HONORARY COMMITTEE

Governor Göran Bengtsson,
Provincial Government Göteborg o Bohuslän, Göteborg, Sweden

Professor Per Ahlberg,
The University of Göteborg, Sweden

Director General Gösta Blücher
National Board of Housing, Building and Planning, Karlskrona, Sweden

Director General Jan Brandborn,
Swedish National Road Administration, Borlänge, Sweden

Director Ulf Dinkelspiel,
Swedish Trade Council, Stockholm, Sweden

Lord Mayor Jörgen Linder,
City Council, Göteborg, Sweden

Director General Bertil Petterson,
Swedish Council for Building Research, Stockholm, Sweden

President Anders Sjöberg
Chalmers University of Technology, Göteborg, Sweden

Consul General of Austria Martin Thomas,
Chief Executive Officer, AB Färdig Betong, Göteborg, Sweden

Senior Industrial Development Officer Halime Şeniz Yalçindağ
Chief, Building Materials Unit, UNIDO, Vienna, Austria

Industrial Development Officer Kojo O. Hagan.

FOREWORD TO THE PROCEEDINGS

I extend a most cordial and fraternal welcome to all delegates to the X Congress.

In this, the Jubilee Congress, it is appropriate to note some special features of the X Congress relating to the proceedings. Many Congresses publish a written transcript of their proceedings which is ephemeral, but those on the Chemistry of Cement are rightfully regarded as landmark publications. They are virtually unique in terms of their frequency of citation by the relevant scientific Community. Most workers in the field regard the published proceedings as affording an unique insight of current awareness and of progress in all aspects of cement science.

The Scientific Committee have taken steps to assure that the Conference proceedings retain this position of eminence. Amongst the steps which have been taken are the following;

- to ensure high but fair standards of refereeing,
- promote uniformity of format and good legibility of the individual contributions,
- reduce the time between final receipt of manuscripts and publication, to ensure that the Congress reflects the state of art up to 1997,
- provide subject indices for the Proceedings to assist rapid retrieval of information and, to facilitate library cataloguing, by providing an ISBN number.

We hope this measures meet with the approval of readers.

I would like to express my thanks to the many individuals and organisations who have facilitated publication of the Proceedings.

First and foremost to Dr. Harald Justnes who has had the major task of receiving manuscripts, and ensuring their orderly progress through refereeing, collation and, finally, despatch to the printer. Many individuals have contributed to the refereeing and it is a tribute to the Scientific Community that so many individuals have contributed generously of their time and energy. Their efforts have immeasurably improved the free communication of ideas and results, and the clarity of the written discussions.

Ultimately the success of the Congress is decided by those who attend as well as by those who use these Proceedings. It is not for me to decide whether future Congresses will be held or, if held, what form they will take. But, if there is a next Congress, it will be held in a new millennium. Never has the pace of change in communication been so rapid: I speculate that this might be the last paper proceedings which will ever be published! But whatever form future Congresses may take, and however its proceedings are disseminated, the fraternity of science and the principle of peer review will, I am confident, continue to be a hallmark of future proceedings.

F.P. Glasser
President of Scientific Committee
23 March 1997

EDITORIAL REMARKS

The papers of the five main themes and sub-topics of the Congress has been distributed between the 4 volumes of the Proceedings in a manner to compromise between two conflicting interests; to make it easy for the reader to find the wanted paper and to have volumes about equal in size. This resulted in proceedings comprising about 2,200 pages distributed in 4 volumes ranging from about 400 to 700 pages each. Volume 1 contains Plenary lectures and Theme I, the content of Volume 2 is Theme II (except additives) and Volume 4 includes Theme IV. The only mixed volume is Volume 3, encompassing Additives from Theme II, Theme III and Theme V.

The volumes are not paginated, but the first page of each paper is marked with a code and number of pages in the upper right corner. If the number of pages are uneven, a blank page is inserted in order to ensure that every paper starts on a right hand page. Since the papers are relatively short (usually 4 or 8 pages) it should be easy to go from one code to the next to find the required paper. The code consists of three parts; volume (arabic numerals), theme (roman numerals) and 3 digits giving the paper number within the corresponding theme. For instance, 3ii091 means paper no. 91 within Theme II found in Volume 3.

Every volume starts with a list of contents for that volume only where authors, titles, code and number of pages are listed in the order they appear. At the end of every volume there is an author index as well as a key-word index giving the corresponding paper codes for the total proceedings. Volume 4 also includes a few colour figures with reference to the corresponding papers after the author and key-word indices.

Finally, I would like to express my sincere thanks to the individuals who in addition to myself have taken active part in the reviewing process of abstracts and/or draft papers:

PLENARY LECTURES

WHY CONCRETE IS NOT ALWAYS DURABLE

Ajoy K Mullick
National Council for Cement and Building Materials, New Delhi, India

INTRODUCTION

Scientists and engineers who trust cement and concrete to be noble building materials can draw little comfort in the fact that only a minor proportion of concrete constructions face durability problems. The somewhat provocative title of this presentation is to activate the search for a 'zero-defect' situtation. Concrete systems are dynamic in nature, and responsive to the characteristics of the service environment. Apart from mechanical properties which govern strength and deformation of concrete, physico-chemical aspects of durability in service are also important manifestations of performance of cements. Durability of concrete has been a subject of discussion in the previous Congresses on the Chemistry of Cement, as indeed in many Engineering Conferences organised from time to time.

Because of its multi-disciplinary nature, it is necessary to take a holistic view of the problem. A grudge among some members of civil engineering fraternity is that the subject of durability of concrete does not receive the attention of scientists (mainly chemists) in the academic institutions that it deserves (Hime, 1993). On the other hand, in a forum devoted to the chemistry of cements, it is unlikely that the aspects of structural design, detailing of sections and reinforcements, and workmanship under situations prevailing in a construction site, all of which also influence the response of a concrete structure to the service environment, can be and will be discussed to any great length. What is possible, however, is to discuss certain chemical aspects of durability of concrete, without being oblivious to the fact that there are other factors in the background, which complete the cause-effect scenario. In other words, it is necessary to view durability of concrete as a 'System' (Mullick and Chandra, 1992).

A common criticism has been that inspite of voluminous research on various aspects of durability of concrete throughout the world for nearly six decades, there seem to be more difficulty in making concrete of adequate durability now, than in the past (Neville, 1987, Gerwick, 1989). Such a situation has been thought to have arisen due to changing properties of cement as presently manufactured in modern cement plants, diversity of usage of cement concrete in various types of construction, inadequate level of workmanship and quality assurance in many construction sites and limitations of specifications of structural concrete (Mehta et al 1992, Mullick and Chandra, 1992). Large incrase in the volume of constructions with resultant increase in number of structures showing signs of distress has also contributed to such a perception. Increased atmospheric pollution in metropolitan cities and industrial townships also add to the problem.

Durability research, in general, follow three distinct streams. The first group deals with identification of processes of concrete deterioration and the basic mechanisms at work. Closely related to this is the second group of investigations on the effects of various factors and parameters on the deterioration processes, leading to steps for improving the durability of concrete. The third group deals with laboratory test methods and site investigations of concrete structures under service environment and recording the performance of concrete.

Examples of the first group of research projects, which have been in the forefront since the Ninth Congress in New Delhi,. are related to delayed ettringite formation (DEF), and deterioration due to climatic and biological causes. In the second group, research dealing with effect of supplementary cementing materials like fly ash, granulated blast furnace slag and silica fume on pore structure, diffusivity, electrical resistance of concrete and improvements in paste-aggregate interface as well as chloride-binding capacity received major attention.

Compared to the first two groups, reports on deterioration of concrete structures in service as well as diagnostic techniques and test methods under field conditions comprised major portion of the published literature. Among the various causes, corrosion of reinforcement in concrete, and alkali-aggregate reaction commanded greater attention.

In such a situation, our capability of building durable concrete structures can not have a one-to-one relationship with the number of research papers published. On the other hand, the relatively large number of papers dealing with deterioration of concrete structures in service indicate that there must be reasons because of which concrete is not always durable.

In this presentation, we will seek possible answers to this question. The present state of knowledge on chemical aspects of durability of concrete will be gone through to identify any gaps in knowledge and, therefore, the approaches required to improve the situation. No attempt will be made to present a comprehensive state-of-art review, or even to cover all aspects of concrete durability. In particular, the subjects of freeze-thaw resistance or resistance to de-icing salts and salt scaling etc. will not be covered, primarily because of the author's lack of familiarity with such field problems.

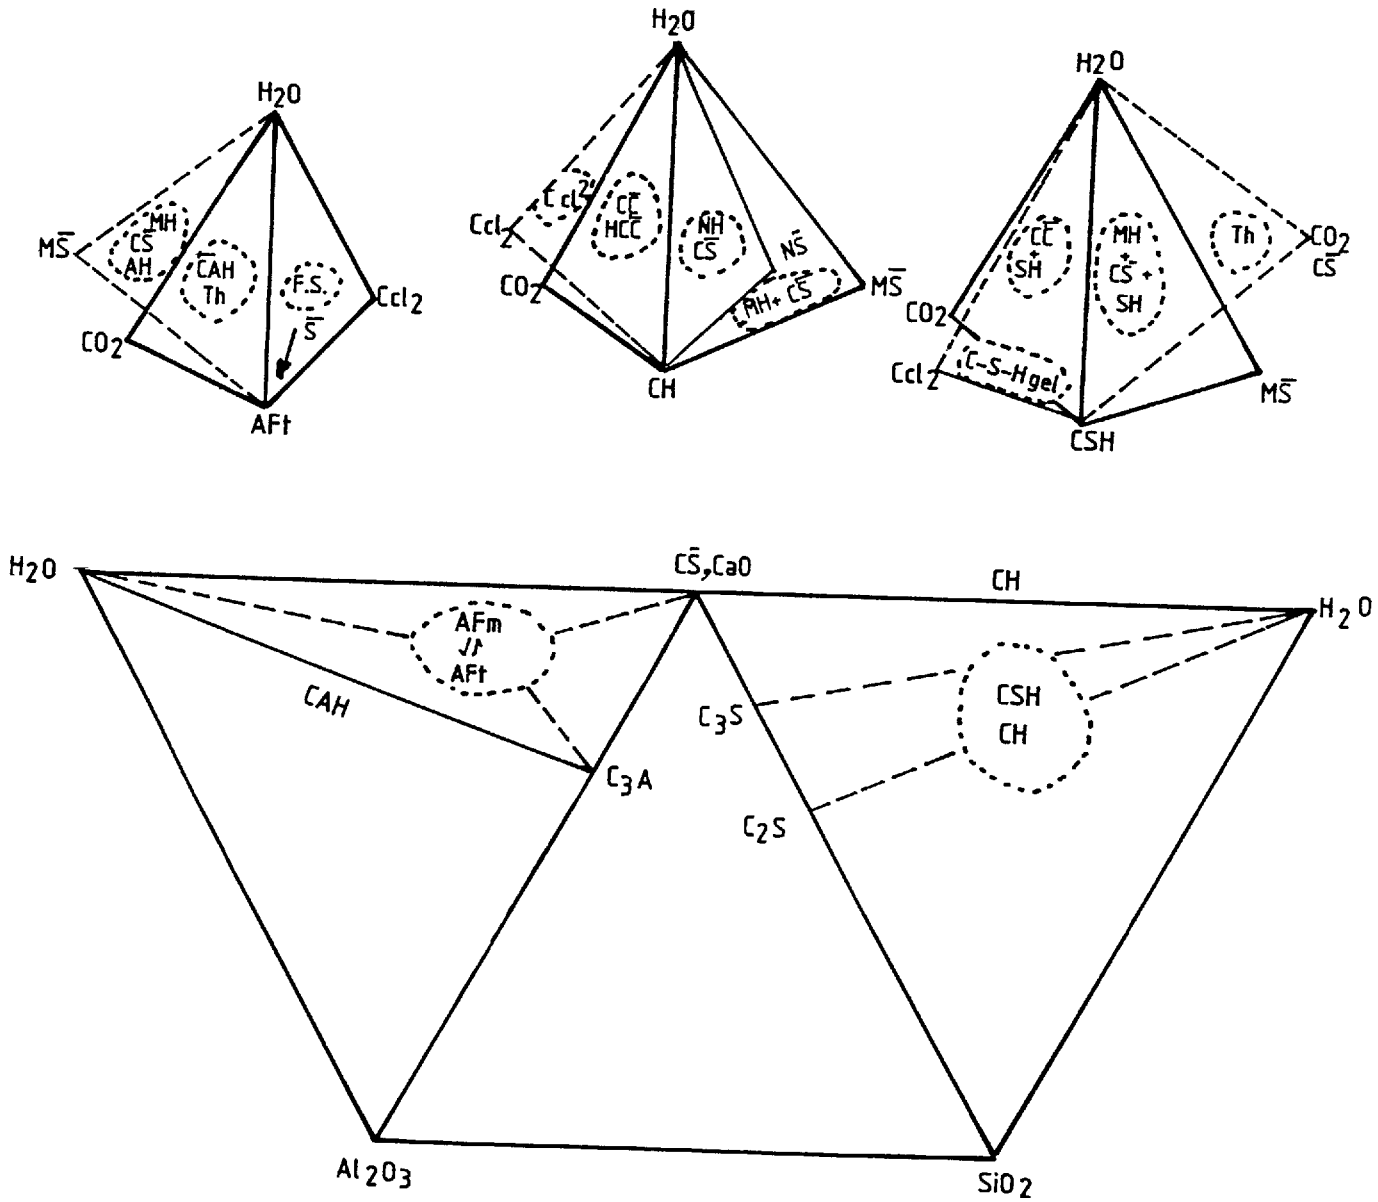
At the time of preparation of this presentation, it was not possible to take into account the papers in the Proceedings of this Congress. No doubt, there will be many contributions devoted to the issues raised in this paper, which will form a complementary knowledge-base.

BASIC CHEMICAL REACTIONS OF DETERIORATION OF HYDRATED CEMENT PASTE

In so far as cement systems are concerned, the response of the hydration products of portland cement comprising CaO - SiO_2 - H_2O and CaO - Al_2O_3 - H_2O in presence of $CaSO_4$, to the principal deteriorating agencies like sulphate (SO_3^{--}), chlorides (Cl^-) and carbon-di-oxide (CO_2) are well documented (Mullick and Chandra, 1992). The basic

chemical reactions, which are widely reported in the literature are depicted in **Fig. 1**. The products of hydration of cement are mainly C-S-H, C-H and C-A-H. While calcium hydroxide and calcium aluminate hydrates are the fast reacting components of the cement pate, C-S-H is also subject to attack by all the three aggressive ions in differnt degrees. In many cases, the type and extent of reaction depends upon the cations.

Sulphate attack on concrete follows two principal reactions; formation of gypsum ($C\bar{S}$) in reaction with CH and reaction of $C\bar{S}$ and C-A-H to form ettringite, Magnesium sulphate reacts, in addition, with the C-S-H phase leading to its decalcification i.e. substitution of Mg^{+} for Ca^{+}, and formation of M-S-H and other expansive salts identified above. Foramation of MH (brucite) in sea-water has also been reported (Van Derwegen et al, 1993). When alkali sulphate concentration is high and conditions are favourable, formation of mirabilite ($N\bar{S}H$) takes place (Mehta, 1993).



Besides being the principal cause of reinforcement corrosion, chloride salts react with hydrate phases also. Reaction of chlorides with hydrates of C_3A and C_4AF, forming Friedel's salt and its ferrite analogue is the primary reason of 'chloride-binding', which will be discussed later on. Magnesium chloride leads to ion exchange between calcium and magnesium. Calcium chloride reacts with cement hydrates to form expansive compound calcium oxychloride ($3CaO, CaCl_2, 15H_2O$) (Collepardi et al, 1994).

CO_2 in air or dissolved in water reacts with calcium hydroxide forming calcium carbonate. It also can react with other products of cement hydration, leading to formation of calcium carbonate and hydrated silica, alumina and ferric oxide. For example, total carbonation of C-S-H can lead to formation of calcite and amorphous silica (Kobayashi et al, 1994). Formation of thaumasite has also been reported. In all such reactions, OH^{-} is consumed, thus lowering down the pH of pore solution.

One may hasten to add that the above description of the mechanism of action by individual ions on individual phases of hydration of cement is rather simplistic. In reality, considerable synergistic interaction takes place. This is discussed further in subsequent sections.

Delayed Ettringite Formation

Once hydrated cement paste in concrete has set and hardened, any appreciable expansion at a later stage can give rise to disruption under conditions of restraint. In recent years, a number of cases of premature cracking and failure of concrete structural elements, which were steam cured, have been reported. The distress has been identified to be caused by formation and reformation of ettringite (Day, 1992, Taylor, 1994, Diamond, 1996). In cement, hydration of C_3A takes place in the presence of gypsum in C_3A - $CaSO_4.2H_2O$ - H_2O system. Ettringite begins to form after 15 minutes. It may later on get converted to monosulphoaluminate hydrate in reaction with uncombined C_3A. Kalousek and Adams (1951) had pointed out that such hydrated sulphoaluminate phases rapidly become undetectable, when the cement paste is cured at a temperature of $70^{o}C$ or above. On dissociation of ettringite, the released sulphate ions enter the pore solution, remain in

monosulphoaluminate form or get adsored in the C-S-H phases. When the hydrated cement, after heat treatment, is stored in water or in saturated condition at ordinary temperature, ettringite is again formed (Taylor 1994). This phenomenon is called 'delayed ettringite formation' (DEF).

Precast concrete products, which are steam-cured for early demoulding, have been reported to have suffered distress due to delayed ettringite formation, typically along with occurence of alkali-silica reaction (ASR) (Shayan and Ivanusec, 1996, Mielenz et al 1995). In such cases, recrystallised ettringite is noticed as bands around aggregate (Taylor 1994), or filling up voids and cracks in the mortar phase or mortar-aggregate boundaries (Shayan and Ivanusec, 1996).

Taylor (1994) has pointed out that expansion due to DEF per se is a relatively weak effect. According to him, expansion and cracking due to DEF can be either very slow or non-existent, unless some other process like ASR, freezing and thawing, microcracking caused by the applied loading or the thermal curing etc. has initiated the damage. On the other hand, Yang et al (1996) have reported that cement pastes cured at $100^{o}C$ and then stored in room temperature, showed expansions after relatively longer storage under water. According to them, DEF expansions in cement pastes did not depend upon presence of aggregate particles or presence of extreneous cracking due to ASR or freezing and thawing etc., although such factors can reduce the induction period for expansion. They postulated that secondary ettringite crystallising in such cases cannot intermix with the outer product C-S-H gel and are forced to occupy voids and the inner zones or form crystalline ettringite bands, which causes expansion of cement pastes.

Diamond (1996) has stated that delayed formation of ettringite in heat cured concrete followed by moist storage under normal temperature is not different from secondary ettringite formed due to excess sulphate or other factors in concretes cured under normal temperature all through, and both show similar pattern of cracking and ettringite deposition. According to Diamond, the observed crack pattern is that of a network with component crack segments running partly along boundaries of aggregates and connecting crack segments through cement paste. The pattern appears to reflect local and inhomogeneous crack propagation rather than general and homogeneous expansion of cement paste. Diamond (1996) emphasised that stress concentration effect associated with ettringite crystallising in cracks or precipitating near crack trips make association of DEF with prior cracking caused by ASR, freezing and thawing or load effects fundamental to the DEF process.

Unsoundness due to Free Lime and MgO

Another source of delayed expansion in concrete is due to hydration of free (uncombined) lime, MgO and calcium sulphate phases in cement, which is commonly known as 'unsoundness' of cement. All national Specifications prescribe accelerated test for unsoundness. Le Chatelier test involves expansion of neat cement paste under boiling water which measures unsoundness due to presence of free lime. Autoclave test involving high temperature and pressure conditions is indicative of expansion due to crystalline MgO phase as well as due to free lime. Because of strict enforcement of Specification requirements, no unsound cement is likely to have been used in constructions. Thus, actual performance of unsound cements under service conditions is

difficult to obtain. Criticisms of soundness tests, mostly autoclave test, arise due to the differences in the hydration products formed under high pressure steam curing, which are different from those formed under normal temperature, and lack of correlation between laboratory test and field perforamance (Mehta, 1977).

Dead burnt CaO and MgO, if present in cement, exist as intercrystallised with the silicate phases. Their hydration reactions are, therefore, delayed and remain localised, and the Ca^{2+} or Mg^{2+} hydroxides formed cannot be dispersed. The surrounding cement paste is partly or fully saturated with alkaline solution, which allows diffusion of Ca^{2+} or Mg^{2+} and OH^- ions out of the supersaturated solution surrounding the hydrated $Ca(OH)_2$ or $Mg(OH)_2$ phases. The slower the rate of hydration of CaO and MgO, as under normal service conditions, the more will be the diffusion and lower will be the effective supersaturation, the crystal growth pressure and hence the expansion.

Chatterjee (1995) has explained that during the autoclaving of the neat cement bars, both the hydration of free oxide and the elongated growth of hydroxide occur simultaneously and quickly. There is no time for diffusion of ions and the lowering of supersaturation. This causes the sharp rise in expansion in the autoclave tests. In the case of water storage, the free oxide particles hydrate slowely and there is the time for the diffusion of ions away from the hydrating oxide particles. This diffusion of materials not only reduces the supersaturation but also removes Ca^{2+}, Mg^{2+} and OH^- ions from the neighbourhood of the hydrating oxide particles, thereby reducing the material source for elongated growth.

The limit of MgO content in OPC is set at 6% in cement Specifications in India and some other countries. This is because of presence of somewhat higher amount of MgO in limestone in some deposits. Together with this, free lime content in Indian cements tend to be somewhat higher, due to marginal quality of raw materials and fuels, that have to be used in some situations. Thus, soundness test by both Le Chatelier and Autoclave are prescribed in IS-Specifications. In order to offset the unsoundness in autoclave test due to presence of free lime, in case a sample fails in autocalve test, aeration of the sample is now permitted before retest. Such aeration is permitted in Le Chatelier test in many countries. The permissible expansion in the aerated sample is lowered to 0.6% i.e. 75% of 0.8% in unaerated samples. Typical results obtained in India shown in **Fig. 2** indicate that in many cases, the samples satisfied the specification requirement of expansion after aeration, even if the expansion were greater than the permissible limit the first time i.e on unaerated samples.

In an on-going investigation on the effect of unsoundness of cement, long-term expansion behaviour of concrete under moist storage conditions, made with two cements which showed unsoundness in Autoclave test, are monitored (NCB, 1997). One cement, prepared in the laboratory, contained 6.1 percent MgO; the other, commercially produced, contained 5.2 percent. Expansions upto three years are shown in **Fig. 3**, which indicate linear expansion upto 0.085 percent in concrete. In absence of any established limiting value, the magnitude of expansion can be compared with those prescribed for other deleterious reactions. For ASR, limiting expansion in concrete prism test as per

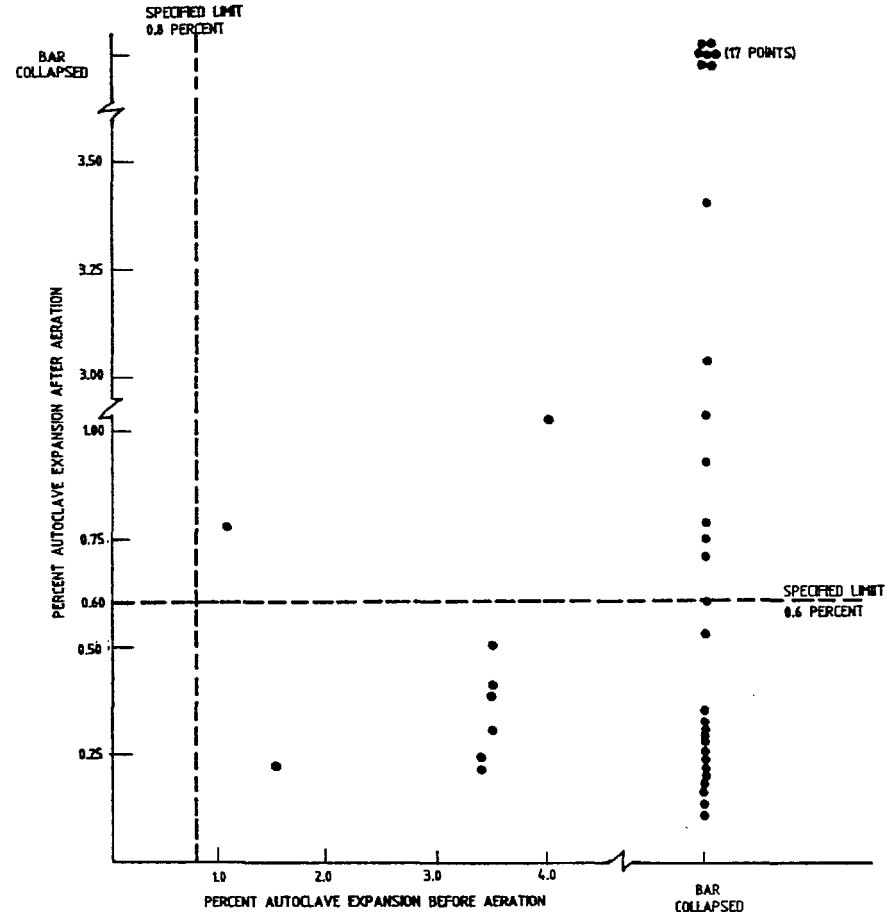

Fig.2 Effect of Aeration on Autoclave Expansion of Unsound Cements

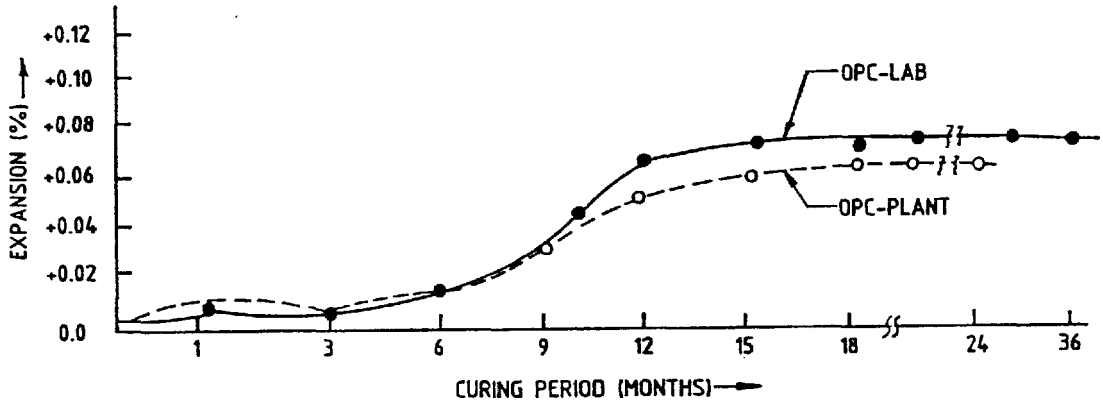

Fig.3 Expansion in Concrete made with High MgO Content under Water Storage

ASTM 1293-95 is held at 0.04 percent, which is lower than what has been obtained with unsound cements. However, no signs of cracking or external distress, neither any retrogression in compressive strength are noticed. Products of hydration of cement

containing 6.1% MgO in normal water storage indicate the presence of C-S-H,CH, ettringite and Brucite (**Fig. 4**). Remains of unreacted MgO after three years of hydration are also detected on XRD, (NCB 1997), which is not shown here. These results are presented with the hope that the significance of accelerated laboratory tests on unsoundness of cement and implications of using such unsound cements in constructions are assessed to a greater extent than done so far.

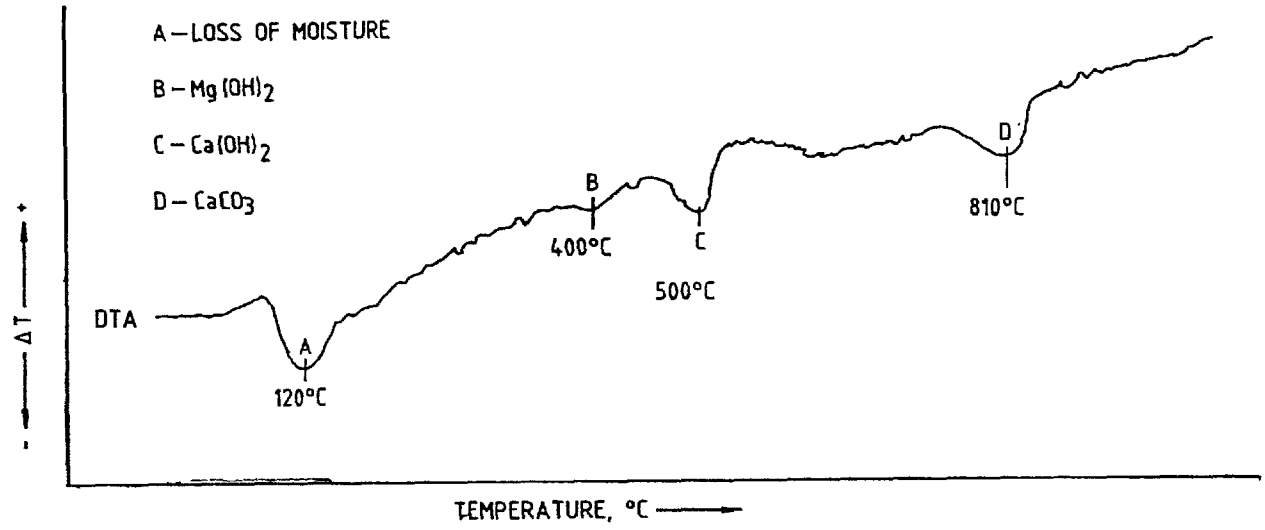

Fig.4 DTA of Hydrated High MgO Cement

Biodeterioration and Environmental Pollutants

Degradation of concrete is caused by biological components including bacteria, spores or fungi, as well as pollutants in the environment (Mullick and Chandra, 1992). The gaseous pollution include SO_2 and NO_2, whereas particulates include SO_4^{2-}, NO_3^-, Cl^- and NH_4^+ besides inorganic matters. Measurements indicate concentrations to be greater during winter months and in open exposures, than in dry months in covered areas (Rendehl et al, 1996). The pH of the leaching solution from the particulates was in the neutral interval (8.37 - 6.13), but during rain periods in open exposure, pH was found to be in the acid interval (7.33 - 3.82).

Both the acidic nature of the environment and ions like sulphates, chlorides and ammonia are known to be aggressive to concrete. NO_2, in association with SO_2, can produce H_2SO_4 in presence of H_2O. Energies like heat and light activate pollutant gases, aerosols and liquids, which can become detrimental to concrete (Chandra, 1990). Samples of concrete from a damaged bridge has shown the presence of reaction products like calcium monosulphoaluminate, carbo-aluminate, chloro-aluminate hydrates, calcium oxy-chloride etc., which were reported to be indicative of attack by atmospheric sulphurous oxides, chlorides and carbon dioxide (Chandra, 1996).

Microscopic examination by SEM of concrete samples from deteriorated structure, 7 to 30 years old, have shown signs of biological deterioration by micro-organisms, which

were yet to be fully identified (Rivas Silva, 1996). The envrionmental humidity varied from dry (12% RH) to moist, and temperature moderate (20°C) to cold (0°C). Microsocpy of concrete samples allowed observation of many morphologies, some of which were identified as micro-organisms. These were in the form of cells, strings and empty tubes etc. In addition, bacteria like Thiobacillus which oxidises iron, and Notrobacteriae, which dissolve Ca-bearing compounds, were observed. Although the identity of the micro-organisms were not established, the metabolism responsible for different kinds of deterioration of concrete observed were postulated (Ribas Silva, 1996).

The extent of deterioration due to atmospheric gases and particulates is location - specific and found to depend upon the level of industrial pollution. Comparing the extent of deterioration of C-steel, zinc, copper and sandstone in old structures located in Stockholm, and in Prague, the corrosion rates were found to be greater in the city, which was more polluted (Rendahl et al, 1996). Risk of distress due to corrosion of reinforcement in concrete has been estimated to be greater in the principal cities of Japan where the pollution is heavy than in some locations where the degree of air pollution is extremely low (Morinaga, 1996).

AGGREGATES AND REINFORCEMENTS IN CONCRETE

Apart from deterioration of the hydrated cement paste itself, considerable attention is paid to the role of hydrated cement paste or the mortar to protect the reinforcement or the aggregates in concrete. The results are distress to concrete structures due to the corrosion of reinforcement and chemical reaction with aggregates respectively. These are briefly discussed below.

Corrosion of Reinforcement

The basic mechanism of corrosion of steel as an electro-chemical phenomenon can be summarised in terms of an anode process and a cathode process (**Fig. 5**) (Mullick and Chandra, 1992).

Anode : Fe (metallic iron) $\longrightarrow 2e^- + Fe^{2+}$ ... (1)

Cathode : $1/2O_2 + H_2O + 2e^- \longrightarrow 2(OH)^-$ ... (2)

and the corrosion undergone by steel is due to combination of iron and (OH^-) ions;

$Fe + 1/2O_2 + H_2O \rightarrow Fe^{2+} + 2(OH) \rightarrow$ iron hydroxide (rust) ... (3)

The oxygen dissolved in water enhances corrosion when the pH is in between 4 and 10. For pH more than 10, reaction (3) takes the form :

$2Fe^{2+} + 3H_2O \longrightarrow Fe_2O_3 + 6H^+ + 2e^-$ ... (4)

$3Fe^{2+} + 4H_2O \longrightarrow Fe_3O_4 + 8H^+ + 2e^-$ ... (5)

For transformation of metallic iron to rust, iron must be available in a metallic (Fe) state at the surface of the reinforcing steel; oxygen and moisture must be available for the

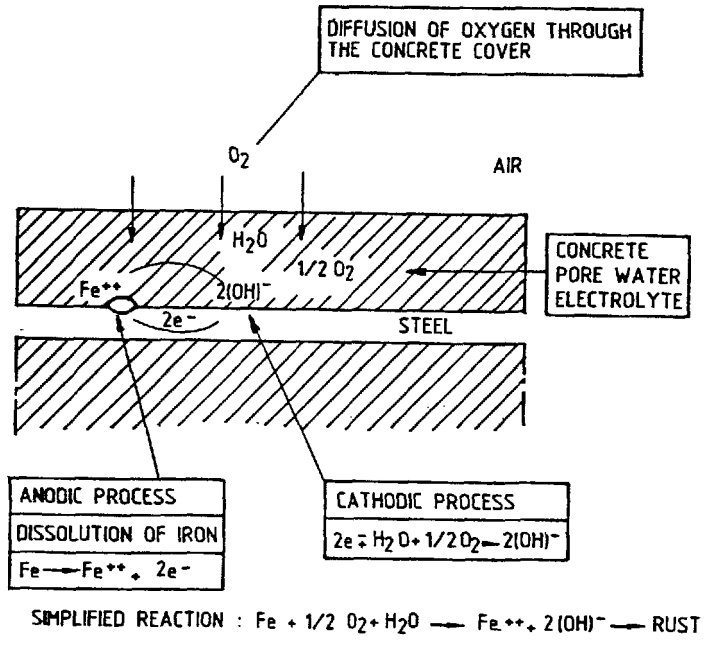

Fig.5 A Simplified Model of Corrosin of Steel in Concrete

cathode process; and the electrical resistivity of concrete must be low to facilitate the electron flow in the metal from anodic to cathodic areas.

From engineering stand point, two types of situations are necessary to be considered. The steel reinforcement, being well protected in the alkaline medium in concrete, would take a certain amount of chloride ion to be present in order that corrosion can take place. On the other hand, if the passivity is destroyed because of one reason or the other, and the pH of concrete is lowered below a certain threshold value, all that is needed for corrosion to take place is oxygen and water, and presence of chlorides is not necessary. Concrete constructions, in order to be durable, have to ensure that the limiting amount of chloride ions is not exceeded in concrete and neither the pH value of concrete is lowered below the threshold value. Practical limits of tolerable chloride ion concentration and limiting pH value are best arrived at by in-service record of concretes.

Chloride ion concentration present in the pore water in an equilibrium situation depends on the other ions present in the pore water; for example, at a given total chloride ion content, the higher the hydroxyl (OH^-) concentration the more free chloride ions are present (Neville, 1995). For this reason, the Cl^-/OH^- ratio is considered to affect the progress of corrosion. The significance of this parameter is discussed later.

Alkali-Aggregate Reaction

In so far as chemical reactions involving aggregate are concerned, expansive reactions entitled alkali-aggregate reaction (AAR) have commanded major attention, although othere reactions involving oxidation of ferrous iron, pyrites or marcasite in aggregate have been reported (Mullick and Chandra, 1992). Chemical reactions between

aggregate containing certain reactive constituents and alkalies and hydroxyl ions released by the hydration of cement can have deleterious effects on concrete. Alkali-silica reaction (ASR) involves rocks and minerals containing reactive forms of silica. Expansion and cracking, leading to loss of strength, elasticity, and durability are among the physical manifestations of ASR. Mehta et al (1992) have identified amorphous silica (e.g. opal), microcrystalline and poorly crystalline silica (e.g. chalcedony), fractured or strained quartz and glassy silica (e.g. andesitic and rhyolitic glasses) as among the commonly known alkali-reactive forms of silica. Depending on the alkali content of cement and the water-to-cement ratio, the pH of the liquid phase in a hydrated portland cement may be 13 and above. Mehta et al (1992) point out that minerals containing silica with a disordered structure would not remain stable in such a strongly alkaline solution. According to them, depending on the degree of disorder, porosity, particle size, and temperature, the deploymerization of silica structure (i.e. dissolution of O-Si-O bonds) will gradually occur, followed by adsorption of the alkali-metal cations on newly created surface of the reaction product. When in contact with water, the alkali-silicate gels swell by sorpotion of water through osmosis. The hydraulic pressure so developed is believed to cause expansion and cracking of the affected aggregate particle, and subsequently the cement paste matrix surrounding it.

Effects of Pozzolana and Slags

Beneficial effects of incorporation of pozzolanic materials like flyash, silica fume or latent hydraulic materials like slag on corrosion of reinfocement and alkali-aggregate reaction have been intensively researched in the recent times. Such beneficial effect in improving the durability of concrete results from formation of dense CSH microstructure, modifications of the pore structure and pore size distribution, lowering the conductivity of concrete and aiding chloride binding etc. The alleviation of alkali silica reaction due to addition of flyash or silica fume is considered to be due to the arrest of alkali ions in the CSH product formed by pozzolanic reaction, which is of lower C/S ratio, in which alkalies from cement can be incorporated. Pozzolona and slag themselves contain alkali; however, these are not supposed to participate in promoting alkali silica reaction and only a fraction of the alkali from pozzolona and slag are supposed to be at par with the alkali derived from ordinary portland cement in causing alkali silica reaction.

Although flyash, slag and silica fume are being used in concrete constructuions for a long time, reports of performance of such structures in service are rather limited. Performance of concrete structures like dams, raod bridges, foundation blocks and concrete tank walls in the United Kingdom, incorporating flyash have been reported by Thomas and Mathews (1993). Results of tests on field samples indicated that while the 28-day concrete strength of concrete incorporating flyash was lower than OPC concrete, strengths at later ages were higher. OPC concrete was more permeable than flyash concrete, sometimes upto 20 times. Flyash concrete showed greater resistance to penetration of chloride ions. There were no signs of ASR in concrete dam using flyash, where the aggregate was reactive and which have resulted in ASR in an OPC concrete dam. It has been a practice in Iceland since last two decades to intergrind silica fume in cement, to mitigate the effects of severe ASR taking place in that country. On the basis of periodic condition surveys, it has been reported that no cases of ASR damage have been found in Icelandic structures built since such a practice began (Gudmundsson and Olafsson, 1996).

Chloride Binding

Chloride ions reside within the concrete system with different amounts of fixicity. Part of the chloride ions remain free in the pore water solution, whereas the remaining part is bound to the products of hydration of cement by adsorption and chemical reaction (Tang and Nilsson, 1993). The phenomena of thus fixing a part of the chloride ions is called 'chloride-binding' capacity of concrete. As a very general rule, bound chloride in ordinary portland cement paste may vary from 40 to 60 percent of the total chloride ions present. Chloride binding by sorpotion is reversible and can be desorbed following drying. Fixation of chlorides in the hydration products follows the progress of hydration of cement. It is thus a function of time.

Such chloride ions which are chemically combined, react with products of hydration of C_3A, forming calcium chloroaluminate hydrate, and its ferrite analogue with C_4AF - phase. In addition, these are physically adsorbed to the pore surface. Chloride ions also get absorbed to the surfaces of pozzolonic additons like flyash etc and enter into chemical reaction with its aluminate phase. As a result, the chloride binding capacity of concrete increases with the C_3A content in the cement, as well as by addition of flyash, slag and silica fumes etc. (Nagataki et al 1993, Dhir et al 1994). Increase in alkali content in cement was found to decrease chloride-binding (Al-Gahtani et al, 1994).

The actual proportion of bound chloride depends upon a number of factors and can change with temperature or humidity. Stability of calcium chloro-aluminate hydrate in the presence of sulphate ions is not fully established and there are stipulations that ultimately such bound chloride ions end up with the formation of calcium sulphoaluminate hydrate in case of simultaneous presence of SO_3^{--} ions, thereby once again increasing the proportion of free chloride available for corrosion process (Neville, 1995). Atmorpheric carbonation leads to increased solubility of Friedel's salt, thereby incrasing the amount of free chloride (Suryavanshi and Swamy, 1996). Talib et al (1994) reported lower chloride binding with increase in temperature.

POSSIBLE REASONS OF INADEQAUTE PERFORMANCE

According to Mather (1994), the procedure for obtaining concrete that will result in desired performance is simply to include the relevant requirements in the contract document and ensure through proper owner quality assurance and contractor quality control that the requirements of the specifications are followed. In other words, **order the concrete that you need and make sure that you get it**. The basic approach to work out appropriate specifications for durable concrete were summarised (Mullick and Chandra, 1992) as;

* characterise the service environment in totality,
* determine severity of environment,
* make concrete impermeable,
* ensure appropraite workmanship, design and detailing

With such a basic approach in view, any instance of insufficient durability of concrete can lead to two possible questions;

* **Was the specification of concrete appropriate to ensure durability under the given service environment?**

* **Were the requirements of the specification adhered to in practice?**

While the first question relates to the overall perception of the issues governing the durability of concrete; the second question is perhaps somewhat easier to answer. It has to be admitted that distress to concrete structure is quite often due to non-adherence to the requirements of specifications. The areas of non-compliance not only relate to use of appropriateness of ingredients of concrete and adequacy of mix proportions, but also to workmanship, notably placing, compaction and curing of concrete.

One major requirement for durability is to make concrete as impermeable and as water-tight as possible. Since presence of moisture is required for most of the chemical reactions, use of as low a water-cement ratio as possible, is helpful. The water permeability of concrete has been tested on laboratory specimens and related to porosity and pore size distribution in the microstructure of the hydrated cement paste. Influences of addition of flyash, slag, silica fume etc and incorporation of chemical admixtures have also been studied. However, in absence of adequate campaction and moist curing, the amount of voids that can be left in the concrete at a macro-scale are much more serious. Poor workmanship, poor quality of concrete, and inusfficient concrete cover to steel reinforcement are quite often reported to be the main causes of deterioration in most cases. Poor placing and compaction techniques result in variable cement content in hardened concrete, variations in ultrasonic pulse velocity and thickness of cover to reinforcement at different locations in the structure. Such locational differences in the quality parameters can themselves set up electro-chemical corrosion cells (Mullick and Rajkumar, 1993).

Depth of carbonation is a good indicator of the health and quality of structural concrete. In sound concrete, the depth of carbonation under normal situations can range from 1 to 6 mm per $(\text{year})^{1/2}$. For a 25 years old concrete, 5 to 30 mm carbonation depth can thus be expected, depending upon the service condition and quality of concrete. Measurements of depth of carbonation ranging from 10 to 65 mm in concrete structures in India, as obtained in our laboratory, or 11 to 66 mm as reported for structures in Singapore and Malaysia (Wong et al. 1993) have been reported. Even allowing for uncertainty in the estimation of carbonation depth using phenolphthalein (Chandra, 1996) under field conditions, these values are much in excess of what is normally expected and thus point to serious deficiency in field practices. Concrete under such a situation cannot be expected to be durable. We will leave it at that.

SPECIFICATION FOR AN INTERACTIVE SYSTEM

In search of possible reasons of non-performance, it is necessary to recognise the interactive nature of various factors and the extent, to which the specifications for concrete cater to these. A System's approach to durability of concrete has been advocated (Mullick and Chandra, 1992). In such a system, deterioration of concrete is seen to be due to a number of causative factors, aided by a host of promoting and accelerating factors. A simple example is of sea-water containing both sulphates and chlorides of various cations; or the soil or ground water in many situations entrain more

than one type of salt, In reality, the micro-environment in an element in concrete is subject to interaction between various chemical and environmental factors and the system is more complex. In many cases, the interaction is synergistic.

Interaction between Aggressive Ions

The products of hydration of cements and attack on these by various aggressive ions, which were discussed before, are such that their stability can be altered by ionic substitution, complexing or forming solid solution. In addition, the kintics of reaction and equilibrium are governed by the hygrothermal conditions. Some examples below will illustrate the point.

* Sulphate attack in concrete due to SO_3^{--} ions, can be significantly mitigated by concommitant presence of high concentration of chlorides (Al-Amoudi, 1995).

* Simultaneous presence of SO_3^{--} ions enhance the risk of corrosion of reinforcement due to Cl^- ions. This takes place due to the competing reactions on C_3A phase of cement both by Cl^- and SO_3^-, thereby reducing the formation of Friedel's salt (which bind chloride ions) and leading to formation of ettringite. This increases the concentration of free chloride ions in pore solution (Saleem et al, 1996).

* Electrical resistivity of concrete, for a given moisture content, was found to be lower in presence of NaCl plus Na_2SO_4 than in presence of NaCl or Na_2SO_4 alone (Saleem et al, 1996).

* Atmospheric carbonation reduces the stability of Friedel's salt and ettringite (Suryavanshi and Swamy, 1996). Ettringite is even less stable in sea water, which contain more than normal CO_2 (Mehta, 1993).

* Simultaneous presence of SO_3^- as Na_2SO_4 increases the alkalinity of the pore solution, which inhibits chloride-binding (Al-Amoudi et al, 1994).

* Synergistic effect of SO_3^- ion on chloride ingress in portland cement concrete is to decrease chloride penetration and diffusivity. Presence of CO_2 at the same time, decreases chloride diffusivity. However, in case of portland cement-slag blend, the effects of SO_3^- and CO_2 on chloride penetration were just the opposite (Tumidajski and Chan, 1996).

* Addition of alkali (KOH) resulted in increase in carbonation of concrete, the rate of carbonation increasing with increase in KOH content (Xu, Rodhe and Chandra, 1996). A catalytic effect of the alkali on carbonation was suggested.

* Extent of carbonation in cement mortar was found to be greater when exposed to a mixture of CO_2 and SO_2 gases, than when exposed to CO_2 alone (Chandra, 1996).

Interaction of Temperature and Humidity

Laboratory research on durability is generally carried out using concrete and mortar specimens under controlled hygrothermal conditions. The temperature is maintained within narrow ranges as per the national norms e.g. 18°C in Europe, 21°C in North America and 27°C in India. The specimens are maintained under moist storage conditions. In order to assess the performance of concrete under site conditions, the effects of temperature and relative humidity (RH), both ambient as well as in pore solutions, have to be taken into account. With increase in the operative temperature, all deleterious chemical reactions can be thermally activated and, therefore, the extent of reaction increases.

Chloride diffusivity of concrete is reported to increase with curing temperature (Detwiler et al, 1994). Increase in electrical conductivity of concrete and depth of carbonation with increase in curing temperature has also been reported (Moriwake et al, 1994). Increase in temperature can cause evaporation of free water from the concrete and lower the internal RH. Coarsening of pore structure takes place.

These bring out the improtance of appropriate moist curing under field condition. Moist curing of concrete beyond 7 days is seldom carried out. There are instances, when the actual curing was much more inadequate. Arafah et al, (1996) has reported that in Middle East countries with high temperature upto 45°C and low relative humidities of about 4 percent during summer, all that goes in the name of curing is actually sprinkling of water without burlap cover for one or two times a day. The effect of such curing practices are usually noted in terms of development of compressive strength. However, the effect of inadequate curing on parameters affecting durability are much more pronounced. Ramezanianpour and Malhotra (1995) have shown that continous moist curing was essential to achieve the highest strength, lowest porosity and the highest resistance to penetration of chloride ions. When concrete, after demoulding, was left to cure under ambient conditions of 38°C and 65 percent relative humidity, the poorest results were obtained.

The interactive effects of temperature and humidty are also manifest on the hydration of the portland cement paste and of mineral additions. Hydration of cement can take place only when the capillary pores are filled with water - either the mix water or curing water imbibed from outside. Hydration reactions cease when the relative humidity within concrete falls below 80% (Spears, 1983). In pozzolana having limited (lime) - reactivities, not much pozzolanic reaction take place even upto 28-days under moist curing (Mullick et al, 1986). When the reactivity of pozzolana is higher e.g. with silica fume, reactions are somewhat faster and even then, there will be an initial period for first few days when no pozzolanic reaction take place. Some contribution to the strength development can take place by the physical action i.e. filler effect.

Continuation of pozzolanic reactions is dependent upon the relative humidity. In Thomas' (1989) experiments, OPC and OPC/PFA pastes after curing for 1,3 or 7 days in $Ca(OH)_2$ solution, were kept at RH from 9 to 93% until the test age of 28 or 180 days and analysed for $Ca(OH)_2$ content and pore structure. It was found that in case of OPC, at RH below 81% the hydration of cement was severly retarded and appeared to cease

below 66% RH. In case of OPC/PFA pastes, at relative humidities of 81% and below, there was little evidence of any pozzolanic reaction at 28 days. However, at the age of 180 days, evidence for some pozzolanic reaction at the RH of 81% was found by a small reduction in the $Ca(OH)_2$ content of the paste. However, little on no $Ca(OH)_2$ depletion was detected in PFA pastes stored for upto 180 days at relative humidities of 66% even after initial curing period of 7 days.

From the foregoing it is clear that in relatively dry environments and after initial moist curing limited to less than 7 days or so, subsequent reaction with pozzolana, flyash or slag can not be realised to the fullest extent. Therefore, all the beneficial effects claimed to be obtained by such mineral additions will not be forthcoming. In particular, the limiting relative humidity can be such, which will lower the pore water pressure to a value of 0.8 or so, in which case, continued hydration reactions of OPC will also be hindered.

Since most of the deleterious chemical reactions like corrosion of reinforcement, sulphate attack and alkali-silica reaction can take place only in the presence of sufficient moisture, the relative humidity of concrete is also important from the deterioration process. Mather (1994) has said that any concrete will be durable regardless of other considerations, if it is allowed to get dry and stay dry. He said that 'dry' in this context means that the evaporable water is allowed to and does escape, and the internal realtive humidity drops below 80 percent, under which conditions there are no longer any chemical reactions that can take place and there is no water that can freeze.

There is wide occurance of corrosion of reinforcement in concrete reported in the Indian subcontinent (Mullick and Rajkumar 1993) as well as from the Middle East (Rasheeduzzafar et al, 1992) where the environments are dry. The question is, is it not dry enough to stay the process of corrosion of reinforcement or sulphate attack ? The same holds for alkali-silica reaction, which have traditionally been associated with hydraulic structures like dams where the concrete is either in contact with water or exposed to moist conditions and high relative humidities. Stark (1991) have shown that internal relative humidity of concrete inside concrete pavements built in arid desert regions of California was of the order of 80 percent and alkali-silica reaction did take place. Similar experiences have also been noted in massive tubro-generator foundation blocks in India, where alkali silica reaction of concrete was noticed, when reactive aggregates were used and the cement content was relatively high (Mullick 1994). In other words, there is an area of uncertainty in relation to relative humidity condition inside concrete which may be low for the beneficial pozzolanic raction to take place, but may not be low enough to stop the deleterious chemical ractions.

Carbonation does not take place either in saturated concrete or in dry condition - it is greatest in intermediate values of relative humidity of the order of 65% (Ewertson and Petersson, 1993). Widespread carbonation of concrete and corrosion of reinforcement are notied to go hand in hand (Mullick and Rajkumar, 1993). Clearly, corrosion of reinforcement do take place in such intermediate RH values, which also support carbonation of concrete. Enevoldsen et al (1994) reported that active corrosion did not

take place below a threshold internal humidity, which was estimated to be 80% from laboratory data and about 70% ambient in the field.

Browne (1982) has stated that concrete resistivity must fall below 5000 to 10000 Ohm-cm in order to support reinforcement corrosion. Increasing moisture content of concrete, as indeed presence of chloride, or sulphate ions have been found to decrase the resistivity of concrete (Saleem et al, 1996). In addition, there is considerable interaction due to simulateneous presence of chloride and sulphate ions. For a given moisture content of concrete, the electrical resistivity was the lowest when both Cl^- and SO_4^- ions were present together than when present singly. Typical results are reproduced in **Fig. 6** and **Fig. 7**. The results showed that in presence of excess chloride ions, even in nearly dry concrete, there is chance of corrosion because of low resistivity. Decrease in electrical resistivity of concrete due to sulphate contamination was also a matter of concern, as the reinforcement corrosion in such situtations will be sustained due to carbonation (Saleem et al, 1996).

The highest corrosion risk is usually associated with concrete which is subjected to cyclic wetting and drying, not only at the concrete surface but also at the reinforcement. The reinforcement will under such conditions experience large local potential variations, since the potential is strongly affected by the oxygen concentration at the steel surface, which in turn is controlled by the moisture state. Large local potential variations are suspected to promote galvanic types of corrosion.

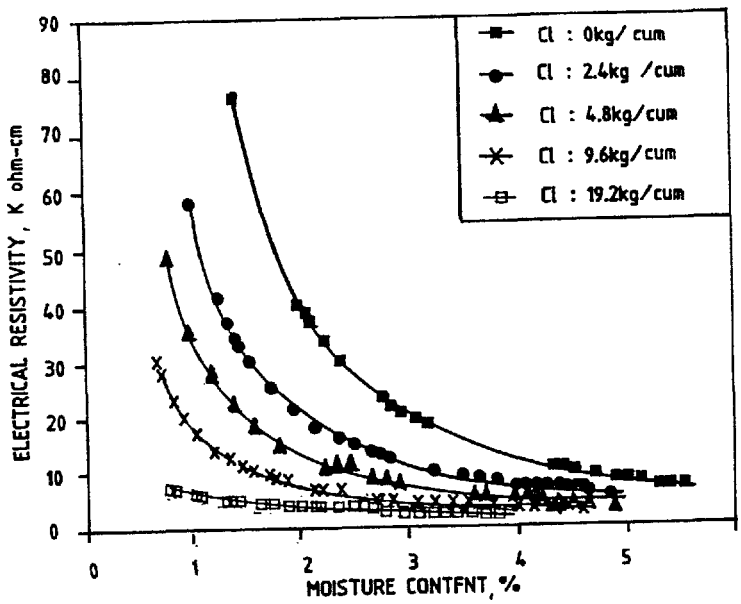

Fig.6 Relationship between Moisture Content and Electrical Resistivity in Chloride-contaminated Concrete (Saleem et al, 1996)

Prolonged drying in combination with saline wetting and drying causes salts to be transported into concrete by means of suction and diffusion (Sandberg, 1996). If the concrete dries at the reinforcement, the concentration of chlorides and other ions in the

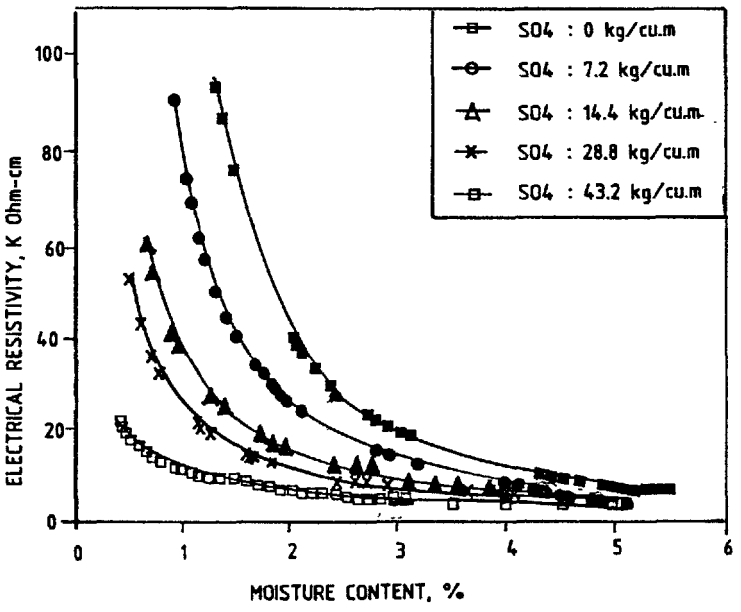

Fig. 7 Relationship between Moisture Content and Electrical Resistivity in Sulphate-contaminated Concrete (Saleem et al, 1996)

pore solution may thus increase. Besides the concentrating effect of solvent removal upon drying, the chloride adsorbing capacity of the cement gel has been found to decrase upon drying. Sandberg (1996) has stated that it remains to be investigated if it is the difference in passive steel potential (e.g. oxygen availability), or any shrinkage cracking at the interface between the reinforcement and the binder matrix, or the more concentrated pore solution, which is the main reason for the increased corrosion activity in concrete subjected to wetting and drying. From practical experience it is known that the moisture state and the thickness of the cover are of vital importance.

Cl - OH - CO_2 Interaction

For corrosion to take place in mild steel stored in the open, presence of only water and oxygen are required. Portland cement concrete provides protection to reinforcing steel by the highly alkaline nature of the pore solution. At high pH around 13, steel is passivated in the presence of oxygen by formation of γ- Fe_2O_3 film as well as the lime-rich layer at steel-concrete interface. Depassivation of steel can take place by the reduction of pore solution pH, which, in turn, is caused by carbonation as well as ingress of chloride ions. Clearly, there is an interaction between Cl^- - OH^- - CO_2, which is critical for corrosion of reinforcement in concrete to take place.

The relationship between chloride content and corrosion of steel depends upon the pH value. **Fig. 8** obtained from data on a large number of concrete structures in India damaged due to corrosion of reinforcement show that the amount of chloride ions that can be tolerated is higher, the greater the pH value and vice versa. In particular, Figure 8 indicates that depassivation was reached at a pH of about 10.

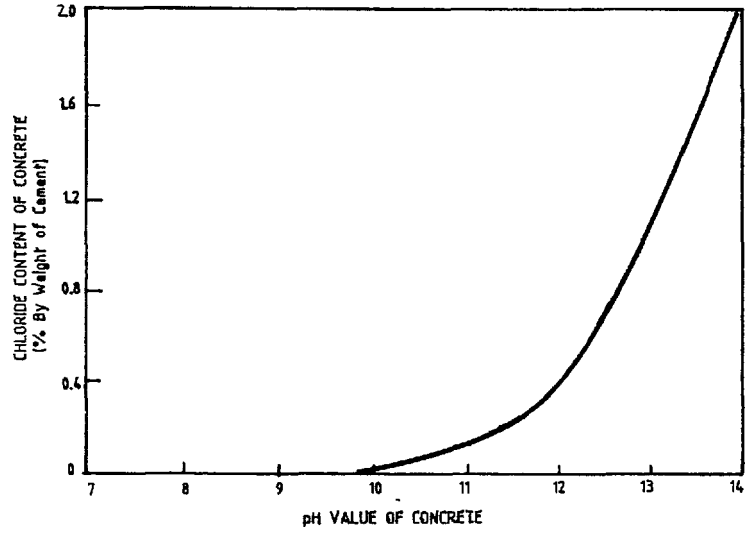

Fig.8 Interaction Diagram of pH Value and Chloride Content in Corrosion-damaged Concrete Structures in India

From corrosion point of view OH^- ion concentration is more important, the latter being related to, but not the same as pH value. The alkalinity in the pore solution in concrete is due to $Ca(OH)_2$ as well as C-S-H phases, the alkali and alumina etc. For pH value of 12.5 corresponding to calcium hydroxide solution, a threshold depassivation Cl^-/OH^- ratio of 0.60 was proposed (Hauzmann, 1968). For higher pH values obtaining in hydrated cement systems, the threshold ratio of Cl^-/OH^- will be lower than 0.60, and for lower pH values the ratio higher (Rasheeduzzafar et al, 1992).

Depending upon the chloride-binding capacity of the cement hydrates, the amount of free chloride ions available for corrosion to take place will influence the relevant Cl^-/OH^- ratio. The pH value of the pore solution itself is dependant on the amount of chloride ions; in general, presence of chloride ions which are acidic in nature lowers the pH value. On the other hand, fixation of chloride ions in the C_3A and C_4AF phases forming Friedel's salt and its ferrite analogue, will increase the OH^- ion concentration in the pore solution (Suryavanshi et al, 1996). Thus the net effect on alkalinity of the pore solution will depend upon the amount of chloride-ions and how much of it is fixed - i.e the same parameters governing the risk of corrosion of steel in concrete.

Carbonation is the primary cause of lowering of alkalinity. The pH value of concrete can be as low as 8.5 due to carbonation. Greater carbonation will lead to greater risk of corrosion. Suryavansi and Swamy (1996) have examined the effect of carbnonation on stablity of Friedel's salt. Typical results reproduced in **Fig. 9** and **Fig. 10** show that due to carbonation in the outer surface of the slab specimens (0-5 mm), both Friedel's salt and ettringite were absent. However, at depths 45-65 mm, where no carbonation had taken place, peaks corresponding to portlandite, ettringite and Friedel's salt were present. These results indicate that in presence of CO_2, the risk of corrosion is also increased due to dissolution of calcium chloro-aluminate and consequent release of chloride ions to pore solution.

(Suryavanshi and Swamy, 1996)

Interactive effects of addition of flyash, slag and silica fume etc on chloride binding and pore solution chemistry are equally complex. Such mineral additions help in chloride binding due to physical adsorption. Because of reaction with $Ca(OH)_2$ liberated by hydration of cement, lowering of pH value is sometimes apprehended. However, presence of enough calcium ions in cement, in excess of what is required to combine with silica in cement and pozzolana, can ensure that a saturated solution of calcium

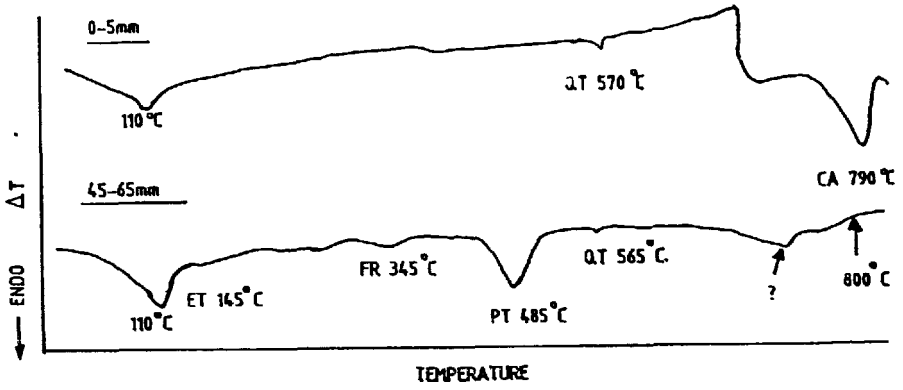

Fig. 10 DTA Thermograms for Slab shown in Figure 9
(Suryavanshi and Swamy, 1996)

hydroxide will always result (Mather, 1994). The alumina and alkalies in the pozzolana and slag also help in maintaining the required pH. Glasser (1989) has pointed out that, because of contribution of alkali content of slags and pH-buffer effect of residual

$Ca(OH)_2$ and C-S-H, the internal pH of slag-cement blends is well above the minimum likely to be required to provide passivation for steel reinforcements.

Rasheeduzzafar et al (1992), found that incorporation of 10 and 20 percent silica fume in cement pastes containing 0.6 percent Cl^- ions by weight of cement resulted in pore solution being 5 and 77 times more aggressive than in plain cement, and Cl^-/OH^- ion ratio much higher than the safe threshold value. A corrolary of higher Cl^-/OH^- ratio in the pore solution of flyash concrete compared with OPC concrete of the same total chloride content was that increasing flyash content was found to decrease the threshold chloride level for corrosion (Thomas, 1996). The threshold levels obtained were 0.70 percent acid - soluble chloride by mass of cement for plain concrete, which gradually decreased to 0.65% for 15% flyash, 0.50% for 30% flyash and 0.20% for 50% flyash added in the concrete mix. In both cases, incrasing the Cl^-/OH^- ratio of the pore solution did not necessarily result in greater ingress of chloride ions or greater corrosion taking place, due to improvements in the pore structure, dense microstructure and increased resistance to chloride ion penetration. Typical results obtained by Rasheeduzzafar et al (1992) and Thomas (1996) are reproduced in **Fig. 11** and **Fig. 12** respectively.

Thus, the actual result will depend upon the extent pozzolanic reaction take place, and the fixicity of chloride ions.

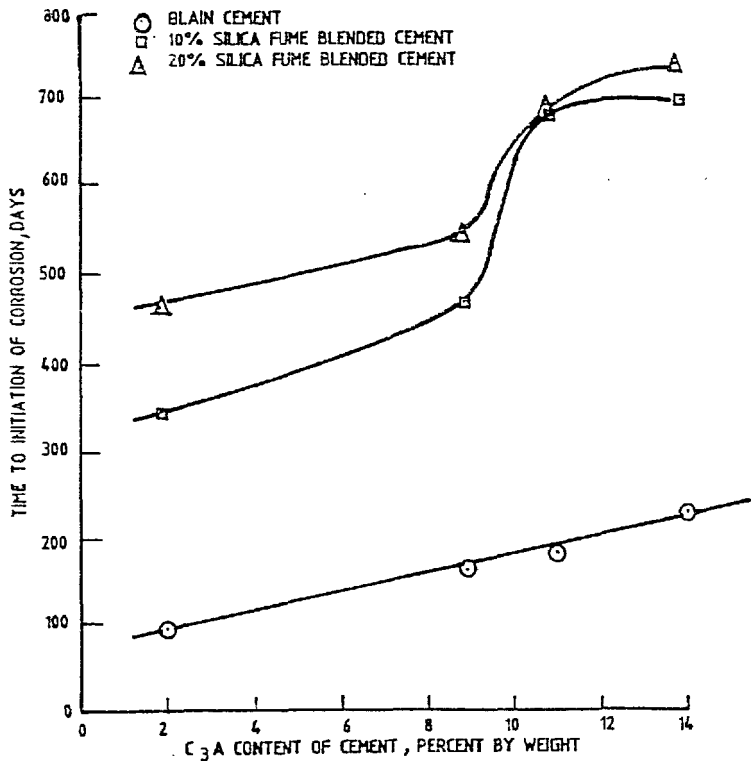

Fig. 11 Effect of C_3A Content of Cement and the Increasing Replacement of Cement by Silica Fume on Corrosion of Reinforcing Steel in Concrete (Rasheduzzafar et al, 1992).

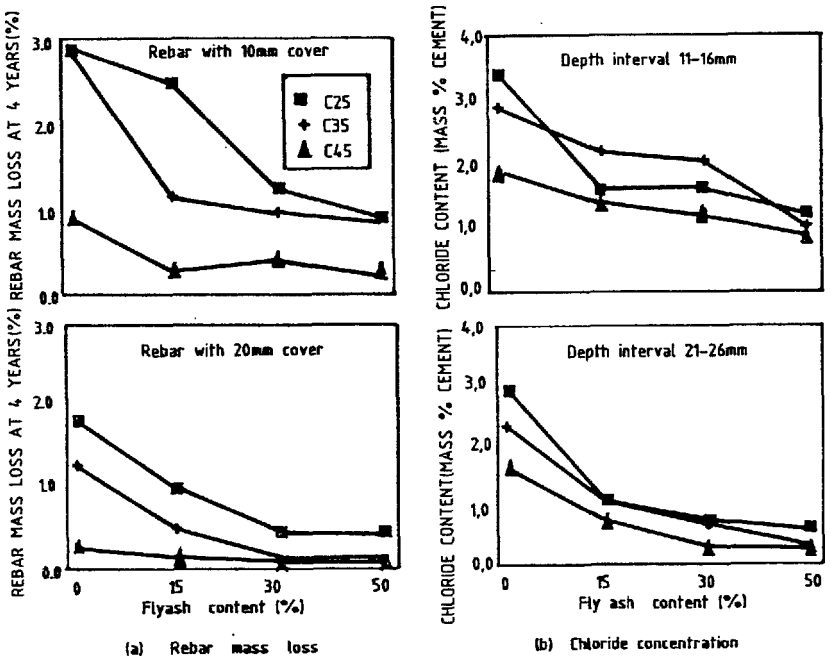

Fig. 12 Effect of Flyash on Concrete Performance after 4 years Exposure (Thomas, 1996)

Interface with Reinforcement

Interfacial regions in concrete, either in contact with aggregate or with reinforcement, are in general quite different from the 'bulk' cement paste in terms of morphology, composition and density. The interficial regions are more porous than the bulk phase, leading to lower density (Mindess, 1989). It consists of a thin rim of massive C-H crystals, in contact with the reinforcement, backed up by a porous layer consisting of needle-like C-S-H and ettringite. The thickness varies from 40 to 50 μm. The passivating film formed at the surface of the reinforcement is a mixture of iron products, like FeO-OH, $Fe(OH)_2$ or $Fe(OH)_3$, and calcium hydroxide. However, when fresh concrete surrounds a steel, rusted due to exposure prior to use, mixing water flows into rust pores, cement hydration products forming in such pores react with the iron products. Oriented platy spinel crystals in the inner layer and mixture of fine-grained spinel and α-FeOOH, with C-H being present in both the layers have been identified (Sagoe-Crentsil and Glasser, 1989).

In spite of the porous nature of the transition zone, passivation is due to the presence of lime-rich layer. The solubility of portlandite maintains an alkaline pH and the presence of portlandite continues to provide adequate pH-buffering to keep the interface region highly alkaline with pH greater than 12 (Sagoe-Crentsil and Glasser, 1989).

Sandberg (1996) has stated that effect of physical adhesion between cement hydrates and iron oxides formed at the steel interface is very important. Formation of voids at the steel-mortar interface is a necessary condition for active corrosion to start in concrete with moderate chloride content. Such voids can form due to inadequate compaction as

well as segregation and bleeding in fresh concrete. Effects of inadequate workmanship on the voidage, strcuture and chemical composition of the interfacial transition zone has not been adequately modelled, and not much is known even on a semi-quantitative order.

THE 'CRITICAL' SYSTEM

Taking into account the very many interactive factors enumerated above, it is possible to identify a situation in practice, which may pose to be critical to the system of durability. Risk of corrosion of reinforcement in concrete is chosen as an example. Presence of aggressive ions like sulphates and chlorides etc., atmospheric carbonation, relatively dry environment and high ambient temperature comprise essential components of such a scenario. Ambient temperature of the order of 35 to 40^{o}C and dry conditions with realtive humidity around 60 percent, coupled with inadeqaute moist curing will not allow hydration of cement and pozzolanic reactions to progress very far. Carbonation will be accelerated, lowering the pH value. Much of the chloride ions will be free in the pore solution and resistivity of concrete will remain below the desired level of about 5000 to 10000 Ohm-cm (Browne, 1982). Cl^{-}/OH^{-} ratio in the pore solution will be higher than the threshold value, leading to corrosion of reinforcement.

It is presumed that the prescriptions of quality of cement, pozzolana, aggregate, admixtures and mix water as required for the anticipated environment and laid down in numerous publications are adhered to. If not, it will add further to the vulnerability of the system. Inadequate workmanship and inappropriate quality assurance will be very detrimental. This aspect is not elaborated here.

Such a critical system can not be simulated in the laboratory, in all aspects. On the other hand, there are many instances of distress of such concrete 'systems' in service. It is essential that condition surveys and case histories report all the durability indicators as obtaining in the structure. These will include, inter alia;

i) Ambient temperature and relative humidty
ii) Moisture content and internal relative humidity
iii) Status of hydration reactions and hydration phases present
iv) Cover thickness, quality of concrete, cement content, w/c ratio
v) Extent of carbonation, by phenolphthalein test and presence of portlandite and/or calcite at various depths by XRD
vi) pH value of pore solution extract and of concrete cover
vii) Ingress of chloride and sulphate ions at different locations
viii) Measure of free (water-soluble) and total (acid-soluble) chloride in concrete
ix) In-situ permeability of concrete, pore size distribution in the hydrated cement
x) Electrical resistivity of concrete; etc.

It is not suggested that the above list be taken as exhaustive. What is being emphasised, is the need of measuring as many relevant durability parameters as possible, which have a bearing on the performance of the system. Careful analysis of data and correlation with

various durability indicators will lead to a better understanding of the causes of distress under field conditions.

DURABILITY WITH NEWER CEMENT SYSTEMS

The discussions so far are based on concrete made with ordinary portland cements, with appropriate addition of flyash, slag or silica fume, wherever so decided. In addition, newer cement systems have been explored with a view to result in conservation of raw materials and energy resources. The status of industrial exploitation of such concepts was reviewed (Mullick, 1992). In view of limited commercial production of these, durability of concrete structures made with such cements have not been adequately investigated and/or reported. Limited laboratory data available, however, indicate interesting possibilities, as discussed below.

Cements in oxide system $CaO - Al_2O_3 - SiO_2 - SO_3$, having assemblages of phases $C_4A_3\bar{S}$, β-C_2S, CA and $C\bar{S}$ etc were postulated and explored by Mehta (1980), and many others. Typical hydration products include ettringite, C_3AH_6, C_4AH_{13} and $C_3A\bar{C}H_{12}$ (Mudbhatkal et al, 1986). A common feature of these systems is the absence of $Ca(OH)_2$ as a product of hydration. Similar trends have been reported in systems with incorporation of MgO, i.e. $CaO - Al_2O_3 - Fe_2O_3 - SiO_2 - SO_3 - MgO$ (Ali et al, 1997). The products of hydration include ettringite, CSH and unreacted β-C_2S and $Ca_3Mg(SiO_4)_2$, the latter phase in the clinker bring essentially inert (**Fig. 13**). Limited durability studies in both the systems indicated improved sulphate resistance and adequate resistance against corrosion of steel reinforcement in accelerated tests (Mudbhatkal et al, 1986, Ali et al, 1997). Results of corrosion tests reported by them are shown in **Fig. 14**.

Interest on these systems arise due to absence of $Ca(OH)_2$ phase as a hydration product, which is one of the fast reacting components of hydrated cement paste in OPC systems. Similar situation exists in alkali activation of slags. The hydration products are poorly crystalline, often of geletinous nature; C-S-H (I), and $[(C,M)_4AH_{13}]$ belonging to the solid solution series with end members C_4AH_{13} and M_4AH_{13} have been identified (Schilling, et al 1994). Ali et al (1996) have also reported similar results, and no $Ca(OH)_2$ was present.

In view of importance of $Ca(OH)_2$ - phase in deleterious alkali-silica reaction of expansion-causing type, the author had speculated that a cement system, which did not contain $Ca(OH)_2$ as a hydration product may be beneficial to alleviate ASR (Visvesvaraya et al 1986). Preliminary investigations on accelerated mortar bar tests with known reactive aggregates and laboratory prepared supersulphated alumino-belite cements ($C_4A_3\bar{S}$ - β-C_2S system) had shown encouraging results which have not been published. Ali et al (1996) have reported that expansion in mortar bar tests with alkali-slag cements and known reactive aggregates was much lower than with high alkali OPC. Changgao and Raihua (1996) have also reported lower ASR activity in accelerated tests of concrete samples made with alkali activated slag-flyash system. In such systems, the alkali ions react with the Al_2O_3, SiO_2 and CaO in ground slag (and ground flyash), hence there is no free soluble alkali available. However, due to the presence of alkali salts in the activators as well as those present in the slags, adequate alkalinity in the pore solution above 13, is maintained, even in absence of $Ca(OH)_2$ phase. Typical results are

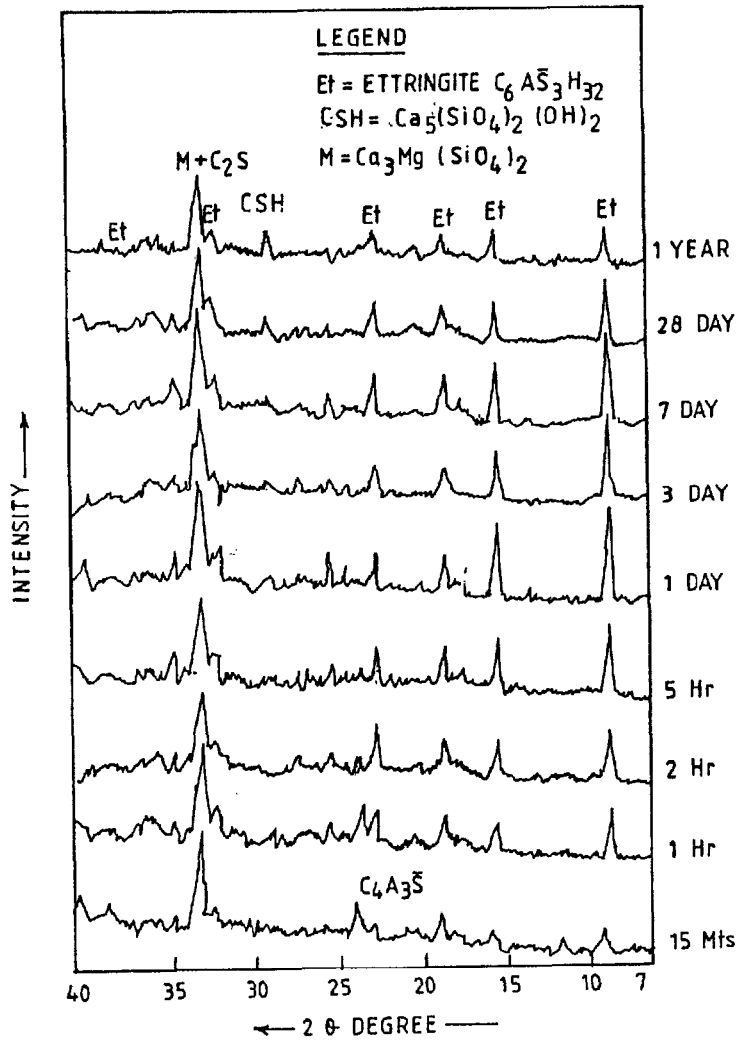

Fig. 13 XRD of Hydrated Sulphoaluminate Belite Cement Containing MgO (Ali et al, 1997)

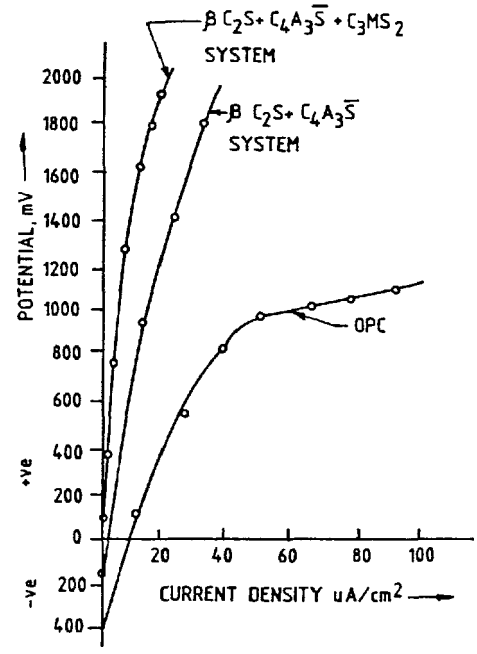

Fig. 14 Accelerated Corrosin Test on Concretes made with Sulpho-aluminate based Cements (Mudbhatkal et al 1986, Ali et al 1997)

shown in **Fig. 15** (Byfors et al, 1989). The rate of chloride ion diffusion was lower than in OPC.

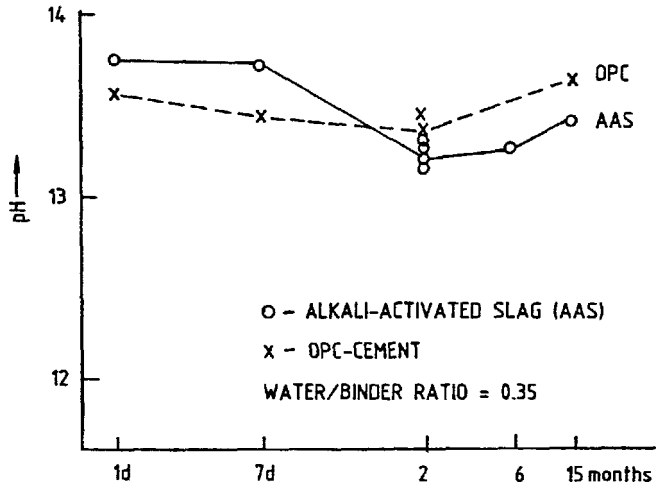

Fig. 15 pH of Pore Solution (Byfors et al, 1989)

Use of lithium-salts in concrete has been known since longtime to alleviate alkali-silica reaction or reducing the expansive and cracking effects associated with ASR (McCoy and Caldwell, 1951). Feasibility studies of intergrinding lithium compounds with portland cement to produce a high alkali ASR-resistant cement has been reported (Gajda, 1996). Lithium hydroxide monohydrate (LiOH) upto 1.2 percent by mass of cement clinker containing about 1.06 percent alkali (Na_2O - equivalent), were interground along with gypsum. Accelerated mortar bar tests showed the level of LiOH to control expansive ASR was at a level slightly in excess of equivalent alkali content of the cement.

CONCLUDING REMARKS

Durability of concrete has been discussed in two aspects. The first is the durability of the products of hydration of cements -- the calcium silicate hydrates (C-S-H), calcium aluminate hydrates (C-A-H) and calcium hydroxide (C-H), against chemical agents like SO_3^{--}, Cl^- and CO_2 etc. The second is the durability of inclusions like aggregate and embedments like mild steel reinforcement in the matrix of hydrated cement paste. Between these two, the situation in the former is somewhat more reassuring. Hydrated cement paste in concrete, by and large, can be made to withstand aggressive chemical environments. In cases of very aggressive environments e.g. in chemical and fertiliser industries, additional external protection to concrete, like coatings, paints and barriers may be required (Mullick, Rajkumar and Jain, 1991). Such applciations have not been discussed in this paper.

Problems do arise in the other aspect, which involves the protective and compatible roles of hydrated cement paste in the composite, in the sense that majority of reports and case studies on distress to concrete structures in service pertain to corrosion of reinforcement or alkali-aggregate reaction. Desperate measures are sometimes recommended to combat

the situation. If the aggregate within economical lead are likely to be reactive, the safest course recommended is to avoid them. Additional protection to mild steel reinforcement like galvanising, epoxy coating, cathodic protection, corrosion inhibitors, removal of chloride ions by realkalisation or ion exchange, use of stainless steel or non-metallic reinforcement like glass-reinforced plastic, are some measures which have sometimes been adopted to avoid distress due to corrosion of reinforcement. Life-cycle cost analyses indicate such desperate measures to be economical in many situations, which goes to show how desperate the situation can be !

Laboratory reseach has helped in great measures in understanding of the problem. Research has also led to understand, why common specifications do not address to the interactive effects of various hygrothermal, environmental and service parameters, which can not be fully simulated in laboratory tests. Reports of investigations on concrete structures in service and case studies should be addressed and carefully analysed to lead to greater understanding of the interactive material - environment system. This will enable to speficy 'concrete that is needed', with greater assurance.

Adequate performance of ordinary portland cements have been demonstrated in majority of concrete structures in service. There is need of more data and reports on performance of concrete incorporating pozzolana and slags, in different types of service environments. Improvement in durability should be the focus of development of newer types of cements, in addition to material and energy conservation.

In conclusion, it must be noted that large majority of concrete structures are indeed durable., With some more insight gained by laboratory research and field investigations and continuous improvements in specifications and construction practices, it should be possible to make concrete a material for all seasons (and all situations).

ACKNOWLEDGEMENT

The author has freely used unpublished results and data on on-going research projects at the National Council for Cement and Building Materials (NCB), New Delhi. Thanks are due to M M Ali, Shri Harsh, K Mohan and S Laxmi, colleagues at NCB, for suggestions and help in preparation of the paper. M S Uppal and K B Puri helped in the preparation of the manuscript. The paper is presented with permission of Director General, NCB.

Recent Results of Solid-State NMR Investigations and their Possibilities of Use in Cement Chemistry

WOLFGANG WIEKER, CORNELIA HÜBERT and DETLEF HEIDEMANN

Technische Universität Berlin, Institut für Bauingenieurwesen, AG Baustoffchemie

1 Introduction

Nuclear magnetic resonance (NMR) spectroscopy and its application to the study of solid substances is a method which can look back now for about 50 years of its successful use. Therefore it shall not be the aim of this paper to give an introduction into the theoretical fundaments of the solid state NMR spectroscopy because there are several books in that field [e.g. 1-4]. In the meantime this method, which is applicable to all substances containing atomic nuclei with a magnetic moment, has been developed to a very powerful tool in the investigation of structural problems of solid state materials.

Because in silicate and cement chemistry a relative big number of elements with a magnetic moment like ^{29}Si, ^{1}H, ^{17}O, ^{27}Al, ^{23}Na, ^{43}Ca, ^{25}Mg and ^{19}F plays a dominant role the NMR technique has got an increasing importance in the material science of building materials.

Already at the VI. International Congress of Cement Chemistry in Moscow in 1974 the first ^{1}H solid-state NMR investigation of 14 Å Tobermorite and $CaNaHSiO_4$ have been presented [5]. At the beginning of the 80th of this century ^{29}Si and ^{27}Al solid-state NMR measurements came more and more in use and it became possible to investigate the chemical structure of silicates, alumosilicates, including zeolites, and aluminates in solid samples without dissolving them (see [6] and references cited therein). Since that time it is possible to decide between four- or sixfold oxygen-coordinated silicon atoms and to determine the number of Si-O-Si bonds of fourfold coordinated silicons (Q^n, n=1,2,3,4, where n denotes the number of bridging oxygens) by means of the measured isotropic ^{29}Si shift values. At the same time similar correlations have been established for the aluminum. The measurement of the isotropic ^{27}Al shifts allow to distinguish between Al atoms in tetrahedral or octahedral coordination with respect to oxygen atoms. Furthermore, NMR experiments can be used to detect possible Si-O-Al bonds in Al_2O_3-containing silicates.

---

present address: WITEGA GmbH, Rudower Chaussee 5, Haus 4.1, D-12484 Berlin

In the last decade solid-state NMR investigations have been performed using ^{23}Na, ^{17}O, ^{25}Mg and even ^{43}Ca nuclei as probe for structural investigations in silicates and CSH phases.

Parallel to the number of nuclei which can be investigated by the NMR technique the sensitivity of the spectrometers has been enormously increased. By developing of sophisticated mechanical (e.g. MAS, DOR) and electronic procedures (e.g. multiple pulse programs, two-dimensional NMR techniques) it also became possible to minimize the line broadening due to the anisotropy of the chemical shift and dipole-dipole- or quadrupolar interactions of the nuclei in order to get a higher resolution of the spectra.

But for the application of solid-state NMR to cement-based materials by our opinion there are still some problems which are e.g.

- the presence of para- and ferromagnetic components in the samples since these can mask the chemical shift effects by large line broadening effects,
- the precision of quantitative determination of structural units from the intensities of NMR spectra due to the widely unknown relaxation time behaviour of the nuclei (especially that of the ^{29}Si nuclei) in different binding states which can lead to saturation effects during the NMR experiments .

In spite of these and many other problems the application of the solid-state NMR to solve questions in the field of silicate- and cement science arising from basic research in scientific laboratories of universities and from the practice of the building material industry has been developed very fast in the recent years. This is demonstrated by an increasing number of publications in that field and that a series of special meetings devoted to the "Application of NMR Spectroscopy to Cement Science" has been created in Guerville (France) in 1992 [7]. The last one of this series was arranged in Bergamo (Italy) last year and a book containing the full papers given on that meeting will appear till to the end of this year [8].

Because it can't be the task of our paper to present on this conference a complete summary of all contributions made since the last congress in Delhi in 1992 to the science of building materials by using NMR spectroscopy the following chapters shall give a short survey on some individually selected results of solid-state NMR investigations in the wide field of cement chemistry, as there are:

- structure of CSH- and CAH-phases,
- influence of alkali-ions on reactive silica and CSH-phases with respect to the alkali-silica-reaction (ASR) in concretes,
- application of NMR to problems of the building material industry.

These examples can be treated only very briefly to show, those who are not very familiar with the solid-state NMR, what is possible to do with this method today and how far this method can be applied in cement and concrete science to solve the problems of preparation and use of building materials.

It is an aim of our contribution to give an encouragement for further studies in this field of science by the presented examples and the cited literature.

2 NMR Studies of the Structure of CSH

The application of the ^{29}Si MAS NMR spectroscopy to the study of the structure of CSH, the poorly crystalline hydration product of C_2S and β-C_2S or alite and belite in portland cement has already a long tradition. Exactly fifteen years ago the first ^{29}Si MAS NMR study of the hydration of C_3S was published [9]. Already this first study has shown that the final hydration product of C_3S, a CSH with a C/S ratio ~1.8, consists only of Q^1 and Q^2 units, higher condensed units do not occur. This result indicates that the silicate part of CSH contains only chains and dimers and that no two- or three-dimensional silicate structures are present in these early hydration products.

In the meantime this has been confirmed by many other groups and it has been established that the intensities of the Q^1 and Q^2 signals vary in dependence on the C/S ratio of the CSH-phase investigated (see e.g. [10] and references cited therein).

Very recently Cong and Kirkpatrick presented a detailed systematic investigation of the structure of CSH with C/S ratios in a range from 0.4 up to 1.8 using ^{29}Si- [11,12] and ^{17}O- [13] MAS NMR spectroscopy.
Some of their ^{29}Si MAS NMR spectra are collected in figure 2.1.

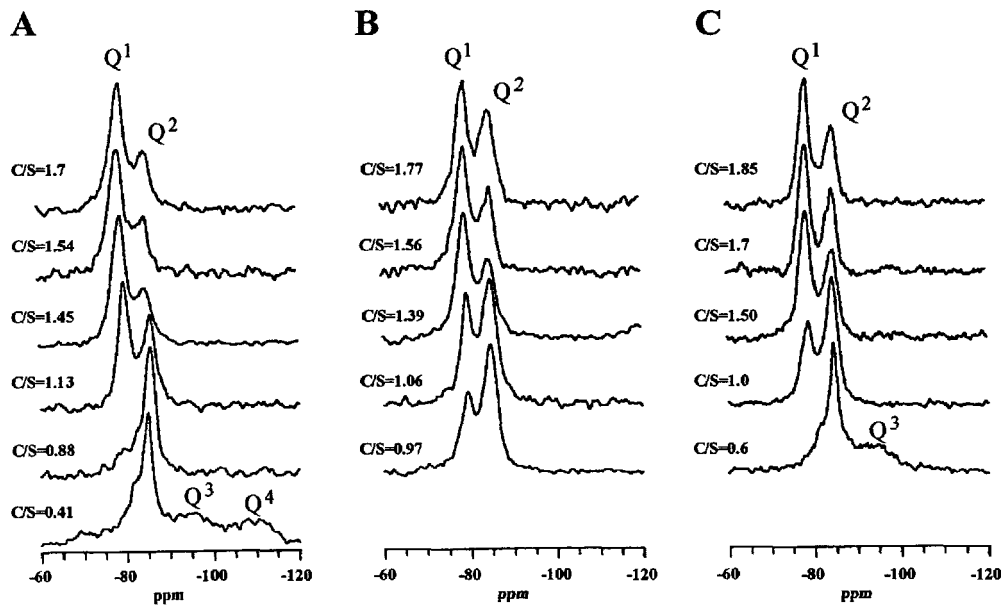

Fig. 2.1. ^{29}Si MAS NMR spectra of different CSH phases with varying C/S ratios formed **A:** by an aqueous reaction of CaO with silica fume; **B:** by hydration of highly reactive ß-C_2S and **C:** by hydration of silica fume with highly reactive β-C_2S (adapted with some changes from [12])

These spectra show again that CSH consist of Q^1 and Q^2 units and that with decreasing C/S ratio the amount of Q^2 units increases. Similar results were obtained by Okada et al. [14] investigating hydrothermally formed CSH.

In the spectra of that CSH phases which were prepared by using fumed silica (fig. 2.1A and 2.1C) a signal for Q^3 units appears at low C/S ratio (silica-rich samples) probably as a result of a "pozzolanic reaction" (see chapter 4). The Q^4 signal of the bottom in fig. 2.1A is due to unreacted silica used in the preparation of this sample.

While the ^{29}Si NMR allows only the characterization of the silicate part of the CSH structure further information can be received from the ^{17}O NMR which probe all parts of the CSH phases, the silicate portion, the calcium-oxygen layers and the water molecules, because oxygen atoms are present in all of them.

Typical ^{17}O MAS NMR spectra from the reaction of CaO and silica fume in a water suspension [13] are presented in figure 2.2A.

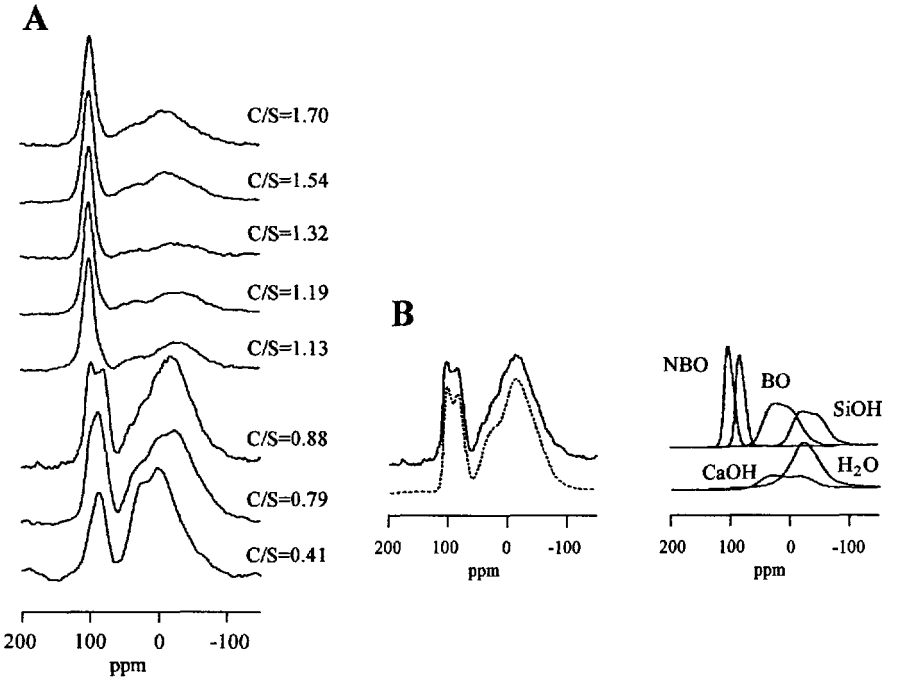

Fig. 2.2. Typical ^{17}O MAS NMR spectra of CSH with different C/S ratio prepared by the reaction of CaO and silica fume with water. **A:** experimental spectra; **B:** result of the line-shape simulation for the sample with C/S ratio of 0.88 (spectra adapted from [13]).

These spectra are much more complicated due to the interaction of the ^{17}O quadrupole moment with the electric field gradients of the different O-sides. The interpretation of these spectra requires a deconvolution of the line-shape by using spectra simulations as presented in fig. 2.2B. By this way it is possible to identify at least six O-sides in the CSH structure, two nonbridging oxygens (NBO) which link a silicon with two or three Ca^{2+}, a bridging oxygen (BO) which links two silicons by Si-O-Si bonds and one oxygen for each of CaOH, SiOH and H_2O.

From both the ^{29}Si- and ^{17}O MAS NMR results a model has been derived for the CSH structure, called "defect-tobermorite structural model" the principle of which is demonstrated in figure 2.3.

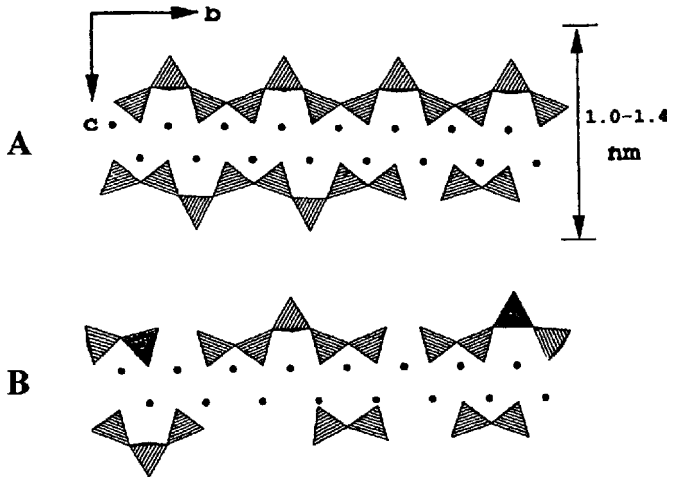

Fig. 2.3. Proposed defect-tobermorite structural model for CSH, showing dreierketten and central CaO layers (filled circles). The interlayer Ca^{2+}, OH^- groups and the H_2O molecules are omitted (adapted from [12]).

The layer A represents a relatively perfect 14 Å tobermorite layer in which only a small portion of the bridging tetrahedra is missing. This picture describes the structure of CSH with a small C/S ratio, in which the Q^2 units from polysilicates with long chainlike structures dominate.

The layer B represents a distorted layer in which individual SiO_4 tetrahedra and silicates with short chains may tilt, rotate or be displaced along the b axis. Most bridging tetrahedra are missing, resulting in many dimeric silicates. This picture describes the structure of CSH with a high C/S ratio.

It is well known from a great number of publications that the C/S ratio of CSH phases can vary in a relatively wide range from C/S ~ 0.4 to ~2.5. This fact leads to the question, what are the counter anions to balance the negative charges at the polymeric silicate anions. Especially, are there H^+ in form of SiOH groups or OH^- in form of $CaOH^+$ cations involved in the formation of the CSH structures?

Charge balance calculations on basis of the NMR results [12] showed that both SiOH and CaOH bonds occur in CSH. The SiOH groups should occur with decreasing C/S ratio while the $CaOH^+$ cations should be expected with an increase of this ratio.

This behaviour is in good agreement with the results of the mentioned ^{17}O investigations [13] and our experimental results of ^1H MAS NMR studies on CSH [15,16].

We found that the CSH phases formed during the hydration of C_3S and C_2S contain mainly protons in H_2O and CaOH but no (or only a very small amount of protons) in SiOH groups.

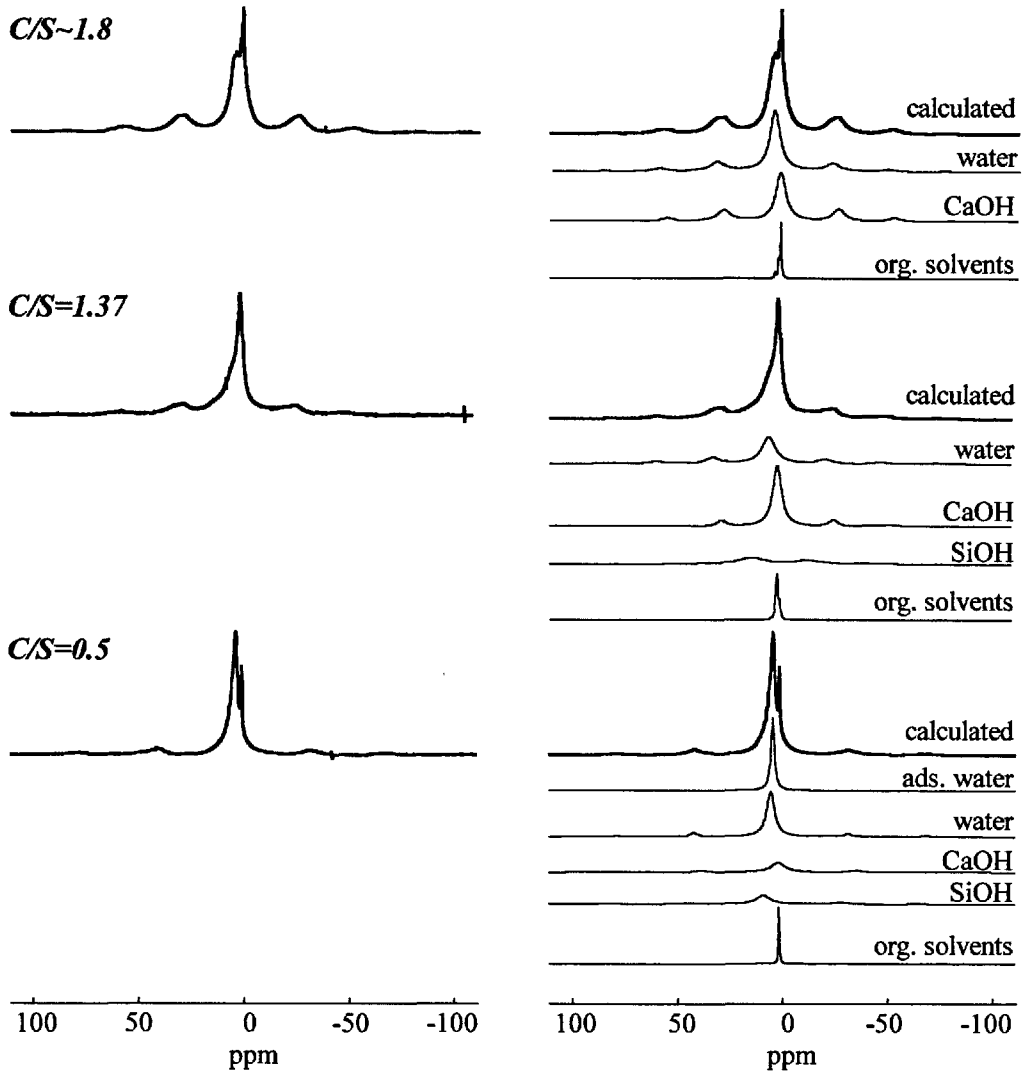

Fig. 2.4. Selected ^1H MAS NMR spectra of CSH with different C/S ratios, on the left the experimental spectra, on the right the results of a deconvolution procedure.

On the other hand, in hydrothermally formed or precipitated CSH phases with C/S ratios between 0.5 and 1.3 we detected besides the protons bonded in H_2O and CaOH also protons bonded in SiOH groups. The corresponding ^1H MAS NMR spectra are presented in fig. 2.4.

In all spectra appeared small signals attributed to mobile protons of traces of organic solvents which we used to stop the hydration reaction [15].

Because the water content of the CSH phases strongly depends on the preparation and the drying procedure used it makes no sense to discuss the relative intensities of the different proton sites. Therefore, we calculated only the ratio of CaOH/SiOH from the deconvolution of the spectra which is not influenced by the amount of proton bonded in water molecules. The calculated CaOH/SiOH ratios are summarized in table 2.1.

These data reflect exactly the prediction of [12] that with increasing C/S ratio the abundance of SiOH decreases and that of CaOH increases.

Tab. 2.1. CaOH/SiOH ratio of the studied CSH

C/S of the sample	CaOH	SiOH
~1.8	1	0
1.37	1	0.45
0.5	1	0.95

As a result of the NMR investigations in this field the chemical structure of CSH phases must be formulated as

Acidic salts of Calcium-hydroxi-polysilicate-hydrates

in which

the amount of acidic and basic groups

and

the condensation degree of the polysilicates

depend on the C/S ratio.

3 NMR Studies of the Structure of CAH

While in the hydration process of calcium silicates poorly crystalline CSH-phases appear, the hydration of calcium aluminates, which are the main components of high-alumina cements and partly present at low concentrations even in ordinary portland cements, leads to well ordered calcium aluminate hydrates and aluminium hydroxide (gibbsite).

Because the hydration of Ca-aluminates involves a conversion of tetrahedrally coordinated aluminum (Al(4) with respect to oxygen) in the anhydrous phases to octahedrally coordinated aluminum (Al(6)) in the hydrates the ^{27}Al MAS NMR is well suited to follow the hydration reaction. The first study in this field was reported by Müller et al. [17] in 1984 following the hydration of CA by use of ^{27}Al MAS NMR. The spectra of that paper (fig. 3.1A) is compared with the spectra of a paper published by Müller et al. [18] on the same subject in 1994 (fig.3.1B) to demonstrate the progress in the ^{27}Al MAS NMR spectroscopy for monitoring the hydration of calcium aluminate cements.

The spectra collected at higher resonance frequency (higher magnetic field) by using higher MAS spinning rates and ^{1}H decoupling (fig 3.1B) show a much higher resolution which allows to follow the formation of C_3AH_6 separately.

Further ^{27}Al MAS NMR investigations were applied to study the hydration of calcium aluminates in white portland cement [19] and different types of high alumina cements [20,21].

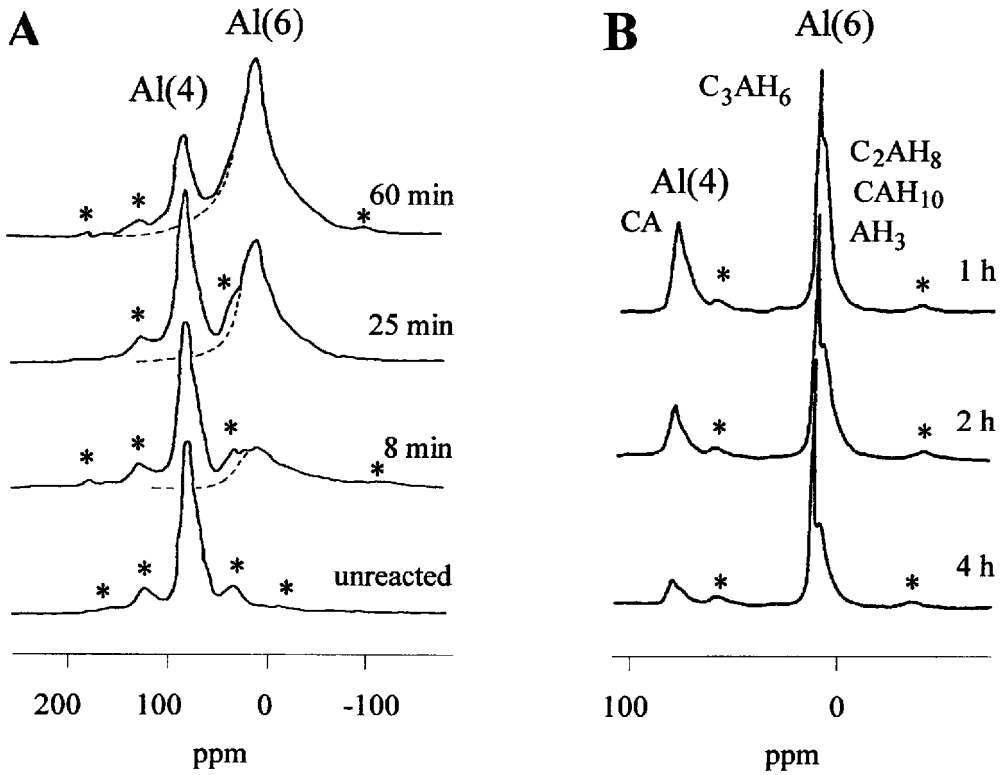

Fig. 3.1. ^{27}Al MAS NMR spectra of hydrated CA cured at 70° C, **A:** 70.4 MHz spectra measured by using MAS spinning rates of 3.3 kHz (adapted from [17]); **B:** 104.2 MHz spectra measured by using MAS spinning rates of about 6 kHz and ^{1}H decoupling (adapted from [18]). * denotes spinning sidebands.

Recently a very detailed ^{27}Al MAS NMR study on the characterization of calcium aluminate phases in cements was published by Skibsted et al. [22]. Besides the analysis of the center part spectra arose from the central transition (m=1/2 m=-1/2) of the Al nuclei even a careful analysis of the spinning sideband manifolds due to the satellite transitions (m=1/2 m=3/2 and m=3/2 m=5/2) was performed. Fig. 3.2A shows the ^{27}Al MAS NMR spectrum of monosulfate ($C_4A\bar{S}H_{12}$), fig. 3.2B the corresponding spectrum of C_4AH_{13} having nearly identical center parts of the spectra (b) but different spinning sideband pattern (c) indicating different quadrupole coupling parameters.

This procedure used in [22] resulted in quadrupole coupling parameters and chemical shift values of high accuracy for the most important calcium aluminates and their hydration products. Based on these data the hydration products of calcium aluminates in high alumina cements and portland cements have been characterized.

It has been established that in the hydrated high alumina cement the CAH-phases C_3AH_6 and AH_3 were the dominating hydration products but also minor amounts of unhydrated CA and CA_2 were observed.

In an ordinary portland cement hydrated for 28 days ettringite and monosulfate were found to be the hydration products of the calcium aluminate phases.

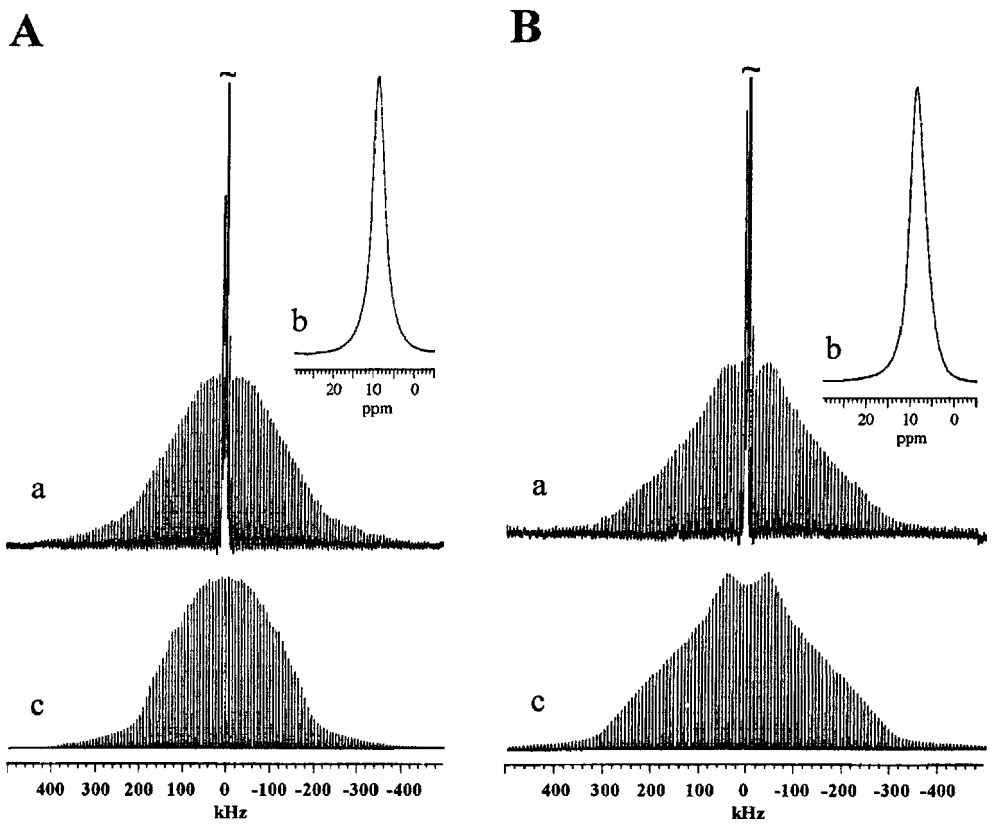

Fig. 3.2. ^{27}Al MAS NMR spectra of $C_4A\overline{S}H_{12}$ (**A**) and C_4AH_{13} (**B**), **a:** experimental spectra, **b:** center bands, **c:** simulated spinning sideband manifolds (adapted from [22]).

4 NMR Studies on the Influence of Alkali-Ions on Reactive Silica and CSH-Phases with Respect to the Alkali-Silica-Reaction (ASR) in Concretes

Since Stanton observed in 1940 the destructive effect of the formation of an alkali containing silica gel in concretes [23] several efforts were made to get a deeper insight into the mechanism of this concrete damaging process.

In the meantime it is well established that the source of this crack formation in concrete is a result of a reaction of alkali hydroxides like NaOH and KOH with reactive silica by which an amorphous alkali silicate gel of unknown constitution is formed (see e.g. [24]). This gel adsorbs water and swells by which stresses are generated in the concrete leading to crack formation and an expansion of concrete constructions. The chemical composition of such gel varies very much with respect to their Me/Ca- and the (Me + Ca)/SiO_2 ratio, where Me=Na, K.

The main problem for a better understanding of the chemical mechanism of the ASR with respect to counteract this destructive effect on a well founded scientific base is that we have a lack of knowledge about the structural types of the silicates in these ASR gels.

Especially in this field during the last two years some new results appeared encouraged by NMR investigations, which shall be presented in this chapter.

In the 80ies Young [25] and Grutzeck et al. [26] investigated ASR gel samples from different concrete constructions by ^{29}Si MAS NMR experiments and found that these gels consist of Q^2, Q^3 and Q^4 groups where the Q^3 groups are the dominating building units. This means that the gels should contain predominantly alkali silicate layer structures.

Some years later in 1993 Cong et al. [27] published ^{29}Si MAS NMR investigations on the reaction of different highly-condensed silica sources (Nevada opal, Beltane opal, cristobalite) with KOH solution in the presence and absence of $Ca(OH)_2$ by which they tried to produce a gel similar to that from real ASR damaged concrete constructions. In the reaction of Beltane opal with mixtures of KOH solution and $Ca(OH)_2$ they found (see fig. 4.1A) that the Q^4 groups of the threedimentional SiO_2 network (signal at -112 ppm) are converted with increasing reaction time to Q^1 (signal in the range of -79 ppm), Q^2 (signals between -82 ppm and -85 ppm) and Q^3 groups (signals in the range from -92 ppm up to -97 ppm).

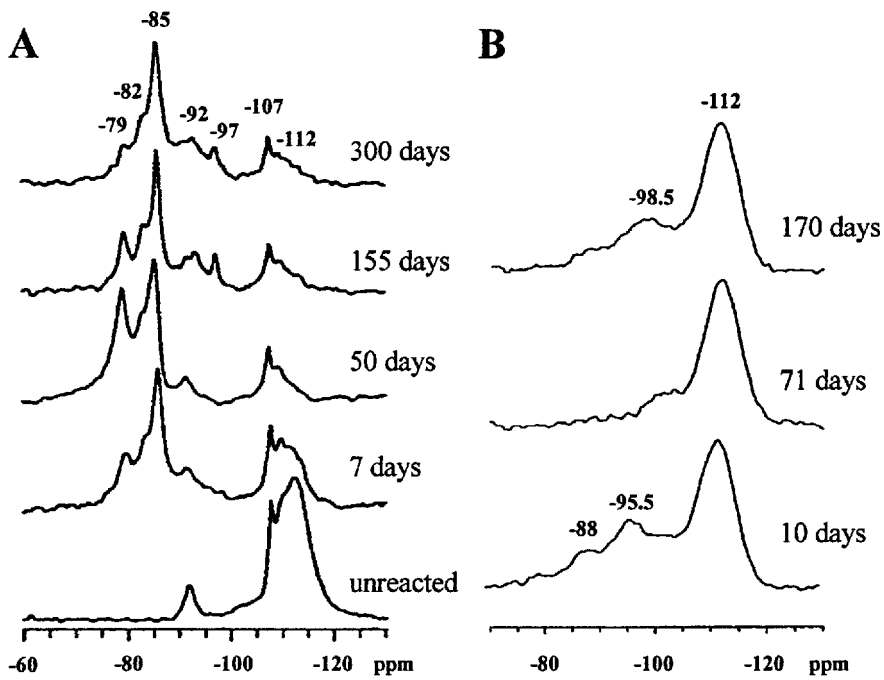

Fig. 4.1. ^{29}Si MAS NMR spectra of the reaction products of Beltane opal with KOH solution. **A:** reaction in the presence of $Ca(OH)_2$, **B:** reaction in the absence of $Ca(OH)_2$ (adapted with some changes from [27]).

The intensities of the NMR signals of the Q^3 groups (δ=-92 till -97 ppm) from the layer silicates are relatively low. But it is surprising that there is one signal with a relatively small line width at -97 ppm which is an indication that a crystalline layersilicate of unknown structure is formed.

A total different set of spectra they obtained when they studied the reaction of Beltane opal only with a KOH solution. The corresponding spectra are presented in fig. 4.1B. The spectra collected till to a reaction time of 170 days show that mainly Q^3 groups (NMR signals between -95.5 and -98.5 ppm) are formed attributed to branching SiO_4 tetrahetra of layersilicates. Q^1 and Q^2 groups are present only in very small amounts.

These differences between the reaction products formed in the reaction of Beltane opal and KOH solution in the presence of $Ca(OH)_2$ and that of opal and KOH solution in the absence of $Ca(OH)_2$ seems to us of great importance with respect to the mechanism of the ASR. But the authors of that paper did not discuss these differences to characterize the chemical process in this reaction.

We will come back to these results later on in this chapter.

To follow the reaction of silica and $Ca(OH)_2$ with water also at the early states of this process Brough et al. [28] used for their ^{29}Si MAS NMR studies ^{29}Si enriched silica which allowed them to collect spectra with a good signal-to-noise ratio in a relatively short time. To exclude the influence of alkali hydroxide they omitted in one of the reactions studied the addition of KOH. In this way they tried to study a "poor" puzzolanic reaction. The resulting spectra of this ^{29}Si MAS NMR investigation which was performed using samples with a solution/solid ratio of 0.7 are presented in fig. 4.2.

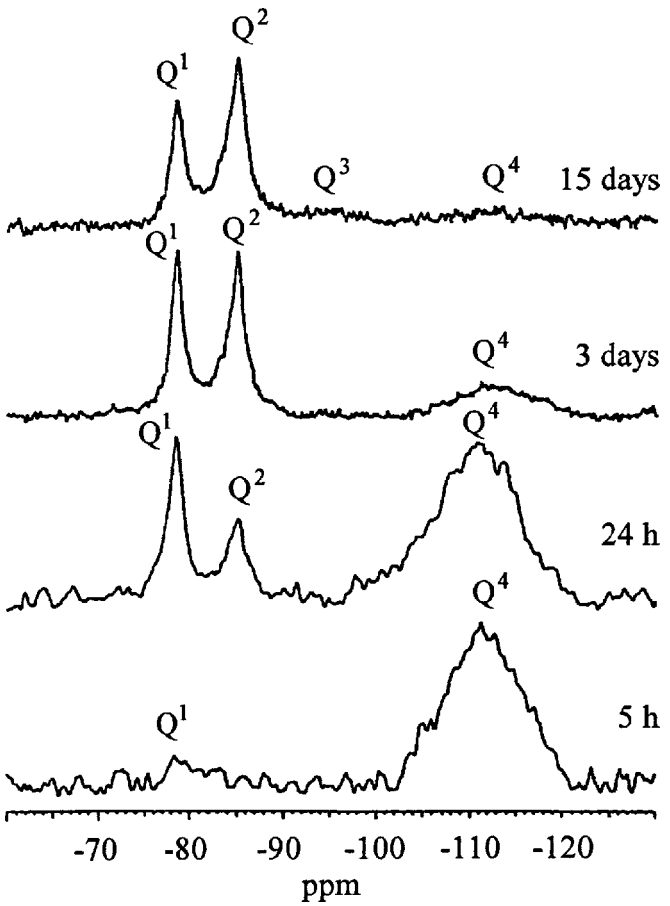

Fig. 4.2. Selected ^{29}Si MAS NMR spectra showing the reaction of calcium oxide with water and silica (adapted from [28]).

From these spectra it can be seen that the Q^4 groups of silica are transferred to Q^1 (end groups) and Q^2 (middle groups) indicating relatively low molecular chainlike anions. Only a very small amount of Q^3 groups can be recognized the nature of which is still unknown. These results are very similar to those of Cong et al. [27] with only one exception that in the paper of Cong et al., possibly as a consequence of the presence of KOH, the Q^3 signal is more intensive. To this difference we will also refer later on in this chapter.

To investigate a reaction which is more similar to the cement hydration Brough et al. studied in the already mentioned paper [28] also the reaction of C_3S with silica and water in the presence of KOH using samples with a solution/solid ratio of 0.5. In the reaction referred here a C_3S containing ^{29}Si in natural abundance and a silica labeled with enriched ^{29}Si were used. Such an experiment is profitable in so far, as one can see in the NMR spectrum only the signals of those silicate species which result from the reaction of the ^{29}Si enriched silica with $Ca(OH)_2$ and KOH solutions while the corresponding reaction products of the C_3S hydration are not detectable because of its low ^{29}Si content. The results of this ^{29}Si MAS NMR investigation are presented in fig. 4.3.

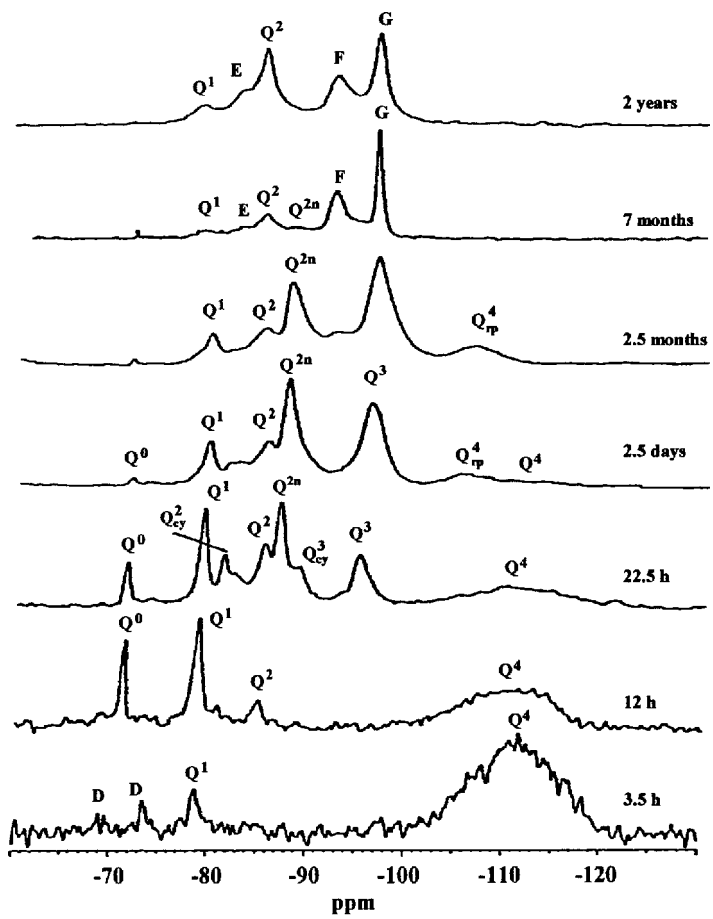

Fig. 4.3. ^{29}Si MAS NMR spectra showing the reaction of KOH solution with a blend of C_3S containing ^{29}Si in natural abundance and silica enriched in ^{29}Si in dependence of time (adapted from [28]).

Already after 12 h of hydration monomeric Q^0, end groups (Q^1) and middle groups (Q^2) groups are formed by the alkaline attack of $Ca(OH)_2$, resulting from the hydration of C_3S, and KOH. In addition to these reaction products after 22.5 h Q^2 groups of cyclic silicates and a second sort of Q^2 groups are formed. But already at this stage of the reaction NMR signals of Q^3 groups (G) appear at -97 ppm with a relatively strong intensity. This signal and a further one (F) in the Q^3 region increases with increasing reaction time. Compared to this the intensity of the NMR signals of the Q^0 groups decreases to zero, so that after 2 years only signals of Q^1, Q^2 and two different Q^3 groups can be detected.

With exception of a higher resolution of the ^{29}Si MAS NMR spectra these results are totally comparable with those obtained by Cong et al. [27] using Beltane opal instead of silica.

The NMR investigations mentioned above clearly show that during the hydration in the system SiO_2 — $Ca(OH)_2$ which is very similar to the C_3S hydration and the puzzolanic reaction only Q^1 (end groups) and Q^2 (middle groups) forming low molecular chainlike polysilicates as in CSH phases are formed.

In contrast to this in the system C_3S — $Ca(OH)_2$ — SiO_2 — alkali hydroxide in addition to the Q^1 and Q^2 groups Q^3 groups can be detected. On the basis of these results we assume that the expansion of concrete in the alkali-silica-reaction is a consequence of the layersilicate formation [29].

But because it was not possible at that time to assign the chemical shift values of the observed Q^3 groups to special type of layersilicate structures and to decide if there are alkali layersilicates which are able to swell, we performed systematic investigations of different alkali silicate minerals consisting of layer structures by means of solid-state NMR studies and tested their ability to give an expansion.

Analyzing the literature we found the following alkali silicate minerals summarized in table 4.1.

Table 4.1. Alkali silicate minerals

mineral	*idealized composition*
Natrosilite	$Na_2[Si_2O_5]$
Silinaite	$NaLi[Si_2O_5] \cdot 2\ H_2O$
Kanemite	$Na[HSi_2O_5] \cdot 2\ H_2O$
Makatite	$Na_2[H_2Si_4O_{10}] \cdot 4\ H_2O$
Magadiite	$Na_2[H_2Si_{14}O_{30}] \cdot x\ H_2O$
Kenyaite	$Na_2[H_2Si_{20}O_{42}] \cdot x\ H_2O$

From these silicates we were most interested in the mineral Kanemite because in 1994 Tapper et al. [30] showed that a synthesis of this compound is possible by the conversion

of the δ-modification of $Na_2[Si_2O_5]$ with SiO_2 in the presence of water in a "solid-state like" reaction, according to the following reaction equation,

$$\delta\text{-}(Na_2Si_2O_5)_x + 2SiO_2 + 7\,H_2O \longrightarrow 2[NaHSi_2O_5 \cdot 3\,H_2O]_x$$

which seems to be very similar to the alkali-silica-reaction.

A detailed investigation of Kanemite by multinuclear solid-state NMR spectroscopy has shown, that the silicate layers of this compound consist of identical SiO_4 terahedra (Q^3 groups) which are characterized in the ^{29}Si MAS NMR spectrum by one sharp signal at -97.7 ppm [31,32].

To follow *in situ* the formation of Kanemite according to the reaction described by Tapper et al. we used in our ^{29}Si MAS NMR experiments silica samples which were enriched in ^{29}Si [33,34].

Selected ^{29}Si MAS NMR spectra of these investigations are presented in fig. 4.4 showing the reaction of two different silica after increasing reaction times.

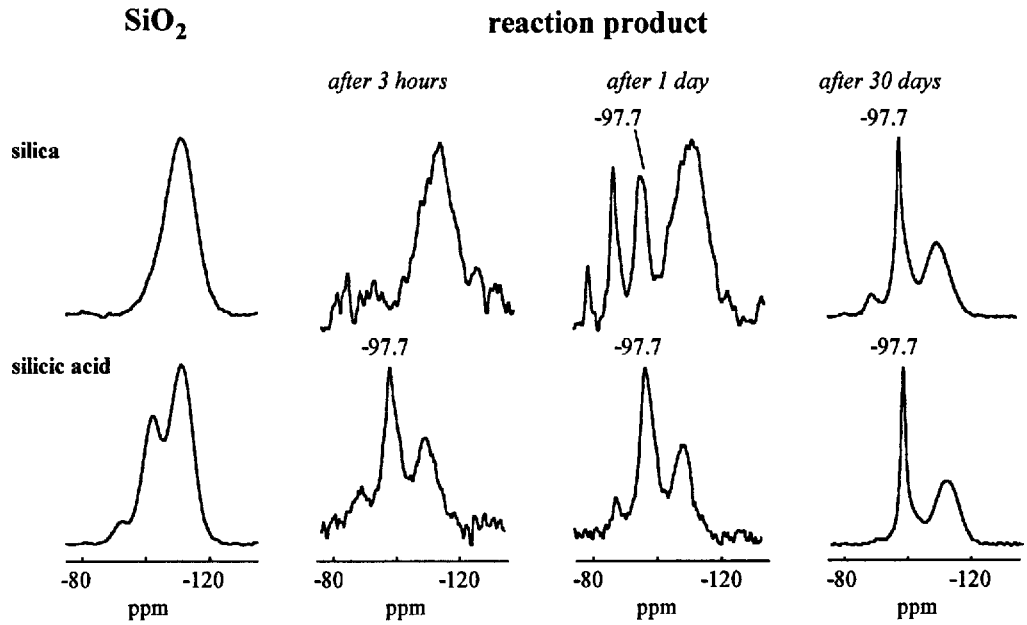

Fig. 4.4. ^{29}Si-MAS-NMR spectra of *in situ* studies of the formation of Kanemite starting from different ^{29}Si-enriched SiO_2 sources at increasing reaction times.

It is clearly to be seen that the Q^4 groups of the starting silica (signals at about -112 ppm) are not directly converted to Q^3 groups of Kanemite (signal at -97.7 ppm). After short reaction times also Q^1 and Q^2 groups can be observed. That means that the degradation of the silica structure goes via the splitting off low molecular silicate species as we demonstrated by degradation experiments of silica gels in alkaline solutions [35]. With increasing concentration of the silicates in the aqueous phase at least high molecular layerslicates are formed as it is a general rule in silicate chemistry.

Even though these experiments are performed with sodium silicates we found the same ^{29}Si NMR signal at -97 ppm for the Q^3 groups as Brough et al. [28] found investigating

the reaction with potassium hydroxide. This means that in both cases the same Kanemite-like silicate layer structures are formed.

To test if the Kanemite formation is connected with an expansion we pressed samples from mixtures of δ-$Na_2Si_2O_5$ and a reactive silica in the mole ratio 1:2 according to the above mentioned equation. The samples were stored in an exsiccator with a relative humidity of 100 %. From fig. 4.5 one can see that this reaction is indeed connected with a relatively high expansion.

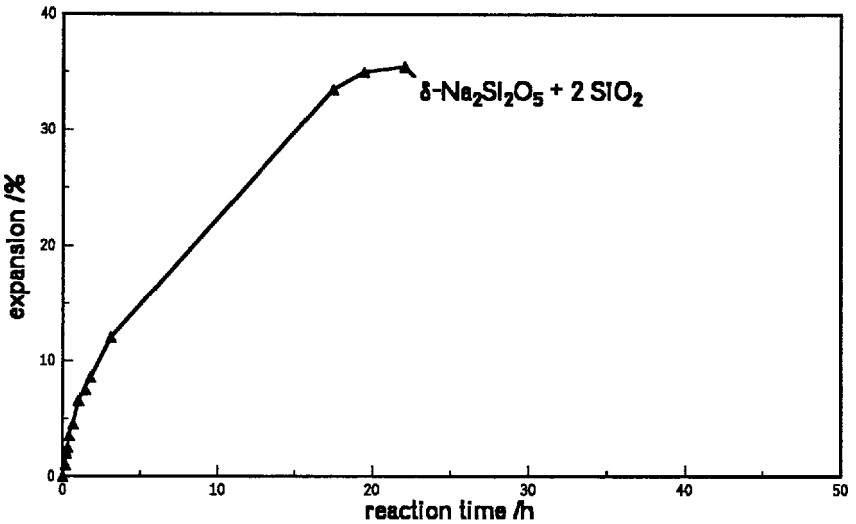

Fig. 4.5. The expansion of Kanemite formed in the reaction of δ-$(Na_2Si_2O_5)_x$ and SiO_2 in the presence of water in dependence on the reaction time.

To demonstrate that this is a real model reaction for the ASR we used instead of reactive silica also minerals i.e. opal or siliceous chalk in the reaction with δ-$Na_2Si_2O_5$. As fig. 4.6 shows we got the same expansion reactions.

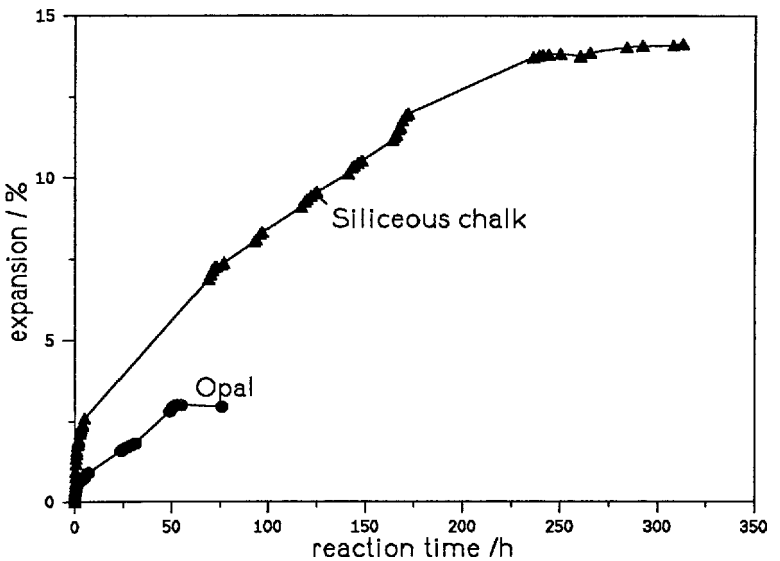

Fig. 4.6. The expansion of the reaction products of δ-$(Na_2Si_2O_5)_x$ and opal and of δ-$(Na_2Si_2O_5)_x$ and siliceous chalk in the presence of water in dependence on the reaction time.

XRD investigations of the reaction products of these experiments show that also in these cases Kanemite as the swelling component is formed.

A further question coming from the above mentioned experiments of Cong et al. and Brough et al. was, in what way $Ca(OH)_2$ will influence this reaction between δ-$Na_2Si_2O_5$ and SiO_2.

Therefore we performed expansion measurements of pressed samples of mixtures from δ-$Na_2Si_2O_5$ and SiO_2 to which $Ca(OH)_2$ was added. These experiments show (see fig. 4.7) that $Ca(OH)_2$ diminishes the expansion but not the total reaction.

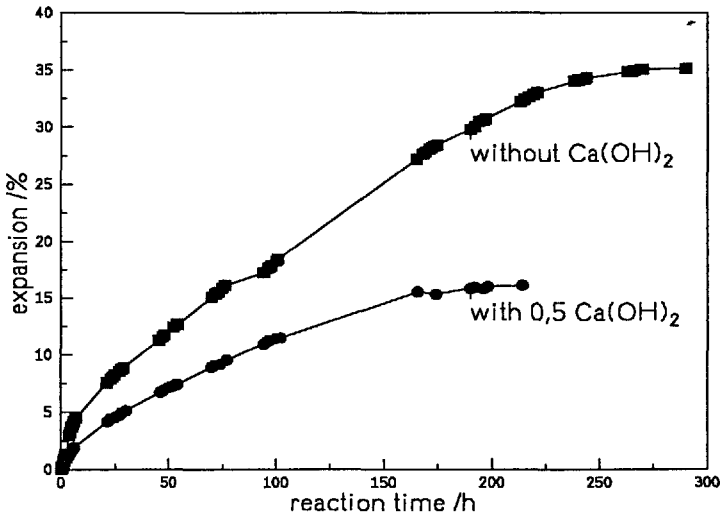

Fig. 4.7. The expansion of the reaction products of δ-$(Na_2Si_2O_5)_x$, SiO_2 and water in the presence and in the absence of $Ca(OH)_2$ in dependence on the reaction time.

Further XRD investigations showed that Kanemite is formed also under these conditions and that the Kanemite structure is not generally changed by a possible incorporation of Ca^{2+} ions by ion exchange into the lattice of Kanemite. The Ca^{2+} containing Kanemite is able to swell like clay minerals with silicate layer structures, too. This would mean that at first alkali silicate layer structures were formed which incorporate Ca^{2+} ions in a secondary reaction step.

On the other hand, in the system SiO_2 — $Ca(OH)_2$ — H_2O or the C_3S — H_2O system without the presence of alkali hydroxides the solubility of Ca-silicates is so low that only very small silicate concentrations can be obtained in the aqueous phases. We know that in very dilute silicate solutions only low molecular silicate species exist which at all the time are precipitated by Ca^{2+} ions. This fact results at least in the formation of the usual CSH phases which are formed in the C_3S- and C_2S hydration as well as in the pozzolanic reaction containing Q^1- and Q^2 groups.

In those cases in which alkali hydroxides are present in the poor aqueous systems of SiO_2 — $Ca(OH)_2$ or C_3S and C_2S , both reaction mechanisms discussed above

- the formation of alkali layersilicate and the following incorporation of Ca^{2+} ions into the layer structures

- the formation of Q^1 and Q^2 groups due to precipitation of low molecular silicate species from the solution by Ca^{2+} ions

are involved in the formation of the hydration products as the ^{29}Si MAS NMR studies referred in this chapter clearly have shown.

Together with the discussions on the mechanism of the alkali-silica-reaction and the structure of the silicates in the ASR gels arose the question if CSH phases itself are able to effect as a SiO_2 source in the alkali-silica-reaction. To answer this question we performed ^{29}Si MAS NMR experiments on samples prepared by hydration of mixtures of δ-$Na_2Si_2O_5$ and different CSH phases [36]. As an example in fig. 4.8 the ^{29}Si MAS NMR spectra of an unreacted CSH phase with a C/S ratio of 1.36 prepared by a hydrothermal reaction of SiO_2 and $Ca(OH)_2$ according to [37] (fig 4.8A) and of the product of the reaction of this CSH with δ-$Na_2Si_2O_5$ in the presence of water vapour after 12 days (fig. 4.8B).

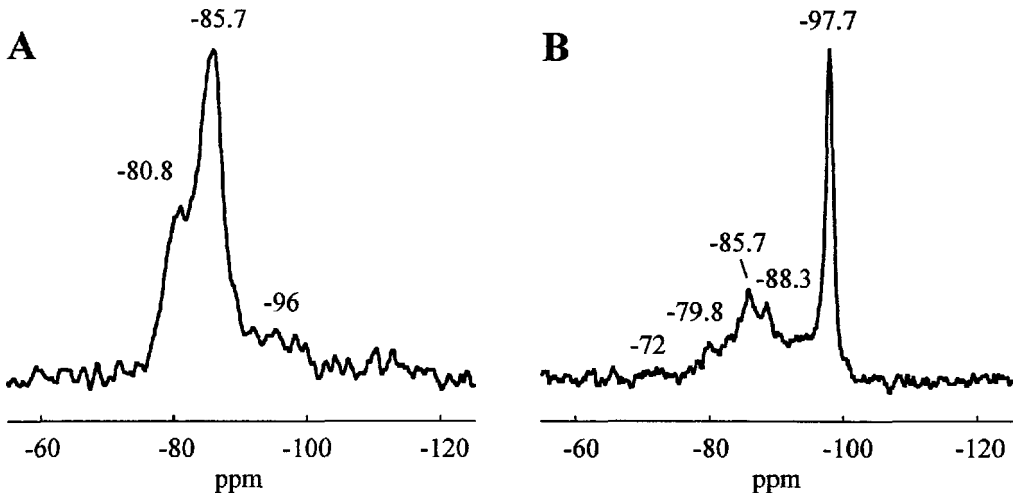

Fig. 4.8. ^{29}Si-MAS-NMR spectra of **A:** CSH, C/S=1.36 and **B:** the product of the reaction of this CSH with δ-$(Na_2Si_2O_5)_x$ in the presence of water vapour after 12 days.

The comparison of both spectra shows at first that also in this reaction Kanemite is formed as demonstrated by the appearance of the small NMR signal at -97.7 ppm. The Kanemite formation goes via a consumption of the original CSH phase visible by the drastic decrease of the intensities of the NMR signals of the CSH in fig. 4.8B. In addition to the signals of Kanemite (-97.7 ppm) and of the residual CSH phase (-80.8, -85.7, -96 ppm) new signals appear at -72 and -88 ppm indicate that during this reaction also low concentrations of monomeric and dimeric silicate species as possible intermediate products are formed.

Expansion measurements on mixes of a CSH phase with C/S=1.3 and δ-$Na_2Si_2O_5$ in the presence of water also show strong expansion (see fig 4.9). ^{29}Si MAS NMR experiments on this sample (not shown here) demonstrate the formation of Kanemite in this case, too.

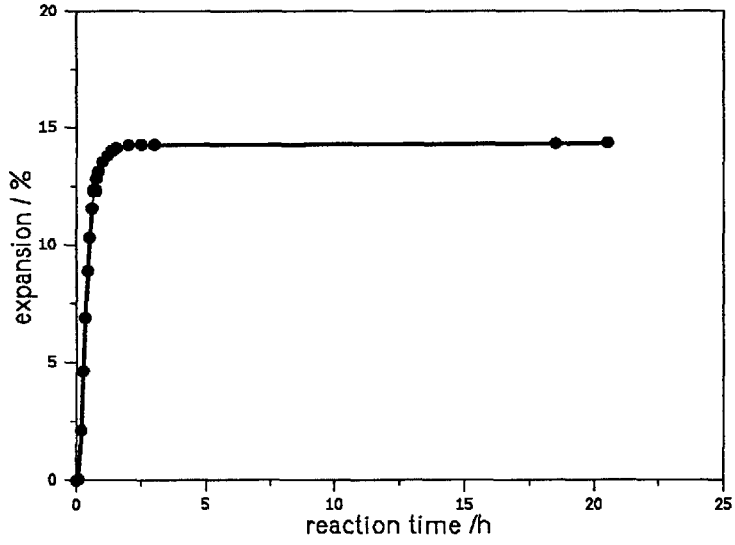

Fig. 4.9. The expansion of the reaction products of a CSH (C/S=1.3) with δ-$(Na_2Si_2O_5)_x$ and water in dependence on the reaction time.

The results indicate that at high alkali hydroxide concentrations CSH phases can be converted to alkali silicates and calcium hydroxide according to the equation

$$Ca_xSi_yO_z + 2x\,NaOH \longrightarrow Na_{2x}Si_yO_z + x\,Ca(OH)_2.$$

These very recent results presented in this chapter showed a few new insights in the understanding of the alkali-silica-reaction but at the same time new question and problems arose from them. In our opinion the further application of the solid-state NMR spectroscopy accompanied with chemical methods should be able to solve also these problems with the aim to reduce or to avoid the corrosion of concrete constructions by ASR in the future.

5 Production Near Application of Solid State NMR

The chemical and engineering properties of portland cements are determined largely by their mineral composition the main constituents of which are alite and belite. In praxis the content of these cement minerals is estimated using the Bogue calculation [38] based on the elemental composition obtained from analytical methods. An improved Bogue calculation has been proposed by Taylor [39].

Already in 1988 Hjorth et al. [19] showed by using ^{29}Si MAS NMR experiments to analyze the alite and belite content of an Aalborg white cement that their results were in significant contrast to the results obtained by the Bogue calculations.

Recently a deep and extensive ^{29}Si MAS NMR investigation of the determination of alite and belite in a large number of different portland cements with variable bulk Fe_2O_3 contents up to 6.7 wt.% was presented by Skibsted et al. [40].

While the ^{29}Si MAS NMR spectra of the crystalline calcium silicates C_3S and β-C_2S are characterized by small well resolved signals (see fig. 5.1A and 5.1B) the spectra of the clinker minerals alite and belite in cements are more complicated. Especially those of the alite modifications consist of much more broader overlapping signals resulting in an unresolved lineshape due to the incorporation of impurities (see fig. 5.1C). The corresponding spectrum of belite is more similar to that of β-C_2S as it is shown in fig. 5.1D.

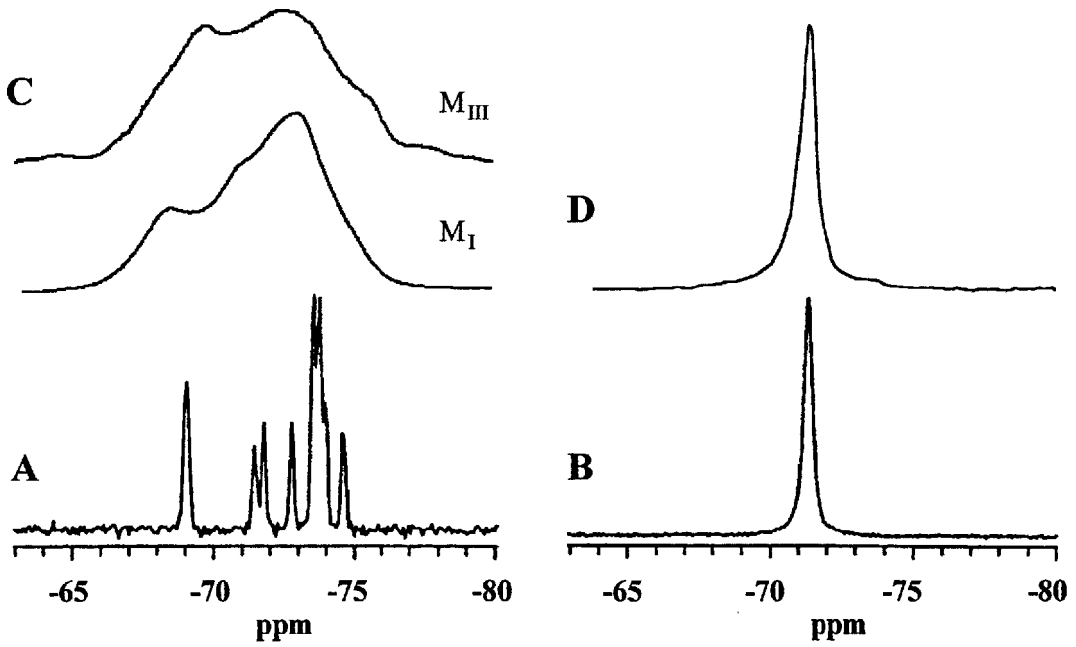

Fig. 5.1. ^{29}Si-MAS-NMR spectra of C_3S.(A), β-C_2S (B), belite (D) and of the M_I and the M_{III} modifications of alite (C). (Spectra A and B were adapted from [41], spectra C and D from [40]).

On basis of the known spectra of alite and belite an improved method for deconvolution of the measured ^{29}Si MAS NMR spectra was developed to decide between the corresponding subspectra of alite and belite and to determine the relative amounts of these minerals. The technique used in [40] is demonstrated in fig. 5.2 for a ^{29}Si MAS NMR spectrum of an oilwell cement.

The results obtained by applying the above illustrated method show that the different cements contain between 5 and 28 wt.% of belite and between 50 and 78 wt.% of alite.

The basis for the high accuracy of these results was that the authors excluded the possibillity of partial saturation effects in their ^{29}Si MAS NMR maesurements by determining the ^{29}Si spin-lattice relaxation times (T_1) for alite and belite in two cements and optimizing the experimental conditions on basis of the T_1 values. The large differences in the T_1 values for alite and belite allowed them to quantify the relative quantities of the two minerals in an independent way. The resulting quantities were in

good agreement with those obtained from the deconvolution of the corresponding ^{29}Si MAS NMR spectra.

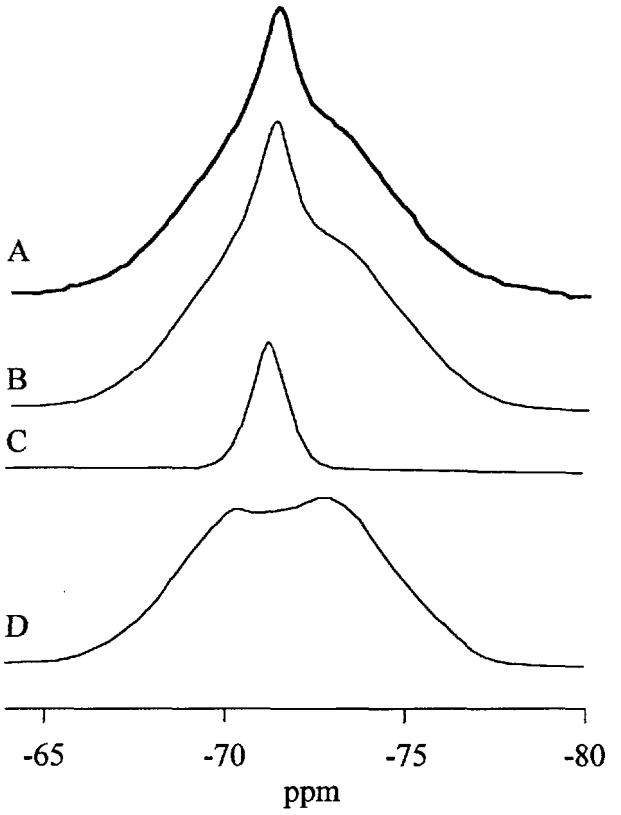

Fig. 5.2. Experimental (A) and simulated (B) ^{29}Si-MAS-NMR spectra of an oilwell cement. The simulated spectrum corresponds to a superimposed subspectrum of belite (C) on a subspectrum of the M_{III} form of alite (D). (adapted from [40]).

These data were compared with those of corresponding Bogue calculations. For the referred example of the oilwell cement the following values were presented (see Table 5.1).

Table 5.1. Results of the determination of calcium silicate phases in an oilwell cement from ^{29}Si MAS NMR, Bogue and Taylor-Bogue calculations (adapted from [40])

^{29}Si MAS NMR		**Bogue calculation**		**Taylor-Bogue calculation**	
alite (wt.%)	belite (wt.%)	alite (wt.%)	belite (wt.%)	alite (wt.%)	belite (wt.%)
72.0	11.2	59.0	17.4	67.4	13.2

This comparison shows that the Bogue calculation strongly overestimates the belite content and underestimates the quantity of alite. In contrast to this the data estimated using the Taylor-Bogue calculation show not such large deviations from the NMR results.

These results suggest that we will have in the future a new and powerful method for the determination of alite and belite in cements.

6 Conclusion

As shown by the selected investigations on some problems of the cement chemistry the solid-state MAS NMR spectroscopy is a powerful method to solve structural problems of amorphous and crystalline compounds in building materials. This method has the advantage that it is possible to investigate the samples directly without chemical conversions.

In this paper we focused our discussions predominantly on the results of NMR measurements. But it has to emphasize that in these investigations it is necessary to have a close collaboration of NMR spectroscopists and chemists beginning from the preparation and the reliable characterization of the samples and ending with the discussion of the yielded NMR spectra.

Such a close collaboration becomes much more important in the future because new and more complicated problems will arise from research on cement based materials and, on the other hand, new and more sophisticated NMR techniques we have not discussed till now will be applied to study solid state problems in this field.

Such techniques are e. g. the two-dimensional NMR spectroscopy which can determine bindings between different SiO_4 tetrahedra ("connectivities") [42] and between SiO_4 tetrahedra and protons [43]. Further new developments in NMR spectroscopy, which can be applicated to research on building materials, are NMR-tomography ("NMRI - nuclear magnetic resonance imaging") allowing e.g. to study the water diffusion in hardened cement pastes [44] or the water distribution in pore systems of building materials [45]. For higher resolution in NMR spectra of quadrupolar nuclei like ^{27}Al, ^{23}Na or ^{17}O the DOR technique (double orientated rotation) comes more and more in use to study scientific problems of the cement chemistry [46]. New developments also appeared in the field of high temperature NMR spectroscopy allowing *in situ* studies up to 2400 K [47].

We are sure that further contributions at this congress on cement chemistry will additional underline the usefulness of NMR investigations in research of building materials.

Process technology

DEVELOPMENT OF SPECIAL CEMENTS

Tamara V. KOUZNETSOVA
Mendeleev University of Chemical Technology of Russia,
Moscow, Russia

ABSTRACT As the production of any kind of cement is based on theoretical and social demands the main trends in the development of special cements are reported. Generally the developments of aluminate, sulphoaluminate, expansive and oil-well cements are discussed.

KEY-WORDS Sulphoaluminate,aluminate cement,expansive cement.

INTRODUCTION

Progress in new technology and engineering,improvement of the existing technological processes in the different field of the production require the creation of special cements whose characteristics were outside the properties of Portland cements and which may replace Portland Cement in special application. More than thirty kind of special cements are manufactured in the world (Chatterji, 1992, Muzhen et al, 1992, Kouznetsova, 1986, Roy, 1986). In this paper the author rewiews some of them.

PHYSICAL-CHEMICAL BASE OF TECHNOLOGY OF SPECIAL CEMENTS

The study of clinker formation.

Fundamental investigations in clinker chemistry were carried out (Butt and Timashev, 1967, Taylor, 1990). The main clinker minerals, their solid phases and polimorphic transformation were studied. At present the great attention is paid to mineral modifies and their influence on the liquid phase of clinkers.

Depending on the nature and the concentration of modifiers, oxide and oxide-salt liquid phases are formed. Their properties depend on the element correlation in local volume of clinker granule. When the salts are disolved at the oxide liquid phase the melt zones appear, where significant ammounts of CaO are disolved, the process of alite formation is enhenced (Osokin et al, 1993).

It was established that mineralogical composition as well as the character of alite and belite crystallization play an important role in the formation of cement properties (Kouznetsova, 1980)

Clinkers with the different degres of crystallization of the constituent minerals provide cements with different comprehensive strengths (Maki, 1980).

It was establised that alite and belite crystals of the industrial clinkers have inhomogeneous compositions. In crystal

cores the relation of CaO/SiO_2 is bigger than in the periphery parts. Inregular distribution of the minor ions are obvious. This leads to the formation of defect crystal structure of minerals, and to changes in their hydraulic activity.

Accumulated knowledge permitted development of high strength cements (Kravchenko et al, 1971). Later this study was transformed to obtain cement with low water requirements (LWR) and high-Performance Concrete (Carino and Clifton, 1991).

Hydration and hardening of cement paste.

Today most of the crystal hydrates composing set cement have been determined, regularities of intergrowth of various crystal hydrates with each other and strength of aggregation of various crystal types have been studied. Models of cement as a composition material have been worked out. The role of crystalline and gellike phases in the formation of hardened cement paste structure has been established. With the help of detailed electron microexaminations, the interrelations between microstructures of the main phases in subject to external load o have been analyzed. It has been shown that the appearance of interphase microcracks, joining together in main cracks of failure is caused by difference between the crystal symmetry of crystals and aggregations.

Microcracks arise at the boundaries microregions with lower symmetry near the zones of portlandite and calcium hydroaluminates. Silicate and aluminate hydrogels resist the development of these microcracks thanks to microstress relaxations and to reinforcement of gels by crystalline aggregations of needle-shaped fibres of calcium hydrosilicates and ettringite.

It is established that dimensions of some fibres and geometric characteristics of aggregations can be changed, affecting the cement composition and its grinding conditions. A mathematical theory of strength of fibre-gellike structures is needed which is able to indicate the best dimensions of fibres and the best arrangement in the aggregates in oder to approximate the optimum characteristics using technological methods.

Thus, theoretical study and experimental data became the base of special cement development.

High Alumina Cement. This cement is characterized by high strength, refractoriness and resistance to corrosive media and molten metal. Concrete strength is known to depend on the mineralogical and granulometric composition.

To optimize the conditions of calcination of alumina cement containing generally monocalcium aluminate the phase condition diagrams of the $CaO-Al_2O_3$ mineralizer system were investigated. The mineralizer was one of the following compounds: calcium chlorides, fluorides, borates and chromates. The mechaniam of interaction of Al_2O_3 and CaO in the presence of these

mineralizers was described and the possibilty of changing of mineralogical composition of high alumina cement was reported.

Modification of hihg alumina cement is carried out by producing barium and strontium aluminates whose application range is limited to 1800°C. For higher temperatures zirconium-bearing cements must be used. These cements include barium zirconium aluminate, calcium zirconium aluminate and strontium zirconium aluminate types. The basic components are barium zirconates and calcium aluminates as well as strontium aluminates and zirconates. These cements exhibit a high heat resistance up to 2400°C, compressive strength up to 65 MPa, and low shrinkage (about 1%).

Spinel-bearing cements include spinel and alkali aluminates. Depending on the spinel composition, these cements relate to two types: aluminomagnesia spanel, $MgO{\cdot}Al_2O_3$, and chromia-magnesia spinel, $MgO{\cdot}Cr_2O_3$. These cements relate to high resistant, early setting, and high strength materials because they contain calcium aluminates in addition to spinels.

Expansive cements. Development of these cements proceed in two ways:
- production of clinker containing C_3S and C_4A_3S simultaneously, used for manufacture of expansive and self-stressing cements (Kravchenko, 1978). The clinker produced contained 50-60% of C_3S and considerable amount of C_4A_3S. The cement made of the such clinker had the initial setting time of 12 to 48 min and the final setting time of 17 to 145 min. The strength at 3 days was 20-40 MPa. A great deal of attention is devoted to the problem of durability of these cements. It was reveled that the samples of concrete made of expansive cement after 10 years had the same durability as those of portland cement.
Thus the cements with composition of $3CaO{\cdot}3Al_2O_3{\cdot}CaSO_4$ as well as its mixture with portland cement represent type of cement resistant to attack by aqveous sulphate and magnesium .

- mix of expansive cement with polymer. Current studies at RCTU and Minskmetrostroj showed the polymer-cement system to have significantly higher mechanical properties. Expansive cement with polymer addition is used for quality chemical basins.
Using fine milled slag or portland cement polymer-slag composite allowed production of doors, window frames and wear-resistant bench tops as a replacement for plastics, asbesto-cement units or aluminum.

Oil-well cements. In order to be an effective seal, the cement must possess the following properties:
-have a low permeability,
-form a good bond with the rock and the casing
-maintain these properties under downhole temperature and pressure conditions, and also whilst the casing undergoes vibration caused by continued drilling.

In addition to providing zonal isolation, the cement also

performs two other important functions:
-protecting the casing against aggressive wellbore fluids,
-protecting the casing against collapse by rock creeping in on the wellbore.

It is known more than 30 types of these cements (Benstead, 1983, Klusov at al, 1987).

Oil-well cements differ in a number of important aspects from construction cements. They need to be of higher reactivity than construction cements and simultaneously to allow sufficient time for pumping the slurries into position in the annulus before hardening.

CONCLUSION

The brief summary of special cement development will be caused by theoretical researches, development of chemistry cement. The high properties of special cements are used for the production of various types of concrete and construction.

UTILISATION OF KILN DUST FOR CLINKER PRODUCTION USING CRI - MODERN VERTICAL SHAFT KILN TECHNOLOGY

Dr (Ms) K RAINA, B NEDUMARAN and S N MEHROTRA
National Council For Cement and Building Materials, New Delhi, India

ABSTRACT Dust collected from the waste gases of cement rotary kiln contain higher concentration of alkalies and chloride. Accumulated dust within the area of the plant, represents permanent source of pollution. The present work establish the utilisation of kiln dust as a useful raw material for clinker manufacture through CRI-Modern Vertical Shaft Kiln (CRI-MVSK) Technology. Analysis of resultant clinker produced indicate low alkali and chloride content, hence making it a low alkali cement.

Key Words: Alkali, Chloride, Microscopy, SEM, XRD

INTRODUCTION

Large quantities of dust are collected from the waste gases of all cement kilns during burning process. Kiln dust represents a material which has already been quarried, ground, blended and partially calcined having fineness of 5000-6000 blaine. The undesirable materials such as potash, sodium, chloride and sulphur from raw materials and fuel concentrate are present in the dust (Malroum, 1994). Large quantity of kiln dust can not be returned to the kiln because of coating and clogging problems especially in wet process kilns. Dust generated from wet process kilns are approximately 8-12%. Indian cement industry generates about 0.4 - 0.6 million tonnes of kiln dust from its 25 wet process cement plants. In many countries including India the disposal of kiln dust is an increasing problem and accumulation of this waste within the area of the plant represents permanent source of pollution as it is a harmfull waste due to its high alkali and chloride content.

Many uses of kiln dust has been surveyed by Bhatty (1984). However National Council for Cement and Building Materials, India has developed an economically viable technology for making cement in a Verical Shaft Kiln using black meal process (Jain et al , 1982). The objective of this investigation is to highlight the feasibility of using kiln dust as raw material ingradient in the black meal process for the manufacture of alkali free cement.

EXPERIMENTAL

Kiln dust was collected from the wet process rotary kiln and other raw materials from a runing VSK plant. The composition of raw materials are shown in Table 1. The raw mix designs were prepared one with maximum kiln dust utilisation (Raw Mix I) second with minimum utilisation of kiln dust (Raw Mix II) and a control raw mix (Raw Mix III) without kiln dust. All these raw meals were nodulised and dried in an oven at 105^{o}C for 2 hours. These dried nodules were fired in an electric furnace at 1450^{o}C with the retention period of 20 minutes. Clinkers obtained were air cooled at ambient temperatures and subjected for elemental analysis to study the volatilisation of alkalies and chlorides from the raw mix. To determine the crystal size, shape and stabilisation of mineral phases following methods were used.

a) Microscopic studies were carried out on polished sections by fixing the clinker in araldite under vaccum. These sections were examined under reflected light using Carlzite, Amplivol

b) SEM studies were carried out on a fractured clinker samples using philips model (ST) M01G Scaning Electron Microscope.
c) X - ray diffraction studies were conducted on ordered samples using DHMax, Rrigaku, Japan diffractometer.

Table 1
Chemical Composition of Raw Materials

Material	CaO	SiO_2	Fe_2O_3	Al_2O_3	MgO	LOI	K_2O	Na_2O	Cl-
Kiln Dust	43.18	14.89	1.59	4.84	1.74	26.44	4.36	0.46	2.18
Lime stone	53.06	0.97	0.03	0.31	0.98	43.09	-	-	-
Clay	1.64	76.53	4.21	9.42	1.21	4.72	-	-	-
Laterite	0.74	16.28	54.96	14.16	0.37	11.47	-	-	-
Coke Breeze	2.55	11.16	2.29	5.11	1.68	75.74	-	-	-

After the bulk firing clinker obtained was ground in a ball mill to a fineness of 30 +/- M^2/Kg with gypsum to maintain a level of 1.75% SO_3. The resultant cement was evaluated for performance characterisation.

RESULTS and DISCUSSIONS

The elemental analysis of raw meals and the resultant clinker is presented in Table 2. Most of the alkalies and chlorides in the raw mixes are due to the presence of kiln dust. It is known that alkalies and chlorides volatalise at 800- 1000°C and the get condenced on cooler parts in the rotary kiln and generate alkali and chloride cycles (Lee,1970). It is also well known that since in the vertical shaft kiln the burning zone is very much on the top and hence all alkalies/ chlorides present in the system get volotalised and escape with exhaust gases through the chimney (Raina, 1995). Hence no alkali/ chloride cycles are generated and do not take part in the solid state reactions. This is clear from the data of Table 2 where alkali contents have gone down from 2.70% to 0.39% and chloride content from 1.12 % to 0.07 % in RM I which is having highest percentage of kiln dust. The values of alkali and chloride contents in RM I and RM II are very close to the value obtained in RM III (Control) which is made without addition of kiln dust.

Optical microscopic studies conducted on clinker I and II samples and mineral phases determine as shown in Table 3 compare favourably with the mineral composition as obtained by Bogues equations. The granulometric results indicates the average crystal size as well as grain size more or less the same. The scaning electron micrographs of clinker I, II and III are shown in plate I, II and III respectively.

The distribution of phases is uniform. Clusters of belite is present in the pores which is expected in the black meal process clinker (Ahluwalia et al, 1992). Alite graines are well formed with sharp edges indicating that no effect of high chloride and alkali content on the morphology of clinker produces by using kiln dust. X - ray diffraction studies on clinker I, II and III reveal the presence of all major phases that is C_3S, C_2S, C_3A and C_4AF as indicated in Fig 1. The percentage of

of alite phase is comparable in all the three clinkers and is in abandance. Physical performance of cement obtained by grinding clinker I, II and III with gypsum is shown in Table 4. The quality of cement is good in terms of early as well as 28 days strength. All the cements pass the soundness tests.

ECONOMIC ASPECTS

Non returnable kiln dust is a by product and free to a cement plant. When it is mixed upto 60 % (say) with the raw materials for production of clinker in VSK, it will correspondingly reduce the cost of raw materials. In India both the cost of installation and production for VSK are lower than those for rotary plant. It is therfore economically attractive also to utilise kiln dust and produce clinker from it in VSK.

CONCLUSION

Kiln dust, a waste from rotary cement plants, inspite of its higher concentration of alkalies and chloride can be used for the manufacture of cement by black meal process of cement manufacture in VSK using as raw material ingredient producing low alkali cement.

ENVIRONMENTAL IMPACT ASSESSMENT OF A SPECIFIC CEMENT PLANT/NEW PROJECT CLUSTER IN INDIA

A D AGNIHOTRI, S GEORGE S M SHINGOTE, S B YADAV AND K V KALYANI
National Council for Cement and Building Materials, New Delhi, INDIA

ABSTRACT In India, cluster of cement plants is fast emerging in limestone rich belts. Environmental Impact Assessment was conducted for Bilaspur-Raipur cluster. Data was analysed, interpreted and environmental load predicted considering overlapping effect of cement plants, to ascertain if expansion or green field cement project can be established.

Key-words: cluster,environmental load,impact prediction, impact evaluation

INTRODUCTION

The cement industry is location specific. It has resulted in the formation of seven clusters near limestone reserves in different states of India. The Bilaspur-Raipur belt in Madhya Pradesh, rich in limestone reserves stretches over 100 km in length. This cluster has nine cement plants with an installed capacity of 11.35 million tonnes per annum. Though the individual cement plants of cluster zone are well equipped with state-of-the-art technology for pollution control and meet the stipulated regulations, the collective environmental impact due to operation of all the plants and other industries in the area, requires monitoring of environmental parameters, assessment, evaluation and management. Thus, what is required is an integrated and comprehensive EIA/EMP study of the cluster zone considering futuristic trend of likely expansions of existing cement plants or coming up of new green field cement projects.

DESCRIPTION OF THE CLUSTER

The cement plants in the cluster are located in Madhya Pradesh (Fig 1).

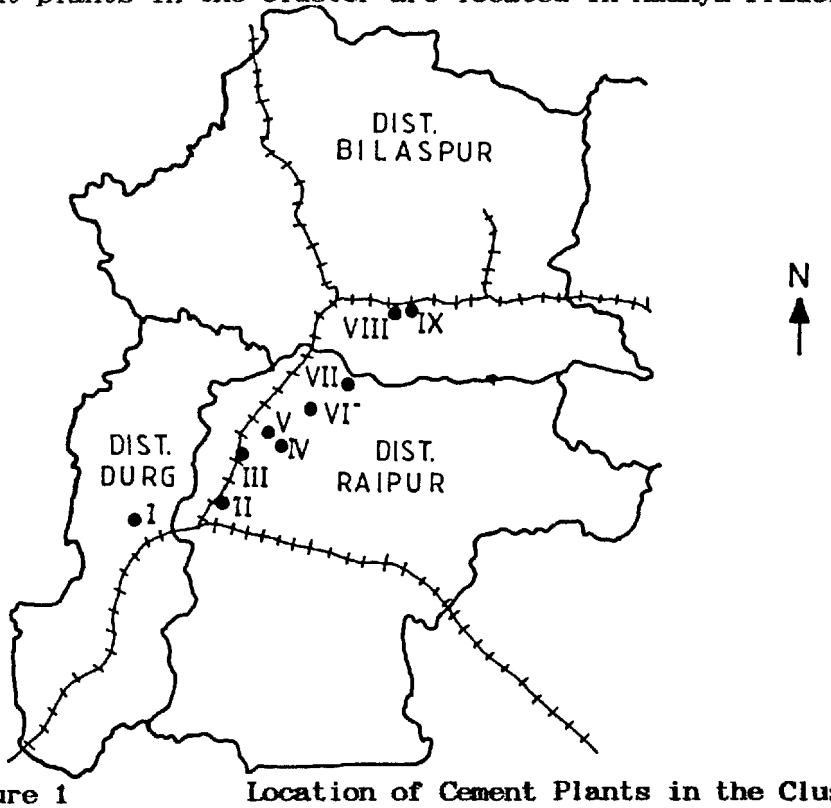

Figure 1 Location of Cement Plants in the Cluster

The distance between plant I & plant No IX is 125 Km by rail. The area lies between 21°18' & 22° 0'-north latitude and 81°30' & 82°27' east longitude at an altitude of 260 m above MSL.

Eight cement plants are based on dry process technology and only one is based on wet process technology. Some plants started production as early as 1964 while some as recent as 1995. The capacities of the kilns vary from 500 tpd to 4500 tpd. The plants have installed modern pollution control equipment like Electrostatic Precipitators (ESP) and Fabric Filters (FF). In addition, water spray system, unit filters etc. are also installed to prevent fugitive emissions.

PRESENT ENVIRONMENTAL STATUS

Measurements were carried out in summer season, 1995 for Stack emission, Noise levels, Ambient Air Quality (SPM, SO2, NOx & CO), Water and Soil quality. Data has been collected/generated on Demographic details, Flora and Fauna, Socio-economic aspects and Meteorology.

The stack emission levels in the plants range from 35 to 149 mg/Nm^3 which meet prescribed standard of 150 mg/Nm^3.

The ambient air quality levels are as follows :-

Parameters	Measured Value (ug/m^3)	Prescribed Std.(ug/m^3)
SPM	90 - 183	200
SO2	6 - 21	80
NOx	10 - 28	80
CO	87 - 203	2000

The average ambient noise levels are 39-54 dBA during day time and 31-42 dBA during night time which meet the prescribed standards of 55 & 45 dBA respectively.

Measurements were carried out for wind velocity & direction, temperature, humidity and rainfall. Wind rose diagrams have been drawn. The average wind speed is 5 Km/hr and predominant wind direction is West. The area is generally dry and arid. Humidity ranges from 6-66% and mean temperature from 18.6 - 45.9°C.

The land use pattern indicates that 68% of area is cultivated, 11% is cultivable waste, 1.5% forest land and 19.5% not available for cultivation. The demographic details such as population, literacy rate, occupational pattern, educational, medical and other amenities available indicate that the population density is 160 persons/sq km and literacy rate is 14.5%. The data on basic amenities suggest that availability of durables, educational, medical, transport and marketing facilities need further development.

ENVIRONMENTAL IMPACT ASSESSMENT (EIA)

The environmental impact assessment/prediction of impact has two distinct dimensions : (i) Assessment of impact of existing projects, and (ii) Prediction of impact for new project.

Assessment of Impact of Existing Projects

EIA was carried out by the individual cement plants, prior to commissioning. This provided the pre-project environmental scenario. It is found that there is a marginal degradation in the ambient air quality by an increase of 10-15 ug/m^3 in SPM. However, there is a tremendous improvement in the socio-economic environment of the habitats which includes educational, medical, transportation, communication, market facilities, drinking water, electricity supply and employment opportunities.

Prediction of Impact for New Projects

Environmental impact for a new one million tonne per annum green field cement project has been predicted using mathematical modelling. The emission rate is estimated as 45 Kg/hr at a stack emission level of 50 mg/Nm^3. The maximum ground level concentration (GLC) in the downwind direction is predicted at 6.8 ug/m^3 and would occur at a distance of 2000 m from project site. The resultant maximum GLC in the area would be within the prescribed standard of 200 ug/m^3. Development of green belt (trees & shrubs) in the downwind direction would considerably arrest the pollutants and the net impact on the inhabitants, flora & fauna beyond the project site would be minimal.

EVALUATION OF IMPACTS

Evaluation of impact has been carried out using Battelle Environmental Evaluation System (BEES). Environmental quality assessment is undertaken by evaluating 21 parameters which are likely to be affected positively or otherwise due to the new cement plant. These parameters are broadly classified under five major categories such as air, water, land, biological and socio-economic environment. The environmental impacts are estimated by calculating an index in terms of Environmental Impact Units (EIU) for each parameter. Relative weight has been assigned to each parameter expressed in Parameter Importance Unit (PIU). The evaluation is based on a total of 1000 PIU. The parameters identified and the relative weights assigned are given in Table 1.

Table 1 **Battelle Environmental Evaluation System (1000) Classification of Parameters**

Air Env. (240)		Water Env. (150)		Land Env (110)		Biological Env. (120)		Socio-Economic Env.(380)	
SPM	90	BOD	60	Landuse	80	Vegetation/ Green belt	50	Employment Potential	100
SO2	30	Turbidity	30	Soil quality	30	Agricultural Crops	30	Communication & Transport	50
NOx	30	Suspended Solids	35			Forestry	20	Educational Facilities	50
CO	30	Dissolved Solids	25			Habitat	20	Std.of living	70
Noise	60							Human Settlement	60
								Health, Safety	50

Impact evaluation has been accomplished through the use of functional relationship of each parameter with the environmental quality. Environmental Quality Index (EQ) varies from 0 to 1.0, where 1.0 stands for excellent and 0 stands for poor Environmental Quality.

EIU is given by EQ multiplied by PIU. The positive value (+33) in Table 2 indicates that the overall impact on the environment is beneficial.

Table 2 **Environmental Evaluation (Battelle Technique)**

Parameters	Imp. Value	Impact Units (EIU)		
		Existing	Predicted	Difference
Air Env.	240	174	165	-9
Water Env.	150	119	119	0
Land Env.	110	95	88	-7
Biological Env.	120	96	91	-5
Socio-Eco. Env.	380	239	293	54
	1000	723	756	33

CONCLUSION

The study reveals that the overall impact on the environment in the cluster area, due to a new green field cement plant, is positive. The area can accommodate additional environmental load towards sustainable development, beneficial to habitat, flora and fauna of the Bilaspur-Raipur cluster. The study provides a model for conducting Environmental Impact Assessment (EIA) studies, for national level institutions, scientific and engineering personnel, regulatory authorities and policy makers concerned with environmental quality management.

CEMENT CLINKER BURNING PROCESS OPTIMIZATION

Victor KLASSEN, Doc.Tech.Sc., Prof., Belgorod, Russia
Valentina BELYAEVA, Cand.Tech.Sc., Senior Researcher, Belgorod, Russia

ABSTRACT The paper provides the results of clinker forming processes investigation in the kilns with clinker dusting and clinker optimum granulation. The ways of clinker burning optimization are shown in order to reduce heat rate and improve cement quality.

Key-words: Clinker formation, Aluminoferrite, Qualitative

INTRODUCTION

Cement clinker burning process optimization provides for heat rate reduction and cement quality improvement. When solving the problem of heat rate reduction one should proceed from the theoretical relationships established by H.Eigen (1953) the essence of which consists in that the closer is heat losses reduction to the kiln hot end the greater are the kiln total heat savings. In operating industrial plants the kiln hot end heat savings are reduced to the heat losses decrease with clinker across the kiln body, and with gas flow by means of heat transfer improvement.

As a rule, fuel saving and quality improvement problems are interconnected and interdependent. The ways shown for heat savings in the kiln hot end favour clinker grading improvement and cement strength properties.

Many of cement mills with non-optimum burning conditions feature large content of fine fraction in clinker - the so called clinker dusting. Clinker dusting impedes clinker cooling, lowers cooler efficiency, impairs heat transfer conditions in the kiln and increases heat losses through the kiln body leading to increase of fuel specific flow. Clinker dust fraction is enriched with alite and depleted of flux minerals. Strength of cement produced of the dust fraction is somewhat higher than of granulated fraction, but generally cement strength properties are higher by 25-35% with clinker dusting than with clinker optimum granulation. More than 0.95 DS (degree of saturation) increasing, $Al_2O_3 \leq 3.2\%$ content in the raw material, re-entry of precipitated dust enriched with R_2SO_4 and KCl, use of high-sulphur fuel

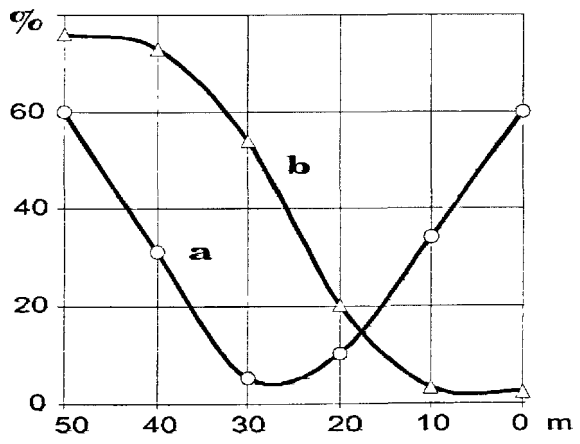

Fig. 1. Changes in the material granulometric composition along the kiln length with clinker dusting (a)

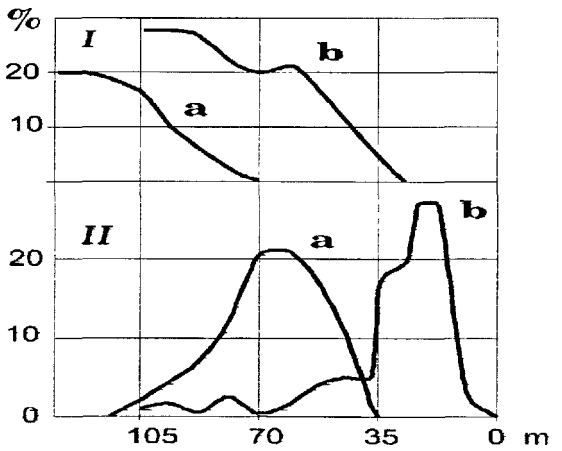

Fig. 2. Changes in material CO_2 (I) and CaOfree (II) amounts along the kiln length with clinker

oil and reducing medium in the kiln promote clinker dust formation. As it has been established, burning condition optimization makes it possible to produce high-quality granulated clinker.

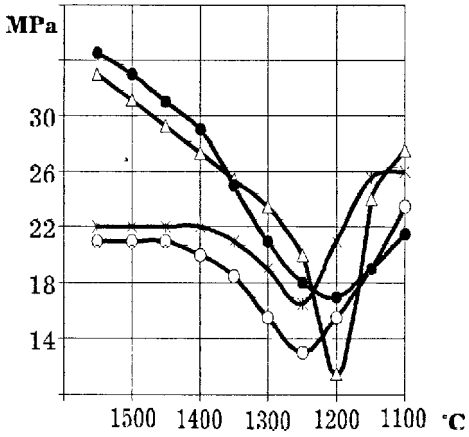

Fig. 3. Effect of additional holding in the kiln upon the strength of the clinker granules

RESULTS AND DISCUSSION

Analysis of the material granulometric composition along the length of kilns of wet and dry production methods shown (Fig.1) that granulated clinker is observed at clinker dusting at a distance of 20-30m from the kiln hot edge, with the granules subsequent destruction. As a result (see Fig. 2) CaO assimilation completes at a distance of 30-35 m from the kiln hot edge, whereas at optimum granulation it competes at a distance of 5-15 m.

Hence clinker dusting occurs as a result of process zones displacement to the kiln cold edge, and burned clinker additional holding at high temperatures. This was confirmed by the laboratory experiments, when additional 30 minutes holding of clinker granules in the kiln in the melt crystallization temperature zone led to 2-2.5 times strength reduction and encouraged granules destruction (Fig. 3).

Alkali and salt containing impurities reduce strength additionally by 1.5-2 times, a 10-fold strength reduction and complete granule destruction occur at burning reducing conditions and at slow cooling in reducing medium, respectively. As a result of the system approaching the equilibrium conditions at slow cooling partial alite decomposition and crystallization of aluminoferrite phases enriched with Al_2O_3.

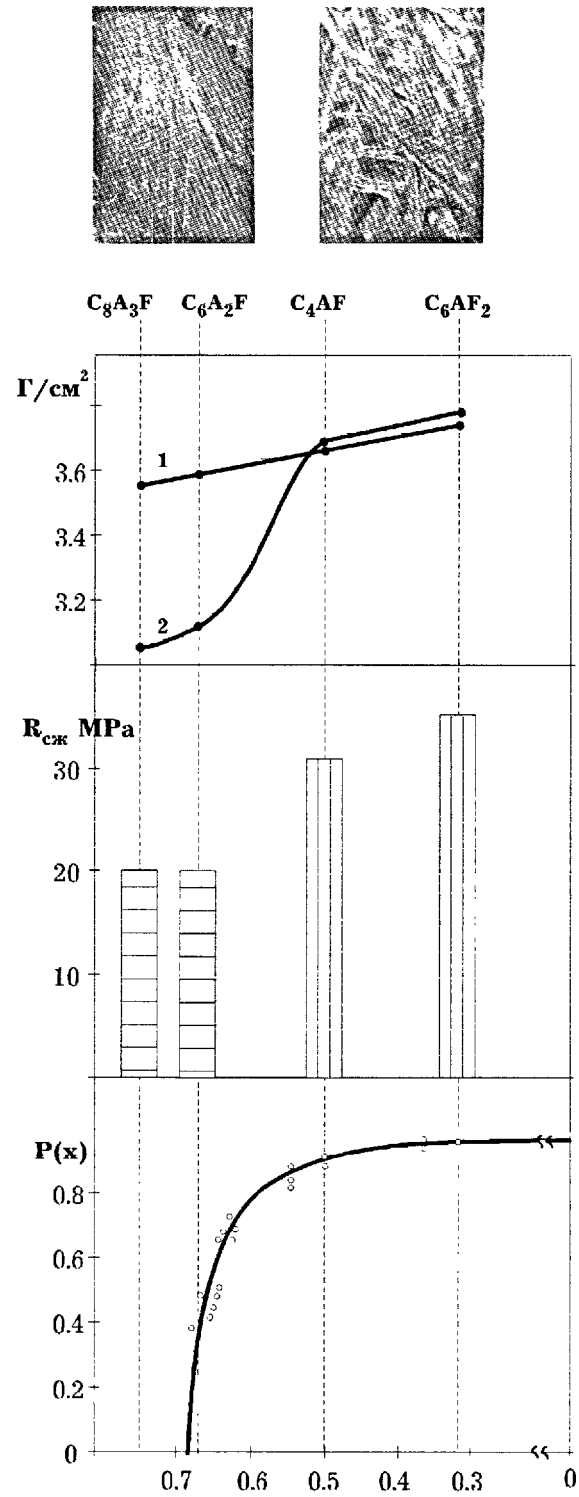

Fig. 4. Macrostructure, density, calculated by X-ray phase analysis (1) and determined by pycnometer (2), calcium aluminoferrite cakes strength and probability of flow in Fe-O-Fe links.

Investigation of series C_8A_3F-C_6AF_2 aluminoferrite phase transformations using Mцss-bauer spectroscopy, X-ray phase and differential thermal analyses made it possible to establish macrostructure discrete change and cake density and strength within the interval of C_4AF-C_6A_2F (Fig. 4).

This phenomenon can be explained when considering effect of diamagnetic dilution upon C2F ferromagnet magnetic properties. $C_2A_xF_{(1-x)}$ orthorhombic structure can be stable only in the presence of exchange interaction between Fe^{3+} ions. While replacing Fe^{3+} with diamagnetic Al^{3+} magnetic interaction between Fe ions, and hence crystalline structure stability and probability of flow in Fe-O-Fe links are reduced. With $Al^{3+}<0.5$ concentration practically all Fe^{3+} ions form a fixed system with $P(x)>0.9$ flow probability. Sudden P(x) reduction starts for $x>0.6$, which corresponds to discrete change of aluminoferrite series properties. P(x) reaches its zero value at $x=0.68\pm0.02$ being critical for magnetic concentration transition, which corresponds to $C_{6.67}A_{2.33}F$ composition. That is why clinker crystallization with Al oxide enriched aluminoferritic phases having lesser cake density and strength, being held in the kiln for a long time, causes formation of the less dense and strong clinker granules showing greater tendency to destruction. Besides, this clinker produces cement of reduced strength.

As it was mentioned above sulphur oxide and sulphur-containing compounds influence greately cement strength. According to the data of V.I.Korneev (1973), C.D.Okorokov (1960) sulphur anhydride is introduced mainly in belite increasing simultaneously its strength when adding gypsum to the initial charge. With high-sulphur fuel oil being used considerable portion of sulphur anhydride is added to the material in the kiln high-temperature portion, including alite formation stage, with introducing into the structure of the latter. According to the data of V.Gatt (1976) up to 2.9% of SO_3 reducing alite astringent properties can be put into C_3S.

It is esdtablished that cement strength is reduced considerably with calcium silico-sulphate being formed in the kiln intermediate zones, or sulphur anhydride being added in high-temperature zones. In this connection clinker quality depends greatly on high-sulphur fuel oil burning conditions. Large excess of combustion air displaying O_2 content in flue gases increases the extent of sulphur oxidation to SO_3 and SO_3 addition in the kiln high-temperature portion resulting in formation of $2C_2S{\cdot}CaSO_4$, which forms alite of reduced activity. It is possible to reduce considerably sulphur addition degree to the material and increase cement strength by 5-15 MPa by changing burning conditions (Fig. 5).

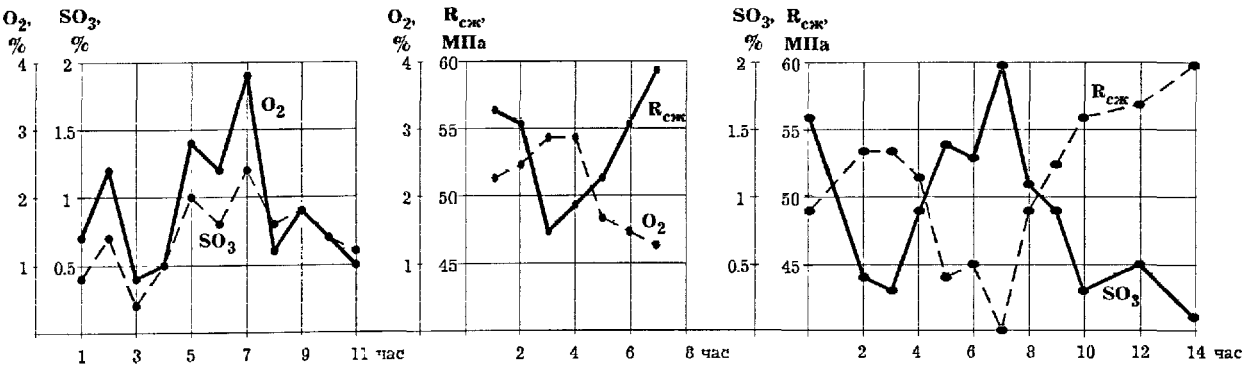

Fig. 5. Effect of O_2 in flue gases upon SO_3 content in clinker and cement strength.

With high SO_3 concentration in clinker reduction of cement strength properties is possible also due to insufficient gypsum introduction during grinding, because some portion of clinker sulphur anhydride is being titrated and, hence, quantity of introduced gypsum is being overstated obviously against its actual content when determining gypsum content in cement by cation method.

CONCLUSION

An important dependence of clinker quality upon burning conditions and fuel burning ones has been established:
- the optimization of a fractional composition and an activity increase are achieved by the decrease in clinker holding time in a cooling zone when aluminoferrite phases enriched with an iron oxide are crystallized out;
- the oxyden content reduction in a flame space favours a quality improvement, particularly using high-sulfur fuel types;
- the decrease in heat losses with clinker coming out of the kiln, through a kiln body and with a gas flow result in the decrease in specific fuel consumption and clinker quality improvement.

TECHNOLOGY AND PROPERTIES OF LOW-ALUMINATE CLINKERS AND CEMENTS

Johann STARK, Building Materials Institute n.a. F.A. Finger, Weimar Construction and Architecture University (Germany)
Aleksandr P.OSOKIN, Ekaterina N.POTAPOVA, Russian University for Chemical Technology n.a. D.I. Mendeleev, Research Technical Centre "Alpha-Cement".

ABSTRACT. A technology has been elaborated and properties investigated of special clinkers and cements containing less than 1 % of Al_2O_3. Optimal compositions and conditions of synthesis of such clinkers from raw materials of various nature and properties have been determined. Kinetics and sequence of synthesis of clinker minerals as well as phase compositions, microstructure and properties of synthesized clinkers have been considered.

KEY-WORDS: aluminoferrite, kinetics, sintering, structure, temperature

Introduction

In order to enhance life durability of concrete which is subject to corrosion attack, frequent changes of temperature, freezing and thawing, moistening and drying, cements are to be used which contain no three-calcium aluminate. Along with it, the concentration of Al_2O_3 in clinker has not to exeed 1 %. To obtain such clinkers, low-aluminate limestone, ferrous and siliceous components are to be used. A raw mix based on these materials is characterized by bad clinkering ability due to low content of the liquid phase during clinkering. The arising melt differs substantially in its composition and properties from melts obtained with the use of traditional Portland cement raw mixes.

Clinkering of low-aluminate mixes

Since no C_3A should arise in the low-aluminate clinker to be developed, changed formulas were used to calculate raw mixes proceeding from obtaining of C_3S, C_2S, C_2F and high-ferrous aluminoferrite phase C_6AF_2 during clinkering. Both pure reagents and natural materials (dolomites and chalks from various deposits, sand, pyrite cinders and various ferrum-containing wastes) were used as raw materials.

Raw mixes with lime saturation factor (LSF) = 0.75 - 0.90 and n (silica modulus) = 2.3 - 3.0 were subject for clinkering for 20 minutes at the temperature of 1450°C. The content of C_3S > 50%, Al_2O_3 < 1% and free CaO < 1% was used as criterion for quality appraisal of synthesized clinker. The raw mix with LSF = 0.85; n = 3.0 and p (alumina modulus) = 0.07 met these conditions most closely. All further investigations were conducted using this raw mix.

In order to explore kinetics of mineral formation the raw mix was subject to burning for 10 to 60 min. at temperatures 1360 - 1465°C. The formation of alite started at the temperature of 1330°C but, at low temperatures, the degree of combining of calcium oxide to form C_3S remained within 0.34 - 0.71 limits when burning duration changed from 10 to 60 minutes (Fig. 1). At temperatures of 1400 - 1425°C, α (degree of combination of CaO with C_2S in C_3S) grows up to 0.8 - 1.0 during the same period. The share of alite increases at temperatures of 1350 - 1450°C (burning time τ = 20 min.) from 25 to 51%. The further increase of the temperature up to 1465°C results in decrease of C_3S content to 41%, may be due to alite decomposition. This is accompanied by the increase of belite content from 32% to 39% with no free calcium oxide.

The obtained results enable one to suggest that the emerging active lime dissolves in the intermediate aluminoferrite phase causing the saturation or supersaturation of the latter. The following reaction takes place:

$$C_3S + C_2F(A) \rightarrow C_2S + C_3F(A)$$

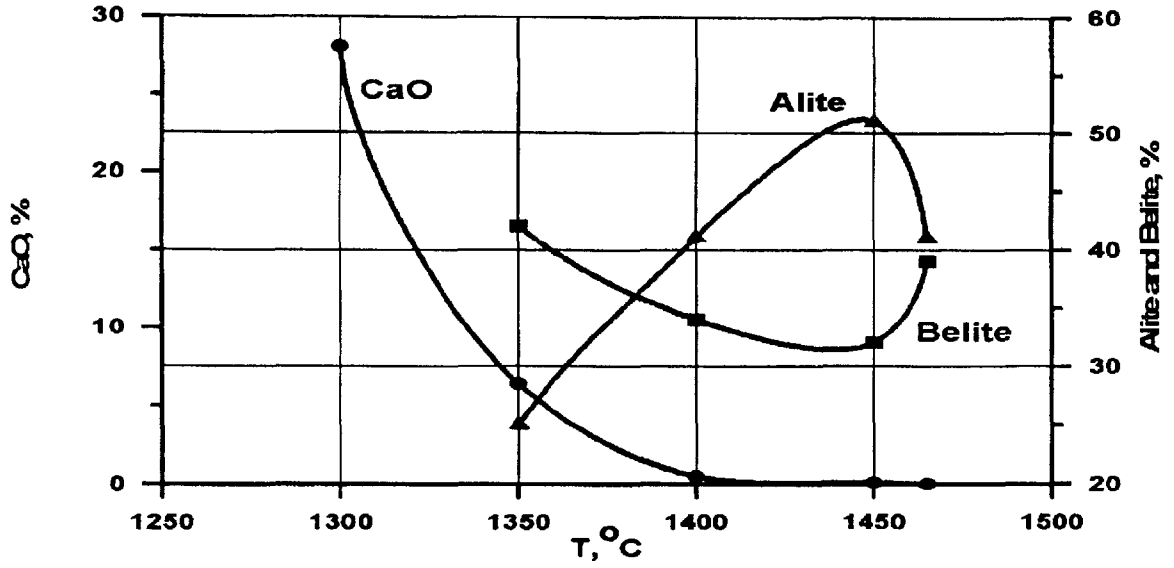

Fig. 1. Impact of clinkering temperature on content of free CaO, alite and belite in clinker (τ =20 min).

In order to describe kinetics of alite formation process 12 kinetic equations were choosen (Osokin, 1993). The nearest convergence of experimental and estimated results took place for R. Kondo and Erofeev-Kolmogorov equations. It was found using the "n" constant of the Erofeev-Kolmogorov equation that at 1350°C the formation of alite occurs in the transition area (n = 0.87); the rate of reaction prevails (n = 1.10) within 1400 - 1425°C and when the temperature increases up to 1450°C, reaction and diffusion rates become commensurable (n = 0.84). The activation energy of alite formation decreases from 75.4 kJ/mol (at 1350°C) to 34.9 kJ/mol (at clinkering temperature of 1450°C).

The analysis of the differential-thermal curve of the raw mix and x-ray phase analysis of cakes syntesized at various temperatures allowed to reveal the sequence of clinker minerals formation. The carbonaceous component becomes decomposed at 760 - 1000°C (max. 950°C), then solid-phase reactions of dicalcium silicate take place (at temperatures above 1060°C), the melt emerges at 1290°C and the formation of three-calcium silicate starts at 1330°C. At temperature of 1350°C there are CaO (d = 2.76; 2.39; 1.69 Å), C_2S in its β- and γ-forms, C_3A (d = 2.699; 1.908; 1.558 Å) and C_4AF (d = 2.770; 2.762; 2.630 Å) present in the low-aluminate clinker cakes (Fig. 2). The increase of burning temperature up to 1400°C causes solution of C_3A in C_4AF; diffraction maximums 2.699 Å (C_3A) and 2.672 Å (C_4AF) vanish and a distinct analytical line 2.678 Å appears relating to C_2F. At 1350°C cakes get often crumbled what confirms the presence of γ-C_2S (see Fig. 2f) but when temperature increases up to 1400°C and 1450°C, dense cakes develop. Analytical line d = 1.752 characteristic for C_3S occurs instead of CaO (d = 1.688 Å) and γ-C_2S (d = 1.754 Å) lines.

Phase composition, structure and properties of clinkers

According to results of the x-ray phase analysis the low-aluminate clinker with LSF = 0.85 and n = 3.0 consisits of 51% C_3S, 32% C_2S, 4% C_2F and 12% of aluminoferrite phase.

The structure of low-aluminate clinker is analogous to Portland's one (Fig.3). Along with distinctly crystallized alite and belite irregularly shaped crystals occur. The intermediate phase is well crystallized as rounded C_2F grains and acicular or prismatic crystals of calcium aluminoferrite.

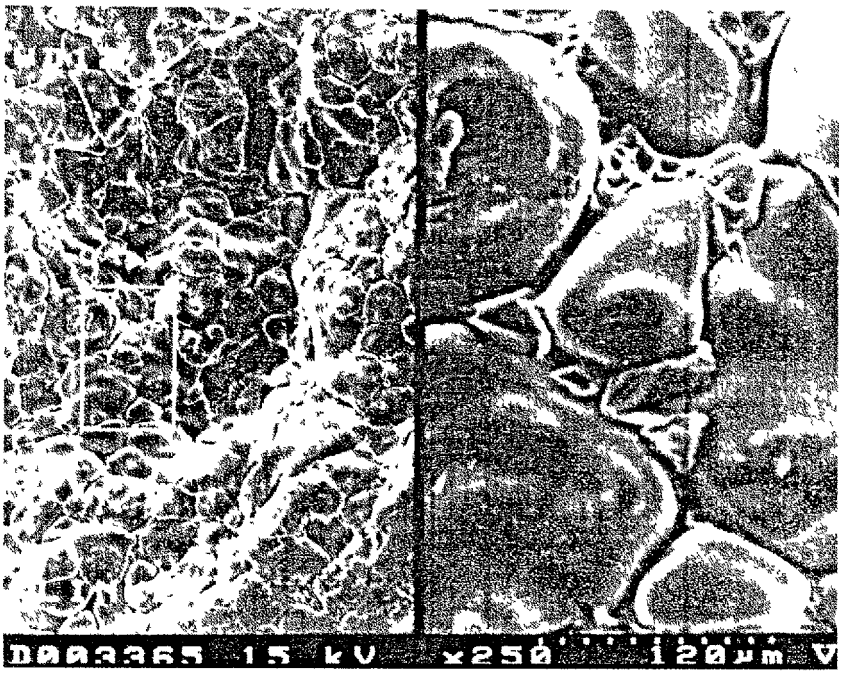

Figure 3. Microstructure of the low-aluminate clinker.

The enhanced content of belite and presence of calcium ferrites provide for reduced grindability of the low-aluminate clinker. The grinding for 10 minutes in a laboratory ball mill ensure the specific surface of 150m^2/kg (grinding of Portland cement clinker under the same conditions ensures S_{spec} of 350m^2/kg). After grinding for 60 min. the specific surface increases to 430m^2/kg. But it should be noted that the hard-to-grind C_2S and C_2F provide for more uniform grinding of clinker since they play the role of additional grinding agents. A study of particle size distribution with the use of a "Fritsch" (Germany) granulometr showed that particles of 7 to 30 mkm (50.6%) prevail in the cement, the residue on a 008 screen is 1.2%. For the Portland cement respective values are 39.9% and 11.4%.

Due to the lack of three-calcium aluminate in the clinker, gypsum added during grinding has no effect on normal thickness and setting time of the cement paste, but changes strength values of the cement. A study of effect of gypsum content (within 0.5 to7%), conditions of hardening and the dispercity of cement (S_{spec} = 260 to 460m^2/kg) showed that the best strength values show cements with specific surface of 320 to 350 m^2/kg, containing 2% of gypsum which were subject to hardening in water: at the age of 28 days their compressive strength was 46 MPa and flexural strength - 6.5 MPa. Unlike the Portland cement, the low-aluminate cement hardens slowly during early periods. The intensive gain of strength begins after 7 days.

With the use of a complex of physico-chemical methods products of hydration of the low-aluminate cement were determined, which at the age of 28 days were presented by the following phases: CSH(II), $Ca(OH)_2$, $C_4A(F)H_{19}$, $C_3A(F)\cdot 3CaSO_4\cdot H_{32}$ and $C_3A(F)\cdot H_6$. The hydration degree was 55 to 68%.

At clinkering temperatures up to 1450°C the diffraction maximum d = 2.678 remains the same while analytical lines d = 2.685 and d = 2.680 appear which can be referred to solid solutions of calcium aluminoferrites. The distinct analytical line d = 1.9395 Å enables one to determine composition of emerging aluminoferrites (Midgley, 1958) as $C_2F_{0.9}A_{0.1}$ or $C_{2.22}FA_{0.11}$. These results coincide with results of x-ray micro spectral analysis of clinkers having various saturation factors (Table 1.)

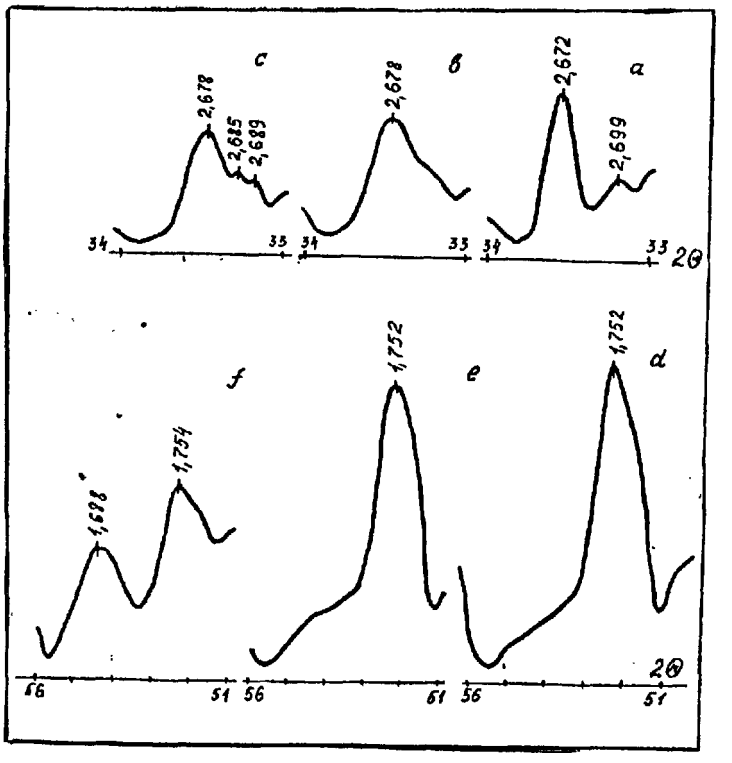

Fig. 2 Fragments of x-ray patterns of clinkers fired at the following temperatures, °C: 1450°C - a,d; 1400°C - b,e; 1350°C - c,f.

Table 1.

LSF of clinker	Composition of calcium aluminoferrites	CaO/SiO_2 ratio of	
		alite	belite
0.75	$3.70CaO \cdot Fe_2O_3 \cdot 0.17Al_2O_3$	2.80	2.18
0.85	$2.85CaO \cdot Fe_2O_3 \cdot 0.11Al_2O_3$	2.85	2.07
0.90	$2.65CaO \cdot Fe_2O_3 \cdot 0.035Al_2O_3$	2.94	2.09

In clinkers with LSF = 0.85 in aluminoferrite phase there are 0.11 moles of Al_2O_3 per 1 mole of Fe_2O_3 (A/F = 0.11). The decrease of the basicity of clinkers (to LSF = 0.75) results in the growth of Al_2O_3/Fe_2O_3 ratio but, for high-base clinkers (with LSF > 0.90) the Al_2O_3/Fe_2O_3 ratio deminishes.

The above study enabled one to develop a set of technical and technological documents and to produce an experimental lot of special low-aluminate clinker and a cement based on it under industrial conditions.

THE THERMOCHEMICAL ACTIVATION OF CLINKER FORMATION

Aleksandr P. OSOKIN, Valerij G. AKIMOV, Ekaterina N. POTAPOVA, Russian University for Chemical Technology, Research-Technical Centre Alpha-Cement, Russian Federation.

ABSTRACT. The thermochemical activation of clinker formation affects positively the mineralogical composition and microstructure of clinker. Areas develop in crystals of minerals with non-ideal ratio ($CaO/SiO_2 \neq 3$ or 2, $CaO/Al_2O_3 \neq 3$) which ensure an increase of clinker hydraulicity including that of belite clinker. The reduction of fuel consumption for the synthesis of such clinker is not less than 7 to 12%.

KEY-WORDS: activation, alite, belite, clinker formation

INTRODUCTION. Significant increase in the cost of fuel and energy necessitates the search for scientific and technical solutions to reduce heat consumption for production of Portland cement with high hydraulicity, including firing of clinker. The process of alite formation in clinker is characterised by the presence of low basicity areas and zones which contain excessive quantities of calcium oxide. The degree of completeness of alite formation depends on the rate of reaction of these micro volumes, which in its turn, depends on the reactivity of CaO and C_2S and the properties of the liquid phase of clinker. Two basic methods can be used to accelerate alite formation depending on the activity of interacting phases: increase the reactivity of solid phases (CaO and C_2S) and modify the liquid phase by adding elements which change its properties. One solution is to synthesise low-basicity clinkers under non-equilibrium conditions ensuring a deviation of the actual phase composition of the clinker from the estimated one (towards increase of alite concentration) with formation of basic minerals with defective structure characterised by increased ability to react with water. This can be achieved using any of following ways: by feeding one of raw materials to the area of clinkering (Osokin, 1993) or by high-speed heating-up of a raw mix with low-basicity LSF = 0.85 to 0.87 (Albats, 1992) as well as by the use of carbonaceous additives from coal mining and benefication wastes (Kouznetsova, 1992). Theoretical considerations and industrial tests evidence that the specific consumption of fuel for clinker production can be reduced by not less than 10 - 25 kg.

EXPERIMENT RESULTS AND DISCUSSION

For comparison, clinkers were chosen (including low-basicity compositions with LSF = 0.85) synthesised from natural raw materials (chalk, clay, shales). The following firing conditions were used (t - sintering temperature; υ_1 - rate of heating-up of the raw mix; υ_2 - rate of clinker cooling; τ - soaking at the maximum temperature):

1. Test mixes

Specimen No.1 (LSF = 0.92; n = 2.00, p = 1.20): t = 1450°C, υ_1 = 6°C/min; υ_2 = 200 °C/min; τ = 30 min;

Specimen No.2 (LSF = 0.85; n = 2.56, p = 2.00): t = 1400°C, υ_1 = 6°C/min; υ_2 = 200 °C/min; τ = 30 min;

2. Experimental mixes

Specimen No.3 (LSF = 0.85; n = 2.56, p = 2.00): t = 1400°C, υ_1 = 20°C/min; υ_2 = 200 °C/min; τ = 30 min;

Specimen No.4 (LSF = 0.85; n = 2.56, p = 2.00): t = 1400°C, υ_1 = 6°C/min; υ_2 = 200 °C/min; τ = 30 min. An additive based on brown coal mining wastes amounting to 1% and containing 9.5 % C was introduced into the raw mix.
Specimen No.5 (LSF = 0.85; n = 2.56, p = 2.00): t = 1450°C, υ_1 = 6°C/min; υ_2 = 200 °C/min; τ = 30 min. A portion of thermally activated carbonaceous component was introduced into the raw mix.
Specimen No.6 (LSF = 0.90; n = 2.58, p = 2.00): t = 1450°C, υ_1 = 6°C/min; υ_2 = 200 °C/min; τ = 30 min. A portion of thermally activated carbonaceous component was introduced into the raw mix.

All raw mixes contained 3% of particles having sizes above 200 mkm, but specimen No.3 featured increased dispercivity (R_{200} = 1%).

The study of chemical and mineralogical composition, microstructures, particuliarity of structure of minerals and synthesised clinkers and their hydraulicity was conducted with the use of x-ray qualitative and quantitative phase analysis, electronic microscopy, x-ray spectral and chemical analysis. It was found that synthesis of all clinkers was complete; mineralogical composition of the clinkers is displayed in Table 1.

Table 1. Mineralogical composition of clinkers.

No.	Modular characteristics			Concentration, %							
				estimated				experimental			
	LSF	n	p	C_3S	C_2S	C_3A	C_4AF	C_3S	C_2S	C_3A	C_4AF
1	0.92	2.00	1.20	57	15	7	15	57	22	7	12
2	0.85	2.56	2.00	48	30	11	9	48	28	11	11
3	0.85	2.56	2.00	48	30	11	9	55	25	13	7
4	0.85	2.56	2.00	48	30	11	9	56	25	11	8
5	0.85	2.56	2.00	48	30	11	9	56	23	11	10
6	0.90	2.58	2.00	60	19	10	9	64	17	11	8

It should be noted that estimated values of mineralogical composition deviate from experimental ones. This is due, first of all, to the presence in raw materials of large amount of various impurities (Ti, Na, K, Mn etc.), involved into the formation of solid solutions in clinker minerals. Moreover, the thermochemical activation of mineral formation affects the clinker composition, too. The amount of alite in less basic thermoactivated clinkers No. 3-5 exceeds reference values (clinker No. 2) by 7-8% and amounts to 55-56%, while the share of belite decreases by 3-5% to 23-25%. A similar phenomenon is observed for high-alite clinkers. In clinkers Nos. 3 - 5, β- and α- modifications of belite are stabilised, however, concentration of the α- modifications of belite is 2 - 4 %. During thermal activation of the suspended carbonaceous component its particles are subject to grinding as result of the thermal shock, but the crystal lattice of arising calcium oxide has no time to assume the stable, cubic structure. As result, products of impulse firing obtain well-developed specific surface (430 m^2/kg), low density (2930 kg/m^3), and increased values of crystal lattice parameter of CaO (4.82 Å) (Osokin, 1993). Under the usual heating-up conditions these parameters, correspondingly, are – 210 m^2/kg; 3180 kg/m^3 and 4.79Å. When passing from the regular firing with slow heating-up to

pulse high-temperature treatment of carbonaceous components, the size of CaO crystals decreases from 1-2 to 0.5 mkm and the number of microscopic distortion of crystalline lattice increases by 4 -10 times. Crystals of the metastable modification are formed, which intensively dissolve in the clinker melt. Its becomes over-saturated with Ca^{2+} ions 2 - 3 times over the equilibrium level. As a result, one can observe an acceleration of alite formation, change of microstructure of clinker grains, formation of a more active triclinic modification of alite with defect structure. According to results of the x-ray micro spectral analysis of alite crystals formed at high degree of melt over-saturated with respect to calcium ion during the initial interaction period, their central area, as compared to the periphery, had an increased content of silicon but decreased calcium and aluminium (zonal structure, with the CaO/SiO_2 ratio increasing from the centre to periphery). This is due to the fact that alite synthesis occurs close to dissolving belite grains in melt areas which are over-saturated with silicate anions. The resulting crystals display a high unit cell volume (2147 $Å^3$ as against 2140 $Å^3$) and increased hydraulicity. Heat of hydration of CaO obtained when heating-up limestone at the rate of 10 degrees/min to 1300°C was 70.8 J/g, but after abrupt firing (τ=1 c at 1650°C) it increased to 108.1 J/g (after 6 hours hydration). An increase of chemical activity of material due to the intensification of decarbonation and decrease in the period of collective recrystallization of CaO and C_2S ensures acceleration of the liquid phase clinkering in industrial rotary kilns. This is confirmed both by the relatively regular size distribution of clinker grains and more uniform crystalline structure of clinkers. The morphology of alite crystallisation becomes more distinct, with prevailing hexagonal grains having sizes from 20 to 40 mkm. The most significant changes in microstructure were observed during the interaction of less-basic clinkers with the thermally activated carbonaceous component.

The difference between structures of reference clinkers and test ones consists in developing greater quantities of zoned calcium silicate crystals with higher lattice defect contents.

To determine the influence of mineralogical composition and peculiarities of the structures of clinker minerals on heat consumption, heat content values of clinkers and main minerals were calculated. The study was based on the measurement of heat effect at dissolving of the material in concentrated hydrofluoric acid HNO_3 mixtures at the standard temperature of 298°C (Osokin, 1989). The solid : liquid ratio was 1:200. Dissolution heat was measured with an adiabatic calorimeter with thermostatic cell. The value of thermal effect at clinker formation depends on the composition of Portland cement. For ordinary alite clinker it is 1900 - 1910 kJ/kg, and for belite one with LSF 0.8-0.85 it is 1580 - 1690 kJ/kg, respectively, i.e. 13 - 17 % less.

A deviation from the ideal ratio CaO/SiO_2= 3.0 and 2.0 of minerals caused by non-uniform distribution of the main and impurity elements in the crystalline lattices is especially significant for thermochemical activation of clinker formation and brings about a change of heat content of materials. For the formation of calcium silicates with the CaO/SiO_2 ratio of 2.8 and 3.2, 665 and 710 kJ/kg, respectively, are required (Table 2). This is 13 and 6 % less, than for the mineral with CaO/SiO_2 ratio of 3.0 (764 kJ/kg). According to results of heat content measurements, the formation of highly active belite is also more energy effective, although values of enthalpy of their formation do not differ significantly (720-726 kJ/kg).

Table 2 Thermal effect of reaction of dissolution of mineral powders ($S_{spec.}$= 3000 g/cm^2) in HF (S:L=1:200) at 298°C and enthalpy of their formation.

No.	CaO/SiO_2	CaO/Al_2O_3	Q, kJ/kg	ΔH_f, kJ/kg
1	2.8	89.3	5.13	665
2	3.0	106.4	3.44	764
3	3.2	121.0	4.25	710
4	1.8	40.0	3.42	726
5	2.0	40.2	3.65	728
6	2.2	44.2	3.55	720
7	14.9	2.8	2.02	781
8	13.1	3.0	2.16	784
9	29.9	3.2	1.89	732

The hydraulicity of cements (2.5% SO_3) at w/c = 0.32 has been assessed by alite hydration degree and by increase strength of hardening cement paste after different periods of curing (Table 3).

Table 3. Hydraulicity of cements

No.	Alite hydration, %			Strength, MPa		
	3 days	7 days	28 days	3 days	7 days	28 days
1	63	68	78	21,3	28,6	40,3
2	60	65	76	16,5	24,3	35,3
3	69	74	87	22,0	27,1	42,3
4	69	76	87	22,7	28,5	42,6
5	68	77	84	21,4	31,0	41,9
6	69	75	85	25,5	34,5	52,1

The hydraulicity of test cements exceeds that of reference ones after any age of curing. The 28 days strength of less basic cements is 35.3 - 42.6 MPa (cements No. 2-5). With the use of thermochemical activation during clinker formation the strength of hardened cement paste can be increased by 6.6 - 7.3 MPa. This exceeds reference values (cement No. 1 with LSF = 0,92) by 1.6 - 2.3 MPa. Similar regularities can be observed in hydration of the basic cement No. 6. No significant differences of phase compositions of cement paste hydration products were found by means of X-ray- and electron-microscopic study. An increase in less basic calcium hydrosilicates, by 7-10%, occurs upon hydration of cements No. 3 - 6. Analysis of alite hydration values has shown that its reactivity in the thermally activated clinkers, regardless of their basicity, was 6-12% higher than in reference specimens, both at early and late hydration periods. This relates to an increase by several orders (1-4) of magnitude in the concentrations of dislocations as detected by electron microscopy (Fig.1) and free charge carriers, concentration of which was calculated for alite crystals areas having $CaO/SiO_3 \neq 3$ with regard to the Hall effect.

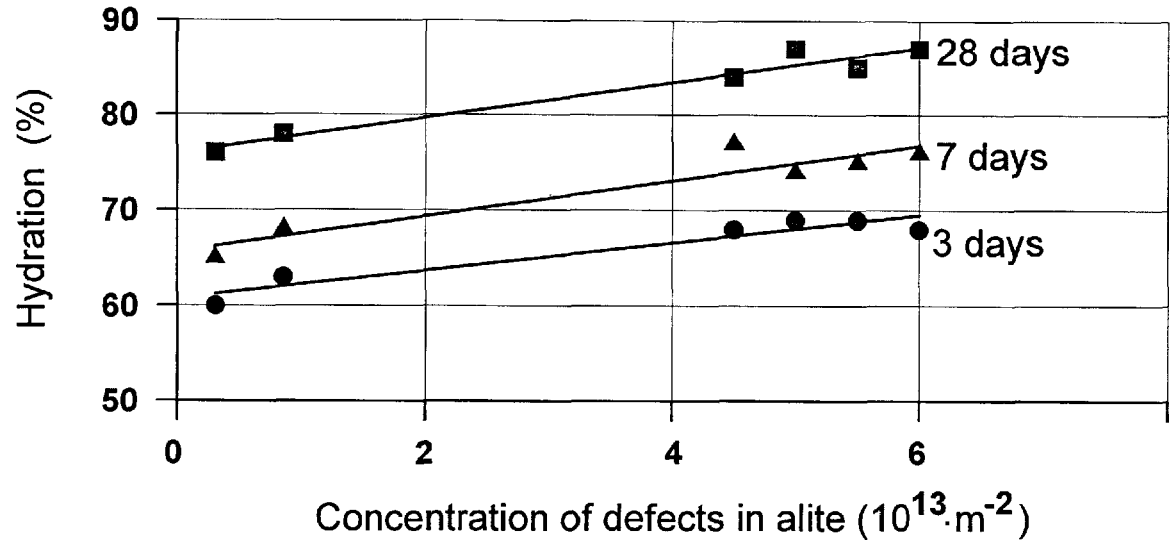

Fig. 1. Dependence of hydration degree on concentration of dislocations in alite crystals.

Thus, in spite of the smaller amount of alite in less basic clinkers, increas in reactivity results both from the chemical thermoactivation of clinker formation by any of the methods considered above and stabilisation of high-temperature belite modifications. Economy of fuel at the syntheses of such thermoactivated clinker will be not less than 7-12 %.

CLINKERING OF PRE-FORMED MIXES

Lev M.SULIMENKO, Boris S.ALBATS, Russian University for Chemical Technology n.a. D.I. Mendeleev, Research-Technical Centre Alpha-Cement, Moscow, Russia.

ABSTRACT. Agglomeration of particles of a material in rotary kilns occurs mainly in the clinkering zone. It is mainly spontaneous and causes instability of the technological process as well as non-uniformity of composition and properties of clinker. The forced agglomeration in the stage of batch preparation or its thermal treatment ensures a higher efficiency of the process and better clinker quality.

KEY-WORDS: nodulization in clinker formation, fineness, rotary kiln, sintering, temperature.

INTRODUCTION. In preheating and clinkering zones of kilns material occurs in the form of polydisperse powder-like mass. Its particles tend towards agglomeration due to excessive surface energy emerging in the course of fine grinding of raw materials.

In most kilns, agglomeration is of spontaneous character and introduces elements of instability to the clinker formation process negatively affecting process efficiency and product quality (Butt and Timashev, 1967; Klassen, 1994). Replacement of powder-like raw mixture with pre-formed pellets or briquettes enables a substantial increase of technical and economical production characteristics (Sulimenko, Albats, 1994).

Results are presented on the investigation of clinkering of pre-formed mixes.

Experimental data and results

Agglomeration of slimes can occur through removal of the liquid phase either by means of mechanical methods (filtration) or thermal ones (spray drying). Both methods are widely known and will not be analyzed in this paper.

In kilns utilizing dry process, the forced agglomeration can be regarded as an effective technological solution. The most widely known one is the pelletizing with binder before feeding into the kiln. Pellets obtained in disk pelletizers are, as a rule, characterized by inhomogeneous laminated structure with ring pores. This provides for reduction of heat resistance of pellets which are partially destroyed in the course of subsequent heating. The more reliable method appears to be the briquetting of raw mixes at 5 Mpa pressure to obtain agglomerates with section of 10 to 15 mm which are able to preserve their form during clinkering.
A promising method is agglomeration of a powder-like raw mix in the process of thermal treatment, for example, while transporting it from a heat exchange cyclone where the temperature of 750-800°C is maintained to a rotary kiln. It is favoured by an increase of the degree of self-adhesion of particles as the temperature increases (Table 1.) as well as by the emerging of pyroplastic properties of the material.

Table 1. Effect of temperature on the stability of inter-particle contacts of chalky marl ($d_{particles}$ = 10 mkm)

Temperature, °C	20	460	700	900
Relative dencity, %	0.51	0.45	0.41	0.36
Rupture strength, Pa	$2.1 \cdot 10^2$	$4.5 \cdot 10^2$	$8.6 \cdot 10^2$	$9.2 \cdot 10^2$
Number of contacts $1/m^2$	$9 \cdot 10^9$	$7 \cdot 10^9$	$5 \cdot 10^9$	$4 \cdot 10^9$
Average stability of contacts, kN	2.3	6.4	12.3	23

An experiment carried out in industrial 7/6.4 x 95 m kiln utilizing dry process gave the following results. The introduction of lignosulfonate water solution at the spout where material is fed to the kiln from the lower cyclone, the prevailing size of particles at the distance of 3 m from the feed end of the kiln increased from 0.19 to 3.1 mm and at the distance of 20 m - from 0.21 to 1.1 mm. The homogeneity of grain size of material increased by 3 to 4 times as well. The size of clinker grains increased from 10.7 to 15.5 mm.

A study of the nature of the material flow along the kiln with and without addition of lignosulfonate with the use of radioactive tracer technique showed that the agglomerated material flows more slowly (by 2 times), especially in the initial stage. On the contrary, in the clinkering zone the velocity increases to a certain extent. The LOI value of the material for 20 m of kiln length decreases in the case of agglomeration from 22 to 19 %. The finished clinker on the basis of agglomerated raw material is characterized by growth of alite content by 5 % and a certain increase of hydraulicity (by 2.5 Mpa).

A relatively low agglomeration degree which, in this case, is accompanied by inevitable attrition of particles in the kiln, will hardly be useful.

In this respect, the most promising method is the hot compaction of powder-like meal (Butt, Timashev et all, 1968; Sekava at all, 1992; Kupper and Rother, 1993; Ivanov et all, 1994). Here, the pressure applied is added to surface tension force ensuring a speed-up of clinkering based on diffusive transfer of material.

According to data obtained by the authors, the recovery of free CaO in the course of solid- and liqiud-phase reactions becomes more intense (Table 2).

Table 2. Assimilation of free CaO during firing of powder and hot-compacted (p = 50 MPa) raw mix.

Firing temperature, °C	Soaking, min.	Content of free CaO, %	
		powder raw mix	raw mix after hot compaction
1250	5	17.51	13.86
	10	15.19	10.04
	15	17.35	11.06
1450	5	7.19	6.07
	10	6.54	4.66
	15	5.82	2.51
	30	4.87	0.56

The shown results suggest that clinker can be obtained at lower, than usual, temperatures.

Specimens compacted under the pressure of 10 MPa at temperatures 800-1000°C show 6 to 8 times greater strength as compared to both cold-compacted specimens and pellets produced in drying zone of the rotary kiln. The dencity of hot-pressed specimens grows approximately by 1.5 times and porosity and specific surface decreases correspondingly evidencing the growth of the contact surface of the material (Table 3).

Table 3. Effect of conditions of specimens forming on their properties

Method of forming	Clinkering temperature, °C	Density, kg/m^3	Total porosity, %	Compression strength, MPa	Specific surface, m^2/kg
Cubical specimens of dried slime	800	1270	55.5	1.6	222
	900	990	69.2	1.3	281
	1000	970	70.5	2.0	285
Cold-pressed briquettes, p=15 MPa	800	1380	53.1	1.7	233
	900	1090	66.2	1.5	206
	1000	1080	67.3	2.2	280
Hot-pressed briquettes (at firing temperatures, p=10 MPa)	800	1690	40.9	8.2	210
	900	1410	55.8	12.5	199
	1000	1390	57.0	12.0	150

Though dencity of specimens grows generally within compaction pressures of 2 to 25 MPa, this process runs most intensely up to 10 to 15 MPa. This is associated with transfer and more compact arrangement of particles. Along with this, partial destruction of small particles and of contacts between them is possible. Large pores (above 10^4 Å) are filled with the material and their volume decreases by 50 times. The further increase of pressure results in reduced intencity of compaction. With pressure growing, the strength of hot-pressed specimens increases according to the power law.

Thus, the forced agglomeration of Portland cement raw mixes is an efficient method of intensification of technogical processes requiring modern technical solutions.

MELTING PROCESS FOR CLINKERISATION - A TECHNICAL REEXAMINATION

S. A. KHADILKAR, P. G. LELE, D. GHOSH, A. K. CHATTERJEE
Research & Consultancy Directorate
The Associated Cement Companies Ltd,
Thane - 400604, INDIA

ABSTRACT In continuation of our studies on clinkerisation through the melting process as reported at the 9th International Congress on Chemistry of Cement, further progress has been achieved on lab and pilot scale. Clinkers were manufactured through melting process at temperatures of 1350 ° C - 1450 ° C. The effect of concentration of fluxes and mineralisers on melting temperature and chemico-mineralogical properties of clinker were studied. The process of progressive liquefaction of raw mixes, changes in melt properties, effect of cooling rate on nature of solidification were some of the aspects studied in some detail. A comparison of microstructural and hydraulic properties of clinker obtained through the melting process and the conventional liquid - phase sintering is presented in the paper, which also highlights the technical feasibility of clinkerisation through melting illustrating the potential advantages and likely disadvantages.

KEY-WORDS Clinker Formation, Melt, Temperature, Ferrite Phase, Characterisation.

INTRODUCTION

In its search for avenues of reducing investment and energy costs in cement manufacture ,the Research and Development Division of the Associated Cement Companies have been investigating a number of alternative approaches at R&D level. Melting process for clinkerisation is one such project which has shown some likely possibilities. Preliminary investigations were reported by the authors at the 9th International Congress on Chemistry of Cement (Khadilkar et al 1992). Since then considerable progress has been made on establishing the feasibility of melting process of clinkerisation at the lab and pilot scale level.This paper summarises the findings on optimisation of compositional parameters to achieve lower fusion temperature of the portland cement raw mix.The paper also discusses the chemico-mineralogical , physico-mechanical and hydraulic potential of the pilot-scale clinkers produced by the melting process,comparing the properties with the clinkers produced by conventional sintering process.

The paper also compares the heat of clinkerisation of melting process to that of conventional sintering route and attempts to draw out a comparative energy requirements of the two processes.

EXPERIMENTAL WORK

Laboratory studies were carried out to assess the influence of compositional parameters on fusion temperature of the ordinary cement raw mixes and to study the effect of different fluxes and mineralisers on phase formation.

Optimisation of compositional parameters

About 30 different raw mixes were prepared with different modulii values (LSF,SM,AM) and Fe_2O_3 contents. The fusion temperature of the raw mixes was determined by Leitz

Heating Microscope.The data base was used for multilinear regression analysis to understand the influence of different parameters on fusion temperature of the cement raw mixes.
The statistical analysis confirmed that LSF and Fe_2O_3 content of clinker have strong relationship with the fusion temperature of the cement raw mixes, as indicated by the correlation coefficients of 0.96.
The multilinear regression is of the first order in nature,the empirical equation relating the burnt raw mixes clinker LSF ,Fe_2O_3 and the fusion temperature is illustrated below:

Fusion temperature (^{0}C) = 2545.6 LSF - 32.77 Fe_2O_3 - 596.05

The theoretically predicted values of fusion temperature and the experimentally determined fusion temperature of different raw mixes are graphically represented in Fig.1which indicates the reliability of the regression equation. The equation is valid when no mineralisers or fluxes other than iron ore ,bauxite, laterite are used.

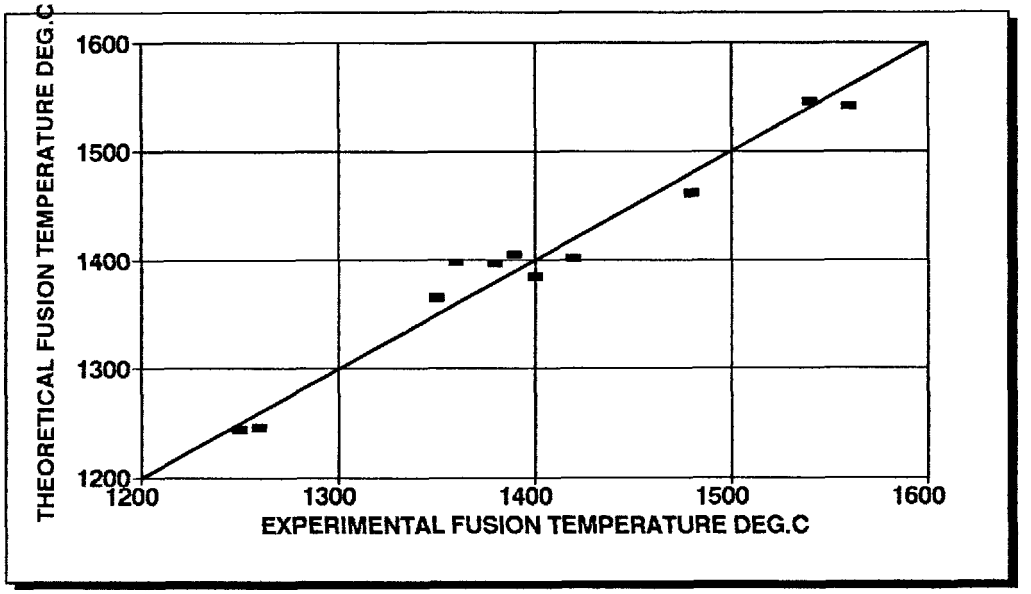

FIG.-1 : RELATION BETWEEN THEORETICAL & EXPERIMENTAL FUSION TEMPERATURE

Effect of fluxes and mineralisers

The effect of fluxes like Borax, K_2CO_3,CaF_2, Blast furnace slag and Basalt (volcanic rock) on the fusion temperature and clinker phase formation was studied.Several raw mixes were designed (RawMixes -A, B, C, D & E) , targeting LSFand Fe_2O_3 in clinkers within a very close range.The details of the raw mixes is given in Table-1.The fusion temperatures of these raw mixes was determined by Heating Microscope.

The raw mixes were also melted in an electrical furnace and the melting process clinkers produced were analysed by X-ray Diffraction Analysis to assess the clinker phase formations. X-ray Diffractograms of the clinkers are shown in Fig.2.

Table 1 **Raw material composition and proportion in raw mixes along with their fusion temperature**

RAW MATERIALS	CHEMICAL COMPOSITION					RAW MATERIAL PROPORTIONS OF RAW MIXES

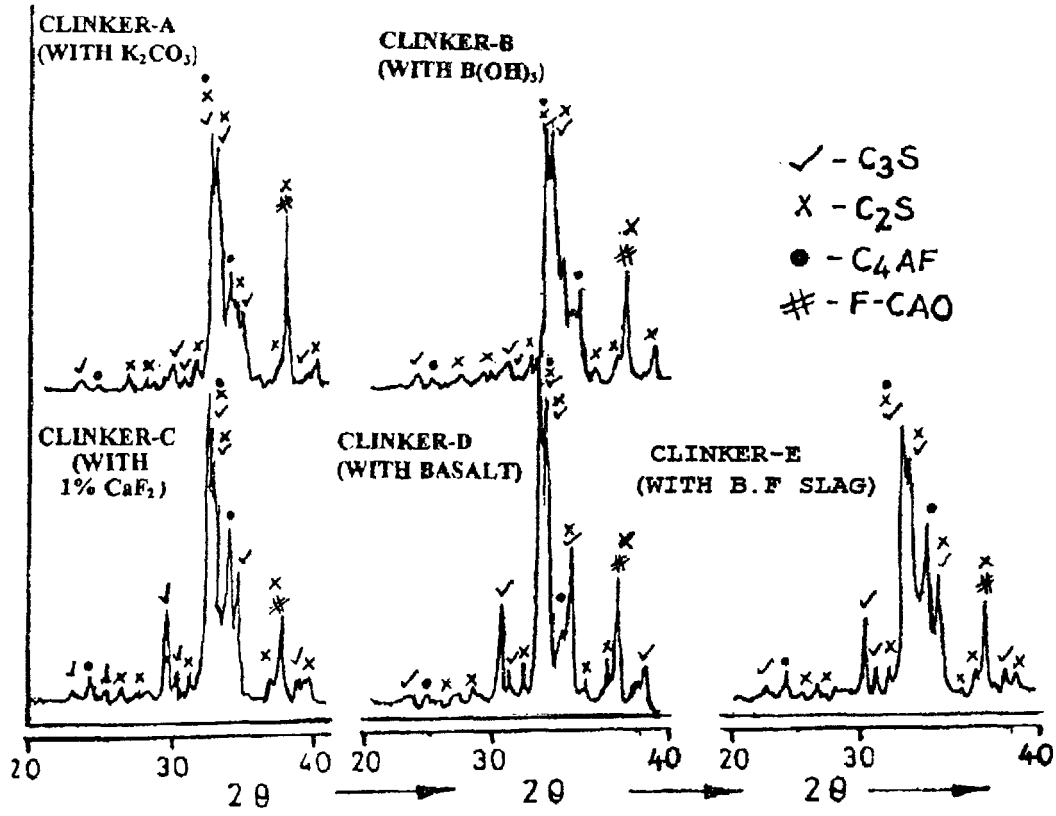

FIG. 2 : XRD SCANS OF CLINKERS WITH FLUXES AND MINERALISERS

The results illustrate that :

- $B(OH)_3$ and K_2CO_3 do not have influence on fusion temperature as well as on clinker phase formation.
- Use of 1% CaF_2 (80 % purity) reduces the fusion temperature by 50 ° C.
- With the use of B.F Slag and Basalt as corrective, the fusion temperature of the raw mixes is lower than expected at the respective LSF and Fe_2O_3 contents,this can be attributed to the lower fusion temperatures of these correctives themselves (1240^0-1260^0 C).
- Clinker phase formation in raw mixes C,D,E i .e . with Basalt, B.F Slag and 1% CaF_2 respectively is better than Raw mixes A and B (with $B(OH)_3$ and K_2CO_3)

Heat Of Clinkerisation Of Melting Process Raw Mixes

The heat of clinkerisation of the pilot scale raw mixes was determined by Thermal Analysis method standardised at the authors' laboratory .The values of heat of clinkerisation for the pilot scale raw mixes were observed to be in the range of 350-380 cal/g as compared to the conventional raw mix values of 390-430 cal/g, which indicates that the Enthalpy values of the melting process mixes were lower than conventional cement raw mixes.

Effect of aqueous quenching

To assess the effect of aqueous quenching on the mineralogy and microstructure of the melting process clinkers were quenched in water. No significant difference was observed in the XRD-pattern,however, the water-quenched clinkers exhibited fine grained alite.Similar observations were reported by the authors in their earlier publication.(Khadilkar et al 1992)

PILOT SCALE CLINKERISATION

Several raw mixes were prepared for pilotscale clinkerisation using limestone of three different sources broadly covering a range of LSF from 0.81 to 0.91 with Fe_2O_3 contents at appropriate levels (according to regression equations) targeting fusion temperatures in the range of 1350° C - 1450 ° C. Some Raw Mixes were also prepared with 0.5% CaF_2 (80 % purity) as mineralisers. The generated data on some of the raw mixes is discussed in this paper viz: PS-1(LSF 0.81), PS-2 (LSF 0.84), PS-3 (LSF 0.87) PS-4 (LSF 0.91) PS-5(LSF 0.91with 0.5% CaF_2) .The chemical composition of raw materials and raw material proportions of the raw mixes is given in Table-2.

Pilot Scale melting process

The secondary crushed raw materials of size 4 - 6 mm were mixed in appropriate proportions and melted in a magchrome refractory lined melting furnace(capacity:25Kg) at temperatures of 1450°C.The fused clinkerised mass was maintained under molten condition for 1 hr; after which it was air quenched using compressed air to produce the clinker.

The pilot scale clinkers so produced were evaluated for chemical composition (Table-3), grindability index (Table-3),mineralogical composition by XRD, microstructural features by Optical Microscopy, and Hydraulic characteristics were assessed by testing the lab-ground cement prepared from the pilot scale clinkers (Table-4).

RESULTS AND DISCUSSIONS

1) Chemical composition of the pilot scale clinkers is given in Table-3. The analysis of the clinkers indicated high free lime content in the range of 3 - 4%,which may be due to limitations of the melting furnace in which the melt could not be made to flow and mix, causing localised inhomogenity.The fusion temperatures observed at pilot scale level were

similar to that predicted by the empirical equation except for P.S-5 in which case it was observed to be lower due to mineralising effect of the CaF_2.

2) Bond Grindability index (Kwh/Sh.Ton) of the pilot scale clinkers found in the range of 22.0 to 24.8 indicating that the melting process clinkers are difficult to grind compared to conventional clinkers which are normally in range of 14.0 to 20.0 kwh/sh.ton.

3) The XRD patterns of the clinkers indicate differences in the peak positions of Belite and Alite as compared to clinkers produced by conventional sintering process. Similar observations have been reported earlier by the Authors(Khadilkar et al 1992) on melting process clinkers.

4) The microstructural features for all the melt process clinkers irrespective of their compositions are more or less similar and somewhat different compared to the clinkers produced by liquid phase sintering. In the melting process clinkers, the alites are mostly prismatic, elongated to rod shaped (Plate-I) or large, stout crystals with wavy margins (Plate-II). The matrix is generally highly differentiated with coarse and small grains. The distribution of the alite, belite and liquid phase is inhomogenous, sometimes large nests of either belite, alite or liquid phase seen. (Plate-III). The belites are mostly β or α' variety. The inhomogeneity and occurrence of coarse crystals are due to insufficient mixing and diffusion of the constituent oxides released from the coarse grains, which in this case were released from coarse particles that were not finely ground. Probably, this could be avoided if the molten material in the furnace is allowed to mix before it is cooled.

5) The lab-ground cements were prepared from the pilot scale clinkers by cogrinding with gypsum. maintaining SO_3 content of 2.2% and fineness of 3000cm^2/g. The physical test results (Table - 4) indicates that the compressive strength of cements increases with increasing LSF (PS-1 to PS-4) and as expected, addition of mineralisers (PS-5) helps in the gain of compressive strengths as well. The cement quality data also indicates (a) possibility of manufacturing Ordinary and Rapid Hardening cements ; (b) the melting process clinker shows the same relationship of increasing compressive strength with LSF like conventional clinkers and (c) unlike the conventional clinkers the melting process clinkers show much higher rate of strength development at later ages than at the early ages.

Process Considerations

Based on the investigations, a schematic flowsheet (Fig.3) for clinker manufacture by melting process and conventional sintering is shown diagramatically to illustrate unit stages of manufacturing in melting process route. It can be seen that in the conventional sintering process, the raw mill grinding and homogenisation can be totally eliminated in the melting process route.

A tentative comparison of energy consumption for clinkerisation using the melting process and the conventional sintering process has been attempted (Table 5) which indicates that the total energy consumption for melting process, quite contrary to the normal expectation may turn out to be lower than the conventional sintering process.

CONCLUSIONS

1) The experimental work defined an empirical equation for predicting fusion temperature of raw material mixes which can be used as a parameter while designing mixes for the melting process of clinker manufacture .Amongst the fluxes and mineraliser as expected, fluorine was found to be effective in lowering the melting temperature.

2) The laboratory investigation has been scaled up to pilot scale levels and clinkers could be manufactured successfully in 25 kg batches.

3) The cements prepared from the melting process clinkers exhibited strength properties, where gain in cement strengths were observed at all ages(1 Day to 28 Days) and the rate of strength development at later ages were higher as compared to the early ages.

4) It is envisaged that melting process route for clinker manufacturing can eliminate the raw material grinding and homogenisation of the conventional route. Tentative calculations on energy consumption for melting process of clinkerisation appears to be attractive.

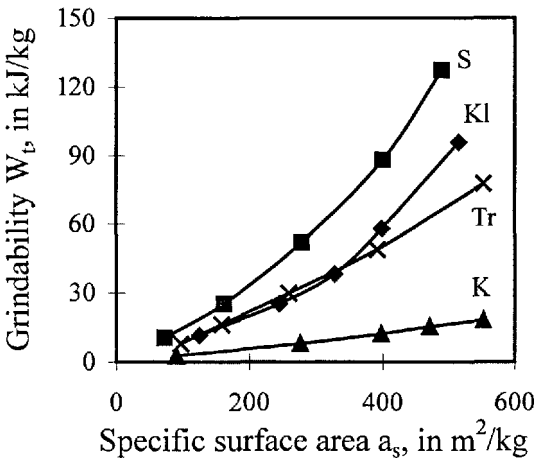
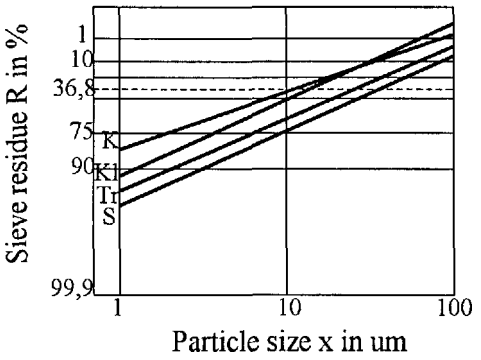
GRINDING TECHNOLOGY AND QUALITY OF COMPOSITE CEMENTS



Ludmilla OPOCZKY and Miklós HILGER,
Cement Research & Development Ltd.,
Budapest, HUNGARY

ABSTRACT
It is proved that particle size distribution highly affects the water demand of cement. Cements of "wide range" particle size distribution are of least water demand. There is a definite relationship between grindability and particle size distribution, i.e. the easily grindable materials provide grinding products of "wider range" particle size distribution. With the aid of suitable combination of materials of different grindability composite cements of advantageous peculiarities can be produced.

Key-words: Composite cements, additives, particle size distribution, grinding technology

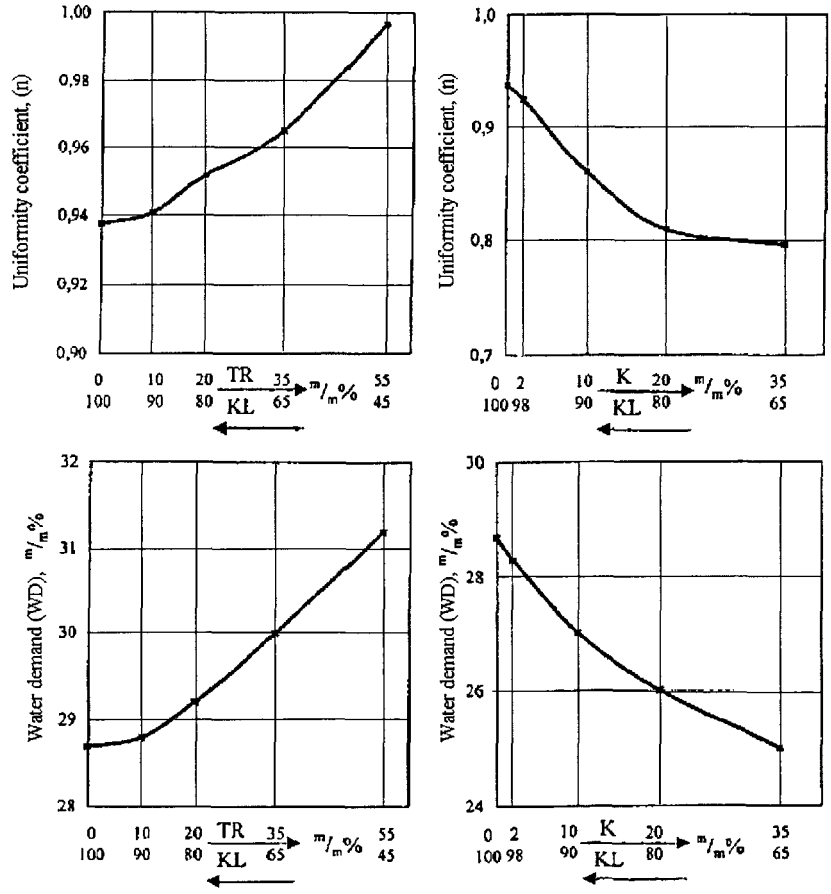


INTRODUCTION
The production of composite cements containing different additives is reasoned by economic and environmental aspects. As regards the composition of composite cements, the European standard suggestions provide a lot of possibilities but do not provide unambiguous bases to select the reasonable composition. The application technical features of multicomponent cements are highly influenced by their grinding technological features (grindability, particle size distribution), in addition to the clinker of given quality and additives. Knowing these features it is possible to produce composite cements of rational composition through the suitable combination of additives. In the following the investigation results representing the grinding technological and quality relationships (composition - grindability - particle size distribution - specific surface - water demand - strength) will be presented.

INVESTIGATION RESULTS
To perform the investigations, clinker (C_3S = 54.7 %; C_2S = 23.1 %; C_3A = 7.1 %; C_4AF = 11.1 %) and hydraulically active (granulated blast furnace slag, fly ash, trass) and inert (limestone) additives were used. In Fig.1. the "specific grindability" (W_t) of the starting materials (except the fly ash) is shown. The specific surface of fly ash was ~300 m^2/kg in its original state. Grindability was determined with the Zeisel-instrument. Fig.2. illustrates the relationship between grindability and particle size distribution. In the figure the particle size distribution curves and characteristic fineness parameters of the milling products produced from the experimental materials in laboratory ball mill under the same grinding time, are shown. Particle composition of the milling products was determined by a CILAS 715 type laser granulometer (3-200 μm). To describe the particle size distribution the RRSB equation and its two constants, i.e. the n factor of uniformity and $\bar{x}$ fineness number were used, respectively. It is to be noted that the factor of uniformity (n) is the number of the "range" of dispersion, the smaller is n the "wider" is the particle size distribution; the fineness number $\bar{x}$ refers to the fineness of the milling product, the smaller is $\bar{x}$, the finer is the product.

Kl:Klinker; S:Blast furnace slag;
Tr:Trass; K:Limestone

Fig.1
Grindabilities of the starting materials



Material	Grinding time	Specific surface	RRSB	
			n	$\bar{x}$
	h	m^2/kg		μm
Blast Furnace (S)	1	200	0,9572	36
Klinker (Kl)	1	350	0,923	18
Trass (Tr)	1	300	1,0628	22
Limestone (K)	1	700	0,6477	15

Fig.2
Grindability and particle size distribution

It can be stated that clinker, blast furnace slag and trass can be more heavily ground ($W_t \sim 35$ - 21 kWh/t), while the limestone can be assigned to the materials of easy grinding ($W_t \sim 5$ kWh/t). It can be seen in Fig.2. that from the easily grindable limestone products of smaller factor of uniformity, i.e. of "wider range" of particle size distribution, from the heavily grindable blast furnace slag and trass products of greater factor of uniformity, i.e. of "narrower range" of particle size distribution can be produced. It is to be noted that fly ashes separated on the elctrofilters and used as additive are of characteristic "narrow range" of particle size distribution ($n \geq 1$) even in their original state and this the result of separation and not that of grinding. Based on the results presented the conclusion can be drawn that the addition of different additives to the cement will affect its particle size distribution in different manner, i.e. it will be "widened" or "narrowed down". As an example, in Fig.3. the formation of particle size distribution and of the factor of uniformity of cements of different trass (a) and limestone (b) contents is presented.

The water demand of cements can be also seen. (Water demand means the water quantity needed to the preparation of cement mash of standard deliquescence.) The addition of trass while "narrowing down" the particel size distribution (the n factor of uniformity increases) increases the water demand of the cement. This effect increases with increasing trass quantity. Similar effect can be experienced in case of fly ash and blast furnace slag, in case of fly ash this is greater than in that of trass and blast furnace slag, in case of trass is greater than in case of blast furnace skag addition. On the contrary, the addition of limestone "widens" the particle size distribution of the cement (the n factor of uniformity decreases), and simultaneously this reduces the water demand of it. This effect can be observed already in case of addition of 2-10 $^{m}/_{m}$ % limestone.

a, b,

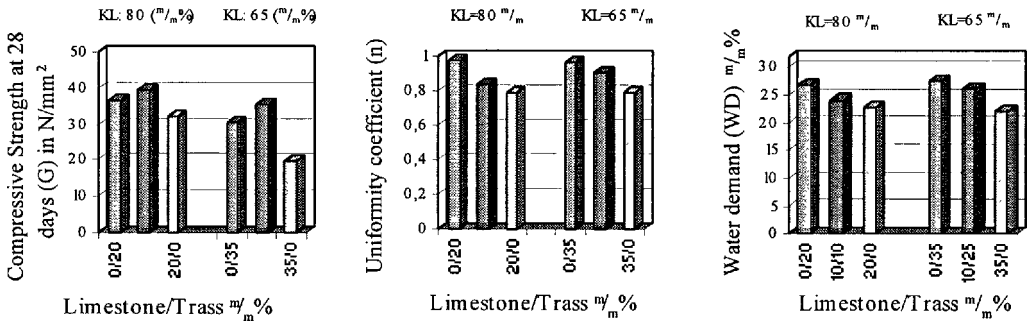


Fig.3

Change of uniformity coefficient (n) and water demand (WD) of cement depending on trass-content (a); on limestone-content (b)

In the course of previous investigations it was demonstrated (Opoczky, 1992) that in case of joint grinding of clinker and limestone, the easily grindable limestone accumulates in the finest (< 5 μm), the clinker in the relatively coarser fraction. The fine particels of limestone are located in the holes and interspaces among the clinker particles providing thus a "complete" space filling". Limestone particles are highly suitable to this due to their morphology. Consequently, with the addition of limestone the particle size distribution and thus the water demand of the cement can be favourably affected. In addition to this positive effect, the addition of the practically inert limestone reduces the strength of the cement. This strength reduction can be compensated by increasing the grinding fineness of the cement only to certain extent, all the more so the limestone inclines to adhesion and agglomeration.When adding hydraulically active additives, besides the grinding fineness that can be reached in practice, as well, cements of required strength can be produced. Nevertheless, most of the hydraulically active additives increase the cement's water demand that becomes obvious in case of cements with high amount of additives. The great water demand of these cements can be reduced by adding suitable limestone.

Our experiments prove that using hydraulically active and inert additives (e.g. trass + limestone) together, clinker-saving composite cements of favourable particle size distribution and water demand can be produced. In Fig.4. the compression strength of 28 days (a), factor of uniformity and water demand (b) of composite cements of ~ 400 m^2/kg specific surface produced by joint

grinding containing trass and limestone and trass plus limestone are seen, that turned to favourable in case of composite cements of trass plus limestone content.

a, b,

Fig.4

Compressive strength (a), uniformity coefficient and water demand (b) of composite cements

MAIN CONCLUSIONS

The water demand of cement is considerably influenced by the particle size distribution. Cements of "wider range" particle size distribution are of less water demand. Additives studied in this work differ not only in the hydraulic activity but in the effect they exert on the particle size distribution and water demand of the cements: the limestone "widens" the particle size distribution and reduces the water demand of the cement; fly ash, trass, granulated blast furnace slag "narrow down" the particle size distribution range and increase the water demand. Additives keep their characteristic particle size distribution even during grinding together with clinker. When preparing cement mash water is added more than theoretically required. This water surplus is used to fill the holes and interspaces among clinker particles and to wet the surface of clinker grains in order that these be moveable beside each other. In a milling product the smaller is volumetric proportion of the solid state matter and the greater is the volume of the holes to be filled, the "narrower" is the particle size distribution. The water demand reducing effect of limestone is related to its "wider range" particle size distribution and to its "space filling" effect. There is a concrete relationship between grindability and particle size distribution, i.e. easily grindable substances produce milling products of "wider range" particle size distribution. By means of the suitable combination of substances of different grindability clinker-saving composite cements of favourable grinding technological and quality features can be produced.

The support of OTKA (National Scientific Research Fund) No. T 14872 is gratefully acknowledged.

CEMENT CLINKER FORMATION FROM FLYASH BY MICROWAVE PROCESSING

Y. FANG, D.M. ROY, Y. CHEN, and M.R. SILSBEE
Materials Research Laboratory
The Pennsylvania State University, University Park, Pennsylvania 16802, U.S.A.

ABSTRACT Cement clinkers based on class F flyash have been prepared by microwave processing at temperatures up to 1350°C. For appropriate chemical compositions, CaO or $CaCO_3$ was the main additional component phase added to the raw material mixture. CaF_2 and $CaSO_4 \cdot 2H_2O$ were used as fluxes or mineralizers to lower processing temperature. The clinkers thereby obtained show compositions with similar phases present in commercial portland cement. Microwave processing is generally characterized by volumetric heating, high heating rate, and a short processing time; combined with considerably energy efficiency.

Keywords: clinker formation; waste material utilization; X-ray powder diffraction

INTRODUCTION

Flyash is a waste product of coal-burning power plants and is being produced in huge amounts. In the United States, for example, more than 70 million tons of flyash is produced each year. The accumulation of flyash not only consumes valuable landfill space, but also results in soil contamination. Because of this, proper disposal of flyash is of great concern, and making use of such a waste material is even more valuable for both environment protection and resource saving.

Flyash can be added to cement as an admixture to produce flyash cement. However, since flyash is mainly composed of hollow or solid glass spheres which generally only hydrate to a limited degree, the strength development of low calcium flyash cement is slow and the mechanical strength is lower than portland cement.

Flyash is mainly composed of SiO_2, Al_2O_3, Fe_2O_3, CaO, etc., similar to portland cements in composition, but different in proportion. By using appropriate correcting materials, it is possible to produce cement clinker based on flyash. Indeed, fly ash is commonly used as feedstock in many cement kilns. In this study, we prepared cement clinker using flyash as a basic material and microwave heating as the processing technique. Microwave processing is emerging as a new technique in ceramic fabrication and is generally characterized by volumetric heating, high heating rates, and short processing time, with a possibility of improvement in product properties. (Sutton, 1989) Among the various microwave processed ceramic materials is the portland cement clinker prepared by Quemeneur et al. (1983) and Fang et al. (1996). Roy et al. (1985) have shown that silica and alumina gels can be easily heated to high temperatures by microwave irradiation. This has been confirmed by Fang et al. (1996) in the study on microwave processing of diphasic aluminosilicate gels. Since glassy silica is the major constituent of flyash, it is expected that flyash can absorb microwaves fairly well and thus be easily heated by microwaves.

EXPERIMENTAL

Starting materials

Class F flyash (supplied by the American Fly Ash Co., Des Plaines, IL) as defined in ASTM C 618 was used as the main starting material. The chemical composition of the flyash is shown in Table 1, along with that of a typical Type III portland cement for comparison.

From Table 1, it is seen that the flyash was rich in SiO_2 but poor in CaO. To produce compositions suitable for cement clinker, CaO was added. Small amounts of CaF_2 and gypsum

($CaSO_4 \cdot 2H_2O$) were used as flux. Coal was added (5%) to the mixture for two reasons: (a) it is present in most commercial raw meals as fuel and, (b) it absorbs microwaves well and favors microwave heating.

Table 1 Chemical composition of the flyash (wt. %) and Type III cement

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O	SO_3	L.O.I
Flyash	53.0	18.6	15.6	6.37	1.26	0.94	2.08	2.02	1.68
Cement*	20.6	4.52	3.02	62.3	2.09	0.24	0.82	3.80	1.12

* Typical Type III, Lafarge Corp., Montreal, Canada.

The weight proportion of the raw mixture was flyash/CaO = 36/60. The amount of flux was CaF_2 = 1.93%, gypsum = 1.45%. Correspondingly, the factors (Tailor, 1990) used in cement industries for proportioning of raw meals, namely, lime saturation factor (LSF), alumina modulus (AM), and silica modulus (SM), are calculated as the following.

$$LSF = CaO / (1.2\ Al_2O_3 + 0.65\ Fe_2O_3 + 2.8\ SiO_2) = 0.97 \quad (1)$$

$$AM = Al_2O_3 / Fe_2O_3 = 1.19 \quad (2)$$

$$SM = SiO_2 / (Al_2O_3 + Fe_2O_3) = 1.55 \quad (3)$$

where each chemical formula represents the weight percentage of the corresponding composition in the mixture. Typical values of LSF, SM, and AM for commercial clinkers are 0.92-0.98, 2.0-3.0, and 1.0-4.0, respectively, depending on the desired properties of the product.

Flyash, CaO, fluxes and deionized water were mixed according to ASTM C 305, with a water/solid ratio of 0.15. The mixture was uniaxially pressed into pellets of 12.7 mm diameter and 5 mm thick. A small amount of water not only promotes development of appropriate green strength, but also favors microwave heating at low temperature since water absorbs microwaves very well.

Processing

The microwave processing was carried out in a 500 W, 2.45 GHz microwave oven (JE43, General Electric Co.). The details of the sintering setup and temperature measurement are described elsewhere.(Fang et al., 1994; Fang et al. 1996) The samples were heated in the microwave oven up to 1350°C and cooled down after a 10 min. soaking.

Characterization

Dilatometry was carried out with a computer-driven system (Innovative Thermal Systems, NY) at a heating rate of 5°C per min. on pure flyash as well as the flyash-based raw mixture in order to characterize the stages of reaction. Powder X-ray diffraction (XRD) was carried out on the clinkers using CuKα radiation on a Scintag x-ray diffractometer (Scintag Inc., Sunnyvale, CA). Calorimetry was conducted at 25°C to measure the heat evolution of the microwave processed clinker and the conventional sample (Type III portland cement) during the first 40 h of hydration. The microwave clinkers were ground with 3% gypsum before being investigated by isothermal hydration calorimetry.

RESULTS AND DISCUSSION

Figure 1 shows the dilatometry curves of (a) pure class F flyash and (b) the flyash-based clinker mixture. Shrinkage took place gradually in pure flyash from 700°C to 1194°C. The smooth and gradual shrinking curve indicates a process of reduction of inter-sphere pores due to necking between the flyash spheres. Above 1194°C, a sharp peak appears in the curve, corresponding to a volume increase and then decrease. This is believed to be a dilation process of the softened flyash spheres followed by collapse of the spheres, releasing the entrapped air. The linear shrinkage at 1200°C was

corresponding to the necking between flyash particles. There was no shrinkage between 950°C and 1120°C. Instead, a plateau appears in this range. This is believed to correspond to the occurrence of clinkering reactions. Above 1120°C. gradual shrinkage continued. There was no dilation near 1200°C as in the case of pure flyash. The total linear shrinkage till 1250°C was 17.5%.

Figure 2 shows the XRD patterns of the clinkers microwave processed for 10 min. at 1150, 1250, and 1350°C, respectively, compared with that of Type III portland cement (PC). The main phase compositions of the microwave processed clinkers were basically the same as PC, composed of alite ($3CaO{\cdot}SiO_2$, or C_3S) brownmillertite ($4CaO{\cdot}Al_2O_3{\cdot}Fe_2O_3$, or C_4AF) tricalcium aluminate ($3CaO{\cdot}Al_2O_3$, or C_3A), etc. The relative proportions of the components were different because of the differences in starting material as well as the processing conditions. In the microwave processed clinkers, the content of alite increased as processing temperature increased (C_3S is considered not to be formed stably below 1250°C, but here is observed as low as 1150°C. However, Gutt (1968) has observed that C_3S is formed at a lower temperature in the presence of fluoride, consistent with the current findings). The sample processed at 1350°C contained more alite than those processed at 1150 and 1250°C. The clinker processed at 1350°C shows very strong diffraction at 32.1° 2θ (d = 2.789Å), indicating that a preferential crystal growth of alite took place during microwave processing.

The hydration kinetics of microwave processed clinker showed that microwave clinker had a slower hydration rate and lower cumulative heat evolution than the commercial Type III PC sample. This was possibly due to the lower content of the main hydraulic minerals achieved in the short period of microwave processing. Additional studies should optimize the clinker and cement composition.

SUMMARY

Microwave processing of cement clinkers based on flyash has been carried out, and appears very promising. The preliminary results show that the phase compositions of the microwave processed clinkers are similar to that of industrial portland cement. Due to insufficient clinkering time, the current microwave processed flyash cement shows slower hydration rate and lower heat evolution which could be improved by optimizing the processing conditions and cement composition.

CLINKER FORMATION IN HIGH-SILICATE LOW-TEMPERATURE MELT

Vladimir D. BARBANYAGRE, The Belgorod Technological Academy of Building Materials, Belgorod, Russia

ABSTRACT Exclusively technological methods have been studied and offered. Due to the involvement of a larger quantity of silica into clinker melt, these methods allow to reduce considerably melt formation temperature and clinker sintering temperature without using catalytic admixtures and low-melting fluxes.
CLINKER FORMATION, MELT, NONEQUILIBRIUM BURNING

INTRODUCTION

The main chemical and physical processes occurring during portland cement clinker sintering are determined by the constitutional diagram of CaO-SiO_2-Al_2O_3-Fe_2O_3 (C-S-A-F) system, as well as ternary and binary constitutional diagrams. However, in view of the fact that the diagrams describe an equilibrium state of the system, and the clinker sintering process is known to be nonequilibrium, the phase composition of clinker may differ considerably from the state of equilibrium described more completely for cooling process. Depending upon cooling rate the phase composition of clinker may be represented either by glass, or by crystalline phases or by mixtures crystalline and glass-like phases.

Unlike clinker cooling processes, nonequilibrium processes related to the heating of a raw mix are not studied properly. Meanwhile, as will be shown in the present paper, under heating very great changes in the quantity of clinker melt, its composition, viscosity and other properties upon which clinker sintering depends may take place. The main result of these changes is a degree of deviation of the mix from a state of equilibrium. Three methods of creating a state of nonequilibrium in the process of cement raw mix heating are considered.

Fast Heating of a Raw Mix

It has been established that the heating rate of the materials may exceed the rate of chemical reaction under fast burning when the raw mix enters a high-temperature zone. As a result original compounds, in the form of low-basicity calcium silicates, aluminate and ferrites, form a high-silicate melt having the composition given in Table 1. Pseudowollastonite and iron bearing melilite are a specific feature of the above melt. Then clinker minerals are formed by means of this melt. Thus, the well-known intensification of clinker sintering processes under the fast burning results partially from time-simultaneous dissociation processes of original compounds and synthesis processes of minerals (Chebukov, 1950). The main reason for the said intensification is the formation of a high-silicate, low-basicity melt.

Cement raw mix with a coarse ground carbonate component

High-silicate, low-temperature melt with the composition similar to that given in Table 1 is formed during the burning of the raw mix with a coarse ground calcium carbonate. Because of the large size of calcium oxide grains, a part of the material (30-35%) concentrated in the centre of coarse grains is temporary withdrawn from the reaction and, as a result, the synthesized compounds have

low basicity and at appropriate temperature (1130 - 1200 °C) they form a high-silicate melt.

The quantity of the melt depends upon a grain composition of the carbonate component and can reach 40 - 50 % of clinker weight. The X-ray phase analysis and the density measurements of granules burnt at different temperatures confirm this. Melt formation at low temperatures increases the effective length of the sintering zone of a rotary kiln. The appropriate increase in the kiln productivity is achieved when a grain composition of a carbonate component is optimal; positive results of using coarse grinding of raw mixes were obtained at cement plants of Russia and CIS countries. These results, according to the present paper, are substantiated theoretically. It should be pointed out that a positive effect obtained due to coarse grinding was explained earlier by exclusively thermotechnical factors, and, in particular, as though thermal power were in excess in the combustion zone of a rotary kiln.

Method of two-batch technology

The main point of this method is that an original raw mix is prepared from two batches which are heated seperately up to a definite temperature, then both the batches in a hot state are mixed and burnt till they sinter at 1300 - 1350 °C (Barbanyagre et al., 1981). The most simple method of calculation of both batch compositions is done by partial withdrawal of a carbonate component from the cement raw mix in the form of an independent batch. Thus, the remaining part of the batch acquires the composition which promotes the production of low-temperature melt with the required composition and properties (Table 1).

Table 1. Low-temperature melt used in two-batch technology.

Sl. No.	Composition of oxides, weight %				Moduli			Melting temperature, °C
	SiO_2	Al_2O_3	Fe_2O_3	CaO	KH*	$\frac{S}{A+F}$	$\frac{A}{F}$	
1	41.53	13.51	9.71	35.25	0.082	1.79	1.39	1135
2	40.21	13.07	9.47	37.25	0.11	1.78	1.38	1170
3	46.28	9.66	5.49	38.57	0.16	3.05	1.76	1205
4	44.74	9.34	5.20	40.72	0.19	3.08	1.80	1220
5	40.68	8.55	6.96	43.81	0.24	2.62	1.23	1235
6	47.83	9.97	9.06	33.14	0.10	2.51	1.10	1200

* $KH = \frac{CaO - 1.65Al_2O_3 - 0.35Fe_2O_3}{2.8SiO_2}$

Thus, the preparation of the mix from two batches makes it possible to obtain a batch with low basicity and minimum melting temperature (1130 - 1220 °C). Due to the use of the whole amount of silica and additional quantity of calcium oxide in the melt, the amount of such melt increases to 50 - 60 % of the whole batch. Unlike the common clinker melt, the melt produced by the two-batch technology contains 5 - 6 times more silica and but only half as much calcium oxide. Its melting temperature is 150 - 200 °C less. All these features characterize it as high-silicate, low-basicity and low-temperature melt. The compound composition of crystallized high-silicate melt includes generally iron-

containing solid solutions of melilite and pseudowollastonite. The advantage of such melt can be shown by way of an example of the burning of a cement raw mix, the initial composition of which is characterized by the following data: Fe_2O_3 = 2,75%; A/F = 1.30; S/(A+F) = 2.20; KH = 0.92; CO_2 = 35,1% (Table 2).

Table 2. The free lime content (%) in a raw mix burnt at a temperature (^{0}C):

A mehtod of burning	1200	1250	1300	1350
Existing technology	41.27	30.34	67.84	1.55
Two-batch technology	17.00	16.69	3.87	0.38

At cement plants the two-batch technology is implemented, for example, by the method of two-side feeding of a rotary kiln. A carbonate batch is fed to the cold end of the kiln and a fusible batch is blown by compressed air into the combustion zone of the kiln through the pipe above the torch. So the whole reaction does not proceed in the solid state, as it occurs as in ordinary technology, but the melt takes part in these reactions and, therefore, synthesis of clinker minerals finishes at 1300 °C, that is 100 - 150 °C lower in comparison with the conventional method of burning. Clinkers produced by the two-batch technology are distinguished by having fine crystals and have a higher hydraulic activity (more than 12 - 15%) because of their less recrystallization.

The use of a two-batch technology saves 7 -8 % of fuel relative to dry process clinker burning and 20 % relative to a wet process kiln (Barbanyagre et al., 1988). However, the feeding of larger amounts of material into the hot end of a rotary kiln requires additional design concepts.

PROSPECTS

A four-component constitutional diagram of C-S-A-F system is of great importance for theory and practice of cement production. But this diagram is studied only partially. Some $C_{12}A_7$-C_2S-C_4AF and C-C_2S-C_4AF sections in the inner part of triangular pyramid as well as in the limited volume of a part of the elementary C_3S-C_3A-C_4AF-C_2S tetrahedra were studied by Lea and Parker. In addition, C_3S-C_3A-C_2S sections were studied at different values of C_4AF (Lea and Parker, 1934).

However, the results of the research show that due to non-stationary conditions and the use of two-batch technology fusible melts are formed, the compositions of which are not studied in the system mentioned above. So it is necessary to examine these areas of C-S-A-F diagram that are not properly studied in chemistry and technology of cement, namely:

- areas with the increased (25% SiO_2) content of silica (high-silica compositions);
- areas with the increased (10% Fe_2O_3) content of iron oxide;
- areas with the increased (15% Al_2O_3) content of aluminium oxide (high-aluminate compositions).

Papers (Barbanyagre, 1981, 1984, 1988, 1991, 1992, 1993) begin researches in this trend. The detailed examination of the above compositions allows development of physico-chemical principles and new techniques and the selection of the compositions of special cements.

CONCLUSIONS

1. Non-stationary technological methods were developed. They allow production of low-temperature melts while burning a cement raw mix with a common composition:
   - a two-batch technology method;
   - a special grading composition of a cement raw mix;
   - the rapid burning of a raw mix.

Low-temperature, high-silicate melts of the above composition accelerate considerably the synthesis of clinker minerals and decrease the temperature of portland cement clinker sintering up to 1300 °C with certain fuel saving because of the reduction in heat losses.

RESEARCH ON THE MECHANISM OF FORMING COATING AND CLINKER MASS IN PRECALCINER KILN SYSTEM

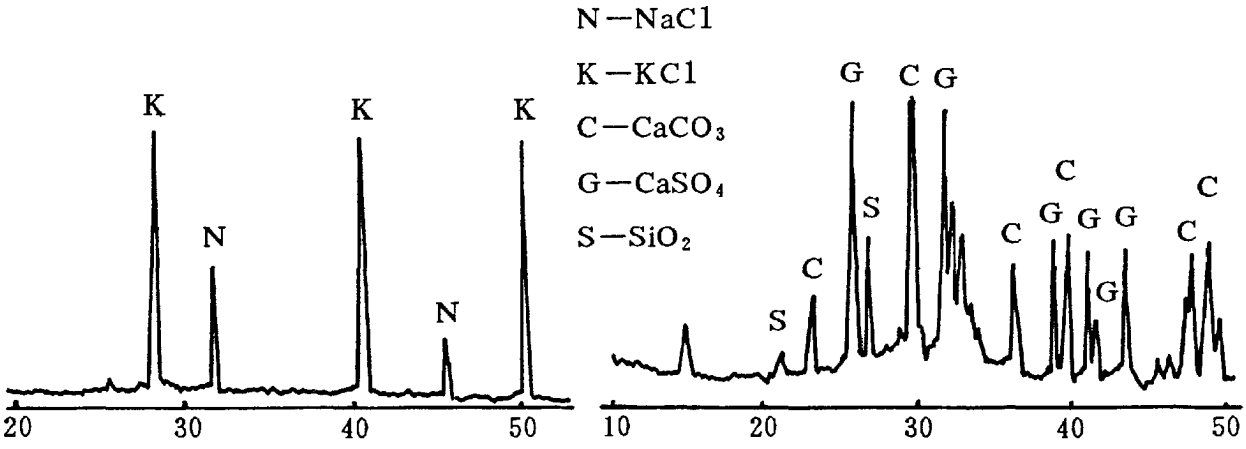
SHI Huisheng, Mater. Sci. & Eng. Dept., Tongji Uni., Shanghai 200092, P. R. China
LU Chunxuan, China Building Materials Academy, Beijing 100024, P. R. China

ABSTRACT The authors have made a study on two kinds of uncommon coatings in suspension preheater and large clinker lumps in the precalciner kiln. The mechanism of forming these coatings and clinker mass in precalciner kiln system has been discussed, and the precautionary measures have been proposed in this paper.

Key-words: Alkali, Chloride, Calcium sulfate, Melt, Temperature

INTRODUCTION

In the manufacture of portland cement clinker the kiln feed and fuel generally contain some minor constituents that are volatile in nature. These are essentially compounds of potassium, sodium, sulfur and chlorine. Unlike the nonvolatile oxides, these constituents occur in the vapour phase as well as in the condensed phases. Because of this dual role, these constituents may cycle and enrich in precalciner kiln system, which can affact kiln operation and product quality. In this paper, effects of these constituents on the formation of uncommon coatings and clinker mass in the precalciner kiln system of XJ cement works have been studied.



ANALYSIS AND DISCUSSION

Formation of coating

Coating is often formed in preheating system of preheater kilns and precalciner kilns. The characteristic minerals such as $2CaSO_4 \cdot K_2SO_4$, $2C_2S \cdot CaCO_3$, $2C_2S \cdot CaSO_4$, $Ca_{10}[(SiO_4)_2(SO_4)_2](OH^-, Cl^-, F^-)$, quadratic $CaSO_4$, KCl and $3CA \cdot CaSO_4$ are likely to form and act as solid and/or liquid bonds binding raw minerals ($CaCO_3$ and SiO_2) and clinker minerals (CaO, C_2S, $C_2(A,F)$, etc.), which results in the formation of coating. Thus, coating is formed together with these characteristic minerals and disappears after they have decomposed. Surely alkali and sulfur constitute them directly. Chlorine promotes their formation and enters into them also (Lu et al., 1993).

In addition to the coatings generally formed in many precalciner kilns, a coating formed in the surface of refractory at the passage from 1-stage preheater to precalciner is discovered in the kiln of XJ cement works. The coating consists of almost pure KCl and NaCl, which is yellow crystals like salt. Severe alkali attacks have occured in the refractory there. Besides, there is another coating in the horizontal air pipe connecting the upper two preheaters. The coating is a hardened cementing mix which consists of quadratic calcium sulfate and raw feed such as $CaCO_3$, SiO_2 and etc.. Its formation and growth cause air resistance to increase greatly, so that the pipe has to be renewed after only

used for a few months.

(a) in passage (b) in air pipe

Figure 1 XRD of uncommon coatings in precalciner kiln system

Table 1 Contents of R_2O, SO_3 and Cl^- in kiln charge (%)

Sample	K_2O	Na_2O	SO_3	Cl^-
Raw feed	0.81	0.47	0.57	0.011
4-stage preheater charge	1.04	0.42	0.54	0.163
3-stage preheater charge	0.79	0.31	0.58	0.236
2-stage preheater charge	1.48	0.60	1.06	0.437
1-stage preheater charge	2.13	0.58	1.38	0.573

From Table 1, it can be seen that all the volatile constituents enriched in kiln charges at various parts to some extent, especially the content of Cl^- in 1-stage preheater charge is much more than that in raw feed. Once the surface temperature of kiln charge and/or refractory are lower than the melting point of alkali chlorides, which can condense there. As a result of unstable thermal conditions the temperature often goes up and down, which cause the alkali chlorides in coating to melt or crystallize over and over again, leading to the formation of pure crystal.

If alkalies are present together with SO_3, alkali sulfates are first formed. Any excess SO_3 may react with CaO to form $CaSO_4$. So the molar ratio of SO_3 to total alkali oxides generally is controlled lower than unity in works. However, even though the molar ratio is lower than unity in raw feed and fuel, because of the enrichment of volatile constituents in kiln system and alkali first reacting with chlorine, the corrected molar ratio is much more than unity in the upper preheater charges, so that the quadratic $CaSO_4$ can be formed. The frequent shut-down of kiln facilitates the formation of this coating in the air pipe.

Formation of clinker mass

In order to avoid forming coating in preheater, XJ cement works intentionally controls

the temperature of kiln gas at kiln inlet below 980℃. As a result, the apparent decomposition rate of hot charge entering the kiln is only 80% and decomposition continues in the back end part of kiln. The partial pressures of CO_2, SO_3, R_2O and Cl^- in the kiln gas increase considerablly and some characteristic minerals mentioned above are formed continuously, so that kiln charge can coagulate into lump there. Sometimes the clinker lump has a diameter over one meter, which makes the kiln has to be shut-down. Large clinker lumps left the kiln contain R_2O and SO_3, especially Cl^- higher than the normal sized clinker does.

Table 2 Composition of charges in precalciner kiln of XJ cement works

From kiln inlet (m)	Sample feature	Contents (%)				Characteristic minerals				Clinker mineral	Raw minerals	
		K_2O	Na_2O	SO_3	Cl^-	KCl	$2C_2S \cdot caCO_3$	$2C_2S \cdot CaSO_4$	$2CaSO_4 \cdot K_2SO_4$	C_2S	$CaCO_3$	SiO_2
8.7	lump	4.10	0.74	9.35	3.96	###	###	###	###	###	+	-
	powder	2.39	0.54	2.20	0.84	##	##	-	-	###	###	###
11.6	lump	3.58	0.72	7.16	3.04	###	###	###	###	###	+	-
	powder	2.29	0.46	2.19	0.84	##	##	-	-	###	###	###
23.2	lump	3.12	0.61	2.99	2.41	###	###	###	###	###	+	-
	powder	2.48	0.50	2.76	0.77	##	##	-	-	####	###	-

Note: + very few, ## few, ### medium, #### much

Table 3 Contents of R_2O, SO_3 and Cl^- in different sized clinkers (%)

Sample	K_2O	Na_2O	SO_3	Cl^-
Center of clinker lump	1.26	0.55	0.79	0.130
Surface of clinker lump	1.20	0.48	0.72	0.087
Normal sized clinker	0.74	0.35	0.65	0.006

Obviously, the mechanism of formation of clinker mass is same as that of coating, i.e., the contents of volatile constituents in local part of kiln charge at certain time are too much, which leads to forming large amounts of characteristic minerals and then causing the formation of coating or clinker mass. The only difference is the position formed, in preheating system or in rotary kiln.

Precautionary measures

Therefore, the fundamental way to restrain and eliminate coating and lump formation is to control the amount of volatile constituents of any local part of kiln charge at any condition not to be excessive. Moreover, the kiln dust must be homogeneously blended into raw meal before it is returned back into the kiln. The times of shut-down of the precalciner kiln must be cut down as low as possible in order to reduce the amount of volatile constituents condensed onto the kiln charge and wall of kiln system. As for the specific conditions in the precalciner kiln of XJ cement works, coating-resistant and alkali-refractory lining accompanied by airblast device should be used to restrain coating formation. The temperature of flue gas at the inlet end of rotary kiln should be increased to more than 1000℃, so that the apparent decomposition rate of hot charge en-

tering the rotary kiln will be raised to 90-95%. Thus the possibility of lump formation will be eliminated. If necessary, the bypass device can be used.

CONCLUSION

The mechanism of formation of clinker mass is same as that of coating in precalciner kiln system. The contents of volatile constituents in local part of kiln charge at certain time are too much, which leads to forming large amounts of characteristic minerals and then causing the formation of coating or clinker mass.

Whether the quadratic calcium sulfate and alkali chlorides are formed relates to the contents of sulfur, alkalies and chlorine, not only in raw feed and fuel, but also in local part of kiln charge.

Designing technological processes correctly and making thermal conditions stable are the key to preventing the formation of coating and clinker mass in precalciner kiln system.

ENERGY-SAVING TECHNOLOGY OF CEMENT PRODUCTION BY MEANS OF COMBINED GRINDING OF CLINKERS OF VARIABLE COMPOSITIONS

Leonid Ya. GOLDSTEIN, AOOT "Giprocement", St. Petersburg, Russia

ABSTRACT The energy saving problem has always been and retains urgent for the cement technology. One of directions of tackling this problem important both in the scientific and practical respects is production and use of clinkers with lower lime content (lower basicity) which are burnt at a comparatively low specific fuel consumption. However, in this case it turns out to be very difficult to maintain the strength characteristics of cement at the wanted level.

The findings of the research and pilot-production works conducted at AO "Giprocement" allow one to suggest an optimal process at which using the energy-saving technology it is possible not only to maintain, but to increase the strength characteristics of cement. First of all at the early hardening ages.

Key-words: interground cement, fuels for clinker making, economy

INTRODUCTION

The data on the fact that clinkers of variable mineral compositions, in particular, of alite and belite one, differ greatly in their grindability are a matter of common knowledge. Many authors were engaged in these problems, among them Koryakin et al in Russia, or more exactly, in the former Soviet Union.

Clearly such clinkers when ground to closely related finenesses are characterized by a variable grain-size distribution (considerably differing grain composition). This property as demonstrated by investigations made, for example, at the institute of NIITsement (Kravchenko et al, 1967) can be used to improve the strength characteristics of cement. So, the authors mentioned above have suggested a method of manufacture of an early-strength cement by means of mixing 30-40% cement containing more than 60% C_3S and more than 5% C_3A with 70-60% cement containing no more than 50% C_3S and no more than 8% C_3A.

