior.

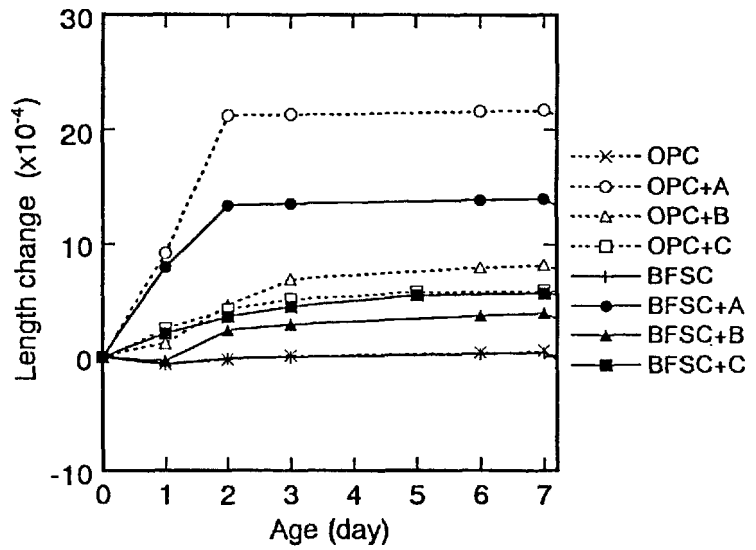

Figure 1 Length change of mortar as a function of age. additive replacement; 10wt%

Mechanical strength

Compressive strength of mortar as a function of age is shown in Fig 2. In both cements, significant loss of compressive strength was not observed by adding expansive additives with replacement ratio of 8 wt%. The exception is for mortar consisting of OPC and additive-A within age of 7 days. While mortars with BFSC resulted in lower compressive strength than that with OPC within age of 7 days, all mortars regardless of cement or additive, resulted in compressive strength of the same level after 28 days.

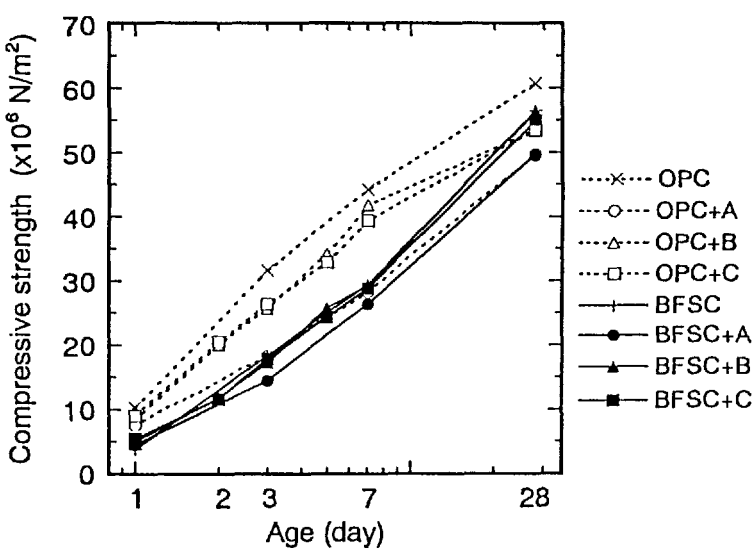

Figure 2 Compressive strength of mortar as a function of age. additive replacement; 8wt%

Heat evolution curve

Figures 3 and 4 show the heat evolution curve of pastes with OPC and BFSC containing 10 wt% of expansive additives. Comparing the exothermic peaks around 10 hours, the peaks of BFSC pastes were about 20% lower than that with OPC pastes.

While OPC pastes with and without expansive additives resulted in nearly the same heat evolution curves, additional exothermic peak was observed at around 30 hours in BFSC pastes with expansive additives. The additional exothermic peak was observed at around 25 hours in case of BFSC paste with additive-A. On the other hand, the additional exothermic peaks in BFSC pastes with additive-B and -C were observed at around 30 to 35 hours with lower heat evolution compared with that with additive-A. The additional exothermic peak suggests the reaction between the expansive additives and the BFS. The reaction between the expansive additives and BFS was confirmed by method using salicylic acid and acetone-methanol solution reported by Kondo et al (1969).

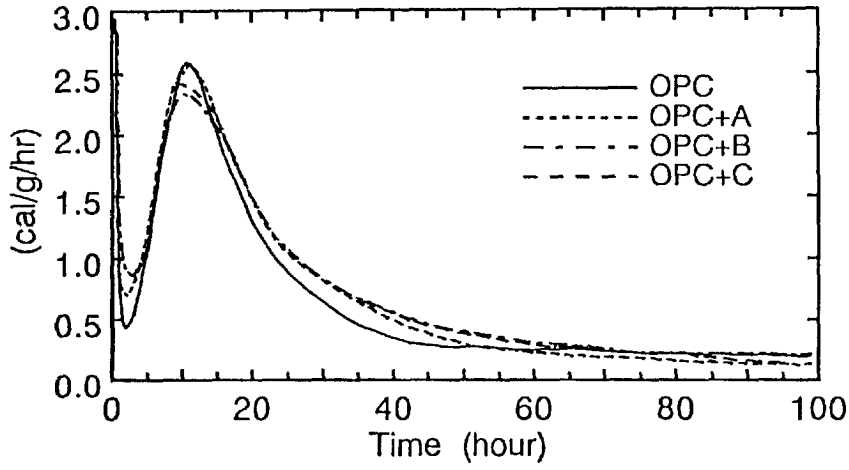

Figure 3 Heat evolution curve of pastes with OPC. additive replacement; 10wt%, W/C=60%, Temp.=20$_o$C

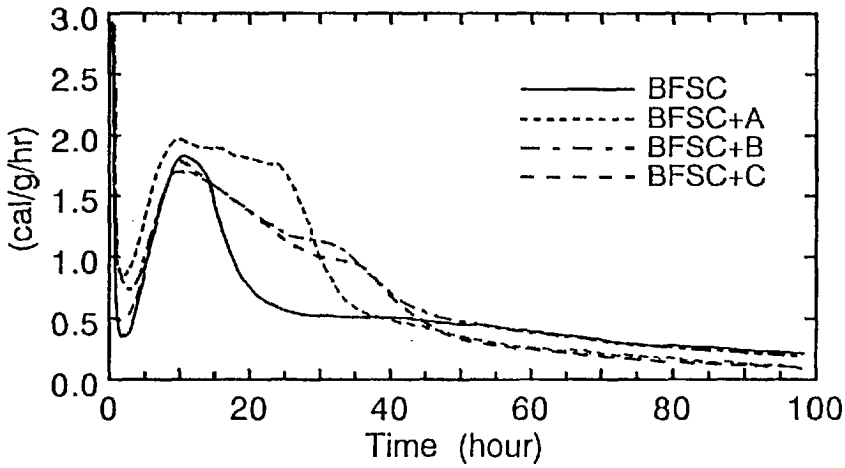

Figure 4 Heat evolution curve of pastes with BFSC. additive replacement; 10wt%, W/C=60, Temp.=20$_o$C

Composition and quantity of hydrates

Calcium hydroxide

Figure 5 shows the change of CH by DSC measurement as a function of age. DSC measurement has a feature of evaluating both crystalline and amorphous forms together, while XRD evaluate only the crystalline form. Comparing the cements, BFSC pastes have lower CH content than that of OPC pastes.

Comparing the expansive additives, pastes with additive of high free lime content (additive-A and -C) have higher CH content than that without additive, and pastes with additive of low free lime content (additive-B) have lower CH content. Although a total amount of CH during hydration from 1 day to 7 days is nearly the same between additive-A and -C, the expansive behavior is quite different as seen in Fig 1. As a conclusion, CH content by DSC measurement

does not show one-to-one correspondence with expansive behavior concerning expansive additives.

In XRD measurement, crystal morphology of crystalline CH was investigated. Figure 6 shows the change of (110)/(001) ratio of CH as a function of age. The ratio of paste with additive-A increases during the age from 1 day to 3 days. As the change of the ratio reflects the change of morphology in crystalline CH, large length change of mortar with additive-A may be related to the change of morphology of the hydrate.

Crystal shape of CH is reported to be influenced by co-existing additives, curing temperature and water/solid ratio (Berger and McGregor, 1973). In case when additive-A, containing 50% free lime, is employed in the system, relatively high degree of supersaturation is presumably maintained in pore solutions with respect to CH. Thus a width/thickness ratio of crystalline CH should be larger compared to the case when additive-B or -C is employed. It seems probable that the difference of crystal shape reflect the degree of supersaturation of pore solutions, and the development of expansive force is correlated to the degree of supersaturation of pore solutions.

At present, the mechanism most widely accepted for expansive behavior is based on the crystal growth pressure or swelling pressure of colloidal form of expansive ingredient (Min et al, 1995). Regarding additive-A or -C, it is conceivable that free lime first forms colloidal CH in supersaturated pore solutions of cement paste and subsequently these colloidal crystallites recrystallize or grow to macro-crystals. The size of very fine crystals of CH is reported as between 10 and 20 nm (Chatterji, 1995). Further study is needed to clarify the relation between the morphology of CH and the expansive behavior.

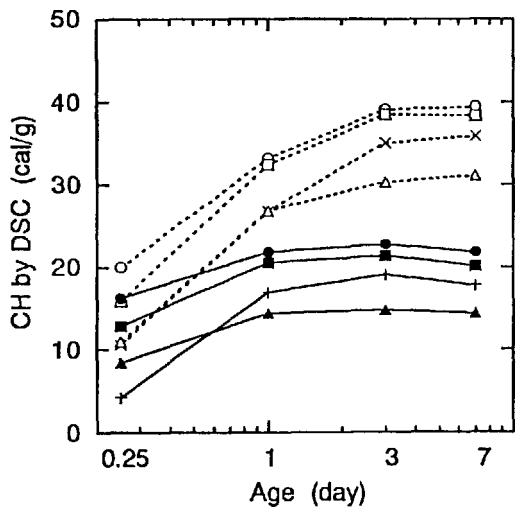

Figure 5 Change of CH in pastes by DSC measurement as a function of age. additive replacement; 10wt%

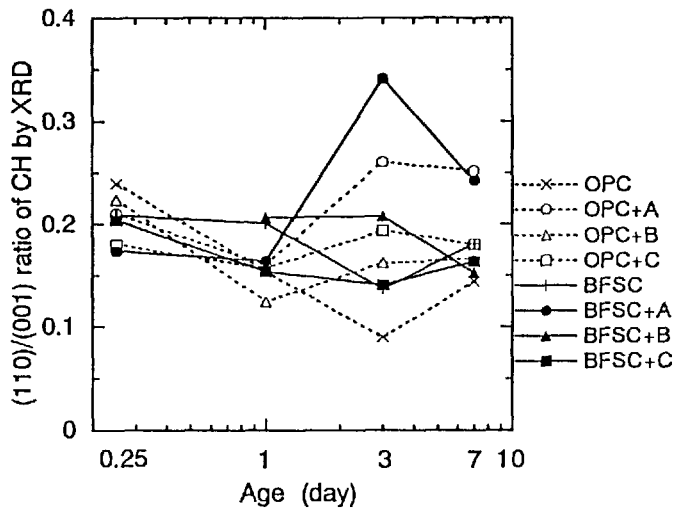

Figure 6 Change of (110)/(001) ratio of CH in pastes by XRD measurement as a function of age. additive replacement; 10wt%

Ettringite and monosulphate

Amount of ettringite and monosulphate measured by DSC as a function of age are shown in Figs 7, 8, 9 and 10, respectively. While BFSC pastes with expansive additives show decrease of ettringite and formation of monosulphate after age of one day, OPC pastes with expansive additives show gradual increase of ettringite with age and no monosulphate is observed within 3 days. Low expansive behavior of mortar with BFSC seems to be partly explained by conversion of ettringite to monosulphate. Furthermore, pastes with expansive additives resulted in higher content of ettringite than that without additive, and among these pastes, paste containing

additive-B which has high hauyne content showed higher ettringite content than other pastes. As seen in Fig 7, at age of 6 hours (0.25 day), higher content of ettringite is observed in paste with additives containing hauyne (additive-A and -B) compared with paste without additive or paste with additive-C.

Remaining peaks of additives were also evaluated in XRD measurements. While XRD peak of free lime was not observed within 6 hours in every paste, hauyne and anhydrite remained in pastes after 6 hours. In paste containing additive-B with high hauyne content, hauyne was observed within 1 day after the hydration started. The high content of ettringite at age of 1 day in paste with additive-B may be related with the remaining hauyne.

Microstructure

Figure 11 shows SEM observations of the pastes at age of 3 days. While few needle-shaped hydrates were observed in BFSC pastes with additives, needle-shaped hydrates of several

micron in length, which seems to be ettringite, were clearly observed in OPC pastes with expansive additives. Sharp platelet hydrates of submicron size, which seems to be monosulphate, were observed in pastes with additive-B in BFSC. These observations are in good agreement with the evaluation of ettringite and monosulphate by XRD and DSC measurements.

Change of pore size distribution of hardened BFSC paste specimens with age are shown in Fig 12. The samples were prepared and cured under unrestrained condition. In paste with high length change, namely BFSC paste with 10 wt % of additive-A (BFSC+A), high portion of pores from 1000 to 20000 nm, and high total pore volume were still measured at age of 7 days. On the other hand, in pastes with low length change, namely BFSC paste with 10 wt% of additive-B and -C (BFSC+B and BFSC+C), decrease of total pore volume and pores over 100 nm, along with increase of pores under 100 nm were measured within 7 days. This phenomenon may be explained by the aggregates of colloidal CH in pore solution of (BFSC+ A).

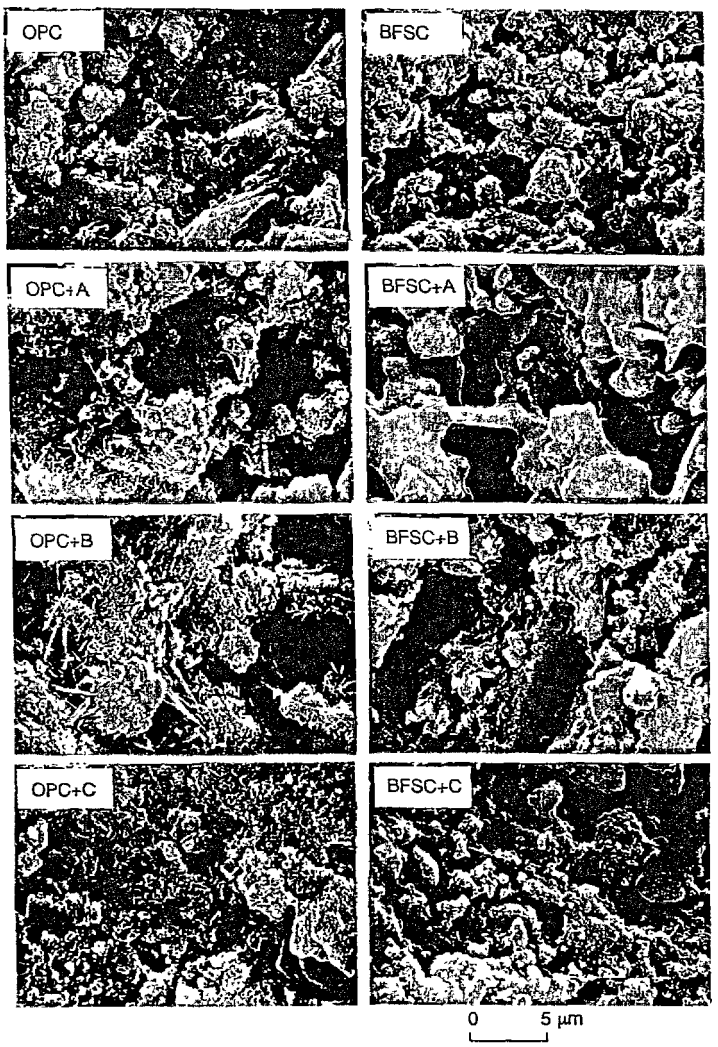

Figure 11 SEM observation of pastes at age of 3 days.

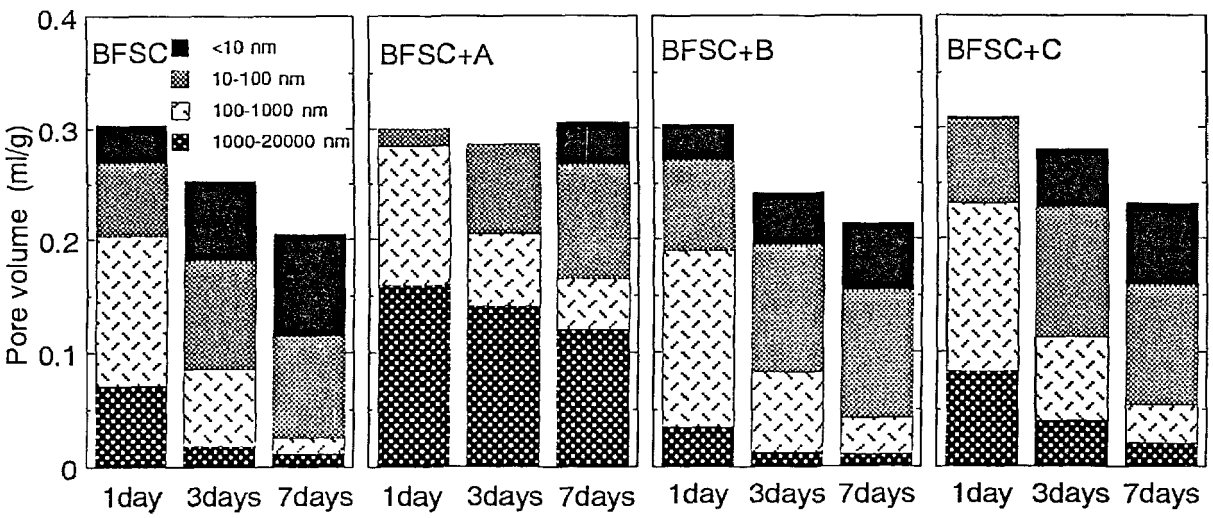

Figure 12 Change of pore volume in pastes as a function of age.

CONCLUSIONS

(1) Large expansion was achieved concerning the new expansive additive which consists of hauyne, anhydrite and free lime, when it was applied to OPC or to BFSC which contains 40 wt% of BFS.

(2) The new expansive additive manifests no harmful effect on strength development of cement matrix, which is similar to the conventional additives.

(3) Low expansion of BFSC paste with conventional type-K additive is considered as a result of high conversion rate of ettringite to monosulphate, and less amount of CH.

(4) The difference of expansive behavior between type-O and the new additive is suggested by the difference of crystal morphology of CH.

MECHANISMS OF SHRINKAGE REDUCTION USING A CHEMICAL ADMIXTURE

Hua AI and J. Francis YOUNG Center for Cement Composite Materials, University of Illinois at Urbana-Champaign, Urbana, IL 61801

ABSTRACT Recently a chemical admixture was developed that reduces drying shrinkage of Portland cement paste by about 30%. The origins of this shrinkage reduction were investigated by studying changes associated with the admixture. Microstructure characterizations such as XRD, MIP, and N_2 adsorption were conducted and shrinkage-weight loss curves were also examined. It was concluded that a change in the surface tension of the pore liquid is the most likely cause of the shrinkage reduction.

Key-words: Admixtures, drying, pore structure, shrinkage

INTRODUCTION

The volume change of hardened Portland cement paste caused by moisture loss has significant effect on the service of concrete structures. Designs must allow for dimensional change caused by drying in order to minimize the stress generated by the external constrains. Shrinkage is a paste property, which is internally restrained by aggregate in concrete (Mindess and Young, 1981). The drying shrinkage behavior of hardened cement paste depends on parameters such as w/c ratio, the age of the paste, curing conditions, cement composition, the drying condition, and the addition of admixtures (Mindess and Young, 1981). These factors determine the microstructure of hardened cement paste and the state of moisture within the paste, which in turn determines the drying shrinkage characteristics of the paste [(Young et al., 1978; Bentur et al., 1980). The pore size distribution and C-S-H characteristics are the primary factors affecting drying shrinkage of pastes.

Many admixtures conventionally used in concrete have shown to have the effect of increasing the drying shrinkage through various mechanisms (Feldman and Swenson, 1975; Young et al., 1978; Bentur et al., 1980). However, a chemical admixture (Eclipse™) was recently developed that reduces drying shrinkage of concrete by about 30% on first drying. The purpose of this investigation is to study the effects of the chemical admixture on the microstructure of hydrated cement and the hydration chemistry, its effect on the shrinkage behavior of cement paste, and identify the origins of this shrinkage reduction.

EXPERIMENTAL PROCEDURES

Sample Preparation

Type I, white Portland cement from Lehigh Portland Cement Co. was used for all sample preparation throughout this investigation. The active ingredient of the shrinkage reducing admixture Eclipse™, designated DPTB, was obtained from ARCO Chemical Company. All samples were prepared at a water to cement ratio of 0.4. The admixture (2 wt% DPTB by the weight of cement) was dissolved in deionized water and mixed with cement powder in a Hobart mixer for 10 minutes. The slurry was then degassed by vibrating under vacuum for 1 min. to eliminate entrapped air bubbles, followed by casting.

Two types of specimens were cast for the purpose of different measurements. For drying shrinkage measurement, thin slabs of 2 mm x 20 mm x 100 mm in dimensions were used. Specimens were cast individually into Plexiglas molds, stored in 100% rh environment at room temperature, demolded after 24 hours and cured in saturated lime water for 1 or 10 days before the shrinkage measurements. Companion samples were also made for microstructure characterizations. They were cast as small cylinders in plastic vials (12.5 mm dia. x 50 mm ht.) and cured at 100% rh. The curing conditions were 1-day, 3-day, 7-day, and 28-day at room temperature.

Shrinkage and Weight Loss Measurements

The thin slabs specimens were used for drying shrinkage measurement and simultaneous weight change due to water loss. Previous experience and reports in literature have shown that

the choice of thin specimens is important in maintaining an equilibrium state of moisture content inside the specimens (Hansen, 1982; Hwang and Young, 1984). Specimens were dried in sealed desiccators maintained at 48% rh, over saturated KNO_2 solution. The length and weight of each specimen were monitored during the course of drying. Micrometer calipers with a resolution of 0.0025mm were used to measure the length of each sample, and an electronic analytical balance with a resolution of 0.0001g was used for weight measurements. Every data point is the average of three replicated measurements.

Qualitative X-ray Diffraction Measurements

At the end of curing period, part of a cylindrical specimen was crushed by hand into a fine powder passing #100 sieve, then immediately put in 105 °C oven to be dried for 48 hours. A Rigaku x-ray powder diffractometer (model D-max II) was used to perform qualitative powder XRD. The measurements used Cu (K_α) radiation, at a scanning speed of 1° 2θ/min., and scanning range from 5° to 65° of 2θ. Ten scans were collected and added together for each spectrum. Powder samples were packed from the back of sample holder to minimize preferred orientations of particles.

Microstructural Characterization

Small pieces (approximately 3-6 mm in dimensions) crushed from a cylindrical specimen were selected for the measurements. A solvent exchange procedure was used to replace pore water with methanol in order to minimize the stress on the solid network induced by drying procedure necessary for this technique. Samples were immersed in methanol for 14 days, with the solvent replaced every 1-3 day. Methanol-exchanged samples were dried at 105 °C in oven for 48 hours prior to testing.

Nitrogen adsorption measurements were carried out using an automated Micromeritics adsorption apparatus (model ASAP 2400). Data were taken on both the adsorption and desorption loop. Surface area was determined by BET analysis of adsorption data, and pore size distribution calculated using the BJH analysis based on Kelvin adsorption theory. The presence of micropores was assessed from v-t plots.

Mercury Intrusion Porosimetry (MIP) Measurements were conducted with the Micrometric Autopore II 9220 using 5cc penetrometers. The maximum intrusion pressure used in the experiment was 415 MPa.

Adsorption of Admixture By Cement

This experiment was designed to examine the possibility of DPTB adsorbing onto the solid surface of cementitious materials. Both unhydrated white cement and the powder made from materials hydrated for 28-day were mixed with DPTB water solution (~0.2 wt% in concentration) at a water to solid ratio of 10 (by weight). At this w/s ratio, the total DPTB available to solid is 2g of DPTB corresponding to 100g of cementitious materials, which is the admixture proportion in the paste.

For up to three days, portions of slurry were taken out of the mixture periodically and filtered to collect liquid for up to three days. The concentration of admixture DPTB in the liquid was analyzed by gas chromatography.

RESULTS

The Drying Shrinkage Characteristics

Figure 1 shows the weight change and drying shrinkage as functions of drying time for admixture added specimens and control. (Three replicates were run for each specimen). The specimens containing DPTB showed more weight change (and hence higher water loss) than control samples after drying for the same length of time. Rapid water loss occurs up to about 50 hours and then gradually slows, although considerable weight change was still observed after 300 hours. In the control samples, rate of the water loss slowed down considerably after the first 20 hours, and an nearly constant weight was reached at around 300 hours.

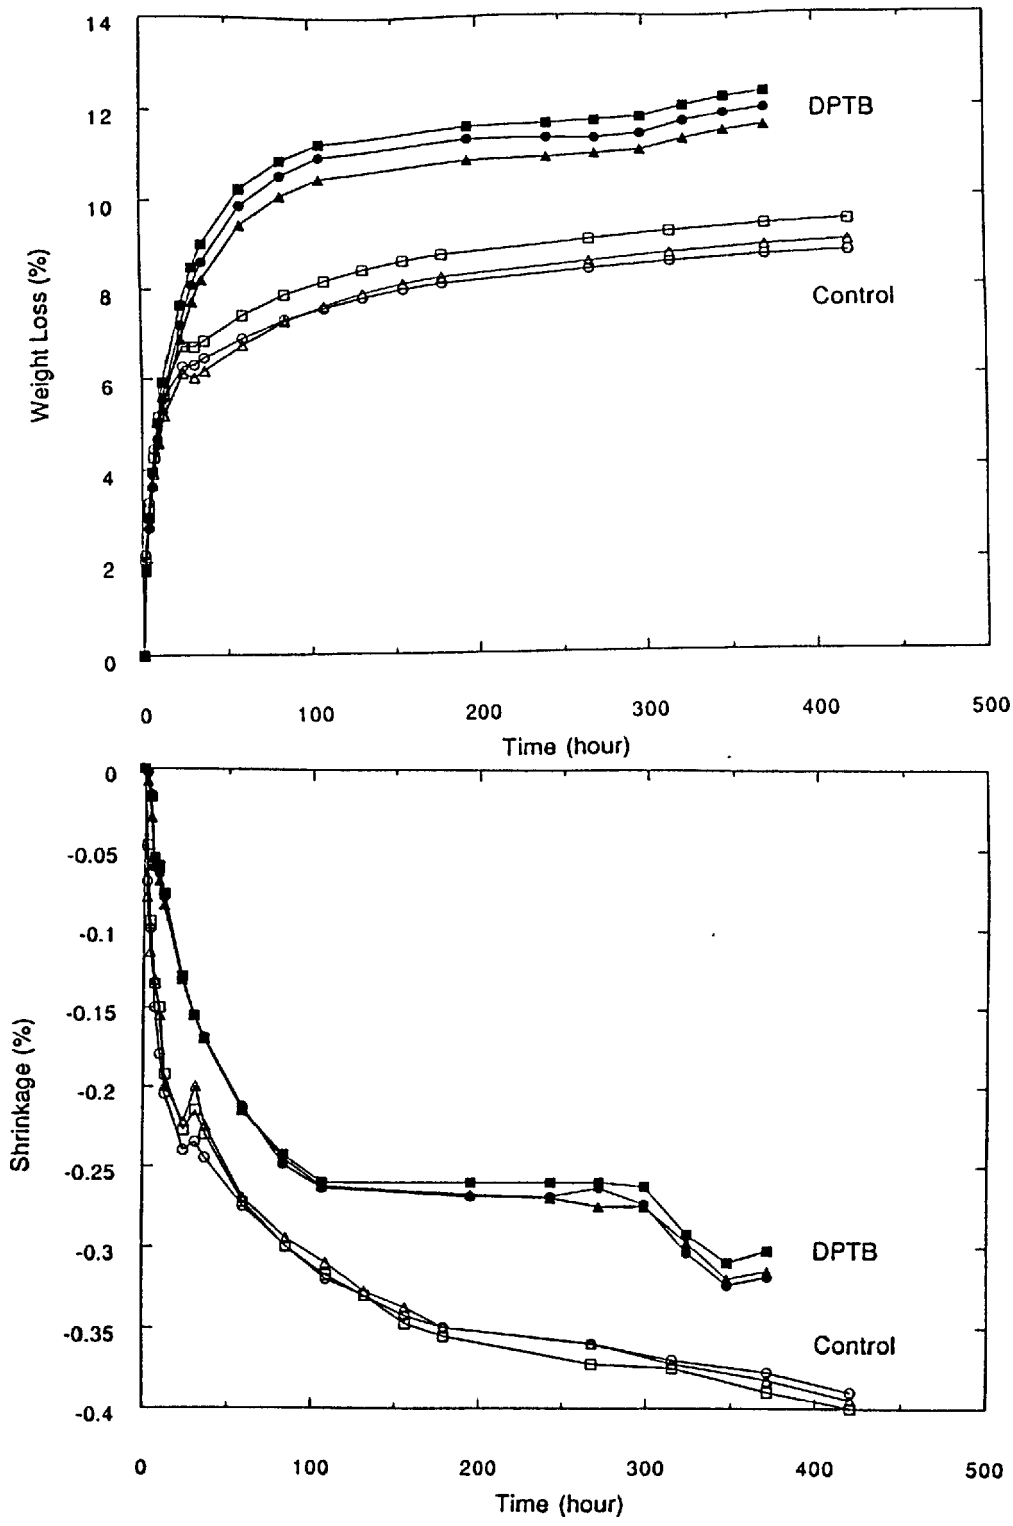

Figure 1. Effect of DPTB on drying of cement paste: a) drying shrinkage v. time; b) weight loss v. time. (10 day old sample).

However the higher water loss in the samples with admixture did not translate into greater drying shrinkage; on the contrary the magnitude of their drying shrinkage is smaller than that of control samples. The rate of length change for the control is greater at all ages. A plot of drying shrinkage versus weight loss is given in Figure 2 to compare directly the effect of water loss on the shrinkage behavior of different samples. For the same amount of moisture removed, paste containing DPTB produces less shrinkage than control sample. The amount of reduction increases as more water removed and is greater in more mature pastes.

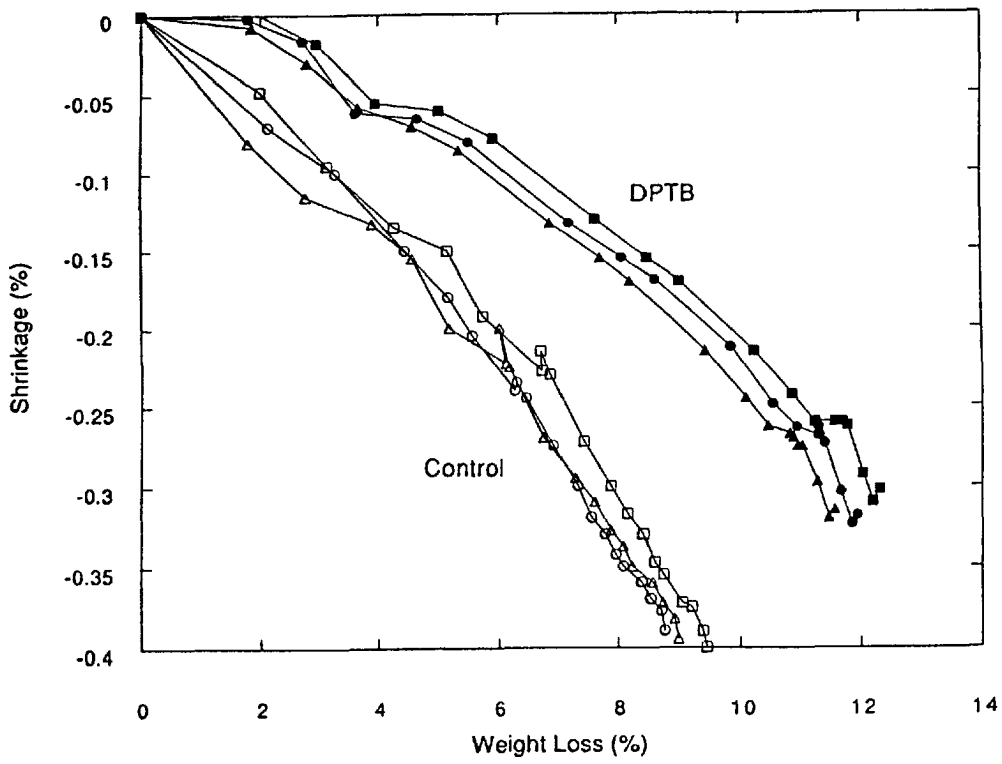

Figure 2. Shrinkage-weight loss curves for cement pastes with and without DPTB.

Phase Compositions

The XRD patterns are essentially identical at both 1 and 28 days indicating that the presence of admixture does not significantly alter the hydration chemistry. Calcium hydroxide (CH) and unhydrated cement are the only crystalline phases detectable in both materials. Similar results were found for more mature paste (28 days old). Qualitative estimations did not reveal any significant changes in the degree of hydration in the presence of DPTB. Thus the admixture does not influence the rate or nature of hydration.

Pore Structure

The Washburn equation was used to calculate the size of the pores from MIP data, using a value of 485.0 dyn/cm for the surface tension of mercury, and a contact angle of 130°. The maximum intrusion pressure used corresponds to a minimum pore size of about 30Å in diameter. Therefore, only those pores in the macropore and mesopore range are accessible by this technique. Figure 3a shows the effect of admixture on the pore size distributions of 1 day and 28 days old pastes obtained by MIP. The difference in the pore size distributions caused by the admixture in one day old cement pastes mainly lies in the macropore range (>500Å in diameter) which are not important for determining shrinkage characteristics (Bentur et al., 1979, 1980). The pore structure in the mesopore range is essentially the same, as suggested by that part of curves being parallel to each other (<500Å in diameter).

Representative mesopore size distributions obtained from nitrogen adsorption data are given in Figure 3b and some additional data reported in Table 1. The nitrogen adsorption measurements confirm the absence of changes on the pore structure in the mesopore range in the presence of admixtures Analysis of v-t curves did not reveal the presence of significant microporosity in any of the samples studied.

The Effect of Surface Adsorption of Admixture

The DPTB concentration remaining in the solution after in contact with cement was measured over time from 1 hr to 3 days. There was no evidence of adsorption of admixture by cement. The concentration of DPTB is constant under various experimental conditions, remaining at its original value.

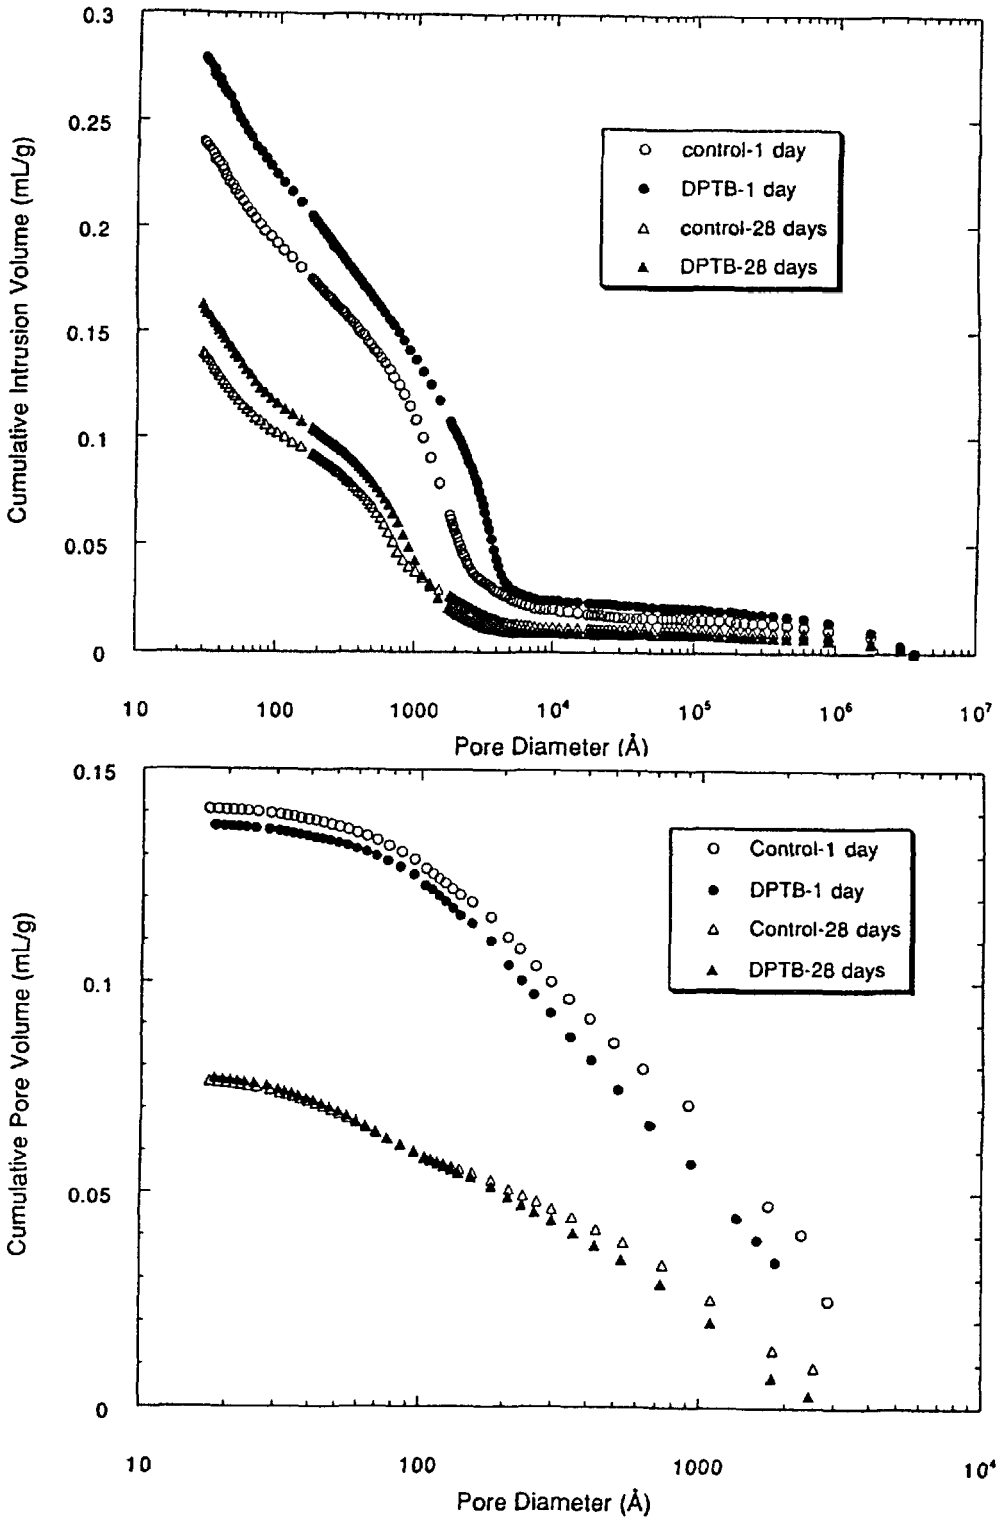

Figure 3. Capillary pore size distribution of cement pastes with and without DPTB. Calculated from (a) MIP data; (b) nitrogen adsorption data.

DISCUSSION

In the past, several microstructural parameters have been correlated with the dimensional change in hardened cement paste upon drying (Young et al., 1978, Bentur et al., 1980.) Shrinkage originates both from induced capillary stress and from changes in disjoining pressure within C-S-H gel. X-ray diffraction reveals no significant changes in either the rate or stoichiometry of hydration when DTPB is added. This, combined with similarities of the nitrogen adsorption measurements, suggests that no significant changes in C-S-H are occurring. Both MIP and

Table 1. Pore statistics of the specimens as measured by nitrogen absorption analysis

Curing Time	Measured parameter	Control	DPTB
1 day	BET surface area (m^2/g)	19.8	20.2
	Total pore volume (cm^3/g)	0.12	0.12
	Micropore volume (cm^3/g)	---	---
3 days	BET surface area (m^2/g)	19.0	18.0
	Total pore volume (cm^3/g)	0.09	0.10
	Micropore volume (cm3/g)	---	---
7 days	BET surface area (m^2/g)	21.0	20.1
	Total pore volume (cm^3/g)	0.09	0.10
	Micropore volume (cm^3/g)	---	---
28 days	BET surface area (m^2/g)	19.6	24.2
	Total pore volume (cm^3/g)	0.08	0.09
	Micropore volume (cm^3/g)	---	---

nitrogen adsorption show no significant change in capillary pore distribution in the mesopore range.

The shrinkage-weight loss curves show an high initial loss of water, that causes little shrinkage when DPTB is present. This agrees well with the higher macroporosity observed by MIP, particularly at early ages. Most of the shrinkage is associated with removal of water from the mesopore system, and in this case shrinkage is less in the presence of DPTB. Since shrinkage is related to the induced hydrostatic capillary stress, this implies that the induced stress is lower in the presence of DPTB. Given that the capillary stress (P_{cap}) is given by:

$$P_{cap} = 2\gamma/r \qquad [1]$$

the only way that the stress can be reduced for a given pore radius (r) is by a reduction in the surface tension of pore solution (γ).

The direct measurements for surface tension of DPTB solution were carried out by Wilhelm slide method (Adamson, 1982) in this study. Figure 4 shows the surface tension of solution as a function of DPTB concentration in water. Since DPTB has a much lower surface tension value, a monolayer of DPTB molecules is formed first on the surface of water when a small amount is added. This monolayer of DPTB will drastically reduce the surface tension of solution from that of pure water (72 Dynes/cm) as illustrated in Figure 4. With more DPTB addition, the surface tension continued to decrease but gradually approaches a constant value. In the real hydrated mix, as water participates in the hydration, the concentration of DPTB in the pore solution is likely to increase to a higher value than the initial concentration. Therefore, the reduction of surface tension provided by DPTB might exceed that expected from a 2% solution. We estimate that surface tension of the pore solutions will drop to about 50 dynes/cm, which is about a 30% reduction in γ and hence in P_{cap}.

The effectiveness of DPTB and related molecules in reducing shrinkage is thought to relate to their lack of adsorption by the hydrating cement. Other molecules that lower surface tension can be removed from solution by adsorption in the early hydration products C_3A and thus are no longer effective at the time water-loss begins. Adsorption of DPTB by hydrates of C_3A was not observed in this study. Therefore, the surface tension of the pore water will remain low during the time water is lost from the paste.

CONCLUSIONS

The effect of chemical admixture DPTB on hydrated cement paste was investigated through the characterization of microstructure and its interactions with the admixture. The results suggest that the presence of chemical admixture did not significantly change the hydration chemistry, the intrinsic structure of C-S-H, and the pore structure of the hydrated paste. The most likely cause for the shrinkage reduction is the reduction in the surface tension of pore solution, acting through the capillary effect, and this is supported by the evidence of direct surface tension measurements. DPTB is not adsorbed by the hydrating cement so that the surface tension will remain low during drying.

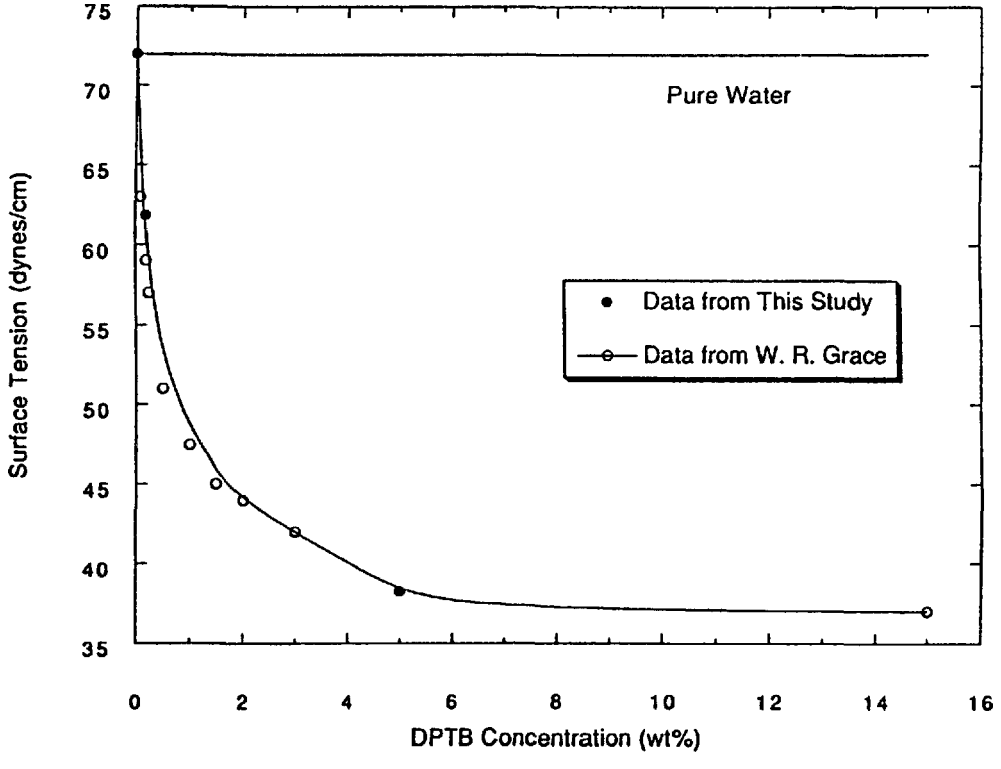

Figure 4. Effect of DPTB concentration on the surface tension of aqueous solutions.

ACKNOWLEDGMENTS

This work was supported by W. R. Grace & Co. We thank Dr. E. Shawl, ARCO Chemical Company for the chromatagraphic analyses of DPTB in solution. Surface tension measurements were carried out with the help of Ms. Lijun Coi, and we thank Prof. S. Granick for the use of the equipment. Additional surface tension data was kindly supplied by Dr. A. V. Kerkar, W. R. Grace & Co.

TOPIC III.B

Influence of admixtures on microstructure development

INFLUENCE OF MELAMINE SUPERPLASTICIZER ON SOME CHARACTERISTICS OF CONCRETE

Anna M. GRABIEC, Agricultural University, Poznań, Poland
Róża KRZYWOBŁOCKA-LAURÓW, Building Research Institute, Warszawa, Poland

ABSTRACT The influence of the superplasticizer on the some characteristics of concrete was determined. Compressive strength after 28 and 360 days, water absorbability and frost-resistance after 200 days of freezing and thawing were tested. The content of bound water in concrete was determined. It was found that there was a decrease in the strength of concrete with superplasticizer after longer periods in relation to the strength of this concrete after 28 days, after testing frost-resistance reaching 29%. This was accompanied by an increase in the bound water content.

Key-words: Admixtures, Bound water, Freeze-thaw damage, Hydration, Superplasticizers

INTRODUCTION

From the point of view of building material technology, both the influence of the superplasticizer on the properties of fresh concrete and the effect of admixture on hardened concrete characteristics changing with time, such as strength parameters as well as water absorbability and frost-resistance - being in a sense durability indicators, are important. In literature we find relatively few well-documented data on the changes of strength and structural characteristics of concrete with superplasticizers, maturing under different conditions of temperature and humidity for longer than 28 days. To evaluate the influence of superplasticizer on concrete it was suggested to use complex tests of physical-mechanical and structural characteristics of concrete. These include determining the compressive strength, water absorbability, frost-resistance, volume density of concrete, as well as determining the bound water content in hydration products and cement hydrolysis and the content of calcium hydroxide. The characteristics of concrete after 28 days are a reference point for comparing their changes after longer periods of concrete hardening.

MELAMINE SUPERPLASTICIZER

Introduction

Superplasticizers are widely used as effective admixtures improving the workability of the mix or reducing the water content in concrete, which should lead to higher compressive strengths and improved durability (Yilmaz and Glasser, 1989). SMF-type superplasticizers consist of salts of sulphonated melamine formaldehyde polymers, with quite large molecular weights, which are most effective with a molecular weight of about 30000. Next to salts of sulphonated naphthalene formaldehyde polymers (SNF) and preparations containing modified sulphonate they form the most numerous group (Masazza, 1983, Taylor, 1990).

Action mechanism

Literature points to three basic physical-chemical phenomena influencing the fluidifynig effect of superplasticizers. These are: dispersion, adsorption and intermolecular repulsion - potential zeta (Taylor, 1990, Collepardi and Ramachandran, 1992). It has not been conclusively determined whether superplasticizers are adsorbed on the surface of the cement grains or on the hydration products as well, particularly on the surface of the hydrated phase of aluminates and sulphates (Masazza, 1981). Not always a higher (in absolute values) zeta potential and what follows, a more effective dispersing action is tied to a greater adsorption of superplasticizers on the surface of cement grains. This results from

various forms of calcium sulphate in the cement - dihydrate, bassanite or anhydrite (Collepardi and Ramachandran, 1992).
There is little data from tests of the microstructure of cement composites with superplasticizers. From the available literature we see that the use of superplasticizers gives a denser structure of the cement paste (Ramachandran et al., 1984, Collepardi and Ramachandran, 1992, Ping Gu et al., 1994). According to Masazza (1983) changes in the morphology and size of cement hydration products affected by superplasticizers apply mainly to ettringite crystals. The admixture causes that in place of the thicker needle-like crystals, smaller and shorter ones are formed, measuring about 1/10 of those obtained in the absence of the superplasticizer and in smaller amounts. These observations are confirmed by Ping Gu et al., (1994), pointing to a cube-like shape of the ettringite crystals modified by superplasticizers. According to Yilmaz and Glasser (1989), ettringite crystals are more distinct and thicker in configurations with the superplasticizer. The size of portlandite crystals is decreased with the addition of the admixture, and their form changes from blocky to a thin, plate one.

RESEARCH

Materials, range and methods

Two series of concrete with natural aggregate were tested, with and without superplasticizer. The cement content in concrete was 350 kg/m^3. Cement with a 4% content of C_3A was used. The content of calcium sulphate calculated for SO_3 was 2.4%. An X-ray analysis showed in this cement the presence of a dihydrate calcium sulphate - gypsum, hemihydrate - bassanite and anhydrous - anhydrite. The content of alkalis in cement calculated for Na_2O was 0.5%, the specific surface of cement according to Blaine was 3003 cm^2/g. The melamine superplasticizer was added to the mix water in the amount of 2.2% with respect to cement mass. The value of the water-cement ratio was 0.43 in the concrete mix without and 0.35 in the mix with the superplasticizer. The consistency of concrete mixes was 7 s according to VeBe. The amount of mix water from the series with superplasticizer decreased by 18%. The tests were conducted on cubes a = 10 cm. The dates and hardening conditions of concrete were as follows: 28 days in standard conditions, 360 days in air-dry conditions, 360 days in water and after 200 cycles of freezing and thawing (freezing in air and thawing in water). The content of bound water in cement hydration products - silicates, aluminates and calcium aluminate-sulphates (HI) and cement hydrolysis - calcium hydroxide (HII) were determined in the concrete, using the thermal differential analysis method (DTG, DTA and TG). The microstructure of the concrete was examined in a scanning electron microscope. Specially prepared fresh fractures of concrete were subjected to observation. The range of magnification was from 20 to 10000x. The analyses had a qualitative character. Qualitative X-ray analysis was conducted on selected samples.

Results

The results of tests of physical-mechanical, and structural characteristics of concrete are given in table 1.Tests of microstructure on fresh fractures of 28-day concrete show a more compact structure in concrete with superplasticizer than in the concrete without the admixture. It should be stressed that in the concrete with superplasticizer there are numerous clusters of ettringite. After 360 days of maturing in air-dry conditions the concrete continues to show a more compact structure than the concrete without the admixture. The occurring hydrates silicates CSH-type have very indistinct, as if washed out contours. In the sample of concrete without superplasticizer CSH have as a rule the structure of crumpled foil, and only in some places they have a fibrous structure. In both types of concrete there are small ettringite crystals. In the sample of concrete with superplasticizer after 360 days in water there are signs of washing out of paste and small cracks. Numerous, unhydrated cement grains have surface etchings. CSH with indistinct contours, similar to those appearing after 360 days in air-dry conditions, are found.

Table 1. Physical-mechanical and structural characteristics of concrete with and without superplasticizer

Tested characteristic of concrete		Result of concrete test	
		without	with superplasticizer
Volume density after days (kg/m^3)			
28 - in standard conditions		2350	2380
360 - in air-dry conditions		2409	2385
360 - in water		2392	2403
200 freezing-thawing cycles		2381	2409
Compressive strength after days (MPa):			
28 - in standard conditions		34.9	34.9
360 - in air-dry conditions		35.5	35.5
360 - in water		38.5	38.5
200 freezing-thawing cycles		31.3	31.3
Water absorbability (%)		4.6	3.4
Frost-resistance - drop in compressive strength (%)		18.5	7.7
Bound water content in products of hydration (HI) and hydrolysis (HII), after days (kg/m^3):			
28 - in standard conditions	HI	49.4	45.2
	HII	9.4	7.1
360 - in air-dry conditions	HI	67.5	57.2
	HII	9.6	7.2
360 - in water	HI	69.4	50.5
	HII	12.0	7.2
200 freezing-thawing cycles	HI	64.3	55.4
	HII	9.5	7.2
Calcium hydroxide content after days (kg/m^3):			
28 - in standard conditions		37.6	28.6
360 - in air-dry conditions		38.5	28.6
360 - in water		50.2	28.8
200 freezing-thawing cycles		38.1	28.9

The occurring ettringite crystals are clearly shorter than those observed in concrete after 28 days. Worth noting is the very rich crystallization of ettringite, in single form and in clusters, apparent only in deep pores. After 200 cycles of freezing and thawing in the concrete with admixture we find micro-cracks passing not only through the pores, but also between them. In these micro-cracks we find ettringite crystals and large table-like crystals, most probably hydrated calcium aluminates. Ettringite crystals are also found in the entire cement paste. In the sample without superplasticizer the surface of the paste shows signs of carbonatization. The micro-cracks pass mainly through air pores. There are many ettringite crystals in them. But in the paste mass there is much fewer of them than in the concrete with admixture. The X-ray analysis of the paste separated from concrete with superplasticizer showed the presence of diagnostic three reflexes of ettringite in all the samples examined (d = 0.973, 0.561 and 0.388 nm). The most distinct is the d = 0.388 nm reflex. Its intensity is greatest in the concrete with superplasticizer, maturing in air-dry conditions, the smallest in concrete after 200 cycles of freezing and thawing. In the concrete without admixture there is only one diagnostic reflex for ettringite (d =

0.388 nm), whose intensity is also lowest in concrete after 200 cycles of freezing-thawing and slightly lower than in concrete with admixture.

DISCUSSION

In order to evaluate the influence of superplasticizer on the physical-mechanical and structural characteristics of concrete we examined the changes of values both in the concrete without, as well as with the superplasticizer. The volume density of concrete without the admixture is contained within 2350 to 2409 kg/m^3. The diversification of the volume density for the various samples of concrete from this series does not exceed 2.5%. In the case of concrete with superplasticizer the volume density is within the range from 2380 to 2409 kg/m^3. The diversification of density does not exceed 1.5%. The water absorbability of concrete with admixture is lower by 26% compared to concrete without the superplasticizer. Frost-resistance expressed in the drop of compressive strength of samples after 200 cycles with respect to strength of control samples - kept in water, is 18.5% for the series of concrete without admixture, and for concrete with superplasticizer it is much lower and stands at 7.7%. It must be noted that in these samples there were no macroscopic signs of damage or loss of mass. At the same time the bound water content (HI) in concrete samples without admixture clearly falls (by 7.3%) with its increased content (by 9.7%) in the samples with the superplasticizer. Other characteristics of the analyzed concretes change depending on the hardening conditions in a diversified way in both series. In concrete without the admixture the values of the tested strength and structural characteristics support the hitherto data. The greatest compressive strength, bound water content and calcium hydroxide is found in concrete maturing 360 days in water. Lesser values are found in concrete maturing in air-dry conditions for 360 days, and the smallest in concrete after 28 days. Freezing-thawing cycles lead to a drop of strength of 8.3% with respect to strength at 28 days and quite a significant increase in bound water content in hydration products (HI) and a slight increase in hydrolysis products (HII). Concrete with superplasticizer shows maximum compressive strength after 28 days of maturing in standard conditions with a minimal for this series bound water content in cement hydration products (HI). After 360 days of hardening in air-dry strength drops by 20%, which is accompanied by an increase in bound water in hydration products (HI) by 26.5% with an unchanged calcium hydroxide content. The same concrete after 360 days of maturing in water is characterized by an even greater drop of strength, at 25% and an increase in the bound water content (HI) by 12% with a constant calcium hydroxide content. The greatest drop in strength in this concrete of 29% was found after 200 cycles of freezing and thawing. At the same time there is an increase in the content of bound water (HI) by 23% with an unchanged amount of calcium hydroxide. In order to compare the degree of cement hydration in both concrete series we used the bound water content in hydration products - HI and hydrolysis products - HII (Fig. 1). According to Yilmaz and Glasser (1989) the $Ca(OH)_2$ content after longer periods of hardening is a reliable indicator of the degree of cement hydration. The ratio of the bound water content in hydration products - HI, i.e. in hydrated aluminate sulfates, aluminates and calcium silicates to the bound water content in hydrolysis products HII, that is in calcium hydroxide, may indirectly characterize the degree of reacting of the cement in concrete. This indicator was used to characterize the changes taking place in both series of concrete. In the concrete without admixture the value of the ratio of bound water in hydration products to water found in hydrolysis products is within 5.3 to 7. Maximum strength in this series of concrete is found in samples with the HI to HII ratio equal to 5.8. Samples with the least strength in this series have the HI/HII ration equal to 6.8. In concrete with superplasticizer the value of the HI/HII ratio is within 6.4 to 7.9. Maximum strength is found in samples with HI/HII equal to 6.4, minimal - 7.7. From the data presented above we see that in samples with the superplasticizer after longer periods of hardening changes take place in the bound water content in hydration products. HI with small hydration of the remnants of unhydrated cement.

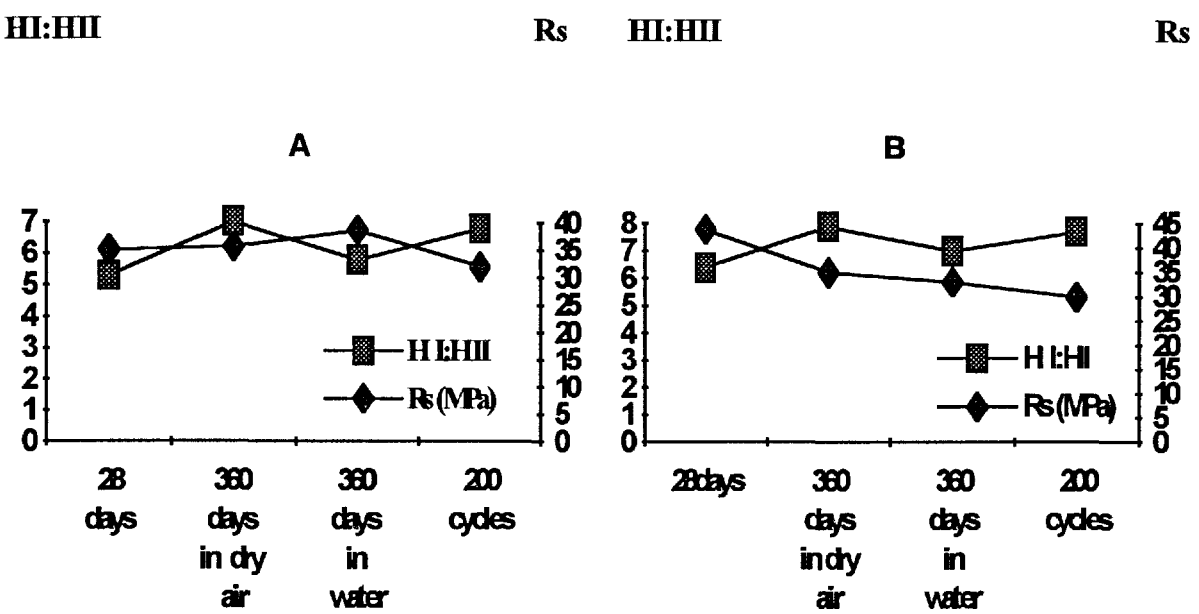

Figure 1 Value of the HI/HII ratio in concrete without (A) and with admixture (B) with respect to the compressive strength of concrete.

This is shown by both the growth of bound water content in hydration products HI, as well as the constant $Ca(OH)_2$ content. In the series without admixture, on the basis of calcium hydroxide content, the degree of hydration of cement is much greater. On the basis of observations in a scanning microscope we find that the microstructure of concrete with superplasticizer is more compact. On the basis of X-ray analysis it was found that the most ettringite is found in the sample of concrete with the superplasticizer after 360 days of hardening in air-dry conditions.

CONCLUSIONS

1. The influence of the superplasticizer is expressed by an increase in the compressive strength after 28 days, lowering of water absorbability and improved frost-resistance compared to concrete without the admixture.
2. The influence of the superplasticizer after 360 days of hardening in air-dry conditions and in water is expressed by a significant lowering of the compressive strength compared to the same concrete after 28 days.
3. The greatest drop in strength with respect to 28-day concrete with superplasticizer is found after 200 cycles of freezing and thawing.
4. The decreases of strength of concrete with superplasticizer are most probably tied to the changes taking place in cement hydration products. This is shown by the significant increase in the amount of bound water in these products in concrete after 360 days of hardening and after 200 cycles of freezing and thawing with an almost constant calcium hydroxide content.
5. In evaluating the effectiveness of the superplasticizer it is not enough to measure the strength after 28 days.
6. For the comparative evaluation of the course of hydration in cement without and with the superplasticizer it is recommended to determine the content of bound water in hydration and hydrolysis products and the calcium hydroxide content.

PERFORMANCE OF HIGH-RANGE WATER REDUCERS IN CEMENT CONCRETE MIXES IN HOT WEATHER CONDITIONS

S C MAITI, National Council for Cement and Building Materials, New Delhi.

ABSTRACT The initial workability and slump-retention period for concretes with Indian superplasticizers are similar to those for concretes with superplasticizers from other countries. The type of cement did not make any difference. The rapid slump-loss of superplasticized concrete in hot weather condition could be checked using the retarder Sodium gluconate. For high-strength concrete mixes, the higher dosage of the superplasticizers enabled the workability to be retained for a comfortable period of time without any retarder.

KEY - WORDS : Superplasticizers, Slump loss, High temperature, Retarders

INTRODUCTION

Superplasticizers require to be evaluated before they are used in concrete construction, as they have to be compatible with the materials of construction, specially with the type of cement used. Addition of superplaticizer to concrete of medium workability renders the mix flowing, within minutes of addition. However, the extreme workability so obtained is transient and depends upon factors like the initial workability, type and dosage of the superplasticizers, atmospheric temperature, addition of retarders etc., apart from cement characteristics. At higher temperature, which is a general feature of many countries, the problem gets aggravated and the high workability of concrete is lost within a short period of time. This is a common feature of all kinds of superplasticizers. The rate of slump-loss gets accelerated when such concrete is subjected to prolonged mixing in ready mixed concrete plants (Ravina and Soroka, 1994). Others controlled the slump-loss by using a polymer (Ramachandran, Beaudoin and shihua, 1989).

SCOPE OF THE INVESTIGATION

The investigation aimed at evaluation of superplasticizers with different types of cement in hot weather condition. The experiments were conducted to evolve a method to check the slump-loss of superplacticized concrete. The mix design aspects of superplasticized flowing concrete were also looked into.

Materials

The performance of two Indian commercial naphthalene-based superplasticizers was compared with that of two imported superplasticizers (one melamine-based and the other naphthalene-based). The cements used are ordinary Portland cement (OPC) and three types of blended cements [two pozzolana-based: PPC-1 (flyash-based) and PPC-2 (burnt clay pozzolana-based) and one blast furnace slag-based: PSC]. The cements conformed to the relevant Indian Standard Specifications. The chemical constituents and the physical properties of the cements used are given in Tables 1and 2 respectively. The coarse aggregate (20mm maximum size crushed rock aggregate) and a natural fine aggregate were used. The retarders used are a commercial product, Sucrose, Citric acid and Sodium gluconate.

Table 1 Chemical Constituents (%) of cements used

Constituents	OPC	Blended cements		Slag cement
		PPC-1	PPC-2	PSC
SiO_2	25.94	28.74	26.76	25.63
CaO	59.86	51.60	50.80	53.47
Al_2O_3	5.21	6.88	9.18	9.43
Fe_2O_3	3.65	3.77	4.34	2.55
MgO	1.77	2.23	1.04	3.97
SO_3	1.50	2.49	-	1.49
Loss on ignition	1.69	2.10	2.52	2.43
Insoluble residue	3.97	16.63	16.31	2.60

Table 2 Physical properties of cements

Properties	OPC	PPC-1	PPC-2	PSC
Fineness, cm^2/gm	3137	4133	3235	3485
Specific gravity	3.15	3.02	3.00	2.87
Setting time (minutes):				
Initial	148	112	130	187
Final	275	207	235	316
Compressive strength: (N/sq mm)				
at 3 days	27.0	23.8	-	23.3
at 7 days	34.5	29.3	31.5	28.0
at 28 days	46.0	40.2	41.8	34.0

EXPERIMENTS CARRIED OUT

Experiments were conducted on high-workability superplasticized concrete mixes of M20 and M 40 grades. The control concrete mix had a medium workability of 25-50 mm slump. Concrete was mixed in a mechanical mixer. Superplasticizer was added to the mix with the last part of the mixing water. The retarder was added along with the cement with the first part of the mixing water.

TEST RESULTS AND DISCUSSIONS

About 0.75 % (by weight of cement) superplasticizer was required to convert 25mm slump concrete to flowing concrete of M20 grade. M 40 grade concrete required about double the dose for producing high-workability concrete mix. This was also observed by others (Rixom and

Mailvaganam, 1986). The dosage requirement in blended cement concrete was the same as in concrete with OPC. The M20 grade superplasticized flowing concrete in general required about 5% (%by weight of total aggregate) more fine aggregate in order to make the concrete mix cohesive. At normal temperature conditions (27°C, 65% RH), there was no rapid workability loss, and the control slump could be obtained even after 2.5 to 3 hours time. In hot weather conditions (40°C, 20% RH), the flowing characteristics of M 20 grade superplasticized concrete were retained only for about 30 minutes. The type of cement (OPC,PPC or PSC) did not make any difference. The initial workability and slump-retention period for concrete with Indian superplasticizers were similar to those for concrete with superplasticizers from other countries. There was no special trend observed for the type of superplasticizer or the type of cement used. The workability of superplasticised concrete could be maintained in hot weather conditions in case of M 20 grade concrete with the retarder Sodium gluconate (0.1% by weight of cement) for all types of concrete (Fig 1). Not all retarders were effective to control the slump-loss of superplasticized concrete mixes. A commercial set-retarder could not alleviate slump-loss. Sucrose although could alleviate the slump-loss at high dosage (0.5% by weight of cement), retarded the setting time of concrete considerably, and was not found useful. Citric acid did not perform well in the case of concrete with PPC.

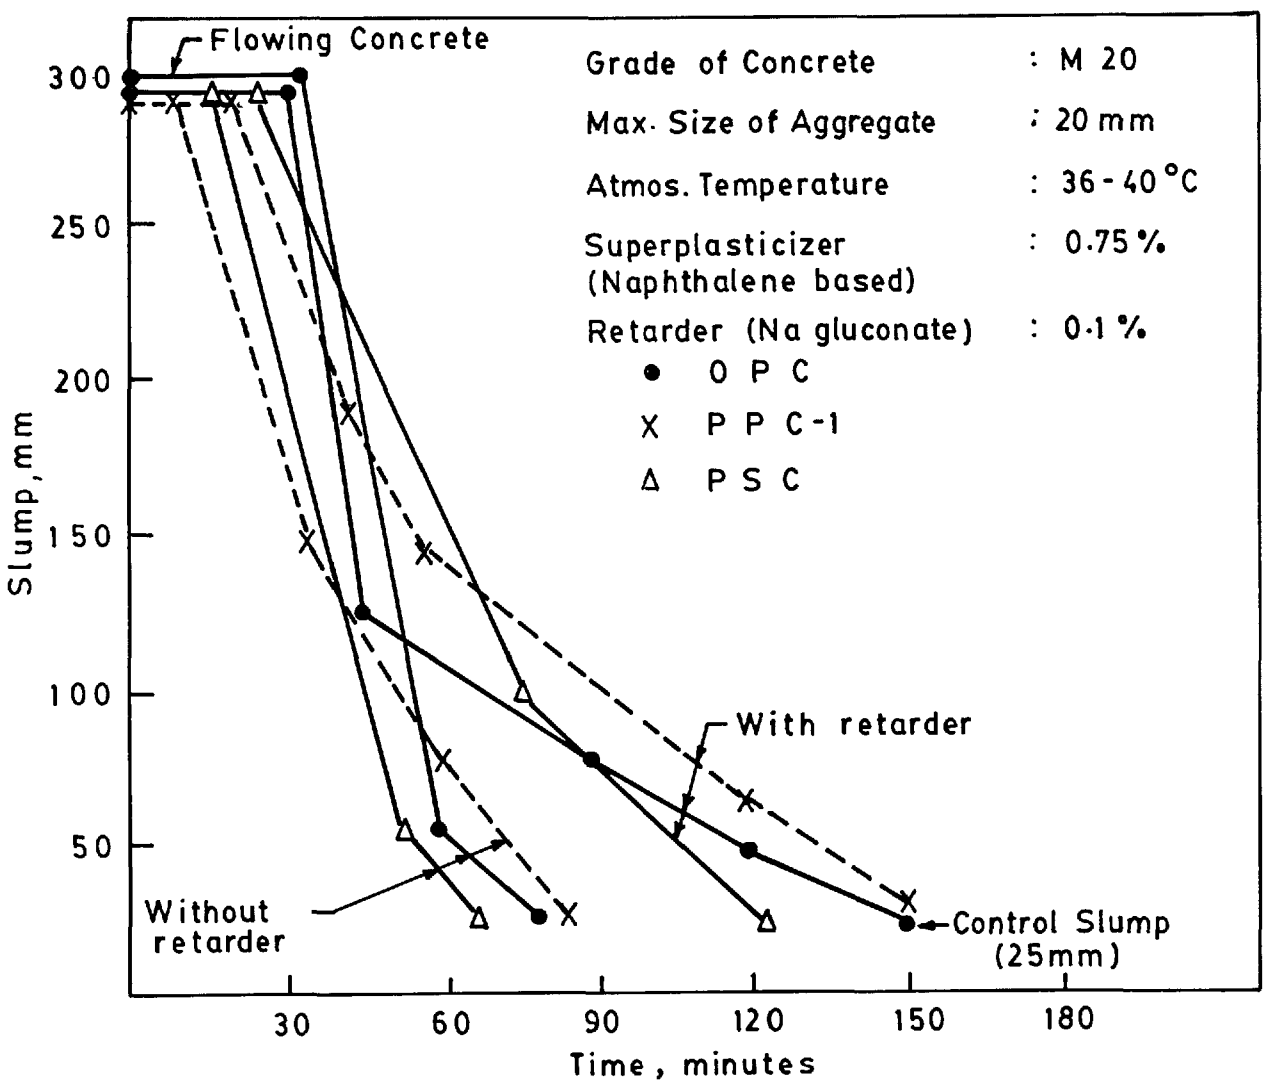

Figure 1 Slump retention of retarded superplasticized concrete in hot weather

For M 40 grade concrete, the comparatively higher dosage of the superplasticizer enabled the workability to be retained for the desired period of time, upto about 3 hours, without any retarder, even at 36-38°C temperature. The blended cement concrete did not make any difference. This is probably because of a cohesive concrete mix of high cement content holding a smaller quantity of mixing water efficiently, and not allowing it to expose to the surroundings causing evaporation. That the higher cement content in concrete reduces the rate of slump-loss, was also observed by others (Mailvaganam, 1979).

LOW-WATER REQUIREMENT BINDERS AS NEW-GENERATION CEMENTS

B. E. IOUDOVITCH, A. M. DMITRIEV, S. A. ZOUBEKHINE, NIICEMENT,

ABSTRACT Low water requirement binders (LWBs) are modified cements Portland types consisted of interground Portland cement clinker (PCC), modifier (M), gypsum and active or inert mineral additions. Their history, chemistry, technology and properties are the objective of this report.

Key-words: Binder. Modified cement. Superplasticizers. Lignosulphonates.

INTRODUCTION AND HISTORY OF LWB

LWBs (Russian name - VNV) were invented in 1984 by Babaev and Bashlykov. They interground ordinary PC (OPC; variant: PCC) with dry M (included water lowering agent based on naphtalensulphonate, regulator of cement setting, intensifier of hardening etc.) and in concrete found the unprecedent water demand fall and strength growth - by minus 30-40% (here and below all % by weight) and by plus ≥3 classes of strength (≥30 MPa) accordingly in compare with high early strength PC (HPC) of 600 mark - the better by Russian standard (GOST 10178). LWB with slag or fly ash had also plus ≥ 2 classes of strength in compare with PCC based cement of such types. These results could not be obtained with M dissoluted in mixing water of mortar and concrete with decreasing of water demand by 18-25% and increasing of their strength under 2 classes. But sometimes mentioned positive effect of dry M-intergrinding (``intergrinding effect``, abbr. IE) is decreased to that of M, dissoluted in mixing water (``plasticizing effect``, abbr. PE). It delayed working out of binder and based products. In 1986 Tarnarutsky and Ioudovitch apart from previous authors made LWB by the same way with M based on lignosulphonates. They got reproducibility of data. After meeting in sci. conference (1987) mentioned authors had been decided to work jointly and in 1-2 years - together with other authors of this report and had established that the time of component intergrinding and high energy of mill charge/ground material impacts is essential for IE and is the *first condition* of IE>>PE. Review of patents had shown that m-lle Peiron (1982) had ground PCC + dry superplasticizer (S) + gypsum + retarder of cement setting and fixed cement disaggregation and PE. Collepardi (1987) introduced dry powdered S in OPC *after* grinding; the result was improving the PE reproducibility. Novelty of IE stipulated LWB research by three ways simultaneosly: 1) producing of LWB parties in pilot and plant mills; testing them in concrete and reinforced concrete with technological, mechanical, construction and environmental experiments and sanitary inspections of LWB producing and using; 2) studies of mechanochemical reactions of LWB formation during grinding in large mills; 3) analysis of hydration / hardening processes and strengthening different types of LWB-based concrete - from high strength to cellular. During 1988 - 1991 in these studies 24 leading research institutes on concrete and building took part with coordination from Ministry of Building (Gosstroy of USSR, namely B. N.Yeltzin, 1988-89, as official) and in 1989 - 1991 - 6 cement plants, some building industry plants and works of M production too. The purpose is to create new range of cement types based on LWB. Publications were not encouraged. In 1991 the prestandard for LWB (USSR Technical Conditions for VNV) and ``Technical Regulations for Concrete Producing and Using on VNV base`` were worked out (not published in the open editions). But after well known circumstances military consumers of super high strength cements (neat LWB) were disappeared and state granted studies were stopped. Further research had been conducted by 3 organizations named in title. This is the first open publication on LWB as a whole from authors of binder. The lack of place determines a conspectiveness of text.

ABOUT LWB FORMATION IN GRINDING PROCESS

It was demonstrated (1992) that the mechanochemical process of LWB formation in plant mill (2.9 x 8.6 m) is *endothermal* (versus *exothermal* for known surface-active matters acc. Rehbinder, 1931) by control of necessary present-position data with Link-system in grinding regimes without and with M. PCC from ring store had initial temperature 88°C, neat OPC had av. sp. surface 400 m^2/kg. The temperature of aspirated air at once after mill outlet after M introducing and regime stabilization had been lowered from 108 without to 104-105°C with M and cement (LWB) temperature - from 137 to 135°C when av. sp.surface raised to 450 m^2/kg. Sp. endotermal effect (EE) estimated was much over 100 J/mol of M. This is the first sign of chemical reaction (RA)``PCC+M``. Other components - gypsum and mineral additions - are passive because there is linear lowering EE during their content increasing. Water adding in the first mill chamber interrupts RA versus it introducing to the last chamber by F.L.Smidth pulverizing method which does not stop RA. It has been concluded that water in mill cannot solve product after high degree of RA. The quick method of RA degree estimation is obtaining the free M in ground material along mill. Ioudovitch and Srl'arenko had worked out optical micromethod of free M estimation in said material and in finish LWB. By this method it have been demonstrated that *IE is obtained only in absence of free M in LWB* (Ioudovitch,1989, unpublished report). This is the *second* technological *condition* of LWB production. Naturally, with increasing free M content in LWB said IE transformes to PE. Unreproducibility of IE, as it is obvious, are concerned to cases of RA interruption by some technological factors - from glassy clinker nodules and phases surfaces during kilns' dusting to over moist cement components etc. Practically by RA reason LWB producing is closely connected with all technological peculiarities of cement production process beginning from raw materials and PCC burning. The phenomenon of difference between PCC composition and properties in *surface* and in *volume* is especially important to LWB production.

Using range of physical and chemical methods among them Auger-spectrometry and gel-chromatography, as main interaction stages (st.) of RA were established: 1) molecular-dense aggregation; 2) chemisorption; 3) implosion (term by Wislozky, 1971, used in tribology) of organic matter of M into the PCC surface layers to the depth abt 1-2 μm during mutual contacting between comminuting PCC particles with M adsorbed on as a solid lubricant in friction pairs; 4) throttling (organic M constituents structure alteration in st.4 of process by chain length and molecular mass); 5) cladding of the active zones on PCC surfaces by M. Necessary precondition for st.1 is free valencies propagation on PCC particles' surfaces what is possible only after the beginning of dislocations motion on PCC surface during grinding. That is the reason of namely *mechanochemical* character of RA and impossibility of LWB obtaining by intimate component mixing. Analysis with help of microstamp contact mechanism of fine fraction formation during cement grinding (Ioudovitch et al., 1981) testifies that initial sp.surface level of dislocation motion and simultaneously minimal level for the RA beginning is 300-330 m^2/kg and real LWB cannot have sp.surface lower than 380-400 m^2/kg. But during the grinding to this min. sp.surface only small quantity of M can take part in RA. To prevent free M residue in LWB and IE $\Rightarrow$ PE the *conformity between M quantity in LWB* (with known M reactivity in relation to given PCC) *and sp. surface of LWB must be maintained.* That is the *third condition* of LWB production. Constancy of PCC and M quality and rational approach to mill charge and working regimen are necessary for obtaining LWB. If on the st.5 said conformity was achieved *LWB* obtained *can be keeping any time* in sacks or in silo *without losses of hydraulic activity* and for 6 months - without losses even early strength too independently of sp.surface values. This is *fourth* and the last *condition* of high quality LWB production. It is based on coordination compounds effect: hydrophobization of external active zones of LWB particles is the result of blockade of potential layers over their surfaces (from this layers water vapour molecules can be attracted to surface in Polanyi adsorbtion theory sense) by organic molecules whose passivity to water vapour in atmosphere explains by electron transition (as in coordination compounds) from external organic surface to

internal chemisorption contacts (RA zones) between M and PCC. Thus LWB hydrophobization is achieved without addition of hydrophobic matter proper that is very important for cement with such high fineness level as LWB.

M itself acc. st.5 can change under the influence of grinding attacks - depolymerize or polymerize if at the early stage of comminution it ``hide itself`` from grinding attacks into the inside of the clinker surface layer, or if it ``flew`` under the action of aspiration through the whole mill without alterations. The second variant is undesirable - this is one of the ways to leave the free M. In the rest cases modifier particles, while undergoing plastic deformations in the grinding process, predominantly shear deformations, apparently are also ``incrusted`` by calcium cations passing into the M from the calcium-enriched dislocation zones of the surface of clinker particles, in which calcium is known to be superstoichiometric (Tarnarutsky, 1977). This fact is diminish the strictness of demands to cation composition of water lowering organic constituent of M. In general, one would think all such conditions are too strict and LWB production is too much complicated process. Really it is not so - all these peculiarities demands knowledge of, careful preparation of all stages of cement technological process and then only habit of the personnel.

ABOUT THE IE FOR INDIVIDUAL MINERALS AND DIFFERENT CLINKERS

The participation of individual clinker minerals and different PCC in the interaction processes with the modifier and the peculiarities of the subsequent hydration and hardening are displayed in Table 1.

Table 1 Interaction of components and clinkers during intergrinding with M and hydration[1] (av. data)

Interaction of minerals and PCC + M	Minerals of PCC				PC clinkers

[2]Free M being absent. [3]With the mixing water. [4]At constant flowability.

ABOUT THE TECHNICAL PROPERTIES OF LWB

Water requirement of equally flowable fresh mortar and concrete (and, in general, of identical consistency, irrespective of the method of its measurement) reduced by 25 to 40%.
Water content of the major hydrated phases lowered in about the same degree, with the exception of portlandite whose amount in the hardened LWB paste is insignificant, but the amorphous $Ca(OH)_2$ content is fairly high, though lower than in the hardened HPC paste.
Strength of both neat (pure-clinker) LWB and LWB with mineral additions (Table 2) is higher, on the whole; this enabling the specific consumption of aggregates (SCA) by the binders (in the project of new Russian standard they have named ``cements of low water demand``) in concrete to be increased

in an unprecedent manner for an inorganic binder and, accordingly, the clinker consumption per 1 m^3 of concrete and per 1 MPa of strenght as well as specific energy inputs per 1 m^3 of concrete to be brought down to an extraordinary low level. Said Russian standard foresees variable W/C to LWB.

Table 2 Strength characteristic of LWB etc. in mortars (by new Russian std.) and in concretes

Cement type	Sp.surface, m^2/kg	Cement composition, wt.%			Modifier=Na-naphtalensul-	Mortar stren. on Russ. std.[2]			Concrete str (sl.3-4 cm)[4]

LWB (comp.Eu.Type V/A)	470	50	25	25	ditto	23	77	59	30	76	51
LWB (comp.Eu.Type V/B)	550	30	35	35	ditto	17	67	48	22	44	36

[1])Quartz. [2])Sp.4x4x16 cm. [3])Std curing (h): 2+3+6(85°C)+3. [4])Cement consumption 375 kg/m^3, sp. 15^3 cm.

Modulus of elasticity lowered by 5-15% versus reference cement of the same mineralogical and material composition in concretes of identical composition.
Lowered exotermicity.
Frost resistance (expressed as the number of freezing/thawing cycles withstood by concrete without noticeable loss of strength) enhanced by a factor of 2 to 3.
High sulphate resistance, with which the corrosion stability of LWBs made of clinker with 9% C_3A is not inferior to the parameters of sulphate resisting PC (GOST 22266) holding no C_3A at all.

CONCLUSION

F. L.Wright maxim ``Each material speaks its own language with us`` is more than true for LWB. The LWB language is unusual for the time being. No wonder too: the SCA difference between OPC and LWB (max. 13 vs. max 27) is so great that it enables to regard LWBs as a new generation of binders. As almost all binders can be produced in the form of LWBs this is a new generation not only for PC, but also of lime, gypsum, slag cements and others. If the expensiveness of M will be lowered, in the XXI century many binders will prevail exactly in the form of LWB.

ACKNOWLEDGEMENTS

Authors are grateful to all former colleagues and among them especially to Ph.D. G.M.Tarnarutsky and Dr. Enrique F. Molina for their valuable contribution to this work.

ABSTRACT Hardening accelerators based on calcium-aluminate glass with different CaO-Al_2O_3 molar ratios were added to cement, and the behavior of setting and strength, amount of hydration product and ion concentration in the solution were measured. It is shown that a higher CaO-Al_2O_3 molar ratio of calcium-aluminate glass, the mortars came to final setting faster, but strength in the early stages was lower. These characteristics were significantly connected with the formation of ettringite and aluminum-rich gelatinous hydrated product.

Key -words: Accelerators, Calucium aluminate, Ettringite, Gel, Pore solution

INTRODUCTION

For the purpose of improving the efficiency of emergency repair work and shotcrete for tunnel excavation, the use of some kind of admixture to accelerate the hardening of cement is required. For this purpose, $12CaO{\cdot}7Al_2O_3$, $11CaO{\cdot}7Al_2O_3{\cdot}CaF_2$, $3CaO{\cdot}3Al_2O_3{\cdot}CaSO_4$ and some amorphous materials of similar chemical composition to those minerals are popular as quick-setting or rapid-hardening materials. In particular, calcium-aluminate glass (hereinafter referred to as C-A glass), with a CaO-Al_2O_3 molar ratio of approximately 12:7, hydrates more rapidly than the other materials mentioned above (Nakagawa et al, 1990) and is utilized as the main ingredient in quick-setting agents for shotcrete and hardening accelerators for concrete. Alkali carbonates are also effective in promoting the hydration of cement. A quick-setting agent for shotcrete made from C-A glass and sodium carbonate has been developed in Japan (Hirose & Yamazaki, 1993). But there are few papers concerning the relationship between hydration and the hardening properties of these accelerators.

Therefore, for this study, samples of C-A glass of different CaO-Al_2O_3 molar ratios were prepared. Hardening accelerators were made experimentally from these glasses, plus anhydrite and sodium carbonate. Setting, strength, amount of hydrate product and concentration of ions in the extracted solution were measured to investigate the influence of C-A glass on the properties of cement mixed with accelerator.

EXPERIMENTS

Materials

Calcium-aluminate glass: Three samples of C-A glass were prepared, that is, glass of intermediate composition between $CaO{\cdot}Al_2O_3$ and $12CaO{\cdot}7Al_2O_3$ (hereinafter referred to as C-A glass L), of equivalent composition to $12CaO{\cdot}7Al_2O_3$ (C-A glass M) and of intermediate composition between $12CaO{\cdot}7Al_2O_3$ and $3CaO{\cdot}Al_2O_3$ (C-A glass H).

Each mixture was melted in an electric furnace at about 1750℃. The molten material was quenched using a twin-roller quenching apparatus made of stainless steel.

Cement: Ordinary Portland cement was used. Table 1 shows the results of chemical analysis of the cement.

Table 1 Results of chemical analysis of the ordinary Portland cement(mass%).

ig.loss	insol.	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	Na_2O	K_2O	Total
1.2	0.2	21.1	4.5	2.7	64.3	1.6	2.4	0.38	0.46	98.8

Anhydrite: Commercially available anhydrite was used. Specific surface area measured by Blaine's method was 390 m^2/kg.

Sodium carbonate: Commercially available sodium carbonate was used.

Preparation of accelerator

C-A glass clinker was ground to 500±10 m^2/kg as Blaine's specific surface area. C-A glass, anhydrite and sodium carbonate were mixed in the proportion of 45:45:10 by mass to prepare the accelerators.

Mix design and preparation method of paste and mortar

The proportion of cement and accelerator was fixed at 90:10 by mass. The water-cement ratio for mortar and paste was 0.5:1, and the sand-cement ratio was 3:1. The sand used was prepared from three kinds of natural silica sand, with particle diameter of approximately 0.15-2.23 mm. Citric acid was added to maintain workability of the paste and mortar as a retarder at the rate of 0.25 mass% to the total amount of cement and accelerator.

Preparation of paste and mortar was carried out according to the flowchart shown in Fig.1. Preparation and curing of samples were done at 20℃.

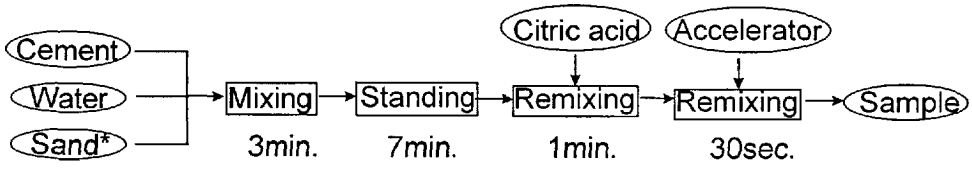

Fig.1 Flow-chart to prepare paste or mortar samples.
*:not mixed when preparing paste sample.

Method

Analysis of the C-A glass: The chemical composition of the C-A glass was measured by X-ray fluorescent analysis. The heat of crystallization of the C-A glass was measured by DSC.

Setting and strength: The hardening properties were measured from final setting time measured by Procter's penetration method. Development of compressive strength was measured using 4×4×16 cm mortar prisms.

Analysis of hydration products: DSC, quantitative X-ray analysis and loss on ignition were determined using paste samples. Hydration of the samples for test was stopped by soaking in acetone to remove excess water.

Pore size Distribution: Pore size distribution was measured by Mercury intrusion porosimetry, using the same sample as mentioned above.

Concentration of ions in the extracted solution: Suspension was extracted from paste sample at particular times by suction or pressing, and filtered with a 0.45 μm mesh to remove fine

particles. A small quantity of hydrochloric acid was added to the solution to adjust pH to about 4, and the concentration of ions was measured. Ca^{2+} and Al^{3+} were measured by ICP, Na^{+} and K^{+} by atomic absorption analysis, SO_4^{2-} by ion chromatography and OH^{-} by neutralization analysis.

RESULTS AND DISCUSSION

Characteristics of the C-A glass

Table 2 shows the results of chemical analysis and $CaO\text{-}Al_2O_3$ molar ratio calculated from the results. Figure 2 shows the relationship between $CaO\text{-}Al_2O_3$ molar ratio and heat of crystallization.

It is observed that the heat of crystallization was highest for C-A glass with a $CaO\text{-}Al_2O_3$ molar ratio of 1.70.

Table 2 Results of chemical analysis of the calcium-aluminate glass.

Sample	Chemical compositions(mass%)				CaO/Al_2O_3
	CaO	Al_2O_3	SiO_2	Total	(molar ratio)
C-A glass L	41.0	53.0	48	98.8	1.41
C-A glass M	45.5	48.7	48	99.0	1.70
C-A glass H	52.2	42.0	49	99.1	2.27

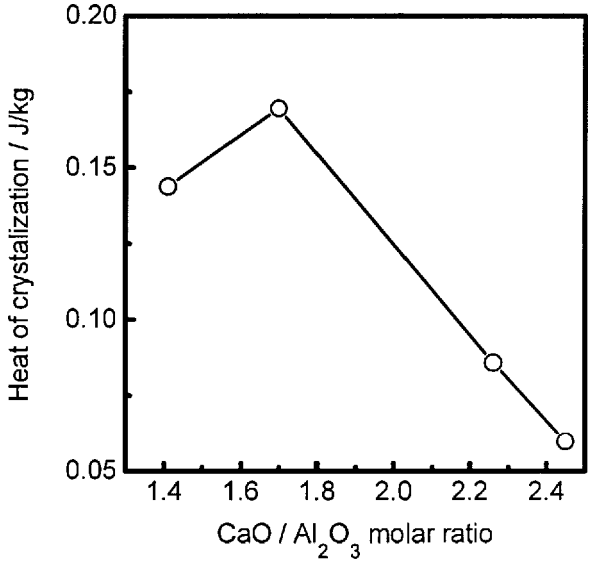

Fig.2 Relationship between heat of crystallization and CaO/Al_2O_3 molar ratio of C-A glass.

Hardening and development of strength

Figure 3 shows the relationship between time of final setting of mortar and $CaO\text{-}Al_2O_3$ molar ratio of the C-A glass.

The time of final setting was shorter with increased $CaO\text{-}Al_2O_3$ molar ratio. According to this result, it appears that the behavior of rapid hardening caused by accelerator consisting of C-A glass was mainly a function of the $CaO\text{-}Al_2O_3$ molar ratio, and is little affected by the heat of crystallization.

Figure 4 shows the compressive strength of the mortar.

At 3 hours and 6 hours, the strength when using C-A glass H, for which $CaO\text{-}Al_2O_3$ molar ratio

was highest, was lower than when using C-A glass L or M, for which $CaO\text{-}Al_2O_3$ molar ratio was lower. The strength at 24 hours when using C-A glass M, for which $CaO\text{-}Al_2O_3$ molar ratio was similar to $12CaO{\cdot}7Al_2O_3$, was a little higher than in the other cases. Later the influence of C-A glass on strength was negligible.

Nakagawa (1990) studied the strength development of cement mixed with C-A glass and anhydrite, and showed that the hydration of Alite in cement was retarded and that the strength in the early ages was suppressed when the $CaO\text{-}Al_2O_3$ molar ratio of the C-A glass was lower than 12:7. He suggested that alumina-gel or other kinds of aluminum-rich gelatinous hydrate product were formed on the surface of cement particles and suppressed their hydration. However, in our study using also sodium carbonate as a component of the accelerator, the results were different from those described in Nakagawa's paper, and strength increased as $CaO\text{-}Al_2O_3$ molar ratio decreased.

One reason for this difference was thought to be that the pH of the interstitial solution was raised by sodium carbonate and that the formation of gelatinous hydration product was suppressed, and the other presumed reason was that the suppression of hydration caused by gelatinous hydration product was diminished as sodium carbonate accelerated the hydration of cement. And from this study, it is suggested that gelatinous hydration product would contribute to the development of strength if formed.

On the other hand, as the hydration of cement progressed and the structure of cement hardened itself was formed after 24 hours, it is observed that the influence of the C-A glass on strength was small [Fig.4].

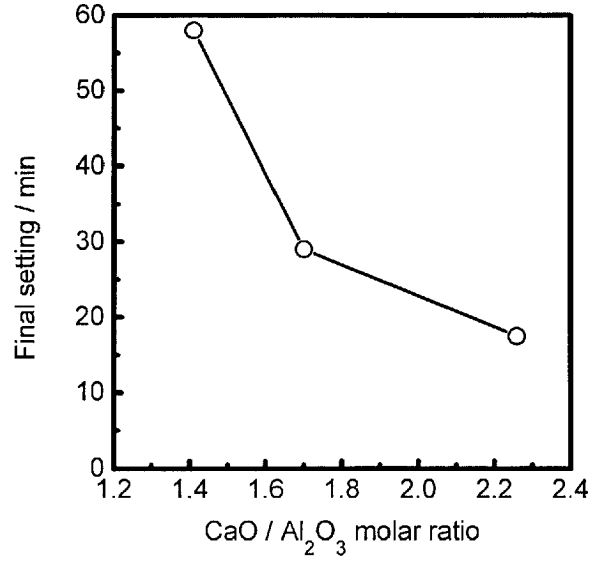

Fig.3 Relationship between time of final setting of mortar and CaO/Al_2O_3 molar ratio of C-A glass.

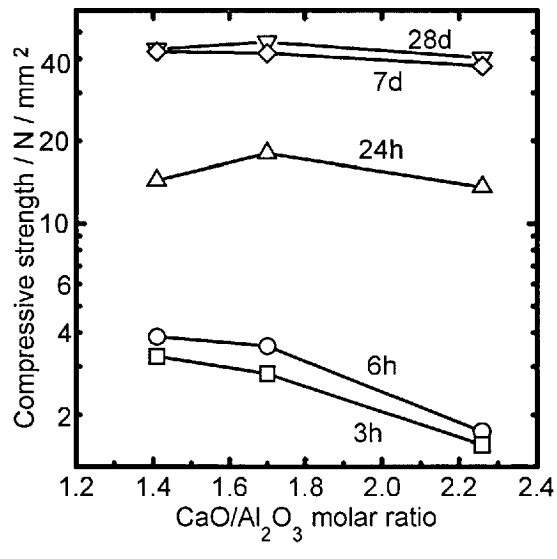

Fig.4 Relationship between compressive strength of mortar and CaO/Al_2O_3 molar ratio of C-A glass.

Change of hydratation products

Figures 5 and 6 show the change in the amount of ettringite and loss on ignition, respectively. Monosulfate and calcium hydroxide were detected after 6 hours by XRD, but quantitative analysis could not be carried out, as the quantities were too small. Further calcium carbonate could not be verified by XRD, because the main peak overlapped with Alite peak.

The hydration rate of cement was measured by quantitative XRD analysis, and it was concluded that the influence of variation of C-A glass on the hydration rate of cement was small, as there

was little diffrence in the decreasing tendency of Alite peak between samples within 6 hours. In the early stages, the amount of ettringite and loss on ignition increased faster when the CaO-Al_2O_3 molar ratio of C-A glass was higher. The increase in loss on ignition at an early stage was mainly attributed to the formation of ettringite. Subsequently, the amount of ettringite increased gradually after reaching about 10 % by mass, and the difference amongst the various C-A glasses became smaller at later stages. On the other hand, loss on ignition increased with time, while the rapid increase of amount of ettringite had stopped. The tendency towards an increase in loss on ignition was different with the C-A glasses tested; i.e., amount of Ettringite began to increase earlier when using C-A glass H than when using C-A glass L or M, but loss on ignition at 3 hours and 6 hours was less when using C-A glass H than when using C-A glass L or M. It is thought that there is excess of Al_2O_3 when ettringirte forms from C-A glass whose CaO-Al_2O_3 molar ratio is low. Material balance was calculated, assuming that same amount of ettringite formed from C-A glass L (CaO-Al_2O_3 molar ratio of 1.41) or C-A glass H (CaO-Al_2O_3 molar ratio of 2.26). For convenience sake, it was assumed that no Al_2O_3 remains when using C-A glass H.

C-A glass L: 1.00 g + CaO:0.28 g + $CaSO_4$:1.68 g → Ettringite: 5.16 g + Al_2O_3:0.11 g
C-A glass H: 1.00 g + CaO:0.17 g + $CaSO_4$:1.68 g → Ettringite: 5.16 g

As calculated above, 0.1 g of Al_2O_3 per 1 g of C-A glass is in excess when the CaO-Al_2O_3 molar ratio is 1.41, compared with when the CaO-Al_2O_3 molar ratio is 2.26. From these calculations, it is thought that the difference in loss on ignition at 3 hours or 6 hours referred to the fact that accelerator consisting of C-A glass L or M produced more aluminum-rich gelatinous hydration product than did C-A glass H, and that the gelatinous hydration product retained greater water content.

