Blastfurnace slag; 2ii068, 2ii074, 3ii082, 3ii093, 3ii095, 3ii096, 3ii098, 3ii099, 3ii101, 3ii102, 3ii103, 3ii104, 3ii115, 3ii122, 3iii009, 3iii017, 4iv001, 4iv005, 4iv009, 4iv015, 4iv035, 4iv040, 4iv063
Blended cement; 1i020, 3ii089, 3ii091, 3ii111, 3ii114, 3ii115, 3ii121, 3v026, 4iv004, 4iv017, 4iv020, 4iv052,
Bogue calculation; 1i039, 3v007, 3v009
Borax; 1i036
Bottom ash; 3ii090
Bound water; 2ii072, 3iii019, 3v019
Brick; 3ii080
Brownmillerite; 1i022, 2ii029, 2ii032,
Burnability of raw mixes; 1i021, 1i030, 1i031, 1i034, 1i040, 1i041, 1i045, 1i048, 1i054
Burning conditions of clinker; 1i018, 1i023

C
Calcium carbonate; 1i042
Calcium aluminate; 2ii022, 2ii025, 2ii050, 3iii022, 3v005
Calcium aluminate cement; 2ii024, 2ii026, 2ii027, 2ii028, 3iii007, 3v018, 4iv003, 4iv025, 4iv026
Calcium aluminate sulphate; 2ii010, 4iv068
Calcium aluminozincates, 1i059
Calcium hydroxide; 2ii049, 2ii059, 3ii082, 3ii106, 3ii107, 3ii108, 3ii112, 3iii031, 3v019, 4iv067
Calcium fluoride; 1i032, 2ii042
Calcium langbeinite; 2ii011
Calcium nitrate; 3iii012
Calcium phosphate; 1i036
Calcium phosphate cement; 2ii063
Calcium silicate; 1i035, 1i055, 2ii055, 2ii050, 2ii062, 4iv054
Calcium sulphate; 1i012
Calorimetry; 2ii021, 2ii025, 2ii041, 2ii066, 3iii032, 3v016, 3v017, 4iv042
Capillary; 2ii048
Carbon dioxide; 1i024, 2ii032, 4iv010
Carbonation; 2ii073, 4iv003, 4iv004, 4iv005, 4iv006, 4iv010, 4iv017, 4iv026, 4iv035, 4iv048, 4iv070, 4iv084
Case studies; 4iv002
Cement; 3ii092
Cement hydration equation; 2ii061, 4iv052
Characterization; 1i008, 2ii062, 3ii088, 3v011, 3v020 3v023, 3v026, 4iv019
Chemical analyis; 3v012
Chemical attack; 4iv015, 4iv026, 4iv028, 4iv031
Chemical prestressing; 3iii016

Chemical shrinkage; 2ii069, 2ii070, 2ii072
Chloride; 1i002, 1i012, 2ii030, 3ii118, 4iv006, 4iv015, 4iv027, 4iv078, 4iv080, 4iv081, 4iv082, 4iv083
Chloride Binding; 4iv016, 4iv069, 4iv070, 4iv078
Classification; 4iv046
Clay; 2ii020
Clinker; 1i048, 1i058
Clinker composition; 1i028, 4iv036
Clinker formation; 1i004, 1i006, 1i008, 1i010, 1i011, 1i026, 1i031, 1i037, 1i043, 1i044, 1i046, 1i049, 1i054, 2ii006, 3ii118
Cluster; 1i003
Coal; 1i047, 3ii090
Composite cements; 1i009, 2ii016, 2ii034, 3ii122
Composition; 2ii007, 2ii071, 3v004, 3v011, 3v026, 4iv007, 4iv023, 4iv060
Concrete; 2ii035, 3ii108, 3iii024, 3iii029, 3v021, 3v022, 4iv025, 4iv035, 4iv073
Cooling of clinker; 3v005
Corrosion; 2ii006, 4iv014, 4iv020, 4iv023, 4iv027, 4iv028, 4iv030, 4iv038, 4iv039, 4iv071, 4iv082, 4iv084
Creep; 4iv018
Cross-linking; 3iii011
Crystal; 2ii015
Crystal size; 1i051, 3iii031
Crystal structure; 1i055, 2ii048
Crystallisation pressure; 4iv049
Crystallography; 2ii054
CSH; 2ii044, 2ii047, 2ii053, 2ii055, 2ii059, 2ii064, 2ii067, 2ii068, 3ii082, 3ii093, 3ii121, 3v001, 3v003, 4iv016, 4iv041, 4iv043, 4iv061, 4iv074, 4iv076
Curing; 2ii037, 2ii078, 3ii091, 4iv055, 4iv059, 4iv067

D

Deformation; 4iv021, 4iv058
Degree of hydration; 2ii051, 2ii053, 2ii062, 2ii077, 3v019, 4iv016
De-icing salts; 4iv006, 4iv035
Delayed ettringite formation; 4iv059, 4iv061, 4iv062, 4iv063, 4iv064
Delayed expansion; 3iii016
Design life; 4iv071
Dicalcium silicate; 1i017, 1i053
Differential thermal analysis; 2ii041, 4iv031
Diffusion; 2ii046, 3ii084, 3ii098, 4iv010, 4iv015, 4iv016, 4iv056, 4iv080, 4iv081
Diffusivity; 4iv008, 4iv009
Dilation; 4iv033
Dispersion; 2ii005
Disposal; 1i027
Dopant; 1i053
Drying; 3iii018, 3v018, 4iv011, 4iv077, 4iv079
Durability; 2ii011, 3ii095, 3iii024, 3v022, 4iv004, 4iv007, 4iv022, 4iv023, 4iv026, 4iv029, 4iv030, 4iv037, 4iv040, 4iv046, 4iv048, 4iv062, 4iv065, 4iv070, 4iv075, 4iv082

E
Economy; 1i036, 3ii114
Ecology; 1i043
Electron microscopy; 1i060
Electron spectroscopy for chemical analyses (ESCA); 2ii044
Electrical conductivity; 4iv011
Electrical impedance; 3ii112
Electrical properties; 4iv079
Electrical resistivity; 3v021
Energy; 2ii046
Environment; 1i003, 3ii093
Equilibria; 2ii057, 2ii058
Ettringite; 1i025, 2ii006, 2ii010, 2ii017, 2ii029, 2ii031 2ii056, 2ii070, 2ii074, 3iii022, 4iv012, 4iv018, 4iv031, 4iv060, 4iv062, 4iv065
Evaporable water; 3v019
Expansion; 2ii006, 2ii074, 3iii017, 3v022, 4iv057, 4iv060, 4iv062, 4iv064
Expansive cement; 1i001, 2ii010
Extraction methods; 3v020

F
False set; 3iii013
Ferrite phase; 1i008, 1i015, 1i060, 3iii005, 3v003
Ferroaluminate; 4iv029
Filler; 1i020, 2ii002, 2ii020, 3ii081, 4iv056
Fineness; 1i007, 2ii001, 2ii002, 2ii018, 2ii043, 2ii060, 3ii088, 3v008, 4iv060
Fingerprinting; 3v010, 3v011
Fire; 4iv073
Fire damage; 4iv067
Flow; 2ii017, 3v024
Flue gas desuphurisation product; 3ii090
Fluidity; 2ii001, 2ii002, 2ii012
Fluoride phases; 2ii043, 3v002
Fly ash; 3ii081, 3ii082, 3ii083, 3ii084, 3ii085, 3ii086, 3ii087, 3ii088, 3ii089, 3ii090, 3ii110, 3ii115, 3ii116, 3ii122, 3v006, 3v020, 3v021, 4iv004, 4iv009, 4iv012, 4iv019, 4iv020, 4iv023, 4iv058, 4iv077
Fracture mechanics; 2ii075
Free lime; 1i016, 1i045, 2ii049, 4iv036
Freeze-thaw damage; 2ii016, 3iii019, 4iv034, 4iv035
Freezing; 4iv033
Friedel's salt; 4iv027, 4iv080
Fuels for clinker making; 1i013, 1i019

G
Gel; 3ii105, 3iii007, 3iii022, 4iv074
Glass; 1i046, 1i051, 3ii088, 3ii119, 4iv030, 4iv055
Grinding aids; 2ii020, 3v014
Grinding technology; 1i009, 1i040

Ground silica; 3ii120
Grout; 2ii005
Gypsum; 2ii040, 2ii044, 2ii060, 3ii093, 3ii115, 3iii025, 3v008, 3v023, 4iv017

H
Hardening; 2ii008, 2ii034, 2ii039, 2ii047, 2ii052, 2ii054, 2ii076, 3ii112, 3v016, 4iv071
Heat capacity; 4iv033
Heat evolution; 2ii021, 2ii035, 2ii051, 2ii076, 2ii077, 3ii102, 3ii105, 3iii029, 3v016, 4iv042, 4iv072
Heavy metals; 1i043, 2ii014, 3v010, 3v013, 4iv041, 4iv043
High alumina cement; 2ii023, 2ii033, 3iii010, 3ii096, 4iv013, 4iv027, 4iv038
High performance; 2ii035, 2ii038, 3ii108, 3v006, 3v021
High strength; 2ii037, 3ii120
High sulphate clinker; 2ii011
High temperature; 3ii111, 3iii020, 4iv067
Humidity; 4iv011, 4iv079
Hydration; 1i022, 1i057, 1i059, 2ii004, 2ii006, 2ii008, 2ii007, 2ii012, 2ii013, 2ii015, 2ii019, 2ii021, 2ii022, 2ii023, 2ii024, 2ii025, 2ii026, 2ii028, 2ii029, 2ii030, 2ii031, 2ii033, 2ii035, 2ii036, 2ii039, 2ii040, 2ii041, 2ii042, 2ii043, 2ii044, 2ii046, 2ii047, 2ii050, 2ii052, 2ii055, 2ii057, 2ii058, 2ii061, 2ii067, 2ii069, 2ii070, 2ii078, 3ii089, 3ii094, 3ii097, 3ii099, 3ii100, 3ii101, 3ii102, 3ii107, 3ii116, 3ii118, 3ii119, 3iii008, 3iii014, 3iii015, 3iii019, 3iii025, 3v006, 3v016, 3v018, 4iv072, 4iv071
Hydrothermal synthesis; 1i017

I
Identification; 3v010
Image analysis; 4iv084
Immobilization; 2ii014, 2ii016, 2ii052, 4iv043, 4iv045
impact prediction; 1i003
Impact evaluation; 1i003
Induction period; 2ii019, 2ii055
Infra red absorption spectra; 3ii104
Inhibitor; 3iii033
Interfacial zone; 4iv050, 4iv051, 4iv053, 4iv056, 4iv084
Interground cements; 1i013, 3v026
Interstitials; 2ii007
Ion exchange resin; 4iv045
Ionic assocoiation, 4iv083
Ions; 2ii036, 2ii046, 2ii065, 3iii012, 3iii013, 4iv075, 4iv079
Iron mud; 1i021
Isomorphism; 1i059

K
Kinetics; 1i005, 1i035, 1i044, 1i052, 2ii019, 2ii023, 2ii028, 2ii043, 2ii055, 3ii098, 3iii008, 4iv076

L
Latex; 3iii008
Leaching; 2ii014, 4iv012, 4iv041, 4iv043, 4iv045
Light microscopy; 3iii031, 3v007
Lignosulphonates; 2ii004, 3iii013, 3iii021
Lime; 2ii049, 2ii074, 3ii084, 3iii005, 4iv010
Limestone; 1i047, 1i048, 2ii022, 4iv018
Long age; 2ii016, 4iv050
Low energy; 1i034, 2ii045
Low temperature; 1i018, 1i029, 1i037, 2ii009, 2ii013, 2ii038, 3iii014, 3v017
Lumos; 2ii079

M
Magnesium chloride; 4iv022
Magnesium sulphate; 4iv022
Magnesium oxide; 1i023, 2ii064, 3v012
Magnesium phases; 1i057
Mass spectroscopy; 3v014
Maturity; 3ii111
Macro Defect Free; 3iii010, 3iii011, 4iv013
Mechanical properties; 3v025
Mechanism; 1i046, 2ii025, 2ii026, 2ii035, 2ii050, 2ii057, 2ii058, 3ii100, 3iii003, 3iii006, 3iii012, 3iii025,, 3v014, 4iv074
Melt; 1i008, 1i011, 1i012, 1i014, 1i029, 1i046, 3v005
Mercury Intrusion Porosimetry; 3ii104
Metakaolin; 3ii113, 3ii114, 4iv011
Method; 2ii021, 3v011, 3v013, 3v016, 3v018, 3v022, 3v023, 4iv081
Microcrack; 4iv021
Microgravity; 2ii075
Microscopy; 1i029, 1i030, 1i039, 1i051, 1i052
Microstructure 1i038, 1i039, 1i047, 1i049, 1i052, 2ii008, 2ii014, 2ii018, 2ii037, 2ii064, 2ii075, 3ii091, 3ii095, 3ii096, 3ii099, 3iii014, 4iv005, 4iv015, 4iv025, 4iv037, 4iv047, 4iv050, 4iv051, 4iv053, 4iv055, 4iv068, 4iv084
Mineralisers in clinker making; 1i028, 1i030, 1i031, 1i033, 1i034, 1i037, 1i050, 3v002
Mineralogy; 1i046, 3ii087, 3ii105
Mineral phase; 1i015, 2ii009, 2ii015, 4iv028
Mixing procedure; 3ii120
Mobility; 2ii065, 4iv083
Modelling; 1i038, 1i044, 1i045, 2ii048, 2ii052, 2ii078, 3ii085, 3ii084, 3iii013, 3v004, 4iv005, 4iv070, 4iv071, 4iv073, 4iv078
Modified cement; 2ii004, 2ii020, 3ii085, 3ii097, 3ii104, 3iii021, 3iii023
Moisture; 2ii079, 3iii011,3v004, 4iv010, 4iv013, 4iv062
Molybdic compounds; 1i054, 1i055
Monosulphate; 2ii056
Mortar; 4iv033

N
Naphtalene Formaldehyde Sulphonate; 3iii003, 3iii009, 3iii030
Nitrate attack; 4iv002
Nodulization in clinker formation; 1i007
Non-equilibrium burning; 1i011
Nuclear Magnetic Resonance; 1i024, 2ii028, 2ii056, 2ii067, 2ii068, 3iii007, 3v001, 3v002, 3v003, 3v004, 3v005, 3v006

O
Oilwell cement; 2ii013, 3iii014
Organic; 3v015
Osmotic pressure; 4iv049

P
Packsetting; 2ii079
Particle size distribution; 1i009, 2ii018, 2ii053, 3ii110, 3v024
Pattern recognitin; 3v010
Penetration; 2ii005, 2ii038, 3ii109, 4iv080
Performance; 4iv073
Permeability; 4iv008, 4iv075
Petroleum coke; 3ii090
pH; 4iv065
Phase composition; 3ii091
Phase diagram; 1i050, 1i052, 2ii024, 2ii057, 2ii058, 4iv066, 4iv074,
Phase transition; 4iv033
Phase transformation; 4iv034
Phosphate; 4iv057
Physical properties; 3v025
Plasticizers; 2ii020
Polymer; 3iii008, 3iii009, 3iii010, 3iii027, 4iv013
Polymorphs; 1i053
Pore size distribution; 4iv077
Pore solution; 2ii036, 3iii003, 3iii013, 3iii022, 3ii091, 4iv040, 4iv069
Pore structure; 2ii037, 2ii066, 3ii111, 3iii009, 3iii018, 3v017, 4iv001, 4iv005, 4iv080
Porosity; 2ii036, 2ii048, 2ii066, 2ii072, 3ii085, 3ii119, 3iii023, 3v017, 4iv006, 4iv007, 4iv008, 4iv013, 4iv017, 4iv024, 4iv040, 4iv048, 4iv054, 4iv078
Portland cement; 3ii107, 3iii006, 3v025, 4iv012
Potentiometry; 4iv083
Powder; 2ii002
Pozzolana; 1i020, 2ii073, 2ii077, 3ii106, 3ii107, 3ii108, 3ii112, 3ii115, 3ii117, 3ii123, 3ii124, 3v001
Pozzolanic cement; 4iv036
Pozzolanic reaction; 3v006
Pozzolanic reactivity; 3ii088
Pre-calciners for clinker making; 1i028
Prehydration; 2ii079
Process parametres; 1i047

Q
Qualitative; 1i004, 3v010, 3v011, 3v015
Quantitative; 1i039, 1i056, 3v007, 3v012, 3v013, 3v015, 3v020
Quartz; 1i048

R
Rapid hardening cement; 2ii017
Rate equations; 1i044
Reaction products; 4iv049
Reactivity; 1i016, 1i018, 1i047, 1i060, 2ii049, 2ii050, 3ii082, 3ii109, 3ii110, 3v020, 4iv016, 4iv050
Refractory; 2ii027, 4iv053, 4iv057
Relative humidity; 2ii073
Residual silica; 4iv049
Retarders; 3iii007, 3iii020, 3iii032
Rheology; 2ii003, 2ii004, 2ii011, 3iii003, 3iii027
Rice husk; 1i019
Rice Husk Ash; 3ii108, 3ii109, 3ii110
Rietveld analysis; 1i039, 1i056, 3v007
Roller compaction; 3ii086
Rotary kiln; 1i007, 1i019

S
Salt scaling; 4iv001
Scanning Electron Microscopy; 1i002, 2ii078, 3ii083, 3ii120, 3iii008, 3v019, 4iv037, 4iv064
Sea water; 4iv025
Secondary ettringite formation; 4iv065
Self deccication; 2ii073
Setting; 1i038, 2ii019, 2ii039, 2ii053, 2ii063, 3ii101, 3ii112, 3iii006, 3iii012, 3iii023, 3iii026, 3v008
Sewage; 3ii123, 3ii124, 4iv038, 4iv039
Shotcreting; 3iii027
Shrinkage; 1i032, 3iii018, 4iv036, 4iv056
Silica; 3ii080
Silica colloid; 3ii106
Silica fume; 2ii037, 3ii105, 3ii106, 3ii110, 3ii116, 3ii120, 3v001, 4iv014, 4iv069
Silica modulus; 1i035
Silicate; 2ii060, 3iii027, 4iv065
Simulation; 2ii078, 3iii001
Sintering; 1i005, 1i007, 1i022, 1i032
Slag; 1i020, 3ii080, 3ii092, 3ii094, 3ii097, 3ii100, 4iv050, 4iv051, 4iv058

Pore structure, chemical interactions and their influence on permeability and diffusivity of gases, liquids and dissolved ions

UTILIZATION OF HIGH SLAG BLASTFURNACE CEMENT FOR HIGH-PERFORMANCE CONCRETE - INFLUENCE OF PORE STRUCTURE AND PERMEABILITY

Eberhard LANG and Jürgen GEISELER, Forschungsgemeinschaft Eisenhüttenschlacken, Duisburg, Germany

Abstract Blastfurnace slag cement has been demonstrated to possess very good properties when utilized as binder for High Performance Concrete (HPC). The porosity of this concrete is very low and the impermeability against organic chemical liquids is very high. HPC is an excellent material for catchment tanks in the chemical industry. Due to its low porosity the freeze-thaw and deicing agent resistance is very high without artificial air voids.

Keywords: Blastfurnace slag, Pore structure, Salt scaling, Superplasticizers,

INTRODUCTION

Results of laboratory investigations as well as long experiences in practice indicate the special benefits of blastfurnace slag cements. This is because of their comparatively low capillary porosity, their high resistance against sulphate attack, against alkali-aggregate reaction and to the diffusion of chlorides into the concrete. Recent research has also shown a high binding capacity of chlorides in blastfurnace slag cement pastes. A further aspect of importance for the corrosion protection of reinforcecement is the comparatively low electrical conductivity of concrete made with blastfurnace slag cement. Due to their low heat of hydration, blastfurnace slag cements help to prevent cracks in concrete structures resulting from temperature stresses at early ages (Weber et al. (1991); Geiseler, Kollo, Lang (1995); Geiseler, Lang (1994)).

EXPERIMENTAL DETAILS

Materials

Blastfurnace slag cement CEM III/A 42,5 (slag content of 50%) and CEM III/B 32,5 (slag content of 77%) were used. Silica fume was used in form of a slurry with a water content of 50%. The coarse and fine aggregates consisted of natural gravel and sand from the Rhine area and crushed air-cooled blastfurnace slag with a particle size distribution of 2/8 mm and 8/16 mm. Different types of superplasticizers were used and this paper highlights the use of superplasticizer based on sulfonated melamine formaldehyde, naphthalene sulfonated polymer, lignosulfonates and poly-carboxylate.

Test Methods

The mortars were tested in accordance with the EN 196 and concrete in accordance with the German standard DIN 1048. The pore size distribution was measured by a Mercury pressure porosimeter series 4000 by Carlo Erba in the range 1.85 to 7500 nm radius. The freeze-thaw and deicing salt resistance of concrete was determined according to Rilem draft recommendation for test method for the freeze-thaw-resistance - tests with sodium chloride solution - CDF (Capillary suction of Deicing solution and Freeze thaw test), RILEM (1995).

The impermeability was tested by a method of the DAfStb (1992). The samples were drilled cores with a length of 150 mm and diameters of 80 mm. These were stored in water at 20°C for seven days and then stored until 56 days at 20 °C and 65% relative humidity. In order to achieve a one-dimensional transport process the cores were sealed at their circumferential surfaces. During the test the burette was filled rapidly with the test liquid to a level of 500 mm above the

sample, and the exact initial level recorded from the graduations. During the subsequent 72-hours test the quantity of liquid which had penetrated could be observed at time intervals which allowed the rate of absorption to be determined.. After 72 hours the cores were unwrapped and split parallel to the longitudinal axis, and the visible penetration front of the liquid was recorded.

RESULTS AND DISCUSSION

Selection of Superplasticizer

From mortar tests the optimal type of superplasticizer for CEM III were selected. Figure 1 shows the influence of the w/c-ratio of different superplasticizers. All these mortars had the same consistence than the normalized mixture with a w/c-ratio of 0.50. Some plasticizer reduced the w/c-ratio in combination with silica fume more than other. In combination with high slag blastfurnace cements superplasticizer based on naphthalene sulfonated polymers showed optimal results with reference to the workability, strength development and modulus of elasticity, for instance FM 1. The water-reducing ability of Ca-lignosulfonates was lower and the early strength was very low in comparison with all the other types of plasticizer. But generally the strength after 28 days is higher and especially the heat of hydration is reduced.

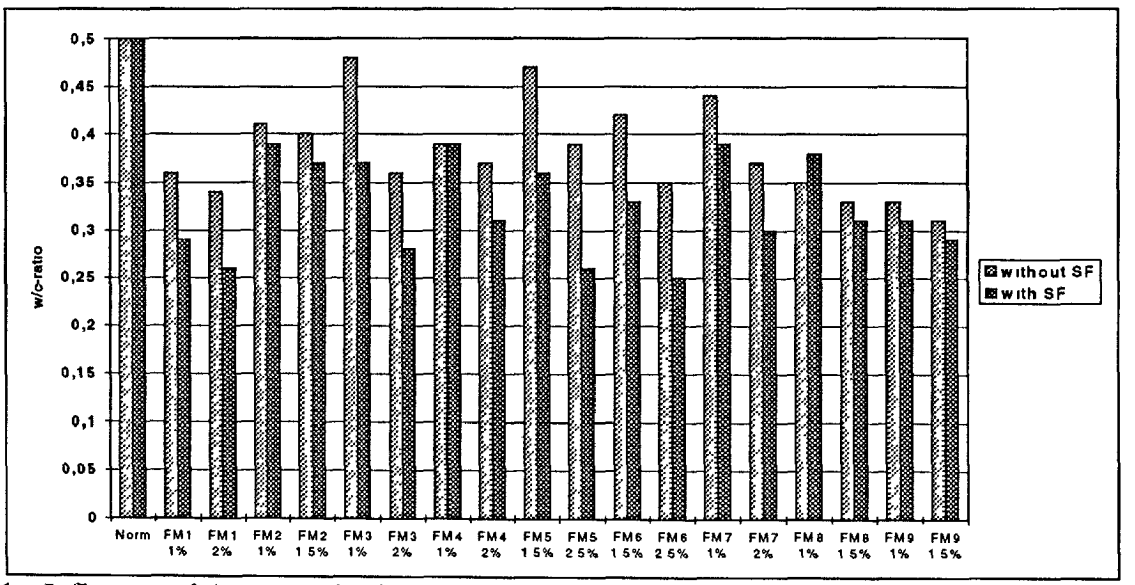

Fig 1 Influence of the superplasticizer of the w/c-ratio of CEM III/B 32,5 with and without silica fume

A statistical series of tests was used to find the optimal content of plasticizer and silica fume for different properties of the cement mortar. Figure 2 (for instance) shows the results of CEM III/A 42,5. Using these results it is possible to minimize the content of silica fume and plasticizer in relation to the desired properties. HPC with high slag blastfurnace cement can be produced without silica fume if the demand for the early strength after two days is lower than 35 MPa. Aptitude tests are necessary.

Porosity

Figure 3 shows the different pore size distribution of CEM IIII/A 42,5 with the superplasticizer FM 1 and two different contents of silica fume. The workability of these four mortars were the same. The capillary porosity > 30 nm was reduced with and without silica fume in the same range. The age of the samples was 28 days. The change of pore size distribution after 28 days is very low.

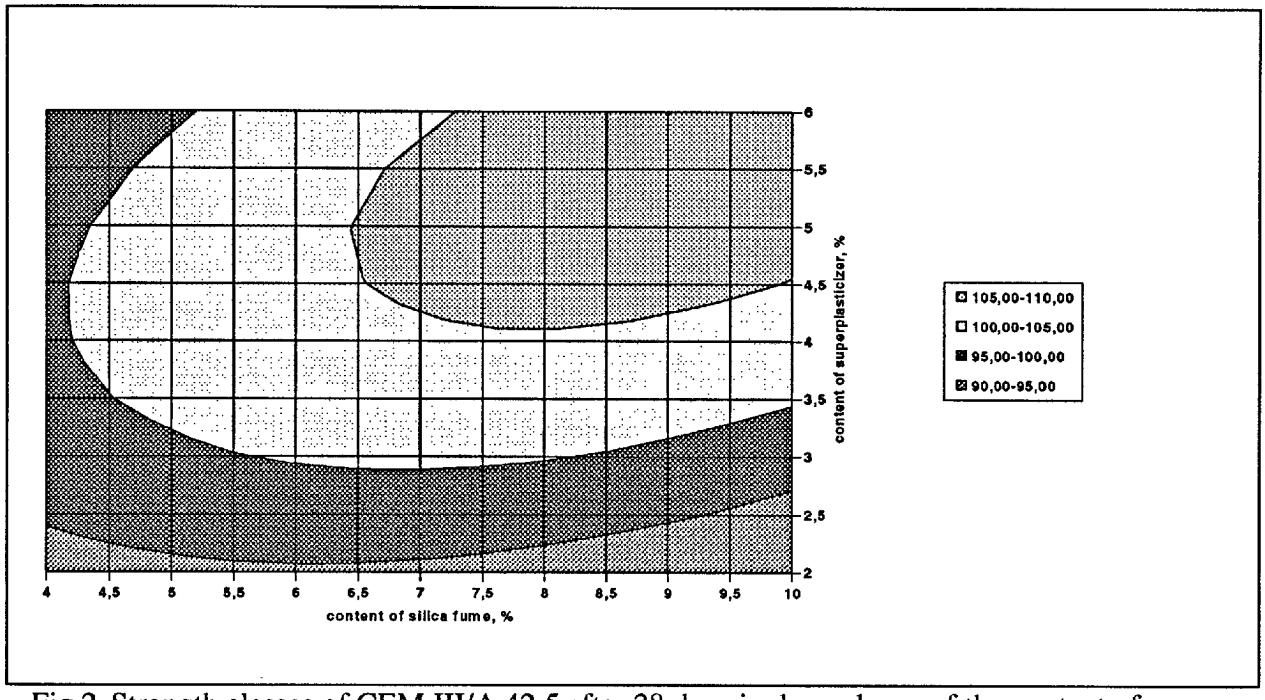

Fig 2 Strength classes of CEM III/A 42,5 after 28 days in dependence of the content of superplasticizer and silica fume

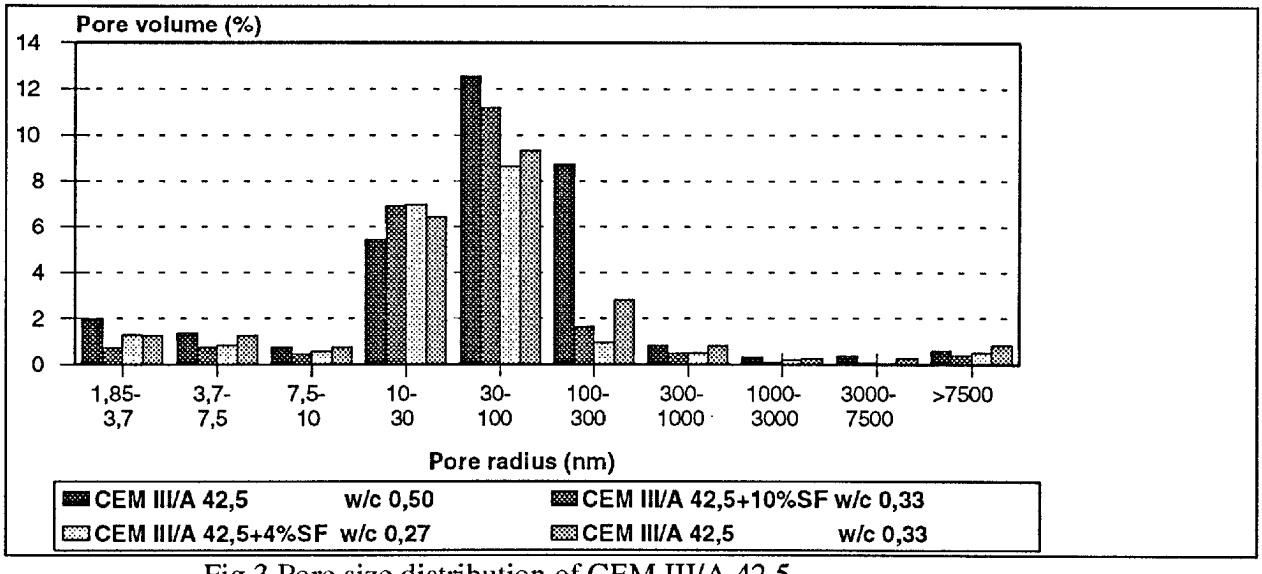

Fig 3 Pore size distribution of CEM III/A 42,5

Impermeability to organic liquids

The chemical industry catchment tanks made of uncoated concrete are secondary retaining barriers for limited periods of time (in general ≤ 72 hours) if the storage tank is damaged. The capillary porosity of concrete with blastfurnace slag cement is lower than of concrete with Portland cement and the chemical resistance in general is higher. Thus a lot of catchment tanks in Germany have been constructed with blastfurnace slag cement. It is for this application why the impermeability of HPC was tested. The research on this field is continuing. Figure 4 gives first results for the penetration depth of 4 different chemical liquids. The ordinary concrete has a cement content of 320 kg/m³ and a water/cement-ratio of 0.50.

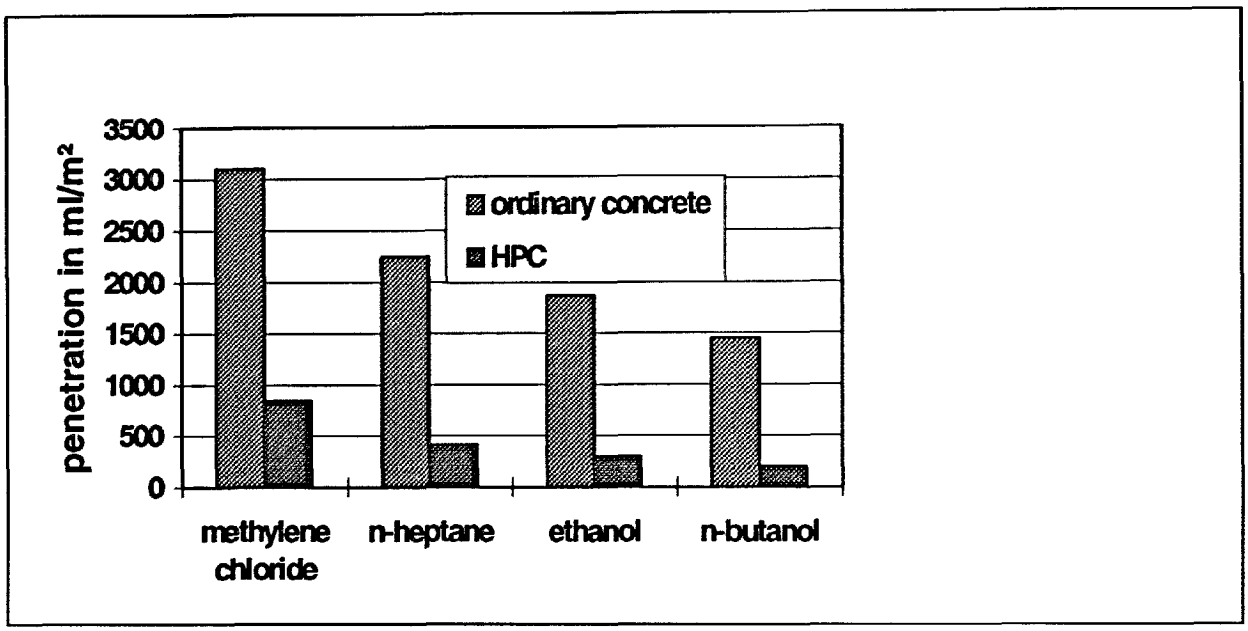

Fig 4: Impermeability of ordinary and high performance concrete

Freeze-Thaw-Resistance

The scaling of ordinary concrete with CEM III/A 42,5 tested by CDF with 3% NaCl-solution ranged between 1000 and 1500 g/m² and for CEM III/B 32,5 between 1500 and 2500 g/m². The scaling of HPC with CEM III/A 42,5 is lower than 300 g/m² and for CEM III/B 32,5 is lower than 1500 g/m². In practice, concretes with blastfurnace slag cements are known to have adequate freeze-thaw resistance having been observed in many sewage clarification plants and waterway constructions in marine environments.

CONCLUSION

All types of blastfurnace slag cements may be used for high performance concrete. The low capillary porosity of concrete made with blastfurnace slag cements is further decreased in HPC significantly but only marginally by the additional use of silica fume. This is the reason why the impermeability of concretes is improved in the same sequence. HPC made with blastfurnace slag cement has a high freeze-thaw-resistance even without air-entraining agents.

ABSTRACT
The degree and the effect of the incorporation of air polluting agents (primarily SO_2 and NO_2) into concrete was investigated, partly by case studies (old concrete structures in chemical-industrial zones or on busy highways), and partly by laboratory tests, on paste and mortar specimens made of different cements and subjected to different atmospheres. Results indicate considerable increase of sulfates in the external layers of concrete structures. Highest sulfate uptake (and lowest pH) was observed in case of concrete incorporating blastfurnace slag.

Key-words: air pollution, acid attack, sulfate attack, nitrate attack, case studies

INTRODUCTION
Worldwide urbanisation and industrialisation cause an increase of some conventional components of the air (e.g. carbon dioxide), and of some polluting ingredients (e.g. sulfur and nitrogen oxides). These affect not only human health, but may have deteriorating effects even on materials considered durable, such as concrete. Several air pollution maps exist (in Hungary air pollution is monitored and mapped by the National Health Authority). According to these data, the most important pollutants - from the point of concrete - are the sulfur and nitrogen oxides, which acidify the air (rainwater of pH = 4 is by no means an exception), and these acid constituents can get into the concrete by dry or wet precipitation through capillaries. The effect of dusts and aerosols is indicrect.

Several researchers have dealt with the response of concrete to the increase of air-CO_2 (Junge, 1963; Levelook, 1971) and other pollutants (Scholl and Knöfel, 1991; Weawer, 1988), and even equations have been derived to predict the mechanism of deterioration (Hensel, 1985). The authors' first observation regarding this topic was when crumpling concrete cover of a concrete railway bridge was investigated and found its gypsum content to be the sevenfold of the original quantity, introduced by the raw materials. The bridge was in the vicinity of a sulfuric acid factory. After this first observation, phenomena has been investigated by case studies and model experiments.

CASE HISTORIES
Table 1. shows some data on old (older than 20 years) reinforced concrete structures being in the vicinity of industrial zones or mass traffic highways. (Percentages in the table refer to cement weight). Some general conclusion can be drawn from these results.

Sulfate (SO_4^{--}) content was the highest in the external layers (less than 1 cm) of the concrete. It was not rare that the quantity of SO_4^{--}-ions here was here three times the normal. In case of low-strength concrete structures, or those being within polluting chemical plants, sulfates were concentrated in the deeper zones (this could be partly attributed to the action of rainwater too).

It is hard to estimate the role of age/strength interrelationships, but it is a fact that the highest SO_4^{--}-concentration was measured in the external layer of the oldest structure.

The structure being most remote from sources of pollution (the Dömös column foundation) showed - in spite of its age - practically no increase of the sulfate content. The nitrate (NO_3^-)-concentration of the structures was considerable in the external layers only, with the exception of a column in a chemical factory, where it was quite high, even in the deeper layers.

(age: 30 years)							

Comparing pH values in the various layers it can be concluded that pH is the lowest in the oldest and crumpled (i.e. low strength) layers. This decrease can be mostly attributed to carbonation, although, in heavily polluted areas other acid media can affect the concrete.

MODEL TESTS

Description of the tests

Starting from industrial raw materials, (ground to 350 m^2/kg Blaine) three sorts of cements were made by a thorough mixing and homogenisation:

- Ordinary Portland cement (OPC)
- Blastfurnace slag-cement, with 40% slag (BFSC)
- Fly-ash cement, with 20% fly ash (FAC)

Prismatic specimens (size 10 × 10 × 50 mm) were made of cement paste (W/C = 0.4) and of mortar (W/C = 0.5, sand fineness max 1 mm). Specimens were removed from the mould after 24 hours and stored in room temperature, 100% R.H. space for 28 days. After that four sides of the mortar prisms were coated with an epoxy paint and all specimens transferred to experimental chambers, containing the following atmospheres:

200 ppm SO_2
80 ppm NO_2
3 vol.% CO_2
air.

The gas mixtures were kept in motion by a fan.

Results with paste specimens

pH values of paste prisms change only slightly, even after 90 days of exposure. **Table 2** shows results. Although changes are slight, it still can be observed that CO_2 affects pH to the highest extent.

Table 2. pH of paste prisms after 90 days of exposure

Type of cement	Starting pH	Curing atmosphere			
		air	CO_2	SO_2	NO_2
OPC	13.05	12.71	12.48	12.65	12.55
BFSC	13.00	12.59	12.00	12.52	12.46
FAC	13.06	12.70	12.39	12.56	1257

The change of sulfate-ion quantity in function of time is shown in **Fig 1**. Independently on cement type, it slightly increases in the beginning; the rate of increase is higher between 90 and 180 days. This increase, at the end of the experiment, was approx. 2.5-, 3- and 6-fold, for FAC, OPC and BFSC, respectively. A yellowish-white salt efflorescence was observed after 90 days in OPC and BFSC pastes; in case of the latter, this salt scaled off after 180 days (**Fig. 2**).