Of great interest from the point of view of increase in the strength characteristics of cement is the use of the other method - of the combined grinding of clinkers of a variable composition. Such attempts have been also taken as evidenced, for example, by patents of Austria. But in this case the clinker of the ordinary (normal) portland cement composition was ground together with the other clinker (sinter) characterized by a very low, uncommon value of the lime saturation factor, KH, according to V.A. Kind. So, the patents of Austria mentioned protected the method of production of cement through combined grinding of clinker of the ordinary composition (KST according to H. Kuehl is more than 90*, KH according to V.A. Kind is more than 0.85*) and of another clinker obtained

---

* It should be pointed out that the values of KST (lime standard) were calculated by the formula:

in sintering at a temperature of 700-1100^{0}C characterized by KH in the range from 0.77 to 0.35 (KST = 85 ÷ 50). It was even recommended to use a sinter with KST = 10-15 which corresponds to negative KH values (so, this sinter represented not a clinker, but is essentially a high-lime (high-basic) slag). The grave disadvantage of the method suggested was the reduction of the strength characteristics of cement at all hardening ages as compared with the ordinary initial cement of the portland cement composition.

Another way has been suggested at AO "Giprocement": a combined grinding of two portland cement clinkers - one of the normal composition (manufactured usually at cement plants) and another one characterized by a well-defined belite composition. We started therewith from the real possibilty of obtaining low-lime (low-basic) clinkers with the use of the equipment available at cement plants considering that production of clinkers (sinters) with very low KH values (of high-lime (high-basic) slag type) in present-day burning units may turn out to be difficult and in some cases even impossible. Here it is worth noting that even preliminary studies showed that at combined grinding of clinkers of a variable composition (first of all, differing in KH values)higher strength characteristics of cement can be obtained as against the corresponding characteristics of cements produced through mixing of the same clinkers preground. The latter cement production process is unlikely to be considered as promising, even though the problem of difficulty of the thorough mixing of cement powders under production conditions is not touched on which is solved easy at the combined grinding of clinkers of a variable composition.

On the basis of the above reasoning, the main object of the experimental works was to determine a possibility and conditions of increase in the strength characteristics of cement by means of the combined grinding of clinkers of a variable composition. It seemed that of the greatest interest was to study the influence of KH value (alite-to-belite ratio) on the process of grinding clinkers ground together and strength characteristics of cements because of variations in their grain-size distribution (grain composition).

RESULTS OF THE EXPERIMENTAL WORKS

The programme of the first experiments carried out at the pilot-production plant of the institute of "Giprocement" provided for obtaining several clinkers of a variable composition (Table 1) with the use of traditional raw materials (limestone, clay, correction additives). The pelletized raw mixes were burnt by the dry process in a small rotary kiln measuring 0.5 x 7.0 m. The clinkers with KH values varying within wide limits were ground in different

---

$$KST = \frac{100 \times \%CaO}{2.8 \times \%SiO_2 + 1.65 \times \%Al_2O_3 + 0.35 \times \%Fe_2O_3}$$

and the KH values - with the formula of V.A. Kind

$$KH = \frac{\%\ CaO_{total} - \%CaO_{free} - 1.65\ \%Al_2O_3 - 0.35\ \%Fe_2O_3 - 0.7\ \%SO_3}{2.8\ (\ \%SiO_{2\ total} - \%SiO_{2\ free}\ )}$$

as is customary in the cement industry of Russia.

ratios in a laboratory mill in two stages: at first - by balls up to a residue of 33-35% on the No. 008 sieve and then - by cylpebs up to the specific surface of 300 m^2/kg.

Table 1 Results of study of cements obtained under pilot conditions (at the pilot-production plant of the institute of "Giprocement")

Proporiton of clinkers with KH, %				Mineral composition, %		Ultimate strength, MPa				Specific power consumption for grinding, kWh /t cement

The results of the standard physical-and-mechanical tests and grindability characteristics (Table 1) showed that it is expedient to be oriented towards the combined grinding of clinkers with the most differing KH values by two reasons. In the first place, this results in a possibility to improve the strength characteristics of cement to the greatest extent, and second, to avoid a marked increase in the specific power consumption for grinding of clinkers. Moreover, it is obvious that production of one clinker with the KH value as low as possible will lead to the maximum reduction of the specific heat consumption (fuel saving) for clinker burning as well as to increase in the kiln unit output (on account of the reduction of the carbonaceous component content of the raw mix).

The first short-run production experiment has been carried out at one cement plant of the Russian Federation using as a carbonaceous component the marble-like limestone with a higher magnesium oxide content (the MgO content of clinkers was 5.1 - 5.4%). The clinkers were burnt in a ø 4.0 x 3.5 x 4.0 x 150 m rotary kiln. When burning the low-lime (low-basic) clinker the process fuel consumption was reduced by about 10 - 12%. The results of the standard physical-and-mechanical tests of cements (Table 2) obtained at combined grinding of the low-lime and ordinary clinkers were not in contraduction with those obtained when conducting pilot-production experiments (Table 1). It should be pointed out that the maximum gain in the cement strength at the combined grinding of clinkers was obtained here (with the low-lime clinker content of the mix under 50%). It may be suggested that the chemical-and-mineral features

of raw materials (probable influence of admixtures, e.g. MgO, on viscosity characteristics of the clinker melt and hence on the clinker misrostructure) have a pronounced effect on the cement strength gain value.

The longer and thorough experimental works under production conditions have been performed at one of the cement plants of the Russian Federation using as one of the basic raw material components the alumina production waste - the nepheline (belite) slurry consisting of β-C_2S for 70-75% on the average. It is well known that such cement plants while operate by the wet production process are characterized by a very low specific fuel consumption for the clinker burning. In spite of it, when burning the low-lime raw slurry with KH = 0.77-0.79 the reduction of the specific fuel consumption of more than 9% was fixed and the kiln cutput increase of 2.5% as well. The burning was executed in a ø 3.6 x 60 m rotary kiln with a slurry thickener for 2 days. The combined grinding of clinkers was also performed during 2 days in a cement mill measuring 2.4 x 13 m. The cement samples were taken at the same time from a cement mill of the same type where only the ordinary clinker was ground. The results of the standard physical-and-mechanical tests given in Tables 3-4 supported the data obtained earlier and further indicated that the greatest gain in the cement strength could be expected at the very early hardening times, e.g. at the age of 1 day. As is generally known, this is particularly important for the construction.

Table 3 Results of tests of physical properties of cements obtained under production conditions

Attempts have been undertaken of comparison studies of the grain-size distribution of the representative samples of cement taken both when grinding under production conditions of the clinker mix and of the ordinary portland cement clinker used for preparation of the clinker mix. The studies were conducted with the help of the "Granulometer - 715" device produced by a French company. The operation principle of this device is based on the dispersion of the light beam leaving the low-power helium-neon laser and crossing the sample of the material to be analyzed suspended in a fluid. As the working fluid use was made of the ethyl alcohol.

The results of the determinations presented in Fig 1 allow to make a conclusion that there are noticeable differences between the grain-size distributions of cements obtained under the combined grinding of clinkers with variable KH values and cement produced when grinding clinker of the ordinary composition. First and foremost, attention is drawn to the fact that cements obtained at the combined grinding of clinkers are characterized by a rather higher content of the finest fractions of the grain composition (from 0 to 6 μm - almost twice - thrice as much). So, the higher strength characteristics of such cements in comparison with the ordinary portland cement become clear and quite explicable. Noteworthy also is the more uniform, relatively smoothly varying by fractions, grain composition of cement obtained through the combined grinding of clinkers.

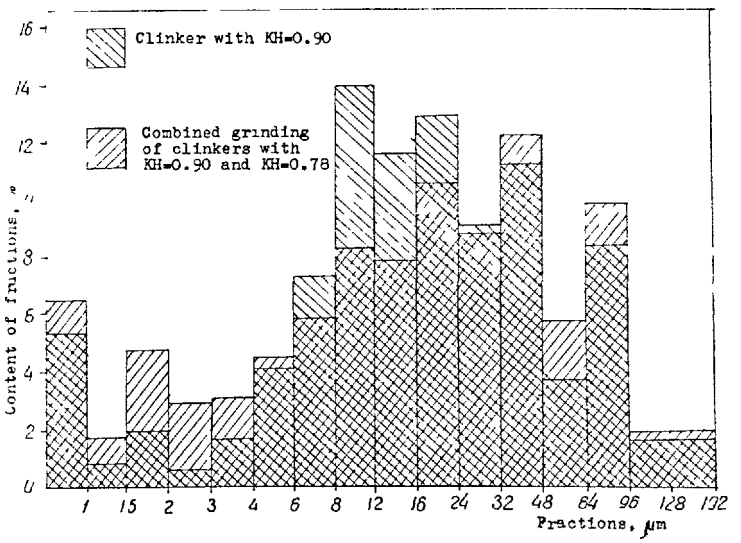

Figure 1 The grain-size distribution of cements

Thus, the data presented convincingly lead to the conclusion that at the combined grinding of materials characterized by variable grindability degrees favourable conditions are set up for both grinding process itself and for properties of the product obtained. The author shares the opinion of some researchers (e.g. Osokin et al, 1983) on a possible influence of the mechanoactivation process of materials ground simultaneously. It is well known that the effect of this process can show itself not only in the increase of their dispersity, but also in the structural variations of the surface layer making for increase in the reactivity of the disperse systems.

CONCLUSIONS

The data presented point, in the author's opinion, to the greatest promise of the suggested process making it possible to improve the most important characteristics of cement in addition to the energy saving. It should be noted that the properties of cements produced through the combined grinding of clinkers of a variable composition can be influenced by many factors which are to be refined to fit the particular conditions. These factors may include the production process (wet or dry) and the associated features of the clinker structure, particularly, of their pore content) as well as the presence in the raw materials of minor components, e.g. MgO, and trace elements and so on. It is also worthy to note that to achieve the best results consideration must be given to not only silicate but also to aluminate and alumoferrite phases ratio. Such data have been obtained at AO "Giprocement" recently.

Low energy clinker formation

MELT STRUCTURE AND PROPERTIES CLINKERS CONTAINING CALCIUM SULPHOFERRITES AND SULPHOALUMOFERRITES

OSOKIN A.P., KRIVOBORODOV Y.R., SAMCHENKO S.V.,
Research Technical Centre of JSC "Alfa Cement",
Mendeleev Chemical Technology University
of Russia, Moscow, Russia

ABSTRACT Calcium aluminoferrites of compositions C_6AF_2, C_4AF, C_6A_2F, pure or contained calcium sulfate, were synthesized by sintering and melting. Melt properties (viscosity and surface tension) of sulphoferrite and sulphoalumoferrite clinkers were studied. The connection between melt properties and their structure was shown. A new type of clinker was obtained consisting of calcium ferrite phases with minor amounts of a sulfate and silica phase.

KEY-WORDS: Solid solution, sulphoaluminoferrite, structure, melt, viscosity.

INTRODUCTION

At present aluminate and sulphoaluminate cements have wide application due to their rapid hardening and high strength. The use of these cements provide the high tightness, low water permeability and crack resistance concrete (Kouznetsova, 1986). Besides special cements based on calcium sulphoferrite are very useful thanks their chemical corrosion resistance (Osokin et al, 1992).

Much interest exists concerning alite-containing sulphoaluminoferrite clinkers, which consist of calcium silicates, which are responsible for strength, and sulphoaluminoferrites, as an expansive agent (Krivoborodov, Samchenko, 1992). This paper deals with the properties of sulphoaluminoferrite cements.

Upon burning raw mixes containing high quantities of gypsum, calcium sulphoferrite and sulphoaluminoferrite formation proceeds in the presence of the sulphate ferrosilicate and alumoferrosilicate melts. Regulation of the properties of these melts allows reduction in energy consumption.

EXPERIMENTAL

Sample preparation

Using chemical reagents, calcium sulfoaluminoferrites were prepared by sintering and melting. Raw mixes were calculated so as to produce aluminoferrites with calcium sulfate. Samples were

prepared by pressure molding (50 MPa) blended mixes with a sintering temperature of 1300 °C and a melt temperature of 1700 °C.

Aluminoferrite and sulphoaluminoferrite clinkers were produced in an experimental rotary kiln using natural raw materials (limestone, bauxite, clay, and gypsum) and a burning temperature of 1350 °C ±50 °C. The raw mixes were calculated to obtain calcium alumoferrite, sulphoferrite, and belite.

The melt region of sulphoferrite and sulphoalumoferrite clinkers is found in the phase diagrams of the systems $CaO-Fe_2O_3-SiO_2$ and $CaO-Al_2O_3-Fe_2O_3-SiO_2$ in its high iron content part as differentiated from sulphoferrite clinkers in which Al_2O_3 is limited to 4-5%; in sulphoaluminoferrite clinkers, it plays the role of a mineral formating oxide.

Calcium sulphate was used as mineralizer and it formed solid solutions with the ferrite phase. The crystallization path of the choosen clinker compositions passes through the invariant points corresponding to the compositions forming in actual practice from melts. In the high iron content part of diagram $CaO-Al_2O_3-Fe_2O_3-SiO_2$, melt is formed at 1623 K; according to (Berezhnoy, 1970) it has the composition 49.6% CaO; 6.5% SiO_2; 17.1% Al_2O_3; 26.8% Fe_2O_3 (melt 1). In the system $CaO-Fe_2O_3-SiO_2$, melt composition is characterized by follow oxide contents: 29% CaO; 5% SiO_2; 66% Fe_2O_3 (melt 2) the liquidus temperature of which is 1463 K (Levin et al, 1964).

Analytical methods

Chemical analysis, infrared spectroscopy (IR), optical microscopy (OM), X-ray powder diffraction (XRD), and scanning electron microscopy (SEM)of polished sections were used to characterize the samples. Each clinker was vacuum-impregnated with an ultra-low viscosity resin, cut to expose a fresh surface, and polished with a series of diamond pastes to 0.25 μm. About 10 nm of carbon was evaporated on the polished surface providing a conductive layer necessary for SEM examination. Samples were examined using an accelerating voltage of 15 kV and a probe current of about 2nA.

The persistence of silicate melts to temperature below that of the solidus and their ability to form glass phase at fast cooling allows us to study melt structures by IRS.

Melt viscosity was determined by rotary viscosimetry, surface tension was studied by method of maximum pressure in gas bubble. Raw mixes according to the compositions of melts 1 and 2 were melted at above liquidus temperature. Minor compounds were added into to melt just prior to measuring the melt properties. After determination, melt samples were fast cooling and the glass state was determined controlled by microscopic analysis.

RESULTS AND DISCUSSION

According to IRS, cooled melts consist of silicon-oxygen SiO_4^{4-} (absorption spectral band 800-980 cm^{-1}) and more polymerized silicon tetrahedra (absorption waves are in the region of 1050-1080 cm^{-1}).

Aluminium and iron ions (Fig.1, 2) are both in IV and VI coordination forms (absorption waves are 400 cm^{-1}, and 500-600 cm^{-1}, respectively).

At clinker burning all minor components enter into the melt composition and change the structure and properties of the melt. The impact of some components on melt structure and properties is collectively more complicated than of individual components. Melt saturated by aluminium and iron oxides has an alumina ratio, AR=0.64. Addition of 6% Al_2O_3 to melts 1 and 2 leads to the change of melt structure and to the displacement of IR - spectrum absorptions from 1050 cm^{-1} to 1070 cm^{-1}. It means that aluminium ions enter into silicon-oxygen parts of the melt and partly into alumino-silicate compounds. In this case, the alumina ratio (AR) of melt 1 increases to 0.9. This small change of melt structure leads to insignificant changes in viscosity, from 0.05 Pa·s to 0.02 Pa·s for melt 2. The viscosity change as a function of Al_2O_3 is a linear function (Fig.3). As AR of the melt decreases from 1 to 0.4 viscosity decreases to 0.01 Pa·s. Such rate of the viscosity decrease is explained by melt structure change. The reduction of the absorption band intensity 1080 cm^{-1} shows that aluminium and iron ions are significantly in VI coordination, as AlO_6^{9-} and FeO_6^{9-}, which are more mobile and promote the intensive viscous flow of melt.

In the melt, calcium sulphate is decomposed to Ca^{2+} and SO_4^{2-} ions and depolymerize silicon-oxygen complexes. Ca^{2+} ions form silicate structures although polymerized silicate and aluminoferrosilicate complexes also occur in the melt. SO_4^{2-} ions displace the dynamic equilibrium between the different coordination forms of amphoteric oxides to the formation of FeO_6^{9-} and AlO_6^{9-}. This is confirmed by IRS data; absorption wave intensity increases in the region of 500-600 cm^{-1}. Melt 1 and 2 viscosities are 0.015 Pa·s and 0.012 Pa·s, respectively.

5% calcium sulphate addition to the melts appreciably reduces melt viscosity but further increases do not change melt properties.

MgO reduces melt viscosity most of all (Fig.3). By analogy with Ca^{2+}, Mg^{2+} ions depolymerizes melt,entering between tetrahedrons SiO_4^{4-}, although at the same time there are polymerized alumoferro-silicate complexes.

The joint action of minor components and calcium sulphate in melt 2 influences acid-base equilibrium in the melt. The increase of the absorption wave intensity in the region of 580-

600 cm^{-1}, the absence of the absorption wave 1070 cm^{-1}, typical for Si-O bond in ferrosilicates shows that aluminium oxide affects acid-base equilibrium. The increase Ca-O bonds with silicon-oxygen tetrahedra in melt compensates the depolymerisation action of MgO on melt structure.

The joint action of calcium sulphate and MgO on the structure and properties of melt 1 is complicated and can be explained by two types of action. Firstly, it influence the depolymerization of aluminoferrite complexes, secondly, the acid-base equilibrium $[MeO_4]^{5-} \rightleftarrows [MeO_6]^{9-}$, where Me - Al^{3+} and Fe^{3+}-ions, is displaced to $[MeO_6]^{9-}$, which are more mobile and promote the decrease of the viscosity.

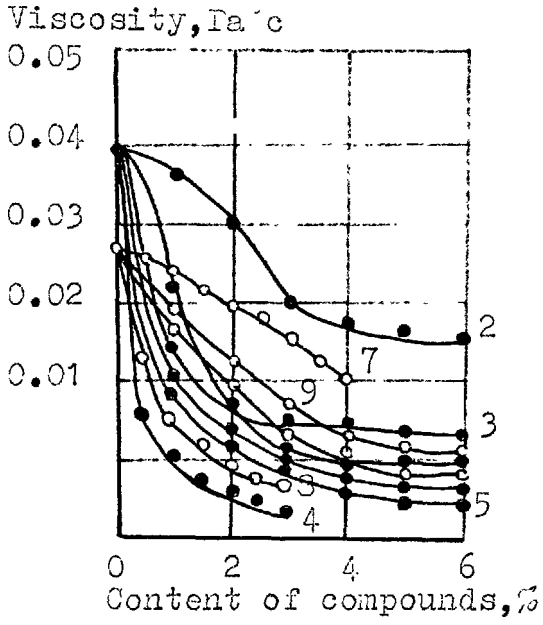

Fig.3 Isothermic lines of viscosity of melt 1 (T=1623 K) and melt 2 (T=1493 K). Some compounds are dissolved in the melts: 1-6 — melt 1, AR=0.64; $CaSO_4$; MgO; $CaSO_4$ and MgO.
7-10 — melt 2 with Al_2O_3; MgO; $CaSO_4$, Al_2O_3+MgO+$CaSO_4$

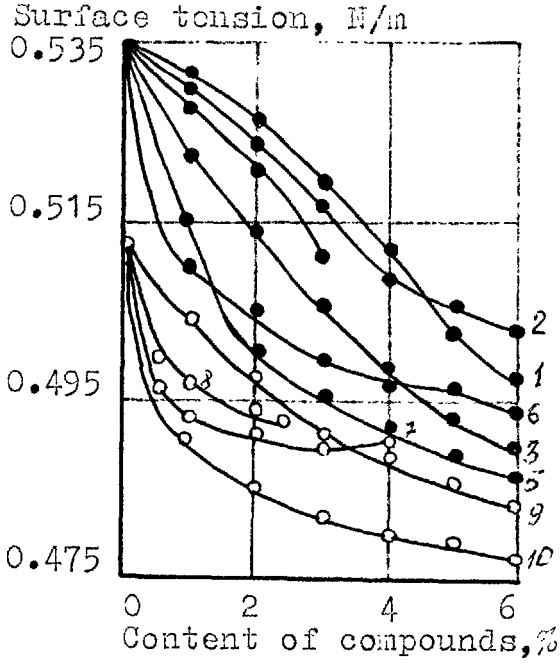

Fig.4 Isothermic lines of surface tension of melt 1 (T=1623 K) and melt 2 (T=1193 K), in which some compounds are dissolved:
1-6 for melt 1: AR>0.64; AR<0.64; $CaSO_4$, MgO; $CaSO_4$ and MgO (AR>0.64); $CaSO_4$ and MgO (AR<0.64);
7-10 for melt 2: Al_2O_3; MgO; $CaSO_4$; Al_2O_3+MgO+$CaSO_4$

When AR<0.64 these effects are absent and melt has lower viscosity. Depending on additive type and AR value, liquidus temperatures are reduced by 30-60 °C. It intensifies mineral formation, and crystallization ability of melt and the synthesis of crystals is improved, because surface tension of the melt is reduced (Fig.4).

Most of all, calcium sulphate reduces the surface tension of the melt because SO_4^{2-} ions have high surface activity and Ca^{2+} ion depolymerizes silicon-oxygen complexes which are in the surface layer of the melt.

Magnesium, alumina and iron ions are characterized by low surface activity which is why they have less influence on the melt surface tension.

It was found that the addition of MgO, Al_2O_3 and $CaSO_4$ into melts of sulphoferrite and sulphoaluminoferrite clinkers reduced melt viscosity and surface tension changed moderately. These factors

are favourable to the compaction in the sintering zone of the rotary kiln and to the dust reduction.

By changing the composition and structure of sulphoferrite and sulphoaluminoferrite clinker melts, through incorporation of the different minor components, it is possible to regulate the formation of calcium sulphoferrite and sulphoaluminoferrite and to modificate these phases.

Using these data, three clinkers were produced on an experimental cement plant with capasity of 1 t/h. The chemical composition of these clinkers is given in Table 1.

Table 1. Chemical composition of clinkers, in weight percent.

Clinker Index	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	R_2O	Σ
AF-8	17.50	7.61	9.93	58.50	1.71	3.67	0.22	99.2
AF-12	20.97	5.60	4.62	62.84	1.95	3.32	0.34	99.6
SFC-6	11.14	3.93	32.64	41.70	2.08	7.53	0.13	99.2

Backscattered electron (BE) imaging and X-ray microanalysis are very useful in examining the microstructure of polished clinker sections. Since the BE signal is proportional to the average atomic number of the material, high-Z phases will appear brighter than lower-Z phases. For cement clinker, free lime will appear brightest, followed by ferrite, alite, belite, aluminate, periclase, and finally the resin-filled voids. X-ray microanalysis can assist in phase identification when clinker phases of similar average Z compositions exhibit similar brightness in the BE image. Clinker phase identification from SEM images is made on the basis of phase brightness, grain morphology, and grain association via the BE image, and chemical composition by qualitative and quantitative EDS analysis.

Clinker AF-8 is a medium- to coarse-grained clinker with euhedral to subhedral alite, well-rounded belite, a dense, blocky ferrite matrix, with lessor amounts of aluminate and alkali sulfates. Brightness of the ferrite phase varies within this clinker and the bright ferrite will be referred to as ferrite-1, and the darker designated sulphoaluminoferrite (ferrite-2). Spot EDS analyses of the ferrites showing ferrite-1 to be higher in iron and ferrite-2 higher in aluminum are consistent with their relative brightness in the BE image.

Clinker AF-12 is similar to the previous clinker being medium to coarsely crystalline with euhedral to subhedral alite, rounded belite, minor aluminate, and a dense, blocky ferrite matrix. Belite and ferrite inclusions in alite are common and alkali sulfates partially fill some of the voids. Spot EDS analyses indicates that variations in ferrite BE intensity reflect

changes in ferrite composition in a similar manner to clinker AF-8.

Clinker SFC, in contrast with the previous clinkers, exhibits a fine-grained microstructure composed of calcium silicosulfate (C_5S_2S), dicalcium silicate (C_2S), and a matrix of calcium ferrites. Two calcium ferrite phases appear in the BE images, the first is bright and massive, much like the ferrites in clinkers AF-8 and AF-12 and the second ferrite occurs as darker, rounded grains enveloped by the bright ferrite. The second ferrite is calcium, iron and SO_3-rich and Al-poor. The dark, blocky belite (C_5S_2S) grains are composed of Ca,Si,S,and Mg.

The degree of hydration (Fig.5) of clinker SFC is 20 to 30 percent greater after three days and 15 to 20 percent greater after twenty-eight days than clinker AF-12 under identical curing condition. Clinker AF-8 is intermediate, between AF-12 and SFC-6.

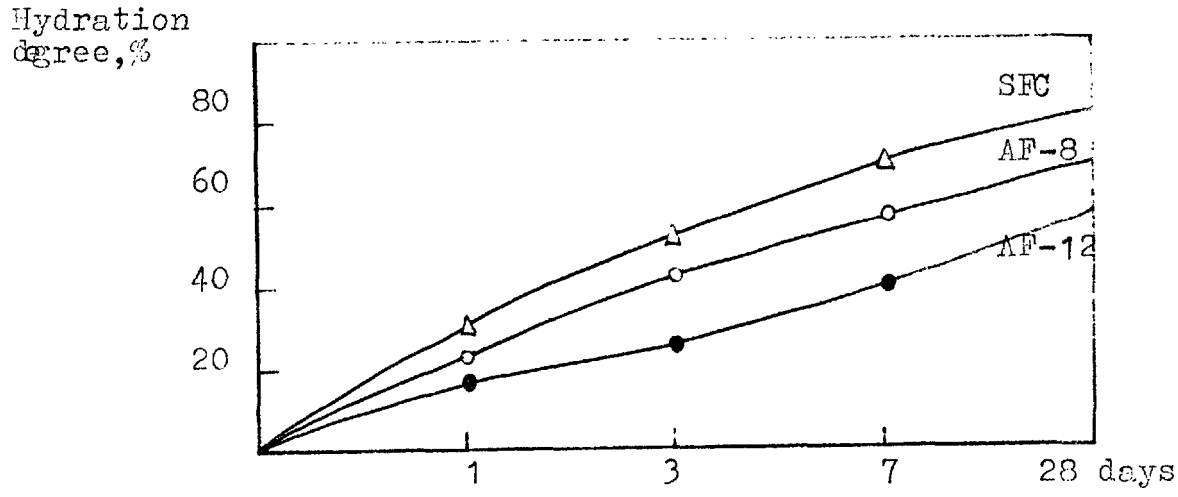

Fig.5 Degree of hydration of clinkers.

Clinker SFC-6 was used as an addition to portland cement clinker. The blend of portland cement clinker (83%), sulfoferrite clinker SFC-6 (10%), and gypsum (7%) was ground to a fineness of 4000 cm^2/g. The resulting cement, whose properties are given in Table 2, is classified as expansive with an expansion of 0.1 percent and a strength of 42 MPa after 28 days of curing.

Table 2. Strength and expansion of cement paste.

Cement	Strength, MPa				Expansion, %			
	1d	3d	7d	28d	1d	3d	7d	28d
PC + SFC	8	20	35	42	0.01	0.02	0.08	0.09

CONCLUSIONS

Melting of calcium aluminoferrites with calcium sulfate leads to sulfoaluminoferrite phases. SO_4 ions replace both tetrahedral AlO_4 and FeO_4 groups. By changing the composition and structure of sulphoferrite and sulphoaluminoferrite clinker melts it is possible to regulate the formation of calcium sulphoferrite and sulphoalumoferrite phases.

A new type of clinker was obtained consisting of calcium ferrite phases with minor amounts of a sulfate and silica phase. This clinker contains 7 percent sulfate and is used for expansive cements.

HIGH-QUALITY PORTLAND CEMENT PRODUCED FROM LOW-BASE RAW MIX WITH LOW ENERGY CONSUMPTION

Boris S. ALBATS, Aleksandr L. SHEIN, Russian University for Chemical Technology n.a. D.I. Mendeleev, Research-Technical Centre Alpha-Cement, Moscow, Russia.

ABSTRACT. An efficient method of reducing energy consumption has been considered which consists in production of clinker with reduced energy consumption from a low-base raw mix similar by its grindability, hardening rate and strength characteristics to ordinary clinker suitable for production of 42.5 class Portland cement.

KEY-WORDS: alite, belite, ferrite phase, mineral phase, synthesis.

INTRODUCTION. It is theoretically shown that the lowering of heat consumption for reduction of raw mix LSF* by 0.1 is close to 3.5% of the total heat consumption for dry process or approximately 2% for the wet one (Merik, 1988). Since this calculation is based on the change of heat consumption for clinker firing only, one can expect a more substantial saving through lowering temperature level of the process and, consequently, reduction of heat losses to environment with waste gases and clinker.

The most widely used way of producing belite clinkers is the thermochemical stabilization of the more active high-temperature modification, α-C_2S, which can be obtained by means of rapid clinker cooling (above 1000°/min within the 1300...900°C range) and addition of barium oxides, alkalies, manganese and $R_2O + Al_2O_3 + Fe_2O_3$; $MgO + Mn_2O_3 + Al_2O_3 + Fe_2O_3$ etc. complexes (Uchikawa et al, 1994., Milke et all, 1994, Moranville-Regourd and Boikova, 1994).
In active belite clinkers, sulfoaluminate, sulfoferrite and sulfoalumoferrite also occur giving reduced saturation factors (Osokin et al, 1993).

Sudakas (1989) and Myasnikova (1992) formulated a concept of reasonability to establish maximal non-equilibrium conditions of belite phase synthesis enabling one to exclude its re-crystallization which affects the further clinker formation in a negative way.

Experimental study

The study was undertaken with the use of raw mixes with LSF = 0.77 to 0.87; n = 1.9 to 2.2 and p = 0.9 to 2.1 based either on pure reagents or on natural components with various mineral compositions. Mixes with LSF = 0.90 to 0.94; n = 2.0 to 2.2 and p = 0.9 to 1.2 were used for reference purposes. These characteristics were calculated proceeding from chemical compositions of raw mixes determined, for CaO, by complexometry (accurate to ±0.3% with fixed concentrations as assessed with regard to the recurrence error); for SiO_2, Al_2O_3, Fe_2O_3, MgO, by photocolorimetry (accurate to ±0.15%); for SO_3, by gravimetry (accurate to ±0.04%).

Conditions of clinker synthsis were as follows: in experimental mixes, the silica component was subject to additional grinding and the rate of heating was increased within the practically accessible limits. Identical rapid air cooling was used for all mixes. Characteristics of some of mixes, conditions of sintering and phase compositions of resulting clinkers are shown in Table 1. The actual phase composition was determined by the quantitative X-ray phase analysis;

* LSF - Lime Saturation Factor

designed compositions were calculated using the Kind method which is customary in Russia. The content of silica phases as calculated by the Kind method can differ by 3-4% from results obtained using the Bogue method (for alite, results calculated by Kind method exceed those obtained by Boggue method). As to C_3A and C_4AF, content of these is practically the same whichever method is used.

According to results of x-ray micro spectral analysis (performed with the use of a Jeol electron microscope equipped with a Link energy dispersion analyser), along with heating rate increasing from 5 to 20 degrees/min and alumina module increasing from 1.2 to 2.0 the CaO/SiO_2 ratio in alite crystals of clinkers produced from low-base carbonate-clay mixes decreases from 3.07 to 2.84 approaching to CaO/SiO_2 ratio of 2.85 characteristic for alite of the ordinary (reference) clinker. On the contrary, the A/F ratio in the alumoferrite phase increases from 0.99 to 2.29 also approaching value characteristic for the ordinary clinker which is 2.04. Here, average molar concentrations of oxides are presented as calculated from results of numerous measurements made on surfaces of crystalline phases with spacing between them being 4 μm.

Mechanism of the process

The mechanism of "alitization" when actual alite content exceeds the estimated one, is achieved as follows. A portion of CaO dissolves in the melt, which is not combined in solid solution with silicate phases (evidenced by CaO/SiO_2 reduction in alite) and reacts with belite leading to formation of additional quantities of alite. Furthermore, a part of C_3A which is unstable at high temperatures is subject to partial decomposition according to the following scheme: $7C_3A \rightarrow C_{12}A_7 + 9C$. Released lime also reacts with belite. $C_{12}A_7$ dissolves in the alumoferrite phase shifting to the aluminate-rich range according to the scheme $C_{12}A_7 + 2C + 7C_4AF \rightarrow 7C_6A_2F$. The schema presented should not be considered as a sequence of solid phase reactions. The precesses occur in the melt by acid-base interaction of Ca^{2+}, $[AlO_4]^{5-}$, $[FeO_4]^{5-}$, $[AlO_6]^{9-}$, $[FeO_6]^{9-}$ ions.

Results

Clinker properties change according to change of phase composition of clinkers and chemical composition of individual phases, particularly when the less dense C_6A_2F prevails. Their grindability and compressive strength as well as hardening rates of obtained cements come close to values characteristic for alite (reference) compositions (Tables 2, 3).

FORMATION KINETICS OF BETA DICALCIUM SILICATE

Vipin K. SINGH, R. PYARE and Vinay K. SINGH, Department of Ceramic Engineering Institute of Technology, Banaras Hindu University, Varanasi - 221 005, India

ABSTRACT A single phase polycrystalline beta-dicalcium silicate has been prepared using chemical processing followed by pyrolysis. Formation kinetics of ß-C_2S in the temperature range 600-1000°C has been studied using X-ray diffraction analysis. The quantity of unreacted lime was determined by glycerol- ethenol estimation method. It was observed that the rate of formation of ß-C_2S increased with rise in temperature as well as with increase in reaction time. The kinetics of its formation has been studied using Arrhenius plot. The activation energy for the formation of ß-C_2S was found to be 7.3 kcal/mol.

Key-words reactivity, free lime, X-ray diffraction analysis, stabilization

INTRODUCTION

Dicalcium silicate (C_2S) is of considerable importance to cement and ceramic technologies. There are five polymorphs of C_2S which can exist at atmospheric pressure: namely α, α'_H, α'_L, ß and γ (Schwieté et al, 1968, Midfley et al, 1974 and Hanic et al, 1987). The ß-C_2S is at normal pressure and room temperature a metastable modification which is probably responsible for its important hydraulic properties. The transformation ß-γ, accompanied by a large volume increase (~12%) takes place (Chan et al, 1992) provided the grain sizes exceed the critical dimensions. The phase does not hydrate and hence the more reactive ß phase has been stabilized at room temperature.

Various strategies have been employed (Roy et al, 1977, Struillon et al, 1980 and Kralj et al, 1986) to produce ß-C_2S without stabilizers and at low temperature : by heating γ-C_2S at 1000°C for several hours and cooling rapidly, by repeated firing of CaO and SiO_2 at 1100°C or from calcium nitrate/oxalate and colloidal/amorphous silica at temperatures ranging between 750 and 1050°C. In the present study a single phase polycrystalline beta dicalcium silicate has been prepared up to 1000°C which is useful to study the stress induced ß-γ transformation toughening of ceramics or as an alternative to cement (as belite cement). The aim of the work was to study the kinetics of formation of beta dicalcium silicate at low temperature.

EXPERIMENTAL PROCEDURE

Analytical reagent grade calcium nitrate and high purity silica gel were chosen for the preparation of ß-C_2S. Dried silica gel was disintegrated in a centrifugal ball mill and sieved through a 90 µm sieve. It was amorphous and no trace of any crystalline phase was found by X-ray diffraction. Calcium nitrate and dried silica gel powder were separately weighed in 2:1 molar proportions to give the C_2S composition. $Ca(NO_3)_2.4H_2O$ was completely dessolved in distilled water and kept on a hot magnetic stirrer. Dried silica gel powder was slowly added into this solution. The slurry was continuously stirred on the hot magnetic stirrer where its temperature was maintained at 80°C. When the slurry was too viscous to stir, the viscous material was baked at 150°C until dryness. The dried powder was fired at temperatures in the range 600-1000°C with holding time from 10 to 300 minutes. Powders were characterized by XRD (ID-3000, SEIFERT) for the determination of different phases present. Unreacted CaO in the fired samples was estimated by the glycerol-ethenol method,

RESULTS AND DISCUSSION

Samples fired in the temperature range 600 - 1000°C in reaction time from 10 to 300 minutes have shown the presence of CS, C_3S, CaO along with ß-C_2S. Fig 1 is the XRD of samples fired at 700-1000°C for 2 hours which shows that appreciable quantity of ß-C_2S is formed in the reaction mixes and the highest peak at $2\theta = 32.4$ seems to be present because of ß-C_2S. For further analysis, peaks due to individual phases were chosen as for ß-C_2S at $2\theta = -41.3$, $d = 2.189$, for C_3S $2\theta = 41.0$ $d = 1.926$, for CS $2\theta = 54.6$, $d = 1.670$ and for CaO at $2\theta = 54.0$, $d = 1.701$. Fig 2 shows the intensity of various phases formed at 600°C up to 5 hours. Monocalcium silicate and tricalcium silicate are formed along with beta dicalcium silicate. Appreciable quantity of unreacted Cao was present at 600°C in the chosen reaction time. The intensity of ß-C_2S increased with time while the intensities of C_3S, CS and free CaO decreased. No free SiO_2 was found which may be because of its rapid utilization for the formation of various silicates or because of its poor crystallinity and the gel form.

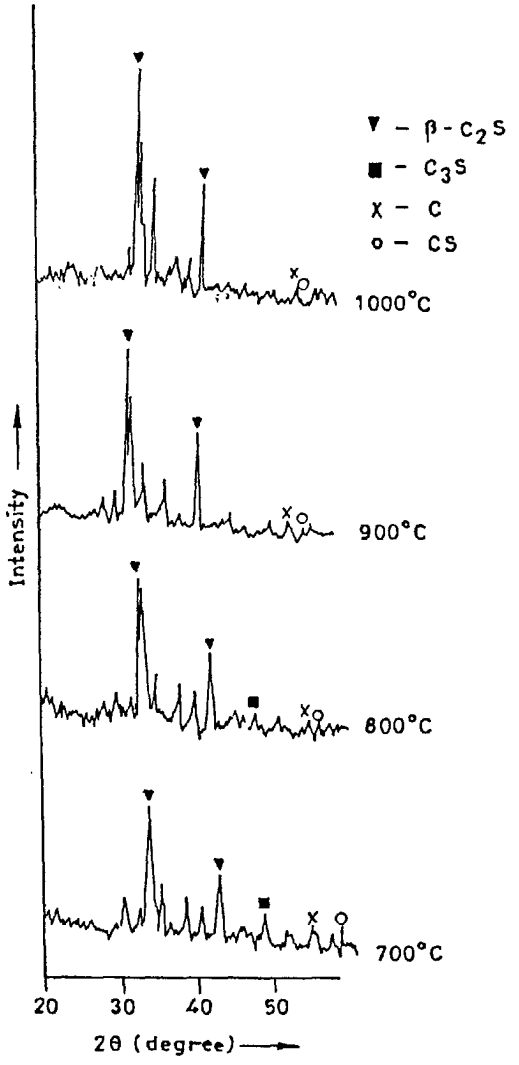

Fig. 1. Intensity of various phases formed at different temperatures in 2 hours

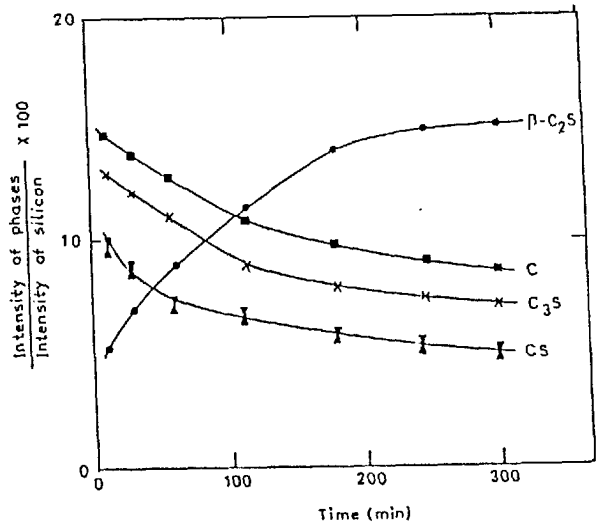

Fig. 2. Intensity ratio of different phases vs reaction time at 600°C

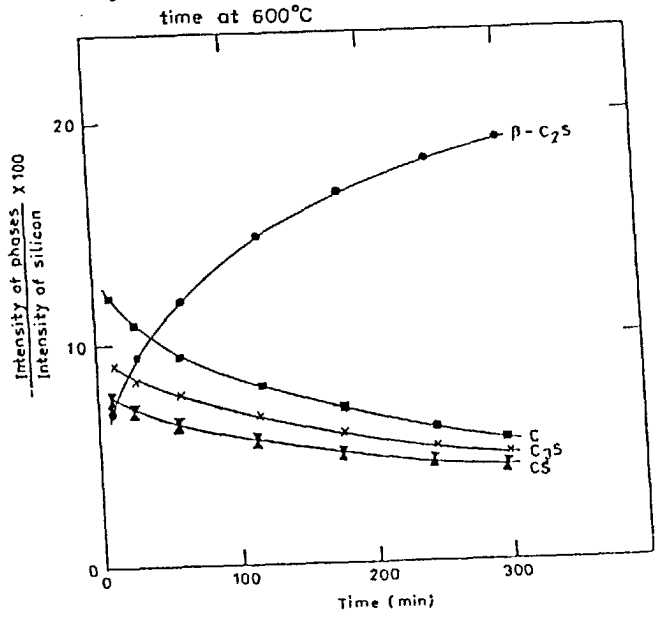

Fig. 3. Intensity ratio of different phases vs reaction time at 700°C

At 700°C the intensity of ß-C_2S was more than that formed at 600°C (Fig 3) which shows that the quantity of ß-C_2S formed at 700°C was more than that at 600°C in similar time. Quantities of CS, C_3S and CaO decreased at faster rate under similar conditions. The amount of these phases decreased at much faster rate at 800°C with increase in the reaction time along with increase in the quantity of ß-C_2S as compared to its formation at 600 and 700°C (Fig 4). No C_3S was detected at 900 and 1000°C. Small quantities of CS and unreacted CaO were observed and their quantities decreased with reaction time at higher rate. Highest rate was observed at 1000°C for the formation of ß-C_2S (Fig 5) where CS and CaO disappeared by about 3 hours and only ß-C_2S phase is left after which is free from reactant and reaction intermediates.

As the temperature increases from 600 to 1000°C, the quantity of ß-C_2S formed increases. It also increases with increase in reaction time at all the temperatures. The curves for the formation of ß-C_2S at different temperatures were found to be parabolic, the log - log plot for which was found to linear. Fig 6 shows the log - log plot of fraction of ß-C_2S formed vs reaction time in minute at 600, 700, 800, 900 and 1000°C. The slope of straight lines obtained was found to increase with increase in firing temperature and hence their slopes were taken as a measure of rate constant 'K'. Fig 7 shows the plot of log k against reciprocal absolute temperature ($1/T^{\circ}K$) which is again a straight line relationship. The slope of the straight line is equal to Q/R where Q is the activation energy and R the universal gas constant. The activation energy calculated from the slope of the plot was found to be 7321.7 Cal/mol.

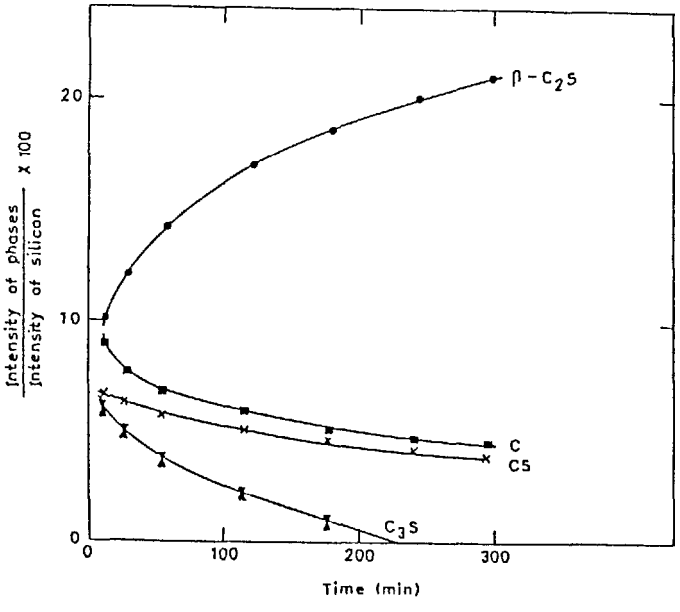

Fig.4. Intensity ratio of different phases vs reaction time at 800°C

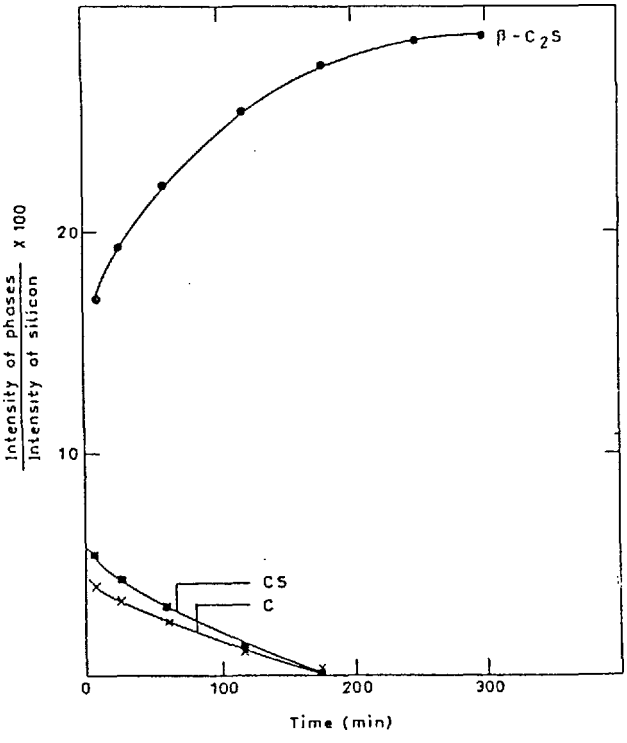

Fig.5. Intensity ratio of different phases vs reaction time at 1000°C

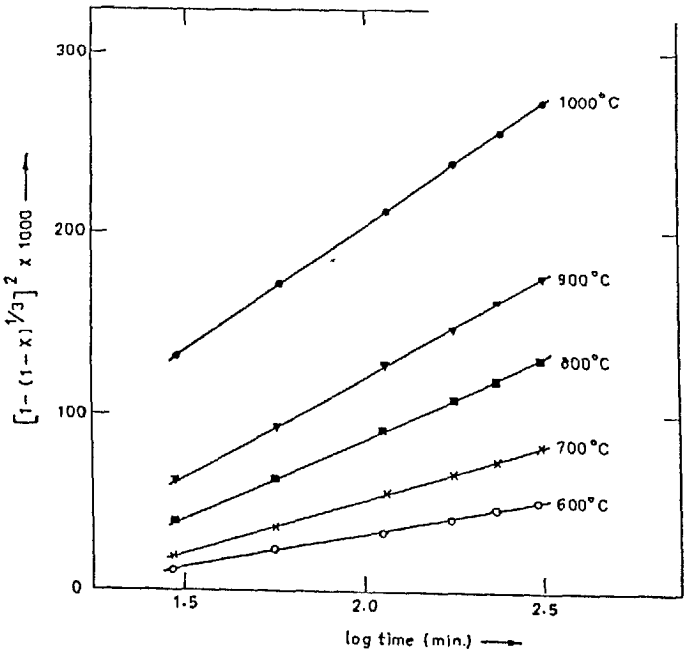

Fig. 6. Formation of β-C_2S

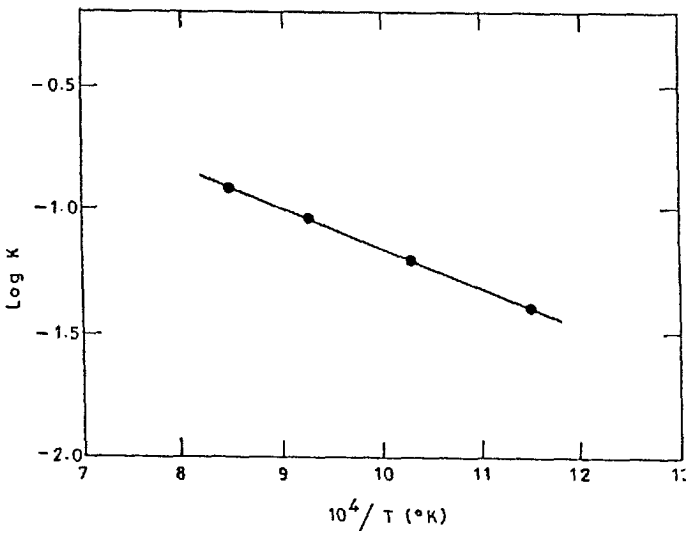

Fig. 7 . Temperature dependence of reaction rate

The key to the quantitative synthesis of β-C_2S at low temperature is the formation of a highly reactive reaction mix of CaO and SiO_2. The synthesis of β-C_2S at low temperature depends on the ability of reactants to combine in order that the kinetics of formation are reasonably fast. SiO_2 is highly reactive because of its presence as gel, poor crystallinity and high surface area. When CaO is formed by the decomposition reaction, it is initially in a highly reactive state due to high surface area and poor crystallinity. However, when annealed at elevated temperature, the oxide rapidly develops a more crystalline structure with lower specific surface and lower reactivity. β-C_2S is retained because of rapid cooling and annealing at 550°C i.e. above the β- inversion temperature for dicalcium silicate.

β-DICALCIUM SILICATE SYNTHESIS BY LIQUID-STATE REACTION

Miroslav M. KOMLJENOVIĆ, Center for Multidisciplinary Studies, University of Belgrade,YUGOSLAVIA
Branislav M. ŽIVANOVIĆ, Center for Multidisciplinary Studies, University of Belgrade, YUGOSLAVIA
Aleksandra ROSIĆ, Faculty of Mining and Geology, University of Belgrade, YUGOSLAVIA

ABSTRACT It is possible to synthesize β-dicalcium silicate by liquid-state reaction (hydrothermal method), via the synthesis of intermediary dicalcium silicate hydrate, using finely ground quartz (<20μm) as a siliceous material. Upon heating, dicalcium silicate hydrate is completely decomposed below 600°C and well crystallized β-dicalcium silicate is synthesized. β-dicalcium silicate produced is stable at room temperature and has a very large specific surface area.

KEY WORDS: β-dicalcium silicate, hydrothermal synthesis,

INTRODUCTION

β-dicalcium silicate is an important constituent of portland cement and is usually synthesized through solid-state reaction between lime and silica, stabilized by the presence of impurities. Also, it can be synthesized by liquid-state (hydrothermal) reaction between lime and silicic acid, via the synthesis of intermediary dicalcium silicate hydrate and without presence of stabilizing impurities, as reported by Ishida et al (1992, 1993). β-dicalcium silicate synthesized by liquid-state is exhibiting considerably higher hydraulic activity.

EXPERIMENTAL PROCEDURE

The starting materials were technical grade lime (70,94%CaO) and finely ground quartz (98,48% SiO_2; 95%<20μm). Experimental procedure (hydrothermal synthesis conditions) is given in Table 1.

β-DICALCIUM SILICATE SYNTHESIS

β-dicalcium silicate samples were synthesized according to following procedure: starting components (molar ratio C/S is given in Table 1) were thoroughly mixed with destilled water, so the water/solid ratio was 10. The suspension was subjected to hydrothermal conditions in an autoclave with constant stirring (200rpm). Intermediary calcium silicate hydrates synthesized were dried to constant mass at 105°C and analyzed for phase identification by XRD and for phase transformation by TGA-DTA up to 1000°C. Samples synthesized were heated up to 1000°C for dehydration and then also analyzed by XRD. Dominant crystal phases of both reaction products are given in Table 1.

RESULTS AND DISCUSSION

Results given in Table 1 indicate that in all experiments α-dicalcium silicate hydrate (α-C_2SH) was synthesized. Depending on the hydrothermal synthesis conditions this predominant phase was accompanied by some other crystal phases, most often lime (CH), which is more present when molar ratio C/S is higher. When molar ratio is constant, lime is more present when temperature is higher (especially above 225°C). In some cases unreacted quartz was also present. Tricalcium silicate hydrate (C_3SH_2), beside α-dicalcium silicate hydrate, was often synthesized. It could be noted that at lower molar ratio higher temperature is needed for the appearance of C_3SH_2 (C/S≥2.0, 225°C; C/S=1.8, 250°C and C/S=1.5, 275°C) and also at higher temperatures higher quantity of C_3SH_2 is present. This dependence could be the dominant factor for reaction controlling.

TGA-DTA studies gave basis for conclusion that α-C_2SH dehydration process is completed under 600°C. After heating up to 1000°C (above the $\beta \rightarrow \alpha'_L$ transition temperature) and on cooling, well crystallized β-C_2S was synthesized. When C/S=1.5 β-C_2S as most predominant phase is accompanied by β-wollastonite (CS), whereas when C/S>2.0 by significant amount of unreacted calcium oxide (C). Unreacted calcium oxide was also more present when temperature is too low (insufficient time for completing reaction) or too high (favouring C_3SH_2 appearance, which is thermally decomposed to β-C_2S and C). Therefore, optimal conditions for β-C_2S synthesis are: molar ratio C/S from 1.8 to 2.0 and temperature from 225 to 250°C.

Specific surface area (BET, N_2) of both hydrated and dehydrated samples as a function of processing temperature was analyzed. The results are given in Table 2, showing that both α-C_2SH (samples 10 and 11) and β-C_2S have a very large specific surface area, although the later was smaller than the former. At 700°C, after the dehydration process has completed, tested samples showed a significant increase of specific surface area (20-70%), but it is not yet clear which phase it can be attributed to, probably some kind of crystalline dicalcium silicate.

Table 2. Specific surface area (m^2/g) as a function of processing temperature

Sample	Temperature (°C)		
	25	700	1000
10	7,60	9,11	4,16
11	6,43	11,16	4,87

CONCLUSION

It is possible to synthesize β-dicalcium silicate by liquid-state reaction (hydrothermal method), via the synthesis of intermediary dicalcium silicate hydrate, using finely ground quartz (<20μm) as a siliceous and lime as calcareous material. Upon heating to 1000°C, dicalcium silicate hydrate is completely decomposed below 600°C and on cooling well crystallized β-dicalcium silicate is synthesized. β-dicalcium silicate produced is stable at room temperature and has a very large specific surface area.

PROPERTIES OF LOW-TEMPERATURE PORTLAND CLINKERS

Albin GARBACIK, Institute of Mineral Building Materials (IMMB), Cracow, Poland

ABSTRACT In the paper properties of energy-saving low-lime clinkers of high hydraulic reactivity have been discussed. Using special raw materials it was possible to reduce the clinkerization temperature down to 1250-1300°C. Clinkers produced on laboratory, semi-commercial and plant scale from marly-chalky raw-mix and marly complete raw material have been investigated. Very high hydraulic reactivity and mechanical properties of the low-temperature belite clinker comparable with OPC clinker was stated.

Key-words: burning conditions of clinker, low temperature, belite, reactivity

INTRODUCTION

The most important problem in the energy-saving low-lime clinker technology is how to obtain binding material with hydraulic properties approximating to those of OPC. In belite cements with a high content of dicalcium silicate (Ca_2SiO_4) problems are caused by the very poor hydraulic activity of this phase. In view of the advantages to be gained from the modification of OPC to higher content of dicalcium silicate, methods are being developed which would increase the hydraulic activity of belite. The aim of these works is to determine the factors which bear an effect on the acceleration of dicalcium silicate hydration and to define the technological conditions for active belite clinker production.

The production technology of active belite clinkers has been confirmed on macro-industrial scale by employment of extremely rapid quenching of belite clinker from clinkerization temperature (Bei and Ludwig, 1990, Stark and Müller, 1988). In Poland however the low-temperature belite clinkers production conditions are being developed (Kurdowski and Garbacik, 1985, Garbacik and Peukert, 1992). Very active belite clinker is produced from raw-mix containing chalky and marly raw materials with high silica modulus and very good burnability. This makes it possible to achieve a considerable lowering the clinker temperature. Low burning temperature and high silica modulus of clinker determine formation of very fine - crystalline very active forms of silicate. Low-temperature belite clinker may be additionally activated by increasing the fineness of cement. The energy consumption for the grinding process is low, owing to the very good grindability of soft-burnt poorly sintered belite clinker.

The article presents selected questions concerning of the technology and properties of low-temperature clinkers, including those produced from marly complete raw material. Complete raw material provides an excellent natural geo-chemical homogenisation of the reaction components and hence ensures specific conditions for synthesis and properties of the clinker.

CLINKER SYNTHESIS

Laboratory and semi-commercial experiments

The synthesis conditions were determined for clinkers sintered from a marly complete raw material. Samples for investigations were taken from an organogenic deposit of chalky raw materials mining by a cement plant. This raw material is used to production ordinary and belite clinkers from marly and chalky raw-mix which, as mentioned above, have excellent burnability. Some parts of this deposit contain marl with a chemical composition similar to the raw-mixes composition for belite and OPC clinker production. The chemical composition of the samples

selected for testing is shown in **Table 1**. The samples of marl, in its natural state, were sintered in a laboratory electric furnace. The sintering temperature was ranged from 1000 to 1400°C at interval of 25°C. The sintering time was fixed at 30 min. The phase composition and free calcium oxide (CaO_{free}) content in the sintered material were inspected by means of X-ray diffractometer and the glycol method respectively. It was stated that depending on basicity of marly complete raw material full clinkerization was achieved at 1200-1350°C. Ca_2SiO_4 was present in the clinkers as β-C_2S form. Despite of the very high silicate module in the raw material and the small concentration of MgO and alkalis, the beginning of the alite synthesis was observed already at temperature of 1225°C.

Table 1 Chemical composition of marly complete raw materials.

Component	Marl 1	Marl V	Marl VI

The laboratory experiments carried out for the sintering of the complete raw material was checked on a semi-commercial scale. A rotary mazout kiln of dimensions 0.57×7 m was used. The complete raw material portions of chemical composition as described in Table 1 were burnt. The furnace was fed with material from the quarry ground down to the grain size of 10-20 mm. The sintering process was monitored by determining the phase composition and content of CaO_{free} in the clinker. The experiments carried out on the semi- commercial scale confirmed the excellent burnability of the complete raw material. The clinkerization process for the tested samples of complete raw material was conducted in temperatures similar to those quoted above for the laboratory tests. The chemical and phase composition of the clinkers burnt in the semi-commercial conditions are given in **Table 2**. The phase composition of the clinkers calculated from Bogue's equations was confirmed by diffractometry. The products of clinkerization were - in order of increasing basicity of the complete raw material - belite clinker containing up to 80% C_2S, belite-alite clinker and alite-belite clinker. In all the samples Ca_2SiO_4 was identified chiefly as β-C_2S form. The lowest-lime clinkers very strong sintered at temperature over 1400°C, was found to give polymorphic transformations β-C_2S to γ-C_2S form.

Plant production

Clinker was produced in a long wet-process rotary kiln with planetary coolers. Two types of clinker were produced: belite clinkers from the complete raw material and belite clinkers from the chalky-marly raw mix. The temperature of synthesis was varied. The temperature in the burning zone and sintering degree were regulated by the amount of the coaldust fed into the kiln. The sintering degree was estimated by measurements of free lime content and litre weight of the clinker. The characteristics of the clinkers produced are shown in **Table 3**. In the process of clinker production from complete raw material the kiln was fed with broken material from the quarry ground down to a grain size between 20-40 mm. The $CaCO_3$ concentration in complete raw material was about of 75 %. The material was sintered at temperature about 1250°C with the litre weight kept within the limits of 1200-1300 g. Belite clinker containing up to of 60 % C_2S was produced. In the clinker C_2S was present as β-C_2S form. Substantial quantities of γ-C_2S form were identified only in harder sintered clinker samples.

Belite clinkers from slurry raw-mix were burnt at a different temperature. The litre weight of the low-temperature clinker was 1150-1250 g. The hard sintered clinker litre weight was about of 1450 g. Belite clinker with LSF 0.80 and containing about of 45 % C_2S was produced (Table 3). No sign of β-C_2S to γ-C_2S transformation was remarked.

CLINKER PROPERTIES

Testing samples

Tests were conducted on samples of the clinkers produced on the semi-commercial and industrial scale. Clinkers displaying the characteristics presented in Tables 2 and 3 produced from the marly complete raw material and from slurry raw-mix were submitted to the tests.

Phase composition and physical properties

The phase composition for the tested samples, as calculated using Bogue's equations and as determined by means of X-ray diffractometer is presented in the already mentioned Tables 2 and 3. The compressive strength of cements obtained by grinding of the clinkers samples to a specific surface of 3500 cm^2/g with 5 % gypsum addition were investigated in compliance with European Standard EN 196-1. The results are given in **Tables 4 and 5** and shown on **Figs 1 and 2**.

Table 4 Mechanical properties of belite clinkers from marly complete raw material.

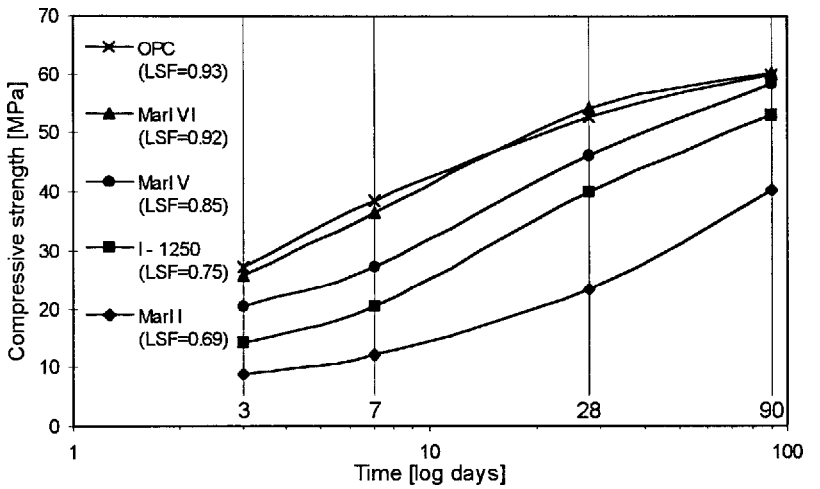

Figure 1 Compressive strength of cement from clinkers in Table 4.

Table 5 Mechanical properties of belite clinkers from marly - chalky raw mix.

Clinker in Table 3			Compressive strength [MPa], after days			
No. of clinker	Litre weight [g]	LSF	3	7	28	90
1.	1150	0.79	26.2	33.4	45.2	54.8
2.	1250	0.80	25.0	33.6	44.3	54.7
3.	1450	0.79	19.4	27.4	38.7	51.1
OPC CEM I 42.5	1480	0.93	27.4	38.7	52.8	59.8

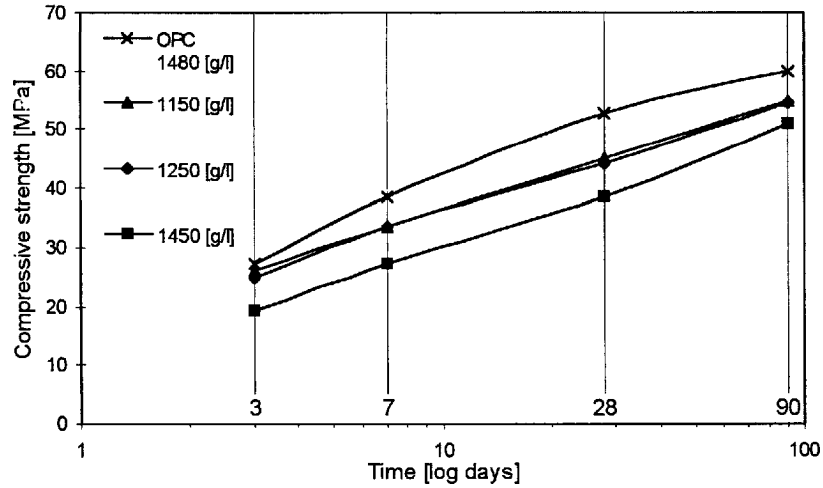

Figure 2 Compressive strength of cement from clinkers in Table 5.

It can be stated that mechanical properties of low-temperature belite clinkers show a clear enhancement in the hydraulic activity. A note worthy feature is the strength development rate of clinkers. This relation may be observed in the comparison of OPC and belite clinker, especially produced from complete raw material (Figs 1 and 2). Low-temperature belite clinkers are marked by high early strength, a poor rate of increase in strength between the third and seventh day of hardening, and another very high rate of strength development after 7 and 28 days of hardening. From the point of view of the production technology for active belite cements this change in the kinetics of hardening is extremely advantageous. The strength development of belite clinker is thereby similar to that for OPC. At a moderate cement fineness, the low-temperature belite clinkers give cements which meet the requirements for CEM I 32.5 and CEM I 42.5.

Heat of hydration

Measurements of the heat of hydration were conducted using a semi-adiabatic calorimeter. The cements obtained from the belite clinkers at various levels of sintering (Table 3) were subjected to these tests. The graphs for the rate of heat for selected cements are shown in **Fig 3**.

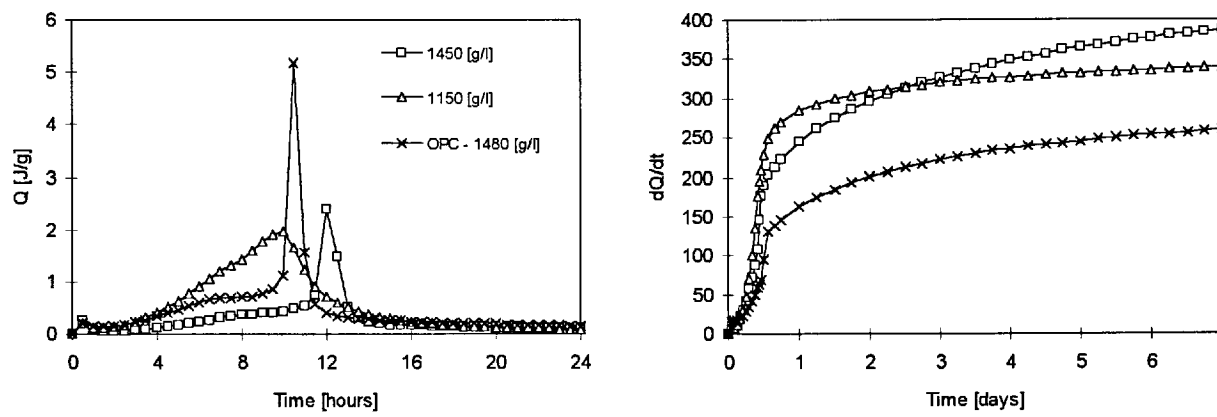

Figure 3 Heat of hydration of cement from clinkers in Table 5.

It may be observed that the curves for the rate of heat emitted by the belite cements are very similar to those characteristic of OPC. The fundamental heat effect shows two maxima typical for the hydration of OPC with the gypsum addition. Thus the hydration mechanism for this active belite clinker must be similar to the hydration process for OPC clinker. The heat of hydration

value of belite clinker varies with the sintering degree. Heat of hydration value of active sofr burnt belite clinker is comporable with OPC clinker (Fig 3). For the low-temperature clinker there is very good correlation between very high heat of hydration and high hydraulic activity and mechanical strength.

Porosity of the clinkers

The porosity of the clinkers was estimated by means of a mercury porosimeter. The results are shown in **Table 6**. The data collected for the porosity tests show significant differences between the porosity of the low-temperature belite clinkers and OPC clinker. In the former case the low-temperature clinkers obtained were found to be characterised by a high degree of porosity, which should explain the enhanced process of hydration and strength development. The highly porous structure of these clinkers also contribute their excellent grindability.

Table 6 Porosity of belite clinkers.

Clinker in Table 4		Porosity [cm^3/g]	
No. of sample	Litre weight [g]	58000 - 5 nm	7500 - 5 nm
1.	1150	0.1876	0.1357
2.	1250	0.1243	0.1098
3.	1450	0.0624	0.0486
I	1250	0.1602	0.1291
OPC clinker		0.0948	0.0468

The microstructure of the clinkers

The crystal habit and dimensions of the mineral phases is a very important aspect of the microstructure of the low-temperature clinkers. These relations were observed with the use of a Zeiss-Jena metallurgical microscope. The changes observed in reflected light for the microstructure of the silicate phases in the tested clinkers are described in **Table 7**.

Table 7 Microstructure of belite clinkers.

Clinker in Table 3		Grain size [μm]		Silicate phase microstructure - microscope tests
Sample No.	Litre weight [g]	Alite	Belite	
1	1150	5-20	5-10	Fundamental mass consists of irregular alite and belite grains. Some part of alite crystals has very fine characteristic pseudo-hexagonal habit. Also small characteristic isometric belite crystals have been observed sporadically.
2	1250	5-20	5-20	Alite and belite microstructure very similar to that of sample No. 1.
3	1450	10-40	20-80	Belite in form of isometric grains with very characteristic set of striations. Type I grains predominant, often with numerous inclusions. Smooth grains without any striations were observed, probably as γ-C_2S.
I	1250	5-20	5-20	Alite and belite microstructure very similar to that of samples 1 and 2.

The described changes in the microstructure of the silicate minerals in the low-temperature belite clinkers provide an explanation for their enhanced hydraulic activity. The very fine crystalline and almost amorphous alite and belite structure in soft sintered clinkers will tend to high hydraulic activity of these phases in the hardening process of cement.

The lowering of the sintering degree exerts a particularly large influence on the microstructure of the dicalcium silicate. The dimensions of the belite range from 80 mm in the strongly sintered clinker to 5-10 mm in the low-temperature clinker. The dominant alite structure in the highly sintered clinkers are crystals with a characteristic pseudo-hexagonal habit. Contrary, alite in the low-temperature clinkers forms fine-grain, xenomorphous structure. The microstructure of clinkers derived from the complete raw material is very similar to that of the low-temperature belite clinkers from raw-mix. However, the microstructure of the clinker obtained from the complete raw material is more tight and with higher density of pores.

CONCLUSION

Belite and alite-belite clinkers produced from the marly complete raw material are marked by specific properties of their microstructure and exhibit favourable mechanical properties caused by the conditions of sintering. Depending on the level of clinker basicity the clinkerization of complete raw material may be achieved at temperatures ranging from 1250-1350°C.

The extremely small dimensions of the Ca_2SiO_4 crystals, which occur in the low-temperature belite clinkers, appear to be stabilizing factor of β-C_2S phase in clinker containing up to 80% belite.

The very good mechanical properties exhibited by the low-temperature belite clinkers are brought about by the enhanced hydraulic activity of the alite and belite as compared with the properties of OPC clinker. The decisive factor is the very fine crystalline structure of these minerals. The quite small amounts of very active alite in the low-temperature belite clinkers has a significant effect on the early strength of these clinkers.

TOPIC I.C

Utilization of industrial by-products and wastes

AGRICULTURAL / INDUSTRIAL COMBUSTIBLE WASTES AS FUEL IN INDIAN CEMENT INDUSTRY

S C AHLUWALIA, V K ARORA, Y P SETHI,
National Council for Cement and Building Materials

ABSTRACT Various combustible wastes such as rice husk, bamboo dust, bagassee, carbon slurry have been studied with reference to their availability, technology of use, logistics, costs etc. The paper gives impact of their use on the quality of product, process related problems, system design for storage, handling, and feeding. Experience of use of these have been reported and technology options suggested.

Key-words: Fuels for cement making, Rotary kiln, Waste material utilisation, Rice husk, Bamboo dust.

INTRODUCTION

India is an agricultural country and the agrobased industries generate nearly 250 million tonnes combustible wastes of which rice husk, bagassee account for nearly 10%. The wastes are widely spread over the country and depending upon logistics, these are considered to be potential cost effective alternate/substitute fuel to coal. The present paper deals with the potential of their use, impact on product quality, appropriate technology and cost effectiveness.

EVALUATION OF COMBUSTIBLE WASTES

The following factors need to be considered in evaluation of the wastes for their suitability in cement manufacturing process.

i/ Availability
ii/ Proximate and ultimate analysis, ash composition
iii/ Ignition and combustion aspects
iv/ Storage, handling, feeding and firing system
v/ Impact on pyroprocessing and clinker quality
vi/ Environmental considerations

INTERNATIONAL STATUS OF USE OF COMBUSTIBLE WASTES

The technological solutions have been evolved for ue of large varieties of agricultural and industrial combustible wastes. The cement rotary kilns have been reported to be one of the most efficient systems of combusting waste fuels and immobilising toxic having matters and other pollutants. Despite this, the actual use of waste fuel is not encouraging. The scrap rubber tyres are being used by the cement plants in Japan and Germany. A few cement plants in Japan are reported to substitute 25% of their main fuel by scrap motor tyres. The use of oil shale in one of the cement plants in Germany replaced fuel oil consumption by about 40%. The use of rice husk, bamboo/raw dust, waste oil etc have been reported to be used in the precalcinator in some of the cement plants in Germany replacing coal upto 30%. Most of the cement plants in North America are using petroleum coke along with coal. In Sweden, the sewage sludge after mechanical dewatering is successfully burnt in cement kilns

POTENTIAL COMBUSTIBLE WASTES IN INDIA

Out of various combustible wastes as outlined earlier, rice husk, bamboo dust, bagassee and carbon slurry seem to have good potential of use as fuel in India.

Rice Husk

The availability of rick husk is about 30 million tonnes per year mainly during harvest time spread over 4 months. Rice husk is very light in weight having bulk density of 100 kg/m^3 and has excellent fluidising property. It contains low moisture content varying from 6-8% whereas volatile matter is found to be high (60-65%). The calorific value is 3000 kcal/kg and hence it can be used as a supplementary fuel to coal. The most appropriate use has been established as a secondary fuel in the precalcinator and fed without further processing.

Bamboo Dust

Bamboo dust, a waste from paper industry is a fibrous material and hygroscopic in nature. The quantity available at present is about 0.5 million tonne per year. It is having a bulk density of 300 kg/m^3. The moisture content in the bamboo dust is initially found to be around 30% which comes down to 2-3% on sun-drying. The calorific value of bamboo dust is 3700 kcal/kg. The typical proximate and ultimate analysis of bamboo dust and its comparison with rice husk & coal is shown in Table 1.

Table 1 : Comparative Analysis of Coal, Bamboo Dust and Rice Husk

Particulars	Coal	Bamboo Dust	Rice Husk
PROXIMATE ANALYSIS, %			
Ash	38.51	13.70	16.21
Volatile Matter	26.14	68.02	64.24
Moisture Content	2.72	2.79	7.13
Fixed Carbon	32.63	15.49	12.42
ULTIMATE ANALYSIS, %			
Carbon	44.27	39.49	34.66
Hydrogen	3.10	3.85	4.37
Nitrogen	0.51	0.42	0.36
Sulphur	0.75	0.08	0.09
Oxygen	12.86	42.46	44.31
Calorific value, kcal/kg	4040	3710	3000

Carbon Slurry

The availability of this waste in the country is limited and projected at only 50 thousand tonnes per year. Carbon slurry is initially stripped off in the absorption column in the form of slurry containing 70-90% moisture and dumped in the lagoons for sun-drying to 50-60% On dried basis, it contains about 95% carbon with less than 1% ash content having calorific value around 7000 kcal/kg. The material has fine grains passing through 40 micron sieve.

Bagassee

About 2 million tonnes of bagassee is available per year in India. The bagassee contains 40-45% moisture with ash content of 2-3%. The calorific value on dried basis is 4200-4300 kcal/kg and can therefore be effectively burnt in the precalcinator as substitute fuel to coal.

IMPACT ON PYROPROCESSING AND CLINKER QUALITY

Since most of the combustible wastes have low ash content as compared to coal, the resultant ash content in the mixed fuel goes down. The use of these wastes in kiln system will have no adverse effect from ash view point. The firing of combustible wastes in the kiln is not favoured as these tend to lower the flame temperature and affect the flame shape for which burner design is required to be modified. These wastes can be burnt effectively in the precalcinator as supplementary fuel.

The potential clinker quality has been worked out with a typical raw mix at 10 and 20% of coal substitution by rice husk or bamboo dust (Table 2). The results indicate that there is an increase in CaO content with corresponding decrease in SiO_2 content which is an indication to the improvement in clinker quality.

Table 2 : Impact of Rice Husk/Bamboo Dust on Clinker Quality

Item	Potential Clinker Quality				
	Coal Substitution				
		By Rice Husk		By Bamboo Dust	
	0	10	20	10	20
SiO_2	20.48	20.41	20.33	20.36	20.24
Al_2O_3	6.33	6.22	6.11	6.23	6.14
Fe_2O_3	4.52	4.52	4.52	4.52	4.52
CaO	64.36	64.51	64.66	64.57	64.77
C_3S	57.34	59.25	61.16	59.77	62.10
C_2S	15.46	13.81	12.15	13.28	11.18
C_3A	9.13	8.85	8.56	8.86	8.62
C_4AF	13.75	13.74	13.73	13.75	13.75

STORAGE, FEEDING AND FIRING SYSTEM

The storage capacity and the quantity of these agricultural/industrial wastes will vary from plant to plant depending upon daily requirement of fuel as well as extent of fuel substitution. However, it is advised to store these wastes calculated to a minimum of 3 days requirement.

Mixing combustible waste with coal in the gantry and then feeding to coal mill leads to a number of operational and handling problems such as reduction in coal mill output rate, entrainment of combustible wastes to the dust collectors and catching fire thereafter and damaging the filters, fire in the coal mill circuit etc. The smooth flow of combustible wastes alongwith fine coal, segregation in the coal feeding bin are some of the problems encountered when combustible wastes are mixed with fine coal and fed to kiln/precalcinator. It is advised to feed combustible wastes only in the precalcinator just at the tertiary air entry in the precalcinator or in the riser duct of the kiln.

UTILISATION OF RICE HUSK/BAMBOO DUST

A Study had been carried out to use rice husk and bamboo dust in Indian cement plants. Based on the investigations a maximum of 20% coal substitution by bamboo dust was envisaged. The high volatile and low

calorific value of rick husk/bamboo dust restricted its use in the kiln firing owing to change in flame shape and its temperature however it did not have adverse effects in the temperature profile of preheater system after firing in the precalcinator. Various options were considered such feeding of rice husk/bamboo dust alongwith coal to grinding mill, mixing with pulverised coal after the mill and directly feeding to precalcinator without grinding. Keeping in view the merits and demerits of various options, it was inferred that rice husk and bamboo dust must be directly fed to the precalcinator without any processing.

STATUS OF COMBUSTIBLE WASTES UTILISATION IN INDIA

The combustible wastes are sporadingly being used by cement plants in the country. Due to their irrational utilisation, the results of coal substitution are not encouraging. Rice husk is reported to have replaced 5-10% coal by five cement plants in the country. These plants reported the problems of storage and handling particularly during rainy reason. No environmental problems were faced by these plants. The plants experienced quick burning of this waste in precalcinator. Two cement plants reported using bamboo dust replacing 5% coal with similar experiences of burning. Two more cement plants are reported to have used the carbon slurry with some problems encountered during feeding. One cement plant replaced about 15% of coal by bagassee.

COST ECONOMICS

The partial substitution of coal by any combustible waste must be evaluated for cost economics after technical evaluation to arrive at the final utilisation of combustible wastes in cement industry. Cost economics has been worked out at varying cost of coal from Rs 1000 to Rs 1600 per tonne and combustible waste from Rs 500 to Rs 600 per tonne depending upon the lead distance and mode of transportation. The savings to the plants on account of coal substitution from 5 to 20% vary from Rs 3 to 35 per tonne clinker.

CONCLUSION

The extent of substitution of coal by the agricultural and industrial wastes depends upon their availability, calorific value and economics of use. Systematic set up for controlled feeding needs to be adopted by the cement industry to achieve lowering of cost of energy input and finally the cost of cement manufacture. Besides this will help in solving the problems of waste disposal and treatment.

THE MULTICOMPONENT CEMENTS (MCs)

Zinovii B. ENTINE, Boris E. IOUDOVITCH
NIICement, Moscow, Russia

ABSTRACT Some new data in the domain of MCs are presented concerning: 1) active mineral additions (AMAs) and fillers; 2) Portland cement clinkers for MCs; 3) grinding aids with non-Rehbinder mechanism of action for MCs and ordinary Portland cement (OPC) production.

Key-words: Additives. Blended cements. Filler. Slag. Pozzolana. Zeolites.

INTRODUCTION

In Russia the terms ``MCs`` or ``MCs of high fineness` degree`` are used (Schubin, Entine, 1992) for denomination of improved varieties of blended cements which are practically equivalent by properties to OPC. From the thirties it had been known that such MCs decrease the energetic consumption and air pollutions in cement production and the cost of concrete. The peculiarities of chemistry and technology of MCs are the objective of this report.

EXTENDED ASSORTMENT OF ACTIVE MINERAL ADDITIONS (AMAs)

Expensive transportation obliges the usage of local AMAs. Some of them had not broadly been used earlier. For MCs producing in Russia it has began application next AMAs (Table 1). AMAs and fillers included firstly in the project of new Russian standard are underlined.

Table 1. New active mineral additions and fillers in Russian MCs

Hydraulic or pozzolanic	Pozzolanic	Fillers
Slags of non-ferrous metallurgy (in connection with its chemical composition)	Zeolitic rocks	Limestones
	Basalts (with amorphised intercrystalline matter)	Dolomites[1]
	Lyparite (rhyolite) types ♦ dense: obsidian pechstein ♦ porous: pumice ♦ crystallise: porphyry ♦ weathered: porphiroides ♦ artificial: glass breakage	Sands ♦ quartz[2] ♦ feldspar ♦ carbonatizated
	Volcanic origin weathered/ /metamorphised shales ♦ with 12 - 25% Al_2O_3 - ordinary; ♦ > 25% Al_2O_3 - extensible; ♦ pyrofillites	Sand stones[2]

Notes: [1] ≤3 weight % as calculated on dolomite in MC. [2] ≤ 10 weight % of pure quartz in MC

Among new AMAs are mainly of interested:

♦ *zeolitic rocks;* in Russia clinopthylolite is the main mineral of; the peculiarity of MC is temporary (by 1-2 months) reduction of strength by 5-15% during 3-12 months of hardening; to avoid reductions Kuznetzova et al. (1989) used mixes of zeolitic and slag or pozzolanic additions; the most probable reason for reduction the periodic way out of the alkalies in hardening MC paste from zeolitic particles to liquid phase and the absorbtion said alkalies from the last by slag/pozzolanic particles; rational selection of zeolitic MC fineness level is also enough for preventing reduction;

♦ *slags of non-ferrous metallurgy* consist up to 60% ferrous oxides (Entine et al.,1983); the greater FeO content in the slag the higher must be oxidizing potential (o.p.) of clinker particles in hardening MC (Entine, Ioudovitch,1996a); one can indirectly evaluate this o.p. by ferrous sulphate introducing upto 3 weight % to plain OPC by joint grinding; if then OPC class of strength has been diminished the clinker o.p. is low (Ioudovitch et al, 1996); methods of o.p. increasing is mentioned below; this MC is recommended for using with the water/cement ratio range up to 0.4 and for hardening without steam curing to prevent the oxidation of unhydrous slag particles; those have been lost an activity after Fe(II) ⇒ Fe(III) transition.

♦ *basalts* are suitable when contain amorphised intercrystalline matter (Nguen, Entine, 1994, Entine et al.,1995); on the contrary *porphyroides* must have some crystals in glass matrix;

♦ *shales* with good pozzolanic activity had been found in Russia recently (Bazoev et al, 1992); the MC based on is the first known expansive cement without burned components having the expansion at the air hardening (at relative humidity level down to 30%).

In Russia fillers are the comparatively new components of MC. The consumers used such MC reluctantly and had some arguments for. New specified conditions for limestone using as filler, for clinker in conjunction with and for MC as a whole (Table 2) are based on the results of industrial experiments (Entine, Ioudovitch, 1996a) and liberate MCs with limestone from defects.

Table 2. The specified conditions for limestone filler, PC clinker and MC based on

Demands to limestone filler			*Demands to PC clinker and MC as a whole*		
			Clinker characteristics		
Compressive strenght	$N.mm^{-2}$	≥400	C_3A content	weight%	≥5
Microhardness	- `` -	≥3000	C_3S content	- `` -	≥50
Calcite content	weight%	≥80	MgO content	- `` -	≤2.5
Clay impurities	- `` -	≤2	P_2O_5 content	- `` -	≤0.15
Dolomite impurities[1]	- `` -	≤10	Free lime	- `` -	≤1.0
			Loss of ignition (L.O.I.)	- `` -	≤0.3
			MC characteristics		
			L.O.I. up to 700°C	- `` -	≤1.0
			Specific surface,	m^2/kg	≥300
			- the better level	- `` -	≥400

Note: [1]Usage of filler with dolomite content higher than 10% is admitted only after experimental checking

In the hardening of MC paste the limestone filler takes part in hydroaluminates' formation in the case of clinker particles prehydration during of MC grinding process especially in situation with non-predried and soft filler used in large quantities. Moreover for MC strength the hydrosilicates semicontact carbonation by filler is worse than that of hydroaluminates particularly in the time of steam curing of concrete and it can cause the cracking of cured reinforced concrete articles

(Dolbilova,1995). Such are the reasons for demands to components and to MC listed in Table 2.

SPECIAL PORTLAND CEMENT CLINKERS FOR MCs

Activation of clinker with high alkali level is realised by using of additives - ``cement promoters`` (Ioudovitch, Zubekhine, 1996) to cement raw mix to increase alite generation rate and clinker o.p. at burning, decrease insoluble residue and R_2O content, exclude the presence of marginal phases - $C_{12}A_7$, R_2O-containing C_3A (the former RC_8A_3), C_2F, CF etc. (Entine, Ioudovitch, 1996b), ensure the better phase composition (Table 3) and reduce the resistance to grinding.

Table 3. Phase composition of high alkaline clinkers for MC in comparison with OPC

Clinkers for OPC (R_2O > 1 weight %) without SO_3 / R_2O balance		Clinkers for MC (R_2O > 1 weight %) with balance SO_3=(0.7–1.0)R_2O in weight %	
Main phases	Marginal phases	Main phases	Weight %
C_3S	R_2O-contained C_3A	C_3S	65 - 75
C_2S	(= RC_8A_3)	C_2S	< 10
C_3A	$C_{12}A_7$	C_3A	8 - 12
$C_2(A,F)$	R_2O-contained $C_2(A,F)$	$C_2(A,F)$	8 - 13
		Minor components and impurities	
	Alkaline ferrites[1] (e.g.$Na_2O.Fe_2O_3$)	Free CaO[2]	≤ 0.5
		Free MgO[2]	≤ 2.5
Minor components and impurities		SO_3	≥ 0.7
Free CaO[3]	Free MgO[3]	Calcium-alkaline sulphates	≥ 1.6
Alkaline sulphates (R_2SO_4)		Insoluble residue	≤ 0.5

Notes: [1]Estimated as an impurity in $C_2(A,F)$ by microchemical reaction with methylenblue (Skl`arenko, Zoubekhine, 1995). [2)] as a rule less than [3)] by the weight.

This is essential mostly for MC because marginal phases not only create obstacles to alite hydration by forming passive glass pellicles around alite crystals in clinker but also form gelious hydrates, firstly AH_3 from $C_{12}A_7$ which the stronger delied reaction C_3A with gypsum in hardened cement paste the more AMA content in MC. Elimination of obstacles raises the MC quality.
Activation of MC based on sedimentary pozzolanas reaches by using the modified Ferrari type clinker with extremely high LSF (upto 1.5), including ``hyperalite`` $C_{3,3-3,8}S$ (65-80%) and free lime (5-15%) in form of $(C - C_2F)_{ss}$ which allows to finish the pozzolan reaction during 1-2 months versus 20-30 years in hardening MC based on OP clinker (Zoubekhine, Ioudovitch, 1996).The low resistance to grinding of the first clinker type (time of grinding the portion of 5 kg in laboratory mill chamber with dimensions .5 m in diameter, .28 m in longitude, milling load 53 kg and angle velocity .7 of critical level upto Blaine number 420–450 m^2/kg is 40–50 min. versus 1.5–4.5 hours for OP clinker) determined by its specific crystal structure guarantees *both* the increasing value of clinker content in the fine MC fraction (≤ 5 μm in effective diameter) that is the principal condition of MC high quality in connection with intensifying action upon the pozzolanic reaction (Entine, 1993) and upon the rate of middle clinker fraction (5–30 μm in diameters) hydration (Ioudovitch, 1972) *and* the best size distribution of alite particles for uniform dissolution in water. For the second type of mentioned clinker time of grinding in same laboratory conditions is shortening to 25–35 min. In compositions with sedimentary pozzolanas such clinker determines extremely low energy consumption by cement mill. Besides in MC it is useful the presence of two mineral additions - the first with larger hardness than of clinker and

the second with lesser hardness for intensification the grinding of clinker part of MC and for disaggregation the last on finish grinding stage accordingly (Entine,1993). Such MC composition brings into concord the low energy consumption in producing and high quality of.

NEW CEMENT GRINDING INTENSIFIERS

In Russia new grinding intensifiers` group had been worked out in eighties. They can increase the mill output by 30 - 100%. The mechanism of action is non-Rehbinder (Rehbinder, 1931, had shown that liquid surface active intensifier acts by decreasing of surface energy of ground particles what can increase the mill output by 15-20% only) and connects with decreasing of dry friction angles (grinding matter by steel and steel by steel). Usually new grinding aid is dry matter which forms chemical bonds with active centers on said particle surfaces permitting the jumping diffusion of the matter from-one-to-another surface dislocation zones to activate them during contact motions. This matter must be able to be added to cement without any harm on technical properties of. For MC it can be liquid too but easy soaked in porous AMA particles. The Russian intensifier based on dry S-3 had increased the output of tube mill with dimensions 3.4 x 10.6 m in MC grinding (with 20–30% of slag upto Blaine number 400–450 m^2/kg) from 37 t/h without aid to 70-75 t/h with it while with Blaine number 300 – 320 such data were 47 and 80 - 85 t/h accordingly (tests had been carried out by Ioudovitch, Babaev, 1992). In Russia for MC grinding mill 2.6 x 13 m (both said mills worked in open cirquit) another Russian intensifier based on lignosulphonates LSTM-2 in the presence of AMA (15%) gave growth of the output from 12–15 to 28–32 t/h (for the first of mentioned Blaine number, Ioudovitch,1982). Because MC must have higher fineness degree than OPC such grinding aids are useful for MC producing.

EFFECTS OF USING IRON MUD AS RAW MATERIAL IN CEMENT MANUFACTURE

Yizhou PAN
Zhejiang Building Materials Scientific Research Institute, Hangzhou, P. R. CHINA

ABSTRACT The effect of iron mud on producing portland cement and the mechanism of influence of five trace component on clinker formation in particular have been studied by XRD , chemical analysis . The results indicated that iron mud was very good and lower priced composite raw materials because it is iron , aluminium oxide raw materials as well as complex trace component mineralizer in cement production .

Key-words: Iron mud Burnability Five trace components

INTRODUCTION

The mineral balance in the nature is disturbed with depletion of natural minerals on one hand and the rapid growth of by products and solid wastes from increased industrial activities creating handing disposal and environmental problems on the other. Industrial wastes containing useful minerals having intrinsic mineralizer potential offer ready to use solution (Kumar 1981 , Mori 1992 , Moranville-Regourd 1992) . Iron mud is a kind of natural material which looked like clay and caused from low level iron ore oxidized in air . There are widespread and great reserves of it in our province in China , It hasn't been exploited due to its poor quality for a long time past . For the purpose of wide application of the solid wastes , we have carried out many studies on it .

EXPERIMENT

Materials and Methods

The chemical and spectral analysis results (table1) indicated the iron mud consist mainly of silicon , iron , calcium and aluminium oxid and five trace components (Mn , Cu , Zn , Ba , Pb, the amount of them is 0.2-1.0%, 0.1-0.3%, 0.2-0.8%, 0.3-0.5% and 0.1-0.3%). In order to study the effect of five trace composition and avoid other impurities interference on clinker formation , the experimental work were divided into two groups . In one group, raw mixes were made by chemical pure reagents with the appropriate amount of five trace components, that was mixed by MnO_2 , CuO , ZnO , Pb_3O_4 and $BaSO_4$ in the same weight proportion . The other group was composed of natural materials and iron mud instead of iron power , same of clay and mineralizer . The samples were preheated at the chosen temperature in electric furnace and cooled in air .

Table 1. Chemical Composition and Price of Materials(%)

Sample	Loss	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Total	Price
Iron Mud 1	9.21	41.50	11.51	30.70	1.36	1.66	95.94	$2.5/t
Iron Mud 2	16.61	24.16	7.28	43.50	2.09	2.45	96.18

RESULTS AND DISCUSSION

1. Effect of five trace components on burnability of raw mixes

Results of burnability of raw mixes by adding five trace components is illustrated in Figure 1 . At the temperature of 1200℃ , the free lime content of the sinter containing 1% five trace components and 1% fluorite (F-5) is 15.8% , but is 30.5% and 24.6% for contrast sample (0-0) and adding 1% fluorite alone sample (F-0) respectively. At 1300℃, the free lime of samples F-5 , F-0 , 0-0 is 1.7% , 5.7% , 12.1% ; and is 0.3% , 1.0% and 3.0% separately at 1350℃ . The free lime of sintered samples at the burning temperature is in the following order : 0-0>F-0>F-5 . The difference in the free lime indicated that addition of five trace components was obtained quite effectively because it could lower the free lime and improve the burnability of the raw meals during the clinkering process .

2. Effect of five trace components on absorption of free lime

Figure 2 show XRD pattern of the samples . The intensity of peaks of free lime (at 2θ=54 , I=1.699) at the burning temperature of 1200℃ are 0-0>F-0>F-5 . When temperature reached to 1300℃ , the peaks of free lime decrease obviously for sample F-0 and disappear for F-5 . The peaks vanish for F-0 and still can been found for 0-0 at the temperature of 1350℃ . This results are in accordance with that of former experiments and testify that five trace components could improve the absorption of free lime efficiently in clinkeration process. The variation of peaks compared alite with belite at the different temperature illustrate the decrease of free lime to sintered samples with the development of belite crystal and formation of alite below 1300℃ , as well as with the disappearance of belite and growth of alite at 1350℃ . The changes of XRD patterns of silicate minerals have directly relation to the kind of addition .

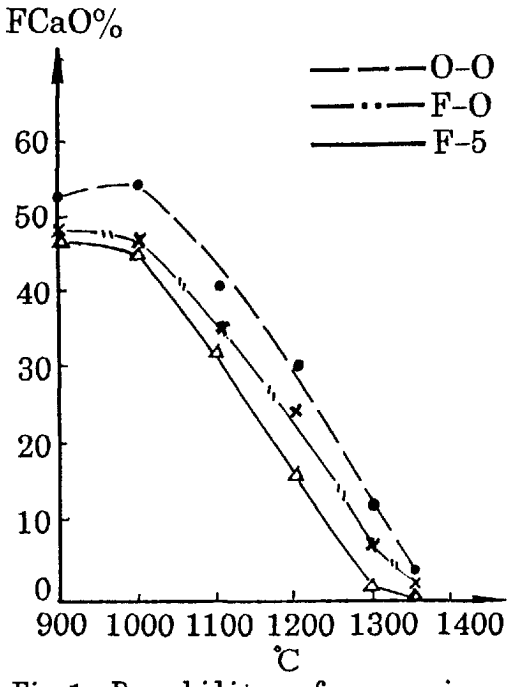

Fig. 1 Burnability of raw mixes
0-0: contrast sample; F-0: 1% CaF_2; F-5: 1% CaF_2+1% five trace components

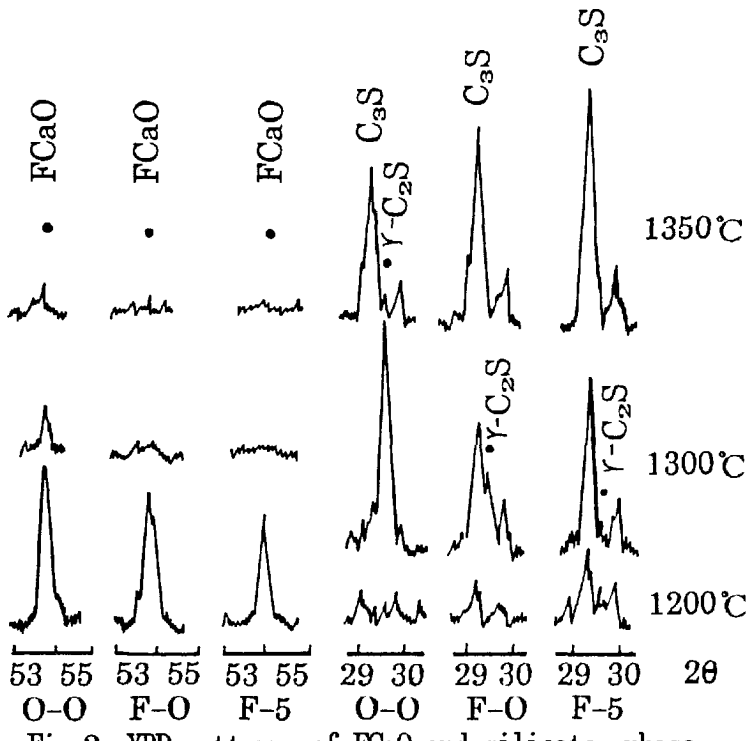

Fig. 2 XRD patterns of FCaO and silicate phase

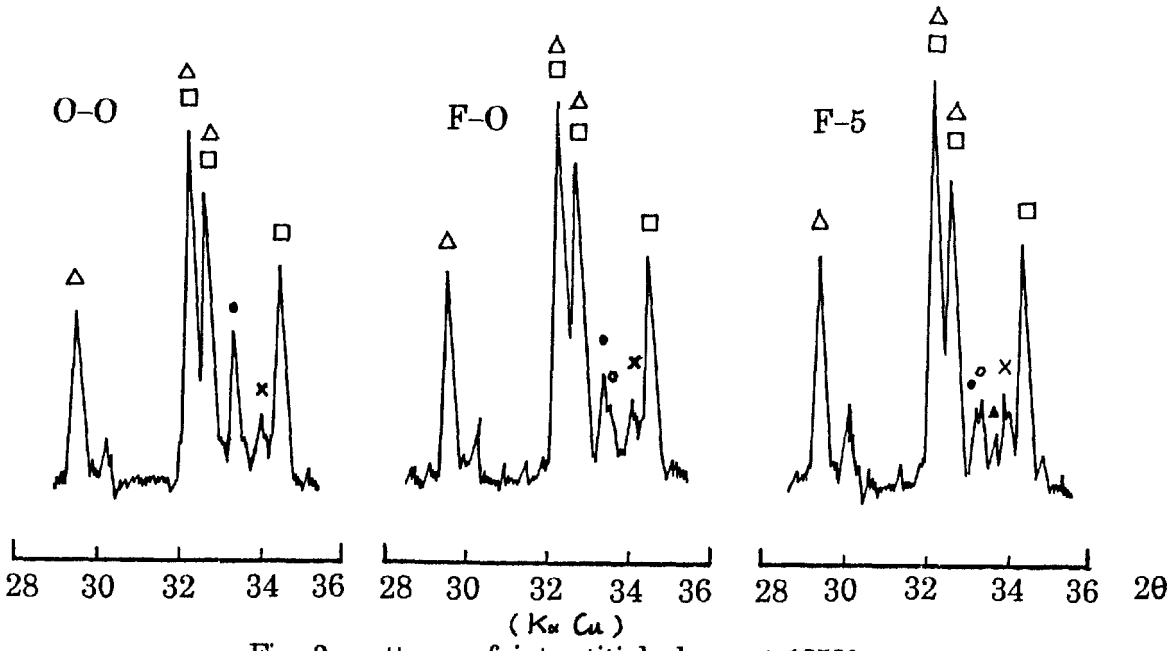

Fig. 3 patterns of interstitial phase at 1350℃
△C_3S, □C_2S, •C_3A, ×C_4AF, ○$C_{11}A_7CaF_2$, ▲C_6A_2C

3. Effect of five trace components on silicate minerals

Figure 2 shows that a number of alite are formed to F-5 sample and only a few to F-0 and no any sign of it is found to 0-0 at 1200℃. At the temperature of 1300℃, The peaks of alite are F-5>F-0>0-0. On the contrary, peaks of belite show opposite results. At 1350℃, the changes of alite are similar to those at 1300℃, moreover, peaks of belite disappear to F-5, F-0 and still can been found to the control sample 0-0. The above results indicated that addition of five trace component was found quite effectively on properties of the liquid phase. The alite micro-crystals formed from solid phases reaction and decomposition of $C_{19}S_7CaF_2$ can continually grow at 1200℃, and get into rapidly develop at 1300℃ and in addition quite a few of alite are formed. The improvement of alite formation at low temperature is obvious compared with CaF_2 doped sample F-0 and pure clinker sample 0-0, which can only be attributed to addition of five trace components, decrease the viscosity and surface tension of the liquid phase and proportionally increase the diffusion velocity of liquid phase, as a result accelerating the reaction of $C_2S+CaO=C_3S$, and providing favorable conditions to form alite quickly.

4. Effect of five trace components on interstitial phase

The C_3A and C_4AF phases are satisfactory crystallized in XRD patterns to 0-0 sample at 1350℃ (Fig. 3). There are some differences to samples F-5, F-0 with 0-0. The presence of fluorite lower and widen peak of C_3A, which indicate $C_{11}A_7CaF_2$ and C_3A phases existed together in clinker, no difference of C_4AF phase has been found to F-0 and 0-0. Peaks of C_3A phase to F-5 are similar to F-0, but the peaks of aluminoferrite phase rise and turn to the direction of C_6A_2F, which are related to five trace components selected into the phase.

5. Effect of iron mud

Addition of iron mud together with fluorite mineralizer provide significantly improves

the burnability and clinker quality. Burnability experiments of raw mixes performed in presence of iron mud compared with other ferrous materials prove the effect of them on clinkering of cement raw mixes to be in following order : iron mud > copper slag > iron powder . Fluorite and iron mud in combination acts as a complex mineralizing agent , producing better results due to combination of CaF_2 with trace components . This composite mineralizer is formed which lowers the temperature of phase transition of solid-liquid phase and reduces the viscosity and surface tension of the liquid phase during the clinkering process and accelerates the rate of ions mobility in liquid and significantly increases the rate of C_3S formation . Based on the results of our laboratory experiments , an industrial production was carried out in six shaft kilns of two plants , for one year and excellent results were obtained . It is found to markedly increase kiln output and quality of clinker as manpower requirement has decreased by improved working of kiln . An increase in kiln output of mean 16.2% corresponded to the coal and electricity saving at mean 4.7% and 13.4% respectively and free lime content also decreased. Beside , raw mixes with iron mud are not only considered as a substitute for all ferrous materials and parts of natural mineral of clay , but also acts as trace composition mineralizer and it has showed significant effect on the output, quality and cost of cement manufacture .

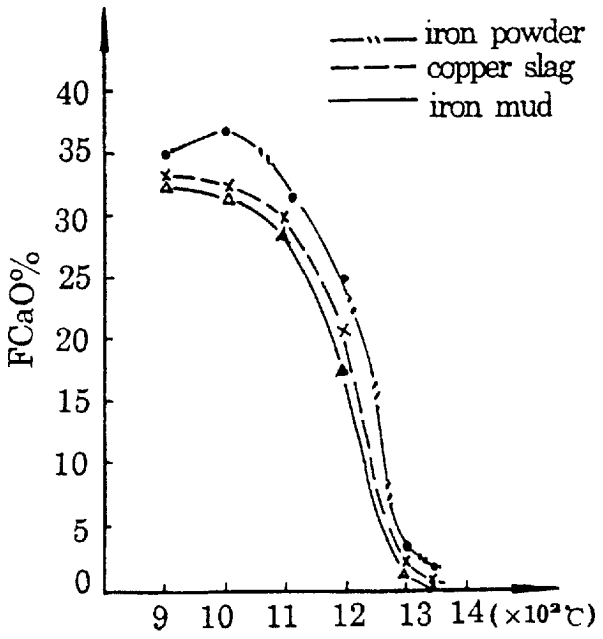

Fig. 4 Influence of iron mud on burnability of raw mix

CONCLUSIONS

1. Five trace components in iron mud increase the combination of cement clinker and this may be attributed to the change of the melt properties through reduction of viscosity and surface tension of melt , and increasing absorption of free lime and accelerating rate of C_3S formation .
2. The results of industrial production experiments indicated that the use of iron mud to produce portland cement can not only promote burnability of raw mixes and achieve fuel saving , but also improve the formation of clinker and the quality of cement .

THE POSSIBILITIES OF UTILIZATION OF WASTE AND RAW MATERIALS CONTAINING Al_2O_3, Fe_2O_3, AND TiO_2 FOR OBTAINING FERRATES.

Zofia KONIK, Andrzej STOK and Janusz IWANCIW, University of Mining and Metallurgy, Cracow, Poland

ABSTRACT The waste materials from the alumina production can be succesfully used in the synthesis of low energy cement clinkers.These clinkers are composed mainly of the C_4AF and $C_4A_3\bar{S}$ phases. In this work the low energy clinker from the red mud and other by-product of high Al_2O_3 content corrected with lime was produced. The phase composition studies of sinters to elucidate the conditions of sintering and the studies of hydratation products were carried out.

Waste material utilization, Sintering, Brownmillerite, Aluminate phase, Hydration.

INTRODUCTION

The cements containing C_2S, $C_4A_3\bar{S}$ and C_4AF are produced at lower energy consumption than the normal portland cements, These cements can be manufactured from the waste materials and usually reveal fairly adequate strength.
The waste materials of high Fe_2O_3 and Al_2O_3 contents , for example so-called red muds, can be used in the C_4AF synthesis. On the other hand, the by-products from alumina industry, having significant Al_2O_3 content can be processed to the sulphate-aluminate $C_4A_3\bar{S}$ containing clinker. These two raw materials, mixed at proper proportion and ground, can be used in the production of sulphate-aluminate cement.

EXPERIMENTAL

The C_4AF phase was produced from the red mud, a by-product in the Bayer alumina production method. The chemical composition of this red mud was as follows:

Table 1 Chemical composition of red mud

Compound	Composition [wt. %]
	red mud
LOI	12.4
CaO	2.1
SiO_2	7.4
Al_2O_3	24.4
Fe_2O_3	40.8
SO_3	0.2
MgO	0.4
TiO_2	7.2
Na_2O	4.5

This red mud was enriched with the lime-bearing raw material of 54,8% CaO content. The mixture of the following composition was prepared: red mud -43 %, lime-bearing component -57%. The raw material thus produced was heated at temperatures:1000, 1100, 1200, 1300 and 1350°C respectively, with subsequent rapid cooling. The products burned at 1000 and 1100°C were poorly sintered, while those burned at 1300 and 1350°C were partially or totally molten. This sinters thus obtained were subsequently ground and subjected to the phase composition analysis by XRD. On the XRD patterns of samples produced at 1000 and 1100°C a considerable amount of unreacted CaO was observed, together with the products, such as C_4AF and C_4T_2F. In the sinter heated at 1200 °C free CaO was not detected and the C_4AF phase was found as a main component together with C_4T_2F and some ß C_2S. At higher temperatures , the C_4AF content decrease. In Figure 1 the XRD pattern of the sinter produced at 1200°C is presented.

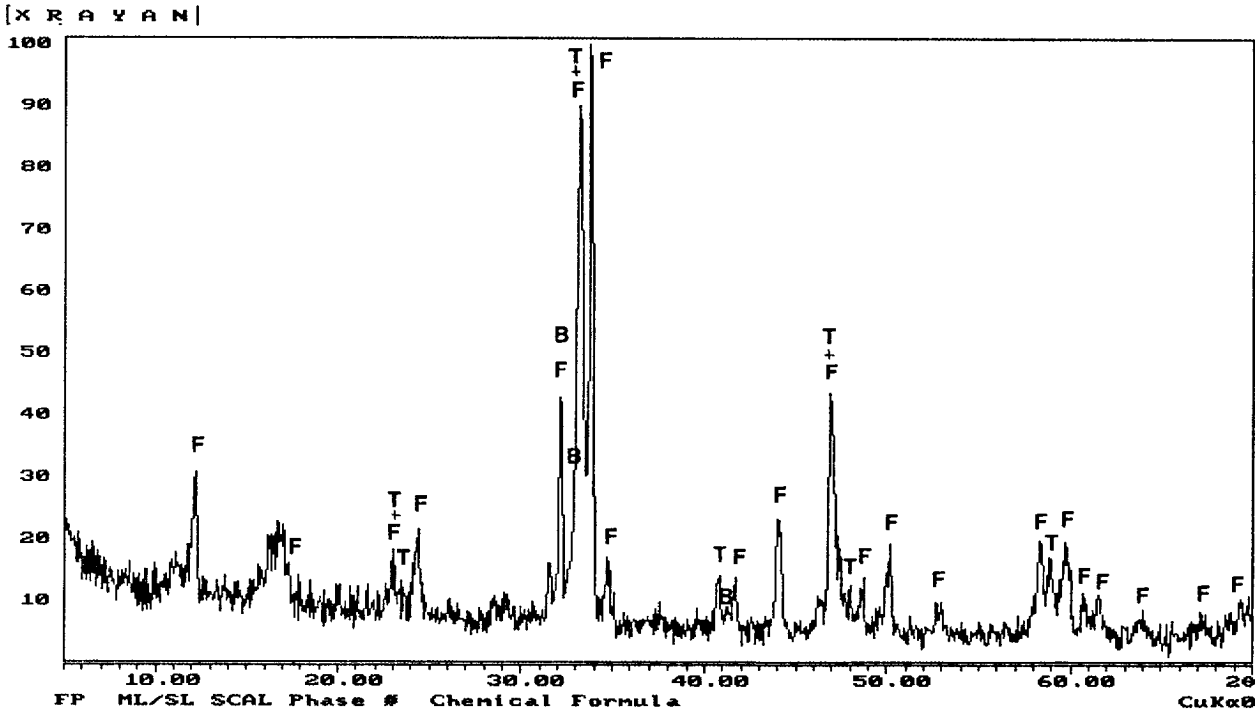

Fig. 1 The XRD pattern of the sinter heated at 1200° C.
F- C_4AF, T- C_4T_2F, B- ß C_2S.

The results of XRD studies have been confirmed by SEM observation.
The C_4A_3S phase was synthesized from the 68% Al_2O_3 containing by-product mixed with lime-bearing component and anhydrite. The raw material thus prepared was subsequently heated at 1250° C. The amount of the C_4A_3S phase in the sintered product has been evaluated for over 70%. The XRD pattern of this sample is shown in Figure 2.
The ground C_4AF and C_4A_3S containing sinters were mixed at 1:1 ratio (without $CaSO_4$ and CaO admixtures), homogenized and hydrated at w/c = 0,33. The rapid setting of cement thus produced occurring within 10 min., was observed (initial setting - 5', final setting - 15').
The samples cured in standart conditions were subjected to the compressive strength tests. The following results have been obtained: 1 day - 11,5 MPa, 3 day - 17,5 MPa, 7 day - 40,8 MPa, 28 day - 48,9 MPa. The standart procedures did not show any undeserable volume changes.
The phase composition determination after 7 days hydration was characterized by XRD.The results are presented in Figure 3.

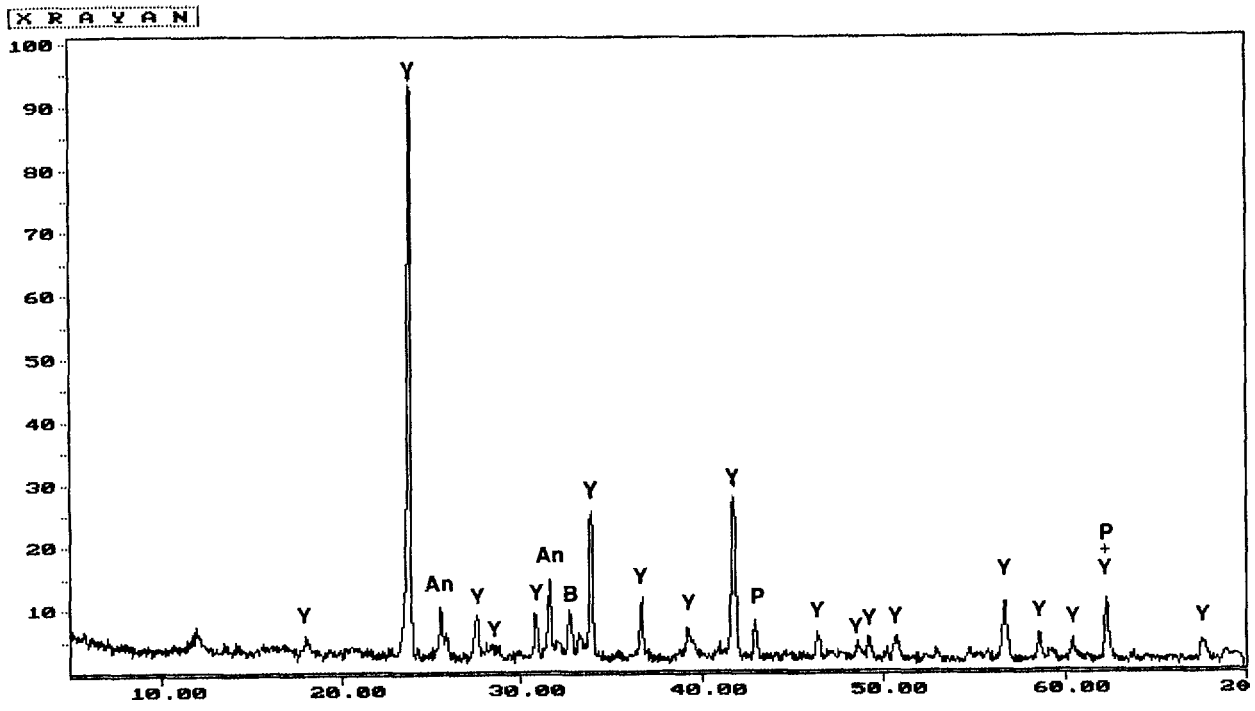

Fig. 2 XRD pattern of $C_4A_3\bar{S}$ containing sinter.
Y - $C_4A_3\bar{S}$ P - MgO B - ß C_2S An - Anhydrite

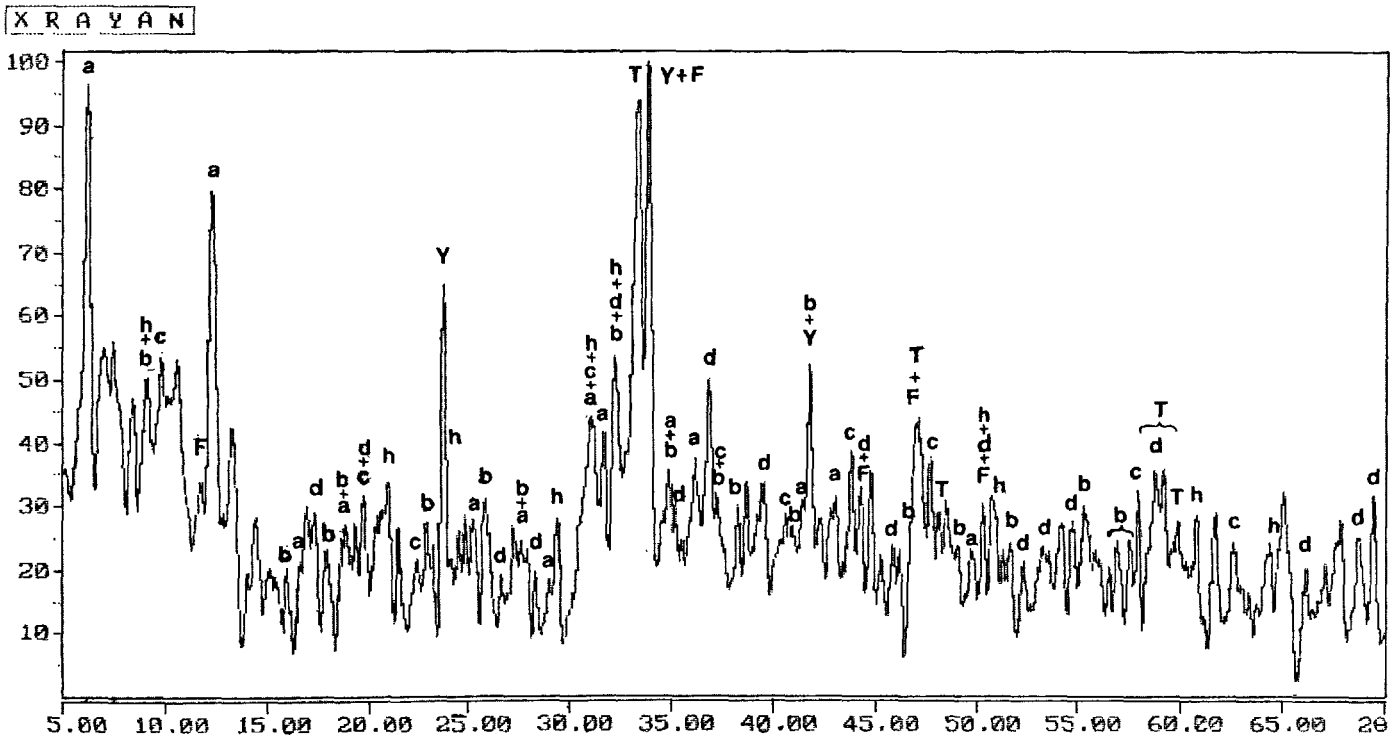

Fig. 3 XRD pattern of 7 days hydrated $C_4AF + C_4A_3\bar{S}$ mixture.
a - CAH_{10} b - $C_3A.(CS)_3.H_{32}$ c - $C_3A.CS.H_{12}$ d - C_3AH_6 h - CSH
F - C_4AF T - C_4T_2F Y - $C_4A_3\bar{S}$

The following hydration products have been found: CAH_{10} , $C_3A.(CS)_3.H_{32}$, $C_3A.CS.H_{12}$, C_3AH_6 and CSH , apart from the residual, unhydrated C_4AF, C_4T_2F and $C_4A_3\bar{S}$ components. The background increase results from the presence of amorphous and poorly crystalline hydration products.

CONCLUSIONS

1. The temperature of reaction between the by-product red mud and lime bearing component to produce the sinter of optimum phase composition was determined for 1200°C. In this temperature C_4AF is formed as a main phase and TiO_2 is bound in the C_4T_2F phase.
2. The mixture of C_4AF and $C_4A_3\bar{S}$ reacts with water to form a significant amount of amorphous and poorly crystalline material. The other, cristalline hydration products are: CAH_{10} , $C_3A.(CS)_3.H_{32}$, $C_3A.CS.H_{12}$, C_3AH_6 and CSH.

THE APPLICATION OF HIGH MAGNESIUM OXIDE CONTENT LIMESTONE IN CEMENT INDUSTRY

Guojun HU, Department of Materials Science & Engineering, Zhejiang University, Hangzhou 310027, P.R.China

ABSTRACT The burning mechanisms of the clinker and autoclave expansion of cement using the high MgO content limestone have been investigated in this paper. Experimental results show that MgO in clinker mainly occur in alite and belite phases. The amount of MgO solid solution in clinker fluxing mineral increases with the increase in the content of fluxing mineral. During the clinker burning process, the amount of periclase in clinker would be reduced to a minimum under the proper proportion and burning conditions. When the mineral additions are added in cement, the autoclave expansion of the high MgO content cement decreases.

Key-words: MgO, Solid Solution, Burning Conditions of Clinker, Autoclave Soundness

INTRODUCTION

As early as the 19th century, there was great attention on the phenomenon that many concrete buildings broke down, because the free MgO (periclase) in cement hydrates and causes the volume expansion. Periclase hydrates very slowly at room temperature, for example, up to years or longer (Kasselouris et al., 1985). When periclase reacts with water and produces $Mg(OH)_2$, the volume of hardened cement paste expands about 117%. As a result, the hardened cement paste cracks or breaks down. Therefore, the MgO content in cement is limited at the range 2.5~6.0 wt% in many countries (Ramachandran et al., 1981 and Rosa, 1965).

MgO in ordinary portland cement comes from MgO containing minerals that are used in cement clinker production. These minerals decompose into magnesium oxide during calcination. Some of MgO dissolves in a liquid phase and clinker minerals. When the clinker cools, the free MgO forms, which is periclase. But, MgO in the solid solution does not hydrate (Reshi, 1983). The amount of limestone producing portland cement clinker is about 80% of the all raw materials, therefore, MgO mainly comes from carbonated limestone. In order to decrease the MgO content in cement, many companies use the high quality limestone. Most of limestone with high MgO content is rarely used in China, for this reason, it is necessary to consider the problem about the application of high MgO content limestone in cement industry(Hu, 1987).

A great amount of research work has been done on the MgO in cement clinker burning, such as the distribution of MgO in clinker, the effects of burning temperature, cooling condition and the periclase hydrate expansion (Dreizler and Knofel, 1982). The aim of this work is to study the burning mechanisms of the clinker using high MgO content limestone, investigate the producing parameter, and test the autoclave soundness of high MgO content cements.

EXPERIMENTAL

Raw materials

The raw materials used for the preparation of clinker were limestone, clay and iron ore, all of which were of industrial origin. Their chemical composition is shown in Table 1. In accordance with research work, the high MgO content limestone was used in experiments. X-ray analysis

results showed that the mineral composition of high MgO limestone was mainly dolomite [$CaMg(CO_3)_2$] (Hu, 1992).

Table 1 Chemical composition of raw materials (wt%)

	CaO	MgO	Fe_2O_3	Al_2O_3	SiO_2	Loss	Total
Limestone(I)	31.91	17.15	0.37	1.25	4.72	43.05	94.62
Limestone(II)	51.94	0.86	0.14	0.76	2.47	42.20	98.37
Clay	0.27	0.81	8.40	19.24	63.13	6.66	98.51
Iron ore	3.14	1.95	44.24	7.55	34.38	3.04	94.08

Note: Limestone(I) is high MgO content limestone

Raw mix proportioning and burning

In this experiment, two essential components were adopted, which were a) different MgO content and b) different KH value(lime saturation coefficient). The samples were burned in electric furnace at the fixed condition(discused as follow) and cooled quickly in air. Table 2 is the chemical composition of clinkers.

Table 2 Chemical composition and modulus of clinkers

	Chemical composition(wt%)						Modulus		
	CaO	MgO	Fe_2O_3	Al_2O_3	SiO_2	Total	KH	SM	IM
Clinker A	65.18	1.52	4.62	5.96	20.80	98.08	0.921	1.97	1.29

Method of clinker analysis

The chemical compositions of clinker and the contents of F-CaO in clinkers were determined by chemical analysis according to Chinese Standard (GB176-87). The contents of MgO in mineral solid solution and F-MgO (periclase) in clinkers were measured by chemical analysis (Building Materials Academy of China, 1989).

Cements

The cement specimens were prepared by intergrinding above clinkers with gypsum (SO_3=1.80 wt% in cement) and different mineral additions--blastfurnace slag or fly ash. The surface area of cements was about 300 cm^2/Kg.

Testing of autoclave soundness of cement

The autoclave soundness of cement neat paste specimens was tested at 2.0 MPa (216 °C) for 3 hours after cured in 100 °C water for 4 hours, according to Chinese standard (GB750-65) (Building Materials Academy of China, 1985).

RESULTS AND DISCUSSION

Study of clinker burning with high MgO content limestone

The clinker containing different MgO content burned

The MgO contents of specimens (clinker A, B, C, D and E) are 1.52 wt%, 5.05 wt%, 6.01 wt%, 8.00 wt% and 11.00 wt% respectively. Samples are burned at 1380 °C for 50 minutes. The MgO contents in different phases of clinker are shown in Table 3.

Table 3 Distribution of MgO in Clinker (wt%)

	Total MgO	F-MgO	MgO in alite and belite	MgO in ferrite phase	MgO in other phases	F-CaO
Clinker A	1.52	0.00	0.86	0.23	0.43	0.26
Clinker B	5.05	2.53	0.92	0.87	0.73	0.74
Clinker C	6.01	3.14	0.74	1.27	0.86	0.32
Clinker D	8.00	4.14	0.73	1.54	1.59	2.15
Clinker E	11.00	6.90	0.74	1.77	1.59	1.96

Note: F-MgO is periclase.

From the X-ray analysis results (Hu, 1992), these five specimens were burned completely and the minerals of clinker were mainly C_3S, C_2S, C_3A and C_4AF. The results of chemical analysis show that the periclase content in clinkers increases with the increasing of MgO content. Besides periclase, remain part of MgO resides in each mineral of clinker. MgO prefer to dissolve in alite and belite phase, and the amount of MgO solid solution is about 1.1 wt% of the total amount of alite and belite phase in clinker.

The clinker burned at different burning temperature

In cement producing process, the clinker would be burned at the range of burning temperature. At the different burning temperature, the minerals of clinker form differently. The distribution of MgO and the formation of periclase also change. Sample C burned at different temperature are studied, the results are shown in table 4.

Table 4 The distribution of MgO of sample C burned at different temperature (wt%) (Burning time is all 50 minutes)

	EXPERIMENTAL Total MgO	F-MgO	MgO in alite and belite	MgO in ferrite phase	MgO in other phases	F-CaO
1200 °C	6.01	5.82	0.12	0.07	0.00	11.50
1250 °C	6.01	5.10	0.12	0.65	0.14	3.30
1300 °C	6.01	3.54	0.48	1.50	0.49	0.26
1350 °C	6.01	3.36	0.74	1.19	0.73	0.14
1375 °C	6.01	3.18	0.72	1.25	0.86	0.14
1380 °C	6.01	3.14	0.74	1.27	0.86	0.32
1400 °C	6.01	2.61	0.72	1.45	1.23	0.16
1420 °C	6.01	1.99	0.74	1.60	1.72	0.12

Below 1300 °C, the mix materials do not burn well, the amount of F-CaO is high and the amount of periclase in clinker is also high. The samples are burned good only when the burning temperature above 1300 °C. In the case, the amount of solid solution of MgO in alite and belite is about 1.1 wt% of the total amount of alite and belite phases. But the amount of solid solution of MgO in ferrite phase and other phases increases with the burning temperature increasing, therefore, the periclase content in clinker greatly reduces. The reason is that MgO can be dissolved in minerals more and more with the burning temperature increasing.

Effect of the different mineral components

During the burning of clinker, due to the different raw materials and burning conditions or the type of clinker, the mineral compositions of clinker change in a certain range. Of course, the amount of MgO solid solution in clinker minerals also changes. When the lime saturation coefficient (KH) increases (modulus SM and IM keeping constant), the amount of fluxing minerals decreases, and the amount of solid solution of MgO in ferrite phase and other phases reduces, therefore, the content of F-MgO in clinker increases(Table 5).

Table 5 Distribution of MgO in clinker with different KH value (wt%)

	KH	Total MgO	F-MgO	MgO in alite and belite	MgO in ferrite phase	MgO in other phases	F-CaO
Clinker K86	0.891	4.98	1.94	0.79	1.21	1.06	0.27
Clinker K88	0.881	4.99	2.43	0.92	0.70	0.90	0.31
Clinker K90	0.899	4.98	2.44	0.94	0.77	0.85	0.67
Clinker K92	0.919	5.00	2.69	0.75	0.71	0.85	2.66
Clinker K94	0.940	4.98	2.96	0.89	0.43	0.72	3.01

The soundness of autoclave of cements containing high MgO content

The soundness of autoclave of cements made by different MgO content clinker

Cements were synthesized by intergrinding different MgO content clinker with gypsum (SO=1.80% in cement). The cement pastes were prepared with a water-cement (w/c) of 0.25 and cured 24 hours at 20±2 °C wet air, then tested the soundness of autoclave(in 100 °C water for 4 hours and at 2.0 Mpa for 3 hours). The test results are shown in Table 6.

Table 6 The expansive rate of autoclave of cements with different MgO content

	Amount in clinker(wt%)		Expansive rate(%)	
	Total MgO	F-MgO	After 4 hours in 100 °C water	After 3 hours at 2.0 MPa
Cement A	1.52	0.00	0.063	0.074
Cement B	5.05	2.53	0.048	0.199
Cement C	6.01	3.14	0.068	0.333
Cement D	8.00	4.14	0.131	broken down
Cement E	11.00	6.90	0.119	broken down

Note: Expansive rate is cement neat paste free expansive value.

It is clear, when the MgO content in clinker is less than 6.0 wt%, the volume expansion causing by periclase hydrated is little. But, when the MgO content in clinker is greater than 6.0 wt%, the cement specimens can not pass the autoclave test. This is the reason why the maximum of MgO content in cement is 6.0 wt% in many country's standards.

The soundness of autoclave of cements with different KH values

From the above experimental results, when the lime saturation coefficient (KH) of clinker increases, F-MgO in clinker increases, then, the autoclave expansive rate of cements produced by these clinkers also increases (Table 7). Because the total amount of MgO in clinker is only 5.0 wt%, these cements can pass the test of soundness of autoclave.

Table 7 The properties of cements with different KH value around autoclave

	Amount in clinker (wt%)		Expansion rate (%)		Compressive strength (MPa)	
	Total MgO	F-MgO	After 4 hours in 100 °C water	After 3 hours at 2.0 MPa	After 4 hours in 100 °C water	After 3 hours at 2.0 MPa
Cement K86	4.98	1.94	0.048	0.154	58.5	52.4
Cement K88	4.99	2.43	0.063	0.168	70.0	45.6
Cement K90	4.98	2.44	0.052	0.198	67.2	51.9
Cement K92	5.00	2.69	0.140	0.310	63.8	36.5
Cement K94	4.98	2.93	0.190	0.376	71.0	39.0

Note: Compressive strength is that of the hardened cement paste ($20x20x20cm^3$)

Because the periclase hydrates and causes expansion, the structure of the hardened cement paste is disturbed to a certain degree. The strength of the hardened cement paste after autoclave reduces. When the periclase content increases, the expansive rate also increases and the strength of the hardened cement paste decreases.

Effect of the mineral additions

Much research work has indicated that, when the mineral additions are added in the high MgO content cement, the expansive rate of autoclave of periclase reduces. There are both physical and chemical effects on above results. The content of F-MgO in cement becomes less because of the adding of the mineral additions. On other hand, these mineral additions absorb the $Mg(OH)_2$, which is the product of periclase hydrating, change the structure of the hardened cement paste, and lessen the expansive rate. Of course, there are different effects with adding of the different mineral additions. The results of Table 8 show that the autoclave expansion of high MgO content cement, which is added blastfurance slag or fly ash, can be restrained effectively. The effect on controlling the autoclave expansion is more obvious with the increasing of the adding amount. For example, the cement D1 containing 8.00 wt% MgO is destroyed after 3 hours autoclave, but the cement D3, D4 and D6, which are added 25 wt% and 40 wt% blastfurnace slag and 30 wt% fly ash respectively, can pass the test of autoclave. The cement E6 with 30 wt% fly ash decreases the autoclave expansion, which is made by the clinker containing 11.00 wt% MgO. The test results also indicate that the fly ash has more obvious effect on controlling the autoclave expansion of high MgO content cement than the blastfurnace slag.

Table 8 The expansive rate of autoclave of cements with adding amount of mineral addition

	Adding amount of mineral addition (wt%)		F-MgO in cement(wt%) (result of account)	Expansive rate (%)	
	Blastfurnace slag	Fly ash		After 4 hours in 100 °C water	After 3 hours at 2.0 MPa
Cement A1	0	0	0	0.063	0.074
Cement A2	13	0	0	0.069	0.080

Cement A5	0	13	0	0.064	0.027
Cement A6	0	30	0	0.007	-0.028
Cement B1	0	0	2.43	0.048	0.199
Cement B2	13	0	2.10	0.037	0.132
Cement B3	25	0	1.80	0.030	0.096
Cement B4	40	0	1.42	0.067	0.075
Cement B5	0	13	2.10	0.031	0.052
Cement B6	0	30	1.67	0.023	0.007
Cement C1	0	0	3.04	0.068	0.333
Cement C2	13	0	2.61	0.048	0.264
Cement C3	25	0	2.23	0.055	0.124
Cement C4	40	0	1.76	0.055	0.091
Cement C5	0	13	2.61	0.050	0.087
Cement C6	0	30	2.07	0.045	0.021
Cement D1	0	0	3.97	0.131	broken down
Cement D2	13	0	3.35	0.064	broken down
Cement D3	25	0	2.94	0.080	0.361
Cement D4	40	0	2.32	0.066	0.236
Cement D5	0	13	3.35	0.070	broken down
Cement D6	0	30	2.73	0.039	0.206
Cement E1	0	0	6.62	0.119	broken down
Cement E2	13	0	5.73	0.110	broken down
Cement E3	25	0	4.90	0.084	broken down
Cement E4	40	0	3.86	0.064	broken down
Cement E5	0	13	5.73	0.087	broken down
Cement E6	0	30	4.55	0.044	0.718

CONCLUSIONS

In order to use the high MgO content limestone in cement industry, the rational producing parameters should be considered. Experimental results show that MgO in clinker mainly solves in alite and belite phases, and the amount of solid solution is about 1.1 wt% of the total amount of alite and belite phases in clinker. The amount of MgO solid solution in clinker fluxing mineral increases with the increasing of the content of fluxing mineral. During the clinker burning process, the periclase in clinker would be minimum under the proper proportion and burning conditions. Experimental results also show that the specimens of normal portland cement containing less than 6 wt% MgO can pass the autoclave test. When the mineral additions are added in cement, the autoclave expansion of the high MgO content cement becomes less. The previous unsound high MgO content cement can pass the test of soundness.

SYNTHESIS AND CHARACTERIZATION OF NEW ALKALI-ACTIVATE CEMENTS

R.I.A. MALEK, and D.M. ROY, Materials Research Laboratory, The Pennsylvania State University, University Park, PA. 16802, USA.

ABSTRACT A novel approach to synthesize aluminosilicate cementitious materials has been developed. The new cement utilizes large volumes of waste materials and industrial by-products and can reduce CO_2 emission resulting from decarbonation of limestone and use of fossil fuel in the kiln. Isothermal calorimetry experiments indicated an acceleration of hydration and the strength is nearly equivalent to that of neat cement pastes. The pore structure of the new systems is finer than normal cement and the reactivities towards alkali-silica reaction are minimal. The magic angle NMR studies indicate that Si/Al ratio is 1-1.3.

Key-words: Aluminosilicate, carbon dioxide, Nuclear Magnetic Resonance, synthesis, zeolites.

INTRODUCTION

There is no longer any doubt that we are entering a period in which the CO_2 emission to the environment must be regulated. The cement industry constitutes the largest volume among manufactured materials in the world and is one of the major contributors to carbon dioxide in the atmosphere. This is the result of decomposition of calcite and use of fossil fuel in the kiln during cement manufacture. In the last two decades, there has been an increasing interest in the use of alkali activated materials as substitutes of Portland cement. Originally, it was limited to the activation of granulated slags using alkali metal hydroxides (Purdon, 1940), but recently the alkali activated cements have been extended to include several industrial by-products and wastes. Therefore, developing means to utilize large volumes of waste materials in blended cements for the construction of infrastructure and other building projects should provide significant economic and environmental benefits (Malek and Roy et al, 1986, 1987a, 1987b and 1993). The use of alkali-activated slags as a binder has significantly increased in recent years. Various national and international standards allow different contents of ground granulated slag in the blends with cement: up to 65% in Great Britain and USA; 70% in Japan; and 80% in Germany, Russian republics, and Czechoslovakia (Roy and Malek, 1993). The chemical activation of slag by different metal salts such as calcium or sodium sulfates or chlorides is sometimes used. Very interesting are the rapid hardening mixtures of slag + fly ash + gypsum + cement or lime (Davidovits, 1983) the purpose of which is to economize the building materials costs and the energy. Thermal activation of slag without chemical activators is another possibility. Roy et al., 1992, summarized studies of Portland cement alkali-activated blends.

A new class of binders is formed by mixing some form of alkaline activator with a wide variety of silicate and/or aluminum rich minerals and glasses to form aluminosilicate frameworks. Therefore different fine-grained alumino-silicates (clay, ground rock, ash, slag) can be used as raw materials. The possible mechanism involves the chemical reaction of aluminosilicate with alkalis and alkali polysilicate yielding polymeric or crystalline Si--O--Al bonds. The new class of aluminosilicate cementitious materials can reduce CO_2 emission resulting from manufacture of Portland cement. It has an advantage over the traditional pozzolanic cementitious materials by being potentially zeolitic in nature which makes it particularly useful in trapping hazardous ions as in the case of radioactive waste disposal and in fixation of the alkali metal ions responsible for alkali-silica (aggregate) reaction. The new cement utilizes large volumes of waste materials and industrial by products such as slags and fly ash and should provide significant economic and environmental benefits.

The durability of aluminosilicate structures arises from the fact that they may form three dimensional networks that encompass the entire structure through chemical bonding. This structure is potentially more durable than the hydrated Portland cement in which the strength is mostly mechanical through foiled sheets of calcium silicate hydrate. Because of the difference in charge between Si and Al, a balancing positive charge must be present for each aluminum in the structure. The existence of positively charged ions in their structure offers an advantage to fix alkali metal cations such including radioactive ions.

The purpose of this paper is to report on the preliminary results on the nature of phases formed and their durability. The effect of these phases on the long-term engineering properties is discussed. In the present investigation, two systems were studied, namely, a low-calcium and a high-calcium systems. A new approach to formulate these systems was followed by adjusting the Si/Al ratio to be nearly equivalent to natural aluminosilicate materials. Additional blends were made with Portland cement.

EXPERIMENTAL

A broad range of alkali-activated aluminosilicate frameworks was prepared with target composition of variable n and m in the formula:

$$\frac{n}{x} M^{x+} [(SiO_2)_m (AlO_2)_n] \cdot yH_2O \qquad [1]$$

where M is an alkali or alkaline earth metal cation. Two systems were studied, namely, low-calcium and high-calcium systems. The low-calcium system is composed of metakaolinite, Class-F fly ash, potassium silicate and potassium hydroxide. The high-calcium system is composed of metakaolinite, Class-C fly ash, ground granulated blast-furnace slag, potassium silicate and potassium hydroxide. Two and three dimensional composition diagrams were used to design the target compositions. Figs. 1 and 2 represent the composition diagrams for aluminosilicate mixtures presented in the present paper, where x = 1, n = 1, and m = 4, for both low-calcium and high-calcium formulations. Blends with cement were prepared as follows:

a. Portland Cement 80% + high-calcium cement 20%
b. Portland Cement 50% + high-calcium cement 50%
c. Portland Cement 80% + low-calcium cement 20%
d. Portland Cement 50% + low-calcium cement 50%

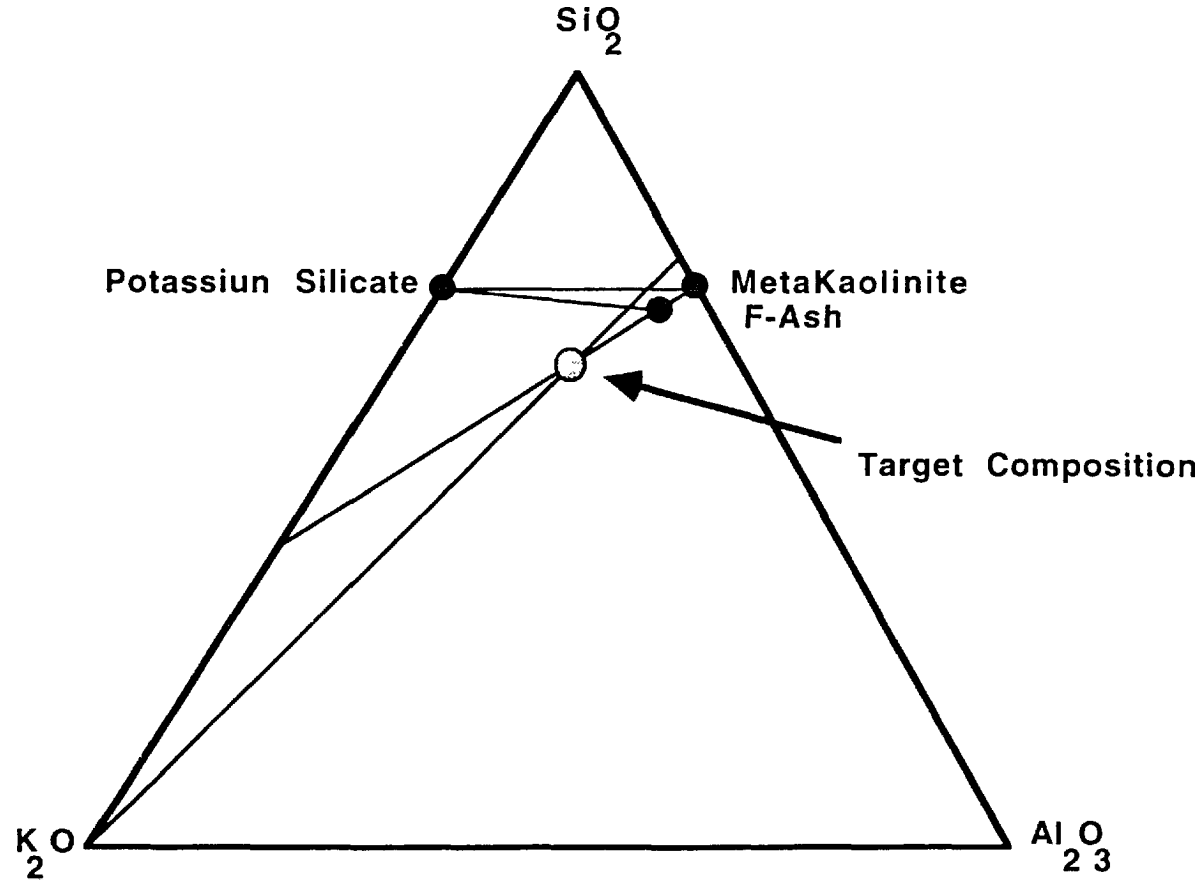

Figure 1. K_2O-SiO_2-Al_2O_3 diagram showing target composition (x=1, n=1, m=4) and components used in formulating the low-calcium aluminosilicate cementitious materials.

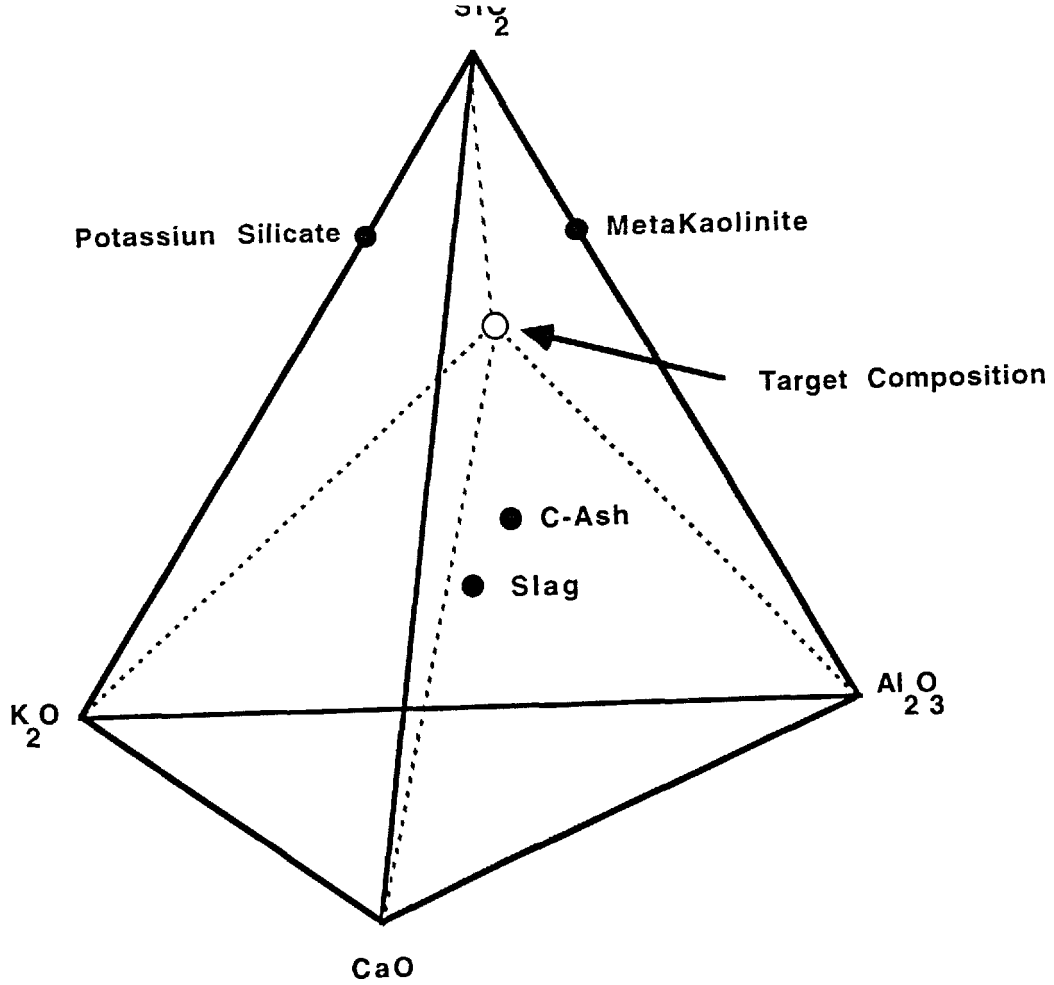

Figure 2. K_2O-CaO-SiO_2-Al_2O_3 diagram showing target composition (x=1, n=1, m=4) and components used in formulating the high-calcium aluminosilicate cementitious materials.

The water content was adjusted to obtain workable pastes (0.35 in the samples presented in this paper). Samples were cured at 38° and 100% saturated humidity. Properties of the samples were monitored, and characterized by various methods. These methods include investigation of mechanical and physical properties. The evolution of the pore system in comparison with plain Portland cement was also made. Mortar bar expansion tests were made according to ASTM C227 standard for alkali-aggregate reactivity using Beltane Opal as a reactive aggregate.

Although naturally occurring aluminosilicate structures are highly crystalline, their formation into cementitious materials is expected to be almost always in a micro crystalline form with crystal dimensions of the order of microns, or at low temperatures, amorphous structures with only short-range order. In addition, the lack of Si, Al ordering means that only average structures will be obtained from diffraction measurements. The solid-state, high-resolution NMR spectroscopy has emerged as a powerful technique for structural investigations of these materials. Solid-state ^{29}Si and ^{27}Al magic angle NMR spectroscopy was used to characterize the products. The spectra were obtained at 7.04T using a Chemagnetics CMX-300 spectrometer. The ^{29}Si spectra were obtained at 59.08 MHz with a 90° pulse and a recycle delay time of 30s. The ^{29}Si shifts were referenced to tetramethylsilane (TMS). The ^{27}Al spectra were collected at 77.48 MHz with a 90° pulse of 5 ms and a recycle time of 2 s. The ^{27}Al chemical shifts were measured with reference to a 1M aqueous solution of $[Al(H_2O)_6]^{3+}$. The ^{29}Si magic angle spinning (MAS) NMR spectra of these systems are expected to show one or a combination of five resonances corresponding to the five local silicon environments: Q^4(4 Al), Q^4(3 Al), Q^4(2 Al), Q^4(1 Al), and Q^4. Al atoms in the framework are always in tetrahedral sites and the ^{27}Al MAS NMR spectra should show single resonances characteristically at 40-60 ppm. Octahedrally coordinated aluminum gives rise to signals at ~0 ppm.

RESULTS AND DISCUSSION

Isothermal calorimetry data of the cement pastes containing 50% of low-calcium and high-calcium blends at 38°C are presented in Figs 3 together with those of neat Portland cement paste for comparison. This figure shows the gradual increase in reactivity as the extent of potassium increases.

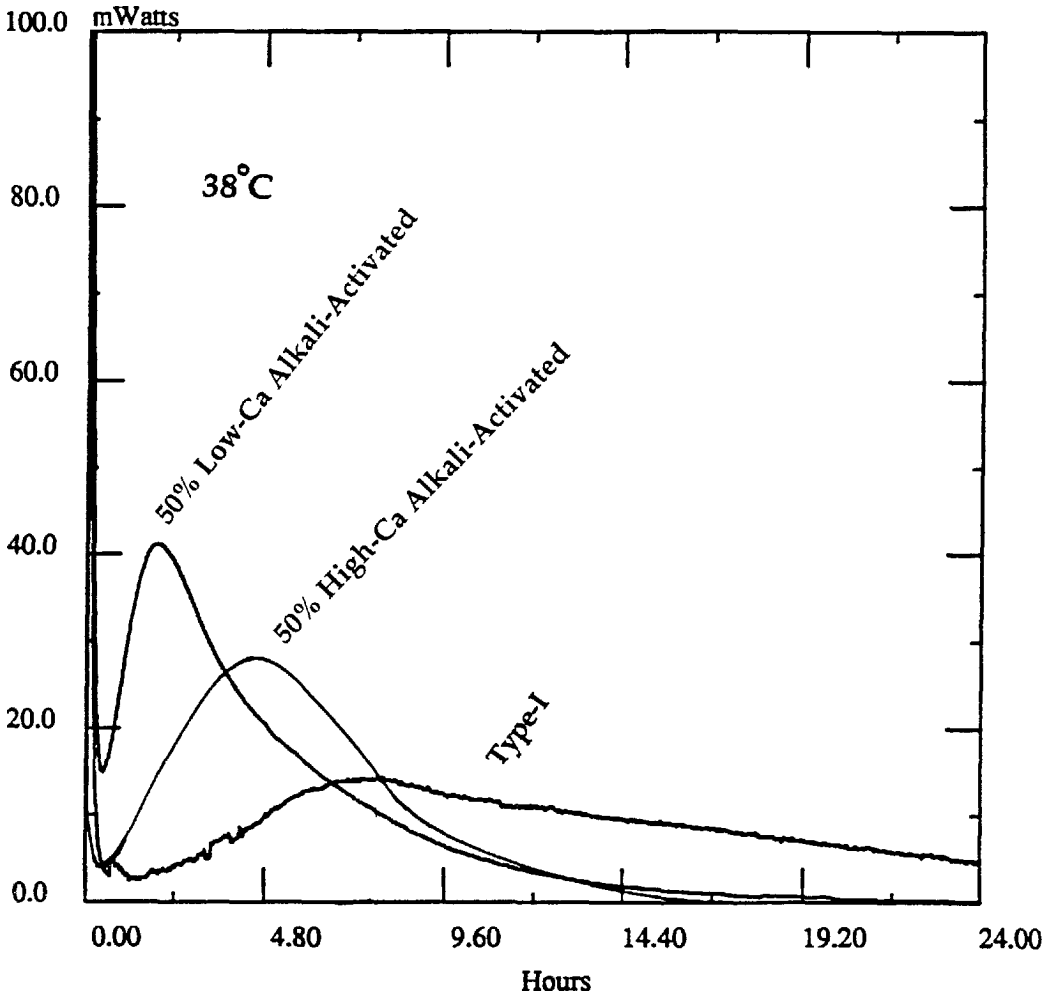

Figure 3. Isothermal calorimetry data of 50% low-calcium and 50% high-calcium materials together with that of neat cement.

Compressive strength data at 7 and 14 days for samples cured at 38°C are presented in Figs 4 and 5, respectively. In these figures, the compressive strength data on neat Portland cement pastes and a commercially available aluminosilicate binder (Pyrament) at the same age and temperature are included for comparison. It is evident that the compressive strength values of cement pastes containing 20% and 50% of high-calcium materials are equivalent to those of neat cement pastes and slightly exceed those of the Pyrament. The corresponding blends made with low-calcium materials are lower in strength but their strength seems to increase with time. The pore structure evolution has been studied by mercury intrusion porosimetry. Results of pore size distributions at 14 days of the blends containing 50% alkali activated materials cured at 38°C are presented in Fig 6. In the same figure, the pore size distribution of the neat cement paste at the same age and curing temperature is shown. It is evident that the alkali activated systems develop a finer pore structure compared to neat cement pastes. In addition, the blends with high-calcium materials seems developing the finest pore structure, possibly because they are more fully reacted. The 28-day mortar bar expansion using ASTM C-227 to test potential alkali-silica reaction are presented in Fig 7. Results of high alkali cement (1.2% Na_2O equivalent), Type-I Portland cement with potassium hydroxide (3% by weight) and Pyrament are included for comparison. It is clear that the alkali activated aluminosilicate materials gave the lowest reaction with silica.

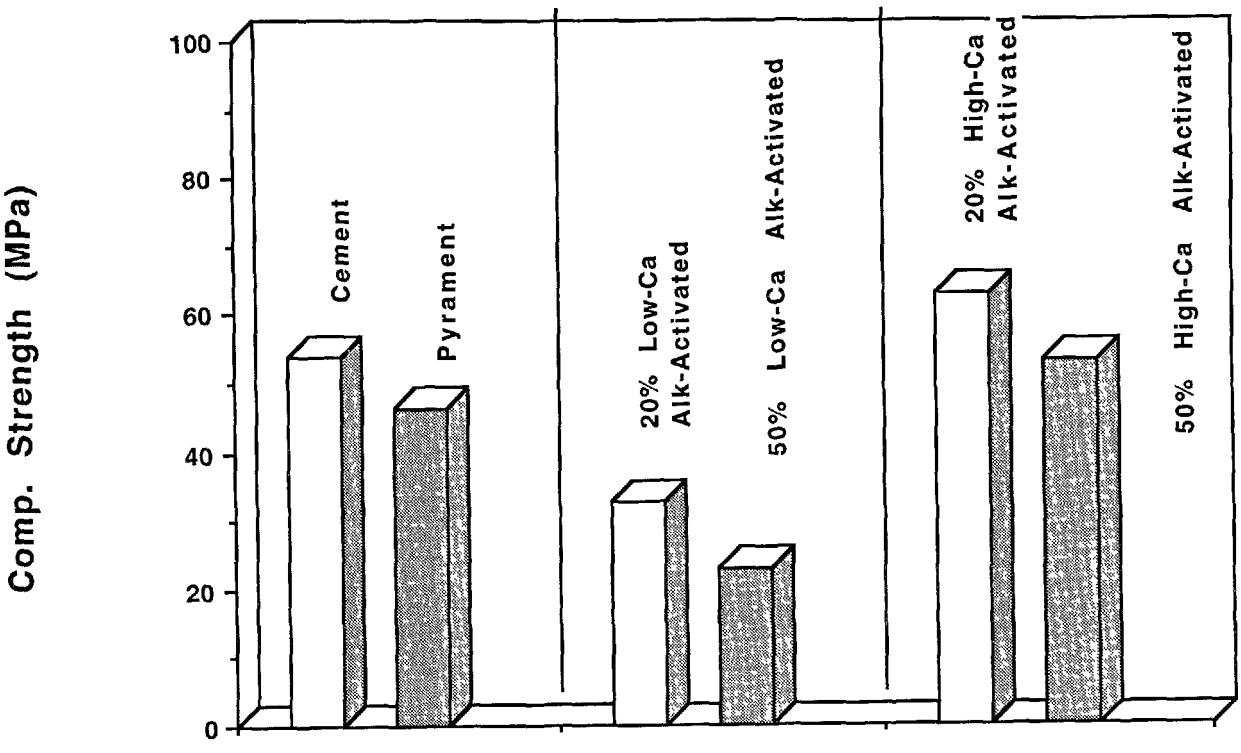

Figure 4. Compressive strength of low-calcium, high-calcium blends, Portland cement, and Pyrament at 7 days, 38°C.

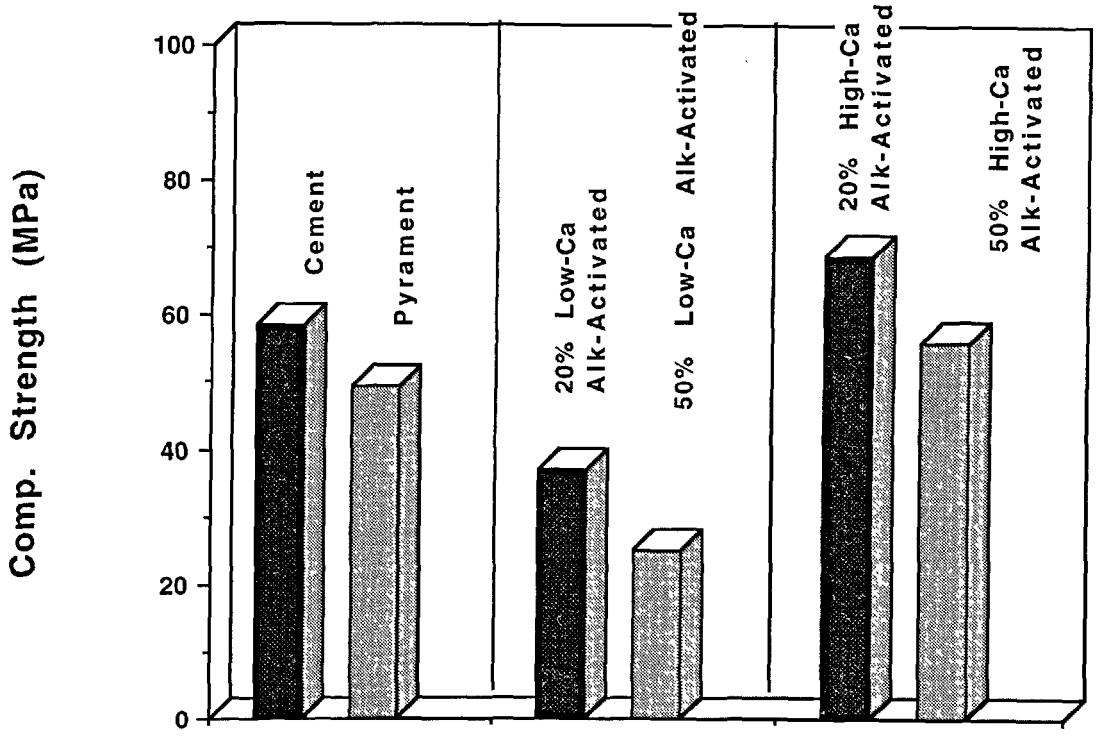

Figure 5. Compressive strength of the low-calcium, high-calcium blends, neat Portland cement, and Pyrament at 14 days, 38°C.

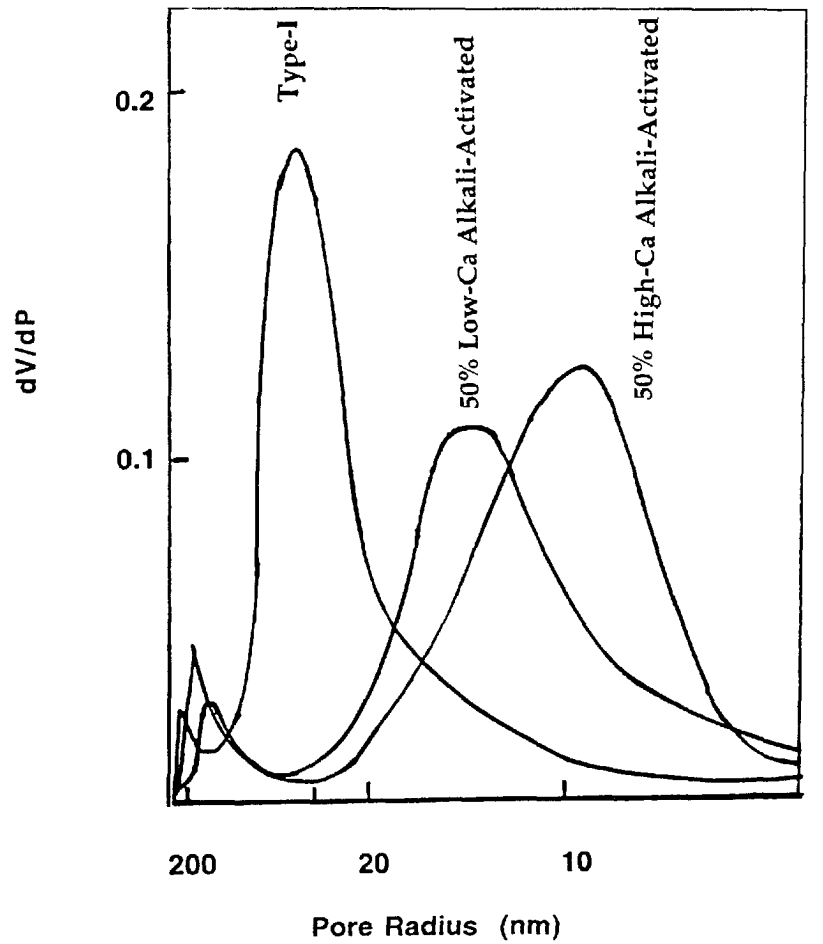

Figure 6. Pore size distribution of low-calcium and high-calcium blends together with those of neat Portland cement paste cured for 14 days at 38°C.

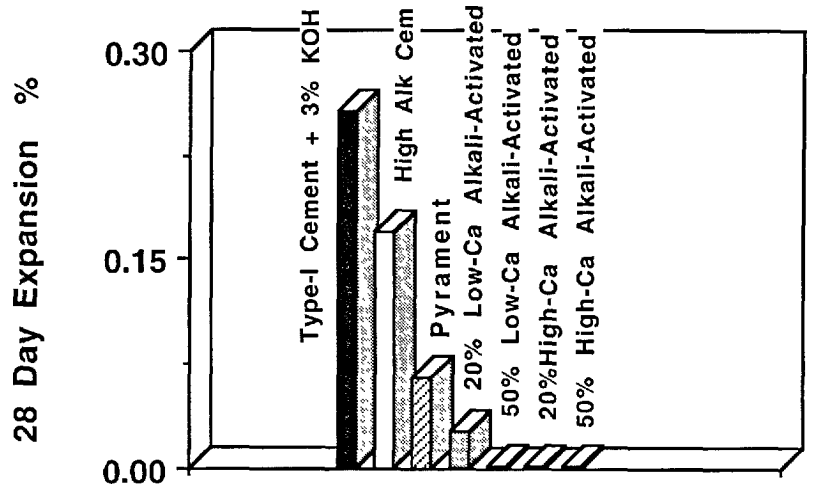

Figure 7. 28-days mortar bar expansions (ASTM C-227) for testing alkali-silica reaction.

The ^{29}Si magic angle NMR spectroscopy of the low-calcium materials cured for 14 days at 38°C is shown in Fig 8. The same figure contains a simulation of the zeolitic peaks Q^n (nAl). The spectrum shows two major features: a broad peak centered at about - 83 ppm arises from the silicoaluminate species Q^4 (4 Al). The broad nature of this peak is an indication of the disordered micro crystalline structure (x-ray amorphous). The other feature is the presence of a series of minor resonances ranging from - 92 ppm to -102 ppm arising from other aluminosilicate species. The peak locations and assignments were estimated and are given in Table I.

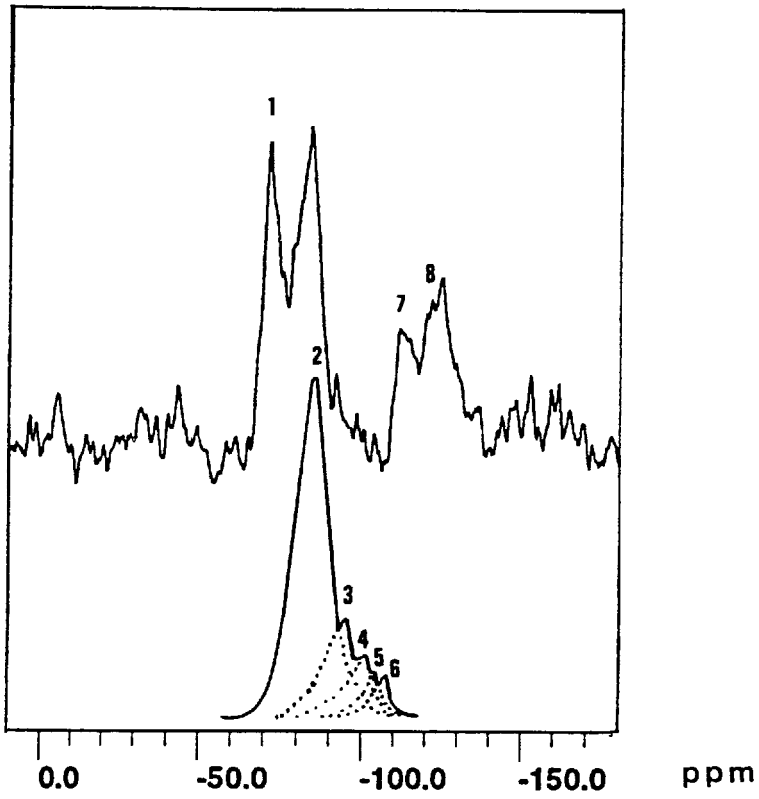

Figure 8. Observed and simulated ^{29}Si magic angle NMR spectroscopy of the low-calcium materials cured for 14 days at 38°C. Peak assignments are given in Table I.

Table I. Calculated parameters of ^{29}Si magic angle NMR spectrum of the low-calcium material cured for 14 days at 38°C.

Peak number	Peak location, ppm	Peak assignment	% Area*
1	- 72	Monomeric SiO_2	
2	- 83	Q^4 (4 Al)	81.4
3	- 92	Q^4 (3 Al)	11.0
4	- 98	Q^4 (2 Al)	3.3
5	- 100	Q^4 (1 Al)	3.2
6	- 102	Q^4	1.1
7	- 110	Unreacted SiO_2	
8	- 1 20	Unreacted SiO_2	

* Peak areas are calculated for the zeolitic peaks only Q^n (n Al).

The relative zeolitic peak areas as calculated from a deconvolution procedure and their relative areas are also given in Table I. The Si/Al ratios were calculated using the relation:

$$Si/Al = \sum_{n=0}^{4} I_{Si}(n\,Al) \Big/ \sum_{n=0}^{4} \frac{n}{4} I_{Si}(n\,Al) \qquad [2]$$

It was found that the Si/Al ratio of K-activated structures is 1.3. In an attempt to find the structure that corresponds to this Si/Al ratio, a comparison was made to known structures that have closest Si/Al ratio. It has been found that the structure of low-Ca materials lies between or a mixture of $KAlSi_2O_6.nH_2O$ (Si/Al = 2) and $KAlSiO_4.nH_2O$ (Si/Al = 1). The spectrum of high-Ca shows a broad peak centered at about -84 ppm. Curve fitting procedures indicate that this peak is a

characteristic of aluminosilicate frameworks with Si/Al ratio of 1 (Fyfe et al, 1991). Comparing this with aluminosilicate structures of the same Si/Al, it was found that the high-Ca structures could be assigned to the formula (K,Ca) $Al_3(SiO_4).nH_2O$. It should be noted that the NMR results reflects the local environments of the Si atoms averaged throughout the structure and do not necessarily imply any simple long-range ordering. Therefore, the low Si/Al ratios predicted from NMR results [m/n ratio = 4 in formula 1] are due to the short-range ordering of these structures. The ^{27}Al magic angle NMR spectroscopy indicates that Al exists in both octahedral and tetrahedral positions in both structures.

The durability of aluminosilicate structures arises from the fact that they exist in three dimensional networks that encompass the entire structure through chemical bonding. This structure is more durable than the hydrated cement in which the strength is mostly mechanical through foiled sheets of calcium silicate hydrate. Because of the difference in charge between Si and Al, a balancing positive charge must be present for each aluminum in the structure. The existence of positively charged ions in their structure explains the ability of these materials to minimize the extent of alkali-silica reaction through tie-in of the alkali metal cations (Malek and Roy, 1983).

CONCLUSIONS

Aluminosilicate materials were developed as an attempt to provide an option to Portland cement with building materials of equivalent or better properties. The synthesized aluminosilicate materials provide significant economic and environmental benefits through reducing the CO_2 emission and utilizing industrial wastes for the construction. The aluminosilicate materials are three dimensional durable frameworks formed by chemical bonding. They fix alkali metal ions in their structure offering an advantage to minimize the extent of alkali-silica reaction.

CALCIUM SULPHOALUMINATE CEMENTS PREPARED FROM LOW-ALUMINA WATERWORKS SLIME

Ko IKEDA, Kunio FUKUDA and Hiromi SHIMA
Department of Advanced Materials Science and Engineering,
Yamaguchi University, Ube 755, Japan.

ABSTRACT Calcium sulphoaluminate cements have been prepared from waterworks slime comprising low-alumina by firing clinkers at 1100℃and 1200℃ with subsequent dosage of much gypsum to the cements. Although compressive strength up to 34.2MPa was reached at 28 d age by paste hydration at W/S 0.40, instability of strength was encountered for some specimens probably due to morphological changes of ettringite during hydration.

Key-words: Sulphoaluminate, Waste material utilization, Ettringite.

INTRODUCTION

Calcium sulphoaluminate cements, henceforth called CSAC's, were originally studied by Viswanathan et al.(1978) and have been practically applied in some countries where bauxite is available to use for alumina source. Much attention has been paid on CSAC's firstly because of low firing temperature and secondly because of less requirement of limestone than for Portland cements in manufacture (Takuma et al.,1994). These properties are all favorable to the environmental conservation in view of saving energy and less emission of carbon dioxide. Mineral compositions of CSAC's are generally characterized by C_4A_3S(Al-hauyne) and belite with minor association of calcium aluminates such as CA and $C_{12}A_7$ and calcium ferrite, although there is a variety enriched in iron to form much amount of C_4AF (Mehta, 1980). So many types of CSAC's can be produced with variable amount of Al-hauyne. When the content of this mineral is high, cements show high early strength. On the contrary, when it is low, the early strength becomes low (Mehta, 1980, Ikeda, 1980). CSAC's are sulphate resistant (Viswanathan et al., 1978) and show good affinity with Portland cement constructions to be repaired so urgently (Chatterjee, oral commun.). Furthermore, CSAC's can be increased in quantity by second dosage of calcium sulphates such as gypsum in quite large amounts after pulverizing the clinkers(Ikeda, 1981, Ikeda et al., 1993, 1994).

In waterworks generally source water is treated with aqueous aluminum polychloride to supply clear water. By this treatment suspending clayey fines are coagulated to sink as slimes and discarded to damping yards after some dewatering processes. The slimes are enriched with alumina-component more or less, generally in the form of gibbsite gel due to hydrolysis of the added polychloride and are considered to be unsuitable to vegetation due to inharmonious chemical compositions with surroundings, when discarded.

CSAC's have superior characters as mentioned, but the most serious problem may be the bauxite whose occurrence is restricted to small number of countries. To cope with

Table 1 Typical chemical compositions for waterworks slimes as dry, in %.

Slime	SiO_2	TiO_2	Al_2O_3	Fe_2O_3	MnO	CaO	MgO	Na_2O	K_2O	P_2O_5	SO_3	LOI	TOTAL
NA-1	38.12	0.51	25.94	5.28	0.19	24.84	1.22	0.65	1.53	1.38	0.28	0.20	100.14
HI-1	40.85	0.34	45.68	5.00	0.79	1.25	0.80	0.51	1.03	0.64	0.23	2.84	99.96

this problem substitutes for bauxite such as anorthosite rocks (Viswanathan et al., 1978), fly ashes (Ikeda, 1984, Sahu and Majling, 1994), multicombination of wastes (Beretka, 1992), dusts of aluminum sash productions and high-alumina blast furnace slags have been studied and above all, the latter two are practically applied in real manufacture. Recently we studied CSAC's prepared from alumina-rich waterworks slimes as the substitutes and successful results were obtained (Ikeda et al., 1993, 1994). In this paper CSAC's will be studied by using alumina-poor waterworks slime with special emphasis to the second dosage of gypsum to the cements.

EXPERIMENTAL

Chemical compositions typical to waterworks slimes are represented in Table 1. In this study NA-1 was used by mixing with appropriate amounts of gypsum and portlandite according to the computer program developed in our laboratory to minimize the amount of free lime based on the chemical compositions of the slime analyzed by the ICP technique as seen in Table 2. The raw meal as mixed was kept for 3 d to dryness at ambient temperature for easy handling which was attainable by forming ettringite, since the slime was wet. After this treatment clinkers were burnt at 1100℃ and 1200℃ for 1 h, each designated as clinkers A and B or cements A and B. Then, the clinkers were pulverized by a pot mill to obtain cements. Finally 2 series and 8 kinds of cements were prepared by blending gypsum as listed in Table 3.

Pastes were prepared by using small scale molds having 1 x 1 x 4 cm dimension. Water to solid ratio, W/S was 0.40 for all specimens. Curings of specimens were performed in 20℃ air having 100 % R.H. for the first day encased with the molds and then, in 20℃ water after demolding at 1 d age. Strength tests were performed at 1 d, 3 d, 7 d and 28 d ages, respectively, for both flexural and compressive strengths, using the 3 prismatic specimens to obtain average values. The span length was 2.5 cm for the 3-point flexural tests. The fractured pieces were collected to store in acetone and then, examined by the XRD and SEM techniques at need as well as the source materials and the raw meal. The amounts of free lime and anhydrite remaining in the clinkers were determined by conventional techniques, ammonium acetate titration and qualitative XRD, respectively.

RESULTS AND DISCUSSION

Waterworks slime and subsidiary sources

Chemical compositions of the waterworks slime, NA-1 are characterized by relatively small amount of alumina and high content of silica vice versa (Table 1). The alumina to silica weight ratio, A/S, considered to be a measure of possible application is 0.68, which may be nearly the lower limit for practical use (Ikeda, 1980). In addition, this slime contains high amount of lime originating from the

JIS 1st grade chemicals were used for gypsum and portlandite.

dewatering process in waterworks. Kaolinite, illite and quartz were identified in the slime by XRD, all originating from the geology of river system in the basin concerned. In addition, presence of tetracalcium hydrate, C_4AH_{13} was observed. This may be attributed to the in situ reaction between gibbsite gel derived from the hydrolysis of aluminum polychloride and slaked lime added to. Therefore, we consider no free gibbsite gel remains in this slime, different from usual slimes. Values of water content and specific surface area are very high as seen in Table 2 where physical characteristics of other sources are also tabulated.

Pretreatment of raw meal

The mixing proportion of source materials is shown in Table 2. Formation of ettringite takes place with consumption of added gypsum and portlandite. The reaction terminated in 3 d and the raw meal became completely dry. On this stage no trace of gypsum was detected, while considerably large amount of remaining portlandite was noted after the reaction at ambient temperature.

Clinker minerals

Formations of Al-hauyne and belite in β -form are obviously seen with minor association of calcium aluminate, CA and sulphospurrite irrespective of firing temperatures as seen in Fig 1. Slight free lime and anhydrite were detected to remain as indicated in Table 3. Potential clinker minerals are tabulated in Table 3 on the basis of computer calculation.

Grindability of clinkers

Present clinkers were very easy to grind. This property is reflected to the fineness of cements represented in Table 3, especially for clinker A due to low temperature firing and also due to very fine character of the waterworks slime itself. We could not prepare cements having standard specific surface area around 3000 g/cm^2 on account of these reasons. Furthermore, we could not prepare pastes for A-0, probably caused by the ultrafine character of cement A. This was improved by second dosage of gypsum. Therefore, we consider the reason of hard kneading is attributed to the free lime included as much as 3.41 percent in clinker A. If remaining anhydrite was much

more in the clinker, A-0 pastes could be prepared.

Strength of pastes

Results of strength tests are summarized in Fig 2. Pastes could not be prepared for A-O due to hard kneading caused by very fast setting as mentioned above. Generally, the strength was higher for A-series than for B-series. A-50 showed high early strength and 35.4MPa was reached at 7 d age. However, slight instability of strength was observed between 7 and 28 d ages, especially to flexural strength. Too much dosage of gypsum makes the strength low as seen for A-80 and A-100.

B-0 showed moderately high early strength, but marked depression of strength was observed in both flexural and compressive strengths. This defect was improved by the second dosage of gypsum as seen in B-80 and B-100, showing smooth development of strength against age. However, the strength was not so high, around 15MPa in compressive strength even at 28 d age. Free lime up to 9 percent is permitted in CSAC clinkers, if clinkers contain sufficient amount of anhydrite (Sudoh et al., 1980). Therefore, more enrichment of anhydrite as well as free lime in clinkers may promote the strength as achieved by Sahu et al., 1994.

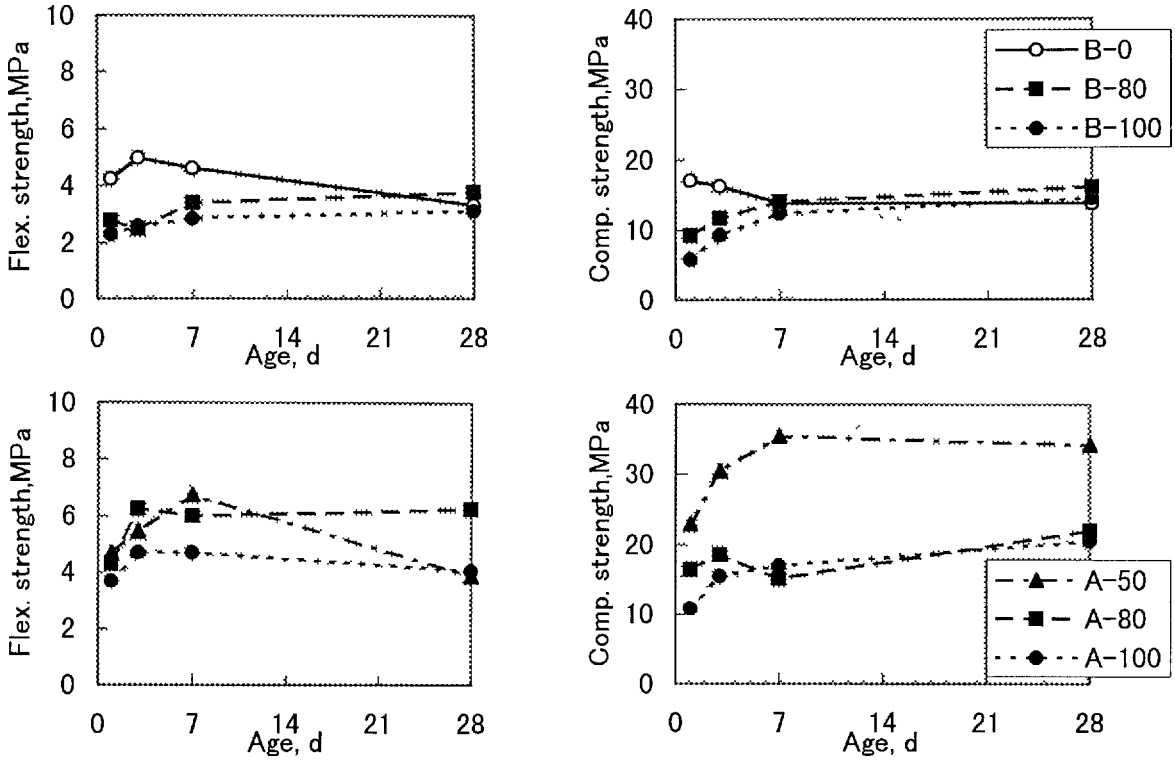

Figure 2 Flexural and compressive strengths for cements A and B.

Hydrates

Basically as tabulated in Table 4, enhanced formation of ettringite associated with minor formations of calcium monosulphate hydrate and/or CAH_{10} was observed throughout all specimens except B-0 where formation of stratringite was detected instead of ettringite. Formation of C-S-H was uncertain by XRD due to the ill-crystalline nature of this mineral, but it was detected in some pictures by SEM. Gypsum remained in abundance even in advanced age. Al-hauyne was not detected in entire range of age due to the rapid hydration nature of this mineral, while abundant C_2S was detected to remain in entire range of age.

Morphological changes of ettringite

This phenomenon is noteworthy in relation to the instability of strength. Ettringites appeared in acicular shapes in the first 1 d humid air-curings with no exceptions. After the 1 d curings, hardened bodies were demolded and saoked in water for subsequent water-curings. On this stage, cracks were suddenly generated

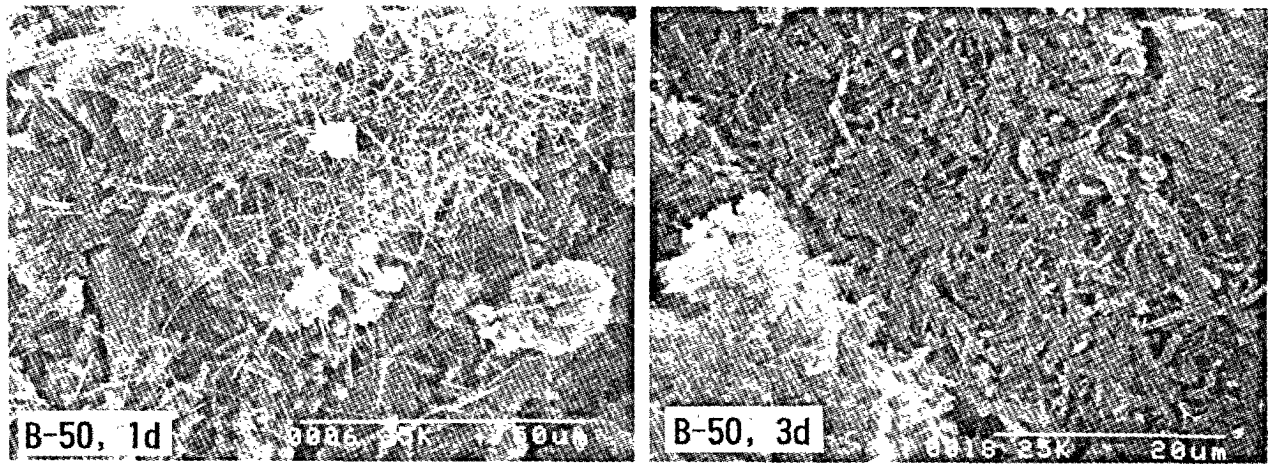

Figure 3 SEM photomicrographs showing morphological change of ettringite.

for specimens B-50 due to well-known expansion caused by ettringites. No cracks were observed in specimens other than specimens B-50. At the moment just after 3 d age, we found drastic changes of morphology of ettringites from acicular to prismatic or acicular to fibre-like for A-series specimens, and from acicular to fibre-like or from acicular to lath-like for B-series specimens. Namely, all specimens were subjected to the morphological changes continuously during water curings. However, the transformations from acicular to lath-like were concentrated at 3 d age and only limited to B-series specimens. The ettringites exhibiting the lath-like shapes were always seen around gypsums in foot print textures as indicated in Fig 3. Therefore, We consider that these morphological changes took place by the through-solution mechanism.

Namely, the original acicular ettringites precipitated from Al-hauyne and gypsum via solution became unstable due to supplying Ca^{2+} ions from belite and precipitated around gypsums in lath-like shapes. Thereby, some volume expansion of ettringite may take place. If the specimens concerned have not sufficient resistance against the expansion on this stage, they will brake. In this respect, B-series specimens all may have a fate of disintegration, but some compensation of voids may take place in B-80 and B-100 specimens due to including much more gypsum. This situation may be the same to A-series specimens. However, cement A has very high specific surface area so that initial hydration may take place under the strong influence of belite hydration from the beginning, releasing more Ca^{2+} ions into the solution. We consider that the differences of transformation schemes of ettringites originate from the differences of initial Ca^{2+} concentrations in solutions. The strength depressions occurring in some gypsum containing specimens may also be related to these transformation phenomena.

Stratlingite

In B-0 hydration, which was not added with second gypsum, stratlingites were found instead of ettringites as encountered in previous study (Ikeda et al., 1994), (Table 4). Initial hydration strength of B-0 was moderately high, but the strength decreased in later age. This may be attributed to crystal size growth of stratlingites as seen in Fig 4, resulting more pore volumes. We did not detected marked presence

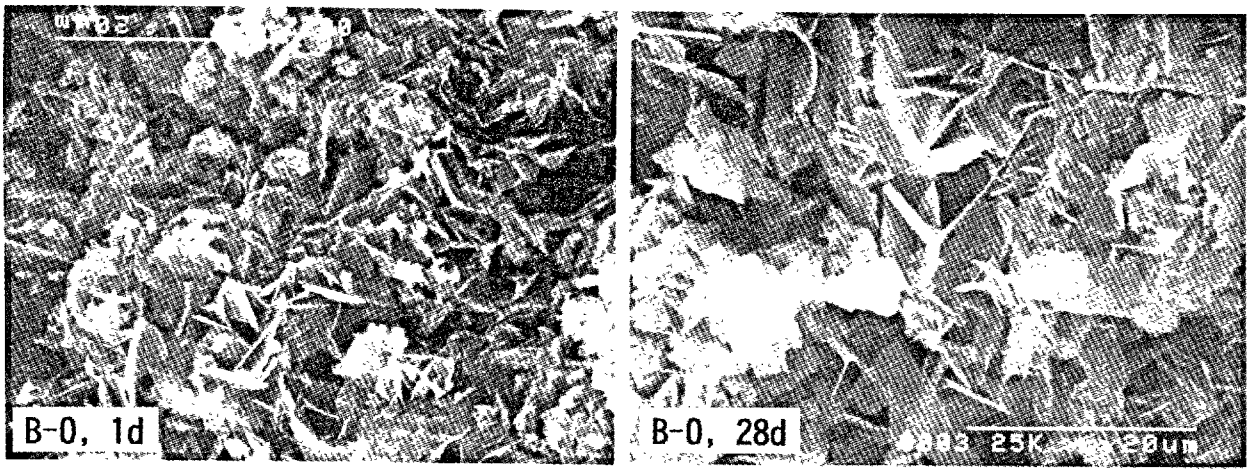

Figure 4 SEM photomicrographs showing development of stratringite.

of monosulphates. Therefore, we believe sulphate ions are incorpotated into the stratlingites.

CONCLUSION

Following conclusions have been drawn in this study.

(1) CSAC's can be prepared from low-alumina waterworks slimes by firing at 1100℃.

(2) Clinkers fired at 1100℃ show high grindability and high specific surface areas of cements around 9000 cm^2/g were reached with ease.

(3) Such finely pulverized cements show hard kneading, which can be improved by second dosage of gypsum as much as 50% to the cements, resulting high early strength, 22.9 MPa at 1 d age by paste hydration at 0.40 W/S.

(4) Clinkers fired at 1200℃ show not so high grindability as 1100℃ ones due to more sintering, resulting less strength and sometimes with cracks, which was discussed in relation to the morphological changes of ettringites from acicular to lath-like.

(5) Some depressions of strength encountered in advanced age may also be caused by the morphological changes of ettringites from acicular to prismatic or from acicular to fibrous, which have more room to be investigated precisely.

POSSIBILITIES OF UTILIZING HIGH SO_3 FLUIDIZED BED ASH IN THE PRODUCTION OF PORTLAND CLINKER AND CEMENT

Ivan ODLER and Hua ZHANG, Technical University Clausthal, Clausthal-Zellerfeld, Germany

ABSTRACT A Portland cement clinker may be produced by burning a raw meal made from a high SO_3 fluidized bed ash and limestone, with added fluorspar, at temperatures lower than those common in the production of conventional clinkers. Such clinker contains most of the present SO_3 in form of the phase C_4A_3s, which is formed at the expense of C_3A. Cements made from such clinker exhibit a strength development and expansion similar to those of conventional Portland cements, whereas the setting time tends to be shortened and the initial hydration heat liberation enhanced.

INTRODUCTION

In the burning of coal in conventional power plants fly ash is produced as the main solid residue. The amount of sulfur in conventional fly ashes is usually low, as most of the sulfur that had been present in the coal is converted to SO_2 and escapes into the environment with the flue gas. The produced fly ash may be used either as a raw meal constituent in the production of Portland clinker, or as a pozzolanic constituent in the production of blended cements, or it may be added directly to concrete mixes to replace a part of cement and fine aggregate.

In recent years a variety of "clean" burning technologies has been developed, in which the SO_2 is either absorbed from the flue gas, or is prevented from being formed by binding the sulfur of the coal within the produced ash. Among the latter technologies those based on fluidized bed combustion found greatest acceptance and are being already widely used. Here, pulverized coal is burnt, after being blended with adequate amounts of limestone, at temperatures of about 850°C. Under these conditions the sulfur present in the fuel is converted to calcium sulfate (anhydrite II) and remains in this form in the formed ash.

Fluidized bed ashes differ distinctly from conventional fly ashes. In addition to calcium sulfate, whose amount depends on the sulfur content of the used fuel, they contain also distinct amounts of free calcium oxide, as limestone must be introduced in over-stoichiometric amounts, to assure a sufficient reduction of SO_2 emission. Due to the reduced burning temperature, a glass phase, normally present in conventional fly ashes, is absent in fluidized bed ashes. Instead, the clay minerals, originally present in the coal, remain preserved, though in partially decomposed form. Other constituents typically present in fluidized bed ashes include quartz, iron oxides, some residual calcium carbonate and residual carbon.

Even though fluidized bed ashes exhibit a distinct hydraulicity/pozzolanicity, they can be used as constituents of blended cements or added to concrete mixes only in limited amounts, due to their high SO_3 content. They are also not suitable to be used as constituents of raw meals in the production of conventional Portland cement clinkers, as elevated SO_3 contents in the raw meal are known to impede or even prevent the formation of the C_3S phase and along with it to increase the free lime content in clinker. In addition, a noticeable thermal dissociation of the anhydrite present in the ash, associated with an escape of sulfur oxide, takes place at temperatures common in clinker burning. Thus, alternative solutions for their use must be sought, to avoid costs associated with their disposal.

In our previous work (Odler and Zhang, 1996), performed with pure chemicals, we found that well burnt clinkers may be produced from raw mixes with high calcium sulfate contents if small amounts of calcium fluoride are added to the mix and the burning temperature is reduced to about 1250-1300°C. Such clinkers contain side by side the phases C_3S and C_4A_3s and may contain, in addition, also the phases C_2S, C_4AF and even C_3A. At the same time the free lime content may be reduced to acceptable levels. Based on these results, within the present work we studied the possibility of using high SO_3 fluidized bed ash in the production of Portland cement. To adjust the oxidic composition of the raw mix the used ash was blended with calcium carbonate. The properties of the resultant cement were conpared with those of a standard Portland cement of a well defined composition.

CLINKER PREPARATION

As starting materials an ash from a fluidized bed combustion unit, installed in a German power plant, was employed. The composition of the ash is given in Table I. The ash was blended with powdered calcium carbonate in a ratio ash : carbonate = 1 : 1.62 . 1.0 per cent of CaF_2 was added to the resultant mix. Te raw mix was burnt in batches of 300g. It was placed into a Pt-dish and burnt in an electric furnace (heating rate: 10°C/min.; max. temperature: 1230°C; burning at max. temperature: 30 min.; cooling in air). In a similar way a reference clinker with a potential phase composition of 70% C_3S and 10% of each C_2S, C_3A and C_4AF was burnt at 1450°C.

By X-ray diffraction the phases C_3S, C_2S, C_3A and C_4AF were identified in the reference clinker and C_3S, C_4AF and C_4A_3s in the experimental high SO_3 clinker. To determine quantitatively the phase composition of the produced experimental clinker, the free CaO was analyzed by the Franke extraction method, the C_3S phase, together with free lime, was dissolved in a methanolic salicylic acid solution, and the mutual ratio of C_4AF and C_4A_33 in the extraction residue was estimated by X-ray diffraction. Table I. shows the phase composition of the clinker found this way, as well as the oxidic composition of the whole clinker and the two fractions separated by salicylic acid extraction.

The texture of the produced experimental clinker was studied by back scatter electron imaging, after impregnating the sample with a low viscosity epoxy resin. As may be seen from Figure 1, the clinker exhibited a significant porosity, unlike conventional Portland clinkers produced at higher burning temperatures.

The grindability of the produced clinkers was assessed by grinding 50 g of the material, precrushed to a size 1-2 mm, in a laboratory swing mill and plotting the Blaine specific surface area of the product as function of grinding time. From Figure 2 it is apparent that the grindability of the experimental high SO_3 clinker was significantly better than that of the reference, apparently due to its great porosity.

CEMENT PROPERTIES

To determine the "optimum gypsum" value, a series of cements was prepared by grinding the experimental clinker with variable gypsum additions to a specific surface area of 300 m^2/Kg. Figure 3 shows the compressive strength of pastes made from these cements (w/c=0.30) after different hydration times. It appears, that after 1 and 3 days the highest strengths were obtained in the cement ground without added gypsum, whereas the 28 day strength was highest in the cement with amounts of gypsum corresponding to 2 % SO_3. An acceptable rheology and normal setting of the pastes was observed both with and without gypsum interground with the cement.

For further studies a cement integround with 2 per cent of SO_3 (as gypsum) was employed. Its setting time was determined with the Vicat method. The strength development was studied on 10x10x10 mm^3 test specimens made out of ISO mortar (cement : sand = 1:3; w/c = 0.5). The

expansion was measured on cement paste test specimens (w/c = 0.30) cured either in humid air or placed under water after three days of humid air curing. Under both conditions any expansion was completed wihin the first 10 days of curing and no further length/volume changes were observed later on. The obtained results are summarized in Table II. If compared to the reference cement, the experimental cement produced from the high SO_3 fluidized bed ash exhibited a distinctly shorter setting time and a roughly equal strength development and expansion.

The hydration heat liberation of both cements, as studied by isothermic calorimetry, is shown in Figure 4. If compared to the reference cement, the experimental high SO_3 cement exhibited a significantly increased hydration heat liberation within the first 5 hours and a reduced one later on.

The hydration process was studied on paste samples in which the hydration was stopped and the non-reacted water was removed by extraction with acetone and ethyl ether. On this material the combined water was determined as the loss on ignition; the free calcium hydroxide, gypsum and ettringite was determined by differential thermal analysis. The interground gypsum became completely consumed within 24 hours in both cements. The ettringite content in the experimental cement paste was consistently above that of the reference paste; in both pastes the amount of ettringite started to decline after the present gypsum had been consumed (Fig. 5). A distinct formation of calcium hydroxide, indicating the end of the induction period in the hydration of C_3S, got under way sooner in the paste of the experimental cement, indicating an increasing reactivity of the present C_3S phase. After 5 hours, however, the amount of calcium hydroxide in the reference cement became higher, apparently due to a higher C_3S+ C_2S content in this cement and due to the formation of ettringite in the hydration of C_4A_3s in the experimental cement paste (Fig. 6). The amount of combined water was higher in the experimental cement at any hydration time, mainly due to the formation if increased amount of ettringite, a phase with an exeptionally high combined water content.

DISCUSSION AND CONCLUSIONS

Our experiments confirmed the possibility of using fluidized bed ashes in the production of Portland cement clinker. A cement produced from clinkers made this way will differ from conventional Portland cements in several respects:

It will contain the phase C_4A_3s among its constituents, whereas the amount of C_3A will be reduced, or this phase will be absent completely.

Due to the presence of C_4A_3s, the cement will exhibit a shorter setting time and a more intensive hydration heat liberation at the beginninng of hydration.

The hydrated paste will contain increased amounts of the AFt phase and reduced amounts of portlandite, however, also here, just as in ordinary Portland cement pastes, the C-S-H phase will remain the main hydration product.

There appear to be several advantages resulting from the use of high SO_3 fluidized bed ashes as raw meal constituents in the production of Portland cement:

Fluidized bed ash, a burdensome end-product od fluidized bed combustion of coal, may be meaningfully utilized and the amount of raw materials from natural sources reduced correspondingly.

The energy consumption in the burning process will be reduced due to the fact that a significant fraction of CaO in the raw meal will be present in decarbonated form, rather than as $CaCO_3$. An additional reduction of energy consumption will be due to the reduced burning temperature employed. Moreover, the residual carbon, consistently found in fluidized bed ashes in variable amounts, may supply a part of the needed energy.

The emission of CO_2 will be reduced due both to a reduced fuel consumption and and a reduced $CaCO_3$ content in the raw meal. At the same time the emission of NOx will be also reduced, due to a lower maximum burning temperature.

The power consumption in the grinding process, and along with it the wear of the grinding

equipment, will be reduced, due to the improved grindability of the produced clinker.

On the other hand, the following facts have to be taken into consideration if using a fluidized bed ash as raw meal constituent:

The necessity to add fluorspar to the raw meal will eliminate a part of savings brought about by the reduced fuel and power consumption.

Some uncertainties may exist about the long term durability of the formed hardened cement paste, mainly due to higher amounts of ettringite in the hydrated material and the possible consequences of a reaction of this phase with the CO_2 of the air.

Concrete mixes made with this kind of cement may not be suitable for steam curing at high temperatures, due to a possible expansion associated with delayed ettringite formation.

The produced cement wil not comply with existing specifications for "Portland cement", mainly due to an SO_3 content higher than admitted.

In related studies S. Gimenez et al. (1991)produced a "white" low iron cement by burning the raw meal with added $CaSO_4$ and CaF_2 and found fluorellastidite ($3C_2S.3CaSO_4.CaF_2$) as the main SO_3 bearing phase. Borgholm et al. (1995) produced a blended cement based on a clinker made from an SO_3 and F containing raw meal and found most of the SO_3 present in clinker in form of $C_2K_2s_3$.

THERMAL DISPOSAL OF ASBESTOS-CEMENT AND RE-UTILISATION IN CEMENT INDUSTRY.

Luigi CASSAR, Gian Luca GUERRINI and Cesare GILIOLI, CTG Italcementi Group, Bergamo, Italy

ABSTRACT This paper describes an environmentally friendly overall process for the disposal of asbestos-cement products by high temperature treatment. The end product could be reuse (a) as ingredient for the production of portland cement, according to present standards (ENV 197/1), or as raw material in cement production cycle (clinkerisation kiln feed).

Key-words: Asbestos-cement, Disposal, Thermal treatment, Waste material utilization

INTRODUCTION

Since the early decades of the century, asbestos fibers were been used in large numbers of different products (fiber-cement products, sprayed insulation, fabrics, etc.) but as is well-known, they (and related manufacts) now are classified as hazardous substances and their use is forbidden in majority of European countries.

The largest quantity of asbestos fibers (about 75%), especially chrysotile, were used to produce asbestos cement products (flat and corrugated sheets, roofing panels, pipes, chimneys, etc.). Reliable estimations about 16-20 millions ton asbestos cement corrugated sheets are installed only in Italy and most of them will be probably removed and substituted with asbestos-free sheets. Generally, these wastes are disposed of in a few specially designed landfills destined to be filled in a short time.

Asbestos-cement products, which consist of about 85% hardened cement paste and about 15% asbestos fibers could, however, be reutilized after appropriate thermal treatment. Several methods for thermal treatment of asbestos wastes have been proposed in literature (see for instance Sakai et al., 1991, Tamas et al., 1991, Clausen et al., 1994, Ambrosius S. et al., 1996), some already in the industrial scale, others only in pilot-plant or laboratory scale: ceramics production, plasma flame or electric furnace, vitrification (using melt accelerators), rock wool production (using mineralizing agents) and various thermo-chemical treatments. In these processes, the processing temperature is normally over the melting temperature of asbestos (T_m = ca. 1350°C). In some cases (for ex. plasma flame treatment), the end product has a chemical composition similar to the process feed material, in other cases the method allows to obtain a completely different material (glass, ceramics, rock wool).

THE PROCESS

The above mentioned processes show several limits because of high costs - due to the high energy consumptions and/or to the additives utilised - and industrial scale-up difficulties. This paper is concerned with an Italian-patented process (Cassar, 1992) which includes the destruction of the asbestos fibers contained in asbestos-cement products by 800°C-900°C temperature treatment in furnaces heated by methane, L.P.G. or in electric furnaces, without production of polluting fumes (no-containing fibers); it is also possible to use other fuels (for ex. combustible oils), but it is necessary to have recourse to adequate filtration systems aimed to prevent fiber emission.

For this reason, a great care was given to obtain an environmentally friendly destruction of asbestos fibers, setting up processing conditions both on laboratory and pilot-plant scale. The process engineering and safety findings obtained in this way form the basis for a possible trial under production conditions on industrial plants.

The process for asbestos-cement sheets consists of several steps, (Fig 1):

◊ in-place incapsulation of asbestos-cement sheets, using polymeric products;
◊ removal, palletization and transportation of manufacts to the oven;
◊ thermal treatment in an oven
◊ grinding of product treated

The process shown includes two possible reutilisation of the final product after the thermal treatment:

⇒ re-use of end product as ingredient for the preparation of Portland cement, according the present standards (ENV 197/1, section 4.8).
⇒ recycling as raw material in cement production cycle (clinkerisation kiln).

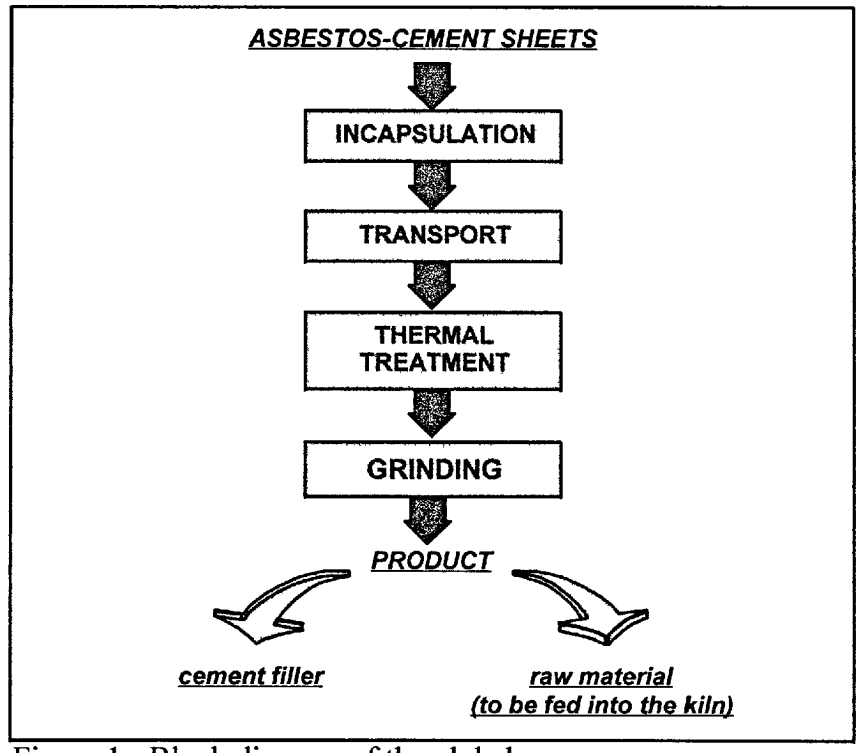

Figure 1 - Block diagram of the global process

The result is a residue-free process which makes it possible to recycle asbestos-cement product at costs comparable with the prices of acceptance in landfills and decisely lower than the costs of other thermal treatments above mentioned.

RESULTS

The inactivation process consists of a pyrolytic asbestos attacking action - by heating the samples to a temperature no lower than 580°C - which allows to eliminate the water present in the molecule, converting the fibrous crysotile into another non-fibrous and inert Mg-silicate (forsterite). Forsterite is an inert refractory mineral which is found in nature as a constituent of olivine. The reaction is:

$$Mg_6(OH)_8Si_4O_{10} = 3Mg_2SiO_4 + 4H_2O + SiO_2$$

Other than forsterite, it can be observed the presence of quartz (SiO_2), diopside ($CaO.MgO.2SiO_2$) and periclase (MgO).

From the morphological point of view, asbestos fibers begin to agglomerate themselves, giving fibrous agglomerates which never have the initial aspect ratio (length/diameter), typical of asbestos fibers, but clearly lower (Le Bouffant, 1983).

Samples were analysed before and after each treatment condition, by using a quantitative method developed in CTG laboratories: (1) material grinding up to 90 mm particle diameter (2) chemical attack using chloride-salicilic acid solution (as provided in ENV 196/4) (3) X-Rays diffraction (XRD) analysis of samples. This method allows to detect asbestos residual contents up to the lower limit of 0.1% weight, the one tenth of corresponding classic XRD analysis. The XRD analysis was completed with Scanning Electron Microscopy (SEM) morphological analysis.

Actually, this adopted sequence - combination of both analytical and microscopical methods - seems to be one of the most accurate methodologies to determine the smallest quantity of asbestos contained in cement products.

Basic study was the optimisation of thermal treatment experimental parameters (temperature, time) of asbestos (chrysotile)-cement samples in a laboratory furnace. Table 1 shows the experimental results referred to different process conditions (temperature = 700-1000°C, time 10-40 min).

Table 1 Asbestos residual contents in samples thermal treated at different process conditions (temperature, time).

	treatment time, min			
	10	20	30	40
temperature, °C				
700	45.8	2.9	0.6	0.2
800	0.2	0	0	0
900	0	0	0	0
1000	0	0	0	0

Quantities expressed as the ratio of main peaks obtained from XRD on chloride-salicilic residuals as regards the samples untreated.

After the thermal treatment, XRD (Fig 2) and SEM analysis (Fig 3) proved that the material doesn't contain any residual asbestos fiber or fibrous structures referable to the same fibers.

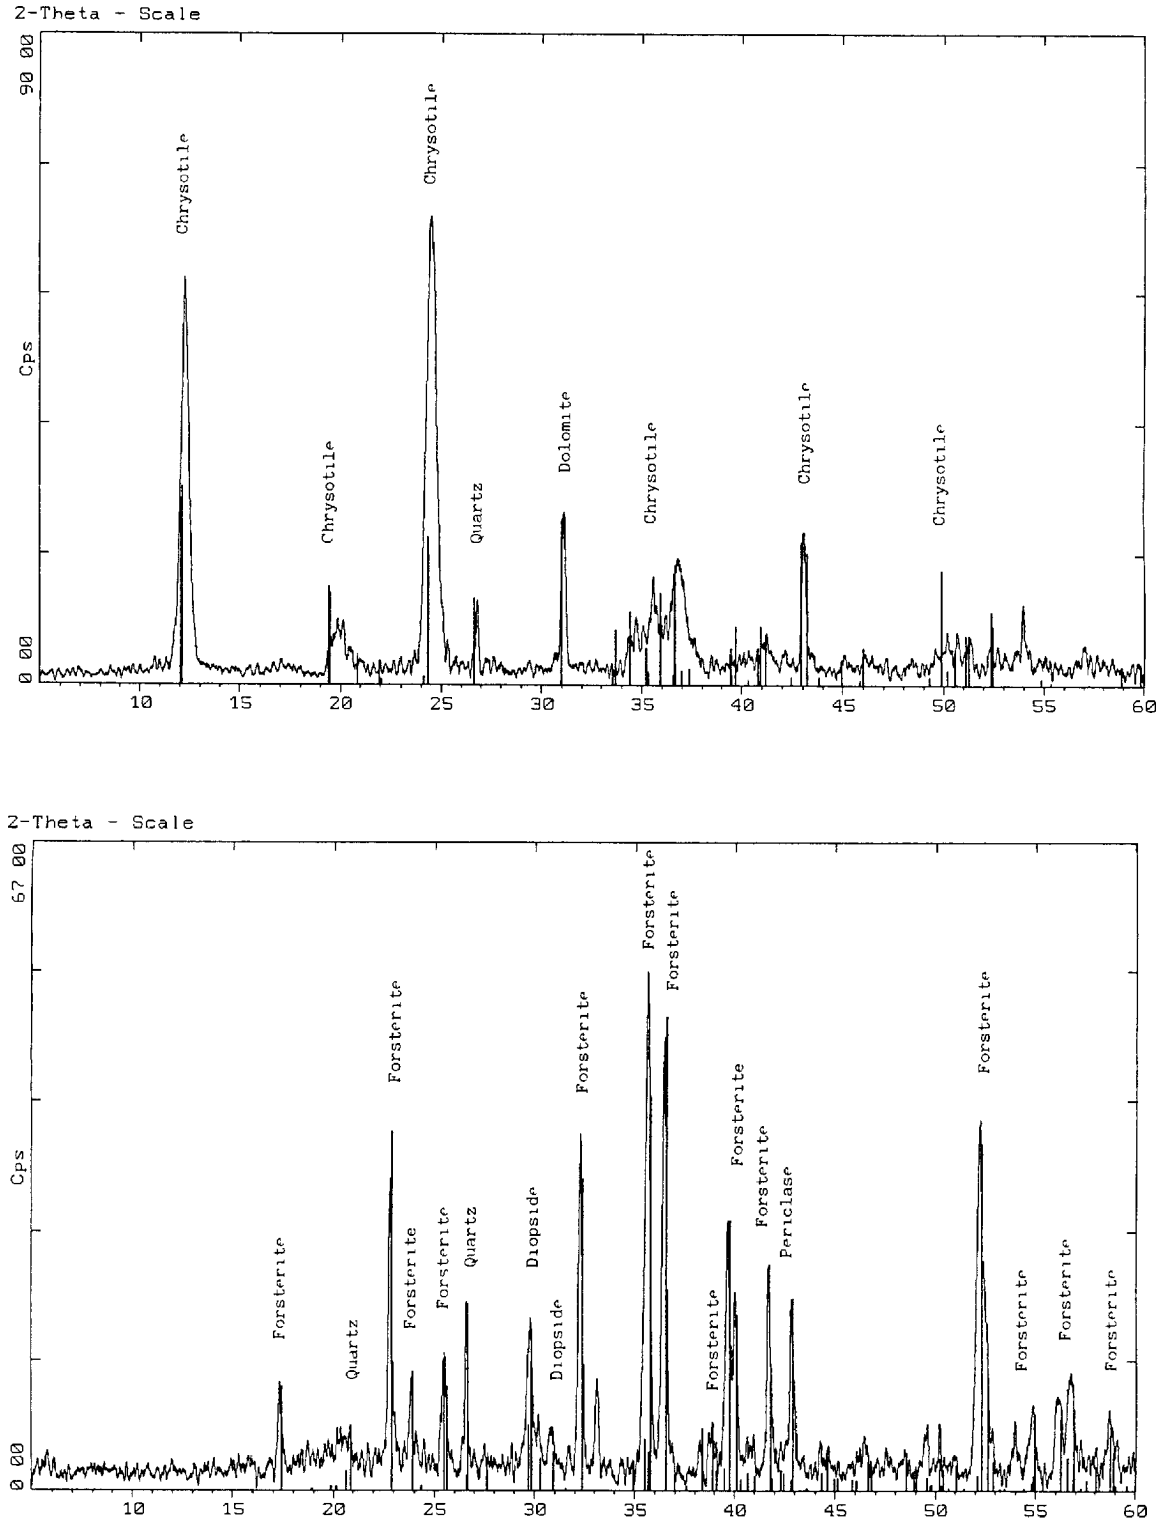

Figure 2 Asbestos-cement samples: XRD on chloride-salicilic acid residue before (up) and after (down) the high temperature thermal treatment

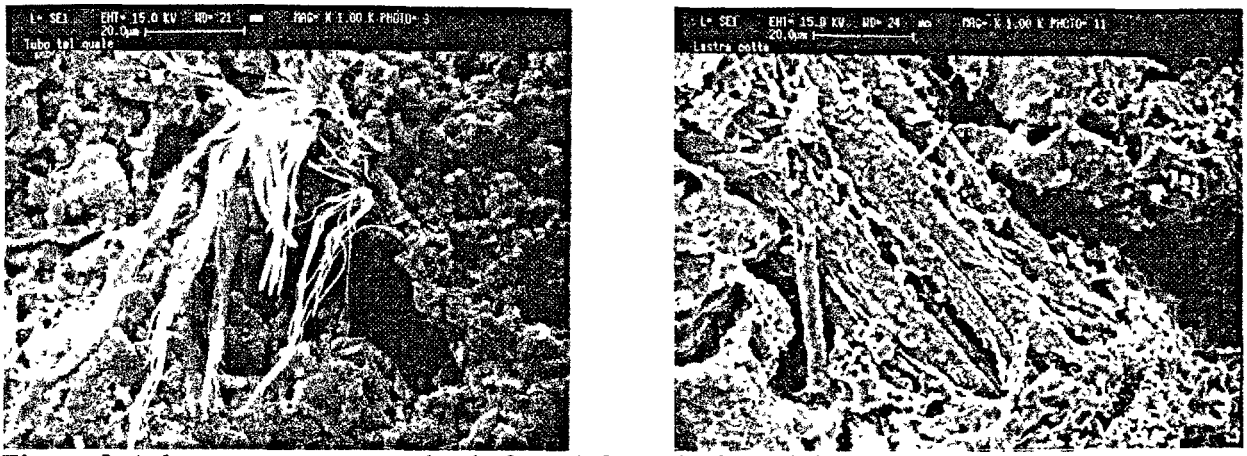

Figure 3 Asbestos-cement samples before (left) and after (right) the high temperature thermal treatment

Elementary microanalysis, executed on samples of material treated, confirmed the presence of pieces containing Mg, derived from the melting of asbestos fibers, having an aspect ratio completely different from original asbestos fibers, Fig. 4. The same powder morphology was observed in the samples first thermal treated and then grinded, so as to obtain a granulometry similar to the cement powder one.

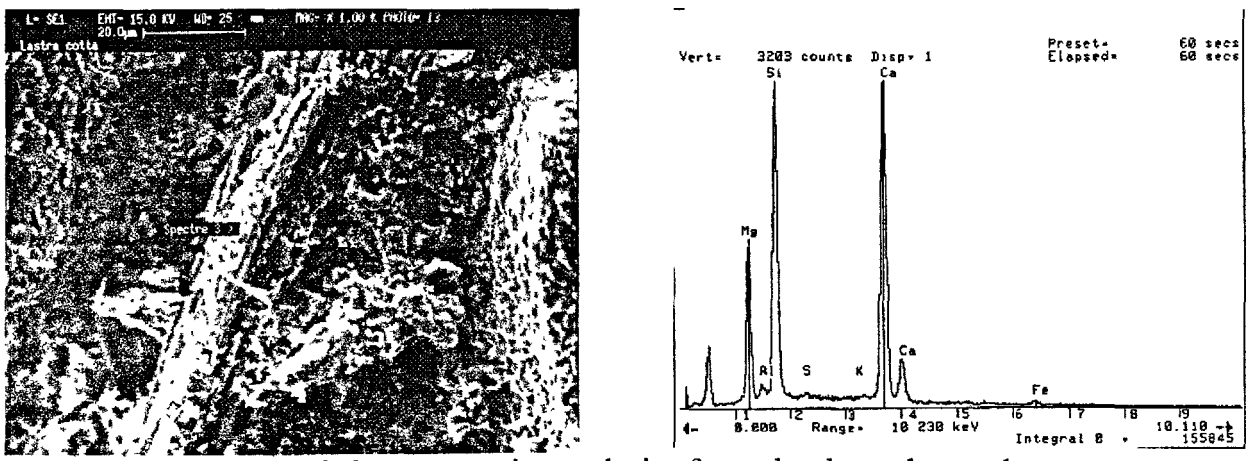

Figure 4 SEM image and elementary microanalysis of samples thermal treated

The material obtained from this process can be used in cement production cycle, since its chemical composition is similar to the cement one:

- as a partial substitute of raw meal feed
- as a mineral filler in cement preparation, as provided by the ENV 197/1 standard, section 4.8.

In both cases, it is necessary to be sure that the standard limit for MgO is not to be exceeded. Further experimental work was done to evaluate the above mentioned applications and to assess the maximum quantity could be re-used for each of them.

In the former case, a high content of MgO in raw meal could provoke undesired reactions: for this reason it was estimated a maximum feed of 5-10%. In the latter case the maximum limit content is provided by the ENV 197/1 standard, that is 5% weight.

No expansion phenomena were observed in standard pastes prepared with cement containing asbestos-cement thermal treated (Le Chatelier test). Besides, evaluation tests in concrete and mortar compositions showed good rheological and mechanical properties in comparison with a cement of similar chemical composition, Table 2.

Table 2 - Workability and mechanical properties of concretes

			reference cement	**cement prepared with 5% material filler**
slump		cm	5	6
VE-BE, sec		sec	3	3
compressive	1 day	MPa	15.6	13.8
strength	7 days	"	33.9	35.8
	28 days	"	37.9	39.0
flexural strength	7 days	"	5.0	5.1
	28 days	"	5.6	6.0

W/C = 0.56, SP = 1.2%, aggregates max. diameter = 20 mm

CONCLUDING REMARKS

After these considerations we can conclude that this suggested process could permit to recycle asbestos-cement wastes completely, as well as all the other asbestos products, which represent a small percentage of the total asbestos wastes.

In a few years the cement industry could be able to recycle the asbestos wastes without applying to landfill disposal.

The process is indeed environmentally friendly and cost effective, in comparison with other proposed methods. Analytical measurements demonstrated the completely disappearance of asbestos fibers.

PRACTICE APPLICATION OF COMPOSITE MINERALIZER TECHNOLOGY INPRECALCINING CEMENT KILN

LI peiquan and LIU changfa, China Building Materials Academy, Beijing, China

Zhuo hongmi, Linguang Cement Plant, China

ABSTRACT Composite mineralizer was adopted in pre-calciner and good results were obtained: 1) the compressive strength of high alkali clinker (R_2O 1.45-1.80%) is remarkably increased, 2) the quality of kiln coating is good, 3) clinker outputs increase by 5-15%, 4) coal consumption decrease by 5-15% and 5) the running period of the kiln is prolonged and the fast speed rotary running rate is raised.

Keywords: Composite Mineralizer, High Alkali Clinker, Pre-calciners.

摘要： 复合矿化剂在窑外分解窑上的生产实践效果良好。

1. 大大提高了高碱熟料(R_2O 1.45～1.80%)的强度，熟料抗压强度，3天43.4MPa，7天50.3MPa，28天由53MPa提高到60.2MPa，稳定地生产了525(R)硅酸盐水泥。
2. 窑皮质量好。熟料易烧性好。
3. 熟料增产5～15%。
4. 节煤5～15%。
5. 窑运转周期延长，快转率高。

叙述了熟料的矿物组成和熟料及水泥的物理力学性能。

阐明了高碱熟料强度大大提高的机理，消除窑外分解窑予热器系统结皮和窑内结球的机理。

INTRODUCTION

At present, the most pressing problem which a precalciner kiln faces is the low running rate, frequent kiln stoppage and lower clinker grade (generally 56MPa). In a precalciner, circulation and amassment of sulphur and alkalis are apt to lead to coating, blocking in the preheater system and globing in the kiln that would lower the clinker qualities and output. The temperature of clinkers emerging from the kiln is high, that causes more breakdown of coolers which influence the running rate of the kiln.

The serious problems which the precalciner is facing can be solved by using composite mineralizer leading to low-temperature burning in portland cement clinker formation.

The technology is the project in "National Science and Technology Achievements highly popularized programme". Its number is I1-5-1-9 and certificate number is 0896. The practice application of "composite mineralizer technology in precalcining cement kiln" has achieved good results:

1. The compressive strength of high alkali clinker (R_2O 1.45-1.80%) was remarkably increased. e.g. the 3-day-strength reached 43.4MPa and 28-day-strength increased from 53MPa to 60.2MPa. So the high-mark(R) portland cement can be consistently produced.
2. The quality of kiln coating is good.
3. Clinker output increased by 5-15%.
4. Coat consumption reduced by 5-15%.
5. The running period of a kiln is prolonged and the fast speed rotary running rate is raised.
6. Composite mineralizer accelerates the decarbonation of $CaCO_3$ and the clinker burning.
7. Composite mineralizer is contributed to eliminate the coating in the preheater system and the globe in the kiln of precalciner.
8. Kiln feed's burnability is good, the operation of burning is convenient and easy to control.

Up to now, in abroad, "The technology of composite mineralizer in low-temperature-burning portland cement clinker" has used in precalcining kiln. "Composite mineralizer technology" and "precalcining technology" are closely intergrated and supplement each other that results in increasing outputs and reducing energy consumption remarkably, as well as improving the quality of clinkers. The new technology is really a effective way deserved to devote major efforts to spread to develop the building material industry.

"The technology of composite mineralizer in low-temperature-burning portland cement clinker" is advancing in the world.

High Alkali Clinker

Chemical composition of clinkers

The chemical composition of the projected clinkers are list in Table 1. The chemical analysis results of the clinkers are basically consistent with the projected composition. Samples group A have been burned for 45 minutes at 1450℃ and samples group B burned for 45 minutes at 1370℃, they were all cooled in the air.

Table 1 Chemical composition of clinkers

Sample No.	Chemica Com position (wt%)								
	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	K_2O	Na_2O	SO_3	F^-
A-0	20.59	6.31	4.62	64.51	1.76	0.81	0.20		
A-1	20.42	6.26	4.60	64.00	1.75	1.58	0.20

B-4	19.31	5.84	4.29	61.41	1.67	3.34	0.20	1.54	0.62

The influence of alkalis in the formation of clinkers

Fig.1 shows the correclation between the f-CaO and alkali content of the samples group A and B.

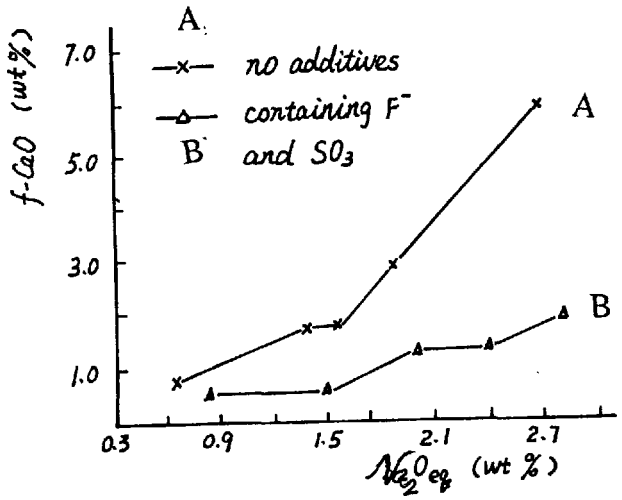

Fig.1 Corrlation between f-CaO and alkali content in the clinker at the burning temperature.

Fig.1 shows:1. With no additive in samples group A, the f-CaO content raise with increasing alkali content. Especially when Na_2O eq exceeds 1.60%, the f-CaO content is extremly high and the clinkers are hard to form. The reasons are:

(1) Large amount of K_2O entering high-temperature melt leads to increasing the liquid phase viscosity and decreasing the diffusion rate of the ion that makes the clinker minerals difficult to form. Furthermore, that the alkalis entering liquid phase increases the alkality, reduces CaO solubility in liquid phase and enlarges CaO initial phase region. These are the reasons why f-CaO raises with increasing alkali content.

(2) Alkalis entering belite phase makes belite constructure more steady and decreasing the absorbing capacity of free CaO that prevents forming alite.

2. Although the burning temperature of samples group B with fluorite and gypsum decreases by 80℃, the f-CaO is still low in clinkers. f-CaOcontent of sample B-3 is only 1.33 when K_2O content is as high as 2.20% (Na_2O eq: 2.43%). It's obviously that the mechanism of the alkalis affecting the clinker formation has been changed by introducing fluorite and gypsum. The reasons are as followed.

(1) Fluroite and gypsum are good flux which can lower the temperature at which liquid phase emerges, and their contribution of lowering the liquid phase viscosity are indicated in many meterials. В У Т Т [1] Pointed out that the liquid phase viscosity increases wih alkalis but decreases with both alkalis and sulphur. It's therefore that fluorite and sulphur together can compensate the negative effect of alkalis in melt viscosity.

(2) Fluorite and sulphur are effective mineralizers and the composite mineralization can make C_3S form at the temperature below the temperature range of its steadiness.

Production in a cement plant

The composite mineralizer technology got great achievements in the production in L plant (precalcining kiln $\phi 3 \times 48M$), solved the importand problem that high alkali clinker can not be produced to high mark (R) portland cement because of the low strength, and resulted in significant social economic interests.

Clinker

1) Minerals in the clinkers

The minerals in the clinkers were determined with XRD and the patterns are shown in Fig.2.

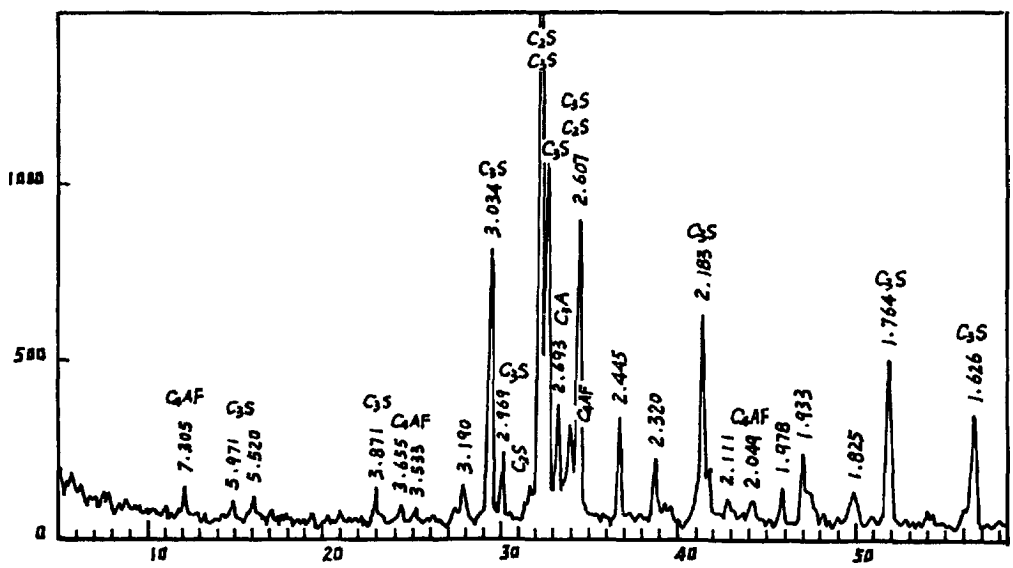

Fig.2 XRD patterns of clinker

Fig.2 shows that the main minerals are C_3S, C_2S, C_3A and C_4AF. The R_2O content in the clinker is as high as 1.45-1.80, so the clinker is high alkali clinker.

2) Physical properties of the clinkers

The physical properties of the clinkers are listed in Table 2.

TABLE 2 Physical properties of the clinkers

Sample No	Standard consisteny %	Sound-ness	Setting time Initial h:m	Final h:m	Compressive streength MPa 3	7	day 28	Bending strength MPa 3	7	days 28
LGC-1	25.00	passed	1:34	4:25	45.8	54.3	63.7	6.6	7.5	9.2
LGC-2	24.50	passed	2:27	4:52	47.0	52.8	61.5	6.5	8.1	9.0
LGC-3	24.50	passed	3:37	5:07	44.8	53.5	64.7	7.3	7.9	8.7
LGC-4	26.00	passed	1:53	4:10	43.4	50.3	60.2	7.2	7.7	8.8
LGC-5	24.75	passed	2:12	4:07	46.2	50.5	61.0	7.0	7.6	8.6

Table 2 indicates that the clinkers compressive strength are above 43.4 MPa for 3-day, above 50 MPa for 7-day and above 60 MPa for 28-day. It's obviously that the clinkers 3-day compressive strength are high.

Cement

The physical properties of porltand cement are given in Table 3.

TABLE 3 Physical properties of portland cement

Sample No	Standard consisteny %	Sound-ness	Setting time Initial h:m	Final h:m	Compressive streength MPa 3	day 28	Bending strength MPa 3	days 28
LGC-1	26.50	passed	3:45	5:20	41.0	64.0	6.3	8.7
LGC-2	26.00	passed	3:31	5:18	42.2	61.9	6.2	8.6
LGC-3	26.00	passed	2:55	4:45	44.2	63.6	6.3	8.9
LGC-4	26.00	passed	3:18	4:46	44.4	62.0	7.0	8.7
LGC-5	26.00	passed	3:39	4:39	41.4	61.5	7.1	8.5

Table 3 shows that the physical properties of portland cement conform with National standard (GB175-92) for 525(R) portland cement perfectly.

DISCUSSION

Why can this technology increase the strength of rich alkali clinkers remar-kably?

The reason is that using composite mineralizer can introduce suitable gypsum and fluorite additives to raw meal. When there is a suitable proportion of SO_3 and R_2O in rich alkali clinkers, R_2O can form R_2SO_4 instead of detrimental minerals $KC_{23}S_{12}$ etc.

emerges with characteristic minerals formation and disappears with minerals decomposition.

Characteristic minerals generally are $2CaSO_4 \cdot K_2SO_4$, $2C_2S \cdot CaCO_3$, $2C_2S \cdot CaSO_4$, $CaSO_4$, $3CA \cdot CaSO_4$, $Ca_{10}[(SiO_2)_2(SO_4)_2](OH,Cl,F)$.

Coating increases the circulation dust contents between the I and V cyclon of the preheater and reduces the thermal efficiency of rotary kiln ramarkably. The raw meal will be difficult to transport because of large quanlity of low melting point alkalis. By-pass and "composite mineralizer low temperature burning portland cement clinker technology" can be used in order to avoid coating, blocking and increase the quality of the clinker.

To control the effect of sulphur and alkalis effectively,sulphur saturation(SG) is often used in Westen Europe industry.

It's necessary to control SG properly when using high alkali raw materials, that contributes to make full use of the energy and fully develop the properties of the clinkers and cements. Generally the SG is controlled in the range from 60% to 100%.

It's better to use "composite mineralizer technology" than control SG single. "Composite mineralizer technology" can not only reduce coating and blocking of the preheater system but also increase the strength of the high alkali clinkers significantly. The burning temperature of the raw meal can be lowered about 100° K and the volatilizing alkali content decreased by adding composite mineralizer. On the other hand, it's necessary to control the atomersphere in the kiln and restrain the volitilization of $CaSO_4$, thus $CaSO_4$ would form complex salts with alkalis that reducing the volitile content of alkalis. That the clinkers emerging with sulphate from the kiln leads to reduce the circulation and amassment of the detrimental compositions and coating, blocking in the preheater system. Furthermore, the composite mineralizing and fluxing effects of gypsum and fluorite increase the decomposing rate of calcium carbonate in kiln feed, lower the burning temperature, decrease the volatility of alkalis and reduced coating and blocking. Therefore, the running rate of the kiln is improved.

Why can "composite mineralizer" prevent globing in the kiln?

There are globes in the kiln because of some detrimental components in the raw meal and fuels such as K_2O, Na_2O, Cl^- and SO_3. That adding right amount of gypsum and controlling the ratio of sulphur to alkalis is contributed to the combination of sulphur and alkalis to form sulphate and fix in the clinkers. So the circulation of alkalis in the kiln and alkali volatility can be reduced and the globe would be difficult to form in the kiln. And also the composite mineralizing and fluxing effects of gypsum and fluorite can increase the decomposing rate of calcium carbonate in kiln feed, lower

that is benificial to late strength. On the other hand, it is predicated that different alkalinity existing in clinkers also influences the process of hydration and hardening of the clinkers and finally rasults in different strength. Because of the high solubility, R_2SO_4 transforms to liquid phase very quickly in case meeting water. So, when the alkalinity of liquid phase increases quickly that impedes the diffussion of Ca^{2+} and decreases the hydrating speed of clinkers in early hydration period. When the alkalis exist as R_2O in clinkers, because R_2O transforms to liquid phase more slowly with minerals hydrating that the diffusion resistance of Ca^{2+} is weaker as well as the hydrating rate is higher. The differences between the two hydrating speeds in early hydration period are bound to result in the difference of crystalizing rate and influence the crystalization and growth of hydration products. As the crystalizing is slow when R_2SO_4 formed in clinkers, the structures and crystalization of hydration products can become perfect. This is a positive factor to later strength development of clinkers.

It is generally believed that CaF_2 is positive to the volatility of R_2O but $CaSO_4$ is negative regarding from the volatility of the alkalis. What is the situation when CaF_2 and $CaSO_4$ coexists? According to our experiments, using low temperature burning technique with fluorite and gypsum would reduce both flying loss of R_2O and possibility of foaming solid solution because gypsum combines R_2O first. At the same time, the severe fluxing effect of fluorite leads to reduce the clinkering temperature and prevent gypsum from decomposing to a certain extent at high temperature. So the combined mineralizing effect of both gypsum and fluorite is fully developed and improve the clinker strength. On the other hand, the alite content of clinkers using this technique are usually above 60% that enhances clinker strength greatly. So the technique is the main factor in improving clinker strength.

Why can the coating and blocking of the preheater system be reduced and the running rate of the kiln be increased by adding composite mineralizer to kiln feeds?

When the kiln feed burn at 1400℃ in the rotaly kiln, some components of the meal and fuel especially the alkalis, sulphur and fluorite will volatilize at burning zone and enter the preheater with waste gas, then condense and return to burning zone with the raw meal. They will partly volatilise again and the refeated vaporization and condensation of the votitile result in the internal circulation. So, the alkali content of the kiln feed increase continuously and cause the remaining alkali content in the clinkers increasing. This is the assemble process of alkalis. When alkali circulation reaches a certain extent, the liquid salts emerge and adhere to the preheater wall becoming coating, that will block the preheater and decrease the utilization of the kiln when seriously coating. The quality of the clinkers will be lowered if the volitile left in the clinkers.

The coating in the preheater system are caused by coherence of the coating characteristic minerals and unreacted raw meal compenents such as $CaCO_3$, SiO_2 and clinker minerals CaO, β-C_2S, C_4AF, $C_{12}A_7$, C_3A etc. Generally speaking, coating

the burning temperature and reduce the alkali volatility that effectively prevent globing in the kiln, better burning conditions and improve the running rate of the kiln.

CONCLUSION

1. The practice application of "composite mineralizer technology" in precalcin-ing kiln leads to good results and remarkable social economic effects.
1) The compressive strength of high alkali clinkers (R_2O 1.45-1.80%) are remarkably increased. e.g. the 3-day-strength reach 43.4MPa, 7-day-strength reach 50.3MPa and 28-day-strength reach 60.2MPa. The 525(R) portland cement have been steadily produced.
2) Both the quality of kiln coating and burnability of the clinkers are good.
3) Clinker outputs increase by 5-15%.
4) Coat consumption reduce by 5-15%.
5) The fast speed rotary running rate is raised and the running period of a kiln is prolonged.

2. The coating in the preheater system of precalcining kiln and globing in the kiln are effectively eliminated by "composite mineralizer technology".

SURFACE MICROPHASES AND CHEMICAL ACTIVITY OF THE ADMIXTURES-CATALYSTS ACTION.

Iya G. LUGININA, Doctor of Science, professor, The Belgorod Technological Academy of Building Materials, Belgorod, Russia.

ABSTRACT *The visual examination of calcite with catalysts in the heating chamber of* the microscope revealed surface microphases before the beginning of dissociation. A positive influence of the aimed addition of catalysts during the production of some cement grades was established. The best effect was obtained in the initial period of the tests conducted for cement strength.

KEY-WORDS. Microscopy, Melt, Low temperature, Strength Development

INTRODUCTION

The wide use of catalysts - mineralizers in the cement technology ensures fuel and power saving and achieves results which often exceed the cost of the additional equipment or the modernization. Zhuravlev (1950) was the first to pay attention to the chemical interaction of NaF with raw mix silica. In subsequent works, researchers addressed to the selection of admixture concentration and raw mix proportioning. In the 1970 - 1980s Russian plants used fluorides, silicofluorides, phosphogypsum and calcium chloride during the production of ordinary and white cement (Volkonsky, 1964). However, studies revealing the essence of proceeding interactions, essential to making efficient use of admixtures, were not made.

OBSERVATION OF DECARBONIZATION WITH A HEATING MICROSCOPE

Numerous measurements of the carbon dioxide quantity during the period of calcite dissociation in the Berg gas burette were taken (Berg, 1952). Having compared kinetics of gas emission of various calcite fractions (Fig 1), it was revealed that while adding an

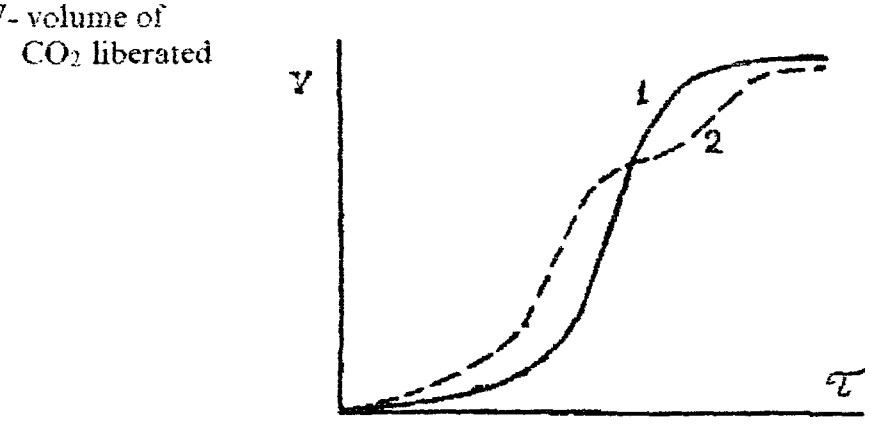

Figure 1 The influence of a catalyst upon the kinetics of carbon dioxide emission.
1 - calcium without a catalyst;
2 - calcium with a catalyst.

admixture the quantity of carbon dioxide may decrease and emission slowed. When the temperature increased, gas emission resumed. It was necessary to establish in which types of compounds carbon dioxide was preserved during a temporary stoppage of dissociation. The observation of dissociation with a polarizing microscope in the heating chamber (Rumyantsev, 1963), supplemented with the X-ray phase analysis of cakes, allowed the causes of the changes to be established. In the heating chamber transparent calcite crystals were fixed in the platinum heater. A drop of NaF, NaCl and Na_2CO_3 aqueous solutions (1 - 5 %) was applied with a needle on the surface of a calcite crystal (2.5 x 1.5 x 0.5 mm) facing the objective lens. A drop diameter was approx. 0.1 mm, a few drops of different solutions were applied on large crystals. Up to 250 - 300 °C the solution dried up, drop boundaries expanded and admixture migration started on the crystal. When applying NaF solution new products concentrating near microcracks were formed round the contour as the drop dried. At 500 °C secondary recrystallization proceeded and a new phase melting at 550 °C separated. Being very mobile, crystals emerged on the melt surface at 620 - 640 °C, which was an indication of gas emission from the melt. Solid products melting at 785 - 795 °C covered calcite at 700 - 780 °C. A thin film of the melt spread rapidly in different directions. The initial melt movement rate was up to 100 μm/sec, but decreased depending upon temperature and the concentration of the admixture. The melt was characterized by the limited temperature of the stability and low viscosity; melt saturated with gas was able to cover a large area. The sequence of the phenomena could change visually, as it reflected the influence of such factors as the condition of a chipped calcite surface, heating-up rate and admixture concentration. The observations showed that the admixture action was multistage and it began before calcite dissociation. The microscope allowed observation of catalyst impurity interacting with a matrix-calcite and new products being formed on its surface. These products caused crystal microheterogeneity in some areas. The limited power of the platinum heater compelled the development of a new attachment to the microscope (Luginina, 1994). A new chamber allowed observations to be made in an atmosphere of carbon dioxide, steam or dry air. A crystal was fixed between flat and point platinum contacts in the ceramic body of the microfurnace which provided for the uniform heating: the platinum contacts conveyed electric current and held the crystal. When conducting the electric current through the crystal at the 6 - 10-th minute of heating NaF melt was observed to move in the direction of the negative terminal. When applying NaCl solution melt was not formed, but the brown colouring was seen, which was an indication that admixture diffusion occurred in the direction of the negative contact. The change in the sign of the contact shifted accordingly the contour of the colouring or the melt (Fig 2). Therefore, surface diffusion of positive ions caused the brown colouring. The chamber was completed with a connecting pipe for the supply of steam or carbon dioxide and the installation of an electromagnet, thus allowing the influence of the magnetic field upon the behaviour of microphases to be observed. The heating of the crystal with the admixture without applyng electric or magnetic fields caused a symmetrical spread of the melt or of colour (Fig 2a). The electric field shifted the melt to the negative terminal (Fig 2b and 2d). The peculiar shifting of the melt along cleavage cracks took place under the influence of a magnetic field (Fig 2c). The observation of the separation of surface compound ions is possible in an electric field of high voltage up to 1.25 kW/cm. Magnetic field strength was 0.445 Tl. In later works (Klassen, 1987) it was established that the admixture decreased the initial temperature of dissociation but at the final stage, carbon dioxide emission proceeded at a higher temperature. The composition of new surface products of the calcite mix, sintered with sodium fluoride, was CaF_2 and $Na_2Ca(CO_3)_2$. Leonov (1988) studied surface microphases in oxides and he is of the opinion that grain surfaces are the main constituent of the structure. Chemical interactions with surface atoms are accompanied by bigger changes in

free energy than the same in the volume; a mass transfer proceeds faster at the boundaries of crystals which are richer in vacancies.

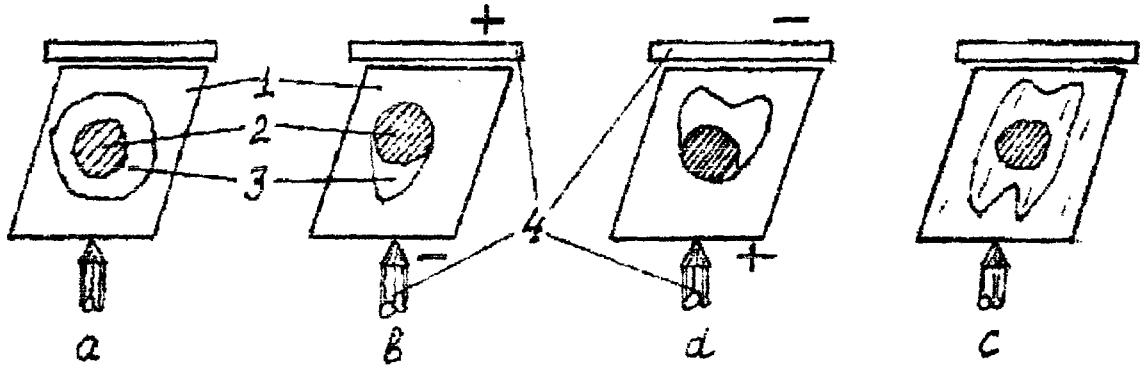

Figure 2 The shifting of the melt (colouring) on calcite crystals under the influence of electric and magnetic fields:
1- crystal;
2- drop of solution contour;
3- contour of the colouring (melt);
4- contacts.

Therefore, unsaturated surface ions are more active on the "fresh" chipped surface of calcite than those located in the volume. The reaction:

$2CaCO_3 + 2NaF = Na_2Ca(CO_3)_2 + CaF_2$

proceeds on the calcite surface under the influence of the admixture when the temperature increases slightly. The double salt is stable within the limited temperature range; a surface microphase melts, and decomposing, it saturates the melt with carbon dioxide; the melt obtains low viscosity and spreads on the crystal surface. The double carbonate melts at 770 °C and decomposes (815 - 820 °C) with formation of CaO and CO_2 according to the reaction:

$Na_2Ca(CO_3)_2 = Na_2CO_3 + CaO + CO_2$.

High efficiency of NaF is conditioned by the emergence of the melt and salts which form low-melting eutectics with $CaCO_3$. The tendency of calcite group minerals to the formation of double salts is well known. Double carbonates including calcium carbonate are known to chemists. However, the connection between the above complexes and the manifestation of a catalyst effect during the production of binders was not observed previously.

RECOMMENDATIONS.

Raw materials in the cement technology are ground finely. The systems with the developed surface have unsaturated valence links of surface ions, a strained crystal lattice, a lot of dislocations and vacancies; surface amorphism is feasible. These factors contribute to the emergence of surface microphases when a catalyst is added. When solving a technological problem the decision was taken to create the most favourable conditions for the interaction of calcite and a catalyst by means of primary contacts. The catalyst addition turned out to be most effective when added during limestone grinding (Luginina, 1994). Similar conditions were created in order to neutralize unwanted impurities in raw materials. Irrespective of the clinker phase composition (alite, fast-hardening, sulphate-resistant and

decorative cements were compared), after the aimed addition of the catalyst the cement strength was 9 - 12 % higher after 3 days' water hardening and it was 6 - 8 % higher after a month's water hardening. The less the age of samples under test is, the higher effect of the initial mixing is. The conditions of the catalyst addition reflected on the phase composition: the content of alite and tricalcium aluminate decreased. The alite phase accepted the minimum quantity of impurities in the form of a solid solution. The production tests of the said method were conducted at two cement plants. According to the technological scheme of one of the production processes the catalyst was added into iron slurry. After changing the grinding conditions the raw mix was better sintered, clinker hardness decreased, clinker dusting stopped and the cement strength increased under hydration (Table 1).

The strength of standard samples which were prepared from the mortar 1:3 and grew hard in water at 20 °C is given in the Table.

Table 1 The influence of mixing conditions upon cement strength.

Age of samples, days	Compressive strength of standard samples, MPa	
	Offered method	Plant method
3	33.3	25.5
7	40.6	33.2
28	50.8	42.9

The plant method consisted in the addition of a catalyst to a raw mix without premixing an additive with one of the components of the raw mix. The proposed method provided for the grinding of the additive with limestone followed by mixing with the rest of the raw mix components.

The catalyst is calcium fluoride with admixtures of sedimentary rocks. The fluoride content in the raw mix was fractions of a percent.

The mixing of a mineralizer with individual components of raw mixes produced a stronger effect upon the increase in the strength during the first days of tests (in 3 and 7 days).

All the plants located near the one applying the above technology used the favourable influence of the mixing conditions. Using sodium silicofluoride as a catalyst, similar results were obtained.

USE OF WASTE LOW GRADE FLUORSPAR AS A MINERALIZER FOR THE MANUFACTURE OF CLINKER/CEMENT

S. P. GHOSH, National Council for Cement and Building Materials, New Delhi, India
K. MOHAN, National Council for Cement and Building Materials, New Delhi, India

ABSTRACT Investigations have been conducted for utilization of low grade fluorspar, a waste from non-ferrous metallurgy as well as from mining, as a mineralizer for the manufacture of clinker/cement from relatively difficultly burnable plant raw mixes. Burnability and microscopic studies have been carried out with different raw mixes prepared in the laboratory and kiln feed from plants with and without different doses of low grade fluorspar as mineralizer. The impact of granulometry of raw mix on burnability vis-a-vis mineralizer addition has also been studied. The cements prepared from clinkers with and without mineralizer have also been evaluated for their physical performance.

KEY-WORDS : Burnability of raw mixes, Mineralisers in clinker making, Microscopy

INTRODUCTION

Various studies have been carried out in different countries on the use of mineralizers for accelerating the clinkering reactions, lowering the burning zone temperature and energy savings. A comprehensive review on the use of mineralizers in clinkering process has been presented by Klemm and Skalny (1976) and Moir and Glasser (1972). Among most of the mineralizers, fluorides have been most experimented mineralizer.

In the present study, investigations have been conducted (a) for utilisation of low grade fluorspar, a waste from non-ferrous metallurgy as well as from mining, as a mineralizer for the manufacture of clinker/cement from relatively difficultly burnable plant raw mixes, and (b) on the impact of granulometry of raw mix on burnability vis-a-vis mineralizer addition.

EXPERIMENTAL

Materials

Two samples of limestone, one sample each of laterite, bauxite, iron ore, and coal and three samples of kiln feeds (plant raw mixes) from different cement plants were used in this study. Waste low grade fluorspar was used as a mineralizer.

Chemical compositions of limestones, laterite, bauxite, iron ore, coal ash and low grade fluorspar are given in Tables 1 and 2.

Table 1 - Chemical Compositions of raw materials, additives and coal ash

Sample Reference	LOI	SiO2	Al2O3	Fe2O3	CaO	MgO
Limestone 1	35.12	12.95	2.90	1.47	45.10	0.80
Limestone 2	36.20	12.37	3.07	1.41	45.33	0.60
Laterite	14.20	15.20	13.10	53.00	1.50	1.00
Bauxite	21.03	6.70	40.27	28.90	1.50	0.70
Iron Ore	-	-	-	90.13	-	-
Coal Ash	-	62.20	27.00	5.00	4.80	0.50

Table 2 - Chemical Composition of Waste low grade fluorspar

SiO2	Al2O3	Fe2O3	CaF2
49.35	2.10	1.50	40.00

Chemical compositions of plant raw mixes (kiln feeds) are given in Table 3.

Table 3 - Chemical compositions of plant raw mixes (kiln feeds)

Sample Reference	LOI	SiO2	Al2O3	Fe2O3	CaO	MgO	LSF	SM	AM
KF-1	35.96	12.19	3.13	2.57	44.63	0.73	1.13	2.14	1.22
KF-2	36.81	11.53	2.71	2.62	45.17	0.42	1.21	2.16	1.03
KF-3	35.66	13.11	2.98	2.4	44.55	0.68	1.06	2.44	1.24

Chemical compositions of two laboratory prepared raw mixes, one designed with limestone-1 and laterite and another designed with limestone-2, bauxite and iron ore are given in Table 4. The plant raw mixes (kiln feeds) and laboratory prepared raw mixes were so chosen as to represent variation with respect to their compositions.

Table 4 - Chemical Compositions of laboratory prepared raw mixes

Sample Reference	LOI	SiO2	Al2O3	Fe2O3	CaO	MgO	LSF	SM	AM
RM-1	35.40	13.00	3.10	2.50	44.20	0.79	1.06	2.32	1.24
RM-2	36.60	12.13	3.03	2.50	44.86	0.60	1.14	2.19	1.21

Method

Raw Mix Preparation and Burnability Studies

Laboratory prepared raw mixes were prepared by weighing raw materials as per the designs of RM-1 and RM-2. The fineness of raw mix RM-1 was kept at (a) 15% residue on 170 mesh and 1% residue on 72 mesh, and (b) 20% residue on 170 mesh and 3% residue on 72 mesh, whereas the fineness of RM-2 was kept at 15% residue on 170 mesh and 1% residue on 72 mesh. The fineness of the plant raw mixes (kiln feeds) KF-1, KF-2 and KF-3 were determined and these were in the range of 15-16% residue on 170 mesh and 1-1.5% residue on 72 mesh. The fineness of fine coal was kept at 15% residue on 170 mesh and 1% residue on 72 mesh.

About 100 gms of raw meal was prepared, for each of the plant and laboratory prepared raw mixes. Proportionate quantity of coal ash (7%), with and wihout different doses (0.5%, 1.0% and 1.5%) of low grade fluorspar was added to the raw meal and homogenized thoroughly. About 10 to 12 mm size nodules were then made manually using tap water. The nodules were then oven dried at 105°C for two hours and the dried nodules were fired at laboratory furnace at 1350°C, 1400°C and 1450°C separately with 30 minutes retention time in each firing. The clinkers so prepared were quenched in water and they were analysed for their free lime contents. Selected clinkers were subjected to optical microscopic examination also.

Burnability studies on the following raw mixes were carried out :

(i) KF-1, KF-2, KF-3, RM-1 (havinig 15% residue on 170 mesh and 1% residue on 72 mesh) and RM-2 with and without 0.5%, 1.0% and 1.5% low grade fluorspar.

(ii) RM-1 (having 20% residue on 170 mesh and 3% residue on 72 mesh) with and without 0.5% and 1.0% low grade fluorspar.

Performance Studies of Cements

The possible effects of low grade fluorspar on the performance of cement was also studied by preparing cements from clinkers with and without low grade fluorspar and comparing their setting times and compressive strengths.

Cement-1 was prepared by intergrinding clinker, prepared at 1450°C from KF-2 without low grade fluorspar, with 5% gypsum and cement-2 was prepared by intergrinding clinker, prepared at 1400°C from KF-2 with 1% low grade fluorspar, with 5% gypsum. The fineness of both cements were kept at around 2700 cm^2/gm.

RESULTS AND DISCUSSION

The effect of addition of low grade fluorspar on the burnability of raw mixes

The results of the burnability studies of the plant and laboratory prepared raw mixes with and without low grade fluorspar at different temperatures are summarized in Tables 5 and 6.

Table 5 - Burnability Studies of Plant Raw Mixes

Sl No	Sample Reference	Dosage of Fluorspar (%)	Free Lime (%)		
			1350oC	1400oC	1450oC
1	KF-1	0.0	1.7	0.9	0.6
2	KF-1	0.5	1.3	0.6	0.3
3	KF-1	1.0	0.6	0.4	0.3
4	KF-1	1.5	0.5	0.4	0.2
5	KF-2	0.0	2.7	1.4	0.9
6	KF-2	0.5	1.8	1.1	0.9
7	KF-2	1.0	1.4	0.9	0.7
8	KF-2	1.5	1.1	0.9	0.5
9	KF-3	0.0	3.3	2.0	1.3
10	KF-3	0.5	3.0	1.9	1.3
11	KF-3	1.0	2.6	1.4	1.3
12	KF-3	1.5	2.0	1.2	1.0

Table 6 - Burnability Studies of Laboratory Prepared Raw Mixes

Sl No	Sample Reference	Dosage of Fluorspar (%)	Free Lime (%)		
			1350oC	1400oC	1450oC
1	RM-1	0.0	1.8	1.3	0.9
2	RM-1	0.5	1.6	0.9	0.8
3	RM-1	1.0	1.3	0.8	0.6
4	RM-1	1.5	1.1	0.7	0.5
5	RM-2	0.0	1.5	0.8	0.5
6	RM-2	0.5	0.8	0.5	0.4
7	RM-2	1.0	0.5	0.4	0.3
8	RM-2	1.5	0.4	0.2	0.2

The results indicate that for both the plant and laboratory prepared raw mixes the free lime contents of clinkers decrease with an increased dosage of low grade fluorspar from 0 to 1.5% at each temperature 1350°C, 1400°C and 1450°C.

The free lime contents of clinkers prepared at 1350°C from KF-1 and RM-2 with 1.0% low grade fluorspar are more or less the same as those of clinkers prepared at 1450°C without low grade fluorspar.

The free lime contents of clinkers prepared at 1400°C from KF-2 and KF-3 with 1.0% low grade fluorspar are more or less the same as those of clinkers prepared at 1450°C without low grade fluorspar.

The free lime content of clinker prepared at 1400°C from RM-1 with 0.5% low grade fluorspar is more or less the same as that of clinker prepared at 1450°C without low grade fluorspar.

The above results indicate that low grade fluorspar acts as a mineralizer and not more than 1% of low grade fluorspar (0.4% CaF_2) is required for obtaining improved burnability. However, the amount of mineralizer and the degree of lowering of burning temperature vary from raw mix to raw mix with minimum lowering of clinkerisation temperature by 50°C and maximum by 100°C.

The above findings are in agreement with the results obtained by Klemm and Skalny (1976), Klemm and Jawed (1980) and Blanco et al (1984).

Optical Microscopic Studies

The clinkers prepared at 1450°C from KF-1 and RM-1 without low grade fluorspar, clinker prepared at 1350°C from KF-1 with 1% low grade fluorspar and clinker prepared at 1400°C from RM-1 with 0.5% low grade fluorspar were subjected to optical microscopic studies.

The clinker prepared at 1450°C from KF-1 without low grade fluorspar shows microhomogeneity with alite and belite occurring mostly in separate clusters. Both these phases are mostly subhedral to anhedral in form without indistinct grain boundaries. Alite and belite grains are mostly regular in shape. The clinker prepared at 1350°C from KF-1 with 1% low grade fluorspar shows better morphology and much less microinhomogeneity. Alite and belite are evenly distributed with the interstitial phases. Alite grains are well formed with distinct boundaries.

The clinker prepared at 1450°C from RM-1 without low grade fluorspar shows predominant microinhomogeneity with alite and belite occurring mostly in separate clusters. Both these phases are mostly anhedral in form with indistinct grain boundaries. Alite grains are mostly irregular in shape. The clinker prepared at 1400°C from RM-1 with 0.5% low grade fluorspar shows better morphology and much less microinhomogeneity. Alite grains are subhedral, tabular to prismatic. Belite grains are anhedral to subhedral, round in form.

The mineral composition by optical microscopy shows that the clinkers prepared with low grade fluorspar have higher alite and lower free lime contents than those prepared without low grade fluorspar.

The above results indicate that clinkers with mineralizer show better burnability and morphology of clinker phases.

The effect of granulometry of raw mix on the burnability of raw mixes vis-a-vis mineralizer addition

The results of the effect of granulometry of raw mix on the burnability of laboratory prepared raw mix vis-a-vis mineralizer additon are given in Table 7.

Table 7 Burnability Studies of Laboratory Prepared Raw Mix with different fineness

	Sample	Dosage of	Residue of Raw Mix (%)		Free Lime (%)		
Sl No	Reference	Fluorspar(%)	+ 170	+ 72	1350oC	1400oC	1450oC
1	RM-1	0	15	1	1.8	1.3	0.9
2	RM-1	0	20	3	2.1	1.6	1.1
3	RM-1	0.5	15	1	1.6	0.9	0.8
4	RM-1	0.5	20	3	1.7	0.9	0.9
5	RM-1	1	15	1	1.3	0.8	0.6
6	RM-1	1	20	3	1.5	0.9	0.6

The results indicate that the free lime contents of clinkers decrease at both the fineness levels with increase in the dosage of low grade fluorspar from 0 to 1.0% at each temperatures 1350°C, 1400°C and 1450°C.

The free lime content of clinker prepared at 1450°C from finer ground raw mix (15% residue on + 170 and 1% residue on + 72) without low grade fluorspar is more or less the same as those of clinkers prepared at 1400°C from coarser ground raw mix (20% residue on + 170 and 3% residue on + 72) with 0.5% and 1.0% low grade fluorspar. The results indicate that even with coarser ground raw mix but by addition of 0.5% to 1.0% low grade fluorspar, the burnabillity of raw mix improves alongwith lowering of burning temperature by 50°C.

The effect of mineralizer on the properties of cement

The results of the effects of low grade fluorspar on the properties of cement are presented in Table 8.

Table 8 - Effect of mineralizer on the properties of cement

Sl No	Sample Reference	Dosage of Fluorspar(%)	Setting Time (Min)		Compressive Strength (kg/cm2)		
			Int.	Final	3-days	7-days	28-days
1	Cement-1	0.0	125	195	200	280	410
2	Cement-2	1.0	135	200	220	310	440

The results indicate that cement prepared from mineralized clinker has slightly higher compressive strengths. This may be due to better quality and morphology of mineralized clinker.

CONCLUSION

Waste low grade fluorspar can be used as a mineralizer for the manufacture of Clinker/Cement from relatively difficultly burnable plant raw mixes. The optimum dosage of the mineralizer coupled with control of the granulometry of the kiln feed can provide the desired results.

USE OF FLUORSPAR AND BARITE FOR IMPROVED BURNABILITY AND CLINKERISATION OF CEMENT RAW MIXES

Ajoy K MULLICK, Subhash C AHLUWALIA, Rakesh BHARGAWA
National Council for Cement and Building Materials, New Delhi, India

ABSTRACT Investigations on the use of barite to improve the lime assimilation of the cement raw mix have indicated improved burnability and lowering of burning temperature by 55°C. Use of fluorspar (0.1-0.25 percent F) significantly lowered the first liquid formation temperature but rendered the raw mix sensitive to temperature change in the range 1355-1400°C with the raw mix fusing at ~1375°C.

Keywords: Burnability of raw mixes, Clinker formation, Mineralizers in clinker making.

INTRODUCTION

The role of minor components in portland cement clinkers used as mineralisers have been discussed and reviewed adequately (Timashev, 1980, Bucchi, 1980, Moir and Glasser, 1992), Some mineralisers provide fluxing action to reduce the temperature of first liquid formation, modifying viscosity and surface tension of the liquid and morphology of crystals. In addition, clinker phase relations and the hydraulic activity are modified by solid solution effects. This paper presents the results of an investigation on the use of naturally occurring fluorspar and barite to mineralise cement raw mixes in a dry process cement plant.

ROLE OF FLUORINE AND BARIUM

Among the various minor components studied, the role of fluorides (F) and barium (Ba) additions are of particular relevance to the present investigation. Performance of a mineraliser depends upon the components and proportions of the raw meal as well as other minor components present. In general, fluoride-bearing mineralisers have been reported to lower the temperature of first liquid formation and reduce the viscosity and surface tension of the clinker liquid (Timashev, 1980). In addition, mineralising action of enhancing the thermodynamic stability of C_3S phase relative to C_2S, enabling the former to be formed at temperature below 1250°C, has also been reported (Welch and Gutt, 1960). On the other hand, barium containing additives are reported to activate C_2S phase by formation of solid solution of Ba in C_2S and modifying interstitial aluminate phases linking belite grains (Rajczyk and Nocum-Wezelik, 1992). The clinkerisation temperature was lowered and hydraulic activity increased. In another investigation, the use of barite was found to be particularly useful in cement clinker with lower LSF and higher C_2S content and although addition of barite increased free lime content, the compressive strength of cement increased due to activation of C_2S phase by Ba (Xianyu, Liqun and Jian, 1992). Combined addition of barite and fluorspar had the additional effect of lowering free lime content and increasing C_3S content and much higher compressive strength were obtained in commercial clinkers.

In appreciating the role of barite as mineraliser, the effect of sulphate have to be taken into account, in addition to Ba. In the oxidising environment of the cement rotary kiln all sulphur compounds are oxidised to SO_3 which is absorbed in the basic cement mix.

Small quantities (0.1-0.5%) of SO_3 have a catalysing effect on fixing CaO and increases the alite content (Butt and Timashev, 1974). SO_3 upto 3 percent is also reported to reduce the melt viscosity significantly. SO_3 when present as R_2SO_4 acts as mineraliser and promotes formation of C_3S from its component oxides and some of the adverse affects of SO_3 are modified (Gutt and Smith, 1971). Presence of SO_3 also improves the clinker grindability.

EXPERIMENTAL

The investigations were aimed at optimising the raw mix including use of mineralisers for a 3700 tpd dry process cement plant with five-stage preheater and a separate line precalcinator of FLS design. The main raw material - limestone was obtained from three different mines and blended at the plant site in a stacker reclaimer. There was considerable variation in the CaO content of limestone from different mines as well as in samples from a single source obtained at different intervals. Typical composition of composite limestone is shown in **Table 1**. Chemical composition of other constituents of the three component raw mix - laterite and bauxite as well as barite and fluorspar to be used as mineralisers are also given in Table 1. Limestone contained about 13.2% SiO_2. Laterite and bauxite, used as corrective materials to supplement Al and Fe in the raw mix, also contained 14 to 15 percent SiO_2.

Table 1 Chemical Analysis of Raw Materials and Mineralisers

Sl No	Raw Materials	LOI	SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	Na_2O	K_2O	$SiO_{2(f)}$	TiO_2	$BaSO_4$	F
1	Limestone (Composite)	35.96	13.20	0.90	2.17	45.60	0.60	0.30	0.42	9.28	--	--	--
2	Laterite	12.98	14.31	58.93	11.45	1.39	0.29	0.14	0.08	--	0.63	--	--
3	Bauxite	11.05	15.12	30.17	34.97	0.92	0.66	0.09	0.02	--	7.09	--	--
4	Barite	0.36	--	--	--	--	--	0.07	0.10	--	--	97.25	--
5	Fluorspar	3.30	18.33	0.78	2.06	45.13	0.30	0.55	0.73	--	--	--	29.85

Coal from different sources obtained commercially, used with lignite (5-10 percent) were blended at the plant site to result in ash content of 30-31 percent and calorific value of 4250-4350 kcal/kg in the blended coal. The raw mix made with such raw materials was difficult to burn. Because of presence of free SiO_2 in raw materials and absorption of coal ash, the mixes had to be lime-rich and free lime in commercial clinkers was of the order of 1.5 percent or more.

The investigations were taken up in two stages. In the first stage, the raw mix was optimised to reduce the free lime in the resultant clinker without lowering cement strength properties. This comprised not only altering the raw mix composition, but also optimising the grinding of raw mixes and fuel as well as control on the entire pyroprocessing. Complete details are given in the Project Report (NCB 1996); as such only salient details will be reported here. The second stage was the use of mineralisers to further improve the burnability of the optimised raw mix, and improve the quality of clinker produced from it.

OPTIMISATION OF RAW MIX

On evaluation of operating and design parameters, the raw mix was aimed to be optimised so as to have LSF 0.88, SM 2.45 and AM 1.5 in the clinker. After repeated trials, three raw mixes RM-A, RM-B and RM-C were chosen for further evaluation. The details of the three mixes along with the mix adopted by the plant so far are given in **Table 2**. The trial raw mixes were prepared with coal ash absorption of 5.5 percent which corresponded to the prevailing level of fuel ash absorption. Fineness of the ground mix had 17 percent residue on 90 μ sieve. Burnability studies were carried out on pressed pellets fired in a laboratory furnace at temperatures of 1350^{o}, 1400^{o} and $1450^{o}C$; the retention time being 20 minutes in each case. The clinkers prepared from the raw mixes after firing were analysed for free lime content. Mineralogy, morphology and microstructure of clinkers were also determined.

Table 2 Comparison of Design Parameters of Raw Mixes

Sl No	Raw Mix	Raw Materials				Moduli Values			Potential Phase Composition				
		Limestone	Bauxite	Laterite	Coal ash	LSF	SM	AM	C_3S	C_2S	C_3A	C_4AF	Liquid content
1	Plant Raw Mix - P	96.0	2.0	2.0	--	0.91	2.74	1.31	49.84	28.46	6.47	11.11	--
2	RM - A	99.75	0.02	2.23	5.5	0.89	2.73	1.35	55.31	23.76	6.73	10.83	24.10
3	RM - B	97.22	0.77	2.01	5.5	0.88	2.60	1.39	50.64	27.43	7.36	11.16	25.38
4	RM - C	96.42	1.67	1.91	5.5	0.87	2.39	1.39	45.39	31.08	7.95	12.04	27.29

The results are presented in **Fig.1**. All the three trial mixes gave free lime content less than 0.5 percent at $1450^{o}C$. Raw mix B was chosen for preparation of bulk clinker which was studied for chemical, mineralogical and physical properties. The potential Bogue composition indicated C_3S and C_2S contents of 49 and 29 percent respectively, which were estimated to be 48 and 32 percent by XRD. Optical microscopic analysis showed fairly well developed and homogeneously distributed phases (NCB, 1996).

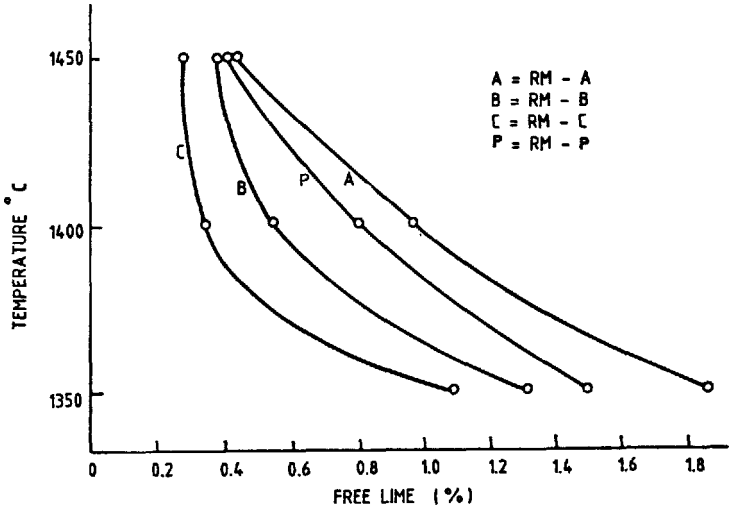

Figure 1 Burnability of Designed Raw Mixes and Plant Raw Mix

EVALUATION OF MINERALISERS

Locally available fluorspar and barite sample were used in the trials. Barite with 97.25 percent $BaSO_4$ contained very little impurities. Fluorspar sample had CaF_2 content of the order of 61.27 percent (F 29.85 percent) and SiO_2 as impurity of 18.33% (Table 1).

Fluorspar

Investigations were carried out using 0.15, 0.25 and 1.0 percent F on all the three raw mixes RM-A, RM-B and RM-C. Full details are available in the Project Report (NCB, 1996), as such results with optimised raw mix RM-B will only be presented. Burnability studies were carried out at 1300, 1350 and 1400°C with retention time of 20 minutes. Heating microscopic studies were also carried out to study the effect of the mineraliser on the first liquid formation temperature.

Burnability isotherms are given in **Fig. 2**. At 1 percent level of F there was softening in temperature range of 1300-1350°C, which was not desirable. At 0.15 percent level F, the burnability temperature (corresponding to 0.5 percent free lime) was 1325°C and for 0.25 percent F, it was 1300°C, compared to 1425°C for raw mix RM-B without mineraliser. Similar trends were obtained with raw mixes RM-A and RM-C also. Thus fluorspar at levels of 0.15 and 0.25 percent F has considerable mineralising effect. Hot stage microscope studies indicated that the raw mixes had a tendency to fuse at 1375°C and were considerably sensitive to temperature, especially with 0.25 percent F : Thus 0.15 percent level F (0.5 percent fluorspar) was chosen for further evaluation.

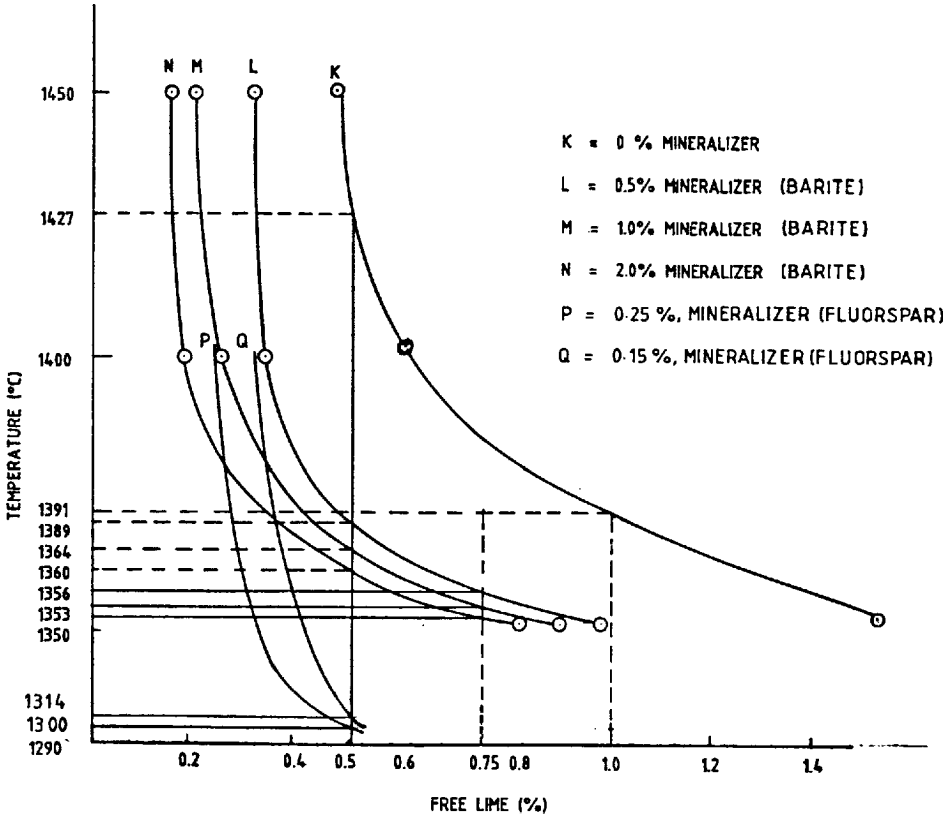

Figure 2 Effect of Barite and Fluorspar Mineralizer on Burnability of Raw Mix RM-B

Barite

Similar burnability studies were carried out on the three raw mixes RM-A, RM-B and RM-C using 0.6, 1.0 and 2 percent BaO. Unlike with fluorspar, no softening upto 1450°C was noticed in hot stage microscopy, when using barites. Burnability studies were, therefore, carried out upto 1450°C. Results of raw mix RM-B as burnability isotherms are shown in Fig. 2 along with those for fluorspar. Barium (Ba) was found to impart mineralising effect in improving burnability by reducing free lime content, although to a lower degree than fluorspar. A dose of 0.5 percent BaO was chosen for evaluation in bulk clinker, as there was no marked advantage of using higher dosages.

Evaluation of Clinker and Cements

Bulk clinkers prepared from raw mix B with 0.15 percent F (with fluorspar) and 0.50 percent BaO (with barite) were compared for physical, chemical and mineralogical characteristics. On the basis of burnability studies, the pelletised mixes were fired at 1450°C when plain raw mix was used and at 1350°C and 1400°C with fluorspar and barite respectively. Ordinary portland cement was prepared in each case by grinding with gypsum (purity 85.57 percent) so as to maintain SO_3 content 1.75 percent, at a fineness of 300 m^3/kg Blaine's. Free lime content in mineralised mixes were less than 0.5 percent (**Table 3**) even when fired at lower temperatures than the parent raw mix XRD studies (**Fig. 3**) revealed increase in C_3S contents with use of mineralisers and use of barite resulted in 53 percent C_3S compared to 49 percent in case of fluorspar (Table 3). Optical microscopy indicated improvement in crystal morphology and microstructure of clinkers containing fluorspar (**Plate 1**) and barite (**Plate 2**) mineralisers. The mineral compositions obtained from optical microsocpy and XRD were in close agreement.

Table 3 Characteristics of Clinkers and Cements from Raw Mix B

Details of Raw Mix and Clinker	Free Lime (%)	Phase Comp. by XRD, %				Properties of Cement						
		C_3S	C_2S	C_3A	C_4AF	IST (mts)	FST (mts)	Comp. St. (N/mm^2) 3d	7d	28d	Soundness Auto. (%)	Lechat. (mm)
Plain, 1450°C	0.35	48	29	6	12	110	160	27.5	39.6	53.0	0.02	1.0
With Barite, 1450°C	0.33	53	28	6	12	100	152	33.1	44.4	57.5	0.02	1.0
With Fluorspar, 1350°C	0.41	49	28	7	13	90	145	28.6	40.5	54.2	0.02	1.0

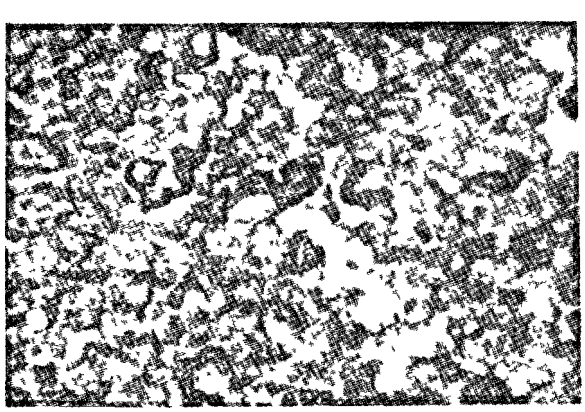

Plate 1

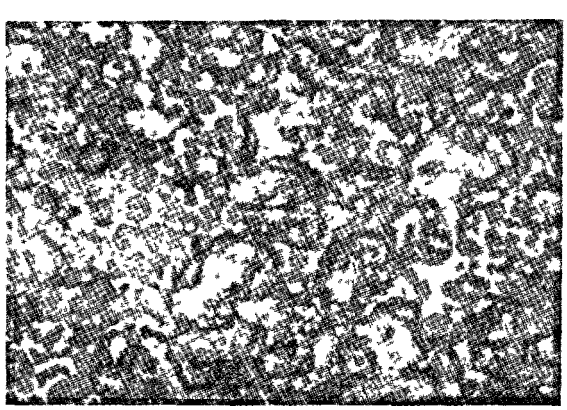

Plate 2

Evaluation of cements prepared from bulk clinkers indicated no change in setting times and increase in compressive strength, especially with barite (Table 3).

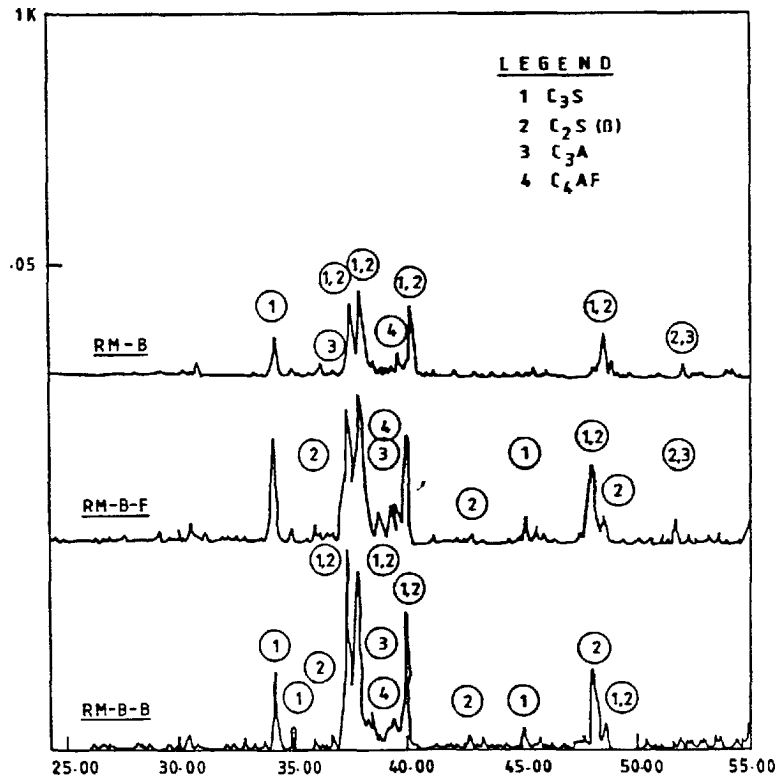

Figure 3 X-Ray Diffractogram of Clinkers Prepared with/without Mineralizers

DISCUSSION

The results of the investigations have clearly indicated that although fluorspar, in the concentrations studied, has considerably higher mineralising effect compared to combined effect of BaO and SO_3 derived from barite as mineraliser, it has severe limitation in application due to high temperature sensitivity of the commercial raw mix mineralised with fluorspar. It could make the pyroprocessing operations difficult, particularly the granulometry, cooling characteristics, morphology and microstructure of the clinker. Literature record conflicting results with use of Ba as mineraliser. The study indicated perceptible advantages, both in terms of lime assimilation as well as clinker quality with use of Barite.