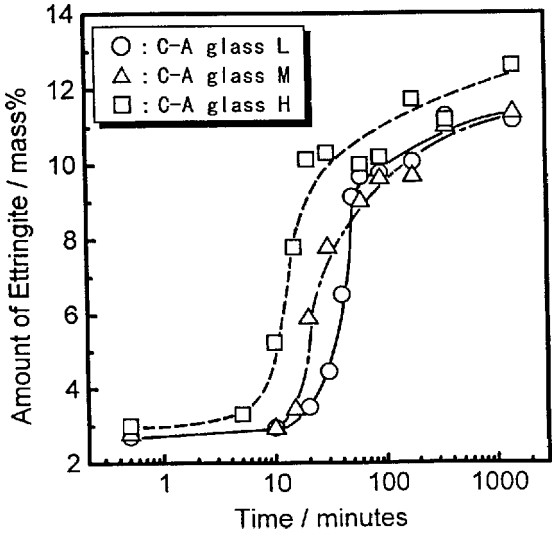

Fig.5 Changes in the amount of ettringite formed in the cement paste mixed with accelerator.

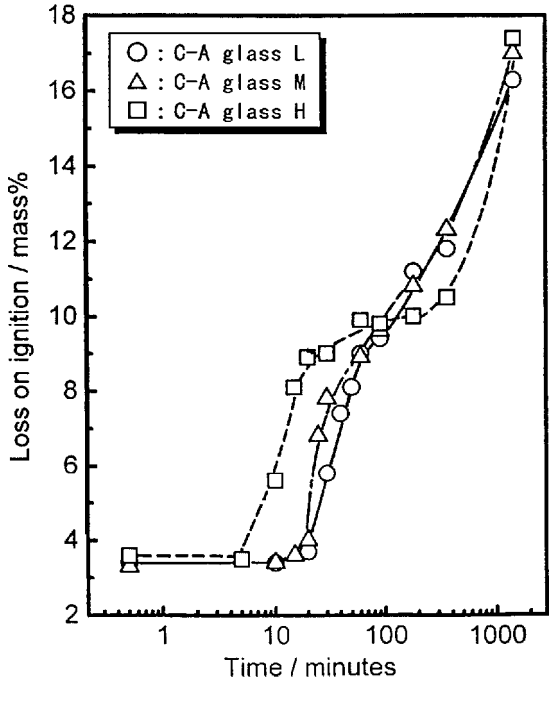

Fig.6 Changes in the loss on ignition of the cement paste mixed with accelerator.

According to the observations made, changes in hydration products relative to the properties of

mortar; the faster the increase in the amount of ettringite, the more rapidly mortar containing accelerator hardened. That is, the behavior of rapid hardening of mortar mixed with the accelerator is attributed to the formation of ettringite. On the other hand, the strength of such mortar at 3 hours or 6 hours was related to loss on ignition. It was mentioned before that for variation in $CaO-Al_2O_3$ molar ratio there was no obvious difference in the decrease in the unhydrated Alite peak by XRD at 3 hours or 6 hours, but there was obvious defference in loss on igniton. That is, a greater amount of some kind of aluminum-rich gelatinous hydration product formation, and this contributes to development of strength when using C-A glass with a lower $CaO-Al_2O_3$ molar ratio.

Change in the pore size distribution

Figure 7 shows the pore size distribution of hardened paste mixed with the accelerator.

There was little difference in total pore volume at each age, even if the $CaO-Al_2O_3$ molar ratio of the C-A glass varied. And the difference between pore volume at three hours and six hours was negligible amongst the various formulations of C-A glass.

Comparing pore size, there was a greater amount of large pores (1.0-10 μm) in the sample using C-A glass H. It is suggested that it was the reason that the strength of mortar using C-A glass H was lower than those using other C-A glasses at 3 hours and 6 hours. At 24 hours, the amount of the large pores decreased, and there was little difference in the amount of large pores amongst the hardened pastes using different formulations of C-A glass.

It is suggested that these results were obtained by the formation of aluminum-rich gelatinous hydration products; i.e., more gelatinous hydration product formed and filled in the pores of the hardened structure when the $CaO-Al_2O_3$ molar ratio was lower, but when the $CaO-Al_2O_3$ molar ration was higher, less gelatinous hydration products were formed, because there was less excess of Al_2O_3.

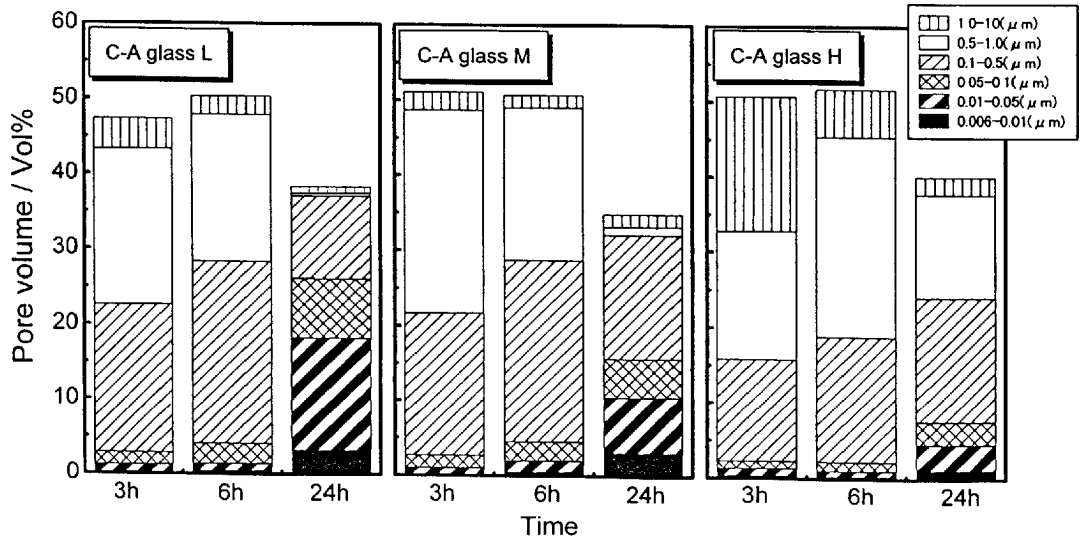

Fig.7 Pore size distributions of hardened cement mixed with accelerator.

Change in the concentration of ions in the solution

Figure 8 shows the changes in the concentration of ions in the solution extracted from paste samples.

While the change in the concentration of ions in plane cement paste was small, in the paste

mixed with accelerator, they varied significantly, regardless of the $CaO-Al_2O_3$ molar ratio of C-A glass.

Considering the relationship between the changes in concentration of ions and the properties of mortar, the time of final setting of mortar corresponded closely with the time when Al^{3+} increased temporarily and decreased subsequently, and Ca^{2+} and SO_4^{2-} decreased.

The concentration of each ion in the solution is an indication of balance between the amount dissolved from cement plus accelerator and the amount consumed to form hydration product. Therefore it is thought that Ca^{2+} and SO_4^{2-} were consumed and their concentration fell, while excess Al^{3+} remained in the solution, with respect to the dissolution of C-A glass and anhydrite and the formation of ettringite.

Noticing the accelerator, Al^{3+} increased to highest level and took the most time to fall when using C-A glass L for which the $CaO-Al_2O_3$ molar ratio was lowest. On the other hand, when using C-A glass M or H for which the $CaO-Al_2O_3$ molar ratio was higher, Al^{3+} changed at a lower level and was consumed rapidly. It is thought that, as the proportion of Al_2O_3 in C-A glass L was higher and the rate of formation of ettringite was lower than those in other formulations of C-A glass, as shown in Fig. 5, the concentration of Al^{3+} reached a high level temporarily. As the amount of ettringite and loss on ignition increased when the concentration of Al^{3+} changed significantly, as shown in Fig. 5 and 6, it is thought that Al^{3+} was consumed to form not only ettringite but also some kind of aluminum-rich gelatinous hydration product. As the $CaO-Al_2O_3$ molar ratio decreased, excess of Al^{3+} was dissolved and the amount of gelatinous hydration product increased.

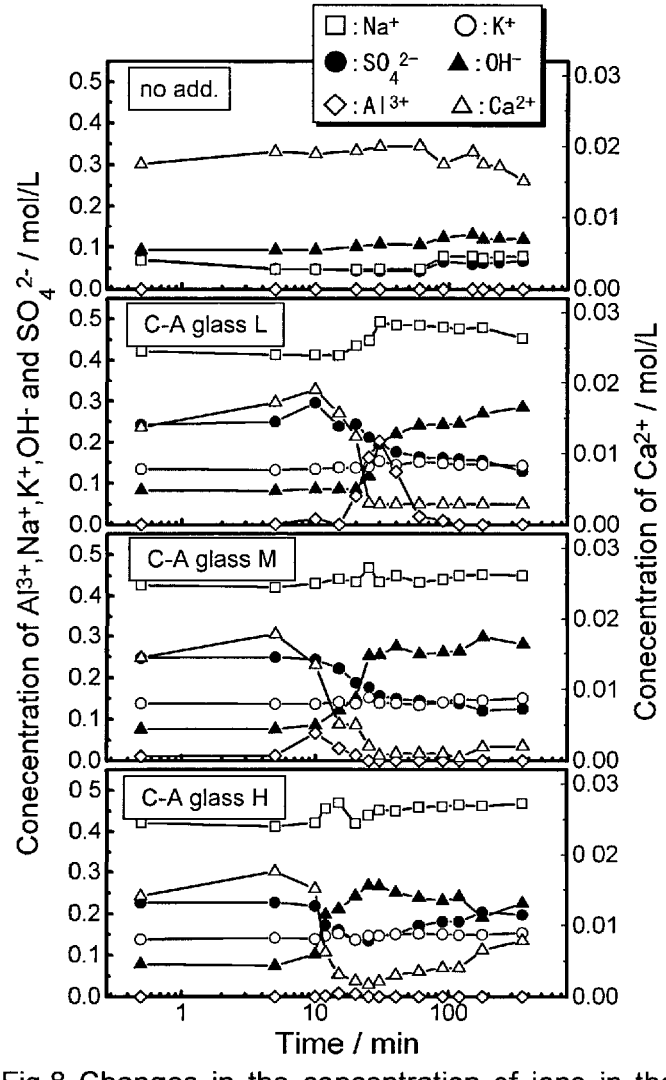

Fig.8 Changes in the concentration of ions in the solution extracted from the cement paste mixed with accelerator.

CONCLUSIONS

Rapid hardening of mortar mixed with accelerator based on calcium-aluminate glass is controlled by the $CaO-Al_2O_3$ molar ratio of calcium-aluminate glass, and the higher the ratio, the more rapidly the mortar hardens. This is caused by ettringite formed from the reaction of calcium-aluminate glass and anhydrite.

The concentration of ions in solution changes significantly when mortar mixed with accelerator hardens rapidly. Beginning with the rapid formation of ettringite, Ca^{2+} and SO_4^{2-} are consumed, and the concentration decreases, while excess Al^{3+} remains temporarily in the solution and is

consumed to form some kind of aluminum-rich gelatinous hydration product.

The compressive strength of mortar at 3 hours and 6 hours is higher when the CaO-Al_2O_3 molar ratio of C-A glass is lower than when the ratio is higher. On the basis of these results, it is suggested that gelatinous hydration products form from the excess of Al^{3+} and contribute to the development of strength when sodium carbonate is a component of accelerator based on calcium-aluminate glass.

ABSTRACT The use of chemical admixtures reacting with cement matrix is considered to improve concrete durability. In the paper the effect of methylosilicone resin solution on cement pastes properties is presented. The rheology, setting time, heat of hydration and porosity of cement pastes made from different types of cement have been investigated. Depending on admixture content very differentiated influence on cement pastes was observed.

Key-words: modified cement, admixtures, setting, porosity

INTRODUCTION

The traditional cement mortars and concretes have properties limiting their application to special constructions, where enhanced durability is required. The main requirements on high performance concrete include mechanical strength, resistance to frost, abrasion properties and resistance to chemical aggression. Designs and construction methods of very durable buildings are realised by maximum densification of concrete structure. Compacting of the concrete structure can be obtained by using various additions. Generally silica fume with superplasticizers are applied. Other additives influencing on rheological properties of concrete mixture and performance properties of concrete are used. In the last decades very considerable progress is observed in research about admixtures and additives to concrete mixes like that; microaggregates, reducers, accelerators, plasticizers, superplasticizers, retarders, air entraining agents and polymer admixtures (Collepardi and Ramachandran, 1992, RILEM, 1995). The least attention has been devoted to the organo-silicone compounds. Effect of organo-silicone compounds in the hardening process of binding material has been the subject of publications in professional literature: Manżurnet et al (1963), Alentjev et al (1965), Artemenko (1989), Domin et al (1995). Nevertheless the problem has not yet been fully recognized. This article presents the effect of resin admixture on the properties of cement pastes. Additive of methylosilicone resin solution was used. The experimental research carried out has been concentrated particularly on the rheological properties.

EXPERIMENTS

The following three types of cement were used for the experiments: Portland cements CEM I 42.5 and CEM I 32.5, which have similar phase compositions but different specific surfaces. Blastfurnace slag cement CEM III/A 32.5 and pozzolanic cement CEM IV/A 32.5 were also investigated. The properties of the cements are represented in **Table 1**.

A 20% solution of methylosilicone resin in potash lye with density 1.27±0.02 g/cm^3 was used as the modifier. It was mixed with water and added into the pastes in appropriate quantities corresponding to the mass of the cement. The resin solution addition to cement paste was ranged from very low quantity of 0.05% up to very large concentration of 5% by mass.

The rheology of pastes, their setting times, kinetics of hydration, porosity of hardened pastes and water requirement of cements was investigated.

Table 1 Properties of cements

Composition	Type of cement			
	CEM I 42.5	CEM I 32.5	CEM III/A	CEM IV/A

C_4AF	5.7	6.3		
Physical properties of cement				
Specific surface area (Blaine) (cm^2/g)	4500	3200	3200	3900

The relation between the apparent viscosity and organosilicone compound content in cement pastes was determined by means of a rotational viscometer. Apparent viscosity was estimated for cement pastes at a constant w/c ratio of 0.5 and 0.4 at a shear rate of $27s^{-1}$. Cement pastes for viscosity determination were mixed during 5 minutes.

Investigations of the physical properties of the cement pastes were conducted in accordance with the European Standard EN 196 series. The initial and final setting time was determined for cement pastes at normal consistency.

The heat of cement hydration was determined using semi-adiabatic calorimetry in compliance with pr. EN 196-8.

The porosity of the tested pastes was determined by the mercury porosimeter method, using a high-pressure measurement to estimate pores size in a diameter range from 3.7 to 6300 nm, and measurement at a low pressure for the 6300 - 53600 nm diameter range. Determination of the pores size distribution was carried out for paste samples with and without resin admixture at normal consistency. The porosity of the cement paste was determined for samples after 3, 7 and 28 days of curing at standard conditions.

RESULTS AND DISCUSSION OF EXPERIMENTS

Viscosity

The apparent viscosity of the cement pastes is presented in **Fig 1**. Investigations of the fresh pastes showed that methylosilicone resin solution influenced the rheology of the cement pastes depending on the type of cement, w/c ratio and resin additive concentration. Adding of resin up

to 0.1% did not change significantly the viscosity of pastes regardless of the cement types and w/c ratio. Further increase in the amount of resin added brought about a variety of effects on the paste rheology depending on the cement types. For resin concentration over 0.2% the apparent viscosity of the Portland cement CEM I 42.5 at w/c ratio 0.4 and 0.5 started to increase rapidly. The behaviour of Portland cement CEM I 32.5 was observed to be quite different. For w/c ratio of 0.5 and 0.4 increments of the resin concentration up to 2% caused a constant decreasing of cement paste viscosity (Fig 1).

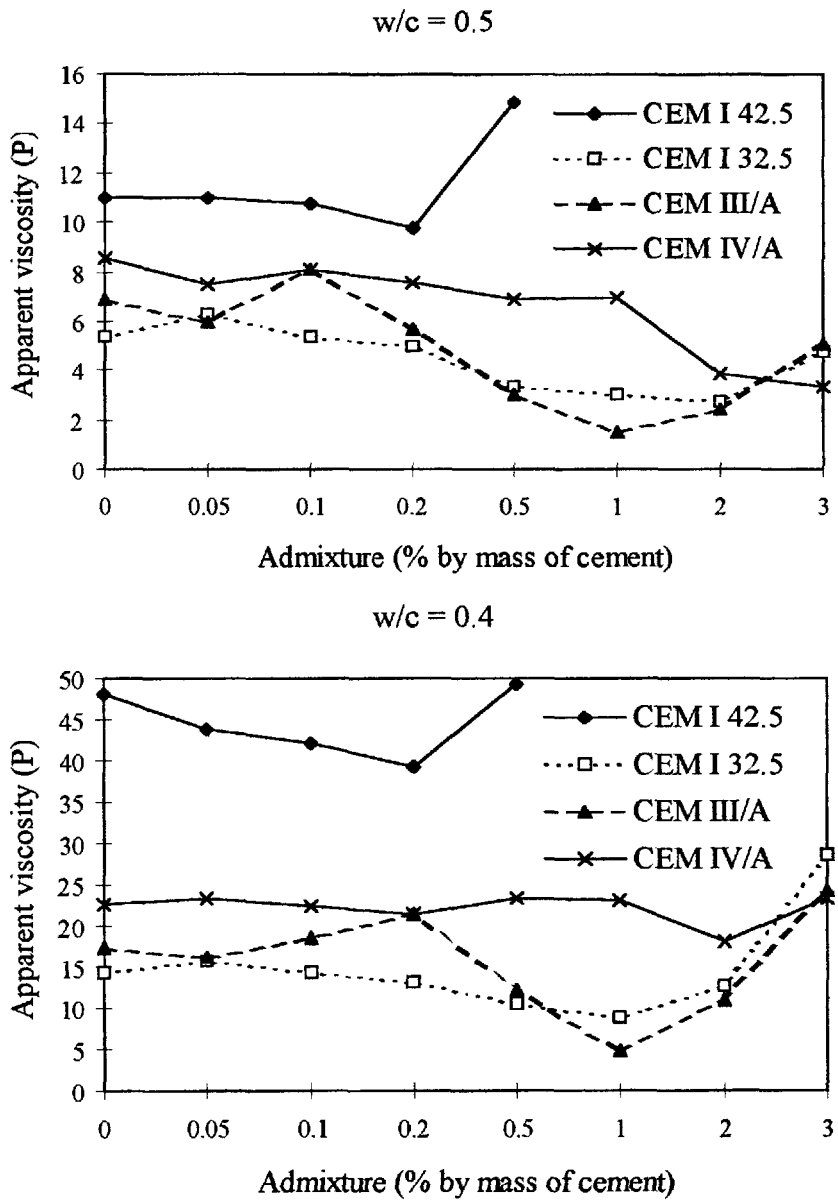

Figure 1 Effect of admixture on viscosity of the cement paste at shear rate 27 s^{-1}

Effect of methylosilicone resin solution on change of paste viscosity for blastfurnace slag cement CEM III/A is similar at both w/c ratio. In this case there was observed strong reducing of cement paste viscosity at 1% resin admixture. The least influence of admixture on paste viscosity was observed for the pozzolanic cement CEM IV/A irrespective of w/c ratio. For all range of the resin concentration the viscosity of pozzolanic cement appeared to be about the same value.

Water demand

The results of water demand tests are presented in **Table 2**. It can be seen that amounts of the methylosilicone resin solution of up to 0.5% in the cement lowered the water demand by approximately 5% for OPC CEM 32.5 and 2% for CEM I 42.5 and CEM III/A. For Portland and blastfurnace cements more than 0.5% admixture caused rapid increasing of cement water demand. It is interesting that no influence of admixture on water demand was observed for pozzolanic cement practically for total range of additive concentration in cement paste.

Table 2 Cement water demand

Quantity of admixture (% by mass of cement)	Water demand (% by mass)			
	CEM I 42.5	CEM I 32.5	CEM III/A	CEM IV/A
0	27.5	27.0	27.0	31.5
0.05	26.0	27.0	27.0	31.5
0.1	26.5	26.0	25.0	31.0
0.2	25.5	24.0	25.0	31.0
0.5	26.5	21.5	25.0	31.5
1	28.0	22.5	25.5	31.5
2	29.0	28.0	26.0	31.5
3	33.0	28.5	27,5	31.5
5	44.0	29.0	28.0	33.0

The test results of the cement water demand determination explain very well changes in the rheological properties of the pastes searched as the influence of the admixture on paste viscosity. As could be presumed the changes of the cement water demand caused by resin admixture influenced on the fluidity and therefore apparent viscosity of cement paste.

Setting time

Effect of the organo-silicone resin admixture on setting time of cement is shown in **Fig 2 and 2a**. The resin solution addition was found as a strong retarder of the initial and final setting time for OPC and blastfurnace slag cements. That retardation effect was accelerated when resin concentration was increased but only up to some limit. After this limit concentration accelerating effect of setting time was observed. That correlation was stated for all types of cements investigated. The highest changes of the setting time was stated for paste made from pozzolanic cement.

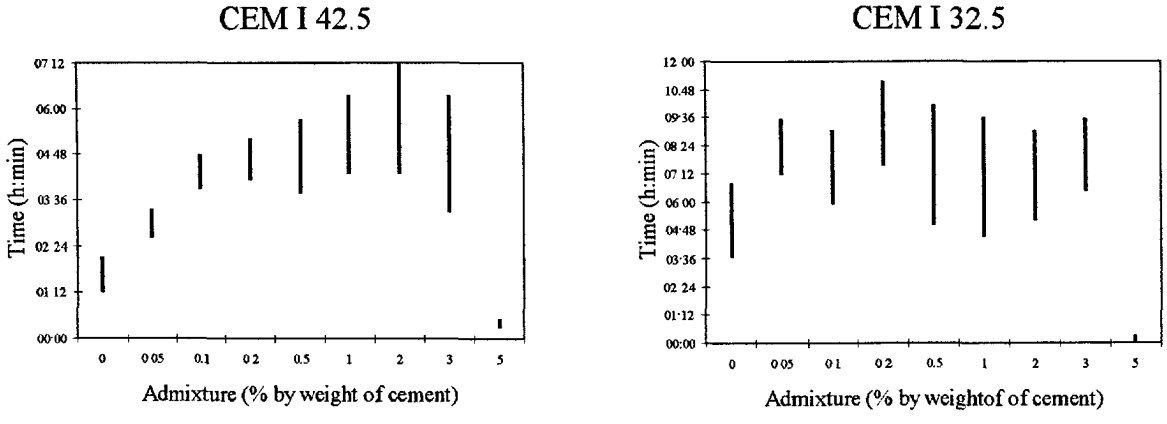

Figure 2 Effect of admixture on setting time of OPC cements

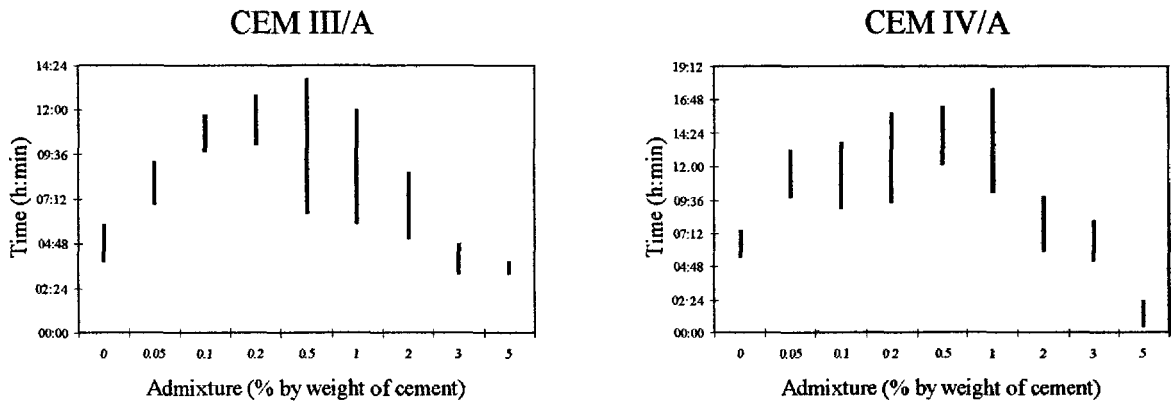

Figure 2a Effect of admixture on setting time of blastfurnace slag and pozzolanic cements

Heat of hydration

OPC, blastfurnace slag cement and pozzolanic cement containing different resin admixture amounts were subjected to tests. The results are shown in **Fig 3, 4 and 5**.

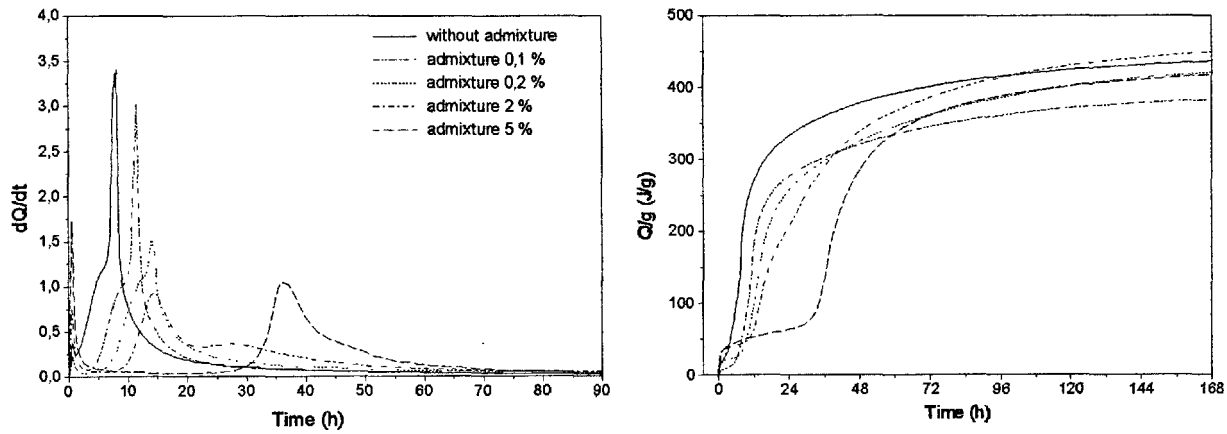

Figure 3 Heat of hydration of OPC CEM I 42.5

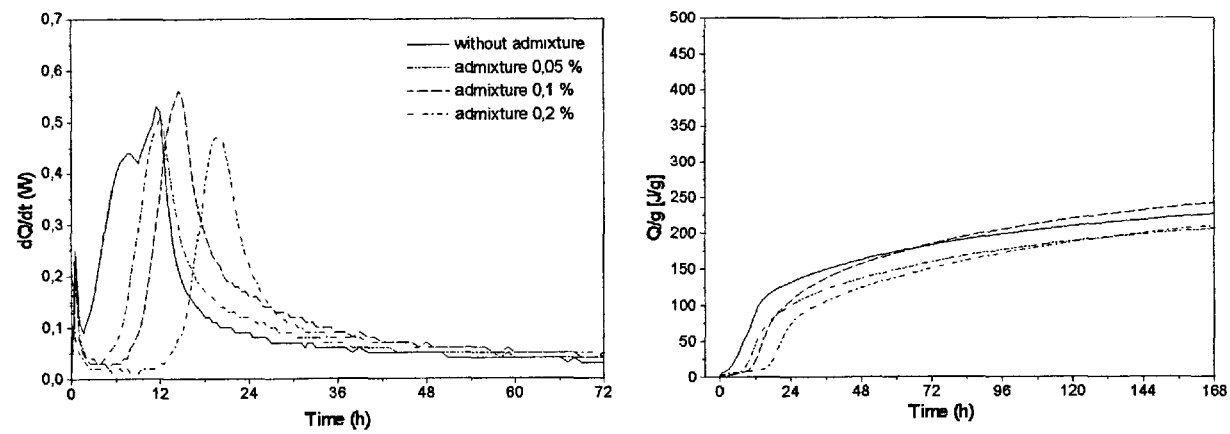

Figure 4 Heat of hydration of blastfurnace slag cement CEM III/A 32.5

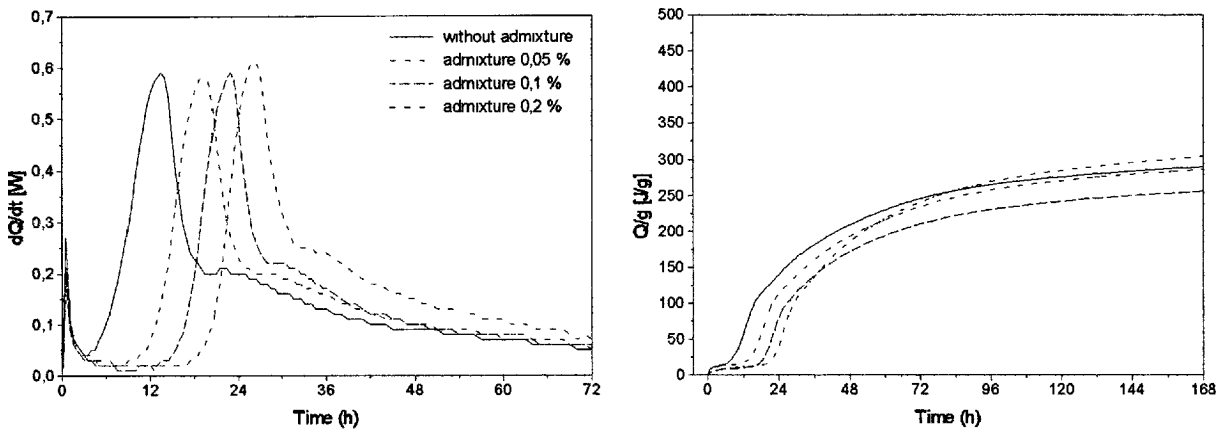

Figure 5 Heat of hydration of pozzolanic cement CEM IV/A 32.5

Analysis of heat of hydration investigations leads to conclusion that the kinetics of cement hydration was clearly influenced by the amount of methylosilicone resin addition. It appeared that heat of hydration value strongly depends on the amount of additive regardless of cement type tested. There was a clear delay effect of the maximum rate of heat emission at low resin addition. In this case a decrease of total heat of hydration value was also observed. Contrary, admixture over 1% was found to increase cement heat of hydration. For blastfurnace slag cement and pozzolanic cement that limit value of admixture addition was 0.1 and 0.2% respectively.

Porosity

The pores size distribution in hardened pastes are shown on **Figs 6, 7 and 8**. Pastes made at normal consistency from Portland cement CEM I 42.5, blastfurnace slag cement CEM III/A 32.5 and pozzolanic cement CEM VI/A 32.5 were investigated.

Analysis of pores size distribution in pastes made from OPC cement shows that the total porosity of the paste with and without admixture decreased with curing time (Figs 6 and 7). However, the pastes with the organo-silicone admixture showed that smaller size pores are predominant. The following conclusions may be drawn from the comparison of the pores size distribution in pastes of OPC cement with and without the methylosilicone resin:

- after 3 and 7 days of curing samples containing the polymer addition up to 0.1% and over 1% were found to increase total porosity. Addition of 0.2 to 1% of polymer was found to decrease the porosity.
- after 28 and 180 days of curing changes of porosity were quite different. In these cases the addition of the organo-silicone compound reduced total porosity in all addition concentrations range. There was a clear shift in the predominant pores size to the lower range of 3.7 - 100 nm. That pore size distribution is considered to guarantee higher tightness and density.

The quite different influence of admixture on pores size distribution in pastes was noticed for blastfurnace slag cement and pozzolanic cement. In comparison to the OPC, blastfurnace slag and pozzolanic cement pastes were found to be more porous (Fig 8). Higher total porosity for blastfurnace slag cement is connected with increasing the number of pores diameter over 100 nm but for pozzolanic cement with increasing porosity in all measuring range.

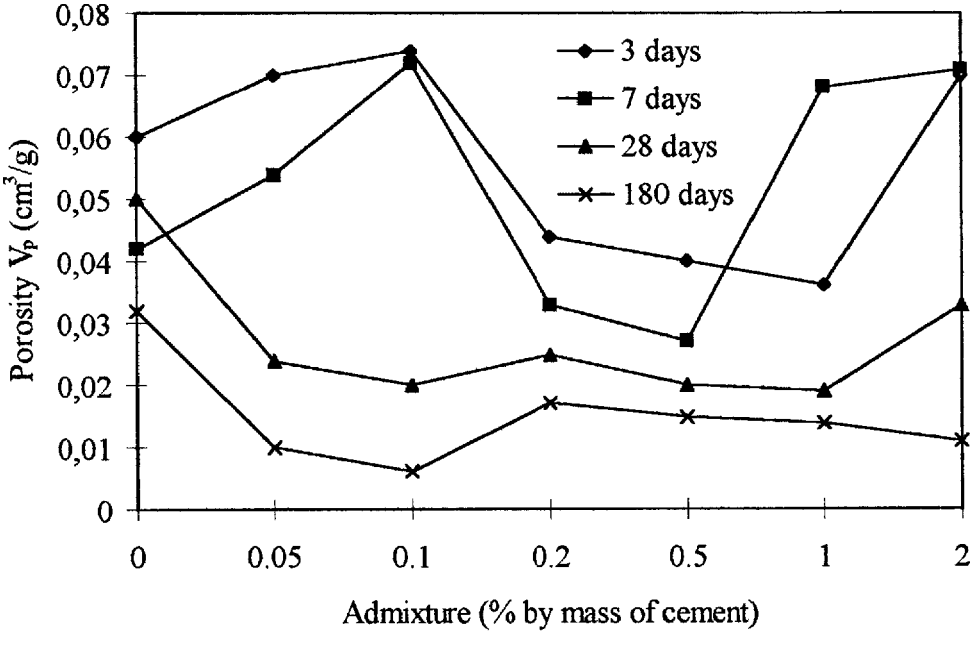

Figure 7 Effect of admixture on total porosity of the cement paste for OPC for different curing time

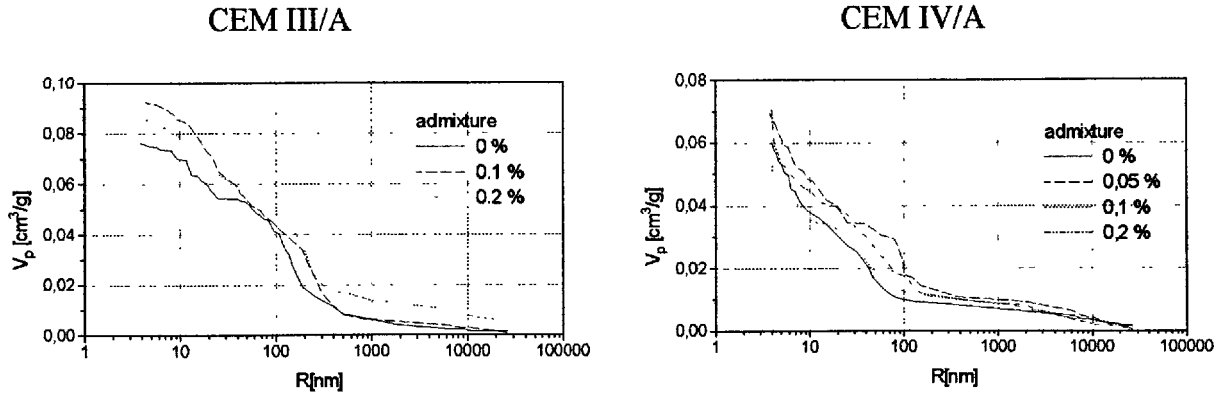

Figure 8 Porosity of cement paste for CEM III/A and CEM IV/A cements

CONCLUSION

The tests conducted to determine the effect of methylosilicone resin admixture on cement paste showed that:

- a silicone resin added to a cement binding material may act either as a plasticizer or as a retarder; the effect depends on the type of cement;
- the addition of up to 0.5% of the admixture contributes the best effect on rheological properties of fresh pastes and also on structure of hardened cement pastes;
- the favourable effect of methylosilicone resin on the porosity structure of cement pastes suggests that it may prove useful in the design and production of high performance concretes HPC.

ABSTRACT Soluble sodium silicates have been used in industry for a wide variety of applications. From detergents to adhesives, and deflocculant aids to corrosion inhibitor, these simply manufactured products have shown great versatility since their initial development in the early 19th century. This paper reviews the use of sodium silicates as cement sealer, integral admixtures for construction, and in specialty formulas for waste disposal.
KEYWORDS: admixtures, concrete, durability

INTRODUCTION

The raw materials for sodium silicate manufacture are soda ash and sand. Heated to 1100-1200°C, the materials fuse and a glass forms upon cooling. This glass is sometimes sold as anhydrous powder that can be dissolved later by the user, or the glass may be dissolved in water at the manufacturing plant. The resulting solution, also known as "water glass," may be sold as it is, or it may be causticized to form more alkaline solutions. Silicate solutions can also be dried to form hydrous powders, or they may be further processed to form hydrous and anhydrous metasilicates. The SiO_2/Na_2O weight ratio of the products typically falls in the range 1.0-5.0, and the liquids typically have an SiO_2 content of 24-36%. Soluble silicates are polymeric materials which are classified by the SiO_2:Na_2O ratio[7]. Diluted in water, the soluble silicates depolymerize to form negatively charged oxygen sites which react with positively charged metal ions in solution to form "metal silicates." These metal silicates are not soluble species but are combined polymeric species, the molecular weight of which varies depending upon pH and ionic strength. Table 1 contains descriptions of the sodium silicates used for this study.

Table 1 - Compositions of sodium silicates used in this study.

ID*	SiO_2/Na_2O wt. ratio	Wt. % water	Comments
N	3.22	62.4	aqueous liquid
D	2.00	55.9	aqueous liquid
OW	3.22	61.4	aqueous liquid with surfactant
SS-65	3.22	-.-	anhydrous powder
G	3.22	18.5	hydrous powder

Sealer

Within the cement and concrete industry, soluble silicates have varied uses. One of the foremost is as a sealant, providing chemical and physical durability to concrete surfaces such as bridges, walls, storage tanks, building blocks, warehouse floors, traffic barriers, slabs, and countertops. The porous nature of the cement matrix and of aggregate/cement interfaces cause such structures to be susceptible to chemical attack by acid or deicing salts and to freeze/thaw damage.

* Supplied by the PQ Corporation, Valley Forge, Pennsylvania USA

Therefore, an effective surface treatment must provide some means of inhibiting the transport of deleterious components.

Among the commercially available concrete sealers, three classes may be defined according to their means of protection. Some sealers are water repellents and include silanes, siloxanes, silicones, and stearates. Others, such as epoxies, polyesters, and vinyls, provide a barrier coating on top of the surface. Those in the third group, which includes aqueous sodium silicates, urethanes, linseed oil, and mineral gums, block pores near and at the surface but do not coat the top of the surface. Lea (1971) reports that sodium silicates have been found useful for protection against aqueous solutions and organic liquids.

The unique feature of the sodium silicate is that it chemically reacts with portlandite to form C-S-H[a] . The presence of CH is detrimental to both the cement's chemical and mechanical durability. CH is water soluble and susceptible to acid attack, and the interfaces around the CH are typically highly porous, thereby increasing permeability while decreasing strength. Penetrating the concrete surface with aqueous sodium silicate, provides the silicate needed to convert CH to C-S-H. As a result, the density and strength increases and the permeability decreases near the surface.

Controlling the penetration depth of the aqueous sodium silicate is critical to its performance as a sealant. On the one hand, the aqueous sodium silicate must penetrate about 3 to 6mm to affect a significant enough volume. However, if the penetration is very deep the aqueous sodium silicate may be too diffuse to be effective. The permeability and moisture content of the substrate are therefore extremely influential in the proper application of an aqueous sodium silicate sealer. Penetration depths may be greater with porous concrete, which would require multiple applications to prevent the aqueous sodium silicate from becoming too diffuse; while a 6mm depth may not be possible with a dense concrete.

Several factors control the penetration depth of aqueous sodium silicate. These include the following: 1) concentration of the aqueous sodium silicate; 2) the moisture content of the substrate; 3) condition of the substrate surface; 4) temperature; 5) mechanical force used during application of the aqueous sodium silicate (e.g., via a high pressure sprayer, brushing, etc.); and 6) presence or absence of wetting agents.

A typical liquid sodium silicate sold for this application would have a SiO_2/Na_2O ratio of ~3, ~30% SiO_2, a density of 1.4g/cc, pH ~11, and viscosity ~180cp. Before using the liquid sodium silicates are typically diluted by 3 parts (on a weight basis). Also, since the moisture content of the concrete is critical, it is best if the aqueous sodium silicate is applied at least four weeks after new concrete is placed. Preparing the surface to be coated is another important factor. For example, preparing a floor for coating includes sweeping, scrubbing with strong cleaning compounds using a scrubbing machine or wire brush to expose the true wearing surface, scrubbing again with soapy water, and then allowing the floor to dry for at least 24 hours depending on the humidity.

---

[a] Typical cement notation us used here, i.e. C=CaO, S=SiO_2, A=Al_2O_3, F=Fe_2O_3, etc.

Absorption is a measurement of a concrete's ability to contain liquid. Absorption is an important property to consider when evaluating the durability of hardened cements and concretes. For instance, Litvan (1992) reported a correlation between absorption and freeze thaw durability of coated concretes. To measure the effect of a surface coating of aqueous silicate, concrete blocks were coated with N and OW silicate in varying weight ratios and were allowed to dry for 24 hours before testing (The OW silicate contains surfactants to improve wetting.). ASTM Standard Method C642-90 was used to test the blocks for absorption.. Concrete specimens were immersed in water for a time not less that 48 hours and until they reached a constant weight. The blocks were then placed into boiling water for 5 hours and weighted again. The voids are calculated from these weights. As shown in Figure 1 the blocks coated with aqueous sodium silicate always absorbed less than the uncoated control. For instance the 3/1 N (silicate/water weight ratio) decreased the water absorption by 30% over the control sample. The 1/1 OW absorbed slightly less water than the 1/1 N suggesting that the surfactant is effecting the penetration of the aqueous sodium silicate into the concrete.

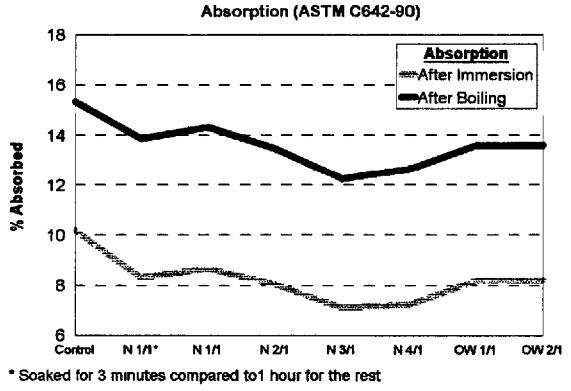

Figure 1 Water Absorption as a Function of Silicate/Water Ratio

Figure 2 shows the percentage voids or degree of porosity of the concrete samples after being coated with aqueous sodium silicate. Again, the 3/1 N sample outperformed the other samples, and showed a 5% decrease in percentage voids over the control. The decrease in percentage voids is directly related to a decrease in permeability and a decrease in the amount of water that can be absorbed. It should be noted that the trend of Figure 2 is the same as the trend in Figure 1. This data suggests that the strength and permeability of the samples will follow the same trend.

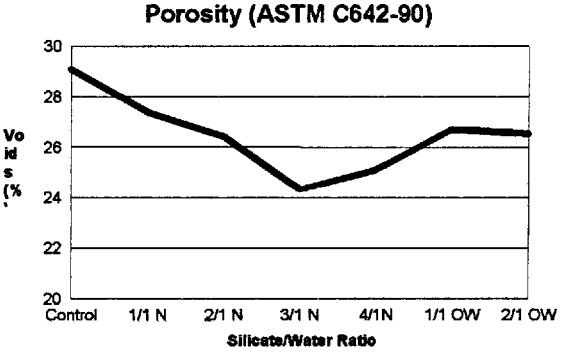

Figure 2 Apparent void space in coated concrete blocks.

The abrasion resistance of coated and uncoated concrete blocks was determined by ASTM Standard Test Method C418. The abrasion coefficient is determined by sand blasting the blocks for one minute and then measuring the volume of concrete removed from the block. A lower abrasion coefficient denotes a more abrasion resistance material. Figure 3 shows that as with the two previous measurements, the 3/1 N coating performed significantly better than the rest. The decrease in abrasion coefficient from the control to the 3/1 N coating is 67%. The other coatings follow the same trend that the percentage absorption and percentage voids data showed. The 1/1 OW has the same abrasion coefficient as the 3/1 N and may be due to the increased degree of penetration achieved with the surfactant in OW.

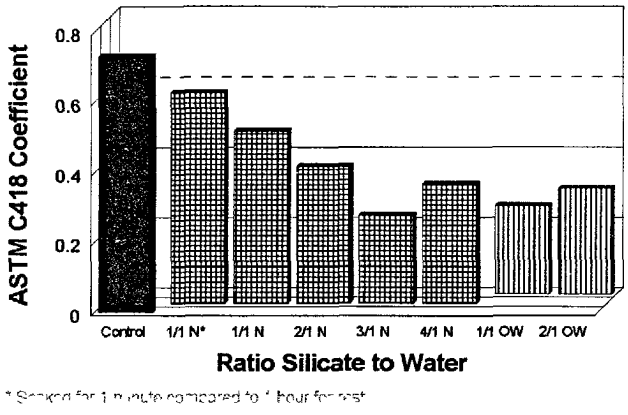

Figure 3 The effect of aqueous silicate coatings on the abrasion resistance of concrete blocks.

In the work of Litvan (1992), the freeze-thaw resistance of 8 types of mortar specimens treated with 57 concrete sealers was measured according to ASTM C666 procedure. Litvan's work is summarized in Figure 4. Litvan concluded that the ability of certain sealers to reduce expansion due to freeze-thaw cycling was directly related to the ability of a sealer to restrict movement of water through the surface region. The silicate based sealers exhibited the lowest degree of expansion in contrast to many sealers that caused greater expansion.

Integral Admixtures for Construction

Sodium silicates are also used as integral admixtures. An excellent example of this use is shotcreting in which liquid silicate is sprayed into a stream of concrete that is being "shot" at a wall or ceiling. The effect of the sodium silicate additions is two fold. The soluble SiO_2 is immediately available to react with the CH and form C-S-H as shown in Figure 5 where powder x-ray diffraction results illustrate the reduction in the CH content as liquid silicates are added to the portland cement paste. As the silica is consumed the alkalis associated with the soluble silicates raise the pH further accelerating hydration. Figure 6a shows the that set times(determined by ASTM C191) are decreased significantly when liquid silicates are used in portland cement pastes. Figure 6a shows that small dosages reduce the set times while higher

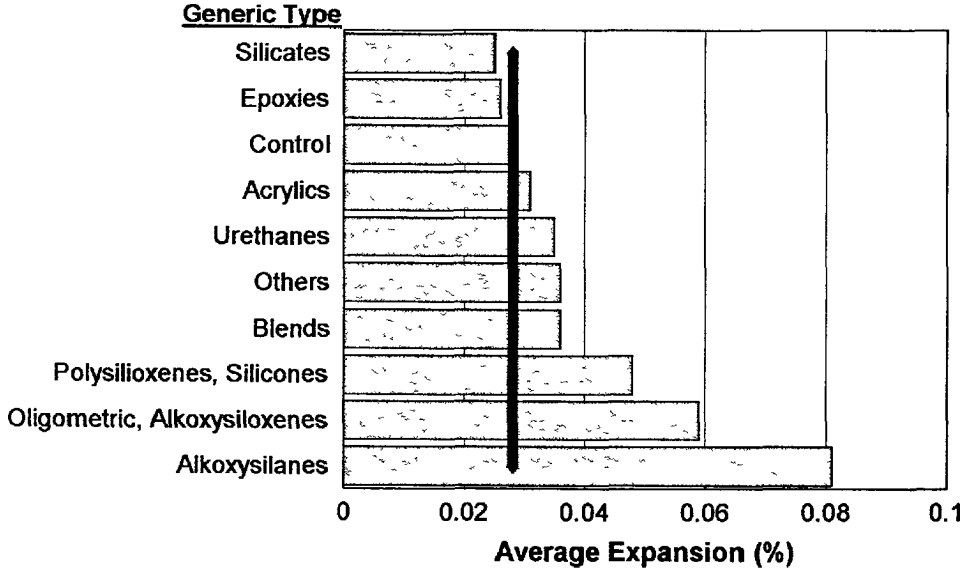

Figure 4 Ultimate average expansion of specimens treated with sealers of various generic types after 300 freeze-thaw cycles (after Litvan (1992)).

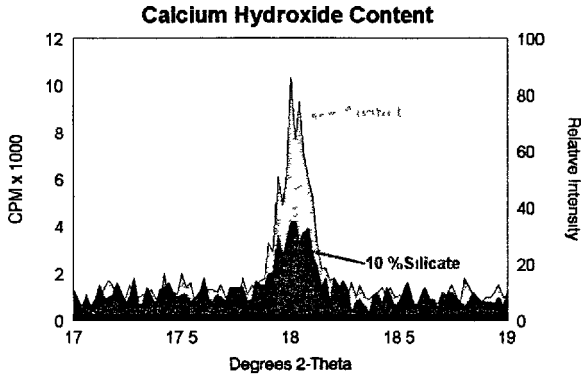

Figure 5 Effect of 10% N silicate addition on calcium hydroxide content in portland cement pastes. The pattern was taken from a 28 day old cement pastes with W/C = 0.4, cured at 25°C.

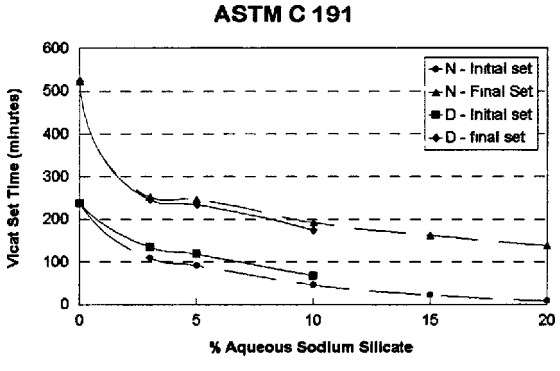
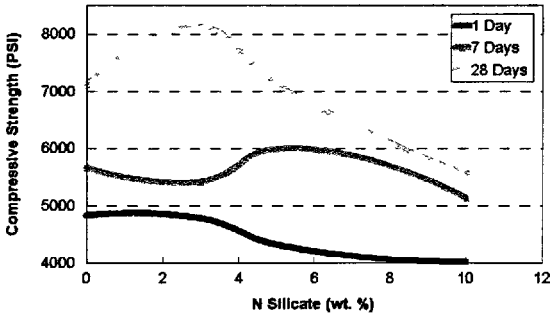


However, in spite of higher strengths at 1 day the anhydrous (SS-65) silicate containing pastes exhibited 28 day strengths similar to the control. In contrast to the hydrous (G) sodium silicates that result in higher 1, 7 and 28 day strengths compared to the control.

Waste Applications



Nine companies, world-wide, offer a chemical fixation system based on portland cement and soluble sodium silicate (Connor (1990)). These stabilization systems are used with a wide range of hazardous materials from heavy metals, organic to nuclear wastes. The objectives of these solidification and stabilizaton (S/S) systems is to eliminate all free liquids, improve handling and physical properties of the wastes, reduce mobility, toxicity and leachability of the hazardous components (PQ Corp. (No date)).

Soluble sodium silicate serves several functions in S/S systems. As shown in Figure 6 silicates can be used as an effective set regulator. The presence of soluble sodium silicate in freshly mixed portland cement has the effect of raising the pH of the pore fluids as well as maintaining a elevated level of dosages do not proportionately further reduce the set times. Figure 6b shows that modest dosages of soluble silicates increase the compressive strength of portland cement pastes. Apparently at higher dosages the rapid setting caused by the soluble silicates results in a more disorder structure and lower strengths.

Figure 7 examines the effect of additions of hydrous (G) and anhydrous sodium silicate (SS-65) powders on the strength developed in portland cement pastes. Regardless of the type of silicate used higher 1 day strengths, compared to the control, were observed. At the levels tested, the smallest additions resulted in the highest gain in 1 day strengths.

(a)

(b)

Figure 6 The effect of aqueous sodium silicate additions on (a) Vicat set times and (b) compressive strengths in portland cement pastes (w/c= 0.40).

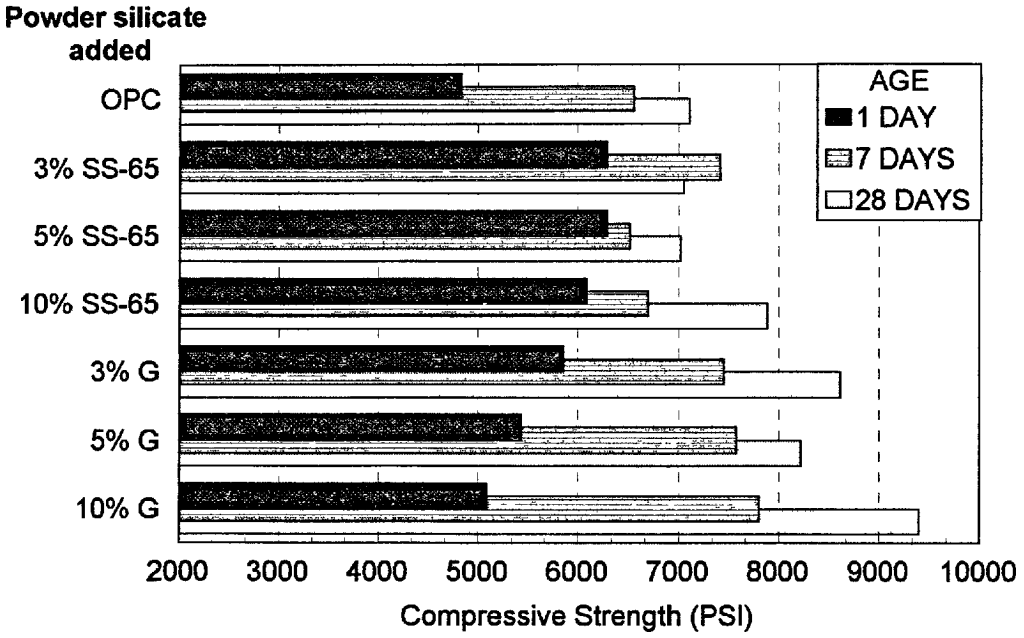


Figure 7 Effect of hydrous (G) and anhydrous (SS-65) sodium silicate powder on 28 day strengths in portland cement pastes.

labile silicon ions in these fluids (Hoffer 1990)). In, cement fly ash, lime and fly ash and kiln dust-based stabilization systems, the gelling time can be controlled from a half minutes to a half hour instead of 24 to 48 hours and still maintain pumpability (Scheetz and Hoffer (1996)).

Secondly, most heavy metals are least soluble at elevated pH ranges generally precipitating as metal hydroxides. In an extensive study, Silsbee and Scheetz (1993) have demonstrated lead extracted from the pore fluids of lead-bearing portland cement/soluble silicate waste forms was solubility limited in the form of lead hydroxide, figure 9.

Finally, as noted above, the reaction of soluble silicate with portlandite formed during the progressive hydration of both di- and tri-calcium silicate contributes to the enhanced formation of C-S-H in the waste form matrix. Effectively there is more "glue" per unit volume, therefore, physical properties of the composite are improved. C-S-H can act as an encapsulant for waste species, as a template for chemisorption of waste species or as a crystal chemical host . The most comprehensive model for C-S-H as a crystal chemical host was presented by Richardson and Groves (1993):

$$\mathbf{Ca_xH_{(6n-2x)}(Si_{1-a}R_a^{[IV]})_{(3n-1)}O_{(9n-2)} \cdot A^{c+}_{a(3n-1)/c} \cdot zCa(OH)_2 \cdot mH_2O}$$

where:

$x = 0.5(6n-w)$

$z = 0.5[w+n(y-2)]$

$for\ 0<y<4;\ n(2-y)<w,2n$

$2<y<4;\ 0<w<2n$

$4<y<6;\ 0<w,n(6-y)$

and $0<a<(n-1)/(3n-1)$

$R^{[IV]}$ = trivalent, tetrahedrally coordinated cation (usually Al or Fe)

A^{c+} = interlayer ion which charge balances the R^{3+} substitution for Si^{4+}.(M^{+})

Ni, Co (Atkins et al (1993)), U, I and Sn are reported to be substituted for Ca^{2+} on the surface of C-S-H. Cr^{3+} is reportedly exchanged for Al^{3+} in poorly crystalline C-S-H. Both Ni and Cd are reported to precipitate as $M(OH)_2$ species.

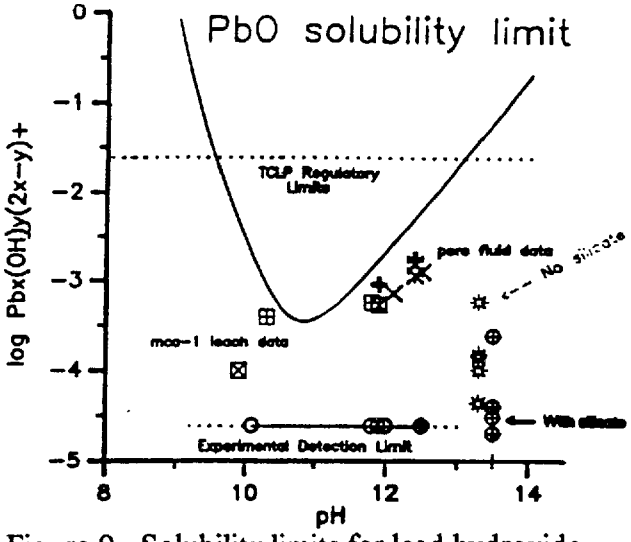

Figure 9. Solubility limits for lead hydroxide established by expressed pore fluids from lead-bearing portland cement waste forms.

SUMMARY

Soluble sodium silicate has a long history as an industrial chemical with a wide variety of used outside of cement and concrete application. This review has focused on its applications as an external sealant and as a reactive chemical admixture that controls has the ability to control both physical and chemical properties of hardened cementitious solids.

Combined admixtures and their mixing techniques

MECHANISM OF ALKALI-CONTAINING COMPLEX CHEMICAL ADMIXTURES AND PORTLAND CEMENTS INTERACTION

Myroslav A.SANITSKY, State University "Lviv polytechnic", Ukraine

ABSTRACT Chemistry of hydration and hardening processes cement pastes with a multifunctional complex admixtures which include surface-active substances and alkali metals salts at ambient and negative temperatures is given. The destructive role of dihydrate gypsum in the portland cement pastes containing carbonates, silicates, sulphates sodium and potassium is established.

Keyword: hydration, mechanism, admixtures, alkali, gypsum.

INTRODUCTION

One of the ways of portland cement systems effectiveness increase is the activation by complex chemical admixtures of polyfunctional action containing surface-active substances and alkali metal salts. Alkali compounds are rather strong activation agents of cement systems hardening and widely used as antifreezing admixtures.So far, the results of alkaline admixtures on the setting characteristics of cement, on the effect of freezing of concrete and on the durability of reinforced concrete construction have been published as following reports: Collepardi and Ramachandran (1992), Krivenko (1992).However, some papers have been published as well: on the influence of alkali metals salts on the compressive strengh of slag-alkaline cements (Glukhovsky, 1989), a phase composition of the hardening products in a system Me_2O-MeO-Me_2O_3-SiO_2-H_2O (Krivenko, 1994) and the effect anti-freeze admixtures have on the setting characteristics of áoncrete at negative temperatures (Mironov and Lagojda, 1975).

SETTING

Introduction

In concrete practice a number of alkali admixtures (soda, potash) in amounts exceeding 1 mass.% lead to the sharp stiffening of concrete mixes. At the same time other salts (sodium nitrite and chloride) may be used in increased amounts (up to 10 mass.%) and they do not exert destructive effect on concrete mixes. That is why it is nessesary in frames of this work to investigate the reason of different effect nature alkali metals salts on portland cement structureforming processes and to classify the alkaline admixtures by mechanism of action on the time of setting of portland cements.

Results and Discussion

Due to the effect of alkali-bearing compounds on the time setting of ordinary portland cement (OPC) they can be divided into two groups.The first group consists of sodium salts such as chloride, nitrate, nitrite not affesting strongly on time of setting. The second group consists of sodium carbonate and silicate, and potassium salts. Even small dosage of these compounds results to the sharp acceleration of grout setting and the loss of the system plastic properties.

Due to the action mechanism the alkali metals salts are attributed to the admixtures undergoing exchange reaction with products of portland cement hydration. Therefore they are to react first of all with calcium hydroxide which is the product of alite phase hydrolysis of portland cement clinker. As a results anion part of admixtures in the process of hydration is bound aluminobearing phases and cations are retained in porous fluid. At the same time it is worthy to take into account the possibility of chemical interaction of alkali-bearing compounds with gypsum dihydrate.

In studying the alkali metals salts additives effect on properties of finely grounded gypsum dihydrate it was ascertained that additives of the second group greatly accelerate its settingtime. X-ray phase analysis data show that following types ofinteraction between gypsum and these additives take place: sodium carbonate and silicate undergo exchange reactions with gypsum forming calcium carbonate or hydrosilicate and mirabilite; potassium sulphate and gypsum form less soluble compound syngenite, which is complex double salt $K_2Ca(SO_4)\ H_2O$; other potassium salts also results to the formation of syngenite instead of low-soluble part of gypsum dihydrate. Syngenite is characterized by fine fibrous crystals and this leads to rapid grout setting. Admixtures of the first group - NaCl, $NaNO_2$, $NaNO_3$ do not interact with gypsum dihydrate and do not effect on paste setting time.

Therefore at large oversaturatios of cement paste liguid phase at the very initial hydration period due to tendency of coarse-grained potassium cation to complex formation with calcium on the one hand and alkali metals carbonates and silicates exchange reactions on the other hand gypsum is removed out of the process of early structure formation and doesn t serve its main function - to be inhibitor of threecalcium aluminate setting in portland cement. Fibrous syngenite crystals which are formed reduce the thixotropic properties of paste in great extern and it causes cement stone destruction, lack of concrete strength and its structure-technical properties. Given results affirm the expediency of alkali metals salts of the second grope usage as admixtures to portland cement without gypsum dihydrate.

As can be seen from Fig.1 the admixtures of the first group even in complex with enhanced content surface-active substances (lignosulphonate and so on) up to 1,0 mass.% do not delay gypsum-free portland cement (GFPC) setting and system stiffens rapidly. But admixtures of the second group together with surface-active substances permit to obtain GFPC with specified setting time. It is significant that potassium salts have more strong effect than sodium salts so cations together with anion part of alkaline metals salts admixtures effect essentially on early structure formation of fine grounded portland cement clinker.

As a result of synergism the alkaline admixtures significantly improve the plastisizing effect of the surface-active substances like LS etc. These complex chemical admixtures have a multifunctional effect and during application of GFPC they exibit the superplastisizer properties. In addition there is the possibility of introduction of alkali metals salts in increased ammounts which are the hardening accelerator and anti-freezing admixtures.

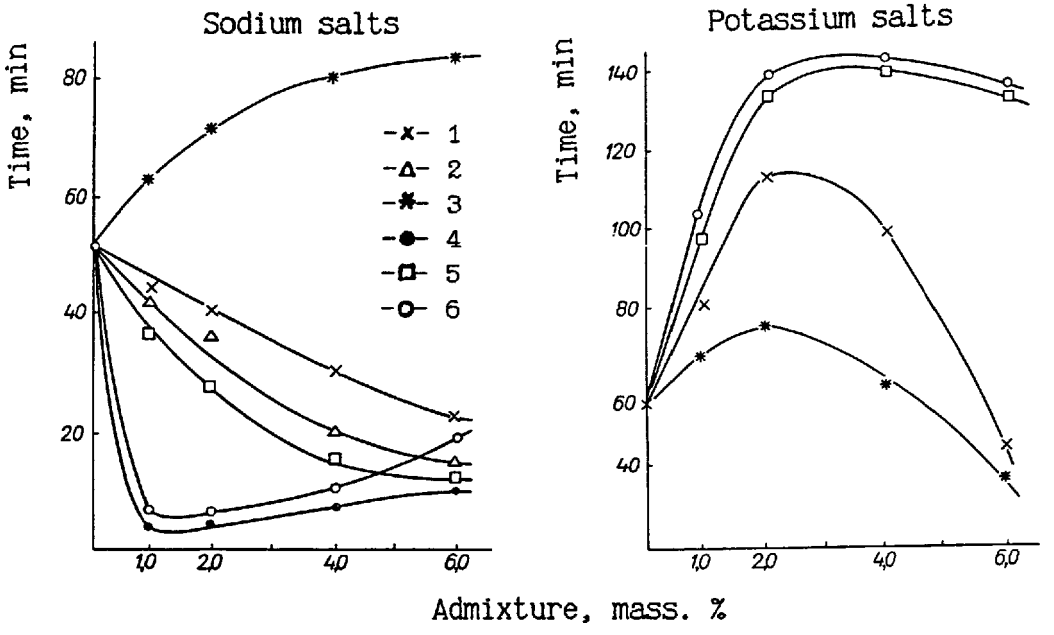

Figure 1 The start of setting GFPC (0.3 % LS) with sodium or potassium salts (carbonate, silicate, sulphate, nitrite, nitrate, chloride corresponding to curves 1-5 respectively)

HARDENING ACCELERATOR

Results and Discussion

The establishment of the causes of destruction phenomena, frequently appearing due to the alkaline admixture effect, allowed to form a group of special portland cements with regulated setting period and accelerated hardening at different temperatures.

The properties of the alkali metal carbonates and sulphates (with plasticizing/inhibiting admixtures) as high-effective hardening activators are fully discovered in GFPC in the process of its utilization. They are also serve as a setting times regulator for binding material which makes it possible to obtain rapid hardening portland cements (Skvara, 1984; Chistiakov and Myasnikova,1992). The properties of GFPC can be determined based on the type and the amount of plasticizing, inhibiting, alkali-bearing and mineral admixtures (Sanitsky and Sobol, 1992).

Among the second group alkali metal salts sodium sulphate became the most wide-spread as a hardening accelerator and potash - as an antifreeze. With the purpose of investigation of the potash and sodium sulphate on the portland cement hardening the admixtures influence on strength, phase composition and minerostructure of monomineral paste was studied.

The strength testing results showed (Fig 2) that 2-10 mass.% sodium sulphate admixture furthers to considerable intensification of the C_3S paste strength increase (in 2,8-4 times at 24 hours). The maximum strength is achieved with the Na_2SO_4 5 mass.% batehing (after 1

and 28 days according to 83% and 138% from the R_{28} C_3S paste strength without admixtures). The complex admixture 0,5 mass. % of LS and 5 mass.% of sodium sulphate or potash leads to the tricalcium silicate early strength reducing. The activation action effect of alkali compounds on -C_2S hardening is slower in a long-term age.

The investigation of the admixtures influence of the alkali metal salts on the aluminate and aluminoferrite phasis hydraulic activity change has been carried out on the C_3A and C_4AF minerals (Fig 2). When adding 5 mass.% Na_2SO_4 the considerable increase of C_3A stone strength is being observed: in early terms - 3 times as much, after 28 days - 4 times as much. 5 mass.% of potash admixture in pure condition increases the paste

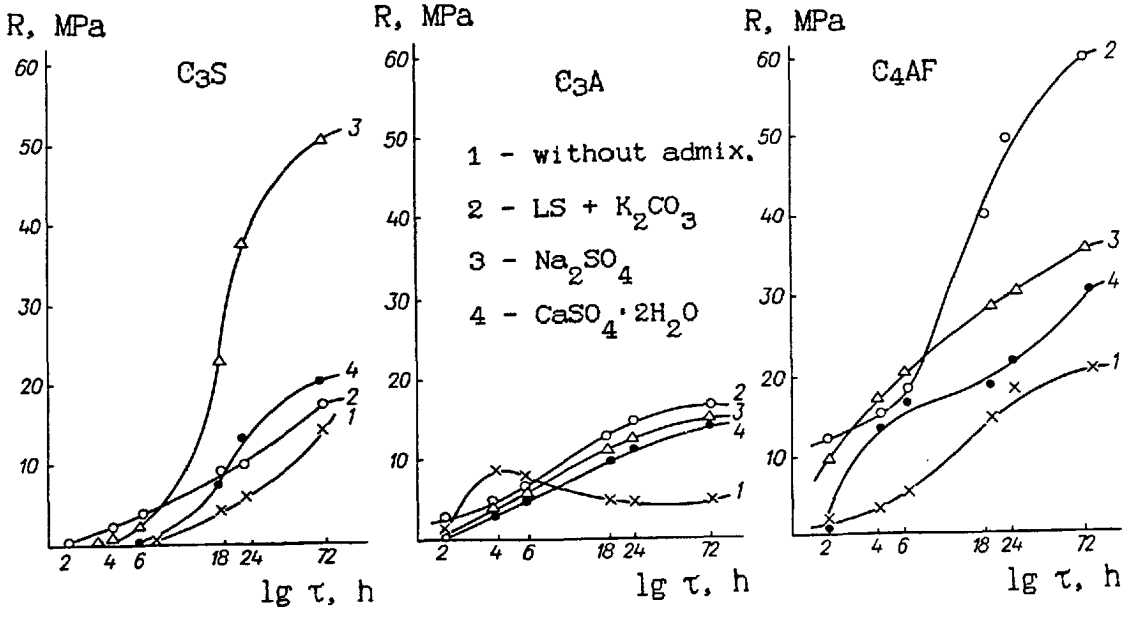

Figure 2 The early strength of monomineral stone with admixtures

strength C_3A only a little. But the complex admixture 0,5 mass.% LS and 5 mass.% potash allows to get the highest inerease of the paste strength in its early hardening period and maximum strength in the long-term age of hardening. Alkali-containing admixtures - sodium sulphate and potash - cause also the C_4AF monomineral paste strength increase. From the said data it follows that sodium sulphate activates the C_3S hardening stronger and potash activates aluminocontaining clinker phases. In this case after 1 day the C_3S hydratation stage increases in two times, C_3A and C_4AF, on the contrary, - reduces. In the case of aluminate phasis the reducing of hydration speed prevents the development of destructive phenomena during the forming of the early cement paste strength.

According to the data of the flame photometry in C_3S suspension just after the gating the alkali-containing admixtures reduce the calcium ions concentration in the liguid phase in 3-5 times, and with the passage of time - much more. With the adding of sodium sulphate in the C_3S suspension considerable calcium and sodium ions concentration reducing is firstly noted.That is connected with the forming of phase $4CaO\ 0{,}9Al_2O_3\ 1{,}1SO_3\ 0{,}5Na_2O\ 16H_2O$. Its building is like those of calcium monohydrosulfoaluminate.

In the processes of early structure-forming in portland cements incorporating alkali-bearing admixtures in amounts exceeding 2 mass.%, the liquid phase has a lower concentration of calcium ions as compared to ordinary portland cement. According to X-ray spectral microanalysis data, the alkali metals salts admixtures are mainly concentrated on the outer hydrates composition. Therefore, scanning electron microscopy shows formation of more fine crystalline microstructure of stone, whereas the trimethylsilylation method shows considerable increase in the polymerization rate of silicon-oxygen anions in hydrosilicates. In the process of C_3A hydration with the said admixtures, crystals of hexagonal AFm-phases are formed which can tightly fit in to each other. So, there is less of cement grains moving apart in the early period of hydration than in the period of ettringite acicular crystals formation. Besided, breakdown effects which occur during the transition of the high-sulphate form of calcium hydrosulphoaluminate into the low-sulphate one and which are accompanied by change in crystal habit and density,do not occur with the increase of hardening time. Together, the factors contribute to the forming of a dense, strong but least stressed structure of the cement paste.

For the model system (75 mass.% C_3S + 25 mass.% C_3A) it is showed that alkalicontaining admixtures considerably intensificate its hardening during the early period (after 1-3 days the strength is reached egually R_{28} of the stone with dyhidrate gypsum admixture). The slowing increase of model system strength with gypsum admixture in the period of 6-18 hours is stipulated by the general porosity increase by 20 %, according to the mercury poroumetry, as much as the result of overcrystalization of ettringite into calcium monohydrosulfoaluminate.

The mechanism of the setting and hardening processes proceeding in GFPC give really picture of alkali-containing chemical admixtures and clinker minerals interaction. The above mechanism is based on the leading part of a big calcium cation in making structures of new hydrate formations. The main processes of the early period in cement pastes are the primery formation of $[Ca_2Al(OH)_6]$ packs which predetermine AFm-phases formation due to the decrease of Ca ions concentration in the cement slurry liguid phase; making of protective shell out of AFm-phases on C_3A and aluminoferrites surface, their structure stabilization with $[CO_3]$, $[SO_4]$ bicharged anions. As a result of rejects polarization effects in the cement slurry owing to the difference in charge of the silicate and aluminum-bearing hydrating mineral surfaces cement particles do not aggregate into coarse clusters even if water requirements are reduced and cement slurry remains plastic.

The directed formation of the cement paste microstructure at early period of hydration including replacement of the acicular AFt-phases by hexagonal AFm-phases and subssequent stabilization of the structure makes for its compaction and prevents development of break-down effects in the hardened paste which accompany transition of ettringite to a low-sulphate form. As a result, the strength of the paste based on GFPC with surface-active substances and alkali metal salts carbonates or sulphates begin to increase considerably.

Technological methods of control over the portland cement systems properties presuppose a direct influence on the processes of their early structure formation and liquid phase

composition. They are determined by selection of mineralogical composition of the Portland cement clinker, type and member of retarders, plastisizers, alkaline metals salts and mineral additions as well as temperature.

The concrete prepared on the rapid-hardening cement systems bases possesses an intensive strength increase (70-80 % of the designed strength is reached in 24 hours at the ambient temperature).

ANTIFREEZING ADMIXTURES

Results

The introduction of gypsum dihydrate (5 mass.%) at frost results to the degradation of C_3S paste with LS and potash admixtures strength at the expense of reduction of its hydration at factor 1,5-2,0 and porosity structure formation caused by transition of potash admixture part (4 mass.% to arkanite not possesing the antifreezing effect.

Potash used as a highly effective hardening accelerator as well as an anti-frost admixture (eutectic temperature -36.5^0 C) for gypsum-free portland cement allows us to obtain binders with accelerated strength ,improved frost resistance and water-proofness as well as gain at negative temperatures. The expensive stress of these binders ability to hardening at negative temperatures (up to -35^0 C). is 5 to 10 times lower at early freezing as compared to OPC with NaCI, $NaNO_2$, K_2CO_3 admixtures.

GFPC with carbonate additives exhibit increased effectiveness when hardening at ambient, low and negative tenperatures. It is due to modifing effect of $CaCO_3$ on aluminobearing phases in the presence of gypsum is exhibited not fully. Two charge plane anions [CO_3] are set out parallel to the layers of [$Ca_2AI(OH)_6$] in the structure of AFm-phases, they compensate the charges of layers and stabilize these phases. Due to hexagonal packing of atoms in crystalline structure such AFm-phases grow together with calcite and other aggregates.

When hardening at lower positive temperatures and at frost up to -10^0 C the possibility of construction monolithic structures with terms of loading which are nearly to summer loading is created. At temperatures -15^0 C such concrete attains 80-100 % of branding strengh in 28 days and posses the capabi ity of hardening at frost -35^0 C. The compressive strength of concrete after 28 days at temperature -15^0 C and after 90 days at ambient temperature are listed in Table 1 for OPC and GFPC with LS and potash admixtures.

In case of using rapid-hardening blended cements prism strength, modulus of concrete elastisity and its adhesive strength with reinforcement is not less than similar indecies for ordinary concrete which harden under normal conditions even if it was affeced by negative temperatures. Besides concrete is characterized by high value of frost resistivity (F 300 and greater) and increased water-proofness.

Table 1. Compressive strength of concrete based on OPC and GFPC with LS and potash admixture at ambient and negative temperatures

CONCLUSIONS

The establishment of the causes of destruction phenomena, frequantly appearing due to the alkaline admixtures effect, allowed to form a group of high early portland cement binders with regulated setting period and accelerated hardening at different temperatures. Technological methods of control over the binding systems properties presuppose a direct influence on the processes of their early structure formation and liquid phase composition.

It was also shown that rapid-hardening portland cement systems with multicomponent alkali-containing chemical admixtures are characterized by a reduced water consumption. The concrete prepared on their bases possesses an intensive strength increase, improved frost resistance and water-proofness as well as ability to hardening at negative temperatures (up to -35^0 C).

ACKNOWLEDGEMENTS

The author gratefully acknowledge Dr.-Ing. G.Shevchuk for her assistance in the experiments, and also Dr.-Ing. V.Melnyk for his improving the manuscript.

CONTROL PROPERTIES OF SULPHO- AND FERRO-ALUMINATE CEMENT CONCRETE WITH SPECIAL ADMIXTURES

Liang ZHANG, Muzhen SU, China Building Materials Academy, Beijing 100024, P.R.China

ABSTRACT The setting time and the workable time of sulpho/ferro-aluminate cement concrete can be effectively controlled with special admixtures without reduction of its early mechanical properties. The setting and hardening regularity of the sulpho/ferro-aluminate cement with the special admixtures was studied at different temperature and the mechanical properties of the hardened concrete tested. In civil engineering practice, good results have been achieved by using these special admixtures.

Key-words: sulphoaluminate, admixtures, setting, strength development

INTRODUCTION

The sulpho-aluminate cement series(SAC) and the ferro-aluminate cement series(FAC), which were both developed by China Building Materials Academy(CBMA) and put into industrial production in 1970's and 1980's respectively, have been well received by civil engineers for the properties of rapid hardening, early-strength, good impermeability, rapid strength development at minus temperature and good corrosion resistance just after they came out in China. In the 3rd Beijing International Symposium on Cement and Concrete held in Oct., 1993, Professor WANG Yanmou, director of State Administration of Building Materials Industry and Professor SU Muzhen, vice-president of CBMA, named sulpho- and ferro-aluminate cement series as the third cement series to make the difference from the first cement series—Portland cement (its major mineral component is C_3S) and the second cement series cement—high-alumina cement (its major mineral is CA).

After 80's, the self-stressing cement in the third cement series was occupying the market step by step for producing self-stressed water pipe, but the application of rapid-hardening cement was still in its narrow applied fields such as repairing, anchoring, structural components joint construction in winter and some small size concrete products. Besides the problem of the production capacity, the most important reason was that the workability of concrete was not able to meet the requirement of construction in situ due to its rapid setting time. At that time, increasing W/C ratio was the only way to prolong the workable time of concrete that resulted in lowering compressive strength and poor durability although the strength of cement itself was higher according to the Standard. For this reason, the rapid hardening cement had not been used in civil engineering in a large scale. After 90's, with the development of the production technology and capacity of the third cement series, the task to develop its market and to enlarge its application fields becomes more and more important. Therefore, controlling the workability of its fresh concrete and the performances of its hardened concrete is the essential prerequisite for the cement to enter into large construction projects.

It is well-known that the successful applications of Portland cement series in civil engineering in recent decades are attributed to the admixtures, which have made concrete meet the requirements for its different performances. By using this experience as reference, we have realized that the third cement series also need to be modified with admixtures in order to bring its excellent performances into full play.

RESEARCH ON THE COMPOSITION OF SPECIAL ADMIXTURES

Designing idea

In order to solve the disadvantages of the third cement series and avoid to bring trouble to on-the-spot construction, the admixtures added should solve the following three problems in particular: the first one is to be able to control setting time and workable time of concrete; the second is to ensure consistency of concrete required for construction and the third is to improve strength and durability of concrete. It is obviously impossible to settle all the problems above mentioned with only one single admixture. Therefore, we selected some varieties of suitable retarder, superplasticizer and air-entrainer to make different compound admixtures with the comprehensive actions of retarding, water-reducing and air-entraining etc. The retarder is the key component in the admixtures.

The effects of many different retarders on setting time, rheological factors, flowability and strength of the pastes and mortars have been tested for picking up the best retarder finally. From our testing results we found the retarder selected has the following three actions for SAC/FAC:

- Retarding setting time effectively;
- Improving workability and prolonging workable time;
- Not affecting early strength and improving later strength at reasonable dosage.

Variety of special admixtures

China is a country with a vast territory and with complicated climate. According to the different aims and requirements, the special admixtures mainly include the following varieties:

①**High-range retarding water-reducer (special superplasticizer),** divided into two types:
Standard(S)—used for preparing high-strength concrete, suitable for the concrete construction at the temperature of 0～25℃ and at the positive and minus temperature in turn.

Retarding(R)—used for preparing high-strength concrete, suitable for the concrete construction at the temperature of above 25℃ in the hot summer.

Considering the difference of temperatures in different areas and in different seasons and the effect of different construction situations, S and R type superplasticizers can meet the different requirement of practical engineerings for setting time and workable time.

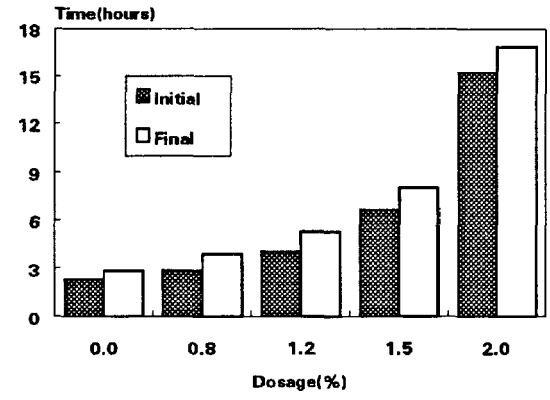

Fig.1 Setting time of the mortar with R type superplasticizer

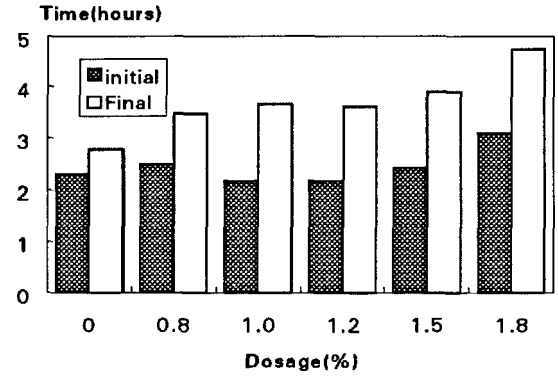

Fig.2 Setting time of the mortar with S type superplasticizer

②**ZB-2 anti-freezing admixture**—used for the winter construction at the temperature of -5 ℃～-30℃.

③**ZB-3 retarding water-reducer**—used for normal concrete to increase workable time, suitable for the construction at positive and minus temperature in turn.

④**ZB-4 pumping aid**—used for commercial concrete transported from ready-mixed concrete plant far away and pumping on-the-spot, capable to control the loss of slump in about 3 hours.

EFFECT OF SPECIAL ADMIXTURES ON PROPERTIES OF FRESH MORTAR AND CONCRETE

Effect of dosage on setting time

Fig.1 and Fig.2 show the effect of the dosage of R and S type of special superplasticizer on setting time of the cement at the temperature of 20℃. By using the special admixture, we can control the initial setting time within 2-15 hours to meet the normal requirement of concrete engineerings. It should be noted that all the setting times of mortar are tested under the same flowability.

The special admixtures are composed of two major compositions, i.e. water-reducing composition and retarding composition. The setting and hardening of SAC/FAC mortar and concrete are mainly controlled by the two factors of water-reducing and retarding which mean that retarder can prolong setting and water-reducer accelerate hardening. For the R type superplasticizer, prolonging setting time and workable time are its leading role because only under this prerequisite, we can get dense and good-qualified concrete thus bring water-reducing and strengthening into full play. For the S type superplasticizer, its purpose is to further develop the early-strength of SAC/FAC concrete which means water-reducing is its leading role at lower positive temperature and positive/minus temperature in turn because under these circumstances, the requirement for setting time is relaxed compared with higher positive temperature.

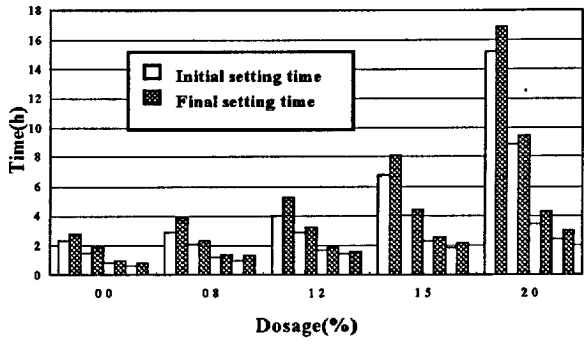

Fig.3 Setting time of concrete at 20, 30, 40 and 50 ℃ with R type superplasticizer.

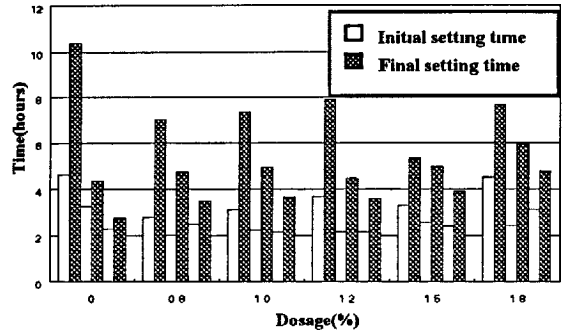

Fig.4 Setting time of concrete at -5, 12 and 20 ℃ with S type superplasticizer

Effect of Ttemperature on setting time

The effects of temperature on setting time of the mortar with R type are shown in Fig.3. Obviously, the setting and hardening of SAC/FAC are very sensitive to temperature. At room temperature, the R type superplasticizer can very effectively prolong the initial and final setting time of the cement but with the increase of temperature, its retarding action on setting time is reduced sharply and the difference between initial and final time is becoming smaller and smaller.

Therefore, it is effective for the retarder to control the setting before the hydration of the cement but once hydration heat is released, the temperature inside of concrete will significantly be increased to cause very quick development of strength

The effects of temperature on setting time of the mortar with S type are shown in Fig.4. Compared with the setting time of the control sample, little change of the ones takes place in the samples with S type superplasticizers though w/c ratios are reduced, that means that water-reducer is playing a main role. That is very advantages for the normal strength development of concrete at lower temperature.

Control slump loss

The curves in Fig.5 and Fig.6 show that the slump loss of SAC/FAC concrete can be effectively

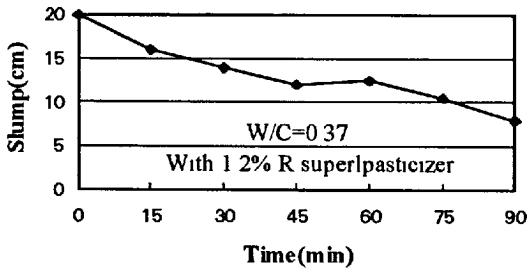

Fig.5 Slump loss of the concrete with the special R superplasticizer

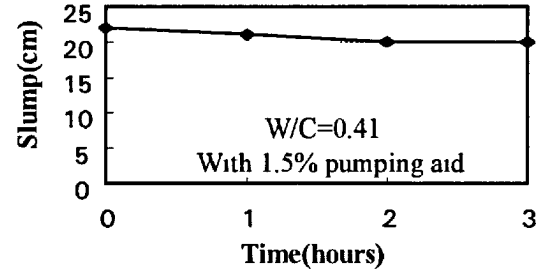

Fig 6 Slump loss of the concrete with the special pumping aid

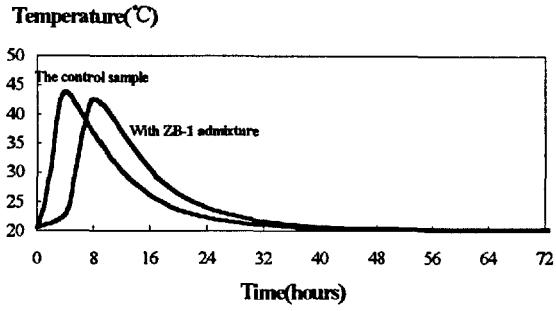

Fig.7 Hydration heat evolution curves

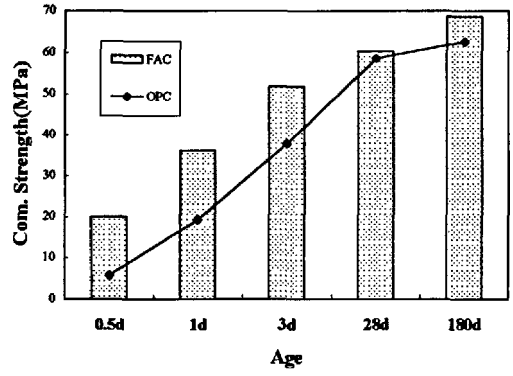

Fig.8 Development of compressive strength

ontrolled by the special admixtures, thus making the concrete meet the requirement of construction in situ and long-distance transportation. By using the special admixtures, we can get the SAC/FAC concrete whose setting time and workable time are able to be controlled.

Effect of special admixture on hydration heat

The hydration heat evolution curves as shown in Fig.7 show that only the time of appearance of the hydration heat peak is postponed but that the shape of the peak is not changed when the special admixture is added, thus retaining the properties of high early-strength and high-strength of SAC/FAC concrete.

PROPERTIES OF HARDENED CONCRETE WITH SPECIAL ADMIXTURES

Strength development at positive temperature

The contras test was made at 20℃ to investigate the strength development of FAC concrete and OPC concrete. FAC and OPC were adopted. The same concrete proportion was used in which the cement content is 450kg/m^3, the dosage of admixture is 1.2% R type special superplasticizer for FAC concrete and 1% sulfonated naptalene superplasticizer for OPC concrete. From the strength development with age(Fig.8), not only does the early-strength of FAC concrete develop much more quickly, but also its later strength goes up steadily.

Strength development at minus temperature

Compared with Portland cement concrete, one of the most excellent performances of the concrete with SAC/FAC is good anti-freezing ability at minus temperature especially at early age. The concrete constructed in winter with SAC/FAC can make use of the hydration heat released concentratedly by the cement itself to cure the concrete itself to gain its strength development, therefor, there is no restriction on the critical strength for this concrete at minus temperature. But the concrete prepared with SAC/FAC without other additives is still not be able to completely resist its freeze injury under fresh condition, so the aim of using special anti-freezing admixture is to keep the fresh concrete with good workability and from its freeze injury before its hardening so as to make the concrete with the admixture to be constructed with simple heat curing measures in winter and ensure the strengths and durability of hardened concrete. With the special

Table1 The strength development at minus temperature

Temperature (℃)	W/C	Slump (cm)	Admixture	Compressive strength (MPa)				
				-7d	-7+3d	-7+7d	-7+28d	-7+56d
-5℃	0.32	17.0	S type superplasticizer	6.7	55.7	61.5	67.2	79.1
-15℃	0.31	9.0	3% Anti-freezing admixture	3.6	43.7	54.2	58.5	70.4
-25℃	0.30	6.0	4% Anti-freezing admixture	56.5		65.8	69.7	70.0

Table 2 Strength development of the FAC concrete (MPa)

Age	1 day	3 days	28 days	6 months	1 year
Compressive strength	44.6	61.9	69.2	80.7	81.0
Splitting strength	2.85	4.24	5.38		5.74

Elastic modulus($\times 10^4$)	34.2	35.6	37.8		

Note: Cement content=480kg/m^3, W/C=0.335, with R type superplasticizer.

anti-freezing admixture, we can prepare not only low and medium grade concrete, but also high-strength concrete. Part of the results are shown in Table 1. -7+3d means that the specimens are cured at given minus temperature for 7 days and then for 3 days under standard condition (20±3 ℃, RH>90%).

Effect On Other Mechanical Properties

Splitting strength, flexural strength, elastic modulus and creep of SAC/FAC concrete have the same development trend with its compressive strength when added the special admixtures as shown in Table 2. By using the admixtures, the high early-strength is not only kept, the other mechanical properties are also improved.

Freezing-Thaw Carbonation Resistance

The loss of the strength of concrete only with the special superplasticizer after 300 freezing-thaw cycles is only 1.62% and the carbonation depth also significantly reduced, as shown in Table 3 and Table 4.

APPLICATIONS IN PRACTICAL CIVIL ENGINEERINGS

At present, the special admixtures for SAC/FAC have been put into production and used in civil engineering. For example, in a cement products plant in Guangdong province, grade C80 centrifugal pretensioning prestressed high-strength concrete pile was pilot manufactured with the special superplasticizer. In the construction of the rebuilt projects of Eastern and Northwestern Third-ring-road, Jing-Shi Highway and Beijing New Railway Station, large span post-tensioned pre-stressed concrete beams with grade C50 ferro-aluminate cement high-strength concrete with the R and S types of special superplasticizer were used in about

Note: The results in the Table were obtained with the specimens carbonated 28 days under the standard condition.

20 overflys. Grade C60 concrete was successfully poured in Shenyang Long Distance Telecommunication Hub with R and S type superplasticizers in the summer and the autumn and with the special anti-freezing admixture in winter at the lowest temperature of -25°C. Grade C50 commercial concrete produced in Tianjin Hangbao Ready-mixed Concrete Plant was used in pumping construction with the special pumping aid. It is worthy to be noted that in the construction of Liaoning Products Building in 1994, grade C70 and C80 concrete with ferro- and sulpho-aluminate cement were applied for the first time in high-rise building in China. The special retarding water-reducer has been used in many concrete products plants for the production of varieties of concrete elements of C20～C40. The special admixtures have played an important role in the applications of SAC/FAC.

CONCLUSIONS

Setting time and workable time of SAC/FAC can be effectively controlled by the special admixture and simultaneously, the mechanical properties of SAC/FAC concrete at the early age are not affected and the durability also improved. The applications of the special admixtures in practical engineering have achieved good results.

RHEOLOGY CONTROL FOR WET SHOTCRETE - A SLUMP KILLING SYSTEM FOR IMPROVED PERFORMANCE

Tate COVERDALE, Jeff CHAMPA, and Larry ECKERT
Master Builders, Inc.
Cleveland, OH, 44122
USA

ABSTRACT
A chemical admixture system for changing the rheology of wet shotcrete as it is applied to vertical and overhead surfaces is described. The method is part of an overall approach to wet shotcreting called Total Consistency Control, and consists of an admixture system utilizing a high molecular weight polyethylene oxide, napthalene formaldehyde sulfonate condensate, and a modified sodium silicate. Using application thickness as a basis of equivalence, the new approach is compared to traditional wet shotcrete chemistries.

Key-words: accelerators, polymer, rheology, shotcreting, silicate

TRADITIONAL ACCELERATORS
Sprayed concrete uses different types of accelerators (Melbye, 1996). The most common types include sodium silicates and sodium or potassium aluminates. Silicates bind the water in the concrete and contribute little to the early hydration process. The water binding results in an immediate loss of slump providing a rapid initial "set" of the sprayed concrete (<10 seconds). Final sets are not typically rapid (>30 minutes depending upon temperature) when compared to aluminate based accelerators. The typical dosage of these accelerators is 3 to 6% of the binder weight as specified. In practice, however, the use of standard grade silicates typically results in dosages of 8% or higher to achieve necessary stiffening. Such an overdose can result in severly limited strength development and various other associated problems. Silicates typically work with all cement types, reduce ultimate strengths less than aluminate based accelerators and are less aggressive to the skin and eyes than the aluminates. Sodium silicates are sensitive to water/cement ratio and temperature. Increasing water/cement ratios and lower temperatures require higher dosages to achieve the same amount of stiffening. Temperature also affects the reactivity and viscosity of sodium silicate admixtures.

Aluminate based accelerators take part in the hydration process and contribute to early strength. They provide a sudden increase in the alkali available to the cement, promoting tricalcium aluminate hydration, and overwhelming the calcium sulfate that moderates the cement hydration. Rapid set and strength development occur. Final set of the sprayed concrete occurs within the first 9 minutes. After 20 to 30 minutes, the strength is usually high enough for the sprayed concrete layer to bear its own weight. The typical dosage of these accelerators is 4 to 8% of the binder weight. The set and strength gain properties enable an increase of layer thickness for the sprayed concrete and also make the aluminate based accelerators more effective in water problem areas. Aluminates can be sensitive to cement type and checking the reactivity of these accelerators with the cement before spraying is a necessity. Aluminate based accelerators reduce final strengths more than silicate based accelerators, and are very aggressive to the skin and eyes requiring greater precautions for safe handling. Potassium aluminate tends to be less sensitive to cement type and generally promotes faster setting and higher early strength when compared to sodium aluminate.

RHEOLOGY CONTROL SYSTEM

Master Builders Technologies (MBT) has developed a Total Consistency Control (TCC) system to control the rheology of shotcrete. This technology is a two component admixture system utilizing incompatible chemistries to produce an instant loss of slump, and, in combination with a modified sodium silicate, set acceleration. The MBT Underground Construction Division developed the system and introduced it throughout Europe in 1994. It has been used worldwide for projects in many countries including Sweden, Norway, Italy, U.K., Saudi Arabia, India, Malaysia, Hong Kong, Australia, Mexico, Venezuela, and, most recently, the United States.

Component A of the TCC system is a plasticizing admixture which contains a high molecular weight polyethylene oxide. This component, added to the concrete as it is batched, improves the workability and pumpability of the concrete. The increased workability of the concrete reduces the water content required for pumping, providing better concrete properties, improved layer thickness when spraying, and lower accelerator consumption. a high molecular weight polyethylene oxide also imparts improved pumping qualities to concrete with a low cement content, with aggregate gradations lacking fines, and with fiber reinforced concrete.