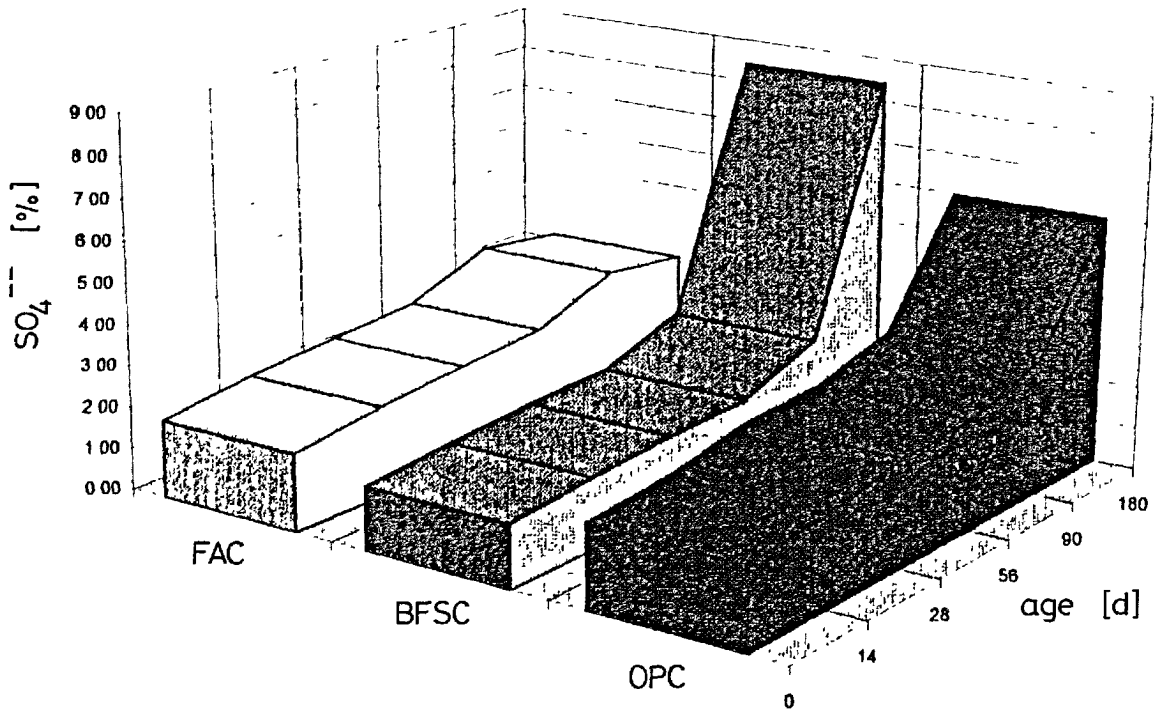

Fig. 1. Change of sulfate ion content, as a function of time, of pastes made of different cements

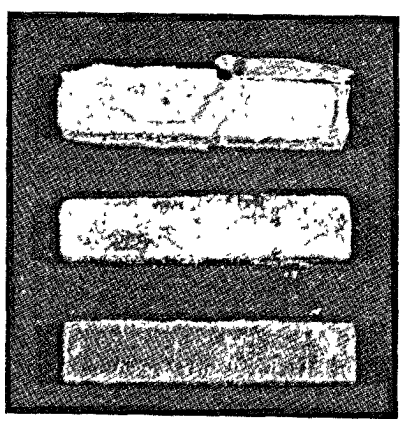

Fig. 2. Light layer on the surface of an OPC paste specimen

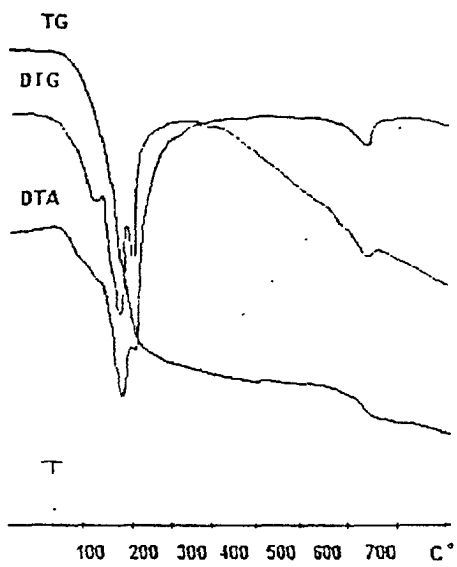

Fig. 3. Thermal curves of the layer

Approx. 80% of this layer consisted of gypsum, as shown by thermoanalytical tests (**Fig. 3**). The origin of this secondary gypsum can be studied with the aid of **Table 3**, which shows the $Ca(OH)_2$ and $CaCO_3$ content of the samples (again by TGA) before the experiment and after 90

days of SO_2-curing. It is evident, that the loss in $CaCO_3$ was - almost independently of cement type - somewhat less than 50%, while the loss of $Ca(OH)_2$ was definitely the highest in case of BFSC, and the lowest in OPC.

The change of nitrate ion quantity in function of time is shown in **Fig. 4.** It is evident that measurable amounts of nitrate could be observed already after 14 days, and by the end of the experiment this increased to 1.2 - 1.4, almost independently of cement quality.

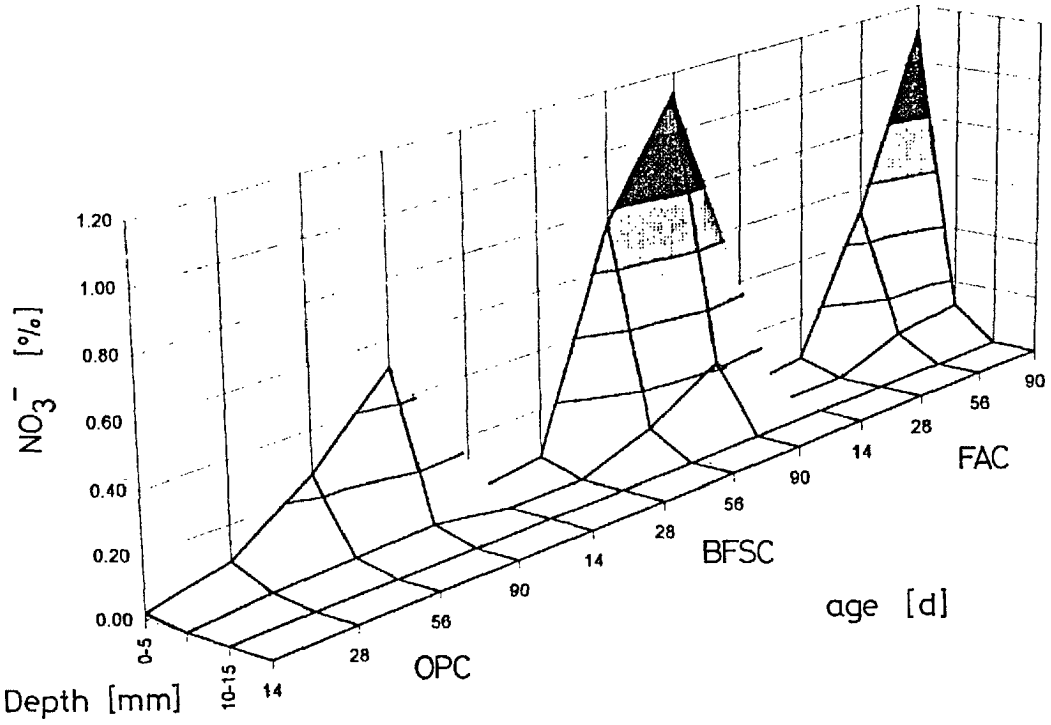

Fig. 4. Change of nitrate ion content, as a function of time, of pastes made of different cements

Table 3 Thermoanalytical results of SO_2-cured paste samples

	Time of curing	H_2O loss of $Ca(OH)_2$		CO_2 loss of $CaCO_3$	
Cement type	[days]	Quantity [%]	Change [%]	Quantity [%]	Change [%]
OPC	0	3.82	-	9.08	-
	90	3.50	-8	4.95	-45
BFSC	0	2.69	-	6.73	-
	90	1.79	-34	2.39	-44
FAC	0	2.95	-	8.87	-
	90	2.57	-13	4.36	-49

Results with mortar specimens

These specimens, being coated by an impermeable layer on their sides, give a possibility to study the depth of corrosive gases. pH values of 90-day old mortar specimens are shown in **Table. 4.**

Table 4. pH values of mortar specimens after 90 days of curing in SO_2 and NO_2.

Cement type	Layer depth	Starting value	Curing atmosphere	
			SO_2	NO_2
OPC	0 - 5	12.42	12.22	12.13
	5 - 10	12.48	12.15	12.26
	10 - 15	12.50	12.16	12.30
	15 - 25	12.51	12.17	12.28
BFSC	0 - 5	12.26	10.60	11.91
	5 - 10	12.26	10.75	11.95
	10 - 15	12.26	11.00	11.97
	15 - 25	12.27	11.20	11.98
FAC	0 - 5	12.35	11.75	11.92
	5 - 10	12.35	11.93	12.02
	10 - 15	12.35	12.00	12.05
	15 - 35	12.36	12.01	12.08

Most intensive reduction of pH can be observed in case of BFSC-mortars, in SO_2 atmosphere; here pH is reduced by one full degree (i.e. hydroxide ion concentration by one tenth), even in deeper layers. pH reduction was less, and least, in case of FAC- and OPC-mortars, respectively.

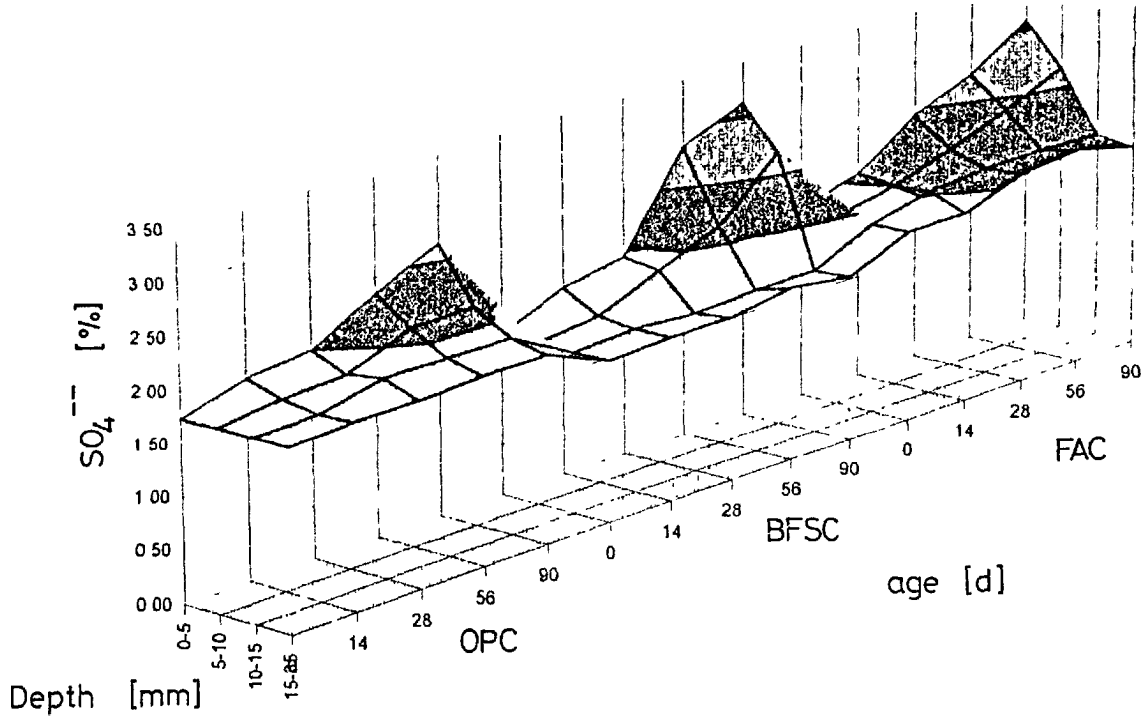

Fig. 5. Change of sulfate ion content, as a function of time, of mortars made of different cements

Increase of sulfate ions, as a function of time is shown in **Fig. 5.** Increase is evident in case of all cements, especially in the external layers, where this increase amounted 1.5-, 1.6- and 2-fold of the original SO_4^{--} content, in OPC, FAC and BFSC, respectively. **Fig. 6** shows a layer, formed on the end of a mortar specimen, subjected to SO_2 gas flow for several hours. 84% of this layer consisted of gypsum, as shown by the thermal tests.

Nitrate ion content in different depths of mortars is shown in **Fig. 7.** No nitrate was found, up to 90 days in layers deeper than 10 mm. In shallower layers nitrates were incorporated, but not to the same extent in case of different cements. Again OPC proved to be superior, where the highest NO_3^--content was only 0.5%, as contrasted to the two other cements, where the nitrate content was approx. the double of the above value.

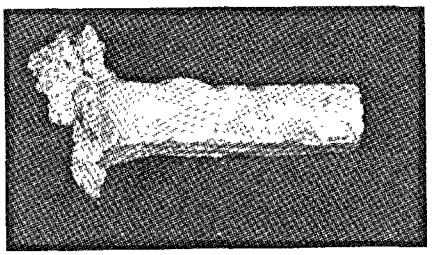

Fig. 6. Layer on a specimen subjected to SO_2 flow

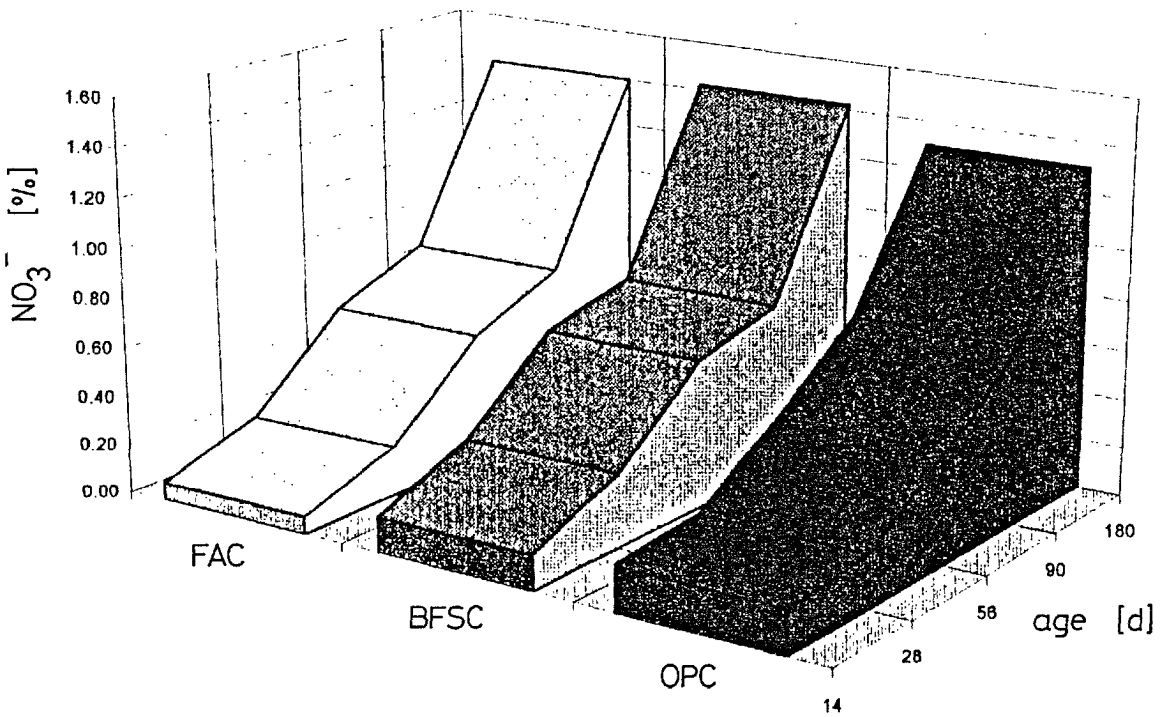

Fig. 7. Nitrate ion content in different depths of mortar specimens

SUMMARY

The degree and the effect of the incorporation of air polluting agents (primarily SO_2 and NO_2) into concrete was investigated, partly by case studies (old concrete structures in chemical-industrial zones or on busy highways), and partly by laboratory tests, on paste and mortar specimens made of different cements and subjected to different atmospheres. Results indicate considerable increase of sulfates in the external layers of concrete structures. Highest sulfate uptake (and lowest pH) was observed in case of blastfurnace slag containing cements. The effect of NO_2 is less intensive: nitrate incorporation amounted to 0.05 - 0.08%, even in case of intensive pollution (with the exception of a structure in a chemical factory, where nitrate content exceeded 6%.

In laboratory experiments OPC showed the least sulfate incorporation, while in case of BFSC, the original sulfate content was doubled after a 180-day exposition to an SO_2-enriched atmosphere. In some cases even a gypsum layer appeared on the surface, formed mainly of the $Ca(OH)_2$-content of the hydrated cement. No significant difference of various cement sorts exists in the response of samples to an atmosphere containing 80 ppm NO_2, although the presence of blastfurnace slag proved to be disadvantageous even in this case.

CARBONATION OF HYDRATED CALCIUM ALUMINATE CEMENT AND ORDINARY PORTLAND CEMENTS OF VARYING ALKALI CONTENT

Mª Teresa GAZTAÑAGA, Sara GOÑI, Ana Mª GUERRERO and Mª Soledad HERNANDEZ, Institute of Construction Science Eduardo Torroja (CSIC), Madrid, Spain.

ABSTRACT Carbonation in laboratory atmosphere (40%-50% rh) of a Hydrated Calcium Aluminate Cement (HCAC) and two Hydrated Ordinary Portland Cements (HOPC) of varying alkali content (1.03% and 0.43% Na_2O equivalent) was studied during a period of 800 days from mixing. The kinetic of the process was followed from the $CaCO_3$ content by means of thermogravimetric analysis. The evolution of the new crystalline carbonated compounds was studied from X-ray diffraction (XRD).

Key-words: Carbonation, alkali, calcium aluminate cement, thermogravimetric, X-ray Diffraction Analysis.

INTRODUCTION

The known problems in structures fabricated in Spain with calcium aluminate cement, between 1950 and 1975, have induced the Spanish researches, in the last years, to intensify the investigation on degradation processes of this kind of cement. Specially, those related to the composition of expressed pore solution, due to the important role that pore solution plays either in the stability of its microstructure or corrosion of metallic reinforcements (Goñi et al. (1991), Gaztañaga et al, (1993), Goñi et al. (1994), Puertas et al. (1995), Goñi et al. (1996), Gaztañaga (1996) and Macias et al. (1996), among others). The present paper is part of an extensive investigation program related to the influence of both ambiental and accelerated 100% CO_2 carbonation on the microstructrue of hydrated calcium aluminate cement (HCAC) and two kinds of hydrated ordinary Portland cements (HOPC) of varying alkali, C_3A and C_3S contents (Gaztañaga, (1996)). The ambient carbonation process is presented in this work. It was studied by X-ray diffraction (XRD) and Themogravimetric analyses during a period of 800 days.

EXPERIMENTAL PROCEDURE

Pastes of two ordinary Portland cements called OPC-1 and OPC-2, of varying alkali and Al_2O_3 contents, and a Fondu Calcium Aluminate Cement (CAC) were prepared with deionized water at a water-to-solid ratio of 0.4. Table 1 and Fig 1 present the chemical composition and XRD analysis of the three cements. The mineralogical composition of both OPC-1 and OPC-2, calculated according to the Bogue equations, is shown in Table 2.

Table 1. Chemical composition of the cements.

(%)	IL	IR	SO_3	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O
OPC-1	3.5	1.6	3.4	19.2	5.9	4.2	59.9	0.58	0.42	0.92
OPC-2	2.0	0.98	3.4	20.6	3.2	3.9	64.3	1.4	0.13	0.45
CAC				2.7	43.5	14.2	38.5	0.44	0.046	0.082

* I.L.= ignition loss
* I.R.= insoluble residue

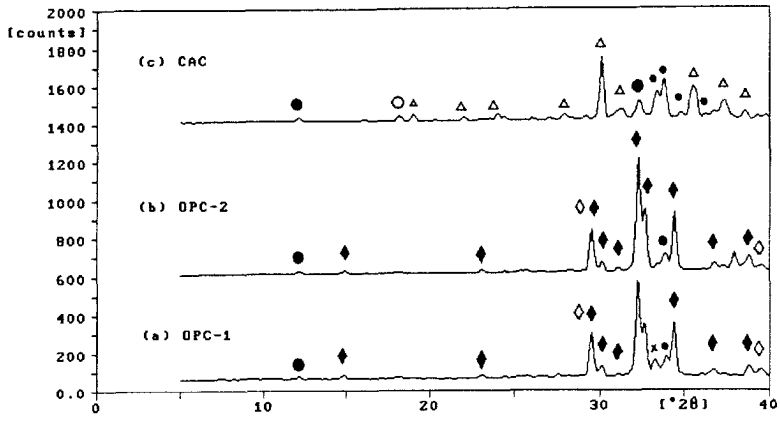

Figure 1 XRD analysis of the unhydrated cements: ● C_4AF; ♦ C_3S; × C_3A; ▲ CA; o $C_{12}A_7$.

Table 2 Mineralogical composition according to Bogue equations (%) by weight.

Cements	C_3S	C_2S	C_3A	C_4AF
OPC-1	43	23	8.5	12.8
OPC-2	68	7.5	1.9	11.9

The OPC-1 has the higher content of both alkali (1.03 Na_2O equivalent) and C_3A (8.5%) in comparison with that of OPC-2: 0.43% (Na_2O equivalent) and 1.9% for C_3A. There are also remarkable differences between the C_3S and C_2S contents for the two cements (Table 2). Series of 12 (1x1x6 cm) specimens were kept at 100% rh and 20±2°C for periods up to 800 days. After 28 days of curing at 100% rh, similar series of samples were stored at the laboratory atmosphere (40%-50% rh) (0.03% CO_2) for equivalent periods.

RESULTS AND DISCUSSION

X-Ray Diffraction Analysis

As shown in Fig. 2, when the three samples were stored during 800 days at 100% rh and 20±2°C, calcite is the only $CaCO_3$ variety formed (see curves (b) in Fig. 2). The intensity of the calcite-XRD-reflections are the highest, whereas those of portlandite ($Ca(OH)_2$) are the lowest, in the case of HOPC-1, what indicates its ability for carbonating even at 100% rh.

For the HCAC the carbonated crystalline compounds detected are the carboaluminate (C_4AcH_{11}) and calcite. The presence of both the cubic C_3AH_6 and hexagonal CAH_{10} shows that conversion has taken place.

In contrast, when the hydrated cements were stored during 800 days at laboratory ambient (40%-50% rh) (curves (a) in Fig 2) the three varieties of $CaCO_3$ (calcite, vaterite and aragonite) develop. Calcite is the predominant one for the HOPC-1 whereas vaterite is the predominant for the HOPC-2. The presence of vaterite could indicate the topochemical carbonation of CSH gel as Sauman (1971),(1972) and Berger (1979), among others, pointed out. The ettringite XRD-reflections disappear when the two HOPC samples are stored at the ambient, showing that ettringite could be carbonated. Accordingly the sulphate content in the extracted pore solution increases from 0.0006M to 0.01 for HOPC-1 samples stored at 100% rh and at laboratory ambient during 800 days, respectively, and from 0.0014M to 0.0022M in the case of equivalent HOPC-2 samples. These results suggest that the

mechanism of ettringite carbonation could be "via dissolution", although the pH of the pore solution (12.0) is considerably higher to that of ettringite dissolution (10.6) (Reardon, 1990).

Similar behaviour was observed and stated in a paper presented in this Symposium by Goñi et al (1997) on carbonation of OPC mortar with and without fly ash addition. The increase of sulphate content of the pore solution caused by carbonation of ettringite together with the decrease of pH are important factors to be considered from the point of view of the corrosion of metallic reinforcements. Kobayashi et al. (1989) also pointed out the release of SO_4^{2-} from ettringite and monosulphate carbonation, which could migrate to the external part of the concrete.

In the case of the HCAC the main carbonated crystalline compounds are the calcium carboaluminate C_4AcH_{11}, vaterite and aragonite. Calcite XRD-reflections appear less intense than those of the sample stored at 100% rh.

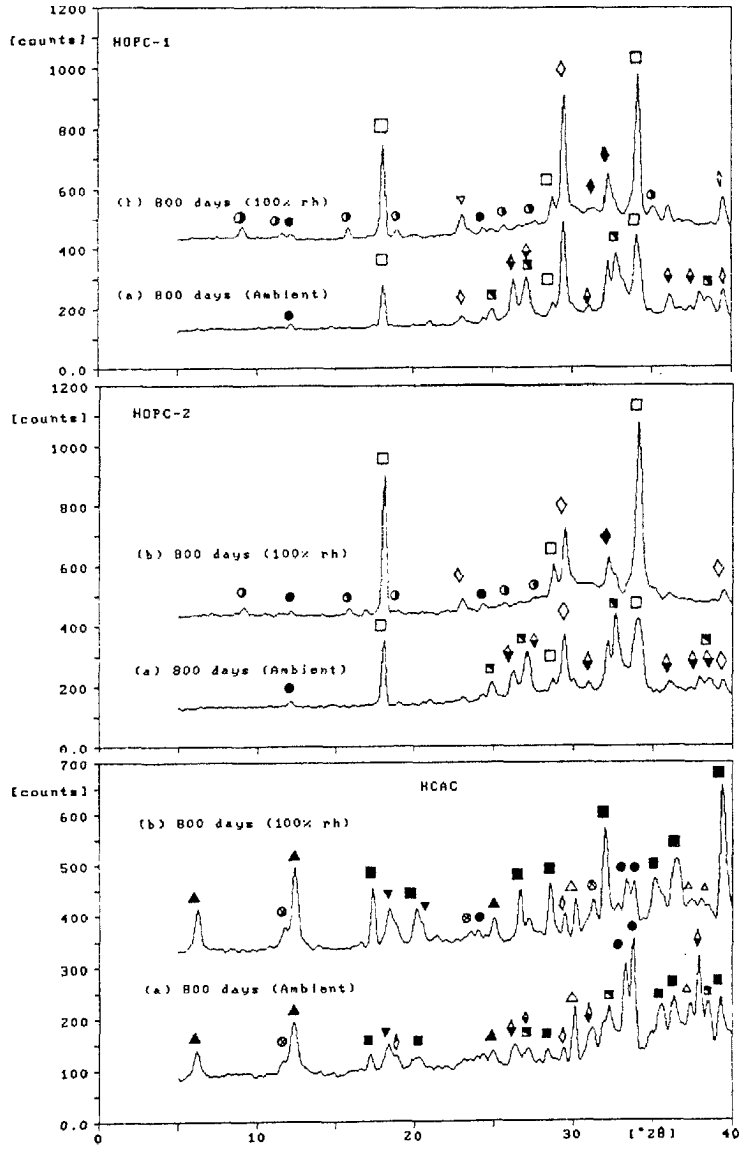

Figure 2. XRD patterns of carbonated samples: ● C_4AF; ♦ C_3S; × C_3A; Δ CA; ▲ CAH_{10}; ■ C_3AH_6; ▼ AH_3(gibbsite); ◊ AH_3(nordstrandite); ◊ Cc(calcite); ◆ Cc(aragonite); ◘ Cc(vaterite); □ CH; ◑ AF_t; ⊗ C_4AcH_{11}.

The XRD-reflections of hexagonal CAH_{10} and cubic C_3AH_6 are remarkably lower, specially those of cubic C_3AH_6, for the sample stored at the ambient. This fact would suggest that either conversion is inhibited, by carbonation of the hexagonal CAH_{10}, or both hexagonal and cubic are being carbonated. If the mechanism of carbonation is via dissolution, hexagonal CAH_{10} will dissolve firstly due to its high solubility product ($Ks = 10^{-7.6}$) in comparison with the cubic C_3AH_6 ($Ks = 10^{-22.3}$). In the former case the pH of dissolution of hexagonal will be 11.35 and in the later case 10.8. Due to this the dissolution of CAH_{10} caused by the neutralization of the pore solution will maintain the pH of the pore solution at a value of 11.35. In the case of carbonation of HOPC, the solubility of portlandite maintains the alkalinity levels of the pore solution at pH values of 12.5. For this reason, among others, ordinary Portland Cements are considered more resistant against carbonation than calcium aluminate cement.

Thermal Analysis

The decomposition of $CaCO_3$ produces a weight loss starting just after that of the portlandite, for the HOPC-2 (Fig. 3). The corresponding DTG curve shows a wide peak with several maxima centered at 620°C, 680°C and 770°C. The later intense peak is due to decomposition of the calcite variety of $CaCO_3$. The others maxima could be attributed to decomposition of either aragonite and vaterite, or to amorphous carbonate. The profile of TG and DTG curves of HOPC-1 are similar to those of HOPC-2. Portlandite is still present after 800 days of exposure to the ambient, as the XRD results also manifested.

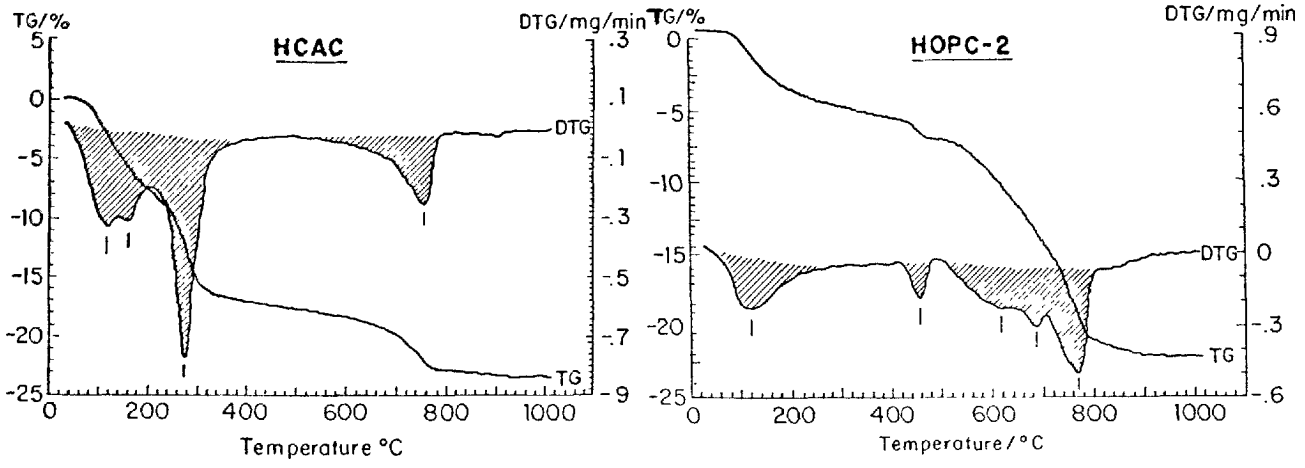

Figure 3. TG and DTG curves of HOPC and HCAC.

In the case of HCAC, the profile of TG and DTG curves is very different. The decomposition of carbonate from both the carboaluminate and $CaCO_3$ gives rise to a weight loss between 600°C and 800°C and a DTG peak centered at 780°C with a shoulder at 680°C.

According to Busnell-Watson and Sharp (1992), the water weight loss of AH_3 gel, hexagonal CAH_{10} and C_4AcH_{11} is produced between 60°C and 130°C; 100°C and 160°C and 180°C and 200°C respectively. The cubic C_3AH_6 decomposition takes place between 290°C and 350°C and that of crystalline gibsitte between 260°C and 330°C. These ranges of temperatures may vary upon different parameters such as; heating rate, amount of sample, dynamic atmosphere, etc.

As shown in Fig. 3 a double DTG peak is detected between 25°C and 200°C with the first maximum centered at 100°C which is due to the AH_3 gel decomposition and the second one centered at 150°C due to the CAH_{10} decomposition. The weight loss between 200°C and 350°C could be due to the water evaporation from both the crystalline gibsitte and cubic C_3AH_6 decomposition. The carboaluminate does not produce an valuable DTG peak.

The main parameters quantified from thermal analysis are presented in Table 3. The cumulative fraction carbonated (CFC) was calculated by dividing the corresponding carbonate contents (expressed as CaO) by the CaO content of unhydrated cements (see Table 1). The 0 days on the Table was the moment in which the samples were exposed to the ambient (after 28 days of curing at 100% rh).

As it can be seen in Fig 4, an inverse linear correlation, with a slope value = -0.47, is obtained between the $Ca(OH)_2$ content and the $CaCO_3$ content for both HOPC-1 and HOPC-2 materials. According to the (1:1) stoichiometry of the $Ca(OH)_2$ carbonation reaction, the value of the slope has to be 1. Therefore, other compounds than $Ca(OH)_2$ are being carbonated.

The same conclusion can be deduced from the higher value (-1.8) of the slope obtained when the combined water is plotted against the $CaCO_3$ content, which suggests that more water molecules are released than the needed for the $Ca(OH)_2$ carbonation reaction. The two last points, corresponding to the combined water of the more carbonated samples, are not considered for the correlation calculus because they probably content some water liberated during carbonation.

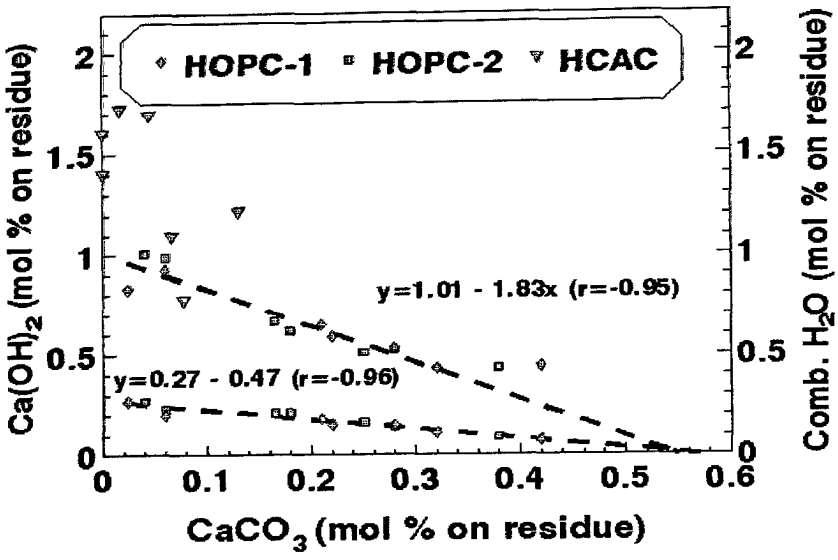

Figure 4. $Ca(OH)_2$ and combined water versus $CaCO_3$ content.

These results corroborated that CSH gel, and probably ettringite, are carbonated at the same time as $Ca(OH)_2$ as Parrot, (1991/92) and Dunster, (1989), among others authors, pointed out. Dunster (1989) stated that the carbonation of both $Ca(OH)_2$ and CSH occurs simultaneously, but a residue of $Ca(OH)_2$ reacts more slowly. This was considered to be consistent with a rate determining process controlled by the CO_2 diffusion through a $CaCO_3$ coating formed on the $Ca(OH)_2$ crystals.

In the case of HCAC, no correlation between the content of both combined water and $CaCO_3$ is obtained. The combined water values are considerably higher than those of HOPC, which indicate the lower porosity of these samples (Gaztañaga, 1996). As expected, when the cumulative fraction carbonated is plotted versus the square root of time (Fig. 5), a linear correlation is found suggesting that diffusion is the rate-controlling of $CaCO_3$ formation.

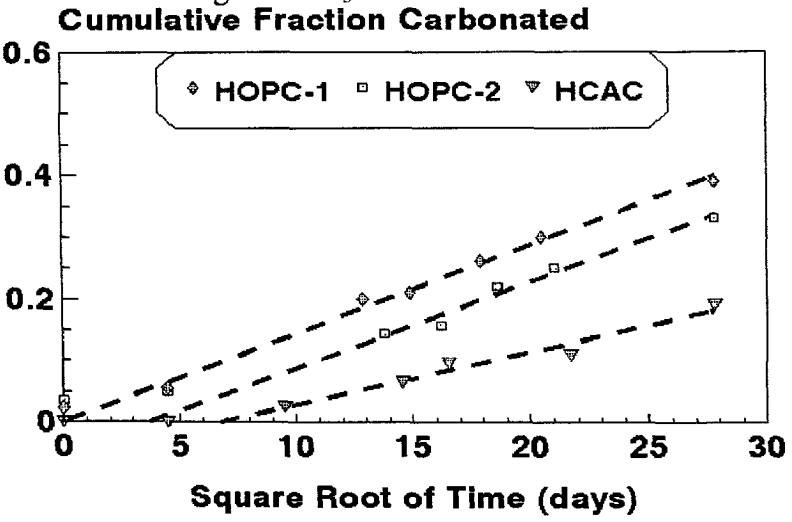

Figure 5. Cumulative fraction carbonated versus time.

HOPC-1 and HOPC-2 have the same slope values (Table 4) but the induction period is longer for the HOPC-2. In contrast, the slope value of HCAC is the lowest and its induction period is the longest.

Table 4 Parameters of the linear correlations of Fig. 5

Cements	r	a	Slope (CFC-day$^{0.5}$)	Induction time (days)
HOPC-1	0.996	0.002	0.014	0
HOPC-2	0.987	-0.05	0.014	13
HCAC	0.981	-0.058	0.0086	46

These results seem to show that the alkali content of the cements do not play any role from the point of view of ambient carbonation, which is in disagreement with the results of Kobayashi and Uno (1990), who found higher carbonation rates for cements with higher alkali content. An hypothetical explanation to this disagreement could be related to the different content of C_3S and C_2S (43% and 23% for OPC-1 and 68% and 7.5% for OPC-2). The minor amount of C_3S in the case of HOPC-1, of higher alkali content, could counteract the action of alkalies. For example, the porosity and pore mean diameter of the HOPC-1 at 28 days of curing (0 point on the graphs) are higher (11.5% and 0.041 μm) than those of HOPC-2 (9.4% and 0.024μm) favouring the initial CO_2 penetration. Accordingly, the absence of induction period can be also explained.

The lowest porosity of HCAC at 28 days of curing (4%) could be one of the microstructural reasons to explain its larger induction period and slower carbonation rate. Information on either porosity and strength changes will be published in a next work. Finally, it is important to take into account that although the HCAC seems to be more resistant against carbonation (during the period studied), its low carbonatable materia (CaO content) could, at longer carbonatable periods of exposure, be consumed before than that of HOPC.

CONCLUSIONS

HCAC presents the lowest carbonation rate during the period studied, that could be due to its lowest porosity. Nevertheless, the lowest amount of carbonatable material in the case of HCAC, could facilitate, at longer carbonation periods, the total carbonation of samples. The hexagonal CAH_{10} to cubic C_3AH_6 conversion is inhibited by the carbonation process. The amount of alkalies of HOPC does not influence the carbonation rate due to the different C_3S content of the two HOPC-1 and HOPC-2 materials. CSH gel and ettringite are carbonated at the same time than portlandite. Consequently SO_4^{2-} ions are released to the pore solution.

MICROSTRUCTURAL CHARACTERIZATION OF THE CARBONATION OF MORTAR MADE WITH FLY ASHES.

Sara GOÑI, Cruz ALONSO, Esperanza MENENDEZ, Ana HIDALGO and Carmen ANDRADE, Inst. EDUARDO TORROJA of Const. Sc., Madrid, Spain.

ABSTRACT Present paper study the microstructural changes produced by the carbonation when fly ashes (FA) are used replacing OPC partially. The resistance to carbonation is significantly reduced when replacement of OPC by FA is higher than 15%. High FA contents (50%) induced changes in the microstructural properties and compounds of carbonated mortar.

Key-words: admixtures, fly ash, carbonation, durability, blended cement

INTRODUCTION

The carbonation of concrete is a matter of increasing concern since many structures have their surface directly exposed to the action of the atmosphere and the standards allow relatively low depth of covers. Carbonation of concrete normally involves a chemical reaction between atmospheric carbon dioxide and that of cement hydration products if there is sufficient pore water. An important consequence is that the alkalinity of the pore fluid drops from a pH > 12.5 to a value of about 8. At this point the risk of corrosion increases significantly (Alonso,1986,1987).The chemical changes induced by carbonation create also variations of microstructure i.e. porosity (Verbeck,1958, Parrot,1987).

Among the factors influencing carbonation rate, the type of cement has an increasing importance due to the increasing use of blended cements (Litvan,1986, Bijen,1991, Parrot,1996). In the case of fly ashes most of the knowledge has been developed in the kinetic of carbonation process (Bijen,1991, Malami, 1994, Torii,1994). However few studies have been done on microstructure changes induced by carbonation in presence of fly ashes. Present paper deals with the microstructural changes provoked by carbonation of mortar made with 0, 15, 35 and 50% replacement of OPC with FA. The influence of the acceleration of the process has also been studied at 100%, 5%, and at atmospheric CO_2 content.

EXPERIMENTAL PROCEDURE

Preparation of specimens

Four identical sets of mortar specimens of 1x1x6cm size were casted with OPC and partial sustitutions of fly ashes ASTM type F (15, 35 and 50%), whose chemical analysis are shown in Table 1. The mortars were prepared at an aggregate to cement + fly ash ratio of 1:3 and deionized water to cement + fly ash ratio of 0.5. Cement and fly ashes were first dry mixed in a mixer. After mixing the specimens were kept sealed for 24 hours in the mould. At the end of this period the specimens were demoulded and cured for 28 days in a humidity saturated chamber.

Table 1 Chemical analysis of the portland cement and fly ash.

%	I.L.	I.R.	SO_3	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O	Cl^-
Cement	1.53	1.92	3.89	19.9	3.05	4.12	63.7	1.55	0.13	0.45	0.02
Fly ash	5.77	0.19	0.00	46.9	17.3	18.1	5.83	1.65	0.54	2.30	0.00

Testing Methodology

After curing, one set of specimens (reference) were characterized by porosimetry, scanning electron microscopy, expressed pore solution analyses (Na^+, K^+, pH, $SO_4^=$, Ca^{+2}, $CO_3^=$ and HCO_3^-) and flexural strength. Similar set of specimens were exposed during one year to the laboratory atmosphere (40%-50%RH) for natural carbonation. Previously to start the accelerated carbonation, the other two sets of specimens were conditioned at 65% RH. Afterwards, the accelerated carbonation started at both 5%CO_2 or 100% CO_2 gas flow. The carbonation evolution was determined several times during the process, by spraying phenolphthalein (pH indicator solution) on a piece of fresh fractured specimen. At the end of the test, the specimens were characterized through the same techniques that those used for reference materials.