CONCLUSION

For difficult-to-burn raw mixes prepared with crystalline limestone having 14 percent silica, optimisation resulted in lowering of free lime content. Further improvements in burnability were achieved with the use of fluorspars as well as barites as mineralisers. Between the two, barite was preferred, as mixes with fluorspars were sensitive to temperature rise and therefore, likely to be difficult to control. The cost of mineraliser was more than offset by lowering the fuel cost, which resulted due to lowering of clinkerisation temperature by 55^{o}C. Decrease in air required for coal combustion could allow increase in clinker production.

CLINKERISATION OF ANHYDRITE WITH PHOSPHOGYPSUM AND CALCIUM FLUORIDE

Ludmila I. SYCHOVA, Mikhail V. ANUFRIEV., Russian University for Chemical Technology n.a. D.I. Mendeleev

ABSTRACT. Problems related to liquid phase sintering in systems based on calcium sulfate, calcium fluoride and phosphogypsum have been considered. Methods of optimisation of a process of liquid phase sintering of gypsum raw mixes have been proposed.

KEY-WORDS: anhydrite, calcium fluoride, sintering, shrinkage, viscosity.

INTRODUCTION. Over the recent years, great attention has been paid to the use of wastes in production of various types of clinkers due, first of all to the necessity of environment protection, as well as to high costs and shortage of natural raw materials. Anhydrite cement, produced from industrial wastes, is a highly efficient construction and finishing material due to a number of remarkable characteristics, namely quick setting and hardening, high strength, water resistance and whiteness. The technology of anhydrite cement consists of firing at 900 - 1000°C a raw mix based on a gypsum-containing component (phosphogypsum) and mineralising additives, introduced to enhance the hydraulicity of the anhydrite. Since phosphogypsum contains technological admixtures which reduce firing temperatures, the study of clinkering mechanism of such raw mixtures is of scientific and practical interest.

RESULTS

The aim of the present study was to investigate processes of clinker formation occurring both in the model system $CaSO_4$-CaF_2, and on the basis of industrial raw components: phosphogypsum and wastes containing calcium fluoride.

The synthesis of anhydrite clinker is accompanied by a number of physico-chemical processes consecutively occuring during firing of gypsum-containing raw mixes, namely dehydration of phosphogypsum, inversion of crystalline structure of anhydrite and its sintering. The formation of clinker pellets at temperatures of 500 - 700°C is determined by processes of re-crystallizations and compaction of anhydrite structure and the local appearance of a small quantity of low-temperature eutectic melt, formed by admixtures (first of all phosphates) of phosphogypsum and calcium sulfate. As the temperature increases, a sulphate-fluorine salt melt appears, the presence of which has a major influence on the structure, composition and properties of clinker. The melt occurs in clinker in the form of drops and interlayers of different sizes.

Shrinkage is the measure of intensity of sintering. The linear sizes of specimens during heating-up were measured by dilatometry. Fig. 1 shows the relation between linear sizes of specimens and the temperature (speed of heating was constant). Data obtained show that the shrinkage of specimens in the model system starts in the temperature range of 450 - 550 °C. The extent of shrinkage is connected to the $CaSO_4/CaF_2$ ratio (mixes were investigated which have molar ratio of components from 8/1 to 0,5/1).The shrinkage grows insignificantly (by 2 - 4%) with increasing proportions of calcium fluoride. However, with the growth of temperature this difference vanishes. Sintering of samples based on phosphogypsum increases, and the temperature at which shrinkage begins decreases.

Due to the process of sintering of systems based on calcium sulphate being complex and poorly studied, equations of chemical kinetics were used for the calculation of shrinkage parameters,

which allow us to describe this process with sufficient accuracy. In this instance the sintering process has been considered as a chemical reaction (Ivensen, 1976).

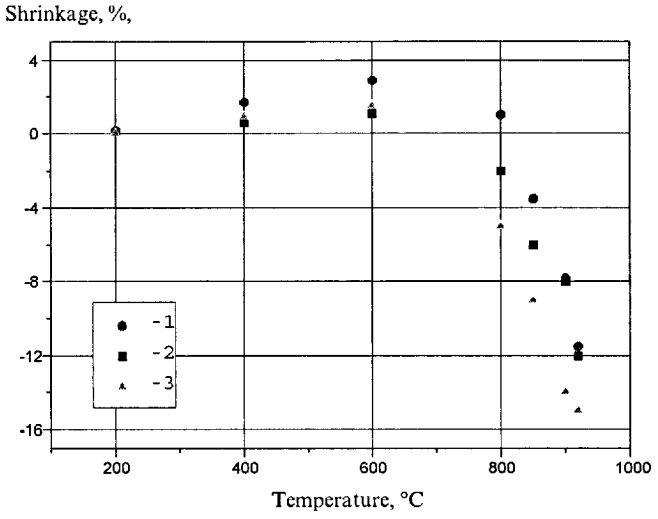

Fig.1 Change of specimens shrinkage in the $CaSO_4$-CaF_2 system during heating-up. Molar ratio $CaSO_4/CaF_2$: 1- 1; 2- 4; 3- 8.

The most accurate description of kinetics of isothermal sintering process can be obtained by means of Kolmogorov's equations (Young, 1969) [1];

$$\varphi = 1 - \exp(-k\tau^n) \quad [1]$$

where φ is the amount of material which has entered into reaction; k, reaction rate constant , s^{-1}; τ, time, s; n, a factor depending on the mechanism of sintering and temperature.

Since the shrinkage is isotropic the value of φ can be determined from changes in specimen length [2];

$$\varphi = (l_1 - l_2)/(l_2 - l_3) \quad [2]$$

where l_1 is the initial length of the specimen; l_2, the length of the specimen at a fixed temperature; l_3, length of the specimen held at the given temperature.

From equations [1] and [2] a dependency can be obtained allowing us to calculate the constants of the process [3]; an energy of activation (E_a) was determined using the Arrenius equation:

$$\ln k + n \ln\tau = \ln\{-\ln(1 - \varphi)\}. \quad [3]$$

Some parameters of the sintering process are shown in the Table 1.

The eutectic melt in the system $CaSO_4$-CaF_2 appears at 951°C. The melt composition is as follows - 63.45 % of $CaSO_4$, 36.55 mass % of CaF_2 (Posypajko, 1980). Its density is 2.528 g/cm^3, viscosity 0.029 Pa·s. This is significantly lower than viscosity of oxide-salt melts which appears during firing of a Portland cement clinker (the viscosity of the salt melt was determined by the vibration method, which consists in the determining relationship between amplitude and frequencies of vibrations of probe immersed into the melt and viscosity of the melt).

Practically, 8 to 12% of melt develops at the production of anhydrite clinker production; it is significantly less, compared to firing of a Portland cement clinker. However, physico-chemical characteristics of the melt (mainly, low density and viscosity) promote synthesis of a high-quality clinker with relatively small amount of liquid phase.

Table 1 Parameters of sintering process in systems $CaSO_4$-CaF_2 and phosphogypsum - CaF_2

Parameter	Molar ratio $CaSO_4/CaF_2$			Molar ratio phosphogypsum/CaF_2
	8 / 1	4/1	1/1	30 / 1
$K*10^2$ at 700°C	0.33	0.10	0.09	0.01
$K*10^2$ at 800 °C	2.04	1.93	1.56	2.90
$K*10^2$ at 900 °C	5.61	4.23	10.2	13.0
n at 700 °C	0.27	0.46	0.41	0.74
n at 800 °C	0.15	0.15	0.20	0.18
n at 900 °C	0.12	0.12	0.07	0.04
A (constant of the Arrenius equation)	$6.46*10^{-4}$	$5.72*10^{-6}$	$9.18*10^{-8}$	$2.79*10^{-17}$
E_a kJ/mol	135218	179224	222680	403400

The amount of melt forming during clinker firing, as well as its properties, can be optimised by introduction of different additives into the melt. Since the viscosity of salt melts is controlled by the mobility of the largest elements of their structure, the introduction of additives containing large anions or anion complexes results in increasing the viscosity of the melt up to 0.014 - 0.020 Pa s. Such components are, for example, glass, $Ca_3(PO_4)_2$, and excessive amounts of $CaSO_4$. On the other hand, excessive amounts of CaF_2 and introduction of the K_2SO_4 additive reduces this factor to 0.007 Pa s (Fig.2). Along with this, in the presence of the potassium sulphate the temperature at which melt starts to develop diminishes by 50°C.
Dependency of viscosity of the salt melt upon the temperature (in logarithmic form) is described by the following equation (Delimarskiy, 1985, Abe, 1982) [4]:

$$\ln \eta = B + E_a / RT \qquad [4]$$

where η, melt viscosity, Pa s; B, a constant; E_a, energy of activation of the viscous flowing, kJ/mol; T, temperature, K.
Results of the study show that dependency between ln η and 1/T is linear, thus, the heating up causes no structure changes in the melt.

The phase composition of the cooled clinker melt includes anhydrite, calcium fluoride and vitreous phase. Crystallisation of phases during cooling of the melt occurs with a deviation from the stoichiometry; the vitreous phase is saturated by the component, which is deficient compared with the eutectic relationship. The microstructure of the cooled sulphate-fluorine melt is formed by tabular and prismatic anhydrite crystals of 10-20 μm (Fig.3). Increasing cooling time brings about a change of morphology of the crystals: they increase in size and assume a distinct crystallographic form. Admixtures present in the phosphogypsum, especially calcium phosphates, develop accicular anhydrite crystals in the crystallised melt.

The insoluble anhydrite is a main phase of clinker. As result it was found that crystalline structure of anhydrite is modified by calcium phosphates present in initial phosphogypsum and additives, introduced into the raw mix. For example, in the presence of calcium phosphates the volume of elementary cell of anhydrite increases from 3.038*10-1 nm^3 to 3.057*10-1 nm^3. Thus, the anhydrite present in the clinker has a distorted, defective crystalline structure. This provides for its increased solubility and, consequently, increased hydration activity.

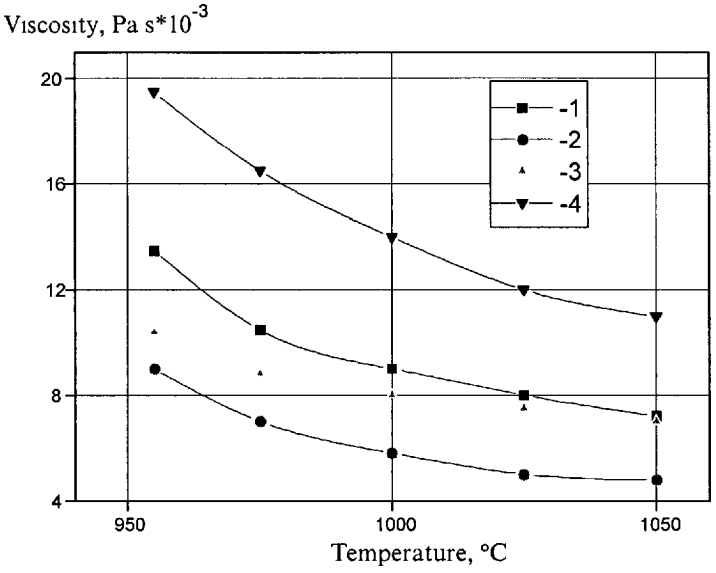

Fig. 2 Dependency of viscosity of the eutectic salt melt in the system $CaSO_4$ - CaF_2 upon the temperature. Content of additives (%):
1. no additives; 2. 4% of CaF_2; 3. 2% of K_2SO_4; 4. 9% of glass.

SYNTHESIS OF MINERALISERS FOR CLINKER MAKING

S.P. GANDHE, D. GHOSH, A.K. CHATTERJEE
Research & Consultancy Directorate
The Associated Cement Companies Ltd.,
Thane - 400 604, INDIA

ABSTRACT The mineralisers used in cement manufacturing are either natural raw materials such as gypsum, fluorspar or industrial by-products like sodium silicofluorides. To achieve process economy and to overcome the problems of usage of high ash fuel , there has been proliferation of usage of mineralisers,however, the main constraint being the effective economic viability. In this context, an attempt has been made to synthesise fluorine based compounds like calcium silicofluoride, iron silicofluoride and sodium silicofluoride using low cost materials like low grade limestone, scrap iron, etc. The efficacy of these synthesised mineralisers was evaluated based on rate of lime combination with temperature. The comparative scenario of these synthetic mineralisers has been depicted vis-a-vis the mineralisers of natural and industrial by product categories in the process of clinkerisation.

KEY- WORDS Synthesis, Mineralisers in clinker making, Waste material utilization.

INTRODUCTION

The Industrial application of mineraliser as a means of energy conservation as well as an avenue to improve quality or to overcome various process problems in clinker burning is well established in India. The Associated Cement Companies Ltd.(ACC) with 12 million tones of installed capacity has been using commercially available mineraliser under diverse process condition at few of its plants. A variety of mineralisers have been used for different objectives, however, the selection is governed by compatibility with a given kilnfeed & process, physical form of mineralisers and source with respect to location of cement plant and cost of transportation. In view of the above considerations together with the rising demand and competitiveness in quality of cement and also the increasing demand of mineralisers in areas other than cement has compelled R&D Division of ACC to undertake studies for synthesis of certain mineralisers.

A range of fluorine based mineraliser using low cost materials were synthesised. The efficacy of these synthesised mineraliser was compared with one another and also with commercially available mineraliser by studying the lime combining behaviour of raw mixes as a function of burning temperature, time and added amount of mineraliser.

UTILISATION OF MINERALISERS / MINERALISER USAGE PATTERN

The selection and use of mineraliser on an industrial scale is primarily to improve quality of clinker or process which depends on its compatibility with the given kilnfeed.

The variety of mineraliser used in ACC's cement plants for various objectives are shown in Table 1

Table 1 Usage Of Mineralisers And Benefits Obtained At ACC Plants

SR. NO.	TYPE OF PLANTS	PROBLEM OF PLANT	MINERALISERS USED	RESULTS OBTAINED	OTHER BENEFITS i.e. SAVING IN KCal/Kg OF CLINKER
1	Semidry Process	Hard burning resulting in high free CaO & low kiln output	Na_2SiF_6	Free CaO reduced. increased kiln output	94
2	Wet Process	Higher consumption of floated limestone due to high loss of lime rich dust.	CaF_2	Reduction in floated limestone by 10%	170
3	Wet Process	Low cement strength 420-525 Kg/cm^2 in 28 days	Gypsum and blue dust combination	Cement strength improved to 540-650 Kg/cm^2 in 28 days	112
4	Wet Process	Unsoundness in clinker	Gypsum and iron ore	Autoclave exp. brought down in freshly ground OPC to less than 0.2%	No data
5	Precalciner Kilns	High generation of dust	Magnesite	Improvement in clinker granulometry	--
6	Wet Process	Unstable coating on refractory lining	Rock Phosphate	Coating stability	--

SYNTHESIS OF MINERALISERS

The experience gained over the years of using mineraliser on a plant scale and also available literature on mineraliser,(Chatterjee et al -1985,Kleem et al -1980,Moir et al -1992) reveals that fluoride either alone or in combination in certain dosages is an effective mineralising compound. Based on this, Fluorine based compounds were chosen for synthesis. In the synthesis the basic objective was to select compounds which are normally found in cement systems and the process of synthesis should yield economically viable product. Therefore the raw materials for the synthesis were chosen to be either waste or reject materials / Chemicals (Subba Rao et al -1984) from process industries. The process involves reaction of commercially available H_2SiF_6 (15%) with limestone (~ 80% purity), scrap iron and soda ash to form Calcium silicofluoride ,Ferrous silicofluoride and Sodium silicofluoride.The details of chemical composition, fineness of the raw material used for synthesising these mineralisers are given in Table 2 and mixed as per stiochiometric proportions. The synthesised products were then examined with respect to their purity, yield and phases formed.

Table 2 Chemical composition of Raw materials used for synthesising mineralisers

Required Size	As in available form	powder form preferably -200 μ	powder form	To be made in small pieces

The following methods were employed for studying Physico-chemical characteristics of synthesised Silicofluoride powders of Calcium, Iron and Sodium.

- Percentage purity of each powder was determined by using Orion's Fluoride ion analyser model-407. The same was reconfirmed by determining other ions other than fluoride by IL - Atomic Absorption model 951.
- X-ray diffraction (XRD) using Siemens model D 500 for determining phase purity.
- IR spectrum of individual powders were taken using Perkin Elmer IR Model-577. The analysis results of lab synthesised Silicofluorides of Calcium, Iron and Sodium are given in Table 3.

Table 3 Analysis of lab scale synthesised Silicofluoride of Calcium, Iron and Sodium

	$CaSiF_6$	$FeSiF_6$	Na_2SiF_6
APPEARANCE	WHITE	BROWNISH GREEN	WHITE
% PURITY F^-	41.8	26.1	45.5
% PURITY	80.0	70.0	75.0
% YIELD	90.0	94.0	97.0
XRD PHASES MAJOR MINOR ABSENT	 $CaSiF_6.2H_2O$ $CaSiF_6$ CaF_2 & CALCITE	 $FeSiF_6.6H_2O$ $FeSiF_6$ --	 Na_2SiF_6 -- NaF
IR SPECTRA - PRESENCE	-- SiF_6	-- SiF_6	-- SiF_6

Percentage purity of $CaSiF_6.2H_2O$, $FeSiF_6.6H_2O$ and Na_2SiF_6 on % F basis is of the order of 80%, 70% and 75% respectively (Table 3) at an yield of over 90%.

XRD Patterns of Calcium Silicofluoride indicates presence of well crystallised phases of $CaSiF_6.2H_2O$ as well as $CaSiF_6$, and phases of CaF_2 & calcite are absent. XRD patterns of Ferrous Silico fluorides and Sodium Silicofluoride indicate well crystallised phases of the respective compounds (Fig. 1). Infrared analysis of all the mineralisers confirm presence of SiF_6 (Fig. 2).

EVALUATION OF SYNTHESISED MINERALISER

For the purpose of evaluating all the synthesised mineralisers, kilnfeed (Table 4) was prepared using pure compounds of Quartz, Technical Alumina, Iron Oxide & Calcite of 99.5% purity.

The effectiveness of the synthesised mineralisers were initially evaluated based on burnability studies at the author's laboratory .In this study synthesised Calcium silico fluoride, Ferrous silicofluoride and Sodium silicofluoride were added to the kiln feed making 0.2 % Fluoride on kiln feed basis and heated in the laboratory furnace at temperatures of 1300 ^{0}C , 1350 ^{0}C,1400 ^{0}C with retention time of 20 minutes in each case. The free CaO at all temperatures and Total CaO at 1400 ^{0}C were determined (Table 5).

Table 4 Composition of kilnfeed prepared from pure compounds & clinker

	% SiO_2	% Al_2O_3	% Fe_2O_3	% CaO	SM	AM	LSF
KILNFEED	14.8	4.1	2.6	44.0	2.2	1.58	0.92
CLINKER	22.4	6.25	3.95	67.1	2.2	1.58	0.92

Table 5 Free CaO in synthetic kilnfeed with synthesised mineralisers

DOSAGES : 0.2 % F^- , KILN FEED BASIS

	% FREE CaO AT			AT 1400 ^{0}C	
	1300 ^{0}C	1350^{0}C	1400 ^{0}C	% F^-	% TOTAL CaO
SYNTHETIC K.F	16.0	4.0	2.0	–	66.4
SYNTHETIC K.F + $CaSiF6.2H_2O$	14.0	2.2	0.8	0.20	66.5
SYNTHETIC K.F + $FeSiF_6.6H_2O$	10.1	2.2	0.7	0.19	66.5
SYNTHETIC K.F + Na_2SiF_6	8.0	1.5	0.6	0.21	66.5

It can be seen from data in Table-5 that all the three synthesised mineralisers were effective in reducing Free CaO content with increase in temperature or at the same temperature, the Free CaO is lower than the feed without mineraliser. Comparatively the Sodium silicofluoride was found to be more effective in kiln feed with pure compound situation followed by Ferrous silicofluoride & Calcium silicofluoride.

In order to understand the effectiveness with respect to kilnfeed prepared from natural materials, a plant kilnfeed was selected for further experiments with Modulli values as LSF : 0.99 SM : 2.27 & AM : 1.24. Expansion shrinkage and burnability (with respect to free CaO)of lab synthesised $CaSiF_6.2H_2O$, $FeSiF_6.6H_2O$ & Na_2SiF_6 as mineralisers with 0.2% F dosage on kilnfeed basis were conducted separately.The technique of shrinkage/expansion & lime combinability was developed in the author's laboratory & the details were published earlier (Chatterjee et al -1985, Page et al -1986). According to this technique the components of appropriately designed raw mix are ground,blended, homogenised and compacted to 33 X 15 mm cylindrical pellets under a pressure of about 500 Kg / cm ^{2}. The pellets are fired at the desired range of temperature following the heating and cooling schedule as necessary.The pellets are drawn out at selected temperatures and the volume,shrinkage/expansion is measured and plotted. The total lime, free lime ,loss on ignition and residual mineraliser contents are also determined in the

fired pellets. As indicated in Fig. 3, the addition of each of these mineralisers enhanced the expansion characteristic indicating a higher extent of solid-solid reactions at temperature range of 900-1100^0 C.The shrinkage indicates the appearance of liquid formation at that temperature and formation of eutectic is indicated by the shrinkage pattern. Steeper the slope of the shrinkage plot, higher is the rate of C_3S formation. The same phenomena is observed as the percent shrinkage is maximum with $CaSiF_6$ (11.4%) than with $FeSiF_6.6H_2O$ & Na_2SiF_6 for which the shrinkage are almost similar viz. 10% & 10.2%.

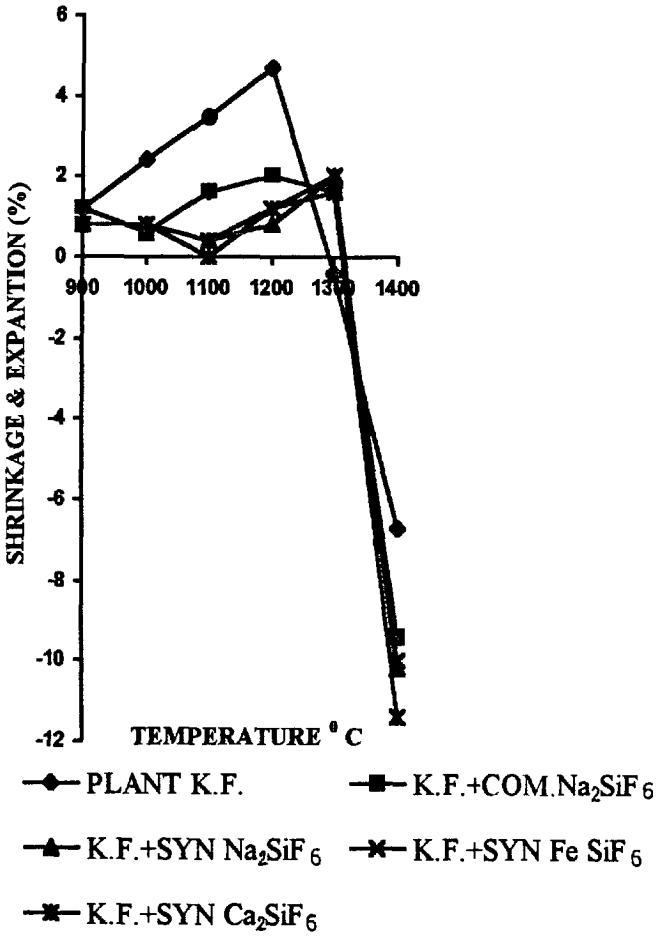

FIGURE 3 EFFECT OF MINERALISERS ON EXPANSION-SHRINKAGE WITH TEMPERATURE

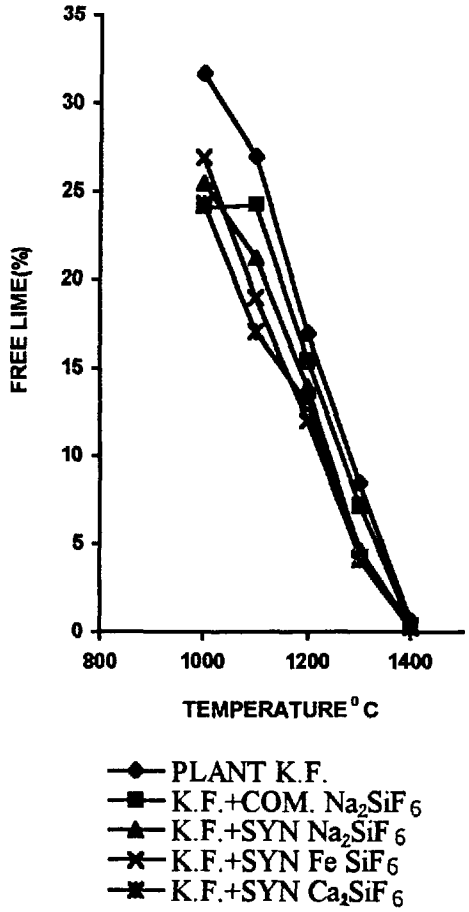

FIGURE 4 EFFECT OF MINERALISERS ON FREE LIME WITH TEMPERATURE

Further in order to understand the effectiveness of the synthesised Sodium silicofluoride, a commercial grade Na_2SiF_6 was also studied on similar lines.The shrinkage observed with commercial grade Na_2SiF_6 is, however, less (9.4%) as compared to that of all the three synthetic Silicofluorides, thus indicating improved sintering performances of the synthetic Silicofluorides over commercial Na_2SiF_6 (Fig 3). The percent free CaO against temperature (Fig. 4) in kilnfeed with and without synthetic mineraliser indicates that at high temperature (1400°C) the free lime is almost same in clinkers from kilnfeed with and without mineralisers but at lower temperature 1000°C to 1300°C the free CaO in fired

material with mineraliser is lower than without mineraliser and is least in the case of Calcium silicofluoride. The data in Fig. 4 also indicates that all the synthetic mineralisers are more effective in reducing free lime than commercial grade mineraliser i.e. Sodium silicofluoride.

In order to understand effectiveness of mineralising compounds at lower temperature reactions (Chatterjee et al -1985, Page et al -1986). ternary plots were prepared based on " free", "unliberated" and "combined" lime at temperatures upto 1000°C using same kiln feed with each of these mineralisers. The ternary plot pattern (Fig.5) shows better combinability of lime and less amount of unliberated lime and free lime with the three synthesised Silicofluorides of Calcium,Iron and Sodium as shown by curves moving more towards the lower right half of the triangle, indicating influence of these mineraliser on liberation and combining of lime due to the improved overall reactivity at the corresponding temperatures.

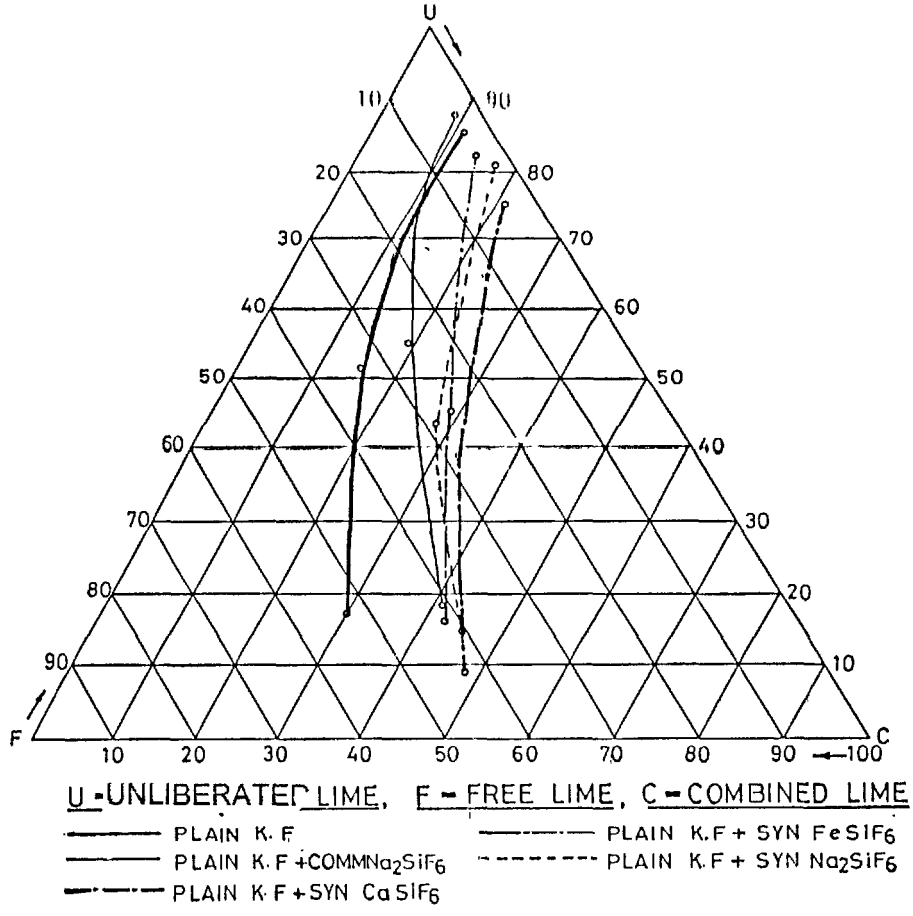

FIG.5. TERNARY PLOT U, F, C AT 800°C, 900°C & 1000°C

CONCLUSIONS

- The technical feasibility of manufacturing three Silicofluorides viz. Calcium Silicofluoride, Ferrous Silicofluoride is established on lab scale.
- All the three Silicofluorides have been found to be effective mineralisers and slightly better compared to commercially available mineralisers.

- Calcium silicofluoride appears to be the most effective mineraliser amongst others.
- The synthesis route of mineraliser opens up the possibility of making mineraliser near to the consumption center or at a central location with obvious advantages in reducing cost of transportation.
- Attempts have ben made to make preliminary estimate of cost for synthesising mineralisers. In this exercise the cost inputs of commercial grade fluosilicic acid, low grade limestone, scrap iron, soda ash and brine solutions were considered alongwith the yield of these mineralisers. The cost of synthesis for Calcium, Iron and Sodium silicofluorides works out to be 0.6, 0.5 and 1.1 times respectively against the cost of commercially available Sodium silicofluoride.
- Although $FeSiF_6.6H_2O$ appears to be cheapest among all the mineralisers, but it has certain limitations such as chemical reactivity, physical size of iron scrap etc.

BURNABILITY OF MINERALIZED WHITE CEMENT: OPTIMIZATION OF RAW MEALS

ABSTRACT A methodology for optimizing cement raw mixes dosages is presented. The methodology is based on a statistical tool generally named Experimental Design. It has been applied to a real case: the manufacture in a Spanish factory of a mineralized cement obtained by using the fluxing and mineralizing pair CaF_2 and $CaSO_4 \cdot 2H_2O$ among the raw materials.

Key-words: Burnability of raw mixes, mineralizers in clinker making, low energy.

INTRODUCTION

Mineralizers and/or fluxes are often added to cement raw meals to accelerate reactions and enhance burnability. In such cases the traditional methods (Ludwig and Ruckensteiner, 1974), (Fundal, 1979), (Christensen, 1979), (Johansen, 1979), for evaluating burnability of raw mixes are inapplicable, rendering evaluation quite difficult.

Burnability can be substantially improved by adding the mineralizing pair CaF_2 and $CaSO_4$ to the raw mixes, especially at temperatures between 1300 and 1400° C. The rate of alite formation in this case is even higher than that found for mixes mineralized with CaF_2 only (Johansen and Kouznestsova, 1992). This higher rate is due essentially to the thermodynamic effect of the widened stability range and primary phase field of crystallization of C_3S induced by CaF_2, together with enhanced ion mobility in the melt due to $CaSO_4$ and CaF_2 and the appearance of a new liquid phase at temperatures under 1200°C (Blanco-Varela et al, 1986) (Giménez and Blanco-Varela, 1995). Fluorellestadite ($3C_2S.3CaSO_4.CaF_2$) is the main compound of such a liquid whose approximate composition by weight is: CaO - 54, Al_2O_3 - 4, Fe_2O_3 - 3, SiO_2 - 11, CaF_2 - 4, $CaSO_4$ - 24.

CaF_2 and $CaSO_4$ can be used to partially replace the traditional fluxes Al_2O_3 y Fe_2O_3, to produce clinkers with low aluminate contents at temperatures between 1300 and 1400° C (Giménez and Blanco-Varela, 1995) (Blanco-Varela et al, 1985, 1990). In this type of material the essentially fluorsulfatic liquid phase is composed mainly of molten fluorellestadite (60 -75% by weight), ferrites and aluminates. The low clinkering temperature of these raw mixes reduces the loss of F_2 and SO_3.

The use of this mineralizing pair to partially replace aluminates is particularly useful in the manufacture of white clinker, because of the potential for energy conservation and because seawater- or sulfate-resistant white cements can be produced when such additives are used (Giménez et al, 1991). A Spanish factory interested in the new process and material proposed to achieve an industrial test. For that, the main objective of this paper is to propose a mathematical model to predict the burnability of raw mixes made using CaF_2 and $CaSO_4$ as fluxes and mineralizers for fabrication white clinker for its implementation in a cement factory.

EXPERIMENTAL

The chemical analyses of the raw materials supplied by the cement factory are shown in Table 1.

A two-level factorial experimental design was used for modelling (Box et al, 1989). The parameters given in Table 2 were considered to be the most relevant for raw mix burnability assessment. That table also shows the two levels (+ and -) defined for each factor.

Lime saturation factor (LSF) selected levels (93 and 98) are in the range usually used in industrial practice. In a previous paper (Blanco-Varela et al, 1996) was demonstrated through the same methodology the little influence of the silica modulus (Ms) (11 o 14) on the final free lime of clinkers. From these results only one level was decided to be used, particularly, the value of Ms=11. These values of Ms are very much higher than those employed in traditional grey and white clinker production. These values are necessary to produce sulfate resistant cement. Clinkerization is possible due to the mineralizing and fluxing effects of CaF_2 and $CaSO_4$. The AR (alumina iron ratio) values in these raw mixes are in the range between 7.3 and 7.6.

Sizes of limestone and sands were selected by sieving, kaolinite is very fine having an average size of 6 μm.

Table 2 Relevant Factors and Corresponding Levels

Factors	Factors Identification	Levels (-)	(+)
LSF	A	93	98
CaF_2 (%wt)	B	0.65	1.30
$CaSO_4$ (%wt)	C	2.6	3.9
Size Particle of Sand (%wt)	D	100% <45 μm	80% <45 μm 20% <45 μm
Size Particle of Limestone (%wt)	E	100% <125 μm	80% <125μm 20% >125μm
Temperature	F	1350°C	1400°C

LSF = Lime Saturation Factor

In the present work the influence of the nature of sand (Sand I and Sand II) on the raw meals burnability has been studied. Sand II was obtained from Sand I by water washing, removing most of the clayey material, resulting in quartz grains which were mineralogically identical.

Sand I mixes were prepared. A 2^{6-1} design was done; this means 32 different experiments or different clinkerizations. These experiments correspond to the 8 different dosages obtained through the combination of three compositional parameters (LSF, % CaF_2 and % $CaSO_4$) at two levels (2^3). Also Sand II mixes were prepared. In this case the design corresponded to a 2^6 one.

The raw mixes were prepared from the corresponding amounts of limestone, sand, kaolin, fluorite and gypsum (the two former with previously selected sizes). The mixes were hand homogenized, taking great care to avoid any modifications of particle size and then dried. The dispersive medium used was ethanol. With each of the raw mixes, cylindrical pellets of 2.5 cm diameter and 1.5-2cm length were prepared.

Temperature treatment of these pellets was done in laboratory kilns at selected temperatures. Heating time was always constant and equal to 30 minutes. The measured variable was free CaO in clinkers through the ethylene-glycol method (UNE Standard, 1986).

RESULTS AND DISCUSSION

The statistical analysis of free CaO values of the all clinkers obtained has been done using the variance analysis method (V.A.), neglecting interactions higher than second order. This V.A. method is based on decomposing observations as a sum of terms, each one depending on a factor or an interaction of factors.

The burnability model of white cement raw mixes prepared using Sand I as raw material, follow the equation [1]:

$$\%\ CaO_{Free} = 3.36 + 0.37\ X_A - 1.05\ X_B - 0.60\ X_C + 0.003\ X_D + 1.57\ X_E + 0.11\ X_F + 0.34\ X_B\ X_C - 0.49\ X_B\ X_E - 0.28\ X_C\ X_E + \Sigma \quad [1]$$

Where $\Sigma \approx N(0, \sigma)$, $\sigma = 0.41$ by Variance Method (V.A.) neglecting interactions greater than second order. The coefficient of determination (R^2) is 98.87%.

The burnability model of those raw mixes prepared with Sand II as raw material, follow the equation [2]:

$$\%\ CaO_{Free} = 4.64 + 0.62\ X_A - 1.62\ X_B - 0.89\ X_C + 0.28\ X_D + 1.70\ X_E - 0.24\ X_F - 0.21\ X_A\ X_B + 0.24\ X_A\ X_D - 0.36\ X_B\ X_E + \Sigma \quad [2]$$

Where $\Sigma \approx N(0, \sigma)$, σ estimation is of 0.51, neglecting interactions higher than third order. The coefficient of determination (R^2) is 97.72%.

Those interactions with coefficients lower than 0.2 have not been considered as significant. In equation [1] and in order to analyze their importance, main factors X_D, and X_F have been considered in spite of having coefficients lower than 0.2.

3.36 or 4.46 %wt are the mean free lime contents found in clinkers obtained by burning raw mixes for 30 minutes at pre-established temperatures. X_A, X_B, X_C, X_D, X_E, and X_F are assigned a value of -1 or +1 depending upon the level, - or +, that each of these factors have in the raw mixes. The coefficient applied to factors $X_A....X_G$, is a measure of each one's contribution to raw mix burnability.

The value of coefficients will depend on the range selected for each parameter. It means that the obtained model can be only applied (in the most strict sense) to explain the burnability of raw mixes having their characteristics parameters within the selected ranges. In this study the chosen range of each parameter were the most adequate for producing fluor-sulfate white clinker.
The statistical analysis of experimental data shows that, the considered factors as well as their interactions, explain 98% of the burnability results of those raw mixes. So, it can be considered that the proposed model explains well the behaviour of the raw mixes studied.

From the analysis of both models the following two aspects can be distinguished:

a) The particular contribution of each of selected factors, as well as their level on the final free lime on clinkers, and

b) Comparison of the models for determining the influence of sand nature on the contribution of the other factors on the burnability of the raw materials.

In relation to the first aspect, it has been verified that, in both models, the factors E (limestone particle size), B (fluorite percentage) and C (gypsum percentage) are the most important factors with respect to clinkers final free CaO contribution. These main factors not only contribute to the free lime content of samples at individudal level but they are involved in the main significative binary interactions. In fact the coefficient of the BE binary interaction is higher than the one´s of some individual factors as sand particle size (D) or clinkering temperature (F).

Then, for example, the effect of limestone particle size (E) on burnability depends not only on its own level but also on CaF_2 and $CaSO_4$ levels.

The great significance of B and C factors (the greater CaF_2 and $CaSO_4.2H_2O$ amount in the raw mix, the lesser is free CaO proportion in the clinker) confirms the important flux-mineralizer role of the fluorite-gypsum pair.

Fourth factor in significance in both models is lime saturation factor (LSF).

The factors D (sand particle size) and F (clinkering temperature) are the parameters which have less influence on the final free lime content of the clinker. But their influence is different in the studied models. Thus, whereas in the Sand II raw mixes the value of the coefficients of these factors are very similar, in the Sand I raw mixes the coefficient of D factor is much less than that of the temperature.

Those raw meals, at which parameters D and E take the maximum level value (see Table II), have about 15% wt of limestone particles higher than 125 μm, while the proportion of sand particles coarser than 45 μm is 3% wt; that is, the ratio between coarse limestone and sand particles is 5:1 in weight. Supposing that in the variation range studied, there is a linear relation between limestone or sand particles percentage higher than 125 μm and 45 μm respectively, and the free CaO percentage produced, the contribution of 1% in weight of coarse limestone and sand particles to the clinker free CaO can be calculated. This contribution would be from Sand I raw mixes:

1 % sand particles > 45 μm = 0.03 % wt CaO
1 % limestone particles > 125 μm = 0.20 % wt CaO

So, the specific contribution of coarse limestone particles to free CaO is more than six times superior to the coarse sand particles contribution. These results have a great technological importance, because of the expensive process to obtain sand particles finer than 45μm; and grinding processes require an important energy cost. The correlation coefficient for the coarse sand fraction obtained in this work is different from that established by others authors (4). However, the experimental conditions in the studies are quite different, and a direct comparation is not possible.

That contribution from Sand II mixes are:

1% wt sand particles > 45 μm= 0.111% wt in CaO
1% wt limestone particles > 125 μm= 0.113% wt in CaO

Thus, the specific contribution of coarse limestone and sand particles to the free CaO, is practically the same.

In Sand I model the sign preceeding temperature coefficient is positive. Then, free CaO content in clinkers, from raw mixes treated at 1350°C is higher that from meals treated at 1400°C. Analysis carried out in ten different clinkers have shown that clinkers obtained at 1350°C have a SO_3 loss lower than 10% .In those obtained at the highest temperature the loss of SO_3 is around 25-40 %wt. This loss of SO_3 and the consequent increase in effective LSF could explain the increase in final free lime content of clinkers obtained at 1400°C.

Although the loss of SO_3 observed in laboratory clinkering tests is very important, the industrial experience shows that the loss of SO_3 is very much lower. This is because of the high partial pressure of SO_2 in the kiln atmosphere from the fuel combustion and SO_2 capture by the incoming feed. Hence the range at adequate clinkering temperature for these raw mixes can be established as being 1350-1400°C.

Comparing equations [1] and [2], some relevant conclusions can be extracted about sand nature influence on the burnability of these white cement raw mixes. In fig. 1 the coefficients of main factors in the two models obtained are shown. In burnability equation [1], almost all coefficients and the independent term are inferior, in absolute value, to those in equation [2], and all except temperature retain the same sign. In any case, the absolute value of temperature coefficient in both models is small, confirming its scarce influence on clinkers free CaO.

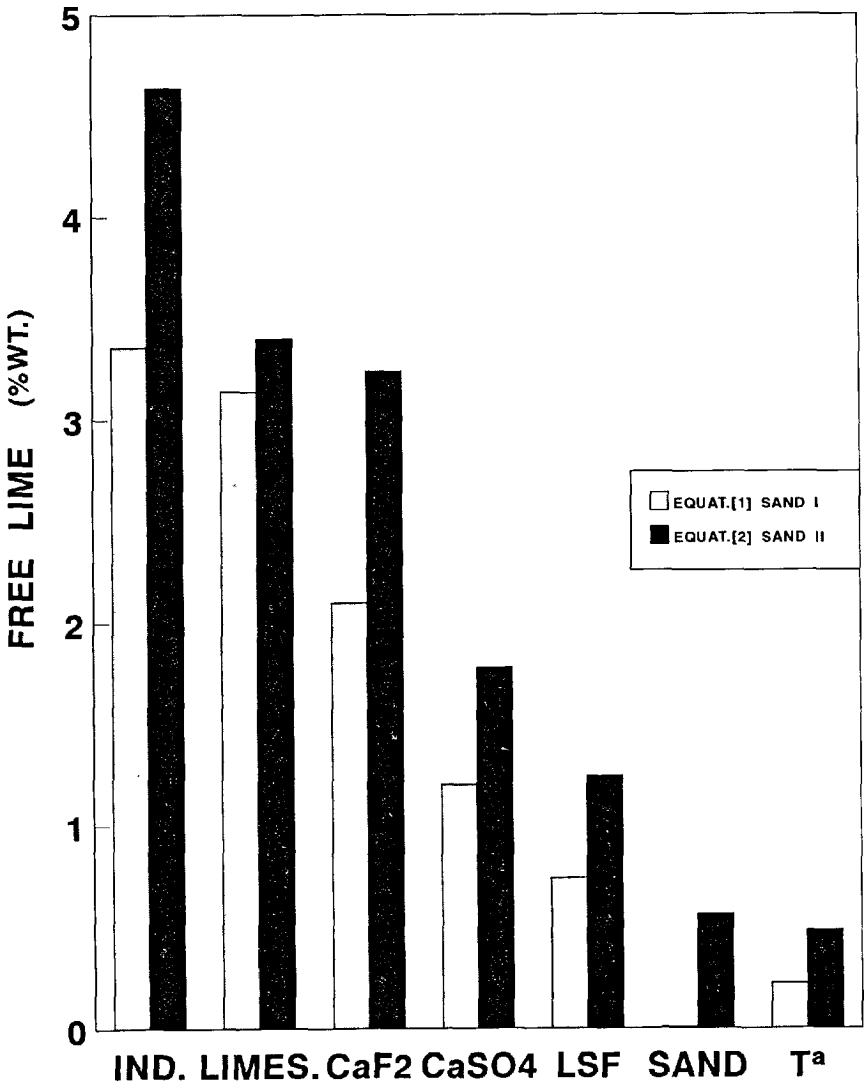

Fig. 1 Contribution of Factors Considered in Eq 1 and 2 on Free CaO Contents in Clinkers.

From these results it can be deduced the better burnability of Sand I raw mixes with respect to Sand II raw mixes. D factor, corresponding to sand particle size, is the greater difference, confirming the positive effect of Sand I on raw mixes burnability.

The enhanced burnability for Sand I raw mixes is due to the presence in their composition of a small proportion of clay (mainly aluminous in contact with quartz grains) acting as a flux. This produces, at adequate temperatures, a certain quantity of melt phase around quartz particles enabling reactions to occur at a higher rate. This clayey material can be very advantageous to enhance formation and stabilization of raw mixes nodules before their kiln entrance, confirming that the industry practice of sand washing allows to have a better control of some parameters (dosage, cromophore elements,etc.) but may make calcination and burnability difficult.

CONCLUSIONS

From the proposed methodology and applying it to industrial raw materials, it is possible to determine the optimal dosage of raw mix for fabrication in the industrial kiln of a white mineralized cement resistant to sulfates and sea water. The dosage is defined from the following parameters:

LSF = 98
Ms = 11
% wt F_2Ca = 1.3
% wt $CaSO_4$ = 3.9
Sand with the characteristics of Sand I.

The industrial test was carried out and a white mineralized clinker with a high quality was obtained. The manufacture of this clinker has an estimated energy consumption of 10% lesser than that of the traditional process.

KINETICS OF $2CaO \bullet SiO_2$ AND $3CaO \bullet SiO_2$ FORMATION IN THE PRESENCE OF SODIUM AND POTASSIUM COMPOUNDS

Silvija LAGZDINA, Uldis SEDMALIS, Riga Technical University, Institute of Silicate Materials, Riga, Latvia

ABSTRACT The formation kinetics of principal portlandcement clinker compounds tricalcium silicate (C_3S) and dicalcium silicate (C_2S) in model systems in presence of sodium and potassium salts (PO_4^{3-}, SO_4^{2-}, CO_3^{2-}, F^-, Cl^-) was investigated. The rate constants and activation energy of reactions in the temperature range 900-1450°C were calculated. Rather all salts used promoted calcium silicates formation. This finding was confirmed in practice. Using alkali rich (4-6% R_2O) starting materials for producing clinker high quality cement was obtained when simultaneously the silica modulus of the batch was increased to 2,5-3,0.

Key-words: additives, alkali, calcium silicate, kinetics, silica modulus.

INTRODUCTION

The long-time experience of producing portlandcement in Latvia has shown (Glasenapp, 1910) that the quality of cement decreases when high alkali content raw materials are used. To explain this fact the investigation of principal portlandcement clinker minerals formation kinetics in model systems with additive of various sodium and potassium salts (4% in terms of R_2O) was carried out. It was established that the R_2O content in the raw materials batch is in a range 0,5-4% which increases in a case of recycling rotary kiln dust catched by electrofilters.

EXPERIMENTAL

Starting materials used were chemically pure $CaCO_3$ and SiO_2 - silica fume with specific area 175 m^2/g and sodium and potassium salts with anions: PO_4^{3-}, CO_3^{2-}, SO_4^{2-}, Cl^-, F^-, the batches were prepared in stoichiometric relations for synthesis C_3S and C_2S, additives were introduced into the batches 4% of R_2O over 100%. Specimens $\varnothing 18 \times 3$ mm were prepared by pressing under 80 MPa. Isothermal treatment was carried out in the temperature range 900-1450°C for 3-120 min. For the C_2S, C_3S formation kinetics study free CaO was determined by the alcohol glycerine method. DTA, X-ray diffractometry and microscopy in the research also were used.

EXPERIMENTAL RESULTS AND DISCUSSION

The conversation degree (α) was calculated from the results of free CaO detection

$$\alpha = \left(\frac{CaO_{total} - CaO_{free}}{CaO_{total}} \right) \cdot 100,\% \qquad [1]$$

With the increase of temperature the degree of conversation CaO changes more sufficiently as with time. In the presence of additive, character of the curves does not change considerably (Fig 1). Initially the process proceeds rapidly but consequently slows down. The curves of C_2S synthesis were similar.

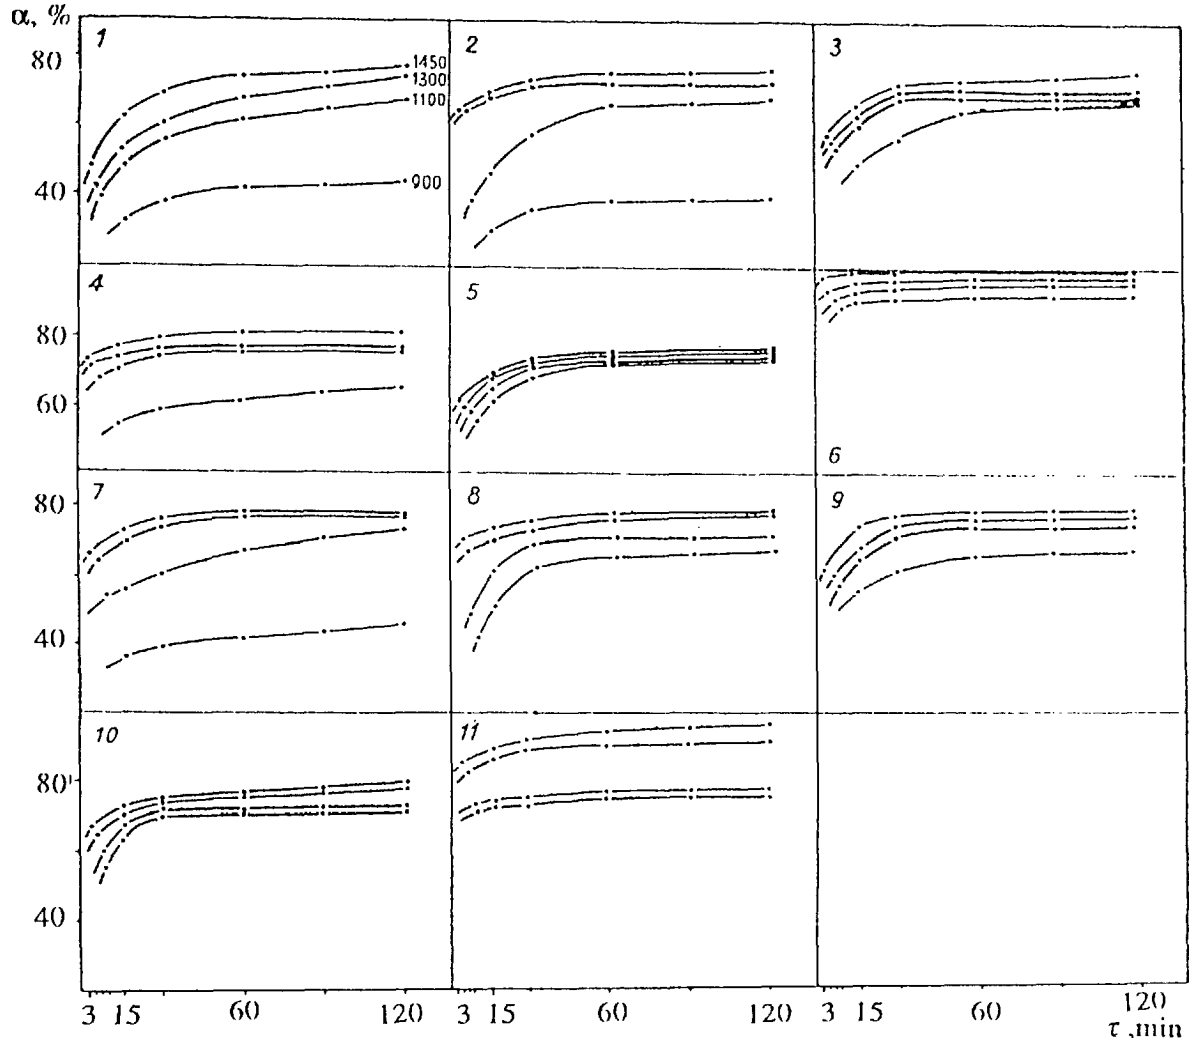

Figure 1 Degree of CaO conversation (α) of synthesis C_3S in dependence on temperature, (τ) time and additive: 1-without additive; 2-Na_3PO_4; 3-Na_2CO_3; 4-Na_2SO_4; 5-NaCl; 6-NaF; 7-K_3PO_4; 8-K_2CO_3; 9-K_2SO_4; 10-KCl; 11-KF.

The rate of C_3S and C_2S synthesis (Table 1) is described by the Kolmogorows equation (Belkevich, 1952)

$$\alpha = 1 - e^{-k\tau^n}, \qquad [2]$$

were α - degree of CaO conversion, k - rate constant, τ - time, n - kinetic parameter.

Kinetic parameter (n) was obtained from the expression [lg-lg(1-α)] versus lgτ (as the tg of the slope of the lines) (Lagzdina, 1969). It was in the range 0,2-0,39. The activation energy (E) of reactions was calculated by Arrenius equation

$$k = k_0^{-E/RT} \qquad [3]$$

Table 1 Values of the constant (k) and the activation energy (E) of C_3S and C_2S synthesis depending on temperature and additives

Additive	C_3S					C_2S				
	$K \cdot 10^2$, min^{-1}, at°C				$E_{900\text{-}1450°C}$	$K \cdot 10^2$, min^{-1}, at°C				$E_{900\text{-}1150°C}$
	900	1100	1300	1450	kJ	900	1100	1300	1450	kJ
without additive	7,9	13,2	16,6	20,9	36,4	5,6	9,3	18,2	25,1	53,5
Na_3PO_4	13,8	22,4	38,0	40,7	46,0	5,3	9,1	19,2	26,1	53,5
Na_2CO_3	18,6	23,4	26,9	31,6	15,5	14,8	19,0	24,0	26,9	19,2
Na_2SO_4	18,2	38,9	44,7	51,3	15,5	11,7	18,6	21,3	27,5	23,0
NaCl	22,4	25,1	27,5	30,2	11,3	15,8	25,1	27,5	31,6	24,7
NaF	69,2	81,3	91,1	-	9,6	50,1	56,2	63,1	-	9,6
K_3PO_4	31,6	23,4	35,5	40,7	34,3	9,1	19,9	37,1	47,9	30,5
K_2CO_3	13,2	40,7	46,8	49,0	34,3	23,4	33,1	44,7	47,9	19,2
K_2SO_4	21,4	28,8	33,1	38,0	24,3	23,4	30,2	38,0	45,7	19,2
KCl	19,0	26,9	39,8	42,7	26,8	33,9	38,9	41,7	47,8	23,0
KF	47,9	52,5	67,6	74,1	15,5	32,3	41,7	50,1	55,0	15,5

Small values of n<1 as well as E allowed to conclude that the limiting stage of C_3S and C_2S formation is diffusion.

The results of investigation demonstrated that rather all salts used promote C_3S and C_2S formation in model systems.

Figure 2 shows that in synthesis of C_3S the temperature of $CaCO_3$ decarbonation from 900°C in batch without additive decreases to 860-880°C with additive of sodium and potassium carbonates, chlorides and fluorides. Possible it is connected with duble salts formation and decomposition of them at temperatures which are lower than that one of $CaCO_3$ decomposition. Solid state reactions also proceeds more rapidly in presence of additives. C_3S formation could be noticed already at 900-950°C. In the presence of potassium salts at 1100°C the phase $KC_{23}S_{12}$ (d/n = 2,75; 2,63; 2,29; 2,24; 1,95; 1,59 Å) was recognized, which dissapeared with elevating the temperature. At the 1300-1450°C the amount of R_2O decreased to 0,3-1,2% nevertheless

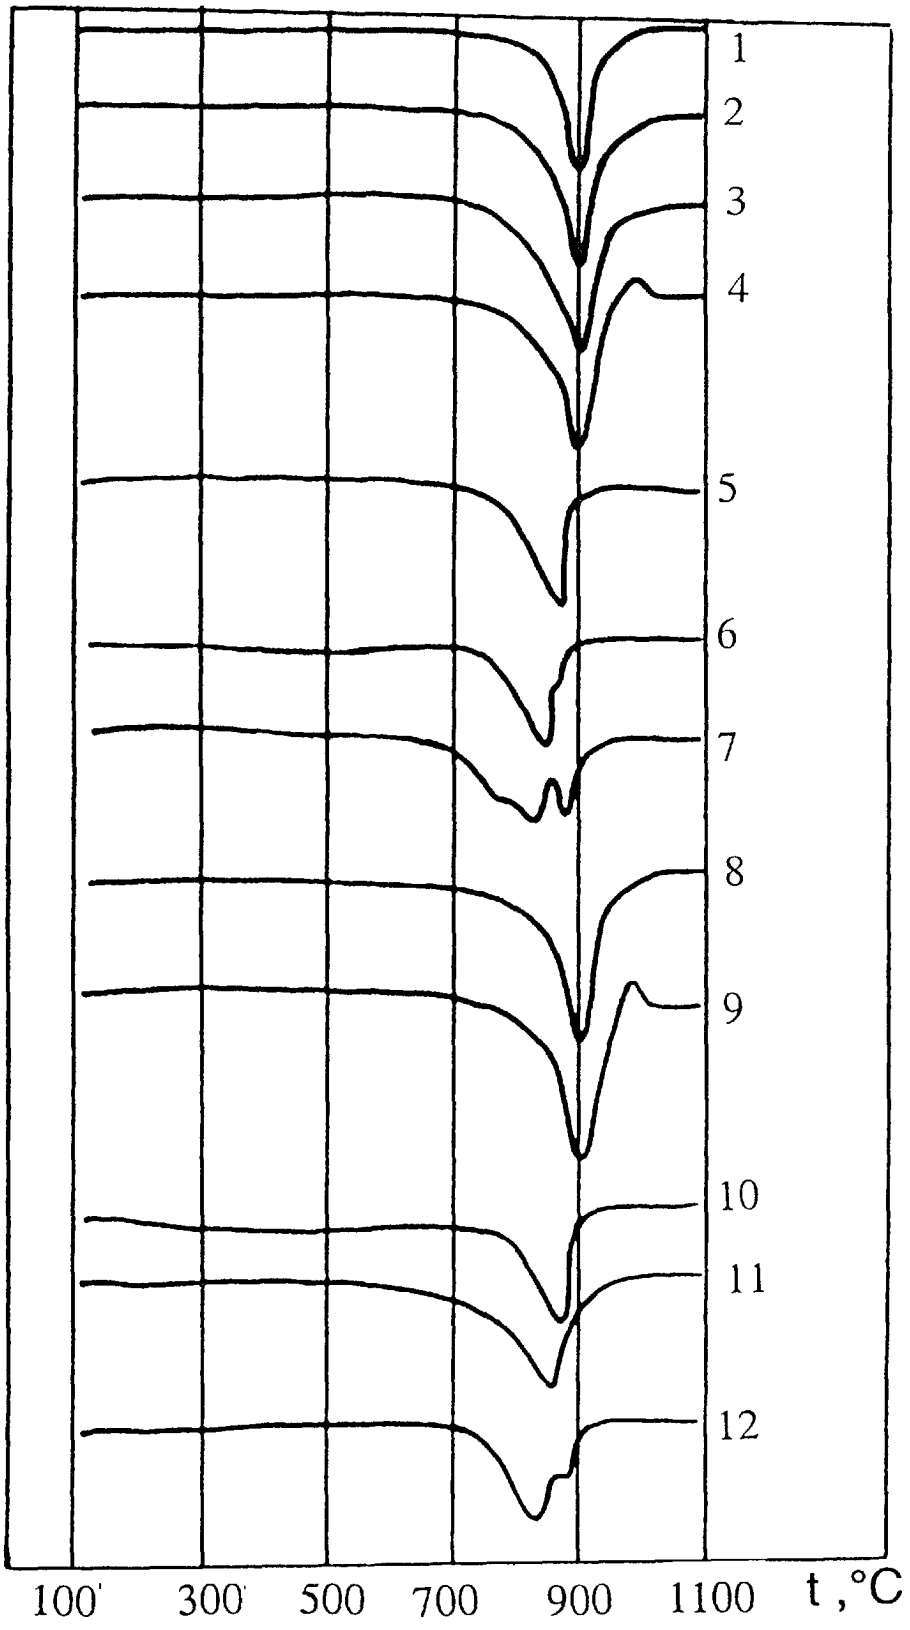

Figure 2 The DTA heating curves of $CaCO_3$ (1) and batches: $3CaCO_3 + SiO_2$ (2); 2 + Na_3PO_4 (3); 2 + Na_2SO_4 (4); 2 + Na_2CO_3 (5); 2 + NaCl (6); 2 + NaF (7); 2 + K_3PO_4 (8); 2 + K_2SO_4 (9); 2 + K_2CO_3 (10); 2 + KCl (11); 2 + KF (12).

there was the consequence of alkali action. The microscopic investigation showed that the size of C_3S crystalls with alkali additive was 20-40μm instead of 2-18μm without additives. Investigations have been carried out also using natural raw materials (Table 2,3).

Table 2 Chemical composition of raw materials, mass %

Raw materials	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	K_2O	Na_2O	Ign. loss	Total
Limestone	5,54	1,57	1,21	49,55	2,03	0,48	0,60	0,10	38,92	100,00
Clay	58,68	14,00	6,33	7,71	2,00	0,07	2,20	0,20	8,79	99,98
Sand	83,24	5,51	2,01	4,41	1,16	0,17	1,65	0,25	1,60	100,00
Fe_2O_3 rich material	15,38	0,50	72,29	2,08	0,70	2,61	0,65	0,85	4,89	99,95
Kiln dust	16,57	5,37	4,05	36,50	1,48	3,64	4,57	1,29	26,54	100,01

Batches containing 1,2-5,1 % of R_2O and with silica modulus n = 2,1-3,0 were prepared. Examples of chemical composition of clinker produced at the factory as well as the compressive strength of cement obtained are given in the Table 3.

Table 3 Chemical composition of clinker and compressive strength of cement (MPa)

Clinker	Chemical composition, mass %						k	n	Specific area	Compressive strength, MPa		
	SiO_2	Al_2O_3	Fe_2O_3	CaO	Na_2O+K_2O	CaO free			cm^2/g	3 days	7 days	28 days
1	20,85	5,85	4,08	64,71	1,40	1,20	0,920	2,10	5103	39,3	42,7	46,9
2	23,07	4,47	4,55	64,65	0,68	0,80	0,854	2,56	5115	47,8	54,2	62,9
3	22,18	4,67	3,77	66,14	0,62	0,84	0,919	2,63	4757	42,4	49,5	61,4
4	23,52	4,54	3,45	64,65	0,64	0,70	0,853	2,94	5469	43,9	51,6	70,6
5	22,96	3,52	3,52	65,63	0,46	0,70	0,920	3,04	5660	38,9	50,9	68,7

$$k = \frac{CaO - (1{,}65 \cdot Al_2O_3 + 0{,}35 Fe_2O_3)}{2{,}8 \cdot SiO_2} \qquad [4]$$

$$n = \frac{SiO_2}{Al_2O_3 + Fe_2O_3} \qquad [5]$$

Taking into account the results obtained it is concluded that if for the producing the cement clinker alkali rich starting materials (kiln dust containing up to 6% of R_2O) are used high quality cement can be obtained when the silica modulus of the batch is increased to 2,5-3,0 instead of 2,1-2,3.

THE EFFECTS OF ADDITIVES ON FORMATION OF C_2S, $C_4A_3\bar{S}$ AND C_4AF

Woo-Hyeong CHAE, Geun-Chang YUM, Hee-Kap OH, Ssangyong Research Center, Taejon, Korea
Sang-Heul CHOI, Hanyang Univ., Seoul, Korea

ABSTRACT Formation of C_2S, $C_4A_3\bar{S}$ and C_4AF were investigated by adding borax, calcium phosphate and barite. It has been found that borax stabilizes β, α'-C_2S, and helps C_4AF formation. Calcium phosphate stabilizes β-C_2S, but has negative effects on C_4AF formation. Barite lowers the forming temperature of C_2S and helps C_4AF formation. The additives hinder $C_4A_3\bar{S}$ formation.
Key-words Modified Belite Cement, borax, calcium-phosphate, barite

INTRODUCTION

Modified Belite Cement (MBC) which is composed of β-C_2S, $C_4A_3\bar{S}$ and C_4AF as major clinker minerals is generally synthesized around 1300℃. At this relatively low firing temperature as compared with that of Ordinary Portland Cement (OPC), small amount of impurity can significantly influence on the clinkerization reaction and physical properties of MBC. There has been many studies showing the effects of additives on the stabilization of high temperature polymorphs of C_2S. Gies (1986) observed the stabilized α' and α type C_2S by the effect of alkali solid solution showing excellent hydration properties of their belite rich cement. Using B_2O_3 as a stabilizer, Jenic (1978) observed the different hydration behaviour between α' and β-C_2S having different structural imperfectness. Matkovic (1986) studied the belite stabilizing effect of P_2O_5 and the relation between microstructure and strength development of hydrates. Zimer (1984) and Nettleship (1993) reported the effect of BaO and SO_3 on C_2S formation. Temperature, viscosity and surface tension of melt can be changed by these additives. In this study, borax comprising of Na_2O and B_2O_3, calcium phosphate comprising of CaO and P_2O_5, and barite comprising of BaO and SO_3, were used for stabilizing C_2S at room temperature in MBC. The effects of these not only on the C_2S stabilization but also on the $C_4A_3\bar{S}$ and C_4AF formation were investigated.

EXPERIMENTAL PROCEDURE

Raw mixtures of C_2S, $C_4A_3\bar{S}$ and C_4AF were prepared using reagent such as $CaCO_3$, SiO_2, Al_2O_3, Fe_2O_3 and $CaSO_4$, and adding 3% of borax, calcium phosphate and barite. They were sintered at temperatures from 1050℃ to 1350℃ for 1 hour and quenched in the air. Free CaO (amount of uncombined CaO) analysis was carried out on the sintered samples. Relative XRD peak intensities of β-C_2S (d=2.794), $C_4A_3\bar{S}$ (d=3.757) and C_4AF (d=2.635) were compared with internal standard material (Al_2O_3 ,d=2.085). With the established MBC clinker composition (60% C_2S, 20% $C_4A_3\bar{S}$ and 20% C_4AF), 3 types of raw mix were prepared by adding 3% of each additive. The raw mixes were sintered at temperatures from 1050℃ to 1350℃ for 1 hour and quenched in the air. Free CaO, XRD, SEM/EPMA were carried out on the sintered samples to identify their clinkerization.

RESULT AND DISCUSSION

Remark) Plain : additives-free raw mix or clinker
NB3 : 3% Borax-bearing raw mix or clinker
CP3 : 3% Calcium Phosphate-bearing raw mix or clinker
BS3 : 3% Barrite-bearing raw mix or clinker

Formation of C_2S, $C_4A_3\bar{S}$, C_4AF

As a result of XRD analysis, γ-C_2S was identified in all additive-free sample fired at 1050~1350℃, while not in additive-bearing samples fired at higher than 1100℃. Fig. 1 and 2 are the results of free CaO analysis and the relative intensity of β-C_2S peak. All the additives had effects on reducing free CaO. In NB3, free CaO was decreased from 1200℃, and α' and β-C_2S peak were observed. These effects can be explained by the fact that formation of melt at low temperature by fluxing effect of borax of which melting point is around 750℃. The melt can physically inhibit $\beta \rightarrow \gamma$ expanding transition through surrounding C_2S grains. And also the result can be explained by the retaining influence of solid solution with Na^{2+} and B^{3+} ions which can easily dissolve into belite phase. (1980) In the form of solid solution containing a few % of Na_2O, Greene (1955) succeeded in bringing the α form to room temperature without inversion by means of rapid quenching. Bates (1955) prepared β-C_2S with boric acid in amounts of less than 1 per cent.

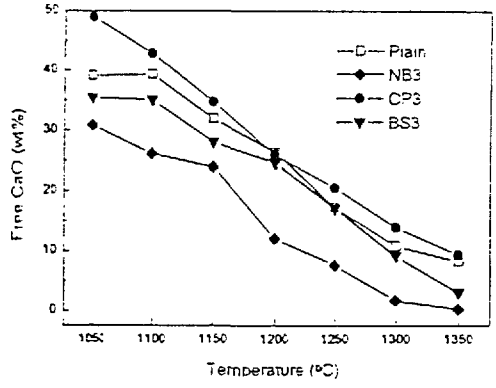

Fig. 1 Changes in free CaO amount with burning temperature in the raw mixtures of C_2S with or without additives.

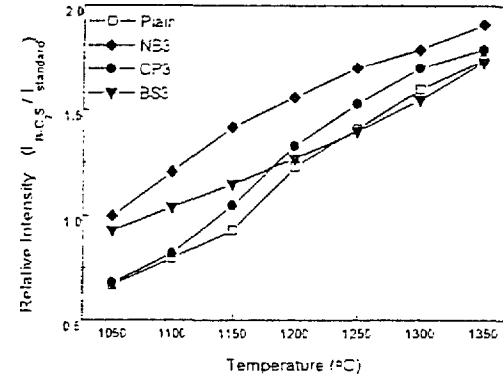

Fig. 2 Changes in XRD peak intensity of β-C_2S with burning temperature in the raw mixtures of C_2S with or without additives

In CP3, larger C_2S peaks than those in Plain were observed. This result also can be explained by the subsititution of P_2O_5 into C_2S. In BS3, large β-C_2S peaks were observed at 1050℃. In this, it seems that by the solution of BaO and SO_3 in C_2S, the $\beta \rightarrow \gamma$ transition temperature can be lowered, thereby β-C_2S can be easily stabilized in the room temperature.

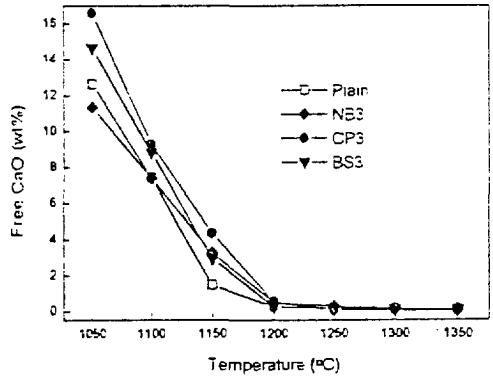

Fig. 3 Changes in free CaO amount with burning temperature in the raw mixtures of $C_4A_3\bar{S}$ with or without additives.

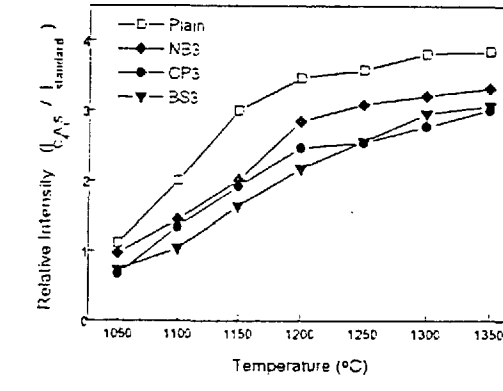

Fig. 4 Changes in XRD peak intensity of $C_4A_3\bar{S}$ with burning temperature in the raw mixtures of $C_4A_3\bar{S}$ with or without additives

Fig. 3 and 4 are the results of free CaO analysis and the relative intensity of $C_4A_3\bar{S}$ peak. In the additive-bearing samples, the results of free CaO analysis were similar to those of Plain, but weaker $C_4A_3\bar{S}$ peaks and peaks of calcium aluminate, which is not found in Plain, were identified in the samples fired between 1200℃ and 1300 ℃.(Fig. 5) From these results, it seems that $C_4A_3\bar{S}$ can be formed directly from the raw materials, CaO, Al_2O_3, $CaSO_4$ in additive-free sample, while as occuring stabilization of calcium aluminate, $C_4A_3\bar{S}$ is formed by the reaction ($3CA+CaSO_4 \rightarrow C_4A_3\bar{S}$), thereby formation of $C_4A_3\bar{S}$ is delayed in additive-bearing samples.
In NB3, free CaO was decreased and the C_4AF peak was increased from 1050℃. (Fig. 6, 7) These results could be related to the melt formation by the fluxing effect of Na_2O and B_2O_3 in borax. An amount of melt helps the aluminium ions moving into crystal lattice of C_2F and speeds up the C_4AF formation. It seems that most of C_4AF is formed at 1250℃, while more viscous melt by the effects of Na_2O and B_2O_3 were formed at higher than 1250℃ and stabilized as glassy state in the room temperature by quenching.

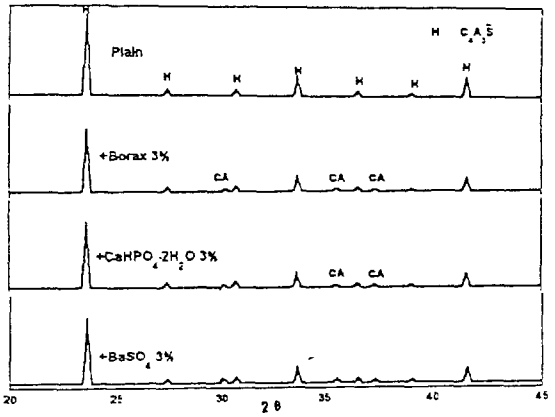

Fig. 5 XRD patterns of each clinkers fired at 1250℃ for 1 hour in the raw mixtures of $C_4A_3\bar{S}$ with or without additives

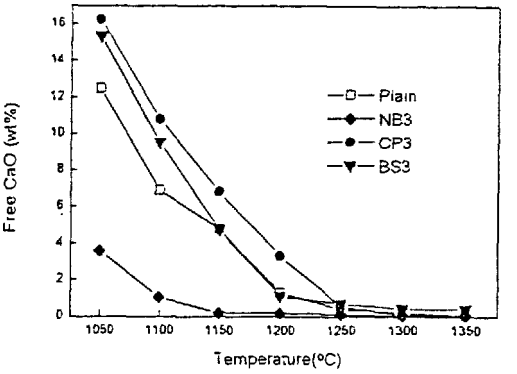

Fig. 6 Changes in free CaO amount with burning temperature of the raw mixtures of C_4AF with or without additives.

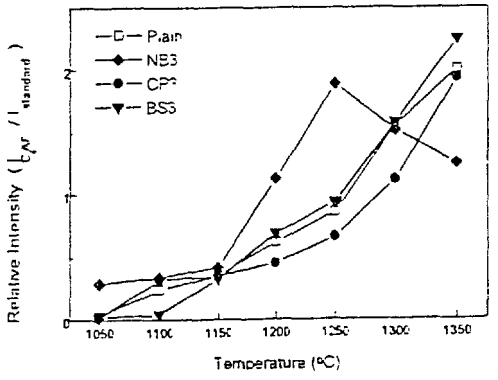

Fig. 7 Changes in XRD peak intensity of C_4AF with burning temperature in the raw mixtures of C_4AF with or without additives

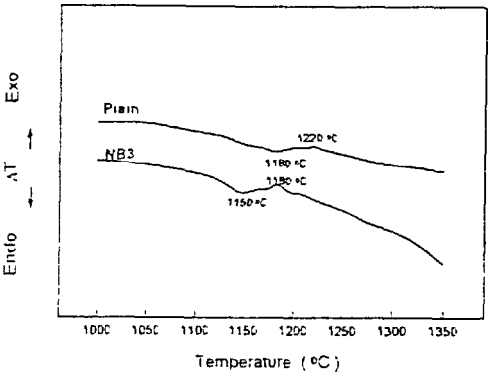

Fig. 8 DTA curves of C_4AF raw mixtures with or without additives

The trend of liquid and C_4AF phase formation is consistent with the result of DTA. (Fig. 8) It seems that the beginning of melt formation is indicated by the endothermic peak at 1150℃ in NB3 and 1180℃ in Plain, and the formation of C_4AF is indicated by the following exothermic peak at 1180℃ in NB3 and 1220℃ in Plain.

In addition to continuous increase of the melt is indicated by the endothermic peak beginning around 1200℃ in NB3. Comparing to Plain, worse-formation of C_4AF was shown at higher than 1150℃ in CP3. This seems because P_2O_5 prefer to form structurally stable $AlPO_4$ with Al^{3+} ions diffused through liquid phase at higher temperature, thereby it doesn't have fluxing effect on C_4AF formation. In BS3, better-formation of C_4AF was shown at higher than 1200℃. It may be related with $BaSO_4$ decomposition at this temperature.

Clinkerization in C_2S-$C_4A_3\bar{S}$-C_4AF system

On each MBC clinker, free CaO (Fig. 9) was less than 1% from 1050℃ in NB3, while from 1250℃ and from 1300℃ in the other samples. XRD analysis of the clinkers fired at 1300℃ (Fig. 10) shows major clinker minerals are β-C_2S, $C_4A_3\bar{S}$ and C_4AF. Considering γ-C_2S still exist in additive-free sample, it seems that each additive stabilze β or α'-C_2S in the other samples.

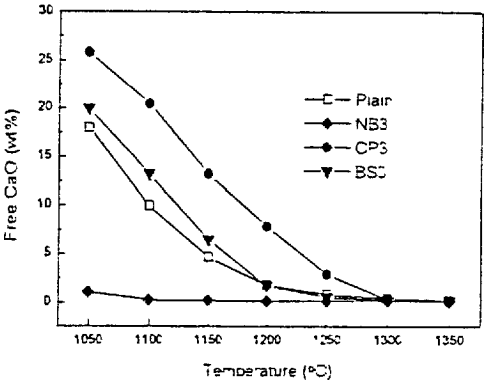

Fig. 9 Changes in free CaO amount with burning temperature in the raw mixtures of MBC clinker with or without additives.

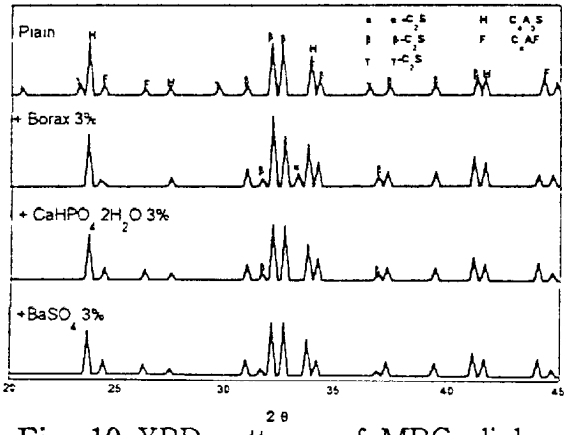

Fig. 10 XRD patterns of MBC clinker with or without additives

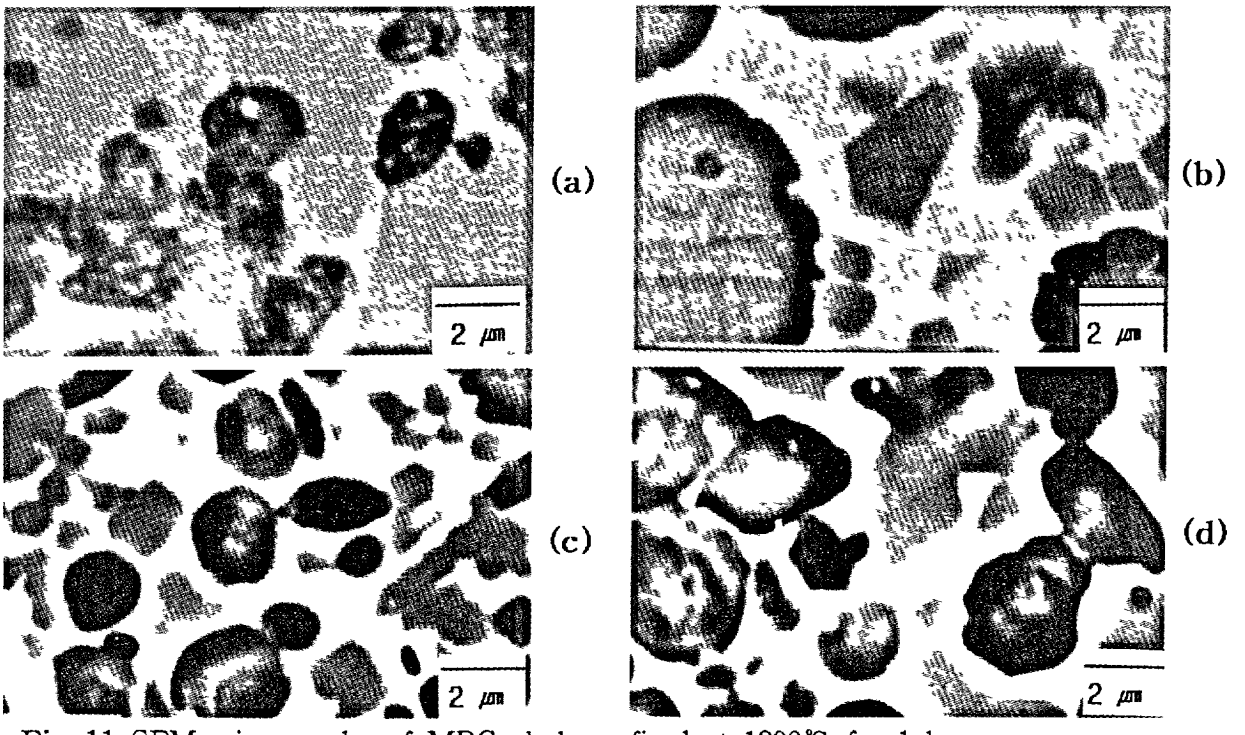

Fig 11 SEM micrographs of MBC clinkers fired at 1300℃ for 1 hr.
: (a)Plain, (b)NB3, (c)CP3, (d)BS3

SEM micrographs of Plain clinker (Fig. 11-a) shows 2~3μm C_2S and 7~8μm $C_4A_3\bar{S}$ crystals. In NB3, (Fig. 11-b) larger C_2S, and smaller $C_4A_3\bar{S}$ than those in Plain were shown. In CP3, (Fig. 11-c) similar size of C_2S and smaller $C_4A_3\bar{S}$ were shown. Larger C_2S and smaller $C_4A_3\bar{S}$ were shown in BS3 (Fig.11-d). In additive-bearing samples, large C_2S crystals might be formed from the result that diffusion of Ca^{2+} ion was hindered by more viscous melt influenced by the additives.

Table 1 Chemical Compositions of C_2S Crystals According to EPMA

	CaO	SiO_2	Al_2O_3	SO_3	Fe_2O_3	Na_2O	B_2O_3	P_2O_5	BaO
Ideal	65.11	34.89	-	-	-	-	-	-	-
Plain	59.96	35.52	2.49	0.62	1.41	-	-	-	-
NB3	63.54	32.76	0.59	0.43	0.63	0.50	1.55		
CP3	63.26	30.72	1.30	0.60	0.98	-	-	3.14	-
BS3	61.12	33.42	1.21	1.52	1.01	-	-	-	1.69

Table 2 Chemical Compositions of $C_4A_3\bar{S}$ Crystals According to EPMA

	CaO	Al_2O_3	SO_3	Fe_2O_3	SiO_2	Na_2O	B_2O_3	P_2O_5	BaO
Ideal	36.76	50.12	13.12	-	-	-	-	-	-
Plain	36.87	47.86	13.13	1.96	0.20	-	-	-	-
NB3	37.14	45.87	13.01	1.77	0.84	0.23	1.14	-	-
CP3	37.09	47.46	12.69	2.00	0.56	-	-	0.20	-
BS3	34.47	46.50	12.69	1.95	0.71	-	-	-	3.68

The incorporation of additive was determined by means of EPMA. Table 1 shows the oxides amount in C_2S crystals. It seems that the less amount of Al_2O_3 and Fe_2O_3 in additive-bearing samples is resulted from better-incorporation of additives in C_2S crystal. Less amount of SiO_2 in NB3 and CP3 is resulted from substitution between SiO_2 and B_2O_3 or P_2O_5 which have tetragonal structures. Table 2 shows the oxides amount analyzed in $C_4A_3\bar{S}$. Na_2O, B_2O_3 and P_2O_5 were less than in case of C_2S. In BS3, more BaO, but less CaO were analyzed. This trend seems to be related with the substitution between Ba^{2+} and Ca^{2+} ions.

CONCLUSION

Borax, calcium phosphate and barite stabilized β-C_2S. Especially, borax stabilized α'-C_2S. No effect or negative effect was observed on $C_4A_3\bar{S}$ formation. Borax and barite accellerated C_4AF formation. In additive-bearing MBC clinker, larger C_2S crystals and smaller $C_4A_3\bar{S}$ crystals were observed than in additive-free clinker. Na_2O, B_2O_3 in borax, P_2O_5 in calcium phosphate and SO_3 in barite well-incorporated in C_2S, and BaO in barite was well-incorporated in $C_4A_3\bar{S}$.

SYNTHESIS OF LOW TEMPERATURE PORTLAND CEMENT CLINKER BY USING COMPOSITE MINERALIZER

R.SANJAASUREN , Centre of Chemistry and Technology of New Materials ,
The National University of Mongolia ,
Ulaanbaatar , Mongolia

P.F.Rymyantsev , Ins. of Silicate Chemistry of Russian Academy of Sciences ,
St. Petersburg , Russia

ABSTRACT In this paper presented the results of physico-chemical studies for synthesis of Portland cement clinker at lower temperature conditions by using basaltoid containing raw mixes in combination with composite mineralizers . It is fixed that in the presence composite mineralizers clinker formation was completed at the temperature of 1250-1280°C .

I. INTRODUCTION

For the last 20-30 years thank to the efforts of many researchers number aspects of mineralizers which were very important and less studied particularly regularity and sequence of intermediate flouride containing silicate compound formation allowing synthesis alite phase at the lower temperature than in the traditional conditions without using mineralizers [1-7].

In the paper presented new experimental data on regularity of influence of modifying substances on physico-chemical characteristics (viscosity , surface tension , mobility of ions etc.) of clinker liquid phase and also on the crystallochemical features of cement clinker minerals structure [8-14].

For the last 10-20 years an interest to searching for new types of aluminosilicate raw materials able to replace (fully or partially) clay rocks in composition of raw mixes for making the Portland cement clinker , and in this sense such magmatic rocks as perlite , basalt , volcanic tufas and slags have a perspective significance.

In this paper were considered questions about possibilities to use the volcanic rock from the group of alkaline basaltoids for the synthesis of the Portland cement clinker. Alkaline basaltoids defer from basalts by the alkaline characters expressed in the mineral composition as well as in chemical composition. Basalts and basaltoids belong to the different groups.

Alkaline amount in basaltoids reaches 5-8 mass percent. One of ways reducing alkaline amount in the clinker is a considerable increasing of thier volatility by the mean of adding mineralizers assisting alkaline volatility during the firing raw mixes.

Goals of this Paper is:

*Experimental basing possibilities of using of alkaline basaltoids in the capacity of the aluminosilicate component for the synthesis of the Portland cement clinker in the presence of composite mineralizers in the low temperature conditions.

EXPERIMENTAL PROCEDURE

Objects of this study were two-and three component mixes consisting of calcium carbonate (or limestone) , basaltoid and iron additions characterized by concrete digital parametres (KM , SM , AM) for making the Portland cement clinker.

Chemical composition of the initial materilas used for making mixes is shown in table 1.

Table 1.

Chemical composition of used initial materials

%	Materials		
	limestone	Basaltoid	Iron ore
SiO_2	5.36	54.16	9.55
TiO_2	-	2.22	-
Al_2O_3	1.27	14.54	1.59
Fe_2O_3	0.22	4.00	64.38
FeO	-	4.35	15.75

6.		77.37	22.63		0.71	2.36	2.20

*-iron-ore was used

Powdered fine initial components , taken in proper dozes (as shown in table 2) , homogemsed by liquid methods (in acetone) in the ball mill during 1-2 hours, and then mixes dryed and prepared briquettes under the pressure in the shape of cylinders with size of 1.5×1.5cm firing had been done in the laboratory silicon carbide furnace with speed of 400°C an hour in the platinium caps and keeping in the certain temperature within 45min and the cooling of samples was on air and slow.

X-rayDiffraction Analysis (XRD) had been done by Diffractometry DRON-1.0 , derivatographic analysis was made by Derivatograph (1500D).

To define starting point of melting temperature of basaltoid rocks and mixes was used the method of electroconductivity of the samples with continuis heating (heating speed is 7° min) on the electric device made in the Institute of silicate chemistry of St.Petersburg, Russia.

RESULTS AND DISCUSSION

1.The thermal behaviour of raw mix composition of "Limestone + Basaltoid"

In the Fig.1 shown Derivatogramma of the mix composition 3, where could been seen that the process of decomposition of carbonate component starts at the temperature of 630°C and ends at the temperature of 950°C. The deep Endothermic peak at the temperature of 915°C on the DTA curve identifies with the decomposition of the basic mass of carbonate component in the studied mix.

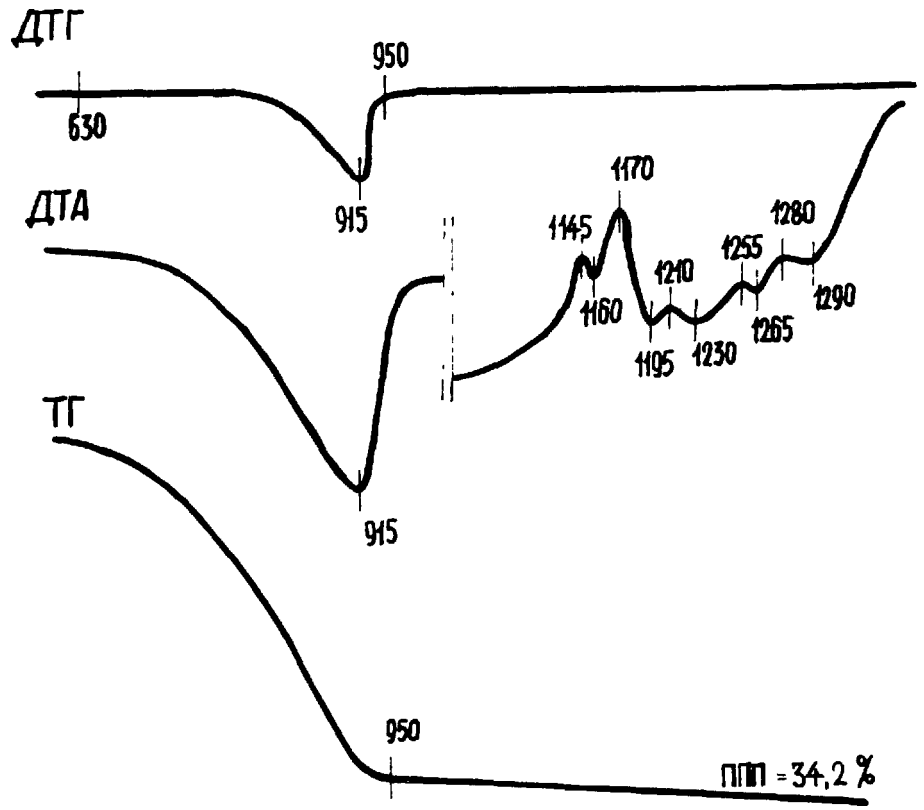

Figure 1. Derivatogramma of the mix composition 3,

In order to define reasons of appearing of series of Endothermic and Exothermic peaks within high temperature section (higher than 1000 °C) of the DTA curve was used the XRD method. Results of XRD studies are shown in Fig.2.

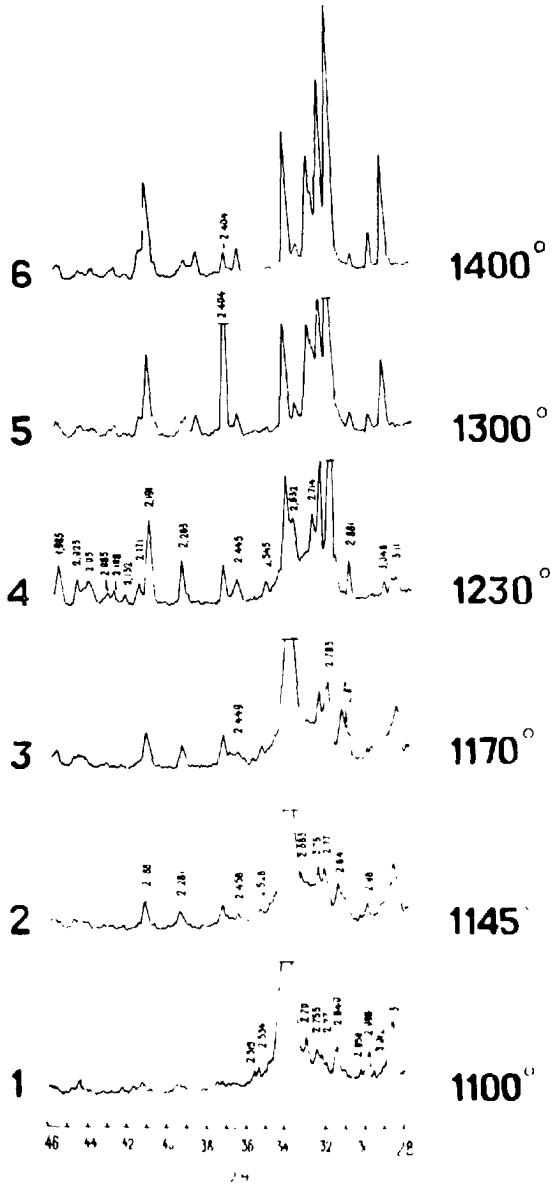

Figure 2. Phragments of the XRD of samples heated till the temperature where thermic effects could be seen on the DTA curve of mix 3.

The XRD analysis have shown that the exothermic peak at the temperature of 1145 °C on the DTA curve caused by $C_{17}A_7$ and gehlenite, the exothermic peak at the temperature of 1175 °C identified with β-C_2S formation, and the small exothermic peak in the range of 1210 °C caused by alite crystallization. Endothermic peaks in the range of 1230 °C and 1265 °C caused by nonequilbrium liquid phases and dissolution of belite phase in them.

In order to define the beginning of the liqiud phase formation temperature in twocomponent mix (Limestone + Basaltoid, with KM=0.93, n=2.43) during the heating process there were made measures of Electroconductivity depending on the heating temperature. These studies have shown that the liquid phase in studied twocomponent mix starts at the temperature of 1015°C [16].

2.The thermal behaviour of raw mix composition of "Limestone + Basaltoid" with addition of composite mineralizers consisting of Fe_2O_3 and CaF_2

In the Fig.3. shown DTG and DTA curves of mixes compositions 3 and 4 (KH=0.93) with addition of 1.0 mass.% CaF_2.

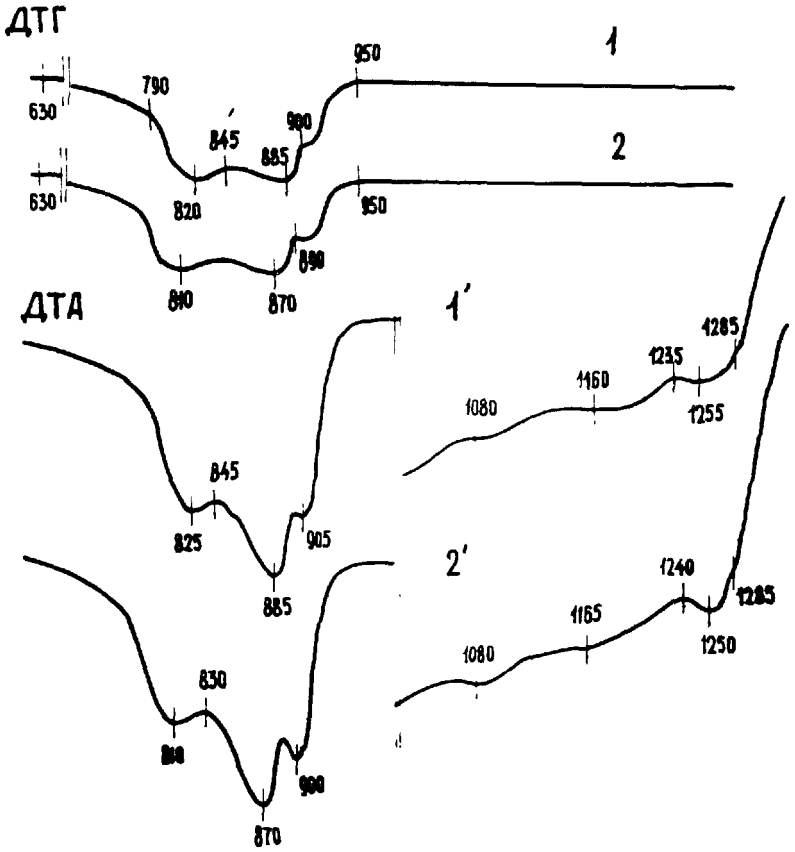

Figure 3. DTG and DTA curves of mixes containing 1.0% CaF_2, 1,1'-raw mix 3, 2,2'-raw mix.

Comparing DTG and DTA curves shown in Fig.1. and Fig.3. it is possible to say that with addition of composite mineralizers Fe_2O_3 + CaF_2 into mixes , phase formation processes during the heating are changing considerably.

Experiments on electroconductivity measures of the mix composition 3 containing the addition of CaF_2 have shown that the liquid phase during the heating of the mix starts at the temperature of 980 °C otherwise with addition 1.0 % mass. CaF_2 into the mix the starting point of the temperature of the liquid phase formation lowered for 35-40 °C [16]. As shown our studies early formation of the liquid phase assists speeding up C_3S , C_3A , C_4AF formation , and also considerable decreasing clinker sintering temperature.

In Fig.4 shown the XRD patterns of clinker samples getting from mixes consisting of natural materials (compositions 3, 4, 5 and 6) with addition 1.0 mass.% each of flouride calcium.

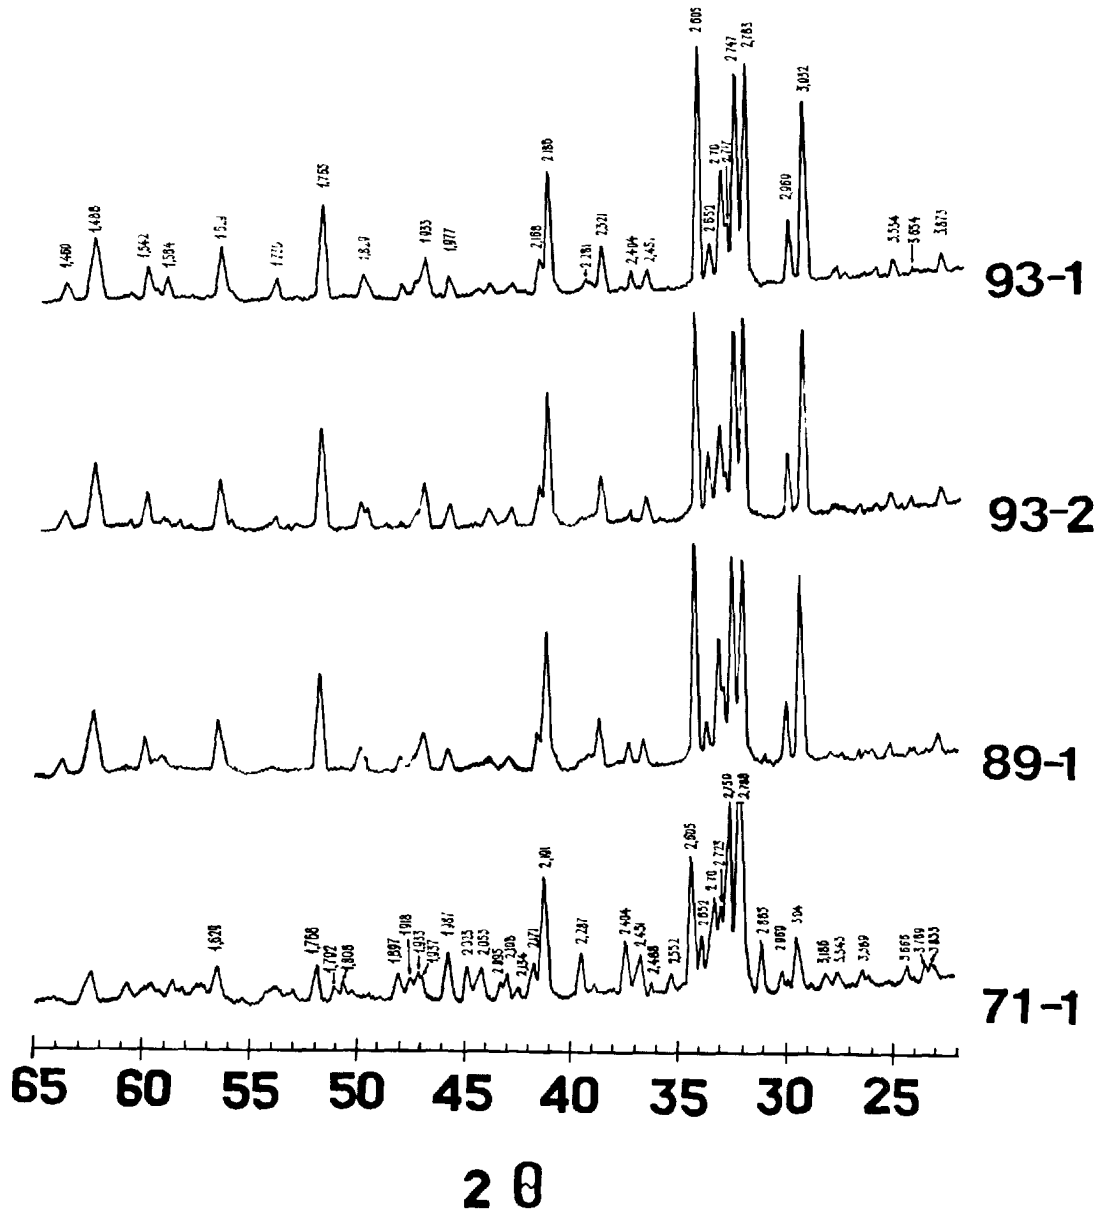

Figure 4. XRD patterns of clinkers made of mixes with addition of 1.0% CaF_2 each
1- composition 3, 1300°C 2- composition 4, 1300°C
3- composition 5, 1280°C 4- composition 6, 1200°C

Analysis of the XRD patterns has shown that on the XRD patterns of simples got from mixes with KH=0.93 and KH=0.89 there are many lines identifying with alite (d=3.534 ; 3.032 ; 2.969; 2.605; 2.321; 2.168; 1.932; 1.829; 1.765; 1.629A° etc.) which indicate considerable alite phase content in these clinkers. Peaks with d=3.873 and 2.717 A° could be identified with α'-C_2S and peak with d=2.747 and 2.81 A° -to α-C_2S phases; peaks with d=2.697 and 1.564 A° indicate the presence of C_3A phase , and peaks with d=2.697 and 2.451 A° could be identified with flouride aluminate calcuim composition-$C_{11}A_7CaF_2$ which has a small quantity. Line with

d=2.652 and 1.730 A^{o} indicative of the presence of aluminoferrite phase, and the line with d=2.651 A^{o} is typical to aluminoferrite phase with composition C_6A_2F.

Because of high content of alite an identification of β-C_2S becomes much more difficult but peaks with d=2.783 (very strong) and 2.451 A^{o} could be identified with C_2S β-forms however these peaks levy on peaks of alite and $C_{11}A_7CaF_2$.

Addition of composite mineralizer Fe_2O_3+CaF_2 promotes acceleration speed of decomposition process of basic components of the raw mixes , and the combining of free oxide CaO depending on the temperature of the firing the mix composition 2 (KH=0.93; n=1.78) containing composite mineralizer Fe_2O_3 and CaF_2 is shown in Fig.5.

The curve in Fig.5 reflects kinetics of the combining of free CaO in the mix composition 1, containing neither Fe_2O_3 nor CaF_2 , and the curve 2 belongs to threecomponent mix containing Fe_2O_3=1.20% without addition of CaF_2 (composition 2) , so course of these curves shows that addition of Fe_2O_3 noticebly accelerate processes of the combining of free oxide calcuim however both mixes can not ensure finishing of clinker formation processes in the low temperature conditions.

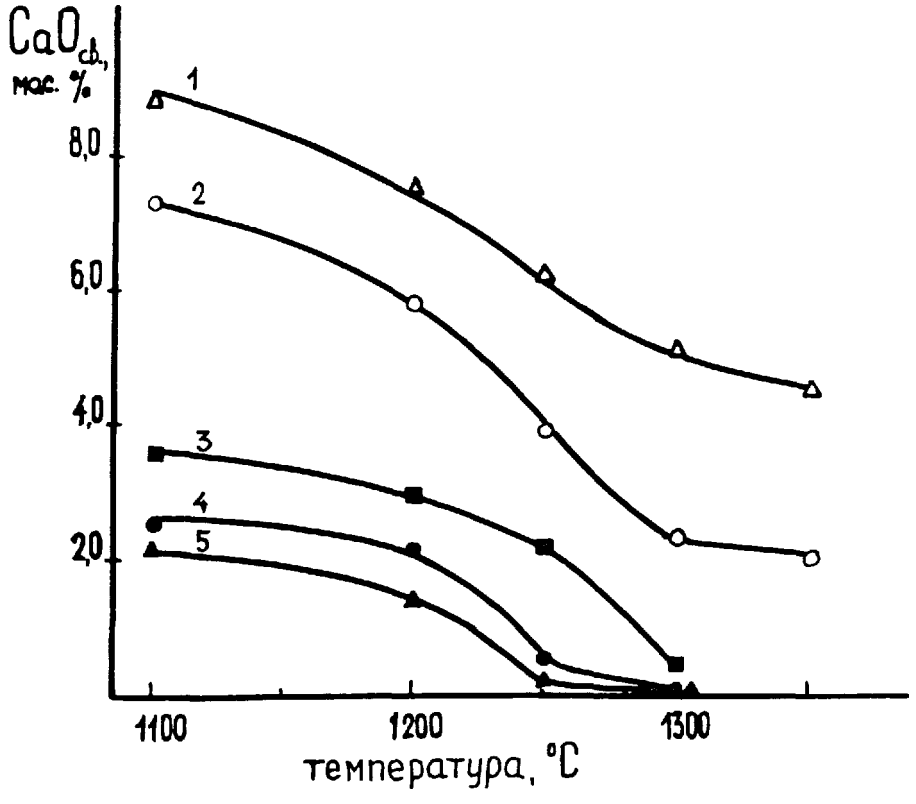

Figure 5. Relationship between free oxide calcuim content in simples and the temperature of the firing of the mix with CaF_2

1- content 1 without CaF_2,
2- content 2 without CaF_2,
3- content 2+0.25% CaF_2,
4- content +0.5% CaF_2,
5- content +1.0% CaF_2

Curves 3,4 and 5 in Fig.5 show kinetics of combining of free CaO in mixes composition 2 containing at the same time either Fe_2O_3 and CaF_2 with different quantities of CaF_2 addition. The course of these curves testifies that together added Fe_2O_3 and CaF_2 into the studied mix strongly accelerate speed of combining of free oxide calcuim and with addition of 0.25 mass.% CaF_2 clinker formation finishes almost at the temperature of 1300°C , and with addition of CaF_2 in the quantity of 0.5 and 1.0 mass.% clinker formation finishes at the temperature of 1250 °C i.e. addition of composite mineralizers containing of Fe_2O_3 and CaF_2 quite strongly intensified physico-chemical processes of clinker formation and allowed to finish clinker sintering at the considerably low temperature.

Microscopis studies have shown that with increasing of CaF_2 dose there is observed sharp increasing of alite phase content and decreasing of belite quantity. Influence of CaF_2 dose in initial mix on the ratio of forming minerals in the clinker could be presented by the following experimental data got by microscopic method analysis:

Quantity of addition CaF_2 (mass.%)	Alite	Belite	Intermediate phase
0.0	30	50.0	15
0.5	65-67	10-12	22-23
1.0	67-69	7-8	21-24
2.0	70	4-5	22-24

Thus composite mineralizer Fe_2O_3+ CaF_2 added in small quantity into basaltoid containing mix has considerable influence not only on the speed of physico-chemical processes of mineral formation during the heating of studied mixes but also on processes of microstructure formation and phase composition of synthesised clinkers.

3.The thermal behaviour of raw mix composition of "$CaCO_3$+ Basaltoid+CuO(ZnO)+ $CaSO_4$+CaF_2"

Last few years we have been conducting researches on influence of following composite mineralizers on the behaviour of raw mixes during thier thermal treatment:

(a) CuO+ $CaSO_4$+CaF_2

(b) ZnO+ $CaSO_4$+CaF_2

Conducted researches' results had shown that the above mentioned composite mineralizers speed up physico-chemical processes of clinker phases formation , and lower the temperature of cement clinker sintering till 1250 °C -1280°C.

Thus addition to the cement raw mix of copper or zinc containing minerilizers together with sulfate and flouride containing mineralizers does not bring to considerable lowering of the temperature of clinker formation process finishing in comparision with composite mineralizer consisting of Fe_2O_3 and CaF_2.

Researches on optimisation of compositions of chemical substances' types as well as of quantity ratio of component included in composite mineralizers composition are continuing in Laboratories of our Centre.

CONCLUSION

1.It is fixed that during the firing of basaltoid containing raw mix with addition of composite mineralizers (Fe_2O_3+ CaF_2) in the range of decomposition (630 °C -950°C) of carbonate component has been observed formation of metastable carbonate spurrite.Spurrite formation starts at 750 °C -770 °C , and the composes completely in the range of 860 °C -885 °C temperature.

2. In the presence of composite mineralizer "Fe_2O_3+ CaF_2" in basaltoid containing mixes starting from 800 °C have formed flouridealuminates and flouridesilicates calcium which assist basic clinker phases in more lower temperature conditions rather than in traditional clay mixes.

3.Flouride calcium (0.5-2.0%) addition to basaltoid containing raw mixes lowers the temperature of liquid phase till 980 °C temperature i.e. approximetely 280 °C lower than in usual clay containing raw mixes.

4.Under the influence of CaF_2 addition alkalis are loosing the properties as inhibitors in consequence of which in basaltoid containing mixes in the presence of CaF_2 alite formation starts from 1000 °C -1100 °C , which is lower 150 °C -170 °C than in clay containing mixes.

5. It is fixed that addition of composite mineralizer consisting of Fe_2O_3+ CaF_2 into the basaltoid containing mix assists more speed clinker minerals formation in consequence of which clinker formation finishes at the temperature of 1250 °C -1280 °C.

APPLICATION OF PARTIAL LEAST SQUARE REGRESSION ANALYSIS IN EXAMINATION OF CORRELATIONS BETWEEN PRODUCTION CONDITIONS, MICROSTRUCTURES IN CLINKER AND CEMENT AND CEMENT PROPERTIES.

Ketil SVINNING, Norcem R & D, NORCEM A.S, Brevik, Norway

Harald JUSTNES, SINTEF Structures and Concrete, Trondheim, Norway

ABSTRACT Statistical models by application of partial least square regression for prediction of cement properties have been evaluated. The model contains variables describing the XRD profile in the range of 2θ equal to (32.9, 34.1)°, free lime, superficial microstructure of clinker and gypsum, detected by TGA, and fineness. Amount of free lime and the XRD profile was found to be a sufficient description of relevant mineralogical structure in clinker for predictions with accepted accuracy of setting time and compressive strength development until 28 days. Predictions of changes in properties by changes in the XRD profile due to changes in the production of clinker have been demonstrated.

Key-words: Modelling, microstructure, setting, strength development.

INTRODUCTION

A general investigation of the microstructure in clinker and cement has been carried out for several years as a project with the main goal of correlating cement characteristics with cement and concrete performance. The two main activities of the project are statistical investigations of : 1) The influence of the microstructure in clinker and cement on cement properties and 2) The influences of productions conditions on the microstructure. Results from 1) and 2) are presented in the two papers Svinning and Bremseth /1/ and Svinning, Bremseth and Justnes /2/, respectively. The objective of the research is to enable design of clinker quality and cement properties by controlling the production conditions in the kiln. This paper will present models for describing correlations between microstructure and cement properties. The paper will also present predictions, in two steps, of influence of production condition in kiln on cement properties. In the first step the influence of the production condition on profiles of selected XRD peaks are predicted, and in the second step the influence of the same profiles on cement properties are predicted.

The part of the microstructure in clinker being investigated is represented as the X-ray diffraction (XRD) profile including dominating aluminate and ferrite peaks in the range $2\theta \in (32.9, 34.1)°$, using CuK_α radiation. The statistical method applied for modelling was partial least square regression (PLSR). To achieve maximal explanation of variance in the properties, the following additional variables are included in the modelling: 1) Amounts of di- and hemihydrate of $CaSO_4$, 2) Mass losses which indicate different kinds of moist exposure and carbonation of clinker minerals during production and storage, 3) Amount of Fe^{2+}, 4) Amount of unhydrated free lime and 5) Fineness of the cement. The values of the two first categories of variables are determined by thermogravimetric analysis (TGA). Cement properties examined

in this work are setting time and compressive strength development until 28 days.

The production conditions whose influence on the properties are to be predicted, are those experienced in the kiln no. 6 at Dalen Plant, Brevik, Norway. The modelling of influence on the microstructure of the production condition is already performed by Svinning et. al. /2/.

METHODS

X-ray diffractograms were recorded at Norsk Hydro a.s, Research Center, Porsgrunn, Norway. The XRD profile was obtained by an X-ray diffractometer in steps of 2θ equal to 0.02 °. The scaling of the intensities and correction of the 2θ - positions of the peaks were based on equalising the areas and adjusting the positions of the diffraction peaks at d = 3.52 Å of anatas (TiO_2), which was added in an amount of 10 wt% to the total samples.

The methods for determination of the values of the other variables included in the modelling of cement properties are described in /1/.

In case of a great number of variables relative to number of observations or objects, data compression by expressing the original x - variables by fewer latent variables or factors could be necessary. Partial least square regression (PLSR) does calculation and optimization of number of factors for maximum explanation of variance, for prediction, in y. In addition, model parameters are calculated for prediction of y for new values of x. PLSR of several y-variables together or a vector of y-variables as well as of one y-variable can be performed. Before the start of the regressions the variables are centered and scaled by putting a weight on each variable. The weight is equal to the inverse of the standard deviation of the respective variable. The iterative algorithms for calibration, validation and prediction are described in detail by Martens and Næs /3/. The software applied for PLSR was UNSCRAMBLER ®. Applications of PLSR in examination of microstructure and clinker quality are presented in /1/ and /2/.

RESULTS

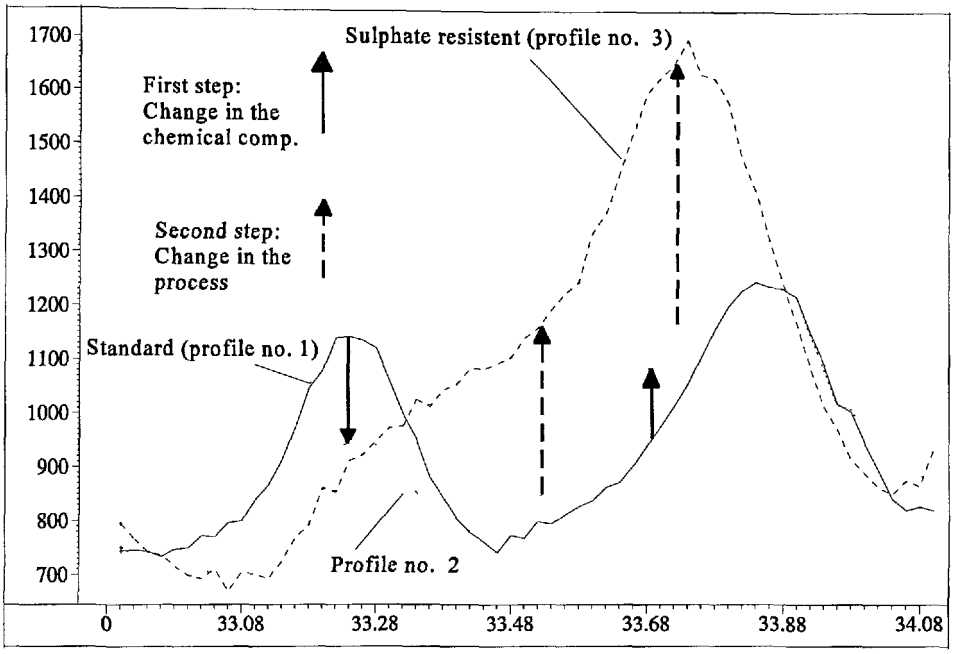
Modelling.

The observation **X** - matrix included in the investigation on influences of the microstructure in clinker and cement on the cement properties, contains 31 variables and 34 observations. The cement samples included in the examinations in this work is the same as in /1/ but in addition 4 more samples are included. The XRD profile is described by intensities at every 0.06° (2θ). A complete list of x-variables is given in table 2. The cement properties to be modelled and defined as y - variables are setting time [min] and compressive strengths [MPa] at 1, 2, 7 and 28 days. Results from the PLSRs are given in table 1.

Table 1: Results from the PLSRs.

Model no.	Variable(s)	Explained variance of total variance for prediction [%]	Number of factors no. for max. explained variance
1	Setting time	76	5
	Compressive strengths:		
2	1 day	86	5
3	2 days	76	5
4	7 "	53	4
5	28 "	60	4
6	Compressive strength development until 28 days (y-vector containing the four latter variables)	67	5

Table 2 contains the model coefficients, b_w, for predicting setting time and compressive strength at 1 and 28 days with weighted data. b_w indicate an influence of a variable relative to the others' on the property. The indication is possible because of the equalisation of the mean values (= 0) of and the variance in the variables in the observation **X** - matrix before the regressions on the variables.



Prediction.

Prediction of changes in properties due to changes in XRD profile in the range $2\theta \in (32.9, 34.1)^\circ$ again due to two chosen cases of changes in the production in kiln no. 6, Dalen Plant, Brevik, Norway will be demonstrated. The first case is from production of standard clinker to production of sulphate resistent clinker, as shown in figure 1 a), and the second from production of standard to high strength clinker, figure 1 b). The changes are simulated to take place in two steps. In the first step only the chemical composition in clinker is changed. In the second step the process parameters are also changed as much as what is necessary to maintain a stable process and an optimal production capacity with respect to satisfying the quality requirements. Some of the changes in the process which influence the XRD profile during step 2 to production of sulphate resistent clinker is as follows: 1) Simultaneous increases in the collinear variables secondary air temperature and amount of NO_x(g) and 2) An increase in volume flow of tertiary air. Similar changes for the change to production of high strength clinker are as follows: 1) An increase in volume flow of tertiary air and 2) An increase in the pressure in the kiln hood.

Table 2. Model coefficient for predicting setting time and compressive strength with weighted data (no. in brackets are referring to what models are applied in table 1).

a)

b)

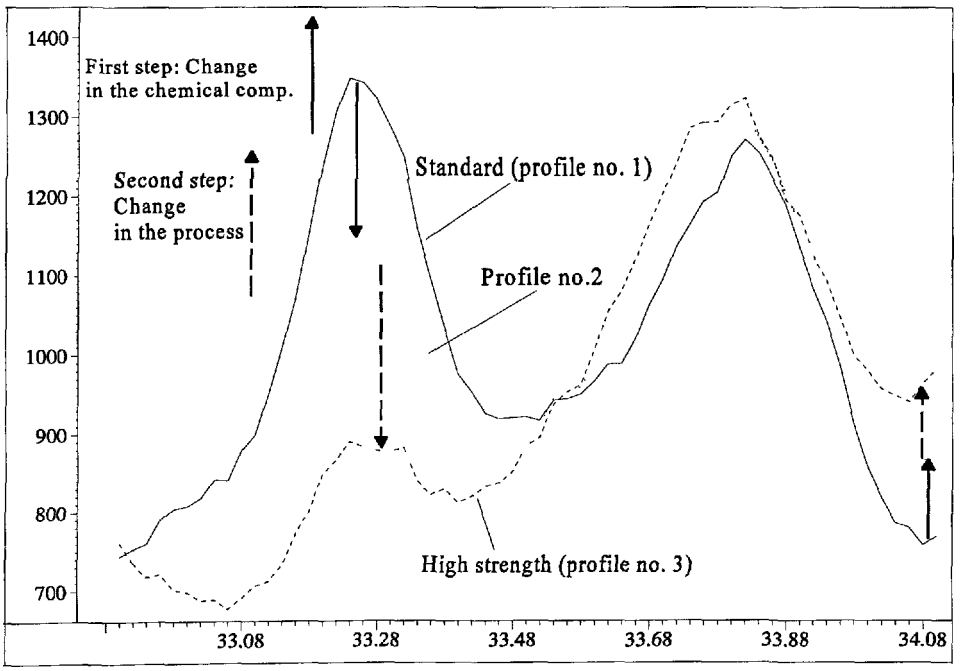

Figure 1. Two cases of predicted changes in the XRD profile [counts] in the range of $2\theta \in (32.9, 34.1)°$ by changing in two steps from the production of one type of clinker to production of another . The types included in the two cases are as follows:

a) From standard, LSF: 95.3, SM: 2.52 , AM: 1.41, to sulphate resistent, LSF: 93.5, SM: 2.61, AM: 0.71.

b) From standard, LSF: 96.1, SM: 2.48, AM: 1.54, to high strength, LSF: 96.1, SM: 3.04, AM: 1.33.

Table 3 gives the predicted values of the setting time and the strength development until 28 days for the XRD profiles described in figures 1 a) and b). In figure 2 the total changes in compressive strength at one day explained by change in the XRD profile are compared with contributions to these totale changes in strength from the changes of each of the 21 intensities included as variables in the models. The changes in strength shown in the figure, are due to changes in the process (second step) to produce sulphate resistent and high strength clinker, respectively.

Table 3: Predicted setting time and strength development until 28 days inclusive standard deviation for the XRD profile described in figures 1 a) and b).

XRD profile no.	Setting time [min]	Compressive strength [MPa] at 1 day	2 days	7 days	28 days
Change from production of standard clinker to production of sulphate resistent clinker:					
1	149±17	17.5±1.8	29.7±2.9	43.8±3.6	59.1±3.9

3	141±9	16.2±0.9	27.2±1.3	41.5±1.6	56.4±1.5
Change from production of standard clinker to production of high strength clinker:					
1	139±12	19.9±1.1	30.5±1.6	42.0±2.0	53.0±2.0
2	146±11	17.8±1.2	29.4±1.6	43.0±2.2	57.4±2.3
3	156±14	14.9±1.7	27.9±2.3	44.0±3.2	62.1±3.4

DISCUSSION

Modelling

SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO and K_2O are shown by Svinning et. al. /2/ to influence the XRD profile in the range of 2θ equal to (32.9, 34.1)°. In this work the chemical composition included as variables in the model in /1/ for predicting the properties is therefore tried replaced by variables describing the XRD profile. In addition, XRD intensities at d ≈ 2.78 and 2.74 Å are excluded from the model. Comparing of the results from this work with previous /1/, approximately the same or even a higher explained variances as the result of the replacement.

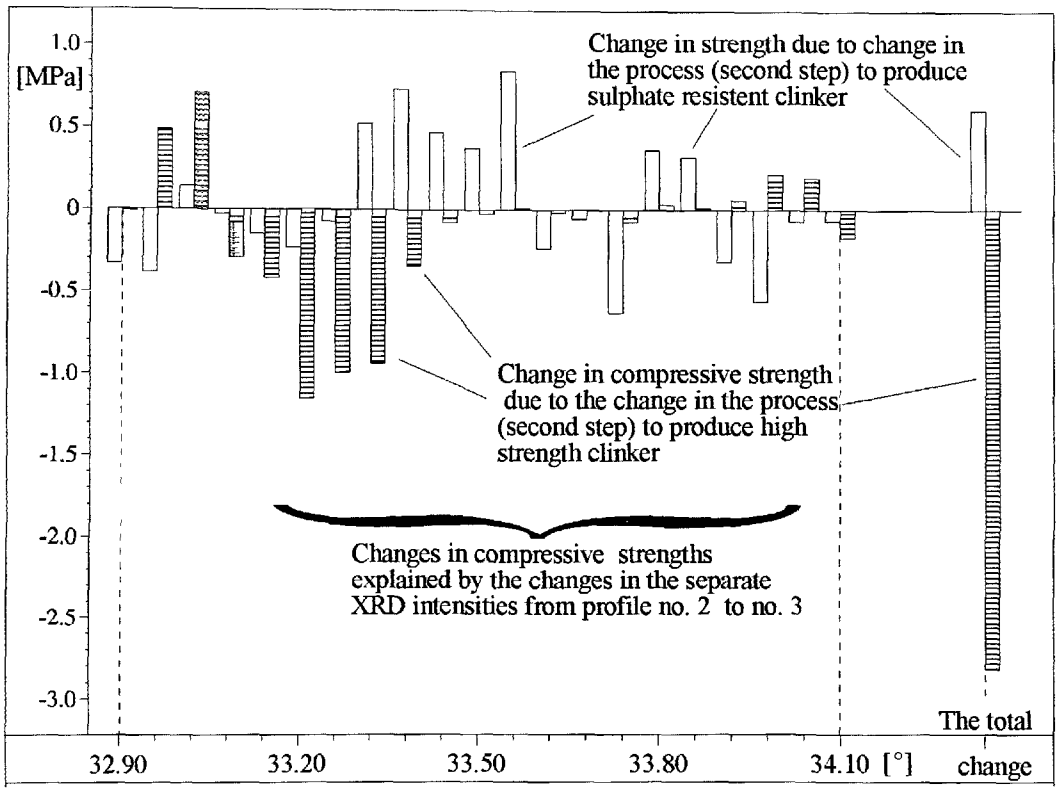

Figure 2.

Contributions to total predicted changes in compressive strength at one day from changes in each of the XRD intensities at $2\theta \in (32.9, 34.1)°$. The changes in strength are due to changes in the process (second step) to produce sulphate resistent (blank bars) and high resistent clinker (shaded bars), respectively.

The XRD profile indicates mainly amounts and structure of aluminate and ferrite, but relative changes in these will of course affect the C_3S/C_2S ratio. There is a general experience that aluminate has a major influence on the properties of cement at early ages than most of the other clinker minerals have. As expected, the explained variance in compressive strength at 1 day is therefore higher than for 28 days.

Studying the model coefficients in table 2 gives the impression that a change in the XRD profile generally results in less relative change in the setting time than in the compressive strength development.

Prediction

In the evaluations of the results from the predictions a predicted change is defined in this work to be significant if there is no overlap of confidance intervals equal to the mean value $\pm$ 1 standard deviation. According to the results in table 3 the only predicted significant changes in the properties are the those in compressive strength at 1 and 28 days for change of

production from standard to high strength clinker. The compressive strength at 1 day is predicted to decrease significantly both with the change in the chemical composition and with the changes in the process. The compressive strength at 28 days is predicted to increase significantly in the both cases.

The change in the XRD profile by changing the process to produce sulphate resistent clinker is pronounced. According to figur 2 relatively high increases in compressive strength at one day explained by changes in a few XRD intensities are predicted. They are, however, almost quite counterbalanced by many more but smaller decreases. The predicted total increase in compressive strength is therefore small and not significant.

CONCLUSIONS

Statistical models for prediction of cement properties have been evaluated. The model contains variables describing the XRD profile in the range of 2θ equal to (32.9, 34.1)°, superficial microstructure of clinker and gypsum, detected by TGA, and fineness. Amount of free lime and the XRD profile was found to be a sufficiant description of relevant mineralogical structure in clinker for predictions with accepted accuracy of setting time and compressive strength development until 28 days. The modelling gave explained variances in setting time and strength development equal, for prediction, to 76 and 67 %, respectively. The explained variance in compressive strength at 1 day was 86 %.

Prediction of changes in properties by changes in the XRD profile due to changes in the production of clinker have been demonstrated. Changing from production of standard clinker to high strength clinker was simulated to take place by first changing the chemical composition and then changing the process. Both changes were predicted to have signifcant influences on the compressive strengths at 1 day and 28 days.

PHASE QUANTIFICATION AND MICROSTRUCTURE OF A CLINKER SERIES WITH LIME SATURATION FACTORS IN THE RANGE OF 100

Hubert MOTZET, Herbert POELLMANN, Uwe KOENIG, Institute for Geological Sciences, Dept. of Mineralogy and Geochemistry, University Halle, Germany
Juergen NEUBAUER, Mineralogical Institute, University Erlangen-Nuremberg, Germany

ABSTRACT
Clinker samples with a Lime Saturation Factor (LSF) in the range of 93 - 103 were investigated by XRF, XRD, SEM-fluorescence and microscopy. A LSF of greater 100 is possible without an exceeded free lime content. Bogue calculation of these clinkers gives negative values for the Belite content and is therefore not useful. The quantification of phases by Rietveld analysis is confirmed by reflected light microscopy. Optical microscopy and SEM-fluorescence give more detailed information on the microstructure of the clinker samples.

Key-words: Quantitative, Microstructure, Bogue calculation, Microscopy, Rietveld analysis

INTRODUCTION
The production of cements with high early compressive strength, like CEM I 52,5 R, is usually done by grinding the clinker to a high specific surface area of more than 450 m^2/kg (BLAINE). In comparison to CEM I 32,5 R the energy consumption of this grinding process is very high. A modification of the clinker phase composition to higher Alite contents causes also higher strength values. Thus part of the expensive electrical energy for running the ball mills can be replaced by the cheaper burning process with less energy consumption, although a higher temperature level in the rotary kiln is needed with increased Alite formation.

To produce a clinker rich in Alite the raw meal has to be designed with a higher lime content. The maximum acceptable content of CaO in a Portland cement clinker was determined by Lea and Parker (1935). If equilibrium is established during burning and cooling, the phase composition can be calculated from the ratio of the four main oxides. The Lime Saturation Factor (LSF) gives the ratio by weight of CaO to SiO_2, Al_2O_3, and Fe_2O_3 with respect to the molar proportions.

The LSF calculation can only be an approximation because of the formation of solid solutions and of neglected minor components. A clinker with a LSF greater than 100 should have free lime. LSF values below 100 can give an approximation at the C_3S/C_2S ratio. Typical clinkers are in the range of 92 - 98 (Taylor, 1990).

This work shows that a LSF of greater 100 does not inevitably lead to an elevated free lime content.

For investigation of the phase composition and the microstructure of the clinkers different quantification methods were used. Besides the BOGUE calculation, that implements the same problems with solid solutions like the calculation of the LSF, Rietveld analysis based on XRD measurement, and reflected light microscopy completed the investigation methods. Additionally the SEM-fluorescence technique was carried out, to investigate the capability of this method in examining the microstructure and for possible application of this method for automatic phase quantification.

EXPERIMENTAL

Sample Preparation

A clinker series of 11 samples was taken from a production plant after the clinker cooler. The production process should be running with a LSF of 100. It should be demonstrated that under this burning conditions no free lime will appear. 1 kg of each sample has been crushed to a particle size of < 4 mm. The fraction 2 - 4 mm was homogenized and separated for the subsequent examinations.

Chemical Analysis: Bogue Calculation and LSF

The chemical analysis has been done by XRF from glass pellets. Volatile elements like alkalies were analysed classically. The free lime content was determined according to the method of Schläpfer and Bukowski (1933). Based on these results, the BOGUE (Bogue, 1929 in Taylor, 1990) and the LSF (Lea and Parker, 1935 in Taylor, 1990) calculation was done as follows:

$$
\begin{aligned}
\text{BOGUE: } c(C_3S) &= 4.071CaO - 7.602SiO_2 - 6.719Al_2O_2 - 1.430\ Fe_2O_3 \\
c(C_2S) &= -3.071CaO + 8.602SiO_2 + 5.068Al_2O_3 + 1.079\ Fe_2O_3 \\
c(C_3A) &= 2.650Al_2O_3 - 1.692\ Fe_2O_3 \\
c(C_4AF) &= 3.043\ Fe_2O_3
\end{aligned}
$$

$$LSF = [CaO/(2.80SiO_2 + 1.18Al_2O_3 + 0.65Fe_2O_3)] * 100$$

The BOGUE calculation results were normalized to 100 %.

Rietveld Analysis

The phase quantification based on the Rietveld refinement is a quite new technique. Its application in OPC quantification is described in detail by Taylor (1993), Möller (1995) and Neubauer (1996, 1997). The basic principle of this method is the comparison and refinement of observed X-ray pattern with pattern calculated from the structure data of all included phases.

For the clinker analysis the crushed samples were ground for 2 minutes in a disc mill to get efficient fineness. All measurements were carried out with a Siemens D5000 X-ray diffractometer. Besides the four main phases periclase and free lime were evaluated. For comparison with the microscopy results and the Bogue results the content of the main phases was normalized to a total of 100 %.

Reflected Light Microscopy

6 to 8 grains of each clinker were embedded in epoxy resin and polished. The surface of this polished section specimen was treated for 30 s with a solution of 1 g salizylic acid in 125 ml deion. water + 125 ml ethyl alcohol. This etching technique colours the clinker minerals and makes a differentiation of alite, belite and the interstitial phase (tricalcium aluminate plus ferrate) possible (Campbell 1986). Small amounts of periclase and free lime were added up and marked as additionals.

The quantitative analysis was done by point counting with a 100x air lens and a step width of 0.4 * 0.05 mm. On each specimen more than 10 000 points were counted. The mass contents of the clinker phases were calculated from the resulting volume-% by the average specific weights (Alite: 3.20 g/cm³, Belite 3.28 g/cm³, Interstitial phase 3.60 g/cm³).The portion of „additionals“ amounts to 1- 2 mass-% in the clinker and was neglected. The values of the three main phases were normalized to 100 %.

SEM-fluorescence

Some of the polished sections that were used for reflected light microscopy were prepared for the SEM-fluorescence. The polished sections were sputter coated with a carbon layer and investigated in the SEM with a OXFORD Mono Cathodoluminescence (CL) system. CL is the process by which electron bombardment of materials results in a characteristic emission of light. Used as a technique within a SEM, detection of CL allows the imaging and mapping of the sample texture (Heard 1996, Wright et al. 1991).

The clinkers were observed with an accelerating voltage of 15 kV. The fluorescence effect of the different phases depends on the stimulation by the beam current. The stimulation of the fluorescing resin at a quite low beam current of 10 µA makes the pore structure visible (Fig. 7). The study of the clinker phases is possible at a beam current of > 50 µA (Fig. 8, 9).

Quantification has been carried out with an image analysis system using fixed grey levels for the three main phases Alite, Belite and Interstitial phase. Clearly differentiated grey values enable an automatic quantification with an image analysis system.

RESULTS

Phase Quantification

The LSF of the 11 investigated samples are given in Table 1. The samples were arranged in order of increasing LSF values. Main attention is put to the samples no. 9 - 11 with a LSF greater than 100.

Tab. 1: Lime Saturation Factor (LSF) of the clinker samples

Sample No.	1	2	3	4	5	6	7	8	9	10	11
LSF	93.4	95.3	96.5	97.6	97.9	99.1	99.2	99.2	101.0	101.9	102.9
C_3S/C_2S ratio *)	5.9	8.5	8.3	10.3	12.0	12.8	12.7	17.5	35.1	35.4	19.2
free lime (m.-%)	0.36	0.08	0.09	0.12	0.45	0.08	0.62	0.64	0.14	0.28	0.31

*) Rietveld results

It could be shown that a LSF of greater 100 does not inevitably cause an elevated free lime content. The free lime content is statistically distributed in the range of 0.1 - 0.6 mass-% with no significant correlation to the LSF. Thus the clinker did not reach the equilibrium, or solid solutions of the clinker minerals falsify the LSF calculation.

The following Figures 1 - 3 show graphically the results of the phase quantification obtained from the three methods Bogue calculation, Rietveld analysis and microscopical point counting.

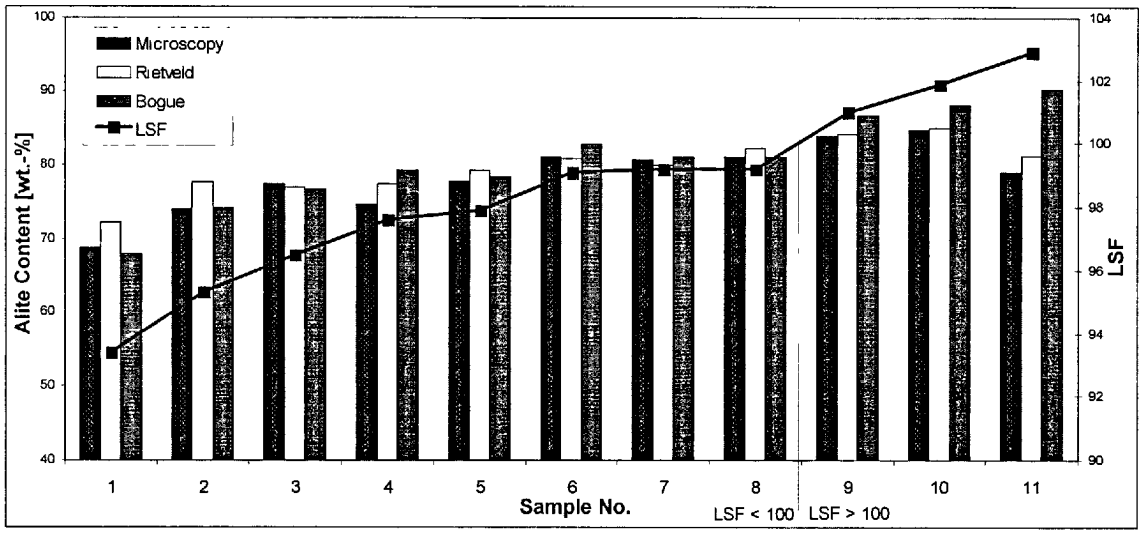

Fig. 1: Alite content in the clinker samples

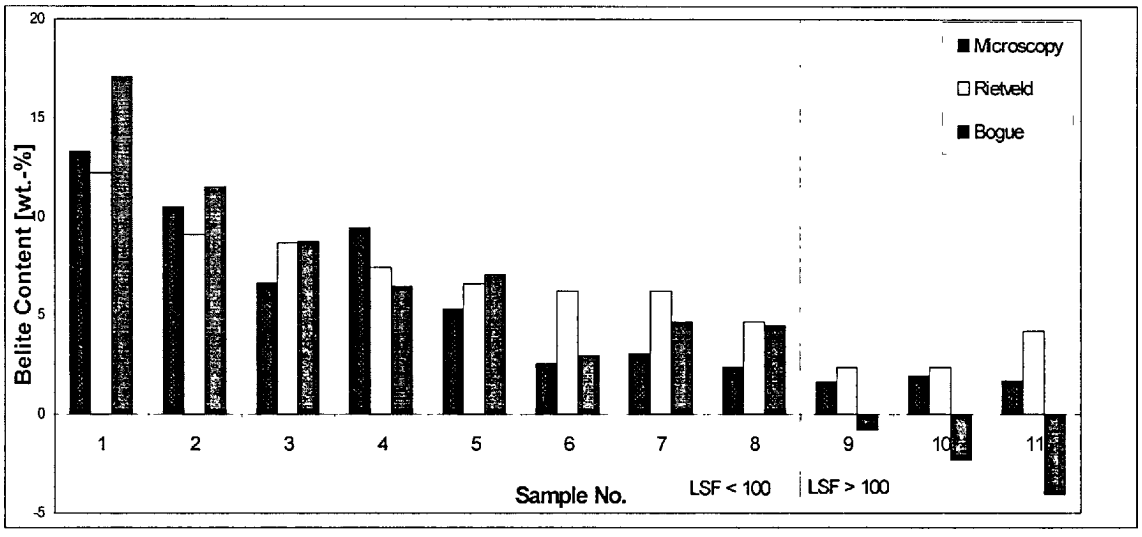

Fig. 2: Belite content in the clinker samples

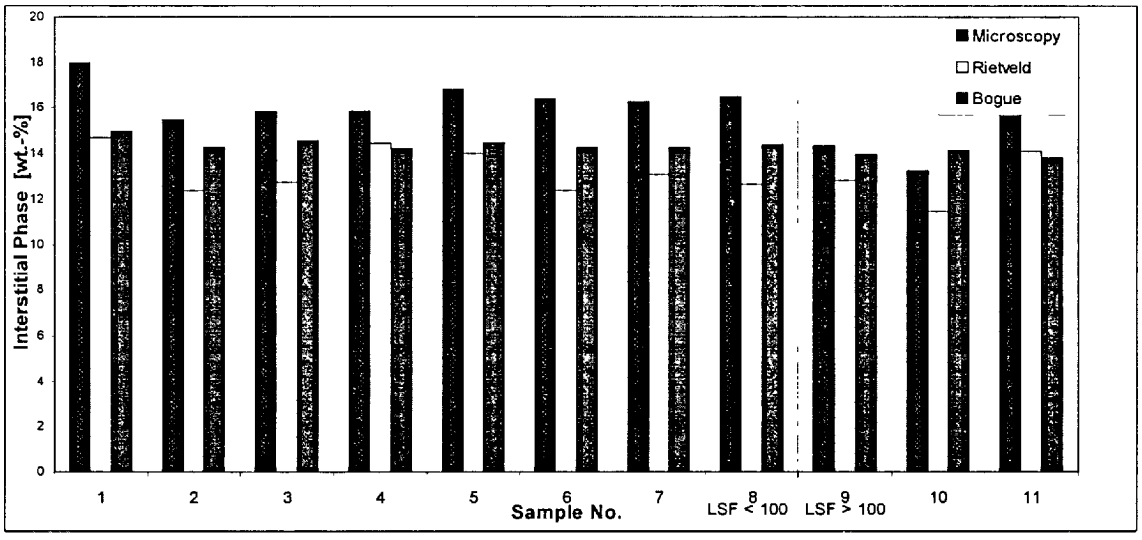

Fig. 3: Interstitial phase content in the clinker samples

Alite content
The three quantification methods give comparable values in the Alite content (except the Bogue calculation of sample no 11). The content of alite in the clinker increases with higher LSF values from approx. 70 m.-% up to 80 m.-%.

Belite content
Common belite contents of about 10 m.-% can be comparable calculated with the three used methods. The microscopic point counting of minor contents below 5 m.-% is difficult because of the clustering of the belites. At LSF values of greater 100 the Bogue calculation gives a negative belite content, although it can be clearly shown by microscopy, that belite exists in clusters in these clinkers (Fig. 5).

Interstitial phase content
The content of interstitial phase is independent from the LSF and more or less constant at about 14 m.%.

Microstructure
The microstructure of the 11 clinker samples has been studied by reflected light microscopy. The mainly idiomorphic alite crystals are in a size of 20 - 30 µm. They are embedded in a grey ground mass of aluminate and ferrate (Fig. 4). The 10 - 20 µm sized Belite can be observed in clusters (Fig. 5) and indicate an inhomogenity of the raw meal respectively coarse quartz grains, which are not disperse grounded by the raw mill.

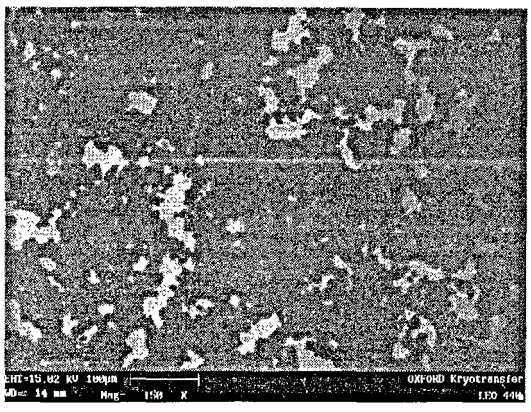

Fig 6: Belite cluster (right part) and Alite (left part) (Sample 10, LSF 101.9) ------ 20 μm

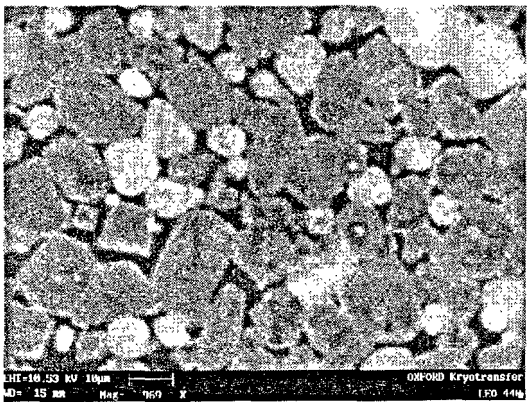
SEM-fluorescence

SEM-fluorescence allows an examination of the microstructure as well as a quantification of the three main phases Alite, Belite and Interstitial phase. When using a fluorescing resin, the pore structure can be studied and quantified at low beam currents (Fig. 7). Increasing the beam current up to 50 μA the characteristic structure of Alite, Belite and Interstitial phase can be observed because of their different fluorescing behaviour. Figure 8 shows the typical idiomorphic Alites (grey) besides rounded Belites (bright) in a dark aluminous ground mass. Even the typical cross lamellaes of the Belite (exsolution effect) and resorbed Belite relicts within the Alite crystals can be seen (Fig. 8, 9).



Quantification results are given only for this particular photographs and not representative for the whole clinker sample. An automatic quantification procedure seems possible by calculating the average of a large number of images obtained by PC controlled sample stage.

DISCUSSION AND CONCLUSION

Increasing LSF values cause higher contents in Alite and decreasing content in Belite. The content of Interstitial phase does not correlate with the LSF. Even clinkers with a LSF greater 100 do not show elevated free lime contents. The calculation of the LSF does not take into account solid solutions of the main clinker minerals and also inhomogenities in the raw meal are not considered.

The Bogue calculation is only a practical technique when the clinker production process is running on a constant level. Under extreme burning conditions or extreme clinker composition the Bogue calculation is not useful for the quality control. The Rietveld analysis represents a new technique with the capability for online quality control. The Rietveld calculation takes into

account the real composition of clinker minerals and of minor phases. The free lime content can be detected simultaneously. Expense for the equipment for the use of Rietveld analysis in automatic clinker quality control is comparable to the expense of chemical analysis and subsequent Bogue calculation.

For special investigations, like pore structure or crystal distribution and size, microscopic techniques are indispensable and vindicate the higher time and personnel expense, which is especially needed for point counting. It could clearly be shown that belite exists in clinkers with a LSF greater 100 in clusters. This indicates that inhomogenities in the raw meal or coarse grained quartz particles occur in the raw meal. Automatic quantification by image analysis is not possible because of the varying colours of the etched clinker minerals, depending on their reactivity with the etching agent and on polishing effects.

The SEM-fluorescence allows a combined examination of the microstructure as well as a quantification of the pore volume and of the clinker minerals. The information on the microstructure is similar to that from reflected light microscopy (crystal distribution, crystal size, resorption and exsolution effects) but the quantification seems to be more comfortable with an image analysis system. Depending on the SEM-beam current the three main phases of the clinkers clearly show different grey levels. The capability of this technique for automatic phase quantification will be investigated in further studies.

ACKNOWLEDGEMENT
The authors wish to thank Dr. Pankau from the Scientific Research Division of OXFORD Instruments for carrying out the SEM-fluorescence studies.

INFLUENCE OF PHYSICAL-CHEMICAL HYDRODYNAMICS PROCESSING OF RAW MIX ON CLINKER QUALITY

Lev M.SULIMENKO, Yuri R.KRIVOBORODOV, Research Technical Centre of JSC "Alfa Cement", Mendeleev Chemical Technology University of Russia, Moscow, Russia

ABSTRACT Using the equipment (RPA) where the raw materials are exposed to the high hydraulic impact and cavitation (HC) it is possible to obtain very-fine grained raw mixture. Its homogenic composition and fineness improved the clinker burnability. Morphology of clinker mineral crystals and C_3S/C_2S ratio in clinker are changed. The most positive results are noticed when fly-ash was used as a raw component instead of clay.

KEY-WORDS: Burnability of raw mixes, grinding technology.

INTRODUCTION

The reactivity of cement raw mixtures, at equal conditions, is a function of the particle size distribution (Goswami, et al, 1990, Johansen and Kouznetsova, 1992, Krivoborodov, et al,1988, Locher, 1975, Sulimenko, 1985). Experiments have shown the burning temperature may be decreased by 50°C for finely ground raw mixes (Sulmenko, 1991). Particle size distribution of the raw mixtures ground in the different mills is different from each other. The researchers showed that the type of equipment influence on the reactivity of raw mixture (Bucchi, 1980, Osbaek and Johansen, 1989). The mechano-chemical activation of raw mixes is effective when the raw mixes are exposed to the frequency of hydraulic impact and cavitation.

EXPERIMENTAL

Materials

Chemical composition of the raw materials used in the experiments is given in Table 1.

Using these components, two groups of raw mixtures were prepared. One of the group of mixture (No 1, 1.1, 1.2) consisted of the traditional components: clay, iron, limestone. In the other group (2, 2.1, 2.2) fly-ash was used instead of clay. The mixtures 1.1 and 2.1 were exposed to hydraulic impact using the equipment RPA. Rotor-pulsative apparatus (RPA) consists of two disks having the coaxical position each to other. All disks have trapezoidal teeth and slots. During rotation of one disk relatively other one the fast alternation of the coincidence and

noncoincidence of the slots, which causes the change of the moving speed of materials through the slots. Pulsation of the liquid flow appears. In the result the materials are exposed to high shear stress, hydraulic impacts, hedrodynamic cavitation and pulsation in the wide range. These factors in association with the intensive mechanical exposure increase the milling processes and improve the size distribution of materials. At the preparation of the mixtures 1.2 and 2.2 only limestone was exposed to hydraulic impact.

Table 1. Chemical composition of raw materials

No	Raw component	Oxides, % by wt.					
		SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3
1	Limestone	4.82	1.69	0.82	50.68	1.16	0.03
2	Clay	66.14	14.16	5.39	4.29	1.62	0.15
3	Iron	1.42	4.52	75.13	2.59	1.05	4.19
4	Fly-ash	56.10	11.42	5.80	15.88	2.20	2.65

Analytical methods

The fineness and particle size distribution were determined by granulometer and sieve analysis. Composition of the different fractions was studied by chemical analysis and XR-diffraction. Besides that DTA was used for study of all the raw mixes. Phase composition of clinker was studied by XRD, optical microscopy. Cement samples were made and tested by Standard methods.

RESULTS AND DISCUSSION

The experimental data showed that the equipment (RPA) promotes the fine structure of materials change: the crystal parameters, crystal defects, phase transformation. Thus, by RPA-grinding calcite transfers into aragonite. Grinding clay, the layer with the AlO_6 is fractured. As a result, material reactivity increases by up to 30% for clay and by 50-60% for limestone.

The change of the fineness and particle structure of raw materials gives the temperature change of mineral formation at clinker burning. According to DTA (Table 2) the temperature of carbonization of raw mixtures decreases by 25-30°C, belite formation decreases by 10-15°C. Clinker melt appears at 1300°C.

The results reveal that grinding of raw mixes by RPA gives a change of mineral composition in clinker (Table 3).

Table 2. Results of DTA

Processes	Temperature, °C mixture numbers					
	1	1.1	ΔT	2	2.1	ΔT
Decarbonization - beginning	670	655	25	680	650	30
Belite formation	1270	1250	20	1270	1255	15
Melt appearance	1330	1300	30	1315	1300	15

Table 3. Mineral composition of clinkers,%

Clinker number	C_3S	C_2S	C_3A	C_4AF
1	62	21	12	6
1.1	68	16	9	5
1.2	67	16	10	6
2	65	22	3	12
2.1	69	17	1	12
2.2	68	18	1	12

Optical microscopy of clinkers 1.1, 1,2, 2.1 and 2.2 represent very good crystallization of alite and belite in comparison with the initial clinker (1 and 2). The mentioned change in clinker gives the different hydraulic activities of cement. In Table 4 rhe test results of cements are given.

Table 4.Strength of cements

No cement	Strength, MPa							
	bending				compressive			
	3d	7d	14d	28d	3d	7d	14d	28d
1	4.2	8.0	11.8	17.8	13.8	37.0	56.0	68.0
1.1	6.9	16.1	18.3	20.0	23.0	60.0	73.0	76.0
1.2	4.9	14.2	18.0	21.1	18.6	51.5	66.0	70.6
2	2.5	5.8	8.8	13.2	11.0	27.0	39.0	51.0
2.1	5.7	15.0	18.8	20.5	19.5	46.4	68.0	82.0
2.2	4.0	12.3	16.0	18.0	13.6	39.0	64.5	81.0

Cements based on activated clinker hardened more rapidly than initial cement and had strength increased by 5-10 MPa at 3 days and 8-30 MPa after 28 days hardening. The most high strength of cement was noticed for clincer burned the activated fly-ash contained raw mixture (2.1, 2.2).

CONCLUSION

Mechano-chemical activation of raw mixes using RPA is effective method to increase the reactivity and burnability of clinker. Cement on base of such clinker riched the higher strength in comparision with cement based on ordinary clinker.

INFLUENCE OF RAW MIX HETEROGENEITY ON EASE OF COMBINATION AND CLINKER STRENGTH POTENTIAL

Graeme MOIR, Blue Circle Industries, Technical Centre, Greenhithe, Kent.

ABSTRACT The range of firing temperatures required to combine raw mixes from 15 cement plants have been related to raw mix heterogeneity and in particular the level of acid insoluble material present in the 90 micron residue. It is also shown that the extent and nature of raw mix heterogeneity has an influence on cement strength development. Mixes with calcareous residues tend to yield higher 28 day strengths than those with siliceous residues.

Key-words: Burnability of raw mixes, Strength development, alite, belite.

INTRODUCTION

The optimum raw meal fineness for optimum kiln operation and clinker quality is mainly determined by raw material mineralogy and the clinker chemistry parameters of LSF, SR and AR‡. Insufficient grinding, perhaps arising from an undersized raw mill, will necessitate hard burning with consequent penalties to fuel consumption, refractory life, clinker grindability and cement quality. Kiln operation may also be adversely affected by kiln and preheater blockages associated with the evaporation and condensation of volatiles. Conversely, excessively fine grinding, whilst permitting lower kiln temperatures, may restrict kiln output as a result of the increased dust loss or recycle within the kiln system.

The influence of raw mix mineralogy, and in particular the relative influences of coarse calcite and silica rich particles on the level of free lime remaining after firing at 1400 C, has been quantified by Christensen (1978) and Fundal (1979). Quartz particles coarser than 44 microns have a marked influence on the ease of combination, whilst for calcite, the significantly sized fraction is that coarser than 125 microns. More recently Fundal (1996) has further refined the predictive model by introducing the influence of the proportion of heterogeneous coarse particles on the chemical composition of the fine fraction. The concept of quantifying raw mix heterogeneity by means of the chemical analysis of different size fractions and relating this to sintering behaviour was examined by Dreizler and Schafer (1990).

The prediction of cement strengths from cement characteristics has been investigated by several workers, eg. Osbaeck (1979), Relis et al (1988) and Tsivilis and Parissakis (1995). In recent years the introduction of computerised databases for cement production quality control has greatly facilitated the interpretation of strength variations and the prediction of cement 28 day strength from quality control data. In-house models have been developed which satisfactorily predict day to day variations in 28 day strength at any one cement plant, but significant differences exist between the predicted strength levels at different cement plants if a common expression is used. This is attributed to differences in clinker microstructure but the factors responsible, kiln feed mineralogy, burning conditions etc., are poorly understood. An investigation was initiated using materials from 15 cement plants to determine whether factors

‡ *In this paper*

$$LSF \quad \frac{CaO}{2.8\ SiO_2 \quad 1.2\ Al_2O_3 \quad 0.65\ Fe_2O_3} \qquad SR \quad \frac{SiO_2}{Al_2O_3 \quad Fe_2O_3} \qquad AR \quad \frac{Al_2O_3}{Fe_2O_3}$$

such as kiln feed heterogeneity and estimated kiln burning temperature might provide an explanation for the differences in clinker strength potential.

COMBINABILITY INVESTIGATION

Experimental Details

Average samples of kiln feed from the 15 plants were split into minus 90 micron, plus 90 micron and plus 150 micron fractions and chemically analysed. The 90 micron and 150 micron residues were also treated with hot 1.0 N HCl to determine the proportion of silica rich material present in the coarse fractions.

The raw mixes were proportioned with fine coal ash to adjust the LSF to the plant's normal value and a sub-sample of the homogenised mixes was formed by hand into nodules of approximate diameter 12 mm. The pellets were fired in a programmable horizontal tube furnace following the heating regimes outlined in Figure 1, and the temperature required to achieve a free lime level of 1% estimated from curves of the type shown in Figure 2.

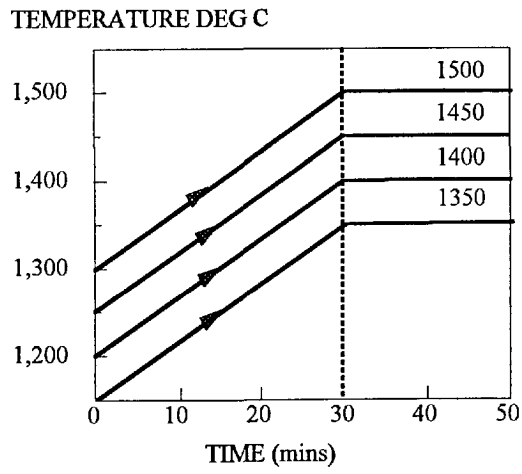

Figure 1 Combinability test heating regime

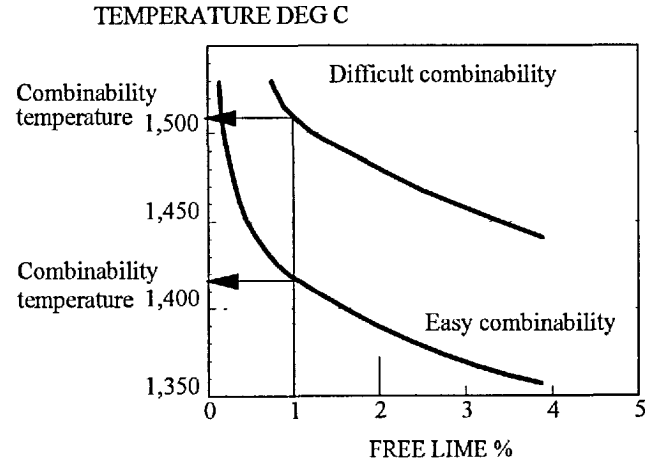

Figure 2 Typical combinability curves

Sub-samples of the ground clinkers were chemically analysed to confirm that chemical parameters similar to those of current clinker production had been achieved.

Results

The chemical analysis data and the combinability results are summarised in Table 1.

Figure 3 illustrates that, as might be expected on account of the relative hardeness of quartz and silica rich minerals, most plants had siliceous (low LSF) residues. Three works had calcareous residues. In the case of plant J, this is attributable to the method of kiln feed preparation in which sand and iron oxide are ground separately from the main raw mix constituents of chalk and clay.

Figure 4 illustrates that there was no clear relationship between combinability temperature and the main clinker chemical parameters of LSF and SR.

The data were analysed using multiple linear regression analysis (MLRA) to relate raw mix fineness and heterogeneity to combinability temperature. Figure 5 illustrates that the range of

LSF = LSF fraction - LSF kiln feed

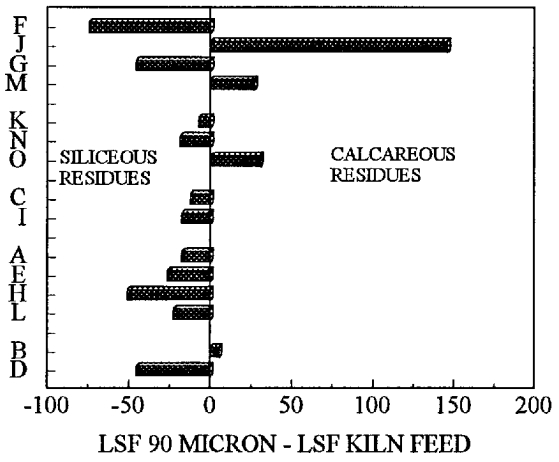

Figure 3 LSF difference between 90 micron residue and kiln feed

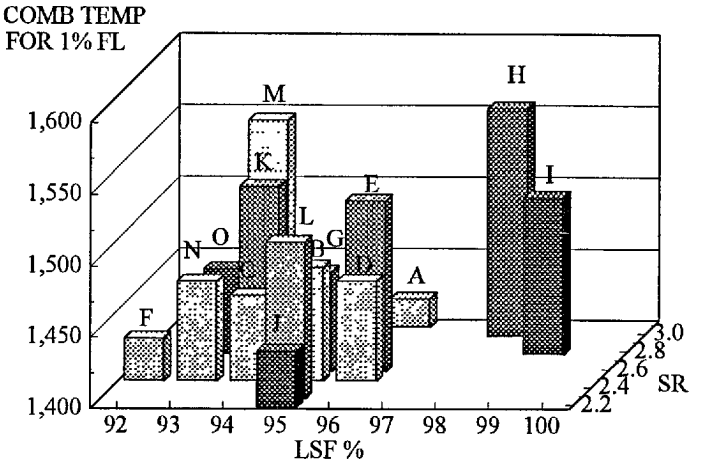

Figure 4 Relationship between combinability temperature and clinker LSF and SR

combinability temperatures could be satisfactorily explained using the relationship

combinability temperature for 1% free lime = 414 + 21 x acid insoluble 90 micron residue
+ 10 x clinker LSF
+ 3 x 150 micron residue
+ 32 x clinker AR.

The multiple correlation coefficient was 0.923.

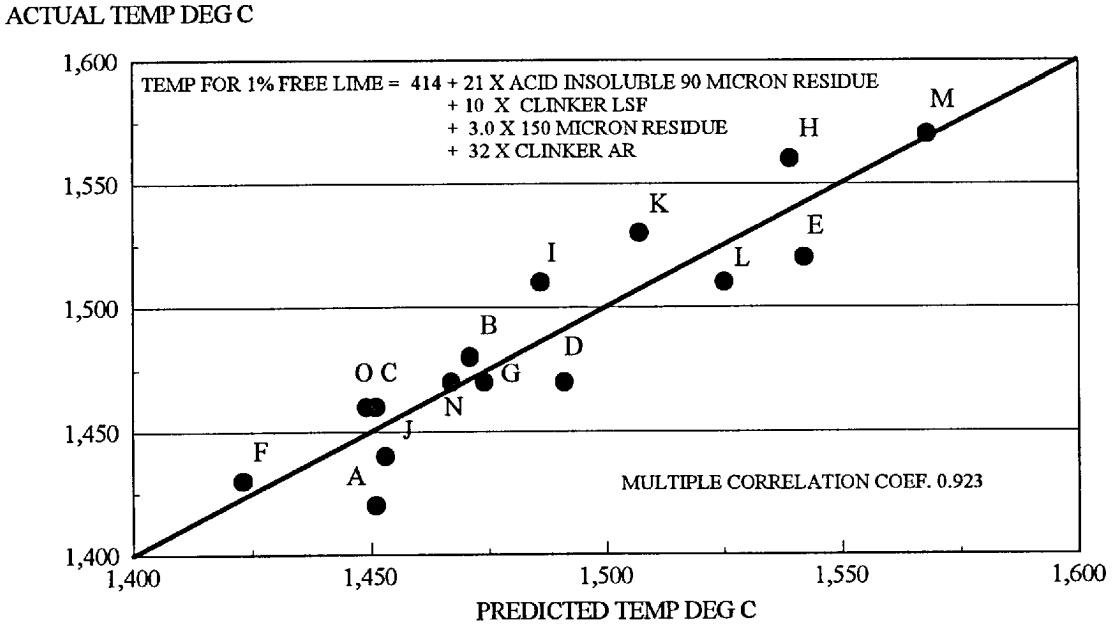

Figure 5 Actual v predicted combinability temperature for 1% free lime

The single most significant parameter was the level of acid insoluble 90 micron residue. If this parameter was excluded from the data analysis then the following relationship was derived:-

combinability temperature 1% free lime = 535 + 4.4 x raw feed 90 micron residue
+ 9.0 x clinker LSF
- 0.33 x LSF of 90 micron residue
+ 34 x clinker AR.

The multiple correlation coefficient was almost unchanged at 0.920.

Discussion

Both of the relationships derived are 'sensible'. It is stressed that they are only likely to be generally applicable within the range of chemistries of the current clinkers, viz. LSF 92 to 99, SR 2.2 to 3.1 and AR 1.2 to 2.5. It was perhaps surprising that with this set of data, increasing AR had a greater negative influence on the combinability temperature than increasing SR. The AR primarily influences the nature of the clinker liquid, viscosity etc., whilst the SR determines the quantity of liquid formed.

The similar correlation coefficient obtained when the terms 'acid insoluble 90 micron residue' and '150 micron residue' were replaced by '90 micron residue' and 'LSF of 90 micron residue' confirm the importance of raw mix heterogeneity on combinability, and in particular the negative influence of a concentration of silica in the coarse fractions.

INFLUENCE OF RAW MIX HETEROGENEITY ON CLINKER STRENGTH POTENTIAL

Analysis of data

Table 2 summarises the chemical and physical characteristics of Type I (pure Portland) cement produced by cement plants A to O.

Table 2 Chemical and physical characteristics of cements.

Predicted strength = 64 - 0 4 residue +0 2 C3S - 13 eq Na2O 2 LOI

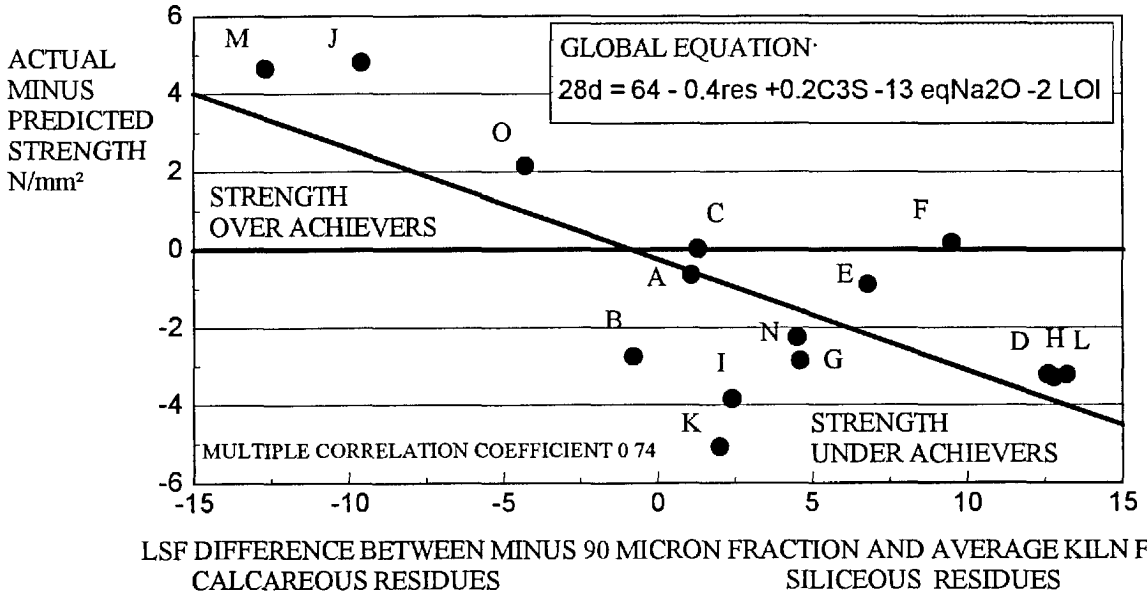

Figure 9 Relationship between predicted and actual strength and raw mix heterogeneity

Cement plant quality control data have been analysed satisfactorily within Blue Circle using MLRA since the mid-1980s. In general it is possible to predict day to day variations at individual plants with reference to 5 key chemical and physical parameters

- 45 micron residue
- C_3S
- eq Na_2O
- SSA
- LOI

When predicting early strength it is the level of soluble alkali, present as alkali sulfates, which is important rather than the total alkali. Early strengths are strongly influenced by surface area but, at least in the EN 196-1 mortar test when using vibration compaction, the influence of this parameter on 28 day strength is relatively small, in comparison with the influence of the proportion of coarse clinker particles, as indicated by the 45 micron residue.

Whilst individual plants must develop their own relationships to achieve the best strength predictions, a so-called "global equation" of the form

28d = 64 - 0.4 residue plus 45 microns + 0.2 C_3S - 13 eq Na_2O - 2.0 LOI

will predict strength fluctuations at most cement plants.

The coefficients used agree closely with those determined in experiments when, as far as practicable, only one parameter was changed at a time. Note that the coefficient for LOI (loss on ignition) is influenced by the source of the loss and should be higher if the contribution is predominantly from prehydrated clinker rather than from $CaCO_3$ introduced as a minor additional constituent.

Figure 6 illustrates that most of the strength variation at plant F over a 12 month period can be satisfactorily explained using the global equation. Similarly, the same equation indicates the trends in strength at plant G (Figure 7) but significantly overestimates the mean strength level. Conversely at plant J (Figure 8) the same equation underpredicts the mean strength level. Table 3 indicates the differences between predicted and actual strength for cements produced by the 15 cement plants.

There is clearly another factor at play in addition to those indicated in the prediction equation. It is believed that this factor is related to clinker microstructure. Although microstructure can be studied using optical microscopy it is rather difficult and time consuming to characterise objectively. In order to determine whether factors such as raw mix fineness, heterogeneity, estimated equivalent kiln burning temperature etc. might provide an explanation for these strength differences the entire data block of raw mix and cement data was analysed using MLRA.

Figure 9 illustrates the main finding. Cement produced from raw mixes with calcareous residues (J, M and O) tend to give higher strengths than those produced from feeds with siliceous residues. There is no significant correlation between strength difference and the estimated equivalent kiln burning temperature.

Discussion

It is suspected that the lower strength potential of clinkers with siliceous raw mix residues may be associated with the presence of belite clusters, formed from relatively coarse quartz or silica rich particles. Belite makes a significant contribution to strength development between 7 and 28 days under standard curing conditions at 20 C (Kelham and Moir 1992).

Maki et al (1995) have studied microscopically the formation of belite clusters from quartz grains and found differences in impurity level which correspond to differences in etching behaviour. It is expected that these differences in etching behaviour may also relate to differences in hydraulic activity.

Campbell (1994) has suggested that "belite nests may have a major control on late strength gain" and proposed a correlation factor to take into account the percentage and type of belite nests when predicting 28 day strengths using the Ono method.

It should be recognised that raw mix heterogeneity is only one source of clinker heterogeneity, and that the poor assimilation of high ash coals can make a major contribution. However, at plants which have coarse siliceous raw mix residues the cement 28 day strength is likely to benefit from finer grinding of the raw mix, or separate grinding of the silica rich component, if this is practicable. The influence of increased raw mix fineness on kiln operation aspects such as the internal dust cycle must also be taken in account.

SOLID STATE REACTIONS IN THE CHEMISTRY OF CEMENT

Otar P. MCHEDLOV-PETROSSYAN, State Technical University of Building and Architecture, Kharkov, Ukraine

ABSTRACT Solid state reactions occur in the initial stages of clinker mineral formation but the appearance of melt obscures the role of the mentioned initial processes. The works of the outstanding Swedish scientist Arvid Hedvall had already showed that various external impacts on the stages in solid state reactions can essentially affect the completeness of interactions in solid state. In this paper the role of activation of solid state reactions is studied.

Key-words: aragonite, calcium carbonate, thermodynamics, solid state reactions

INTRODUCTION

At the level of modern technological development different variants of impacts on the reactions in solid state are examined. The analysis of different methods of activation of the solid state reactions are discussed.

SOLID STATE REACTIONS

Selection of raw mixture components of higher activity

Portland cement is usually made from a raw mixture of calcium carbonate and clay. By calcium carbonate we mean calcite, and by clay - kaolinite. Meanwhile with the development of the building materials industry and the availability of increasing number of technogenic products we can often see the replacement of the components by the latter (Zhavoronkov et al., 1979) and on the other hand more detailed study of the mineral composition of the raw mix components can be observed (Mchedlov-Petrossyan et al., 1980). As mentioned above it is very important to look at the impact of the "Hedvall effect" (Hedvall, 1938, 1943, 1966) on the process of solid state reactions in the raw mix. For instance, sometimes (though seldom) calcium carbonate can be replaced partly by aragonite, and clay - by various silicate minerals - montmorillonite, pyrophillite and others.

If we examine the results of the thermal analysis of these raw materials we can see that for the most compounds taking part in this reactions, on reaching the interval characteristic of interaction temperature, effects characterizing modifying transformations or dissociation can be observed. So, for aragonite, the effect of slow transformation into calcite takes place at 410-450 ^{o}C, for kaolinite in the region of 500 ^{o}C (and on grinding even lower), for

pyrophillite and for monothermite at 400-600 °C. Earlier (Ramachandran and Sereda, 1971) the possibility of using the "Hedvall effect" for the study of clinker minerals activity was shown. Therefore in choosing the raw mix components and planning a technological process it is necessary to take into account the possibility of activation of solid state processes in a wider aspect.

Especially interesting is the fact that by prolonged grinding, calcite transforms into aragonite at room temperature (Burns and Bredig, 1956).

Thermodynamic calculation (Nikolayev et al., 1984b) shows that for aragonite $T_{\Delta G=0}$ is approximately 150 °C lower than for calcite which results in the intensity of solid phase reactions. In high degree it depends on admixture of silicate components in the carbonate part. The study of the influence of the physico-chemical properties of calcium carbonate on the clinkerization (Nikolayev et al., 1984a) showed that the presence of clay impurities allows C_2S to be obtained in the temperature interval 780-830 °C.

Preliminary thermo-mechano-chemical impacts on the initial components

Partial decarbonatation of the raw mix leads to entering of active calcium oxide into the kiln while the dehydrated clay intensifies the solid state reactions. A deep grinding of preliminary dehydrated clay component leads to the same result. The Hedvall effect plays a specific part in fine grinding, chemical influences, and modification of phase transformations.

The measure of activity of the solid phase is the difference:

$$\Delta G_{exc} = \Delta G_{act} - \Delta G_{norm},$$

where ΔG_{exc} is excess energy, ΔG_{act} and ΔG_{norm} are Gibbs energies for activated and normal state, respectively. ΔG_{exc} is increased by structural defects (free surface, lattice distortion, dislocations etc.). Therefore this problem belongs to mechanochemistry (Heinicke, 1984).

Of great interest is the use of jet mills (Yudovich and Akunov, 1989). It was found that the addition of CaF_2 accelerates the formation of C_2S (Ayed et al, 1992) and that different compounds of calcium, for example $Ca(NO_3)_2$, or the addition of NaF promotes the C_2S forming (Singh et al, 1992). As to aragonite, though it needs prolonged grinding it can appear as a result of microadmixtures (PbO, MgO) or microadditives (water vapour, alkali) in raw mixtures. Sometimes raw mix includes a considerable (more than usual) quantity of quartz and some amount of alkali. In this case, water vapour results in intensifying the interaction. It should be noted that more and more interest is given to mechano-chemical activation of solid phase reactions through selecting grinding conditions (Boldyrev et al., 1987) and

consideration of shear deformations (Enikolopian, 1989) which can lead to substantial acceleration of processes.

External physico-technical impacts on the reaction mixture

The velocity of solid state reactions can also be accelerated by the influence of electrical (Kröger, 1964) or magnetic (Budnikov et al., 1950) fields, as well as by ultrasonic fields (Pines et al., 1969). All this is to be taken into account while working out improved methods of clinker production.

HEAVY METALS CONTENT OF RAW MATERIALS, CLINKER AND DUST OF CEMENT PLANTS

Marina V. KOUGIYA, Giprocement, Phys.-Chem. Studies, St. Petersburg, Russia

ABSTRACT Data on contents of 10 heavy metals of raw materials, raw mixes, dust and clinker from five cement plants of Russia are presented. The results obtained are compared with the findings of investigations in Germany, USA, England and India.

KEY-WORDS: ecology, heavy metals, clinker formation.

INTRODUCTION

In view of environmental controls and improved potentialities of analytical equipment, Sprung and Rechenberg (1978) determined Pb and Zn contents of limestones and clays used at cement plants, as well as of clinker. Kræmar, Linner, Weisweiler (1994) carried out determinations of more than 23 trace elements in cement materials of Germany. Tulles (1992) presented averaged data for 89 North American cement plants on contents of 12 heavy metals of dust and cement. Moir and Glasser (1992) gathered information on contents of 10 heavy metals in clinkers of cement plants of England. Krishnan, Gore et al (1992) determined concentrations of 12 trace elements in raw materials, mixes and dust of cement plants of India.

EXPERIMENTAL

For investigations use was made of raw materials, slurries, electrostatic precipitator dust and clinker of five wet process cement plants located in various regions of Russia. The contents of Mn, Mo, Pb, Cr, Tl, Co, Ni, Zn, Cu and V were monitored. The analysis was performed with the help of atomic absorption as well as of X-ray spectrum analysis procedure developed with the participation of the author. The data obtained are presented in Table 1 and 2. Maximum permissible concentrations in soil were presented by Bespamyatnov (1985). Concentrations of trace elements in samples taken from three fields of electrostatic precipitators were also determined: the results are presented in Table 3.

Table 1 Heavy metals content of raw materials and fuel

Zn	g/t	210	220	220
Cu	g/t	20	18	18
V	g/t	30	40	40

DISCUSSION OF RESULTS

The least quantity of heavy metals was found in carbonaceous rocks; clays are more enriched in trace elements. Variations in contents of heavy metals and their qualitative composition are associated with the geologic age and origin of natural rocks of regions where the plants are located. This correlates with geochemical data (Shcherbina, 1972) and the findings of Sprung and Rechenberg. Concentrations of trace elements for all rocks did not exceed the regional background contents and maximum permissible concentrations in soils (Bespamjatnov, 1985).

Similar data were obtained for coals. For these technogeneous materials, heavy metals concentrations were much higher. For example, contents of Cu, Pb and Zn are hundreds to thousands times greater then those of natural rocks. Besides, thallium, in amounts of 5-8 g/t, In occurs in amounts of 3-6 g/t and Ge - 6-10 g/t in pyrite cinders. High concentrations of As (3000 g/t) and Sb (250-300 g/t) were also noted. In this connection it is desirable to keep the pyrite cinders content of the mix as low as possible.

The trace elements concentrations of raw slurries were in line with their content of initial raw materials and in accordance with raw material components ratios of the total mix mass. Cu, Zn, Pb, Cr, Ni, Mn were revealed as the main bound elements in clinker. This correlates with the data obtained by Sprung, Weisweiler, Moir. The higher contents of about the same set of heavy metals were encountered in the electrostatic precipitator dust, this is in agreement with findings of Krishnan. The Mn, Mo, Cr, Zn, Cu, V contents were lower than those of clinker, but Co and Pb concentrations were higher. Attention is drawn to the increase in the thallium content for all dust samples studied. It was found that finer particles were precipitated in electrostatic precipitators: the lower were the CaO and SiO_2 contents, the higher were the contents of K_2O and certain heavy metals. This suggests the probability of trace elements carrying out together with fine particles of dust and gases.

CONCLUSIONS

The studies conducted have shown a good correlation between the data on the heavy metals content of natural cement raw materials and fuel used and valid control values for soils, i.e. the environmental compatibility of these materials has been demonstrated. The situation with technogenous materials in the form of clinker, cinders and dusts is more complicated. As to clinker it should be pointed out that this is a product where concentrations of heavy metals are within the limits valid for air-dry soils. The permissible total contents are almost not exceeded, but for Cu, Zn, Ni the environmental impact of which is assessed to be far less. The studies are to be continued for drawing up heavy metal balances as applied to wet process kilns for determination of atmosphere emission composition and elaboration of environmental control measures.

MODELLING THE KINETICS OF CLINKERISATION

S C AHLUWALIA*, R K GOSWAMI AND S HARSH

National Council for Cement and Building Materials,
New Delhi, India

ABSTRACT An attempt has been made to evolve a general model for the kinetics of clinkerisation in the temperature range of 1300-1450°C. Experimental studies were conducted on industrial raw mixes and a Jander type polynomial function was made to fit on the data. It is found that reaction velocities for most of the materials can be related by values of N as 12 and 14 in the temperature range of 1300-1375°C and 1375-1400°C respectively.

Key-words: Rate equations; Kinetics; Clinker formation; Modelling

INTRODUCTION

The alite formation reaction has a low rate and occurs in the temperature range of 1300-1500°C. Formation of alite, though possible in the solid state, is preceeded or accompanied by melt formation in practice. The melt phase is formed at around 1300°C and plays a vital role in the kinetics of alite formation. It is very fluid and strongly wets the solid phases. Further it has good transport properties, is capable of dissolving substantial amounts of all major and minor components and is present in sufficient amount not only to bridge adjacent grains but also to facilitate materials transport over longer distances.

The solid reactants CaO and C_2S get dissolved in the melt and counter diffuse. The dissolved CaO and C_2S react to form C_3S

$$CaO + C_2S \longrightarrow C_3S \qquad \ldots\ldots\ldots [1]$$

Initially the C_3S remains dissolved in the melt. However, when the melt gets super saturated with C_3S, the C_3S crystallizes out from melt. For such reaction Jander [1931] proposed following equation

$$(1-\sqrt[3]{1-\alpha})^2 = Kt \qquad \ldots\ldots\ldots [2]$$

Where, α is reaction ratio, t the time of reaction and K is a constant. The reaction ratio for clinkerisation reaction can be defined as

$$\alpha = \frac{CaO_T - CaO_f}{CaO_T} \qquad \ldots\ldots\ldots [3]$$

Where CaO_T is total calcium oxide content of clinker and CaO_f is free calcium oxide at any time t.

The logarithmic form of Jander's equation

$$\log (1 - \sqrt[3]{1-\alpha}) = 1/2 \log K + 1/2 \log t \qquad \ldots\ldots\ldots [4]$$

indicates that the plot of $\log (1 - \sqrt[3]{1-\alpha})$ and log t should be a straight line having a slope of 0.5 on log t axis.

* Presently with OCL (India) Ltd., New Delhi

Several studies [Kondo, 1960] have indicated that slope of lines obtained for clinkerisation reaction varies over a large range and changes with the temperature of reaction. Therefore, a more general form of Jander's equation is considered to represent the clinkerisation reaction as :

$$(1 - \sqrt[3]{1-\alpha})^N = K\,t \qquad \ldots\ldots\ldots [5]$$

or

$$\log (1-\sqrt[3]{1-\alpha}) = (1/N)\ \log K + (1/N)\ \log t \qquad \ldots\ldots\ldots [6]$$

The results of present study indicate, the value of N can be as high as 10-18.

EXPERIMENTAL

Well characterised raw mixes (Table-1) were fired in pellet form in laboratory muffle furnace at temperatures of 1300°, 1350°, 1400° and 1450°C for soaking periods of 5, 10, 15, 20, 25, 30 and 35 minutes. The free lime in the resulting clinker was estimated by ethylene glycol method.

Table 1 : Chemical Analysis of Raw Mixes (Clinker Basis)

Sl No	CaO%	SiO_2%	Al_2O_3%	Fe_2O_3%	MgO%	K_2O%	Na_2O%	SO_3%
CL-1	65.76	20.23	4.94	3.27	3.80	0.57	0.32	Nil
CL-2	63.20	20.73	4.75	4.58	4.05	0.87	0.33	0.69
CL-3	64.99	21.03	6.44	4.96	1.00	0.93	0.13	0.16
CL-4	64.15	23.44	5.62	3.75	2.00	0.31	0.24	ND

RESULTS AND DISCUSSIONS

Values of the function $\log (1- \sqrt[3]{1-\alpha})$ were computed from the experimentally determined values of CaO_f for various time intervals at different temperatures. These values were plotted soaking period against log t (t=in minutes). Data was found to be linearly correlated and the characteristic parameter of best fit lines are summarised in table 2.

Above data shows that the value of slope varies in narrow range i.e. 0.0562 (θ=3.22°) and 0.0978 (θ=5.59°). However, when converted to N(=1/slope), the variation extends from 10.22 to 17.79. The value of N remains confined to a smaller range of 10 to 13 for the observation recorded at 1300°C and 1350°C, and have a tendency to centre around 12. In the higher temperature range (1400-1450°C), the value of N is scattered from 10 to 18. Leaving aside two extreme cases on either side, the range comes down to 12 to 16. Also, it has a tendency to centralise around 14. This implies that the slopes of the lines tend to become gentler as the reaction temperature is increased.

An earlier study on the subject [Kondo, 1960] has reported the value of N as low as 0.6 and as high as 11.9. It is further reported that average value of N in higher temperature (1375-1450°C) range was 5. In contrast, the present study establishes

Table 2 : Results of linear regression analysis

Temperature		CL - 1	CL - 2	CL - 3	CL - 4
1300°C	Slope	0.0797	0.0801	0.0825	-
	Intercept	-0.4479	-0.3637	-0.3286	-
	N(=1/Slope)	12.54	12.48	12.12	-
1350°C	Slope	0.0894	0.0820	0.0771	0.0979
	Intercept	-0.3967	-0.3378	-0.2903	-0.2401
	N(=1/Slope)	11.19	12.19	12.97	10.25
1400°C	Slope	0.0693	0.0715	0.0978	0.0640
	Intercept	-0.3230	-0.2743	-0.2881	-0.1790
	N(=1/Slope)	14.43	13.98	10.22	15.62
1450°C	Slope	0.0811	0.0741	0.0689	0.0562
	Intercept	-0.2986	-0.2504	-0.2391	-0.1605
	N(=1/Slope)	12.33	13.49	14.51	17.79

the value of N at 12 for lower temperature range (1300-1375°C) and at 14 for higher temperature range (1375-1450°C). The cause of marked deviation from the theoretically established value of 2 (Eq. 2) probably lies in the fact that cement raw mixes have a wide particle size distribution and their shapes also differ from ideally considered spherical particles on account of mineralogy and size reduction unit operations. A comparatively narrower distribution of values of N in 1300-1350°C range indicates that rate of reaction is more or less same for all types of materials at the time of appearance of liquid phase. As the temperature of reaction goes up, the properties of liquid phase, like viscosity and surface tension, are affected to a great extent. Therefore, the rate of reaction shows larger variations and becomes material dependent in this temperature range.

CONCLUSION

It is not found possible to propose a unified model for the reaction velocity of clinkerisation, mainly on account of variations in chemical composition, mineralogy and particle size distribution of raw mixes. However, the values of N taken as 12 and 14 for the temperature ranges of 1300-1375°C and 1375°C-1450°C respectively shows good agreement with experimentally observed values.

BURNABILITY OF CEMENT RAW MIXES AT 1400°C

S C AHLUWALIA*, R K GOSWAMI AND S HARSH

National Council for Cement and Building Materials,
New Delhi, India

ABSTRACT A mathematical model for determining the amount of free lime in clinker, obtained by firing raw mixes at 1400°C for 30 min. has been proposed. The model is based on chemical composition of clinker and fineness of raw mix. The model is valid over a wide range of compositional and fineness variations and statistical confidence level of 95%.

Key-words: Burnability of raw mixes; Free-lime; Modelling

INTRODCUTION

Burnability of cement raw mixes is assessed by a number of empirical burnability indices and burnability factors, which qualitatively give the relative ease of burning a raw mix. Need had always been felt of a model to assess burnability quantitatively as the amount of free lime in clinker after burning the raw mix under some standard conditions. Kock (1974) presented a statistical model based on a large number of chemico-mineralogical parameters as well as fineness of the raw mix. To improve the reliability, the model was based on at least one reference testing and chemico mineralogical parameters of the reference sample are used for computation. As the model requires a large number of inputs including a reference testing, it becomes quite cumbersome to work and the convenience offered by earlier indices and factors is lost. Further, a fresh reference testing will be required for a different set of raw materials. Christensen (1981) has treated the matter in a different way and proposed that the occurence of free lime in clinker, with LSF less than 100, is due to microinhomogeneities and macroinhomogeneities and both should be considered separately. They proposed a statistical model based on LSF and SM only for computation of free lime due to microinhomogeneities and suggested an empirical approach for the other part. The model required estimation of certain minerals like calcite, quartz and acid insoluble residue in various sieve fractions of raw mix. The model proposed is as under:

$$CaO_f = 0.33\,[LSF + 5.1\,SM - 107] + 0.93\,SiO_2^{+44} + 0.56\,CaCO_3^{+125} + 0.2\,Aq^{+44} \quad \ldots\ldots\ldots [1]$$

Where CaO_f=Free lime in clinker after firing at 1400°C for 30 min

SiO_2^{+44} = Weight percent of quartz coarser than 44 μm.

$CaCO_3^{+125}$= Weight percent of Calcite Coarser than 125 μm.

Aq^{+44} = Weight percent of acid insoluble residue, other than quartz, coarser than 44 μm.

* Presently with OCL (India) Ltd., New Delhi

The last three terms in Eq. 1 are designed to predict the free lime content coming from coarse minerals or macroinhomogeneities while the first term gives statistical estimate of free lime coming due to microinhomogeneites.

This paper reports the development of a statistical model based on modulii values of raw mix and its fineness, with a view to minimize the experimental work.

EXPERIMENTAL

Well characterized raw mixes covering a wide range of oxide composition, modulii values and fineness were chosen for this study. The raw mixes were intermixed with coal ash (5-6%) to consider the influence of coal ash absorption. Chemical analysis of corresponding clinkers is given in table 1. The mixes were pelletised and fired at 1400°C for a period of 30 minutes in electrical muffle furnace. Free lime of resulting clinker was estimated by ethylene glycol method.

RESULTS AND DISCUSSIONS

Experimentally measured values of free lime in clinker after firing at 1400°C for 30 min. are listed as CaO(1) in table 2. As the aim of present work was to develop a purely statistical model, it was decided to retain the first term of Eq 1 as such and replace the last three terms by a single term as under:

$$CaO_f = 0.33\ [LSF + 5.1\ SM - 107] + A \quad \ldots\ldots\ [2]$$

The difference between experimentally measured free lime and free lime given by first term of Eq 2 is listed as CaO(2) in table 2. In fact, these are the values for which a model is required to be developed. As the term A reflects the free lime contribution by coarse mineral particles, attempts were therefore made to correlate the CaO(2) values with various powers and roots of

CaO(1) = Free lime after firing the raw mix at 1400°C for 30 min. (Experimentally Measured)
CaO(2) = CaO(1) - 0.33 [LSF + 5.1 SM - 107]
CaO(3) = Calculated free lime (according to Eq 4)

residue on various sieves. Best results were obtained with square root of residue at 90 um sieve. The linear regression equation

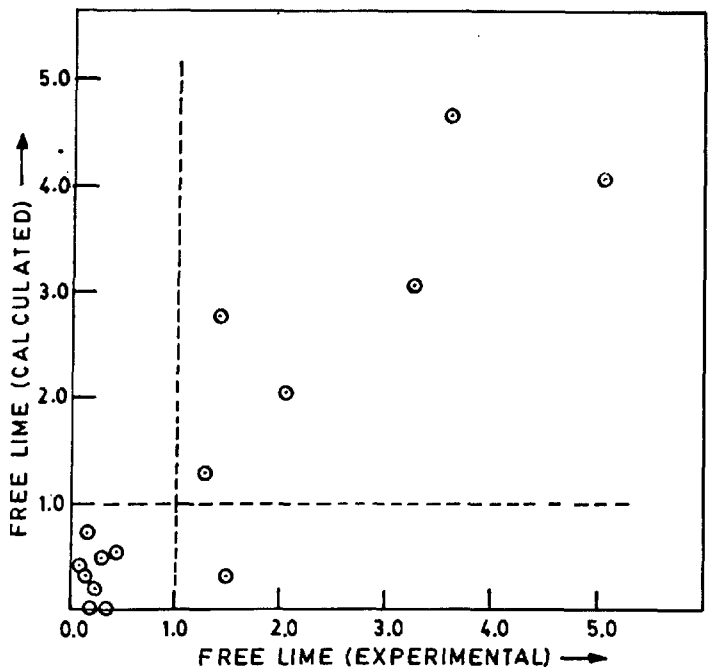

FIG 1 SCATTER DIAGRAM OF CALCULATED vs. EXPERIMENTALLY MEASURED FREE LIME

obtained is as under :

$$A = 0.21 + 0.59\sqrt{R_{90}} \quad \ldots\ldots\ldots [3]$$

The relationship has a correlation coefficient of 0.606 as against the listed values of 0.497 and 0.623 at 95 and 99 percent confidence levels respectively for relevant degrees of freedom. The model was further subjected to analysis of variance and F test. All these tests show that the model is significant statistically to a level of 95% or more. When combined with Eq 2, a complete relationship can be given as:

$$CaO_f = 0.33\ LSF + 1.68\ SM + 0.59\sqrt{R_{90}} - 35.1 \quad \ldots\ldots\ldots [4]$$

Free lime values calculated using this relationship are tabluted under CaO(3) in table 2. The differences between experimentally determined and calculated free lime values for various samples are listed in the last column of table 2. Scatter diagram of calculated free lime values [CaO(3)] verses experimentally measured free lime [CaO(1)] content is shown in Fig. 1. Taking a critical value of 1.0%, it is observed that the predictions in most of the cases are in line with experimental observations.

CONCLUSION

A statistically significant model, valid over a wide range of compositional and fineness variations for calculation of free lime in clinker has been developed. The model does not explicitly take into account the influence of minor constituents but implies their influence over normal range of their occurence in clinker. The residue of raw mix on 90 um sieve is found to be a significant parameter for calculation of free lime. The relationship has been developed for a firing temperature of $1400^{o}C$ and 30 min. duration, but free lime content at other durations can be calculated using mathematical formulations of kinetics of clinkerisation.

THE LIQUID PHASE ALITE GENERATION MODEL IN SINTERING PORTLAND CEMENT CLINKER

Zinovii B. ENTINE, Boris E. IOUDOVITCH,
NIICement, Moscow, Russia

ABSTRACT From XRDA, IRS and ferromagnetography of the sintered and quickly cooled raw mix samples, an alite generation model in the presence of liquid phase has been worked out.

Key-words: Clinker formation. Mechanism. Melt. Glass. Mineralogy.

INTRODUCTION

Some facts in the genesis of clinker phases are impossible to explain by taking into account only one reaction for alite formation: $C_2S + C = C_3S$. Among them these are the decrease of C_3A content to nothing and consequent rise up to its potential level in the presence of clinker melt (Entine et al.,1978), the appearance of $C_{12}A_7$ and its disappearance (Sapozhnikova, 1983) and the analogous behavior of calcium ferrites (Nikolaev, 1985). The objective of this investigation was to develop an alite generation model originally to explain these facts.

EXPERIMENTAL AND METHODS

For clinker burning a vertical tube electric kiln was used with Pt-heating winding of variable steps. This kiln had a stable vertical temperature distribution in the interval from 1100 to 1450$\pm$ 0.5°C on the height levels range about 250 mm with each level fixed within 0.1 mm by means of microcathetometer. It had a Pt crucible to contain the cement raw mix sample (upto 3 g / space) hung by a Pt-thread along the kiln axis. Rupture of said thread guaranteed quick cooling of the crucible in a cup of Hg under the kiln. The higher burning temperature demands a shorter thread length. The slowest cooling (2 - 3 h.) was achieved by switching off the heating element with the crucible in the kiln. Cement raw mix samples with silicate components - clays, coal ash and its mix, limestone and pyrite ore, were burned in the said kiln for 15 and 30 minutes at constant temperature in the interval of 1100 - 1400°C with the gradation of 25°C. The majority of samples were quickly cooled. With pregraduated scales for X-ray diffraction analysis (XRDA), infra-red spectrometry (IRS) and ferromagnetography instruments for clinker mineralogy composition calculations, the actual content of clinker phases was found. Optical, transmission and scanning electron microscopy and electron microprobe analysis were used for structure studies.

RESULTS

Raw mixes chemical compositions were characterized with lime saturation factor (LSF) by V.A.Kind [= (C - 1,65A - 0,35F)/2,8S] (Duda, 1977) 0.92 $\pm$ 0.005, silicate and aluminate moduli [n = S/(A+F) and p = A/F] are equal to 2.2 $\pm$ 0.1 and 1.3 $\pm$ 0.1 respectively, with average clinker potential composition, %: C_3S 61.5, C_2S 14.7, C_3A 7.4, C_4AF 13. The schematic graphs of content data (weight %) based on XRDA analitical reflections of C_3S, C_3A, C_4AF and free lime, on IRS absorbtion line for $C_{12}A_7$ (Sapozhnikova, 1983) and on ferromagnetography , utilising the much higher permeance of C_2F and CF relative to C_4AF and to a clinker as a whole (Nikolaev,1985), for raw mix with ash and for clinker burned and quickly cooled samples are given in Fig.1.

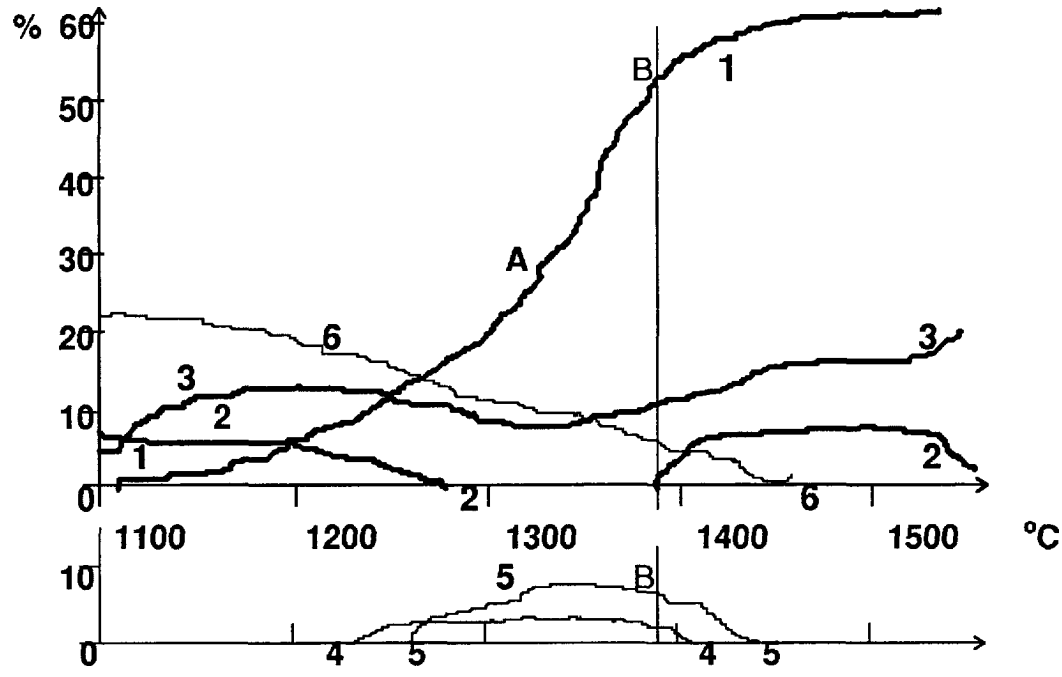

Figure 1 The phase formation in burned and quickly cooled raw mix based of ash
Designations: 1- C_3S, 2 - C_3A, 3 - $C_2(A,F)$, 4 - $C_{12}A_7$, 5-C_2F+CF, 6 - C.

These data show that with quick cooling the C_3A content really decreases from initial extremum (which is almost equal to its potential level) to nought with following increase up to the potential level and so for $C_2(A,F)$ content but with non-zero-minimum as free lime is completely assimilated. In cases of clay or clay + ash based raw mixes, one can see a single difference: the initial extremae of C_3A and C_4AF content are much less than potential levels. In all raw mixes the lower cooling rate accords to the higher minimum values of C_3A and C_4AF contents in samples burned in the temperature interval of 1250 - 1325°C and in this condition the minimum C_3A content is above zero. Simultaneously in this temperature interval the maximum rate of alite generation is obtained (this maximum accords to maximum value of the inclination angle of tangent line on the rising alite content graph - point A on Fig.1). When C_3A and C_4AF contents decrease are termed the initial extremae the secondary $C_{12}A_7$, C_2F and CF rise; that is evident from ISR and magnetography data. The last phases, which marginal (below) have no visible XRDA reflections that testifies to their noncrystalline form. After the burning temperature increases to 1350 - 1400°C the marginal phases content in quick cooled samples decreases gradually to zero. Simultaneously the lower cooling rate corresponds to lower contents of the marginal phases and to the higher alite content.

DISCUSSION

All data obtained are in accord with the next two pairs of equations, defining a the cyclic conjugate reversible reaction model:

$$9\ C_2S + 7\ C_3A \Leftrightarrow 9\ C_3S + C_{12}A_7, \quad [1]$$

$$C_{12}A_7 + 9\ C \Leftrightarrow 7\ C_3A. \quad [2]$$

$$6\ C_2S + 7\ C_4AF \Leftrightarrow 6\ C_3S + C_{12}A_7 + 3\ C_2F + 4\ CF, \quad [3]$$

$$C_{12}A_7 + 3\ C_2F + 4\ CF + 3\ C \Leftrightarrow 7\ C_4AF. \quad [4]$$

The conjugation of reactions within said pairs and among them is determined by the condition that one or more reaction products are the reagents for next and previous reactions. This model also takes into account: 1) the marginal phases appearing in the course of alite generation by the reason of the lower rate of reactions in Eqs 2 and 4 compared with reactions in Eqs 1 and 3 accordingly, especially in the initial part of temperature interval (1100°C - point A); 2) their disappearance when the degree of reactions in Eqs 1 and 3 is more than 70-75% in consequence of decreasing the rate of last reactions compared with reactions in Eqs 2 and 4; 3) the coincidence the minimae of C_3A and C_4AF content with point.A - maximum rate of alite generation; 4) the greater rate of reactions in Eqs 1 and 2 versus reactions in Eqs 3 and 4 and, as a consequence, - shift in the position of point A and an aluminate character of clinker melts in the range of 1100 - 1225°C, has been reported (Konovalov et al.,1962) and in our case is obtained from observing the refractive index of cooled melt particles in immersion probes by optical microscope; 5) sumultaneous formation of secondary $C_{12}A_7$ in the reaction pairs, beginning in the first of them, and secondary C_2F and CF in the second pair. It can be noted that this point has been known long ago (Bogue, 1955): in ferrous systems, C_2F + CF are analogs for $C_{12}A_7$+C_5A_3 in alumina systems. Moreover, the $C_{12}A_7$ is evolved from the melt with excess of oxygen content compared to its stoichiometrical composition (Taylor, 1990), just as the C_2F and CF have the oxygen deficiency in the same sense. That may be one of reasons for the simultaneousness of these marginal phase formations; the redox conditions in the kiln, namely in the clinker melt, must play a decisive part; 6) reactions in Eqs 1 - 4 are reversible: in Eqs 1 and 3 - with slower cooling than 1 hours from 1300 to 1175°C, in Eqs 2 and 4 - with slower heating of the kiln than 1-2 hours at 1350 - 1450°C and shorter - at the higher temperature range. These are the reasons why alite dissociation occurs without free lime crystallisation in slowly cooled clinkers and clinker glass pellicles (with thickness of 1 ÷ 3 μm) formation around crystals in overheated and quickly cooled clinkers which one can see by means of electron microscopy; 7) by electron microprobe analysis of clinker ferrous phase in the layer with thickness of about 1 μm around the part of alite crystals one cannot fix some iron; it would be concluded that these alite crystals are formed by reactions in Eqs 1 and 2 and the rest are alite crystals formed by reactions in Eqs 3 and 4; 8) the complex of such phenomena is impossible without dissociation of all reagents in the melt to ionic groups which are well preserved as anionic fragments particularly of the annular frameworks of crystal lattices (Taylor, 1990); 9) Impurities influence these reactions and cause some accessory reaction` schemes:

$$3\ C_{12}A_7H \Rightarrow 7\ C_5A_3 + 3H\uparrow + C, \qquad [5]$$

where $H = H_2O$, with excess of oxygen in the melt, and then

$$7C_5A_3 + 28\ C \Rightarrow 21C_3A, \qquad [6]$$

$$C_5A_3 + 3\ C_2F + 15\ C \Rightarrow 18\ C_3A + 3\ C_4AF. \qquad [7]$$

Reactions in Eqs 6 and 7 may be the direct reason for said alite dissociation because of the large lime demand; and so the reaction which had found by Boikova et al (1976) at the presence of much alkalies without sulphate equivalent ($R=Na_2O_e = Na_2O+0{,}66K_2O$):

$$3\ C_{12}A_7 + 20\ C + 7\ R \Rightarrow 7\ RC_8A_3. \qquad [8]$$

Now we use `` $RC_8A_3$`` as a designation of alkalies contained forms of tricalcium aluminate.
The binding of C by the last reaction is the reason why the free lime cannot be used as a measure of clinker burning degree in such cases.

This model is used to explain how plant kiln condition variations affect clinker (cement) characteristics, e. g.: 1) the presence of marginal phases in underburned clinkers (see, for example the line B, Fig. 1), sometimes with small amount of free lime but the result is bad cement quality; 2) the presence of two alite forms (e.g. polymorph modifications) with different sets of impurities; 3) simultaneousness of FeO and C_2F+CF formation in sintering underburned or overburned clinkers (in the last case, as a consequence of the inverse course of Eq 4 etc.) with generation of C_2F+CF especially in the cases of p = A/F < 0,8 in raw mix that provokes the clinker dusting in rotary kilns by decreasing the melt viscosity which decreases the hydration rate of cement because of deficiency of electron vacancies in the crystal lattices of the clinker phases (Chatterjee et al.,1964); 4) cases of cement false set, created by presence of $C_{12}A_7$ or RC_8A_3 in clinkers; 5) low frost and chemical resistance of concrete in the presence of marginal phases in cement at the level higher than 1-2% because of direct and undirect negative influence of them upon the cement hydration rate and degree and the structure of hardened cement pastes, mortars and concretes.

CONCLUSION

This model is fully coordinated with phase relations in system CaO - Al_2O_3 - SiO_2 etc. Moreover, Toropov (1956) had written an equation close to Eq 1 only on the base of deep analysis of the Rankin -Wright phase diagram of the relevant system. But at that time he was not supported by colleagues. The present model had been firstly suggested as a working hypothesis about eighteen years ago for explaining such sets of data as given in Fig. 1 and used by us for improving clinker burning process and cement quality - practically without publications but as well as without any contradictions with practice in cement plant and cement customer works. After Zhmoidin - Chatterjee reported (1986) pseudomolecular annular structures in some slag melts it becomes possible to conclude that this phenomenon can exist in clinker melts. The experimental arguments for this point of view have been obtained (Zubekhine, Ioudovitch, 1996). All that rather improves the scientific base of the present model but a better understanding of the role of redox and of the role of impurities in clinker melts is needed for the development of these models.

INTERRELATIONSHIP OF CLINKER PROPERTIES WITH PROCESS PARAMETERS IN COAL FIRED KILNS

V.K. GORE, S.A. KHADILKAR, P.G. LELE, D. GHOSH
Research & Consultancy Directorate
The Associated Cement Companies Ltd.
Thane - 400 604, INDIA

ABSTRACT The Indian Cement Industry is characterised by the use of limestones of widely differing geological age and consequently vastly differing mineralogical and microstructural characteristics on one side and use of coal of different geological age and characteristics on the other that include the variation in the ash content from 15 to 40% and volatiles from 20 to 40%. These input variations, when coupled with different processes operating in plants, create situations where the interrelationship of clinker properties with process parameters turns out to be a complex phenomenology. In this complexity, an attempt has been made, based on a large number of operational data of industrial kiln systems to isolate the variations in some of the critical coal characteristics and limestone mineralogy on the clinker mineralogy and microstructure. A few case studies have been discussed where the interrelationship between clinker properties and process parameters were used for process optimisation.

KEY-WORDS Limestone, Coal, Process parameters, Microstructure, Reactivity.

INTRODUCTION

The Cement manufacturing in the present hardware systems and with use of diverse fuels and raw materials is a complex process. Only parametric interrelations, however emperical, can only ensure stable operation. Based on this concept the operational data base of the company has been used to study the parametric interrelations.

The input variations of coal and limestone characteristics due to their source, coupled with different processes of cement manufacture lead to certain implications in terms of raw mix design and processing conditions, imprints of which are revealed by the microstructural characteristics of clinker. In this complexity the authors have made an attempt to identify certain practical interrelationships that might be of direct use in material selection, process optimisation and trouble shooting.

CATEGORISATION OF LIMESTONE AND COALS

Categorisation Of Limestone

Attempts have been made to categorise the limestones through use of a chemical index; termed as the hydraulic modulus (C+M)/(S+A+F). The limestones were observed to get categorised into three clusters each representing the geological ages of the limestone deposits

Cluster-A : Tertiary deposits HM in the range of 4.0 to 6.8
Cluster-B : Vindhyan deposits HM in the range of 2.2 to 4.7
Cluster-C : Archaean deposits HM in the range 1.8 to 2.4

Other chemical indices viz (C+M)/S, (C+M)/(A+F) and silica modulus have also been used to indicate the nature and type of correctives that would be required for use of these limestones for cement manufacture (Fig. 1) The chemical, mineralogical, microstructural and physico-mechanical characteristics of the three clusters is summarised in Table 1 The following inferences can be drawn from the illustrated features.

The quality of limestone shows a deterioration from Tertiary to the Archaean formations The tertiary deposits with (C+M)/S ratio of 5.7 to 11.4 and a lime to flux ratio (C+M)/(A+F) of 11.3 to 23.1, would require high siliceous and ferrugenous correctives while in the Archaean formations with (C+M)/S ratio of 2.1 to 2 8 and lime to flux ratio of 11.3 - 13 9 use of high grade limestone and aluminous/ferrugenous correctives would be a necessity. Lower HM values for the Archaean formations illustrate that these deposits would invariably require beneficiation

The decrease in HM values from Vindhyan to the Archaean deposits is indicative of an increased metamorphism and higher extent of basic and acidic intrusions

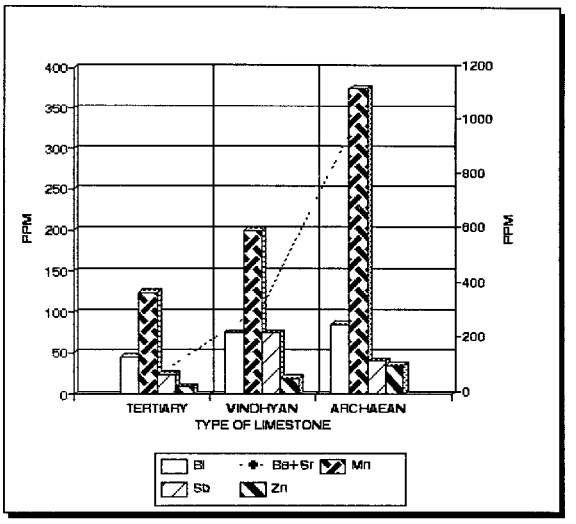

Fig. 1 : Compositional Characteristics of Limestones.

Fig. 2 : Distribution of Trace Elements in Limestone

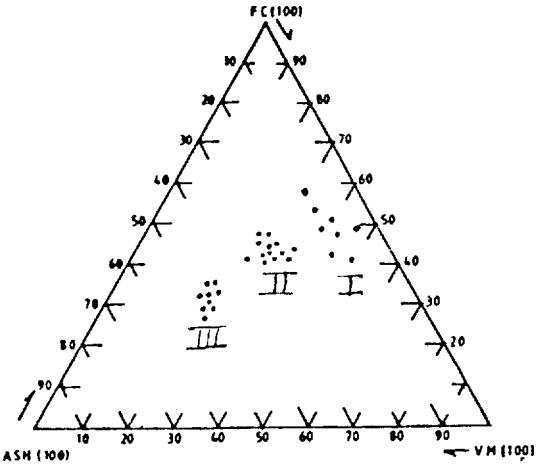

Fig . 3 Ternary Diagram of Coals

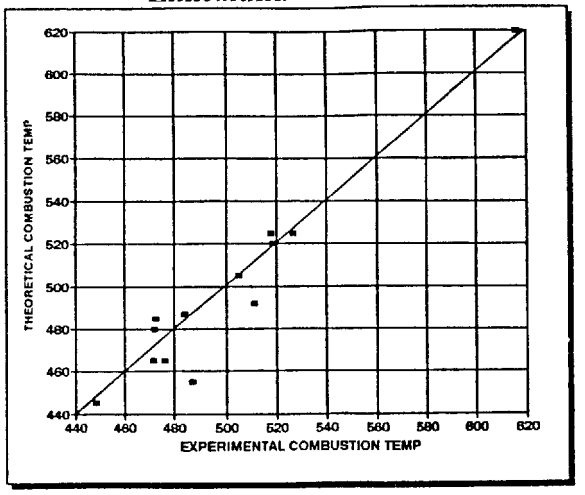

Fig . 4 Relation between Theoretical and Experimental C.C.T

This is also indicated by the increase in crystal size of Calcite and Quartz, increase in Bond grindability index and Wear index of the limestones of these deposits. The trend of metamorphism from Tertiary to the Archaean deposits is also exemplified by the relative increase in levels of the trace elements viz. Ba, Sr, Mn, Bi and Zn. (Fig. 2) from Tertiary to the Archaean deposits.

Categorisation Of Coal : The Indian coal formations are called the Gondwana coals named after the hypothetical supercontinent Gondwana. The coals are of drift origin with high mineral matter contents, thoroughly disseminated. Some mesozoic and tertiary coals are also found in the country. Using a ternary plot of VM, FC & Ash content of coals (Fig.3),attempt have been made to classify the coals into three groups.

Group I : Tertiary
Group II : Upper Gondwana
Group III : Lower Gondwana

Ultimate, proximate composition of coals, Hardgrove index, Ash fusion temperature, volatile combustion temperature and complete combustion temperatures are summarised in Table 2. The volatile combustion temperature and complete combustion temperatures were determined by DTA analysis. The **Complete Combustion Temperature** being the temperature at which the entire carbonaceous content of coal gets burnt.

It is evident form the data that :

- Group I (Tertiary) coals have higher VM, fixed Carbon, Calorific Value with lower ash content. As Hydrogen content of these coals is higher, there is a decrease of H/C ratio which is related to increase in aromaticity of the coals. Such characteristics are associated with High volatile bituminous coals, i.e. higher rank coals tending towards the anthracitic ranks. Expectedly such coals would possess higher complete combustion temperature.
- Group II & Group III are coals representative of the general coals of Upper & Lower Gondwana in which the coal seams are invariably interbedded with sandstone and shales of sedimentary origin. Such coals have highly fluctuating VM, not necessarily related to the calorific value.
- The Ash fusion temperature(AFT) of all the coals illustrate a high relation to the oxide composition of coal ash. Statistical analysis of the data reveals that the correlation could be exemplified by an empirical relation given below :

$$\mathbf{AFT(deg\ C) = 21.92\,SiO_2 - 2.92Al_2O_3 + 31.56Fe_2O_3 - 399.15Na_2O + 32.877SO_3 + 11.865CaO + MgO + 101.61K_2O} \quad [1]$$

- The data base on coal was also used for multilinear regression analysis to understand the factors influencing the complete combustion temperature of coal. The statistical analysis indicate that VM, Carbon content, % free carbon. (Fixed Carbon - Elemental Carbon/Fixed carbon), Hydrogen content, Sulphur content and combustion temperature of volatiles(C.T.V), have a strong relationship with complete combustion temperature, as indicated by correlation coefficient of 0.975. The correlation can be represented by an empirical equation which would be applicable to any rank of coals.

$$\mathbf{Complete\ Combustion\ Temp\ (^{\circ}C) = 1.7117\,C + 1.5367VM + 5.3276\ Free\ C + 11.013H_2 + 11.3045S + 0.8284C.T.V - 418.46} \quad [2]$$

The theoretically predicted values and experimentally determined values of Complete Combustion Temperature are graphically shown in Fig. 4

- Trace element distribution (Table 2) indicates that the distribution of these elements is more a function of the type of mineral deposits in the vicinity of the colliery rather than the age or rank of coals.

INTERRELATIONSHIP OF COAL AND LIMESTONE CHARACTERISTICS

The type of limestone and coal use by plant would substantially influence the raw mix design, selection of communition hardware and process parameters of cement manufacture. These influences would get eventually reflected in the mineralogical, microstructural characteristics of the clinker. In earlier publications from the authors laboratory (Hargave et al 1983,1985) attempts were made to evolve microstructural indices of clinker to assess the effect of different processes of

cement manufacture and also to relate these indices to the hydraulic potential of the clinker(Venkateswarn. et al 1991). Some of these microstructural indices are also influenced by the mineralogy and microstructural characteristics of limestones and quality of coal. In these case studies discussed below an attempt has been made to isolate the variations of coal and limestones characteristics to assess the influence on clinker mineralogy and microstructure.

CASE -1: This case study relates to Plant-A with limestone of the tertiary deposits (Chemical composition in Table-3) using Group II Coal (Upper Gondwana) having average ash content 25.9% and Ash fusion temperature of around 1420 deg C. The plant is a dry process plant of capacity 3000 TPD with suspension preheater and pre calciner. The clinker composition and microstructural features are given in Table-3. The microstructural studies reveal the following:

- Phase index of 1.38 is indicative of higher content of C_3S formation and also reflects on higher reactivity of the limestones.
- The morphological index(MOI) of Alite and Belite are 4.4 and 0.9 respectively which is indicative of good crystallinity of the silicate phases.
- The chord length index value is 6.0 which is indicative of easy grinding characteristics of the clinker.
- Cluster size of 0.23 mm is indicative of lower crystal size of quartz in limestone and homogeneous distribution of coal ash. This is also further substantiated by lower cluster frequency observed.

CASE-2 : This case study relates to Plant B having limestone similar to Plant A but using Group III coal with ash content in the range of 35 - 38%. The plant is also a dry process plant with suspension preheater and precalciner of comparable capacity. Thus primarily the plant differs from Plant A in terms of quality of coal used. The microstructural indices are summarised in Table-3. Trials carried out at the plant using Group-I Coal (C-1) with ash content of 11.8%, VM of 29.7 %, CV 6422 cal/g indicated a change in the microstructural indices of the clinker which reflect on suitability of microstructural indices for assessing the effect of coal characteristics.

- The phase index of the Plant B clinker (2A) with Group III coal was 1.00 with morphological index of alite and belite being 3.0 and 0.5 respectively with Cluster frequency of 0.25 mm and cluster index of 0.2. The chord length index was observed to be 1.77.

With use of Group-I coal the microstructural indices of the clinker (2B) were MOI of alite and belite 4.2 and 0.8 respectively with cluster size of 0.25 and cluster frequency of 0.2. The chord length index was 8.8.

It could be noted here that use of Group-I coal have resulted in clinker microstructural indices similar to Plant-A, thus modification in clinker quality characteristics could be achieved by the change in quality of coal.

CASE-3: This case study is of a semi wet process plant with suspension preheater and precalciner of capacity 2500 TPD(Plant C) .The Plant uses limestone of Archaean deposits having higher extent of free silica content and coarser sizes of Calcite and Quartz. However, the plant also uses floated limestone, the extent of requirement of the floated

limestone depending on quality of coal. The plant presently uses coal of Group-II and trials were conducted with two coals of Group-I variety (C-1 & C-2), C-2 coal was of higher rank with higher complete combustion temperature. While the other coal C-1, was similar to the one used in the trials at plant Group-I coal used at Plant-B.With use of coal with higher combustion temperature (C-2) the plant reported number of processing problems:

- The coal mill outputs were decreased substantially.
- Fine coal residues on 90 microns were higher.
- Reducing condition were observed at the Kiln inlet which accelerated the formation of coatings/build-ups at the kiln inlet and preheater cyclones which affected the pyroprocessing operations

These processing problems were subsequently diagnosed to be due to (a) Poor grindability of the coal (Hard Grove Index 45).(b) Lower ash fusion temperature (1370-1400 ^{0}C). (c) Higher complete combustion temperature of coal (620 ^{0} C)

While use of the other variety of Group-I coal the clinker indices showed drastic changes (Table-3) and inspite of the use of limestone of Archaean deposits the clinker quality was compared to Plant A/B clinkers. Use of this quality coal not only improved the kiln performance but also resulted in substantial decrease in floated limestone consumption.

CASE-4: This case study relates to a cement plant (Plant D) using the same limestone (Vindhyan) in semi dry process (Lepol grate) and dry process with suspension preheater and precalciner using Group-II quality of coal. The microstructural indices of the clinkers exemplifies the effect of process of cement manufacture (Table-3).

- The semi dry process clinker exhibit lower values of morphological indices of alite and belite and although the ash absorption is lower in the semi dry process and Quartz size is not coarse in limestone, the cluster size and frequency observed is 0.4 mm and 0.4% respectively, which is indicative of localised ash absorption. On the contrary, the dry process clinker exhibits higher phase index, lower cluster size and frequency and higher values of morphological indices of alite and belite indicative of better crystallinity of silicate phases.

BEHAVIOUR OF TRACE ELEMENTS IN DIFFERENT PROCESSES OF CEMENT MANUFACTURE

In the different case studies presented in this paper, the trace element concentrations in the clinker if compared with that of the raw materials and fuel (ash). The following observations can be made on trace element behaviour :

- Concentration of Ba, Sr in the clinker do not exhibit any enrichment in clinkerisation process
- Concentration of Cu, Zn, Sb and Pb were observed to be higher in clinker as compared to the limestone and coal ash. The order of the degree of enrichment of these elements being Pb > Sb > Cu > Zn. The trend is indicative of volatile cycle of these elements in the kiln system. The enrichment is relatively more in dry process and semi wet process (Plant A, B & C) than in semi dry process (Plant D - 4A clinker) where kiln dust was not circulated.The authors have presented in detail the behaviour of trace elements in different processes in earlier publications(Khadilkar et al 1993)

CONCLUSIONS

- The Indian limestones categorised on the basis of Hydraulic Modulus tend to get clustered as per the geological ages. The other chemical indices can be resorted to for choice of correctives.
- The trace elements distribution in limestone has been observed to be related to the metamorphism of the limestone deposit.
- The Indian coals of Gondwana origin can be clustered based on Ternary plots of VM,FC and ash content, this clustering have been observed to be also related to ranking of coals.
- Empirical equations have been derived for prediction of Ash fusion temperature of coal ash, and Complete combustion temperature of coal. These parametric interrelations could be used for optimising pyroprocessing conditions and quality of clinker produced.
- Microstructural Indices of clinker have been used to exemplify the influence of limestone and coal characteristics coupled with cement manufacturing processes.
- The trace elements Ba and Sr do not exhibit tendency of forming volatile cycles, while Cu,Zn, Bi and Pb have been observed to show such a tendency. The extent of enrichment of these elements in clinker depend up on the type of process and volatility of other volatiles like Na_2O,K_2O and SO_3.

EFFECT OF COARSE QUARTZ AND LIMESTONE GRAINS ON THE PROPERTIES OF RAW MEAL, CLINKER AND CEMENT

László SAS,
CEMKUT Kft - Cement Research & Development Ltd.
Budapest, HUNGARY

ABSTRACT
In the course of laboratory and plant experiments and starting from different raw materials the effect of coarse (45, 80, 150, 300 μm) quartz and limestone grains on the burnability of raw meal, on the textures of clinkers and on the strength of cements was investigated. It was stated that the quality deteriorating effect of coarse quartz grains is much stringer than that of the limestone grains. The presence of coarse quartz grains deteriorates directly the burnability of raw meal and the texture of clinkers, and indirectly the strength of cements.

Key-words: Burnability of raw mixes, Clinker, Texture, Strength, Limestone, Quartz

INTRODUCTION
The research aimed at the investigation of the relationships between grinding fineness, grain size distribution, lime saturation, reactivity and burnability of raw meal produced from raw materials of different origin and the clinker microstucture with special regard to the effect of quartz and limestone grains of supercritical size.

LABORATORY EXPERIMENTS
The chemical, mineral and microstructural peculiarities of two raw materials deriving from two cement factories (limestone, clay) were studied since the differences among these peculiarities may affect the features of raw meal produced from them (grain size distribution, reactivity etc.). Raw meals of different lime saturation and grinding fineness were produced from these raw materials and the features of burnability of the raw meals were studied. Subsequently, the effect of raw material particles of supercritical size (quartz > 45 μm; limestone > 150 μm) on the burnability of raw meals and on the clinker microstucture was investigated. Limestones and clays deriving from two different cement factories were marked by I. and II.

Investigation of the raw materials
The chemical composition of limestones, clays and of the auxiliarily used pyrite cinder was analyzed (Table 1), the petrographic characteristics of limestones were studied under optical microscope in thin sections (Figs. 1 and 2), while the mineral composition of clays was studied by X-ray diffraction (Table 2).

Table 1.
Chemical composition of limestone, clay and pyrite cinder

Components, %	Limestone I	Limestone II	Clay I	Clay II	Pyrite cinder
Ignition loss	43.05	41.36	10.27	9.65	2.08
SiO_2	1.48	5.62	58.17	62.27	3.14
Al_2O_3	0.61	1.16	13.01	12.34	0.76
Fe_2O_3	0.28	0.46	5.03	4.60	84.76
CaO	54.36	50.71	6.69	5.07	7.19

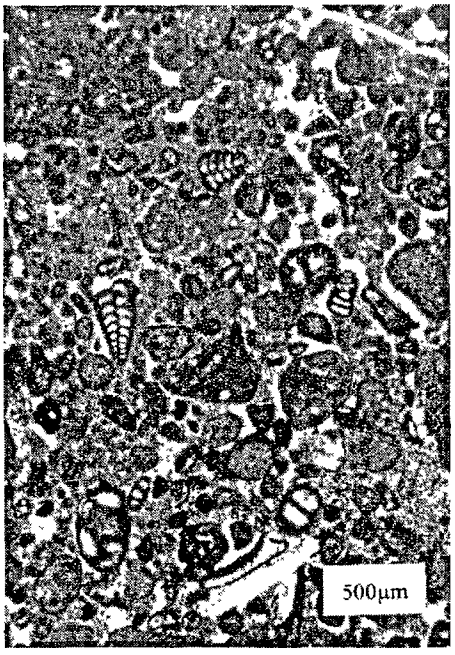

Fig.1
Texture of the limestone I

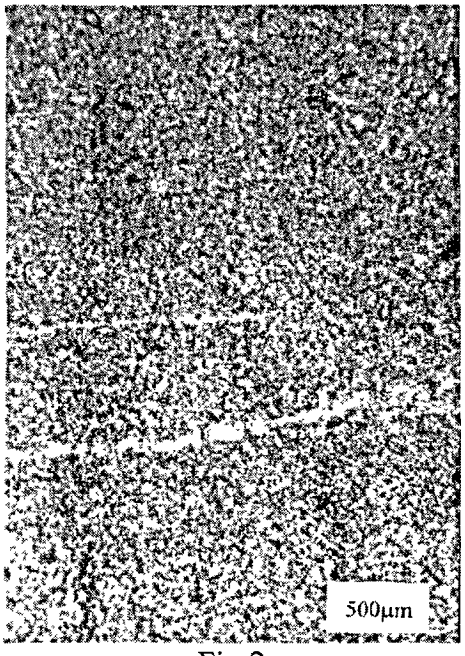

Fig.2
Texture of the limestone II

Table 2.
Mineral composition of the clays

Component, %	Clay I	Clay II
quartz	33	38
calcite	9	10
dolomite	6	2
feldspar	8	6
illite	14	12
montmorillonite	5	8
kaolinite	7	11
amorphous	18	13

It can be stated that limestones are pure and of high calcite content. Sample I is a compact Lower Cretaceous limestone containing intra- and bioclasts while Sample II is a compact Triassic limestone of recrystallized texture. As a result of mechanical effects the limestone I disintegrates to greater grains (~ 0.2 mm). As regards the chemical and mineral compositions of clays, these are rather similar, the quartz content of sample II is somewhat higher.

Effect of grinding fineness and lime saturation on the burnability of raw meals

Raw meal mixtures of different lime saturation (LSF = 90, 94, 98) but of the same silicate modulus (SM = 2.45) were produced and ground in laboratory mills to different specific surface (Blaine number: 4000, 5000, 6000 cm^2/g), respectively. The grain size distribution and burnability features of these raw meals were studied. To characterize the grain size distribution the parameters of the RRSB equation were used ($\bar{x}$ - fineness number; n - factor of uniformity). As an example, in Table 3. the results of raw meals of LSF = 94 and Bl = 5000 cm^2/g are shown, the values being characteristic of other samples, as well. Results of burnability analyses are shown in Fig.3.

Table 3.
Grinding fineness and grain size distribution of raw meal milling products
(in case of LSF = 94, Bl = 5000 cm2/g)

Raw materials	Moduli	Parameters of the RRSB equation		Specific surface
		n factor of uniformity (-)	$\bar{x}$ fineness number (μm)	(cm^2/g)
I.	LSF=94 SM = 2.45 AM = 1.40	0.7068	26	5000
II.	LSF=94 SM = 2.45 AM = 0.97	0.8250	21	5000

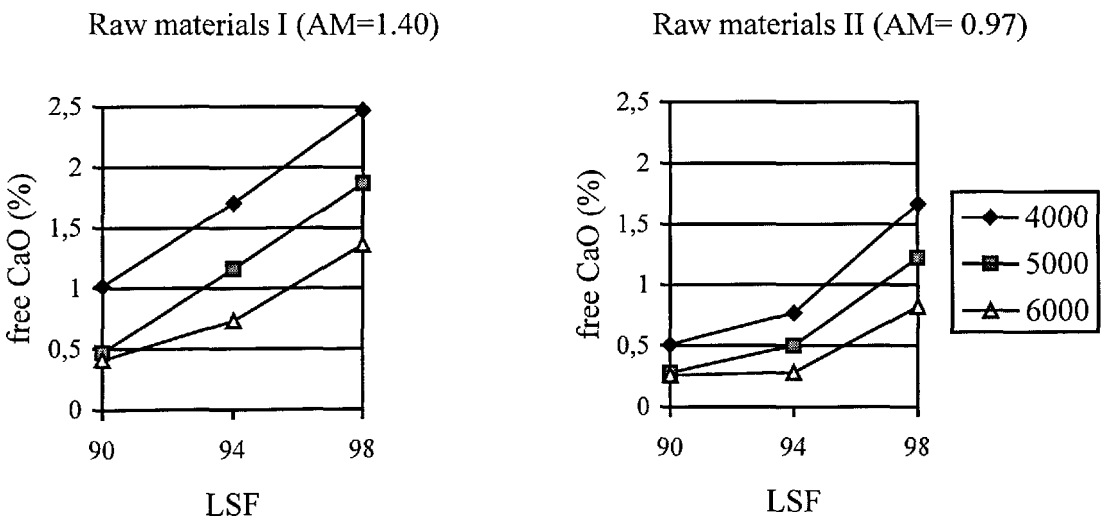

Fig.3.
Results of burnability tests of raw meals produced from the raw materials I and II
(Blaine number: 4000, 5000, 6000 cm^2/g)

It can be stated that in case of limestone II of recrystallized texture a raw meal milling product of "narrower" grain size distribution (n) and finer state ($\bar{x}$) can be produced in case of raw meal of all sorts of grinding fineness.
Further, it can be stated that those raw meals produced from raw materials II are of more favourable burnability features. The free CaO content of raw meals I increases nearly linearly with lime saturation, while in case of raw meals II this hardly changes up to LSF = 94, then it begins suddenly to increase.

Effect of quartz grains of supercritical size (> 45 μm)

Having used the raw materials I and II mixtures were produced for experiments from which when adding 1 % quartz the raw meals of lime saturation and silicate modulus studied above can be produced. Mixtures were ground to 5000 cm^2/g specific surface and 1 % quartz was added.

Quartz fractions were produced by grinding and fractionation of "normal sand". Quartz fractions of four different grain size were added: ~ 45 μm; ~ 80 μm;~150 μm and ~300 μm. The effect of 1 % quartz fractions on the burnability can be seen in Fig.4.

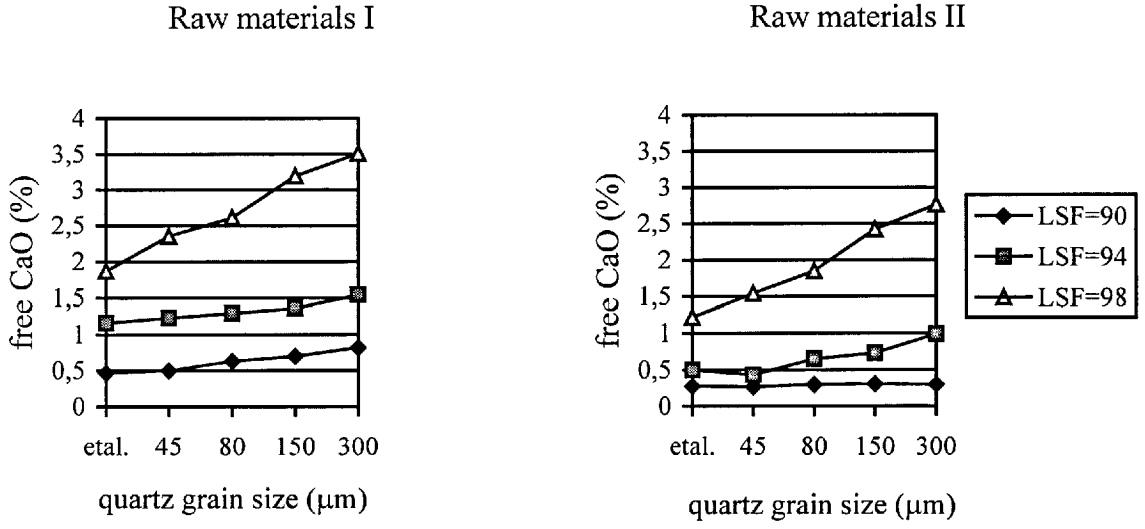

Fig.4.
Effect of quartz grains of different size on the burnability of raw meal

It can be stated that the quality deteriorating effect of quartz grains of supercritical size increases parallel with the increase of lime saturation, in case of raw meals of high lime saturation the presence of coarse quartz can be considered to be harmful. Quartz grains of different size have had nearly the same effect in case of different raw materials.

Investigations under optical microscope (Champbell, 1986) and literature data (Dorn, 1978, 1980) proved that quartz grains of 45 μm grain size do not result in observable changes. Grains greater than 45 μm generate nearly the same changes in case of different raw materials. Parallel with the the increase of quartz grain size the dimension of the developing belite clusters also increases.Quartz grains of 80 μm generate 150-250 μm belite clusters, those of 150 μm 200-300 μm ones while from the 300 μm quartz grain a belite cluster of 400-900 μm is generated. Parallel with the increase of belite clusters the appearance of "nests" becomes characteristic, i.e. in the centre of the belite cluster a hole is developed that was the locality of the reacted and absorbed quartz grain. Belite clusters are often interconnected forming continuous belite regions. Belite clusters can be considered as phases poor in lime since the CaO needed to the formation of alite cannot enter the belite clusters and react within them. Thus, in the phases abundant in lime the quantity of free CaO increases.

In Figs. 5 and 6 belite clusters of ~600 μm developed from quartz grains of 300 μm can be seen. In Fig.5 an unreacted quartz is seen in the centre of the belite cluster that is surrounded by closely pressed belite crystals of ~100 μm (there is practically no "intermediate phases"). In Fig.6 three types of belite clusters can be observed: 1 - belite "nest" in the centre of which a pore is seen; 2 - belite cluster with unreacted quartz in the middle; 3 - belite cluster consisting of closely pressed crystals.

It can be stated that a belite cluster is formed from the quartz grain of supercritical size the diameter of which is twice and half times greater than that of the quartz grain (>45 μm) and this means a volume of increase of 8-15 times.

Fig. 5.
Belite cluster forned from quartz particle of 300 μm (LSF=94)

Fig. 6.
Belite clusters of different type from quartz particles of 300 μm (LSF=94)

Effect of calcite grains of supercritical size(>150 μm)

The experiment was performed similarly as described above the only difference was that 1 % calcite of different size was added to the suitably composed and ground raw meals. The different calcite fractions were produced from the limestone II. The effect of 1 % calcite fractions on the burnability can be seen in Fig.7.

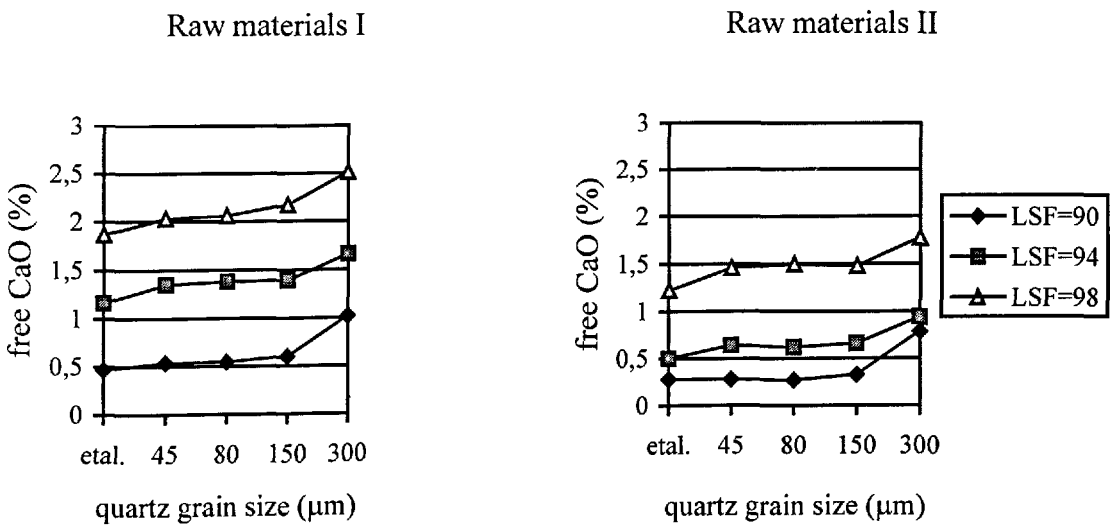

Fig. 7
Effect of calcite grains of different size on the burnability features

It can be stated that calcite fractions of 45, 80, 150 μm size do not affect remarkably the burnability features. The calcite fraction of 300 μm size slightly deteriorated the burnability in all cases.
The effect on burnability and clinker microstructure is rather similar in case of different raw materials.
Investigations under the optical microscope proved the grains of 45 and 80 μm size do not alter the textural peculiarities. When adding limestone grains of 150 and 300 μm size the quantity of free CaO increases parallel with the increase of saturation factor. In samples of low lime saturation the free CaO can be observed as free CaO clusters of 150 and 300 μm size developed from the coarse limestone. Parallel with the increase of lime saturation the quantities of "racemose" and individual free CaO clusters are also increasing, in addition to that of the "clusters". Consequently, free CaO clusters of nearly the same size develop from the limestone grains of supercritical size (Fig. 8).

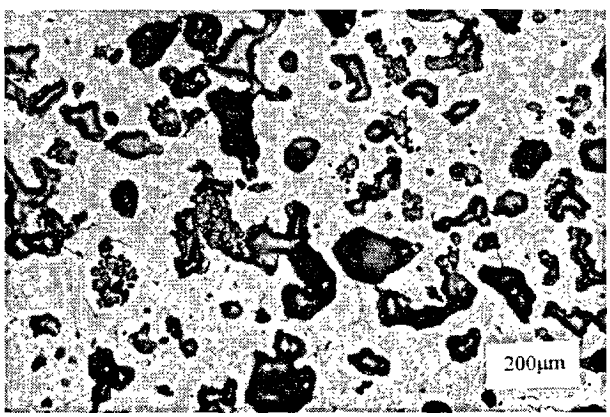

Fig.8
Free CaO cluster and "racemose" free CaO formed from limestone grain of 150 μm (LSF=98)

PLANT EXPERIMENTS

In the course of experiment furnace meal of different silicate modulus but of the same lime saturation was produced under plant conditions (DCM Ltd/Vác/Hungary - 2700 t clinker/day), from which clinker was burnt and cement was ground. The peculiarities of furnace meals, clinkers and cements were studied.

Furnace meals

The chemical composition, grinding fineness, the quartz content of coarse fractions as well as the burnability features were studied. Results are seen in Table 4. The Zeisel grindability of clinkers burnt from furnace meals can be seen in Fig.8.
Cement was ground from clinkers under plant conditions, in the same cement mill, under the same wind separation conditions and of the same specific surface (Blaine number: 3200 cm^2/g). Results of compression strength tests of these cements are seen in Fig.9.

Table 4.
Main characteristics of furnace meals

		Sample sign		
		L I	L II	L III
Moduli	AM	1.55	1.63	1.73
	SM	2.51	2.20	2.08
	LSF	100.6	100.6	100.3

Burnability test				
free CaO	%	5.28	4.38	3.89

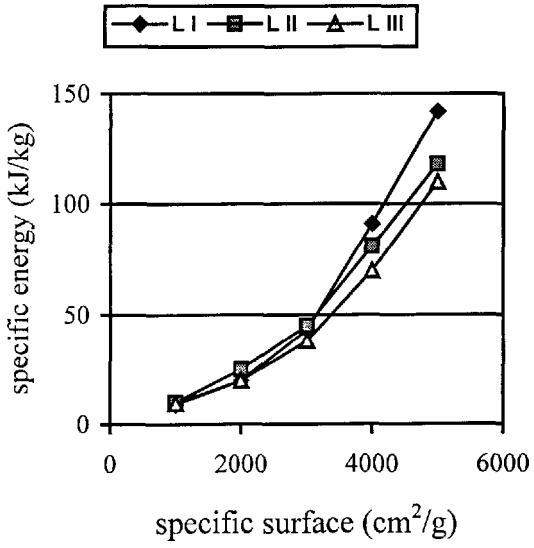

Fig.9
Grindability test by the Zeisel method

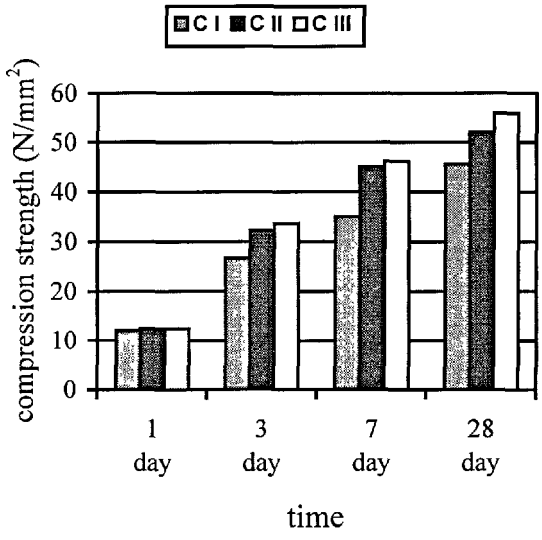

Fig.10
Results of compression strength tests of cements

It can be stated that the quartz content unfavourably affects directly the burnability of furnace meals and the grindability of clinkers, while indirectly the strength of the cements.
In the course of clinker burning the degree of completion of clinker formation processes is controlled by the analysis of free CaO content. In the course of burning furnace meals with large-sized and high quantity quartz this may be misleading. The lime saturation of belite clusters forming from the quartz crystals proceeds slowly and in a complicated way. When the quartz quantity increases in the furnace meal and it is desired to keep the free CaO contents prescribed to the furnace meal of low quartz content, the furnace meal has to be considerably overburnt. This overburning deteriorates the heat consumption of burning and reduces the

lifetime of fire resistant material on the one hand, and reduces the hydraulic activity of alite and belite, increases the danger of swelling due to delayed hydratation of CaO, on the other.
Since among the cement industrial raw materials quartz bears the highest hardness, quartz is responsible for the wearing phenomen occurring in the raw material grinding and transporting equipments.

STATEMENTS AND CONCLUSIONS

Based on the investigations performed the following can be stated:

- Limestones of nearly the same chemical and mineral composition considerably differ from each other and this affects the grain size of raw meals produced from, them and in this way affects their burnability features;
- Parallel with the increasing specific surface and decreasing lime saturation burnability becomes easier, the measure of these changes, however, depends on the starting raw materials;
- Quartz grains of supercritical size unambiguously deteriorate the burnability of raw meals, the grade of which is increased when grain size is growing. In case of high lime saturation the presence of large-sized quartz is harmful;
- Belite clusters of different types and of a diameter twice as large as that of the quartz grains are formed from the coarse quartz grains that form belite regions. Parallel with this phenomenon the quantity of free CaO that cannot enter the belite clusters, also increases;
- Limestone grains of supercritical size less deteriorate the burnability of raw meal than the quartz grains do. Free CaO cluster of nearly the same size is formed from the coarse limestone.

In case of all studied raw materials the addition of 1 % quartz and limestone particles of different size resulted in changes of nearly the same measure and character in the burnability and in the microstructure.
Plant experiments proved that the increase of quartz content of supercritical size in furnace meals unambiguously reduces the burnability of raw meals, the grindability of clinkers and the strength of cements.

EFFECT OF ALKALIS AND SO_3 ON TRICALCIUM SILICATE FORMATION AND MICROSTRUCTURE

Hai Moon CHEONG, Ssangyong Cement Industrial Co. Ltd., Taejon, KOREA
Sang Heul CHOI, Hanyang University, Seoul, KOREA
Ki Sung HAN, Inha University, Inchon, KOREA

ABSTRACT K_2SO_4 was immiscible with oxide clinker melt and could not affect C_3S formation as well as microstructure. The optimal K_2O and SO_3 content was 1.43 of SO_3/K_2O mole ratio. Whereas C_3S crystals with exceeding K_2O were grown round and in a much larger size. C_3S was hindered severely by Na_2SO_4. Since C_2S was stabilized by Na^+ and SO_4^{2-}, it could not react to give C_3S formation. C_3S crystal with Na_2SO_4 had very irregular surfaces and much inclusions.

Key-words : alkali, SO_3, C_3S, clinker formation, microstructure

INTRODUCTION

There have been growing interest in the minor components of clinker because of changes in burning technology, the concern for energy conservation, and strict environmental regulations Minor components derived from raw materials, fuel, refractories and other plant materials can affect not only the reactions of clinker formation but also the hydraulic properties of the resulting cements(Taylor, 1990). Until now, many researchers have been studying the effects of minor components (Moranville-Regourd et al, 1992 ; Moir et al , 1992).

Alkali-and-SO_3-bearing compounds can be found in whole processes of cement manufacturing, preheater, kiln lining, kiln dust, flue gas and storage silo as well as in clinker(Jawed et al, 1977 ; Glasser, 1980). Alkali elements such as K and Na lead to harmful effects on clinkering and hydration properties such as higher clinkering temperature, rapid setting and the strength decrease at later ages. If SO_3 could coexist, alkalis used to react with SO_3 preferentially to form alkali sulfate. SO_3 has been considered as an effective mineralizer which makes the clinker melt at lower temperature, decreases the viscosity and surface tension of the melt and increases the mobility of the ions(Butt, 1974 ; Bucchi, 1980). However, SO_3 has harmful effects on the formation of C_3S at higher SO_3 concentration(Strunge et al, 1985, 1986 and 1990 ; Maki, 1986). The authors reported that the critical amount of SO_3 in C_3S formation was 1.4 wt.% in absence of alkalis(Cheong et al, 1993). Up to the present time, many results for alkalis and SO_3 on the clinker formation and cement hydration do not coincide and especially the relationship between alkali and SO_3 has not become clear yet In this study, the effect of alkali and SO_3 on C_3S formation and microstructure was investigated, using K_2SO_4, Na_2SO_4, K_2CO_3, Na_2CO_3 and $(NH_4)_2SO_4$.

EXPERIMENTAL PROCEDURE

Materials

It was well known that the mechanism of C_3S formation was diffusion - precipitation in which C_2S and CaO were dissolved into the clinker melt(Kondo et al, 1968). In this study, C_3S formation from the reaction of C_2S and CaO in presence of clinker melt was chosen. Synthesis of C_2S and cliker melt were prepared prior to the addition of alkalis and SO_3. C_2S was synthesized by firing the mixture of 2 moles of $CaCO_3$ and 1 mole

of SiO_2 at 1400 ℃ for 3 hours. The clinker melt was prepared by firing the mixture(CaO 54.8, Al_2O_3 22.7, SiO_2 6.0 and Fe_2O_3 16.5 wt%) at 1450 ℃ for 3 hours. The composition and structure of this clinker melt is similar to the interstitial phase of the commercial ordinary Portland cement. As alkalis and SO_3 sources, reagent grades of K_2SO_4, Na_2SO_4, K_2CO_3, Na_2CO_3 and $(NH_4)_2SO_4$ were used. $(NH_4)_2SO_4$ is decomposed to ammonia and SO_3 gas in firing process, so it is regarded as gaseous SO_3.

Synthesis of the clinkers with alkali and SO_3

For the batch mixtures of C_3S, molar ratio of C_2S and $CaCO_3$ was 1 : 1, and 25 wt.% of crushed clinker melt was added. And various alkalis and SO_3 sources were mixed. These batch mixtures were calcined at 1000 ℃ for 1 hour and sintered at 1450 ℃ for 30 minutes, and then cooled rapidly in ambient air.

Characterization of the clinkers

For the characterization of the resulting clinkers, chemical analysis, quantitative X-ray diffractometry, optical microscopy and SEM/EDS were carried out.

RESULTS AND DISCUSSION

Effect of K_2SO_4 and Na_2SO_4 on C_3S formation.

First, effect of K_2SO_4 and Na_2SO_4 on C_3S formation was studied, because alkalis reacted preferentially with SO_3 to form alkali sulfate. The desired content was varied to 6 wt%(SO_3 base). Fig. 1 and 2 are the results of free lime and C_3S formation content of the clinkers sintered at 1450 ℃ for 30 minutes with the various amount of K_2SO_4 and Na_2SO_4. When Na_2SO_4 was added by only 1 wt.%, free lime content increased remarkably. However increasing K_2SO_4 content did not make free lime content increase. With increasing free lime, C_3S content decreases. In case of K_2SO_4, C_3S formation was almost constant. Results of the determination of clinker products by quantitative XRD showed that C_3S was the major phase when free lime was small in quantity.

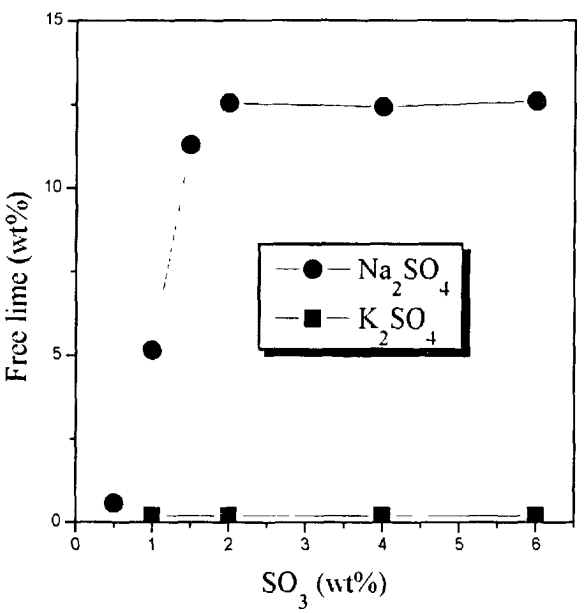

Fig. 1 Free lime content of the clinkers with various dosages of K_2SO_4 and Na_2SO_4

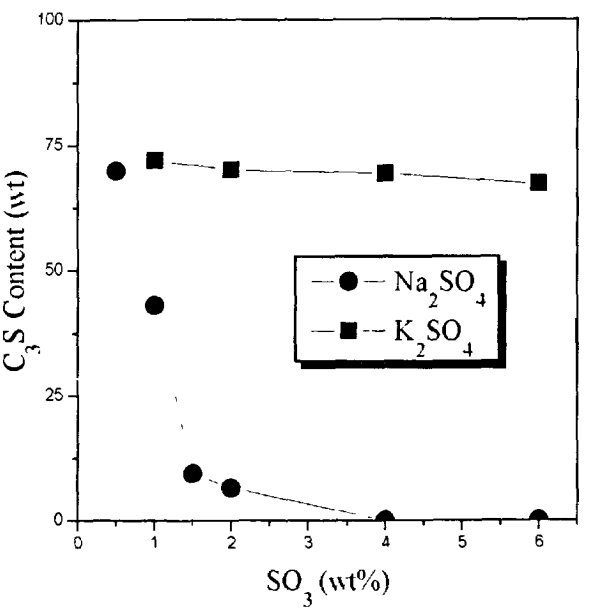

Fig 2 C_3S content of the clinkers with various dosages of $K_2SO_4$and Na_2SO_4.

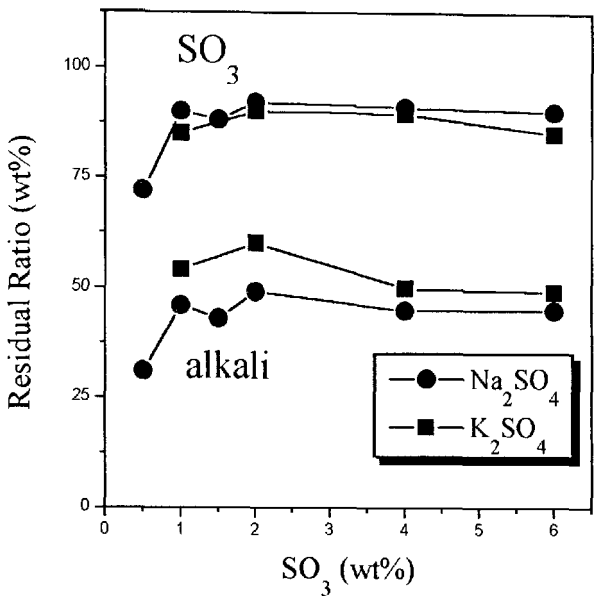

Fig. 3 Alkalis and SO_3 content of the clinkers with various amounts of K_2SO_4 and and Na_2SO_4.

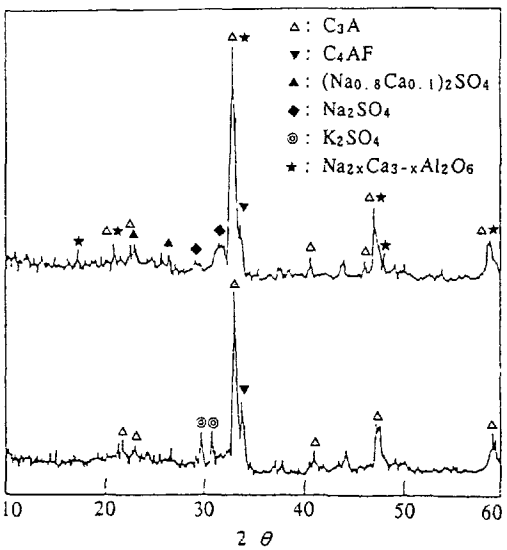

Fig. 4 XRD patterns of the residue after salicylic-methanol. solution method.

However with larger amount of free lime, C_3S phase diminished and C_2S and CaO became major phases. In Na_2SO_4 addition, it was considered that C_2S and unbounded CaO did not react to form C_3S.

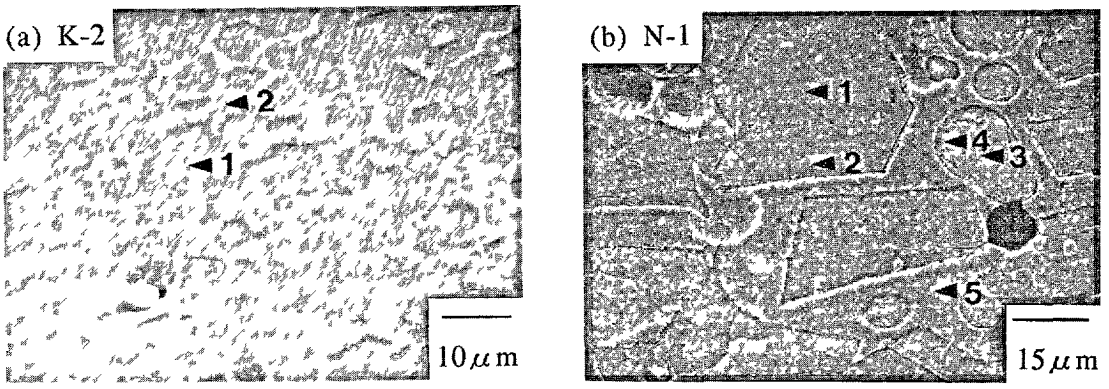

Fig. 3 indicates alkali and SO_3 content of the clinkers. 70 - 95 percent of SO_3 and 40 - 60 percent of alkalis resided. Potassium resided in the clinker more than sodium.

In order to check on alkali and SO_3-containing compounds, the clinkers were treated by salicylic-methanol method(Gutteridge, 1979), and the residue characterized by XRD(Fig. 4). While Na_2SO_4 addition resulted in compounds such as $(Na_{0.8}Ca_{0.1})_2SO_4$ and NC_8A_3, K_2SO_4 did not react with other components.

Fig. 5 shows the distribution of alkalis and SO_3 in the clinkers. More K, Na and S were detected in interstitial phase than in calcium silicate. Especially a large amount of Na and S were also incorporated in C_2S crystal. It was considered that $2Na^+$ ions were substituted for Ca^{2+} and $2SO_4^{2-}$ for SiO_4^{4-} (Ghose, 1980).

In case of Na_2SO_4, it was found that amount of C_3S decreased remarkably. K_2SO_4 did not hinder C_3S formation. For examination into this phenomena, the process of clinker formation during burning was investigated. The sample with 6.0 wt.% of Na_2SO_4 was heated up to 1450 ℃, and then analyzed at each temperature from 1000 ℃ to 1450 ℃. The sample with 6.0 wt.% of K_2SO_4 also was analyzed for the comparison with Na_2SO_4, although formation of C_3S was not prevented at high concentration. Fig. 6 shows XRD patterns of the clinkers with 6wt% of K_2SO_4 and Na_2SO_4 sintered at various temperature. In case of Na_2SO_4, C_2S and unreacted CaO were present at 1450 ℃, so C_3S formation did not occur. On the other hand, K_2SO_4 did not form any intermediate products, and C_3S formation was not hindered .

Fig. 7 indicates SEM/EDS result of the clinker with 6 wt.% of Na_2SO_4 at 1350 ℃. A large amount of Na and S were also incorporated in C_2S crystals.

	Sample	Point	CaO	SiO_2	Al_2O_3	Fe_2O_3	SO_3	K_2O	Na_2O
(a)	K_2SO_4	1 (C_3S)	71 45	22 14	1 45	2 19	1 64	1 14	
	2wt%	2 (Interstitial)	54 64	4 60	23 25	14 99	1 70	0 84	
		1 (C_3S)	67 75	21 50	5 30	3 87	0 46		1 11

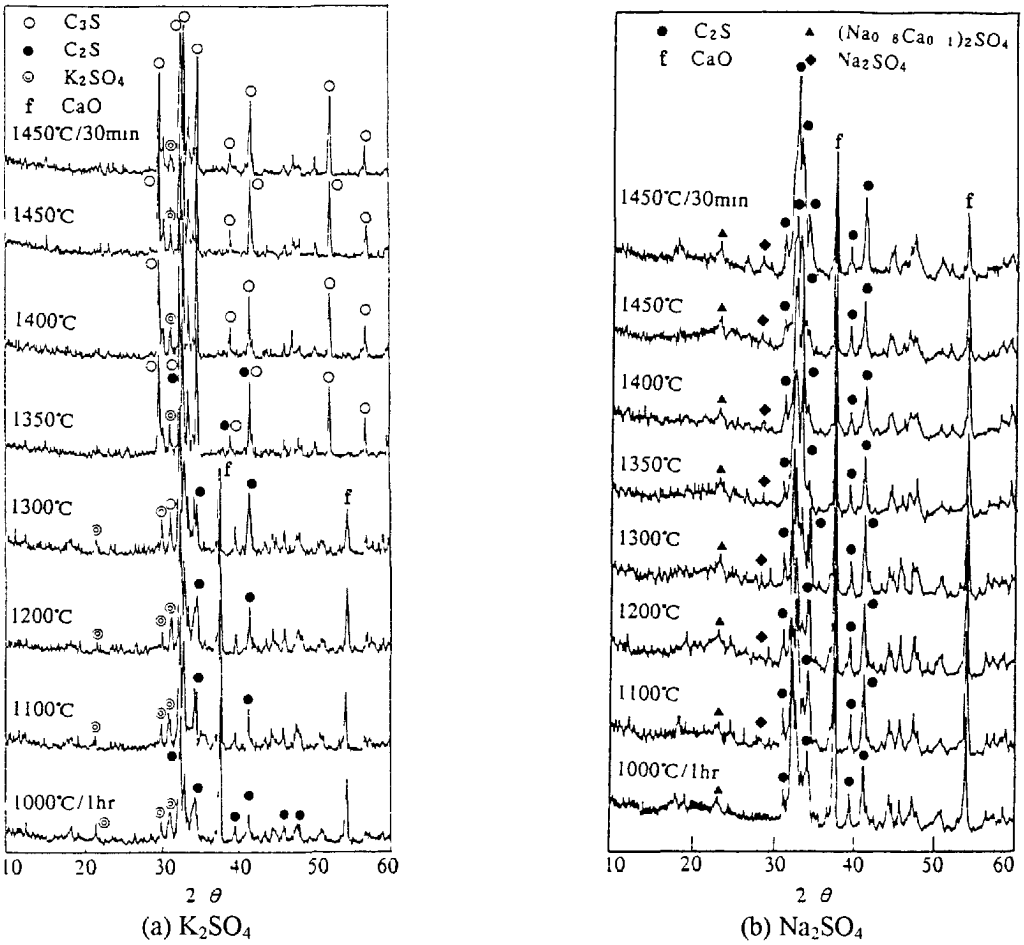

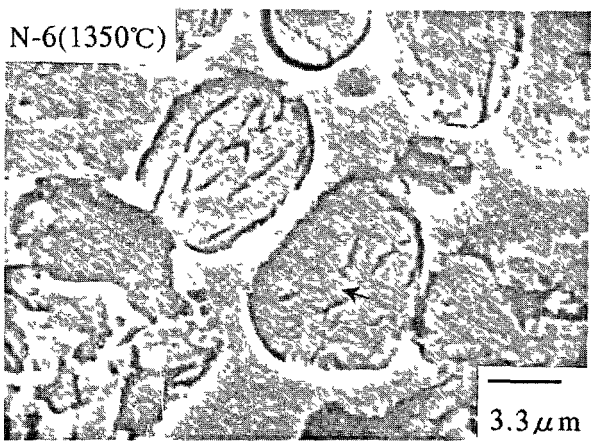

Fig 6 XRD patterns of the clinkers with 6wt% (a) K_2SO_4 and (b) Na_2SO_4 sintered at various temperature

It was considered that C_2S stabilized by Na^+ and SO_4^{2-} could not react to form C_3S. As mentioned above, K_2SO_4 appeared to be immiscible with other components, so it could not influence the dissolution of C_2S and CaO into clinker melt.

Fig 7 SEM micrograph and EDS analysis of the clinker with 6wt% Na_2SO_4 sintered at 1350 ℃

Relationship between alkali and SO_3 for C_3S formation

Effect and optimal content of alkali and SO_3 were investigated using K_2CO_3, Na_2CO_3 and $(NH_4)_2SO_4$ as alkali s and SO_3 sources. $(NH_4)_2SO_4$ which was decomposed into ammonia and SO_3 gas could be regarded as gaseous SO_3 condition. The clinkers were prepared by sintering at 1450 ℃ for 30 minutes. Alkalis and SO_3 content were varied upto 6 wt% respectively.

Fig. 8 illustrates the response surface plot for the free lime content of the clinkers. The optimal K_2O and SO_3 content was 1.43 of SO_3/K_2O mole ratio. Exceeding K_2O and SO_3 led to abrupt increase of free lime. However only 1 wt% of Na_2O and SO_3 promoted C_3S formation. Exceeding Na_2O and SO_3 hindered C_3S formation strongly. Exceeding alkalis had more negative effect on C_3S formation than exceeding SO_3. When SO_3/Na_2O was also 1.43, a little C_3S was formed. A small amount of Na_2SO_4 was formed in this mole ratio and these phases were immiscible with clinker melt, thus C_3S crystals were formed locally. Although K and Na were the same alkali group, their influences on C_3S formation revealed to be very different. It was considered that the degree of sulfatization for K_2O was much higher than in case of Na_2O.

Fig. 9 and 10 shows the optical micrographs of the clinkers. C_3S crystals with 1.43 of SO_3/K_2O mole ratio were never changed in size and morphology(Fig. 9(c)). C_3S crystals with exceeding K_2O were grown round and in a much larger size(Fig. 9(b)), whereas C_3S crystals with exceeding Na_2O had very irregular and rough surfaces and contained more inclusions than those grown with K_2O(Fig. 10(a)(b)(c)). However exceeding SO_3 had facet surfaces and also grew largely(Fig. 9(a)). It was the reason why the growth rate of C_3S crystals with exceeding Na_2O was more rapid and unstable. C_2S with alkalis had better developed-lamellae structure than SO_3(Fig. 9(d), Fig. 10(c)(d)). Prismatic C_3A crystals resulted from alkalis substitution were shown(Fig. 9(d)).

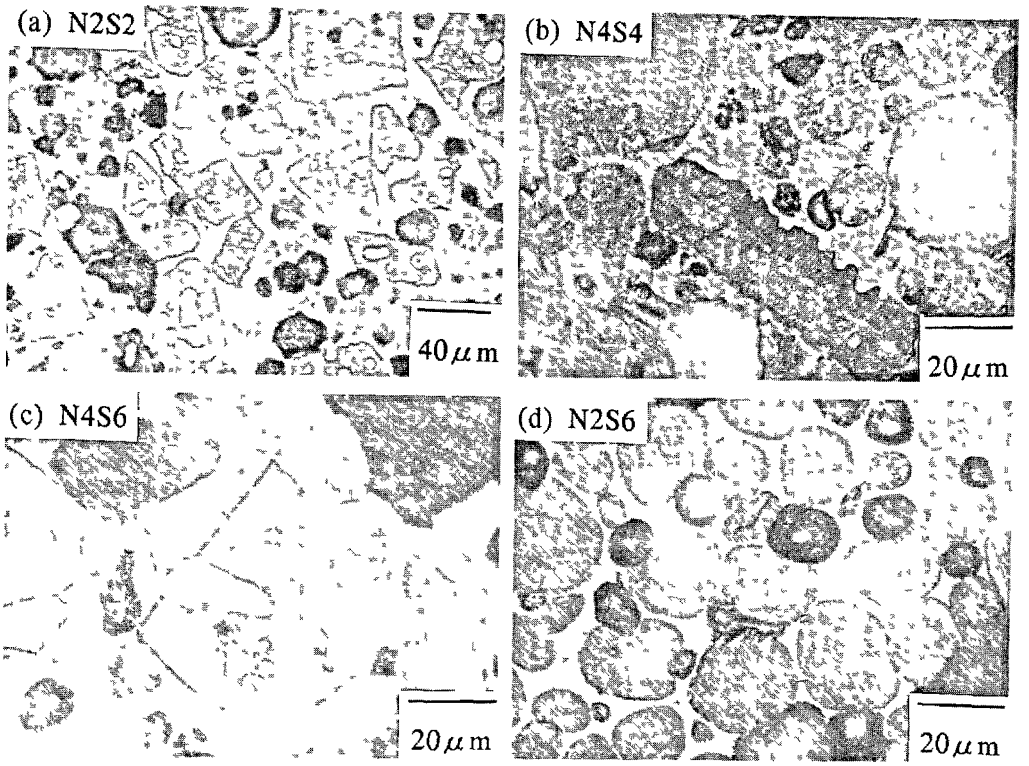

Fig 10 Optical micrographs of the clinkers with various Na_2O and SO_3 content
(N Na_2O S SO_3 number Added amount)

CONCLUSIONS

Effect of alkalis and SO_3 on C_3S formation and microstructure was studied, using K_2SO_4, Na_2SO_4, K_2CO_3, Na_2CO_3 and $(NH_4)_2SO_4$ The conclusions are as follows

1 When Na_2SO_4 was added by only 1 wt %, free lime content was more than 5 wt % However much K_2SO_4 did not make free lime content increase It was considered that C_2S stabilized by Na^+ and SO_4^{2-} could not react to form C_3S On the other hand, K_2SO_4 did not form any other intermediate products

2 The optimal K_2O and SO_3 content was 1 43 of SO_3/K_2O mole ratio Exceeding K_2O and SO_3 led to rapid increase of free lime However only 1 wt% of Na_2O and SO_3 promoted C_3S formation Exceeding Na_2O and SO_3 hindered C_3S formation strongly

3 C_3S crystals with 1 43 of SO_3/K_2O mole ratio were never changed in size and morphology C_3S crystals formed with exceeding K_2O were grown round and in a much larger size, whereas C_3S crystals with exceeding Na_2O had very irregular and rough surfaces and contained more inclusions than those grown with K_2O However exceeding SO_3 had facet surfaces and also grew largely It was the reason why the growth rate of C_3S crystals with exceeding Na_2O was more rapid and unstable

INFLUENCE OF SODIUM AND FLUORINE ON THE STABILITY AND POLYMORPHISM OF ALITE

Ömer ANDAÇ, University of Aberdeen, Scotland.*
Fredrik Paul GLASSER, University of Aberdeen, Scotland.

ABSTRACT Phase relations have been studied in part of the NaF-CaO-SiO_2 system by isothermal annealing at 800°-1300°C followed by examination of quenched charges at ambient using microscopy, X-ray and electron diffraction and wavelength dispersive microprobe. Extensive solid solution occurs between Ca_3SiO_5 and $NaCa_2SiO_4F$. The crystallography and constitution of ordered alite-like phases containing Na and F are described. General theories of the reactivity of activated alite are discussed.

Alite, Mineralised clinker, Phase diagram: Ca_3SiO_5 - $NaCa_2SiO_4F$

INTRODUCTION

The application of fluxes and mineralisers to cement production has been discussed at every preceding International Congress on the Chemistry of Cement. Mineral additives to cement systems may act as fluxes, to assist in the development of a liquid phase and improve its transport properties, or may act as mineralisers, to enhance the stability of a particular phase - normally alite - with respect to others. Some substances act as both flux and mineraliser.

Fluorine is prominent as a fluxing and mineralising additive. It is known to stabilise aluminates, notably the fluorinated form of "$C_{12}A_7$", i.e., $C_{11}A_7 \cdot CaF_2$, but the extent of fluorine substitution in silicates, if any, is less well established. Shame and Glasser (1987) showed that coupled substitution of Al and F for Si and O led to formation of extensive alite-type solid solutions. The lower stability limit of alite, with respect to its disproportionation to mixtures of CaO and Ca_2SiO_4, decreased from ~1250°C for pure alite, to as low as ~1050°C.

Other fluorine-containing silicates are known: notably the phase whose formula is now established as $Ca_{11}Si_4O_{18}F_2$; also, $Ca_5Si_2O_8F_2$. Moreover, Perez-Mendez et al (1984) reported solid solutions based on alite having the type formula $Ca_{6-0.5x}Si_2O_{10-x}F_x$: values of x ranged up to 1.0. However, these phases have melting points well below those normally used in clinkering and are unlikely to persist at normal clinkering temperatures; moreover, they have relatively high fluorine contents. Thus they are unlikely ever to be important constituents of commercial clinkers. Attention has therefore returned to coupled substitutions based on alite and we report on part of the system NaF-CaO-SiO_2.

RESULTS

Experimental

Samples were prepared from analytical reagent grades of $CaCO_3$,CaF_2 and a silica source, either crushed optical-grade quartz, ~0.08 wt % non-volatile with HF, or pre-reacted Ca_3SiO_5 made from $CaCO_3$ and SiO_2. Approximately 32 compositions were prepared on join Ca_3SiO_5 - $NaCa_2SiO_4F$, mostly in the range 0-60 mol % $NaCa_2SiO_4F$. These were annealed in air in electric furnaces controlled to ±2°C for vertical tube quench furnaces or ±10°C for muffle furnaces. Charges were examined primarily by powder X-ray diffraction and backscattered electron microscopy; point analyses used a wavelength dispersive analytical system. In this way, selected

crystals could be analysed directly for both F and O as well as for Ca, Si and Na. Fluorine loss was monitored by weight change, supplemented by wet chemical bulk analysis of representative charges for fluorine using a F-sensitive electrode. Where appropriate, DTA, electron diffraction and high temperature X-ray diffraction were used to provide additional characterisation data.

Data Analysis

Single crystals of $NaCa_2SiO_4F$ were grown from the melt and the crystal structure determined by classical X-ray single crystal analysis. The structure is closely related to that of alite: oxygen not attached to Si in alite is wholly and preferentially replaced by fluorine in $NaCa_2SiO_4F$ (Andaç et al, 1997).

The system Ca_3SiO_5 - $NaCa_2SiO_4F$ is not binary at low temperatures, below which Ca_3SiO_5 decomposes, nor above the solidus where extensive incongruent melting occurs. Nevertheless, the system is binary at some temperatures and a phase diagram, depicted as a binary system, Fig. 1, is helpful to depict the complex relationships amongst the alite-like phases. Data used in its construction are given in a Thesis (Andaç, 1996)

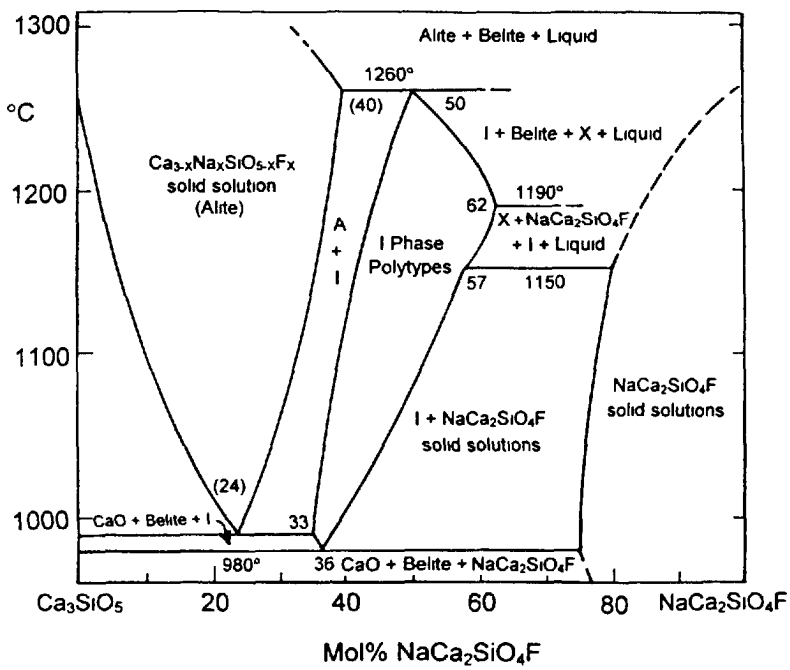

Figure 1. Phase diagram of the Ca_3SiO_3 - $NaCa_2SiO_4F$ system. Detail has been omitted except in those portions which behave as a binary system.

Fig. 1 shows the main features of the phase diagram at temperatures above 850°C. Alite structured solid solutions having the general formula $Na_xCa_{3-x}SiO_4(O_{1-x}F_x)$ extend to a maximum of x = 0.36 at ~1270°C. Perhaps of more interest is the extension of the stability field of homogeneous alite type solid solutions to lower temperatures, reaching a thermal minimum of ~990°C at x ~0.24. Formation and decomposition reactions at the lower limit of stability of Ca_3SiO_5 are extremely sluggish (x = 0), but become more rapid at intermediate x values, in the range 0.05, to 0.15, despite the decrease in temperature. However reaction again becomes

sluggish towards the thermal minimum. Thus reversibility has been demonstrated along part of this curve, but the 990°C limit is based only on the forward reaction, i.e., formation of alite solid solutions from reactants.

The solid solutions obtained at ambient appear by powder X-ray diffraction to be triclinic at x = 0, but monoclinic in the range x = 0.08 to 0.18 and rhombohedral in the range x = 0.27 and 0.36. Nevertheless, the rhombohedral cell could not be indexed commencing with the cell dimensions reported by Jeffrey (1952), despite lack of significant shifts in the positions of symmetry-related reflections. Given the near constancy of ionic radii of the species, Na~Ca and F~O, this near constancy of the main reflections is not surprising. Table 1 shows the apparent unit cell obtained by indexing the reflections on a triclinic cell. There is no doubt from backscattered electron imaging that chemical homogeneity is maintained over the limits cited, but the exact symmetry of the quenched solid solutions is unknown. Table 1 is therefore mainly useful to show how, when indexed on a self consistent basis, unit cell parameters remain essentially unchanged. The high temperature X-ray data were more diffuse than at ~25°C but no difficulty was encountered in indexing 1100°C powder patterns between x = 0 and 0.36 on a rhombohedral cell with $\underline{a}$ ~ 7.15 and $\underline{c}$ ~ 25.57Å. Thus the high-F alites are rhombohedral at ~ 1100°C but, while remaining at least pseudo-rhombohedral at ~ 20°C, have a true symmetry and cell size which remains to be defined.