Component B of the TCC system, which is added at the shotcrete nozzle, is a modified sodium silicate and napthalene sulfonate blend that acts as a set accelerator and as the TCC activator. The modified sodium silicate is more effective than traditional silicates in that a lower amount is required to achieve the same performance. The TCC activator reacts with the a high molecular weight polyethylene oxide of Component A providing instant slump loss. The modified sodium silicate acts as a slump killer and a set accelerator.

The consistency control of this system enables the use of a lower accelerator dose to attain the same build thickness of sprayed concrete. The two polymer components of the TCC System react together to cause an instant loss of slump. In combination with the already lower water/cement ratio, the sharp slump loss allows a lower accelerator dose. This provides a thixotropic consistency to the sprayed concrete, leaving it more plastic as it hits the substrate yet able to build thickness. This thixotropic behavior provides better bonding properties, less rebound, and increased build thickness. The low accelerator dose keeps any decrease of the final strength due to the accelerator to a minimum, and provides a longer finishing window when shotcrete is to be used as a final lining or cover. The effects of this system also serve to reduce ultimate drying shrinkage. Through these methods the quality of the in place sprayed concrete is significantly improved.

IN HOUSE STUDY

A series of experiments was performed at an outdoor testing facility to demonstrate the performance of the TCC system for wet shotcrete. These experiments consisted of using a very high quality bagged concrete as the base material, and several different combinations of accelerators and a single water reducing/thixotropic admixture.

Basis for experiment

The underlying premise for these experiments was to compare different shotcrete systems on the basis of equivalent vertical build up thickness. In the experiments described here, three different accelerators were used: 1) modified sodium silicate (SA430), 2) modified sodium silicate containing a a high molecular weight polyethylene oxide (TCC 766), and 3) sodium aluminate (SA100). These accelerators were combined with a high quality concrete both with and without

the use of a thixotropic, water reducing admixture (Polyheed SG). Each system was calibrated to achieve the same vertical build up thickness, and then measurements of required accelerator, set time, and compressive strength were taken.

Experimental description

Materials and curing

The mix design for the concrete used in this evaluation is shown in Table 1. This material was manufactured in 25 kg bags to ensure accurate admixture dosing and operational convenience. Concrete was continuously produced in 8 - 10 bag batches in a stationary paddle mixer attached to a concrete pump. For both the plain concrete, and the concrete containing admixtures, the following parameters were measured on the first batch produced: slump, DIN flow, unit weight, and concrete weight per pumped stroke. Material from subsequent batches was assumed to have maintained the same plastic properties. Care was taken to ensure that shooting of test specimens utilized fresh material, as in some cases concrete had to sit in the lines for nozzle cleaning, etc.

Table 1 - Concrete Mix Design

	wt. %	kg/m^3
cement	22.3	455
silica fume	1.8	37
sand	52.2	1070
stone (10 mm)	23.7	490

Test specimens for set time and compressive strength were taken from 610x610x90 mm panels which were shot after measuring the build up thickness. These panels were cured under wet burlap and black plastic sheets for 24 hours, then cored for compressive strength samples.

Equipment

Concrete was mixed and pumped using a dual piston, swing tube pump (Powercreter 10) with an estimated output of 7.6 m^3 per hour, through 30.5 m of 38 mm diameter hose. The spray application utilized a typical air/admixture injection nozzle (WSN 100). Compressed air was supplied to the nozzle at a pressure of 6.8 ATM and volume of 5 m^3 per minute. Accelerating admixtures were delivered using an air diaphragm pump at a pressure of 6.8 ATM, and the volume was controlled using a manually adjusted needle valve near the nozzle.

Shotcreting conditions and accelerator measurement

As mentioned before build up thickness was used as the point of comparison in this study. In order to somewhat accurately measure build up thickness, a build up platform was utilized as a shooting substrate (Beaupre, 1994, pp 137). This platform, along with the general shooting setup is depicted in Figure 1. The platform was made of hardened concrete with dimensions of 305x305x25 mm, and was positioned approximately 100 mm from a supporting concrete wall. The shooting surface was treated to have exposed aggregate with a profile of approximately 6 mm. Build up thickness was measured by shooting continuously onto the platform with the same nozzle position until the concrete fell under its own weight. Since this measure was taken visually, it is considered to be accurate to only the nearest 10 mm. The nozzle was held

approximately 1.2 m from the platform. The purpose of this platform was to limit the variability of build up thickness due to the area of the base build up of concrete.

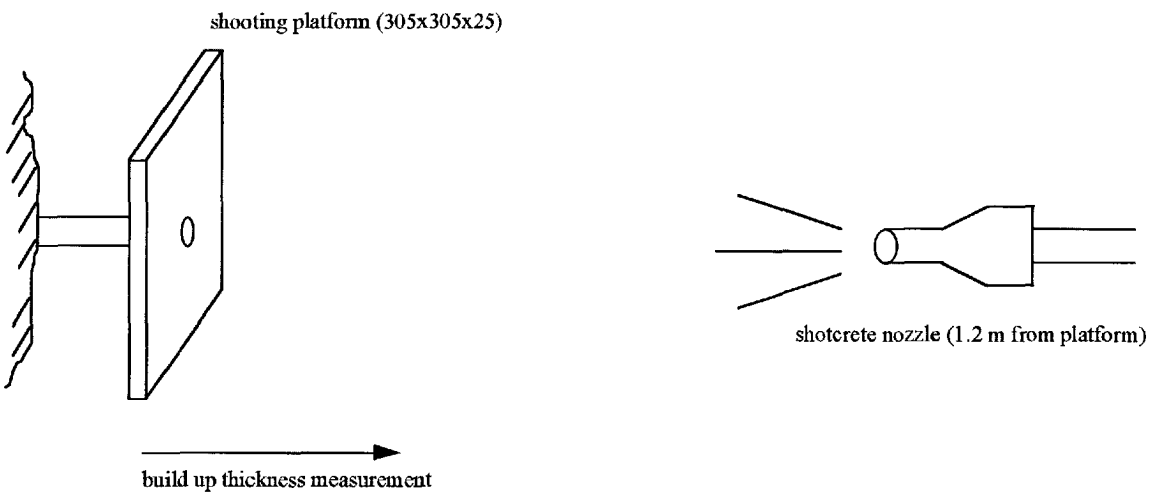

Figure 1 - Shooting setup for build up thickness measurement

Once the needle valve setting on the nozzle was determined, specimens were shot, allowing the determination of the accelerator dosage by measuring the amount of concrete sprayed, and the amount of accelerator used. The reported accelerator dosages are based on the total cementitious content of the concrete (cement and silica fume). With the equipment employed, calibrating to the desired build up thickness turned out to be a significant practical challenge, and in some cases, comparisons can be drawn only on equivalent accelerator doses.

Experimental results

The results from the seven test conditions are shown in Table 2. In these tests, initial set was determined using a penetration device, with 3.4 MPa as the criterion for initial set. All mixes were performed on the same day after two days of trial work. Mixes 1 and 2 were performed in the early morning, and the subsequent mixes were performed in the afternoon in a 3.5 hour time span.

Discussion of results

The results described in the table above will be discussed as two basic experiments: those without a nozzle added accelerator, and those with a nozzle added accelerator. Although all of the shooting was done on the same day, the conditions under which the first two mixes were made were quite different than the last five. Mixes 1 and 2 were made in the early morning as stated above. The bagged concrete had been stored under cover and was relatively cool, as was the ambient temperature (~ 18.3 C). The mixes used with accelerator were performed in the afternoon when the sun was out and the ambient temperature was about 29.4 C. This difference is evident in the water required to produce essentially the same slumps between the morning and afternoon mixes. Because of this difference, comparisons between mixes 1 and 2 and the mixes utilizing accelerator (3 - 7) should be made with caution.

Mix number one was a plain concrete that was pumped and sprayed without any water reducer or accelerator. The richness of the concrete is evident by the relatively low water to cement ratio needed to achieve the measured slump and flow. The unit weight and gravimetric air content are consistent with the mix design of this concrete. This mix was easily pumped and surprisingly built up to a thickness of 180 mm. The curing conditions favored a faster setting material, being in the sun and covered with black plastic sheeting. The quality of the concrete mix is again evident in the compressive strength achieved.

Mix two contained a lignosulfonate based water reducing and thixotropic admixture at a dosage rate of 980 ml per 100 kg of cement. With this dosage the water content was reduced by 31% from mix one while still achieving essentially the same slump and flow.The admixture also increased the air content which has been shown to have a slump killing effect (Beaupre, 1994, pp 146). Since most of the air entrained in the concrete is lost due to the turbulence and mixing action of the shotcrete nozzle, the concrete that passes through the nozzle loses slump that is caused by the entrained air. Perhaps of more importance, the concrete attains thixotropic characteristics due to the thickening chemistry in the admixture. This is evident by the fact that the vertical build up thickness was almost double that of the plain even though the slump and flow were the same. The lower water to cement ratio also resulted in excellent compressive strength.

The third mix was a plain concrete similar to mix 1, but a sodium aluminate accelerator was added at the nozzle. The required dosage to achieve 380 mm of build thickness was 3.2%, which is at the low end of what is probably used in the field (typical ranges of 4 - 8%). This material achieved initial set in 2 minutes, which is also long compared to what is typical for these accelerator chemistries (< 60 seconds). Even at this low dose, the strengths were drastically lower than mix 1, even considering the higher water to cement ratio.

Mix number 4 was a concrete containing water reducer, similar to mix 2, which used the sodium aluminate accelerator as did mix 3. At a lower dosage of accelerator the material had a

surprisingly high build up thickness of 480 mm. The combination of the lower accelerator dose, and the retarding effect of the lignin based water reducer extended the initial set to 3 minutes. The high build up thickness can be attributed to the thixotropic nature of the admixture, since more build was achieved with less accelerator than in mix 3, even though the slumps of the pumped concrete were about the same.

The fifth mix utilized the plain concrete and the modified sodium silicate accelerator at a dose of 1.6% by weight of cementitious material. At this dosage, the build up of 380 mm was not achievable, and the compressive strengths were somewhat lower than mix 1, but not as reduced as mix 3 which utilized the aluminate accelerator.

The sixth mix was made from a concrete containing water reducer and was accelerated using the modified sodium silicate. The required dose of accelerator to build up 380 mm (actually 400 mm) was 2.1%. The addition of the silicates at this dosage level does appear to lower the compressive strength of the concrete, but the strength levels are still very high in comparison to the aluminate accelerator and typical 24 hour design criteria. The longer setting times, also allow the concrete surface to be finished if this is desired.

The seventh and last mix described in this study utilized the complete TCC system; concrete containing water reducer and the modified sodium silicate containing the slump killing agent. With this system a very modest 1.5% accelerator was necessary to achieve a build up thickness of 380 mm. The lower amount of silicate required due to the slump killing agent resulted in a 12% increase in 1 day compressive strength over the straight silicate (mix 6).

The underlying trends from this study confirm much of what is already common knowledge in the shotcrete industry. The use of a water reducer provides significant improvement in compressive strength and to some extent the ability to hang thicker layers of shotcrete.The use of both silicate and aluminate accelerators results in decreases in compressive strength, and that trend is proportional to the accelerator dosage.

This study has also shown that for equivalent build up thickness, the modified sodium silicate appears to be as effective as sodium aluminate in terms of the dosage required (compare mixes 4 and 6). At equivalent doses, however, the aluminate accelerator gives a much greater loss in compressive strength than the modified sodium silicate. This study has also shown that by utilizing a slump killing system in addition to the modified sodium silicate accelerator, even less accelerator is required to achieve the same build up. This results in even less compressive strength reduction.

A significant advantage of the water reducing/thixotropic admixture that was not addressed in this study is the lubricating effect of the thixotrope. All concretes in this study were made with similar slumps to analyze the effect of the acceleration/slump killing systems. Since the thixotropic agent used with the water reducing chemistry provides excellent lubrication, significantly lower slumps may be pumped than what is usually observed with plain or otherwise plasticized concrete. The advantage of pumping concrete with lower slump is that higher build up thickness may be achieved. Thus, the ultimate advantage of the TCC system was not fully demonstrated in this study.

CONCLUSIONS

The TCC system represents the results of years of R&D and constitutes a new direction for shotcrete that provides improved performance without affecting or sacrificing the strength of the end product. In the past, increased early strengths meant increased dosages of accelerators and significant reduction in long term strength and quality. With this new technology increased performance can be achieved without increasing accelerator dosages.

MECHANICAL ACTIVATION OF ORDINARY PORTLAND CEMENT AND CEMENT WITH ADDITIVES

Živko SEKULIĆ, Institute for Technology of Nuclear and Other Mineral Raw Materials, Belgrade, Yugoslavia
Miodrag STEFANOVIĆ, Cement Factory "Novi Popovac", Popovac, Yugoslavia
Branislav ŽIVANOVIĆ, Center for Multidisciplinary Studies, University of Belgrade, Belgrade, Yugoslavia

ABSTRACT
In this work, mechanical activation of ordinary portland cement (OPC) and cement with additives (PC 30d) in vibro mill was investigated. The analyses of cement specific surface area and X-ray diffractometry were performed. Besides, physico-mechanical properties of cements, before and after mechanical activation, were investigated. It was found out that mechanical activation results in increase of specific surface area, but also in change of mineralogical composition. The final consequence is increase of compression strength in activated cements. The compresion strength of OPC before activation (specific surface area 288 m^2/kg) was 43 MPa; after mechanical activation during 3 minutes (specific surface area 420 m^2/kg), it was 55.2 MPa. Compression strength of cement with additives, PC 30d (specific surface 380 m^2/kg) before the treatment was 43.1 MPa, while after mechanical activation, it was 51.1 MPa (specific surface 540 m^2/kg). Obtained results show that mechanical activation improves the mechanical properties of cements under investigation.

Keywords: Activation, specific surface, X-ray Diffraction Analysis, strength development.

INTRODUCTION
The investigation results in the area of mechanical activation of the silicate systems indicated that it could also be applied on standard portland cement (OPC) and cement with mineral additives (tuff and limestone). It was assumed that induced physical and structural changes in mechanically activated cements would cause certain energy changes in clinker minerals and mineral additives contained in cement which might improve mechanical characteristics of cements and their overall quality (1-4).

EXPERIMENTAL
The experiments of mechanical activation were performed in vibro mill with rings (Humboldt Wedag AG 954/3). The cement samples were obtained from the cement factory "Novi Popovac", Yugoslavia. In Table 1 the characteristics of used samples such as chemical composition, specific surface area (obtained by Blain method) and modules, are presented. Portland cement (OPC) contains 95 % of the portland cement clinker and 5 % of plaster. Cement with additives contains 75 % of the portland cement clinker, 5 % of plaster, 16 % of tuff and 4 % of limestone. The objective of our investigation was to obtain, by mechanical activation, specific surface area of 400 m^2/kg (for OPC) and 500 m^2/kg (for PC 30 d). In order to determine the time of mechanical activation necessary to reach reqired surface area, a great number of time dependent experimens was performed.

It was found out that optimal time of mechanical activation was 3 minutes for OPC and 4 minutes for PC 30 d.

Table 1 Characteristics of the starting cements

Characteristics	PC	PC 30d
SiO_2	19.59	16.11
Al_2O_3	5.22	4.71

loi	2.60	5.04
Free CaO	1.26	0.23
Humidity, at 105°C	0.80	1.30
Specific surface, (m^2/kg)	288	380
Saturation degree (SD)	94.97	97.39
Silicate modul (SM)	2.50	2.27
Aluminate modul (AM)	2.01	1.97
Hydraulic modul (HM)	2.28	2.29

RESULTS AND DISCUSSION

During the investigations, the analyses of specific surface area and X-ray analyses of investigated cements, prior and after mechanical activation, were performed. Physico-mechanical investigations of unactivated and activated cements were also carried out. The X-ray analyses of the starting and mechanically activated cements are presented in Fig.1. The maximal peak intensities are given in Tab.2. As can be seen from Fig.1 and Tab.2, maximal peak intensities characteristic for all investigated mineral decreased for both OPC and PC 30 d cements. This indicates that mechanical activation caused certain changes on the level of the mineral microsturucture.

In Tab.3, physico-mechanical characteristics of both starting and activated cements are presented. On the basis of these results, it can be seen that desired specific surface areas were produced, with cca 10 % discrepancies. Oversize per 1 cm^2 of 4900 mesh screen was lowered from 4.4 % to 0.6 % for OPC, from 4.0 % to 0.8 % for PC 30 d. After mechanical activation of investigated samples water, demand remained almost unchanged; the beginning of binding period was promoted in both cement types, while it's ending for

activated PC 30 d was slightly postponed (2h,40 min : 3 h). Bending strength and compression atrength of activated cements were improved after three days, remaining like that till the 28 th day of solidification (Tab.3).

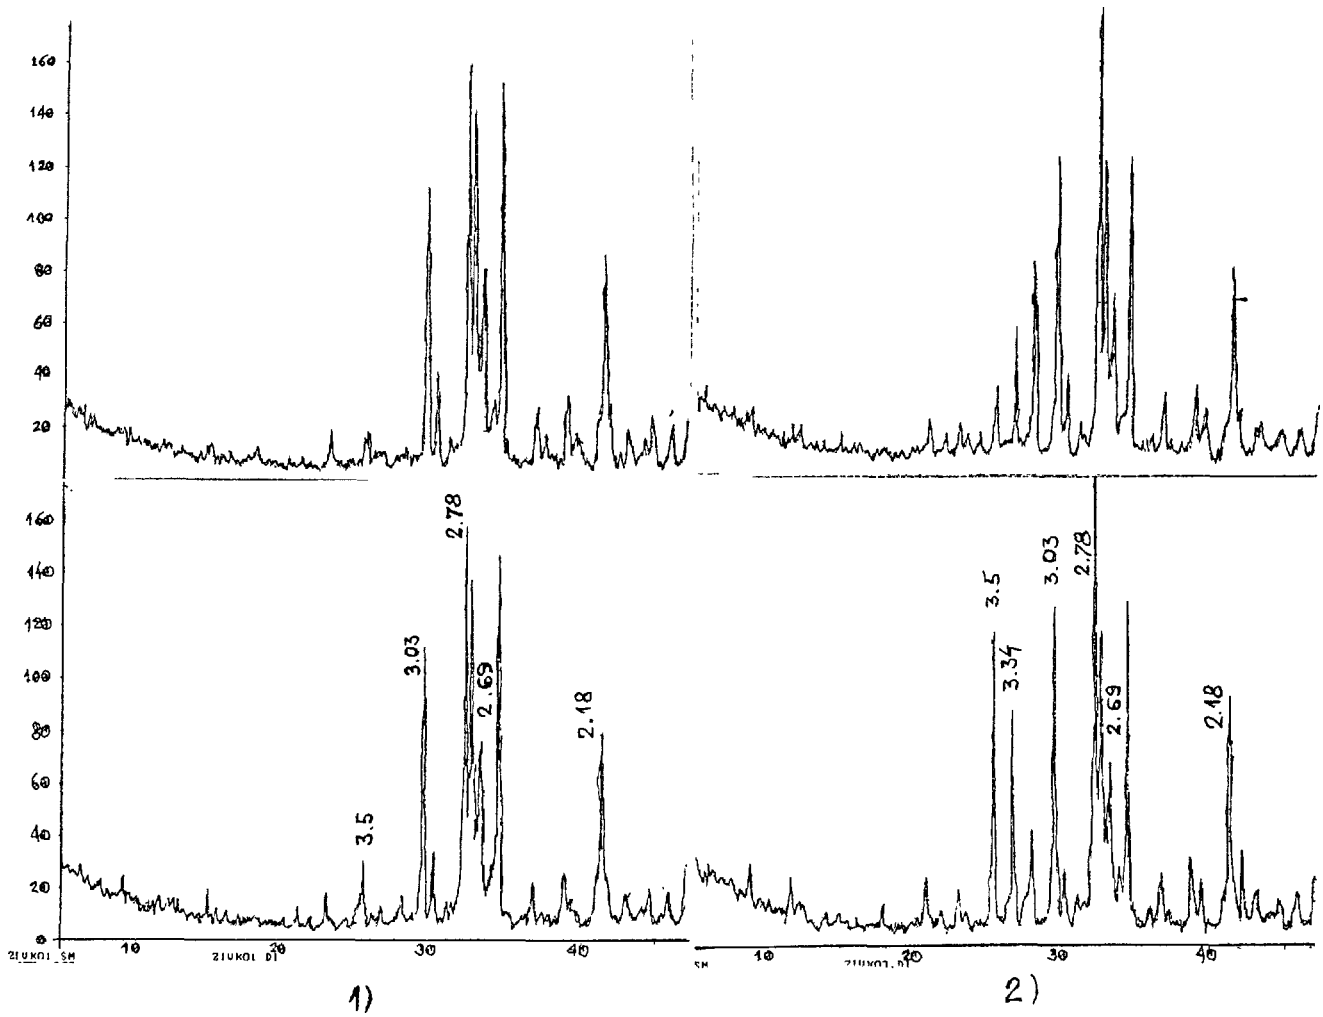

Figure 1 Diffractograms of starting and mechanically activated cements: 1- OPC; 2- PC30d

Table 2 Maximal peak intensities in x-ray diffractograms

Cement type		$C_3S + C_2S$ d = 2.78	C_3A d = 2.69	Anhydrite d = 3.5	Calcite d = 3.03	Quartz d = 3.34
PC	starting	177	83	32	125	
	activated	166	71	16	119	
	change,(%)	7	15	50	5	
PC 30d	starting	250	71	135	125	100
	activated	193	69	29	114	58
	change,(%)	23	3	79	7	

By comparing results of the x-ray analysis (Tab.2) and mechanical investigations (Tab.3), one can see that: a) mechanical activation od OPC caused increase of the specific surface area from 288 m^2/kg to 420 m^2/kg and increase of the compression strength in the 28 day solidification period of 28,4 % b) mechanical activation of PC 30 d caused increase of the specific surface area from 380 m^2/kg to 540 m^2/kg within 4 minutes, thus causing increase of the compression strength, in 28 days, of 18,6 %.

Table 3 Physico-mechanical properties of cement prior and after mechanical activation

	Bending strength after (MPa)			Compee-sion strength after (MPa)		
	3 days	7 days	28 days	3 days	7 days	28 days
starting OPC	5.7	6.9	7.5	25.6	31.2	43.0
activated OPC	6.2	8.0	9.0	33.0	40.8	55.2
increase, (%)	8.8	15.9	20	28.9	30.7	28.4
starting PC 30d	5.5	6.9	7.8	24.0	34.4	43.1
activated PC 30d	6.0	6.9	8.3	30.2	41.7	51.1
increase, (%)	9.1	0	6.4	25.8	21.2	18.6

CONCLUSION

Mechanical activation of portland cement and cement with additives caused increase of bending strength and compression strength after 28 day solidification. In other words, mechanical acitvation in vibro mill with rings of only 3 mins (for OPC) and 4 mins (for PC 30 d) significantly improved quality of investigated cements. This quality improvement is, in our opinion, the consequence of the microstructural changes in the minerals present in investigated cements, increased free energy and intensified hydration process.

Influence of type, dose, addition time and mixing time

INFLUENCE OF ADMIXTURE TYPE AND CONCRETE TEMPERATURE ON STRENGTH AND HEAT OF HYDRATION OF CONCRETE

Juha KOMONEN and Vesa PENTTALA
Helsinki University of Technology, Concrete Technology, Espoo, Finland

ABSTRACT Twelve admixtures (plasticizers, non-chloride accelerators, retarders), four mixing temperatures, three cement contents, and three retarder dosage procedures influencing hydration heat of in-situ concretes were measured. Heat evolutions were compared by units kJ/kg-cement and MJ/m³-concrete. Mixing temperature was the most significant variable. Plasticizer based on modified polycondensate of cyanureamide and formaldehyde was more efficient than SMF and SNF based ones. Strength was measured by 150 mm cubes from the age of 14 hours onwards.

Key-words: concrete,admixtures,temperature,workability, heat evolution, strength development.

INTRODUCTION

This article deals with the methods by which early compressive strength of ready-mixed concrete can be reliably assured (Komonen and Penttala, 1997). There have been numerous studies on the subject and the basic factors which govern the early compressive capacity are known but when good workability of concrete is strived at the same time very few articles are found. At least in Finland, there is scarce information available on the properties of various ready-mixed concretes during the first 24 hours.

EARLY STRENGTH GAIN

The evolution of early strength of concrete can be affected in many ways but the most common methods are changing of the composition or temperature of concrete. Almost all concrete properties, including the strength, can be shown to be a function of water cement ratio. Lower water cement ratios give usually better properties in question. However, when extended workability is needed the decrease of w/c is restricted. Naturally, the rate of cement hydration accelerates as a function of temperature but if the rate is advanced too much, special measures have to be taken into consideration in order to achieve the desired workability.

Admixtures are mainly used to modify the properties of concrete and to make them more suitable for concreting works due to economical reasons or such other purposes as saving energy. In many instances an admixture might be the only feasible means of achieving the desired result. The dosage level of different plasticizers required to achieve certain workability varies from product to product. Also due to differences in chemical compositions the effects of superplasticizers on the hydration rate of cement differ significantly. It is very risky to model the effect for different types of products in general, and it is not unusual to find, that a particular superplasticizer works well in one concrete mixture but behaves rather strangely in another, Aïtcin et al. (1994).

SCOPE OF THE RESEARCH

The aim of the investigation was to compare various methods to accelerate strength development of concrete and to get information about its benefits and disadvantages. Additional aim is to give recommendations of different methods in enhancing the strength development at early age. The concretes investigated had a workability time so that they could be properly placed even after 120 minutes after mixing.

MATERIALS, METHODS, AND TESTS

The binder used in the tests was a rapid hardening cement CEM II A 42.5 R of local origin produced by Finnsementti Oy, **Table 1**. City tap water was used. The admixtures investigated are shown in **Table 2**. Aggregate was rounded granite with a particle density of 2670 kg/m³. The aggregate grading was combined from nine fractions (up to 32 mm) and had sieve passing values 3, 7, 12, 20, 28, 43, 56, 76, and 100 % with sieve sizes 0.125, 0.25, 0.5, 1, 2, 4, 8, and 32 mm, respectively.

Proportioning and mix design

Workability was defined by Vebe test, which is a common test of consistency in Finland. The concretes were proportioned with respect to workability (Vebe time less than 5 seconds after 120 minutes from mixing). The cement amount was decreased when plasticizers were used. The dosage amount of an expensive non-chloride accelerator was determined by using the equal

relative cost with plasticizer. The concretes were proportioned using the basic volumetric equation of concrete. Mix design of the test concretes is given in **Table 3**.

Heat of hydration

The heat of hydration was calculated by means of temperature measurements in concrete in a semiadiabatic condition. A similar arrangement was utilized by Smeplass and Maage (1990). In every batch about 3.5 liters of fresh concrete was isolated from the surroundings by a disposable box of expanded polystyrene at the age of 15 minutes. The temperature of concrete was measured with a copper/constantan thermocouple (K-type) which was placed in the middle of the specimen. The temperature development of isolated concrete and ambient air were registered by a data logger at 15 minutes intervals for at least 24 hours. Due to the semiadiabatic nature of the apparatus, the heat flow through the polystyrene box had also to be taken into account in the calculations. This heat loss was evaluated by means of fully hydrated test specimens and is noticed as a heat liberation term in **Eq 1**. The rate of total heat energy generated in the hydration was determined from the temperature measurements by the following equation:

$$\frac{dQ}{dt} = \frac{dT_c}{dt} \cdot c_{fresh} \cdot m_c + \lambda_b \cdot (T_c - T_a) \qquad [1]$$

where Q is the total heat generated (J), t is the time (s), c_{fresh} is the specific heat of fresh concrete (1050 J/kg•K), m_c is the mass of concrete in the calorimeter (kg), λ_b is the thermal conductivity of container (0.30 J/s•K), T_c is the temperature of concrete (K), and T_a is the temperature of ambient air (K).

The rate of heat hydrated per kilogram binder is given by dividing **Eq 1** by the mass of binder (kg) in the calorimeter. This unit is a good indicator when the properties of cement are in question, but the definition like this does not indicate the real differences between mixes. More illustrative one is the hydration heat per cubic meter concrete, the definition of which the cement content in concrete is taken into account in the comparisons. The rate of heat hydrated per cubic meter concrete is obtained when **Eq 1** is divided by the mass of concrete (kg) in the calorimeter and multiplied by the density of fresh concrete in kg/m^3. This semiadiabatic method, by which the hydration heat was calculated by means of the heat loss through the container, was found efficient for comparative studies of in-situ concretes.

Concrete manufacturing, fresh and hardened concrete tests, curing

All the aggregate fractions were pre-heated (max 65° C) or cooled when the concretes were produced at various temperatures. The dry ingredients were mixed for 30 seconds before the water was added into the rotating mixer and thereafter mixing was continued for three minutes. When admixtures were used the addition procedure of water was changed. First ¾ of water was added into the rotating mixer and mixed for one minute. Then ¼ of water blended with the admixtures - plasticizer or non-chloride accelerator or retarder together with plasticizer - was added and mixing was continued for additional three minutes. This was dosaging type C. The properties of admixture R3 were also investigated by two other mixing procedures A and B. In type A the retarder was blended with ¾ of water. In type B the retarder blended with water was mixed at first with cement. Next the aggregates were added and mixing continued for one minute. Thereafter the plasticizer was added and the mixing was continued for three additional minutes.

The workability loss was measured by a Vebe consistometer test, a slump test, and a flow test. The air content and density were measured after mixing. Compressive strength was tested using three 150 mm cubes at the age of 14 hours and 1, 7, and 28 days. The specimens were cured at

20° C and 45% relative humidity after demoulding from the age of 24 hours onward if not tested before.

RESULTS

In **Table 3** the most important fresh and hardened concrete properties of the concretes are presented. The cumulative heat of hydration of the first 24 hours after mixing and the rate and time of maximum heat gain of some concretes are also shown. The cumulative heat gains are presented in megajoules per cubic meter concrete in **Fig 1**. The initial hydration heat peaks - the rapid first reactions of cement after contact with mixing water - were not registered by this measurement procedure because the reactions took already place in the mixer. The evolutions of heat of hydration of cement during 24 hours after mixing are presented in **Figs 2 and 3**.

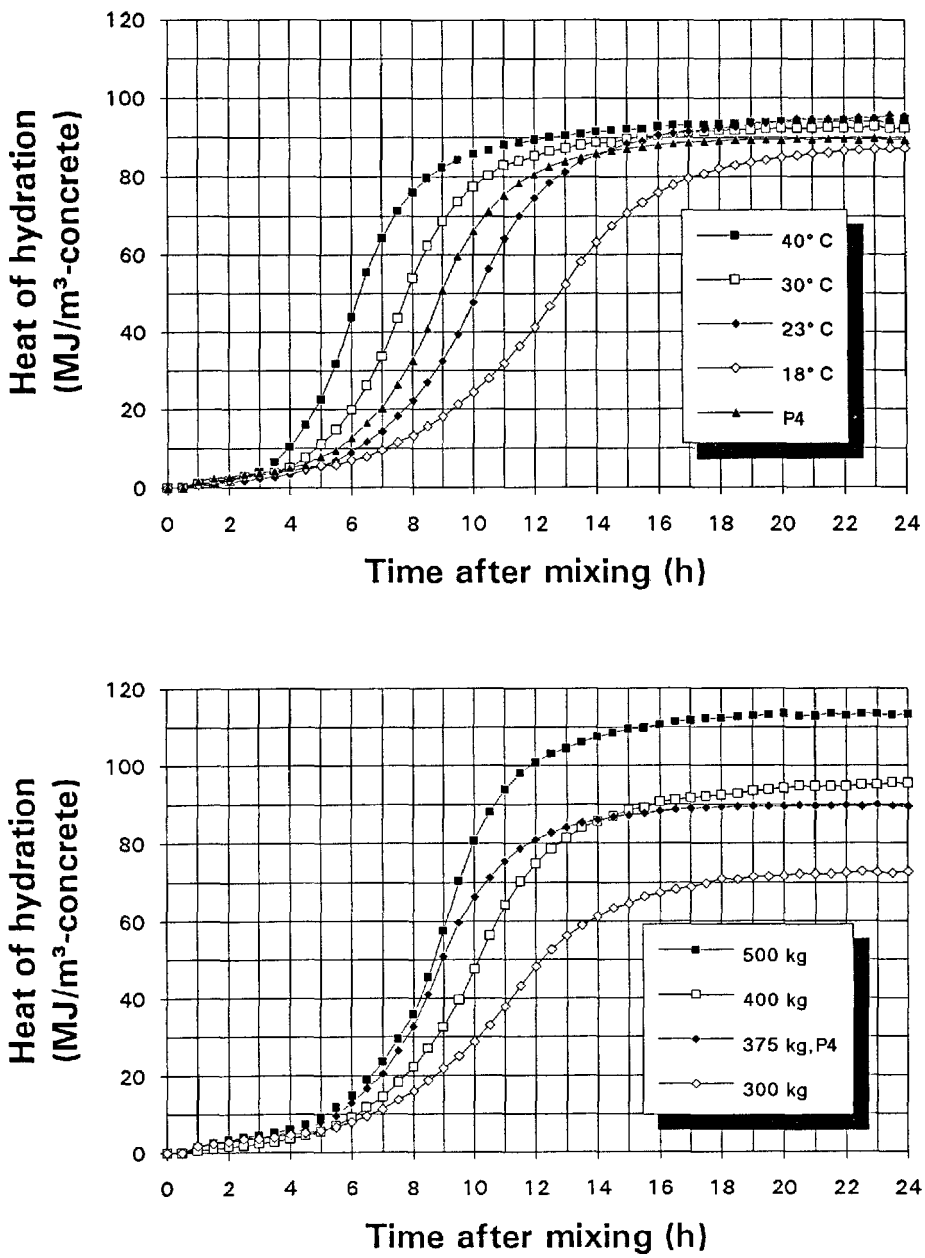

Figure 1. Effects of mixing temperature and binder amount on the heat of hydration of concrete. Hydration heat of concrete made with plasticizer P4 is also shown.

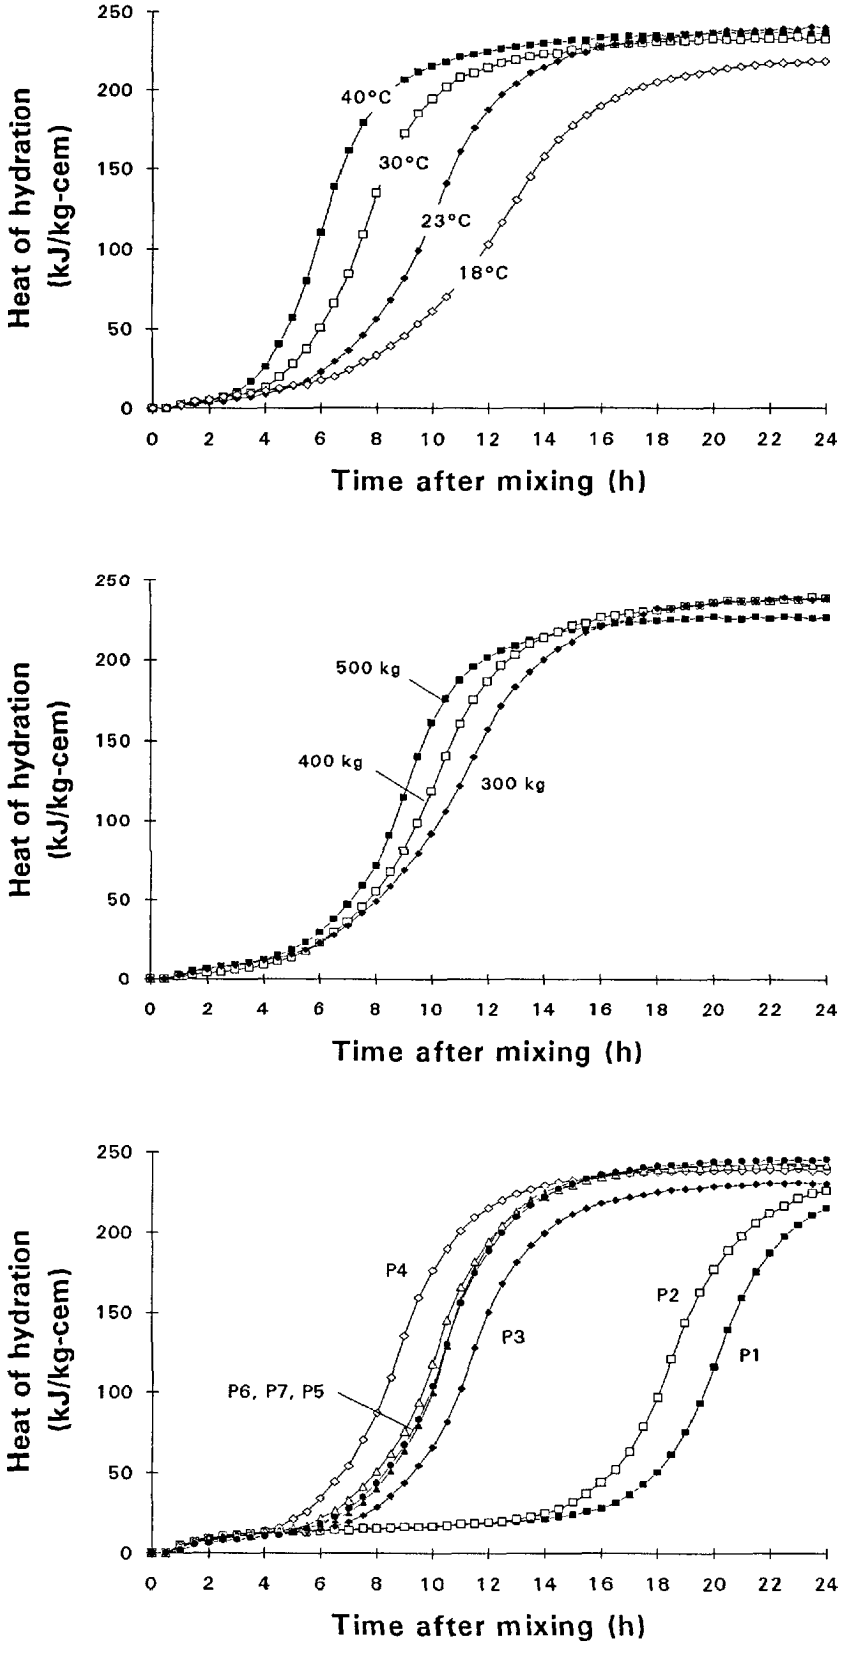

Figure 2. Effect of mixing temperature, binder amount, and plasticizer type on the heat of hydration of cement.

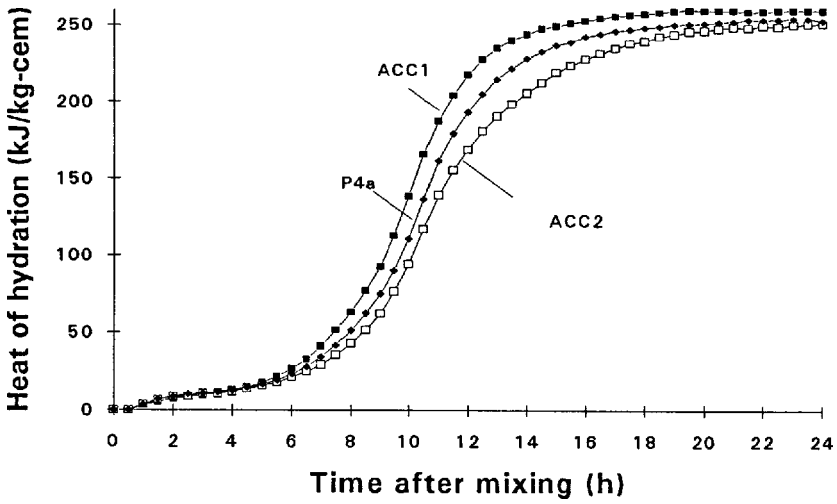

Figure 3. Effects of non-chloride accelerators and plasticizer on the heat of hydration of cement.

CONCLUSIONS

All the results and discussions are given in detail in Komonen and Penttala (1997). This presentation focuses only on the conclusions.

1. Mixing temperature was the most significant variable. The higher the mixing temperature was the earlier the heat gain took place. In spite of the higher water cement ratio the hydration reactions were advanced when the mixing temperature was increased.

2. High mixing temperature did not ensure early compressive strength. It did not accelerate the strength gain enough to compensate for the strength loss originating from water increase to ensure the workability desired. These effects cancelled each other at the age of 14 hours after mixing and the compressive strength of concretes mixed at 23, 30 and 40° C did not differ from each other at this age. At later ages the effect of water-cement law was dominant. The desired workability was obtained without retarders even at mixing temperature of 40° C.

3. The high cement content of the test concretes increased the rate of heat gain but had no effect on the induction period of cement. High cement content assured early strength gain. Compressive strength correlates with the cement content between the ages of 14 and 24 hours after mixing.

4. The efficiency of the different plasticizers varied considerably at early ages. The most efficient plasticizer was based on modified polycondensate of cyanureamide and formaldehyde. The second best plasticizers were based on sulphonated melamine-formaldehyde or modified naphthalene-formaldehyde polycondensate and the most inefficient plasticizer studied in this research project was lignosulfonate-based. Plasticizers based on lignosulfonates delayed the hydration reactions more than 9 ½ hours. The retarding and air-entraining effects of the admixtures based on lignosulfonate are in a good agreement with data generally accepted (e.g. Aïtcin et al. 1994 and Collepardi, 1984).

5. The chemical composition of plasticizer effected on the early strength gain but had very little effect on later strength. The plasticizers could be classified according to compressive strength after 14 and 24 hours from mixing.

6. The application of plasticizer together with a decrease of 25 kg in the cement content was equivalent to an addition of 100 kg cement content when an increase in the early strength gain of concrete was strived at.

7. The most effective non-chloride accelerator was based on organic sodium salts. This non-chloride accelerator and the reference plasticizer used gave quite equal evolutions of hydration heat and compressive strength. However, it has to be kept in mind that both concrete types were designed with respect to equal cost and equal workability, which governed the admixture dosage amounts.

8. The most efficient retarder was based on the water soluble alkali salts of orthophosphoric acid and alkyl aryl sulphonates and saccharides. This retarder delayed hydration reactions 2 ½ and 5 hours by dosages of 0.1 and 0.2 % of the weight of cement, respectively.

9. The efficiency of the retarders can be assured with the right mixing procedure. The best was the procedure in which cement, aggregates and three quarters of the total water amount were first mixed for one minute after which one-quarter of the total water amount including both plasticizer and retarder was added. It seems to be advantageous if the early reactions between cement and water take place before the retarder or other admixture is added.

10. All three retarders investigated gave equal compressive strengths after 24 hours from mixing. The method by which the retarder was added into the concrete had no effect on the compressive strength at the age of 24 hours after mixing. However, the effect of retarder amount (0, 0.1, and 0.2%) on the compressive strength was statistically significant at the age of 24 hours after mixing.

11. When hydration heat properties of various concretes are compared the definition megajoules per cubic meter concrete should be applied in the comparison. In this respect the accelerating effect of plasticizer P4 was found to be impressive. Concrete with cement content 375 kg and with plasticizer P4 (1.3%) gave much more earlier heat evolution than the concrete having a cement content of 400 kg and better early strength than the concrete having a cement content of 500 kg.. However, the total heat evolution at 24 hours after mixing correlated significantly with the cement content.

INTERACTION MECHANISM OF CHEMICAL ADMIXTURES AND THEIR INFLUENCES ON MICROSTRUCTURE

Weimin JIANG and Della M. ROY, Materials Research Laboratory, The Pennsylvania State University, University Park, PA 16802, USA

ABSTRACT This study examines the interaction mechanisms between the chemical admixture and hydrating cement and influences of admixture on microstructure development. The mechanism of action of chemical admixture was explained by the interaction effects and the synergistic effects. The properties of cements and chemical admixture were studied using TGA, IR, zeta-potential, viscometry, chemical analysis and SEM-EDX. This study also attempts to discuss effects which contribute to hydration of the cement/admixture combination.

Keywords: admixtures, naphthalene formaldehyde sulphonate, superplasticizers.

INTRODUCTION

The emergence of chemical admixtures as a modern technique has resulted in advancements in concrete production, and for this reason a bright future is predicted for this technique in the 21st century. There is now general recognition that chemical admixtures provide a cost effective method of producing high-performance concrete which also has other merits of improving various properties of fresh concrete and markedly increasing the strength and durability of hardened concrete. Experts predicted that the most recent technological developments in concrete technology rely on enhanced admixture efficiency rather than on improvements in cement manufacturing (Nawy, 1996 and Aïtcin and Baalbaki, 1995). The progressive general contractor would be willing to pay the cost of admixtures, and derive great benefit from them, especially where innovative construction techniques are involved. McFarland et al. (1990) described that superplasticizers (also known as high range water reducers-[HRWR]) can be distinguished from water reducers by the effective deflocculation and the high dispersion of cement particles when used in the mix design. Collepardi (1994) stated that 1970's superplasticizers could join air entraining agents of the 1930's as two of the revolutionary developments in concrete technology in the century.

It is somewhat surprising that cement-admixture compatibility problems are becoming more and more frequent, especially in the field of superplasticizers (Aïtcin, 1994). From engineering practice, various cases have led to recognition of cement/admixture incompatibility, or "abnormal concrete performance in the presence of admixtures" (Helmuth et al., 1995). Different superplasticizers will behave quite differently with different cements, or when combined with a second admixture. The compatibility between cement and admixture could be identified as a result produced by interaction mechanisms (Hewlett and Young, 1987 and Ramachandran, 1995). In addition, the compatibility significance of this problem was recognized as a requirement which needs to be met with the development of new generation chemical admixtures. This also is due in part to the fact that the acceptance standards for superplasticizers themselves now are not very tightly written. Among the benefits to be derived from this research is a better understanding of the factors that modify concrete properties when adding an admixture deliberately to the concrete, and by controlling the chemistry and processing to produce the desired microstructures and properties. It should be noted that the superplasticizers exert their action by decreasing the surface tension of water and by equidirectional charging of cement particles (Nawy, 1996). However, the method of addition of superplasticizer can affect the increase in slump significantly. In the immediate mode, admixture is mixed with water; in the delayed mode either admixture was adding after 1 min of mixing or waiting for the last minute of mixing. Jawed et al. (1979) suggested that the combination of a lignosulfonate with either an alkali carbonate or bicarbonate in conjunction with cement and water gives rise to several unusual effects which appear to be the result of a synergistic interaction. One goal of this study is to attempt to discuss the similar synergistic effects which contribute negatively to cement/admixture incompatibility.

EXPERIMENTAL PROCEDURE

Materials and mixing

Ordinary portland cement (OPC) type I (The chemical composition in Table I), MRL code# I-35, was obtained from Keystone Cement Co. It has a density of 3.12 g/cm^3 and BET surface area of 0.88 m^2/g. The particle size distribution range determined by micromeritics sedigraph is 1.2 - 50 μm. The superplasticizing (SP) chemical admixture, Mighty-150 (sulfonated naphthalene formaldehyde condensate), specific gravity 1.213, solid content 42%. was used in some formulations (Table II). Pastes and mortars were first prepared by adding admixtures and water, resting for 3 min, again mixing for 2 min (2-3-2 mix sequence). In order to check slump loss, the superplasticizer was added during the last minute of mixing in several cases.

Table I The chemical composition of Type I OPC (wt. %)

Type I	Code#	SiO_2	Al_2O_3	CaO	Fe_2O_3	MgO	K_2O	Na_2O	SO_3	L.O.I

*Ciment Fondu (Lafarge Aluminous Cement Co.) containing 1.95% TiO_2.

Table II Mixture proportions (by weight)

Paste	Mortar
OPC (type I cement) + deionized water at w/c = 0.22, 0.25, 0.3, 0.35, 0.4 adding Mighty 1%, 2%, 2.5% by cement wt% casting in ø1.25 in.x 1.5 cylinders	OPC:Sand (C 109 ASTM) ::1.0:2.25 at w/c = 0.3, 0.35, 0.44 adding Mighty 1%, 2%, 2.5% by cement casting 2 in. cubes

Experimental Methods

BET surface area—Nitrogen adsorption and desorption isotherms were measured using a Quantachrome Autosorb-1 Automatic Sorption Analyzer.

SEM-EDX—An International Scientific Instruments ISI-DS 130 dual stage Scanning Electron Microscope (SEM) with a Kevex Energy Dispersive X-ray analyzer (EDX).

ESEM—An ElectroScan ESEM with a cooling stage was used. The specimen was observed using a beam voltage of 20 keV, a beam current of 100 μA, at chamber pressure of 4 torr at temperature of 9°C, and a working distance of about 8 mm.

Zeta-potential of cement (in presence and absence of superplasticizer) was measured by the microelectrophoretic technique; more detail is given elsewhere (Malek and Roy, 1993).

IR—Infrared Spectrophotometer used was a Perkin-Elmer (model 283B). The sample preparation method followed the KBr disc method.

DTA-TGA—Differential thermal analysis of materials was performed on a Perkin Elmer System 7/4 with a DTA 1700 unit. In all cases the heating rate was either 10 or 20°C/min and Pt/Pt 10 Rh thermocouples were used. A Harrop Laboratories Thermogravimetric analyzer (TG 716) was used in this study with a Cahn balance.

Viscometer—A Haake Buchler coaxial cylinders rotational viscometer, Rotovisco™ RV 12 with the standard M 500 Measuring Drive, was selected.

Isothermal conduction calorimeter—A thermostatically controlled Haake F3 water circulator with heating and cooling equipment was used in conjunction with a Thermonetics Corporation calorimeter. In each case 3 g of powder was placed in metal container, then 1.5 g of water was added.

Pore solution—Samples of the aqueous phase in contact with alkali activated cement pastes were obtained by expression of the pore solution from hardened cement pastes under high pressures of 500 MPa at ages ranging from 15 minutes to 90 days.

RESULTS AND DISCUSSION

Effects of admixture adsorption on cement and rheological properties

BET data are given in Table III, and the setting time is in Table IV. There is little difference between results with or without Mighty-150 (SP), if w/c is unchanged. However, when reducing w/c to 0.22, BET surface is down to 1.96 m^2/g. The Ca^{2+} concentration in the cement-mighty-150 system is higher than in the control only. Fig 1 show the concentration of calcium ion and superplasticizer (SP) during hydration the first 24 hours in pore solution. The concentration of superplasticizer was determined by absorbance measurements (Jawed et al., 1979). When Mighty-150 was used, the rheological changes associated with setting time change of paste were determined to investigate the effects of admixture adsorption on cement and flow, yield value, plastic viscosity and zeta-potential. Setting is a poorly defined phenomenon (Struble and Lei, 1995). It is important to understand both the changes associated and physical (microstructural) changes associated with setting under superplasticizer's effect. Fig. 2 shows Haake flow curves of fresh paste of OPC (type I) with Mighty-150 1% (a/c wt%). The results indicated that although addition of superplasticizer decreases the yield stress and apparent viscosity in the early stage in the superplastizer-cements system, the magnitude of such decrease is qualitatively proportional to the amount of superplasticizer added and the water to cement ratio. However, with time elapsing the situation of "slump loss" may happened. After 30 min, the yield stress increased slightly is corresponding to a "slump loss". The negative zeta potential generated on the cement particles is illustrated in Fig. 3, which is consistent with those reported by Roy and Daimon (1980). The zeta potential of control (OPC only) is around +5 mV (Malek and Roy, 1993), which will shift to negative with a very small admixture addition, 0.1%, indicating that the dispersant was adsorbed on the particle surfaces. The increase in zeta-potential will cause cement particles to deflocculate (minimizing the yield stress) and setting the immobilized water free.

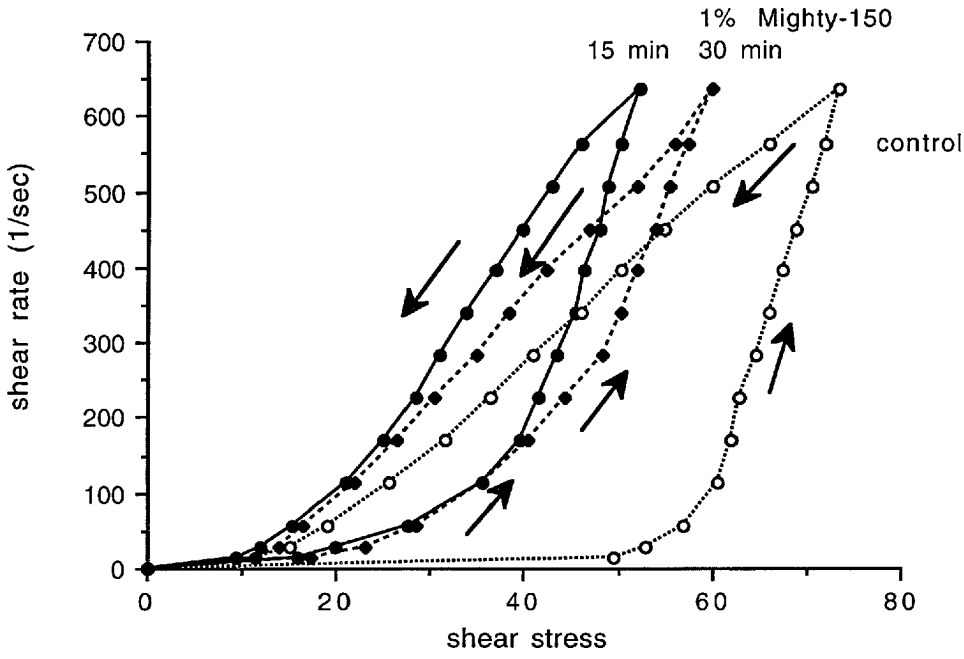

Figure 2 Haake flow curves of fresh paste of OPC (type I) with mighty-150 1% (a/c wt%)

Mode of interaction

The superplasticizers is a surfactant which acts by the way of adsorption predominantly at the solid-water interface (Hewlett and Young, 1987). Adsorption occurs via the polar backbone rather than the negatively charged end group causing the highly charged end to be thrust towards the solution. In this way, cement grains and small particles acquire an increased negative charge—any entrained air will also be negatively charged—and hence the mixture becomes mutually repulsive. Fig. 3 shows the tendency for zeta potential of OPC and Ciment Fondu to increase (negative magnitude) as a result of superplasticizer adsorption. Although, Ciment Fondu has a relatively larger negative zeta potential, the desired benefits of improved workability in the presence of Mighty-150 are not obtained to the expected degree, which will be reported elsewhere, and is consistent with data of Banfill and Gill (1993).

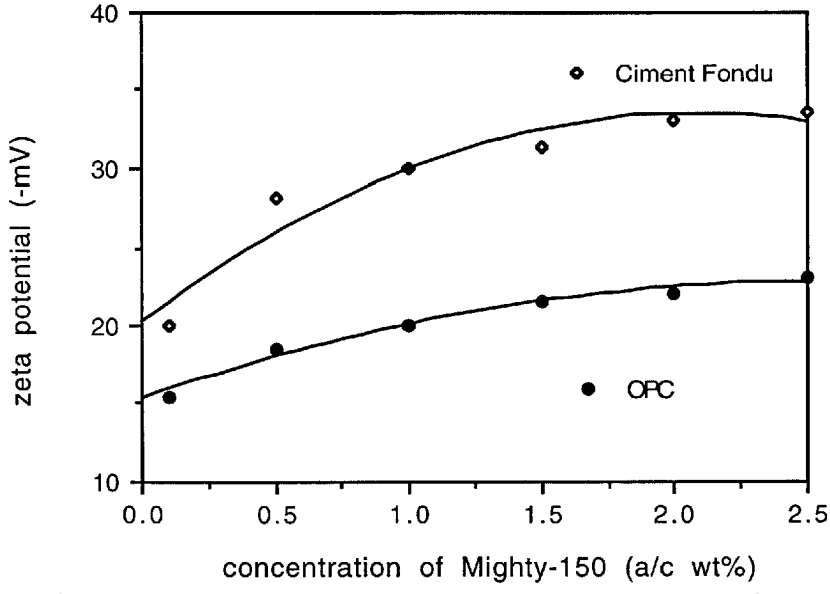

Figure 3 Zeta-potential of cement at different concentration of superplasticizer.

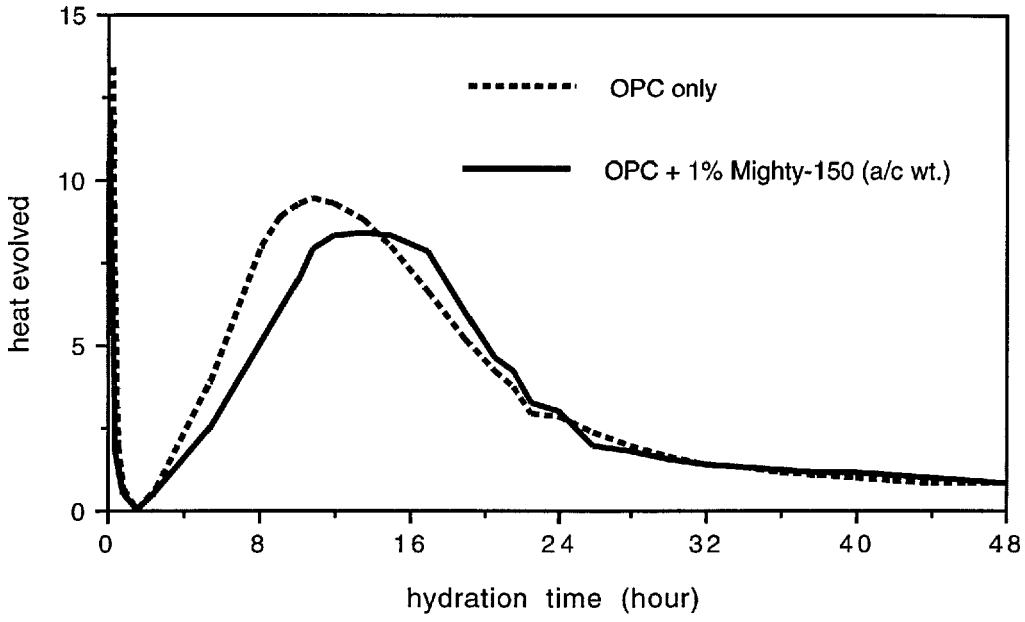

Figure 4 Calorimetric curves showing the rates of heat evolution as functions of time for portland cement + 1% SP at w/c = 0.5 during the first 24 hours of hydration.

Influences of admixture on hydration and microstructure development

Fig. 4 gives calorimetric curves showing the rates of heat evolution as functions of time for portland cement + 1% Mighty-150 at w/c = 0.5 during the first 24 hours of hydration. It seems that superplasticizers delay sightly OPC hydration, as in previous results (Dodson, 1990). Table IV of setting time also shows that when the w/c is unchanded, adding Mighty-150 delays setting slightly. However, when w/c ratio is decreased, setting time is reduced. The effect on microstructure of paste is based on the considerable ability to facilitate reducing the water content, with a consequent improvement in related characteristics of concrete (increased of compressive and flexural strength, decrease of permeability, creep, shrinkage).

Synergistic interaction

Fig. 5(A) is an SEM image of an OPC paste with 1% Mighty-150 after 18 hours hydration. It is shown that the better dispersion of cement particles in a superplasticized concrete produces a finer capillary structure. Fig. 5(B) x-ray sulphur map around the hydration products is shown. When compared with control (OPC only), extra sulphur is derived from Mighty-150. The sulphur-bearing products are also verified by EDX analysis, with results indicating that those kinds of product exist on the surface of cement particles. Fig. 6 illustrates the IR spectra in KBr disc.of Mighty-150. A series of spectrum of extracted Mighty-150 also made followed method described by Hime et al (1965). Those results will be reported elsewhere. It can be seen that both the composition of cement and the constitution of admixture must be known if the potential interactions are to be under stood (Hewlett and Young, 1987). The original compound from Mighty may converted into other substances by interaction with the cement components. The action of water reducers involves adsorption in the cement-superplasticizer system. In several cement/admixture incompatibility cases, successful analysis requires that results be related back to the original compound by "chemical intuition". The rate and amount of adsorption of superplasticizers on cement may identify the synergistic interaction of different factors. For instance, the solid-water interface (Stumm, 1992) may refer to the cement-superplasticizer, cement-set-accelerator (Justnes and Nygaard, 1995), or cement-corrosion-inhibitor (Nmai, 1995). According to this research, it seems that the adsorption reactions affect the surface charge of suspended cement particles and influence their aggregation and transport. However, more research is needed.

Table IV setting time

Setting time	OPC only at w/c = 0.35	OPC+1% SP at w/c = 0.35	OPC + 1% SP at w/c = 0.3	OPC + 1% SP at w/c = 0.22
Initial	4:17	4:30	3:53	2:56
Final	4:34	5:12	4:10	3:15

Combination of chemical admixture and mineral admixture

The influences of the actual combinations of chemical admixture and mineral admixture is a practical subject which attracts intensive attention. Uchikawa (1996) pointed out that increased chemical admixture is required with increasing fineness of mineral powder. Fly ash requires approximately 1.5 times as much chemical admixture as limestone powder. The more the adsorbed quantities of admixture, the larger of requirements are. Fig. 7 shows thermogravimetric (TGA) data for OPC + 1% (a/c wt%) and 5% silca fume after hydration 7 days. The content of combined water in paste with 1% Mighty-150 is lower than that of the control. TGA data shows two endothermic peaks, the first peak, 110°C, is due the capillary water, the second peak, 420-480°C, is due to portlandite. No major difference is suggested between the two TGA patterns. Increase of the strength of OPC with superplasticizer may be caused by densification of the structure under effect of admixture.

CONCLUSION

From this study the following conclusions may be drawn:

- Results shows the increased negative zeta potential of OPC and Ciment Fondu as a result of superplasticizer adsorption. Ciment Fondu has a relatively larger negative zeta potential. IR spectra in KBr disc.of Mighty-150 (reference) were illustrated.
- The present study shows that superplasticizers delay slightly OPC hydration, and setting time, when the w/c is unchanged.
- The adsorption reaction affects the surface charge of suspended cement particles, which influences their aggregation and transport.
- The content of combined water in paste with 1% Mighty-150 is lower than those of control. It is suggested that no major difference exists between both TGA patterns.

EFFECT OF CHEMICAL ADMIXTURES ON CH CRYSTAL GROWTH

Guy ROSENTHAL and Lynn BROWER, Master Builders Technologies, Cleveland, OH 44236 USA

ABSTRACT

A variety of small organic molecules have been examined in alite and OPC pastes for their effects on crystallization kinetics and crystal morphologies in the early stages of hydration. Admixtures were observed to remarkably affect $Ca(OH)_2$ (CH) size and morphology in alite paste, with aspect ratios (a/c) ranging from greater than 50 to less than 1. Differences were far less pronounced in cement paste. Computer modeling of interactions between organic molecules and CH surfaces showed a consistent preference for adsorption on the denser 001 surfaces over 100 surfaces.

Key-words: admixtures, alite, calcium hydroxide, crystal size, light microscopy

INTRODUCTION

The strength of a structural member is determined by the most efficient failure mode. For ordinary, moderate-strength concrete, crack propagation in compression or in tension occurs along the interface between paste and aggregate. The interfacial transition zone (ITZ) is thus considered to be the weakest aspect of concrete, and efforts to make significant gains in strength, as well as durability, have focused upon producing physical and chemical changes within the ITZ (Ahmed and Struble, 1995).

The disposition of $Ca(OH)_2$ (CH) crystals within the ITZ is a matter of some disagreement. CH crystals appear to precipitate preferentially within the ITZ (Patel, et.al., 1995) and, due to their plate-like habit, tend to self-orient with their ab crystallographic planes parallel, suggesting a mechanism for crack propagation and for fluid ingress between the oriented crystals. The lamellar nature of the individual crystals also provides a ready cleavage plane parallel to the ab plane.

Some disagreement persists, however, as to the orientation of the CH tablets relative to the aggregate surfaces. On the basis of microscopic observations, some investigators have concluded that the plates are oriented parallel to the aggregate surface (Maso, 1980), and some have concluded just the opposite (Afridi, et.al., 1990). Intuitively, one might conclude that a preferred orientation of plates perpendicular to the aggregate surface would result in a stronger ITZ (Groves, 1981, Barker, 1984), but in order for CH crystals in this orientation to effectively interfere with crack propagation, they would need to make contact, or even bond, with the aggregate surface. Irrespective of the orientation, however, it follows that removing the preferred orientation of the precipitating crystals, if not removing the CH entirely, from the ITZ can result in an increase in strength, and even a decrease in permeability, of a concrete or mortar sample.

Previous work by Berger and McGregor (1972) focussed upon the effect of inorganic admixtures on CH crystal morphology. Much is known about CH morphology in crystal grown from solution (Tadros, et.al., 1976, Barker, et.al., 1987) In this work, the crystal growth of CH from cementitious media is studied in the presence of a variety of organic modifiers which may have the effects of complexing calcium ions in solution and/or adsorbing preferentially upon specific crystal surfaces, thus influencing both the kinetics and morphology of CH growth. In concert

with the crystal growth experiments, a series of modeling studies were performed to investigate the possibility of preferential interaction of organic molecules with CH surfaces.

CRYSTAL GROWTH MODIFICATION

CH crystal growth was studied using the method of Berger and MacGregor, which involves spreading a thin layer of paste on a quartz microscope slide, beneath a cover slip, and placing the slide in 100% relative humidity for curing. Alite (C_3S) provides a paste which is more transparent than OPC, as well as a chemically simpler system.

Samples were prepared by combining alite or OPC (Type I) with water containing 0.5% by weight organic modifier, with a water/solids ratio of approximately 1.2. The thin paste was then spread on a microscope slide, covered, and cured at room temperature in a sealed Petri dish over water. The thickness of the samples averaged about 200 μm. Samples were examined under a polarizing microscope at 1, 4, 7 and 14 days.

After 24 hours, CH crystals were quite small, when observed, with largest dimensions usually less than 5 μm. 4-day observations yielded the best combination of optical transparency and contrasting results. By 7 days, most samples appeared quite opaque under the polarizer. The crystals were generally viewed down the crystallographic a axis, thus the basal (ac) plane is perpendicular to the slide. This was inferred from the pronounced striations observed in nearly all crystals, parallel to their longest observed dimensions. It was assumed that the crystals that were observed either spanned the thickness of the sample, from cover slip to slide, or occurred in microvoids, without significant amounts of amorphous paste above and below.

In alite, the reference CH crystals after 4 days of curing were relatively isotropic. Interestingly, while the aspect ratios (a/c) of measured crystals averaged around 2, no crystal was ever observed with an aspect ratio less than 1, i.e. the striations always appeared parallel to the longest observed dimension. Many organic modifiers had significant effects on CH growth habit (Table 1), and some resulted in extremely small crystals, rather than the normal case with several observed crystals of longest dimension greater than 50 μm.

In OPC, the results were more uniform. In almost every case, CH plates with aspect ratios greater than 5 resulted. Often the crystals were extensively twinned, resulting in star-like configurations in two dimensions. While this result is not surprising, it provides further evidence that C_3S has a pore solution chemistry which is not representative of Portland cement for the purposes of studying CH crystal growth. Only naphthalic acid, 2-carboxycinnamic acid and 2-ketoglutaric acid yielded relatively isotropic crystals.

MODELING OF MOLECULE-SURFACE INTERACTIONS

Modeling studies were conducted using the Cerius^2 program, minimizing interaction energy between a single molecule of organic modifier and a calcium-rich 001 (hexagonal) or 100 (rectangular) surface. Charges were assigned using semi-empirical and/or Qeq-based calculations. Molecules were given an initial impulse toward the surface and interaction energy was allowed to minimize over 5000 steps (5 ps) at 300 K.

malonic acid
1,2 diaminocyclohexane;
naphthalic acid
2-ketoglutaric acid

Note: Maleic acid, 2,2'-iminodibenzoic acid, 1,1-cyclopropanedicarboxylic acid and 1,2,3,4,5,6 cyclohexanehexacarboxylic acid all resulted in many very small crystals after 4 days.

Using all of the molecules in the optical microscopy study, interaction energies were calculated to be 50-75% lower (more negative) on the 001 surface than the 100, due to the higher positive charge density on that surface. The calculated interaction energies for energy-minimized configurations, corrected for base energies of the free organic molecules, are summarized in Table 2. All of the molecules studied oriented themselves with at least two close (<2.4 A) Ca-X (X = O,N) contacts per X atom. Thus, in the absence of covalent molecule-surface interactions or unsymmetrical charge distributions around basic atoms, all organic bases found a minimum energy configuration which simply maximized nearest-neighbor opposite charge interactions and minimized intramolecular repulsions. In molecules containing π bonds, the carbon backbone preferred to lie flat in order to maximize interaction of the positive surface charge with the π cloud.

Table 2. Interaction energies of molecules with $Ca(OH)_2$ surfaces.

Molecule	E(001)	E(100)	E(001)/E(100)
malonic acid	-456	-296	1.54

Clearly, the model also neglects the interactions of solvent molecules with crystal surfaces or with solvated basic molecules. While the model can examine negatively-charged or rough surfaces, it cannot account for competition at nucleation sites between precipitating ions and organic species in solution. Further work will involve development of the crystallization model.

CONCLUSIONS

The potential exists to substantially influence CH crystal growth from solution, using small organic molecules as modifiers. However, CH crystal growth in alite paste is markedly different from growth in OPC paste. Ions and/or nucleation surfaces present in the two environments act as morphology modifiers themselves.

Computer modeling indicates that organic bases will preferentially adhere to the close-packed 001 surfaces, due to coulombic factors. This interaction leads to growth perpendicular to the basal plane and plate-like crystals. Further development of the model is necessary to account for directional interactions, solvation and crystallization kinetics.

Hydration characteristics and new Hydrates using organic additives (carboxylates and sulfonates)

Pöllmann,H. & Stöber, St. Department of Mineralogy, University of Halle / Germany.

Abstract The use of organic additives is common in cement chemistry. In this study the use and the interaction of carboxylates and sulfonates were investigated. Different salts and compounds were used and the hydration mechanisms and formation of new hydrates due to the concentration were studied. A crystallochemical comparison due to properties of the organic compounds used as additives is given. Chain length, rings, substitution of carbon atoms and the change in hydration characteristics are described by heat flow calorimetry. New phases were synthesised purely for comparison purposes. Reaction mechanisms as a result of impurities of additives were included in the study. An improvement of additive usage and better understanding of reactions can be given. The fixation of organic ions in lamellar hydrates will be described.

Key-words: Accelerators, Additives, Afm phase, Calorimetry, Retarders

Introduction

The use of additives (Table 1) in cement industries plays an important role in manipulating a raw material in its physical and chemical abilities. To improve the knowledge of the basic mechanisms it is important to do fundamental scientific work on the main compounds of OPC, calcium aluminates C_3A, (C_4AF) and calcium silicates C_3S, C_2S. Mostly, only the resulting effect of additives is documented. Therefore the observation of the course of hydration by heat - flow calorimetry and combined XRD was done. On the other hand it is important to determinate the hydration products under equivalent conditions at special temporary hydration stages too. Pöllmann, Kuzel and Auer described new solid solutions and pure phases of calcium aluminate salts with different organic and inorganic ions.

Table 1 Organic acids used additives

Methane sulfonic acid	CH_3SO_3H
Ethane sulfonic acid	$C_2H_5SO_3H$
Propane sulfonic acid	$C_3H_7SO_3H$
Calciummethanesulfonate	$Ca(CH_3SO_3)_2$
Calciumethanesulfonate	$Ca(C_2H5SO_3)_2$
Benzene sulfonic acid	$C_6H_5SO_3H$
Toluene p-sulfonic acid	$C_7H_7SO_3H$
Xylol sulfonic acid	$C_8H_9SO_3H$
Formic acid	CH_2O_2
Acetic acid	$C_2H_4O_2$
Propionic acid	$C_3H_7O_2$

With the influence of additives retardation and acceleration occurs, depending on concentration, temperature and specific substances. Acids and salts give a retarding effect on the hydration of silicate phase forming a new hydration maxima. The heat evolution of the cement hydration changes as a function of additive concentration. Furthermore gel structures and chelates with different crystallinity were detected. At high additive concentrations precipitates of the organic compound were formed. The organic cations can enter the

interlayer of TCAH - like structures forming solid solution series (A) and pure phases (B) (Table2:)

Table 2: Table of new calcium aluminum hydrates with organic ions

A $[Ca_4Al_2(OH)_{12}]^{2+}$ $[(R)_2 \cdot nH_2O]^{2-}$	R = H-(CH_2)n-COO^- R = (C_6H_5)-(CH_2)n-COO^-
B $[Ca_4Al_2(OH)_{12}]^{2+}$ $[2x(OH)_2$ $(2-2x)(R)_2 \cdot nH_2O]^{2-}$ 0<x<1	R = CH_3-(CH_2)n-SO_3^- R = (C_6H_5)-(CH_2)n-SO_3^-

Experimental

1. The synthesis of lamellar salts had been done by preparing freshly synthesised educts $CaO \cdot Al_2O_3$ (CA), CaO and respective acids (Table 1) with CO_2 free H_2O W/F - Value = 10 in a glove box. In order to reach better homogeneity an get an higher reaction degree, the pastes were kept in a shaking tool.
Investigations had been done after 3 months of reaction time. Using a special sample holder for wet samples hydration stages at 100% r.F. and 35% r.F. could be exactly determinated.
The metric parameters of the new phases were refined by least squares method using cell parameter values of isotypical structures in combination with 2 Theta - values of the different XRD pattern. In addition the stability of the products will be tested concerning heat resistance and binding strength of organic ions and water molecules in the interlayer by using thermal methods. Optical methods, such as SEM and polarisation microscopy were used too.

2.The course of hydration of several pastes was investigated by using heat flow calorimetry in combination with XRD. As a commercial sample material OPC 42,5 R was used to demonstrate the influence of organic acids. 1g of cement was mixed with 1 ml water or an organic solution was added by injection method. The measured curves were used to determinate quantitative and qualitative effects of development and temporary changes of the hydration of OPC as a function of concentration, C - chainlength of acids, and arrangement of functional groups.

Crystallography

Mechanisms of hydration with respect to crystallography and chemical admixtures were determined. The Afm-Phases were synthesised using carboxylic or sulfonic acids or Ca- salts (Fig.1). Some reactions are described exemplary.

1. $CA + 2CaO + Ca(C_6H_5SO_3)_2 + nH_2O \longrightarrow C_3A \cdot Ca(CtH_5SO_3)_2 \cdot nH_2O$
2. $CA + 3CaO + CH_3SO_3H + nH_2O \longrightarrow C_3A \cdot Ca(CH_3SO_3)_2 \cdot nH_2O$
3. $C_3A + Ca(HCOOH)_2 + nH_2O \longrightarrow C_3A \cdot Ca(HCOOH)_2 \cdot nH_2O$

After 3 months the pastes were investigated by XRD with a special sample holder tool for humidity. The crystallinity was not equal in all samples. Beside well crystallised calcium aluminates containing acid ions with short C-chains (methane-, ethanesulfonates), precipitates with toluene p-sulfonic xylolsulfonic ions of minor crystallinity were developed. It was proofed that at 100% of relative humidity several hydration stages of calcium aluminate hydrates were stable.

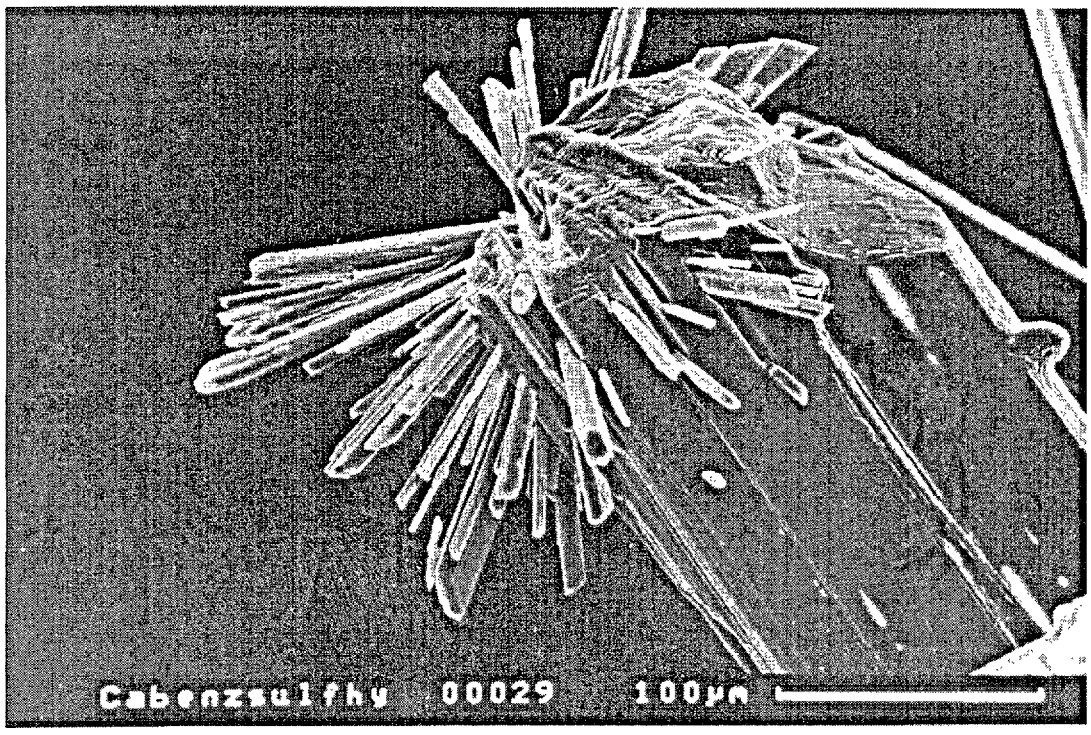

Fig.1 SEM Photography: Crystals of Calciumbenzenesulfonate Monohydrate

Drying until 35% r.F. water molecules were forced to leave the interlayer. The exchange of water between interlayer and surrounding is a reversible process. The formed crystal-structures are not isotypical with the TCAH structure at 100% and 35% r.F.. X-Ray investigations of calcium aluminate hydrates (Fig.2) with interlayered aliphatic - or aromatic sulfonate ions demonstrate, that the c_o-Dimension is equal to the layer thickness c'. Moreover structures with different triclinic or monoclinic crystal systems especially of calcium aluminate carboxylates were formed.

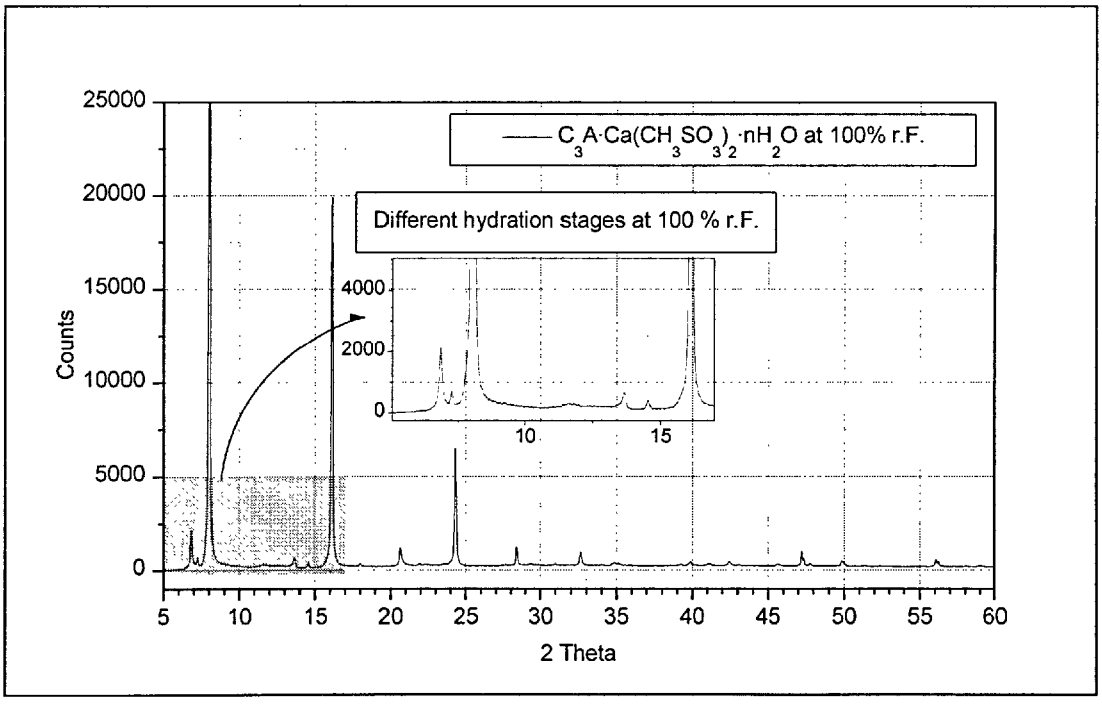

Fig.2 XRD - Pattern of $C_3A{\cdot}Ca(CH_3SO_3)_2{\cdot}nH_2O$

The system TCAH - Monobenzenesulfonatehydrate is illustrated in Figure 3. Neither at 100% r.F. nor at 35% r.F. solid solutions are stable in the range of 10 to 90% $Ca(C_6H_5SO_3)_2 \cdot nH_2O$. The quantity of the phases $C_3A \cdot Ca(CH_3SO_3)_2 \cdot nH_2O$ and $C_3A \cdot Ca(OH)_2 \cdot 18H_2O$ (TCAH) changes linear. Solid solutions were not formed in the system $C_3A \cdot Ca(CH_3SO_3)_2 \cdot nH_2O$ - $C_3A \cdot Ca(OH)_2 \cdot nH_2O$ at 35% and 100% r.F.. At 100% r.F. several coexisting hydration stages are stable too.

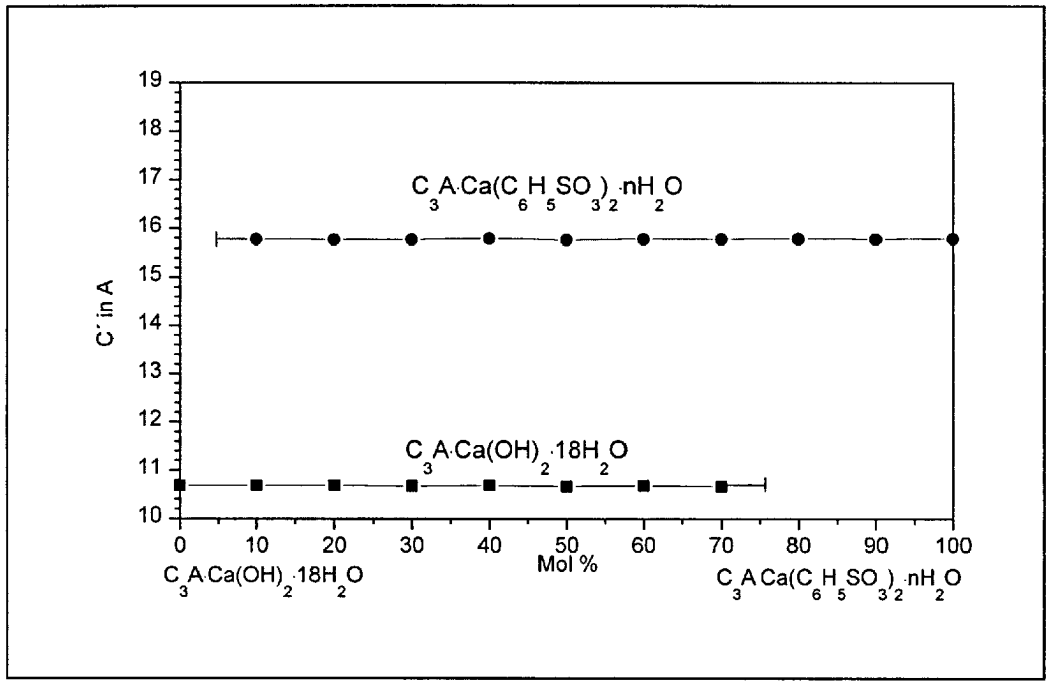

Fig.3 Solid solution system TCAH - $C_3A \cdot Ca(C_6H_5SO_3)_2 \cdot nH_2O$ 100% r.F.

The crystallographic data is given in Table 3. Furthermore gel structures of minor cristalinity are stable in the precipitates of the system TCAH - Monoetanesulfonatehydrate in the range of 20-70% $Ca(C_2H_5SO_3)_2$. Drying of these structures forces conversion to Portlandite, Hydrogrossular and organic calciumsalts.

*100% r.F.

**35% r.F.

With longer chain length of the aliphatic carboxylic acids the distance c´ increased.
The fact is, that increasing c´ interlayer dimensions are not linear, because the organic ions are not fixed in the in c_o-direction.

Heat flow calorimetry
The hydration reaction of OPC was studied under the influence of several additives with special subject.

1. Sulfonic acids with increasing C_nH_{2n+1}-chain.
2. Influence of Calciummethane - and Calciumethanesulfonates.
3. Carboxylic acids with increasing amounts of C_nH_{2n+1}-chain.
4. Aromatic sulfonates with increasing amounts of C_nH_{2n+1}-groups.

The influence of aliphatic sulfonic acids show that retardation occurred with increasing chain-length (Fig.4). The Hydrationmaxima of methanesulfonic - and propanesulfonic acid roses up about 15 h. The integration of the heat of reaction over 72h indicated an exponential decrease o heat with increasing chain length. Carboxylic acids did not retard the cement reaction. With reference to the additive-free sample the hydration was accelerated up to 1h 20 min. Longer C_nH_{2n+1} chains caused retardation.

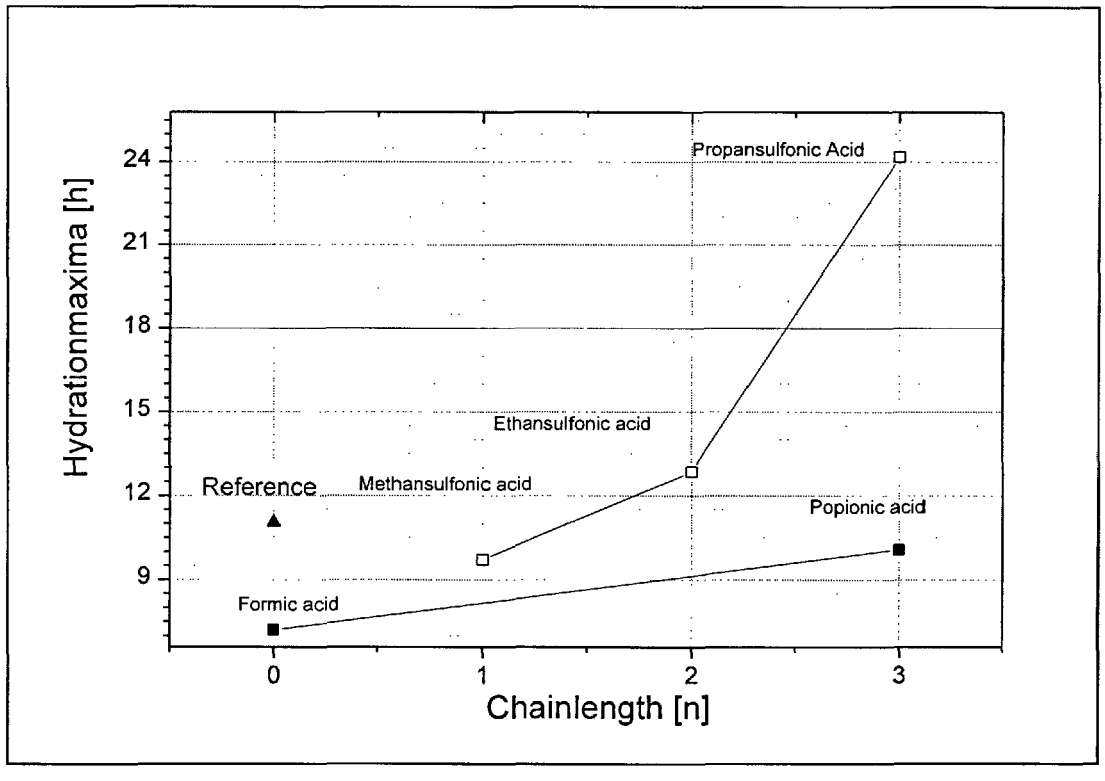

Fig.4 Hydration effects as a function of increasing chain length

The temporary influence of methanesulfonic and ethanesulonic acids (Fig.5) on the OPC hydration behaviour was quite similar. Increasing additive amounts caused retardation. The effect was much stronger using methanesulfonic acid. High concentrations of these acids caused different effects. The use of calcium salts for example calciummethanesulfonate and calciumetansulfonate (Fig.6) forced a secondary hydrationmaximum which is well developed with decreasing additive concentration.

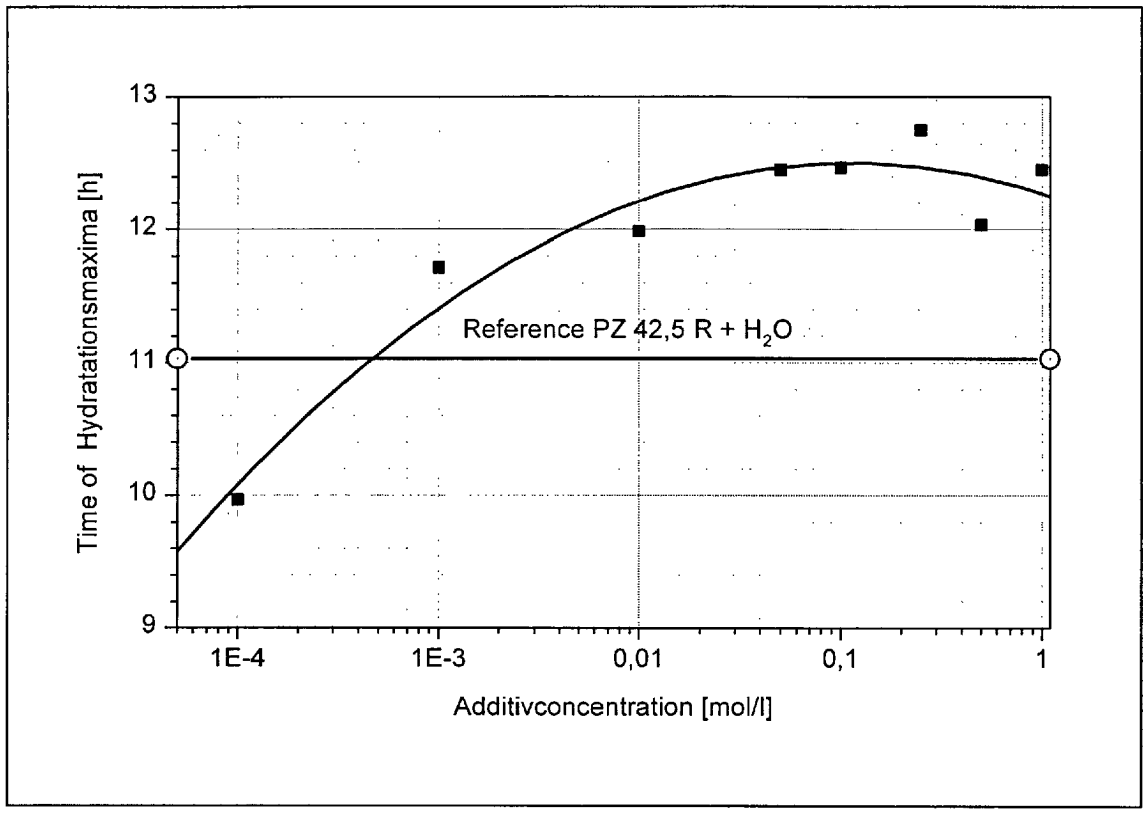

Fig.5 Influence of Ethanesulfonic acid on the hydration of OPC

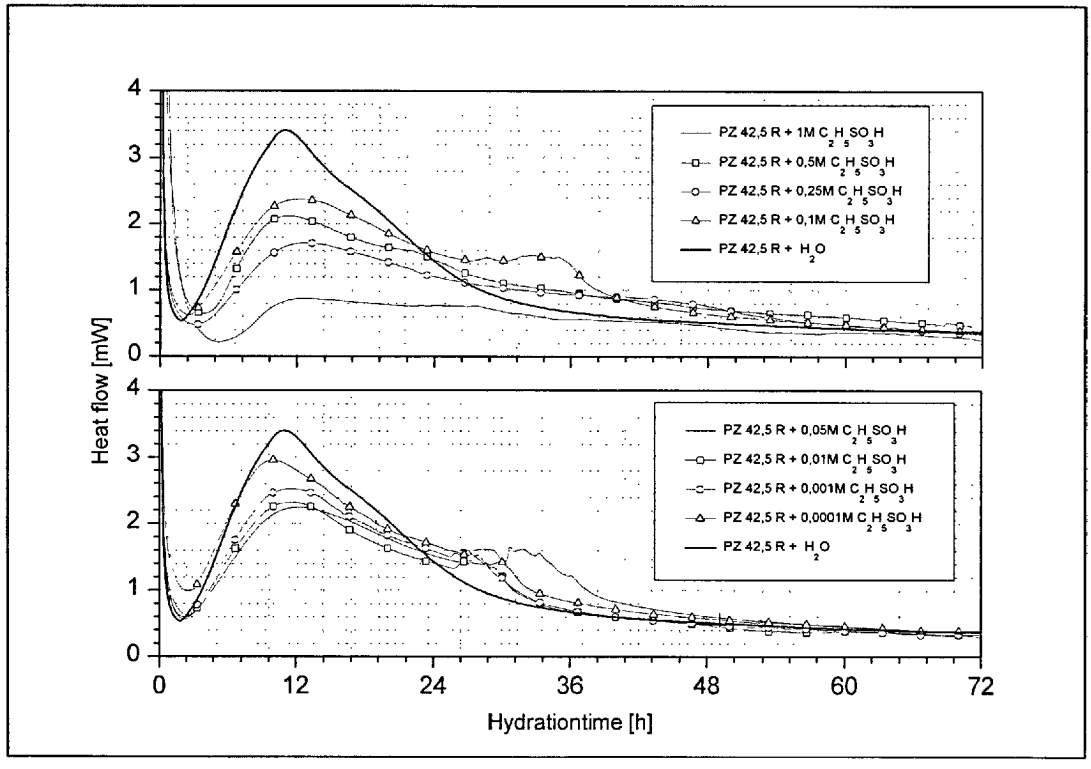

Fig.6 Heat flow calorimetry: Addition of Calciumethansulfonate to OPC

Calciumions in combination with acid ions using $Ca(C_2H_5SO_3)_2$ (Fig.7) retarded the hydration exponentially about 1 h relative to the additive free sample. Concentrations of Calciummethanesulfonate show acceleration and retardation which belongs to specific concentrations.

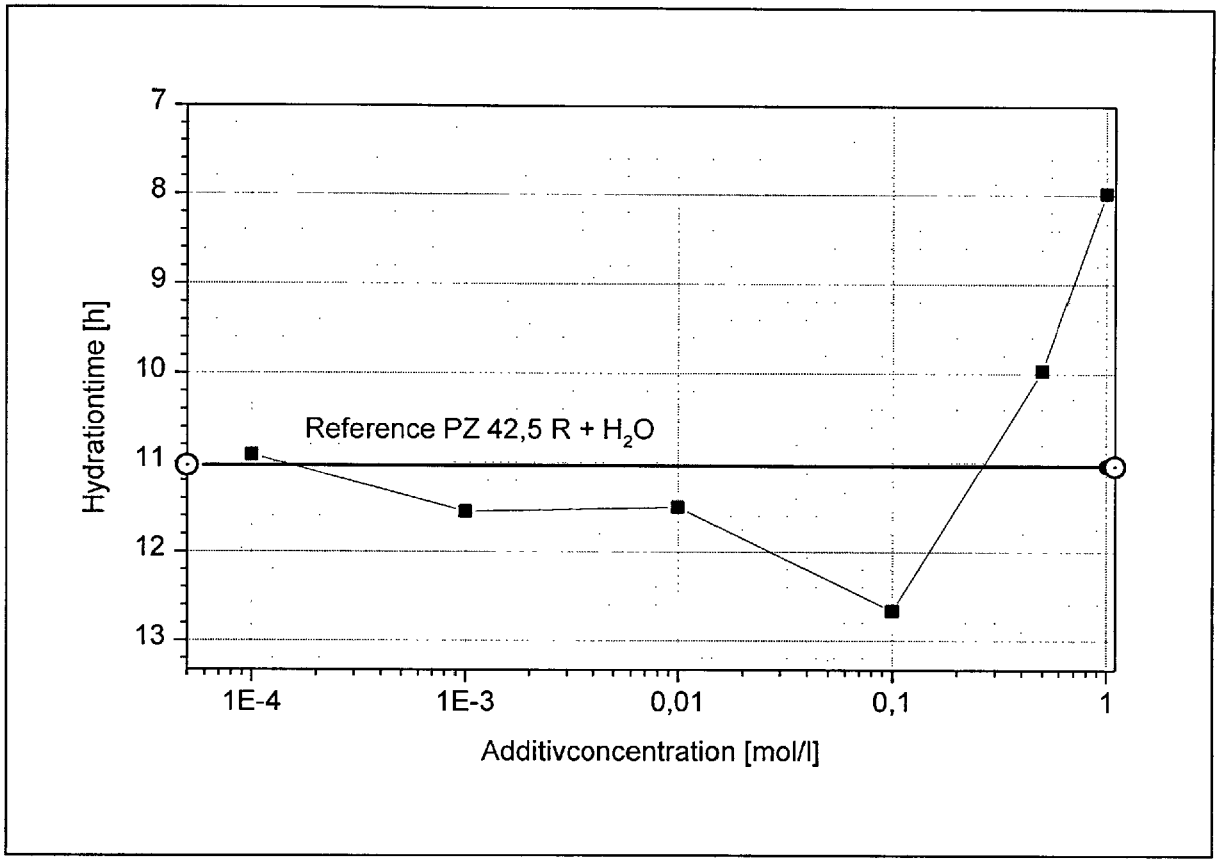

Fig.7 Hydrationmaxima as a function of the Calciumethansulfonate concentration

Aromatic sulfonic acids have a strong influence on the heat of hydration until 72 h. After a long induction period, especially of toluene p-sulfonic acid, the OPC hydration was slowed down.