Porosimetry and pore size distribution were investigated by mercury porosimetry.The SEM observation was accompanied by simultaneous microanalysis. The pore solution was extracted by a high pressure device. The Na^+ and K^+ concentration were determined by atomic absorption spectroscopy, and sulphate concentration by ion chromatography. The pH was measured using a combined electrode for the range 0 to 14.

Table 2 summarizes the testing time for each condition. High FA contents significantly reduced the carbonation time.

Table 2 Duration of carbonation for the various fly ash additions and type of carbonation.

Test Cond.	Carbonation time (days)			
	0% FA	15% FA	35% FA	50% FA
Reference	0	0	0	0
Natural	365	365	365	365
5% CO_2	365	365	175	99
100% CO_2	365	365	35	24

RESULTS

Pore solution analyses

The composition of the expressed pore solution at the begining and at the end of the carbonation processes is represented in Fig 1. As shown the pH data are good indicators for the carbonation state. The higher the replacement of cement with fly ash is, the higher the pH drops for the three carbonation conditions. The total neutralization of the pore solution, according to the phenolphthalein indicator (pH<9), is only achieved for accelerated carbonation in the presence of high fly ash content. After 1 year of natural carbonation, the pH value of the pore solution is still high except in that of high FA content (50%), which seems to indicate that the total carbonation has not been reached, at least in the pore solution. This is probably due to the highest uncarbonated content of $Ca(OH)_2$ in plain OPC. As a consequence of carbonation, alkalies (Na^+ and K^+) are dramaticaly removed from the pore solution (Fig 1).

An opposite behaviour is observed with $SO_4^=$ ions as they dramaticaly increase with carbonation process (Fig 1). This behaviour is stronger for accelerated carbonation and for the high cement replacement with fly ash (50%).

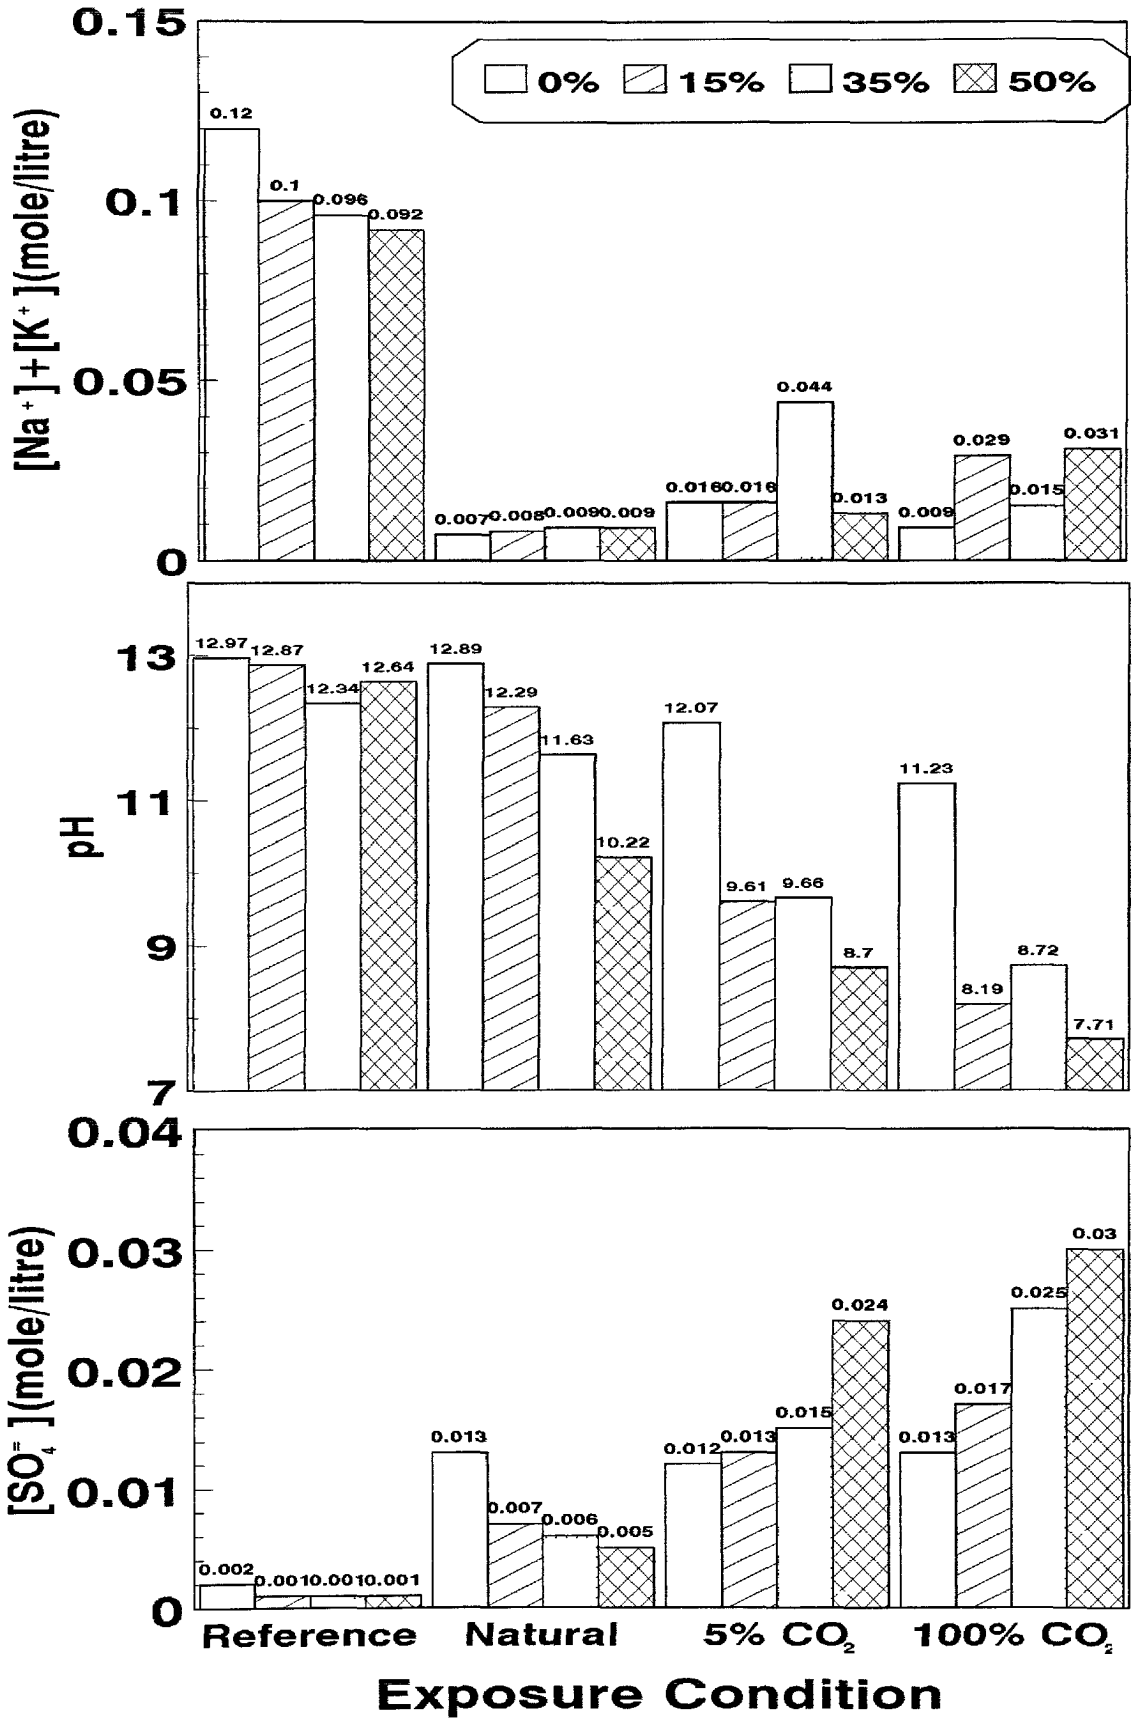

Figure 1 Pore solution analysis.

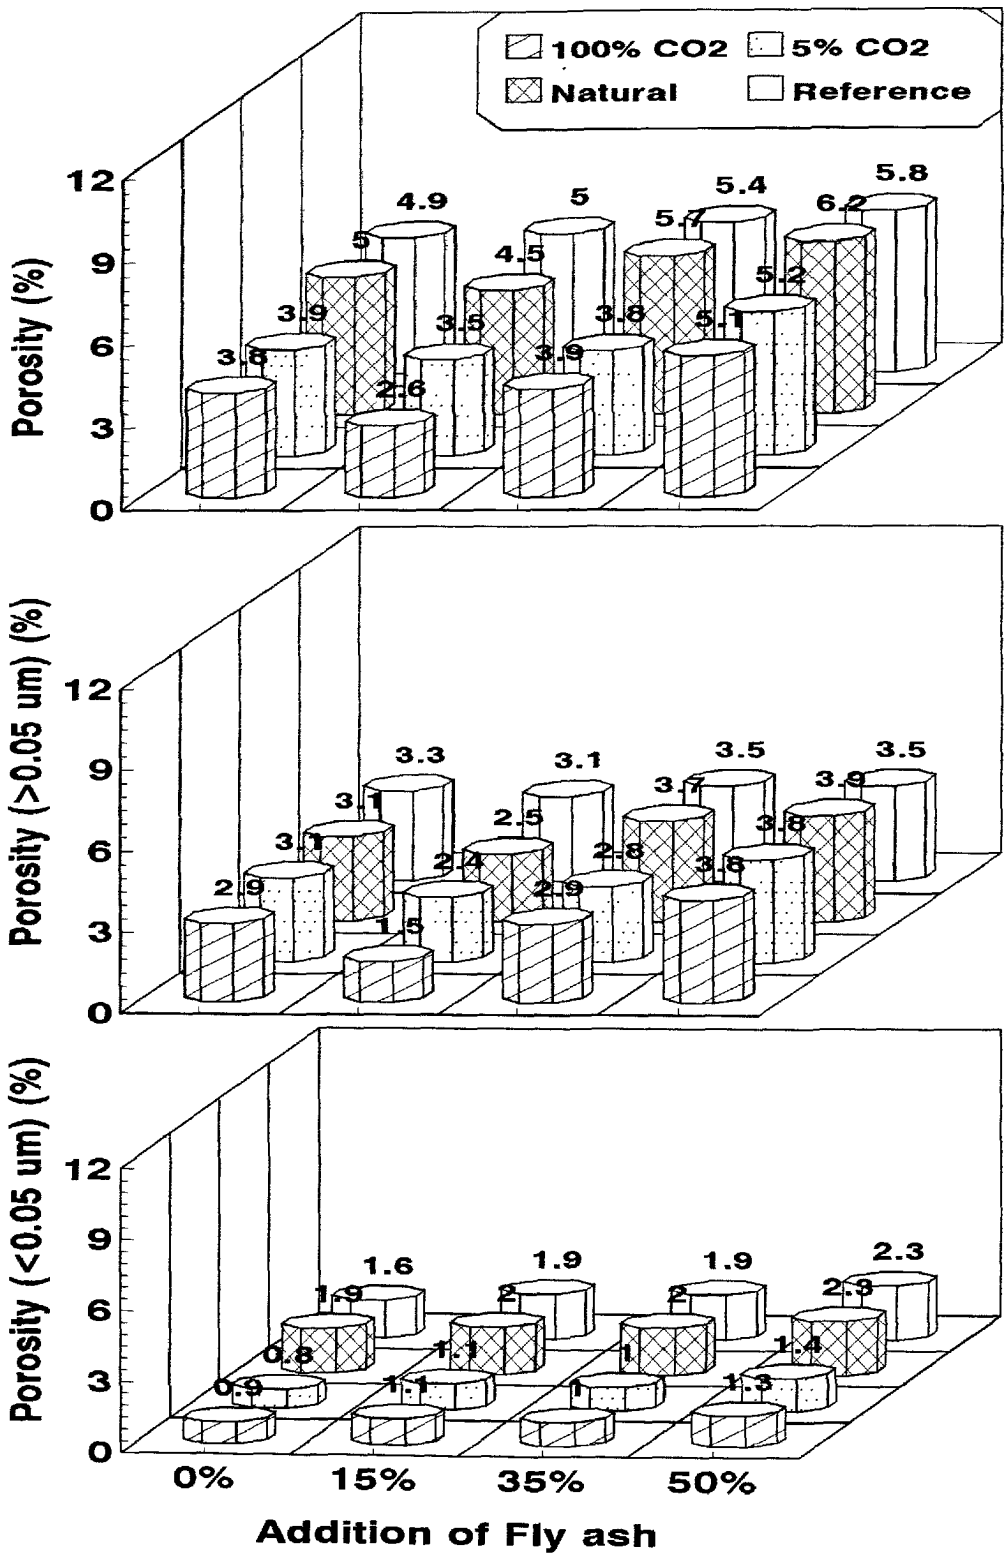

Figure 2 Porosity of the samples.

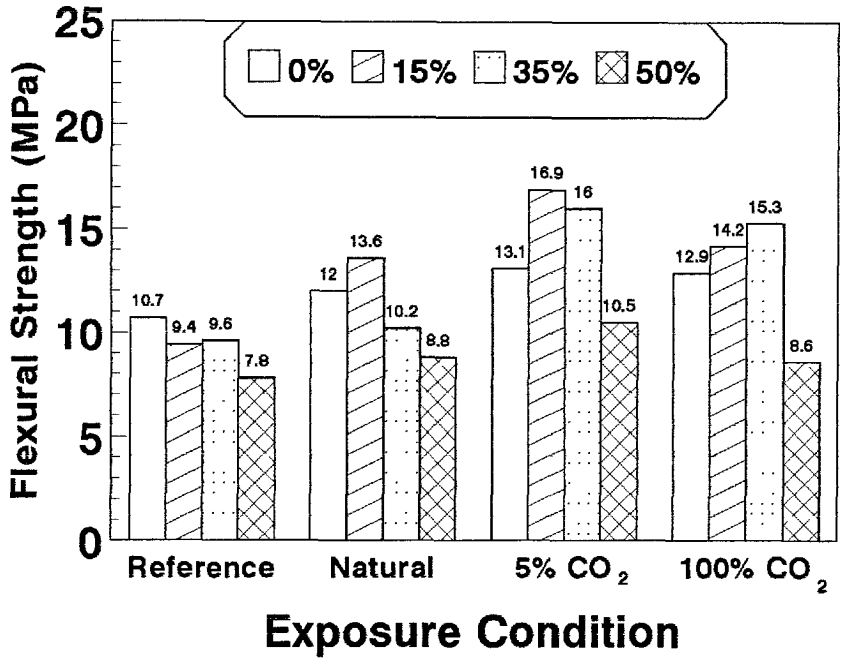
Microstructural and flexural studies

The changes of porosity caused by carbonation are represented in Fig 2. As expected, the decreasing total porosity is a funtion of the carbonation. In the case of the highest FA content (50% in present case), the changes in porosity have been less relevant than those of OPC (22% reduction in OPC respect to 12% with 50%FA). In general, both size pores (>0.05μm and <0.05μm), decreased as a result of the carbonation, being remarkable the decreasing percentage (45%) in the pores of lower size. The changes of mechanical flexural strength caused by the carbonation (Fig 3) are opposite to the porosity ones. So, an increase of the flexural strength is produced in all the samples.



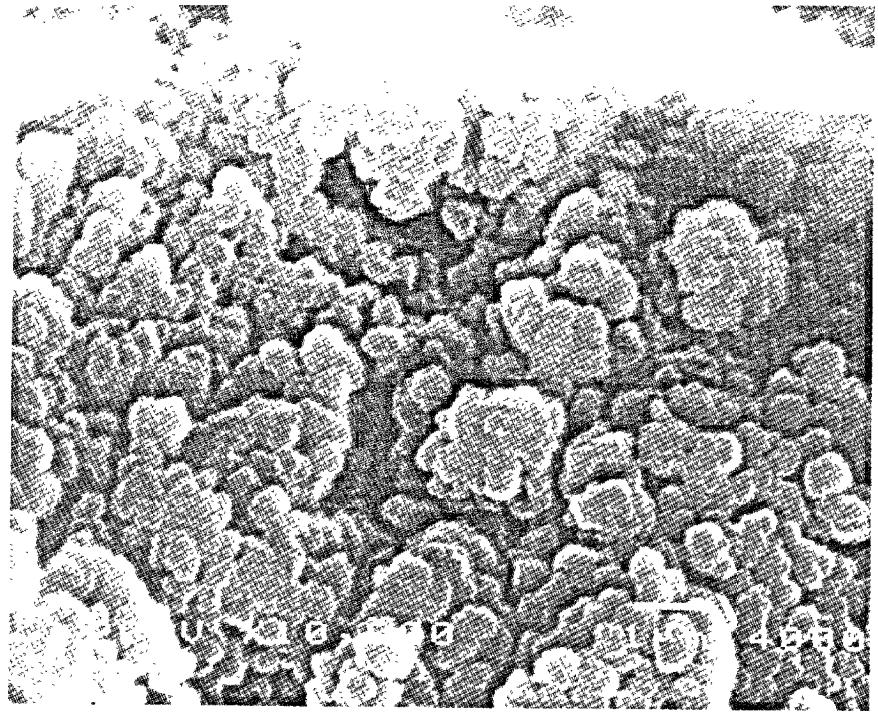


Figure 3 Flexural strength results.

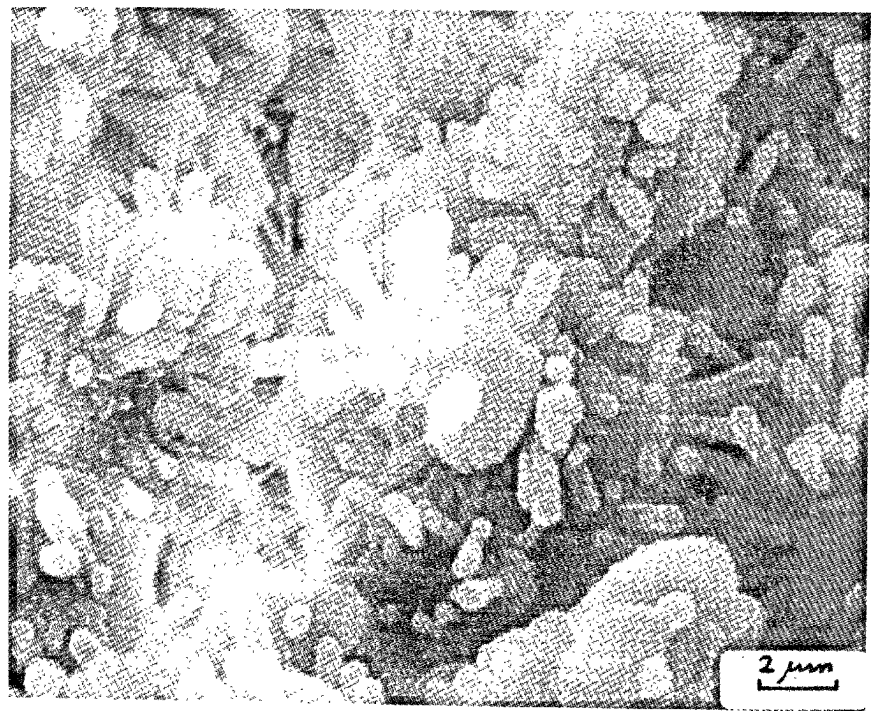

DISCUSSION

In general, for plain OPC concretes, the carbonation process involves the transformation of both the solid phase and pore solution. These changes result in a densification of the microstructure of the paste as the carbonation products fill the pore system obstructing the continuity of the pores. Nevertheless, the reasons for these changes, are still unkown, being a subject of discussions and controversy in the case of concrete made with pozzolanic additions.

According to the porosity changes the more relevant aspect is the lower reduction in porosity with high fly ash replacement.Similar results were found by Distler (1994) and Malami (1994) when using cement with low clinker or high fly ash content.There are some differences in behaviour if the carbonation is natural or accelerated. In the natural carbonation, after one year exposure, the total porosity decreases slightly with low fly ash content (<15%), whereas for higher additions of FA (35% and 50% in present experimentation) the total porosity increases slightly.This means that the material is almost not affected from the point of view of its porous microstructure. Although full carbonation results are necessary to confirm this behaviour. The

(a)

(b)

Figure 4. (a) SEM photograph of the mortar without fly ash addition, carbonated at 100% CO_2. (b) SEM photograph of a mortar with 50% fly ash addition, carbonated at 100% CO_2.

pore solution reveals that only in presence of FA the values of pH are below 12.5 where the dissolution of the portlandite has taken place. Nevertheless, these changes are not manifested in porosity, (see Fig 2).

When the carbonation is accelerated, the densification of the microstructure is clearly observed. The lower densification also occurs with high FA replacement. But in this case the samples are completely carbonated. SEM studies of mortar specimens (Figs 4(a) and 4(b)) confirmed that the OPC sample, carbonated with 100% CO_2 (a), has denser aspect than the one with 50% FA replacement (b).

On the other hand, the neutralization of the pore solution causes a dissolution of ettringite and CSH gel (Reardon (1990)), what justifies the dramatic increase of sulphate ions in the pore solution, as Kobayashi et al. (1989) and Gaztañaga et al. (1997) have also detected.

In Fig 5 the dissolution of ettringite needles is shown. The dramatic decrease of Na^+ and K^+ concentration could be due to their absorption by the solid hydrated phases in order to balance the decalcification of CSH gel, as other authors pointed out (Taylor (1990), Gaztañaga (1996). Page (1983), Sergi (1986). From X-ray diffraction data calcite and vaterite were the only crystalline carbonated phases detected irrespective of the carbonation rate, although the amount of vaterite increases with the percentage of fly ash sustitution. The natural exposure condition also promotes higher amounts of vaterite respect to 100% CO_2.

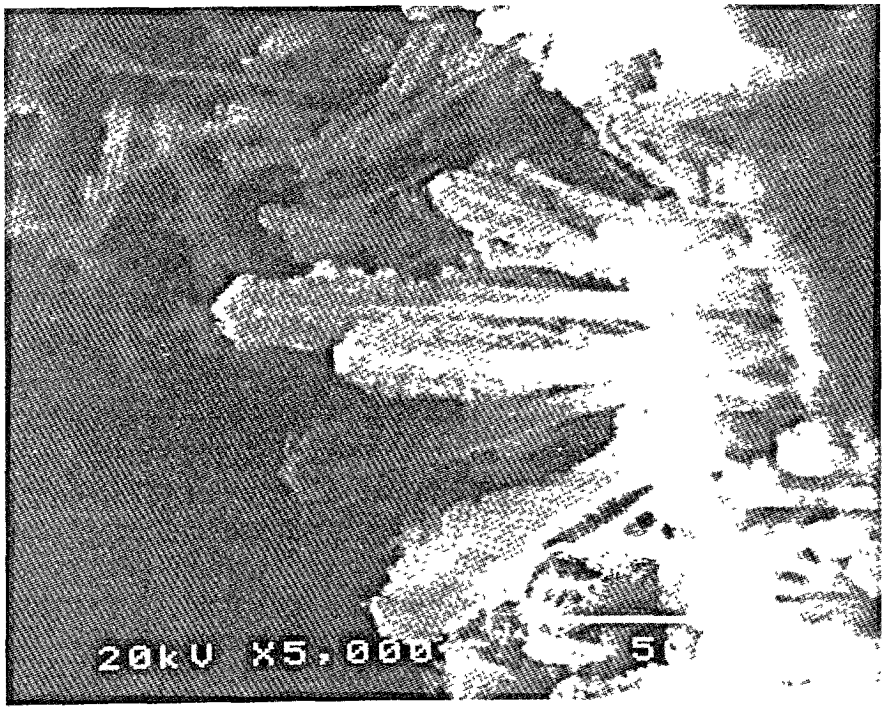

Figure 5 SEM photograph of a mortar with 50% fly ash addition, carbonated at natural condition.

CONCLUSIONS

The replacement of OPC by FA < 15% does not modify the carbonation process. On the contrary 50% replacement alters the microstructure of the carbonated compounds which result in a less dense system. Sulphates are released to the pore solution in higher concentration as FA replacement increases.

ACKNOWLEDGEMENTS

The authors are grateful to the spanish fly ash producers, specially to ASINEL, ENDESA, OCICARBON and OCIDE which have supported present experimentation.

CARBONATION MECHANISM IN THE GRANULATED BLAST FURNACE SLAG CONCRETE

Seppo MATALA, Helsinki University of Technology, Concrete Laboratory, Finland

ABSTRACT Gel structure and the greater liability of GBFS concretes for carbonation of the CSH gel, and the lack of calcium hydroxide in hydrated GBFS mixes, were found to explain the powerful redistribution of porosity in GBFS concretes. GBFS compositions are more disposed to carbonation of the CSH gel, which transforms the initially relatively dense gel towards a more porous silica hydrate gel. On the basis of literature and the test results a carbonation model to explain the redistribution of porosity during carbonation of the GBFS concrete is proposed.

Key-words: Carbonation, Modelling, Pore structure, Microstructure, Blastfurnace slag

INTRODUCTION

Carbonation changes the chemical, mineralogical, microstructural and pore structural characteristics of the paste in concrete. Changes occurring in pore structure alter the durability charasteristics of concrete, especially carbonation rate and frost and frost-deicing resistance. For these reasons the knowledge about the mechanism by which the observed changes take place in the OPC and GBFS concretes during carbonation is of great importance. The following discusses the microstructural and pore structural differences in the OPC and GBFS concretes before and after carbonation and carbonation of different phases in concrete. Finally, a carbonation model to explain the redistribution of porosity during carbonation of the GBFS concrete is presented.

MICROSTRUCTURAL DIFFERENCES IN OPC AND GBFS CONCRETES

Similarities in the overall microstructure of OPC and GBFS concretes can be seen in the existence of three well-defined regions in the binder pastes, and the presence of CSH gel in these areas. There is wide consensus as to the separation of these regions as follows: 1) an area of inner hydration products formed within the original grain boundaries; 2) an area of outer or external hydration products formed between the grains; and 3) an area situated in the interface between the binder paste and aggregate particles. Hydration products and their proportions formed in these regions differ depending on the chemical composition of the slag and cement.

The first defined region can be thought to form within the binder grain boundaries, where the morphologies of OPC and GBFS gel structures differ significantly due to differences in hydration kinetics. In OPC pastes the formation of shells around the clinker grains is the first eventual feature in the development of cement paste microstructure with regard to its later age properties. This shell is composed of CSH products and CH, and inward or outward extensions of ettringite needles or thin calcium monosulfate plates. The inner hydrate consists of CSH gel, small quantities of CH, and AFm rather than AFt phases which are reported to exist outside the shell in the outer hydrate and in transition zones (Diamond 1987, Scrivener 1989).

In GBFS pastes the glassy slag hydrated in OPC forms first a layer of Portland cement hydrates on its surface, followed by the formation of a so-called inner hydrate layer due to the attack of Ca^{2+} ions and alkali metal ions from the supersaturated solution (Tanaka et al. 1983). The inner hydrate layer comprising well-crystallized hydrates becomes denser; the diffusion of Ca^{2+} ions from outside slows down, and the dissolution of Ca^{2+} and Al^{3+} ions from the unhydrated slag is accelerated. These ions are partially bound in the hydrated layer and also move to the outside

aqueous phase, taking part in the formation of the outer hydrate. The surface layer of the slag particle transforms gradually into the inner hydrate by the supply of Ca^{2+} ions, developing a crystallized and dense structure. The Ca/Si ratio has been observed to be higher in the outer than in the inner hydrate, and lowest in the surface layer where concentrations of Al^{3+} and Mg^{2+} ions are highest (Regourd 1987). Mg-rich phases at the border of the inner hydrate have also been reported by Feng et al. (1989). The space left by the original unhydrated slag particle is assumed to be occupied by the hydration products of the inner hydrate, the hydrates of the skeleton hydrate layer on the surface of the unhydrated slag, and the residual unhydrated slag grain. Once the slag grain is consumed totally, the innermost portion of the inner product forms a porous network consisting mainly of hydrotalcite (Glasser 1989).

The outer hydrate and the transition zones in OPC and GBFS pastes are obviously very similar. the differences can be found in the quantities of the AFt and CH phases and porosities which are higher with the OPC pastes.

Hydration products formed during the hydration of GBFS/OPC blends are CSH, AFt and AFm phases, and hydrogarnet and hydrotalcite-like phases. Mixed forms of calcium aluminate and calcium magnesium hydrates have also been reported. The CSH gel in hydrated GBFS blends activated by OPC possesses the typical Ca/Si ratio of roughly 1.2-1.5 to 1.7-2.2, the former belonging to the pastes of high slag contents and the latter being typical average values in pure OPC pastes and in the outer slag hydrate with moderate or low slag contents. The elemental distribution from the skeleton to outer hydrate shows increasing Ca/Si ratio, decreasing Al/Si ratio from the inner to the outer hydrate, and clear Mg enrichment in skeleton hydrate, strongly supporting the existence of a hydrotalcite-like phase in this gel space (e.g. Odler and Hinrichs 1989, Taylor 1990, Uchikawa et al. 1991, Richardson and Groves 1992b, Matala 1995).

In hydration the free lime in GBFS pastes is consumed faster than it is liberated from alite and belite phases. This means that the amount of free lime in slag cements increases as hydration progresses only for a certain period, and declines thereafter. The amount of CH for OPC pastes is typically from 20% to 28% depending on curing time and on water-binder ratio. The corresponding values for the GBFS pastes with high slag contents are 3-10 % showing a gradual decrease with curing time and water-binder ratio. Generally the non-evaporable water or the chemically bound water contents are clearly lower for GBFS pastes, being roughly 50-80% of those in OPC pastes depending on the mix composition.

According to the literature two main observations concerning the pore structural differences of the OPC and GBFS concretes can be drawn. First, GBFS seems to give a finer pore structure than OPC when the curing time exceeds 28 days but a coarser structure with shorter curing times. The results are in accordance with the differences in hydration kinetics and hydration products formed in OPC and GBFS pastes. Different results are obtained with regard to total porosity. In most cases this seems to be higher with GBFS replacement, but when long curing times are used it appears lower.

Feng et al. (1989) have studied the porosity of GBFS mixes separately in the skeleton and inner and outer hydrates. At fully hydrated slag grain, the inner product comprising the volume of the original slag boundaries had a porosity of 53-61% and the remaining hydration product a porosity of 20-22%. This was explained by a decrease in specific volume occurring during gel crystallization and by continuing outward migration of Ca, transforming the once dense inner

slag hydrate shell to a more porous microstructure. This results in an accumulation of residual porosity on the site of the former slag grain. Total porosity is changed only slightly, and the lowered permeability is a consequence of the pore size redistribution. The observation is well in line with the conclusion of the total porosity and permeability in GBFS blends drawn by Harrison et al. (1987). The distribution of macroscopic porosity into three well-defined parts in the GBFS gel structure is of great importance in its further behavior. If the gel structure remains in this state when hydration ends and the aging processes begins, the minor changes in the gel structure of the inner slag hydrate (ISH) layer may cause changes in overall permeability and in the ability of the binder matrix to become water saturated in a moist environment.

CARBONATION OF OPC AND GBFS CONCRETES

Carbonation mechanisms

Carbonation can be defined as an aging process whereby dissolved CO_2 in pore solution or free CO_2 in pores attacks the unhydrated or hydrated products of cement by a through-solution process or by a topochemical process, changing the chemical, mineralogical, microstructural and pore structural characteristics of the binding component of concrete. In cement based materials carbonation is able to change almost all components in paste comprising unhydrated, hydroxylated and hydrated phases. The volume fraction of the CH and CSH phases in fully hydrated OPC pastes is roughly 70 to 75 wt.-% of the hydrated phases. This means that also the carbonation products of these phases represent the majority of all carbonated products in OPC and GBFS concretes. However, there exists a variety of aluminate and sulphate phases able to carbonate. The most important of these are tri- and monosulfate phases and the cubic and hexagonal forms of aluminate hydrates. Carbonation of these phases have been discussed earlier (Matala, 1995).

From hydroxylated phases the role of the CH phase in the carbonation of OPC and GBFS concretes is evidently the most important. The CH content in OPC paste may reach 25 wt.-% and in GBFS paste half of that, while the percentage of carbonatable alkali oxides in OPC is only 2 to 3% and in GBFS cements even lower. Carbonated forms of alkalis are highly unstable. The MgO content in slag cements may rise to 12-14 wt.-%, and enrichment of Mg ions is observed at specified sites such as the inner and skeleton hydration products of slag binder. The exact forms of hydration or hydroxylated products at Mg rich cites are still unclear. In principle, the formation of $MgCO_3$ in low basicity solution may be possible with concretes of high slag contents.

Carbonation of the CH phase is obviously very similar in both OPC and GBFS concretes. The main difference naturally lies in the amount of carbonates precipitated from the CH phase, GBFS concretes showing the lower amounts. Carbonation of CH is generally assumed to take place, and even to finish, before the carbonation of other components in cement paste begins. However, this assumption has recently been proved to be incorrect. Simultaneous progression of carbonation of the two main carbonatable components in cement paste have been reported by e.g. by Bier (1988), Matsusato et al. (1992), Richardson et al. (1992) and Matala (1995). This is confirmed by the simultaneous existence of silica gel as a residue of carbonated CSH gel and CH in cement paste.

The differences in CSH compositions, in overall gel structures and in CH contents between GBFS and OPC pastes evidently affect the carbonation process. In principle, the carbonation

process is similar for CSH gel formed from either GBFS or OPC, although changes in the Ca/Si ratio may affect different kinetics in the carbonation process. Carbonation of CSH gel have been studied e.g. by Essing and Hilsdorf (1976), Suzuki et al. (1985), Bier (1988), Richardson et al. (1992), Ikeda et al. (1993), Atlassi (1993) and Matala (1995). Bier and Matala have studied the carbonation of the CSH gel in GBFS concretes.

The level by which the CSH gel carbonates depends on the degree of carbonation in the paste and on the initial amount of CH and on the moisture content of paste. It is obvious that the pore structure controls also the balance between the carbonation of the CH and CSH phases. The more open pore structure enables the mobility of water serving the carbonation of the CH phase. In the aforementioned studies on the carbonation of the CSH gel it is observed that different types of modified CSH and/or SH gel develops and calcium carbonate in a form of calcite, vaterite and aragonite precipitates. Richardson et al. (1992a) have reported the silica hydrate gel to be a three dimensional network of silicate units. Ikeda et al. (1992 and 1993) have observed that the double chain structure with Si-O-Si bridges of the silicate phase in non-carbonated tobermorite was destroyed and a silica gel with a three dimensional cross-linked framework structure being formed instead. Noticeable in the last study was the finding that the double chain structure still exists at relatively high degrees of carbonation from 60% to 80%. Suzuki et al. (1985), Bier (1988) and Atlassi (1993) have reported that during carbonation the so-called Ca-modified CSH gel being formed first, after which CSH loses its SiO_2 to form amorphous silica gel. In the process a new organization of SiO_4 tetrahedra takes place in the gel. The layered structure of CSH is bound by two of four corners in tetrahedra, but with the amorphous silica gel all corners may act as bridging components forming a three-dimensional and porous network of silicon chains. Carbonation products exist as microcrystallized material on the surface of the modified gel or as a part of it. The gel is only partly in its original form, being mostly an SH gel.

The morphologies of calcium carbonates depend on the sites where and on time when precipitation takes place. In the beginning, vaterite forms first transforming later to calcite. Further small pore sizes, as in the inner CSH, inhibit the crystallization of calcite and preferably vaterite, aragonite or modified CSH-$CaCO_3$ type product is formed. Richardson et al. (1992a) observed that calcite and vaterite precipitated in the outer product of CSH gel, with a microcrystal size of the order of 100 nm. At a later stage only very fine 10 nm poorly crystalline vaterite particles formed in the inner product gel. Obviously the inner product of CSH suffers from a net loss of calcium due to the fact that it does not contain pores large enough to allow for the nucleation of carbonates. In general, vaterite is the first product in the carbonation process, and is a poorly and small-crystallized form of $CaCO_3$ that converts easily to calcite if there is space enough for precipitation. Aragonite is also a small-crystallized form that is observed to be very soluble in chloride solution (Stark and Ludwig 1995).

Effects of carbonation on pore structure

The effect of carbonation on the pore structure of OPC blends has been widely studied. Pore size distribution becomes denser due to loss of coarse capillaries; continuity of pores decreases, resulting in lowered permeability. Some contradictory results of the effect of carbonation on the total porosity exist, but the general understanding is that overall porosity is diminished. Certain redistribution of the finest pores 1.5 to 20 nm caused by the carbonation of the CSH gel is reported by Essing and Hilsdorf (1976). Few studies exist on the pore structural changes in carbonated GBFS concretes, mortars or pastes. E.g. Litvan and Meyer (1986), Bier (1988), Distler et al. (1992), De Ceukelaire et al. (1992), Parrot (1992) and Matala (1995) have worked

in the field. Bier observed that carbonation in an atmospheric climate coarsens the pore structure of GBFS pastes but not of OPC pastes. They explained this phenomenon in terms of the formation of a porous silica gel resulting from the decomposition of CSH. An overall decrease in porosity was observed both in total porosity and especially in capillary porosity, the latter occurring especially in small capillaries where $CaCO_3$ precipitates from CH. In carbonated OPC pastes the decrease in total and capillary porosity was caused by a change in porosity in the range 2 to 20 nm. Slight coarsening was observed in the range 100 to 200 nm, which correspond to the coarsest pores of SH. The specific surface area determined by SAXS decreased due to carbonation in the outer CSH gel of OPC paste. Total porosity decreased in carbonated GBFS concrete, as in OPC concrete, but with no observable decrease in capillary porosity. The portion of small capillaries decreased clearly. The outer CSH gel disappeared and was replaced by porous SH gel, and the specific surface area decreased strongly due to carbonation.

Identical results on coarsening of the pore structure in GBFS blends was reported by Litvan and Meyer (1986), Distler et al. (1992), Parrot (1992) and De Ceukelaire et al. (1992) and Matala (1988 and 1995). In the last study a clear differences in the redistribution of porosity between the OPC and GBFS binders during carbonation took place. Coarsening of the pore structure, i.e. the increase in the macroporosity ($r>4$ nm) and the corresponding decrease in gel porosity, takes place with both binder types but at the expense of different gel pore ranges. The reduction in total porosity and increased capillarity due to carbonation takes place with OPC blends at the expense of micropores ($r<1.5$ nm) and with GBFS blends due to the reduction in microcapillaries ($1.5 \text{ nm} < r < 4$ nm). The ISH gel is the most probable site for the large amount of microcapillaries in GBFS blends. The outer slag hydrate in GBFS clearly resembles obviously the gel structure in OPC blends. The skeleton structure between the ISH and the unhydrated slag is the most porous part among the slag hydrates within the initial border of the slag particle. Now, coarsening of the ISH gel during carbonation opens the dense barrier between the closed skeleton porosity and the relatively open outer porosity. As a result, redistribution of the porosity in GBFS compositions causes a certain increase in permeability of the matrix, enabling the ingress of CO_2 through the ISH hydrate and the precipitation of carbonates also in the skeleton space and, to a certain extent, also in the coarsened ISH gel.

CARBONATION MODEL FOR GBFS CONCRETE

The model to be presented in the following is only a contribution toward explain the pore structural changes in carbonated OPC and GBFS concretes. It is based on the literature and on the test results of the project in which the effect of carbonation on the pore structure of OPC and GBFS concretes were studied mainly by low-temperature calorimeter, MIP, XRD, TG and IR methods (Matala 1995).

The main differences in the hydration kinetics of GBFS and OPC pastes lie in their *in-situ* products,but according to the literature the outer CSH formed is alike. Naturally OPC pastes comprise more portlandite and sulfate phases, which play an important role during carbonation in the most porous spaces of the cement matrix, in large capillaries and in porous transition zone areas. In GBFS pastes the dense inner slag hydrate layer (ISH) separates the two areas of the most porous hydrates, the outer slag hydrate (OSH) and the skeleton hydrate (SKH), as shown in Fig 1. In OPC pastes the inner hydration product is more porous but the connection of its homogeneous structure to the unhydrated material is more uninterrupted (Fig 2).

Carbonation begins with the attack of dissolved carbon dioxide in the OSH gel. In this phase available calcium hydroxide is consumed and tri- and monosulfates begin transforming to their carbonated forms. Carbonation resembles that of OPC, with the exception that more Ca^{2+}ions must be released from CSH to maintain the alkalinity in the pore solution. Carbonates precipitate as calcite or as vaterite in the open capillaries in the transition zones between the aggregate particles and binder paste and the OSH gel (stages 1 and 2, Figs 1 and 2). Due to the lower lime content in GBFS paste, simultaneous carbonation of the CH and CSH gel is more likely in GBFS. When the most easily available CaO is consumed, the CSH gel starts losing its Ca^{2+} and OH^- ions present in the interlayer regions of the tobermorite-like gel or mixed tobermorite-jennite like gel.