Table 1. Self-consistent unit cell parameters of $Na_xCa_{3-x}SiO_{5-x}F_x$ solid solutions: italic values are esd's.

X	a(Å)	b(Å)	c(Å)	β(°)	Volume (Å^3)
x=0.04	33.073(0.007)	7.064(0.003)	18.556(0.006)	93.891(0.029)	4325.08 (1.79)
x=0.08	33.096(0.005)	7.061(0.002)	18.578(0.003)	94.050(0.019)	4330.67(1.08)
x=0.18	33.080(0.013)	7.059(0.003)	18.573(0.007	94.023(0.041	4326.98(2.61)
x=0.27	33.038(0.015)	7.063(0.004)	18.565(0.007)	94.035(0.038)	4320.36(2.05)
x=0.36	33.045(0.017)	7.064(0.003)	18.561(0.007)	94.074(0.033)	4321.40(2.15)

Samples quenched in the range 33-62 mol % $NaCa_2SiO_4F$, depending on quench temperature, often appeared homogeneous yet gave a distinctive X-ray powder pattern. Fig. 2 shows tracings from two regions of the diffraction patterns which are generally considered to be diagnostic for alite modifications. As might be expected from its high symmetry, $NaCa_2SiO_4F$ has a relatively simple pattern while the slightly substituted alite, pattern c, exhibits the line splitting characteristic of a low symmetry alite. The pattern b of the phase designated as I, (I = intermediate) has similarities to, but is distinctively different from that of a more highly substituted rhombohedral alite, pattern d.

Moreover, the differences characteristic of the I phase persist to high temperatures as shown by high temperature X-ray powder patterns. Mixtures of two phases, I phase + alite, were frequently encountered in a consistent manner, indicating the existence of a two-phase region. Fig. 3 shows a portion of a pattern obtained at 1100°C. Some evaporation of Na and F occurs in the course of stabilising the temperature and in the time taken to record the pattern, so the initial value of x, from experience, will have decreased from its target value of 0.40 to about 0.36. The association of specific reflections with either alite or I phase allows for thermally-induced shifts in reflection positions.

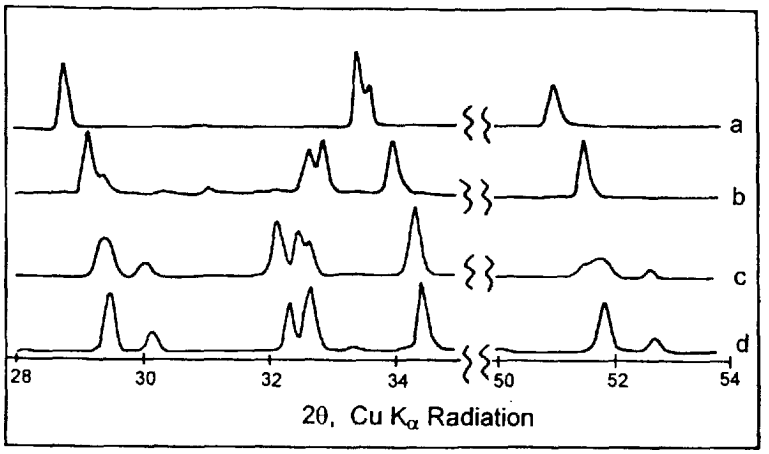

Figure 2. X-ray powder patterns, showing regions diagnostic of alite phases Trace (a) is of $Na_2Ca_2SiO_4F$, trace (b) is of the I phase, at x = 0.42, trace (c) is of a partially-stabilised alite at x = 0.04 and trace (d) is of a pseudo rhombohedral or rhombohedral alite at x = 0.36. All traces were obtained at ~ 20°C.

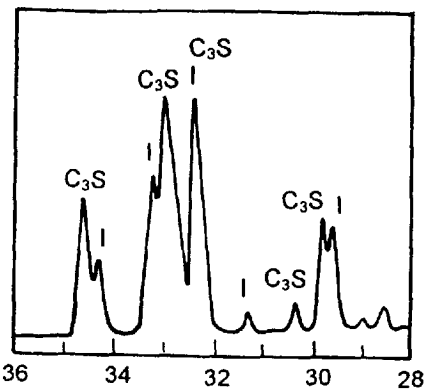

Figure 3. High temperature X-ray powder pattern obtained at 1100°C, CuKα radiation, nominally at x = 0.46, showing the assignment of reflections to a mixture of alite and I phase solid solutions. Slight loss of F during heating occurs, so the effective x value is probably ~ 0.36.

A corresponding larger batch, at x = 0.36, was heated in a muffle furnace at 1070°C. Fluorine loss from the larger batch was negligible. Twenty one crystals were analysed by EMPA; the results are shown as a histogram in Fig. 4. The postulated mechanism of solid solution demands that Na = F, and this condition is well met by all the analytical data. However the results form a bimodal distribution: the left-hand population group is associated with an alite- type solid solution and the right-hand group, with I phase These bimodal distributions were observed in numerous other appropriate temperature-composition experiments and these results from EPMA of compositions which, from X-ray powder diffraction, were believed to lie in the two-phase gap, help to confirm the validity of this conclusion and to define its extent on each isotherm.

Crystallography of the I phase and its relation to alite

The crystal structure of Ca_3SiO_5 may be viewed as a stacking sequence of elementary layers, each having the composition $M_3(TO_4)x$. In this view, $NaCa_2SiO_4F$ consists of a regular two-layer repeat sequence while Ca_3SiO_5 is built of more complex stacking sequences. Different investigators have reported different sequences for alite and it is probable that all those reported sequences occur, although conditions for their formation are not well defined. However, electron diffraction revealed that the I phase is comprised of two hitherto unreported stacking sequences. The *c* (or pseudo *c*) axis periodicities of these stackings correspond to 15 and 24 layer repeats. Fig. 5 shows the elementary layer unit and sufficient of the proposed stackings, together with translation motions, necessary to visualise the structure of the 15 and 24 layer variants. All I phase preparations examined consisted of mixtures of these two variants although not always in the same proportions. No firm and consistent evidence was obtained showing that significant differences in Na:Ca or F:O ratios occurred between the two variants.

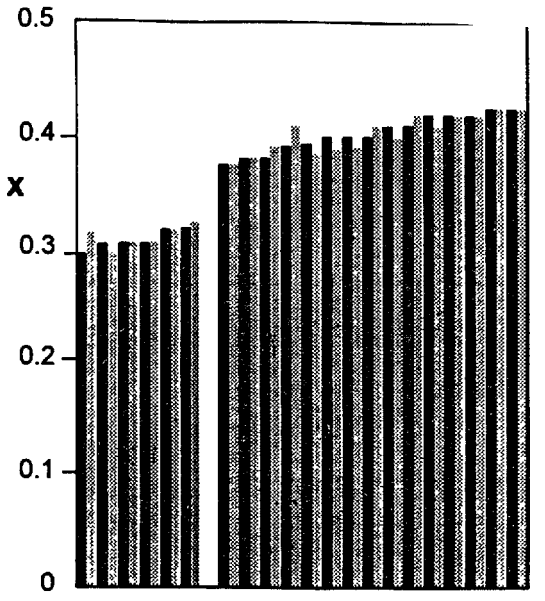

Figure 4. Analysis cluster of a quenched charge at x ≃ 0.36 heated at 1070°C consisting, by XRD of a mixture of C_3S and I phases. Analyses were made by EMPA of selected single crystals. 21 out of 24 analyses were accepted: 3 were rejected because Na + Ca ≠ 3 and or O + F ≠ 5. The x values are paired: dark for Na, shaded for F. A division into two populations is suggested, one on the left of C_3S (alite) type and the other, rather Na + F richer, of I phase.

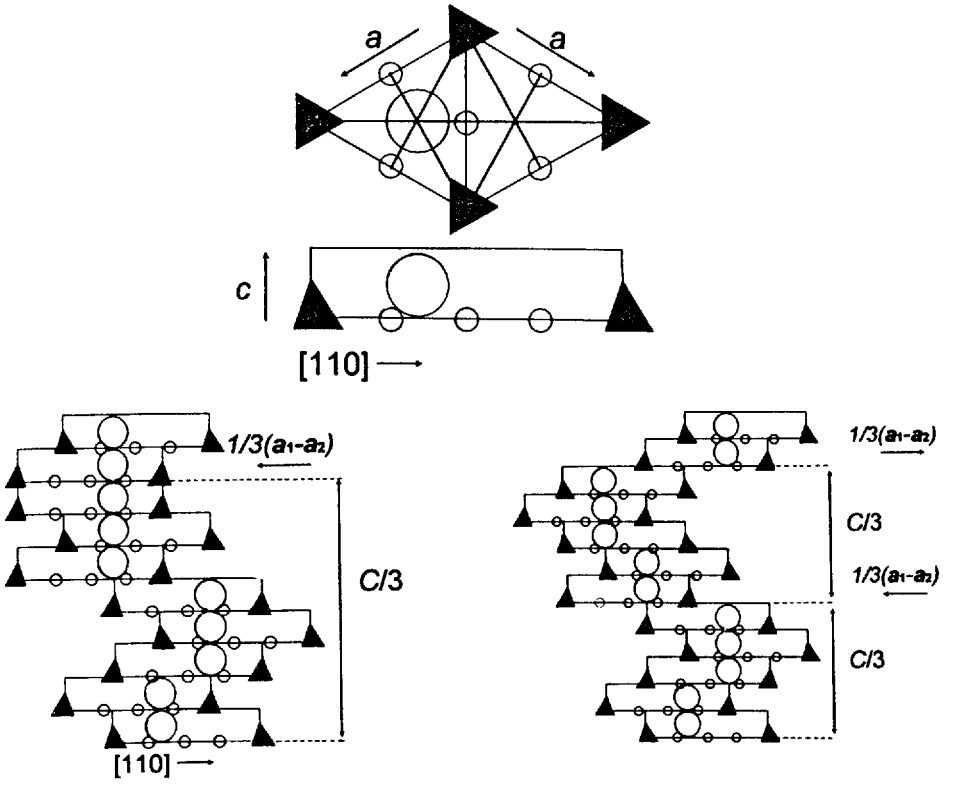

Figure 5. Structure of phase I. At the top is a drawing in two projections of the elementary layer unit common to alite type structure. Silicate tetrahedra are shown: large open circles are oxygen, small open circles are calcium. These are partly replaced by fluorine and oxygen respectively. The sketch at lower left shows stacking and translations necessary to form the 24 layer sequences (3 x 8 layer blocks) and at the lower right, the 15 layer sequence (3 x 5 blocks)., Both 24 and 15 layer sequences are characteristic of the I phase.

Reactivity towards water

No systematic studies of reactivity have been made in the course of the present study, but both Na and F substituted alites and I phase are very reactive towards water. Na_2CaSiO_4F, on the other hand, is only feebly reactive.

DISCUSSION

The present study raises a number of questions. Firstly, is the I phase best regarded as a new polymorph or as a polytype of Ca_3SiO_5, albeit with substantial chemical doping? Given that some compositions can be transformed reversibly from I phase to C_3S type, or vice versa, by changing temperature, but always with an intervening two phase gap, I behaves operationally, as though it were a polymorph. However, in this view, the polymorph must have two polytypic variants: the 15 and 24 layer stackings. Transformation between 15 and 24 layer stackings is not readily accomplished: the mechanisms involved suggest that the transformation must be at least semi-reconstructive. Indeed, it is characteristic of many polytypic mixtures that, once formed, the polytypic distribution is difficult to alter.

How many variants of the alite structure occur? At present we do not know the answer: probably, quite a few. The structural stabilities of the variants are envisaged as being controlled partly by chemistry, and partly by availability, without undue penalty in terms of increasing the free energy, of the translational mechanisms necessary to create the new structures. These translations result in the introduction of shear planes, which behave like an extended defect. Thus alite type structures gain additional entropy stabilisation and characteristically become stable at temperatures in the range >900-1200°C, i.e. at substantially lower temperatures than pure Ca_3SiO_5.

The reactivity of the alite structure towards water has been the subject of much debate. It is suggested that the reactivity arises from three factors. Firstly, absolute thermodynamic instability at typical (0-60°C) cement hydration temperatures, is a primary requirement for rapid reaction. This is a characteristic shared with other silicates, notably α, α', β and β' Ca_2SiO_4, all of which are reactive at ambient. Secondly, the presence of extended defects throughout the structure enhances reaction rate. Translation motions, occurring every five or eight elementary layers in the I phase, are postulated to be the principal source of defect-conditioned reactivity, although the contribution of other types of defect to reactivity is not excluded. Finally, at least some of the chemical constituents must be soluble and, moreover, soluble so as to condition a high pH. This high pH is favourable for breaking M-O bonds which are, in any event, unstable in aqueous solutions. Both Ca_3SiO_5 and the I phase meet all three criteria and are reactive: $NaCa_2SiO_4F$, on the other hand, is thermodynamically stable at ambient so it fails one of the criteria.

ACKNOWLEDGEMENT

Ömer Andaç would like to thank the Turkish Government for a scholarship which allowed him to pursue PhD studies at the University of Aberdeen. The financial support of the Engineering and Physical Sciences Research Council for the electron microprobe and to Alison Coates, for her assistance with probe calibration and techniques, is also gratefully acknowledged. Dr Eric Lachowski contributed greatly to the taking and interpretation of the electron diffractions.

CRYSTAL SIZE AND CONTENT OF THE ALUMINATE PHASE IN PORTLAND CEMENT CLINKER

Alberto SAINI, Centro Ricerche UNICEM, Guidonia, Italia
Nicoletta GIULIANI, Centro Ricerche UNICEM, Guidonia, Italia

ABSTRACT As the aluminate phase decreases, its crystal degree evolves from well developed crystals to a crystal size tending to diminish till to give aluminate a microcrystal appearance. In accordance to microscopy examination, the main aluminate phase XRD reflex (2θ = 33.2) also tends gradually to decrease till to vanish by forming a glassy state. Beyond a C_3A value calculated by Bogue equation, formation of a C_3A glassy state occurs. This is of interest for a sulphate resistant cement formulation because a glassy C_3A is less susceptible by sulphate attack.

Key-words: aluminate phase, crystal size, glass, microscopy, x-ray diffraction analysis.

INTRODUCTION

Through an investigation about clinkerization conditions with the aim to improve the raw meals burnability, the effectiveness of an iron ore addition to make burning easier, through a silica modulus decrease, has been industrially tested.
To get a comprehensive and exhaustive characterization, chemical analysis of industrial clinkers has been supported by an XRD and Optical microscopy (OM) examination with the purpose to point out possible phase variations in the interstitial material. The XRD-OM combined use allows to detect a simultaneous decrease of content and crystal size of the aluminate phase, as the addition increases.

The microscopy examination has been conventionally performed on a suitable grain size fraction of the as-received clinker. This fraction has been encapsulated, polished and etched, while the XRD pattern has concerned clinker residues resulting from two selective extractions to remove the interfering phases such as the silicate and sulphate phases ones. The procedures to prepare the samples for the XRD and OM analyses are reported in the following experimental part.

EXPERIMENTAL PART

The procedures to prepare the samples of analysis and the modalities to remove the interfering phases by selective extractions have been previously reported (Saini, 1994; Tabikh, 1971; Burkes, 1983) and are now briefly mentioned.

A) Sampling and preliminary quartering

To obtain a representative sample to analyze by XRD (D 500, Siemens) and optical microscopy (Leitz, Laborlux 12 Pol S), any as-received clinker sample has been preliminary quartered so to obtain enough material for both the techniques. One half has been crushed to obtain the fraction for the microscopical test, while the other has been finely grounded for XRD analysis, as following reported.

B) Sample preparation for XRD analysis

Crushed clinker is finely wet grounded and then dried by evaporation. Silicon powder, previously grounded, is used as internal standard for quantitative analysis according to Chung's Method (Chung, 1974). It is mixed in known proportions with the finely grounded material and subsequently it is wet milled. After the liquid evaporation, the resulting material is selectively extracted to remove the silicate and sulphate phases by treatment with an alcoholic maleic acid solution and then with an aqueous NH_4Cl solution.

C) Preparation of samples for microscopical reflected light examination

The crushed clinker fraction is encapsulated and the sample located in a vacuum bell to remove the air bubbles. After an oven curing, the sample is polished and then its surface etched with KOH water solution. C_3A stains blue while C_4AF remains brightly white (Campbell, 1986; Hoffmänner, 1973).

CHEMICAL, MINERAL, MICROSCOPICAL AND BY SELECTIVE EXTRACTION ANALYSIS

Chemical and mineralogical analysis of three series of clinkers (A, B and C) coming from different plants are reported in the Tables 1 and 2.

Table 1 Chemical analysis

	Serie A			Serie B			Serie C

LF 1450°C	22,46	25,45	25,90	23,10	24,97	25,29	26,34	26,16	26,17

Mineral composition has been calculated by Bogue and Newkirk modified (MgO > 1%) formulas (Gailland et al., 1973) and according to Holderbank equations (Eqs. 1, 2, 3 and 4) (Holderbank, 1977).

$$C_3S = C_3S_{Bogue} + 4.0\,MgO + 5.5\,K_2O \quad [1]$$

$$C_2S = C_2S_{Bogue} - 1.5\,MgO - 2.2\,K_2O \quad [2]$$

$$C_3A = C_3A_{Bogue} + 7.8\,Na_2O + 1.5\,AM - 2.1\,SO_3 - 5 \quad [3]$$

$$C_4AF = C_4AF_{Bogue} - 6.5\,Na_2O - 1.7\,AM + 5.0\,Mn_2O_3 + 3 \quad [4]$$

Additionally, phase contents have been experimentally evaluated by optical microscopy through the known point counting technique (Hoffmänner, 1973; Cetic, 1978). The C_3A content has been evaluated by XRD on the clinker residue from selective extractions (Table 3). Phase composition

by selective extraction is reported in Table 3. It shows, respectively, the values of silicate amounts (corrected by the free CaO chemical one), those of sulphate and then of interstitial phases ones, including aluminate and aluminoferrite.

XRD ANALYSIS

After the silicates and sulfates removal, residues have been XRD examined. A few patterns of clinker samples before (ruled area) and after (blank area) the selective removal are as an example reported in Fig 1. To overcome the remarkable overlapping peak phenomena and then to allow the measure of the aluminate phase through the evaluation of its integrated peak areas, the Diffrac AT FIT by Siemens program application is suggested. It involves the angular region (33-35 2θ) including the main aluminate reflection at 33.3 2θ, the 33.1 2θ peak of noncubic forms (if there are any), then the aluminoferrite peak at 33.9 2θ and its doublet at 33.5 2θ.

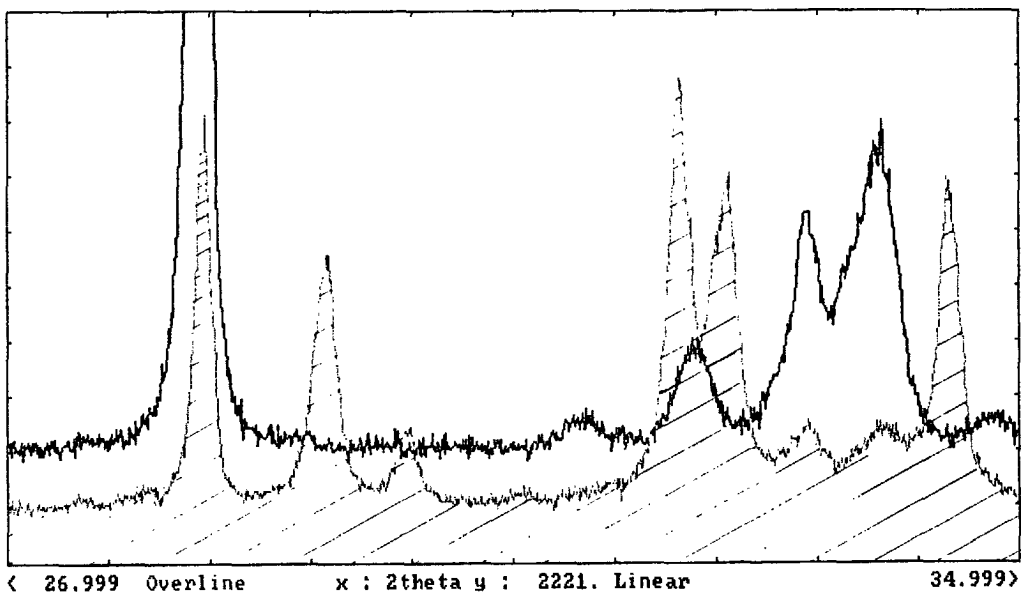

Figure 1 Overlapping of clinker XRD patterns before and after selective extractions.

In Figs 2, 3 and 4 a zoomed pattern's portion, that is the angular region from about 32.8 2θ to about 34.4 2θ, including the experimental profile (black trace) and the fitted ones by deconvolution (differently marked), is reported.

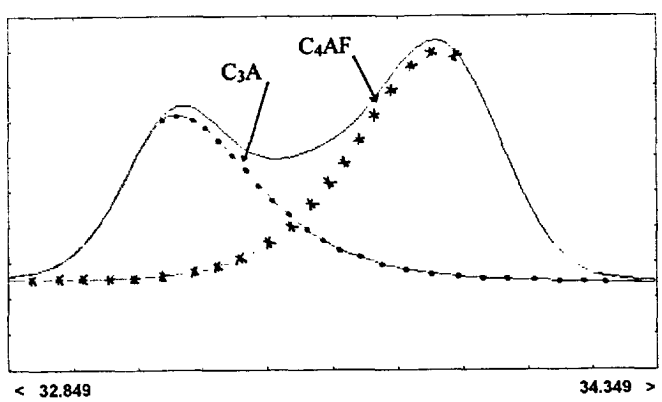

Figure 2 Trends of experimental profile and deconvoluted ones (sample C1).

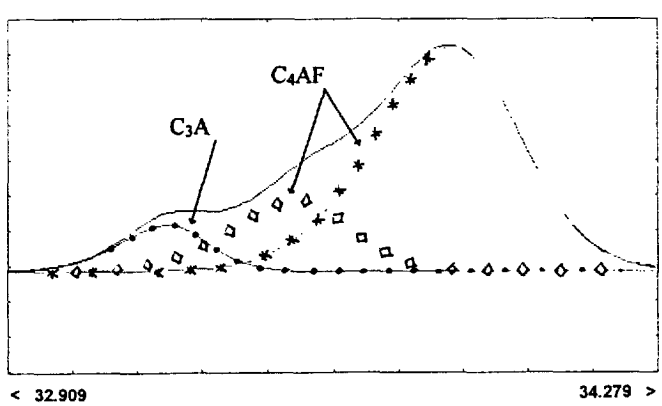

Figure 3 Trends of experimental profile and deconvoluted ones (sample C2).

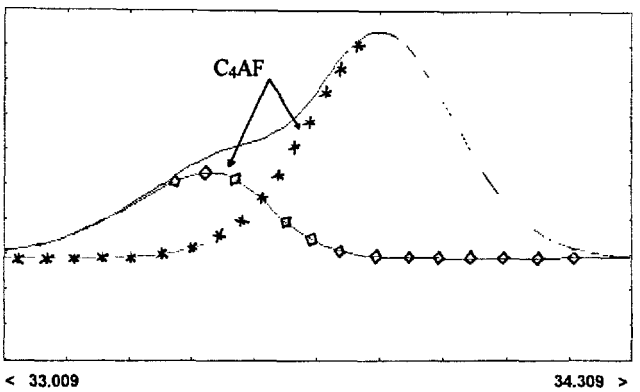

Figure 4 Trends of experimental profile and deconvoluted ones (sample C3).

The other figures include two graphics to immediately control the accuracy of the fitting program application; they show, respectively, the overlapping degree of the experimental profile and that obtained by the sum of the lines and the background (Fig 5) and the residual pattern that is the algebraic sum between the values of the deconvoluted profile and the experimental one (Fig 6).

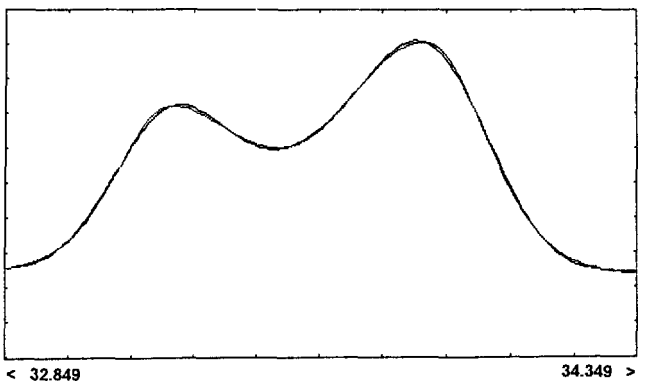

Figure 5 The overlapping between the experimental profile and the deconvoluted one

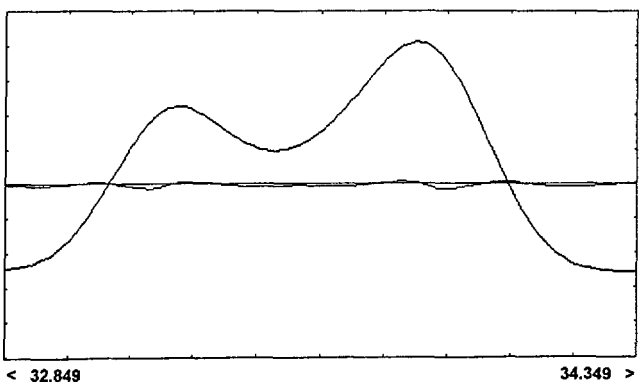

Figure 6 The residual pattern

The comparison between calculated values by Bogue-Newkirk formulas or Holderbank equations and experimental ones by XRD confirms (Table 4) the XRD technique trend to generally underestimate aluminate phase (Regourd, 1986). This trend could be explained by taking in account the situation, detected by optical microscopy, in terms of shapes and crystal sizes. Really, combined use of microscopy and XRD allows to notice a progressive size reduction of the C_3A crystals as its content, calculated or experimentally measured, changes. More particularly, in the

clinkers having a middle C_3A content (samples A1, B1 and C1), aluminate phase forms large and well developed (15-30 microns) prismatic crystal (Fig 7).

Table 4 % Aluminate phase: comparison between calculated and XRD data

	A1	A2	A3	B1	B2	B3	C1	C2	C3
Bogue - Newkirk	7,8	4,9	3,4	8,7	5,2	3,8	7,4	6,1	3,1

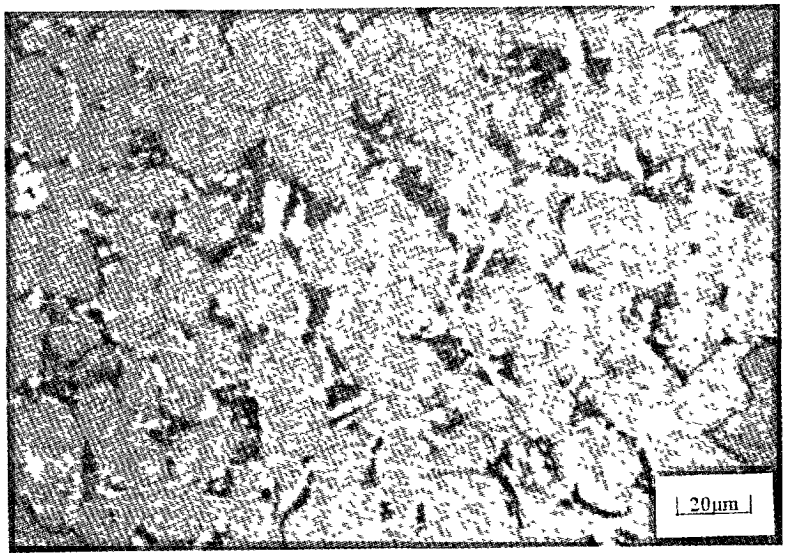

Figure 7 Sample C1. Well formed C_3A cubic crystals.

As the C_3A content decreases (samples A2, B2 and C2), an amount of microcrystalline crystals starts to occur, next to crystals still well formed but smaller than the previous ones (Fig 8).

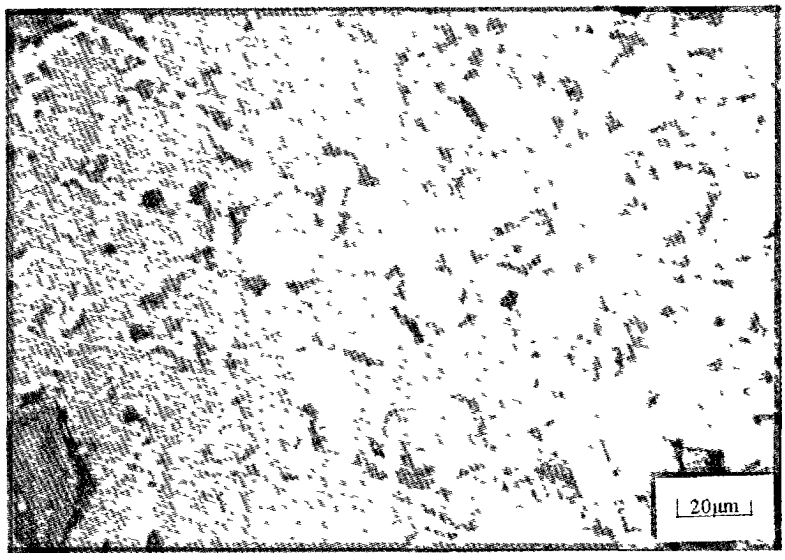

Figure 8 Sample C2. Middle size C_3A crystals.

This amount gradually increases till to prevail when the C_3A content values become very low (samples A3, B3 and C3) (Fig 9). Clinkers of this group have only very small C_3A crystals so to be almost reflexes-free and then XRD undetectable (i.e., Fig 4).

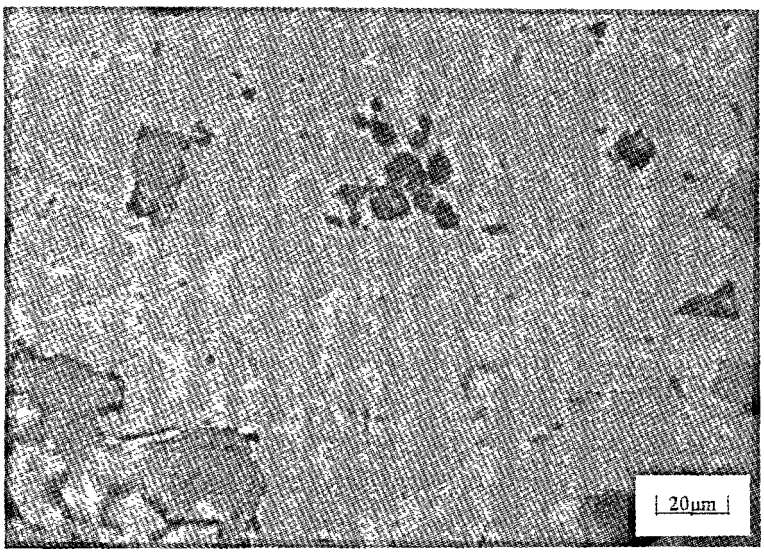

Figure 9 Sample C3. Very small size C_3A crystals.

According to this, difference between measured and calculated values could be explained. Data in Table 4, as well as those reported in a previous paper of the same Authors (Saini and Giuliani, 1994), confirm that Holderbank equations give values closer to XRD data.

CONCLUSIONS

The point that aluminate phase, below a calculated C_3A value differing from clinker to clinker, assumes a crystal size such as to be transparent to X-ray and to have amorphous behavior is of interest from an application point of view. In the light of what literature reports about the low reactivity of a glassy aluminate phase (Han, 1982; Locher, 1975,1980,1982; Regourd, 1978; Sylla, 1975; Lea, 1970; Zgambo, 1987; Carin, 1991; Tsuyuki, 1986), the occurrence of this X-ray amorphous phase when C_3A content decreases below a certain value could be of interest in terms of sulphate resistant cement formulation. Also Alunno Rossetti (1995) recently confirms Parker's observations. Parker (1939) observed that cements cooled rapidly showed greater resistance in sulphate solutions than specimens of the same composition and curing, but cooled more slowly. In his study Alunno Rossetti examined synthetic cements prepared using different concentrations of C_3A with vitreous or crystalline structure and he considered also the influence of various curing conditions. The results obtained show that cements with vitreous C_3A are less expansive than those with crystalline C_3A (At room temperature (20°C) the sulphate expansion is 50 percent reduced and more than four-five times with low (90°C) and high (190°C) pressure steam curing). Sulphate expansion is further reduced when glassy C_3A concentrations increased (expansion is four times reduced at 20°C and about five and twelve times at 90°C and 190°C, respectively). Really, in the presence of a hard sulphate attack, cements having an XRD measured C_3A content not above 1% have frequently required. The fulfilment of this severe condition involves the manufacturing of a very low C_3A clinker consistently with some main actual sulphate resistant cement regulations (ASTM C150, UNI 9156 and its revision FA262, ENV 197-X, BS 4027). The combination of a very low C_3A content with the lower reactivity of a glassy aluminate clinker phase is consistent with a formulation of high-sulphate resistant cement. In this connection, the paper, on one hand, points out the similar trends of C_3A content and its crystal

size, on the other hand suggests an XRD procedure to evaluate the crystalline C_3A content. This procedure, based on an analysis by a profile fitting program performed on a residue from two selective extractions for the removal of interfering phases, could be useful, in authors's opinion, for the cement standardization and its control.

TRANSFORMATION-INDUCED MICROTEXTURES IN BELITES

Koichiro FUKUDA, Iwao MAKI and Suketoshi ITO
Department of Materials Science and Engineering, Nagoya Institute of Technology,
Nagoya, Japan

ABSTRACT Upon polymorphic phase transition of $\alpha \rightarrow \alpha'$, the α'-phase nucleates within the parent α-phase so that there is a good lattice matching across the interface. The coherent interfaces occur in parallel with $<210>_{\alpha}$ and form an angle of 27° with $(001)_{\alpha}$. The transition is a nucleation and growth process, of which the start and finish are shown on a time-temperature-transformation diagram. As a function of the cooling rate, the phase constitution and microtexture after the transition can be predicted from the diagram. Within the completely inverted α'-phase grains, a remelting reaction successively occurs; a liquid phase nucleates and grows heterogeneously on the lamella boundaries leading to a decrease in impurity concentration in the host α'-phase. The resulting microtexture depends on the cooling history as well as on the wettability of the belite lamellae by the exsolved liquid. The progress of the α'-to-β martensitic transformation during cooling is detected by the growth of the plate-like reliefs on the parent crystal surface. Upon heating, the reverse transformation occurs with the shrinkage of the reliefs. The growth and shrinkage behavior and negative thermal hysteresis are in conformity with the thermoelasticity.

Key-words: Belite, Microstructure, Microscopy, Kinetics, Phase diagram.

INTRODUCTION

Microtextures of belites (broadly defined as Ca_2SiO_4 solid solutions in the present paper) carry a wealth of information on the thermal history of portland cement clinkers especially during cooling. When the belites are cooled from elevated temperatures, phase transformations occur successively, leading to the formation of complex microstructures within the crystals. These microtextures mainly depend on temperatures of belite formation and on cooling rates. Accordingly, we can deduce the detailed cooling history of the clinkers from quantitative information (e.g., chemical composition and phase constitution) on the reaction products.

The microtextures induced by phase transformations during cooling have been classified into four types: I, Ia, II and III (Insley, 1936; Insley *et al.*, 1938). The texture denoted by Type I is characterized by "two or more sets of intersecting lamellae". The texture of Type Ia is distinguished from that of I by "the presence of discrete particles along what are apparently traces of twinning planes". The texture of Type II is described as "a single set of parallel twinning lamellae". The Type III, "often containing irregular cracks or veinlets but without distinctive twinning lamellae, occurs sometimes as overgrowths on crystals of type I and Ia and sometimes as individual crystals." The present study deals with the relationship of the phase transformations in belites to these intracrystalline microtextures. The transformations concerning the above are the polymorphic transition of $\alpha \rightarrow \alpha'$, the remelting reaction of $\alpha \rightarrow \alpha' +$ liquid, and the martensitic transformation of $\alpha' \rightarrow \beta$. The remelting reaction requires atomic diffusion, while the rest involve no diffusion process. Because the α'_H-to-α'_L transition does not affect the relevant microtextures, both phases were simply represented by α' in the present paper.

POLYMORPHIC PHASE TRANSITION OF $\alpha \rightarrow \alpha'$

Stereographic Analysis of Lamella Structure

The lamella structure of the Type I belite is formed by the α-to-α' transition. During further cooling, the α'-phase is often inverted to the β-phase, leading to the formation of polysynthetic twinning at the submicroscopic level within each lamella (Groves, 1982; Fukuda and Maki, 1989a; and Kim *et al.*, 1992).

The orientation of the lamellae in the host α-phase was found by observation of three kinds of orientation defined polished sections, of which the polished surfaces were perpendicular to the *c*-axis, the *a*-axis and <210> of the former α-phase (Fukuda and Maki, 1989a). Because the striations appear as intersections of the lamellae and the polished surfaces, the overall lamella structure was determined by the stereographic analysis of the striation directions. The result showed that there were six sets of crystallographically equivalent lamellae, each of which is parallel to $<210>_\alpha$ and intersects $(001)_\alpha$ at an angle of 27° (Fig 1).

Orientation of Perfectly Coherent Interface Boundaries Between α- and α'-phases

In homogeneous nucleation and growth transformations, the structural relationship between the new phase and the matrix will determine the nature of the interface between them (Putnis and McConnell, 1980). When both phases have a similar structure, the new phase may be oriented in the form of lamellae within the matrix so that there is a good lattice matching across the interface (Robinson *et al.*, 1977).

In the nucleation of the α'-phase lamellae within the host α-phase, the interphase boundaries were expected to be perfectly coherent (Fukuda and Maki, 1993a). The orientation of such coherent interfaces was determined by the matrix algebra analysis as used in martensitic transformations (Wayman, 1964). Because of the trigonal symmetry for the parent α-phase, there were six sym-

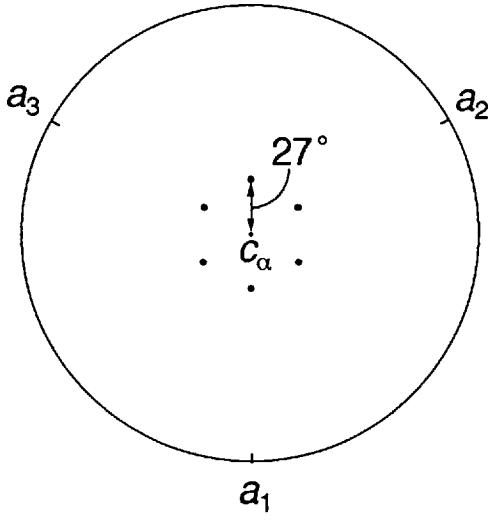

Figure 1 Stereographic plotting of six symmetrically related lamellae. The lamellae are in parallel with $<210>_\alpha$ and form an angle of 27° with $(001)_\alpha$.

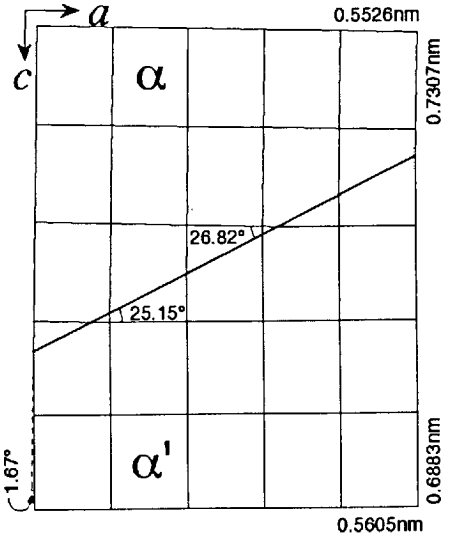

Figure 2 Lattices of the α- and α'-phases, fitted together at the coherent interface. The interface intersects $(001)_\alpha$ at 26.82°.

metrically related sets of interfaces in all, which intersected $(001)_\alpha$ at 26.82° (Fig 2). This is in fair agreement with 27° obtained experimentally. In a similar manner, the intersection angle of 27.64° was obtained as the most probable one at the transition temperature (1425°C) by Fukuda (1994c), taking into consideration the temperature dependence of cell parameters for the α- and α'- phases (Yamaguchi *et al.*, 1963; Regourd *et al.*, 1968; and Saalfeld, 1975).

Determination of Crystallographic Orientation from Striation Directions

The stereogaphic understanding of the overall lamella structure (Fig 2) enables us to produce every kind of geometrical features of the striations on any orientational polished surface. By comparing the striation directions found from calculation with those by observation, we can reconstitute the crystallographic orientation of the parent α-phase. Figure 3B shows schematically the striations observed in Fig 3A, together with the angles between them. The orientation of the parent α-phase axes was superimposed on the figure, indicating that the inclination of the c_α-axis from the surface normal was about 9°.

Kinetics

The α-to-α' transition is a nucleation and growth process. Thus, the transition process was shown on the time-temperature-transformation (TTT) diagram (Fukuda *et al.*, 1993b). In Fig 4, the left C-shaped curve represents the time and temperature at which the product α'-phase is first detectable, and the right curve the time at which the reaction is complete. In the region between the two curves, the belite is composed of both the α- and α'-phases, and the fraction of the α'-phase increases with time for a given temperature. The broken lines in the figure give the thermodynamic transition temperature between α and α'; the α'-phase exists in equilibrium with the parent α-phase at 1280°C. The temperature

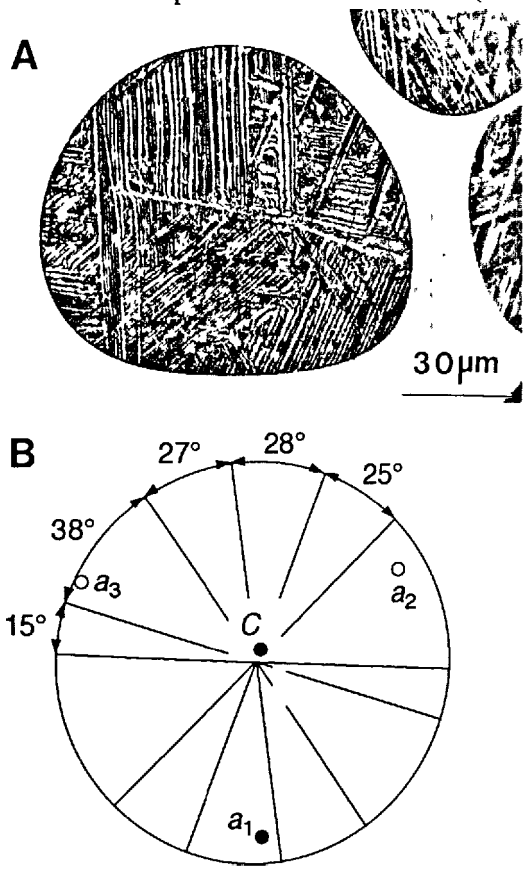

Figure 3 (A) Lamella structure in belite. Polished section. Reflected light. (B) Probable orientation of crystallographic axes of the parent α-phase. Stereographic plotting. Heavy lines represent the six orientational striations observed in A.

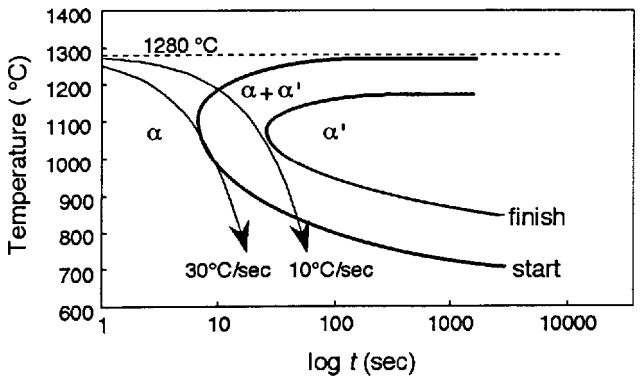

Figure 4 Time-Temperature-Transformation diagram for the α-to-α' transition in belite with the chemical formula: $(Ca_{1.87}Na_{0.13})_{\Sigma 2}(Si_{0.90}Al_{0.04}Fe_{0.03})_{\Sigma 0.97}O_{3.83}$. The cooling curves in the figure are for the linear cooling from 1280°C.

at which the transition occurs at a maximum rate was about 1100°C. With decreasing concentration of foreign oxides (Na_2O, Al_2O_3 and Fe_2O_3) in solid solution, the time at which the reaction is first detectable decreased steadily.

Two cooling curves for the linear rate of 30°C/sec and 10°C/sec have been superimposed on the TTT diagram (Fig 4). The fastest cooling curve does not cross the starting C-shaped curve, and hence the α-phase will be quenched without the α-to-α' transition being initiated. For a cooling rate between 30°C/sec and 10°C/sec, the transition will start at around 1150°C, though it will not be complete. Thus, the crystal grains must show the α'-phase lamellae in the host α-phase. During subsequent cooling, the transition of α' → β will occur within the lamellae, and the resulting crystal will be made up of the β-phase lamellae and the α-phase host at ambient temperature. For a cooling rate lower than 10°C/sec, the α-phase will be entirely inverted to the α'-phase. After that, the remelting reaction, as mentioned below, will immediately occur within the crystal.

REMELTING REACTION*

Phase Stability

On the CaO-SiO_2-Fe_2O_3 ternary phase diagram, the liquidus field of Ca_2SiO_4 extends toward the $CaFe_4O_7$ component (Levin *et al.*, 1964); the liquid coexisting with Ca_2SiO_4 varies in composition along the line Ca_2SiO_4-$CaFe_4O_7$. Fukuda *et al.* (1995a) established the phase diagram of this pseudobinary system as given in Fig 5. The diagram shows that, when the α-phase crystal coexisting with liquid is cooled below 1290°C, the remelting reaction occurs.

To illustrate an ideal sequence of the cooling process in the system, we will consider the changes which take place in the mixture of the α-phase crystal (composition S1) and the liquid (L1) at 1600°C (Fig 5). When the mixture is cooled to 1200°C, the α-phase crystal (S1) will decompose into the liquid (L2) and the α'-phase crystal (S2), which is lower in impurity concentration than the former α-phase. At the same time, from the liquid (L1) coexisting with the α-phase (S1), the α'-phase crystal of composition S2 will be newly nucleated.

The direct transformation of α → liquid + α' shown in the diagram (Fig 5), however, seems to require a large activation energy. Accordingly, the α-to-α' polymorphic transition first occurs upon cooling without a change in chemical composition. After the transition, the liquid exsolves heterogeneously on the lamella boundaries because of the favorable activation energy for nucleation (Fukuda *et al.*, 1992a).

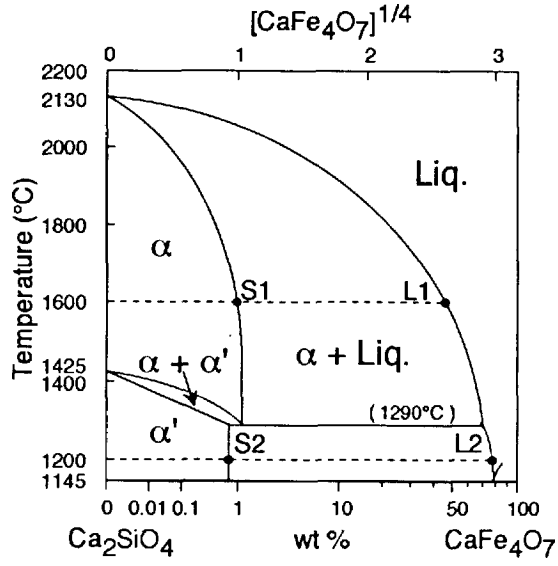

Figure 5 Phase diagram of the P_2O_5-bearing pseudobinary Ca_2SiO_4-$CaFe_4O_7$ system. For convenience, $[CaFe_4O_7]^{1/4}$ was used as the concentration scale.

*A reaction in which a solid decomposes into another solid and a liquid during cooling. The first report on the remelting reaction in belite given by Fukuda *et al.* (1992a).

Wettability of Belite Lamellae by Exsolved Liquid

The rate of the remelting reaction depends on the wettability of the α'-phase lamellae by the exsolved liquid as well as on the temperature (Fukuda *et al.*, 1993c and 1994a). The difference in wettability should come from the chemical composition of the exsolved liquid, which depends on the kinds of impurities and their relative concentration (Al/Fe ratio) in the parent α-phase belite.

When the wettability is low, the liquid forms droplets on the lamella boundaries (Fukuda *et al.*, 1992a). The belite with Al/Fe < 1 exsolved such liquids (Fig 6). The liquid with minimum interfacial area would immediately reach a local equilibrium with the belite matrix. Inside the lamellae, the remelting reaction was hardly expected to occur because of the large activation energy for homogeneous nucleation of the liquid. Under these conditions, the rate-determining step was the volume diffusion of foreign ions from the bulk to the liquid droplets on the lamella surfaces, and thus the reaction was very sluggish. The reaction rate after the formation of droplets was so low that, despite slow cooling, the outline of the belite grains and the intracrystalline lamella structure tended to remain for a long time. This microtexture showing liquid droplets disposed in lines on the lamella boundaries has been denoted as Type Ia.

On the contrary, the liquid exsolved from the belite with Al/Fe > 1, due to the high wettability, spread over the lamellae and disintegrated the lamella structure (Fukuda *et al.*, 1993c). Because of the large interfacial area between the lamellae and the liquid, the reaction proceeded until the parent crystals were completely replaced by the new α'-phase crystals (Fig 7). During the decomposition process, the impurity concentration continued to decrease, and various microtextures (e.g., "fingers extending into the matrix material" by Insley, 1936, and "serrated edges" by Insley *et al.*, 1938) resulted. From the liquid coexisting with the α-phase crystals, the α'-phase crystals (labeled "P" in Fig 7) were newly precipitated and usually overgrew the former α-phase crystals. This texture has been denoted as Type III. During further cooling, the transition of $\alpha' \rightarrow \beta$ should

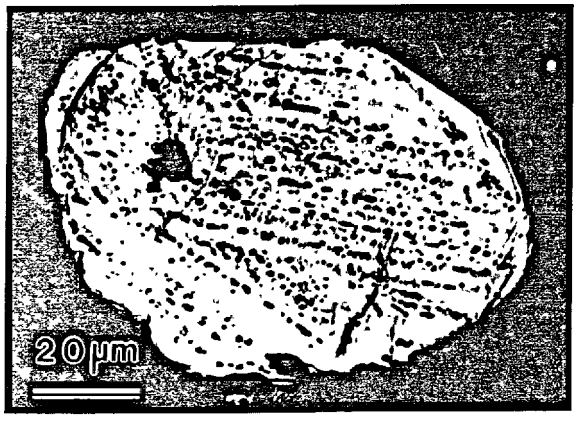

Figure 6 Optical micrograph using transmitted light under crossed polars. The small liquid droplets (now glass at ambient temperature) disposed in lines on the lamella boundaries indicate that the remelting reaction occurs after the α-to-α' polymorphic transition. The chemical formula of the parent crystals is: $(Ca_{1.931}K_{0.030}Al_{0.004}Fe_{0.006}\square_{0.029})_{\Sigma 2.000}$-$(Si_{0.936}P_{0.067})_{\Sigma 1.003}O_4$ (Al/Fe = 0.7 < 1).

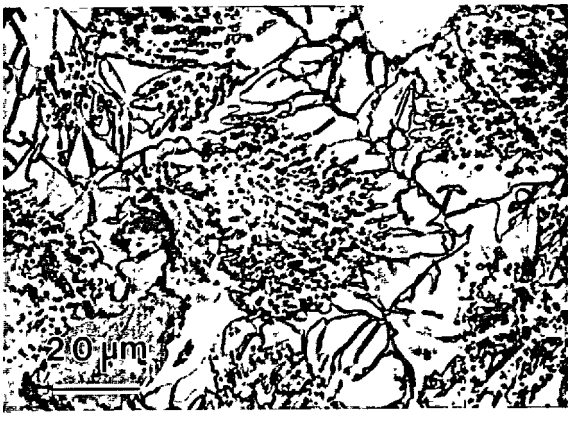

Figure 7 Optical micrograph using reflected light. Etched with nital. Cooled from 1600°C at 36°C/min and quenched at 1200°C. The chemical formula of the parent crystals is: $(Ca_{1.960}Mg_{0.015}Na_{0.017}K_{0.005}Ti_{0.004})_{\Sigma 2}$-$(Si_{0.917}Al_{0.048}Fe_{0.021}S_{0.008})_{\Sigma 0.994}O_{3.954}$ (Al/Fe = 2.3 > 1). The inner part (labeled "I") shows many inclusions of the exsolved liquid.

occur within the overgrown crystals, leading to the formation of the polysynthetic twinning frequently on $(100)_\beta$ and rarely on $(001)_\beta$ (Kim *et al.*, 1992). When the twin planes were almost perpendicular to the polished surface and the specimen was properly etched, the single orientational lamella structure, which has been denoted as Type II, would be observed under the reflected light.

Kinetics

The quantitative relationship between the fraction remelted and the cooling rate was determined for the belites doped with Na_2O, Al_2O_3 and Fe_2O_3 (Fukuda *et al.*, 1995b). Because the Al/Fe ratio was larger than 1, the remelting reaction proceeded to its final stage with prolonged heat treatment. The β-angle varied most sensitively with the Na/(Na+Ca) ratio (= x) according to $\beta\ (°) = 94.55 - 8.86x$ ($0 \le x \le 0.03$). The decrease in x caused by the remelting reaction was therefore detected by the increase in β. When the belite was cooled at a constant rate r (°C/sec) over the temperature range in which the remelting reaction occurred, the fraction remelted (ζ) was expressed by $\zeta = 1\text{-}\exp(-1.33r^{-0.25})$.

THERMOELASTIC MARTENSITIC TRANSFORMATION

The α'-to-β phase transformation has been considered to be martensitic (Groves, 1981, 1982 and 1983; Barnes and Ghose, 1983; Kim *et al.*, 1992). Recently, Fukuda *et al.* (1996a, 1996b) have reported that the transformation was thermoelastic. They confirmed the relief effect, which is characteristic of martensitic transformations, on the parent crystal surface. The growth and shrinkage behavior of the plate-like reliefs (martensite plates) during cooling and heating was observed in situ under a high-temperature optical microscope to determine the transformation temperatures. The thermal hysteresis (A_s - M_s) was negative in accord with the thermoelasticity (Delaey, 1991), where A_s and M_s are the start temperatures of the reverse and forward transformations, respectively.

Because of the transformation being athermal, the transformed fraction remained unchanged when the temperature was kept constant. As the temperature was decreased from M_s, the fraction increased up to M_f, at which the reaction was complete. Accordingly, the phase constitution at any temperature (T) during cooling was determined as α' ($M_s < T$), α' and β ($M_f \le T \le M_s$) and β ($T < M_f$). Upon heating, the reverse transformation occurred, which was also athermal between A_s and A_f (the finish temperature).

INCOMMENSURATE PHASE TRANSFORMATION

A one-dimensional incommensurate phase has been reported to occur in the belites doped with P_2O_5 (Saalfeld, 1971; Saalfeld and Klasla, 1981; Fukuda and Maki, 1989b; Fukuda *et al.*, 1994b) or other oxides (Jelenic and Bezjak, 1982; Fukuda *et al.*, 1992b). The crystal grains consisted of orthorhombic domains related by 120° rotation around the c-axis of the former α-phase. The domains were at the submicroscopic level and the boundaries were irregular. Thus, the crystal grains showed mottled extinction under crossed polars. From the electron diffraction pattern, all the reflections were expressed by $Q = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* + n\mathbf{k}$ using four indices (h, k, l, and n) with $\mathbf{k}$ as the

wave vector (Fukuda *et al.*, 1994b). This vector was redefined using N and the unit vectors **a*** and **c*** as $(1/N)\mathbf{a}^*+\mathbf{c}^*$, where N is the modulation wavelength. A good correlation was observed between N and P/(Si+P) ratio. From the relationship, a commensurate phase with $N = 4$ is expected at P/(Si+P) = 0.148. The crystal structure may be close to that determined by Saalfeld and Klaska (1981), who refined the structure of $6Ca_2SiO_4 \cdot 1Ca_3(PO_4)_2$ (P/(Si+P) = 0.250 and $N = 3.75$) assuming $N = 4$.

TRANSFORMATIONS OF BELITE IN NORMAL CEMENT CLINKERS

The belite in cement clinkers is mostly formed in the stable temperature region of the α-phase. Upon cooling, the α-to-α' transition usually occurs. Because of its isothermal process, the fraction transformed increases with decreasing cooling rate. With rapid cooling, the belite can be composed of both the α- and α'-phases. The product α'-phase will be completely inverted to the β-phase as long as M_f is higher than the ambient temperature, which is often the case with the belite in normal clinkers. When the α-phase belite is cooled more slowly, it can be inverted to the α'-phase completely. After that, the remelting reaction will immediately occur. The resulting microtexture depends on the cooling rate as well as on the Al/Fe ratio of the parent α-phase.

EFFECT OF Al_2O_3 AND Fe_2O_3 IN THE FORMATION OF DICALCIUM SILICATE PHASE

V K MATHUR, K M SHARMA AND R S GUPTA
National Council for Cement and Building Materials,
New Delhi, India

S C AHLUWALIA, OCL India Ltd., New Delhi, India

ABSTRACT Infrared and XRD studies of the Fe_2O_3 and Al_2O_3 doped dicalcium silicate phase indicate that Al_2O_3 in the system $CaCO_3$ and SiO_2 (2:1) stabilizes β-C_2S phase while Fe_2O_3 leads to the formation of β- and γ-C_2S. The activation energies (Ea) of C_2S formation decreases upto addition of 0.5 wt. percent with both the dopents and then rises with increasing concentration of dopants.

Key-words: Activation energy,Dicalcium silicate,Dopant,Polymorphs

INTRODUCTION

Cationic and anionic dopants have been reported to have a significant effect on the formation and stabilization of various polymorphs of dicalcium silicate mineral and some of the investigators (Lai, et al 1992) have reported results at variance, which could be due to difference in experimental conditions. A systematic study of the effect of number of dopants on the kinetics of formation and stabilization of various polymorphs of dicalcium silicate have been reported earlier (Ahluwalia and Mathur, 1986,1988 and Mathur, Gupta and Ahluwalia, 1992). The present paper is a part of these investigations and deals with the effect of Al_2O_3 and Fe_2O_3 as dopants.

EXPERIMENTAL

Different mixtures of calcium carbonate and quartz powder (purity > 99.5 %) were prepared in 2:1 molar ratios without and with varying concentrations of Al_2O_3 and Fe_2O_3 as dopant. Nodules were prepared from these mixtures. These nodules after drying at $100^{\circ}C \pm 5^{\circ}C$ were stored for experimental work.

DTA studies of the above samples were conducted on Mettler thermal analyser (TA-1) and formation temperature of C_2S phase and other minor compounds were recorded (Table 1). For identification of the products formed, the starting materials were again fired to the temperature where the thermal peaks obtained. These fired samples were then quenched in liquid nitrogen and stored in air tight containers. The quenched products were then identified by IR (Perkin Elmer model IR - 621) in 1800 - 400 cm^{-1} region and XRD (Philips model PW 1120 diffractometer with Ni-filtered Cu radiation). The Ginstling - Brownshtein diffusion equation (Feng and Shangren, 1986 and Mathur et al 1992) was used to calculate the rate constant Kr and the activation energy (Ea) was calculated by the Arrhenius equation.

RESULTS AND DISCUSSION

IR and XRD studies of the quenched products without and with varying concentrations of Al_2O_3 as dopant revealed that β-C_2S

phase is formed in all these samples alongwith some minor compounds of calcium aluminates (Table 1, Fig. 1). Al_2O_3 as dopant in concentration range of 0.1 - 0.5 wt. percent forms small quantities of $CaAl_2O_3$, 1.0 wt. percent $Ca_2Al_2SiO_7$ and 5.0 wt. percent of Al_2O_3 as dopant forms $Ca_3Al_2O_6$ $Ca_2Al_2SiO_7$, $CaAl_2O_4$ (Ahluwalia and Mathur, 1988). A drop in intensity of absorption band was observed at 890 cm^{-1} (Bensted and Varma, 1974) which could possibly be due to substitution of Al^{3+} in SiO_4 tetrahedra. Strong IR bands at 520, 540 and 840 cm^{-1} correspond to β -C_2S while at 898 cm^{-1} to C_3A with 5.0 wt. percent of Al_2O_3 dopant (Fig. 1).

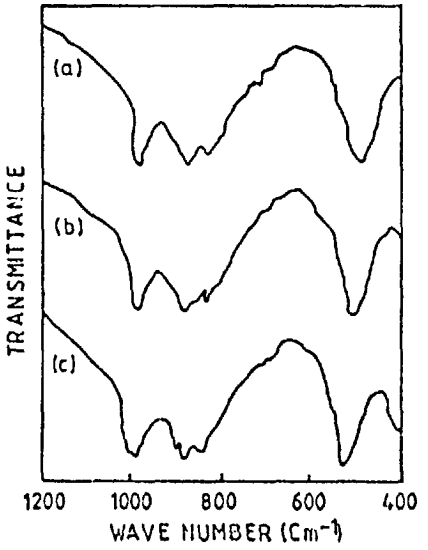

FIG 1 IR SPECTRA OF Al_2O_3 DOPED DICALCIUM SILICATE PHASE

(a) 0.1 % (b) 1.0 % (c) 5.0 %

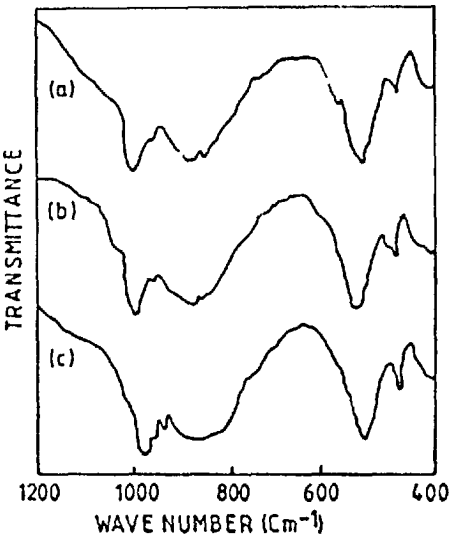

FIG 2 IR SPECTRA OF Fe_2O_3 DOPED DICALCIUM SILICATE PHASE

(a) 0.1 % (b) 1.0 % (c) 5.0 %

IR and XRD studies of the Fe_2O_3 doped C_2S revealed that by increasing the concentration of Fe_2O_3, stabilization of γ-C_2S phase is more intense while occurrance of β -C_2S phase decreases (Table 1, Fig. 2). The IR bands appearing at 440, 445 and 565 cm^{-1} correspond to γ-C_2S while at 520 and 845 cm^{-1} to β -C_2S phase. The most predominant peak of γ -C_2S phase appears at 855 cm^{-1}. With 1.0 wt. percent Fe_2O_3 . α -Fe_2O_3 is formed in small quantity while with 5.0 wt. percent of Fe_2O_3 small quantities of Fe_3O_4, $CaFe_3O_5$ and FeO are also formed. It is inferred that some Fe_2O_3 may be reduced to Fe_3O_4 and FeO due to limited supply of air and high temperature. This FeO is said to be responsible to stabilise γ-C_2S phase (Ahluwalia and Mathur, 1988). The strong band corresponding to β -C_2S phase at 890 cm^{-1} was found missing. The shifting of the band indicates that iron is partially substituted for silicon.

The activation energy (Ea) of the reaction process of C_2S phase formation in pure system was reported to be 180 KJ mol^{-1}, (Mathur, et al, 1992) which decreases to 154 KJ mol^{-1} with 0.5 wt. percent Al_2O_3 and to 148 KJ mol^{-1} with 0.5 wt. percent Fe_2O_3 (Table 1). By further addition of these dopants Ea again starts rising (Table 1) which may be attributed to the formation of the other minor compounds alongwith dicalcium silicate phase.

Both Al3+ and Fe3+ substitute Si4+ in its tetrahedral yielding a compound of chemical composition $Ca_2 [M_x SiO_{4-x/2}]$ where M is Al^{3+} or Fe^{3+} as also reported by forest (1967).

Table 1 KINETICS & POLYMORPHISM OF 2 $CaCO_3$: SiO_2 SYSTEM WITH VARYING CONCENTRATIONS OF DOPANTS

Dopant's Name	Concentration of Dopant in $2CaCO_3 : SiO_2$ System (% wt.)	DTA Peak after $CaCO_3$ Decomp. (^oC)	Activation Energy of Reaction Process of C_2S Formation ($KJ\ mol^{-1}$)	Constituents Formed as Discerned by IR and XRD of Liquid Nitrogen Quenched Samples
Al_2O_3	0.0	1425	180	β-C_2S, γ-C_2S
	0.1	1445	163	β-C_2S, $CaAl_2O_4$
	0.5	1445	154	β-C_2S, $CaAl_2O_4$
	1.0	1445	158	β-C_2S, $Ca_2Al_2SiO_7$
	5.0	1420	165	β-C_2S, $Ca_2Al_2SiO_7$ $CaAl_2O_4$, $Ca_3Al_2O_6$
Fe_2O_3	0.1	1440	160	γ-C_2S, β-C_2S ($\beta > \gamma$)
	0.5	1430	148	γ-C_2S, β-C_2S ($\gamma > \beta$)
	1.0	1430	152	γ-C_2S, β-C_2S ($\gamma > \beta$) α-Fe_2O_3
	5.0	1400	158	γ-C_2S (Most intense), β-C_2S (small qty) FeO Fe_3O_4, $CaFe_3O_5$

CONCLUSION

Al_2O_3 with different concentration stablizes β-C_2S alongwith other phases e.g. $CaAl_2O_4$ C_2AS (Gehlenite) and $Ca_3Al_2O_6$. Fe_2O_3 with all concentration studied helps the formation of a mixture of and C_2S phase with other iron bearing phases like α-Fe_2O_3, Fe_3O_4, $CaFe_3O_5$ etc. Activation energy (Ea) of reaction process of C_2S phase formation decreases upto 0.5 wt. percent with both the dopants and then rises by further addition of any of these dopants, which could be attributed to the formation of other minor phases.

THE INFLUENCE OF MOLYBDIC COMPOUND ON FORMATION OF CEMENT CLINKER

Yizhou PAN Yuechong CHI Xingfu FU
Zhejiang Building Materials Scientific Research Institute, Hangzhou, P. R. CHINA

ABSTRACT In this paper , the effect of different form of molybdic compounds on clinker formation is studied , and the formation rate for clinker with composite mineralizer has the following order: [MoS_2+CaF_2] > [MoO_3+CaF_2] > [$CaSO_4$+CaF_2] > no mineralizer .

Key-words: Molybdic compounds Burnability of raw mixes Clinker formation

INTRODUCTION

Reducing energy consumption and improving clinker quality are two of the main purpose in the development of cement technology . In order to raise output and quality as well as to save energy , great attention has been paid worldwide to low burning temperature in clinker process with the mineralizer .

It is found that molybdic compounds acting as mineraliers would produce different effect on clinker formation due to the difference form of them during the studies on producing portland cement with trace components in tailings of molybdenum-iron ore (Pan 1992) . A lot of reports about the mineralizers have been published , but few of them deal with the research field of tailings of molybdenum-iron ore as mineralizer (Timashev 1980 , Xu 1993 , Chen 1993 , Li 1993). In this paper , the effect of separate addition of MoO_3 , MoS_2 , $CaSO_4$ and the complex effect of them combined respectively with fluorite was studied vis-a-vis gypsum-fluorite mineralizer . The results show that the composite mineralizer MoS_2+CaF_2 exhibit better effect on absorption of free lime than others in clinkerization process .

EXPERIMENT

Materials and Methods

Raw mixes for experiments were proportioned by chemical pure agents according to the parameter : $KH=(CaO-1.65AL_2O_3-0.35Fe_2O_3)/2.8SiO_2=0.917$, $SM=1.96$, $AM=1.25$, and mixed in a ceramic mill for 30 min , then were made into cylinder 15 mm in diameter and 20 mm in height . The samples were placed in electric furnace and preheated at the chosen temperature for a certain time interval and cooled in air . Free lime in the sintered samples was determined by using glycerin-alcohol solution .

RESULTS AND DISCUSSION

Effect of separate mineralizer

When the content of separate compounds doped in mixtures is 1% (Fig. 1) , the

This project is supported by the Zhejiang Natural Scientific Foundation, P. R. China

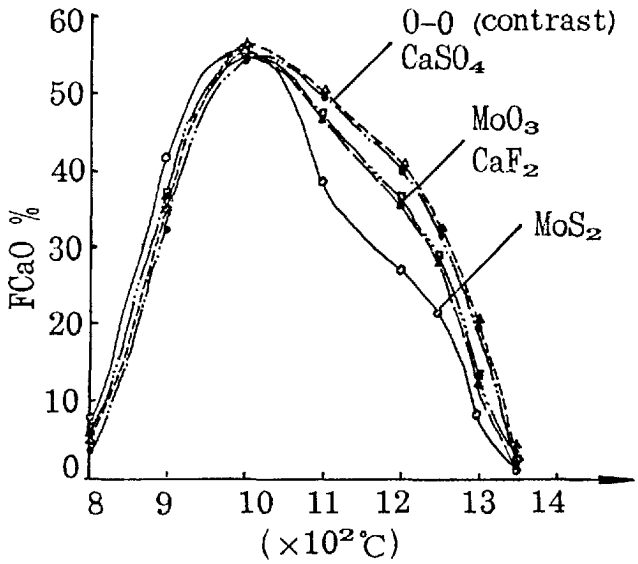

Fig. 1 Effect of mineralizer in 1% addition on burnability of raw mixes

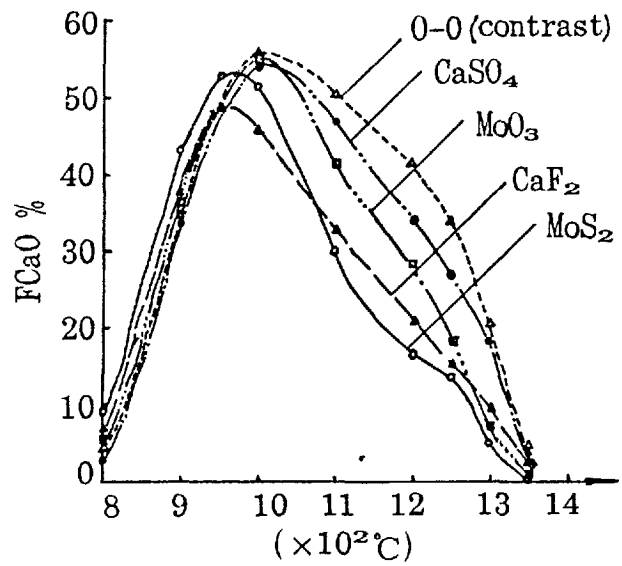

Fig. 2 Effect of mineralizer in 2% addition on burnability of raw mixes

free lime of mixture with MoS_2 contained was significantly lower free lime than others at 1000-1300℃ , and mixture with MoO_3 or CaF_2 was second low and mixture with $CaSO_4$ appears close to contrast sample . At 2% addition of compounds alone (Fig. 2), the maximum point of free lime to mixtures with CaF_2 or MoS_2 is early 50℃. The difference of free lime at 1100-1300℃ is obvious and the quantity of it is in the following order : 0-0 > $CaSO_4$ > MoO_3 > CaF_2 > MoS_2 . It is worth to mention that the region of this temperature is important stage of appearance of early liquid and the formation and the decomposition of intermediate transition phases as well as nucleation and crystal growth of alite . During the clinkering process , the remarkable reduction of free lime create advantage condition to form alite quickly and improve the clinkeration of raw mixes at lower temperature . The experimental results prove that MoS_2 mineralizer exhibit better effects on free lime absorption , especially in low temperature in clinkering process .

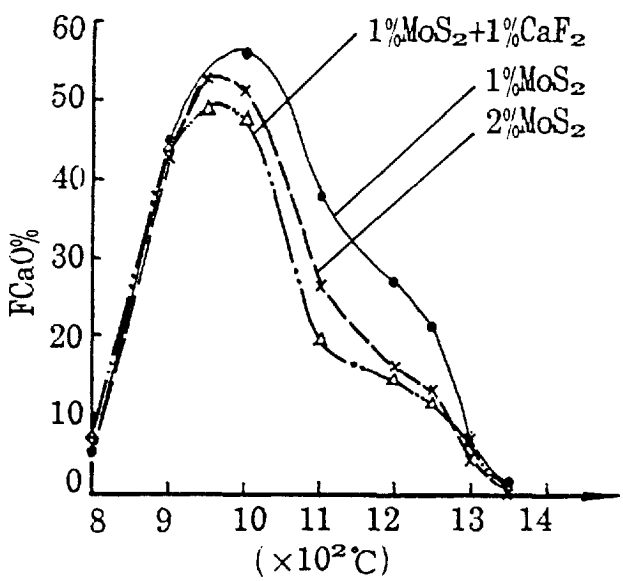

Fig. 3 Effect of MoS_2 on burnability

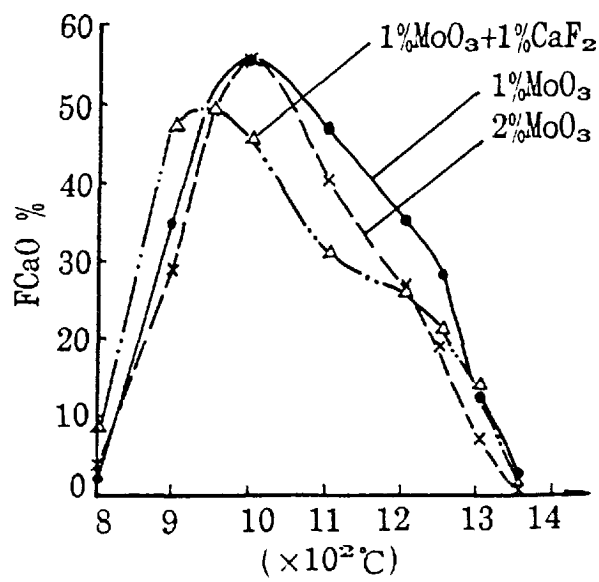

Fig. 4 Effect of MoO_3 on burnability

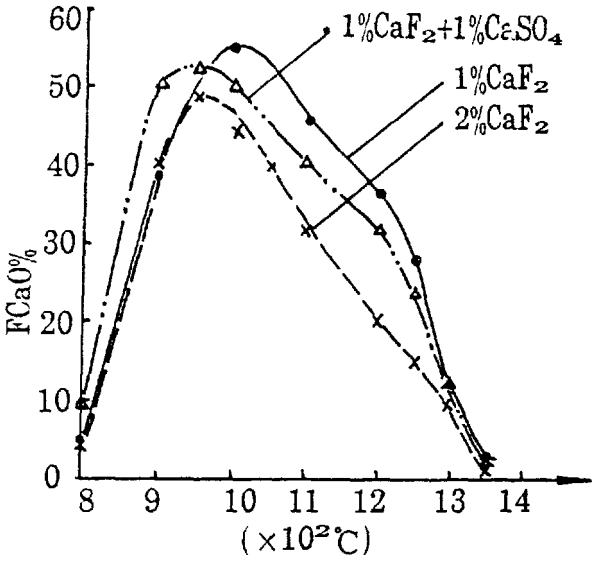

Fig. 5 Effect of CaF_2 on burnability

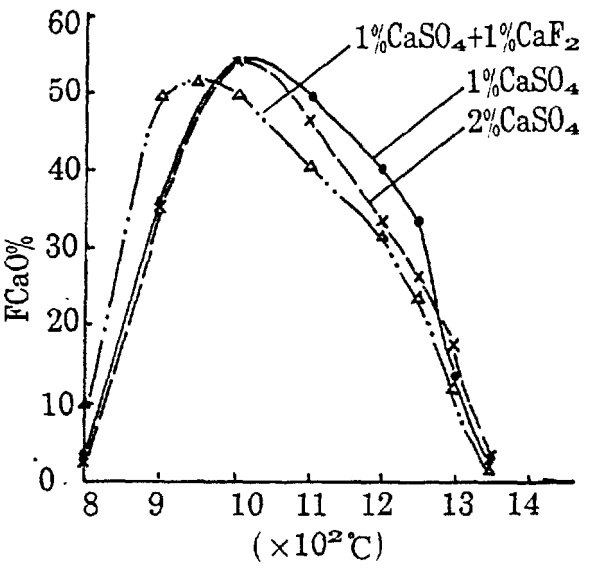

Fig. 6 Effect of $CaSO_4$ on burnability

Effect of complex mineralizer

The maximum point of free lime appears 50℃ early to mixture with MoS_2+CaF_2 and the free lime quickly decrease at 1000-1100℃ which may be attributed to formation of early liquid and intermediate transition compounds (Fig 3) . The mixture has lower free lime vis-a-vis mixture with MoS_2 alone .

MoO_3 and CaF_2 in combination (Fig 4) can improve the decomposition of $CaCO_3$ and make the maximum point of free lime 50℃ early and exert a considerable effect on reducing free lime within the temperature region of 950-1200℃ , moreover , this action is not obvious at 1250-1350℃ in comparison with that of MoO_3 alone .

The complex effect of $CaSO_4$ and CaF_2 on accelerating the decomposition of $CaCO_3$ and lower the free lime of clinker is evident compared to the effect of $CaSO_4$

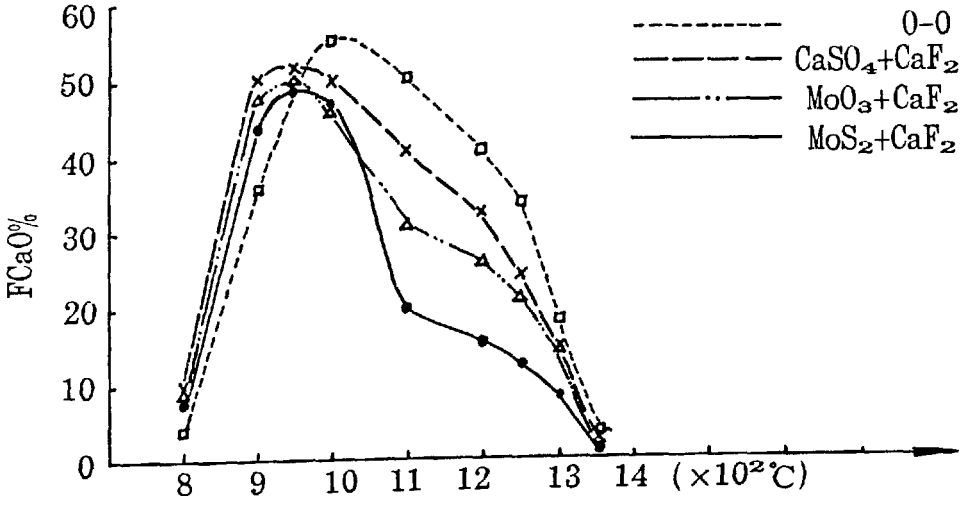

Fig . 7 Effect of complex mineralizers on burnability of raw mixes

alone (Fig. 5, 6) , but is smaller than that of 2% CaF_2 addition and higher than that of 1% CaF_2 addition .

Comparison of the complex mineralizer

The common behaviors of MoS_2 , MoO_3 , and $CaSO_4$ combined with CaF_2 respectively would improve decomposition of $CaCO_3$ and let the maximum point of free lime of mixtures ahead of 50℃ (Fig 7) . The decrease rate of free lime in mixtures at 1000 -1300℃ is MoS_2+CaF_2 > MoO_3+CaF_2 > $CaSO_4$+CaF_2 > 0-0 , and indicated difference among them is 10% separately at 1100℃ as well as the difference of free lime decrease when the temperature rise . The effect of complex mineralizer on reducing free lime is MoS_2+CaF_2 in first place , MoO_3+CaF_2 in second , and $CaSO_4$+CaF_2 in third . The different form of molybdic compounds produce the different influence on burnability of raw mixes and formation of clinker . The obvious effect of complex mineralizers on reducing free lime is owing to the decrease of liquid viscosity and the lower temperature of the liquid appearance which led to accelerate formation of alite and improve the burnability of raw mixes .

CONCLUSIONS

1. The formation rate to mixtures with separate mineralizer sintered at given temperature has the following order: MoS_2 > MoO_3 = CaF_2 > $CaSO_4$ > pure clinker at 1% addition ; and MoS_2 > CaF_2 > MoO_3 > $CaSO_4$ > pure clinker at 2% addition .
2. The common effect of MoS_2 , MoO_3 and $CaSO_4$ combined with CaF_2 respectively would improve the decomposition of $CaCO_3$ and make the maximum point of free lime earlier 50℃ .
3. The difference from of molybdic compound appears the difference behaviors on absorption of free lime and the effect of complex mineralizers on clinker formation is in the order of [MoS_2+CaF_2] > [MoO_3+ CaF_2] > [$CaSO_4$+CaF_2] > control sample .

ABSTRACT In this paper the influence of Mo ionic geometry size , electric structure and charge on silicate and aluminoferrite phases and selective distribution in minerals are studied on base of some concepts of solid physics and structural chemistry., and the effect of Mo ion on chemical activation of ferrite phase is also investigated .

Key-words: MoO_3 Calcium silicate Aluminoferrite Crystal structure

INTRODUCTION

The scope for utilizing tailing of minerals and industrial wastes to produce cement has recently widened owing to the necessity to utilize wastes and exploit new raw material resources . It is verified that the use of tailings of molybdenum iron produce cement clinker is not only considered as a substitute for all ferrous materials and parts of natural minerals of limestone and clay , but also acts as mineralizers instead of mineral gypsum and results in improving quality and output and decrease cost of cement manufacture (Pan 1992) . The mechanism of trace elements Mo on clinker formation has been discussed in published papers , but the solid solubility and distribution of Mo in various phases of clinker and the effect of it on structure of clinker are not clear from published date (Timashev 1980 , Kakali 1989 , Kakali 1990) . These problems need further studying . In this paper the influence of Mo ionic geometry size , electric structure and charges on silicate and aluminoferrite phases and selective distribution in minerals are studied on base of concepts of solid physics and structural chemistry .

EXPERIMENT

Materials and Methods

Raw mixes for the experimental work were proportioned by natural limestone , clay and iron power with the appropriate amount of chemical pure reagent MoS_2 according to the designed ingredients and mixed in a homogenizer . All raw mixes were thermally treated in an electrical furnace and cooled rapidly in air . Clinkers were fired at 1350℃ for one hour and gypsum (3% w/w) were respectively ground in a ceramic mill for 40 min, keeping w/c= 0.3 in all the cases , the mortar compressive strengths were measured on 20×20×20 mm specimens .

RESULTS AND DISSCUSION

Distribution of molybdenum in various phases of clinker

A previous study showed that the Mo is mainly dissolved in the interstitial phase and least in the silicate phase (Pan 1992) . It is further supported by the point energy spectrum analysis in clinker mineral phase (Fig. 1) , that Mo exists in a relatively minor amount and is similar contents of solid solution in dicalcium silicate and

This project is supported by the Zhejiang Natural Scientific Foundation, P. R. China

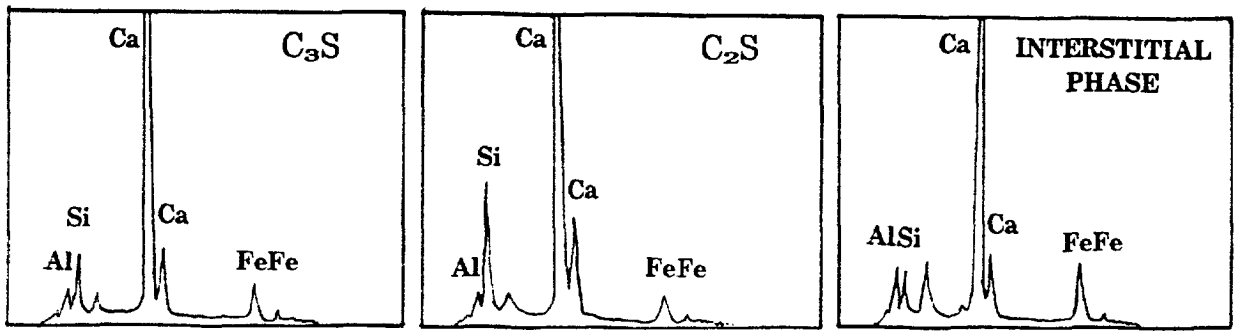

Fig. 1 The point energy spectrum curve of clinker with Mo

tricalcium silicate . Figure 2 shows the X-RD patterns of clinkers with and without Molybdenum . As it can be seen , the principal phases of clinker are satisfactory crystallized . The peaks of aluminate in two samples are similar but aluminoferrite of clinker containing Mo rise obviously . This indicates that molybdenum in interstitial phase mainly dissolved in the aluminoferrite phase .

Effect of molybdenum on silicate phase

As is known that silicate phase in clinker (C_3S , C_2S) is built up of the skeleton structure of silicon-oxygen radicals . Amphoteric Al^{3+} and Fe^{3+}ions with Si^{4+} ions can form partial dissolved solid solution due to radius difference between Al^{3+} , Fe^{3+} ions with Si^{4+} ions is >38%(table 1), as well as they exhibit a lower polarizability than do the silicon ions . Therefore , there is only minor replacement of Si^{4+} by Al^{3+} or Fe^{3+} . The different ratio of radius between Mo^{6+} ions with Si^{4+} ions is 47% , but the radius of Mo^{6+}ions is close to Fe^{3+} and Al^{3+}ions . The Mo ions in clinker may replay part of Fe^{3+} and Al^{3+} ions dissolved in alite and belite . Moreover , Mo^{6+} ions have high polarization ability and substitution potential of MoO_4^{2-} for SiO_4^{4-} forming solid solution . The amounts of substitution was limited by the difference of ion radius and charges . Therefore , the total amount of Mo dissolved in silicate phase is minor , which is in agreement with experimental results , the effect of adding Mo ions on internal structure of silicate phase is limited .

Table 1 Characteristic of Ions

Ions	Ionic Radius (R) A		Difference of Radius (%) $(R_i-R_{Si})/R_{Si}$	Polarizability C^2 / R	
	IV	VI		IV	VI
Si^{4+}	0.34	—	0	47.0	—
Ca^{2+}	—	1.08	—	—	3.7
Fe^{3+}	0.57	0.73	68	15.8	12.3
Al^{3+}	0.47	0.61	38	19.1	14.8
Mo^{6+}	0.50	0.68	47	72.0	52.9

Aluminoferrite solid solution with molybdenum

The XRD analysis indicate that Mo in clinker interstitial phase mainly existed in aluminoferrite phase . It is worth to discuss effect of Mo^{6+} ions on Fe^{3+} ions in the phase . Amophoteric Fe present in the mineral in the form of tetrahedral $[FeO_4]^{5-}$ and octahedral $[FeO_6]^{9-}$ groupings . For the radius difference of Mo^{6+}ion with Fe^{3+} is 12% , smaller than 15% , and the type of crystal structure of both ions is same , so they can form complete dissolved solid solution for each other. When Mo ions get into lattice of aluminoferrite phase , the formation of substitution type solid solution make the crystal structure strongly distorted and violate charges balance of original crystal as result improving the activity of ferrite phase .

Effect of molybdenum on the strength of clinker

Figure 3 shows the results of clinker mortar strength tests . Compared with the clinker samples without Mo, samples mixed with Mo exhibit better strength increase at early ages (3 days) at 0.5%-3% MoO_3 addition . The strength of clinker mixed with 2% MoO_3 reaches the maximum one and 0.5% MoO_3 addition in clinker is considered as optimum with high compressive strength which was measured at 28 days . the strength change of clinker containing Mo ions may be connected with Mo ions concentrated in the aluminoferrite phase according to the distribution of Mo in various phase .

Formation of solid solution of the substitution type

The radius of Mo ions is close to Fe ions and Mo can form complete dissolved solid solution with Fe ions in ferrite as well as cause the Fe coordination changes . When Mo ions replacing Fe ions and forming substitution type solid solution , Mo ions having smaller radius and higher valence and polarizability than that of Fe ions may occupy tetrahedral vacancies and make Fe^{3+} ions position from low coordination to higher one. The distance between iron and oxygen at octahedral is higher than that at tetrahedral. Therefore these results decrease the strength of Fe-O bands which were readily broken down in hydration process and increase the hydration of ferrite .

Effect of electrovalence

The replacement of Fe^{3+} by Mo^{6+} in aluminoferrite phase belongs to heterovalent replacement and creates cation vacancies to compensate unbalancing electric valences . The reaction of vacancies may be expressed by the following equation .

$$MoO_3 \xrightarrow{Fe_2O_3} Mo_{(Fe)}^{+++} + V_{(Fe)}''' + 3O_O^{\times}$$

The increase of vacancies amounts in ferrite phase lattice bring about the strong

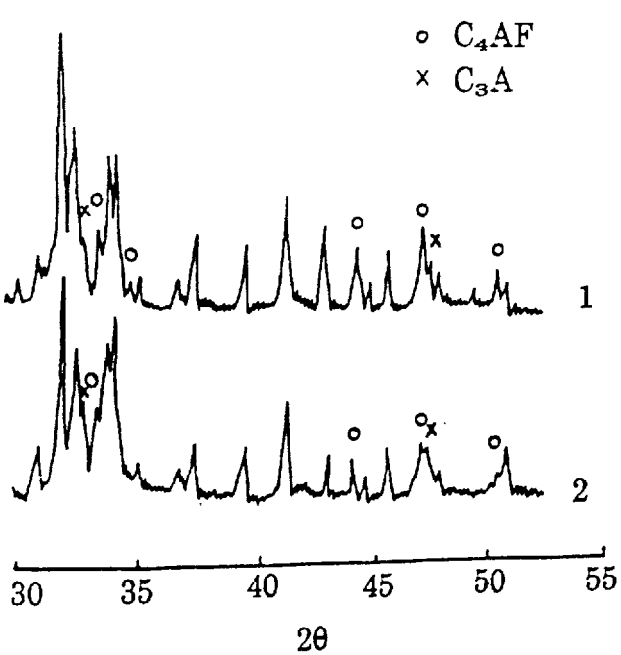

Fig. 2 XRD patterns of clinker
1. Clinker with Mo 2. Pure clinker

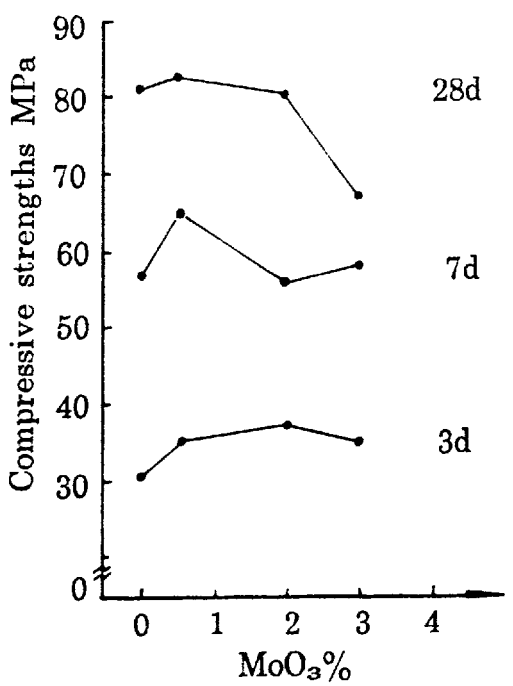

Fig. 3 Compressive strength of clinkers with different amounts of MoO_3

lattice distortion of the crystal structure and raising the internal energy . This results in all system get into thermodynamic instability , the vacancies of Fe^{3+} and composition defects in aluminoferrite produced in hetrovalent replacement destroy original regular arrange and increase the crystal imperfection and structure distortion as well as become the starting place of hydration when H^+ and OH^- ions of water enter the lattice of the crystal during the hydration process .

Polarizability of ions

The combination of ions in aluminoferrite crystal may be looked as mutual stacking of iron oxygen radius, Fe enters vacancies of tetrahedral and octahedral stacked by oxygen . Mo^{6+} ions having higher positive charges and smaller radius than that of Fe^{3+} ion , the polarizability of it is more than 4 times and 15 times of Fe^{3+} and Ca^{2+} ions respectively (table 1) , and that is able to affect the distortion of O^{2-} ions electric clouds and make them close to Mo^{6+}ions, which leads not only to increase the distance of Fe , Ca with O ions , reduce the strength of Fe–O and Ca–O bonds as well as create crystal structure distortion of ferrite with Mo , but also to raise the internal energy and instability of all structure and improve the chemical activity of the minerals .

Therefore one of the reasons of high early strength to clinker containing Mo is closely related to Mo^{6+} ions replacing Fe^{3+}ions to form solid solution of substitution type and produce a series of changes in aluminoferrite internal structure and increase the activity of hydration .

CONCLUSIONS

1 . Because of the characteristic of Mo ions , such as ionic radius , electrovalence and the polarizability . It is difficulty to form part dissolved solid solution with Si ions in silicate minerals , The proportion of Mo ions in silicate solid solution is finite .
2 . The radiuses of Mo and Fe ions are relatively close , Mo ions can form complete dissolved solid solution with Fe ions in aluminoferrite phase . This is the reason for molybdenum mostly dissolved in interstitial phase .
3 . In the clinker with Mo, the electric valence of Mo ion is different with Fe and solid solution of substitution type is formed when heterovalent replacement of Fe^{3+} ions by Mo^{6+}ions in aluminoferrite phase . This will modify the coordination number of iron ions, increase crystal imperfection and structure distortion , violate the regular range of atoms and result in higher internal energy and promoting aluminoferrite hydration .

CRYSTAL STRUCTURE REFINEMENT OF NA-SUBSTITUTED C_3A BY RIETVELD ANALYSIS AND QUANTIFICATION IN OPC

F. GOETZ-NEUNHOEFFER and J. NEUBAUER
Department of Mineralogy, University of Erlangen, Germany

ABSTRACT

In some OPC clinker non-cubic C_3A occurs alone or together with cubic C_3A. The presented study deals with full profile Rietveld quantification of C_3A in OPC clinker. Calculated and synthesized cubic and Na-substituted C_3A were refined as single phases, mixtures and synthetic blends of OPC.

Key-Words: Aluminate phase; quantitative; Rietveld analysis; structure; X-ray Powder Diffraction.

INTRODUCTION

During production process of Portland cement the clinker has to be controlled on-line to ensure a constant quality. The properties of the clinker are strongly depending on quantity and composition of the clinker phases. Phase quantification is commonly performed by Bogue calculation, microscopic methods or XRD-methods. An innovative and very reliable method to quantify multicomponent mixtures is the Rietveld analysis of XRD-data. Because the Rietveld method uses a pattern-fitting algorithm, all reflection lines for each phase are considered and overlapping reflections are not problematic. Phases with variable chemical composition can be formed during production process due to varying raw mixture composition and burning conditions. The possibility of structure refinement of this phases in the same step as phase quantification shows the advantage of the Rietveld analysis.

The aluminate phase C_3A is a main constituent of OPC clinker besides alite, belite and C_4AF. Normally C_3A crystallizes in the cubic space group Pa3 (Mondal & Jeffrey, 1975). C_3A forms solid solutions with some minor components such as Na_2O, MgO, K_2O, Fe_2O_3 etc., present in OPC clinker (Taylor, 1990). Substitution of Ca^{2+} by Na^+ leads to symmetry changes from cubic to orthorhombic and monoclinic (Takéuchi et al., 1980). In some OPC clinker non-cubic C_3A can be determined alone or together with cubic C_3A. For this study only the structures of cubic and orthorhombic C_3A were chosen for comparing the results of their quantification in OPC by Rietveld analysis. It was to clarify whether it is advisable to quantify C_3A phase in OPC with the cubic structure even when orthorhombic C_3A is found together with cubic C_3A.

EXPERIMENTAL

Cubic C_3A was prepared starting from a mixture of finely ground CaO and Al_2O_3. For synthesis of orthorhombic C_3A mixture of CaO, Al_2O_3 and the desired amount of Na_2CO_3 was used. In the case of orthorhombic C_3A certain excess of Na_2CO_3 was added to counteract the evaporation of Na_2O. The mixtures were sintered for 1h at 1350°C and after cooling finely powdered in a disc mill. Sintering and grinding process was performed ten times to get cubic and orthorhombic C_3A free of mayenite ($C_{12}A_7$). These by solid-state reaction synthesized samples and different blends of pure alite, belite, brownmillerite, cubic and orthorhombic C_3A were characterized by using X-ray powder diffraction method. All diffraction data were recorded with a SIEMENS D5000 X-ray diffractometer. For Rietveld analysis a modified program of S. A. Howard [a)] was employed.

[a)] A program for Rietveld analysis of X-ray and Neutron powder diffraction data: H 2.0

DESCRIPTION OF STRUCTURES

Cubic C_3A

The unit cell of cubic C_3A contains 72 Ca, 48 Al and 144 O atoms and the asymmetric unit consists of six Ca, two Al and six O atoms. The structure of cubic C_3A is built of sixfold rings of two types of distorted AlO_4 tetrahedra centered on threefold axes. (Mondal & Jeffrey, 1975). The rings of $(Al_6O_{18})^{18-}$ are highly puckered, such that the aluminum atoms lie near to six of the corners of a cube (Figure 1). The real cell (SG= Pa3, a_o=15,263Å, Z=24) is composed of 64 pseudo-cells. Eight of these subcells are occupied by $(Al_6O_{18})^{18-}$-rings. The Ca atoms occupy 56 body-centering positions of the subcells leaving eight of them vacant. The corners of the subcells are occupied by all of the 48 Al atoms and the remaining 16 Ca atoms. Depending on their position in the structure, two types of Calcium coordination can be distinguished (Moranville-Regourd & Boikova, 1992):

a) The Ca(1), Ca(2), and Ca(3) atoms at the corners of the subcells are octahedrally coordinated to the oxygen atoms
b) The Ca(4), Ca(5), and Ca(6) atoms in centered positions are irregularly coordinated

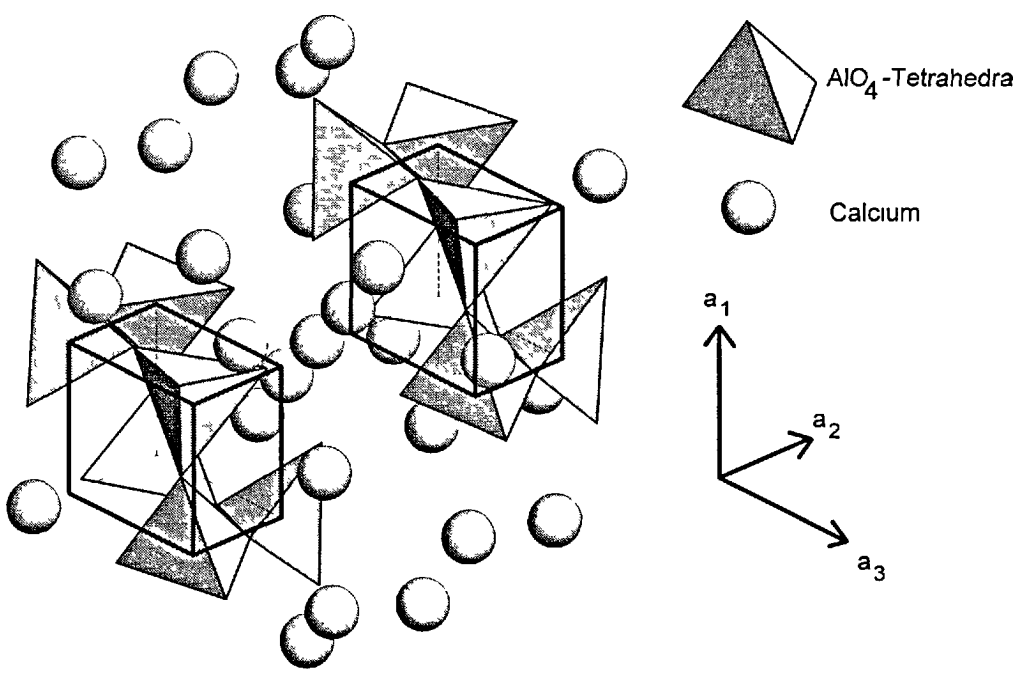

Figure 1: Part of the structure of cubic C_3A (Plotted with ATOMS[b)] according to structure data of Mondal & Jeffery, 1982)

Orthorhombic Na-substituted C_3A

The unit cell is now half the cubic cell volume with c_o-parameter remaining almost unchanged and with a_o different from b_o (SG=Pbca, a_o=1.0875Å, b_o=10.859Å, c_o=15,105Å, Z=12) (Nishi & Takéuchi, 1975). The Ca and Al atoms are distributed in the structure at positions very near to the corners and body centers of the pseudocubic subcells. Six tetrahedra are joined to form a distorted $(Al_6O_{18})^{18-}$-ring with a pseudo-threefold axis through the origin and the point 0,1/2,1/4.

---

b) ATOMS for Windows, V3.2, 1995, Eric Dowty

With regard to the pseudo-threefold axis, the apices of the tetrahedra are alternately pointing in one direction and the other Figure 2). There are 36 available locations for the 34 Ca atoms in the unit cell. The excess locations are preferably distributed in the set of Ca(5) positions to accommodate one half of the Na atoms. The remaining Na atoms are located at the centers of the tetrahedral rings, the origin of the cell.

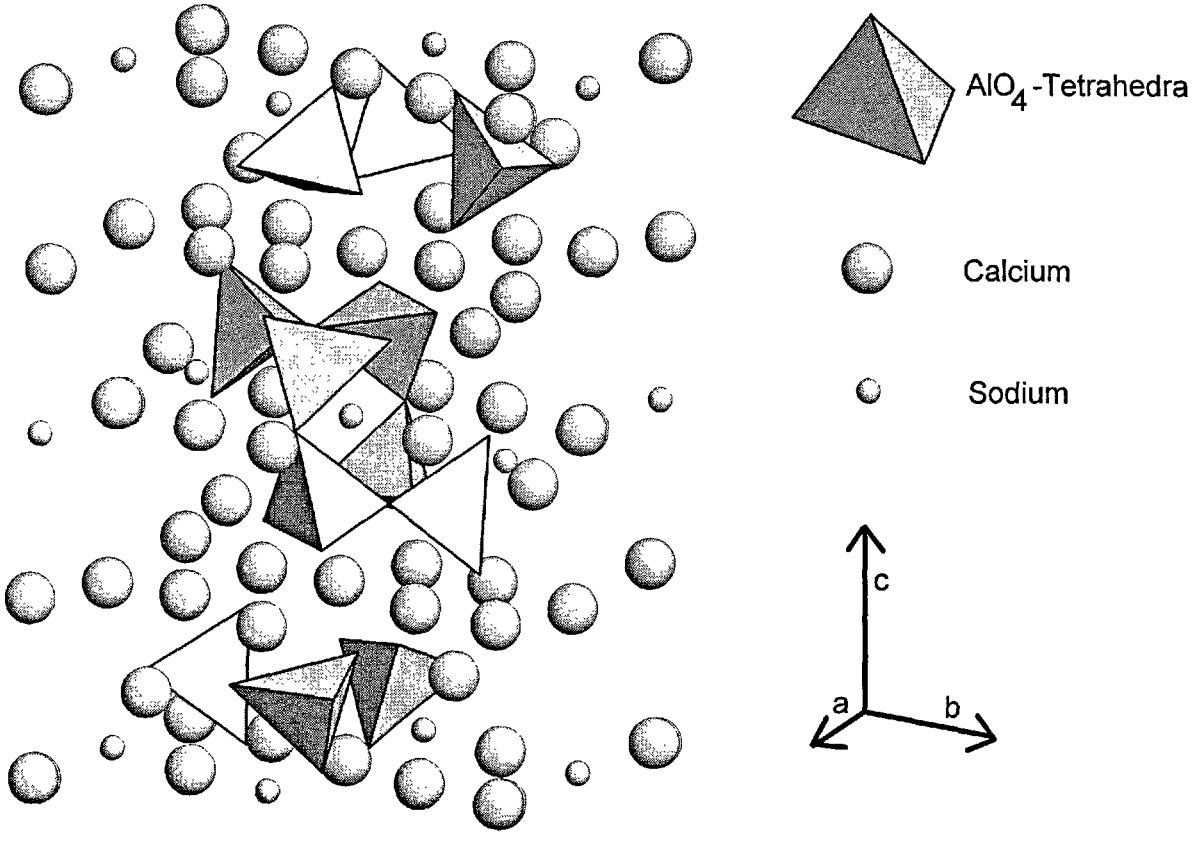

Figure 2: Part of the structure of orthorhombic Na-substituted C_3A (Plotted with ATOMS according to modified structure data of Nishi & Takéuchi, 1975)

RIETVELD REFINEMENT OF CALCULATED PLOTS

Theoretical XRD-diagrams of cubic C_3A on basis of structural data of Mondal & Jeffery (1982) and orthorhombic Na-substituted C_3A according to structural data of Nishi & Takéuchi (1975) were calculated with the Rietveld program. In Figure 3 two important ranges of the diagrams are plotted with the indices of the reflections (32,7-33,5°2Theta and 47,2-48,3°2Theta). The main reflection (044) of the cubic C_3A splits into the (224) and (400) reflections for the orthorhombic Na-substituted C_3A. In the second range it is shown that the (008) reflection of the cubic phase splits into (440) and (008) reflections for the orthorhombic phase.

Refinement of orthorhombic Na-substituted C_3A with the structure of cubic C_3A

Refinement of a calculated pattern of orthorhombic C_3A with the cubic structure shows best the main problem of accurate quantification of orthorhombic C_3A. Intensities of the difference plot are much higher than intensities of the refined phase. The symmetry change leads to split reflections for the orthorhombic phase with the consequence that neither intensities nor peak position can be refined correctly with the structure of the cubic phase.

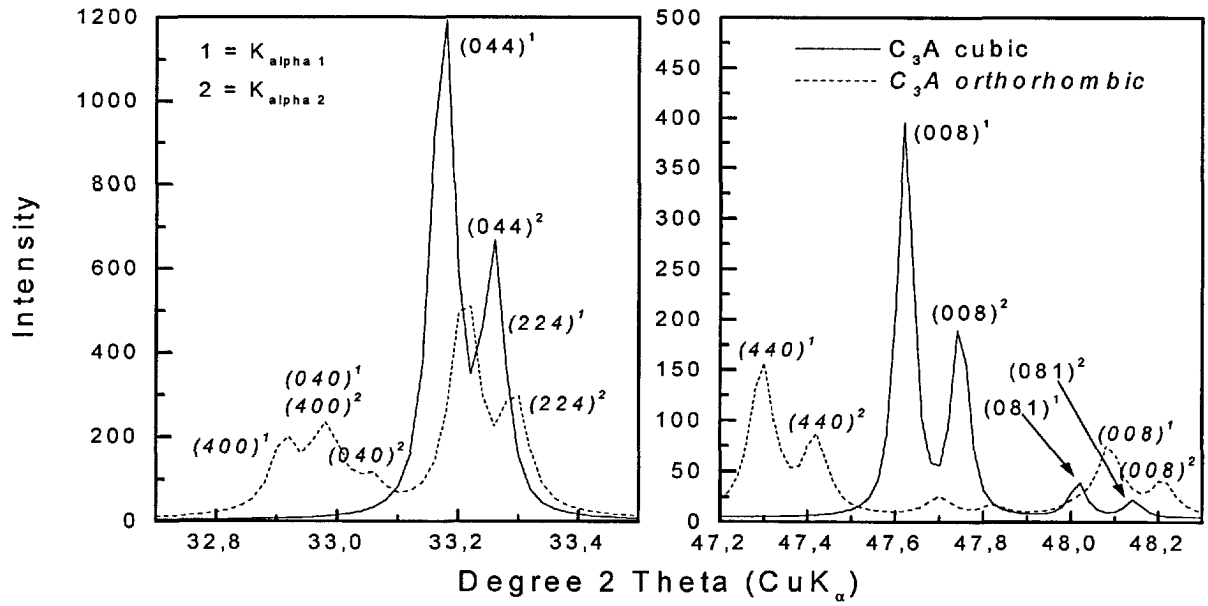

Figure 3: Calculated XRD-diagrams of the cubic C_3A and the orthorhombic Na-substituted C_3A

RIETVELD REFINEMENT OF SYNTHESIZED C_3A

In the next step full profile refinement of the synthesized C_3A phases was performed in order to control purity of the syntheses and to find a refinement procedure which gives the best fit of calculated with the observed pattern. In case of orthorhombic Na-substituted C_3A additionally occupancy factors were included in the refining procedure.

Refinement of pure cubic C_3A

For the refinement of cubic C_3A structural data of Mondal & Jeffrey (1982) were applied. The observed data were recorded with 0.02 °2 theta step size and 8s counting time. The refinement procedure included zero shift, background parameter, scale factor, Pearson coefficient, FWHM parameter, and lattice parameter. The remaining differences of calculated and observed pattern of cubic C_3A are due to intensity differences between refined and observed pattern. This fluctuations in intensity which are explained by statistical deviations can be reduced by increasing counting time. Table 1 shows the refined a_0-lattice parameter and residual errors.

Table 1: Refined a_0-lattice parameter and residual errors of cubic C_3A

	a_0-lattice parameter [Å]	*R [%]*	*R_{Bragg} [%]*
cubic C_3A	15.263±0.001	8.2	9.6

Refinement of pure orthorhombic Na-substituted C_3A

Synthesized orthorhombic Na-substituted C_3A, with a formula close to $Ca_{8.5}NaAl_6O_{18}$, was refined with the modified structural data of Nishi & Takéuchi (1975). One part of the Na atoms occupy positions at the centers of the tetrahedral rings and the other Na atoms are preferably accommodated in the set of Ca(5) positions.

The observed data were recorded with 0.02 °2 theta step size and 8s counting time. The refinement procedure included zero shift, background parameter, scale factor, Pearson coefficient, FWHM parameter, lattice parameter, and the occupancy factors. Table 2 shows the refined lattice parameter and residual errors.

Table 2: Refined lattice parameter and residual errors of orthorhombic Na-substituted C_3A

	a_o [Å]	b_o [Å]	c_o [Å]	R [%]	R_{Bragg} [%]
orthorhombic C_3A	10.866±0.001	10.846±0.001	15.115±0.001	8.2	8.8

RIETVELD REFINEMENT OF MIXTURES OF CUBIC AND ORTHORHOMBIC C_3A

Three mixtures of cubic and orthorhombic Na-substituted C_3A were investigated to proof the accuracy of quantification by the Rietveld method. The observed data were recorded with 0.02 °2 theta step size and 4s counting time. The refining procedure included zero shift, background parameter, scale factor, FWHM parameter, and lattice parameter. The results of quantification are listed in Table 3. From five independent experiments a maximum standard deviation of 0.7 wt. % was determined for both modifications of C_3A.

Table 3: Quantification of different mixtures of cubic C_3A and orthorhombic Na-substituted C_3A

Theoret. comp. [wt. %]		*Calc. Comp. [wt. %]*		*R [%]*	*R_{Bragg} [%]*	
Cubic	*Orthorh.*	*Cubic*	*Orthorh.*		*Cubic*	*Orthorh.*
50.0	***50.0***	50.7	49.3	9.8	7.6	8.8
75.0	***25.0***	73.7	26.3	10.4	6.9	12.0
25.0	***75.0***	26.7	73.3	8.0	7.4	12.3

Refinement of a mixture of 50% cubic C_3A and 50% orthorhombic Na-substituted C_3A

Figure 4 shows parts of the observed and refined plots of a mixture 50% cubic C_3A and 50% orthorhombic Na-substituted C_3A. In the range between 32.7 and 33.5° 2Theta the difference plots shows divergence at the positions where the $K_{\alpha 1}$ and $K_{\alpha 2}(044)$ reflection of the cubic phase and the $K_{\alpha 1}$ and $K_{\alpha 2}(224)$ reflection of the orthorhombic phase are overlapping.

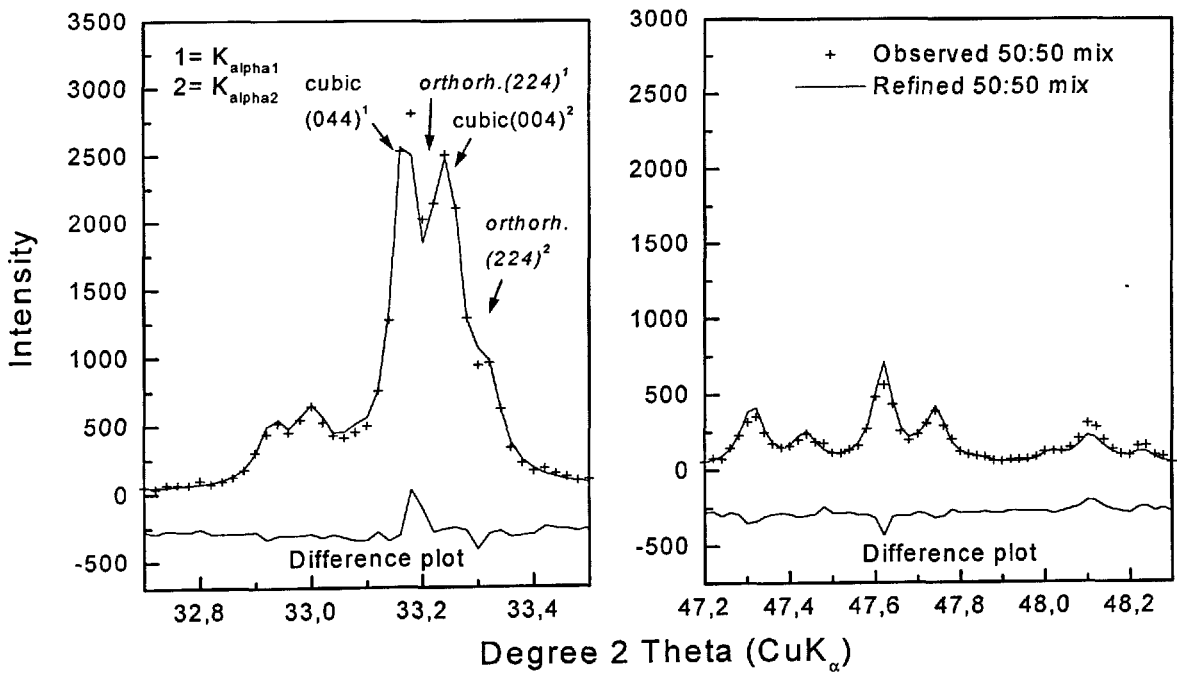

Figure 4: Parts of the observed and refined plots of a mixture 50% cubic and 50% orthorhombic C_3A

This divergence is due to statistical causes and can be diminished by reduction of step size or by increasing counting time. This does not influence the goodness of quantification. It could be shown that the optimized refining procedure which includes cubic and orthorhombic phase leads to very precise quantification results of a synthetic mixture of both phases.

RIETVELD REFINEMENT OF DIFFERENT SYNTHETIC BLENDS OF OPC WITH CUBIC AND ORTHORHOMBIC C_3A

Three synthetic blends of OPC clinker with cubic and orthorhombic Na-substituted C_3A were investigated and quantified by the Rietveld method. The observed data were recorded with 0.02 °2 theta step size and 4s counting time. The refining procedure included zero shift, background parameter, scale factor, FWHM parameter, and lattice parameter. The results of quantification are listed in Table 4 (Appendix A). From several independent experiments a maximum error of ±1.5 wt. % was determined for alite and belite and a maximum error of 0.8 wt. % for C_4AF and both modifications of C_3A.

In the last step of the presented investigation three synthetic clinker were quantified by the Rietveld method. Based on the results of the refinements of the mixtures of cubic C_3A and/or orthorhombic Na-substituted C_3A three quantification routines were created for evaluation of synthetic blends of OPC clinker:

Only C = refinement of the total C_3A in the blend with cubic structure
Only O = refinement of the total C_3A in the blend with orthorhombic structure
C&O = refinement of the total C_3A in the blend with both cubic and orthorhombic structure

The compositions of clinker A, B and C are listed in Table 4 (Appendix A). Total content of C_3A in synthetic clinker A - a mixture of cubic C_3A and orthorhombic Na-substituted C_3A with pure synthetic alite, belite and brownmillerite - is 15 wt. %. For synthetic clinker B only orthorhombic Na-substituted C_3A (15 wt. %) and for synthetic clinker C only cubic C_3A (10 wt. %) was added to pure synthetic alite, belite, and brownmillerite.

Figure 5 shows the results of quantification of cubic and orthorhombic Na-substituted C_3A in three mixtures of synthetic OPC clinker with different quantification routines.

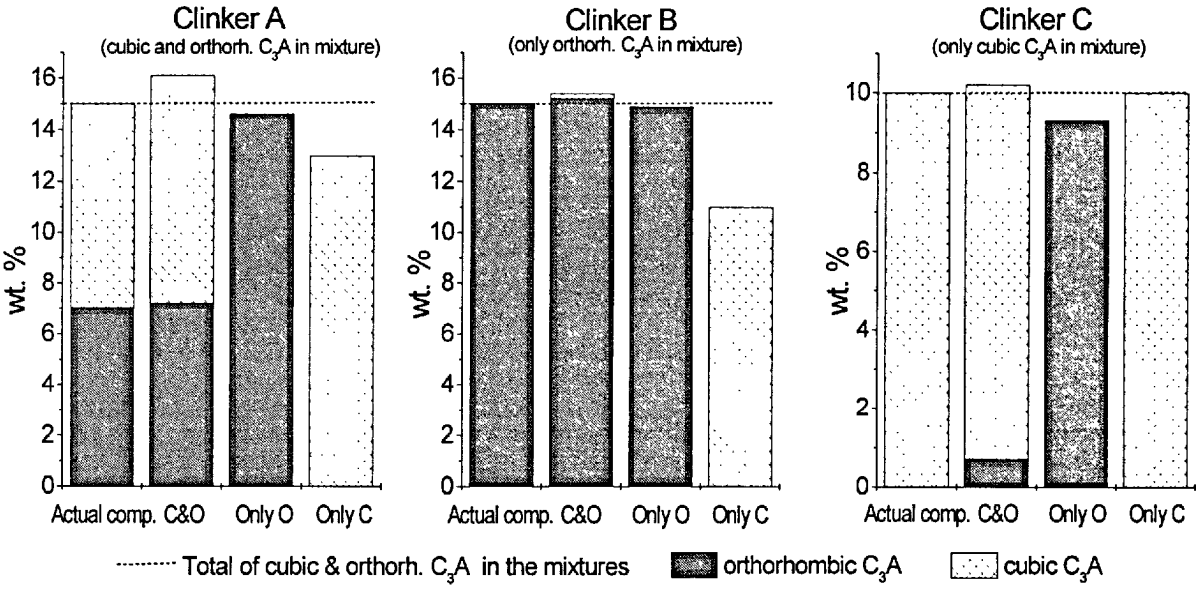

Figure 5: Results of C_3A quantification of three mixtures of synthetic OPC clinker with different quantification routines

For synthetic clinker A which contains cubic and orthorhombic C_3A the quantification routine ***O*** (both modifications were refined together with orthorhombic structure) and ***C&O*** (refinement with cubic and orthorhombic structure of C_3A) are leading to the best results for C_3A. In case of synthetic clinker B, which contains only orthorhombic C_3A, quantification results of both routines ***O*** and ***O&C*** are matching the actual content of C_3A in the blend. The best quantification of C_3A in clinker C (only cubic C_3A was added to the mixture) can be achieved with routine ***C***, but quantification with routine ***C&O*** is also reproducing the overall composition of the blend satisfactory. For quantification with routine ***O*** the error is still below 1 wt. %.

Results show best agreement of calculated and actual content of C_3A using refinement routines with only ***O*** or ***C&O***. Pure orthorhombic C_3A (clinker B) calculated with cubic structure (only ***C***) leads to deviations up to 4 wt. % from the given content. The main disadvantage of routine ***C&O*** is that more parameters have to be refined compared with routine ***C***. In case of very low contents of C_3A routine ***C&O*** is running not enough stable. After evaluating the results of all tested refinement procedures we found that routine ***O*** is best representing the overall content of C_3A in the synthetic clinker. This routine gives very precise results either for clinker A (cubic C_3A and orthorhombic Na-substituted C_3A in the mixture) or clinker B (only orthorhombic Na-substituted C_3A in the mixture) or clinker C (only cubic C_3A in the mixture).

CONCLUSION

For the refinement of cubic C_3A structural data of Mondal & Jeffrey (1982) were applied. Synthesized orthorhombic Na-substituted C_3A, with a formula close to $Ca_{8.5}NaAl_6O_{18}$, was refined with the modified structural data of Nishi & Takéuchi (1975). The best refinement of orthorhombic Na-substituted C_3A was achieved by using in addition to the structure data of Nishi & Takéuchi (1975) a position for the Na atoms in the set of Ca(5) which were refined together in one step.

A refinement procedure for different mixtures of cubic C_3A and orthorhombic Na-substituted C_3A which led to optimized quantification results was developed. It could be shown that the optimized refining procedure which includes both cubic and orthorhombic phase leads to very precise quantification results of a synthetic mixture. Remaining differences are due to statistical causes and can be diminished by reduction of step size or by increasing counting time.

For adjustment the results of Rietveld quantification of C_3A phase to quality control of OPC clinker we have tested the method with different blends of synthetic clinker with compositions of ordinary Portland cement clinker products. We found that routine ***O*** is best representing the overall content of cubic and orthorhombic C_3A in the synthetic clinker and is leading to very precise quantification results.

Nevertheless it has to be taken in account that the results of quantification of pure cubic and orthorhombic Na-substituted C_3A of very good crystallinity in the different mixtures can not be compared directly with the results in a multiphase system like OPC with 5-15 wt. % of C_3A phase and much lower crystallinity. For this reason the results need the adaption to an ordinary produced Portland cement clinker in a final step.

ACKNOWLEDGMENT

We thank P.O.G. Gaeberlein for performing the experimental part - syntheses and XRD - of the investigation.

PHASES IN HIGH-MAGNESIUM CLINKERS

BOIKOVA A.I., FOMICHEVA O.I. and LUGININA I.G.
Institute of Silicate Chemistry Russian Academy of Sciences, St.-Petersburg, Russia

ABSTRACT Phase composition and chemical compositions of phases in commercial clinkers containing up to 7 wt% MgO were studied by means of X-ray diffraction method and electron probe microanalysis. For comparison the phases in clinkers with a small amount of MgO (less than 1 wt%) were also considered. As usual all commercial clinkers studied contained a certain amount of other minor components (Na_2O, K_2O, MgO, TiO_2, SO_3). The hydration reactivity (degree of hydration) of MgO directly in clinkers was investigated by means of X-ray diffraction method.

Key-words: magnesium phases, solid solutions, hydration

INTRODUCTION

At the present time the problem of utilization of clinkers and cements with more than 5 wt% MgO is widely discussed, particularly with MgO content about 7 wt%. It is known that only about 2 wt% MgO can be incorporated into the lattices of four main clinker phases as a component of solid solutions. However, there are clinkers which contain less than 1 wt% MgO. Thus the amount of MgO in clinkers may be within sufficiently wide limits. One may suppose that phases in all such clinkers will differ concerning MgO content in solid solutions. Therefore the properties of magnesium containing clinkers and cements will depend not only on uncombined MgO (Periclas) but also on MgO content in phases as a component of solid solutions. The main task of our investigation consisted in elucidating the role of MgO in the formation of phases in clinkers with different amounts of this oxide. For all this it is necessary to pay attention to the presence of other minor components in solid solutions too.

EXPERIMENTS AND RESULTS

Chemical composition of phases of magnesium containing clinkers was studied by EPMA. Clinkers with MgO content both less than 1 wt% and about 7 wt% of this oxide were chosen. The results of chemical analysis of some clinkers studied are shown in Table 1. Two of them (N 1 and N 2) contain less than 1 wt% MgO while three clinkers (N 3, N 4 and N 5) contain about 6.5-7.0 wt% MgO.

Table 1 Chemical compositions of clinkers studied (wt %)

N clinkers	Oxides										Loss of ign.
	CaO	Al_2O_3	Fe_2O_3	SiO_2	Na_2O	K_2O	MgO	TiO_2	P_2O_5	SO_3	
1	65.16	4.31	4.06	23.13	0.36	0.80	0.66	0.43	0.03	0.20	0.78
2	66.62	5.56	3.77	21.34	0.17	0.86	0.65	0.18	0.09	0.34	0.45
3	61.20	5.14	4.34	20.13	0.12	0.78	6.41	0.00	0.05	0.33	0.91
4	60.62	5.27	4.84	19.82	0.11	1.16	6.37	0.00	0.11	1.16	0.44
5	60.17	5.01	4.17	20.28	0.21	1.51	6.92	0.22	0.15	0.89	1.00

Phase composition of clinkers studied depended both on MgO content and on the presence and the amount of the other minor components. X-ray diffraction analysis showed that clinkers with less than 1 wt% of MgO did not contain any Periclas (uncombined MgO) while in clinkers with about 7 wt% MgO there was about 6 wt% of Periclas. K_2SO_4 was detected in clinkers with potassium and sulphur. Almost all clinkers with these components contained belite in β- and α'- modifications. As usual alite was in a monoclinic form. Depending on the amount of Al_2O_3 and Fe_2O_3 aluminoferrite phase is a polycomponent solid solutions on the basis of 6:2:1 ($6CaO\ 2Al_2O_3\ Fe_2O_3$) or of 4:1:1 (clinker 5). X-ray and microscopical examination also showed that the presence of a considerable amount of magnesium in the clinker provides for the alite stable formation and existence conditions because magnesium suppresses the destructive influence of sodium, potassium, titanium, phosphorus and sulphur on the alite (Boikova, Fomicheva and Galafutnik, 1994; Moranville-Regourd and Boikova, 1992). The quantity of alite formed becomes maximal in clinkers with a high magnesium content. Thus, the X-ray examination of phase composition of clinkers with different amounts of alkali oxides showed that the material with 5-7 wt% MgO contained a higher quantity of alite (20% as high) than the clinker with less than 1 wt% MgO.
Chemical composition of phases in clinkers containing less than 1 wt% MgO and in those with about 7 wt% MgO were examined by means of EPMA. Table 2 contains the results of EPMA. The averaged data are given.

When analyzing the chemical composition of phases in magnesium containing clinkers attention should be drawn to the following points.
Firstly, the amount of MgO in the solid solutions of all phases increases with increasing amount of this oxide in clinkers. It is evident from the EPMA results. For example the amount of MgO in alite (clinker N 1 and N 2) is about 0.5 wt% while in alite of clinkers N 3, N 4 and N 5 it is about 1.7-1.8 wt%. The same is true for belite, calcium aluminoferrite and aluminate phases (see Table 2). It is useful to mention that among all clinker phases magnesium prefers to be situated into the lattice of calcium aluminoferrites due to Mg favourable tetrahedral and octahedral sites. Therefore the amount of MgO in the calcium aluminoferrite solid solutions is much greater than in any other phases. However the aluminoferrite phase in clinkers with a small amount of MgO (clinkers N 1 and N 2) contains smaller quantities of this oxide than that in clinkers with about 7 wt% MgO (clinker N 3, N 4 and N 5).

Secondly, attention should be drawn to the role of MgO in the formation of clinker silicate phases. It was found that the amount of minor components in the alite and belite solid solutions increases with the increase of MgO in the clinker (see Table 2). For example, the amount of minor components (in oxides) in alite solid solutions (clinkers N 1 and N 2) is about 2 wt% while that in clinkers N 3, N 4 and N 5 is about 4 wt%. This is approximately that maxima amount of minor components which can be incorporated into the alite lattice. This is also the case with belite phase. The amount of impurities in the belite lattice in clinkers with ≈ 0.5 wt% MgO is about 4.85 wt% while that in clinkers with 6.5-7.0 wt% MgO is about 6.5 wt%. The explanation for this fact comes probably from the decrease of viscosity of clinker liquid phase with increasing MgO amount which facilitates the process of complex composition phases formation. Earlier on the basis of investigation of commercial clinkers it was shown that the greatest amount of minor components are concentrated in the aluminate (≈ 12-13 wt% in oxides) and aluminoferrite (≈ 10-11 wt%) clinker phases owing to the peculiarities of their crystal structures. Belite and alite (especially the latter) are less capable of adopting minor component into the lattices than two other phases. Thus the maximum amount of minor components in the lattice of C_2S (belite) is about 6 wt% and that in C_3S (alite) is about 4 wt% (Boikova, Esayan and Lazukin, 1980; Boikova, 1986). Indeed the amount of impurities in the

lattices of alite and β-belite was found to be the maximal possible for these phases in high-magnesium clinkers.

Table 2. Chemical composition of phases in magnesium containing clinkers (wt %)

[x] Clinker numbers are the same as in Table 1.
Abbreviations: a -alite, b - belite, af - aluminoferrite and al - aluminate phases.

EPMA showed that some high-magnesium clinkers contained individual crystals of unusual belite whose chemical composition differed from that of ordinary belite (β-belite). These unusual belite was identified as α'- and α-phases. These modifications contained somewhat more minor components in the lattices than β-belite and were similar to Bredigite and Nagelschmidtite. Clinker Periclas contain minor components in the lattice as well namely about 0.8 wt% CaO. 1.5 wt% Fe_2O_3 and 0.2 wt% SO_3.

Hydration behaviour (degree of hydration) of Periclas was examined by means of X-ray diffraction analysis according to the change of relative intensity of maxima. The experiment was unusual in that the hydration of this phase was studied directly in the clinker in the presence of other phases. For analysis the maximum at 20 43^0 in the pattern

was chosen which was overlapped neither by the maxima of other phases nor by those of hydration products. Samples were prepared in the paste form with a w/c ratio of 0.4 and placed into special cuvettes covered with a transparent amorphous and inert film. The sample of unhydrated clinker was also covered with such kind of film for identical conditions of X-ray patterns production. The experiment temperature was 20-22°C. When analyzing the results of hydration process of clinker phases on the basis of X-ray patterns attention should be paid to the fact that after a month of hydration under the conditions above Periclas was not found to have reacted with water in detectable amounts while the other phases did. Fig. 1 demonstrate quite clearly these results.

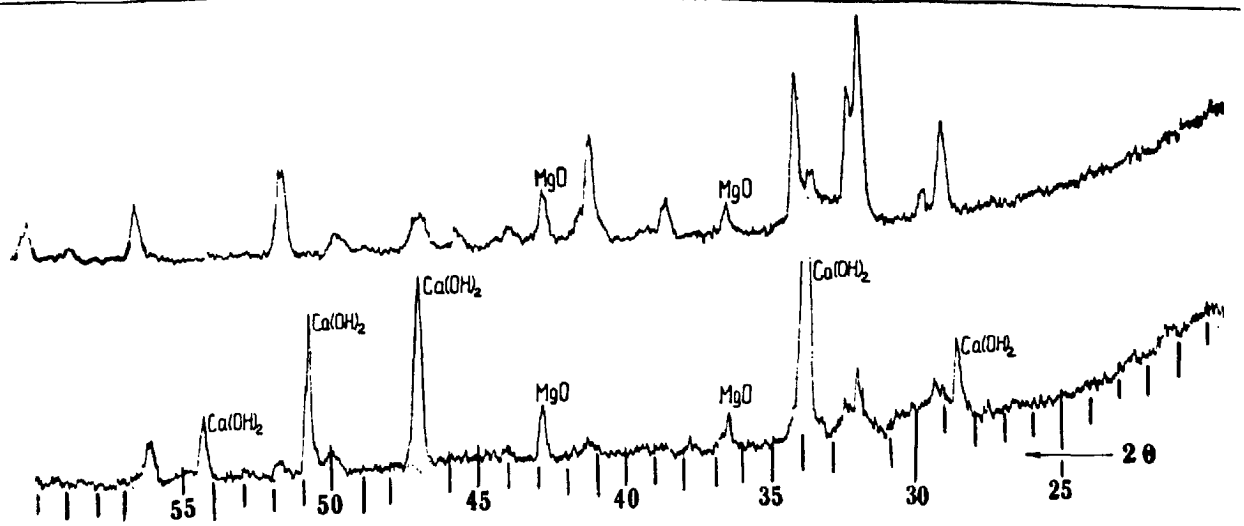

Figure 1 X-ray diffraction patterns of unhydrated (the upper pattern) and hydrated (the lower pattern) clinker N 3

The upper pattern in Fig.1 is one of clinker N 3 which shows the maxima of all main clinker phases including Periclas. The lower pattern is the pattern of the same but hydrated clinker N 3. One can observe in this figure unchanged MgO maxima, $Ca(OH)_2$ maxima as a result of hydration first of all of silicate phases and weakly intensive maxima of unreacted part of the main phases (alite, belite, calcium aluminoferrite and aluminate phases). Only after three month of hydration about 10-15 % of Periclas was found to have reacted.

CONCLUSION

When analyzing the data of the EPMA of phases for chemical composition of high-magnesium clinker, attention must be drawn to the following facts. All phases in high-magnesium clinkers contain the greatest possible amount of MgO as a solid solutions component. The MgO amount in phases of complex chemical composition is increased with the increase of the amount of this oxide in clinkers. The properties of high-magnesium clinkers and cements depend not only the amount of uncombined MgO (Periclas) but also on the amount of MgO in phases of complex composition. With increasing of MgO content in clinkers the amount of minor components in the solid solutions of silicate phases (alite and belite) is increased.

The quantity of alite formed becomes maximal in clinkers with high-magnesium content since magnesium oxide suppresses the destructive influence of sodium, potassium, titanium, phosphorus and sulphur on the alite structure. Due to EPMA we succeeded in detecting uncombined MgO (Periclas) even in clinkers containing less than 2 wt% MgO which we failed to achieve by X-ray diffraction method.

Investigation of periclas hydration (by X-ray method) in clinkers in the presence of other phases shows extremely passive behaviour of this phase during interaction with water under ordinary conditions.
So periclas was not found to have hydrated in detectable amount after a whole month of interaction with water.
Probably periclas begins to hydrate while other clinker phases have already interacted with water to a great exstent.
Periclas hydration inside the material during a long period of time has a negative effect on the properties of this material due to destructive character of the process.

BARIUM CONTAINING CLINKER PHASES

BOIKOVA Alexandra I., FOMICHEVA Olga I. and GRISHCHENKO Lubov V.
Institute of Silicate Chemistry of the Russian Academy of Sciences; St.-Petersburg, Russia

ABSTRACT Special role of barium is connected with protective properties against radiation of cements containing this element. This paper contains the results of the investigation of the distribution of barium between phases in commercial barium containing portland clinker by means of electron probe micro analysis. Besides barium containing clinker phases of complex chemical composition (polycomponent solid solutions) were synthesized and studied. Hydration properties of barium containing phases were also studied. Compressive strength of phases synthesized was determined.

Key-words: clinker barium phases, compressive strength

INTRODUCTION

It is known that barium containing wastes and components are used for clinker production. However there are no accurate data about interaction of barium with clinker phases. Such kind of investigation is primarily connected with the definition of the role of barium in the distribution of this element between the four main clinker phases in commercial clinkers. It is also important in this respect to possess information about the possibility of solid solution formation between $3CaO\ SiO_2$ and $3BaO\ SiO_2$ as well as between $2CaO\ SiO_2$ and $2BaO\ SiO_2$. It is known that there is wide field of solid solution between C_2S and Ba_2S on the basis of C_2S. However the information about the solid solutions of Ba_3S in C_3S is rather contradictory. There is also no common opinion about the existence of the compound $3BaO\ SiO_2$. Besides there are contradictory data about the influence of barium on the hydration properties of clinker phases as well as clinkers and cements.

EXPERIMENTS AND RESULTS

Barium containing commercial clinker was examined with respect to the distribution of barium between alite, belite and calcium aluminoferrite by means of electron probe microanalysis (EPMA). Attempts to find the aluminate phase suitable for EPMA failed.

All crystals looked like a fine intergrowth within the aluminoferrite phase.
Phase composition of clinker studied was determined by X-ray diffraction method and microscopic examination. According to these findings clinker contained alite, belite in the β- and α'-modifications, calcium aluminoferrite on the basis of 4:1:1 and not too much aluminate phase. Chemical composition of clinker studied is given in Table 1.

Table 1 Chemical composition of clinker (wt %).

SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	BaO	Na_2O	K_2O	SO_3	L.of Ign.	Σ
20.90	4.90	5.46	0.30.	62.73	0.95	0.65	0.35	0.95	0.36	2.90	100.45

The chemical composition of alite, belite and calcium aluminoferrite is presented in Table 2, according to EPMA results. Only some data are given here.
The results obtained show that barium tends to be incorporated into the belite lattice. So, barium becomes a component of polycomponent belite solid solutions together with other components (Na, K, Mg, Al, Fe, S). Polycomponent solid solutions of clinker phases may

be presented both in atomic and in oxide forms. In $2CaO\ SiO_2$ lattice Ba^{2+} can occupy the positions of Ca^{2+}.

Table 2 EPMA results of the chemical composition of phases.

Oxides wt% / Phases	Na_2O	K_2O	MgO	CaO	BaO	Al_2O_3	Fe_2O_3	SiO_2	SO_3
alite	0.2	0.2	1.2	70.0	0.1	1.1	1.7	25.5	0.0
	0.2	0.2	1.2	71.5	0.1	1.2	1.6	23.9	0.0
belite	1.1	2.6	0.5	59.2	1.0	1.4	2.0	32.8	0.2
	1.4	2.0	0.5	60.0	0.6	1.2	1.7	33.0	0.2
calcium alumino-ferrite	0.0	0.2	1.7	44.1	0.3	21.7	32.3	0.0	0.0
	0.1	0.2	2.1	41.3	0.4	22.4	32.9	1.0	0.0

EPMA showed the aluminoferrite phase to contain a smaller amount of barium then did belite. Less suitable for barium incorporation seems to be the crystal lattice of alite (see Table 2).

Another task of this study consisted in the synthesis of phases of complex composition having analogy with real clinker phases and in the investigation of their hydration properties (the compressive strength). Phase batches composition was chosen according to EPMA data of commercial clinker. The preparation of each of the phases appeared to be possible choosing an appropriate heat treatment schedule. Heat treatment of batches of each phase depends on their characters. The samples in the form of tablets were burnt under the following conditions: all samples were heated up to 1000°C and exposed at this temperature during 30 min; then the burning temperature of alite samples was raised up to 1450°C, the exposure was from 40 min up to 1 hour 20 min; the burning temperature of belite was 1350°C, the exposure was 40 min; the burning temperature of calcium aluminoferrite was 1300°C and the exposure 40 min. However after this burning schedule alite still contained some amount of uncombined CaO. Therefore alite was burnt a second time at 1450°C with 40 min exposure. The chemical composition of phases obtained was examined by chemical analysis. The identification of phases was made by means of X-ray diffraction. Table 3 gives the chemical composition of phases synthesized.

Table 3 Chemical compositions of phases obtained.

Oxides wt% / Phases	Na_2O	K_2O	MgO	CaO	BaO	Al_2O_3	Fe_2O_3	SiO_2	SO_3
alite 1	0.12	0.10	1.45	69.99	0.69	1.54	1.64	24.28	0.0
2	0.10	0.10	1.47	70.62	0.56	1.03	1.51	24.37	0.0
3	0.10	0.10	1.24	70.74	0.82	1.25	1.25	24.84	0.0
belite 1	1.10	2.46	0.61	57.25	2.08	1.54	1.44	32.45	0.25
2	1.15	2.08	0.62	58.14	1.52	1.33	1.62	32.83	0.30
3	0.82	2.46	0.43	57.69	1.07	1.40	2.04	33.20	0.29
4	1.16	1.87	0.40	58.78	0.71	1.25	1.63	33.13	0.39

	0.18	0.37	1.86	40.77	0.64	21.43	32.48	1.43	0.0

As an example we give the formula of each of the phase in atomic and in the generally accepted oxide form.

Alite (sample 1 according to the Table 3):
$3.09CaO\ SiO_2\ 0.005Na_2O\ 0.002K_2O\ 0.089MgO\ 0.01BaO\ 0.037Al_2O_3\ 0.025Fe_2O_3$;
$Ca_{3.09}\ Si_{1.00}\ Na_{0.01}\ K_{0.004}\ Mg_{0.09}\ Ba_{0.01}\ Al_{0.07}\ Fe_{0.05}\ O_{5.38}$.

Belite (sample 1):
$1.89CaO\ SiO_2\ 0.033Na_2O\ 0.048K_2O\ 0.028MgO\ 0.026BaO\ 0.028Al_2O_3\ 0.017Fe_2O_3$
$0.006SO_3$;
$Ca_{1.89}\ Si_{1.0}\ Na_{0.066}\ K_{0.096}\ Mg_{0.028}\ Ba_{0.026}\ Al_{0.056}\ Fe_{0.034}\ S_{0.006}\ O_{4.18}$;

Calcium aluminoferrite (sample 1):
$3.76CaO\ 1.08Al_2O_3\ 1.0Fe_2O_3\ 0.02Na_2O\ 0.015K_2O\ 0.17MgO\ 0.03BaO\ 0.13SiO_2$
$Ca_{3.76}\ Al_{1.08}\ Fe_{1.0}\ Na_{0.04}\ K_{0.03}\ Mg_{0.17}\ Ba_{0.03}\ S_{0.13}\ O_{10.50}$.

Fig.1 shows the X-ray diffraction patterns of the barium containing alite, belite as well as calcium aluminoferrite.

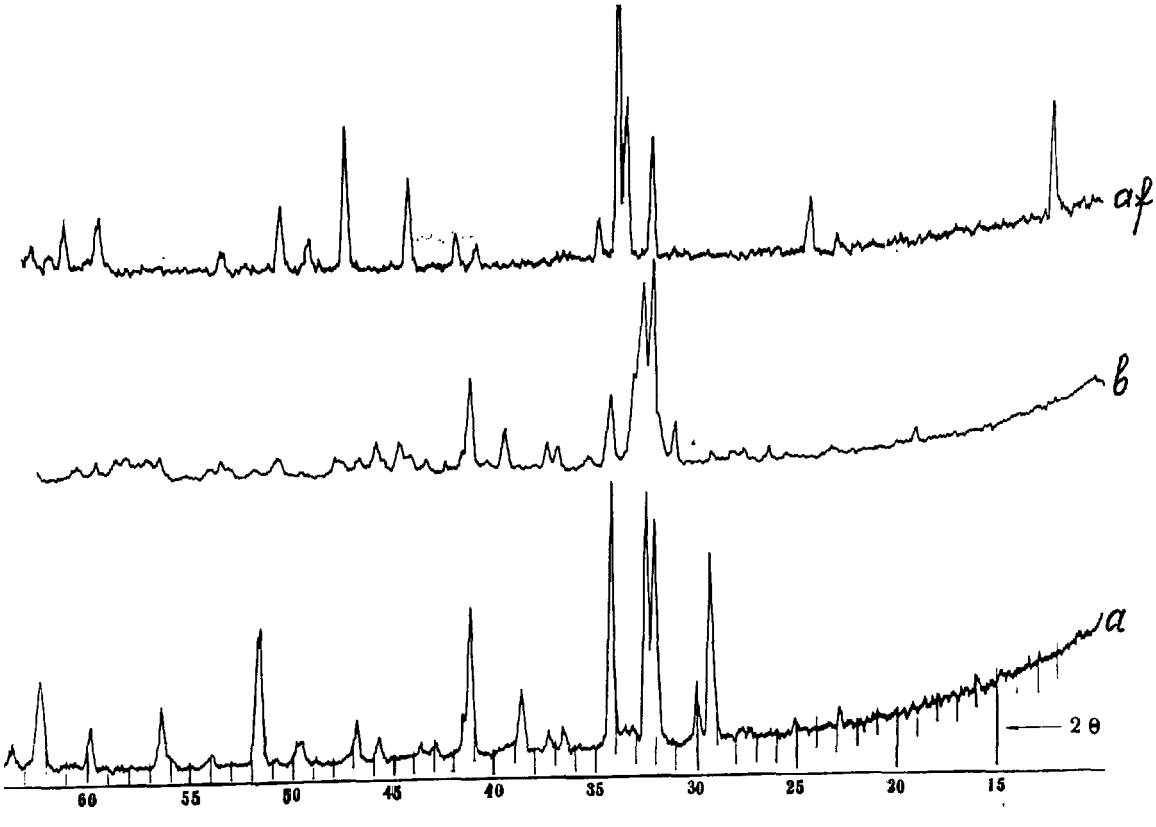

Figure 1 Bariumcontaining clinker phases synthesized: a - alite, b - belite, af - calcium aluminoferrite.

The broadening of many reflections in belite X-ray pattern is an evidence of imperfect crystallization of this phase.
X-ray examination permitted to reveal that samples of belites contain β-, α'- and α-modifications. Alite with Ba in its lattice is characterized by monoclinic symmetry.
Investigation tending towards obtaining the solid solutions of $3CaO\ SiO_2$ with $3BaO\ SiO_2$ have been taken up. Batches calculated on s.s. containing from 1.0 up to 5.0 wt% Ba_3S were burnt at 1500°C. It was revealed that samples with 1 wt% Ba_3S and more

contained C_2S and uncombined CaO. The more barium in the solid solutions batches the more C_2S and free CaO in the products. Barium appears to prevent the formation of C_3S. Solid solutions apparently can contain less than 1 wt% Ba_3S. As for Ba_3S, we would like to stress that the fact of existence of this compound is debatable. It is useful to mention, that there is a wide field of solid solutions between C_2S and Ba_2S on the basis of C_2S.
Due to the instability of C_3S or alite in the presence of barium it is better to use bariumcontaining wastes for clinkers with low Lime Saturation Factor (LSF).

The compressive strength of barium containing phases synthesized were examined. The value of compressive strength was obtained as the average sum of four measurements. The measurements were made on 10x10x10 mm cubes; w/c = 0.3; the granulometric composition was controlled by sieve N 0071; the temperature of experiment was 20-22^{0}C. The 28-day compressive strength of barium containing alites and calcium aluminoferrites were for alite: N 1 - 57 MPa; N 2 - 36 MPa; N 3 - 57 MPa and aluminoferrite: N 1 - 40 MPa; N 2 - 43 MPa. The sample number is the same as in Table 3.

Barium containing belite phases hardened very slowly. Their 28-day compressive strength was practically neglegible. The value of 3-month compressive strength was in the range of 12.5 - 17.5 MPa. It is important to mention that when estimating phase compressive strength value and considering the influence of barium it is necessary to take into account the presence of both barium and other minor components in solid solution structure.

CONCLUSION

The results of electron probe microanalysis (EPMA) of barium containing clinker shows thet barium tends to be incorporated first of all into the belite lattice. The aluminoferrite phase contained a smaller amount of barium. Less suitable for barium incorporation seems to be the crystal lattice of alite.

The complex phases analogous to phases of commercial clinkers were synthesized in laboratory conditions. The polycomponent solid solutions of belite contained the greatest amount of barium but not exceeding 2 wt% (as BaO). It was found that barium promoted stabilization of α' - and α - modifications of belite of complex composition. The synthesized Ca-aluminoferrite phase was obtained with smaller amount of BaO in polycomponent solid solutions. The smallest barium content was found in synthesized alite. It is important to stress that in the presence of barium alite is decomposed into belite and uncombined CaO.

Important conclusion could be drawn from the behaviour of alite in the presence of barium i.e. from its decomposition. It is resonable to use the barium containing wastes for clinkers with low Lime Saturation Factor.
The examination of hydration properties of barium containing phases permit to observe that barium containing belites seem to gain compressive strength quite slowly while barium containing alite is characterized by high value of compressive strength (up to 57 MPa). The value of compressive strength in calcium aluminoferrite is also high.

MONOMINERAL BINDERS IN $CaO-Al_2O_3-ZnO$ SYSTEM

Vladimir D. BARBANYAGRE, The Belgorod Technological Academy of Building Materials, Belgorod, Russia

ABSTRACT Two new ternary compounds having the composition of $3CaO{\cdot}2Al_2O_3{\cdot}ZnO$ and $14CaO{\cdot}5Al_2O_3{\cdot}6ZnO$ were synthesized in the $CaO-Al_2O_3-ZnO$ system. Their atomic structure, roentgenometric characteristics and some physicochemical properties were determined. Synthesized calcium aluminozincates are hydraulic binders and can be used as high-temperature putty under the conditions of a higher sulphuric anhydrite concentration.
CALCIUM ALUMINOZINCATES, BINDER, ISOMORPHISM, HYDRATION

INTRODUCTION

Zinc compounds are active catalysts in the processes of cement clinker sintering, only yielding to fluorides a little bit in this respect (Odler, Schmidt, 1980). The decrease in the quantity of an aluminate phase in clinker is observed with increasing ZnO concentration above 1%. It indirectly testifies to the fact that, first of all, zinc reacts with calcium aluminate and probably forms a more complex, ternary compound. This circumstance prompted an independent study of high-temperature interactions in the $CaO-Al_2O_3-ZnO$ system.

Ternary compounds of calcium aluminate with alkali oxides having the composition of $Na_2O{\cdot}8CaO{\cdot}3Al_2O_3$ and $K_2O{\cdot}8CaO{\cdot}3Al_2O_3$ (Susukawa, 1956), with barium oxides: $BaO{\cdot}2CaO{\cdot}4Al_2O_3$ (Brisi, 1962), strontium oxides: $Sr{\cdot}2CaO{\cdot}3Al_2O_3$ (Massazza, 1959) and magnesium oxides: $MgO{\cdot}3CaO{\cdot}2Al_2O_3$ (Majumdar, 1964), are known. However, judging from the literature available to us, the $CaO-Al_2O_3-ZnO$ system had not been studied.

HIGH-TEMPERATURE INTERACTIONS IN $CaO-Al_2O_3-ZnO$ SYSTEM

Fifty mixes having different molar ratios of components were prepared from original calcium, aluminium and zinc oxides of a chemically pure type. The components, as tablets, were heated up to 1450 °C in a furnace with silicon carbide electric heaters and were subjected to isothermal holding for 30 minutes (Barbanyagre, et al., 1990, 1991, 1992, 1994). Burning products were studied by X-ray phase, chemical, crystal optic, thermal and petrographic analyses. Diffraction peaks were revealed in diffractograms of a number of compositions which did not belong to original oxides and the known two-component compounds; they testified to the formation of a new unknown phase or phases. Varying the composition of mixes and burning conditions, we managed to produce a sinter in which diffraction peaks of original oxides and the known two-component compounds were practically absent. Crystal optic and petrographic analyses showed that the cake consisted of, at least, two phases with different refractive indices, crystal morphology and colour.

Using the different solubilities of these two phases in 1N hydrochloric acid, we managed to isolate one of the phases in a rather pure state and determine its preliminary bulk composition and roentgenometric characteristic. After that similar data were obtained for the second phase, too. The first phase occurring in the form of prismatic, colourless and white crystals was called a high-temperature phase (a HT phase). The second phase, represented by crystals of

an orange colour, was called tentatively a low-temperature phase (a LT phase). The ratio of oxides in moles, as follows:

a HT phase: $CaO : Al_2O_3 : ZnO = 3 : 2 : 1$

a LT phase: $CaO : Al_2O_3 : ZnO = 2.31 : 2 : 1.09$.

THE SYNTHESIS OF CALCIUM ALUMINOZINCATES

For the synthesis of the LT phase in the form of a hard polycrystalline cake it is sufficient to heat up a mix of original oxides to 1350° with 30 minutes' isothermal holding and subsequent fast cooling in air. The sequence of LT phase synthesis reactions has the following form:

$$CaO+Al_2O_3+ZnO \xrightarrow{850\text{-}1000^\circ C} CaO \cdot Al_2O_3 \xrightarrow{1000\text{-}1100^\circ C} CaO \cdot Al_2O_3+ZnO \cdot Al_2O_3$$

$$\xrightarrow{1100\text{-}1200^\circ C} CaO \cdot Al_2O_3 + ZnO \cdot Al_2O_3 + \text{LT phase} + \text{HT phase} \xrightarrow{1250\text{-}1300^\circ C}$$

$$ZnO \cdot Al_2O_3 + \text{LT phase} + \text{HT phase} \xrightarrow{1300\text{-}1350^\circ C} \text{LT phase}$$

The interaction of oxides in the mix having predetermined composition starts at 850 °C with $CaO \cdot Al_2O_3$ formation. Subsequently $ZnO \cdot Al_2O_3$ is formed within a range of 1000 - 1100 °C. The synthesis of calcium aluminozincates starts at 1100 °C and is complete at 1350 °C.

The synthesis of the second HT phase requires a slightly higher temperature and proceeds in the following sequence:

$$CaO+Al_2O_3+ZnO \xrightarrow{850\text{-}1000^\circ C} CaO \cdot Al_2O_3 \xrightarrow{1000\text{-}1050^\circ C} CaO \cdot Al_2O_3+ZnO \cdot Al_2O_3+\text{HT phase}$$

$$\xrightarrow{1100\text{-}1200^\circ C} CaO \cdot Al_2O_3 + ZnO \cdot Al_2O_3 + \text{LT phase} + \text{HT phase} \xrightarrow{1250\text{-}1300^\circ C}$$

$$ZnO \cdot Al_2O_3 + \text{LT phase} + \text{HT phase} \xrightarrow{1300\text{-}1400^\circ C} \text{HT phase}$$

The sequence of phase transformations under the synthesis of calcium aluminozincates has a multistage character with the formation of a number of intermediate compounds. It should be pointed out that both calcium zincates coexist within a certain range of temperatures and original oxide compounds. This fact created considerable difficulties at the initial stage of the synthesis of new phases and the interpretation of their roentgenograms.

THE SYNTHESIS OF CALCIUM ALUMINOZINCATE MONOCRYSTALS

The synthesis of calcium aluminozincate monocrystals was made to determine an atomic structure and specify a composition and physicochemical properties of new compounds (Table 1). The conditions of monocrystal synthesis were selected on the basis of the thermal analysis data and accomplished by a very slow crystallization of original melts.

The X-ray analysis of monocrystals (Ilyinets, Barbanyagre, 1990) allowed us to determine an atomic structure and a chemical formula of synthesized phases:

a LT phase: $Ca_{14}Al_{10}Zn_6O_{35}$ or $14CaO \cdot 5Al_2O_3 \cdot 6ZnO$ ($C_{14}A_5Z_6$)

a HT phase: $Ca_3Al_4ZnO_{10}$ or $3CaO \cdot 2Al_2O_3 \cdot ZnO$ (C_3A_2Z).

Table 1. Characteristics of synthesized zinc-containing compounds

Index	$Ca_{14}Al_{10}Zn_6O_{35}$	$Ca_3Al_4Zn_6O_{10}$
Molecular formula	$14CaO \cdot 5Al_2O_3 \cdot 6ZnO$	$3CaO \cdot 2Al_2O_3 \cdot ZnO$
Chemical composition, weight %	CaO = 44.04 Al_2O_3 = 28.65 ZnO = 27.30	CaO = 37.09 Al_2O_3 = 45.03 ZnO = 17.88
Cell parameters, Å	a = 14.868	a = 5.142 b = 16.756 c = 10.710
Space group	F23	Pbc2i, Z=4
Single crystals habit	Cubooctahedral	Hexagonal prismatic
IR-absortion bands (cm^{-1})	910; 850; 760; 700; 660; 560; 520; 485; 440	910; 800; 760; 680; 660; 585; 510; 440

Single crystal colour	Orange	Colourless
Solubility: alcohol, acetone HCl, NaOH water	 non-soluble soluble hydrates	 non-soluble soluble hydrates
Hydrate phases	$CaO \cdot 2ZnO \cdot 5H_2O$; $n\,Zn(OH)_2 \cdot y\,Al(OH)_3 \cdot aq$; $2CaO \cdot Al_2O_3 \cdot 8H_2O$; Phase of non-established composition (d=7.98; 8.1 Å)	$2CaO \cdot Al_2O_3 \cdot 8H_2O$; $n\,Zn(OH)_2 \cdot y\,Al(OH)_3 \cdot aq$; Phase of non-established composition (d=7.98; 8.1 Å)

ROENTGENOMETRIC CHARACTERISTIC OF CALCIUM ALUMINOZINCATES

Roentgenometric characteristics of $Ca_3Al_4ZnO_{10}$ and $Ca_{14}Al_{10}Zn_6O_{35}$ monocrystals determined according to the powder method within a range of 2Θ = 5-164° are given in Tables 2 and 3. The diffractogram measurements of polycrystalline products of a solid-phase synthesis of the LT phase and the HT phase turned out to be identical accordingly. The diffractograms of both the compounds are characterized by the availability of the considerable number of intensive diffraction peaks which are not overlapped by reflections of calcium aluminates, aluminoferrites and silicates, what allows their certain identification in compositions of cements and other complex ceramic materials.

HYDRATION OF CALCIUM ALUMINOZINCATES

The interactions of calcium aluminozincates with water were studied in the diluted suspension at a liquid-to-solid ratio of 100 : 1 and in the paste at a liquid-to-solid ratio of 0.25 - 0.50 (Barbanyagre, Timoshenko, 1994).

C_3A_2Z Hydration

According to the data of the X-ray phase analysis a hydration product in the suspension has the following composition: $2CaO{\cdot}Al_2O_3{\cdot}H_2O$ (C_2AH_8); $n\,Zn(OH)_2{\cdot}y\,Al_2(OH)_3{\cdot}aq$ and an X-ray amorphous gel phase forming a diffusion halo within a range of 2Θ = 15 - 26° and 30 - 42° in the diffractogram. Hydrate phases are carbonized comparatively easily with $C_3A\,CaCO_3{\cdot}12H_2O$ formation.

$C_{11}A_5Z_6$ Hydration

$C_{14}A_5Z_6$ hydration in the suspension produces the following hydrate phases: $CaO{\cdot}2ZnO{\cdot}5H_2O$ (CZ_2H_5); $n\,Zn(OH)_2{\cdot}y\,Al(OH)_3{\cdot}aq$; C_2AH_8; gel formation is not observed.

HYDRAULIC PROPERTIES OF CALCIUM ALUMINOZINCATES

Hydraulic properties of calcium aluminozincates were studied in the form of pastes at a liquid-to-solid ratio of 0.25 - 0.50. Due to the limited quantity of the synthesized material, setting time and strength were determined using samples with reduced sizes under nonstandard conditions. For C_3A_2Z, initial set occurs in 45 minutes and the completion of the set in 55 minutes. For $C_{14}A_5Z_6$, set is completed in 30 seconds and retarders are required for practical applications.

It was established that saccharose, boric acid, citric acid and glycerine considerably retarded the setting. Sodium salts, acetic acid, hydrochloric acid and triethanolamine accelerated the setting. In that case gypsum additions up to 10 % did not exert a considerable effect.

The strength of cube-samples having 1.4 cm edge size and 20 ± 2 °C is given in Table 4.

* 11-15 according to the literature data

The data given in Table 4 show that calcium aluminozincates can be used as special-purpose hydraulic binders as they surpass many well-known calcium aluminates in strength. In this case the hydration degree of $C_{14}A_5Z_6$ samples reached 30 % in a day, 38 % in 3 days, 42 % in 7 days and 50 % in 28 days. Although its degree of hydration was 1.5 times higher, as compared with C_3A_2Z, the strengths of both the binders were roughly similar.

$C_{14}A_5Z_6$ hydration products are distinctly more crystalline relative to C_3A_2Z where gel predominates. Unlike calcium aluminates, the recrystallization of hexagonal hydroaluminates into cubic C_3AH_6 is not observed even after 6 months' water hardening under the hydration of calcium aluminozincates.

Calcium aluminozincate having the $C_{14}A_5Z_6$ composition was identified by us in the composition of white clinker, when adding zinc oxide into the original raw mix. A new phase is synthesized within a temperature range of 1000 - 1200 °C, and at 1280 °C it forms a melt having low viscosity, which accelerates considerably the formation of all clinker minerals. $C_{14}A_5Z_6$ is crystallized out only under slow cooling, occurring in the form of glass during fast clinker cooling. Calcium aluminozincate having the $C_{14}A_5Z_6$ composition decreases the sintering temperature of white clinker by 100 - 150 °C and increases its hydraulic activity by 15 - 20 % and whiteness by 7 - 8%.

CONCLUSIONS

1. A rare variant of heterovalent isomorphism is observed in the process of a high-temperature interaction in the CaO - Al_2O_3 - ZnO system. According to

it zinc statistically substitutes aluminium in alumino-oxygen tetrahedra with the formation of hitherto unknown ternary phases.

- $Ca_3Al_4ZnO_{10}$ or $3CaO{\cdot}2Al_2O_3{\cdot}ZnO$ (C_3A_2Z);
- $Ca_{14}Al_{10}Zn_6O_{35}$ or $14CaO{\cdot}5Al_2O_3{\cdot}6ZnO$ ($C_{14}A_5Z_6$).

New compounds are synthesized from an oxide mix having an appropriate composition at 1300 - 1400 °C and can be produced in the form of monocrystals under appropriate slow cooling of melts.

2. The determined roentgenometric characteristics, atomic structure and some physicochemical properties of synthesized calcium aluminozincates allow their certain identification in the composition of more complex materials and map out the areas of practical application. Both the compounds are hydraulic binders surpassing many calcium aluminates in their strength.

3. The regularities established under study of the CaO - Al_2O_3 - ZnO system are of more general character and continue being studied on the basis of similar systems involving tin, zirconium, titanium and other elements. Although the results obtained are tentative, they predict the formation of new binders and certain correlation in the theory of binding properties manifestation.

ABSTRACT The composition, distribution and defect structure of ferrite in sulphate resisting portland cement clinker was studied by electron microscopy. The hydration kinetics of synthetic ferrite solid solutions and model cements has been investigated by differential scanning calorimetry. The hydration products were characterised in the scanning electron microscope. Comparisons of early hydration rates were made with sulphate resisting production cements. Internal and external factors affecting the reactivity of ferrite are discussed.

Key-words: Ferrite phase, solid solution, electron microscopy, reactivity, AFt phase

INTRODUCTION

The rheological properties of concrete and mortars made using sulphate resisting industrial cements have been found to be somewhat variable. Many of these changes have been related to the extent of dehydration of the added gypsum. However, hydration studies and other results indicate that some of these variations are probably related to the reactivity of the clinkers and at these early times, particularly the changes in the characteristics of the ferrite phase. Ferrite is the major oxide interstitial phase in sulphate resisting portland cement (SRPC), while aluminate occurs in such small amounts that it is usually hard to detect by X-ray powder diffraction or X-ray elemental mapping (Bäckström & Hansen; 1996 and 1997), cf. Fig. 1. The hydration reactions of ferrite have been reviewed by Brown et al. (1986) and Sjöstedt (1996). Our approach has been to perform electron microscopy studies of SRPC clinker ferrites, followed by hydration investigations of synthetic ferrites mimicing those in the clinker and finally comparisons with hydrating SRPC.

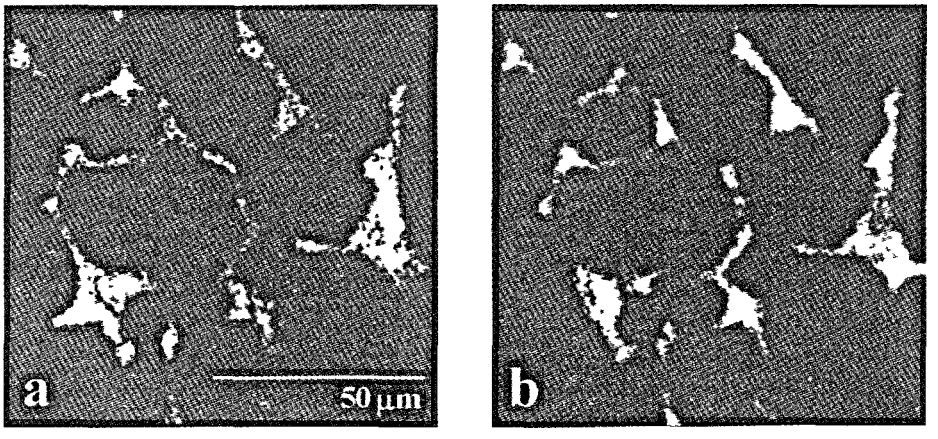

Fig. 1. Elemental maps of polished SRPC clinker; (a) Al and (b) Fe. Areas with both Al and Fe contain ferrite, while areas with Al alone indicates aluminate, e.g. in the lower left corner.

EXPERIMENTAL

Preparation of samples Swedish production clinker was ground to an average particle size of 5 μm. The powder was then stirred with salicylic acid dissolved in methanol for 24 h, vacuum filtered and washed with acetone. Polished clinker was obtained according to a standard procedure used for preparing specimens for clinker microscopy (reflecting light), but excluding the final acid etching. Two powder mixtures, no 1 and 2 in Table 1, were prepared using ferrite, Ca_2AlFeO_5 prepared at 1350°C, and the following chemicals; $CaSO_4 \cdot 2H_2O$ (Merck, p.a.), Ca_3SiO_5 (prepared from $CaCO_3$ and SiO_2 at 1450 °C) and ground quartz (SiO_2). Two synthetic solid solution series of composition $Ca_2(Al_xFe_{1-x})_2O_5$ (x= 0 to 0.67) were prepared by firing the appropriate proportions of the constituent oxides at 1450°C and at 100°C below the respective melting point, until the free lime content was 0.5 wt% or below. In the instance of the lower temperature preparations, a maximum of three firings with intermediate grinding was required. All were then ground to a Blaine surface of 300 m^2kg^{-1} and the BET surface, and particle size distribution to 0.1 μm determined. Two types of mixture (no 3 and 4, Table 1), were prepared from ferrite solid solutions to simulate the nominal phase composition of Swedish SRPC. The alite in these samples was purchased from CTL, Skokie, Illinois, USA. This had to be shaken with water (H_2O/solid = 2 by weight) for 5 min, then rapidly filtered and acetone dried, before final drying for 30 min at 800°C, because preliminary mixtures using the original alite were found to be extremely unreactive, as compared to earlier studies using pure C_3S of the same Blaine surface. K_2SO_4 (Merck, puriss) was used in mix 4. 0.5 g of no 1-3 were mixed with 0.5 ml of distilled water for 30 s, using a spatula. 0.5 g of no 4 was mixed with 0.5 ml 0.05 M KOH (Merck). The hydration was stopped by mixing with acetone (99.5%) for 30 s, followed by vacuum filtering, and washing with acetone 4 times with final drying by vacuum filtering for 8 min.

Table 1. Composition (wt%) of mixtures in hydration experiments.

No	ferrite	gypsum	C_3S	alite	K_2SO_4	quartz
1	60.0	20.0	-	-	-	20.0
2	60.0	20.0	10.0	-	-	10.0
3	15.0	5.0	-	50.0	-	30.0
4	15.0	3.7	-	50.0	1.3	30.0

X-ray powder diffraction The X-ray diffraction spectra of the ferrite solid solutions were recorded in reflection mode on a Siemens D500 diffractometer (CuKα1 radiation) and were inspected for phase purity. The hydrated samples (no 1-2); pure Ca_2AlFeO_5; and extracted interstitial materials were mixed with Si and mounted on Scotch tape. X-ray powder diffraction films were recorded using a Guinier-Hägg camera (CuKα1 radiation). The phases were identified and the unit cell parameters determined using the least squares method.

Electron microscopy A JSM-840A scanning electron microscope, interfaced with a Link AN10000 energy dipersive X-ray microanalysis system, was used in these studies. Elemental analysis was performed on polished clinker, extracted interstitial material and the hydrated samples 1 and 2. Small amounts of extracted clinker and hydrated samples were mounted on copper stubs covered with a conducting polymer. A thin layer of carbon was then evaporated onto the samples. Secondary electron images were taken of the hydrates formed in samples 1 and 2, after small amounts of the samples had been mounted on copper stubs using adhesive tape and then covered by sputtering with a thin layer of gold. The extracted interstitial phases were dispersed on copper grids with a holey

carbon film, and then investigated using a transmission electron microscope JEM-2000FX (200 kV) equipped with a Link AN10000 X-ray microanalysis system, or a JEM-4000EX (400 kV).

Differential scanning calorimetry The hydrated samples were sealed in pans, with a 50 μm laser pierced hole in the lid to control the dehydration process. Aluminium oxide was utilised as an inert reference material in the measurements. The temperature range covered was 25 °C to a maximum of 400 °C and the samples were heated at a rate of 20 °C min^{-1}. A Perkin Elmer-DSC7 differential scanning calorimeter was used. The enthalpy of dehydration of the AFt was calculated from analysis of the area of the main DSC peak, in relation to the consumption of gypsum, in reactive mixtures containing 30% C_4AF, 15 % gypsum and ground silica. The enthalpy was estimated to be 540±40 Jg^{-1}; the value used to calculate the AFt content in all the pastes, as compared with the value of 590 Jg^{-1} for pure ettringite quoted by Struble (1986), although values as high as 790 Jg^{-1} have been found (Eber, private communication).

RESULTS AND DISCUSSION

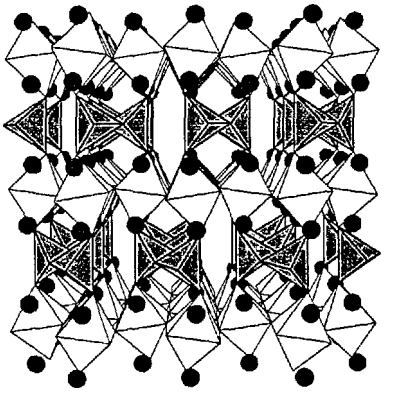
Clinker ferrite

Extended defects. The structure of synthetic $Ca_2(Al_{0.5}Fe_{0.5})_2O_5$ contains chains of tetrahedra along the c direction, all pointing in the same direction as shown in Fig. 2. In the corresponding iron compound $Ca_2Fe_2O_5$, the chains in the bottom layer point forward, while those in the top layer point backward. A phase transition takes place close to the composition $Ca_2(Al_{0.3}Fe_{0.7})_2O_5$. Electron diffraction studies of extracted clinker ferrite (Landa-Cánovas & Hansen, 1996 and in prep.) show that the structure is essentially that of $Ca_2(Al_{0.5}Fe_{0.5})_2O_5$. But electron diffraction has in addition revealed sheets of diffuse scattering, which indicate the presence of disordered line-defects along the c direction in clinker ferrite. We propose that the disordered line-defects consist of single chains of tetrahedra pointing in the opposite direction compared to the basic structure in Fig. 2. The number of defects in a crystal increases with annealing temperature and defects are known to increase the subsequent reactivity of a material. It has for example been shown that planar defects in the structurally related compound $YBa_2Cu_3O_7$ serve as points of attack, when the crystal surface is exposed to water (Rupeng et al. 1992).

Substitutions. The unit cell parameters of ferrite from Swedish SRPC and ordinary Portland cement (OPC) are similar to those determined for synthetic Ca_2AlFeO_5, see Table 2.

Table 2. Lattice parameters

sample	a/Å	b/Å	c/Å
ferrite - SRPC	5.550(1)	14.526(4)	5.347(2)
ferrite - OPC	5.541(2)	14.516(5)	5.328(2)
Ca_2AlFeO_5	5.560(1)	14.511(2)	5.343(1)
AFt - sample 1	11.213(6)	-	21.51(2)
AFt - sample 2	11.163(3)	-	21.959(4)



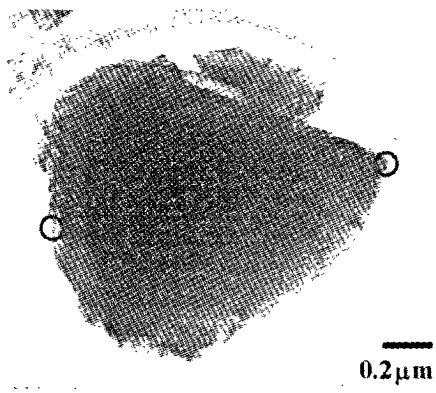


Fig. 2. Crystal structure of $Ca_2(Al_{0.5}Fe_{0.5})_2O_5$ (C_4AF) seen along the c direction. Octahedra are preferentially centred by Fe atoms, the tetrahedra by Al, while spheres represent Ca atoms. Oxygens (omitted for clarity) are situated at corners shared by two polyhedra.

Nevertheless, X-ray microanalysis of extracted clinker ferrite performed in a transmission electron microscope (TEM) shows that trivalent ions in the crystals are subject to substantial substitution according to the scheme: 2 M(3+) ↔ M(2+) + M(4+); M(3+) = Al, Fe; M(2+) = Mg, Mn; M(4+) = Si, Ti). Many of the analyses exhibit an atomic ratio Al/Fe in the range 0.7-0.9, with an average composition of $Ca_{2.03}Al_{0.72}Fe_{0.87}Mg_{0.11}Mn_{0.05}Si_{0.17}Ti_{0.03}O_5$, which is very similar to values obtained on the same sample using a scanning electron microscope (Bäckström & Hansen, 1997). The higher spatial resolution of the analyses in the TEM reveals the presence of more Al-rich areas, see Fig. 3. The ratio Al/Fe can thus change rapidly on the micrometer scale. The most Al-rich analysis observed (Al/Fe = 1.90) gave the composition $Ca_{1.96}Al_{1.20}Fe_{0.63}Mg_{0.06}Mn_{0.03}Si_{0.09}Ti_{0.01}O_5$. Similar short-range variations in ferrite composition has been observed in oil-well cement clinker by Richardson et al. (1993). The influence of dopant ions on the reactivity of ferrite is hard to predict and has to be studied experimentally.

Synthetic ferrite

Hydration and additives. The hydration studies, on mixture 1 and 2 using DSC, showed that in presence of sulphates, the hydration starts with the formation of sulphate-AFt (ettringite), while gypsum is being consumed. When the calcium sulphate has been depleted, unreacted ferrite remains and AFm phase (monosulphate) starts to form, whilst AFt disappears. When the hydration is carried out in the presence of tricalcium silicate and added gypsum, the formation of AFt is delayed, due to the introduction of a pronounced dormant period during AFt formation, see Fig. 4. It appears that a high concentration of hydroxide is necessary for the creation of this extended induction period, since it also occurs when C_3S is replaced by $Ca(OH)_2$ or KOH (Emanuelson, 1995; Emanuelson, Henderson & Hansen, 1996). There seems to be general agreement that this type of behaviour is due to the formation of a protective layer of products on the hydrating grains (Brown et al. 1986).

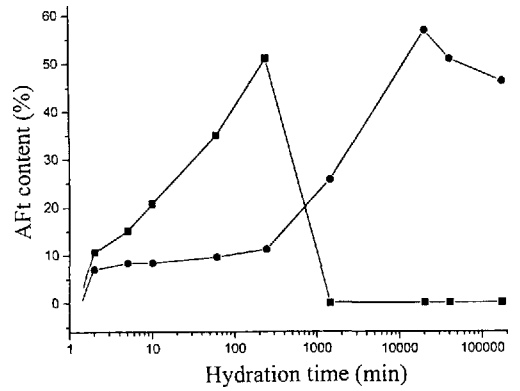

Fig. 3. Transmission electron micrograph of a ferrite grain extracted from SRPC clinker. Elemental analysis of the circled areas gave Al/Fe ratios of 0.7 (left) and 1.4 (right).

Fig. 4. Formation of AFt phase from $Ca_2(Al_{0.5}Fe_{0.5})_2O_5$ (C_4AF) and gypsum (squares) or gypsum + C_3S (circles) as a function of time.

Protective product layer. The morphology of the AFt formed in the presence of gypsum (no 1) and also added C_3S (no 2) are compared in Figs 5a-b and c-d. This shows that the initial crystals of AFt are much smaller when formed in the presence of a base. The observation is consistent with the notion of microcrystalline ettringite forming a protective layer, which causes retardation of the hydration reaction as shown in Fig. 4. Elemental analysis indicates that the AFt crystals formed with a base present tend to be more iron-rich (Al/Al+Fe ≈ 1/2) than those produced without base (Al/Al+Fe ≈ 3/4); compare the c axis expansion in Table 2 (Emanuelson & Hansen, manuscript).

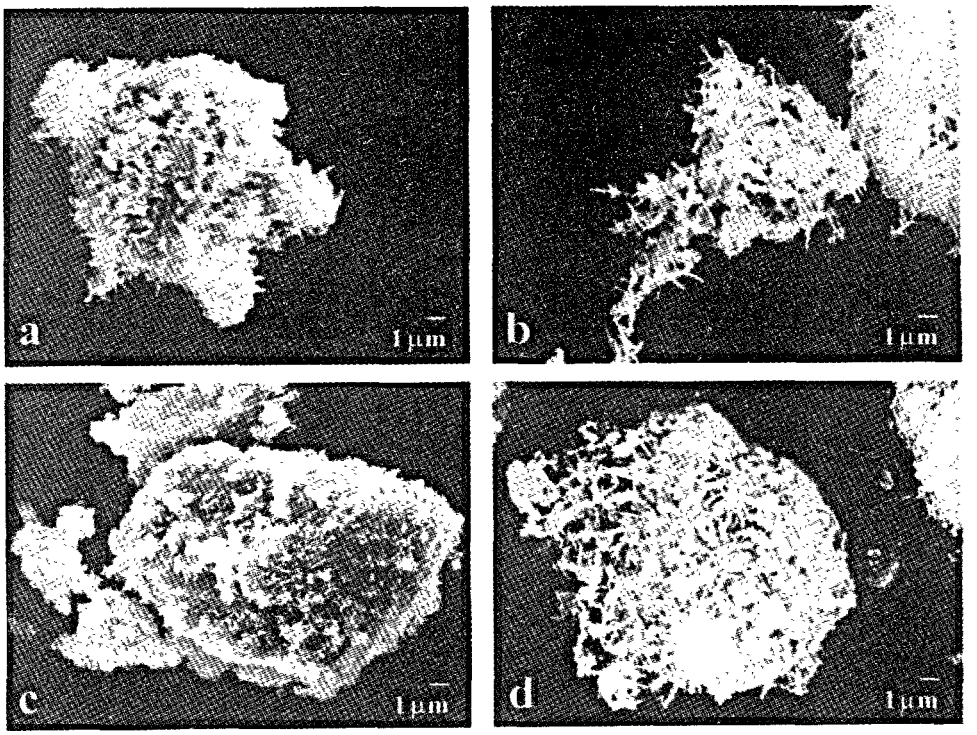

Fig. 5. Scanning electron micrographs of AFt crystals formed from synthetic C_4AF; (a) water with gypsum, 5 min; (b) water with gypsum, 2 h; (c) water with gypsum and C_3S, 5 min; and (d) water with gypsum and C_3S, 28 days.

It has been suggested that an amorphous iron-rich compound forms when ferrite is hydrated. This gel should also contain some calcium according to Brown (1987) and Liang & Nanru (1994). In both of our samples, dark particles can be seen in the light microscope, which we interpret as pseudomorphs after ferrite grains, see Fig. 6. These pseudomorphs have been observed earlier by Fukuhara et al. (1980). Our investigations reveal that the dark phase is X-ray amorphous, but its chemical composition is fairly constant and corresponds to $CaFe_4O_7 \cdot xH_2O$ (CF_2H_x), if the iron is assumed to be trivalent and a minor content of Al is neglected. This phase is another candidate for the formation of the protective layer.

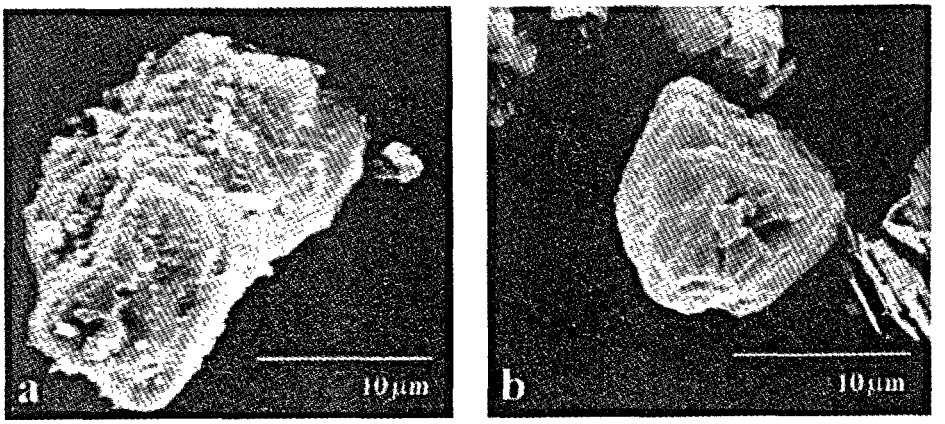

Fig. 6. (a) Grain of synthetic C_4AF with a terraced morphology. (b) Ferrite pseudomorph consisting of $CaFe_4O_7 \cdot xH_2O$ (CF_2H_x).

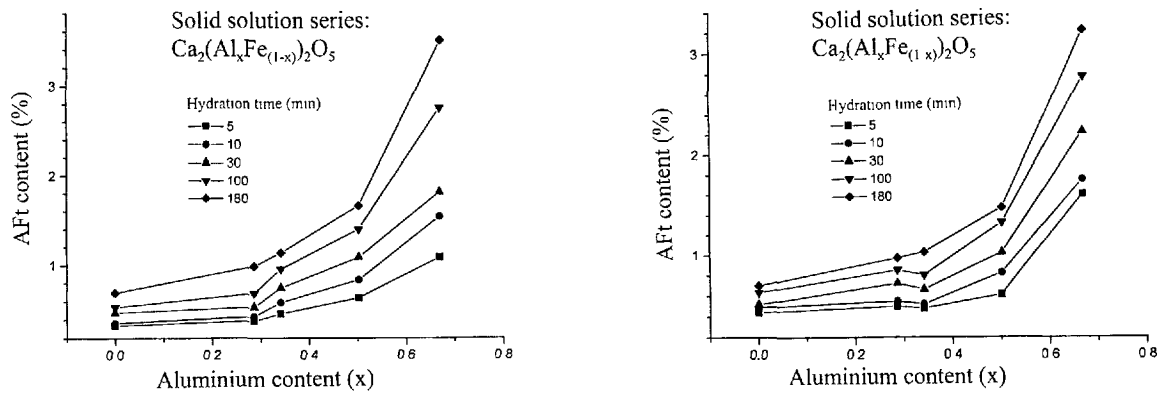
Model cements and SRPC

Early hydration of ferrite solid solutions. The influence of increasing the aluminium content in the solid solution series $Ca_2(Al_xFe_{1-x})_2O_5$ on the early hydration behaviour has been studied. This has been monitored by measuring the rate of formation of the ettringite-like AFt phase using DSC. Mixes (no 3) simulating the typical phase composition of a Swedish SRPC were used, as they were considered appropriate for comparison with the early reactivity of production cements. The results obtained for the two series produced in melt condition and in the solid state are presented in Fig. 7. The similar reactivity of the solid solution formed from the melt and that prepared in the solid state could be due to insufficient cooling rates, leading to similar defect concentrations in both series. The results show a near continuous, relatively small, increase in the rate of formation of AFt with increasing Al content, with the significant increase occurring between x = 0.5 and 0.67. The greatest overall differences were, however, only observed after 100 min hydration. These results are consistent with those obtained by Negro & Stafferi (1979). Although their hydration times, like many others Boikova (1986), or Carlson (1964), tend to be on the days time scale. Smith (1962) found a structural change close to x = 0.3 in the solid solution series and interestingly there is a small jump in the rate in just this region, see Fig. 7.



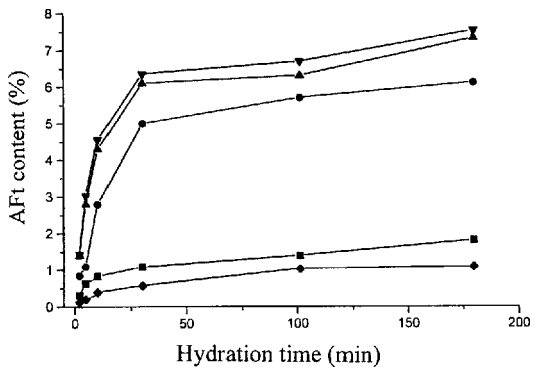


Fig. 7. Influence of the Al content on the formation of AFt (wt%). The ferrite solid solution prepared at 1450 °C (left) and the series prepared at 100 °C below the respective melting points (right).

Early hydration of SRPC. The hydration behaviour of sulphate resisting cements produced during 1995 has been studied and the results summarised in Fig. 8. These have been separated into three reactivity (wt% AFt) bands according to results obtained from 20 cements; two, did, in fact, have somewhat lower reactivity, but these have not been included. In addition, the diagram includes the hydration results obtained for $Ca_2(Al_{0.5}Fe_{0.5})_2O_5$ (C_4AF); the solid solution member, with the Al/Fe molar ratio close to that of the interstitial phase in production cements. There is a large difference in the rate of formation of the AFt phase between the cements and the apparently equivalent synthetic blend (no 3) of similar particle size distribution and BET surface. This is especially true of the paste hydrations containing alkalies (mix no 4); simulating the initial pore solution concentration of Swedish SRPC (Henderson, unpublished results), when an even lower rate of AFt formation is observed; see Fig. 8. However, without further analysis of the surface microstructure of the complex multiphased clinker particles (Scrivener, 1984), in the ground cements, it is difficult to compare the available surface of the interstitial phase, with that of the ground synthetic ferrites. Clearly the cement ferrite phase reacts far more rapidly from the very intial stage during mixing itself, as shown by the differences after only 2 min hydration, see Fig. 8. Simply, increasing the Al content to the solid solution limit does not appear to increase the initial reactivity enough (see Figure 7), to explain the

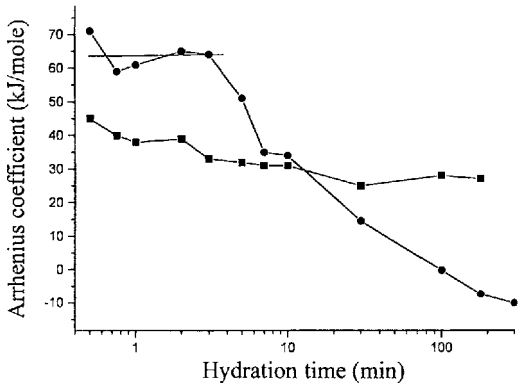

Fig. 8. Comparison between the reactivity of production SRPCs (triangles, dots) with that of synthetic ferrite (C_4AF) mixes in water (squares) and potassium hydroxide (diamonds).

Fig. 9. Comparison between the Arrhenius temperature coefficient, for the formation of AFt from a production SRPC (dots) and a model cement containing synthetic ferrite, C_4AF (squares).

very large differences observed, even though equivalent compositional variations are present in the interstitial phase of high ferrite clinkers (Richardson et al. 1993). However, the increased relative reactivity of the end member (x = 0.67) compared to that of the earlier members could be important.

Temperature effects. Further indications of the difference between the hydration behaviour of the cement ferrite phase and the apparently equivalent synthetic phase was found from the results of hydration studies undertaken at two different temperatures, i.e. 1.9 and 23.3 °C. The results obtained were analysed assuming the Arrhenius equation, $k(\%AFt) = Ae^{-E/RT}$, where the rate constant k is substituted by the AFt content at a given time, at temperature T and E is the nominal activation energy. The temperature coefficient of the rate of formation of AFt as a function of the hydration time is shown in Fig. 9. The differences in the Arrhenius "activation energy" observed, would clearly indicate a change in the mechanism of the complex heterogeneous reaction, leading to the development of the AFt phase, between that for the synthetic phase in mix 3 compared to that for the apparently similar ferrite phase in SRPC. In the instance of the synthetic ferrite, there appears to be small continuous decrease throughout the period studied. In contrast, only during the first 3 min hydration of SRPC is there a consistent value of 64 ± 5 $kJmol^{-1}$, but thereafter there is a continuous rapid fall to negative values after 100 min, indicative of the reaction becoming increasingly dependent on the nature of the product layer. Only during the first 3 min is there any similarity between the two materials. Thereafter they rapidly diverge, with more reactive cement phase hydration becoming increasingly dependent on the product layer, whilst the synthetic phase never appears to reach this stage, due probably to the small amount of product formed. Although, in the instance of the cements, the mechanism apparently becomes increasingly dependent on the amount of product (AFt), after only few minutes hydration; nevertheless, the absolute rate of formation remains initially far higher, than that of the synthetic phase. It is therefore, possible to compare the solid state reactivity of different ferrites, with that of the cements, only during the very initial stages, when the more primary solid surface mechanism is predominant and not when the product layer controls the rate. In the instance of the present cement hydration results, this begins to occur after only 3 minutes hydration. The reasons for such large differences in the rate of formation of AFt remain uncertain.

Conclusions

Clinker ferrite. Ferrite in industrial SRPC clinker exhibits a disordered array of one-dimensional crystal structure defects. Normally, about 20% of the trivalent ions in clinker ferrite are substituted by a mixture of divalent and tetravalent ions, as compared to Ca_2AlFeO_5. However, the aluminium content in ferrite crystals can sometimes vary considerably on the micrometer scale.

Synthetic $Ca_2(Al_{0.5}Fe_{0.5})_2O_5$. The presence of a base is necessary in order for gypsum to retard the formation of AFt during hydration. When a base is present, the early AFt crystals are much smaller and the AFt is richer in iron, compared to hydration with gypsum alone. Iron-rich pseudomorphs after ferrite grains have a fairly constant composition, i.e. $CaFe_4O_7 \cdot xH_2O$, and are X-ray amorphous.

Model cements with $Ca_2(Al_xFe_{1-x})_2O_5$. Hydration of mixtures simulating SRPC indicates that the ferrite becomes more reactive with increasing Al content. No difference in reactivity could be detected between a ferrite solid solution prepared in the solid state and one prepared from the melt.

Model cement and SRPC. Comparison between the AFt formation in hydrating production SRPCs and model cements with Ca_2AlFeO_5 shows that the initial reactivity of SRPC is higher than that of the model cements. Only part of the difference in reactivity can be attributed to (i) the presence of about 2 wt% $Ca_3Al_2O_6$ in the SRPC, (ii) possible enrichment of Al close to the surface of clinker ferrite grains, (iii) excess relative surface area of clinker ferrite.

Temperature effects. If the temperature is lowered to 1.9 °C, the hydration mechanism of SRPC is strongly affected. No such change is observed in the case of a model cement.

KEY-WORD INDEX

A

Accelerated test; 3iii033
Accelerators; 3ii103, 3iii005, 3iii012, 3iii014, 3iii022, 3iii027, 3iii032,
Acid attack; 3ii109, 4iv002, 4iv021, 4iv038, 4iv039, 4iv040
Activation; 1i006, 2ii016, 2ii045, 2ii062, 2ii076, 3ii083, 3ii092, 3ii094, 3ii098, 3ii099, 3ii100, 3ii103, 3ii104, 3ii113, 3ii114, 3iii028, 4iv047
Activation energy; 1i053
Activity coefficient; 4iv083
Additives; 1i009, 1i020, 1i035, 2ii003, 2ii009, 2ii045, 2ii074, 3ii116, 3iii017, 3iii032
Adiabatic temperature rise; 4iv072
Admixtures; 2ii012, 2ii034, 2ii036, 2ii047, 3ii087, 3ii095, 3ii097, 3iii001, 3iii002, 3iii004, 3iii009, 3iii018, 3iii019, 3iii023, 3iii024, 3iii025, 3iii026, 3iii029, 3iii030, 3iii031, 3v015, 4iv004
Adsorption; 2ii001, 3iii002, 4iv077
AFm phase; 2ii032, 3iii032, 3ii089, 4iv034, 4iv061
AFt phase; 1i060, 4iv034, 4iv041, 4iv059
Aggregate; 2ii015, 3v024, 4iv053, 4iv057
Air entraining; 4iv031, 4iv057
Air pollution; 4iv002
Alinite; 2ii030, 3ii118
Alite; 1i006, 1i015, 1i041, 1i050, 2ii040, 2ii042, 2ii056, 3ii107, 3ii117, 3iii005, 3iii031
Alkali; 1i002, 1i012, 1i028, 1i035, 1i049, 2ii012, 2ii065, 3ii083, 3ii098, 3ii100, 3ii103, 3ii113, 3ii114, 3ii117, 3iii025, 4iv003, 4iv028, 4iv055, 4iv066
Alkali aggregate reaction; 3iii033, 3v022, 4iv048
Alkali silica reaction; 4iv047, 4iv049, 4iv065, 4iv074
Alkali silicate solutions; 4iv049, 4iv065
Alkaline cement; 4iv046
Alumina; 2ii027, 2ii026, 3iii010
Aluminate phase; 1i001, 1i022, 1i051, 1i056, 2ii041, 2ii060, 3iii010, 3iii015, 4iv027, 4iv034, 4iv066
Aluminoferrite; 1i004, 1i005, 1i055, 2ii031
Aluminosilicate; 1i024, 4iv046
Anhydrite; 1i032, 2ii011, 2ii022, 2ii029, 3ii092, 4iv059
Aragonite; 1i042
Arc furnace dust; 4iv042
Asbestos; 1i027
Ash; 3ii080
Autoclavation; 3ii120, 4iv054
Autoclave soundness; 1i023
Autogeneous shrinkage; 2ii069, 2ii070, 2ii071, 2ii073

B

Backscattered electron image; 2ii014, 4iv061
Bacterial attack; 4iv038, 4iv039
Bamboo dust; 1i019

Barite; 1i036
Barium phases; 1i058
Belite; 1i006, 1i015, 1i018, 1i041, 1i052, 2ii007, 2ii040, 2ii045, 2ii056, 3v009
Belite cement; 1i036
Binder; 1i059, 2ii047, 2ii054, 3ii080, 3ii101, 3iii021, 4iv057
Blastfurnace slag; 2ii068, 2ii074, 3ii082, 3ii093, 3ii095, 3ii096, 3ii098, 3ii099, 3ii101, 3ii102, 3ii103, 3ii104, 3ii115, 3ii122, 3iii009, 3iii017, 4iv001, 4iv005, 4iv009, 4iv015, 4iv035, 4iv040, 4iv063
Blended cement; 1i020, 3ii089, 3ii091, 3ii111, 3ii114, 3ii115, 3ii121, 3v026, 4iv004, 4iv017, 4iv020, 4iv052,
Bogue calculation; 1i039, 3v007, 3v009
Borax; 1i036
Bottom ash; 3ii090
Bound water; 2ii072, 3iii019, 3v019
Brick; 3ii080
Brownmillerite; 1i022, 2ii029, 2ii032,
Burnability of raw mixes; 1i021, 1i030, 1i031, 1i034, 1i040, 1i041, 1i045, 1i048, 1i054
Burning conditions of clinker; 1i018, 1i023

C

Calcium carbonate; 1i042
Calcium aluminate; 2ii022, 2ii025, 2ii050, 3iii022, 3v005
Calcium aluminate cement; 2ii024, 2ii026, 2ii027, 2ii028, 3iii007, 3v018, 4iv003, 4iv025, 4iv026
Calcium aluminate sulphate; 2ii010, 4iv068
Calcium aluminozincates, 1i059
Calcium hydroxide; 2ii049, 2ii059, 3ii082, 3ii106, 3ii107, 3ii108, 3ii112, 3iii031, 3v019, 4iv067
Calcium fluoride; 1i032, 2ii042
Calcium langbeinite; 2ii011
Calcium nitrate; 3iii012
Calcium phosphate; 1i036
Calcium phosphate cement; 2ii063
Calcium silicate; 1i035, 1i055, 2ii055, 2ii050, 2ii062, 4iv054
Calcium sulphate; 1i012
Calorimetry; 2ii021, 2ii025, 2ii041, 2ii066, 3iii032, 3v016, 3v017, 4iv042
Capillary; 2ii048
Carbon dioxide; 1i024, 2ii032, 4iv010
Carbonation; 2ii073, 4iv003, 4iv004, 4iv005, 4iv006, 4iv010, 4iv017, 4iv026, 4iv035, 4iv048, 4iv070, 4iv084
Case studies; 4iv002
Cement; 3ii092
Cement hydration equation; 2ii061, 4iv052
Characterization; 1i008, 2ii062, 3ii088, 3v011, 3v020 3v023, 3v026, 4iv019
Chemical analyis; 3v012
Chemical attack; 4iv015, 4iv026, 4iv028, 4iv031
Chemical prestressing; 3iii016

Chemical shrinkage; 2ii069, 2ii070, 2ii072
Chloride; 1i002, 1i012, 2ii030, 3ii118, 4iv006, 4iv015, 4iv027, 4iv078, 4iv080, 4iv081, 4iv082, 4iv083
Chloride Binding; 4iv016, 4iv069, 4iv070, 4iv078
Classification; 4iv046
Clay; 2ii020
Clinker; 1i048, 1i058
Clinker composition; 1i028, 4iv036
Clinker formation; 1i004, 1i006, 1i008, 1i010, 1i011, 1i026, 1i031, 1i037, 1i043, 1i044, 1i046, 1i049, 1i054, 2ii006, 3ii118
Cluster; 1i003
Coal; 1i047, 3ii090
Composite cements; 1i009, 2ii016, 2ii034, 3ii122
Composition; 2ii007, 2ii071, 3v004, 3v011, 3v026, 4iv007, 4iv023, 4iv060
Concrete; 2ii035, 3ii108, 3iii024, 3iii029, 3v021, 3v022, 4iv025, 4iv035, 4iv073
Cooling of clinker; 3v005
Corrosion; 2ii006, 4iv014, 4iv020, 4iv023, 4iv027, 4iv028, 4iv030, 4iv038, 4iv039, 4iv071, 4iv082, 4iv084
Creep; 4iv018
Cross-linking; 3iii011
Crystal; 2ii015
Crystal size; 1i051, 3iii031
Crystal structure; 1i055, 2ii048
Crystallisation pressure; 4iv049
Crystallography; 2ii054
CSH; 2ii044, 2ii047, 2ii053, 2ii055, 2ii059, 2ii064, 2ii067, 2ii068, 3ii082, 3ii093, 3ii121, 3v001, 3v003, 4iv016, 4iv041, 4iv043, 4iv061, 4iv074, 4iv076
Curing; 2ii037, 2ii078, 3ii091, 4iv055, 4iv059, 4iv067

D

Deformation; 4iv021, 4iv058
Degree of hydration; 2ii051, 2ii053, 2ii062, 2ii077, 3v019, 4iv016
De-icing salts; 4iv006, 4iv035
Delayed ettringite formation; 4iv059, 4iv061, 4iv062, 4iv063, 4iv064
Delayed expansion; 3iii016
Design life; 4iv071
Dicalcium silicate; 1i017, 1i053
Differential thermal analysis; 2ii041, 4iv031
Diffusion; 2ii046, 3ii084, 3ii098, 4iv010, 4iv015, 4iv016, 4iv056, 4iv080, 4iv081
Diffusivity; 4iv008, 4iv009
Dilation; 4iv033
Dispersion; 2ii005
Disposal; 1i027
Dopant; 1i053
Drying; 3iii018, 3v018, 4iv011, 4iv077, 4iv079
Durability; 2ii011, 3ii095, 3iii024, 3v022, 4iv004, 4iv007, 4iv022, 4iv023, 4iv026, 4iv029, 4iv030, 4iv037, 4iv040, 4iv046, 4iv048, 4iv062, 4iv065, 4iv070, 4iv075, 4iv082

E
Economy; 1i036, 3ii114
Ecology; 1i043
Electron microscopy; 1i060
Electron spectroscopy for chemical analyses (ESCA); 2ii044
Electrical conductivity; 4iv011
Electrical impedance; 3ii112
Electrical properties; 4iv079
Electrical resistivity; 3v021
Energy; 2ii046
Environment; 1i003, 3ii093
Equilibria; 2ii057, 2ii058
Ettringite; 1i025, 2ii006, 2ii010, 2ii017, 2ii029, 2ii031 2ii056, 2ii070, 2ii074, 3iii022, 4iv012, 4iv018, 4iv031, 4iv060, 4iv062, 4iv065
Evaporable water; 3v019
Expansion; 2ii006, 2ii074, 3iii017, 3v022, 4iv057, 4iv060, 4iv062, 4iv064
Expansive cement; 1i001, 2ii010
Extraction methods; 3v020

F
False set; 3iii013
Ferrite phase; 1i008, 1i015, 1i060, 3iii005, 3v003
Ferroaluminate; 4iv029
Filler; 1i020, 2ii002, 2ii020, 3ii081, 4iv056
Fineness; 1i007, 2ii001, 2ii002, 2ii018, 2ii043, 2ii060, 3ii088, 3v008, 4iv060
Fingerprinting; 3v010, 3v011
Fire; 4iv073
Fire damage; 4iv067
Flow; 2ii017, 3v024
Flue gas desuphurisation product; 3ii090
Fluidity; 2ii001, 2ii002, 2ii012
Fluoride phases; 2ii043, 3v002
Fly ash; 3ii081, 3ii082, 3ii083, 3ii084, 3ii085, 3ii086, 3ii087, 3ii088, 3ii089, 3ii090, 3ii110, 3ii115, 3ii116, 3ii122, 3v006, 3v020, 3v021, 4iv004, 4iv009, 4iv012, 4iv019, 4iv020, 4iv023, 4iv058, 4iv077
Fracture mechanics; 2ii075
Free lime; 1i016, 1i045, 2ii049, 4iv036
Freeze-thaw damage; 2ii016, 3iii019, 4iv034, 4iv035
Freezing; 4iv033
Friedel's salt; 4iv027, 4iv080
Fuels for clinker making; 1i013, 1i019

G
Gel; 3ii105, 3iii007, 3iii022, 4iv074
Glass; 1i046, 1i051, 3ii088, 3ii119, 4iv030, 4iv055
Grinding aids; 2ii020, 3v014
Grinding technology; 1i009, 1i040

Ground silica; 3ii120
Grout; 2ii005
Gypsum; 2ii040, 2ii044, 2ii060, 3ii093, 3ii115, 3iii025, 3v008, 3v023, 4iv017

H
Hardening; 2ii008, 2ii034, 2ii039, 2ii047, 2ii052, 2ii054, 2ii076, 3ii112, 3v016, 4iv071
Heat capacity; 4iv033
Heat evolution; 2ii021, 2ii035, 2ii051, 2ii076, 2ii077, 3ii102, 3ii105, 3iii029, 3v016, 4iv042, 4iv072
Heavy metals; 1i043, 2ii014, 3v010, 3v013, 4iv041, 4iv043
High alumina cement; 2ii023, 2ii033, 3iii010, 3ii096, 4iv013, 4iv027, 4iv038
High performance; 2ii035, 2ii038, 3ii108, 3v006, 3v021
High strength; 2ii037, 3ii120
High sulphate clinker; 2ii011
High temperature; 3ii111, 3iii020, 4iv067
Humidity; 4iv011, 4iv079
Hydration; 1i022, 1i057, 1i059, 2ii004, 2ii006, 2ii008, 2ii007, 2ii012, 2ii013, 2ii015, 2ii019, 2ii021, 2ii022, 2ii023, 2ii024, 2ii025, 2ii026, 2ii028, 2ii029, 2ii030, 2ii031, 2ii033, 2ii035, 2ii036, 2ii039, 2ii040, 2ii041, 2ii042, 2ii043, 2ii044, 2ii046, 2ii047, 2ii050, 2ii052, 2ii055, 2ii057, 2ii058, 2ii061, 2ii067, 2ii069, 2ii070, 2ii078, 3ii089, 3ii094, 3ii097, 3ii099, 3ii100, 3ii101, 3ii102, 3ii107, 3ii116, 3ii118, 3ii119, 3iii008, 3iii014, 3iii015, 3iii019, 3iii025, 3v006, 3v016, 3v018, 4iv072, 4iv071
Hydrothermal synthesis; 1i017

I
Identification; 3v010
Image analysis; 4iv084
Immobilization; 2ii014, 2ii016, 2ii052, 4iv043, 4iv045
impact prediction; 1i003
Impact evaluation; 1i003
Induction period; 2ii019, 2ii055
Infra red absorption spectra; 3ii104
Inhibitor; 3iii033
Interfacial zone; 4iv050, 4iv051, 4iv053, 4iv056, 4iv084
Interground cements; 1i013, 3v026
Interstitials; 2ii007
Ion exchange resin; 4iv045
Ionic assocoiation, 4iv083
Ions; 2ii036, 2ii046, 2ii065, 3iii012, 3iii013, 4iv075, 4iv079
Iron mud; 1i021
Isomorphism; 1i059

K
Kinetics; 1i005, 1i035, 1i044, 1i052, 2ii019, 2ii023, 2ii028, 2ii043, 2ii055, 3ii098, 3iii008, 4iv076

L
Latex; 3iii008
Leaching; 2ii014, 4iv012, 4iv041, 4iv043, 4iv045
Light microscopy; 3iii031, 3v007
Lignosulphonates; 2ii004, 3iii013, 3iii021
Lime; 2ii049, 2ii074, 3ii084, 3iii005, 4iv010
Limestone; 1i047, 1i048, 2ii022, 4iv018
Long age; 2ii016, 4iv050
Low energy; 1i034, 2ii045
Low temperature; 1i018, 1i029, 1i037, 2ii009, 2ii013, 2ii038, 3iii014, 3v017
Lumos; 2ii079

M
Magnesium chloride; 4iv022
Magnesium sulphate; 4iv022
Magnesium oxide; 1i023, 2ii064, 3v012
Magnesium phases; 1i057
Mass spectroscopy; 3v014
Maturity; 3ii111
Macro Defect Free; 3iii010, 3iii011, 4iv013
Mechanical properties; 3v025
Mechanism; 1i046, 2ii025, 2ii026, 2ii035, 2ii050, 2ii057, 2ii058, 3ii100, 3iii003, 3iii006, 3iii012, 3iii025,, 3v014, 4iv074
Melt; 1i008, 1i011, 1i012, 1i014, 1i029, 1i046, 3v005
Mercury Intrusion Porosimetry; 3ii104
Metakaolin; 3ii113, 3ii114, 4iv011
Method; 2ii021, 3v011, 3v013, 3v016, 3v018, 3v022, 3v023, 4iv081
Microcrack; 4iv021
Microgravity; 2ii075
Microscopy; 1i029, 1i030, 1i039, 1i051, 1i052
Microstructure 1i038, 1i039, 1i047, 1i049, 1i052, 2ii008, 2ii014, 2ii018, 2ii037, 2ii064, 2ii075, 3ii091, 3ii095, 3ii096, 3ii099, 3iii014, 4iv005, 4iv015, 4iv025, 4iv037, 4iv047, 4iv050, 4iv051, 4iv053, 4iv055, 4iv068, 4iv084
Mineralisers in clinker making; 1i028, 1i030, 1i031, 1i033, 1i034, 1i037, 1i050, 3v002
Mineralogy; 1i046, 3ii087, 3ii105
Mineral phase; 1i015, 2ii009, 2ii015, 4iv028
Mixing procedure; 3ii120
Mobility; 2ii065, 4iv083
Modelling; 1i038, 1i044, 1i045, 2ii048, 2ii052, 2ii078, 3ii085, 3ii084, 3iii013, 3v004, 4iv005, 4iv070, 4iv071, 4iv073, 4iv078
Modified cement; 2ii004, 2ii020, 3ii085, 3ii097, 3ii104, 3iii021, 3iii023
Moisture; 2ii079, 3iii011,3v004, 4iv010, 4iv013, 4iv062
Molybdic compounds; 1i054, 1i055
Monosulphate; 2ii056
Mortar; 4iv033

N
Naphtalene Formaldehyde Sulphonate; 3iii003, 3iii009, 3iii030
Nitrate attack; 4iv002
Nodulization in clinker formation; 1i007
Non-equilibrium burning; 1i011
Nuclear Magnetic Resonance; 1i024, 2ii028, 2ii056, 2ii067, 2ii068, 3iii007, 3v001, 3v002, 3v003, 3v004, 3v005, 3v006

O
Oilwell cement; 2ii013, 3iii014
Organic; 3v015
Osmotic pressure; 4iv049

P
Packsetting; 2ii079
Particle size distribution; 1i009, 2ii018, 2ii053, 3ii110, 3v024
Pattern recognitin; 3v010
Penetration; 2ii005, 2ii038, 3ii109, 4iv080
Performance; 4iv073
Permeability; 4iv008, 4iv075
Petroleum coke; 3ii090
pH; 4iv065
Phase composition; 3ii091
Phase diagram; 1i050, 1i052, 2ii024, 2ii057, 2ii058, 4iv066, 4iv074,
Phase transition; 4iv033
Phase transformation; 4iv034
Phosphate; 4iv057
Physical properties; 3v025
Plasticizers; 2ii020
Polymer; 3iii008, 3iii009, 3iii010, 3iii027, 4iv013
Polymorphs; 1i053
Pore size distribution; 4iv077
Pore solution; 2ii036, 3iii003, 3iii013, 3iii022, 3ii091, 4iv040, 4iv069
Pore structure; 2ii037, 2ii066, 3ii111, 3iii009, 3iii018, 3v017, 4iv001, 4iv005, 4iv080
Porosity; 2ii036, 2ii048, 2ii066, 2ii072, 3ii085, 3ii119, 3iii023, 3v017, 4iv006, 4iv007, 4iv008, 4iv013, 4iv017, 4iv024, 4iv040, 4iv048, 4iv054, 4iv078
Portland cement; 3ii107, 3iii006, 3v025, 4iv012
Potentiometry; 4iv083
Powder; 2ii002
Pozzolana; 1i020, 2ii073, 2ii077, 3ii106, 3ii107, 3ii108, 3ii112, 3ii115, 3ii117, 3ii123, 3ii124, 3v001
Pozzolanic cement; 4iv036
Pozzolanic reaction; 3v006
Pozzolanic reactivity; 3ii088
Pre-calciners for clinker making; 1i028
Prehydration; 2ii079
Process parametres; 1i047

Q
Qualitative; 1i004, 3v010, 3v011, 3v015
Quantitative; 1i039, 1i056, 3v007, 3v012, 3v013, 3v015, 3v020
Quartz; 1i048

R
Rapid hardening cement; 2ii017
Rate equations; 1i044
Reaction products; 4iv049
Reactivity; 1i016, 1i018, 1i047, 1i060, 2ii049, 2ii050, 3ii082, 3ii109, 3ii110, 3v020, 4iv016, 4iv050
Refractory; 2ii027, 4iv053, 4iv057
Relative humidity; 2ii073
Residual silica; 4iv049
Retarders; 3iii007, 3iii020, 3iii032
Rheology; 2ii003, 2ii004, 2ii011, 3iii003, 3iii027
Rice husk; 1i019
Rice Husk Ash; 3ii108, 3ii109, 3ii110
Rietveld analysis; 1i039, 1i056, 3v007
Roller compaction; 3ii086
Rotary kiln; 1i007, 1i019

S
Salt scaling; 4iv001
Scanning Electron Microscopy; 1i002, 2ii078, 3ii083, 3ii120, 3iii008, 3v019, 4iv037, 4iv064
Sea water; 4iv025
Secondary ettringite formation; 4iv065
Self deccication; 2ii073
Setting; *1i038, 2ii019, 2ii039, 2ii053, 2ii063, 3ii101, 3ii112, 3iii006, 3iii012, 3iii023, 3iii026,* 3v008
Sewage; 3ii123, 3ii124, 4iv038, 4iv039
Shotcreting; 3iii027
Shrinkage; 1i032, 3iii018, 4iv036, 4iv056
Silica; 3ii080
Silica colloid; 3ii106
Silica fume; 2ii037, 3ii105, 3ii106, 3ii110, 3ii116, 3ii120, 3v001, 4iv014, 4iv069
Silica modulus; 1i035
Silicate; 2ii060, 3iii027, 4iv065
Simulation; 2ii078, 3iii001
Sintering; 1i005, 1i007, 1i022, 1i032
Slag; 1i020, 3ii080, 3ii092, 3ii094, 3ii097, 3ii100, 4iv050, 4iv051, 4iv058
Slump loss; 3iii003, 3iii020
Sodium chloride; 4iv022
Solid solution; 1i014, 1i023, 1i057, 2ii059, 1i060, 3v009
Solid state reactions; 1i042
Solidification; 4iv042
soluble glass; 2ii033

Sorption isotherms; 4iv077
Specific surface; 3iii028
Spectrophotometry; 3v012
Stability; 4iv065
Stabilization; 1i016, 2ii045, 4iv041
Standards; 3v025
Steam curing; 3ii102, 4iv036, 4iv063
Steel; 4iv014, 4iv082
Steric repulsive force; 3iii001
Strain softening; 2ii075
Strength; 1i048, 1i058, 3ii109, 4iv057
Strength development; 1i029, 1i038, 1i041, 2ii007, 2ii017, 2ii018, 2ii033, 2ii051, 2ii053, 2ii054, 2ii060, 2ii063, 2ii072, 2ii076, 2ii077, 3ii085, 3ii089, 3ii097, 3ii111, 3ii117, 3ii119, 3ii121, 3iii004, 3iii026, 3iii028, 3iii029, 3v024, 4iv024, 4iv052, 4iv054, 4iv055, 4iv056, 4iv058, 4iv063
Strength retrogression; 4iv019
Stress; 4iv049
Structure; 1i005, 1i014, 1i056, 2ii054, 2ii066, 2ii067, 2ii068, 2ii069, 2ii076, 4iv007, 4iv025, 4iv042, 4iv043, 4iv075
Sucrose; 3iii006
Sulphate; 1i049, 2ii012
Sulphate attack; 4iv002, 4iv018, 4iv020, 4iv021, 4iv024, 4iv057, 4iv059
Sulphate resistance; 3iii004, 3iii015, 4iv017, 4iv019, 4iv023
Sulphoaluminate; 1i001, 1i025, 2ii029, 3iii026, 3v009, 4iv029, 4iv030, 4iv068
Sulphoaluminoferrite; 1i014
Superplasticizers; 2ii002, 2ii004, 3iii001, 3iii002, 3iii019, 3iii020, 3iii021, 3iii030, 4iv001
Support; 2ii015
Synthesis; 1i015, 1i024, 1i033, 2ii064, 3ii113

T

Temperature; 1i005, 1i007, 1i008, 1i012, 2ii021, 2ii023, 2ii026, 2ii043, 2ii066, 3iii002, 3iii029, 3v001, 4iv047, 4iv060, 4iv068, 4iv069
Terminology; 4iv046
Texture; 1i048
Thawing; 4iv033
Thermal stress; 4iv072
Thermal treatment; 1i027
Thermodynamics; 1i042, 2ii024, 2ii057, 2ii058, 2ii059, 2ii062, 2ii066, 4iv039, 4iv066
Thermogravimetry; 2ii049, 3ii105, 3iii011 4iv003, 4iv037
Thermoporosimetry; 3v017
Tobermorite; 2ii064, 2ii065, 3v003
Trace components; 1i021
Transmission Electron Microscopy; 2ii068
Tricalcium silicate; 1i049 2ii041, 2ii044

U

Unreacted core model; 2ii051

V
Vibration; 2ii017
Viscosity; 1i014, 1i032, 2ii001, 2ii003, 2ii005
Void spacing factor; 3v024
Volume change; 2ii009, 2ii039, 2ii071, 2ii072, 4iv031

W
Waste disposal; 4iv012
Waste material utilization; 1i010, 1i019, 1i022, 1i025, 1i026, 1i027, 1i033, 2ii052, 3ii081, 3ii093, 3ii101, 3ii116, 3ii118, 3ii119, 3ii121, 3ii123, 3ii124, 3v003, 3v013, 4iv014, 4iv024
Water; 4iv075
Water sorption; 4iv008
Water suction; 4iv008, 4iv011, 4iv078
Water-to-cement ratio; 2ii071
Waterglass; 3ii092
Wedge splitting; 2ii075
White Portland Cement; 3iii004
Workability; 2ii011, 3iii029

X
X-ray Diffraction Analysis; 1i051, 1i016, 2ii041, 3iii028, 3ii087, 3ii114, 3v008, 4iv003
X-ray Fluorescense Analysis; 3v011
X-ray Powder Diffraction; 1i002, 1i010, 1i056, 2ii065, 4iv018

Z
Zeolites; 1i020, 1i024, 4iv028, 4iv045, 4iv046
Zeta potential; 3iii001, 3iii002

List of contents for Volume 2

II PORTLAND, BLENDED AND SPECIAL CEMENTS

II.A Rheology

H. Fujiwara, S. Nagataki, A. Dozono: "Effect of Size Distribution of Powders on Yield Value and Viscosity of Mortar", 2ii001, 7 pp

E. Sakai, S. Hoshino, Y. Ohba, M. Daimon: "The Fluidity of Cement Paste with Various Types of Inorganic Powders", 2ii002, 8 pp

H. Kikukawa, T. Iisaka, Y. Ishikawa: "A Study on the Method of Estimating Rheological Constants of Cement Paste Containing Chemical Admixtures", 2ii003, 8 pp

L. Opoczky, A. Papo: "Reological and Hydration Properties of a High Strength Gypsum-Free Cement", 2ii004, 8 pp

E. Asakura, T. Suzuki, H. Ogata, Y. Maejima, H. Fujisawa: "Penetrability of Suspension Grout Influenced by Dispersion Characteristics of Ultrafine Cement in the Grout", 2ii005, 4 pp

II.B Hydration kinetics and microstructure development

M.M. Ali, R. Bhargava, S.C. Ahluwalia: "Hydration Characteristics of Magnesia Assimilated Sulpho Aluminate - Belite Cement", 2ii006, 6 pp

T. Ikabata, H. Takemura: "Influence of the Composition of Interstitial Phases on the Hydration Properties of Belite Cements", 2ii007, 4 pp

L.G. Sudakas, L.B. Vasiliyeva: "Distinguishing Features of Hardening of Portland Cement Systems on a Basis of Clinker of Various Microstructure", 2ii008, 4pp

I. Grosvalds, S. Lagzdina, U. Sedmalis: "Dolomitic Roman Cement - Low Temperature Hydraulic Binder", 2ii009, 4 pp

J. Stark, I. Chartschenko: "Theoretical Fundamentals of the Application of Expansive Cement Concretes", 2ii010, 6pp

V. Michaud, R. Suderman: "Sulphate Solubility in High SO_3 Clinkers", 2ii011, 10 pp

A. Tagnit-Hamou, S. Bouraoui: "Effect of Alkali Sulfates on Cement Hydration at Low and High Water-to-cement Ratios", 2ii012, 8pp

A. Klusov, Y.R. Krivoborodov, A. Achmetov: "The Change of the Liquid Phase Composition and Properties of Hardened Cement Paste at Low Temperature", 2ii013, 4 pp

H. Uchikawa, S. Hanehara, H. Hirao: "Behavior of Heavy Metal Elements in the Hardening of Cement Paste", 2ii014, 7 pp

A. Olginsky: "Formation of Hydration on Mineral Support", 2ii015, 4 pp

P.G. Komokhov, N.N. Shangina: "Controlling the Hydration of Portland Cement and Concrete's Physical and Chemical Properties by the Surface of Mineral Aggegates", 2ii016, 4 pp

N. Kondo, Y. Nikaido, S. Nakaya, M. Handa, T. Ando, E. Sakai, M. Daimon: "Relationship between Ettringite Formation and the Development of Strength for Rapid Hardening Cement", 2ii017, 8 pp

S.P. Ghosh, K. Mohan: "Interrelationship among Lime Content of Clinker, its Microstructure, Fineness of OPC Grinding and Strength Development of Hydrated Cement at Different Ages", 2ii018, 4 pp

V. Chistyakov, V. Shevchenko, A.E. Degtyaryev, A. Poltavtsev: "Kinetic Peculiarities of Hydrate and Structure Formation in Portland Cement at Initial Stages of Hardening", 2ii019, 4 pp

S.P. Sivkov, D. V. Mundshtukov, I. Jedda: "Organo-Mineral Fillers for Cements", 2ii020, 4 pp

A.V. Usherov-Marshak, O.P. Mchedlov-Petrossyan, A.G. Sinyakin: "The Thermokinetic Factor in Cement Hardening", 2ii021, 4 pp

Y. Ohba, A. Nakamura, L. J. Kyu, E. Sakai, M. Daimon: "Influence of $CaCO_3$ on the Hydration of Various Types of Calcium Aluminates with Anhydrite", 2ii022, 8 pp

V. Chistyakov, V. Serbin: "Sequence of Hydration Process During Hardening of High Alumina Cement", 2ii023, 4 pp

D. Damidot, P. Barret: "Calculation of the Maximum Supersaturation Curve of C_2AH_8 in the CaO-Al_2O_3-H_2O system at 20°C", 2ii024, 8 pp

D. Damidot, F. Sorrentino: "Modification of the Hydration Process from $C_{12}A_7$ to C_3A at 20°C", 2ii025, 8 pp

A. Rettel, D. Damidot, K. Scrivener: "Study of the Hydration of Mixtures of CA and α-Al_2O_3 at Different Temperatures", 2ii026, 8 pp

T.V. Kousnetsova, A.A. Abdel-Kader: "Influence Solid Solution of Calcium Aluminate on Alumina Cement Properties", 2ii027, 3 pp

A.B. Kudryavtsev, T.V. Kouznetsova: "On the Possibilities of the *in situ* Studies of Hydration of Aluminate Cements Using ^{27}Al NMR and Proton Relaxation Rate Measurements", 2ii028, 8 pp

J. Berekta, N. Sherman, M. Marroccoli, A. Pompo, G.L. Valenti: "Effect of Composition on the Hydration Properties of Rapid-Hardening Sulfoaluminate Cements", 2ii029, 8 pp

L. Ji, X. Ren, M. Su: "Effect of Chloride on Hydration Properties of Alinite Cements", 2ii030, 4 pp

Y. Chen, L. Shi: "Rate of Ettringite Formation from Calcium Aluminoferrite Hydration", 2ii031, 8 pp

M. Ecker, H. Pöllmann: "Synthesis and Charcterization of CO_3-containing Ca-Al-Fe Hydrates", 2ii032, 4 pp

P.V. Krivenko, E.K. Pushkaryeva, S.V. Shapet'ko: "Alkaline Aluminate Binders", 2ii033, 4 pp

S. Peukert: "Cement for High Performance Cement Concretes", 2ii034, 4 pp

Y.N. Sheen, C.L. Hwang: "Hydration Mechanism of High Performance Concrete", 2ii035, 4 pp

EFFECT OF SIZE DISTRIBUTION OF POWDERS ON YIELD VALUE AND VISCOSITY OF MORTAR

Hiromi FUJIWARA, Nihon Cement Co., Ltd., Tokyo Japan
Shigeyoshi NAGATAKI, Tokyo Institute of Technology, Tokyo, Japan
Akito DOZONO, Nihon Cement Co., Ltd., Tokyo Japan

ABSTRACT: This paper clarifies the relationship between size distribution of powders and rheological properties (yield value and viscosity) of mortar, which directly affect the properties of high fluidity concrete. The results of this study show that yield value of mortar is influenced by the n-value of the Rosin-Rammler equation, which is the main factor of excess water volume in mortar, and that viscosity of mortar is influenced by the Blaine surface area, which results from the effect obtained by combining absorption of superplasticizer and thickness of water film.

Key-words: adsorption, fineness, fluidity, viscosity

INTRODUCTION

In recent years, high fluidity concrete, which demonstrates the properties of high fluidity and resistance to segregation, has been receiving particular attention. In order to achieve resistance to segregation, a viscosity controlling admixture is added or the amount of powder is increased. Another method of achieving effective resistance to segregation is adjustment of powder grading. Therefore, it is necessary to clarify the relationship between grading and the rheological properties of concrete or mortar. For this paper, the relationship between powder grading and viscosity and yield value of mortar were studied.

RELATIONSHIP BETWEEN POWDER GRADING AND RHEOLOGICAL PROPERTIES OF MORTAR

Outline of experiment

The two principal factors affecting grading distribution conditions, Blaine fineness (BF) and the n-value (NV), or distribution constant of the Rosin-Rammler equation, were varied and mortar was mixed using these powders; the yield value and viscosity, which are the rheological properties of these mortars, were measured and their relationship with BF and with NV was investigated.

Materials used

Normal Portland cement (NPC: BF=3,210 cm^2/g, specific gravity=3.15, NV=1.06) and limestone powder (LS: specific gravity=2.70) were used. Chemical composition of NPC is

shown in Table 1. Limestone was ground to BF in the range of 2,200~10,000 cm^2/g using a ball mill and mixed with cement in the proportions of 1 : 1 by volume. The results, as shown in Fig 1, were 51 types of powders within the range BF=3,500~7,500 cm^2/g, NV=0.7~1.1. ß-Naphthalene sulfonic acid (NS) was used as the superplasticizer and crushed sand (specific gravity=2.61, FM=2.91, percentage of solid volume=66.2%) was used as the fine aggregate. Fig 2 shows the grading curve for fine aggregate.

Table 1 Chemical composition of normal Portland cement (NPC) and moderate-heat Portland cement (MPC)

Cement	Ig. loss	Insol	CaO	SiO_2	Al_2O_3	Fe_2O_3	MgO	SO_3	Na_2O	K_2O	TiO_2	P_2O_5	MnO	f-CaO	Total
NPC	1.6	0.3	61.6	20.1	5.0	3.0	1.1	2.0	0.38	0.43	0.26	0.06	0.17	0.6	96.00
MPC	0.7	0.1	64.2	23.1	3.8	4.0	0.8	2.1	0.32	0.39	0.19	0.05	0.08	0.4	99.83

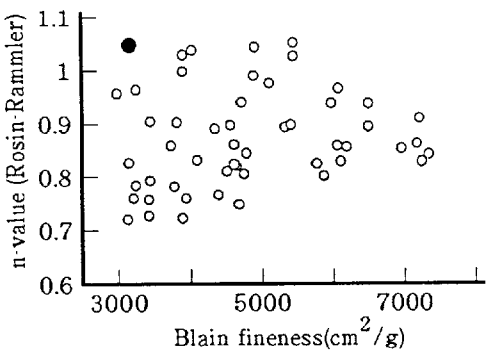

Fig 1 Blaine fineness and n-value

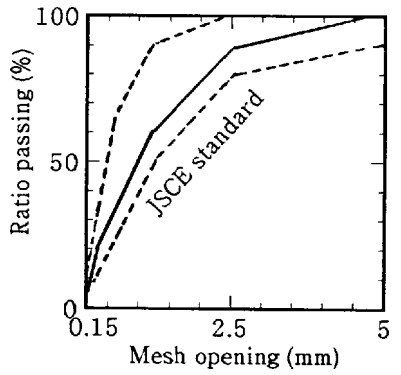

Fig 2 Grading curve for fine aggregate

Conditions of experiment

Mortar, composed of powder, water and fine aggregate in the proportions 22.7 : 22.9 : 54.5 (% by vol.) was mixed in a two-liter paddle mixer for two minutes. This composition is equivalent to the mortar component used in standard high fluidity concrete.

Test items

The yield value and viscosity of the mortar were measured immediately after mixing using a rotation viscosimeter.

Results of experiment

Yield value of mortar

The contour line of the yield value of mortar is shown in Fig 3. From these results it is clearly seen that the yield value of mortar is strongly influenced by the NV; the smaller the NV, the lower the yield value. Further, as the BF decreases, the yield value decreases slightly.

However, for NV lower than 0.8, it was confirmed that the yield value tends to increase as the NV decreases. This is thought to result from changes in the fineness distribution caused by early hydration.

Viscosity of mortar

Fig 4 shows the contour line of the viscosity of mortar, which differs greatly from that of the yield value. Thus, the NV exerts a strong influence when the BF is in the range below 4,000 cm^2/g, and the viscosity decreases as the NV becomes smaller. However, when BF is in the range above 4,000 cm^2/g, the influence of the BF exceeds that of the NV and as the BF increases, viscosity increases. In general, the yield value and viscosity are strongly interrelative and as the yield value increases, viscosity also increases. Therefore, when BF is in the range below 4,000 cm^2/g, it is thought that the influence of the yield value is stronger. However, when the BF exceeds 4,000 cm^2/g, it is thought that other factors are at work. Further, as for the yield value, when the NV is in the range below 0.8, it was confirmed that viscosity increases as the NV decreases. As for yield value, this is thought to result from changes in the fineness distribution caused by early hydration.

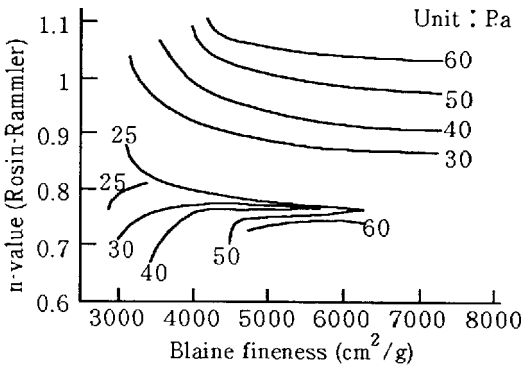

Fig 3 Relationship of contour line of yield value with Blaine fineness and n-value

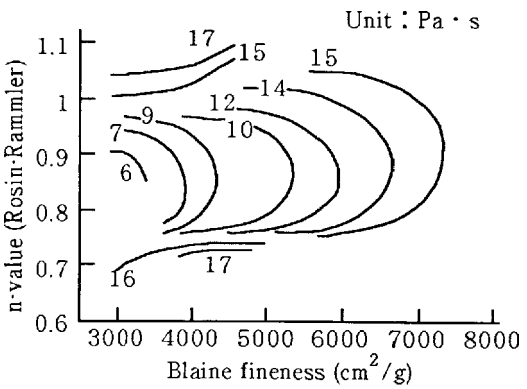

Fig 4 Relationship of contour line of viscosity with Blaine fineness and n-value

FACTORS INFLUENCING YIELD VALUE AND VISCOSITY OF MORTAR

Packing ratio

Outline of experiment

Using the powders in Fig.1, packing tests were carried out by tapping and the packing ratio was measured. Material was heaped in a cylindrical vessel and the vessel was dropped 500 times from same level by using a powder tester to provide a constant packing ratio.

Results and discussion

The contour line for packing ratio is shown in Fig 5. NV exerts a strong influence on packing ratio and packing ratio increases as NV decreases. The influence of BF is small, but it was confirmed that packing ratio increases slightly as BF decreases. This is in accordance with prior information that as the fineness distribution becomes wider and the particle size increases, the packing ratio increases (Powder Technology, 1986). Further, Fig 5 shows a trend similar to that shown for yield value (Fig 3). In general, packing ratio is an indicator of the volume of water required to fill the voids in the powder and shows that, as the packing ratio increases, the volume of excessive water increases. The results of this experiment show that there is a close relationship between yield value and volume of excessive water.

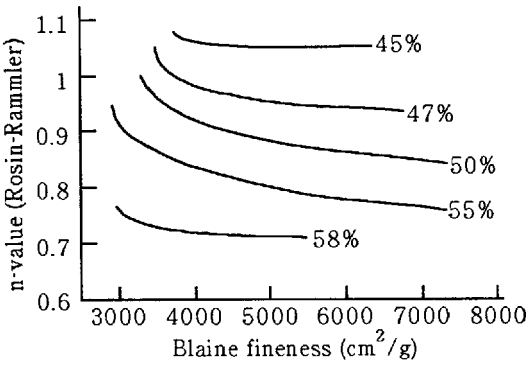

Fig 5 Relationship of contour line of packing ratio with Blaine fineness and n-value

Changes in grading due to early hydration

Outline of experiment

NPC having a constant BF of 4,720 cm^2/g and NV in the range of 0.70~0.94 was controlled at 4 levels; each was mixed to form a paste having W/C=40% and 2% addition of NS. Five minutes after water was poured, hydration was stopped by adding acetone and changes in fineness were measured.

Results and discussion

Table 2 shows the NV, BF and fine particles with particles of 1μ or smaller before pouring water and fine particles and NV five minutes after pouring of water. From these results, it can be seen that fine particles content increases as NV decreases before water is poured, but the ratio of fine particles decreases sharply when water is poured, resulting in a great increase in the NV. In particular, for powder with NV of 0.8 or less before pouring water, the relationship between large NV and small NV is reversed after pouring water. This is thought to be a result of the great amount of bridging by fine particles which occurs during hydration. This phenomenon, where the trend of the NV is reversed after pouring of water for NV of 0.8 or lower, is also assumed to be the cause of the reversal in yield value and viscosity of mortar.

Table 2 Powder grading distribution characteristics before and after pouring water

Grade	Before pouring water				After pouring water	
No.	Fine particles (%)	BF (cm^2/g)	NV	Packing ratio (%)	Fine particles (%)	NV
1	6.5	4,720	0.94	47.6	6.1	0.97
2	7.9	4,710	0.86	54.2	6.6	0.90
3	9.0	4,720	0.76	56.8	6.5	0.85
4	9.8	4,720	0.70	58.4	6.8	0.87

Excessive thickness of water film

In the studies by Yoshino et. al (1993), when the yield value and type of additive in the paste were the same, the viscosity of the paste formed a linear relationship with the thickness of the water film (Yoshino, 1993). Further, it is known from studies by Uchida, that the effects of cement fineness which influences fluidity of mortar do not change the effect of the trend or basic properties of the fluidity of the paste (Uchida, 1990). The excessive thickness of the water film on the mortar paste was calculated by the following equation and the relationship with grading was studied.

Excessive thickness of the water film $(\mu)=(1-Vc/Gc)/(Vc\cdot\rho\cdot F)\times 10{,}000$ [1]

Vc: volumetric ratio of powder in paste
Gc: tapping packing ratio
ρ: specific gravity of powder (g/cm^3)
F: Blaine fineness (cm^2/g)

Fig 6 shows the contour line of excessive water film thickness based on these calculations. From the figure, it can be seen that the thickness of the water film decreases as the NV or the BF increases. If Fig 6 is compared with Fig 4, it seems that the thickness of the water film affects the viscosity of mortar, but the trend is not completely the same. Therefore, in order to explain the trend of viscosity of mortar, it is necessary to consider other factors as well as the thickness of the water film.

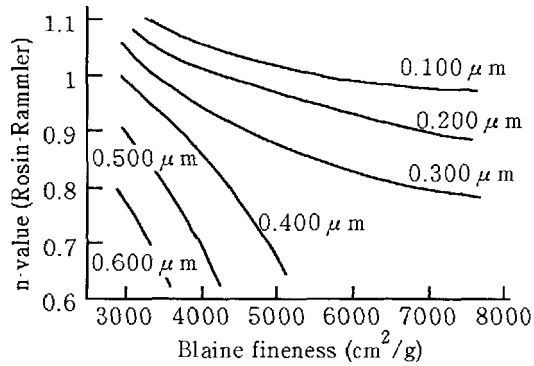

Fig 6 Relationship of contour line of excessive water film thickness with Blaine fineness and n-value

Absorption of superplasticizer

Outline of experiment

Moderate heat Portland cement (MPC: specific gravity=3.22; chemical composition as shown in Table 1) within the range of BF=3, 160~6,240 cm^2/g, NV=0.75~1.05 was graded into 11 finenesses and mixed with water and fine aggregate in the proportions 18.4 : 29.6 : 52.0% by volume; superplasticizer in the amount of 3.0% by weight of cement was added and the mortar mixed. Five minutes after pouring water, the liquid phase was extracted by suction filtering and diluted to 1/1,250 and 1/2,500; absorption of the superplasticizer was calculated by absorptimetry.

Results of experiment and observations

The contour line of superplasticizer absorption was drawn based on the results of measurement and is summarized in Fig 7. From these results, it was found that as the NV decreases and the BF increases, the amount of superplasticizer absorption increases. For the purpose of investigating the relationship between absorption and viscosity, superplasticizer absorption, and yield value and viscosity of mortar were measured for four points (No. 1~4) on the excessive water film thickness 0.200μ line in Fig 7; the results are shown in Fig 8. From this figure, it can be seen that, even when excessive water film thickness is constant, the increase in superplasticizer absorption causes an increase in viscosity. From this, it was learned that: 1) as BF increases, excessive water film thickness decrease is accompanied by increases in superplasticizer absorption and viscosity; and 2) as the NV decreases, excessive water film thickness increases but the increase in superplasticizer absorption offsets the effect on viscosity. These results are assumed to indicate the trend of viscosity as shown in Fig 4.

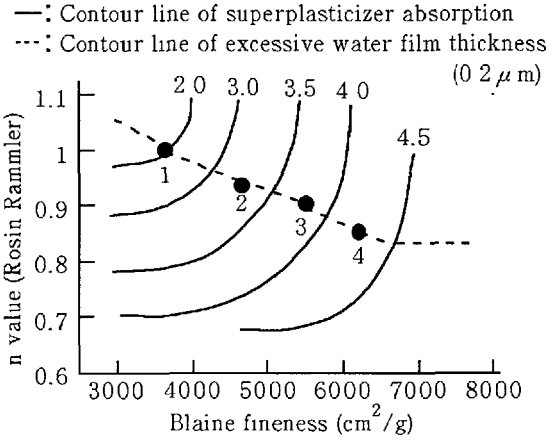

Fig 7 Relationship of contour line of superplasticizer absorption with Blaine fineness and n-value

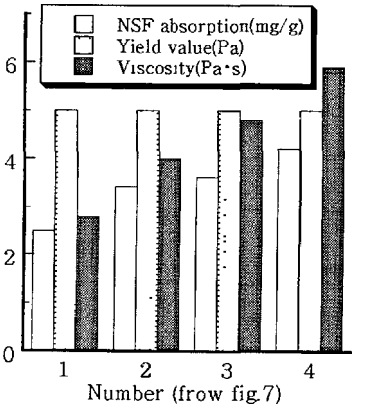

Fig 8 Relationship of superplasticizer (NSF)absorption with yield value and viscosity

CONCLUSION

In this study, the viscosity and yield value of the mortar component which have a great effect on the properties of high fluidity concrete and their relationship with the Blaine fineness and NV as calculated by the Rosin-Rammler equation were studied. As a result, the following three points were learned.

1) The influence of the NV of the powder which controls the volume of excessive water is the factor controlling yield value of mortar.
2) For NV 0.8 or lower, the yield value and viscosity increase as the NV decreases. This is the result of changes in fineness distribution due to early hydration.
3) In the Blaine fineness range of 4,000 cm^2/g or lower, viscosity is influenced in the same way as yield value; however, above that range the effect of Blaine fineness becomes a controlling factor and viscosity increases as Blaine fineness increases. This is thought to result from the complex effects of excessive water film thickness and amount of absorption of superplasticizer.

THE FLUIDITY OF CEMENT PASTE WITH VARIOUS TYPES OF INORGANIC POWDERS

Etsuo SAKAI, Seiichi HOSHINO*, Yoko OHBA and Masaki DAIMON
Department of Inorganic Materials, Tokyo Institute of Technology, Tokyo, Japan
*Central Research Laboratory, Nihon Cement Co., Ltd., Tokyo, Japan

ABSTRACT Lime-stone powder are under development in order to enable production of flowing concrete without need for vibration during their placement. Influence of various types of inorganic powders having the same particle size distribution of ordinary cement on the fluidity of cement paste with polycarboxylate type AE high range water reducing agent has been investigated. It is clear that the shape and the packing of powders are influencing the fluidity of cement paste with superplasticizer.

Key-words: Fluidity, Filler, Fineness, Powder, Superplasticizers

INTRODUCTION

In Japan, many investigators have been studied the properties of flowing concrete with various types of inorganic powders and polycarboxylate types of AE high range water reducing agents (Okamura and Ozawa,1994). And the flowing concrete with lime stone powder or granulated blast furnace slag were practically applied to National projects such as Honshu-Shikoku Bridges (Yasuda et al,1993) or ordinary concrete products. By using of inorganic powders, the fluidity and segregation of flowing concrete is improved and the dosage of AE high range water reducing agent is reduced compared with the case of same fluidity of concrete without inorganic powders. On the other hand, lime stone powder was very useful for the saving of energy and the production amounts of CO_2 gas for cement production and portland limestone cement was used in Europe (ECS,1992). Many investigators have been suggested that monocarbonate and hemicarbonate were produced by the reaction of C_3A and limestone powder (Grandet and Olliver,1980,Kuzel and Pollman,1991). The more detail studies of it's reaction mechanism and mechanisms of improvement for fluidity of cement with limestone powder are necessary. We have reported the reaction mechanisms of limestone powders and various types of calcium aluminate such as C_3A,amorphous $C_{12}A_7$ and $C_{11}A_7 \cdot CaF_2$ by quantitative measurements of anhydrates or hydrates (Hosokawa et al,1995, Nakamura et al,1996a).

In this report, we discuss the fluidity of cement with various type of inorganic powders such as lime stone powder, granulated blast furnace slag, fly ash and fused silica with various fineness including the particle size distribution similar to ordinary portland cement, from view points of their shape and packing properties. In addition, new (polycarboxylate) types of AE high range water reducing agent having polyethylene oxide graft chains are need for the development of flowing concrete. Therefore the dispersion mechanisms of these agents are introduced by the calculation of interparticle potential using measured the segment density and the thickness of adsorbed polymers (Sakai and Daimon,1996b).

POLYCARBOXYLATE TYPE AE HIGH RANGE WATER REDUCING AGENT

AE high range water reducing agent has a higher water reducing ratio, small change of slump with the passage time and less set retarding properties. It is now being used

extensively in flowing concrete. These are not the group such as naphthalene sulfonate formaldehyde high condensate or melamine resin sulfonate which have been used hitherto for the production of high strength and flowing concretes with a great slump loss, but the one named action mechanism generically as polycarboxylate group. Polycarboxylate group fundamentally comprise macromolecules having polyethylene oxide graft chains.

As for the factors related to the stabilization of the dispersive system by the macromolecule, it is thinkable that the steric hindrance due to the action of adsorbed macromolecule and the depletion stabilization due to the action of non-adsorbed macromolecule have important. This functions as repulsion. Using the interparticles potential curve obtained from the sum total of repulsion and van der Waals interaction, argument concerning the stabilization of disperse system is started.

$$V_{\text{interparticle potential}} = V_{\text{steric hindrance}} + V_{\text{depletion stabilization}} + V_{\text{van der waals interraction}}$$

We have been calculated interparticle potential of alite in alite-water system with macromolecule which are shown in Fig 1 and have degree of polyethylene oxide graft chain having the polymerization(n) from 7 to 90 (Sakai and Daimon,1996b). Steric hindrance effect was calculated by the thickness of actual adsorbed polymer and the segment density of adsorbed polymer, while depletion stabilization was calculated by the volume fraction of polymer. Calculation is made paying attention to only polyethylene oxide chain and the volume fraction was obtained by using of Rotational Isometric State-Monte Carlo Method. Magnitude of van der Waals interaction can be obtained by the use of Hamarker constant. According to Lifshitz theory, Hamarker constant of C_3S and C-S-H can be

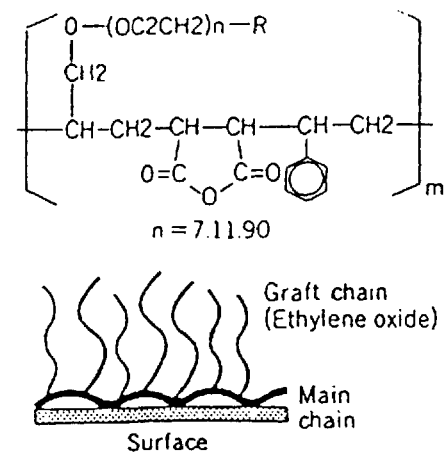

Figure 1 Molecular structure

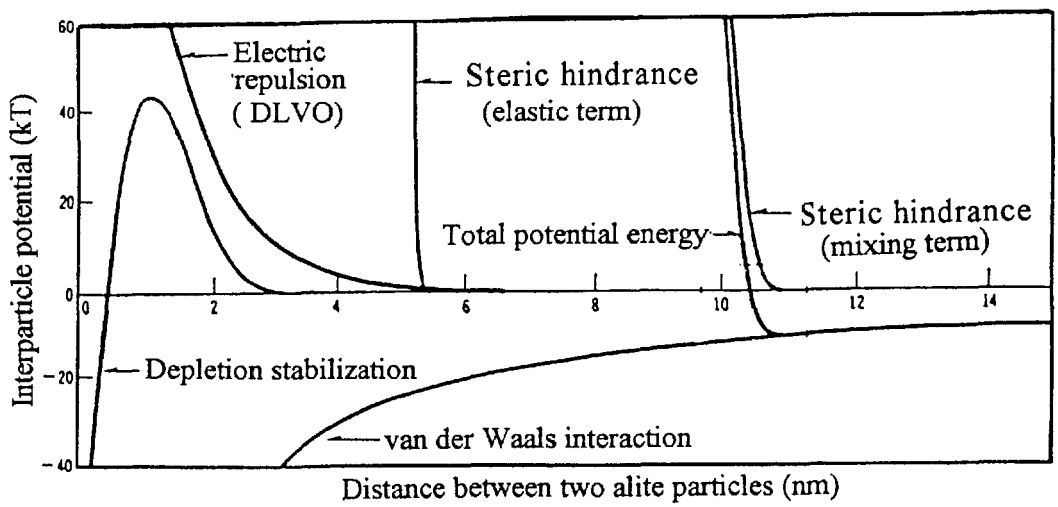

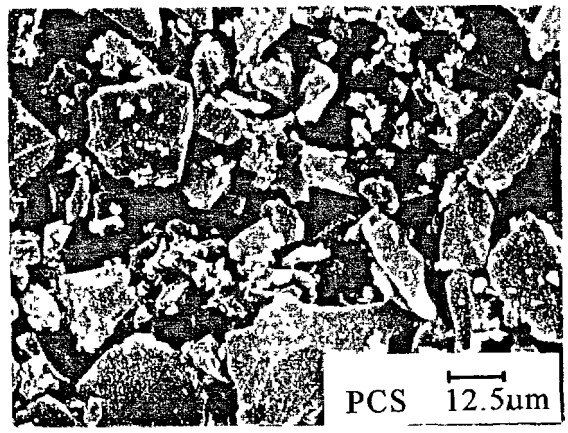

Figure 2 Interparticle potential of alite with AE high range water reducing agent

calculated. Fig 2 shows the inter-particle potential in the case of n=11 is adsorbed to alite particles with a radius of 1 μ m. In addition, electric repulsion effect calculated by DLVO theory was also shown. Van der Waals force exerts attraction from long distance and the mixing effect of steric hindrance effect puts out a strong repulsive power from some distance to prevent aggregation. On the other hand,depletion stabilization and the electric repulsion effect works just at short distance and does not exert a strong repulsive power. Therefore,an important factor to play a role for the dispersion of cement particles may be van der Waals force and steric hindrance effect of adsorbed AE high range water reducing agent having polyethylene oxide graft chains.

SHAPE EFFECT OF PARTICLES

Influence of shape of powders were investigated on the fluidity of cement paste. The fluidity of paste is indicated to $1/\eta$. The apparent viscosity(η) of paste was measured by rotating cylinder viscometer at 20℃. Prepared fused silica have about same particle size distribution of ordinary portland cement as shown in Fig 3. Particle size distribution of powders was measured by laser type of light scattering method. Various types of fused silica were separated by precision air separator Samples having the class range of below 7,7-12,12-20 and 22-33 μ m were respectively obtained. Prepared crushed fused silica (PCS) and prepared spherical fused silica (PSS) were produced by the combination of their samples. SEM photographs of these powders are shown in Fig 4. The spherical shape of PSS can be observed. SiO_2 contents of their fused silica are over 99.9% and their specific gravity are 2 22

The replacement ratio of these powders to cement were changed from 10 to 40%. Water to powder ratio was 0 9vol% and the dosage of polycarboxylate type of AE high range water reducing agent having polyethylene oxide graft chains was1 6% of powder by weight. If the dosage of this agent is added over this value,the fluidity of paste in not changed and indicated the constant fluidity. Fig 5 shows the fluidity of paste with PCS and PSS. The fluidity of paste is

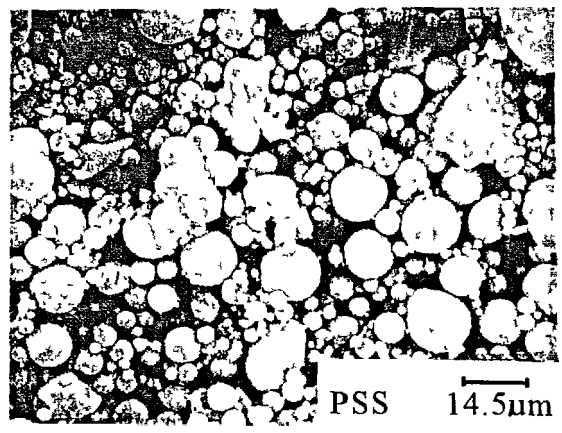

Figure 4 SEM photographs of PCS and PSS

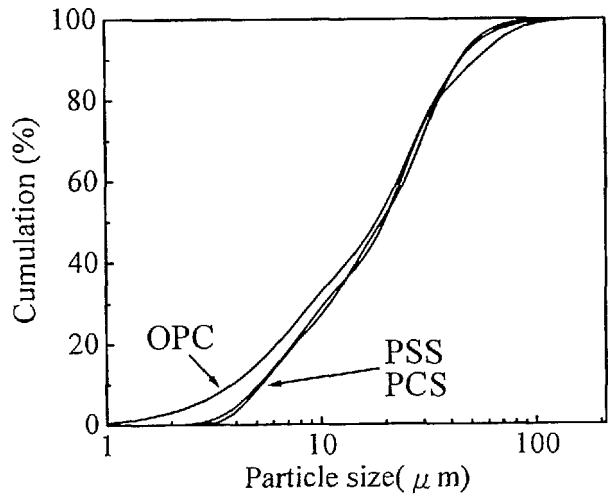

Figure 3 Particle size distribution.

increasing with the increasing of replacement ratio of prepared fused silica. And the fluidity of paste with PSS is larger than that of paste with PCS. Fig 6 shows the relation between to the fluidity of paste with fused silica and the replacement ratio of PSS to PCS. The replacement ratio of fused silica to cement is 40%. When the replacement ratio of spherical powders is increased, the fluidity of paste is improved. A plot of the fluidity of paste and the replacement ratio is found to be approximately linear. Particle size distributions of PSS and PCS are indicated the same results. Therefore, it is clear that the shape of powder is influenced on the fluidity of paste.

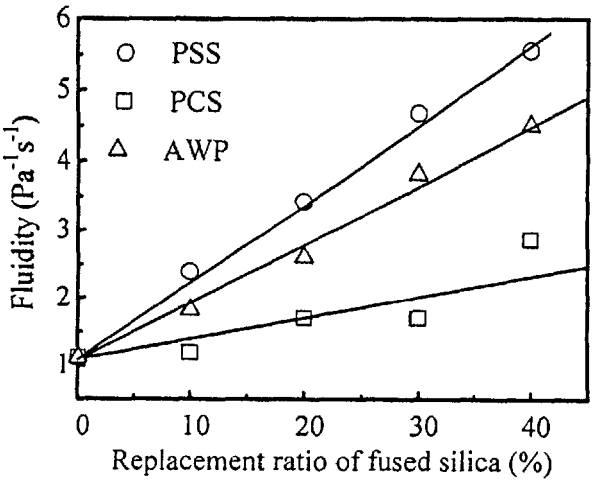

Figure 5 The fluidity of pastes with PSC or PSS

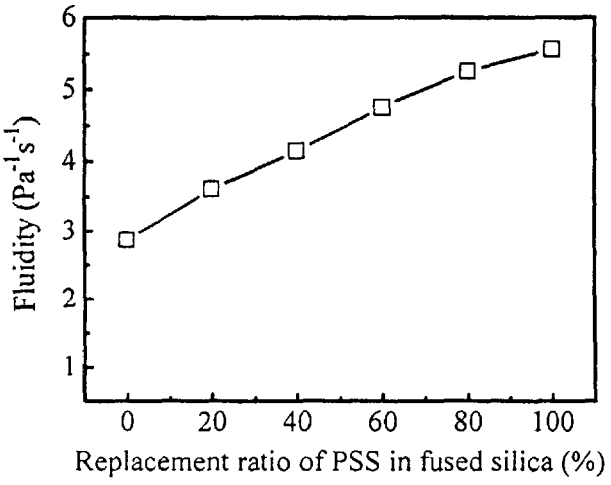

Figure 6 Influence of PSS contents on the fluidity of paste

Fig 7 shows the packing density of cement paste with PCS or PSS. Packing density was measured by next method. In pastes with PCS or PSS, powder cakes containing water and supernatant water were separated by centrifuge (6000rpm,10min). Ratio of powder to powder cake is the packing density of paste. The tendency of packing density is indicated the same results for the fluidity of pastes. The higher the packing density of paste,the higher the fluidity of paste. The packing density of paste is related to the amounts of retention water in cluster of powder. The difference in amounts between total water and retention water of paste (called free water) is effected on the fluidity of paste. The smaller the amounts of retention water, the higher the fluidity of paste. The amounts of retention water of paste with PSS is smaller than that of the paste with PCS. Fig 8 shows the flow model of pastes with PSS or PCS.

By the addition of water, the amounts of free water of paste with PCS are prepared the same values of the case of paste with PSS. The fluidity of these pastes (AWP) is increased as shown in Fig 5. But the fluidity of paste with PSS is smaller than that of AWP paste. The difference in fluidity between the AWP paste and the

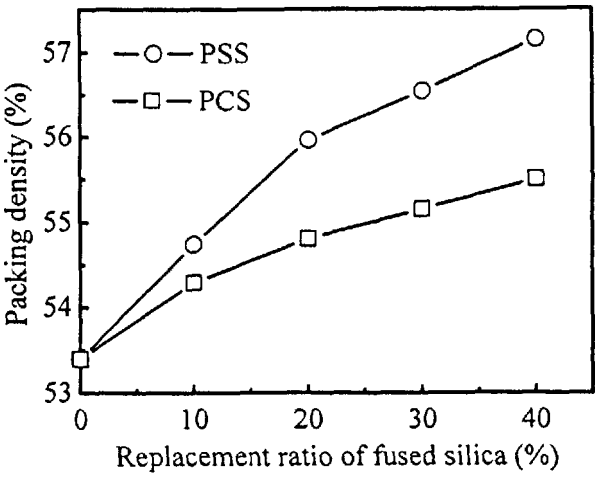

Figure 7 Packing density of paste with PCS or PSS.

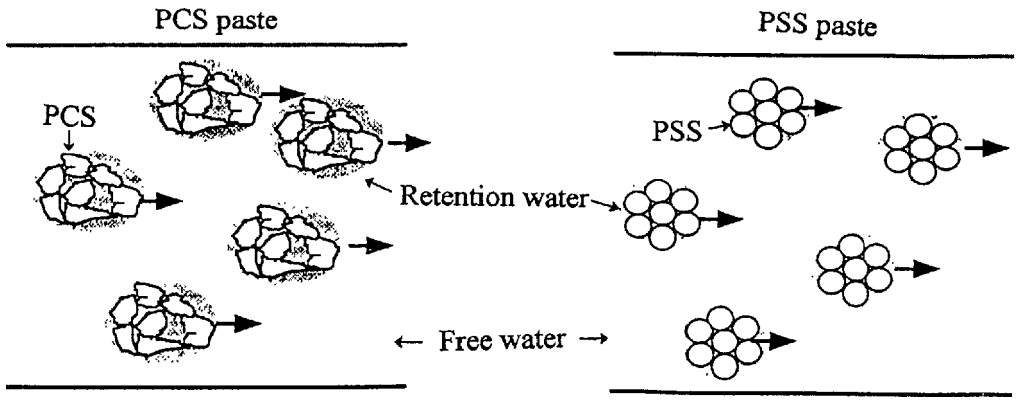

Figure 8 Schematic illustrations of flow model of PCS and PSS pastes

paste with PCS is related to the effect of packing effect. And the difference of the fluidity of paste with PSS and AWP paste may be contributed to ball bearing effect. Therefore, the shape effect of inorganic powders on the fluidity of paste consists of the packing effect and the ball bearing effect of powders.

INFLUENCE OF VARIOUS TYPES OF INORGANIC POWDERS

Table 1 shows the chemical compositions of various types of inorganic powders. Prepared inorganic powders having the particle size distribution similar to ordinary cement are made by air separation and mixing as mentioned above. Experiments carried on used prepared granulated blast furnace slag (PBFS), prepared limestone (PLS), prepared fly ash (PFA), PCS and PSS. When prepared powders are used, the effect of particle size distribution of powders on the fluidity of paste can be neglected.

Table 1 Chemical composition of inorganic powders

Samples	Ig.loss	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O	Total C
PBSF	0.2	34.5	14.0	0.5	41.0	6.8	0.22	0.29	-
PLS	43.2	0.7	0.2	0.1	55.2	0.4	0	0	-
PFA	1.1	63.4	17.4	4.8	4.3	1.5	0.71	0.8	0.54

Table 2 shows the packing bulk density and the sphericity factor (packing bulk density/specific gravity) of inorganic powders and the fluidity of cement paste with prepared inorganic powders. In measurement of fluidity of paste, the replacement ratio of prepared inorganic powders is 40% and the water to powder ratio is 0.9vol%. The dosage of AE high range water reducing agent is 1.6%. By using of powders having higher sphericity factor, the fluidity of paste can be improved. Sphericity factor of PSS is higher than that of PCS. Sphericity factor of particles is related to shape of particles as shown in Fig 4. The higher the sphericity factor of powders, the higher the contents of spherical particles. Sphericity factor of PFA is smaller than that of PLS or PCS. This is contributed to the contents of carbon. It was reported that the contents of carbon having a irregular shape in PFA is determined the fluidity of cement paste with PFA (Lee et al,1996c). Sphericity factor of powders is one of the main factor in order to improve the fluidity of cement paste with inorganic powders.

Table2 The fluidity of cement paste with various types of inorganic powders and their shape factor(Sphericity factor = Packing bulk density/Specific gravity)

Samples	Specific gravity	Packing bulk density	Sphericity factor	Fluidity($Pa^{-1}s^{-1}$)

OPC: Ordinary portland cement

INFLUENCE OF PARTICLE SIZE DISTRIBUTION

Fig 9 shows the particle size distributions of classified limestone (LS) powders. Classified limestone powders were prepared by hydraulic elutriation of limestone powder (Blaine's specific surface area:440m^2/kg, Specific gravity;2.71). Relation between to the fluidity of cement pastes with classified limestone powders and their average particle size are shown in Fig 10. The replacement ratio of classified limestone to cement is 20% by weight. Water to powder (cement+classified limestone powder) ratio is 0.9vol% and the dosage of polycarboxylate AE high range water reducing agent is 1.6% by weight of powders. The average particle size of ordinary portland cement is18 μ m. The fluidity of cement paste with samples B,C and D having average particle size similar to ordinary cement are lower than that of cement paste with coarse or fine classified limestone powders (samples A and E).

Fig 11 shows the packing density of paste with classified limestone powders. These

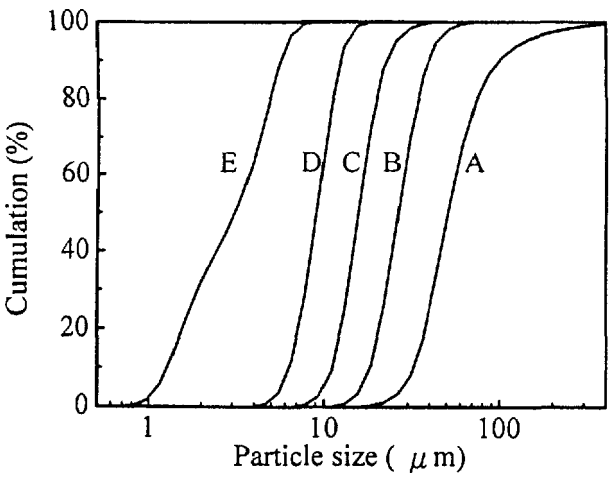

Figure 9 Particle size distribution of classified LS.

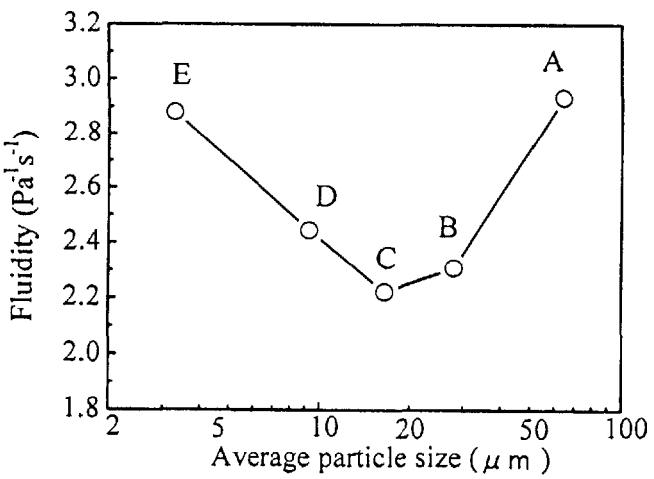

Figure 10 The fluidity of cement pastes with classified LS.

values are measured by above-mentioned method. The packing density of pastes with coarse or fine classified limestone powder (samples A or B) is larger than that of the others. Packing density of paste is related to the amounts of retention water or free water as shown in Fig 8. The higher the packing density of paste, the larger the amounts of free water. By using A or B, the amounts of retention water is reduced and the amounts of

free water is increased. Therefore, the fluidity of cement paste with A or E is superior to the others.

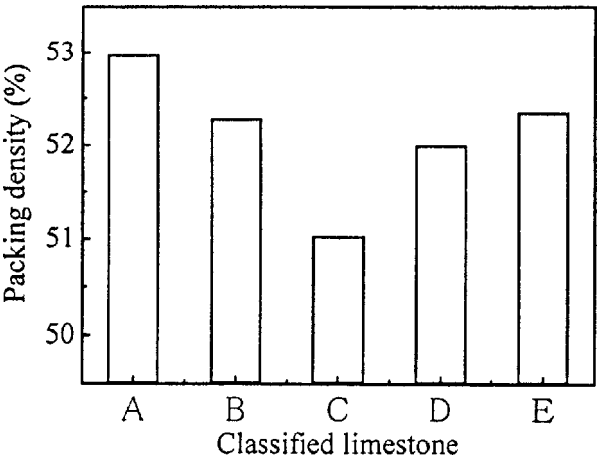

Figure 11 Packing density of pastes with classified LS.

Fig 12 shows the fluidity of cement paste with the mixtures of two kinds of classified limestone powders compared with the case of ordinary portland cement with or without prepared limestone powder. Replacement ratio of mixtures to cement is 20%. Symbol AB and BA mean the blended ratio of A and B are respectively 2:1 and 1:2. By using of the mixtures, the fluidity of paste is improvement compared to the case of using of prepared limestone powder. The fluidity of cement paste with sample AE (mixture of coarse and fine samples) is largest than that of the others. These phenomena may be caused on the amounts of free water in pastes. Generally, the packing density of powders is increased by mixing of two kinds of particles having the different particle size (Dallavalle,1948). The higher the packing density of powders, the larger the amounts of free water in paste. The packing density of the mixture of cement and limestone is determined by their particle size distribution. In order to development of suitable particle size distribution of powders for flowing cement concrete, more detail investigations are necessary.

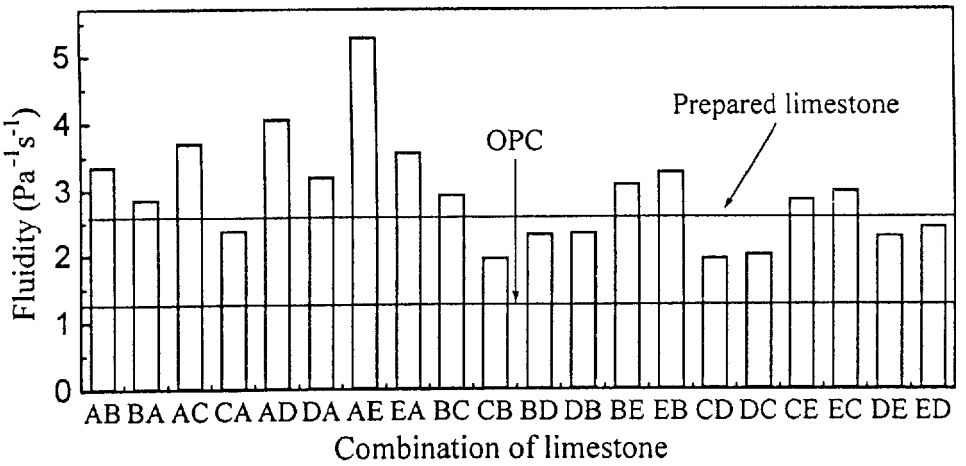

Figure 12 Influence of the mixtures of classified LS on the fluidity of pastes.

CONCLUSION

In order to clarify the mechanisms of inorganic powder for the fluidity of flowing cement concrete, we investigated the fluidity of cement pastes with polycarboxylate type of AE high range water reducing agent and classified or prepared powders. In addition,the dispersion mechanisms of polycarboxylate type AE high range water reducing agent based on the calculation of interparticle potential were introduced. An important factor to play a role for the dispersion cement particles may be van der Waals force of particles and steric hindrance effect of these agents. The shape and particle size distribution of inorganic powders are influenced on the fluidity of cement with these powders. The

larger the sphericity factor of inorganic powders, the higher the fluidity of cement paste with these powders. And the fluidity of cement paste with fine or coarse or these mixtures larger than that of cement paste with the others. These were related to the packing density of cement paste with inorganic powders. The higher the packing density of paste, the higher the fluidity of paste. The shape effect of inorganic powders on the fluidity of paste consists of the packing effect and ball bearing effect of powders.

ACKNOWLEDGEMENTS

The authors would like to thank Mr.S.Takahashi and Mr.T.Nagata of Japan Cement Association, for their help during the air separation of inorganic powders.

A STUDY ON THE METHOD OF ESTIMATING RHEOLOGICAL CONSTANTS OF CEMENT PASTE CONTAINING CHEMICAL ADMIXTURES

Hiroji KIKUKAWA, Dept. of Civil Engineering, Meijo University, Japan
Takeo IISAKA, Dept. of Civil Engineering, Meijo University, Japan
Yasuaki ISHIKAWA, Dept. of Civil Engineering, Meijo University, Japan

ABSTRACT Research into viscous behavior of cement pastes containing chemical admixtures led to a viscosity equation of cement pastes. The authors propose a method of estimating their plastic viscosity using this equation. Estimation of yield values was also made possible by determining the relationship between the plastic viscosity and the yield value.

Key-words: Additives, Rheology, Viscosity

INTRODUCTION

Qualities of cement paste, which forms the matrix of mortar, directly affect qualities of concrete. After a series of investigations on the rheology of mortar and concrete, the authors began the present study by exploring a method of estimating the rheological constants of cement paste. A number of reports have been published on the methods of estimating the plastic viscosity and yield value of cement paste containing no chemical admixtures (Petrie, 1976, Kakuta and Akashi, 1978, and Murata and Kikukawa, 1985). However, the use of chemical admixtures, such as an air-entraining agent and water-reducing agent has become general practice in recent years. With the aim of eventually proposing a viscosity equation for concrete containing chemical admixtures, the authors conducted basic research to derive a viscosity equation mainly from the viscous behavior of cement paste containing chemical admixtures. This paper proposes a method of estimating the plastic viscosity of such cement pastes. Simultaneously, the estimation of the yield value of cement paste was also made possible by experimentally determining the relationship between the plastic viscosity and the yield value. Attempts were also made to formulate a method of estimating rheological constants whereby the changes in temperature and elapsed time are incorporated, as rheological constants depend on these factors.

MATERIALS AND MIX PROPORTIONS

Ordinary, high-early-strength, ultrahigh-early-strength, and moderate heat portland cements were used for the experiments. Their physical properties are given in Table 1.

Table 1 Physical properties of portland cements

	O P	H P	U H P	M P
Specific gravity	3.15	3.14	3.11	3.20
Specific surface area (cm^2/g)	3240	4450	6290	3000

Note) OP : Ordinary portland cement.
HP : High early strength portland cement.
UHP : Ultra high early strength portland cement.
MP : Moderate heat portland cement.

The chemical admixtures used are a proprietary water-reducing agent and superplasticizer, whose main components are polyol complexes and highly condensed triazine compounds, respectively. They contain no chlorides and are not air-entraining. Their dosage is expressed in solid equivalents to be consistent with other admixtures. The water-cement ratio ranges from 40 to 80% with a regular increment of 5 percentage points. The dosage of the water-reducing agent and superplasticizer ranged from 0.01% to 0.12% in terms of solid percentage by mass of cement.

EXPERIMENTS

Cement pastes were mixed using a Hobart type mortar mixer as follows: Add all ingredients in the mixer and mix for 1 min at a low speed of 157 rpm. Rest for 30 sec, during which time scrape off any material adhering to the paddle and wall of the mixing bowl. Mix finally for 2 min at a high speed of 396 rpm. The mixtures were tested immediately after mixing. The temperature of the freshly mixed samples was adjusted to 10, 20, and 30°C. Subsequent tests were conducted at 30 min intervals up to 150 min following the initial test. At each test time, the J funnel efflux time, flow spread, and rheological constants were determined. An inner cylinder rotating type viscometer was used for measuring the rheological constants.

VISCOSITY EQUATION

Plain cement paste

Roscoe's viscosity equation (1952), which is an application of Einstein's viscosity equation to high concentration suspensions, was used as the basis, on the assumption that cement paste is a suspension in which cement particles are suspended in water:

$$\eta_{re} = \left(1 - \frac{1}{C} \bullet V\right)^{-K} \tag{1}$$

where

η_{re} = relative viscosity
C = coefficient for percentage of absolute volume of solute
K = shape factor for agglomerates of solute
V = volume concentration of solute

Roscoe's equation assumes that solute particles behave collectively, and therefore is applicable to a suspension with a significantly high concentration. However, it assumes that suspended particles are uniform and spherical, and therefore is not applicable to particles with complicated shapes. For this reason, the authors arranged the experiment results with respect to the shape factor, K, of the agglomerates, and found that K can be expressed as a linear function of the specific surface area of cement by Blaine. Accordingly, the viscosity equation incorporating the specific surface area of cement particles is written as:

$$\eta_{re} = \left(1 - \frac{1}{C} \bullet V\right)^{-(K_1\phi + K_2)} \tag{2}$$

where

ϕ = specific surface area of cement by Blaine (cm^2/g)
K_1 = -15.6 (experimental constant)
K_2 = 11.2 (experimental constant)

The plastic viscosity of plain portland cement paste can be estimated from Eq. (2) by assuming that the viscosity of the suspending medium (viscosity of water) η_0 is 1×10^{-3} Pa·s (20°C). It is known that the plastic viscosity of cement paste with different temperatures immediately after mixing can be calculated by the following equation (Kikukawa, 1987):

$$\Delta\eta_{t1} = a_1(W/C)^2 + b_1(W/C) + c_1 \tag{3}$$

where

$\Delta\eta_{t1}$ = change in plastic viscosity (Pa·s/°C) per degree C of temperature change
W/C = water-cement ratio
a_1, b_1, and c_1 = 1.50, -1.84, and 0.576, respectively (experimental constants)

The following is the method of correcting plastic viscosity values for a different temperature of cement paste:

(1) Determine the plastic viscosity of cement paste at 20°C using Eq. (2).
(2) Determine the changes in the plastic viscosity per degree C of cement temperature using Eq. (3) for each water-cement ratio, and calculate the plastic viscosity of cement paste at a desired temperature.

The following has been found regarding the effect of elapsed time after mixing:

There is a time span in which the plastic viscosity increases linearly from immediately after mixing. Such a time span length depends on the temperature of freshly mixed paste: about 120, 90, and 60 min when the temperature is 10-15°C, 20-25°C, and 30°C, respectively, in a cement paste with a water-cement ratio of 0.40 to 0.60. The increment of plastic viscosity per unit time is approximated by a quadratic curve of paste temperature.

$$\Delta\eta_{ct1} = \alpha_1 t^2 + \beta_1 t + \gamma_1 \tag{4}$$

where

$\Delta\eta_{ct1}$ = increment in plastic viscosity of cement paste per unit time after mixing (Pa·s/h)
t = paste temperature (°C)
α_1, β_1, γ_1 = experimental constants as given in Table 2

Table 2 Coefficients in eq 4

W / C	0.40	0.45	0.50	0.55	0.60
α_1	0.0016	0.00033	0.00017	0.00017	0.00012
β_1	-0.029	-0.0019	-0.0015	-0.0031	-0.0033
γ_1	0.340	0.139	0.099	0.066	0.050

The ratios of the values thus estimated to measured values have been proven to approach the expected value, 1 (Kikukawa, 1987).

Cement paste containing chemical admixtures

The viscosity equation of cement paste containing chemical admixtures is also assumed to be basically similar to Roscoe's equation. Test results were arranged with respect to the shape factor of agglomerates, K, as shown in Fig. 1. As seen from the figure, K is expressed as linear functions of the fineness modulus (specific surface area by Blaine) of cement: $K = K_3\phi + K_4$. Also, K_4 varies depending on the water-cement ratio (W/C) and is expressed as an exponential function of the volume concentration of cement paste as shown in Fig. 2: $K_4 = K_5 V^b$. The authors attempted the formulation by assuming that the effect of the addition of water-reducing agents on the viscosity loss of cement paste is equivalent to the effect of reducing the water-cement ratio (W/C). In this case, the shape factor and absolute volume percentage of agglomerates are the same as the case with no water-reducing agents. As a result of the experiment, the relationship between the coefficient for the dosage of the water-reducing agents, A, and the dosage of the water-reducing agents, P (solid percentage by mass of cement) is as shown in Fig. 3 and expressed as $A = \xi P^n$. Consequently, the following can be presented as the viscosity equation for cement paste containing water-reducing agents:

$$\eta_{re} = \left[1 - \frac{1}{C} \cdot V\left(1 - \xi P^n\right)\right]^{-\left(K_3\phi + K_5 V^b\right)} \tag{5}$$

where
P = dosage of water-reducing agents (solid percentage by mass of cement)
ξ = 0.152 (experimental constant)
n = 0.680 (experimental constant)
$K_3 = 3.107 \times 10^{-5}$ (experimental constant)
K_5 = 1.422 (experimental constant)
b = -1.345 (experimental constant)

The ratios of plastic viscosity values of cement paste estimated using Eq. (5) to measured values approach the expected value, 1, as given in Table 3. The plastic viscosity of cement paste containing water-reducing agents can therefore be estimated satisfactorily using Eq. (5).

The correction equation of the plastic viscosity for a different temperature of cement paste was obtained as follows:

The plastic viscosity and yield value of cement pastes made with one brand of ordinary portland cement (see Table 1) were measured using a rotational viscometer. The water-cement ratios of the cement pastes were 0.45, 0.50, 0.55, and 0.60 and the temperatures of freshly mixed pastes were 10, 20, and 30°C. The measurements are shown in Fig. 4. The figure reveals that, even when water-reducing agents are contained, the plastic viscosity of cement paste increases as the paste temperature rises, suggesting that the viscosity increase due to solvation with the suspending medium surpasses the viscosity loss of the suspending medium due to temperature rise. A linear relationship is observed between the temperature and the plastic viscosity of pastes in the paste temperature range of 10 to 30°C. The average increments in plastic viscosity per degree C rise in the temperature of cement pastes were 0.085, 0.021, 0.014, and 0.0099 Pa·s for water-cement ratios of 0.45, 0.50, 0.55, and 0.60, respectively.

The relationship between the water-cement ratio and the plastic viscosity increment is approximated by an exponential curve as shown in Fig. 5. The same tendency was observed with dif-

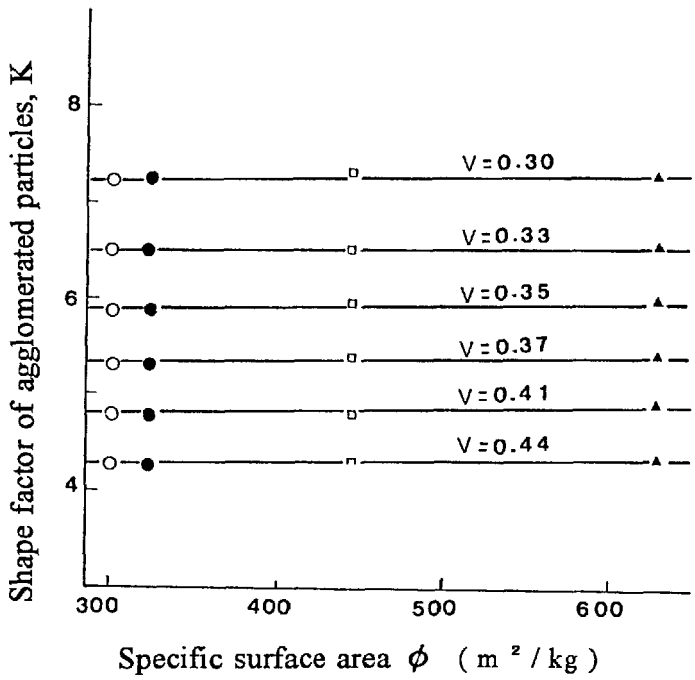

Figure 1 Relationship between shape factor of agglomerated particles in cement paste and specific surface area of cement

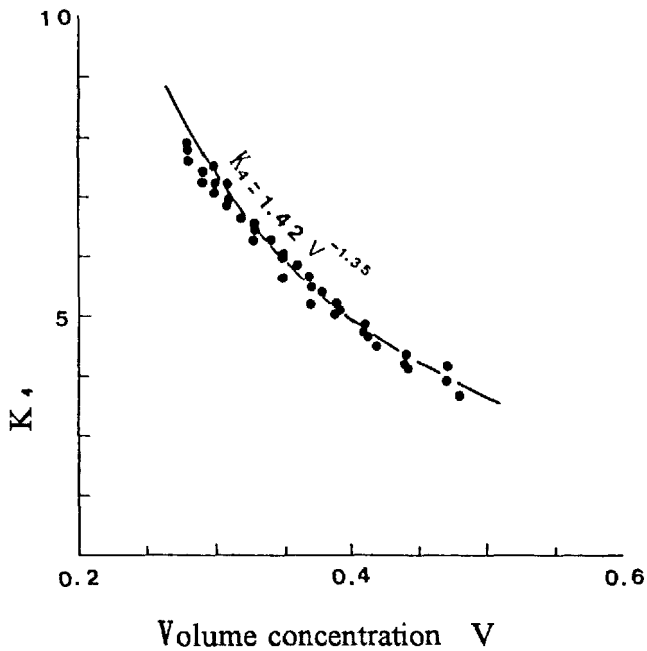

Figure 2 Relationship between experimental constant K_4 and volume concentration of cement

ferent dosages of admixtures. Accordingly, the relationship between the water-cement ratio and the plastic viscosity increment is expressed as:

$$\Delta\eta_{t2} = a_2 \cdot W/C^{b_2} \qquad (6)$$

where

$\Delta\eta_{t2}$ = change in plastic viscosity per degree of temperature change of cement paste containing water-reducing agents (Pa·s/°C)
W/C = water-cement ratio
a_2 = 0.0002 (experimental constant)
b_2 = -7.245 (experimental constant)

The effects of elapsed time after mixing on the plastic viscosity of cement pastes containing admixtures were incorporated as follows:

The increments in the plastic viscosity of cement pastes made of one brand of cement paste (see Table 1) were measured at 30, 60, 90, 120, and 150 min after mixing. The water-cement ratios of the pastes were 0.45, 0.50, 0.55, and 0.60, and their temperatures immediately after mixing were 10, 20, and 30°C. The measured increments are shown in Fig. 6.