Discussion and summary

The results of the addition of carboxylic and sulfonic acids and salts to OPC indicate that acceleration, retardation and heat suppression can occur as a function of concentration, chain length and functional groups ($-SO_3H$, -COOH, C_6H_5-). The different existing salts of various carboxylic acids and acids itself were used as additives. The crystallochemical change of bond mechanisms and delayed setting and hardening was tested using a model OPC. Using the size of organic molecules as well as functional groups and cations the influence on setting and hardening can be described. Besides well crystallised hydration products, chelates, gel-structures and semi crystalline phases occurs. The reactionproducts stand in relation with TCAH (tetracalcium aluminate hydrate), partly with different crystal system and structure. Because of fixation of organic ions in the interlayer the c_o- distance c´ will grow with increasing size of the molecules. A linear increase with different C-chainlength was not observed. Phases with ettringite structure containing organic ions were not observed. Only the small formate ion enters the structure of ettringite and forms formate-ettringite.

EVALUATION OF CHEMICAL INHIBITORS FOR ALKALI-AGGREGATE REACTION BY ACCELERATED TESTS

Yoshihiko OHAMA, Katsunori DEMURA, Hiroyuki IWASAKI, Department of Architecture, College of Engineering, Nihon University, Koriyama, Fukushima-ken, 963 Japan

ABSTRACT The effectiveness of the addition of chemical inhibitors such as hexyl trimethoxy silane, lithium nitrite and hydrogen peroxide to mortars containing reactive andesite and opal for inhibiting alkali-aggregate reaction is tested by applying three accelerated tests in which mortar specimens are stored at 40°C and 100%RH, fully and partially immersed in a 2.5% NaCl solution for 189 days. It is concluded from the test results that the hydrogen peroxide and hexyl trimethoxy silane are considerably effective for inhibiting alkali-aggregate reaction, but the lithium nitrite is ineffective.

Key-words : Alkali-aggregate reaction, Inhibitor, Accelerated tests

INTRODUCTION

An alkali-aggregate reaction problem in reinforced concrete structures has drawn worldwide attention in the construction industry in recent years. However, effective measures for inhibiting the alkali-aggregate reaction have not been found till now, and it is most important in the current concrete technology to find out such measures for improving the durability of the concrete structures. It has been reported that alkyl alkoxy silane, lithium nitrite and hydrogen peroxide can be used as chemical admixtures to inhibit the alkali-aggregate reaction by the authors (Ohama, Demura & Kakegawa, 1989) and other researchers (Hibino, Tsuyuki & Ishida, 1994). However, the inhibition of the alkali-aggregate reaction by the addition of these admixtures has been evaluated under different test conditions. On the other hand, it was reported by some papers (e.g., Kawamura, Takeuchi & Sugiyama, 1994) that the alkali-aggregate reaction is promoted by alkalis from the outside of concrete. In the present study, the partial and full immersion tests of mortars in a chloride solution are discussed as the test methods to check up on this fact.

In the present paper, mortar specimens containing a reactive andesite or opal with chemical inhibitors such as hexyl trimethoxy silane, lithium nitrite and hydrogen peroxide are prepared, and evaluated for alkali-aggregate reaction by applying three accelerated tests due to storage at 40°C and 100%RH, full immersion and partial immersion in a 2.5% NaCl solution. The effects of the inhibitors on the expansion due to alkali-aggregate reaction are examined. Furthermore, the effectiveness of the partial and full immersion tests as rapid tests is also discussed.

MATERIALS

Cement

Ordinary portland cement as specified in JIS (Japanese Industrial Standard) R 5210 (Portland Cement) was used in all the mortar mixes. The properties of the cement are listed in Table 1.

Aggregates

Toyoura standard sand (size, 0.3mm or finer) as specified in JIS was used as a nonreactive aggregate for all the mortar mixes. Takayama crushed andesite (size, 5mm or finer) and Iou-island opal (size, 5mm or finer) were employed as reactive aggregates for the mortar mixes. The properties of the reactive aggregates, tested according to Appendix 7 [Method of

Specific Gravity	Blaine's Specific Surface (cm^2/g)	Setting Time (h-min)		Compressive Strength of Mortar (MPa)		
		Initial Set	Final Set	3d	7d	28d
3.16	3250	2-14	3-08	16.0	26.3	41.5

Chemical Compositions (%)			Total Alkali Content (%)
MgO	SO_3	ig.loss	
1.7	2.1	1.2	0.63

Testing Alkali-Silica Reactivity of Aggregate (Chemical Method)] of JIS A 5308 (Ready-Mixed Concrete) are listed in Table 2.

Table 2 Properties of Reactive Aggregates, Checked by Chemical Method.

Type of Reactive Aggregate	Dissolved Amount of Silica (Sc) (mmol / l)	Decrease in Alkali Concentration (Rc) (mmol / l)	Interpretation of Results
Andesite	461	121	Deleterious
Opal	1608	224	Deleterious

Chemical inhibitors

Hexyl trimethoxy silane [$C_6H_{13}Si(OCH_3)_3$: HTMS], lithium nitrite ($LiNO_2$) and hydrogen peroxide (H_2O_2) were used as inhibitors.

TESTING PROCEDURES

Preparation of specimens

In accordance with Appendix 8 [Method of Testing Alkali-Silica Reactivity of Aggregate (Mortar-Bar)] of JIS A 5308, mortars containing reactive aggregates were mixed with a cement-aggregate ratio of 1 : 2.25 (by mass) and inhibitor contents of 0, 0.5 and 1.0% of cement. The water-cement ratio of the mortars was adjusted to be a flow of 170±5, and the total alkali content of the mortars was adjusted to be 2.5% as Na_2O equivalent by using a 2N aqueous solution of the sodium hydroxide specified in JIS K 8576 (Sodium Hydroxide). A mixture of 20wt% nonreactive aggregate and 80wt% reactive andesite or a mixture of 90wt% nonreactive aggregate and 10wt% opal was used as an aggregate for the mortars. Gauge plugs for measuring the length change of the mortars were installed in molds. Mortar specimens 40×40×160mm were molded, and then subjected to a 1-day-20°C-80%RH-moist plus 1-day-20°Cwater cure.

Measurement of expansion

The measurement of the expansion of mortar specimens was conducted according to the dial gauge method specified in JIS A 1129 (Methods of Test for Length Change of Mortar and

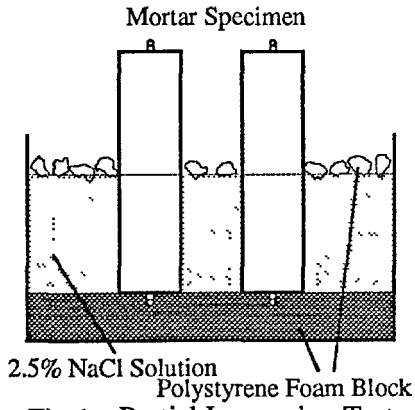

Fig.1 Partial Immersion Test of Mortar Specimens in 2.5% NaCl Solution.

Concrete). After water cure, the initial length of the mortar specimens was measured, and then the mortar specimens were stored at 40°C and 100%RH, or fully and partially immersed in a 2.5% NaCl solution as shown in Fig.1. Their expansion was measured at storage or immersion periods of 7, 14, 21, 28, 35, 42, 49, 56, 63, 70, 77, 84, 91, 105, 119, 133, 147, 161, 175 and 189 days.

TEST RESULTS AND DISCUSSION

Fig.2 shows the expansion of mortars containing reactive aggregates with inhibitors during storage at 40°C and 100%RH. The expansion of the mortar containing a reactive andesite without any inhibitor is increased with additional storage period, and becomes nearly constant at a storage period of 84 days. Its expansion at a storage period of 189 days is 0.36%. On the other hand, with additional storage period, the expansion of the mortar containing an opal without any inhibitor is increased, and attains 0.47% at a storage period of 189 days. The expansion of the mortars containing the reactive andesite with HTMS is slightly increased with additional storage period regardless of HTMS content, and becomes nearly constant at a storage period of 84 days. The expansion of the mortars containing the opal with HTMS is changed to a less extent up to a storage period of 49 days, and then is slightly increased. Such a

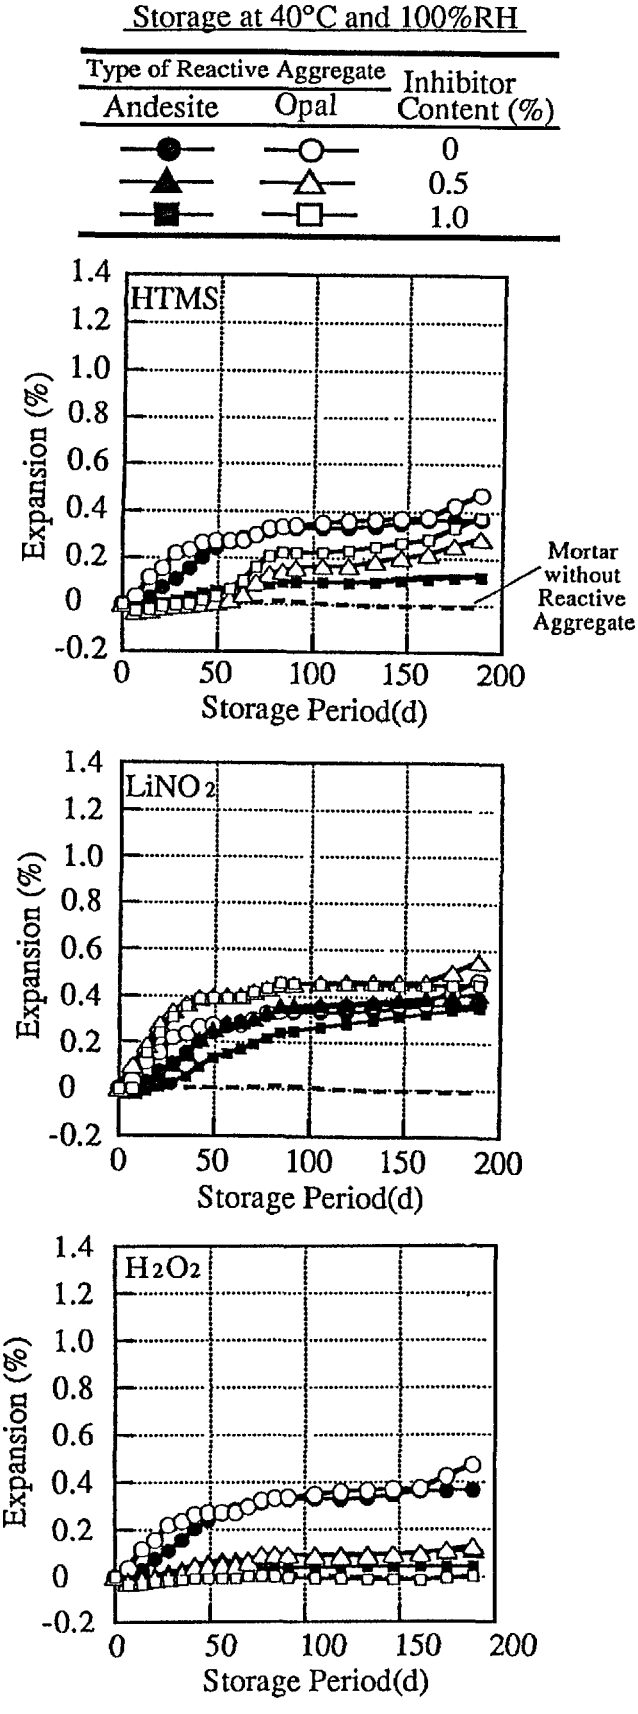

Fig.2 Expansion of mortars containing reactive aggregates with inhibitors during storage at 40°C and 100%RH.

marked reduction in the expansion by use of HTMS is ascribed to the water repellency which is given to the surface layers of the reactive aggregates, cement hydrates and alkali-silica gel in the mortars ; moreover, an increase in the entrained air content of the mortars due to the surface activity of HTMS contributes to a reduction in the expansion. With additional storage period, the expansion of the mortars containing the reactive aggregates with $LiNO_2$ is increased regardless of the type of aggregate and inhibitor content, and is nearly equal to that of the mortars containing reactive aggregates without any inhibitor. In a previous paper (Saito, Kitagawa & Hasaba, 1992), $LiNO_2$ in the mortar is found to form waterproof layers on the reactive aggregate surfaces, and inhibit a reaction between pore solution in the mortar and the reactive aggregates. However, no effectiveness of $LiNO_2$ against the expansion is recognized in this study because of its low content. The expansion of the mortars containing the reactive aggregates with H_2O_2 is changed to a less extent regardless of the type of aggregate and inhibitor content. It is reported that H_2O_2 attacks the reactive aggregate surfaces by strong oxidation action, and inhibits the alkali-aggregate reaction (Hibino, Tsuyuki & Ishida, 1994). The marked effectiveness of H_2O_2 against the expansion is also recognized in this study.

Fig.3 represents the expansion of mortars containing reactive aggregates with inhibitors during full immersion in a 2.5% NaCl solution. The expansion of the mortar containing a reactive andesite without any inhibitor is increased to some extent with additional immersion period, and becomes 0.18% at an immersion period of 189 days. With additional immersion period, the expansion of the mortars containing an opal without any inhibitor is markedly increased up to 0.68% at an immersion period of 189 days. The expansion of the mortars containing the reactive aggregates with the inhibitors is increased with additional immersion period. The expansion of the mortars containing the opal is much larger than that of the mortars containing the reactive andesite irrespective of the addition of the inhibitors. In the mortars containing the reactive aggregates, their expansion is reduced with increases in the contents of HTMS and H_2O_2 as inhibitors. However, the expansion of the mortars containing the opal tends to increase with an increase in $LiNO_2$ content. Such a tendency is not recognized in the mortars containing the reactive andesite with $LiNO_2$.

Fig.4 illustrates the expansion of mortars containing reactive aggregates with inhibitors during partial immersion in a 2.5% NaCl solution. The expansion of the mortars containing a reactive andesite without any inhibitor is increased to some extent with additional immersion period, and becomes 0.07% at an immersion period of 189 days. With additional immersion period, the expansion of the mortars containing an opal without any inhibitor is increased, and becomes nearly constant at an immersion period of 161 days. Its expansion at an immersion period of 189 days is 0.50%. Such an expansion of the mortars containing the reactive aggregates without any inhibitor is smaller than that of the same mortars fully immersed in the 2.5% NaCl solution. The effects of the inhibitors on the expansion behavior of the mortars containing the reactive aggregates in the partial immersion are similar to those in the full immersion. The expansion of the mortars containing the reactive aggregates is considerably decreased by the addition of HTMS and H_2O_2.

Figs.5 and 6 show the relation between inhibitor content and the expansion and reduction in expansion of mortars containing reactive aggregates after 189-day storage at 40°C and 100%RH, 189-day full immersion and 189-day partial immersion in a 2.5% NaCl solution. The relative reduction in expansion of the mortars is calculated as follows :

$$\text{Reduction in expansion (\%)} = [(Ero - Era) / (Ero - Eno)] \times 100 \quad [1]$$

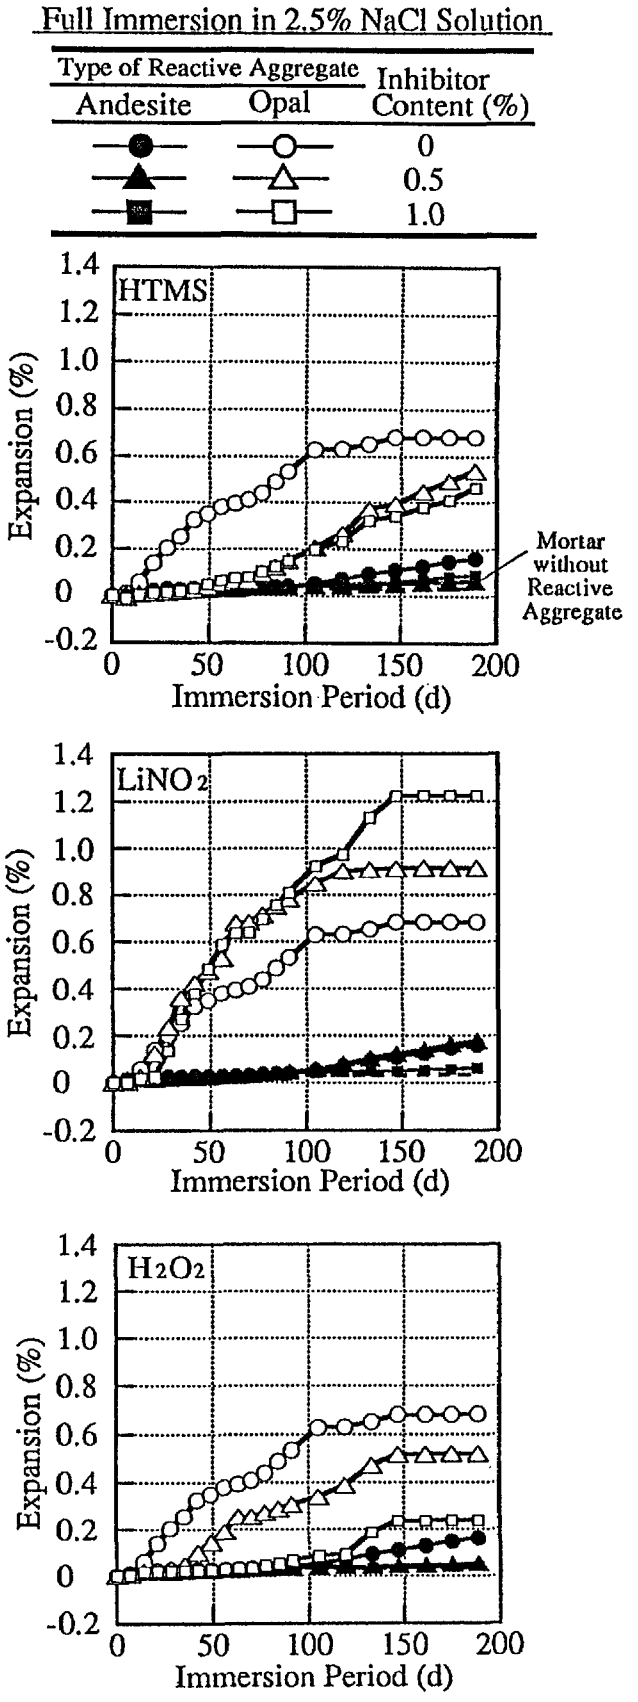

Fig. 3 Expansion of mortars containing reactive aggregates with inhibitors during full immersion in 2.5% NaCl solution.

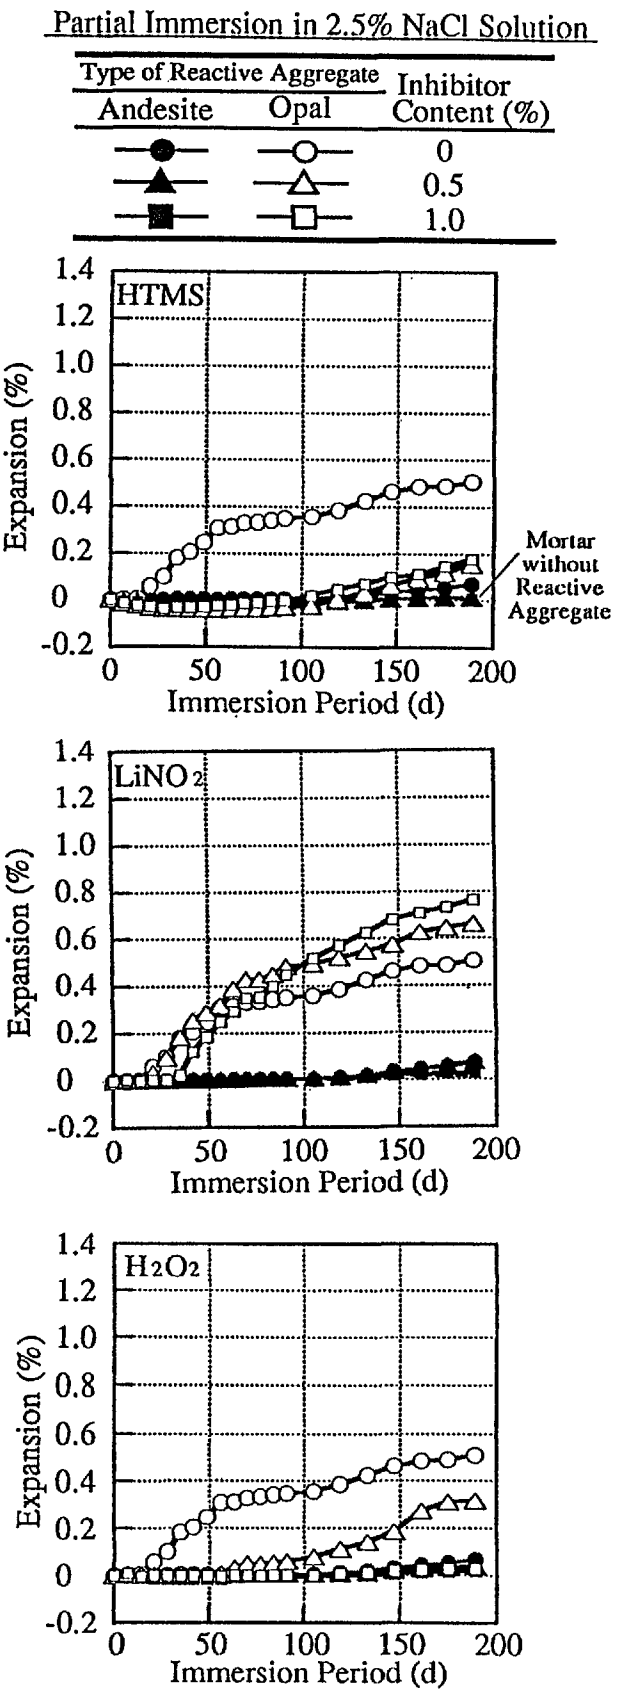

Fig. 4 Expansion of mortars containing reactive aggregates with inhibitors during partial immersion in 2.5% NaCl solution.

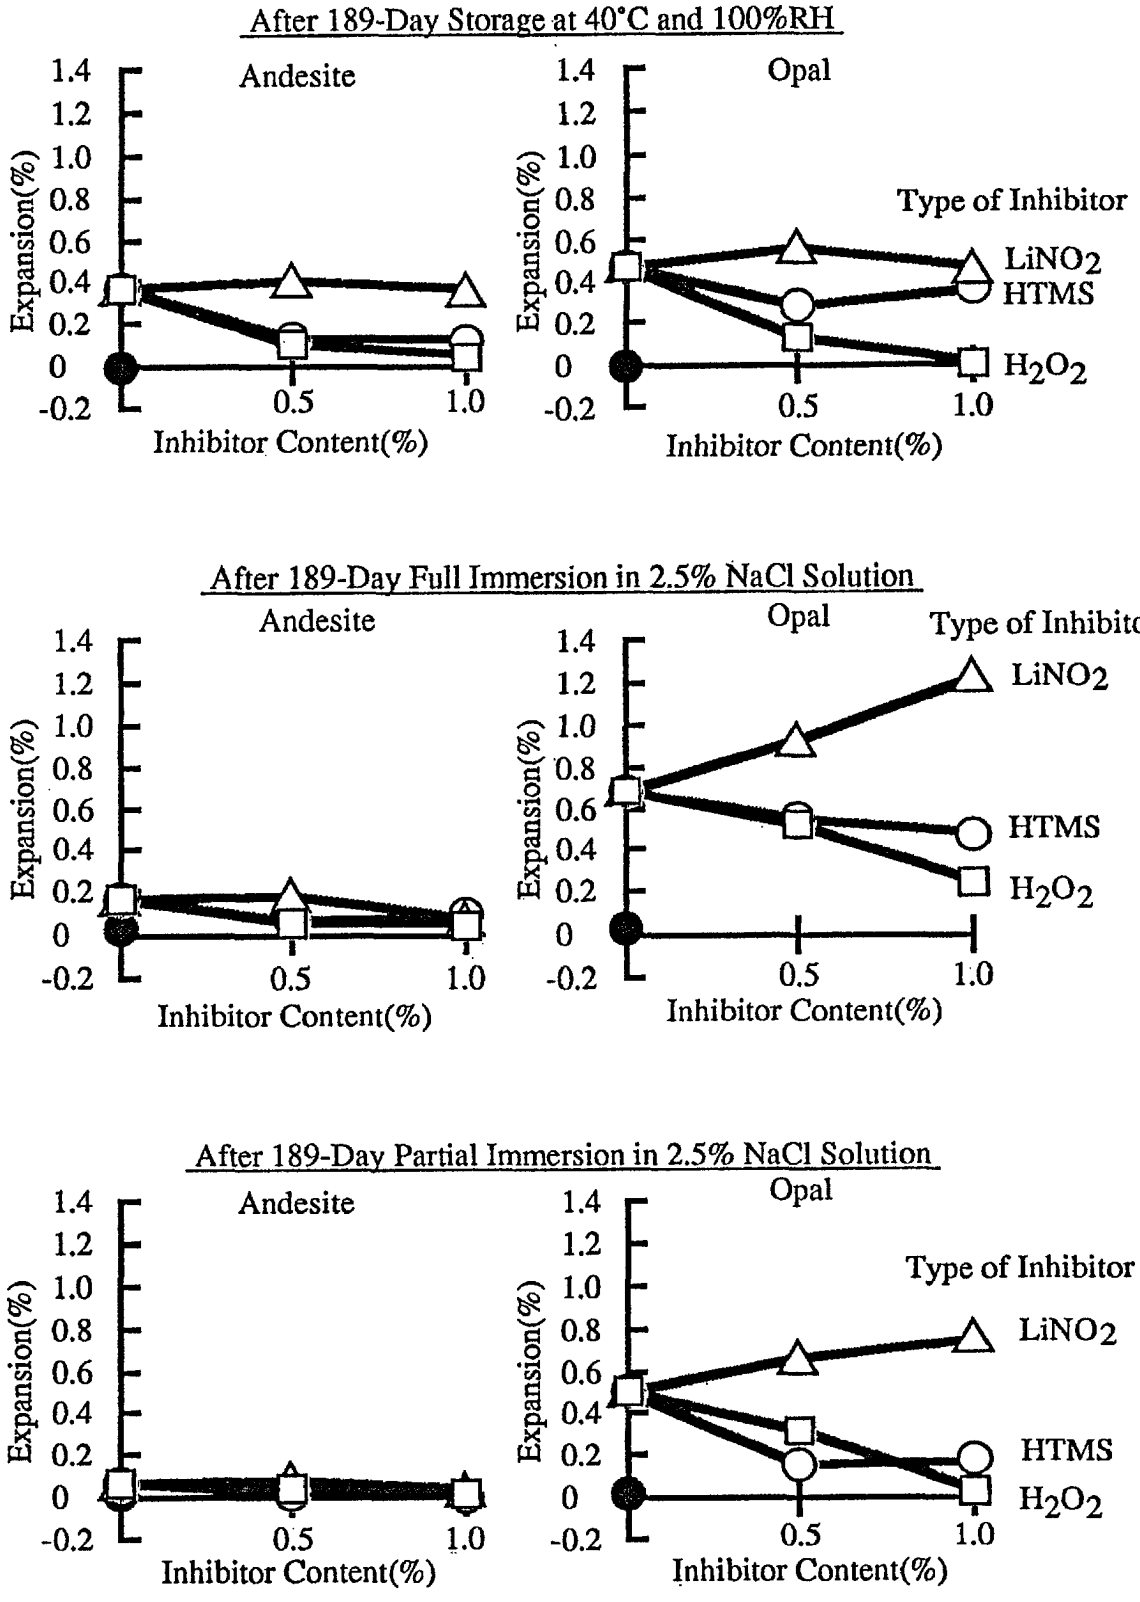

Fig.5 Inhibitor content vs. expansion of mortars containing reactive aggregates with inhibitors.

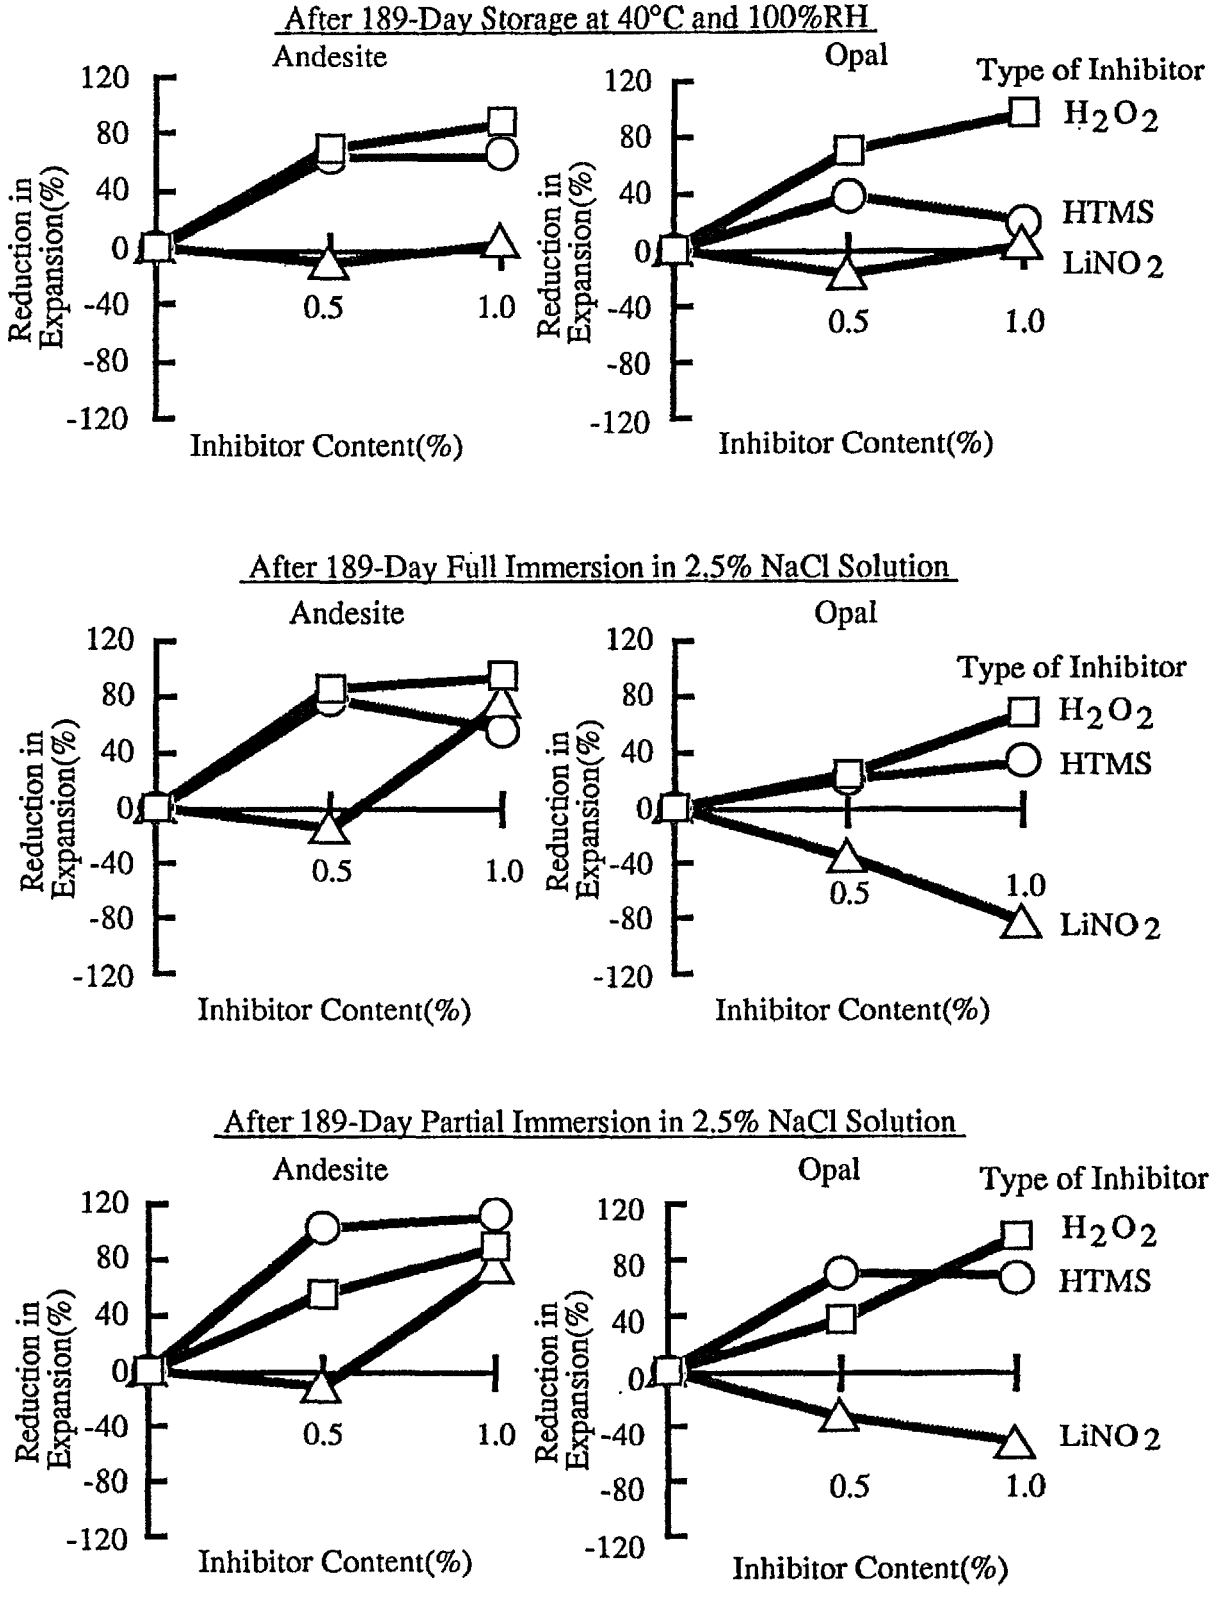

Fig.6 Inhibitor cotent vs. reduction in expansion of mortars containing reactive aggregates with inhibitors.

where Era is the expansion of the mortars containing the reactive aggregates with inhibitors at an immersion period of 189 days, Ero is the expansion of the mortars containing the reactive aggregates without any inhibitor at an immersion period of 189 days, and Eno is the expansion of the mortars without any reactive aggregate and inhibitor at an immersion period of 189 days. In the full and partial immersion tests, an increase in the expansion of the mortars containing an opal due to the addition of $LiNO_2$ is observed. Except for such a case, the expansion of the mortars containing the reactive aggregates is reduced with an increase in the inhibitor content. The addition of 1.0% of HTMS or H_2O_2 to the mortars containing the reactive aggregates provides a 60% or more reduction in the expansion regardless of the type of reactive aggregate and test conditions. From the above-mentioned test results, the effectiveness of the inhibitors to prevent alkali-aggregate reaction is influenced by the test conditions and the type of the reactive aggregate used to prepare mortar specimens. However, HTMS and H_2O_2 can be used as chemical inhibitors for inhibiting alkali-aggregate reaction.

CONCLUSIONS

The conclusions obtained from the above-mentioned test results are summarized as follows :
(1) In general, the expansion of mortars containing reactive aggregates with and without inhibitors is increased with additional storage period at 40°C and 100%RH, and full or partial immersion period in a 2.5% NaCl solution. However, the effectiveness of the inhibitors to prevent alkali-aggregate reaction is influenced by the test conditions and the type of the reactive aggregate used to prepare mortar specimens.
(2) Except for some cases, the expansion of mortars containing reactive aggregates is reduced with an increase in the inhibitor content. The addition of 1.0% of HTMS or H_2O_2 to the mortars containing the reactive aggregates gives a 60% or more reduction in the expansion regardless of the type of reactive aggregate and test conditions. HTMS and H_2O_2 can be used as chemical inhibitors for inhibiting alkali-aggregate reaction.

ABSTRACT ^{29}Si enrichment has been used to enable acquisition of multiple high quality ^{29}Si NMR spectra from samples of C_3S hydrating *in situ* in a MAS NMR probe. The growth of silicate chains in the hydrate was consistent with progressive linking together of dimeric hydrate with monomers. The pozzolanic reaction of C_3S with SiO_2 produced hydrate that was much more ordered and contained longer chains; selective ^{29}Si enrichment of the SiO_2 showed that hydrate formed from the SiO_2 was more ordered, and contained longer chains than the remainder of the hydrate.

Key-words: C-S-H, Nuclear Magnetic Resonance, Pozzolana, Silica fume, Temperature.

INTRODUCTION

This paper describes studies of the kinetics of calcium silicate hydration by ^{29}Si MAS NMR. It summarises results published elsewhere (Brough *et al.*, 1994a and 1995), and the reader is referred to the original papers for full experimental details, and more complete analysis of the data. The notations of cement chemistry and silicate NMR assignments are also detailed in Brough *et al.* (1994a). The aim of this paper is to demonstrate the power of ^{29}Si enrichment and selective enrichment for the study of the kinetics of cement hydration. Simple C_3S hydration and pozzolanic reaction with amorphous silica were chosen as model systems where the materials required are easily synthesised, but the techniques would be equally applicable to other systems.

RESULTS AND DISCUSSION

C_3S Hydration

For the hydration of C_3S, the relative rates of reaction were studied at a range of temperatures. The use of ^{29}Si enrichment and the aquisition of a series of spectra from a single sample gave rise to data of very high quality. The good signal to noise ratios enabled accurate quantification of the spectra. The lack of quenching avoided the possibility of the quenching procedure changing the nature of the sample. All the data were acquired from the same sample (not from separate portions taken from a larger sample). Thus uneven reaction of the sample will not introduce noise into the data.

In order to acquire results *in situ* it was necessary to acquire spectra quickly, since the polymerization of the system was changing rapidly with time, and NMR of conventional samples is relatively slow (perhaps 3-12 hours to obtain a typical spectrum.) Thus it was necessary to use ^{29}Si enriched material. 95%+ enrichment was chosen to obtain the best possible spectra as quickly as possible (line broadening due to dipolar interactions was minimal.) During in situ acquisition, the samples needed to be spun (to obtain MAS spectra).

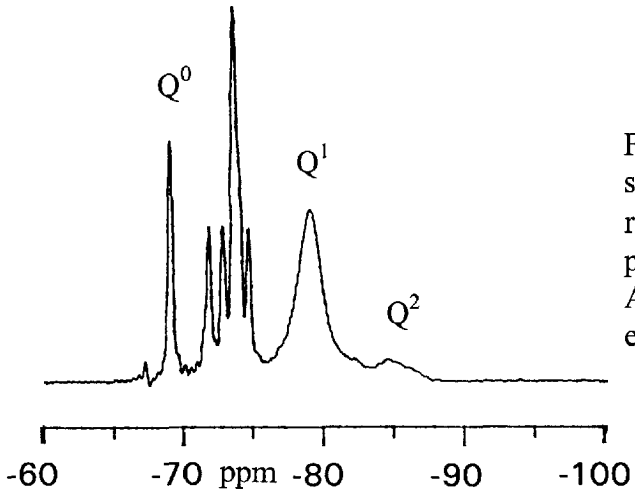

Figure 1 Representative ^{29}Si MAS NMR spectrum of C_3S hydrated at a water to solids ratio of 0.5 for 1 day at 20°C. The isotropic peaks are labelled with the peak assignments. A time series of spectra were acquired from each sample.

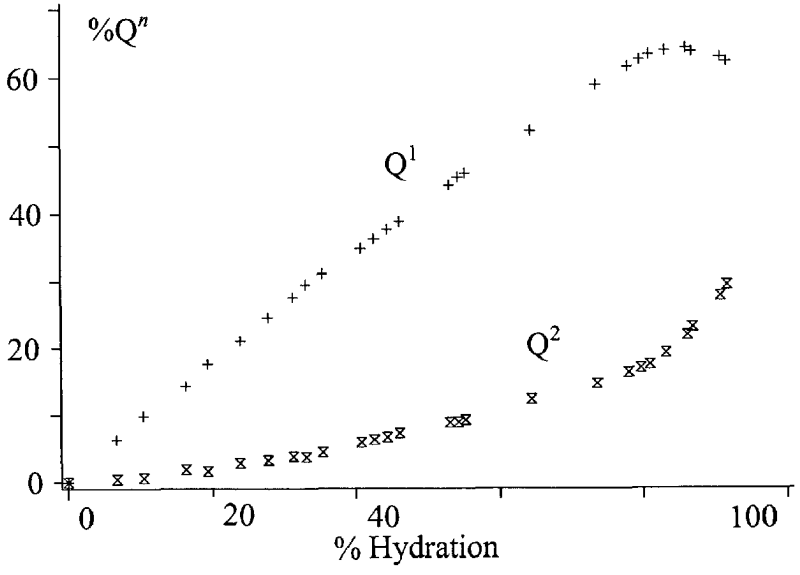

Figure 2 Q^n intensities for C_3S hydration plotted with respect to percentage of hydration (calculated from NMR as the percentage of silicate units no longer remaining as Q^0 species) at 20°C.

They were sealed in small plastic inserts in order to avoid loss of liquid. Control experiments were performed, and it was found that the MAS process had little effect upon the hydration kinetics, or the nature of the majority products.

It is possible to investigate the overall degree of reaction, but this is more readily studied by calorimetry. In this study we concentrate upon the evolution of product structure. C_3S was hydrated at temperatures from 20°C to 75°C and the polymerization of the products studied by ^{29}Si MAS NMR (Figure 1). The results are in agreement with previous studies (Lippmaa *et al.*, 1982, Clayden *et al.*, 1984). The product C-S-H contained only linear chains (Q^1 and Q^2 silicate species). In none of these systems were Q^3 or Q^4 species observed. The relative amounts of the Q^n species present were quantified, and the results for hydration at 20°C are shown in Figure 2. Note the low noise values in these two figures, due to the use of C_3S enriched in ^{29}Si.

The average chain lengths were calculated from the Q^1/Q^2 ratio, and are shown in Figure 3. At all three temperatures, the initial hydrate (by extrapolation to 0% hydration) is essentially dimeric. With hydration, the chain length increases. Various models for the growth of chain length can be proposed, but only some of them are consistent with the observed data.

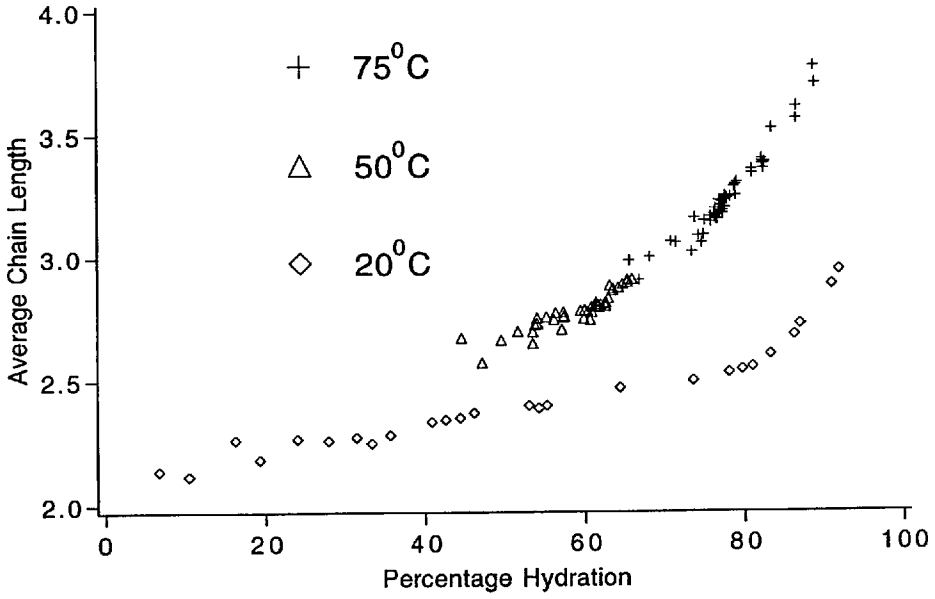

Figure 3: Average chain lengths (calculated as $2 + 2(Q^1/Q^2)$) plotted with respect to degree of hydration at temperatures of 20, 50 and 75°C. Data are only available at later stages of hydration for the hydration at higher temperatures due to the very rapid nature of the earlier hydration.

For hydration at 20°C the initial hydrate is dimeric, and contains Q^1 species, but at later stages of reaction, Q^1 species are consumed and additional Q^2 species are formed. It appears that the dimeric hydrate is being converted to polymeric hydrate. This rules out the possibility that monomers react to form Q^2 species directly at late ages; such a mechanism cannot account for the fall in Q^1 intensity. There must be additionally a conversion of dimeric hydrate to polymer, by joining of chains. A mechanism linking dimers with monomers is consistent with the drierketten structural units believed to be present in C-S-H (Richardson and Groves, 1992), and with previous TMS studies which found silicate anions as follows: dimer, pentamer, octamer, etc. (Hirljac *et al.*, 1983, Dunster *et al.*, 1989) On the basis of this model, the observed results can be extrapolated to complete hydration. A chain length of approximately 4 to 5 is expected, which is consistent with studies of very old samples of C-S-H. (Rodger *et al.*, 1987, Macphee *et al.*, 1988)

Arrhenius energies for the two stages of reaction were calculated assuming a two stage reaction. For the formation of Q^1 species, an energy of $35 kJmol^{-1}$ was found while for the formation of polymer, an energy of $100 kJmol^{-1}$ was determined (this includes the formation of dimer and subsequent polymerization.)

In addition to MAS NMR spectra, ^{29}Si CPMAS spectra were obtained. These enabled the observation of traces of hydrated monomeric species (obscured in the MAS spectra by the large peaks due to anhydrous monomeric species). CP spectra are not directly quantitative, but by comparison with the MAS spectra, and study of the CP dynamics, it was estimated that 2% of monomer was formed during the induction period at 20°C with a larger amount at 75°C. The hydrated monomeric species persisted through to late stages of hydration.

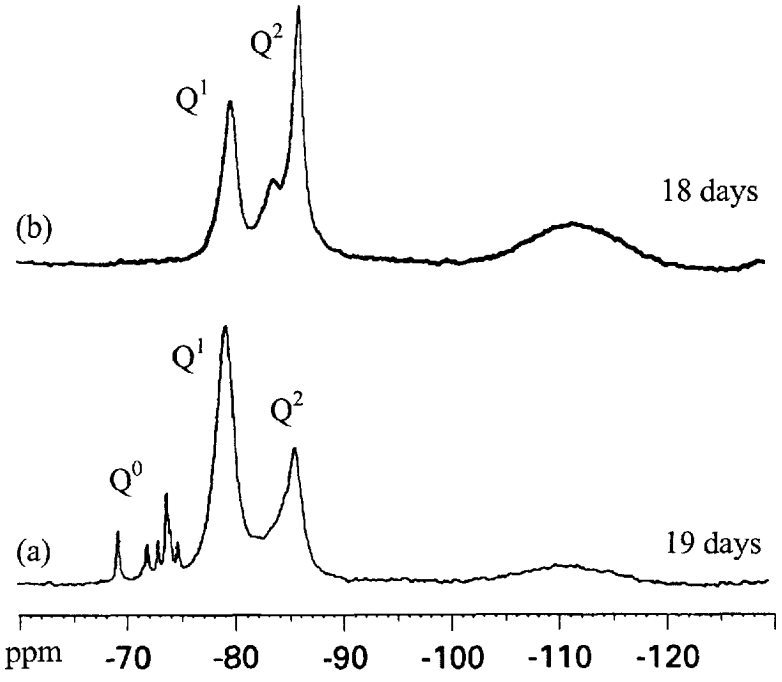

Figure 4: Selected ^{29}Si MAS NMR spectra showing the hydration of a mixture of SiO_2 and C_3S and having an overall Ca/Si atomic ratio of 1 with a water to solids ratio of 0.5. 5Hz exponential line broadening was applied to these spectra. (a) Both reagents enriched in ^{29}Si to 95%+, (b) Only the SiO_2 is enriched.

Pozzolanic Reaction

The pozzolanic reaction takes place in blended cements, where the lime liberated during the hydration of the calcium silicates reacts with a source of silica. The amount of free lime is reduced, leading to increased durability of the cements under some circumstances. In addition, the Ca/Si ratio of the hydrates may be reduced.

In this reaction, there are two reagents, the cement and the silica source, which release silicate groups into the system. In this study we used C_3S and silica. Enrichment of just one of these silicate sources makes it possible to observe selectively silicate groups that originated from that starting material. For useful comparisons to be possible, the ^{29}Si enriched and natural abundance reagents must be of the same reactivity. It was not possible to obtain silicas having the same reactivity, but ^{29}Si enriched and natural abundance samples of C_3S were prepared by the same route. Thus a pozzolanic paste in which both reagents were ^{29}Si enriched was compared with a paste in which only the silica was enriched.

The hydration of the doubly enriched system (Figure 4a) was found to be similar to that observed previously for pozzolanic pastes. The silica resonance could not be reliably quantified, due to an excessively long T_1. This made it impossible to determine the degree of reaction of either the silica or the C_3S. The chain length was significantly longer at all ages, and the hydration of the C_3S was somewhat accelerated. In addition, the peaks were sharper than those formed in the hydration of C_3S, indicating that there was a smaller range of silicate environments in the products. Either they were more crystalline, or more homogeneous.

Analysis of the spectra in which only the silica was enriched (Figure 4b) is more complex. It is no longer possible to assess an average chain length, because the degree of enrichment of

the Q^1 and Q^2 species is not known. The enriched portion of the hydrate contains many more Q^2 groups, and that contains even more well defined peaks than the doubly enriched system, indicating that the enriched ^{29}Si species end up in hydrate that is more crystalline or more homogeneous than the bulk hydrate in this system. Two possibilities arise for the greater prevalence of the ^{29}Si species in the Q^2 sites.

1) The ^{29}Si species from the silica might be preferentially distributed into the Q^2 sites within a homogeneous hydrate with a relatively short average chain length. This might arise if the hydrate formed initially from unenriched C_3S, with dimeric C-S-H, and then later polymerized by insertion of linking silicate bridges from enriched SiO_2. In this case these Q^2 sites would be preferentially observed. This can be discounted in this system, since the degree of preferential reaction required would be implausibly large.

2) Alternatively, the hydrate may be zoned, with the areas containing silicate species from the silica having a significantly longer chain length. Such regions would be rather more ordered, due to the very long chains, and might be expected to give rise to more sharply defined resonances as is indeed observed.

In the spectra of the pozzolanic materials, the Q^2 region contains not just one peak but two. The origin of the splitting is not clear, but it probably arises from different sites within the drierketten chains. The tentative assignment by Brough *et al.* (1994b) of the downfield peak to bridging or linking tetrahedra in the chains seems reasonable, and can explain the observed intensities. Cong and Kirkpatrick (1994) have noted that in the crystal structure of Hamid (1981), only one of the chains appears to have the distinct geometry required to produce this shift, giving a 1:5 ratio to the main Q^2 peak. More recent results by Klur *et al.* (1997) (for synthetic C-S-H's) support the assignment of the extra peak to bridging sites. It is unlikely that the two peaks result from hydroxylated and non-hydroxylated species, since they are excited to a similar extent in CP spectra. Q^3 species are also observed in the pozzolanic hydrate. The very large peak width of the Q^3 species suggests that they are associated with the silica resonance, perhaps with a Ca modified silica gel.

TEM studies could not be carried out on the very small samples used for this work, so that parallel compositional information is not available. Overall the Ca/Si atomic ratio is 1.0, but complete reaction did not occur within the timescale of the experiments, so that the Ca/Si ratio of the C-S-H cannot be calculated. The initial hydrate from both the silica and overall consists largely of dimer. On current models of C-S-H (Richardson and Groves, 1992) it is likely that this material has a Ca/Si ratio of at least 1.25, so that more polymerized hydrate which forms later might have a much lower Ca/Si ratio. However, significant amounts of silica may also remain unreacted. Also, the change of silicate polymerization in the C_3S system suggests that significant changes to the polymerization of the early hydrate may occur as hydration proceeds.

CONCLUSIONS

^{29}Si enrichment is an excellent tool for the study of hydration kinetics by ^{29}Si MAS NMR. For C_3S hydration, the kinetic data strongly support the drierketten model for C-S-H and also enable the calculation of Arrhenius energies. For the pozzolanic system, full quantification was not possible, since the silica was found to have a long T_1 as supplied. In future however, dissolution and reprecipitation in the presence of low levels of paramagnetic impurities could be used to synthesise a silica with a shorter T_1.

The use of selective enrichment proved to be very useful in studying the mechanism of the pozzolanic reaction of microsilica in the presence of C_3S. Silicate species from the silica formed a hydrate that had significantly longer chains than the bulk hydrate in the system, and that also contained a smaller range of silicate environments.

HIGH-TEMPERATURE ^{19}F NMR OBSERVATION OF FLUORINE ACTIVITY IN CLINKER PROCESSING

Laurent BONAFOUS and Pierre COLOMBET, CTG Italcementi group, Guerville, France
Catherine BESSADA, Dominique MASSIOT and Jean-Pierre COUTURES, CRPHT, Orléans, France

ABSTRACT A sample of an industrial raw-mix containing 1% CaF_2 has been heated in a specially designed probehead of a NMR spectrometer, which allows signal recording as a function of sample temperature from room temperature to ca. 1500°C. ^{19}F NMR spectra analysis indicates that CaF_2 disappears at about 1000°C to form at least two other phases which grow simultaneously as the temperature increases above 1000°C. From the values of the isomer shifts, these two later phases are suggested to be $Ca_3(Si_{1-x}Al_x)O_{5-x}F_x$, with $x<0.10$, and $C_{11}A_7.CaF_2$, solid solutions, confirming the mineralizing effect of CaF_2 in clinker formation.

Key-words : Nuclear Magnetic Resonance, Mineralizers in clinker making, Fluoride phases.

INTRODUCTION

High-temperature multinuclear (^{29}Si, ^{27}Al, ^{19}F, ^{17}O) NMR study of the clinkering process has recently been carried out for the first time using a model raw-mix made of laboratory reagents, with weight composition: 64.3% CaO, 21.2% SiO_2, 5.0 % Al_2O_3, 2.0% Fe_2O_3, 5.0% $CaSO_4$, 1.5% K_2O, and 1.0% CaF_2 (Bonafous et al., 1997). Concerning fluorine, the thermal evolution of the NMR response was characterized by the appearance of a relatively narrow line from 1000°C, specifically in the vicinity of the temperature where C_3S was observed to start to be formed (ca. 1050°C). This line was suggested to be the signature of a phase involving « mobile » fluorine (not necessarily a liquid), in agreement with the absence of dipolar and chemical shift anisotropy broadenings which usually render unobservable ^{19}F (I=1/2) in solid state compounds. This line was observed to be present as the sample temperature was raised from 1000°C to 1450°C.

In order to contribute to illucidate further the role of fluorine as a mineralizer or/and flux for the formation of C_3S in the process of clinkerization, which is a question which has given rise to controversy (see for instance Shame and Glasser, 1987, and Taylor, 1990a), a different raw-mix with 1% CaF_2 addition has been studied using the same NMR apparatus. This second raw-mix was a sample of an industrial raw-mix taken at one of the french plants of Italcementi Group. Based on the comparison with the signals recorded for various fluorine containing silicates and aluminates, as explained below, it is confirmed that a significant amount of fluorine is involved in solid solutions from ca. 1000°C to the highest temperature that can be afforded using this set-up (ca. 1450°C).

EXPERIMENTAL

Materials

The studied industrial raw-mix was composed of a mixture of marly limestone and brown clay with addition of 1 wt.% CaF_2. As detemined using X-ray fluorescence analysis, the bulk composition of the as-obtained industrial clinker is 65.1% CaO, 19.9% SiO_2, 5.6% Al_2O_3, 2.8% Fe_2O_3, 2.4% MgO, 1.1%SO_3 (3.4% eq. $CaSO_4$) 1.0% K_2O, 1.0% CaF_2, 0.3% TiO_2 and minute amounts of various other oxides (total equal to 0.8%). To reproduce the presence of sulfates arising from the fuel, as evidenced from the above clinker bulk composition, an equivalent amount of calcium sulfate has been added to the raw meal.

Known reference fluorine containing phases (see Table 1) were synthetized from reagent grade CaF_2 and relevant oxides. The mixtures were ground in an agate ball-mill and moulded into tablets prior to allowing them to react at high temperature in a holed sealed platinum crucible. The reaction steps and final phases were controlled using powder X-ray diffraction at room temperature (Philips PW 1729 with Ni filtered CuKα radiation) and electron scanning microscopy (Cambridge Stereoscan 100). Spurrite $2C_2S.CaCO_3$ and potassium containing apatite-type phases such as $K_3Ca_2(SO_4)_3F$ (Triviño Vásquez, 1985) were not considered in this work, since they are usually evidenced as sedimentary coating of obstacles or cooler surfaces in preheater or kiln (via condensation of volatiles), which cannot occur in the present experiment.

NMR spectroscopy

The NMR experiments were performed using a Bruker MSL 300 spectrometer operating at 7.04 T. The ^{19}F spectra (I=1/2, 100% abundant), obtained at 282 Mhz with a single pulse excitation sequence, have been measured in static conditions for high temperature experiments and under Magic Angle Spinning (MAS) at room temperature for reference compounds. The reported chemical shifts are referenced to ^{19}F resonance in trichlorofluorocarbonate ($CFCl_3$).

High Temperature Experiments

The high-temperature device is an evolution of the previously described high temperature NMR setup (Taulelle et al., 1989, Coutures et al., 1994 and Bonafous et al., 1995). This setup is based on the heating of a MgO capped sample container, placed in the probehead and irradiated both from the top and the bottom by two CO_2 lasers (λ=10.6 μm). The container is thermally insulated from the axial Helmholtz coil (diameter 15 mm) tuned to the resonance frequency of fluorine, by a ceramic shield. The temperature gradient inside the container was measured to be less than 10 and 25°C at 1000 and 1500°C, respectively. As the use of a thermocouple is impossible during a NMR experiment, the temperature has been calibrated outside the magnet. The heating protocol was the following. A 5 minutes equilibration time was taken after each increase of the laser power. A typical 25 minutes duration was necessary to obtain a signal with satisfactory signal-to-noise ratio. With temperature increments of 50°C, the overall experiment from room temperature to 1450°C lasted about 10 hours.

It has to be noticed that there exists a strong ^{19}F probe signal arising from the probe radio frequency components themselves which clearly shows up at room temperature. This background signal has not been suppressed in the spectra presented in Fig 1. It even shows some evolution with increasing temperature.

Reference phases

In static conditions, which is the case for the experiment described above in which the heating device does not allow the spinning of the probehead, the room temperature solid phase ^{19}F signal is in general not visible, due to dipolar broadening and chemical shift anisotropy. This is the case for the studied materials. ^{19}F chemical shift data at room temperature were hence obtained for reference fluorine containing phases (see Table 1) using MAS (Magic Angle Spinning). Then, the dependence of the chemical shift upon temperature was investigated using the static high temperature NMR device described above.

RESULTS

Raw-mix

For the raw-mix the most illustrative spectra obtained as a function of temperature are shown in Fig 1. In the lower temperature domain, i.e. in the temperature range where the decompositions of limestone and clay occur to give then belite and aluminate from decomposition products, a sharp signal (located at -97 ppm) can be observed. It appears at ca. 300°C and remains observable at the same position up to about 900°C and slightly shifted to -105 ppm between ca. 950 and ca. 1050°C. In the higher temperature range (above 1050°C), this signal disappears for the benefit of two broader signals. These two signals are located at -82 (poorly defined) and -119 ppm, respectively, and their intensities increase simultaneously as the temperature increases.

Reference phases

The ^{19}F room temperature line chemical shift values for the most relevant fluoride compounds for this study are given in Table 1. Concerning CaF_2, both industrial and pure samples exhibit a line at -105 ppm. The other studied compounds are those that can be expected to be formed owing to the bulk composition of the mix, in particular the known C_3S stabilized solid solutions and fluor-ellestadite $3C_2S.3CaSO_4.CaF_2$ (Gilioli et al., 1979). $Ca_{6-x/2}Si_2\ O_{10-x}\ F_x$ is one of the possible explicite formulae of $3C_3S.CaF_2$ with a structure related to that of C_3S via partial substitution of F^- for O^{2-} and concomitant omission of half the same quantity of Ca^{2+} (Pérez-Méndez et al., 1985; Ye Qing et al., 1992). $Ca_3\ (Si_{0\,85}\ Al_{0.15}\ )\ (O_{4\,85}\ F_{0\,15})$ is the solid solution synthesized by Shame and Glasser (1986), where Al replaces Si in the structure of C_3S as F substitutes for O, to balance the electrical ionic charges. The former C_3S based solid solution shows two resonance lines of nearly equal intensity at -111 and -116 ppm, whereas the latter shows a single line at -120 ppm. All compounds exhibit broader lines in the high temperature spectrometer, visible only at temperatures higher than 500°C, as explained above, within their respective stability temperature range, the average tendency being a shift towards slightly less negative values for the chemical shift as the temperature increases (+2 ppm at 1000°C, with respect to room temperature) except fluor-ellestadite which was observed to show a single line from 700°C (-103 ppm) to 1200°C (-102 ppm) instead of two lines at room temperature (-87 and -100 ppm).

Table 1 ^{19}F room temperature MAS NMR chemical shift values (ppm vs. $CFCl_3$) for various fluorine containing phases prepared from reagent grade CaF_2 and oxides.

Composition	chemical shift
CaF_2	-105
$C_{11}A_7.CaF_2$	-82
$Ca_{6-x/2}Si_2\ O_{10-x}\ F_x$ with x=0.15	-111; -116
$Ca_3\ (Si_{0\,85}\ Al_{0\,15}\ )\ (O_{4\,85}\ F_{0\,15})$	-120
$3C_2S.3CaSO_4.CaF_2$ (fluor-ellestadite)	-87; -100

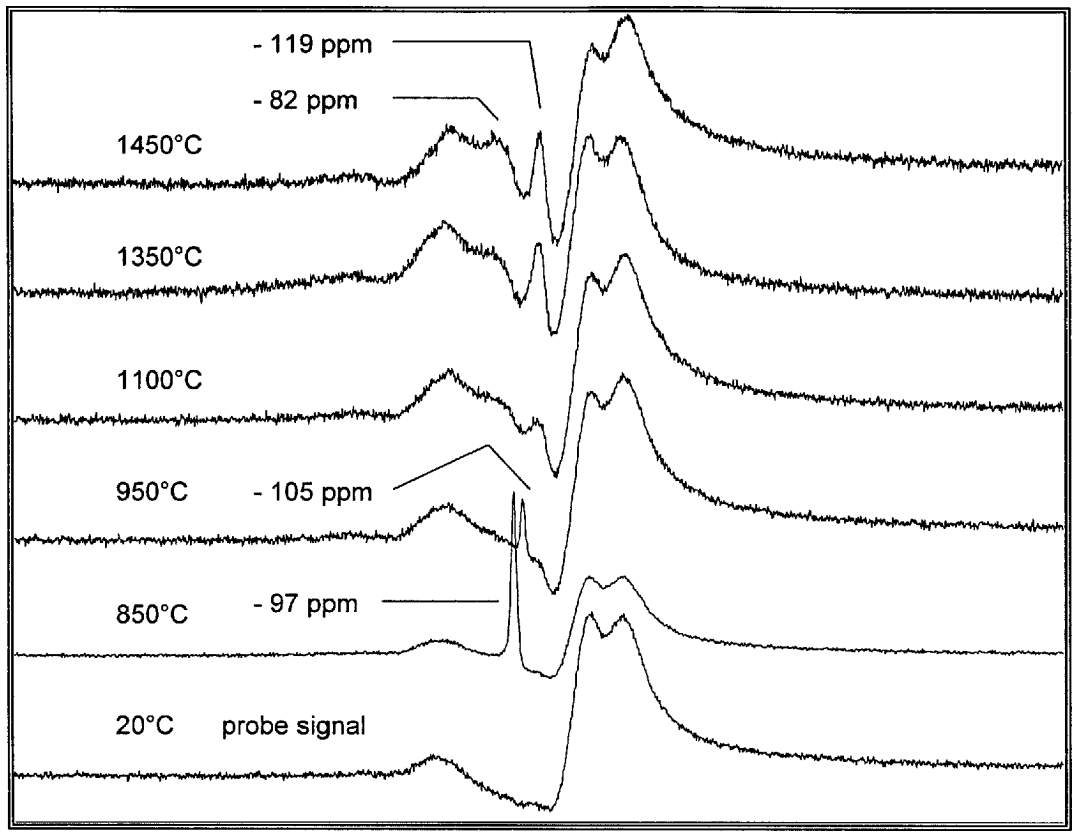

Figure 1 ^{19}F (static) NMR spectra for the studied raw-mix, as a function of temperature.

DISCUSSION

As far as the lower temperature range is concerned, where CaF_2 is known to favour limestone decomposition (Taylor, 1990b), the observed signal can be assigned only to CaF_2, since no other fluoride is expected to be formed in this range. The fact that the signal is visible from a much lower temperature (300°C) than that from which it was observed for the previously studied model raw-mix (Bonafous et al., 1997), which contained lime instead of limestone, may thus be considered as indicative of a reactivity-correlated mobility of fluorine (allowing line narrowing) in the process of limestone decomposition. It may be noted that another difference between the two mix is the presence of water traces in the presently studied industrial mix (including bound water in clay) whereas the previous one was totally dry. Specifically, it may be assumed that water plays a role to promote fluorine activity for limestone decomposition via intermediate formation of HF and subsequent reaction of HF with $CaCO_3$ to yield CaF_2, H_2O and CO_2. HF formation would then in turn favour F mobility in bulk CaF_2 due to vacancy production in the vicinity of its surface leading to F diffusion. This mobile fluorine would therefore give rise to the observed line at -97 ppm, i.e. slightly shifted from the position observed for CaF_2 taken alone (-105 ppm, see Table 1). Once the carbonate decomposition is completed at higher temperature, normal CaF_2 signal appears again at -105 ppm, in agreement with what is observed at ca. 950°C (Fig 1).

In the higher temperature range, the chemical shift values of the two observed signals (-82 and -119 ppm) are nearly identical, within experimental accuracy, to those observed at room temperature for $C_{11}A_7.CaF_2$ and Ca_3 $(Si_{0.85}$ $Al_{0.15})$ $(O_{4.85}$ $F_{0.15})$, i.e. -82 and -120 ppm, respectively

(Fig 1 and Table 1). Knowing that the ^{19}F chemical shift values are almost insensitive to temperature variations as discussed above (the variation is less than 2 ppm in the studied temperature range), it may thus be inferred that the above solid phases are simultaneously formed in the conditions of the present experiment, above ca. 1050°C. This interpretation is further supported by the observed larger width of these two lines, consistent with envolvement of fluorine in solid solutions. Note that the (Al,F) content in the studied synthetized C_3S solid solution has been choosen equal to the limit of (Si,O) substitution (0.15) determined by Shame and Glasser (1987). Obviously, the true content in the studied raw-mix is somewhat lower. Considering that all the fluorine is involved in this phase, x can be calculated equal to 0.10 from the mix composition. Since $C_{11}A_7.CaF_2$ is also assumed to be formed, then it may be deduced that $x<0.10$. Accordingly, we shall consider the general formula $Ca_3(Si_{1-x}Al_x)O_{5-x}F_x$ ($x<0.10$) as representative of the observed solid solution. The same kind of remark can be done as regards $C_{11}A_7.CaF_2$, which forms a continuous range of solid solutions with $C_{12}A_7$, that is to say, the present results do not allow its precise composition.

As a consequence, it may be stated that fluorine acts as a mineralizer in the present circumstances, i.e. using the studied mix composition and at the heating rate employed in this experiment, and avoiding condensation and reaction of volatiles. These findings are in fair agreement with the results obtained by Shame and Glasser (1987) who demonstrated that mixtures of $Ca_3(Si_{1-x}Al_x)O_{5-x}F_x$ solid solutions and $C_{11}A_7.CaF_2$ can be formed from ca. 1050°C, thus lowering the limit of C_3S thermodynamic stability.

No signals corresponding to fluor-ellestadite nor $Ca_{6-x/2}Si_2\ O_{10-x}\ F_x$ ($3C_3S$-CaF_2) are evidenced in this study, as opposed to the conclusions of Gilioli et al. (1979) who suggested that those phases might be of interest in the firing process of clinker. This discrepancy may be explained by considering that the mix they studied was free of Al_2O_3, which is not the case here.

CONCLUSION

This work supports the previous conclusions by Shame and Glasser (1987) concerning both the fluorine mineralizing action to promote C_3S formation and the predominant F/Al synergetical effect in the formation of solid solutions at high temperature. In addition, it gives evidence that such a mechanism does occur, not only in the simplified mix they use (CaO-SiO_2-Al_2O_3-CaF_2), but also in a real more complicated mix, as the one used in a kiln. We finally stress the fact that the present experiment does not reproduce exactly the conditions of a kiln as regards both heating rate and volatiles cycle. In particular, the heating rate used in the present in-situ NMR study, is much lower by at least 10 times, which implies conditions closer to reaction reversibility.

ABSTRACT Surface dissolution of the solid-aggressive solution interface has been demonstrated during leaching of cement pastes by water. The rate of degradation is initially governed by the laws of diffusion, and in the longer term by the surface dissolution. Nuclear magnetic resonance techniques (^{29}Si MAS-NMR and ^{57}Fe Mössbauer spectroscopy) show that substitution of iron for calcium in CSH greatly slows surface dissolution.

Key-Words: CSH, Ferrite phase, Nuclear Magnetic Resonance, Tobermorite, Waste material utilization

INTRODUCTION

Short-lived, and possibly long-lived, radioactive waste is stored in concrete containers (casks, disposal structures, etc.). It is therefore essential to predict the behaviour of these containers in aggressive medium. One of the worst-case scenarios is leaching of cement paste by flowing water of low ionic content.

In cement structures, hydrates are in equilibrium with an interstitial solution of approximate pH 13. Contact with a demineralized solution of pH=7 creates a degraded zone between the core and surface of the leached structure. The resulting decreasing concentration gradient of hydroxyls alters the chemical equilibria in the degraded zone, thereby inducing dissolution and precipitation of secondary phases: Faucon et al. (1997a). Adenot (1992) has shown that in the degraded zone dissolution-precipitation occurs much faster than diffusion. The surface of the cement cannot be at equilibrium since it is in contact with a demineralized solution. Its behaviour must therefore be hypothesized. If it is assumed that the cement surface does not dissolve, the rate of degradation is governed by the diffusion of ionic species in the degraded layer. The long-term behaviour of the cement can be modelled by solving Fick's equations for a semi-infinite medium, taking account of

the different solid-liquid equilibria: Adenot and Faucon (1997). This yields a $\sqrt{t}$ law predictive of degradation (where t is time).
However, the $\sqrt{t}$ diffusive regime is only valid if there is no surface dissolution. If the hydrate resulting from dissolution-precipitation in the surface layer is finally attacked by the aggressive solution, the solution of Fick's equations will yield erroneous results. We have studied the rate of surface dissolution in different cement pastes. Nuclear magnetic resonance techniques (^{29}Si MAS-NMR and ^{57}Fe Mössbauer spectroscopy) clarified the mechanisms underlying the slowing of surface dissolution.

EXPERIMENTAL CONDITIONS

Three cement pastes each containing the same C_3S, synthesized by Ciments Français, were studied (Table 1). Aluminium and iron were added in the form of C_3A and iron nitrate (FN), respectively, in order to study their influence on the rate of degradation. When introduced, FN was neutralized by addition of lime.

Table 1 Sample composition (% per unit mass)

Sample	% C_3S	% C_3A	% FN	% CaO
1	100.0	-	-	-
2	85.0	15.0	-	-
3	81.3	-	15.5	3.2

Samples (7 cm diameter, water/cement ratio 0.38) were kept for one month in a solution saturated in portlandite, and were then placed in a solution kept deionized at pH 7 by recirculation through a mixed bed of ion-exchange resins. Tests were performed under an inert atmosphere (N_2). After six months of leaching, the degraded layer (thickness 50 to 100 microns) was removed for study by NMR and Mössbauer spectroscopy. X-ray diffraction spectroscopy was first used to identify the crystallized phases of each degraded layer.

Table 2 X-ray diffraction of surface layer specimens

Sample	Sound zone	Surface layer
1	CH, CSH	CSH
2	CH, C_3AH_6, C_4AH_8	CSH, C_3AH_6, AH_3
3	CH,	CSH, C_3FSH_4

The Mössbauer study was performed using a ^{57}Co:Rh γ-ray source, the spectrometer comprising an electromagnetic vibrator with a triangular velocity signal. All spectra were recorded at ambient temperature. Each sample was exposed to the ^{57}Co source for about two days. The isomer shifts are given with reference to α-Fe. Each spectrum consisted of several doublets whose relative intensities, isomer shift, quadrupolar splitting and half-widths (HWHM) of lorentzian lines were determined using a least square fit procedure.
Solid-state NMR experiments were performed on a Bruker MSL 300 NMR spectrometer, in a 7.03 Tesla field, at a ^{29}Si frequency of 59.617 MHz. ^{29}Si MAS-NMR spectra were recorded with a spinning rate of approximately 4 kHz in double-bearing 7-mm ZrO_2 rotors. Spectra were accumulated using single-pulse excitation and high-power 1H decoupling with a 60-kHz rf field. A recycle time of 59 s was used. The number of scans varied from 800 to 2000 for the superficial layer. $[Si(CH_3)_3]_8Si_8O_{20}$ was used as a secondary standard, the major peak being at 11.6 ppm relative to tetramethylsilane (TMS, $Si(CH_3)_4$).

RESULTS

Rate of degradation

Figure 1 shows the dissolution of the solid-liquid interface as a function of time. Thinning of the surface layer occurred as a linear function of time, reflecting dissolution of the sample in contact with the aggressive solution. Degradation was accelerated by the presence of aluminium and slowed by iron.

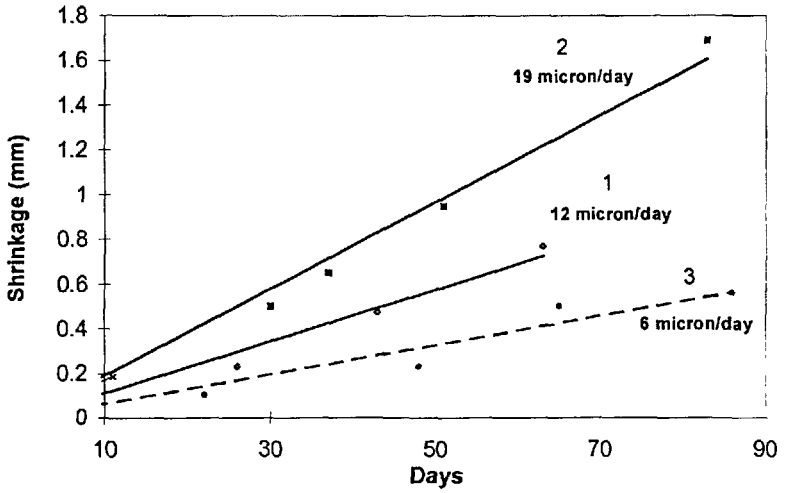

Figure 1 Surface dissolution of samples.

These data clearly show that surface dissolution may be considerable, and should be taken into account in predictions of behaviour of cement structures, independently of diffusion.

Silicon NMR (Samples 1& 2)

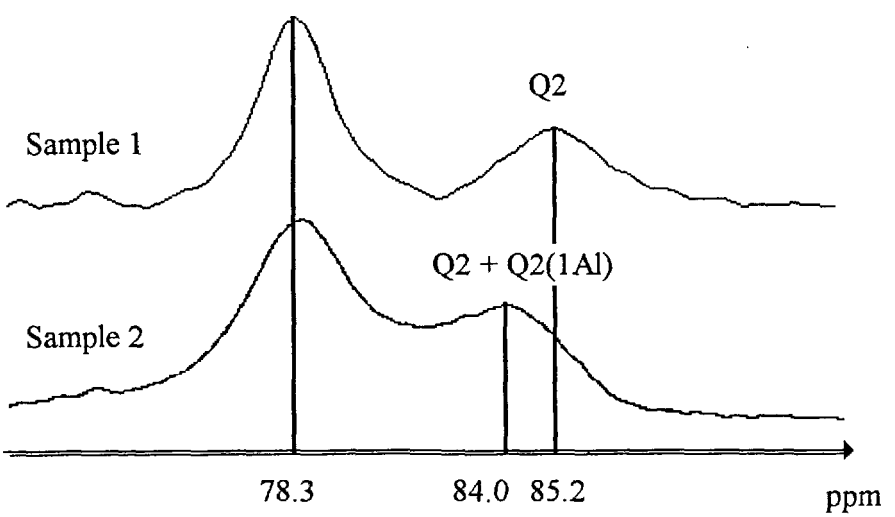

Figure 2 ^{29}Si MAS-NMR spectra of sound cement pastes.

Only samples 1 and 2 could be studied by NMR (Fig 2). The third contained iron, which is paramagnetic and partially destroyed the silicon signal.
In the sound paste of samples 1 and 2, the ^{29}Si MAS-NMR spectra were characteristic of that of

CSH of Ca/Si ratio 1.7 (Klur, 1996). The percentages of Q1 tetrahedra (linked to a single tetrahedron) and Q2 tetrahedra (linked to two other tetrahedra) indicates that the CSH of the sound paste comprise short chains of silicon tetrahedra (2 to 5 tetrahedra).
The chemical shift of the Q2 tetrahedra of sample 2 was smaller than that for pure C3S paste. Mägi et al (1984) have shown that the chemical shift of a Q2(1Al) tetrahedron for which one of the second neighbour silicons is substituted by an aluminium is 5 ppm less than that of a Q2 tetrahedron.

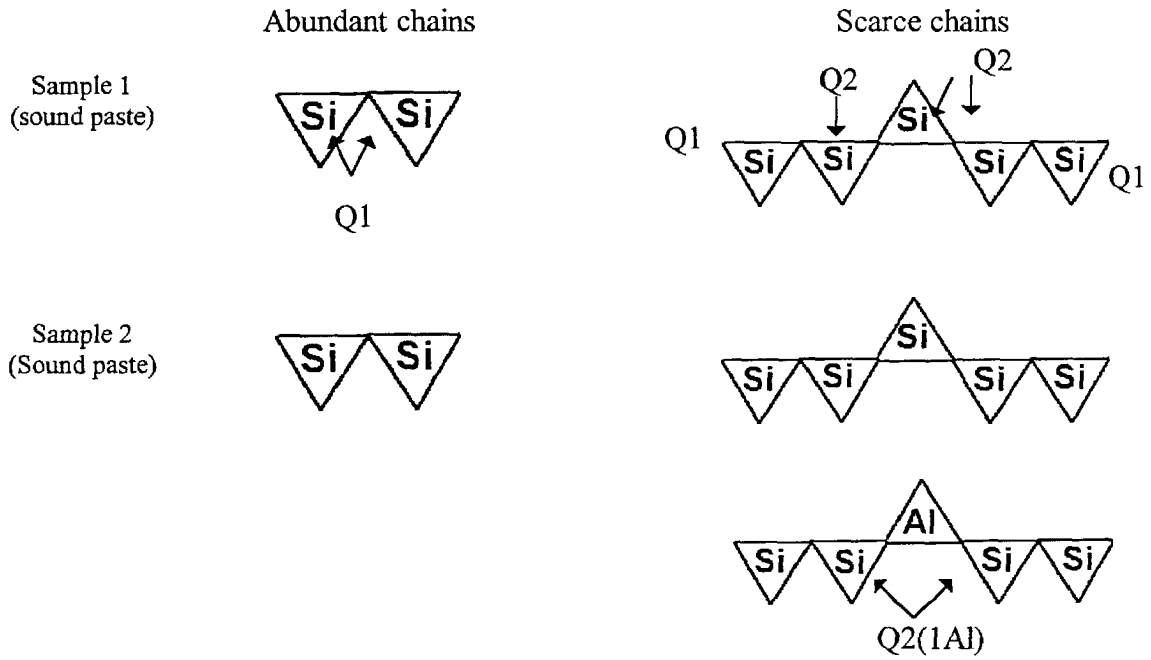

Figure 3 Types of chains of tetrahedra of the CSH in two sound cement pastes.

Aluminium introduced into sample 2 in the form of C_3A is therefore partially incorporated into the CSH. However, the percentage of silicon Q2 tetrahedra substituted by aluminium remains very low since the between-sample difference in chemical shift of the Q2 peak is small. Figure 3 shows the types of chains seen in the CSH of the two pastes.
The ^{29}Si MAS-NMR spectra of the degraded layers (Fig 4) are characteristic of those of CSH. The absence of Q0 silicon tetrahedra (no silicon as second neighbour) shows that no $4H^{+} \Leftrightarrow Si^{4+}$ substitution occurred in the C_3AH_6 structure in sample 2.
The percentage of Q1 has decreased in the two samples and that of Q2 has increased. The chains of tetrahedra of the CSH are therefore lengthened. The mean chain length increased from 2.5 in the sound zone of the two samples to 5 in the surface layers.
In sample 2, chain lengthening is accompanied by marked incorporation of aluminium in the CSH network since most of the Q2 silicons are, in fact, Q2(1Al) silicons. The latter have an aluminium as their second neighbour. This therefore yields the chains of tetrahedra of the "degraded" CSH shown in figure 4.
Leaching of cement pastes therefore results in "polymerization" of the CSH. In sample 2, the aluminium released by the dissolution of C_4AH_8 (Table 2) is in part incorporated into the CSH where it partially substitutes for silicon in the tetrahedral position.

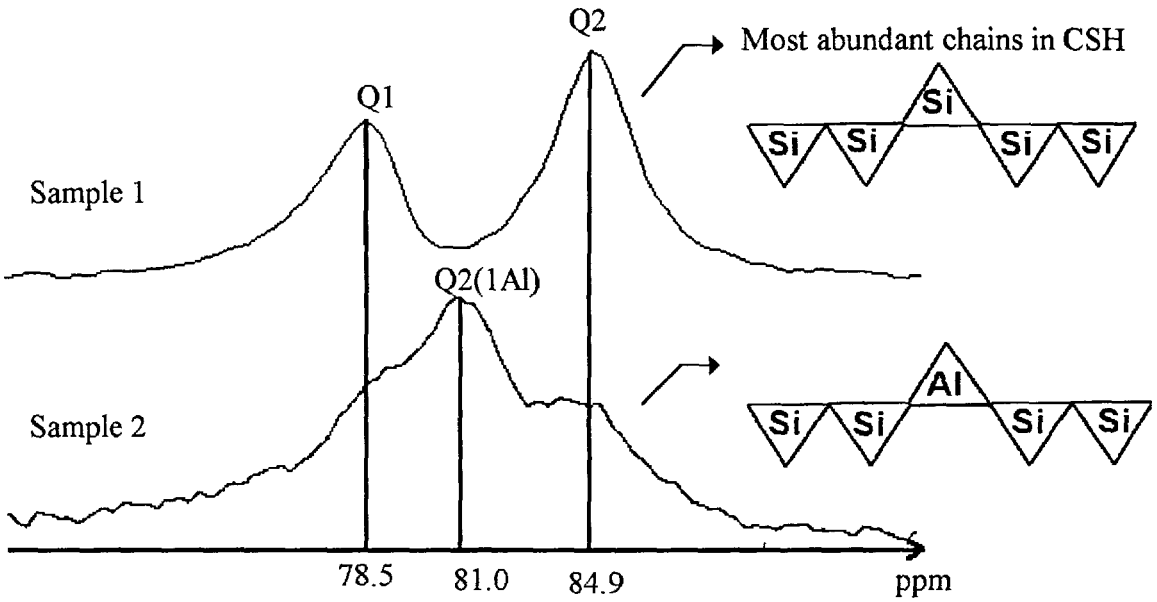

Figure 4 ^{29}Si MAS-NMR spectra of surface layers.

^{57}Fe Mössbauer spectroscopy (sample 3)

Sample 3 contained iron introduced in the form of iron nitrate, which dissolves on contact with water, thereby allowing incorporation of iron into hydrates. In sound paste (Figure 5), the isometric shifts, characteristic of the environment of iron, were all above 0.40 mm/s, i.e. characteristic of octahedrally coordinated Fe^{3+}. Iron is therefore not substituted for silicon. The quadrupolar coupling constants are characteristic of the symmetry of the incorporation sites and are close to the values determined by Labhasetwar et al (1991). for iron substituting for labile calcium (Δ_{labile} = 0.8 mm/s) and nonlabile calcium ($\Delta_{nonlabile}$ = 0.4 mm/s) in tobermorite, the structure of which is similar to that of CSH (Taylor, 1986). The band widths are characteristic of crystallized or nano-crystalline structures. It therefore appears that trivalent iron partially substitutes for the labile and nonlabile calciums of the CSH.

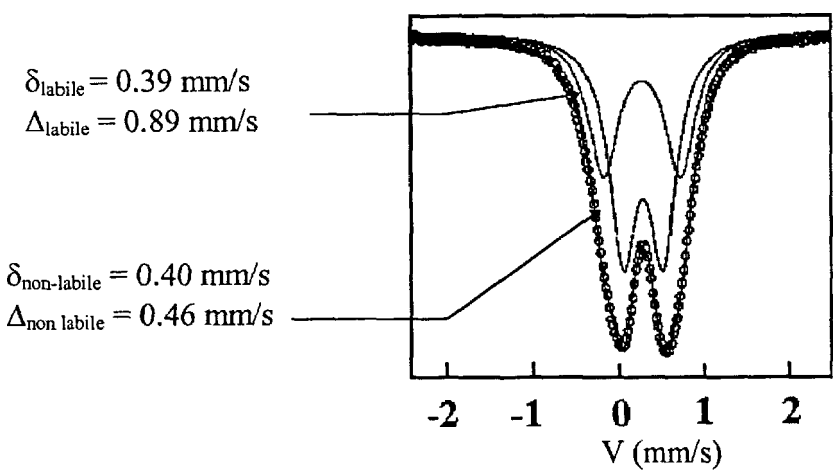

Figure 5 ^{57}Fe Mössbauer spectroscopy of sample 3 (surface layer).

DISCUSSION

Competition between diffusion and surface dissolution

Interface shrinkage occurred as a linear function of time (Fig 1). Two degradation mechanisms competed: degradation provoked by diffusion of the ionic species through the interstitial solution of the paste, and dissolution of the surface layer. It is vital for the prediction of long-term behaviour of cement structures to know which mechanism predominates over the stipulated storage period.
Rate of degradation in the diffusive regime
Assuming no shrinkage of the interface, solution of Fick's equations for a semi-infinite medium indicates that the thickness of the degraded layer, e, can be expressed in the following form:

$$e = \sqrt{D_{app} t}$$

where D_{app} is a constant with the same units as a coefficient of diffusion.
The following expression is then obtained for V_1, the rate of degradation in the diffusive regime:

$$V_1 = \frac{\sqrt{D_{app}}}{2\sqrt{t}}$$

V1 will therefore be large in the early stages of degradation, but small for longer times.
Limit time, t_0, of the validity of the diffusive regime
Figure 1 indicates that the interface shrinks at a constant rate V_2:

$$V_2 = K_2$$

where K_2 is a time-independent constant.

The limit time, t_0, of the validity of the diffusive regime will be reached when V_1 is equal to V_2, i.e.

$$t_o = \left(\frac{\sqrt{D_{app}}}{2K_2} \right)^2$$

D_{app} was approximately 15,000 µm2/day for each sample. The results given in figure 1 allow calculation of t0 for each sample.

Table 3 Time (t_0) after which the surface dissolution will govern degradation

Sample	1	2	3
V_2 (µm/day)	19	12	6
t_0 (days)	10	26	104

After t_0, surface dissolution will occur faster than diffusion-induced degradation. Dissolution of the surface in contact with the aggressive solution will determine the rate of degradation, and should therefore be minimized.

Effect of Al^{3+} and Fe^{3+} on the rate of degradation

Figure 1 (like table 3) shows that the surface layer of sample 1 dissolved quicker than that of sample 2. The ^{29}Si MAS-NMR results (Fig 2) and X-ray diffraction findings show that the CSH contain chains of five silicon tetrahedra on average. C_4AH_8 initially present in the surface layer of

sample 1 dissolved. The aluminium released precipitated in the form of AH_3 of low solubility at pH near neutrality (Damidot and Glasser, 1995) and was partially incorporated into the CSH, substituting for the Q2 silicons in the chains. This substitution creates a charge deficit compensated by the protonation of one of the oxygens of the tetrahedra (Fig 6). The resulting surface layer therefore dissolves much faster. The aluminium-substituted CSH therefore dissolve faster than nonsubstituted CSH. In contrast, partial replacement of divalent calcium by trivalent iron slowed the CSH dissolution (Figs 2 and 5). The excess charges introduced by the substitution are compensated this time by the loss of a proton (Labhasetwar et al., 1991, and Faucon et al., 1996, 1997b), yielding the structure shown in figure 6.

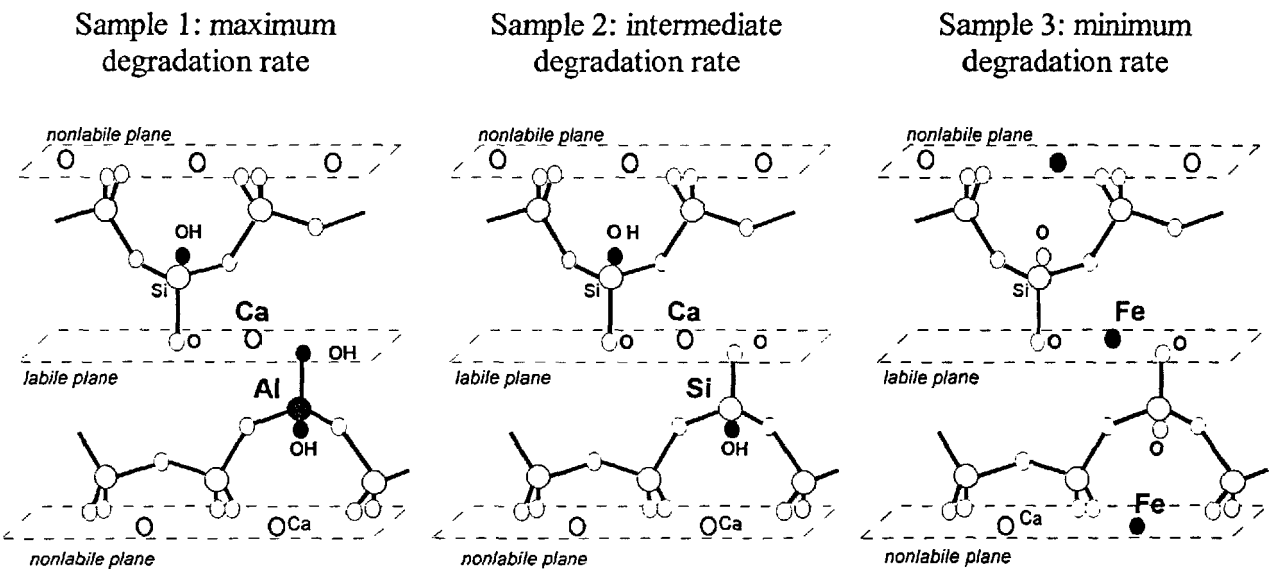

Figure 6 Structures of the different CSH of the degraded surface layers

The incorporation of iron reduced the solubility of CSH at pH near neutrality, whereas the presence of aluminium had the opposite effect. We are currently studying the solubility of the different CSH.

CONCLUSIONS

The degradation of cement by leaching with water results from the combined action of diffusion and dissolution of surface matter. In the short- and medium-term ($t < t_0$), degradation results from the diffusion of ionic species from the interstitial solution of the cement paste to the aggressive solution. The rate of degradation is governed by the rate of diffusion in the degraded layer. In the long-term ($t > t_0$), the rate of surface dissolution outstrips diffusion and therefore governs degradation.

These observations are fundamental for the prediction of the long-term behaviour of cement structures. The diffusive properties of the materials are important, but in the long term the rate of dissolution of the material at pH 7 is crucial.

NMR shows that that this dissolution is linked to that of the CSH, the main constituents of cement paste. Contact with a demineralized solution induces surface precipitation of short-chain CSH. Cationic substitutions in the CSH may increase or reduce their solubility and hence affect the rate of surface dissolution. Degradation is accelerated when aluminium substitutes for silicon in CSH and is slowed when iron replaces calcium.

EXPERIMENTAL-STATISTICAL MODELING AND ANALYSIS OF THE CHAIN "COMPOSITION - NMR-SIGNAL - PROPERTIES" OF CEMENT COMPOSITE

Tatiana LYASHENKO and Vitaly VOZNESENSKY, Odessa State Building and Architecture Academy, Odessa, Ukraine
Shimon BOYKO and David SHTAKELBERG, Standard Institute of Israel, Jerusalem, Israel

ABSTRACT Nuclear Magnetic Resonance (NMR) has been used to determine moisture content of colloid and capillary-pore structure in hardening composites. Quantities of 4 composition ingredients have been varied according to optimal design of experiment, 18 composites being studied. Polynomial models "composition - strength", "composition - moisture content", and "moisture content - strength" have been built and used for analysis of structure formation and prediction of composite quality.

Key-words: Composition, Modeling, Moisture, Nuclear Magnetic Resonance.

INTRODUCTION

The progress of research physical methods makes it possible to include NMR-signals (S_{NMR}), as intervening informative element, into traditional chain "composition X - properties R" of composite. The analysis of "from X to S_{NMR}" links might serve adding to knowledge of structure formation mechanisms. Studying the links "from S_{NMR} to X" might help in developing the methods of compositions identification. Mathematical description of "S_{NMR} - R" relations would present the base for prediction and express-control of products quality.

The purpose of this work has been to analyze the influence of composition of cement composite hardening for τ days ($1 \le \tau \le 28$) on composite strength $R(\tau)$ and parameters $U(\tau)$ of moisture content determined with NMR-method.

Two basic engineering situations have been considered. The first is the case of "full" information on $R(\tau)$ and $U(\tau)$ being available, that would be useful primarily when studying structure formation process. In the second case available is only 1-3 days information about structure formation, on which strength R_{28} must be predicted and water dosage at concrete mixing plant be controlled.

METHODS OF STUDYING AND RESULTS OF MODELING THE STRENGTH OF CEMENT COMPOSITES (CONCRETES) AT AGE OF 28 DAYS

Design and methods of experiment

Eighteen cement composites (concretes) have been studied, their four components varied according to D-optimal experimental design (Voznesensky et al, 1989), allowing four-factor quadratic experimental-statistical models (ESM) to be built and analyzed. Concretes base composition and raw materials (save fine filler especially introduced into study) have corresponded to those used by one of leading Israel firm manufacturing concrete mixtures.

The levels of varying the composition factors (with water content in mixtures, W=200 dm^3/m^3, being constant) and their normalization rules are shown in Table 1. Non-linear transformation is used for factor x_4 varied non-proportionally. Quality indices - properties of technological mixture and hardened concrete (compression, tensile and bending strength, modulus of elasticity, shrinkage, and others) were determined to Israel and International standards.

Table 1 The levels of composition factors in the experiment.

	Level			
	lower	basic	upper	Normalization Rule
	x_i= -1	x_i=0	x_i= +1	-1 ≤ x_i ≤ +1
X_1= C = Cement (C_3S=62.0, C_3A=8.4%, Sp.s.=290 m^2/kg), kg/m^3	250	280	310	x_1 =(X_1-280)/30
X_2 = CA/S - crushed aggeregate (4.75-19 mm) and sand ratio	1.98	2.23	2.48	x_2 =(X_2-2.28)/0.25

The method to estimate structure-formation parameters has been based on well known fact that changes in relaxation times of protons and amplitudes on NMR-spectrograms characterize the process of cement hydration. Cumulative curves obtained upon integrating the spectrograms give additional index, integrated NMR-signal, that has proved to be proportional to amount of free moisture in hardening system (correlation coefficient being 0.99).

The spectrograms for the fixed times of hardening (from 0 to 504 h) were taken with CORESPES spectrometer. Diameter of cuvette to be sealed and placed between electromagnets being restricted to 20 mm, so crushed aggregate was removed from technological mixture (x_2 not included into corresponding models). At the same hours the amounts of chemically bound water were also determined.

Models for concrete strength R_{28}

The analysis of composition influence on concrete mix and concrete quality indices after 28 days has been carried out on adequate models with significant estimates (at 10% risk) of their coefficients. Got for R_{28} has been model [1].

$$R_{28} = 24.7 + 4.3x_1 - 0.7x_2 + 1.9x_2^2 + 1.6x_1x_2 + 1.2x_2x_3 + 0.8x_2x_4 + 0.7x_3x_4 \quad [1]$$

This ESM describes, with error of 1.0 MPa, "composition - strength" field (Voznesensky and Lyashenko, 1989) that has following parameters: $R_{28.max}$ = 34.4 (at C/W=1.55, CA/S=2.48, A=0.7, F=60), $R_{28.min}$ = 18.1 (at C/W=1.25, CA/S=2.30, A=0.42, F=60), ΔR_{28}=16.3 MPa, K_R=($R_{max}/R_{min})_{28}$ = 190%. Three-factor ESM [2] describes the composition field of strength without considering x_2 (CA-S ratio).

$$R'_{28} = 25.2 + 4.3x_1 + 1.1x_4^2 + 1.4x_1x_4 + 0.8x_3x_4 \quad [2]$$

Its error of 1.45 MPa including disregarded influence of large-size aggregate is naturally greater than that of [1]; coordinates of extrema ($R'_{28.max}$ =32.8, $R'_{28.min}$=19.8) also shift. Such models, however, are necessary in simultaneous analysis with the models for structure formation parameters of cement composites, determined by NMR. Solved with ESM of type [1] for each property has been the complex of engineering problem (Voznesensky et al, 1989). Effect of each ingredient of composition on service and structural characteristics has been analyzed on one-factor curves passing through extremum points. Shown in Fig 1 are such functions of factor influence on R_{28} (fine lines) and R'_{28} (thick lines).