When more CO_2 penetrates the binder matrix and dissolves in the pore water, and when the availability of buffering Ca^{2+} ions from the OSH gel becomes insufficient, the ISH gel serves as a buffering reserve for the pore solution with increased CO_3^{2-} concentration in the OSH gel space. Interlayer water in the gel, adsorbed water on gel surfaces and on pore walls, and water released during carbonation guarantee the mobility of Ca^{2+} ions by diffusion to the species of the OSH gel large enough for precipitation of carbonates (stages 2 and 3, Fig 1). Overall porosity in the ISH increases as a consequence of the net loss of calcium and water from the gel matrix. It is possible that lost Ca^{2+} ions from the ISH framework may be partly replaced by Mg^{2+} ions enriched in the ISH gel. In any case, the net effect is increased porosity. Once the porosity in this pore space has increased enough, the penetration of CO_2 into the ISH and through it into the SKH gel is eventual (stage 4, Fig 1). More Ca^{2+} ions are released and carbonation may proceed as precipitation of the finest morphologies, i.e. vaterite in SKH gel and partly also in the most porous spaces of the ISH gel (stage 5, Fig 1).

In OPC pastes the dissolution of Ca^{2+} ions from the outer and inner CSH gel is slower than in GBFS pastes, since the lime from CH enables longer buffering of the pore solution. Consequently the transformations of the CSH gel structure take longer throughout the cement matrix, in the inner and outer hydrates, and also in the transition zones (stages 2 to 4, Fig 2).

The morphology of calcium carbonates inside the borders of the initial slag particle, i.e. in the spaces of ISH and SKH, is vaterite and its further crystallization into calcite is probably impossible or very slow. Two facts supports this polyform. First, there is insufficient space in these gels for the formation of well-crystallized calcite. Second, the enrichment of Mg^{2+} ions in the gel space inhibits vaterite from transforming into calcite. Calcium carbonates formed in the inner CSH of OPC blends clearly also have the metastable polyform of vaterite, but only due to lack of precipitation space rather than the incorporation of foreign ions. The more open structure of OPC compositions in this gel space may also enable precipitation of more crystallized polyforms. The morphologies of calcium carbonates in the outer hydrate gel are vaterite, aragonite and calcite for both binders. The metastable phases vaterite and aragonite are formed first, followed by transformation into calcite to an extent determined by the dimensions of the open porosity.

When modeling the carbonation process in GBFS concrete with high slag content, the role of MgO should not be neglected. Mg^{2+} ions in the ISH and SKH gels have deviating ionic radii that retard or totally inhibit crystallization of calcite in these gel areas. Evidently then, these ions form part of the mixed vaterite phase. There are, however, at least in principle, two ways in which carbonates involving MgO compounds can form. The first is the formation of magnesium

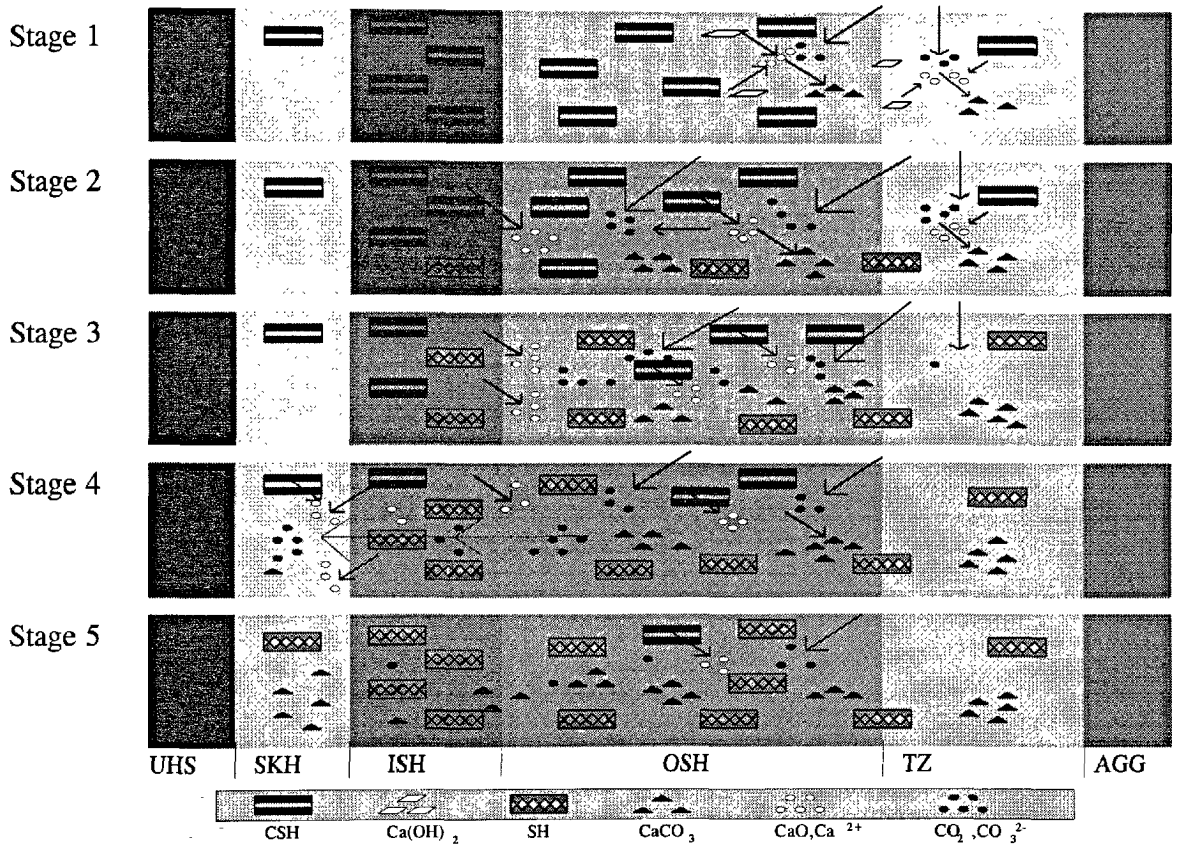

Figure 1. Schematic representation of the proposed carbonation model for GBFS concrete.

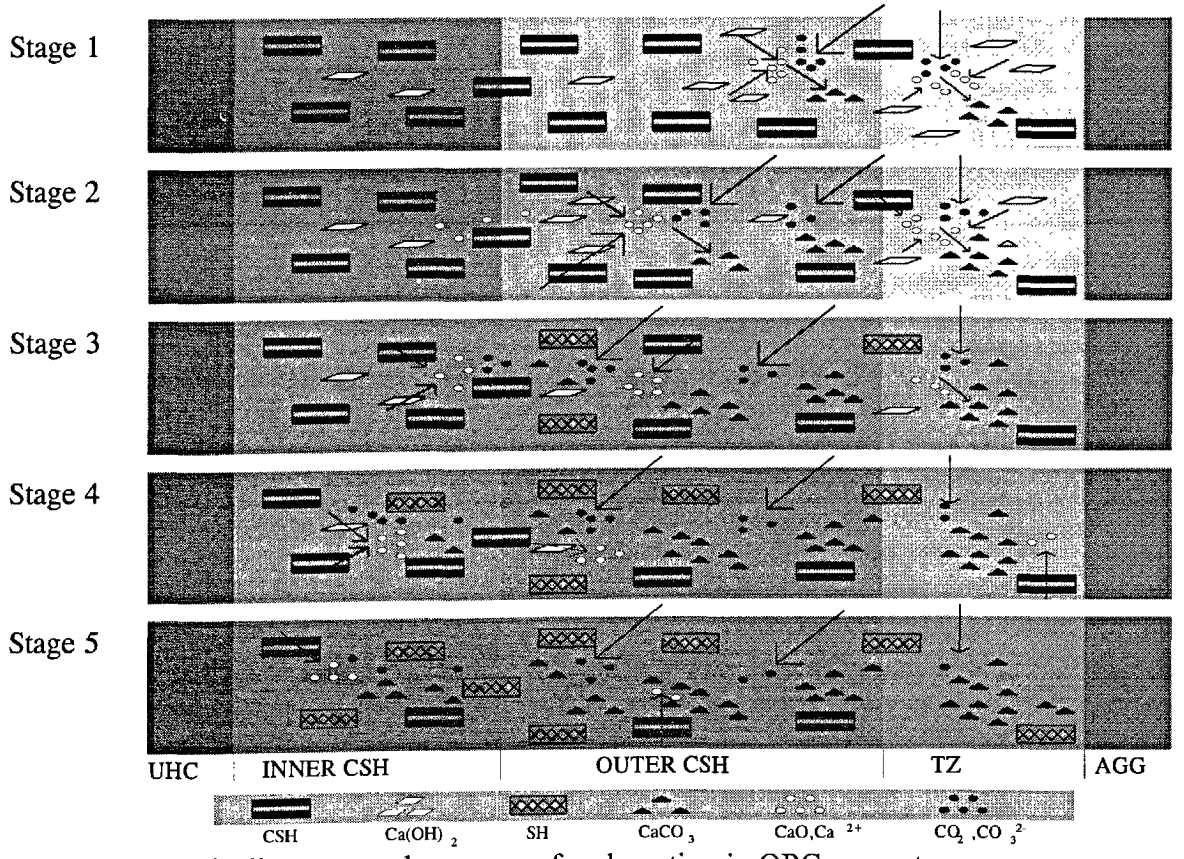

Figure 2. Schematically presented progress of carbonation in OPC concretes.

Figs 1 and 2 are also supplied as colour print for clarity at the end of proceedings.

carbonate from the brucite phase. Although the solubility of this phase in water is low, it is possible that at a low pH level of high CO_3^{2-} concentration in the pore solution it dissolves, and that subsequent formation of $MgCO_3$ is possible. Possibly this kind of direct carbonation seldom occurs in extreme conditions of well-saturated pastes with high CO_3^{2-} concentrations in the pore solution. The second is the existence of hydrotalcite $M_6A\bar{C}H_{12}$ by itself in GBFS concrete. What the chances are of this compound forming during carbonation is not clear. Perhaps its appearance is merely associated with the hydration process as a result of the direct reaction of cement containing carbonates with magnesium aluminate hydrates, being analogous to the direct formation of carboaluminates. Its separation from monosulfate and carboaluminate phases by XRD is obscure, and at least the results of XRD tests in this study do not support the formation of hydrotalcite during carbonation at relatively low RH.

Redistribution of pore sizes during carbonation is explained by the changes in interlayer regions of the tobermorite-like gel or of the mixed tobermorite-jennite-like gel, by the silicon polymerization that results, and by the loss of interlayer water of the gel. Calculations of C/S and H/S ratios showed that CSH gel in GBFS mixes loses roughly 75% of its CaO and about 40% of its H_2O during carbonation. The corresponding losses with OPC mixes were 70% and 50%. The rearrangement of silicon tetrahedra after the escape of Ca^{2+} and OH^- ions causes a certain volumetric decrease in the remaining gel. A rough estimate for the volumetric decrease due to the 75% loss of Ca^{2+} ions from the CSH network could be as high as 40%. One dimensional change is about 20%. Assuming that the CSH gel is composed of two of the three 14 Å tobermorite layers, with one adsorbed water layer between and along the sheets, one dimensional decrease of 20% in the thickness of the initial gel is enough to double an average gel pore radius of 1.5 nm. Negative pressure in the gel at low RH assists the rearrangement of silicon tetrahedra in the remaining SH gel into more ordered position. Of course, this contributes to the increase in gel pore space.

Carbonation at low RH accelerates modification of the pore structure in the ISH gel and, possibly due to the parallel effects of carbonation and drying, the changes are greatest at the lower level of intermediate humidities, i.e. 45% to 50% RH. When carbonation occurs at higher RH the coarsening process differs from the described one. Ingress of CO_2 into the pore system of the OSH gel and the transition zone is slower but the effect is the same as described in stages 1 and 2 above. Differences exist with regard to the transformation of the ISH gel and to the changes in the SKH gel. The higher degree of saturation in the pores enables the dissolution of Ca^{2+} ions from unhydrated slag, and Ca^{2+} ion diffusion occurs through the ISH gel to the OSH gels. This may take place by direct diffusion or by a restoring process in which lost Ca^{2+} ions from the tobermorite-jennite-like gel of the ISH needed to buffer the pore solution in the OSH gel are replaced by the Ca^{2+} ions dissolved in the SKH gel. This leads to a net increase in the porosity of the SKH gel, the porosity of the ISH gel remains unchanged, and the barrier between the more open gel structures of the SKH and OSH gels may densify even further. The open porosity of the SKH gel remains isolated from the rest of the paste as long as the ISH preserves its density. If carbonation proceeds at lower RH or drying-induced coarsening of the ISH gel begins, the density of the isolating barrier diminishes and the gel structure becomes more permeable. The porous SKH gel then comes within the field of activity of the penetrated substances.

As a consequence of both the above hypotheses, the gel structure coarsens. The more homogeneous structure of the inner hydrate in OPC compositions gives a relatively smaller redistribution in overall porosity of the binder matrix than is the case in GBFS mixes. At what

rate coarsening occurs depends naturally on the predominant RH. At high RH, carbonation is slow and carbonation-induced coarsening is at least partly compensated for by further hydration. However, as the results with samples cured by repeated wetting and drying treatment show, a certain amount of coarsening takes place anyway.

CONCLUSIONS

The proposed carbonation model explains the strong redistribution of the gel and capillary porosity found in the GBFS concretes. In that the role of the inner slag hydrate is of great importance. This initially very dense layer before carbonation becomes porous and permeable during the carbonation of the CSH gel affecting the decrease of gel porosity below 4 nm and the corresponding increase in coarser capillary porosity. Coarsening of the inner slag hydrate gel causes an overall increase in the porosity of the ISH gel space and in the continuity of pores in GBFS concrete, as the dense separative barrier is lost between the most porous parts of the GBFS matrix, the outer slag hydrate and the skeleton hydrate. The phenomenon was very observable in microcalorimetry tests in which the preparation of samples did not alter the pore structure. Due to the microstructural and pore structural differences the coarsening of pore structure of OPC concretes is much smaller.

The observed phenomenon declines the durability properties of carbonated GBFS concretes. Increased capillary porosity affects increased permeability and decreased frost and salt-frost resistance. Calcium carbonates in GBFS concretes were found to exist extensively in the polyforms of vaterite and aragonite. These polyforms have been reported to be very soluble in chlorine solution. Hence the frost-salt resistance is further diminished by chemical degradation.

EFFECT OF THE CARBONATION ON A 54-YEARS OLD CONCRETE ROAD PAVEMENT

Simonetta PAGLIOLICO (Politecnico di Torino, Italy)
Luciano CUSSINO, Francesco CURCIO, Roberto FERRARI (Centro Ricerche Unicem, Guidonia, Italy)

ABSTRACT Samples of concrete from the demolition of a non-reinforced road pavement built in 1938 have been studied, to evaluate the transformations occurred during its 54-years working life. The concrete slab thickness was 250 mm. By means of the phenophtalein method, the depth of carbonation has been measured: this showed that carbonation occurred from both sides of the slab (external and internal), a non-carbonated zone remaining in the middle. On carbonated and non-carbonated pieces, XRD, DTA, TGA, SEM and Porosimetry tests have been performed, with several physical and mechanical tests. Differences in the microstructure of the two phases have been recognized; these however have not influenced significantly the mechanical behaviour and the working life of the road. The slight decrease in compressive strengths due to the action of deicing salts (frequently used on this road, exposed to severe winter weathers) depends on the fact that carbonation has limited the deleterious effects of the calcium ossychloride formation.

Key Words : carbonation, cloride, de-icing salts, porosity

INTRODUCTION

Concrete samples taken during the demolition of non-reinforced slabs of a road pavement cast in 1938, have been studied to assess the changes that have occurred in the 54 years period.
It has been noticed that the 25cm thick slabs have undergone carbonation, as determined by the phenolphtalein method, to almost the same depth on the upper and the lower surface, while the central part is not carbonated.
Samples of both the carbonated and non-carbonated zones have been investigated by XRD, DTA and TGA, porosimetry, SEM, with the aim of studying the effects of carbonation.
Compressive strength and other physical properties have been measured on cubic samples sawed from both the carbonated and the non carbonated zones.
The differences in the microstructure caused by carbonation, as revealed by this investigation, did not bring about any sizeable effect on the mechanical behavior and on the useful life of the pavement.
The roads around Casale Monferrato before 1940 were mostly paved with concrete. Particularly a lenght of 5 km of Road 31 was paved in 1938 with 3.30 x 4 m, 25 cm thick slabs. These were separately placed by interposing wooden casing. The road had only one line 7 m wide lane.
Until recently Road 31 has been subjected to all the traffic going from Alessandria to Vercelli.
When the concrete surface was demolished and replaced by a bituminous concrete surface it was still in good service condition, even if some slabs showed cracks, probably caused by ground settling and the surface was very smooth.
This road perfomed satisfactorily for 54 years without any maintenance (except the filling of the joints with bitumen).
The good state of the slabs in 1992 is shown in Fig. 1.
Concrete was made up by Portland cement and river Po aggregates, mainly silicious, of the Casale Monferrato area. This town was at the time an important cement and hidraulic limes producing center, since natural marl was very abundant nearly.
The typical Casale Monferrato clinker had the follwing moduli:
Hydraulic modulus = 2.16, Silica modulus = 2.38, Alumina ratio = 2.15, LSF = 0.95.

Figure 1 : state of concrete slabs in 1992

The cement had the characteristics required by the 1925 italian standard (Table 1).

Table 1 : italian cement standard characteristics required by 1925

Max residue by sieve of 900 apertures	< 2 %
Max residue by sieve of 4900 apertures	< 20 %
Minimum density	> 3,00 g/cm^3
Setting time beginning	1 h
Setting time end	from 6 to 12 h
Flexural strength 7 days	≥ 18 kg/cm^2
Flexural strength 28 days	≥ 25 kg/cm^2
Compressive strength 7 days	≥ 180 kg/cm^2
Compressive strength 28 days	≥ 250 kg/cm^2
SO_3	< 1,50 %
MgO	< 3,00 %
$CaO / (SiO_2 + Al_2O_3 + Fe_2O_3)$	> 1,7

This type of cement, as far as compressive strength is concerned, can be compared to a 15N/mm^2 cement according to UNI-EN 196-1.

EXPERIMENTAL

During the demolition of the slabs several blocks were picked up and later used to obtain the samples.

Carbonation

A block of about 30 cm was sawed and the fresh surface treated with phenolphtalein. A non cabonated central zone was evident. The carbonation depth was about 7 cm from the top surface and about 5 cm from the bottom surface (Fig. 2).
As a result we have two types of concrete samples: carbonated and non-carbonated.

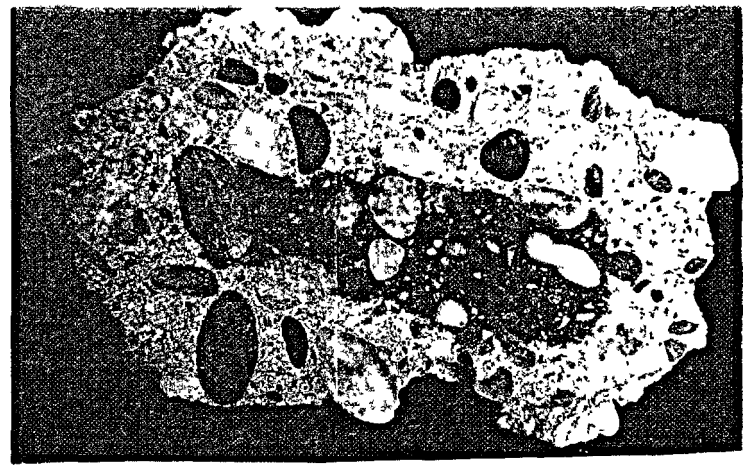

Figure 2 : carbonation depth

X-Ray Diffraction

In both types of samples we can see (Fig 3) hydrated calcium silicate (9.9 Å peak), quartz, calcite

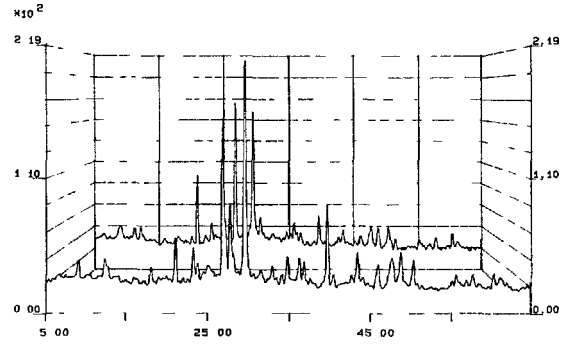

Figure 3 : X-Ray diffraction

Moreover, in the spectrum of non-carbonated concrete hydrated calcium chloroaluminate (3 CaO . Al_2O_3 . $CaCl_2$. $1OH_2O$) is present (7.92 Å, 2.93Å), while vaterite is present in the carbonated sample (3.57 Å, 2 93 Å)

Deicing salts did not react with aluminates since there is no evidence of damage. Particularly, on the carbonated surface the coumpound 3 CaO . $CaCl_2$. 15 H_2O, whose formation is thought to take place when chlorides attack concrete (Berntsson L , 1982, Monosi S., 1989; Monosi S.1990; Collepardi M ,1992), could not form since portlandite had been transformed into $CaCO_3$ by CO_2. One could have, instead, the formation of chloroaluminate, which in turn by reacting with CO_2 can originate hydroargillite, aragonite and vaterite (Rcharts W ,1969). The presence of vaterite in the carbonated sample and chloroaluminate in the non carbonated one seems to substantiate the above hypothesis.

DTA and TGA

The TGA curves up to 1100 °C (Fig. 4-5) show a total weight loss of 21% for carbonated concrete and 22% for the non carbonated one. The weigth loss at 420°C of the carbonated sample is about half that of the non carbonated sample and this is due to carbonation, while at 1030°C a larger loss is shown by the carbonated sample.

The DTA curve shows two endothermic peaks around 100°C, due to hydration products wich are almost absent in the carbonated sample and this is in agreement with the X-ray diffraction data.

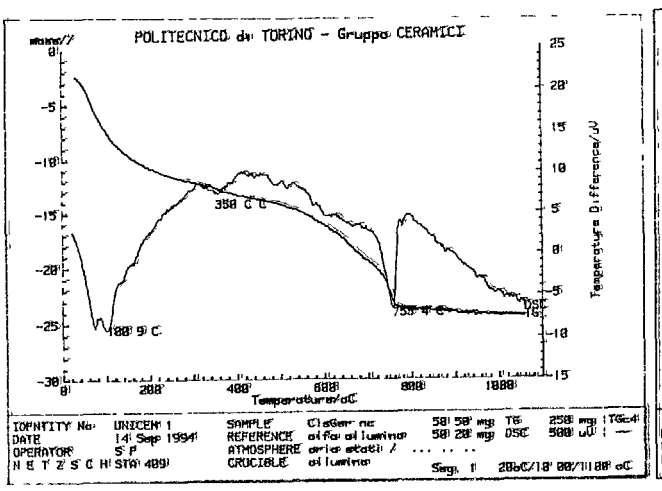

Figure 4 : DTA and TGA of not-carbonated

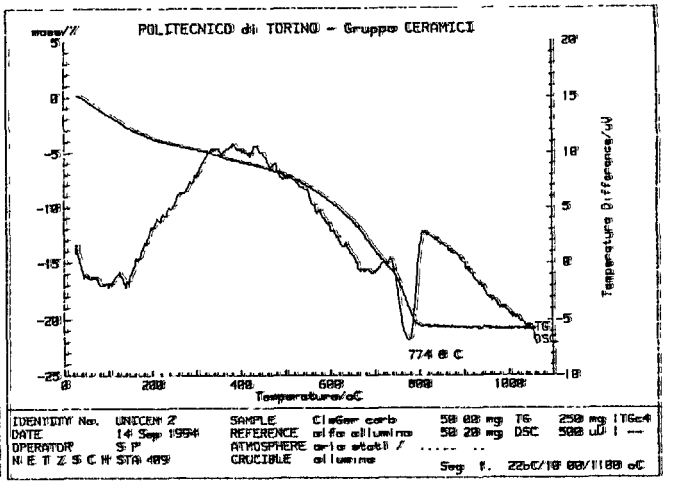

Figure 5 : DTA and TGA of carbonated

SEM

The SEM micrographs (Fig. 6-7) show a more compact and less porous carbonated sample. Also, the acicular crystal of carbonated concrete are covered by a large quantity of products of the carbonation process. Additional investigation are needed

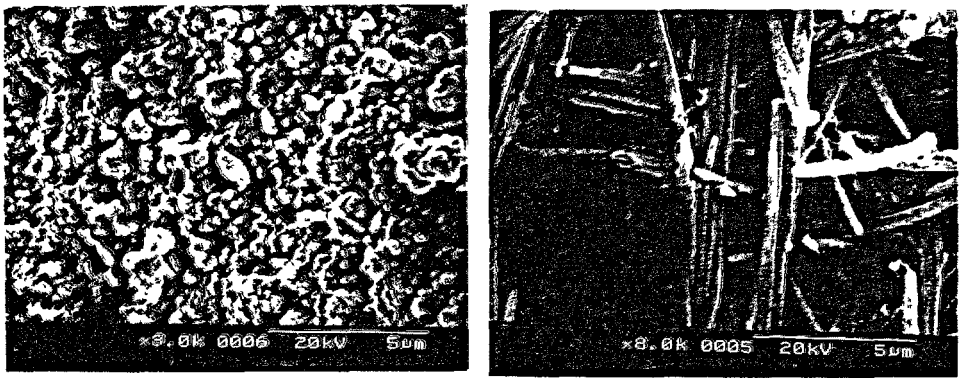

Figure 6 : SEM micrographs of not-carbonated

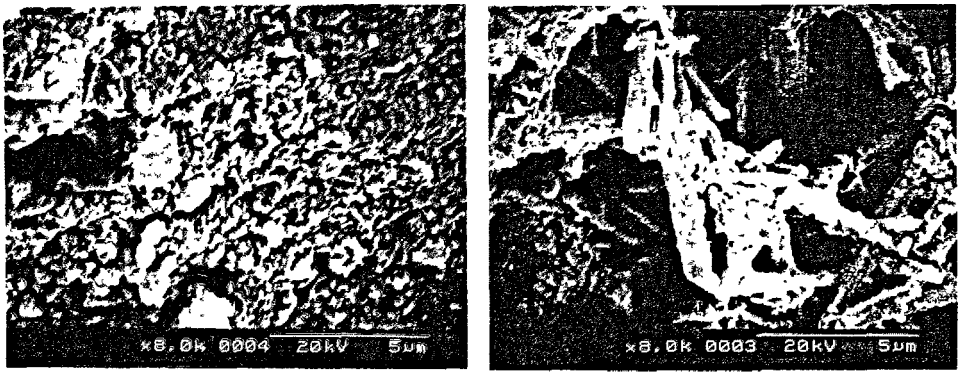

Figure 7 : SEM micrographs of carbonated

Porosimetry

It has been carried out by a mercury intrusion porosimeter on fragments of the two types of samples. The results are reported in Table 2, the figures are the average of the three most omogeneous data out of four mesurements. The carbonation did not modify the pore structure, as can be seen from the value of the mean radius, derived from the frequency curve.

Table 2 : porosimetry results

	Carbonated	Not carbonated
Total porosity (%)	25,6	19,7
Medium ray (μm)	0,05	0,05
Superficial specific area (m^2/g)	6,40	5,0

The specific surface area of the carbonated sample is, as expected, somewhat higher. The total porosity of carbonated concrete has increased. This is surprising and not in line with the SEM data that showed, at first sight, a less porous carbonated concrete as a consequence of the formation of carbonation products. The situation can be explained by considering that in the carbonated sample there is a chloride concentration, varying as a function of the depth, from 0.13 to 0.06% by weight.
The increased porosity may originate from the initial attack by the chloride, with the formation of calcium oxychlorides, because the frequent use of deicing salts. The development of the carbonation process seems to have slowed down and minimized the chloride attack. The use of deicing salts in Northern Italy during winter is very frequent and, also, the road under examination goes through the town. Anyway, we must remark that a porosity aroung 20% indicates a correctly made concrete, with a water/cement ratio near 0.50, certainly less than 0.55.

Physical and mechanical properties
Cubic samples of about 60 mm side were cut by using a diamond saw from one of the largest blocks, after determination of the carbonated area by the phenolphtalein method. Density and compressive strenght measurements were carried out (Table 3). Each reported value is the average of two samples. The data agree with the higher porosity of carbonated samples, wich gives a slight reduction of the mechanical properties. One could have expected, as a consequence of carbonation and the resulting increase in compactness, an increase in compressive strength. But the use of deicing salts changed the situation and the carbonation limited to a minimum the formation of oxychlorides (Collepardi M.; Monosi S., 1992; Collepardi M., 1994). The density value indicates that the concrete was accurately cast and had a low water/cement ratio.

Table 3 : physical and mechanical results

	Carbonated	Not carbonated
Compressive strength (N/mm2)	13,5	15,5
Density (g/cm3)	2,30	2,38

CONCLUSIONS

It can be said that this 54 year old pavement, even if deeply carbonated and with a relatively low compressive strength but in line with the performances required by the standards of the time, behaved remarkably well for a long time and with heavy traffic, without any maintenance, except the filling of the joints with bitumen. In this case the carbonation process played a positive role in limiting the effects of the frequently used deicing salts.

ABSTRACT Porous concrete is a polymer modified cement concrete, designed to obtain high open porosity. The addition of polymer emulsion to the mixture provides the required workability and strength. The paper presents the results of the experimental study and discusses the structure of the porous polymer cement concrete and its performances.

Key-words: Composition, durability, porosity, structure.

INTRODUCTION

Porous concrete, also referred to as very open concrete (VOC) is a polymer modified concrete, designed to obtain high porosity (25% to 30% accessible porosity). This open structure makes the VOC well suited to be used as top layer on roads since it provides noise reducing capacities and good drainage properties. The durability and low maintenance, proper to concrete, allow to presume a long service life and little or no rutting under heavy traffic, which makes the open concrete preferable over open black topics.

The porosity is achieved by means of a gap-graded aggregate distribution in which there is a very low proportion of fine aggregates. In this research aggregates 4/7 mm are used, together with a small amount of fine sand 0/1 mm. Addition of polymer emulsion to the mixture gives the VOC the necessary tensile and compressive strength to withstand thermal stresses and traffic loads.

Laboratory tests concentrated on the physical and mechanical properties of the porous concrete, such as workability, porosity, strength, resistance against abrasion, freezing and thawing resistance and adhesion on a concrete sublayer. Three different kinds of polymer emulsions are tested. Besides the test results, the paper discusses the specific structure of the VOC and the influence of the cement-polymer paste on this structure and on the properties of the VOC.

MIXTURE PROPORTIONING

The basic mixture proportions are given in Table 1. The coarse aggregate size is chosen to be 4/7 mm and occupies 50 % of the volume of the fresh mixture. Larger aggregate sizes produce larger porosity but will diminish the workability of the VOC and the evenness of the surface, which is required for the noise reducing properties (Onstenck et al., 1994). A small amount of fine sand 0/1 mm is used. The cement used is CEMIII/A/42,5/LA. This cement is used because it is less subjected to shrinkage and it provides good resistance against environmental actions, primarily frost-thaw and thawing salts.

Four different types of polymer emulsions are used: two acrylic emulsions, one styrene-acrylic

emulsion and one styrene-butadiene emulsion. The polymer-cement ratio is equal to 0.10 (weight solid mass of the polymer emulsion/weight cement). The water-cement ratio is equal to 0.3 (water of the emulsion included).

Table 1 Mixture proportioning for the VOC

Coarse aggregate 4/7	1350 kg/m^3
Fine aggregate 0/1	90 kg/m^3
Cement CEM III/A/42.5	280 kg/m^3
Polymer emulsion (50% solids)	56 kg/m^3
Water (emulsion water not included)	56 kg/m^3

The mixing of the VOC is done as described by Ohama (Ohama Y., 1995): first the coarse aggregates, the sand and the cement are placed in the mixer. During mixing, first the water and consequently the polymer emulsion are added. Afterwards, mixing continues during 2 minutes. The curing conditions were taken similar to the outdoor conditions: the samples were covered by a polyethylene sheet during two days. After demoulding the samples were stored under laboratory conditions, sheltered from air current.

PROPERTIES OF THE FRESH MIXTURE

The workability of the fresh mixture is tested by means of the flow-test, according to NBN B15-233. The flow-index varies between 1.42 and 1.55 for the different mixtures, as indicated in Table 2.

Table 2 Results of the flow-test for the different mixtures

Acrylic emulsion 1	1.42
Acrylic emulsion 2	1.53
Styrene-Acrylic emulsion	1.55
Styrene-Butadiene emulsion	1.53

The first acrylic emulsion used gave a lower workability-index. This lower performance could be observed through all the tests. This can be explained by the type of polymer emulsion used: the first acrylic emulsion contains 50% solids, the second acrylic emulsion on the contrary only 30%. It seems that especially the larger amount of water, present in the second case improves the workability of the VOC. Also the type of polymer is important: the styrene-acrylic and the styrene-butadiene emulsion both contain 50% of water. Even though they show a good workability.
Another property of the fresh mixture is the behavior at compaction. This property is depending on the compaction method used (shocking, vibrating, with or without an extra weight placed on top of the sample), on the amount and the composition of the cement-polymer paste, on the sizes and the form of the aggregates and on the type of polymer modification. The possibility to compact is measured by means of the degree of compaction, equal to the density after compaction, divided by the calculated density at 27% porosity. The mixture proportioning is made to obtain approximately 27% of air volume into the sample at 100% vibration, with a (fresh) density equal to 1830 kg/m^3. Table 3 shows the results for the mixtures made with different types of polymers after shocking the samples and after vibration during 30 seconds. The third column shows the

density calculated on the fresh mixture, by means of a cylinder with a content equal to 8 liter, after compacting the fresh mixture by shocking the sample 8 times on the shock table, used for the ABRAMS flow-test according to the standard NBN B15-233 .

Table 3 Degree of compaction

	Vibrated		Shocked		Fresh mixture	
	density [kg/m^3]	degree of compaction [%]	density [kg/m^3]	degree of compaction [%]	density [kg/m^3]	degree of compaction [%]
Acrylic emulsion 1	1703	93%	1355	74%	-	-
Acrylic emulsion 2	-	-	1827	100%	1847	101%
Acrylic-Butadiene emulsion	1977	108%	1718	94%	1842	101%
Styrene-Butadiene emulsion	1981	108%	1699	93%	1821	99%

Similar results as in the flow test appear: the first acrylic emulsion reaches a much lower degree of compaction than the mixtures made with the other polymer emulsions, even though an identical compaction method is used. Differences between the other polymer emulsions are small, especially for the fresh mixture, where the degree of compaction is a reflection of the workability. Remarkable however is the good performance of the second acrylic emulsion: in spite of the low content of solids in the polymer emulsion, the mixture obtains a high degree of compaction and also produces good mechanical properties and a high durability.

The results show that the density obtained after compacting the sample depends not only on the compaction method, but also on the polymer emulsion used. To reach a degree of compaction of 100%, which corresponds to a porosity of 27%, it is necessary that the coarse aggregates are well positioned one towards the other to fit into each other. Shocking apparently does not produce enough energy to turn the aggregates into the right position. When the samples are vibrated, the coarse aggregates can more easily turn to form a compacter volume. To compact, the aggregates also have to overcome the frictional resistance between the aggregates. This is promoted by the polymer-cement paste. During mixing, the polymer-cement paste forms a fine layer around the aggregates. Polymer modification improves the compactibility of the concrete, due to the ball bearing action of the polymer particles and the dispersing effect of the surfactants, added to the emulsion (Ohama Y., 1995) and allows a good surrounding of the aggregates. The influence of the polymer in general is clearly visible: without polymer addition, the cement paste is not able to form a continuous layer around the aggregates. Therefore, the degree of compaction as well as the workability will be much lower in that case. The cement paste will not be continuously distributed over the material, which will also cause a decrease in strength.

The form of the aggregates is also important: gravel (round aggregates) will roll more easily over each other and will lead to a VOC with a smaller porosity, at the same compaction energy; VOC made with broken porphory aggregates on the other hand will be submitted to a much higher internal friction and will have a lower workability and a higher porosity. The form of the

aggregates will partly determine the final porosity of the VOC.

PROPERTIES OF THE HARDENED POROUS CONCRETE

The test program for the hardened porous concrete concentrated on the relationship compressive/tensile strength versus total/accessible porosity, related to the dry density of the samples. The test program included also performance and durability tests, such as freezing and thawing resistance, resistance against abrasion and against alkaline environment and the determination of the adhesion of the VOC on a concrete sublayer.

The relation total porosity-compressive strength is investigated by measuring the total porosity and the strength after 28 days on cubes of 150x150x150mm^3. Also the dry density of the cubes is measured. The relation total porosity-compressive strength and the relation total porosity-dry density are both linear (Fig 1 and Fig 2). A similar relation can be found between the tensile strength and the total porosity.

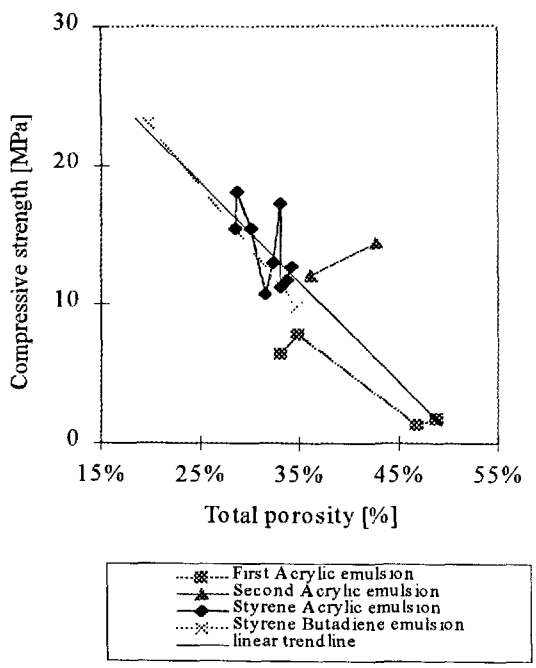

Figure 1 Total porosity-compressive strength

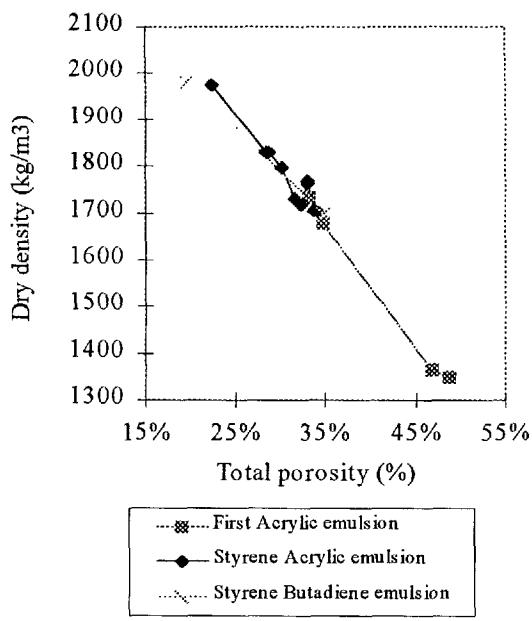

Figure 2 Total porosity-dry density

The influence of the kind of polymer is not directly visible in the relation strength-porosity. The kind of polymer plays a role in the compaction degree, obtained with the addition of a certain amount of energy, and consequently in the obtained porosity. Therefrom one observes the high porosity and the low strength for the samples made with the first acrylic polymer emulsion, since the possibility to compact was much lower for this mixture.

The durability of the VOC is tested on samples, which simulate the pavement conditions: VOC is laid on a concrete sublayer according to the wet-in-wet method. First the concrete sublayer (150 mm thick) is placed. After approximately three hours, the VOC layer (40 to 70 mm thick) is placed on top of the not completely hardened sublayer. Depending on the time between the placing of the two layers and depending on the compaction method of the VOC, the VOC and the concrete

sublayer will penetrate into each other. This will improve the adhesion of the VOC to the sublayer, but will gradually diminish the porosity over the height of the VOC layer.

The following performance and durability tests will be discussed briefly: abrasion test, road simulation test and resistance against freezing and thawing, with or without the addition of salts. The tests are carried out on samples made with the styrene-acrylic emulsion.

The abrasion test revealed promising results: no damage was visible and the abrasion was limited to 5% loss in thickness. The road simulation test showed similar results: after 100 000 cycles with a tire, which was inclined over 5° and submitted to a force equal to 5.5 kN, only a few aggregates came out of the VOC. These tests indicate that the VOC can withstand loads imposed by heavy traffic.