The increment in plastic viscosity with time increased as the water-cement ratio decreased and as the paste temperature increased. The increment in plastic viscosity per unit time is expressed as a linear function of the paste temperature as follows:

$$\Delta\eta_{ct2} = a_3 t + b_3 \qquad (7)$$

where

$\Delta\eta_{ct2}$ = increment in plastic viscosity of cement paste containing water-reducing agents per unit time (Pa·s/h)
t = temperature of sample (°C)
$a_3 = \alpha_2 (W/C)^2 + \beta_2 (W/C) + \gamma_2$ (experimental constant)
$b_3 = a_4 (W/C) + b_4$ (experimental constant)
W/C = water-cement ratio
α_2 = 0.400, β_2 = 0.508
γ_2 = -0.162, a_4 = -0.942, b_4 = 0.608

0.70	983	0.31	0.028	0.35	0.35	1.00
			0.045	0.33	0.33	1.00
			0.090	0.30	0.31	0.97

Note) * : Solid percentage by weight of cement.

Table 4 Ratios of calculated plastic viscosity values to measured values of cement paste containing a water reducer incorporating changes in time and temperature

Time elapsed (min.)	Temperature of cement paste (°C)						A／B		
	20		25		30				
	Calculated value A	Measured value B	Calculated value A	Measured value B	Calculated value A	Measured value B	20°C	25°C	30°C
30	0.500	0.532	0.593	0.578	0.686	0.707	0.94	1.03	0.97
60	0.564	0.582	0.664	0.678	0.765	0.768	0.97	0.98	1.00
90	0.628	0.638	0.736	0.743	0.844	0.838	0.98	0.99	1.01
120	0.692	0.738	0.807	0.825	0.923	0.855	0.94	0.98	1.08
150	0.756	0.828	0.879	0.861	1.001	1.028	0.91	1.02	0.97

Note 1) Ordinary portland cement is used.

2) Water cement ratio is 0.55.

3) Water reducer content is 880 (g/m^3).

The ratios of the plastic viscosity values of cement paste estimated as mentioned above to the measured values nearly approached the expected value of 1 as given in Table 4.

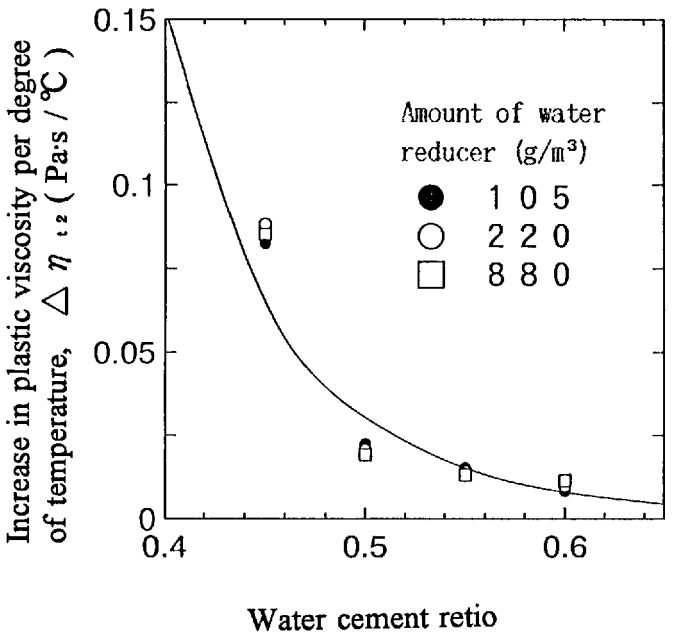

Figure 5 Increase in plastic viscosity versus W/C

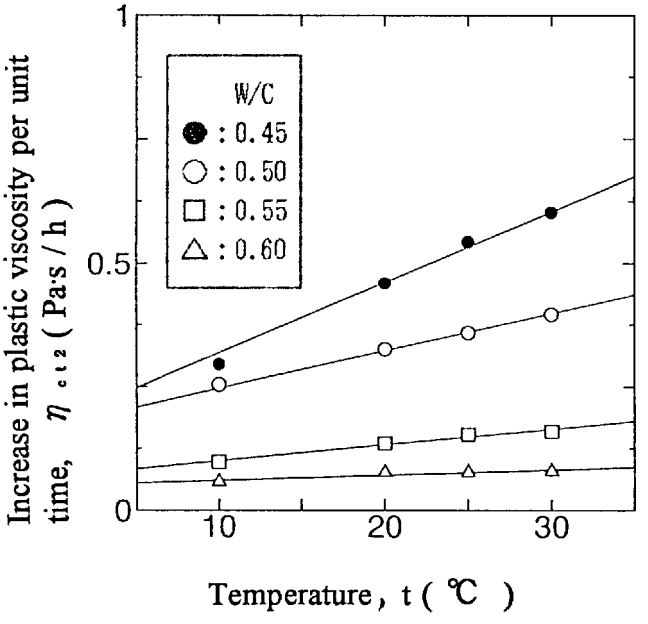

Figure 6 Increase in plastic viscosity per unit length of time after mixing of portland cement paste

RELATIONSHIP BETWEEN YIELD VALUE AND PLASTIC VISCOSITY

Where high concentration suspension is concerned, as the concentration of the suspended material increases, the plastic viscosity increases and the yield value is considered to increase due to reduced distances between suspended particles. When no chemical admixture is contained, the plastic viscosity is linearly proportional to the yield value. It has been confirmed that the yield value can be estimated using this relationship (Murata and Kikukawa, 1985).

The use of admixtures is found to bring about subtle changes in the plastic viscosity and yield value, leading to an exponential relationship between them as shown in Fig. 7.

$$\tau_f = n_1 \eta_{Pl}^{\ n_2} \qquad (8)$$

where
n_1 = 13.16 (experimental constant)
n_2 = 2.17 (experimental constant)

The ratios of the yield values estimated by Eq. (8) to the measured values are nearly the expected value, 1. When the cement paste contains water-reducing agents, its yield value can be estimated by Eq. (8).

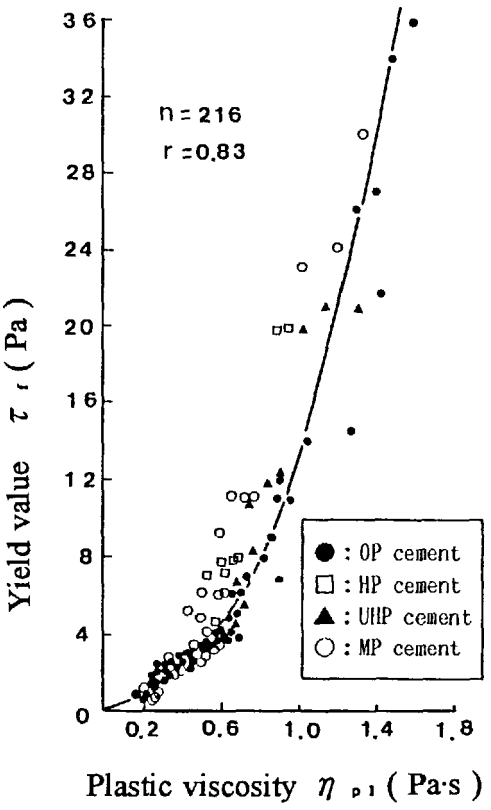

Figure 7 Relationship between yield value and plastic viscosity of cement paste

CONCLUSION

The rheological constants of cement pastes containing various water-reducing agents at different times and temperatures can be satisfactorily estimated by using a viscosity equation and temperature correction equation.

RHEOLOGICAL AND HYDRATION PROPERTIES OF A HIGH STRENGTH GYPSUM-FREE CEMENT

Ludmilla OPOCZKY, Cement Research & Development Ltd. Budapest, Hungary
Adriano PAPO, The University, Inst. of Chemistry, Udine, Italy

ABSTRACT
The very high strength, good workability, increased frost resistance etc. of gypsum-free cement are assured by the homogeneous and compact microstructure of the cement as well as by the presence of calcium-silicate hydrates (C-S-H-phase) of higher polycondensation degree. Flow curves of such cement pastes are of pseudoplastic type, and the shear-dependent behaviour pastes can be described by the Bingham-model.

Key-words: rheology, hydration, lignosulphonates, superplasticizers, modified cement.

INTRODUCTION
In the course of research work the production technology of gypsum-free high strength cement (in the following MNC) was developed and its pilot plant production was realized. The basis of MNC is an ultrafine clinker of suitable mineral composition and of uniform particle size distribution, to which the mixture (in the following LSN) of Ca-lignosulfonate (in the following LS) and Na-carbonate (in the following N) is added in 1-1.5 $^{m}/_{m}$ % quantity in order to control the binding and hardening. The MNC-cement is workable even at low w/c (0.2-0.35), and it is characterized by rapid increase of strength and high final strength (70-80 MPa). The research aimed at the investigation of the rheological and hydration features of MNC pastes as well as that of the microstructure of the hardened pastes.

RHEOLOGICAL INVESTIGATIONS
Rheological measurements were carried out with a ROTOVISKO RV 20 type coaxial cylindrical rotation viscosimeter. As starting material a clinker milling product made from plant clinker (C_3S = 63.6 %, C_2S = 12.9 %, C_3A = 8.6 %, C_4AF = 10.5 %), ground in laboratory ball mill was used, of which the specific surface was ~ 550 m^2/kg. LSN additive was added to the clinker milling product in different quantities (1.1-1.8 $^{m}/_{m}$ %). Comparative analyses were also made with a clinker milling product containing 6 $^{m}/_{m}$ % gypsum. Pastes were produced from the cements, changing the water-cement factor between 0.36 and 0.42 in case of MNC and between 0.38 and 0.54 in case gypsum-containing cement. Measurements were performed under constant shearing velocity ($\dot{\gamma}$) as well as under the gradual decrease and increase of the shearing velocity and the hysteresis curves were determined (PAPO et al. 1994). In the following some important results will be presented.

Shear-dependent behaviour of MNC cement pastes
In the course of measurement, subsequently to mixing, the cement paste was studied under constant shearing velocity. The initial shearing stress (τ_i) belonging to each shearing velocity was determined that corresponds to the structural state just after mixing, and the minimal shearing stress (τ_e) corresponding to the shearing record and function of time was also determined. In this way information was gained on the time dependence of the shearing process and on the initial section of hardening process of the cement.

The final as well as the starting and equilibrium flow curves can be determined for each shearing velocity. The area between the two curves is characteristic of the thixotropy. The shearing stress (τ_i) and shearing velocity (τ_e) data determined experimentally were inscribed into rheological models of different $\tau = f(\dot{\gamma})$ type (Bingham, Casson, Wiliamson, Herschel-Bulkley etc.). In case of all models most suitable parameters can be produced by minimization of variance of the experimental and calculated values.

The equilibrium flow curves of MNC pastes prepared with different w/c factors (besides adding 1.1 $^{m}/_{m}$ % LSN), and of the MNC pastes of different LSN content under a given w/c = 0.38 are shown in Figs. 1 and 2, while the flow curves of the clinker + gypsum mixture are seen in Fig.3.

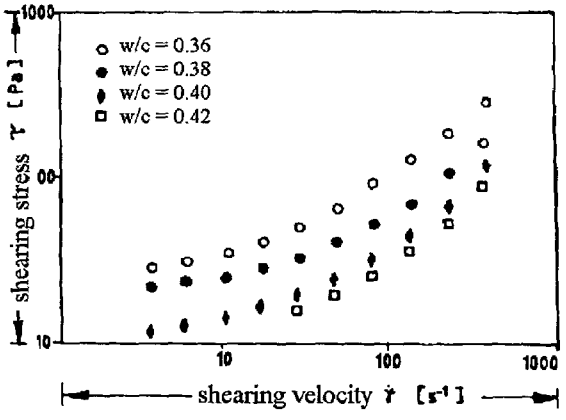

Fig. 1.
. Flow curves of MNC pastes at different w/c factors (LSN = 1.1 $^{m}/_{m}$ %)

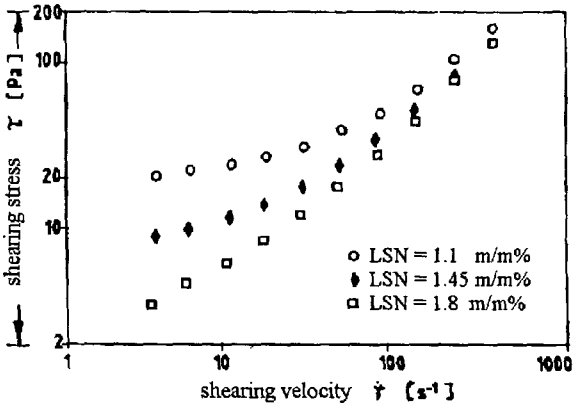

Fig. 2.
Flow curves of MNC pastes under constant w/c factor and under addition of of different LSN

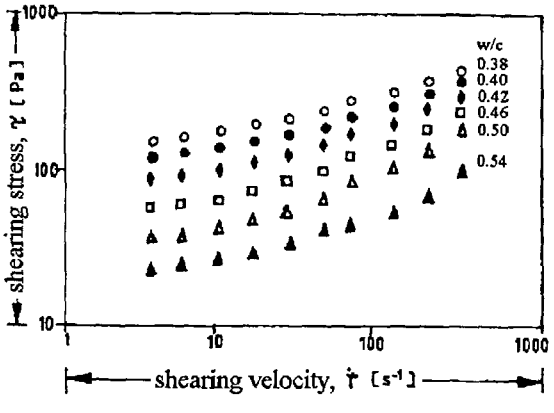

Fig. 3.
Flow curves of pastes made of the mixture of clinker milling product + 6 $^{m}/_{m}$ % gypsum under different w/c factors

All the flow curves are of pseudoplastic type and all substances studied possess flow limit, respectively. The shear-dependent behaviour of MNC pastes can be described by the Bingham model (Fig.4), that of the gypsum-bearing cement pastes by the Casson and Herschel-Bulkley models (Fig.5). Cement pastes with gypsum content are of higher viscosity and flow limit than the MNC pastes.

Relationship between the Herschel-Bulkley flow limit and Casson-parameter and the w/c factor in case of pastes made of clinker milling product and gypsum.
x: Herschel-Bulkley flow limit; o: Casson flow limit; * : Casson viscosity (η_∞).

When MNC pastes are exposed to shearing, their structure undergoes a decomposition process: the shearing stress - time relationships displays a shearing stress peak (τ_P) that can be related to the reconstruction of the structure immediately after mixing. Shearing reduces this value to a minimum (τ_e), that can be related primarily to the thixotropic decomposition, then the shearing stress begins gradually to grow as a function of time, when the structure begins to develop (Fig.6).

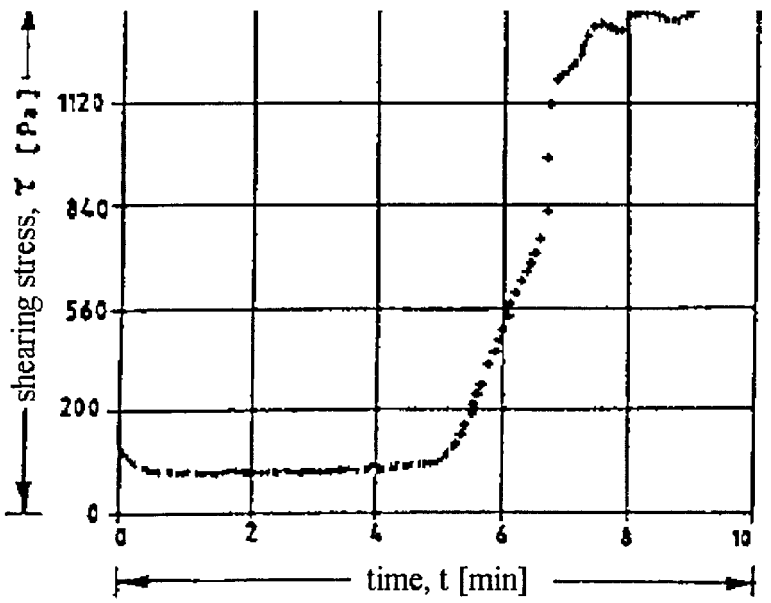

Fig. 6.
Shearing stress - time relationship of the MNC paste
(w/c = 0.38; LSN = 1.1 $^{m}/_{m}$ %;
$\dot{\gamma}$ = 234 s^{-1}).

Let us study in detail the growing section of shearing stress. The temporal growth of shearing stress proceeds in three steps: the initial development proceeds with reduced velocity, then a transitional section follows and finally the ultimate development takes place with increasing velocity. This behaviour is illustrated in Fig.7. where ln (τ - τ_e) is plotted as a function of ln t. The transitional section lies usually within the induction or lower period of the hydration process of the cement. Here a delay time can be presumed that indicates the end of the "sleeping" period and the start of the main phase of hydration.

In Fig.7 the shearing stress - time curves of a given MNC paste recorded at different shearing velocities are shown. The relationship of t_d and $\dot{\gamma}$ can be seen in Fig.8. The relationship is approximately of force law type:

$$t_d = 41.8\ \dot{\gamma}^{0.344} \qquad [1]$$

As it is shown in Figs. 9. and 10, t_d is linearly proportional to the LSN concentration. The function of the t_d-LSN concentration can be described with the linear relationship below:

$$t_d = -51.9 + 51.9\ LSN \qquad [2]$$

Hydration of the MNC cement

The experimental sample was prepared in laboratory ball mill, produced from the clinker of a mineral composition presented earlier, its specific surface was ~ 550 m^2/kg (n factor of uniformity 0.913, $\bar{x}$ fineness number 8 μm), to which 1.25 $^{m}/_{m}$ % LSN was added. With w/c = 0.25 cement paste was made from the MNC cement. For comparison, a cement paste was prepared (in the following OPC) from the same clinker containing 6 $^{m}/_{m}$ % gypsum, with a specific surface of ~ 300 m^2/kg (n = 0.899, $\bar{x}$ = 21 μm), with w/c = 0.31. Experiments were also carried out with gypsum-free cement pastes containing only Ca-lignosulfonate in 0.4 $^{m}/_{m}$ % and only Na-carbonate in 0.8 $^{m}/_{m}$ %, with w/c = 0.25. Fig.11. shows the strength of the MNC and OPC cements (a), the $Ca(OH)_2$ content determined from thermogravimetric curves (b), the chemically bound water quantity (c) as a function of hardening time. In Figs. 11b and 11c the characteristic curves of pastes containing only LS and only N are also seen.

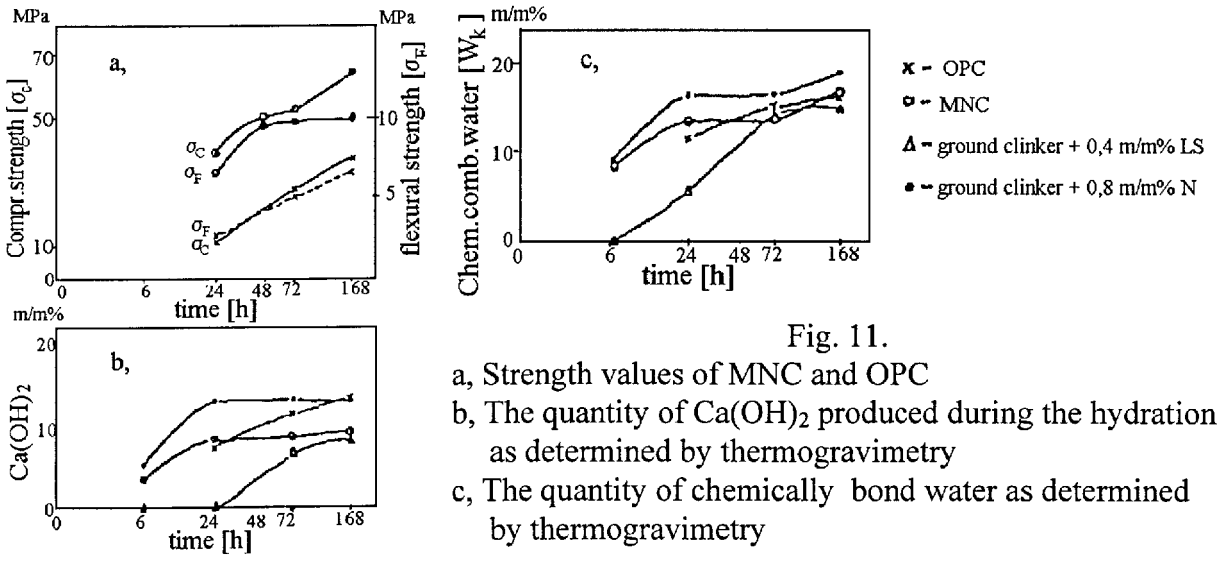

Fig. 11.
a, Strength values of MNC and OPC
b, The quantity of $Ca(OH)_2$ produced during the hydration as determined by thermogravimetry
c, The quantity of chemically bond water as determined by thermogravimetry

MNC is characterized by the rapid increase of strength (after 24 hours ~ 40 MPa) and by the high final strength (after 28 days ~ 28 MPa). In case of MNC the quantity of $Ca(OH)_2$ increases up to 24 hours, then hardly changes. The chemically bound water shows similar changes, the only difference is that between 72 and 168 hours further increase can be experienced. The quantity of $Ca(OH)_2$ is nearly the same in MNC, in later times it is always lower than that of OPC. The endothermal peak characteristic of the decomposition of $Ca(OH)_2$ occurs by 15-20 °C lower in the MNC, than in the OPC. In case of cement paste containing only LS the peak characteristic of the decomposition of the $Ca(OH)_2$ occurs only at 72 hours, the quantity of chemically bound water is also minimal in the early periods. The most intense hydration can be observed in the cement paste containing only N, the quantities of $Ca(OH)_2$ and of the chemically bound water are highest. The hydration heat values determined on the basis of dissolution heat measurements are seen in Table 1.

Table 1.

Time	Hydratation heat J/g MNC	OPC
6 hours	75.3	-
1 days	215.8	216.6
3 days	257.6	290.9
7 days	290.2	429.2

It can be seen that at 24 hours the hydration heats of MNC and OPC are practically the same but parallel with the hardening time the difference increases. So, at 7 days (168 hours) the hydration heat of MNC is lower by 33 % than that of OPC. It can be stated that in case of MNC cement the high compression and flexural strengths are accompanied by relatively low hydration degree. As to the derivatographic and X-ray diffractometric analyses, in case of MNC in addition to the hexagonal calcium-aluminium hydrates (C-A-H) C-S-H phases are also formed at the beginning of hydration. Later (between 24 and 48 hours) the increase of the quantity of C-S-H phase slows down but in spite of this phenomenon the strength of the cement considerably increases. The strength of the C-S-H phase highly depends on the degree of polycondensation of the SiO_4^{4-} anions. Analytical results concerning the anion structure of potassium silicates developed during the hydratation of MNC are shown in Table 2. Analyses were performed by means of trimethysilylation.

Table 2.
Trimethylsilylation data of hydrated cement pastes

	Age: 24 hours					Age: 168 hours					
	QM_4	Q_2M_6	Q_3M_6	Q_3M_8	O/M	QM_4	Q_2M_6	Q_3M_6	Q_3M_8	Q_4M_8	O/M
MNC	55.98	39.43	1.39	3.20	0.7861	49.73	44.82	-	5.75	-	1.0168
Ground clinker +LS	70.26	25.74	-	4.00	0.4232	46.39	46.23	2.06	5.33	-	1.1550
Ground clinker +N	49.24	44.05	-	6.72	1.0310	39.19	49.25	0.90	7.69	3.00	1.5530

QM_4	- monosilicate	$[SiO_4]^{4-}$	Q_4M_8	- cyclotetrasilicate	$[Si_4O_{12}]^{8-}$
Q_2M_6	- disilicate	$[Si_2C_7]^{6-}$	Q	- SiO_4^{4-}	
Q_3M_6	- cyclotrisilicate	$[Si_3O_9]^{6-}$	M	- trimethyl-silyl group	$[CH_3]_3$-Si-
Q_3M_8	- linear trisilicate	$[Si_3O_{10}]^{8-}$	OM	- [dimer+oligomers]/monomer	

It is shown that in MNC, in addition to the disilicate hydrates of remarkable quantity trisilicates are also formed at 24 hours, their quantities increase as a function of time. The addition of LS hampers the initial hydration of Ca-silicates (24-48 hours), thus less hydration product is formed but the polycondensation processes of anion are accelerated, this is why the product of 24 hours contains trisilicate hydrate of considerable quantity. The presence of N

considerably accelerates both the hydration of calcium silicates and the polycondensation processes of anions. The main constituent of the solidified MNC paste is the C-S-H phase, in its compact, homogeneous microstructure the columnar crystals of portlandite characteristic of the traditional portland cement cannot be detected. The pore structure of hardened MNC paste is extraordinarily dense and uniform (Fig.12/a), while this relatively stable pore structure is formed at an early stage of hydration (Fig.12/b). Total porosity of the hardened MNC paste does not exceed 13-15 % with pore sizes and pore size distribution markedly differing from those of OPC. In MNC paste at the age of 24 hours the 45 nm sized and at 7 days the 25 nm sized pores are predominating. Close relationships between strength, frost resistance and porosity are shown in Fig.12 and 13. For example, Fig.13 illustrates, on one hand, that MNC paste incorporates only a minimal quantity of pores in which water can freeze at -15 to -20 C, and the very-very slight expansion of the paste upon freezing, on the other.

a, MNC b, OPC

CONCLUSIONS

The MNC cement is characterized by the rapid increase of strength and the high final strength. MNC cement is fairly well workable at small w/c factors (0.2-0.35).

The flow curves of MNC pastes are of pseudoplastic type, its shear-dependent behavious can be best described by the Bingham model.The structure of MNC pastes decomposed at shearing is redeveloped immediately after mixing. The development of the structure proceeds in three steps: the initial formation proceeds with reduced velocity, then a transitional section follows and the final formation proceeds with increasing velocity. The transitional section lies within the induction and "sleeping" periods of the hydration process of the cement and the so-called delay time (t_d) indicates the beginning of the main hydration phase of the cement. t_d is linearly proportional with the LSN additive concentration.

The high strength of the hardened MNC cement is assured by the homogeneous and compact microstructure of the cement and by the presence of calcium silicate hydrates (C-S-H phase) of greater degree of polycondensation. The addition of the mixture of Ca-lignosulfonate and Na-carbonate (LSN) increases the rate of hydration, promotes the early formation of the stable pore structure and accelerates the polycondensation process of calcium silicate hydrates. In the development of the strength of the MNC cement the following facts play decisive role: the ultrafine state and uniform particle size distribution of the clinker milling product; the phenomenon that already in the age of 24 hours an extremely compact and stable pore structure is developed in which - due to the small pore size - there is no space for the formation of novel hydration product and for crystal growth. This is favourable to the formation of calcium silicate hydrate oligomers of higher degree of polycondensation, of higher strength and of less space demand.

PENETRABILITY OF SUSPENSION GROUT INFLUENCED BY DISPERSION CHARACTERISTICS OF ULTRAFINE CEMENT IN THE GROUT

Etsuro ASAKURA*, Tetsuya SUZUKI**, Yasunari MAEJIMA* and Hiroyuki FUJISAWA*
* Mitsubishi Materials Corporation, Japan
** Civil Engineering Research Institute, Hokkaido Development Bureau, Japan

ABSTRACT Ultrafine cement particles agglomerate easily in suspension grout and form many particles larger than the maximum cement size of 12 μm. This would be the main reason why the grout tends to be injected unsatisfactorily into the ground composed of fine sand. Therein, the simultaneous application, namely addition of chemical admixture and short time use of ultrasonic vibrator is helpful to prevent particles from agglomerating in the grout for a long time, and facilitates the grout penetration even into fine sand.

Key–words: Grout, Penetration, Dispersion, Viscosity

INTRODUCTION

It is said that the suspension grout is difficult to be injected into the ground composed of comparatively fine grains (e.g., Mori et al. 1991). However, in recent years, strengthening of such ground has been increasingly required in Japan owing to high demand of civil constructions even upon such ground. In this paper, the authors investigate the main cause of the difficulty of the grout penetration into fine sand and propose the countermeasure for ensuring the satisfactory injection thereof.

EXPERIMENTAL

Materials

Two kinds of ultrafine cement were used in this work. One is the ultrafine cement named for FINE HARD (cement A) produced by Mitsubishi Materials Corporation. The other is the half–and–half mixture (cement B) composed of above cement A and kaolin clay collected at Itaya district, Japan. The size distribution of these two materials measured by a model CILAS 715 laser granulometer is shown in Table 1. The materials to be studied were mixed with distilled water in a container by means of a mechanical stirrer and an ultrasonic vibrator. The chemical composition of ultrafine cement A is shown in Table 2. The ultrafine cement A consisting of Portland cement and blast furnace slag has Blaine surface area of 1,260 m^2/kg, maximum grain size of about 12 μm and the 50 % grain size of about 3.0 μm. While, kaolin clay has maximum grain size of about 8 μm and the

Table 1 Particle size distribution of ultrafine cement A and kaolin clay

	Cement A	Kaolin

>12 μm	0.3%	0.0%
>32 μm	0.0%	0.0%
50% grain size	3.0 μm	3.1 μm

Table 2 Chemical composition of ultrafine cement A

SiO_2	31.6%
Al_2O_3	13.6%
Fe_2O_3	0.7%
CaO	46.4%
MgO	6.1%
SO_3	1.6%

50 % grain size of about 3.1 μm. As might be seen, such kinds of clay are occasionally mixed with ultrafine cement in order to improve the penetrability of grout. β-naphthalene sulfonate formaldehyde high condensate (NSF) was used as chemical admixture.

Specimen preparation

Grouts were synthesized through mixing of each ultrafine cement and distilled water under the water/cement ratio of 6.0 by means of an electrical mixer for one minute at 25℃. Therein, say in the comparison test of several specimen, NSF and/or ultrasonic vibration were used for some samples to facilitate uniform dispersion of the ultrafine cement in the grout. NSF with the amount of 0.5 % or 1.0 % against the total weight of cement which is dissolved in water was prepared prior to mixing with the ultrafine cement. At the same time, the ultrasonic vibration could be undertaken to the grout contained in a 300 ml beaker for one minute by using a ultrasonic cleaner whose vibration frequency was set to be 40 kHz.

Size distribution of ultrafine cement in grout

The measurements were performed by aforesaid laser granulometer in which an ultrasonic generator is equipped as a standard accessory. However, as a matter of course, such ultrasonic generator was not operated during this measurement procedure in order to avoid further dispersion of the agglomerated cement particles in grout. A very small amount of the grout sample was taken at every 0, 30 and 60 minutes after mixing, then let them disperse in an excessive amount of distilled water and the size distribution was measured as to respective samples.

Viscosity of grout

The viscosity of the grouts was obtained by using a coaxial rotational viscometer (Shibaura system "Digital Vismetron VDA").

Penetrability of grout into fine sand

As shown in Fig.1, the testing apparatus consisting of a cylindrical separating funnel of 200 ml in which Japanese standard sand (106 – 300 μm in diameter, and normally used for the cement mortar test) with 20 cm thickness was filled was adopted to measure the penetrability of the grouts into dense as well as fine sand bed. The grout of 300 ml was poured into the funnel, and the penetrating depth into the fine sand was measured from outside of the funnel as the index of its penetrability.

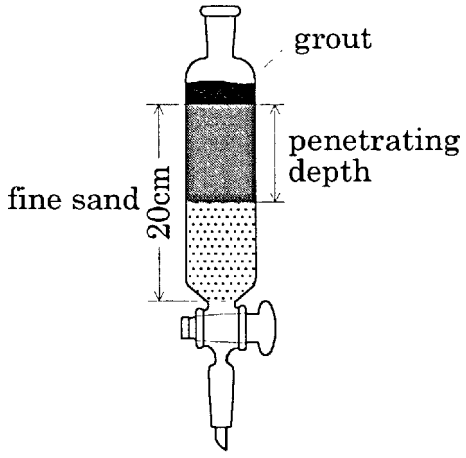

Fig.1 Setup for penetrability test of grout

RESULTS AND DISCUSSION

Ultrafine cement A

Table 3 shows the influence of different dosage of NSF together with or without ultrasonic vibration against the properties of grouts composed of ultrafine cement A. The grout sample taken immediately after mixing with neither NSF addition nor ultrasonic vibration

Table 3 Properties of grouts with ultrafine cement A

NSF (%)	Ultrasonic Vibration (sec.)	Time (min.)	Particle size distribution of ultrafine cement in grout (%)				Viscosity ($\times 10^{-3}$ Pa·s)	Penetrability (cm)

contained 36.3 % particles which was larger than 12 μm, and its penetration depth was only 4.0 cm. This large particles might be caused by agglomeration of ultrafine cement whose maximum size is about 12 μm. While, the addition of 0.5 % NSF to the above mentioned grout reduced the rate of large particles as well as the viscosity of the grout. Furthermore, when ultrasonic vibration was undertaken to this sample, such tendency became clear more or less. This phenomenon is deemed to be the reflection of the dispersion effect by ultrasonic vibration on the agglomerated particles in same effect as the case of NSF. However, in this case, the amount of larger particles and the viscosity of the grout increased gradually as time goes by, which conducted its penetrability to be lower consequently. On the other hands, the addition of 1.0 % NSF made the particle size and the viscosity maintained almost constant for 60 minutes, and then the penetration was remarkably improved, exceeding 20 cm, regardless of whether ultrasonic vibration was applied or not.

Ultrafine cement B

In a same manner as above mentioned test for cement A, Table 4 shows the influence when cement B was used. Comparing to the case of cement A, the grout of cement B tended to contain many larger particles over 32 and 96 μm and became more viscous when ultrasonic vibration was not undertaken. This might be due to agglomeration between cement and kaolin promoted by mixing of kaolin clay, and its penetrability into fine sand became worse accordingly. When only ultrasonic vibration was undertaken without NSF addition, the viscosity increased abnormally, presumably owing to the

increase of fine clay particles. It was revealed that the case that the penetration depth of the grout exceeded over 20 cm was the only case of the addition of 1.0 % NSF together with ultrasonic vibration In this case, ultrasonic vibration gave a pronounced effect towards dispersion of the agglomerated particles for a long time, and consequently larger particles over 12 μm had disappeared and the viscosity became low.

CONCLUSION

The purpose of this study is to clarify the main cause that makes the penetration of suspension grout difficult into fine sand, and then conduct countermeasures thereof. The conclusion can be summarized as follows :

1) Ultrafine cement particles agglomerate easily in suspension grout and form many particles larger than the maximum size of cement, which tends to be remarkable with the lapse of time after grout mixing. This phenomenon is deemed to cause the condition of the viscosity increase as well as unsatisfactory injection of grout.

2) Regarding the countermeasure, the combination of addition of chemical admixture and short time use of ultrasonic vibrator is helpful to prevent particles from agglomerating in the grout for a long time and to decrease its viscosity, and finally facilitates the grout penetration even into fine sand.

HYDRATION CHARACTERISTICS OF MAGNESIA ASSIMILATED SULPHOALUMINATE - BELITE CEMENT

M M ALI, R BHARGAVA* AND S C AHLUWALIA**

National Council for Cement and Building Materials, New Delhi, India

ABSTRACT Clinker composition containing mineral phases $C_4A_3\bar{S}$, C_2S, C_3MS_2, C_4AF, $C\bar{S}$ and upto 10 percent MgO showed rapid hardening with almost complete hydration of $C_4A_3\bar{S}$ in one day. C_3MS_2 remained inert upto one year studied. Autoclave and potential sulphate expansions were 0.15 and 0.04 percent respectively. The cement showed much resistance to corrosion of reinforcement steel in sea water.

Key-words: Clinker Formation, Corrosion, Ettringite, Expansion,Hydration

INTRODUCTION

In oxide system $CaO-Al_2O_3-Fe_2O_3-SiO_2-SO_3-MgO$, several phase assemblages of phases such as $C_4A_3\bar{S}$, C_2S, C_2AS, C_3MS_2, C_4AF, $C\bar{S}$ etc. have been reported which have cementitious properties (Ali et al, 1992, Beratka et al, 1992, Ikada, 1990, and Mehta, 1980). In presence of MgO formation of C_3MS2 phase occurs which is stable upto 1381°C (Schlandt, 1966). The temperature of clinkerization is generally lower and there is a potential of making cement using low grade high MgO limestone and by product waste materials (Ali, 1992, Mehta, 1980).

In the present investigation sulphoaluminate belite cement containing upto 10% MgO has been prepared and studied for the hydration products, performance characteristics, sulphate resistance and corrosion of steel embedded in concrete. A comparative evaluation of corrosion in ordinary and sea water curing over a period of 1 year using OPC and high magnesia sulphoaluminate belite cement has been presented.

EXPERIMENTATION

High magnesia sulpho aluminate - belite cement was prepared by preparing raw mix using limestone, clay, bauxite, gypsum and MgO powder. Raw materials were ground and raw mix with fineness of about 12 percent residue on 170 mesh was nodulized and fired for one hour at 1325°C by keeping in an electric furnace and air quenching the resultant clinker. The clinker was evaluated for mineral phases using x-ray diffractometer and scanning electron microscope for morphology of clinker. Clinker sample was ground in a ball mill to achieve a fineness of about 26 M^2/Kg Blaines's. The cement was analysed for constituent oxides and physical performance characteristics determined as per IS : 4031 - 1988. The hydration study was carried out by preparing cement paste at w/c ratio of 1.0 in plastic bottles by keeping for 15 minutes, 1, 2, 5 hours, 1, 3, 7, 28 and 360 days and arresting hydration through acetone treatment. Mineralogy was determined using x-ray diffraction. The hydrated specimen in lump form and having smooth and shining surface along the base of containg bottles were also studied under reflected light in optical microscope alongwith the SEM of fractured surface. The cement was evaluated for potential sulphate expansion as per ASTM-C 452-1989.

---

* Shree Cement, Beawar, Rajasthan, India
** OCL India Ltd., New Delhi, India

The cement was also tested for corrosion activity in steel embedded in concrete along with OPC by curing the two in ordinary and sea water composition for one year and then measuring potentials generated in steel (Gouda, 1975).

RESULTS AND DISCUSSION

The potential phase composition of the clinker without addition of MgO is shown in Table 1.

Table 1 Potential Mineral Phases of the Clinker

Phases	$C_4A_3\bar{S}$	C_2S	C_4AF	$C\bar{S}$
Proportion (%)	32	40	20	8

Two clinkers with 10 and 11 percent MgO replacing CaO were fired. Mineral phases developed are shown in Fig. 1.

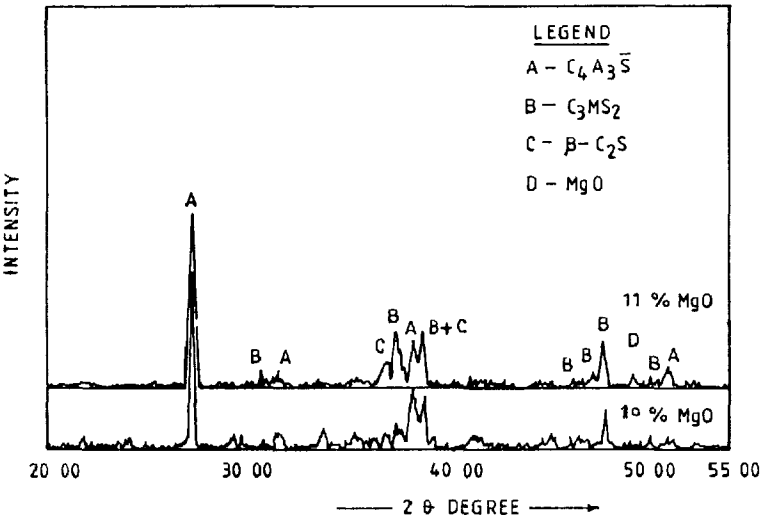

Figure 1 XRD of Clinker Samples

Clinkers fired at 1325°C were found well burnt and XRD studies showed formation of $C_4A_3\bar{S}$, C_3MS_2 and C_2S. Mix with 11 percent MgO indicated appearence of periclase in small amount.

The fracture surface morphology of clinker is shown in SEM (Fig 2).

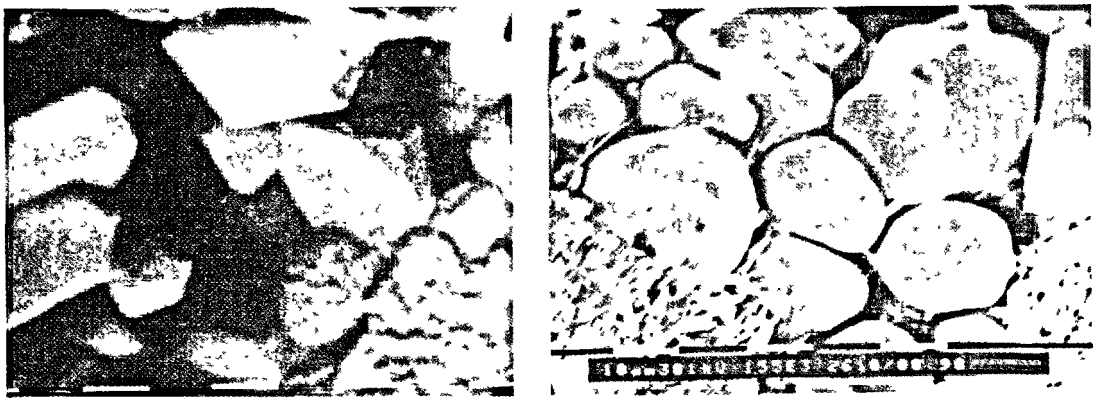

Figure 2 SEM of Clinker Sample

The crystals of $C_4A_3\bar{S}$ are well developed hexagonal tabular shaped along with coarse grained two grained rounded particles of silicate phases which are evenly distributed.

The chemical analysis of clinker is given in Table 2.

Table 2 : Constituent Oxides in Sulphoaluminate Belite Cement

Constituents	LOI	SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	SO_3	Na_2O	K_2O	TiO_2	FCaO
Weight (%)	0.63	14.06	6.45	18.68	40.41	9.93	7.8	0.24	0.14	0.40	0.2

The physical performance characteristics of sulphoaluminate - belite cement is given in Table 3.

Table 3 : Performance Characteristics of Cement

	Property	Values
1.	Fineness, Blaines (M^2/Kg)	26.0
2.	Setting Time (Minutes)	
	Initial	35
	Final	80
3.	Autoclave Expansion (%)	0.15
4.	Compressive Strength (N/mm^2)	
	1 Day	18.0
	3 Day	21.0
	7 Day	25.0
	28 Day	34.5

It is clear from Table 3 that the cement shows rapid hardening and substantial strength gain at one day of hydration. Autoclave expansion is only 0.15 percent which indicates that even with 10 percent MgO the cement is volume stable which is expected in view of the near absence of periclase and presence of non hydraulic MgO bearing phase. The XRD of autoclaved sample showed presence of C_3MS_2(Fig 3)as non-hydraulic phase.

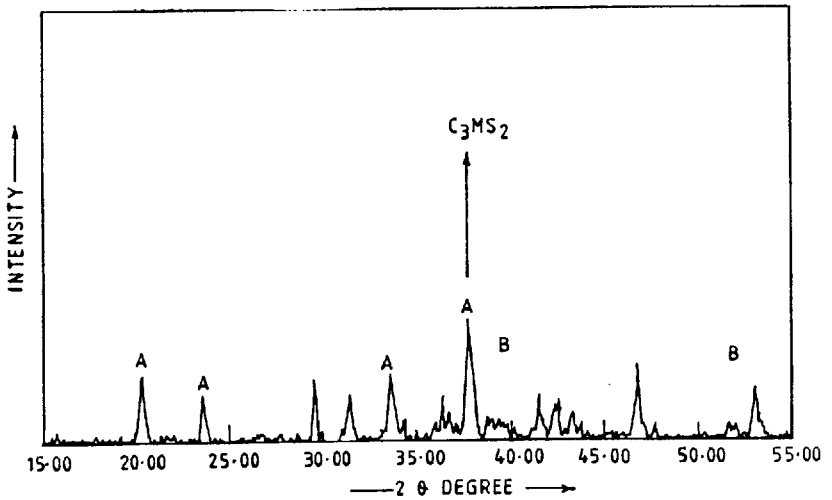

Figure 3 XRD of Autoclaved Cement Sample

The hydration phases developed under ambient water curing are shown in figure 4.

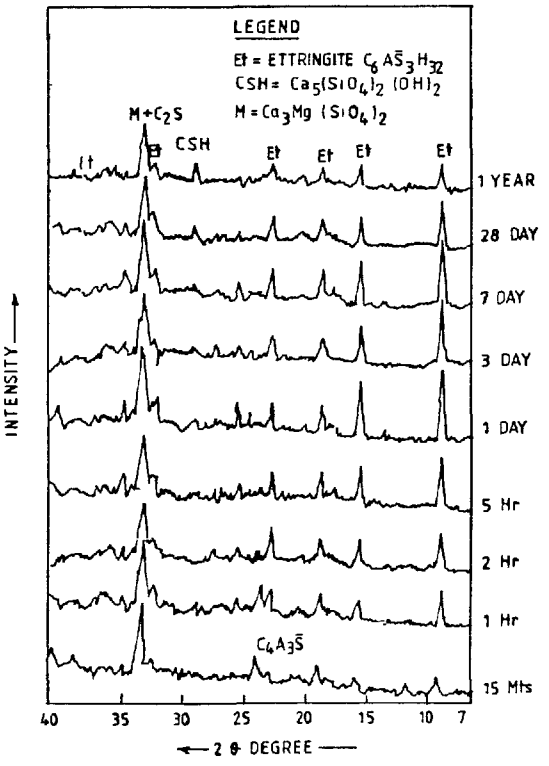

Figure 4 XRD of Hydrated Cement Samples

Figure 4 shows that the hydration of $C_4A_3\bar{S}$ occurs rapidly and at one day as is evident from the disapperance of pak at 2O=23.92 and apperance of ettringite peak at 2O=9.08. Its hydration led to a considerable formation of ettringite in 15 minutes. The hydration of C_2S is slower (Ono, 1989) and the XRD patterns do not clearly show the rate of hydration as the C_2S peaks are masked by C_3MS_2. However formation of crystalline CSH appears in XRD at one year of hydration.

The rapid hardening and higher strength characteristics at early ages are owing to rapid hydration of $C_4A_3\bar{S}$ and C_2S phases (Hanayawa, 1975, Kasselouri et al, 1995).

The optical micrographs of hydrated samples (Fig 5) showed crystalline needle shaped hydrates of ettringite.

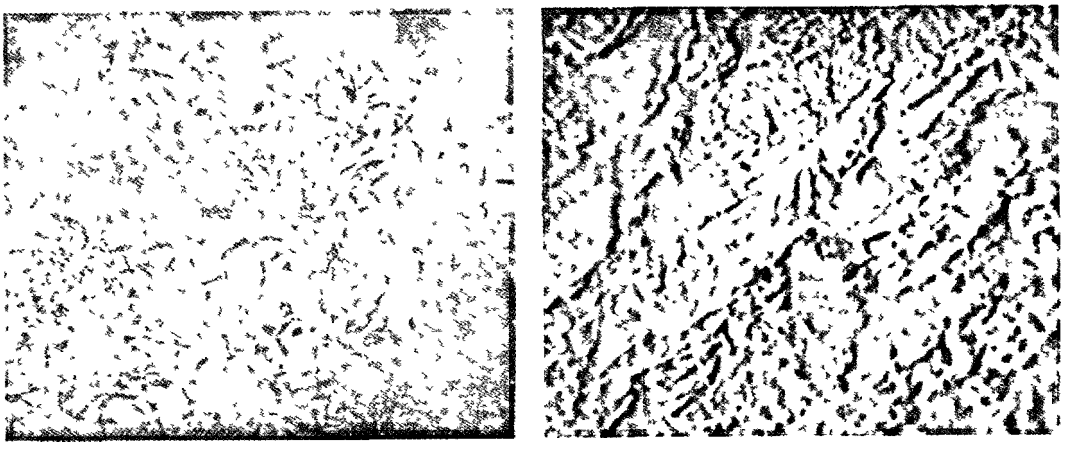

Figure 5 OM & SEM of hydrated Samples

The ettringite crystals fill the void spaces in the paste and form dense mass. SEM of hydrated specimens show that at later ages, the needles get converted into rounded prismatic forms.

The potential sulphate expansion determined was found to be 0.04 percent which is comparable to the limit prescribed for ASTM V type cement. Therefore sulphoaluminate-belite cement could be used for constructions in sulphate bearing environment.

Measurement of corrosion in reinforcing steel embedded in sulpho aluminate cement and OPC is shown in Fig 6.

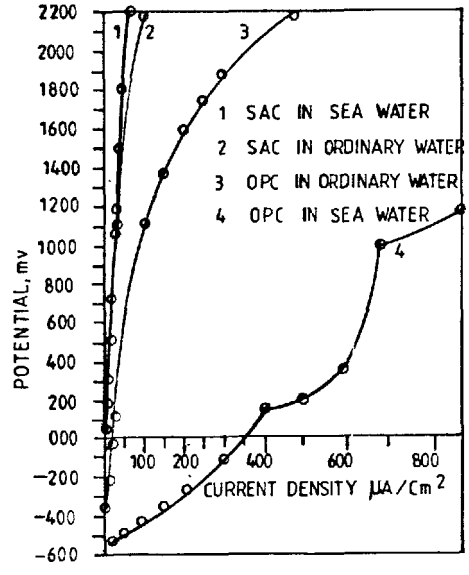

Figure 6 Corrosion test of Steel reinforced Sulphoaluminate (SAC)and Ordinary Portland Cement (OPC)

It is clear that sulphoaluminate-belite cement is highly resistant to corrosion of reinforced steel compared to OPC upto a period of one year studied.

CONCLUSIONS

1. Sulphoaluminate belite cement is a low temperature, energy saving cement and can exploit low grade, dolomitic limestone in its manufacture.
2. The high magnesia sulphoaluminate belite cement containing 10 percent MgO fixed mostly as C_3MS_2 was found to be volume stable.
3. The C_2S phase hydrates at slower rate due to presence of coarse grain size.
4. The cement is resistant to sulphate attack and shows resistance to corrosion of reinforcing steel compared to OPC in sea water conditions.

INFLUENCE OF THE COMPOSITION OF INTERSTITIAL PHASES ON THE HYDRATION PROPERTIES OF BELITE CEMENTS

Tatsuo IKABATA and Hideki TAKEMURA, Cement/Concrete Research Lab.,
Sumitomo Osaka Cement CO. LTD., Japan

ABSTRACT The hydration properties of belite cement were investigated by varying the composition of the interstitial phases. Results indicated that the heat of hydration / compressive strength of mortar ratio was at a minimum when the composition of the interstitial phase was near to C_6AF_2. Additionally, concrete tests were conducted using belite cement having a minimum ratio of heat of hydration / compressive strength of mortar.

Key-words: Belite, Composition, Hydration, Interstitials, Strength development

INTRODUCTION

Following recent advances in concrete technology, there has been an increase in the rapid construction of concrete buildings and structures composed of large-sized units or modules. When such massive concrete structures are built, effective methods to reduce thermal stress, caused by hydration during the course of concrete hardening, are important to avoid cracking of the structures and improve their durability. To resolve this problem, low-heat Portland cement has recently come into use. This type of cement is now often used also when high strength and flexibility are required of concrete. To date, several types of low-heat Portland cement, including belite rich cement (named belite cement) with a C_2S content ranging from 50 to 75%, have been studied. (Ikabata et al, 1990and 1991; Yoshida and Igarashi, 1991; Nawa et al, 1993) Most of these types of low-heat Portland cement used C_3A-C_4AF for the interstitial phase. However, few studies have examined the influence of the composition of the interstitial phase in this type of cement.

The present study was undertaken to examine the effects of interstitial phase composition on the hydration properties of belite cements, i.e., the effects on the hydration heat and mortar strength. In addition, concrete pieces made of selected belite cements were tested.

SAMPLE PREPARATION

Synthesis of clinker

The raw mixes were prepared by grinding a mixture of SiO_2, Al_2O_3, Fe_2O_3, $CaCO_3$, $Mg(OH)_2 \cdot MgCO_3$, Na_2SO_4, K_2SO_4, Na_2CO_3 and K_2CO_3, which were chemical reagent grade materials. The raw mixes were molded under pressure, then heated in a furnace for 1 hour at 1,450° C. After that, all clinkers were quenched in the air.

The clinkers were characterized by chemical analysis, X-ray diffraction and observation by reflective microscopy. The chemical composition and calculated mineral composition of the clinkers are shown in Table 1.

Preparation of cement

The clinkers were mixed with gypsum and ground using a ball mill to a Blaine fineness of 290 to 300 m^2/kg (Experiment 1) or 440 to 460 m^2/kg (Experiment 2). The amount of SO_3 was 2% (Experiment 1) or 1.0, 1.5 and 2.0 (Experiment 2).

EXPERIMENTAL PROCEDURE

Standard tests (Experiments 1 and 2)

The heat of hydration of the cement and the compressive strength of mortar were measured according to the method proposed by Japanese Industrial Standards (JIS R5203, 1987 and JIS R5201, 1992). In Experiment 1, both samples were tested at 1 week , 4 weeks, 13 weeks and 1 year. On the other hand, 1, 4 and 13 weeks samples were tested in Experiment 2.

Table 1 Chemical and mineral composition of clinker

Experiment	Sample	clinker									SO_3 of Cement (%)
		SiO_2 (%)	Al_2O_3 (%)	Fe_2O_3 (%)	CaO (%)	Na_2O eq.(%)	C_3S (%)	C_2S (%)	IM	interstitial phases	
1	A	28.0	4.0	3.5	62.9	0.34	11	72	1.14	C_3A-C_4AF	2.0
	B	27.1	3.7	3.5	63.8	0.37	24	60	1.06	C_3A-C_4AF	2.0
	C	28.0	4.2	2.4	63.5	0.38	14	70	1.75	C_3A-C_4AF	2.0

	G-1.5										1.5
	G-2										2.0

Concrete tests (Experiment 2)

Table 2 Mix proportion of concrete

Water-cement ratio (%)	Sand-aggregate ratio (%)	Unit content (kg / m^3)				Chemical admixture (l / m^3)
		Cement	Water	Sand fine aggregate	Coarse aggregate	
50	39	300	150	710	1160	0.75

Concrete tests were conducted using sample (G -2) and commercial low-heat Portland cement. The concrete samples were mixed in the proportions listed in Table 2 using a double shaft pugmill mixer. After mixing the concrete samples, slump, compressive strength and adiabatic temperature rise of each concrete were measured.

RESULTS AND DISCUSSION

Characterization of clinker

Our analysis of mineral composition by X-ray diffraction revealed that the C_2S contained in the test samples was of β-phase. The interstitial phases of samples A through C were found to be composed of C_3A and ferrite phases, while those of samples D through G were composed of ferrite alone. These findings are consistent with the mineral composition shown in Table 1. The features of the interstitial phases as observed under a reflective microscope also agreed with the findings shown in Table 1. Type I belite formation was seen in all clinkers. As the ratio of the amount of Al_2O_3 to the amount of Fe_2O_3 contained in the clinker (the Al_2O_3/Fe_2O_3 ratio) became smaller, the crystal size of the belite phase formed became greater. Fig. 1 shows representative results obtained by reflective microscopy. The increase in the crystal size of the belite appeared to be related to changes in the viscosity of the liquid clinker following a decrease in the Al_2O_3/Fe_2O_3 ratio.

Experiment 1

Figures 2 shows the relationship between the mineral composition and the heat of hydration in Experiment 1, while Figures 3 shows the relationship between the Al_2O_3/Fe_2O_3 ratio of the clinker (IM) and the compressive strength of the mortar in the same experiment. When the C_3S content

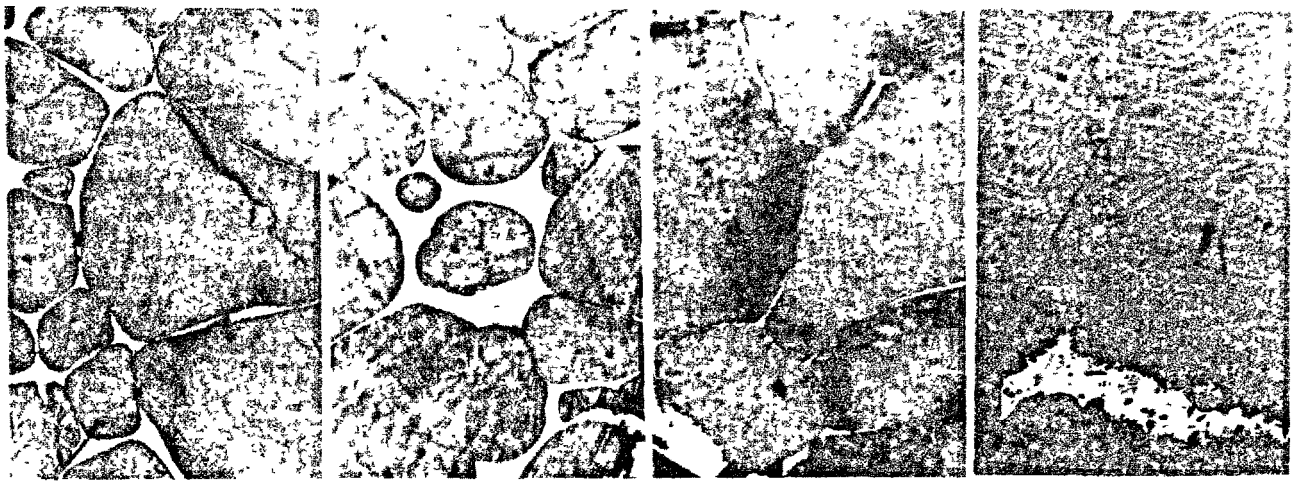

Fig 1 Polished and etched surface of the belite clinker.

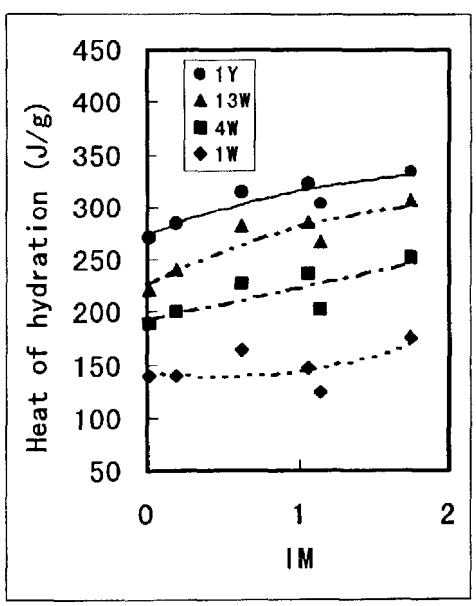

Fig 2 Relationship between IM and heat of hydration.

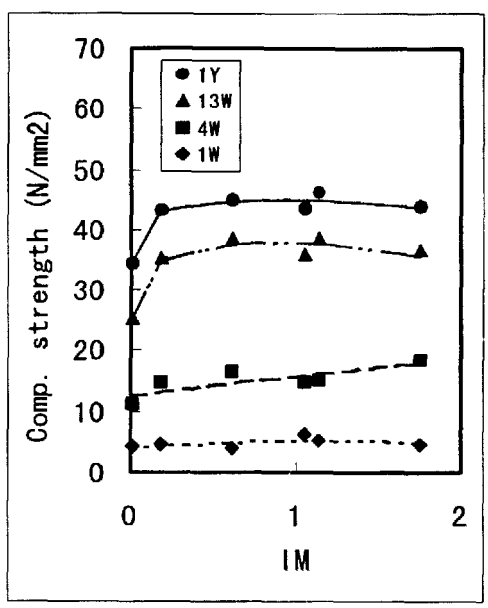

Fig3 Relationship between IM and compressive strength

was the same, an increase in the Al_2O_3/Fe_2O_3 ratio resulted in an increase in heat of hydration. This increase in heat of hydration was greater in samples of lower age. A characteristic relationship was observed between the compressive strength of the mortar and the interstitial phase composition. That is, in samples of relatively low ages (less than 4 weeks), an increase in the Al_2O_3/Fe_2O_3 ratio tended to increase the compressive strength of the mortar, while in samples more than 13 weeks old, the compressive strength reached a peak when the Al_2O_3/Fe_2O_3 ratio was about 0.6 (corresponding to type C_4AF). When the ratio of heat of hydration to the compressive strength of the mortar was analyzed in relation to the interstitial phase composition, as shown in Fig 4, it was found to be lowest when the Al_2O_3/Fe_2O_3 ratio was about 2 (corresponding to type C_6AF_2). The interstitial phase types C_4AF through C_6AF_2 therefore seem to be most suitable for belite cement.

Experiment 2

Following the findings obtained in Experiment 1, clinker (G) was synthesized and used for producing belite cement with an interstitial phase composition close to type C_6AF_2. Using this clinker, the optimum amount of gypsum that should be added to the belite cement was examined. Before beginning this experiment, we had expected that the amount of SO_3 needed would be smaller than that used for ordinary low-heat cement on the grounds that the Al_2O_3/Fe_2O_3 ratio of this belite cement is low. However, the ratio of heat of hydration to the compressive strength of the mortar was low when the SO_3 content in younger samples was small, and this ratio showed no difference associated with the SO_3 content in 13 week old samples. Therefore, contrary to our expectation, 2% seems to be the optimum SO_3 concentration.

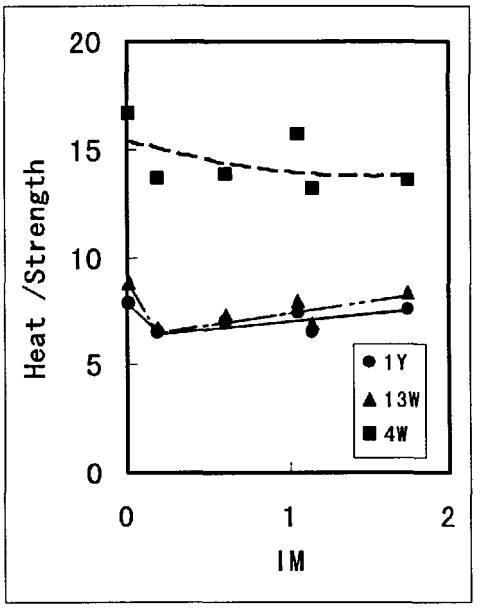

Fig 4 Relationship between IM and the ratio of heat of hydration / compressive strength

Table 3 shows the results of concrete tests using belite cement with the above-mentioned optimum SO_3 concentration and a commercial low-heat cement. Although the initial strength of the belite cement was not satisfactory, this cement was found to have two favorable features: (1) the concrete had a high strength when measured 28 days or more after it was made from this cement; and (2) the adiabatic temperature rise was low.

Table 3 Results of concrete tests

Sample	slump (cm)	Air (%)	Compressive strength (N/mm^2)			Adiabatic T.R. (℃)
			1W	4W	13W	
G-2	8.5	4.7	4.6	35.1	50.5	35.9
L.H.	6.0	4.9	15.6	33.4	44.7	40.1

CONCLUSIONS

1. Judging from the compressive strength of the mortar and the heat of hydration, the optimum interstitial phase composition of belite cement is C_4AF through C_6AF_2.
2. A test of concrete made of belite cement with a C_6AF_2 type composition of the interstitial phase revealed that this belite cement has two favorable features (an excellent long-term strength and a low adiabatic temperature rise).

DISTINGUISHING FEATURES OF HARDENING OF PORTLAND CEMENT SYSTEMS ON A BASIS OF CLINKERS OF VARIOUS MICROSTRUCTURE

Lev G.SUDAKAS, Giprocement, Phys.-and Chem.Studies, St.Petersburg, Russia
Lyudmila B.VASILIYEVA, Giprocement, Phys.-and Chem.Studies, St.Petersburg, Russia

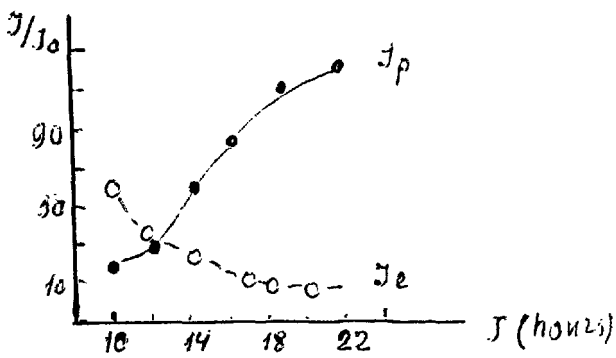
ABSTRACT The diffirent in the microstructure of commercial portland cement clinkers at their completely identical origin and chemical-and-mineral composition tells upon the dynamics of formation at hardening of crystalline phases-portlandite and ettringite. This dynamics determines to a large extent the strength of systems at control ages and is controllable with the help of chemical additives.

Key-words: Hardening, Hydration, Misrostructure

INTRODUCTION

The description of portland cement clinkers through their misrostructure dates back to the end of the XIXth century (Le Chatelier, 1887). In the modern times investigation (Sheikin, 1960), (Kuznetsova, 1968), (Sudakas, Kraplya et al, 1975) a link was established between the clinker microstructure and the strength of the associated cement systems. It was shown in one of the recent works (Kraplya and Sudakas, 1986) that the hardening systems on a basis of commercial clinkers differ in dynamics of variations in their content of portlandite, $Ca(OH)_2$, and proposal was made that the varying strength of such systems can be attributable to these differences.

EXPERIMENTAL



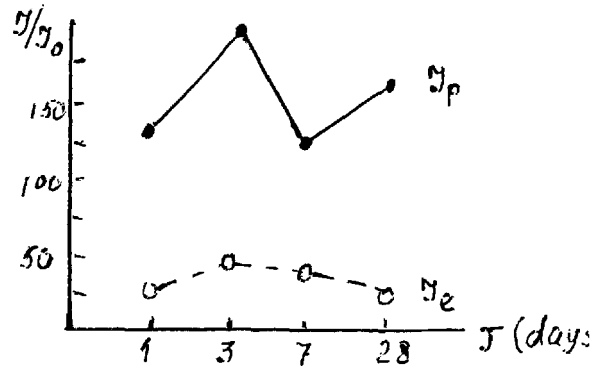
5 clinkers of the Ulyanovsky plant sampled under the petrographic control were taken for the investigations. All the clinkers were burned from one type of slurry within 3 days. The clinkers differed in their microstructure in the range from 2 to 6 on the Giprocement scale. The clinkers did not differ in their chemical-and-mineral composition as demonstrated by the chemical analysis data: KH=0.92; n=2.06÷2.1; p=1.3÷1.4; $\%SO_3$=0.97÷1.17; %MgO=1.12÷1.14; $\%R_2O$=0.73÷ 0.86.

The clinkers were ground with 4.5% gypsum stone to the specific surface of 300±10 m^2/kg. The tests were conducted in accordance with the Russian standard GOST 310.4 (Table 1).

Table 1 Compressive strengths of cements on a basis of clinkers of various microstructure

Misrostructure, Giprocement scale number	Compressive strength, MPa			
	1 days	3 days	7 days	28 days
2	16.4	24.6	28.7	36.6
3	17.4	32.6	34.8	38.0
4	14.3	30.4	36.9	42.6
5	16.2	34.0	38.6	45.7
6	12.7	25.4	45.0	50.0

Concurrently investigation was made into dynamics of changes in the content of the main crystalline new formations - portlandite and ettringite. Their content was assessed by the intensity of the X-ray diffraction peaks of 4.90 A for portlandite and 9.8 A for ettringite. Fig 1-1 through 1-5 show the dynamics at different basis of clinkers of various microstructure.



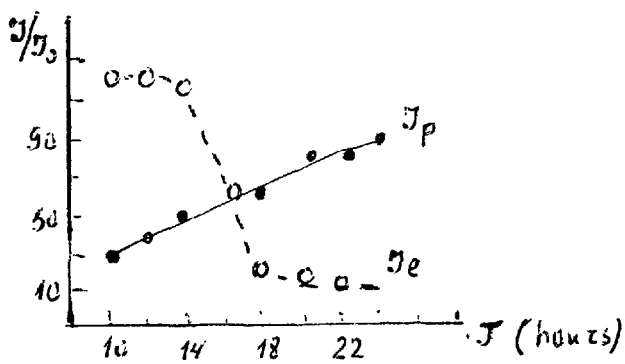


Fig 1-1 Clinker, 2 numbers

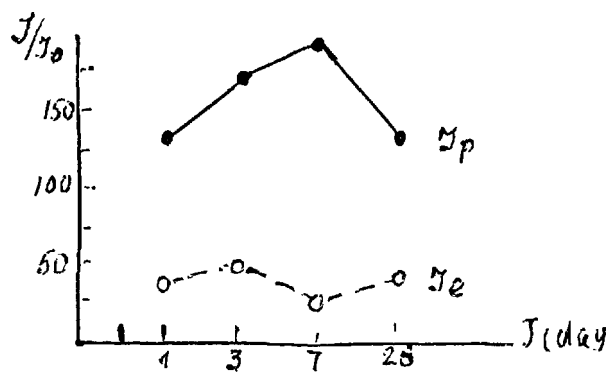

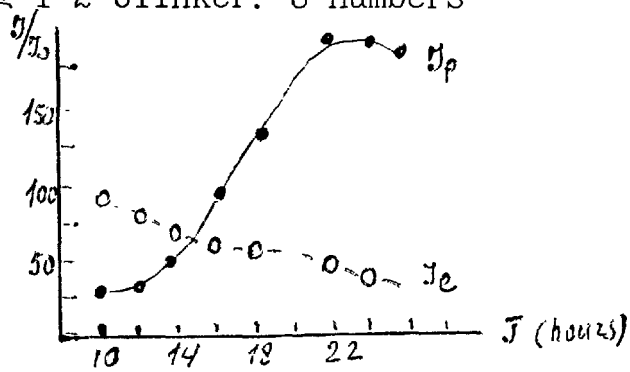

Fig 1-2 Clinker. 3 numbers

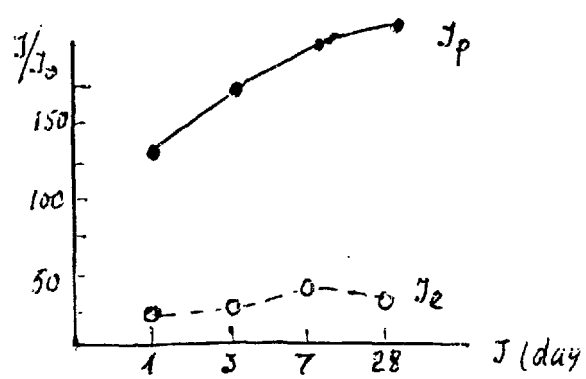

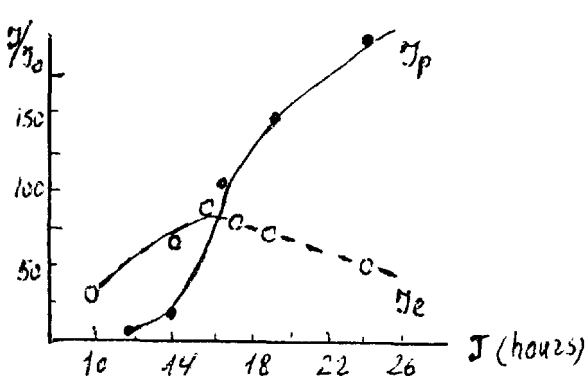

Fig 1-3 Clinker, 4 numbers

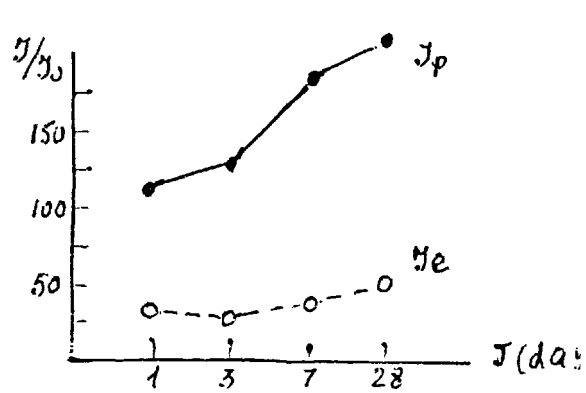

Fig 1-4 Clinker, 5 numbers

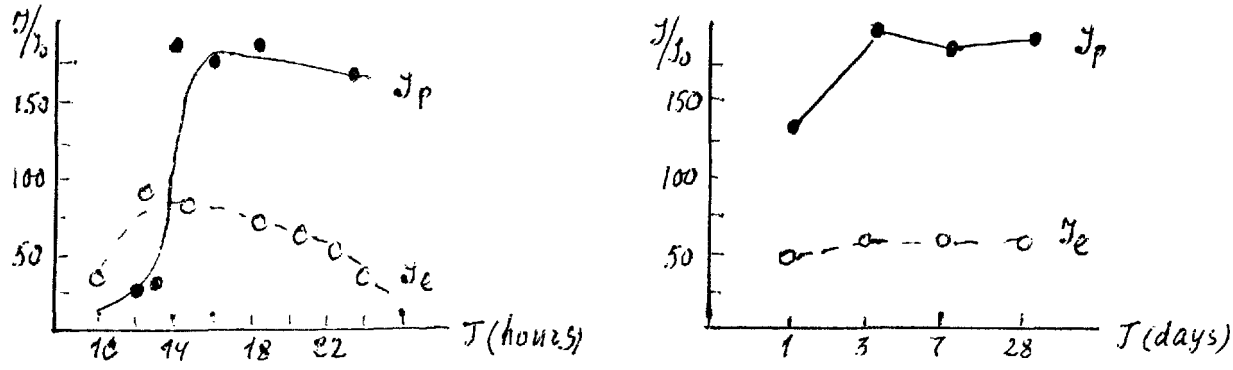

Fig 1-5 Clinker, 6 numbers
Figure 1 Dynamics of changes in the content of portlandite (p) - and ettringite (e) - in hardening cement systems on a basis of clinkers of varying microstructure

A possibility to change the dynamics of the crystalline phases formation with the help of chemical additives was examined at a time. Fig 2 shows such a change at introduction of 0.1% monosubstituted ammonium citrate into the system on a basis of clinker with the microstructure of 2 numbers. The compressive strengths of such systems were as follows: at the age of 3 days - 20.8; at the age of 7 days - 27.8; at the age of 28 days - 47.4 MPa.

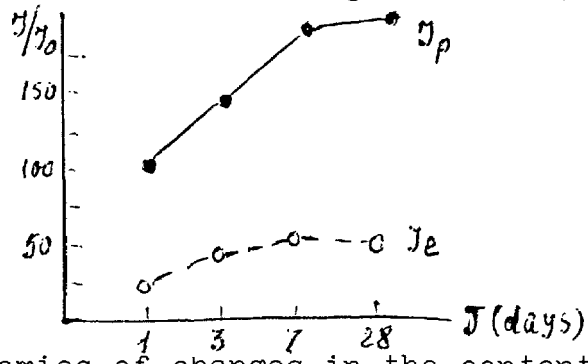

Figure 2 Dynamics of changes in the content of portlandite (p) - and ettringite (e) - in hardening cement systems on a basis of clinker with microstructure of number 2 with addition of 0.1% monosubstituted ammonium citrate

DISCUSSION OF RESULTS AND CONCLUSIONS

The difference in the clinker microstructure tells upon the strength synthesis unambiguously: the more perfect is the clinker microstructure, the higher is the 28-days strength systems. at the early ages, particularly at 1 day, the dependence therewith can be inverse. The clinkers with disordered structures (2,3 numbers) at the age of 1 day can give higher strengths than the ones with ordered structures (6 numbers). This correlates with the change in the content of crystalline phases. The less crystallochemically ordered clinkers because of their rather high chemical activity in the first (up to 10) hours form systems with a higher than usual initial content of ettringite and portlandite (the latter is formed after 6-7 hours of hardening). Later on the clinker structural order leads to a monotone increase in the crystalline phases conent of the hardening system, while in system based on clinkers of the inferior microstructure the formation of the crystalline phases is retarded and on frequent occasions takes on an alternating character. This points to the destruction of crystalline structures formed initially in the hardening systems.

Thus, such a change in dynamics of the crystalline phase formation is one of the causes of the lower strength of the cement stone.

This is supported also by the experiense of introduction of the ammonium citrate additive into the system of disordered clinker microstructure (number 2). The dynamics of the crystalline phase formation takes on the character inherent in systems based on clinkers of a perfect microstructure, and this results in the strength increase at the control ages.

DOLOMITIC ROMANCEMENT - LOW TEMPERATURE HYDRAULIC BINDER

Ilgars GROSVALDS, Silvija LAGZDINA, Uldis SEDMALIS, Riga Technical University, Institute of Silicate Materials, Riga, Latvia

ABSTRACT Dolomitic romancement although has advantages of low manufacturing cost because of low embodied energy and convenient use in building industry, has some essential limitations also- quick setting (begin 5-10 min, end 10-25 min) and uneven volume change during hardening of cement. These shortages were overcame by wetting and keeping in a storage in moist atmosphere for about 2 weeks dolomitic material obtained by firing domerite (dolomite containing 18-25% of clay) before milling as well as using additive.

Key-words: additives, mineral phase, low temperature,volume change.

INTRODUCTION

In Latvia dolomitic romancement was known long ago. It was produced as far back as in 1865 using as raw material domerite i.e. clayey dolomite by firing at the temperature 800-900°C and fine milling. The fired product can be considered as clinker only conventionally, because it is not sintered and dense. Dolomitic romancement like portlandcement is a hydraulic binder, however the mechanical strength of romancement is about one fourth as that of portlandcement. At the same time the mechanical strength of romancement after some days of hardening is greater as that of lime after 28 days of hardening. Essential limitations of dolomitic romancement are it quick setting, uneven volume change during hardening and small mechanical strength (5-10 MPa). The purpose of present investigation was to overcome quick setting, uneven volume change as well as to improve the mechanical strength of dolomitic romancement.

RESULTS AND DISCUSSION

Raw material used was Sloka-Kudra domerite. The chemical and mineralogical composition of Sloka-Kudra domerite and Sloka-Slocene domerite, the latter for comparision, are given in Table 1.

Table 1 Chemical and mineralogical composition of domerite , mass %

Ingredients	Sloka-Kudra deposit	Sloka-Slocene deposit
loss on ignition	37,68	39,70
SiO_2	12,06	13,88
Al_2O_3	3,64	1,91
Fe_2O_3	2,38	1,27
CaO	26,65	25,40
MgO	16,99	17,51
	Σ=99,40	Σ=99,67
dolomite+calcite	77,7+5,4	81,06
clay	16,3	18,61

Domerite was crushed by laboratory jaw crusher, screened into the sizes 3-7 mm and fired in the muffle kiln at temperatures 800, 850, 900°C. The rate of raising the temperature was 10°C/min, the entire time at the maxima temperature - 4h. The firing temperature was chosen on the basis of DTA results (Fig 1).

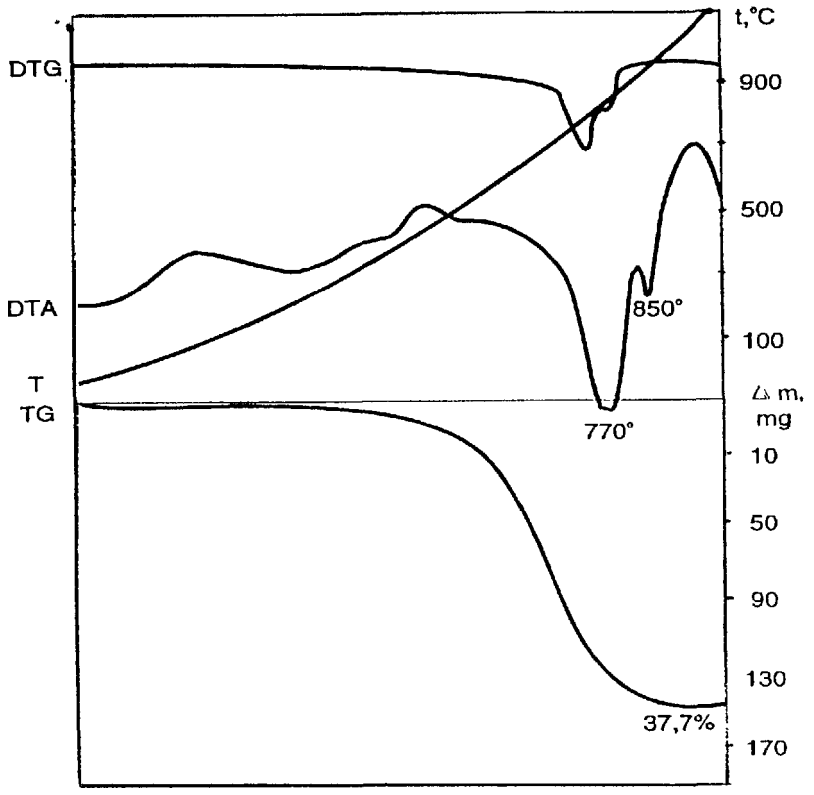

Figure 1 Derivatogram of Sloka-Kudra domerite;
curves: DTG - differential mass losses;
DTG - differential thermal analysis;
T - temperature;
TG - mass losses.

In the DTA curve the first endotherm at 770°C is due to the decarbonation of $MgCO_3$, the second - at 850°C relates to the decarbonation of $CaCO_3$. 850°C have been established to be the optima firing temperature of Sloka-Kudra domerite for obtaining dolomitic romancement. The main phases in material identified by powder X-ray diffraction (XRD) patterns are: β-$2CaO{\cdot}SiO_2$ (d/n=2,98; 2,51; 2,41Å), $2CaO{\cdot}Fe_2O_3$(d/n=2,80; 2,68; 3,70 Å); MgO(d/n=2,108; 2,43; 1,49Å); $CaO{\cdot}Al_2O_3$(d/n=2,98; 2,51; 2,41Å); $CaCO_3$(d/n=3,03; 1,87; 2,09Å). Free CaO is determined by saccharate method. The quantitative phase composition of material calculated from the results of chemical analysis is listed in Table 2.

Table 2 The quantitative phase composition of dolomitic romancement in dependence on the firing temperature of domerite

Phase	% of phase at the temperature	
	800°C	900°C
free CaO	2,00	4,35
$CaCO_3$	13,70	2,29
$CaO{\cdot}Al_2O_3$	8,09	9,58
$2CaO{\cdot}Fe_2O_3$	2,83	2,83
$2CaO{\cdot}SiO_2$	41,19	50,04
free MgO	13,21	21,61
total MgO	27,48	28,97
insoluble residue	3,74	1,23
total	99,03	99,34

Formation of various calcium containing phases is in agreement with DTA data-it is confirmed that simultaneously with decomposition processes of carbonates solid state reactions of formation of new phases take place. In Table 3 characteristic properties of dolomitic romancement obtained at 850°C and containing various additives are shown. Using special additive the setting time of dolomitic romancement is prolonged - with 1% - 2,5 times, with 2% - 4,7 times. Uneven of volume change is avoided and the mechanical strength is increased combining 2% of special additive with other additives such as; superphosphate; $CaSO_4 \cdot 2H_2O$ etc. (Table 3).

Table 3 Characteristic properties of dolomitic romancement containing 2% of special and other additives.

Additive	Water demand, %	Setting time		Change in volume	Compressive strength, MPa		Strength, %

It is stated that the fast hydration of the calcium aluminate ($CaO \cdot Al_2O_3$) is the factor which causes the quick setting of dolomitic romancement. The free lime activates this process. The way to avoid the influence of calcium aluminate and free lime is wetting and storage of fired dolomitic material in moist atmosphere before milling as well as using special additive. These procedures avoid also uneven volume change caused by overburned MgO, but simultaneously reduces the mechanical strength of dolomitic romancement. To improve the mechanical strength various additives are used. The most suitable additives and optima concentration of them are established. However the mechanism of interaction between additives and main phases of dolomitic romancement is not clear. It is proposed that up to optima concentration of

additives the chemical interaction between additives and active phases of romancement take place. But above the optima concentration additives are as aggregates and in some extant even hinder the chemical processes. It results in reducing the bonded water and mechanical strength of dolomitic romancement.

THEORETICAL FUNDAMENTALS OF THE APPLICATION OF EXPANSIVE CEMENT CONCRETES

Jochen Stark, Institute of Building Materials at the University Weimar, Germany
Igor Chartschenko, Institute of Building Materials at the University Weimar,Germany

ABSTRACT. The greatest stability of properties is found in expansive cements made on the basis of calcium aluminate sulphate and/or the formation of ettringite. The factors influencing the properties of ettringite-forming expansive cements are represented in a phenomenological model. The factors influencing the properties and the process of expansion are analysed.

Key-words: Expansive cement, ettringite, calcium aluminate sulphate

INTRODUCTION

Nowadays all the types of expansive cement that are suitable for industrial use cocsist of a matrix-forming binder and swelling components. Most of the expansive cements used in the building trade are based on ettringite, i.e. in addition to various types of Portland cement they also include additives containing calcium aluminosulphates as swelling components. The volume change which can be achieved when an expansive cement hardens depends to a great extent on the kinetic harmonization of these two processes which actualy operate in opposite directions. The swelling process depends on the quantity of the etrimgite, ist morphologiy, and the nature of ist formation, i.e. whether it crystallizes in the solution or on the surface of particles. The swelling potential can also be altered by changes in the ratio between the Portland cement matrix and the swelling component, as well as by the addition of various additives which have a specific effect on the ionoc content of the reaction solution.

Phenomenological model of expansive cements

Practical experience shows that the greatest stability of properties is found in expansive cements made on the basis of calcium aluminate sulphate and/or the formation of ettringite. The properties, i.e. first of all the process of expansion, which may be represented in the form of a tree ("expansive cement tree") (Fig. 1), depend on "external" and "internal" factors of influence. By the influence of these factors on the mechanism of ettringite formation, on the morphology of ettringite phase, on the amount of ettringite phase formed, on the kinetics of ettringite formation and on the properties of the portland cement matrix, which is called the fifth root of the expansive cement tree, the process of the formation of microstructure during the hardening of expansive cement can be controlled. The "external" factors of influence are temperature (sun), moisture (rain or drying-out) and the extent of impediment to the expansion process.

The "internal" factors of influence are, first of all, the hydraulic activity of the Portland cement portion, the expansive components and the additives which determine the content of ions in the reaction solution in the process of hydration. In addition, there are, of course, the water-cement ratio and the additives which enable the desired coordination between the hardening of the Portland cement matrix and the formation of ettringite to be achieved. The desired properties of expansive cements and a control of the expansion process in time and space can only be achieved if the processes which all five "roots" have to go through under the "external" and "internal" factors of influence are under control. As in nature, it is difficult to decide which root is the most important for the life of the tree and the quality of the fruit (in this case the properties of expansive cements). All of them make a different but equally important contribution.

Hydration and formation of the microstructure in expansive cements under the influence of "internal" factors

The physical-mechanical characteristics of expansive cements and expansive cement concretes are closely correlated with the relationship between the speed of hardening of the expansive cement matrix (= Portland cement portion) and the speed of ettringite formation in the first 3 to 5days of hardening and/or with the active formation of the microstructure of the hydrated cement. This may, for instance, be achieved by deliberately changing the fineness of both components of the expansive cement, i.e. the expansive cement matrix and the expansive component (Cohen and Richardts, 1982).

According to several authors (Cohen and Richardts, 1982; Kusnezova, 1986; Clastres et al, 1984; Deng and Tang, 1994; Ludvig; 1991) and our own test results (Chartschenko et al, 1994; Chartschenko and Stark, 1993a and 1993b; Chartschenko, 1994) there is no universally valid relationship between the amount of ettringite formed and the amount of expansion. An interdependence does only exist if the quality of all components of expansive cement is constant and the external conditions do not change (Kusnezova, 1986).

By changing the concentration of ions and particularly the OH-content in the reaction solution it is possible to exert an active and deliberate influence on the crystallization of ettringite and the formation of a certain type of crystal (Cohen and Richardts, 1982). Practically, by means of the properly adjusted pH-value during the initial hardening of expansive cements the morphological formation of ettringite and thus the formation of the microstructure of the hydrated cement may be controlled.

Our investigations have shown that different mineral additives to high-alumina/gypsum expansive cement (TG-QZ) can influence the ion-content and particularly the content of OH-ions in the reaction solution and in this way also the kinetics of ettringite formation, the morphology of ettringite and finally the properties of expansive cement. The expansive cement was produced by homogenizing a mixture of high alumina cement and ground gypsum in the stoichiometric relationship of the ettringite for 60 minutes. Mineral additives were silica powder (SF), ground opal (O) as natural puzzolanic component, siliceous chalk (K) burnt at 1000°C and ground, pure calcium hydroxide (CH) and ground silica sand.

Our investigations have shown that depending on the type of mineral additives the pH-value of the pore solution of high alumina/gypsum expansive cement (TG-QZ) differed greatly in the first 24 hours after mixing had begun (addition of mixing water) (Fig. 2).

Particularly interesting are the properties of TG-QZ with calcium hydroxide (CH) and siliceous chalk (K). These additives showed an very great difference between amount of expansion and compressive strength (Fig. 3 and 4). Although just after mixing the pH-value was nearly the same, it decreased from 12.5 to 9.7 within the first six minutes when burnt siliceous chalk was used and then remained constant for up to 72 hours. The analysis of the products of hydration showed that ettringite was formed at the same speed and after three days amounted to about 85%. In TG-QZ with calcium hydroxide the pH-value remained practically constant for the first ten minutes and decreased to 9.6 in the following 10 minutes. After a period of stabilisation on this level in the following 7 hours the pH-value increased to 12.3 and remained constant for 28 days. The formation of ettringite amounted to 70% after 24 hours and after 48 hours had achieved 90% of the final value.

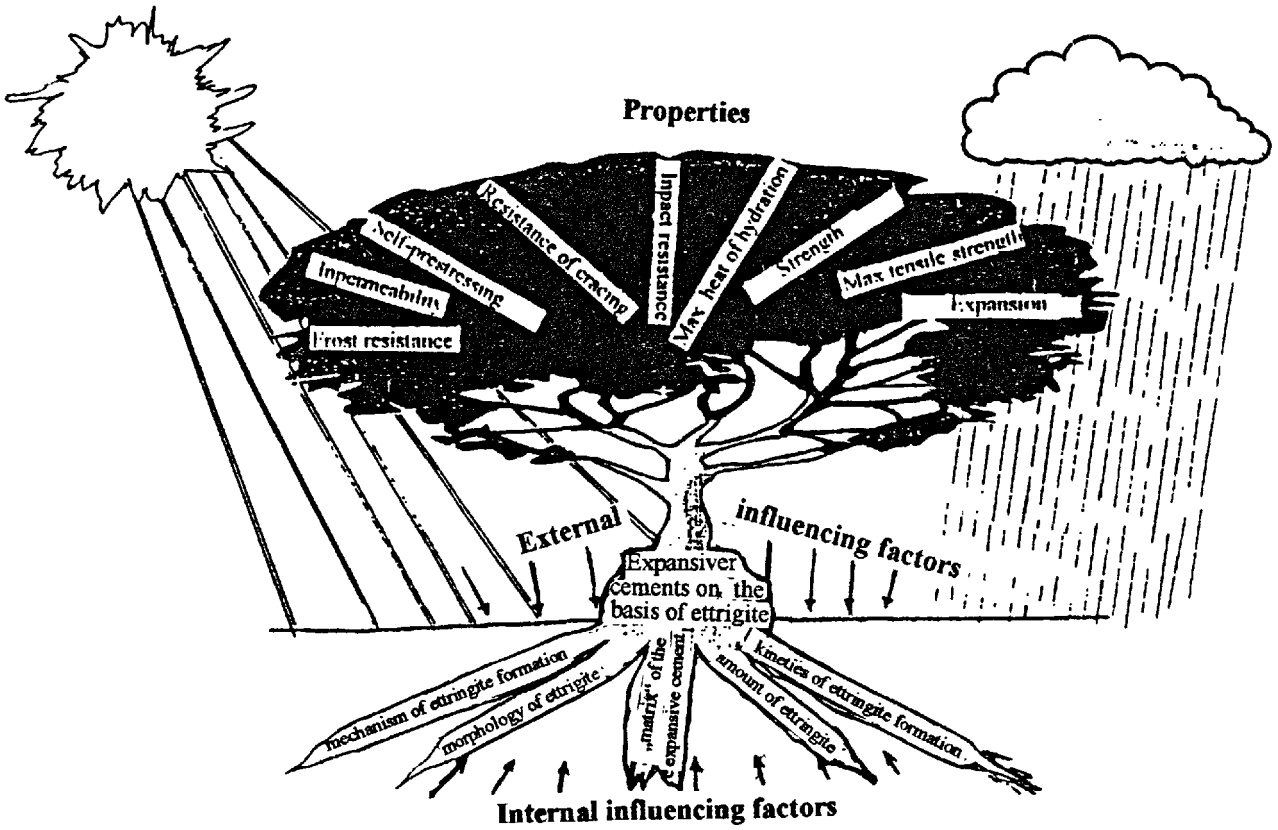

Figure 1: Expansive cement „tree"

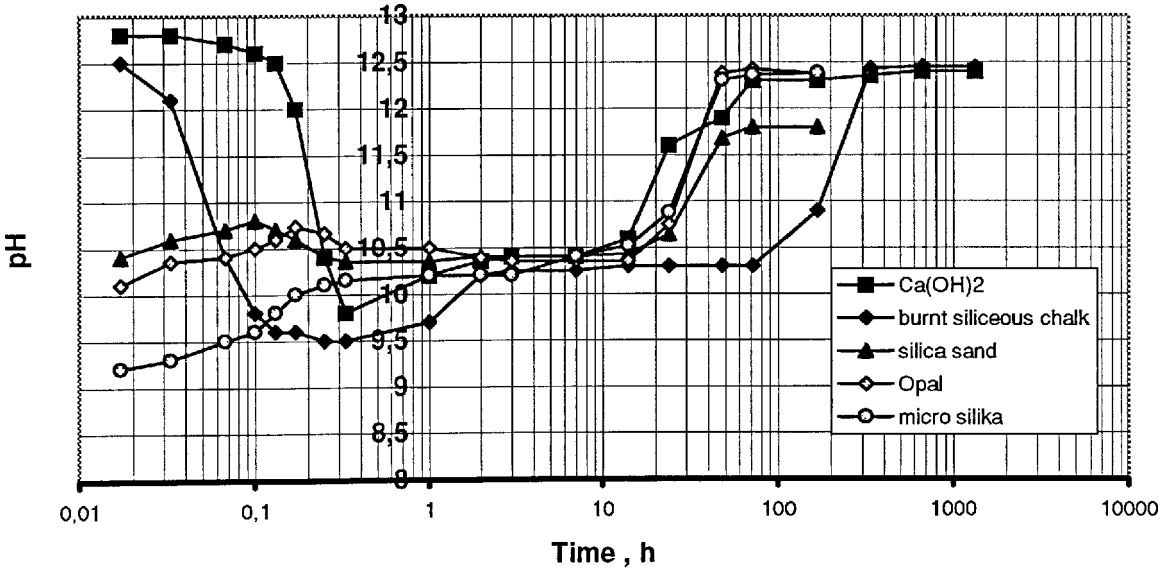

Figure 2: Changes in pH-value during the hydratation of high alumina/gypsum expansive cement with different mineral additives

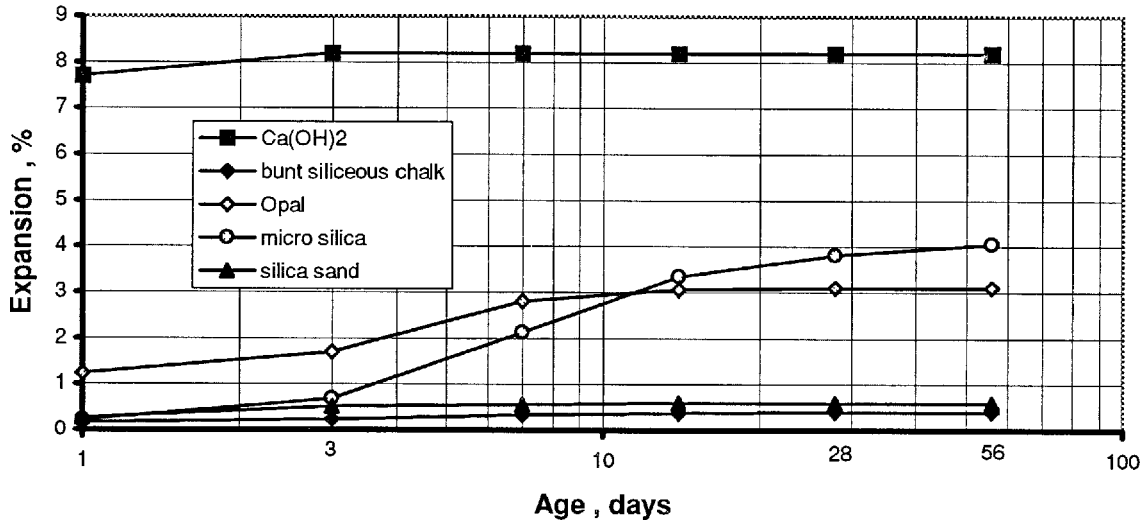

Figure 3: Amount of expansion of high alumina/gypsum expansive cement with different mineral additives

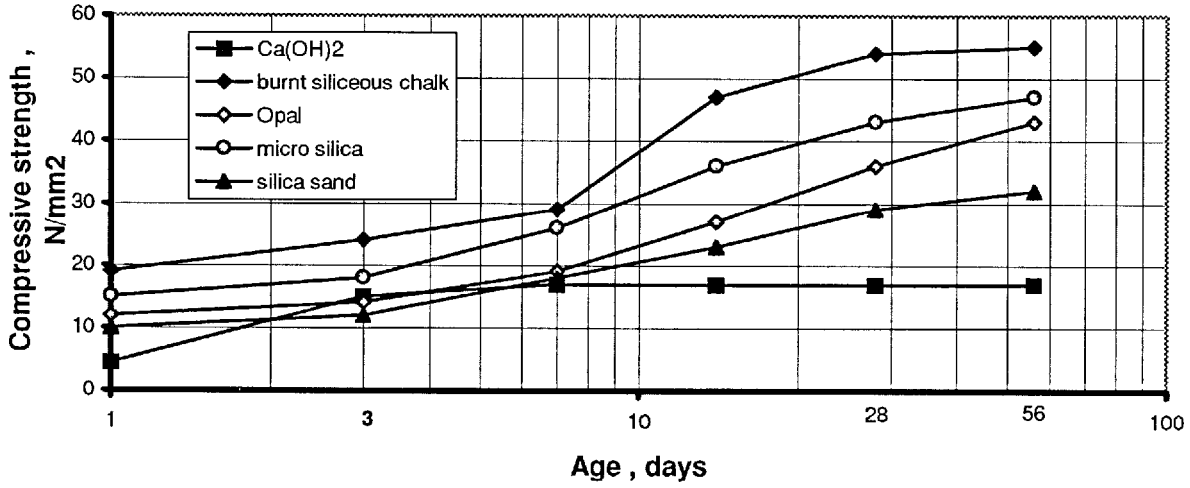

Figure 4: Compressive strength of high alumina/gypsum expansive cement with different mineral additives

The interspace between the separating layer and the unhydrated clinker minerals becomes too small and the ettringite shell is destroyed. After the destruction of the ettringite shell around the clinker mineral particles the process of hydration is continued as can be seen from the strong increase of the pH-value (Fig. 2). After this period a highly active expansion process with an increase in volume by more than 8% can be observed (Fig. 4).

The hydration process of TG-QZ with burnt siliceous chalk (K) as an additive, its kinetics of ettringite formation, process of expansion, and other properties of the hydrated cement differ greatly from the preceding descriptions, although the pH-value in the first minute was nearly the same. The phase analysis of siliceous chalk after burning at 1000°C showed that this additive contained calcium oxide as well as calcium silicate of a low basicity. Each component had a specific influence on the kinetics of the ettringite crystallization, its morphology and finally on the properties of the expansive cement. In the first two minutes the hydration process of TG-QZ is similar to that of the above mentioned expansive cement with calcium hydroxide. The higher pH-value of 12.3 is due to the calcium oxide content in the burnt siliceous chalk. It may be considered to be the cause of the increased solubility of the calcium aluminates just after mixing and of the formation of the separating layer of fine crystalline ettringite on the surface of unhydrated cement clinker particles. Burnt siliceous chalk contains only a relatively small amount of calcium oxide or calcium hydroxide after mixing with water and these amounts are quickly neutralised by calcium aluminate. Therefore, only a rather thin layer of ettringite crystals is developed whose strength and density are lower than in the case of pure calcium hydroxide. After a reaction time of about 60 minutes the pH-value increases from 9.4 to 10.3 which may be considered a consequence of the destruction of the ettringite layers. The phase analysis in this period showed an increase in ettringite content and proportionally a decrease in gypsum content in the hydrated cement. Due to the difference in concentration of hydration products below the separating layer and beyond it ettringite nuclei "dart" at a high speed deeply into the capillary pore space near the cement particles where they crystallize. First studies into the formation of ettringite under an environmental scanning electron microscope confirm that in the presence of reacting agents ettringite forms suddenly and not as previously assumed by slow growth of the crystals.

The ettringite nuclei play the role of a crystallization centre, i.e. as the nucleus of the crystallization of the primary ettringite. Microscopic examinations showed that in the further course of hydration single clusters of ettringite developed independently and without any connection to each other. It may be concluded that in this case the crystallization pressure of the hair-shaped ettringite does not contribute to the increase in volume of the cement paste and rather plays the role of a fibre reinforcement for the gel-like hydrates.

The consequence of these stresses is an increase in volume of up to 0.25% during the hardening of the expansive cements in the first three days, the formation of fine crystalline hair-shaped ettringite which crystallises under the influence of the low pH-value of 10.2, and at the same time the development of pressure. These results confirm that the amount of expansion is not only determined by the amount of ettringite formed but that the morphology of ettringite, which depends on the pH-value, also plays an important role.

SULFATE SOLUBILITY IN HIGH SO_3 CLINKERS

V. MICHAUD & R. SUDERMAN,
LAFARGE CANADA INC., Corporate Technical Services, Montreal, Quebec, Canada

ABSTRACT Changes in the cement manufacturing process such as the use of higher sulfur fuels have tended to raise clinker sulfate levels and SO_3/alkali ratios. As a consequence, interground gypsum additions to cement have dropped because more sulfate is available from the clinker. Also, these clinker sulfates tend to be available as double sulfate salts; calcium langbeinite instead of potassium sulfate.
What is the impact of clinkers with high SO_3 level on concrete performance; mainly on its workability and durability ? The aim of this study is to provide some answers to this question.
Calcium langbeinite is rapidly dissolved. Because of its dissolution rate and ability to form "blocking ettringite", high calcium langbeinite clinkers should provide improved rheological properties. Moreover, cements made with clinkers containing significant quantities of calcium langbeinite should have a similar workability and durability to a cement made with a low sulfate clinker to which larger quantities of gypsum have been added.
The dissolution rate of anhydrite potentially existing in very high SO_3/alkali clinker has also been simulated. Experiments indicate that it dissolves and reacts quite quickly so that it should not provide any durability problem if present in cement and concrete.

KEY-WORDS : high SO_3 clinker, clinker anhydrite, calcium langbeinite, workability, rheology, durability.

INTRODUCTION

Changes in the cement manufacturing process such as the use of higher sulfur fuels, reduced dust wasting and lower SO_x emissions have tended to raise clinker sulfate levels and SO_3/alkali ratios. As two of the direct consequences :

- interground gypsum additions to cement have dropped because more sulfate is available from the clinker,
- calcium langbeinite ($Ca_2K_2(SO_4)_3$) is present as the predominant clinker sulfate phase, instead of arcanite (K_2SO_4) and aphthitalite ($K_3Na(SO_4)_2$) for low SO_3/alkali clinker.

Very few studies have been done on the impact of high SO_3 level clinkers on concrete performance. The aim of this study is to shed some light; mainly on its workability and durability.

Sulfate ions play an important role on concrete performance at short term ; namely its workability. According to the nature of the sulfate phases, they will have different dissolution rates and solubilities. If they provide sufficient quantities of calcium and sulfate ions to the solution, they contribute to the formation of the hydrated calcium sulphoaluminate layer at the surface of the C_3A and, for a period of time, "block" further aluminate hydration. If the sulfate and calcium ions are less readily soluble,

C_3A hydration is not slowed, and hydrated calcium aluminate phases and ettringite are formed in the solution away from the surface of the C_3A particle. Because of their morphologies, if these phases are present in sufficient quantities, they adversely affect concrete rheology.
When cement is prepared from clinker with a low SO_3/alkali ratio, the sulfate phases; alkali sulfate, gypsum and hemihydrate, have a good efficiency in slowing C_3A hydration. The hemihydrate, by providing a much higher quantity of calcium and sulfate ions into solution than the gypsum, contributes the most to blocking C_3A hydration.
It is known that calcium langbeinite dissolves quite rapidly but its rate has not been determined in relation to the early hydration reactions. Because calcium langbeinite is present in clinkers with high SO_3/alkali ratios, which could require little or no interground gypsum addition, it will be determined if this phase can be dissolved rapidly enough to slow C_3A hydration.

It has recently been suggested that high SO_3 clinker could contain anhydrite (Mielenz et al., 1995) and that it would dissolve particularly slowly because of the high temperature of clinkerization. They alleged that it would continue liberating sulfate ions into the solution for a long period, forming ettringite, and therefore would have a negative effect on concrete durability.
Clinker anhydrite is certainly not common. Up to now it has never been detected even in modern industrial clinkers with a relatively high SO_3 level (Miller, 1996). Therefore, it might only be present in clinkers with extremely high sulfate amounts.
This study will examine the dissolution rate of anhydrite potentially existing in clinker as it could impact on concrete durability.

DISSOLUTION RATE OF CALCIUM LANGBEINITE AND DETERMINATION OF ITS EFFICIENCY TO BLOCK C_3A HYDRATION.

High SO_3 clinker containing calcium langbeinite has been simulated by pure phase materials and hydrated without any addition of calcium sulfate up to one hour. Solid and liquid phase evolution with time have been followed.
The pure clinker phase materials used are the ones implicated in early hydration; calcium langbeinite, C_3A and $Ca(OH)_2$. The calcium hydroxide represents clinker free lime which provides a source of calcium and hydroxide ions for short term hydration, soon after water is added.

Two different initial quantities of calcium langbeinite were used. The amount of water added was calculated to be equivalent to clinkers containing :

- 0.74% K_2O and 2.1% SO_3,
- or 1.18 % K_2O and 3.36 % SO_3, respectively

hydrated at a water/cement ratio of 0.35.

Experimental conditions

Calcium langbeinite (either 0.223 or 0.357 mole per liter) , C_3A (0.185 moles per liter) and $Ca(OH)_2$ (0.675 moles per liter) were stirred at 23°C with water for various times between 5 seconds to 1 hour.
At selected time intervals after water addition, the liquid and solid phases were separated by filtering. The solid phases, after being washed with acetone and ether,

were analyzed by X.R.D. The solution concentrations were measured by atomic absorption spectroscopy for calcium and potassium, by turbidimetry for sulfate and by titration with a 0.05 N HCl solution in the presence of helianthine indicator for the hydroxide ions.

The calcium langbeinite was synthesized by heating an inter-ground mixture of arcanite and gypsum in the stoechiometric proportions of calcium langbeinite in a closed container at 800°C for 48 hours.

Dissolution rate of calcium langbeinite

For the two initial quantities of calcium langbeinite, the changes in the solution concentration with time are shown in Fig 1 (Fig 1(a) is an enlargement of Fig 1(b)).

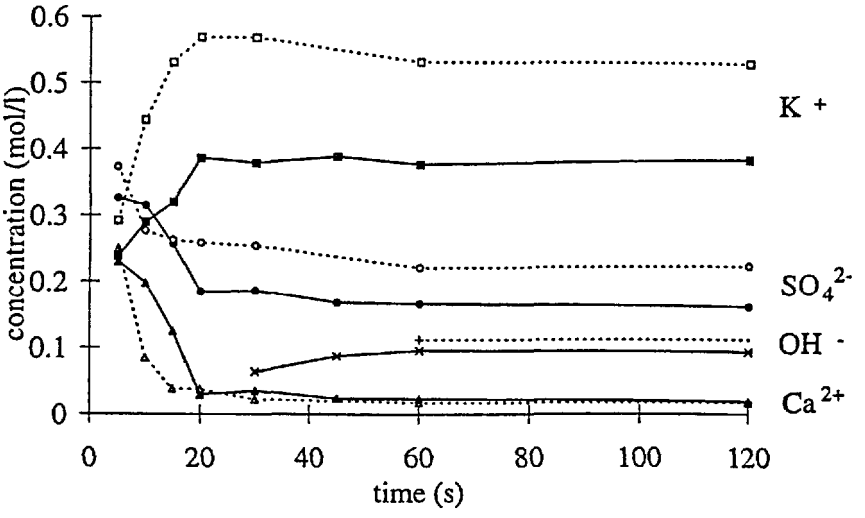

Figure 1a

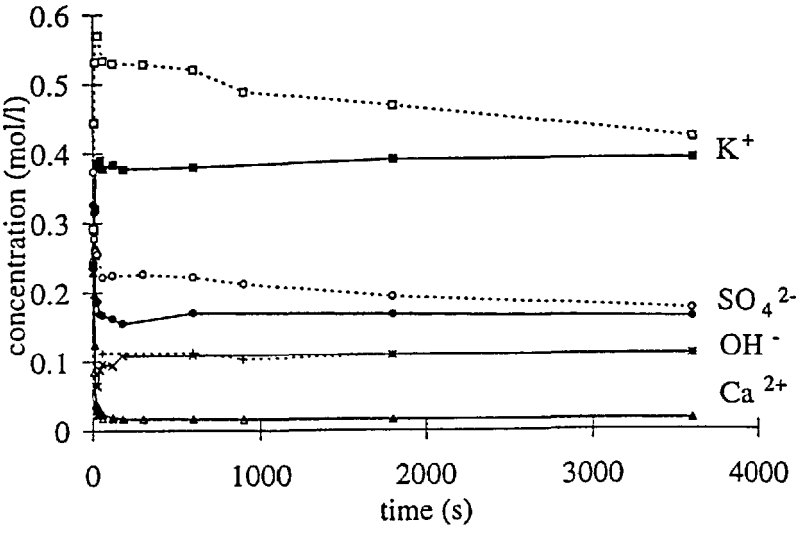

Figure 1b

Figure 1 Evolution of the ions in solution for mixtures of calcium langbeinite, C_3A and $Ca(OH)_2$. The dotted lines represent an equivalent clinker SO_3 of 2.1% and the solid lines a clinker SO_3 of 3.36% hydrated at a water/solids ratio of 0.35.

From these results and the XRD analysis of the residual solid phases, the calcium langbeinite reacts very rapidly. It is mostly dissolved after 5 seconds and totally after 20 seconds. Its dissolution initially liberates a very high quantity of calcium, sulfate and potassium ions into the solution.

How does the system evolve once the solution is very concentrated in calcium, sulfate and potassium ions ? The solution is supersaturated with respect to gypsum for the two amounts of calcium langbeinite and to syngenite only for the higher initial amount of calcium langbeinite. These phases precipitate consuming calcium, sulfate and potassium ions. Whatever the initial quantity of calcium langbeinite, gypsum begins to precipitate as soon as 10 seconds of hydration, and its quantity increases up to 30 seconds of hydration. With the higher initial quantity of calcium langbeinite, syngenite is also precipitated after 30 seconds and its quantity increases up to 1 hour.
The calcium and sulfate ions also react with aluminate ions provided by C_3A to form ettringite. This latter phase can be detected by X.R.D. after 3 minutes of hydration.
However, after one hour, only a very minor quantity of C_3A has reacted.

As shown on Fig 1(a), the solutions for the two initial quantities of calcium langbeinite tends towards the same composition ($[K^+]$=0.385 mol/kg, $[Ca^{2+}]$= 0.0153 mol/kg, $[SO_4^{2-}]$= 0.155 mol/kg, $[OH^-]$=0.11 mol/kg), determined by the phases in thermodynamic equilibrium with the solution; ettringite, gypsum, syngenite and portlandite.

The almost instantaneously dissolution of the calcium langbeinite liberates a very high quantity of calcium and sulfate ions into the solution. This condition, in conjunction w-ith the small amount of C_3A that had reacted after 1 hour indicates that calcium langbeinite can form a "blocking" ettringite layer around the C_3A.

Is the calcium langbeinite as efficient as the sulfate phases in a cement composed of low SO_3 clinker, arcanite, gypsum, and hemihydrate in blocking C_3A hydration ?

To compare the ability of calcium langbeinite in blocking C_3A hydration with either potassium sulfate and gypsum or hemihydrate, the same experiments were performed using blends of potassium sulfate and gypsum, or potassium sulfate and hemihydrate, instead of calcium langbeinite. Relative quantities of K_2O, SO_3, C_3A, calcium hydroxide and water have been maintained identical to the ones for the simulated clinker with an equivalent SO_3 of 2.1%.
The gypsum used was an industrial grade product with 97 % purity. The hemihydrate was prepared by heating the gypsum at 100°C for 14 hours.

The changes in solution with time for the mixture containing potassium sulfate and gypsum are compared with the ones containing calcium langbeinite and are shown in Fig 2.

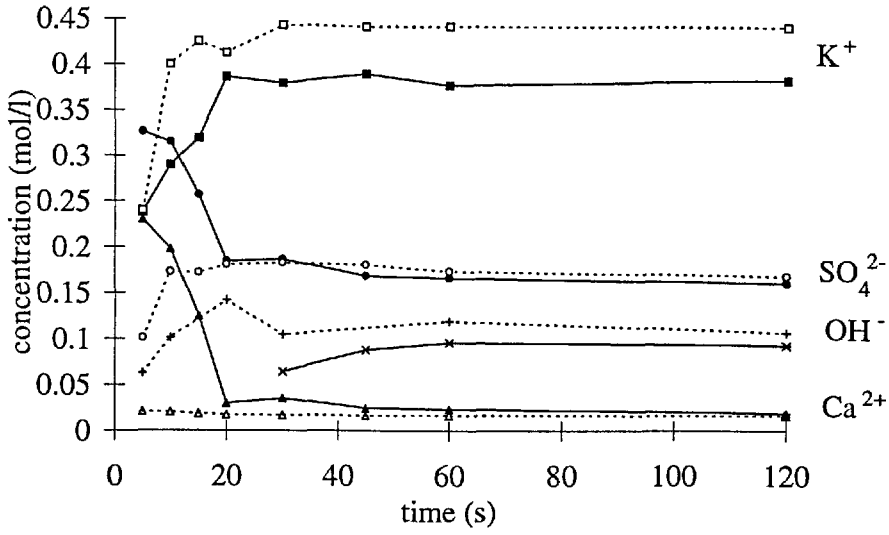

Figure 2 Comparison of the evolution of the ions in solution for mixtures containing either calcium langbeinite or potassium sulfate and gypsum. C_3A and $Ca(OH)_2$ are also present. The dotted lines represent potassium sulfate and gypsum. The solid lines represent calcium langbeinite. The initial sulfate quantity in both cases is equivalent to a clinker with 2.1% SO_3.

From these results and the XRD analysis of the residual solid phases, the mixtures initially composed of either calcium langbeinite, or arcanite and gypsum :

- have a different behaviour for the first 20 seconds of the hydration. At 5 seconds, the sulfate and calcium ions concentrations of the calcium langbeinite mixture is much higher than of the potassium sulfate and gypsum mixture; 0.32 mol/l versus 0.10 mol/l for the sulfate and 0.23 mol/l versus 0.021 mol/l for the calcium ions.
- have a similar behaviour after 20 seconds of hydration. They contain the same solid phases; gypsum, portlandite and also ettringite detected after 3 minutes of hydration. The ionic concentrations are virtually identical and governed by the solid phases in equilibrium with the solution.
  Syngenite is also present in a very minor amount after one hour for the mixture initially conposed of arcanite and gypsum.
  The only difference is the lower potassium concentration for the mixture initially composed of calcium langbeinite; a consequence of the stoichiometry of the calcium langbeinite used here. Its $K_2SO_4/CaSO_4$ ratio is slightly less than 0.5.

Therefore, the calcium langbeinite is at least as efficient as potassium sulfate and gypsum in slowing C_3A hydration.

The changes in the solution concentrations with time for the mixture containing potassium sulfate and hemihydrate are compared with the ones containing calcium langbeinite and are shown in Fig 3. (Fig 3(b) is an enlargement of Fig 3(a)).

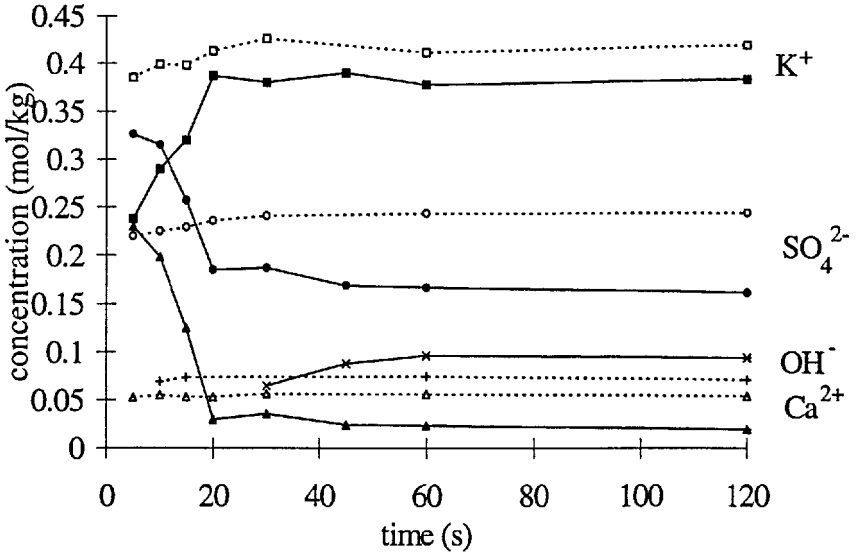

Figure 3a

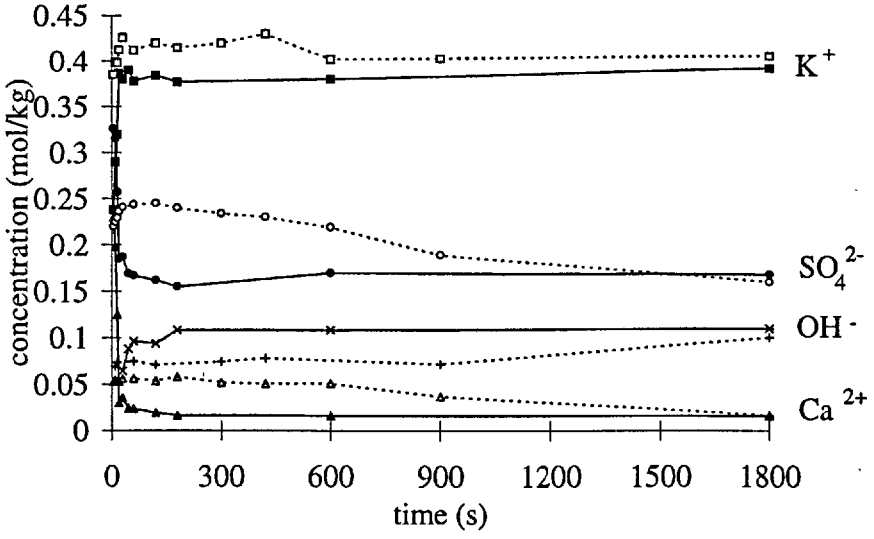

Figure 3b

Figure 3 Comparison of the evolution of the ions in solution for mixtures containing either calcium langbeinite or potassium sulfate and hemihydrate. C_3A and $Ca(OH)_2$ are also present. The dotted lines represent potassium sulfate and hemihydrate. The solid lines represent calcium langbeinite. The initial sulfate quantity in both cases is equivalent to a clinker with 2.1% SO_3.

For the first 15 minutes, the concentrations of calcium, sulfate and hydroxide ions in solution are different for the two mixtures. For the first seconds, due to the instantaneous dissolution of calcium langbeinite, the mixture initially containing this

phase exhibits higher calcium and sulfate ion concentrations than the hemihydrate and potassium sulfate mixture. After 15-20 seconds, the reverse is true and the hemihydrate mixture provides higher calcium and sulfate ion concentrations. This results from the presence of residual hemihydrate in this mixture for the first 5 minutes. The calcium and sulfate concentrations in solution are at that time determined by its solubility. Then the quantity of hemihydrate decreases until it is not detectable after 10 minutes. At the same time, after 5 minutes, gypsum begins to precipitate and its quantity increases up to 30 minutes. This is accompanied by a decreasing of the sulfate and calcium concentrations and an increasing of the hydroxide ion concentration. The concentrations tend towards those of the mixture of calcium langbeinite. Ettringite begins to be detected by XRD after 3 minutes of hydration.
After 30 minutes of hydration, the mixtures initially containing either calcium langbeinite or arcanite and hemihydrate, have identical behaviors. The ion concentrations and the solid phases are nearly similar; gypsum, portlandite and ettringite. At that time, the solution is virtually in equilibrium with the solid phases. A small amount of syngenite is also detected after one hour in the arcanite and hemihydrate mixture.

From these results, it is difficult to determine if the calcium langbeinite is as effective in slowing C_3A hydration as potassium sulfate and hemihydrate. For the first few seconds calcium langbeinite provides the solution with more calcium and sulfate ions however after 20 seconds the situation reverses.

THE DISSOLUTION RATE OF ANHYDRITE.

In this part of the study, the dissolution rate of anhydrite potentially existing in very high SO_3/alkali clinker was studied by hydrating model systems simulating clinker containing anhydrite.
For comparison and to predict the influence of clinker anhydrite on concrete durability, a mixture with a similar chemical composition but containing gypsum instead of clinker anhydrite has also been examined.

Clinker and cement have been simulated using pure phase materials; C_3A, $Ca(OH)_2$, calcium langbeinite and anhydrite or gypsum. Since anhydrite may only be found in clinker with a very high SO_3 / alkali ratio in conjunction with calcium langbeinite, the mixtures used here contain both.
Clinkerisation temperatures of 1400°C are typical and the burning zone residence time is 10 - 20 minutes. Thus in order to synthesize anhydrite similar to that which could be present in clinker, it was produced from gypsum burned at 1400°C for 2 hours. For comparison, dissolution rates of natural anhydrite and anhydrite synthesized from gypsum burned at 500°C have also been determined.

Experimental conditions

Mixtures containing C_3A (0.875 moles per liter), portlandite (1.0135 moles per liter), calcium langbeinite (0.223 mole per liter) and either anhydrite or gypsum for comparison (0.335 moles per liter), were stirred at 23°C for various times between 2 hours and 16 days. These amounts correspond to a clinker or cement which contains 0.74% K_2O, 2.81% SO_3 and 3.12% Al_2O_3, hydrated at a water / solids ratio of 0.35.

The solid phases were examined by XRD. The ionic concentrations were measured for the first 5 days.

Results and interpretation

Fig 4 indicates that the 1400°C anhydrite dissolves at the same rate as natural anhydrite. It has totally reacted at 4 days. The 500°C anhydrite dissolves much faster.

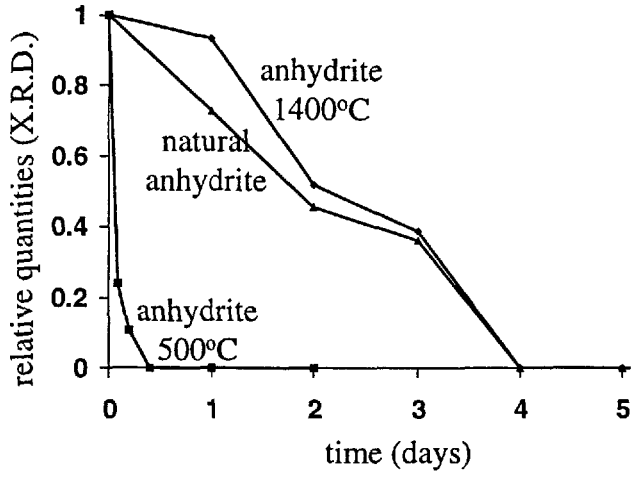

Figure 4 Evolution of the anhydrite amount for mixtures containing either 1400°C, 500°C or natural anhydrite. Calcium langbeinite, C_3A and $Ca(OH)_2$ are also present.

The changes with time of the amounts of the various solid phases present in the hydrating mixtures containing calcium langbeinite and gypsum are shown in Fig 5. They have been determined from XRD analysis.

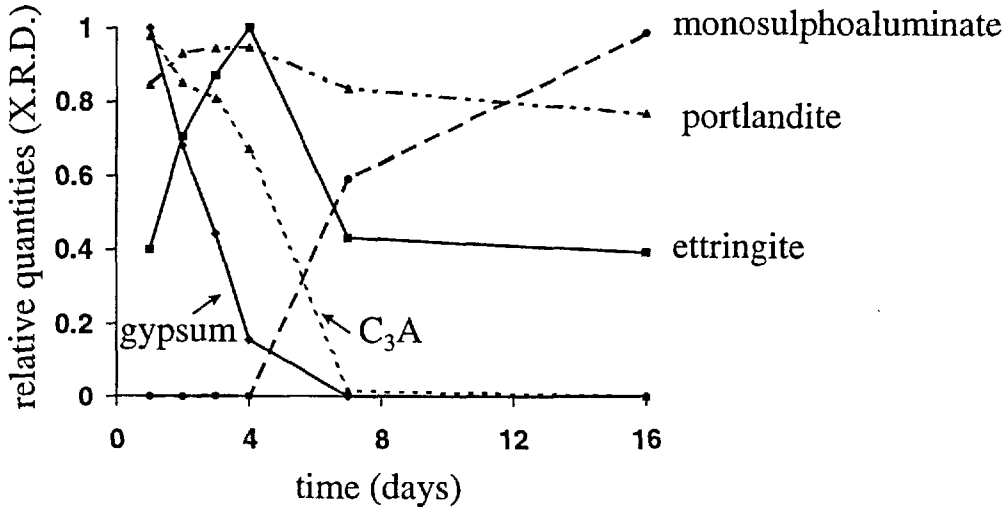

Figure 5 Evolution of the various solid phases quantities with time for the mixture of gypsum, calcium langbeinite, C_3A and $Ca(OH)_2$.

Secondary gypsum is precipitated from calcium langbeinite within a few minutes of the start of hydration. The solid residue at that time is composed of gypsum, ettringite, portlandite, a very little quantity of syngenite and residual C_3A. C_3A is converted to ettringite while significant quantities of gypsum are present. For this period, the solution concentrations remain constant regulated by the solid phases in

equilibrium with the solution; $[K^+]$=0.385 mol/kg, $[Ca^{2+}]$= 0.0153 mol/kg, $[SO_4^{2-}]$= 0.155 mol/kg, $[OH^-]$=0.11 mol/kg.
After 5-6 days, when the gypsum amount is negligible, the amount of ettringite begins to deplete as the remaining calcium and aluminate reacts with ettringite to form monosulfoaluminate.

This study has been carried out without calcium silicates. However, even if C-S-H were present, the equilibria should not be appreciably different. A thermodynamic calculation from ionic activities, by using the method by Pitzer and Mayorga (1973) has shown that the C-S-H phase is in equilibrium with the hydrated phases present in the first 5 days; ettringite, gypsum, syngenite and portlandite and its presence does not affect the concentrations in solution.

The evolution with time of the amounts of the various solid phases present in the hydrating mixtures containing calcium langbeinite and either 1400°C anhydrite or gypsum are compared in Fig 6. They have also been determined from XRD analysis.

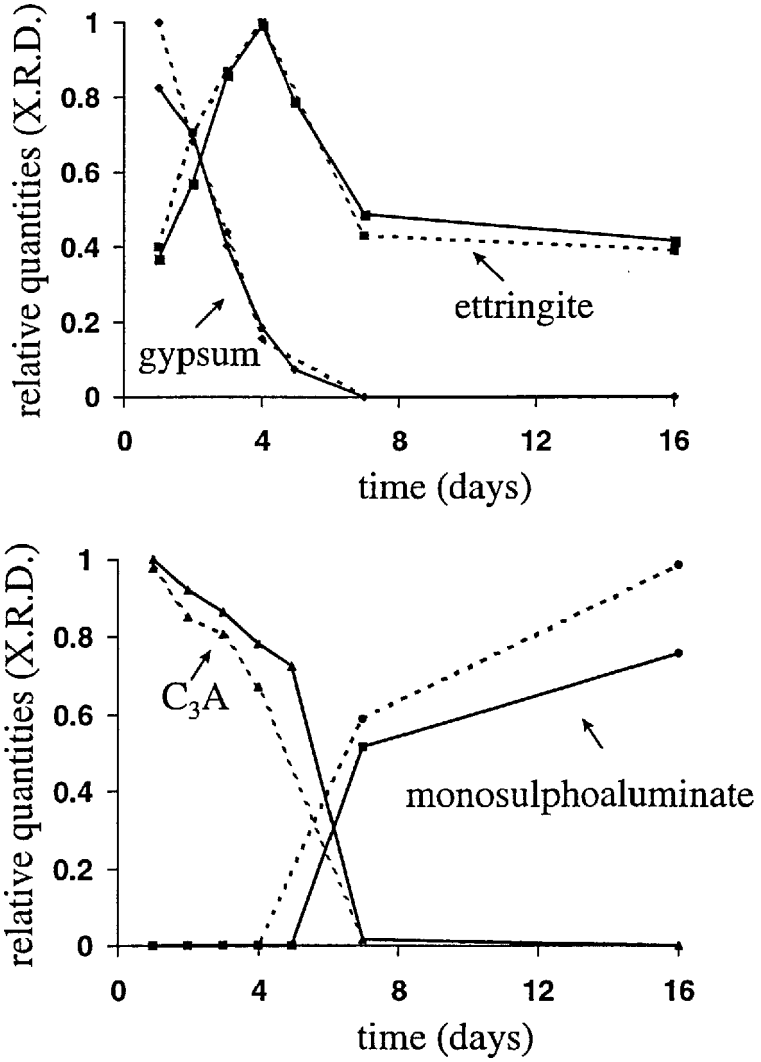

Figure 6 Comparison of the evolution of the various solid phases quantities with time for the mixture containing calcium langbeinite and either gypsum or 1400°C anhydrite. C_3A and $Ca(OH)_2$ are also present. The dotted lines represent gypsum. The solid lines represent 1400°C anhydrite.

Fig 6 shows that the two mixtures have a similar evolution of the hydrated phase amounts with time. It is also true for the portlandite, not shown here. Also, the anhydrite is gone before the remaining C_3A reacts with ettringite to form monosulfoaluminate. Therefore, the presence of anhydrite in the clinker should not affect the durability of the cement paste.

CONCLUSIONS

The present study shows that calcium langbeinite, one of the sulfate forms found in clinkers with high SO_3 level and SO_3/alkali ratio, is rapidly soluble. Cements made with clinkers containing significant quantities of calcium langbeinite even without addition of any calcium sulfate, should have similar performances at short and long term to a cement made of a low sulfate clinker to which large quantities of gypsum have been added.

As for anhydrite, the study indicates that even if it is burned at 1400°C for 2 hours, it has a relatively high dissolution rate. If present in clinker, it should not adversely affect the durability of concrete.

This study also provides indications of the maximum content of potassium in cement to avoid syngenite precipitation and associated false set. For a cement containing only potassium as alkalis, this phase will precipitate if the concentration of potassium in the pore solution is higher than 0.39 mole per liter. In a hydrating cement system with a w/c ratio of 0.5, this corresponds to an available K_2O content of 0.93%.

EFFECT OF ALKALI SULFATES ON CEMENT HYDRATION AT LOW AND HIGH WATER - CEMENT RATIOS

Arezki TAGNIT-HAMOU and Salaheddine BOURAOUI

Faculty of Applied Sciences, Université de Sherbrooke, Sherbrooke (Québec) CANADA

ABSTRACT The optimum SO_3 content in cement is determined by the required setting time and compressive strength, as well as rheological properties and expansion of the paste. Part of the SO_3 found in cement is provided by alkali sulfates. In this study, three differents clinkers having high and low C_3A contents were investigated with different forms of alkali sulfates and/or calcium sulfates. Test results indicate that the sulfate form has an important effect on the slump of cement paste. This slump is negatively affected by the presence of arcanite or aphthitalite but improved by calcium langbeinite . Mortars made with gypsum addition give the best compressive strength at 28 days. The action of the superplasticizer is affected by alkalis from alkali sulfate.

Key-words: Admixtures, alkali, fluidity, hydration, sulfate.

INTRODUCTION

Cement hydration is a complex phenomenon. The effect of the major phases of portland cement have been reviewed extensively by various researchers. The effect of minor elements has however been less studied and can lead to different interpretations. The addition of different forms of calcium sulfates (gypsum, hemihydrate or anhydrite) to the clinker controls the hydration of C_3A. This hydration is controlled by providing SO_4^{2-} and Ca^{2+} ions to the solution to precipitate ettringite ($C_3A.3CaSO_432H_2O$). The influence of calcium sulfate on rheological characteristics of cement paste is not only dependant on the calcium sulfate content, but also on its solubility (Tang and Tresouthick, 1992). The faster the SO_4^{2-} ions go into the solution, the better the workability and its retention can be.

Sulfate ions in paste solution are not provided only by adding calcium sulfates, but also by the alkali sulfates of the clinker . These alkali sulfates are very soluble (more than any added calcium sulfate) (Bensted, 1983). Depending on its form, the alkali sulfate provides different alkalis (K^+, Na^+) or calcium ions (Ca^{2+}) to the solution. The alkalis are known as activating agents for the cement hydration.

In low W/C ratio concretes, the control of rheological properties is critical because of the low water content and the need to use superplasticizer. The interaction between C_3A, sulfates and alkalis is complicated by superplasticizer addition (Tagnit-Hamou and Aïtcin, 1993).

In this paper, results on the effect of different alkali sulfates on fluidity and compressive strengths of three different cement pastes and mortars are presented.

ORIGINS AND FORMS OF ALKALI SULFATES IN CEMENT

Portland cement clinker is produced by heating a raw mix of calcium carbonate (limestone), aluminosilicates (clay) and iron to a temperature of about 1450° C. In the raw mix and near the main constituents (silicon, aluminium, calcium and iron) there are some minor constituents: magnesium, potassium, sodium, sulfur and others. Nowadays, extensive energy-saving attempts have resulted in a change in pyroprocessing technology, the decreasing in low alkali raw materials and of course, the severe environmental restrictions lead to an increase in alkali and sulfate concentrations in clinker. Clinker contains four main mineralogical phases, i.e. tricalcium silicate (C_3S), dicalcium silicate (C_2S), tricalcium aluminate (C_3A) and tetracalcium aluminoferrites (C_4AF). Alkalis and sulfur give rise to alkali sulfates because sulfur makes prior demands on the alkalis. The remainder can be introduced in the crystal structure of the phases.

Potassium sulfate (K_2SO_4) is likely to occur either alone or in one of two double sulfate forms, aphthitalite ($Na_2SO_4.3K_2SO_4$) or calcium langbeinite ($2CaSO_4.K_2SO_4$). Sodium sulfate may occur in double sulfate form (aphthitalite) only. Calcium sulfate occurs either alone or as calcium langbeinite, subject to the prior formation of double alkali sulfate (Jawed and Skalny, 1977; Pollit and Brown, 1968; Tagnit-Hamou and Sarkar, 1990). The ratio of total clinker sulfur to total alkali, determines the quantity of alkali sulfate. This ratio is known as sulfatization degree ($SD\% = SO_3 \times 100 / 1.292\ Na_2O + 0.85K_2O$). Kiln environments have some effect on double salt formations. Calcium langbeinite is formed in oxydating conditions, but aphthitalite is better formed in reducing conditions (Mander and Skalny, 1977). After the formation of alkali sulfates, the remaining alkali and sulfur are combined in silicate, aluminate and aluminoferrite phases. Sodium is mainly incorporated in C_3A lattice and gives rise to orthorombic C_3A . These phases are known as less reactive than the cubic form. Potassium and sulfur are substituted mainly in C_2S (Regourd, 1983).

OBJECTIVE

This research is divided into two parts. The first part investigates the effect of addition of different alkali sulfate and calcium sulfate forms on cement hydration, at constant SO_3 content. The second part deals with the effect of addition of different alkali sulfate forms combined with mixtures of gypsum and hemihydrate on cement hydration, at constant alkali contents.

EFFECT OF DIFFERENT CALCIUM SULFATE AND ALKALI SULFATE FORMS ON CEMENT HYDRATION, AT CONSTANT SO_3 CONTENT

Three clinkers are mixed and ground in laboratory ball mill with different additions of calcium sulfates (gypsum or hemihydrate) or alkali sulfates (arcanite, aphthitalite or calcium langbeinite). The clinkers used have different phase compositions (Table 1). The K01 and K02 clinkers have the same C_3A content (6%); however, the K01 clinker has a mixture of cubic and orthorombic, while the K02 clinker had a cubic C_3A. Clinker K03 has 9% of C_3A in cubic form (Figure 1). Alkali sulfates are synthesized in laboratory ovens and controlled by X-ray diffraction.

Table 1 Chemical and Bogue compostions of tested clinkers

Chemical composition (%)				Phases composition (%)			
Clinker	K01	K02	K03		K01	K02	K03
SiO_2	21.3	21.99	22.22	C_3S	65	70	69
Al_2O_3	4.6	4.05	4.35	C_2S	12	11	11
Fe_2O_3	4.0	3.02	1.75	C_3A	6	6	9
CaO	65.3	65.9	66.33	C_4AF	12	9	5
MgO	2.2	2.82	2.92	CaOf	0.6	1.4	0.3
SO_3	0.8	0.6	0.78	L.O.I.	0.5	0.4	0.5
Na_2O	0.25	0.34	0.30	SD*	72	91	100
K_2O	0.92	0.26	0.46				
Na_2O eq.	0.80	0.51	0.61				

* $SD = SO_3 . 100 / 1.292\ Na_2O + 0.85\ K_2O$

Sulfates are added in order to ensure 3% of SO_3 for the K01 and K02 clinkers and 4.5% for the K03 clinker which has a higher C_3A content. The cement Blaine fineness was kept constant at 360 m^2/kg. Table 2 summarizes the characteristics of the cements.

Table 2 Cements SO_3 and alkalies (as Na_2O) composition

Cement	SO_3 (%)	Na_2Oeq (%)	Cement	SO_3 (%)	Na_2Oeq (%)	Cement	SO_3 (%)	Na_2Oeq (%)
C01G	3.0	0.8	C02G	3.0	0.51	C03G	4.5	0.61
C01H	3.0	0.8	C02H	3.0	0.51	C03H	4.5	0.61
C01CL	3.0	1.38	C02CL	3.0	1.13	C03CL	4.5	1.57
C01Arc	3.0	2.54	C02Arc	3.0	2.37	C03Arc	4.5	3.48

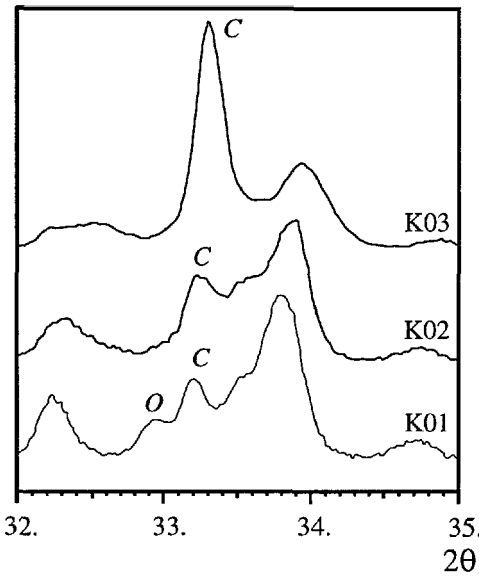

Figure 1 X-ray diffraction spectrum of three clinkers (C= cubic C_3A, O= Orthorombic C_3A)

All cements grouts were mixed with water at two different W/C ratios, 0.50 and 0.30. A naphtalene-sulfonate superplasticizer (SP) was used with the lower W/C grout. The optimum superplasticizer content was selected for each cement using the flow time test measured by the Marsh Cone (Baalbaki, 1990). The hydration was followed by X-ray diffraction, calorimetry and extracted pore solution analysis by atomic absorption for Ca^{2+} and K^+ and by colorimetry for SO_4^{2-}. Cement grouts and mortars were also tested for rheological and compressive strength behavior.

Results

Figure 2 shows the mini-slump results of the three cement pastes at W/C ratios of 0.50 and 0.30.

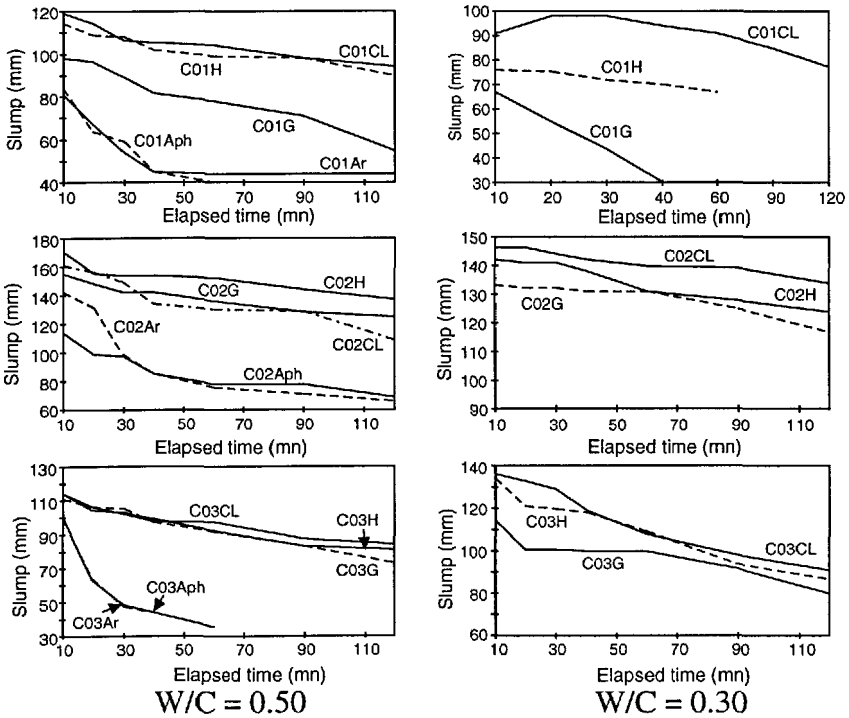

Figure 2 Mini-slump versus hydration time of the three cement pastes at W/C 0.50 or 0.30.

Despite these clinkers' identical major phase contents, with the C01 series cements, in all the cases, lower slumps and faster slump loss were obtained than with the C02 series. This is because of the reactivity of C_3A. Because of its orthrombic C_3A content, the K01 clinker is less reactive than the K02 clinker. This leads to a faster ettringite formation in the C02 cements, which exhibits better slump retention. According to Sorrentino (Sorrentino, 1996), the ettringite formed with reactive C_3A is an effective hydration controler which is not the case with needle-like crystallized ettringite formed with less reactive C_3A . The reactivity of those cements is also shown in the calorimetric analysis (Figure 3).

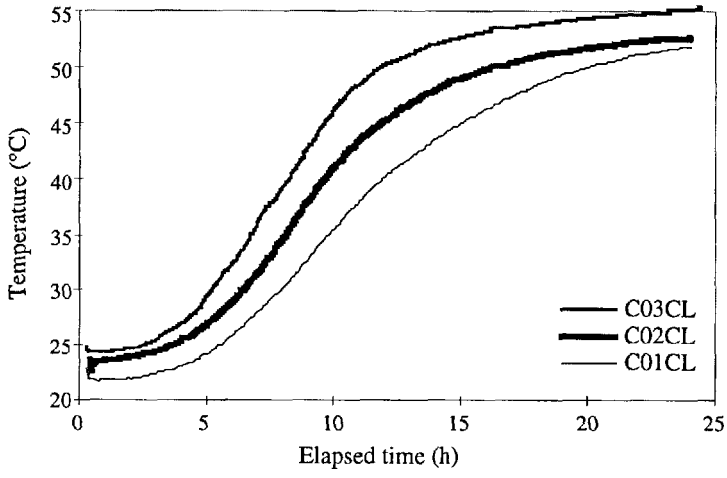

Figure 3 Calorimetric analysis of C01CL, C02CL and C03CL cements

Because of the lower C_3A content, the cements of the C02 series show higher slump than those of C03 series despite a higher SO_3 content (4.5%) in the latter series. Due to high alkali content, the cements of all three series with arcanite or aphthitalite show very poor slump at 0.50 W/C and do not flow at all at a W/C of 0.30, even with 0.8% superplasticizer content.

Calcium langbeinite cement shows very good slump, which was equal or better than the hemihydrate or gypsum cements, despite its high alkali content. This good slump of calcium langbeinite cement is enhanced at the low W/C of 0.30. This is due to very fast release of SO_4^{2-} and also Ca^{2+} ions into the solution.

In order to follow the effect of high alkali content on SP content, the mini slump of different pastes prepared with cements from C01, C02 and C03 series incorporating aphthitalite (C01 Aph, C02 Aph and C03 Aph) was measured. The pastes had a W/C of 0.50 and varying SP contents. Figure 4 summarizes the results.

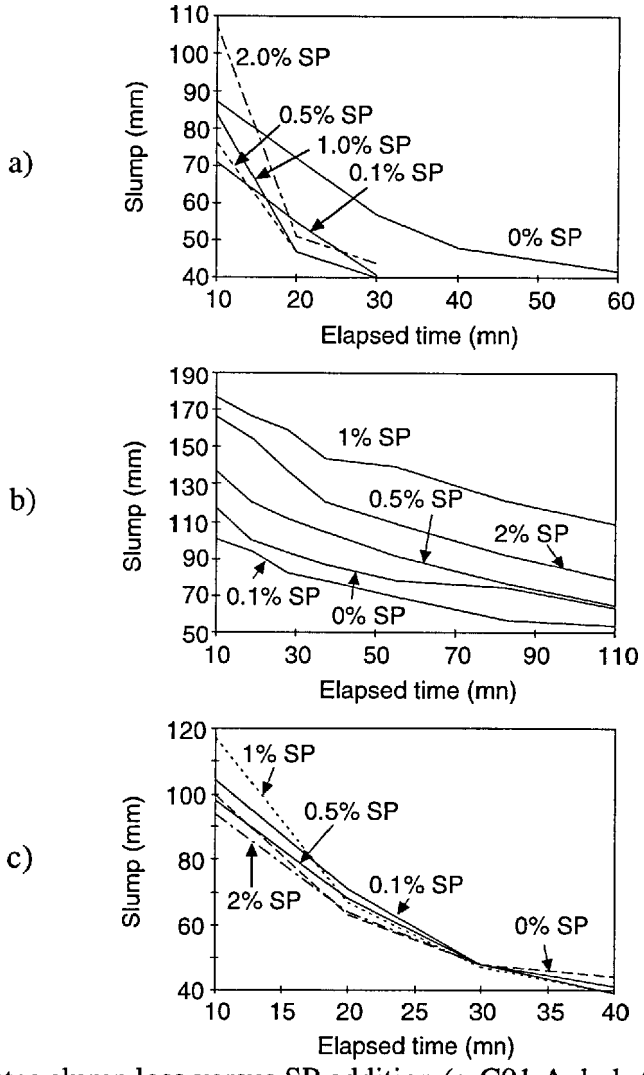

Figure 4 Cement pastes slump loss versus SP addition (a-C01 Aph, b-C02 Aph, c-C03 Aph) at 0.50 W/C

This figure shows that even at 0.50 W/C, the C03 cements need at least 1% of SP to reach the same slump as the lower alkali content cements. Such pastes exhibit sharp loss in fluidity. The less reactive C_3A (C01) and the high C_3A content cements (C03) show very fast slump loss, and the effect of SP dosage disappears after 30 minutes. At a 2% SP dosage, the slump loss is more critical than the case of 1% SP content. It is clear here that with this amount of alkalies (2.5% for C01 Aph, 2.37% for C02 Aph and 3.48% for C03 Aph), it is impossible to improve the flow of the paste, especially when the C_3A content is high (C03) or when it is less reactive (C01). According to Nawa et al. (Nawa et al., 1989) the low alkali sulfate content in the clinker decreases the SP adsorption on C_3A and C_4AF and increases the paste fluidity by a better effect on silicate phases. An excessive alkali sulfate content, however, increases the viscosity by compressing the electric double layer of the silicate phases and the strong floculation of cement particles.

From extracted pore fluid analysis of C02 and C03 cements after 10 and 60 minutes of hydration for pastes with 0.50 W/C, it is clear that because of their high solubility, arcanite and aphthitalite are providing more SO_4^{2-} ions to the solution at given time than the other sulfates followed by calcium langbeinite (Figure 5). Among the various calcium sulfate types, the hemihydrates give more SO_4^{2-} ions to the solution than that of the gypsum. The difference in SO_4^{2-} provided by arcanite or aphthitalite and calcium langbeinite is that the former is converted to gypsum or syngenite but arcanite or aphthitalite stays in the solution, as confirmed by XRD. This is also shown by the low Ca^{2+} content in the pore solution in the case of calcium langbeinite. This shows that the SO_4^{2-} ions alone are not sufficient to

control the paste fluidity; the concentration of Ca^{2+} ions are also very important. For that reason, calcium langbeinite shows good ability to control cement paste fluidity. This effectiveness is also shown at a W/C of 0.30 with SP which is even better than calcium sulfates because of its slow conversion to gypsum or syngenite.

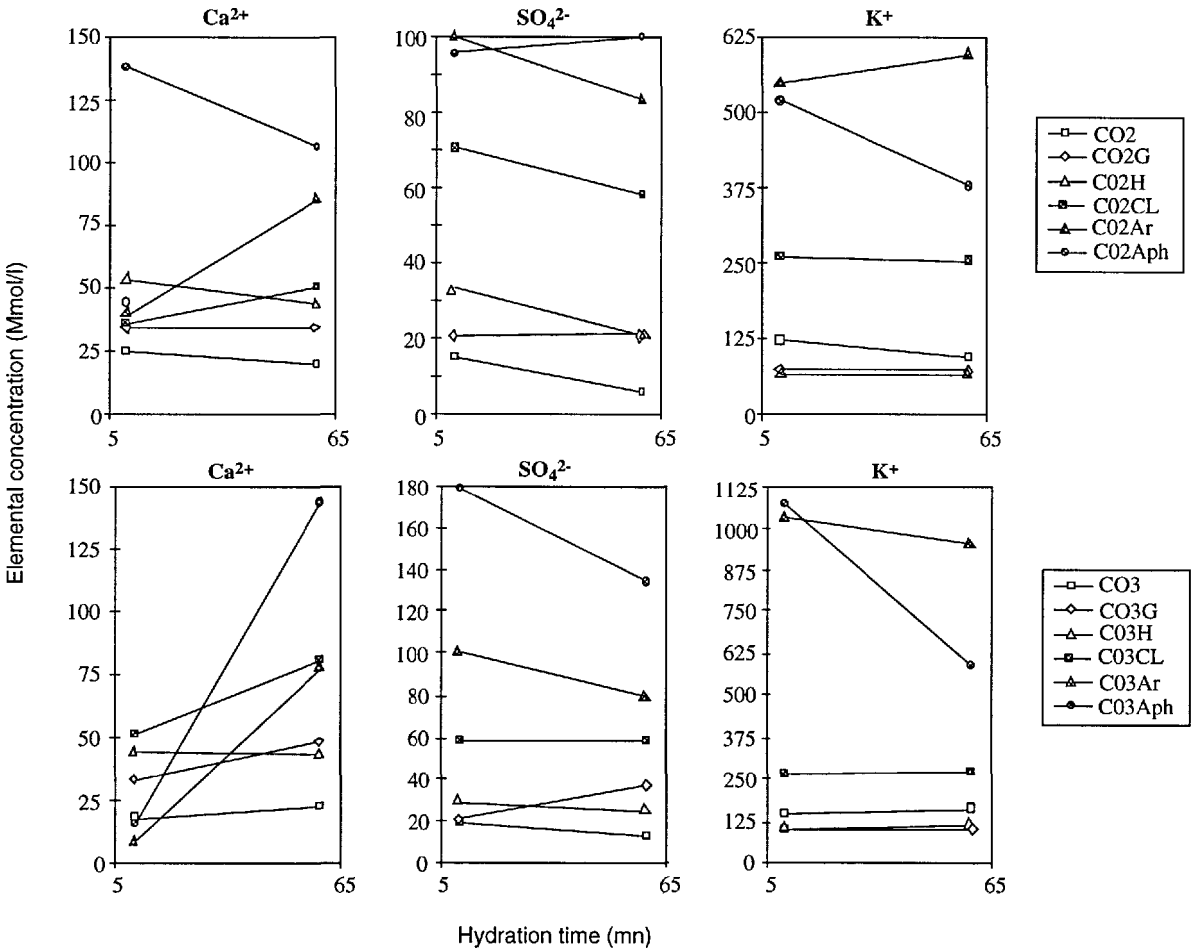

Figure 5 Extracted pore fluid analysis of C02 and C03 cement pastes at 0.50 W/C ratio

EFFECT OF DIFFERENT ALKALI SULFATES COMBINED WITH THE MIXTURE OF HEMIHYDRATE AND GYPSUM ON CEMENT HYDRATION, AT CONSTANT ALKALI CONTENT

The two clinkers K02 and K03 were all ground with different additions of alkali sulfates to ensure 1.2% Na_2O eq. in each cement. A mixture of gypsum and hemihydrate was also added to ensure a content of 3% SO_3 in the K02 clinker and 4.5% in the K03 clinker. One can note that to reach this goal with the K02 clinker, there was no need for gypsum or hemihydrate in the case of calcium langbeinite. The cements' Blaine fineness was kept constant (around 370 m^2/kg).

Results

Figure 6 shows the mini-slump results of cements pastes prepared at 0.50 and 0.30 W/C ratio.

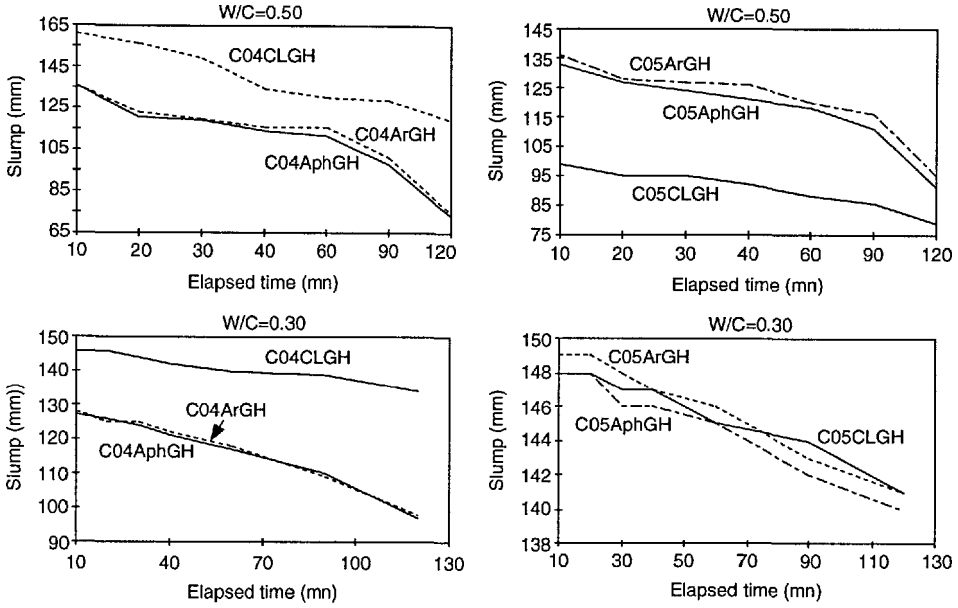

Figure 6 Mini-slump versus hydration time of the C04 and C05 cements at 0.50 and 0.30 W/C ratio

Again, the effectiveness of calcium langbeinite is shown to improve the paste fluidity. Even at the same alkali content (1.2% Na_2O eq.), calcium langbeinite cements exhibited the best flow with the K02 clinker. This confirms again that with the same alkali and SO_3 contents, the type of alkali sulfate is important, and Ca^{2+} ions from calcium langbeinite can control the alkali effects on fluidity. When the alkali sulfates, are mixed with gypsum and hemihydrate, they give rise to bad fluidity by syngenite and gypsum crystalization. This is the case for arcanite and aphthitalite cements but also for calcium langbeinite cement produced with the K03 clinker. At the low W/C ratio, the fluidity was well improved.

Compressive strength

The compressive strength results of all cement grouts are presented in Table 3. The well-known positive effect of alkalis on compressive strength at early age and negative effect at 28 days is noted here.

Table 3 Compressive strength of mortars

Cement	Compressive strength (MPa)						Cement	Compressive strength (MPa)					
	W/C = 0.50			W/C = 0.30				W/C = 0.50			W/C = 0.30		
	1d	7d	28d	1d	7d	28d		1d	7d	28d	1d	7d	28d
C02G	15	36	43	39	65	80	C04CLGH	25	34	38	44	56	68
C02H	14	28	32	34	59	73	C04ArGH	28	33	39	44	49	58
C02CL	15	28	33	35	43	57	C04AphGH	25	32	39	44	49	57
C02Ar	17	24	28	--	--	--	C05CLGH	24	33	39	54	60	68
C02Aph	17	24	29	--	--	--	C05ArGH	28	37	43	49	55	62
C03G	18	43	50	50	78	91	C05AphGH	25	37	42	48	55	61
C03H	15	31	34	37	67	80							
C03CL	16	30	35	39	55	69							
C03Ar	20	29	30	--	--	--							
C03Aph	20	29	31	--	--	--							

Cements with gypsum alone exhibited very good strength at all ages, especially at 28 days. This is more pronounced at a W/C of 0.30. Calcium langbeinite gives good results at early and late ages. In mixed calcium and alkalis sulfate cements, calcium langbeinite shows the best results mainly at 0.30 W/C .

CONCLUSION

The form of C_3A has a profound effect on the fluidity of cement paste. The effect of addition of alkali sulfates on such fluidity can be positive by providing sulfate (SO_4^{2-}) and calcium (Ca^{2+}) ions to the pore solution, or negative by the activating effect of alkali ions (Na^+, K^+), or by crystallization of syngenite. At high content in cement aphthitalite or arcanite present mainly the negative effect and require large amounts of calcium sulfate to control this effect which is worst at a low W/C ratio and with superplasticizer. Calcium langbeinite shows very good ability to control the very early cement hydration by providing Ca^{2+} and SO_4^{2-} ions to the pore solution. This ability is better at a low W/C ratio system containing SP. The best 28-day compressive strength is obtained when gypsum is incorporated in the cement.

THE CHANGE OF THE LIQUID PHASE COMPOSITION AND PROPERTIES OF HARDENED CEMENT PASTE AT LOW TEMPERATURE

Anatolij KLUSOV, RAO "GAZPROM", Moscow, Russia
Yuri KRIVOBORODOV, RCTU, Moscow, Russia
Asat ACHMETOV, Tumengazprom, Tumen, Russia

ABSTRACT Liquid phase composition, pH, density, electric conduction and freezing temperature during hardening of cement paste at +20 and -5°C with NaCl and $CaCl_2$ were studied. Oil-well cement of G-type was used. It was established that $CaCl_2$ reacted with calcium aluminate and ferrite earlier than ettringite. This fact excludes corrosion of the drill pipe.

KEY-WORDS: Hydration, low temperature, oilwell cement.

INTRODUCTION

There are many problems connected with the gas and oil deposit exploitation in the Arctic. In the first place is complicated geological conditions requiring special cements to isolate the pressured or week zones encountered whilst drilling of a well. On the other hand the rock temperature varies between -10 and 0°C. Therefore it is necessary that the cement should set at low temperatures, that the surrounding ground should not be disturbed by erosion during drilling or cementing or in the subsequent life of the well. Mixture based on Portland cement and $CaCl_2$ or NaCl could be used. But in spite on data of many researchers (Bensted, 1983, Butt and Kolbasov, 1976, Mironov and Lagoida, 1975, Skalny and Young, 1980, Taylor, 1990, etc.) on cement hydration at low temperature, using such accelerators as calcium chloride, they were not applied. Technical barriers appearing due to scepticism connected with the posibilities of cement paste destruction and well corrosion have been discussed. At the same time it impeded the study of hydration and structure formation of cement paste with high quantity of calcium and sodium chlorides.

EXPERIMENTAL

Materials and techniques

For study oil-well cement including C_3S=63.4%, C_2S=11.7%, C_3A=8.4%, C_4AF=12.2% was used. Using this cement and its mixture with 8% $CaCl_2$ or 8% NaCl standard samples were prepared. They cured at +20°C and -5°C in water. Hydrated products were examinated by XR-diffraction, differential thermal analysis (DTA), IR-spectroscopy (IRS) and electron microscopy (EM).

RESULTS AND DISCUSSION

At 20°C the main hydrate products are ettringite (endotherm at 140°C in DTA curves, absorption wave is in region 1120 cm^{-1}), CSH(I), which is observed by endotherm at 135°C, absorption wave of 980 cm^{-1} at IRS-curves, the fibrous material distinquished by EM) and $Ca(OH)_2$ crystallized in hexagonal crystals. NaCl-additive promotes the formation of $3CaO{\cdot}Al_2O_3{\cdot}3CaCl_2{\cdot}30H_2O$ (endotherm at 352°C and d=0.314 nm at XRD powder diffraction pattern).

At $CaCl_2$ presence the transoformation of CSH(I) into CSH(II) increases and besides them $3CaO{\cdot}CaCl_2{\cdot}16H_2O$ is formed, which observed by endotherm at 580°C on DTA-curves.

The hydration temperature decrease up to -5°C leads to the delay of ettringite formation. Addition of NaCl leads to C_4AH_{13}, $3CaO{\cdot}CaCl_2{\cdot}16H_2O$ formation. $CaCl_2$ accelerates the crystallization of $3CaO{\cdot}CaCl_2{\cdot}16H_2O$, CSH(II) and $3CaO{\cdot}Al_2O_3{\cdot}3CaCl_2{\cdot}30H_2O$.

Hydration of cement paste proceeds at the continuous change of ion composition of liquid phase, which influence on structure formation of cement paste. At same time liquid phase composition depends on the cement type, clinker structure, the presence of minor components in it, the addition of chemical compounds, and temperature conditions of hardening.

Liquid phase of cement paste hardened at 20°C is characterized by supersaturated $Ca(OH)_2$.Concentration of SO_4^{2-}ions is the result of two factors: in the first is the dissolution of $CaSO_4$, on the other hand ettringite is formed with the increase supersaturation of $Ca(OH)_2$.

NaCl addition into cement paste leads to high increase of Ca^{2+} ion concentration in liquid phase as well as the concentration of SO_4^{2-}ions, which showed that ettringite formation rate is reduced(Fig.1).

$CaCl_2$ addition of more than 10 times increases the supersaturation of liquied phase by Ca^{2+}. Nevertheless chlorine-ion decreases due to its adsorption by calcium hydrosilicates and formation of hydroxideclhoride compounds. The fast formation of ettringite was obvious.

At the presence of NaCl, the temperature increase does not influence on kinetics of liquied phase composition change: concentration maximum of Ca^{2+}, Na^{+}, SO_4^{2-} and pH reached up to 4 hours of hydration at 20°C. During 8 hours, concentration Cl^{-} ions decreased due to calcium hydroxide formation.

At -5°C concentration of Ca^{2+} ions increase during 1 hours, after that it is stabilized. At the presence of $CaCl_2$ and NaCl in this conditions (-5°C) the fast and large quantity of calcium hydroaluminachloride formation was obvious.

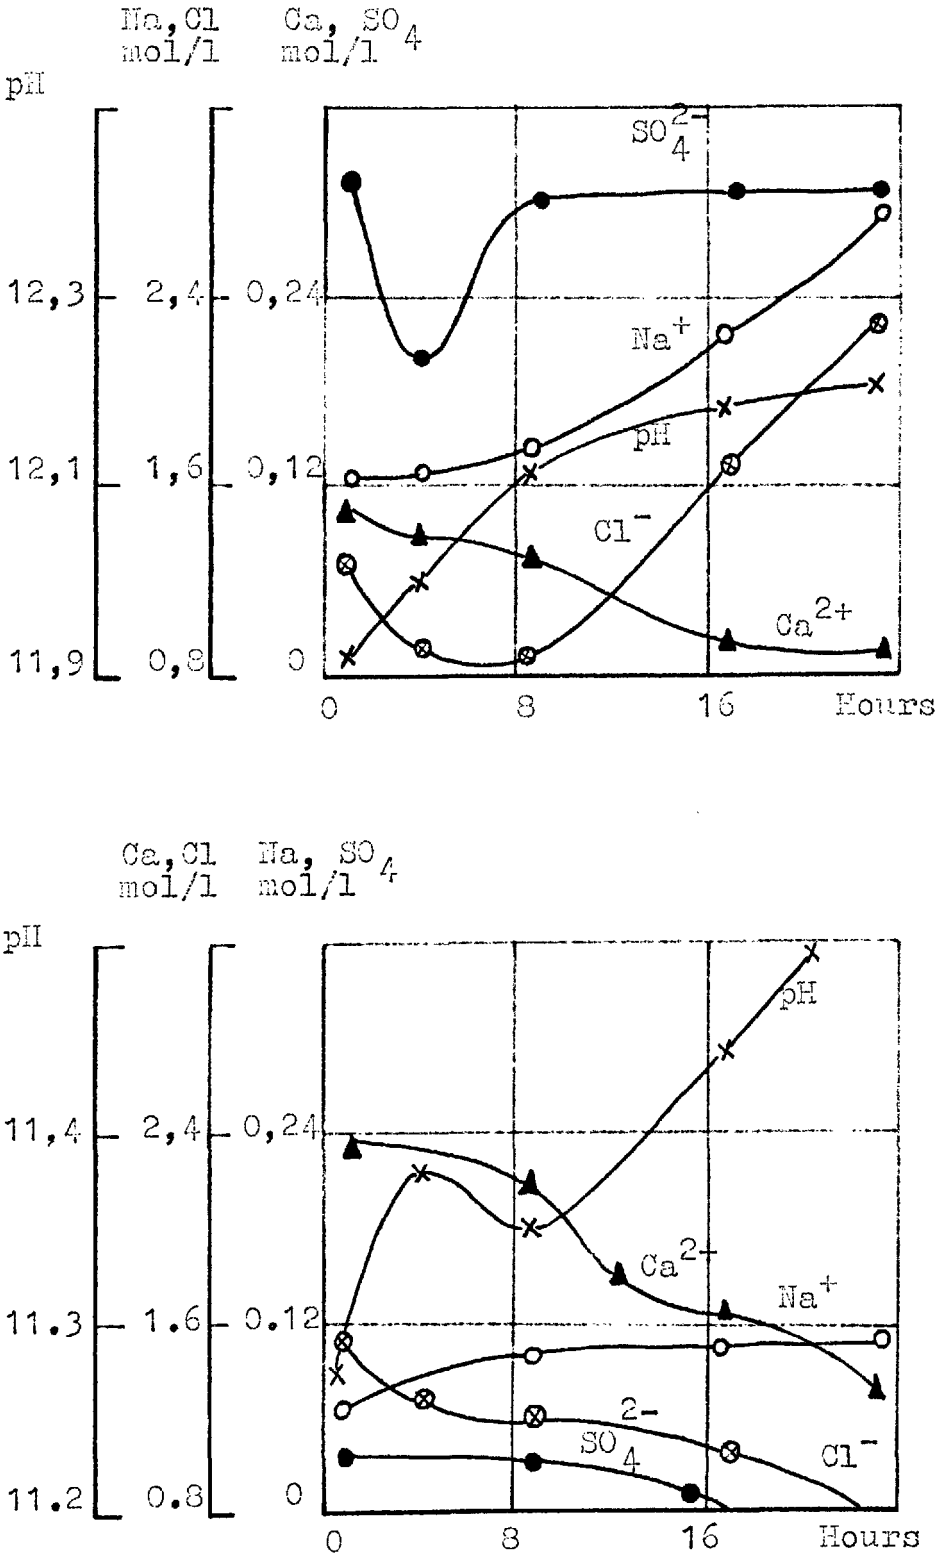

Fig.1 The change of ion concentration and pH of liquid phase in cement paste (temperature -5°C).

Comparing analysis of experimental data shows as follows:
- at 20°C ettringite formation proceedes not only through the solution but topochemically on the surface of gypsum grains because their solubility are less than C_3A crystals,
- at $CaCl_2$ presence the formation of calcium aluminochloride compounds proceeds simultaneously with ettringite formation,
- at -5°C cement hydration is stopped and only the addition of NaCl and $CaCl_2$ decreases the freezing temperature of liquid phase. In this case cement hydration takes place and hydrated products are formed. It was established that $CaCl_2$ and NaCl reacted with calcium aluminate therefore calcium aluminochloride is formed rapidly. Ettringite is crystallized after $3CaO \cdot Al_2O_3 \cdot 3CaCl_2 \cdot 30H_2O$ formation. At this time pH of liquid phase as well as Na^+ concentration increases. This excludes the corrosion of drill pipe string.

CONCLUSION

In presence of high concentration of $CaCl_2$ and NaCl in cement paste, calcium aluminochloride compound is formed.
The high pH of liquid phase of cement paste, and the absence of oxygen medium in air-tight grouting hole, exclude the corrosion of steel.

BEHAVIOR OF HEAVY METAL ELEMENTS IN THE HARDENING OF CEMENT PASTE

Hiroshi UCHIKAWA, Shunsuke HANEHARA and Hiroshi HIRAO,
Chichibu Onoda Cement Corporation, Japan

ABSTRACT The rate of hydration, morphology and composition of hydrates, distribution and dissolution of minor and trace element in and from, respectively, the hardened cement paste prepared by adding small amounts of various elements including heavy metals were investigated using normal portland cement and blastfurnace slag cement containing 50% of slag in order to clarify the effects of them from waste recently often used as alternative raw material and fuel on the properties and performance of concrete.

Key-words:Microstructure,Backscattered electron image,Heavy metals,Immobilization,Leaching

INTRODUCTION

With the spread of the utilization of waste as alternatives to the raw materials and fuel for manufacturing cement, it is feared that the elements of heavy metals, halogens and others remaining in cement detrimentally affect the performances of concrete (Uchikawa, 1992; Uchikawa, 1994; Uchikawa et al, 1997).

In this paper, the distributions of minor and trace elements of heavy metals, halogens and others in hardened cement paste and the quantities of them dissolved from the hardened specimens are determined and the effects of those elements on the hydration of cement and the formation of hardened structure are investigated.

EXPERIMENTS

Sample and preparation of cement paste

Normal portland cement and blastfurnace slag cement containing 50% of slag shown in Table 1 are used. The elements of heavy metals, halogens and others are added to the mixing water at the preparation of cement paste. The added amounts of them are fixed as shown in Table 2 considering the quantities of them previously contained in the waste (Shirasaka et al, 1996). The elements of heavy metals, halogens and others are added as their nitrates, chlorides, alkaline salts or ammonium salts. The W/C of cement paste is 0.5. It is weighed out into a 200ml-hermetically sealed vessel made of polyvinyl chloride to age at 20°C for 14 days. After aging, hardened cement paste is cut into pieces 5mm square with a diamond cutter and these pieces are immersed in acetone to terminate the hydration and dried in RH of 11% or D-drying to submit to various tests.

Table 1 Composition and fineness of cement used

	Chemical composition (%)								Bl'

Analyses of hydration of cement and hardened cement paste

The rate of hydration of cement is estimated by the determination of combined water using the ignition loss at 1000°C and of amount of Ca(OH)2 produced by Thermogravimetry - Differential Scanning Calorimetry (TG-DSC). The hydrates are observed by powder X-ray diffractometry.

The distribution of the elements of heavy metals, halogens and others is determined and the content of them are determined by the point analysis at twenty points by computer aided electron probe microanalysis (CMA/EPMA). The structure of hardened cement paste is observed by secondary electron image and back scattered electron image with a scanning electron microscope (SEM). The pore structure is determined by mercury-intrusion porosimetry.

Measurement of quantities of elements of heavy metals, halogens and others dissolved from hardened cement paste

The dissolved amounts of elements are measured according to Notification No.13 of Environment Agency of Japan as follows : the hardened cement paste at the age of 14 days is crushed into particles 0.5 to 2.5mm in diameter; the particles are immersed to pure water ten times as much as them; the mixture is shaken at 20°C for 6 hours; the particles are separated by filtration; and the contents of various elements in the filtrate are measured by high-frequency inductively coupled plasma analysis (ICP) or ion chromatography.

Table 2 Amount of minor and trace element added to cement for preparing cement paste

Element	added mount of element (%)	Type of salt
F	0.5	ammonium salt
P	0.5	ammonium salt
Cl	2.0	chloride
Ti	0.2	nitrate
V	0.1	ammonium salt
Cr	0.1	potassium salt
Cr^{6+}	0.1	ammonium salt
Mn	0.1	nitrate
Cu	0.1	nitrate
Zn	0.2	nitrate
As	0.1	sodium salt
Sr	2.0	nitrate
Cd	0.1	nitrate
Sb	0.1	chloride
Ba	0.2	nitrate
Hg	0.1	nitrate
Pb	0.1	nitrate

RESULTS

Effects of elements on hydration of cement

As mentioned above, the elements of heavy metals, halogens and others were added to cement as the form of salts. The effects of anions bound to the elements concerned will be reported separately.

The measured values of the combined water and the amount of Ca(OH)2 produced in normal portland cement and blastfurnace slag cement are illustrated in Fig 1. C-S-H, monosulfate hydrate (AFm) and Ca(OH)2 are identified in the hardened cement paste, while no ettringite (AFt) is identified.

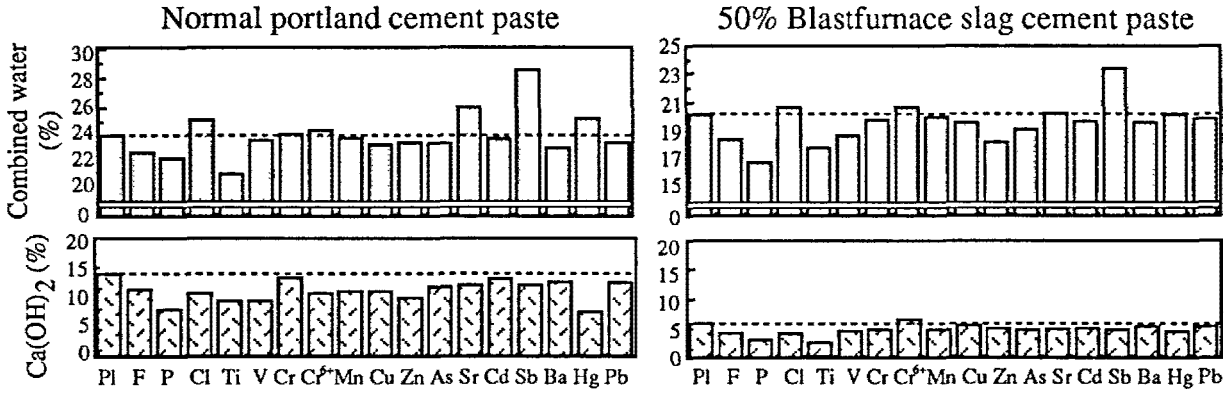

Figure 1 Amount of combined water and Ca(OH)2 in hardened normal portland cement paste and 50% blastfurnace slag cement paste prepared by adding various elements

Normal portland cement and blastfurnace slag cement contained 24.0 and 20.2% of the combined water, respectively. The content of combined water in normal portland cement paste adding Cl, Cr(III, VI), Sr, Sb, Ba and Hg was higher and that in blastfurnace slag cement paste adding Cl, Mn, Sr and Sb was higher than that without addition of them. Meanwhile, the amount of Ca(OH)2 produced in normal portland cement paste and blastfurnace slag cement paste adding those elements were less than that without addition of them. Maybe this is mainly because C-S-H with high Ca/Si ratio was produced.

The hydration of cement in normal portland cement and blastfurnace slag cement is remarkably depressed by adding P and Ti but accelerated by adding Cl, Sr, and Sb.

Effects of elements on morphology of hydrates and hardened structure

The secondary electron image of the fracture surface and the back scattered electron image of the polished surface of normal portland cement paste adding the elements of heavy metals, halogens and others are illustrated in Fig 2 together with those of the cement paste without adding any of

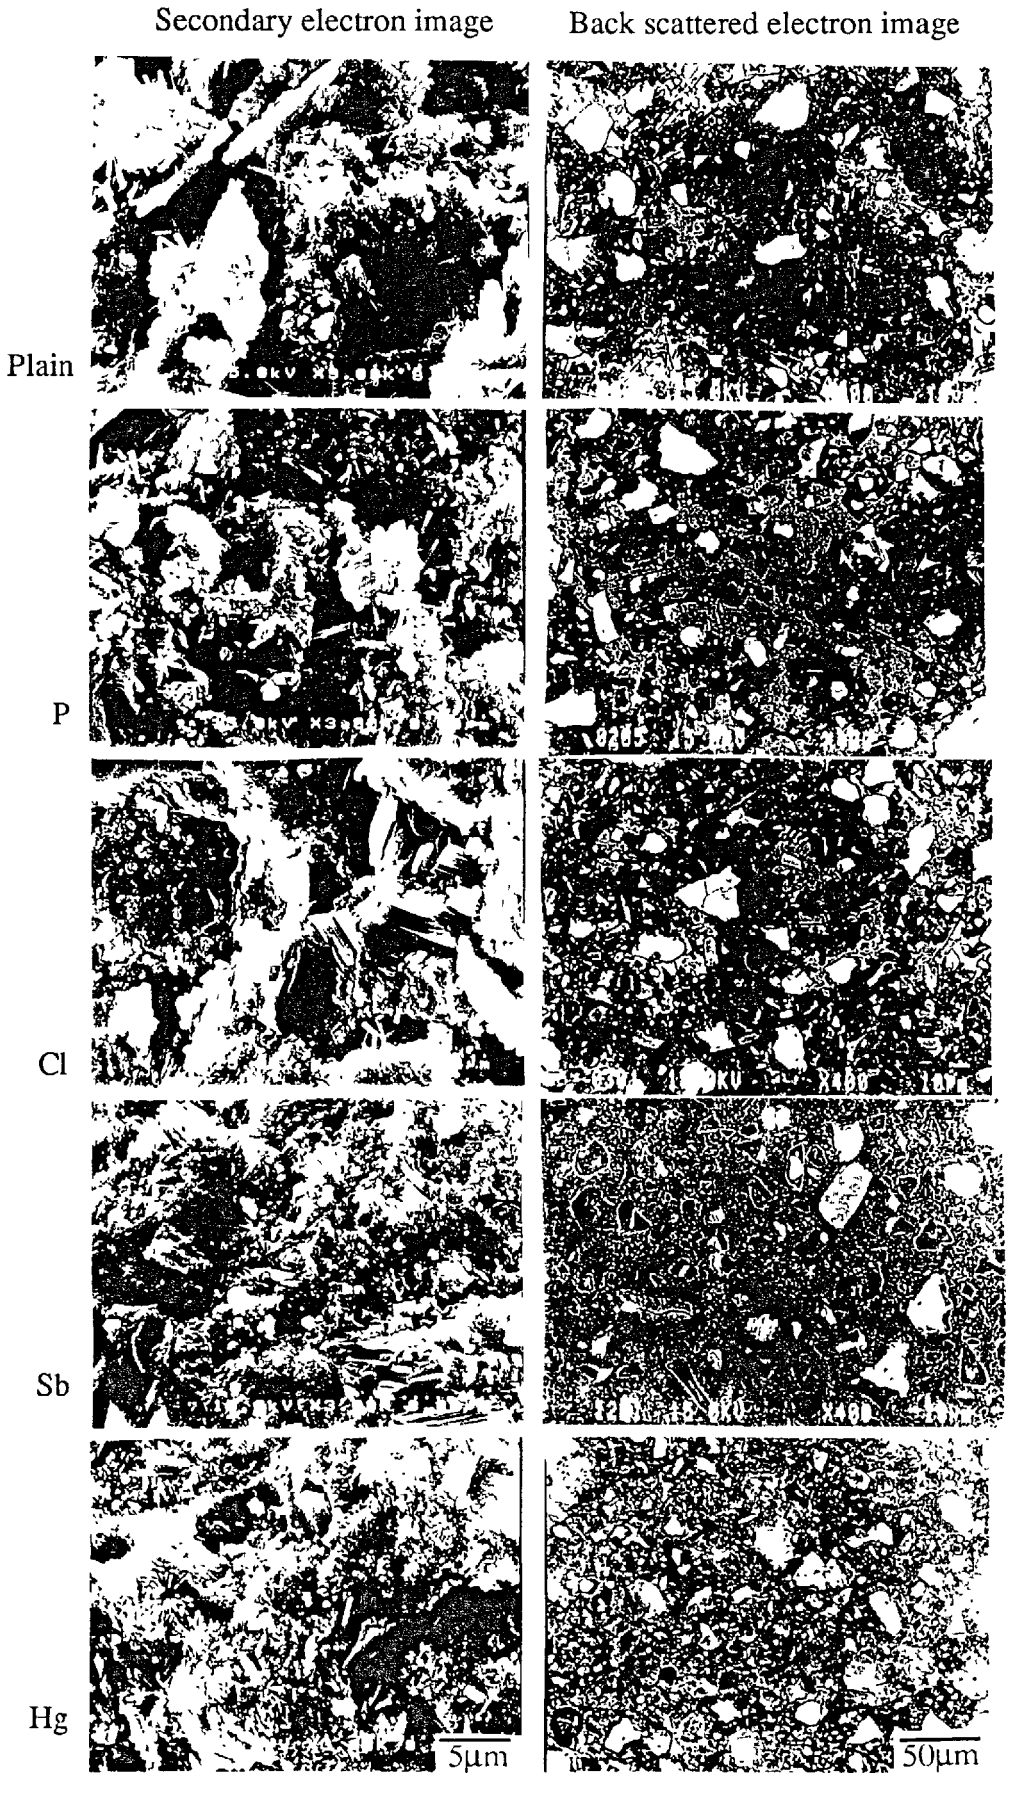

Figure 2

Secondary electron image and back scattered electron image of hardened cement paste prepared by adding various elements (W/C=0.5, 20°C, 14days)

those elements. The figure reveals that large crystals of $Ca(OH)_2$ were deposited in layers between the deposit of type I columnar C-S-H 1μm long and 0.1μm in diameter and that of type III equi-dimensional C-S-H and the platy AFm are scattered. The back scattered electron image reveals that type IV C-S-H(inner-hydrate) 5 to 10μm thick existed on the surface of unhydrated alite particles, and that the hydration of belite hardly proceeds and some of it were surrounded by the crystals of $Ca(OH)_2$.

The thickness of type IV C-S-H (inner-hydrate) on the surface of alite was reduced by half that in normal portland cement paste without containing the elements by adding P to it, which suggests the hydration of alite particles was depressed. The size of the crystal of $Ca(OH)_2$ is approximately 30 μm which is larger than that in the cement paste without adding the elements. It is inferred from the dark color tone of the back scattered electron image of the deposit of C-S-H that it is porous. The deposit of C-S-H in its own shape was 2μm long and 0.2μm in diameter, which was larger than that in the cement paste without adding the elements.

The thickness of type IV C-S-H (inner-hydrate) on the surface of alite in the cement paste adding Cl was 1.5 times as large as that in the cement paste without adding the elements. This suggests that the hydration of alite was accelerated. C-S-H without having its own shape predominated. $Ca(OH)_2$ was deposited in layers connecting the cement particles.

C-S-H deposited in the cement paste adding Sb was as fine as 0.1μm and most of it did not have its own shape. $Ca(OH)_2$ was deposited in layers between the C-S-H crystals. The back scattered electron image reveals that the unhydrated alite particles are extremely fewer than those in the cement paste without adding the elements. This suggests that the hydration of alite remarkably proceeded. Meanwhile, a relatively large quantity of the interstitial phase unhydrated was observed in hardened specimens.

The texture of the hydrated cement paste adding Ti was similar to that in the cement paste adding P. The fine columnar crystals of C-S-H was tend to grow radiately in the cement paste adding Cd or Hg. Although the texture of hardened cement paste adding the other elements were similar to that in the cement paste without adding the elements, the morphology of C-S-H, $Ca(OH)_2$ and Afm were changed.

Effects of elements on pore structure

The capillary pore size distribution of the hardened normal portland cement paste and blastfurnace slag cement paste is illustrated in Fig 3. Volume of gel pore of 6nm or under corresponding to the distance between the C-S-H crystal intra-layers increases with the increase of the production of C-S-H (Uchikawa et al, 1990). The content of gel pore was increased by adding Cl, Sr and Sb though it was slightly increased by adding Cr, Ba and Hg. The

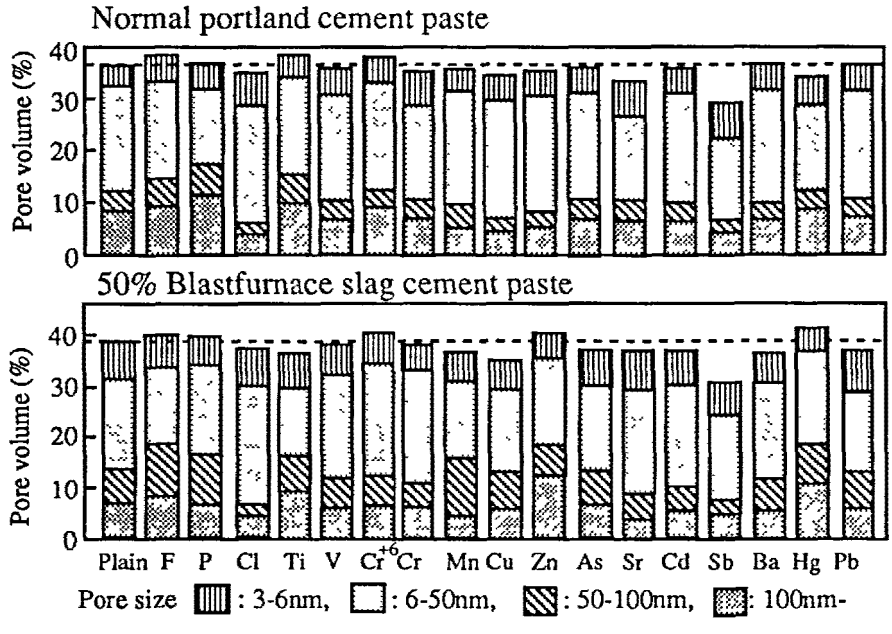

Figure 3 Structure of capillary pore of hardened cement paste prepared various elements measured by mercury porosimeter

capillary pore volume as small as 50 nm or less had the same trend as the gel pore. The total pore volume was generally decreased, but the volume of pore as small as 50 nm or under was increased by adding the elements having an effect increasing the content of combined water to the hardened paste. This suggests that the hydration reaction proceeds in it. The same tendency was observed in case of blastfurnace slag cement paste.

Distribution of element to hydrates in hardened cement pastes

The distribution of each element contained in C-S-H, $Ca(OH)_2$ and AFm of the hardened cement paste prepared by adding minor and trace elements was determined from the analytical result of by the point analysis and imaging with EPMA. The result of point analysis is listed in Table 3. Since any standard samples of V, As, Cd, Sb and Hg were unavailable, the data concerning these elements were omitted. The two-dimensional distributions of the elements added at the mixing cement with water are illustrated in Fig 4 together with the back scattered electron images of the fields of view corresponding to them.

Table 3 Concentration of element in each hydrate of hardened paste determined by point analysis using EPMA

Element	Concentration of element in each hydrate determined by EPMA (%)			
	C-S-H	AFm	$Ca(OH)_2$	
F	0.54 - 0.82	0.05 - 0.24	0.00 - 0.04	
P	2.26 - 6.10	0.32 - 0.80	0.20 - 0.35	(as P_2O_5)
Cl	0.16 - 0.38	1.31 - 2.88	0.01 - 0.10	
Ti	0.14 - 0.32	0.22 - 0.35	0.05 - 0.09	(as TiO_2)
Cr	0.04 - 0.10	0.08 - 0.11	0.00 - 0.04	(as Cr_2O_3)
Mn	0.07 - 0.11	0.03 - 0.05	0.00 - 0.03	(as MnO)
Cu	0.06 - 0.11	0.06 - 0.10	0.00 - 0.02	(as CuO)
Zn	0.08 - 0.14	0.07 - 0.11	0.00 - 0.02	(as ZnO)
Sr	2.03 - 3.10	0.81 - 1.03	0.10 - 0.32	(as SrO)
Ba	0.09 - 0.14	0.09 - 0.12	0.00 - 0.01	(as BaO)
Pb	0.15 - 0.21	0.04 - 0.07	0.00 - 0.04	(as PbO)

A large quantity of P was contained in C-S-H, while a relatively small quantity of it was contained in monosulfate hydrate (AFm) and $Ca(OH)_2$. P also seems to be deposited as fine crystals of calcium phosphate.

F was mainly contained in C-S-H, while it was less contained in AFm and hardly contained in $Ca(OH)_2$. Maybe this is because F was converted to CaF_2 which was deposited in C-S-H. F^- is easily substituted for OH^-. The hardened paste contained some portions with high concentration of F. This suggests the existence of the congregate texture of fine CaF_2 crystals.

Cl were mainly contained in AFm and the content of it in C-S-H was 1/10 or under as much as the content in AFm. Cl was hardly contained in $Ca(OH)_2$. It is estimated that Cl in AFm partially forms a Friedel's salt and that the bonds of Cl is loose and Cl is partly adsorbed onto the surface of the crystal. Cl contained in the hardened cement paste was relatively easily dissolved in it as mentioned later.

V is distributed to the position corresponding to AFm and C-S-H.

Although Cr^{3+} was less unevenly distributed to each hydrate, it was tend to be more distributed to AFm than to C-S-H. It was hardly contained in $Ca(OH)_2$. Some places with high content of Cr observed by EPMA may be formed by the deposition of Cr as $Cr(OH)_3$. Cr^{3+} in AFm is easily substituted for Al^{3+}. It is considered that Cr^{3+} in C-S-H is adsorbed onto the surface of crystal and between the layers (Ivey et al, 1990). It is considered that Cr^{6+} is either substituted for SO_4^{2-} in AFm or AFt as a solid solution of CrO_4^{2-} or taken up between the intra-crystal layers in C-S-H.

Although Mn was also less unevenly distributed to each hydrate, it was tend to be more distributed in C-S-H than in AFm. It is also hardly contained in $Ca(OH)_2$. It is considered that Mn^{2+} and Mn^{3+} are substituted for Ca^{2+}, and Al^{3+} or Fe^{3+}, respectively, and these ions exist in C-S-H and AFm. EPMA reveal that most of those ions existed in type IV C-S-H (inner-hydrate) on the surface of alite particles.

Fig 4 is given in the colour photo section at the end of the proceedings.

Cu was distributed equally to C-S-H and AFm but hardly distributed to $Ca(OH)_2$. And it was relatively evenly distributed to hardened paste.

Zn was mainly distributed to C-S-H and AFm. It is considered that Zn is substituted for Ca in C-S-H or bonds Ca on the surface of it into calcium containing zinc oxide compound and that Zn^{2+} and ZnO_4^{6-} are substituted for Al^{3+} and SO_4^{2-}, respectively, as solid solutions. Zn was relatively evenly distributed to hardened paste.

As was hardly unevenly distributed to each hydrate. Sr was largely distributed to C-S-H and relatively largely to AFm. It is hardly distributed to $Ca(OH)_2$. It is considered that Sr^{2+} is substituted for Ca^{2+} in these hydrates as solid solutions. Cd and Sb are hardly unevenly distributed to each hydrate.

Ba is mainly distributed to C-S-H as same as Sr. Although a small quantity of it was contained in AFm, it was not contained in $Ca(OH)_2$. EPMA reveals that some portions had high concentration of Ba. It is considered that the rest of Ba as a solid solution of hydrate is deposited as a $Ba(OH)_2$. EPMA results reveals that Hg was mainly adsorbed to C-S-H. Pb was relatively largely fixed to C-S-H and hardly contained in AFm and $Ca(OH)_2$.

Dissolution of minor and trace elements from hardened cement paste

The quantities of minor and trace elements dissolved from hardened cement pastes of normal portland cement and blastfurnace slag cement are illustrated in Fig 5.

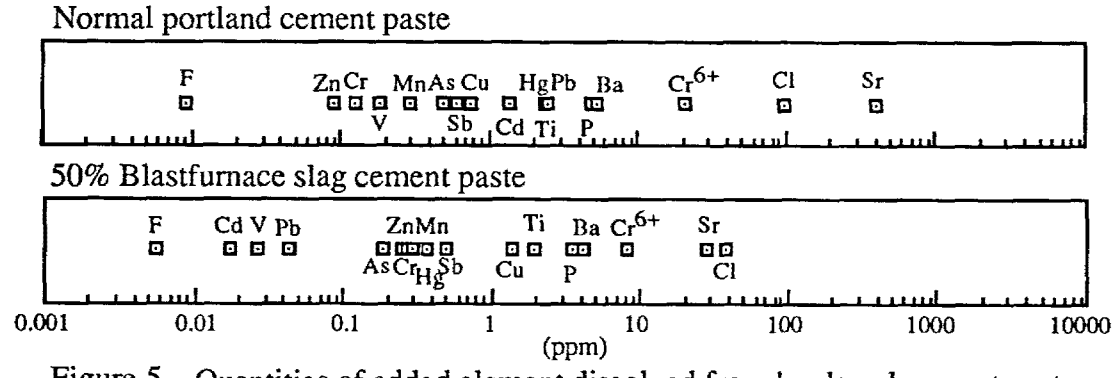

Figure 5 Quantities of added element dissolved from hardened cement paste

More than 1ppm of the elements dissolved from the hardened normal portland cement paste included Cl, Sr, P, Cr^{6+}, Ti, Cd, Ba and Hg. The quantity of Cr^{6+} dissolved from it among them exceeded the general emission criteria. More than 1 ppm of the elements dissolved from the hardened blastfurnace slag cement paste included seven components of Cl, Sr, Cr^{6+}, P, Ba, Pb, Ti and Cu. The quantities of the elements of heavy metals, halogens and others dissolved from the hardened blastfurnace slag cement paste were generally less than those dissolved from the hardened normal portland cement paste. For example, those of Cd and Pb were reduced to approximately one-hundredth, that of Cr^{6+} was reduced by half and those of Cl, Sr, V and others were remarkably reduced. The elements dissolved as much as 1 ppm or less from the hardened normal portland cement paste including Zn, Cr, Mn and Cu showed the increased quantities of dissolution from the blastfurnace slag cement paste.

Cl has relatively high solubility that most of it exists in the pore water and accordingly it is easily dissolved in the outside. Even the elements fixed as Friedel's salt are also unstable. It is considered that Sr and Ba once fixed in hydrates by substituting for Ca are leached out. Although the elements of heavy metals, halogens and others are more easily dissolved from the hardened paste than those contained in clinker because in this study these elements are added to cement paste together with the mixing water, most of the added amounts of elements except the elements of Cl, Cr^{6+}, Sr and Ba were fixed in the hardened cement paste within a range from 0.1 to 2%.

As mentioned above, the quantities of the elements of heavy metals, halogens and others dissolved from the hardened paste of blastfurnace slag cement were generally less than from that of normal portland cement. Maybe this is because the amount of deposited Ca(OH)2 forming a porous texture for passing those ionized elements (Uchikawa et al, 1989) were small and a large quantity of C-S-H with low Ca/Si easily adsorbing co-existing elements were produced.

CONCLUSIONS

The rate of hydration, morphology and composition of hydrates, distribution and dissolution of minor and trace element in and from, respectively, the hardened cement paste prepared by adding small amounts of various elements including heavy metals were investigated using normal portland cement and blastfurnace slag cement containing 50% of slag. The results obtained are summarized as follows:

1) Although the amounts of combined water in normal portland cement paste and blastfurnace slag cement paste containing Cl, Cr, Sr, Sb, Ba and Hg were higher than those without adding any elements, amount of Ca(OH)2 produced was reduced by adding any of those elements. The change of the volumes of gel pore and the total pore were coincide with that of the amount of combined water.
2) The C-S-H produced by adding P and Ti were as large as 2 μm long and 0.2 μm in diameter and were idiomorphic. Non-idiomorphic were increased and the layer structure of Ca(OH)2 between cement particles was formed by adding Cl. The C-S-H was non-idiomorphic and the size of it were reduced as fine as 0.1 μm by adding Sb. The back scattered electron images revealed that the C-S-H layers formed by adding Cl, P and Ti were thick and the rate of hydration were high in this order. This suggests that the higher the rate of hydration, the smaller the C-S-H crystal was and the poorer the development of its own shape was.
3) The elements of heavy metals, halogens and others added to cement paste distributed more in C-S-H and AFm than in Ca(OH)2 in such a manner that P, F, Sr and Pb congregated in C-S-H, Cl did in AFm, but Ti, Cr, Mn, Zn, Ba, As, Cd and V distributed equally in both hydrates. When large quantities of P, F, Cr, Cl, Zn and Ba were added, the compounds composed of respective elements were deposited.
4) The quantities of the elements of Cl, Sr, Cr^{6+}, Ba and Ti dissolved from the hardened pastes of normal portland cement and blastfurnace slag cement were more than 1 ppm, especially that of Cr^{6+} exceeded the general emission criteria. The quantity of an element dissolved from the hardened blastfurnace slag cement paste was less than that of ordinary portland cement. For example, those of Cd and Pb were as small as approximately one-hundredth and that of Cr^{6+} was as small as a half. Since Cl has high solubility, it is easily dissolved out. Although Sr and Ba are substituted for Ca and once fixed as hydrates which are easily leached out. Most of the Added amounts of elements, except Cl, Cr^{6+}, Sr and Ba were fixed to the hardened cement paste when the addition of elements were within a range from 0.1 to 2% . Less quantities of the elements dissolved from the hardened blastfurnace slag cement paste may be caused by few cluster of Ca(OH)2 forming a porous texture for passing those ionized elements and by a large production of C–S–H with low Ca/Si easily adsorbing the co-existing elements.

FORMATION OF HYDRATION ON MINERAL SUPPORT

Alexander OLGINSKY, D. Sc. (Eng.) Kharkov State Automobile
and Highway Technical University, Kharkov, Ukraine

ABSTRACT The degree of joining of hydrates with mineral support by "criterion of mating" is suggested to be determined. Forecast of the compactness of contact zone is carried out by special programme, based on the account of parameters of crystallic lattice of mating mineral phase. Main cement hydrates (and the products of their corrosion) are divided into five classes.

KEY-WORDS: Aggregate, Crystal, Hydration, Mineral phase, Support.

INTRODUCTION

Many works were dedicated to the problems of hydration of cement minerals and formation of hydrates. It is well known that, regularity of formation of hydrates are influenced by chemical additives, temperature, pressure and also under the influence of mineral support. However, problem of establishment of the regularity
of formation of compact contact of hydrates with the minerals of cement materials is not sufficienly studied. This problem includes the questions about the formation of hydrates on mineral support, particularly, oriented increase of hydrates on the surface of aggregate. As a result forms the compact zone of contact in composite materials and rises their operational resistance.

The oriented crystallization of different substances on metallic support is studied in detail (Palatnik, 1964; 1971). There exsist experimental data about the possibility of regular joining of different cement hydrates between themselves (Butt et al, 1972;
Timashev and Kolbasov, 1981) and also with calcite and quartz (Butt et al, 1970; 1971). These studies coinfirm the formula of (Royer, 1928).

$$\Delta=(a_1 - a_2) / a_1, \qquad [1]$$

a_1 and a_2 of crystallic lattice of mating mineral phases.

According to this formula, the possibility of intergrowing the crystalline phase is evaluated on the base of parameters "a", "b" and "c" of crystallic lattice of mating mineral phases. Incorrect are the statements that, the same type of connection, the principle of geometrical similarity of contacting crystals of mineral phases and closeness of parameters of crystallic lattice is the obligatory condition. At chemical interaction among contacting substances, the epitaxical growth is possible for the substances with Δ not more than few percent. From solutions, crystals grow at $\Delta < 15\%$. It is established that perfection of mating increases with the decrease of value.

At significant similarity between crystal-chemical properties and the parameters of lattice of increasing crystals and support, the formation of nucleus in the field of spiral dislocation can be mainly relied upon. If the growing crystals are distributed extremely
dissimilarly, then this is an evidence for the influence of deformed fields of surface upon forming the nuclei.

FORMATION OF NUCLEI ON THE CRYSTALLIC SUPPORT

Introduction

Formation of nuclei on the crystalline support may take place as the form of continuous growth and spontaneous crystallization. In the first case an atom, which reached the support, migrates on its surface toward an active center. These centers are the different defects of crystallic lattice, dislocation, steps of spalling or unfinished atomic planes. Migration of atom takes place until it does not occupy the position with minimum energy. These surface defects are the "atomic traps", which contribute to accumulate depositable particles. Different distortions of surface offer the place of "flow" for migrating atoms.

Theory

Unlike the first way of nucleus formation (Palatnik, 1964; 1971) spontaneous crystallization is not unacceptable for cement systems, since spontaneous formation of nuclei happens when oversaturation of liquid phase exceeds the critical value. In our case this is not realistic.

Hydrolysis of cement minerals is less active process than the formation of true solutions. Additionally, in the zone of contact with mineral support the processes of adsorption and ion exchange are developed. At insignificant oversaturation, which may take place in liquid phase of cement paste, the nuclei will join along the bulges on the surface of the support. On crystal surface of an aggregate with significant contents of impurities in solution, the formation of "parallel growths of solid solution" (mating) will take place. Formation of growths of four types may be possible: one crystal is the direct continuation of another; crystallic growths are formed along the common surface (cristallographic plane); in one line (axis); in the common point (at the center of growth).

Oriented growing of new formations on crystal support received the name "epitaxy". It may take place by two similar mechanisms, which display the successive stages of epitaxic crystallization. By one mechanism atoms or molecules of new formations in accordance with the requirements of minimum inter-phase surface energy, continue crystallic lattice of the support preserving its symmetry. The value of the periods of lattice of support in the plane of mating (at the same symmetry) may be preserved . The second mechanism is realized, if there is big discrepancy between the periods of plane cells on the boundary of mating between the new formation and the support.

Analysis of Laue-patterns and microdiffractogramms of contact zones of mated crystals showed (Butt et al, 1972; Timashev and Kolbasov, 1981), that intergrowth may take place after the diagram of Royer-Fridel. It is realized along plane nets, identical in form and approximately equal in dimensions through superposition of crystallic lattices of contacting mineral phases without formation of "contact seam" (Butt et al 1970; 1971) . In such way, the formula of Royer (Royer, 1928) is applicable for the evaluation of possible mating of hydrate phases between themselves and with minerals of the support. And on the base of value of Δ up to 15%, the perfection of structure of contact zone "hydrate (the product of corrosion) - mineral of support" may be evaluated . This determines the ability of crystallic lattices of contacting elements to form epitaxic structures of intergrowth.

Minerals in the surface zone of aggregate, as well as the hydrates originated on their surface, may have an infinite number of different orientiations in relation to each other. That is why it is reasonable to establish the value of potential interaction of their crystallic lattices by the summary and medium intensity of the interaction between hydrates and minerals an aggregate (Dubnytchky et al, 1993) . Such system is realized in the programming language "C ++" in IBM compatable computer.

Results

For cement hydrates and the products of their chemical corrosion was found the sum of potential interactions in the scale of - S, with each of main rock forming minerals of aggregate within certain quantity of interaction - n.

Widespread cement hydrates : portlandite; hydroaluminates of calcium containg 3, 6, 8, 13 and 19 molecules of water; gel of tobermorite and its 0,9; 1,1; 1,4 nm varieties; low-basic hydrosilicates of CSH type; double-basic hydrosilicates; C_2SH_2; xonotlite, okenite, girolite, hillebrandite; complex compounds of calcium carboaluminates, hydrosulfoaluminates, chloroaluminates of calcium; and also the products of corrosion - gypsum, calcite were evaluated. As mineral supports were considered natural and artificial minerals represented by unhydrated and hydrated silicates; aluminosilicates, carbonates, oxides and hydroxides (42 minerals).

The level of mating of hydrates (or products of corrosion) with the minerals of aggregete was suggested to be determined by the value of relation S/n, so called the "criterion of mating" .

We succeeded to reveal the tendency of cement hydrates to grouping (Fig.1) by the ability to form epitaxic intergrowths with support. The five classes of cement hydrates with the different level of intergrowing with the minerals of aggregate were selected:
I class - most active; II - highly active; III - active; IV - medium active; V - low active.

Reliability of selection of classes is confirmed by the compactness of grouping of different mineral phases, caused by the closeness of criterions of mating, and also by the neighbourhood of compounds close in crystallochemical aspect.

Classification of hydrate phases follows the closeness of the values of criterions of mating combined in certain groups. For example, in the first class there are hydrates with close crystallochemical parameters - different double basic hydrosilicates and secondary calcite (product of corrosion). The possibility of mating of hydro-silicates of type 1.1 nm tobermorite with the surface of clay mineral beydelite was shown. According to the value of Δ =0.4% the most possible mating may take place between "b" axes - of beydelite and "c" - of tobermorite.

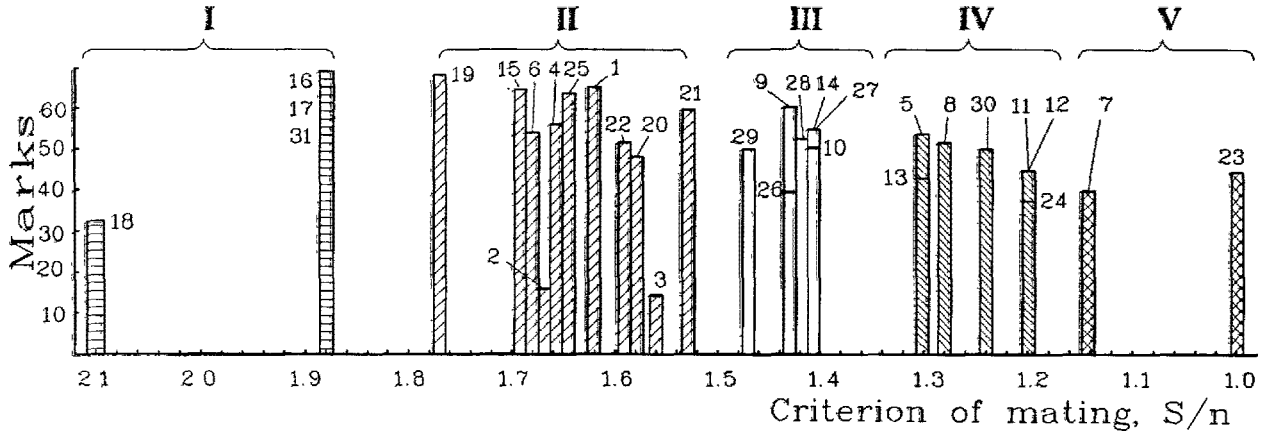

Figure 1. Classification of hydrates by the criterion of their mating with the minerals of aggregates:

1 - portlandite; 2 - CAH_3; 3 - C_3AH_6; 4 - b C_2AH_8; 5 - C_4AH_{13}; 6 - C_4AH_{19}; 7 - alumosilicate; 8 - $C_3A{\cdot}CaCO_3{\cdot}13H_2O$: 9 - gel of tobermorite; 10 - 0.9 nm tobermorite; 11 - 1.1 nm tobermorite: 12 - 1.4 nm tobermorite; 13 - CSH I; 14 - CSH II; 15 - low-basic hydrosilicate ; 16 - double-basic hydrosilicate 1; 17 - double-basic hydrosilicate 2; 18 - C_2SH_2 1; 19 - C_2SH_2 2; 20 - xonotlite; 21 - okenite; 22 - girolite; 23 - afwillite; 24 - hillebrandite; 25- $C_3A{\cdot}CaSO_4{\cdot}12H_2O$; 26 - $C_3A{\cdot}CaSO_4{\cdot}32H_2O$; 27 - carboaluminate; 28 - chlorinealuminate 1; 29 - chlorinealuminate 2; 30 - gypsum; 31 - calcite.

The suggested classification of cement hydrates by the criterion of mating, allows to evaluate their potential possibility, while forming strong epitaxical aggregation with mineral filler. This will ensure predicting the possibility of obtaining the compact and strong structure of contact zone in cement materials.

CONTROLLING THE HYDRATION OF PORTLAND CEMENT AND CONCRETE'S PHYSICAL AND CHEMICAL PROPERTIES BY THE SURFACE OF MINERAL AGGREGATES

P.G.KOMOKHOV, University of Means of Communication, St.Petersburg, Russia
N.N.SHANGINA, University of Means of Communication, St.Petersburg, Russia

ABSTRACT The process of hydration of portland cement may have a different degree and composition of formed products, depending on the acid-base properties of aggregates' surfaces. Fine-ground mineral additives with the predicted properties of the surface can be used for I) improving concrete's mechanical properties; 2) obtaining concrete protecting from ionizing radiation.
Activation, composite cements, freeze-thaw damage, immobilization, long age

INTRODUCTION

The existence of different types of active centres of three-calcium and β-two-calcium silicates and their influence on the process of cement's hydration has been proved by a number of methods (Decamp, 1976; Chatterji, 1983 and Boikova, 1984). Besides, there are conceptions about the possibility to control the hydration and the properties of a cement stone by introducing substances, including almost insoluble ones, which are able of influencing the active centres of clinker minerals or the electronic sub-structure of the surface (Svatovskaya and Sychyov, 1983).

When using a fine aggregate as a constituent of concrete one should take into consideration its properties such mineralogical composition, specific area and pozzolanic activity. Normally, the presence of active centres on the aggregate's surface and its influence on the hydration of cements is not estimated. In this research the acid- base properties of surfaces of aggregates used in cements were investigated with the indicator method.

ACID-BASE PROPERTIES OF MINERAL AGGREGATES

The differences in the acid-base properties of mineral aggregates' surfaces can be seen when the adsorption centres distribution (ACD) curves, built for such widespread natural mineral aggregates as fine-ground basalt and natural purely quartz sand, are compared (Fig. 1).

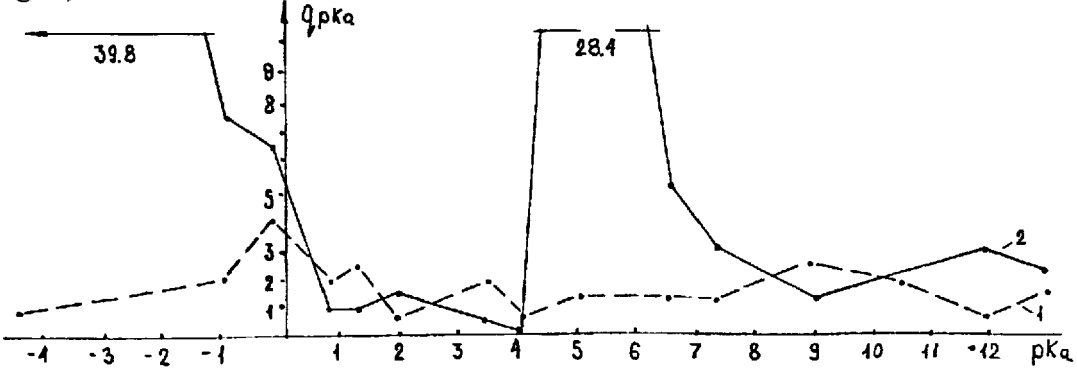

Figure 1 Distribution of acid-base centres on the surface of 1. - natural sand and 2. - basalt

The specific area of the studied samples is equal (0.9 - 1.16 m^2/g). The curves are built on the coordinates $q_{pKa}x = S(_{pKa}x)$, where $q_{pKa}x$ is the content of active centres equivalent to the amount of the adsorbed indicator of such acidic force ($_{pKa}x$).

Table 1 gives the generalized data, which allow to estimate the acid-base properties of substances' surfaces by the area of stripes on ACD spectra.

Table 1 Distribution of acid-base centres on the surface of mineral substances

Mineral substance	Area of stripes on ACD spectra		
	pKa^x from 5 to 0	pKa^x from 0 to 7	pKa^x from 7 to 14
Limestone	17,30	9,76	10,97
Marble	4,62	9,45	4,04
Natural gypsum	6,65	8,14	15,05
Shungite	46,54	22,93	45,59
Shungisite	40,75	22,11	16,39
Zeolite (Clinoptilolite)	47,10	22,58	13,18
Basalt	95,78	41,71	15,55
Clay (Kaolinite)	26,26	44,63	42,95
Ceramsite	12,94	15,38	11,51
Slag 1	27,80	58,22	22,59
Slag 2	19,07	10,17	4,86
Pure quartz	3,41	20,43	6,18
Quartz sand	7,45	8,70	10,32
Sea sand	28,87	26,67	30,97

INFLUENCE OF ACID-BASE PROPERTIES OF AGGREGATES SURFACES ON THE STRENGTH OF THE CEMENT STONE

The results of testing of samples made of portland cement with aggregate admixtures, as well as the investigation of cement's hydration products allow us to make the following conclusions:

1) The replacement of a part of cement by substances, which have intensive stripes on the ACD spectrum in the sphere of acidity indication pKa =0-7, does not reduce, and in some cases even increases the cement's strength. The typical example is the equal strength of a cement stone and a mixed binding cement containing 50% basalt. During the investigation of the hygration products of cement with basalt additives with the x-ray phase analysis method, an increase in the degree of hydration was established. Such influence of the aggregate is explained by the accepting properties of atoms of the surface's metal, capable of activating the surface of clinker minerals.

2) The presence on the aggregate's surface of strong Lewis's base centres (pKa = 5-0) can increase the ionic content OH^- in the contact zone between the aggregate and cement, locally increasing pH and favouring the transfer of calcium ions in the mortar for the compensation of the negative charge

3) The intensification of the donor properties of the aggregate's surface atoms (pKa>7) is accompanied by the lowering of the degree of clinker minerals' hydration and a

decrease in the material's strength, which is explained by the capacity of substances-donors of electrones to suppress the activity of clinker minerals surface

Table 2 Changing of acid-base properties of the aggregate's surface and the strength of the cement stone sample.

Aggregate	Area of stripes on ACD spectra			Changing of strength in compression, % of the control samples	
	pKa = -5-0	pKa = 0-7	pKa = 7-14	7 days	28 days
Natural sand	28,87	26,67	30,97	93	88
Natural sand after a heat treatment at t = 600°C	13,07	39,27	21,75	126	117
The same at t = 900°C	28,31	9,12	22,08	74	91
Modified natural sand $NiCl_2$**	7,62	48,12	10,0	162	147

* The strength of the cement stone without an aggregate is taken for 100%; the aggregate content is 20% of the cement's weight; w/c = 0.29

** The modification is done by the injection of $NiCl_2$ from the water solution.

OBTAINING CONCRETE OF HIGHER FROST-RESISTANCE

The changing of the acid-base properties of the aggregate's surface in the case of modification, as the data of x-ray phase and differential thermal analyses show, increases the degree of cement's hydration and changes the composition of the formed calcium hydro-silicates. The content of low base C-S-H rises, with which an increase of concrete's frost-resistance is connected (Fig.2).

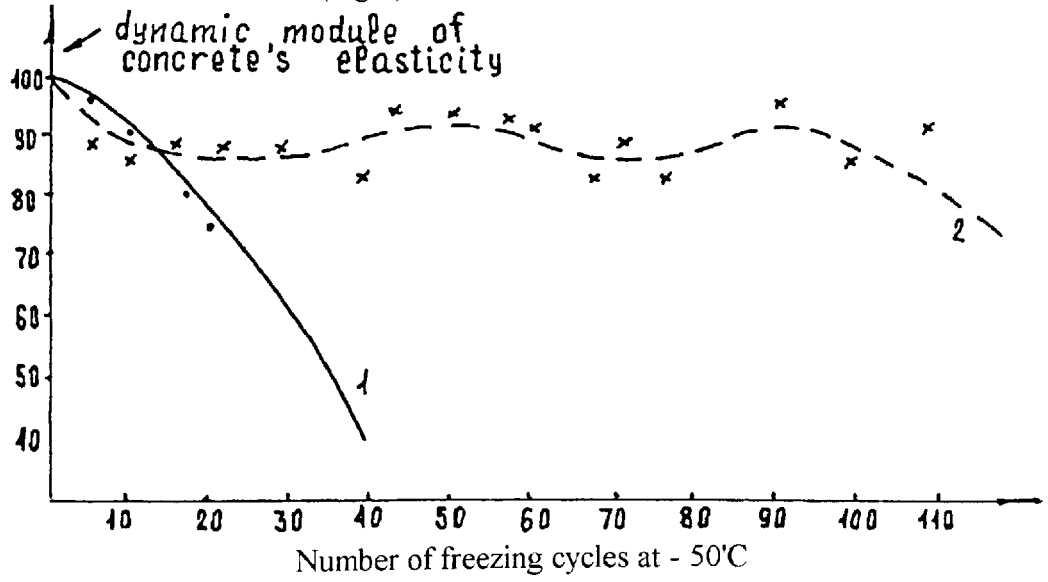

Figure 2 Changing of the dynamic module of concrete's elasticity during frost resistance tests 1 - control composition; 2 - with the aggregate (modified sand $NiCl_2$).

OBTAINING CONCRETE FOR PROTECTION FROM IONIZING RADIATION

The choice of the carbon-containing aggregate for concrete was based on the data of Table 1. Natural shungite has peaks of high intensity on the ACD spectrum in the sphere of acidity indication pKa from 7 to 4, which has a negative effect on cement hydration. The heat treatment of, with the purpose of obtaining the artificial material shungisite, changes the properties of the surface. The area of stripes on the ACD spectra in the sphere pKa = 7-14 is reduced by three times, the activity in the sphere pKa = 5-7 being invariably high. Figure 3 shows the kinetics of changing of concrete's strength with normal hardening and γ-radiation.

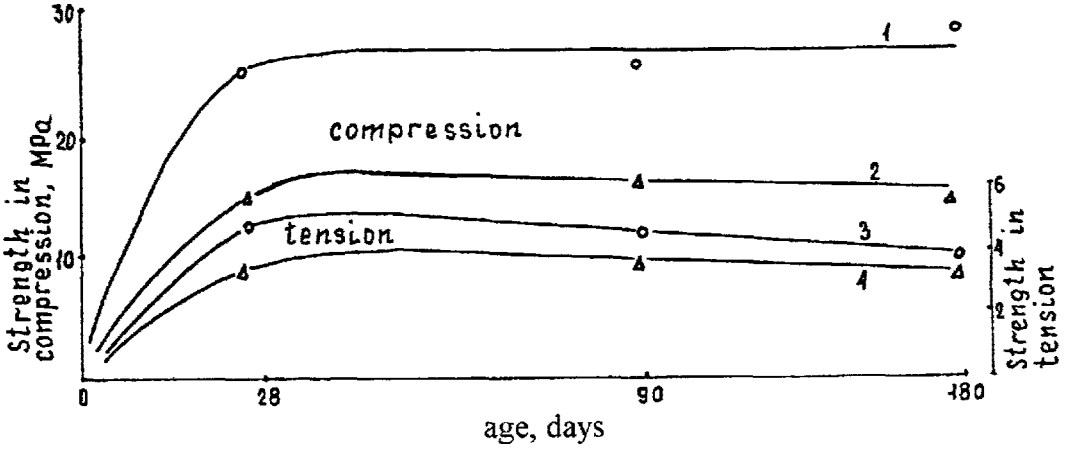

Figure 3 Kinetics of changing of concrete's strength (the aggregate is shungisite) with γ-radiation. 1 and 3 - concrete's strength when radiated. 2 and 4 - concrete's strength of control samples of normal hardening .

ABSTRACT The greatest factors for the bond strength development of rapid hardening cements are the vibration and the flowability. In the case of cement which produces ettringite form water pouring, the flowability lowers with time, and it should be given a stronger vibration in order to provide a high bond strength. In the case of cement which forms a little ettringite for several minutes from water pouring, the flowability is maintained until the termination of handling time and high bond strength is developed easily by the vibration.

Key-words : rapid hardening cement, strength development, ettringite, vibration, flowability

INTRODUCTION

In Japan, sudden increase in traffic density has caused remarkable damage to the floor slab of the bridge by the old design standard. It can't be coped with by local repairing when the damage spreads a extensive area. On this account, "superstructure reinforcing method with overlaid reinforced concrete" is adopted for reinforced construction to extend the whole floor slab.

The outline of the superstructure reinforcing method with overlaid reinforced concrete is as follows. First, the weak portion on the surface of the existing floor slab to be reinforced is removed, next the concrete which is used rapid hardening cement and mixed with steel fiber by 1.27vol% ($100kg/m^3$) is placed. Then the floor slab is made to have greater thickness than before, and further rapid hardening concrete is vibrated and finished the surface by a concrete finisher. An example of the superstructure reinforcing method with overlaid reinforced concrete was showed by a cross section in **Figure 1**. The characteristics against shearing and bending stress of the floor slab are increased by this reinforcing method (Express highway research foundation of Japan, 1995).

The main properties required for the rapid hardening concrete the reinforced the steel fiber are prescribed that slump is 50±15mm and handling time is more than 40min, compressive strength at three hours is $24N/mm^2$ more and bond strength is $1N/mm^2$ or more. Particularly the bond strength is a important property. The reinforcement effect by this method is reduced to half, if the old and new concrete isn't unified. When a kind of rapid hardening cement varies, bond strength is different in the present situation. The influence of the vibration for the bond strength of a rapid hardening concrete has been reported already (Express highway research foundation of Japan, 1995). The bond strength development varied the rapid hardening cement. However there are few reports about it (Momiyama et al,1996).

This report intends to clarify the relationship between ettringite formation and bond strength clear by grasping the factors affecting the bond strength and by analyzing of the initial stage of hydration of the rapid hardening cements.

THE RAPID HARDENING CEMENTS

In the superstructure reinforcing method with overlaid reinforced concrete, the rapid hardening cement is used in order to satisfy a prescribed property which the compressive strength at 3 hours is24N/mm^2. In this report, two kinds of rapid hardening cement was examined. The one was a cement Type-A that was burned and crystalline calcium fluoro aluminate ($11CaO \cdot 7Al_2O_3 \cdot CaF_2$). The other was a cement Type-B that was admixed high early strength portland cement with amorphous calcium aluminate ($12CaO \cdot 7Al_2O_3$). Both $11CaO \cdot 7Al_2O_3 \cdot CaF_2$ and $12CaO \cdot 7Al_2O_3$ are materials that have the property of quick setting. **Table 1** showed the chemical composition of two types of rapid hardening cement.

Test conditions of concretes and mortars

The mixing of concretes and mortars were carried out in a 50 liter capacity vertical pan mixer. The mixing time was fixed 3 minutes. Then a retarder was added by 0.2% to the cement Type-A in order to be equal with Type-B at the handling time. It was dissolved in mixing water to be used.

The bond strength was measured about rapid hardening concretes reinforced with steel fiber and mortars of C/S=1/2. In the bond test using concrete, the relationships between the bond strength and the slump loss, the slump value and vibration time were examined. In the mortar test, relationship between the bond strength and water-cement ratio (W/C) was investigated.

Table 3 showed the mix proportion and the test conditions.

Method of bond strength

Table 4 showed the mix proportion and the physical properties of the base concrete used for the bond strength test. The method of the bond strength test was as follows :

i) The surface of the base concrete was roughed. The surface was dry same as the actual construction.

ii) The rapid hardening concrete or mortar was placed on the base concrete.

iii) The jointing concrete or mortar was given vibration by a vibrator.

iv) The cores were bored by a drill with 10mm diameter after 2 hours or more from the mixing.

v) The bond strength was measured by tension tester at 1day.

The concrete or the mortar was were placed at immediately after mixing unless the time was specified. **Table 5** showed items of the evaluation and the method. All experiments were conducted in a constant-temperature chamber at 20±2℃.

Method of analysis of initial hydration for cement pastes

Two cement paste were mixed at a water-cement ratio (W/C) of 0.5. In the same way as in the concrete test, the retarder was added by 0.2% to the cement Type-A, and was dissolved in mixing water to be used. Mixed paste was put in a styrene bottle, and was stored in an experimental chamber at 20±2℃. Hydration was stopped after a predetermined time, and sampling was made. The hydration stop method was as follows : A large quantity of acetone was added to grind the material using an alumina mortar. (Nikaido et al, 1995) Thereafter, it was dried in a constant temperature bath at 50℃ for 16 hours. Sampling time was 5, 30, 60, 90, 120,180, and 300 minutes.

Specimens sampled were analyzed in term of X-ray diffraction added with α-alumina by 10% as the internal standard. Ettringite determination was conducted by applying the method of least squares to the ettringite peak (d=0.973nm) to calculate the area.

RESULTS AND DISCUSSION

The bond strength of the rapid hardening concretes

a) The relationship between the time from mixing and the slump loss

Concerning rapid hardening concrete Type-A and Type-B, the relationship between the time from mixing and the slump was investigated. The result was shown in **Figure 2**. The handling time for the rapid hardening concrete was 40 minutes for Type-A, and 33 minutes for Type-B. The concrete used cement Type-A decreased the slump with passed time from mixing. However the concrete with cement Type-B changed little slump with time.

b) The relationship between the time of concrete placing and the bond strength

The bond strength at 1 day of concretes were measured with various time of concrete placing from mixing. These concretes were vibrated for 20 seconds. The result was shown in **Figure 3**. The time in Figure 3 corresponded to the slump loss as shown in Figure 2. In the case of cement Type-A, the bond strength reduced in proportion to the time of concrete placing. In the case of cement Type-B, the bond strength decreased with time likewise. However, the bond strength of the concrete Type-B had a lower rate of reduction than that of concrete Type-A. The fractured section was a boundary between base concrete and joined concrete.

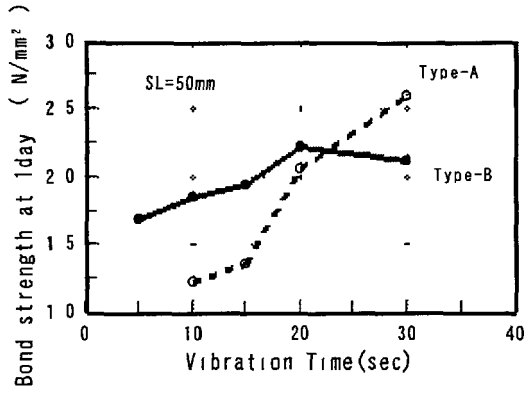

Fig.5 The relationship between Vibration time and Bond strength at 1day

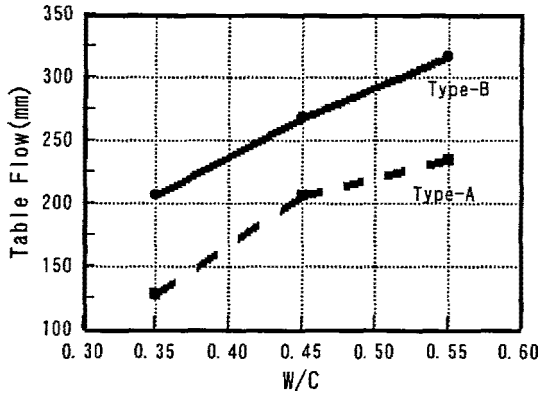

Fig.6 The relationshoip betweem Mortar Flow and Water-cement ratio,W/C

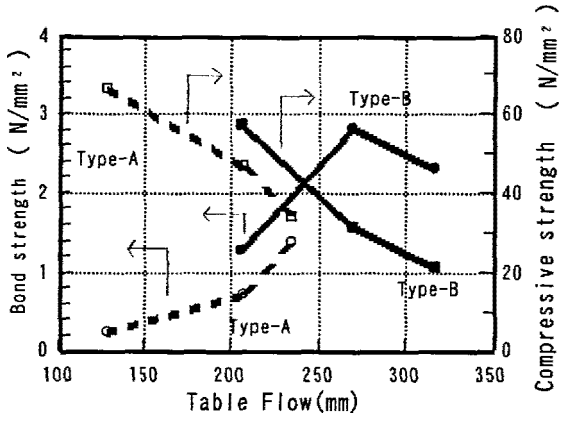

Fig.7 The Relationship between Mortar flow and Bond strength and Compressive strength at 1day

c) The relationship between various slump and the bond strength

The relationship between the slump and the bond strength for concrete Type-B was tested with the vibration time varied. **Figure 4** showed the result. When the vibration time was 10 seconds, the bond strength wasn't affected by the slump, and was almost fixed. However, in the case of the vibration time with 20seconds, the bond strength became higher with lower slump.

d) The relationship between the vibration time and the bond strength

Concerning concrete Type-A and type-B whose slump was 50mm, the change in the relationship between the vibration time and the bond strength was investigated, and its result was shown in **Figure 5**. The bond strength of Type-A was higher with the longer vibration time. The difference of the bond strength between Type-A and Type-B was shortened, when the vibration was longer. The bond strength of Type-B decreased at vibration time 30 seconds and was lower than that of Type-A. Therefore it is considered that the most suitable condition of the vibrating compaction is different between Type-A and Type-B.

The bond strength of the rapid hardening mortars

Table flow, compressive strength and bond strength of mortars were examined, when water-cement ratio (W/C) was varied 0.35 , 0.45 and 0.55 for cement Type-A and Type-B. The vibration time was set to 20 seconds for Type-A mortars. In the case of Type-B, the mortar of W/C = 0.35 was vibrated for 20 seconds, and the others were given no vibration. At the same W/C, Type-B took higher flow than Type-A (**Figure 6**). **Figure 7** showed compressive strength and bond strength ranged by the flow table spread. Type-A showed higher than Type-B about the compressive strength, however Type-B had higher the bond strength than Type-A. Mortar having high flowability develops strong bond strength with no vibration. The flow table spread of Type-B mortar mixed with W/C = 0.55 was 317mm. This mortar was broken itself when measured the bond strength. The destruction of mortar happened to cause that the tensile strength was weaker than the bond strength. In Figure 7, the bond strength and the compressive strength were in inverse proportion. Therefore it's thought that the bond strength is affected by flow table spread, that is, the flowability, and that the compressive strength does not become a great factor for the bond property.

As results of various bond strength test, it's found that two types of rapid hardening cement

having different flowability take different bond strength development by the vibration. A mechanical mechanism of the vibration compacting of a concrete is explain by the next process. When a vibration is given to a concrete, a force of inertia acts to particles in the concrete whereby the shearing resistance between the particles is lost. Then the concrete become to move. Afterwards the concrete particles are subsided or moved by gravity, and arranged again (MURATA, 1996). On this account, to give the vibration energy to the concrete is to move it, and then high bond strength is obtained. It's considered that the concrete having high flowability is easy to be moved by vibration. Therefore, it's thought that the concrete used with Type-A can't be promoted a movement by a vibration, unless a stronger vibration energy is given in it. And it's considered that it may be possible to prevent the bond strength from lowering if even concrete with slump-loss is given strong vibration.

In the case of Type-B, it is similar as Type-A that the bond strength increases in proportion to magnitude of given vibration energy. Its bond strength become higher than that of Type-A since Type-B has higher flowability and is liable to be moved. However the bond strength of Type-B lowers when the vibration time is too long. It's supposed that this trend appears with a concrete having higher flowability conspicuously. In the case of mortar as a grout material, it is considered that strong bond strength is developed with no vibration. It's necessary to study in detail measurement of the vibration energy by the response value of the concrete in the future.

Initial stage of hydration of the rapid hardening cement pastes

In previous sections, it is found that the fresh concrete or mortar which is not setting is important for the bond strength development. The rapid hardening cement develops the strength early by means of ettringite formed by hydration of calcium aluminate (Uchikawa,1972). **Figure 8** showed the result obtained by determining ettringite with XRD. It has been found the rapid hardening cement Type-A and Type-B differ in amount of formation of ettringite during initial hydration process from water pouring to terminated handling time. In the case of cement Type-A, formed ettringite was seen immediately after water was poured. The handling time of Type-A finished when the formation of ettringite has progressed to some degree.

It's considered about the concrete of Type-A that the rate of slump loss is fast since the ettringite is formed more by degrees from water pouring. However the correlation between a quantity of the ettringite formation and termination of the handling time is a subject in the future.

In the case of cement Type-B, a little ettringite was found for several minutes from water pouring. The handling time was over when the ettringite started to form suddenly. Therefore it's thought that the flowability is maintained until the termination of handling time. The following can be considered about the bond strength development for the vibration, the flowability and the initial hydration process.

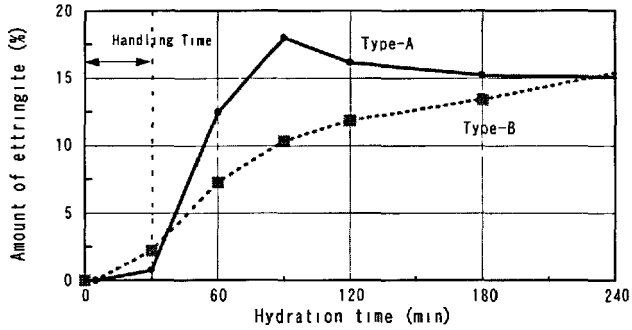

Fig.8 The relationship between the hydration time and amount of ettringite by XRD

The flowability is maintained during handling time. Then the concrete or mortar is liable to be moved by vibration. In the case of cement Type-A, ettringite is produced continuously from the early stage. The concrete or mortar of Type-A should be moved by given a stronger vibration in order to obtain a high bond strength. On the other hand, the bond strength of the concrete or mortar of cement Type-B is higher than one of Type-A if the vibration is given it. Its reason is considered that Type-B is liquefied easier than Type-A since Type-B forms less ettringite than Type-A during handling time. However, when too strong vibration is given it, the reason which the bond strength is lowered is considered that a thin layer having a plenty of segregation water and low strength is formed at the jointing surface between the base concrete and the rapid hardening concrete because cement Type-B is moved easily.

CONCLUSION

In our study, the followings were made clear about the relationship between the ettringite formation and the development of bond strength for two kinds rapid hardening cement.

i) The development of bond strength is affecting the vibration energy given to the concrete and the flowability of the concrete or the mortar, and the compressive strength isn't a strong factor for the bond property.

ii) It is considered that to give the vibration energy to the concrete and mortar is to move it, and then high bond strength is obtained.

iii) The most suitable condition of the vibrating compaction is different between cement Type-A and Type-B.

iv) The flowability is different since the ettringite formation is different at initial stage of the hydration between Type-A and Type-B.

v) In the case of Type-A, the flowability lowers with time, and the concrete or mortar should be given a stronger vibration in order to provide a high bond strength, since ettringite is produced continuously form water pouring.

vi) In the case of cement Type-B, the flowability is maintained until the termination of handling time and high bond strength is developed easily, since a little ettringite is formed for several minutes from water pouring by the vibration. However, the bond strength is decreased when too strong vibration energy is given to it.

The correlation between a quantity of the ettringite formation and the termination of handling time, and a measurement of magnitude of the vibration energy given to the concrete are subjects in the future.

INTERRELATIONSHIP AMONG LIME CONTENT OF CLINKER, ITS MICRO-STRUCTURE, FINENESS OF OPC GRINDING AND STRENGTH DEVELOPMENT OF HYDRATED CEMENT AT DIFFERENT AGES

S. P. GHOSH, National Council for Cement and Building Materials, New Delhi, India
K. MOHAN, National Council for Cement and Building Materials, New Delhi, India

ABSTRACT A rational correlation among lime content of clinker, its microstructure, fineness of OPC grinding and strength development of hydrated cement at different ages has been established. The study shows that the two most important factors affecting strength development of hydrated cement are : (i) mineral phase composition and microstructure of clinker, and (ii) particle size distribution of ground cement. The granulometry of clinker affects its grindability, measurable in terms of specific surface, whereas the mineral phase composition and microstructure of clinker affects the variations in (a) particle size distribution of ground cement, and (b) strength development of hydrated cement at different ages.

KEY-WORDS: Microstructure, Fineness, Strength development, Particle size distribution

INTRODUCTION

Microscopical observation is the most handy method to check the quality of cement. The microscopical method has been successfully used on the quality control in Japan, the USA and Canada. The relations between the burning conditions and the microscopical characters of clinker minerals are rather simple. The relations between the hydraulic activity and the microscopical characters are complicated. There are many factors which are closely related with activity, but cannot be detected by microscope. Howevere, the principal parts of the factors can be derived from the burning conditions, which can be detected by microscope. And so, the 28 days strength can be predicted by microscopical observation. The early strength at 1, 3 and 7 days is strongly influenced by the particle size distribution of cement, the contents of alkali and sulphates, C_3A solid solution and probably many other unknown factors. Therefore, the early strength cannot be predicted by microscopical observation (Ono, 1980).

In distinction to methodologies (Ono et al, 1965 and Ono, 1980), evolved for prediction of 28 days strength of cement from formulae based on morphology and microstructure of the corresponding clinker, the present investigation aims at establishing a rational correlation among lime content of clinker, its microstructure, fineness of OPC grinding and strength development of hydrated cement at different ages.

CASE STUDIES

Studies on day-to-day variation in cement strength for two dry process plants - plant A and plant B - have been carried out. The data reported in the present study has been collected from two plants over a considerable period of time (3-4 months). From operational view point, since the particle size distribution of ground cement is dependent upon the cement mill type and design, number of compartments, grinding media type and compartment-wise loading, the studies have been done under the aforesaid process and operational parameters remaining nearly constant. The details of cement mill of both the plants are given in Table 1.

Table 1 Details of Cement Mill of Plants A and B

	Parameters	Plant A	Plant B
(i)	Capacity	80 TPH	80 TPH
(ii)	No of Compartments and length	2;4.85m x 8.15m	2;4.5m x 8.15m

(vii)	Mill Outlet draft (mm WG)	150-160	160-170

Effect of lime content of clinker and fineness of cement on strength development of OPC

In general, compressive strength development in hydrated OPC is conventionally attributed to lime content of the base clinker and fineness (specific surface) of ground cement. The results of the effect of lime content of clinker and fineness (specific surface) of cement on strength development of OPC for both plants A and B are shown in Table 2.

Table 2 Clinker CaO, Cement fineness and Compressive Strength

Sl No	Sample Reference	Clinker CaO (%)	Specific Surface m2/kg	Compressive Strength (MPa)		
				3-days	7-days	28-days
	Plant A					
1	OPC-1	62.5	260.0	18.0	26.0	40.0
2	OPC-2	63.5	265.0	20.0	29.0	40.0
3	OPC-3	64.5	260.0	23.0	32.0	41.5
4	OPC-4	62.5	275.0	20.0	27.5	41.5
5	OPC-5	63.5	277.5	21.0	31.0	42.5
6	OPC-6	64.5	277.5	24.0	34.5	43.0
7	OPC-7	62.5	292.5	23.0	32.0	46.0
8	OPC-8	63.5	292.5	27.0	36.3	47.0
9	OPC-9	64.5	290.0	28.5	40.0	49.0
	Plant B					
10	OPC-10	63.5	252.5	21.0	29.0	42.0
11	OPC-11	64.5	255.0	26.5	35.0	43.0
12	OPC-12	65.5	252.5	27.5	37.0	45.0
13	OPC-13	63.5	272.5	24.0	36.0	47.0
14	OPC-14	64.5	270.0	27.5	39.0	48.0
15	OPC-15	65.5	270.0	29.5	41.0	47.0
16	OPC-16	63.5	285.0	29.5	39.0	49.0
17	OPC-17	64.5	285.0	31.5	43.0	50.0
18	OPC-18	65.5	282.5	33.0	44.0	50.0

In order to make a proper analysis and to arrive at a correct conclusion, only those clinkers have been included in the Table 2 which have more or less the same free lime and litre weight.

The results indicate that for plant A the compressive strengths at 3 and 7 days increase by about 20-30% and 20-25% respectively with increase in lime (CaO) content of clinker from 62.5% to 64.5% but with more or less the same fineness of cement. However, the compressive stsrength at 28 days is not affected much with increase in lime content of clinker. Similarly, for plant B the compressive strengths at 3 and 7 days increase by about 15-30% and 15-25% respectively with increase in lime content of clinker from 63.5% to 65.5% but with more or less the same fineness of cement. However, the compressive strength at 28 days remains unaffected with increase in lime content of clinker.

The results also indicate that for Plant A the compressive strengths at 3, 7 and 28 days increase by about 20-25%, 20% and 15-20% respectively with increase in fineness of cement from 260.0

m^2/kg to 290.0 m^2/kg but with same lime content of clinker. However, for plant B the compressive strength at 3, 7 and 28 days increase by about 20-40%, 20-35% and 10-20% respectively with increse in fineness of cement from 252.5 m^2/kg to 285.0 m^2/kg, but with same lime content of clinker.

The overall results show that for any particular plant, although higher lime content of clinker and finer grinding (higher specific surface) of cement is generally found to give a higher strength, the relationship is found to be mostly non-linear in majority of cases.

Effect of mineral phase composition and microstructure of clinker on strength development of OPC

The results of the effect of mineral phase composition and microstructure of clinker on strength development of OPC for both plants A and B are shown in Table 3.

Table 3 Mineral Phase Composition and microstructure of Clinker and Cement Compressive Strength

		Mineral Phase Composition %					Compressive Strength MPa		
Sl No	Sample Reference	C3S	C2S	C3A	C4AF	Microstructure	3-days	7-days	28-days
1	Clinker-1 (Plant A)	25-40	30-35	11-13	10-12	Alite with irregular outline and inclusion of belite. Belite better developed with twinning. More microhomogeneity in its normal phase distribution.	18.0-28.5	26.0-40.0	40.0-49.0
2	Clinker-2 (Plant B)	30-45	25-40	10-12	11-13	Well developed alite and belite. No twinning of belite. Rims of belite around alite and inclusion of belite within alite rare. More homogeneous microstructure.	21.0-33.0	29.0-44.0	42.0-50.0

The results indicate that the compressive strengths at 3 and 7 days of clinker-2 (from plant B) are higher than those of clinker-1 (from plant A), but the compressive strength at 28 days is more or less the same. This is because of higher C_3S content and better microstructure of clinker-2. Clinker-1 has 25-40% C_3S, whereas clinker-2 has 30-45% C_3S. Clinker-1 has alite with irregular outline and inclusion of belite. Belite is better developed with twinning. There is more microinhomogeneity in its normal phase distribution. Whereas, clinker-2 has well developed alite and belite and there is no twinning of belite. Rims of belite around alite and inclusions of belite within alite are rare. This clinker has more homogeneous microstructure.

Effect of particle size distribution on strength development of OPC

The results of the effect of particle size distribution of cement on strength develoipment of OPC for both plants A and B are shown in Table 4.

Table 4 Particle size distribution and compressive strength of cement

Sl No	Sample Reference	Particle Size Distribution (%)		Compressive Strength MPa		
		+90/u	+45/u	3-days	7-days	28-days
1	Cement-1 (Plant A)	8-12	35-40	18.0-28.5	26.0-40.0	40.0-49.0
2	Cement-2 (Plant B)	6-10	30-35	21.0-33.0	29.0-44.0	42.0-50.0

The result indicate that the compressive strengths at 3 and 7 days of cement-2 (from plant B) are higher than those of cement-1 (from plant A), but the compressive strength at 28 days is more or less the same. This is because of better particle size distribution of cement-2 as compared to cement-1. Cement-2 has 6-10% residue on 90/u and 30-35% residue on 45/u, whereas cement-1 has 80-12% residue on 90/u, and 35-40% residue on 45/u. The better particle size distribution of cement-2 is due to higher C_3S content and better microstructure of clinker-2.

The above findings are in agreement with the results obtained by Frigione and Mara (1976).

Effect of granulometry of clinker on grindability

The results of the effect of granulometry of clinker on grindability, measurable in terms of specific surface of ground cement, for both plants A and B are shown in Table 5.

Table 5 Clinker granulometry and grindability

Sl No	Sample Reference	Clinker Granulometry (%)			Specific Surface (m2/kg)
		+ 25mm	+ 12.5mm	+ 6.5mm	
1	Clinker-1 (Plant A)	10-15	10-25	15-20	240-290
2	Clinker-2 (Plant B)	8-12	15-20	20-2520-25	250-310

The results indicate that clinker-2 (from plant B) is easier to grind as compared to clinker-1 (from plant A). This is because of smaller size nodules of clinker-2. Clinker-2 has 8-12% residue on +25mm, 15-20% residue on +12.5mm and 20-25% residue on +6.5mm, whereas clinker-1 has 10–15% residue on +25mm, 10-25% residue on +12.5mm and 15-20% residue on +6.5mm.

CONCLUSION

The two most important factors affecting strength development of hydrated cement are : (i) mineral phase composition and microstructure of clinker, and (ii) particle size distribution of ground cement. The granulometry of clinker affects its grindability, measurable in terms of specific surface, whereas the mineral phase composition and microstructure of clinker affects the variations in (a) particle size distribution of ground cement, and (b) strength development of hydrated cement at different ages.

KINETIC PECULIARITIES OF HYDRATE- AND STRUCTURE FORMATION IN PORTLAND CEMENT AT INITIAL STAGES OF HARDENING

Valeriy CHISTYAKOV, Kiev State Technical University of Construction and Architecture, Ukraine
Valentin SHEVCHENKO, Metastrom Ltd., Kiev, Ukraine
Anatoliy DEGTYARYEV, Stock Society "Podylskiy Tsement", Kamenetsk-Podolskiy, Ukraine
Alexandr POLTAVTSEV, Kiev State Technical University of Construction and Architecture, Ukraine

ABSTRACT The regulations under which the processes of hydroxylation, polarization and condensation of new formations in the hardening Portland cement system have been experimentally revealed and discussed. The obtained results demonstrate that the initial stages of hardening, which cover the period from the moment when water was added to a cement, affect essentially the processes of nucleation and formation of a primary matrix based on how a condensation - crystallization structure (a bearer of strength of a cement paste) develops.

Key-words: Hydration, Kinetics, Induction period, Setting.

INTRODUCTION AND EXPERIMENTAL

The study is based on a phenomenon of resonance of elastic vibrations of a disperse structure of cement paste within a range of sound frequencies varying from 500 to 1500 Hz (Grankovskiy, 1984). A resonance frequency reflects variations in elastic characteristics of the hardening system (Khaikin, 1971). The works (Chistyakov et al, 1986) demonstrate that, along with determination of elastic properties, the above method allows to observe change in dispersion degree of the hardening system. It was proved theoretically and experimentally that the increase in resonance amplitude ($A_{res.}$) of hardening cement paste indicates the increase in degree of dispersing of the particles, whereas the decline of $A_{res.}$ may be attributed to the processes of aggregation and condensation of new formations.

Using a specially designed device "IG-IR"(Grankovskiy, 1984) at a value of input energy some orders lower than that resulting in destruction of the system, the quantitative dependencies reflecting variations in in elastic properties ($\omega_{res.}$) and dispersivity ($A_{res.}$) of the particles of the hardening cement pastes were produced. The patterns of the hydrating cement (points 1-12, Fig 1) were taken along with determination of amplitude- frequency characteristics. The hydration of the samples was stopped by washing out the water by 96 % ethanol. Solid residue was dried at 40^0C. The identification of the samples was done using X-ray Diffraction(XRD), Differential Thermal Analysis (DTA), and Infrared spectroscopy (IR).

RESULTS AND DISCUSSIONS

Considering the processes of hydrate formation in dependence with variations in elastic properties ($\omega_{res.}$) and degree of dispersing of the hardening system ($A_{res.}$) (Fig 1) allowed to reveal some regularities of strength development in portland cement paste. After mixing with water, the initial stage of hydration of portland cement is characteristic of the following general features:
a). high velocity of interaction of cement with water and intensive dispersing of the primary cement particles (Fig 1, curve Δm and $A_{res.}$, interval 0-1);
b). increase in interfacial surface and degree of its hydroxylation (Fig 1, curve I_1/I_o; Fig 2, data of IR spectroscopy).

c). gain of critical (at a given stage of hardening) degree of water content in the new formations (Fig 1, curve Δm, point 3; Fig 2, data of DTA). The increased content of the OH^- groups which are centers of physical adsorption of water (Kiselev and Lygin, 1972) is a cause of immobilization and structurization of a liquid phase in the surrounding of dispersion particles;
d). accumulation in the hardening system of excess energy. A characteristic total exothermal convexity of the DTA curves-patterns 2 and 3 proves, according to (Berg, 1962), the presence of finely dispersed hydrate new formations that are known to possess the excess energy (Fig 2);
e) retardation of the hydrate formation processes (Fig 1, curve Δm, interval 1-2);
f) gain by the cementitious system of critical metastable state (Fig 1, point 2) and initiating of the processes of inner structural condensation in the dispersion particles (curve $A_{res.}$, interval 2-3) with lowering the degree of their hydroxylation (curve I_1/I_0) and release within the interval 3-4 of some portion (10-30%) of the earlier bound water (curve Δm), strength of the hydrating system not increasing, but some loss of strength is observed (decline of $\omega_{res.}$).

During rearrangement of the initially formed hydrates their flaking from the cement grains takes place and new not hydrated surfaces occur. This correlates well with the increase in intensity of the lines appropriate for clinker minerals in the XRD. This effect is clearly seen in variations of intensity of the line d= 0.259 nm appropriate for C_3S and β-C_2S. Some increase in chemical activity of the liquid phase promoting intensification of the hydrate formation processes is fixed within the interval 4-5. After rearrangement of the primary structure upon achievement of critical concentration of new formations and setting an interstructural condensation causing strength gain is fixed. The processes of condensation of the new formations of a cement- water dispersion are found to be regulated by a value of excess energy and degree of hydroxylation of the surface of hydrates.

Within the interval 4-8 the above processes repeat, meanwhile a cause for this turned out to be phase transformations of the primary new formations and they occur in the conditions already formed periodic colloid structure.

Induction period

In the curve Δm reflecting a rate with which new formations attract water are fixed two sections (1-2 and 5-6) in which the rate of hydration does not change in practice (Fig 1). A wide band of continuous absorption within a field 1500- 4000 cm^{-1} is seen on the IR spectrums of the patterns selected within these time intervals giving proofs to the formation in the system of symmetrical hydrogen bonds characteristic of high rate of polarization (Tsundel, 1972). The occurrence of such bonds may exist in cases when, as a result of dispersing the solid phase particles, the distance between tetrahedrons $(SiO_4)^{4-}$ does not exceed 0.3 nm.The interaction of proton with ion O^{2-} in a crystalline lattice of the clinker mineral is a cause of initial elementary act of cement hydration. By strengthening the polarization of hydrogen bonds detected by the IR spectroscopy, the process of transfer of the proton by the hydroxyl oxygen ions or moleculars of water to ion of oxygen in the structures of clinker minerals. The amount of water bound per time unit in the section 1-2 lowers by 15-20 times as compared with the initial stage (interval 0-1). Thus, the polarization effects regulating the intensity of cement protonization is found to be one of the reasons initiating induction period.

Setting of cement

Some researchers consider ettringite as the main factor of setting. However, the latest experimental data does not prove this point of view. So, Bensted (1983) showed that during the

setting a share of ettringite in practice did not rise. While setting (Fig 1,curve Δm, interval 8-11), the degree of cement hydration increased insignificantly- from 5.6 to 6.2 %. The initial setting (point 8) corresponds to increase in dispersion degree (curve $A_{res.}$) and interface surface of the hardening system. With the use of dispersive analysis of the patterns of hardening cement selected as guided by the kinetic curves of structure formation a multiply as compared with the initial cement increase in quantity of the particles with size up to 4 μm (10-fold) and within a range from 4 to 10 μm (two-fold) within the interval 8-11 is fixed. This results in immobilization of the earlier bound water. Thus, the setting of cement is caused, predominantly, by immobilization of water by cement particles and primary hydrosilicate phases dispersing during this stage.

After the setting of cement paste a stable increase in intensity of the XRD lines appropriating for $Ca(OH)_2$ is fixed. An intensive increase in elastic properties and strength of the system after point 11 is caused by the formation of a space framework of portlandite as well as predominance of condensation processes over dispersing and destructive ones.

CONCLUSIONS

The experimental study allowed to demonstrate that a chemical potential and physical state of liquid phase, degree of hydroxylation of new formations which determine the intensity of hydrate formation, degree of interaction of associates, elastic properties of the hardening system and collective directivity of energy and concentration fluctuations vary cyclically at a stage of formation and colloid structure development.

The characteristic transition periods of structure formation corresponding to a predominant flow of dispersing or aggregation (condensation) processes in a cement-water dispersion were revealed. The intensity of flow and degree of completeness of these processes determine the conditions for formation of the matrix on a base of which the cement stone structure develops. The optimal actions and periods corresponding to rearrangement of the hardening system intensify and modify naturally occurring periods of transition of quantitative changes in the system into its qualitatively new state. Taking into account the revealed regularities allows to appoint optimal time of applying and technological regimes (moulding, repeated vibration, curing, etc.) (Grankovskiy, 1984 and Chistyakov, 1994).

ORGANO-MINERAL FILLERS FOR CEMENTS

Serge P. SIVKOV, Dmitry V. MUNDSHTUKOV, Imed JEDDA, D. Mendeleev University of Chemical Technology of Russia, Moscow, Russia

ABSTRACT The smectite and kaolinite clays modified by SNF plasticizer were used as filler additives to portland cement. It has been established, that the modified clays facilitate a grinding procedure, improve a granularity of cements, reduce their w/c ratio. The compressive strength and density of cements thus is increased considerably.
Key-words: filler, clay, grinding aids, plasticizers, modified cement.

INTRODUCTION

The properties of a hardened cement paste such as compressive strength, porosity, impermeability, dimensional stability, etc. are improved proportionaly with the reduction in the water/cement (w/c) ratio of a fresh mix. Plasticized cements containing so called superplasticizers as additives water-reducers have the w/c ratio by 25-50 % less than ordinary cements. Their compressive strength reaches 75-80 MPa. Such cements enable to create high-performance cement composites (Babaev et al., 1990, Durekovic, 1992, Batrakov et al., 1988).

The technology of production of plasticized cements consists in simultaneous pulverisation of clinker portland, gypsum, puzzolanic admixtures with a dry powder of a superplasticizer. But there's too great a superplasticizer consumption in this process (up to 2-5 % mass.) becaus of its chemiosorption and destruction that are intensified by high temperature in a cement mill (Nanazashvili and Babaev, 1990).

This article deals with scope for an application of organo-mineral nanocomposites to production of plasticized cements. In the organo-mineral nanocomposite the molecules of an organic substance (polymers or monomers) are intercalated within interplanar spaces, channels and cavities of a molecular dimension in the crystal structure of an inorganic material (Theng, 1982, Tunney and Detellier, 1993, Messersmith and Giannelis, 1993). The resulting hybrides possess unique mechanical, electrical, optical and thermal properties. Thus, the intercalated polymer exhibits higher thermal and chemical stability not observed in a bulk polymerized macromolecules and can be liberated by dissolution or by decomposition of the host (Wang and Pinnavaia, 1994, Wu and Lerner, 1993).

EXPERIMENTAL

The high-plastic smectite (montmorillonite ≈ 88 %) and kaolin (kaolinite ≈ 94 %) clays and the industrial sulphonated naphthalene formaldehyde superplasticizer (**SNF**) were used for the synthesis of organo-mineral plasticizers (**OMP**). The clays and the superplasticizers were mixed in 1:1, 2.5:1 and 5:1 ratios. The mixture was wetted by adding the necessary amount of water, than homogenized during 12 hours and dried at 80 °C.

Ordinary portland clinker (C_3A = 9 %, C_3S = 58 %) was taken for experiments. Gypsum (5 %) and **OMP** (1 and 3 %) were applied as additives to cement. The pure clays and pure dry **SNF** plasticizer were used for grinding of control cements. The grinding procedure was carried out in the laboratory mill "Pulverisette-7" closely under steady conditions.

RESULTS AND DISCUSSION

Table 1 gives the Blaine specific surface of the pulverized cements.

Table 1 Blaine specific surface and w/c ratio of cements

	Blaine specific surface, $m^2 \cdot kg^{-1}$		W/C ratio for constant fluidity,	
Cement	OMP smectite	OMP kaolin	OMP smectite	OMP kaolin
Control	383.0		30	
+ 1 % SNF	411.3		23	
+ 1 % pure clay	403.6	418.7	29	27
+ 1 % OMP 1:1	409.3	429.0	23	23.5
+ 1 % OMP 2.5:1	416.1	436.2	24	24
+ 1 % OMP 5:1	418.0	438.9	26	25.5
+ 3 % pure clay	409.2	429.6	32	31
+ 3 % OMP 1:1	426.0	445,7	21	20
+ 3 % OMP 2.5:1	437.5	452,9	22	20.5
+ 3 % OMP 5:1	438.3	477,7	23	23

A significant increase in the specific surface area of the cements with **OMP** can not be explained only by the clay's influence because, on the one hand, the addition of pure clays changes the specific surface area slightly and, on the other hand, the BET surface specific of the clays modified by **SNF** is 1.4-1.5 times lower than the one of the starting clays (54.82 *v.* 39.18 $m^2 \cdot g^{-1}$ for smectite and 21.87 *v.* 15.11 $m^2 \cdot g^{-1}$ for kaolin respectively).

The particle size analysis of cements performing with laser-diffraction particle size distribution analyser "Analysette-22" shows (Fig. 1 and Table 2) that in cements with **OMP** the content of fine particles is increased. The granularity of cement with 1 % **SNF** differs slightly from the one of the control cement.

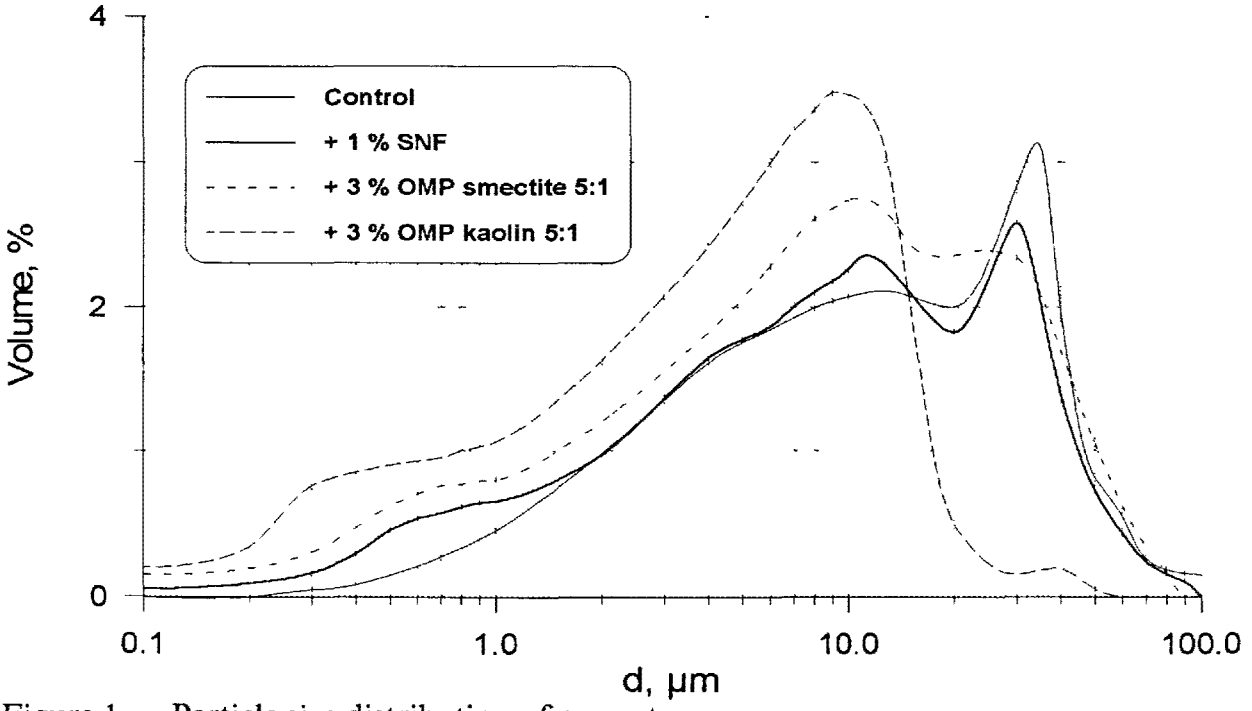

Figure 1. Particle size distribution of cements

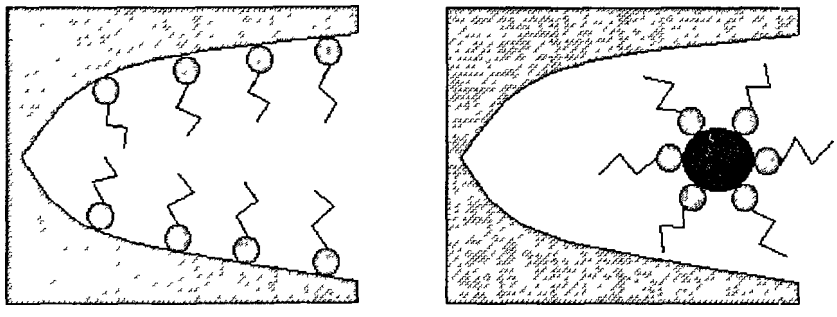

According to the classical Rebinder's theory adsorption of molecules of a tensioactive substance on a surface of solids decreases the surface energy, promotes microfissures sprawl and inhibits particle agglomeration (Fig.2a).

Table 2. Particle size characteristics of cements

Cement	Arithmetic mean diameter, μm	Geometric mean diameter, μm	Spec. surface area (calc), $m^2 \cdot ml^{-1}$	Spec. surface area (BET), $m^2 \cdot g^{-1}$
Control	15.45	8.29	1.89	1.10
+ 1 % SNF	14.75	8.01	1.92	2.14
+ 3 % OMP smectite 5:1	13.30	7.29	2.05	2.24
+ 3 % OMP kaolin 5:1	8.66	5.21	2.85	2.32

Nevertheless when cements are ground with a dry superplasticizer in a dry atmosphere of a cement mill it is difficult to presume the separation of a superplasticizer into individual molecules, its diffusion and the uniform spread over the cement particle surface. On the other hand the **OMPs** have the slight hardness and are ground quikly to particles < 1 μm. Penetration of fine **OMP** particles with molecules of the tensioactive substance adsorbed on their surfaces within microfissures of clinker portland (Fig. 2b) facilitates and expedites the grinding of cements, hinders the aggregation of cement grains.

The w/c ratio of the cements containing **OMPs** is less than w/c of the cements with 1 % **SNF**, though with 3 % **OMP** of the 5:1 composition the content of superplasticizer in cement is no greater than 0.5 % (Table 1).

a b

Figure 2. Scheme of **SNF** and **OMP** action

High fluidity of the cement paste is related with an increase in the fine fraction content in cement and with the better conservation of **SNF** during grinding procedure.

Table 3 gives mechanical and structural characteristics of hardened cements. The measurements were carried out for the cement pastes of constant fluidity.

The best values of the compressive strength were obtained for the cements with **OMP** on the kaolin base. It should be noted that at the age of 1 and 3 days the compressive

strength of cements with **OMP** is less than the compressive strength of cement with 1 % **SNF**, but it is more than the one of the control cement.

Table 3. Compressive strength and porosity of cements

Cement	R_{28}, MPa	Total porosity, %	Open porosity, $cm^3 \cdot g^{-1}$
Control	46.8	18.0	0.057
+ 1 % SNF	54.2	15.1	0.039
+ 3 % OMP smectite 5:1	71.6	14.6	0.032
+ 3 % OMP kaolin 5:1	77.9	11.8	0.034

The cements with **OMP** have lower values of total and open porosity than the control cement and the cement with 1 % **SNF**, wich is related with a decrease in the w/c ratio and with a compaction of hydrated cement by fine clay particles.

There were no any changes in the phase composition of hydrated cements with **OMP** compared with the cement containing 1 % **SNF** observed.

CONCLUSION

The organo-mineral nanocomposites have a greater effect on grinding of cement, plasticity of a cement paste, mechanical and structural characteristics of a hardened cement than pure **SNF** superplasticizer. Besides clays other inorganic materials of an appropriate structure and slight hardness (amorphous silica, zeolites, $Ca(OH)_2$, etc.) show promise to be used for the syntesis of **OMP**.

THE THERMOKINETIC FACTOR IN CEMENT HARDENING

Alexander V. USHEROV-MARSHAK, Otar P. MCHEDLOV-PETROSSYAN, Anatoly G. SINYAKIN, State technical University of Building and Architecture, Kharkov, Ukraine

ABSTRACT The important role of the thermokinetic factor in the hardening of cement is established. The interrelation between parameters of time and temperature of hardening as a result of natural and artificial heat impact is marked. The necessity of quantitative evaluation and registration of thermokinetic characteristics of different cements within the range of informative (computer) technologies of concrete is shown.

KEY-WORDS: Calorimetry, Heat evolution, Hydration, Metod, Temperature

INTRODUCTION

In 1984 (Usherov-Marshak, 1984) a classification of hardening processes of binders by thermokinetic signs - velocity and fullness of heat evolution of hardening - into three types was suggested. Many of cement properties - setting velocity, hardening growth and others are determined by the type of thermokinetic regularities, presence and duration of the principal periods of the hardening (inductive, accelerated and decelerated) as well as the intensity of the hydration reactions. It is proved that for the regulation of the hardening process the parameters of heating impacts must be assigned with consideration for thermokinetic characteristics.

METHOD OF THERMOKINETIC ANALYSIS

In the chemistry of cement the calorimetry is widely used. The principal difference of our method which we call thermokinetic analysis is the possibility of computer registration and interpretation of dependences of $dQ/d\tau=f(\tau)$, $Q=f(t)$ and $dQ/d\tau=f(Q)$ kind with simultaneous interpretation of hydration periods and the prediction of heat evolution.

Earlier was given the description of calorimetric experiment methods with the interaction of disperse character and the original mathematic apparatus for building nonisothermal dependencies for different variants of heat impacts in the interval 20-180^0 C (Usherov-Marshak and Sinyakin, 1992). The development of the treatment brings about the formal and conceptual modelling of hydration reactions after the data of heat evolution. The obtained information is automatically directed in the computer banks of the thermokinetic knowledge.

WHAT IS THE THERMOKINETIC FACTOR ?

The thermokinetic factor of hardening (TKF) - is the reason which rules the process as result of interaction between two important and differing in their nature physical parameters - temperature and time. TKF is the result of manifistation of the mechanism and kinetics of elementary acts of hydration - adsorption, chemical reaction, dissolution, crystallization and others under the influence of temperature conditions.

The effect of TKF is obvious in the cases of hydration of highthermal monomineral binders - CaO and $3CaO \cdot Al_2O_3$. They belong to the first type of thermokinetic regularities. High indices of reaction velocity and heat evolution stipulate selfheating of hardening mixes. The discrepancy between the velocity and hydration degree destroys the structure of hydrates and does not allow the rise of strength at normal conditions (20^{0}C). In this case natural heat impact is manifested.

Lowering of hydration temperature to 0^0C and lower changes the degree of velocity and fullness of reactions and leads to the formation of stable new formations with enough strength.

Another example is the hydration of MgO. Low velocity of heat evolution at 20-50^0C changes into rough growth over 60-70^0C. The hydration becomes uncontrollable. The natural heat impact causes the change of the type of thermokinetic regularity and possible alteration in reactions mechanism.

The hydration of lowbasic binders of the third type regularities - slags, ashes, calciumoxide-silica-compositions is accompained by very low heat evolution. Activation of the hydratation by alkalies and sulfates insignificantly intensifies reactions. The contribution of endoeffects resulting from dissolving and break of the bonds of Ca-O, Al-O, Si-O type is high. Therefore TKF plays insignificant role in the evolution of hydration and formation of their nature. The natural heat impacts through hydration heat of cement raise the TKF meaning in massive concrete constructions. Therefore thereby we use low exotermal cement, introduce additives and cool the massives.

THERMOKINETIC FACTOR AND ARTIFICIAL HEAT IMPACTS

The coherence principle

Artificial heat impacts are stipulated through elevated (80-180^0C) or so called negative (0-20^0C) temperatures, chemical additives and others. They change the condition and character of hardening process, change the degree of use of the binders, the strength and durability. The character of the natural and artificial impacts is different but within any temperature interval is characterised by common time parameters, the moment, intensity and continuance of application. Earlier was shown (Mchedlov-Petrossyan, 1991) the necessity of the coordination of impact parameters with the hydration kinetics (the coherence principle).

To estimate the influence of time and temperature while assigning the regime of cements and concrete hardening different conditional indices, coefficients, "degree-hours" and others were offered. But they had no physico-chemical sense. The thermokinetics allows to overcome methodological complications. Principal physico-chemical indices of velocity and completeness of heat evolution are appraised. The apparatus of thermokinetic analysis allows to receive and interprete the results for any hardening regime.

The data of Fig1. are illustrating the truth of this conclusion by the example of the thermokinetic indices at the hardening of C_3S. The experimental data provide possibility according to calorimetric results to estimate the influence of alteration in the moment of heat impact within the interval of 2-6 hours, velocity - 10-30^0C/hour and duration of heating 0-8 hours. The heating temperature changes from 30^0C to 80^0C. As a matter of fact this is the search for the optimal regime for concrete hardening with consideration of TKF. With help of thermokinetic dependencies $dQ/d\tau=f(\tau)$ and $Q=f(\tau)$ the direct proportion between impact moment of heat treatment and maximum of the process velocity is marked. It is important that value of dQ/dt decreases with the rise of application time from 11 to 7 cal/g•h, the hydration completeness with the exception of short period (to 10 hours) is practically the same. The regulation of heating velocity from 10 to 30^0C/hour proportionally shifts the emergence time and data of maximum of heat evolution from 11 to 7.5 cal/g•h. This is quite explicable. But some slowering of the velocity of the initial reactions leads to the increase of $Q=f(\tau)$.

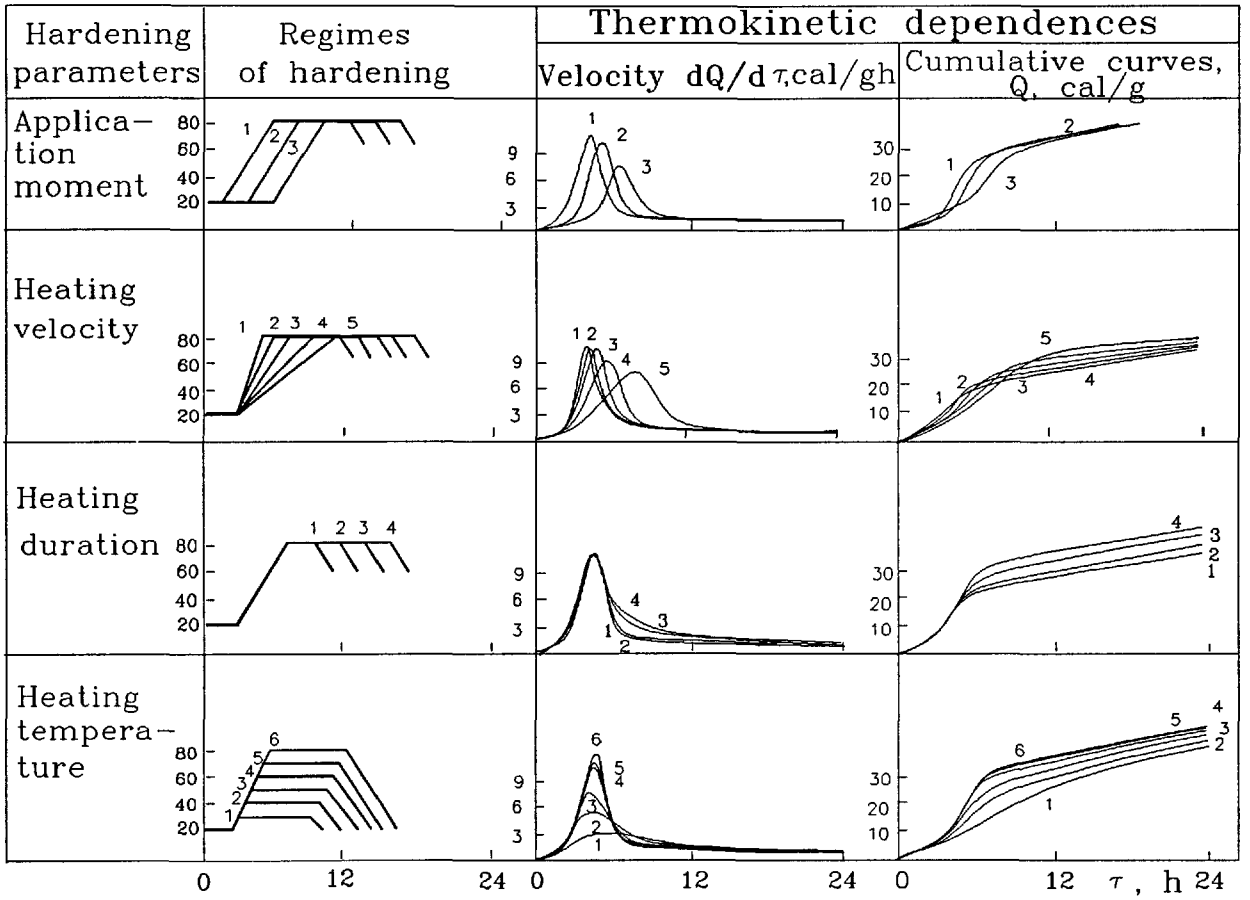

Figure 1 Non-isothermal heat evolution at the hardening of $3CaO \cdot SiO_2$

Earlier a discussion took place about the applicability of the Le-Chatelier principle for the substantiation of the parameters of the heat impacts. The jist of the discussion is that if before the end of heating of the hardening mix the process velocity does not reach the maximum the cooling must lower its completeness. If the principal exotherm appears before heating - the continuance of the isotherm does not essentially influence the growth of fullness of heat evolution. For the hardening C_3S the increase of duration of the heating in the studied interval contributes to the growth of the degree of the use of hardening properties.

Unlike this for cements the integral heat evolution depending on their activity, kinds of mineral or chemical additives can fall or rise. Especially evident is the rise of heat evolution by introducing surface active agents, hindering the initial hydration. In the nonisothermal thermokinetics most appreciable is the role of hardening temperature boundary (Fig 2). The absolute meaning of the maximum of exotherm rises proportional to the rising of these parameters. But the heat evolution falls. Principally important is that the information of TKF allows to formulate the bases of data and knowledge for expert systems and information technologies of cement and concrete (Frohnsdorff et al, 1988, Usherov-Marshak and Sinyakin, 1994).

INFLUENCE OF $CaCO_3$ ON THE HYDRATION OF VARIOUS TYPES OF CALCIUM ALUMINATES WITH ANHYDRITE

Yoko OHBA*, Akinori NAKAMURA**, Jong Kyu LEE*,
Etsuo SAKAI*, and Masaki DAIMON*
* Dept. of Inorganic Materials, Tokyo Institute of Technology, Tokyo, Japan
** Cement & Building Materials Laboratory, Tokuyama Co., Ltd., Yamaguchi, Japan

ABSTRACT Limestone powders were investigated for the filler cement as ecological materials and as a functional cement for the flowing concrete. However, the reactions between limestone powders and calcium aluminates were not clear, quantitatively. In this study the reactions between the limestone powders and the calcium aluminates such as C_3A, $C_{11}A_7{\cdot}CaF_2$ and $C_{12}A_7$ glass, were examined and effects of anhydrite to above reactions were investigated, quantitatively.

Key-words: Calcium aluminates, Limestone powders, Hydration, Anhydrite.

INTRODUCTION

Various types of calcium aluminates were widely used for the main composition of super high early strength cements and rapid hardening cements, and additives. Recently, the amounts of the reinforcement of the bridge girder and so on, and the repairment increased, where calcium aluminates were used with $CaSO_4$. And $CaSO_4$ are used as additives for the high strength concrete. For such progressing technologies of construction, the fluidity must be required to the super high early strength cement. On the other hand, the limestone powders were used for the filler cement as ecological materials and for the flowing concrete as functional cement, and were investigated (Hosino et al, 1995). Therefore, the super high early strength and the high flow concrete used the super high early strength cement together with limestone powders will be important as advanced construction technology.