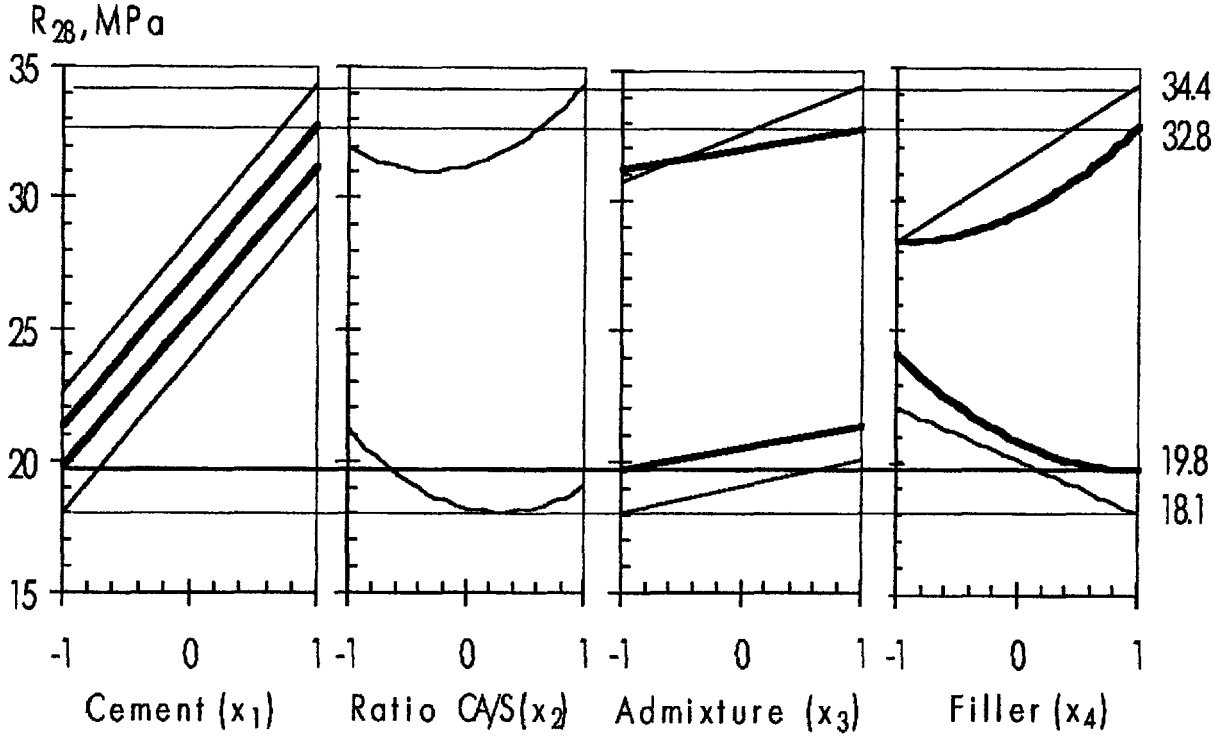

Figure 1 One-factor models of the influence of composition ingredients on concrete strength R_{28} at zones of its maximum and minimum.

There is no need to comment the effect of C (x_1), identical to that of C/W with W=const. The influence of polymer-containing additive is positive in extremum zones.

Non-trivial is the fact of ambiguous effect of filler. If the composite was prepared with increased dosages of cement and admixture (the region of $R_{28.max}$), then raising filler concentration from 3 to 20% would increase composite strength. But the same variation in composition would cause the strength to decrease, if composite contained little admixture and cement (i.e., at high W/C).

ANALYSIS AND USE OF NMR-RESULTS

Estimation of moisture state of cement composite over first month of hardening by parameters determined with NMR

Moisture content U has been estimated on the base of its linear relation with integrated NMR-signal (automatically got from cumulative curves after integrating NMR-spectrograms). Initial content of moisture U_0, i.e., free water amount (g/kg.dried) was determined in fresh mixture ($\tau = 0$ hardening days).

During hardening for $\tau > 0$ days the quantity of moisture goes down to U_τ (Fig 2, plots corresponding to averaged values for 18 compositions). The difference $\Delta U_\tau = U_0 - U_\tau$ characterizes the outflow of free moisture from "heavy" water films onto arising hard surfaces of gel and capillary components of developing structure of cement paste. Part of physically bound water switches to higher energy level of interaction with material. NMR-parameters reflect sufficiently well the variations of pore radii from 20 to 2000 A° as cement stone structure develops (Halperin et al, 1994).

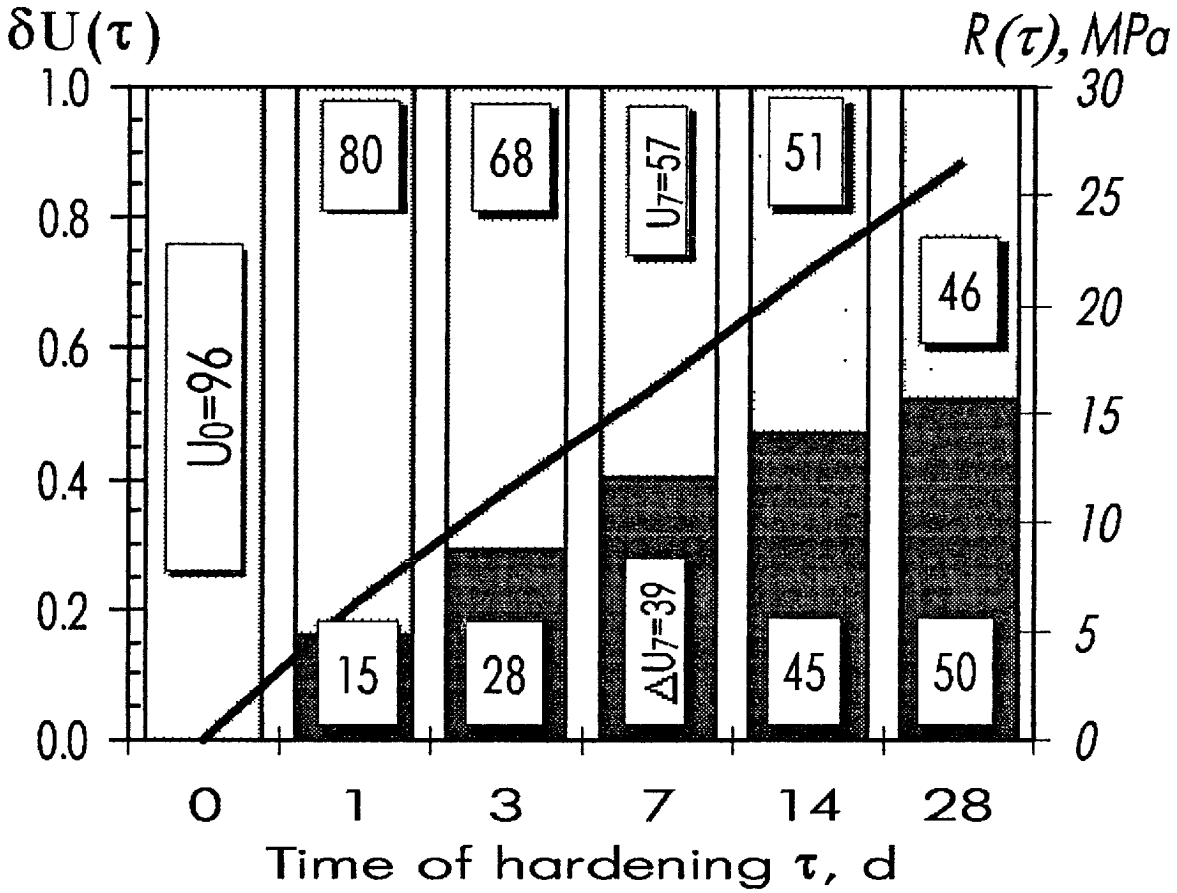

Figure 2 Variations of parameters determined by NMR and cement composite strength during 28 days of hardening.

For each of 18 concretes at age of τ = 1, 3, 7, 14, and 28 days compression strength R_τ was determined. For corresponding composites (with X_2=0) obtained from NMR-analysis was the information on time parameters U_τ characterizing moisture content:

- in colloidal structure, of low energy level of bond - $U_{1(3,7,14,28)}$,
- in capillary-pore structure, of high energy level of bond - $\Delta U_{1(3,7,14,28)}$.

The level and forms of moisture content define structure formation in hardening cement composite to a large degree (Shtakelberg and Sychev, 1990). Increasing of moisture content of capillary-pore structure in hardening cement composite, $\Delta U(\tau)$, proportional to decreasing of $U(\tau)$, proceeds similarly to a rise of strength, as can be seen in Fig 2.

Relation between varying content of moisture and growing strength of hardening composite

Similarity of $\Delta U(\tau)$ and $R(\tau)$ processes leads reasonably to linear relation between ΔU and R at any fixed time $1 \leq \tau \leq 28$. For all composites, irrelative to their compositions, model [3] has been calculated, that, with correlation coefficient 0.86 confirming linearity hypothesis at risk less then 0.1, has the error of 4.0 MPa. Linear relations of $\Delta U(\tau)$ and $R(\tau)$ for each of 18 composites studied are more deterministic (Fig 3), coefficients of correlation for the most part are over 0.98.

$$R(\tau) = k_0 + k_1 \Delta U(\tau) = -1.16 + 0.504\, \Delta U(\tau) \qquad [3]$$

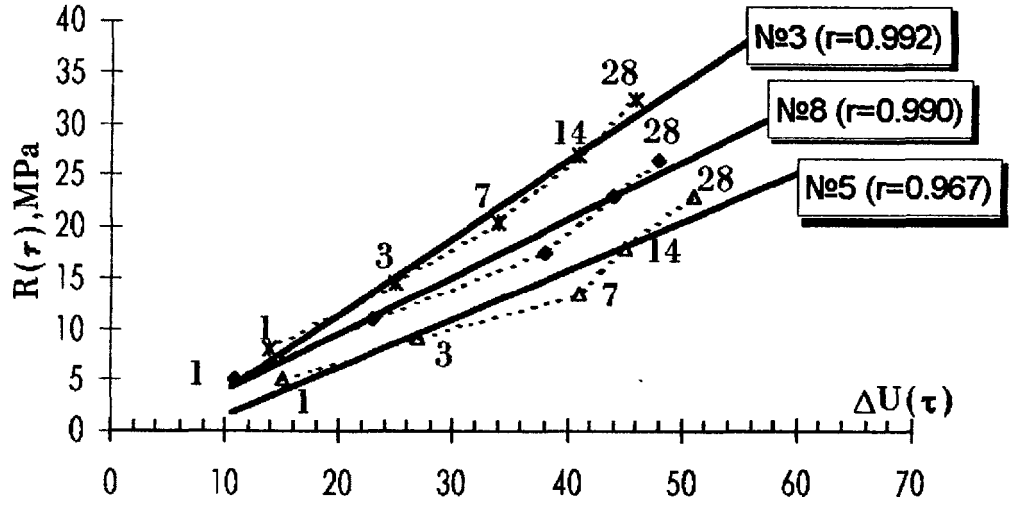

Figure 3 Linear relations of strength R(τ) and moisture content ΔU(τ) in hardening concretes (numbers of days indicated alongside labels).

Numeric estimates of coefficients in these models depend on concrete composition (as seen in Fig 3), that is, k_0 and k_1 are functions of factors C, A, F. The models $k_0(x_1, x_3, x_4)$ and $k_1(x_1, x_3, x_4)$ make it possible to analyze the influence of composition factors on parameters of structure formation process determined with NMR. Yet analysis has shown that ESM for other variables, following from [3], are more convenient for technological interpretation.

Effects of composition factors on structure formation parameters defined through NMR-analysis

The complex of ESM of type [3] describing relationship of R(τ) to ΔU(τ) for 18 composites (their compositions varied to optimal design) allows a number of non-trivial technological problems to be solved with the aid of computational experiments.

Problem 1 - about effects of amounts of cement, admixture, and filler on strength of hardening composites with equal content of moisture in capillary-pore structure.

It is too complicated to provide given level of moisture content at high energy level, determined with NMR, for each of 18 composites in real, physical experiment. It is rather simple (Voznesensky et al, 1989) to solve the problem through computational experiment with statistical models (with reasonable risk defined by non-adequacy errors of the models).

Fig 4 illustrates the way by which 18 "experimental" values of strength of capillary-pore structure, R{ΔU = 50} MPa, for 18 cement composites of equal structure-moisture level ΔU = 50 g/kg.dried (achieved clearly during different time of hardening - see Fig 3) has been determined.

On these results model [4] has been built describing the influence of composition factors on strength R{ΔU = 50}, for 18 cement composites of equal structure-moisture level ΔU = 50, with error of 2 MPa.

$$R\{\Delta U=50\} = 22.6 + 3.8x_1 - 1.2x_3 - 2.6x_3^2 + 5.7x_4^2 + 1.4x_1x_3 + 1.7x_1x_4 + 2.4x_3x_4 \qquad [4]$$

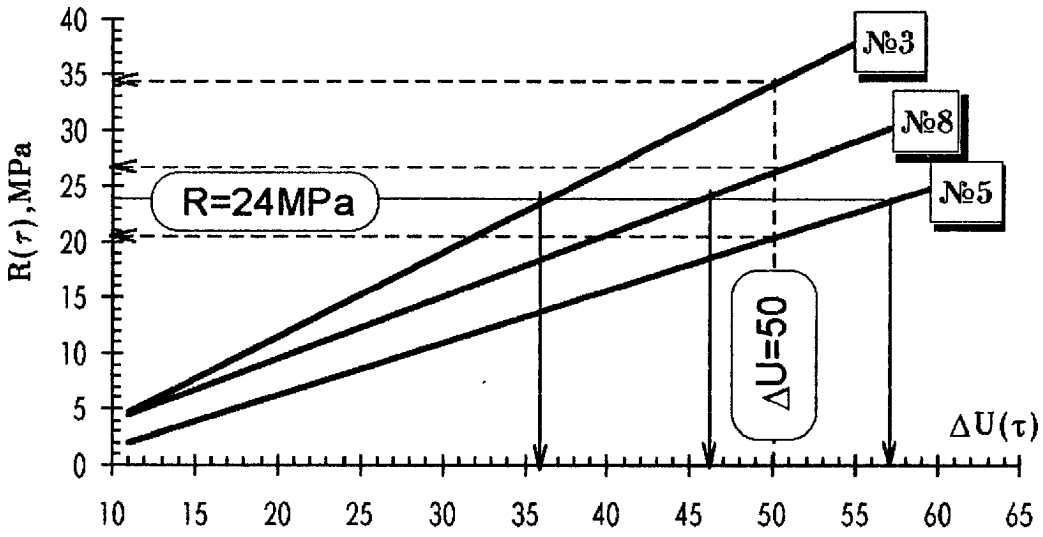

Figure 4 Determination of moisture content $\Delta U(\tau)$ in equally strong concretes (continuous lines) and strength $R(\tau)$ of concretes with equal content of moisture (dash lines).

One-factor models passing through extremal points of this ESM are shown in Fig 5. Upper curves relate to composite with high amounts of cement and filler and optimal concentration of admixture (A=0.56 kg/m^3), whereas lower curves correspond to composite of low content of cement and admixture with introducing great quantity of filler (about 18% of cement mass).

Variations in cement dosage for both composites have practically the same effect on $R\{\Delta U=50\}$; corresponding plots in Fig 1 demonstrate full analogy. Similarity is not observed, however, when comparing effects of filler on $R\{\Delta U=50\}$ and R_{28} at extremal points of Eq 4.

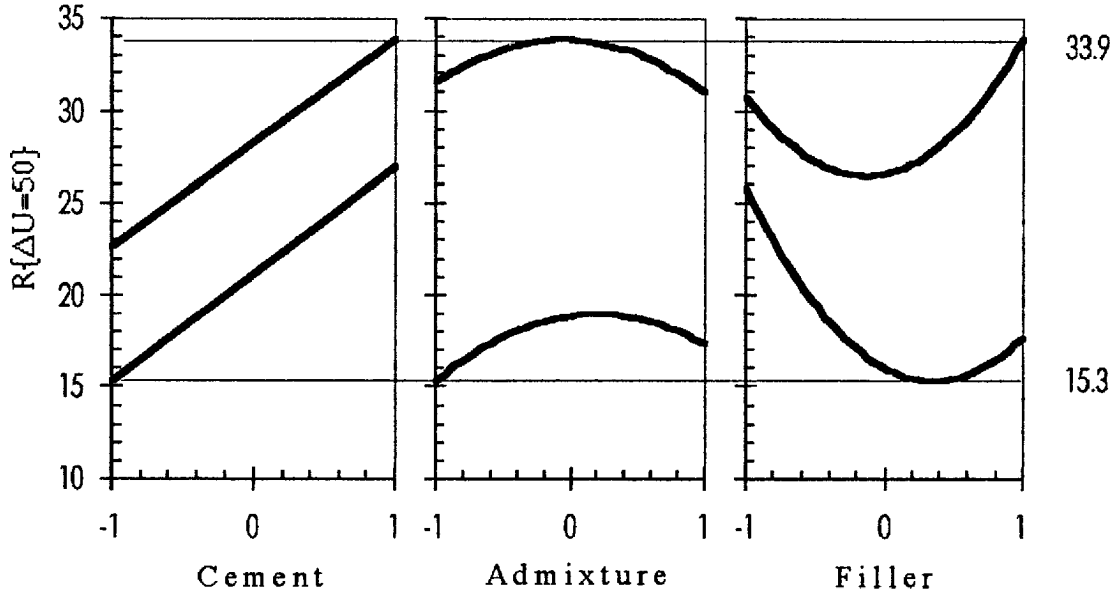

Figure 5 One-factor models of component effects on composite strength in maximum and minimum areas under condition of equal content of moisture.

In composites with increased cement content small concentrations of filler merely augment the quantity of non energy-saturated ("parasite") contacts of solid elements in hardening system, the strength of which falls. As concentration increases this negative effect might be overridden by growing "cramped conditions" (Sychev, 1974) of cement hydration, that would give rise to composite strength by 10% (when moving from -1 to +1). Negative effect of filler "parasite contacts" prevail in composites with low content of cement, for its volume concentration is almost 20% less than in the fist case. As a result the strength reduces by 33%.

Problem 2 is about composition factors influence on moisture content in capillary-pore structure, $\Delta U\{R = 24\}$, for composites of equal compression strength (24 MPa).

Initial information is got analogously to problem 1, as shown by continuous lines in Fig 4. It is logical to assume that variables $\Delta U\{R=const\}$ and $R\{\Delta U=const\}$ are inversely proportional. Three-factor ESM [5] describes (with 6% error) the influence of C, A, and F on this structure formation parameter.

$$\Delta U\{R=24\} = 51.7 - 6.4x_1 + 2.4x_3 + 2.8x_1^2 + 3.6x_3^2 - 9.4x_4^2 - 2.3x_1x_3 - 2.3x_1x_4 - 3.8x_3x_4 \qquad [5]$$

One-factor models passing through extremal points of Eq 5 are presented in Fig 6. In contrast to Fig 5 upper curves correspond to low-cement composites with increased content of filler. Lower row of curves characterizes compositions with large amount of cement , A and F at low levels.

For 5 curves the hypothesis of $\Delta U\{R=const\}$ and $R\{\Delta U=const\}$ being in inverse proportion may be accepted. Yet for composites with high level of C different phenomenon comes to light. With increasing concentrations of polymer-containing admixture far greater part of physically bound water must switch to upper energy level to provide equal strength of composites.

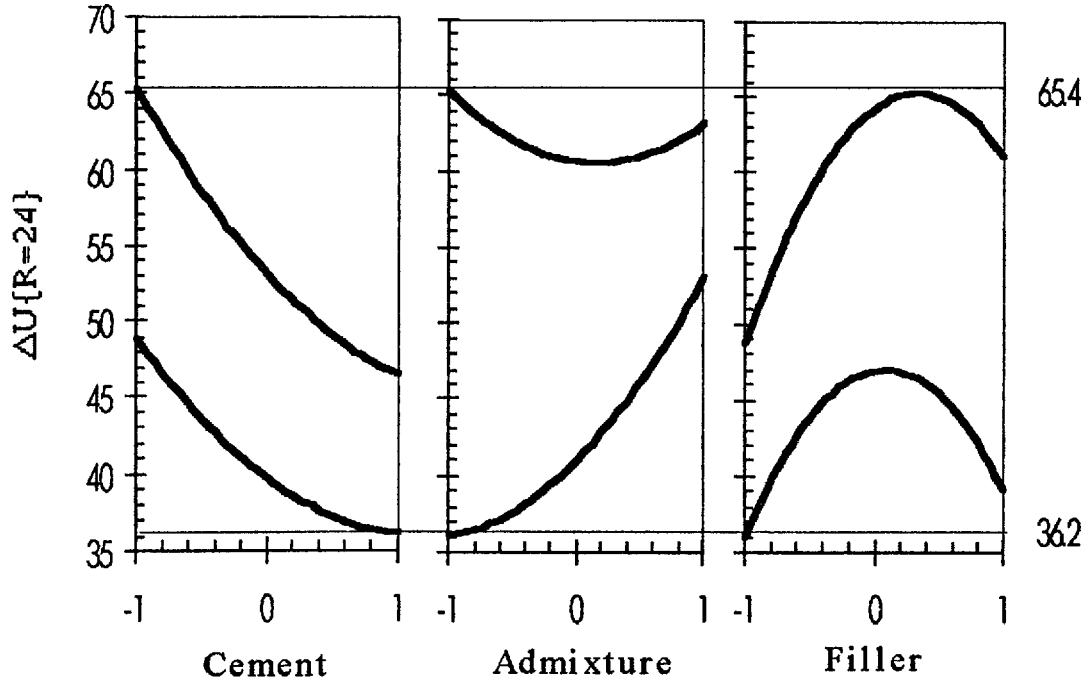

Figure 6 One-factor models of ingredient effects on moisture content ΔU of equally strong concretes (R=24 MPa) in maximum and minimum regions.

Using the results of NMR-analysis of young cement composites to predict concrete strength at age of 28 days

Comparison of various ways of building the models for predicting R_{28} has shown that it is reasonable to include into these models the normalized arguments, $-1 \leq w \leq 1$, comprising determined with NMR parameters of cement composites over 1-3 days of hardening. From the "fan" of models obtained ESM [6], in particular, might be considered sufficiently useful (prediction error about 18%).

$$R_{28}(w_1,w_3,w_{10}) = 26.0 + 11.9\, w_3 - 4.0\, w_{10} + 3.2\, w_1^2 + 3.4\, w_3^2 + 3.1\, w_1 w_{10} + 3.4\, w_3 w_{10} \qquad [6]$$

Eq 6 accounts for initial content of moisture, $w_1 = (U_0 - 112)/34$, moisture content of capillary-pore structure after 1-day hardening, $w_3 = (\Delta U_1 - 19)/9$, and moisture transformed to this high energy level between 1st and 3rd days, $w_{10} = [(\Delta U_3 - \Delta U_1) - 12]/4$.

If in addition to NMR results the information on chemically bound water could be incorporated in models of type [6], then prediction error for R_{28} would reduce approximately 20%. The error might be sharply decreased if technologist was assured of accurate dosage of all components (but water). In this case taking account of CA, S, D, and F amounts in conjunction with express physic-chemical data makes it possible to predict R_{28} with accuracy not worse than that on results of concrete compression tests, $R_1,\ldots, R_3$.

CONCLUSION

Optimal design of experiment offers substantial savings in resources when studying cement composites (especially with application of complex physic-chemical methods). Experimental-statistical models therewith allow most fully engineering information to be derived from experimental data.

It has been found on the base of ESM that polymer-containing admixture and the filler, modifying the character of structure formation (changing properties of thin film water, setting "cramped" conditions of hydration, increasing a number of parasite micro-contacts, etc.), affect ambiguously on composite quality indices.

Moisture content parameters of hardening concrete have been determined and the influence of composition factors on them estimated with the help of NMR. This has made possible to build multi-factor models for predicting 28 days concrete strength (with 15% error) on results of NMR-analysis of 1-3 days cement composites.

COOLING OF LIQUID CALCIUM ALUMINATES MONITORED BY ^{27}Al NMR TIME RESOLVED EXPERIMENT

B. TOUZO, D. MASSIOT, D. TRUMEAU, A. DOUY and J.P. COUTURES
CRPHT / CNRS, 1D, Av. de la Recherche Scientifique, 45071 ORLEANS CEDEX 2 FRANCE

ABSTRACT The free cooling of aerodynamically levitated liquid calcium aluminates droplets has been monitored by time-resolved ^{27}Al NMR. The results allow characterisation the structure and dynamics of these liquids from 2400K via the supercooled state, and to observe crystallisation. For liquid CA, the NMR relaxation time and the macroscopic shear viscosity appear to be related to the same microscopic fluctuations. Liquid CA_6 behaves as predicted by the phase diagram, and allows us to propose incongruent fusion for CA_2.

Key-words: Calcium aluminates, Nuclear magnetic resonance, cooling, melt

INTRODUCTION

Nuclear Magnetic Resonance of ^{27}Al is well known to provide characterisation of the local environment of aluminium in the solid state. As previously shown (Coutures, 1990, Massiot, 1995) it is still sensitive at very high temperature in the liquid phase. It is thus possible to characterise the average structure as well as the the dynamics of the liquids from chemical shift and relaxation time measurement. Furthermore, as ^{27}Al spectra can be obtained in one scan and as relaxation times are short, the evolution of the NMR parameters can be followed in real time even for fast dynamical process like quenching. In the experimental design used in this study an aerolevitated sample placed inside the NMR probe is heated by lasers (Massiot, 1995). When the laser heating is stopped, the sample cools freely, and NMR spectra can simultaneously be recorded. We report here some of the results obtained for the CaO-Al_2O_3 binary system.

EXPERIMENTAL

The experimental design for NMR measurements is described in **Fig 1**. A spherical sample (2 mm ∅) of calcium aluminate is placed in a convergent-divergent nozzle in which it levitates on an adjustable air jet. The whole is placed in the RF-coil of a vertical NMR probe. The sample is heated from the top and the bottom of the cryomagnet by two continuous wave CO_2 lasers. The levitation regime is checked by video and the infra red emission ($\lambda = 0.85$ µm) of the sample is monitored via an optical fiber and externally calibrated for temperature. With this setup temperatures above 2400 K can be reached . ^{27}Al NMR spectra of liquid calcium aluminates can be obtained in only one scan and show a single narrow line (80-100 Hz). As measured in previous works (Massiot, 1995, Touzo 1995), the spin system undergoes an extreme narrowing regime (high temperature), where $T_1 = T_2 \approx 4$ ms at 2400 K. These conditions make it possible to follow in real time, by ^{27}Al NMR, the cooling of the sample. When the lasers are shut down, the sample cools freely to room temperature. Simultaneously ^{27}Al NMR spectra and IR emission are recorded every 50 ms. Triggering of the recording is set one second before the interruption of the laser heating to check the high temperature steady state. In these experimental conditions, only the liquid part of the sample leads to a significant signal.

RESULTS AND DISCUSSION

Liquid compositions ranging from 0 to 84 mol% CaO have been observed. there was no weight change of the sample during the experiments. Results obtained for the composition CA_6 are shown in **Fig 2** as an example. Before laser shut down, temperature, chemical shift (δ), full width at half maximum ($\nu_{1/2}$) as well as magnetisation (M) are constant, show the stability of the system. Then liquid behaviour is monitored over a range of ~700 K (2400-1700K) down to supercooled liquid. The magnetisation increases with decreasing temperature according to Curie's law, proving that we observe all the ^{27}Al spins of the sample. When the sample crystallises, the temperature increases sharply and the magnetisation drops. This recalescence (Coutures, 1994) can be observed by ^{27}Al NMR of the residual liquid in favourable cases. When the amount of liquid phase decreases, the signal-to-noise ratio decreases and the results obtained from fitting the spectra scatter. In these experimental conditions (absence of heterogenous nucleation, 200 $K.s^{-1}$ cooling rate), liquid calcium aluminates in the composition range 40-75 %mol CaO can vitrify. For those compositions, a smooth continuous evolution is observed for all the NMR parameters from liquid to the supercooled state.

Liquid calcium aluminates

At 2400 K, δ is a linear function of the composition and takes values from 58 ppm for Al_2O_3 to 85 ppm for the 84%mol CaO composition. This has been interpreted as an increase of the average Al coordination number with increasing Al_2O_3 content, in agreement with MD computations (Poe, 1994). Those liquids were proposed to consist of AlO_4, AlO_5 and AlO_6 polyhedra with rapid exchanges between different configurations. This has been partly confirmed from a glass of $C_{40}A_{60}$ composition in which ^{27}Al MQ-MAS spectrum clearly evidences the existence of AlO_4 and AlO_5 species (Massiot, 1996).

As δ and T are measured at the same instant, we can observe the thermal dependance of the chemical shift, δ, versus temperature. For all compositions of the $CaO-Al_2O_3$ binary system, we observe a linear correlation: dδ/dT depends on the liquid composition and has been related to structural evolution in the liquid. Al_2O_3 (dδ/dT = +2 ppm/1000K) is expected to undergo only small structual change with temperature (Florian, 1995), while CA (-4.6 ppm/1000K) shows the strongest evolution. The latter is estimated to be +0.2 increase in coordination number per 1000K (Massiot 1995). It is also worth noting that all liquids having a slope less than -2 ppm per 1000K vitrify ; chemically, this corresponds to compositions around CA (Touzo, 1995).

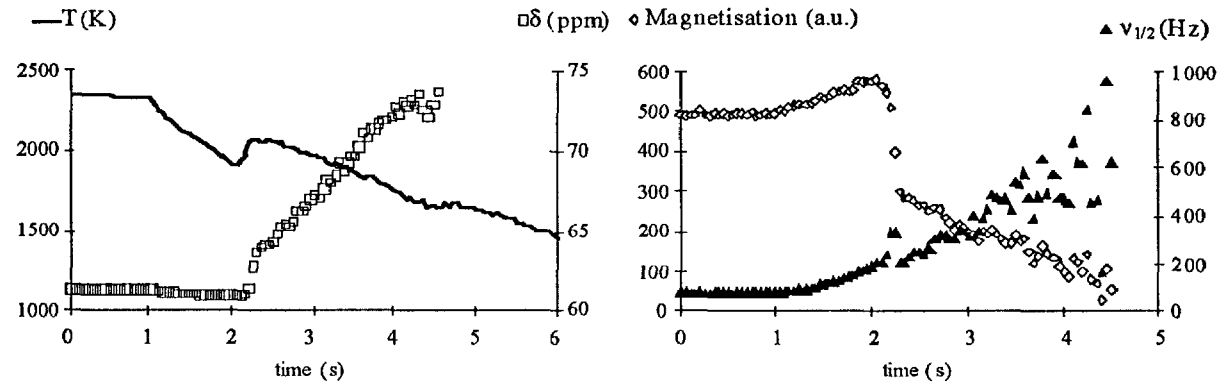

Figure 2 : Time resolved experiment for the CA_6 composition liquid

As these liquid are in extreme narrowing regime, the relaxation times T_1 and T_2 are equal and linked to the line width $\nu_{1/2}$ by the relation $T_1 = T_2 = 1/(\pi.\nu_{1/2})$. Linewidths then give access to the dynamics of these liquids during cooling. Quadrupolar interaction is the dominant interaction when observing ^{27}Al in solid state. A most sensible hypothesis is then that relaxation is induced by the fluctuations of this interaction and we can estimate a correlation time, τ_C, for atomic movements in the liquid, which are the origin of the NMR relaxation. In a similar way it is also possible to compute a correlation time τ_S for the shear viscosity from the Maxwell equation (Dingwell, 1990): τ_C and τ_S computed from the viscosity measurement made by Urbain (1983) are shown in **fig. 3**. The two sets of fully independent data are remarkably similar ; they both have the same magnitude and temperature dependance. Furthermore, the NMR data acquired in the supercooled liquid state follow the extrapolated curved proposed by Urbain. We thus consider that both ^{27}Al relaxation and viscous flow have the same microscopic origin, in the interconversion of AlO_4, AlO_5 and AlO_6 species (Massiot, 1995).

Crystallisation of CA_6

As mentioned above, crystallisation can be observed as long as liquid remains in the sample and its viscosity is not too high. This is the case for the CA_6 composition (**fig 2**). According to the phase diagram (Nurse, 1965), CA_6 presents a peritectic solidification. The evolution of the measured NMR data are very different from that observed for the congruent solidification of Al_2O_3 (Florian, 1995). In the case of CA_6, ^{27}Al NMR spectra shows an evolution in two steps : there is first a rapid change within 250 ms with a 48% magnetisation loss, i.e. 48% of the aluminium atoms go into the solid phase. By this time δ increases from 61 to 63.8 ppm and the

temperature goes up (recalescence). Then the temperature starts to decrease again, while M and δ shows continuous evolution until the signal disappears. The chemical shift evolution is large compared to that observed for liquids with temperature, and implies a chemical modification. Comparison of the δ value after the sharp increase to the values obtained for liquid calcium aluminate at constant temperature leads to the composition of $C_{24}A_{76}$ (Touzo, 1996). A similar composition can be computed by considering the magnetisation loss and assuming that

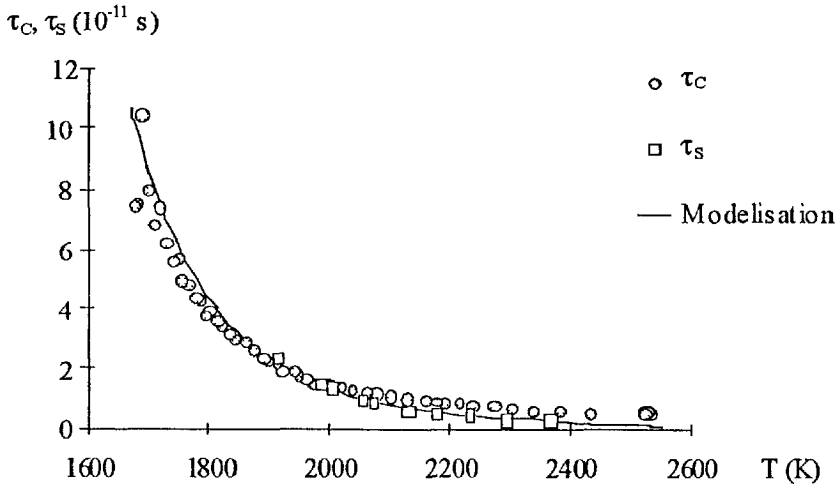

Figure 3 : Evolution of the correlation times τ_C (NMR) and τ_S (shear vicosity) and modelisation (Urbain, 1983) with temperature.

aluminium oxide first crystallises. This is in argreement with the peritectic solidification of CA_6 as described by the phase diagram of the $CaO-Al_2O_3$ binary system, where liquid CA_6 first transforms to solid Al_2O_3 + Liquid. After the rapid evolution step, the chemical shift increases rapidly and continuously, again evidencing a change of the chemical composition of the remaining liquid, while the magnetisation decreases. The chemical shift continues to increase far beyond the values for CA_2 (67.3 ppm). In these conditions, CA_2 appears to melt incongruently, in agreement with the experimental determination proposed by Nurse *et al.* (1965).

The Study on the Properties of High Performance Concrete Paste by Using NMR

Chao L. HWANG, National Taiwan Institute of Technology, Taipei, Taiwan, R.O.C..
Ping K. CHANG, Private Van Nung Institute of Technology, Jungli, Taiwan, R.O.C..

ABSTRACT In this study, solid ^{29}Si-NMR and compressive test were used to analyze macro and micro structure properties and hydration models of high performance concrete (HPC) paste. Test results showed that the replacement of fly ash for cement made the polysilicate forming reaction prominent. The decrement of cement affected the packing density and hence diminished the early strength. In addition, the contribution of fly ash to the ultimate strength of HPC is also acknowledged.
Key Words : NMR, Hydration Model, HPC, Pozzolanic Reaction, Fly Ash

PREFACE

The ingredient of High Performance Concrete (HPC) is same as the traditional concrete, but their design algorithms have some difference (Hwang, 1994). Hydration mechanism of traditional concrete has been explained through heat evolution, setting time, penetrative resistance, pulse velocity, compressive strength, X-ray defraction analysis and micrograph observation (Mindess, et al, 1981). NMR, an advanced method, will be helpful to understand the characteristics of HPC hydration behavior to discuss macroscopic correlation of paste hydration with help of the aforementioned traditional measuring techniques.

HYDRATION BEHAVIOR

In ^{29}Si-NMR (spectrogram), the chemical shifts of Trialcium silicate clinker and its hydrate C-S-H gel were Q^0 (-70 ppm), Q^1 (-80 ppm) and Q^2 (-87 ppm) (Lipma, et al., 1980). Due to the increment of signal (peak) intensity, the hydration mode of paste might be obtained. NMR has an advantage for the analysis of amorphous (noncrystal) components in the specimen, and this is good for C-S-H product analysis (Pietersen, et al., 1992).

TEST METHOD

Fly ash content and age were adopted as hydration parameter in this research. Test material such as local class F fly ash and type I OPC were used to make various paste specimens with W/B = 0.35. Upon completion of compressive test, the representative specimens were taken

for the performance of ^{29}Si-NMR NMR test (Bruker MSL 200 HMz). The condition, data and method of spectrogram test were shown in the literatures (Hwang, et al., 1994).

RATE OF HYDRATION

The hydration rate of paste has inverse proportion to the degree of hydration (doh). While the doh is lower, the hydration rate is quite fast. The initial hydrolysis has an extremely fast reaction. As the doh is more complete, the hydration rate nearly stops (Justnes, et al. 1990). The initial hydrolysis is a fast but unbalanced "chemical reaction", and later it is converted to "diffusive reaction" as hydration mechanism, so it is possible to apply "diffusion" formula for calculating the reaction rate of paste after the first day as follows:

$$\dot{\alpha} = d\,\alpha/dt = \alpha\, e^{-Q/RT} \quad \text{---------- [1]}$$

In this formula [1], Q is activation energy and is a constant for certain cement material. R is also a constant, and T is an absolute temperature. Therefore, $\alpha\, e^{-Q/RT}$ on the right side of formula [1] is a fixed value and has a right ratio to α^{-n}, i.e., formula [1] may be changed into formula [2], and k and n are coefficients.

$$\dot{\alpha} = d\,\alpha/dt = k\,\alpha^{-n} \quad \text{---------- [2]}$$

$$\text{i.e. } \alpha^{n} d\,\alpha = k dt \quad \text{----------[3]}$$

$$(\alpha_1^{n+1} - \alpha_0^{n+1}) / n+1 = k\,(t_1 - t_0) \text{ Integral may obtain} \quad \text{----------[4]}$$

The relationship for doh (α) and age (t) can be obtained from ^{29}Si-NMR information. The relationship between C-S-H reaction rate ($\dot{\alpha}$) and doh (α) in the paste can be obtained from regression as shown in formula [5]. The result may be explained when calcium silicate contacts moisture, the surface immediately produces extreme contact reaction. Clinker in the solution appears irregular hydrated rather than a hydrated crystal, and such reaction is violent surface reaction. Exothermal hydration also appears extremely fast discharge. When Ca^{+2} ion in the solution has reached the maximum concentration, i.e. chemical-controlled acceleration reaction (Justnes, et al., 1990), hydration acceleration is converted to "diffusive control" upon reaching the peak. Because ion movement in the solution is limited, cement grains not hydrated is engaged in hydration in a solid, and hence hydration velocity decreases sharply. At an later and stable stage diffusive hydration becomes much slower, so the curve is nearly horizontal and the doh will be nearly zero after 50% attained. The above formula is mainly influenced by cement fineness and C_3S and fly ash content.

$$\dot{\alpha} = d\,\alpha/dt = 44.69 * 10^{-4.54e^{-2\alpha}} \quad [5]$$

HYDRATION MODEL

The doh (α) of paste, degree of pozzolanic reaction (α_p), polysilicate length (Psi) and compressive strength (fs) all have a right proportion to the age.

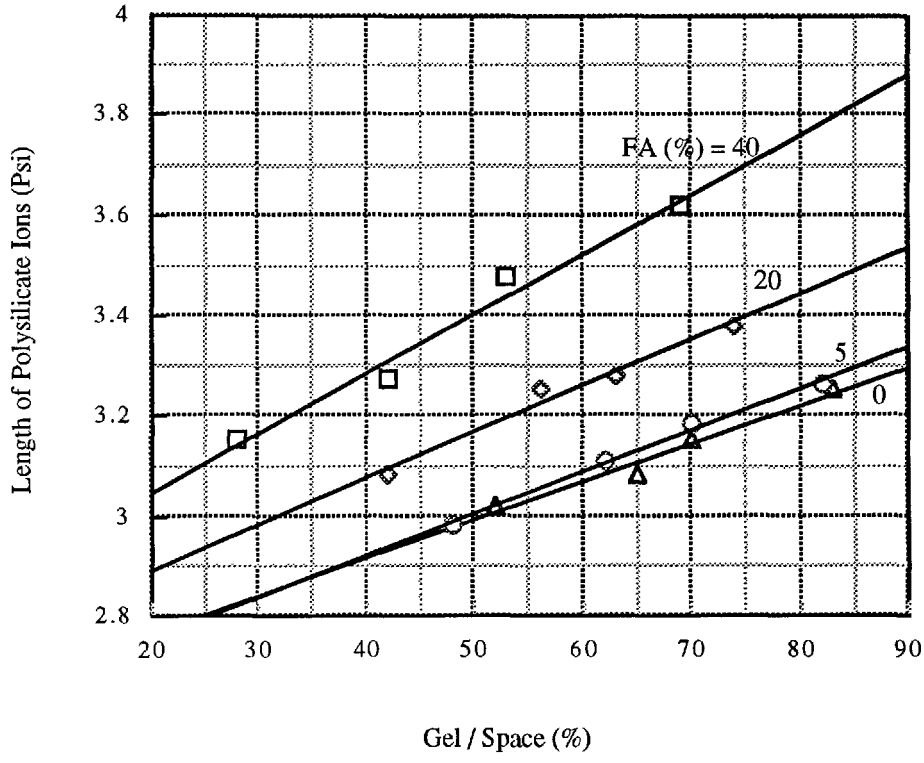

Figure 1 Relationship between the length of polysilicate ions and gel-space ratio of cement paste

Fig.1 shows there is a right proportion between polysilicate length (Psi) and gel-space ratio (G/S), i.e. in the paste the greater the silicon anion length is, the bigger the G/S will be; the higher the fly ash content is, the curve tends to move toward the left top. These explains that under same G/S, the more the fly ash content increases, the greater the polysilicate length will be. The fly ash is helpful to pozzolanic reaction , and while more fly ash is added, the reaction becomes more significant. It shows fly ash is good for long term strength and durability for HPC.

Under the same polysilicate legnth, G/S is reduced with the increase of fly ash content, i.e. under the same polysilicate length, the structure of pure paste is denser than the structue of paste added with fly ash. G/S means space gel packing density, and the higher the G/S

value is, the greater the polysilicate legnth will be. In other words, the addition of fly ash is helpful to have "pozzolanic reaction" which would br directly shown on silicon reaction.

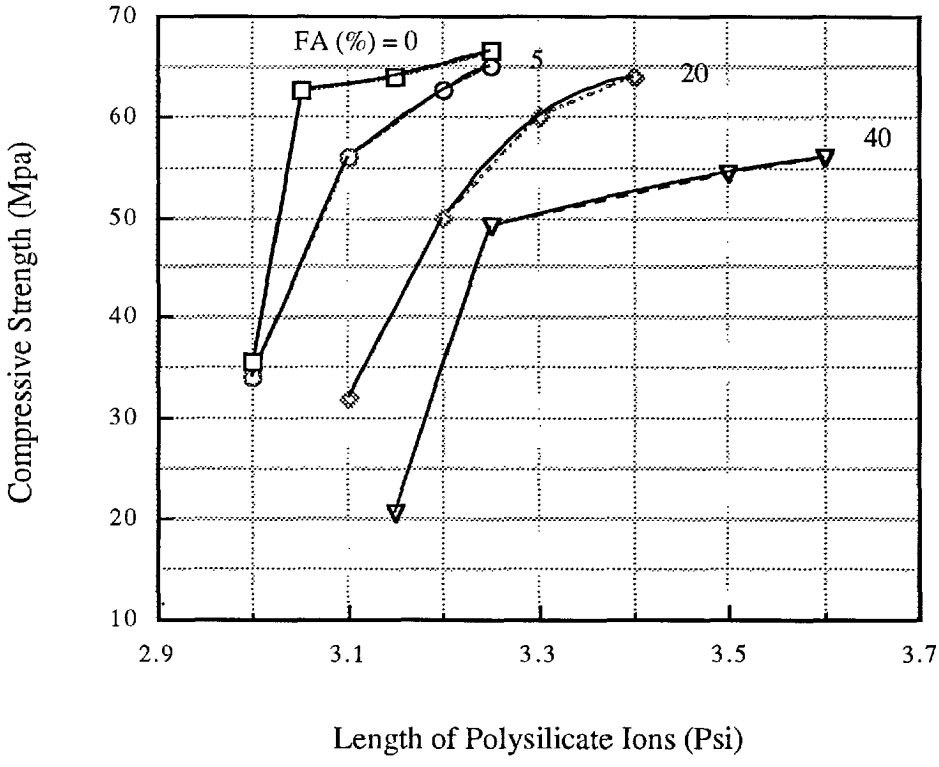

Figure 2 Relationship between the length of polysilicate anions and compressive strength of cement paste

When fly ash content is greater, the curve tends to move toward the right bottom. Silicate anion length of the paste with fly ash is greater than that of pure cement paste, because its stucture is looser, i.e. gel space is smaller as shown in Fig.1, and therefore the strength of paste with fly ash is less than that of pure cement paste. It is thus known the paste strength, except for polysilicate length, should depend on packing density of hydrant growth (i.e. G/S) and it may achieve better strength (γ^2>0.97). Fig. 2 shows the relationship between polysilicate length and strength. From the point of inflection, basically the higher the fly ash content is, the larger the strength in Fig.1 will be, and it is related to system C-S-H gel.

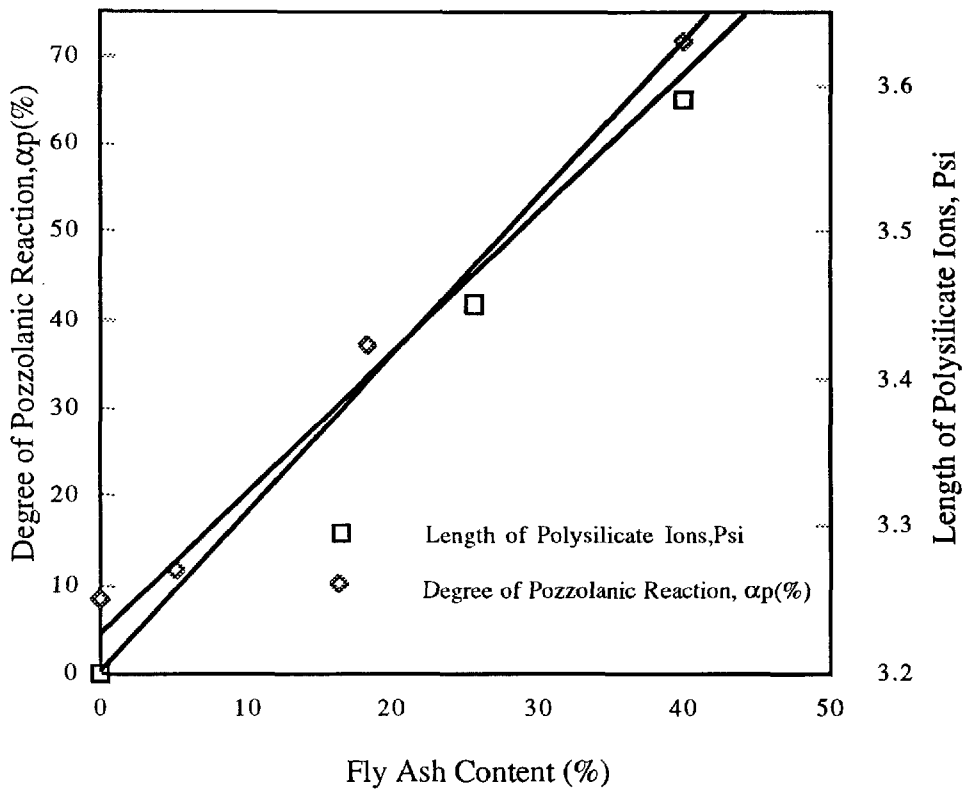

Figure 3 Relationship among the length of polysilicate anions, fly ash content and pozzolanic reaction of cement paste with age of 120 days.

Figure 3 shows the relationship among fly ash content, polyilicate length and pozzolanic reaction of the paste at the age of 120 days. It indicates while the fly ash content increases, the pozzolanic reaction (α_p) increases as well as the polyilicate length (Psi), i.e. pozzolanic reaction and polysilicate length have a right proportion to fly ash content. According to previous experiences, the excess of fly ash content is not good to hydration space density,. because the total volume of hydrated gel is reduced, so the strength will decrease accordingly. However, from physical and chemical viewpoint, proper fly ash content would promote cement strength efficiency to produce HPC (Malhotra, 1994). Figure 4 shows the relationship between pozzolanic reaction and doh of paste. According to ^{29}Si-NMR specter of pure cement paste and paste with 5% of fly ash, there is no fly ash peak, i.e. no pozzolanic reaction, so no corresponding curve appears, but only the relationship of paste with 20% and 40% of fly ash is shown. It also shows pozzolanic reaction has a right proportion to hydration because the hydration is necessary for cement to produce $Ca(OH_2)$ which enables fly ash to produce pozzolanic reaction. Therefore, the doh of paste is necessary for the degree of pozzolanic reaction. Accordig to the above result, it may indicate NMR is a good tool for the analysis of hydration reaction. Further, it implies in the HPC the paste has more

significant influence than the aggregate, but on the analysis it can not be ignored the reaction between the interface of paste and agregate is important for the long-term properties of HPC.

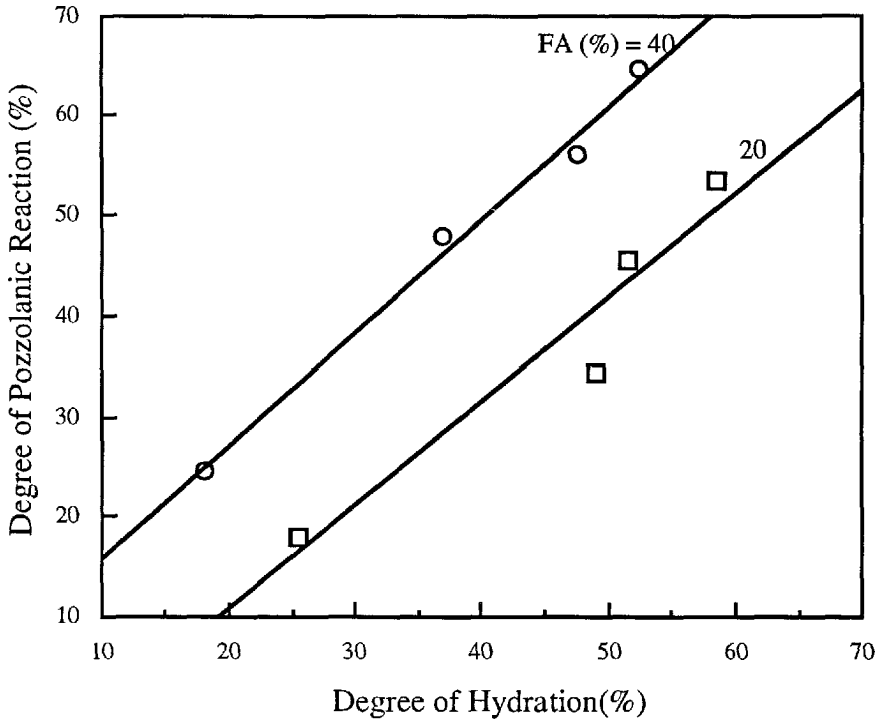

Figure 4 Relationship between the degree of pozzolanic reaction and hydration of cement paste

CONCLUSION

(1) NMR can give semi-quantative data to unhydrated cement content, C-S-H gel, doh polysilicate length and degree of pozzolanic reaction and to establish hydration model of paste in HPC through hydration rate analysis with various parameters.

(2) The doh for the paste is increasing in company with the increase of age and its polysilicate length has a right proportion to the age.

(3) At the same age, polysilicate length of fly ash paste is greater than that of pure cement paste, and pozzolanic reaction is larger, too. Polysilicate anion length has the right proportion to G/S. This gives positive effect to the boundary and may improve long-term strength of HPC with less paste.

ACKNOWLEDGMENT

We, all the authors give our deep thanks to Mr. Y. N. Sheen for assistance in data analysis.

X-ray diffraction (XRD)

QUANTITATIVE X-RAY ANALYSIS OF OPC CLINKER BY RIETVELD REFINEMENT

J. NEUBAUER, Mineralogical Institute, University Erlangen-Nürnberg (Germany)
H. PÖLLMANN, Department of Mineralogy and Geochemistry, University Halle, (Germany)
H.W. MEYER, KHD Humboldt Wedag AG, Cologne (Germany)

ABSTRACT

Samples of Portland cement clinker were taken at various operating conditions from two clinker production lines. Quantitative phase distribution was investigated by XRF (Bogue calculation), by microscopy (point counting) and by XRD (Rietveld analysis). Evaluation and comparison of the results, the Rietveld - and microscopic quantification yield a very high degree of accuracy. Therefore Rietveld calculation can be introduced as a high performance instrument in automatic quality control systems of the clinker- and cement production.

Key-words: Rietveld analysis, quantitative, Bogue calculation, light microscopy

INTRODUCTION

A main challenge in efficient and reliable quality control of Portland Cement production is the development of a practical and quick method to determinate the mineralogical composition of clinker and cement. Until nowadays the most frequently applied method to estimate the mineralogical composition is the procedure according to Bogue (1929). The disadvantage of this method is that the phase composition is calculated on basis of the chemical composition. Even if it is assumed that the chemical composition of the four main phases (alite, belite, tricalcium aluminate and ferrate) is well known, thermal equilibrium for a complete crystallization has to be realized. However in the technical process of cement clinker production thermal equilibrium is practically not existing. Therefore the results of the Bogue calculation do not exactly represent the real mineralogical composition of a clinker or cement.

Microscopical techniques of point or line counting are scientifically well recognized methods to determine alite and belite content. Furthermore information about the microstructure of the clinker can be obtained. Determination of the so called interstitial phases ferrate and tricalcium aluminate is problematic as the crystals of these phases are usually of submicroscopic size. Moreover this technique offers no reliable potential for automatization and is too time-consuming for practical applications in on-line quality control. The development of new computer aided image analysis do not meet the requirements and standards of technical usability yet.

During the last few years since digitalization of the Bragg-Brentano powder diffraction equipment efforts were made to determine phase composition by XRD methods. The most difficult problem for this method of quantification is the wide range of overlapping reflections of the main components, especially alite and belite and preferred orientation of some phases. Figure 1 presents the patterns of calculated mixtures (Rietveld method) with different ratios alite/belite.

For this reason standard XRD phase quantification by single peak measurement can not be applied successfully in the case of alite and belite because the only reflection of belite free from overlapping is of low intensity (31.1° 2θ Cu Kα).

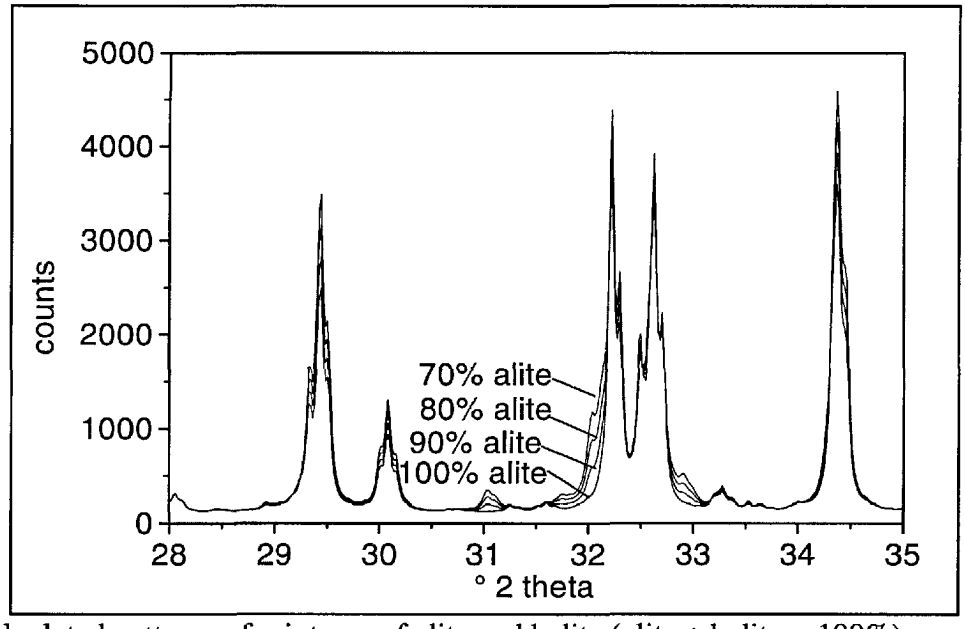

Fig. 1: Calculated patterns of mixtures of alite and belite (alite + belite = 100%)

Advances in electronic data processing enable the application of a method which calculates, compares and refines X-ray patterns from even very complex structure data. This method was initially by Rietveld (1969) for neutron diffraction and has been transcripted to X-ray diffraction a few years later. So-called full profile refinement is able to deal even with phasé mixtures up to 15 compounds. Increasing calculation performance of modern PC's allows quantification of a complex mixture within one minute. This method offers a large potential for automatization in quality control. Applications concerning OPC clinker quantifications are reported by Klaska (1996), Möller (1995), Mumme (1995), Neubauer et al. (1996) and Taylor & Aldridge (1993).
Described investigations in the following article were carried out to evaluate performance and accuracy of Rietveld quantification in comparison to Bogue and microscopic methods. Based on the results development and introduction of a practical application of the method is planned as an integrated part of the quality- and process control system of modern cement plants.

EXPERIMENTAL

Investigations were initiated and coordinated by KHD Humboldt Wedag AG. Three different quantification methods were applied at three independent laboratories to minimize subjective influences by the investigator. Sampling, primary preparation and chemical analysis were carried out by Humboldt Wedag AG in Cologne. Microscopic investigations were done at the Mineralogical Institute at the University Halle. XRD investigations including Rietveld quantifications were performed at the Mineralogical Institute, University of Erlangen-Nuernberg.

Sampling and preparation

Investigations of sample series A and B were carried out on seventeen representative clinker samples taken after the clinker cooler at different operating conditions during a period of one month. 1 kg of each clinker sample was crushed in a laboratory impact crusher to a fineness of < 4mm. The fraction ranging from 2 - 4 mm was received by hand screening of this material. This homogenized and divided material was used for all further analyses. Portions of this ma-

terial were finely ground to meet the requirements of XRF and XRD and wet chemical analysis.

Chemical analysis and Bogue calculation

XRF specimen discs were prepared in a flux by fusing a mixture of finely ground clinker and sodium-tetra-borate. For this reason the volatile compounds, such as chlorine, sulfate and alkalis had to be analyzed separately. Chlorine was directly quantified by coulometric titration. Sulfate was determined as total SO_2 with the aid of an IR-detector installed after an induction furnace. Alkalis (K_2O, Na_2O) were determined by flame photometrical analysis using reference solutions. Determination of free lime content of a clinker was carried out according to the method of Schläpfer & Bukowski (1933)

Based on the results of a chemical analysis the potential phase composition of the clinker was calculated according to the method of Bogue. The total CaO-content of clinker was reduced by the amount of free lime. As the degree of sulfatization of clinker is < 100, no further correction of total CaO was necessary. Following formulas are valid (clinker with an alumina ratio > 0.638):

$$c(C_3A) = 2.650*Al_2O_3 - 1.692*Fe_2O_3$$
$$c(C_4AF) = 3.043*Fe_2O_3$$
$$c(C_3S) = 4.071*CaO - 7.600*SiO_2 - 6.718*Al_2O_3 - 1.430*Fe_2O_3$$
$$c(C_2S) = 8.600*SiO_2 + 5.068*Al_2O_3 + 1{,}079*Fe_2O_3 - 3{,}071\ CaO$$

A standardization of the results of the Bogue calculation to a total of 100 % was carried out, to enable the comparison with Rietveld analysis and microscopical determination.

Microscopic Investigation

Crushed and screened clinker was homogenized. 6 to 8 grains of the particle size fraction 2 - 4 mm were embedded in epoxy resin and polished. The surface of this polished section specimen was treated for 30 seconds with a solution of 1 g salicylic acid in 125 ml destilled water and 125 ml ethyl alcohol.

Depending on etching time the clinker phases appear in different colors according to their different interaction with the acid solution. After 30 seconds alite is colored blue and belite is colored brown. The tricalcium aluminate and the ferrate-phase are not affected within this 30 s and appear colorless. By this etching technique an optical discrimination of alite, belite and the interstitial phase (tricalcium aluminate plus ferrate) is possible. Due to crystal size and the crystallinity a quantitative, microscopical differentiation of the interstitial phase into tricalcium aluminate and ferrate is not possible. Small amounts of periclase and free lime were recorded as subordinate compounds.

Quantitative analysis was performed by point counting with a 100x air lens and a step width of 0.4 * 0.05 mm. 10 000 points were counted of each section specimen. Mass contents of clinker phases were calculated from the resulting vol.% by the average specific weights (alite: 3.20 g/cm³, belite 3.28 g/cm³ interstitial phase 3.60 g/cm³). Subordinate compounds (approx. 1-2% by mass) were disregarded by calculation of alite, belite and interstitial phase. Finally a standardization of the results to a total of 100% was carried out.

Rietveld quantification

Rietveld refinement is based on comparison of an observed X-ray pattern and a pattern calculated from structure data of one or more phases. Calculation is finished successfully when the residual error is minimized by the refinement of global and structural parameters.

Prior to the investigation of clinker samples, the accuracy of the quantification by Rietveld refinement was verified on different synthetic clinker which were mixed from pure synthetic OPC phases. Chemical composition of clinker phases was chosen according to H.F.W. Taylor (1990) and modified to receive synthesis products free from additional phases. Rietveld refinement of synthesis proofed a purity larger than 99%. In table 1 the chemical composition of the main phases is summarized.

Table 1: Chemical composition of the synthetic clinker phases (in wt.%)

Phase	CaO	SiO_2	MgO	Fe_2O_3	Al_2O_3	Na_2O
Alite	72.6	25.6	1.1	0.7	-	-
Belite	64.0	34.2	0.5	0.9	-	0.4
C_3A	62.3	-	-	-	37.7	-
C_4AF	46.2	-	-	32.8	21.0	-

Pure alite, belite, tricalcium aluminate and brownmillerite were ground simultaneously at different ratios, examined by X-ray diffraction and quantified by the PC software of Wiles and Young (1981) modified by Howard. All mixtures were prepared and measured 5 times for calculating the standard deviation. In Table 2 the results are listed.

Table 2: Quantification of different synthetical mixtures with standard deviation.

Physical Mixture	**actual quantity**	**Alite** calculated	**Belite** calculated	**C_3A** calculated	**C_4AF** calculated	**standard deviation**
Alite	65	64.8				0.9
Belite	20		20.8			0.8
C_3A	10			9.6		0.6
C_4AF	5				4.8	0.6
Alite	55	55.3				1.1
Belite	25		25.4			1.2
C_3A	10			9.7		0.6
C_4AF	10				9.6	0.6
Alite	70	69.9				0.7
Belite	15		15.7			0.8
C_3A	5			5.0		0.6
C_4AF	10				9.4	0.9

values in wt.%

Average values of quantification indicate the excellent agreement with the real mineralogical phase composition. Deviations from the real composition is in any case below 1 wt.%. A maximum standard deviation of 1.2 % was found for 5 repeating experiments. Therefore a

single measurement of a technical clinker should deviate not more than 2 wt.% from the actual composition.
In figure 2 a powder diffraction pattern of a mixture of the four synthetic main components, a calculated pattern and an actual cement clinker pattern are plotted. A good agreement of the results was achieved.

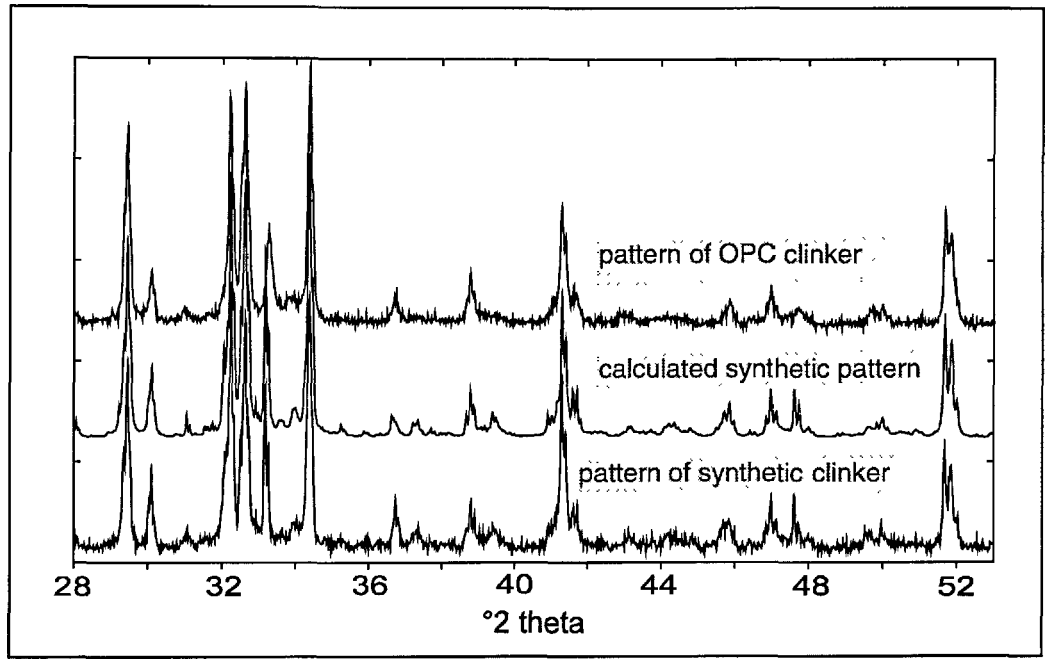

Fig. 2: Comparison of the X-ray pattern of a mixture of the four synthetic main components, the calculated pattern and an actual cement clinker pattern

Based on the above results a Rietveld control file had to be created and tested for its accuracy to quantify technical Portland cement clinker samples.
The crushed and screened Portland cement clinkers were ground for another 2 minutes in a disc mill. Samples were prepared in a front loading sample holder. All measurements were carried out with a Siemens D5000 X-ray diffractometer using Diffrac-AT software with the following adjustments:

Generator: 50 mA, 40 kV
Tube: fine focus
X ray: Cu Kα
Slits: fixed 0,5°, 0,5°
Detector slit: 0,1°
Detector: scintillation
Step/Time: 0.02° 2θ / 2s
Range: 10° - 55° 2θ

The following structure data were used after modification:

alite: Nishi & Takeuchi (1985)
belite: Jost et al. (1977)
C_3A: Mondal & Jeffrey (1975)
C_4AF: Colville & Geller (1971)

Rietveld refinement was carried out on a PC with a P200 processor using software of Wiles and Young (1981) modified by Howard. The control file for refinement was standardized and adapted for each clinker sample series - this allows refinement by a "press button" method. Calculation time for each quantification was approximately one minute. Besides the four main clinker phases periclase and free lime were evaluated. Again a standardization of the results to a total of 100% was calculated for comparison purposes.

RESULTS

A first series of 12 clinker samples (series A), taken under various operation conditions from a clinker production line was analyzed and evaluated to determine the accuracy and performance of Rietveld full pattern refinement. The variation of the phase composition of clinker samples, which is influenced by the operating conditions of the kiln line is evaluated and a comparison of the three described quantification methods is given. A second set of data from clinkers of another cement plant was sampled while firing different fuels and wastes (series B). No microscopical analysis could be carried out on sample series B.

1. Operating conditions

In table 3 general information on the quality of clinker samples and some essential operation parameters concerning the sampling periods are summarized.

Table 3: Required clinker quality and operation conditions of the kiln.

sample	clinker quality	typical operating conditions of the kiln
A1	Cem I class 52.5	normal operation, T (sintering zone) 1284°C
A2	Cem I class 32.5 and 42.5	Kiln starting period, T (sz) 1116°C
A3	Cem I class 32.5 and 42.5	4.5 h after operation start, T (sz) 1100°C
A4	Cem I class 32.5 and 42.5	normal operation, T (sz) 1299°C
A5	Cem I class 32.5 and 42.5	normal operation, T (sz) 1218°C
A6	Cem I class 32.5 and 42.5	conversion from HS to normal clinker T (sz) 1131°C
A7	Cem I class 32.5 and 42.5	start of kiln operation, T (sz) 1100°C
A8	Cem I class 32.5 and 42.5	normal operation T (sz) 1188°C
A9	Cem I class 32.5 and 42.5	normal operation T (sz) 1232°C
A10	Cem I class 32.5 and 42.5	operation not at optimum, T (sz) 1100°C
A11	Cem I class 32.5 and 42.5	normal operation T (sz) 1143°C
A12	Cem I class 32.5 and 42.5	normal operation T (sz) 1162°C

sample	typical operating conditions of the kiln
B1	1,9% O_2, 1400°C, fuels(in t/h): 2,6 waste oil, 5,7 coal, 0,5 photo sewage
B2	2,5% O_2, 1430°C, fuels(in t/h): 4,6 waste oil, 3,1 coal, 0,33 photo sewage
B3	3,8% O_2, 1400°C, fuels(in t/h): 2,7 waste oil, 5,8 coal, 0,5 photo sewage
B4	3,9% O_2, fuels(in t/h): 9,2 coal, 0,4 photo sewage
B5	2,6% O_2, 1300°C, fuels(in t/h): 6,4 waste oil, 0,5 photo sewage

O_2 partial pressure measured at kiln exit. Due to the measurement techniques the sintering zone temperature has to be considered as relative.

2. Comparison of quantification data

An overview and comparison of the results achieved by Bogue calculation, microscopical determination and Rietveld quantification is plotted in Figures 3-8.

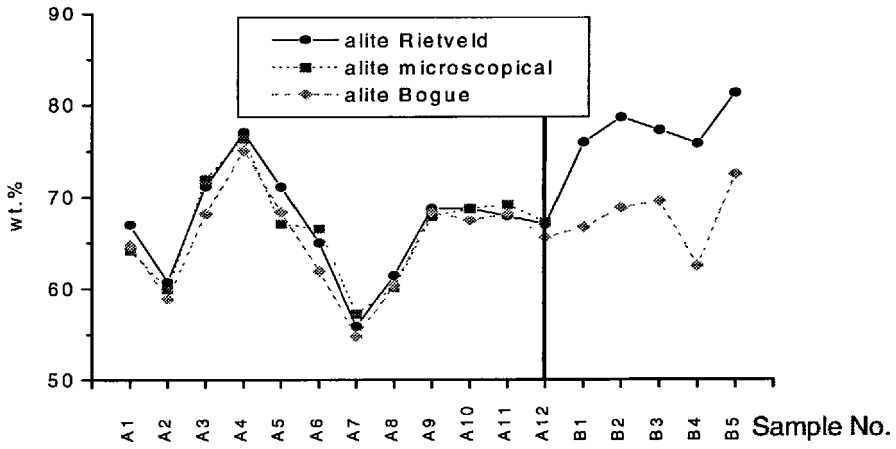

Figure 3: Alite content in samples

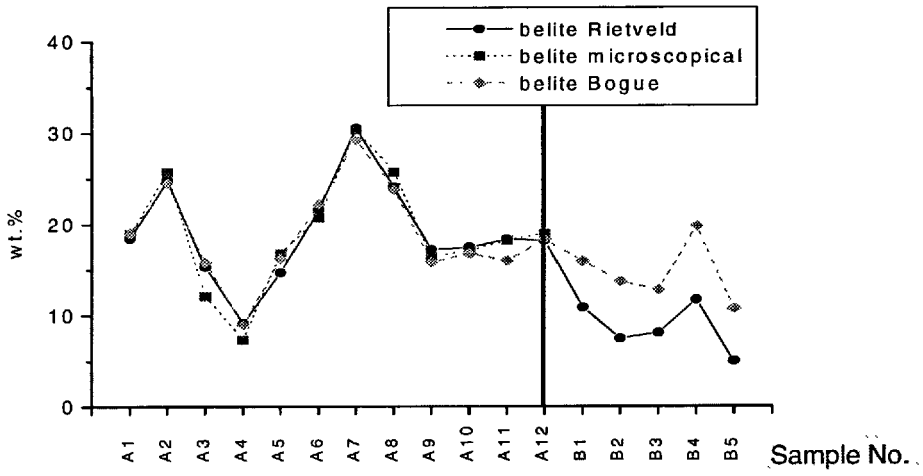

Figure 4: Belite content in samples

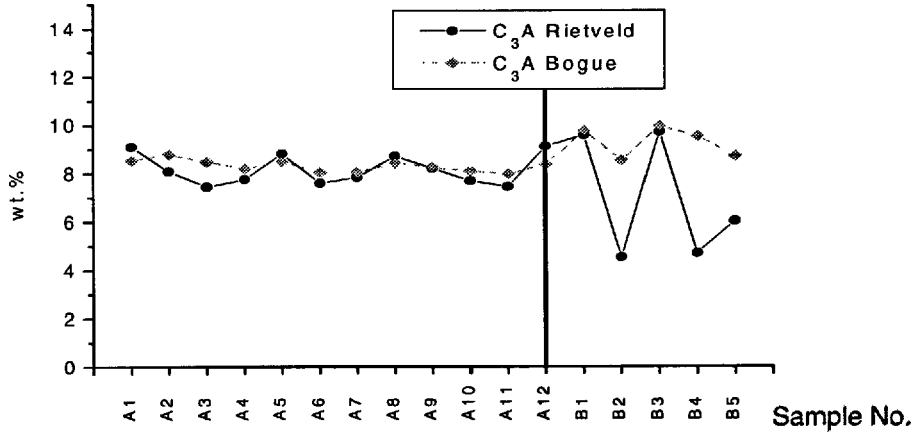

Figure 5: C_3A content in samples

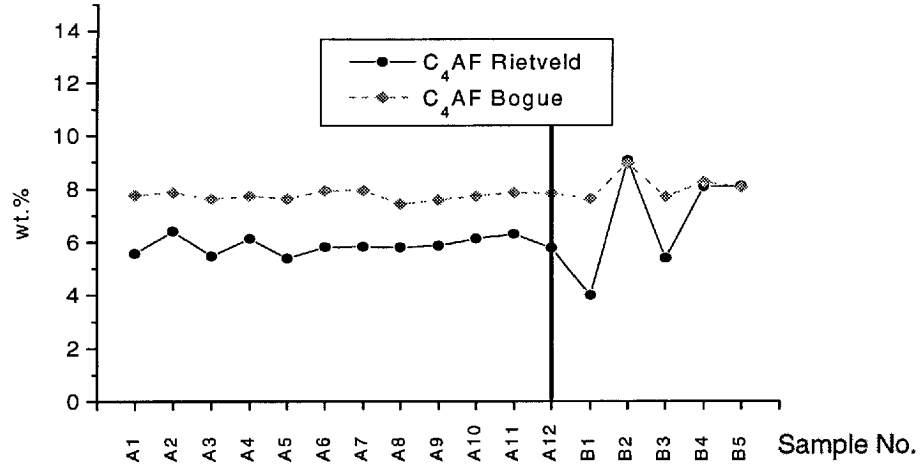

Figure 6: C_4AF content in samples

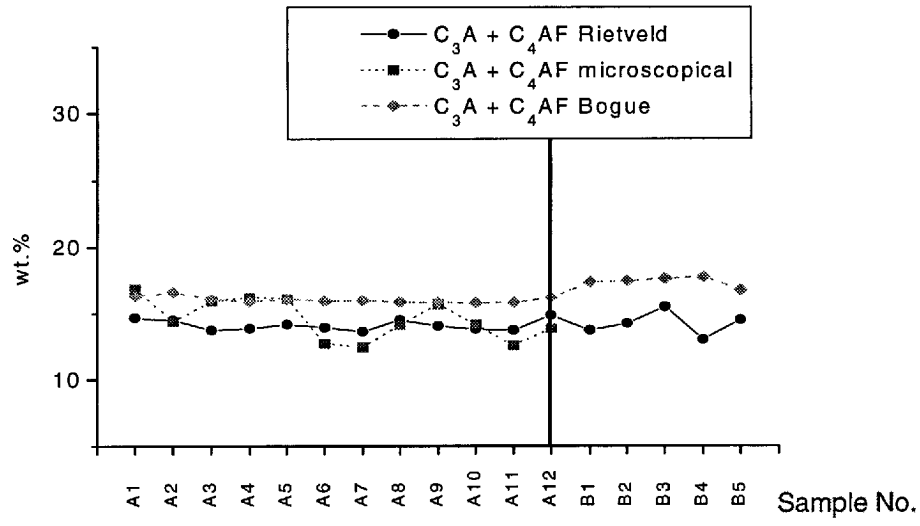

Figure 7: $C_3A + C_4AF$ content in samples

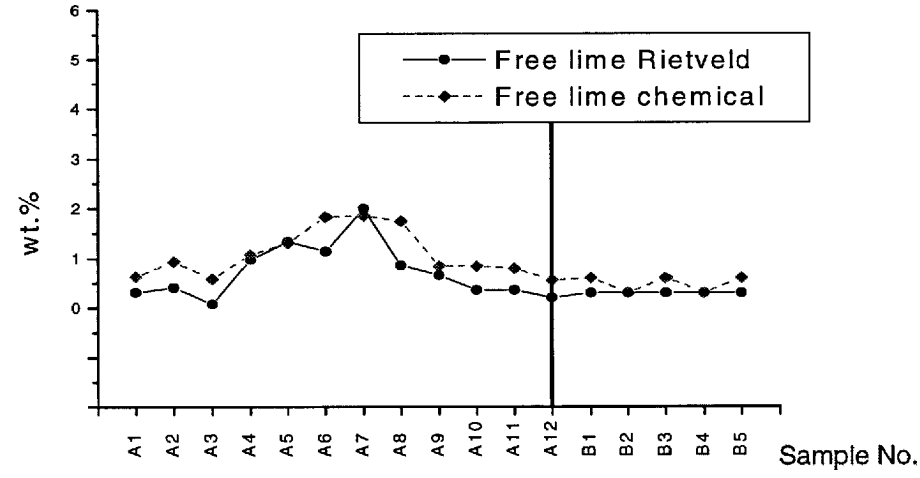

Figure 8: Free lime content in samples

Detailed results of the quantification are given in the appendix.

2.1 Sample series A

A comparison of sample series A indicate a good agreement of quantification results for alite and belite determined by Bogue calculation, microscopic examination and Rietveld analysis respectively (Figures 3 and 4). Concentration of C_3A are in well agreement comparing Bogue calculation and Rietveld analysis (Figure 5). In contrast, a significant difference in the quantity of brownmillerite determined by Bogue calculation and Rietveld analysis (Figure 6) was found. This difference is attributed to the incorrect assumption of the Bogue calculation the chemical composition of brownmillerite is C_4AF. As a consequence total iron content of clinker are calculated as brownmillerite of this composition. For this reason solid solution series of alite, belite and C_3A towards iron containing crystals are not taken into account by the Bogue calculation. According to detailed investigations by Rietveld refinement, the actual chemical composition of brownmillerite is $C_4(A,F,M,S,T)$. Furthermore, dependent on concentration and availability of iron, a variation in the chemistry and the amount of brownmillerite occur. Comparison of the quantification of the interstitial phase (C_3A + C_4AF) indicates a significant difference between the results of Bogue calculation and Rietveld analysis (Figure 7). This is again a consequence of the fixation of iron and aluminum in alite and belite structures. Therefore higher amounts of silicate phases were detected at the expense of interstitial phase by the Rietveld method. Due to the distribution of interstitial phase even in small pores, results obtained by microscopic examination of the quantity of interstitial phase have to be judged as intermediate in relation to Rietveld quantification and the Bogue calculation. In case of the interstitial phase the accuracy of a microscopic quantification is limited. Furthermore, the quantity of the additional clinker components, like free lime and periclase are simultaneously determined by the Rietveld method. In figure 8 the results of free lime concentration of clinker samples indicated by the Rietveld quantification and a wet chemical analysis are compared. A satisfying correlation of the results of both methods with regards to the low concentrations of free lime was achieved.

2.2. Data Set B

For sample series B only a comparison of the results obtained with Bogue calculation and Rietveld quantification was carried out. With respect to sample series A correspondence of both methods is poorer. Concerning alite and belite a similar trend as in sample of series A was found. In contrast absolute values differ up to 10 %. In case of C_3A and brownmillerite relative quantification differs up to 50 %. Therefore a selective solution of clinker material in K(OH) and salicylic acid followed by chemical analysis and Rietveld refinement of the residue was carried out. It was found out, that the results of the Rietveld quantification are accurate (Sieber, 1996 in print). Sintering of clinker under varying oxygen fugacities in the kiln atmosphere and variation of burning conditions caused by different fuels (waste oil, photo sewage, coal) result in differences in the chemical composition and crystallographical properties of clinker. In such cases Bogue calculation fails because of its inflexibility to adjust the variability of chemical compositions of clinker minerals.

DISCUSSION

As demonstrated by this investigation the Rietveld quantification method is an efficient tool in clinker - and cement characterization. Once a refinement strategy (the control file) is adjusted to a cement and/or clinker routine measurements are carried out by the „press button“ method.

During the adjustment work an accuracy test done by comparison of the clinker with the physically mixed synthetic clinker guarantees excellent quantification results.
In further study reduction of counting time by using a variable slit configuration for the X-ray equipment was reached. Detection of pattern and Rietveld calculation can be done within 15 minutes. Hence Rietveld quantification method could be introduced in on-line process control management.
An application of Rietveld quantification method to quality control of cements containing sulfates (gypsum, bassanite, anhydrite) and/or other additives (e.g. calcite, quartz etc.), as well as the process control of the cement mill is feasible. Generally the minimum concentration determinable is dependent on phase configuration. Usually the compounds can be detected down to a range of approximately 0,3 wt.% without any deterioration of the accuracy.
The Rietveld quantification method offers a plenty of advantages:

- very high potential for automatization
- fast method (analyzation and calculation within 6 minutes)
- determination of a huge number of phases in one step:

alite	anhydrite
belite	bassanite
aluminate	gypsum
brownmillerite	calcite
lime	quartz
periclase	

- high accuracy
- easy documentation
- simple handling
- low investment

ACKNOWLEDGMENTS
The authors wish to thank Walter Mayerhofer for carrying out the XRD investigations very accurately. Mr. Hubert Motzet was responsible for microscopic investigations. The very time consuming point counting was done by Uwe König.

APPLICATION OF X-RAY DIFFRACTOMETRY IN COMMINUTION OF GYPSUM

G.GOSWAMI, B.N.MOHAPATRA, P.K.PANIGRAHY AND J.D.PANDA
Dalmia Institute of Scientific and Industrial Research, Rajgangpur-770017, India.

ABSTRACT The paper demonstrates that during comminution of cement, the degree of crystallinity of gypsum as determined by X-ray diffraction (XRD) decreases with increase of grinding time and in the process increases the setting times of the cement. From a large number of experimental tests, it has been established that XRD can be applied to control gypsum grinding to achieve desirable setting times of cement.

Key - word : Gypsum, X-ray Diffraction Analysis, Setting, Fineness.

INTRODUCTION

Recent studies have shown that comminution of gypsum plays an important role in determining the cement properties, particularly setting times. Bensted (1982) and Goswami et.al (1990) studied the effect of comminution on early hydration of Portland cement. Soroka et.al (1986) determined the effect of gypsum contents and fineness on mechanical properties of cement. Theisen (1983) examined the relationship between gypsum hydration and strength development of cement. Although variations on the effects of gypsum comminution on cement properties are generally regarded to be due to the morphological changes in the calcium sulphate, Kanare et.al (1984) and Menetrier et.al (1980) failed to find discrete particles of any form of calcium sulphate in commercial cement and in an integrated mixture of gypsum and C3S respectively. This suggests the possibility of loss of crystallinity of calcium sulphate phase during comminution. Keeping this in view, the present study examines the loss of crystallinity of gypsum during comminution by X-ray diffractometry (XRD) and consequently the application of XRD in controlling the comminution process in order to achieve desirable setting times of cement.

MATERIALS EXAMINED AND EXPERIMENTAL PROCEDURES

An industrial Portland cement clinker containing - 64.2% CaO, 21.4% SiO2, 5.8% Al2O3, 3.5% Fe2O3, 3.8 % MgO, 0.92% K2O and 0.08% Na2O and a by-product gypsum with 39.5% SO3, 0.85% P2O5 and 0.25% F^- were taken for the study. For preparation of blended Portland slag cement (PSC) an Indian Blast Furnace Slag having 32.0% SiO2, 26.1% Al2O3, 0.5% Fe2O3, 30.0% CaO, 7.5% MgO, 1.1% TiO2, 0.61% Na2O and 0.46% K2O was used. For preparation of normal cement a mix containing 95% clinker and 5% gypsum was ground in a laboratory ball mill. Slag content in the examined PSC was kept at 30% level. For the controlled experimental cements, gypsum was ground for different times, either with the clinker or separately. In case of separate grinding, ground clinker and gypsum were later mixed in a ball mill.

Normal cement properties including setting times and compressive strength were determined according to the Indian Standard 4031 - 1988. X-ray Diffraction (XRD)

patterns of the samples were obtained using Ni-filtered Cu-Kα radiation at 40 kV, 20 mA. Crystallinity of gypsum was determined by recording XRD pulse counts for gypsum at 2θ 11.7 (dA$\circ$=7.56) after background correction.

RESULTS

Fig.1 shows the XRD peaks for gypsum in ordinary Portland cement ground for different times. Gypsum XRD pulse counts with the properties of the corresponding cement sample are recorded in Table-1. It is found that with increase of grinding time, XRD pulse counts decrease and along with that setting times increase. It is also found that with decrease of grinding time and hence increase of gypsum XRD intensity, cement sample shows in general,a marginal increasein strength. In a similar experiment with PSC, it was found that in almost identical fineness, while cement with gypsum XRD counts 300 recorded initial and final setting times 415 and 455 minutes respectively, that with XRD counts 1550 recorded initial and final setting times 145 and 240 minutes respectively, strengths remaining almost similar.

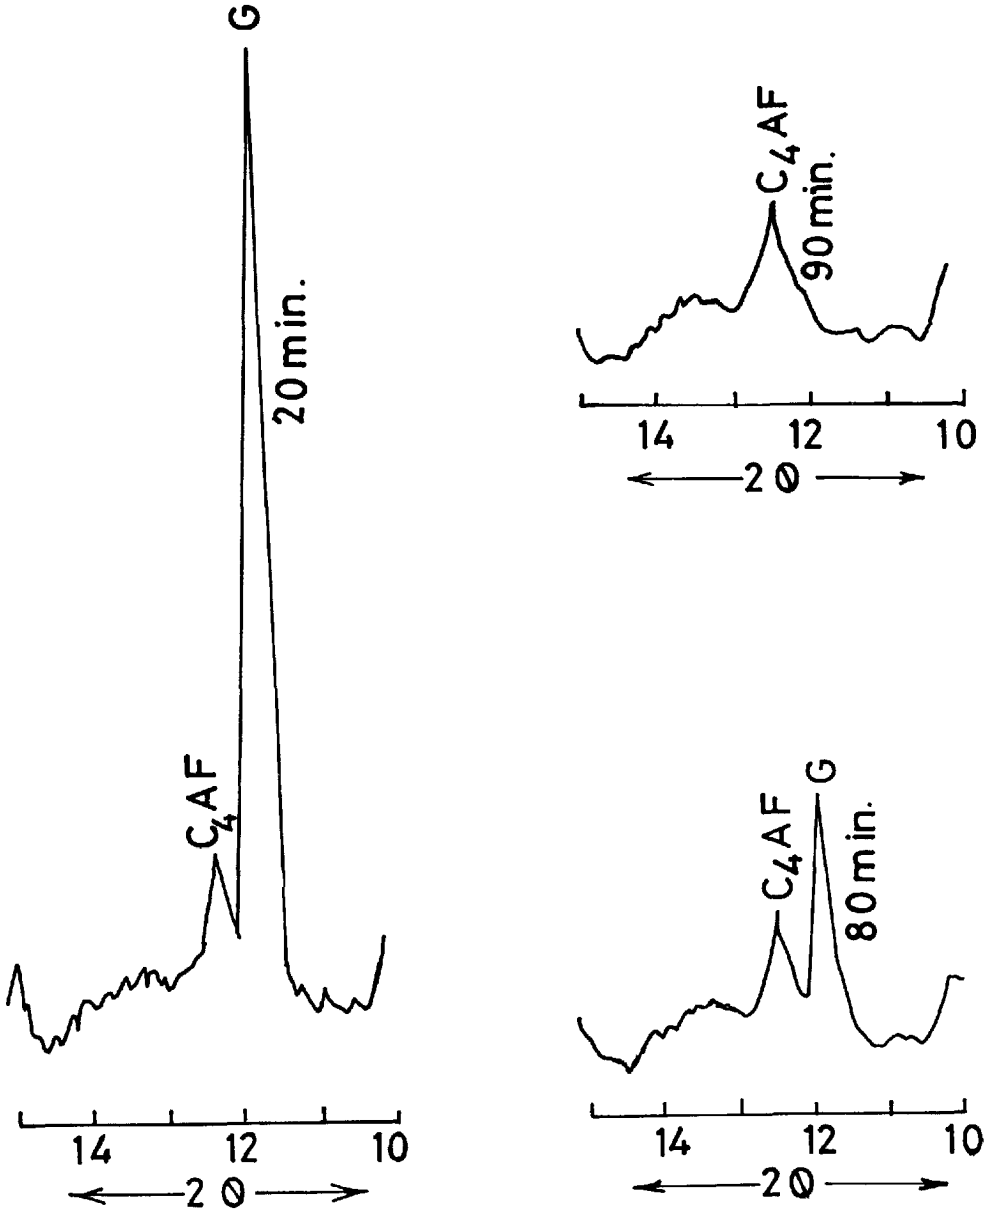

Figure 1 XRD peak intensities (Cu-Kα) of gypsum (G) ground for 20, 80 and 90 minutes in identical cement fineness

DISCUSSION

Table 1 shows that with increase of grinding time, XRD pulse counts or crystallinity of gypsum decreases. In a similar study on amorphism, Anderson (1975) has shown that on grinding silica material an amorphous layer forms around the original crystal. It is conceivable that with the increase of fineness relative volume of amorphous layer increases, although the thickness of the layer remains same. For example, Anderson (1975) calculated that with a constant 0.03 micron thickness of amorphous layer, volumes of amorphous material would be 1.8 and 93% of 10.0 and 0.1 micron spheres respectively. This explains the decrease of XRD pulse counts of gypsum with increase of cement grinding time.

Table 1 XRD pulse counts for Gypsum at $2\theta=11.7$ (Cu-Kα) and corresponding cement properties

GYPSUM				
Grinding time in minutes	20	30	40	90
XRD pulse counts	1060	880	620	NIL
CEMENT				
Sp.Su. Blaine (cm^2/g)	2932	2925	3000	2988
Setting times (minutes)				
Initial	175 (38)	270 (59)	325 (71)	456 (100)
Final	263 (51)	334 (65)	400 (78)	516 (100)
Compressive strength (kg/cm^2)				
3-Days	307 (113)	290 (107)	280 (103)	272 (100)
7-Days	350 (99)	325 (92)	347 (99)	352 (100)
28-Days	505 (116)	438 (100)	457 (104)	437 (100)

(Figures in parentheses, are in percentage of setting times and compressive strengths of cement with gypsum ground for 90 minutes).

In normal cement grinding, gypsum being much softer (Mohs Hardness - 2) than clinker gets ground to much finer state than the latter. That in identical grinding condition gypsum becomes finer and loses its crystallinity more rapidly than the clinker phases is evident from the fact that after grinding for 90 minutes of the cement samples examined, while crystallinity of gypsum got lost completely, producing no XRD pulse, the cement clinker phases including C4AF showed distinct XRD peaks (Fig.1). Effect of grinding on amorphisation of gypsum was also reported by Juhasz and Opoczky (1990). It might be that because of this fineness and amorphism, it is often difficult to find discrete particles of any form of calcium sulphate in commercial cement (Kanare et. al. 1984, and Menetrier et. al 1980). It is conceivable that with increase of and consequently formation of ettringite increases, leading to retardation of setting times. Accordingly amorphism, the reactivity of calcium sulphate with the cement phases gets intensified and consequently formation of ettringite increases, leading to retardation of setting times. Accordingly whenever it becomes necessary to reduce the setting times, as in the case of the use of by-product gypsum known to extend the setting times, it is desirable to retain some portion of the gypsum in crystalline state.

During the present study a large number of tests were conducted for different cement composition having identical fineness but made with gypsum ground to different fineness adopting both the process of intergrinding of clinker and gypsum and separate grinding followed by intermixing of the two components. In all cases it was found that setting times decreased with increase of XRD intensity of gypsum, without much change in other properties of cement. Thus it is found that XRD intensity of gypsum can be used successfully to control the comminution of gypsum in order to achieve desired setting times of the corresponding cement.

AN APPROACH TO REFINE THE BOGUE'S PHASE COMPOSITION OF SULPHO-ALUMINATE BELITE CEMENT

Július STRIGÁČ*, Department of Ceramics, Glass and Cement, Faculty of Chemical Technology, Slovak Technical University, 812 37 Bratislava, Slovak Republic
Jozef KRIŠTÍN, Central Laboratory of Electron-Optical Methods, Faculty of Natural Sciences, Comenius University, 842 12 Bratislava, Slovak Republic

Martin T. PALOU*, Ján MAJLING*

ABSTRACT Pt-encapsulated sulphoaluminate-belite (SAB) cement samples were heated up to 1450°C, slowly cooled and partially equilibriated at 1200°C. Chemical composition of coexisting solid solutions was measured on polished sample surfaces by the electron probe microanalysis. Bogue phase composition of two test SAB cements prepared at usual conditions (1200°C, 1 hr) calculated for the nominal chemical composition of phases is in better agreement to their experimental phase composition than Bogue phase composition calculated for the chemical composition of phases determined in this work (taken as solid solutions). Non-equilibrium nature of the prepared SAB cements is a reason for this discrepancy.

Key-words: Sulphoaluminate, Belite, Solid solutions, Bogue calculation.

INTRODUCTION

The phase composition of ordinary portland clinkers is usually calculated according to Bogue's method, which is a flexible (Taylor, 1989) and a practical procedure satisfying the need for a simple and sufficiently reliable estimation of the clinker phase composition. In principle, such calculation can be extended to any mineralogical or ceramic system, if the identity of phases present in the system is known beforehand. In a more general sense it can also be applied in cases in which the relevant phase assemblages are established in the course of computation (Majling et al, 1989).

At usual conditions five crystalline phases would create a simple phase assemblage in a case of sulphoaluminate belite (SAB) cement belonging to the five component oxide system CaO-SiO_2-Al_2O_3-Fe_2O_3-SO_3. The most thoroughly studied SAB cements are those based on the mineral phase assemblage composed of C_2S, $C_4A_3\bar{S}$, C_4AF, $C\bar{S}$ and C. Recent computations of the phase composition of SAB cements are based on clinker phases taken as stoichiometric minerals (Metha, 1977 and Majling et al, 1993), because of the lack of underlying data. The results of Muzhen et al (1992) and Andac and Glasser (1995) are filling this gap partially. They refer however to complex solid solutions including K_2O, Na_2O, MgO, TiO_2 oxides and are applicable to clinkers prepared from the corresponding raw materials.

The aim of the present work is to establish the chemical composition of coexisting solid solutions inside the specified phase assemblage and to use it for the Bogue calculation of clinker phase composition of clinkers prepared inside the mentioned five component oxide system from pure chemicals.

EXPERIMENTAL

Initially two clinkers having the nominal phase composition: SAB 1; 20% C_2S, 20% $C_4A_3\bar{S}$, 40% C_4AF, 20% $C\bar{S}$, and SAB 2; 30% C_2S, 20% $C_4A_3\bar{S}$, 30% C_4AF, 20% $C\bar{S}$ were selected for experimentation. The phase composition was converted to the corresponding oxide contents. For the preparation of clinker samples analytical reagent grade $CaCO_3$, Al_2O_3, Fe_2O_3,

$CaSO_4.2H_2O$ and silica gel were used in the appropriate weight ratios. The mixtures were homogenised in an agate mortar and calcined in an electric furnace at 1000°C for 1 hr. The calcined products were again homogenised, pelleted into short cylinders and heated again to 1000°C for 0.5 hr. The obtained pellets were encapsulated into Pt-tubes (ϕ = 5.25 mm) by welding the ends of tubes.
The encapsulated samples were heated up to 1450°C and hold at this temperature for 15 minutes. They were then continuously cooled to 1200°C at a cooling rate of approx. 0.6°C/min (the sample SAB 2 with a soak at 1200°C for 4 hrs).
The phase composition of the products was examined by XRD by a Philips powder diffractometer using CuKα radiation. The chemical composition of solid solutions was determined by electron probe microanalysis (EPMA) JSM 840. For the EPMA study the samples were impregnated with epoxy resin, polished and coated with carbon. SEM imaging was carried out by backscattered electrons.