The freezing and thawing resistance is determined according to the European standard prEN 1340 (1993) on samples made with different polymer emulsions. Cores were taken from the two layer samples and were at the sides completely surrounded with an impermeable rubber cloth, in such a way that the VOC is completely submerged in water or ice during the whole test. 28 cycles are carried out, varying the temperature between -20°C and +20°C. To test the influence of a freezing medium, some of the samples were submerged with a 3% NaCl-solution. At the end of the test, the samples were unpacked, cut in two and visually inspected.

The samples made with the second acrylic emulsion and with the styrene-butadiene emulsion, tested without freezing medium were cracked at the transition of the VOC to the sublayer. For the samples, were the two layers flowed into each other, the crack was capricious, for the samples where the transition line was clearly visible, the crack formed also a straight line. The samples made with the styrene-acrylic emulsion showed no damage.

The samples tested with the 3% NaCl-solution were not damaged in the transition zone between the open concrete and the sublayer, but the upper surface of these samples was attacked by the salts. All the samples in this case showed similar damage: the aggregates from the upper surface were ripped of. Although the results were not completely satisfying it can be said that the VOC showed good durability, since the freezing-thawing test is very severe: in real circumstances, the water can flow out of the VOC due to the large porosity before freezing.

To ameliorate the freezing thawing resistance, a new mixture proportioning is introduced, where a part of the sand is replaced by cement. The polymer-cement ratio is not changed. Further study has to be made to reveal the influence of the amount of polymer emulsion added.

STRUCTURE

VOC is characterized by a specific structure with a large porosity. At 100% compaction it is composed of 50 volume-% coarse aggregate, 23 volume-% mortar (cement, polymer emulsion, water and sand), and 27 volume-% air. Macroscopically, three phases can be distinguished, which are homogeneously spread over the material (Fig 3). One phase consists of coarse aggregates and is discontinuously divided over the material. The second phase is continuously spread over the material and consists of the cement-polymer paste. This paste forms a matrix in which the coarse aggregates are embedded: the paste forms a fine layer (0.5 to 1 mm thick) around the aggregates and binds them together by means of 'bridges'. The third phase consists of the large pores, connected with each other through the material. These pores form a second matrix, twinned with

the cement-polymer comatrix.

Figure 3 shows an enlargement (50 X) of the mortar-film around an aggregate and of a 'bridge' connecting the aggregates, taken by means of a scanning electron microscope (SEM). Ideally the VOC is composed to contain just enough mortar to form a film around the aggregate and to connect the aggregates by means of "bridges", but not enough mortar to fill the open pores between the aggregates.

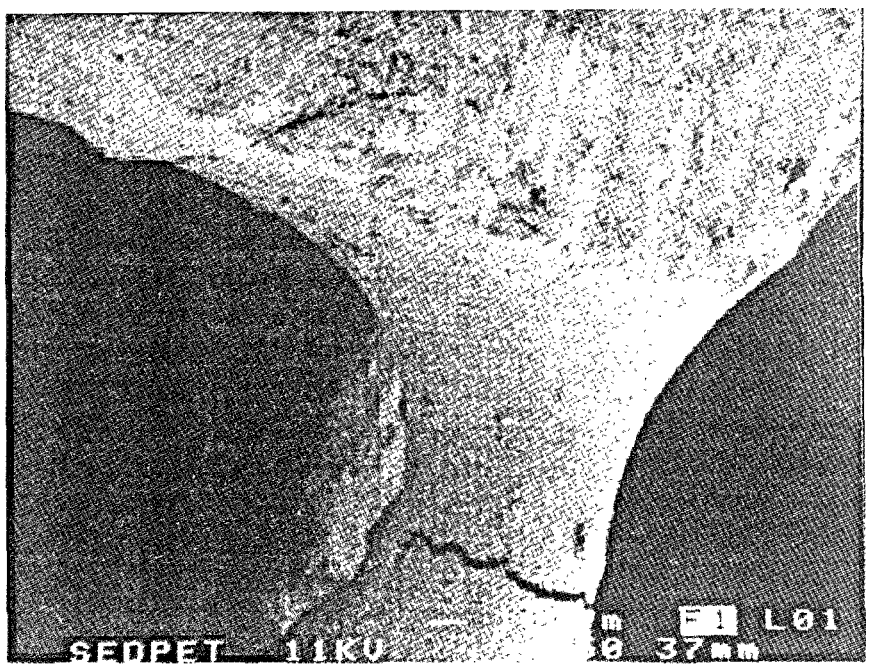

Figure 3 Cement-polymer comatrix around and in between aggregates (50 x)

Comparison between the samples made with and without polymer emulsion, indicates that the polymer facilitates the adhesion of the cement-polymer paste to the aggregate. A visual control of reference samples without polymer addition showed an incomplete covering of the aggregates by cement paste. With polymer addition (Fig 4), one observes a complete covering of the aggregate by the cement polymer paste. However the adhesion of the cement-polymer paste to the aggregate is present though not uniform. As shown in the central part of Fig 4 small pores and small cracks are present along the aggregate. This larger porosity decreases the strength of the transition zone. Ideally the VOC should contain a high amount of large pores, but a very low amount of small pores, which means that the difference between the total porosity and the accessible porosity should be as small as possible.

The task of the cement-polymer paste is dual: it provides the workability of the fresh mixture and enables a good compaction of the mixture; secondly after combined hydration and polymerization it produces a comatrix in which the aggregates are embedded. This comatrix provides the strength of the VOC. As seen in Fig 3, failure will occur in the weakest point: cracks occur at the bridges, where the cross-section is the smallest.

In general, failure occurs at three different places (Fig 5): in the bulk cement-polymer paste, in the transition zone between the aggregate and the paste and through the aggregate itself. In the second

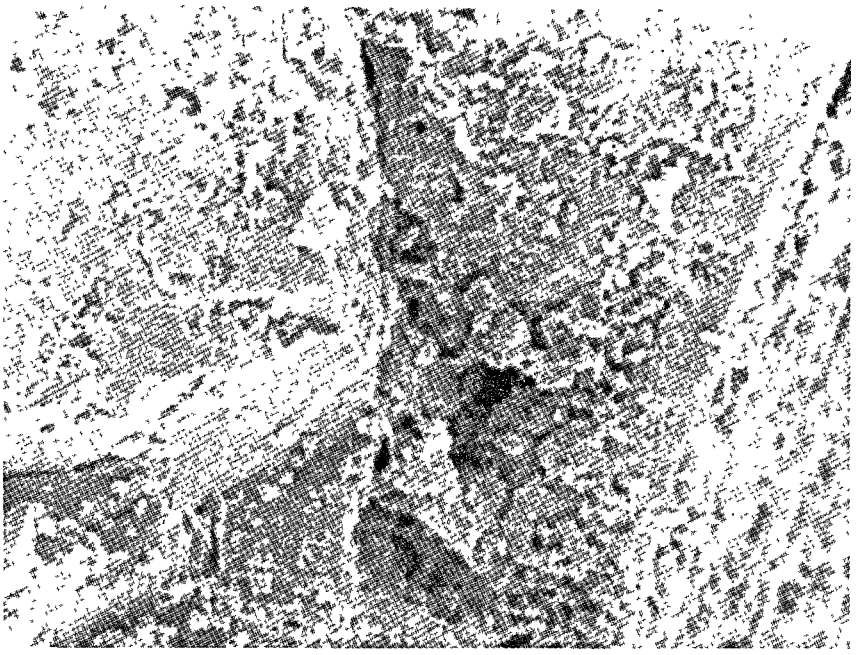

Figure 4 Transition zone between the polymer-cement and the aggregate (400 x)

case the cement-polymer paste is ripped off the aggregate. This is due to the larger porosity of the transition zone and to the non-uniform adhesion of the cement-polymer paste to the aggregate. The addition of the polymer emulsion will contribute to the stiffness and the tensile strength of the very open concrete: the formation of a continuous polymer film through the comatrix will increase the elasticity of the comatrix and will enlarge the resistance to tensile forces. However, care has to be taken to set bounds to the amount of polymer emulsion added. If a large amount of polymer

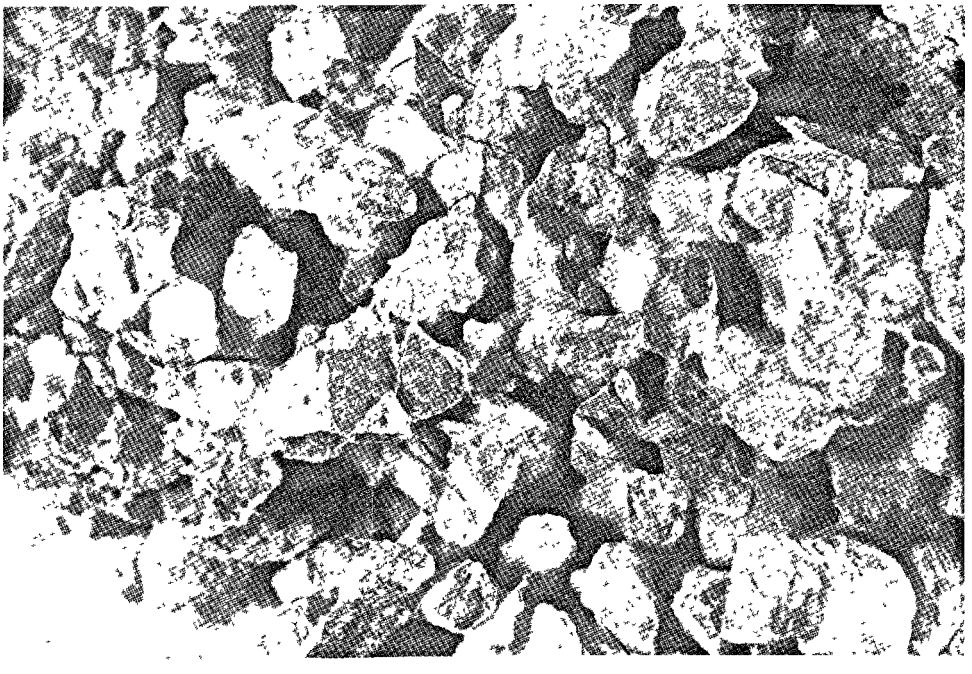

Figure 5 Fracture surface of VOC after compression test

emulsion is added, the cement particles can be completely surrounded by polymer emulsion and further hydration of the cement particles will be prohibited, and the formation of a continuous structure will not be possible anymore.

This kind of structure can also arise from a faulty mixing procedure: if the addition of the polymer emulsion to the mixture takes place before the water is added, the polymer emulsion will immediately enclose the cement particles and will prevent all contact with water to allow further hydration. The 'ideal' situation, where the cement hydration and the polymerization act together and where the cement hydrates are covered with polymer films will not be possible in such case. Besides an excessive amount of polymer will make porous concrete uneconomical.

CONCLUSIONS

Porous concrete is a polymer cement concrete, built up of three phases: the aggregates, the cement-polymer phase and the open pores. The open pores are connected with each other through the material and form a second matrix besides the matrix, consisting of cement hydrates and polymer films. The addition of the polymer emulsion improves the workability of the fresh mixture, enables a high degree of compaction and ameliorates the mechanical properties of the porous concrete. Care has to be taken at mixing: the addition of the polymer emulsion to the mixture before the addition of the water can hinder the continuous hydration of the cement particles.

THE UNSATURATED MASS TRANSFER THROUGH HARDENED CEMENT PASTE MODIFIED BY THE PARTIAL REPLACEMENT WITH SILICA-FUME: THE SORPTIVITY AND VAPOUR PHASE TRANSPORT

Don FAIRHURST, University of Central Lancashire, Preston, England
Dr Andrew K PLATTEN, University of Central Lancashire, Preston, England

ABSTRACT In this paper the Sorptivity is reaffirmed from its introduction by Philip with a simplified mathematical method examined. Published values for the Sorptivity of hardened cement pastes are scarce for silica-fume blended pastes. This paper addresses the latter point, with values presented for pastes at 1, 3 and 7 days of age for 5 and 10% replacements. Further, values are presented for the vapour phase permeability obtained by diffusion cell technique, of 1, 3, and 7 day old hardened cement pastes, modified by partial replacement with silica-fume at 5% and 10% levels.

Key-words: Water sorption, Water suction, Porosity, Diffusivity, Permeability

INTRODUCTION

The fundamental transport mechanism underlying the unsaturated mass transfer through a porous body is the capillary diffusion. Under isothermal conditions, and disregarding osmotic effects, the hydraulic Diffusivity is a dominant function of the moisture content. For these defined conditions, the movement of moisture within the porous body is created by potentials arising from moisture gradients within the body and the subsequent attainment of equilibrium between these potentials. For practical purposes, the unsaturated state more readily reflects field conditions for building structures subject to wetting and drying cycles. This places an emphasis upon the study of unsaturated mass transfer and the need to develop models based on experimental data, that will allow predictive analysis of the serviceability of cementitious structures. To facilitate this, three transfer mechanisms have been studied for hardened cement pastes only.

In this paper, the Sorptivity (mathematically related to the hydraulic Diffusivity), is discussed with values presented for the Sorptivity of Condensed Silica-fume (csf) pastes. Unsaturated flow theory, however describes two phases of moisture movement within the porous body (liquid and vapour).

RELATED WORK

The effects on silica fume addition has been reported by many workers with respect to the mass transfer properties of concretes. In the context of concrete, the sensitivity of the Sorptivity to variations in the water/cement ratio and compaction, have been examined by Hall (Hall and Yau, 1987). Where, the Sorptivity was reported to reduce in magnitude with respect to increased compaction, but being relatively insensitive to the water/cement ratio. The presence of aggregate is known to reduce the Sorptivity (Marchese and D'Amore, 1990), both structurally in terms of tortuosity, and chemically at the paste/aggregate interface. Further, the quality and composition of concrete is variable within a very short distance from the cast surface (Emeritus, 1987), leading to anisotropic medium whose mass transfer properties are not constant. Such phenomena has been shown to influence the Sorptivity (McCarter, 1993). This paper considers the effects of silica fume inclusion, to the cement paste, with respect to the properties of

unsaturated mass transfer. Thus, dispersion and chemical effects associated with the presence of aggregates in concrete or mortars, require further study.

GENERAL CONCEPTS

Liquid Phase Unsaturated Flow

Derivation of the Sorptivity and General Unsaturated Flow Equation

It is common place to consider the parameter of Sorptivity as the rate of hydraulic absorption and infiltration of moisture into the porous matrix. The Sorptivity as a material property relates to the mass transfer of moisture into an initially dry porous body, where the driving force is predominantly derived from capillary tension.

Philip (1957), introduced the term Sorptivity (S), as a material property to describe the cumulative absorption (i), into a medium for elapsed time (t), with i being expressed so:

$$i = (\theta_1 - \theta_0)\int_0^1 x \, d\theta \qquad [1]$$

For the one dimensional flow of a liquid from a saturated surface into an initially dry semi-infinite porous solid, the distance (x), advanced of the wetting front, with respect to time, is given by:

$$x(\theta,t) = \lambda(\theta)\, t^{0.5} \qquad [2]$$

giving:

$$\lambda(x,t) = x\, t^{-0.5} \qquad [3]$$

In this instance the volumetric moisture content (θ), is taken as being a single function of λ, and substituting Eq 3 into Eq 1, gives the cumulative mass absorbed for elapsed time as:

$$i = \left[(\theta_1 - \theta_0)\int_0^1 \lambda \, d\theta\right] \cdot t^{0.5} \qquad [4]$$

with, the Sorptivity being defined by:

$$S = (\theta_1 - \theta_0)\int_0^1 \lambda \, d\theta \qquad [5]$$

Eq 3 states that the relationship for the distance advanced for the infiltrating moisture is linear with respect to the square root of time. Thus, not only can i be determined, but also the moisture content and its position in the porous body.

Experimentally, moisture gradients can be determined either destructively (Bruce and Klute, 1956), or by non-destructive means such as Gamma-spectrometry (Kumaran and Bomberg, 1985), and Electrical Resistivity (McCarter *et al*, 1996).

Simplified solutions exist (Kirkham and Powers, 1972), when the mass transfer properties are known, then prediction of the both the cumulative mass absorbed and distance advanced of the wetting front is possible. Though these solutions are an over simplification and more readily suited to soil hydrology, the basic relationship of porosity to both absorption and distance advanced are shown by:

$$i = \left(-2n_e\, k\, \Delta h_t\, A^2\right)^{0.5} \cdot t^{0.5} \qquad [6]$$

and,

$$x = \left(\frac{-2k\, \Delta h_t}{n_e}\right)^{0.5} \cdot t^{0.5} \qquad [7]$$

where,

k = the permeability (cm sec^{-1})
h_t = the hydraulic suction derived from the internal pore structure (cm)
n_e = the effective porosity

It is clear that i is proportional to the square root of the effective porosity, n_e with x being inversely proportional to the square root of n_e. The relationship of $i(t^{0.5})$, is considered in this paper. Eqs 6 and 7 introduce the components of the Darcy saturated flow equation (Darcy, 1856), expressed so:

$$i = -k\left(\frac{h}{x}\right) \qquad [8]$$

With, the second term RHS representing the hydraulic gradient, or pressure acting over distance. It must be remembered that Eq 8 is valid for flow through a saturated body and must be adapted for unsaturated flow, *viz.* k is a function of θ, possessing high values reaching saturation and decreasing to zero at dryness. The reduction in k with lowering θ is due primarily to reductions in the cross section available for flow and reduction in continuity of the liquid phase, thus flow must occur by other means than direct transfer (Rose, 1963); with h being a function of θ, whose magnitude is greater at low values, and zero at saturation. Thus, k and h must be qualified as being functions of the moisture content, $k(\theta)$ and $h(\theta)$, resulting in the extended Darcy flow equation, expressed as:

$$\frac{\partial \theta}{\partial t} = -\frac{\partial}{\partial x} k(\theta)\left(\frac{\partial h}{\partial x}\right) \qquad [9]$$

or, in the form of a moisture concentration difference, by:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x}\left(D(\theta)\frac{\partial \theta}{\partial x}\right) \qquad [10]$$

where,

D = hydraulic Diffusivity (cm^2 sec^{-1})

and is defined by:

$$D(\theta) = K(\theta)\frac{\partial \psi}{\partial \theta} \qquad [11]$$

where,

ψ = capillary force (cm) equivalent to h_t

Eqs 9 and 11 form the basis deriving solutions to the vapour phase flow now discussed.

Vapour Phase Unsaturated Flow

In the case of vapour transfer, ψ is the moisture potential in thermodynamic equilibrium with the water in a porous material with atmospheric pressure as datum, and is related to vapour pressure by:

$$rh = \exp\left(\frac{-Mg\psi}{RT}\right) \quad [12]$$

giving:

$$\left(\frac{RT}{Mg}\right) \ln rh = -\psi \quad [13]$$

$\left(\frac{RT}{Mg}\right)$ = 14279m for water at 30°C the working temperature used in this work, with the negative term indicating an expenditure of work associated with suction. Thus, where the vapour pressure potential determined by Eq 13, the vapour permeability is solved by:

$$i = -k_v \frac{\Delta\psi}{x} \quad [14]$$

with the vapour Diffusivity solved using Eq 11 by:

$$D_v(\theta) = k_v(\theta)\left(\frac{\partial\psi}{\partial\theta}\right) \quad [15]$$

The relationship of vapour phase transfer to that of hydraulic, can be observed at the tail of a moisture distribution plot. Though differentiating is difficult to determine from such plots, isolation of the vapour phase makes quantitative analysis possible, and therefore provides a full history of the moisture transfer process.

MATERIALS DETAILS

In this study, pastes used for the determination of the Sorptivity were modified by Elkem 500S "Microsilica", and for vapour phase analysis modified by "Micropoz". Samples used in the study of the Sorptivity were cast from 100mm diameter moulds, de-moulded after one day, and bath cured until the age of test. The samples were then cut to expose the structure of the paste and dried to a constant mass in a vacuum oven at 40°C. Samples used in the study of vapour phase flow were cast from 40mm diameter rings (≈2mm thickness), bath cured until the age of test and dried as before to a constant mass. A constant water/cement ratio of 0.5 was used throughout this study.

EXPERIMENTAL

The determination of the Sorptivity was undertaken using the method detailed by Hall (1989); where water from a free-water reservoir, is allowed to vertically infiltrate an isotropic sample of uniform initial moisture content. The cumulative mass absorbed was determined gravimetrically with respect to elapsed time.

Porosity was determined gravimetrically using water displacement. The samples were subjected to a vacuum pressure of 1 bar, for 10 minutes to remove entrapped air within the pore structure, which was displaced by infiltrating water. Samples were left to absorb water for 24 hours, whereupon their saturated mass was determined.

Vapour phase analysis was undertaken using a modified method of BS 3177 (1959); where the mass transfer through a sample, brought into an equilibrium moisture content, was determined gravimetrically with respect to elapsed time.

The samples were subjected to various relative humidities in a Vindon humidity cabinet. A vapour sink was supplied from silica-gel, maintaining zero moisture content in the diffusion cell. Thus, a potential difference in vapour pressure acted between the samples surface, inducing vapour flow.

RESULTS

The Sorptivity

The Sorptivity for the pastes studied in this work has been derived from the gradient of a straight line plot of $i(t^{0.5})$. For a straight line to be represented, four conditions must be satisfied: 1) the material must be homogeneous throughout the region of ingress, 2) the capillary absorption must be normal to the inflow face, neither converging nor diverging, 3) the water must be freely available at the suction surface, and 4) gravitational effects must not affect the absorption process. The pastes studied in this work satisfy the four conditions.

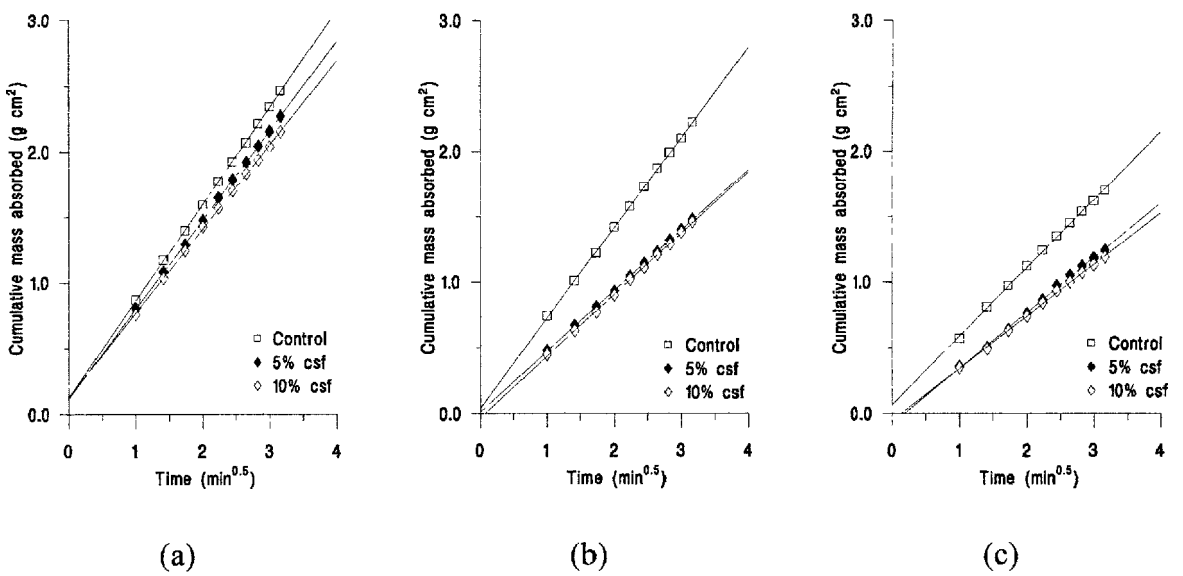

Figure 1 Cumulative mass absorbed for elapsed time for pastes at 1, 3 and 7 days of age (1a, 1b and 1c)

Qualification of the linear relationship of mass absorbed to the square root of time is illustrated in Fig 1, thus satisfying the four conditions of derivation from the gradient of $i(t^{0.5})$. Collectively, the data illustrate the effects of hydration on the water absorption properties of the

pastes. Individually, the data provides clear evidence of the effect of csf replacement, both for age of paste and percentage of replacement. Specific values for the Sorptivity of the pastes are presented in Table 1, with the results summarised as follows:

Table 1 Values for the Sorptivity

Age (days)	Replacement (%)	Sorptivity (mm $min^{0.5}$)
1	0	7.35
	5	6.82
	10	6.40
3	0	6.88
	5	4.62
	10	4.69
7	0	5.20
	5	4.20
	10	3.96

- 1 day pastes, Fig 1(a)- Though the water absorption of the pastes are comparable, both 5% and 10% csf replacement pastes exhibit reductions in the order of 7% and 12% respectively compared to the control paste.
- 3 day pastes, Fig 1(b)- At 3 days of age, the pastes exhibit reductions to 1 day values in the order of 6%, 32% and 27% for the control, 5% and 10% pastes respectively. Further, comparison with the control paste for the same age shows the 5% and 10% to have lower Sorptivity values in the order of 30% and 32% respectively, where a distinct banding is evident for csf pastes.
- 7 day pastes, Fig 1(c)- At 7 days of age, reductions in the Sorptivity are exhibited by all pastes, with values representing reductions in the order of 29%, 38% and 38% from day 1 values. Comparison with the control paste at the same age, shows the csf pastes again exhibiting lower values, in the order of 32% and 36%, for 5% and 10% replacement respectively.

For all ages of pastes, it is evident from the values presented, that whilst there is some reduction to the Sorptivity for increased csf replacement, this reduction is negligible.

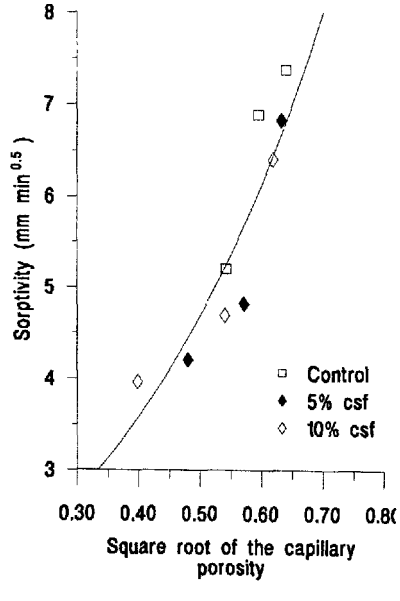

Figure 2 Relationship between the Sorptivity and square root of the porosity

Relationship between the Sorptivity and Porosity

A simplified method for deriving the cumulative mass absorbed has been discussed, Eq 6, where the Sorptivity was shown to be proportional to the square root of the porosity. Whilst it is reasonable to assume the Sorptivity to be proportional to the porosity mathematically, the linear relationship is not found to exist in the case of the cement pastes studied in this work. This is illustrated in Fig 2, where the plotted data follows a best fitted exponential curve (Sorptivity = $\exp^{(1.61x)}$), though the accuracy of the fit is only 0.82 which is not sufficient to derive a confident relationship. It seems probable that for the case of cement pastes, the relationship is not linear due to a wide pore size distribution and the effects of tortuosity, though this requires further investigation.

The porosities of the pastes studied in this work are presented in Table 2, where it is evident that at day 1, the porosities for all pastes are comparable and that it is at later ages that distinct reductions relative to csf replacement are apparent.

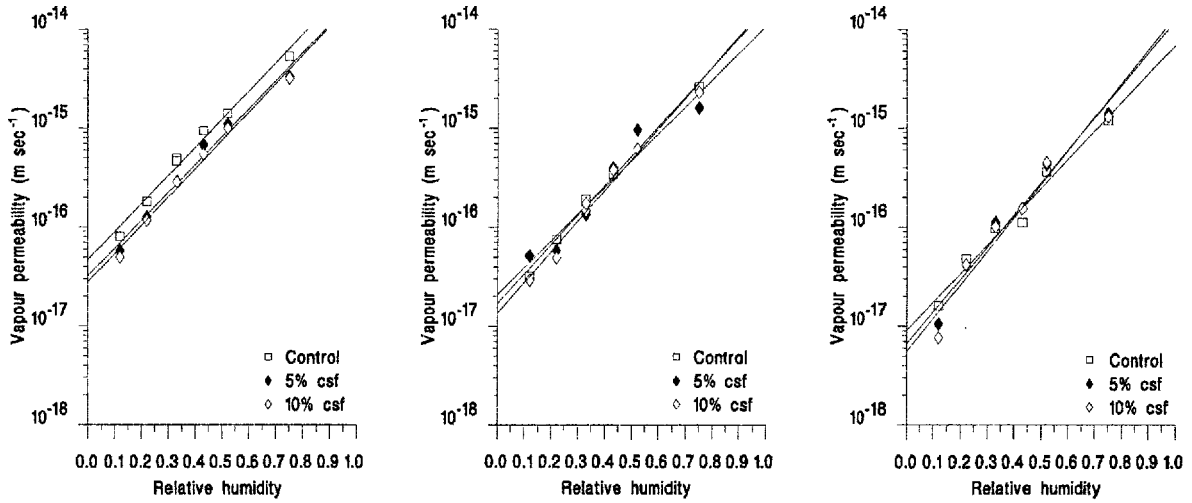

Table 2 Values for the porosity

Age (days)	Replacement (%)	Porosity (n_e)
1	0	40.94
	5	39.89
	10	38.27
3	0	35.36
	5	32.71
	10	29.20
7	0	29.46
	5	23.13
	10	15.85

The Vapour Permeability

The vapour permeabilities of the cement pastes studied in this work illustrate reductions for degree of hydration (age of paste at test), and for csf replacement. The latter is clearly shown in Fig 3a, where clear separation is evident between the control paste and the csf replacements. This trend is less pronounced at day 3 and 7, where all pastes exhibit comparable values.

All data illustrate that for increasing relative humidity: i.e. increasing moisture content; the vapour permeability increases in magnitude. This relationship supports the proportionality of the mass transfer to the permeability as a function of the moisture content of the paste, as reported by Rose (1963).

(a) (b) (c)

Figure 3 Vapour permeabilities with respect to relative humidity and age of pastes at 1, 3 and 7 days of age (3a, 3b, 3c)

CONCLUSIONS

- The Sorptivity is sensitive to changes in capillary porosity and reducing capillary pore radii, which are associated with hydration and csf replacement. The Sorptivity can therefore provide qualitative information on the durability of the paste.

- Results presented in this paper show that csf replacement reduces the mass absorption of cement pastes, both for increased percentage and for degree of hydration: i.e. age of paste.

- The proposition that the Sorptivity is proportional to the square root of the porosity has been shown to be invalid in this instance.

- A mathematical derivation of the unsaturated vapour transport mechanisms of the Permeability and Diffusivity, has been presented based on the liquid phase unsaturated flow equation.

- The vapour Permeability of csf replacement pastes has been shown to be reduced at day 1, but thereafter (upto 7 days of age), values are comparable to normal paste.

- The vapour Permeability has been shown to be a function of the moisture content, and to increase in magnitude with increasing relative humidity.

- Though values for two properties of unsaturated mass transfer have been reported, this study requires further investigation in relation to the inclusion of aggregates and their effects on the named properties.

MOISTURE DISTRIBUTIONS AND THE HYDRAULIC DIFFUSIVITY OF HARDENED CEMENT PASTES MODIFIED BY PARTIAL REPLACEMENT WITH PFA AND GGBS

Don FAIRHURST, University of Central Lancashire, Preston, England
Dr Andrew K PLATTEN, University of Central Lancashire, Preston, England

ABSTRACT Cement replacements, such as pfa and ggbs, have been found to modify the microstructure of the cement matrix. Blended hardened cement pastes at the age of 28 days, with pfa and ggbs replacement levels of 10, 20 and 30%, were studied in the unsaturated condition. It is shown that 30% replacement enhances the performance of cement paste with respect to penetrating water. Further, values are presented for the hydraulic Diffusivity as a function of moisture content.

Key-words: Diffusivity, Blastfurnace slag, Pulverised fuel ash

INTRODUCTION

Durability issues for cementitious media are inherently related to the barrier qualities of the concrete. Aggressive compounds present in the environment, such as chloride ions and sulphates, may be carried in solution during the transport of moisture through the cement matrix. Further, the absorption of such compounds can lead to deterioration of the calcium hydroxide $Ca(OH)_2$ content of the hardened paste, leading to increased porosity and further infiltration of moisture (Sims, 1994). Predominantly, field concretes are not subjected to saturated conditions, and where such instances do arise, the diffusion of oxygen and not water is the primary concern. This observation places emphasis upon the study of unsaturated transfer processes, such as the hydraulic Diffusivity, where moisture gradients exist between the surface and inner mass. This paper is concerned with capillary phenomena in relation to pastes, and though such data obtained cannot be directly applied to predictive models for concrete, it does constitute an advancement in the study of the unsaturated mass transfer through cementitious media.

GENERAL CONCEPTS

Classical theory describes that for an initially dry porous body, the mass absorbed and depth of penetration obey a square root of time relationship (Kirkham and Powers, 1972). This relationship however, is subject to: a) the material properties such as porosity (Hall and Yau, 1987), and time (Emerson, 1990). It has been proposed (Hall, 1981), that the advance of the wetting front can be assumed to be sharp, where a steep moisture gradient exists over a relatively short distance lying behind the leading edge. Thus, enabling rudimentary prediction of the depth advanced, from data of the mass absorbed. Published results of the advancing wetting front for cement pastes are, however, uncommon. This paper addresses the latter point.

MATERIAL DETAILS

Following established mix design procedures and prescribed levels of cement replacement (BS 5328, 1991), the pastes replicated accepted practice. The cementitious factors (C_f) for pfa and ggbs were taken as being 0.3 and 0.7, respectively. The water/cement ratio was defined by $W / (C+C_fF)$, where, W is the water content, C is the cement content and F is the replacement content. A constant water/cement of 0.5 was used in this study, with all pastes being bath cured until test at 28 days of age.

THEORETICAL

Assuming the gravitational effects to be minimal, one-dimensional vertical flow in an homogeneous body can be written in a similar manner to the non-linear diffusion equation (Bruce and Klute, 1956).

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x}\left(D(\theta)\frac{\partial \theta}{\partial x}\right) \quad [1]$$

where,

θ = volumetric moisture content (cm^3 water cm^{-3})
t = time (sec)
x = distance (cm)
D = hydraulic Diffusivity (cm^2 sec^{-1})

The initial and boundary conditions governing flow are:

$$\theta(x,t) = \theta_i \quad x>0 \quad t=0 \quad [2a]$$
$$\theta(x,t) = \theta_s \quad x=0 \quad t\geq 0 \quad [2b]$$

Assuming θ to be a function of a single variable $\lambda(x,t)$, the Boltzmann transformation:

$$\lambda = xt^{-\frac{1}{2}} \quad [3]$$

Thus, restating the relationship to the square root of time. Eq 1 now becomes the ordinary differential equation:

$$-\frac{\lambda}{2}\frac{d\theta}{d\lambda} = \frac{d}{d\lambda}\left(D\frac{d\theta}{d\lambda}\right) \quad [4]$$

Thus, Eq 1 can be integrated subject to the boundary conditions Eq 2a and 2b:

$$D(\theta) = \int_{\theta_i}^{\theta_i} \lambda d\theta \quad [5]$$

The Diffusivity being a function of the moisture content. The solution to $D(\theta)$ is the initial step in resolving the unsaturated flow equation, Eq 6:

$$D(\theta) = K(\theta)\left(\frac{\partial \psi}{\partial \theta}\right) \quad [6]$$

where,

K = hydraulic conductivity (cm sec^{-1})
ψ = capillary force (cm)

EXPERIMENTAL

Water was allowed to vertically infiltrate paste columns from a free-water reservoir for an initial moisture content, θ_i. At pre-determined times, the samples were removed, sectioned (at 5mm intervals), and weighed immediately to obtain the mass of each element. After drying to a

constant mass at 105°C, θ_0 ($\theta_i = \theta_0$), the elements were weighed, saturated, θ_s and re-weighed. Thus, the normalised moisture content, θ_r could be determined for each element and plotted with respect to distance. The effect of direct drying has been reported to have a significant effect upon the microstructure and transport properties of cement pastes (Parrott, 1983); such effects could not be determined at the time of this study and are therefore acknowledged, but not accounted for. As a check, the pastes were examined by Scanning Electron Microscopy to ascertain the presence of microcracks, none were evident in the pastes studied.

RESULTS

In this paper, results for the depth of penetration and values for the hydraulic Diffusivity, are presented where the linear relationship to the square root of elapsed time is preserved, thus satisfying Eq 3. The time for which this relationship exists is dependant on the physical properties of the specific paste. A typical moisture distribution plot, from which the hydraulic Diffusivity can be numerically derived, is illustrated in Fig 1.

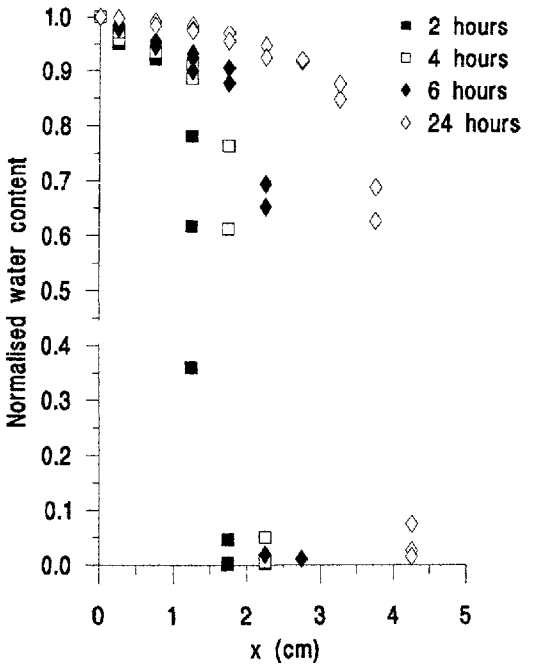

Figure 1 Moisture distributions for 20% replacement ggbs with respect to time (θ_r against x for different times)

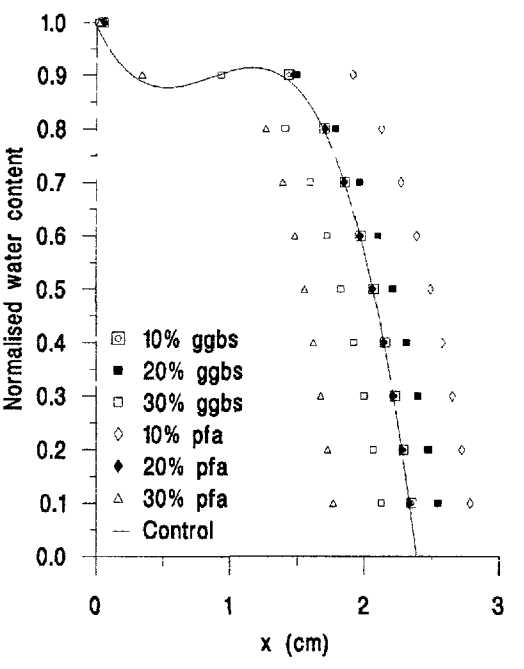

Figure 2 Moisture distributions after 6 hours infiltration for the pastes studied in this work

Moisture distributions for the pastes studied in this work are presented after six hours of infiltration, in Fig 2. The data points have been derived from a least squares polynomial fit determined from raw experimental data. It is noteworthy that the form of the wetting front suggests similarity of shape for the cement pastes tested in this work.

With respect to depth of penetrating moisture, the curves illustrate enhanced performance for increased cement replacement, subject to the following qualifications. For example, there is marked separation between 10% and 30% pfa replacement pastes, with the latter indicating enhanced performance characteristics. Conversely, for ggbs pastes there is little separation between 10% and 30% replacement.

Hydraulic Diffusivities for the pastes studied in this work are presented in Fig 3. There is little separation between the data points indicating that for porous systems such as cement pastes the hydraulic Diffusivity is approximately constant for a given moisture content.

The significance of the moisture content with respect to the hydraulic Diffusivity is also convincingly illustrated in the figure. For the pastes studied, the diffusion rate increases approximately by three magnitudes from dryness and saturation. This conforms to unsaturated theory, as Eq 5.

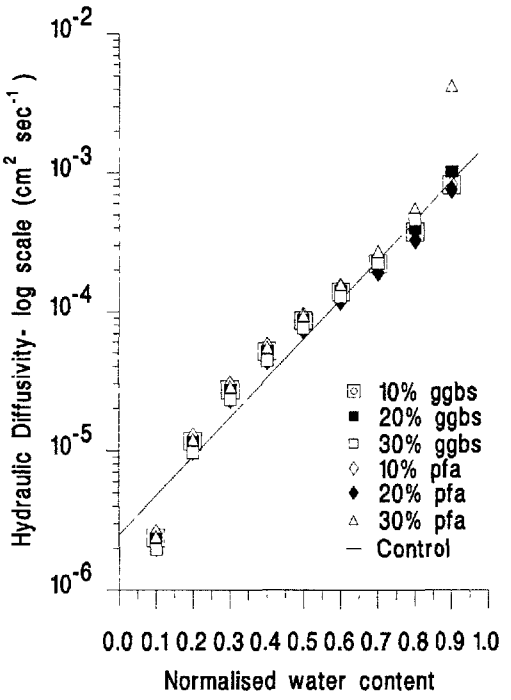

Figure 3 The Hydraulic Diffusivity $D(\theta)$, for pastes at 28 days of age (control paste is given as best fit line)

CONCLUSIONS

- Pfa and ggbs replacement levels of 30% enhance the performance of cement pastes to penetrating moisture. At lower levels of replacement, the performance is comparable to the control paste.
- The hydraulic Diffusivity is a strongly variant function of the moisture content. Indeed, the moisture state is the dominant factor in the Diffusion rate for unsaturated flow.
- Though the assumption of the sharp wetting front in this instance leads to the under estimation of the actual distance advanced, it is important to remember that certain degradation mechanisms require high moisture contents to be active. Thus, simplification can be justified for these purposes.