The reactions of the limestone powders ($CaCO_3$) during the hydration of cements were investigated for the filler cements (Sakai et al, 1993) and for portland cement (Asaga and Kuga, 1995, and Grandet and Olliver, 1980). It was cleared that C_3A was reacted with $CaCO_3$ and produced monocarbonate (Kuzel and Pollman, 1980, Manabe et al, 1961, and Hosokawa et al, 1995). However, the reactions of $CaCO_3$ between calcium aluminates $C_{11}A_7{\cdot}CaF_2$ and calcium aluminate glass of $C_{12}A_7$ composition ($C_{12}A_7$ glass) were not cleared quantitatively .

In this study, we investigated the reactions between $CaCO_3$ and calcium aluminates with and without $CaSO_4$, quantitatively.

EXPERIMENTAL

Materials

C_3A and $C_{11}A_7{\cdot}CaF_2$ were synthesized in a laboratory electric furnace at 1350 °C and 1300 °C, respectively, from chemical reagents ($CaCO_3$, Al_2O_3 and CaF_2). $C_{12}A_7$ glass was synthesized by quenching meltage at 1600 °C. Limestone powders ($CaCO_3$: calcite, Tsukumi Japan) and anhydrite ($CaSO_4$, Thailand) were granulated and their specific

surface areas were shown in Table 1.

Table 1 Specific surface areas of materials (Blaine's method)

Materials	C_3A	$C_{11}A_7 \cdot CaF_2$	$C_{12}A_7$glass	$CaCO_3$
Specific surface area (m^2/kg)	410	390	385	510

Sample preparation

Calcium aluminates and $CaCO_3$ were mixed, where the Al_2O_3 / $CaCO_3$=1 in molar ratio. $CaSO_4$ was added to the mixed powders, and the amount of $CaSO_4$ varied from 0 to ettringite composition. They were kneaded with distilled water at 20 °C, and the water / solid ratios in weight were 0.8 to form pastes. The pastes were poured into polystyrene bottles (5 ml), and sealed with polystyrene films. They were cured at 20 °C for 1 - 28 days. After the curing time, the samples were crushed in excess acetone, and were dried by an aspirator for 16 hours. The amount of the combined water was estimated by the ignition loss (at 1000 °C, for 30min.) and by the amounts of $CaCO_3$.

Measurement of reaction ratios and amounts of hydrated products by XRD

The phases in the hydrated samples were identified by XRD. The amounts of C_3A, $C_{11}A_7 \cdot CaF_2$, $CaCO_3$, C_3AH_6 and $C_3A \cdot CaCO_3 \cdot 11H_2O$ were decided by XRD (Isizaki et al., 1988). Pure C_3AH_6 and $C_3A \cdot CaCO_3 \cdot 11H_2O$ were synthesized by the hydration of pure C_3A. MgO as internal standard was added to the sample in 10 weight %, and the scanning speed was 0.02 deg. (2 θ) / 20sec..

RESULTS AND DISCUSSION

The reactions of between various type of calcium aluminates and $CaCO_3$

Table 2 shows the hydrated products and unhydrated materials at each reacting duration in C_3A, $C_{11}A_7 \cdot CaF_2$ or $C_{12}A_7$glass - $CaCO_3$ systems measured by XRD.

At 1 - 28 days, C_3AH_6 and monocarbonate were formed in the systems of C_3A - $CaCO_3$ and $C_{11}A_7 \cdot CaF_2$ - $CaCO_3$. In the system $C_{12}A_7$ glass - $CaCO_3$, C_2AH_8 and monocarbonate were formed at 1 -7 days, and at 28 day only monocarbonate existed as the hydrated product.

Table 2 Hydration products of various calcium aluminates with $CaCO_3$

	Hydration time (days)	1	3	7	28
C_3A $-CaCO_3$	Products	C_3AH_6 Mc	C_3AH_6 Mc	C_3AH_6 Mc	C_3AH_6 Mc
	Unhydrated materials	C_3A $CaCO_3$	C_3A $CaCO_3$	C_3A^* $CaCO_3$	$CaCO_3$
$C_{11}A_7 \cdot CaF_2$ $-CaCO_3$	Products	C_3AH_6 Mc	C_3AH_6 Mc	C_3AH_6 Mc	C_3AH_6 Mc
	Unhydrated materials	$C_{11}A_7 \cdot CaF_2$ $CaCO_3$	$C_{11}A_7 \cdot CaF_2$ $CaCO_3$	$C_{11}A_7 \cdot CaF_2^*$ $CaCO_3$	$CaCO_3$
$C_{12}A_7$glass $-CaCO_3$	Products	C_2AH_8 Mc	C_2AH_8 Mc	$C_2AH_8^*$ Mc	Mc
	Unhydrated materials	$CaCO_3$	$CaCO_3$	$CaCO_3$	$CaCO_3$

Mc : monocarbonate, * : small amount

Figure 1 shows relations between the reacting duration and the reaction ratios of C_3A and $C_{11}A_7{\cdot}CaF_2$ measured by XRD. The reaction ratios of both C_3A and $C_{11}A_7{\cdot}CaF_2$ increased till 1 day and increased to 28 day. At 28 day, both reaction ratios showed 100%.

Figure 2 shows the reaction ratios of $CaCO_3$ in each systems. In C_3A system, the reaction ratio of $CaCO_3$ was 53% at 1day, and 79% at 28day. In $C_{11}A_7{\cdot}CaF_2$ system, it was 25% at 1 day, and 30% at 28 day. In $C_{12}A_7$ glass system, 11% of $CaCO_3$ reacted 1 day and 47% at 28 day. The amount of the reacting $CaCO_3$ in $C_{12}A_7$ glass - $CaCO_3$ system was less than those of other calcium aluminates systems at 1day, and the results agreed with the earlier report about the hydration of $C_{12}A_7$ glass (Hosokawa et al., 1995).

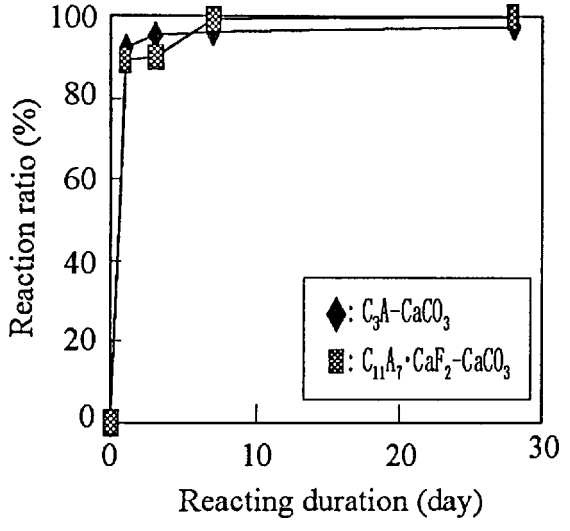

Figure 1 Reaction ratio of various calcium aluminates measured by XRD.

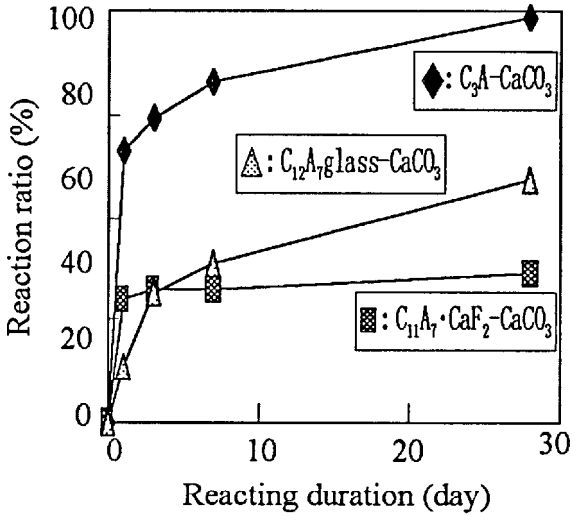

Figure 2 Reaction ratio of $CaCO_3$ measured by XRD.

Figure 3 shows the relations between the amount of reacted $CaCO_3$ (mol) and the amount of produced monocarbonate (mol). In C_3A - $CaCO_3$ system, the slope of the solid line is 1. The reaction formula for the formation of monocarbonate was written as Eq 1.

$$C_3A + CaCO_3 + 11H_2O \rightarrow C_3A{\cdot}CaCO_3{\cdot}11H_2O \quad [1]$$

In $C_{11}A_7{\cdot}CaF_2$ - $CaCO_3$ and $C_{12}A_7$glass - $CaCO_3$ systems, the slope of the dashed line is 0.53. The theoretical formula for the formation of monocarbonate in $C_{11}A_7{\cdot}CaF_2$ - $CaCO_3$ system was written as Eq 2.

$$C_{11}A_7{\cdot}CaF_2 + 4CaCO_3 + 52H_2O \rightarrow 4(C_3A{\cdot}CaCO_3{\cdot}11H_2O) + 2Al(OH)_2F + 2AH_3 \quad [2]$$

For the systems $C_{11}A_7{\cdot}CaF_2$ - $CaCO_3$ and $C_{12}A_7$glass - $CaCO_3$, the slope was 0.53 (dashed line), was not 1 (solid line). It was thought that the part of $CaCO_3$ existed as a gel. Then Eq 2 can be written as Eq 3.

$$C_{11}A_7{\cdot}CaF_2 + 4CaCO_3 + 52H_2O \rightarrow 2.12(C_3A{\cdot}CaCO_3{\cdot}11H_2O) + 1.88(C_3A_{2.1}{\cdot}CaCO_3{\cdot}11H_2O{\cdot}1.1Al(OH)_2F{\cdot}14.2H_2O)gel \quad [3]$$

The amounts of unhydrated $C_{12}A_7$ glass and produced C_2AH_8 were difficult to measure directly, so they were estimated as follows. The reaction formula for the formation of

monocarbonate in $C_{12}A_7$ glass - $CaCO_3$ system was written as Eq 4, theoretically.

$$C_{12}A_7 \text{ glass} + 4CaCO_3 + 53H_2O \rightarrow 4(C_3A \cdot CaCO_3 \cdot 11H_2O) + 3AH_3 \quad [4]$$

As $C_{11}A_7 \cdot CaF_2$ - $4CaCO_3$ system, the slope was 0.53 and the part of reacted $CaCO_3$ existed as a gel. Then Eq 4 can be written as Eq 5.

$$C_{12}A_7 \text{ glass} + 4CaCO_3 + mH_2O \rightarrow 2.12(C_3A \cdot CaCO_3 \cdot 11H_2O) + 1.88(C_3A_{2.6} \cdot CaCO_3 \cdot nH_2O)\text{gel} \quad [5]$$

In this system, unreacted $CaCO_3$ and the formed monocarbonate were observed, but C_3AH_6 or C_2AH_8 were not detected by XRD at 28 day. Supposing that the reactions except Eq 5 did not occur in the system, the combined water of the gel (n) was estimated. Then Eq5 was written as Eq 6. Therefore the amount of the reacted $C_{12}A_7$ glass was estimated from the amount of the reacted $CaCO_3$ given by Eq 6.

$$C_{12}A_7 \text{ glass} + 4CaCO_3 + 53.4H_2O \rightarrow 2.12(C_3A \cdot CaCO_3 \cdot 11H_2O) + 1.88(C_3A_{2.6} \cdot CaCO_3 \cdot 16H_2O)\text{gel} \quad [6]$$

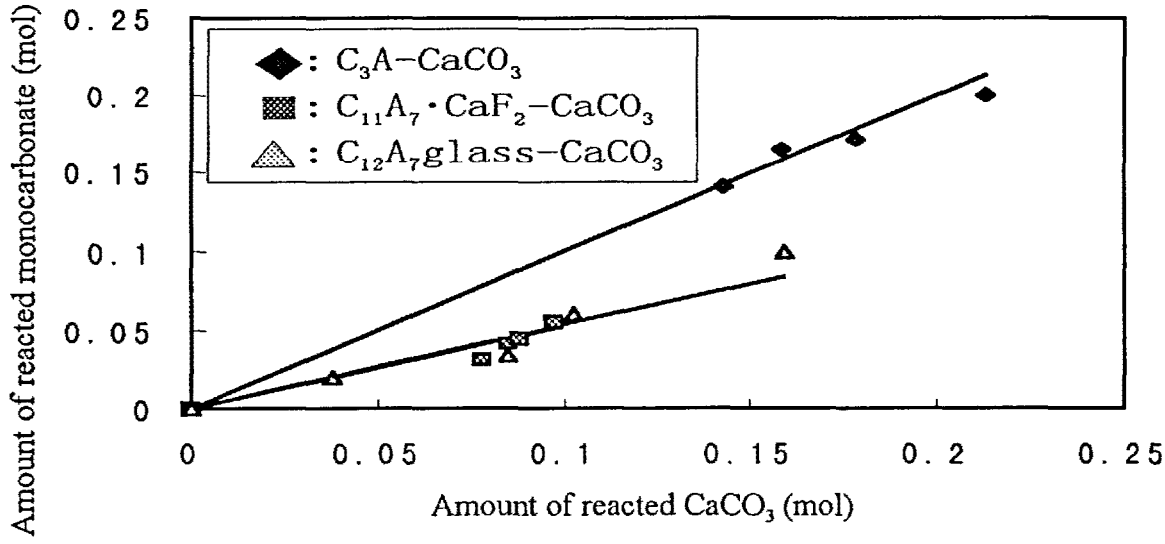

Figure 3 Relations between amount of produced monocarbonate and reacted $CaCO_3$.

In case of existing C_2AH_8 together, other reaction was also occurred. In this case, the amount of unreacted $C_{12}A_7$ glass was calculated from the amount of the combined water from Eqs 6 and 7.

$$C_{12}A_7 \text{ glass} + 51H_2O \rightarrow 6C_2AH_8 + 3AH_3 \quad [7]$$

Phase composition of hydrated various calcium aluminates - $CaCO_3$ systems

Changes in the phase compositions of the hydrated systems of C_3A, $C_{11}A_7 \cdot CaF_2$ and $C_{12}A_7$glass - $CaCO_3$ are shown in Figs 4, 5 and 6, respectively. The phase compositions are shown in weight percent of the unhydrated counts, (because the density of each compounds was unknown.)

In C_3A - $CaCO_3$ system, following reactions occurred;

$C_3A + 6H_2O \rightarrow C_3AH_6$ [8]
$C_3A + CaCO_3 + 11H_2O \rightarrow C_3A{\cdot}CaCO_3{\cdot}11H_2O$ [1]
$C_3AH_6 + CaCO_3 + 6H_2O \rightarrow C_3A{\cdot}CaCO_3{\cdot}11H_2O$ [9]

Till 1 day, the reactions of Eqs 8 and 1 proceeded simultaneously. Most of C_3A reacted for 1 day. After 1 day, while the reaction of Eq 9 proceeded until all C_3AH_6 or $CaCO_3$ was consumed, the amount of the produced monocarbonate kept on increasing.

In $C_{11}A_7{\cdot}CaF_2$ - $CaCO_3$ system, the following reactions were thought to proceed;

$C_{11}A_7{\cdot}CaF_2 + 31H_2O \rightarrow 4C_3AH_6 + 2Al(OH)_2F + 2AH_3$ [10]
$C_{11}A_7{\cdot}CaF_2 + 4CaCO_3 + 52H_2O \rightarrow 2.12(C_3A{\cdot}CaCO_3{\cdot}11H_2O)$
$+ 1.88(C_3A_{2.1}{\cdot}CaCO_3{\cdot}11H_2O{\cdot}1.1Al(OH)_2F{\cdot}14.2H_2O)$gel [3]

The same as the C_3A system, the reactions of Eqs 10 and 3 proceeded simultaneously till 1 day. Not so remarkable as the C_3A system, C_3AH_6 reacted with $CaCO_3$ to form monocarbonate. In this system, the reaction formula for the formation of monocarbonate was expressed as Eq 3.

In the $C_{12}A_7$ glass - $CaCO_3$ system, the following reactions were thought to occur;

$C_{12}A_7$ glass $+ 51H_2O \rightarrow 6C_2AH_8 + 3AH_3$ [7]
$C_{12}A_7$ glass $+ 4CaCO_3 + 53.4H_2O \rightarrow 2.12(C_3A{\cdot}CaCO_3{\cdot}11H_2O)$
$+ 1.88(C_3A_{2.6}{\cdot}CaCO_3{\cdot}16H_2O)$gel [6]

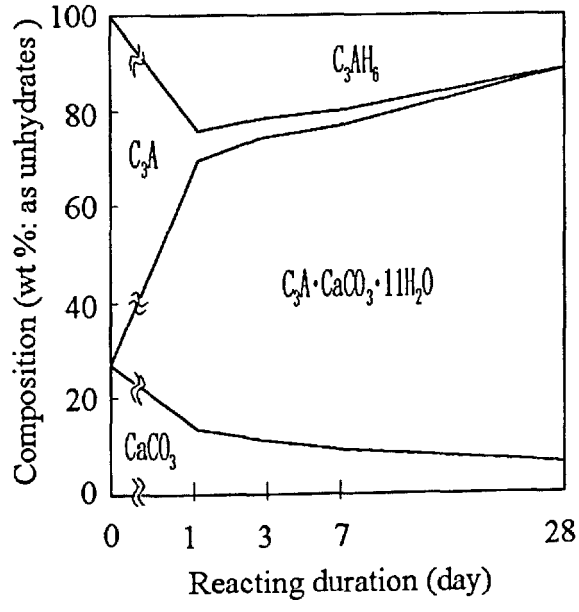

Figure 4 Composition change of hydrated C_3A-$CaCO_3$ system.

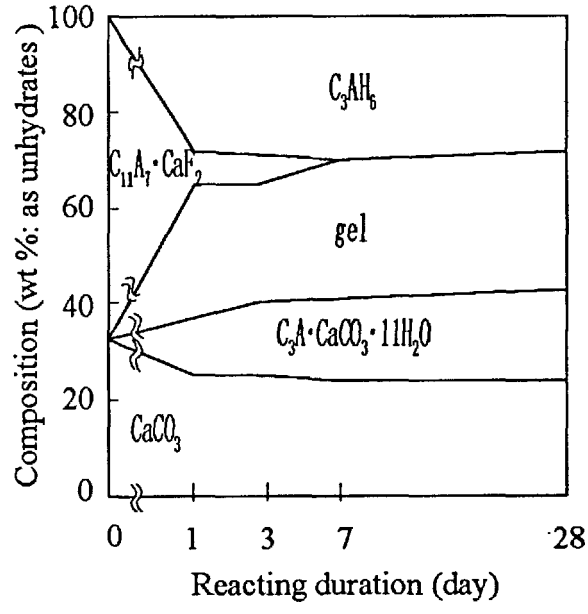

Figure 5 Composition change of hydrated $C_{11}A_7{\cdot}CaF_2$-$CaCO_3$ system.

In this system, at 1 day, most of C_2AH_8 produced and $CaCO_3$ hardly reacted. Therefore the reaction Eq 7 proceeded predominately. At 28 day, as mentioned above, the reaction in the $C_{12}A_7$glass - $CaCO_3$ system was written as Eq 6.

Calcium aluminate hydrates reacted with $CaCO_3$ and monocarbonate formed in the various calcium aluminates - $CaCO_3$ systems. In the hydrated systems of $C_{11}A_7 \cdot CaF_2$ - $CaCO_3$ and of $C_{12}A_7$glass - $CaCO_3$, $CaCO_3$ was suggested to be included in the gel. But the further experiment was necessary to discuss about it .

Reactivity of $CaCO_3$ in hydrated calcium aluminates - $CaSO_4$ - $CaCO_3$ systems

Figure 7 shows relations between the reaction ratio of $CaCO_3$ and the molar ratio of $CaSO_4$ / C_3A at 7 and 28 days in the C_3A - $CaSO_4$ - $CaCO_3$ system. Without $CaSO_4$, 79% of $CaCO_3$ reacted at 28 day sample. But with $CaSO_4$, the ratio of $CaCO_3$ decreased with the increasing of the ratio of $CaSO_4$ / C_3A. When the ratio of $CaSO_4$ / C_3A more than 2.5, $CaCO_3$ did not react until 28 day.

Figure 8 shows relations between the reaction ratio of $CaCO_3$ and the ratio of $CaSO_4$ / $C_{11}A_7 \cdot CaF_2$ at 7 and 28 days in the $C_{11}A_7 \cdot CaF_2$ - $CaSO_4$ - $CaCO_3$ system. Without $CaSO_4$, 30% of $CaCO_3$ reacted at 28 day sample. But with $CaSO_4$, the ratio of $CaCO_3$ decreased with the increasing of the ratio of $CaSO_4$ / $C_{11}A_7 \cdot CaF_2$. $CaCO_3$ did not react, where $CaSO_4$ / $C_{11}A_7 \cdot CaF_2 = 12$ of the ettringite composition, till 28 day.

Figure 9 shows relations between the reaction ratio of $CaCO_3$ and the ratio of $CaSO_4$ / $C_{12}A_7$ glass at 7 and 28 days in $C_{12}A_7$glass - $CaSO_4$ - $CaCO_3$ system. Similar to the other calcium aluminates systems, without $CaSO_4$, 47% of $CaCO_3$ reacted at 28 day sample. But with $CaSO_4$, the ratio of $CaCO_3$ decreased with the increasing of the ratio of $CaSO_4$ / $C_{12}A_7$glass. $CaCO_3$ did not

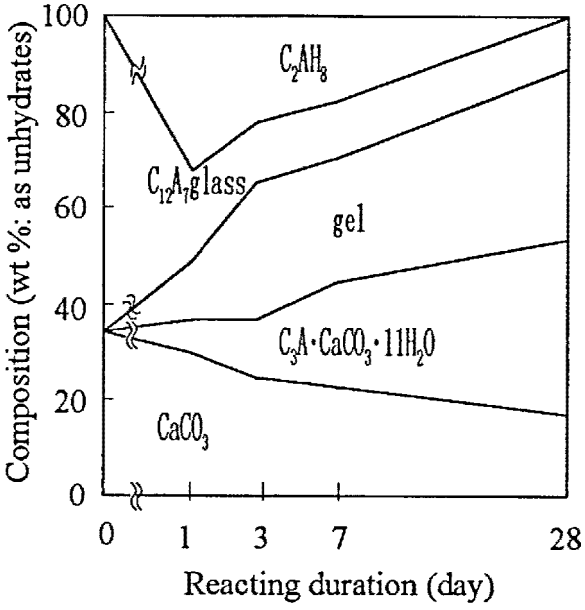

Figure 6 Composition change of hydrated $C_{12}A_7$ glass-$CaCO_3$ system.

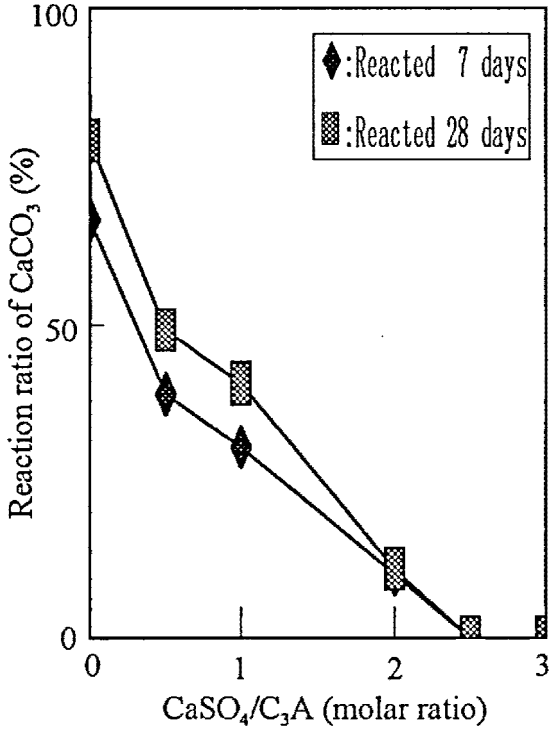

Figure 7 Relations between $CaSO_4/C_3A$ ratio and reaction ratio of $CaCO_3$.

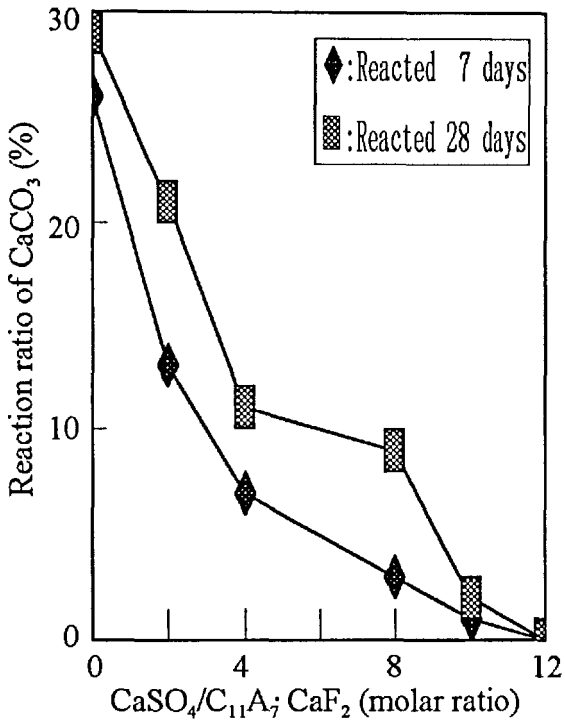

Figure 8 Relations between $CaSO_4/C_{11}A_7 \cdot CaF_2$ ratio and reaction ratio of $CaCO_3$.

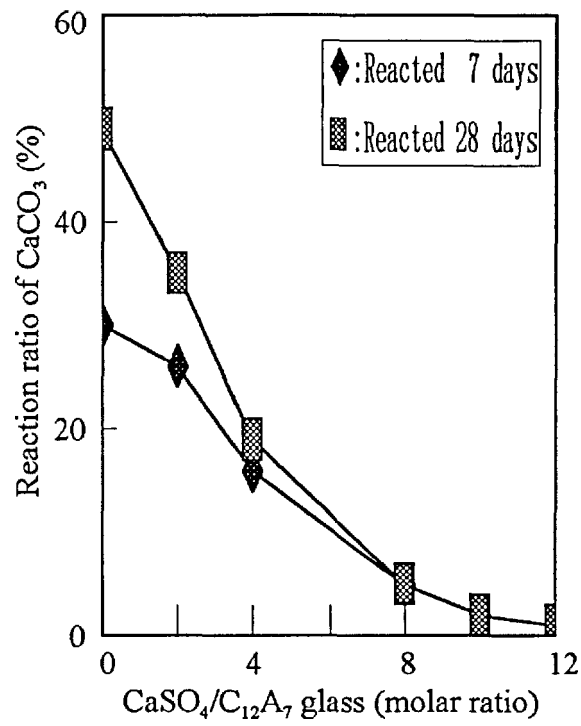

Figure 9 Relations between $CaSO_4/C_{12}A_7$ glass ratio and reaction ratio of $CaCO_3$.

react, where $CaSO_4$ / $C_{12}A_7$ glass = 12 of the ettringite composition, till 28 day.

In all the calcium aluminates - $CaSO_4$ - $CaCO_3$ systems, mentioned above, C_3A, $C_{11}A_7 \cdot CaF_2$ and $C_{12}A_7$ glass without $CaSO_4$, the reaction ratios of $CaCO_3$ showed the highest value.

The reaction ratios of $CaCO_3$ decreased with the increasing of the additional $CaSO_4$. $CaCO_3$ did not react when the amount of $CaSO_4$ closed to the composition of ettringite. But the ratio of $CaSO_4$ less than that of the composition of ettringite, $CaCO_3$ greatly influenced the hydration mechanisms of calcium aluminates - $CaSO_4$ systems.
As a results, in order to use the limestone powders as the inert filler, the required amount of $CaSO_4$ was near the composition of ettringite.

CONCLUSION

The hydration of the various types of calcium aluminates, C_3A, $C_{11}A_7 \cdot CaF_2$ and $C_{12}A_7$ glass, and the reactivity of $CaCO_3$ with or without $CaSO_4$ has been investigated. The following results were derived.

1) The reaction ratios of $CaCO_3$, in various types of calcium aluminates - $CaCO_3$ systems, C_3A, $C_{11}A_7 \cdot CaF_2$ and $C_{12}A_7$ glass, were 79%, 30% and 47%, respectively.
2) The molar ratio of produced monocarbonate / reacted $CaCO_3$ was 1 when C_3A-$CaCO_3$ system. But when the calcium aluminate was $C_{11}A_7 \cdot CaF_2$ or $C_{12}A_7$ glass, the ratio of produced monocarbonate / reacted $CaCO_3$ was 0.53. That might be caused by the gel including $CaCO_3$.
3) Various types of calcium aluminates reacted with $CaSO_4$ rather than $CaCO_3$ predominately, and the reaction of $CaCO_3$ was controlled by the amount of $CaSO_4$.

SEQUENCE OF HYDRATION PROCESS DURING HARDENING OF HIGH ALUMINA CEMENT

Valeriy CHISTYAKOV, Kiev State Technical University of Construction and Architecture, Ukraine
Vladimir SERBIN, National Technical University of Ukraine, Kiev, Ukraine

ABSTRACT The results of experimental studies on hydration kinetics peculiarities of high-alumina cement minerals in the conditions of steam curing are summarized and discussed. The process of hardening of cement has been demonstrated to be characterized by a sequence under which the processes of hydration of minerals CA and CA_2 occur and different intensity of crystallization of C_3AH_6 and AH_3.

Key-words: High alumina cements, Hydration, Kinetics, Temperature

INTRODUCTION AND EXPERIMENTAL

With the use of a specially designed device "IG-IR" (Grankovskiy, 1984) allowing to determine the elastic characteristics of the system ($\omega_{res.}$) and change in degree of dispersion of the hardening system ($A_{res.}$) the processes of structure formation in the cement paste and stone have been studied at 70^0C (Fig 1). The increase in the resonance amplitude ($A_{res.}$) proves the prevalence of dispersing processes, while the decline of $A_{res.}$ is caused by the aggregation (condensation) processes (Chistyakov et al, 1986). In accordance with the structure formation curves $\omega_{res.}$ and $A_{res.}$ a selection of patterns of the hardening cements was made. Specially treated patterns were examined using X-ray diffraction (XRD), Differential Thermal analysis (DTA) and Infrared spectroscopy (IR). Points and figures on the structure formation curves (Fig 1) correspond to numbers of the patterns. The heating of the cell filled with cement paste was done in a steam-air medium with a velocity of 4^0C/ min. to simulate the heating regime of hot pressing technology of the compositions based on high alumina cement.

RESULTS AND DISCUSSIONS

An intensive increase of the interface surface (curve $A_{res.}$) caused by the dispersing of the primary particles of the cement and hydrolysis of clinker minerals CA and CA_2 are fixed immediately after cement is mixed with water.

The data of XRD prove that the primary weakly crystallized hydrates start to form from the moment when a cement is mixed with water and during mixing of the cement paste. In point 2 (Fig 1), when the temperature of the cement paste approaches 50^0C, the intensity of the line appropriate to AH_3 and C_3AH_6 increased to some extent. The interval 1-2, in accordance with character of the curves $\omega_{res.}$, $A_{res.}$ and Δm, corresponds to a first stage of structure formation of the cement paste, and the degree of hydration Δm increases insignificantly (from 2.28 for non-hydrated cement to 5.13%).

A sharp lowering of the values of $A_{res.}$ after point 2 proves the aggregation of disperse phase and intensive condensation processes. The inner stresses occurring in the structure being formed occur as a result of this process and a primary formed colloid network turned out to be disturbed as a result of their relaxation. This destructive process is fixed by a sharp loss of the elastic properties of the hardening cement paste (decline of values of $\omega_{res.}$ after point 2). The interval 2-3 with total duration 7 min. corresponds to the setting of the cement paste. A sharp increase of

rate of binding water (interval 2-3, curve Δm) is fixed at the moment of setting. The amount of water bound with new formations has increased twice: from 5.13% (pattern 2) to 11.5% (pattern 3). The elastic properties of the hardening system enhance greatly ($\omega_{res.}$= 550 Hz in point 2 and 900 Hz in point 3, Fig 1).

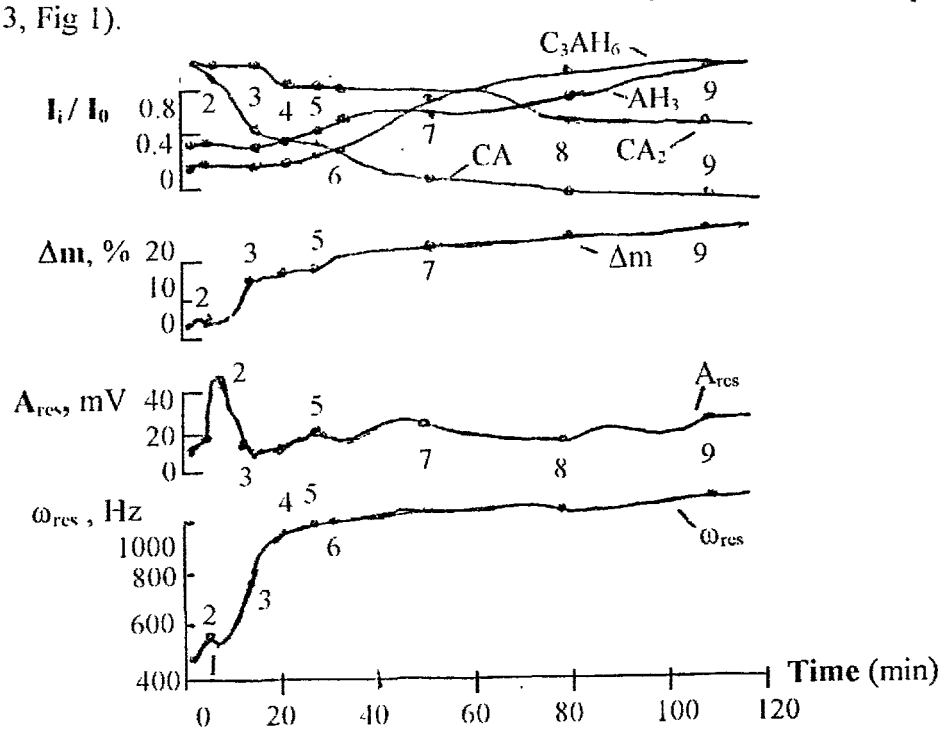

Figure 1 The kinetic curves of structure formation of the cement paste and stone at 70°C : $\omega_{res.}$- resonance frequency (Hz), $A_{res.}$- resonance amplitude (mV), Δm- degree of hydration (loss of mass by the pattern while heating up to 1000°C,%). Figures on the curves correspond to numbers and time of selection of XRD, DTA, and IR patterns.

I_i/I- the ratio of intensities of lines on X-ray diffractograms; I_i - the intensity of lines CA (d=0.295 nm), CA_2 (d=0260 nm), AH_3(d=0.482 nm), C_3AH_6 (d=0.55 nm) of a corresponding pattern; I- the intensity of a line characteristic of: CA-d=0.295 nm (non-hydrated cement); CA_2-d=0.260 nm (non-hydrated cement); AH_3-d=0.482 nm (pattern 9), C_3AH_6-d=0.515 nm (pattern 9).

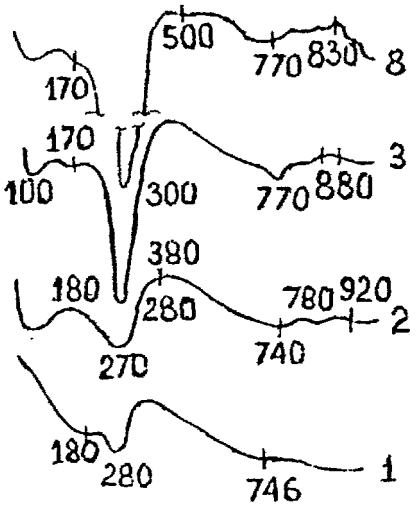

Figure 2 The DTA curves of the patterns selected according to structure formation development (designations as in Fig 1).

The hydration of clinker minerals and crystallization of hydrates was evaluated by variations in intensities of characteristic lines appropriate to above compounds on the X-ray diffractograms. The lines to be examined were selected for they would be characteristic only for one compound and to escape superposing of distances between the planes of other compounds. The line with d=0.295 nm was selected for CA, and 0.260 nm, 0.515 nm and 0.482 nm - for CA_2, C_3AH_6 and AH_3, respectively. The data produced testify to a more intensive hydration of CA as compared with CA_2. Was found that 50% of CA and 14% of CA_2 have reacted in point 3. After the setting is over (interval 3-4) the formation of hydrates slows considerably as compared with the previous period. After point 4 the CA_2 does not hydrate in practice and the hydrates are formed predominantly as a result of CA hydration The interval 4-6 is characteristic of the greatest intensity of AH_3 and C_3AH_6. The data of XRD demonstrate that gibbsite crystallizes with a greater velocity.

The interval 6-7 corresponds to the induction period for both CA and CA_2 (Fig 1). Meanwhile, the formation of hydrates is not over. C_3AH_6 is formed more intensively and is accompanied by retardation of crystallization of AH_3. A retardation of the processes of binding water is fixed within the interval 7-8 (Fig 1, curve Δm), and the hardening system is characterized by maximum values of ω_{res} reflecting elastic properties of the cement paste.

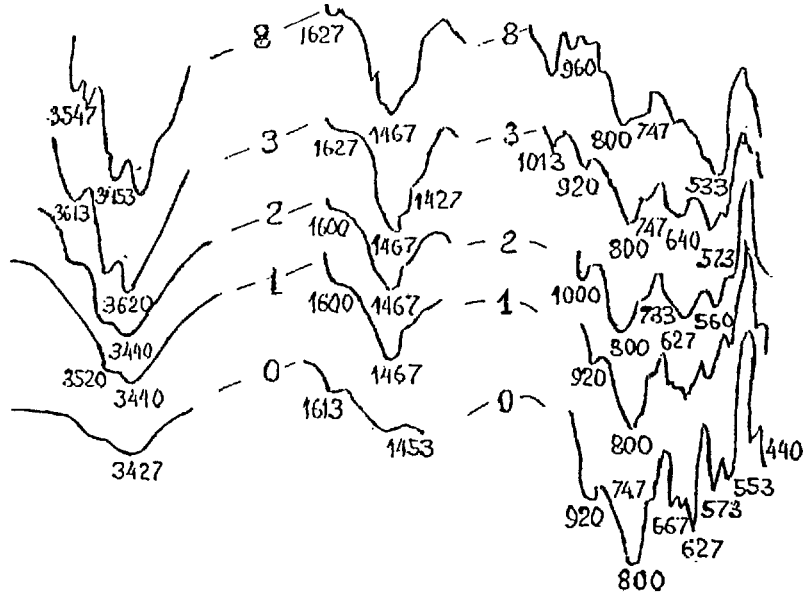

Figure 3 The IR- spectrums of the patterns selected according to structure formation development (designation as in Fig 1, the curve 0- infrared spectrum of non-hydrated cement).

The endotherm at 90°C appears on the DTA curve of the pattern 8 again, the intensity of endotherm at 170°C becomes weaker (Fig 2). Additional endotherm appears at 240°C, and testifies to the formation of carboaluminate of calcium $3CaOAl_2O_3$ $CaCO_3$ $12H_2O$. This conclusion correlates well with the data obtained using XRD.The endotherm within a field of 300°C on the DTA curve of the pattern 8 splits into 300 and 320°C. This effect is caused by the increase of the content of AH_3 and C_3AH_6 in the hardening system. The effect that appeared at 500°C may be referred to both AH_3 and C_3AH_6. Resulting from further heat treatment of the hardening system phase transformations of the hydrates take place what finds its reflection on the DTA curves and disappearance of some replicas on the X-ray diffractograms. Simultaneously, the intensive crystallization of AH_3 is observed.

The fragments of IR spectrums of the patterns of hardening cements selected according to a structure formation development (Fig 1) are given in Fig 3. Change in intensity of the bands 440cm^{-1} (bonds CaO-O in calcium-oxygen octahedrons) are fixed. The presence in the cement minerals of calcium- and alumino-oxygen polyhedrons initiates the superimposing of the Al-O- and Ca-O-bonds within an interval 400-600 cm^{-1} as well as the occurrence of "mixed" Al-O-Ca vibrations. A variation in intensities of the absorption bands 530 cm^{-1} which reflects the Al-O-Ca-bonds in the structure [(OH)O_4Al-O-CaO_4OH)] or [(OH)$_2O_3$Al-O-CaO_3(OH)$_2$] is fixed. This effect may be attributed to change in the degree of polymerization of the octahedrons and the degree of their hydroxylation. At the moment of setting, some growth of intensity of the bands of AH_3 (3660, 3625, 3540, and 1020 cm^{-1}) and C_3AH_6 (3628, 522 cm^{-1}) is fixed (Kuznetsova, Talaber, 1988).

During the hydration and increase of the interface surface, the adsorption of carbonic acid from the air to produce carbonate complexes (bands 1370-1480 cm^{-1}) takes place. At different stages of hardening the intensity of this process varies resulting from prevalence of the hydrates that are present. A maximum carbonization of aluminate complexes is reached after the setting of the cement (pattern 4). A cyclic change of degree of dispersing of the hardening system resulting from rearrangement of metastable forms of hydrates is observed at this period. The greatest changes in the IR-spectrums are fixed within a field 3000-4000cm^{-1} characteristic of stretching vibrations of hydroxyl-ions. According to structure formation development (Fig. 1), a positive effect of heat treatment on the hardening system is over near point 8. The prevalence of the condensation processes observed near point 7 (curve $A_{res.}$) and stabilization of the elastic properties (curve $\omega_{res.}$ before point 8) are changed by the strengthening of dispersing and destructive processes.

CONCLUSIONS

The process of hardening of high-alumina cement at 70^{0}C is characterized by a consequence of hydration of minerals CA and CA_2. At the moment of setting (interval 2-3) a sharp growth of the rate with which water is bound is fixed. This period is characteristic of the formation of calcium hydroaluminates detected by XRD in an amorphous state. An intensive joint crystallization of AH_3 and C_3AH_6 is observed after the setting. A heat treatment of the hardening high-alumina cement allows to minimize the formation of metastable hydroaluminates of calcium CAH_{10} and C_2AH_8 to produce at 70^{0}C a cement stone composed of stable hydrate phases AH_3 and C_3AH_6.

After 1.5 hrs of hydrothermal treatment, the processes initiating the strengthening of a cement stone become considerably slower (after point 8). Further heat treatment results in the intensification of phase transformations of hydrates, rearrangement of the cement stone structure formed and the development of destructive processes.

CALCULATION OF THE MAXIMUM SUPERSATURATION CURVE OF C_2AH_8 IN THE $CaO-Al_2O_3-H_2O$ SYSTEM AT 20°C

Denis DAMIDOT, LAFARGE Laboratoire Central de Recherche, St-Quentin Fallavier, France
Pierre BARRET, Laboratoire de Recherches sur la Réactivité des Solides, Dijon, France

ABSTRACT The knowledge of the maximum supersaturation curves of the hydrates is of great importance in order to understand the hydration process. In the $CaO-Al_2O_3-H_2O$ system, only parts of the maximum supersaturation curve of C_2AH_8 have been determined experimentally. As it is very difficult to advance theories in order to calculate the maximum supersaturation values, we have developed a calculation method which is based on experimental data and thermodynamic calculations. This method which has been applied to the maximum supersaturation curve of C_2AH_8, can also be used for other systems.

Key-words: Calcium aluminate cement, Hydration, Thermodynamics, Phase diagram

INTRODUCTION

Hydraulic binders react through a dissolution precipitation mechanism whose driving force is based on a higher solubility of the solids that is dissolved relatively to the hydrate that precipitates. Thus during the dissolution process, the composition of the aqueous phase reaches supersaturated region with respect to the hydrate which precipitates after an induction period. The duration of the induction period mainly depends on the supersaturation value which is reached: higher supersaturation values decrease the duration of the induction period. As a consequence, if the induction period is less than 1 second, the precipitation seems to be immediate for human eyes. An hydraulic binder will have a setting time which is very closely related to the amount of hydrate formed and thus to the duration of the induction period before the start of the period of growth of the hydrates. Thus the setting time is linked with the ability of the solid which dissolves, to reach the highest supersaturation as possible in order to have the shortest induction period. This aptitude will mainly depends on the position of the equilibrium curve of the solid that dissolves relative to the region of supersaturation that induces a quasi-immediate precipitation of the hydrate (practically no induction period). This last region is delimited by a maximum supersaturation curve with respect to the hydrate that precipitates. It can exist two main cases that are represented on Fig 1:

- in case A, the equilibrium curve of the solid that dissolves is on the left of the maximum supersaturation curve. As a consequence, it is possible to reach the equilibrium curve of the dissolving solid during the hydration process. The aqueous phase is supersaturated with respect to the hydrate, but it exist an induction time before the start of the hydrate precipitation as the supersaturation value is not high enough to induce an immediate precipitation. This case represents hydraulic binders that do not induce a rapid setting such as CA.
- in case B, the maximum supersaturation curve with respect to the hydrate is reached first. This induces a rapid hydrate precipitation which prevents the aqueous phase to reach the equilibrium curve with respect to the solid that dissolves. This case corresponds to hydraulic binder that sets rapidly such as C_3A.

Most of the experimental and theoretical work on the hydration is generally based on the knowledge of the equilibrium curves of the hydrates and sometimes on the solids that dissolves, and also on the kinetic paths. However the determination of the maximum supersaturation curves did not find the same enthusiasm even if these are as important in order to understand the mechanism of the early hydration which is linked with the workability of hydraulic binders. This

may be due to the experimental difficulties in order to determine these curves but also to the impossibility to calculate them theoretically without any experimental data.

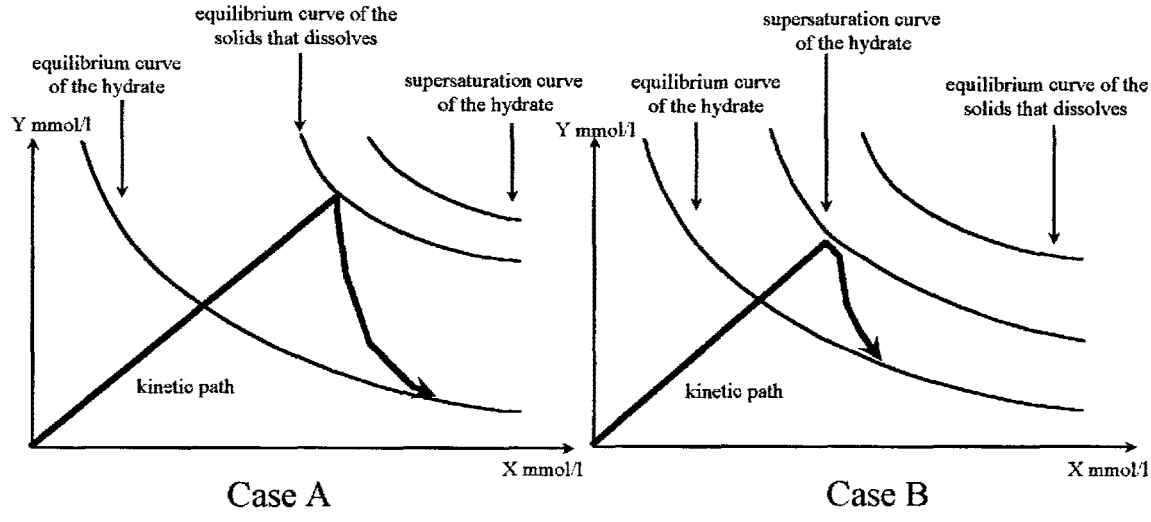

Fig 1. Schematic representation of the two major cases that can occur during the early hydration of hydraulic binders.

From our knowledge, some points of the maximum supersaturation curves have been defined experimentally for C-S-H (Barret, 1986) and for C_2AH_8 (Bertrandie, 1977, Barret, 1980). The maximum supersaturation curve of C_2AH_8 (named curve I) is very important in order to understand the hydration process in the $CaO-Al_2O_3-H_2O$ system. However curve I is not very well defined from the experiments (Fig 2).

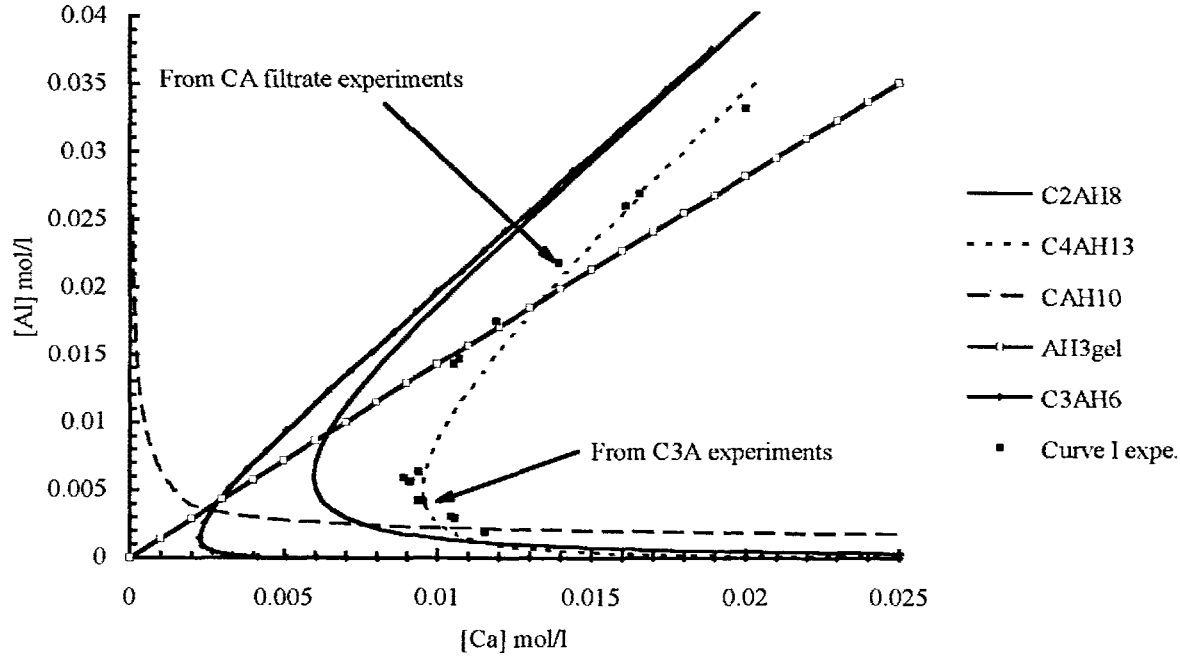

Fig 2. Experimentally determined points of the maximum supersaturation curve with respect to C_2AH_8 (curve I) added to the $CaO-Al_2O_3-H_2O$ phase diagram calculated at 20°C

It exists an unknown part between the two groups of points which correspond to two different types of experiments. The first group has been obtained by the modification of the composition of supersaturated solutions recovered during CA hydration (Bertrandie, 1977). The second group was defined during C_3A hydration in various lime solutions (Barret, 1980). It should be possible to reach experimentally the unknown part of curve I using $C_{12}A_7$ hydrated in various solutions. But we wanted to find a general method that enables us to calculate a maximum supersaturation curve by combining the data of some experimentally determined points of this curve and thermodynamic calculations.

EXPERIMENTAL: METHOD OF CALCULATION

In a first approach, Barret (Barret, 1994) dried to calculate the curve I from curve m (curve of iso-supersaturation with respect to C_2AH_8 and AH_3): curve I was similar to curve m but with a supersaturation value (βm) of 12. This method was accurate enough in the upper part of curve I (high aluminate concentrations) but could not describe the bottom part of curve I: curve I was crossing the equilibrium curve of C_2AH_8 and thus describing some aqueous compositions undersaturated with respect to C_2AH_8. This problem was the consequence of curve m equation which is similar to C_4AH_{13} but with a value of the solubility product divided by 2: C_2AH_8 and C_4AH_{13} equilibrium curves always cross whatever the value of the solubility product.

In the present approach, we started to calculate the supersaturation value of C_2AH_8 (β2) at the experimental points that define curve I using a speciation program derived from PHREEQE (Parkhurst, 1980). The following dissolution equation for C_2AH_8 was considered:

$$2CaO.Al_2O_3.8H_2O \Rightarrow 2\,Ca^{2+} + 2Al^{3+} - 10H^+ + 13H_2O$$

The use of Al^{3+} and H^+ as ionic species instead of $Al(OH)_4^-$ and OH^- respectively is due to the thermodynamic database which is associated to PHREEQE. As a consequence, the value of the solubility product of C_2AH_8 at 20°C differs from the usual value which is calculated with $Al(OH)_4^-$ and OH^- (Barret, 1994):

$$K_{C2AH8} = (Ca^{2+})^2(Al^{3+})^2(H^+)^{-10}(H_2O)^{13} \text{ with Log } K_{C2AH8} = 60.79 \text{ at } 20°C \qquad [1]$$

There is no obvious relation between the calcium concentration and β2 (Table 1). On the contrary, the value of β2 appears to increase monotonously with the aluminate concentration in the aqueous phase (Fig 2). This behaviour can be accurately fitted with an exponential growth function (Fig 2 and Table 1):

$$\beta 2 = 2.934156.10^{0.05235.[Al]} \quad \text{with [Al] in mmol/kg and T=20°C} \qquad [2]$$

For a given aluminate concentration it is possible to estimate the value of β2 using Eq. 2. Thus we can calculate the iso-supersaturation curve with respect to C_2AH_8 for the corresponding β2 value: Log $K_{\beta 2}$ has to be considered in Eq. 1 instead of Log K_{C2AH8}:

$$\text{Log } K_{\beta 2} = \text{Log } K_{C2AH8} + \text{Log } \beta 2 \qquad [3]$$

Two of these iso-supersaturation curves are represented on Fig 3 for β2 equal to 6.05 and 40.52 which correspond to [Al] equal to 6 and 21.78mmol/kg respectively. From these curves, it is possible to determine the calcium concentration which corresponds to the starting aluminate concentration:

- [Ca]=9.02mmol/kg for [Al]=6mmol/kg and β2=6.05

- [Ca]=13.95mmol/kg for [Al]=21.78mmol/kg and β2=40.52

Each pair of points, ([Ca],[Al]), represents one point of curve I. Thus if the same method is used for all [Al] concentrations ranging from 0.1 to 40mmol/l, it is possible to determine accurately curve I.

Table 1. Aqueous phase composition for experimentally determined points of curve I (Bertrandie, 1977, Barret, 1980) and value of the supersaturation with respect to C_2AH_8 (β2) obtained with the experimental points and from Eq. 2

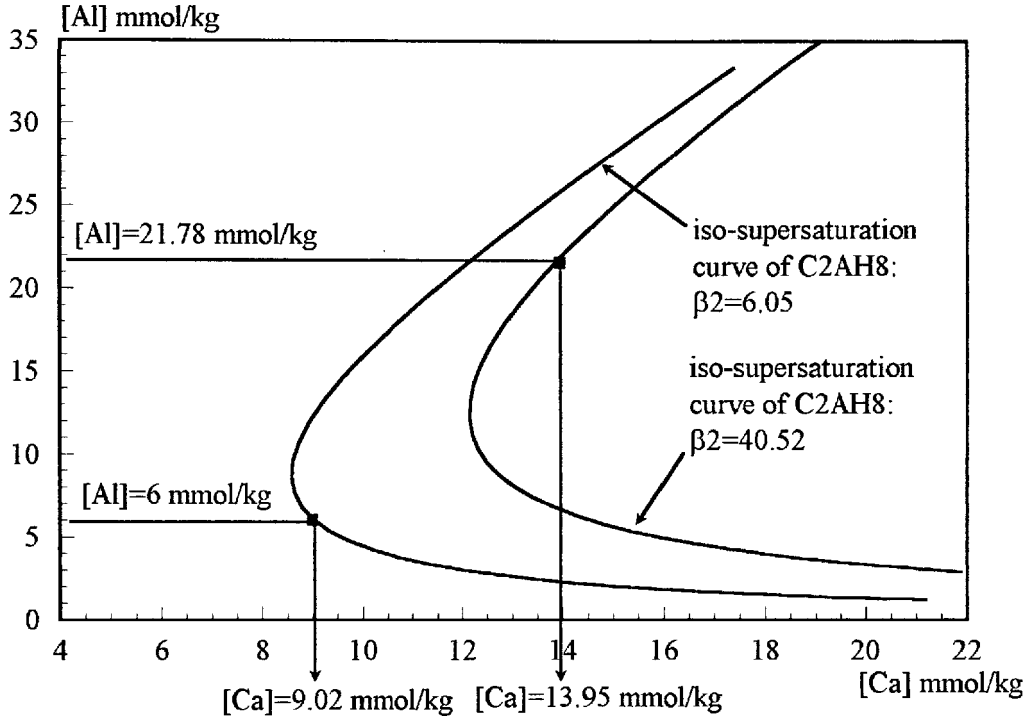

Fig. 4. Calculated iso-supersaturation curves with respect to C_2AH_8 and corresponding pairs of ([Ca],[Al]) concentrations which belong to curve I.

RESULTS & DISCUSSION

The results of the calculation of curve I at 20°C are given in Table 2. The calculated curve I was added to the $CaO-Al_2O_3-H_2O$ phase diagram (Fig 5): this curve is in good agreement with the experimental data. As expected, curve I remains in the supersaturated region with respect to C_2AH_8 and never crosses the equilibrium curve of C_4AH_{13}.

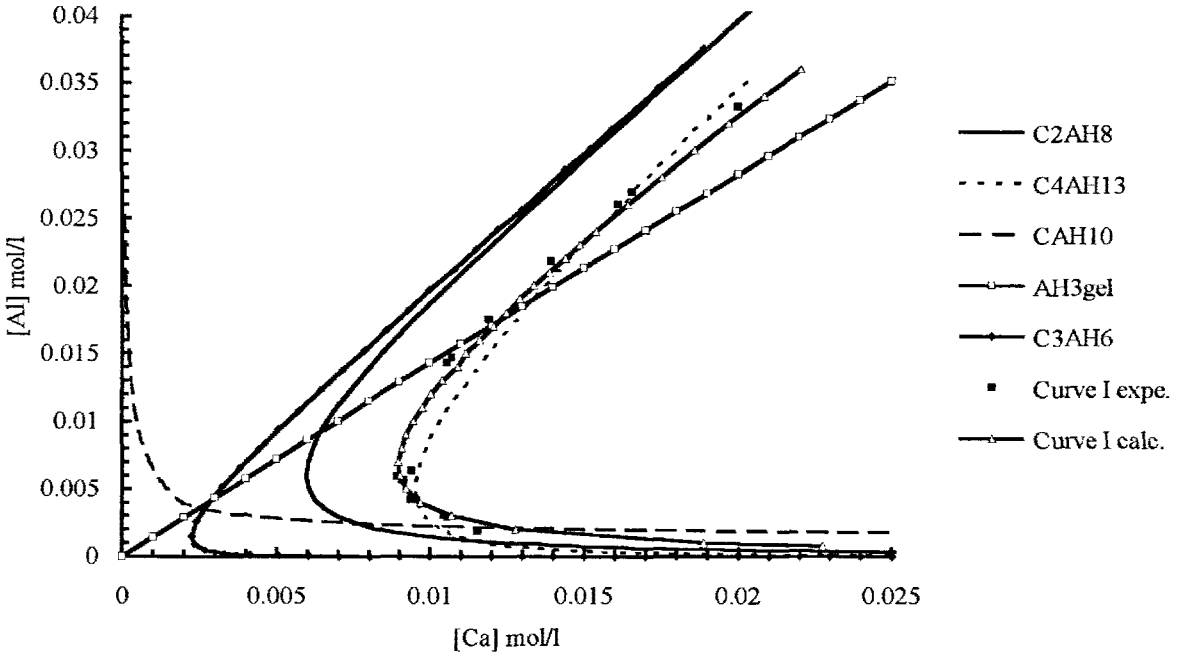

Fig. 5. Calculated curve I added to the phase diagram of the $CaO-Al_2O_3-H_2O$ system at 20°C

It is noticeable that the supersaturation values that have to be reached to induce an immediate precipitation of C_2AH_8 decrease markedly with a decrease of the aluminate concentration. This behaviour is expected to be linked to the increase of pH that occurs concomitantly. The position of curve I enables us to determine the systems that can lead to a rapid precipitation of C_2AH_8. We have to consider the calcium to aluminate molar ratio, $(C/A)_{dissol}$, of the ions accumulated in the solution by the dissolution of the anhydrous solid at the hydration beginning (this molar ratio can be different of the C/A ratio of the solid):

- If $(C/A)_{dissol}$ is lower than 1.25, curve I is never reached during the dissolution process and thus C_2AH_8 is never precipitated rapidly: an induction period is observed. In this last case, the aqueous phase can also be supersaturated with respect to other hydrates that can precipitate before or along with C_2AH_8 depending on their respective induction period. These systems are generally slow: case of CA hydration for example.
- If $(C/A)_{dissol}$ is higher than 1.25, curve I is reached and C_2AH_8 is precipitated rapidly. Once C_2AH_8 has been precipitated, the composition of the aqueous phase reaches some regions on the left part of curve I and other solids may precipitate if the aqueous phase is supersaturated with respect to them. In this case, an induction period with respect to these hydrates may be observed. However the initial precipitation of C_2AH_8 is often sufficient enough to induce a rapid setting of the system. These systems are representative of $C_{12}A_7$ and C_3A hydration.

Thus curve I is very important as it governs most of the early hydration in the $CaO-Al_2O_3-H_2O$ system. Moreover it can unable other maximum supersaturation curve of hydrates to be reached due to C_2AH_8 precipitation. As a consequence, these curves are never obtained experimentally. C_4AH_{13} seems to be an exception as it precipitates concomitantly with C_2AH_8 without any noticeable induction period during C_3A hydration.

Several factors can modify the nucleation and thus change the maximum supersaturation values that induce the immediate precipitation; temperature, presence of solids that provide nucleating sites, presence of foreign ions in the aqueous phase... The specific weight of these parameter is difficult to assess. However the influence of ions that only modify the ionic strength of the

solution without enabling some new solids to precipitate, can be estimated by thermodynamic calculations. For example, the influence of NaOH addition at different concentrations has been investigated. The main influence of NaOH is to shift the upper branch of the equilibrium curve of C_2AH_8, toward higher aluminate concentrations (Fig 6). If we consider a filtrate obtained during the induction period of CA hydration, the composition is close to [Ca]=20mmol/kg and [Al]=36mmol/kg. The filtrate lies in the supersaturated domain with respect to C_2AH_8 (Fig 6) and presents an induction of about 10 hours. Bertrandie (Bertrandie, 1977) reduced and even suppressed this induction period by adding a saturated lime solution ([Ca]=22mmol/l): the filtrate composition was shifted almost vertically to lower aluminate concentrations and as a consequence the supersaturation value was increased and curve I was reached. If a NaOH solution is added to the filtrate, the calcium and aluminate concentrations are not changed, but due to the shift of the equilibrium curve of C_2AH_8, the supersaturation value with respect to C_2AH_8 is increased. Thus if the increase of the supersaturation value is high enough, C_2AH_8 could precipitate immediately without any induction period (Fig 6).

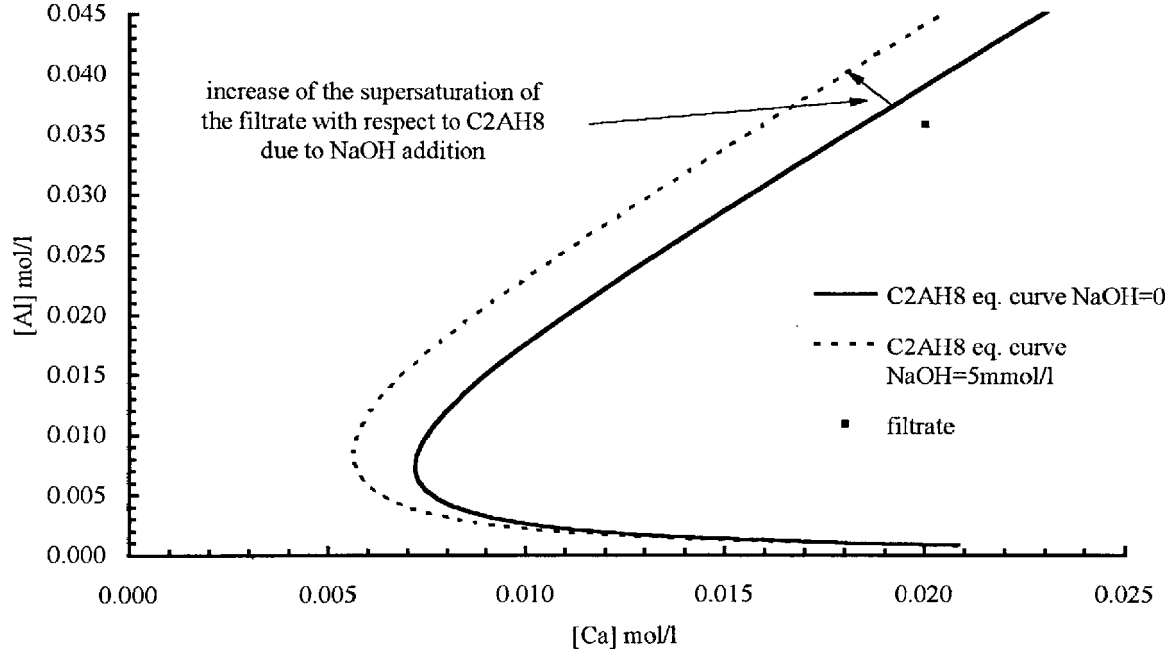

Fig 6. Influence of NaOH on the position of C_2AH_8 equilibrium curve.

We tested this hypothesis by following the electrical conductivity of stirred filtrate. The procedure was the following: 2ml of a given NaOH solution was added to 80 ml of filtrate. We used 41, 82 and 205mmol/l NaOH solutions in order to add 1, 2 and 5mmol/l NaOH to the filtrate. The induction period was reduced with 1mmol/l and suppressed with 2 and 5mmol/l (Fig 7) in a similar manner as observed with Bertrandie by just adding lime solutions to the filtrate (Bertrandie, 1977). The values of β2 were calculated for the different cases (Table 3).

Table 3. Calculated values of β2 for different compositions of the filtrate

[Ca] mmol/kg	[Al] mmol/kg	[Na] mmol/kg	β2	induction period
20	36	0	67	yes
20	36	1	104	yes
20	36	2	159	no
20	36	5	307	no
20	33	0	170	no

It is noticeable that the minimum β2 value which induces the immediate precipitation of C_2AH_8 in pure water (β2=170) is similar to the value of β2 found with 2mmol/l NaOH which is the first NaOH concentration that removes the induction period (β2=159). This point is very important as it enables us to calculate the curve I in the presence of sodium ions which are often brought by admixtures. In the presence of NaOH, the curve I calculated previously will be just shifted in a manner similar to the equilibrium curve of the hydrates as β2 values determined by Eq. 2 remain valid.

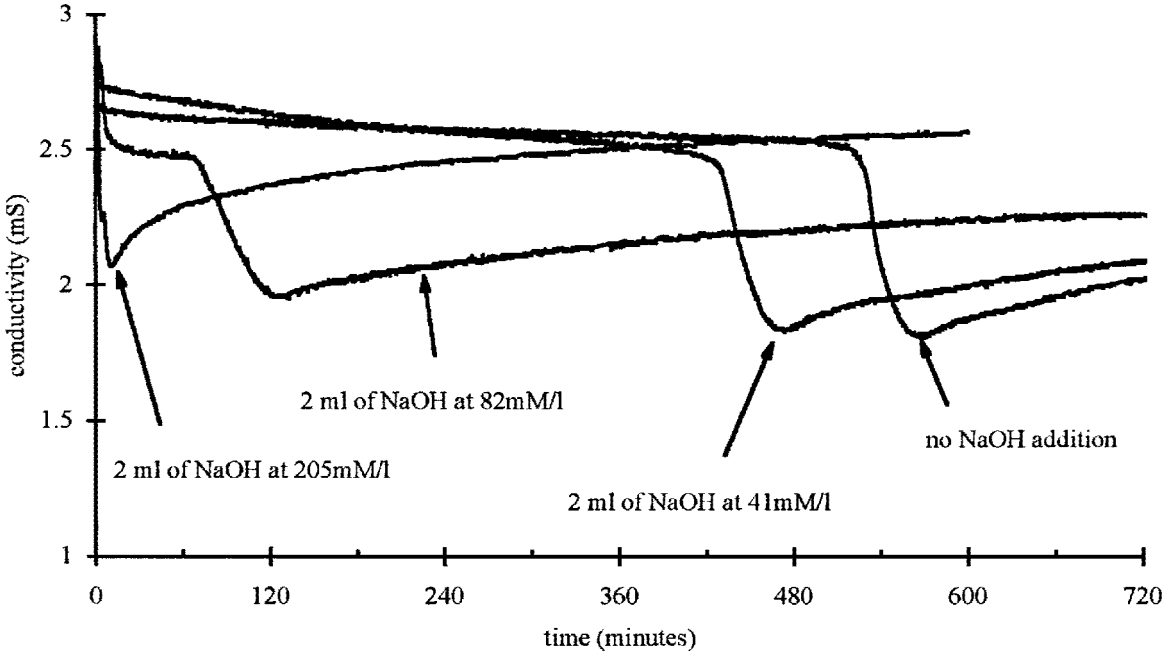

Fig 7. Conductivity of supersaturated filtrate in the presence of added NaOH solution.

CONCLUSION

A method to calculate the maximum supersaturation curve with respect to C_2AH_8 (curve I) at 20°C has been developed. This method is general and can be used for other systems. It also appears that the supersaturation value with respect to C_2AH_8 along curve I, is not markedly modified in the presence of NaOH. As a consequence, the method is still applicable in this case. However these kinds of calculation cannot take directly into account the influence of temperature or other parameters such as nucleating sites on solids added to the system: further experiments are crucially needed to bring new data on this important aspect of the hydration of cements.

MODIFICATION OF THE HYDRATION PROCESS FROM $C_{12}A_7$ TO C_3A AT 20°C

Denis DAMIDOT and François SORRENTINO, LAFARGE Laboratoire Central de Recherche, St-Quentin Fallavier, France

ABSTRACT

Mixtures ranging from $C_{12}A_7$ to C_3A have been obtained by a sintering process. The hydration of these mixtures has been studied in paste form by microcalorimetry and in diluted suspension by conductivity measurements. The hydration process of the mixtures can be classified in two groups depending on the C/A ratio of the mixtures. For mixtures having a C/A ratio lower than 2.3, the hydration advances through two steps which are separated by a short induction period. On the other hand, the hydration of mixtures having a C/A ratio higher than 2.3, proceeds through an unique step and therefore is very rapid. The differences in hydration behaviour have been explained in taking into account the precipitation of C_2AH_8.

Key-words: Hydration, Mechanism, Calcium aluminate, calorimetry.

INTRODUCTION

The hydration of both $C_{12}A_7$ and C_3A leads to short setting times at room temperature. This is a consequence of the rapid kinetic of hydration of both $C_{12}A_7$ and C_3A. However the hydration mechanisms at 20°C of $C_{12}A_7$ and C_3A are not similar. First the different stoechiometries of these two calcium aluminate induce different compositions for the aqueous phase and the precipitation of different hydrates at the hydration beginning (De Jong, 1968, Capmas, 1990): C_2AH_8 is observed with both $C_{12}A_7$ and C_3A whereas C_4AH_{13} is only obtained with C_3A. Moreover calorimetric experiments indicate that C_3A hydration proceeds through an unique step (only one exothermic peak) (De Jong, 1968), while $C_{12}A_7$ hydration displays two steps (two exothermic peaks) (Edmonds, 1988). These differences can be used to explain that the setting time of C_3A is shorter than the setting time of $C_{12}A_7$. This behaviour remains in mixtures of $C_{12}A_7$ and C_3A (Ménétrier-Sorrentino, 1986); the setting time of a mixture of 63% $C_{12}A_7$ - 28% C_3A (% by weight) is 1 minute whereas it is 45 minutes for a mixture of 85% $C_{12}A_7$ and 6% C_3A. In this previous example, the first mixture behaves more like C_3A and the second one is closer to $C_{12}A_7$. The aim of this study was to determine the composition in the $C_{12}A_7$-C_3A that delimits mixtures having a behaviour similar to $C_{12}A_7$ from mixtures behaving like C_3A. Thus the hydration of several mixtures of the system $C_{12}A_7$-C_3A was investigated in paste or in diluted suspension in order to determine their hydration mechanism relatively to $C_{12}A_7$ and C_3A.

EXPERIMENTAL

The sample were prepared by mixing the desired contents of pure ANALAR $CaCO_3$ and alumina in order to obtain the compositions given in Table 1. Then the mixtures were sintered at 1450°C in platinum crucibles and air atmosphere. The sintering process is followed by a slow cooling period. The samples were ground in order to have the same fineness of about 300m^2/kg SSA. Then the samples were checked by XRD and SEM using EDX analysis. Hydration was followed by isothermal calorimetry on paste having a W/C ratio of 1 but also on stirred suspension (W/C=10) with a specially designed calorimeter (D. Damidot, 1990). Conductimetry experiments were also performed on stirred suspensions (W/C=10). During these experiments, it was possible to recover 15 ml of the suspension in order to analyse the aqueous phase composition by ICP and the solids by XRD and SEM. The hydration was stopped by washing the solids by acetone and ether.

Table 1. Chemical compositions of the mixtures studied in the $C_{12}A_7$-C_3A system

Sample name	weight % CaO	weight % Al_2O_3	molar % $C_{12}A_7$	molar % C_3A	C/A molar
C48A52 ($C_{12}A_7$)	48	52	100	0	1.72
C50A50	50	50	88.4	11.6	1.86
C53A47	53	47	67	33	2.14

C59A41	59	41	23.2	76.8	2.70
C62A38 (C_3A)	62	38	0	100	3.00

RESULTS

The calorimetry results are given in Figures 1 and 2 which correspond to two different cases. Calorimetry curves that present two exothermic peaks like $C_{12}A_7$ (Fig 1) and those that only contain one initial exothermic peak as C_3A (Fig 2). The scale of the two figures is similar in order to facilitate a comparison. However the intensity of the first exothermic peak varies significantly between the samples (Table 1).

C62A38	228.19	4 mn 40		

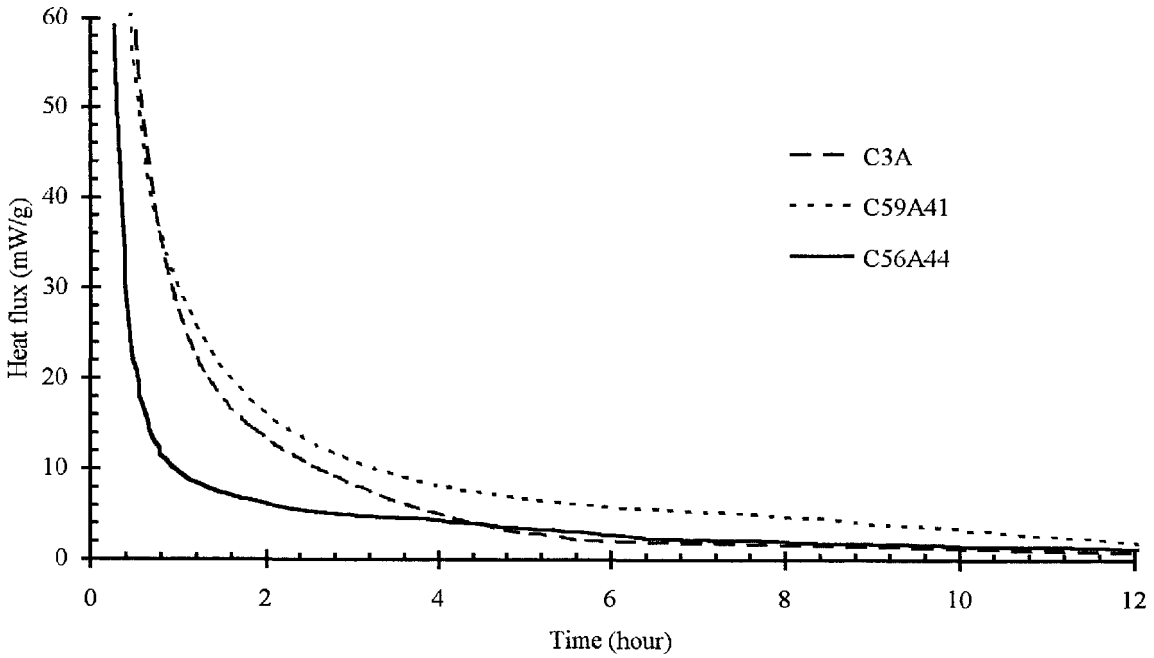

Fig 2. Calorimetry curves obtained with C_3A, C56A44 and C59A41 at 20°C and W/C=1

It is important to follow the changes in the aqueous phase in order to understand the mechanism of the hydration. However it is difficult to study the aqueous phase in paste and stirred suspensions are often used instead. As it is not obvious that pastes and suspensions behave in the same manner, calorimetry experiments were performed on suspensions for C50A50 and C56A44 (Figs 3 and 4).

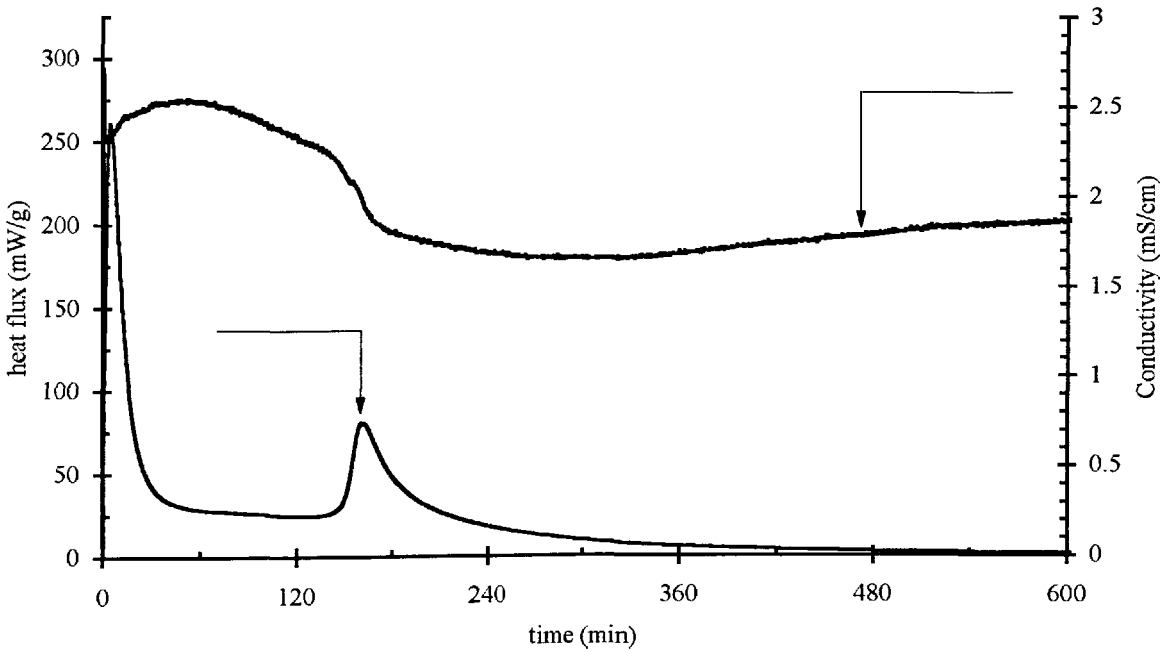

Fig 3. Conductimetry and calorimetry curves obtained simultaneously with C50A50 at 20°C in stirred suspension (W/C=10)

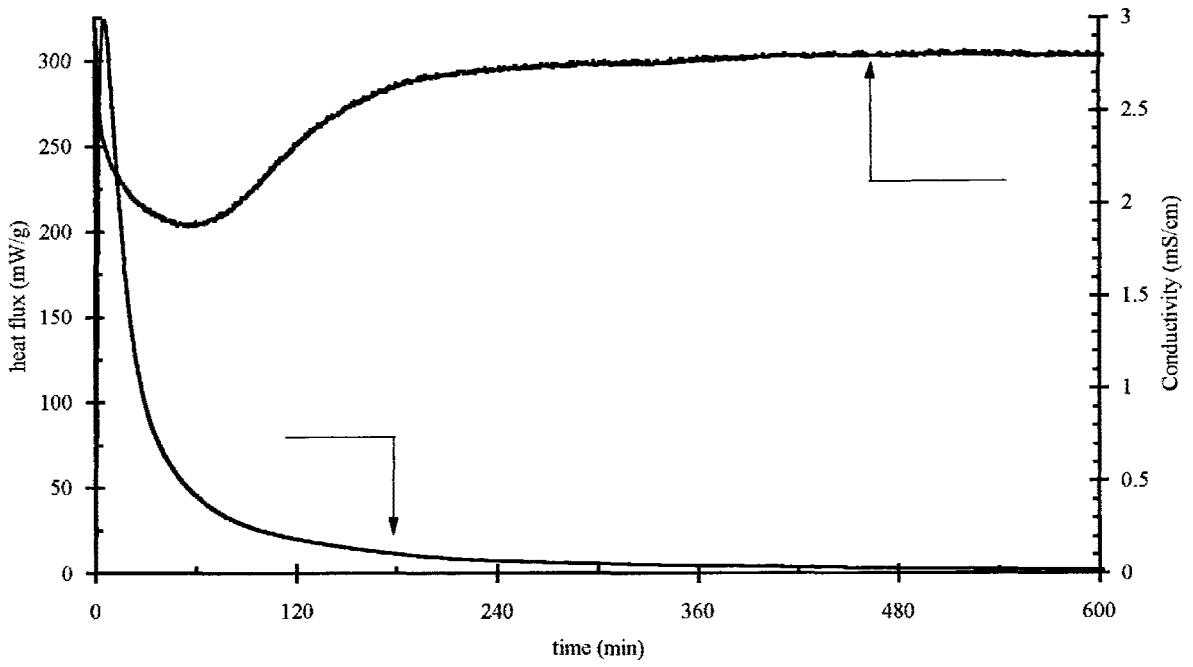

Fig 4. Conductimetric and calorimetric curves obtained simultaneously with C56A44 at 20°C in stirred suspension (W/C=10)

It appears that the calorimetric curves obtained in stirred suspensions maintain similar features than those recorded on pastes: presence of two exothermic peak for C50A50 and only one for C56A44. Thus the hydration mechanism in suspension is expected to be similar to the paste one. The evolution of the electrical conductivity of the aqueous phase, also enables us to differentiate the samples. The aspect of the conductivity curve of C50A50 is close to that of $C_{12}A_7$ (Capmas, 1990, Ménétrier-Sorrentino,1989) (Fig 3): a very rapid increase during the first minute, then a slight decrease during 5 minutes which is followed by an increase during 1 hour. This period corresponds to the first exothermic peak. Then the conductivity decreases slightly during a period of moderate heat flow and decreases more rapidly in the region where the second exothermic peak is observed. Finally a plateau of conductivity is observed when the liberated heat flow is very weak. The conductivity curve of C56A44 is simpler (Fig 4): a rapid increase of the conductivity during the first minute which is followed by a long decrease during the following first hour which corresponds to the main part of the exothermic peak. Then the conductivity increases again during two hours that coincides to the ending part of the exothermic peak. Finally the heat flow is very weak and a slightly descending conductivity plateau is observed.

The aqueous phase has been analyzed at different periods in order to understand further the evolution of the electrical conductivity. The samples C53A47 and C56A44 have been chosen as they delimit the two behaviours previously evidenced (Tables 3 and 4).

Table 3. Composition of the aqueous phase during C53A47 hydration at 20°C and W/C=10

180	8.03	2.70	12.08	5.93
1430	8.87	1.96	12.27	9.05

After 2 minutes of hydration, the composition is close between the two samples. However the C/A molar ratio of the aqueous phase is less than the C/A molar ratio of the solids. This may be due to a more rapid dissolution rate of $C_{12}A_7$ relative to C_3A. The precipitation of an hydrate can also be an explanation as the conductivity decreases between 1 and 2 minutes of hydration. The analysis of the solids confirms that C_2AH_8 is already formed in a detectable quantity by XRD after 2 minutes hydration (Tables 5 and 6). For hydration times longer than 2 minutes, C53A47 and C56A44 evolve differently; C/A ratio of the aqueous phase remains almost constant for C53A47 whereas it increases for C56A44. The precipitated solids also differ: C_2AH_8 is the main hydrate for both C53A47 and C56A44 but C_4AH_{13} and its carbonated forms, calcium hemicarboaluminate hydrate and calcium monocarboaluminate hydrate, are observed. After one day hydration, C_3AH_6 is also found for C56A44. Once more, these differences reflect perfectly the two behaviours derived from $C_{12}A_7$ and C_3A. For both samples, the hydration is fast; $C_{12}A_7$ and C_3A are almost completely consumed after 3 hours hydration. However the hydration seems to be faster for C56A44 compared to C53A47.

DISCUSSION

The mechanism of the hydration of $C_{12}A_7$ and C_3A has to be described in order to differentiate the samples of the $C_{12}A_7$-C_3A system. We have to consider first, the phase diagram of the system CaO-Al_2O_3-H_2O at 20°C (Fig. 5). This diagram contains the calculated equilibrium curves of C_2AH_8, C_4AH_{13} and C_3AH_6. The equilibrium curves of CAH_{10}, AH_3 and CH have been omitted to have a more readable diagram. The maximum supersaturation curve with respect to C_2AH_8 (curve I) has also been added. Curve I which has been determined experimentally by Barret et al. (Barret,1980a and 1980b), delimits the aqueous phase compositions which precipitate C_2AH_8

immediately without any induction period (on the right of curve I) from the compositions that produce an induction period before precipitating C_2AH_8 (part between the right of C_2AH_8 equilibrium curve and the left of curve I). The composition of the aqueous phase at various hydration time (kinetic path) hydration has been plotted on the $CaO-Al_2O_3-H_2O$ phase diagram for $C_{12}A_7$ (Fig 5). During the hydration of $C_{12}A_7$, the composition of the aqueous phase reaches the supersaturated domain with respect to C_2AH_8 and finally curve I. The C/A molar ratio of $C_{12}A_7$ which dissolves is 1.72 and the C/A ratio of C_2AH_8 which precipitates is 2. As a consequence, the aqueous phase is enriched in aluminate and the C/A ratio decreases as explained by Barret (Barret, 1994). The kinetic path follows approximately the curve I, until it intersects the equilibrium curve of $C_{12}A_7$ superficially hydroxylated (sh): [Ca]≈24mmol/l and [Al] ≈45mmol/l. During this process which takes about 10 minutes in our experimental conditions (20°C and W/C=10) and which corresponds to the first exothermic peak, an important quantity of C_2AH_8 is formed. Then the reaction rate is reduced due to an induction period originated by the nucleation of AH_3; the concentrations generally pass from 24 to 21mmol/l for calcium ions and from 45 to 42mmol/l for aluminate ions. This process corresponds to the period between the two exothermic peaks. As soon as the nucleation rate of AH_3 is high enough, the global reaction rate increases again and the second exothermic peak is observed. Finally $C_{12}A_7$ is exhausted and the aqueous phase evolves slowly toward the equilibrium state. It is important to notice that AH_3 is not detected by XRD as it firstly precipitates as a gel.

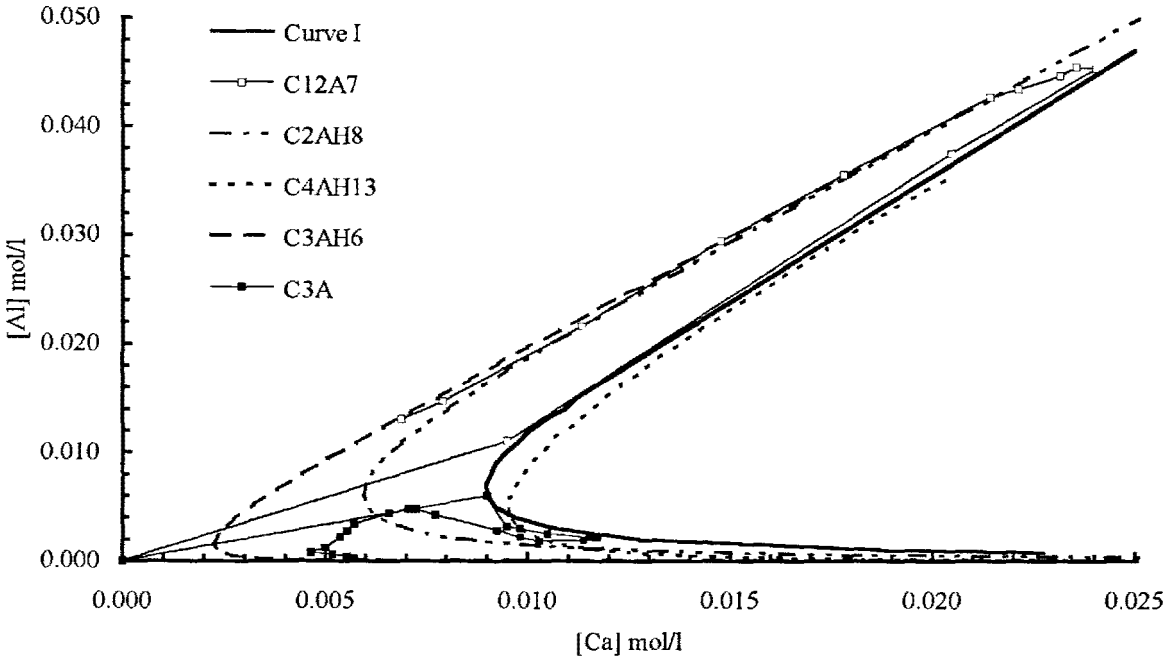

Fig 5. Kinetic path for the hydration of $C_{12}A_7$ and C_3A at 20°C

The kinetic path of C_3A hydration has also been drawn (Fig 5). Similarly to $C_{12}A_7$, C_3A dissolves congruently until it reaches curve I as demonstrated by Barret (Barret, 1980a). At this point C_2AH_8 precipitates but in this case, the C/A molar ratio of the aqueous phase increases; the C/A ratio of C_3A which dissolves is greater than the C/A ratio of C_2AH_8 which precipitates. Thus the aqueous phase can enter the supersaturated region with respect to C_4AH_{13} which precipitates as soon as a sufficient supersaturation is reached. This corresponds to the important exothermic peak observed at the hydration beginning. Once C_3A is almost completely consumed, the continuation of hydrate precipitation, reduces the concentrations in solution and leads the aqueous phase in the undersaturated domain with respect to C_4AH_{13}. From this point, C_4AH_{13}

can be transformed into C_2AH_8 but also into C_3AH_6 and the aqueous phase evolves slowly toward equilibrium. Calcium monocarboaluminate hydrate is often formed due to carbonation.

The previous discussion demonstrates that the different mechanism of hydration for $C_{12}A_7$ and for C_3A are linked to the precipitation of C_2AH_8 which depends on the position of curve I on the $CaO-Al_2O_3-H_2O$ phase diagram. This demonstration is also applicable to the $C_{12}A_7-C_3A$ system. The aqueous phase composition of samples having a C/A molar ratio lower than 2 is expected to move toward the upper part of the $CaO-Al_2O_3-H_2O$ phase diagram and thus behaves like $C_{12}A_7$: rapid precipitation of C_2AH_8, followed by a short induction period due to AH_3. On the contrary, for samples having a C/A ratio higher than 2, the precipitation of C_2AH_8 increases the calcium concentration and drives the aqueous phase composition toward the bottom part of the $CaO-Al_2O_3-H_2O$ phase diagram. This induces a rapid precipitation of C_4AH_{13} along with C_2AH_8 in one kinetic step. The kinetic paths for C53A47 and C56A44 are reported on Figure 6. The kinetic path of C56A44 evolves as suspected even if there is a restricted number of points that describe it: once curve I is reached, the C/A molar ratio of the solution increases (Table 4). The evolution of the kinetic path of C53A47 is less obvious with the 4 points that define it: the curve I is reached but the kinetic path does not really follows curve I toward higher calcium and aluminate concentrations. On the other hand, C50A50, displays the expected behaviour: the maximum concentrations are [Ca]=22mmol/l and [Al]=41mmol/l.

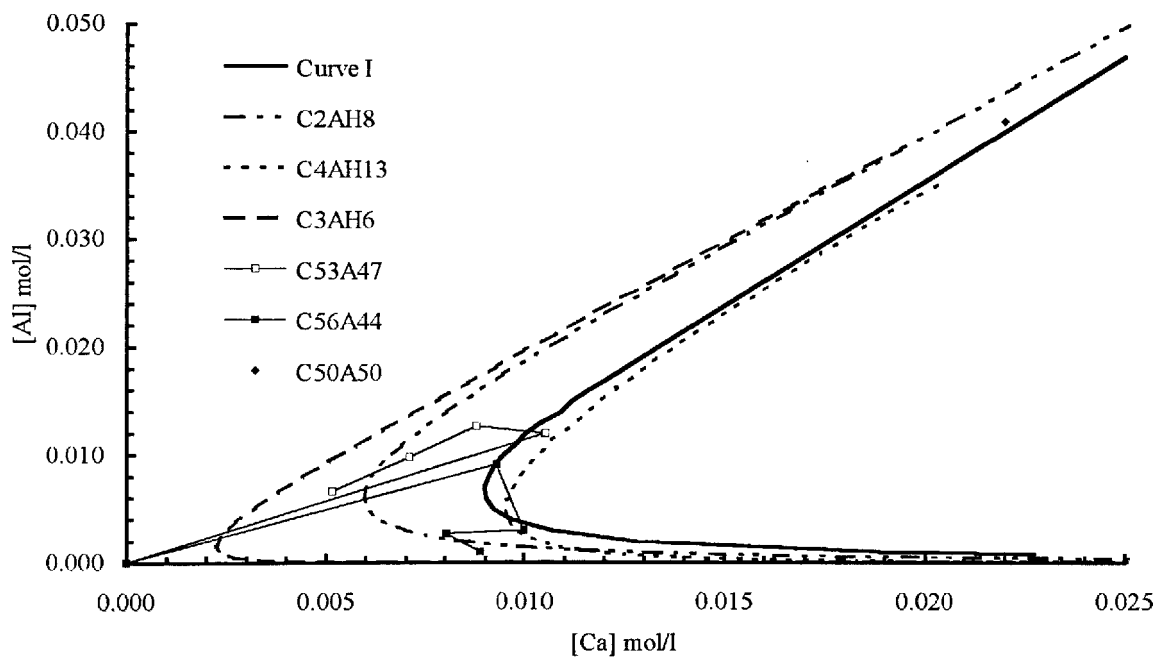

Fig 6. Kinetic path for the hydration of C53A47 and C56A44 at 20°C and maximum concentrations reached with C50A50.

From our previous hypothesis, C53A47, C56A44 and C59A41 which have a C/A molar ratio higher than 2, should behave as C_3A. This is correct except for C53A47 which behaves closer to $C_{12}A_7$ than to C_3A. In fact, this is not the C/A molar ratio of the solid which is important but the C/A molar ratio of the dissolution process. These two C/A molar ratios can be different even if the dissolutions of $C_{12}A_7$ and C_3A are congruent, if we consider different rates of dissolution between $C_{12}A_7$ and C_3A. For C53A47, the solid C/A molar ratio is 2.14 whereas the C/A molar ratio of the solution after 2 minutes of hydration is only 1.66. Similarly we are obtaining a C/A value of 2.42 for C56A44 and a value of 2.04 in solution after 2 minutes of hydration. This

suggests that the dissolution rate of $C_{12}A_7$ is faster than the one of C_3A. Moreover these differences of dissolution rate, induce a variable C/A ratio of the dissolution process during the hydration: C/A of the dissolving solids should be lower at the hydration beginning and then higher compared to the solid C/A molar ratio. This process may complicate the hydration mechanisms especially for samples which have a C/A molar ratio close to 2.

CONCLUSION

The hydration mechanisms of samples ranging from $C_{12}A_7$ to C_3A can be classified into two categories depending on the C/A molar ratio of the samples:

- if the C/A ratio is lower than 2.3, the hydration proceeds through two main steps in a similar way as $C_{12}A_7$,
- if the C/A ratio is equal or higher than 2.3, only one step exists at the beginning of the hydration as observed during C_3A hydration.

These differences can be explained by the precipitation of C_2AH_8 which occurs in all cases after less than 2 minutes of hydration:

- If the solid which dissolves induces a C/A molar ratio of the aqueous phase which is lower than 2, the precipitation of C_2AH_8 decreases the global C/A ratio of the aqueous phase. As a consequence, the kinetic path is expected to reach higher calcium and aluminate concentrations.
- On the contrary, if the C/A ratio of the dissolution is higher than 2, the precipitation of C_2AH_8 increases the C/A ratio of the aqueous phase. The kinetic path is expected to reach high calcium concentrations and low aluminate ones.

The fact that the limiting C/A molar ratio of the samples is 2.3 instead of 2, indicates that $C_{12}A_7$ dissolves more quickly than C_3A at the initial hydration.

STUDY OF THE HYDRATION OF MIXTURES OF CA AND α-Al_2O_3 AT DIFFERENT TEMPERATURES

Angelika RETTEL, Denis DAMIDOT and Karen SCRIVENER, LAFARGE Laboratoire Central de Recherche, St-Quentin Fallavier, France

ABSTRACT

Alumina which is added to calcium aluminate cements is not an inert material with respect to the hydration: the specific surface area and the soluble Na_2O content of alumina are the main parameters which influence CA hydration. Adding alumina most often increases the reaction rate. When mixtures of CA and alumina are hydrated at different temperatures, this accelerating effect is added to the effect of the hydration temperature. The anomalous increase of setting time for CA paste between 20 and 35°C is known, but can thus be reduced or even suppressed by adding alumina. This behaviour has been attributed to the increase of the nucleation rate of AH_3 in the presence of alumina.

Key-words: Calcium aluminate cement, Alumina, Hydration, Temperature, Mechanism.

INTRODUCTION

Alumina is often added to calcium aluminate cement in some refractory applications: for example mixtures containing 55% (by weight) of CA and 45% of α-Al_2O_3 have a total Al_2O_3 content of 80%. It has been previously demonstrated that the specific surface and the soluble Na_2O content of alumina are the main parameters which influence CA hydration at 20°C (Damidot, 1995). The effect of these two parameters is not similar on the dissolution and induction periods that precede the massive precipitation of the hydrates which leads to setting in the paste. The dissolution period is longer for the mixtures of CA and α-Al_2O_3, regardless of the alumina content in comparison to pure CA. This can be explained by the dilution of CA by Al_2O_3. The influence of CA dilution is reduced by high soluble Na_2O contents. Alumina accelerates the induction period: the higher the specific surface area, the greater the acceleration. This is due to the seeding effect of AH_3 contained on the alumina surface which increases the rate of AH_3 nucleation. On the other hand, sodium ions coming from soluble Na_2O, have a discontinuous effect on the duration of the induction period: it is longer at low Na^+ concentrations and shorter otherwise. The addition of the effects of soluble Na_2O and of the specific surface of Al_2O_3 on the dissolution and induction periods, generally results in a reduction of the setting time at 20°C for mixtures containing 45% α-Al_2O_3. The hydration of CA at different hydration temperatures is also complex and has been widely studied (Bushnell-Watson, 1986, Capmas, 1990, Edmonds, 1988, Murat, 1980, Rettel, 1985). Most of the explanations of this phenomenon rely on nucleation difficulties of the hydrates. We have recently proposed a new hypothesis based on changes in the nucleation rate: the CAH_{10} nucleation rate decreases with the temperature whereas the AH_3 nucleation rate would increase (Damidot, 1997). Thus the CAH_{10} nucleation rate would control the induction period for temperatures lower than about 27°C for pure CA, whereas the AH_3 nucleation rate does this for higher temperatures. The presence of alumina which modifies the nucleation rate of AH_3, is thus expected to modify the anomalous setting behaviour.

The aim of this work is to understand better the addition of the effects of soluble Na_2O and of the specific surface area of α-Al_2O_3 for different hydration temperatures. Previous results seem to indicate that a global accelerating effect remains (Rettel, 1993) and is able to suppress the anomalous increase of the setting time observed for CA pastes for hydration temperatures between 20 and 30°C. The hydration of CA and α-Al_2O_3 mixtures have been investigated on pastes (W/C=0.5) by calorimetry and also on diluted suspensions (W/C=10). The study of

suspensions instead of pastes gives us the possibility to study more accurately the dissolution and induction periods that occur before the massive precipitation of hydrates which induces the setting in paste.

EXPERIMENTAL

Pure CA was synthesised by heating a mixture of α-Al_2O_3 and $CaCO_3$ at 1500°C. The major phase was CA along with a trace of CA_2: no $C_{12}A_7$ was detected by XRD or by SEM on polished sections. The properties of the alumina used in this study are summarised in Table 1. The presence of Na_2O in the alumina comes from the Bayer process which involves sodium aluminate. Total Na_2O content of the alumina was determined by X Ray fluorescence spectroscopy but more important, the soluble Na_2O content was measured: alumina suspensions (alumina/water = 10) were stirred for 24 hours and then Na^+ concentration was determined. In order to avoid as far as possible, the influence of soluble Na_2O, washed alumina were also used.

Table 1. Characteristics of the alumina used in the mixtures

alumina name	specific surface area (m^2/g)	α-Al_2O_3 content (%)	total Na_2O content (%)	soluble Na_2O (mM/l)
A1	0.6	> 95	0.3	0.5
A2	9.2	> 70	0.2	2.11

Mixtures of CA and 30, 45 or 60% alumina were investigated. The hydration of these mixtures was followed by differential isothermal calorimetry at 15, 20, 25 and 30°C in paste W/C=0.5. The time at the maximum of the second exothermic peak was associated to the setting time. The hydration was also investigated on suspensions (W/C=10) by recording the electrical conductivity at 15, 20, 23, 27 and 35°C. The presence of alumina does not change the shape of the conductimetric curve for CA: Figure 1 gives as an example, the conductimetric curve obtained for CA hydrated at 20°C.

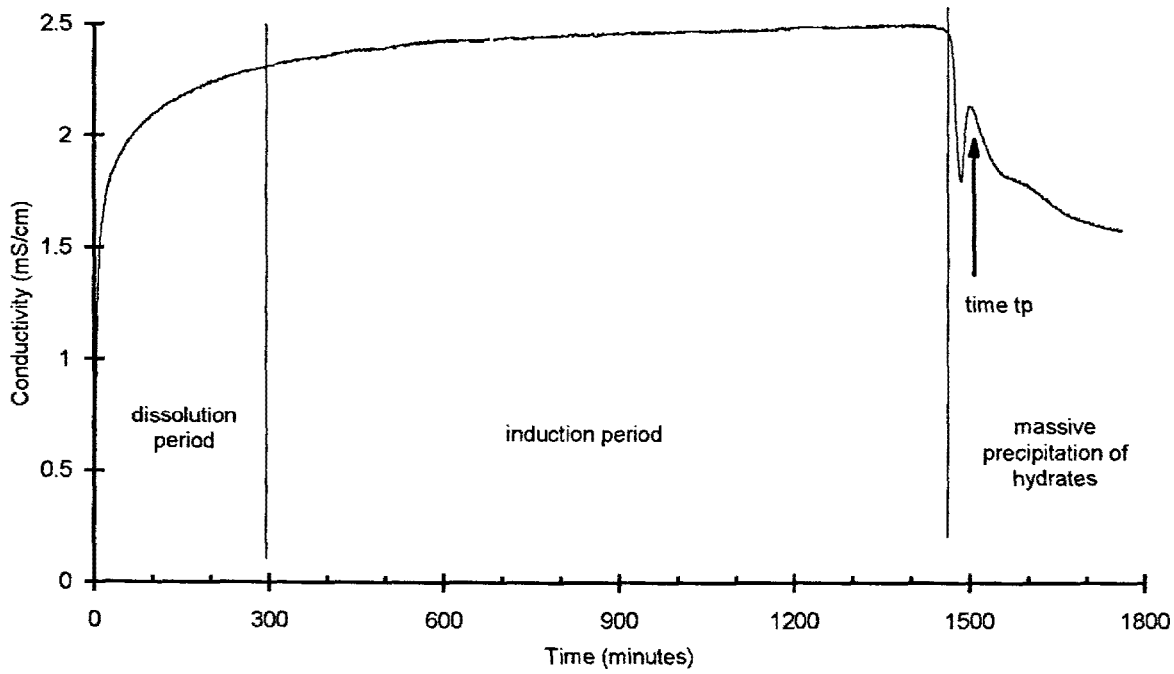

Fig. 1. Conductimetric curve obtained during the hydration of CA at 23°C in water at W/C=10.

The conductimetric curve of Figure 1 can be divided into three periods:

- dissolution period: this corresponds to the accumulation of ions in solution by the dissolution of CA: the conductivity increases rapidly at the beginning and then more slowly. This period ends when the composition of the solution comes into equilibrium with superficially hydroxylated CA (CA_{sh}) (Barret, 1994).
- induction period: the beginning of this period corresponds to a slightly increasing conductivity plateau during which the composition of the aqueous phase stays almost constant. During the induction period, the kinetics is governed by the rate of nucleation of the hydrates and not by the dissolution rate of the cement. The rate of nucleation increases slowly before reaching a critical number of nuclei that allows the growth.
- growth period: when growth starts, concentrations in solution such as the conductivity decrease markedly and the aqueous phase becomes more and more undersaturated with respect to CA_{sh}. In order to overcome this phenomena, the dissolution rate of CA increases and as a consequence a small increase of the conductivity is observed. However the growth rate of the hydrates becomes rapidly faster than the dissolution rate of CA and the conductivity decreases again. During this period, a massive precipitation of the hydrates occurs and this leads to setting in the paste. It is this period that corresponds to the second exothermic peak observed by calorimetry on paste. Thus in order to compare calorimetric and conductimetric results, the time at the maximum of the dissolution rate of CA during this period, tp on Figure 1, will be considered: it is the time at which the massive precipitation of hydrates occurs.

RESULTS

Calorimetry on paste (W/C=0.5)

Mixtures of 55% CA and 45% α-Al_2O_3 were used for paste experiments. Compared to pure CA, the hydration is quicker in the presence of alumina at all tested temperatures (Fig. 2).

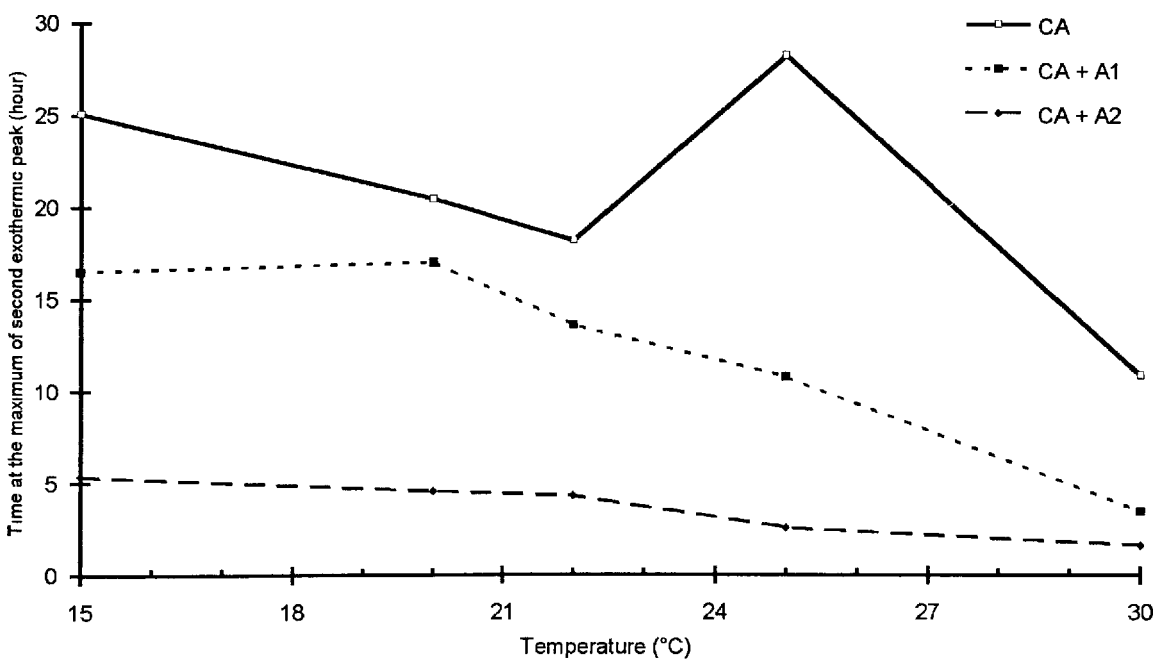

Fig. 2. Time at the maximum of the second exothermic peak recorded during calorimetric experiments on pure CA or mixtures of 55% CA and 45% alumina at different hydration temperatures

Furthermore, alumina A2, which has a higher specific surface area than A1, induces a greater acceleration of the hydration as we already demonstrated at 20°C (Damidot, 1995). The hydration rate is markedly modified for the mixture that contains A1: the setting occurs about 10 hours earlier at 30°C compared to 15°C, but we can still observe a maximum delay at 20°C. Compared to pure CA, this delay occurs at a lower temperature i.e. 20 instead of 25°C and the retardation is of lower intensity. On the contrary, a retardation of the setting temperature with an increase of the hydration temperature is no longer observed with alumina A2: the setting time decreases continuously with the temperature. It also appears that temperature has less effect on the setting time compared to alumina A1. As a consequence, an increase in the temperature reduces the difference of the hydration rate between the two mixtures.

Conductivity on suspensions (W/C=10)

The same mixtures as in paste experiments were also studied by conductimetry in order to verify that the behaviour was identical in paste or in suspensions. The massive precipitation of the hydrates observed during CA hydration still passes through a maximum delay for temperatures ranging between 20 and 35°C (Fig. 3) as already reported (Capmas, 1990). Mixtures of 55% CA and 45% A1 or A2 display a quicker hydration rate than pure CA and, similar to the paste experiments, A2 induces a greater acceleration. Thus, paste and suspension experiments are in perfect accordance despite the fact that the time, tp, of the massive precipitation of the hydrates defined by conductimetry does not correspond exactly to the time at the maximum of the second exothermic peak determined by calorimetry. For temperatures ranging from 20 to 35°C, the two mixtures increase their respective hydration rates continuously when the temperature is increased as was observed with the pastes. Unfortunately, we did not make some experiments at 15°C; this would have enabled us to confirm that a retardation could be observed with alumina A1 at 20°C.

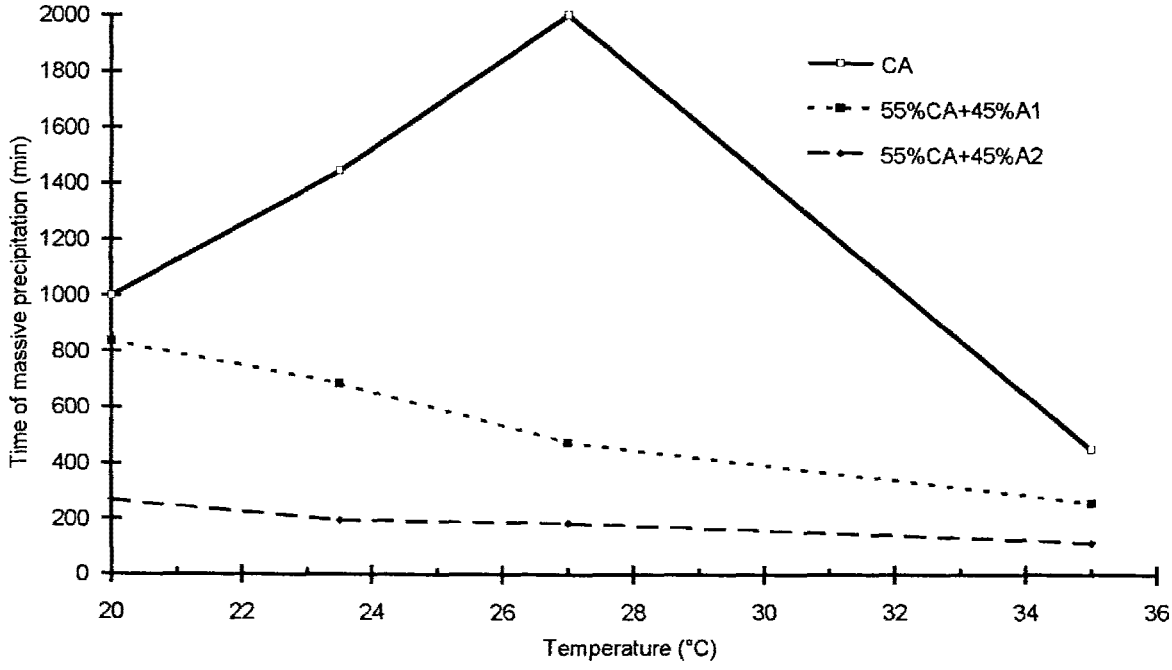

Fig. 3. Time of the massive precipitation for CA and mixtures of 55% CA and 45% of alumina (W/C=10) at different temperatures.

Some specific experiments were devoted to differentiate the effects of soluble Na_2O and of the specific surface area of alumina. First, CA was hydrated in a 10 mmol/l NaOH solution; this NaOH concentration is known to induce a marked acceleration of the hydration rate of CA or

mixtures of CA and alumina at 20°C (Damidot, 1995). The hydration rate remains accelerated for temperatures higher than 20°C relative to CA hydrated in water, but the time of the massive precipitation of the hydrate passes a maximum at 23°C (Fig. 4). As a consequence, the presence of NaOH due to the soluble Na_2O, does not seem to suppress the anomalous setting behaviour.

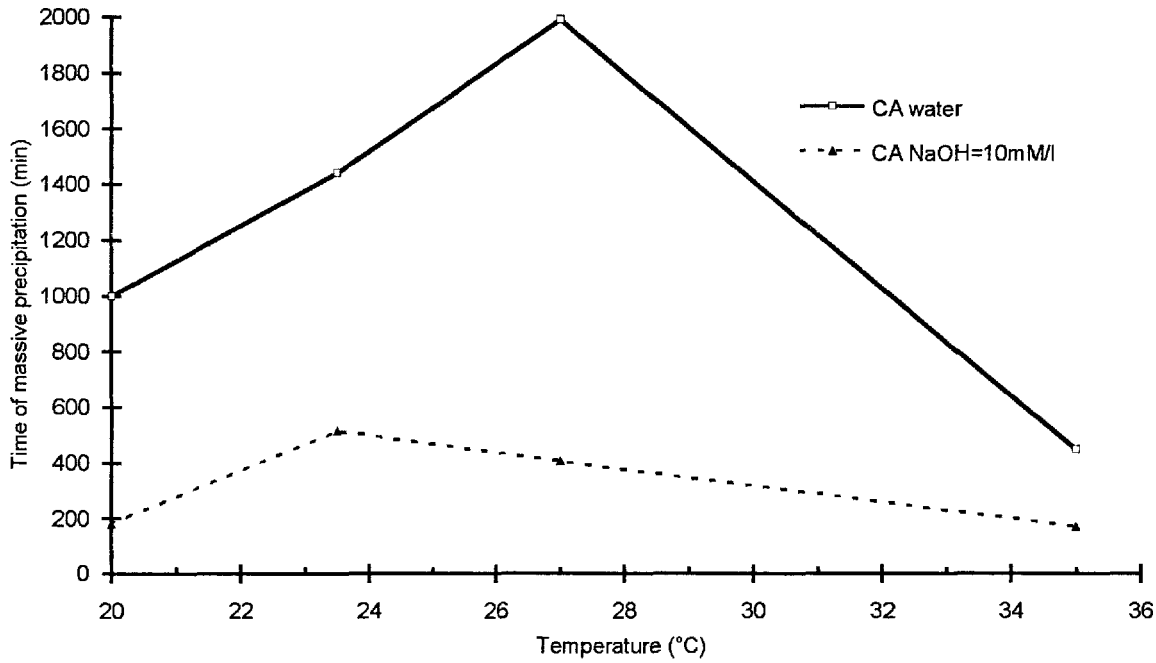

Fig. 4. Time of the massive precipitation for CA hydrated in 10 mmol/l NaOH (W/C=10).

Secondly, mixtures containing different amounts of washed alumina A2 were hydrated at different temperatures (Fig. 5).

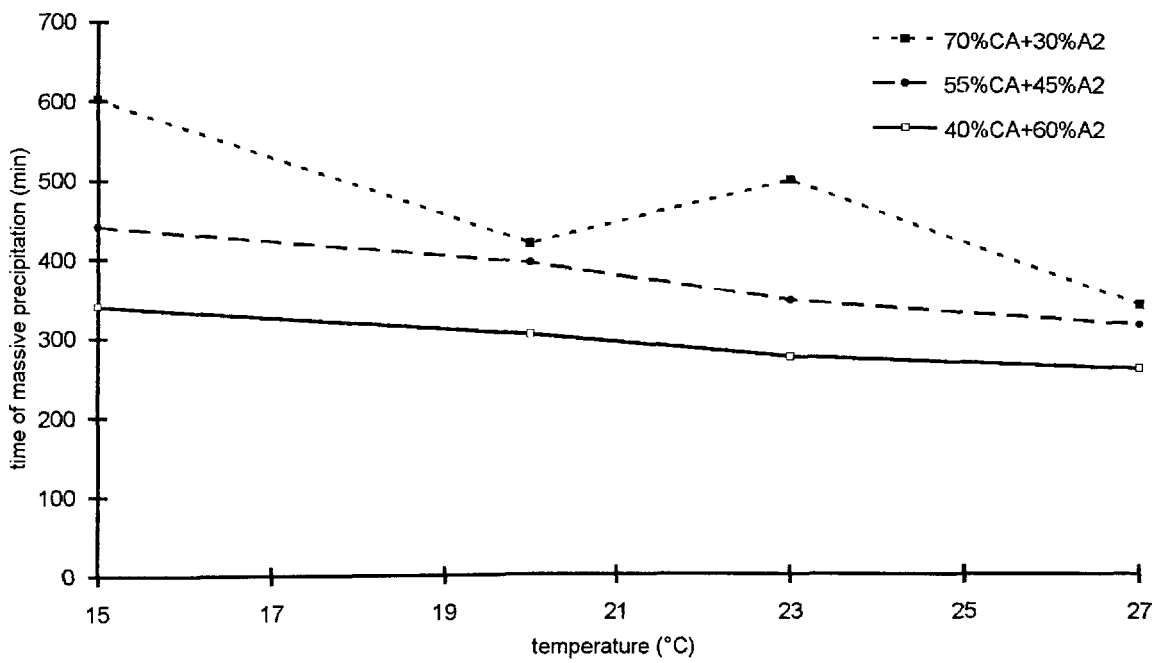

Fig. 5. Time of the massive precipitation for mixtures of CA and <u>washed</u> alumina A2 hydrated in water (W/C=10) at different temperatures.

The hydration is accelerated even more as the amount of alumina is high for all of the studied temperatures. It is also noticeable that with the lowest alumina content, 30%, a maximum delay is observed at 23°C whereas the time of massive precipitation decreases continuously for the other two mixtures (45 and 60%). Thus, the higher the alumina surface area is, the quicker the reaction rate is. This confirms what was observed with alumina A1 compared to alumina A2 in mixtures containing 45% alumina (Fig. 2). Temperature does not modify the difference of rate between mixtures containing 45 and 60% of alumina. The effect of the specific surface area is able to remove the anomalous setting behaviour observed with pure CA.

DISCUSSION

The anomalous setting behaviour observed for CA for temperatures between 20 and 30°C can be suppressed in the presence of alumina due to the effect of the specific surface area of the alumina. The Na_2O released by alumina into the solution as Na^+ and OH^- does not seem to remove the anomalous setting behaviour. This has been demonstrated previously (Damidot, 1995) and in this work, the alumina accelerates the induction period: the higher the specific surface, the greater the acceleration. These results are consistent with the effect of lithium salts on the hydration of calcium aluminate cement at different temperatures: lithium ions are able to suppress the anomalous setting behaviour depending on the concentration of lithium ions (Damidot, 1997). This behaviour is due to a strong increase of AH_3 nucleation rate by incorporating lithium ions in the structure of AH_3 (Damidot, 1996). Thus, the effect of lithium ions and alumina are similar, an increase of AH_3 nucleation rate, but their relative intensity are not equivalent due to two different mechanisms. Alumina acts on AH_3 nucleation rate due to a seeding effect: it exists some AH_3 on the surface of alumina that can be evidenced easily by diffuse reflectance Fourier transform infrared (DRIFT) (Fig. 6): The infrared bands at 3656, 3546-3550, 3465-3477 and 3427-3440 cm^{-1} are associated with the OH stretching modes of a bayerite-type species, while the bands at 3624, 3527, 3460 and 3380-3396 cm^{-1} are related with those of a gibbsite-type species (Lee, 1995). This seeding effect is expected to be all the more important with alumina having higher specific surface areas. This effect is not as effective compared to the incorporation of lithium ions in AH_3 and also may differ depending on the relative amount of bayerite versus gibbsite.

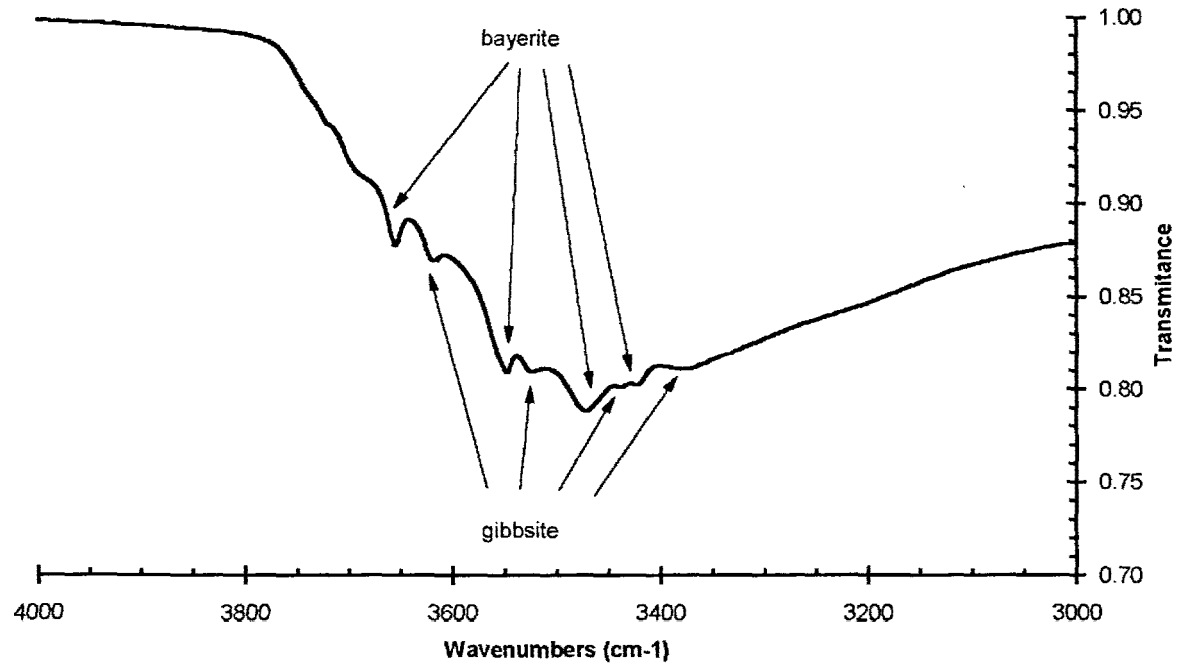

Fig 6. DRIFT spectrum obtained on washed alumina A2

The reduction of the intensity of the anomalous setting behaviour or its suppression by alumina can be explained in taking into account the hypothesis that we made to explain the action of lithium salts (Damidot, 1997): as it can seem on Figure 7, the nucleation rate of CAH_{10} decreases slowly with temperature up to 15°C and then decreases more rapidly. This would be a consequence of the decrease of CAH_{10} stability with an increasing temperature. On the other hand, the nucleation rate of AH_3 increases with temperature with a stronger increase from 22°C. Thus the controlling mechanism of the induction period passes from CAH_{10} to AH_3 at the maximum of the duration of the induction period (lowest nucleation rate) which corresponds to 27°C on Figure 7.

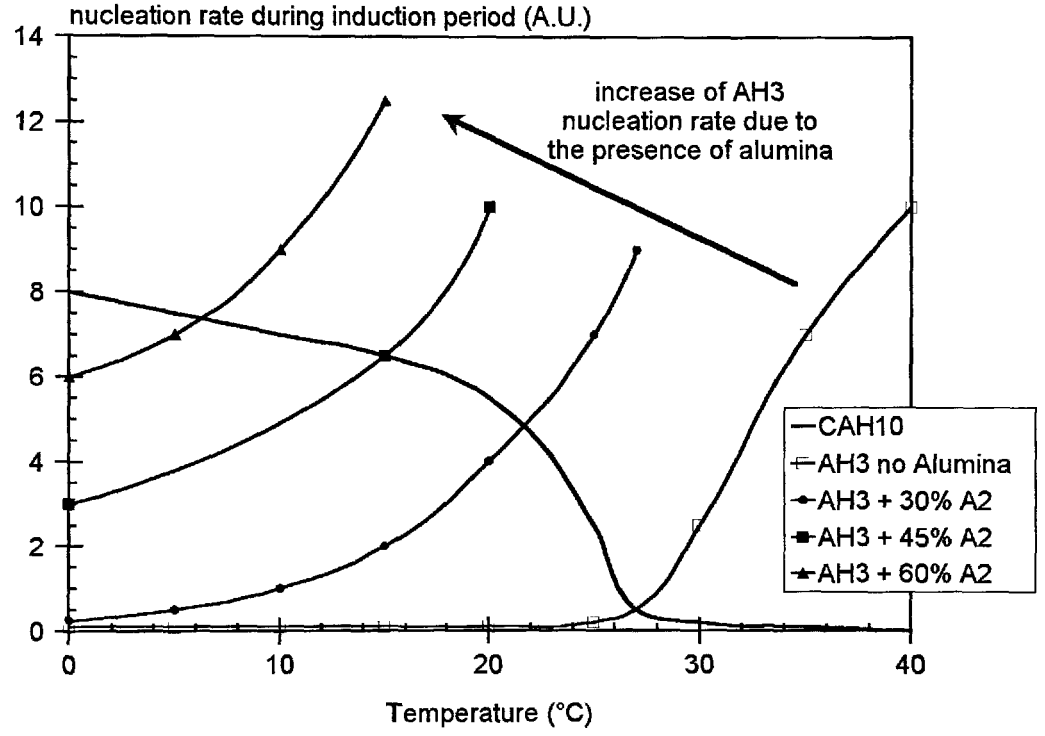

Fig 7. Relative nucleation rate for CAH_{10} and AH_3 as a function of the temperature and effect of alumina on AH_3 nucleation rate.

The change in the controlling hydrate, also induce a different chemical reaction for CA hydration. If CAH_{10} controls the induction period, CAH_{10} is the main hydrate and the chemical reaction of CA hydration can be simplified as: CA + 10H => CAH_{10}. On the contrary if AH_3 governs the induction period, AH_3 and C_2AH_8 are the main hydrates: 2 CA + 11H => AH_3 + C_2AH_8. C_2AH_8 is a consequence and not the cause of the suppression of the anomalous setting behaviour for CA hydration. On the other hand, the precipitation of C_2AH_8 before the induction which occurs in mixtures of CA + $C_{12}A_7$, induces the formation of some AH_3 which act as seed during the induction period and thus may accelerate this period depending on the amount of seeds: case of Fondu cement which also displays an anomalous setting time behaviour but of lower intensity compared to CA. This last example is very close to the effect of adding alumina if we except the diluting effect of alumina (less CA in a mixture compared to pure CA). If we consider the experiments with different quantities of washed alumina A2 (Fig. 5), AH_3 nucleation rate is expected to increase as a function of the alumina content of the mixture: this has been arbitrary represented on Figure 7. As a consequence of the increase of the nucleation rate of AH_3, the temperature which induces the change in the control of the induction period by either CAH_{10} or AH_3, is shifted to the left, i.e., to lower temperatures. Furthermore, the intensity of the decrease

of the nucleation rate during this period, is more and more reduced and globally the retardation is not observed as the dissolution period is continuously decreases with an increase of the temperature (Fig. 7).

CONCLUSION

The effect of alumina on CA hydration can be understood by taking into account two main parameters: the specific surface area and the release of Na^+ and OH^- ions due to soluble Na_2O contained in alumina. In order to understand the changes in the anomalous setting time behaviour of CA in the presence of alumina, these effects have to be added to the effect of the temperature. This corresponds in a first approach, to the evolution of the nucleation rate of CAH_{10} and AH_3 with temperature relatively to the same evolution in the presence of alumina. Compared to pure CA, the presence of alumina increases AH_3 nucleation rate and as a consequence the temperature shifts that induces a maximum retardation to lower temperature and also reduces the intensity of the retardation. As a consequence a marked anomalous setting time of CA behaviour between 20 and 30°C can be suppressed in the presence of alumina even if this behaviour can remain at temperatures lower than 20°C but with a very low intensity. The presence of admixtures can also induce variations of the nucleation rate of CAH_{10} and AH_3 and as a consequence can modify the behaviour of CA + alumina mixtures. But the additivity concept of the different effects remains and can be used to explain the complex behaviour of these systems.

INFLUENCE SOLID SOLUTION OF CALCIUM ALUMINATE ON ALUMINA CEMENT PROPERTIES

Tamara V. KOUZNETSOVA, RCTU, Moscow, Russia
Adel A. ABDEL KADER, TIMS, Cairo, Egypt.

ABSTRACT: Solid solution of calcium aluminate with addition of CaF_2, MgO and ZrO_2 was investigated in order to correlate solid solution composition to hydration characteristics. Based on these results, sintering parameters for various high alumina cements have been recommended.

Key-words: **A**=Alumina **C**=Calcium aluminate cement **R**=Refractory

INTRODUCTION

In the last decade, the issue of increasing the efficiency of refractories use in metallurgical for their use in metallurigical, chemical, petrochemical industries and in the producing of building materials, has experienced a substantial advancement. Efficiency works and duration exploitation of refractory aggregates depend on refractory mixture (materials) which can be used as custom articles refractory lining and refractory concrete. Using refractory materials as a refractory concrete led to the speed-up of the rate of building refractory aggregates by 3-4 times, and the decrease in capital outlays by 2-3 times, in comparison with traditional refractory bricks. However, using concrete as a refractory material (Kouznetsova and Talaber, 1988) have some shortcomings. For example, as the decrease in its strength at high temperatures. High refractoriness properties of concrete manufactured from high alumina cement are of great interest and are always used in different industries.

EXPERIMENTAL

The main phases of alumina cement were synthesized such as 12 $CaO.7Al_2O_3(C_{12}A_7)$, $CaO,Al_2O_3(CA)$ and $CaO.2Al_2O_3(CA_2)$(Kouznetsova, 1986). Also these minerals have been prepared with the addition l and 5% CaF_2, 3 and 10% MgO and 2 and 10% ZrO_2.

Raw mixtures stoichiometrically prepared for $C_{12}A_7$, CA and CA_2 minerals production in pure state, as well as with above calculated additives. In these investigations we used the following materials, $CaCO_3$, Al_2O_3, CaF_2, MgO and ZrO_2 marke (h.d.a). Phase were synthesized by grinding stoichiometric proportions of given materials in fused alumina ball mill. Batch of each phases were moulded and pressed using a thrust of 30 MPa. The specimens were demoulded, dried and heated at 1200-1400°C for 60-120 minutes depending on the phase character. For preliminary check of complete sintering reactions, the fired mineral powders were tested for free lime and unreacted alumina.

RESULTS

The results indicate that, the synthesis of minerals depend upon the firing temperatures and on the soaking time at these temperatures. Complete dissociation of $CaCO_3$ happned at 850°C (Serry et al, 1987) then the heated minerals at this temperature contain CaO and Al_2O_3. XRD Patterns for sintered mixtures at 900°C confirm presence of CA (d = 0.297, 0.252, 0.241 and 0.190 nm) and its amount increases with increasing firing temperature up to 1150°C.

Addition of calcium fluoride in raw mixture causes besides the CA formation, $C_3A_3CaF_2$ was formed (d = 0.308, 0.288, 0.267 and 0.197mm). Also, the CA_2 synthesis is the presence of CaF_2 the CA_2 and C_3A_3. CaF_2 were formed. Activation energy of the aluminate phases synthesis with additives is 78 kj/mol, while is 110 kj/mol for calcium aluminates without additives (Saha and Paddar, 1984).

Analogous experiments were carried and using ZrO_2 as additives. Chemical analysis together with XRD showed that the sintered samples consisted of $C_{12}A_7$,CA, CA_2 and $C_7A_3ZrO_2$ at 1000°C. As the temperature increases from 1100 to 1400°C , the change ratio of the above mentioned phases are shown in Table 1.

Table 1 : phase composition of sintered samples containing ZrO_2

Firing	Diffraction maximum of minerals (nm)					
Temperature °C	$CaCO_3$	Al_2O_3	$C_{12}A_7$	CA	CA_2	$C_7A_3ZrO_2$
600	0.303	0.3860	-	-	-	-
700	0.303	0.3870	0.493	-	-	-
800	0.303	0.3870	0.493	0.298	-	-
900	0.303	0.3860	0.494	0.298	-	-
1000	0.303	0.3860	0.496	0.299	0.446	0.284
1100	-	0.3860	0.497	0.299	0.448	0.284
1200	-	0.3860	0.497	0.299	0.449	0.284
1300	-	0.3860	0.497	0.299	0.449	0.284
1400	-	0.3860	-	0.299	0.449	0.284

The compound $7CaO.3Al_2O_3.ZrO_2$, was determined using XRD and its X-ray power patterns:d = 0.284, 0.224,0.196 nm.

Results of investigations in all cases showed that, the addition of MgO in raw mixture, for $C_{12}A_7$, CA and CA_2 production, caused magnesium spinel and preclase to be formed. thus, the diffraction pattern of the basic minerals is different as a result of the formation of solid solution, as shown in Table 2.

Table 2: Phase composition of the sintered sample containing MgO

Temperature	Diffraction maximum of minerals (nm)			
°C	$C_{12}A_7$	CA	CA_2	MgO%
600	0.490	0.296	-	-
800	0.487	0.294	-	10
900	0.491	0.296	-	-
900	0.485	0.293	-	10
1000	-.490	0.297	0.446	-
1000	0.484	0.290	0.444	10
1100	0.490	0.297	0.446	-
1100	0.483	0.290	0.443	10
1200	0.490	0.297	0.447	-
1200	0.483	0.290	0.450	10
1300	0.490	0.297	0.446	-
1300	0.483	0.290	0.440	10

These showed the correlation between the phase composition of contents and their properties. For example, the compressive strength of cement paste reduces as a result of the presence of MgO. Al_2O_3. On other hand, the presence of these compounds caused an increase in the refractoriness of the cementstone.

The presence of $C_{11}A_7.CaF_2$ and $C_3A_3.CaF_2$ caused a reduction in the strength in early stages of hydration, but it rises constantly during the long time hardening.

Zirconium oxide contained cement have higher strengths both at early stages as well as at long time hardening. Also, the addition of ZrO_2 improves high alumina cement quality by increasing its strength and refractoriness of cementstone.

CONCLUSIONS

Aluminate Phases (CA, CA_2) form solid solution with MgO,ZrO_2, CaF_2, etc. Solid solution of CA and CA_2 hydrate faster and have better refractory properties.

ON THE POSSIBILITIES OF *IN SITU* STUDIES OF THE HYDRATION OF ALUMINATE CEMENTS USING ^{27}AL NMR AND PROTON RELAXATION RATE MEASUREMENTS.

Andrew. B. KUDRYAVTSEV. NMR Laboratory, D. Mendeleev University of Chemical Technology of Russia , Moscow, Russia
Tamara. V. KOUZNETSOVA. Cement Technology Dept., D. Mendeleev University of Chemical Technology of Russia , Moscow, Russia

ABSTRACT. Wideline ^{27}Al nmr spectroscopy and the measurements of means and variances of proton relaxation rate have been applied to the investigation of hydration of CA, CA_2 and C_3A. A selective fast hydration of one of the six non–equivalent AlO_4 tetrahedra in the crystal lattice of CA has been found from the deconvolution of nmr spectra. Difference nmr spectra were used to investigate the hydration of CA_2 and C_3A. The contents of free water were derived from the data on means and variances of proton relaxation rates. A significant release of water from the adsorption layer occurs at about 400 - 500 min. of hydration of CA.

Key-words: Calcium aluminate cement, Hydration, Kinetics, Nuclear Magnetic Resonance

INTRODUCTION.

Nuclear magnetic resonance has been successfully used in many studies of hydration of various cements and their components. Application of advanced solid state nmr methods (MAS, PE-MAS, *etc.*(see in J. Skibsted et al., 1993) is possible in the cases of comparatively stable samples, i.e. those hydrated for at least one or several days, or of artificially stabilized specimens of minerals hydrated for shorter times. In the latter cases the problem is that the liquid phase still present at earlier stages of hydration is destroyed and dissolved products are forced to crystallize under conditions far from normal. The *in situ* studies of cement hydration provide more reliable information on the state of cement pastes during the induction period and the initial crystallization of products. In many cases these stages are of short duration and the measurements must be fast. Proton magnetic relaxation measurements as well as ^{27}Al nmr spectroscopy comply with these requirements. These methods have been applied to the study of hydration of modified calcium sulphoaluminates (A.B. Kudryavtsev and T.V. Kouznetsova, to be published). A significant increase in the proton relaxation rate was observed during induction period which could not be unambiguously assigned due to the absence of the data on the dissolution of original grain. Such data can be obtained from the analysis of wideline ^{27}Al nmr spectra.

The lineshape of a ^{27}Al nmr spectrum of a powdered mineral is a convolution of a gaussian lineshape (caused by relaxation) and of a complicated lineshape arising from the averaging of quadrupolar shifted resonances over all orientations. In many instances such parameters as quadrupolar coupling constant, chemical shifts, electric field asymmetry factors can be estimated. In some cases, on the other hand, the lines are so broadened that they can be considered a collection of gaussian lineshapes.

Proton relaxation time measurements when used to study the hydration of cements are far from being a trivial experiment. These systems are heterogeneous from several points of view: water is distributed between bulk liquid and adsorption layer. The adsorption layer is inhomogeneous in

itself and contains centers with different relaxation efficiency. Powdered materials (when not specially fractionated) are polydisperse and multicomponent. The properties of corresponding pastes are dependent on the distribution of particles over the grain's size and composition. The exchange of water molecules between different states in such systems is usually slow which is reflected by a non–exponential relaxation of water protons. By analyzing non–exponential re–equilibration of longitudinal and transverse nuclear magnetization it is possible to identify several products in hydrated cement pastes. This method, known as *spin–grouping* (H. Peemoeller and M. Pintar, 1980), requires, however, prolonged measurements and could not be used in kinetic studies of hydration of fast setting cements. Recently a new method of nuclear magnetic relaxation studies (A.B. Kudryavtsev et al., 1994) has been suggested for the measurements of the means and variances of relaxation rates in heterogeneous systems. This method only requires the initial part of re–equilibration curve to be analyzed and is sufficiently fast to be used in kinetic studies. In the presented paper the possibilities of the wideline ^{27}Al nmr and the measurements of means and variances of relaxation rates have been explored using the samples of specially synthesized and fractionated (grain size 28 - 40 μm) CA, C_2A and C_3A. Water-to-cement ratio was 0.4.

^{27}Al MNR DATA.

Hydration of CA.

^{27}Al nmr spectra of CA obtained at various stages of hydration are shown in Fig. 1A. According to J. Skibsted et al. (1993) the line observed in the spectrum of anhydrous CA is a superposition of the lines from 6 non–equivalent AlO_4 tetrahedra in the crystal structure of CA. After the addition of water a new narrow line appears at 80 ppm which is connected (A.B. Kudryavtsev et al., 1990) with tetracoordinated Al species in liquid phase. The intensity of this line remains approximately constant during about 100 min of hydration and then starts to decrease. After 100 min of hydration another line (with a maximum around zero ppm) appears in these spectra (Fig. 1, curve t=102min) which reflects the well known formation of octahedrally coordinated hydrated aluminate species (D. Mueller et al., 1984). At approximately the same time the low–frequency part of the line of original solid begins to disappear (Fig. 1A). This means that the dissolution of original solid is selective concerning the nonequivalent species present in the crystal structure. At long hydration times this part of the original line seems to disappear completely. In order to follow quantitatively the growth of new solid and the disappearance of the initial grain the spectrum of *anhydrous* CA was approximated by a sum of 6 gaussians of *equal* integral intensities and their parameters were determined by non–linear regression. Spectra of hydrated CA were approximated by a larger number of gaussians. Positions of maxima, widths and normalizing factor were adjusted to achieve an adequate description of the experimental lineshape in the spectrum of anhydrous CA: The parameters of the spectra of hydrated samples were estimated adjusting the individual integral intensities of all the lines keeping fixed the positions and widths of the lines of original solid. Because of the overlapping of the lines of initial solid the estimates of their intensities were strongly correlated which was a source of several observed artifacts (e.g., the component #3 is 'vanish' immediately upon the addition of water, Fig. 1 B). The real changes in original solid may be represented by a set of lines the total intensity of which does not increase and/or smoothly runs downwards. For example, the total sum of the intensities of *all* original lines after being constant for 100 minutes of hydration decreases smoothly during the remaining period of observation (Fig. 2). The widest lines of the original solid are the inner lines and their behavior is the most correlated. However the sum of their integrals is approximately constant during hydration (Fig. 2).

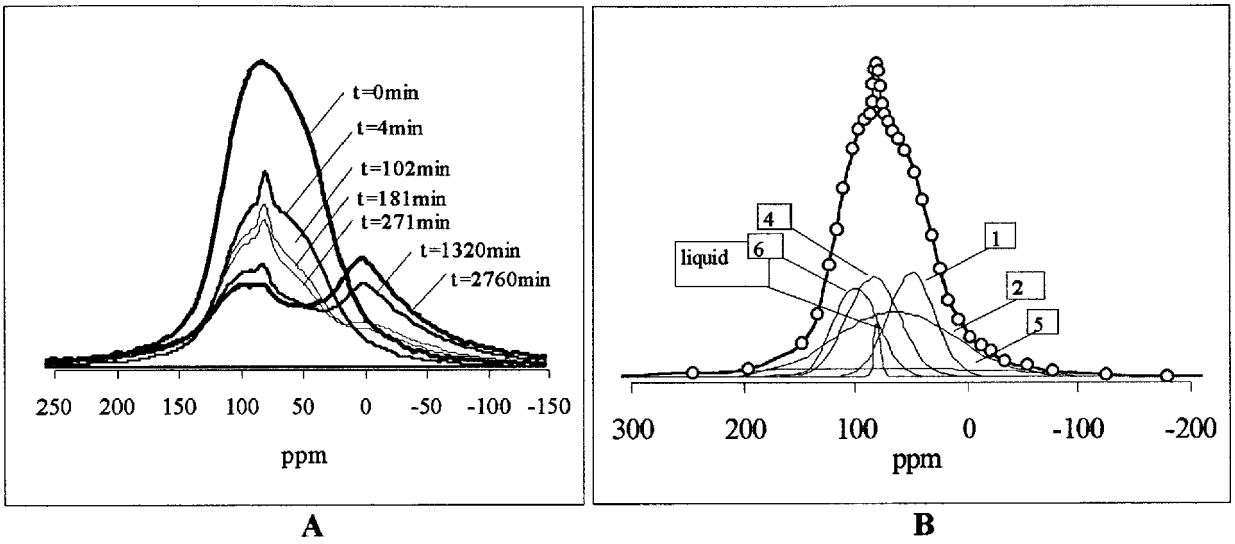

Figure 1. ^{27}Al nmr spectra (78 MHz) of hydrated CA(A) and deconvolution of the curve corresponding to 4 min of hydration (B).

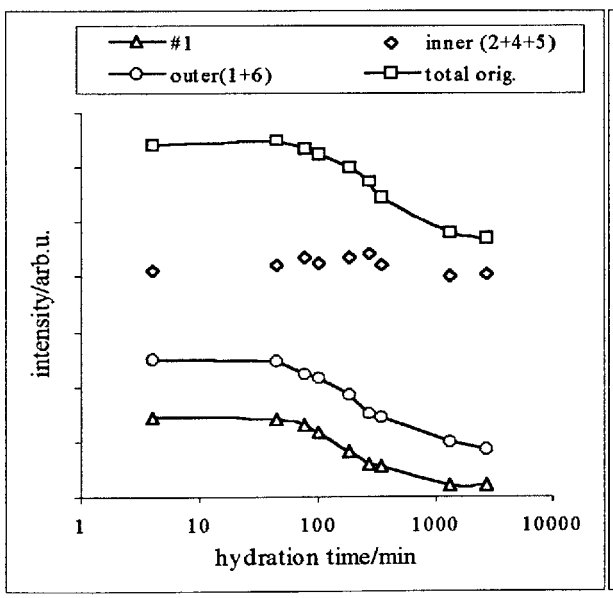

Figure 2. Development of the intensities of different sets of lines of original solid during the hydration of CA.

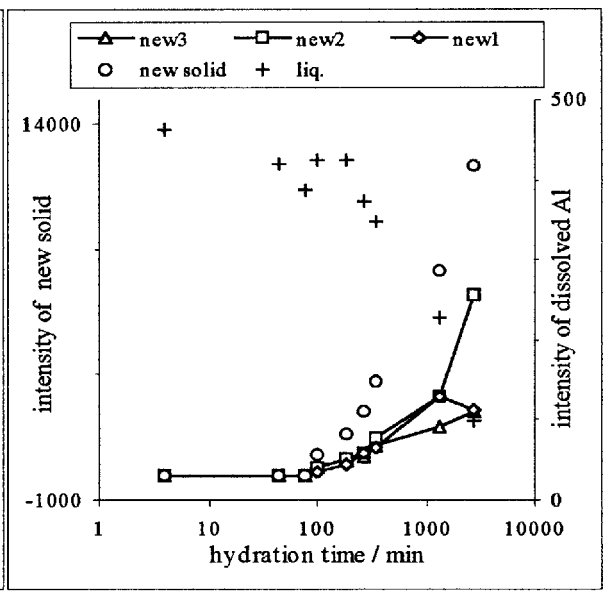

Figure 3. Development of the intensities of the lines of the products of hydration of CA.

The outer lines are comparatively narrow and one of them (having the lowest resonance frequency) shows an approximately exponential decay down to practically zero intensity at 2 days of hydration. Fortunately, the lines of *hydrated products* are significantly shifted from the lines of original solid and their intensities are not so strongly correlated. The line of aluminate in liquid phase is distinguished by its small width. From one to three lines of solid hydrated products were necessary for an adequate description of the experimental lineshapes at different stages of hydration. They overlap strongly, therefore it was impossible correlate these processes with the transformation of the primary product CAH_{10} (after approximately 10 hours of hydration) into C_2AH_8 (T. Kosmach et al., 1993). The total amount of new solid increases smoothly and is always much higher than the amount of aluminum in the liquid phase (mark the different scales

for these intensities in Fig. 8). The growth of a new hydrated phase is accelerated while the concentration of aluminum in the liquid phase is decreased. These facts indicate that the liquid phase should be considered not as a mother liquor but as an intermediate layer between the original solid and hydrated products. The amount of the *dissolved* aluminate ions is stationary during induction period. The total amount of *aluminum* in the original solid is also stable. What processes actually occur during this time is not clear from ^{27}Al nmr spectra.

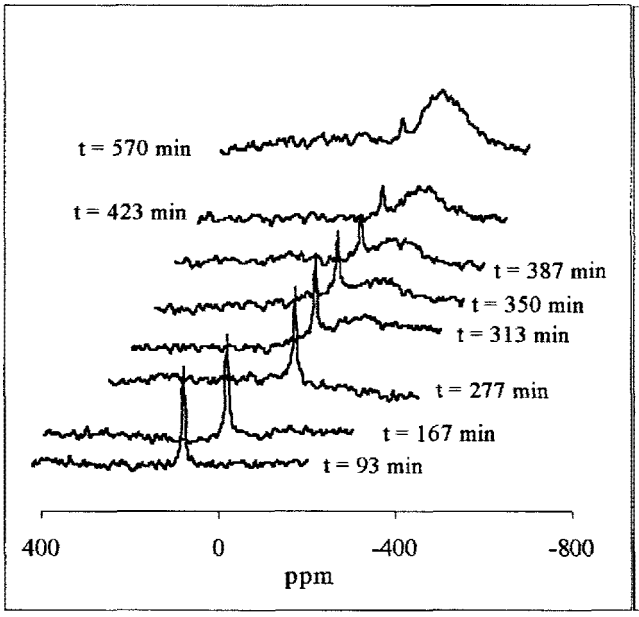

Figure 4. Difference spectra of hydrated and anhydrous CA_2.

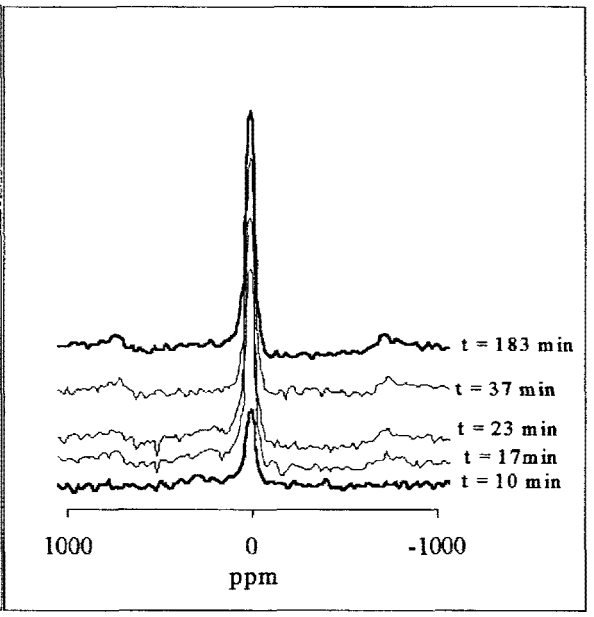

Figure 5. Difference spectra of hydrated and anhydrous C_3A.

Hydration of CA_2.

CA_2 is hydrated much slower than CA. At 10 hours of hydration the peak of hydrated products is barely visible as a shoulder to the central line in ^{27}Al nmr spectrum. However, the difference spectra, Fig. 4, of a hydrated sample and the original solid show a gradual decrease of the narrow signal at 80 ppm and a growth of the line at ca. 0 ppm (hydrated solid products). The moment of the first appearance of new solid can easily be determined from these spectra (between 277 and 313 min). The absolute amounts of the dissolved aluminum (as $[Al(OH)_4]^-$ ions) and of crystallized products of hydration are much smaller than in the case of hydrated CA.

Hydration of C_3A .

An intense line of new solid is visible in the spectra of hydrated C_3A at the shortest possible hydration times which can be investigated by ^{27}Al nmr. Difference spectra thus obtained (Fig. 5) contain one comparatively narrow central line of hydrated products, accompanied by broad satellites. Only three experimental points can be obtained before the intensity of the line of hydration product reaches a stationary level.

PROTON RELAXATION RATE MEASUREMENTS

Theoretical background.

In the presence of differently relaxing species nuclear magnetic relaxation is *multi-exponential irrespective* the rate of exchange between these species. However, at the rates of exchange higher than the difference of relaxation rates, the fraction of the fast relaxing component

decreases with increasing exchange rate and approaches zero. *Multi-exponentiality* of relaxation, i.e. a non–zero *variance of relaxation rate* indicates the presence of differently relaxing species the higher the precision of measurements the higher is the limiting exchange rate at which the multi-exponentiality may be observed. Small variance could therefore be a result of either a small content of one of the phases in slow exchange or a fast exchange between the phases present in comparable quantities. The parameters (relaxation rates and populations) of the experimentally determined (as in spin-grouping method) in such systems re-equilibration curves contain both the relaxation and exchange terms. For example in the case of slow exchange the experimental relaxation rates R_B and corresponding population, x_B, of one of the phases in a two-site system are (e.g. in: A.B. Kudryavtsev and W. Linert, 1996),:

$$R_B \approx R^0_B + p_A k - k^2/4\Delta R \qquad x_B \approx p_B + 2p_A p_B/\Delta R \qquad [1]$$

However it can be shown, that *means* and *variances* of relaxation rate are independent of the exchange rate and always are:

$$\langle R_1 \rangle = R_A x_A + R_B x_B = R^0_A p_A + R^0_B p_B \qquad [2]$$

and

$$V(R) = \langle R_1^2 \rangle - (\langle R_1 \rangle)^2 \qquad [3]$$

The parameters of a heterogeneous system derived from $\langle R_1 \rangle$ and V(R) do not contain therefore the contributions from exchange processes. The populations and and relaxation rates in the phases can be determined from $\langle R_1 \rangle$ and V(R) using certain models. If the distribution of water molecules over relaxation rates in adsorbed state is sufficiently narrow to be characterized by a single relaxation rate R_A then the average relaxation rate is:

$$\langle R_1 \rangle = xR_B + (1-x)R_A = R_A - x(R_A - R_B) = R_B + (1-x)(R_A - R_B) \qquad [4]$$

where x is the fraction of water molecules in bulk liquid ($x = p_B$), R_B is the relaxation rate of water protons in bulk liquid (for pure water R^0_B is about 0.3 sec^{-1} at 25°C). The variance of relaxation rates under the same conditions is:

$$V(R) = \langle R_1^2 \rangle - \langle R_1 \rangle^2 = x(1-x)(R_A - R_B)^2 \qquad [5]$$

The ratio, α, of the variance, Eq. 5, to $(\langle R_1 \rangle - R_B)^2$ is:

$$\alpha = V(R)/(\langle R_1 \rangle - R_B) = x/(1-x) \qquad [6]$$

and

$$x = \alpha/(1 + \alpha) \qquad [7]$$

The relaxation rate in adsorbed state can be calculated by substituting the fraction *x* in Eq. 4 by its value from Eq. 7:

$$R_A = R_B + (\langle R_1 \rangle - R_B)(\alpha + 1) \qquad [8]$$

The experimental values of means and variances of relaxation rates were obtained (according to A.B. Kudryavtsev et al., 1994) by fitting the re–equilibration curves of longitudinal magnetization to Eq. 9:

$$A = A_0(1 - \exp(-a\tau + b\tau^2)) \qquad [9]$$

where A is the amplitude of an nmr signal in a saturation-recovery sequence, $a = \langle R_1 \rangle$, and $b = 0.5$ V(R). The kinetics of hydration reflected by the changes in $\langle R_1 \rangle$ and V(R) in hydrated CA are shown in Figs. 6 and 7. The estimates of $\langle R_1 \rangle$ and V(R) depend on the region in which the curve was analyzed, i.e. on the number of points of experimental data used in regression, Figs. 6, 7. The shifting of the truncation point of experimental curve (imposed to obtain adequate descriptions at different stages of hydration) produces steps or breaks in the kinetic curves. A correct quantitative analysis can only be performed within the regions explored under identical experimental settings. Qualitatively such curves can be analyzed by 'pasting' these parts together.

Hydration of CA.

At the initial stage (0 -200 min. of hydration) both the means and variances of relaxation rate are not high. A sharp rise of $\langle R_1 \rangle$ and V(R) at t_{hydr} = 250 - 350 min. indicates the beginning of crystallization of hydrated phases. The mean relaxation rate passes through a maximum at about 350 min, whilst the variance proceeds to increase, although at a slower rate. This maximum was observed by T. Kosmach et al. (1993) and was attributed to the transformation of CAH_{10}, into CAH_8 and AH_3. Small initial variances if relaxation rates mean that either the amount adsorbed water is low or the exchange rate between bulk liquid and adsorbed state is high. Observed increase in V(R) may be connected with the increasing viscosity of liquid phase (slower exchange) and/or penetration of water molecules into micropores (higher fraction of adsorbed molecules).

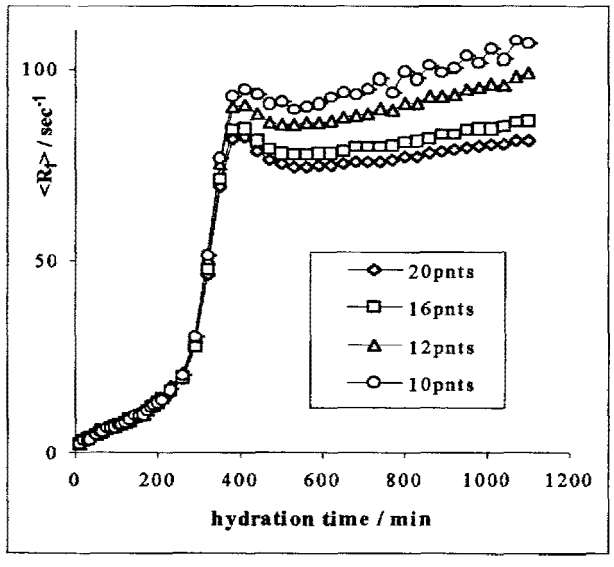

Figure 6. Development of $\langle R_1 \rangle$ during the hydration of CA.

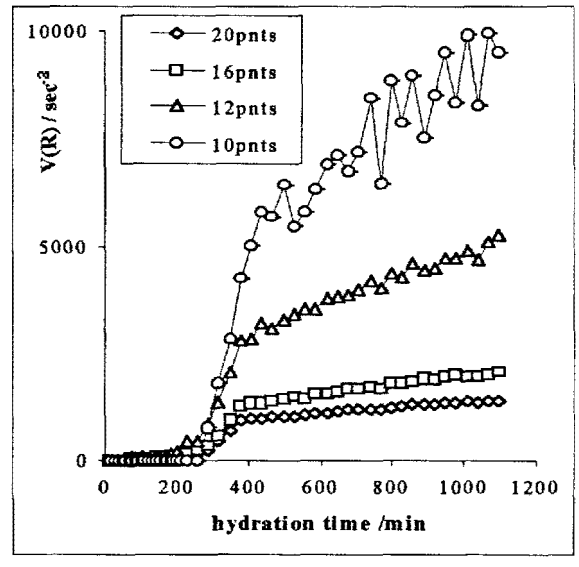

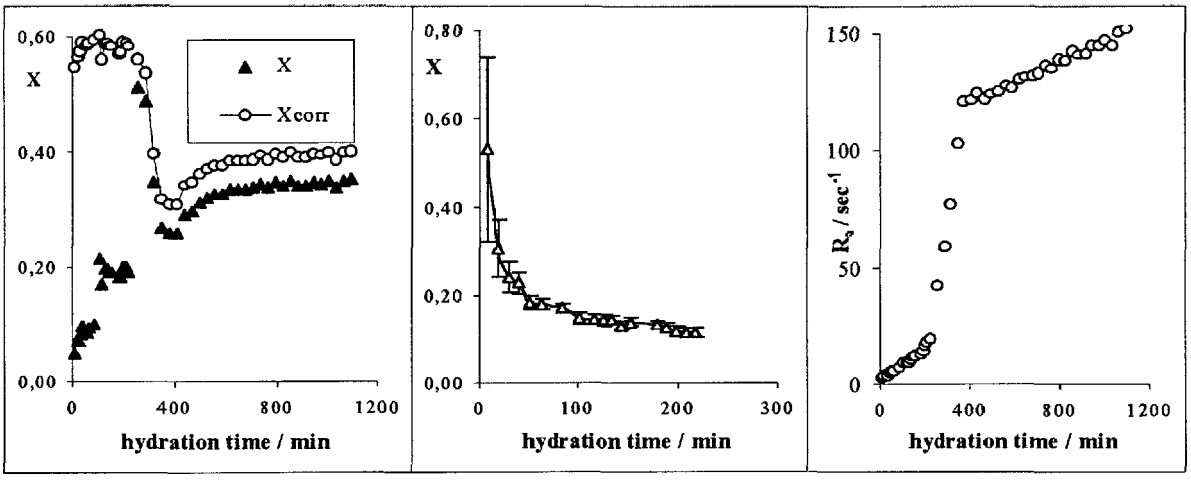

Figure 7. Development of V(R) during the hydration of CA.

Supposing that low initial variances were caused by a weak adsorption of water we assume implicitly that bulk water and adsorbed water exist in slow exchange. The relaxation rate R_B can then be identified with the relaxation rate in a solution separated from a suspension (0.366 sec^{-1} in the solution centrifuged from a freshly prepared paste of CA). The results of the calculations of α and x using this value of R_b are shown in Fig. 8A. Because $\langle R_1 \rangle$ and V(R) were measured using three different sets of re–equilibration delays three regions of the curve 'X' are observed in Fig. 8A). By shifting upwards the parts of this curve a continuous dependence of the fraction of 'free

water' can be obtained (curve 'Xcorr' in Fig. 8). Supposing that low initial variances were caused by a fast exchange the ratio α should be calculated using $R_B \approx \langle R_1 \rangle (t_{hydr} \dashrightarrow 0) = 2.0\ sec^{-1}$. In this case we implicitly assume that a polymolecular layer with fast exchange was initially formed with $R_B \approx 2.0\ sec^{-1}$. This layer yields upon hydration a kinetically distinct layer ('adsorbed state'). characterized by the relaxation rate R_A. Such calculations lead to α and x decreasing with hydration x, Fig. 8B, which reflects the diminishing amount of the initial polymolecular adsorption layer at the initial stage of hydration.

A ($R_b = 0.36\ sec^{-1}$) **B** ($R_b = 2.0\ sec^{-1}$) **C**

Figure 8. Kinetics of the conversion of free water molecules (A,B) and of the development of relaxation rate in adsorbed state (C).

The relaxation rates in adsorbed state, R_A, (calculated according to Eq. 8, Fig. 8C) are small comparing to the relaxation rates in a monomolecular layer on similar solid surfaces (about 100 sec^{-1}). This means that the phase 'A' is also a polymolecular adsorption layer. The observed increase in R_A shows that molecular mobility is decreased by a certain processes, which must be connected with nucleation because the other alternative: the increasing concentration of dissolved products, does not correspond with approximately constant intensity of the signal of dissolved products in ^{27}Al nmr spectra at this period (see above).

After the beginning of crystallization new solid phase attracts water from both the bulk liquid and polymolecular adsorption layer. The phase 'A' in this case is the adsorption layer of this newly formed crystals possessing of a high adsorption capacity. The water being more thinly distributed over the solid surface the calculated R_A approaches the values characteristic for a monomolecular adsorption. It is remarkable that the dependence of R_A on hydration time consists of three straight lines and does not contain either maxima or breaks of continuity (Fig. 8C). This shows that the influence of surface in the adsorption layer kinetically separated from 'bulk water' is continuously increasing.

Hydration of C_3A

The curves in Fig. 9A show that both the means and variances of relaxation rate are increasing steadily starting from comparatively high values. They pass through a flat maximum at about 500 min. of hydration. The fraction of free water, x, and the relaxation rate, R_A, reflect a release of adsorbed water and an increasing mobility of water in the 'adsorption layer' after 500 min. of

hydration (Fig. 9B). The release of water might be connected with the growing size of crystals and lesser specific surface. On the other hand the water within the phase 'A' can be transformed from adsorbed state into the water of crystallization. Such transformation can be accompanied with an increase of molecular mobility due to a free rotation along some axis in a crystal lattice.

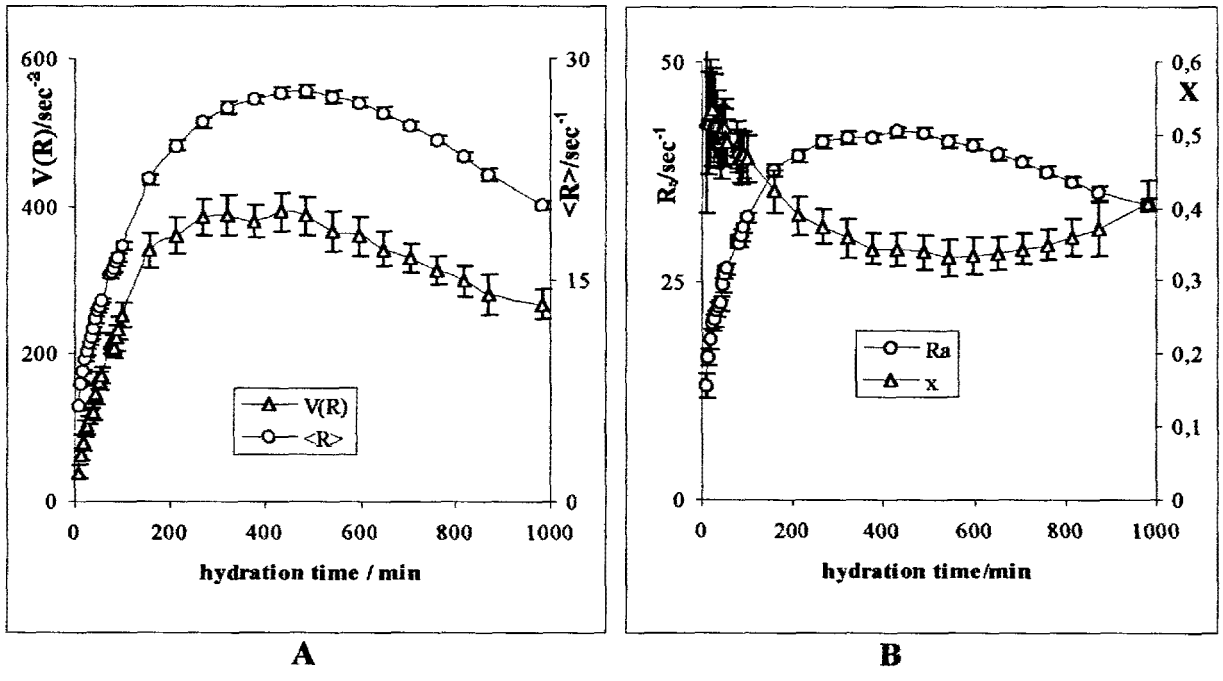

Figure 9. The development of the means and variances of relaxation rate (A) and of the free water content and relaxation rate in adsorbed state during the hydration of C_3A (B).

EFFECT OF COMPOSITION ON THE HYDRATION PROPERTIES OF RAPID-HARDENING SULFOALUMINATE CEMENTS

Julius BERETKA and Natalie SHERMAN, Commonwealth Scientific and Industrial Research Organization D.B.C.E., P.O. Box 56, Highett, Victoria 3190, Australia

ABSTRACT The influence of $C_4A_3\overline{S}$ and C_4AF on the properties of sulfoaluminate cements has been studied. Cements containing about 30-40% $C_4A_3\overline{S}$ hydrated with w/s ratios ranging from 0.35 to 0.50 showed the best behaviour. The resistance of sulfoaluminate cements to CO_2 attack was improved by the incorporation of C_4AF.

Key-words: Sulfoaluminate, Brownmillerite, Anhydrite, Hydration, Ettringite.

INTRODUCTION

The properties of calcium sulfoaluminate cements are influenced mainly by $C_4A_3\overline{S}$ which forms ettringite according to the following reactions:

$$C_4A_3\overline{S} + 8\,C\overline{S} + 6\,C + 96\,H \rightarrow 3\,(C_6A\overline{S}_3H_{32}) \quad [1]$$

$$C_4A_3\overline{S} + 2\,C\overline{S} + 38\,H \rightarrow C_6A\overline{S}_3H_{32} + 2\,AH_3 \quad [2]$$

The microstructure of ettringite is strongly dependent on the presence of lime (Metha, 1973). Ettringite produced by the reaction in Eq 1 is expansive and this property is exploited in special applications such as shrinkage-resistant and self-stressing cements (Kurdowski et al, 1986).

Ettringite formed in the absence of lime by the reaction in Eq 2 is non-expansive and generates high early strength in cementitious systems. Rapid hardening sulfoaluminate-based cements have higher mechanical strength and require lower synthesis temperature than ordinary portland cements (OPC) (Muzhen et al, 1992). It also allows the use of considerable amounts of industrial wastes and by-products as raw materials (Beretka et al, 1993).

According to the stoichiometry of the reaction (Eq 2) a $C\overline{S}/C_4A_3\overline{S}$ weight ratio of 0.45 and a relatively high water/solid ratio of 0.78 by weight are required for the full formation of ettringite. Hence the $C_4A_3\overline{S}$ concentration in cement and the amount of water in the mixture must be adjusted so as to ensure optimum properties. Accordingly, if the $C_4A_3\overline{S}$ content is too high, strength reduction may occur due to excessive porosity of the hydrated systems; on the other hand, when the $C_4A_3\overline{S}$ content is too low, the ettringite concentration within the hydration products is no longer sufficient to give adequate mechanical strength.

Sulfoaluminate clinkers can be conveniently diluted with blending components in order to lower the $C_4A_3\overline{S}$ concentration. However, they usually contain considerable amounts of other phases like C_2S, $C_5S_2\overline{S}$, C_3A and C_4AF, depending on the synthesis temperature as well as the composition and proportioning of the raw materials used. The positive role played by calcium disilicate C_2S in $C_4A_3\overline{S}$-based cements is clearly defined as in OPC, since it contributes to the strength and durability of the hydrated systems (Ikeda, 1980; Sudoh et al, 1980). Calcium

sulfosilicate $C_5S_2\overline{S}$ hydrates very slowly and can only contribute to the ultimate strength of the system (Sherman et al, 1995). The hydration of C_3A is fast, it competes with that of $C_4A_3\overline{S}$, and is responsible for early setting (Beretka and Sherman, 1992). C_4AF, like C_3A, gives hydration products which react with ettringite, and generate monosulfate ($C_4A\overline{S}H_{12}$) that is a phase more resistant to carbonation than ettringite (Belz et al, 1995). Due to its moderate rate of hydration, C_4AF does not cause the usual problems associated with the presence of C_3A and can enhance the durability of calcium sulfoaluminate cements, particularly at later ages.

Therefore, regarding the role played by the individual components of these cements, the effects of $C_4A_3\overline{S}$ content and of the presence of C_4AF need to be examined and are here discussed.

EXPERIMENTAL

Raw materials

Natural materials (limestone, bauxite), industrial byproducts (phosphogypsum, fly ash) and pure analytical grade reagents were used for the raw mixes. The commercial materials were the same as used previously (Beretka et al, 1993; Sherman et al, 1995). The pure reagents grade materials used were not analyzed.

Synthesis and procedures

The various cementitious compositions were prepared by firing them in an electric oven. The cements were obtained in a single firing or prepared by blending individually synthesized components. Then they were ball-milled dry to pass a 53 μm sieve with a residue of 5%.

Hydration

Small (2 g) specimens were mixed with the selected amounts of water, then placed in a plastic envelope and cured for various time intervals at a constant temperature (23 or 55°C). At the end of the hydration period the reaction was stopped with acetone and the material dried with ether (Beretka et al, 1993).

Qualitative and quantitative analyses

XRD, SEM, DTA and TGA were employed for the qualitative analysis of the cured specimens. XRD was also used for the qualitative analysis of the anhydrous systems; and TGA was also employed for the measurement of ettringite concentration in the hydrated cements.

Mechanical testing and carbonation studies

The compressive strength was determined on paste cubed specimens, 25 mm in size, which were cast, then cured at 23 °C and 100% RH for various times. Some of the samples were submitted to accelerated carbonation that was carried out in a carbonation chamber (4% CO_2, 60% RH) for different times to up to 28 days, before testing.

RESULTS AND DISCUSSION

Effect of $C_4A_3\overline{S}$ content

Five calcium sulfoaluminate cements, obtained by heating mixtures of limestone, bauxite, phosphogypsum and fly ash for 4 hours at 1200 ° C, have been investigated.

The proportioning of the raw mixes has been formulated so as to obtain products containing the

three components, $C_4A_3\overline{S}$, $C_5S_2\overline{S}$, $C\overline{S}$. The minor phases which may have formed were ignored. In the five cements the $C_4A_3\overline{S}/C_5S_2\overline{S}$ weight ratio was varied between 1:5 and 2:1; the ratio between $C\overline{S}$ and $C_4A_3\overline{S}$ was kept constant and equal to 0.5, that is a slightly higher value in respect to the stoichiometric ratio (0.45) fixed by Eq 2. This reaction is the only one that has been considered during the hydration process, since the calcium sulfosilicate contribution has been neglected due to its poor hydraulic behaviour. Table 1 shows the compositions examined.

Table 1 Compositions (wt %) of sulfoaluminate cements.

System / Component	A	B	C	D	E
$C_4A_3\overline{S}$	15.4	22.2	28.6	40.0	50.0
$C_5S_2\overline{S}$	76.9	66.7	57.1	40.0	25.0
$C\overline{S}$	7.7	11.1	14.3	20.0	25.0

Hydration has been carried out in two different sets of experiments: (i) the first one on compositions from B to E using a constant water/total solids ($C_4A_3\overline{S} + C_5S_2\overline{S} + C\overline{S}$) ratio of 0.4; (ii) the second one (compositions A to E) using a constant water/reactant ($C_4A_3\overline{S} + C\overline{S}$) ratio of 0.86, that is ~10% higher than that required by stoichiometry of Eq 2 (0.78). For the second set of experiments, in spite of the excess water, the use of a superplasticizer was required for improving the workability of systems A and B, characterized by the lowest w/s ratios (Table 2).

Table 2 Water/solid ratios, w/s, for the second set of hydration experiments (constant water/reactant ratio, 0.86).

System	A	B	C	D	E
parts of $C_4A_3\overline{S} + C\overline{S}$	1.50	1.50	1.50	1.50	3.00
parts of water	1.29	1.29	1.29	1.29	2.58
total solids	6.50	4.50	3.50	2.50	4.00
w/s	0.20	0.29	0.37	0.52	0.65

Values of compressive strength and ettringite concentration are plotted in Figs 1 and 2, respectively, as a function of time for compositions cast at the w/s ratio of 0.4. It is possible to notice that as the $C_4A_3\overline{S}$ content increases, the mechanical strength rises for all the four systems examined to up to 28 days curing. For longer hydration times the strength of B and C cements is about constant, while the strength of cement D slowly decreases, and cement E shows a rapid

drop in strength, due to expansion and cracking.

The ettringite content for the above compositions (Fig 2) increases with the amount of $C_4A_3\overline{S}$ present, and in fact after 1 day curing it reaches a remarkably high value, then slowly increases to an almost constant value, except for system E. This particular system (E) after 28-56 days hydration shows a further growth in ettringite content.

Such behaviour has to be related to the water content of the paste. System E would require a much higher water content for complete hydration (Table 2) than the one used here. As a consequence, when the gauging water has been consumed, the further hydration of $C_4A_3\overline{S}$ is achieved by the absorption of water from the curing environment (100% RH). This delayed hydration is responsible for the expansive phenomena, due to ettringite formation on the surfaces of hardened samples. The fact that this phenomenon does not occur at 67% RH, strengthens this hypothesis.

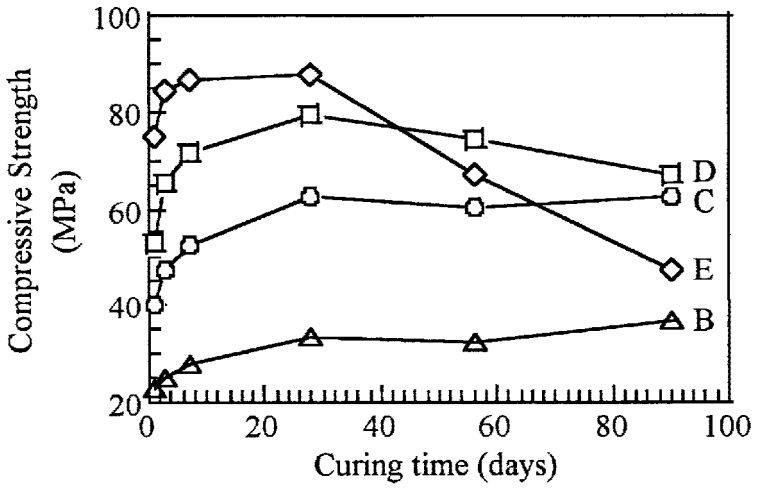

Figure 1 Compressive strength for compositions hydrated with w/s 0.4.

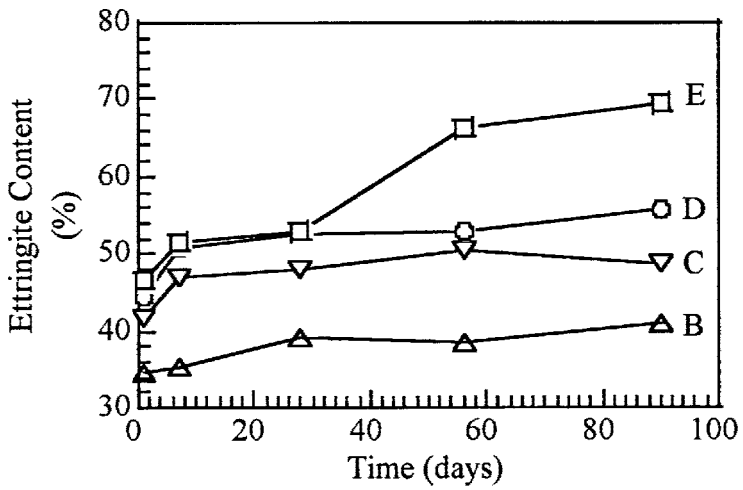

Figure 2 Ettringite content for compositions hydrated with w/s 0.4.

Table 3 confirms the critical role played by the water content (second set of experiments). The

compressive strength and ettringite content data are reported for different curing times for the five systems investigated. The highest mechanical strength is shown by cement B, followed by cements D, C, A and E respectively. Compositions A and E do not give a good compromise between the $C_4A_3\overline{S}$ content and the amount of water used. In fact, cement A has a low $C_4A_3\overline{S}$ (and ettringite) content while cement E has a high one. In spite of its high ettringite concentration, cement E gives lower strength due to the high porosity induced by the water content.

Table 3 Compressive strength, (MPa) (left upper corners) and ettringite content, wt (%) (right lower corners) for compositions hydrated with water/reactant ratio of 0.86.

Time(days) / System / w/s	1	3	7	28	56
A 0.20	35.7 22.7	42.3 24.2	45.0 25.5	57.9 27.6	61.5 29.7

C 0.37	36.3 39.7	48.7 43.6	59.4 46.4	61.8 49.1	66.8 48.5
D 0.52	35.8 48.8	49.5 53.0	59.7 56.7	70.7 60.3	70.5 60.3
E 0.65	27.8 53.6	41.0 58.2	46.2 62.4	54.6 65.2	57.3 66.7

Differently from the first set of tests, the systems hydrated with a water/reactant ratio of 0.86 were dimensionally stable, since the water content was sufficient to obtain complete hydration for all compositions.

Role of C_4AF

Samples of synthetic monosulfate ($C_4A\overline{S}H_{12}$) and samples of the systems F and G shown in Table 4 were also investigated. Monosulfate was obtained by hydrating a mixture of $C_4A_3\overline{S}$, C_3A and $C\overline{S}H_2$ (Beretka and Sherman, 1992). System G was prepared by blending a mixture of individually synthesized $C_4A_3\overline{S}$, $C\overline{S}$ and C_4AF in a stoichiometric ratio suitable for ettringite-monosulfate transformation (weight ratio 1:0.45:1.6).

Pure $CaCO_3$, Al_2O_3, $CaSO_4{\cdot}2H_2O$ and Fe_2O_3 were used as raw materials for each synthesis. $C_4A_3\overline{S}$ was obtained by heating at 1260 °C for 4 hours; $C\overline{S}$ at 850 °C for 1 hour and C_4AF at

1300 °C for 4 hours. Composition F was obtained in a similar way as the previous ones. Its composition is only slightly different from that of the system D reported previously in Table 1. The good resistance of monosulfate to CO_2 attack is demonstrated by Figs 3a and 3b, which show the XRD results of a sample before and after accelerated carbonation, respectively. The carbonation products present in minute quantities are attributed to traces of ettringite in the synthesized monosulfate samples.

Table 4 Compositions (wt %) of sulfoaluminate cements.

Component / System	$C_4A_3\overline{S}$	$C_5S_2\overline{S}$	$C\overline{S}$	C_4AF
F	42.9	40.0	17.1	—
G	32.8	—	14.7	52.5

Fig 4 illustrates the ability of the C_4AF-containing system of generating monosulfate at the expense of ettringite.

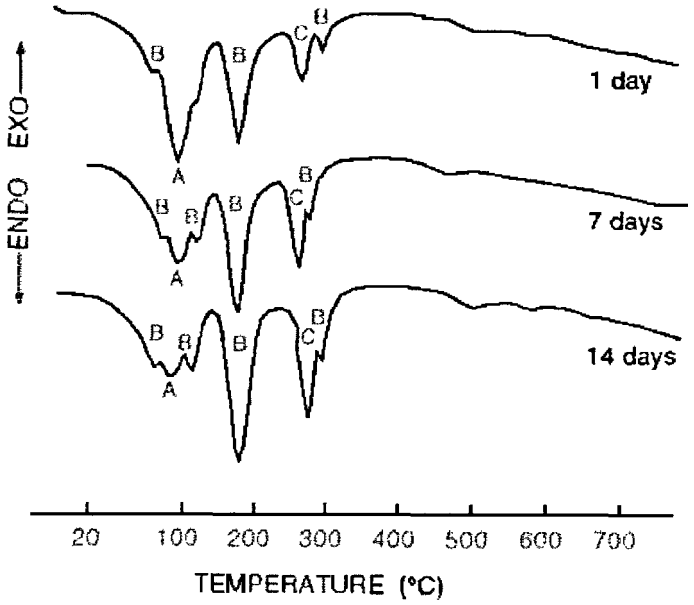

Figure 4 DTA traces for composition G hydrated at 55°C; w/s 0.5. A = $C_6A\overline{S}_3H_{32}$; B = $C_4A\overline{S}H_{12}$; C = alumina gel.

The positive effect of C_4AF in $C_4A\overline{S}$-containing systems can be demonstrated by the good compressive strength and resistance to carbonation of specimen G (Table 5).

Table 5 Retained compressive strength (%) for samples F and G after accelerated carbonation.

Days of carbonation / System	1	3	7	28
F	100.6	87.8	78.4	66.5
G	98.7	96.5	106.7	117.6

CONCLUSIONS

Non-expansive ettringite generated by the hydration of sulfoaluminate cements produces high mechanical strength. Since this hydration requires a relative high stoichiometric amount of water, it is necessary to optimize the $C_4A_3\overline{S}$ concentration and the water content of the mix. C_4AF incorporated in sulfoaluminate cements has a favourable influence on their resistance to carbonation.

EFFECT OF CHLORIDE ON HYDRATION PROPERTIES OF ALINITE CEMENT

JI Lin, REN Xiantai and SU Muzhen, China Building Materals Academy, Beijing 10002, China

ABSTRACT Hydration of alinite cement is studied by calorimeter, TGA, XRD, and SEM/EDAX. Ion content in the hydration solution is determined by ICP and wet chemical analysis .The action of Cl^- in alinite cement hydration and its effect on the formation of hydration products are revealed. The hydration reactivity of alinite cement is quite high because of rather rapid hydration of minerals containing Cl^-.Forming $C_3A \cdot CaCl_2 \cdot 10H_2O$ will reduce soluble Cl^- and compose an intergrowth structure with CSH gel.So that strength of alinite cement is enhanced.

Key-Words : Alinite Chloride Hydration

INTRODUCTION

The main minerals containing Cl^- in alinite cement are alinite phase and $C_{11}A_7 \cdot CaCl_2$, which hydrate quickly due to Cl^- in the structure. $C_{11}A_7 \cdot CaCl_2$ phase in clinker must be limited in a content,e.g.10%,or quick setting may occur. When $C_{11}A_7 \cdot CaCl_2$ hydrates the product is the Friedel' s salt and no Cl^- is released, which prevents Cl^- being free.

Alinite has a higher reactivity with water and hydrates more fast than alite (Boikva,1986). It hydrates so fast that after 15 minutes of adding water large amount of Al^{3+},Ca^{2+},Cl^- solve into the liquid phase. Such a high reactivity of hydration is quite profitable to the early strength of cement.

Alinite cement is an energy-saving product and has a good strength characteristics. But its application is restricted because of soluble Cl^-.So it is necessary to investigate and recognize the regularity of Cl^- release

EXPERIMENTAL

Raw mixtures were made from limestone, Clay, flyash, as well as chemical agents, $CaCl_2$ and MgO. The burning temperature was 1250 ℃. Alinite cement was made by mining 95% clinker and 5% gypsum and its strength and the rate of hydration heat evolution were tested. Pure phases were made from chemical agents.

The hydration of alinite cement and the pure phases was studied with W/C=10 and by curing in sealed plastics bottles which was rotated for various ages. Samples were filtered ,of which the filtrate solution was determined by ICP and chemical analysis and the remaining was analysised by TGA, XRD, SEM/EDAX after drying in vacuum.

RESULTS AND DISCUSSION

Alinite content in the cement is about 50 ~ 60% and it plays an important role in cement properties Figure 1 gives the rate of heat evolution of alinite hydration, which reaches the first peak value, 0.0132J/s.g, in 15 minutes after adding water when a great number of Al^{3+},$Ca^{2+}$and Cl^- solve into the liquid phase (see Table 1). In 6 hours the second peak of heat evolution appears and the contents of ions in the solution come up to more than 70% of their final values. Figure 2 shows that the ions enter into the liquid fast during early ages, e.g, the contents of Al^{3+},Ca^{2+} and Cl^- are in the first day are 94%,82% and 76%, respectively, of their final values. Figure 3 reveals that the content

of Cl^- in the solution of hydrated alinite reaches the highest value after three days, It is much lower in that of hydrated alinite cement and its solving rate is slower and slowes with the period which is caused by the Friedel' s salt, $C_3A.CaCl_2.10H_2O$ that fixes Cl^-.

Table 1 Characteristics of alinite hydration in early ages (w/c=10)

	hydration heat reaction rate	Al_2O_3 * μg/ml	CaO * μg/ml	Cl^- * mg/ml	fixed wate %	Ca(OH) %	hydration rate %
15 min	0.0131 J/g.s	22.5	3.3	3.3	0.8	0	9.1
6 hour	0.0126 J/g.s	28.5	7.1	7.01	14.57	12.35	36.36
1 day		30	9.2	7.17	22.58	21.03	43.45

* ion contents in liquid phase determined by ICP

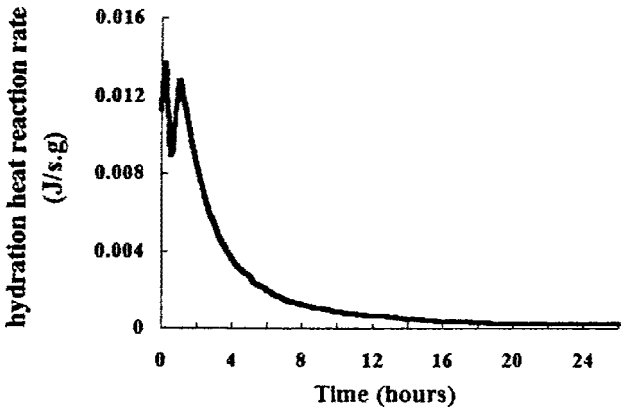

Fig 1 Heat evolution of alinite hydration

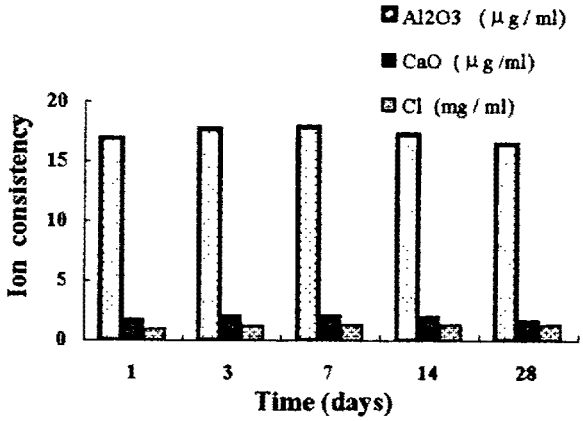

Fig 2 ion contents in the liquid phase of alinite cement hydration VS time

Table 2 lists the hydrated extent of cement and pure phases, from which no marked effect of W/C on the early hydration rate of alinite is observed. The hydration rate of alinite samples with different W/C are similar in the first three days and then slow down for lower W/C. It is the characteristics of alinite that its hydration may reach quite high extent even in rather low W/C, so the W/C needed by alinite cement is also quite low, which corresponds to the result by Ftikos(1991).

Table 2 Hydration extents of alinite cement and its pure phases (%)

	W/C	1 day	3 day	7 day	14 day	28 day
Alinite	10	43.45	51.19	78.57	>95	
	0.25		53.39	53.57		61.90
$C_{11}A_7 \cdot CaCl_2$	10	44.83	>90			
	0.25		34.47	47.73		54.55
$\beta-C_2S$	10	22.41	39.66	41.35	48.28	62.07
Alinite Cement	10	34.59	47.44	64.24		81.66

Figure 3 shows that the fixed water in hydrated alinite increases fast during the initial three days and then tends to increase slowly. while that of alinite cement increases smoothly. In TG curves (Fig 4) the fixed water of hydrated cement includes three parts: fixed water in CSH gel at below 250 ℃, combined water on hydrated aluminate phase at 250 ~ 450 ℃,and structural water of $Ca(OH)_2$ at about 450 ~ 550 ℃. XRD shows (Fig 5)that the main products of alinite cement hydration include $Ca(OH)_2$, AFT, CSH, $C_3A{\cdot}CaCl_2{\cdot}10H_2O$,ferrite phase as well as a little C_3AH_6 and CAH_{10}.

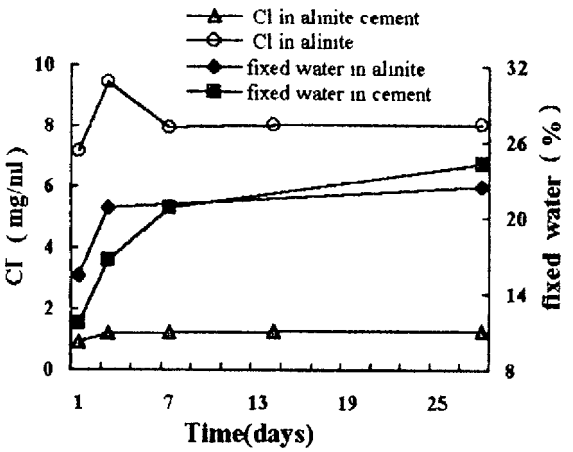

Fig 3 Fixed water and Cl^- solved in liquid of hydrated alinite cement VS ages

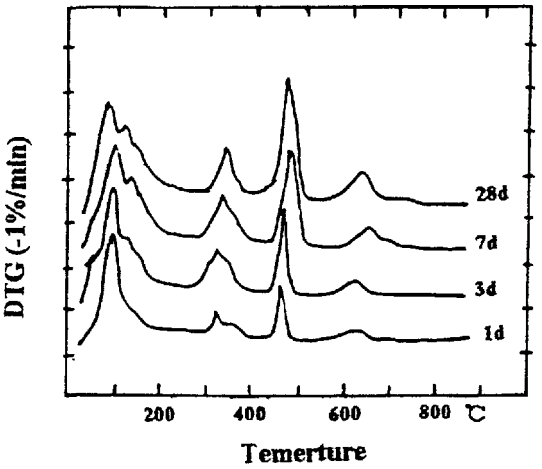

Fig 4 TGA curves of hydrated alinite cement

Addition of gypsum changes the hydration process of alinite cement: AFT is the prior product to $C_3A{\cdot}CaCl_2{\cdot}10H_2O$ because AFT is more stable in thermodynamics so delays $C_3A{\cdot}CaCl_2{\cdot}10H_2O$ formation (Richarty 1969). Rapid hydration of alinite increases Ca^{2+} in liquid phase, which retards the hydration of ferrite phase. In other hand, the raise of Cl^- concentration accelerates β-C_2S hydration producing additional $Ca(OH)_2$ (Ramachandran 1981). $C_{11}A_7{\cdot}CaCl_2$ hydrates to form $C_3A{\cdot}CaCl_2{\cdot}10H_2O$ which fixes some Cl^- coming from alinite hydration. Moreover, EDAX evidence shows that CSH gel may fix about 3.5% Cl^-.

By SEM analysis on cement pastes hydrated for 3 days, CSH gel is recognized around unhydrated minerals and on the hollow part of the crystal (Fig 6), Ettringite shaped as willow leaves is observed in the intervals of other crystals (Fig 7). CSH gel on alinite matrix and $C_3A{\cdot}CaCl_2{\cdot}10H_2O$ crisscross each other and become the inter growth (Fig 8). The reason to form such a structure is that Cl^- diffuse but of CSH gel and forms Friedel' s salt with aluminate on the surface of CSH gel. Such a crisscross and intergrowth structure can contribute an excellent strength to alinite cement, e.g. the compressive strength of alinite cement after 3 days is as high as 49.5 MPa (Table 3).

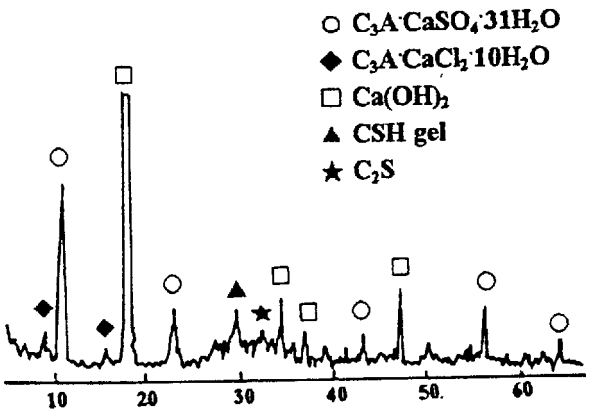

Fig 5 XRD spectrogram of alinite cement for 28 day

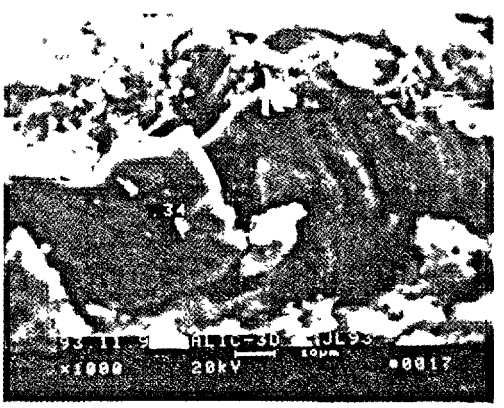

Fig 6 CSH, AFt as well as unhydrated crystals

Table 3 Compressive strength of alinite cement and the minerals containing Cl^- (MPa)

	W / C	3 day	7 day	28 day
Alinite Cement	0.25	49.5	57.1	69.3
Alinite	0.25	42.3	58.9	65.4
$C_{11}A_7.CaCl_2$	0.36	48.2	53.2	64 2

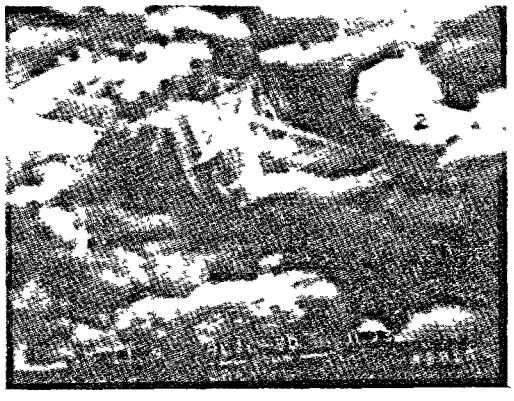

Fig 7 AFt crystals shaped as willow leaves

Fig 8 Intergrowth of CSH and $C_3A\,CaCl_2\,10H_2O$

CONCLUSION

During alinite cement hydration Cl^- combines with aluminate phase to form $C_3A\,CaCl_2\,10H_2O$ which brings out much lower level of free Cl^- in the hydrates of alinite cement than on alinite hydrates.

phases containing Cl^- may reach quite a high hydration extent in early ages and W/C does not markedly affect early hydration of alinite.

The main hydrates of alinite cement are $Ca(OH)_2$, $C_3A\,CaSO_4\,31H_2O$, $C_3A\,CaCl_2\,10H_2O$, CSH gel, ferrite phase as well as a little C_3AH_6 and CAH_{10}.

Cl^- releases out from CSH gel and combines with aluminate on the surface of CSH to form a crisscross and intergrowth constructure with Friedel' s salt, which leads to an excellent strength of hardened cement pastes.

RATE OF ETTRINGITE FORMATION FROM CALCIUM ALUMINOFERRITE HYDRATION

CHEN Yimin and SHI Liping, China Building Materials Academy, Beijing 100024, China

ABSTRACT Ettringite formation from hydration of the mixtures with mole ratio of $CaSO_4 2H_2O$ / C_4AF or C_6AF_2 from 1:3 to 4:1 is studied. Before exhaustion of gypsum the hydrates are AFt with Fe^{3+}, $Fe(OH)_3$ gel with Ca^{2+} and somewhat $Ca(OH)_2$. The first and main DTG peak of AFt dehydrates $26H_2O$ corresponding to its constitutional formula. The hydration equations are deduced and their rates are illustrated, which depends on Al / Fe and is not affected by the amount of gypsum but is retarded by lime.

Key–words: Ettrigite, Aluminoferrite, Hydration

INTRODUCTION

Calcium aluminoferrite is a solid solution series in which the ratio Al_2O_3 / Fe_2O_3 varies in a large range. A typical composition in cement clinker is C_4AF and in some cases it may be C_6AF_2 or C_6A_2F. It is well known (Taylor, 1990) that the first crystalline product of ferrite phase hydration in the presence of $CaSO_4$ is AFt containing Fe^{3+} and later is replaced by AFm. The rate of hydration reaction of the ferrite phaes decreases with the Fe / Al ratio in it and is retarded by CH. Metha (1973a,b) attributed the retardation to forming a fine AFt crystal covering on the unhydrated particles. Fukuhara et al (1981) concluded that the AFt phase formed from C_4AF in pastes at 20℃ had an Al / Fe ratio of about 3 and postulated that FH_3 was also formed. Brown (1987) indicated that the initial AFt phase made form C_4AF contains little or no Fe^{3+} and an iron oxide gel containing some Ca^{2+} is formed by C_4AF hydration in the presence of gypsum. The later products are similar to that introduced by Fukuhara et al(1981). Xi (1992) synthesised ettringite solid solutions with 0–100% substitution of Fe_2O_3 for Al_2O_3 in special conditions.

EXPERIMENTAL

C_4AF and C_6AF_2 were synthesized at 1380℃ and 1280℃, respectively, from chemical agents and ground into the size listed in Table 1. Their average diameters are 21.7μm and 21.4μm, respectively. These ferrite phases were mixed with $CaSO_4 2H_2O$ and CaO according to the ratio listed in Table 2 and then added with distilled water. Water / solid is 0.5 for most samples and water / $CaSO_4 2H_2O$ is 1.5～1.3 for the samples in which $CaSO_4 2H_2O$ / ferrite is 3 / 1 or 4 / 1 in order to meet the needs of forming AFt.

Samples were cured at 25℃ for various periods and then ground in large amount of ethanol and dryed in vacuum. Determination is made by DUPONT 1090 Thermal Analyser for TG and DTG, Regago D_{max}-ⅢA X-ray Diffractor for XRD. A part of samples were obeserved by SEM and EDAX to analyse the composition of AFt.

RESULTS AND DISCUSSION

AFt formation from C_4AF hydration

Hydration products

Fig.1 and Fig.2 give DTG curves and XRD spectrograms, respectively, of some hydrated samples. On DTG curves, the temperature of main peaks of AFt, $CaSO_4 2H_2O$, AFm, $Fe(OH)_3$ gel is 100–140℃ , 150–160℃ , 180–200℃ , and 280–300℃ , respectively, in which the range of peak temperature is due to various contents of phases. In fact the main peak of AFt usually starts below 100℃ and ends at higher than 200℃ and its minor peaks locate at much higher temperature. So the main peaks of gypsum and $Fe(OH)_3$ gel always contain some water of AFt.

It is obvious that the products of C_4AF hydration in the presence of gypsum are AFt, which transforms to AFm after exhaustion of gypsum in the samples with raw $CaSO_4 2H_2O / C_4AF \leqslant 3$, and a $Fe(OH)_3$ gel phase. In the sample C4-12, AFt does not increase any longer after 21 days but $CaSO_4 2H_2O$ always exists and no any AFm appears, which means that C_4AF has been used up and the amount of $CaSO_4 2H_2O$ in the raw mixture is somewhat higher than that needed by AFt formation. It can also be believed that less than 25% Al_2O_3 in AFt is replaced by Fe_2O_3 and the raw mole ratio of $CaSO_4 2H_2O$ to C_4AF should be near 4 if both of C_4AF and $CaSO_4 2H_2O$ totally hydrates to form AFt.

Fixed water in AFt

Table 3 lists the DTG data at the time when $CaSO_4 2H_2O$ disappears and the main peak of AFt reaches the largest value. The number of fixed water included in the first and main DTG peak of AFt is calculated by:

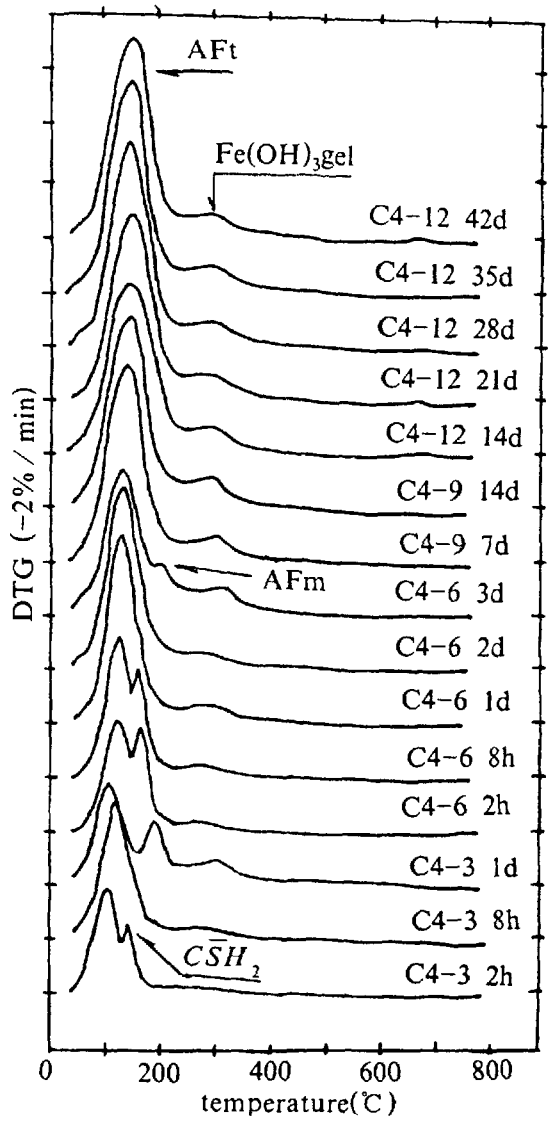

Figure 1 DTG curves of hydration products of C_4AF in the presence of gypsum (20℃ / min)

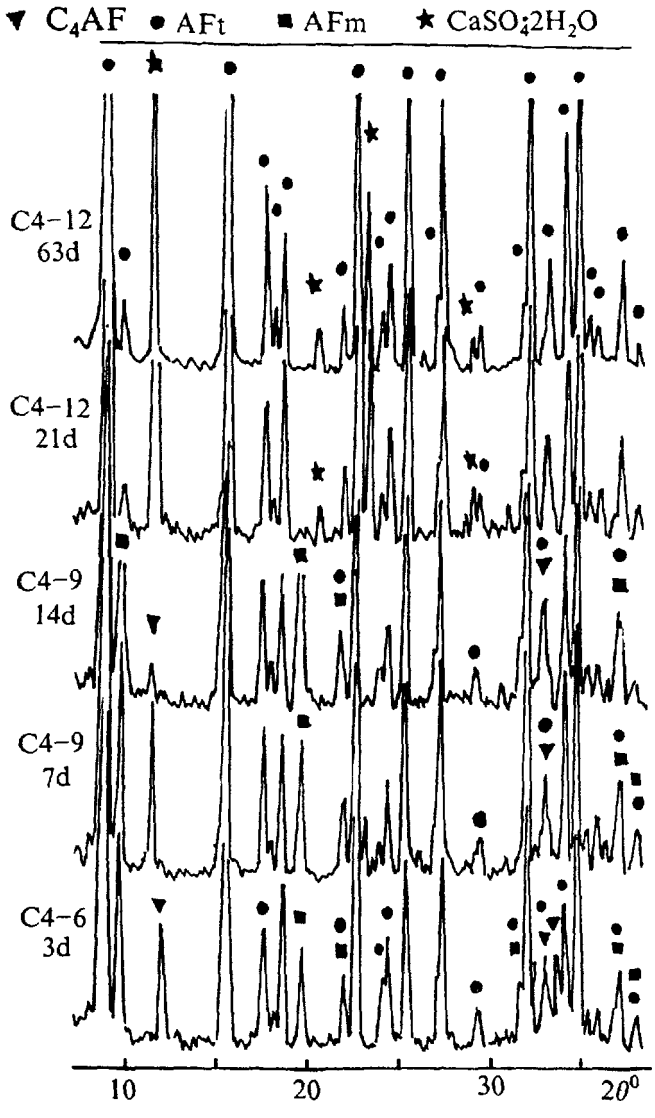

Figure 2 XRD spectrogram of hydration products of C_4AF in the presence of gypsum

$$n = (3 \times M_{CaSO_4} \times W_{H_2O}) / (M_{H_2O} \times W_{CaSO_4}) \quad [1]$$

where M_{CaSO_4} and M_{H_2O} are molecular weight of $CaSO_4$ and H_2O, respectively, and W_{H_2O} is the losing weight of AFt in its first peak and W_{CaSO_4} is the weight of $CaSO_4$ in the sample which can be calculated from both of the raw ratio of $CaSO_4$ to C_4AF and the residue weight of the sample after heating. The average value of n from the results in Table 3 is 25.9. Due to the sampling is not exactly at the time when all AFt forms, so it is reasonable to believe that n = 26 which is identical with the constitu-

tional formula, $[Ca_3(Al,Fe)\cdot(OH)_6\cdot 12H_2O]_2\cdot(SO_4)_3\cdot 2H_2O$ (Taylor, 1990), in which $26H_2O$ are weakly combined in the structure and easily released during heating.

* a little of AFm exists

Rate of AFt formation in samples with different ratio of $CaSO_4 2H_2O$ to C_4AF

The time all gypsum combining into AFt can be deduced from the main dehydration peak of AFt. In Figure 3 solid line is the result of six samples with the ratio of $CaSO_4 2H_2O$ to C_4AF from 1:3 to 2:1 and the points is the result of C4-6 in various periods. They are quite identical with each other, which reveals that there is a definite rate of AFt formation from C_4AF hydration in presence of gypsum which is independent of the ratio of $CaSO_4 2H_2O$ to C_4AF.

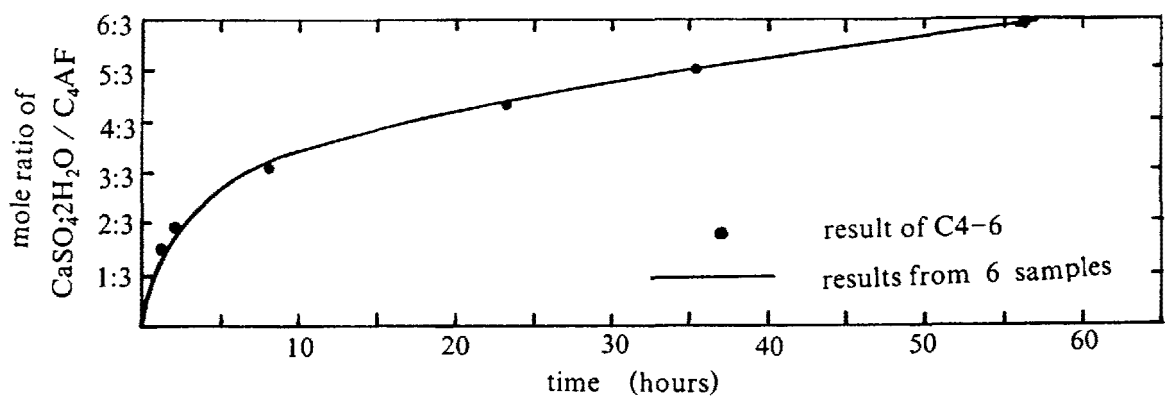

Figure 3 AFt formation rate vs $CaSO_4 2H_2O$ exhaustion time

Substitutional amount of Fe_2O_3 for Al_2O_3 in AFt

Both main dehydration peak of AFt and $CaSO_4 2H_2O$ end at about 210~220℃, in which 1 mol AFt contains 3mol $CaSO_4$ and 26 mol H_2O while 1 mol $CaSO_4 2H_2O$ contains 1mol $CaSO_4$ and 2 mol H_2O. It is not difficult to deduce the following formula:

$$G = \frac{CaSO_4(inAF_t)}{CaSO_4(total)} = \frac{3}{20}\left(\frac{W_{H_2O} \times M_{CaSO_4}}{W_{CaSO_4} \times M_{H_2O}} - 2\right) \qquad [2]$$

where W_{H_2O} is the weight of total water contained in the main peaks of AFt and $CaSO_4 2H_2O$ and W_{CaSO_4} is the weight of total $CaSO_4$ in the sample. G is the percentage of $CaSO_4$ entering AFt of total $CaSO_4$ in the sample.

If there is no Fe_2O_3 in AFt it needs 3 mol $CaSO_4 2H_2O$ for each mole C_4AF to hydrate and form AFt. On the other hand, if Fe_2O_3 is substituted for 25% Al_2O_3 in AFt the G of the sample will be 100% in the end. In fact, after 21 days, 28 days, 35 days and 63 days of hydration the G of C4–12 is always about 93% and less than 94%, which means that about 3.75 mol gypsum is needed for 1mol C_4AF to hydrate and form 1 mol AFt and that about 20 mol% Al_2O_3 in AFt is replaced by Fe_2O_3.

EDAX determination on a lot of points shows that the amount of Al_2O_3 substituted by Fe_2O_3 in AFt is about 18～30mol% and in most of detected points it locates in 20～25 mol% which supports above calculation result. In addition, EDAX shows that in hydration products there is a gel phase made mainly of Fe and small amount of Ca, i.e. $Fe(OH)_3$ gel containing $Ca(OH)_2$.

Chemical equation and reaction rate of C_4AF hydration to form AFt

Based on above experiment result, analysis and calculation, the chemical reaction equation representing C_4AF hydration in the presence of gypsum to form AFt can be put forward as following:

$$4C_4AF+15CaSO_4 2H_2O+140H_2O \rightarrow 5\,[C_3(Al_{0.8}Fe_{0.2})_3CaSO_4 32H_2O] +6Fe(OH)_3gel+Ca(OH)_2gel \quad [3]$$

where $Ca(OH)_2$ gel exists inside $Fe(OH)_3$ gel. The reaction rate determined from all samples is given in Figure 4.

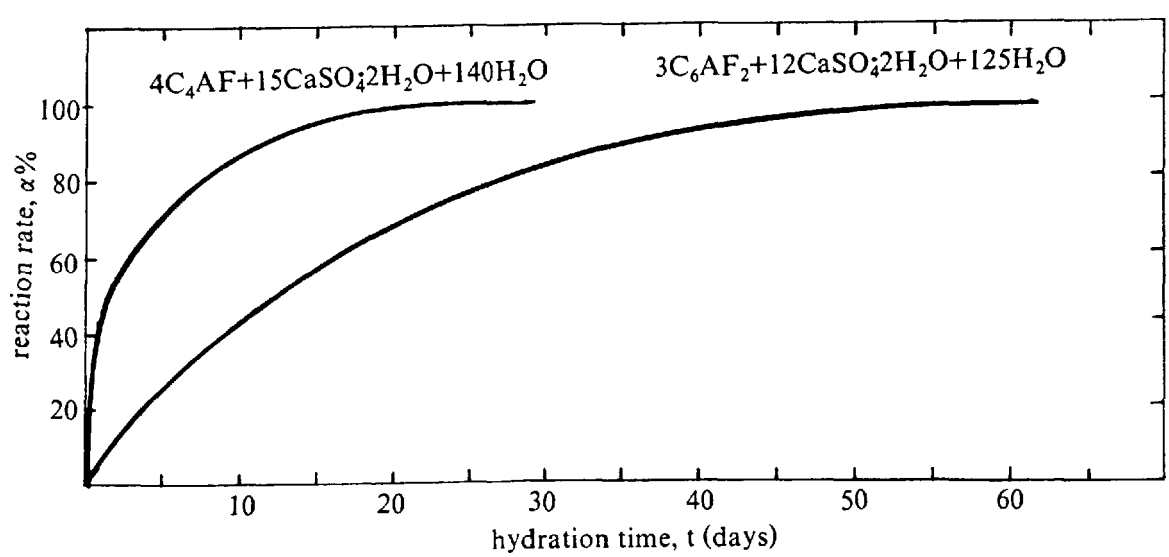

Figure.4 Reaction extent, α, of calcium aluminoferrite hydration to form AFt vs time,t

AFt formation from C_6AF_2 hydration

Figure 5 and Figure 6 present DTG curves and XRD spectrograms of C_6AF_2 hydration products in presence of gypsum, respectively. The process of

C_6AF_2 hydration is similar to that of C_4AF: The products includes AFt containing Fe^{3+} and $Fe(OH)_3$ gel containing Ca^{2+} before gypsum is exhausted and then AFt transforms to AFm. But some differences are recognized by DTG evidence: the gel phase is more in C_6AF_2 hydration products and there is an individual $Ca(OH)_2$ phase which has transformed to $CaCO_3$ during drying treatment. It is obvious that the rate of AFt formation from C_6AF_2 hydration is slower than that from C_4AF.

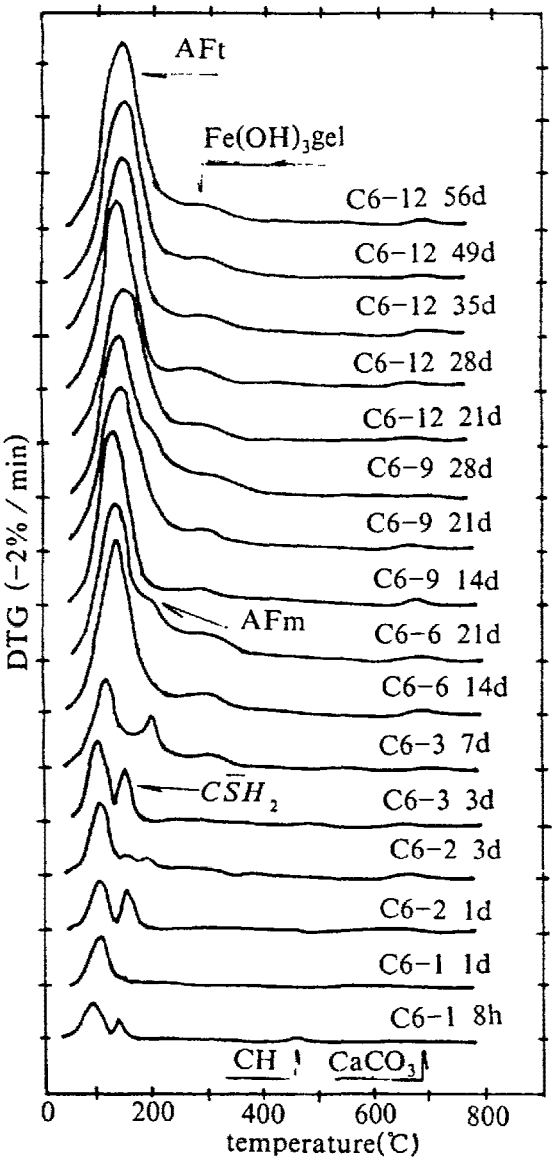

Figure 5 DTG curves of C_6AF_2 hydration products in the presence of gypsum (20℃ / min)

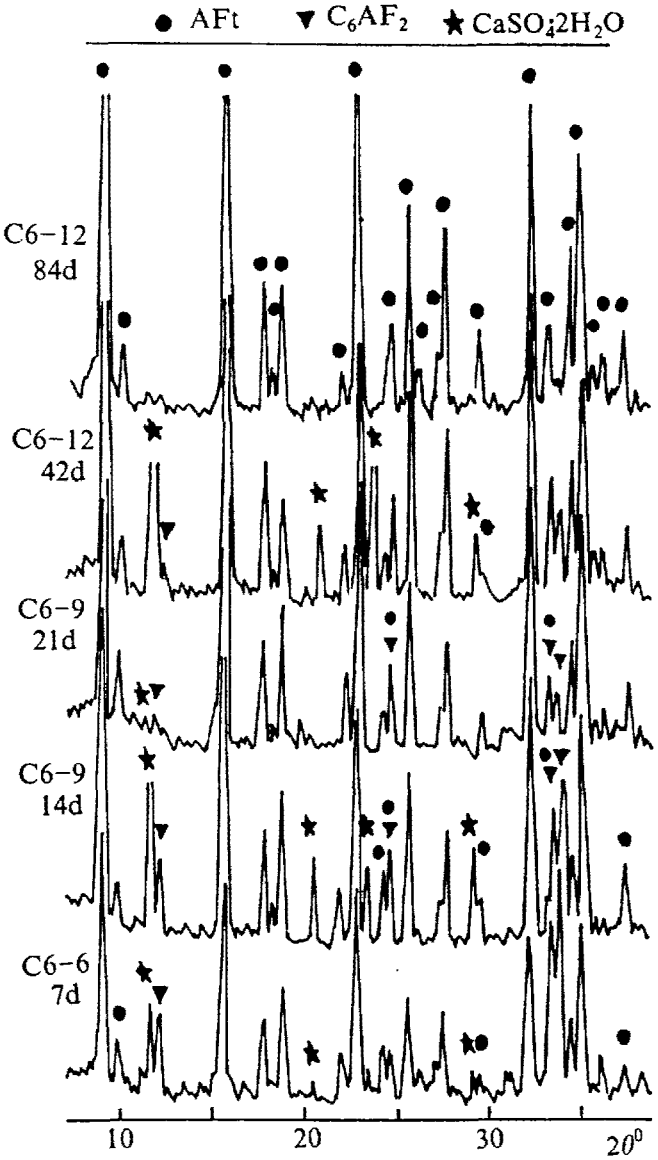

Figure 6 XRD spectrograms of C_6AF_2 hydration products in the presence of gypsum

In sample C6-9 AFm phase appears after 28days. In sample C6-12, after 56 days gypsum disappears, AFt will not increase any more and AFm will not apppear at even

longer time. The value of G calculate from Eq.2 reaches 100%. So the largest mole ratio of $CaSO_4 2H_2O$ to C_6AF_2 for all of them to hydrate and enter into AFt is 4, which means the substitution of Fe_2O_3 for Al_2O_3 in AFt is about 25mol% and is higher than that of $CaSO_4 2H_2O$ to C_4AF. Therefore the reaction equation may be expressed as:

$$3C_6AF_2+12CaSO_4 2H_2O+125H_2O \rightarrow 4[C_3(A_{0.75}F_{0.25})3CaSO_4 32H_2O]+10Fe(OH)_3gel+6Ca(OH)_2gel \quad [4]$$

where both $Fe(OH)_3$ gel and $Ca(OH)_2$ are more than that in Eq.3, which is one of reasons to delay ferrite hydration and AFt formation. The rate of this reaction, determined from all samples, is given in Figure 4.

Effect of CH on AFt formation from ferrite hydration

Figure 7 and Figure 8 give DTG curves of some hydrated samples of C_4AF and C_6AF_2, respectively, in the presence of both gypsum and lime. Comparing these with Figure 2 and Figure 5 introduces that $Ca(OH)_2$ retard AFt formation from ferrite hydration though does not change the products, which may also explain the slower rate of C_6AF_2 hydration than that of C_4AF to some extent.

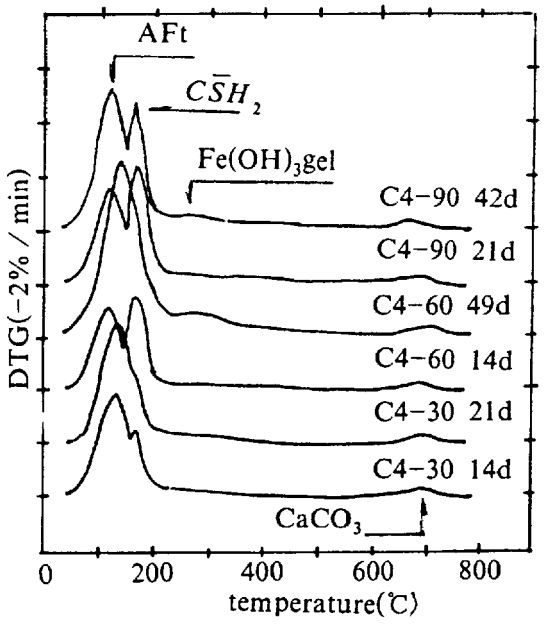

Figure 7. DTG curves of hydration products of C_4AF in presence of gypsum and lime

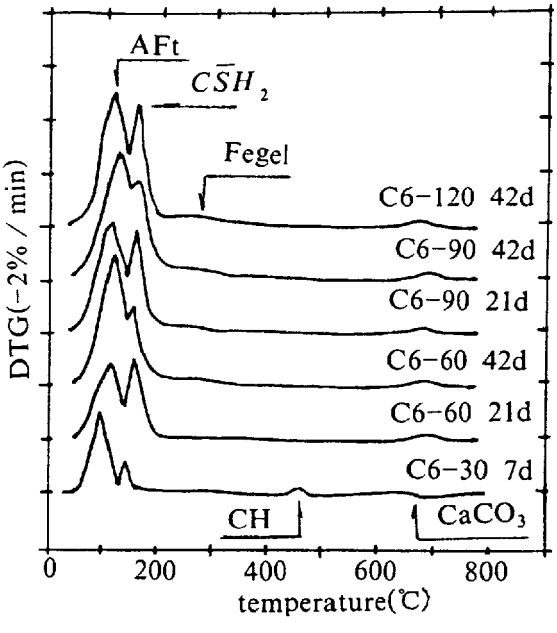

Figure 8. DTG curves of hydration products of C_6AF_2 in presence of gypsum and lime.

CONCLUSION

Products of calcium aluminoferrit hydration in the presence of gypsum include AFt containing Fe^{3+} and $Fe(OH)_3$ gel containing Ca^{2+} and, in the case of C_6AF_2, some $Ca(OH)_2$. After gypsum is used up, AFt will be gradully replaced by AFm.

In DTG curves the main peak of AFt dehydrates 26 H_2O, which corresponds to its constitutional formula, $[Ca_3(Al, Fe)(OH)_6 \cdot 12H_2O]_2(SO_4)_3 \cdot 2H_2O$ in which 26 H_2O are

conbined weakly. Other 5~6 H_2O will be released at higher temperature.

The reaction of ettringite formation from calcium aluminoferrite hydration can be represented by following chemical equations:

$4C_4AF+15CaSO_4{\cdot}2H_2O+140H_2O \rightarrow 5[C_3(A_{0.8}F_{0.2})3CaSO_4{\cdot}32H_2O]+6Fe(OH)_3gel+Ca(OH)_2gel$

$3C_6AF_2+12CaSO_4{\cdot}2H_2O+125H_2O \rightarrow 4[C_3(A_{0.75}F_{0.25})3CaSO_4{\cdot}32H_2O]+10Fe(OH)_3gel+6Ca(OH)_2gel$

As illustrated in Figure 4, the speed of AFt formation from C_4AF hydration is faster than from C_6AF_2, which is caused by the contents of $Fe(OH)_3$ gel and $Ca(OH)_2$ in the products. Under the present conditions in less than 1 month all C_4AF has hydrated and formed AFt but it need about 2 months for C_6AF_2 to totally hydrate. $Ca(OH)_2$ addition will markedly retard the hydration of both C_4AF and C_6AF_2 to form AFt.

ABSTRACT
The hydration characteristics and properties of new hydrates containing iron and of solid solutions containing iron and aluminum are described. Especially the influence of CO_3^{2-} on formation conditions is investigated. The phase relations, the formation conditions from anhydrous compounds and the properties of the hydrates are given .

Key-Words: AFm phase, Brownmillerite, Carbon dioxide

INTRODUCTION
Calcium aluminate hydrates and calcium aluminoferrate hydrates have a great significance on the formation and the stability of concrete and on the immobilisation of pollutants. The hydration of aluminate phases under the influence of various anions has already been widely investigated and different hydrates are well known. Iron containing phases with varying anions, however, are only little known yet. For a better understanding of the meaning of AFm phases in cement chemistry and environmental chemistry, iron containig AFm phases vere investigated. Due to the importance of carbonate to all technical processes, the investigations applied especially to CO_3^{2-} containing phases.

EXPERIMENTAL
The synthesis were made by mixing the hydroxides of aluminum and iron with calcium oxide and sodium carbonate in excess water (saturated portlandite solution). The hydroxides were always freshly precipitated from solutions of aluminum chloride or iron chloride with an ammonia solution and afterwards carefully washed with hot water. For synthesizing calcium aluminoferrate hydrates, aluminum and iron hydroxide were always precipitated together. Additional synthesis were made by mixing calcium aluminoferrates of the Brownmillerite type with calcium oxide and sodium carbonate in excess water. The reactions were carried out in 50 ml high density polyethylene bottles. The reaction times lasted from 6 weeks to 6 month. The progress of the reaction of all samples could be observed at all samples by turning the colour from red to colourless. All synthesis were carried out at room temperature.

The originated phases were investigated by x-ray powder diffraction, scanning electron microscopy, thermal analysis and infrared spectroscopy. X-ray patterns of dry samples were recorded with a Siemens diffractometer D 5000 and patterns of wet samples with a Phillips diffractometer and a special climate camera. Some samples were additionally investigated by high temperature x-ray diffraction. The wet samples were dried at 35 % rel. humidity over a saturated solution of calcium chloride. All samples were carefully treated, wet samples were only handled in a glove box with CO_2-free atmosphere.

RESULTS AND DISCUSSION

Pure phases

For this investigation it was necessary, that the following pure phases had been characterized:
Monohydroxide $3CaO{\cdot}Al_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O$
Monocarbonate $3CaO{\cdot}Al_2O_3{\cdot}CaCO_3{\cdot}11H_2O$
Iron monohydroxide $`3CaO{\cdot}Fe_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O´$
Iron monocarbonate $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$
Monohydroxide and monocarbonate were already investigated by Fischer & Kuzel (1982) and Pöllmann (1984) and are well known. Iron monohydroxide is described by Negro & Stafferi (1979) and Rogers & Aldridge (1977). Own investigations show, that a phase with the composition $3CaO{\cdot}Fe_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O$ is not stable at room temperature. Iron monocarbonate was synthesized and investigated.

Iron monocarbonate

The reaction time for iron monocarbonate took 6 month. After that time in the scanning electron microscope hexagonal platy crystals with about 1 to 5 µm in diameter could be observed. The chemical analysis of the dried sample is in accordance with the formula $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$. The wet and the dried sample show the same lattice parameters: a_o = 591,7 pm; c_o = 4767,9 pm; SG: $R\bar{3}\,c$

Thermal analysis and high temperature x-ray diffraction show, that at temperatures higher then 135°C the main layer starts dehydrating and the structure gets destroyed. More particular data will be given in an extra paper.

Pseudobinary systems

The system $3CaO{\cdot}Al_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O$ - $`3CaO{\cdot}Fe_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O´$,
Synthesis with the following compositions were made:
$4CaO + (2x)Al(OH)_3 + (2\text{-}2x)Fe(OH)_3;\ 0 \le x \le 1$
No other AFm phase then $3CaO{\cdot}Al_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O$ was formed. In iron containing samples portlandite and iron hydroxide were always present.

The system $`3CaO{\cdot}Fe_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O´$ - $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$
The following synthesis were made:
$4CaO + 2Fe(OH)_3 + (x)Na_2CO_3;\ 0 \le x \le 1$
The only stable AFm phase at room temperature is $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$. In samples with a molar ratio Fe_2O_3 / CO_2 < 1 iron hydroxide and portlandite could always be found.

The system $3CaO{\cdot}Al_2O_3{\cdot}CaCO_3{\cdot}11H_2O$ - $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$,
For the investigation synthesis with the following compositions were made:
$4CaO + (2x)Al(OH)_3 + (2\text{-}2x)Fe(OH)_3 + Na_2CO_3;\ 0 \le x \le 1$
Samples containing both aluminum and iron are belonging to the solid solution series
$3CaO{\cdot}(x)Al_2O_3{\cdot}(1\text{-}x)Fe_2O_3{\cdot}CaCO_3{\cdot}nH_2O;\ 0 < x < 1$
In contrast to the pure phases monocarbonate and iron monocarbonate, the solid solutions are forming two different hydrates at room temperature:

A rhombohedral phase containig 12 H_2O per formula is stable at 100 % rel. humidity. A triclinic phase containing 11 H_2O is formed by drying at 35 % rel. humidity. The phase transformation is irreversible. Figs 1 and 2 show the lattice parameters of the rhombohedral phase and the d (0 0 1)-spacings of the triclinic phase.

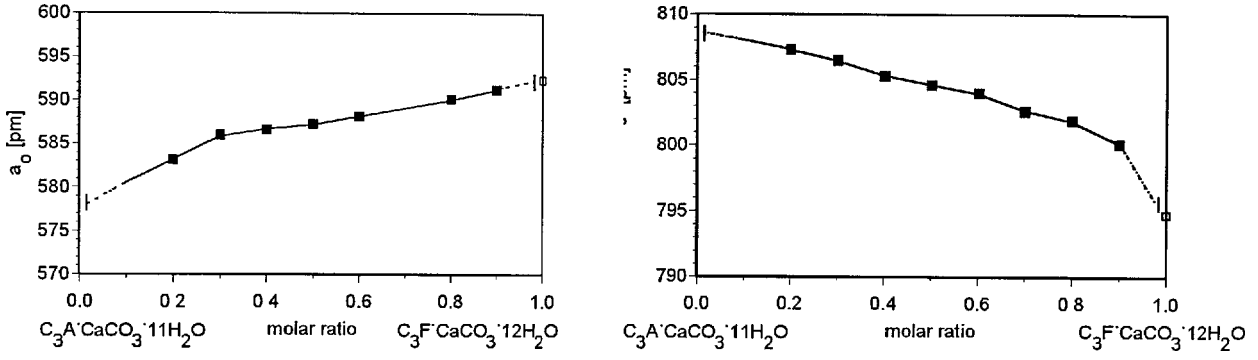

Figure 1: Lattice parameters of the rhombohedral phase in the system

$3CaO{\cdot}Al_2O_3{\cdot}CaCO_3{\cdot}11H_2O$ - $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$

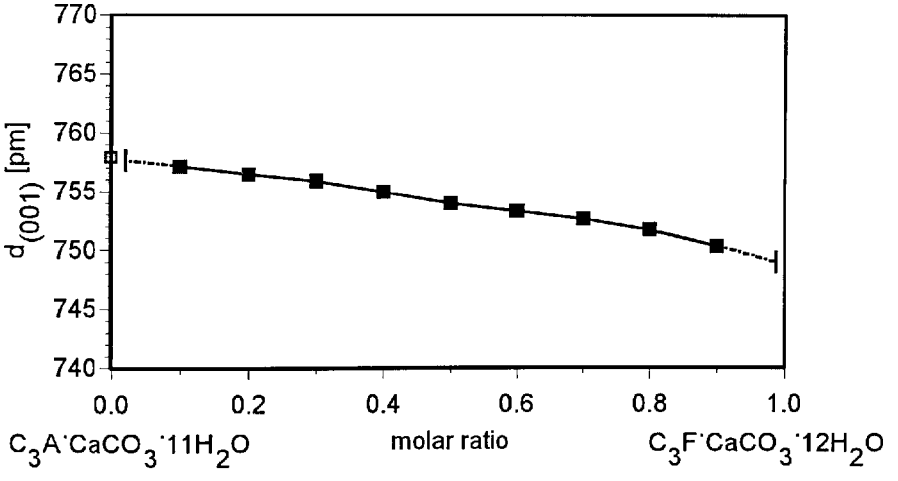

Figure 2: d (0 0 1)-spacing of the triclinic phase in the system

$3CaO{\cdot}Al_2O_3{\cdot}CaCO_3{\cdot}11H_2O$ - $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$

Pseudoternary system

For investigations in the pseudoternary system $3CaO{\cdot}Al_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O$ - `$3CaO{\cdot}Fe_2O_3{\cdot}Ca(OH)_2{\cdot}nH_2O$´ - $CaO{\cdot}Al_2O_3{\cdot}CaCO_3{\cdot}11H_2O$ - $3CaO{\cdot}Fe_2O_3{\cdot}CaCO_3{\cdot}12H_2O$ the following synthesis were made:

$4CaO + (2x)Al(OH)_3 + (2-2x)Fe(OH)_3 + (y)Na_2CO_3$; $0 \leq x \leq 1$; $0 \leq y \leq 1$

Additionally to the upon described AFm phases, in the pseudoternary system one additional solid solution series appeared:

$3CaO{\cdot}(x)Al_2O_3{\cdot}(1-x)Fe_2O_3{\cdot}0.5CaCO_3{\cdot}0.5Ca(OH)_2{\cdot}11.5H_2O$, $0 < x \leq 1$

Besides these phases no further AFm phases are stable in the pseudoternary system at room temperature. Fig 3 shows the d-spacings of the investigated AFm phases.

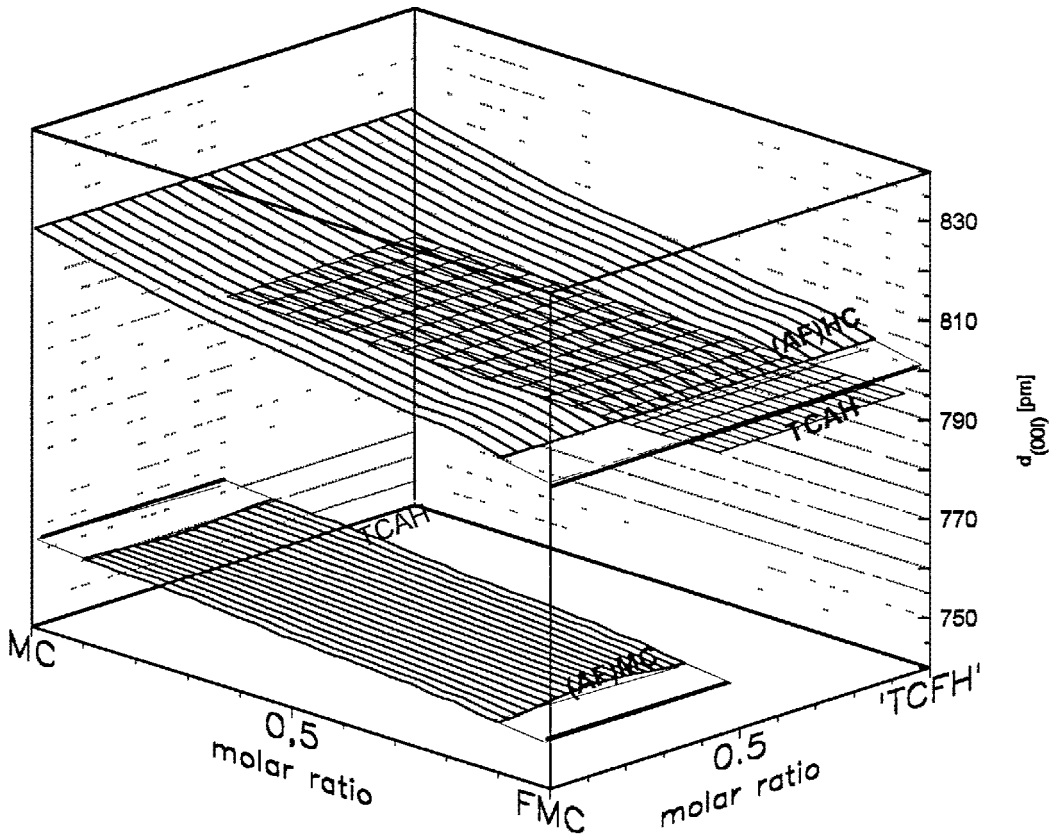

Figure 3: d-spacings of AFm phases in the system $3CaO\ Al_2O_3 \cdot Ca(OH)_2\ nH_2O$ - $`3CaO \cdot Fe_2O_3 \cdot Ca(OH)_2 \cdot nH_2O´$ - $CaO \cdot Al_2O_3\ CaCO_3\ 11H_2O$ - $3CaO \cdot Fe_2O_3 \cdot CaCO_3\ 12H_2O$ at room temperature and 35 % rel. humidity

MC:	$3CaO\ Al_2O_3\ CaCO_3 \cdot 11H_2O$

ALKALINE ALUMINATE BINDERS

Pavel V KRIVENKO
Ekaterina K PUSHKARYEVA
Sergey V SHAPET'KO
Scientific Research Institute on Binders and Materials, Kiev, Ukraine

ABSTRACT Physico-chemical regularities of manufacturing alkaline aluminate binding systems with the use of aluminate raw materials like wastes and by-products, spinel-containing additives and sodium soluble glass with silicate modulus 1-2.8 have been revealed. Principles of synthesis of a paste made with the above binders featuring stable thermo-mechanical characteristics within a wide temperature range have been demonstrated and discussed.

Key-words: high alumina cement, soluble glass, srtrength development, hydration

INTRODUCTION

Strength of a paste and concrete composed of high alumina cements is known to be a function of temperature (Kravchenko, 1960) and sharply declines while transformation of hydroaluminates from hexagonal into cubic syngonia. Is found to be possible to regulate the ratio between hydroaluminates in the hardening product by changing pH of the mixture (Talaber J, 1976). According to known works (Zaldat et al, 1991), while adding to calcium aluminates the solutions with increased pH, the hydration processes accelerate and the processes of transformation of hexagonal hydroaluminates of calcium into cubic ones (C_3AH_6) intensify resulting in losses of strength. The possibility of manufacturing concrete having stable thermo-mechanical characteristics from aluminates of calcium and sodium metasilicate has been proved by Krivenko et al (1984). Other researchers (Berger et al; 1973) demonstrate that increasing pH of the solution suppresses hydrolysis and inhibits velocity with which a mineral CA hydrates, as well as results in dissolution of C_3AH_6 with the formation of hexagonal hydroaluminates of calcium. Thus, a question of how the alkaline solutions affect the intensity and directions of flow of hydration processes, synthesis of strength of a cement paste made with calcium aluminates remained open and initiated this study. Analyzing physico-chemical regularities of manufacture of concrete with stable thermo-mechanical characteristics from calcium aluminates revealed by Krivenko et al (1984), as well as the works in the field of regulation of structure and properties of a fire-resistant stone based on alkaline binding systems (Pushkaryeva, 1995), allowed to assume the possibility of producing alkaline aluminate binders (AAB) featuring enhanced thermo-mechanical characteristics within a wide temperature range by lowering intensity of the formation of calcium hydroaluminates while hardening in the presence of alkali metal compounds. This lead to synthesis of thermostable compounds to provide such structure of a material that changes its porosity insignificantly under action of thermal loads.

MATERIALS AND TESTING TECHNIQUE

Minerals $CaO{\cdot}Al_2O_3$ (CA), $CaO{\cdot}2Al_2O_3$ (CA_2) and $MgO{\cdot}Cr_2O_3$ (MCr) have been synthesized from chemically pure substances such as $CaCO_3$, Al_2O_3, MgO, and Cr_2O_3 that were taken in stoichiometric ratios. Used in the experiments were: a top quality (extra pure) high alumina cement with 72 % Al_2O_3 (HAC), standard high alumina cement with 39 % Al_2O_3 (AC) as an aluminate constituent of AAB, waste from production of chromo-magnesium refractories as a

fine additive, and sodium soluble glass with silicate modulus M_s=1.0-2.8 and density ρ=1100-1300 kg/m^3 as an alkaline component. Physico-chemical processes of hydration and dehydration were investigated with the use of a set of methods such as XRD, DTA, IR spectroscopy.

DISCUSSION OF RESULTS

A model system CA-CA_2-MCr-Na_2O·nSiO_2 synthesized from chemically pure compounds was studied to reveal a principal possibility of producing the AAB.

To determine the influence of such factors as silicate modulus and density of soluble glass, mineralogical composition of cement, curing conditions on strength characteristics the investigated field was restricted by vertexes of a triangle with the following content of minerals: V_1=7%CA + 43%CA_2 + 50% MCr; V_2=10%CA + 90%CA_2; V_3=45%CA + 45% CA_2 + 10% MCr. The investigations were directed by a specially synthesized MTQ-plan (in cooperation with Professor V. Voznesenskiy, Odessa, Ukraine), in which a mix triangle was shifted along a square indicating variations in modulus of soluble glass M_s =1-2 and density ρ of the solution from 1200 to 1300 kg/m^3 (Figure 1).

It was established that the increase in density of water glass solution always results in strength gain. The paste characteristic of the highest strength is formed when the solutions of low-modulus soluble glass (M_s=1.0-1.5) are added to the alumina binders with the increased content of mineral CA_2. When the use is made of alumina binders composed predominantly of mineral CA, the highest strength cement stone is formed with sodium soluble glass having Ms=2.0-2.8. Increasing the silucate modulus of soluble glass results in strength decline. The introduction into a binder composition of chromo-magnesium spinel in a quantity of 25-45 % promotes the enhancement of residual strength of the cement stone after firing to reach a level exceeding 70% of its initial strength.

The influence of change in silicate modulus and density of soluble glass is found affect 1.5-2 times stronger the strength of AAB as compared with that of minaral composition and curing conditions (normal hardening or steam curing).

The AAB made with AC (composed mainly of CA) and HAC (composed mainly of CA_2) were found to have quick strength gain at first stages of hardening and considerable retardation of strength gain with time as compared with the cements in which water was used as an admixture (Table 1).

The study's results indicate that an increased quantity of a gel phase of gibbsite composition is formed during hydration products of the AAB and the formation of low basic hydroaluminates of calcium occurs with a slower rate. The strength gain observed while drying the specimens (up to 70-120 MPa) may be attributed to a densification of the structure and crystallization of gibbsite what is accompanied by decline of the intensity of destructive phenomena associated with transformation of the hexagonal hydroaluminates of calcium into cubic ones (C_3AH_6).

Indicated in the model system CA-CA_2-MCr-Na_2O nSiO_2 insignificant variations in strength of the AAB at varying their mineralogical composition allows to replace up to 50 % of AC or cements hydrated with water. By the data of XRD, the interaction of sodium silicates with calcium aluminates occurs at T= 800-1000^{0}C with the formation of gehlenite, and the reaction

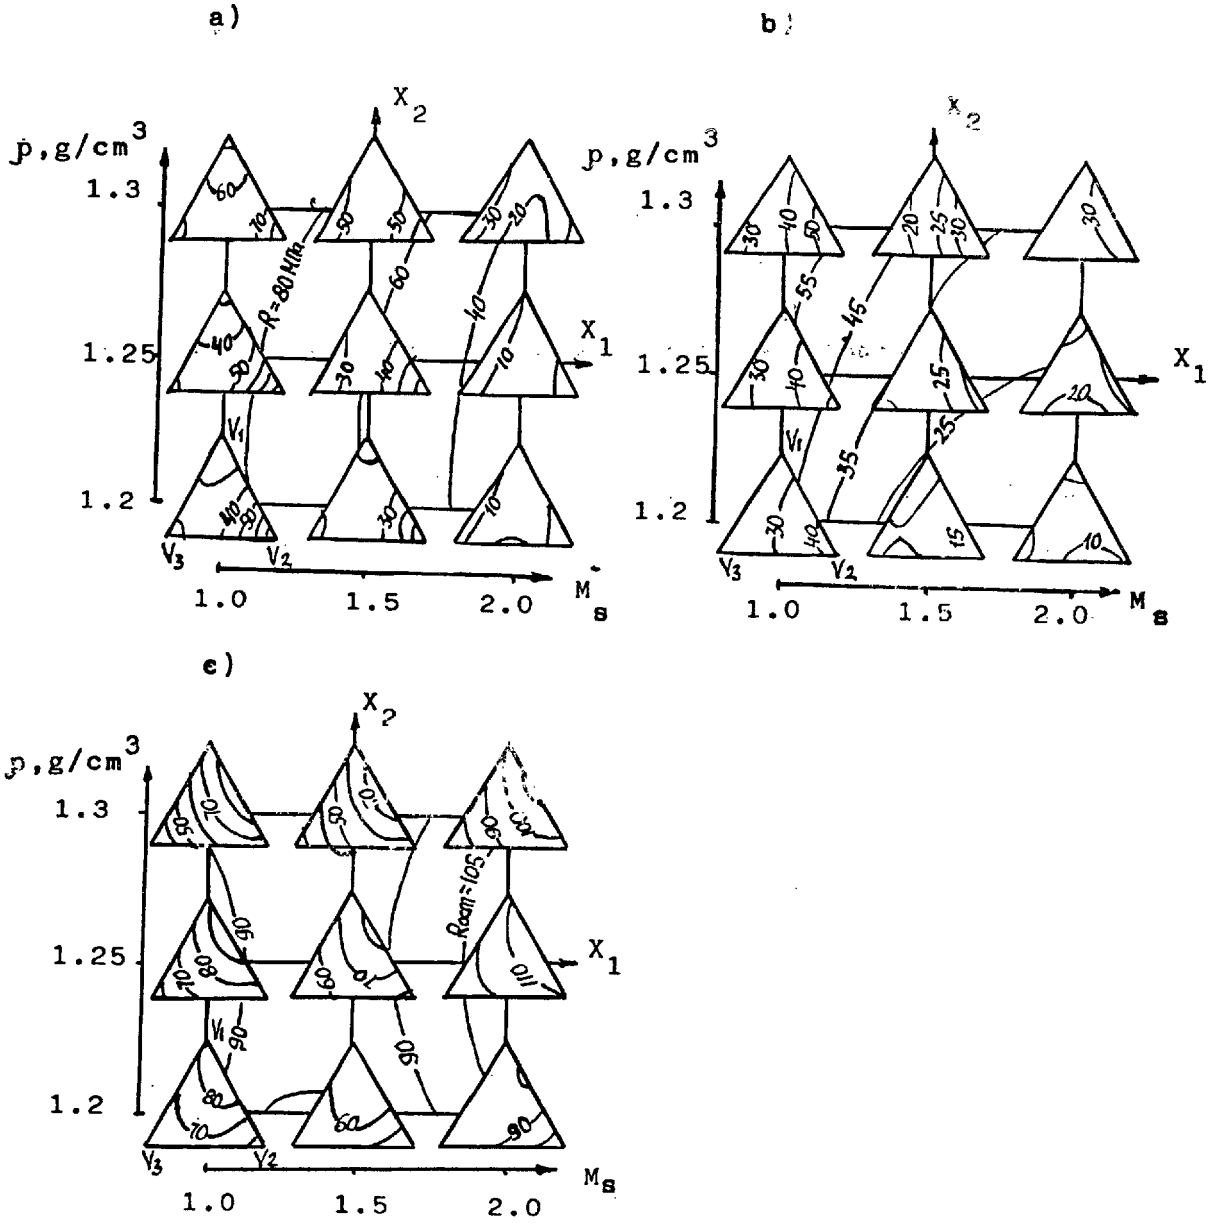

Figure 1. Isoparametric diagrams of variations in compressive strength (a, b) and residual strength after firing (c) for the binders of a system CA-CA_2-MCr-Na_2O nSiO_2 mH_2O after a) 7 days of curing; b) firing at T=800°C.

Table 1. Initial setting time and strength VS silicate modulus of water glass.

Type of cement	Silicate modulus	Initial setting	Compressive strength (MPa) after, days				
			1	3	7	14	28
High alumina cement	1.0	6 min	21.8	22.5	38.3	51.5	74.5
	1.5	9 min.	19.0	24.3	30.0	35.5	48.3
	2.0	3 hrs - 15 min	19.5	22.5	23.5	25.5	34.3
	2.8	more than 8 hrs	0.5	1.5	1.5	2.0	2.5
	water	3 hrs - 13 min.	24.5	54.5	62.8	66.5	96.3
Alumina cement	1.5*	momentary	-	-	-	-	-
	2.0*	15 min.	40.0	47.2	52.1	-	-
	2.8*	32 min.	38.9	47.0	53.4	-	-
	water	45 min.	22.7	43.2	58.1	-	-

NOTE: * 1.5 % Na_3PO_4 (by a cement mass) was introduced as a retarder.

HAC with a finely dispersed additive from used chromo-magnesium refractories. The developed binder compositions differ with a smooth flow of the processes of strength loss while firing, the residual strength enhances with increase of silicate modulus of soluble glass and reaches 60- 100 % of initial strength, exceeding considerably that of traditional aluminate cements hydrated with water. By the data of XRD, the interaction of sodium silicates with calcium aluminates occurs at T=800-1000°C with formation of gehlenite, and reaction between aluminate constituent of cement and chromo-magnesium additive resulted in formation of the alumo-magnesium spinel - $MgAl_2O_4$.These variations in mineralogical composition enhance stability of the AAB while heating.

Basing on the binders developed with a finely dispersed additive and chamotte aggregate the formulations of heat-resistant concretes have been developed. These concretes are characteristic of strength after drying 50-70 MPa, after firing 35-58 Mpa, thermo-resistance- 42 (on HAC) and 60 (on AC) water-heat cycles (12-15 cycles of conventional aluminate cement-based concretes).

CONCLUSIONS

1. The processes of formation of a heat-resistant paste based on AAB have been studied and the formulations to provide stable strength characteristics within a wide range of temperatures have been developed. The main factors determining strength of the paste have been revealed, namely: characteristics of soluble glass, curing conditions and basicity of calcium aluminates.
2. The hydration products of AAB are characteristic of the increased content of a gel phase of gibbsite composition and an insignificant content of hexagonal hydroaluminates of calcium thus providing lack of strength losses while drying and smooth course of dehydration processes while firing without deterioration of the cement structure.
3. A finely dispersed chromo-magnesium additive, not changing the composition of both hydration and dehydration products, while firing at a temperature exceeding 1000°C, interacts with an aluminate constituent of the cement to form an alumo-magnesium spinel $MgAl_2O_4$ providing stability of structure of the fired paste and concrete. By introdusing a spinel-containing additive in a quantity 10-50 % by cement mass the concretes featuring strength 56-81 MPa, residual strength after firing at T=800-1000°C- 60-80%, and thermo-resistance- 60 water-heat cycles may be produced.

CEMENT FOR HPC CONCRETES

Stanisław PEUKERT, Institute of Mineral Building Materials (IMMB), Cracow, Poland

ABSTRACT In the paper the authors take up the subject of modification of cement properties for concretes of high strength and increased durability. They point up the possibility of obtaining HPC concretes from so called gypsum-free cements containing a complex additive stimulating rheological properties and hardening processes of concrete mixes. Possible application of silica fume additive and superplasticizers for said cements makes possible obtaining concretes with compressive strength higher than 100 MPa.

Key-words: composite cements, admixtures, hardening

INTRODUCTION

Technical, ecological and economic reasons have created an increased interest in the issue of making concrete objects of high strength and durability. In most cases the possibility of manufacturing high performance concrete HPC consist in admixtures of microsilica SF and superplasticizer SP added to concrete. Compacting of the concrete structure by the application of the mentioned above additives gives rise to an increase concrete strength and durability. The problems of design and practical implementation of low-porosity MDF and DSP concretes have been the subject of numerous publications. The principles presented in the major papers at the last Congress on the Chemistry of Cement (Roy, 1992, Collepardi and Ramachandran, 1992) continue to hold. Analysis of these data along with the recent experimental results (Gjørv, 1995) reveals that the question of the cement choice in design and practical application of MDF and DSP concretes is treated as a marginal issue. It is often assumed that these technologies yield HSC concrete in any conditions whatever on the application of OPC. However, many years of research by our Institute have shown the advantages of making the appropriate selection of special cements to make of HPC concretes according to the class of strength required and the specific areas of application (Peukert et al., 1996, Peukert, 1992). In the paper the phase composition of special cements and the additives required to modify their properties according to HPC technology requirements have been discussed.

PHASE COMPOSITION OF CEMENT

The results of research carried out by IMMB in the field of HSC concretes show that the best possibilities for design and making are obtained by the application of high-strength cement with a high calcium silicate content. This cement is produced from clinker with a high silicate module 3.0 or over (Peuketr, 1984). The silicate content in the clinker is over 80%. There is a corresponding limitation in the content of C_3A and C_4AF in the clinker. This type of phase composition of the clinker gives the best possibilities for the adaptation of the cement properties to modify parameters of HPC concretes. The enhanced silicate module in the clinker has an advantageous effect on the cement strength development, as shown in **Fig 1**.

The early and normative strength of the high silicate cement, and hence also of the cement matrix strength of HPC concrete, may be controlled very effectively by modification of cement lime saturation factor LSF and fineness of cement. Cement with a high silicate content also affords a good level of stimulation for the strength of HPC cement matrix through the addition of microsilica and a superplasticizer. A restricted C_3A content in the cement improves the fluidization effect of SP addition. On the other hand the composition of the cement ensures the

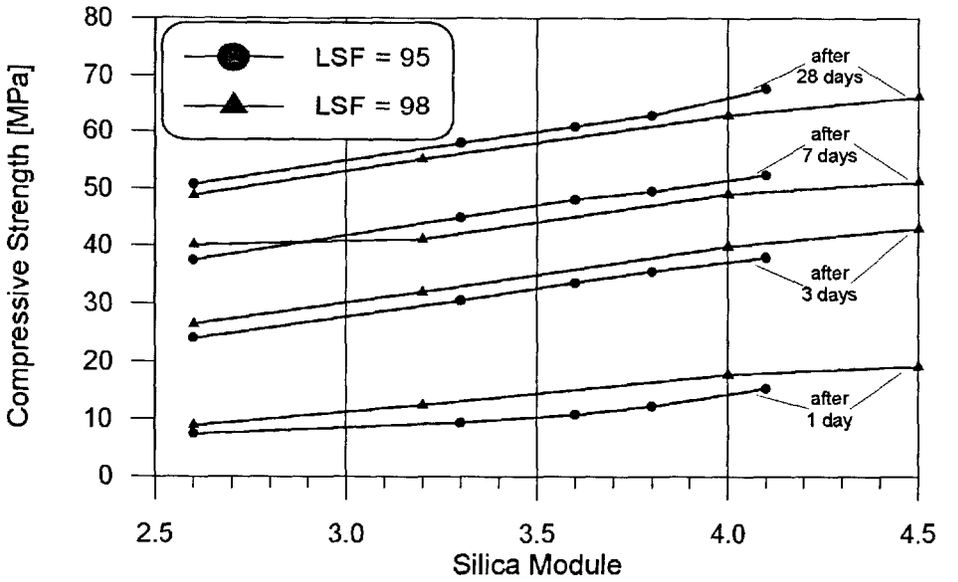

Figure 1 Influence of silica module on compressive strength of cement.

production of a greater amount of the CSH and CH phases during hydration process. The SF additive is thus particularly efficiently bonding in the pozzolana reaction with CH. The product of this reaction increasing amount of the CSH phase, which fills up the micropores of the hardening cement binder, enhances the compacting effect of the cement matrix. These phenomenons have been illustrated in **Figs 2 and 3**.

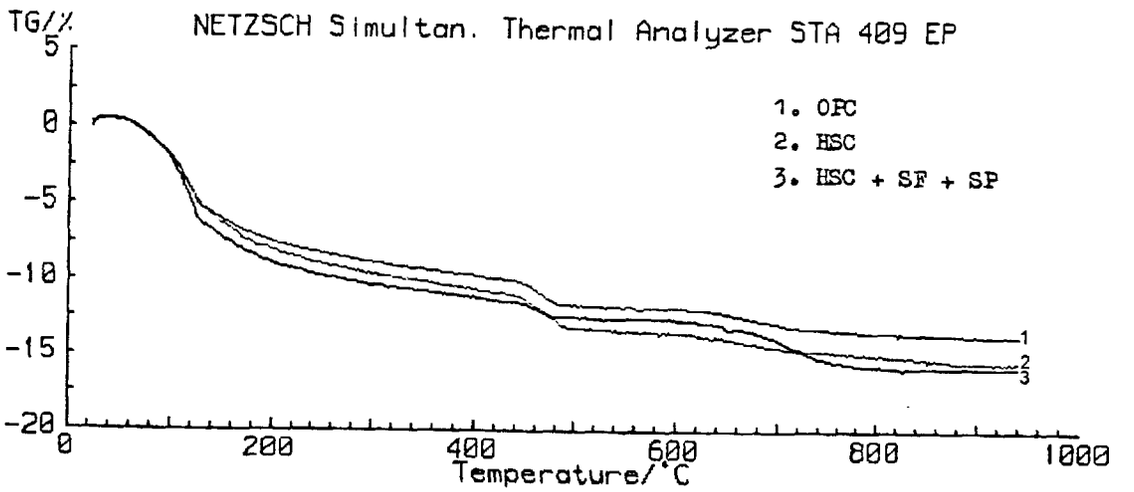

Figure 2 Thermogravimetric curves of cement pastes.

Thermogravimetric tests carried out on cement paste (Fig 2) confirm an increase of the C-S-H phase content in high-strength cement with SF additive (the first effect on TG curve). Already after 2 days of maturing the clear reduction of CH content which may be observed in cement with an SF additive confirms the great influence pozzolana reaction on hydration processes. This effect is least in cement with a microsilica additive due to the bonding of CH by SF (CH decomposition effect on TG curve at temperature of approx. 450°C). The great compacting effect of the paste structure from high-silicate cement with a microsilica additive is directly confirmed by measurements of porosity by means of mercury porosimeter (Fig 3). The reduced porosity of the matrix and the high density HPC concretes produced from cement with a high

silicate content gives a set of very good durability properties, such as frost resistance and resistance to sulphate and chloride corrosion (Peukert et al., 1996, Peukert, 1992).

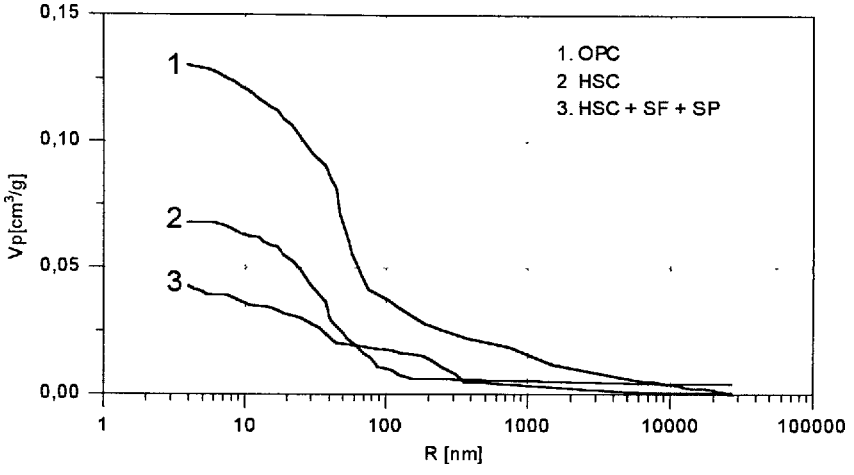

Figure 3 Porosity of cement pastes.

CEMENT SETTING REGULATOR AND HARDENING ADDITIVES

Alongside its mechanical properties, the high silicate cement is also recommended in HPC concrete technology for its increased potential to improve SP fluidization effect. In general, cements with a limited C_3A content are less water-requiring. On the other hand the use of anhydrite in these cements instead of the universally applied gypsum gives a particularly large lowering of the water demand of cement, **Table 1**. This fact has been applied in the technology for the production of the "gypsum-free" cements used for HPC concretes. The excellent workability of these cements creates the opportunity for the limitation of SP consumption in MDF and DSP concretes.

Table 1 Water demand of cements.

Type of cement	C_3A contents, [% by mass]	Control setting agent, [% by mass]	
		Gypsum, $CaSO_4 \cdot 2H_2O$	Anhydrite II $CaSO_4$
SRC, CEM I 42.5	2.5	25.0	22.0
OPC, CEM I 42.5	9	26.0	24.0
	11	26.5	25.0
	13	27.5	27.0

For the super-rapidly hardening HPC concretes it is essential to modify the kinetics of hardening in the cement through the addition of hardening activators. The effects of the alkaline activators, K_2CO_3 and Na_2CO_3, have been shown to be highly efficient in silicate cements. These additives give a very good early strength of the cement, with a simultaneous high normative strength.

The application of the mentioned above hardening activators reduces the setting time of cement then often needs to use the addition of setting retarders. Good retardation effects may be obtained by using SP of Ca-LS type with an extra additive, according to needs, of the hydroxycarboxilic acids. The potential for the modification of strength of the gypsum-free cements with described above complex additive of modifiers is shown in **Table 2**.

Table 2 Properties of cements modifying by complex additive.

Cement		Paste			Mortar					
Concentration of complex additive	Specific surface area	Water demand	Setting time		Consis-tency	c/w ratio	Compressive strength, after days, MPa			
			initial	final						
% by mass	m^2/g	wt. %	h^{min}		cm		1	3	7	28
5.5	0.45	23.5	1^{50}	2^{10}	18.0	2.86	20	45	52	61
7.5	0.45	22.5	1^{55}	2^{20}	18.2	3.03	22	47	54	63
5.5	0.55	21.5	1^{02}	1^{08}	18.3	3.03	37	58	71	81
7.5	0.55	20.5	1^{08}	1^{14}	18.2	3.03	43	61	72	83

The strength of concretes produced from describe above cements, granite aggregate and containing 10% additive of silica fume, is shown in **Table 3**.

Table 3 Mechanical properties of HPC concretes.

No of concrete sample	c/w ratio	Compressive strength, after days, MPa				
		0,25	1	3	7	28
1.	2.5	3.3	40.8	51.3	66.2	78.7
2.	3.5	7.7	58.5	68.5	81.4	94.2
3.	2.5	3.1	39.8	57.5	62.3	78.4
4.	3.5	6.3	49.5	61.2	78.4	97.8

CONCLUSIONS

Cements with a high silicate content appear to be particularly useful in design and production of HPC concretes. The cements applicated in the MDF and DSP technologies gives an extremely good means of controlling the rheological properties of concrete mixes and performance parameters of concrete.

Gypsum-free cements with a silicate content over 80% particularly favourable influence the fluidization effect of superplasticizers additive, also in the presence of the alkaline hardening activators, K_2CO_3 and Na_2CO_3.

HYDRATION MECHANISM OF HIGH PERFORMANCE CONCRETE

Yeong N. SHEEN, National Taiwan Institute of Technology, Taipei, Taiwan.
Chao L. HWANG, National Taiwan Institute of Technology, Taipei, Taiwan.

ABSTRACT The hydration mechanism of HPC was studied in this paper. Setting behavior, ultrasonic pulse velocity, strength development and calorimetric curve were measured simultaneously. Among them a coincident trend was shown just as the result observed for blended cement paste. The heat evolution curve of HPC has delayed accordingly by the amount of cement and the transition zone appeared later than normal concrete.

Keywords: Hydration mechanism, High Performance concrete(HPC), Heat evolution.

RESEARCH SIGNIFICANCE

The hydration of high strength and high flowing HPC was studied. The HPC with fixed paste amount and three W/B compared with traditional high strength concrete (HSC). Heat evolution, penetrative resistance, pulse velocity, electrical resistivity and compressive strength were conducted to build up quality assurance and basic theory for the application of HPC.

TEST PLAN

The materials used in this study met the requirement of ACI 363. Based on the densified mixture proportion algorithm, HPC with different W/B was prepared to meet the requirement of f'c at 56 day > 56 MPa and slump > 230 mm. High strength concrete was designed by ACI 318. The material and mixture proportion are shown in Table 1.

Table 1. The Mixture of Concrete

Type	N	W/C	W/B	W/S (%)	Mixture Proportion (kg/m^3)							
					Fly Ash	Sand	Coarse aggregate	Cement	Slag	Water	SP	UW
HPC	1.3	0.43	0.28	7.2	177	929	738	376	20	126	35	2401
		0.50	0.32	7.8				342	18	158	14	2376
		0.67	0.40	8.9				285	15	183	8	2335
HSC	2.1	0.34	0.34	11.5	0	825	586	719	0	244	0	2374

After mixing with water, heat evolution, penetrative resistance and ultrasonic pulse velocity were measured during the first 100 hr. Also pulse velocity, electrical resistivity and compressive strength were measured at 28, 56, 120 and 180 days.

RESULT AND DISCUSSION

Cement content varies from 285 kg/m^3 of HPC to 719 kg/m^3 of HSC in this study. The main heat source of HPC is cement. Hence HSC has the highest heat with the rapidest hydration due to the largest amount of cement as shown in Fig. 1.

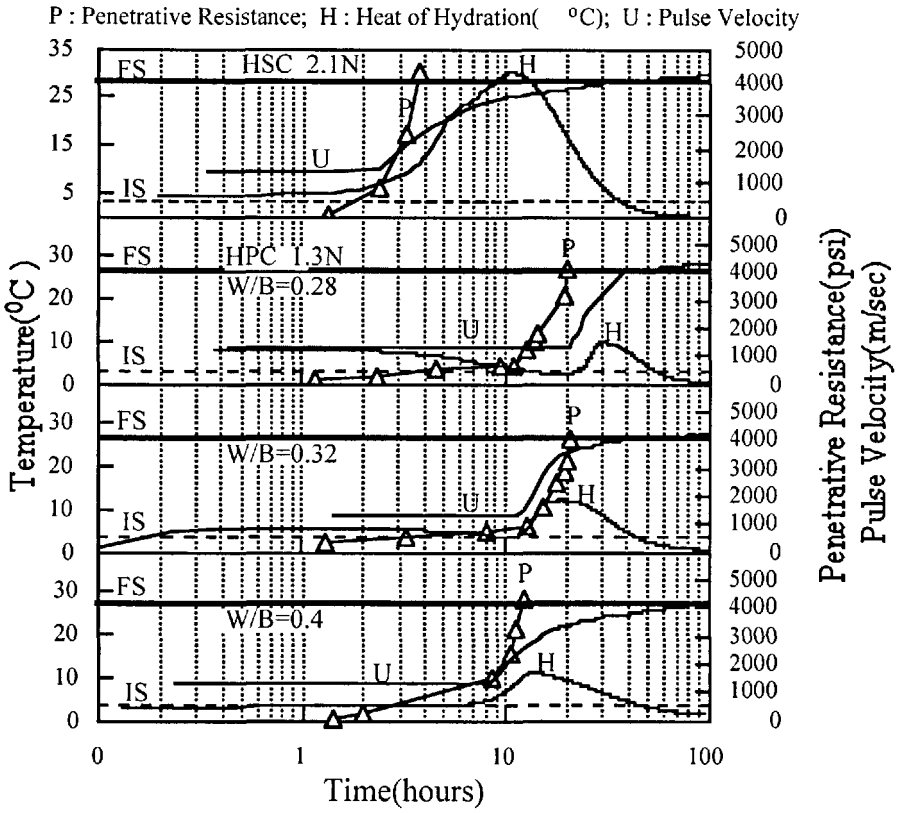

Figure 1 Hydration mechanism of HPC (1.3n) with various W/B

It is also shown that there is a close relationship among heat evolution, penetrative resistance and pulse velocity. Such behavior is quite similar to the observation of transition zone (TSZ) in the previous researches on paste. Large amount of calcium hydroxide (CH) grows during this period and ultrasonic velocity as well as penetrative resistance largely grows in TSZ. Heat peak also increases as the increment of cement. It may indicate there is same physiochemical variation in this zone. At same amount of paste, the smaller the W/B of HPC is, the higher the compressive strength will be. After 56 days the strength of HPC with W/B = 0.32 and 285 kg/ m^3 of cement exceeds that of HSC with W/C = 0.34 and 719 kg/m^3 of cement. Pulse velocity, compressive strength and electrical resistivity increase with time as shown in Fig. 2.

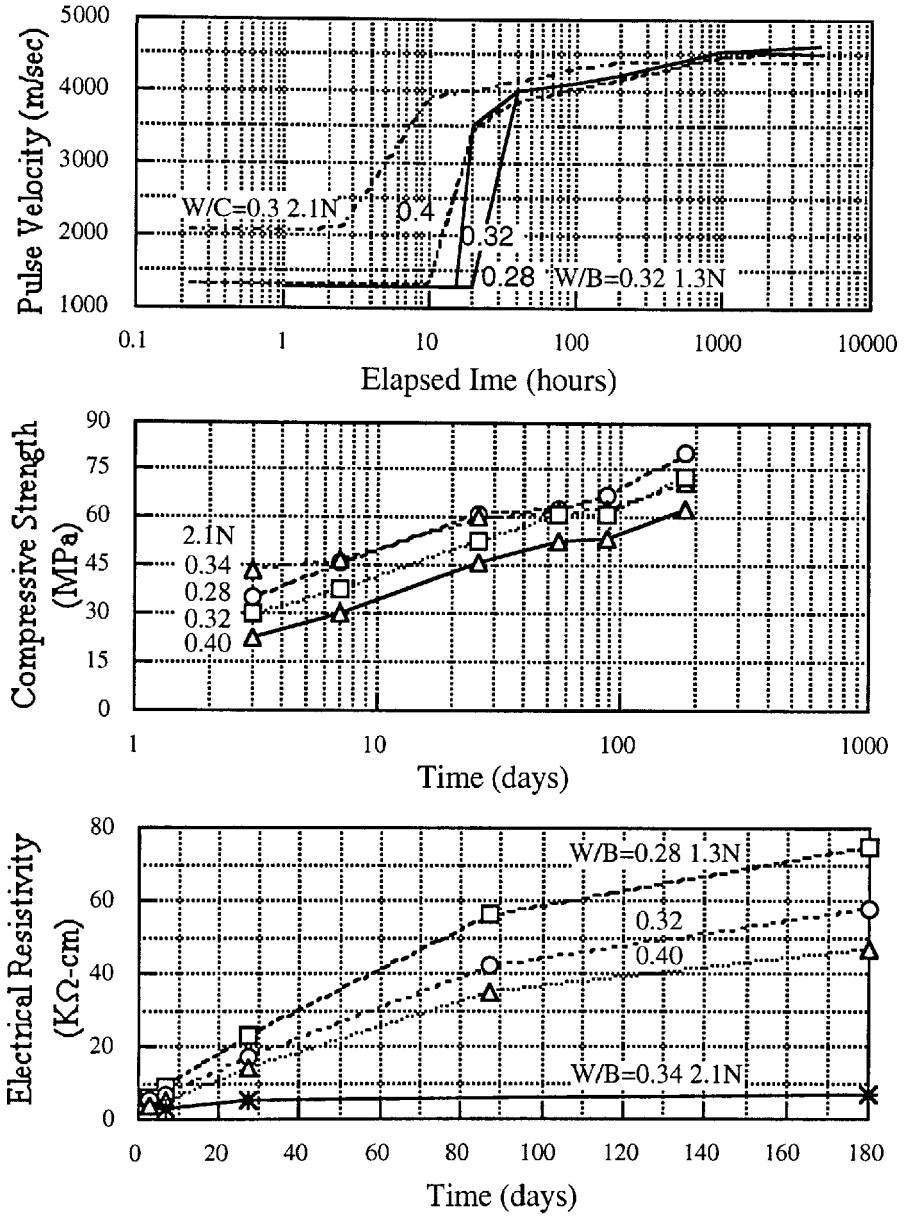

Figure 2 Development of pulse velocity, compressive strength and electrical resisitivity of HPC with various W/B

However, the ultrasonic pulse velocity and long-term strength of HSC with rich cement have shown degradation. Electrical resistivity at all ages is below 10 kW-cm mainly due to without pozzolanic material. The lower the W/B of HPC is, the higher the electrical resistivity will be. The electrical resistivity of HPC is ten times greater than that of HSC without pozzolan. And hence, it can be concluded that HPC with the addition of pozzolanic material would obtain better water penetrative resistance and durability.

CONCLUSION

Hydration behavior of HPC with different W/B is similar to that of cement paste with or without pozzolan. The peak of heat evolution curve increases as the increment of cement amount. The pulse velocity, penetrative resistance and heat evolution curves have transition zone in the same duration. The results have shown that the more cement there is, the worse the properties will be. Therefore, the addition of pozzolan is helpful to maintain long-term strength and durability of concrete for construction needs .

HIGH PERFORMANCE CONCRETE: STUDY OF MORTAR PORE SOLUTION

Jorge. D. SOTA, J., LEMIT - CIC. Techn. Univ. La Plata. Argentina.
Graciela M. GIACCIO, LEMIT - CIC. Nac.Univ. La Plata. Argentina.
Raúl L. ZERBINO, LEMIT - CONICET. Nac.Univ. La Plata. Argentina.

ABSTRACT Many studies have shown that the capilary porosity of concrete is strongly related with their physico mechanical properties specially its strength and durability. The knowledge of the characteristics of liquid phase, present in pores, enables to study the process of hydration of cementitious systems. In this case mortars corresponding to conventional and high performance concretes are compared. A pressure of 450 MPa was applied to express pore solution. Capilary porosity, testing ages and the presence of different mineral admixtures were included as variables.

Key-words: Admixtures, Hydration, Ions, Pore solution, Porosity.

INTRODUCTION

During the last 20 years several special concretes have been developed, most of them restricted to particular situations. However, the interest in High Performance Concrete (HPC) continuously increased as its use is extended to a wide range of field applications; HPC have been applied in the construction of many important structures and they were generally specified in order to assure long service life.

Concrete is a material where pores of different types and sizes are randomly distributed together with discontinuities in the microestructure such as interfaces. This porosity not only implies differences in mechanical properties but also affects the permeability, allowing the movement of fluids liable to produce material degradation.

HPC are characterized by its high strength and durability, obtained as consequence of their low water to cement ratio, high content of cement and the use of superplastizicers and many times mineral admixtures. Previous studies have shown that the matrices of high performance concrete have a higher amount of unhydrated cement than conventional concrete; at the same time some differences in the morphology of hydration products have been observed. These facts are strongly related with the significant reductions in the porosity of the cementitious system.

The knowledge of the characteristics of liquid phase present in pores results of interest to the study of the process of hydration of cementitious systems. In this case the characteristics of conventional and high performance concretes are compared. This paper shows some results from a research program on the microstructure of high performance concrete, particularly those related with the analysis of pore solutions. In this case the porosity of the system (conventional vs. high performance mortar) and the presence of mineral admixtures were included as variables.

EXPERIMENTAL PROGRAM

The pore solution of different mortars was analyzed (Na^+, K^+, Ca^{2+}, CO_3^{2-}, HO^-). The expression of pore solution from hardened mortars was realized applying a pressure of 450 MPa. The used methodology was refered in Longuet et al (1973), a general description of the apparatus (materials, operation, analytical procedures) can be found in Barneyback and Diamond (1981). In many papers this methodology was applied in order to discuss the development of alkali-silica

reaction in cementitious systems Struble and Diamond (1981), Diamond et al (1981), Diamond (1983), Sota et al (1995) or the chloride binding capacity of the hardened cement pastes Page (1983).

To compare the composition of pore solution of high performance and conventional concretes, mortars representative of their matrices were studied. Water to cement ratios (w/c) equal to 0.35 and 0.55 were selected. Different types of mixtures including several mineral admixtures (silica fume and natural pozzolans) were sudied. The physical and chemical characteristics of cement and pozzolan are given in Table 1.

Table 1. Fineness and chemical analysis of the natural pozzolan and the cement.

Test	Normal Portland Cement	Natural Pozzolan
Surface area, Blaine (m^2/kg)	350	700
Chemical analysis (%)		
Loss on ignition	3.50	6.40
Silicon dioxide (SiO_2)	20.90	68.50
Aluminum oxide (Al_2O_3)	3.10	14.20
Ferric oxide (Fe_2O_3)	4.30	2.40
Calcium oxide (CaO)	62.70	-----
Free lime	----	2.70
Magnesium oxide (MgO)	0.85	0.18
Sulphur trioxide (SO_3)	2.00	0.00
Sodium oxide (Na_2O)	0.11	2.40
Potasium oxide (K_2O)	0.79	3.12

Eight mortars were prepared using these materials and a siliceous natural river sand. No chemical admixtures were added. Two reference mortars, M-1 (w/c=0.35) and M-2 (w/c=0.55), with portland cement and without mineral admixtures were made. In mortars M-3 and M-4, 15 % by weight of cement was replaced by a natural pozzolan, while in mortars M-5 and M-6 the same percentage of pozzolan was added to cement content. In the same way, 15% (by weight of cement) of silica fume was added to cement content in mortars M-7 and M-8. Mix proportions are given in Table 2. Cylinders of 50 mm x 100 mm were cast; they were sealed and kept at 20 C until the age of testing (1, 3, 7, 28 and 90 days).

Table 2. Mortar mix proportions.