In the second part of the study two clinkers were prepared from chemicals by their heating at 1200°C in a bed of $C_4A_3\bar{S}$, for 1 and 3 hrs. Their mineralogical composition was checked by XRD.

RESULTS AND DISCUSSION

Establishment of the chemical composition of coexisting solid solutions

The objective of sealing the samples in platinum tubes was to prevent the loss of sulphates at high temperatures. Slow cooling of samples from 1450°C was applied to ensure the melt assisted growth of crystals which was expected to result in their increased size and the fairly developed morphology suitable for the EPMA.
XRD analysis of samples SAB 1 and SAB 2 showed the presence of small amount of free lime besides the expected phases β-C_2S, $C_4A_3\bar{S}$, C_4AF and $C\bar{S}$ respectively.
Microstructural examination of phase distribution of the clinker SAB 1 is shown in Figs 1 and 2 and of SAB 2 is shown in Fig 3.

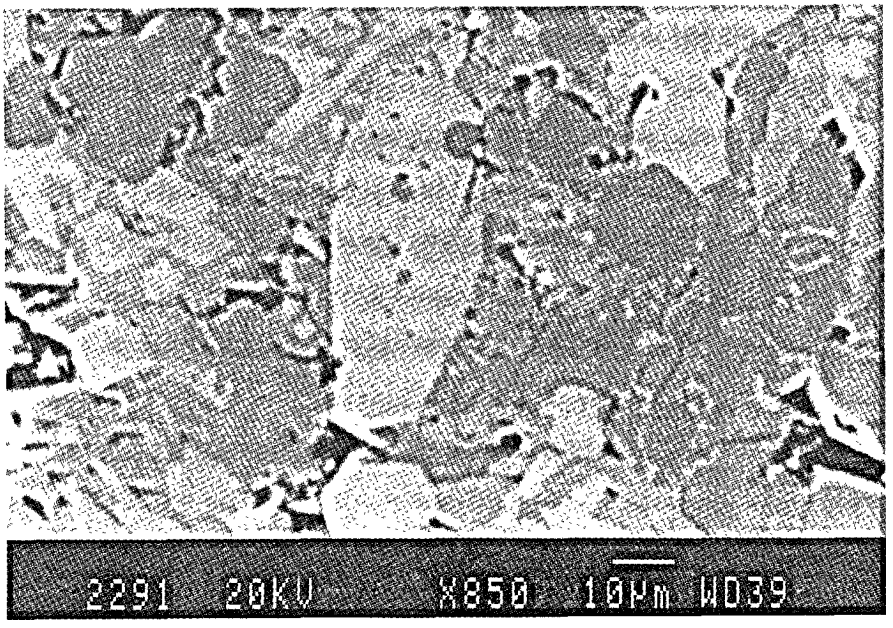

Figure 1 The backscattered SEM micrograph of clinker polished section of sample SAB 1.

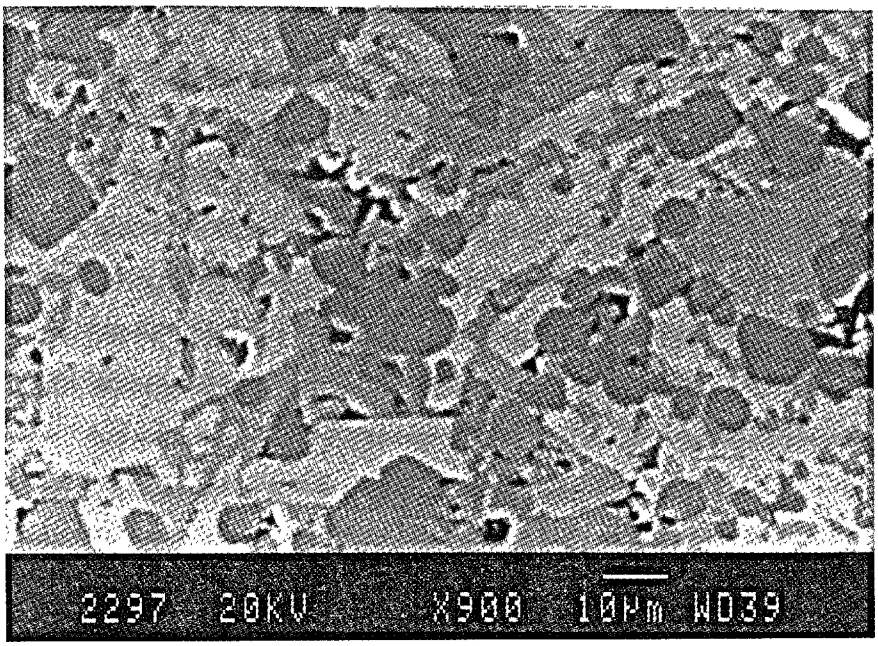

Figure 2 The backscattered SEM micrograph of clinker polished section of sample SAB 1.

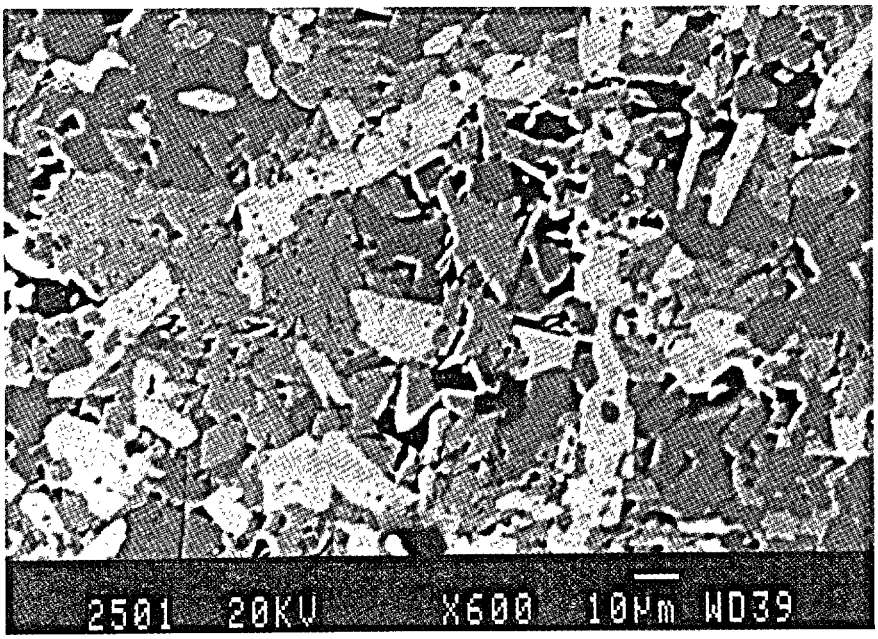

Figure 3 The backscattered SEM micrograph of clinker polished section of sample SAB 2.

The C_2S, $C_4A_3\bar{S}$, C_4AF and $C\bar{S}$ phases in SEM micrographs are well identified. The phase $C_4A_3\bar{S}$ is found in angular hexagonal dark grey crystals surrounded mainly by C_2S and C_4AF. The ferrite phase appears as large bright crystals with clean margins. The C_2S forms grey regions with a clear margins too. The $C\bar{S}$ appears as a dark grey regions with not quite well developed morphology, fuzzy margins and the crystals exhibit parallel cracks.

The chemical composition of clinker minerals from microprobe analysis is summarised in Table 1 and Table 2.

The ferrite phase C_4AF contains an increased amount of Fe_2O_3 which brings it essentially close to the C_6AF_2 stoichiometry. It also contains small quantity of SO_3 and SiO_2. The calcium sulphoaluminate phase $C_4A_3\bar{S}$ contains very small amount of SiO_2 and Fe_2O_3 substituting Al_2O_3 to about 2 wt % in both the cases. The dicalcium silicate, β-C_2S has a little increased ratio

of CaO/SiO_2 needed to compensate SO_3, Al_2O_3, and Fe_2O_3 admixtures. The anhydrite $C\bar{S}$ contains very small quantities of SiO_2, Al_2O_3 and Fe_2O_3. Comparison of the chemical composition of solid solutions determined with a data given for corresponding phases in literature will be published elsewhere (Strigáč et al, unpublished results).
Besides these main phases there were two another phases found in SAB 1 and SAB 2, containing simultaneously CaO, SiO_2 and SO_3 as major oxides. Moreover, an additional phase in SAB 2 was observed containing increased contents of Al_2O_3 and Fe_2O_3. The referred phase from SAB 1 has ratio CaO/SO_3 equal to 1.9. This ratio indicates $C\bar{S}$ phase and increased ratio is required to compensate for Al_2O_3, Fe_2O_3, SiO_2 admixtures. The phase from SAB 2 has CaO/SiO_2 ratio equal to 2.6. The ratio indicates C_2S phase modified with about 10 % admixtures Al_2O_3, Fe_2O_3 and SO_3. This phase is not considered to be related to $C_5S_2\bar{S}$ phase because of the too low content of SO_3. The chemical composition of these two phases needs to be confirmed in a next study. These results are therefore not taken into further account.

A comparison of the calculated and the experimental phase composition of model SAB clinkers

Two clinkers were prepared for the given purpose. Their chemical composition can be found in Table 4.

Table 4 Chemical composition of experimental clinkers prepared at 1200°C for 1 hr.

wt %	CaO	SiO_2	Al_2O_3	Fe_2O_3	SO_3
SC	60.32	23.63	10.74	2.28	3.03
SD	57.78	19.43	8.31	12.64	1.83

The XRD patterns of clinkers prepared at 1200°C, 1 hr, are given in Figs 4 and 5.

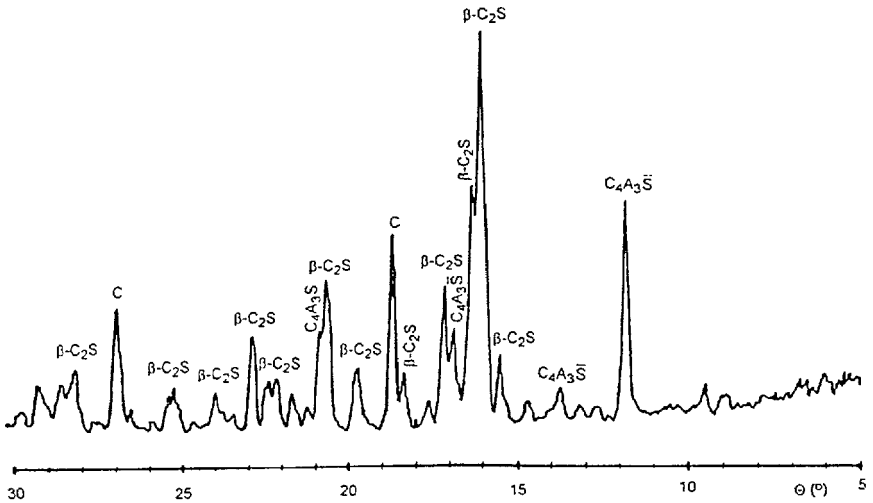

Figure 4 XRD pattern of the clinker SC prepared at 1200°C for 1 hr.

Bogue phase composition of these clinkers calculated for stoichiometric phases is given in Table 5 and the phase composition calculated for the phases taken as solid solution (referenced in Table 1) is given in Table 6. It is seen now that the chemical composition of clinkers (Table 4) was not taken arbitrarily but it was deduced from the presumed singular (three phases, C_2S, $C_4A_3\bar{S}$ and C_4AF) composition, at which the composition of phases was expected to comply the data given in Table 1.

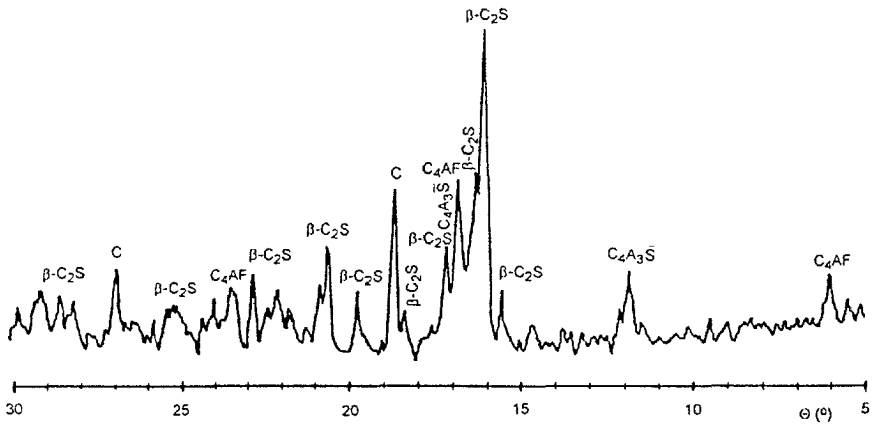

Figure 5 XRD pattern of the clinker SD prepared at 1200°C for 1 hr.

Table 6 The phase composition of experimental clinker calculated for clinker phases taken as solid solutions.

wt %	C_2S_{ss}	$C_4A_3\bar{S}_{ss}$	C_4AF_{ss}	$C\bar{S}_{ss}$	C
SC	80.4	16.8	2.6	0.0	0.0
SD	65.0	4.2	30.5	0.0	0.0

The present comparison of results relies only on the visual inspection of powder patterns and comparison of their diffraction intensities and number of phases identified with the forecasted (calculated) phase quantities given in Tables 5 and 6. It is seen by this comparison that the powder patterns in Figs 4 and 5 show the presence of free calcia, a phase which should not be present, if solid solutions were formed in an extent corresponding to those present in the encapsulated sample slowly cooled from the high temperature. On a qualitative scale there is therefore a better agreement between the X-ray phase composition and calculated phase composition for stoichiometric clinker minerals than a phase composition calculated for solid solutions. By prolonged heating of cement samples the free calcia decreases. We may conclude therefore that the phase composition of solid state sintered cement samples (no mineralising effect of impurities or alkalis) is away from the equilibrium phase composition, after 1 and 3 hrs burning of the clinker at 1200°C and in this case the phase computation may be preferred which relies on the stoichiometric composition of phases.

The chemical composition of solid solutions determined in this work may be used to predict the phase composition of clinkers in order to get the idea about the limit the phase composition would approach at the not quite common burning conditions. On the other hand the stoichiometric composition of phases gives quite satisfactory estimation of phases present at usually burning regimes.

CONCLUSIONS

Chemical composition of coexisting solid solutions was determined inside the phase assemblage C_2S, $C_4A_3\bar{S}$, C_4AF, $C\bar{S}$ and C. The stoichiometry of ferrite phase established for slowly cooled samples from 1450°C strongly differs from its usually accepted stoichimetric composition (C_4AF). Its stoichiometry can be more adequately represented by the composition corresponding to C_6AF_2. In a course of equilibration of the clinker system the change in the Fe/Al ratio of the ferrite phase is the one of the dominant changes.

The model clinkers synthesised at usual burning conditions (1200°C, 1 and 3 hrs) are not equilibrium products and their phase composition is in better agreement to Bogue composition calculated for stoichiometric clinker phases than the phase composition calculated for phases taken as solid solutions.

QUALITATIVE IDENTIFICATION OF CLINKERS AND CEMENTS — SOME RESULTS AND POSSIBILITIES

Ferenc TAMÁS*, Márta PÁTKAI-HORVÁTH*, Éva KRISTÓF-MAKÓ*

ABSTRACT The qualitative identification of clinkers and cements is based on the fact that trace elements contained in them, and their proportion, retain the characteristic "chemical fingerprint" of the raw materials. The selection of trace elements requires care: best "fingerprint" elements are Mg, Mn, Sr, Ba, Ti and Zr. Clinkers and cements manufactured in Hungarian and Austrian cement factories had been analysed for the above elements (by ICP-ES). Results are interpreted statistically, by „pattern recognition" methods. Dendrograms constructed of analytical data show the possibilty of differentiation by unsupervised learning.

Key-words: qualitative, identification, fingerprinting, pattern recognition, heavy metals

INTRODUCTION

The problem: how to determine the *origin of cement* in concrete. This is a challenging problem, both scientifically and practically (even in case of criminal investigation).

The problem can be solved by the analytical determination of certain elements contained in cements, and the statistical processing ("Pattern Recognition") of analytical data. These elements act as „chemical fingerprints", by which the identification of the manufacturer can be done. As an extension, isotopic distributions can help too, but this is beyond the scope of this paper.

SELECTION OF "FINGERPRINT" ELEMENTS

Not all elements are good for identification. Several aspects should be taken into consideration, when selecting the „fingerprint" (dactylogrammatically relevant) elements. Some important aspects: dactylogrammatically relevant elements *A.* should not be main elements, as cements, manufactured all over the world contain same main elements, and even their ratio is very similar, depending only on cement type, and not cement origin; *B.* should come from the main raw materials (limestone, marl, clay, etc.) an not from the fuel, from refractories, from grinding media wear; *C.* should be thermally stable, as volatile ones evaporate at hot zones and condense at cooler places, thus their amount may vary by kiln conditions; *D.* should be present in measurable quantities; *E.* should not form soluble ions at pH > 10, as in the highly basic environment of concrete this ions can migrate.Above considerations exclude several elements. A list of elements which are definitely inadequate: *A.* Main elements (Ca, Si, Al, Fe, S, alkalies). *B.* Fuel may contain V (fuel oil), Zn, Pb (waste tyres), etc. Older kilns are frequently lined with magnesite-chrom refractories, thus excluding Cr. Grinding media contain steel alloy elements, excluding W, Mn and Cr. *C.* .Alkali-, Tl- , Sn-compounds (esp. chlorides) are easily volatilized. Point *D.* excludes rare earths, noble metals, etc., while point *E.* excludes Cr, Mn, U.

What remains after that? Sr, Ba, Mn, Mg, Ti, Zr, and possibly some others, not investigated yet. Sr and Ba are always present in limestones; their quantity and ratio is fairly constant,

depending on their geological origin, thus they are dactylogrammatically reliable. Mn, although mentioned above (points B and E), can still be used. To investigate the effect of grinding media wear, pure quartz has been ground in a ball mill with steel media for extended time (3 days), but its Mn content was less than 20 ppm; besides the presence of manganates or permanganates have never been reported.. The Mn content of cement is usually higher by 1 or 2 magnitudes. Goguel and StJohn (1993) have used the Ca-Sr-Mn plot for identification.

Our experience (Tamás, 1996; Tamás and Kristóf-Makó, 1996) has shown that the Sr-Ba-Mn 3-element approach (3EA) is not fully adequate, esp. in case of sulfate resistant clinkers, having a high iron content. For the time being, three more elements (Mg, Ti and Zr) are added. According to recent experiences, this 6-element approach (6EA) gives a possibility of a more satisfactory identification.

The knowledge of the concentration of the "fingerprint" elements can be used, in itself, for a rough estimation only. For a more satisfactory resolution, analytical data should be statistically processed, using "pattern recognition" methods. These are described in detail in our priveious publications (Tamás, 1996; Tamás and Kristóf-Makó, 1996)

EXPERIMENTAL

Materials

This paper gives results of clinkers and cements made in two Hungarian cement factories, as well as 27 cements made by various Austrian factories. In case of Hungarian materials, the origin and the type of the sample was known; Austrian factories gave sample numbers only, without describing details. (One of the samples, No. 16 has an extraordinary trace element composition, with all concentrations higher than in any other sample).

Sample preparation

Clinker samples were crushed to 2 mm, reduced to approx. 20 g and hand-ground in an agate mortar to pass sieve 0.045 mm. In case of cement samples there was no need of grinding. Small, but hopefully representative samples were used for further tests.

1 g, exactly weighed sample was dissolved in concentrated hydrochloric acid, SiO_2 removed by precipitation (evaporating in the presence of gelatin) and the precipitate washed out several times. The filtrate was analysed by ICP-ES (Inductively Coupled Plasma Emission Spectrography). This method is advantageous when absolute ppm values are needed, as standardization can be done by reagent grade chemicals of known concentration. The simpler, less time-consuming "slurry method", where the sample, of fineness < 50 μm is suspended in de-ionized water, nebulized in a spray chamber and introduced directly in the plasma unit proved to be insatisfactory. (A NIST standard cement sample was used for standardization, although, for our purposes, where only relative values are needed, unstandardized concentration data can be applied too).

Analytical method

An ARL/3410 type ICP spectrometer was used, with a mini-plasma torch, using a radiofrequency generator, 27.17 MHz of 650 W power. The spectrometer contains a Czerny-Turner vacuum monochromator. Spectral range 165-800 nm. Computation: EPIC (Evolutionary Program for Instrument Control) software, IBM PS/2 computer, with a PC DOS 3.0 system. The wavelengths used in this study (in nm): Mn = 257.610, Mg = 279.553, Sr = 407.771, Ba = 455.403, Ti = 336.121, Zr = 349.621.

Results

Analytical results are shown in **Table 1.** one of two parallels. If deviation between parallels was higher than 5%, a third, decisive analysis was made.

Explanations to Table 1.

- All analytical data are expressed in (μg/g) units.
- Two numbers are seen in Col. "Number". The first refers to actual sample No, as shown in the coming Figures; the second (in brackets) is an older number, for internal use only, and to facilitate finding of already published data
- Col. "Symbol" contains alphanumericals. Samples 1 - 19 come from 2 Hungarian factories, (D for Dunai Cement, L for Lábatlani Cement), and are clinker or cement samples. The symbol after the shilling stroke (/) gives type: O for ordinary portland cement clinker, S for sulfate resistant portland cement clinker, OPC for ordinary portland cement, BFSC for blastfurnace slag cement. Samples 20 - 45 come from Austrian factories, without giving any details. Here the sample No., as given by the factory is shown in this column. Austrian sample No. 16 was left out of this table. Its extraordinary composition (all 6 constituents higher than those of any other sample) suggests that it was neither clinker nor cement.
- Col. "Group" gives the grouping by statistical processing. The number can be 1, 2, 3 or 4 (see later, in figures, and under heading "Results and Discussion").

Discussion of results

Statistical data evaluation shows that all samples are similar over $S > 0.8$, as shown by the the dendrogram and by the Karhunen-Loeve transformation (from 6 to 2 dimensions). Detailed results are shown in **Figs. 1.**, **2.** and **3.**

Four groups can be seen in the dendrogram, constructed by "distances" in the six-dimensional space **(Fig. 1)**. (The grouping is indicated also in **Table 1**, Col. 3). S (similarity) values of the groups: $S_1 > 0.90$, $S_2 > 0.88$, $S_3 > 0.81$ (this is the lowest), $S_4 > 0.86$. A very distinct group (1a in Fig. 4) is formed by the Lábatlan ordinary clinkers, with $S > 0.95$. Some Austrian materials belong to this group too, but less significantly. In Group 2, the Dunai ordinary clinkers form a distinct group, with $S_3 > 0.96$. Here again an Austrian group is intermixed in a less significant way. The two L/S samples belong to this group too. Nothing is known of the origin of samples in Group 3 and 4. These are Austrian samples (although two Hungarian OPC's, No. 17 and 18) also belong to Group 4. The two extremes, No. 24 and 29, shown by the KL transformation (referred to above) are members of Group 3, but at rather low similarity levels ($S < 0.85$).

In **Fig. 2.** (KL transformation of results), the four cluster groups can be easily separated by a quasi-horizontal line (dotted). In **Fig. 3.** the Sample No. is shown. From this it is evident that the two samples, belonging to the extreme left part of the figures are due to samples 24 and 29. These are Austrian samples, where the exact origin is not known. But it is striking that these two samples are very high in Mn; this is why they are rather far for the other KL-transformed points belonging to Group 3.

Possibilities

The research described in this paper is necessarily only a beginning step, to be continued in three directions:

1. Analysis of already investigated and new samples for still more elements, which may be dactylogrammatically relevant.

2. Continuation of research to study cement identication and finally the same in case of concrete (here the separation of the effects of hydraulic additives and aggregates will cause serious problems).

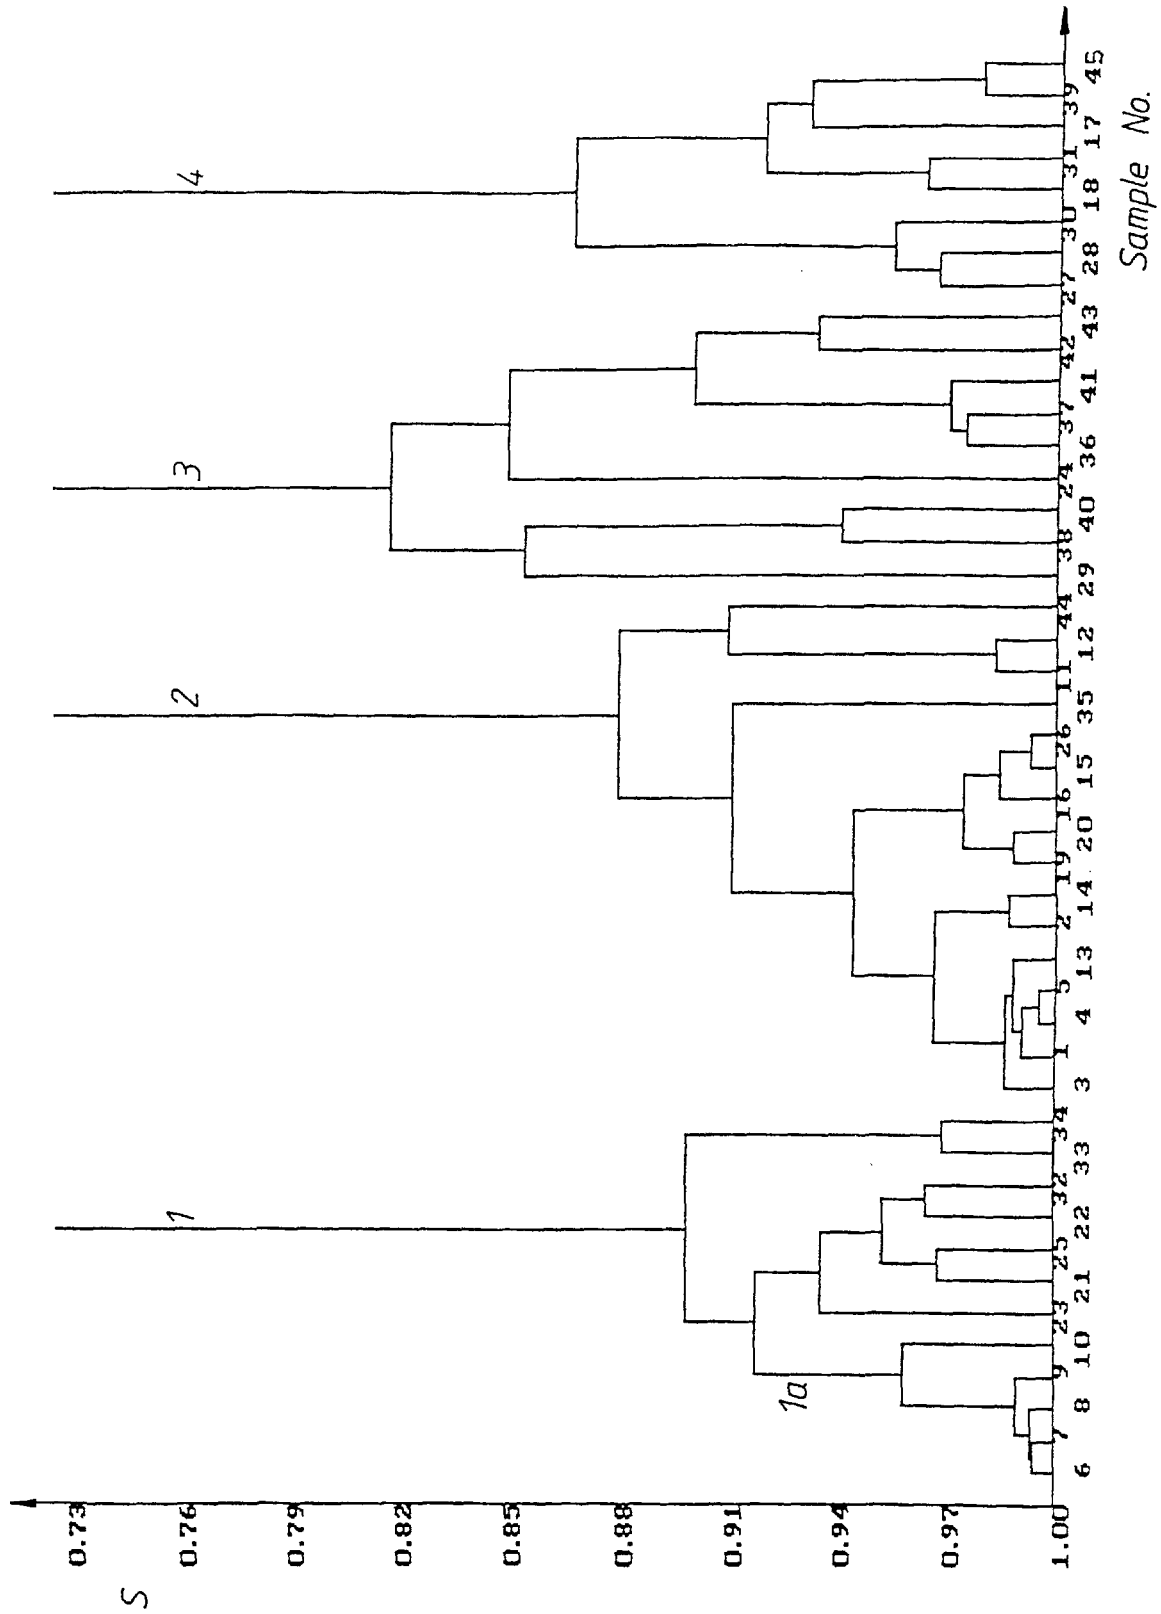

Figure 1. Dendrogram for the 45 investigated samples

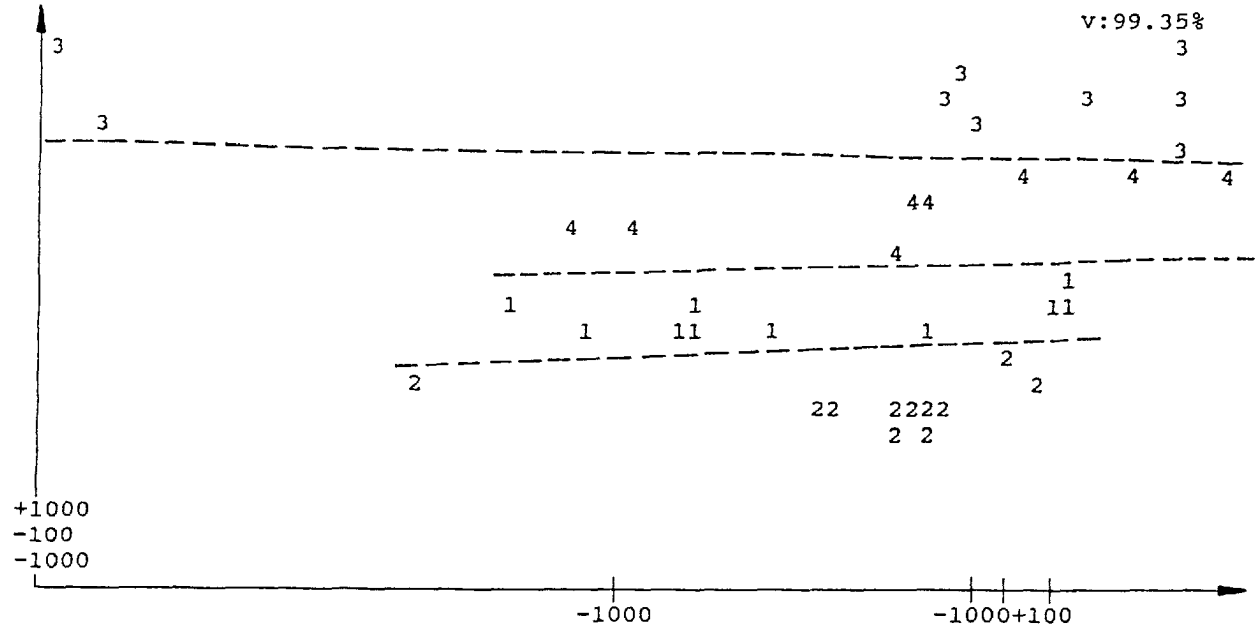

Figure 2. KL transformed data from 6 to 2 dimensions. Numbers refer to Group numbers

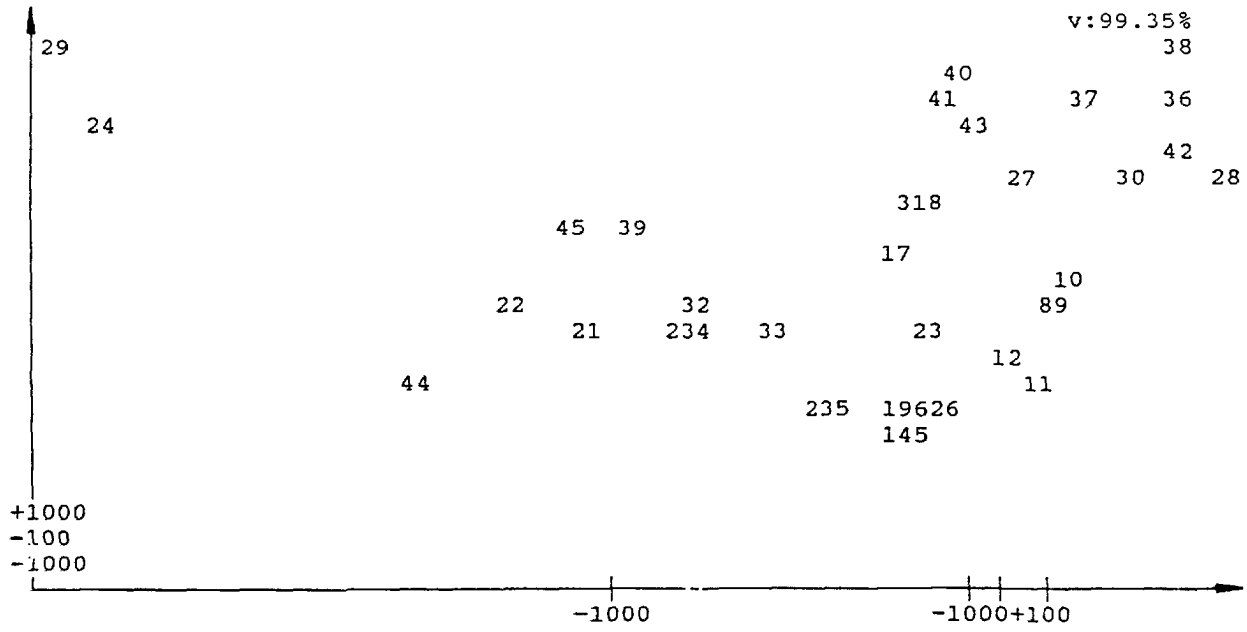

Figure 3. KL transformed data from 6 to 2 dimensions. Numbers refer to Sample numbers

3. The establishment of national, then regional and finally worldwide databases. This sort of research definitely needs international cooperation.

FINGERPRINTING S.A. CEMENTS BY CHEMICAL ANALYSIS

J. Herman POTGIETER, Pretoria Portland Cement Technical Services, P.O. Box 40073, Cleveland, Johannesburg, South Africa

ABSTRACT There are three cement manufacturers in South Africa, having plants in various parts of the country. Due to geological differences in their raw materials, as well as different quality assurance systems and kiln configurations/operations, the various cements produced differ from one another. From a marketing point of view, as well as in the case of some customer queries, it is necessary and useful to be able to distinguish cements made by the various producers. This paper presents a graphical representation of the respective chemical analyses as well as some typical chemical parameters employed to accomplish these distinctions.
KEY-WORDS Composition, Characterization, Method, Qualitative, X-ray Fluorescence Analysis

INTRODUCTION

The South African cement industry owed its beginnings to the demand created by the discovery of gold in 1886 and the subsequent development of the mining industry. The industry today consists of three players: Pretoria Portland Cement Co. Ltd. (PPC), Blue Circle Ltd. (BC) and Alpha Ltd. (AC). The major deposits of limestone, which is the main raw material in the manufacture of cement, lie in the North West and Northern Cape Provinces, and vary in distance from about 250 to 500 km from Johannesburg, the centre of the industrial and economic area of the country, known as the Gauteng region. Cement compositions are governed by, amongst others, raw material constraints, kiln configurations and operating procedures and quality assurance systems. Therefore the chemical compositions of the cements produced by the different producers vary significantly.

In South Africa the chemical composition of cement must conform to the requirement of the South African Bureau of Standards (SABS) specification 471-1971. This specification only limits the MgO content to a maximum of 5%, the SO_3 content to a maximum of 3.5% for OPC and 3% for SRC and the loss on ignition (LOI) to a maximum of 4.5%. From a marketing perspective, as well as in the case of customer queries, it is often necessary and convenient to be able to distinguish between the cements from the various producers. This matter is becoming increasingly important world wide and only a limited amount of work has been done in this area(Goguel et al., 1993; Tamas et al., 1996).

EXPERIMENTAL

Samples of OPC from the various producers and also different geographical locations in South Africa were analysed on a Siemens MRS 400 X-Ray Fluorescence spectrometer after suitable preparation into pressed pellets and fused glass beads, using an appropriate calibration set up from standard reference materials. The elements which have been found to be most useful for characterisation purposes are Al, Fe, Mn, Ti, Mg, S, K, and Na. The two major elements Si and Ca are of little use. The results obtained are summarised in Table 1. The compositions of the various cements are ratioed against a set of reference values which lie midway between the average compositions of the various producers, as shown in Table 2.

RESULTS

A schematic representation of the ratio values of PPC cements from the Jupiter (Johannesburg) and Port Elizabeth plants on an ordinary x,y graph is given in Figure 1. However, the emerging shape has little impact in illustrating the significant difference between the two cements from a chemical

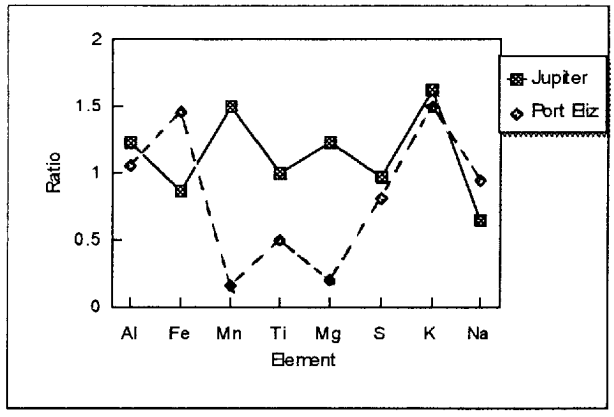
point of view.



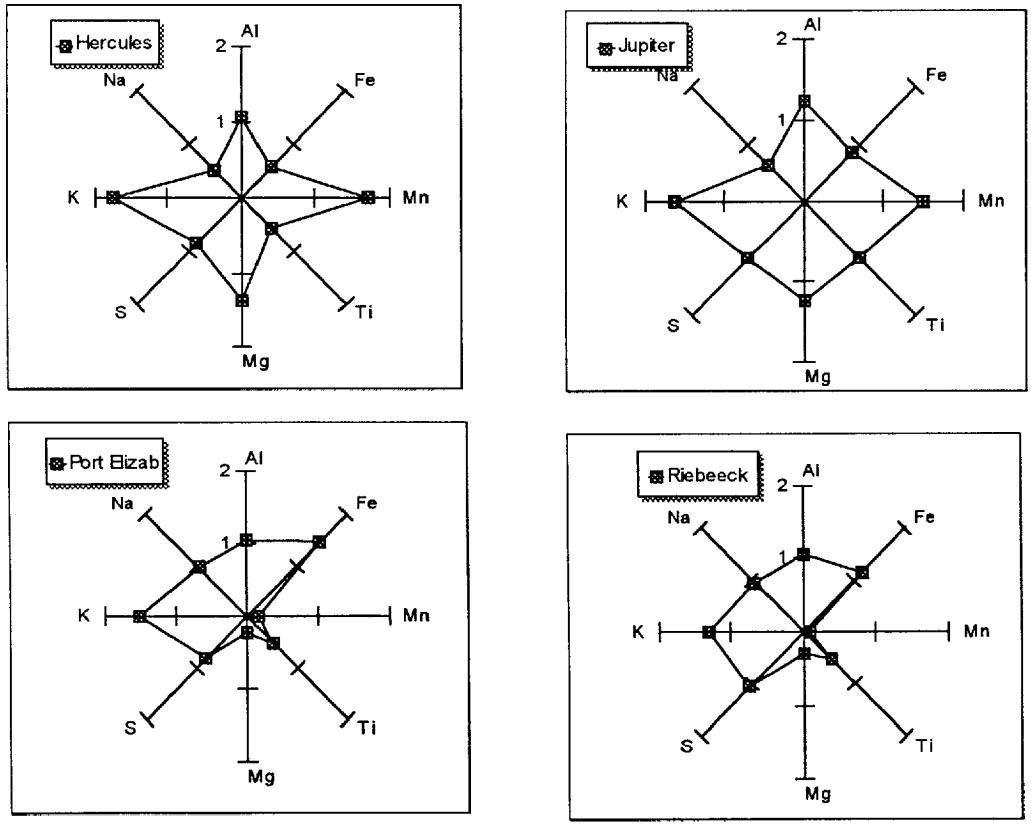


Figure 1 Representation of the ratio values of PPC cements from Jupiter and Port Elizabeth

When one represents the ratio values of the various cements, including these two, in radial fashion at 45^0 angle to one another as "star plots", the visual impact of their chemical differences are much more striking, as can be seen in Figure 2.. If the chemical analyses of the different cements are kept in a regularly updated data base, a library of cement "star plots" can be built up. This could enable one to speedily overlay a standard against an unknown, thus facilitating identification of the unknown cement. The big advantage of the "star plots" is that it utilise a whole suit of elements instead of just one or two to accomplish identification.

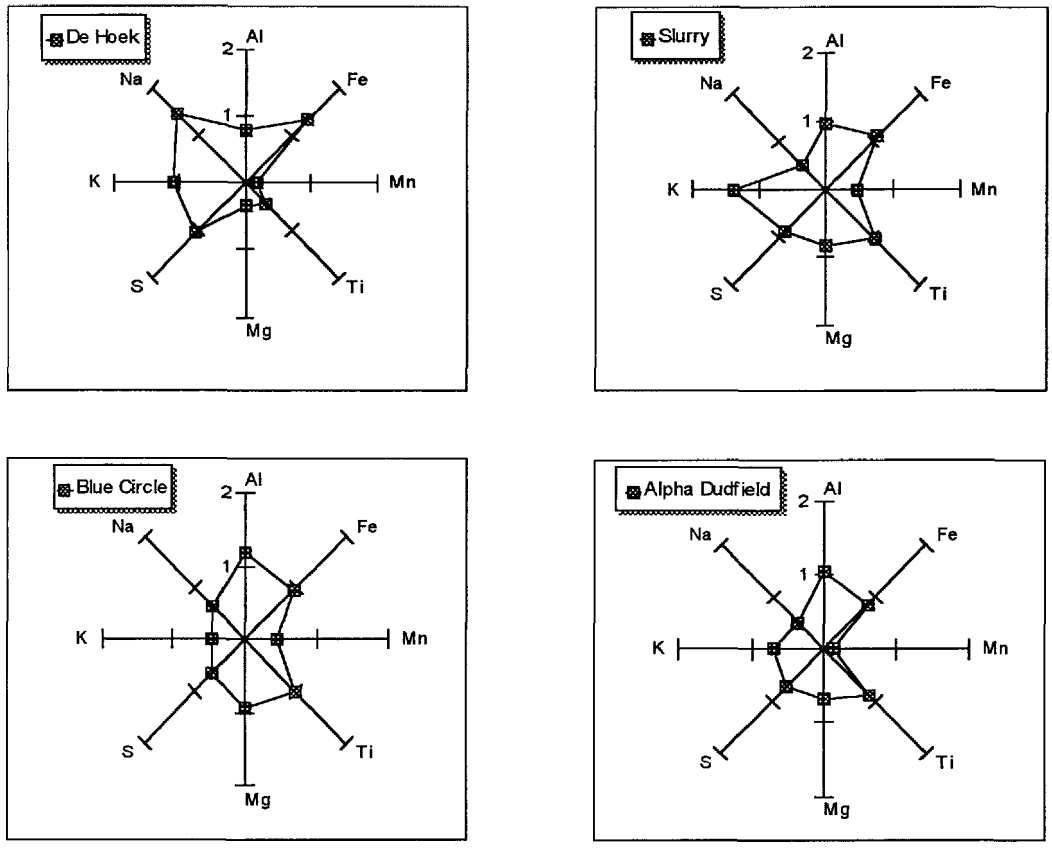

Figure 2 Star plots of the chemical composition of various South African cements

Alkalies are quite important constituents of cement, especially when strength development and possible alkali-silica reactions in concrete made of different cements are considered. The alkali contents, as well as the Sr content, of the various cements produced in South Africa varies significantly among the different producers and also among the different geographical areas in which the cement is produced. This feature can be used as an additional identification tool to determine from which area and producer a cement originate. The alkali equivalents together with typical Sr

Table 3. Alkali equivalents of various South African cements.

Producer	Geographical Area	SrO value (ppm)	Na_2O Equivalent Alkalies(%)	K_2O Equivalent Alkalies(%)
PPC Hercules	Gauteng	319	0.56	0.85
PPC Jupiter	Gauteng	219	0.56	0.85
PPC De Hoek	Western Cape	3328	0.58	0.88
PPC Riebeeck	Western Cape	2619	0.53	0.81
PPC P. Elizabeth	Eastern Cape	1224	0.59	0.89
PPC Slurry	North West Prov.	177	0.46	0.70
Alpha Dudfield	North West Prov.	192	0.28	0.43
BC Lichtenburg	North West Prov.	166	0.25	0.38

values of the various cements are indicated in Table 3 below.

It is clear that there are major differences between the various alkali equivalents and SrO values of the various geographical areas as well as between the different factories and also producers in one specific area. These parameters could therefore be utilise for discrimination and identification purposes.

CONCLUSIONS

A useful way of uniquely identifying cements from various geographical locations and made by different producers in South Africa have been presented. The main advantage of this method is that it utilises not just one or two chemical characteristics of a cement, but of whole suite of elements. The proposed method is furthermore visually striking and easy to use.

ACKNOWLEDGEMENTS

The author gratefully acknowledges Prof. James Willis of the Department of Geology, University of Cape Town who introduced the basic concept in South Africa, as well as the work done by his colleague Mr. Barrie Butcher in this regard. Mrs. Karen van der Merwe of the Council for Geosciences is aknowledged for analysis of SrO in the various samples used. This paper is published by permission of Pretoria Portland Cement Co. Ltd.

ABSTRACT A new direct spectrophotometric method for the determination of magnesium oxide in Portland cement and cement clinker is proposed. The method is based on the reaction of Mg with quinizarin(1,4-dihydroxyanthraquinone) in water-ethanol solution at pH 9.5-10.3. Fundamental study of the complexation reaction of magnesium(II) with this reagent is described. The mono-ligating complex formed under the optimum conditions, allows the determination of 0.5-3.9 $\mu g\ ml^{-1}$ of magnesium. The determination is not affected by any of the other constituents normally present in Portland cement materials .

Keywords : cement analysis, MgO determination, spectrophotometry .

INTRODUCTION

In a dry process cement plant the production of Portland and other types of cement can be divided into two segments, namely (a) processing of the raw materials to raw meal/kiln feed and (b) pyro-processing of the kiln feed to give cement clinker. The raw meal is pre-heated, pre-calcined and clinkerized by a combination of endothermic and exothermic reactions. Clinker is the basic component in the production of cement, which when combined with other elements, results in the formation of various cement types. Portland cement clinker consists substantially of four crystalline clinker 'phases' in close interpenetrating association. MgO and other foreign oxides are usually incorporated in clinker phases. MgO-rich clinker may also contain free magnesium oxide (periclase) which is undesirable because if it is present in substantial amounts, it may cause expansion of concrete, similar to that caused by lime, but more surreptitious. The damage it causes may remain undetectable for years. The magnesium expansion effects are commonly referred to as "unsoundness" of the cement. The high proportion of MgO favours the dissolution of "C_2S" and free lime at higher temperatures and lets "C_3S" form more quickly. It reduces viscosity and surface tension of the clinker melt and increases ionic mobility.

Inside the cement plant, on-line control of the composition of raw meal is needed to maintain the composition of cement to within strict requirements. In addition, the variability of the raw materials used is continuously and constantly traced. The development of new procedures for elemental analysis of cement constituents is desirable because the increasing demand for more analytical results requires faster, selective and precise methods which offer some measure of quality. There must be a method to determine the magnesium oxide content of cement materials. It is the main objective of this work to make use of visible spectrophotometry in the determination of magnesium. Selective determination of Mg^{2+} in presence of Ca^{2+} using common reagents is difficult to performe and several methods have the drawback of the interference from excessive amounts of Ca^{2+} (Sugawara et al, 1973 ; Jimenez et al, 1975 ; Banerjee et al, 1976 ; Sinha et al, 1978,1982 ; Ying-Quan et al, 1982 ; Robiseh et al, 1983 ; Lopez et al, 1986 ; Pal et al, 1992,1994). The standard methods (BS, 1985 ; ASTM - C 114, 1994) for magnesium-content analysis of Portland cement are complicated and require a long time to carry out the determination. It is aimed in the present study to develop a new spectrophotometric method for

the rapid analysis of MgO content of Portland cement and cement clinker, which is superior to other recommended methods in terms of selectivity and sensitivity. The instrument used is cheaper and the running cost lower than those for XRF, AAS or ICP-AES techniques.
In this paper fundemental study of the complexation reaction of magnesium(II) with quinizarin is described and a direct spectrophtometric method for the determination of MgO content of cement materials is presented. The validity of the method was thoroughly examined. MgO content analysis of SRM cement samples of the US NIST have been used to illustrate the results which can be achieved.

EXPERIMENTAL

Apparatus

A Perkin Elmer Lambda 12 spectrophotometer and Radiometer pH meter (M210) with a Radiometer combined glass electrode were used for measurement of absorbance and pH respectively. The pH meter was calibrated regularly befor use with standard buffer solutions. All the spectrophotometric and pH- metric measurements were performed in 50% (v/v) ethanol at 20°C. The pH values in water-ethanol medium were corrected as discribed elsewhere(Douheret, 1967).

Chemicals and Solutions

Standard Magnesium Solution : A stock solution (1 ml = 0.49 mg Mg) was prepared using high purity $MgCl_2$ in 0.05 M HCl and standardized against EDTA.
Quinizarin (QUIN) stock solution : 10^{-3}M in ethanol. Prepared directly using the purified reagent (E. Merck). Other reagents include sodium perchlorate, perchloric acid and sodium hydroxide standard solutions. Solutions of the foreign ions used for interference studies were prepared using the chloride, sulphate or nitrates of the metal cations and potassium or sodium salts of the anions to be tested. pH adjustment of solutions investigated was performed by the addition of either dilute perchloric acid or sodium hydroxide. The ionic strength was kept constant at I = 0.1 mol l^{-1} ($NaClO_4$).

Standard Procedures:

Procedure for Magnesium(II):

In a 25 ml calibrated flask, place a suitable volume of magnesium solution containing less than 80 µg of magnesium, 6 ml of 10^{-3} mol l^{-1} QUIN solution in ehtanol and 2.5 ml of 1 mol l^{-1} $NaClO_4$ solution. Adjust the pH to 10 and dilute to volume with doubly distilled water, keeping the ethanol content at 50% v/v. Mix the solution thoroughly and measure the absorbance at 630 nm against a reagent blank, similarly prepared but containing no magnesium.

Magnesium Oxide Content Analysis of Portland Cement, Clinker and Raw Meal

Step 1 : Dissolution of Sample. Weigh accurately 1.0 gm of the sample (dried at 110°C) into a beaker and dissolve it in the minimum volume of hydrochloric acid. Heat to dryness, add 25 ml of HCl (1+1) to the residue, digest and filter the insoluble residue into a 250 ml calibrated flask and then dilute to volume with bidistilled water.

Step 2 : Procedure for MgO determination in cement materials. Transfer a 2.5 ml aliquot of the sample solution into a 25 ml calibrated flask. Add 6.0 ml of 10^{-3} mol l^{-1} QUIN solution. After mixing with 6.5 ml of ethanol and 2.5 ml of $NaClO_4$, adjust the pH to 10 using NaOH solution added dropwise and mixing thoroughly after each addition. Dilute to volume and mix. Measure the absorbance of the solution at 630 nm against a reagent blank of the same pH as the reference.

RESULTS AND DISCUSSION

Acid-base properties of the reagent

The absorption spectra of QUIN solution in 50% (v/v) ethanol and at various concentrations of $HClO_4$ or NaOH were recorded as the dependence $A = f(\lambda)$ for various pH (see Fig. 1). The reagent yields three coloured acid-base forms in solutions of pH 1.5-11.2 : LH_2, LH^- and L^{2-}. There is a pronounced transformation from the yellow form (LH_2) to the orange red species (LH^-) at pH 8.2-9 . The red form is converted to violet (L^{2-}) at pH > 10.8 . The protonation scheme of the reagent indicate that gradual association of protons with the oxygen of the bis(hydroxyl) substituents is carried out at pH $\leq$ 10.8 and $\leq$ 8.2. It has been spectrophotometrically determined at the working pH region of solutions and 50% (v/v) ethanol that pK_{a1} (LH_2/LH^-) = 8.5 $\pm$0.03 and pK_{a2} (LH^-/L^{2-}) = 10.65$\pm$ 0.05 at I = 0.1.

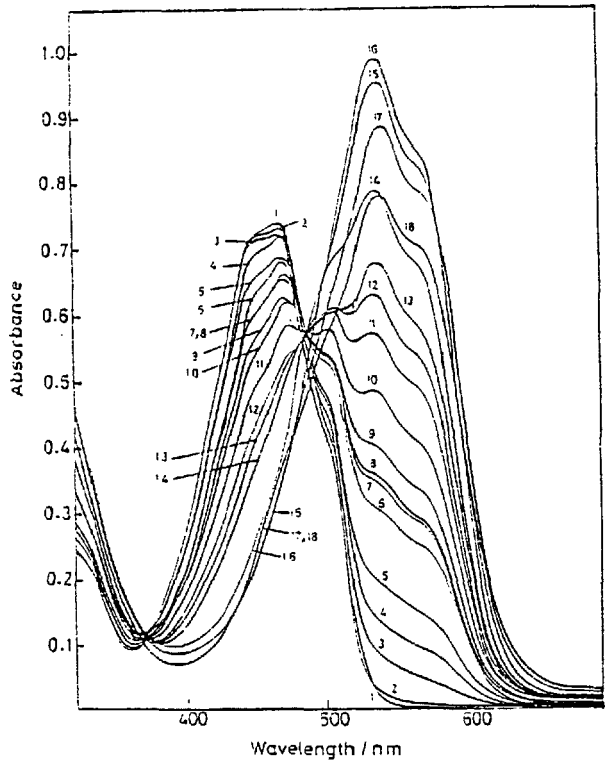

Figure 1. Absorption Spectra of $2x10^{-4}$ mol l^{-1} QUIN at different pH values, 50% (v/v) ethanol, pH : 1) 1.5; 2) 3.8; 3) 6.35; 4) 6.60; 5) 6.8; 6) 7.20; 7)7.3; 8) 7.4; 9) 7.6; 10) 7.9; 11)8.1; 12) 8.25; 13)8.45; 14) 8.7; 15)10.1; 16) 10.6; 17) 10.9; 18) 11.1

Complexation Equilibria of Mg^{2+} with QUIN

An aqueous Mg^{2+} solution reacts with ethanolic solution of QUIN in alkaline medium (optimum pH 9.5-10.3) to form a blue complex species . The absorption spectrum of the magnesium complex shows an absorbance maxima at 630 nm, where the reagent does not absorb. The magnesium complex is completely formed within 5 min of mixing of the reagents and remains stable for at least 4 hr .

The complexation reaction of Mg^{2+} with QUIN is investigated in 50% (v/v) ethanol over the pH range 8-10.8. The solution spectra are recorded in the presence of an excess of the metal ion, in equimolar solutions and in the presence of an excess of the reagent. For all solutions investigated, the absorption spectra are analogous and exhibit an abosprtion band at 630 nm irrespective of the component ratio (C_L/C_M) in solution. The absorption spectra of the Mg-QUIN system with reagent blank as reference are shown in Fig.2 .

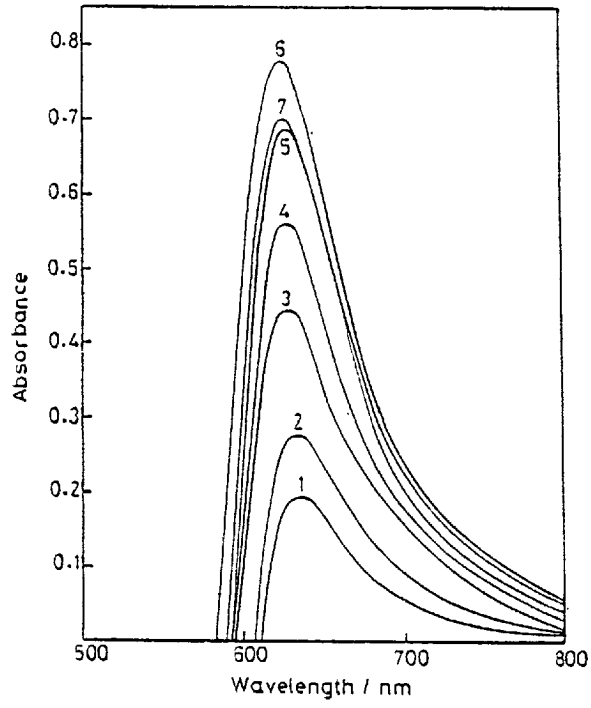

Figure 2. Absorption Spectra of Mg^{2+} - QUIN Complex . $C_L = 2.5x10^{-4}$ mol l^{-1}, $C_M = 1.5x10^{-4}$ mol l^{-1}. 50% (v/v) ethanol, pH : 1) 8.05; 2)8.2; 3) 8.45; 4) 8.7; 5) 9.2; 6) 10.15; 7)10.65 .

The absorbance *versus* pH graphs for solutions of different component ratio show the range of formation of Mg-QUIN complex species and indicate a single chelate equilibrium (c.f. Fig.3). The complexation reaction in the pH 8.2-10.3 is assumed to be carried out according to the general equilibrium

$$mMg^{2+} + nLH_x \rightleftharpoons Mg_m L_n H_b^{(2m-q)+} + qH^+$$

(where b = xn-q)

The absorbance versus pH graphs for the Mg-QUIN system were interpreted using the relations derived earlier (Sommer et al, 1976; Idriss et al. 1988) and the generalized approach described previously (Voznica et al, 1980) .

The following equilibria were assumed during the analysis of the absorbance versus pH graphs.

$$Mg^{2+} + LH^{-} \rightleftharpoons MgL + H^{+} \qquad [1]$$

$$Mg^{2+} + LH_2 \rightleftharpoons MgL + 2\,H^{+} \qquad [2]$$

By considering the acid-base equilibria of QUIN in 50% ethanol and the distribution ratio of the reagent species at different pH (c.f. Fig. 4.)one can assume that the monoionized form of this reagent (LH^{-}) is the prevalent ligand species in the pH range of complexation. The analysis of the ascending part of the absorbance - pH graphs gives the best fit for equilibrium in Eq. 1 and the formation of MgL complex species. The existence of this equilibrium was confirmed in solutions containing excess of one component and in equimolar solutions.
For equilibrium (1), in solutions containing excess of QUIN, it holds that:

$$\Delta A = \varepsilon_1 C_M - \Delta A\ [H]^q / {}^*K_{11} C_L^n \qquad [3]$$

$$\text{Log}\,[\,\Delta A / (\,\varepsilon\, C_M - \Delta A)\,] = q\,pH + \log {}^*K_{11} + n \log C_L \qquad [4]$$

The following equations are valid for equilibrium (1) in solutions with excess of metal ions:

$$\Delta A = \varepsilon_1 C_L - (\Delta A - \varepsilon\, C_L)\,[H]^q / {}^*K_{11} C_M \qquad [5]$$

$$\log\,[\,(\Delta A - \varepsilon\, C_L) / (\varepsilon_1 C_L - \Delta A) = q\,pH + \log {}^*K_{11} + \log C_M \qquad [6]$$

with the values n = q = 1

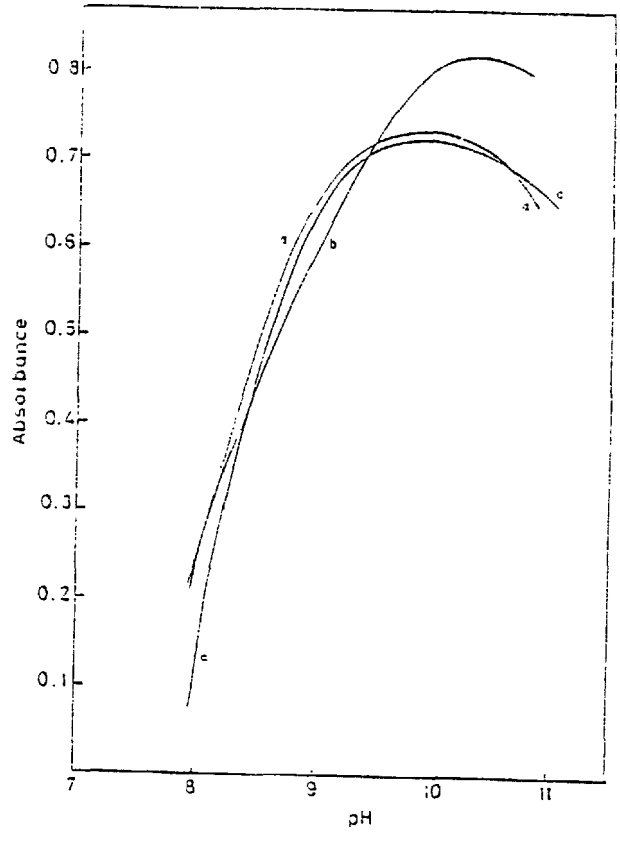

Figure 3 : Absorption versus pH graphs for Mg^{2+} - QUIN system of various concentrations of components, λ = 630 nm, I = 0.1 mol l^{-1} $NaClO_4$, 50% (v/v) ethanol. a) $C_M = 2\times10^{-3}$ mol l^{-1}, $C_L = 2.5\times10^{-4}$ mol^{-1}; b) $C_M = C_L = 2.5\times10^{-4}$ mol l^{-1}; c) $C_M = 1.5\times10^{-4}$ mol l^{-1}, $C_L = 2.5\times10^{-4}$ mol l^{-1} .

The metal : ligand ratio and the number of hydrogen ions liberated were further confirmed by the method of Betteridge and John (Betteridge et al, 1973).

The results obtained indicate that only one proton is liberated during the complex forming reaction and Eq. (1) is predominant. On the other hand, the coordination of a single Mg^{2+} with QUIN at pH 10.2 is confirmed independently by analysis of the $A = f(C_M)$ dependence at $\lambda = 630$ nm by using the relations given elsewhere (Idriss et al, 1993).

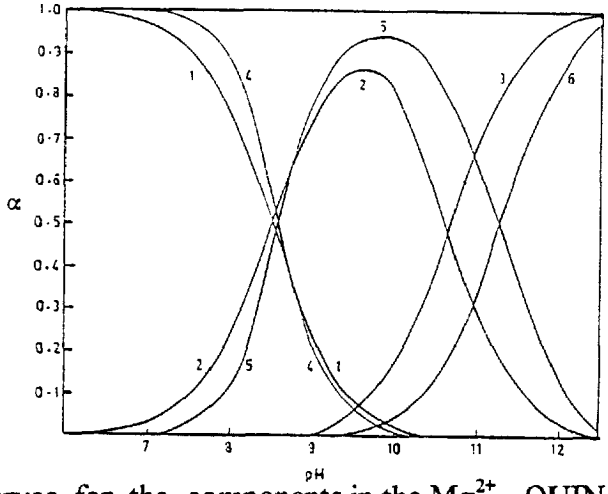

Fig 4. Distribution curves for the components in the Mg^{2+} - QUIN system, 50% (v/v) ethanol. I = 0.1 mol l^{-1} $NaClO_4$. Curves 1-3; $C_L = 2x10^{-4}$ mol l^{-1}, α = 1) $[LH_2]/C_L$; 2) $[LH]/C_L$; 3) $(L^-]/C_L$ Curves 4-6; $C_L = 2.5x10^{-4}$ mol l^{-1}, $C_M = 1.5x10^{-4}$ mol l^{-1}, α = 4) $[Mg]/C_M$; 5) $[MgL]/C_M$; 6) $[MgL(OH)_2]/C_M$

Side reactions involving the formation of hydroxo complexes prevent the appearence of definite plateaux on the absorbance versus pH graphs . The analysis of the descending branch of the graphs, above pH 10.6 for solutions of different component ratio confirms the existence of hydrolytic reaction of the MgL complex :

$$MgL + 2H_2O \rightleftharpoons MgL(OH)_2 + 2H^+ \qquad [7]$$

The stoichiometry of the Mg-QUIN complex was further verified by the method of continuous variations. In solutions having $C_o = C_M + C_L = 2.4 \times 10^{-4}$ mol l^{-1} at pH 10, a component ratio of 1:1 (metal to ligand) was obtained.

The calculated values of the equilibrium (log $^*K_{11}$) stability constant (log β_{11}) and molar absorptivity of the magnesium-QUIN complex are listed in Table 1.

Table 1. Mean value of equilibrium constant (log $^*K_{eq}$)[a], stability constant (log β)[b] and molar absorptivity of Mg-QUIN complex (50% v/v ethanol, I = 0.1 mol l^{-1} $NaClO_4$), 20°C .

Equilibrium[c]	Constant	Log constant	Molar absorptivity $l\ mol^{-1}\ cm^{-1}$
[MgL] [H]/[Mg][LH]	$^*K_{11}$	- 4.69	
[MgL]/[Mg][L]	$^*\beta_{11}$	5.95	4700 (λ = 630 nm)

a- From the absorbance versus pH graphs, b- $^*\beta_{11} = {}^*K_{11} / K_{a2}$, c- Charges are omitted .

Effect of foreign ions

The tolerance of the method to foreign ions was investigated with solutions containing 60 µg of Mg per 25 ml and various amounts of foreign ions. Magnesium was then determined as Mg

(QUIN) under the optimum conditions as described in the given procedure . The tolerance criterion for a given ion was taken to be the deviation of the absorbance values by more than ± 2% from the value expected for Mg alone . The determination of magnesium as the Mg(QUIN) complex was possible in the presence of Al^{3+}, V^{5+}, Mn^{2+}, Fe^{3+},Hg^{2+}, Mo^{6+}, Cu^{2+} (about 25 - fold excess). Also, Ni^{2+}, Cd^{2+}, Zn^{2+}, Pb^{2+}, Ba^{+2} , Sr^{2+} and Ca^{+2} are tolerated at about 40 fold excess. The presence of SO_4^{-2}, Cl^-, Br^-, NO_3^-, ClO_4^- , PO_4^{-3} up to about 100-fold excess caused no interference. The alkali metal ions have no interferring effect on the determination .

Calibration graph, detection limit and precision

Under the optimum conditions cited above, a linear calibration graph for the Mg-QUIN system was obtained up to a concentration of 3.9 μg ml^{-1} of Mg^{2+} with a molar absorptivity of $4.7x10^3$ l mol^{-1} cm^{-1} at 630 nm. A Ringbom plot showed that the optimum concentration range for the determination of magnesium was 0.85-3.2 μg ml^{-1}. The Sandell's sensitivity of the reaction was found to be $0.88x10^{-3}$ μg cm^{-2}. The reproducibility of the method was checked by analyzing a series of five solutions each having a Mg concentration of 2.4 μg ml^{-1}. The relative standard deviation was found to be 0.81% .

MgO content analysis of Portland cement

The potential of QUIN as a reagent for direct spectrophotometric determination of magnesium(II) prompted us to explore further the applicability of the method for the determination of MgO in Portland cement and cement clinker. The results of our study indicate that the determination of magnesium content of cement can be achieved precisely under the optimum conditions adopted (c.f. Fig. 5).

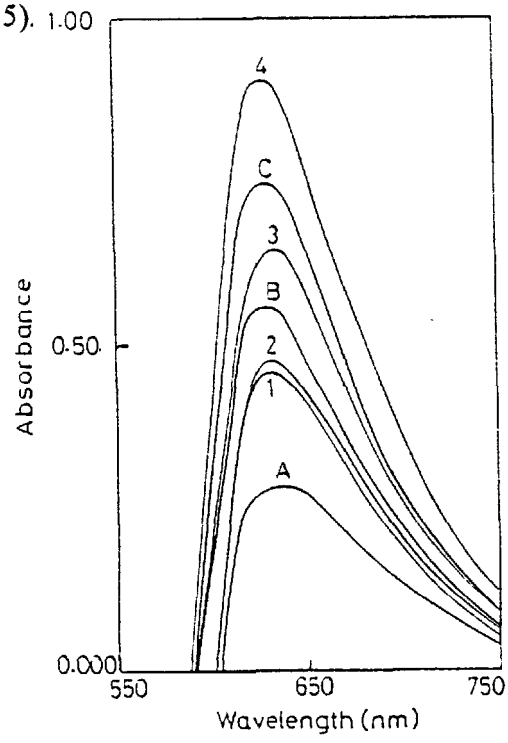

Fig 5. Spectrophotometric determination of magnesium with QUIN; $C_L = 2x10^{-4}$ mol l^{-1}, pH = 10, 50% (v/v) ethanol. Curves A,B and C ; Absorption spectra of Mg-QUIN complex; $C_{Mg} = 6x10^{-5}$ (A); $1.17x10^{-4}$ (B) and $1.55x10^{-4}$ mol l^{-1} (C) Curves 1-4 : Solution spectra of cement materials (1,2,3 = 10 mg sample; 4 = 7.5 mg sample); 1) clinker; 2) cement; 3) SRM (1889); 4) SRM (1880). MgO found (%) = 0.98 (1), 1.04 (2), 1.38 (3) and 2.59 (4)

Replicate MgO content analysis of SRMs of the US NIST : 1880, 1881, 1886, and 1889 were performed. In the precision study, five determinations were carried out for each sample, statistical evaluation of data indicated good precision of the proposed method which make it possible to apply it to the routine analysis of cement. Analysis of samples of cement materials containing various proportions of magnesium is feasible over the concentration range 0.85-3.2 $\mu g\ ml^{-1}$ of Mg^{2+}. The detection limit (at 95% confidence level) of the method for the mean of five analysis was calculated as 25.3 $ng\ ml^{-1}$ for Mg. Some results obtained for the analysis of cement standard reference materials are given in Table 2

Table 2 Application of the proposed method to the direct spectrophotometric determination of MgO in some Portland cement materials .

Sample*	Statistical term	Magnesium determination, % MgO
Cement	$\bar{x}$	1.03
	s	1.64×10^{-2}

SRM 1880	$\bar{x}$	2.63
	s	2.85×10^{-2}
	95% CL	$\bar{x} \pm 0.035$

* Number of determinations for each sample (n) = 5, $\bar{x}$ = mean recovery (%), s = standard deviation (%), CL = confidence limit (%), Test solution of the samples investigated contained 5-10 mg of cement material per 25 ml ($^{++}$) certified amounts : MgO = 1.38% (1889), 1.6% (1886), 2.63% (1881), 2.61% (1880) .

CONCLUSION

The proposed spectroscopic method utilizing quinizarin allows precise and accurate determination of MgO content of cement . The method has reasonable selectivity and is inexpensive . It save a lot of time in determining magnesium oxide in cement, clinker and raw meal samples and could replace the present test methods for cement analysis .

ANALYSIS OF THE TRACE ELEMENTS IN RAW MATERIALS AND CEMENT BY MEANS OF ICP-AES

Shigeru TAKAHASHI, Hiroyuki ANZAI, Hiroyuki NEMOTO
Japan Cement Association, R&D Laboratory

ABSTRACT The trace elements in cement and raw materials were determined by means of ICP-AES. The elements analyzed are V, Cr, Ni, Cu, Zn, Sr, Cd and Pb.
The samples were decomposed by alkali fusion used lithium metaborate or hydrofluoric acid-hydrochloric acid-hydrogen peroxide. The concentrations in sample solution were determined by calibration curve method or addition method. The recoveries of each element in coal fly ash (the standard reference material of NIST, 1633b) were examined.

Key-words : Heavy metals, Method, Quantitative, Waste material utilization

INTRODUCTION

In the cement industry, various waste and sludge have been used for a part of raw materials of cement clinker recently. In this case, the trace elements in raw materials or cement should be analyzed quickly because it is necessary to judge whether the amount of trace elements in waste and sludge is suitable for raw materials of cement.
The multielement is analyzed high sensitively by means of ICP-AES. This analytical method is applied to soil and coal fly ash (Yamashige, 1984 and Haraguchi, 1984), etc.. But, ICP-AES analysis has been hardly applied to the trace elements of cements and raw materials.
This paper describes the rapid analytical method of the trace elements both on raw materials and cement by means of ICP-AES.

EXPERIMENTAL

Instrument

The instrumentation, operating parameters and analytical lines for the emission measurements are summarized in Table 1. The calibration curves were made by joining the points for the blank and standard with straight lines.

Chemicals and standard solutions

Lithium metaborate used was special grade reagent. Hydrofluoric acid and hydrogen peroxide used were spectrochemical grade reagent. Hydrochloric acid used was ultrapur for trace analysis. Standard solutions for calibration curves were prepared by adding diluted the commercially available standard solutions(1000mg/ml) for atomic absorption spectrometry to blank solution.

Procedure

The procedures of alkali fusion decomposition(AFD) and hydrofluoric acid decomposition(HAD) are shown in Fig 1.

The concentrations of elements in final solutions were determined by caliblation curve method and addition method. The final solution (I) and (III) were prepared for caliblation curve method, and the final solution (II) and (IV) were prepared for addition method.

In addition method, the concentrations of elements in final solutions were calculated from **Eq 1.**

$$\text{Concentration} = I_c \times C_{ass} / (I_a - I_c) \quad [1]$$

where C_{ass} : Concentrations of added elements in final solution (II) or (IV)

I_c : Net intensity of final solution (I) or (III)

I_a : Net intensity of final solution (II) or (IV)

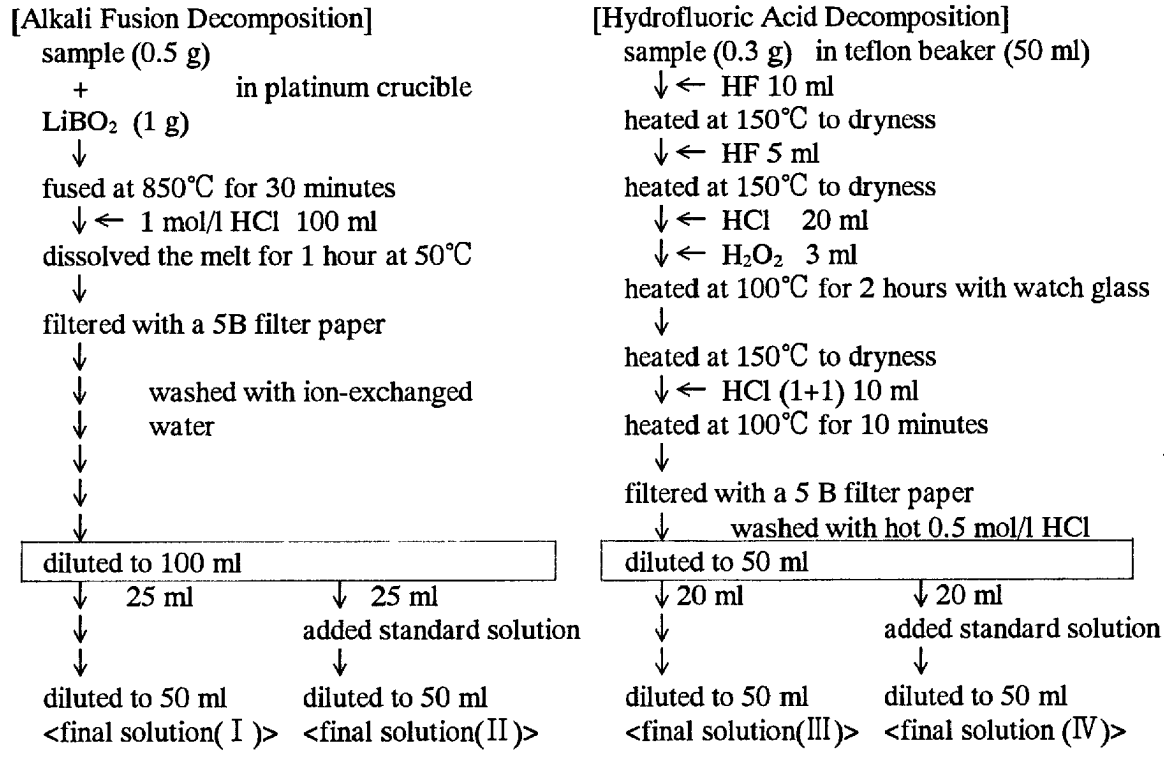

Figure 1 The procedures of alkali fusion decomposition and hydrofluoric acid decomposition

RESULTS AND DISCUSSION

Insoluble residue

Insoluble residues of samples are shown in Table 2. Insoluble residues were 0.05-0.62%. These insoluble residues were influential in determining track elements and all samples were able to be decomposed by both alkali fusion and hydrofluoric acid decompositions.

Table 2 Insoluble residues of samples (%)

Sample	Decomposition	
	Alkali fusion	Hydrofluoric acid
Coal fly ash(*)	0.20	0.20
Portland cement	0.62	0.35
Lime stone	0.19	0.19
Clay	0.17	0.22
Silicious rock	0.12	0.05

(*) Standard reference material of NIST,1633b

Lower limit of determination

The lower limits of determination of each element were calculated from **Eq 2**, and are shown in **Table 2.**

$$\text{Lower limit of determination} = C_s \times (10 \times S_b / I_s) \quad [2]$$

where C_s : Concentration of standard solution for calibration curve method

S_b : Standard deviation of the measured intensities of blank solution at analytical line

I_s : Net intensity of standard solution for calibration curve method

Table 2 The lower limits of determination of each element

Element	Final solution (ng/l)		Sample (mg/kg)	
	Alkali fusion	Hydrofluoric acid	Alkali fusion	Hydrofluoric acid
V	3.33	2.33	1.33	0.97
Cr	3.33	2.33	1.33	0.97
Ni	6.66	5.00	2.66	2.08
Cu	6.66	4.00	2.66	1.67
Zn	1.66	1.66	0.66	0.69
Sr	8.32	6.66	3.33	2.78
Cd	2.33	1.33	0.93	0.55
Pb	16.6	15.0	6.64	6.25

Recoveries of coal fly ash

The recoveries of each element were examined with coal fly ash (standard reference material of NIST, 1633b). The results are shown in **Table 3.** In AFD, the recoveries determined by calibration curve method were 92.2 - 105.2% and by addition method were 93.7 - 100.3% on V,Cr,Ni,Zn,Sr and Pb, and there was no difference between both methods. The recoveries of Cu were 66.1% and 71.6% respectively, and the evaporation of copper during fusing were found in AFD.

In HAD, the recoveries determined by addition method were 95.3 - 100.8% except Cd. But, the recoveries determined by calibration curve method were lower than addition method, and it is recognized that the determination by the calibration curve method is influenced by the physical interference in hydrofluoric acid decomposition(Hiraguchi, 1986).

The recovery of Cd were larger than 100% in all analytical conditions. It is neccessary to be concentrated by solvent extraction for determining the near content of lower limit of determination, because the intensity at the analytical line(228.802nm) of Cd is affected by spectral interference of major elements in sample.

Table 3 Determined values and recoveries of coal fly ash

Element	Certified value (mg/kg)	Alkali fusion decomposition		Hydrofluoric acid decomposition	
		Calibration curve	Addition	Calibration curve	Addition
V	295.7±3.6	284.6 (96.2%)	296.6 (100.3%)	278.2 (94.1%)	296.7 (100.3%)
Cr	198.2±4.7	198.6 (100.2%)	195.7 (98.7%)	173.7 (87.6%)	188.8 (95.3%)
Ni	120.6±1.8	121.6 (100.8%)	117.0 (97.0%)	106.6 (88.4%)	120.7 (100.1%)
Cu	112.8±2.6	74.6 (66.1%)	80.8 (71.6%)	109.7 (97.3%)	112.9 (100.1%)
Zn	(210)	209.4 (99.7%)	206.4 (98.3%)	187.6 (89.3%)	211.6 (100.8%)
Sr	1041 ±14	1095 (105.2%)	1028 (98.8%)	956 (91.8%)	1041 (100.0%)
Cd	0.784 ±0.006	1.33	1.67	1.2	1.6
Pb	68.2 ±1.1	62.9 (92.2%)	63.9 (93.7%)	58.1 (85.2%)	67.9 (99.6%)

The number of tests is 3 and the determinated values are average. Values in parentheses are the recoveries.

Analysis of cement and raw materials

The average contents and the standard deviation of reproducibility are shown in **Table 4**. The maximum of the standard deviation gave 1.60mg/kg on V,15.2mg/kg on Cr, 2.61mg/kg on Ni, 3.39mg/kg on Zn, 3.77mg/kg on Sr and 2.25mg/kg on Pb. From these results, the alkali fusion decomposition and the hydrofluoric acid decomposition are able to be applicable to the anlysis of these elements in addition method.

For the analysis of Cr in cement and raw materials, the averages of HAD were lower than AFD. But the analysis of coal fly ash did not show this tendency remakably (**Table 3**). Though it is known generally that Cr^{3+} products chromyl chloride in perchloric acid solution and chromyl chloride evaporates above 150℃, (Haraguchi, 1984 and Vandecasteele, 1993) it is a doubtful whether the chromyl chloride evaporates during hydrofluoric acid decomposition procedure, and so the HAD is not suitable for determining chromium.

For the analysis of Cu in cement and raw materials, the maximum of standard deviation of reproducibility gave 10.2mg/kg on AFD and 1.34mg/kg on HAD. The averages on AFD were larger than those on HAD, and these results were different with the result ot coal fly ash.

Table 4 The average contents in cement and raw materials and the standard deviation of reproducibility

(mg/kg)

DIRECT DETECTION OF GRINDING AIDS IN A CEMENT MATRIX

Pierre CASSAT and Jean François MULLER.
Laboratoire de Spectrométrie de Masse et de Chimie Laser, University of Metz, France.
Angélique VICHOT and Pierre COLOMBET.
Centre technique Groupe Italcementi-Ciment français, 78931 Guerville Cedex, France.

ABSTRACT The present study is devoted to the enhanced detection of grinding aids into a cement matrix. The utilized method was the Laser Desorption Fourier Transform Mass Spectrometry without preconcentration step. It is shown that triethanolamine could be accurately detected at a dosage as low as 350 ppm. This molecule and triisopropanolamine were also detected on each of the pure mineral phases of clinker. The experiments suggest that both molecules exhibit different affinities for each of those phases.

KEY-WORDS : Grinding aids, Mechanism, Mass spectrometry

INTRODUCTION

In many cases, grinding aids are used in clinker grinding to decrease the energy consumption to obtain a given fineness or flow of cement. It is supposed that their positive effect stems from the fact that they interact with the surface of the anhydrous phase particles to form a film which prevents agglomeration. However direct evidence and analysis of such an interaction is not straightforward because only minute amounts of grinding aids are added to clinker (< 500 ppm). Hence, so far, precise investigation and deep knowledge of their mechanism of action, with the aim of improving clinker grinding, are rather limited. To achieve a direct route for such an analysis, the Laser Desorption Fourier Transform Mass Spectrometry (LD-FTMS) technique has been used.

EXPERIMENTAL

Chemical

Clinker pure phases (C3S, C2S, C3A and C4AF) were first prepared from laboratory grade calcium carbonate and the relevant oxides mixed in stoichiometric amounts and subsequently sintered at high temperatures. Then they were ground separately in a lab mill, in presence of triethanolamine (TEA) or triisopropanolamine (TIPA) both at the concentration of 500 ppm. The Blaine area values obtained for each sample are indicated in Table 1. The same grinding operations were carried out for an industrial clinker to which 5 weight percent of gypsum had been added. However, in this case, only the detection of TEA (at various concentrations : 350, 500, 1000 ppm) has been investigated.

	C_3S	C_2S	C_3A	C_4AF
TEA	2850	2758	1363	1204
TIPA	2900	2850	1263	1136

Table 1 :Blaine area values (cm^2/g) of the different mineral phases ground for 1 hour in presence of 500 ppm TEA or TIPA.

Fourier Transform Ion Cyclotron Resonance (FT-ICR) laser microprobe

The utilized laser microprobe set-up allows to analyse solid samples. Studied cement and clinker pure phases, which are finely divided powders, were pressed into pellets (5 tons during 20 minutes) for analysis. The obtained samples which were ca. 0.5 mm thickness and ca. 10 mm diameter were fixed on the holder. Analyses were performed on a laser microprobe Fourier Transform mass spectrometer (Muller et al., 1989 and Pelletier et al., 1988). This instrument is a modified, differentially pumped dual-cell Nicolet Instrument FTMS 2000 (nowadays Extrel FTMS millipore, Madison, WI, USA) operating at a 3 Tesla magnetic field strength and coupled with a reflexion laser interface and special sample manipulation hardware.The ionization step was performed using an excimer laser charged with ArF mixture (λ = 193 nm, pulse duration = 23 ns, output energy = 250 mJ) or KrF mixture (λ = 248 nm, pulse duration = 23 ns, output energy = 250 mJ). The laser beam was focused on the sample, which was placed inside the source cell, by means of several internal lenses and an external adjustable telescope. This configuration allows the adjustment of the laser beam diameter from 5µm to several hundreds of µm corresponding to a power density varying between 10^{10} and 10^5 W/cm^2 with an energy at the sample surface of approximatively 60 µJ per pulse. The viewing system, using an inverted Cassegrain optics design, allows sample visualization with X300 magnification (Muller et al., 1989 and Pelletier et al., 1988). A large sample surface can be swept and analysed (ca. 1 cm^2). Coarse and fine *x, y, z* manipulations of the sample stage can be achieved by micromanipulators with the spacial resolution attainable by micrometers.

The experiment sequence used for these analyses was as follows :

- At first, ions are formed by a laser induced ionization in the source cell (residual pressure : $5x10^{-8}$ Torr).
- During the ionization event, the conductance limit is kept as the trap potential (typically +1V) to confine ions to the source side. This conductance limit can eventually be grounded to transfer ions to the analyser side (residual pressure : 10^{-9} Torr) to achieve better resolution in heterodyne mode (Marshall, 1990).
- A variable delay period follows, during which ion/molecule reactions can occur.
- Ions are then excited by a frequency-excitation chirp and the ions image current is detected, amplified, digitized and Fourier transformed to produce a mass spectrum.

RESULTS AND DISCUSSION

At the laser wavelength of 193 nm, the grinding aids (TEA and TIPA) were detected in each of the four pure constitutive phases of clinker. Spectra (fig 1) show the unquestionable detection of TEA in C_2S via the presence of the peak at m/z=118 uma. Concerning TIPA, it could also be undoubtedly detected from the apparition of the peak at m/z=146 uma (fig 1). Indeed, at this wavelength value, the incident photon energy is 6.14 eV and the desorption process of organic molecules is known to be based essentially on a gazous photoionization step. Accordingly, both peaks correspond to the homolytic fragmentation of the alkanolamine βc-c bond as illustrated in figure 2.

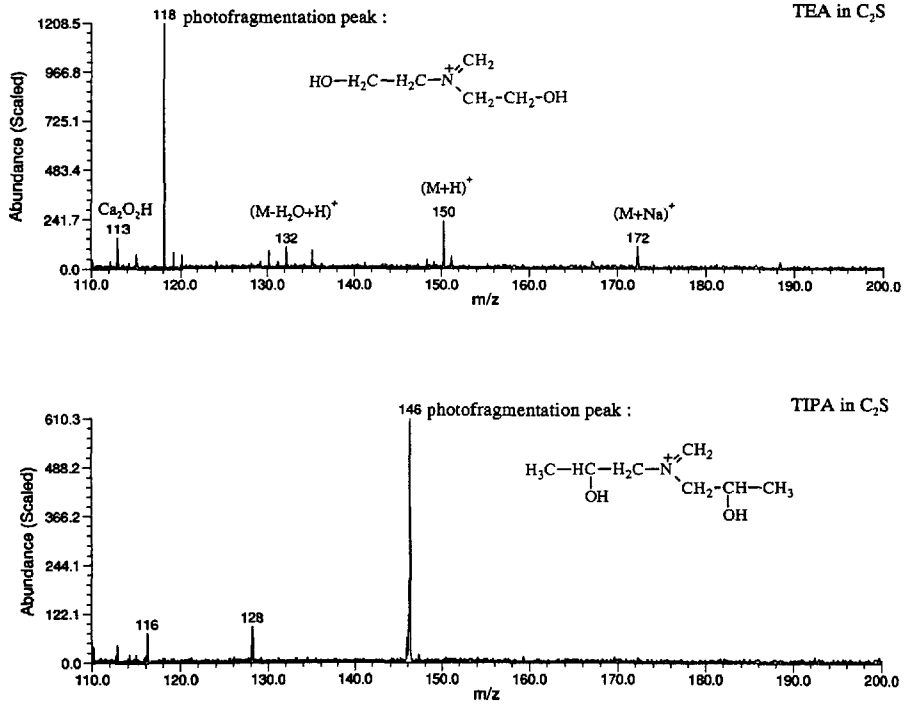

Figure 1 : Mass spectra of TEA and TIPA (500ppm) in C2S.

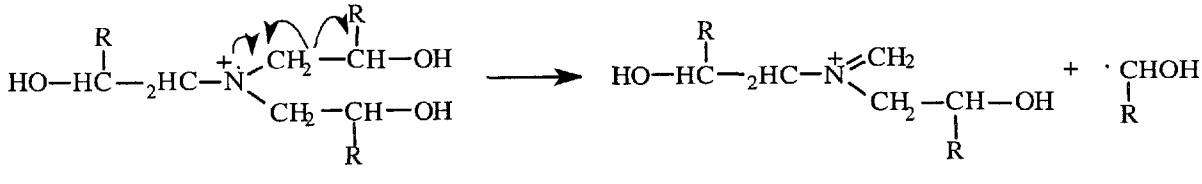

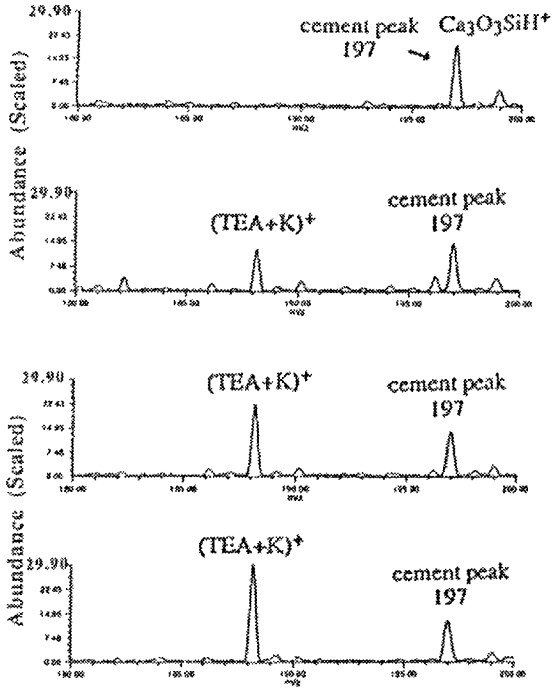

Figure 2: Proposed fragmentation scheme for the studied alkanolamines (For TEA R=H ; For TIPA R= CH_3)

Analysis of the other clinker different constitutives phases (C3S, C3A and C4AF) reveals similar spectral stamps. Observation of the peak intensities of TEA and TIPA (table 2) shows a major difference between C2S and C4AF from one hand, and C3S and C3A from the other hand. For the latter phases, the intensity is an order of magnitude larger than for the former phases, implying a smaller surface affinity for both TEA and TIPA.

	C2S	C3S	C3A	C4AF
TEA	1208	**4969**	**5220**	619
TIPA	610	**4204**	**5210**	661

Table 2 : Comparison of the grinding aid peak intensities in the four studied phases.

As for the industrial clinker, the ionization step has been done at λ = 248 nm (fig. 3). TEA was observed to be detectable at all studied concentrations. Its presence was evidenced by the apparition of a peak at m/z= 188 uma corresponding to the cationized $(TEA+K)^+$ peak, typical of a laser desorption process at this wavelength.

a) cement without grinding aids

b) cement with 350 ppm TEA

c) cement with 500 ppm TEA

d) cement with 1000 ppm TEA

Figure 3 : Mass spectra of TEA in a cement grounded in a lab mill.

It can be shown that the intensity ratio $(TEA+K)^+$ peak / cement peak ($Ca_3O_3SiH^+$, m/z=197) is a linear function of TEA concentration (y = 0.188+0.0024 x ; r=0.98) from which the detection threshold can be estimated at ca. 150 ppm.

QUALITATIVE AND QUANTITATIVE ANALYSIS OF ORGANIC COMPOUNDS IN CEMENT AND HARDENED CEMENT

Akira OHNO and Takanori YAMAMOTO, Sumitomo Osaka Cement CO. LTD.,
Cement/Concrete Research Lab., Japan

ABSTRACT An analytical system using a pyrolysis - gas chromatography / mass spectrometer (pyro - GC / MS) was developed for qualitative and quantitative analysis of organic compounds in cement and concrete. Alkylation treatment was useful for detection of polar compounds which were difficult to analyze by GC. A cryogenic N_2 oven controller was used for analysis of the low molecular weight compounds.

Key-words: Admixtures,Organic,Qualitative,Quantitative

INTRODUCTION

There are many reports about quantitative analysis of organic compounds in hardened cement; Kroone(1971), Commolly(1980), Yilmaz(1989) etc. These methods show good sensitivity and good precision. But these methods usually need complex treatments to separate the organic compounds from the hardened cement. Moreover, these methods are valid only for specific components. We developed a new method using pyro - GC / MS; Ohno(1993). This method is applicable to a multicomponent system and also to qualitative analysis.

THEORY OF PYRO-GC/MS

Organic compounds in hardened cement are pyrolyzed in the Pyrolyzer and move from solid phase to vapor phase. The pyrolysis products in the vapor phase pass through a GC column at a different speed. Then at the detector, each product is detected at a different retention time. When MS is used as a detector, each product is ionized. The mass spectra of each peak is obtained by measurement of the mass of each ion. Each product shows a different mass spectra. Therefore, we can analyze a sample qualitatively from the mass spectrum and quantitatively from the peak area. However, the concentration of admixture in cement is usually very low, and can not be detected by the SCAN mode. In this case, the selected ion monitor(SIM) mode is used. Table 1 shows the analytical conditions of pyro - GC / MS.

Table1 Analytical Conditions

Pyrolyzer	JHP-3(Japan Analytical Industry)
Pyrolysis Temp.	764℃ 10seconds
Gas Chromatograph	HP5890A(Hewlett Packard)
Column	DB-1701(J&W) 30m×0.25mm i.d.
Column Temp.	50～300℃ 25℃／min.
Carrier Gas	He 1ml／min.
Mass Spectrometer	HP5970B(Hewlett Packard)

ANALYSIS OF ORGANIC COMPOUNDS IN CEMENT AND HARDENED CEMENT

Analysis of naphthalene sulfonate formaldehyde condensate(NSF) in hardened cement

Figure 1 shows the chromatogram of NSF solution(1.0wt%). A strong peak is observed at 5.7 min. Figure 2 shows the mass spectra of the peak. The ion with mass / charge = 128 shows the highest

intensity. This means that the mass / charge of the ion which is suitable for SIM of NSF is 128.

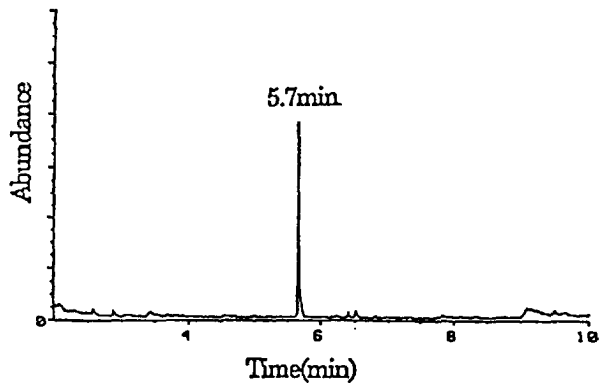

Figure 1 Chromatogram of NSF solution monitored by SCAN mode

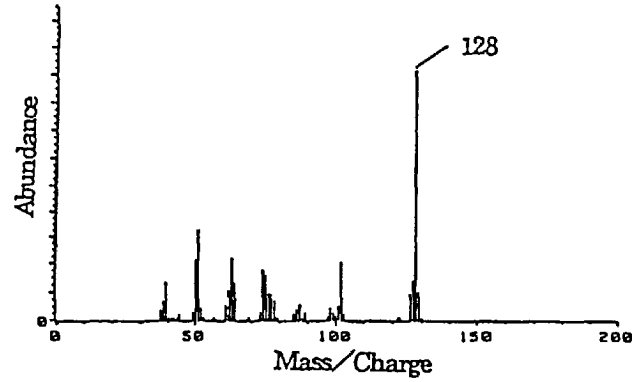

Figure 2 Mass Spectra of the peak at 5.7min

Figure 3 shows the calibration curve of NSF in cement paste monitored by SIM mode. It shows a good linearity. The amount of NSF in hardened cement can be analyzed by using this calibration curve. The kind of admixture also can be analyzed by using a data base of mass / charge for SIM and retention time of available admixtures.