INFLUENCE OF MOISTURE CONTENT ON THE EFFECTIVE DIFFUSION COEFFICIENT OF CO_2 IN LIME MORTARS WITH DIFFERENT POROSITIES

Koenraad VAN BALEN, Prof., K.U.Leuven, Department of Civil Engineering, Belgium
Christophe VAN DEN BRANDE, civ.eng., K.U.Leuven
Eleni-Eva TOUMBAKARI, ass., K.U.Leuven, Department of Civil Engineering, Belgium
Dionys VAN GEMERT, Prof., K.U.Leuven, Department of Civil Engineering, Belgium

ABSTRACT The influence of the moisture content of hygroscopically moistened samples on the diffusion coefficient of CO_2 is important only for very high relative humidities. For water wetted samples, the diffusion coefficient decreases almost linearily with increasing water content, with an asymptotic smoothing in the capillar water content region. Diffusion becomes negligible, when the moisture content reaches the critical value below which only damp transport is possible. However, significant diffusion of CO_2 still takes place for moisture contents between the critical and capillar water content.

Key-words: carbon dioxide, carbonation, diffusion, lime, moisture.

INTRODUCTION

Lime mortars of various compositions have been widely used for centuries before being gradually replaced by cement mortars, both in new constructions and for restoration purposes. However, the last decades have seen an increase in examples of masonry deterioration due to mechanical and physicochemical incompatibilities between cement and stone, which brought about a renewed interest for the study of lime mortars. Due to the deformability and physical compatibility with masonry, the latter tend nowadays more and more to substitute pure cement mortars. However, the state of the art of lime performance and mechanical behaviour reveals a relatively small research history. Van Balen (1991) developed a mathematical model for lime mortar carbonation. This model has been limited to the study of CO_2 diffusivity up to the critical moisture content. In order to extend the mathematical model beyond this value, the influence of diffusivity has been further studied at water contents above the critical water content.

CARBONATION, HYGROSCOPIC BEHAVIOUR AND DIFFUSIVITY

Carbonation of lime mortars

The hardening of lime mortars is initiated by drying. After partial drying of the mortar, during which capillar forces provide the cohesion of the material, the carbonation reaction is allowed to take place, causing the further hardening of the lime mortar. The lime carbonation reaction can be described as follows:

$$Ca(OH)_2(s) + CO_2(g) \rightarrow CaCO_3(s) + H_2O \quad [1]$$

It can be divided in the following main stages:

Dissolution of $Ca(OH)_2$: $Ca(OH)_2$ (solid) $\rightleftharpoons Ca^{2+}$ (aq) + $2OH^-$ (aq) [2]
Carbon dioxide diffusion through the gaseous phase of the pores and reaction:

$$Ca^{2+}(aq) + 2OH^-(aq) + CO_2(g) \rightarrow CaCO_3(s) + H_2O \quad [3]$$

The role of water is fundamental for these reactions to occur. On the one hand, it occupies the volume of the pores, hindering the gas diffusion process. The diffusion coefficient of CO_2 in the air is 0.139 cm^2/sec and in water 10^4-10^5 times less (Richardson, 1988). On the other hand, it provides the medium, where reactions can take place. Carbonation is thus retarded when the material is saturated with water or, on the contrary, at low relative humidities when no water is present on the pore surface. The optimum water content for carbonation is the water content that corresponds to maximum adsorption on the surface of the pores before capillary condensation. The material's water content and the pore volume and geometry play therefore a key role in the diffusivity of carbon dioxide.

Hygroscopic behaviour of lime mortars

If a hygrothermal equilibrium between the pores and the environment is assumed, all pores with diameters smaller than the Kelvin diameter are completely filled with water, while the walls of the remaining pores will be covered with a continuous film of water molecules (Papadakis et al., 1991b). The Kelvin diameter can be computed by the Kelvin equation:

$$\ln\phi = - (4\sigma_w \cos\theta)/(\rho_w R t d_{eq}) \quad [4]$$

in which ϕ is R.H./100, σ_w is the surface tension (in N/m), θ is the contact angle (in°) and d_{eq} is the equivalent diameter (in m). During hygroscopical loading of the material, the water content remains too low to permit water transport through the sample. When the water content reaches values above the critical water content, e.g. due to rain, water transport through the material occurs. When the maximum water content (capillary moisture content) is reached, air is prohibited from flowing out of the material. Van Balen (1991) has shown that lime mortars are materials with a low hygroscopicity.

Effective gas diffusivity

In a binary gas mixture, the flux density is proportional to the concentration gradient in the direction of the diffusion and is described phenomenologically by Fick's first law:

$$N_A = -D_A \, dC_A/dx \quad [5]$$

in which N_A is the rate of transfer of a gas A (in moles of A per sec per m^2 of the medium normal to the direction of the flux), D_A is the diffusion coefficient of A (in m^2/sec) and dC_A/dx is the concentration gradient of A (in moles of A per m^3 per m). In porous materials, diffusion of gases occurs only through the gaseous phase of the open pores. In this case, the transport mechanism of gas is described by the following equation:

$$N_{eff} = -D_{eff} \, dC_A/dx \quad [6]$$

in which N_{eff}, D_{eff} are the "effective" rate of transfer and the "effective" diffusion coefficient respectively. The term "effective" is used to indicate that a transport coefficient applies to a porous material and not an homogeneous region. In a cylindrical pore, there exist different diffusion regimes, depending on the pore radius and the diffusing gas molecules. The influence of the latter is taken into account through the definition of the mean free path λ (in m)

$$\lambda = RT/NP\pi d^2 \quad [7]$$

in which R is the universal gas constant (8.314 J/mol K), P the pressure (in Pa), T the temperature (in K), N the number of Avogadro (6.023 10^{23} /mol) and d the molecular diameter (in m). If the radius r of the capillary and the gas pressure are such , that the mean free path is large compared to the pore diameters, Knudsen diffusion starts taking place. Knudsen diffusion appears for $r/\lambda < 0.1$ (Youngquist, 1970) . When $r/\lambda > 10$, ordinary molecular diffusion predominates. Finally, for r/λ between 0.1 and 10, combined diffusion occurs. Apart from the effective diffusion coefficient D_{eff}, the flow of gases within a porous solid can also be described by the diffusion resistance number. This number compares the diffusion resistance of a porous material to that of an air layer with the same volume in identical environmental conditions (p, T):

$$\mu = D_{AB}/ D_{eff} \qquad [8]$$

in which D_{AB} is the diffusion coefficient of a gas in air (in m^2/sec) and D_{eff} is the effective diffusion coefficient within the porous solid (in m^2/sec).

EXPERIMENTAL PROGRAM

Materials and specimens

A dry slaked hydrated lime has been used. In order to investigate the influence of the porosity upon diffusion, two different types of sand have been chosen. The norm sand fulfills the DIN 1164 and the finer sand of Zutendaal fulfills the specification n° 200 of the Flemish Ministry of Public Works (100 % passing throught the 0.5 mm sieve). Previous experiments have determined consistency values between 1.45 and 1.55 in order to achieve a good mortar workability. The compositions and physical properties of the samples are listed in Table 1. After being cured for two weeks in 20°C and 60 % R.H., the samples have been placed in a glass bulb containing 100 % CO_2 for six weeks in order to carbonate completely. Therefore, any carbon dioxide consumption during the diffusion measurements has been avoided. The grain-size distribution of the norm sand results in a higher density and, consequently, a lower porosity than the Zutendaal sand.

Table 1 Mix proportions and physical properties of the lime mortars

	Water (gr)	Sand (gr)	Lime (gr)	W/L	Mean bulk density (gr/cm^3)	Porosity	
						Water satur. %	Mercury Intrusion porosity %
Mortar 1 Zutendaal sand	425	1400	300	1.42	1.743	35.2	30.7
Mortar 2 norm sand	300	1350	256	1.17	1.909	28.2	28

Experiments

Previous studies concerning the hygroscopical behaviour of identical lime mortars showed that a significant moisture content occurs only for the highest levels of R.H. (Van Balen, 1991, Van Balen et al., 1994). Therefore, two values of R.H. have been chosen for the study of the hygroscopical

behaviour of lime mortars. After carbonation, the samples have been placed for a minimum of 6 weeks in two glass bulbs under (20°C, 86% R.H.) and (20°C, 98% R.H.) respectively before the measurement of their hygroscopic water content. The critical water content has been determined as follows: water saturated samples have been covered by wax except for one surface, placed for 20 days in a controlled environment (20°C, 60% R.H.) and allowed to dry. The cumulative humidity loss, the remaining water content and the dry flux have been measured in function of time. The critical water content corresponds to the change in the slope of the humidity loss versus time curve. This means that water vapore diffusion starts to govern the drying process. The capillar and saturation water contents have been measured according to NBN B 05-201. The pore size distribution of the samples has been determined with a mercury porosimeter. Effective diffusivity has been studied experimentally, using a Wicke and Kallenbach type of setup. It comprised a non-dispersive infrared adsorption analyser (UR AS 10E, Hartmann and Braun), manometer, flow regulating needle valves and diffusion cell. The analyser was linked to a PC, which recorded continuously the concentration of carbon dioxide. The setup is given in Fig 1.

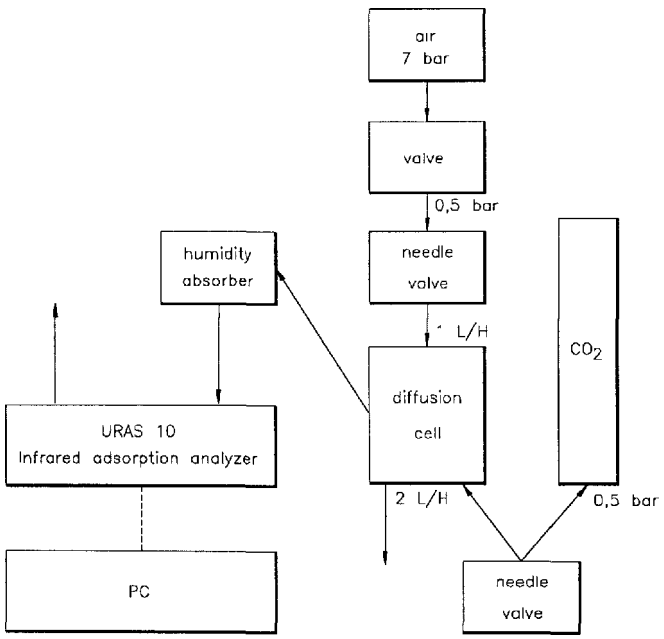

Figure 1 Experimental setup for effective diffusivity measurement of mortar

RESULTS

Microstructure

The pore size distribution of the fully carbonated samples is shown in Fig 2. The better grain size distribution of the norm sand results in a lime mortar with higher density and lower porosity than those of the Zutendaal sand mortars. However, both materials can be classified as "rough" porous materials (i.e. with pore volume peaks at around 1μm). Since the mean free path of carbon dioxide is λ= 0.045μm, bulk diffusion will dominate. The results concerning the various typical water contents of the samples are presented in Table 2. In the case of 86% R.H., the equivalent diameter is 0.014μm. Only 1.6% of the pore volume of the Zutendaal sand mortars and 1.5% of the norm sand mortars is below this value. The equivalent diameter for 98% R.H. is 0.11 μm and the

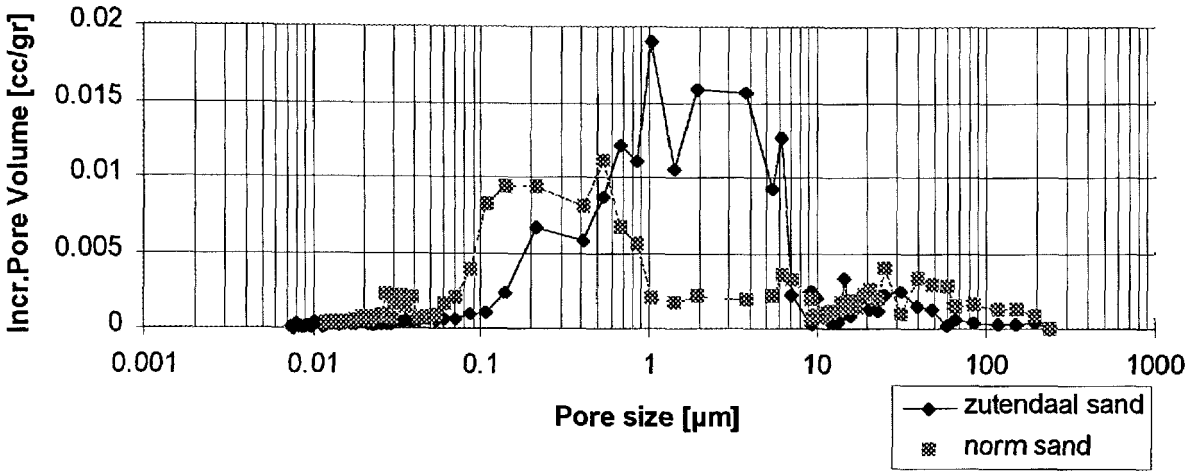

Figure 2 Pore size distribution of the mortars measured by mercury intrusion porosimetry

Table 2 Hygroscopical water contents (kg/m3)

	Mortar 1 Zutendaal sand	Mortar 2 norm sand
Moisture content at 86% R H	5 58	4 42
Moisture content at 98% R H	22.29	27.9
Critical water content	60 0	70 0
Capillar water content	215 9	208.7
Saturation water content	352.5	287.5

corresponding volumes become 6.33% and 9.72% for the Zutendaal sand and norm sand respectively. It was therefore confirmed that lime mortars cannot be significantly wetted through hygroscopic action.

CO_2 diffusion for hygroscopically moistured samples

The diffusion coefficient of the hygroscopically loaded samples is presented in Fig 3 The hygroscopic action, even for R H as high as 98%, does not have any significant impact on the diffusion coefficient. Application of linear regression analysis on these results gives the following equations

Zutendaal sand mortars: $D_{eff} = 4\ 52\ E\text{-}09\ w + 1.69\ E\text{-}06$ [9]

Norm sand mortars: $D_{eff} = 1.71\ E\text{-}09\ w + 1.36\ E\text{-}06$ [10]

CO_2 diffusion for water wetted samples

Measurements of at least ten different water contents have been carried out on different mortar samples, prepared either with Zutendaal or with norm sand. The results are presented in the Figs 3 till 7 below. These water contents have been achieved as follows: after diffusion testing of the

dry samples, water was added gradually from their upper surface, until the CO_2 concentration in the mixing chamber dropped below 1%. Then the samples were placed for about 1 week in a glass bulb in 98% R.H. and 20°C.

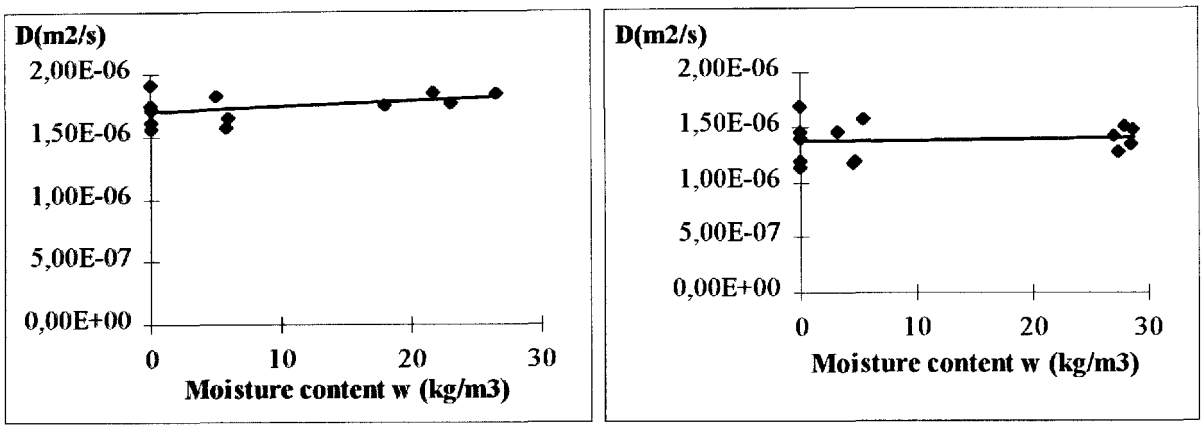

Figure 3 Diffusion coefficient of CO_2 for Zutendaal sand mortars (left) and norm sand mortars (right)

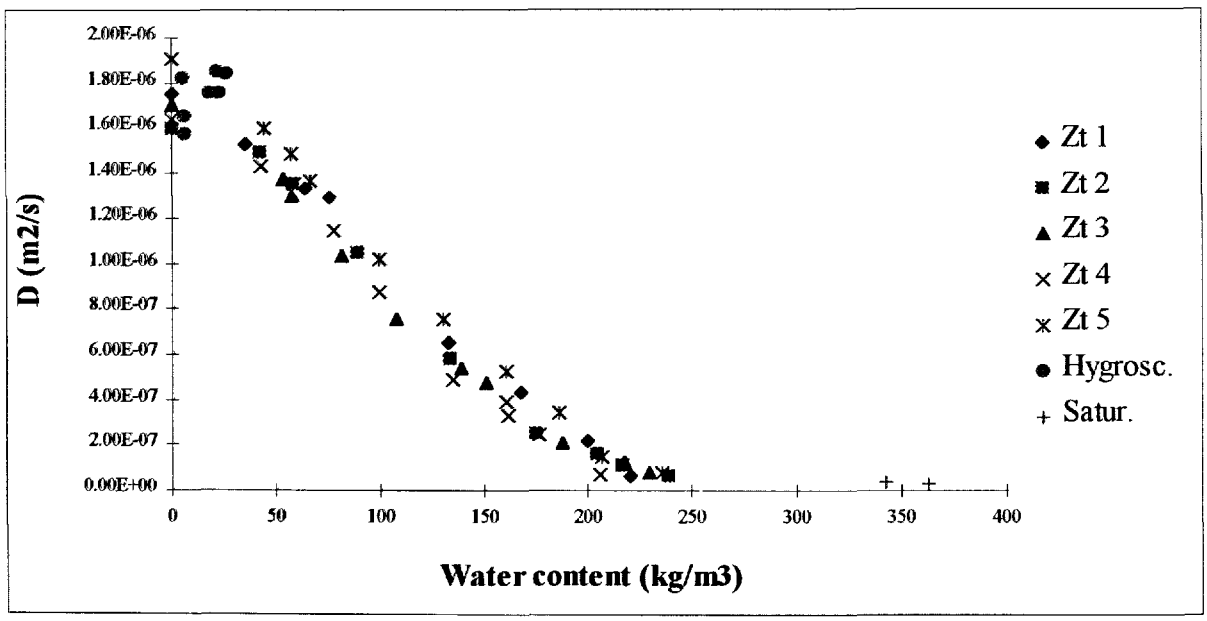

Figure 4 Diffusion coefficient for CO_2 of Zutendaal sand mortars

Concerning the Zutendaal mortars, for water contents below the critical water content, the slope of the diffusion coefficient curve is less pronounced than for water contents above this. This indicates that diffusivity is easier, since no continuous water paths are present in the specimen. Once the critical water content is reached, an almost linear decrease of the diffusion coefficient occurs. Finally, close to the capillar water content, the curve is flattened. The same tendency has been observed in the mortars made with norm sand: the diffusion coefficient decreases slowly below the critical water content, strongly between the critical and capillar water content till it reaches the capillar water content (Figs 4 and 5). Corresponding tendencies are observed relative to the diffusion resistance number, which does not significantly change up to the critical water content, then it starts increasing slowly and, above the capillar water content it increases almost exponentially (Figs 6 and 7).

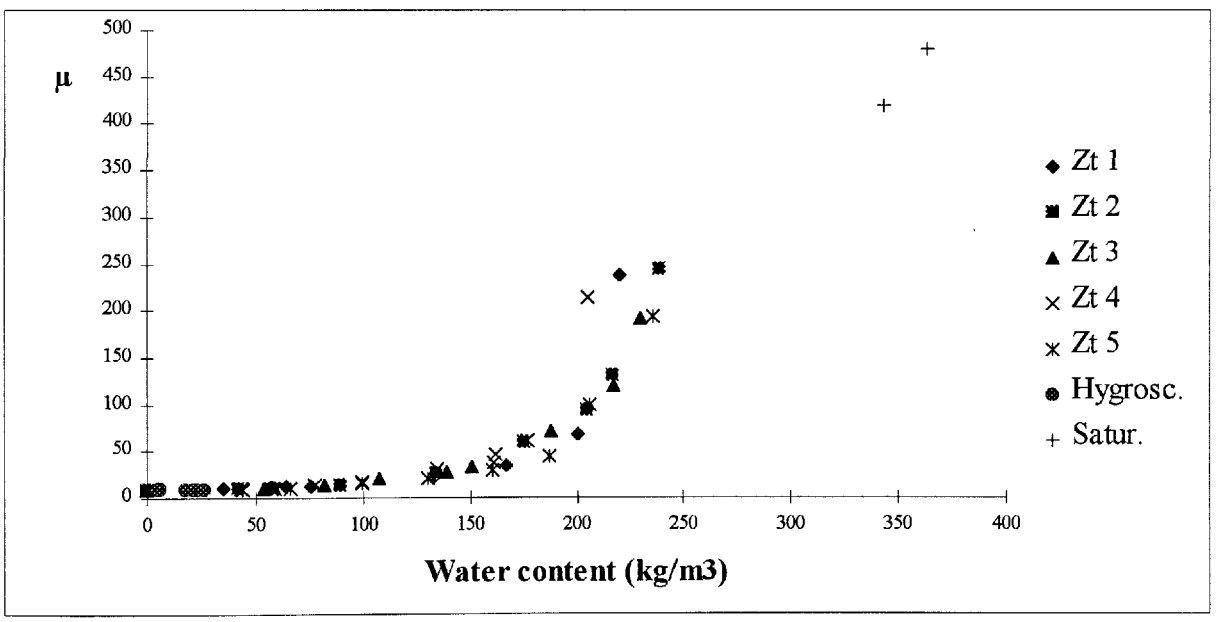

Figure 6 CO_2-Diffusion resistance number for Zutendaal sand mortars

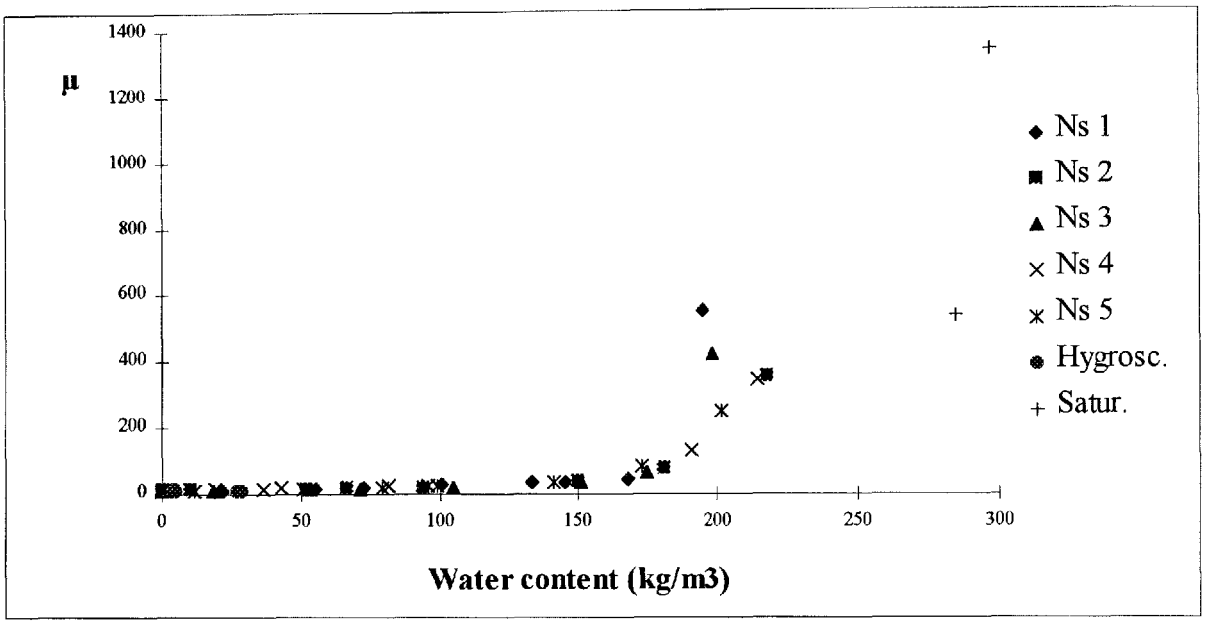

Figure 7 CO_2-Diffusion resistance number for norm sand mortars

CONCLUSIONS

Diffusivity measurements have been carried out, in order to describe the CO_2 transport within a carbonated lime mortar. It is assumed that there exists hygrothermal equilibrium between the pores and the environment. Under these conditions, the influence of the water content on CO_2-diffusivity is much less pronounced than e.g. in cement mortars. In practice, CO_2 diffusion still takes place at high water contents and is prohibited only above the capillar water content. The reason for this behaviour, which contrasts sharply to the behaviour of cement and concrete, must be attributed to the coarser pore size distribution of a lime mortar. The results of the research match with experimental findings that carbonation of lime mortars still occurs at high relative humidity. They also allow to extend the carbonation model developed for cases where the lime mortar has a water content higher than the critical water content. If the pore configuration permits to the lime mortars to carbonate even at very humid environments, it equally assures the water vapour transfer inside a masonry wall. This is obviously hindered when cement mortars are applied on masonry. Water is obliged to search an alternative path, namely through the more porous stones. This mechanism can be at the origin of the failure of many recent restorations of masonry buildings.

DESORPTION AND INFILTRATION WITHIN THE SURFACE REGION OF EXPOSED CONCRETE

W John McCARTER, Heriot-Watt University, Edinburgh, Scotland.
David WATSON, Blyth and Blyth, Consulting Engineers, Edinburgh, Scotland.

ABSTRACT Water infiltration and subsequent moisture loss from the surface region of concrete samples were investigated. Data are presented on the moisture loss, volumetric gain, internal RH and electrical conductivity for plain OPC concrete and concrete containing metakaolin replacement. Monitoring electrical conductivity at discrete points within the surface 100mm allows an assessment of the convective zone, moisture distribution and on-going hydration / pozzolanic activity.
KEYWORDS Drying, Water suction, Humidity, Electrical Conductivity, Metakaolin.

INTRODUCTION

Absorption of water into the surface region of reinforced concrete, its distribution within this region and subsequent loss plays a important role in many of the processes that degrade concrete. Ingress of deleterious ionic species, corrosion, freeze-thaw damage, sulphate attack, ASR etc. are all dependent upon the presence of water. Cement microstructure, and therefore type and age of the concrete, has a role to play in this respect. Although it is relatively easy to measure the moisture flux through the surface, there is a dearth of information on the distribution of moisture within the surface zone and the influence of cementitious binder. This study presents some the results from a more extensive testing program in which concretes were subjected to cycles of drying and re-wetting extending over a period of 12 months. Electrical monitoring techniques and relative humidity (RH) measurements were employed to investigate the change in moisture state of the concrete within the surface 100mm. In parallel with these measurements, water gain and moisture loss were recorded.

EXPERIMENTAL

For the current work, concrete mix proportions and strengths (in MPa at 28 days and 360 days) are given in Table 1 with the water to cementitious binder ratio being 0.4 for both mixes. The binders comprised ordinary Portland cement (OPC) and OPC with metakaolin (MK) replacement. Crushed rock aggregate and matching fines were used throughout. Samples took the form of 150mm x 160mmϕ cylinders; pairs of stainless-steel pin-electrodes (1.5mmϕ) were cast into the samples at twelve discrete depths from the bottom (i.e. suction) surface. Four cavities were pre-formed (not drilled) in each sample during casting for internal RH measurements. After demoulding at 24-hours, the sides and top surfaces of the cylinders were sealed, the bottom (i.e. test) surface was then placed in water for 28 days.

Table 1: Mix proportions and strengths. (All materials in kg/m^3).

Mix	OPC	20mm	10mm	Fines	MK	F_{28}	F_{360}
OPC	525	775	390	530	-	72.1	81.4
OPC/MK	470	775	390	520	55	80.7	85.2

At 28 days all samples were then conditioned in cabinets under controlled temperature and humidity: 10%RH at 20°C for a period of 23 days followed by 60%RH for a further 5 days. The specimens were then subjected to a 24-hour water infiltration test during which volumetric gain measurements were taken at discrete time intervals. Samples were then allowed to dry for a

further period of 300 days in an atmosphere of 55-60%RH at 20°C before being subjected to a second 24-hour infiltration test, with volumetric gain being monitored as before.

Electrical conductance measurements were recorded using an impedance analyser operating at a frequency of 10kHz. The electrode array was calibrated in solutions of known conductivity thereby enabling conductance measurements to be converted to conductivity. Internal RH was measured using a Rotronic humidity probe inserted into the cavities. During infiltration testing, a perspex cap was secured to the suction surface of the sample with a head of approximately 850mm of water maintained on the surface; the volumetric gain was obtained from graduated burette on the cap. Mass loss was measured gravimetrically.

RESULTS AND DISCUSSION

The cumulative moisture loss per unit area of drying surface (in mm^3/mm^2) after the first and second drying periods outlined above are presented in Table 2 and denoted, respectively, i_{D1} and i_{D2} . During the two, 24-hour infiltration periods detailed above, data were plotted in the form (McCarter et al 1992; Dias, 1993),

$$i_W = A_W + S_W\sqrt{t} \qquad [1]$$

where i_W is the cumulative volume of water absorbed per unit area of inflow surface (mm^3/mm^2), t is the elapsed time (in hours) and S_W is the *sorptivity* of the material ($mm/h^{1/2}$); A_W is the intercept value on the t = 0 axis. The sorptivity is obtained from the slope of the i versus $\sqrt{t}$ curve. Sorptivity coefficients and intercept values obtained for the first and second infiltration tests are presented in Table 2 and denoted, respectively, S_{W1} and S_{W2} and A_{W1} and A_{W2}.

Table 2: Drying and Infiltration Results

Mix	i_{D1} mm^3/mm^2	A_{W1}	S_{W1} $mm/hr^{½}$	i_{D2} mm^3/mm^2	A_{W2}	S_{W2} $mm/hr^{½}$
OPC	1.025	0.244	0.039	2.809	0.292	0.122
OPC/MK	0.742	0.071	0.027	1.272	0.216	0.041

From Table 2, the sorptivity (S_W) values obtained after the short and long term drying regimes increase by a factor of ≈3 for the OPC mix but only ≈1.5 for the OPC/MK mix. These values reflect the moisture loss during the previous drying cycle which is quantified in terms of i_{D1} and i_{D2} . The drying loss (i_D) values gives an indirect, but simple, assessment of the water-vapour diffusion from the surface region which, itself, will be linked to microstructure. The differences in S_W values between the two mixes become more apparent with duration of drying. The OPC/MK concrete also displays a lower intercept (A_w) value. The intercept is as a result of rapid filling of open surface pores (Hall and Tse, 1986) on the face of the test specimens.

Figure 1 displays the variation of internal RH and electrical conductivity through the surface 100mm. Five profiles are presented for each mix:

(i) RH and conductivity immediately after curing period;
(ii) RH and conductivity just prior to the first absorption test and immediately after the 24-hour absorption test; and,
(iii) RH and conductivity just prior to the second absorption test and immediately after the 24-hour absorption test

As conductivity values can vary by over an order of magnitude between drying and subsequent rewetting, the conductivity axis has been placed on a logarithmic scale for both mixes. This also

allows all data points to be presented on the same axis without masking the general trends and also allows easier comparison of absolute values for the mixes. Rather than considering each conductivity and RH profile individually, it is more appropriate simply to highlight salient features from the responses. With reference to the conductivity profiles at the end of each drying period, conductivity values increases in the opposite direction to the direction of moisture loss. Values thus reflect the increasing degree of pore saturation with depth. When the conductivity drying profiles are taken in conjunction with the subsequent (respective) wetting cycle then the following should be noted:

(a) after the wetting cycle the zone of influence of the advancing water front can be detected as conductivity values have increased relative to the respective values before infiltration. There are points, however, were the conductivity values are unchanged. The point where the drying and wetting profiles become coincident is taken to represent that part of the surface zone most influenced by drying action - the so-called *convective zone* (van Brakel, 1980; Tutti, 1993). The depth of the convective zone (CZ) determined in this fashion is presented in Table 3 below for both mixes, where the subscripts 1 and 2 represent the first and second drying/wetting periods respectively.

(b) at depths greater than 60mm (i.e. those levels which could be assumed to be unaffected by drying action and water infiltration) there is a decrease in conductivity values with time relative to the respective values at 28-days cure. This can be attributed to on-going hydration and pozzolanic activity. This effect is more evident in the OPC/MK concrete due to the slower pozzolanic activity of the MK. Self desiccation of the binder could also contribute to reduction in conductivity and RH (Jensen and Hansen, 1995).

(c) generally, OPC/MK concrete has lower conductivity values than plain OPC concrete. This can, in the main, be explained by the increase in tortuosity and discontinuity of the pore network within the OPC/MK concrete;

Table 3: Depth of convective zone (CZ) estimated from conductivity profiles and RH profiles.

	CZ determined from conductivity profiles		CZ determined from from RH profiles	
Mix	CZ_1	CZ_2	CZ_1	CZ_2
OPC	25	30	30	30
OPC/MK	25	30	20	25

The internal RH measurements mimic the conductivity profiles (note that RH measurements were taken over the surface 45mm, whereas conductivity are presented over the surface 100mm). As vapour is lost from the surface region RH decreases and subsequently increases on rewetting increases, although not to its original level at 28-days cure. As with the conductivity profiles obtained before and after absorption, the RH profiles display a similar feature in that there is a *cross-over* point on the curves. This is taken to represent the depth of the convective zone discussed above and values obtained from the RH data are also presented in Table 3. These two sets of results agree well although conductivity profiles would appear to be more sensitive, particularly after short periods of drying and where replacement material is used in the binder.

CONCLUDING COMMENTS

Discretised conductivity measurements can provide a qualitative picture of how the moisture profile changes within the sample during drying and wetting. The testing methodology introduces a *third dimension* to the interpretation and understanding of water and moisture movement within the surface region of exposed concrete.

ABSTRACT
The leaching behavior of Portland cement and Portland cement/pulverized fuel ash mortars have been investigated by confined cell leach test. Marked differences in both the chemical and microstructural developments of the two mortar types have been identified. These features, which may be significant to the use of cementitious materials in waste containment, are explained in terms of the progress of leaching, as observed in the chemistries of the effluent solutions. The presence of PFA leads to a progressive development of a dense, low permeability, low pH product, while the PC mortar virtually maintains its original permeability and pH.

Key-words Portland cement, pulverized fuel ash, leaching, ettringite, waste disposal

INTRODUCTION
Assessment of the leaching performance of cementitious materials in a saturated environment is becoming more important with the increase in their use for waste disposal or containment purposes. Conventional wastes can be solidified and stored within cementitious lagoons, or cast into secondary containment drums, prior to disposal. This paper is concerned with the results from an accelerated confined Cell Leach Test (CCLT) (Unsworth 1997), in which samples have been subjected to a through flow by de-ionized filtered water. The work presented here shows the results for Portland cement (PC) and PC:pulverized fuel ash (PFA) barriers. The results are part of a wider research program (Unsworth, 1996) in which the CCLT was developed and tested using various toxic and aggressive solutions.

EXPERIMENTAL METHODS AND TECHNIQUES
The testing apparatus was of a similar design to a standard geotechnical triaxial cell (Michetis, 1985), with a confining pressure applied to the sample to stop external seepage and a hydraulic head applied to induce a through flow. The effluent was sequentially collected and its pH monitored. The elemental concentration of the effluent was measured using flame photometry for Ca, Na and K ions. Verification and trace element analysis (S, Mg, Al, Si) were undertaken by the developed copper disc evaporation test (Dhir *et al* 1995).

A Portland cement, complying with BS 12(1989) was used. The PFA complied with BS 3892:Part 1, and sieve analysis indicated a fineness of 0.9%. The methodology used for cell testing is described elsewhere (Unsworth 1997). Results shown are for a confining pressure of 400 psi and a pressure head of 300 psi.

RESULTS
Figures 1 and 2 show the results for PC and (50:50) PC:PFA mortars, tested under identical conditions. The results are representative of several similar test runs, and show the results from the longest test durations. The x-axis is a function of the effluent volume collected and the measured capillary porosity, this has been corrected for the changing porosity with test age. Testing was carried

out for all the elements present within cement. The Figures only include those elements found to be within detectable limits.

PC MORTAR

There is almost immediate Sodium (Na) leaching, with a rapid rise to a maximum concentration by two pore volumes (PV). Potassium (K) starts to leach from one PV rising to a maximum by three PV. This rise is accompanied by a slight release of sulfur (S). The region between the two dotted lines marks the area of most interest for the PC mortar. As the alkali metal concentrations start to decline, an increase in the Calcium (Ca) concentration is apparent. This rises steeply to a maximum concentration of 530 µg/l. Accompanying this there is a small temporary increase in the S concentration. Once the Ca has reached its maximum value Na and K leaching has effectively ceased, and there is maintenance of a steady Ca concentration. The pH of the effluent solution rises with an increase in alkali metal concentration, and is at its maximum value at the maximum alkali concentration, then drops to a consistent 12.5 during the Ca only leaching. Permeability shows a similar though less pronounced development to the pH.

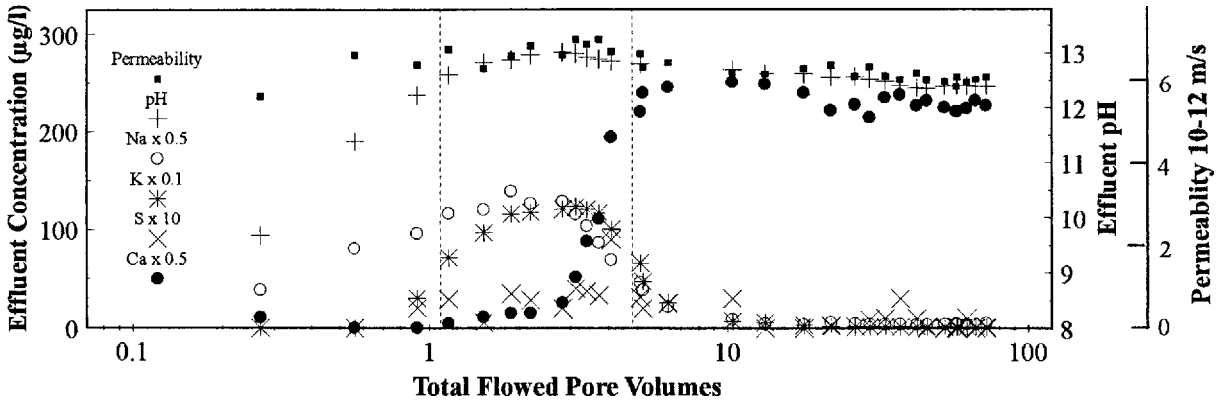

Figure 1. Effluent concentration, Permeability and pH data, for Portland cement mortar.

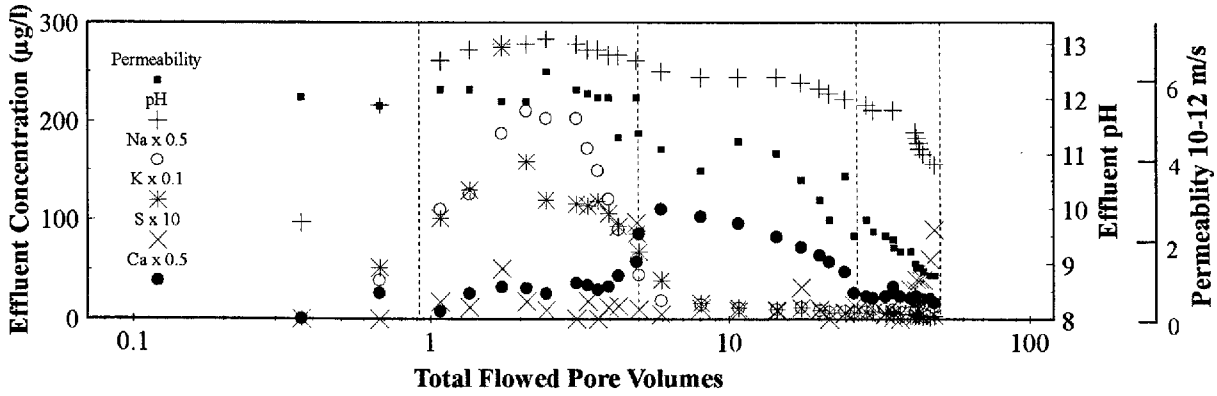

Figure 2 Effluent concentration, Permeability and pH data for Portland cement:PFA mortar.