MIX	Proportions (gr.)						
	water	cement	natural sand	natural pozzolan	silica fume	w/c	w/(c+a)
M-1	157	450	700	-	-	0.35	0.35
M-2	165	300	805	-	-	0.55	0.55
M-3	157	382	700	67.5	-	0.41	0.35

M-5	157	450	626	67.5	-	0.35	0.30
M-6	165	300	756	45	-	0.55	0.48
M-7	157	450	612	-	67.5	0.35	0.30
M-8	165	300	746	-	45	0.55	0.48
w/c: water to cement ratio			w/(c+a): water to cement + mineral admixture ratio				

Test results

The results of the analysis of pore solution are given in Table 3. The variation with age of the concentration of calcium ion in pore solution of mortars with low and regular porosity is plotted in Fig 1. In a similar way, Figs 2 and 3 show the changes in sodium and potasium concentrations.

Table 3. Results of the analysis of pore solution. (expressed in meq/l)

	Age	Mortar							
	(days)	M-1	M-2	M-3	M-4	M-5	M-6	M-7	M-8

	28	7	7	7	7	9	8	120	60
	90	8	12	7	9	26	9	116	58

DISCUSSION

Regarding the behaviour of reference mortars (M-1, M-2) in Fig 1 it can be seen that there are not significant differences of Ca^{2+} in pore solution when w/c varies from 0.35 to 0.55. Although there are important differences in cement content, calcium concentration is limited by the sparingly soluble calcium hydroxide. The higher porosity of 0.55 mixes makes easier the hydration of cement. For both w/c ratios Ca^{2+} ions concentration remains almost constant as age increases.

A different situation appears when silica fume was added, then Ca^{2+} ion content is notably higher in 0.35 than in 0.55, and it increases with time. This fact can be explained considering that silica fume enhances cement dispersion and then, hydration process. When cement is replaced by natural pozzolans (M-3 and M-4) no differences between w/(c+a)=0.35 and 0.55 mixes were detected, being calcium concentration almost constant along the time. When pozzolan is added to cement content, a similar behavior can be observed in M-6 but in M-5 (w/c=0.35) there is a tendency to increase calcium concentration with time.

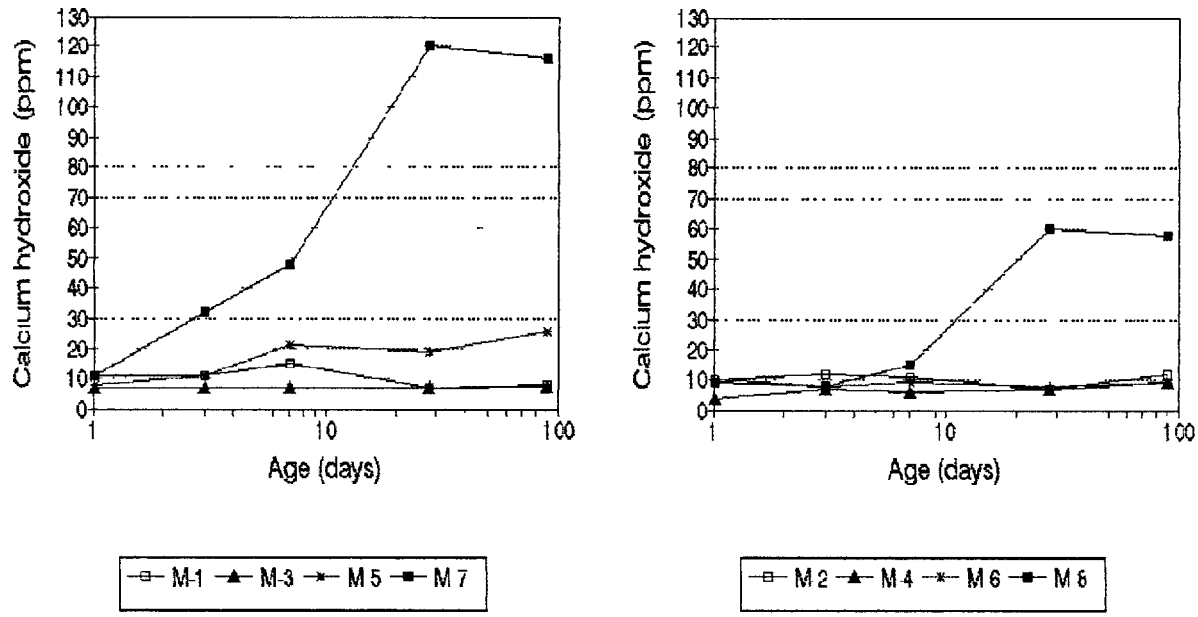

Figure 1 Variation with age of Ca^{2+} concentration of high performance and conventional mortars.

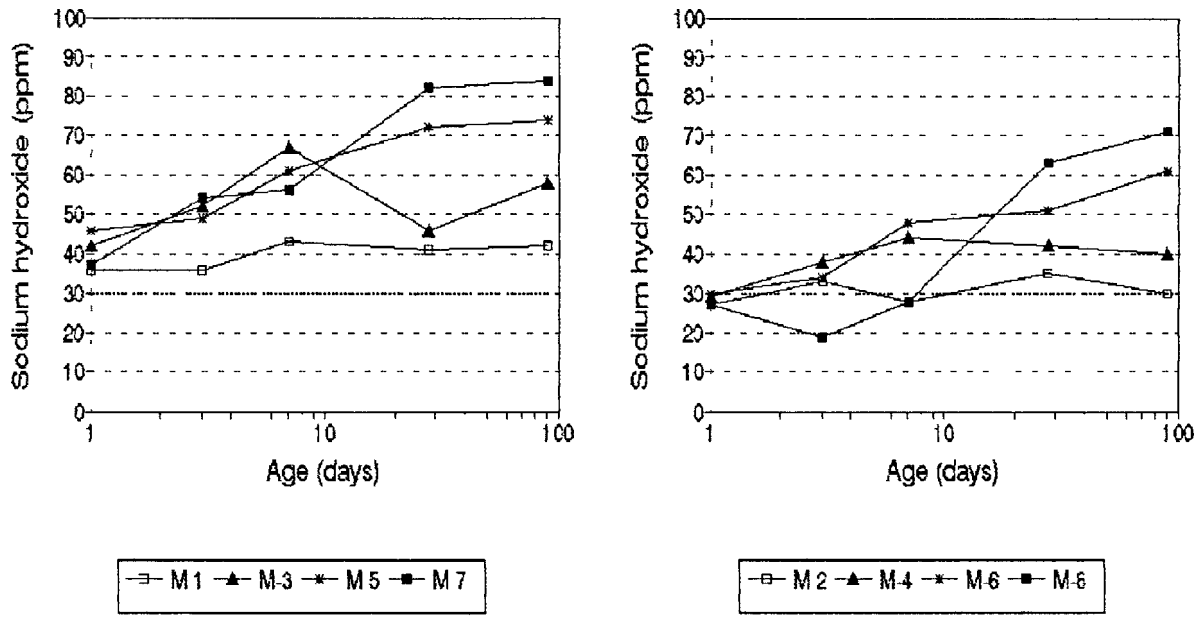

Figure 2 Variation with age of Na^{+} concentration of high performance and conventional mortars.

Fig 2 shows that Na^{+} contents are always higher in high performance (low w/c ratio) than in conventional mixes. This behaviour can be justified regarding the differences in cementitious material content of the mortars. In reference mortars Na^{+} sligtly increases with age. When mineral admixtures are used it tends to increase. The most significant increments with time take place when silica fume was added (M-7, M-8), followed by pozzolan addition (M-5, M-6) and finally pozzolan as partial cement replacement (M-3, M-4). In all cases Na^{+} is higher in mortars with silica fume or pozzolan than in plain mortars (no admixtures).This fact is attributed to the Na^{+} ions supplied by the mineral admixtures but also to the dispersion effect of the ultrafine particles which enhanced the solubility of the cations.

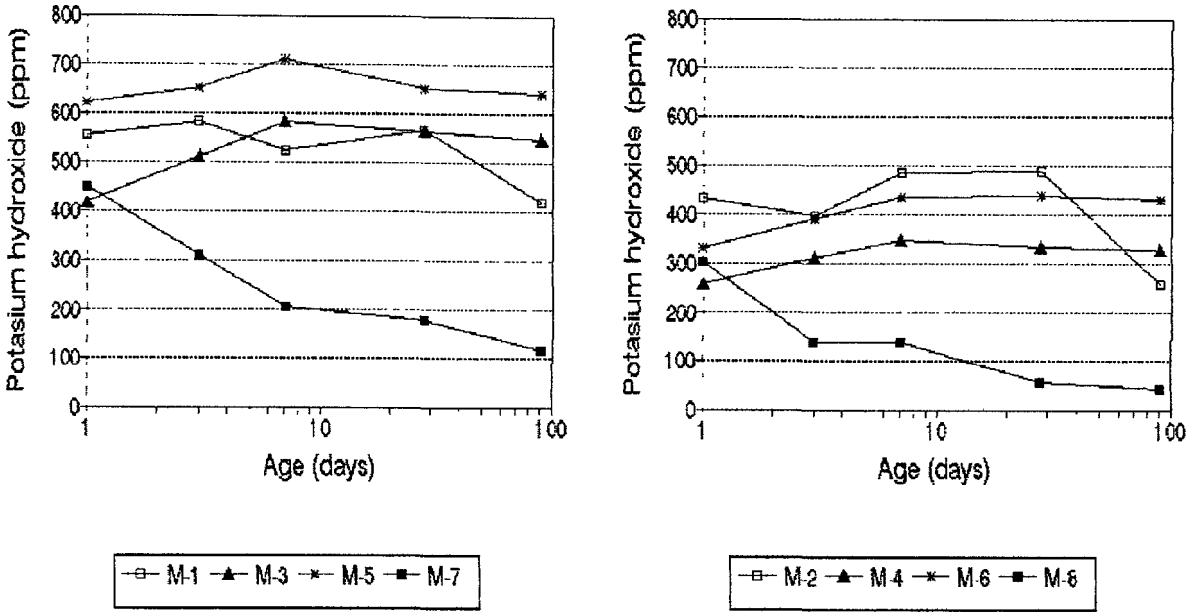

Figure 3 Variation with age of K^+ concentration of high performance and conventional mortars.

The variation of the concentration of K^+ with age of high performance and conventional mortars is represented in Fig 3. As in the case of sodium, K^+ contents are always higher in the mixes of lower porosity (w/c=0.35). In reference mortars K^+ remains relatively equal until the age of 28 days and then it starts to decrease. In pozzolan mortars it increases during the first days (probably due to the K^+ supplied by the admixture) and then they start to decrease slowly. On the contrary, when silica fume was added the content of K^+ is continously and strongly reduced since the begining. This reduction in K^+ can be justified considering that these ions are the first ones that are fixed by the silicates. This effect was more important in mortars of lower porosity.

Finally, regarding the variation of the different ion contents it can be thought that in M-7 and M-8 the rate of hydration of cement increases due to the dispersion effect of silica fume particles, then there is a higher capacity to fix K^+.

PROPERTIES AND MICROSTRUCTURE OF ULTRA HIGH STRENGTH CEMENT COMPOSITES

Hai Moon CHEONG, Jung Ryoul LIM and Dong Won CHO
Ssangyong Cement Industrial Co. Ltd., Taejon, KOREA

ABSTRACT The medium-sized and pozzolanic particles were favorable for DSP cement system, since they produced denser packing and their pozzolanic reaction reduced $Ca(OH)_2$ and formed C-S-H with lower C/S ratio. The suitable particles were slag. Curing temperature had great effect on the compressive strength development. High temperature curing promoted pozzolanic reaction as well as Portland cement hydration. Autoclave curing produced the best compressive strength.

Key-words : Microstructure, High strength, silica fume, Pore structure, Curing

INTRODUCTION

In recent years many studies for ultra high strength cement composites have been reported. Ultra high strength cement composites would be used extensively for the construction, chemical and mechanical materials(Wise, 1985 ; Yoshihiko, 1991 ; Young, 1991 ; Roy, 1992). DSP(Densified System containing homogeneously arranged ultra fine Particles) cements had the more densified system with ultra fine particles such as silica fume and superplasticizers. Since DSP cement was first described in H.H. Bache(1981), the studies of DSP cements have been widely applied in the area of high strength cement composites. DSP cement had good mechanical properties due to lower water-cement ratio(W/C) and denser, homogeneous microstructure(Lu, 1993).

For more compacted and homogeneous hydrated cement matrices, multi-components DSP cements with the medium size particles ranging from silica fume to cement would have been studied(Lu. 1993 ; Yokoyama, 1994). And silica fume was one of the pozzolanic materials, however its reaction was less active than Portland cement, and a large dosage of superplasticizers retarded the early cement hydration. To accelerate the early cement hydration the various curing conditions have been investigated. High-temperature and high-pressure curing were widely used to increasing the strength of DSP cements(Sun, 1993). Especially high-temperature curing at 200 ℃-400 ℃, in spite of some cracking and shrinkage, produced much higher strength. Until now many researches have been reported to optimize the curing conditions for the best properties.

In this study, using various medium size particles whose size distribution ranged from silica fume to Portland cement, the ultra high strength cement composites with more densely-compacted and homogeneous hydrated cement matrices were prepared, and the influence of curing conditions on the microstructure and physical properties was investigated.

EXPERIMENTAL PROCEDURE

Materials

Ordinary Portland cement(Ssangyong Cement Industrial Co., Korea) and Silica fume(Grade 940-U, Elkem Materials A/S, Norway) were used. As medium-sized particles, ggbf slag(granulated ground blast furnace slag with the blaine 8000cm^2/g, Pohang Steel Industrial Co., Korea), fly ash(classified fly ash, Boryoung Power plant, Korea), paper sludge ash(Ssangyong Paper Industrial Co., Korea) and calcined bauxite(ground red bauxite, China) were used. The chemical compositions are shown in Table 1.

Table 1. Chemical Compositions of Raw Materials.

Materials	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O	SO_3	TiO_2	P_2O_5	f-CaO	LOI	Ave.Dia (um)

The preparation and characterization of ultra high strength cement composites

The mix proportions(wt%) was cement/silica fume/medium size particle=7:1:2. The superplasticizers (Melment F10, melamine formaldehyde condensate) was added with 3wt% of this mixtures. The solid powders were mixed with water(water/solid=0.16 - 0.20) by the planetary mixer for 6 minutes. The specimens were cast in 50 x 50 x 50 mm mold and demolded after 1 day and cured in water at 20 ℃ for 28 days. For the characterization of the specimens, XRD, DT/TGA, SEM/EDS, mercury intrusion porosimetry and compressive strength test were employed.

To investigate the influence of curing conditions, the ultra high strength cement composites were prepared under various curing conditions as shown in Table 2 and their mechanical and hydration properties were analyzed.

Table 2. Curing Conditions

Notation	Curing condition	
W	. In water	. 20±5 ℃
AU	. Autoclave	. 180 ℃, 10atm., 24hrs.
DO	. Dry oven	. 200 ℃, 24hrs.
HT	. In water	. 80±5 ℃, 24hrs.
AU+DO	. Autoclave	. Autoclave(180 ℃, 24hrs.)→ 20 ℃ 24hrs. in air → Dry oven(200 ℃,24hrs.)
HT+DO	. Hydrothermal+dry oven	. Hydrothermal(80 ℃, 24hrs.)→ 20 ℃, 24hrs. in air → Dry oven(200 ℃,24hrs.)

RESULT AND DISCUSSION

Influence of medium size particles

Fig. 1 shows the compressive strength of the specimens cured in water for 28 days with various kinds of medium-sized particles such as ggbf slag, fly ash, paper sludge ash and calcined bauxite. Medium-sized particles made compressive strength increase. Especially the ggbf slag showed higher compressive strength than other particles. Water demand changed with the kind of medium-sized particles due to their particle size distribution and surface properties. Ggbf slag-containing composites could be mixed at a lower W/S ratio. It was considered that they had more densely packing than other composites. In general, it was well known that the compressive strength decreased with increasing W/S ratio. However there is no relationship between compressive strength and W/S ratio, because W/S ratio was lower compared with theoretical water demand (W/S=23.5%) and lower W/S(< 0.18) led to lower workability. The suitable W/S ratio was 0.18 - 0.20. Ggbf slag gave better compressive strength. It was assumed that they made more densely-packed structure in fresh state and better hydrated matrices by more active hydraulic reaction than other powders.

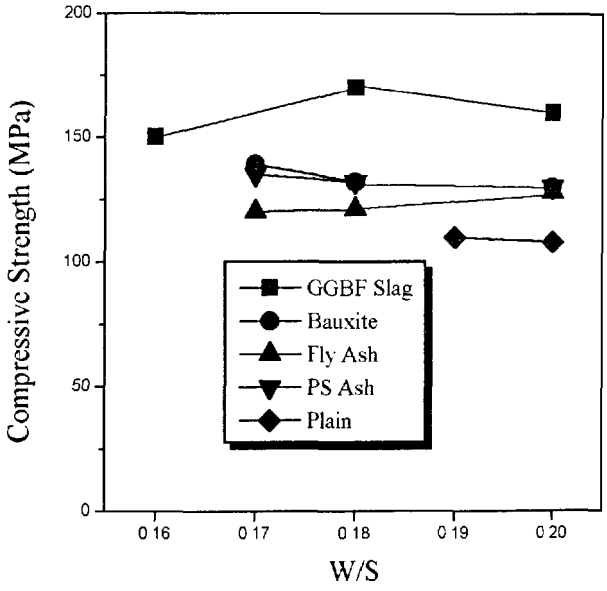

Fig. 1 Compressive strength of ultra high strength cement composites with various medium-sized particles. (Cured in water for 28 days)

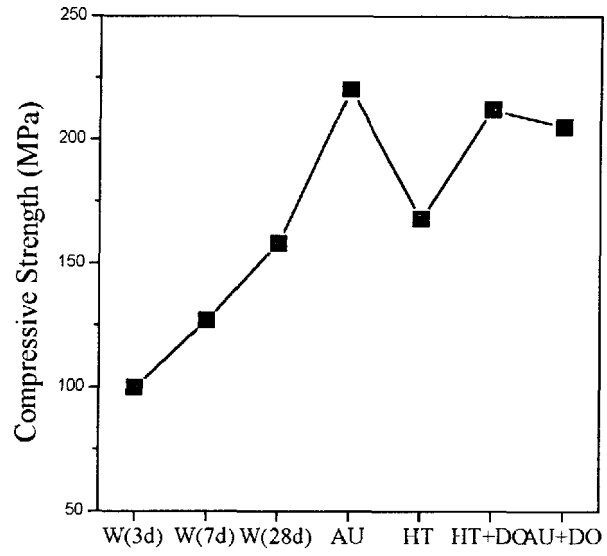

Fig. 2 Compressive strength of ultra high strength cement composites with various curing conditions.

The medium-sized and pozzolanic particles were favorable for DSP cements system, since they produced denser packing in fresh state and their pozzolanic reaction reduced $Ca(OH)_2$ and formed C-S-H with lower C/S ratio. The suitable particles were ggbf slag. The compressive strength seemed to be unaffected by the mechanical properties of medium-sized particles.

Influence of curing conditions

Fig. 2 shows the relationship between compressive strength and curing condition. As shown above, ggbf slag-containing composites showed better compressive strength, so they were chosen for investigation of curing condition. As the curing temperature was higher, the compressive strength increased. Curing temperature had great effect on the compressive strength. High temperature curing promoted pozzolanic reaction as well as Portland cement hydration. Autoclave curing produced the best compressive strength.

After hydrothermal+dry oven curing, the compressive strength increased remarkably. XRD data indicated that the autoclave curing showed higher degree of hydration. Under hydrothermal curing and water curing, only C-S-H was observed, and under autoclave and hydrothermal + dry oven curing, the tobermorite crystals as well as C-S-H were observed. Fig. 3 shows the pore size distribution of the specimens with various curing conditions. After autoclave and hydrothermal curing, the specimens contained lower total porosity. The specimens which showed higher compressive strength contained less macroporosity (over 15 μm). The small capillary pore (below 0.01 μm) did not greatly influence on the compressive strength. After dry oven curing, the medium capillary pore (below 0.05 μm) increased. Autoclave curing produced the best compressive strength because of the denser hydration products and tobermorite formation. Although hydrothermal + dry oven curing increases medium capillary porosity (below 0.05 μm) and total porosity slightly, the compressive strength increased. The reasons of this result were the tobermorite formation and reducing of macroporosity which influenced on the mechanical property.

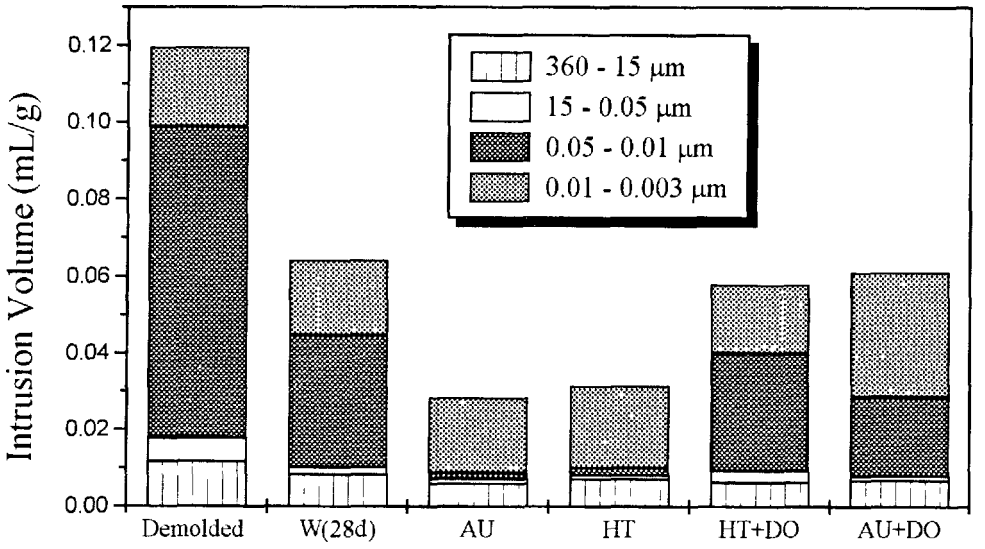

Fig. 3 Pore size distribution of the ultra high strength cement composites with various curing conditions.

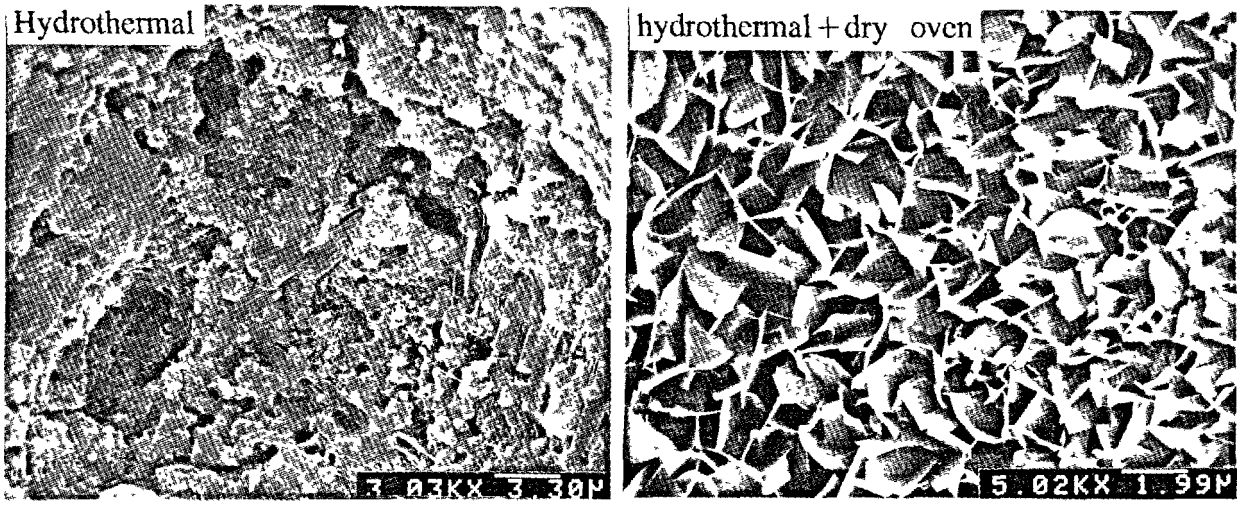

Fig. 4 SEM micrographs of macropores for the specimens with hydrothermal and dry oven curing.

Fig. 4 shows SEM micrographs of macropores for the specimens with hydrothermal and dry oven curing. After hydrothermal curing, the amorphous C-S-H was observed in the pores. After dry oven curing, tobermorite crystals were observed in the pores(this exhibited the same result as autoclave curing) Since denser microstructure by the hydrothermal curing had been heated at 200 ℃, the autoclave-like-reaction occured because dense matrix acted as the closed system(Wise 1985). In this case, tobermorite crystals were formed in the entrapped air and large capillary pores.

CONCLUSIONS

Using various medium-sized particles whose size distribution ranged from silica fume to Portland cement, the ultra high strength cement composites were prepared, and the influence of curing conditions on the microstructure and physical properties was investigated. The conclusions are as follows.

(1) The medium-sized and pozzolanic particles were favorable for DSP cements system, since they produced denser packing and their pozzolanic reaction reduced $Ca(OH)_2$ and formed C-S-H with lower C/S ratio. The suitable particles were ggbf slag.

(2) Curing temperature had great effect on the compressive strength. High temperature curing promoted pozzolanic reaction as well as Portland cement hydration. Autoclave curing produced the best compressive strength.

(3) After hydrothermal+dry oven curing, the compressive strength increased remarkably. It seemed that the microstructure became denser by the hydrothermal curing and tobermorite crystals were formed in macroporosity by the dry oven curing at 200 ℃.

HIGH PERFORMANCE CEMENTOUS BINDER

Jun-Feng WANG, Schomburg & Co. KG, Detmold, Germany

ABSTRACT In comparison to a normal Portland cement (CEM I 52.5 R according to DIN 1164) shows the newly developed high performance cementous binder not only a good hydraulic property, but also a high strength development (ca. 45 N/mm² after 1 day and 105 N/mm² after 28 days according to DIN 1164 by a very low water cement ratio). The mortar and concrete which was improved with the high performance cementous binder show a very good chemical and mechanical resistance because of the very low porosity in hardened cement stone.

Key-words: High performance cementous binder (HPCB), Penetration, Low temperatur

INTRODUCTION

Portland cement, usually meaning Ordinary Portland Cement (OPC), are massive building material for normal constructional use. Specifications of Portland cement are based partly on chemical composition or physical properties such as setting time or compressive strength developed under standard conditions. In general, the setting time of a OPC is between 60 - 240 min. and its compressive strength between 32.5 - 52.5 N/mm² after 28d (determined in accordance with DIN 1164). In the following investigations on a newly developed high performance cementous binder - modified with chemical admixtures on the basis of Portland cement - is reported and its actions is discussed.

SAMPLE PREPARATION

For comparative purposes of comparison with the newly developed high performance cementous binder (HPCB) a commercially available Portland cement (CEM I 52.5 R) was also investigated. The corresponding properties of the fresh cement pasts, cement mortar and concrete of the HPCB and the Portland cement were tested in accordance with DIN 1164 and DIN 1048. Prisms (4x4x16 cm) were used in the tests of cement mortar and cubs (15x15x15 cm) were used for tests of concrete.

The mortar prisms and concrete cubes were removed from molds after 1d and then cured partly under water (20°C), in a climate room 20°C/65% RH. Partly prisms of cement mortar were cured in a deep freezer (ca. -20°C), in a fridge (ca. 5°C) and in a drying cabinet (ca. 50°C) until the testing term.

The resistance against chemical attack on the cement mortars were determined with diesel, 20% NaCl solution and 5% lactic acid.

RESULTS AND DISCUSSION

Properties of fresh cement pasts

The dates of fresh cement pasts which were determined according to DIN 1164 are presented in Table 1.

Table 1 : Properties of fresh cement pasts

samples	CEM I 52.5 R	HPCB
w/c ratio (standard stiffness)	0.285	0.200
initial setting min.	130	280
final setting min.	180	360

Table 1 shows that the w/c ratio of HPCB (0.200) by standard stiffness is lower than the w/c ratio of CEM I 52.5 R (0.285), the water demand can be reduced by about 42%. In comparison to the CEM I 52.5 R the setting time of HPCB is significantly retarded until to 280 min. (initial setting) and 360 min. (final setting).

Properties of cement mortars

The compositions of cement mortars and the resulting water cement ratio at approximately constant spread measure are given in Table 2.

Table 2 : Composition of cement mortars

Samples		A	B
CEM I 52.5 R	g	450	-
HPCB	g	-	450
Standard sand*	g	1350	1350
w/c ratio		0.500	0.300
Spread measure**	cm	16.0	16.0
Flexural strength after 16h	N/mm^2	2.11	5.70
Compressive strength after 16h	N/mm^2	8.15	28.8

* : According to DIN 1164 part 7
** : According to DIN 1060 part 3

The results in Table 2 show that the sample A with CEM I 52.5 R has a high w/c ratio of 0.500, at the similar water consistency the sample B with HPCB achieves a very low w/c ratio of 0.300. This means that in comparison to the reference mortar (sample A) a water reduction (sample B) of up to ca. 40% is achieved (Wang et al, 1995).

All test specimens after their demoulding were stored up to their testing in different curing conditions. The strength development of cement mortars determined according to DIN 1164 are presented in Fig 1.

The strength development of HPCB at early age is very positive, after 16h the compressive strength has achieved already 28.8 N/mm^2 (see Table 2) contrary to sample A only 8,15 N/mm^2. The results in Fig 1 show that the sample B achieves not only a high strength improvement during the initial phase of the hydration (45.5 N/mm^2 after 1d, curing in water), but also in the course of later strength development (105 N/mm^2 after 28d, curing in water).

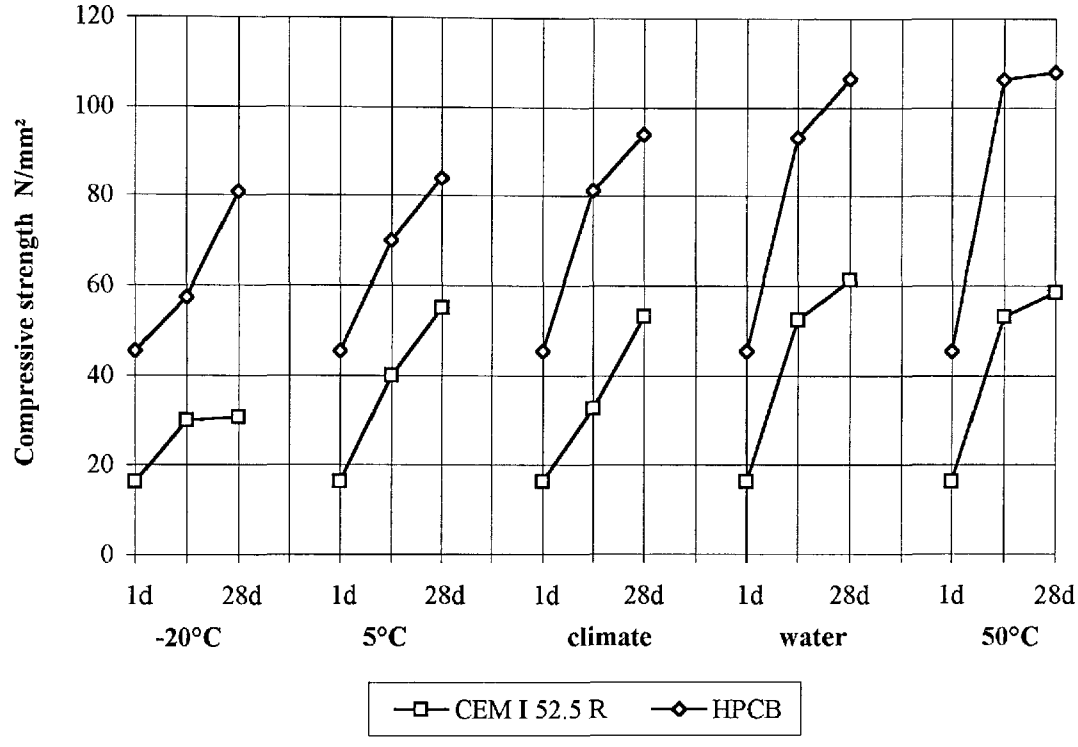

Figure 1 : Development of compressive strength of cement mortars in different curing conditions

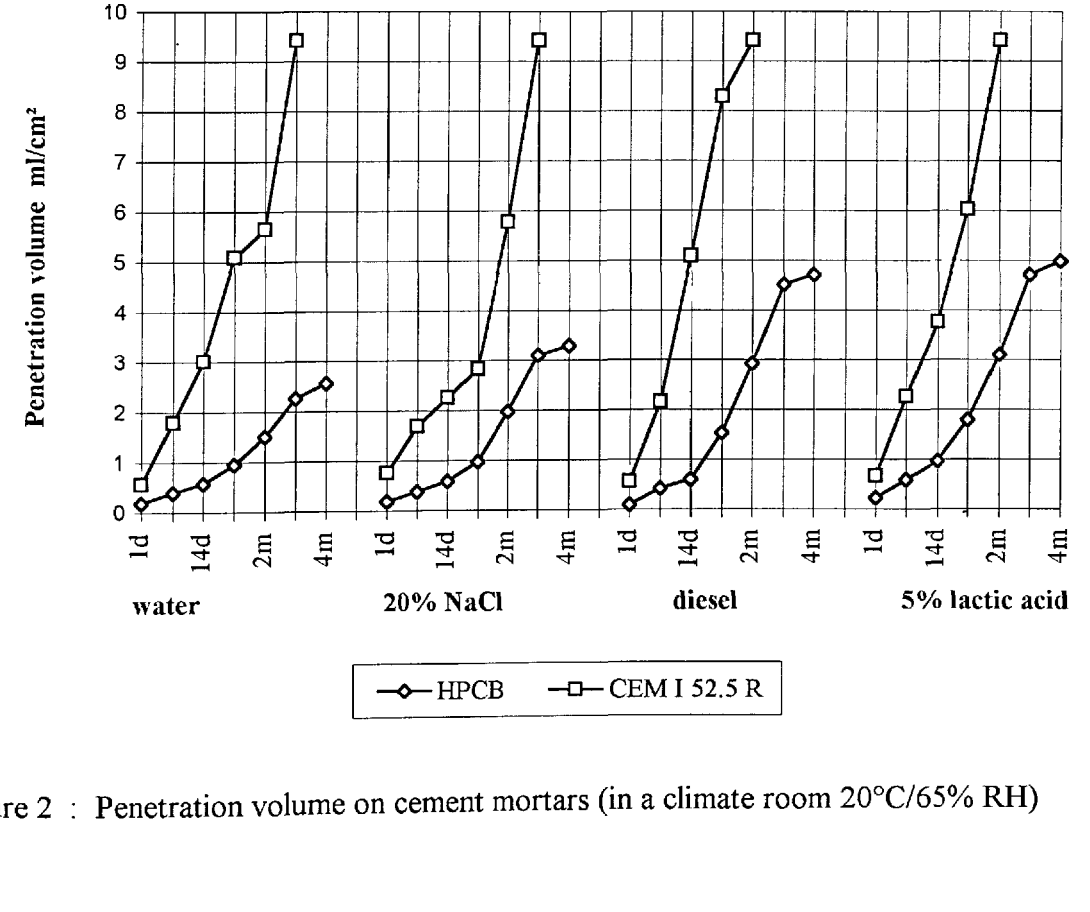

Figure 2 : Penetration volume on cement mortars (in a climate room 20°C/65% RH)

The strength development of cement mortars is appreciably influenced by the curing conditions (Fig 1), especially by the low temperature (-20°C) and high temperature (50°C). It is to see that the strength of HPCB increases further by -20°C from 57.4 N/mm² after 7d until 80.8 N/mm² after 28d, but the strength development of sample A, Portland cement is total stopped because of the low temperature from 30.0 N/mm² after 7d until 30.6 N/mm² after 28d. This means that the HPCB in comparison to Portland cement has a good hydration behavior by low temperature because of the lower water cement ratio and the dense microstructure (Wang et al, 1996) in hardened cement stone.

The compositions of cement mortar which were used for penetration tests are presented Table 3 Specimens of cement mortars were stored after demoulding until 7d in a moisture cabinet (20°C/95% RH) and then 1d in a climate room 20°C/65% RH for trying, the glass cylinder for penetration test were pasted over cement mortar with epoxy resin. The penetration volume on cement mortar were tested with different solutions (water, diesel, 20% NaCl solution and 5% lactic acid).

Table 3 : Compositions of mortars for penetration tests

Samples		A	B
CEM I 52 5 R	g	630	-
HPCB	g	-	630
Quartz sand 0-2 mm	g	1170	1170
w/c ratio		0.390	0.260
Spread measure*	cm	16.0	22.5

* : According to DIN 1060 part 3

The results of penetration tests are shown in Fig 2. It can be seen that the penetration volume on HPCB mortar are much lower than the Portland cement CEM I 52.5 R and the penetration rate of different solutions on HPCB mortar after 3 months tends to slow down.

CONCLUSIONS

The newly developed HPCB - a modification of Ordinary Portland Cement - has not only a very high early strength, but also a good strength development in course of the later hydration because of the very low water demand of the high performance cementous binder. In comparison to Portland cement the HPCB shows a very good strength development by the low temperature too The mortar and concrete which are improved with the high performance cementous binder have a very good resistance against the chemical and the mechanical attack because of the very dense microstructure of the hardened cement stone.

BLENDS OF BASIC CEMENTS OF DIFFERENT PHASE COMPOSITIONS HYDRAULIC BEHAVIOUR STUDIES

A.S. HEBLE, K. VISHWANATHAN, A.K. CHATTERJEE
Research & Consultancy Directorate
The Associated Cement Cos. Ltd.
Thane 400 604, India

ABSTRACT Generically different basic cements - Ordinary Portland Cement, Calcium Aluminate Cement, Calcium Sulpho Aluminate Cement and Calcium Fluoro Aluminate Cement are in production in company facilities. These cements have been studied in isolation or in combination to understand their complex hydraulic behavior. The setting and hardening,Volume change,Strength progression and Retrogression,Formation of hydrated phases etc. are features studied and reported in this paper.

KEY-WORDS Setting ,Hardening,Volume change,Hydration

INTRODUCTION

In India, under the auspices of the Associated Cement Cos. Ltd. a variety of special cements are in regular commercial production. In addition, a host of modified or composite cementitous formulations based on these cements are made and used in industrial applications like heavy machinery foundation, bolting of mineroofs, concrete structure repairs, etc. Depending on their end use, they differ in properties like setting and hardening, strength development, expansive properties, etc. A need was therefore, felt to undertake a study to understand the complexities of hydraulic behaviour of such formulations on account of the phases appearing in the basic cements and their influences in hydraulic reactions. The paper enumerates some of these aspects of study on setting and hardening, expansion, strength progression or retrogression, formations of hydrated phases, etc. In some formulation the effect of cold temperature on the strength development is also dealt with.

MATERIALS USED

The basic materials in the studies are from commercial production facilities. These are Ordinary Portland Cement (OPC), High Alumina Cement (HAC), High Purity Calcium Aluminate Cement (CAC), Calcium Sulpho Aluminate - Belite cement (CSA-B) as well as Calcium Sulphoaluminate Clinker (CSA-C), and Calcium Fluoro Aluminate Clinker (CFA).The chemical and phase compositions are given in Table 1. The present paper deals with the early age hydration studies of the following types of blend prepared from the above base materials

(a) : OPC blended with 10% & 50% of HAC, CAC, CSA-B and CSA-C separately ; OPC blends with 10% special cements have also been studied with additional gypsum mixing
(b) : HAC, CAC, CSA-B and CSA-C blended with 10% OPC
(c) : Two different low-temperature hydration blends
(d) : HAC blended with 10% & 50% CSA-B and CSA-C seperately,HAC with 10% special cements have also been studied with additional gypsum mixing.

Table - 1 : Chemico-mineralogical characteristics of basic ingredients of blends

METHODOLOGY

All the above formulations were subjected to different tests for evaluation which are indicated below :

a) Neat cement pastes (W/C 0.4) were cast and the hardened cement pastes were demoulded at designated period such as 1 day, 3 days and the samples were washed in alcohol and vacuum dried to prevent any continuance of hydration. These samples were subjected to X-Ray diffraction analysis with scanning speed of 0.2° two theta per minute using a Siemens D-500 X-Ray Diffractometer. Selected samples were also observed under Jeol JSM 5400 Scanning Electron Microscope to observe the presence/development of hydrated phases and their morphology.

b) Setting Time was determined with the help of a Vicat Apparatus.

c) Compressive Strength was determined on samples prepared with A/C 3.0 & W/C 0.4. As some amount of expansive property was expected in these mortars, prism of 40X40X160 mm were restrained from all sides till the age of the test.

d) Expansion Test was carried out with the same mortar that was used for strength test.

e) Low temperature effect was studied on the calcium sulpho aluminate and calcium fluoro aluminate cement formulations for the strength development at temperatures down to -5°C.

RESULTS

Ordinary Portland Cement Blends

The trends of variation of compressive strengths of OPC blends at early ages are depicted in Fig. 1(a) & (b). Considering the strengths of reference OPC as 100% at 1,3 & 7 day the relative quantitative variations of strengths of 10% and 50% blends are shown in Table 2. From this table it is evident that when 10% or 50% of HAC or CAC is blended with OPC, the fall in strength is seen right at 3 days hydration but the fall maintains thereafter at the same sort of level in both the situations. Increase in the percentage of the aluminate cements does not reflect in any detectable difference, although the purity of the aluminate cements does affect the magnitude of the strength deterioration.

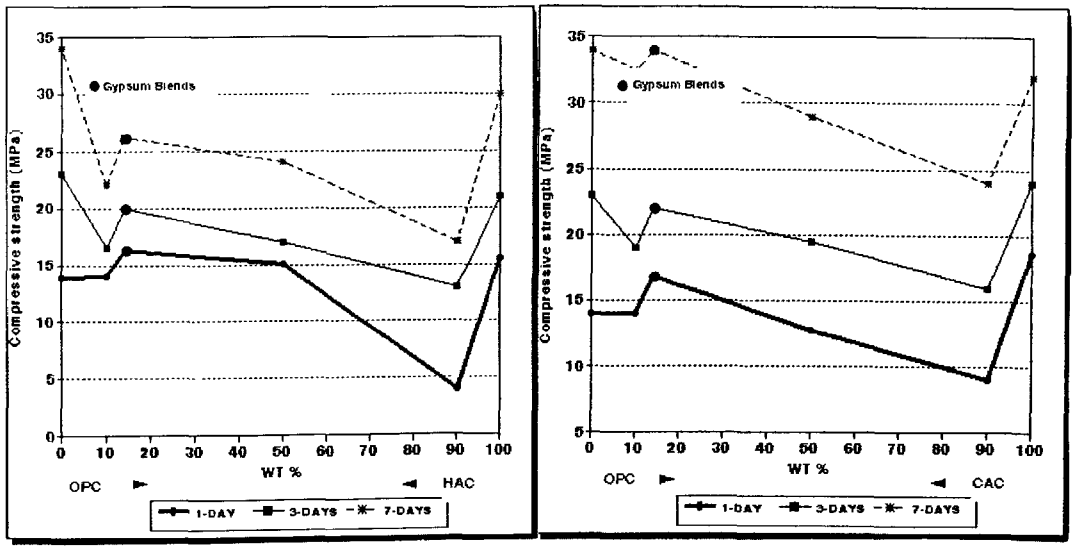

Table 2 OPC System : OPC + Basic Cement :
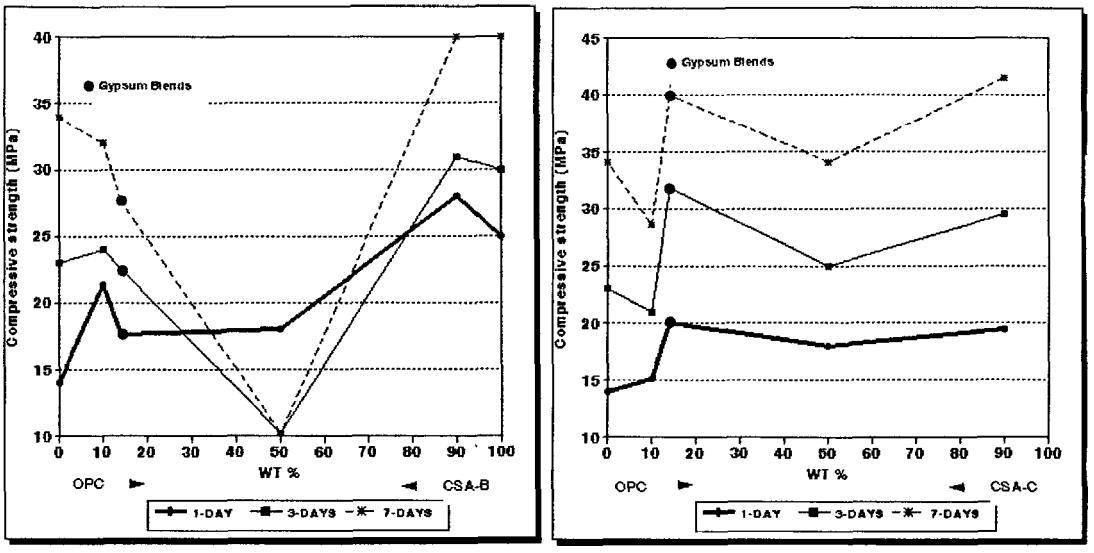
Relative quantitative variation of strengths (% of OPC Strength)

OPC + Basic + Gypsum	50 : 50 : 00 Blend			90 : 10 : 00 Blend			86 : 9.5 : 4.5 Blend			10 : 90 : 00 Blend		
	1D	3D	7D	1D	3D	7D	1D	3D	7D	1D	3D	7D
OPC + HAC	108	74	71	108	101	72	65	116	87	29	56	50
OPC + CAC	91	85	85	91	100	73	96	120	96	64	70	70
OPC + CSA -B	129	44	30	129	108	91	94	126	98	200	135	117
OPC + CSA -C	129	109	100	129	152	104	84	144	139	139	128	122
OPC + CFA	168	117	97	168	133	107	100	139	144			

On the other hand the blending of 10% and 50% CSA-B and CSA-C indicates more erratic trend in strength characteristics.Fig.1(c) & (d).While immediately after 24 hours of hydration there is generally an increase but later there is progressive deterioration; the strength reduction in the case of 50% blends of CSA-B is quite precipitous.



The hydration related information of the above blend systems is summarised in Table 3 &4. The substantial reduction in setting time in all blends and progressively increasing expansions both in free and restrained state in blend with 50% CSA-B, 10% CSA-C & 50% CSA-C are worth noting. These properties need to be seen in the context of formation of hydrated phases in these blends.

Among the hydrated products the C-S-H gel phases, although seen with the help of SEM, could not be detected by XRD owing to their amorphous poorly crystalline nature. Only crystalline hydration products were identified by XRD. As can be seen from the Table 4, 50% & 10% CSA-C blends show major Ettringite phase both at 1 & 3 days. Whereas in the case of 50% CSA-B Ettringiee formed on 1 day gets partly converted to monosulphate on third day,further part of C_4A_3S phase still remains as unhydrated phase.

On addition of 1% Superplasticiser to OPC + CSA-C blend with 4.5% gypsum, complete rheology of the mix changed from a plastic to flowable, and gave a working time of 30 minutes and compressive strength rise of 20 - 25% at 1 & 3 days compared to blend without superplasticiser. A SEM photograph showing formation of Ettringite phase in the cement paste is shown in Fig 3.(a).The OPC blends with CSA-B & CFA set and gain strength even at low temperature although the rise is slow. This property is not observed in OPC as can be seen in Table 5.

High Alumina Cement Blends

The trends of variation of compressive strengths of HAC blends at early ages are indicated in Fig.2. Considering the strength of reference HAC as 100% at 1,3 & 7 day, the relative quantitative variations of strength of various blends with CSA-B & CSA-C are shown in Table 6. From Table 6 it is evident that all the HAC & CSA-B blends are more or less steady and higher strength potential right from 1 day to 3 days, hydration but in the case of HAC+ CSA-C blends fall in strength is seen right from 1st day in the case of 50% blend and the blend with gypsum.

(a) **(b)**

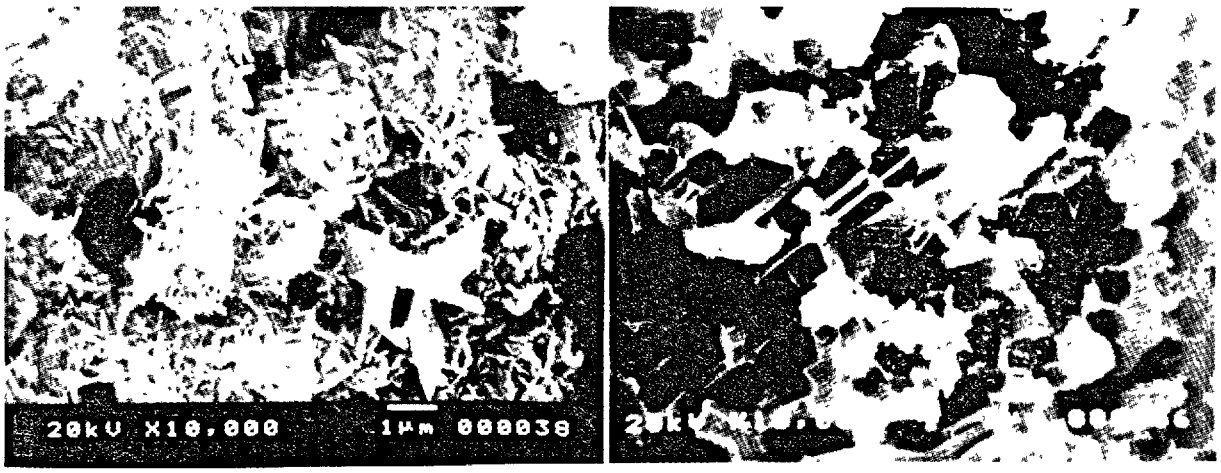

Fig 2 Variation of compressive strength of HAC blends
(a) HAC & CSA-B blends (b) HAC & CSA-C blends

The hydration related information of the blend system is summarised in Table 7. In the case of 50% CSA-B Ettringite appears as a steady phase both at 1D & 3D hydration along with appearance of Monosulphate at 1 day, the latter slightly increases but the strength fall is not seen This may be due to substantial formation of Stratlingite right from one day which remain unchanged even after 3 days hydration (Fig. 3b) which may be responsible for slight gain in strength from 1 to 3 days, however, no evidence of conversion of aluminate phases was noticed. But in 50% blend with CSA-C no Ettringite is seen and Monosulphate appears right at 1st day and is responsible for the erratic trend in strength.

In these systems there appears substantial reduction in setting times in all the blends and progressive increase in the expansion values as the percent CSA-B or CSA-C increases in HAC and part conversion of Ettringite to Monosulphate is seen at 3day hydration in almost all the cases.

CONCLUSIONS

- In the specially tailored blends of OPC with other binders like Calcium Aluminate or Calcium Sulphoaluminate based cements, the original phase assemblage of the latter assumes critical significance. The presence of aluminates other than CA in the aluminate cements or presence / absence of belite along with Calcium Sulphoaluminate requires a careful consideration in achieving the desired setting, hardening and expansion characteristics.
- The supplementary influence of gypsum separately incorporated in certain blends or the use of superplasticisers in some often significantly alter the strength properties and workability respectively.
- For low temperature applications appropriate blends can better be based on either sulphoaluminate or fluoroaluminate cements.
- In all OPC based blends there was virtual absence of crystalline CSH phase and in all HAC blends studied the nonappearance of C_3AH_6 is also worthy to note.
- The optmisation of setting characteristics, strength properties and expansion behaviour appears easier if the trend of appearance of hydrated phases are considered.

EFFECT OF GYPSUM ON THE HYDRATION OF ALITE AND BELITE

Hirotaka USHIYAMA Yoshiyuki SHIGETOMI and Yasushi INOUE, Cement/Concrete & Building Materials Research Laboratory, Tokuyama Corp., Tokuyama, Yamaguchi, Japan

ABSTRACT The effect of gypsum on the hydration of alite and belite was investigated. Mixtures of alite or belite with gypsum were mixed with water at 0.5 w/c. The experiment was carried out by means of XRD, DTA, EPMA and chemical analysis, and also the compressive strength developement of the paste was measured

INTRODUCTION

Gypsum in portland cement plays an important role for the hydration of C_3A, so there are many papers related to the hydration of C_3A clinker-gypsum system. And there are not so many papers related to the hydration of calcium silicate clinker-gypsum system(Yamaguchi et al, 1959, Benture, 1976), however it is also important to investigate the hydration of this system in order to make more clear the role of gypsum on the hydration of portland cement. In this paper the effect of gypsum on the hydration of calcium silicate clinker is investigated, comparing the effect on the hydration of alite and that of belite.

EXPERIMENT

Synthesis of alite and belite

Based on the paper by Yamaguchi(1968), the raw mixtures for synthesizing alite and belite were prepared respectively from chemical grade reagents and heated in electric furnace. Alite:Raw mixture for Alite was heated three times at 1500℃ for two hours with intermediate grinding and finally groud to 3000cm²/g of Blaine value. Belite:Raw mixture for belite was heated at 1500℃ for two hours, cooled and heated at 1000℃ for one hour. This product(Belite-1 or B-1) was found to be β-C_2S and not to contain interstitial phase like as C_3A by XRD. However, by EPMA analysis B-1 was found to contain a very small amount of interstitial phase. This phase was eliminated by KOSH solution (Gutterridge, 1978), and the product was heated at 900 ℃ for 1 hour , then Belite-2(or B-2) which did not contain interstitial phase was obtained. B-1 and B-2 were ground to 3000cm²/g of Blaine value respectively and B-2 was also found to be β-C_2S XRD. The chemical compositions of alite, belite-1 and belite-2 are shown in Table 1.

Experimental method

Chemical grade gypsum was added to alite and belite so as to get SO_3 content(=SO_3/alite or belite weight ratio)being 0, 1, 2, 3, 5 or 7%. Hydration temperature was 20℃, and water to solid ratio was 0.5 in all experiment. The hydration degree was determined by XRD internal standard method with Al_2O_3.

Table-1 Chemical Ccmposition (wt%)

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O
Alite	26.1	1.2	-	71.6	1.0	-	-
Belite-1	32.5	2.8	1.2	62.7	0.5	0.2	0.1
Belite-2	33.8	1.3	0.7	63.5	0.5	0.1	0.1

RESULTS AND DISCUSSION

Hydration of alite

As is shown in Fig 1 the hydration of alite was accelerated by addition of a small amount of gypsum, and was most accelerated in case of SO_3 content of 1～2%. The degree of hydration, however, shows an increase below 10%. In SO_3 content of more than 2% the hydration degree becomes smaller with increase of SO_3 content. This tendency was also seen

in the amount of $Ca(OH)_2$ produced as shown in Fig 2. But, as to combined water this tedency was not clearly seen as shown in Fig 3.

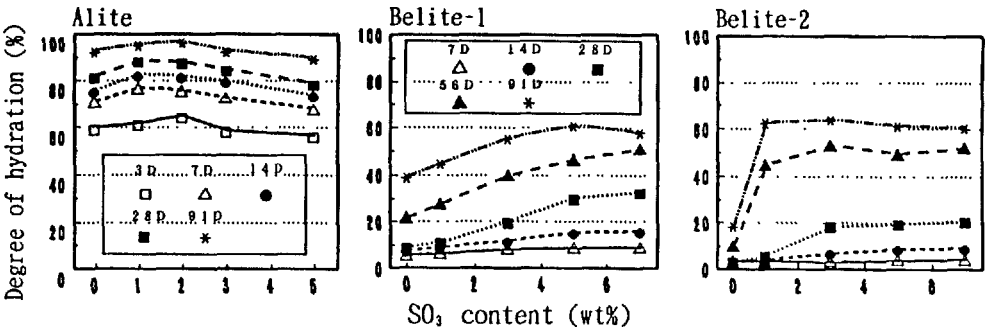

Fig. 1 Effect of gypsum content on the degree of hydration

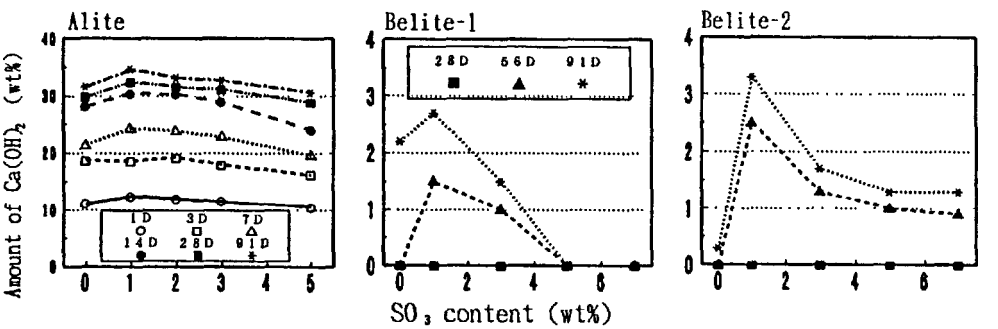

Fig. 2 Effect of gypsum content on the amount of $Ca(OH)_2$ produced

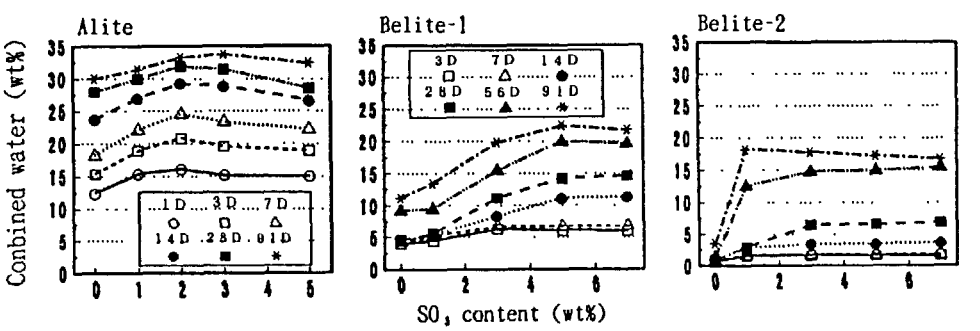

Fig. 3 Effect of gypsum content on combined water

Hydration of belite

As is shown in Fig 1 , even though the SO_3 content is increased to 7% the hydration of B-1 and B-2 in 7 days is not almost accelerated. In 28 to 91 days, however, the hydration is largely accelerated by addition of gypsum. This tendency is seen in combined water as shown in Fig 3. However, this tendency is not seen in $Ca(OH)_2$ produced, that is, in SO_3 content of more than 1% the amount of the produced $Ca(OH)_2$ is decreased with increase of SO_3 content as shown in Fig 2. This is considered to be due to formation of ettringite. By comparison of the hydration of B-1 and B-2 within small SO_3 content, B-2 is influenced more largely than B-1. That is, in SO_3 content of 1% the hydration of B-2 is largely accelerated in 56 to 91 days and even though SO_3 content is increase to more than 1% the hydration degree does not become larger than that in SO_3 content of 1%.

On the other hand the hydration degree of B-1 in 56 to 91 days was affected by SO_3 content, that is , the more the SO_3 content the larger the hydration degree. This means that gypsum added to B-1 was consumed for formation of ettringite and little amount of gypsum remains for accelerating the hydration of belite. It is considered that a small amount of gypsum is sufficient for accelerating the hydration of belite without interstitial phase.

Compressive strength of paste

The highest strength of alite paste is shown in SO_3 conten of 1 to 2 %, and in more than 3 % the strength lowers with the insrease in SO_3 content. The paste strength of belite becomes higher with the increase in SO_3 content as shown in Fig 4.

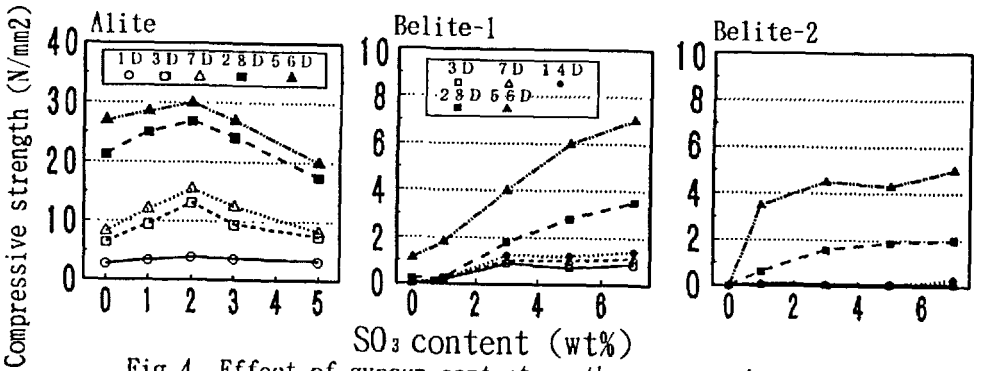

Fig. 4 Effect of gypsum content on the compressive strength

Results of EPMA analysis

Photo 1 shows the back scattered electron images and the EPMA images of S element distribution of the alite- and belite-paste (SO_3 content=5%) before and after hydration. For the alite, gypsum almost disappears already in 7 days and S disperses uniformly in the whole area. On the other, for the belite-2, gypsum remains in initial grain size even in 28 days. These results coincides with those of XRD analyses in Table 2.

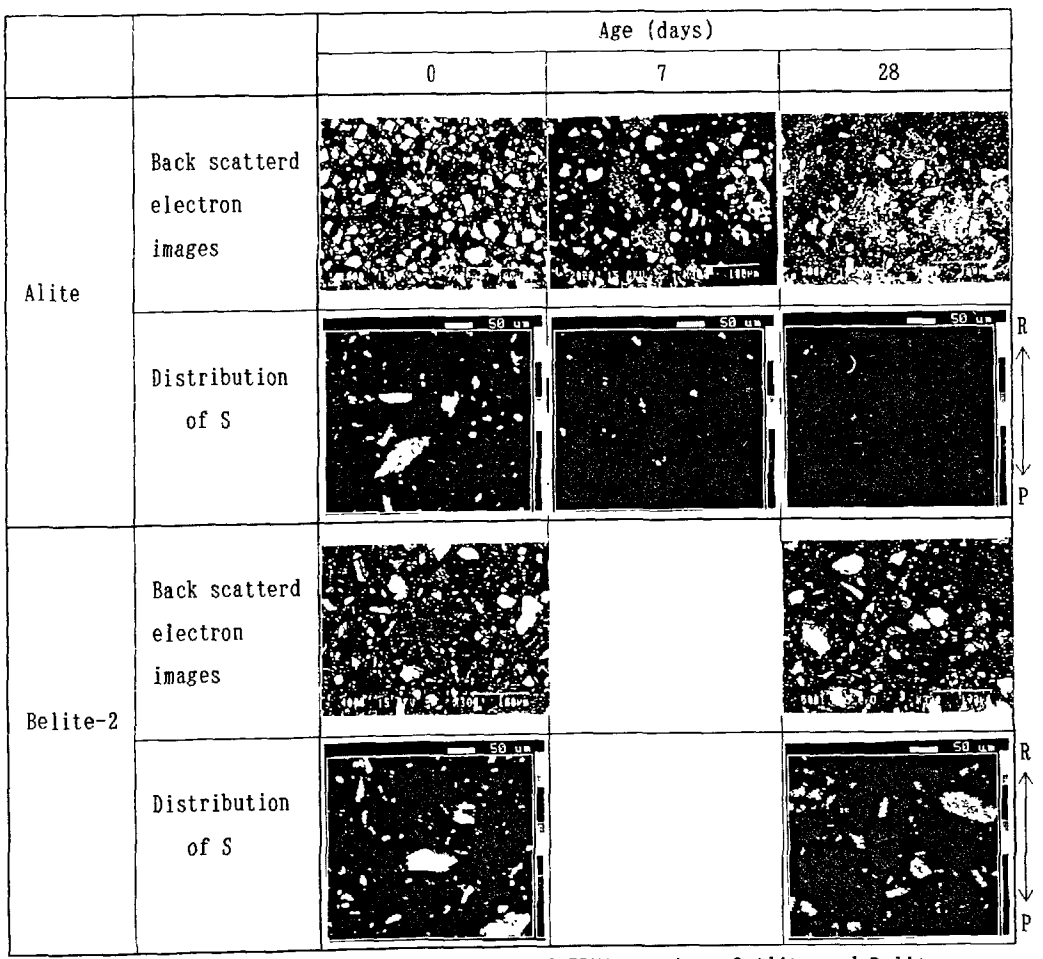

Photo. 1 Back scatterd electron images and EPMA mapping of Alite and Belite

(R:Rich P:Poor)

Discussion on the action of gypsum on alite and belite hydration

Odler(1980) investigated the interaction between gypsum and the CSH-phase formed in C_3S hydration and stated that SO_4^{2-} ions from gypsum are physically adsorbed to the surface of the CSH-phase and an equilibrium exists between the amount of SO_4^{2-} ions adsorbed and the calcium sulphate concentration in the liquid phase. It is also considered that in the hydration of alite-gypsum system amorphous gypsum is produced by combination of Ca^{2+} ion from the hydration of alite and SO_4^{2-} ion from gypsum added initially. In any case it is considered that SO_4^{2-} ion concentration in the liquid phase is rather high , even though not so high as that in the saturated gypsum solution. Consequently it is considered that relatively many SO_4^{2-} ions are liable to move in the liquid phase especially because of mutual diffusion of SO_4^{2-} and OH^-. It is also considered that through the gel pore a part of SO_4^{2-} ions are able to move to the surface of alite grain which have not yet hydrated, affects the surface and accelerates the hydration (Kondo, 1975).

G:Gypsum E:Ettringite M:Monosulphate -:no detect

In case of much addition of gypsum:The hydration type of alite after accelerating period is rather diffusion-controlling (Fujii, 1978). If gypsum is added too much, the gel pore would be blocked with sulphate hydrate, therefore water would not be able to diffuse easily to the unhydrated surface and the hydration would be delayed. On the other hand the hydration type of belite after accelerating period is rather reaction-controlling. Thererfore even though gypsum is added too much the hydration acceleration would not be prevented.

CONCLUSION

Effect of gypsum on the hydration of alite and belite was studied. The results obtained are as follows.

(1) The hydration of alite is accelerated by addition of a small amount of gypsum. The hydration is most accelerated in SO_3 content of 1 to 2%, and in SO_3 content of more than 2 % the degree of hydration lowers with increase of SO_3 content.

(2)The hydration of belite is not almost accelerated in 7 days even though SO_3 content is increased to 7%. In 28 to 91 days the hydration was largely accelerated by adition of gypsum. SO_3 content of 1% is sufficient for accelerating the hydration of belite-2 which does not contain interstitial phase. SO_3 content of more than 1% does not prevent the hydration to be accelerated.

(3)The paste compressive strength of belite becomes higher with increase in SO_3 content.

THE EFFECT OF C_3S ON THE HYDRATION OF C_3A

E. EL AOUNI, CPR SOUISSI BP 6210 Rabat-Instituts 10101, Rabat, MOROCCO
M. BENKADDOUR, Département de Physique, Faculté des Sciences, Oujda, MOROCCO

ABSTRACT The cubic phase coming from the hydration of C_3A appears since the first minutes with the hexagonal phases. After 24 h, it is probable that some water is not only adsorbed, but strongly bound as in a hydrate. In the presence of C_3S, two new phases are observed by DTG. The calcium hydroxide coming from the hydration of C_3S is probably less crystalline, and less stable towards thermal decomposition, than that coming from hydration of free CaO.

Key-words: C_3A+C_3S, Hydration, DTG, X-ray Diffraction Analysis, Calorimetry

INTRODUCTION

It is usually admitted that the first products of C_3A hydration are the hexagonal hydrates C_2AH_8 and C_4AH_{13} which are metastable. They transform later into the cubic hydrate C_3AH_6 which is more stable. A disagreement exists between different researchers about the time of this conversion (Breval, 1976; Collepradi et al, 1978; Tashiro and Oba, 1980; Ramachandran and Mei, 1987). Ramachandran and Mei (1987) found a DTG and DSC peak at about 100°C which the attributed to the adsorbed water. However, we found only few investigations concerning hydration of C_3A+C_3S (Corstange et al, 1973; Ghorab et al, 1988). The aim of the present paper is a contribution to the C_3A hydration alone and in the presence of C_3S in comparison with the literature.

EXPERIMENTAL PROCEDURE

Materials

C_3A and C_3S are synthesized from reagent grade $CaCO_3$, Al_2O_3 and SiO_2, by heating the mixtures in appropriate molar ratios. Sometimes we have noted that C_3S was slightly green. Probably the platinum of the crucible (or its oxide) diffuses into C_3S causing this colour (Amossé and Allibert, 1991). Experiments are carried out to establish this hypothesis. C_3A+C_3S was prepared by grinding the sample in a laboratory mill to a Blaine specific surface of about 300 m^2/kg.

Methods

TG and DTG curves of pastes with w/s = 0.5 were obtained by a thermoanalysator G70 SETARAM. The heat development was measured by a Biocalorimeter BCP ARION for pastes with w/s = 1. XRD patterns of the samples were obtained by a Rigaku diffractometer completely automated.

RESULTS AND DISCUSIONS

Fig 1 shows TG and DTG curves of C_3A hydrated for 15 min. The peak at 100°C is attributed to the desorption of water. This result is not in agreement with the view of researchers who suggest that this peak is present only in the presence of admixtures (Milestone, 1977; Sersale et al, 1980). It is also in disagreement with the result of a work in which this peak is particularly evident in the presence of hexagonal hydrates (Monosi et al, 1983). This peak increases up to 16h, after which it decreases. Probably, water is strongly bound. But it is important to note that the cubic hydrate C_3AH_6 appears simultaneously with the hexagonal phases (peaks at 320 and 500°C). This result is not in agreement with a lot of workers (Breval, 1976; Collepardi et al,

1978; Tashiro and Oba, 1980). The formation of C_3AH_6 soon after is probably due to the important heat rate of hydration. Fig 1 depicts also the peak attributed to the hexagonal phases (180°C). XRD confirm the result of DTG (Fig 2).

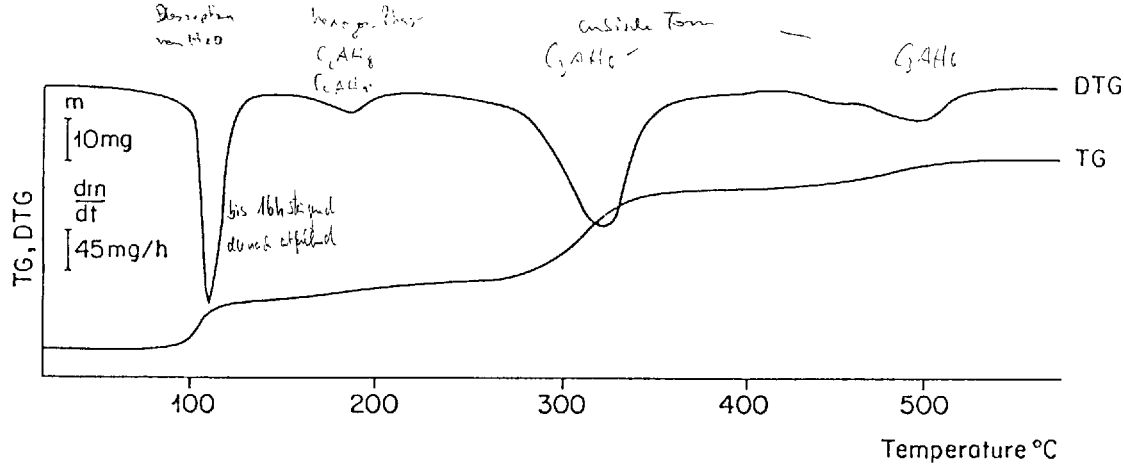

Figure 1 TG and DTG curves of C_3A hydrated for 15 min.

The rate of heat evolution as a function of time shows a large peak during the first 30 min (Fig 3). In the presence of C_3S this peak decreases when the amount of C_3S increases. When the time of hydration increases, two new phases are observed by DTG. The first one can be detected as a peak at 170°C. This peak present in the beginning, seems to disappear at 24h. The second one is observed by the splitting of the peak at 320°C (Fig 4). Water is not adsorbed. The dissolution of Ca^{2+} must be very important. The appearance of these two phases can be related to the work of other researchers (Regourd et al, 1976).

For certain mixtures two peaks were observed around 500°C corresponding to CH. We concluded that CH coming from C_3S hydration probably is poorly crystallized and less stable (Fig 5). Investigations on C_3A+C_3S synthesized simultaneously are carried out.

A STUDY ON THE HYDRATION ACTIVITY OF ALITE CONTAINING $\overline{F}$ AND $\overline{S}$

YE Qing,
Department of Civil Engineering, Zhejiang University of Technology, Hangzhou 310014, P.R.China

ABTRACT The hydration activity of Alite containing $\overline{F}$ and $\overline{S}$ in a series of Alite-CaF_2, Alite-$CaSO_4$ and Alite-CaF_2-$CaSO_4$ systems was studied by XRD, SEM/EXAD, QXDA, DTA, conductive calorimeter and chemical analysis. Results indicated that hydration activities of Alite ($\overline{F}$), Alite ($\overline{S}$) and Alite ($\overline{F}$, $\overline{S}$) were obviously influenced by the solid solubility of $\overline{F}$ and $\overline{S}$. The early hydration activity of Alite ($\overline{F}$) was very poor and could be improved by the substitution of $\overline{S}$ in Alite ($\overline{F}$). Furthermore the particularly combined substitution of $\overline{F}$ and Fe_2O_3 in C_3S was the source of reducing the early hydration activity of Alite ($\overline{F}$). The results suggest that as compound mineralizer both gypsum and fluorite may be used in manufacture of cement by low temperature burning technology.

Key-words: Alite, Calcium fluoride, Hydration

INTRODUCTION

Al_2O_3 and Fe_2O_3 act as fluxing agents in the CaO-SiO_2 system, thus reducing the appearance point of liquid phase to 1338 ℃ and quickening the reaction of C_3S synthesis. However, the introduction of fluxing agents cannot change the basic law of thermodynamics so that in this system C_3S can only be synthesized at a temperature higher than 1250 ℃. The introduction of mineralizer CaF_2 causes the formation of C_3S containing $\overline{F}$ and the appearance of liquid phase at 1185 ℃ (Tanaka, 1968). Hence, the presence of $\overline{F}$ leads to a variation of liquid phase characteristics in this system, and the solid solution of $\overline{F}$ causes the change of the thermodynamic performance of the C_3S crystal. Meanwhile, it will be definitely accompanied by a change of C_3S crystal texture and hydration activity (Gutt,1968 and YE, 1992). CaF_2 and $CaSO_4$ act not only as effective mineralizers, but also act as fluxing agents in the production of cement. It is possible to sinter portland cement clinker at a low temperature, in this way. The purpose of this study was to research the hydration activity of Alite containing $\overline{F}$ and $\overline{S}$, namely Alite ($\overline{F}$), Alite ($\overline{S}$) and Alite ($\overline{F}$, $\overline{S}$). This study was identified as being useful to the production of cement at a low temperature.

PREPARATION OF SPECIMENS AND TESTING METHODS

Preparation of specimens

Pure C_3S was synthesized at 1650 ℃ and its crystal type was T_1. Alite was synthesized from the above C_3S by addition of 1%Al_2O_3 ,1%Fe_2O_3 and 1%MgO at 1350 ℃ and its crystal type was M_2. Specimens of Alite or C_3S containing $\overline{F}$ and $\overline{S}$ [Alite ($\overline{F}$), Alite ($\overline{S}$) and Alite ($\overline{F}$, $\overline{S}$)] were synthesized from the above Alite or C_3S by addition of CaF_2 or $CaSO_4$ at 1350 ℃. The compounds used were all of analytical by pure grade.

Experimental methods

Microstructure analysis

The specimens were subjected to XRD, QXDA and chemical analysis. Parts were also analysed by XPS, SEM/EDAX and high temperature microscope in order to determine the crystal type, solubility and purity of these specimens.

Testing hydration activity during early hedration

Rates of heat evolution during the early hydration (36 hours) were determined by conduction calorimetry under the testing condition of specific surface area of samples 300-350m^2/Kg (Blain), water-cement ratio 0.80, and curing temperature 20±2 ℃.

Testing the degree of hydration

Hydration degrees of Alite containing $\overline{F}$ and $\overline{S}$ were tested by determing $Ca(OH)_2$ quantitatively by QXDA under the testing condition of the specific surface area 300-350 m^2/Kg,water-cement ratio 0.30, curing temperature 20±2 ℃ and relative humidity > 90%.

Testing strength development

The strength development was determined by testing compressive strength on cubic specimens with 20mm length under the testing condition of the specfic surface area 300-350 m^2/Kg, water-cement ratio 0.30 cruing temperature 20±3 ℃ and relative humidity > 90%.

Equipment and testing conditions

1. X-ray diffraction analyser: D/Max-A type, (Cu target used) tube electric current 100mA, tube voltage 40 KV.
2. X-ray photoelectron spectroscopy analyzer: KA-ES-300 type.
3. Scanning electron microscope: ASM-SX type, its energy spectrum is EDAX-9100.
4. Conduction calorimeter: made by Building Materials Academy of China.

Code names of samples

Code names AFi, ASj and iAj represent samples of Alite ($\overline{F}$) (Alite containing or added with i% CaF_2), Alite ($\overline{S}$) (Alite containing or added with j% $CaSO_4$) and Alite ($\overline{F}$, $\overline{S}$) (Alite containing or_added with i% CaF_2 and j% $CaSO_4$), respectively. Alite represent C_3S solid solution containing 1%Al_2O_3, 1%Fe_2O_3 and 1%MgO. $\overline{F}$ and $\overline{S}$ represents $F^-$and SO_3 respectively.

RESULTS AND DISCUSSION

Analysis of crystal structure

The crystal types of Alite ($\overline{F}$), Alite ($\overline{S}$) and Alite ($\overline{F}$, $\overline{S}$) are illustrated in Fig.1. The crystal type and coloring phenomenon of Alite ($\overline{F}$) show: M_2, greenish-grey (pure Alite) → M_3, deep iron red (Alite containing 1% CaF_2) → R, dark red (containing > 2%CaF_2). Therefore $\overline{F}$ was a stabilizer for high temperature crystal type of Alite. The solid solution of $\overline{F}$ made Alite ($\overline{F}$) colored and its color was changed from greenish-grey into dark red with the solubility of $\overline{F}$ increased. The limit solubility of $\overline{F}$ in Alite was 1.5% (namely 3.4% CaF_2). The crystal type and color of Alite ($\overline{S}$) show: M_2, greenish-grey (pure Alite) → M_2, greenish-grey (Alite

containing 1% $CaSO_4$) → M_1, greenish-grey (containing > 2% $CaSO_4$). The crystal type of Alite ($\overline{S}$) was decreased and the colors of all Alite ($\overline{S}$) samples were greenish-grey with the solubility of S increased. The limit solubility of $\overline{S}$ in Alite was 2.2% (namely 4.0% $CaSO_4$). The variable law of crystal type and coloring phenomenon of Alite ($\overline{F}$, $\overline{S}$) was determined mainly by $\overline{F}$ solubility, for instance, M_2, greenish grey [Alite ($\overline{F}$, $\overline{S}$) containing 0% CaF_2 and 1% $CaSO_4$] → M_3, pink (containing 1% CaF_2 and 1% $CaSO_4$) → R, iron red (containing 2% CaF_2 and 1% $CaSO_4$). The curve of limit solubilities of $\overline{F}$ and $\overline{S}$ in Alite was obtained (the imaginary line in Fig.1). The color of Alite ($\overline{F}$, $\overline{S}$) became lighter with the solubility of $\overline{S}$ increased.

Hydration activity of Alite ($\overline{F}$)

Rate of heat evolution during early hydration

Fig.2 and Tab.1 show the heat evolution curve for control sample Alite and Alite ($\overline{F}$) determined by conduction calorimetry. The final time of induction period of Alite was 3.0h and the final time (the main heat evolution peak) of acceleratory period 15.0h. The rate of main heat evolution peak $(dQ/dt)_m$ was 6.39 W/Kg and the heat evolved during early 36 hours Q_{36} was 3.80×10^5 J/Kg. But all samples of Alite ($\overline{F}$) (AF0.5, AF1, AF2 and AF3.5) did not reach the final time of induction period during early 36 hours. It indicates that the early hydration activity of Alite containing $\overline{F}$ was very poor.

Degree of hydration

Fig.3a shows degrees of hydration obtained by QXDA for Alite and Alite ($\overline{F}$). At the ages of 1, 3 and 7 days hydration degrees of Alite ($\overline{F}$) samples AF0.5, AF1, AF2 and AF3.5 were much lower than one of control sample Alite. At 1-day age hydration degrees of all Alite ($\overline{F}$) samples were 6%, much lower than one of Alite 30%. At 3-day age degrees of AF0.5, AF1, AF2 and AF3.5 were respectively 30%, 30%, 14% and 12%, lower than one of Alite 49%. At 7-day age, the distinction of hydration rate between low and high solubility of $\overline{F}$ was obviously shown, and the degrees of hydration for AF0.5, AF1 and AF3.5 were respectively 71%, 64% and 20%. At 28-day age the degrees of all Alite ($\overline{F}$) samples were almost equal to one of Alite. It is clear that the incorporation of $\overline{F}$ into Alite affected the early period of hydration and did not affect the later period.

Compressive strength

The hydration process of Alite ($\overline{F}$) sample AF3.5 was much unusual. At 3-day age AF3.5 had not completed its induction period. Its 7-day compressive strength was 17.6 MPa, much lower than the one of Alite 41.2 MPa. But its 28-day compressive strength was 66.7 MPa, higher than one of Alite 61.7 MPa (shown in Tab.2).

Hydration activity of Alite ($\overline{S}$)

Rate of heat evolution during early hydration

The final time of induction period of Alite ($\overline{S}$) sample AS4 was 5.5h, more than one of Alite 3.0h (shown in Fig.2) and its final time of acceleratory period 18.0h, more than one of Alite 15.0h. $(dQ/dt)_m$ of AS4 was 6.89W/Kg, more than one of Alite 6.39W/Kg. Because of its high heat evolution rate in deceleratory period, Q_{36} of AS4 was 4.51×10^5 J/Kg, much more than one of Alite 3.80×10^5 J/Kg. It is clear that the incorporation of $\overline{S}$ into Alite delayed the

1A3	1.0	3.0	M_3	10.2	23.0	6.46	409.0
CFeF1	1.0	1% Fe_2O_3	R	> 36	/	/	42.3

acceleratory period 2 hours.

Degree of hydration

At 1-day and 3-day ages the hydration degrees of Alite ($\overline{S}$) sample AS1, AS3 and AS4 were almost equal to one of Alite. But at 7-day and 28-day ages their hydration degrees were a little lower than one of Alite (Fig.3b).

Compressive strength

The 3-day, 7-day and 28-day compressive strengths of Alite ($\overline{S}$) sample AS4 were respectively 28.3, 38.2 and 58.5 MPa, and were almost equal to one of Alite (Tab.2).

Hydration activity of Alite ($\overline{F}$, $\overline{S}$)

Rate of heat evolution during early hydration

The hydration reaction of Alite ($\overline{F}$, $\overline{S}$) sample 1A3 was delayed in comparison with Alite and Alite ($\overline{S}$) sample (shown in Fig.2). Its final time of induction period was 10.2h and its final time of acceleratory period 23.0h, and its $(dQ/dt)_m$ was 6.46W/Kg. Becaus of its high rate of heat evolution in deceleratory period, its Q_{36} was 4.09×10^5 J/Kg, more than one of Alite. In comparison with AS4, the heat evolution curve of 1A3 after induction period broadly resembled the curve of AS4 and was delayed for 5.0h. $(dQ/dt)_m$ 6.46W/Kg of 1A3 was almost equal to $(dQ/dt)_m$ 6.89W/Kg of AS4 and the time 12.5h of 1A3 undergoing acceleratory period was almost equal to the time 12.8h of AS4. The sample Alite ($\overline{F}$, $\overline{S}$) 1A3 had both hydration property of Alite ($\overline{F}$) and the one of Alite ($\overline{S}$). The induction period of Alite ($\overline{F}$, $\overline{S}$) was long due to the very poor hydration activity of Alite ($\overline{F}$) in early hydration. Q_{36} of 1A3 overtook the one of Alite due to $\overline{S}$ solution improving hydration activity of Alite ($\overline{F}$).

Degree of hydration

At 1-day age, the hydration degree of 1A3 (shown in Fig.3c) was 21%, lower than one of Alite 30%, and the degrees of 1A1, 1A2, 2A1 and 2A2 all were under 10%. At 3-day age the degrees of all samples Alite ($\overline{F}$, $\overline{S}$) were lower than one of Alite, but the gap of the degrees between Alite and Alite ($\overline{F}$, $\overline{S}$) was reduced. At 7-day and 28-day ages the degrees of all Alite ($\overline{F}$, $\overline{S}$) were almost equal to Alite.

Compressive strength

The 3-day, 7-day and 28-day compressive strengths of Alite ($\overline{F}$, $\overline{S}$) sample 1A3 were respectively 26.7, 39.2 and 65.3MPa and were almost equal to one of Alite (Tab.2).

Hydration activity of C_3S ($\overline{F}$,F)

Rate of heat evolution during early hydration

Sample $C_3S(\overline{F},F)$ (CFeF1, namely C_3S containing 1%Fe_2O_3 and 1%CaF_2) did not reach the final time of induction period during early 36 hours like Alite ($\overline{F}$) sample AF1 (Fig.2).

Degree of hydration

At 1-day, 3-day and 7-day ages the hydration degree of CFeF1 was respectively 6.7, 18.6 and 8.1%, much lower than one of Alite. And in comparison with AF1, the degree of CFeF1 was

Tab.2 Compressive strengths of Alite containing $\overline{F}$ and $\overline{S}$

Code name of sample	Additive amount in Alite (%)		Crystal type	Compressive strength (MPa)		
	CaF_2	$CaSO_4$		3d	7d	28d
Alite	/	/	M_2	27.6	41.2	61.7

Alite	-	1.0	1.0	1.0	M_2	GG	29.8 GG	49.1 GG	70.6 GG	76.5 GG

Note: DIR means Deep Iron Red, IR means Iron Red, LIR means Light Iron Red, GG means Greenish Grey.

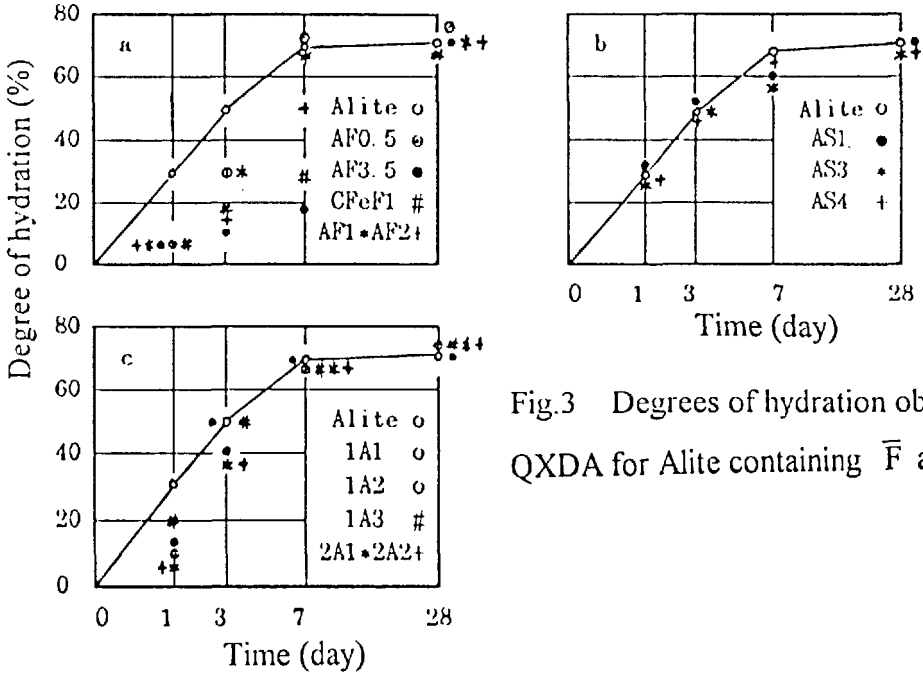

Fig.3 Degrees of hydration obtained by QXDA for Alite containing $\overline{F}$ and $\overline{S}$

almost equal to one of AF1 at 1-day age, and was much lower than one of AF1 at 3-day and 7-day ages. Till 28-day age the degree was almost equal to one of AF1 and Alite (shown in Fig.3a).

Decolorizing phenomenon of Alite ($\overline{F}$) in hydration period

With hydration degree increased, the color of sample Alite ($\overline{F}$) became lighter, from deep iron red into greenish-gey. For instance, the color of AF1 hydrate was iron red at 1-day and 3-day ages, and became light iron red at 7-day age and greenish-grey at 28-day age (show in Tab.3)

The soure of decreasing the hydration activity of Alite ($\overline{F}$) in early period

It is known that the early hydration activity of $C_3S(\overline{F})$, C_3S ($\overline{F}$,A) and C_3S ($\overline{F}$,M) was not obviously decreased (Aldous, 1983 and Nurse). In this study it was obtained that the early hydration activity of C_3S ($\overline{F}$,F) was very poor. Now it is clear that the source of very poor hydration activity of Alite ($\overline{F}$) in early period should be attributed to the particularly combined solution of $\overline{F}$ and Fe_2O_3 in C_3S. It is known in this paper that the solution of $\overline{F}$ and Fe_2O_3 in C_3S had a mutual effect, the incorporation of $\overline{F}$ into C_3S restrained the solution of Fe_2O_3 in C_3S , and the particularly combined solution of $\overline{F}$ and Fe_2O_3 made C_3S or Alite colouring. The colors of both Alite ($\overline{F}$) and C_3S ($\overline{F}$,F) were iron red whose early hydration activities were very poor and the color of their hydration samples had become lighter from iron red into greenish grey almost till 7-day or 28-day age when their hydration degrees were equal to one of Alite.

The solution of $\overline{F}$ and $\overline{S}$ in C_3S or Alite had a mutual effect and restraint. The incorporation of $\overline{S}$ into C_3S or Alite made Alite ($\overline{F}$) decoloring from iron red into pink. And according to the hydration activities of Alite ($\overline{F}$), Alite ($\overline{S}$) and Alite ($\overline{F}$, $\overline{S}$), the incorporation of $\overline{S}$ could reduce the particularly combined solution of $\overline{F}$ and Fe_2O_3, and could improve the hydration activity of Alite ($\overline{F}$).

CONCLUSION

1. The early hydration activity of Alite ($\overline{F}$) (Alite containing $\overline{F}$) was very poor and could be improved by the substitution of $\overline{S}$ (in Alite containing $\overline{F}$). The particularly combined substitution of $\overline{F}$ and Fe_2O_3 in C_3S or Alite was the source of reducing the early hydration activity of Alite containing $\overline{F}$.

2. The hydration activity of Alite ($\overline{S}$) was almost equal to one of Alite.

3. The early hydration activity of Alite ($\overline{F}$, $\overline{S}$) was poorer and its induction period was longer than one of Alite. With $\overline{F}/\overline{S}$ ratio reduced, its early hydration activity was improved.

HYDRATION CHARACTERISTICS OF $11CaO \cdot 7Al_2O_3 \cdot CaF_2$

Qijun YU and Xiuji FENG, Institute of Materials, Wuhan University of Technology, China
Shuichi SUGITA, Dept. of Civil Engineering, Hachinohe Institute of Technology, Japan

ABSTRACT The effect of temperature, fineness and water solid ratio (w/s) on the hydration properties and hydrates of $11CaO \cdot 7Al_2O_3 \cdot CaF_2$ ($C_{11}A_7 \cdot CaF_2$) were studied. With the increase of hydration temperature and specific surface its early hydration is improved and setting time shortened. At different temperatures the hydration processes of $C_{11}A_7 \cdot CaF_2$ are all in accordance with the equation of $[1-(1-\alpha)^{1/3}]^N=Kt$ even though its hydrates are varied with temperature. As w/s is increased its hydration rate is enhanced but hydrates remains unchanged.

Key-words: Fineness, Fluoride phases, Hydration, Kinetics and Temperature

INTRODUCTION

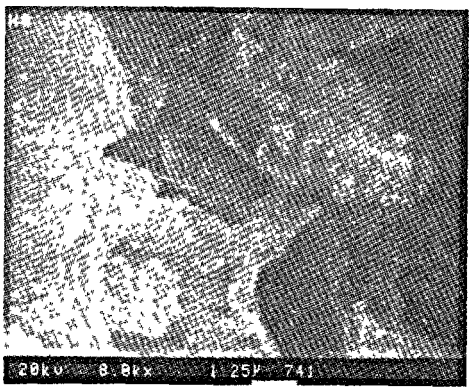
$C_{11}A_7 \cdot CaF_2$ is an important constituent of fluorine-contained cement and has a great influence on cement properties, especially the setting and early strength of cement, to which much attention was paid and many studies on its formation in cement clinkering and its effect on cement properties have been done (Wang et al., 1985, Wang et al., 1988 and Klemm et al.), but the hydration and setting characteristics of itself under different conditions have not been profoundly investigated yet. As all the calcium aluminates, such as C_3A, CA, CA_2 and $C_{12}A_7$, are different from each other in hydration and setting properties, so a thorough investigation is necessary to fully understand the hydration characteristics of $C_{11}A_7 \cdot CaF_2$.

EXPERIMENTAL AND RESULTS

Preparation of $C_{11}A_7 \cdot CaF_2$ and its hydration samples

Analytical agents of $CaCO_3$, Al_2O_3 and CaF_2 were dried at 105°C for 2hr and then ground to wholly passing a 0.06mm seive. A homogeneous mix with a mole ratio of $CaCO_3$: Al_2O_3 : CaF_2=11.00 : 7.00 : 1.08, considering a loss of 8.01% CaF_2 during the formation of $C_{11}A_7 \cdot CaF_2$ at high temperatures (Yu, 1992), was burnt at 1250°C for 2hr, then quenched to room temperature in the air of R.H. <5%, and finally ground to 202 m^2/kg, 342 m^2/kg and 453 m^2/kg of Blaine specific surface after it was identified as $C_{11}A_7 \cdot CaF_2$ by the methods of XRD and chemical analysis. Samples of hydrated $C_{11}A_7 \cdot CaF_2$ for XRD, SEM and DTA tests were made by mixing the ground $C_{11}A_7 \cdot CaF_2$ of 342 m^2/kg with distilled and CO_2 free water at a w/s of 1.0. The samples were sealed and cured at 15°C, 25°C, 30°C, 40°C and 60°C respectively to definite ages (Table 1), then they were dried at 20°C in a vacuum drier after finely ground in the presence of ethylalcohol.

Analysis of hydrated $C_{11}A_7 \cdot CaF_2$ by XRD, SEM and DTA



Hydrates exsiting in the hydrated $C_{11}A_7 \cdot CaF_2$, detected by XRD, are shown in Table 1 and no other kinds of crystalline hydrate were observed. Figs 1 and 2 are the SEM photos and DTA curves of the hydrates. Within present observations it can be concluded that the hydrates of $C_{11}A_7 \cdot CaF_2$ at different temperatures are mainly as follows:

(1) Hydrates at 15°C: The initial hydrate is CAH_{10}, which is as same as that of CA (Edmonds and Majumdar, 1988a) but different from that of $C_{12}A_7$ (Edmonds and Majumdar, 1988b). After hydrated for 2hr C_2AH_8 and C_3AH_6 are formed in sequence, and after 3d unhydrated $C_{11}A_7 \cdot CaF_2$ can not been observed by XRD. In addition, Fig 1-a and Fig 2 (H_5 and H_8) show there is also alumina gel AH_x in the hydrates. The peaks nearby 90°C and 300°C in the DTA curves are respectively attributed to the loss of adsorbed and/or enveloped water in AH_x and the decompo-

sition of C_3AH_6 in the form of: $7C_3AH_6 \rightarrow C_{12}A_7H + 9CH + 32H$. As hydration temperature rises this peak is drifted towards high temperature side. The peak ranged from 260°C to 270°C is due

to the conversion of AH_3 (gibssite) to AH. The transformation of C_2AH_8 to C_3AH_6 and AH_3 is characterized by the small band near 250°C.

(2) Hydrates at 25°C: The hydrates are C_2AH_8, C_3AH_6 and alumina gel (Table 1 and Fig 1-d). With the development of hydration the amount of C_2AH_8 is reduced and after 7d it disappears. Fig 1-e shows the well grown C_3AH_6 crystals of icositetrahedron.

(3) Hydrates at 30°C, 40°C and 60°C: The hydrates at these temperatures, whether the initial or final, are only C_3AH_6 and alumina gel, therefore larger peaks attributed to C_3AH_6 (300°C) can been observed in Fig 2 ($H_{25}-H_{36}$). Because of C_3AH_6 having a larger C/A ratio than that of CAH_{10} and C_2AH_8 more alumina gel will be formed at these temperatures, which is corresponded to the enlargement of the peak nearby 260°C in the DTA curve.

N	2.6	3.8	19.7	23.0	34.5
K	10.6×10^{-3}	8.0×10^{-3}	2.1×10^{-7}	1.3×10^{-9}	1.3×10^{-13}

Kinetics of the hydration of $C_{11}A_7 \cdot CaF_2$

For the quantitative analysis of hydrated $C_{11}A_7 \cdot CaF_2$ the internal standard method in QXRD was adopted by using α-Al_2O_3 as reference and pure $C_{11}A_7 \cdot CaF_2$, C_3AH_6 and C_2AH_8 as standard samples. The results are also shown in Table 1, but in which the amount of C_2AH_8 is not listed because it falls short of 5% in all the samples. Fig 3 shows the variation of the amount of C_3AH_6 and unhydrated $C_{11}A_7 \cdot CaF_2$ with hydration time.

By defining the percentage of hydrated $C_{11}A_7 \cdot CaF_2$ as hydration degree α it was found that α satisfactorily fit to the following equation suggested by R. Kondo et al. (1968):

$$[1-(1-\alpha)^{1/3}]^N = Kt \qquad [1]$$

where α is the hydration degree of $C_{11}A_7 \cdot CaF_2$ at time t, K is the reaction rate constant and N is the constant related to reaction mechanism. Frequently, N<1 suggests that the reaction is controlled by automatically catalytic reaction, while $N \fallingdotseq 1$ is by boundary reaction and $N \geqq 2$ is by diffusion process. Fig 4 shows ln $[1-(1-\alpha)^{1/3}]$ is linear with ln t, and from which the N and K at different temperatures can be obtained (Table 2). From Table 2 it can be seen that the hydration of $C_{11}A_7 \cdot CaF_2$ between 15°C and 60°C is dominated by diffusion process for N>2 in all the cases.

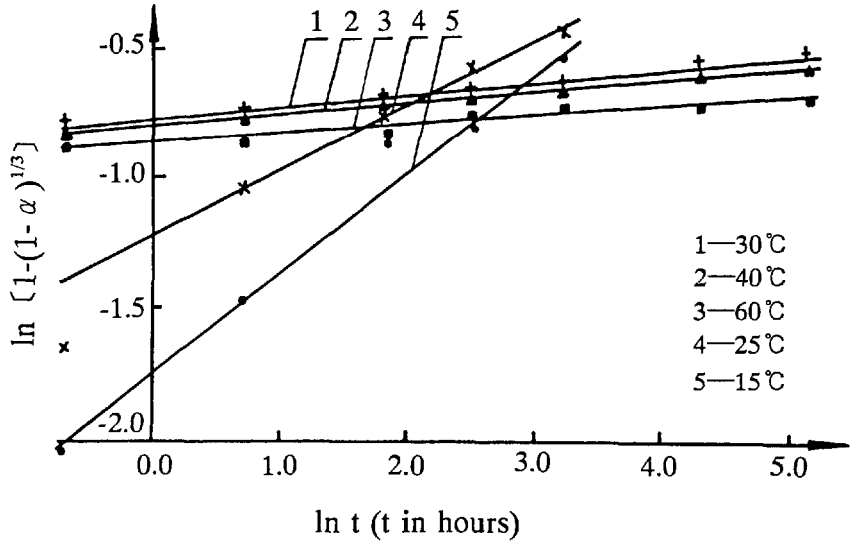

Figure 4 ln $[1-(1-\alpha)^{1/3}]$ vs ln t for hydrated $C_{11}A_7 \cdot CaF_2$ at different temperatures.

Effect of w/s and fineness on the set and hydration of $C_{11}A_7 \cdot CaF_2$

At 25°C the products of hydrated $C_{11}A_7 \cdot CaF_2$ with a w/s of 10.0 are C_3AH_6, C_2AH_8 and alumina gel. The relations between hydration time and the amount of formed C_3AH_6 and residual $C_{11}A_7 \cdot CaF_2$ are shown in Fig 5.

Table 3 Effect of fineness on the setting time (min) of $C_{11}A_7 \cdot CaF_2$ paste (w/s=0.6)

No.	Specific gravity	Blaine surface area (m^2/kg)	Initial set	Final set
S_9	2.69	202	13	23
S_{10}	2.69	342	0	10
S_{11}	2.69	453	0	5

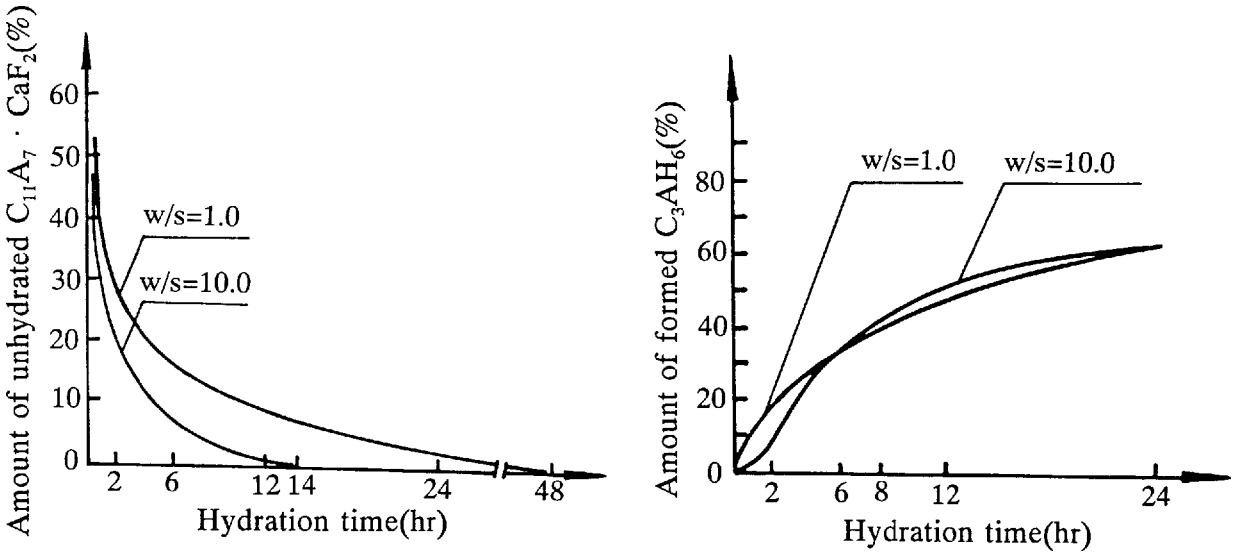

Figure 5 Amount of $C_{11}A_7 \cdot CaF_2$ and C_3AH_6 in hydrated $C_{11}A_7 \cdot CaF_2$ vs time at a w/s of 1.0 and 10.0.

The heat evolution profiles of hydrating $C_{11}A_7 \cdot CaF_2$ with different fineness are shown in Fig 6. The tests of setting time were conducted on the pastes with a w/s of 0.6 at 20°C by the Vicat apparatus. When initial set occurs within 3min after $C_{11}A_7 \cdot CaF_2$ is immersed to water the initial setting time was defined as 0min here (Table 3).

DISCUSSIONS

Effect of hydration temperature on the hydration of $C_{11}A_7 \cdot CaF_2$

Below 30°C the hydration degree of $C_{11}A_7 \cdot CaF_2$ is increased with temperature, while above 30°C it is decreased with the rise of temperature and after 5-20 hours it becomes less than those

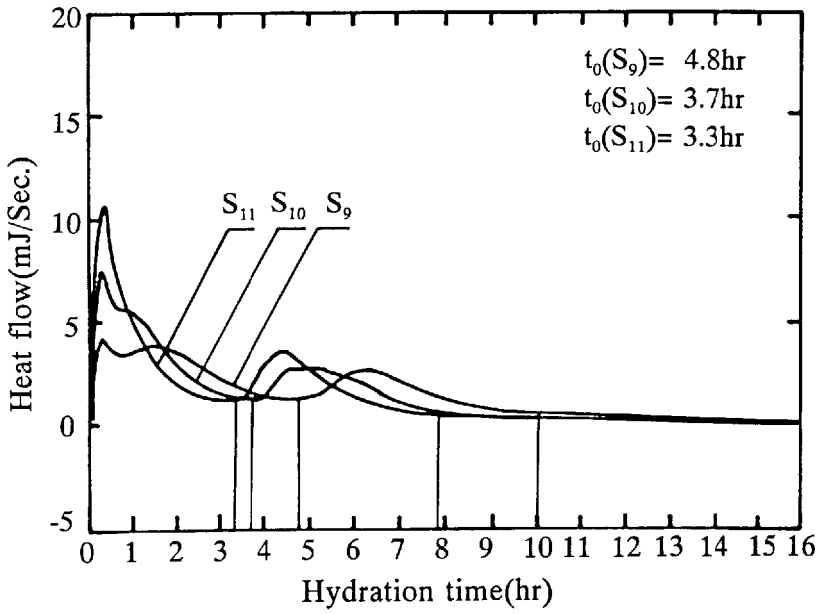

Figure 6 Effect of fineness of $C_{11}A_7 \cdot CaF_2$ on its heat evolution rate in hydration (30℃, w/s=10.0)

at 15℃ and 25℃ (Fig 3). For example, in the samples hydrated for 3d at 15℃ and 25℃ unhydrated $C_{11}A_7 \cdot CaF_2$ could not be found by XRD but in those hydrated at above 30℃ for 7d there yet exsited 6-12% of $C_{11}A_7 \cdot CaF_2$ even though at this time about 80% of $C_{11}A_7 \cdot CaF_2$ was hydrated only for 30min (Table 1). This phenomenon is similar to the variation of hydration rate of $C_{12}A_7$ with temperature observed by Edmonds and Majumdar (1988b). Why is the hydration of $C_{11}A_7 \cdot CaF_2$ retarded in adverse with temperature rise above 30℃? In our opinions this is because: (1) as hydration temperature rises its initial hydration is accelerated in a large scale and in a short time a lot of hydrates are produced, which constitute barriers on the surface of $C_{11}A_7 \cdot CaF_2$ grains and prevent the contact of them with water, (2) the increase of N in Eq 1 with temperature (Table 1). In Wu's (1988) opinion the N is dependent on reaction resistance, the larger the resistance, the bigger the N. Here the reaction resistance is primarily comprised of diffusion resistance for N>2. Thus the increase of N, i.e. the enhancement of diffusion resistance, necessarily results in the delay of hydration. The formation of compact hydrates shown in Fig 1-f gives direct evidence for the increase of diffusion resistance with temperature, (3) reaction rate constant K is decreased with the rise of hydration temperature, and (4) much water is consumed due to the formation of more amorphous alumina gel (AH_x), leading to the decrease of available water for further hydration.

On the contrary the amount of hydrated $C_{11}A_7 \cdot CaF_2$ and formed C_3AH_6 are increasing quickly with hydration time at 15℃ and 25℃, and $C_{11}A_7 \cdot CaF_2$ can hydrate completely after 3d. The reasons for this are: (1) at these temperatures no thick barriers envelope unhydrated $C_{11}A_7 \cdot CaF_2$ grains as the hydration rate is comparatively low, (2) the hydration products are large in size and with a porous structure, as shown in Fig 1-a—Fig 1-e, through which water can easily penetrate to the surface of $C_{11}A_7 \cdot CaF_2$ grains, and (3) large rate constant K is held at these temperatures.

Effect of water solid ratio(w/s) and fineness on the hydration of $C_{11}A_7 \cdot CaF_2$

From Fig 5 it can be found that the hydration of $C_{11}A_7 \cdot CaF_2$ is accelerated greatly when w/s is increased from 1.0 to 10.0. At a w/s of 10.0 $C_{11}A_7 \cdot CaF_2$ was completely hydrated only in 14 hours while there was about 8% residual $C_{11}A_7 \cdot CaF_2$ in the sample with a w/s of 1.0. The influence of w/s on the early hydration of $C_{11}A_7 \cdot CaF_2$ and portland cement was compared by Yu (1992), and greater accelerating effect of w/s on the hydration of $C_{11}A_7 \cdot CaF_2$ was observed. In the hydrating $C_{11}A_7 \cdot CaF_2$ with a w/s of 0.6-1.0 initial and final set occurred only in several minutes, coherently much water was rapidly consumed in the formation of hydrates. Furthermore, the hydrates adjacent to $C_{11}A_7 \cdot CaF_2$ grains hindered the further hydration. These phenomena have not been observed in the contorl samples of hydrated portland cement, but by rising w/s they can be greatly changed.

At 25℃ whether at a w/s of 1.0 or 10.0 the kinds of hydration products of $C_{11}A_7 \cdot CaF_2$ were the same and after hydrated for 24hr no difference in their amount of C_3AH_6 was found.

When the Blaine specific surface of $C_{11}A_7 \cdot CaF_2$ is increased from 202 m^2/kg to 342 m^2/kg its initial and final setting time are decreased from 13min to 0min and from 23min to 10min respectively (Table 3), and the first heat evolution peak, completed in 8-12 min, is enlarged evidently (Fig 6), which indicate that not only $C_{11}A_7 \cdot CaF_2$ can set very quickly but also its fineness does have a great effect on its hydration rate and setting time. The onset of the second peak in Fig 6, which corresponds to the end of induction period of the hydration, is possibly associated with the beginning of the accelerated hydration of $C_{11}A_7 \cdot CaF_2$ due to the fail of the barriers of hydrates on the surface of hydrating $C_{11}A_7 \cdot CaF_2$ grains. The relation between the heat evolution and hydration time of above samples are respectively in agreement with following equations:

S_9 : $1/P=1.54\times10^{-3} + 1.05\times10^{-2}(1/t-t_0)$, $t_0=4.8$, $\tau=6.83$, $P_\infty=705.4$, $r=0.98$ [2]

S_{10} : $1/P=1.98\times10^{-3} + 4.38\times10^{-2}(\ 1/t-t_0\ ),\quad t_0=3.7,\quad r=0.97$ [3]

S_{11} : $1/P=1.38\times10^{-3} + 6.02\times10^{-2}(\ 1/t-t_0\ ),\quad t_0=3.3,\quad \tau=4.36,\quad P_\infty=723.8,\quad r=0.98$ [4]

where P is the heat evolution (kJ/kg) at time t (hr), t_0 is the time in hours at which induction period of hydration ends, τ is the half life period (hr) of the hydration, P_∞ is the total heat output of hydrated $C_{11}A_7 \cdot CaF_2$ (kJ/kg) and r is the linear correlation factor, from which it can be known that the half life period (τ) and induction period of the hydration of $C_{11}A_7 \cdot CaF_2$ are gradually shortened with the increase of its fineness.

Hydration products of hydrating $C_{11}A_7 \cdot CaF_2$ at the time of initial and final set

At 25°C the products exsiting in the hydrated $C_{11}A_7 \cdot CaF_2$ with a w/s of 0.6 at the time when initial and final set occurred were determined by XRD and TG-DTA. Except for a large amount of unhydrated $C_{11}A_7 \cdot CaF_2$ there were only a small amount of C_2AH_8, C_3AH_6, $C_3AH_{8\text{-}12}$ and alumina gel in the both hydrates. It is just because of the rapid formation of these products that makes the paste set quickly.

CONCLUSIONS

1. At 15°C and at a w/s of 1.0 $C_{11}A_7 \cdot CaF_2$ can be nearly hydrated completely after 3d and the hydration products are mainly C_3AH_6, alumina gel and a small amount of CAH_{10}, C_2AH_8.
2. At 25°C the initial hydration products of $C_{11}A_7 \cdot CaF_2$ are C_3AH_6, C_2AH_8 and alumina gel. The C_2AH_8 will be gradually changed to C_3AH_6 with hydration time and disappear in the paste after 7d. Simultaneously amorphous alumina gel AH_x will crystallize to gibssite (AH_3).
3. At and above 30°C the hydrates of $C_{11}A_7 \cdot CaF_2$ are only C_3AH_6 and alumina gel, and its hydration degree is reduced with the rise of temperature.
4. Between 15°C and 60°C the hydration degree (α) of $C_{11}A_7 \cdot CaF_2$ is varied with hydration time (t) in the form of: $[1-(1-\alpha)^{1/3}]^N=Kt$, and after hydrated for half an hour its hydration enters the process controlled by diffusion.
5. The hydration degree of $C_{11}A_7 \cdot CaF_2$ is enhanced with water solid ratio but the kinds of hydrates are kept unchanged. As the fineness of $C_{11}A_7 \cdot CaF_2$ increases, its heat evolution rate in early hours is raised evidently, induction period is shortened gradually and initial, final set are further accelerated.

INTERACTION BETWEEN GYPSUM AND C-S-H PHASE IN C_3S HYDRATION USING ESCA

Nam-Ho KIM, Young-Jin LEE Construction Materials Laboratory, Tong Yang Central Laboratories, 38-1 Jung-Ri, Kusung-Myun, Yongin Kyungki-Do 449-910, Korea
Woo-Sik UM, Hee-Soo LEE, In-Shik LEE, Material Testing Team, Korea Testing Laboratory for Industrial Technology, KAITECH, 222-13, Kuro 3-Dong, Kuro-Gu, Seoul 152-053, Korea

ABSTRACT We studied the hydrated reaction of C_3S and gypsum mixture using ESCA (electron spectroscopy for chemical analysis). The chemical shifts of Ca, Si, O and S binding energies were measured in the systems of gypsum, gypsum-free C_3S and C_3S-gypsum mixture after hydration. We find out from the observed chemical shift that SO_4^{2-} tetrahedron is bound by the C-S-H phase which is a main product of the hydrated C_3S in the presence of calcium sulfate from chemical shift. X-ray diffraction pattern, wavelength dispersive x-ray spectroscopy and differential scanning calorimetry analysis were also used to study the hydration reaction between C_3S and gypsum.

Key-words: CSH, ESCA, Gypsum, Hydration, Tricalcium silicate

INTRODUCTION

One of the most important technological parameters in the manufacture of portland cement is the addition of the optimum amount of gypsum to clinkers. Gypsum is added mainly to prevent flash set caused by the rapid hydration of C_3A phase, but the amount of gypsum added also affects the physical properties of mature cement paste. When portland cement clinker is blended with the optimum amount of gypsum, the paste has maximum compressive strength and minimum drying shrinkage (Lerch, 1946). It is generally believed that the optimum effect of gypsum is associated with its intensive reaction with the C_3A phase. However, there are many indications (Copeland et al., 1967, Copeland et al., 1969 and Kalousek, 1965) that gypsum may react with the silicate phase in portland cement, and alter the chemical constitution and microstructure of the C-S-H gel formed.

It has been reported that the increase in the amount of gypsum accelerates the hydration of the silicate phases but lowers the mechanical quality of the C-S-H gel (Ish-Shalom et al., 1972 and Bentur, 1976). Some papers have reported that it is caused by the replacement of the sulfate ion in the amorphous structure of C-S-H phase (Odler, 1979 and Ménétrier, 1980). Therefore, our study reports further attempts about the incorporation of sulfur ion in the C-S-H structure using the ESCA and other analytical tools.

EXPERIMENTAL PROCEDURE

The C_3S used for the hydration was made by mixing and calcining $CaCO_3$ and SiO_2. The gypsum ($CaSO_4 \cdot 2H_2O$) of 3.1 wt% was intermixed with the C_3S and

it was hydrated at room temperature for the selected periods of time in distilled water (50 wt% for the gypsum and C_3S mixture). The hydration was interrupted by washing the paste in acetone and drying in a desiccator. The hydration sample of C_3S without gypsum also was prepared. X-ray diffraction (XRD), differential scanning calorimetry (DSC), scanning electron microscopy (SEM) and wavelength dispersive x-ray spectroscopy (WDX) were used to study the phase transition during the hydration. The electron spectroscopy for chemical analysis (ESCA) was carried out at room temperature under the ultra high vacuum condition (-1×10^{-8} Pa) using a two-chamber spectrometer with the monochromatized x-ray source of Al-Kα ($h\nu = 1486.6$ eV).

RESULTS AND DISCUSSION

Fig. 1 represents the XRD patterns of the hydrated C_3S and gypsum mixture. The pattern at 15 minutes shows the peaks of $CaSO_4 \cdot 2H_2O$ and C_3S. By 6 hours, the peaks for the $CaSO_4 \cdot 2H_2O$ and the C_3S are reduced and $Ca(OH)_2$ starts to grow. The gypsum has completely reacted and the peaks for $Ca(OH)_2$ becomes much stronger in the hydrated samples after 19 hours. The C-S-H phase which may be formed could not be identified from XRD patterns because of its poor crystallinity. As the peak for $Ca(OH)_2$ in the hydrated C_3S without gypsum was detectable after 19 hours, the acceleration of C_3S hydration reaction by gypsum could be confirmed.

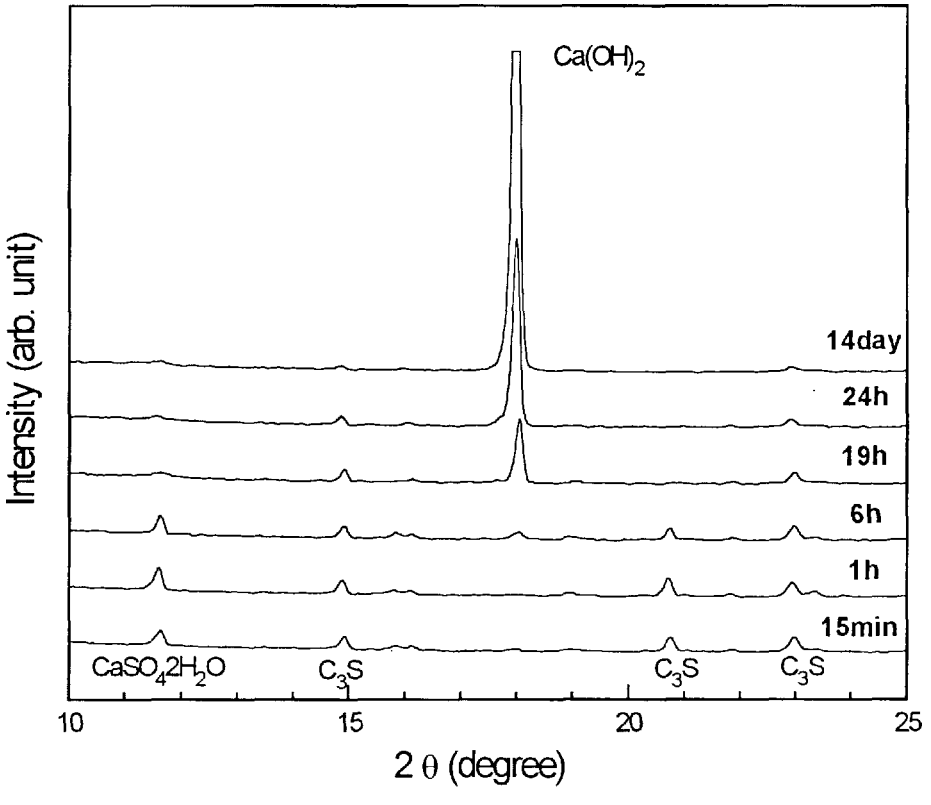

Fig. 1 XRD patterns of the C_3S and gypsum mixture with changing the hydration time.

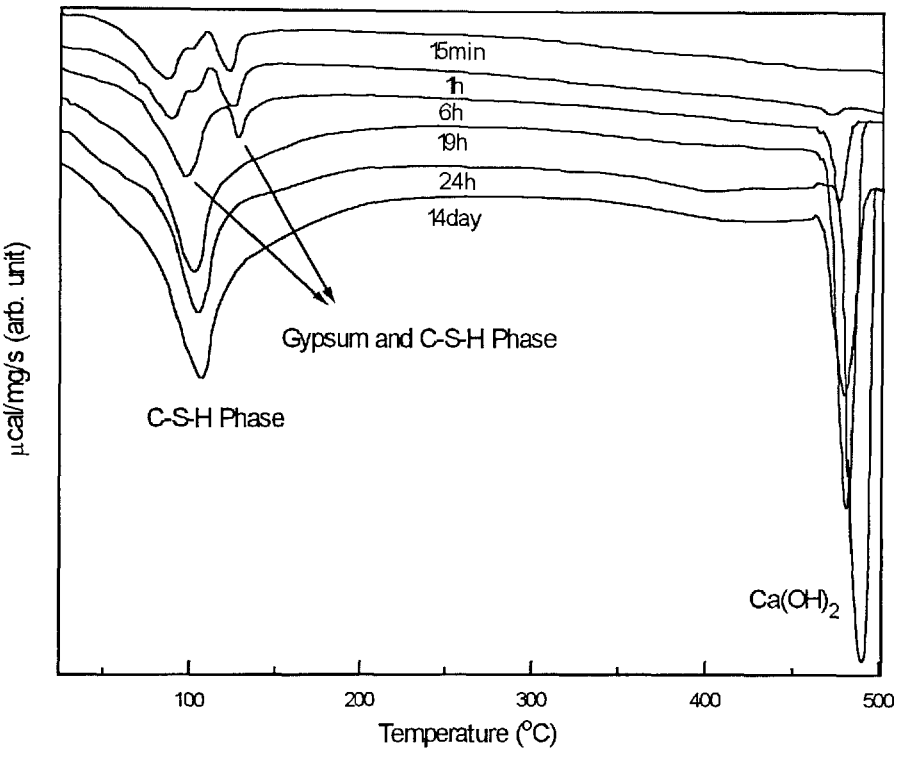

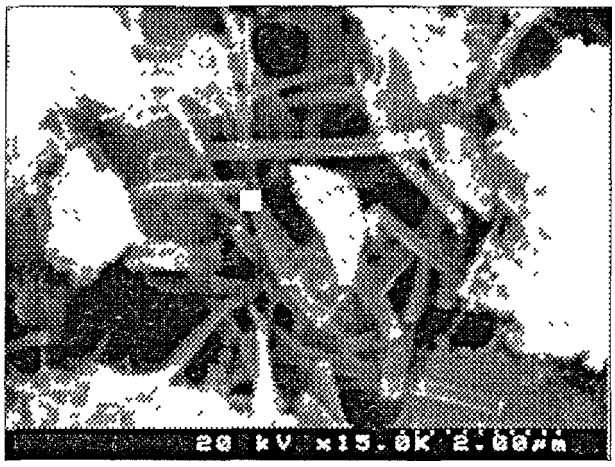

Fig. 2 DSC curves of the C_3S and gypsum mixture with changing the hydration time.

The phase transformation of C_3S during hydration reaction was also studied using DSC as shown in Fig. 2. As the hydration progresses, the gypsum content detectable by DSC decreases until no gypsum endotherm could be observed for the sample hydrated at 19 hours. The C-S-H and the $Ca(OH)_2$ phases were already detectable after 15 minutes and 1 hour hydration. The $Ca(OH)_2$ phase formed in the first one hour, not detectable by XRD, is believed to be amorphous or microcrystalline phase (endotherm at about 460-490°C), whereas the one formed after 1 hour is crystalline (Ménétrier et al., 1980). As hydration time advances, the endotherm for C-S-H phase shifts to higher temperatures (from 85 to 105°C) and broadens. XRD and DSC analysis results show indirectly that sulfate ion may replace the silicate ions in the amorphous structure of C-S-H. There is no possibility for sulfur ions to participate in $Ca(OH)_2$ phase and only small amount of Si are located in that phase (Ménétrier et al., 1980).

The incorporation of sulfate ion into C-S-H phase was also studied by observing the microstructure using SEM and WDX as shown in Fig. 3 and 4. Fig. 3 (a) shows the well-developed needle-like shape of C-S-H phase and the quantity of sulfur ions which may be incorporated in the C-S-H of the hydrate C_3S and gypsum mixture. Sulfur ions were detected in the several part of the microstructure and its quantity changed as shown in Fig. 3 (b). The quantity of sulfur ion increases and the ratio of Ca/Si decreases with moving WDX analysis

point toward the well-developed needle-like C-S-H phase, which originates from the C-S-H phase variation from the gel-like phase formed on the surface of unreacted C_3S grain to needle-like phase during the hydration (Melzer et al., 1989). The trend of Ca/Si ratio decrease agrees with the reported relationship between Ca/Si ratio and degree of hydration (Bentur, 1976). Therefore, this result indicates that the incorporated amount of sulfur ion grows with the phase transformation of C-S-H phase during hydration advancement. The microstructure of hydrated C_3S phase without gypsum shows fibrous bundles of C-S-H phase and Ca/Si ratio is higher than that of the sample in Fig. 3, meaning the lower degree of hydration.

	● area
Ca	79 1644 %
Si	21 8217 %
S	0 0139 %

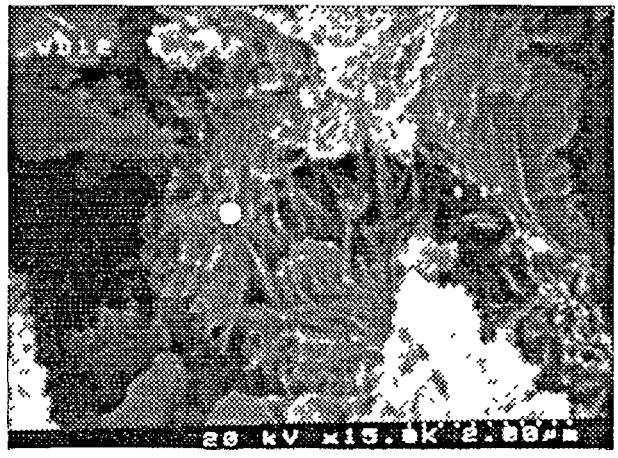

Fig. 4 SEM and WDX analysis in C-S-H phase (atomic percent) for 14 days hydrated C_3S.

In order to observe the sulfur ion behavior and the changes of the chemical environments of each ion in C-S-H phase, specimens of gypsum, 14 days hydrated C_3S and C_3S-gypsum mixture were studied using ESCA. The variation of atomic chemical environment can be identified by virtue of the chemical shift, resulting from variance of electrostatic screening experienced by core electrons as valence electrons are drawn towards or away from the atom of interest.

The wide scan spectra of ESCA for $CaSO_4 \cdot 2H_2O$ and hydrated C_3S and C_3S-$CaSO_4 \cdot 2H_2O$ is shown in Fig. 5. Narrow scan peaks for Ca 2p3, O 1s, S 2p and Si 2p in Fig. 6 were obtained from the wide scan spectra. After the deconvolution of each emission, binding energies were corrected by C 1s peak and summarized in Table 1. All the binding energies of Ca 2p3, O 1s, S 2p and Si 2p emissions for $CaSO_4 \cdot 2H_2O$, hydrated C_3S and C_3S-$CaSO_4 \cdot 2H_2O$ are nearly constant. This result means that chemical environment of each element does not change very much.

Ca in $CaSO_4 \cdot 2H_2O$ structure is surrounded by O and H_2O, and S by four O's resulting in the structure of tetrahedron (Evans, 1966). In imperfect tobermorite-like and jennite structures of C-S-H phase, Ca is known to be also bonded by O, OH and H_2O, and Si is located in the center of oxygen tetrahedron

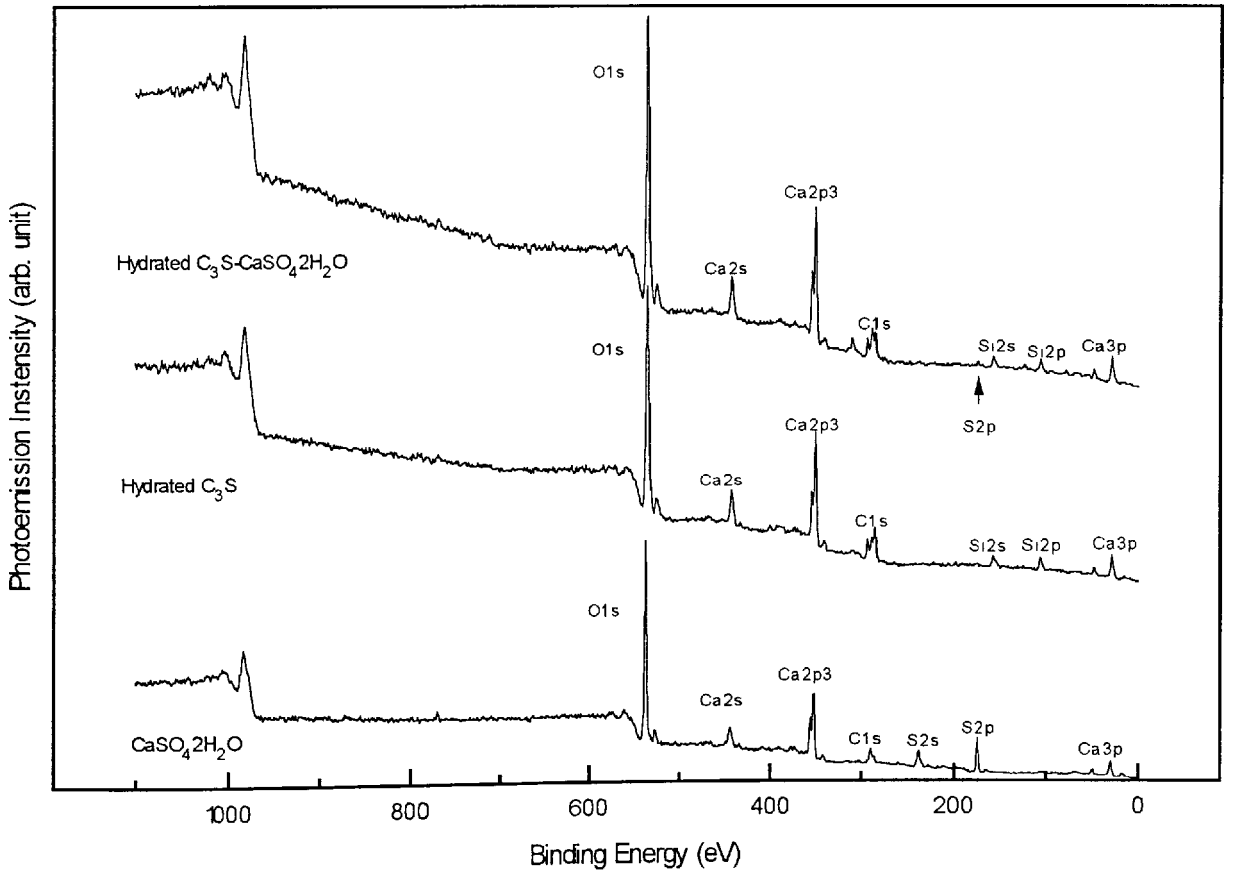

Fig. 5 ESCA wide scan spectra for $CaSO_4 \cdot 2H_2O$ and 14 days hydrated C_3S and C_3S-$CaSO_4 \cdot 2H_2O$

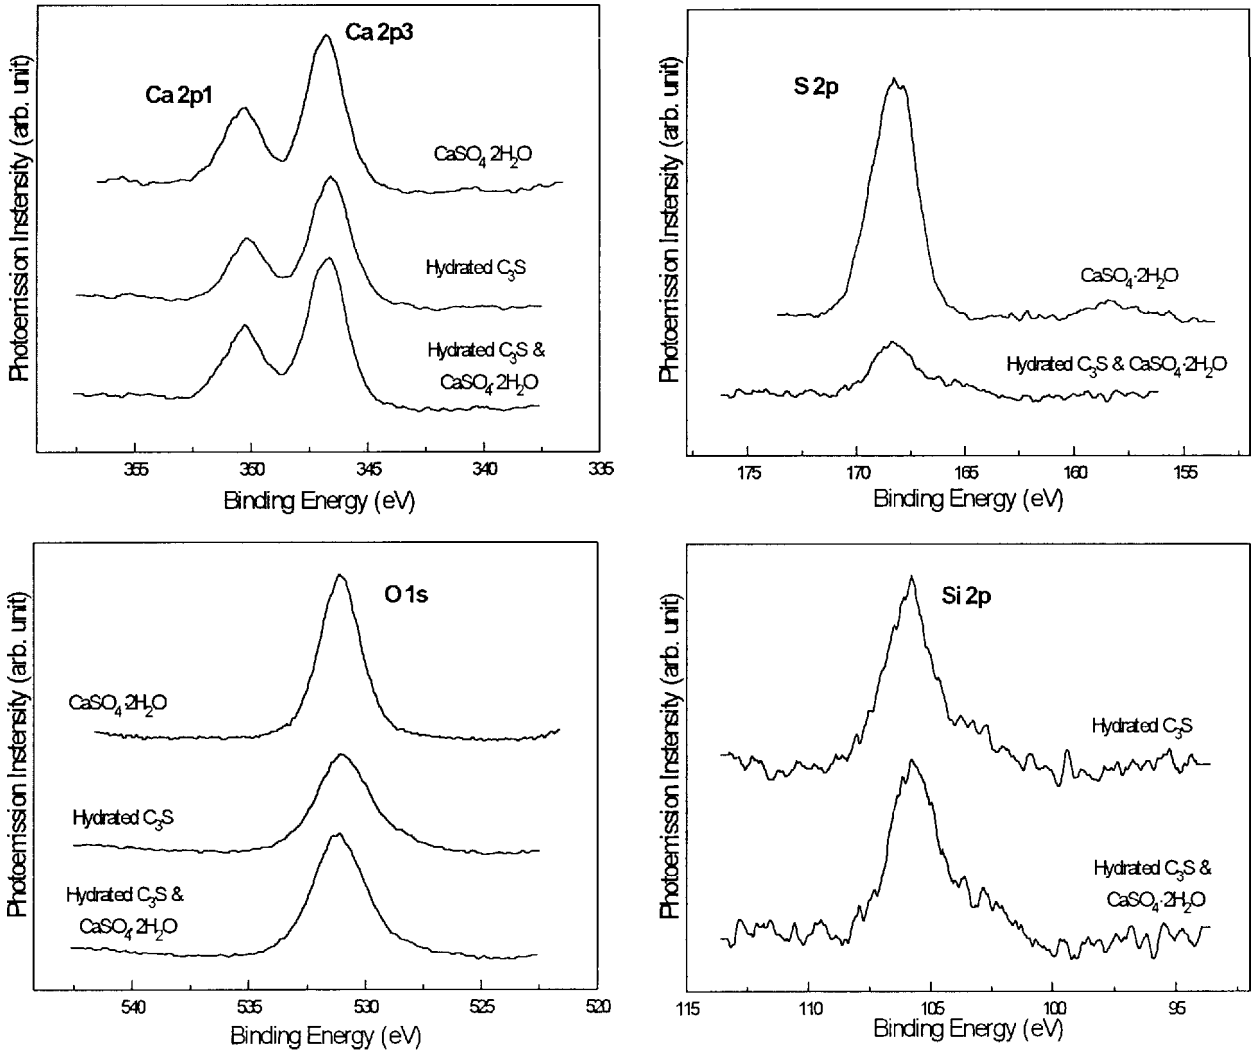

Fig. 6 ESCA narrow scan peaks of $CaSO_4 \cdot 2H_2O$, and 14 days hydrated C_3S and C_3S-$CaSO_4 \cdot 2H_2O$

Table 2-1-1 Binding energies of each element

Element \ Sample	$CaSO_4 \cdot 2H_2O$	Hydrated C_3S	Hydrated C_3S + $CaSO_4 \cdot 2H_2O$ (3.07wt%)
Ca 2p3	346.80	346.55	346.70
O 1s	531.15	531.05	531.15
S 2p	168.30	-	168.65
Si 2p	-	101.50	101.44

which consists of the finite chains (Taylor et al., 1980). Therefore, from no difference between Ca 2p3 and S 2p binding energies for $CaSO_4 \cdot 2H_2O$ and hydrated C_3S-$CaSO_4 \cdot 2H_2O$, it is assumed that Ca of $CaSO_4 \cdot 2H_2O$ is incorporated in C-S-H and $Ca(OH)_2$ phases, and that S does in the form of oxygen tetrahedron like SiO_4^{4-} tetrahedron because of the absence of $CaSO_4 \cdot 2H_2O$ in 14 day hydrated C_3S-$CaSO_4 \cdot 2H_2O$ mixture shown by XRD and DSC analyses (Fig. 1 and 2). It is also believed from constant binding energies of Ca 2p3, O 1s, S 2p and Si 2p emissions for hydrated C_3S and C_3S-$CaSO_4 \cdot 2H_2O$ that the addition of gypsum to C_3S does not affect the bonding of each ion consisting C-S-H phase.

CONCLUSIONS

It is observed that C_3S and gypsum react completely during the hydration, using XRD and DSC. WDX results show that the sulfur ion of the reacted $CaSO_4 \cdot 2H_2O$ is incorporated in C-S-H phase, and the participated amount of sulfur ion increases with the higher degree of C-S-H hydration which was verified by Ca/Si ratio variation. It is conceived from the same ESCA binding energy of sulfur ion in SO_4^{2-} tetrahedron of $CaSO_4 \cdot 2H_2O$ as that of sulfur ion incorporated in C-S-H phase that the sulfur ion in C-S-H phase is in the form of SO_4^{2-} tetrahedron similar to SiO_4^{4-} tetrahedron C-S-H phase

HYDRAULIC ACTIVITY OF LOW TEMPERATURE DICALCIUM ORTHOSILICATE MODIFIED BY BaO ADDITION

Krystyna RAJCZYK, Institute of Mineral Building Materials, Opole, Poland

ABSTRACT The studies on the BaO influence on the structure and properties of dicalcium orthosilicate produced at 1300°C were carried out.The β polymorph was stabilized by excess BaO. The effect of $BaSO_4$ and $BaCO_3$ on the hydraulic activity and hydration products was investigated. The results give the possibility of the Ba containing by-products utilisation in the low energy cement technology.

Keywords: belite, activation, low energy, stabilization, additives

INTRODUCTION

Dicalcium orthosilicate is an important constituent of the low energy belite clinker, produced at lowered temperature. Despite of numerous research works, the problem of the belite hydraulic activity improvement is still unresolved. The studies on the active belite low temperature synthesis on the industrial scale are therefore of particular importance.

The technology of the low energy belite cementitious material has been worked up in the Institute of Mineral Building Materials, as a research project [Rajczyk, Nocuń 1992; Rajczyk, Kurdowski, Weryński 1992]. The belite phase was activated with barium addition, introduced to the raw mixture. The industrial by-product from barite plant was the source of Ba. It has been found that barium was incorporated to the dicalcium silicate structure thus modifying the hydraulic properties of this phase.

The role of BaO in clinker, particularly the question of the α' - dicalcium orthosilicate stabilisation was the subjest of many reports [Revergat, Choisnet 1981]. In the presented work the results of the studies on the BaO influence upon the dicalcium silicate structure and properties are shown.

EXPERIMENTAL

The silicate phase was synthesized from the chemically pure raw materials: calcium carbonate and siliceous acid at 1300°C. $BaSO_4$ or $BaCO_3$ were added as Ba-bearing components, at assumed BaO content corresponding to 3,0 % BaO in final product. The effect of BaO on the hydraulic properties of belite thus produced was investigated.

RESULTS AND DISCUSSION

The synthesized samples revealed some differences in phase composition as it has been found by XRD. Only in the barium sulphate doped sample some amount of admixture was detected. In all samples the β dicalcium silicate polymorph occurred as a main componenet. In the sample without admixture the γ polymorph was found. The XRD patterns of synthesized, unhydrous samples are presented in Fig.1. The peak d=0.282 nm at the plots for BaO doped samples is attributed to the α' polymorph. A substantial amount of free CaO was found both by XRD and chemical analysis.

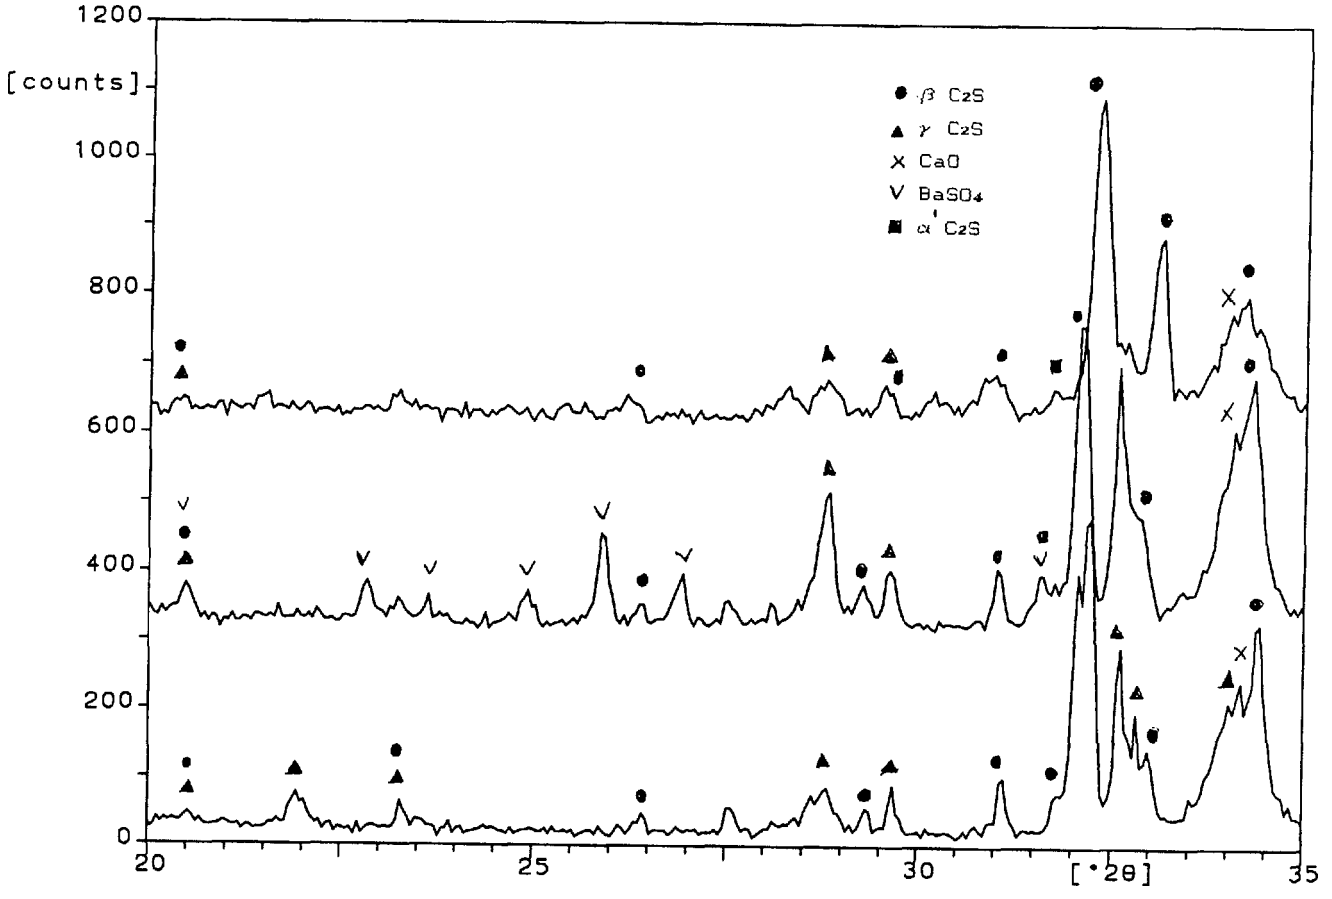

Figure 1 XRD patterns of dicalcium silicate samples.
a) - without admixture, b) - with $BaSO_4$, c) - with $BaCO_3$.

SEM observation revealed the effect of $BaSO_4$ and $BaCO_3$ on the microstructure of dicalcium silicate crystals. One should notice the presence of coarse belite grains with the free CaO inclusions. In the Ba doped samples the lamellar structure with the numerous fissures is evident. In the reference sample without admixture a significant amount of the γ - polymorph is observed (Fig.2). In Fig.2 the microstructure of samples after 90 days hydration is also presented. The progress of hydration is visible particularly in the case of the sample doped with $BaCO_3$. The belite grains are covered with the C-S-H of honeycomb structure. In the sample without additive the needle-like C-S-H is shown. The $BaSO_4$ long needles are detected on the grains on silicate grains doped with this compound.

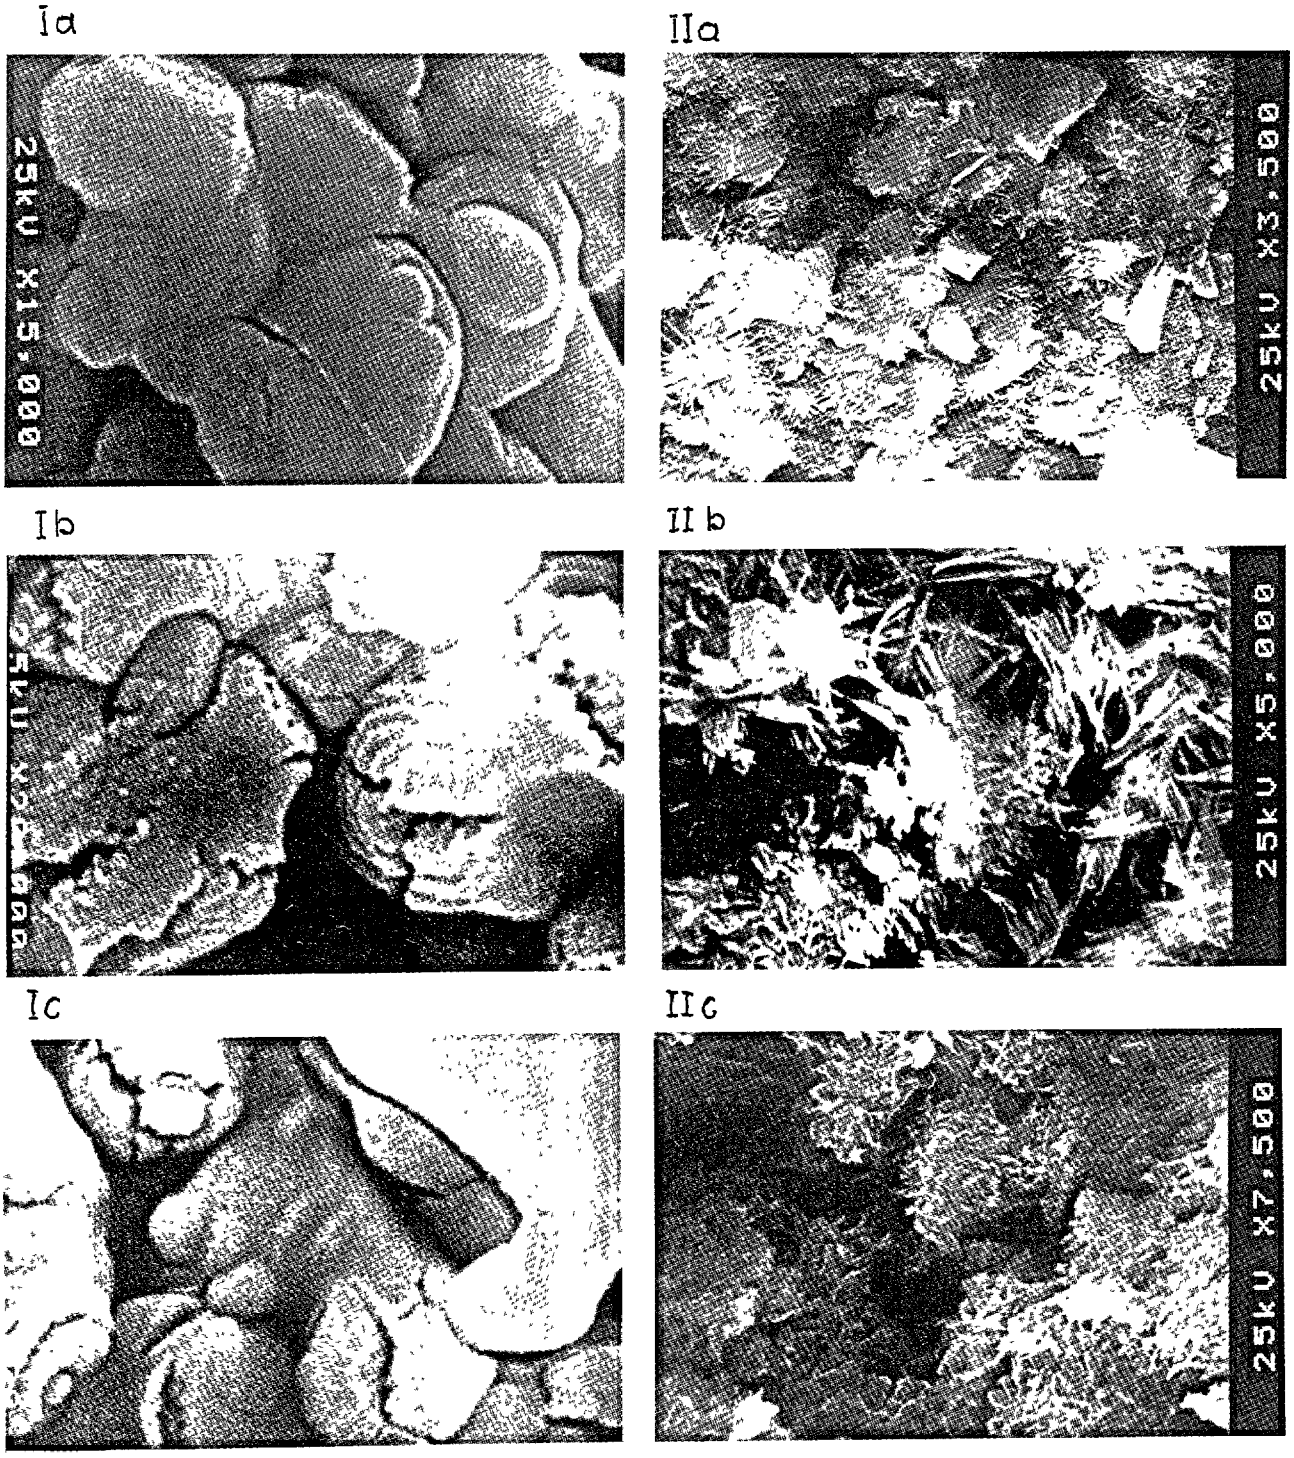

Figure 2 Microstructure of anhydrous belite sample [I]and hydrates after 90 days [II]. a) - without admixture, b) - with $BaSO_4$, c) - with $BaCO_3$.

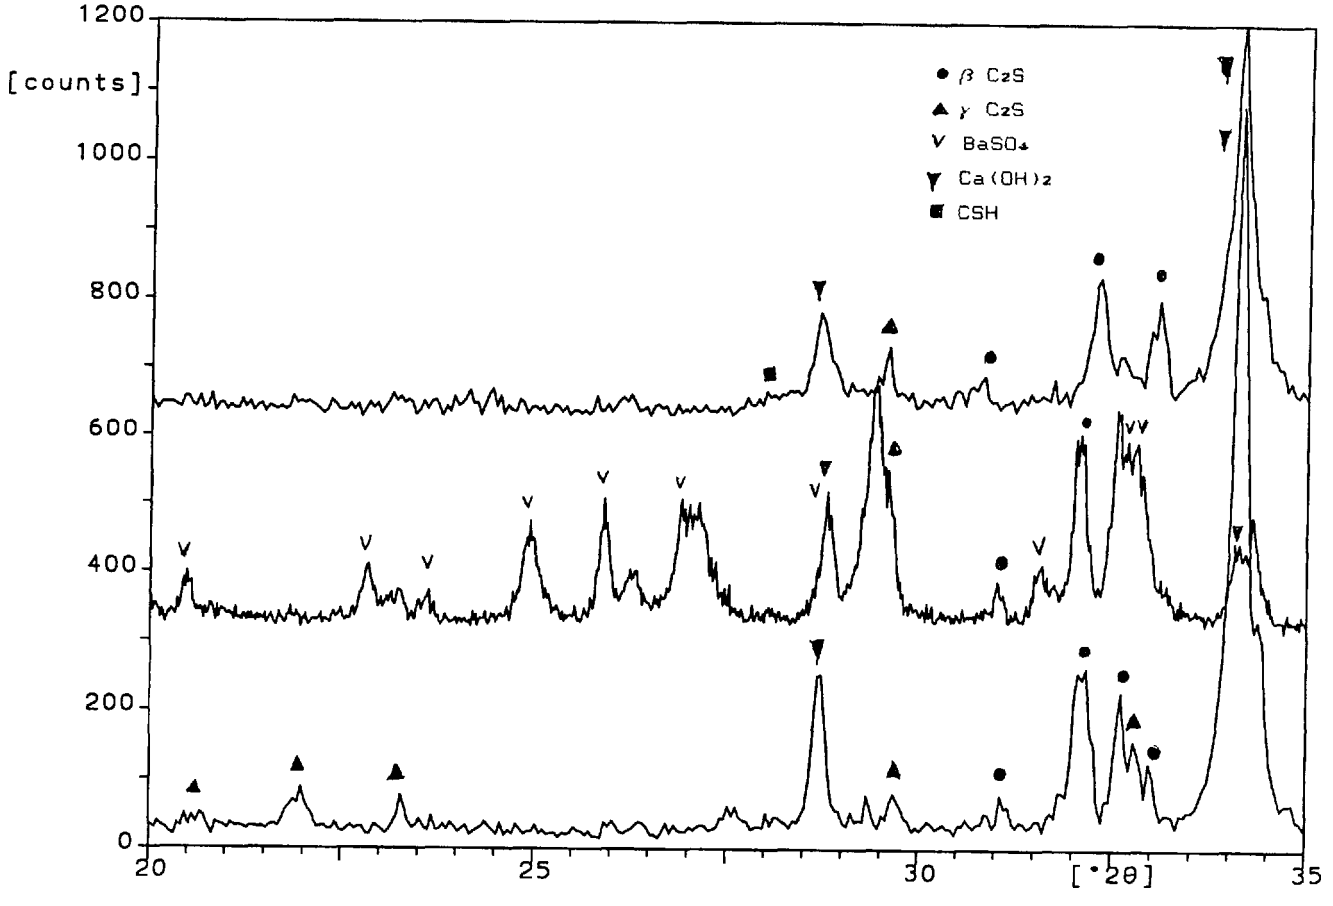

Figure 3 XRD patterns of hydrated dicalcium orthosilicate:
a) - without admixture, b) - with $BaSO_4$, c) - with $BaCO_3$.

SUMMARY

As it results from the data presented above, the structure of dicalcium orthosilicate can be modified by barium addition to the raw mixture, giving the material of better hydraulic properties. The effect is more pronounced when Ba occurs in form of $BaCO_3$.

THERMODYNAMICAL AND CRYSTAL-CHEMICAL ASPECTS OF INORGANIC BINDERS HYDRATION

Sh.M. RAKHIMBAEV, D.Sc., Professor.
Belgorod Technological Academy of Building Materials, Belgorod, Russia.

ABSTRACT The equation of the kinetics of heterogenous reactions with due account of kinetic and diffusion control has been proposed. The dependence of a hydration activity upon a salt basicity, the energy of atomization, ionization and hydration of a metal (cation), the affinity for an anion proton, has been established by the methods of chemical thermodynamics. The alkali activation of slags and ashes is connected with the dissociation constant of acids, the salts of which they are.

KEY-WORDS Hydration, Energy, Diffusion, Ions

INTRODUCTION

The best substantiated method to assess hydration activity of binders is by calculation of the difference of free energies of hydration products and initial nonhydrated compounds (Babushkin et al., 1962). However, this method is of no practical value because, to determine the thermodynamic properties of hydrated phases it is necessary to synthesize them in quite a pure state: this is difficult. It should be pointed out that the use of thermodynamic methods to characterise hydration processes meets with difficulties; most experts admit that reactions of clinker formation and binder hydration are mainly under diffusion control. But the use of thermodynamic methods of the calculation is based upon the assumption that the process is controlled in a kinetic field. It is necessary to confine the fields of thermodynamic application.

Kinetics of Hydration

The author suggested that kinetics of heterogeneous processes should be described by the equations (Rakhimbaev, 1990) :

$$(t/m) = (t/m)_o + k_1 m \quad [1]$$

$$(t/m) = (t/m)_o + k_2 t \quad [2]$$

where (t/m) is a value inverse to a current rate of a heterogeneous process; $(t/m)_o$ is an inverse initial rate; k_1 and k_2 are retardation coefficients.

The author's conception lies in the fact that a heterogeneous process starts at a maximum rate (m/t) under the given conditions. It is determined by kinetic factors, i.e. by binder reactivity with respect to water. When a binder particle is covered with a film of hydration product, diffusion resistance of which becomes quite high, the process passes into the area of internal diffusion control. The coefficients k_1 and k_2 in Eqs [1] and [2] characterize the intensity of the diffusion resistance of the film of reaction products which cover binder particles.

Eq [1] describes the kinetics of processes with extensive retardation when specific diffusion resistance of the reaction product film is constant throughout the whole process. A retardation coefficient has a measuring unit $[k_1] = sec/m^2$. It is inverse to a diffusion coefficient $[D] = m^2/sec$, i.e. Eq [1] is similar to the well-known equation of kinetics of processes with internal diffusion control and a constant diffusion coefficient in terms of time (Budnikov et al., 1965).

Eq [2] describes the processes in which specific diffusion resistance of the reaction product film increases with time. This process is characterized by a diffusion coefficient which apparently decreases with time.

The analysis of the experimental data on kinetics of hydration and the hardening of portland cement and other inorganic binders shows that at the initial stage hydration rates increase with time, as during this period its rate is determined by the processes of dissolution and hydrolysis, by the formation and the growth of hydrated phase nuclei and by heterogeneous crystallization under high supersaturation conditions, i.e. it is under kinetic control. Then the process passes into the area of internal diffusion control. The last stage is described well by Eq [2]. It follows from the above that thermodynamic methods can be used for the calculation of hydration processes of inorganic binders. They allow assessment of the maximum possible hydration activity of binders at the initial stage of their interaction with water when the diffusion resistance of hydration products may be neglected. It follows from Eqs [1] and [2] that if the initial rate $(m/t)_o$ is equal to 0, i.e. the process has a kinetic limitation, its current rate (m/t) is equal to 0 at any moment of time irrespective of diffusion characteristics.

Thermodynamics of the Initial Hydration Stage

In view of the above, the author used a chemical thermodynamic method for the calculation and prediction of hydration activity of inorganic salts of weak acids and strong bases, among these are portland cement, alumina cement, various slags, etc. (Karpov et al., 1968).

For this let us consider an elementary and easily-calculated equation of a hydration reaction of a salt having a composition of M_aRO_n (particular cases – Ca_2SiO_4, $Ca_3Al_2O_6$, etc.). At the first stage of the interaction with water these salts are dissolved and hydrolyzed, shown by the equation:

$$M_aRO_{n(sol)} + a\,H_2O_{(l)} = a\,M^{x+}_{(s)} + a\,OH^{-}_{(s)} + H_aRO^{ax-}_{n(s)} \qquad [3]$$

where (a) is a stoichiometric coefficient; (sol), (l), (s) are an aggregative state of compounds and ions; solid, liquid and solution states respectively in this case.

The free energy, ΔG, of dissolution and hydrolysis as per the equation is equal to:

$$\Delta G = a\Delta G_{M^{x+}_{(s)}} + a\Delta G_{OH^{-}_{(s)}} + \Delta G_{HaRO^{ax-}_{n(s)}} - \Delta G_{MaRO_{n(sol)}} - a\Delta G_{H_2O(l)} \qquad [4]$$

It follows from this equation that hydration activity of salts increases with increase of their basicity (a), free energies of the formation of a cation $\Delta G_{M^{x+}_{(s)}}$, an anion $\Delta G_{HaRO^{ax-}_{n(s)}}$ and with decrease of the free energy of the formation of an initial solid-state salt.

The free energy of salt formation characterizing its stability decreases from calcium silicate to calcium aluminate (when their basicities are the same), which is the main reason for the increase in the hydration activity in the same series. The free energy of the formation of various dicalcium silicate modifications drops from a gamma to alpha prime, which is the reason for the increase in their hydration activity in the same series, $\alpha' > \gamma$.

The reason for a higher hydration activity of glassy compounds as compared with crystals of the same composition is a lower free energy of the formation of the former ones. The measure characterizing the difference of the hydration activity of glass and crystals of the same composition is the free energy of crystallization.

The Effect of Cation and Anion Composition upon Hydration Activity

The author calculated free energies of dissolution and hydrolysis of the series of silicates, aluminates, ferrites, germanates, titanates of some univalent and bivalent metals. It was established that the activity of orthosilicates and metasilicates decreased in the series of Cs, Rb, K, Na, Ba, Li, Ca, Mg, Mn, Co, Fe, Pb, Be, Zn, Cu salts. The activity of calcium salts drops in the series:

$In_2O_6^{6-}, Ga_2O_6^{6-}, Al_2O_6^{6-}, PbO_4^{4-}, GeO_4^{4-}, Fe_2O_5^{4-}, SiO_4^{4-}, TiO_3^{2-}, SiO_3^{2-}$.

Based upon thermodynamics, calculations using Born-Haber cycles were formulated (Rakhimbaev, 1968, 1978) using the following equation for cation formation energy $\Delta G_{M_{(s)}^{x+}}$:

$$\Delta G_{M_{(s)}^{x+}} = \Delta G_{\text{hydration}M_{(g)}^{x+}} - \Delta G_{M_{(g)}} - \Delta G_{\text{ion}M_{(g)}} \qquad [5]$$

where $\Delta G_{\text{hydration}M_{(g)}^{x+}}$ – free energy of gaseous ion $M_{(g)}^{x+}$ hydration; $\Delta G_{M_{(g)}^{x+}}$ free energy of metal formation in a gaseous state – metal atomization; $\Delta G_{\text{ion}(g)}$ – metal ionization energy in a gaseous state.

It is seen from the last equation that the free energy of the cation formation in solution, which exerts a considerable effect upon the hydration activity of weak acid salts, grows with increase in the cation hydration energy but decreases as the atomization energy of the corresponding metal increases; also as its ionization potential increases.

The initial data and calculation results of free energies of dissolution and hydrolysis of some orthosilicates are given below:

	$-\Delta G_{M_aRO_{n(sol)}}$ (kJ/mole)	$-\Delta G_{H_aRO_{n(s)}^{ax-}}$ (kJ/mole)	$-a\Delta G_{M_{(s)}^{x+}}$ (kJ/mole)	ΔG (kJ/mole)
Ba_2SiO_4	2157.85	1039.12	1097.78	15.503
$Ca_2SiO_4(\beta)$	2199.75	1039.12	1110.35	56.565
$Ca_2SiO_4(\gamma)$	2203.94	1039.12	1110.35	60.755
Mg_2SiO_4	2057.29	1039.12	905.04	134.080
Pb_2SiO_4	1248.62	1039.12	-48.604	361.597
Zn_2SiO_4	1525.16	1039.12	278.216	251.819
Fe_2SiO_4	1386.89	1039.12	186.874	217.042

In going from alkali salts to alkaline-earth salts and then to univalent and bivalent metals of transition groups, a sharp drop in the hydration activity of silicates, aluminates, ferrites, germanates is explained by a considerable increase in the atomization energy and the ionization potential in the same series. At the same time the first Eq [5] component (i.e. the free energy of

the cation hydration $\Delta G_{hydration M^{x+}_{(g)}}$) of the elements of the main and secondary subgroups differs little and depends mainly upon a valency and a radius of ions. The free hydration energy of univalent ions of sodium, potassium and lithium is considerably less than the same of bivalent atoms of the second group including transition elements (zinc, manganese, copper, cobalt, iron). A higher hydration activity of barium and calcium silicates and aluminates, as compared with compounds of secondary subgroup elements (Zn, Mn, Pb), is explained by a higher free energy of the hydration of the former ones, which depends upon their little energy of the atomization and ionization potentials.

The calculations showed that in an alkaline medium the free energy of the hydrolysis of low-basicity silicates (components of slags and ashes) was higher than it was in water. At the same time the alkaline activation of slag may be considered as anion depolymerization with hydroxyl addition. The higher dissociation constant of a polyacid is, i. e. the stronger it is as an acid, the more readily it is depolymerized. Hence it follows that a tendency to alkaline activation grows in the series: aluminates, titanates, silicates, phosphates. This series agrees with the experimental data on alkaline activation of slags and ashes.

Thus, the experimentally determined regularities of the influence of a cation composition and an anion one and that of a compound phase state upon the hydration activity of inorganic salts find a theoretical explanation.

Let us consider the factors determining a high tendency to the hydrolysis of anions of silicates, aluminates and other salts of weak acids as compared with sulphates, phosphates and other salts of strong acids.

Effective Charges of Ions and Hydration

The author showed (Rakhimbaev, 1968, 1978) that the effective charge of an ion in anions RO_4^{a-} increased in the series of nitrates – sulphates – silicates – germanates – aluminates – gallates – indates. The higher the effective charge of an oxygen ion in an anion is, the higher its affinity for a proton is, the less a dissociation constant of the corresponding acid is, the weaker it is as an acid.

HYDRATION AND STRUCTURE FORMATION OF INORGANIC BINDERS

Magdelinka RADENKOVA-YANEVA, University for Architecture, Civil Engineering and Geodesy, Sofia, Bulgaria

ABSTRACT Special features of structure formation during hydration of inorganic binders with salts and complex admixtures are considered. The processes of formation of a coagulation structure and its transition into a structure of condensation-coagulation type are discussed. The results received are explained on the basis on the above mentioned succession of the structure formation processes. A structure model of hydrated cement pastes in the early stages of hydration is proposed. The practical use of theoretical consideration is shown.

Key-words: Admixtures, binder, CSH, hardening, hydration.

INTRODUCTION

Hydration of inorganic binders in their practical use takes place in highly concentrated suspensions - cement pastes, mortars and concretes. This is a spontaneous process, which is subordinate to the regularities of the heterogeneous chemical reactions. The dissolution of the solid metastable phase (clinker minerals) is an obligatory stage and calcium hydrosilicates, hydroaluminates and hydroferrites are precipitated from the supersaturated solution.

The interaction between cement and water takes place on the surface of the cement particle and is controlled by diffusion. In the products of the reaction an inner and an outer part (Kondo, 1968) or even an intermediate layer are formed (Pommersheim, 1980). Hydration products have an irregular structure and inconstant composition. In the early stages of water - cement interaction calcium hydrosilicates have a colloid character. Gel from C-S-H phase is generated and the primary structure of the cement stone is formed - the system is setting and hardening. These processes are due to the coagulation of the cement particles and the hardening of the coagulated structure (Segalova and Rebinder, 1954; Rebinder, 1956; Shchukin et al, 1979, 1980; Jiang et al, 1995, 1996).

The present investigation aims to establish the influence of salts and complex admixtures on the hydration processes and on the structure formation of inorganic binders in the early stages of their interaction with water, and to formulate some additional considerations concerning the origin of coagulation - thixotropic and condensation - crystallization structures.

EXPERIMENTAL

Materials

The investigation is performed with pastes on the base of ordinary cements and binders containing no cement clinker. The mineral composition of the clinkers used (calculated according Bogue) is shown in Table 1. Binder without cement clinker is received from belite middling slime, which is a byproduct obtained in the production of aluminum oxide from nonbauxite materials and contains as a main component approximately 80 % β-$2CaO.SiO_2$. Its composition and properties are very close to those of dicalcium silicate in portland cement clinker (Bojenov et al, 1966). As the belite middling slime has a bad activity (low rate of interaction with water) it is activated with hydraulic lime.

Table 1 Mineral composition of the clinkers

Mineral composition, %	Clinker No 1	Clinker No 2
C_3S	35.45	40.08
C_2S	40.12	34.13
C_3A	6.50	11.26
C_4AF	1.15	0.46

In the investigated cement systems salts and complex admixtures are added, designated as **A**, **B**, **C**, **D** and **E**. Admixture **A** is a mixture from Na_2SO_4 and $NaNO_3$; admixture **B** contains $CaCl_2$, $NaNO_3$ and $NaNO_2$; admixture **C** consists of $CaCl_2$ and water-soluble methylolmelamine polycondensate; admixture **D** contains admixture **B** and water-soluble epoxy resin; admixture **E** is a mixture of water-soluble epoxy resin and water-soluble methylolmelamine polycondensate.

Experimental methods

Cement pastes are prepared by mixing with water according to EN 196-1. The setting time (initial and final) is determined by Vicat tests (EN 196-1). The shear strength (cohesion forces) is determined by using MGU device (Rebinder, 1949). From the curves shear strength versus time of hydration, the time for structure formation (t_{sf}) is determined.

RESULTS AND DISCUSSIONS

The results received are shown in table 2 and table 3 and characterize the structure formation processes in the early stages of hydration (up to 8 - 10 hours). They show that salts admixtures accelerate the beginning and the end of setting and decrease the time for structure formation. The complex admixtures have a lower influence on the mentioned properties.

Table 2 Setting time of the pastes with admixtures

Admixture	Type of binder					
	Binder without cement clinker		Cement No 1		Cement No 2	
	initial	final	initial	final	initial	final
	hour - min.		hour - min.		hour - min.	
Without admixture	2 - 55	6 - 30	2 - 00	4 - 25	1 - 15	3 - 10
2 % admixture A	2 - 20	5 - 50	1 - 30	3 - 55	1 - 00	2 - 30
3 % admixture A	2 - 15	5 - 05	1 - 15	3 - 25	0 - 45	2 - 15
Admixture B	0 - 50	2 - 05	1 - 10	2 - 15	1 - 05	2 - 40
Admixture C	2 - 40	6 - 05	1 - 45	3 - 55	1 - 25	3 - 05
Admixture D	1 - 25	2 - 45	1 - 50	4 - 20	1 - 10	4 - 55
Admixture E	1 - 15	3 - 30	1 - 25	3 - 15	1 - 20	5 - 10

The data obtained can be discussed in view of the specific character of the admixtures and their influence on the coagulation of the investigated systems.

The systems we have studied belong to the joined - dispersive microheterogeneous systems. They consist of water, fine binder particles and finedisperse hydrate products.

Table 3 Time for structure formation (t_{sf}) of pastes with chemical admixtures

Admixture	Type of binder		
	Binder without cement clinker	Cement No 1	Cement No 2
	hour - min.	hour - min.	hour - min.
Without admixture	7 - 20	7 - 30	8 - 40
2 % admixture A	5 - 20	6 - 45	7 - 10
3 % admixture A	4 - 45	6 - 05	6 - 45
Admixture B	5 - 35	5 - 30	6 - 40
Admixture C	5 - 10	5 - 20	6 - 05
Admixture D	4 - 50	6 - 10	6 - 10
Admixture E	5 - 45	5 - 15	7 - 05

The latter are received during clinker minerals dissolution with simultaneous passing of calcium (Ca^{2+}), silicate, aluminate and alumoferrite ions in the solution. The latter form the negatively charged nuclei of the colloid particles. Positively charged ions (H^+, Ca^{2+}, Na^{2+}, etc) are adsorbed on their surface and an electric double layer is generated. The kind and quantity of the ions in the adsorption layer determines the value of the electrokinetic potential (zeta potential) of the system, and consequently the interparticle interaction. The coagulation in such kinds of systems is provoked by adding of electrolytes. In this process the diffusion layer is diminishing proportionally to the concentration and the valency of the ions with a charge opposite to the ions determining the ζ - potential; the latter decreases gradually and the system comes near to its isoelectric condition. In the borderline case the ζ - potential is equal to 0 and as a result of the loss of the aggregative stability a coagulation occurs - coagulation contacts are generated. This is possible in case that the particles come close to a definite distance - h_{min}. In such a case we think that a short distance coagulation occurs and the structure formed has a coagulation-thixotropic character. For such a structure Van der Waals forces of interparticle interactions are typical.

In the evolution of the hydration processes due to the additional precipitation of the hydration products near the coagulation contacts and to the continuous changes in the solid and liquid phase of the system, a condensation - crystallization structure is formed. This structure is irreversible because of the valent bonds formed between the particles. The considerations pointed out, concerning the mechanism of structure formation, show that the coagulation in a short distance is an obligatory condition for the following crystallization contacts occurring and for the cement systems.

In accordance with the above exposed, the influence of the electrolytes added in the hardening cement pastes is connected with the diminishing of the size of the double electric layer of the colloid particles, with the decreasing of the value of the ζ - potential and with the creation of conditions for short distance coagulation. As a result the time for structure formation is shortened (see Tables 2 and 3).

At the same time the liquid phase (pore solution) becomes supersaturated regarding to Ca^{2+} and SO_4^{2-} and gypsum crystals are precipitated. Calcium ions are brought out of the adsorption layer

of the colloid particles. After a fast coagulation, crystallization contacts are formed and a condensation - crystallization skeleton is developed.

Complex admixtures, containing an organic component, have a weaker influence on the processes of structure formation. They decrease in a lower degree the time for structure formation and in some cases (cement No 2) they even increase the end of setting in comparison to the samples without admixtures (see Table 2). This can be explained with the mineral composition of the clinker, respectively the content of $3CaO.Al_2O_3$ and the behavior of the organic component of the admixture. The organic admixtures used make adsorption layers mainly on the aluminate component of the system. In this way the processes of short distance coagulation are retarded which results in decreasing of the time for structure formation.

The data obtained in our investigations, considered according to our theoretical concepts and the proposed model for structure formation, are different from some other authors' considerations (Jiang, 1995,1996) and explain more clearly the formation of a structure with coagulation - thixotropic character.

CONCLUSION

The processes of structure formation of the inorganic binders are discussed using the DLVO theory. It is pointed out that as a first stage of the hydration a coagulation structure with thixotropic character is formed, and this structure later on is transformed in a skeleton of condensation - crystallization type. The processes of coagulation are dealt with in detail and the problem of short distance coagulation and the factors, influencing it, is discussed.

The investigations conducted and the results obtained show that the used admixtures influence the cement systems structure formation according to their character and the type of the binder. They promote decreasing or even reduce to zero the coagulation process energy barrier, which is due to the double electric or adsorption layer. The experimental results conform well to the adopted model for short distance coagulation contacts formation during the structure formation in cement systems.

The practical value of the investigations performed is connected with the technology parameters of concrete manufacture. The time for setting and hardening determines the conditions for concrete mixtures processing, placing and compacting during building concrete structures.

THE STRENGTH OF THE HYDRATED PHASES IN THE PORTLAND CEMENT PASTES

Vadim BABKOV and Ildar KARIMOV, Ufa State Petroleum Technological University, Russia

ABSTRACT A theoretical model for the strength of the hydrated phases in the Portland Cement pastes is proposed assuming that Portland Cement paste consist of separate crystals with contacts. The strength of model determined the main features, such us crystals size distribution, area of contact-section of crystal relationship, space direction of crystals. In this model, failure take place gradually breaking weak elements before strong elements. Two kind of failure through crystals, along contacts. The model is bases on theory of fracture mechanics and theory of probability.

Key-words: crystal structure, modelling, capillary porosity

INTRODUCTION

The main feature of the hardened of Portland Cement pastes is the structure-mechanical non-homogeneity which is characterized by different strengths of separate structural crystals and stress distribution to the crystals while loading. The different strengths of separate crystals is very dependent on the size distribution of crystals. The typical size of separate crystals of the hardened Portland cement paste (diameter of needle-shaped form crystals, thickness of lamellar form crystals) is in the range of 5-20 nm to 1 μm. A.F.Ioffe (1974) and G.V.Bereshkova (1969) have shown that the tensile strength R_k of separate crystals of rock-salt and quartz change in 100 time when the diameter of needle-shaped form crystals is in the range of 0.1-20 μm.

MODEL

To describe the function $R_k = f(a)$ proposed (Babkov and Polak, 1977):

$$R_k = R_m (a_* / a)^n, \qquad [1]$$

where R_m - theoretical strength of crystalline phase; a - typical size of separate crystals; a_* - non-defects crystal size; n - coefficient intensity lowering strength when increasing a.

The different strengths of separate crystals depend on area of contact - section of crystals relationship, different strengths contact and crystal as well. The stress distribution to the crystals while loading is linked with space direction of crystals and others. We considered a model for the crystalline phase of Portland Cement paste which consist of separate crystals united by contacts. The crystals are of difference size. All crystals have a space direction along three axies in the same probability. We considered two kind of failure: through crystals, along contacts.

If crystals have strong contacts then failure occur through crystals. In this case loading fracture weak crystals and redistributes on the strong crystals. If stress is lesser or of equal strength of weakest crystal, then the structure is stabile. For intermediate condition specific load is expressed by

$$R = \frac{1}{3} V_m R_m (a_* / a)^n \int_{a_0}^{a} \varphi(a) da, \qquad [2]$$

where $\varphi(a)$ - function size distribution of crystals; a - size the greatest remaining crystals $(a_0 \le a \le a_m)$; a_0, a_m - accordingly lesser and greatest characteristic size of crystals; V_m - relative volume of crystalline phase.

When loading is increased to break all crystals, this load corresponds to the strength crystalline phase R_{kc} which equal extremum to Eq 2 for a. For even distribution function $\varphi(a) = \frac{1}{a_m - a_0}$ when $a_0 \ge a_*$ it will be

$$R = \frac{1}{3} V_m R_m (a_* / a)^n \frac{a - a_0}{a_m - a_0}; \qquad [3]$$

$$\frac{dR}{da} = \frac{1}{3} V_m R_m \frac{a^n}{a_m - a_0}(a - na + na_0) = 0; \quad a_{cr} = \frac{na_0}{n-1};$$

$$R_{kc} = \frac{1}{3} V_m R_m (a_* / a_0)^n \frac{a_0}{a_m - a_0} \cdot \frac{(n-1)^{n-1}}{n^n}. \qquad [4]$$

Eq 4 take place by $a_* \le \frac{n+1}{n-1} a_0$, $n > 1$. For non-fulfilment of this conditions the strength is expressed by

$$R_{kc} = \frac{1}{3} V_m R_m (a_* / a_m)^n \qquad [5]$$

For even distribution and $a_0 \le a_*$, $a_* \le a_{cr} \le a_m$ the strength correspond to Eq 4. For non-fulfilment of this conditions the strength is expressed by

$$R_{kc} = \frac{1}{3} V_m R_m \int_{a_0}^{a_*} \frac{1}{a_m - a_0} da = \frac{1}{3} V_m R_m \frac{a_* - a_0}{a_m - a_0}. \qquad [6]$$

This calculations were carried out for other function distribution including the normal law distribution. The calculation strength through crystals for crystalline phase of Portland Cement pastes (at $V_m \approx 0.72$; $R_m \approx 4 \cdot 10^3$ MPa; $a_* \approx 50$-100 nm; a_0-a_m=5-1000 nm; $n \approx 1.2$-1.6) to carry out for several function distribution is given by tensile strength in the range 80-200 MPa. The analysis of Eqs 4-6 show that in order to increase the strength of crystals with strong contact, it is necessary to decrease large crystals size.

If crystals have weak contact then failure occurs along contacts. In this case the mechanism of failure and strength structure determine overload contacts with reference to stress of area section of crystals and heterogeneous tensity in contacts. Out of equilibrium case the stress in contact equal the stress in crystal divided by specific area contact η which equal area contact - section of crystal relationship. For intermediate condition specific load is expressed by

$$R = \frac{1}{3} V_m R_m \eta \int_{\eta}^{\eta_m} \varphi(\eta) d\eta, \qquad [7]$$

where R_m - the strength of contact; $\varphi(\eta)$ - function distribution of specific area contact η.

For even distribution function $\varphi(\eta) = \frac{1}{\eta_m - \eta_0}$ the strength of crystalline phase along contacts it will be

$$\text{- at } \eta_0 \le \eta_m / 2: \quad R_{kc} = V_m R_m \frac{\eta_m^2}{12(\eta_m - \eta_0)}, \qquad [8]$$

$$\text{- at } \eta_0 \ge \eta_m / 2,\ 0.5 \le \eta_m \le 1: \quad R_{kc} = \frac{1}{3} R_m V_m \eta_0. \qquad [9]$$

The calculations of strength along contacts for crystalline phase of Portland Cement pastes ($0.2 \le \eta_m \le 1$; $0.1 \le \eta_0 / \eta_m \le 0.5$) carried out for several function distribution gives tensile strength in the range 25-150 MPa.

The analysis of Eqs 7-9 show that in order to increase the strength of crystals with weak contact it is necessary to decrease number of contacts, to develop area of contacts, to increase the strength of contacts, levelling specific area contacts. In the latter case stress in contacts become homogeneous.

The second main factor of influence on the strength of the hardened Portland Cement pastes is capillary porosity which occupy of 10-40% total volume. The strength of Portland Cement stone R_c one can connect with concentration hydrated phase so-called "gel:space" F. If structure consist of separate structural elements with the same local densities then all elements will fail at the same time. In this case the strength of structure it will be

$$R_c = R_{kc} F^2. \qquad [10]$$

The real structure is inhomogeneous when the separate structural elements have a different local densities. The mechanism of failure of this structure is "stepped" when breaking overloaded structural elements (Babkov and Polak, 1980). For intermediate condition specific load is expressed by

$$R = R_{kc} v^2 \int_{0}^{v_m} \varphi(v) dv, \qquad [11]$$

where $\varphi(v)$ - function distribution of local density v; v_0, v_m - accordingly lesser and greatest value of v.

For even distribution function of local density $\varphi(v) = \frac{1}{v_m - v_0}$ (for the present instance

$F = \frac{v_m + v_0}{2}$) the strength of porous material, for example Portland Cement stone it will be

$$R_c = R_{kc} \frac{4v_m^3}{27(v_m - v_0)}. \qquad [12]$$

Eq 12 take place by $v_0 \le 2/3v_m$. For non-fulfilment of this condition the strength is expressed by $R_c = R_{kc} v_0^2$. The calculations by Eq 12 and other function distributions, including the normal law distribution (Babkov and Karimov, 1996), it is shown that Eq 12 correspond to expression proposed by Powers and Brownyard (1948)

$$R_c = R_{kc} F^s, \qquad [13]$$

where s=2.5-3.5 depending on $\varphi(v)$. This value s correspond with value s=2.6-3.0 received by Powers and Brownyard (1948) for Portland Cement stone.

CONCLUSION

The calculated strength of the hardened Portland Cement pastes shown that the structure-mechanical inhomogeneity decrease the theoretical strength by 50-100 times, while the capillary porosity decrease the strength by 3-10 times.

AN INVESTIGATION INTO THE CHEMICAL NATURE OF THE REACTIVITY OF LIME

C. A. STRYDOM, Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa
J. H. POTGIETER, PPC Technical Services, P O Box 40073, Cleveland 2022, South Africa

ABSTRACT
The hygroscopic nature of lime causes it to react with water vapour in the atmosphere to form $Ca(OH)_2$. In the presence of CO_2, any slaked lime immediately reacts with the CO_2 at temperatures above 300 °C to give $CaCO_3$. Loss in the reactivity of lime can both be attributed to rehydration and recarbonation. The mass loss curves of lime samples clearly show the percentage rehydration and recarbonation and it serves as an indication of the reactivity of the lime samples.

Keywords : Lime, reactivity, free lime, calcium hydroxide, thermogravimetry

INTRODUCTION
The thermal decomposition of limestone (mainly $CaCO_3$) has been the focus of many researchers, particularly those dealing with cement technology, as it is the most energy demanding reaction taking place during the clinkering process (Kasselouri, Dimopoulus and Parissakis, 1995). Masonry cements are also produced by intergrinding cement clinker, gypsum and limestone, which can be partially or totally replaced with hydrated lime. The limestone and lime improve the workability of the mix and also act as water retention agents to prevent too rapid drying when the cement is used for plastering purposes.

The percentage calcium content of lime containing samples is determined in the cement industry by the XRF method, and it is then directly expressed as the %CaO, which of cause, is not always correct, since $Ca(OH)_2$, $CaCO_3$ and other compounds could have formed also. The percentage free lime (CaO) is of particular importance for hydration and neutralization reactions. This percentage is determined using a method measuring the amount of CaO and $Ca(OH)_2$ simultaneously, and denoting it the "available free lime". The reactivity of the lime is tested using the DIN slaking test. Water is added to a lime containing sample in an adiabatic container, it is stirred and the time (in seconds) taken for the reaction mixture to reach a temperature of 60 °C is used to get the reactivity index:

$$R_{DIN} = {}^{2400}/_{t}$$

The reactivity index is thus an indication of the amount of CaO, available for hydration and/or neutralization, in the lime sample.

In industry it is sometimes found that lime samples with a high percentage "available free lime", give low reactivity values, or that the reactivity decreases dramatically with time (days) although the availability value remains constant. The hygroscopic nature of lime causes it to react with water vapour to form $Ca(OH)_2$, while any CO_2 in the atmosphere could react with lime to form $CaCO_3$. It was

found that the rate of uptake of CO_2 for this equilibrium reaction, is comparable to that of the decomposition reaction even at relatively small sample masses and high flow rates of an inert gas (Sinev, 1988).

It is the purpose of this study to determine whether there is any relationship between the reactivity of lime and the percentage $Ca(OH)_2$ and $CaCO_3$ in a sample. The rehydration and recarbonation of lime samples in the precence of water vapour and carbon dioxide were also investigated.

EXPERIMENTAL

Sample preparation

Pure $CaCO_3$ and $Ca(OH)_2$ were obtained from Merck to compare the thermogravimetric decomposition curves of the pure samples to that of the lime samples. The unslaked lime, received from Lime Acres, where it was burnt from limestone at 1200 °C, were crushed and screened into a -4.75 mm + 1.0 mm fraction. This fraction was divided into 5 equal parts of 200 g each. The first portion's reactivity was immediately measured on a LRT 60 reactivity meter according to the standard procedure. The remaining 4 samples were exposed outside the building to relatively dry atmospheric conditions and their reactivities were similarly measured on 1 day intervals (Table I). Immediately after measuring a sample's reactivity, XRF analysis was performed on the sample on a Siemens MRS 400 XRF spectrometer (Table II). The hydrated lime sample was obtained from Lime Acres, where the unslaked lime was passed through a commercial type hydrator.

Table 1 : Reactivity values (R_{DIN}) after exposure to atmosphere

Day number	Time (s)	Reactivity (R_{DIN})
0	80	30
1	1209	1.98
2	1413	1.70
3	∞	Never reached 60 °C
4	No analysis attempted	

Thermogravimetry

A Netzsch STA 409 simultaneous TG/DSC instrument was used to collect thermogravimetric data. Nitrogen was employed as a dynamic atmosphere, except in the case where the samples were subjected to a 50% CO_2 : 50% air mixture and an atmosphere where this mixture was purged through water at 20 °C. The flow rate in all cases was 20 $cm^3.min^{-1}$. Temperature calibration was achieved using the ICTAC recommended DTA standards. Sample masses varied between 20 and 50 mg. To relate all results a heating rate of 5 °C.min^{-1} was used throughout.

RESULTS AND DISCUSSION

Fig. 1 contains the thermogravimetric decomposition curves for pure $Ca(OH)_2$, pure $CaCO_3$ and the limestone samples. The mass loss of 22.5% between 350 and 460 °C, observed for $Ca(OH)_2$ indicates the persence of a small amount of impurities in the pure sample, as the theoretical value is 24.3%. The mass losses between 600 and 840 °C, of respectively 43.5 and 43.4 % observed for the $CaCO_3$ sample and limestone sample indicate that both mainly consist of calcium carbonate (the theoretical value being 43.97%). The hydrated lime sample shows a mass loss of 20.9% between 340 and 460 °C, indicating a 86% rehydration of the lime sample prepared as described under sample preparation and also a 1.8% mass loss between 560 and 800 °C, indicating a 4% recarbonation of the sample.

To determine the uptake and influence of CO_2 on the limestone and hydrated lime samples, both were heated in an atmosphere containing 50% CO_2 and 50% air, they were cooled down in this atmosphere for 90 minutes, the atmosphere was then switched to nitrogen and the mass loss curves measured to determine the amount of recarbonation of the samples. This was repeated with the addition of purging the gas mixture of CO_2 through water at 20 °C, to determine whether the presence of water vapour enhanced the uptake of CO_2 and/or H_2O.

In the presence of the 50% CO_2 - 50% air atmosphere, the decomposition of the carbonate occurs only between 850 and 950 °C, in comparison to the values of 600 and 840 °C for the sample in an inert atmosphere (Fig. 2). This clearly indicates the strong influence of any partial pressure of CO_2 on the decomposition

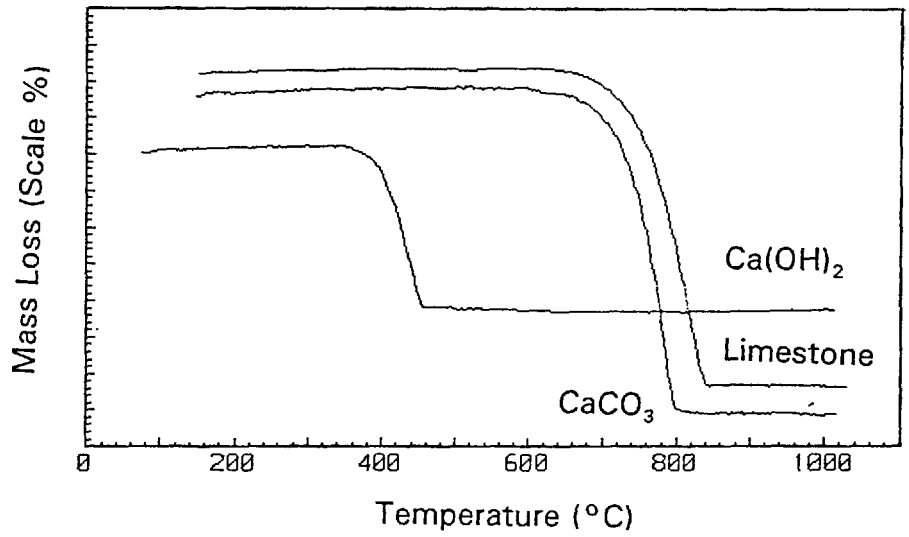

Fig 1 : Thermogravimetric decomposition curves for pure $Ca(OH)_2$, pure $CaCO_3$ and the limestone sample (heating rate 5 °C.min^{-1}).

of $CaCO_3$. On cooling down from 1000 °C to 25 °C in 90 minutes in the CO_2 gas mixture, in the presence and without the presence of water vapour, only recarbonation of the lime seems to occur, as no $Ca(OH)_2$ decomposition curves are observed on reheating the samples in nitrogen. The only difference between the presence and absence of water vapour being that an average recarbonation of 56% occurrs without water vapour and an average of 64% in the presence of water vapour. The presence of water vapour thus clearly enhances the uptake of CO_2.

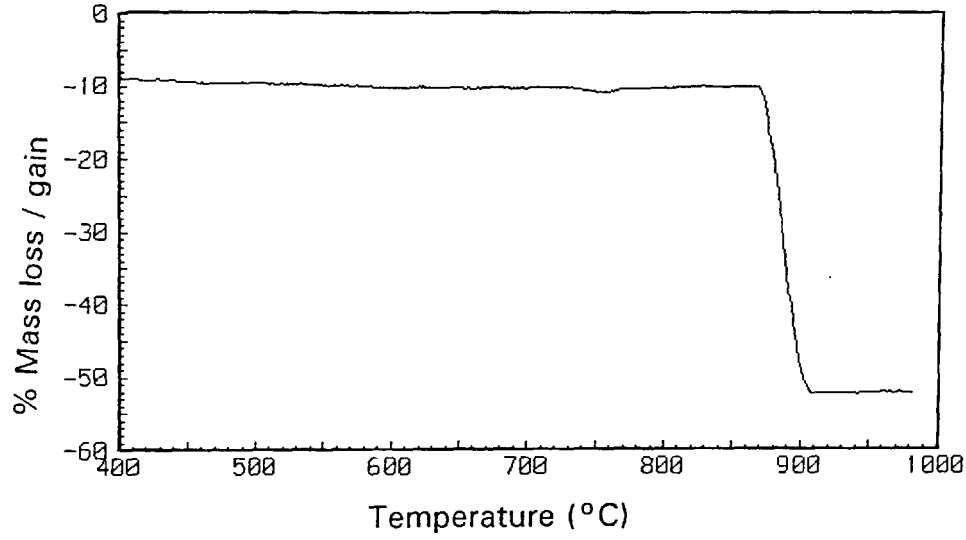

Fig. 2 : Thermogravimetric decomposition curve of $CaCO_3$ in a 50% CO_2 - 50% air atmosphere, using a heating rate of 5 °C.min^{-1}.

As was seen in Fig. 1, the hydrated lime sample starts to decompose to CaO at 340 °C under the conditions used. Heating the hydrated lime sample in the mixture of CO_2 and air, results in an increase in the mass from 300 °C to 520 °C. This can only be attributed to the immediate uptake of CO_2 as soon as CaO is formed from

the decomposition of $Ca(OH)_2$. The mass loss observed between 850 and 920 °C, indicates an immediate recarbonation of 93% at the temperatures between 300 and 520 °C. The same tendency was observed when heating the hydrated lime sample in the CO_2 mixture in the presence of water vapour (Fig. 3). In this case the immediate recarbonation was 94%.

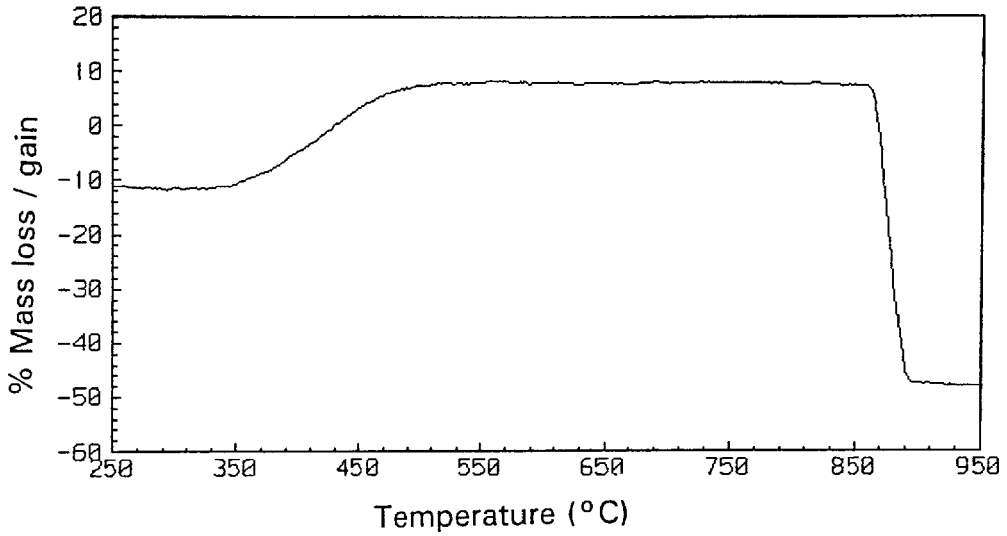

Fig 3 : Thermogravimetric curve of hydrated lime in a 50% CO_2 - 50% air atmosphere (heating rate 5 °C.min^{-1}).

Cooling down the samples in the various atmospheres, changing the atmospheres to nitrogen and obtaining the decomposition curves, gives approximately the same results as for limestone, i.e. a 57% recarbonation having taken place in the absence of water vapour and a 65% recarbonation in the presence of water vapour. Some of the decomposition curves of the lime samples with different reactivities are given in Fig. 4. It is clear that rehydration and recarbonation occurred. The samples being in the presence of a very low partial pressure of CO_2, only recarbonated to a maximum of 1.4% at the experimental conditions.

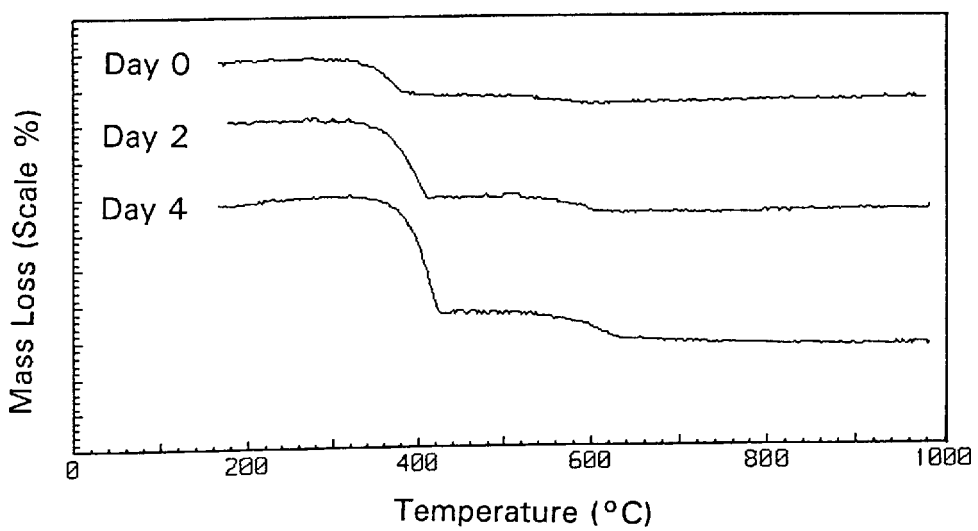

Fig 4 : Thermogravimetric curves of lime samples exposed to the atmosphere for days as indicated (heating rate 5 °C.min^{-1}).

Rehydration increased with time, starting at 4.1% for the sample with reactivity of 30, to 13.1% for the sample exposed to the atmosphere for 4 days (reactivity unmeasurably low). Fig. 5 gives an indication of the relation between reactivity and % rehydration and total % rehydration and recarbonation.

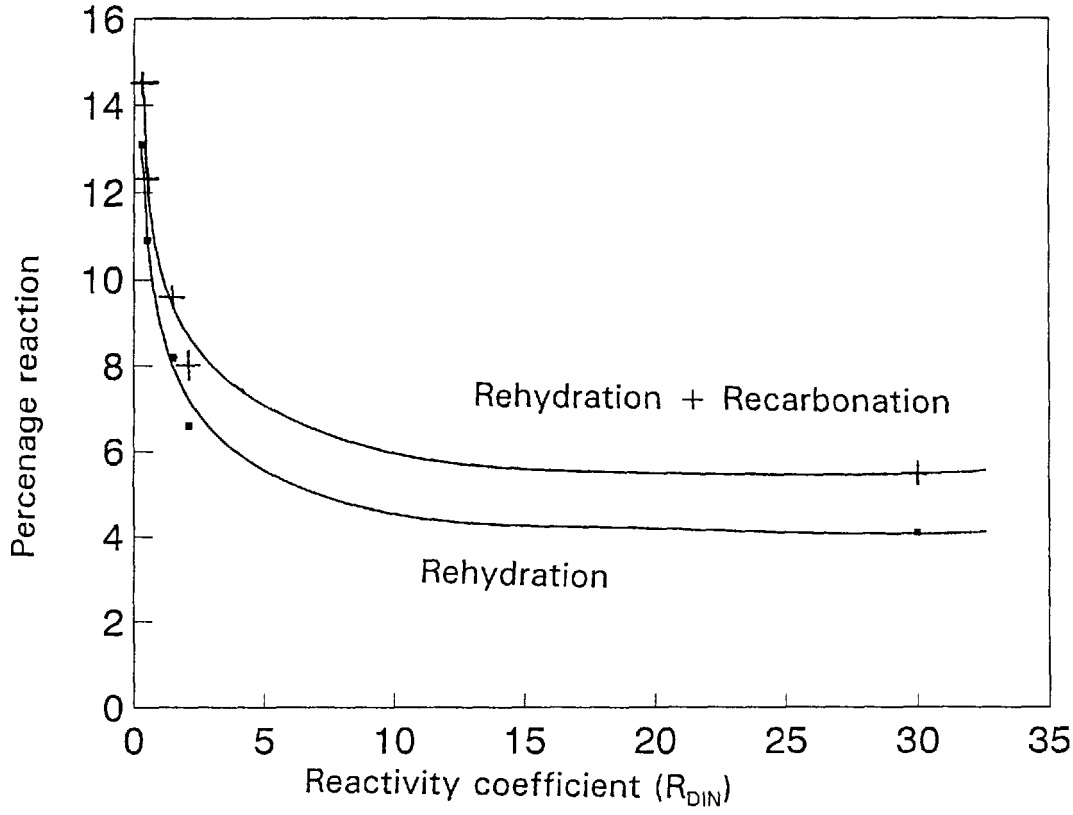

Fig. 5 : Plot of reactivity coefficient value versus the percentage rehydration and the total of the percentage rehydration and recarbonation.

CONCLUSIONS

The loss in reactivity of lime can be attributed to both the rehydration (formation of $Ca(OH)_2$) and the recarbonation (formation of $CaCO_3$) of lime. The extend to which these two occur, depends highly on the partial pressure of both water vapour and CO_2. The recarbonation reaction taking place at an increasing rate, to such an extend that as soon as CaO is formed from the dehydration of $Ca(OH)_2$, it immediately reacts with CO_2 at temperatures above 300 °C to form $CaCO_3$. In industry great care has to be taken to store reactive lime away from any moisture and carbon dioxide gas. The percentage rehydration and the total percentage rehydration and recarbonation, as determined by thermogravimetry give a good indication of the reactivity coefficient value. The reactivity coefficient R_{DIN} decreases sharply with increasing rehydration and recarbonation.

REACTIVITY AND MECHANISM OF HYDRATION OF CEMENT PHASES

Reinhard TRETTIN, Institute for Geosciences, University of Mainz, Mainz, Germany

ABSTRACT The main factors for the kinetics of the hydration of phases are primarily the potential reactivity, which depends on the crystal structure, and secondarily the qualities of a reaction layer forming on the surface of the anhydrous compounds at the beginning of the hydration (observable with the AFM). The potential reactivity of the structure increases with the basicity of oxygen induced by an increase of the number of calcium atoms in the coordination sphere of the oxygen.

Key-words: Reactivity, hydration, mechanism, calcium silicate, calcium aluminate

INTRODUCTION

The macroscopic kinetics of cement hydration is the result from very complex reactions. The degree of hydration with respect to time depends on the interaction of a number of various factors. The different clinker minerals have a very variable reaction behaviour with respect to water and are influenced themselves in their reaction with the ion concentrations in the common solution phase. In addition, the reaction is not predominantly continuous but is characterised by periods of various hydration rates.

Several reviews of models to the explanation the reactivity and the mechanism of hydration have been published in the literature (Taylor, 1990a, Massazza and Daimon, 1992). Until now the mechanisms of the hydration of the single clinker phases is not understood completely. This applies to the more complicated polyphase system of the cements to an even greater extent. Further research is therefore necessary for a better understanding of the causes of the various reactivity and the mechanisms of hydration of clinker phases.

REACTIVITY AND CRYSTAL STRUCTURE

The anhydrous calcium silicates and calcium aluminates show very different reactivities towards water. There are some theories to explain the different reactivities based on of the differences in the crystal structure, but most of them are not correct regarding modern structural data. This was demonstrated by Jost and Ziemer (1984) for the theories of openness of structure, distortion of polyhedra, and relations to the coordination number of calcium. Moreover, the theories do not explain the differences in reactivities of β- and γ-Ca_2SiO_4. Jost and Ziemer (1984) proposed a hypothesis, in which they suggest that the major factor for reactivity is building units of Ca-O polyhedra linked through face-sharing. The reactive calcium silicates contain such face sharing Ca-O polyhedra. However, the face sharing-polyhedra cannot be the main factor for the reactivity. In the reactive phase $CaAl_2O_4$ and in CaO no building units of face-sharing Ca-O polyhedra exist.

In order to understand the structural causes of the differences in the reactivity towards water it is necessariy to look at the mechanism of the initial reaction with water. In agreement with Barret et al. (1983) it is suggested that the first step in the reaction with water is a transfer of protons from water to the oxygen atoms in the solid phase. This means it is more probable that the oxygen basicity is the major factor for reactivity.

A differentiation of the reactivity of the clinker phases and other calcium silicates and calcium aluminates is possible in simplified form with the degree of hydration determined experimentally to same time of hydration:

$$C_3S > C_2S > C_3S_2 > CS$$
$$C_3A > C_{12}A_7 > CA > CA_2 > CA_6.$$

The hydraulic reactivity generally also increases with the CaO content per unit formula. This differential series does not make any distinction of reactivity differences possible between the reactive β-C_2S and the inactive γ-C_2S. Therefore it is better for a more realistic analysis of the reativity of the substances with water to examine the content of the calcium in relation to the volume. The density of the Ca atoms per unit volume of the substances should then be a measure for the oxygen basicity.

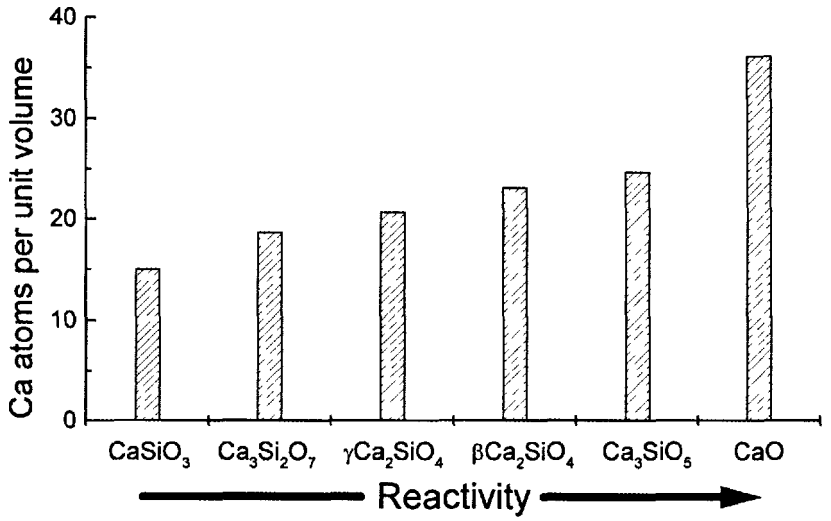

Figure 1 The density of the Ca atoms per unit volume of calcium silicates

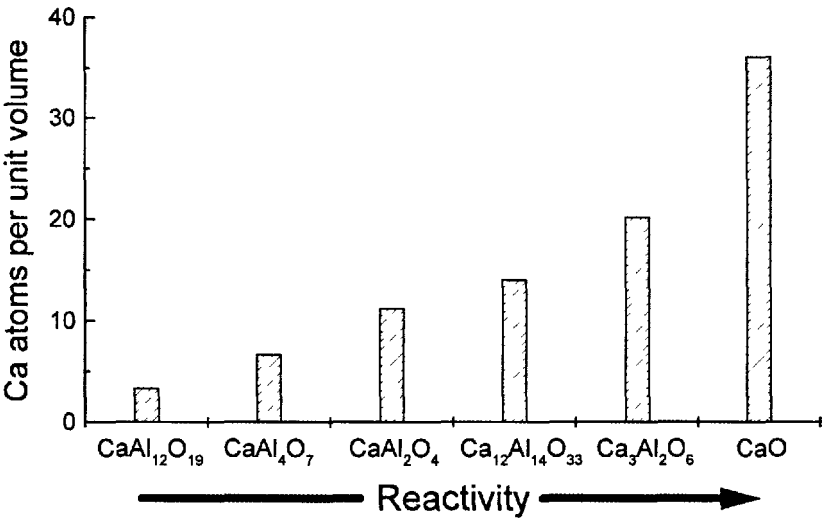

Figure 2 The density of the Ca atoms per unit volume of calcium aluminates

Indeed, it was found that with increasing number of Ca atoms per unit volume the reactivity of the calcium silicates and calcium aluminates increases; the results are shown in Figs 1 and 2. Also the differences in reactivities of β- and γ-Ca_2SiO_4 are pointed out and the results are in good agreement with the reactivity series of calcium aluminates.

On analysis of the nearest neighbours of the oxygen in the different compounds, it is seen that very different neighbour atoms are available here. The chemical composition of the clinker phases is in an area between SiO_2 and Al_2O_3 with very low reactivity with waters on one side and the highly reactive CaO on the other side. The environment of the oxygen also changes with respect to the chemical composition and crystal structure of the compounds. Oxygen atoms are linked only to calcium (Ca-O-Ca) in the highly reactive calcium hydroxide while oxygen atoms are linked predominantly to silicon or to aluminium and calcium (Ca-O-Si , Ca-O-Al) in the calcium silicates and calcium aluminates. In contrast, oxygen atoms are linked only to silicon or to aluminium in the unreactive SiO_2 and Al_2O_3.

The mean relationship of the different atoms also should show a connection with the basicity in the neighbourhood of the oxygen next to the integral density of the Ca atoms per unit volume. On the basis of the structural data (ICSD, 1996), the environment around the oxygen has been studied for the calcium silicates and calcium aluminates. It is shown in Figs. 3 and 4 that, with increasing reactivity, the ratios of Ca/Si and Ca/Al of the nearest neighbours of oxygen increase which induces an increase in the oxygen basicity. The grading of reactivity of calcium silicates and calcium aluminates are also in good agreement with the differences in experimentally estimated reactivities. Furthermore they show the differences in the reactivity of β- and γ-Ca_2SiO_4.

These results, with the correlation between reactivity and the ratios of Ca/Si and Ca/Al of the nearest neighbours of oxygen, support the hypothesis that the oxygen basicity is important for the transfer of protons from water to the oxygen atoms. This concept of the reasons for the reactivity is in a generalised form also applicable to other compounds.

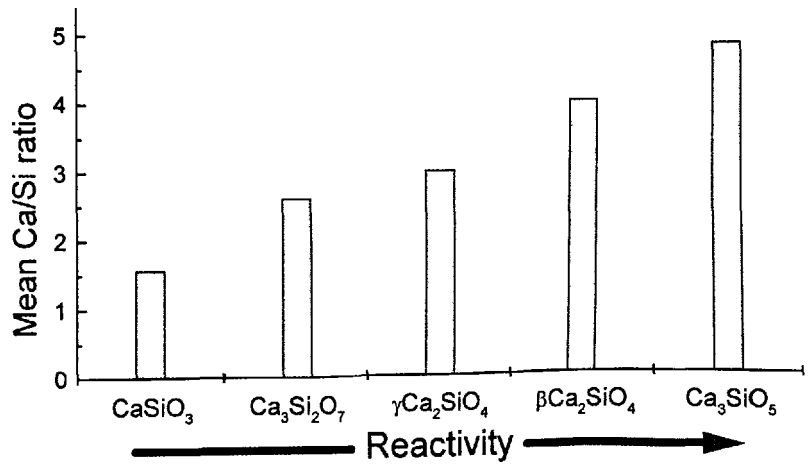

Figure 3 The ratios of Ca/Si of the nearest neighbours of oxygen in calcium silicates

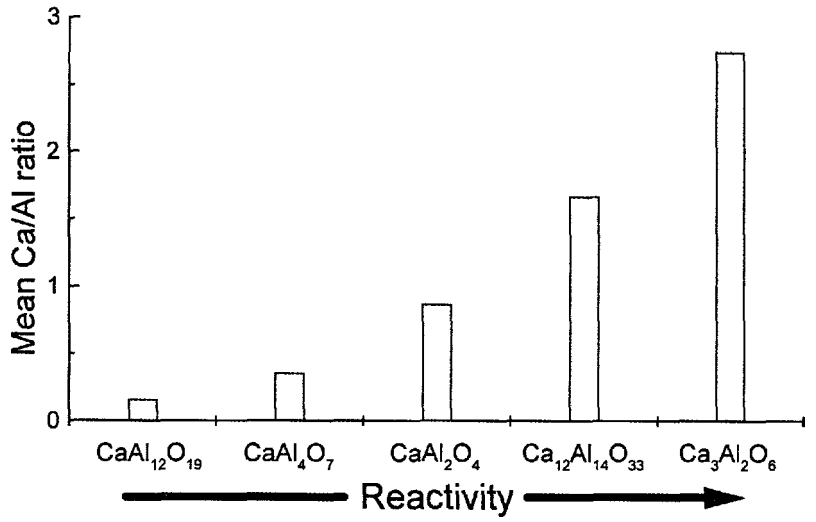

Figure 4 The ratios of Ca/Al of the nearest neighbours of oxygen in calcium aluminates

The calcium aluminates have a higher reactivity then the calcium silicates at the same density of calcium atoms per unit volume. This is caused by the smaller electronegativity of the Al with respect to Si, influences the oxygen basicity.

The distances between different ions and the polyhedra structures have also been investigated and a statistical analysis was applied but no additional generalisations for both calcium silicates and calcium aluminates were found.

The previous discussions to the structural causes of the reactivity only pertained to the ideal structure of the compounds. It has however to be taken into account that defects and foreign ions have an additional influence on the reactivity.

HYDRATION MECHANISM

In the first section, only the reactivity of the calcium silicates and calcium aluminates towards water on the basis of the crystal structure was discussed. The hydration of the single compounds however is not continuous. The reaction passes through different periods of various rates of hydration at which maximums and minimums partially appear. This means that the course of the reaction is still determined by other factors. In the literature there are numerous models to explain the kinetics the hydration, this have been summarising reviewed in Taylor (1990) or Massazza and Daimon (1992). But up until now the mechanism of the hydration is not sufficiently clear.

To obtain a better understanding of the causes of the kinetics of hydration, several early studies were carried out. Different methods were used such as isothermal heat-flow calorimetry, gas adsorption measurements, ESCA and analysis of the liquid phase. From the results it may be deducted based on the theory of Stein et al (1967, 1977) that the primary hydration products cover the surface of the anhydrous compounds and determine the continuation of the hydration by their permeability Trettin at al (1986, 1991). The permeability of the reaction layer depends on the chemical composition, the porosity and the kinetics of its formation. Generally reaction layers rich in calcium have little permeability in the hydration of calcium silicates. On the other

hand, if the formation of a reaction layer with low Ca/Si ratio is favoured then a more permeable reaction layer is formed and the hydration is accelerated.

The origin of the induction period in the hydration of C_3S is attributed to the formation of a reaction layer rich in lime, which exhibits a lower permeability. Former results of investigations indicate that a reaction layer already is formed immediately after contact with water at the beginning of the hydration. In order to get more information about the formation of the reaction layer on the surface the atomic force microscope (AFM) was used (Topometrix TMX 2000). Initially, examination of single crystals of the C_3S was performed. The single crystals of C_3S (triclinic) were grown using the method of Nurse (1949). The AFM images of the surface of C_3S after a time of hydration of 15 seconds is shown in Figure 5. It can be seen that an initially smooth surface already is covered by a reaction layer. The thickness of the reaction layer increases with time of hydration, these new reaction products become more increase and show a stronger height profile. Figure 6 shows the reaction product layer after a time of hydration of 15 minutes in the induction period. The observations made with AFM appear to support the protective layer hypothesis.

A specific influence of the hydration kinetics of a single clinker phase is possible through a corresponding change in the qualities of the reaction layer, which can be achieved by change of the chemical composition of the solution phase. The hydration of C_3S and C_2S is accelerated by reduction of the calcium ion concentration in the solution phase which produced a more permeable layer poor in calcium. Examples for a such acceleration mechanisms are additions which reduce the calcium ion concentration such as SiO_2 or an increase of the water/solid ratio which has a corresponding effect.

The hydration would be retarded by a high level of calcium ion concentration in the solution phase if the formation of a layer rich in calcium with low permeability is favoured. This is achieved for example by hydration in a previously saturated calcium hydroxide solution.

On examination of the influence of the grinding time on the hydration of C_3S, an agreement with Kondo et al (1968) was found in that after longer milling the hydration is retarded. The Induction period is longer and the second maximum is shifted to longer time (from 310 to 560 minutes).These results are surprising because acceleration of hydration by activation is more probable. By the investigation of the solution phase in the very early stage of hydration, it was found that the calcium ion concentration increased with time of milling. Therefore in agreement with the hypothesis of mechanism of hydration the retardation of the hydration is caused by a more impermeable reaction layer rich in calcium.

Similarly to the hydration of the calcium silicates, it was found that the hydration of calcium aluminates is also determined by formation of a primary reaction layer on the surface. It was shown for the hydration of CA (Trettin et al 1987), $C_{12}A_7$, CA_2, CA_6 (Trettin 1989) and C_3A (Trettin et al 1992). Fore instance, the origin of the induction period in the hydration of CA is also contributed to the formation of a reaction layer, which exhibits a lower permeability. From studies on the mechanism of C_3A hydration in the presence of gypsum it may be deducted that in agreement with the literature (Taylor 1990b) the retardation of hydration is caused by a reaction layer.

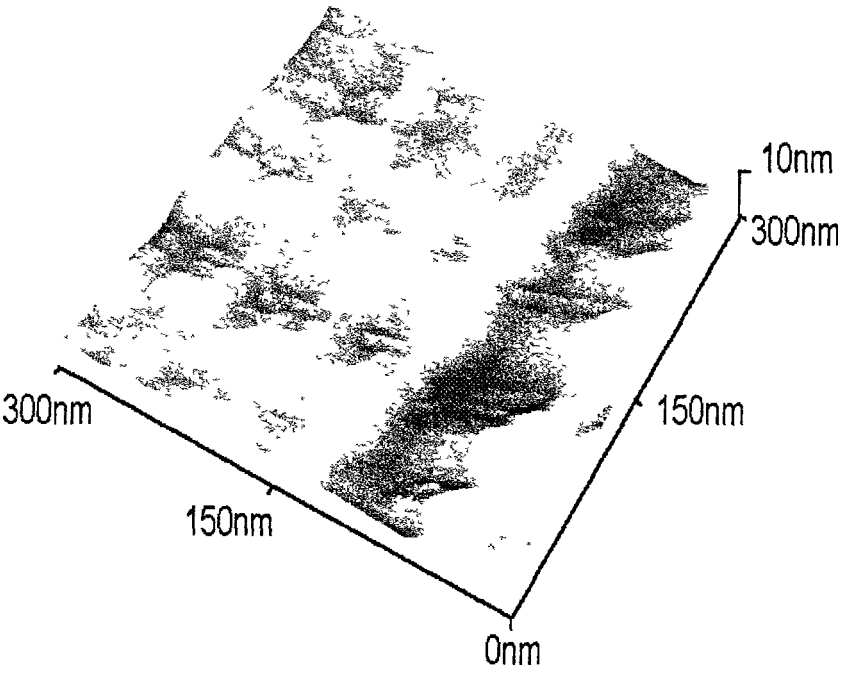

Figure 5 AFM images of the surface of a C_3S single crystal after 15 seconds of hydration

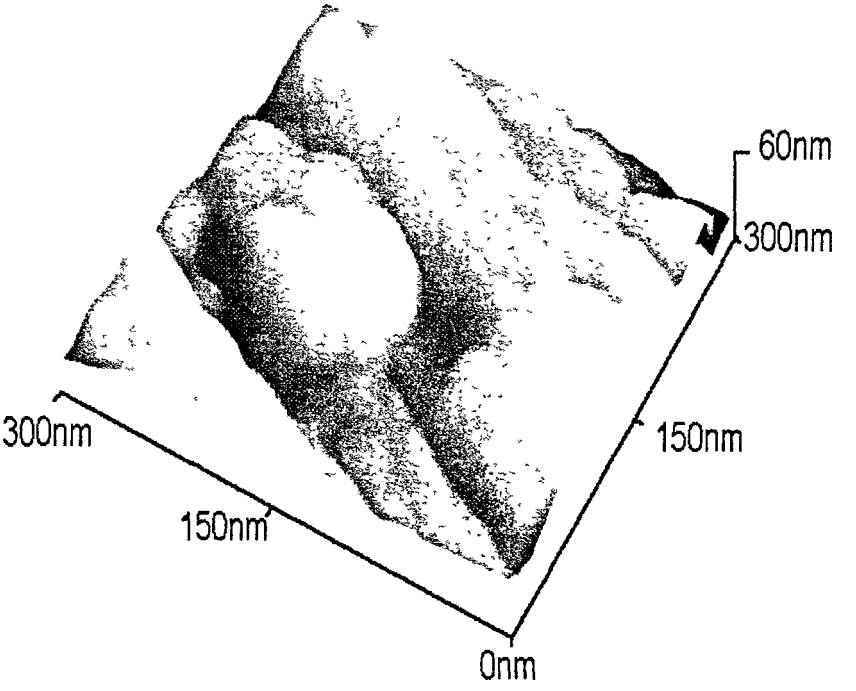

Figure 6 AFM images of the surface of a C_3S single crystal after 15 minutes of hydration

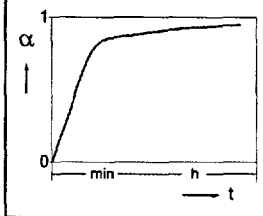

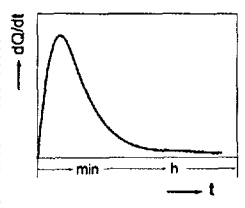

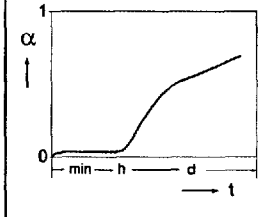

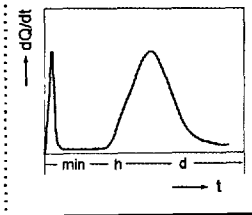

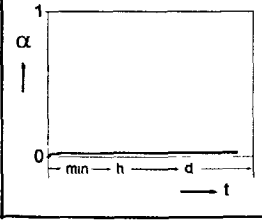

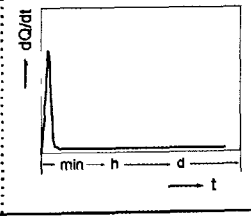

REACTION MODEL

The macroscopic kinetics of the hydration of cement clinker phases depends on several factors. The reactions are very complex and involve several processes. The most essential potential factor for the reaction with water is the crystal structure of the anhydrous compounds. This

means, a sufficient reactivity of the crystal structure is absolute necessary for the reaction. The potential reactivity is determined by the oxygen basicity. The reactivity of the crystal structure is the most essential factor for hydration which however is reduced by the formation of the reaction layer. This layer forms a physical diffusion barrier around the grains. Therefore the permeability becomes a further essential factor for the kinetic of the hydration. The permeability of the reaction layers depends on different factors such as chemical composition of solution, structure, kinetics of formation and transformation, solubility and stability.

It is possible that the different clinker phases can be summarised with respect to their structural potential reactivity, the kinetics of hydration and influence of the reaction layer into groups, see Tab. 1.

Table 1 Overview for relations between the kinetics of hydration, the potential structural reactivity and the influence of the reaction layer for different calcium silicates and calcium aluminates

	Degree of reaction (α)	Rate of heat liberation (dQ/dt)	Reactivity caused by structure	Influence of reaction layer	Compounds
1			very high	initial low; increasing after longer times of hydration till diffusion determines the rate of hydration	C_3A $C_{12}A_7$ — C
2			medium to high	primarily caused the induction period; increasing after the acceleration period till diffusion determines the rate of reaction	C_3S C_2S CA CA_2
3			very small	not determinable	C_3S_2 CS CA_6

CONCLUSIONS

The various reactivity of the calcium silicates and calcium aluminates depends mainly on the crystal structure. It is suggested (in agreement with Barret et al., 1983) that the first step in the reaction with water is a transfer of protons from water to the oxygen atoms in the solid phase. Therefore the oxygen basicity must be the most essential factor for reactivity. The oxygen basicity depend on the environment around the oxygen atoms. Increasing electronegativity of the nearest neighbour atoms correspond with increasing of the reactivity. This means, that with increasing reactivity the ratios of Ca/Si and Ca/Al of the nearest neighbours of oxygen increase.

The structural reactivity do not, in general, determine the kinetics of the hydration. The course of hydration is influenced by the formation of the reaction layer. This layer forms a physical diffusion barrier. The origin of the induction period or retardation in the hydration of reactive calcium silicates and calcium aluminates is contributed to the lower permeability of the reaction layer.

A specific influence of the hydration kinetics of a single clinker phase is possible through a corresponding change in the qualities of the reaction layer, which can be achieved by change of the chemical composition of the solution phase.

ACKNOWLEDGEMENTS

The author is very grateful to Mrs. W. Rosenbusch for the sample preparation and Prof. H. Niehus, E. zur Mühlen and Mrs. K. Braune for their help in AFM measurements.

DEVELOPMENT OF A KINETIC MODEL FOR HYDRATION OF CEMENT

Fuminori TOMOSAWA, The University of Tokyo, Tokyo, Japan

ABSTRACT A hydration model of cement is proposed to describe not only a microstructure formation of cement paste but also the time-dependent characteristics such as development of strength and rigidity, heat liberation, temperature rise, thermal stress, early age creep, setting phenomenon, etc. The model is expressed as a single equation composed of four rate determining coefficients which determine the rate of formation and destruction of initial impermeable layer, the activated chemical reaction process and the following relent diffusion controlled process.

Key-words: Unreacted core model, Degree of hydration, Heat evolution, Strength development

INTRODUCTION

The setting and hardening process of concrete where the concrete changes from fresh state to hardened concrete is an essential problem to be clarified for many features of concrete engineering, such as predicting strength development, temperature rise by heat of hydration, early age shrinkage and creep. However, researches on this process have been conducted so far rather on the basis of empirical methods than theoretical analysis, and in many cases only series of sets of experimental data could have expressed the time dependent behavior of the concrete in this process. Naturally, the process is dependant on the hydration process of cement, thus the hydration model is indispensable to deal with this problem theoretically.

A lot of hydration model has been proposed so far. Most of them were, in the beginning, simple applications of experimental data under constant curing conditions to empirical equations or applications of a first~order reaction equation which could not describe the actual change of rate of hydration in the whole stage. These empirical models could hardly describe the whole stage of the hydration or the changing rate of hydration, for example, under varying temperature curing conditions. The first order reaction model was too simple to describe the complicated phenomena like hydration of cement. Some of them described the reaction well, such as models developed by late Prof. R. Kondo (1968), but from the view point of practical application to concrete engineering, they had some difficulties to be effectively used.

As the hydration of portland cement is an extremely intricate and compound process, it might be impossible to make a perfect model which describes the whole reaction process accurately from the view point of chemistry of cement. However, to develop a model which can be applied to the problems of concrete engineering might be possible and that development of the model can contribute to better understanding of the hydration process from the engineering point of view. An engineering model does not mean a simple model, but it needs to simulate the hydration process as correctly as possible and can describe the effects of all the factors which come into the process.

A kinetic model of hydration of cement which has been developed from this standpoint (Tomosawa, 1974) is presented in this paper.

DESCRIPTIVE MODEL OF HYDRATION

Basic concept

To describe the process of hydration is in effect to express the changes in the degree and rate of reaction over time. In regard to the practical aspects of hydration as well, such as strength development and heat generation, the main concern is how they increase and change with time. However, this does not mean that the rate of hydration is directly determined as a function of time. The rate of hydration at a point in time is determined by the amount of cement that has gone through a hydration process by that time, amount of water available for hydration at that time, as well as temperature and pressure (this paper does not take pressure into account). Conventional

hydration models have tended to try to express the degree and rate of hydration directly as functions of time. However, such an approach cannot describe the phenomenon correctly. The hydration rate after 5 hours from the time of cement-water contact, for instance, widely varies depending on the curing temperature. Accordingly, the author proposes here a model that expresses the hydration rate using the degree of hydration.

Descriptive model

The hydration process of a cement particle that is assumed to be spherical is modeled as follows:

(i) The cement particle initiates hydration the moment it is brought into contact with water.
(ii) The hydrate formed by the reaction adheres to the cement particle, gradually covering it up. The cement particle remains spherical as a whole.
(iii) The hydrate has a volume twice the original cement volume.
(iv) The liquid phase, which is assumed to be water, diffuses through the hydrate layer and reaches the surface of the cement particle (reacting surface) and chemically reacts with cement there. This continues the reaction.
(v) Part of the hydrate produced at the reacting surface moves out through the formed layer of hydrate. Accordingly, nearly equimolar counter diffusion of water and hydrate (presumably ions) is assumed to be taking place in the hydrate layer.
(vi) It is assumed that, in the so-called dormant period in the initial stage, there is a process in which the reaction resistance increases in inverse proportion to the reaction degree (film formation) followed by a period in which the reaction resistance decreases in proportion to the square of the reaction degree (film breakage).
(vii) The rate of reaction decreases more rapidly than assumed in a normal diffusion-determined process. Several explanations are conceivable to account for this phenomenon. It is assumed here that the radial effective diffusion coefficient in the hydrate layer is reduced by the deposition of part of subsequently produced hydrate on the inner surfaces of pores in the hydrate layer. Another convincing explanation is the reduction in the amount of water which is present outside of the hydrate layer and is available for the reaction. Though this parameter is included in the model, it is tentatively assumed to be constant.

MATHEMATICAL MODEL OF HYDRATION

The outline of the mechanism of cement hydration is as stated above. In short, the hydrate as such inhibits subsequent reaction. The so-called unreacted core model (Yagi and Kunii, 1953) is often applied to the case where the reaction product deposits or remains between the reactants, inhibiting the reaction.

Basic equation

At time t, a cement particle covered by cement gel is represented by **Fig 1**. The origin of time is when the particle is brought into contact with water. Then the following equation holds:

$$4\pi r_t^2[N_w]_{r=rt}=4\pi r^2 N_w \qquad [1]$$

where r_t = radius of unhydrated cement particle
r = an arbitrary radius between r_t and R_t
R_t = total radius including the gel layer
N_w = flux of water at r towards the reaction surface

The following equation is obtained from the basic equation(s) of diffusion:

$$N_w=D_e(dC_w/dr) \qquad [2]$$

where D_e = effective diffusion coefficient of water in the cement gel
C_w = abundance concentration of water at r

Eq1 and **Eq2** lead to:

$$r_t^2[N_w]_{r=rt}=r^2 D_e(dC_w/dr)$$

This is integrated under the following boundary conditions:

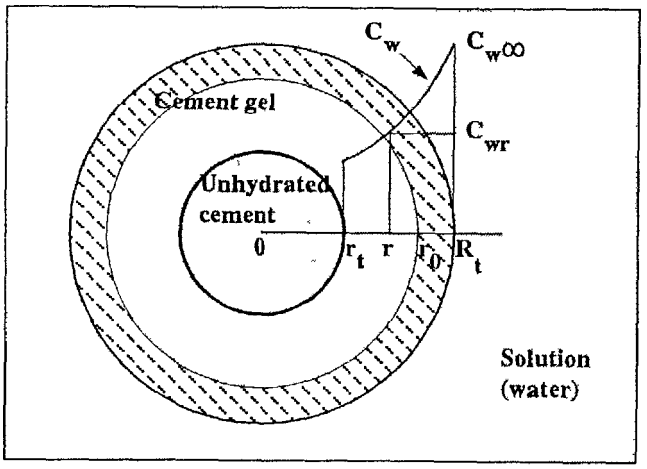

Fig.1 Unreacted core model for a particle of cement

When $r = r_t$, $C_w = C_{wr}$
When $r = R_t$, $C_w = C_{w\infty}$

Then the following equation is obtained:

$$r_t^2[N_w]_{r=rt}(1/r_t-1/R_t)=D_e(C_{w\infty}- C_{wr}) \quad [3]$$

As the overall reaction rate, R, equals the diffusion rate at the total area of the reaction surface,

$$R=4\pi r_t^2[N_w]_{r=rt} \quad [4]$$

Eq3 and **Eq4** lead to:

$$R = 4\pi D_e \frac{C_{w\infty} - C_{wr}}{\frac{1}{r_t} - \frac{1}{R_t}} \quad [5]$$

The overall reaction rate, R, also equals the chemical reaction rate of water and cement at the reaction surface. If the chemical reaction rate is assumed to be linear in regard to the abundance concentration of water, the following equation holds:

$$R=4\pi r_t^2 k_r C_{wr} \quad [6]$$

where k_r = coefficient of reaction rate per unit area of reaction surface

From **Eq5** and **Eq6**, C_{wr} is eliminated as follows:

$$R = \frac{4\pi C_{w\infty}}{\frac{1}{D_e}\left(\frac{1}{r_t} - \frac{1}{R_t}\right) + \frac{1}{k_r r_t^2}} \quad [7]$$

If it is assumed that the reaction surface shifts from rt to r_t-dr_t while t becomes t+dt, then the following equation holds in regard to unit area of the reaction surface:

$$dt[N_c]_{r=rt}=-dr_t \rho_c$$
$$\therefore dr_t/dt=-1/\rho_c[N_c]_{r=rt} \quad [8]$$

where $[N_c]_{r=rt}$ = flux of unhydrated cement into the reaction surface
ρ_c = density of unhydrated cement

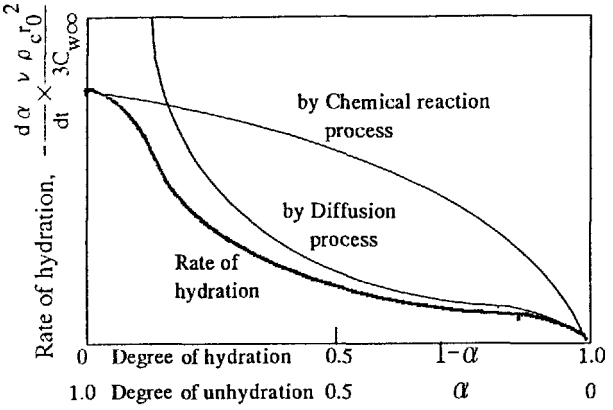

Fig.2 Rate of hydration determined by two different process

If the stoichiometric ratio by mass of water to cement is assumed to be ν, then:

$$[N_w]_{r=rt} = \nu\,[N_c]_{r=rt} \qquad [9]$$

From **Eq4**, **Eq8**, and **Eq9**:

$$R = -4\pi r_t^2 \nu\, \rho_c \cdot dr_t/dt \qquad [10]$$

Substituting this into **Eq7** and rearranging the equation lead to:

$$-\frac{dr_t}{dt} = \frac{C_{w\infty}}{\nu\rho_c r_t^2}\,\frac{1}{\frac{1}{D_e}\left(\frac{1}{r_t}-\frac{1}{R_t}\right)+\frac{1}{k_r r_t^2}} \qquad [11]$$

If it is assumed that $r_t=r_0$ when t=0 and that the ratio of the volume of unhydrated cement at t=t to that of t=0 is the degree of unhydration, α, then:

$$\alpha = \left(\frac{4}{3}\pi r_t^3\right)\Big/\left(\frac{4}{3}\pi r_0^3\right) = \left(\frac{r_t}{r_0}\right)^3 \qquad [12]$$

Also, if the hydrate has a volume twice as large as that of unhydrated cement, then:

$$\left(\frac{4}{3}\pi R_t^3\right)\Big/\left(\frac{4}{3}\pi r_0^3\right) = \alpha + 2(1-\alpha) = 2-\alpha$$

$$\therefore (R_t/r_0)^3 = 2-\alpha \qquad [13]$$

Eq12 is differentiated as follows:

$$\frac{dr_t}{dt} = \frac{r_0^3}{3r_t^2}\frac{d\alpha}{dt}$$

Consequently, **Eq11** is rearranged with respect to the degree of unhydration, α, as follows:

$$-\frac{d\alpha}{dt} = \frac{3C_{w\infty}}{\nu\rho_c r_0^2}\,\frac{1}{\frac{1}{D_e}\left\{\alpha^{-\frac{1}{3}}-(2-\alpha)^{-\frac{1}{3}}\right\}+\frac{1}{k_r r_0}\alpha^{-\frac{2}{3}}} \qquad [14]$$

This equation suggests that when α is near 1, or in an early stage of reaction, the reaction rate is determined by the chemical reaction (the k_r term governs), whereas when α is near 0, or in the final stage of the reaction, the reaction rate is determined by diffusion (the D_e term governs). In an intermediate stage, the reaction rate is determined by both (see **Fig 2**).

Introduction of dormant period model

Equation 14 does not express the dormant period in the beginning of hydration. The low reaction rate during the dormant period is not negligible, as reaction proceeds significantly in a few hours where high temperature curing is done, for instance. The characteristics of this early reaction can be considered as being caused by a certain substance whose mass transfer resistance suddenly increases from the state of zero and then suddenly decreases. It can be assumed that a layer having such a pattern of mass transfer resistance exists between the unhydrated cement particle and the external gel layer. If the abundance concentration of water at the outer and inner interfaces of the layer are assumed to be C_{wII} and C_{wIII}, respectively (see **Fig 3**), the overall reaction rate, R, can be considered similarly as follows:
R equals the rate of passing through the initial film. Therefore,

$$R=4\pi r_t^2 k_d(C_{wII}-C_{wIII}) \qquad [15]$$

where k_d = mass transfer coefficient

R also equals the diffusion rate within the gel layer and reaction rate at the reaction surface:

$$R = 4\pi D_e \frac{C_{w\infty} - C_{wII}}{\frac{1}{r_t} - \frac{1}{R_t}} \qquad [16]$$

$$R=4\pi r_t^2 k_r C_{wIII} \qquad [17]$$

Consequently,

$$R = \frac{4\pi C_{w\infty}}{\frac{1}{k_d r_t^2} + \frac{1/r_t - 1/R_t}{D_e} + \frac{1}{k_r r_t^2}} \qquad [18]$$

This is rewritten using the unhydrated degree, α:

$$-\frac{d\alpha}{dt} = \frac{3C_{w\infty}}{\nu\rho_c r_0^2}\left(\frac{1}{\frac{1}{k_d r_0 \alpha^{2/3}} + \frac{\alpha^{-1/3} - (2-\alpha)^{-1/3}}{D_e} + \frac{1}{k_r r_0 \alpha^{2/3}}}\right) \qquad [19]$$

The first term of the denominator in the brackets on the right side of the equation relates to the initial reaction, indicating its reaction resistance. This affects only a very early stage when $\alpha \fallingdotseq 1$, and therefore $\alpha^{2/3}$ is assumed to be 1. In this case, the reaction rate is determined by k_d. Here kd is assumed to be expressed as the sum of the term in inverse proportion to the reaction degree, $(1-\alpha)$, and the term in proportion to the square of $(1-\alpha)$:

$$k_d=B_d/(1-\alpha)+C_d(1-\alpha)^2 \qquad [20]$$

The first term indicates that the reaction resistance increases as the reaction proceeds (formation of impermeable film), and the second term indicates the reaction resistance suddenly decreases after hitting the peak (breaking of the film). Other forms of kd may be conceivable. It is necessary that the model agrees well with the measurements of the initial reaction including the dormant period.

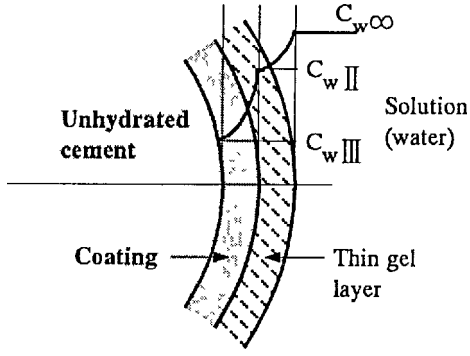

Fig.3 Schematic model of a cement particle in the dormant period

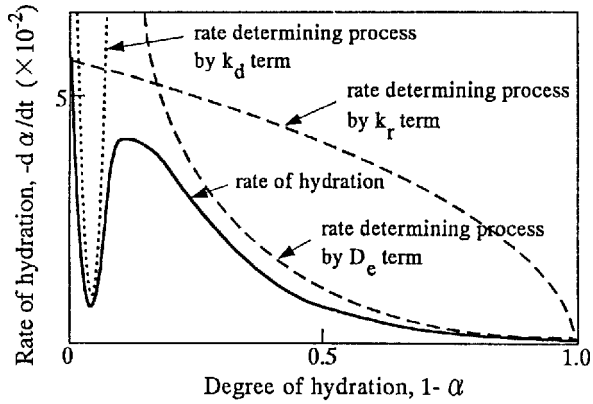

Fig.4 Rate of hydration expressed by the model and 3 types of rate determining processes

Changes in effective diffusion coefficient

The model up to the previous section does not agree well with the measurements. Higher reaction rates are calculated by this model in later stages of reaction. From among several options for correcting this, here the method mentioned in (vii) under "Descriptive model" above is adopted. As a result, the changes in the effective diffusion coefficient are expressed as follows:

$$D_e = D_E\left(\ln\frac{1}{1-\alpha}\right)^2 \qquad [21]$$

Whole process hydration model

Consequently, a mathematical model of hydration is obtained as follows:

$$-\frac{d\alpha}{dt} = \frac{3C_{w\infty}}{\nu\rho_c r_0^2}\left(\frac{1}{\frac{1}{k_d r_0} + \frac{\alpha^{-1/3}-(2-\alpha)^{-1/3}}{D_e} + \frac{1}{k_r r_0 \alpha^{2/3}}}\right) \qquad [22]$$

where k_d and D_e is defined by **Eq20** and **Eq21**, respectively.
By adequately selecting the coefficients, **Eq22** is plotted as the solid lines shown in **Fig 4**. The broken lines represent the rate-determining processes, indicating that the reaction rate is determined by them.

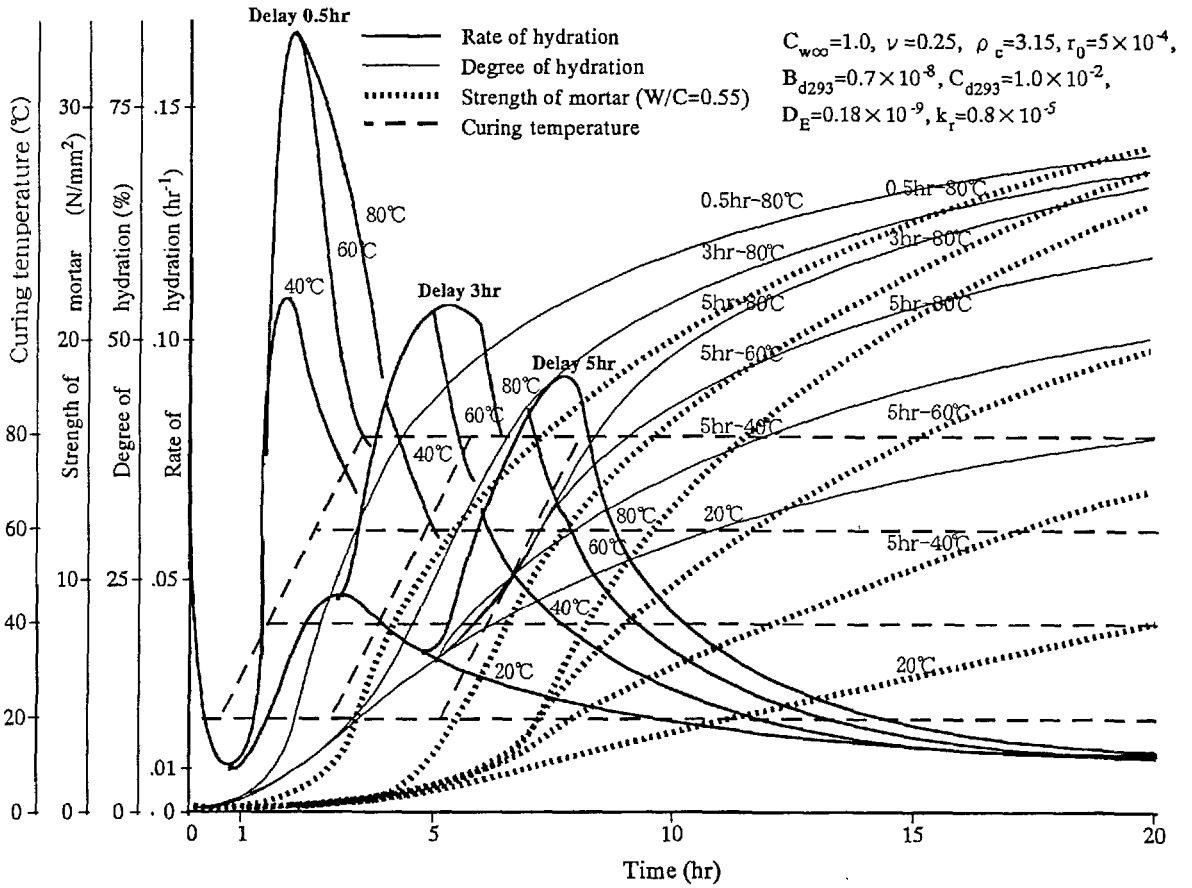

Fig.5 Simulation of hydration of cement under various curig conditions

Values of mass transfer coefficients

Coefficients k_r and D_E among the four mass transfer ratios contained in the model were determined so as to agree with the overall cement hydration degree obtained from the reaction degrees of minerals composing cement at 20℃ proposed by the PCA Group (Copeland et al., 1960). Coefficients B_d and C_d were determined so as to express the general characteristics of initial reaction. Also, the constants were selected as follows:

$C_{w\infty} = 1.0$, $\nu = 0.25$, $\rho_c = 3.15$, $r_0 = 5\times10^{-4}$ cm
$B_d = 0.7\times10^{-8}$ cm·hr^{-1}
$C_d = 1.0\times10^{-2}$ cm·hr^{-1}
$k_r = 0.8\times10^{-5}$ cm·hr^{-1}
$D_E = 0.18\times10^{-9}$ cm·hr^{-1}

Values of temperature coefficients

The effect of temperature on hydration is introduced to each mass transfer coefficient. Accurate relationships are considered to be obtainable by experimentally determining the changes in the reaction rate. Here it is assumed that B_d is in proportion to the square of absolute temperature, and that C_d, D_E, and kr follow Arrhenius' law. The values for the coefficients given in the previous section are those for 20℃. Therefore the coefficients at θ K are expressed as follows:

$$B_{d\theta} = B_d\sqrt{\theta/293}$$
$$C_{d\theta} = C_d\exp\{-\beta_1(1/\theta - 1/293)\} \quad [24]$$
$$k_{r\theta} = k_r\exp\{-\beta_2(1/\theta - 1/293)\}$$
$$D_{E\theta} = D_E\exp\{-\beta_3(1/\theta - 1/293)\}$$

The following values of β_1, β_2, and β_3 are considered appropriate from the strength development data of mortar during high temperature curing (Kishitani and Tomosawa, 1968), etc.

$\beta_1 = 0.3 \times 10^4$
$\beta_2 = 0.42 \times 10^4$
$\beta_3 = 0.40 \times 10^4$

SIMULATION OF HYDRATION AND STRENGTH DEVELOPMENT

Thus the mathematical model has been obtained with typical values of the constants. This makes possible the simulation of hydration under any changing temperature. An example of the calculation result is illustrated in **Fig 5**. This shows the rates and degrees of hydration with a fixed temperature of 20℃, as well as those with a precuring period of 0.5, 3.0, and 5.0 hr, maximum temperature of 40, 60, and 80℃, and curing at a temperature rise gradient of 20℃/hr. It represents well the increase in the reaction rate associated with the temperature rise, as well as the changes in the reaction rate when the temperature stops rising. The figure also contains a compressive strength development curves of mortar as an application example. These were calculated by assuming that the strength is proportional to the cube of the gel-space ratio (Powers, 1964) at a point of time, which is determined from the degree of hydration at that time.

Similarly, if the generation of hydration heat is assumed to be proportional to the degree of hydration, exotherm curves can be obtained as well. The model can also simulate the situation in which the heat generation in turn accelerates the reaction.

CONCLUSION

The author devised a simulation model that expresses the entire process of hydration of portland cement with a single kinetic equation. This model is characterized by the independence of rate-determining processes. This enables researchers to attempt other equations based on different assumptions for each rate-determining process, modify the values of mass transfer coefficients or temperature dependency, and conduct model experiments to assess their validity. The humidity dependency of the reaction rate may be introduced by modifying $C_{w\infty}$ in **Eq22**.

SIMULATION OF CEMENT-HARDENING IN THE PRESENCE OF CARBON USING HYDRA2D

R.J. van EIJK and H.J.H. BROUWERS University of Twente, Department of Civil Engineering and Management, P.O. Box 217, 7500 AE Enschede, The Netherlands

ABSTRACT In the present study the cement hydration simulation program Hydra2d is adjusted in order to simulate the influence of reaction-rate limiting contaminants such as carbon. The water absorbing effect of activated carbon is simulated and resulted, among other things, in high porosity microstructures and lower hydration degrees.

Key-words: modelling, hardening, hydration, immobilization, waste material utilization.

INTRODUCTION

The solidification of waste materials in a cement matrix has several advantages. A waste problem can be solved, the use of primary materials is decreased and in general recycling of materials will take place. Waste materials, however, can influence the hydration reaction by interacting with all components in the matrix that are involved in the cement reactions. One example of such an interaction is presented here, namely a water absorbing species such as active carbon. Active carbon can be added to the cement matrix in order to bind organic contaminants (Conner, 1990). However its presence during hydration causes extra porosity in the cement as it removes the water needed for the cement reactions. The carbon is able to bind water several times its weight (Capelle and de Vooys, 1983). In this paper the effect of carbon on hydration is demonstrated by numerical simulation of the hydration process.

HYDRA2D

Modelling of cement hydration can be done in many ways (Jennings et al., 1996). A digital-image-based cement paste microstructure model has been developed at the NIST (Bentz and Garboczi, 1990). The computer program in which this model is implemented has been used for simulation studies on the electrical conductivity of cement (Christensen et al., 1991) and the percolation of phases (Bentz and Garboczi, 1990). It can be used to study the development of the fine porosity and gel structure during hydration and to investigate the influence of the hydration conditions on the final microstructure.

In this study the two dimension version of this program, called Hydra2d, was used in which the cement mixture is presented as a 2 dimensional matrix of 200 x 200 pixels. Cement particles are presented as discrete spheres and filler particles can be added as 1 pixel elements. An aggregate can be placed in the middle and extends in one dimension. Every pixel in the system is assigned a phase including C_3S, CSH, CH, Inert and Porosity.

When all pixels are placed the hydration starts following the principle of dissolution-diffusion-precipitation (Bentz and Garboczi, 1992). A hydration cycle starts by the determination of all cement (C_3S) pixels that are in contact with porosity. These pixels perform a random move and when this move is into porosity the particle is dissolved. All dissolved pixels diffuse randomly until a reaction or precipitation takes place. The cement reaction in this model has the following volume stoichiometry (C =CaO, H=H_2O, S=SiO_2) (Young and Hansen, 1987):

$$C_3S + H => 1.7\ C_{1.7}SH_4 + 0.61\ CH \quad [1]$$

This means that 1 volume unit of cement reacts with water to produce 2.31 volume units of solid product. This volume expansion results in the moulding of a rigid microstructure. The present model does not take chemical shrinkage into account.
After the dissolution step all dissolved pixels perform random moves. Diffusing CSH precipitates into solid CSH upon contacting a solid C_3S or CSH surface. Diffusing CH has a chance, depending on its concentration, to nucleate spontaneously and precipitate into solid CH upon contacting a solid CH surface. When no more diffusing pixels are present a new hydration cycle is started. When hydration is completed after a given degree of hydration or number of cycles phase compositions can be determined by pixel counts on the final structure. Also the composition as a function of the distance to the aggregate can be determined in order to obtain information about the Interfacial Zone near the aggregate (Garboczi and Bentz, 1991).

ADJUSTMENTS

General adjustments in the program were made in order to be able to measure results during hydration without loosing the microstructure developed so far. An extra option was added for the addition of Portland C cement in one step. The amount of particles is adjusted automatically in the presence of aggregate or carbon particles in order to maintain a constant w/c ratio.

Next, the Hydra2d program was adjusted to simulate the influences of activated carbon. The presence of a water absorbing species is added to the program by introducing a new phase called Carbon. This phase can be introduced into the system as particles as well as aggregate or filler. This phase also will be detected for dissolution and when a random move into porosity takes place, the Carbon is converted into a phase called Carbon Water and stays in place. In this way the conversion is executed in the same way as the conversion of C_3S into diffusing CSH. Extra pixels of the Carbon Water phase are placed randomly in the simulation field replacing porosity and simulating overall water binding. Contrary to dissolved cement particles the Carbon Water particles do not diffuse but stay in place. Carbon Water pixels are counted separately, but will be regarded as extra porosity because they represent weak spots in the cement matrix.

SIMULATION RUNS

Simulations were executed using different compositions of the starting structures. In all structures an approximation of the particle size distribution of Portland C cement was used (Souwerbren, 1995). In all structures a w/c ratio of 0.45 was employed and the same initial cement particle distribution. In Table 1 the used particle size distribution is summarised.

Table 1. Particle size distribution of used cement.

d-size (μm)	particles (n)
5	318
10	53
15	16
25	4

In the center of the 200 x 200 matrix an aggregate of size 10 x 200 pixels was placed. Carbon particles were introduced as 10 μm spheres, representing the mean size of Powdered Activated Carbon particles (Capelle, 1983). All carbon was assigned a reactivity factor of 5, implying that every Carbon Water pixel generates 5 extra Carbon Water pixels. In order to keep a constant starting w/c ratio some of the 10 μm C_3S particles were replaced by the 10 μm carbon particles. Four simulations were executed in the presence of an inert aggregate and 0, 1, 3 and 7 % (v/v) 10 μm carbon particles. The 7 % Carbon simulation can be considered as an extreme case. Two simulations were executed in the presence of a Carbon aggregate with and without an extra 3 % (v/v) carbon particles to simulate the effect of a large Carbon particle in the cement. In Table 2 all these initial conditions are tabulated.

Table 2. Phase compositions of starting microstructures (%(v/v)).

Structure	a	b	c	d	e	f
Porosity	55	55	53	50	55	53
C_3S	40	39	38	37	39	38
Carbon	0	1	3	7	5*	8*
Aggregate	5	5	5	5	5	5

* Includes 5 % Aggregate.

All simulations were executed during 15 cycles. Compositions were measured after 0, 5, 10 and 15 cycles. At the same time w/c ratios and degrees of hydration were determined.

RESULTS

The final microstructures are presented in Fig. 1 (see end of volume). Carbon Water, implying weak spots, appear all over the microstructure as expected. Most Carbon Water is found around the carbon particles itself or near the carbon aggregate.

Table 3 presents the phase compositions in the simulated microstructures after 15 cycles

Table 3. Compositions after 15 cycles.

Structure	a	b	c	d	e	f
Porosity	18	14	9	3	10	4
C_3S	11	12	14	17	14	17
CSH	47	44	41	34	42	36
CH	17	16	14	12	15	12
Carbon	0	0	1	3	2*	4*
Carbon Water	0	6	14	24	14	25
Total porosity	18	20	23	28	24	29

* Includes remaining of aggregate.

Fig 1 is found in the colour photo section.

From Table 3 it can be seen that a small addition of water absorbing material has a relatively large effect on the final composition of the cement. For example, an addition of 1 % carbon causes a decrease of 3 % in the amount of CSH and 3 % extra porosity. So, though the initial amount of porosity was 1 % less (see Table 2), the final amount is 2 % higher. The hydration degree is decreased by 5 % after 15 cycles. Table 3 also learns that, comparing (d) with (f), that the final composition is nearly the same when the carbon is placed as particles (7% in structure (d)) or as aggregate and particles (5 + 3 = 8% in structure (f)).

Fig. 2 show the porosity fractions as function of the distance from the aggregate at the end of all simulations. The interfacial zones are relatively small (5 μm) compared to experimental results (Scrivener, 1989). When a carbon aggregate is present an extreme high porosity fraction is present near the aggregate, due to the Carbon Water that stayed in place after diffusion from the aggregate surface into the solution. It should be realised that for structures (e) and (f), the aggregate thickness is reduced by its dissolution (see Fig. 1). However, in Fig. 2 the distance is taken from the original aggregate boundary. In fact, the aggregate shrinked almost 1 pixel on both sides. The region immediately adjacent to this shifted reactive surface would correspond to an aggregate distance of -1 in Fig. 2 and here the porosity tends to unity. On the other hand, the thickness of the interfacial zone is hardly affected by the Carbon. This results from the fact that the presence of Carbon does not influence the particle packing near the aggregate.

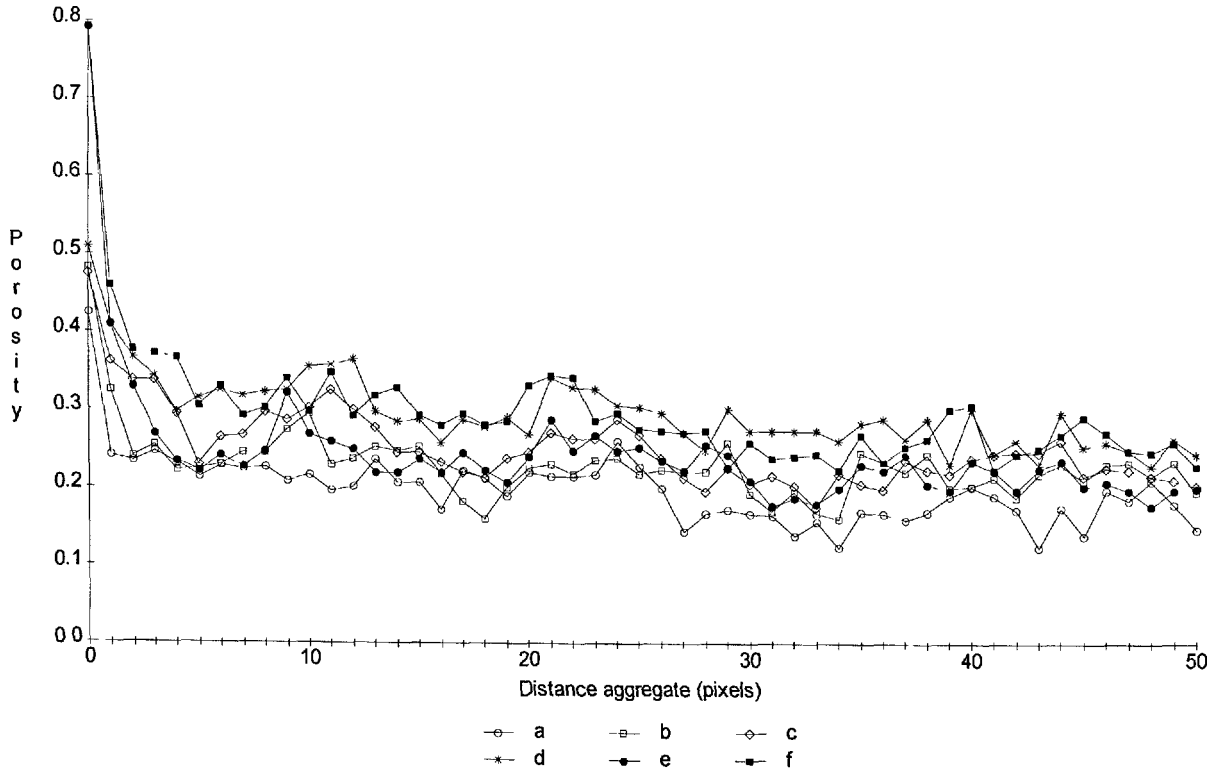

Figure 2 Porosity fractions as function of the distance from the aggregate (1 pixel is approximately 1 μm).

The overall porosity, determined by adding all porosity and Carbon Water in the total microstructure, increases strongly when Carbon was present in the initial structure. Fig. 3 shows the development of this total porosity during all simulations.

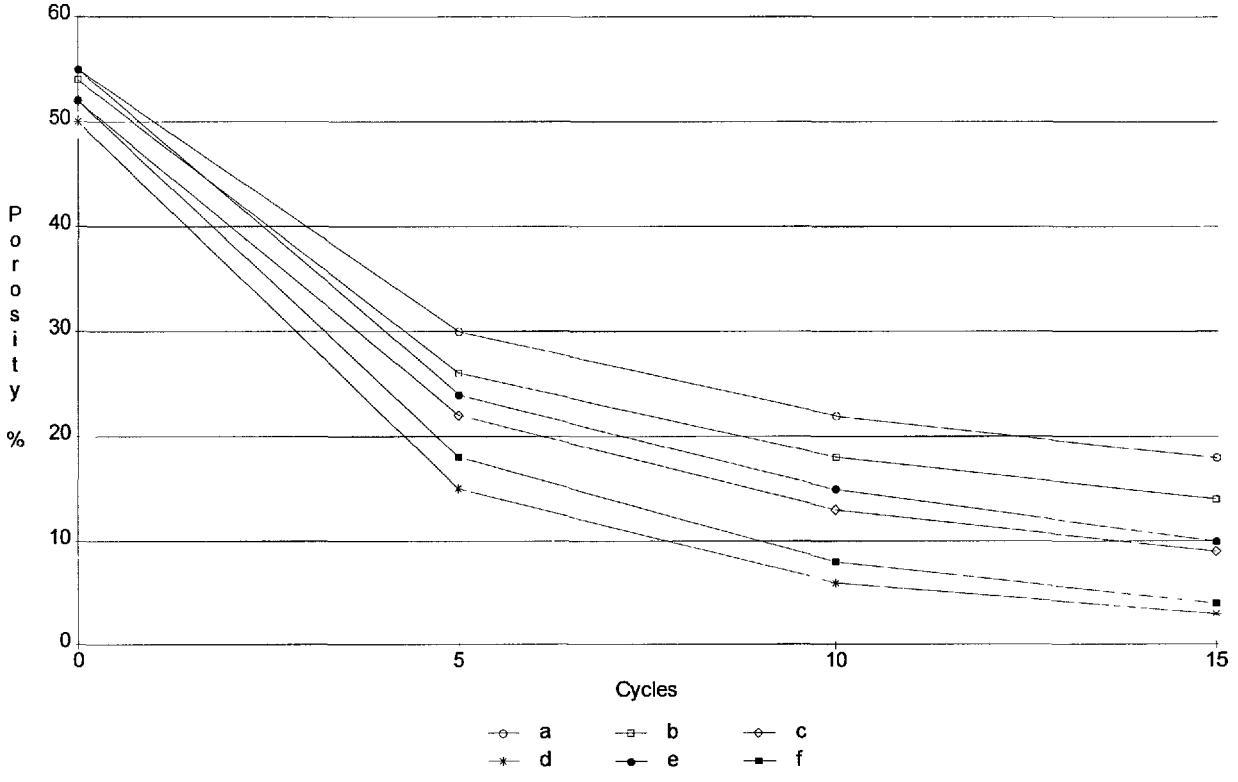

Figure 3 Total amount of porosity (%) during simulation.

Fig. 4 shows the hydration degrees during 15 cycles for all simulations. It is obvious that the hydration degree decreases strongly in the presence of carbon, which might be expected. Figs. 3 and 4 again illustrate that the d) and f) structures, which contain the same total amount of Carbon, closely correspond to each other. Though for the latter most Carbon is added as aggregate, the final result corresponds to the d) structure, in which the Carbon is placed as spheres.

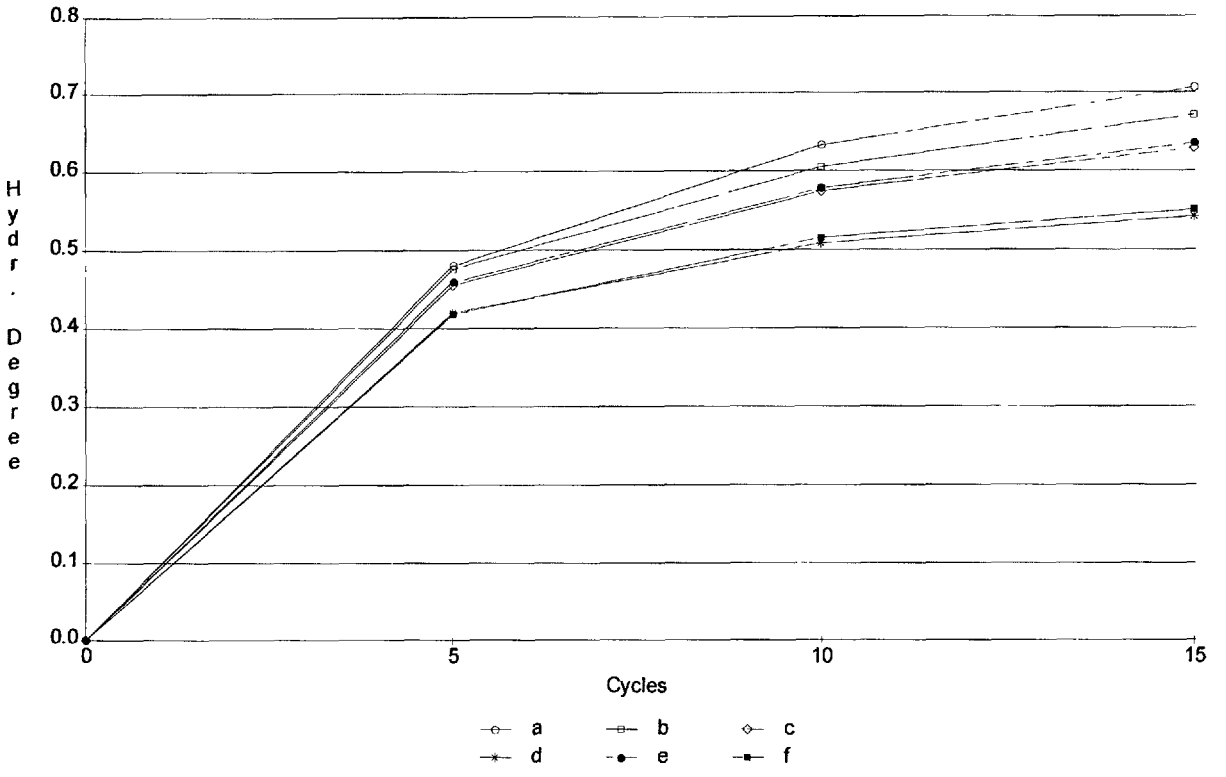

Figure 4 Hydration degrees during simulations.

CONCLUSIONS

The Hydra2d program appeared to be very suitable to simulate the hydration of cement in the presence of water absorbing species. A few adjustments in the program code were adequate in order to accomplish this. The microstructures formed in the presence of carbon as water absorbent showed high porosity. This follows directly from the introduction of extra porosity each time when Carbon is converted into Carbon Water. The hydration degrees decreased strongly in the presence of relatively small amounts of active carbon. This effect is caused by the increase of the replacement of porosity by Carbon Water resulting in a lower growing space for CSH. Also it is caused by the Carbon Water pixels that replace the porosity surrounding the cement particles, thereby decreasing the amount of possible moves into porosity and lowering the dissolution possibility for cement pixels.

The carbon pixels were assumed as static in the presented model. The effect of diffusion is considered minor because carbon pixels are already placed randomly into the system. The probability of a carbon pixel moving into the solution should be adjusted using experimental results. It is yet unknown whether this probability is the same as the probability of a cement particle going into solution.

Ongoing research comprises the modelling of cement hydration in the presence of contaminants or immobilisates. This can only be done when the most abundant influences of the contaminants on the hydration process are known and quantified. When this is done the corresponding necessary adjustments can be made. A new version of the model that takes into account more aspects of the hydration process will be used for this purpose because it offers more possibilities for adjustment.

PHYSICO-CHEMICAL PARAMETERS DETERMINING HYDRATION AND PARTICLE INTERACTIONS DURING SETTING OF SILICATE CEMENTS.

André NONAT, Jean-Claude MUTIN and Shi Ping JIANG, Laboratoire de Recherches sur la Réactivité des Solides, CNRS-Université de Bourgogne, Dijon, France.

ABSTRACT Setting of tricalcium silicate results from interactions between anhydrous or very partially hydrated particles. Two fundamental steps have been identified : the coagulation of cement grains during the first minutes following the mixing, and the rigidification of the coagulated structure which arises simultaneously with the acceleration of the calcium silicate hydrates (C-S-H) formation. There exists a critical range of lime concentration required to coagulate cement particles and to enable C-S-H to stiffen the coagulated structure depends on their solubility.

Key-words : Setting, Strength development, Degree of hydration, CSH, Particle size distribution

INTRODUCTION

Hydration, setting and hardening are all related to the main properties of hydraulic binders, that is to say, the ability to get a hard material by mixing cement powders with water (eventually aggregates) but they involve different processes with different mechanisms. Hydration is a chemical process which, from the anhydrous cement powder and water, through several chemical reactions leads to the formation of hydrates. This complex process has thermodynamic, kinetic and structural features which depend on both chemical and physical parameters. Setting is a definite time event which corresponds to the transition from a soft state of the paste to an hardened state.

Hardening is certainly the less ambiguous term, it involves increase in the strength of the material. It depends on a lot of physicochemical parameters such as degree of hydration, water to cement ratio (W/C), curing conditions, etc.... There are reasons to believe the elementary processes during hardening and setting as being the same.

The purpose of this paper is to examine the interactions that may exist between these simultaneous processes, which all together contribute to build up the complex materials that are cement paste and concrete. The experimental investigation of the elementary processes involved in the chemical and physical evolutions of a system of hydrating particles has given answers to the following questions:

- What are the features of hydration, i.e., the chemical reactions, the nature of the products and the parameters determining thermodynamics, kinetics, and their structural and microstructural properties?
- What are the processes involved in setting and the determining parameters?
- What are the interactions between hydration and setting?

Taking into account that real Portland cement is a complex mixture of different phases, we focused our attention on Ca_3SiO_5, the main component of this cement, as a reasonable easier model system.

Considering the fact that both chemical and mechanical properties change the most during the earlier part of the temporal evolution of the solid-liquid system, we focused our attention on the period following the mixing to the setting of the paste, i.e., the first 24 hours of the evolution.

CHEMICAL AND MECHANICAL EVOLUTIONS OF A NORMAL TRICALCIUM SILICATE PASTE

Hydration of tricalcium silicate proceeds through three successive reactions becoming successively simultaneous (Barret et al, 1986) :
- the dissolution of Ca_3SiO_5 ,providing calcium, silicate and hydroxide ions in solution;
- the precipitation of calcium silicate hydrate (C-S-H).The stoichiometry of C-S-H given by the calcium to silicon ratio (Ca/Si, or C/S) depends on the lime concentration in solution;
- the precipitation portlandite ($Ca(OH)_2$).

Fig 1 shows the evolution versus time of the chemical compositions of the solid and liquid phases and the mechanical evolution of the system.

Based on this figure, two important remarks can be made:
- 1/ Setting, which corresponds to the time at which the Vicat needle does no more penetrate the paste, occurs when only less than 5% of tricalcium silicate has hydrated. This means that the set paste is a continuously connected network of very partially hydrated Ca_3SiO_5 particles.
- 2/ The most important changes of the lime concentration in the pore solution occurs between mixing and setting. Thus, the lime concentration may be an important parameter controlling both hydration and setting processes.

In order to investigate hydration and setting phenomena, we have developed experimental procedures allowing control of the ionic concentrations in a better way than in paste. They are based on conductimetric, calorimetric and granulometric measurements on more or less diluted suspensions of particles (0.5<W/C<300) (Damidot et al ,1990, Damidot and Nonat, 1992, Nonat and Mutin, 1992, Jiang et al,1995,1996).

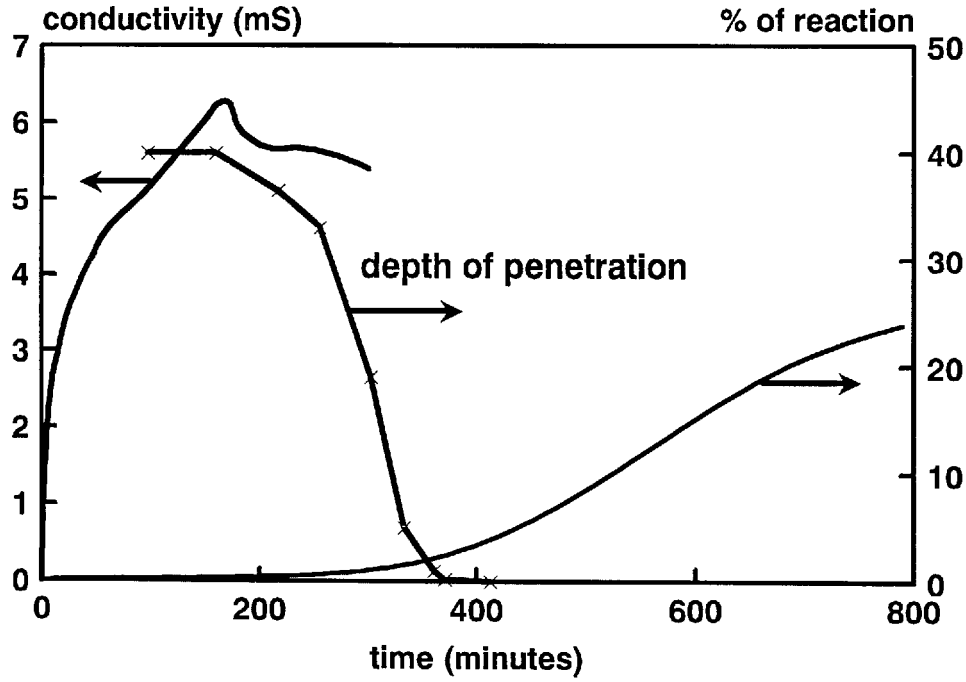

Fig 1. Chemical and mechanical evolutions versus time of a Ca_3SiO_5 paste (W/C=0.5, T=25°C) represented respectively by the electrical conductivity of the pore solution, the advancement of the hydration and the depth of penetration of the Vicat needle.

PARAMETERS CONTROLLING THE HYDRATION OF TRICALCIUM SILICATE

Kinetics of Ca_3SiO_5 hydration

The way how lime concentration controls the kinetics of hydration of Ca_3SiO_5 is described in detail in another report of these proceedings (Nonat et al, 1997). It is however useful to remind here that the kinetics of the reaction does not depend very much on the water to tricalcium silicate ratio. This result is illustrated in Fig 2 showing the advancement of hydration versus time for different liquid to tricalcium silicate ratios. In these cases Ca_3SiO_5 was mixed with a saturated lime solution. It is then possible to simulate the chemical conditions of hydration in paste in diluted suspensions.

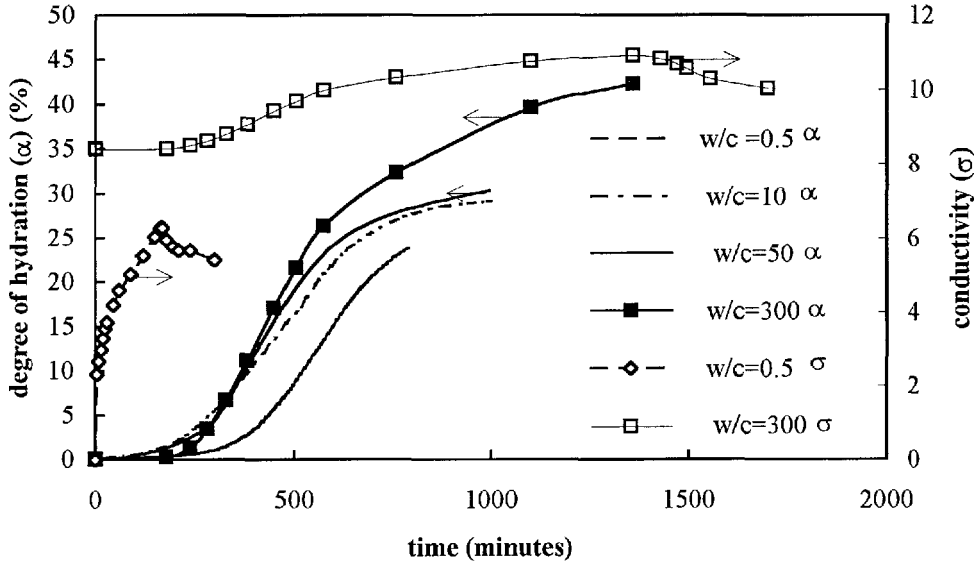

Fig 2. Comparison of the advancement of hydration of Ca_3SiO_5 in saturated lime concentration for suspensions with different water to tricalcium silicate (W/C) ratios.

The length of the period of low chemical activity (so-called dormant period) is fixed by the number of C-S-H nuclei which depends on the lime concentration and the W/C ratio. The percentage of reaction when the hydration rate decreases depends on the growing mode of C-S-H also fixed by the lime concentration.

PROCESSES AND PARAMETERS CONTROLLING THE SETTING OF TRICALCIUM SILICATE PASTE

Setting results from the transformation of a dense suspension of more or less dispersed particles in a mechanically irreversible network of connected particles. An understanding of setting depends on knowledge of the processes involved in that transformation and of the parameters that determine the mechanism. Using the ability to control hydration in dilute suspensions, we used a granulometric method to study the evolution of the particle suspensions dispersed or not by ultrasonic (US) waves (Nonat and Mutin, 1992, Jiang et al, 1995, 1996).