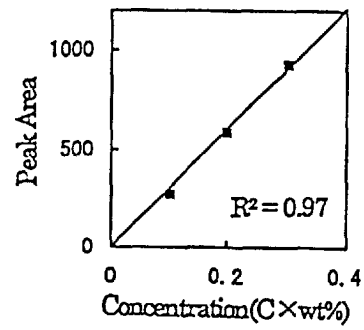

Figure 3 Calibration curve of NSF in cement paste monitored by SIM mode (Mass/Charge = 128)

Analysis of polar compounds

Methylation treatment of polar compounds

The compounds which have many hydroxyl or carboxyl groups, such as a sodium gluconate(SG) are usually difficult to analyze by GC due to their high polarity. Many organic admixtures contain such polar compounds. Alkylation of these polar compounds was effective treatment for analysis; Challinor(1989) etc. We used tetramethylammonium hydroxide(TMAH) as an alkylation aid. Eq 1 shows the methylation reaction of polar compounds by TMAH.

$$\text{R-OH} \xrightarrow[\text{heating}]{\text{TMAH}} \text{R-OCH3} \qquad [1]$$

$$\text{R-COOH} \xrightarrow[\text{heating}]{\text{TMAH}} \text{R-COOCH3} \qquad [2]$$

Analysis of SG in hardened cement

Figure 4 shows the chromatogram of the SG solution(1.0wt.%) and mass spectra of the main peak monitored by SCAN mode. No peak was observed without treatment. However, a large peak was obtained by methylation of SG. Figure 5 shows the calibration curve of methylated SG in cement paste monitored by SIM mode(mass / charge = 159). It shows a good linearity. These findings show that the methylation is effective treatment for analysis of polar compounds in hardened cement.

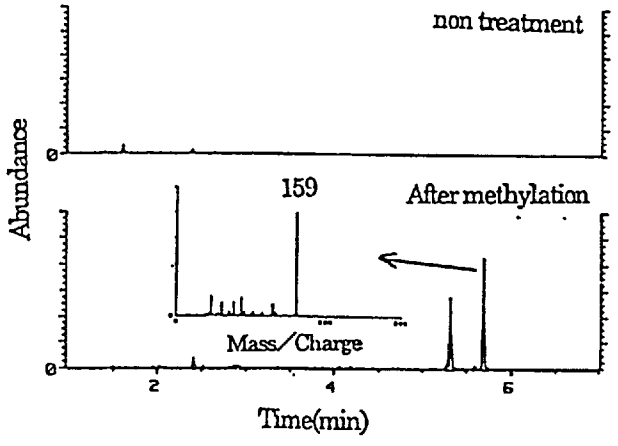

Figure 4 Chromatogram and Mass spectra of the main peak of SG solution monitored by SCAN mode

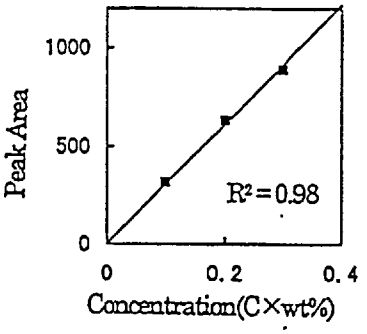

Figure 5 Calibration curve of SG in cement paste monitored by SIM mode (Mass/Charge = 159)

Analysis of low molecular weight compounds

Use of cryogenic N_2 oven controller

The boiling temperature of the pyrolysis products of the low molecular weight compound is very low. The retention time of these products is very short and peaks overlap with the. peak of CO_2 gas. Decrease of column temperature delays the retention time of product. However, usually analysis by GC is impossible under room temperature. We used cryogenic N_2 oven controller to separate the peak of products from that of CO_2. This apparatus can cool the column under 0 ℃.

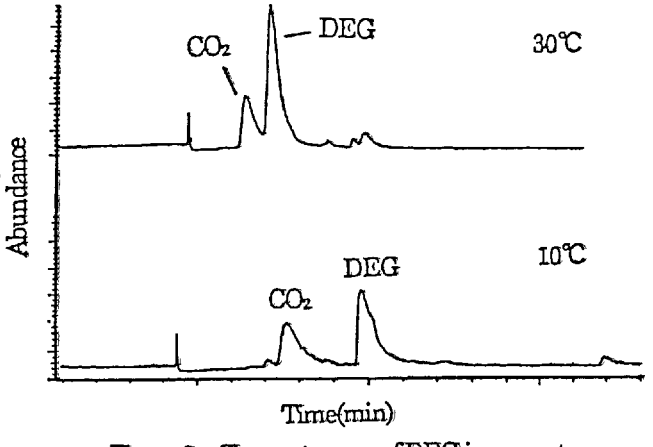

Figure 6 Chromatogram of DEG in cement monitored by SIM mode (Mass/Charge = 31)

Analysis of diethylen glycol(DEG) in cement

DEG is usually used as a grinding aid of

cement clinker. Figure 6 shows a chromatogram of DEG in cement(0.02wt%) measured at 30℃ and 10℃ using a cryogenic N_2 oven controller. Partially overlapped peaks of DEG and CO_2 were completely separated into each peak at a low temperature.

CONCLUSION

The pyro - GC / MS method is superior for qualitative and quantitative analysis of organic compounds in hardened cement. Polar compounds can be detected by methylation of samples. The cryogenic N_2 oven controller is useful for the analysis of low molecular weight compounds.

CALORIMETRIC ANALYSIS IN THE CHEMISTRY OF CEMENT

Alexander USHEROV-MARSHAK, State technical University of Building and Architecture, Kharkov, Ukraine

ABSTRACT There has been carried out the analysis of the possibilities of employing calorimetry in the cement chemistry and technology at the stages of its production and hardening. There are discussed some results of the thermokinetic and thermodynamic approaches to the studying of the early cement hydration stages and formation of cement stone microstructure. An accent is put on the necessity to solve some conceptual problems of cement chemistry within informative technologies and expert systems.

KEY-WORDS: Calorimetry, Heat evolution, Hardening, Method, Hydration

INTRODUCTION

Calorimetry is one of the most objective and informative methods of research in chemistry and technology of cement (Schwiete and Roth, 1973, Mchedlov-Petrossian et al, 1984). The cement binding properties are predetermined by thermodynamic instability and crystal-chemical nature of minerals. Hydration is a typical slow-going unbalanced process with exothermal nature of reactions. Heat evolution at phenomenological level depicts the effect of technological factors at the stages of manufacturing and hardening of cements.

In spite of essential importance and great volume of the stored calorimetric information the cement chemistry still remains incomplete. Estimation of the technological factors effect, approximation to the description of hydration mechanism and kinetics, creation of the computer data and knowledge bank on the hardening process and properties of cements - are just the main objects of calorimetry.

METHODS OF CALORIMETRIC ANALYSIS

To study hydration heat data, rate and completeness of heat evolution use is made of isothermal, adiabatic (thermos) and scanning calorimetric methods (Hemminger and Höhne, 1984). Chemical thermodynamic and heterogeneous kinetics, modelling and information science are also applied to interpret experimental data.

The most widely used method now is differential microcalorimetry, i.e. highly sensitive method of continuous measurement of minor quantities of hydration heat. The specifics of the dispersion interaction in "cement-water" system makes it necessary to consider thermodynamic instability of the reagents. Before the reaction they are isolated from one another. There should be provided equally accessible despersion phase and dispersion condition, total wetting of cement irrespective of W/C. To meet the requirements there were elaborated special loading devices to locate, isolate, bring into contact and mix reagents (Usherov-Marshak, 1984).

Fulfilment of the above conditions makes it possible to carry out correctly the thermokinetic analysis (TKA). In doing so (Fig 1) we can solve problems at 5 and even more levels (Usherov-Marshak and Sopov, 1995). The first one is to form the basic thermokinetic dependences - $dQ/d\tau=f(\tau)$ and $Q=f(\tau)$. The second level is the conceptual discrimination of induction, accelerated and retarded periods of reactions. This approach makes its possible to classify

the reactions as fast or slow-going on a non-formal basic. A long-term prediction of heat evolution depending on Q=f(τ) refers to the third level of TKA.

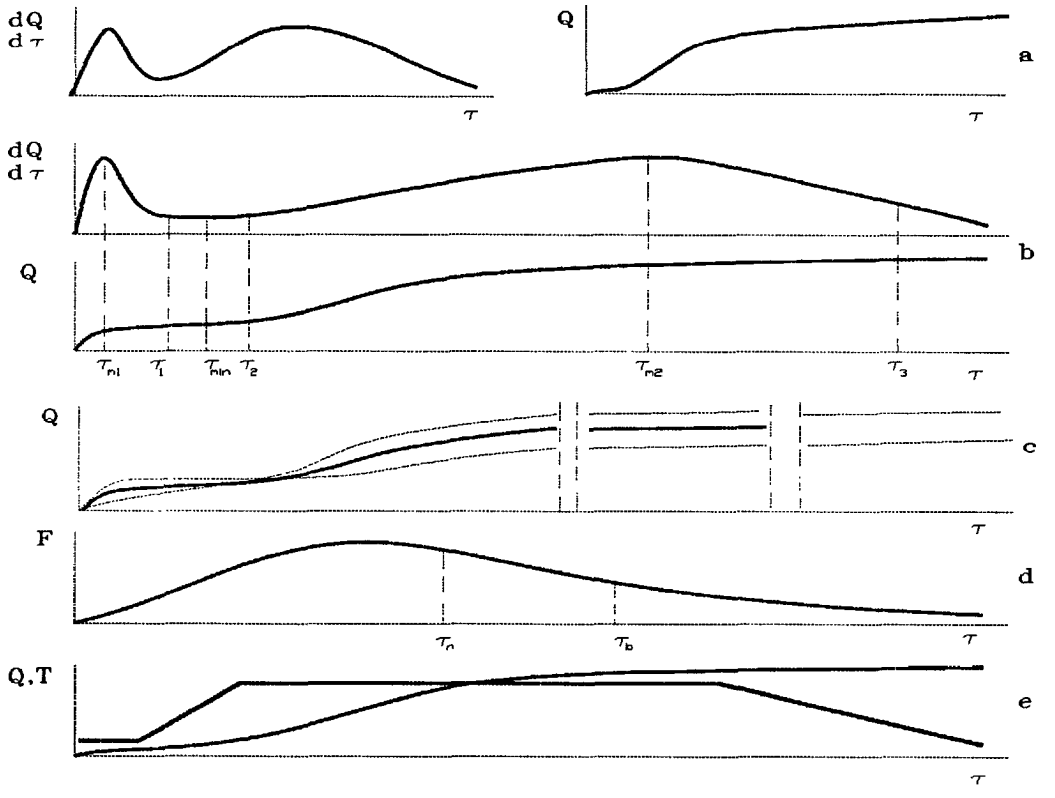

Figure 1 Levels of Thermokinetic analysis.
a - Treatment of the experimental results. Thermokinetic dependences.
b - Pick-out of the typical stages.
c - Prognosis of the heat evolution.
d - Building of the kinetic models.
e - Nonisothermal dependences.

The three level data are required to calculate the cement hydration (transformation) rate and degree in case of kinetic modelling and description of reactions at the 4th level. Its development provides for plotting of selfcoordinated models (Usherov-Marshak and Korobov, 1990) since it lacks a common mechanism monitoring the hydration at any stages of hardening. Here it is necessary to mention the incomplete and insufficient character of the works by Kondo and Ueda (1968), Pommersheim and Clifton (1979). Their approach to the problem is based on simplification, physical and mathematical description of a period selected formally by means of a single law, i.e. that of crystallization, diffusion, etc. The classical selection of the hydration stages according to Kondo (1968) is not universal.

The fifth level of research solves the problem of obtaining the thermokinetic dependences for nonstationary temperature conditions of any hardening mode (Usherov-Marshak and Sinyakin, 1992). At the successive levels of TKA it is expedient to find out quantitive interrelation of heat evolution readings with the structural strength and durability.

Attempts were made to use the differential scanning calorimetry (DSC) for estimation of the phase transformations, icebuilding, parameters of microstructure within the range of 2-10 nm. We have employed the lowtemperature poremetric method (Usherov-Marshak and Sopov, 1994) on the basis of concepts of the surface phenomena thermodynamics. The dependence of water crystallization, temperature (T) in pores and capillars of cement stone on their radius (Rn) is estimated accounting for the thermodynamic balance of water and ice. The experimental results help to determine the temperature of "water-ice" phase transitions, the apparent crystallization energy, the volume and distribution of micropores with respect to their dimensions and under certain assumptions the shape of pores (Fig 2).

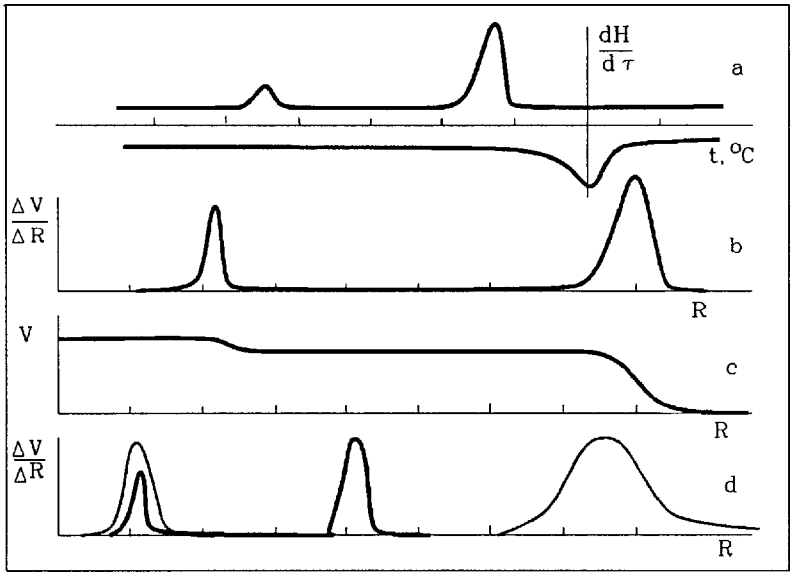

Figure 2 Levels of thermodynamic analysis.
a - Water crystallization (1), melting of the ice (2).
b - The pore-distribution by their dimensions.
c - Volume of the micropores.
d - The pore-distribution on their forms.

THERMOKINETICS OF THE HYDRATION EARLY STAGES

One of the advantages of the calorimetric research consists in obtaining reliable results without interfering with the processes of hardening, without stopping them, destroying the samples, etc. This is essentially important at the earliest stages when the hydratation degree is rather small and identification of the reaction products is difficult.

The hydration of minerals and polymineral cements is not equally studied. Comparative analysis of the results of thermokinetic experiments made by various authors is rather complicated due to non-identity of the studied samples. There are no standard samples in the cement chemistry. Therefore reproduction of results even for the "model" binding agent $CaSO_4 \cdot 0.5H_2O$ is rather low.

The physical and chemical peculiarities of the hydration of α and β modifications of semihydrate of calcium sulphate, the constancy of Q/α ratio during the whole process (1.5-3 hours) enable to use the conceptual modelling. The well-known models of Avraami-Yerofeev, Ridge and Schiller had been tested for fitness to experimental data. The position of Q_{max} (α_{max}) on the

dQ/dτ=f(Q) dependence proves the validity of the concept of the nucleus formation limiting stage. Its rate varies according to the exponential law with regard to "compressing" sphere model. Other models proved to be nonvalid.

Previously we have shown certain limitation in accepting Avraami-Yerofeev model to describe C_3S hydration within α=0.03-0.13 narrow interval. Calculation of the values of ΔG^+ apparent energy activation and ΔS^+ free entropy activation proved the nucleus formation limiting function. By its behaviour the C_3S solid solution hydration is analogous to estimated (test) dependences (Fig. 3). But the value of first exoeffect is lower which correlates with the replacing ion hydroxide solubility. It is quite probable that in the process of transition into a solution the modelling ions make up nucleus formation, i.e. the centers of $Ca(OH)_2$ early crystallization. Duration of induction period becomes shorter. The utmost hydration completeness is typical for C_3S solid with Ca^{2+} and Ba^{2+} ions. The data analysis using Avraami-Yerofeev model had proved heterovalency substitutions of Ca^{2+} ions with Fe^{3+}, Mn^{3+}, Al^{3+}, S^{6+} do not change the reaction rate constsant. In case of isovalency substitution with Cd^{2+}, Ba^{2+}, Ni^{2+}, Co^{2+} ions the reaction rate constant increases in proportion to the admixtured ion radius value. TKA makes it possible to quantitatively estimate the effect of the modifying oxides.

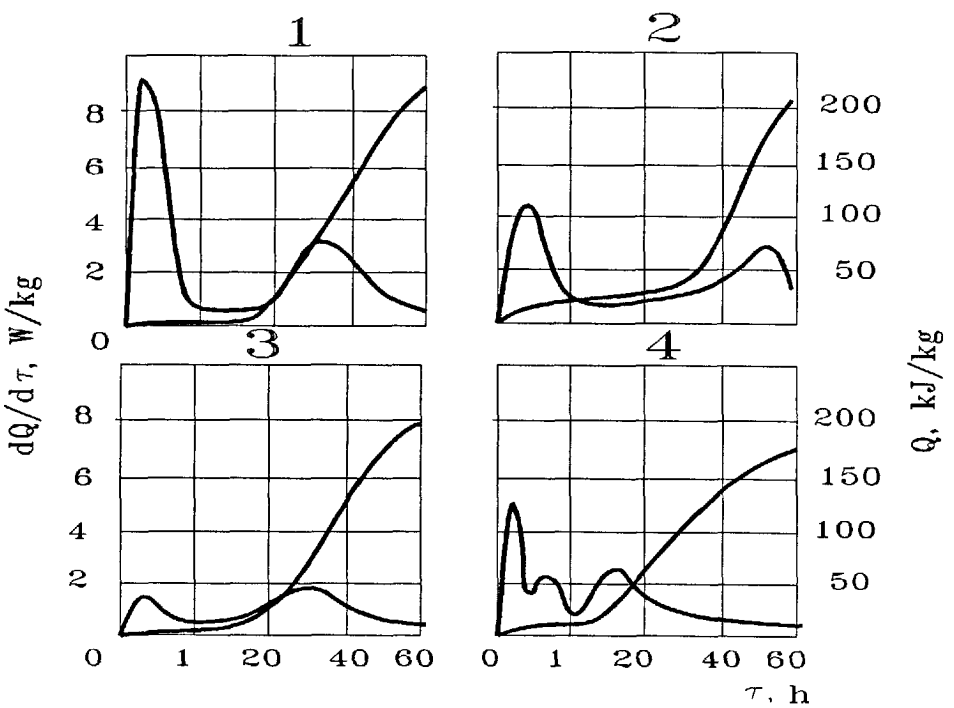

Figure 3 Thermokinetics of hydration of the solid solution.
1 - C_3S; 2 - C_3S + CaO; 3 - C_3S + Fe_2O_3; 4 - C_3S + Al_2O_3

Heat evolution of clinker aluminate phases is studied not so well. Reactivity of $CaO-Al_2O_3$ system minerals decreases in the $C_3A > C_2A_7 > CA > CA_6$ series. The $dQ/d\tau=f(\tau)$ dependence behaviour is complex and diverse (Fig. 4). This is linked with formation and recrystallization of the C_4AH_{13}, C_2AH_8 and C_3AH_6 type hydroaluminates, temporary existence of $Al(OH)_3$ as gibbsite and bemite. During C_3A hydration no induction period is fixed. The $C_{12}A_7$ hydration is determined by C_4AH_{13} recrystallization into C_3AH_6. Additional exoeffect is marked. The CA hardening thermokinetic curves are typical for the processes with clearly manifested induction period. This is explained by certain difficulties of hydroaluminate crystallization in $Al(OH)_3$ gel medium. The experiment had manifested differences in the kinetics of early hydration of the crystal and amorphous structure calcium aluminates obtained as a result of clinkering or melting. The reaction intensity of the minerals resulting from melting is somewhat lower.

The thermokinetics of hardening of certain minerals in which $CaSO_4 \cdot 2H_2O$ is present as well as of their mixtures is naturally more complicated. Yet their phase transitions are easily evident and identified. For instance, transformation of the calcium highsulphate hydrosulphate aluminate into monosulphate.

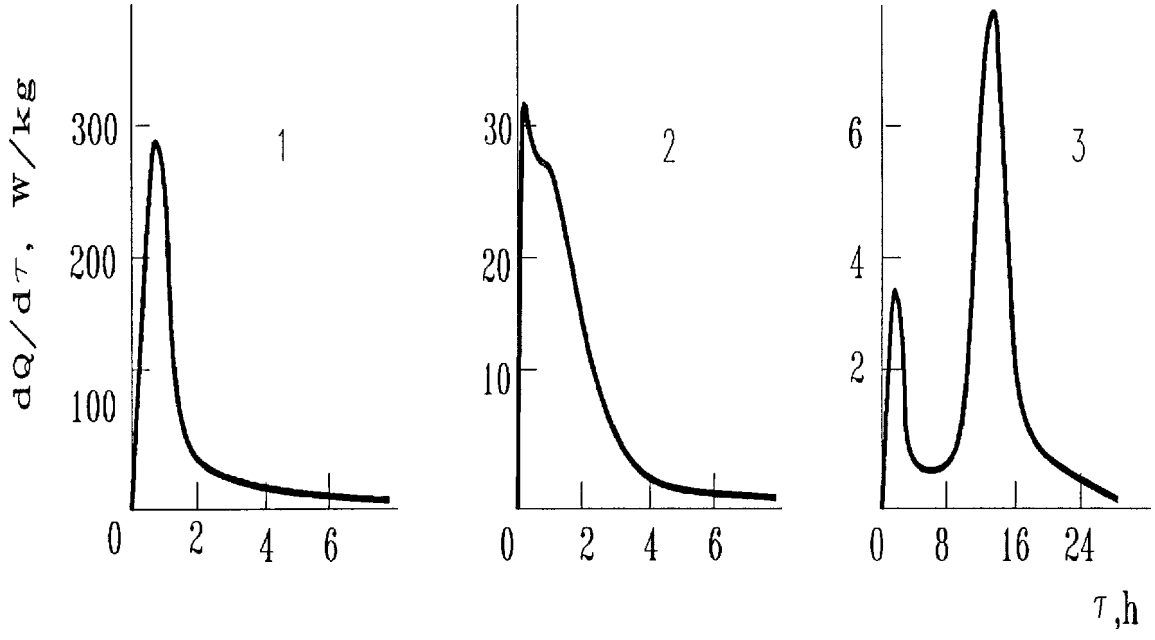

Figure 4 Thermokinetics of hydration of the calcium-aluminates.

Theoretically and practically the TKA of cement hydration with chemical admixtures like plasticizers, hardening promoters or inhibitor introduced at the stages of cement and concrete production is highly effective (Ramachandran, 1984, Wilding et al, 1984). Technological results of their effect are associated with manifistation of exoeffects as well as intensity and duration of early hydration major stages.

It is known that the surface-active substances, i.e. the base of plasticizers and superplasticizers, change to a great extent the process of the hydration elemental acts, namely, adsorption, nucleus formation, crystallization, etc. The plastification mechanism consists in surface-active substances adsorption by hydrates and its effect is determined through the molecular mass and the degree

of polycondensation of the oligomers of which the plasticizer is composed. An increase in polynaphthalenesulphonates molecular mass results in the proportional growth of the first exoeffect value at the expense of the dispersive action and better wetting conditions of C_3S. The time of the second exoeffect is displaced by a few to 350h. An increase in duration of the induction period from several up to 300 hours is quite natural. The intensity of reactions is reduced, the hydration is actually blocked, and, simultaneously the mixture water consumption falls down.

TKA provides for a better understanding of this mechanism and motivation of the new methods of obtaining highly effective binding substances by implementing surface-active agents when grinding cement. This results in mechanochemical activation of cement (Usherov-Marshak and Bondar, 1992) although the C_3S and C_3A initial hydration intensity and completeness are reduced (Fig.5). It is evident that some changes of the hardening elemental acts, shown by calorimetry, are the reason for increasing the binding properties efficiency. They are termed as low-water-requirement binder. In this case up to 70% of the clinkers can be replaced with the inert dispersive components.

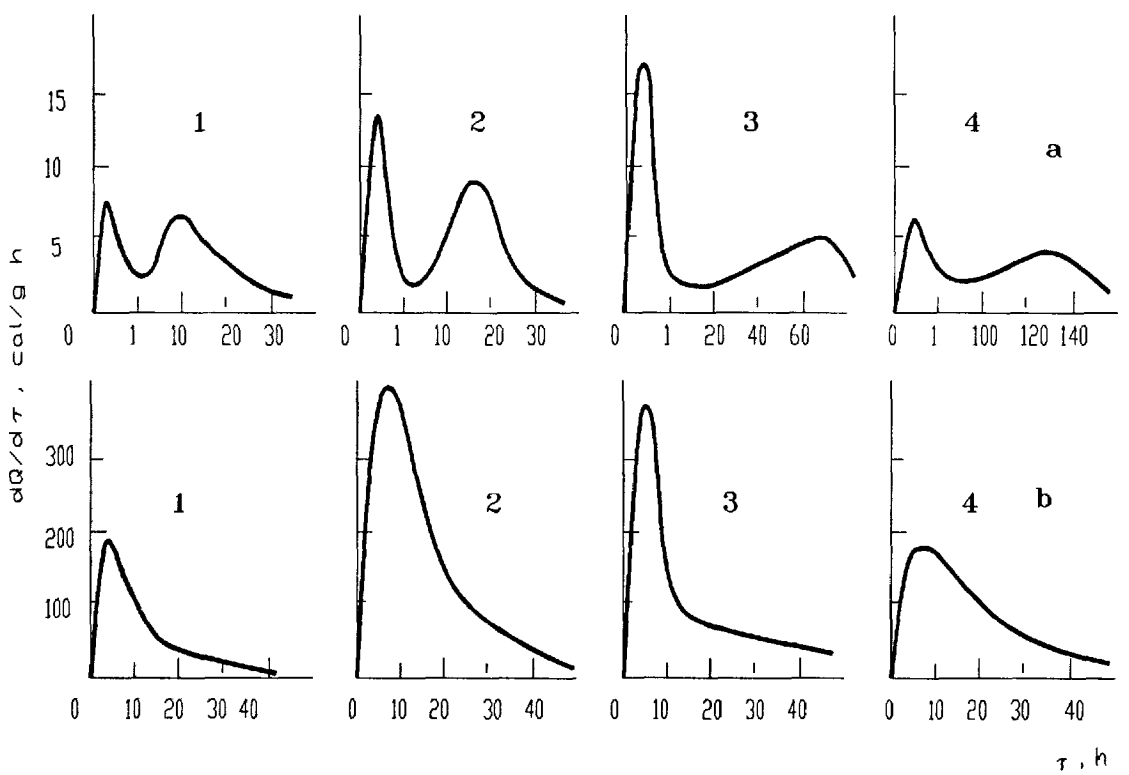

Figure 5 Thermokinetics of hydration.
a - tricalcium silicate; b - tricalcium aluminate
1 - initial mineral; 2 - post-grinding mineral;
3 - the same with surfactant, added with water of mixing;
4 - mechanoactivated binder.

The kind and concentration of the cement and concrete admixtures define the manifistation moment, intensity and duration of the heat effects. This phenomenon is termed by us as the "thermokinetic selectivity" of the admixtures effect and allows to classify the admixtures quantitatively.

The temperature factor is of special importance in hardening. Calorimetry provides for studying the early hydration within the interval of 5-180 ^{0}C. This is the hardening interval of the accelerated hardening cements under higher temperatures, in steam-and-pressure cured conditions, for grouting cement (Bensted and Ankett, 1990). At this the hydration scope decrease was recorded. For C_3S it equals 60-70 ^{0}C, for CA it is 40-50 ^{0}C. It was demonstrated that a somewhat retarded hydration of minerals and cements due to surface-active substances does not affect the binding properties at 80-90 ^{0}C. The effect estimation of the isothermic and nonstationary conditions of the cement hardening will be considered in a special report to be delivered at this Congress.

In recent years a new impulse has been given to the TKA hydration of the slagcontaining substances including slag-alkaline and binding ones (Usherov-Marshak et al, 1994, Shi and Day, 1995). The initial endoeffect - the result of the presence of the primary part of solution - fixed at the thermokinetic dependences. But this is a matter of special research. The experiment results interpretation is not always correct (Schutter and Taerwe, 1995). It is caused by the uncorrect interpretation of the 3 rd exo-effect on the dependence $dQ/d\tau = f(\tau)$.

THERMOCHEMICAL AND THERMODYNAMIC ANALYSIS

Thermochemical analysis of cements has not undergone any substantial changes as compared with the classical works by Eitel. Definition of the cement hydration heat with the help of the solution calorimetry methods, as was proved by CemBuro's research, does not exclude substantial errors in the results. This is caused by methods of the samples preparation, calibration of the calorimeters used, etc. Yet, the method is approved as the international one.

The potential of the above said thermodynamics of phase transitions and of scanning calorimetry is still poorly employed in the cement and concrete chemistry and technology. The method of differential scanning calorimetry is more often used instead of thermal analysis to identify icebuilding and the hydration degree. The differential scanning calorimetry as a method of thermoporometric research is more perspective in studying the cement stone structure. Microporosity and the laws of its formation also make a topic for a report at the Congress. Here we should mention high effectiveness of the microporosity calorimetric analysis from the viewpoint of the quantitive confirmation of correctness (validity) of the known kinetic diagrams of formation, interactions and changes in hydrosulphatealuminate, hydroaluminate and hydrosilicate structure types in the process of cement hardening. At some previous Congress the researchers dealt only with the morphology description and the material composition of new formations.

CONCLUSION

The further development of calorimetry is associated with the conceptual problems of cement and concrete chemistry. This includes standardization of samples, uniformity of the experimental conditions and interpretation.

From year to year the importance of calorimetric data to be stored in international computer data banks and informative storing systems will gain even greater value in data processing technologies and expert systems (Fronsdorff and Clifton, 1988, Usherov-Marshak and Sinyakin, 1994). The calorimetric centre of Kharkov Civil Engineering and Architecture University is willing and ready to cooperate.

THERMOPOROSIMETRY IN THE PORE ANALYSIS OF CONCRETE

Seppo MATALA, Helsinki University of Technology, Concrete Laboratory, Finland

ABSTRACT A calculation method to analyze the pore volume and pore size distribution in concrete based on thermoporosimetry was developed. A hypothetical pore size distribution typical for concretes was used in the determination of the correction factor of the entropy changes due to the superficial phase transformations. The paper presents theoretical background of the method, and discusses on the validity of the method.

Key-words: Porosity, Pore structure, Thermoporosimetry, Low temperature, Calorimetry

INTRODUCTION

In studies of the pore structure, the selection of the testing procedure is of great importance. Each method has its own limitations. The conventional mercury intrusion method used mostly in the characterization of pore structures able to detect pore sizes over 2 to 4 nm in radius. This method, however, is quite sensitive to the preparation of samples, and the need to dry the sample beforehand obviously changes the pore structure of the finest pore range. During the last twenty years, thermoporosimetry has been used in the characterization of pore structure of cement based materials, e.g., by Fagerlund (1973), Sellevold (1980), Bager (1984), Beddoe and Setzer (1990) and Setzer (1990). These methods are based on the utilization of Kelvin's equation, and in the entropy of phase transformation, the effect of the superficial phase transformations on the entropy changes were neglected. Brun et al. (1977) included these factors in the method. On the basis of the aforementined research the calculation method was further developed. In this paper theoretical background of the method is presented and discussed. A full description of the method is presented in the reference Matala 1995.

THERMOPOROSIMETRY IN THE PORE ANALYSIS

Theoretical basis

Brun et al. (1977) have derived a differential equation for the triple point temperature dependent on the entropies and volumes of three phases (liquid, solid and gaseous) and on the free surface extension energies and curvatures of two interphases (solid-gas and solid-liquid) as follows:

$$\left(\frac{S_s - S_g}{V_s - V_g} - \frac{S_l - S_s}{V_l - V_s}\right) dT = \frac{V_g}{V_g - V_s}\, d\left(\gamma_{sg} \frac{dA_{sg}}{dV_g}\right) - \frac{V_l}{V_l - V_s}\, d\left(\gamma_{sl} \frac{dA_{sl}}{dV_l}\right) \qquad [1]$$

where S and V are the specific entropy and the volume of phases, subscripts l, s and g denote the phases liquid, solid and gas, γ is surface tension and dA/dV is the curvature of the interphase. Eq 1 shows that the curvatures of two of the three interphases should be known in order to calculate the triple point temperature in a general case. In the special case where the solid-gas interphase is plane and its curvature is zero, as in the case of full saturation, the Eq 1 can be presented in the form:

$$\Delta S_f\, dT + V_l\, d\left(\gamma_{sl} \frac{dA_{sl}}{dV_l}\right) = 0 \qquad [2]$$

where ΔS_f is the solidification entropy of the condensate. Assuming that solidification takes place by nucleation in a porous saturated material, the curvature of the nucleus equals that of the

pore radius subtracted by the thickness of the layer where phase transformation cannot take place. If the interphase has a spherical shape, the curvature dA_{sl}/dV_l equals $-2/R_n$, where R_n denotes the radius of the nucleus and Eq 2 can be expressed as:

$$R_n = 2 \cdot \gamma_{ls} \Big/ \int_{T_0}^{T} \frac{\Delta S_f}{V_l} dT \qquad [3]$$

Numeric formulation of the solidification energy

The measurable solidification energy of pore water can be evaluated theoretically if the change of entropy during phase transformation can be formulated. In a fully water saturated porous system the solid-gas interface is plane, and the change in entropy of the water-ice system of pores for temperature change $T_0 \rightarrow T$ and for the corresponding changes in pressure of liquid phase $P_0 \rightarrow P_l$ and solid phase $P_0 \rightarrow P_s$ can be expressed by the equation:

$$\Delta S_f = \Delta S_{f0} + \int_{P_l}^{P_0} \left(-\frac{\partial v_l}{\partial T} \right)_P dP + \int_{T}^{T_0} \left(\frac{c_l}{T} \right) dT + \int_{T_0}^{T} \left(\frac{c_s}{T} \right) dT + \int_{P_0}^{P_s} \left(-\frac{\partial v_s}{\partial T} \right)_P dP \qquad [4]$$

The first term in Eq 4 is the basic entropy and the second and the fifth term represent the effects of the compression heat of phases due to the change in pressure, assuming that the phases are incompressible. The third and the fourth term take into account the changes in the specific heat of the liquid and solid due to the depression of temperature. Eq 4 can be rearranged into the following form :

$$\Delta S_f = \Delta S_{f0} + \int_{T_0}^{T} \left(\frac{c_s - c_l}{T} \right) dT + \left[\left(\frac{\partial v_l}{\partial T} \right)_P - \left(\frac{\partial v_s}{\partial T} \right)_P \right]_T \cdot (P_s - P_0) + \left[\left(\frac{\partial v_l}{\partial T} \right)_P \right]_T \cdot (P_l - P_s) \qquad [5]$$

In Eq 5 P_s is the vapor pressure of ice at temperature T, and P_l-P_s can be expressed by Laplace's equation:

$$P_l - P_s = -\frac{\gamma_{ls}}{R_n} = -\int_{T_0}^{T} \left(\frac{\Delta S_f}{v_l} \right) dT \qquad [6]$$

Brun et al. (1977) noticed that Eq 5 is not fully accurate when the solidification of ice is considered. It does not take into account the effect of the entropy of superficial phases. During the solidification of ice there occur changes of interphase between the layers that do not freeze and the adjacent phase (water before solidification and ice afterwards). Brun (1977) derived the correction factor of entropy due to this additional entropy variation by considering the equality of chemical potentials and the equilibrium of three interphases at triple point. We derived a new relationship between the temperature depression and the enthalpy in the solidification of pore water. The comprehensive derivation of the solidification enthalpy is presented in the reference Matala (1995b). It is based on the numeric formulation of Eq 5, but the effect of superficial phase transformations on the total entropy has been considered in a way that is more convenient for the pore structure of concrete. Since this increase in entropy is a function of the pore geometry, the correction factor was derived in our study by utilizing a hypothetical pore size distribution corresponding to the finest capillary pore structure of cement pastes and mortars. In thermoporometric approaches of the first generation, the effect of the superficial phase transformations on the total entropy has been neglected although its influence may be within the

limits of 20% to 40% of the total entropy, depending on the pore structure (Matala 1995b). The finer the pore structure and the lower the temperature, the higher this effect is.

Using the linearized correcting factor due to the entropy changes of the superficial phase transformations and multiplying this by the equation derived by Brun, the numeric expression for the entropy at the nucleation point was developed into the following form:

$$\Delta S_{f\,np} = \frac{(1+0.004\cdot\theta)\cdot\left[-1.2227-4.889\cdot\ln\left(1+\frac{\theta}{T_0}\right)+10.124\cdot10^{-3}\cdot\theta+1.265\cdot10^{-5}\cdot\theta^2\right]}{1-4.556\cdot10^{-5}\cdot\left(\theta-0.227\cdot\theta^2\right)}, \qquad [7]$$

where θ is the freezing point temperature in °C. The enthalpy at nucleation point $W_a=(273.15+\theta)$ $\Delta S_{f,np}$ has been presented in Fig 1 together with the enthalpy values proposed by other investigators. Numerically, the solidification energy W_a based on Eq 7 can be expressed within the temperature range $0 > T > -60°$ C by a quadratic equation:

$$W_a = 334+4.83\cdot\theta+0.0125\cdot\theta^2\,, \qquad [8]$$

where W_a is expressed in J/g and θ in °C. The enthalpy proposed by Fagerlund in Fig 1 differs from the values given by Eq 8 and proposed by Brun since Fagerlund's expression neglects the effects of superficial phase transformations and compression heat of phases. The difference between Eq 8 and Brun's expression is due to different assumptions in the determination of the entropy of superficial phase transformations. Brun's correcting factor is a function of surface tension of liquid-solid interface and temperature depression. At a specified nucleation point, it corrects the entropy values of the superficial phases in previously frozen pores by an amount dependent on the surface tension of the nucleating pore. Obviously, this overestimates the effect of superficial phase transformations on the entropy values for the wide range pore structure normally observed in cement pastes, but Brun's equation gives correct values with the pore structure in the vicinity of the nucleation point. The hypothetical pore structures used in the testing of Brun's equation were very fine for ordinary cement pastes and mortars observed by different testing methods. A coarser pore size distribution resulted in an increase of 20% at -50° C for the entropy at the nucleation point, and the curve was approximately linear. Theoretically, the way by which the correction factor was determined is not absolutely correct since it is a function of pore size. However, this approximation must be used for the calculations. Otherwise, the calculations consist of a very complicated iterative process, where the correct pore size distribution must be derived step by step and the entropy of the previous pore system should be taken as a starting value for the next calculation step.

Pore size distribution in thermodynamic approach

The relation between an ice sphere R_n and freezing point temperature θ can be calculated using Laplace's equation [6], which gives the relationship between the difference in the vapor pressures of the liquid and solid and the surface tension of liquid-solid interface and its curvature. In the literature, there are many contradictory proposals for the values of surface tension between water and ice. Eq 9 is derived from experimental values presented in the literature at temperatures from 0 to -30° C. In that γ_{ls} is expressed in N/m and θ in °C. The relation between the ice sphere R_n and freezing point temperature θ can be calculated directly from Eq 3 by applying the

relationships derived before and inserting the equations of γ_{ls} (Eq 9), $\Delta S_{f,np}$ (Eq 7) and v_l (Eq 10) into Eq 3 and setting $T\text{-}T_0 = \theta$.

$$\gamma_{ls} = (36 + 0.25 \cdot \theta) \cdot 10^{-3} \qquad [9]$$

$$v_l = 1.000132 \cdot (1 - 9.1 \cdot 10^{-5} \cdot \theta + 1.035 \cdot 10^{-5} \cdot \theta^2) \qquad [10]$$

Since all the parameters in Eq 3 are expressed as a function of temperature, the numeric integration is possible. The relationship between ice sphere radius and temperature according to Eq 3 is presented in Fig 4, and it can be expressed by quadratic Eq 11 with good accuracy.

$$R_n = \frac{-2 \cdot (36 + 0.25 \cdot \theta)}{1.222 \cdot \theta + 0.0068 \cdot \theta^2 - 8.67 \cdot 10^{-7} \cdot \theta^3} \qquad [11]$$

The ice sphere radius as a function of nucleation temperature is strongly dependent on the assumptions taken in the evaluation of the surface tension of the water-ice interphase. It gives clearly smaller values for the ice sphere than the equations based on the surface tension of the liquid-vapor interphase, e.g., Fagerlund's expression (Fig 2).

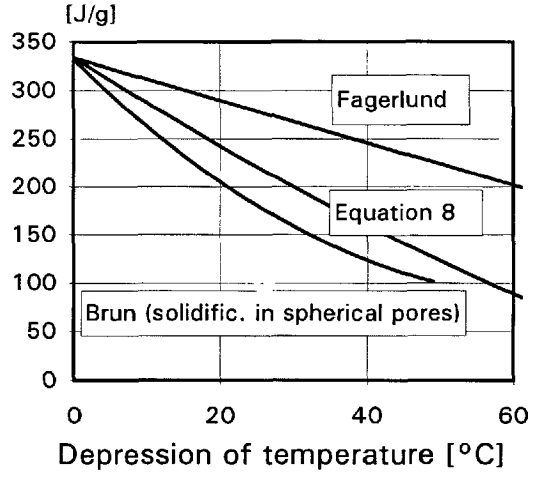

Figure 1. Enthalpy at nucleation point for spherical pore structure.

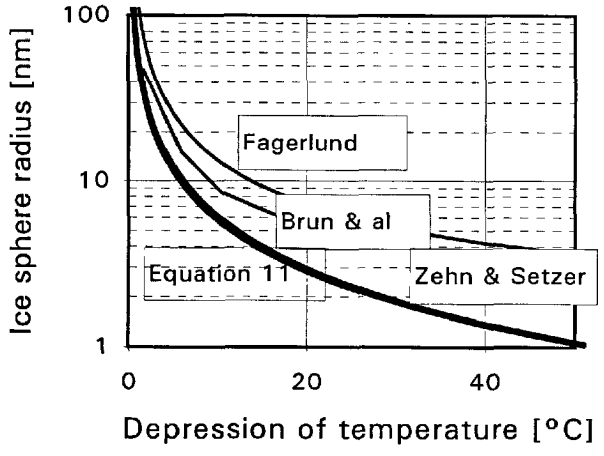

Figure 2. Different expressions for the size of ice sphere radius.

Fig 2 shows that the curves calculated by Eq 11 and by the method presented by Brun deviates only somewhat from each other. This is due to the fact that, although the entropy in Brun's equation differs markedly from the entropy value used in Eq 7, this effect is compensated by the higher value of surface tension .

When the ice sphere radius R_n has been formulated as a function of temperature depression, the pore size R_p can be calculated if the thicknesses of the adsorbed water layer and the liquid-like layer are known. Fagerlund (1973) has derived Eq 12 for the adsorbed water layer:

$$t_{ad} = 1.97 \cdot \sqrt[3]{1/(-\theta)} \ , \qquad [12]$$

where t_{ad} is expressed in nm and θ in °C. A new formula for the thickness of the liquid-like layer was derived starting from Takagi's quintic equation (Takagi 1990). A general

approximation for the thickness of the liquid-like layer δ [nm] as a function of the radius of ice sphere r_{ice} [nm] and temperature depression θ [°C] is as follows:

$$\delta = \frac{0.9 + 0.1 \cdot \log r_{ice}}{\frac{3}{(\log r_{ice})^{0.938}} + \theta \cdot \left(0.07 \cdot \log r_{ice} - 0.0365 + \ln \sqrt[3]{\frac{\log r_{ice} + 0.12}{\log r_{ice} - 0.12}} \right)} \quad [13]$$

The total thickness of the adsorbed water and the liquid-like layer of ice sphere can be calculated by summing Eqs 12 and 13. Fig 3 shows the magnitude of this layer as a function of temperature depression at the nucleation point.

Now, the pore size R_p can be calculated by adding the values of the adsorbed water layer and the thickness of the liquid-like layer to the value of ice sphere radius (Eq 11). For a spherical pore shape and always during nucleation, R_n is taken directly from Eq 11. In fusion, for a cylindrical pore, the multiplier 2 in the numerator of Eq 11 vanishes according to Laplace's equation. The curves for the spherical and cylindrical pore radii in nucleation and for the cylindrical pore radius in fusion are presented in Fig 4. The direct relationship between the temperature depression and pore radius in nucleation and in fusion is given by Eqs 14 and 15.

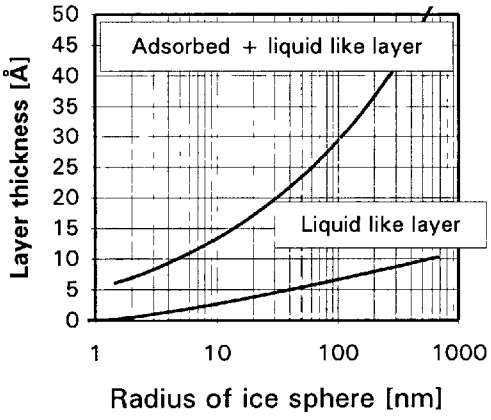

Figure 3. Thickness of the non frozen layers at nucleation point.

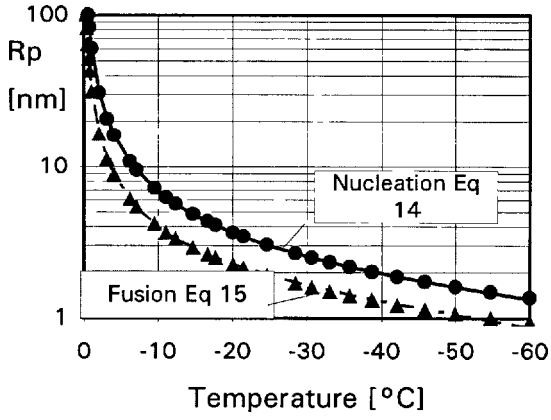

Figure 4. Pore radius R_p in nucleation and in fusion for a cylindrical pore.

$$R_{p_n} = 0.584 + 0.0052 \cdot \theta - \frac{63.46}{\theta} \quad [14]$$

$$R_{p_f} = 0.757 + 0.0074 \cdot \theta - \frac{33.45}{\theta} \quad [15]$$

In Eqs 14 and 15, $R_{p,n}$ and $R_{p,f}$ are the values of pore radius in nucleation and in fusion in nm and θ is temperature in °C.

Calculation method

Determination of the porosity and pore size distribution of saturated material using water as condensate by an iterative calculation method is presented e.g. in the references Matala 1995b.

DISCUSSION OF THE METHOD

Theoretical considerations

The principle behind thermoporosimetry is very simple: The phase transformation energy evolved during freezing or melting of the condensate in pores between the specified temperatures is measured calorimetrically, and corresponds to the pore volume in the pore ranges which relate to the solidification or fusion temperature of the condensate.

Although the principle is simple, there are many approximations in the theory on which the method is based. The energy evolved during phase transformation can be measured with high accuracy, but the correct evolution of entropy of the applied condensate before, during and after solidification and fusion is more difficult to calculate. Entropy changes in the adsorbed water layer, in the ice sphere, and in the interphases must be known. Supercooling of water lowers its freezing temperature and these thermodynamic properties are poorly understood.

The second difficulty lies in the phase state of the pore water. Pure pore water in cement paste is generally assumed in this context, but various impurities are known to exist. The effect of these substances on the entropy of water and ice, and on the entropy due to curvature of the water-ice interphase, are usually neglected. The values of surface tension for the solid-gas interphase, solid-liquid interphase and/or liquid-gas interphase must be known. One of these can be expressed as a function of the others, but in a case of incomplete saturation two of these must be formulated, and the surface tension of solid-liquid interface must be known in a state of full saturation. Unfortunately the reported values in the literature are mostly based on calculations using homogeneous nucleation theory or on the tests with samples having large pore diameters.

The third category of uncertainties lies in the freezing phenomenon in the porous system. The volume change during solidification affects the changes in the strain state of the matrix if the developed pressure cannot be released through the non-frozen pore space. If the matrix is unable to resist these strains it breaks down, and the calorimetric readings may include part of the fracture energy. How significant for analysis of the fusion thermogram are the changes in pore structure due to freezing pressure? Further, if the matrix is strong enough and transport through the pore space is prevented, what really occurs in the pores? Is solidification possible at all? These phenomena may play a certain role especially in the gel pore range.

Hysteresis between solidification and fusion thermograms

As a phenomenon, hysteresis is known to exhibit in the imperfectly elastic material systems, in which the reaction of the system to changes is dependent upon its past reactions to change. The phenomenon is clearly noticeable in the characterization of porous systems, especially, by the sorption and capillary methods; e.g. the adsorption-desorption and MIP tests. The facts causing hysteresis in porous cementitious materials are not comprehensively explained, but generally they are associated with the pore geometry and pore continuity. Obviously, the inelasticity and viscoelasticity of concrete have influence on this behavior.

According to Eqs 14 and 15 and Fig 4 the pore geometry explains some part of a strong hysteresis between the solidification and fusion thermograms seen in Fig 5. If the pore shape is strictly spherical the curvature of ice sphere remains the same when fusion takes place as it was when solidification took place, and the fusion and solidification temperatures are the same. On

the other hand, if the pore shape is cylindrical the curvature of ice-water interface becomes equal to the inverse of radius in fusion, but in solidification the spherical nucleus grows spontaneously through the cylindrical pore hence the curvature of ice-water interface is two times the inverse of radius. E.g. Eq 11 gives the radius of 1.37 nm for the nucleating ice at -40° C. In fusion, the same ice in cylindrical pore melts at -20.8° C. Obviously, the irregularity of pore system; likely layered than cylindrical shape, may give even higher hysteresis. Another feature in pore geometry which causes hysteresis can be derived from the differences in solidification and fusion energies. Solidification enthalpy (Eq 8) is dependent on the enthalpy caused by the entropy changes due to the superficial phase transformations. This, on the other hand, is strongly dependent on the pore geometry. If this effect is included in the consideration above, the ice formed in cylindrical pore at -40° C melts at -17° C.

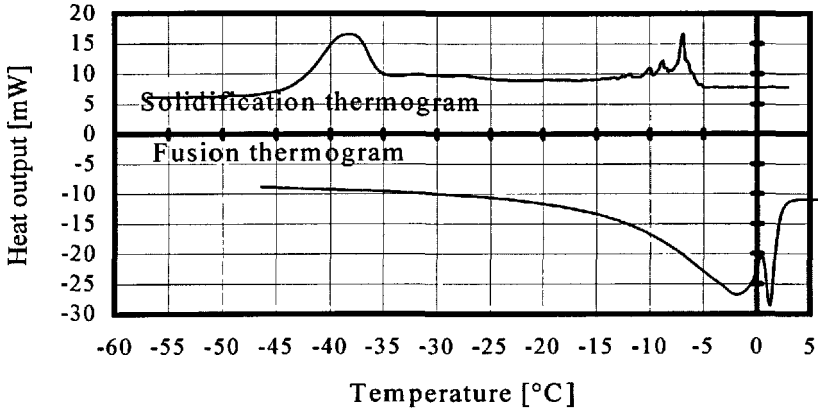

Figure 5. Solidification and fusion thermograms.

Although the pore shape explains a quite representative part of hysteresis there exist possibly also other facts. Enüstün et al. (1978) proposed that melting is controlled by the radii of cavities and the freezing by the radii of openings between the cavities. They state that since, by geometric necessity, the latter radii are on the whole smaller than the former, the model may form a basis for a theory to explain the observed freezing-melting hysteresis. In terms of this plastic ice theory, capillary freezing and melting take place by virtual movement of the ice-water interface along the capillary channels. The same type of hypothesis for the freezing-melting hysteresis is proposed by Sellevold and Bager (1980). They present that the spreading of the ice front through a pore system with variable cross sections would be controlled by the pore necks and the melting by the sizes of pores rather than of the necks, and hence, the hysteresis gives information about the continuity of the pore system.

Whatever the reasons for the hysteresis are; the pore shape, the pore continuity or some other reasons, the fact is that the direct calculation of pore size distribution from the fusion thermogram is unrealistic. This is shown by examples in the reference Matala (1995b). However, Setzer (1990) has presented a cyclic scanning method for DSC to analyze the fusion thermograms. Hence, the effect of supercooling of pore water being evident in solidification could be eliminated. Setzer found that ice, formed in freezing from -40° C to -55° C, melts in a very large temperature range giving a detected fusion heat at -35° C to -5° C in the DSC run. Further, the difference of the fusion thermograms with the reversal temperatures of -40° C and -38° C has a distribution between the temperatures from -25° C to -3° C and a peak at - 10° C. Setzer's results gives evidence of the effect of pore shape on hysteresis discussed above and supports the theory used in the evaluation of Eqs 14 and 15.

Validity of the Laplace's equation at small pore sizes

In the determination of the pore sizes according to Eq 14 it was assumed that the Laplace's equation is valid also at small pore sizes. The solidification thermograms in Fig 5 shows that the secondary peak exists at around -40° C. This peak denotes the pore radius of 2 nm and the radius of nucleating ice about 1.4 nm.

In the literature, e.g. Sellevold and Bager (1980) and Sidebottom and Litvan (1971, it is discussed that application of the capillary theory in small pore sizes may be questionable. These suspicions are based on the theories to explain the freezing phenomenon in porous saturated material. However, two strong evidences of the solidification by nucleation and of the relationship between the temperature depression and pore size can be found in the literature. First, it is widely accepted that all the gel water except for a couple molecular layers on internal solid surfaces is freezable in temperatures used in this study (Litvan 1972, Tada 1987, Zech and Setzer 1989 and Setzer 1990). Tada's finding that third to sixth layers are able to change their thermodynamic state already at around -40° C fits nicely on the estimated gel pore radius of 2 nm presented above. Further it is stated that an *in situ* freezing in gel pores is possible since there is an unfrozen adsorbed layer between the surface of the matrix and the pore ice which reduces the change in surface energy on freezing (Setzer 1990, p.417). Some evidence of the freezing of gel pore water can be found from the study where the gel pore volume of high strength pastes were determined by the LTC method and by the N_2-gas adsorption method. Both methods gave the same pore range for gel porosity (Matala 1995a).

Perhaps the strongest evidence of the applicability of the Laplace's equation also at gel pore range can be found from the investigation in which the solidification temperature of water was studied with materials of the known pore sizes; Vycor glass and five alumina porous plugs with the pore radii of 2.4 to 10.5 nm (Brun et al. 1977). The results are given in Fig 6 which shows that calculated pore radii by Eq 14 are extremely well in accordance with the experimental values.

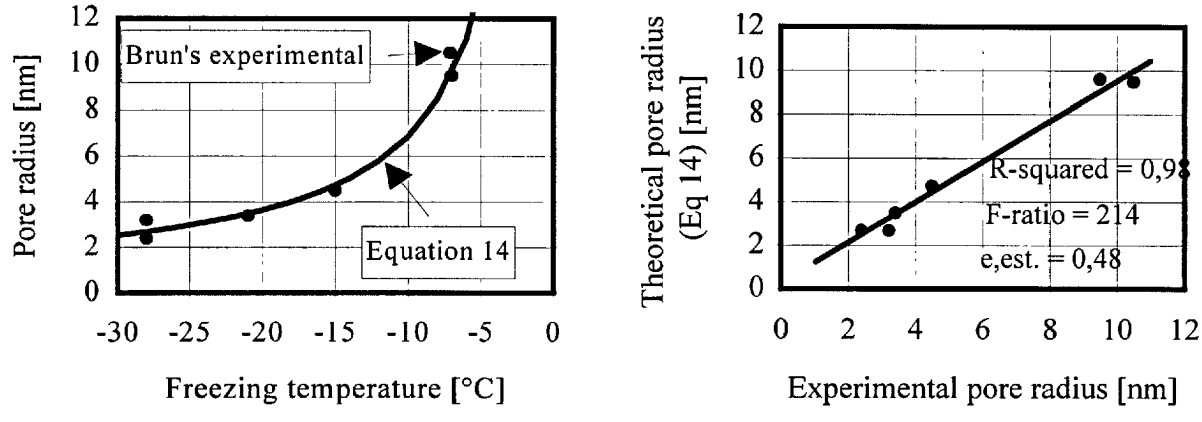

Figure 6. Comparison between experimental (Brun 1977) and theoretical (Eq 14) values of pore radii.

Consideration above shows the validity of Eq 14 in the calculations of pore size distribution by solidification thermograms and that the gel porosity is possible to estimate by the LTC method. However, it should be remembered that the whole solidification heat observed at -40° C does not consist of the heat caused by the nucleation of gel pore water. It comprises also the heat output of

the superficial phases; i.e., the adsorbed water layer of larger capillary pores, the thickness of which decreases in temperatures below the pore nucleation temperature.

Experimental uncertainties

Sample used for low temperature calorimetry are quite large. This, and although a temperature rate is slow, causes a lag in temperature over the sample. In addition, the pore space is measurable only within the limits of its saturation. If total porosity is of interest, there must be some certainty of water saturation in the sample. The aforementioned theoretical and experimental uncertainties should be taken into account as limiting factors when analyzing the results of thermoporometric measurements and when drawing conclusions about pore structure on the basis of any thermoporometric approach.

A COMPARISON OF TWO DIFFERENT METHODS FOR STOPPING THE HYDRATION OF MONO CALCIUM ALUMINATE AT 20°C

Steffen MÖHMEL, Wolfgang GESSNER, Barbara KÖDDERITZSCH
Institut of Applied Chemistry Berlin-Adlershof e.V., Berlin, Germany

ABSTRACT
The influence of two different methods commonly used to stop the hydration of cements (freeze drying and washing with acetone and diethylether, respectively) on the reaction of mono calcium aluminate with water is compared. Investigations by XRD, N_2 adsorption (specific surface area), DTA-MS and ^{27}Al-NMR (degree of hydration) have shown that washing with the organic solvents effects both the surface of CA* grains and the hydration products formed. In view of this fact freeze drying would appear to be the preferred method for stopping the hydration of CA.

Key-words: Calcium aluminate cement, Hydration, Drying, Method

INTRODUCTION
For a better understanding of the hydration of a cement it is often desirable to stop or quench the reaction at a particular point during the hydration process to examine the extent of hydration and the nature of the hydrates formed at the samples obtained in this way.
Various methods may be used to eliminate uncombined water and to stop the hydration. But only little is published about the influences of these methods on the hydrated cement. Although it is known that several of the hydration products of calcium aluminates are able to incorporate organic compounds - for example C_4AH_{13} (Lavanant, F., 1965, Massazza, F. et al., 1982), C_2AH_8 (Young, J.F., 1971) and AH_3 (Kee Kwong, K.F.N. and Huang, P.M., 1978) - the most common and suitable method is grinding and washing the material with organic solvents (Bachiorrini and Guilhot, 1982). An other usual procedure to stop the hydration of cements is freeze drying. Chandra et al. (1980) noticed by SEM investigations that freeze drying is an effectiv and useful method to study cement hydration. However Vernet and Noworyta (1992) found that the dissolution rate of C_3S is influenced by both, washing with organic liquids and freeze drying as well. In addition the latter causes a cracking of the unhydrated C_3S grains.
Because of these different statements investigations were carried out to compare the influence of freeze drying and washing with acetone and diethylether, respectively, on the course of hydration of monocalcium aluminate after times between 8 hrs up to 28 days at 20°C.

EXPERIMENTAL
The CA used was free of $C_{12}A_7$ and shows a specific surface area of 0,80 m^2/g (BET).
The hydration experiments were carried out in an atmosphere free of CO_2 with a water/solid phase ratio of 0,5 at 20°C. For details of the experimental conditions see Geßner et al. (1993) and in literature quoted there.
To stop the hydration process after given (identical) times the samples were either ground in acetone, washed with acetone and ether and then dried in vacuum over silica gel or frozen in liquid N_2 and then dried in a freeze dryer (CHRIST ALPHA 2-4).
The hydrated and stopped samples were characterized by using the following methods:

- ^{27}Al NMR	:	hydration degree
- X-ray powder diffraction	:	semi - quantitative determination of the hydrate phases
- Adsorption of N_2	:	specific surface area
- DTA-MS	:	decomposition of the hydration products

* shorthand notation is used; C=CaO, A=Al_2O_3, H=H_2O

RESULTS AND DISCUSSION

The course of hydration of the CA in the range between 8 hrs and 28 days is illustrated in **Figs 1 - 3**, showing the development of the hydration products related to the degree of hydration **(Fig 1 and 2)** and that of their specific surface area **(Fig 3)** for the samples stopped with the different methods. A comparison of the samples stopped with acetone / ether on the one hand and with freeze drying on the other hand indicates several effects. Firstly there seems to be a higher degree of hydration in case of the material stopped with the organic solvents. Secondly the proportion of crystalline hydration products is higher in case of the freeze dried samples (especially the amount of CAH_{10} and C_2AH_8) - this may be in connection with the significant higher amount of amorphous products in the samples treated with acetone / ether (see **Fig 2**) - but the kind of the occuring hydration products is not influenced by the stopping procedure.

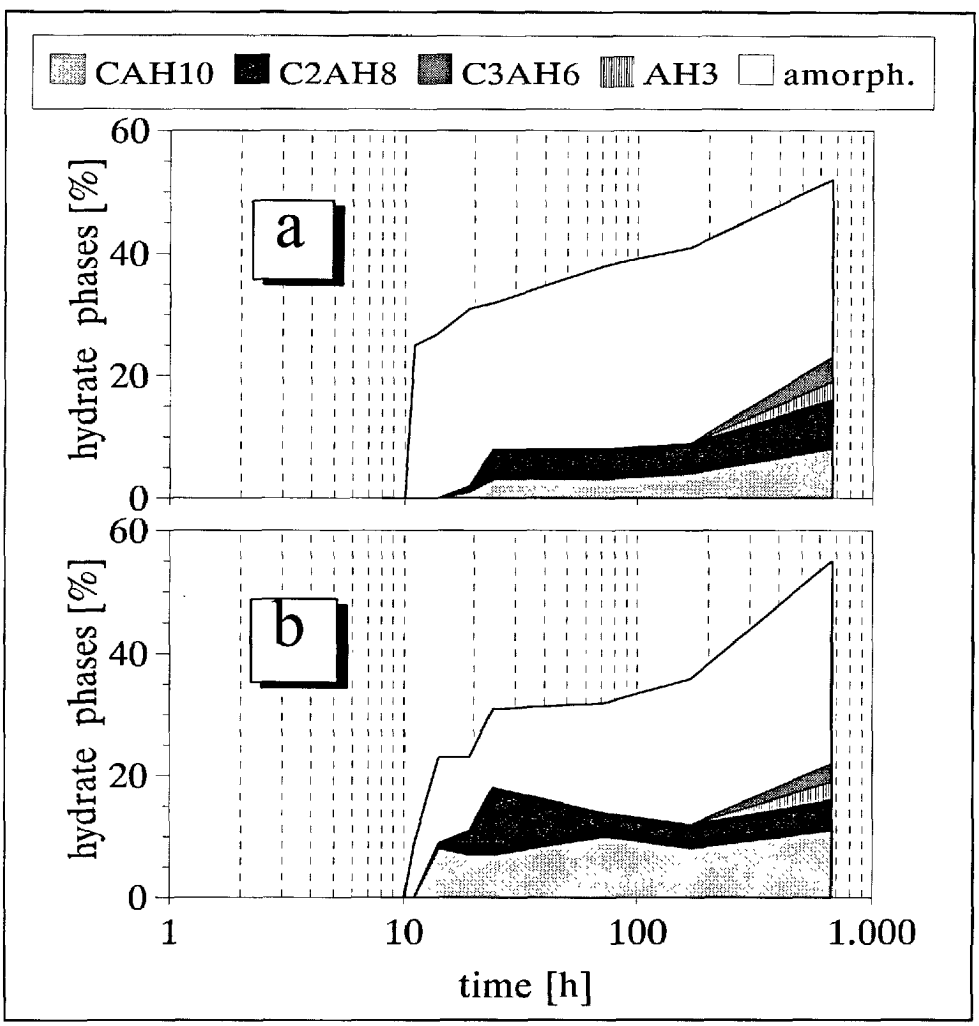

Figure 1 The development of the hydration products by stopping hydration with acetone / ether (a) and freeze drying (b), respectively

Thirdly, the specific surface area of the hydration products **(Fig 3)** also varies in dependence on the method for stopping the hydration. The freeze dried samples usually show a higher surface area during the investigated period than those stopped with acetone / ether. Nevertheless the course of the specific surface area seems to be the same for both series.

Thus it is evident that the method for stopping the reaction of CA with water influences the course of hydration. Compared with freeze drying stopping the hydration with acetone /ether leads to a higher degree of hydration, a higher amount of amorphous and a smaller part of crystalline products and finally to a lower specific surface area of the hydration products.

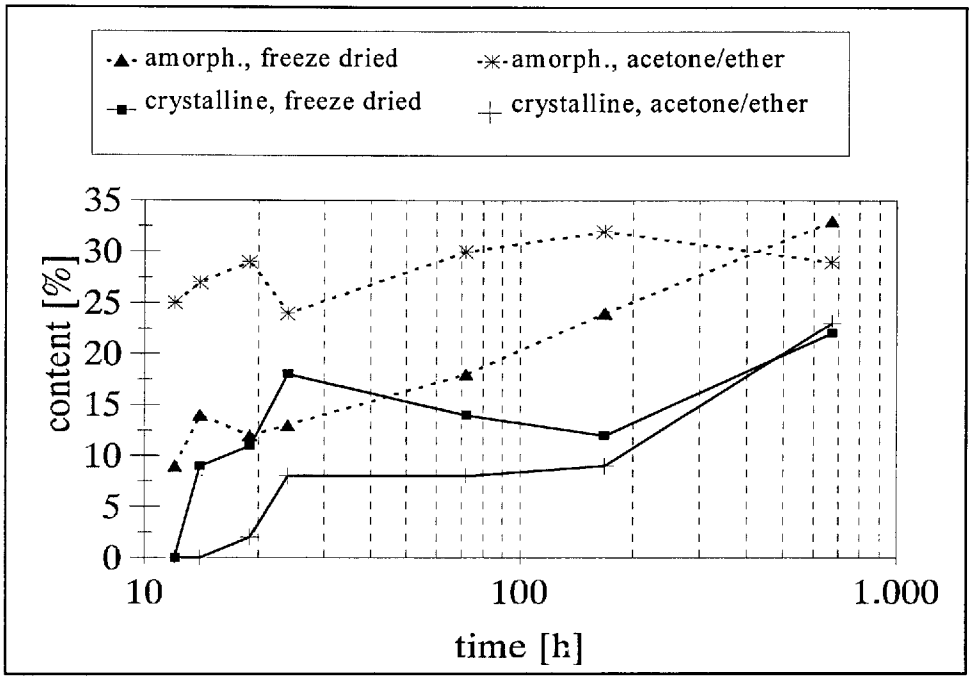

Figure 2 Comparison of the crystalline and amorphous parts of the hydration products in dependence on the method for stopping hydration

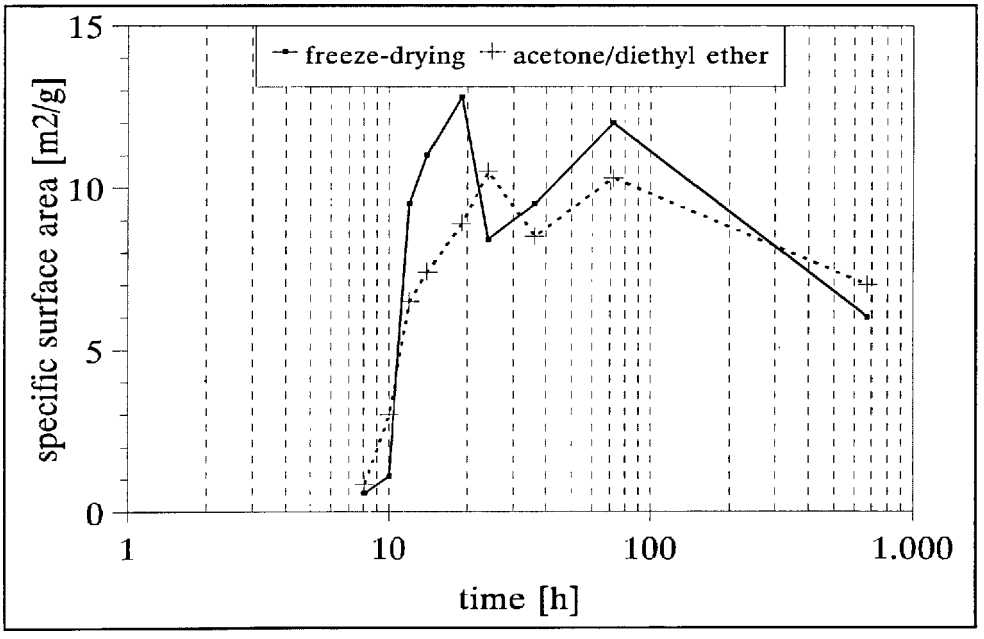

Figure 3 The course of the specific surface area of the hydration products in dependence on the method for stopping hydration

These differences are especially pronounced in the range between 10 hrs and 1 day. After longer times (7 - 28 days) the observed differences diminish and seem to disappear.
Supposing that especially the treatment with the organic solvents leads to changes in the characteristics of the hydration products investigations were carried out to study the influence of acetone and ether on mono calcium aluminate and calcium aluminate hydrates.
Therefore first of all DTA and DTA-MS investigations were made to find out whether there are organic compounds detectable in the hydrated specimens or not. **Fig 4** shows the DTA curves for the samples hydrated 14 hours and stopped with freeze drying and organic solvents,

respectively. The results largely agree with those of the XRD measurements. The CA sample stopped with freeze drying shows a large and broad endothermic peak in the range 120-160°C, indicating a relative high proportion of CAH_{10} and/or C_2AH_8. The smaller peak at about 280°C is attributable to the coinciding effects caused by the decomposition of AH_3 and C_3AH_6. Whereas the peak at the lower temperature is smaller in case of the sample stopped with acetone / ether that at 280°C is much higher. Considering the XRD results and because of the fact that C_3AH_6 is not known to occur in an amorphous state this second peak is likely related to AH_3 (possible with small amounts of C_3AH_6).

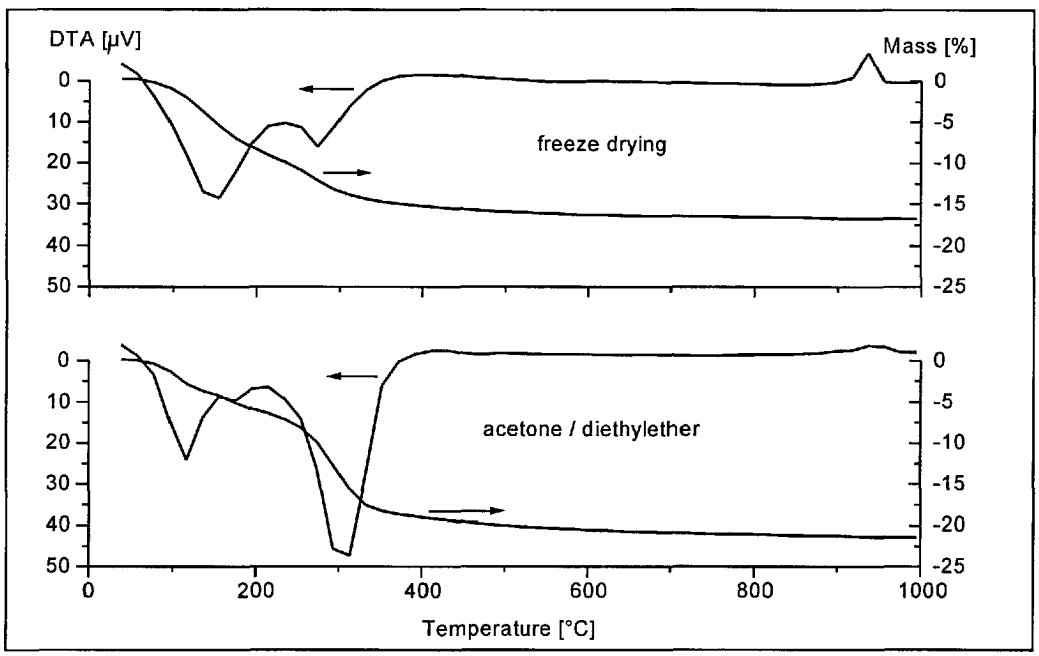

Figure 4 DTA/TG for the samples hydrated 14 hours at 20°C

The results of investigations with a combination of the DTA equipment with a mass spectometer show that traces of both acetone and ether are detectable in the samples stopped with the organic solvents (**Fig 5**).

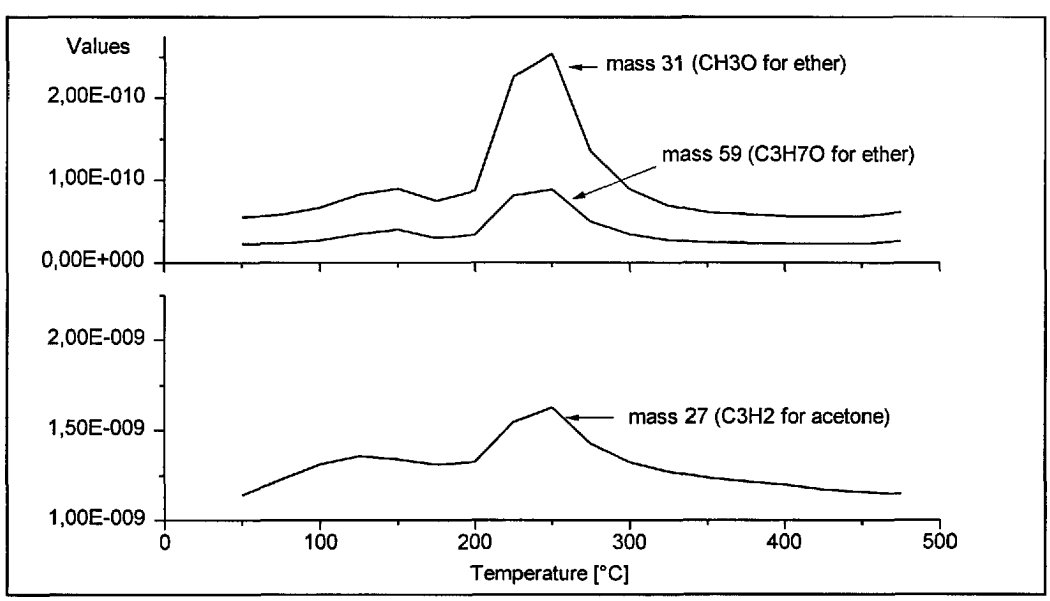

Figure 5 Mass-spectrometry for the sample hydrated 14 hours at 20°C and treated with acetone / diethylether

It is evident that a relative high amount of organic compounds is released in the range 200-300°C. In addition a small effect at about 120°C can be observed which is in good agreement with the endothermal decomposition of CAH_{10} and/or C_2AH_8 indicated in the DTA pattern. The more pronounced peak is in accordance with the beginning of the AH_3/C_3AH_6 peak. Therefore the organic compounds seem to be connected with the hydration products of the CA especially with the AH_3 but in an lower extend also with the CAH_{10} and C_2AH_8, respectively. Because of the drying procedure in vacuum over silica gel for at least 24 hours after grinding and washing with the organic solvents it could be concluded that these organic components are not only adsorbed but incorporated in the structure of these hydration products.
Further investigations were carried out with synthetic calcium aluminate hydrates to analyse the influences of a posttreatment on these phases. For that purpose pure samples of CAH_{10}, C_2AH_8, C_3AH_6 and AH_3 (gibbsite) were washed with acetone / ether and freeze dried, respectively, and then examined by XRD and N_2 adsorption. An inner standard was used for the XRD examination to compare the crystallinity (calculated from the area of the peak with the highest intensity in the XRD pattern) of the untreated phase (always 100%) with that of the stopped samples. The results of these investigations are summarized in **Table 1**.

Table 1 Comparison of the specific surface area (s.s.a.) and crystallinity of the hydration products untreated, treated with organic solvents and freeze dried

phase	untreated		treated with acetone / ether		freeze dried	
	s.s.a. [m^2/g]	crystallinity [%]	s.s.a. [m^2/g]	crystallinity [%]	s.s.a. [m2/g]	crystallinity [%]
CAH_{10}	33,3	100	31,3	86	39,9	76
C_2AH_8	8,9	100	9,0	88	8,5	92
C_3AH_6	4,9	100	244,5	181	2,9	96
AH_3	111,9	100	120,7	112	101,3	106

It can be seen from **Table 1** that the treatment with acetone / ether influences the crystallinity and specific surface area of the hydration products of CA. The crystallinity of CAH_{10} and C_2AH_8 appears to decrease whilst that of C_3AH_6 and AH_3 increases. The specific surface area shows an astonishing increase in case of the C_3AH_6 and a small one for AH_3. Especially the significant increase in the specific surface area and crystallinity of the C_3AH_6 is remakable and should be further investigated.
In contrast to the treatment with the organic solvents freeze drying appears to modify only CAH_{10} in a significant manner.
To examine a possible influence of the stopping procedure on the calcium aluminate itself a CA sample was treated for 1 hour in running water (to dissolve the CA surface but to prevent the precipitation of hydration products on the grains) and after that washed with the organic solvents and freeze dried, respectively. The results of the investigations of these materials are shown in **Table 2**.
It is evident from **Table 2** that also the unreacted CA is influenced by the method of stopping the hydration. Especially differences in the cristallinity of the treated samples are observed whereas their specific surface area is nearly the same. The crystallinity is lower in case of washing the samples with the organics than for those stopped with freeze drying. The apparent higher degree of hydration of the specimens treated with acetone / ether (see **Fig 1**) may be in connection with this stronger amorphisation of the unreacted CA.

Table 2 Comparison of the specific surface area and crystallinity of the washed CA in dependence on subsequent treatment

phase	subsequent treatment	sp. surface area [m^2/g]	crystallinity [%]
CA	/	0,8	100
CA	freeze drying	2,9	83*
CA	washing with acetone / ether	3,0	74*

* no hydration products were detectable

Taking all the results together it is evident that especially the treatment with the organic solvents leads to changes of the unreacted CA and the hydration products as well. Thus the observed smaller proportion of crystalline phases and the corresponding higher amount of amorphous products in the samples washed with the organics may be caused by a partial interaction of acetone and ether with the hydration products. This is deduced from the behaviour of the pure hydrates by contact with acetone and ether. Obviously an incorporation of these solvents take place leading to a partial amorphisation especially of CAH_{10} and C_2AH_8 and so to the observed smaller proportion of crystalline phases and higher amount of amorphous products. This assumption corresponds with the results of the DTA-MS investigations showing that organic compounds are released from the specimens in connection with the decomposition of the hydrates. However there is no evidence for a crystallisation of hydrates initiated by the treatment with aceton as mentioned by Murat (1988).
The higher degree of hydration of the samples stopped with acetone / ether could be attributed to changes of the unreacted CA as it is reflected by the results shown in **Table 2**. Only the lower specific surface area of the specimens of the series treated with acetone / ether can't be explained by changes caused by the organic solvents. Therefore the differences in the course of the specific surface area may be attributed to the freeze drying. Although there is no clear evidence for the occurance of microcracks caused by freezing - as described by Vernet and Noworyta (1992) - the higher specific surface area of the freeze dried specimen may be due to that.
The observed diminishing of the differences after longer times (28 days) may be attributed to contrary influences of the organic solvents on the different hydration products.

CONCLUSION

A comparison of two methods used to stop the hydration of mono calcium aluminate shows that at ages up to 7 days the quantity of crystalline hydrates, especially CAH_{10} and C_2AH_8, observed after freeze drying was larger and less amorphous products were found than in specimens washed with organics. Furthermore freeze dried samples also have a higher specific surface area and a lower degree of hydration. These different influences are obviously caused by an incorporation of the organics in the hydration products and by changes of the surface of the unhydrated CA grains.
At longer hydration times (28 days) the differences caused by the method used to stop the hydration seem to decrease.
Though also freeze drying seems to effect the hydration the described results show that this method appears to be more suitable for stopping the hydration of calcium aluminates than a treatment with organic solvents.

STUDIES ON CEMENT HYDRATION BY WATER SORPTION AND STATIC HEATING

Ewa T.STĘPKOWSKA, Institute of Hydroengineering PAS, Gdańsk, Poland
Ajoy K. MULLICK, Surrinder K.HANDOO, National Council for Cement and Building Materials, New Delhi, India
Jose-Luiz PÉREZ-RODRIGUEZ, Miguel Angel AVILES and Eduardo GOMEZ
Instituto de Ciencia de Materiales de Sevilla, Spain.

ABSTRACT Quantitative study of hydration products of a cement powder and a cement paste by water sorption and weight loss on static heating is presented. Evaporable water was 2.5-3 times higher in paste, portlandite content was only by 1/3 higher and non-evaporable water content increased more than twice. XRD, SEM and DTA study of cement powder and paste is also reported.

Key-words: Bound water, Degree of hydration, Evaporable water, Scanning Electron Microscopy, Calcium hydroxide.

INTRODUCTION

The estimation of specific surface and hydration products in the cement powder was suggested by measurement of water sorption and weight loss on static heating (Stępkowska et al., 1996). Therefrom were estimated: the specific surface both in air dry state and in hydrated state, the content of evaporable water (at 110°C), of non-evaporable water (composed of zeolitic water and chemically bound water) and of portlandite. The influence of certain parameters on cement hydration products was evaluated, such as age of cement, sorption time (representing setting time), water availability (representing water/cement ratio), cement pretreatment and container material (representing the reinforcement).

Here the hydration of a Portland cement powder is presented and compared with the cement paste stored for two years.

MATERIALS

Ordinary Portland Cement (OPC) indicated the chemical composition (in form of oxides) as: SiO2 21.48%, Al2O3 4.50%, Fe2O3 3.40%, CaO 60.03%, MgO 6.08%, SO3 1.73%, free CaO 0.20%, LOI (1000°C) 1.56%. Cement paste prepared at w/c = 0.4 was stored for two years, ground to pass 100 mesh sieve and it was studied simultaneously with the cement powder.

METHODS AND RESULTS

Water sorption/retention test

5 g samples both of the cement powder and of the powdered paste either air dry (WS) or predried at 110°C (WSo) were placed in aluminium containers (3x2x1 cm), successively for two weeks at normal atmospheric pressure, at 30°C in desiccator over a suitable solution: in water sorption at R.H.= 50%, 95% and 100%, in water "retention" (WR) at R.H. = 100%, 95% and 50%. This was followed by heating successively (including untreated samples) at 110°C (1d), 220°C (8h), transferring to ceramic dishes, which resulted in contact with air, and heating farther at 400°C (4h) and 800°C (1h). Weight changes were measured and calculated in percent referring to the final weight at 800°C. Weight balance, DTA and XRD indicated decomposition of $CaCO_3$ at this temperature (Stępkowska et al., 1996). Results are presented in Fig. 1. The standard deviation was generally 0.1-0.4%. Exceptionally in three cases of high R.H. it was 0.8-1.0%.

SEM

JEOL JSM-5400 Scanning Electron Microscope was used, equipped with EDXR unit. Fig. 2 shows the similarity of microstructure after WR measurement and of the paste as known from the literature. The gel is exceptionally well hydrated; it contains calcium silicate aluminate, including some Fe and K. Irregular plates enclose pores of several micrometers size. After wetting-drying procedure many calcite crystallites on the sample surface were found.

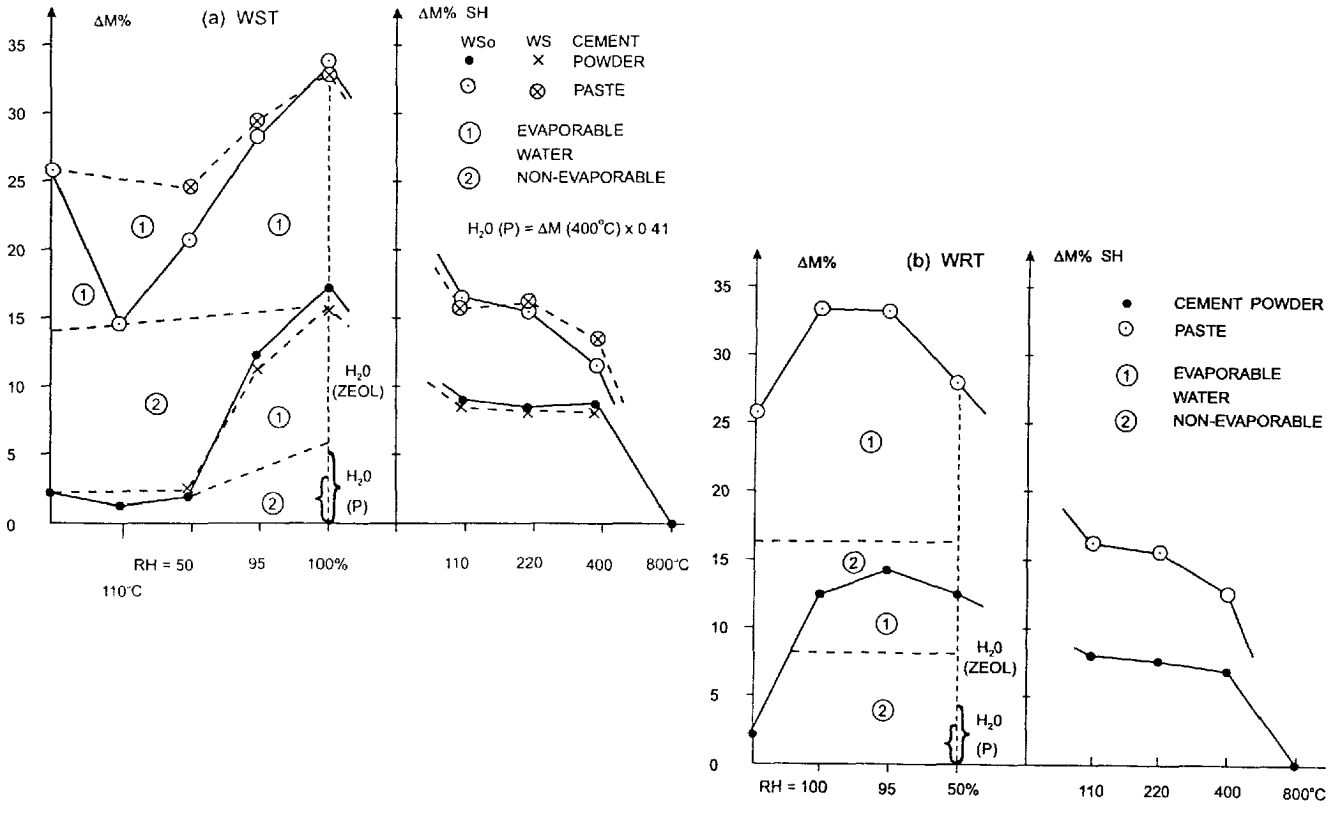

Figure 1. Change in sample weight (ΔM) during the WS test (a) and WR test (b) and static heating (SH).

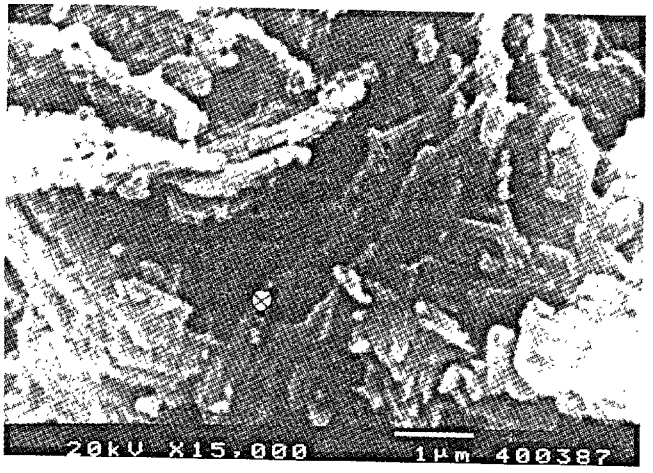
XRD

Siemens Kristalloflex D 501, equipped with graphite monochromator CuKa and the computer SICOMP PC 16-20 was used. Important portlandite peaks were found in cement paste and no calcite was present. Similar was the XRD pattern of the WR sample with lower portlandite peaks. No calcite was found after heating at 800°C. Peaks were interpreted according to Taylor (1990), Fig. 3.



DTA

Thermal study was performed on Derivatograph MOM Budapest (mgr. Z. Sułek). The total weight loss in cement powder was 3.71 %, as compared to 2.5% measured in static heating (SH). In cement paste it was 28.82 % wherefrom 6.19 % escaped between 500 and 1000°C; in SH of cement paste it was 26.6% and 6.82%, respectively.

A pronounced dehydration endotherm was found in the paste at 120°C (with secondary minima about 70 and about 200°C), a smaller one was observed at 510°C corresponding to dehydration of portlandite and the smallest - at about 790°C, due to calcite decomposition, ending abruptly before 800°C.

DISCUSSION

Water sorption/retention is proportional to the specific surface. which was calculated in cement powder as 2.75 m^2/G (coefficient used was 585 m^2/G H_2O), whereas in hydrated state it was 44 m^2/G for cement powder and 96 m^2/G for cement paste (assuming six-molecular sorbed water layer and the coefficcient 556 m^2/G H_2O, Stępkowska et al., 1996). Cement powder after oven drying at 110°C (WSo) sorbed more water at R.H.= 95% and 100%, than the air dry one. This was observed also in some calcareous soils (unpublished data) and it was interpreted that oven drying disturbed some cementing bonds (there - carbonate cementation, here lime cementation) and thus the water sorption could proceed more freely.

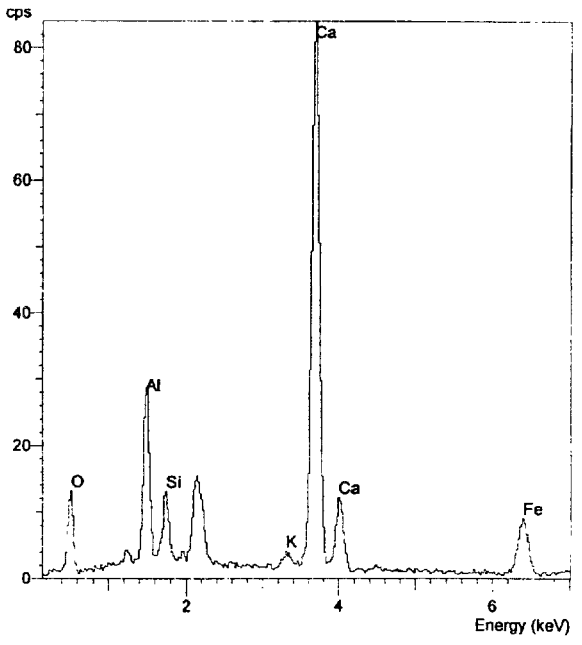


Fig. 2. Cement powder after WRT ; SEM 15,000x (387). Point EDXR indicates Ca:Al:Si = 5:2:1

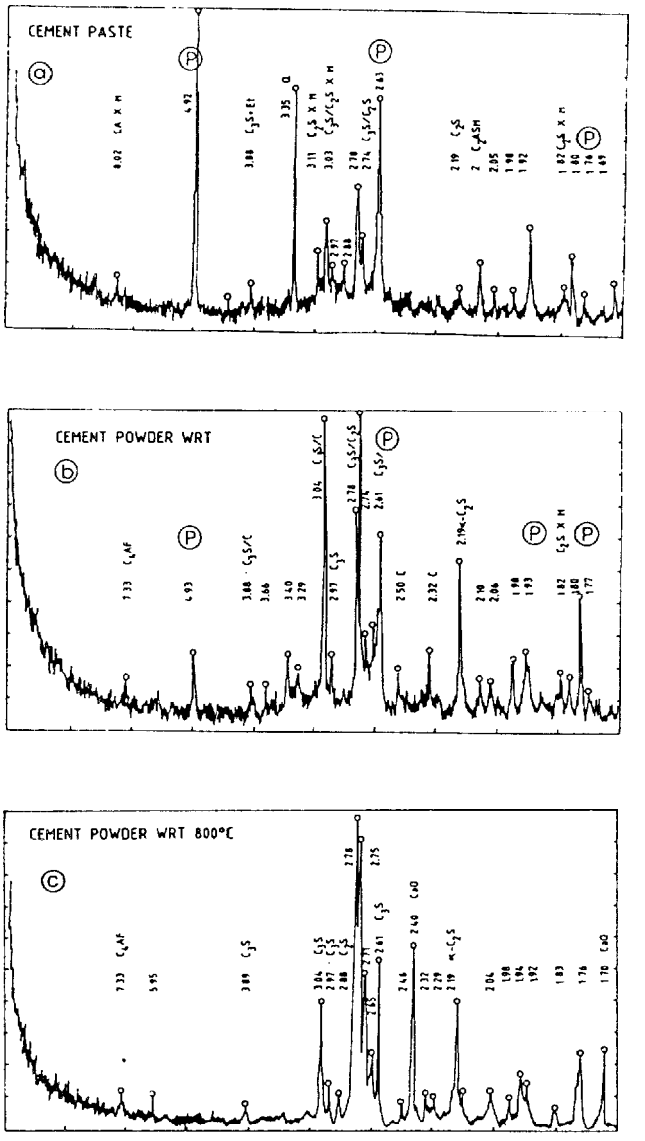

Fig. 3. XRD traces of cement paste (a) and cement powder after WR test (b) and after heating at 800°C

The total increase in weight was by more than one half lower after hydration in water vapour (WS/WR test) than after hydration in liquid water (paste), due to the difference in the hydration time: one month at R.H.= 95% to 100% as compared to two years in paste. In cement powder a full hydration was observed in selected places only as in Fig. 2. In Fig. 1a it is shown that the total increase in weight of cement powder reached about the value of non-evaporable water in cement paste.

Contributions of the evaporable water and non-evaporable water in the total weight increase were in the paste approximatelly equal: about 17% (evaporable) + 16% (non-evaporable) = 33%.

In WS test the contribution of the evaporable water was somewhat lower, but still both were almost equal. On the other hand in WR test the ratio of their contributions was exactly 1:2. The arrangement of grains was frequently more compact in WR test than in WS test, due to the surface tension of

water films at the saturated water vapour pressure (R.H.=100%). Thus spacial hindrances were preventing full hydration and the contribution of evaporable water content was lower.

A negligible change in weight was observed between 110 and 220°C (<1%). This represented the residual sorbed water in interlayer spaces and/or ettringite. Only in untreated cement paste (SH) this amounted to 2.8%.
Portlandite which developed on hydration during the WS/WR test, transformed up to 400°C into calcite, which decomposed at 800°C evolving CO_2 [Taylor, 1990, Ramachandran et al., 1964, Stępkowska et al., 1996].

Multiplying the weight loss beween 400 and 800°C [-ΔM(400- 800°C)] by the stoichiometric coefficient 0.41 = $M(H_2O)/M(CO_2)$ the amount of water chemically bound in portlandite is evaluated.This calculation is correct if the total portlandite transforms at 400°C into calcite and if no calcite is formed below 110°C. Both were proved by XRD in a previous paper (Stępkowska et al., 1996).
Subtraction of [H_2O (portlandite)] from the non-evaporable water content results in evaluation of the other part of stongly bound water, which could be described as "gel" water or "zeolitic" water according to the definitions used in soil science and in cement science (Powers and Brownyard, 1947, Bensted, 1983).

The amount of portlandite water measured in WS test was not much lower than in the paste rehydrated in water vapour (3.4-3.6% as compared to 4.8-5.4%, i.e. increase by about 1/3) in spite of the big difference in hydration time. Also some geometrical hindrances prevented the full formation of portlandite in WR test resulting in a lower value: for cement powder it was 2.9% and even in the paste it was somewhat lower, i.e. 4.6%.

Bigger differences were observed in formation of zeolitic water: it was more than twice as high in paste than in WS test. This means that the reactive centers to form portlandite are used quicker than the reactive centers to promote hydration.
The minor dependence of portlandite content on the hydration time (1-28 days) was observed by Handoo et al.(1996). Taylor (1990) indicates that 70% C3S transforms within 28 days into portlandite and within 1 year only 10% unreacted compound remains. Correspondingly a low C_3S peak was observed by XRD in the paste (Fig. 3).

CONCLUSIONS

Hydration of cement powder in water vapour proceeds in a similar way as in liquid water. Portlandite forms quickly and its content increases only marginally with time. Sorbed water content and zeolitic water content depend strongly on hydration time. Specific surface and contents of water in these states can be evaluated from water sorption and weight loss on static heating.

QUANTITATIVE DETERMINATION OF THE CRYSTALLINE AND AMORPHOUS PHASES IN LOW CALCIUM FLY ASHES

P. ARJUNAN, M.R. SILSBEE and D.M. ROY, Materials Research Laboratory, The Pennsylvania State University, University Park, PA 16802.

ABSTRACT Glassy/amorphous phases and crystalline phases present in low calcium fly ashes were quantitatively extracted by hydrofluoric acid and phosphoric acid respectively using a new chemical phase analysis technique. The results of this chemical phase analysis technique are compared with 1) a conventional x-ray diffraction(XRD) method using an internal standard and 2) quantification using full spectra x-ray diffraction analysis technique. The result of the chemical phase analysis technique compare well with the results obtained using QXRD.