PC:PFA

K and Na leaching commence simultaneously, in higher concentrations than with PC mortar. K in particular reaches a very high value of 2800 µg/l. Ca starts leaching out early, but at a low level of c.40 µg/l. This level is maintained until both the K and Na concentrations have begun to fall. There is a temporary leveling off in the K concentration, prior to its final fall. The Ca concentration increases at this point to c.220µg/l, and then progressively decreases to the base value of 40µg/l towards the end of

the test. Three main S peaks are observed, coinciding with the K peak, commencement of increase in Ca content and at the end of the test run. The sample permeability remains fairly constant to the point where the alkali concentration falls and the Ca concentration increases. From this point it progressively falls (to $1/8^{th}$ of its original value) in parallel with both the pH and Ca concentration. At the end of the test an increase in S is apparent, this corresponds to a sharper drop in pH, to its final value of 10.8. Upon removal physical examination revealed a highly friable sample.

SEM STUDIES

PC Mortar: X-ray and SEM studies at different test ages revealed an increase in ettringite concentration within the pore voids. Figure 3a shows a large pore void in the 160 day old PC control mortar, filled with $Ca(OH)_2$ crystals with dense CSH microstructure surrounding it. Figure 3b from the void/CSH boundary of a 160 day old cell test sample, shows the start of ettringite formation in a void. Ettringite was observed in the voids but not to any large extent in the interparticulate spaces or amongst CSH. From SEM micrographs it appears that the edge of the void acts as a permeable membrane, with ettringite only forming inside the pore. Figure 3c shows a large void with ettringite needles and CH blades.

PC:PFA Mortar: Figure 4a shows the dense microstructure of the PC:PFA mortar, with a cenosphere embedded in a 'slab' of CH. Figure 4b shows the remains of heavily leached CH particles within a pore, while Figure 4c shows calcium aluminate hydrate plates intermingled with CH.

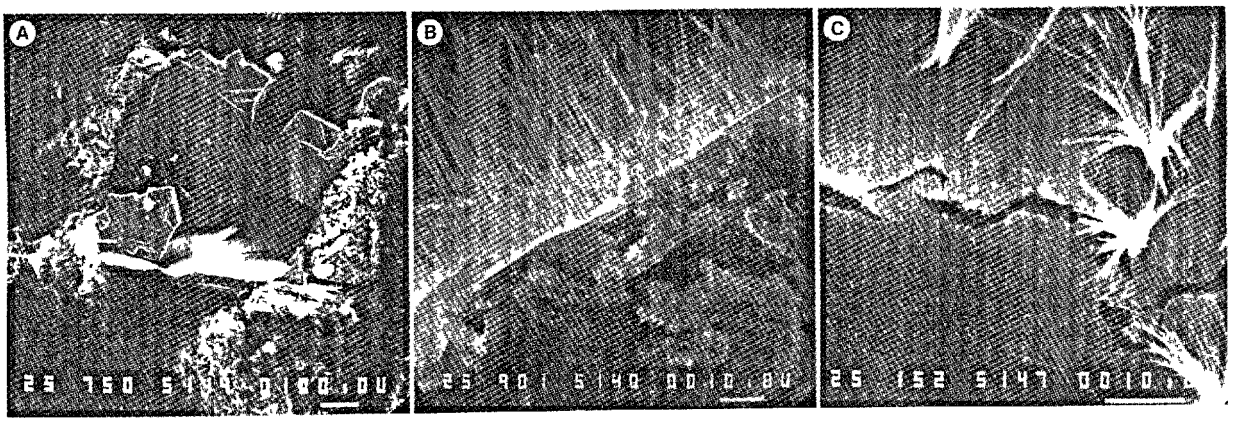

Figure 3 160 day old PC mortar; a - control, b, c - leached cell samples.

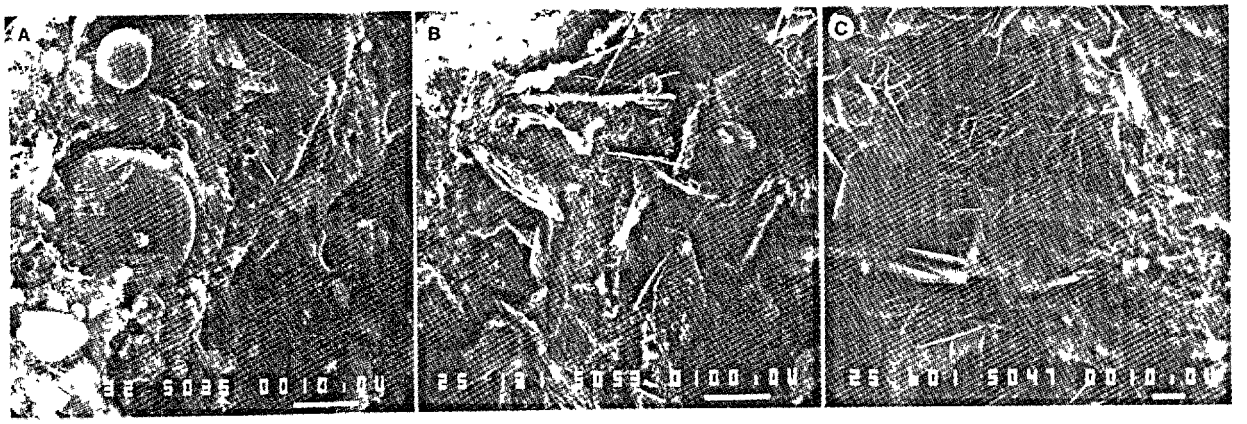

Figure 4 160 day old PC:PFA mortar; a - control, b, c - leached samples.

DISCUSSION

The leaching of the alkali metals follows known solubility data and the predictable test behavior is found for the PC mortar. The introduction of the PFA to the binder, however, profoundly influences both the chemical and physical development during testing. While the greater and more rapid rise and fall of the alkali content of the effluent in the early test stages may be attributed to the greater availability and accessibility of the alkalis from the PFA, the subsequent behavior of S, Ca, permeability and pH is due to the dynamic environment established by the CCLT in the test sample. Ca-bearing pore fluids flowing through the sample, readily react with the high quality fly ash, hydration continues, consuming CH from the solution thus causing a fall in the Ca effluent concentration thus causing a reduction in effluent pH. The continuing production of CSH from the PFA hydration densifies the microstructure, reducing porosity, pore connectivity and overall permeability. The final drop in pH below that expected from a CH solution is evidence that Ca leaching from CH has ceased. The small increase in S at the end of the test (bearing in mind the 10x scaling factor) may come from the solution of early formed ettringite within the sample. The source of calcium is therefore indicated to be CSH, and is reflected in the reduction in effluent pH.

Physical and microstructural evidence suggests that the PC mortar is more heavily affected by the through flow. Ettringite formation although only observed in the voids, could be disrupting the sample integrity. The friable nature is due to both the leaching of the CH, CSH and ettringite. The PC:PFA however was almost impermeable by the cessation of testing. The continuing production of CSH from hydration of the PFA causes a considerable change in sample porosity and connectivity. The formation of the CAH follows known patterns and is due to a the unavailibility of S within the binders.

CONCLUSIONS

The cell test results for the PC mortar show predictable trends, with maintenance of a constant Ca concentration and pH level after initial alkali leaching. The permeability remains constant throughout the test, despite the observed development of friability.

The high initial alkali leaching with the PC:PFA sample, indicates the availability and accessibility of the alkalis from the PFA. The Ca concentration falls from a low maximum, a consequence of continuing PFA hydration. This trend is paralleled by both pH and permeability.

These observations are of significance in selection of cementitious materials in the field of waste containment. Where permeability and pH are controlling factors.

INVESTIGATIONS ON MOISTURE ABSORPTION AND ITS EFFECT ON THE PERFORMANCE OF HAC BASED MDF CEMENT

S HARSH, S K HANDOO AND S C AHLUWALIA*

National Council for Cement and Building Materials, New Delhi, India
*OCL India Ltd., New Delhi, India

ABSTRACT Moisture absorption by MDF cement at ambient relative humidity above 70 percent was 1.6 percent after 25 days of exposure and partially reversible at lowered humidity. MDF cement sheets stored at ambient humidity showed slight warpage. Immersion in water caused much higher weight gain and loss of flexural strength which was partially or completely recovered on drying. XRD studies revealed formation of C_3AH_6 in water immersed specimens.

Key-words: Macro Defect Free, Moisture, Polymer, Porosity, High alumina cement

INTRODUCTION

Moisture absorption leading to loss of strength and dimensional instability of MDF cement products has been reported (Poon et al, 1987; Young, 1991). The MDF cement has a high volume fraction (upto 30%) of water soluble polymer and a largely unhydrated cement fraction. Both are prone to attack by moisture. Attempts to improve the moisture resistance of MDF cement by using cross-linking/coupling agents have met with varying degree of success (Young, 1991).

The present paper reports additional data on moisture uptake by HAC based MDF cement which apart from substantiating the earlier findings suggests the need for further investigations on improving the water sensitivity of MDF cement products. The extent of moisture absorption at ambient humidity and on immersion in water is reported alongwith its consequent effect on the performance and mineralogy of MDF cement products.

EXPERIMENTAL

High alumina cement (HAC) having 32.95% CaO and 45.39% Al_2O_3 and 88 % hydrolysed polyvinyl alcohol (PVA) were used in the two compositions given in Table-1 to prepare MDF cement sheets of 30x30x0.3 cm following the method of Birchall et al (1981, 1982). Strips of 12x3 cm. were cut from large uncured sheets. Some of the cured specimens were soaked in hexamethylene diisocyanate (HMDI) for 1, 3, 18 and 24 hours followed by drying in oven at 80°C.

Moisture absorption was followed by recording the weight change of MDF cement specimens exposed to ambient humidity or immersed in water, upto a period of 50 days. After immersion in water for 1, 4 and 14 days, 3 strips were tested for flexural strength in wet state and three strips were tested after drying in oven. Water immersed MDF cement strips were dried at 80°C and powdered for XRD investigations.

Table 1 MDF Cement Compositions

Composition	HAC	PVA	Water
	(Parts by Weight)		
A	100	6	12
B	100	5	13

RESULTS AND DISCUSSION

Moisture absorption by MDF cement

Moisture absorption by MDF cement product, of composition A, at ambient relative humidity of 72-76 percent (Fig.-1), was relatively rapid initially resulting in 1.48 percent gain in weight after 22 days of exposure. Further moisture absorption took place at a slower rate, resulting in total weight gain of 1.6 percent after 43 days of exposure. A fall in humidity from 76 to 70 percent (on 32nd day) caused the sample to give off some of the absorbed moisutre. The fall in humidity from 76 to 58 percent, 43rd day onwards, resulted in 15.6 percent of absorbed moisture being given off,i.e., a residual moisture content of 1.36% on 53 rd day. These observations are in line with the earlier findings on the dependence of moisutre absorption on relative humidity (Young, 1991). Absorption of moisture by polymer phase and further hydration of cement grains are the factors causing moisture uptake by MDF cement. The loss of absorbed moisture at lower humidity indicates the partial reversibility of moisture absorption which is caused by drying up of the polymer phase.

Moisture absorption and resulting weight gain by MDF cement product was much higher on immersion in water. Specimens 1 and 2 of composition A and B absorbed moisutre rapidly at first and later at a progressively slower rate, gaining 14.7 and 11.1 percent weight respectively after immersion for 50 days in water (Fig.-2). Relatively lower weight gained by composition-B is on account of a lower percentage of polymer used as compared to composition A, suggesting a decrease in moisture sensitivity.

The factors leading to a change in the weight of water immersed specimens could be : (i) absorption of water by polymer phase and further hydration of cement leading to weight gain and, (ii) dissolution of polymer and leaching of cement hydration products in surrounding water leading to weight loss, as already reported (Young,1991). The sample weights reported here were recorded for wet specimens and thus included both the chemically combined and physically absorbed water. Oven drying of specimens at 80°C, after 50 days of

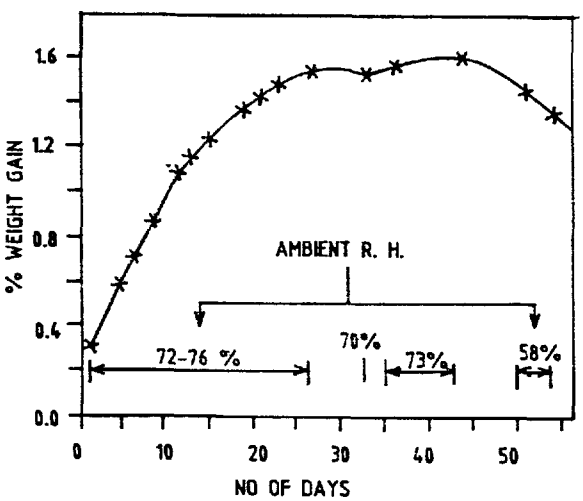

Fig. 1 Moisutre absorption by MDF cement at ambient humidity

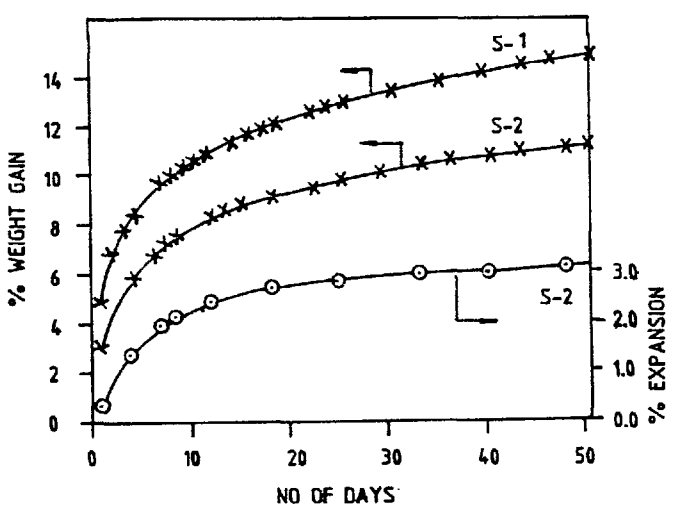

Fig. 2 Moisture absorption and expansion of MDF cement on immersion in water

immersion resulting in lowering of 25-39% of the weight gained, indicated evaporation of physically absorbed water. However, the samples still showed a net gain in weight, indicating that the weight loss on account of dissolution of polymer and leaching of cement was more than made up by further hydration of cement. However, after shorter immersion periods of 1-14 days, generally a net loss of 1-2.5% was observed in the weight of dried specimens.

Immersion of MDF cement in water also caused expansion leading to an increase of 3 percent in the length of specimen-2 (Fig.-2). At later ages, water immersed samples also underwent warpage. Small specimens exposed to ambient humidity did not show any apparent warpage, but larger specimens of 30x30x0.3 cm. showed slight warpage on being stored at ambient humidity.

Effect of Immersion in Water on Flexural Strength

Immersion in water for 1 day lowered the average flexural strength of wet specimens by 54.7 percent (Fig. 3). Drying at 80°C restored most of the lost strength. After longer immersion periods of 4 and 14 days the average drop in flexural strength was 68.7 and 73.02 percent respectively. However, on drying the specimens not only recovered the lost strength but showed a net gain over starting strength (Fig. 3).

Swelling and softening of polymer (Canon & Groves, 1986; Poon et al, 1987) and increase of porosity on account of dissolution of cement hydration products/ polymer (Young, 1991) could be the primary causes of the loss of strength in wet specimens. On drying MDF cement is reported to regain strength partially (Poon et al, 1987). The recovery of strength in dry specimens in our studies is seen to be partial after 1 day immersion, but complete after immersion for 4 days and 14 days. The probable reason for such a recovery is that the porosity created during early immersion periods could be getting filled up at later ages by cement hydration products. The unhydrated cement fraction present in MDF cement, would hydrate on immersion in water and the hydration products thus formed could get deposited in the pores created by earlier leaching of cement hydration products/dissolution of polymer. Filling up of pores, created in MDF cement on heating upto 500°C, by cement hydration products has also been reported (Young,1992).

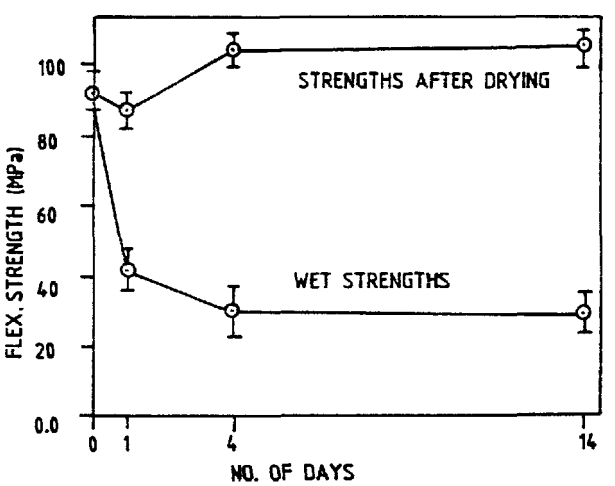

Fig. 3 Effect of immersion in water on flexural strength

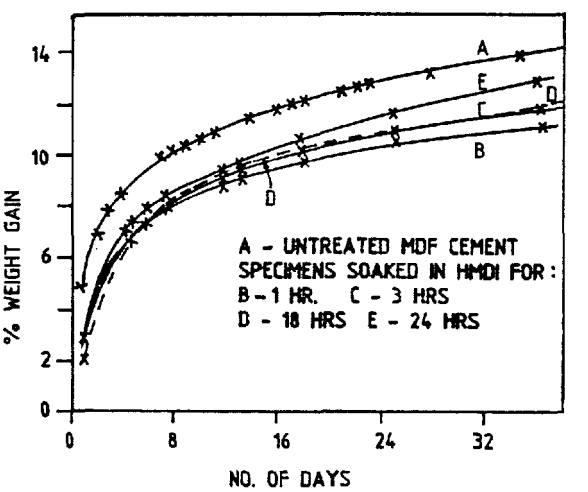

Fig. 4 Moisture absorption by HMDI soaked specimens on immersion in water

Effect of Soaking in HMDI on Moisture Absorption

Impregnation of MDF cement with hexamethylene diisocyanate (HMDI) causes cross-linking of PVA molecules and is reported to improve the moisture resistance of MDF cement (Kataoka, 1988). In our studies, improvement in the moisture resistance was attempted by soaking the cured MDF cement strips in HMDI for 1 to 24 hours. Moisture absorption by HMDI treated strips, on immersion in water for 1 day was lowered by 50-60 percent as compared to the moisture absorbed by untreated specimens (Fig.-4). However moisture absorption increased steadily on continued immersion in water. The time of soaking in HMDI did not influence the moisture absorption characteristics. Soaking of cured MDF cement in HMDI was not found effective in improving the moisture resistance, which could possibly be due to non-penetration of HMDI to any significant depth inside the specimen.

Mineralogical Investigations

Analysis of XRD patterns showed that the crystalline hydrated phase C_3AH_6, which was absent in unexposed MDF cement specimens was formed in water immersed specimens. The intensity of XRD peaks corresponding to C_3AH_6 was higher at longer immersion periods indicating growth of C_3AH_6 in specimens on continued immersion. On the other hand, the peaks corresponding to CA grew weaker. However, even after 14 days CA was present in the specimens, indicating scope for further hydration.

CONCLUSIONS

1. Moisture absorption by MDF cement at ambient humidity above 70 percent was significant and partially reversible at lowered humidities.
2. The moisture absorption on immersion in water was much higher leading to 10-14% gain in weight after 50 days,besides expansion and warpage.
3. Immersion in water initially causes a net loss in weight indicating increased porosity but a net weight gain at later ages indicated filling up of pores by cement hydration products.
4. Immersion in water for 1-14 days caused a lowering of flexural strength, which was partially or completely regained on drying.
5. Soaking the cured MDF cement in hexamethylene diisocyanate was not found to be effective in improving moisture resistance.

EFFECT OF SILICA FUME INCORPORATION IN CONCRETE ON THE CORROSION PROTECTION OF EMBEDDED REINFORCEMENT.

Hamdy A.El-SAYED, Ali H.ALI and Basil A.El-SABBAGH
Building Research Institute, Cairo, Egypt.

ABSTRACT Silica fume (SF) has been demonstrated to assist retaining the reinforcement passivity and accentuate its resistance against the effect of harsh surrounding environments even after long-term curing. 10% silica fume in concrete continues to prove that it is the "optimum dosage". Incorporating a superplasticizer into the concrete mix is beneficial for up-grading steel passivity.

Key words : Corrosion - Steel - Silica fume - Waste material utilization

INTRODUCTION

The present work is the third part of a series of investigations devoted to determining silica fume effects on cement and concrete chemical, physical and mechanical characteristics as well as its role in counteracting salt attack on concrete (El-Sayed, Ali and El-Sabbagh, 1995 and 1996). It has been found that, 10% silica fume- to which a superplasticizer has been added-represents "the optimum dosage" to replace cement in order to achieve maximum strength improvement and maintain the alkaline nature of the concrete as well as increase its chemical resistance. The current third part of the work has endeavoured to study the effect of silica fume incorporation in concrete on the passivity retention of embedded reinforcement and hindrance of the corrosive attack due to invading aggressive agents from surrounding media.

EXPERIMENTAL

The ingredients of the concrete mix used were ordinary Portland cement, sand and gravel. The mix proportions were 1:2:4, respectively. The water cement ratio was 0.6, by mass. When using silica fume (SiO_2=96%, Particle size< 0.5μm and surface area=20m^2/g), the required amount was admixed to the cement before adding it to the dry concrete mix. Sulfonated naphthalene formaldehyde (SNF) superplasticizer was used as a high range water-reducer (HRWR). To keep the same workability (the same slump value) as that of the control concrete, the W/C ratio for the HRWR-incorporating concrete has been reduced to 0.47. The required amount-expressed as a percentage of cement by mass-was dissolved in the mixing water before adding it to the dry mix.

For pH measurements of concrete extract, plain or silica fume-incorporating concrete samples were cured in a humidity chamber for 28 days, then, a representative sample was powdered. 400g of the concrete powder were stirred in 1000ml of distilled water for 2hrs, then, the pH value of the concrete extract was measured.

The reinforcing steel used was mild steel, 6mm in diameter. Prepared reinforcing steel rods were centrally placed in cylindrical 5x10 cm steel moulds, then, the active-predetermined- areas were completely covered by the prepared concrete. The samples were cured for 24 hrs after casting, then, demoulded and continuously cured in the test media. The corrosion behavior of the steel-in-concrete electrodes was studied by means of the galvanostatic anodic polarization technique. The steel-in-concrete was made as an anode in a circuit using an auxiliary platinum electrode as cathode. A constant current density of 10μA/cm^2 was applied to the steel electrode and the corresponding potential was recorded as a function of time.

RESULTS AND DISCUSSION

It is expected that, when silica fume is used as a partial cement replacement, the pH of the concrete will decrease due to: a) the reduction in the cement content and the consequent reduction in the $Ca(OH)_2$ liberated upon cement hydration, b) the pozzolanic reaction of silica fume and the consumption of part of the liberated $Ca(OH)_2$ and 3) the reduction in the alkali-pore water concentration. Consequently, the reduction in pH associated with silica fume incorporation in concrete has been determined in order to assess the effect of silica fume on stabilizing (or destabilizing) the passive iron oxide film on the reinforcing steel surface. Thereafter, the work has been directed to investigate the effect of admixing concrete with silica fume on the corrosion behavior of embedded reinforcement upon exposure to different aggressive media,

Influence of silica fume on the pH of the water soluble concrete extracts

Water soluble extracts from concrete incorporating silica fume at the dosages 0,5,7.5,10 and 15% in absence and in presence of SNF superplasticizer were prepared for pH measurements. The results are given in Table 1. It can be seen that, the pH of the concrete extract of the control sample reaches 13.8. Replacement of cement by silica fume up to 15% reduces the pH to 13.2. It is to be noticed that, using a superplasticizer with silica fume in concrete does not alter the pH value relative to that of the control concrete except for the 15% silica fume concrete where the pH is reduced by only 0.1 unit, thus, being 13.7.

As the passivity of steel in concrete in maintained above pH 11.5 (Gouda, 1970), therefore, in case of silica fume at dosages up to 15%, the reduction in the pH value of the concrete will be far from sufficient to destabilize the passive iron oxide film on the steel surface with the consequent increase in vulnerability to corrosive attack. In addition, utilization of a superplasticizer with silica fume in concrete adds another benefit to the course of improving concrete characteristics which is maintaining the pH value of the concrete very close to that of the control sample. In other words, maintaining the highly alkaline nature of the concrete.

Table 1 pH values of water soluble extracts of silica fume concrete

Silica fume in concrete mix	**Silica fume %**				
	0.0	5	7.5	10	15
In absence of SNF	13.8	13.3	13.3	13.3	13.2
In presence of SNF	13.8	13.8	13.8	13.8	13.7

Corrosion behavior of reinforcing steel in silica fume concrete cured in different aggressive media

The overall property of concrete which controls its protective capabilities is its electrical resistivity. This is modified by factors such as porosity, chemistry of pore water, particularly pH, and aggressive ions content. High electrical resistivity of concrete will limit the corrosion of embedded reinforcement. As the corrosion of steel in concrete is associated with the formation of local electrolytic cells on the steel surface, thus, the quantity of electricity flowing through such local cells (overcoming the electrical resistivity of concrete) is equivalent to the amount of metallic corrosion in accordance to Faraday's law (Gouda, 1975):

The quantity of electricity Q(mC/cm^2)= Current density (mA/cm^2) X Time to reach passivation (s)

Consequently, the higher the quantity of electricity (or the longer the time to reach passivation) the lower is the corrosion resistance.

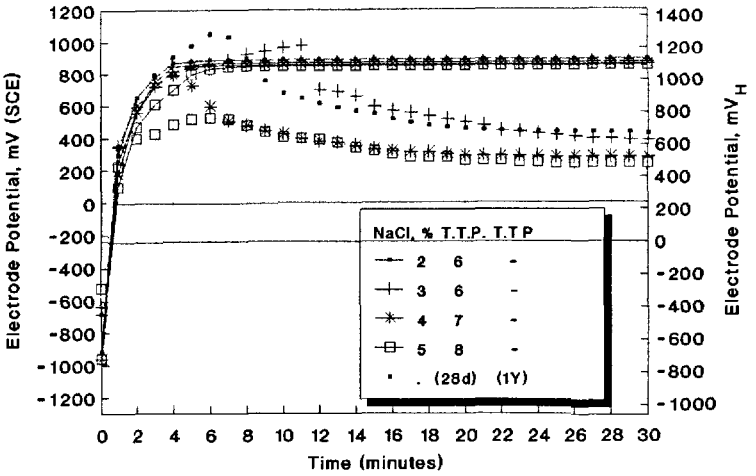
Therefore, in the present study the effect of silica fume in concrete upon modifying the concrete resistivity, hence, protecting the steel reinforcement against the corrosive effect of diffusing aggressive ions has been evaluated by determining the anodic polarization behavior of steel in concrete incorporating 5,7.5, 10 and 15% silica fume, as a cement replacement by mass, at a constant applied current density of $10\mu A/cm^2$ and recording the time to reach passivation potential (TTP). Such recorded time has been taken as a measure for the degree of steel passivation. If TTP is ≤ 7 , 7-15 and ≥ 15 minutes, the degree of passivation has been considered "high", "moderate" and "low", respectively (El-Sayed, 1994). The concrete curing media were selected simulating some of the affecting media in practice, namely, 2 , 3 , 4 and 5% NaCl solutions, 5 , 6 and 7% Na_2SO_4 solutions and sea water. The W/C+S ratio was 0.6. The curing ages tested were a relatively short-term age (28 days) and a long-term one (1year). For every curing medium, the performance of reinforcing steel in silica fume-free concrete has been determined as a reference (control) sample. The influence of incorporating SNF superplasticizer in the silica fume concrete on the corrosion behavior of the steel reinforcement has been determined as well.

Anodic polarization behavior of reinforcing steel in silica fume concrete cured in chloride media.

Chlorides may be either introduced into fresh concrete from chemical admixtures or from chloride contaminated concrete components or they may penetrate hardened concrete from external sources (such as deicing salts, sea water, underground water, etc.). In either case, some of the chloride ions will be available and presumably aggressive in the pore solution. The capacity of concrete to bind chlorides as well as the resistance it offers to their penetration are important factors in suppressing the corrosive effect of chloride ions. Therefore, the influence of silica fume inclusion in concrete on affecting the embedded steel passivity upon exposure to chloride media has been investigated. Firstly, the anodic polarization behavior of reinforcing steel in silica fume-free concrete cured in 2,3,4 and 5% NaCl solutions has been determined. Figure 1 presents the curves obtained after 28 days curing age compared to those obtained after 1 year age.

It is evident that, upon curing the steel-in-concrete for 28 days in NaCl solutions of concentrations varying from 2 to 5%, the steel passivity is not impaired and passivation potential could be reached after the elapse of 6 , 6 , 7 and 8 minutes for the steel in concrete cured in 2 , 3 , 4 and 5% NaCl, respectively. The fact that one should not rely on the apparent short-term behavior of reinforced concrete and should assure the behavior retention on the long-term is evidenced by the data obtained upon extending the curing age to 1 year. Figure 1 depicts that the observed steel passivity upon curing for 28 days in the different chloride media is a deceiving behavior where such passivity could not be maintained upon curing for 1 year and breakdown of steel passivity has occurred even at the lowest chloride concentration (2%).

A survey on investigations e.g. : (Biczok, 1964) , (Gouda, 1973), (Regourd; 1981) and (Buenfeld, 1986) concerning chloride attack on reinforced concrete indicated that, direct chemical damage of concrete by extraneous chlorides in unusual, but, chloride ions are capable of



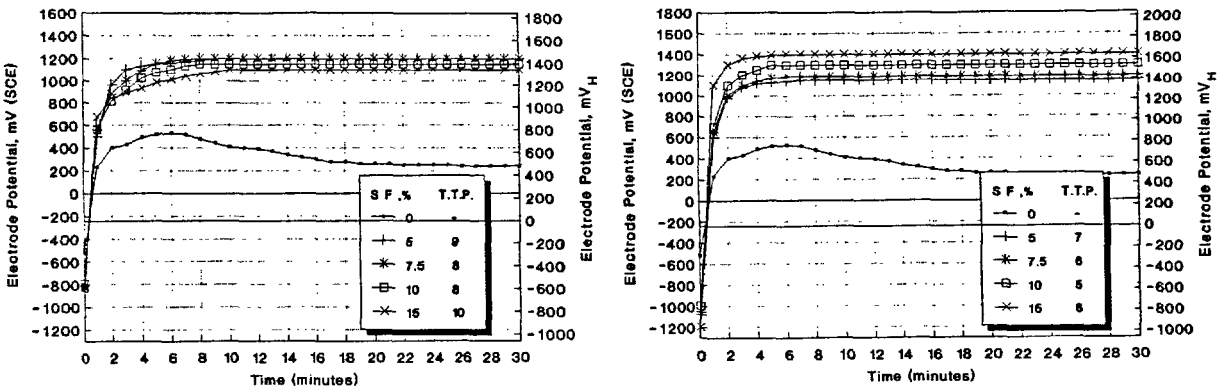


Figure 1 Anodic polarization of reinforcing steel in silica fume-free concrete cured in NaCl solution for 28 days (-) and 1 year (....) .

diffusing into concrete to exacerbate other deleterious reactions. The essence of these investigations is that, the individual actions of chlorides include: counteraction of the passivating effect of the hydroxyl ions derived from the cement hydration; depression of the pH of the pore fluid in the cement matrix; an increase in the conductivity of the cement paste, thus, facilitating the flow of the corrosion current; migration within the concrete to establish concentration corrosion cells; causing an increase in concrete shrinkage, and, therefore, a greater risk of cracking and oxygen access to embedded steel; reduction in the long-term polymerisation of the calcium silicates and, accordingly, an increase in the permeability of the concrete and exacerbation of sulfate attack and alkali-silica reaction in concrete. The real problem caused by chloride attack of concrete is the corrosion of the embedded steel reinforcement. It has been found (El-Sayed, 1993) that 2% NaCl, by mass of cement, incorporated in concrete represents the threshold concentration below which the steel passivity is being safe.

The effect of incorporating silica fume in concrete at the dosages used i.e. 0 , 5 , 7.5 , 10 and 15% on hindering the corrosion of steel reinforcement that could ensue upon curing in NaCl media of concentrations 2,3,4 and 5% for 28 days and 1 year has been investigated. Also, the effect of admixing silica fume concrete with SNF superplasticizer on the corrosion behavior of the embedded reinforcement has been evaluated.

Figure 2 (a and b) presents the anodic polarization behavior of reinforcing steel in silica fume concrete in absence and in presence of SNF superplasticizer after long-term curing for 1 year in the highest chloride concentration (5%) as an example of the results obtained. The curve pertaining to the admixture-free concrete is included in each figure for comparison.

These results show clearly that, using silica fume in concrete improves its ability to protect embedded reinforcement against the corrosive effect of diffusing chlorides. 10% silica fume, as a cement replacement by mass, in concrete represents the "optimum dosage" that offers the highest electrical resistivity i.e. the shortest time to reach steel passivation. Incorporating a

(a) (b)

Figure 2 Anodic polarization of reinforcing steel in concrete in absence (a) and in presence (b) of 0.5% SNF admixed to 5 , 7.5 , 10 and 15% Silica fume after curing in 5% NaCl solution for 1 year (C = SF, SNF - free concrete).

superplasticizer into the concrete mix is beneficial for up-grading the steel passivity. This is evidenced by shorter times to reach passivation relative to times elapsed in absence of the superplasticizer. Such high degree of corrosion protection afforded by silica fume-superplasticized concrete may be attributed to the gained low permeability, high electrical resistivity, limited mobility of chloride ions and reduced oxygen and chloride diffusion from outer media. It is worth mentioning that, the use of silica fume to obtain maximum cement savings in concrete may bring about adverse effects that may mitigate its beneficial role in improving the degree of steel passivation. Thus, an overdose of silica fume in concrete-exceeding 10%- could lead to- in addition to a certain extent of reduction of pore solution pH- an increase of the free chlorides, thereby, increasing the Cl^-/OH^- ratio and, hence, the risk of affecting the steel passivity. This is evident from Fig 2a where TTP has reached after 10 minutes for 15% silica fume dosage compared to 8 minutes for 10% silica fume as well as 6 minutes compared to 5 minutes, respectively, upon using SNF superplasticizer (Fig.2b).

Anodic polarization behavior of reinforcing steel in silica fume concrete cured in sulfate media

It is known that, $Ca(OH)_2$ and C_3A are the most vulnerable constituents of cement to sulfate attack. Hence, due to the reduction in the lime content-the phase mainly responsible for maintaining the steel passivity in concrete-depassivation of the steel could occur by invading sulfate ions from outer media. Therefore, reinforcing steel passivity as influenced by the incorporation of silica fume in the encasing concrete after curing in 5 , 6 and 7% Na_2SO_4 solutions for 28 days and 1 year has been investigated. Also, the effect of admixing the silica fume concrete with SNF superplasticizer on the reinforcement passivity has been assessed. Figure 3 introduces an example of the results obtained, thus, presenting the anodic polarization curves for the reinforcing steel in concrete incorporating 5 , 7.5 , 10 and 15% silica fume in presence of 0.5% SNF superplasticizer after curing for 1 year in the highest sulfate concentration (7%). The curve obtained for steel in admixtures-free concrete is included for comparison. It can be seen, while passivation of the steel in the silica fume-free concrete has reached after significantly long time interval (20 min.) reflecting a "low" grade of passivity, silica fume concrete revealed a significant suppression of the sulfate destructive attack as shown by the short time intervals elapsed to reach passivation. This effect could be attributed to the retardation in the ingress of the sulfate ions through the concrete due to its reduced permeability in addition to the adsorption of

part of the penetrating sulfate on the surface of the silica fume gel formed in the concrete. 10% silica fume still represents the optimum amount to be used as a cement replacement in concrete from the standpoint of maintaining a high degree of steel passivation resisting the sulfate attack. Also, addition of a superplasticizer to silica fume concrete has a distinct positive effect on retaining a high degree of steel passivity remarkably resistant to sulfate attack.

Anodic polarization behavior of reinforcing steel in silica fume concrete cured in sea water

Sea water, as a complex salt solution, is one of the most hostile media whether towards concrete or steel reinforcement. Therefore, it deemed of great interest to assess the prohibitive influence that silica fume in concrete could offer to the embedded reinforcement upon confronting such highly aggressive medium.

It is to be mentioned that, determination of the anodic polarization behavior of reinforcing steel in silica fume-free concrete after curing in sea water revealed that the steel passivity could sustain the sea water attack till a curing age of 28 days (TTP=12 min., a "moderate" grade of passivity), whereas steel passivity could not tolerate the sea water effect upon extending the curing age to 1 year and breakdown of steel passivity has occurred. Consequently, the anodic polarization behavior of reinforcing steel embedded in concrete incorporating 5 , 7.5 , 10 and 15% silica fume in absence and in presence of SNF superplasticizer after curing in sea water for 28 days and 1 year has been investigated. The results obtained for the latter curing age are graphically represented in Fig 4 (a and b) as an example of the data obtained. The curve pertaining to the steel in the admixtures-free concrete is included for comparison.

These results show clearly that, incorporation of silica fume in concrete has maintained the steel passivity even upon curing in sea water for 1 year. A noteworthy feature is that incorporation of 10% silica fume in concrete could retain a "high" degree of passivity to the steel reinforcement. Below 10% silica fume dosage, the steel passivity is "low" and above it the steel passivity is "moderate". In addition, utilization of SNF superplasticizer has enhanced the steel passivity and emphasized that 10% silica fume is the "optimum dosage" to be used where passivation has reached after very short time interval (3 minutes).

CONCLUSIONS

1. The reduction in pH of the concrete mix associated with the inclusion of silica fume at dosages up to 15%, as a cement replacement by mass, is far from sufficient to destroy the passivity of embedded steel reinforcement. In addition, utilization of a superplasticizer with silica fume concrete assists maintaining the pH value very close to that of the silica fume-free concrete.

2. Silica fume in concrete increases its electrical resistivity. This in addition to its role in reducing the penetration of aggressive ions are the main reasons for the better corrosion resistance of steel in silica fume concrete inspite of the shortage in the lime reservoir in the concrete.

3. 10% silica fume represents the "optimum dosage" to be used as a cement replacement in concrete on the basis of its role in retaining a high degree of steel passivity and combating the effects of highly aggressive salts migrating from surrounding media, an effect that is explicit even on the long-term. Incorporating a superplasticizer in the silica fume concrete mix is beneficial in this respect and is highy recommended.

CHLORIDE RESISTANCE OF THE PASTES AND MORTARS CONTAINING MINERAL ADDITIVES

Jan DEJA, University of Mining and Metallurgy, Kraków, Poland

ABSTRACT Partial replacement of portland clinker by mineral additions such as ground granulated blast furnace slag, silica fume strongly influenced the resistance of the pastes and mortars to the chloride solution. The diffusion coefficient of Cl ions in the pastes containing different binders have been studied. The mechanical and structural properties of the mortars stored in water as well as in chloride solution were measured. High chloride resistance of the samples containing mineral additives as well as nonclinker binders have been confirmed.

Key-words: blastfurnace slag, chemical attack, chloride, diffusion, microstructure

INTRODUCTION

One of the most aggresive agents affecting constructions of reinforced concrete are chloride ions. They are particularly dangerous because they lower pH of a pore filling solution adjacent to the reinforcement causing it's rapid corrosion. Chloride corrosion is a major problem in a field of an underground, marine and highway engineering. The decisive factor in a durability aspect of a concrete construction being exposed to the action of chlorides is the diffusion rate of these ions in a concrete structure and stability of hydration products in binding materials reacting with chloride solutions.