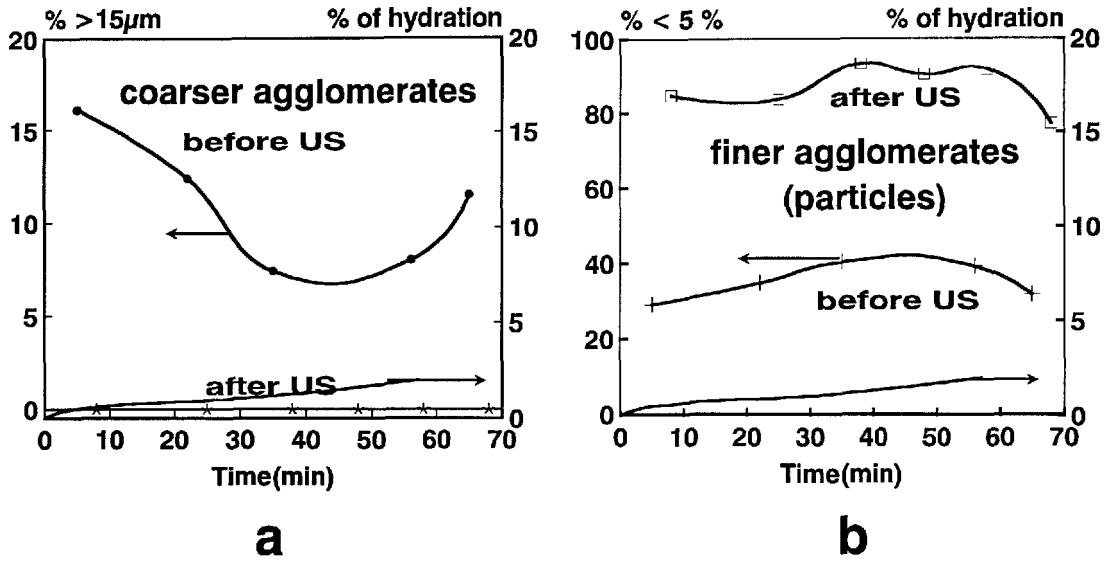

Fig 3. Evolution versus time of the percentage of coarser (a) and finer (b) granulometric classes of Ca_3SiO_5 suspension mixed in initially saturated lime solution (W/C=300). The corresponding advancement of the hydration is indicated. Granulometric measurements are performed with a photosedimentometer CAPA 500 (or 700) HORIBA. During the experiment the suspension was subjected continuously to a gentle stirring and periodically to a ultrasonic treatment (during 30s, power 300 W). The coagulation is indicated by the variation of the granulometric curves before and after ultrasonic (US) treatment.

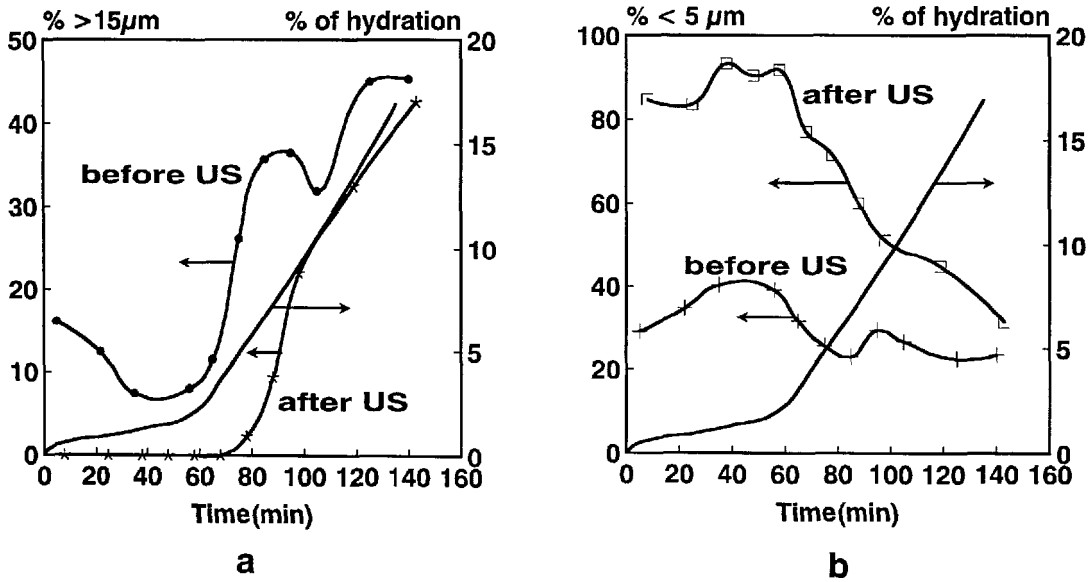

Fig 4. The evolution of the coarser (a) and finer (b) granulometric classes of the same suspension as Fig 6 are represented during the accelerated period of hydration (the percentage of hydration increase distinctly after 60 min.). The same ultrasonic (US) treatment becomes less and less dispersive: the coarser population increases as the finer one decreases, showing the irreversibility of contact interaction between particles due to the hydrates bridging effect.

The coagulation and rigidification processes

Fig 3 shows the case of a suspension of Ca_3SiO_5 in a lime saturated solution ([CaO]=22 mmol/l, W/C=300); it represents the evolution versus time, on one hand, of the percentage of the coarser (Fig 3a, D>15μm) and finer agglomerates (Fig 3b, D<5μm) in suspension and on the other hand, the percentage of hydration The time during which there is practically no hydrate formation (the nucleation period) is about 60 minutes. During this time, before initial dispersion by ultrasonic waves, Ca_3SiO_5 particles are aggregated, and distributed as 16% coarser agglomerates and 30% finer. Ultrasonic treatment disperses the agglomerates since the populations become 90% finer and 0% coarser agglomerates. About 10 minutes after ultrasonic treatment, the population becomes virtually as before, showing the mechanical reversibility of the interparticular bonds. Further sonication again destroys the aggregates and the particles again agglomerate when ultrasonic treatment is stopped . this is the **coagulation** phenomenon in terms of colloid science

Fig 4 shows that, after the nucleation period, as soon as C-S-H formation accelerates, the US treatment destroys less and less agglomerates. **C-S-H formed at the particle contacts rigidify them.** Only a significant increase of US power allows to break the rigidified aggregates. So, setting proceeds through, at least, two fundamental steps:

- the coagulation at the origin of the essential contacts between particles,
- the rigidification by hydrates at the contact points between anhydrous particles

Parameters determining the coagulation process.

Coagulation is due to attractive forces between particles. These forces may result from interactions from various origins, van der Walls forces, chemical interactions, electrostatic forces or solvation forces (Delville, 1992) in which the ionic constitution of the solution surrounding each particle plays an important role. In the present case, the respective concentrations of calcium, silicate and hydroxide ions are not independent, they are fixed by the solubility equilibrium of C-S-H.

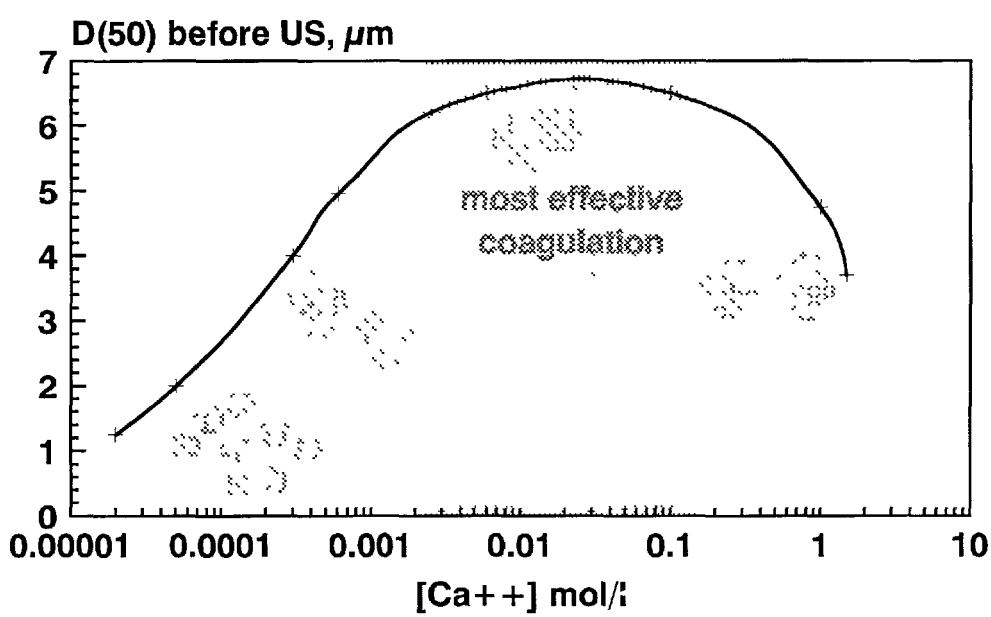

Fig 5 Value of the median diameter (D_{50}) of the agglomerates measured before ultrasonic treatment during the coagulation period versus the calcium concentration in solution.

By controlling these concentrations in solution, we have determined the evolution of the coagulation process. Fig 5 shows the variation versus calcium concentration, of the median diameter, D_{50}, of the agglomerates before ultrasonic treatment which corresponds to 50% of the cumulative granulometric distribution. This curve indicates that coagulation is most effective in the range 1-100 mmol/l. On an other hand, we have proved, by electrophoresis measurements, that the zeta potential of the Ca_3SiO_5 and C-S-H particles is the same and increases from -20 mV to + 20 mV in the same range of lime concentration than granulometric measurements. It equals zero when the lime concentration is about 3 mmol/l (Nachbaur et al, 1997). The coagulation of C_3S particles may then be explained by the evolution of surface charges of unhydrated compounds and hydration products. The high content of Ca^{++} near the surface of particles in suspension promote the coagulation either by adsorption on the surface from solution or by screening the electric double layers around the particles and bridging mechanisms. It must be noticed that during Ca_3SiO_5 hydration under normal conditions, calcium concentration is such as coagulation always occurs.

Parameters determining the rigidification process

Rigidification occurs as soon as hydrates rigidify the contacts between particles. It is revealed in diluted suspensions by the time at which the characteristic dimension of aggregates, after sonication, increases. A systematic study of rigidification in suspensions, having initial calcium and silicate concentrations in the ranges 0-22 mmol/l and 20-0 mmol/l, respectively, shows that rigidification occurs as soon as calcium concentration reaches about 10 mmol/l, whatever the percentage of precipitated hydrates. This is illustrated in Fig 6 where the evolution of the average

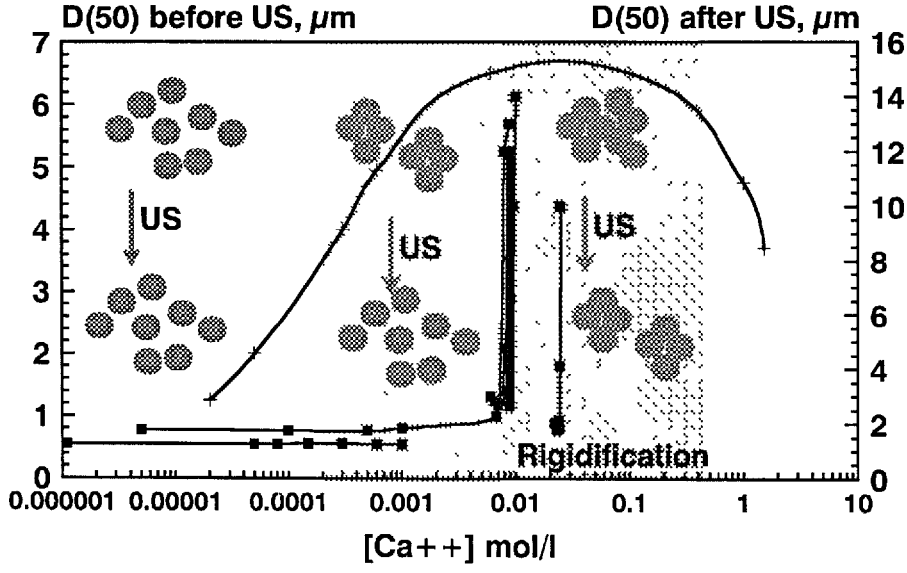

Fig 6 Evolution versus the calcium concentration in solution, of the median diameter of agglomerates measured after sonication.

diameter of the coagulates is plotted against the lime concentration in solution. Below 0.1 mmol/l, rigidification cannot occur, because the particles are always dispersed Between 0 1 and 100 mmol/l, particles coagulate but the coagulates are rigidified only when the lime concentration in solution is higher than 10 mmol/l. In fact, this threshold value corresponds to the concentration at which the solubility of C-S-H in solution becomes very low (Fig 7) Only in such conditions, does C-S-H precipitate on the surface of anhydrous grains, where it is able to bridge particles. In

the case where the calcium concentration cannot reach this threshold value at complete hydration of Ca_3SiO_5, rigidification never occurs. This clearly shows that hydration is not sufficient for setting.

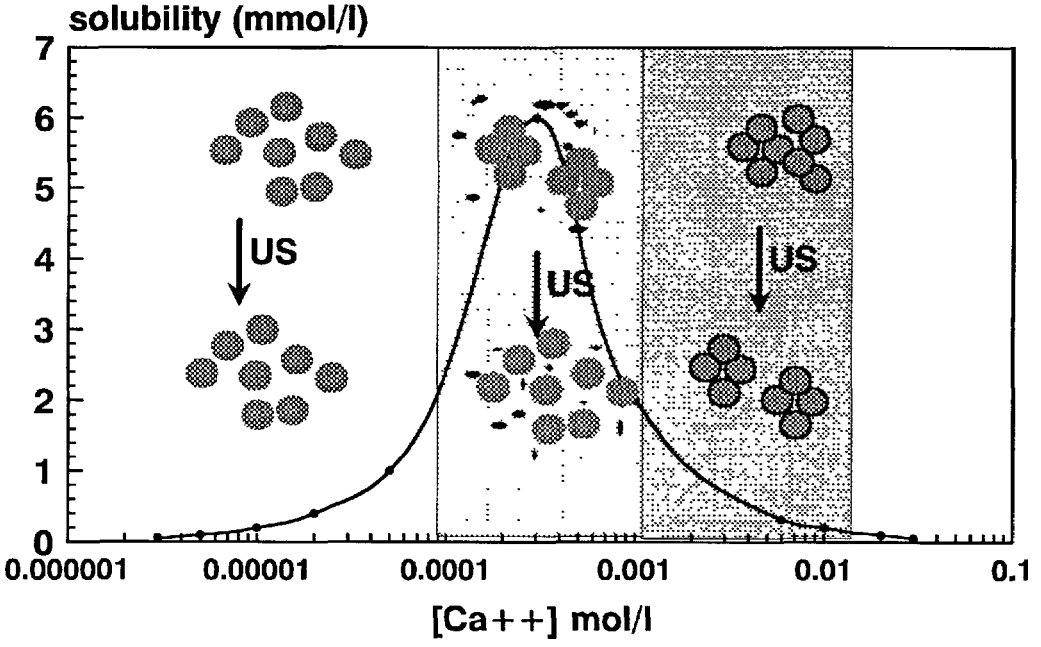

Fig 7. The evolution of the solubility of C-S-H with the calcium concentration in solution is compared with the calcium concentration in solution domains in which the coagulation and rigidification processes are most effective. Above the threshold concentration of 10 mmol/l, the solubility of C-S-H is very low, the coagulation is most effective, consequently does C-S-H precipitate on the surface of the coagulated particles and does rigidify the agglomerates.

CONCLUSION

A systematic study of the effects of lime concentration on the behaviour of suspensions of Ca_3SiO_5 during their hydration leads us to conclude that lime concentration in solution determines the particle interactions and the solubility of hydrates which control the coagulation and rigidification processes at the origin of setting. Coagulation which provides the contacts between particles results from particles interaction in accordance with DLVO theory. Rigidification is due to the strengthening of the contacts by hydrates. The nature of forces between C-S-H particles are not yet clearly identified but they may be the same as during coagulation.

Coagulation and rigidification must occur for setting of cement paste, but these conditions are not sufficient. The coagulated structure must lead to a continuously connected network of particles. This last condition depends on the solid volume fraction and the dimension of cement grains.

THE COLLOID-CHEMICAL PRINCIPLES OF THE STRENGTH THEORY OF CONTACT HARDENING CEMENTS

Raisa F. RUNOVA, Kiev State Technical University of Construction and Architecture, Ukraine
Arkady N. PLUGIN, Kharkov State Academy of Railway Transport, Ukraine

ABSTRACT The contact hardening cements form strong waterresistant stone during heating-free pressing. To ensure development of such property the substance structure must be in disordered (amorphous) state. A model of strength of such systems is presented. The electrosurface properties and interactions in dispersed systems compose the basis of the model.

Key-words: binder, hardening, structure, strength development, crystallography.

INTRODUCTION

V.D.Glukhovsky and R.F.Runova (1976) have published some experimental results discovering the phenomenon of contact hardening of mineral disperse systems including the hydration products of cement. The products of pre-hydration of cement have the same properties (Glukhovsky et al, 1980). In the opinion of these authors, the amorphous state of a substance structure plays the principal role in the process of contact hardening. The hydrated industrial waste products may be used as cements of contact hardening as well (Glukhovsky et al,1986). It was shown by Glukhovsky et al (1991) that the silicate powders are compatible with the metal and polymeric ones. The heat emission under load was registered in the results of physico-chemical research on analysis of energy characteristics of the process of contact hardening (Runova,1992). The results included thermo-baro-graphical data. In this work, the next step of this complex research is presented. The authors offer experimental data analysis with the twofold goal: to extend knowledge of strength forming mechanism and to develop an analytical model of strength in binders of contact hardening.

The most important resulting conclusion was that the hydration and condensation processes in contact hardening cements can be separated in time. It means that the artificial stone formation procedure (structure formation) is a result of the physical and chemical processes in the contacts between the particles of high-dispersed system during their attraction under compression without a change in chemical composition. It allows to use physico-chemical theory of dispersed systems strength by Rehbinder-Schukin (1964) extended by A.N.Plugin (1988, 1989, 1995) in application to binding materials with regard to electrosurface properties and interactions for this purpose.

OBJECTS AND METHODS

The artificial monomineral substances of amorphous submicro-crystalline structure of calcium silicates and hydrosilicates, sodium and potassium hydroaluminumsilicates and their anhydrous compounds as well as metakaolinite were used as the binders of contact hardening. The hydrothermal synthesis and dehydration of hydrates technologies were used to obtain the substances. The X-ray analysis was applied to identify their structure. The dispersity of the specimens determined after D-drying was within the limits of 8-10,000m^2/kg. The cylindric samples for compression strength testings were 20 mm in diameter and height. They were made with the use of dry pressing techique at pressures 50-500 MPa . The testings for strength were carried out right after the pressing R_1 , and after 28 days of water storage R_2. The Rehbinder method was applied to evaluate the strength of bonding in the elementary contacts r_1 between the compressed particles.

The development of the analytical model of strength was based on the fact that structure and strength

of binders are the result of the rise of either electroheterogeneous contacts (EHC) between the oppositely charged surfaces of the structure forming particles (Plugin,1989) or concentration electro-homogeneous contacts (below concentration contacts CC) between the same charged surfaces. The latter contacts rise at high electrolyte concentration or when the surfaces are mechanically pressed together (Plugin and Plugin,1995). The bonds in such contacts are due to attraction between the oppositely charged potential determining ions in the active centers of the structure forming elements (SE) in the EHC and attraction between a potential determining ions of the SE and an anti-ions of a melt or solution in the CC. The distances between the elementary contacts depend on the surface concentration of the active centers of the SE $a=(1/n)^{1/2}$.

In view of it, the modified equation of tensile strength of dispersed systems by Rebinder-Schukin was used as an assumption to obtain the analytical model of strength $R_t = n \cdot P$, where n - the number of the elementary contacts (on the active centers) in a unit of stretched area, $1/m^2$; P - the strength of bond in the contact, N (Rehbinder et al.,1964; Plugin et al.,1995). Substituting the known expressions for ion-ion and ion-dipole interaction and for density of surface charge in double electric layer (DEL), the following formula of tensile strength of hardened cement paste was derived:

$$R_t = \left(\frac{z_2 e \psi_1}{32\pi^2 d_1 h^2} + \frac{z_2 \mu \psi_1}{8\pi^2 z_1 d_1 h_\mu^3}\right)\gamma = \left(\frac{508 z_2 \psi_1}{d_1 h^2} + \frac{773 z_2 \mu \psi_1}{z_1 d_1 h_\mu^3}\right)\gamma,$$

where ψ_1 -the electrosurface potential of the SE, V; e - the charge of electron, Kl; μ -the dipole moment of a molecule of water, Kl·m; z_1 , z_2 , h - the valences of the ions and the distance (m) between them in an elementary contact; h_μ -the distance between the ion and water molecule in an elementary contact, m; d -the distance between the ions which form dense DEL, m; γ - the share of the contacts of EHC or CC type in the total number of the contacts (for the systems considered $\gamma=1$). The method by A.N.Plugin (1988,1989) was used to evaluate the electrosurface potentials of the SE with account for their chemical compositions. The values of z_1 , z_2 , d_1 , h and h_μ were found with the help of the given schemes by the known crystalline structures of the considered or similar compositions.

EXPERIMENTAL AND CALCULATED RESULTS OF THE STRENGTH

The datas on strength of contact hardening cement paste are shown in the Tables 1 and 2.

Table1 The compression strength - to - chemical composition relationship (P_{pres}=200 MPa).

Sample No	Chemical composition	Compression strength, MPa, after:		$K_w = R_2/R_1$	r_1, N	R_t^{calc}, MPa
		pressing, R_1	28 days in water, R_2			
1	$CaO \cdot SiO_2 \cdot 2H_2O$	48.0	49.0	1.0	10^{-8}	49.0
2	$2CaO \cdot SiO_2 \cdot 1.5H_2O$	45.0	46.0	1.0	10^{-9}	46.0
3	$CaO \cdot SiO_2$	25.0	44.0	1.7	-	24.1
4	$Na_2O \cdot Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$	11.5	10.0	0.9	10^{-10}	11.5
5	$Na_2O \cdot Al_2O_3 \cdot 2SiO_2$	8.0	7.6	0.9	10^{-10}	7.5
6	$K_2O \cdot Al_2O_3 \cdot 2SiO_2 \cdot nH_2O$	7.6	7.5	1.0	-	10.0
7	$K_2O \cdot Al_2O_3 \cdot 2SiO_2$	6.0	5.5	0.9	-	6.4
8	$Na_2O \cdot Al_2O_3 \cdot 4SiO_2 \cdot 2H_2O$	11.4	10.5	0.9	10^{-9}	10.3
9	$Na_2O \cdot Al_2O_3 \cdot 4SiO_2$	7.0	6.0	0.8	10^{-10}	6.8
10	$Al_2O_3 \cdot 2SiO_2$	5.5	4.0	0.9	10^{-11}	5.9

Table 2 The strength - to - compression pressure relationship.

Chemical composition	R_c, MPa, after pressing under load P_{pr}						R_c^{calc}, MPa
	50	100	200	300	400	500	
$CaO{\cdot}SiO_2{\cdot}2H_2O$	22.0	30.5	68.0	143.0	192.5	275.6	507
$Na_2O{\cdot}Al_2O_3{\cdot}2SiO_2{\cdot}2H_2O$	9.4	22.2	50.0	52.5	58.8	68.0	82

In Table 1 strength of the pressed samples depends on the chemical compositions of substances. Particularly, it depends on the presence of alkali and, especially, alkali-earth (Ca) oxides (calcium containing hydrosilicates have maximum but metakaolinite $Al_2O_3{\cdot}2SiO_2$ - minimum strength) and water molecules in composition (hydrogel shows two times better results for calcium hydrosilicates than the anhydrous product). All the contact hardening binders are highly waterresistante.

The fact that the calculated and experimental results on strength are very close is evidence of the correctness of both the assumed theoretical prerequisites and the analytical model of strength. Based on such model, one can analyse how strength of the contact hardening binders depends on the structural and electrosurface characteristics. Besides, it allows to extend knowledge of strength forming mechanism. The data for analysis are given in the Table 3.The structural and electrosurface characteristics are assumed on the basis of the crystalline structures. The blocks (walls) of portlandite are the main SE in the structure of the calcium hydrosilicates (HSC) with potential determining ions (PDI) Ca^{2+} and the hydrosilicate gel with PDI $[Si_2O_7H_4]^{2-}$ and $[SiO_4H_2]^{2-}$. The bicalcium silicate strips of Ca-polyhedrons with PDI Ca^{2+} are the SP and the bivalence silica-oxygen tetrahedra are the anti-ions (AI) in dehydrated calcium silicates by Ilukhin. The particles with frame structure formed by aluminum silicate tetrahedral rings with complex anions $[Al_2Si_2O_8]^{2-}$, $[Al_2Si_4O_{12}]^{2-}$ or Na^+ as an active centers (AC) are the SE in alkali aluminumsilicates. At last, the silica-oxygen nets with AC formed by $O[SiO_3]^{2-}$ and dehydrated layers of alumo-oxygen tetrahedrons with AC formed by tetrahedral cations of $O_5[Al_2O_2]^{2+}$ are the SE in metakaolinite. The distances a between the AC vary within 14.3-32.1 nm.These data are coordinated with known experimental data about active centers.

Table 3 The calculated characteristics and strength of samples.

Sample No	SFE	PDI-PDI(AI)	h, nm	h_μ, A°	R_c, MPa	R_μ, MPa	ψ, v	a, nm	Con-tact
1	CH_2S	Ca^{2+}-H_2O-$[Si_2O_7H_4]^{2-}$	0.6	0.362	31.0	18.0	+0.53	20.3	EHC
2	$CH_2CSH_{0.5}$	Ca^{2+}-H_2O-$[SiO_4H_2]^{2-}$	0.6	0.385	29.0	17.0	+0.53	20.3	EHC

10	S,A	$O[SiO_3]^{2-}$-O-$[Al_2O_2]O_5^{2+}$	0.92	-	5.9	-	+0.33	32.1	EHC

where: C - CaO , S - SiO_2, A - Al_2O_3, H - H_2O, O - oxygen atom.

Calcium silicates have higher strength, which is caused by the higher valency of cation as well as by smaller sizes of anion in the contacts. Furthermore, the ion-dipole interaction in hydrate compounds additionally contributes in strength. As the compression pressure Rpr increases beyond 50 MPa the water molecules are gradually displaced from the elementary contacts. In this case the chemical ion bonding h=2.4A° in length is established in the contacts. Correspondingly, strength increases. Its limit calculated values are equal to 507 and 82 MPa for the samples No2 and 4 correspondingly (the experimental values are 275,6 and 68 MPa). The behavior of R_1-R_{pr} relationship (Table 2) demonstrates that the limits of strength capabilities of contact hardening binders are far from being reached. The preliminary grinding of the source binders bares the active centers and the subsequent pressing restores the destructed contacts thanks to the long-range action of electrical field of the potential determining ions in the active centers. The binders with submicrocrystalline and amorphous structures and, therefore, with maximum specific surface of the SE have the maximum number of the bared active centers (and maximum of surface energy). It predetermines the necessity to provide the above-mentioned state of structure to the binders considered.

CONCLUSION

Disordering of substance structure which stipulates the presence of surplus surface energy can be considered as thermodynamic basis of contact hardening cements. This energy is realised during mutual approach of the particles with extremely developed surface. As a result, the condensation of a dispersed system with the artificial stone forming takes place. From the point of view of the physical-chemical theory of strength of dispersed systems with allowance for electrosurface interactions, strength of contact hardening binders is caused by the presence of the electroheterogeneous (EHC) or concentration (CC) contacts. The long-range action of bonds in the contacts ensures reducting of the destructed by grinding ones during pressing. The analytical model of strength of binding substances is presented. It can be effectively used in further research works and in the contact hardening binders manufacturing.

CALCIUM HYDROXIDE CONCENTRATION IN SOLUTION : PARAMETER DETERMINING THE KINETICS OF THE EARLY HYDRATION OF TRICALCIUM SILICATE AND THE CHARACTERISTICS OF THE PRODUCTS.

Andre NONAT, Xavier LECOQ , Sandrine GAUFFINET, Laboratoire de Recherche sur la Réactivité des Solides, CNRS-Université de Bourgogne, Dijon, France.

ABSRACT The lime concentration in the solution is found to be the parameter controlling the kinetics of the hydration of tricalcium silicate. The lower the lime concentration, the shorter the duration of the induction period and the weaker the percentage of reaction corresponding to the limitation of the reaction rate by the diffusion of water and ions through the layer of C-S-H. The experimentally observed variations tend to prove that the axial growing rate of C-S-H increases with the lime concentration. The evolution of the growth mode is described from numerical simulations.

Key-words : Hydration, Kinetics, Calcium Silicate, CSH , Induction period

INTRODUCTION

In normal conditions, when cement powder is mixed with water, kinetics of reaction follows a sigmoïd law (**Fig 1**) with an induction period, an accelerated period and finally a period during which the reaction is drastically slowed down by the diffusion of water and ions through the layer of hydration products. Considering the large number of published papers, conflicting results appear with respect to both hydration products and hydration mechanisms (Taylor et al, 1984). In this paper we try to establish the processes limiting kinetics. The results on which the discussion is based are obtained by studying paste and more or less stirred diluted suspensions in water or lime solutions.

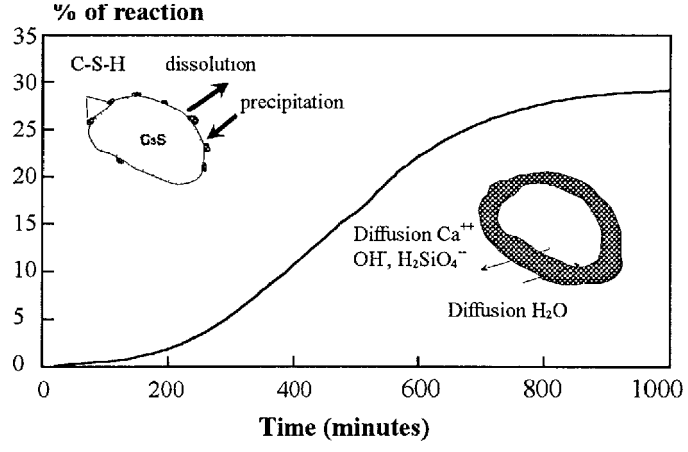

Figure 1 Typical evolution versus time of the percentage of hydration of tricalcium silicate in paste (water/C_3S =0.5) and schematic evolution of the grain covered by the product.

CHEMICAL REACTIONS

In normal conditions (w/c=0.5) hydration of tricalcium silicate proceeds through three reactions which become successively simultaneous :

- the dissolution of tricalcium silicate, C_3S
- the precipitation of calcium silicate hydrate, C-S-H,
- the precipitation of calcium hydroxide, CH.

C_3S dissolution

The first chemical interaction between C_3S and water occurs as soon as tricalcium silicate contacts water. It leads to the protonation of SiO_4^{4-} ions on the C_3S surface (Barret et al,1980, Damidot et al,1994). After this first interaction, protonated species can then pass into solution and C_3S dissolves congruently :

$$Ca_3SiO_5\ _{superf\ hydrox} + 3\ H_2O = 3\ Ca^{2+} + 4\ OH^- + H_2SiO_4^{2-} \qquad [1]$$

If the W/C ratio is greater than 3000, all C_3S dissolves in water. Conversely, when the W/C ratio is lower than 3000, [CaO] and [SiO_2] reach respectively a plateau and a maximum, lower values than the solubility of C_3S. The silica concentration decrease is due to the precipitation of C-S-H which limits the pure dissolution of C_3S. The critical concentrations of 5.5 and 1.7 mmol/l of CaO and SiO_2 respectively are the values at which C-S-H precipitates spontaneously corresponding to the maximum supersaturation with respect to this phase.

Precipitation of C-S-H

As mentioned above, when the supersaturation maximum with respect to C-S-H is reached, its precipitation starts.

$$x\ Ca^{2+} + H2SiO_4^{2-} + 2(x-1)\ OH^- + y\ H_2O = (CaO)_x\ SiO_2\ (H_2O)_{y+x-1} \qquad [2]$$

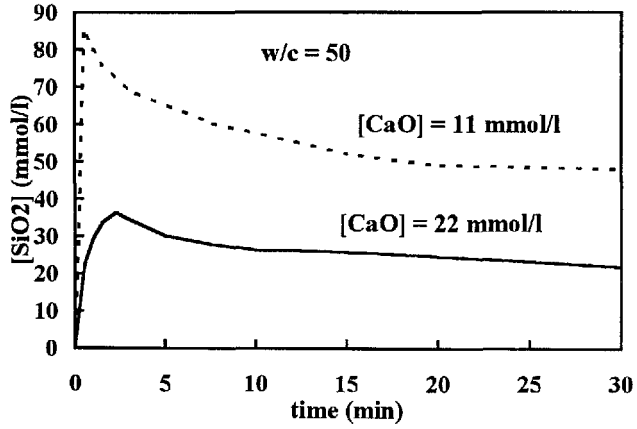

Figure 2 Variation of silicate concentration versus time during the earlier part of hydration in different lime solutions. The maximum value corresponds to the critical supersaturation with respect to C-S-H.

Table 1 : Variation of the quantity of nucleating C-S-H during the first 30 minutes with initial lime concentration of the solution in which C_3S is hydrated (W/C=50).

[$Ca(OH)_2$] mmol/l	quantity of nucleating C-S-H (µmol)
11	65
19.5	45
22	35
33	10

The stoichiometry of precipitating C-S-H, expressed by the calcium to silicon ratio (C/S) and the water to silicon ratio (H/S), depends on the lime concentration in solution. C/S varies between 1 and 2 when [CaO] varies between 1 and 30 mmol/l (Nonat, 1994). During this initial

precipitation, lime concentration remains constant while silica concentration decreases from its maximum value to a quasi steady state. The quantity of C-S-H nucleating after reaching the critical supersaturation depends on the lime concentration in solution (**Fig 2**), the higher the initial lime concentration, the lower the quantity of nucleating C-S-H (**Table 1**). It depends also on the W/C ratio since for a given concentration, higher the volume of solution, greater the number of mole of silica precipitating from the solution.

After this stage, silica concentration does not vary much whereas the lime concentration increases. The quasi-steady state with respect to the silica concentration is due to the fact that the rate of consumption of silicate ions by the precipitation of C-S-H is equal to the silicate release by the C_3S dissolution (Barret and Bertrandie, 1986). So, according to Eqs 1 and 2 and considering the dependence of the Ca/Si ratio in C-S-H with respect to the lime concentration in solution, the rate of accumulation of Ca^{2+} and OH^- in solution depends

i - on the lime concentration due to :

- the Ca/Si ratio dependence

$$Ca_3SiO_5(sh) + z\,H_2O = (CaO)_{C/S}\,SiO_2\,(H_2O)_{H/S} + (3\text{-}C/S)\,Ca^{2+} + 2(3\text{-}C/S)\,OH^- \quad [3]$$

- and probably to the evolution of the Ca/Si ratio of the already precipitated hydrates that Ca/Si ratio corresponds to a lower lime concentration :

$$(CaO)_{xi}\,SiO_2\,(H2O)_{yi} + (xf\text{-}xi)\,Ca^{2+} + 2(yf\text{-}yi)\,OH^- = (CaO)_{xf}\,SiO_2\,(H2O)_{yf} \quad [4]$$

ii - on the W/C , it is more rapid as the suspension is more concentrated i.e. small W/C ratio (**Fig.3**).

Precipitation of calcium hydroxide, portlandite

The increase of the lime concentration ends with the start of precipitation of portlandite $Ca(OH)_2$ revealed by the drop in the electrical conductivity of the solution when the maximum of supersaturation with respect to this phase is reached (about 36 mmol/l at 25°C- **Fig 3**).

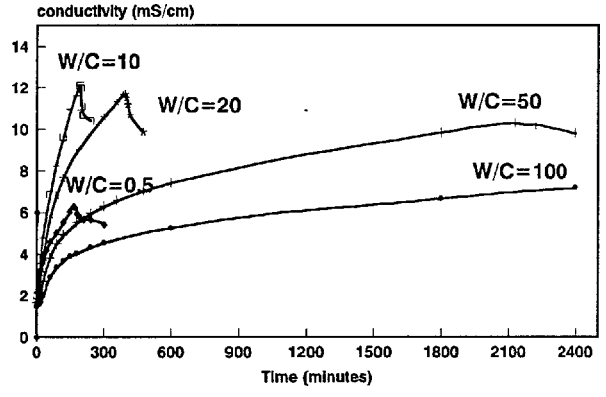

Figure 3 Evolution versus time of the electrical conductivity of the solution which is proportional to the lime concentration during C_3S hydration in water with different Water/C_3S ratios.

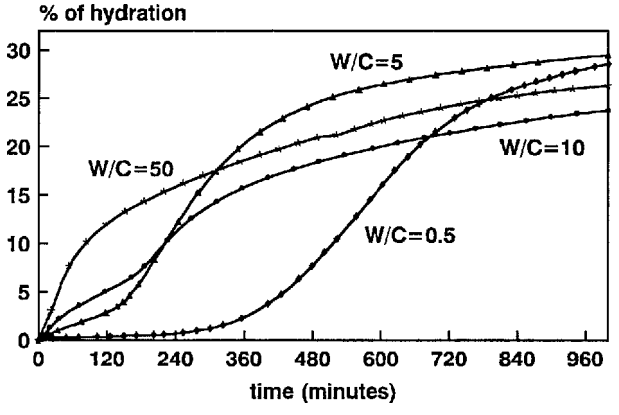

Figure 4 Evolution versus time of the percentage of reaction during C_3S hydration in water with different Water/C_3S ratios.

KINETICS OF REACTIONS

influence of W/C ratio

It was show in the previous part that the chemical reactions involved in the hydration process do not depend very much upon the experimental conditions (i.e. especially the W/C ratio). On the contrary, the kinetics of these reactions are influenced by W/C ratio when reaction begins in pure water. **Fig 4** shows the percentage of hydrated C_3S versus the time of hydration in pure water for W/C ratios ranging from 0.5 to 50. They were calculated from both calorimetric and conductimetric data (Damidot and Nonat, 1994) During the major time of hydration, the rate of C-S-H precipitation is equal to the rate of C_3S dissolution, these also are the evolution curves of the formed C-S-H quantity. Kinetic regime changes from a parabolic law for the highest W/C ratios to a sigmoïdal law for the lowest ones with the succession of two steps for the intermediate values. In the case of high W/C ratios, the reaction is the fastest at the beginning and it continuously decreases following a law characteristic of a limitating diffusion process. In the case of low W/C ratio (paste), the reaction rate is initially very weak, accelerated and finally decelerated in the same way as for high W/C ratios, but the limit is greater.

It has been shown in Fig 3, that depending on the W/C value, the lime concentration increases more or less rapidly from 6 mmol/l, corresponding to the critical supersaturation with respect to C-S-H, to 36 mmol/l, the critical supersaturation with respect to CH. Comparing the evolution of percentage of reaction and the lime concentration versus time lead to associate a rapid initial evolution with a low lime concentration and the high final percentage of reaction with a high lime concentration. Experiments where hydration begins in concentrated lime solutions confirm this view (**Fig 5**): kinetics do not depend very much on W/C ratio and the evolution of percentage of reaction is close to the one observed in water at low W/C ratio. These observations lead to conclude that it is not the W/C ratio, but the lime concentration which is the important parameter.

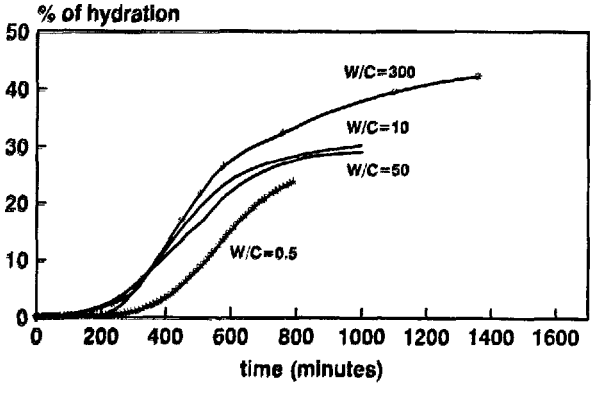

Figure 5 Evolution versus time of the percentage of reaction during C_3S hydration in saturated lime solutions with different Solution/C_3S ratios.

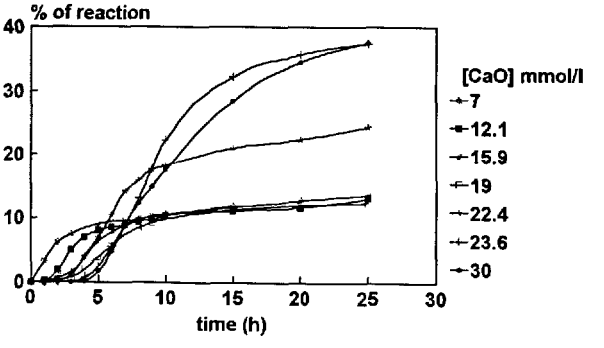

Figure 6 : Evolution versus time of the percentage of reaction during C_3S hydration in different lime solutions. The lime concentration is kept constant during all the process (W/C=57).

Influence of lime concentration

Hydrations of C_3S by keeping constant lime concentration in solution have been undertaken for different value of [CaO] ranging between 6.5 and 30 mmol/l. To maintain constant lime concentration in solution during the hydration process, the 3-C/S moles of $Ca(OH)_2$ not

consumed by the C-S-H precipitation (Eq.3 must be taken out); this is obtained by replacing a volume $V=(3-C/S)/C_0$, C_0 being the initial lime concentration to be keeped constant, by the same volume of pure water. The lime concentration is monitored by continuously measuring the electrical conductivity of the solution which is proportional to the lime concentration in the conditions of the experiments. **Fig 6** shows the evolution of the percentage of reaction corresponding to the hydration of C_3S keeping constant the lime concentration in solution at different values in the range 10 - 30 mmol/l. All these kinetic curves have a sigmoid shape. At high lime concentration, the kinetic curves look like a typical hydration of a C_3S paste. The main changes concern the duration of the induction period and the percentage of reaction at the end of the decelerated period, when hydrates completely cover the surface of anhydrous grains:
- the initial period of slow rate including the induction period is very short (few minutes) at low lime concentration and becomes longer and longer when the lime concentration increases,
- the percentage of the reaction at the end of the decelerated period increases with a drastic dicontinuity around 20 mmol of lime per liter of solution.

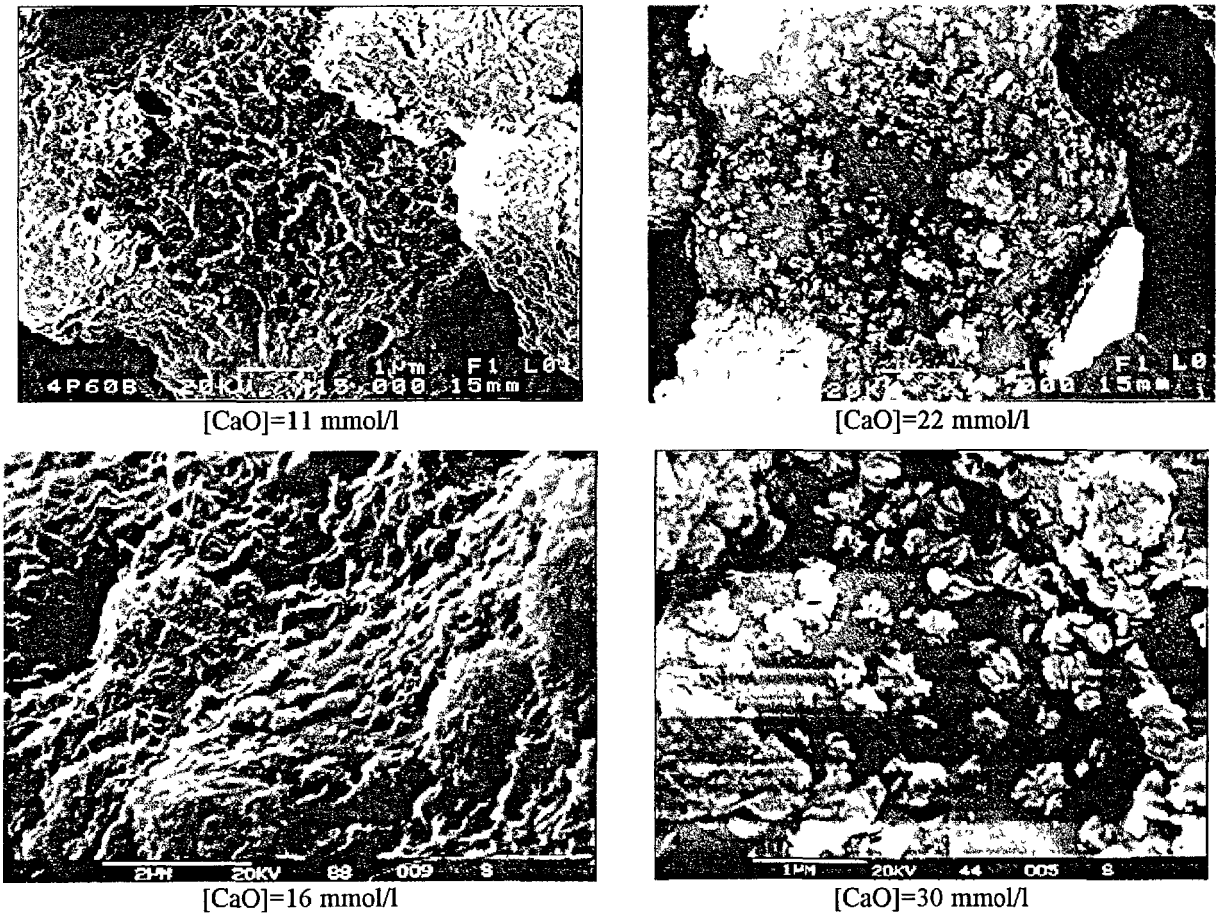

Figure 7 Morphology of C-S-H covering the surface of C_3S when it is hydrated increasing lime concentration solutions.

This behaviour may be associated to the fact that at low lime concentration, there are more nuclei than at high lime concentration (see Table 1). But the change of lime concentration is also associated with a change of morphology of C-S-H which precipitates as it appears on **Fig 7**; at low lime concentrations ($\leq$ 20 mmol/l) C-S-H has a typical honeycomb structure while at high lime concentration ($\geq$ 20 mmol/l), it precipitates with a denser structure as far as it may be

deduced from classical SEM. So the evolution of kinetics with lime concentration may be also due to the modification of growth mode of C-S-H with lime concentration. In order to make allowances for nuclei number and growth mode effects, two type of experiments have been made:

- in the first one (**Fig 8**) , different C_3S samples were prehydrated during 30 minutes in different lime solutions to get different number of nuclei, and then, prehydrated samples were hydrated in the same lime solution to fix the growth mode of C-S-H.
- in the second one (**Fig 9**), samples were prehydrated in same conditions i.e. have the same number of C-S-H nuclei on the surface of C_3S grains, and then hydrated in different lime solutions to vary the growth mode of C-S-H.

Whatever the growth mode, the effect of the number of nuclei essentially controls the acceleration of reaction while the growth mode controls the percentage of reaction for which the surface is completely covered by C-S-H.

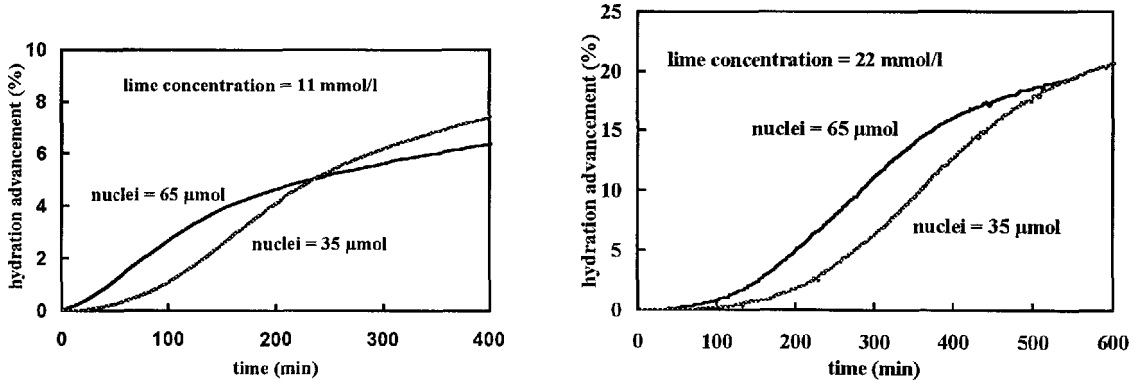

Figure 8 Evolution versus time of the percentage of reaction during hydration of seeded C_3S with different quantities of C-S-H. (a) at low lime concentration (b) at high lime concentration (W/C=57).

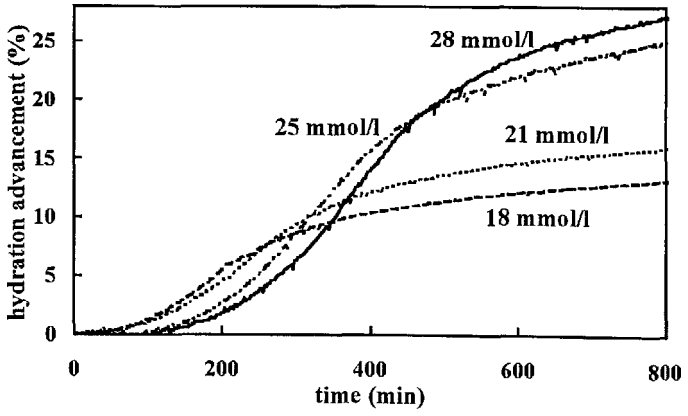

Figure 9 Evolution versus time of the percentage of reaction during hydration of a same seeded sample of C_3S in different lime solutions. The lime concentration is kept constant during all the process (W/C=57).

Morphology and growth mode of C-S-H

At low lime concentration, C-S-H have a morphology much more smoothed on the surface than at high lime concentration suggesting that C-S-H laterally grows faster than at high lime

concentration (**Fig 7**). This would be the reason why, in these conditions, the surface becomes completely covered by a lower quantity of hydrate than at high lime concentration. The quantification of « axial growth rate » and « lateral growth rate » of C-S-H has been attempted with numerical simulations. Nucleation of C-S-H on C_3S surface has been simulated by a randomly generated matrix in which each « 1 » represents a C-S-H nucleus and each « 0 » an element of free C_3S. The dimension of matrixes is 500 x 500 . The percentage of « 1 » with respect to « 0 » is proportional to the experimental number of nuclei per surface unit. The lateral growth is simulated by the convolution product of the « surface matrix » by a « growth matrix ». The dimension of the growth matrix is equal to the number of generated elements of C-S-H per element at each iteration. The axial growth is obtained by superposing, at each iteration, k layers identical to that got by lateral growth with the hypothesis of the growth is identical in each point of the surface. It is so a linear function of the number of iteration. This simulation of C-S-H growth is only valid while the diffusion through the layer of product does not limit the reaction. In this case, the model account well for the variation of the number of initial nuclei (**Fig 10**). It is then possible to find the dimensions of the growth matrix characteristic of the « lateral growth » and the values of k, characteristic of the « axial growth » to fit the experimental kinetics for the different values of the lime concentration (**Fig 11**). The variations of the lateral and axial growth rates versus the lime concentration are plotted on **Fig 12**. They are in accordance with the hypothesis of the variation of the growth mode with the lime concentration. The lateral growth is very fast at low lime concentration and its rate decreases rapidly when the lime concentration increases. Conversely, axial rate does not vary much with lime concentration, but its value shows a clear discontinuity at about 22 mmol/l, the second is about 1.5 times the first. The variation versus lime concentration of many properties of C-S-H shows such a discontinuity, for exemple Ca/Si ratio and structural properties. This is corresponding to two different C-S-H phases, β-C-S-H and γ-C-S-H, for which structural modifications are proposed (Nonat and Lecoq, 1997).

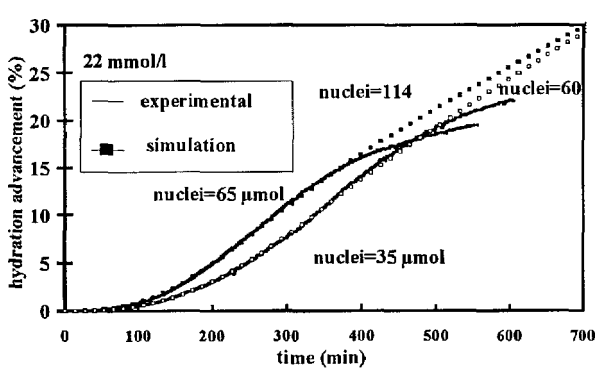

Figure 10 Evolution of the experimental and simulated percentages of reaction during hydration of seeded C_3S with different quantities of nuclei with a growth mode corresponding to a high lime concentration.

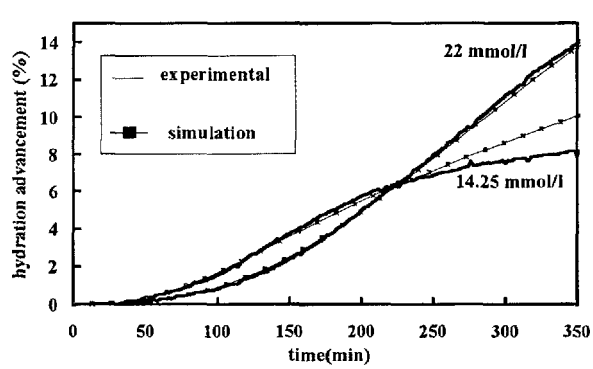

Figure 11 Evolution of the experimental and simulated percentages of reaction during hydration of seeded C_3S with growth modes corresponding to low and high lime concentrations in solution.

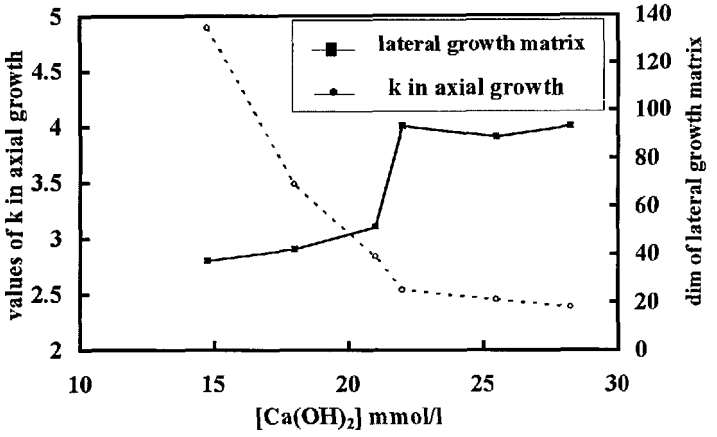

Figure 12 Variation versus lime concentration of the characteristics of the lateral and axial growth rates of C-S-H on the surface of C_3S.

CONCLUSION

Hydration of tricalcium silicate is a complex solid-liquid reaction during which the value of the main parameter controlling kinetics and the properties of the product varies. It has been identified by artificially maintaining constant its value and then its effects have been quantified. On the other hand, simple numerical simulations of the growth kinetics appear to be helpful to characterise the growth mode of a nano-crystalline product, C-S-H. It would be possible to also get data on the properties of the two different C-S-H phases with respect to diffusion by extending the numerical model to period limited by diffusion trough the C-S-H protective layer.

ABSTRACT ^{29}Si magic-angle spinning (MAS) NMR spectroscopy is shown to be a valuable tool for obtaining the quantities of alite and belite in hydrated Portland cements. The hydration (1 - 180 days) of a white Portland cement with 10 wt.% silica fume added is investigated and the degrees of hydration for alite, belite, and silica fume are determined. It is demonstrated that ^{27}Al MAS NMR spectra of hydrated Portland cements can give quantitative information about the formation of ettringite and the conversion of this phase to monosulphate during hydration.

Key-words: Nuclear Magnetic Resonance, Alite, Belite, Ettringite, Monosulphate.

INTRODUCTION

Solid-state MAS NMR spectroscopy has become an important tool for studying the chemistry of cements and for obtaining new structural information about the crystalline and amorphous phases in cement-based materials. The majority of MAS NMR investigations of cementitious systems have employed the ^{29}Si nuclear spin as a probe to follow the formation of the C-S-H gel and to obtain its average chain length of SiO_4 tetrahedra in hydrated samples of C_3S (Lippmaa *et al.*, 1982), β-C_2S (Barnes *et al.*, 1985), and Portland cements (Barnes *et al.*, 1985 and Hjorth *et al.*, 1988). These studies utilized the fact that the ^{29}Si isotropic chemical shift reflects the degree of condensation of SiO_4 tetrahedra (Q^n, n = 0, 1, 2, 3, 4), a relationship which has also been used in ^{29}Si MAS NMR investigations on the structure of C-S-H gels (Brough *et al.*, 1994 and Cong and Kirkpatrick, 1996). Recently, Skibsted *et al.* (1995) showed that the content of alite and belite in anhydrous Portland cements can be determined from computer deconvolutions of the ^{29}Si MAS NMR spectra combined with elemental analysis of the bulk SiO_2 content. In the present work this method has been extended to include the ^{29}Si resonances from the Q^1 and Q^2 units in the C-S-H gel, thereby allowing the quantities of alite and belite in hydrated cements to be obtained. Combining these quantities with those from a similar analysis of the anhydrous Portland cement gives the degrees of hydration for alite and belite, which are of utmost importance to the cement chemist.

In a preliminary ^{27}Al MAS NMR investigation of a white Portland cement, before and after 40 days of hydration, Hjorth *et al.* (1988) showed the potential of this spin nucleus in following the hydration reactions for the small quantities of calcium aluminate (C_3A) in Portland cements. This employs the difference in ^{27}Al isotropic chemical shift of ca. 60 ppm for Al in tetrahedral (Al[4]) and octahedral (Al[6]) coordination. More recently, synthetic samples of the calcium aluminates present in Portland and high alumina cements have been accurately characterized by ^{27}Al MAS NMR (Skibsted *et al.*, 1993). In that study it was shown that first of all the variation in ^{27}Al quadrupole coupling parameters for these samples provides the tool (using MAS NMR) for identification of different phases containing Al in the same coordination state. Furthermore, it has been demonstrated that ^{27}Al MAS NMR represents a unique method for studying the nature of the incorporation of Al guest-ions in the alite and belite phases of Portland cements (Skibsted *et al.*, 1994). In the present work we investigate the hydration kinetics for the formation of ettringite during the early hydration stages of Portland cement and show that the subsequent conversion of this phase to monosulphate can be followed by ^{27}Al MAS NMR.

Table 1 Estimated phase compositions from Bogue calculations for the studied white (wPc) and ordinary (oPc) Portland cements.

	C_3S	C_2S	C_3A	C_4AF	$CaSO_4$	free CaO	Na_2O eq.
wPc	63.9	22.6	4.3	1.0	3.6	2.4	0.16
oPc	56.2	18.5	7.8	8.0	4.7	1.3	0.27

EXPERIMENTAL

Hydrated samples of a rapid-hardening white Portland cement (wPc) and an ordinary Portland cement (oPc), both obtained from Aalborg Portland A/S, Denmark, were studied by ^{29}Si and ^{27}Al MAS NMR, respectively. The blaine fineness of the cements were 426 m^2/kg (wPc) and 317 m^2/kg (oPc) and their estimated phase compositions from a standard Bogue calculation are given in Table 1. 10 wt.% of silica fume (specific surface of 23 m^2/g) and 3.5 wt.% of a melamin-based superplasticizer (Sikament FF) were added to the wPc. The hydration of the wPc mixture employed a water/cement ratio of 0.25. The water was added in two steps during the mechanical mixing in order to ensure dispergation of the silica fume. During hydration the cement paste was kept in sealed glas ampoules at 30° C. At appropriate time intervals the samples were crunched and the hydration process was stopped with ethanol followed by drying at 105° C. The hydration of the oPc was performed in a similar manner, however, employing a water/cement ratio of 0.5, no superplasticizer, and a hydration temperature of 20° C. After one day of hydration the hardened samples were transferred into a new set of sealed containers with high humidities. The hydration was stopped by grinding with acetone and the samples were dried in a desiccator filled with dry N_2.

^{27}Al and ^{29}Si MAS NMR spectra were obtained on a Varian XL-300 (7.1 T) spectrometer, equipped with a home-built CP/MAS probe for 7 mm o.d. zirconia rotors (Jakobsen *et al.*, 1988), employing spinning speeds of ca. 7.0 kHz. The ^{27}Al MAS NMR spectra were recorded using high-power ^1H decoupling, a 15° flip angle, a 2 s relaxation delay, and 2,000 - 16,000 scans, while the ^{29}Si MAS NMR experiments employed a 45° flip angle, a 30 s relaxation delay, and 2,000 - 10,000 scans. ^{27}Al and ^{29}Si chemical shifts are given in ppm relative to external samples of 1.0 M aqueous $AlCl_3$ and neat tetramethylsilane, respectively.

RESULTS AND DISCUSSION

Degrees of hydration for alite and belite from ^{29}Si MAS NMR.

^{29}Si MAS NMR spectra following the hydration over a time scale of three months for the white Portland cement (wPc), with 10 wt.% silica fume added, are shown in Fig. 1. In accordance with previous studies (Barnes *et al.*, 1985 and Hjorth *et al.*, 1988) these spectra display ^{29}Si resonances from the isolated SiO_4 tetrahedra in alite and belite (Q^0: -68 to -76 ppm), the end groups and middle chain SiO_4 units in the amorphous C-S-H gel (Q^1: -76 to -81 ppm, Q^2: -81 to -90 ppm), and from the fully condensed SiO_4 tetrahedra in the silica fume (Q^4: -95 to -129 ppm). The Q^0 region of the ^{29}Si MAS spectra shows a narrow resonance at -71.3 ppm from the unique SiO_4 tetrahedra in β-C_2S, which is superimposed on a broader peak originating from overlapping resonances from the 18 structurally different Si sites in the monoclinic M_{III} form of alite. A visual examination of the spectra in Fig. 1 indicates that the C-S-H gel is formed mainly at the expense of alite and silica fume, while the intensity of the resonance from β-C_2S decreases only slightly with increasing hydration time.

Improved information about the consumption and formation of the individual ^{29}Si species is obtained from numerical simulations of the individual ^{29}Si MAS spectra (cf. Fig. 2). The method for deconvolving the ^{29}Si MAS NMR spectra employs the approach recently used in similar analyses of anhydrous cements (Skibsted *et al.*, 1995), however, with the extension of including a

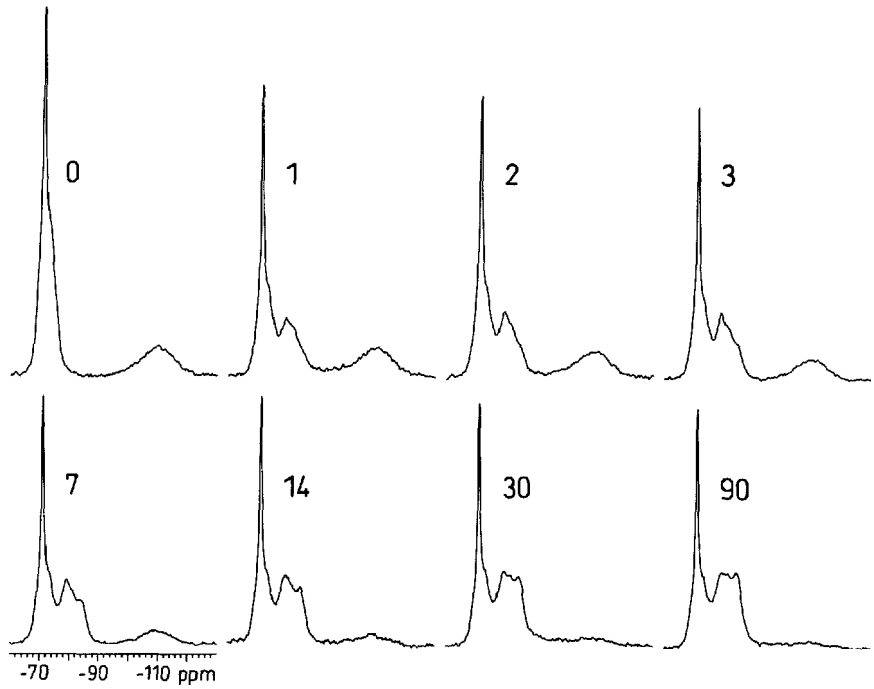

Figure 1 ^{29}Si MAS NMR spectra following the hydration of the wPc with 10 wt.% silica fume added. The time of hydration is indicated in days for the individual spectra.

simulated subspectrum of the ^{29}Si resonances for the Q^{1+2} units of the C-S-H gel. The subspectra of alite and belite are obtained from deconvolutions of ^{29}Si MAS spectra of synthetic samples of β-C_2S and the monoclinic M_{III} form of alite, while five resonances with Gaussian and/or Lorentzian line shapes are used for the Q^{1+2} units. The relative intensities for the individual components are obtained from least-squares optimization of the alite/belite subspectra and the five resonances for the Q^{1+2} units to the experimental spectrum. In addition to the intensities, the optimization allows the linewidths of the individual subspectra to be varied in order to account for variations in line broadening of the individual ^{29}Si MAS spectra. The optimization gives the relative molar intensities for Si in alite, belite, and the C-S-H gel. Combining these intensities with the bulk SiO_2 content of the anhydrous wPc (from an elemental analysis) and the relative intensity for silica fume allows calculation of the quantities of alite and belite in the hydrated sample and thereby a determination of the degrees of hydration for these phases. The relative intensity for silica fume is obtained by integration of the experimental spectra, since the broad resonance from this phase does not overlap with the peaks from the other components.

Optimization of the alite and belite subspectra to the ^{29}Si MAS NMR spectrum of the anhydrous wPc gives the molar intensity ratio $C_2S/C_3S = 0.334 \pm 0.021$. Assuming stoichiometric phase compositions for the calcium silicates this ratio corresponds to 17.5 ± 1.2 wt.% C_2S and 69.6 ± 1.6 wt.% C_3S, when combined with the bulk SiO_2 content (24.44 wt.%). The C_3S/C_2S quantities from ^{29}Si MAS NMR are somewhat lower/higher than those estimated from the Bogue calculation (Table 1). This observation is in general agreement with the earlier reflected light microscopy study by Kristmann (1977) and the recent ^{29}Si MAS NMR investigation (Skibsted *et al.*, 1995) of a series of Portland cements. Both studies find that the C_3S and C_2S values from Bogue calculations on average are ca. 8 wt.% lower and ca. 6 wt.% higher, respectively, than those determined experimentally. An improved estimate of the alite and belite contents in Portland cements may be obtained using the non-stoichiometric compositions for these phases proposed by Taylor (1990). Employing these compositions, along with the molar C_3S/C_2S ratio from ^{29}Si MAS NMR, give the quantities of 19.4 ± 1.6 wt.% belite and 72.7 ± 1.3 wt.% alite for the wPc.

The results of the deconvolution of the ^{29}Si MAS NMR spectra in Fig. 1 and a similar spectrum for the wPc after six month of hydration are illustrated in Fig. 3 by plots of the degrees of hydration for alite, belite, and silica fume as function of the hydration time. The graph for alite shows that ca. 40 % of this phase has been consumed after one day, indicating that the hydration stage, where the rate of hydration increases and the C-S-H and the remaining cement solidifies, is terminated. Thus, the studied time evolutions for the alite and belite hydration characterize the subsequent period, where the hydration rate decreases because the C-S-H gel covers the alite and belite grains. This leads finally to a stage of slow hydration, which is limited by the rate of diffusion of species through the dense C-S-H pore network around the alite and belite grains (Billingham and Coveney, 1993). Fig. 3 shows that the degrees of hydration for alite and belite display almost linear relationships with the logaritm of the hydration time for the final stage of hydration. Similar correlations have been observed by ^{29}Si MAS NMR for the hydration of synthetic samples of β-C_2S and C_3S employing a water/powder ratio of 0.5 (Barnes *et al.*, 1985). However, in that work higher degrees of hydration were reported for the synthetic phases relative to those observed here for alite and belite in the wPc. This difference is ascribed to the lower water/cement ratio used for the wPc and to the significant decrease in relative humidity (RH) in the pores of the cement paste, which has been measured for the studied samples of hydrated wPc (Jensen and Hansen, 1995). A lower RH in the pores reduces the chemical motive power of the hydration and reduces the size of the water-filled spaces. This hampers the diffusion of reacting species and nucleation and growth of the hydration products. The results from ^{29}Si MAS NMR (Fig. 3) indicate that the C_2S hydration is more hampered by the low RH than the C_3S hydration. This is in agreement with earlier reported RH measurements on Portland cement pastes (Patel *et al.*, 1988), which showed that the hydration rate for C_2S is very sensitive to variations in RH. The degrees of hydration for the silica fume (Fig. 3) appear to be less affected by the decrease in RH compared to the hydration of alite and belite. This is in accord with the ^{29}Si MAS NMR observations by Justnes *et al.* (1992) and may reflect the fact that the pozzolane reaction of silica fume in cement pastes only requires a small amount of H_2O to be present as an independent component (Sellevold *et al.*, 1982).

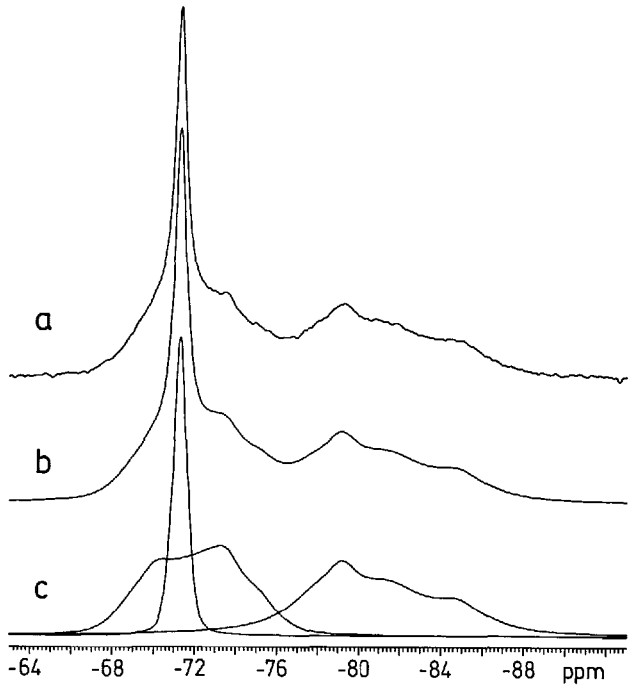

Figure 2 (a) ^{29}Si MAS NMR spectrum of the wPc after 3 days of hydration illustrating the spectral regions for the Q^{0-2} units only. (b) Deconvolution of the spectrum in (a) employing the optimized subspectra for alite, belite, and the Q^{1+2} units in the C-S-H gel shown in (c).

Portland cement hydration followed by ^{27}Al MAS NMR.

The bulk Al_2O_3 content in Portland cements is normally in the range 3 - 7 wt.%, where the major part is present in the so-called interstitial material, which contains the calcium aluminate (C_3A) and ferrite ($C_4A_xF_{2-x}$; $0 < x \lesssim 1.4$) phases. The calcium aluminate phase is the fastest hydrating component in Portland cements and the idealized hydration reaction for this phase in the presence of calcium sulphate can be described as

$$C_3A \xrightarrow[\text{fast}]{C\bar{S}+H} C_6A\bar{S}_3H_{32} \xrightarrow[\text{slow}]{C_3A+H} C_4A\bar{S}H_{12}. \qquad [1]$$

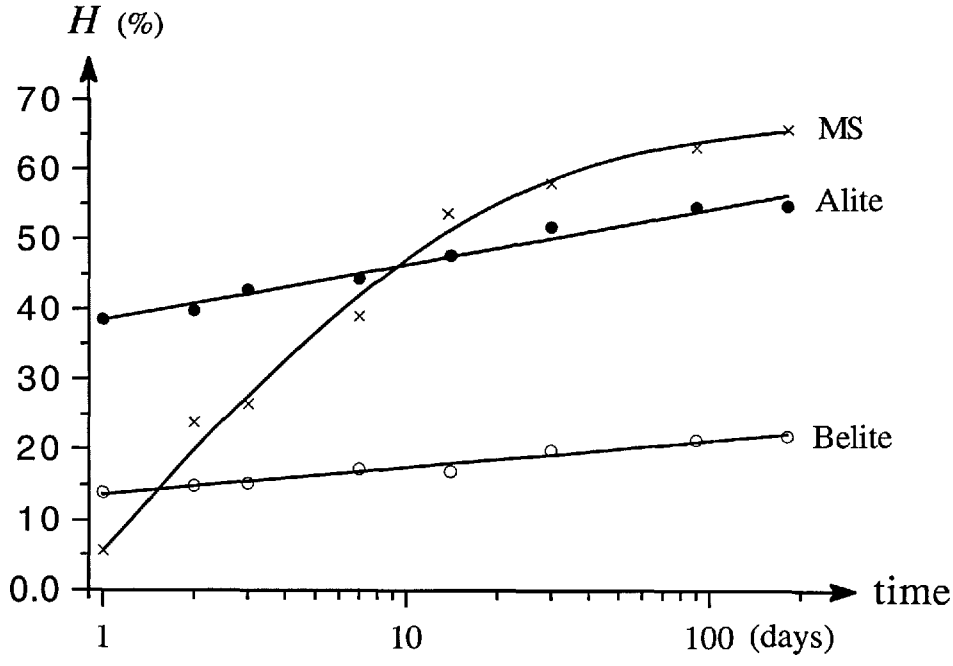

Figure 3 Degrees of hydration (*H*) for alite, belite, and silica fume (MS) for the wPc with 10 wt.% silica fume added as function of the hydration time.

The ferrite phase reacts more slowly with water and forms hydration products similar to those produced by C_3A. Although the basic reactions for these phases are well-known (Taylor, 1990), reliable quantitative studies of these hydration processes are still lacking. The principal aim of this work is to quantitatively characterize the hydration kinetics for the formation of ettringite ($C_6A\bar{S}_3H_{32}$) and its conversion into monosulphate ($C_4A\bar{S}H_{12}$) rather than directly investigating the consumption of the calcium aluminate phase. Thus, the ^{27}Al MAS experiments have been performed using a spinning speed of $\nu_r = 7.0$ kHz at a magnetic field of 7.1 T, which facilitate the observation and distinction of ettringite and monosulphate, because these phases have small (but different) quadrupole couplings (Skibsted *et al.*, 1993). On the contrary, the observation of C_3A by ^{27}Al MAS NMR requires considerably higher spinning speeds ($\nu_r \approx 20$ kHz at 7.1 T) in order to obtain undistorted central transitions because of the strong ^{27}Al quadrupole couplings for this phase (Skibsted *et al.*, 1991).

^{27}Al MAS NMR spectra following the hydration of the oPc from 10 min. to 28 days, and illustrating the spectral regions for the ^{27}Al central transitions, are shown in Fig. 4. The ^{27}Al MAS spectrum before hydration (Fig. 4) displays an asymmetric Al[4] centerband with the highest peak intensity at 79 ppm and a minor peak at ca. 10 ppm from Al[6]. The Al[4] resonance originates from the ^{27}Al guest-ions in the calcium silicate phases (Skibsted *et al.*, 1994), while the Al[6] centerband is ascribed to a minor quantity of a hydrated phase. The calcium aluminate phase is not observed due to its strong quadrupole couplings, which cause a large linebroadening of the central transition. The ferrite phase is neither observed because of the strong dipolar couplings between the ^{27}Al nuclear spins and the spins of the unpaired electrons of the Fe^{3+} ions, resulting in a severe linebroadening of the resonances from this phase. The ^{27}Al MAS spectra of the hydrated oPc demonstrate, even within 10 minutes of hydration, the observation of a narrow Al[6] resonance with the center of gravity at 12.9 ppm. This resonance is easily assigned to ettringite using the earlier reported ^{27}Al quadrupole coupling and isotropic chemical shift data for synthetic calcium aluminate hydrates (Skibsted *et al.*, 1993). The intensity of the central transition for ettringite increases during the induction period (0 - 12 hours) and the following period (12 hours - 2 days), where the major part of the C-S-H is formed and the cement paste solidifies. After one day of hydration a minor shoulder is observed at the low-

frequency side of the centerband from ettringite. During the following hydration the intensity of this peak increases significantly and at the expense of the ettringite resonance. The low-frequency resonance (center of gravity at 9.0 ppm) is easily assigned to Al in monosulphate (Skibsted *et al.*, 1993), and thereby the ^{27}Al MAS spectra in Fig. 4 illustrate the conversion of ettringite into monosulphate during the later stages of hydration. The formation of monosulphate is generally difficult to observed by techniques such as X-ray diffraction and thermal analysis. This is due to the fact that monosulphate is probably interstitified within or near the amorphous C-S-H gel (Taylor, 1990), resulting in a lack of long-range order, which may prevent a reliable observation by X-ray diffraction and lead to a somewhat different thermal behaviour compared to synthetic monosulphate.

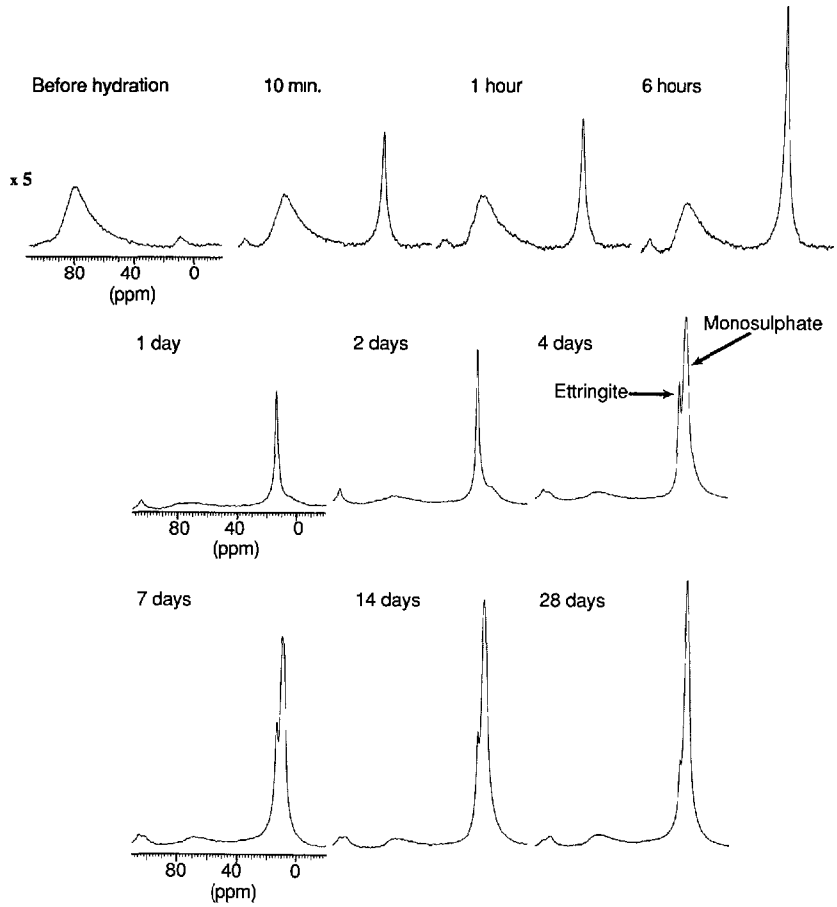

Figure 4 ^{27}Al MAS NMR spectra following the hydration of the oPc. The intensities for the upper row spectra are expanded by a factor of five relative to the other spectra.

The quantities of ettringite and monosulphate in the hydrated oPc samples can be determined from the ^{27}Al MAS spectra (Fig. 4), employing numerical simulations, spectral integrations, and the intensity observed for an external reference sample. The time evolution for the formation of ettringite (Fig. 5) shows a maximum following hydration for ca. two days. At this time the monosulphate formation initiates and the quantity of this phase increases considerably during the following hydration. After eight days of hydration the quantity of monosulphate exceeds the maximum amount of ettringite observed after ca. two days. The results summarized in Fig. 5 thereby indicate that the hydration of the calcium aluminate phase closely follows the mechanistic scheme given in Eq. [1]. This result is in good agreement with an earlier XRD study of the hydration of synthetic C_3A in the presence of gypsum and an excess of calcium hydroxide (Kuzel and Pöllmann, 1991), where the quantity of ettringite was observed to increase gradually until the SO_4^{2-} anions were consumed after hydration for ca. 65 hours. Following this period the remaining C_3A reacted rapidly with ettringite to produce monosulphate.

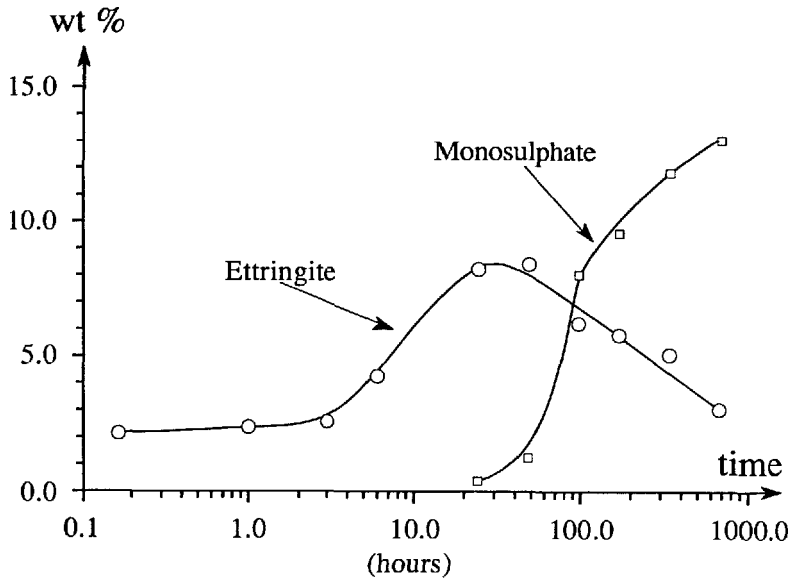

Figure 5 Quantities of ettringite and monosulphate in the hydrated oPc from ^{27}Al MAS NMR as function of the hydration time.

The quantitative analysis of the ^{27}Al MAS NMR spectra in Fig. 4 also allows a determination of the quantities of Al[4] guest-ions in the calcium silicate phases. Before hydration this concentration corresponds to a quantity of 1.0 ± 0.2 wt.% Al_2O_3 in alite and belite, in good agreement with earlier reported Al[4] impurity-ion concentrations in Portland cements (Skibsted *et al.*, 1994). During hydration the Al[4] resonance in the Fig. 4 spectra shifts ca. 10 ppm towards lower frequency. The resonance at lower frequency is assigned to Al^{3+} impurity ions in the C-S-H gel based on the result from an ^{27}Al MAS study of a semi-crystalline C-S-H gel, where an ^{27}Al resonance with a similar line shape and chemical shift was observed (Richardson *et al.*, 1993). A rough estimation of the Al guest-ions in alite/belite and in the C-S-H gel may be obtained from the ^{27}Al MAS spectra in Fig. 4. For example, for the oPc sample hydrated for 28 days we estimate an Al^{3+} impurity concentration corresponding to 0.2 wt.% Al_2O_3 in alite/belite and 0.9 wt.% Al_2O_3 in the C-S-H gel.

CONCLUSIONS

High-resolution ^{27}Al and ^{29}Si MAS NMR are valuable quantitative tools for characterization of the hydration kinetics for alite, belite, and the calcium aluminate phase in Portland cements. The quantities of alite and belite and the degrees of hydration for these phases in hydrated Portland cements can be obtained from ^{29}Si MAS NMR, employing spectral deconvolutions and the bulk SiO_2 content from an elemental analysis. For a white Portland cement with 10 wt.% silica fume added ^{29}Si MAS NMR reveals degrees of hydration for alite and belite, which display almost linear relationships with the logaritm of the hydration time. The measured decrease in relative humidity in the pores of the cement paste decreases the hydration rate for belite considerably, but only affects the reaction of silica fume slightly. ^{27}Al MAS NMR spectra following the hydration of an ordinary Portland cement show the formation of ettringite even within 10 minutes of hydration. The maximum quantity of ettringite is observed after ca. 2 days. After this period ettringite converts rapidly into the thermodynamically stable phase monosulphate.

ACKNOWLEDGEMENT

The authors wish to thank the Cement and Concrete Laboratory, Aalborg Portland A/S, Denmark for providing the white anhydrous Portland cement and the hydrated samples of the ordinary Portland cement. The use of the facilitites at the University of Aarhus NMR Laboratory, sponsored by Teknologistyrelsen, the Danish Research Councils (SNF and STVF), Carlsberg-fondet, and Direktør Ib Hensriksens Fond, is acknowledged.

PHASE DIAGRAMS RELEVANT TO HYDRATION OF C_3S. PART 1: A CASE FOR METASTABLE EQUILIBRIUM

ABSTRACT The possibility of interpreting the chemistry of the aqueous phase of C_3S pastes in terms of phase diagrams has been tested with experiments that first perturb the system and then follow its return to an equilibrium state. Other experiments using an environmental scanning electron microscope show the existence of a protective layer around C_3S during the induction period. Evidence suggests that at about the time of set, this layer undergoes a phase transformation with morphological and physical changes that could be associated with the end of the induction period.

Key-Words: Phase Diagram; Hydration; Thermodynamics; Equilibria; Mechanism

INTRODUCTION

The mechanism that controls the rate of hydration during the early stages of reaction between cement and water has been debated for more than a hundred years. Much attention has also been focused on pure tricalcium silicate (C_3S), the main component of portland cement, which follows rate laws similar to portland cement, and is generally less complex. The most difficult period to understand is the induction period, several hours when chemical activity is slow, followed by more rapid reaction. The length of the induction period can be shortened or lengthened by many hours with the addition of relatively small amounts of chemical admixtures. Two main schools of thought have focused on 1) the role of a protective layer and 2) delayed nucleation of product. Both of these possibilities could explain a slow reaction followed by a period of acceleration.

Interest in understanding the mechanism extends past academic curiosity. For example, developing new admixtures that control the rate of reaction is of both engineering and economic importance. Furthermore, the distribution of products throughout the microstructure as well as attempts to control the microstructure through chemistry are dependent on understanding and controlling the mechanism of reaction.

A question that has emerged in the last few years is whether or not the portland cement system, or even the pure C_3S system, can be analyzed with a phase diagram. As with other systems, such as metals and ceramics, once an equilibrium phase diagram is established, nonequilibrium conditions can be investigated For example, rates of phase change and associated grain size can be related to rates of transition across phase boundaries. The problem with cement-based materials is that they are always changing, especially during the early stages of reaction, and instantaneous measurements are difficult to make. Thus, the question becomes one of whether or not an equilibrium condition, that in principle must exist, can be achieved, or nearly achieved, in the reacting system. This is a question frequently considered by chemical engineers. This paper summarizes some recent results that may

help refine our understanding of the chemistry of the early reaction between tricalcium silicate (C_3S) and water.

EQUILIBRIUM

Because equilibrium has several different meanings, and criteria for evaluating whether or not a system is near equilibrium have evolved over the years, a few important points will be discussed here. First, equilibrium is seldom achieved. Rather, metastable equilibrium or equilibrium with a metastable phase that persists for a long time is common. Throughout this paper the word equilibrium will include the almost indistinguishable state of metastable equilibrium. Transformation to a more stable equilibrium with the passage of time is always a possiblility.

At time zero, as the C_3S starts to dissolve, the aqueous phase is undersaturated with respect to all the relevant phases discussed here. With dissolution, the concentration of the components increases and within minutes fall on a curve in the SiO_2-CaO-H_2O phase diagram, now referred to as C-S-H (M). The location of the curve is generally agreed upon, but the interpretation of the curve is a subject of debate, and thus is the subject discussed here.

A few important concepts are typically invoked when considering whether or not an equilibrium model is appropriate. These concepts are as follows (Smith and Missen, 1982):

1) Equilibrium can be interpreted in terms of forward and reverse reactions that proceed at the same rate. Therefore, the total amount of the reactants and products will not change with time. In the case of a dissolved solid, the amount of dissolved material can be represented by concentration, or more accurately the chemical potential.
2) The system should not change with time. If there is a disturbance which results in a shift out of equilibrium, the system will proceed in a direction which reverses the imposed changes, thereby moving back into equilibrium. This is known as Le Chatelier's principle.
3) Equilibrium occurs independently of the previous history of the system. In other words, equilibrium is a state function. This means that the conditions that define equilibrium do not depend on the path, or the direction, from which equilibrium is approached. In the case of solubility, equilibrium concentrations should not depend on whether or not the initial conditions were supersaturated or undersaturated.
4) Equilibrium can be considered in terms of global versus local conditions. Global equilibrium occurs when the entire system is in the same equilibrium state. During steady-state equilibrium, however, the system is subject to a potential gradient resulting in a flux of mass. In this case, part of the system will be close to equilibrium while another part will be either at a different equilibrium or out of equilibrium. Specifically, we consider that C_3S is never even close to equilibrium with the aqueous phase - equilibrium is between the aqueous phase and a surface layer. Thus, only local equilibrium can be considered here.

Equilibrium between a solid and an aqueous phase occurs between the solid and its dissolved components. When studying the hydration of C_3S, the aqueous phase is most easily analyzed. One of the fundamental issues in cement-based systems is whether the concentration of components in the aqueous phase can be interpreted in terms of equilibrium with a solid and, if so, what can be inferred about the solid. If the reaction simply involves solid C_3S and water going to other solid products,

then the concentrations of components in the aqueous phases would simply be the result of a competition between dissolution and precipitation and equilibrium is not relevant. This possibility has been considered (Barret and Bertrandie, 1988).

Because C_3S and water constitute a reacting system, and because C_3S is unstable when exposed to water, it is not obvious that equilibrium has much relevance. In other words, the system is always far from equilibrium and therefore in an unstable state. The reaction between C_3S and water is extremely slow during the induction period. If this is a result of waiting for product nuclei to form than the aqueous phase should approach a state of equilibrium with C_3S, but this is almost certainly not the case (Jennings, 1986, Jennings, 1988, Stein, 1972). It is difficult to believe that the rate of dissolution is intrinsically slow because dissolution occurs rapidly at the start of the reaction. If a protective layer causes such a slow reaction, it allows a local equilibrium between the aqueous phase and the layer to be established. This paper develops an argument in support of a protective layer.

As discussed below, there is considerable evidence for a layer of product forming around the unreacted solid which might serve to slow the dissolution of C_3S. The question now is whether the concentrations of components in the aqueous phase are the result of a competition between slowly dissolving C_3S and slowly forming product, or by a rapid adjustment to equilibrium with the layer?

If the system is approaching equilibrium with the layer and the layer has a solubility distinctly different from C_3S, then the layer must be considered a phase in itself. The main issue is whether or not the aqueous phase is moving towards any type of equilibrium, stable or metastable, with this layer. Thus, we are not considering global equilibrium but rather a local equilibrium with the aqueous phase. In a sense, equilibrium is being considered to describe the aqueous phase at a local level, while steady state describes the system on a global level.

THE INDUCTION PERIOD

Evidence for a local equilibrium comes from the aqueous phase when concentrations of components from a large number of experiments at different times and reaction conditions (including different mixing conditions) are plotted on a ternary SiO_2-CaO-H_2O diagram. These points typically form a smooth curve. At this point during the reaction, the system is undersaturated with respect to calcium hydroxide (CH). If we accept that the data falls on C-S-H(M), a curve with one degree of freedom, then invoking Gibb's phase rule with three components (at constant temperature and pressure) forces the conclusion that two phases are present, one is the aqueous phase. Since C_3S cannot be the other phase (much too soluble), then the surface of C_3S must be surrounded by another phase which is some form of C-S-H. Therefore, this system is being governed by equilibrium. In other words, any change brought about by slow dissolution of C_3S is adjusted for by precipitation of product. The system approaches equilibrium rapidly compared to these changes, and the equilibrium is between a product layer and the aqueous phase.

It is possible that extraordinary coincidence could explain the one degree of freedom with concentrations given the wide range of reacting and mixing conditions from which the data was taken (Jennings, 1986). Thus, the issue of kinetic competition is still not absolutely settled in that we could have a slowly dissolving reactant, whose rate is controlled by the layer, and a slowly forming product. Since there is scatter in the data, the idea of drawing a curve and calling it one degree of

freedom might be an oversimplification. The scatter could be the result of changing conditions in the kinetic competition, the system's inability to exactly achieve equilibrium, or experimental error, or a combination of two or more of these mechanisms. One test would be to disturb this balance and follow whether or not the aqueous phase remains in a new state or returns to the equilibrium state.

One type of experiment has been performed repeatedly to explore the system's ability to maintain equilibrium even if the system is altered. The object is to perturb the system and track the concentration of components in the aqueous phase to see if it stays perturbed or returns to the C-S-H (M). The addition of water or lime to the paste at various times throughout the induction period, imposes huge perturbations and then concentrations in the aqueous phase are followed. The brief experimental sequence and a typical result are described in Fig 1 and Fig 2 and, as can be seen, the system returns to the equilibrium concentrations very rapidly.

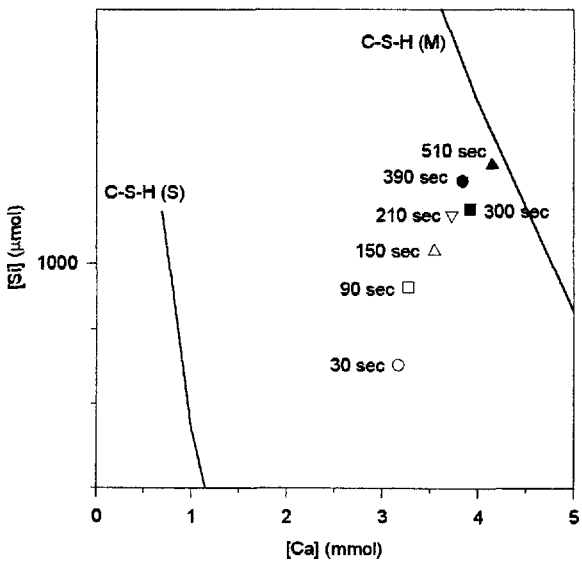

Figure 1: Typical results from dilution experiment. C_3S and de-ionized water were mixed at a water/cement (w/c) ratio of 0.5 by hand for 5 minutes. The sample was allowed to sit for 10 minutes and was then slowly poured into a de-ionized water batch which diluted the sample to a w/c=20. Following dilution, the aqueous phase was extracted at various times (indicated on the graph) using a pipet and filter paper (particle retention=5-10 µm). Ion concentrations in the extracted aqueous phase were analyzed using inductively coupled spectroscopy (ICP) analysis.

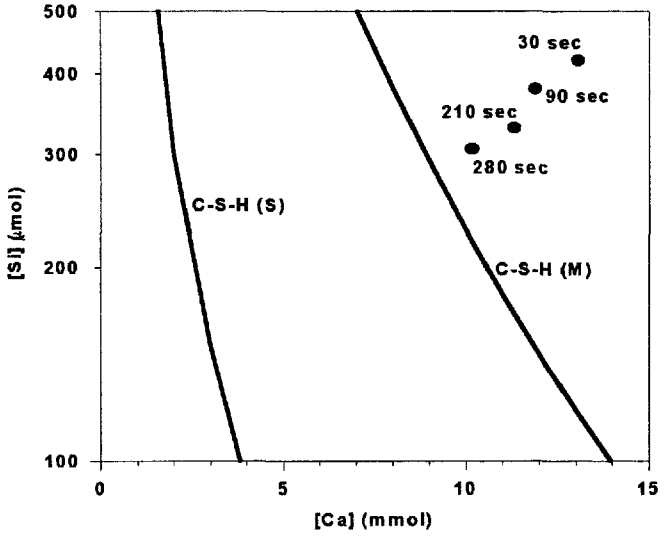

Figure 2: Typical results from CaO addition experiment. C_3S and de-ionized water were mixed at a water/cement (w/c) ratio of 0.5 by hand for 5 minutes. The sample was allowed to sit for 10 minutes and CaO was then added. Following CaO addition, the aqueous phase was extracted at various times (indicated on the graph) using a pipet and filter paper (particle retention=5-10 µm). Ion concentrations in the extracted aqueous phase were analyzed using inductively coupled spectroscopy (ICP) analysis.

There is also physical evidence for a metastable layer. An early surface layer has been observed on C_3S particles at high w/c ratios (Groves, 1983, Double and Hellawell, 1976, Ings et al, 1983). Additionally, Bergstrom and Jennings (1992) and, more recently, Meredith et al (1995) have used an environmental scanning electron microscope to note that the surface of C_3S particles in normal w/c pastes is covered with a gelatinous material very early in the hydration process. X-ray photoelectron spectroscopy studies also support the early formation of a layer on the C_3S surface. Regourd et al (1980) noted a sharp decrease in the C/S ratio of the C_3S surface, followed by an increase, and another decrease to a final value of 1.5-2. This seems to suggest two different types of early hydrate; the latter, with the C/S ratio ~ 1.5-2, is believed to be a metastable phase which controls the early hydration and gives rise to the induction period. In addition, Jennings (1986, 1988) suggests there are two phases, one stable with respect to the other.

Thus, both physical and chemical evidence suggests that both a layer forms and that it is in equilibrium with the aqueous phase. The question now is why does the induction period come to an end, or perhaps, why does the layer become ineffective.

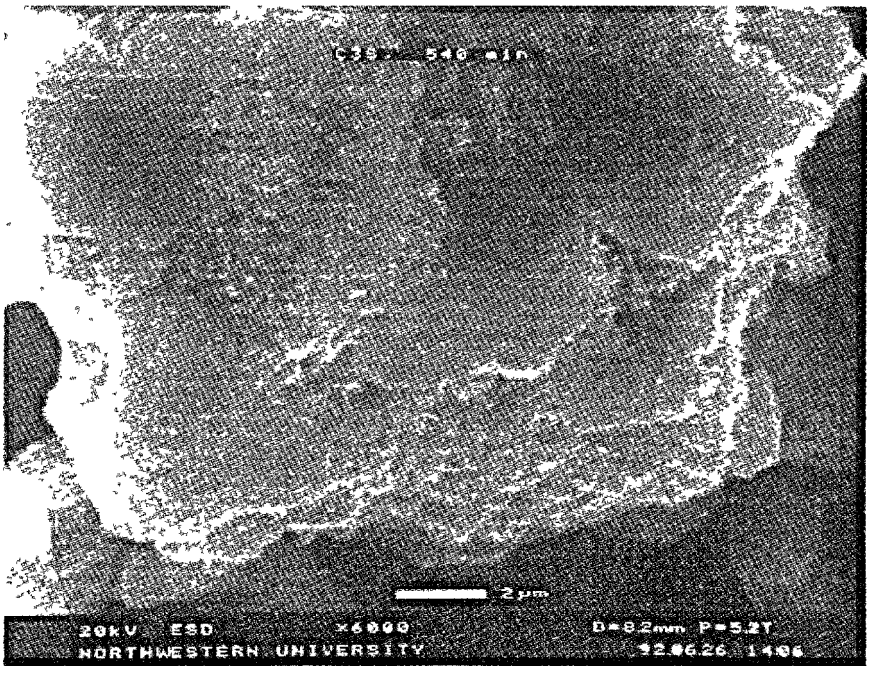
A CASE FOR A LAYER--METASTABLE C-S-H

As discussed above, there are two types of C-S-H, one metastable with respect to the other. These have been designated C-S-H (M) and C-S-H (S). It is tempting to speculate that a conversion from one to the other is the basic mechanism that triggers the end of the induction period. Extensive investigation, however, found little or no change, either physical or chemical, at the end of the induction period as measured by calorimetry.

Environmental scanning electron microscope (ESEM) micrographs (Sujata and Jennings, 1992) have suggested that the texture of the surface layer begins to change only around the time of set. Typical results are shown in Fig 3. These are consistent with the surface area measurements.

Finally, the aqueous phase chemistry has been studied extensively and it is typically found that a transition occurs from the upper curve to the lower curve about the time of set. Data from this study can be seen in Fig 4. Again, this data is consistent with a phase change occurring at the time of set.

SUMMARY



All indications are that the C_3S-water system behaves as if it is nearly at equilibrium. It obeys Gibbs' phase rule and it responds to perturbations in a manner consistent with equilibrium. This equilibrium is with a C-S-H layer that is a distinct phase. Furthermore, at about 4-6 hours there appears to be a phase change associated with the nucleation of a more stable form of C-S-H. However, this phase change occurs at a time significantly later than the end of the induction period as defined by calorimetry.

ABSTRACT A new phase diagram, based on a wide range of data, is presented for the CaO (C)-SiO_2 (S)-H_2O (H) system. This phase diagram provides important new insight into understanding the hydration of cementitious systems and supports the idea of a metastable C-S-H layer as the cause of the induction period. A mechanism for the end of the induction period is considered: a eutectic solidification reaction. First, a layer forms, and during the induction period a metastable equilibrium triangle is established between C_3S, the metastable C-S-H layer, and solution. When a sufficient level of calcium supersaturation is reached, CH and C-S-H begin to form cooperatively starting at the metastable layer, and two separate local equilibria are established at the product/solution interface and at the product/C_3S interface. Interpretation of this diagram in the β-C_2S system has also been made. Differences between C_3S hydration and C_2S hydration are accounted for by the proposed phase diagram.

Key-Words: Phase Diagram; Hydration; Thermodynamics; Equilibria; Mechanism

INTRODUCTION

The development of a phase diagram for the CaO (C) - SiO_2 (S) - H_2O (H) system has long been an elusive goal in cement and concrete research. A relevant phase diagram for cementitious systems must contain C_3S and C_2S, the major components of portland cement; water; and the products of the hydration reaction. Phase diagrams are a powerful tool and are frequently used to understand and design the microstructure of materials.

As noted by Brown (1989), it is difficult to describe the CaO - SiO_2 - H_2O system in terms of a phase diagram since traditional phase diagrams assume equilibrium. In the cement system the concept of absolute equilibrium has proven inadequate; one must instead consider constrained or metastable equilibria which control phase development and stability.

At the present time, only rough sketches of this phase diagram have been published. For example, Williamson (1968) has presented a ternary diagram showing where the C-S-H phase field must exist, and Taylor et al (1984) have presented a more extensive map of the major phase fields. While these are helpful in describing the process of hydration, they are not very useful for predicting or controlling reactions. Brown (1989) has presented a more detailed diagram accompanied by a series of proposed mechanisms for the hydration of C_3S. However, there is a

definite need for a more exact phase diagram consistent with the experimental data that has been accumulated to date.

One of the desirable characteristics of any phase diagram of this system is a logical explanation for the end of the induction period. Taylor et al (1984) have reviewed the four existing main hypotheses. Two of these hypotheses involve a protective surface layer on the C_3S surface which is either destroyed by osmotic bursting or rendered more permeable by aging or by a phase transformation The other two hypotheses cite nucleation of either the CH or C-S-H phase as the trigger which ends the induction period. In this case, growth of product relieves supersaturation and allows dissolution of unreacted cement. Much of the experimental evidence gathered to date seems to support the nucleation of C-S-H as the governing factor in the end of the induction period. However, there is also some evidence for the surface layer hypothesis (Taylor, 1990). Taylor (1990) notes that, in the most likely scenario, two or more of these mechanisms work in conjunction to ultimately end of the induction period.

As discussed in Part I, phase diagrams are very important tools for studying the hydration of cement-based materials. This paper presents a proposed phase diagram for the CaO - SiO_2 - H_2O system which appears to be consistent with most of the experimental evidence collected to date. It also can be used to help support a mechanism for the end of the induction period involving a eutectic solidification reaction. The hydration of C_3S is discussed throughout, and extensions to the hydration of β- C_2S are also made.

MAPPING THE PHASE DIAGRAM FOR THE C/S/H SYSTEM

The goal of our research was to create a ternary phase diagram consistent with all of the data observed to date. The major phases in portland cement, C_3S and C_2S, along with one of the major products, CH, can easily be placed on the phase diagram in their respective locations. Each was assumed to be a line compound[1] for the purposes of the discussion which follows. Mapping the phase field of the C-S-H phase was far more challenging. It was assumed that there are two separate types of C-S-H which form (see Part I): a metastable phase which controls the early hydration and causes the induction period, and a more stable phase which develops later and causes the material to set. Although this theory is not universally accepted, both phases are introduced here in order that they be included in discussion.

Metastable C-S-H Phase

There is evidence (see Part I) to state that the onset of the induction period is caused by a form of C-S-H which slows ion dissolution from hydrating C_3S and C_2S. Brown et al (1984) determined that this layer probably forms within 30 seconds of wetting the solid surface, moving the system toward a metastable equilibrium between C_3S, solution, and the slow growing C-S-H surface layer. Jennings (1986) referred to this phase as C-S-H (B) [subsequently C-S-H (M)] and showed that the solubility of this phase is significantly greater than that of the stable C-S-H phase, C-S-H (A) [subsequently C-S-H (S)].

---

[1] The concept of a line compound refers to the representation of its free energy vs. composition function as a vertical line located at the stoichiometric composition.

The metastable phase, C-S-H (M), has been placed on the phase diagram using an assumed composition of $C_{1.85}SH_{2.65}$. These values fall well within the range determined by the X-ray photoelectron spectroscopy studies (Regourd et al, 1980) and also support the idea of a supersaturated phase relative to the stable C-S-H phase boundary described in the next section. It is interesting to note that these values are very close to that determined for jennite ($C_9S_6H_{11}$), a mineral which can be synthesized from CH and hydrous silica in aqueous suspensions (Taylor, 1990). Whether any relations exist between jennite and this metastable C-S-H phase is a topic for future investigations.

Stable C-S-H Phase Boundary

The placement of the C-S-H phase boundary in Fig 1 (bounding its two-phase field with CH) is governed by the following assumption: the CH formed during this reaction is separate from the C-S-H phase. Other authors, notably Taylor (1990), have argued that the CH forming within the C-S-H layers is an integral part of that phase and they should be considered together. However, for the remainder of this paper, we will assume that the two phases are separate, though they may be intimately mixed.

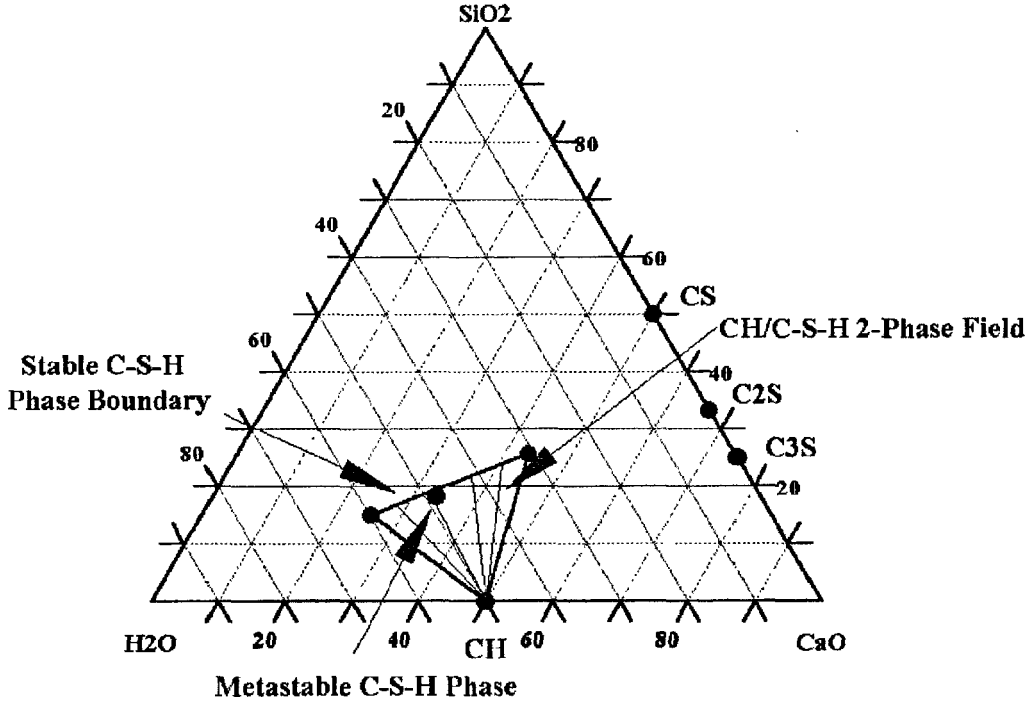

Figure 1: Ternary diagram for the $CaO-SiO_2-H_2O$ system showing the placement of the line compounds CS, C_2S, C_3S, and CH; the metastable C-S-H phase; and the stable C-S-H boundary limiting the C-S-H and CH two-phase field.

The first, easiest, and most obvious way to distinguish between these phases is via the stoichiometric reaction equations. Young and Hansen (1987) studied saturated C_3S pastes to arrive at a C-S-H composition of $C_{1.7}SH_4$. This result was compared with a composition of $C_{1.7}SH_{3.35}$ derived from the work of Locher (1966) and Brunauer and Kantro (1964). An additional comparison was made with the work of Jons and Osbaeck (1982), but there was doubt as to whether all of the capillary water had been excluded and this value will not be used in this paper.

Direct experimental data on the composition of C-S-H is more difficult to obtain when the C-S-H and CH are considered separately due to the difficulty in discretizing between the two mixed phases. Three main experimental techniques are used to separate the two phases: quantitative x-ray analysis (QXDA), thermal methods such as thermal gravimetric analysis (TGA), and extraction methods using aqueous media or free lime. In general, extraction methods detect more CH than either thermal methods or QXDA (Taylor, 1990). The lower values of thermal methods and QXDA are generally attributed to adsorbed, amorphous, or interlayer CH (Taylor, 1990), which is the exact value we are trying to quantify. Hence, we concentrated on values gathered from extraction methods. Only the work of Odler and Dorr (1979a) used an extraction method following D-drying, resulting in a composition of $C_{1.6}SH_{1.32}$. Their work cited many authors who found typical compositions of $C_{1.7}SH_{1.3\text{-}1.5}$ using D-drying techniques. It is important to note that not all of the cited results differentiated between C-S-H and CH in the hydration product; these results were included in our analysis because of their consistency with the results of Odler and Dorr (1979a). We take a final composition value of $C_{1.7}SH_{2.1}$ for C_3S equilibrated at 11% relative humidity from the work of Young and Hansen (1987).

Examining all of the data, a general consensus for a C/S ratio of about 1.7 was found, with differing H/S ranging from H/S=4 for saturated pastes to H/S=1.3-1.5 for D-dried pastes. The C-S-H phase boundary limiting the C-S-H and CH two-phase field was then mapped as a straight line of C/S=1.7 between the two H/S limiting values mentioned above. This is obviously an approximation and far more work into the position of this boundary is needed.

Gathering all of the data described above gives a good approximation of a phase diagram for the C-S-H system. Fig 1 shows this ternary diagram with the stable C-S-H and CH field represented by the tie lines, and the metastable C-S-H phase placed as described above. The implications of this phase diagram will be discussed in this next section.

IMPLICATIONS OF THE PROPOSED PHASE DIAGRAM

Early Hydration and Onset of the Induction Period

The early hydration period is marked by a rapid period of ion dissolution and an exothermic reaction (Gartner and Gaidis, 1989). The dissolution and reaction rates suddenly and rapidly decrease followed by a period of very slow reaction, the induction period. Approximately 1-2% of the C_3S is consumed during this time.

As noted above, there is sufficient evidence to state that the slowing of the ion dissolution is due to a surface layer of C-S-H which forms rapidly during this period. This surface layer is almost certainly a metastable phase. Calcium dissolution is subsequently controlled by this surface layer resulting in a nearly constant concentration of calcium during the induction period, as shown by experimental data (Taylor, 1990).

Insight into the physical properties of this layer is vital to understanding the early hydration process. It is probably a very thin layer which is non-uniform in thickness, being thicker around active dissolution sites on the C_3S surface (Fierens and Verhaegen, 1976a). Since its C/S ratio is less than 3, as more C_3S reacts, free calcium ions are generated. These ions then diffuse through the layer and dissolve into solution, accounting for the rise in calcium concentration with time (e.g. Brown et al, 1984). The layer correspondingly thickens as the reaction proceeds toward a metastable three-phase equilibrium state. This is consistent with several studies by X-ray photoelectron spectroscopy (Regourd et al, 1980, Jawed et al, 1980, Jawed and Skalny, 1982) and electron microscopy (Ings et al, 1983), as noted by Gartner and Gaidis (1989).

The phase diagram representing the metastable state, which we believe to be approached during the early hydration and induction periods, is shown in Fig 2. It shows the metastable three-phase triangle between C_3S, aqueous solution, and the metastable C-S-H phase which has a C/S ratio between 1.8 and 2. We believe that this phase diagram is consistent with all of the experimental evidence discussed above.

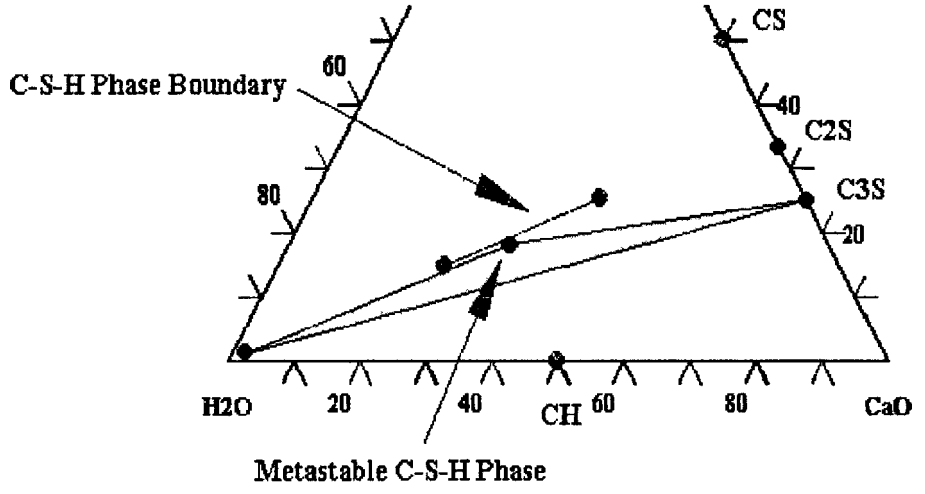

Figure 2: Metastable equilibrium phase diagram for the $CaO\text{-}SiO_2\text{-}H_2O$ system. The triangle indicates the metastable equilibrium between C_3S, solution, and metastable C-S-H.

Induction Period

During the induction period C_3S reacts at a very slow rate. As it reacts, the C-S-H surface layer thickens and the aqueous solution continues to become more calcium rich, eventually becoming

supersaturated with respect to CH (Taylor, 1990). The resulting supersaturation level is still too low, however, for homogeneous CH nucleation.

CH may precipitate at areas of local supersaturation in the solution (Odler and Dorr, 1979a, Odler and Dorr, 1979b, Fierens and Verhaegen, 1976b, Young et al, 1977). The presence of these crystals may not affect the local metastable equilibrium present at the surface of the C_3S, and thus would not affect the overall hydration process. Similarly, seeding the paste with CH crystals, as attempted by Uchikawa (1984), does not appear to influence the local equilibria present at the C_3S/solution interface. Thus, seeding does not accelerate the end of the induction period. Rather, the presence of these CH crystals may have a slight retarding effect, as noted by Uchikawa (1984), as they provide a surface upon which calcium ions in solution may precipitate. In this case, the calcium concentration in the solution drops, requiring more time to reach the supersaturated state necessary to induce the eutectic solidification reaction described below.

End of the Induction Period

As discussed in Section 1 and in Part I, there is still a great deal of debate about the end of the induction period. Each of the four main theories still offers an incomplete explanation for this phenomenon. Since this paper argues that a protective metastable layer is the cause of the induction period, the destruction or disruption of this layer must be explained. Additionally, as discussed in Section 1, the nucleation of both CH and C-S-H have been mentioned as possible triggers for the end of the induction period. We shall now set forth a mechanism which combines these hypotheses and is consistent with the phase diagram presented in Section 2: a eutectic solidification reaction.

Eutectic Solidification Reaction

A eutectic solidification reaction involves the nucleation of two solid phases cooperatively from the liquid according to the following equation:

$$L \rightarrow \alpha + \beta \qquad [1].$$

This phenomenon occurs in many metal systems such as Al-Cu and Al-Fe. Many different morphologies result, which are usually classified into either *normal* or *anomalous* reactions. In this paper we are discussing a normal eutectic solidification reaction; the resulting morphology from this reaction consists of lamellae of alternating phases, as shown in Fig 3a (Porter and Easterling, 1981).

Rapid cooperative growth in these systems is controlled by short range diffusion between neighboring lamellar tips as shown in Fig 3b. Material rejected from the α phase is incorporated into the β phase, and vice versa. The overall growth rate is controlled by the rate at which this diffusion can occur and is thus controlled by the spacing between lamellae, λ (shown in Fig 3b) (Porter and Easterling, 1981). For a spherical colony, λ will be very small initially and will tend to increase as the lamellae grow further away from the particle. Because λ is determined by supersaturation and remains constant, the lamellae often branch to shorten the inter-lamellar spacing.

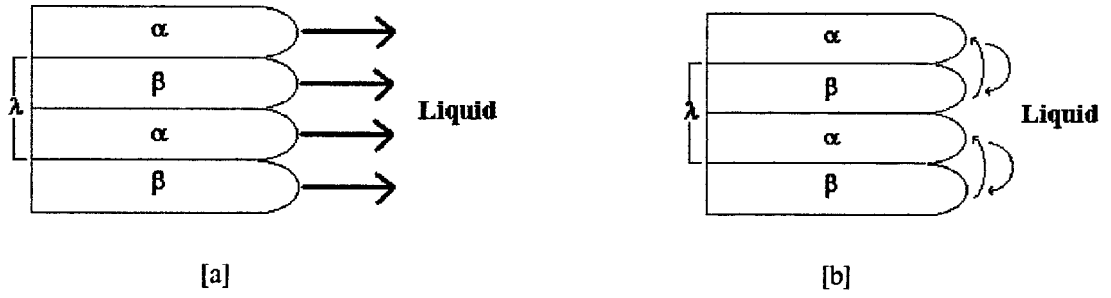

Figure 3: Morphology and mechanism of eutectic solidification reaction. [a] Alternating lamellae of α and β phases. Arrows indicate growth direction into liquid. [b] Diffusion controlled growth between adjacent lamellae. Arrows indicate diffusion of atoms in liquid to form α and β (after Porter and Easterling, 1981).

Extending this reaction to the C/S/H system gives the resulting nucleation equation:

Aqueous Solution → C-S-H + CH [2].

The C-S-H lamellae will contain interspersed micro-crystals of CH. As calcium is rejected from the C-S-H, it will be incorporated into the CH; similarly, as silicon is rejected from the CH, it will be incorporated into the C-S-H. Later, the CH may coarsen into larger particles elsewhere in the microstructure.

This reaction follows naturally from the phase diagram presented in Section 2. Fig 4 depicts the situation which we believe to be present at the end of the induction period. The left hand triangle (1) shows the equilibrium between solution, $C_{1.7}SH_4$, and CH. It represents the local equilibrium governing behavior at the product/solution interface. This triangle describes the ternary eutectic solidification reaction where solution decomposes into $C_{1.7}SH_4$ and CH. The right hand equilibrium triangle (2) between C_3S, $C_{1.7}SH_{1.3}$, and CH describes the slow reaction behavior at the C_3S/product interface.

It is important to note that the original C-S-H layer does not just disappear; rather it is converted from a metastable form of C-S-H with approximate composition $C_{1.85}SH_{2.65}$ to a stable form of the phase with a C/S ratio of approximately 1.7 and water content ranging from H=1.3-4.0. Fig 5 illustrates this change from a step function to a phase with a gradient of water contents. Additionally, the liquid phase moves from a point on the solubility curve for metastable C-S-H (M) (Jennings, 1986) (corresponding to point L on Brown's diagram (Brown, 1989)) to a point on the solubility curve for stable C-S-H (S) (Jennings, 1986) (corresponding to point I on Brown's diagram (Brown, 1989)). The relative positions of the metastable equilibrium triangle and the two stable equilibrium triangles are shown in Fig 6.

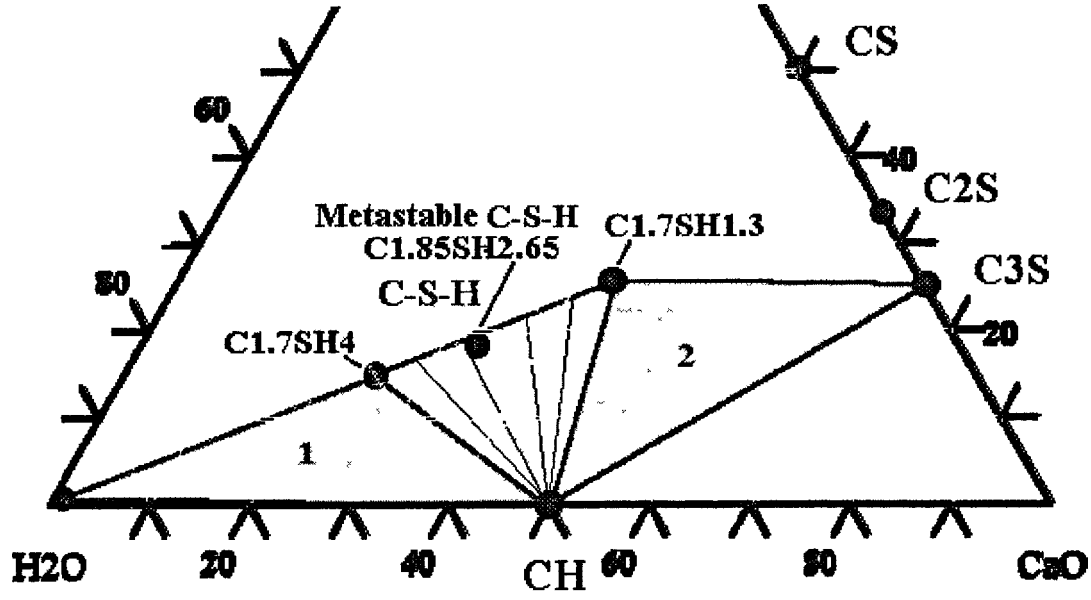

Figure 4: "Equilibrium" phase diagram for the $CaO-SiO_2-H_2O$ system. Equilibrium triangle number 1 is the equilibrium between solution, C-S-H, and CH. Equilibrium triangle number 2 is the equilibrium between C_3S, CH, and C-S-H.

The idea of an alternating layered structure consistent with that produced by the eutectic solidification reaction has been proposed by Williamson (1968). 'From both the morphology and the chemistry it is apparent that the calcium silicate hydrate can be thought of as a form of two phase material similar to a eutectic or eutectoid.' He proposed a *constitutional supersaturation* process to account for the resulting layer morphology in which the heat of hydration depresses the equilibrium concentration of calcium at the growth interface. A supersaturated state occurs at that point, which then leads to the growth of protuberances he called "sheafs of wheat". This idea, although different from what is proposed, supports the importance of supersaturated states in the hydration of C_3S.

Kantro et al (1962) have also proposed an alternating layer structure as the final result of the hydration process. However, they considered the CH to be a part of the C-S-H and not a separate phase.

Experimental Evidence

There is considerable experimental evidence to support the idea of a eutectic solidification reaction. First and foremost is the presence of microcrystalline CH in C-S-H pastes as noted by Groves. He found such crystalsin pastes of very low water/cement (w/c) ratio (Groves, 1981) and, more recently, pozzolonic cement pastes (Groves and Richardson, 1994) using transmission electron microscopy (TEM). The typical morphology of these crystals is a cluster of lamellae approximately 10 nm thick. The crystals also appear to align themselves locally, though the degree of alignment varies widely. Both studies imply the intimate mixing of CH and C-S-H on the nanometer level; this mixing would be the logical result of a eutectic solidification reaction.

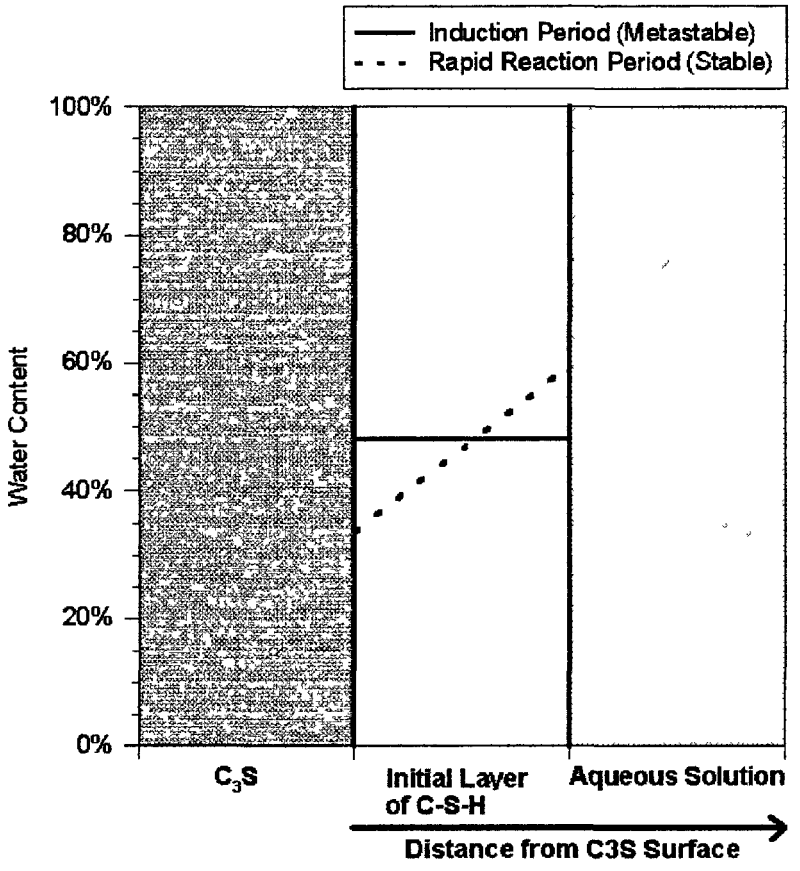

Figure 5: Transition from metastable C-S-H phase of constant water content to stable C-S-H with a gradient of water contents. The solid line represents the water content of the initial metastable C-S-H phase ($C_{1.85}SH_{2.65}$) The dotted line represents the gradient of water contents present in the C-S-H produced by the two equilibrium reactions $C_{1.7}SH_{1.3}$ at the C_3S/C-S-H interface, and $C_{1.7}SH_4$ at the C-S-H/aqueous solution interface.

However, no microcrystalline CH has been found in pastes of normal w/c ratios. This absence of CH may be the result of a leaching process from the inner to the outer C-S-H hydration product. No CH was observed under TEM examination in the inner product in a 26 year old C_3S paste of w/c=.45 (Groves, 1987). The outer product, on the other hand, has a very wide range of morphologies with substantial water-filled empty space. Outer C-S-H is probably the result of the left hand equilibrium triangle in Fig 4 along with CH crystals, and could explain the lack of microcrystalline CH in normal w/c ratio pastes As large crystals form, a coarsening process may occur, with smaller CH crystals dissolving and growing upon the larger CH crystals. Since the smallest CH crystals will be those which form in the dense inner product, these should be the first to be consumed by this coarsening process.

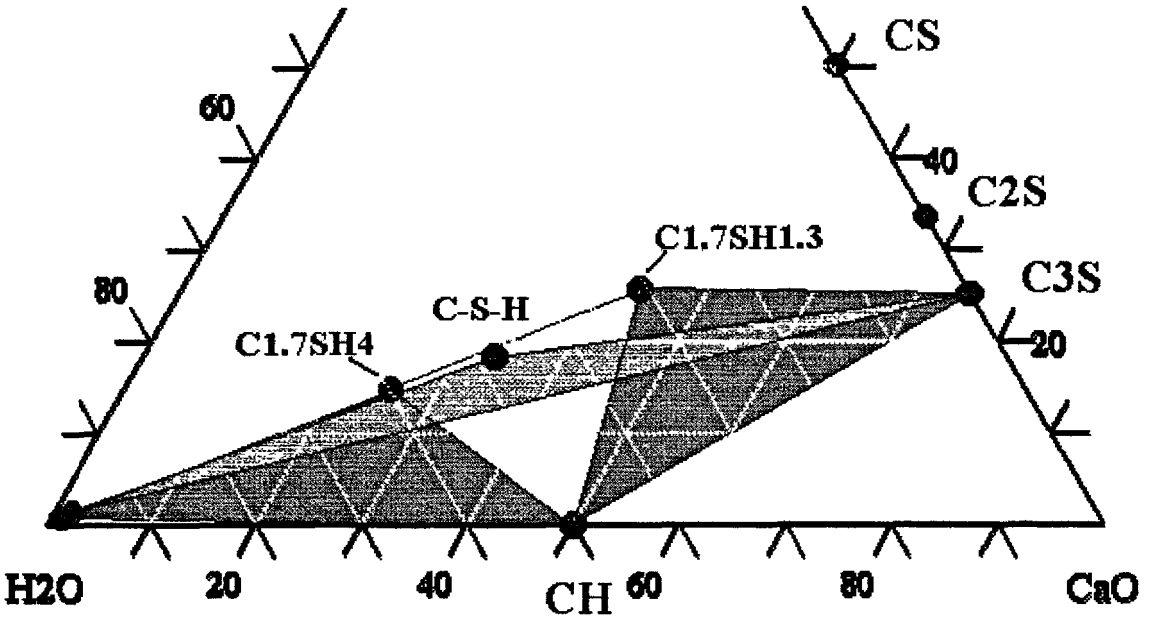

Figure 6: Phase diagram for the $CaO-SiO_2-H_2O$ system. Both stable and metastable equilibrium triangles are shown.

Groves (1987) has noted in the 26 year old C_3S paste mentioned above that there are large CH crystals which possess protuberances growing into the open space of the outer product C-S-H. These protuberances could easily be the result of a coarsening process. The crystals also appear to be very well bonded to the outer product C-S-H. Additionally, Groves notes the presence of plate-like CH crystal of only a few tens of nm in thickness. These smaller crystals suggest that very small CH specimens may have been present at some time in the past.

The C/S ratios for the inner and outer product of the 26 year old paste and a 2 year old C_3S paste support this hypothesis. The C/S values for the outer gel ranged from 1.25-2.07, with a mean of 1.72; the inner gel ranged from C/S=1.27 to C/S=1.78, with a mean of 1.66. Since these values do not discriminate between C-S-H and CH in the paste, it is likely that this higher C/S ratio can be attributed in part to the leaching effect described above. This mechanism would be independent of other proposed mechanisms for C/S ratio discrepancies, such as different silicate polymerization states (Taylor, 1990).

This leaching process is also consistent with the results of Stade and Wieker (1980) who found that CH could be leached from C-S-H with C/S ratios > 1.25. However, below this limit little or no CH could be extracted. Additionally, all of the leached pastes had a C/S ratio of 1.25 following the extraction process; this value may represent the lower extension of the C-S-H phase

boundary. However, since the C-S-H caused by the hydration of C_3S typically has a C/S ratio of approximately 1.7, it would be expected that CH could be extracted from this phase.

It is possible that this coarsening effect was also occurring in the very low w/c ratio pastes mentioned above in which microcrystalline CH was present. However, the very low amount of aqueous phase may have inhibited the diffusion of the smaller CH crystals to the large CH crystals.

This leaching effect could also partially explain why the inner product never fully densifies. As stated by Powers (1961) and noted by Groves (1987), there is no obvious explanation for silicon diffusing to the outer product area before reacting; rather, it should react in the inner product area to form a fully dense phase. Powers hypothesized that the pore spaces left in the inner product eventually become too small for further nucleation of hydrate and remain unfilled. A second mechanism could be the leaching effect described above, which would leave nanometer scale pores as the microcrystalline CH plates dissolve.

A final compelling piece of evidence is the proximity on the phase diagram of the metastable phase and phase boundary to phases which are believed to exist in cement-based systems. Using compositions from Taylor (1990), tobermorite and jennite were plotted on the phase diagram in several different forms: equilibrium composition (jennite and 1.4 nm tobermorite), de-hydrated composition (metajennite and 1.1 nm tobermorite), and an early form in which only dimeric polymerization of the silicon ions has occurred. Fig 7 shows the locations of these phases. Note that jennite with dimeric polymerization falls extremely close to the proposed metastable phase, while the other phases fall above the C-S-H phase boundary. This suggests that our proposed metastable phase may be a form of unpolymerized jennite. As the reaction proceeds, polymerization occurs and provides the driving force necessary to drive the system towards the stable C-S-H phase boundary. When this boundary is crossed, precipitation of C-S-H and CH occurs through the two stable equilibrium triangles indicated by the phase diagram.

Deceleratory Period and Final Slow Reaction

As the main reaction proceeds, it eventually reaches a point where the reaction rate is very slow. This is known as the deceleratory period, and it is not very well understood, as noted by Gartner and Gaidis (1989). They describe three main hypotheses for the slowed reaction rate: (1) the dissolution of C_3S becomes rate limiting; (2) the diffusion of reactants through the hydration products becomes rate limiting; or (3) the deposition of hydrates is prevented by a lack of free space. Gartner and Gaidis (1989) state that the most probable limiting step is the diffusion of the silicate ion through the reaction product layer. The conclusion of Gartner and Gaidis (1989) is also consistent with a eutectic solidification reaction.

EXTENSIONS TO β-C_2S

The hydration of β-C_2S is very similar to the hydration of C_3S in terms of its products and mechanisms except that it reacts much slower and there is much less CH (Taylor, 1990). A possible phase diagram for this system is shown in Fig 8. This phase diagram is consistent with both a slower reaction rate and less CH production. Again, CH seeding cannot be used to

supplement dissolution because only the chemistry present within the metastable C-S-H layer is important.

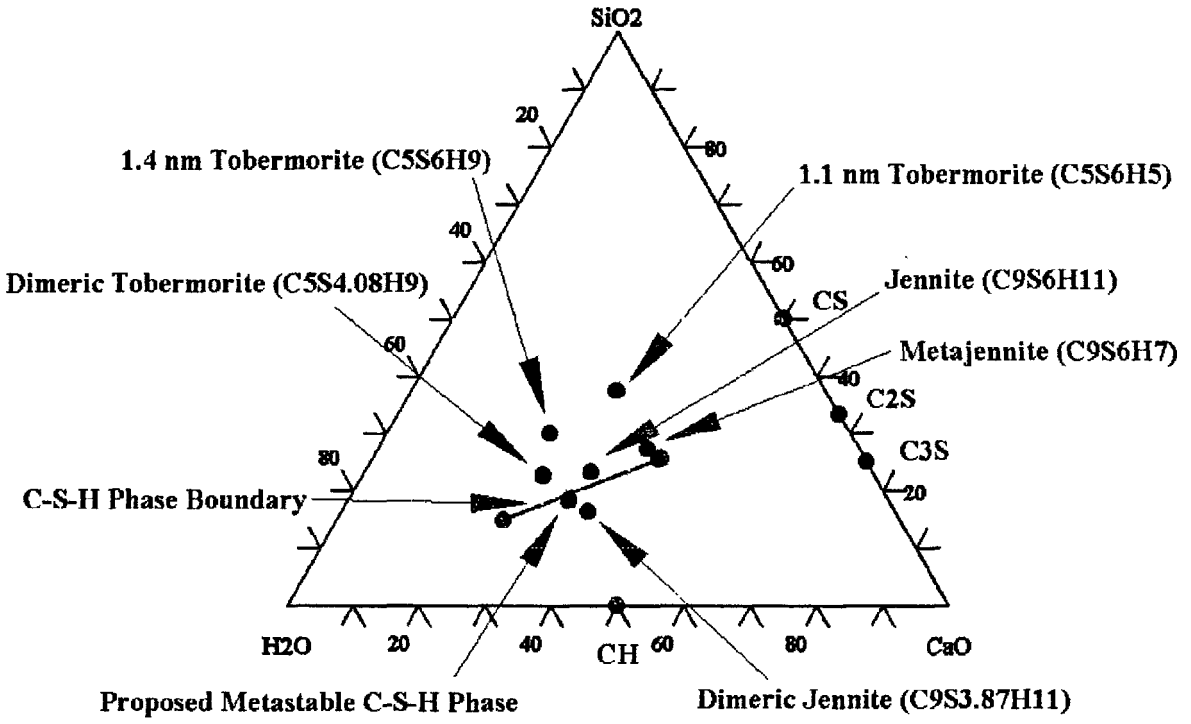

Figure 7: Proximity of various phases of jennite and tobermorite to proposed metastable C-S-H phase and C-S-H phase boundary.

The slower reaction rate could be the result of less calcium going into solution. Since the C/S ratio of C_2S is much closer to that of the proposed metastable C-S-H phase than is C_3S, there should be considerably less calcium going into solution because most of it is consumed in thickening the metastable layer. This thickening has been observed indirectly by electron spectroscopy for chemical analysis (ESCA) (M`en`etrier et al, 1980). As less calcium goes into solution, more time is required to reach the calcium supersaturation level necessary for the eutectic solidification reaction to begin.

A lower amount of CH produced is also predicted by the phase diagram. The lever rule for ternary alloys predicts that approximately twice as much CH should be produced in the hydration of C_3S than in C_2S. This is consistent with the accepted stoichiometric equations which predict three times as much CH production in the hydration of C_3S than in C_2S (Mindess and Young, 1981). The differences are probably due to the crudeness of the proposed phase diagram and the assumptions made in developing the stoichiometric equations.

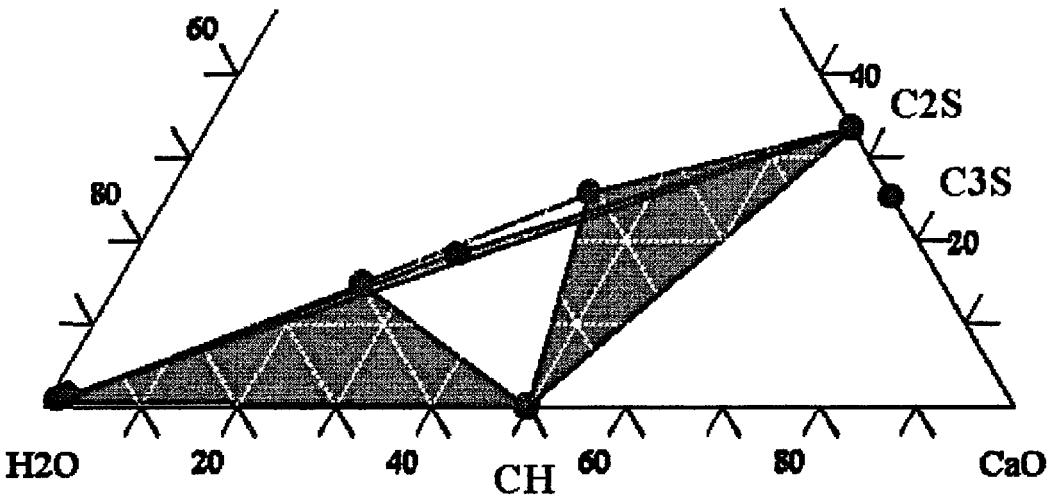

Figure 8: Phase diagram for the $CaO-SiO_2-H_2O$ system. The large left-hand triangle indicates the stable equilibrium between C-S-H, CH, and aqueous solution. The large right-hand triangle indicates the stable equilibrium between C_2S, CH, and C-S-H. The long skinny triangle indicates the metastable equilibrium between solution, C_2S, and metastable C-S-H.

Note that the phase diagram gives no insight as to why certain C_2S phases hydrate while others are inactive in water. This does not invalidate the proposed phase diagram since they may be the result of mechanisms which cannot be represented on a phase diagram. However, further study into the reasons why these phases do not hydrate is needed.

SUMMARY

A new phase diagram for the CaO (C)-SiO_2 (S)-H_2O (H) system is presented and discussed in terms of a very early reaction and later reaction. This phase diagram provides new insight into understanding the hydration of cementitious systems. The phase diagram is consistent with a rapid forming, semi-permeable C-S-H layer as the cause of the induction period. This phase has a C/S ratio of 1.8-2.0 and is almost certainly metastable.

A mechanism for the end of the induction period is proposed: a eutectic solidification reaction. This reaction occurs most commonly in metals and results in two lamellar phases growing cooperatively. It is proposed that the hydration of cement occurs via this reaction when the concentration of calcium achieves a sufficient level of local supersaturation to induce CH and C-S-H nucleation. As these phases are dependent upon the thermodynamic equilibria near the interface of C_3S and water, this reaction would explain the early presence of CH crystals in the bulk solution and why CH seeding does not accelerate hydration. This reaction results in an

equilibrium between $C_{1.7}SH_{4.0}$, CH, and solution at the product/solution interface and an equilibrium between $C_{1.7}SH_{1.3}$, CH, and C_3S at the product/C_3S interface.

THERMODYNAMIC AQUEOUS SOLUBILITY DIAGRAM FOR THE BINARY SOLID-SOLUTION SYSTEM C-S-H - H_2O

Michael KERSTEN, IOW Geology Section, Seestr. 15, D-18119 Rostock, Germany
(e-mail: kersten@io-warnemuende.de)

ABSTRACT A thermodynamic solid solution - aqueous solution model for a binary non-ideal mixing of the end-members portlandite and Ca-silicate, with known pK's and a miscibility gap at C/S > 3, predicts a maximum in Gibbs free-energy of mixing (ΔG^M) of -3.2 kJ/mol to occur at a C/S ratio of 1.6. Predicted Ca and Si solubilities and pH values agree with experimental data reported from the literature. It is also possible to predict the solubility of trace metals bound into the C-S-H host phase which will be exemplified for the case of Zn.

Key-words: CSH, Calcium hydroxide, Solid solution, Thermodynamics

INTRODUCTION

C-S-H gel dissolves incongruently in pure water, with aqueous Ca concentrations being much higher than those of Si. The extent of the incongruent dissolution behaviour is gradually increasing with the C/S ratio of the solid phase. In spite of this complex dissolution behavior, a close inspection of the data published over a period of 50 years revealed that the concentration of Ca and Si in the aqueous phase must be guided by a yet not well understood thermodynamic equilibrium (Jennings, 1986). A common approach to fit the relationship between the Ca vs. Si solubility curve and the C/S ratio of the C-S-H solids is based on the assumption of variable solubility products of the main components portlandite and calcium silicate as a function of the particular C/S ratio. This empirical approach enables to describe experimental data on equilibria in the C-S-H - H_2O system and speciation modeling involving ion association (using MINEQL: Berner, 1988, and Bennet et al., 1992) or ion interaction models (using Pitzer equations: Reardon, 1990). However, this approach has three major drawbacks: (i) it is not justified by thermodynamic principles, (ii) it does not incorporate any structural information such as the non-ideal mixing behavior due to mixing gaps known for the C-S-H solid solution system, and (iii) it is not possible to extend this approach to multi-component systems in a predictive sense, if the composite solubility product vs. composition relationships have previously not been measured for that systems. I will therefore introduce a new approach ("inverse modeling") based on both thermodynamic principles and structural information for the C-S-H gel, to derive a thermodynamic equilibrium relationship between the composition of the solid solution and the respective aqueous phase composition.

THE NEW THERMODYNAMIC MODEL

The C-S-H phase is essentially a solid solution of portlandite in an imaginary low-C/S-ratio calcium silicate component (Richardson and Groves, 1993). This widely accepted compositional model is based on a highly disordered layer structure comprising finite dreierketten silicate chains of length *3n-1* in solid-solution with a variable amount of $Ca(OH)_2$, where for individual structural units n = 1, 2, 3, etc. The simplest possible silicate endmember composition with integer stoichiometry (C/S = 1) can be formulated as $Ca_2H_2Si_2O_7 \cdot 3H_2O$. This endmember (abbreviated as CS) is assumed to be congruently soluble with a unique solubility product

given by Berner (1988) or Bennet et al. (1992). For the formulation of a solid-solution aqueous-solution (SSAS) equilibrium model, first the solubility products of the end-members assumed to compose the solid solution have to be determined by the mass action laws:

$$Ca_2H_2Si_2O_7 \cdot 3H_2O = \{H_3SiO_4^-\}^2\{CaOH^+\}^2 = K_{CS}^2 \quad [1]$$

$$Ca(OH)_2 = \{CaOH^+\}\{OH^-\} = K_{CH} \quad [2]$$

The solubility products have been recalculated with activities of the monovalent Ca-species $CaOH^+$ as a common cation to give values of $pK_{CH} = 4.0$ and $pK_{CS} = 7.8$, using the thermodynamic database listed in Table 1.

Table 1 The thermodynamic database: Formation constants of the aqueous species

aqueous species	formation reaction	logK
OH^-	$H_2O - H^+$	- 14.00
$H_3SiO_4^-$	$H_4SiO_4 - H^+$	- 9.86
$H_2SiO_4^{2-}$	$H_4SiO_4 - 2H^+$	- 22.91
$CaOH^+$	$Ca^{2+} + H_2O - H^+$	- 12.78

The thermodynamic equilibrium in this binary system is described by the equivalence of the chemical potentials of the solid and aqueous phase components:

$$\{H_3SiO_4^-\}\{CaOH^+\} = K_{CS}(1-X_{CH})\lambda_{CS} \quad [3]$$

and

$$\{CaOH^+\}\{OH^-\} = K_{CH}X_{CH}\lambda_{CH} \quad [4]$$

The solid phase activities are given as the product of their respective mole fraction, X, and solid activity coefficient, λ (not to mix up with the aqueous activity coefficient γ). Dividing Eq 3 by Eq 4 and removing the common cation yields the well-known Berthelot-Nernst distribution law:

$$X_{CH}/1\text{-}X_{CH} = D\{OH^-\}/\{H_3SiO_4^-\} \quad [5]$$

where D, the distribution coefficient, is given by:

$$D = K_{CS}\lambda_{CS}/K_{CH}\lambda_{CH} \quad [6]$$

Eq 5 is the classical expression of a SSAS system at thermodynamic equilibrium. Another expression for the SSAS equilibrium is obtained by simply adding Eqs 3 and 4 to give:

$$\Sigma\Pi_{eq} = (\{H_3SiO_4^-\}+\{OH^-\})\{CaOH^+\} = (a_{CH}K_{CH}) + (a_{CS}K_{CS}) \quad [7]$$

where the left term is the "total solubility product" variable $\Sigma\Pi$, which is fixed by the right term to the total solubility product constant $\Sigma\Pi_{eq}$ at thermodynamic equilibrium (Lippmann, 1980; Glynn and Reardon, 1990). The latter is dependent on the composition of the solid solution, while the variable $\Sigma\Pi$ does not depend on the solid phase composition. The $\Sigma\Pi_{eq}$ constant can be calculated (using Eq 7), if the individual activities of the components in the solid

phase (a_{CH} and a_{CS}) are known at thermodynamic equilibrium. Alternatively, $\Sigma\Pi_{eq}$ can be calculated if the activity fractions of the substituting ions in the aqueous phase are known. The activity fractions are defined as:

$$\chi_{OH^-} = \{OH^-\}/(\{H_3SiO_4^-\}+\{OH^-\}) \quad [8]$$

$$\chi_{H_3SiO_4^-} = \{H_3SiO_4^-\}/(\{H_3SiO_4^-\}+\{OH^-\}) \quad [9]$$

Substituting these two relations into Eq 7 and rearranging by expressing the activities of the solid phase components in terms of their activity coefficients and mole fractions yields:

$$\Sigma\Pi_{eq} = \frac{1}{\frac{\chi_{OH^-}}{K_{CH}\lambda_{CH}} + \frac{\chi_{H_3SiO_4^-}}{K_{CS}\lambda_{CS}}} \quad [10]$$

$\Sigma\Pi$ - X - χ phase diagrams can now be constructed from total solubility product expressions (Eqs 7 and 10) together with the appropriate mole and activity fractions as co-ordinates (Lippmann, 1980; Glynn and Reardon, 1990). Analogous to phase diagrams for binary solid - melt systems, a SSAS phase diagram is a plot of a "solidus curve" (the total solubility product defined by Eq 7) and a "solutus curve" (Eq 10), with the $\Sigma\Pi$ variable as the ordinate. Both the solidus and solutus curves form a characteristic loop common in phase diagrams involving (complete) solubility of two phases. The loop becomes wider when the difference in the solubility products of the end members increases. Horizontal tie-lines ("conodes") can be drawn between the solutus and solidus curves, thereby giving the solid-phase and aqueous-phase compositions for the series of possible thermodynamic equilibrium states.

The SSAS diagram differ from traditional phase diagram representations in that it uses aqueous activity products and activity fractions rather than elemental concentrations and mole fractions to define the composition of all phases in the system. For the present case, two different scales are used for the abscissa: an activity-fraction scale χ_{OH^-} relating to the aqueous-phase composition, and a mole-fraction scale X_{CH} defining the solid-phase composition. The benefit of the activity-fraction scale is that there is no necessity to consider the extent of ion pairing and/or complexation with other ions in the aqueous solution. The speciation effect is important in the alkaline solutions of cementitious systems, where ion pairs that form complete or nearly-complete solid-solution series may not have similar complexing affinities. As a consequence, a speciation model of ion complexation in the aqueous solution will be required for the construction of the diagrams from experimental total Si and Ca concentration data.

The solidus and solutus curves can be plotted and used to predict the solubility of any ideal solid-solution at thermodynamic equilibrium (i.e., at $a_i = X_i$). The description of the thermodynamic properties of a non-ideal solid-solution, and consequently of the solid-phase activity coefficients vs. solid composition relations, requires knowledge of the excess-free-energy of mixing of the solid solution, that is of the deviation of its free-energy of mixing from that of an ideal solid solution:

$$\Delta G^E = \Delta G^M + \Delta G^{M,id} \quad [11]$$

The Gibbs free-energy of mixing ΔG^M of a solid-solution can be considered to be the difference between the actual free-energy of the solid-solution and that of a compositionally-equivalent mechanical mixture of the endmember components. For an ideal binary solid-solution, the free-energy of mixing for endmember components *i* and *j* will be:

$$\Delta G^{M,id} = RT\ (X_i \ln X_i + X_j \ln X_j) \qquad [12]$$

No experimental data exist, however, on ΔG^M functions of the C-S-H composition, and therefore on solid-phase activity coefficients for that system. Empirical relationships for the compositional dependence of the solid-phase activity coefficients obtained from a Gibbs-Duhem integration, using the Guggenheim subregular model for the excess-free-energy of mixing of a binary solid solution, has been successfully used to fit laboratory solubility data for a variety of SSAS systems (Glynn, 1991):

$$\Delta G^E = RT\ (X_i \ln\lambda_i + X_j \ln\lambda_j) = X_i X_j RT\ [\alpha_0 + \alpha_1(X_i - X_j)] \qquad [13]$$

with the dimensionless empirical parameters α_0 and α_1, from which the following expressions for the solid activity coefficients in the C-S-H system can be derived:

$$\ln\lambda_{CS} = X_{CH}^2\ [\alpha_0 - \alpha_1(3X_{CS} - X_{CH})] = X_{CH}^2\ [\alpha_0 - \alpha_1(3 - 4X_{CH})] \qquad [14]$$

and

$$\ln\lambda_{CH} = X_{CS}^2\ [\alpha_0 + \alpha_1(3X_{CH} - X_{CS})] = X_{CS}^2\ [\alpha_0 + \alpha_1(4X_{CH} - 1)] \qquad [15]$$

Structural information of the C-S-H solid-solution behavior can be used to estimate the α_0 and α_1 parameters which is a better approximation than the commonly used assumption of an ideal solid solution (i.e., $\Delta G^M = 0$). Complete solid-solution series in the C-S-H system are not known; i.e., this system deviates from ideality, because the solubility of the two end-members is limited in the lime-rich part and the partial solid-solution series is not isomorphous. Although initial dissolution of C_3S may be congruent, the hydrated solid has always a C/S ratio less than 3, and no C-S-H can be synthesized beyond a C/S > 3 (i.e., $X_{CH} > 0.67$). This miscibility gap information can be exploited to calculate the Guggenheim α_0 and α_1 parameters using the MBSSAS computer program (Glynn, 1991). However, no information on the solubility of the silicate endmember in $Ca(OH)_2$ is available. It may be assumed to be negligible as a first approximation, because the portlandite lattice has no structural units where the silicate chains could fit in. The upper boundary was arbitrarily set to $X_{CH} = 0.95$, because the MBSSAS program becomes unstable at higher values. With this miscibility gap information for the C-S-H solid-solution system, a value of -2.3 for the α_0 and 3.4 for the α_1 coefficient at 25 °C can be obtained. Fig 1 shows the resulting SSAS equilibrium phase diagram.

DISCUSSION

Verification of the model can be done using experimental data published in the literature upon the necessary recalculations. As mentioned above, an aqueous speciation and activity coefficient model is required in order to determine aqueous phase compositions from the ion activity scale of the solutus (Eq 8) at a given solid composition (and, *vice versa*, solid-solution composition at a given aqueous phase composition for verification with experimental data). Experimental data published by Fujii and Kondo (1981) and Greenberg and Chang (1965) were

selected, because the authors used C-S-H precipitates for their solubility evaluations, obtained by stirring hydrated silica and calcium hydroxide in a suspended state for several weeks. The final aqueous equilibrium at 25-30 °C was determined under absence of any unreacted calcium silicates such as C_3S. The published total concentrations of the components were transferred to the respective species activities with the thermodynamic database listed in Table 1, and the reported pH and ionic strength data. Ion activity coefficients were calculated using the Davies equation by help of the speciation program MICROQL provided by Westall (1986).

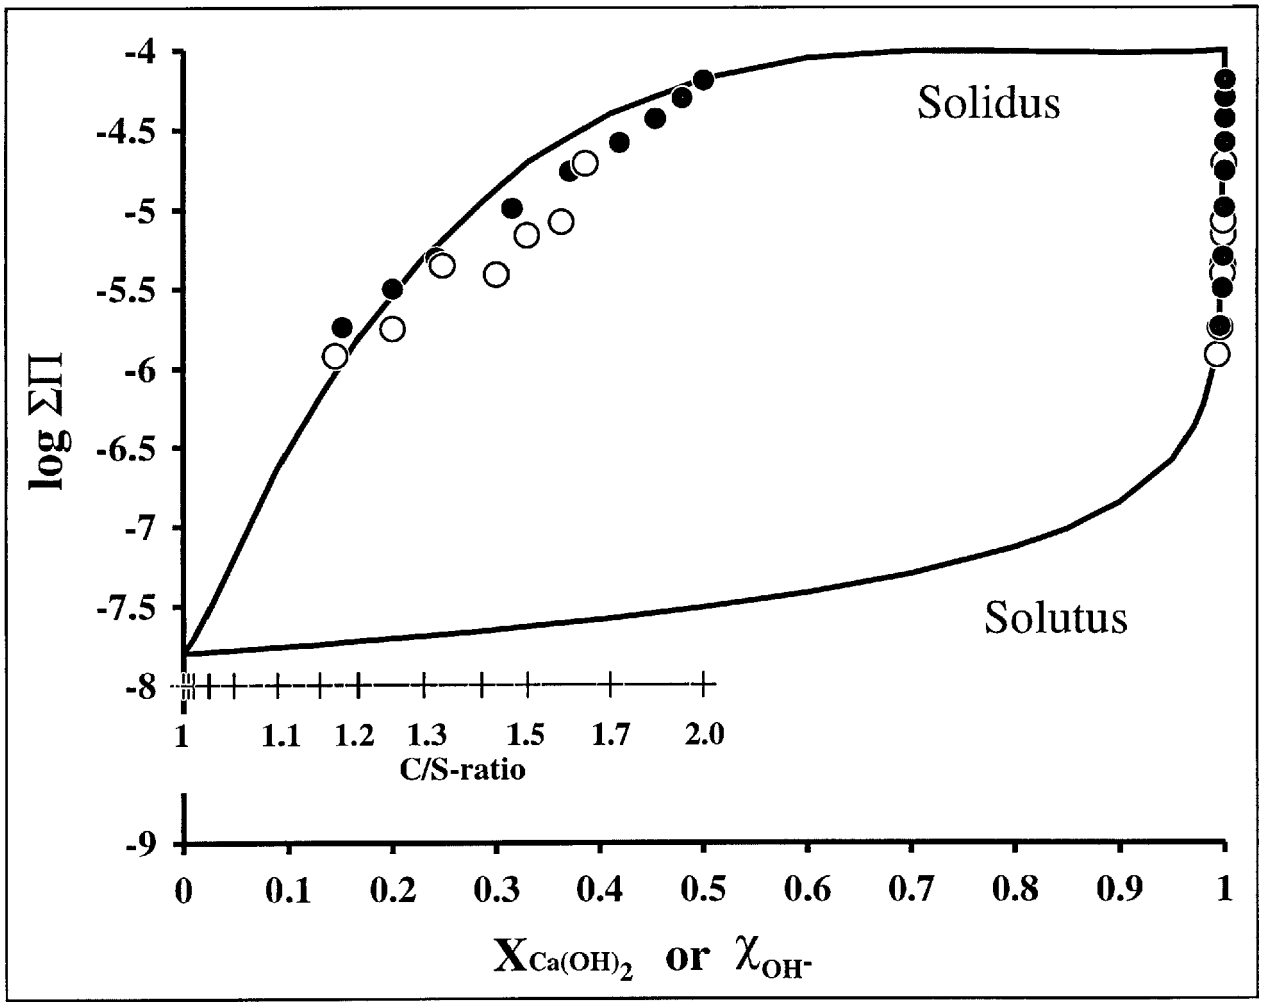

Figure 1. SSAS diagram for the pseudo-binary C-S-H - H_2O system. $\Sigma\Pi$ values for the solid and the aqueous phase are plotted on the ordinate against two superimposed scales on the abscissa: $X_{Ca(OH)_2}$ refers to the concentration of Ca in the solid (upper "solidus" curve calculated from Eq 7), and χ_{OH^-} refers to the activity of hydroxyl-ions in the aqueous solution (lower "solutus" curve calculated from Eq 10). The asymmetric, non-ideal mixing behavior is represented by a mixing gap at C/S > 3 ($X_{Ca(OH)_2} > 0.67$). The dots represent experimental data on aqueous suspensions of C-S-H components with varying C/S ratios for verification of this model (filled dots from Fujii and Kondo, 1981; open dots from Greenberg and Chang, 1965).

Both the solidus and solutus curves in the SSAS diagram constructed by the inverse modeling exercise are perfectly matched by the experimental data. Data pairs on solid and solution composition lie on the solidus and solutus curves, respectively, and can in fact be bound with a horizontal tie-line (not indicated in Fig 1). This verifies also the basic assumption of thermodynamic equilibrium for the selected experimental data. The C-S-H gel is a solid-solution system, capable of adjusting its composition in response to the aqueous solution composition within relatively short time. This is not surprising given the high reactivity of this amorphous solid with a very high specific surface (values of >100 m^2/g are common). Kinetic conditions that cause solid-solutions to react as metastable one-component solids of fixed composition as used in the stoichiometric or primary saturation concepts seem not to play a significant role.

The SSAS model is useful to explain some unique features of the C-S-H - H_2O system which have not yet been understood. In cement pastes, except in the very early stages of reaction, the average C/S ratio of the gel is constant at 1.5 - 1.7 (Taylor, 1992). The model predicts a minimum in the Gibbs free-energy of mixing (ΔG^M) of -3.2 kJ/mol to occur at a C/S ratio of 1.5 (Kersten, 1996). The gain in ΔG for solid solutions below or above that value must therefore decrease when approaching that mol ratio leading to a cease in further reactivity of the C-S-H gel formed. It is in fact difficult to prepare C-S-H gels with a C/S ratio of above 1.5 by reaction of, e.g., calcium hydroxide with silica gel or calcium nitrate and tetraethylorthosilicate.

The SSAS equilibrium approach enables also to predict the dependence of the incongruent solubility of C-S-H on the C/S ratio. The extremely low solubility of the Ca-silicate endmember compared to portlandite implies a strong preferential partitioning of Si in the solid phase. As a consequence, the solutus curve in the SSAS diagram shows a strong asymptotic behaviour due to the dominance of the hydroxyl ions in the activity fraction χ_{OH^-} (Eq 8). The total Si concentration in solution can be predicted given the C/S ratio of the solid (conode from the solutus) and the pH of the solution. In the same manner, total Ca concentrations can be calculated given the C/S ratio, the pH of the solution, and the total solubility product $\Sigma\Pi$ (Eq 7).

Only a narrow range of aqueous-phase compositions can coexist in equilibrium with solid mole fractions in the C/S range 1 - 2. The range of pH values, e.g., have been reported to lie in between 12.0 ± 0.3 (Berner, 1988). Within this range, small changes in the aqueous composition imply drastic changes in the solid equilibrium composition. This behaviour might explain the appearance of compositional variations on a micrometre scale recognized by SEM studies of C-S-H phases (Taylor, 1992). The much greater solubility of portlandite leads to the result that even from a Ca-rich solution (saturated with respect to portlandite), the equilibrium precipitate is low in C/S ratio. Only when the Si concentration in the aqueous solution becomes by more than three orders of magnitude lower than the corresponding Ca concentration, which occurs in later stages of C_3S reaction due a hindrance of Si diffusion into solution through the reactant rim, will a more Ca-rich C-S-H phase ($C/S \geq 1.5$) precipitate.

It should be stressed, that the total solubility product $\Sigma\Pi$ (Eq 7) gives the activities of the ions $CaOH^-$ and $H_3SiO_4^-$ from which the total Ca and Si concentrations have to be recalculated. Fig 2 shows a diagram of total dissolved Si concentrations (in µM on a logarithmic scale) vs. total dissolved Ca concentrations (in mM) in suspensions of C-S-H gels with solid compositions in the range $1.1 < C/S < 1.5$ at pH values of 11.7 and 12.3. The pH is a sensitive parameter which

has not been previously accounted for. The experimental data from various sources plot in between both curves. These data were chosen only from suspension experiments which yield tobermorite-like C-S-H as represented, e.g., by the lower solubility curve A published by Jennings (1986). However, both solubility curves A and B given by Jennings (1986) never cross and as a consequence, jennite-like C-S-H having the upper solubility curve B is always metastable with respect to tobermorite-like C-S-H having the lower solubility curve A. Both the pH-curves also bracket the model curve calculated by Gartner and Jennings (1987).

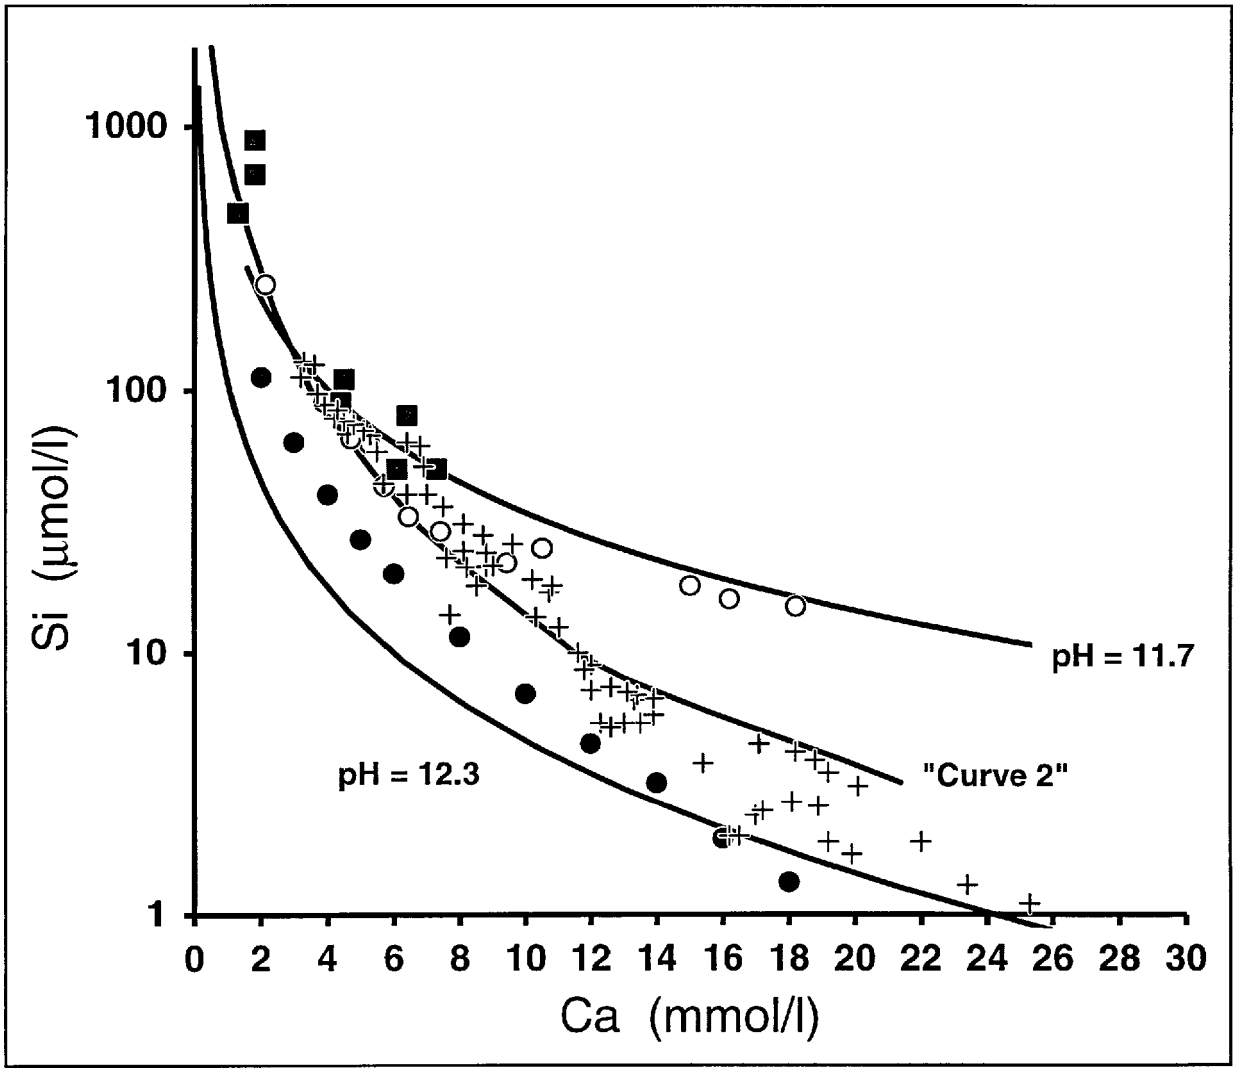

Figure 2. Plot of predicted total Si and Ca concentrations in an aqueous phase in equilibrium with C-S-H gel, calculated for two different pH values and a C/S range of 1.1 - 1.5. A speciation programme (MICROQL) has been used to calculate the aqueous activities by the Davies equation for an ionic strength of I = 0.04. The model curve for tobermorite-like C-S-H of Gartner and Jennings (1987, curve 2) plots in between both curves, as well as the many experimental data points taken from the literature (+ Brown et al., 1984, ● Fujii and Kondo, 1981, o Greenberg and Chang, 1965, and ■ Suzuki and Nishikawa, 1985).

There are two main applications for SSAS theory: (i) prediction of solid-solution solubilities as shown above, and (ii) prediction of the distribution of trace components between solid and aqueous phases for chemical modeling of cementitious solidification/stabilization (S/S) processes. The latter is the most promising application, because it is possible to extend this model to multi-component systems in a predictive sense, e.g. by calculation of ternary SSAS phase diagrams in the case of solid solution of a trace toxic element (heavy metal or radionuclide) into the C-S-H gel. In the brucite-type crystal structure of portlandite, the Ca^{2+} cation can be replaced isomorphously by, e.g., Zn^{2+} or Cd^{2+} ions without significant deformation of the lattice (Shpynova and Melnik, 1985). It would therefore be not surprising if these cations substitute at a crystal-chemical level in the octahedrally coordinated $Ca(OH)_2$-layers of C-S-H phases in later stages of the stabilization process after decomposition of the metastable Ca-metallate phases (i.e., within a few days: Lieber and Gebauer, 1969). The aqueous solubility of such trace metal "impurities" in the C-S-H host phase can therefore be represented by a SSAS diagram of the ternary metal hydroxide - Ca-hydroxide - Ca-silicate system which will be detailed in another paper (Kersten et al., in prep.). This finding is also important for the assessment of the long-term fate of cementitious S/S systems, because the carbonation effect may then be represented as a change from the ternary hydroxide to a binary carbonate SSAS system for a variety of bi-valent metals. Some minor but important hydrate phases like ettringite, monosulphate, hydrogarnet and hydrotalcite also form extended multi-component solid-solution series with trace metals. SSAS diagrams of these ternary or even quaternary systems may also be calculated, because most of the endmember components are congruently soluble and the mixing gaps are relatively well known.

FACTORS AFFECTING CEMENT STRENGTH STUDIED BY MODEL CEMENTS MADE OF CLINKER MINERALS

György BALÁZS*, Margit BOROS*
Ferenc TAMÁS**

*Technical University, Dept. of Building Materials, Budapest, Hungary
**University of Veszprém, Dept. of Silicate- and Materials Engineering, Veszprém, Hungary

ABSTRACT Clinker minerals (of known chemical and phase composition) were produced and 57 different "Synthetic Cements" made of them by varying composition (primarily the C_3A, C_4AF and gypsum ratio) and grinding fineness. Compressive strength can be increased by increasing grinding fineness; splitting-tensile strength reaches highest value at 350 m^2/kg Blaine and decreases with increasing fineness. The C_3S/gypsum reaction precedes the C_4AF/gypsum reaction, irrespectively of the C_3A/C_4AF/gypsum ratio.

Key-words: Strength development Fineness Gypsum Aluminate phase Silicate

INTRODUCTION

The modeling of cement properties by using synthetic mixtures of clinker minerals is a common practice, although the validity of data for hardening mechanism and kinetics are often questioned. This paper deals with the the hardening of 57 sorts of such "Synthetic Cements"; mineralogical composition, grinding fineness and gypsum content were the variables. Investigated parameters included strength of pastes (at 20°C, ages ranging from 6 hours to 90 days), and their non-evaporable water (NEW) content (by TGA). Results are compared with those obtained by the linear combination of similar results obtained with the pure clinker minerals.

EXPERIMENTAL

Clinker minerals C_3S, β-C_2S, C_3A and C_4AF were produced at the University of Veszprém. Their purity was controlled by X-ray diffraction. The gypsum was pure $CaSO_4.2H_2O$, of theoretical composition.

Composition of paste samples was adjusted in a way that C_3S contents (with the exception of 2 series) was always 50%; C_3A, C_4AF and gypsum contents were changed systematically, finally the mixture was extended by β-C_2S to make 100%. In most experiments the synthetic raw materials (of 300 m^2/kg Blaine surface are) were weighed and subsequently homogenized in a ball mill for 40 mins. The surface area of the mixtures became 360 ± 5 m^2/kg by this treatment. In some cases, cements of different fineness (low ≅ 200, high ≅ 500 m^2/kg) have been used.

Pastes were made with 30% water (based on solid weight). 12 cubes (edge length = 20 mm) and 6 prisms (10×10×50 mm) were made of each set, stored (with the exception of the 6 hr. test) in the mould, and subsequently in 100% r.h. room temperature atmosphere. Tests were made at ages of 6, 24 and 48 hr., 7, 28 and 90 d. Compressive strength was measured on the cube specimens. To reduce deviation, a special spherical joint was made, where the geometric centre of the cube and the sphere were coincident. Splitting-tensile strength was measured on the prisms.

Thermal (TGA, DTA, DTG) tests were made immediately after strength testing, from the fragments, by a Derivatograph (type Paulik-Paulik-Erdey, manufactured by MOM, Budapest). Heating rate was 10°C/min, top temperature 1000°C, sample mass approx. 1000 mg. A Pt crucible was used, reference DTA material was Al_2O_3. Weight loss data refer to the anhydrous material (heated to 1000°C). Thermal weight losses up to approx. 170°C were considered as adsorptive and layer water; over that as NEW (exact temperature determined by the DTG curve). The CO_2, coming from the decomposition of $CaCO_3$ was calculated to the water content of $Ca(OH)_2$, and considered as portlandite.

Degree of hydration was calculated by the NEW content, but similar other indexes were calculated too (e.g. by water content of portlandite or of the ferrite phase). The following equation was used for C_3S hydration:

$$6\ C_3S + 18\ H \rightarrow C_5S_6H.H_4 + 13\ CH$$

The above formula corresponds to Taylor's "tobermorite" (Taylor, 1964); it has been adopted by testing the validity of five other formulae used for the evaluation of pure C_3S samples of different parameters, as grinding fineness, w/c ratio, age, etc. This formula proved to be most satisfactory.

The 1 mole of structural water of Taylor's tobermorite is lost between 560 and 800°C, i.e. after the dehydration of portlandite, but before the decomposition of $CaCO_3$.

The formula used for C_2S hydration is:

$$7\ \beta\text{-}C_2S + 14\ H \rightarrow C_5S_6H.H_4 + C_2S.H_2 + 7\ CH$$

adopted from Kurczyk and Schwiete (1963), who found a tobermorite-like phase as hydration products of both calcium silicates; hydrated β-C_2S however yields microcrystalline, nearly amorphous product, as proved by electron microscopy. This means the presence of uncertain peaks (rather bands) on both XRD and thermal patterns, even after more than 1 year of curing. In case of β-C_2S therefore total NEW was calculated, without making a distinction between the various hydrated phases.

Formulae for aluminate and ferrite hydration are the following (Š = SO_3):

$$3\ C_3A + 4\ CŠ + 50\ H \rightarrow C_3A.3CŠ.32H + C_3A.CŠ.12H + C_3AH_6$$

and

$$3\ C_4AF + 4CŠ + 53\ H \rightarrow C_3AF.3CŠ.32H + C_3AF.CŠ.12H + C_3AFH_6 + 3CH$$

Approx. dissociation temperatures (exact values by the DTG peaks): CH ≅ 460-560°C, $C_5S_6H.H_4$ ≅ 560-700 °C, $C_3A.3CŠ.32H$ ≅ 130-150 °C, $C_3A.CŠ.12H$ ≅ 150-250 °C, C_3AH_6 ≅ 280-430 °C, $C_3AF.3CŠ.32H$ ≅ 160-180 °C, $C_3AF.CŠ.12H$ ≅ 180-260 °C

RESULTS AND DISCUSSION

Results are not shown as tables, only as figures, constructed from the numerical data.

The effect of fineness

Formerly it has been determined (**Figs. 1. and 2.**) that by increasing the grinding fineness of C_3S, compressive strength and splitting-tensile strength increased and decreased, resp., while in case of β-C_2S, a strength optimum exists in case of medium fineness. More recent tests (**Fig. 3**) gave similar results: the splitting-tensile test, although it increases over a medium fineness (350

m^2/kg Blaine), but only insignificantly, while cube strength increase by increasing fineness varies, depending on the composition.

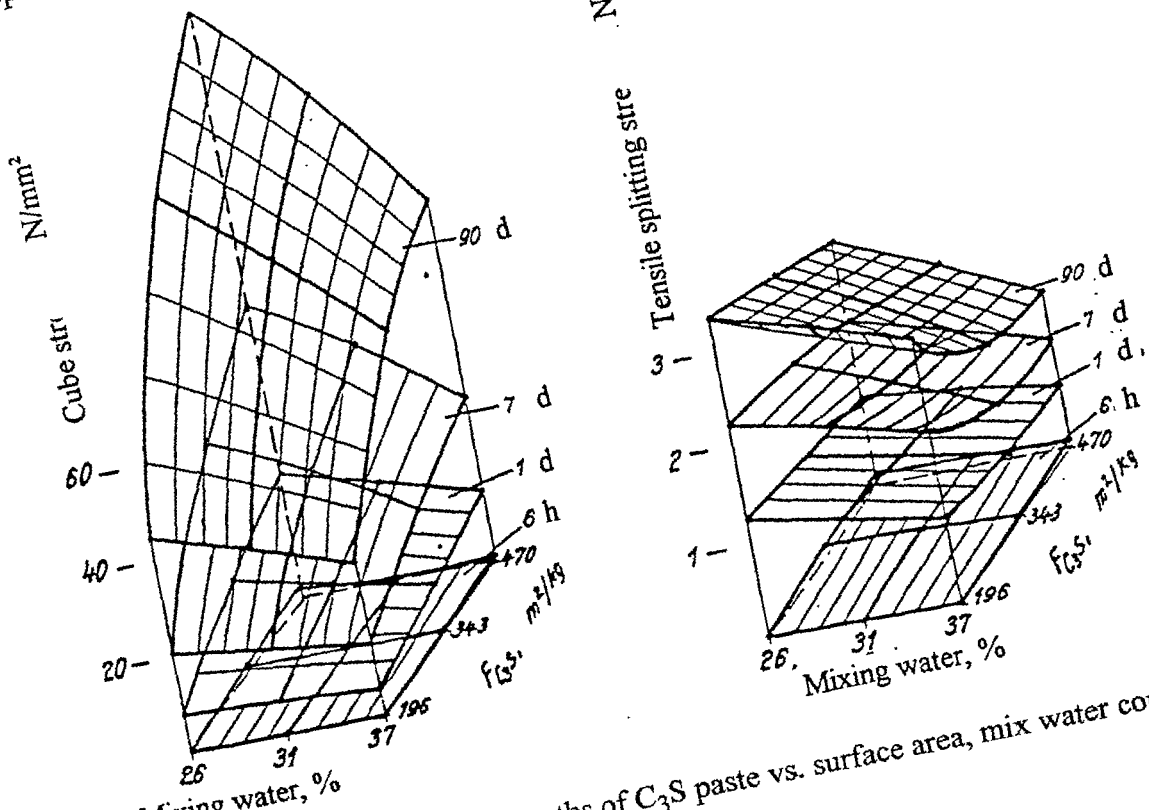

Fig. 1. Cube and splitting-tensile strengths of C_3S paste vs. surface area, mix water content and age of the paste

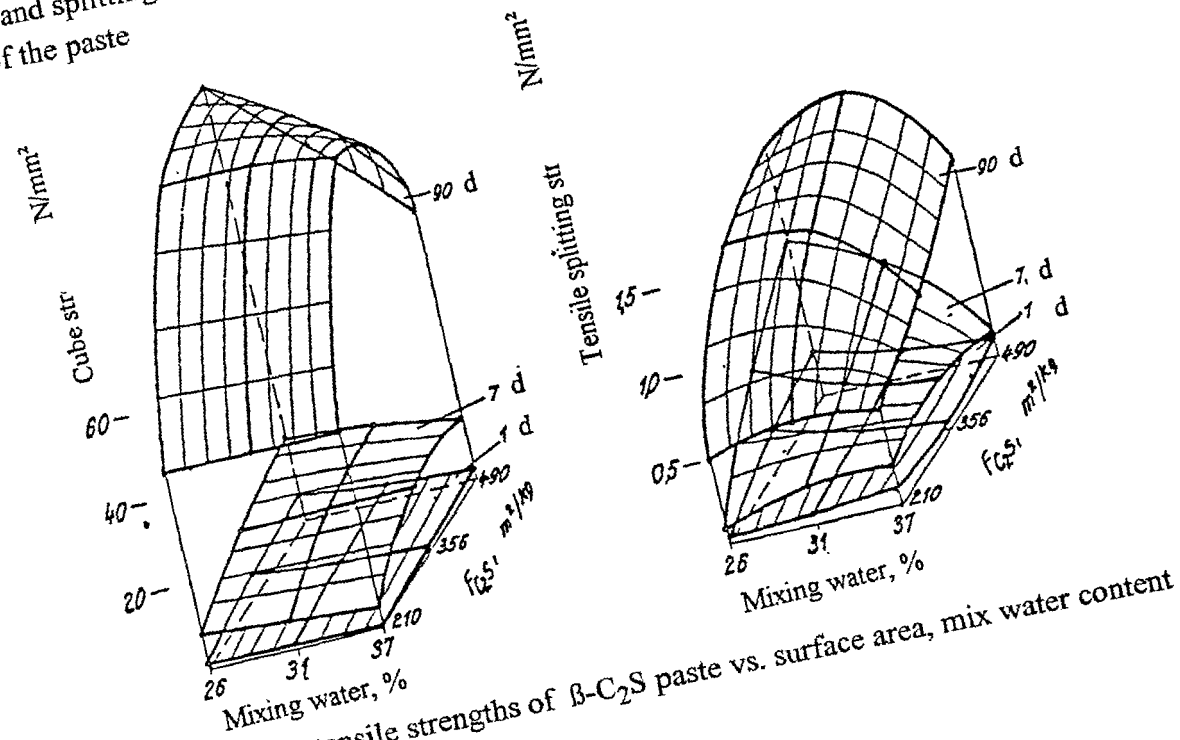

Fig. 2. Cube and splitting-tensile strengths of ß-C_2S paste vs. surface area, mix water content and age of the paste

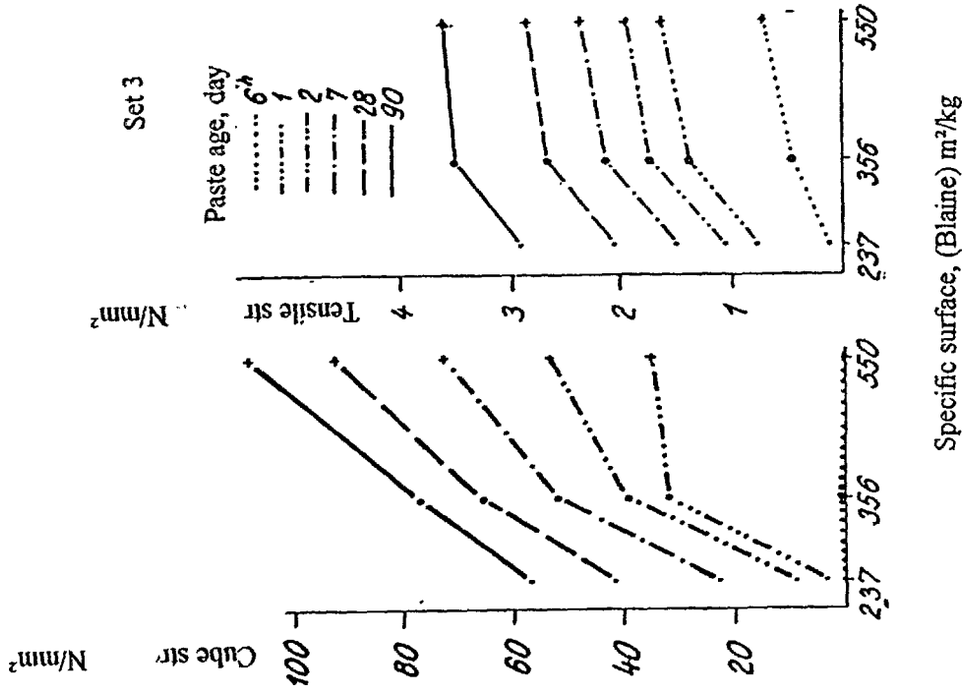

Fig. 3. Strengths of samples in Set 3. vs. age and surface area

The effect of mineralogical composition

Comparing actual strengths with those calculated by the proportional combination of clinker mineral strengths, it is obvious that actual strength is always higher than the calculated one. This can be explained by the fact that cement paste is a heterogeneous system, i.e. microstructure is formed in a different way than in the more or less homogeneous system of clinker minerals; in other words, cement hydration is more complicated than clinker mineral hydration, and alite is much more reactive than is pure tricalcium silicate. This might lead to a conclusion that experiments made with pure clinker minerals are superfluous. If, on the other hand, not absolute values, but trends are considered in case of "synthetic" cements (i.e. those artificially made of pure clinker minerals), such experiments are still of value as they doubtlessly help the interpretation of complicated processes taking place during cement hydration.

Differences between C_3S and β-C_2S hydration

Kinetic differences are the most important. This is due to the fact, that the structure of C_3S is less dense, thus hydration processes have a higher rate than in the case of densely packed β-C_2S. In case of mechanisms, both similarities and differences exist, as proved by NEW contents and hydration degrees. A topochemical mechanism exists in both cases; still quality, quantity and morphology of reaction products - as shown by the thermal tests - may differ considerably.

One of the hydration products of both C_3S and β-C_2S is $Ca(OH)_2$, portlandite; its crystallinity, however is very different: $Ca(OH)_2$, coming from C_3S is well crystallized, gives a distinct XRD pattern and is dehydrated at $\cong$ 500°C; C_2S-born $Ca(OH)_2$, on the other hand, is much less in quantity and is nearly amorphous, gives almost no XRD or DTA/DTG peaks. Well-crystallized portlandite, having crystallized in large hexagonal plates, reduces compressive strength. A common experience that the ratio of NEW contents of the two silicate minerals is higher than

the ratio of cube strengths (identical ages obviously presupposed). This means that by the quantity of strength-carrying phases (as established by the NEW contents) a higher cube strength could be expected in case of C_3S. This decrease can be attributed to the presence of the large portlandite crystals. However this strength reduction is not observed in case of high-fineness pastes; cube strength of β-C_2S does not increase proportionally with NEW, the majority of which is bound to gel hydrates. A similar comparison between splitting-tensile strength and NEW content shows a much better correlation, showing that a close connection exists between this sort of strength and the water contant bound in the gel.

The ferrite + gypsum reaction

Comparison of DTG curves definitely shows that no topochemical reaction takes place between C_4AF and gypsum (**Figs. 4.** and **5.**). It is clear by this comparison, that at the age of 6 hr. curves are similar, i..e. the C_4AF + gypsum reaction did not start yet at this age. Crystallization of iron-containing hydrates starts only after 7 days, and this goes continually on. This means that the reaction between C_3A and gypsum always precedes the reaction of C_4AF and gypsum, irrespectively of the C_3A/C_4AF/gypsum ratio of the system. The quantity of C_4AF has a much lesser effect on hydration than C_3A and gypsum.

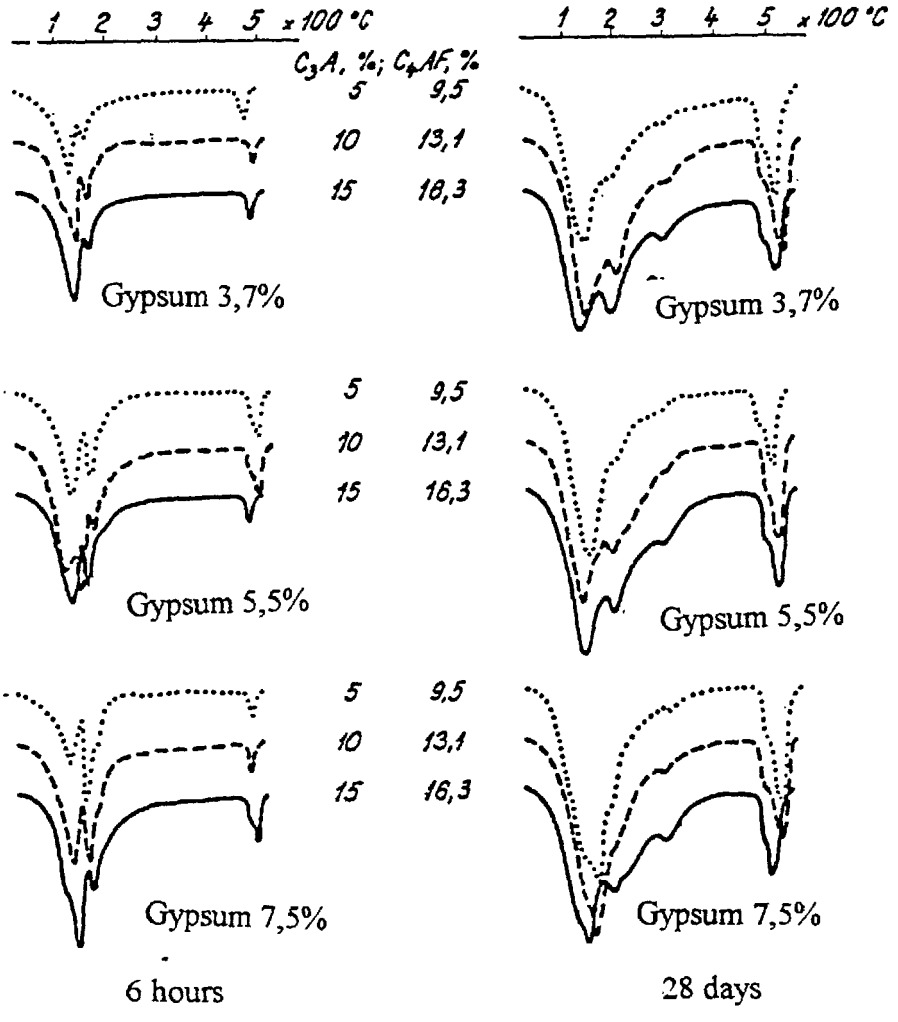

Fig. 4. DTG curves of samples with simultaneously increased C_3A and C_4AF contents at ages of 6 hr. and 28d.

These results corroborate the opinion expressed by Jawed at al. (1980) that a competition exists in hydration cement between C_3A and C_4AF for gypsum, and this is won by the more reactive C_3A.

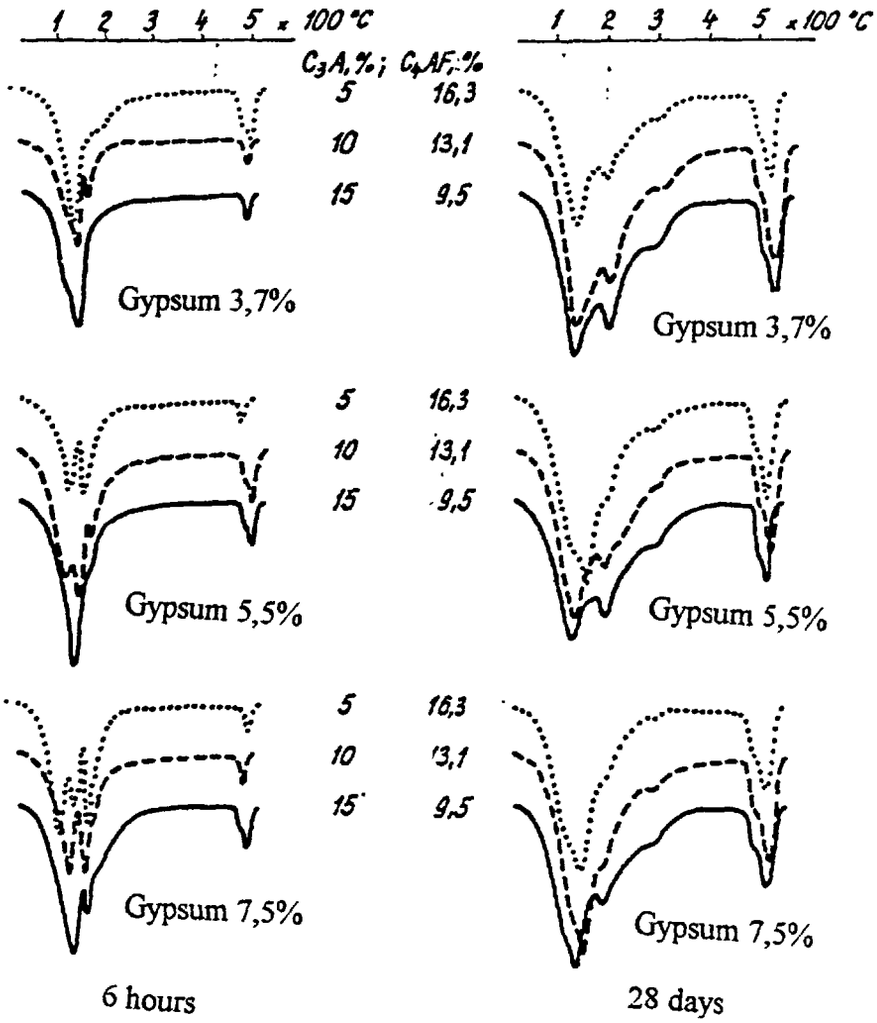

Fig. 5. DTG curves of samples with increasing C_3A and decreasing C_4AF contents at ages of 6 hr. and 28d.

When investigating the effect of Al-containing phases, the quantity of C_3S was kept constant (50 %), but the quantities of C_3A, C_4AF and gypsum had been changed. This necessarily involved the change of the quantity of β-C_2S too (10 to 30 %). The C_3A/C_4AF/gypsum ratio, has a considerable effect on strength, but this effect is quite different in case of compressive and tensile strengths, as indicated above. **Figs 6. - 8.** show a different approach: here the quantity of C_4AF was kept constant, while the quantities of C_3A and gypsum were changed. Cube strength was the highest at medium gypsum content (5.5 %), and the more, the higher the C_4AF content of the paste and the higher its age. In case of splitting-tensile strength, however, highest values were shown by pastes containing medium C_4AF and low C_3A.

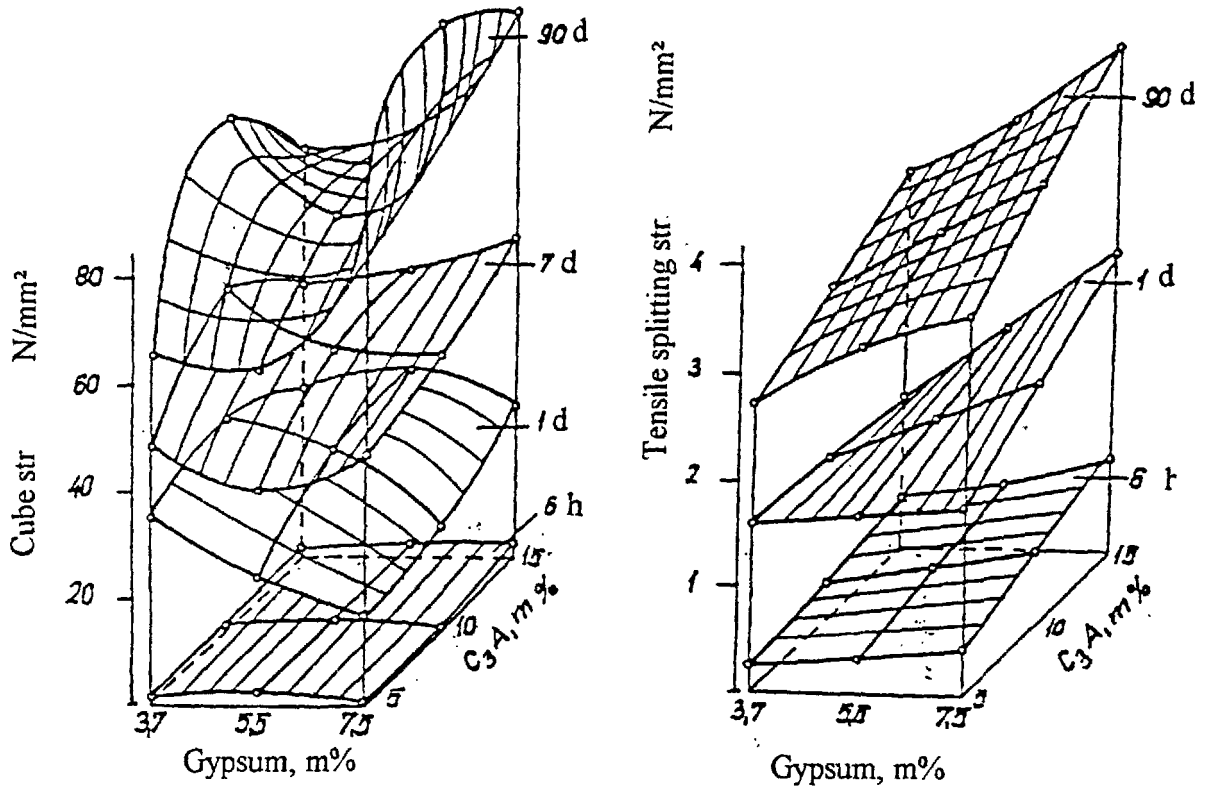

Fig. 6. Cube and splitting-tensile strengths of sets containing 9.5% of C_4AF vs. increasing gypsum and C_3A contents

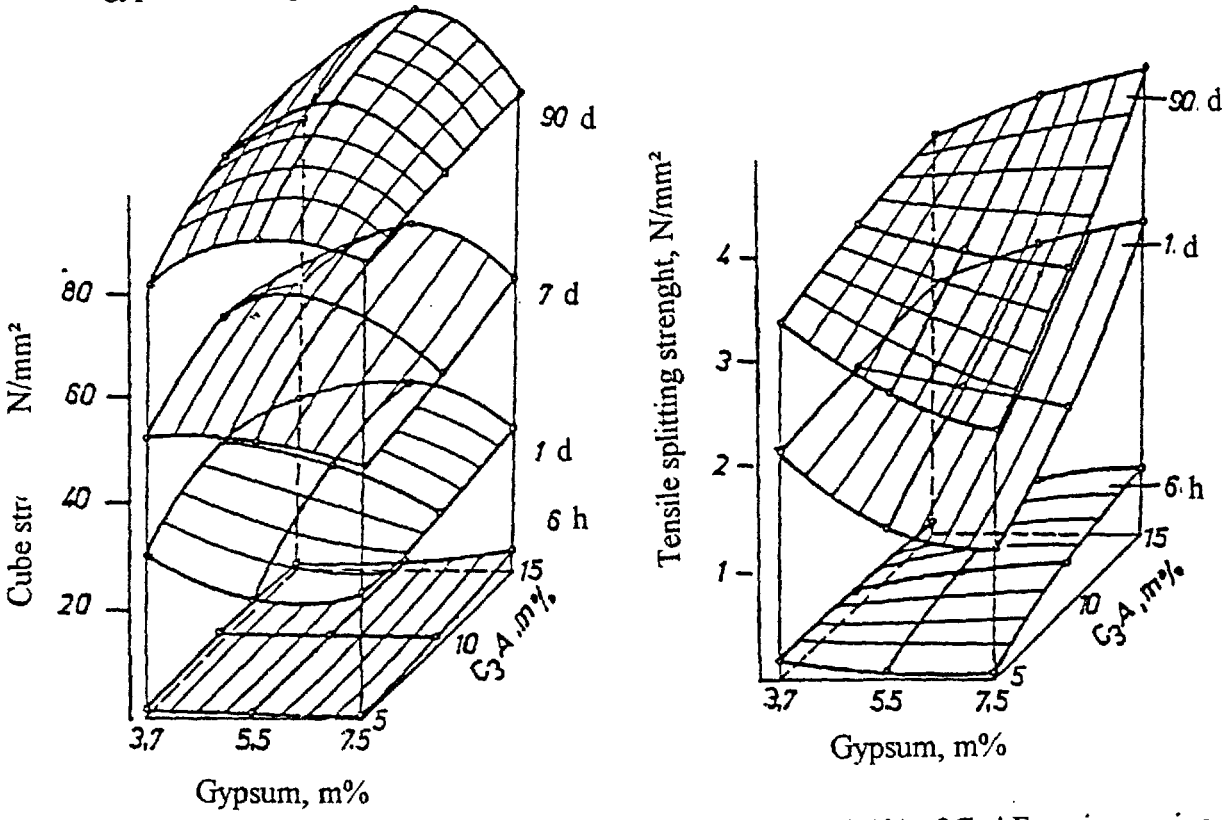

Fig. 7. Cube and splitting-tensile strengths of sets containing 13.1% of C_4AF vs. increasing gypsum and C_3A contents

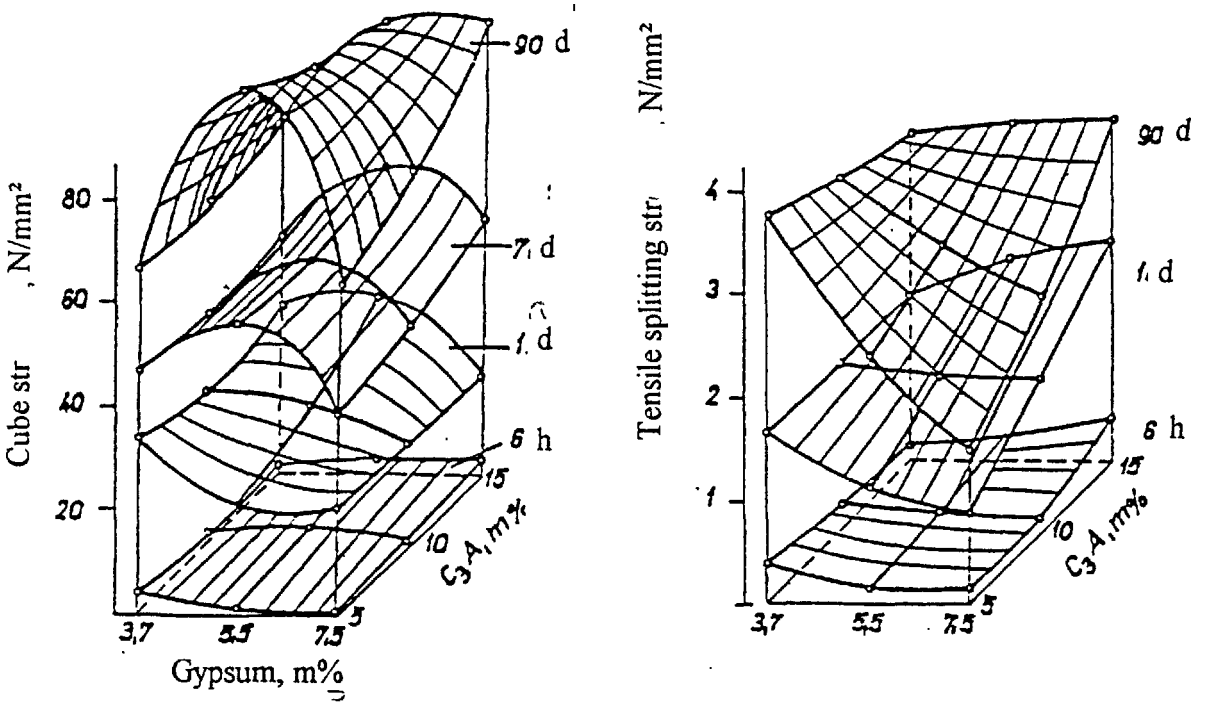

Fig. 8. Cube and splitting-tensile strengths of sets containing 16.3% of C_4AF vs. increasing gypsum and C_3A contents

CONCLUSION

Several formulae exist in the literature to calculate "optimum" or "minimum" gypsum content for cements to attain a high strength. These contain usually two variables only: C_3A-content and fineness. It is concluded that these two factors are inadequate to predict optimum gypsum content and the incorporation of C_4AF-content is necessary; and different formulae ought to be derived for compressive and tensile strengths.

THE CEMENT HYDRATION EQUATION AND ITS APPLICATION TO SEVERAL HYDRATION CRITERIA ACCORDING TO THE LITERATURE

Konstantin SIDERIS. Building Materials, Democritus University of Thrace, Xanthi, Greece
Kosmas K. SIDERIS. Reinforced Concrete, Democritus University of Thrace, Xanthi, Greece

ABSTRACT The cement hydration equation $K = K_\infty \pm b*t^{-p}$ introduced by Sideris (1993) is represented. This equation is applied to 25 cements and clinker phases hydration criteria according to the literature (heat of hydration, non evaporable water, $Ca(OH)_2$ elimination, density, total porosity, porosity with pore diameter D> 75 Å, gas permeability, specific surface, vapor and water sorption, compressive strength of cement paste, mortar and concrete, flexural strength of mortar, pulse velocity, rebound hammer units). The same equation is also applied to the clinker phase's hydration criteria of C_3S, C_2S, C_3A, and C_4AF pastes' compressive strength and non evaporable water and to the $Ca(OH)_2$ elimination of C_3S pastes.

Key-words: Cement hydration equation, hydration.

INTRODUCTION

In order to determine the time dependence of cement hydration the exponential function $K = K_\infty \pm b*t^{-p}$ was introduced by Sideris (1993), where K is the value of the examined hydration criterion, t the age of hydration and p the hydration number.Although cement hydration equation is a usefull scientific tool for the understanding of the course of several hydration criteria, it is known mainly from its application to the criterion of pastes', mortars', and concretes' compressive strength.

Table 1 Hydration criteria.

Cement hydration criteria	**Equations**
1. Heat of hydration (cal/g)	Q: $Q=Q_\infty-bt^{-p}$
2. Non evaporable water (%)	W_n: $W_n=W_{n\infty} - t^{-p}$
3. $Ca(OH)_2$ elimination (%)	CaO: $CaO=CaO_\infty-bt^{-p}$
4. Density (g/cm^2)	d: $d=d_\infty+bt^{-p}$
5. Total porosity (%) 6. Porosity when D> 75 Å (cm^3/g)	P: $P=P_\infty+bt^{-p}$
7. Gas permeability	G_p $G_p=G_{p\infty}+bt^{-p}$
8. Specific surface (m^2/g)	O_s: $O_s=O_{s\infty}-bt^{-p}$
9. Vapor sorption (%) $V_s=V_{s\infty}-bt^{-p}$ 10. Water sorption (%)	W_s: $W_s=W_{s\infty}+bt^{-p}$
11. Compressive strength of cement paste (MPa)	β_D: $\beta_D=\beta_{D\infty}-bt^{-p}$
12. Compressive strength of mortar (MPa)	β_D: $\beta_D=\beta_{D\infty}-bt^{-p}$
13. Compressive strength of concrete (MPa)	f_c: $f_c=f_{c\infty}-bt^{-p}$
14. Flexural strength of mortar (MPa)	β_B: $\beta_B=\beta_{B\infty}-bt^{-p}$
15. Pulse velocity (km/sec)	V_t: $V_t=V_\infty-bt^{-p}$
16. Rebound hammer units	R_t: $R_t=R_\infty-bt^{-p}$
Clinker phases' hydration criteria	
Compressive strength of Clinker Phases (MPa): 17) C_3S, 18) C_2S, 19) C_3A, 20) C_4AF	β_D: $\beta_D=\beta_{D\infty}-bt^{-p}$
21. $Ca(OH)_2$ elimination of C_3S paste (%)	CaO: $CaO=CaO_\infty-bt^{-p}$
22-25. Non evapor. water of C_3S, C_2S, C_3A and C_4AF paste (%)	W_n: $W_n=W_{n\infty} - t^{-p}$

In this work the cement hydration equation is represented and applied to the hydration criteria indicated in Table 1. In each case the measured values were taken from the literature.

CEMENT HYDRATION EQUATION

The first and second phases of the hydration, characterized by a hydration criterion K in the co-ordinate system with K on the ordinate and $(1/t)^p$ on the abcissa, follow a straight line path (Fig 1, where K=Q). The quantitative relationship is given by the following equation (Sideris, 1993):

$$\mathbf{K = K_\infty \pm b*t^{-p}} \qquad [1]$$

in which: K: is the hydration criterion examined (Table 1).

K_∞: is a constant, which represents the intersection of the straight line of Eq. 1 with the ordinate

b: is the slope of the straight line of Eq. 1.

t: is the hydration time expressed in days (t>>0).

p: is the hydration number, depending only on the chemical composition of the cement type used.

Equation $K = K_\infty \pm b\, t^{-p}$ applies to the hydration criteria shown in Table 1. It is important to notice that the value of the hydration number p remains the same as long as the chemical composition of the cement type used also remains the same (Sideris, 1993).

The value of the hydration number p does not depend on:

1. the hydration criterion used
2. the curing temperature [5-60°]
3. the fineness of the cement
4. the ratio w/c
5. the aggregates' grading curve and the aggregates' quality when the hydration criterion of the compressive strength of mortar or concrete is examined.

The linear propotionality between two hydration criteria

The combination of the value pairs of any two hydration criteria for the same cement, show that there is a linear relationship between these hydration criteria (Fig 2, Sideris, 1993). This indicates that each linear correlation between two hydration criteria for a given cement or a clinker phase, specifies a functional relationship which is characterised by the same hydration number.

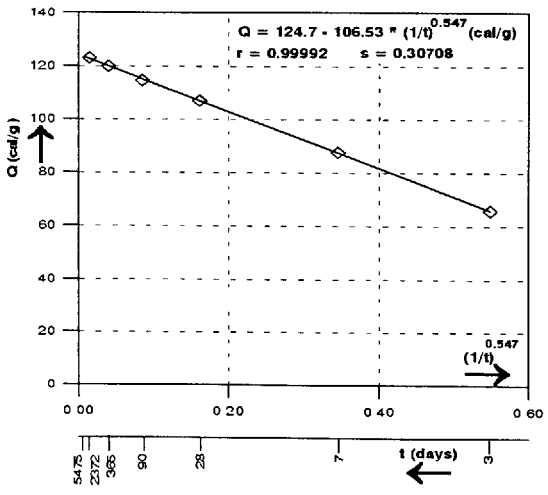

Figure 1 Heat of hydration as a function of hydration time [measured values taken from Verbeck et al (1964)]

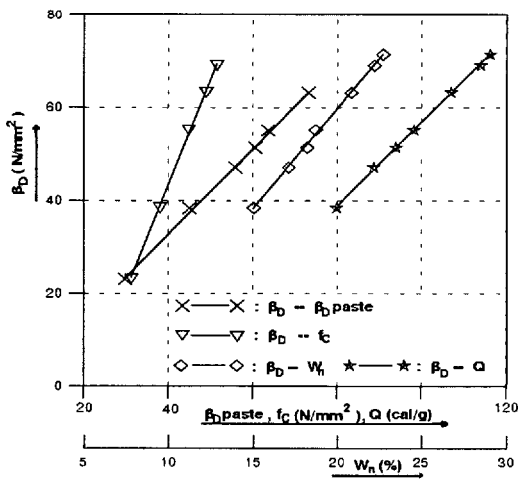

Figure 2: Correlation between the mortar compressive strength (β_D) and other hydration criteria (Sideris, 1993).

Final hydration time

Experimental determination of the final hydration using long-term trials is very difficult because of the very slow decay of the reaction and the inaccuracy of the methods of measurement, and has no practical significance as the results would only be available after several years. It is therefore proposed (Sideris, 1993) to take a period of 15 years as the end of hydration at storage temperatures between 5 and 60° C corresponding to the measured results of the long-term trials by Verbeck et al (1964) and Verbeck et al (1950). This final time was substituted in the hydration equation for all the application examples described in the present work.

Degree of hydration

To determine the true degree of hydration which gives the actual reaction conversion at any given hydration age, it is necessary to use a hydration criterion which is scientifically exact. The most suitable for this purpose is the heat of hydration determined with the heat-of-solution calorimeter. Table 2 contains an example of the calculation to determine the degree of hydration. The hydration equation was used to give the final heat of hydration approximately after 5475 days (15 years). The value of p=0.547 used here is determined by Sideris (1993).

Table 2 Determination of the hydration equation for the heat of hydration and of degree of hydration [measured values taken from Verbeck et al (1950)].

Hydraton age (days)	3	7	28	90	365	2372	5475

Degree of hydration Q_{calc}/Q_{5475}	**0.534**	**0.710**	**0.868**	**0.934**	**0.973**	**0.995**	**1.000**

Evaluation of the hydration number p.

The value of the hydration number p can be estimated with the use of any hydration criterion shown in Table 1, as below. The accuracy of the determination of the value of p depends on the accuracy of the measured values of the hydration criterion used.

For the evaluation of the hydration number p of a particular cement with known chemical composition (or a clinker phase), two different methods may be used.

Method 1

The evaluation of the hydration number p may be obtained using the formula (Sideris, 1993):

$$\frac{(1/t_1)^p - (1/t_2)^p}{(1/t_1)^p - (1/t_3)^p} = \frac{K_2 - K_1}{K_3 - K_1} \qquad [2]$$

In this case three measured values (K1, K2, K3) of the hydration criterion used are needed. These values must be determined with high accuracy in order to obtain a reliable value of the hydration number p. Even a small deviation of one or more of the measured values leads to unreliable values of p. Such accuracy of the measured values K1, K2 and K3 may be obtained only using the hydration criterion of the heat of hydration. The use of the formula shown above is not recommended when the hydration criterion of the compressive strength of cement paste, mortar or concrete is used. In this case the second method mentioned below is suggested.

Method 2

This method can be used with any of the hydration criteria shown in Table 1. It is specially recommended though for the evaluation of the compressive strength, since the measured values in this case are not of high accuracy. In this case the use of 6-8 measured values is recommended. The value of p is estimated with higher accuracy if the criterion of the compressive strength of mortar is used, according to DIN 1164 or ASTM/C- 349.

Use of different values of p

Initially, the point of intersection of the hydration lines for the two phases is determined approximately by graphical means (Fig. 7). This is accomplished by substituting different p values, until the measured values lie on two straight lines. The best value of p is determined based on the measured values of the criterion examined (Table 3). The compensating computation (linear regression) of the Q_{meas} values versus the corresponding ages, expressed by the formula t^{-p}, leads to different values of the correlation coefficient (r) and the standard deviation (s). The best value of the hydration number, in the examined case, was estimated to be p=0.4166 (the same p value is also obtained by use of the formula 2) as shown in Figure 3 It is also noted that the best value of p corresponds to the maximum value of the correlation coefficient (r) and the minimum value of the standard deviation (s).

Table 3 Evaluation of hydration number p.[measured values taken from Verbeck et al, (1964)].

Hydration number p	correlation coefficient	standard deviation	Heat of hydration at the age of (days)							
p	r	s	days	7	28	90	365	2372	4745	5475
-	-	-	Q_{meas}	**60.9**	**79.6**	**88.1**	**95.4**	**98.4**	**100.7**	-
0.3166	0.995940	1.5099		62.27	78.18	87.10	94.24	99.96	101.36	101.61

0.4666	0.998720	0.8480		60.45	80.04	89.08	95.08	98.86	99.60	99.74
0.5166	0.996830	1.3337		60.03	80.70	89.65	95.20	98.46	99.06	99.16

Table 3 and figure 3 contain the values determined for r and s using the measured values for the heat of hydration taken from Verbeck et al, (1964) (cement type II, No 5, W/C = 0.4, hydration time from 7 days to 13 years). The values of Q calculated with the hydration equations for the corresponding p values show, that the error that arrises from the best value by ±0.05 is less than

1%. It is therefore not necessary to calculate the hydration number very accurately for the hydration equation or, in particular, for the strength equation.

Use of special PC program

The best value of the hydration number p is automatically estimated by the use of a special PC program. Table 4 contains an example of the estimation of the hydration number when 10 measured values of the mortar's compressive strength are used (Sideris K.K. et al, 1996). Linear regression is performed for the measured values β_D versus the corresponding hydration age (t), initially for the 6 last pairs up to the 10 pairs. The p value is estimated to be p=0.159≈0.16. The pairs β_{Dmeas} - t_{2-28} and β_{Dmeas} - t_{1-28} lead to unsuitable p values (p=0.001) since the measured values of days 1 and 2 belong to the first phase of the hydration.

Table 4 Use of special P/C programm.

The following example (Table 5) is intended to explain how the hydration equation is drawn up when the criterion of concrete's compressive strength is examined (K=f_c). In this case the p value is estimated from the measured values of concrete's compressive strength, taken from Hansen, (1990). The same values are used for the determination of the equation of concrete's compressive strength. The hydration equations plotted in Figures 4-25 were determined with the same procedure. The p value was estimated in each case as above.

CONCLUSIONS

The application of the hydration equation to 25 cement and clinker phases hydration criteria indicates, that the equation with the general form $K = K_\infty \pm b*t^{-p}$ is applicable to all the established hydration criteria of cement and clinker phases.

The compensating computation (linear regression) of the Q values, measured for a hydration period of 6.5 and 13 years, over the corresponding hydration times, expressed by t^{-p}, gives rise to a correlation coefficient of 0.9999-0.9994. This correlation shows a very strong linear relationship between Q and t^{-p}, which signifies that the exponential hydration equation is linear with the heat of hydration criterion in the t^{-p} scale.

The equation $Q = Q_\infty - b*t^{-p}$ constitutes the exact equation which gives quantitavely the course of the chemical reaction of the cement hydration. This is because the heat of hydration is the singular scientifically exact criterion of the hydration of cement.

From the examples given for the pozzolanic and slag cements it can be seen that these cements have a similar hydration behavior to Portland cements. The hydration equation can therefore also be applied to these cements.

The applications of the hydration equation to compressive strength of cement paste, mortar and concrete for long hydration periods (from 28 days to 7 years) show that the correlation coefficient reach a value of 0.99 - 0.999. These results indicate that the hydration equation is generally applicable to the hydration criteria of the cement and concrete compressive strength. The hydration equation is also applicable in the cases of non-destructive tests.

ENERGY AND ELECTRONIC TRANSFORMATIONS IN THE PROCESS OF BINDERS SOLIDIFICATION.

Larisa B. SVATOVSKAYA, Saint-Petersburg University of Transportation, Russia

ABSTRACT Correlations between the energy of chemical reactions in the process of solidificating and strength of paste are evaluated, introducing the notions of thermodynamic reserve (TR) and coefficient of thermodynamic strengthening (CTS). Physicochemical categorization of binders and fillers is proposed, wich take in to account mechanisms of material and energy transformations on the electronic level. Donor-acceptor and energetical interactions are assumed as a basis of chemical design of physico-mechanical features of paste on the base of binders.

Activation, calcium silicate, characterization, degree of hydration, thermodenamics.

ENERGY TRANSFORMATIONS IN THE PROCESS OF BINDERS SOLIDIFICATION

Proposed energy aspect of toughness is based on following propositions by Svatovskaya (1996):

1. Correlation between energies of chemical reactions and mechanical properties of the system, reflected by toughness of stone. It can be a reaction, for instance,of hydration. Toughness of stone in such a case, depends on values of reaction energy changes in standard conditions. This value ΔH^0_{298} depends on nature of interacting materials and products of reaction. Considering the first law of thermodynamics, it is possible to claim that full energy, which is required for destroying of a material, received by the spontaneous chemical reactions, passed wholly, can not rise above the value of energy, liberated in these reactions ΔH^0_{298}. It is possible also to claim that value of energy, reflected in toughness, $\sigma^0 < \Delta H^0_{298}$ of reaction, and that the more negative ΔH^0_{298} of reaction, the more can be toughness of material σ^0, on one hand, and the more it stability in enviroment, on the other. Since the smaller is the value of ΔH^0_{298} of hydrates, the greater is the value of ΔH^0_{298} of the reaction, so the material toughness σ^0 is the function of products-hydrates enthropy changes.

2. In the binders, in which source phases are present in the majority by phases, having high share of a covalent bond (more than 50 %) and so, in the difference for instance from gypsum, not change completely in final products sufficiently long, energy of not yet passed reactions at a moment of the time τ_i is the reserve of toughness of the material. In such a cases, difference of enthalpy changes is a thermodynamic reserve TR_{II}:

$$TR_{II} = \Delta H^0_{298} - \Delta H^0_{298i}\,, \qquad [1]$$

where ΔH^0_{298}-is a full energy of reaction, liberated with the assumption that conversion of source products into final ones has occurred completly; ΔH^0_{298i} - an energy of already realized reaction at given time τ_i .The value of TR_n is the difference in enthalpy values, and is the base of increasing of material toughness, or otherwise thermodynamic reserve (TR) of toughness. If at a moment of the time τ_i, for instance 28 days, ΔH^0_{298i} provide energy of failure σ_i, but total energy content can provide the energy of failure σ_0, then

$$\Delta\sigma=\sigma_0-\sigma_i, \qquad [2]$$

provides by thermodynamic reserve (TR), i.e. energy of nonreacted substances, which are the system reserv at a given time τ_i.

Increasing in time the toughtness of cement systems on the base of materials by mainly covalent nature is connected with consumption of the energy reserves of these materials in reactions, for instance, of hydration. Thereby, thermodynamic reserve possess binders on the base of phases with high share of covalent bond, which are "alive" in the sense of going in them thermodynamic process justified by spontaneouse reactions ($\Delta G<0$), wich replenish the system by the energy. In ceramic or metallic materials there are no such a reserve of toughness .

3.Energy reserve of spontaneous strengthening at the cost of replenishing of the system by the energy of chemical reactions at different points can be described not only in terms of the energy content of the systems (enthalpy-parameters), but as well in terms of the free energy or the Gibbs free enrgy of the reaction ΔG^0_{298}:

$$TR_G=\Delta G^0_{298}-\Delta G^0_{298i} \qquad [3]$$

In such a case, while value $\Delta G_{298i}<0$, alongside with spontaneous chemical reaction, take place spontaneous strengthening of the systems in certain conditions and on certain mechanisms. The larger the amount of nonreacted substance, the larger is TR at a given moment of the time τ_i.

4. At a moment of the time, when thermodynamic reserve of toughness is exhausted, toughness takes a maximum value, which can increase or decrease at the cost of the contribution of other reactions or processes, for instance reactions of polycondensations.

5. Thermodynamic description of toughness of material, received by the realization of the spontaneous chemical reaction, allows to forecast strengthening of the materials on the base of binders, using not only parameter TR, as well as other parameter - coefficient of thermodynamic strengthening (CTS) in relative units or in percent. CTS represents a ratio between the TR and ΔH^0_{298}, whos energy can be evaluated in terms of enthalpy or free Gibbs energy (Eqs 4 and 5).

$$CTS_H = \frac{TRH}{\Delta H^0_{298}} \quad [4]$$

$$CTS_G = \frac{TRG}{\Delta H^0_{298}} \quad [5]$$

For systems on the base of phases with mainly ion bonds TR at an age of already one day is a zero and CTS material is a zero also, as far as share of conversions of substances is close to 100 %. For substances with mainly covalent nature of bond, CTS in same temporary intervals is more than zero and the larger is the covalent component, the larger is the value of CTS of the systems and the larger is strengthehing of the system in time. The value of CTS, evaluated in percent, gives information on that, what part of energy of chemical reaction is in the reserve and, accordingly, what energy reserve CTS and TR are to be found by the calculation of the reaction with provision for degree of reaction, definied for instance, on degree of hydration. Correction for spontaneous strengthening of "alive" systems in time allows to forecast the exploitation behaviour of materials in the environment in conditions of different sort of aggression. Calculations of TR and CTS are founded on experimental data of degrees of hydration of materials. Thermodynamic aspect of toughness allows to control energy content and toughness of the system at least one of following ways.

a). To orientate the process of hydration on forming the products with the smallest enthalpy of formation; in this case in accordance with the proposition 1 toughness of system will the largest. In the University of Transportation was designed new additives, which orientate hydration process to form the hydrates with the smallest enthalpy and thereby allowed to get a concrete, having under natural solidification toughness two times higher, than reference sample at an early age of 2-3 days.

b). The use of the reduction of temperature as a way of ordering of the system, accompany liberation of energy. As shown by Svatovskaya, Sychov, Smirnova (1989) at the temperature of 269 K the degree of hydration is increases, possible at the cost of of increase protons mobility at rapid mechanism of protron transfer and, besides, the amount of $CaCO_3$ increases under these conditions at the cost of the $Ca(OH)_2$ by carbonation. The degree of ordering of the system, growth of the hydration degree and forming of a carbonate has its energy share in total energy content of the system reduction, and accordingly, growing of toughness.

c). Injection in solidificating system fillers, including hydration-active, which reduce energy content of the system at the cost of the own chemical reactions or at the cost of catalysis of the main materials hydration.

The development of the thermodynamic aspect of toughness, considering energy nature and system toughness reserves, in which hard phases have mainly covalent

nature of bond, stipulates consideration of mechanisms of chemical reactions, which are to occur in the binder in the system of solids or quasisolids.

ELECTRONIC TRANSFORMATION LEVELS IN THE PROCESS OF BINDERS SOLIDIFICATION.

Electronic phenomenas in the process of binders solidification is a collection of phenomena with the transmission of electrons and electronic couples, exist in spontaneously solidificate systems and influence on processes of hydration, accordingly, solidification and on system toughness, on some mechanical characteristics also, such as flow and fragility. Electronic phenomenas of binders touch a construction of materials: on the level of realization of chemical bond, on the level of donor-acceptor bond, on the level of reduction-oxidation reactions and on the level of the reduction-oxidation and acid-base catalysis. The first level of electronic phenomenas accounting allows to get cements with flow characteristics (Svatovskaya, 1986), the second, the third and the fourth levels allow to control reactions in binder systems, using chemical categorization of binders and fillers (Svatovskaya, 1985).

Table 1 Categorization of binders according to the electronic family of Mendeleev table.

Binders	Examples	Acceptor of Electronic Couple	Electronic Level	Orbital Electronegativity, eV
s-cements	$2CaO*SiO_2*nH_2O$	Ca^{2+}	4s	2.33
p-cements	$Al_2O_3*nP_2O_5*mH_2O$	Al^{3+}	3p	6.01
d-cements	$ZnO*nP_2O_5*mH_2O$	Zn^{2+}	3d	-1.02

In Tables 1 and 2 are presented categorizations, which allow to consider cements, fillers, contact areas and interactions between them coming from the unified basis. Categorization in connection with the position in the Mendeleev table on the sign of belonging to the electronic family allows to forecast first; manifestation of binder characteristics as characteristics of electronic analogues s -, p - and d - elements; and secondly - toughness of chemical bond in hydrates.

The third particularity of binders categorizations consists of that, that it will allow to foresee a glue system ability, or otherwise, adhesive characteristics, for instance, p- and d- cements possess higher glue ability (adhesion) than s- cements, since energy of p-and d- orbital is higher than energy of s-orbitals, other things being equal.

Table 2 Categorization of fillers on the base of chemical nature.

Fillers	Place in Mendeleev Table		Electronic Construction		Nature of Chemical Bond	
	quantum numbers	type of filler	ΔE, eV	electrical propeties	Pirsons parameter, $r_k/r_a*\Delta x$	type
$CaCO_3$ $MgCO_3$	$4s^0$ 3sp	s-acceptor	>3.5	dielectric	0.6-1.5	ionic
$Al_2O_3*2SiO_2*H_2O$	$3sp^2$	p-acceptor	>3.5	dielectric	0.06-0.14	ionic-covalent
Fe_2O_3	$4s^03d^5$	d-acceptor	2.2	semiconductor	0.14-0.6	ionic-covalent
SiO_2	$3sp^3$	donor	>3.5	dielectric	0.06-0.14	covalent
Cu	$4s^23d^{10}$	donor	0	conductor	0	metallic
Fe	$4s^23d^6$	acceptor	0	conductor	0	metallic

The fourth particularity of this categorizations: it allows to forecast mechanical characteristics of artificial stones: more flexible, dumbbell-like directivity in the space, characteristic of p-cements, and fillers will promote more "flexible" structure of material , i.e. higher bending strength. In materials, the origin of toughness which lie in chemical reactions, forming new phase is capable to interact hereinafter with the surface of other solid (adhesion) by opening, donor-acceptor bond systems for instance. By classifying filler in the chemical system by its beloging to the electronic family, so depending on cation, it is possible to select s- , p- , d- fillers. Herewith, belonging of cation to the family, gives with provision for values of main quantum number information about energy and configuration of electronic orbital of cation. The use of such sort of notions, series of clay-materials are obtained, in which is used structure motive of silicates aluminum as well as are received composits, containing d-fillers, i.e. materials, having surface for instance, 3d-ferric (III) cations, distinguished by high energy of electronic configurations. As 3d-filler, slag can be used. However, structured - sp^2-motive can be present and in the source material - a reagent, not only filler; in this case it also dictates flat direct motive to the structure a material, brought about reduction of its fragility.

Categorization of fillers by particularities of solid electronic construction and nature of bond reflected by parameters of ΔE or $r_k/r_a*\Delta x$ allows to foresee influences of surface within the framework of notions reduction-oxidation and

acid-base catalysis. On this notions, materials which are mainly ion by nature, dielectrics are to shift balances of proton reactions on the principle of hard acids and bases; for metals (conductors) and semiconductors is also important ability to have a vacant electronic orbital.

INVESTIGATIONS ON CALCIUM PHOSPHATE CEMENTS

Peter VANIS and Ivan ODLER, Technical University Clausthal, Clausthal-Zellerfeld, Germany

ABSTRACT: The setting and strength development of pastes made from blends of dicalcium and tetracalcium phosphate may be accelerated by using a Na- K- or NH_4- phosphate solution, rather than pure water, as mixing liquid. Similarly, the strength development of compacts made from these starting materials becomes accelerated by placing them into these solutions, or into a solution whose ionic composition corresponds to that of the human body fluid. This effect is due to an accelerated conversion of the starting Ca-phosphates to hydroxyapatite, the phase responsible for the cohesion of the material.

INTRODUCTION

Calcium phosphate cements have been widely studied in recent years [e.g. Brown 1986, 1991, 1992, Chow 1991, Monma 1984, 1988, Williams 1992, Xie 1991]. In all of them hydroxyapatite [$Ca_5(PO_4)_3OH$; abbr. HAp], the phase thermodynamically most stabile in the ternary system CaO-P_2O_5-H_2O at pH > 4,8, is fomed as the final reaction product of the cementing process. The great interest in calcium phosphate cements is mainly due to their excellent biocompatibility, based on the fact that hydroxyapatite, in a solid solution with fluorapatite, is the mineral component of human bones and teeth.

The starting compounds in most, though not all, calcium phosphate cementitious systems are dicalcium phosphate [$CaHPO_4$; abbr. DCP] or dicalcium phosphate dihydrate [$CaHPO_4.2H_2O$; abbr. DCPD] in combination with tetracalcium phosphate [$Ca_4(PO_4)_2O$; abbr. TeCP]. If suspended in water, both substances are dissolved in the liquid phase and hydroxyapatite, which is less soluble, precipitates.

$$CaHPO_4 + Ca_4(PO_4)_2O = Ca_5(PO_4)_3OH \qquad [1]$$

This dissolution/reprecipitation reaction forms the basis of the setting and hardening of calcium phosphate cements. In addition to hydroxyapatite, also β-tricalcium phosphate [$Ca_3(PO_4)_2$; abbr. β-TCP] and octacalcium phosphate [$Ca_8H_2(PO_4)_6.5H_2O$; abbr. OCP] may precipitate as intermediate reaction products, however, both of them eventually convert also to the more stabile hydroxyapatite.

Even though the conversion of DCP (or DCPH) and TeCP to HAp may take place in pure water, diluted phosphoric acid is being most widely used as the mixing liqud, to accelerate the rate of reaction. Also employed were some other mixing liquids, such as solutions of soluble fluorides, calcium hydroxide or sodium silicate. Other factors that may affect the rate of setting and the attained strength include the particle size of the starting materials and the addition of HAp-seeds to the mix.

As in the reaction between DCP (or DCPH) and TeCP neither an acid nor a base are liberated, the pH of the liqud phase is supposed to stay close to the singular point for DCP (or DCPH) and TeCP, i.e. at around pH=7.4. However, in performed experiments a time dependent variation of the pH value was observed, apparently due to differences in the dissolution rate of both starting substances.

In our previous work on cementing reactions in the system CaO-SiO_2-P_2O_5-(H_2O) we observed that the rate of setting depended greatly on the pH of the liquid phase and that the hardening

process could be accelerated by the presence of soluble phosphates [Vanis 1996]. Inspired by these observations, in the present work we studied whether and to what an extent the setting/hardening process of DCP+TeCP based Ca-phosphate cement may be controlled in a similar way. The experiments were performed both on pastes made from a DCP+TeCP blend as well as on compacts produced by isostatic compaction, that were kept in various phosphate solutions.

EXPERIMENTAL

Preparation of the starting DCP+TeCP powder

The employed DCP was a commercial product with at purity of >99.5%

To produce TeCP in the laboratory, stoichiometric amounts of pulverized $CaCO_3$ were introduced into a concentrated $(NH_4)_2HPO_4$ solution under stirring, at 70-80°C. The suspension was stirred still for additional 7 hours and then dried at 110°C. The obtained residue was burnt in an electric furnace for 3 hours at 1350°C, to obtain pure TeCP, with a residual free lime content of < 0.1%.

$$4\,CaCO_3 + 2\,(NH_4)_2HPO_4 = Ca_4(PO_4)_2O + 4\,NH_3 + 3\,H_2O + 4\,CO_2 \qquad [2]$$

Equimolar amounts of DCP and TeCP were comminuted and blended by grinding the material in a laboratory ball mill for three days. The characteristics of the produced DCP+TeCP powder were as follows:

Particle size distribution (laser granulometry):

$D_5 = 0.5\ \mu m$
$D_{50} = 7.0\ \mu m$
$D_{95} = 76.1\ \mu m$

Specific surface area (BET_{N2}) = 4.6 m^2/g

Performed studies

For studying the setting characteristics, Na-, K- ad NH_4- phosphate solutions with different pH values were prepared by dissolving pertinent amounts of XH_2PO_4 and X_2HPO_4, where X = Na, K or NH_4, in water. Such solution were mixed with the DCP+TeCP powder in a ratio: 0.5 ml of solution per 1 g of powder. Similar mixes were prepared also with pure water. The progress of setting of the obtained pastes was studied by the Vicat needle penetration method. The results were expressed as curves in which the needle penetration depth was plotted as function of time.

The strength properties of the produced Ca-phosphate cement were studied both on pastes and on compacts. In the preparation of the pastes pure water or saturated solutions of Na_2HPO_4, K_2HPO_4 and $(NH_4)_2HPO_4$ were employed as mixing liquids. In all instances the liquid was mixes with the DCP+TeCP powder in a ratio: 0.5 ml of liquid per 1 g of powder. Test specimens 10x10x60 mm^3 prepared from the paste were cured in humid air at 20°C and tested for flexural and compressive strengths after different times of curing.

The compacts to be tested were produced by isostatic compaction in which the DCP+TeCP powder was exposed to a maximum pressure of 200 MPa. This way the porosity was brought down from an initial value of about 0.38 ml/ml (in samples exposed to a pressure of 0.1 MPa) to about 0.12 ml/ml in the produced compacts. This compaction procedure was selected to obtain low porosity, a uniform degree of conpaction and a homogenious texture within the whole sample. From the produced compacts (cylinders about 17 mm in diameter) test specimens 10x10x60 mm^3 were produced by cutting with a diamond saw and subsequent polishing. The produced specimens were then stored in the folowing liquids until testing: 1-2: pure water at 20°C and 80°C ; 3-5: saturated solutions of Na_2HPO_4, K_2HPO_4 and $(NH_4)_2HPO_4$ at 20°C and 6: a liqud whose ionic composition corresponded to that of the human body liquid [biosolution: Na^+ = 142 mMol; K^+ = 5 mMol; Mg^{+2} = 1.5 mMol; Ca^{+2} = 2.5 mMol; Cl^- = 147.8 mMol; HCO_3^- = 4.2 mMol; HPO_4^{-2} = 1 mMol; SO_4^{-2} =

0.5 mMol]. The flexural and compressive strength, modulus of elasticity and fracture energy values shown in Figure 2 and inTable 1 were determined on five parallel specimens.

X-ray diffraction and thermoanalytical studies were performed on samples in which the hardening reaction was stopped and the free water removed by the d-drying procedure.

RESULTS

Setting

Pastes prepared with pure water did not exhibit setting for at least 10 hours neither at 20°C nor at 80°C. The setting characteristics at 20°C of pastes in which phosphate solutions were employed as mixing liquids are shown in Figure 1. It appears that the rate of setting depended greatly on the pH value of the liquid phase. Up to about pH=7-8 mixes produced with any of the phosphate solutions set almost instanteniously, whereas at higher pH the setting process became well controllable and slowed down as the pH value increased.

Compressive strength development of pastes

Pastes produced from the DCP+TeCP powder by mixing it with water did not exhibit measurable strength even after 28 days of curing, whereas those in which saturated phosphate solutions were used as mixing liquids attained distinct strengths within a few days.The results found in these pastes are shown in Figure 2. It appears that the obtained strength values depended greatly on the phosphate solution employed and increased in the order Na-phosphate < NH_4-phosphate < K-phosphate.

Compressive strength development of compacts

Figure 2 shows also the compressive strength development of DCP+TeCP compacts after storing them in different solutions for different periods of time and at different temperatures. It appears that the strength of the material depended greatly on the liquid in which it was stored. Remarkably, test specimens stored in the K-phoshate solution exhibited significantly higher strengths than those stored in solutions of Na- or NH_4-phosphate. Samples stored in pure water at 20°C exhibited also measurable strengths, however, the strength value found at any curing time were lower than those of samples stored in phosphate solutions. Expectedly, an increase of the water temperature from 20°C to 80°C resulted in a distinct increase of the strength values. Test specimens stored in the "bio-solution" developed their strength at the beginning rather slowly, however, they exhibited high strength value after 7 and 28 days.

Physico-mechanical properties of compact.

Table 1. shows the 28-day compressive and flexural strength, modulus of elasticity and work of fracture values of the compacted material. All these parameters varied in a wide range, depending on the liquid in which the test specimens were stored and on the employed temperature. They were highest in samples stored in the K-phosphate solution and lowest in those kept in plain water at 20°C.

Reaction products

The phase composition of the DCP+TeCP compacts stored in different solutions was studied by X-ray diffraction. After 28 days, in samples stored in the K-phosphate solution, just as in those stored in the "bio-solution" neither non-reacted dicalcium nor tetracalcium phosphate could be identified, indicating a complete consumption of these original calcium phosphates in the hardening reaction. Hydroxyapatite was found as the sole crystalline phase present. Contrary to that, distinct amounts of dicalcium phosphate and tetracalcium phosphate, besides of hydroxyapatite, were still found in all remaining samples. The amount of these phases was distinctly lower in the materal cured in water at 80°C than in that stored at 20°C.

Table 1. Physico-mechanical properties of DCP+TeCP compacts after curing 28 days in different solutions

	Compr. str. (MPa)	Flex. str. (MPa)	E-modulus (GPa)	Fract. energy (Nm/m^2)
H_2O - 20°C	29.4	5.8	22.3	37.9
H_2O - 80°C	50.3	14.6	29.9	146.2
Na_2HPO_4 - 20°C	36.4	14.5	31.3	129.5
K_2HPO_4 - 20°C	125.3	28.6	43.7	471.2
$(NH_4)_2HPO_4$ - 20°C	31.2	14.6	30.6	133.5
Bio-solution - 37°C	91.1	15.2	34.6	148.9

In thermogravimetry studies the hardened d-dried samples exhibited a thermal decomposition associated with an almost contineous weight loss at temperatures above about 50°C (Figure 3). The samples did not exhibit a noticeable shrinkage, as measured by thermodilatometry, up to about 1000°C, however, they shrank distinctly between about 1000°C and 1450°C.

DISCUSSION AND CONCLUSIONS

The obtained results revealed a significant accelerating effect of alkali and ammonium phosphates on the rate of the reaction between dicalcium and tetracalcium phosphate, yielding hydroxyapatite. It is remarkably, however, that the rate of the reaction depended not only on the presence of orthophosphate anions in the liquid phase, but also on the quality of the pertinent cation. Not unexpectedly, the rate of reaction was accelerated also by increasing the curing temperature.

Another factor that was found to exhibit an effect on the rate of setting and probably also on the overall rate of reaction was the pH of the liquid used in the preparation of the calcium phosphate cement pastes. Thus, the setting time of such pastes may be conveniently controlled just by altering the pH of the employed alkali or ammonium phosphate solution.

Expectedly, hydroxyapatite was identified as the sole crystalline reaction product by XRD. However, the way how the hardened material thermally decomposed suggests that, in addition to a well crystallized form that decomposes at temperatures of around 1300°C, some of it may have been formed in a highly dispersed form decomposing at distinctly lower temperatures. There exists also the possibility that some additional non-crystalline C-P-H products were formed in the hardening process.

The existing strength differences found after 28 days of curing appear to be mainly due to differences in the degree of DCP+TeCP conversion to HAp. The differences between strength values found in pastes and compacts are obviously mainly due to different degrees of porosity existing in both types of samples.

In the performed experiments we were also able to demonstrate a conversion of the prepared

DCP+TeCP compacts to a high strength, hydroxyapatite based material in a solution whose ionic composition corresponded to that of the human body fluid. Such results suggest the possibility of using DCP+TeCP compacts in such surgical applications, where the in vivo conversion of the material to hydroxypatite, rather than a direct implantation of hydroxyapatite based implants, may be beneficial.

THE ROLE OF MgO IN THE SYNTHESIS OF C-S-H AND TOBERMORITE

Zdzisław PYTEL, Jan MAŁOLEPSZY, University of Mining and Metallurgy, Department of Material Science and Ceramics, Cracow, Poland

ABSTRACT The effect of Mg^{2+} on the reaction in the CaO, SiO_2 and MgO containing mixtures in hydrothermal conditions was investigated. It has been found that the magnesium ions are incorporated to the calcium silicate hydrate structures in a limited amount. The excess Mg admixture can produce the magnesium silicate hydrate phase. Additionally, the influence of Mg^{2+} ions on the morphology of tobermorite crystals was observed.

Key-words: CSH, tobermorite, magnesium oxides, synthesis, microstructure

INTRODUCTION

The calcium silicate hydrates are produced usually during the autoclaving of lime-sand or lime-silica mixtures. At temperatures not exceeding 180°C, C-S-H or tobermorite are formed as main hydration products, depending on the duration of thermal treatment (Taylor, 1964). These phases affect significantly the practical properties of autoclaved building materials.

Tobermorite was found by Heddley, as a naturally occurring mineral in Tobermory, Scotland, in 1880. In some other places (Ireland, California, Japan), tobermorite occurs as a component of the so-called contact zones. However, it is known mainly as a synthetic mineral produced from different lime- and silica-bearing components under the saturated steam pressure, at 110° to 180°C. The first synthesis of 1.13 nm tobermorite was carried out by Flint, McMurdi and Wells, in 1938 (Flint et al, 1938). It was subsequently synthesized and examined by Heller and Taylor (Heller, 1951) as well as by Kalousek (Kalousek, 1955a). The tobermorite phase was produced from lime or cement mixtures with quartz or amorphous silica.

The synthesis of tobermorite is carried out in heterogeneous lime-silica suspensions. The reactions proceeds through several intermediate stages in which the poorly crystalline materials are formed, with varying C/S molar ratio (Rademaker and Reiman, 1994). At temperatures close to 180°C calcium silicate hydrate transforms to crystalline 1.13 nm tobermorite, with definite chemical composition, given by the formula $C_5S_6O_{18}H_2{\cdot}4H_2O$. However, the tobermorite material is not stable, and undergoes further transition to xonotlite or gyrolite as the temperature or duration of hydrothermal treatment increases.

The foreign ions in the structure of tobermorite have been the subject of special interest. The substitution of Ca^{2+} by several cations, e.g. Co^{2+}, Pb^{2+}, Cd^{2+} and Ni^{2+} but not Cr^{6+} were reported (Komarneni et al, 1986). The possibility of Ca^{2+} replacement by Mg^{2+} was also reported (Shrivastava et al, 1991). However, it should be underlined that these substitutions were carried out by ionic exchange between the crystalline tobermorite and solution of concentration in the range 100 to 1000 ppm. On the other hand there are not many reports of substitution during the synthesis of tobermorite; this means the process in which tobermorite is produced from the mixture containing the substituting components.

There are different opinions dealing with the position of Mg^{2+} in the structure of 1.13 nm tobermorite. According to data reported by Petrovič (Pertovič, 1973a, 1974b) and Mitsuda (Mitsuda, 1973a), the isomorphous substitution of Ca^{2+} by Mg^{2+} does not occur. Only the paragenesis of calcium and magnesium silicate hydrates is possible on autoclaving. Another point of view was presented by Diamond (Diamond et al, 1966). This author confirmed the occurrence of isomorphous substitutions in tobermorite and determined their limits; a 7.5% limit of Mg^{2+} substitution was thus found.

EXPERIMENTAL

Sample preparation

The tobermorite was produced from silica and lime admixtured with periclase. The two siliceous components were used: colloidal SiO_2 and quartz. The CaO was produced by thermal dissociation of analytically pure $CaCO_3$ at 1150°C for 4 hours. The MgO-periclase was produced by $Mg(OH)_2$ dehydration at 1300°C for 1 hour. The materials were preliminary ground to pass a 63 μm sieve.

Two variant procedures of tobermorite preparation were applied. In the first, the initial mixture with constant C/S molar ratio equal 5:6=0.83 (denoted as M), i.e. corresponding to „theoretical" tobermorite was doped with variable amount of periclase. In this way samples containing 0, 5, 10, 15, 20 and 40% MgO added in relation to the CaO constant content in the basic batch were prepared. Thus a series of constant C/S and (C+M)/S varying in the range 0.83 to 1.27 was produced. In the second series, samples were prepared at constant (C+M)/S=0.83 molar ratio with variable C/S molar ratio respectively (denoted as KGM0). The C/S molar ratio decreased because of gradually lowered CaO content. Every 0.2 mole CaO was replaced by an equivalent MgO portion.

The particular components were carefully weighted, homogenized as dry materials and subsequently mixed with distilled water free of CO_2 to produce pastes. These pastes were placed in "Teflon" containers and autoclaved in laboratory autoclaves at constant temperature 180°C, for 2, 4, 8, 12, 48 and 72 hours respectively. The samples were subsequently treated with acetone, to stop the hydration process, and dried at 50°C. The materials thus obtained were subjected to the phase composition and microstructure determination. For this purpose the following techniques were applied: DTA, TG, XRD, FTIR, SEM and EDS.

Results and discussion

In the mixtures composed of CaO, MgO and SiO_2 at constant C/S=0.83 and variable (C+M)/S molar ratio, calcium silicate hydrate is produced as a basic material in hydrothermal conditions at 180°C. The transition of structure from nearly amorphous C-S-H to the crystalline tobermorite is a function of time. In short reaction times (2, 4 and 8 hours) amorphous C-S-H is a dominating product. A considerable amount of tobermorite is produced at longer autoclaving times. C-S-H is identified on XRD pattern from the strongest, broadened peak corresponding to d=0.307 nm. On the DTA curve, in turn, it is identified from the endothermic peak in the range 80° to 190°C, attributed to C-S-H dewatering (Fig. 1).The H_2O in the C-S-H structure is also seen on the IR curves, as 1640 and 3440 cm^{-1} bands (Fig. 2). The sharp exothermic peak on the DTA curve at 795°C, attributed to formation of wollastonite, proves additionally the formes presence of calcium silicate hydrate. In Fig. 3 the microstructure of gel-like C-S-H is shown. The C/S on the fractured surface was estimated to be 1.5; this implies that this product is C-S-H(I). For longer autoclaving times the tobermorite phase was produced, with characteristic, skeletal octahedral, plate-like crystals (Fig. 4). The C/S molar ratio for this phase was determined to be 0.8, it close to the theoretical value. The presence of tobermorite was also confirmed in the IR spectrum.

In the presence of MgO amorphous and crystalline hydration products are formed, depending on the time of thermal treatment. At 180°C for 8 hours synthesis time the C-S-H content increase is observed to the maximum value in M15 and subsequently, a reduction of C-S-H takes place with increase of tobermorite content. It means that magnesium ions lower the limit of stable tobermorite formation and thus accelerates the tobermorite crystallisation. A similar trend is observed in the products of 72 hour synthesis, in which the tobermorite phase dominates. In the presence of MgO, the morphology of tobermorite is strongly affected. The elongation of plate-

like crystals gives way to lath-like or needle-like forms; xonotlite fibrous crystals are also observed. These crystals are localized in the pores, as can be seen in Fig. 5.

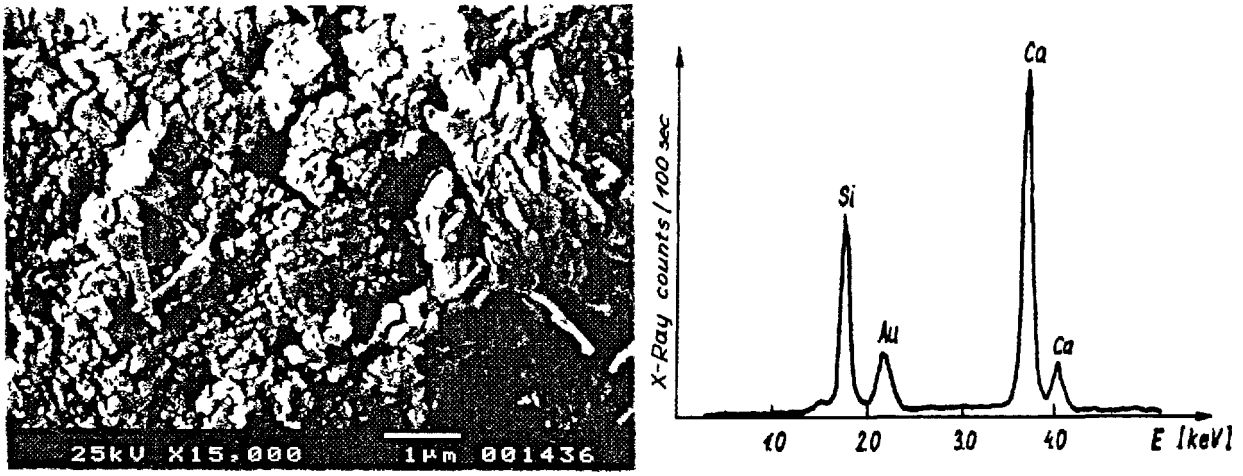

Figure 3. Scanning electron micrograph of C-S-H phase with EDS analyse

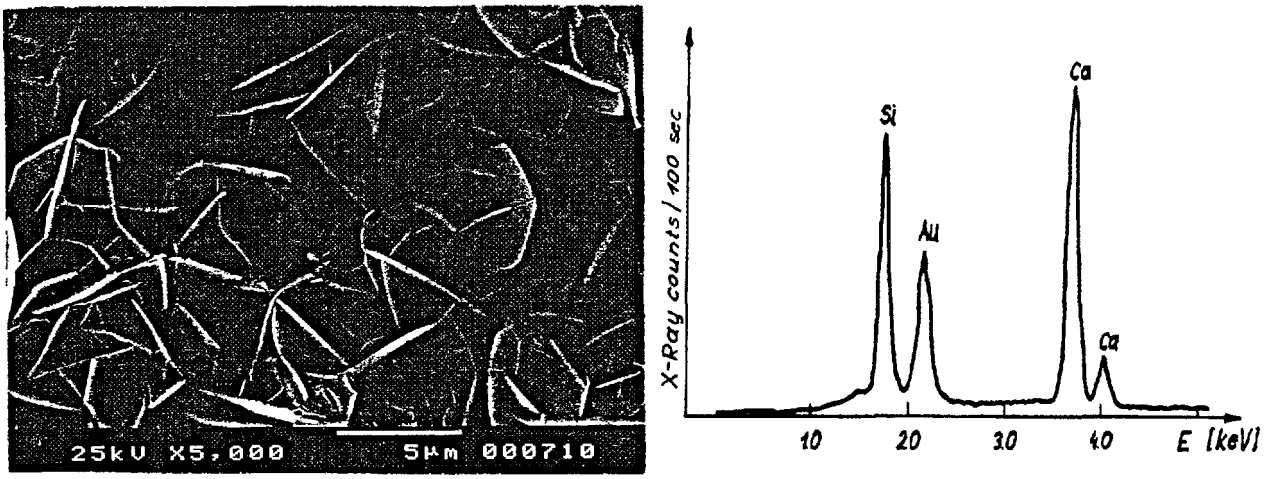

Figure 4. Scanning electron micrograph of tobermorite with EDS analysis

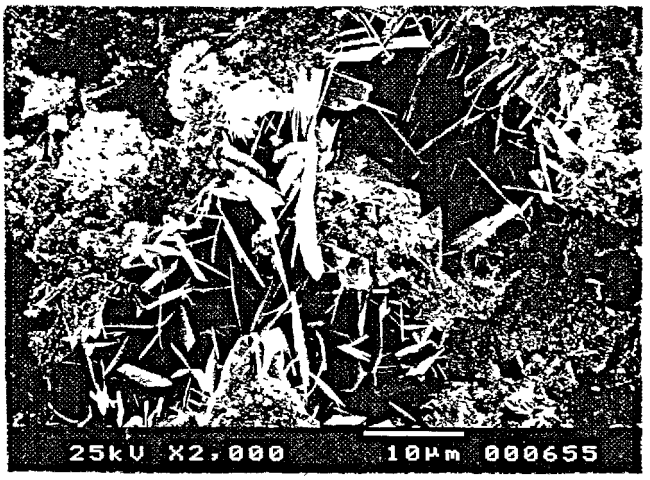

Figure 5. Scanning electron micrograph of tobermorite and xonotlite

In the mixtures prepared at constant (C+M)/S and variable C/S molar ratios similar results to those described above have been obtained only for the samples with higher CaO and low MgO contents. There are the samples of the following composition. $C_{0.8}/S_{1.0}$ (KGM0), $(C_{0.6}+M_{0.2})/S_{1.0}$

(KGM02) and $(C_{0.4}+M_{0.4})/S_{1.0}$ (KGM04). The DTA curves of these samples are plotted in Fig. 6. One can notice that the tobermorite is a main product in the Mg doped samples, irrespectively from the time of autoclaving.

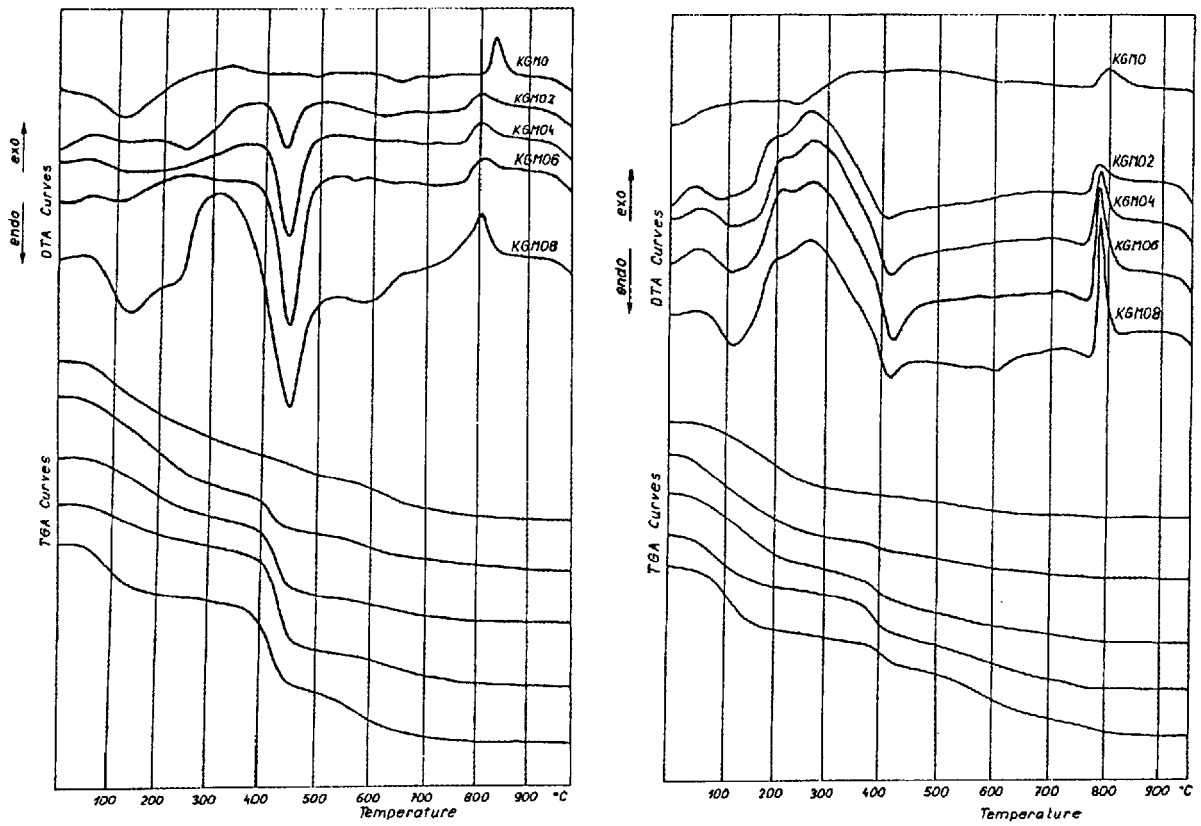

Figure 6. Thermal data of autoclaved samples with constant (C+M)/S and variable C/S ratio: after 8 hours hydrothermal treatment (left), after 72 hours hydrothermal treatment (right)

Unreacted $Ca(OH)_2$ was detected only in the KGM08 hours autoclaved sample, without MgO, in which the C-S-H of C/S=1.5 was produced. In turn, in the 72 hours autoclaved sample of the same composition the tobermorite was present exclusively. Therefore one can conclude that the Mg ions accelerate the transformation C-S-H → tobermorite in such a way that the Mg ions are incorporated to the structure of tobermorite and a solid solution is thus produced. The upper limit of tobermorite stability is also reduced by the presence of Mg. The tobermorite phase transforms more easily to xonotlite, as observed under SEM.

Quite different results were obtained for the samples with MgO content higher than CaO, i.e. in $(C_{0.2}+M_{0.6})/S_{1.0}$ (KGM06) and $M_{0.8}/S_{1.0}$ (KGM08). The rate of hydration in these mixtures is low - after 8 hours treatment an unreacted residue of quartz, brucite and portlandite is observed. The hydration products are composed of C-S-H and M-S-H in mixture without CaO, a product of amorphous character. The latter phase is evidenced by d=0.67 and d=0.304 nm XRD peaks. Obviously, the progress of reaction in the mixtures subjected to 72 hours autoclaving is clearly seen - the portlandite peaks on the XRD pattern disappear while those for brucite become significantly weaker. The magnesium silicate hydrate occurring as the main hydration product, identified from the set of XRD data, viz. d=1.022 to 1.134, 0.456 and 0.248 to 0.256 nm. These results correspond well with those reported by Kalousek (Kalousek, 1954b) and Mitsuda (Mitsuda, 1977b). The M-S-H gel is the first product between the magnesium hydroxide and silica, with M/S molar ratio 1.5. The cryptocrystalline magnesium silicate is formed as an

intermediate product in the synthesis of talc or chrysotile. In the presented study the M/S molar ratio was estimated for 0.7; the microstructure of M-S-H gel is shown in Fig. 7.

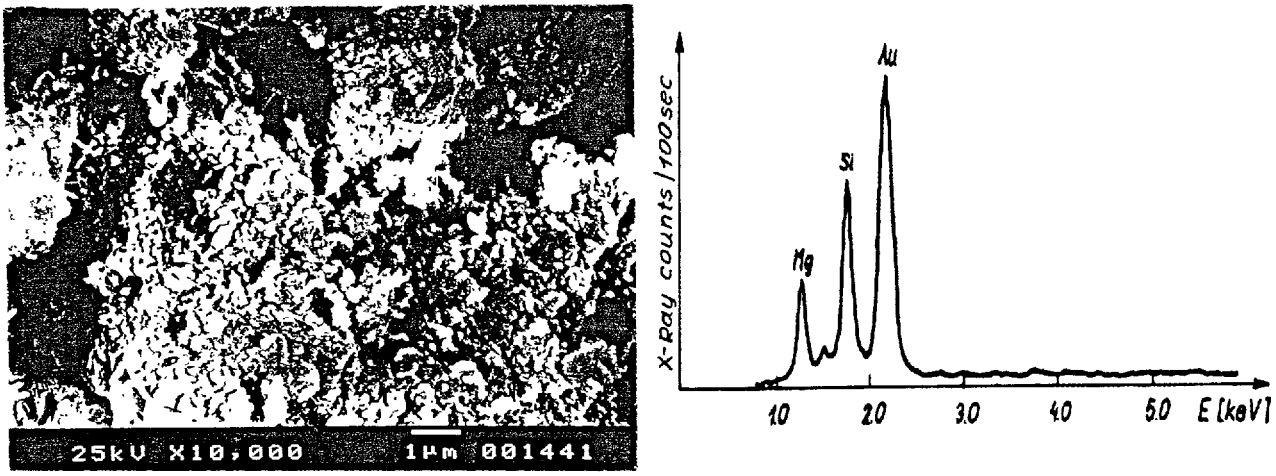

Figure 7. Scanning electron micrograph of M-S-H gel with EDS analyse

Irrespectively of time of thermal treatment, the brucite appears at MgO content not lower than 6% (sample M15). The free brucite content increases with MgO in the samples M20 and M40. At lower MgO content, i.e. in M5 and M10, brucite is not observed. This means that the Mg^{2+} from $Mg(OH)_2$ dissociation forms isomorphic substitutions in the structures of C-S-H and tobermorite, up to a certain limit; the excess occurs as brucite. The decreasing $Mg(OH)_2$ in samples M20 and M40 prove that Mg^{2+} reacts with the silicate component to produce a magnesium silicate phase. This is observed as a crystalline product only after at longer time of thermal treatment.

Summary

At 180°C, the crystallinity of final products depends on the duration of thermal treatment. At shorter times (2, 4, 8 hours respectively); nearly amorphous hydration products are observed, mainly so-called C-S-H. Crystalline tobermorite appears with time. The amount and structure of hydration products is influenced by Mg^{2+} ions. C-S-H synthesis is accelerated at MgO additions up to 6.03%, upon 8 hour autoclaving. Subsequently, an acceleration of tobermorite crystallisation occurs. The Mg^{2+} ions are incorporated to the structure of products. The limiting value for MgO diluted in the structure approximately 6.0%. Any excess MgO is hydrated to form brucite or, at longer times, react with the siliceous component producing a magnesium silicate hydrate of poorly developed structure. The morphology of tobermorite crystals is strongly affected by the presence of Mg^{2+} ions. The elongation of skeletal octahedral tobermorite plates disappears with increased MgO contents and needles or fibres appear.

THERMAL BEHAVIOUR OF TOBERMORITE INTERCALATED WITH ALKALI IONS

Naomichi HARA, Norihiro INOUE and Hiroaki NOMA
Kyushu National Industrial Research Institute, Tosu, Japan

ABSTRACT Normal type 1.1 nm tobermorite could be transformed into anomalous or mixed type by immersing in aqueous alkali solutions such as NaOH, KOH, NaCl and KCl solutions. When the resulting anomalous or mixed type was rinsed in water, normality was recovered. These results suggest that alkali ions are reversibly intercalated between the layers of tobermorite to increase anomaly, where alkali ions function as hydrated ions binding water molecules in their immediate vicinity.

Key-words: Tobermorite, Alkali, Ions, Mobility, X-ray Powder Diffraction

INTRODUCTION

Tobermorite (1.1 nm) is classified into three types according to its thermal behaviour, viz. 1) normal type (Taylor, 1964), which is converted to 0.9 nm tobermorite by dehydration in heating in the air at about 300°C, 2) anomalous type (Gard and Taylor, 1957), which keeps the basal spacing at about 1.1 nm even after dehydration, and 3) mixed type (Chatterji, 1973), which shows an intermediate behaviour between normal and anomalous types. However, all the types are converted to β-wollastonite in further heating in the air at about 800°C.

Hara and Inoue (1980) investigated relationships among thermal behaviour, synthetic conditions and lattice parameters of hydrothermally synthesized 1.1 nm tobermorite and have clarified that factors which decrease the lattice parameter c_o, viz. decrease of Ca/Si and H_2O/Si mole ratios, increase of crystallinity and the presence or addition of alkalis accelerate the formation of anomalous type, but the presence or addition of aluminium ions, which increases the lattice parameter c_o, accelerates the formation of normal type. Normal type is transformed into anomalous type via mixed type in prolonging the reaction time, which results in the increase of crystallinity of tobermorite.

In an extension of these studies, the present authors found out that normal type tobermorite was easily transformed into anomalous or mixed type only in immersing in aqueous alkali solutions. This and some other findings are reported in this paper.

METHODS AND RESULTS

Preparation of normal type tobermorite

In hydrothermal preparation of 1.1 nm tobermorite, starting Ca/Si mole ratio and reaction time affect thermal behaviour of the resulting tobermorite as shown in Table 1 (Hara and Inoue, 1980).

Table 1 Basal spacing (nm) of tobermorite after heated at 400°C for 20 hours.

Reaction time hours	Starting Ca/Si mole ratio			
	0.6	0.7	0.8	0.9
6	1.09–0.98 m	0.99–0.96 m	1.13 a	–
12	1.13 a	1.03 m	0.97 n	0.96 n
24	1.13 a	1.13 a	1.13 a	1.10–0.97 m

n : normal type; a : anomalous type; m : mixed type.

Namely, low Ca/Si mole ratio is favourable for the formation of anomalous type but high Ca/Si mole ratio for normal type. Increase of reaction time increases the anomaly of tobermorite. Based on these results, the starting Ca/Si mole ratio and reaction time for the preparation of normal type 1.1 nm tobermorite to be used for the following experiments were set at 0.8 and 12 hours, respectively.

A slurry with Ca/Si mole ratio 0.8 and water/solid weight ratio 3 was prepared from quartz (Ig loss 0.38, SiO_2 98.13, Al_2O_3 1.16, Fe_2O_3 0.04, Na_2O 0.10, K_2O 0.14 %; Blaine specific surface area 319 m^2/kg), CaO obtained by calcining precipitated $CaCO_3$ at 1,100°C and water, and reacted in an autoclave at 180°C for 12 hours. The resulting slurry was dried and ground in an agate pot mill. The reaction product was 1.1 nm tobermorite. In heating in the air at 400°C for 20 hours, it was converted to 0.9 nm tobermorite with the basal spacing 0.96 nm, which was a typical normal type tobermorite.

A batch of thus prepared normal type tobermorite was divided into small portions and each portion was given for immersion-treatment under various conditions as follows:

Effect of immersing temperature and time

Firstly, normal type tobermorite was immersed in 50 times (by weight) 0.5 % NaOH and KOH aqueous solutions at temperatures ranging from 20° to 80°C for 24 hours. As a control, a portion of the same tobermorite was immersed in deionized water under the same conditions. After immersion-treatment, excess water was removed by decantation and each residue was freeze-dried. The resulting sample was heated in an oven at 400°C for 20 hours and then given for x-ray diffractometry. Thermal behaviour of tobermorite was discussed due to the change of basal spacing of heated tobermorite thus determined by x-ray diffractometry.

The relationship between immersing temperature and basal spacing of heated tobermorite is summarized in Fig 1. Tobermorite immersed in deioinized water showed a slightly larger basal spacing after heated compared with the untreated one (original) but still within the range

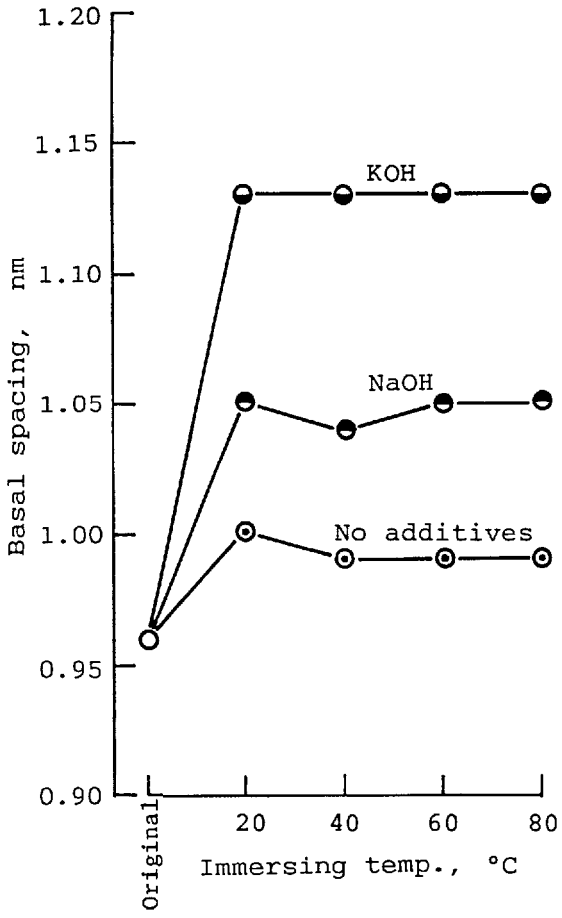

Figure 1 Immersing temperature vs basal spacing of tobermorite after heated at 400°C for 20 hours.

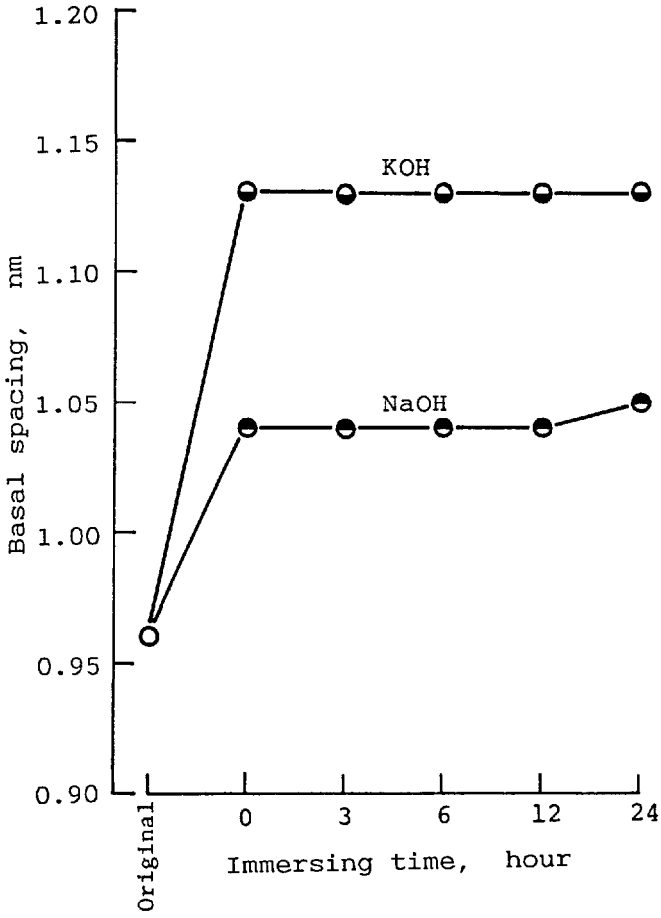

Figure 2 Immersing time vs basal spacing of tobermorite after heated at 400°C for 20 hours.

classified as normal type. Immersion in NaOH solution gave mixed type having the basal spacing after heated 1.05 nm and in KOH solution anomalous type having the basal spacing after heated 1.13 nm. Namely, the presence of alkali ions increased anomaly even at room temperature, and K^+ ions were remarkable in its effect.

Secondly, effect of immersing time was investigated in the range from 0 to 24 hours at temperature fixed at 20°C. The sample taken out from alkali solutions as soon as immersed was designated as "0 hour". The relationship between immersing time and basal spacing of heated tobermorite is summarized in Fig 2. In spite of the length of immersing time, short or long, normal type tobermorite was transformed into anomalous type in KOH solution and into mixed type in NaOH solution. In NaOH solution, anomaly of tobermorite was increased a little by prolonging the immersing time from 12 to 24 hours as shown in Fig 2 as increase of the basal spacing.

Effect of alkali concentration

In the above experiments, normal type tobermorite was immersed in 50 times (by weight) alkali solution, and then about 80 % alkali solution was removed by decantation before freeze-drying. As the result, about 5 % (by weight) alkali still remained in freeze-dried tobermorite. In order to clarify the effect of alkali concentration, immersion-treatment was carried out by using alkali solutions with various concentrations. NaOH and KOH aqueous solutions with various concentrations were prepared to have solid alkali/tobermorite weight ratio after freeze-drying ranging from 0.1 to 5 %. Immersing temperature was set at 20°C. Normal type tobermorite was immersed in 50 times (by weight) solution and taken out instantly. This procedure corresponds to "immersing time 0 hour" in the above experiment shown in Fig 2. The following procedures were the same as the abovementioned experiments. The relationship between alkali concentration and basal spacing of heated tobermorite is summarized in Fig 3. Vertical lines extending from circular dots in Fig 3 correspond to the broadening of x-ray diffraction line width of respective basal spacings, which was caused by low crystallinity of corresponding tobermorite. In both NaOH and KOH solutions, anomaly was increased according to increase of alkali concentration, where 2 % KOH was enough to give anomalous type and 1 % NaOH mixed type.

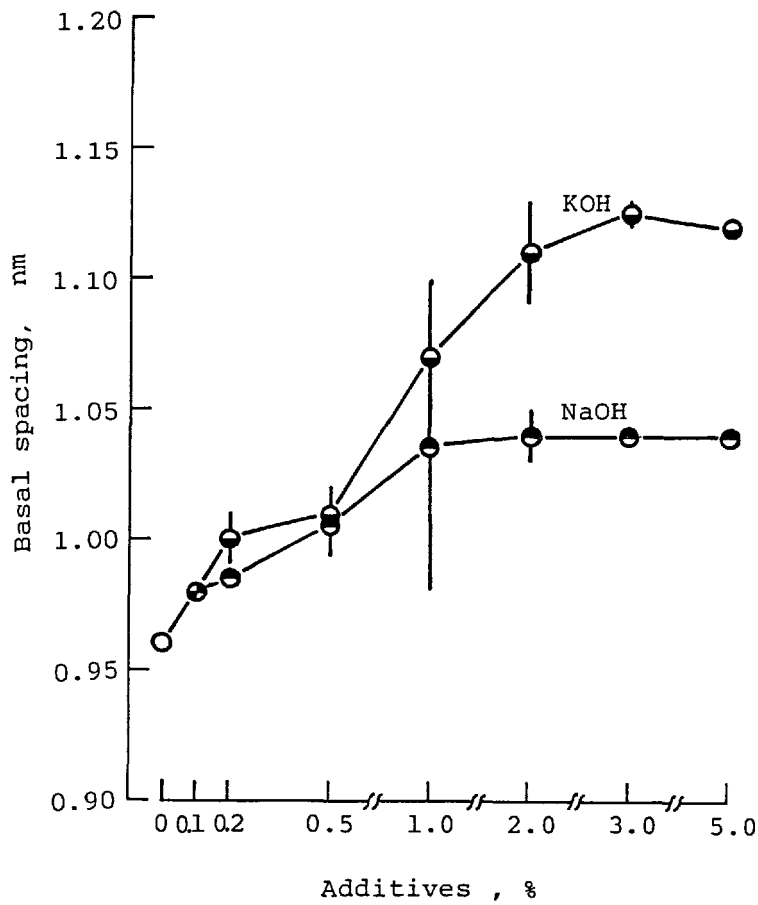

Figure 3 Concentration of alakli solution vs basal spacing of tobermorite after heated at 400°C fo 20 hours.

Removability of alkalis from tobermorite

If results obtained from the above experiments suggest that alkalis are intercalated between the layers of tobermorite, it may be possible to remove thus intercalated alkalis by rinsing in water. In order to confirm this possibility, immersion-treated tobermorite was rinsed in water under

various conditions. Results are summarized in Table 2.

Table 2 Removability of alkalis from tobermorite.
(Basal spacing after heated at 400°C for 20 hours, nm)

Processing conditions	1	2	3	4	5
a) 20°C, 0 hour					
NaOH 0.5 %	1.04 m	1.04 m	0.98 n	–	–
KOH 0.5 %	1.13 a	1.10 a	0.98 n	–	–
b) 20°C, 24 hours					
NaOH 0.5 %	1.05 m	1.05–1.03 m	0.97 n	1.03>0.99 m	1.03, 0.98 m,n
KOH 0.5 %	1.13 a	1.13–1.10 a	1.00–0.98 n	1.10 a	1.13 a
c) 20°C, 24 hours					
NaCl 0.5 %	1.03–1.01 m	–	–	–	0.98 n
KCl 0.5 %	1.13–1.10 a	–	–	–	1.00–0.96 n
d) 20°C, 24 hours					
NaCl 1.0 %	1.05–1.03 m	–	–	–	1.00–0.98 n
KCl 1.0 %	1.13–1.10 a	–	–	–	0.98 n

– : These processing conditions were omitted.
Processing conditions of samples after immersed in alkali solutions :
1. Freeze–drying. 2. Filtration. 3. Filtration and rinsing in water.
4. Freeze–drying and then rinsing in water.
5. Freeze–drying and then ultrasonic rinsing in water.

When normal type tobermorite was immersed in 0.5 % alkali solution at 20°C for 0 hour and freeze–dried, NaOH solution gave mixed type and KOH solution anomalous type with the basal spacing after heated 1.13 nm. However, when freeze–drying was replaced by filtration for tobermorite immersed in KOH solution, anomaly was slightly decreased to give the basal spacing after heated 1.10 nm as shown in Table 2, 2–a.

When 0.5 g tobermorite, which was immersion–treated for 0 hour and filtered, was rinsed in 50 ml deionized water three times, both mixed type obtained in NaOH solution and anomalous type in KOH solution were transformed to normal type having the basal spacing after heated 0.98 nm (Table 2, 3–a). Even for tobermorite immersion–treated for 24 hours and filtered, similar results were observed but recovered normality was inferior to that of tobermorite immersion–treated for 0 hour.

For freeze–dried samples, rinsing and ultrasonic rinsing in water were given, but only a slight recovery of normality was observed for tobermorite immersion–treated in NaOH solution (Table 2, 4–b, 5–b).

Similar experiments were tried by using NaCl and KCl aqueous solutions as shown in Table 2. Immersion at 20°C for 24 hours and freeze–drying gave mixed type in NaCl solution and anomalous type in KCl solution. These samples were freeze–dried ones, but normality was easily recovered by ultrasonic rinsing. These results suggest that alkalis from alkali chlorides are more easily removed by rinsing in water than those from alkali hydroxides.

CONCLUSIONS

Normal type tobermorite was easily transformed into mixed type or anomalous type when immersed in alkali solutions such as NaOH and KOH aqueous solution. KOH solution was higher in its effect to increase anomaly than NaOH solution. Thus obtained anomaly was recovered to a certain extent by rinsing in water. Similar phenomena were observed when immersed in alkali chloride solutions such as NaCl and KCl aqueous solution. However, alkali chlorides were inferior to alkali hydroxides in the effect to increase anomaly. These results suggest that alkali ions are reversibly intercalated between the layers of tobermorite.

When it comes to ionic radii of alkalies, K^+ is larger than Na^+. But when ionic radii are compared as hydrated ions which bind a certain number of water molecules in the immediate vicinity of alkali ions, hydrated K^+ is smaller than hydrated Na^+ (Ushio, 1976).

In addition, hydrated K^+, which is of "negative hydration", is more mobile than hydrated Na^+ in aqueous solutions (Samoilov, 1957). These seem to be the reasons why K^+ ions were more effective than Na^+ ions not only to increase anomaly by immersing in alkali solutions but also to recover normality by rinsing in water.

As for the reason why the presence of alkali is favourable for the formation of anomalous type, McConnell (1954) has suggested that alkali ions present between the layers of tobermorite may stabilize its basal spacing to increase anomaly, noticing similarity of tobermorite to vermiculite where the basal spacing of Na–vermiculite is more stable than that of Ca–vermiculite. Alkali ions intercalated by immersion–treatment seem to contribute similarly to enhance the stability of the basal spacing of tobermotire, which results in the increase of anomaly.