Key-words: Fly ash, Characterization, Extraction methods, Quantitative, Reactivity

INTRODUCTION

The reactivity of low calcium fly ash in concrete is determined to a large extent by amorphous phases. The crystalline phases are also known to be reactive though at a slower rate. It is very important to determine the quantity of crystalline and amorphous phases present in fly ash in order to evaluate their behavior in concrete. A number of studies have appeared concerning the evaluation of glassy content using various acid leaching techniques as following reports: Watt and Thorne (1966), Hulett et al. (1980), Hemmings and Berry (1988), Berry et al. (1987). However, a quantitative method for determining both crystalline and amorphous phases in fly ash never has been established. The purpose of the present study is to develop an accurate chemical procedure for measuring the various crystalline and glassy contents of the fly ash.

Basis of the method

Glass/amorphous phases were removed from the crystalline phases by etching with 1 % HF. In the case of the crystalline phases, orthophosphoric acid is used for selective removal of mullite and iron oxide phases from quartz. Mullite and iron oxide phases are calculated as difference from soluble silicates and quartz. Phosphoric acid forms water soluble complexes with both silicic acid and metallic oxides(Young (1974), Talvitie (1951)). Upon heating a silicate material with 85% phosphoric acid, vigorous boiling takes place accompanied by an increase in temperature. The boiling subsides as the acid approaches 100% concentration at about 220° C. With further heating between 230° C to 250° C the orthophosphoric acid, by loss of water, converts to pyrophosphoric acid as shown in Eq 1 and simultaneously dissolves the silicates.

$$\underset{\text{Orthophosphoric acid}}{H_3PO_4} \xrightarrow{>230^\circ C} \underset{\text{Pyrophosphoric acid}}{H_4P_2O_7} \xrightarrow{>315^\circ C} \underset{\text{Metaphosphoric acid}}{HPO_3} \qquad [1]$$

The clear, viscous solution obtained remains stable upon dilution with water, permitting a simple separation from quartz by filtration through paper.

EXPERIMENTAL PROCEDURE

Chemical phase analysis

Two types of low calcium fly ashes, American and Australian in origin were used for the study. A two step chemical phase separation is adopted. A number of probe experiments were conducted with different concentration of HF solution at different contact time for the removal of glassy phase. Similarly a number of preliminary experiments were conducted with ortho phosphoric acid for the separation of quartz and other crystalline phases.

Quantitative x -ray diffraction using single peak calibration.

In a sample containing glassy and crystalline phases, the mass fraction of each crystalline phase can be determined by measuring the integrated intensities of peaks at selected 2Θ values as ratios to the integrated intensity of an added internal standard(Popovic and Greta 1987). The samples were sieved to pass 325 mesh and paste mounts were prepared on a zero background quartz plate using ethanol. X-ray diffraction patterns were obtained for the original fly ash. The powder patterns were gathered over the range of 5^{o} 2Θ to 60^{o} 2Θ at the scanning rate of 2^{o} 2Θ per minute. In the second instance, the fly ash samples were doped with known amounts of pure quartz and mullite in different weight fractions. The XRD powder patterns were gathered over the same range for the doped samples. In the third instance, the powder pattern for 100% quartz and mullite samples were obtained using the same measurement conditions. The weight fractions of the unknown samples were calculated from the calibration curve.

Quantitative x -ray diffraction using full spectra calibration.

A quantitative x-ray powder diffraction (GMQUANT) computer program developed by Smith et al.(1987) has been used in this study. The unique approach employed in this method is the utilization of the full diffraction pattern of a mixture and its reconstruction as a weighted sum of diffraction patterns of the component phases. The fly ash sample was mixed intimately with corundum in the ratio of 1:1 and sieved to pass through 325 mesh. The powder pattern was gathered over the range of 5^{o} 2Θ to 75^{o} 2Θ at a scanning rate of 2^{o} 2Θ per minute. The intensities of the unknown pattern were fitted with the already available known working data base using the menu-driven interactive computer programs known as GMQUANT.

RESULTS AND DISCUSSION

Chemical phase analysis

A number of preliminary experiments were conducted to optimize the contact time and concentration of HF solution. The powder x-ray diffraction pattern for 1%HF treated ash clearly indicates(Fig 1b) the removal of all the glassy phase which was indicated by a broad hump in the original fly ash(Fig 1a). Similarly, the pattern for ortho-phosphoric acid treated ash(Fig 1c) confirms the removal of all the phases except quartz. The SEM micro structure for untreated fly ash (Fig.2a) shows the typical smooth faced round fly ash particle. The SEM for the ash after treatment with HF indicates(Fig.2b) the complete removal of glassy content and the presence of skeletons of quartz and mullite particles.

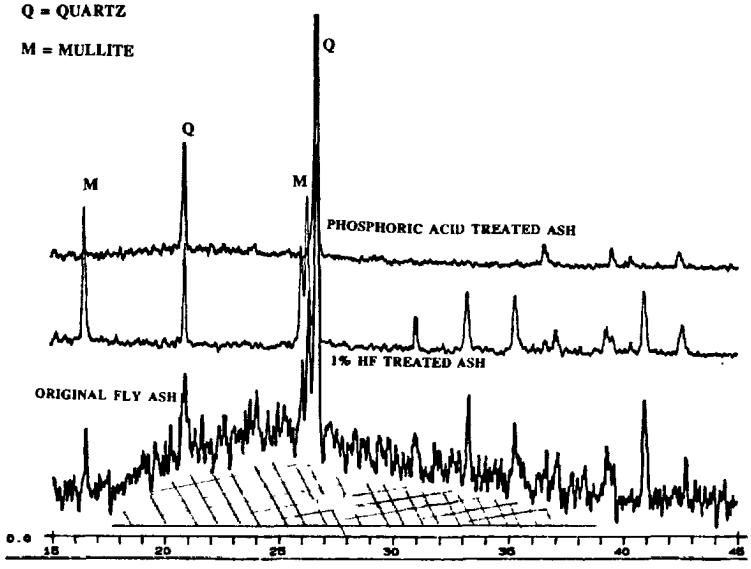

Figure 1. The X-ray diffraction pattern for a) the original fly ash, b) the fly ash treated with 1% HF and c) the fly ash treated with Orthophosphoric acid.

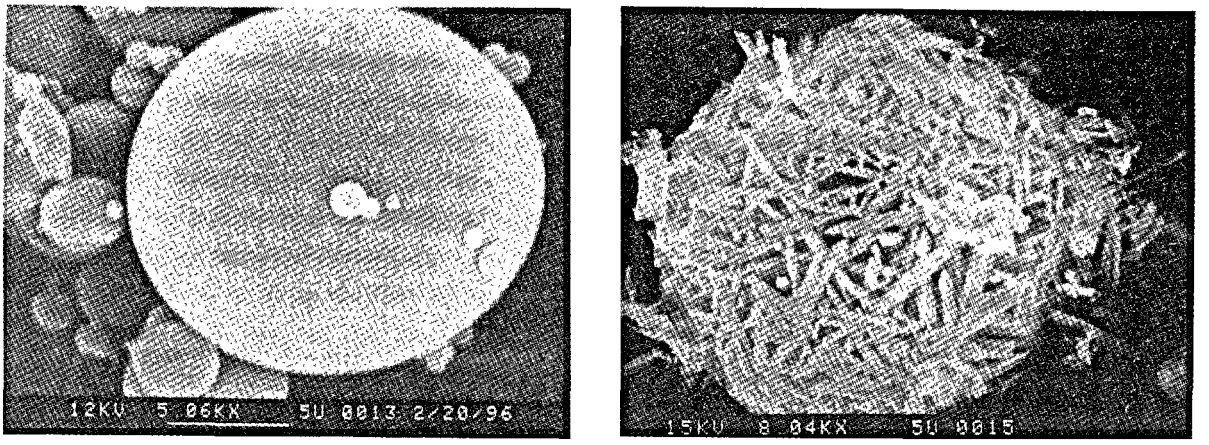

Figure 2. SEM picture showing the fly ash a) before and b) after HF treatment

Rate of dissolution of quartz and mullite in ortho phosphoric acid

In order to determine the rate of dissolution of mullite in pyrophosphoric acid and the extent of quartz dissolution during this period, known amounts of pure quartz and mullite were treated with orthophosphoric acid. The results indicate (Fig.3) that about 15 to 17 minutes of refluxing time is required for the complete removal of mullite. The results also indicate that about only 0.8 to 1.0% quartz is dissolved during this period.

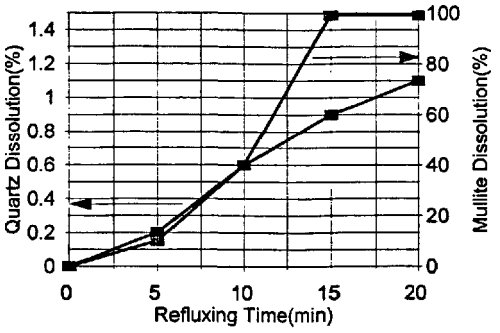

Figure 3. Rate of dissolution of quartz and mullite in pyrophosphoric acid.

Chemical phase analysis procedure

The procedure is as follows: To 1.0g of very fine(<325 mesh) fly ash sample 100 mL of 1% HF was added in an polythene container. The container was placed on an agitating table and agitated for 4 to 6 hours at room temperature. The contents were filtered using Whatman filter paper (pore size 5.4μm) and washed thoroughly with water. The residue was first dried at 100°C for 2 hours and ignited to incinerate the filter paper. The loss in weight was estimated as the soluble silicates. In the second step, 25mL of 85% orthophosphoric acid was added to the residue and the flask was placed directly on a preheated electric heater. When boiling subsides, the flask was swirled for 3 seconds at 1 minute intervals in order to minimize superheating and to keep the sample distributed throughout the acid. At the end of 15 minutes the flask was removed from the heater and placed on the cool surface. After cooling to room temperature, 125mL of hot(60 to 70°C) water was added to the flask and swirled vigorously until the syrupy phosphoric acid is completely dissolved. The contents were filtered using Whatman filter paper (pore size 5.4μm) and washed thoroughly first with cold water and 2 or 3 times with 1:9 HCl and followed by one or two washings with cold water. The filter paper with the residue was ignited in a tarred platinum crucible, first at low heat to char the paper, and finally at about 950° C. The crucible was cooled in a desiccator and weighed.

The residue was moistened with 1 : 1 sulfuric acid and hydrofluorized with 5 mL or more of 48% HF. The difference in weight after hydrofluorization was calculated as quartz.

Comparison of chemical phase analysis results with XRD methods

The quantitative amounts of amorphous and crystalline phases present in the fly ash estimated by the three methods are given in Table 1. In the chemical method, the amounts of quartz and soluble silicates were determined as mentioned earlier and the amounts of mullite and other crystalline phases were calculated as mass difference. In the case of QXRD by single peak calibration, quartz and mullite were calculated from the calibration curves and soluble silicates were obtained as mass difference, whereas in the case of GMQUANT, all the phases were calculated from the background corrected full diffraction pattern.

Table 1. Amount of crystalline and amorphous phases obtained using three methods.

PHASE	WEIGHT PERCENTAGE(%)		
	Chemical	Qxrd	GMQUANT
QUARTZ	17	12	18
MULLITE	11*	13	12
HEMATITE	NIL	NIL	NIL
SOLUBLE SILICATES	70	73*	69†

* By difference; †: Unaccounted phases;

The chemical phase analysis and GMQUANT technique show similar results. The degree of difference in results obtained for QXRD single peak calibration may be attributed to either preferred orientation of the crystals present in the fly ash or variation of crystallite perfection between the sample and standard.

CONCLUSION

A novel two step chemical phase analysis technique is proposed for the estimation of both amorphous and crystalline phases present in the low calcium fly ashes. The results of this technique compare well with the results obtained using full spectra quantitative X-ray diffraction. The chemical phase analysis technique is simple and can be performed with ordinary laboratory glassware. This technique can be used for the quick evaluation of potential pozzolanic reactivity of low calcium fly ashes.

NON-DESTRUCTIVE EVALUATION OF RICH FLY ASH HPC

Chao L. HWANG, National Taiwan Institute of Technology, Taipei, Taiwan
Iuan Y. JANN, National Taiwan Institute of Technology, Taipei, Taiwan

ABSTRACT HPC with large amount of pozzolan has been successfully applied. Due to the densified mixture proportion algorithm (DMDA) and under the strict quality control the bleeding and segregation problems have disappeared. By NDT (V-meter) the strength at the designed age of 56 days could be predicted. Large variation of pulse velocity and electrical resistivity (another NDT) showed the deficiency in the conventional rich-mix concrete, and were harmful to long-term durability.

Key words: High performance concrete (HPC), Fly ash, Electrical resistivity.

INTRODUCTION

In Taiwan, the HPC with the designed strength of 56 Mpa at 56 days was successful used in the steel columns of Kaohsiung T&C Tower. Another, the basic limitation was imposed upon cement content less than 400 kg/m^3, water content less than 200 kg/m^3, with slump=230~270 mm, slump flow spread=500 mm and without bleeding and segregation occured(Chern, Hwang, and Tsai, 1996). The designer applied DMDA and introduced a large amount of pozzolans into HPC, of which fly ash and slag aimed to partially replace sand and cement, respectively. The typical mixture proportion is shown in Table 1. Upon completion of pouring HPC with V_p = 1.3n and W/B = 0.32, V-meter was used to evaluate the uniformity of concrete, and the strength was measured at the age of 56 days to build the relationship. The pulse velocity and electrical resistivity of HPC were compared with those of conventional concrete.

Table 1. Typical mixture proportion and fresh concrete property of HPC

V.P (n)	W/B	W/C	Binder (kg/m^3)			Aggregate (kg/m^3)		Mixing Water (kg/m^3)		Slump (cm)		Flow (cm)	
			Cement	Slag	Fly Ash	Coarse	Sand	Water	SP (%)	0 min	45 min	0 min	45 min
1.1	0.32	0.39	312	16	139	873	928	123	23.10	-	-	-	-
1.2	0.32	0.42	364	19	141	942	801	152	15.31 (4.2)	25	24	55	56
1.4	0.32	0.41	434	23	132	882	750	174	13.04 (3.00)	25	26	57	57

2.1 (ACI)	0..32	0.32	719	0	0	586	825	244	0	-	-	-	-

n : the least void

UNIFORMITY EVALUATION

Pulse velocity along pouring and perpendicular direction of the specimen is shown in Fig. 1. It shows no significant difference in any direction under different paste amount due to uniformly mixed HPC without segregation problem (Hwang, et al, 1996), fewer defects in transition zone of aggregate and paste, and pozzolanic reaction by fly ash with lower cement and water content.

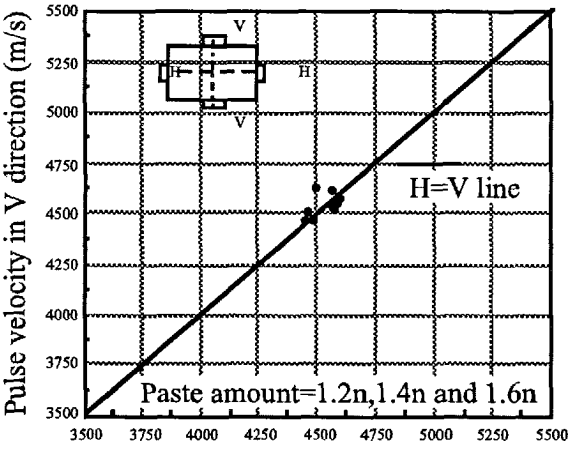

Figure 1 The relationship of pulse velocity in V and H direction of HPC

STRENGTH PREDICTION

Ultrasonic pulse velocity has been used for strength prediction and also is a feasible NDT method (Anderson Seals, 1981). The relationship between ultrasonic velocity and strength of NDT is as shown in Formula (1). The data prepared with various mixture proportions and cored specimens in the laboratory were collected to obtain the correlation constants a, b as shown in Formula (2). It successfully predicts the designed strength of HPC at 56 days as shown in Fig. 2.

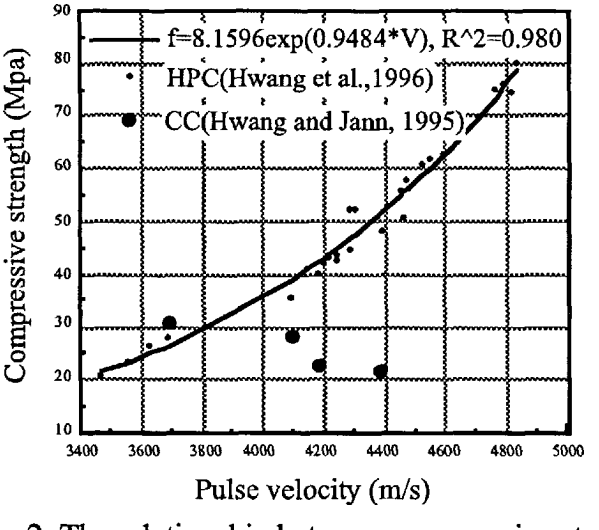

Figure 2 The relationship between compressive strength and pulse velocity of CC and HPC

$f = a\, e^{bv}$, where a, b are constants ---------- (1)

$f = 8.1596\, e^{0.9484v}$, $R^2 = 0.980$ ---------- (2)

Because of limited cement content in use, HPC is different with the conventional concrete. Under DMDA, cement paste is used only to fill the porosity among aggregates. High flowing HPC is achieved by the addition of pozzolan and chemical admixture to reduced water and cement amount. Referring to Fig. 3, the early strength of HPC was dominated by cement content. Concrete with lower cement content would obtain higher strength after 56 days, and hence it shows long-term strength was governed by W/B (water cementitious material ratio), but not W/C. The concept is accepted by ACI 318-95. Although conventional concrete without pozzolan could reach high strength, according to Fig. 2 it shows low pulse velocity occured by microstructure defects, which would cause durability problem (Hwang and Jann, 1996).

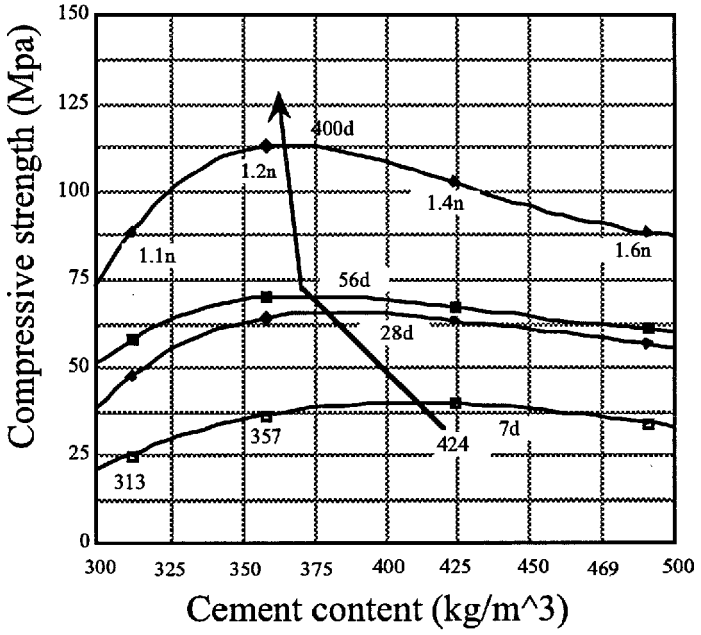

Fig 3. The effect of cement content on pulse velocity and compressive strength of HPC

DURABILITY EVALUATION

Resistivity can be used as an indication for durability of concrete. The electrical resistivity of HPC and conventional concrete at 56 days were measured as shown in Table 2. It shows high paste amount and high W/B may obtain lower resistivity because more capillary pores from pre-existing water in concrete can conduct ion migration, but harmful to long term durability. The addition of pozzolan can refine

the pore size and reduce pore volume, and the resistivity is about 6 times higher than that without any pozzolan.

Table 2. The comparison of electrical resistivity in HPC and CC

Type	n	W/B	Electrical Resistivity (kΩ-cm)			
			3d	28d	90d	180d
HPC	1.3	0.28	4	21	58	75
		0.32	4	16	42	58
		0.40	4	13	35	48
CC (ACI)	2.1	0.32	4	6	8	9

CONCLUSION

In this study the two NDT of ultrasonic pulse velocity and resistivity were conducted to evaluate the properties of concrete. It is found that by DMDA the quality of HPC can be evaluated accurately. The concrete with rich cement paste and without any pozzolan would has the strength as same as that of HPC, but has lower pulse velocity and resistivity. The NDT hence is a useful tool for measuring the soundness and durability of concrete. It also reveals that proper amount of fly ash in HPC under low cement content is helpful to its durability.

LIMITATIONS OF STANDARD TEST METHODS TO PREDICT DELAYED DAMAGING ALKALI-AGGREGATE REACTION (AAR) IN CONCRETE

Mihai NADU, Michael SCHIEBER, Jacob NISSENBAUM ,Michael BRAIMAN and Michael LUKACH, School of Applied Science of the Hebrew University, Jerusalem 91904 Israel. Shimon BOYKO and David SHTAKELBERG, Standard Institution of Israel 7, Yad Harutzim St., P.O.B. 10258, Jerusalem , Israel.

ABSTRACT Length measurements on concrete prisms, stored in 100% humid air at 38°C, made with a limestone aggregate sample containing ~ 4% SiO_2 with 410 kg cement and 5 kg Na_2O equivalent per 1 m^3 of concrete, show the following expansions: insignificant prior to 5-6 month , 0.05% after 11 month, 0.14% after 12 month and 0.20% after 2 years. The expansion kinetics suggests a "late expanding alkali-silicate/silica reaction".The same aggregate did not show any reaction when tested according to the ASTM C227, C289 or C1260.
Key-words: Alkali-aggregate reaction, methods for AAR, expansion, durability of concrete

INTRODUCTION

An Alkali-Aggregate Reaction (AAR) research, taking into account the specific Israeli conditions, started for the first time in Israel some four years ago (Nadu et al,1996). The present paper deals with an aggregate sample that turned out to be particularly interesting for alkali reactivity research. This aggregate sample, supplied from a quarry situated in the north of Israel, was known as a "pure limestone" and was considered to be a comparative blank (non alkali - reactive) sample. Considerations based on the chemical analysis corroborates the assumption of non-reactivity. The different grain sizes of the aggregate were analyzed by the the Central Laboratory of Nesher Cement Ltd., by induction coupled plasma. (Table 1).

Table 1 Chemical parameters of the limestone aggregate sample, wt%

	Fine aggregate				Coarse aggregate
	0.3-0.6 mm	0.6-1.1.8 mm	1.18-2.36mm	2.36-4.75mm	4.75-19 mm
SiO_2	**4.00**	**3.90**	**4.20**	**4.40**	**3.60**
Al_2O_3	**0.14**	**0.15**	**0.16**	**0.19**	**0.19**
CaO	**53.00**	**53.00**	**52.80**	**53.10**	**51.00**
MgO	**0.26**	**0.28**	**0.28**	**0.28**	**2.12**
CaO:MgO ratio	**204**	**189**	**189**	**190**	**24**

The chemical analysis corroborates the assumption of non-reactivity: a) The sample is not suspected of alkali-silica reactivity (ASR) since it contains less than 5% SiO_2 insoluble residue in HCl (Fournier & Berube,1993); b) The sample is not susceptible to alkali-carbonate reactivity (ACR) according to a new CSA A23.2-26A-94 test, consisting of plotting on a graph, the CaO/MgO ratio as function of the Al_2O_3 content. For a CaO/MgO ratio $\geq$ 24 and for a content of $\leq$ 0.19% Al_2O_3 the sample is placed on the non ACR zone of the graph..

The limestone sample was studied by several AAR methods which led to inconclusive results but the non-reactivity assumption was finally refuted when our investigations comprised simultaneously: (1) high alkali containing concrete specimens, stored in warm and humid air; (2) late ages (11 month and more) measurements; (3) testing by the AS/SR version of the concrete prism expansion method (former 1990 Canadian CSA & 1990 French AFNOR-NF;

Hooton,1996). For the above conditions, concrete containing this aggregate, does show a strong late-expanding alcali-silicate/silica reaction (AS/SR).

Note: The former 1990 CSA Standards was replaced in June 1994 when our concrete specimens were 18 month old. The new 1994 CSA looks like the combined former CSA & French standards (410 kg cement /m3 of concrete) The AS/SR designation no longer exists.

EXPERIMENTAL PROCEDURE AND STANDARD REQUIREMENTS

Introduction

The samples have been tested for AAR using five known standard methods : **(I)** The 24 hour chemical method; **(II)** The two week "NBRI" mortar bar test; **(III)** The long term (2 years) mortar bar expansion method, at 38°C in 100% relative humidity; **(IV)** The same as in **"(III)"** but on concrete prisms; **(V)** The same as in **"(IV)"** but at 22°C. The test methods **I, II, III and V** gave inconclusive results or gave results that did not show alkali-reactivity for this investigated concrete aggregate sample. Only test method **IV** showed under certain conditions deleterious alkali- aggregate reactivity.

(I) The 24 hour ASTM C289,1994 chemical test with an altered graph (Fig.1)

The test consisting of the immersion of graded aggregate sample in 1N NaOH solution at 80°C for 24 hours, is followed by chemical analysis of the filtered solution for dissolved silica (Sc) and for reduction of alkalinity (Rc). The results are plotted on a graph showing four regions of

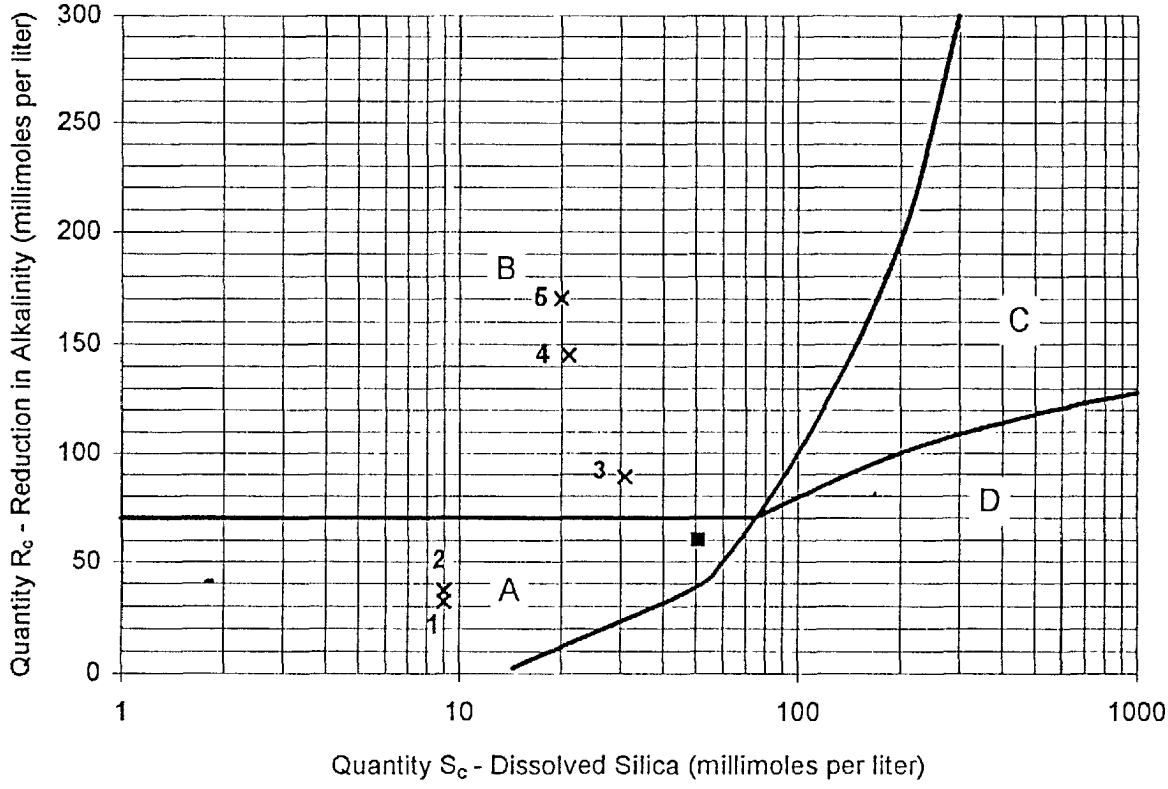

Figure 1 Evaluation of the AAR results by the 24 hour chemical method ASTM C289 with an altered graph. Sc is plotted on a logarithmic scale (Bredsdorf et al,1960; Romanian Standard STAS 5440,1970): **x1...x5** - Limestone aggregate samples, ■ - Sea sand sample from Ashdod

aggregates: (A) "innocuous"; (B)"generally non-reactive", but in this field the interference of carbonates in the reaction between SiO_2 and NaOH leads to inconclusive results requiring long term mortar bar or concrete prism expansion methods; (C) "highly reactive, potentially deleterious", but if the pessimus (worst) percentage of reactive silica is exceeded, the mortar bars might display non significant expansions; (D) "deleterious reactive". The original ASTM graph comprises three regions, the (A+B) region being considered innocuous. The chemical test was excluded from the last CAN/CSA. We think that it should be considered an alternative method for future AAR test of siliceous limestone. The alternative method consists of performing the ASTM procedure on the insoluble residue obtained by dissolution of the carbonates in hydrochloric acid (Dron,.1992; Berube & Fournier,1993; Barisone & Restivo,1996). In order to find the worst proportion of reactive particles the chemical method has been altered becoming a "kinetic" test (French NF-P18-589; Sorentino et al 1992). The kinetic test is criticized e.g., by Barisone & Restivo (1996) as nonreliable for the petrography of Italian aggregates

(II) The 2 week NBRI mortar bar test (ASTM C1260,1995, or CSA A23.2-25A,1994).
Mortar bars, 25 by 25 by 285-mm ASTM C227, are maintained at 80°C, one day in water up to the zero reading and afterward in 1N NaOH solution. Fournier&Berube (1993) and CAN/CSA A23.1-94.Appendix B suggested the following mortar bar expansion limits in 14 days: <0.10% for innocuous aggregates and ≥ 0.15% for deleterious aggregates. Shayan et al (1988) suggested that:(i) mortar bar expansion of 0.10% in 10 days and 0.10% in 22 days are to be taken as indicating reactive aggregate of short induction period and long induction period, respectively; (i,i) for some slowly reacting carbonate rocks a concrete prism test is more suitable than mortar bars for assessing the reactivity. Unfortunately, we performed measurements for only 2 weeks.

(III) The long term mortar bar test. (ASTM C227,1990 & CAN/CSA A23.1-90.Appendix B).
The reactivity limits are 0.05% at 3 months or 0.1% at 6 months or more, for mortar bars with high alkali content(1.25% Na_2O equivalent relative to the cement weight or 7.5 kg Na_2O equivalent per $1m^3$ of mortar) maintained at 38°C, in wet air . According to Hooton & Rogers (1989) the absorbent material used in the ASTM containers might cause diminished expansions due to the alkali-leaching of the mortar bars. The test is not included in the 1994 edition of CSA Standard.. For our future work we consider an alternative method which would replace the mortar bars 25 by 25 by 285 mm with mortar prisms 40 by 40 by 160 mm according e.g., to the European experience (Grattan-Bellew,1989) and to the Japanese standard JIS A 5308.

(IV,V) The long term concrete prisms expansion method

Generalities
Two versions (ACR and AS/SR) of the former CSA A23.2-14A,1990 and the French Standard NF P18-587,1990 were applied. Each former version of the CSA was intended to test concrete aggregate suspected to suffer from alkali carbonate reaction (ACR) or Alkali Silicate/Silica Reaction (AS/SR).The main difference between the two former versions is the storage temperature of the specimens in moist air, being 23°C for ACR and 38°C for AS/SR. The former CSA was replaced in June 1994 with the new CSA A23.2-14A-M94. The main modifications are: (i) the cement content increased from 310 to 420 kg/m^3 and an alkali content of 1.25 %Na_2O equivalent (eq.) by mass of cement, resulting in an increase of the alkali content in concrete from 3.90 to 5.25 kg. Na_2O eq./m^3 ; (i,i) a 38°C storage temperature in moist air is

required for all the specimens, independent of the AAR type. The French standard and the experimental variant M4/38 (Table 2) look like the new CSA (Portland Cement content in concrete of 410 kg/m^3, corresponding to 5.13 kg Na_2O eq/m^3).

Experimental conditions (CSA A.23.1 & A.23.2 & , A.23.2-14,1990 and Table 2)
Specimens: Three prisms of 75-mm by 75-mm by 285-mm, having a 250- mm- gauge length, with studs, were used for each experimental variant.

The aggregate contained 16% very fine, 24% fine and 60% coarse grains. The 0.15-0.60 mm aggregate was a quartz sand extracted from the Mediterranean seaside, frequently used in the manufacture of concrete. The sample of the sea quartz-sand are placed in region A "innocous aggregate" of the reactivity graph (Fig.1) It was graded together with the 0.60-4.75 mm limestone aggregate according to the grading requirements of ASTM C 227,1989. The coarse limestone aggregate was separated by 19, 14, 9.5 and 4.75 mm sieves and recombined taking equal portions by mass of the three sizes of the material.

The cement: A low alkali Portland cement, containing 0.47% alkalis.

Mixing water and slump: The amount of water (with optional addition of NaOH) should correspond to an 80 mm fresh concrete "slump" (CSA A.23.1 & A.23.2,1990) however the fresh concrete with 310 kg cement/m^3 (mixtures M1 and M2 in table 1) was "no slump" since a small increase of the water/cement ratio causes the fall of the concrete cone, immediately after the mold removal. For a cement content of 410 kg/m^3, (mixtures M3 and M4 in Table 1) the desired slump was easily obtained.

The compressive strength of the concrete was determined for each mixture on 100mm cubes. Comparing the mixtures M1 with M2 and M3 with M4, it appears obvious that NaOH addition in the mixing water acts as a strong retarder of the hardening especially for early ages (7 and 28 days). At 6 months, the retarder effect is diminished (Table 2)

Table 2 Concrete mixtures and experimental variants for AAR testing

Name of the concrete mixture	M1	M2	M3	M4
Water- cement ratio (w/c)	0.63	0.62	054	0.52
Portland Cement content in concrete (kg/m^3)	310	310	410	410
Additional alkalis through the mixing water	No	Yes	No	Yes
Alkali content (as Na_2O equivalent) provided from the cement and from the mixing water				
-Relative to the cement weight (%)	0.47	1.25	0.47	1.25
-Relative to the concrete (kg/m^3)	1.46	3.90	1.93	5.13
Slump of the fresh concrete (mm)	0	0	~80	~80
Density (kg/m^3)	2360	2350	2350	2370
Compressive strength (MPa): -7 days	31	21	38	23
-28 days	42	34	55	34
-180 days			66	59
Average expansion at 2 years (%):				
-Storage in 100% humid air at 22±2°C	-0.005	-	-0.008	0.002
-Storage in 100% humid air at 38°C	0.007	0.011	-	0.188
Negative (-)values represent shrinkage changes				

Standard requirements

CSA and ASTM requirements: **(a)** The former CSA considers that ACR expansions are deleterious, if the length change exceeds 0.010% after 3 months or 0.025-0.040% after 12 months (depending on the micro-climate to which the structure is to be exposed). **(b)** ASTM C1105,1989 considers deleterious ACR expansions of >0.015% after 3 months or 0.025% after 6 months or 0.030% after 12 months (independent of the micro-climate). **(c)** The former CSA considers that AS/SR expansions are deleterious, if the length change exceeds 0.040-0.075% after 12 months (depending on the micro-climate to which the structure is to be exposed). **(d)**The new Canadian Standard considers that expansions are deleterious, independent of the AAR type, if the length change exceeds 0.040% after 12 months , noting that "in critical structures such as those used for nuclear containment or large dams, a lower expansion limit may be required" (CAN/CSA A23.1-94. Appendix B).

French requirements. To the best of our knowledge there are no French standard limits for critical AAR expansions,of the concrete prisms NF-P18-587,1990. It seems to be accepted a 0.040% limit at 8 months, to indicate reactivity, but it is still being discussed (Corneille & Bollotte.1994). However it seems that the interpretation of the French test results is covered by the Canadian standard limits. In the future, significant AAR compositions for mortar bars and concrete prisms methods are to be prepared taking into account the experimentally found worst ("pessimum") content of the reactive particles (NF-P18-589,1992; Corneille & Bollotte, 1994).

EXPERIMENTAL RESULTS

(I) AAR studies by the 24 hours chemical test

On the graph (Fig.1) five tested samples are placed as follows: two samples in region **A**, three others on the doubtful region **B**, due probably to the presence of carbonates interfering with the reaction between NaOH and the dissolved silica. In order to clarify if the tested aggregate is reactive, long term tests are required by ASTM C33.

(II) AAR studies by the 2 week mortar bar test

After 14 days of storage at 80°C in 1N NaOH solution, an average expansion of 0.08% was recorded showing no alkali reactivity for the tested concrete aggregate.

(III) AAR studies by the long term mortar bar test

Even for mortars with high alkali content ,obtained by adding NaOH in the mixing water, the length changes were small (up to 0.013 % in 2 years), sensibly less than the reactivity limits

(IV) AAR studies by the long term concrete prism method

These studies comprise four concrete mixtures and six experimental variants (Table 2). Each experimental variant was labeled with the name of the concrete mixture (M1, M2, M3 or M4) and the temperature (in °C) of the wet air environment in which the specimens were stored. Storage. temperatures were 22°C or 38°C. According to the specifications of the ACR version of the former Canadian standard, the small length changes recorded for specimens M4/20, prove that the tested aggregate is not alkali carbonate reactive (CSA A 23.1.App. B & A 23.2-14, 1990). The same fact results logically from the chemical analysis according to the new CSA requirements(CSA A 23.2-26A, 1994). Fig. 2 shows the length changes vs. time up to 2 years for each specimen (#151, #152, #153) of the M4/38 experimental variant. The length changes (up to 2 years) for each specimen of the experimental variants M1/22, M1/38, M2/38, M3/22

and M4/22 are insignificant small, sometimes within the error of measurement, consequently the length changes are not placed on Fig.2. Trying to distinguish (at different ages), the non-reactive, the marginally or the very reactive aggregates, the expansion kinetics of each of the three specimens of the experimental variant M4/38 is compared with the Canadian typical AAR expansion curves comprised in the 1990 CSA A.23.1 App.B. For a better understanding, a comparison is made between the expansion kinetics of the M4/38 specimens and the values obtained by interpolation in the expansion curves comprised in the 1990 CSA A.23.1 App.B (Table 3). Figure 2 and table 3 show that the tested aggregate generates inside the concrete a very strong late-expanding alkali-silicate/silica reaction. It is also obvious that in comparison with the Canadian limits the beginning of the expansions appears much later and in a sudden manner at ~11 month, with subsequent expansions developing abruptly to high values.

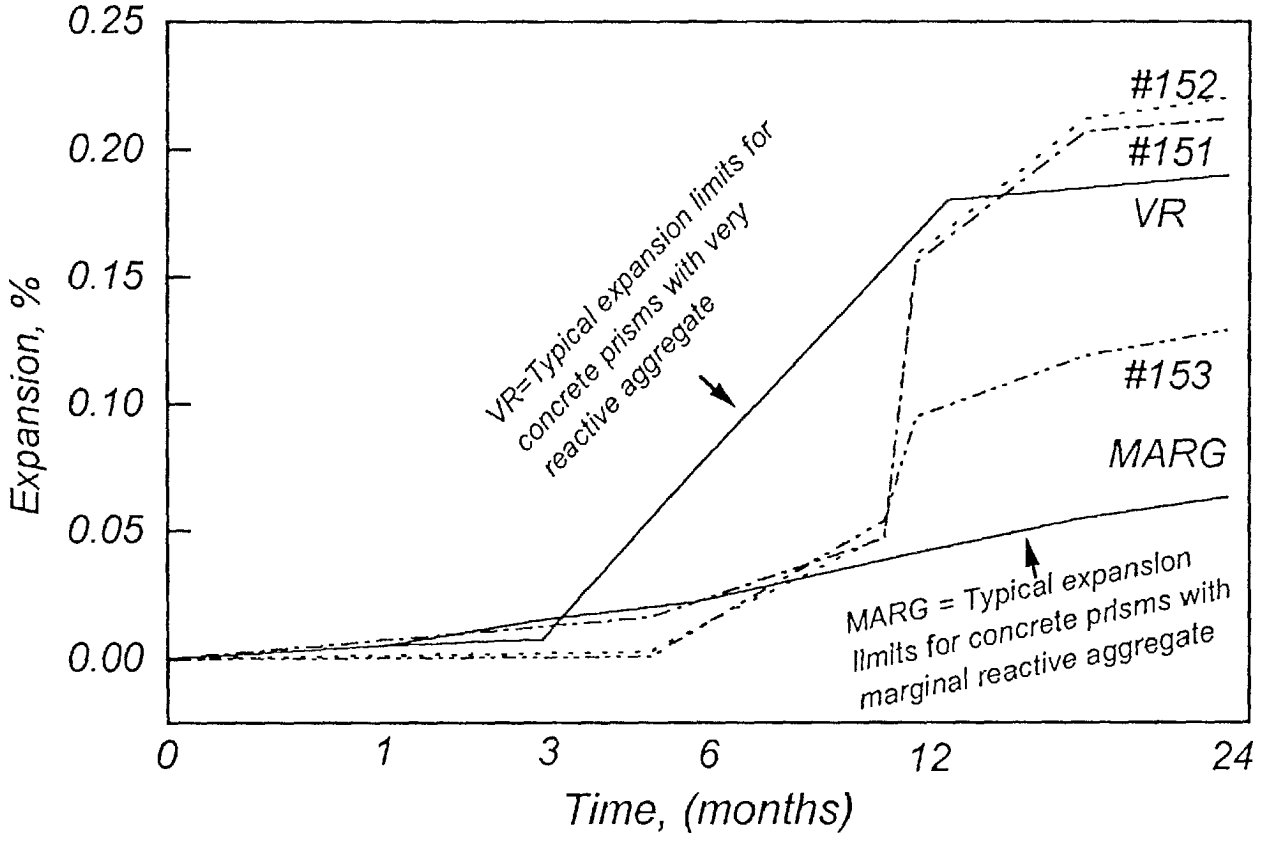

Fig 2 Expansion kinetics for each of the three M4/38 studied specimens (**#151,#152,#153**) are shown as dotted lines and are compared with solid lines **"VR"** and **"MARG"** representing the Canadian "characteristic expansion curves for concrete prisms made with the greywacke-slow/late-expanding alkali-silicate/silica reactive aggregates" adopted from page 100 of the former CSA A23.1. App B-90. The time is plotted on a square cubic root.

DISCUSSION

The long term expansion kinetics of concrete prisms with the limestone aggregate suggests a new case of " strong late expanding alkali-silicate/silica reaction". This behavior was not foreseeable by accelerated test methods and becomes obvious after some 11 months of measurements. Based on a detailed AAR study of Quebec rock-quarries, Fournier & Berube (1993) concluded that carbonate aggregates containing less than 5% insoluble residue or

involving expansions less than 0.1% after 14 days in the NBRI method are innocuous. However, our limestone concrete aggregate sample which passed both requirements is a deleterious aggregate. Unfortunately, the field of validity of each accelerated test method depends on the chemical, physical and geological peculiarities of the tested aggregate. International reputed AAR test methods, have sometimes limitations, e.g., turn out to be unable to predict delayed damaging reactions, as in the present paper described behavior of a certain Israeli limestone aggregate containing apparently insignificant quantities of residue insoluble in HCl, and tested according to the above mentioned non altered standard methods **(I, II, III, IV, V)**.

Table 3 Expansion kinetics of the M4/38 concrete specimens, compared to interpolated values from the expansion curves comprised in the 1990 CSA A.23.1 App B (%)

AGE (Month)	5	11	12	24
Expansion of the specimens of the experimental variant M4/38				
Concrete specimen #151	0.016	0.047	0.156	0.201
Concrete specimen #152	0.003	0.048	0.159	0.212
Concrete specimen #153	0.001	0.050	0.095	0.129
Average expansion	0.007	0.050	0.136	0.188
Reactivity limits by interpolation on the 1990 CSA curves				
Very reactive	>0.05	.>0.13	>.0.15	>0.18
Marginal reactive	0.03-0.05	0.035-.015	0.04-0.15	0.06-0.18
Non reactive	<0.03	<0.35	<0.40	<060

The Israeli cement users are generally unaware of AAR and its possible effects on the durability of the concrete structures. In the near future, our AAR research must drive to the appearance of AAR Israeli standards to avoid the repetition of structure failures similar to the ones which appeared 12 years ago in Belgium (Van Gemert.1989 and 1996), in the United Kingdom [Hoobs.1989 and 1996], in Japan (Okada.1989; Okada and al.1996) and in other countries where awareness on AAR arose. According to Oberholster (1996), "in most instances where ASR have been diagnosed in structures , the durability and serviceability have been greatly affected and the service life in many cases significantly reduced...owners of such structures are hard pressed for funds for the high costs of reparation and maintenance".

CONCLUSIONS

The present paper shows that concrete aggregates considered to be non reactive according to accepted testing procedures are in fact potentially deleterious for concrete structures due to their late AAR attack. Therefore it is very important to develop new methods of testing (or to improve the classical methods) which should identify such late AAR attacks. So for example it is possible to predict the AAR behavior of slowly reacting aggregates by an improved NBRI mortar bar expansion method according to Shayan et al.(1988) and by the use of autoclave methods (Fournier & Berube, 1993; the French standard NF P18-590-1993) which accelerate the AAR It is possible to test the reactivity of carbonate aggregates by use of alternative methods to the 24 hours chemical method ASTM C-289 (Dron,.1992; Berube & Fournier,1993; Barisone & Restivo,1996; French NF-P18-589; Sorentino et al 1992).

ACKNOWLEDGMENT

The AAR studies in the Hebrew University of Jerusalem were financially supported by the Israeli Cement Foundation and were performed in cooperation with the Jerusalem Branch of the

Israeli Standard Institution. Thanks are given also to the Nesher Cement Ltd., for their collaboration in some of the laboratory works.

ON THE MECHANICAL PROPERTIES OF COMPACTED NEAT CEMENT PASTE, CEMENT MORTAR AND GYPSUM PASTE

Gerardo DIAZ, Departamento de Ingeniería de los Materiales, IDIEM, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, Casilla 1420, Santiago, Chile.
Pablo KITTL and Víctor MARTINEZ, Departamento de Ingeniería Mecánica, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, Casilla 2777, Santiago, Chile.

ABSTRACT The critical stress intensity factor, K_{IC}, was determined in cement paste and cement mortar. The correlation factor between K_{IC} and the fracture stresses in cement mortars under compression was 0.98. The splitting test was made in neat cement paste and neat gypsum paste. The results for K_{IC} and for splitting were analysed by Weibull's statistics determining then the corresponding parameters and mean values. For K_{IC} Weibullian two-parameter functions were obtained whereas for splitting Weibullian two- and three-parameter functions were obtained.

Key-words: Characterization, Gypsum, Method.

INTRODUCTION

The traditional method for obtaining the critical stress intensity factor in mode I of fracture, K_{IC}, requires the generation, by fatigue, of an initial crack. This procedure, owing to its laborious application, implies a limited number of samples for determining K_{IC}. When dealing with brittle materials the problem even becomes more complex. For these reasons, a simplified method to determine K_{IC} in brittle materials has been developed and successfully applied to glass, cement mortar and compacted neat cement paste, where some results have been obtained (Díaz et al, 1994a; Díaz et al, 1994b; Kittl et al, 1996). The said method consists in making a pseudocrack in samples of rectangular cross-sectional area which later are subjected to the three-point bending test. Then, the first scope of this work is the statistical analysis of K_{IC} in paste and mortar of cement, studying thereof the size effect and the correlation between K_{IC} and the compressive fracture stress, in the case of cement mortar.

In order to characterise brittle materials from the probabilistic standpoint, diverse method may be employed (Weibull, 1939; Kittl et al, 1988). In this work the splitting test is used to characterise cement paste and gypsum paste. Thus, the second scope of this work is to obtain the Weibull's parameters in neat cement paste and in neat gypsum paste under splitting.

EXPERIMENTAL PROCEDURE

In the manufacturing of the samples of compact cement paste used for obtaining K_{IC}, commercial portland cement devoid of additives was employed. The cement was mixed with a 4%, in weight, of water and was introduced in a steel rectangular mold with the dimensions 55x20 mm and then a compacting pressure of 35 MPa was applied to it in order to obtain samples of 4 mm high. The samples were stored in a moist room, with 99% of humidity and at 23° C, during 24 hours. After concluding the 24 hours, the samples were submerged in water until saturation in order to the process of hydration of the same ones could advance as rapid as possible. Afterwards, the samples were again introduced into the moist room until completing 7 days of hydration. The process of hydration was stopped by putting the samples into a furnace at 110° C during 24 hours, later they were stored into a desiccator until the moment of preparing them for testing. In this way, 50 samples were made. A half

of the samples were transversely cut at the middle of the length by using a diamond saw. One of the transversal edges of these little pieces were polished by using a mechanical polishing disk, edges that, later, were going to generate the profile of the crack induced. Then, two little pieces were sticked to a complete sample by using epoxy resin, as is shown in Fig. 1. Hence, the epoxy resin was left to polymerise during 24 hours at room temperature. Afterwards, the samples were subjected to the three-point bending test which allowed to obtain 25 samples with L=39 mm long, b=20 mm wide and W=10 mm high and a crack size a=5 mm. The precedent process for the generation of the crack is analogous to the one employed in the preparation of the glass samples (Kittl et al, 1996), except that in the samples of compact cement paste it was not necessary to make a transversal scratch because in the internal constitution of the cement there are a great number of cracks which are very easy to be observed by electron microscopy and that, for reasons of space, are not shown here.

In the case of portland cement mortar, 54 samples of 160 mm long, 40 mm wide and 40 mm high and 32 samples of 160 mm long, 40 mm wide and 25 mm high were prepared. A transversal crack was induced to every sample along all its width and in the middle of its length, with a size of 15 mm and 9.4 mm for the first and second set, respectively. The samples were fabricated according to the RILEM's procedure. Afterwards, the samples were stored into a moist room, with 99% of humidity, at temperature of 25° C, until to complete 7 days. The crack was generated by introducing a steel lamina into the samples, in the fresh state. The steel lamina was retirated after the first day of curing in a moist room. Two thicknesses of lamina were employed: 0.5 mm and 1.0 mm. From the group of 54 samples, a half was made with the lamina of 0.5 mm and the remaining one with lamina of 1.0 mm thick. From the group of 32 samples of 25 mm high, all of them were made with lamina of 0.5 mm thick. All samples were subjected to the three-point bending test, with a testing span of 100 mm, in moist state, immediately after completing the 7 days of curing.

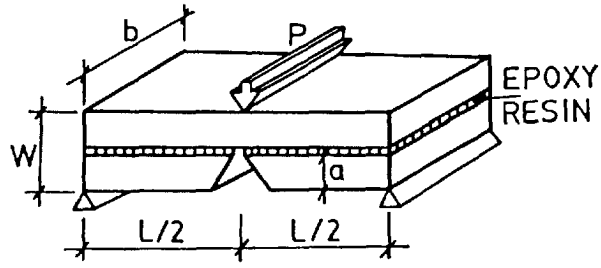

Figure 1 Form of addition with the epoxy resin used in the fabrication of the cement paste samples tested by the three-point bending test.

The critical stress intensity factor K_{IC} was determined by the expression:

$$K_{IC} = \sigma Y\sqrt{a} = \frac{3}{2}\frac{PL}{bW^2}Y\sqrt{a}; \quad Y = Y\left(\frac{L}{W}, \frac{a}{W}\right) \qquad [1]$$

where Y is a function depending on the geometry of the sample obtaining from tables (Chermant, 1975), a is the crack size and σ is the expression of the maximal stress of fracture for the case of the three-point bending test and P is the fracture load.

In order to perform the splitting test in neat cement paste and neat gypsum paste, the following methodology was adopted. Commercial cement and gypsum devoid of additives was employed. The cement was mixed in a steel cylindrical mold with 0.019 m length and 0.019 m diameter and then a compacting pressure of 25 MPa was applied. The process of hydration was similar as samples used in order to obtain K_{IC}, but the treatment into the moist room was until completing 14 day of hydration. In this way, 29 samples were made.

In the case of compact gypsum paste the gypsum was mixed with 20%, in weight, of water and was introduced in a steel cylindrical mold obtaining samples with 0.017 m length and 0.019 m diameter and then a compacting pressure of 12 MPa was applied. The samples were stored at room temperature during 24 hrs. After concluding the 24 hrs., the samples were stored for 24 hrs in a dessicator. The process of hydration was stopped by placing the samples into a furnace at 60^0 C during 2 hrs, later they were stored into a dessicator until the moment of testing. In this way, 39 samples were made.

In the splitting test the strength at fracture was determined using the following expression:

$$\tau = \frac{2P}{\pi L d} \qquad [2]$$

where P is the splitting load at fracture, L and d are the length and diameter of cylinder, respectively, and τ is the maximal splitting stress at fracture.

The probabilistic analysis of data obtained for K_{IC} and for fracture stress by splitting τ was made by using respective Weibull's diagrams.

THE PROBABILITY DISTRIBUTION FUNCTIONS

According to Probabilistic Strength of Materials (Weibull, 1939; Kittl et al, 1988), if the critical stress intensity factor K_{IC} follows a Weibull's distribution, this can be pointed out as follows:

$$F(K_{IC}) = 1 - \exp\left\{-\frac{B}{B_0}\phi(K_{IC})\right\} \qquad [3]$$

where F is the cumulative probability, ϕ is the Weibull's specific risk function, B_0 is the unit length and B is the crack width which, particularly in this work, is equal to beam width b, as can be seen in Figure 1. The Weibull's specific risk function, when assuming some analytical expression known a priori for it, can be expressed as follows:

$$\phi(K_{IC}) = \begin{cases} \left(\frac{K_{IC} - K_{ICL}}{K_{IC0}}\right)^m & K_{ICL} \le K_{IC} < \infty \\ 0 & 0 \le K_{IC} \le K_{ICL} \end{cases} \qquad [4]$$

where m and K_{IC0} are the Weibull's parameters depending on the process of generation of the crack and on the material manufacturing and K_{ICL} is the lower limit value for the critical stress intensity factor under which no crack propagation occurs. When $K_{ICL}=0$ the Weibull's specific risk function of two parameters is obtained, being them m and K_{IC0}.

According to Probabilistic Strength of Materials (Weibull, 1939; Kittl et al, 1988), the cumulative probability of fracture for splitting, when the function ϕ is of two parameters and of form similar to the one set forth in Eq 4, is given by:

$$F(\tau) = 1 - \exp\left\{ -\frac{Ld^2}{V_0}\left(\frac{\tau}{\tau_0}\right)^m \int_0^1 \int_0^{\sqrt{1-\eta^2}} \left[f(\xi,\eta)\right]^m d\xi d\eta \right\} \quad [5]$$

where V_0 is the unit volume, L is the cylinder length, d is its diameter and τ is the maximal stress of fracture. The function $f(\xi,\eta)$ is determined from Elasticity theory and it defines the stress field acting in the splitting test. As in the case of K_{IC}, m and τ_0 are the Weibull's parameters depending on manufacturing process of the material but now for splitting. When ϕ is a three-parameter function then one has:

$$F(\tau) = 1 - \exp\left\{ -\frac{Ld^2}{V_0}\left(\frac{\tau_L}{\tau_0}\right)^m \int_{V(\xi,\eta)} \left(\frac{\tau}{\tau_L} f(\xi,\eta) - 1\right)^m d\xi d\eta \right\} \quad [6]$$

where τ_L is the stress under which no splitting fracture of the material occurs and $V(\xi,\eta)$ is the volume given by $\tau f(\xi,\eta) \geq \tau_L$.

ANALYSIS OF RESULTS

Determination of K_{IC}

Figs. 2 and 3 show the respective diagrams for compact cement paste and cement mortar. Weibull's specific risk functions of two parameters, in a first approximation, were respectively obtained, given by the form of the curves shown in Figs. 2 and 3. In Fig. 3, Weibull's diagrams for the mortar cement samples identified by M1, M2 and M3 are shown. M1 is the curve corresponding to those 27 samples of 40 mm height whose crack was generated by a steel lamina of 1 mm thickness and M2 is the curve corresponding to those 27 samples of 40 mm height and whose crack was generated by a steel lamina of 0.5 mm thickness. In both curves the samples are of the same size. Likewise, M3 is the curve corresponding to the 32 samples of height 25 mm and for which the crack was generated with the lamina of 1.0 mm thickness. In these three curves, the size effect due to the thickness, or the crack width between M1 and M2 and, also, the same effect between M2 and M3 can be studied. When comparing the curves M1 and M2, in the Weibull's diagram, there is a shift to the left when the thickness of lamina generating the crack is increased, i.e., the cement mortar behaves as a Weibullian material when considering the critical stress intensity factor. However, if considering the height of the beam, an inverse Weibullian shift is observed because the curve moves to the right when the height of the beam is increased, as can be observed when comparing curves M1 and M3.

In Table 1, the respective parameters and the mean values of the critical stress intensity factor are shown. According to Table 1, the values found for the mean values of the critical stress intensity factor in the mode I are within the ranges of magnitude that appear in the literature when they are determined by the traditional method. Therefore, the procedure described herein and then put

into practice becomes efficient in the determination of the critical stress intensity factor in the mode I when applying in brittle materials, as was made here for portland cement paste and portland cement mortar.

From each one of the 32 samples of portland cement mortar, M3, two pieces, which were tested in compression, were obtained. The mean strength, σ_C, was determined for every sample and it was correlated with the respective value of K_{IC} associated. In Fig. 4 is shown the result of plotting the pairs (σ_C,K_{IC}) which allows to obtain a factor of correlation of 0.98. In accordance with the high value of this factor of correlation, the determination of the compressive mean strength in portland cement mortars is an excellent and indirect indicator in the determination of the critical stress intensity factor in the mode I.

	M3	3.98	0.13	0.33

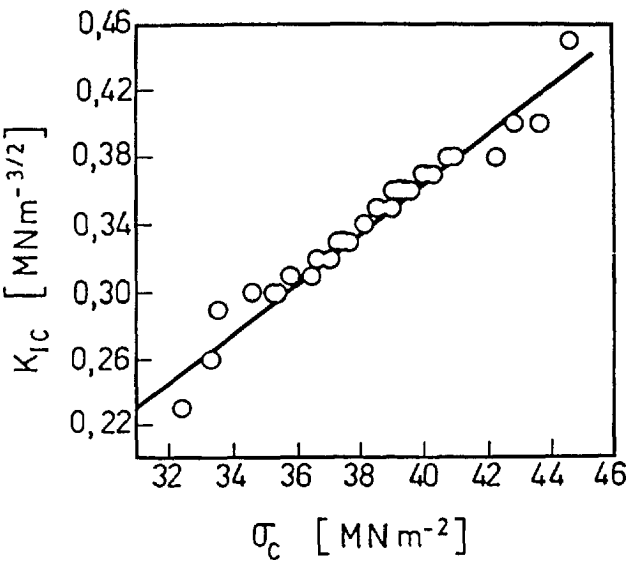

Figure 4 Correlation between the mean compressive strength, σ_C, and the critical stress intensity factor for the cement mortar (M3).

Determination of splitting fracture stress

In Figs. 5 and 6 are shown the Weibull's diagrams for the compacted pastes of cement and gypsum, respectively. Both diagrams were made with the experimental results of the splitting tests performed to both groups of samples. The mean strengths of fracture for the pastes of cement and gypsum were 14.5 MPa and 7.7 MPa, respectively. In view of the form adopted by the distribution of experimental data, as can be observed in Figs. 5 and 6, both materials present different Weibull's specific risk functions. The expression of this function is given by Eq 4 which for the case of our interest, splitting, the parameters are m, τ_0 and τ_L and the random variable is the fracture stress by splitting, τ. The parameters m and τ_0 are parameters depending on manufacturing process of the material and τ_L is the stress under which there is no fracture. When observing Fig. 5 is deduced that curve is adjusted with a Weibull's function of two parameters, i.e., $\tau_L=0$, whereas in Fig. 6 the corresponding curve follows one of the same type but of three parameters, i.e., $\tau_L\neq0$. Therefore, in the case of compacted paste of gypsum, the value of τ_L, obtained in a first approximation by a graphic interpolation, was 5.8 MPa. The

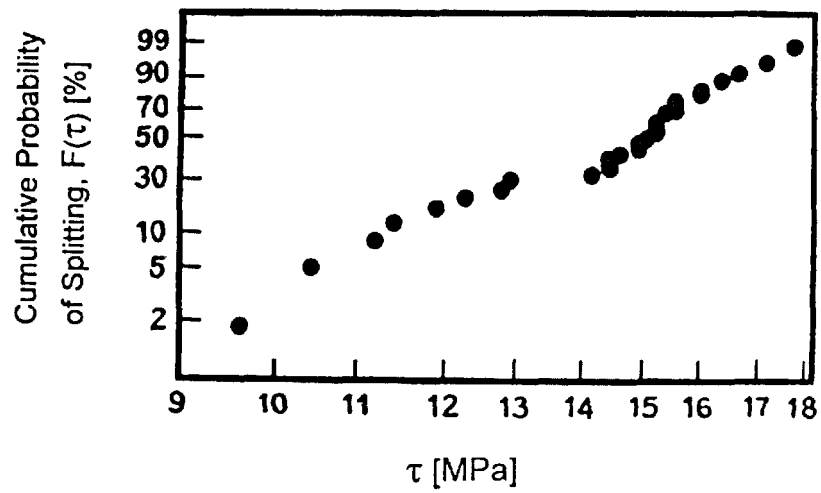

Figure 5 Weibull's diagram for the cumulative probability of splitting fracture stress for samples of neat cement paste.

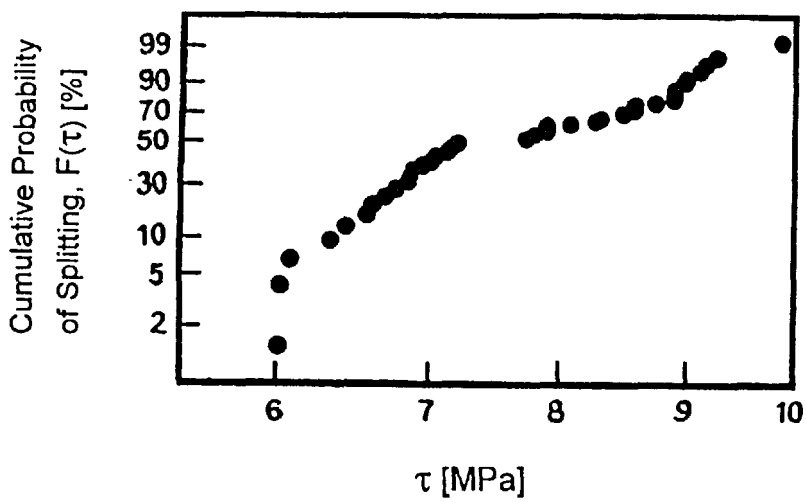

Figure 6 Weibull's diagram for the cumulative probability of splitting fracture stress for samples of neat gypsum paste.

parameter m, which is inversely related to dispersion, was 7.2 and 8.5 for cement paste and gypsum paste, respectively. Thus, the experimental data of the compacted cement paste exhibited a greater dispersion.

In preliminary results, which are not shown due to lack of space, the size effect has been studied in both pastes, determining thereof in the case of gypsum a shift to the left in the Weibull's diagram. This means the greater the size the lesser the splitting fracture stress, which fact is in accordance with Weibull's statistics theory. On the other hand, in the case of compacted cement

paste the size effect is not verified, as was already observed in samples tested under compression (Kittl et al, 1983).

CONCLUSIONS

A simplified method to determine K_{IC} in compacted neat cement paste and cement mortar was developed and proved by means of the generation of a pseudocrack. The values obtained thereof are in accordance to the ones obtained by the traditional methods. When the functions of probability distribution of K_{IC} were studied, Weibull's specific risk functions of two parameters were obtained in cement paste and cement mortar. A good correlation between the mean compressive strength and the critical stress intensity factor in mode I was established. The values are within the ranges of magnitude that traditional method produces. This reveals the efficiency of the method developed here and the possibility to apply it successfully to the determination of the critical stress intensity factor in mode I in other kinds of brittle materials. The method applied here is important because it allows to obtain a large number of samples in order to determine K_{IC} with a minimal cost, making thus sure a statistical analysis with a Weibull's diagram.

According to splitting tests performed in cement paste and gypsum paste Weibull's functions of two and three parameters, respectively, were obtained. In the case of gypsum paste is important to consider the existence of parameter τ_L=5.8 MPa, since it defines the stress limit under which no splitting fracture is produced. The size effect could be observed in gypsum samples whereas in cement samples the same was not observed.

PARAMETERS RELEVANT FOR STANDARDIZATION OF SAND AND MORTAR STRENGTH

Z. B. Entin, L.S. Nefyodova, CEMISCON, Moscow, Russia

ABSTRACT. Properties of sands (void factor and specific surface values) which affect characteristics of a standard cement mortar like flowability, average mass of specimens after demolding and the corresponding strengths have been tested and analyzed using four standard polyfractional sands from Germany, Spain, England and Poland. It is shown that the effect of certain factors on the strength of mortars can be substantial enough even for the standardized methods. These are to be taken into consideration while standardizing the sand.

KEY-WORDS: aggregate, flow, particle size distribution, strength development, void spacing factor.

INTRODUCTION. The particle size distribution of a sand with established values is a necessary condition, but it is, by no means, the only one making the vulnerable for standard testing of cement mortars. The universally accepted criterion, in this instance will be, the comparison of 28 days strength values with the use of sand under test and the reference sand. The difference for 20 mixes using 3 cement types has not to exceed 5% for at least in 95% cases.

The void factor is not subject to normalization usually with regard to the standard sands used for cement testing, whereas with regard to building sand it is one of the quality criteria. It is common opinion that the quality of building sand with particle size distribution of 2.5 to 0.14 mm has void factor not less than 38% in loosely bulk state. An optimal combination of big, average and small grains which ensures the void factor of such polyfractional sand, it can be reduced to 30%. In this work typical properties of several polyfractional sands have been considered and the flowability of mortars, average mass after demolding of the specimens and strengths were measured.

EXPERIMENTAL. Several standard polyfractional sands which confirm EN-196-1 requirements for particle size distribution from Germany DIN EN 196-1, Spain UNE 80.101-88/CEN 196-1, England CEN 196 Part 1 and Poland PN-68/B-11000 have been used. The void factors of these standard sands in loosely packed state after compaction by shaking and after compaction by vibration have been determined. The results are shown in Table 1.

Table 1. Void factors of standard sands

Description	loosely packed	after compaction by shaking	after compaction by vibration
German	36	29	29
Spanish	40	35	34
English	39	30	28
Polish	37	32	31

Specific surface areas of monofractions of German, Spanish and Polish sands was determined by low temperature nitrogen adsorption. The results are shown in Table 2.

Table 2. Specific surface values of monofractions of standard sands , cm^2/g

Description	monofraction size, mm					for sand as a whole
	2.00 - 1.60	1.60 - 1.00	1.00 - 0.50	0.50 - 0.16	0.16 - 0.08

Polish	952	2879	832	1250	1489	1695

The variation in the specific surface values may affect the mechanical strengths of the mortars. In order to see this effect mortars specimens have been made with different types of cements. The properties of the cements used are shown in Table 3.

The flowability of the standard mortars made with different sands and cements have been determined by measuring the spread of a standard cone on shaking table according to Russian State Standard GOST 310.4-81. The water to cement ratio was kept constant at 0.50. The specimens were prepared and hardened in accordance with the EV 196-1 standard. Mass of the specimens was measured immediately after demolding. The results are shown in Table 4.

Table 4. Properties of mortars for various standard sand and cements according to EN 196-1.

While cleaning the natural sand various chemical reagents can be used. It is marked that these reagents affect the strengths of the mortars made with the sands thus obtained. English sand was treated with the water solution of $Al_2(SO_4)_3$, $CaCl_2$, and $FeCl_3$. After multiple washing followed by subsequent drying, these were used in comparative tests. The results are shown in Table 5.

Table 5. Effect of residual reagents used for precipitating slams on the properties of standard mortars.

-	192	591	56.1
$0.25Al_2(SO_4)_3$	206	567	43.5
-	182	588	45.3
$20CaCl_2$	196	583	43.7
$20FeCl_3$	186	579	42.1

DISCUSSIONS OF RESULTS. Standard sands used from different countries have shown differences in the void factors which varies from 36% to 40% in loosely bulk state, from 29 to 35% after compaction by shaking and 28% to 34% after compaction by vibration. This observed difference in the void factor of standard sands being identical in the particle size distribution probably relates to the variation of grain form (shape) and predominance of rounded or angular form in monofraction (Table 1).

Substantial differences in the specific surface values in the same monofraction size have been noticed for the sands from different countries. (Table 2). The maximum total surface value calculated by specific surface of monofractions with regard to their mass % was observed for Spanish sand (2713 cm^2/g with monofractions varying from 1439 to 3953 cm^2/g) and the minimum one for the Polish sand (1695 cm^2/g with monofractions varying from 832 to 2879 cm^2/g).

It is seen from Table 2 and 4 that the difference in the void factors and specific surface values of sand caused differences in the characteristics of the standard mortars and their strength properties. This can be attributed to the difference in the shape of the particles, which subsequently affects the adhesion between the sand particle and the cement. Consequently it influences the strength. On the average for all the cements tested, the flowability of mortars under w/c 0.50 was 197 mm for German sand, 173 mm for Spanish and English sand and 229 mm for Polish sand.

Average mass of specimens after demolding was 594, 583, 585 and 570 g, correspondingly for German, Spanish, English and Polish sand. Difference in strength values for the mortars based upon Polish sand as compared with other sand under investigation reaches 10-12 N/mm^2 after 28 days.

According to the results of approximately 200 samples of mortar testing the average value of mass of specimens after demolding for German and English sands which have comparable mortar strengths is 587g and the probable lowest values about 575g with 90% probability. These factors can be considered as indirect characteristics while assessing the suitability of polyfractional sands for the use as standard ones according to EN 196-1.

It is also noted that besides the peculiarities of the sand grains shape the residual reagents used to accelerate precipitation of impurities (slams) when washing and beneficating natural sands during the production of standard polyfractional sands according to EN 196-1 significantly influence the strengths (Table 5). Out of the 3 reagents used as coagulants for the precipitation of slams , the most unfavourable results are obtained when using aluminium sulphate. In that case the reduction in strength reaches 12.6 N/mm^2.

CONCLUSIONS

On the basis of the tests done, the following conclusions are drawn:

Particle size distribution of sand can not be taken as reliable factor in assessing the suitability of standard sand.

For developing standard sands according to EN-196-1, it is reasonable to make a comparative tests measuring the flowability at w/c =0.50, average mass of the samples after demolding and strength.

The residual reagents used for precipitating slams have also detrimental effect on the strength of mortars made from the sands thus produced.

COMPARISON OF PHYSICAL AND MECHANICAL PROPERTIES OF PORTLAND CEMENT ACCORDING TO LVS EN 197-1 AND ГОСТ 10178-85

Jānis KĻAVIŅŠ, A/S (Joint-Stock Company) "Brocēni", Latvia
Aigars MIEZIS, A/S (Joint-Stock Company) "Brocēni", Latvia

ABSTRACT

As a result of research, a comparison of physical and mechanical properties of cement was made, according to two standards : Latvian standard LVS EN 197-1 which is identical with the European Standard and former USSR: ГОСТ 10178-85, which was in force in Latvia until the year 1995. The kinetics of hardening of the Portland cements CEM I 42,5 R and CEM I 32,5 R, by the methods defined in both of said standards, were investigated. The physical and mechanical properties of various samples of composite Portland cements, according to both standards, were determined.

Key-words: Portland cement, Mechanical properties, Physical properties, Standards

INTRODUCTION

Since 1995, the quality of Portland cement in Latvia is tested according to the standard EN 197-1 which fully meets the requirements of the European standard EN 197-1:1995. Because of this, the question becomes important what are the relations between the physical and mechanical properties of Portland cements prepared according to standards EN 197-1 and ГОСТ 10178-85.During the period from March 1994 through March 1996, A/S Brocēni carried out parallel tests of physical and mechanical properties of Portland cements CEM I 32,5 R and CEM I 42,5 R produced by the A/S Brocēni according to the standard EN 197-1 and standards of the former USSR: ГОСТ 10178-85. Altogether more than 70 parallel batches of samples of CEM I 32,5 R were produced and more than 30 parallel batches of samples of CEM I 42,5 R. The samples according to EN 197-1 were produced using the compression device : vibration table with the amplitude of 0.75 mm. To prepare the samples according to the standard ГОСТ 10178-85, a vibration table with the amplitude of 0.35 mm was used. The vibration frequency in both cases was the same: 3000 vibrations per minute.

As raw material for the production of the Portland cement, A/S Brocēni uses the Portland cement clinker of its own make, as well as gypsum from the deposite of Saurieši (Latvia). For the clinker produced by A/S Brocēni, it is typical to have medium high density coefficient according to Kühl - 97±2, contents of Al_2O_3: 4.8 - 5.5%, contents of C_3A: 6.0 - 7.5%, medium high contents of Na_2O eq (0.7 - 1.1). A/S Brocēni produces CEM I 32,5 R and CEM I 42,5 R from one and the same clinker. The difference is only in the fineness of grinding : for CEM I 32,5 R -- on average 320 - 350 m^2/kg after Blaine, but for CEM I 42,5 R -- 370 - 400 m^2/kg after Blaine.

EXPERIMENTAL PART

Introduction

The results of investigations of physical and mechanical properties of the Portland cements produced according to EN 197-1 and ГОСТ 10178-85 allow the conclusion that there is significant difference in methods of testing of both standards. As it is known, the hardness of cement is influenced by two factors: the fillers used in production and the ratio between water

and cement (w/c). To assess the hardness of cement, concrete prisms are made according to the methods of both standards, where the corresponding sand is used as the filling substance to make these prisms. The granulometric contents of this sand, as seen in Table 1, is very different. 10178-85 provides the use large-grain sand which meets the requirements of ГОСТ 6139-86. On the other hand, the EN 197-1 standard provides the use of multi-fraction sand.

Table 1. The requirements for sand used in cement testing

Requirements	ГОСТ 10178-85	EN 197-1
Content of SiO_2	>98.0	>98.0
Loss on ignition	<0.3	<0.5
Humidity	<0.2	<0.2
Admixtures	<1.0	-----
Cumulative sieve residue 2.0 mm	------	0
Cumulative sieve residue 1.6 mm		7 ± 5
Cumulative sieve residue 1.0 mm		33 ± 5
Cumulative sieve residue 0.9 mm	< 1.0	
Cumulative sieve residue 0.5 mm	> 92.0	67 ±5
Cumulative sieve residue 0.16 mm		87 ± 5
Cumulative sieve residue 0.08 mm		99±5

It must be noted that when using the sand which corresponds to the requirements of ГОСТ 10178-85, for preparation of concrete samples with w/c relation and compressing methods according to EN 197-1, the obtained results of compressive strength are significantly lower than when using the sand required by the standard EN. The results are given in Table 2.

Table 2. The influence of sand of different standards on compressive strength (N/mm^2)

	Compressive strength (N/mm^2)				
Sand used	1 day	2 days	3 days	7 days	28 days
ГОСТ 10178-85	2.6	5.9	9.3	14.3	24.0
EN 197-1	14.4	26.0	30.7	40.2	51.2

There are also differences in production of samples according to the water added. As it is known, the water quantity influences the compressive strength at the beginning of the process of hardening. Increasing the w/c ratio, the resistance against pressure at the beginning of the hardening process usually decreases. According to the EN 197-1 standard, the w/c ratio is constant : 0.5, while according to the ГОСТ 10178-85, this ratio is variable, depending on the normal consistency of cement and usually falls between 0.37 to 0.41. The results of comparative examinations made in the laboratories of A/S Brocēni show that there is still a correlation the between the results of tests according to both methods. The difference in compressive strength after 2 days of hardening is 5 - 6 N/mm^2 in favour for ГОСТ 10178-85. The correlation of compressive strength between samples prepared by both methods after 2 days of hardening is much better for cement CEM I 42,5 R (0.815) than for cement CEM I 32,5 R (0.565). The compressive strength after 7 days of hardening differes not so much, according to ГОСТ 10178-85 it is on average only by 2 - 3 N/mm^2 higher than the hardness of samples made according to the EN 197-1. Correlation between the two methods in this case is 0.755. The average after 28 days is by 0.5 - 2 N/mm^2 higher for EN 197-1 cement samples, as compared with samples made according to the ГОСТ 10178-85. The results of resistance against pressure for samples made by both technologies are given in Tables 3 and 4.

Table 3 The comparison between compressive strength of the Portland cement CEM I 32,5 R according to ГОСТ 10178-85 and EN 197-1

Time of hardening (days)	Average compressive strength according to EN 197-1 (N/mm^2)	Average compressive strength according to ГОСТ 10178-85 (N/mm^2)	Standard deviation (EN 197-1)	Standard deviation according to ГОСТ 10178-85	Correlation between resistance against pressure
2	21.9	27.5	1.06	1.97	0.565
28	46.9	45.9	2.14	2.54	0.477

Table 4 The comparison between compressive strength of the Portland cement CEM I 42,5 R according to EN 197-1 and ГОСТ 10178-85

Time of hardening (days)	Average compressive strength according to EN 197-1 (N/mm^2)	Average compressive strength according to ГОСТ 10178-85 (N/mm^2)	Standard deviation (EN 197-1)	Standard deviation according to ГОСТ 10178-85	Correlation between resistance against pressure
2	24.8	30.2	2.11	2.68	0.815
7	39.1	41.4	2.15	3.06	0.755
28	50.4	50.3	3.47	2.08	0.661

There is no certain correlation between both methods of standards as regards other physical and mechanical properties. Thus, for example, the correlation between the initial and final setting time according to both standards is 0.31-0.38. The initial setting time for the cement made according to the EN 197-1 is approximately 30 minutes delayed as compared with ĆĪŃŅ samples, while the end of setting does not actually differ. These differences can be explained in connection with the fact that according to the LVS EN 197-1 standard the samples, during the examination period, must be kept in moisture cabinet with relative humidity above 90%, while there is no such requirement according to the ГОСТ technology. The results of setting time tests are given in the Table 5.

Table 5 The comparison of initial and final setting time

Cement type	setting time	LVS EN 197-1	ГОСТ 10178-85	Coef. of correl.
CEM I 32,5 R	initial (min)	187.5	159.5	0.375
	final (min)	279.4	271.9	0.31
CEM I 42,5 R	initial (min)	191.5	157.7	0.22
	final (min)	283.9	271.5	0.14

The methods of determining the fineness of cement are incomparable. The specific surface of Portland cement in the case of the EN 196-6 standard and ГОСТ 10178-85 is different. The correlation coefficient between the two methods is < 0.7 which is an evidence that both methods are incompatible.

The physical and mechanical tests of properties of composite Portland cements

During the period from March 1994 through March 1996, in A/S Brocēni laboratory the samples of composite Portland cement were made, using fly ash of burnt shale from the Narva Power Plant (Estonia), Brocēni limestone and fly ash from the Riga Power Plant as an addition. By grinding these additives to the Portland cement clinker, in the amounts of 5, 15, 25 and 35%,

samples of the composite Portland cement were obtained which correspond to following types of EN 197-1 : CEM II/A-T; CEM II/B-T; CEM II/A-L; CEM II/B-L; CEM II/A-Q; CEM II/B-Q.

The results of investigation of the kinetics of hardening of the composite Portland cement show that when the share of additives in cement increases, the differences between the hardness (N/mm^2) of samples made according to technologies of EN 197-1 and ГОСТ 10178-85 decreases.

In samples, with the amount of additives of 5 and 15 %, the compressive strength after 2 days of hardening, is higher by 2 - 5 N/mm^2 as compared with cement without additives, when testing the hardening according to both standards. However, after 28 days of hardening, there is practically no difference, if testing is done according to ГОСТ 10178-85, but the compressive strength is much lower (by 4 - 12 N/mm^2) if tested according to EN 197-1. When the proportion of additives reaches 25% and more, the compressive strength in both cases is much lower when tested according to both standards. The results of tests are shown in Table 6.

Table 6 Comparison between various composite Portland cements

Type of s additives	Proportion of additives	Compressive strength (N/mm^2)					
		after 2 days		after 7 days		after 28 days

A CONTRIBUTION TO THE KNOWLEDGE OF THE PROPERTIES OF PORTLAND-LIMESTONE CEMENT CONCRETES, WITH RESPECT TO THE REQUIREMENTS OF EUROPEAN AND ITALIAN DESIGN CODE

Vito ALUNNO ROSSETTI, University "La Sapienza", Rome, Italy
Francesco CURCIO, Unicem Centro Ricerche, Guidonia, Italy

ABSTRACT The properties of Portland Limestone cements produced in two italian factories, conforming the new italian standard on cement UNI-ENV 197-1, have been tested, both on cement and on concrete, in comparison with Portland Cements. The aim of the test program was to verify the suitability of these new cements for structural concrete design, with reference to European and Italian Codes.

Key-words: blended cement, interground cement, composition, characterization

INTRODUCTION

The adoption of the European standard on cement ENV 197-1 in Italy as the new national standard UNI ENV 197-1, has introduced in this country the production and utilization of Portland Limestone cements, wich were not allowed by the previous regulations (and obviously not utilized and known).

Although such cements had already been used for the production of structural concrete in several countries abroad, and some literature was available, see for example Albeck and Sutej (1990) and Baron and Douvre (1987), the italian designers felt the need to verify the properties of structural concrete made with Portland Limestone cements of national production and the relationships of such properties whith those given by the design Codes.

To such purpose the authors have performed an intensive laboratory testing program with the aim to characterize the performances of Portland-Limestone cement concrete with respect to all physical and mechanical properties and their relationships contemplated by the national Code of Design and by European standard EN 1992. The results have been compared to reference concretes made with Portland Cement.

Tests have been done regarding compressive, flexural and tensile strengths, shrinkage elastic modulus, fracture energy, monotone and cyclic compression curves, creep. Some evaluation of the durability of the same concretes by means of water permeability, chloride and sulphate penetration, carbonation and sulphate attack have been performed. The experimental results confirm that concretes made with Portland Limestone cement behave consistently whith the recalled Codes of design.

MATERIALS

Cements

Industrial cements produced in two different plants (named B and G) have been utilized. For each plant, two samples have been collected: a Type I 42,5 R Portland cement (named respectively PB or PG, depending on the production plant) and a Type II/A-L 42,5 R Portland-limestone cement (named LB or LG), both produced with the same industrial clinker and gypsum; no other costituent has been utilized, apart from limestone in LB and LG. One commercial TEA-based grinding aid has been used in all cases.

In the aim to strenghten the influence on concrete properties given by the presence of limestone into Type II/A-L cements, the amount of limestone in the two samples has been increased up to the limit of 20 % by mass established by the standard for the composition of that type of cement. Actually, Type II/A-L 42,5 R Portland-limestone cements today available on the Italian market (B's and G's products included) are produced with a consistently reduced amount of limestone and differ much less than LB and LG from the corresponding Type I cements in terms of fineness, setting time and EN 196-1 mortar compressive strength. In the Authors' intention, if LB and LG perform satisfactorily, it is to be expected that any commercial Type II/A-L product will do the same: its behavior should in fact be somehow inbetween LB's (or LG's) and the corresponding PB's (or PG's) ones. Physical and mechanical properties of the four cements used in the present testing program are reported in Table 1.

Table 1 Physico-mechanical properties of the cements (according to test methods UNI EN 196)

	PCB	LCB	PCG	LCG
Retained at 0.063 mm sieve (%)	2.03	1.05	4.60	2.30
Retained at 0.090 mm sieve (%)	0.56	0.20	1.05	0.60
Blaine specific surface, m^2/kg	345.0	482.5	362.0	489.5
Water demand (%)	26.6	27.6	27.6	26.2
Initial setting time (minutes)	100	125	115	140
End of setting (minutes)	150	190	195	205
Compressive strength (MPa)				
1 d	16.8	15.2	14.1	16.0
2 d	25.1	24.3	25.9	24.9
3 d	30.5	29.2	30.2	29.3
7 d	38.5	38.1	37.2	35.9
28 d	49.4	46.5	48.6	45.9

In Table I are presented the properties of the cements. It can be observed that the limestone cement from factory B presents a slightly higher water demand with respect to its "parent" portland cement; the contrary holds for the G factory products; this can be explained with differences due to the hardness and grindability of clinkers and limestones (expecially Blaine surface, overall fineness and, even if not measured, a greater fineness of the clinker fraction). The mortar properties are practically the same up to 7 days; at later age the PC mortars show a compressive strength appreciably higher (about 10%), due to the dilution effect of the limestone.

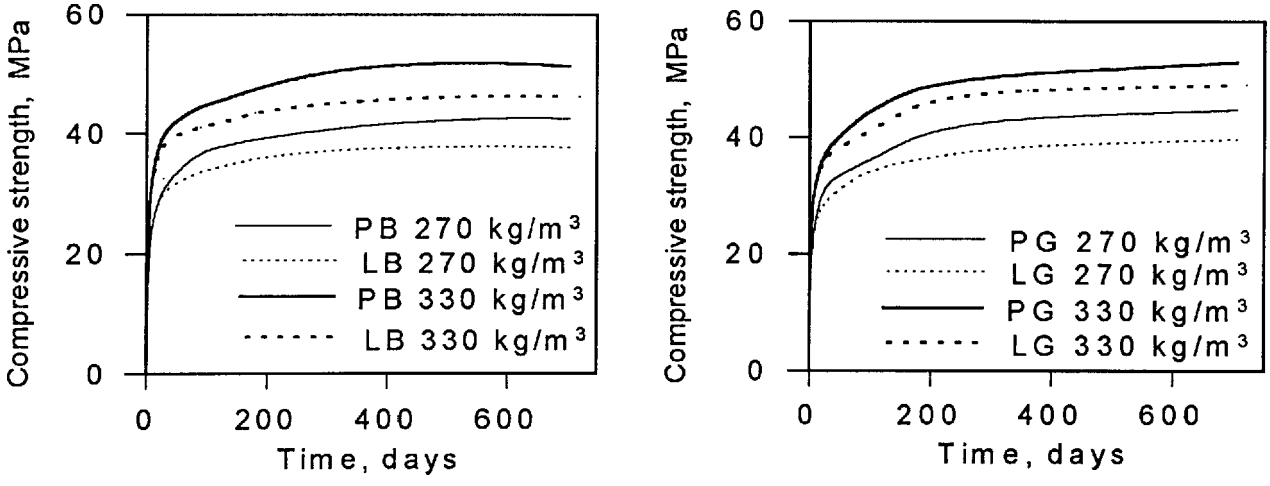
Concretes

Concrete mixes, of the same consistence and with two cement dosages, such to obtain characteristic strengths Rck of about 25 and 30 MPa on cubes, were proportioned in the laboratory, using the standard siliceous laboratory aggregates, with a Bolomey grading. In Table 2 the compositions and characteristics of the fresh concretes are reported, and the 28 days compressive strength. The favourable effect of the limestone addition on the water demand of concrete can be appreciated, both at lower and at higher cement dosages, so that the difference in strength measured on mortars at 28 days is almost recovered in concrete at the same age. Also small differences in compaction index can be noticed, that seem to indicate a favourable influence on the response to vibration of limestone cement concrete.

Table 2 Composition and characteristics of concretes

CEMENT FACTORIES B, G	PCB	LCB	PCB	LCB	PCG	LCG	PCG	LCG
Cement dosage (kg/m3)	270	270	330	330	270	270	330	330
Water/cement ratio	0.65	0.64	0.55	0.53	0.63	0.62	0.54	0.53
Air (%)	2.0	2.0	1.7	1.8	2.0	1.8	2.0	1.8
Density (kg/m^3)	2399	2399	2409	2399	2399	2399	2409	2409
Slump(cm)	10	11	10	11	10	10	10	10
Compaction index	1.05	1.03	1.05	1.02	1.07	1.05	1.05	1.05
Compressive strength Rc, 28 d, MPa	30.7	30.0	39.7	38.0	31.6	29.1	37.5	36.5

TEST RESULTS



Mechanical properties taken into consideration in the design standards have been determined.

Compressive strength

Fig. 1 and 2 show the evolution of *compressive* strength measured on *150 mm cubes* up to 1 year. For the cements B the values at the first days show a substantial equivalence, whilst at later ages (from 180 days) the limestone cement strength results are about 30 % lower, due to the reduced presence of clinker; for the G cements the results are practically equivalent.

The compressive strength at 28 day has been also measured on 150x300 mm *cylinders (fc)*; the mean ratio Rc/fc is 1.40; this value, higher than the values normally found for portland cement concrete has to be verified.

Splitting tensile strength (fct,sp) has been measured on cylinders (150x300 mm), according to UNI 6135-72; three point Flexural strength (fct,fl) has been measured on concrete prisms (10x10x50 cm) according to UNI 6133-83 . Table 3 presents the results; the values obtained on limestone cement concrete are generally lower than on the corresponding portland cement concrete.

Figures 1 and 2. Compressive strength in time

The values of fct,sp and fct,fl have been compared with the corresponding values calculated from Rc, by means of the relationships given by the EC 2; the differences between experimental and calculated values are on average about ±15 % of the experimental value; the difference looks acceptable, taking into account the sensitivity of the method.

Table 3 Splitting and flexural strength, MPA

Cement and dosage kg/m^3	PCB 270	LCG 270	PCB 330	LCB 330	PCG 270	LCG 270	PCG 330	LCG 330
Splitting 28 days	2.3	2.7	2.9	2.7	3.2	2.1	4.1	2.6
Splitting 365 d	2.8	2.6	3.0	3.0	3.0	2.5	3.8	2.9
Flexural 28 days	5.0	4.8	6.4	5.3	3.6	4.7	4.7	4.7
Flexural 365 days	6.6	5.4	7.6	7.0	5.4	5.8	6.4	6.1

Elastic moduli of the concrete have been determined at 28, 60 and 90 days following UNI 6556; the results, shown in Table 4 indicate that no substantial differences exist between portland cement and limestone cement concretes.

Table 4 Elastic moduli, MPa .10^{-3}

Cement and dosage kg/m3	PCB 270	LCB 270	PCB 330	LCB 330	PCG 270	LCG 270	PCG 330	LCG 330
28 days:	26.0	24.5	28.0	27.5	25.1	25.4	27.2	27.1
60days	28.5	26.2	29.1	28.4	26.1	26.7	29.6	28.6
90 days	29.3	28.1	30.2	29.3	27.2	27.2	30.2	29.7

The experimental E moduli have been compared with those calculated by means of the expression $Ecm = 9.5(fck+8)^{1/3}$ given by EC 2; fck has been evaluated from the Rc values at 28 days, taking into account the coefficient fc/Rc=0.83 given by the code, and a k value of 6 MPa. The experimental values are always greater than those calculated, the average difference is about 10 %.

Fracture energy

The fracture energy has been determined following the draft recommendation 50 - FMC, by means of three-point bend tests on notched beams, 100x100x840 mm.

The results obtained (averages of two samples) are reported in Table 5; considering the sensitivity of the method the pairs of values for corresponding mixes of portland and limestone cement can be deemed to be alike, the only exception being the very low value of the sample LCB 270.

Table 5 Fracture energy

Cement and dosage kg/m3	PCB 270	LCB 270	PCB 330	LCB 330	PCG 270	LCG 270	PCG 330	LCG 330
Fracture Energy, N/m	176	123	216	197	145	162	201	207

Shrinkage

The shrinkage of the concretes has been measured following the standard UNI 6555 at a R.H. value of 50% ; the final results are reported in Table 6. Both shrinkage evolution and final values show no differences between the limestone cement and portland cement concretes. The

experimental values (between 0.54 and 0.67) are in satisfactory agreement with the indications of EC2 Code (0.6) and greater than the value given in the italian standard (0.3).

Table 6 Shrinkage at one year

Cement and dosage kg/m3	PCB 270	LCB 270	PCB 330	LCB 330	PCG 270	LCG 270	PCG 330	LCG 330
Shrinkage, μm/m	635	640	680	690	540	560	615	595

Creep

Creep tests have been performed by loading at 28 days the prismatic specimens (150x150x600 mm) at 1/3 of their compressive strength, at a R.H. of 50 ± 5%. In Table 7 are reported the observed values of creep (subtracting elastic deformation and shrinkage from the total deformation). The results give evidence to an appreciable difference in behavior of portland cement and limestone cement concretes, the first showing on average a creep about 17 % smaller than the latter; a possible cause could be that there is less cement gel on which the compressive stress develops its action.

Table 7 Creep results (m/m . 10^6)

Cement and dosage kg/m^3	PCB 270	LCB 270	PCB 330	LCB 330	PCG 270	LCG 270	PCG 330	LCG 330
Creep at 360 days	718	1102	778	914	824	972	756	869
Creep coefficient ($\varepsilon v / \varepsilon e28$)	1.43	2.10	1.24	2.56	2.02	2.19	1.48	1.66

The experimental creep coefficients have been calculated as the ratios between the observed creep values and the elastic deformation at 28 days; the values vary from 1.24 to 2.19 and result appreciably smaller than the corresponding values given by EC2 and the italian regulations .

Durability

To assess the behaviour of limestone cement concrete from the point of view of durability related properties, tests of water absorption at atmospheric pressure, according to UNI 7699, carbonation (UNI 9944), chloride (UNI 7928) and sulphate penetration (UNI 8019) have been performed.

Table 8 Durability related properties..

Cement and dosage	PCB 270	LCB 270	PCB 330	LCB 330	PCG 270	LCG 270	PCG 330	LCG 330
Water absorption % UNI 7699	4.8	4.8	4.2	4.5	5.5	5.5	5.3	5.1
Carbonation at 900 days, mm	20	10	18	13	19	21	15	16
Chloride penetration 28/60 days, mm	43/63	102/113	38/49	48/79	212/281	197/264	115/183	146/182
Sulphate penetration 28/60 days, mm	98/116	105/126	73/106	87/107	200/300	181/242	170/190	132/152

The data reported in Table 8 do not show great differences between the different types of cement; on the contrary the data could indicate some difference between cements from different factories. Water absorption, chloride and sulphate penetration are indeed greater, both for portland and limestone type, for the G factory cements.

One difference between cements that can be envoked to explain the different behaviour is to be find in the residue to the sieves; being the same the overall Blaine fineness, the greater fineness of the B factory cements (smaller residue) causes a lower permeability and a smaller water penetration. Another difference that can influence both chloride and sulphate penetration, is a slightly higher (about 2 %) content of C_3A in the B cement.

CONCLUSIONS

Taking into account what has been observed in the introduction about the peculiarity of the limestone cements used in the present tests, containing the maximum limestone dosage allowed by the cement standard, the results of the tests on the portland cements and limestone cements show that the difference in performances is very small and that the two types of cement are practically equivalent. In particular it can be observed that:

- the properties of fresh concrete confirm the favourable effect of limestone cement on the water demand in concrete; this is reflected also by the mechanical strength;
- the differences in mechanical strengths of concrete at 28 days, taking into account the differences in cement strengths, are very small; at longer ages the strength of limestone cement concretes are about 10 % lower than those of the corresponding portland cement concretes; the differences in elastic moduli are very small; the values evaluated from the EC2 expression are about 10 % lower than the experimental ones;
- the fracture energy does not appear to depend clearly on the type of cement: for the limestone cement produced at the B works Gf is greater than for the corresponding portland cement; the opposite holds for the G production;
- the shrinkage behaviour of the portland and limestone cement is the same;
- the creep results are the only case of apparent difference among the two cements oberved in this test program;
- chloride and sulphate penetration, water absorption, carbonation depth, chloride and sulphate penetration are not different for the two types of cement; differences noticed between the two factories are related to the different sieve residues and C_3A content.

Adsorption; 2ii001, 3iii002, 4iv077
AFm phase; 2ii032, 3iii032, 3ii089, 4iv034, 4iv061
AFt phase; 1i060, 4iv034, 4iv041, 4iv059
Aggregate; 2ii015, 3v024, 4iv053, 4iv057
Air entraining; 4iv031, 4iv057
Air pollution; 4iv002
Alinite; 2ii030, 3ii118
Alite; 1i006, 1i015, 1i041, 1i050, 2ii040, 2ii042, 2ii056, 3ii107, 3ii117, 3iii005, 3iii031
Alkali; 1i002, 1i012, 1i028, 1i035, 1i049, 2ii012, 2ii065, 3ii083, 3ii098, 3ii100, 3ii103, 3ii113, 3ii114, 3ii117, 3iii025, 4iv003, 4iv028, 4iv055, 4iv066
Alkali aggregate reaction; 3iii033, 3v022, 4iv048
Alkali silica reaction; 4iv047, 4iv049, 4iv065, 4iv074
Alkali silicate solutions; 4iv049, 4iv065
Alkaline cement; 4iv046
Alumina; 2ii027, 2ii026, 3iii010
Aluminate phase; 1i001, 1i022, 1i051, 1i056, 2ii041, 2ii060, 3iii010, 3iii015, 4iv027, 4iv034, 4iv066
Aluminoferrite; 1i004, 1i005, 1i055, 2ii031
Aluminosilicate; 1i024, 4iv046
Anhydrite; 1i032, 2ii011, 2ii022, 2ii029, 3ii092, 4iv059
Aragonite; 1i042
Arc furnace dust; 4iv042
Asbestos; 1i027
Ash; 3ii080
Autoclavation; 3ii120, 4iv054
Autoclave soundness; 1i023
Autogeneous shrinkage; 2ii069, 2ii070, 2ii071, 2ii073

B

Backscattered electron image; 2ii014, 4iv061
Bacterial attack; 4iv038, 4iv039
Bamboo dust; 1i019

Barite; 1i036
Barium phases; 1i058
Belite; 1i006, 1i015, 1i018, 1i041, 1i052, 2ii007, 2ii040, 2ii045, 2ii056, 3v009
Belite cement; 1i036
Binder; 1i059, 2ii047, 2ii054, 3ii080, 3ii101, 3iii021, 4iv057