It is generally accepted that chloride ions diffusing through cement paste, substitute in it's structural constituent OH^- groups: Feldman (1986), Midgley at al (1984), Goto et al (1981), Page et al (1981), Midgley et al (1980). Following, these groups diffuse in the opposite direction into solution. Attention must be given to the fact that migration of ions in the hardened paste does not constitute a simple diffusion. In certain cases $C_3(A,F)\cdot CaCl_2\cdot 10H_2O$, and also basic chloride $Ca(OH)_2\cdot CaCl_2\cdot H_2O$ forms. Additionally, Goto at al (1981) found that cement paste behaves similarly to electropositive, semi-permeable membrane. As the effect of an absorption of Ca^{2+} ions, hydrates'surfaces are positively charged, which in turn leads to a creation of an electrical double layer that limits migration of cations. That's why, diffusion coefficients of chloride ions determined from Fick's equation are to be treated as "effective" only. As for the rate of diffusion of chlorides, structural constituent of cement and mineral additives to the concrete have essential significance. The smallest ratio of a diffusion flow resistance exist in portland cements with low content of C_3A - Efes et al (1985). Employment of slags or pozzolanas (fly-ash, silica fume) as additives to cement or concrete, lowers the effective rate of diffusion of Cl^- even 10^{-3} times - Efes et al (1985), Tomas et al (1990). Also, very good resistance properties to the destructive action of chloride ions have alkali activated slag binders: Deja et al (Montreal 1991, Nice 1994 and Sheffield 1994). The author conducted research of a diffusion rate of Cl^- ions through the partitions made from the pastes of portland cement, blast-furnace cement, alkali activated slag binders and cements modified by addition of granulated blast-furnace slag and active silica.. Beside diffusion coefficients, phase compositions, texture and resistance qualities of mortars based on a specific pastes were tested accordingly.

CHARACTERISTICS OF RAW MATERIALS

In the conducted research were employed: portland cement (CEM I 32.5R),blast-furnace cement (CEM III A 32.5), ground granulated blast-furnace slag and silica fume. Table 1 shows characteristics of these materials.

Additionally, as the activators for alkali activated slag mortars and pastes, sodium waterglass with silicate module MK=1.5 and sodium carbonate were used. Standard, silica sand was used in mortar preparations.

Out of the pastes, tiles were made, 5 mm thick each and subsequently they underwent premilinary curing in standard conditions (temp.20±2 °C, relative humidity around 95%).

Exposure of samples

After initial period of premilinary curing tiles were placed in a specially prepared test cell (Fig.1). Each of the tiles worked as a divider between two solutions: NaCl solution of 196g/l concentration and saturated solution of $Ca(OH)_2$. Concentration of chloride ions inside of chambers filled with saturated solution of $Ca(OH)_2$ was measured in 30 days intervals. Measurements were conducted using amperometric titration method with $AgNO_3$ as a precipitation agent.

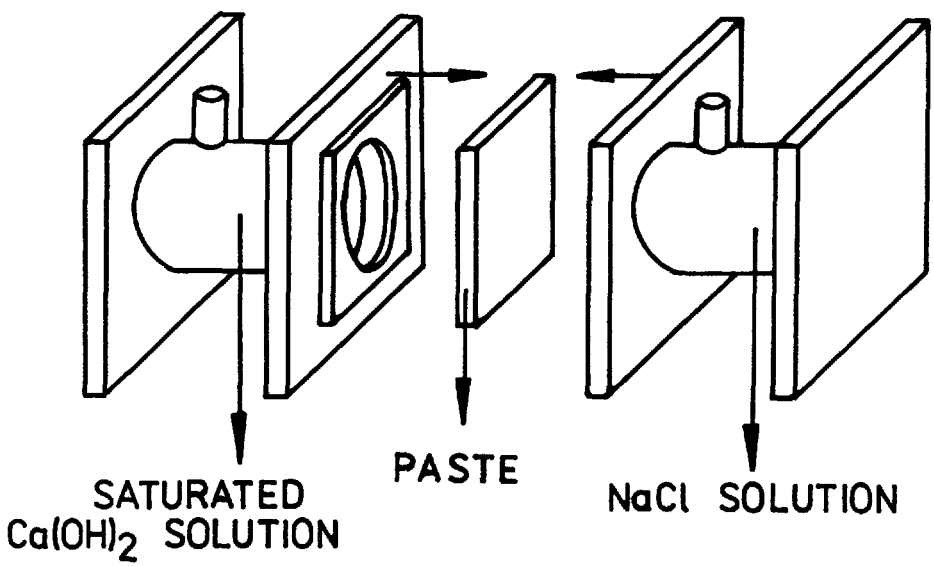

Figure 1. Diagram of a test cell for measuring of a diffusion rate of chloride ions.

Test results

Basing on a determinated contents of Cl^- in the solutions, and using Fick's Law, coefficients of diffusion were calculated. Following auxillary assumptions were taken into account during these calculations:

- during diffusion process, quantity of chlorides on the side of a high concentration is constant and equals initial concentration *Co*.
- within the timeframe from t_i to t_{i+1} diffusion takes place at mean concentration gradient equal to:

$$gradC = \frac{(Co - C_{(t_i)}) + (Co - C_{(t_i+1)})}{2d} \qquad [1]$$

- mean flow of diffusion "$\bar{J}$" within intervals of t_i to t_{i+1} can be expressed as:

$$\bar{J} = D \cdot gradC \qquad [2]$$

Calculated, mean "effective" diffusion coefficients for particular pastes are shown in Table 3.

Table 3. Diffusion coefficients of Cl^- in pastes:

Type of paste	Mean „effective" diffusion coefficients $\cdot 10^{-13}$ [m^2/s]

To emphasize diferrences between diffusion coefficients, their mean values for a duration of a research period (0 - 120 days) are shown on Fig. 2.

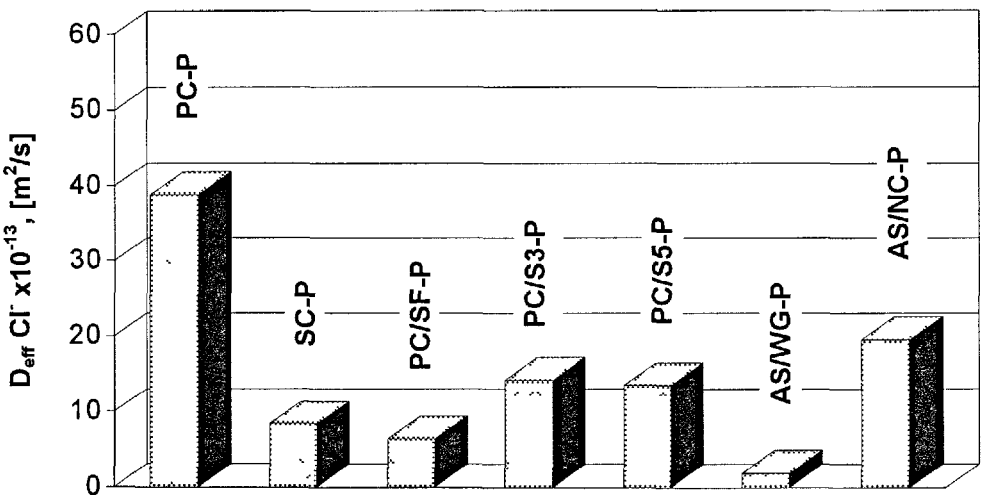

Figure 2. Mean "effective" diffusion coefficients of Cl^- in a 0 - 120 day interval.

The results shown in Table 3 and Fig 2 indicate significant influence of the mineral additives in a course of a diffusion process of chloride ions. If we are to analyze values of $D_{eff\,Cl}$ ratios during entire measurement process (120 days), we will see that they are the least advantageous for a "clean" portland cement. Then, noticeable high "tightness" against diffusing Cl^- shows in the cases of blast-furnace cement (SC-P), portland cement with an addition of a silica fume (PC/SF-P), and above all in an alkali activated slag paste activated with a water glass (AS/WG-P). Also, addition of a ground granulated blast furnace slag (20%) caused almost triple decrease in values of "effective" diffusion coefficient of Cl^-.

Analysis of the results leads to the conclusion that determining factor for this process lies within it's initial period (0-30 days). In most cases samples show the highest values of $D_{eff\,Cl}$. During the

next interval (30-60 days) these values are clearly lower (temporary sealing of a structure), and then again they increase (60-90 and 90-120 days). It seems that these fluctuations are caused by changes in characteristics of pastes as a result of a reaction between chlorides and hydrated phases of paste.
These changes in values of coefficients are the least visible in a case of a slag paste activated with a water glass; within whole time interval they are on a visibly lower level than in the case of other pastes.

Also, low values of $D_{eff\,Cl}$ have to be noticed when achieved in a case of a paste containing 7.5% of a silica fume (PC/SF-P). It has to be noted that in the case of this paste, to achieve consistency similiar to that of the other samples (very high specific surface of silica fume) w/c ratio of 0.41 had to be applied. Introduction of a superplasticizer and limiting w/c ratio to the level of 0.35 wold surely help achieve significantly lower values of $D_{eff\,Cl}$ than one of $6.4 \cdot 10^{-13}$ m^2/s .

RESISTANCE OF MORTARS TO THE CHLORIDE CORROSION

Standard mortars were prepared based on the pastes which contents were shown in Table 2. In all cases values of w/c ratio were equal to 0.5 except of an alkali activated slag mortar when w/c ratio of 0.45 was applied. (In this case, consistency identical to the other samples was achieved at w/s= 0.45, comparing to those of w/c =0.5).

After 28 days of a preliminary curing in a standard conditions, some of the samples were moved to the container filled with a NaCl solution of 196g/l concentration and other samples (as control samples) were placed in a container filled with tap water. Then, after 30, 90 and 180 days of curing, their resistance to bending and compression was tested accordingly. Based on a results, so called corrosion resistance ratio - Locher (1966) - values were calculated for bending and pressing (R_{Cl}/R_{water}). The results of a compressive strength tests are shown in Table 4, and calculated values of corrosion resistance ratios at bending and pressing are presented in Table 5.

Table 4. Compressive strength of the mortars.

Type of mortar	Compressive strength, MPa					
	30 days water	30 days NaCl	90 days water	90 days NaCl	180 days water	180 days NaCl
PC-M	40.6	43.2	43.2	53.7	52.2	40.7
SC-M	46.9	48.0	51.0	59.6	51.4	50.4
PC/SF-M	42.9	42.2	44.2	50.7	51.5	53.2
PC/S3-M	37.5	39.4	42.1	47.4	46.5	39.5
PC/S5-M	42.2	43.1	44.4	48.7	45.7	45.5
AS/WG-M	101.9	107.0	107.6	125.0	108.2	111.7
AS/NC-M	41.0	42.5	49.0	63.4	59.5	61.9

The results of a strenghth testing relate well to the observations of a diffusion coefficients of chloride ions. After 180 days under influence of an aquatic environment highly concentrated with chlorides, portland cement mortar shows the greatest loss of durability, it's compression resistance falls 22%.

In all cases, introduction of mineral additives caused improvement in a corrosion resistance factor. Very high strenghts of alkali activated slag mortars must be noted, both: those cured in

Table 5. Calculated ratios of corrosion resistance in mortars after 180 days of curing.

Type of mortar	Bending resistance $R_{180\ Cl} / R_{180\ water}$	Compression resistance $R_{180\ cl} / R_{180\ water}$
PC-M	1.03	0.78
SC-M	1.14	0.98
PC/SF-M	1.14	1.03
PC/S3-M	1.06	0.85
PC/S5-M	1.07	0.99
AS/WG-M	1.02	1.02
AS/NC-M	1.34	1.04

water and ones cured in a corrosive solution as well (AS/WG-M, AS/NC-M). Particularly high strenghts were noted (over 100 MPa) in the case of a slag mortar activated with water glass.

PHASE COMPOSITION AND MICROSTRUCTURE RESEARCH

After 180 days of curing samples of mortars in a NaCl solution, tests using diffraction method and microscopic observations with scanning microscope were conducted. These tests proved accomplished earlier results of a diffusion and strenght research.

In a standard portland mortar, the greatest quantities of Friedel's Salt ($C_3A \cdot CaCl_2 \cdot 10H_2O$) were found, also high numbers of portlandite and certain quantities of ettringite were registered. Presence of these phases were also observed in the remaining mortar samples based on cement, but their quantities were noticeable lower. The typical microstructure of portland cement mortar after 180 days of curing in NaCl solution is presented on Fig. 3.

Only in the case of alkali activated slag binders (non-clinker binders) their phase composition was diametrically different. Next to the typical of these binders significant quantities of CSH phase, there were none of the phases associated with products of corrosion as determined microscopically and by X-rays (alkali activated slag mortar microstructure is presented on Fig. 4).

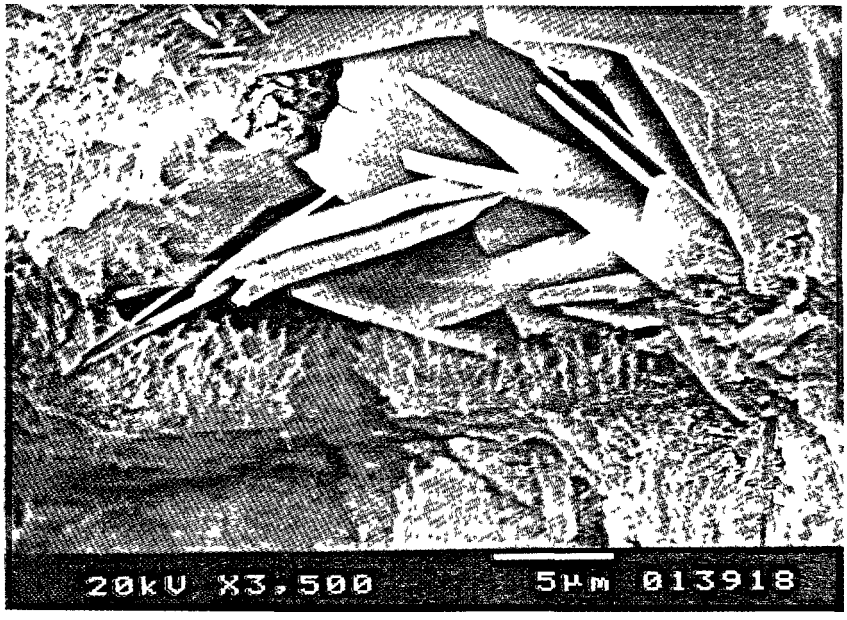

Figure 3. Microstructure of portland cement mortar after 180 days in chloride solution.

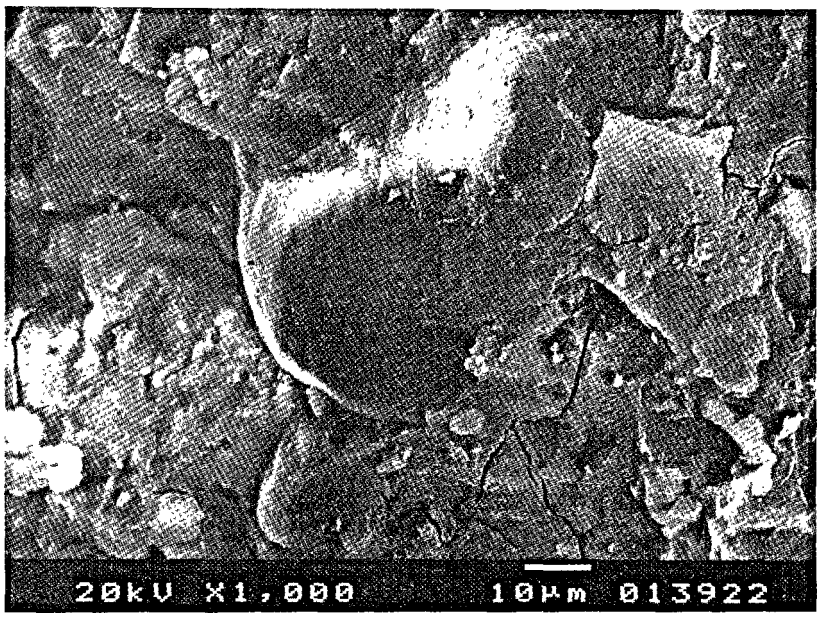

Figure 4. Microstructure of alkali activated slag mortar (AS/WG-M) after 180 days curing in NaCl solution.

CONCLUSIONS

Conducted research unequivocally confirmed a positive influence of mineral additives (granulated blast-furnace slag, silica fume) on the chloride ions diffusion process in a cement pastes and mortars. Also, earlier results indicating very high "tightness" of alkali activated slag mortars and pastes against chloride ions were confirmed - Deja et al (Nice 1994, Sheffield 1994).

If the quantity of chloride ions that diffused through the tile made of portland cement is given a value of 100%, in a case of a paste with addition of silica fume, only 16.5% of this value migrated, and regardingly only 5.1% in a case of a slag binder activated with water glass.

The results achieved during research of a diffusion rate of chloride ions relate well to the results of strength testing (corrosive resistance of mortars under influence of a water based NaCl solution).

Based on a positive relation between results accomplished by these two methods, it is allowed to assume that applied method of checking the rate of ions' diffusion could be used as a quick way to assess corrosion resistance properties of a wide variety of binders.

CHLORIDE BINDING OF CEMENT PASTE CONTAINING FLY ASH

Udo WIENS, Peter SCHIESSL, Institute for Building Materials Research (ibac),
University of Technology, Aachen, Germany

ABSTRACT The life time of reinforced concrete structures exposed to chlorides (see-water, deicing salts, etc.) strongly depends on the quality of the concrete cover. The rate of chloride ingress into concrete depends on the pore structure and the capacity of the hydration products to bind chlorides. It is well known that the use of fly ash improves the resistance of portland cement concretes against chloride attack. The main beneficial effect of fly ash or blast furnace slag is related to the refinement of the pore structure reducing diffusion rates. Limited studies exist about the influence of fly ash on the binding capacity of chlorides in concrete.

Key-words: Fly ash, Chloride binding, Diffusion resistance, CSH, Degree of hydration/reaction

INTRODUCTION

The densifying effect which fly ash has on the microstructure of materials is well known from numerous publications. In this context, the primary effect of fly ash is accountable to the sealing of pore openings and the narrowing of pore channels by the hydration products of the pozzolanic reaction („pore blocking effect"), as a result of which the permeability of concrete is reduced substantially (Marsh et al., 1985, Ngala et al., 1995, Schiessl and Haerdtl, 1994). The capillary pore volume is reduced only minimally if at all as a result of this effect, but certain parts of the pore volume are no longer accessible for the transport of media.

This phenomenon is confirmed by investigations on the resistance to chloride diffusion of mortars produced with the same raw materials as apply to the results presented in this publication regarding chloride binding in cement paste (Schiessl and Wiens, 1997). Schiessl and Wiens (1997) determined the resistance of mortars to chloride diffusion by the means of a so-called migration method (developed by Tang and Nilsson, 1992). In this rapid test the transport of chloride ions is accelerated by the induction of an electrical field, thus reducing the test period to < 7 days. From this rapid test, so-called migration coefficients for chloride can be caclulated, which are directly correlatable with pore structure parameters at a specific testing time. Compared to conventional diffusion tests the rapid test method has the advantage that the influences of time-dependent changes in pore structure are nearly eliminated. This is of particular interest with regard to additions, such as fly ash or blast-furnace slag, reacting over a long period. The pore structure of concrete and mortar with these materials changes over a period of years. It is thus often very difficult to specify the time at which a steady state prevails in conventional diffusion cells for determining intrinsic diffusion coefficients.

The pore parameter which should best reflect this „pore blocking effect" is the threshold radius. This parameter determined by the mercury intrusion porosimetry characterizes the pore radius below which a continous network of pores exists. The smaller this value, the lower will be the continuity of the pore network. Fig. 1 shows the interrelationship between the threshold radius and the migration coefficient $D_{Cl,M}$ that characterizes the resistance of mortar or concrete against chloride diffusion. The good correlation between the migration coefficient and the threshold radius confirms the model concept that permeability is reduced primarily through the reduction of this pore entry radius due to pozzolanic reaction of the fly ash (Fig. 1).

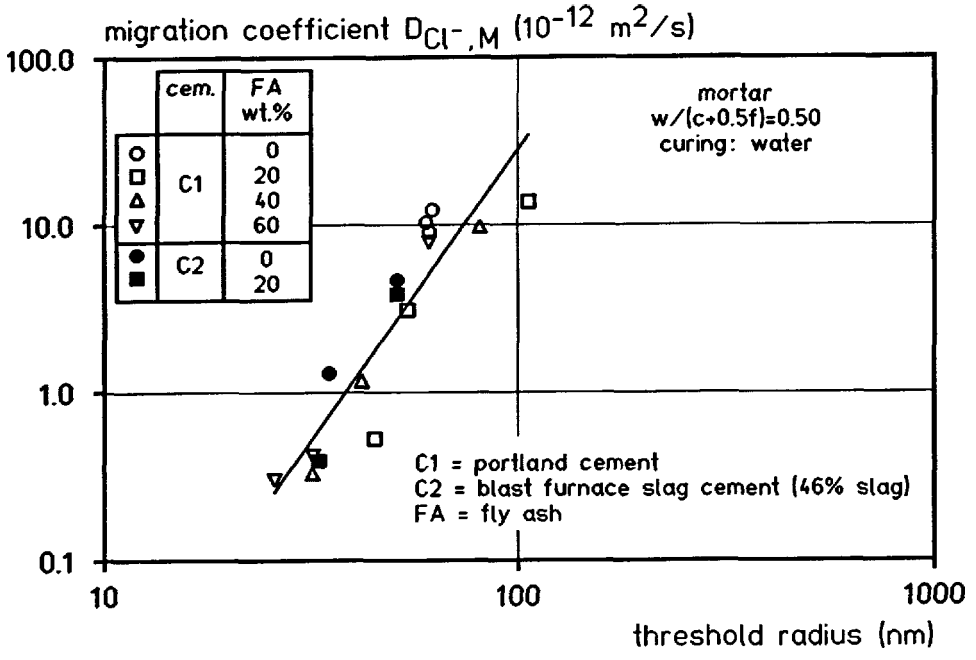

Figure 1: Relationship between the migration coefficient $D_{Cl,M}$ and the threshold radius (Schiessl and Wiens, 1997)

The pozzolanic reaction of the fly ash distinctly reduces the threshold radius as compared to the reference mix. The effect becomes more pronounced as fly ash content increases. This influence of fly ash occurs even with blast furnace slag cements, but it is less significant with these cements, since the reaction of the slag has already densified the pore structure.

In addition to microstructural changes, the binding capacity and the interactions of the ions with the surface of the CSH-gel are also of decisive importance to a realistic representation of chloride transport in concrete. The relationship between the migration coefficient and the threshold radius presented in Fig. 1 indicates that the reduction in ionic diffusion resulting from the use of fly ash is not accountable solely to the reduced continuity of the pore system due to the reaction of the fly ash. The mixes containing fly ash tend to reveal lower migration coefficients than those determined for the pure Portland cement mix at the same threshold radius. This indicates an increased chloride binding capacity or an intensification of the interactions between the gel surface of the CSH phases and the chloride ions in mixes containing fly ash, which has been confirmed by the studies carried out by different authors (Arya et al., 1990, Jensen and Pratt, 1989, Roy et al., 1986, Ngala et al., 1995).

The chloride binding capacity of cement paste is generally determined by establishing the difference between free and total chloride content. These parameters are relatively easy to determine, e.g. by pressing out pore solution or by acid decomposition. Another, more practical method of estimating the chloride binding capacity, which was applied in the course of the investigations presented here, involves determining sorption isotherms by immersing granulated cement paste into chloride solutions of varying concentrations (cf. Tang and Nilsson 1993, Tang and Nilsson 1991). The chloride sorption of the cement paste is then determined by the reduction of the chloride concentration in the storage solutions. Desorption tests which are performed after the chloride adsorption process enable the strength of the chloride binding to be deduced. This binding strength diminishes in the following order: chemically bound chloride (firm incorporation

into the crystal lattice of new reaction products) => chemisorptively bound chloride (e.g. covalent bond in the surface layer of the solid) => physiosorptively bound chloride (attachment due to van der Waal's forces). Thus, the chloride binding capacity of mixes containing fly ash has been studied on granulated cement paste immersed in 0.05, 0.1 and 0.5 molar NaCl-solutions (age: 365 days). Up to 40 wt.% of portland cement was replaced by the same amount of fly ash, respectively. From the interrelationship between the amount of free and bound chloride isotherms have been deduced to quantify the binding capacity. As sorptive binding processes cannot be considered separately from the available gel surface, the quantity of CSH-phases which is formed in the cement paste is determined on the basis of a hydration model which takes due account of the constituent of CSH resulting from the pozzolanic reaction of the fly ash (Haerdtl, 1995).

MATERIALS AND METHODS

Materials

A Portland cement, CEM I 32.5 R, and a fly ash of medium fineness from a dry bottom furnace approved as a concrete addition in accordance with German standard DIN 1045 (low calcium fly ash, class F according to ASTM C 618) were included in the test programme. The chemical compositions and selected physical properties of the raw materials are summarised in Table 1. The mineralogical composition of the Portland cement clinker was calculated according to Bogue from the results of the chemical analysis.

Table 1: Chemical and mineralogical composition and physical properties of the raw materials

Item	Unit	CEM I 32.5 R	Fly ash
Chemical Composition			
SiO_2		19.4	46.9
Al_2O_3		5.43	28.1
Fe_2O_3		3.07	9.24
CaO		63.4	3.54
MgO		1.03	2.02
K_2O		0.74	3.06

40 µm-residue (air jet sieve)	wt.%	27.4	23.6

n.d.: not determined

In order to produce the cement paste, the raw materials were mixed for 3 minutes and then poured into PE bottles without bubbles, up to the rims of the bottles. To prevent sedimentation

of the solids in the water, the specimens were rotated upside down for 24 hours, until hardening took place. The fly ash content of the produced cement pastes was 0, 20 and 40 wt.%, in relation to the total binding agent content (c+f). The water/cement ratio of the cement paste mixes without fly ash was 0.50. For the mixes containing fly ash, the w/(c+f) ratios were selected so as to enable roughly the same compressive strength to be attained after 28 days (see also Schiessl and Wiens, 1997). This was achieved via the uniform calculation of the fly ash with a cement equivalence value of k = 0.50 to the (w/(c+k·f)) value. According to the studies by Tang and Nilsson (Tang and Nilsson, 1993), the influence of the w/c on the sorptive binding of chloride in cement paste containing Portland cement is negligible.

Adsorption and desorption isotherms, $Ca(OH)_2$ and bound water content

In order to determine the chloride binding, adsorption tests were carried out on cement paste specimens according to the method described in (Tang and Nilsson, 1993). For this purpose, the cement paste (age: 365 days) was comminuted into grain size fractions of 0.5/1 mm and 0.063/0.125 mm, and the hydration process was stopped by placing the cement paste in methanol. 25 g of the granulated and dried cement paste respectively was then subjected to 50 ml of chloride solution of varying concentration (0.05, 0.10 and 0.50 molar NaCl solution in 0.2 molar KOH), and the chloride concentration in the solutions was subsequently determined after the cement paste had been in the solutions for a period of 1 and 5 days, via potentiometric titration. At the end of the adsorption test after 14 days' subjection to chloride, the residual chloride solution was filtered and the chloride concentration in the solution was determined. The specimen was then subjected once again to 50 ml of 0.2 molar KOH over a period of 14 days (desorption test) and the quantity of chloride released into the solution was determined via titrimetry. Prior to beginning the adsorption test and after completing the desorption test, thermogravimetric analyses were carried out on the specimens in the temperature range between 30 and 890 °C, in order to determine the bound water content and the calcium hydroxide content (for details see Meng and Schiessl, 1997). The calcium hydroxide bound by the fly ash was determined from the difference between the mix containing fly ash and the reference mix.

Determination of reacted fly ash content

As sorptive chloride binding takes place primarily on or in the surfaces of the hydration products, it is expedient to relate the chloride fraction which is bound in the cement paste to the total quantity of CSH phases which are formed in the course of cement hydration and the pozzolanic reaction. In the case of cements, it is common to determine the degree of hydration, e.g. from the quantity of chemically bound water, and thus to ascertain the quantity of CSH phases which are formed. In the case of fly ash, it is not possible to deduce the reacted fly ash content directly from the quantity of $Ca(OH)_2$ bound by the pozzolanic reaction. For this purpose, it must be known how much $Ca(OH)_2$ is converted when the complete fly ash content reacts. The reacted fraction of fly ash can only be determined via indirect experimental methods. Determination was carried out by applying the selective dissolving method in accordance with DIN V ENV 196 - 4; 1993, which is normally carried out to determine the content of pozzolanic material in non-hydrated cement, to cement paste specimens with 20, 40 and 60 % fly ash content by weight, in relation to (c+f). In contrast to the experiments to investigate chloride binding, the w/(c+f) value of the cement paste specimens was set at a uniform 0.50. The experiments relating to selective dissolution were carried out as part of a research project to explain the reaction processes in cement paste containing fly ash and silica fume with the aim of evolving thresholds for the application of these pozzolanic substances (Schiessl and Meng, 1996, Meng and Schiessl, 1997), and were not a direct part of the experiments to investigate chloride binding. The cement paste specimens were produced from the same raw materials, however. The dried cement paste is

treated in methanol with a solution of hydrochloric acid and salicylic acid. As a result, the clinker minerals and a proportion of the sulphate component are dissolved in the cement. Slowly, under constant stirring, 2.0 ± 0.1 g of the dried cement paste specimen which had been ground to a fineness of < 0.125 mm was placed in a 400 ml beaker containing 200 ml of the acid mix. This mix was then stirred for 30 minutes. After 24 hours, the solution was filtered through a weighed filter. The insoluble residue was washed approximately six times with 100 ml of methanol. The filter and insoluble residue were dried at 105°C until a constant mass was attained, cooled to room temperature in a desiccator and weighed.

After this treatment the unreacted fly ash content and a proportion of the sulphate component in the insoluble residue is left. After determination of the sulphate content in the insoluble residue and a corresponding correction, the reacted fly ash content can be calculated by subtraction.

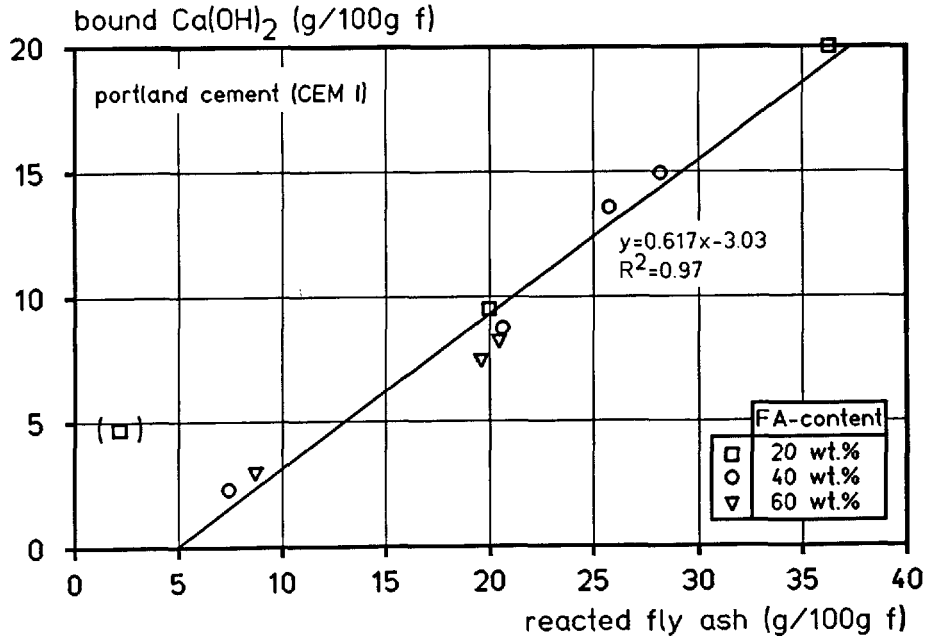

Figure 2: Relationship between the quantity of bound-$Ca(OH)_2$ and the reacted fly ash content; cement paste; w/(c+f) = 0.50; age: 7, 91, 365 and 640 days (Schiessl and Meng, 1996)

Fig. 2 shows that a relatively good correlation exists between the amount of reacted fly ash and the bound $Ca(OH)_2$ measured in dependence of the fly ash content. On the basis of this correlation, it is possible to determine the lime-binding capacity of the fly ash during the reaction in the cement paste. The slope of the line reveals a lime-binding capacity of 0.62 g of $Ca(OH)_2$ per g of reacted fly ash.

RESULTS AND DISCUSSION

When chloride enters into the concrete, chemical and physical (sorptive) binding processes take place. A number of findings have already been published with regard to the purely chemical binding of chloride in hydration phases (e.g. Friedel's salt) (Richartz, 1969, Smolczyk, 1984). These findings are frequently based on experiments in which chloride was added to the fresh concrete and mortar. Adsorption and desorption experiments provide a more effective method of assessing chloride binding under realistic practical conditions for the structural components, as these experiments primarily detect the quantity of chloride which is sorbed at the gel surface in

the course of the chloride transport process. Chloride sorption can have a substantial influence on the rate of transport. Fig. 3 and 4 show the time-dependent chloride sorption of the 0.5/1 and 0.063/0.125 mm cement paste fractions as a function of the fly ash content, by reference to the 0.1 molar NaCl solution (initial concentration).

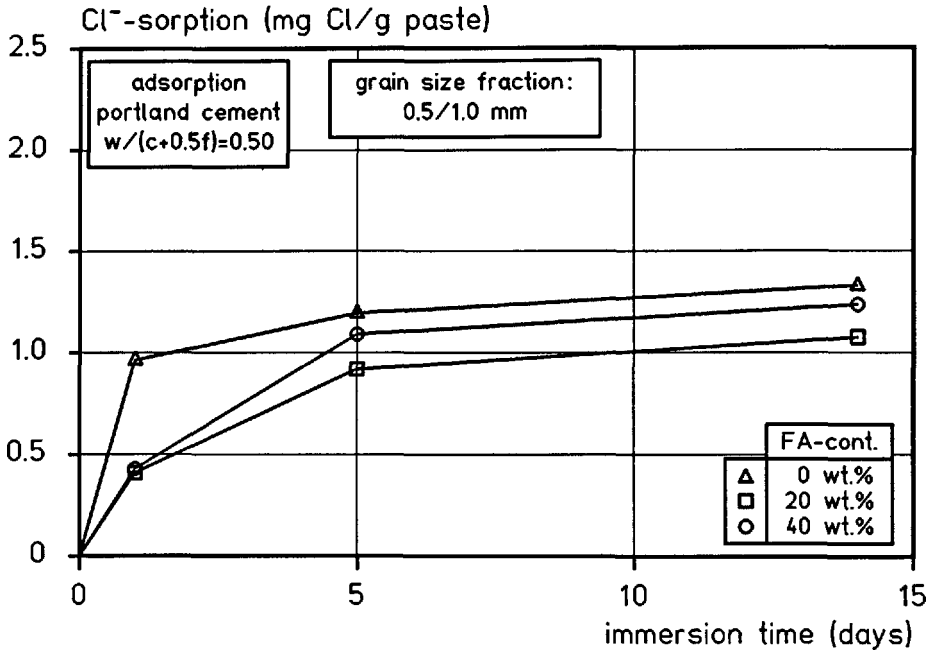

Figure 3: Time-dependent chloride sorption of the 0.5/1 mm fraction; w/(c+0.5·f) = 0.50; age of specimens at immersion in 0.1 molar NaCl solution: 365 days

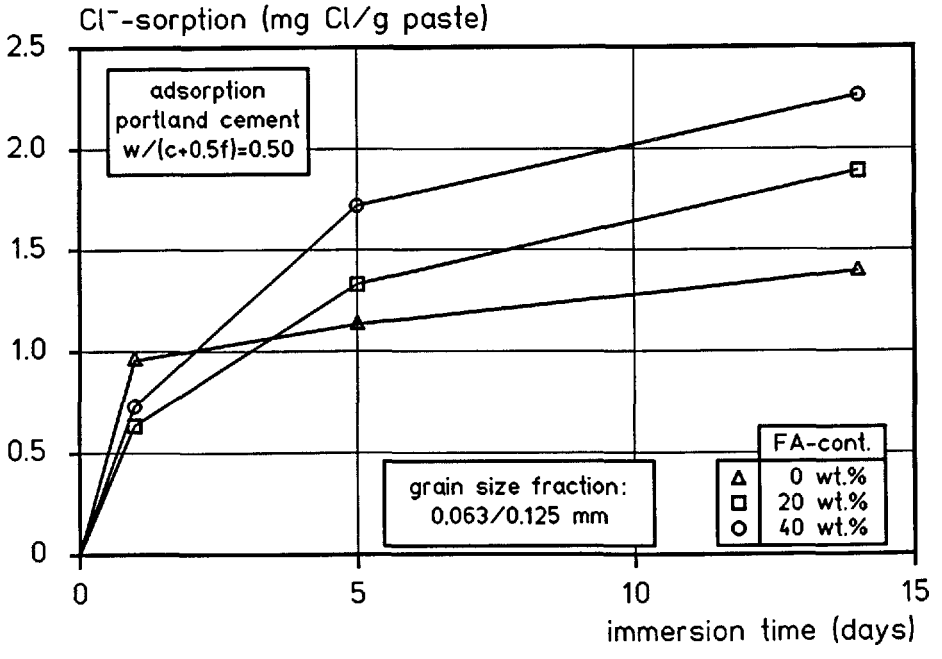

Figure 4: Time-dependent chloride sorption of the 0.063/0.125 mm fraction; w/(c+0.5·f) = 0.50; age of specimens at immersion in 0.1 molar NaCl solution: 365 days

The results obtained with the 0.5/1 mm grain-size fraction (Fig. 3) show that a state of equilibrium has apparently been attained between the storage solution and the pore solution, and that there is a tendency for smaller quantities of chloride to be bound in mixes containing fly ash. When the diffusion routes are further shortened by finer grinding of the cement paste specimens (0.063/0.125 mm fraction, Fig. 4), markedly higher quantities of chloride are bound in comparison to the reference specimen containing pure Portland cement, while the chloride-binding capacity of the pure Portland cement mix is virtually independent of the granulated material's grain size. As a result of the above-described microstructural densification (pore-blocking effect) in mixes containing fly ash, not all the pore spaces and pore walls are reached in the 0.5/1 mm grain-size fraction over a period of 14 days (cf. Fig. 1). As the sorption of chloride takes place primarily on and in the surfaces of the CSH phases, it is expedient to relate the results to the quantity of CSH phases. In this context, the term "CSH phases" refers to the totality of hydrate phases resulting from cement hydration and the pozzolanic reaction of the fly ash, with the exception of the $Ca(OH)_2$. In order to determine the CSH content, Haerdtl's formulation (Haerdtl, 1995) was selected, according to which the CSH content at the age of 365 days can be calculated as follows:

$$CSH_{(365)} = w_{n(365)} + \alpha_{(365)} - CH_{(365)} + \text{bound}\,CH_{(365)} / 0.62 \quad (g/100g\,c) \qquad [1]$$

whereby:

$w_{n(365)}$ non-evaporable water at 365 days,

$\alpha_{(365)} = \frac{w_{n(365)}}{w_{n(\infty)}}$ degree of hydration of the cement,

$$w_{n(\infty)} = 0.237 \cdot C_3S + 0.209 \cdot C_2S + 0.400 \cdot C_3A + 0.167 \cdot C_4AF = 22.2 \ (g/100g\,c) \qquad [2]$$

maximum of non-evaporable water, calculated from the mineralogical composition of the clinker (cf. table 1), (Haerdtl, 1995),

$CH_{(365)}$ calcium hydroxide content of cement paste at 365 days,

bound $CH_{(365)}/0.62$ quantity of CSH phases produced during pozzolanic reaction of the fly ash (1g of fly ash binds 0.62 g of $Ca(OH)_2$; corresponds to the slope of the straight line in Fig. 2).

It can be seen from Eq. [1] that in case of a low calcium fly ash as used in these test series no additional water is bound in the course of the pozzolanic reaction. Solely calcium hydroxide is the constituent in the pozzolanic reaction forming CSH-gel and the bound water content in the reaction products of the fly ash correspond to the bound water in the $Ca(OH)_2$. Table 2 summarizes the CSH content levels determined in accordance with Eq. [1] for the individual cement paste specimens at the age of 365 days.

Table 2: CSH content of the cement paste specimens at the age of 365 days; results of thermogravimetric analysis (CEM I 32.5 R)

Cement content	Fly ash content	$w_{n(365)}$	$\alpha_{(365)}$	$CH_{(365)}$	bound $CH_{(365)}$	$CSH_{(365)}$
wt.%		g/100 g c	%	g/100 g c		g/100 g (c+f)
100	0	17.3	78.1	21.6	-	73.8
80	20	18.3	82.5	15.8	5.8	75.5
60	40	18.8	84.4	10.7	10.9	66.0

At the age of 365 days, the CSH content as a percentage of the total binding agent content is higher in the mix containing 20 wt.% fly ash than in the reference mix, on account of the pozzolanic reaction of the fly ash. Smaller quantities of CSH phases are formed in the mix with 40 wt.% content, due to the reduced cement content. The contribution of the fly ash to the CSH content is not sufficient to compensate for the reduction in cement content. Fig. 5 shows the bound chloride content as a percentage of the CSH content in the cement paste specimens for all the examined storage solutions (0.05, 0.1 and 0.5 molar NaCl; 0.063/0.125 grain-size fraction), in the form of adsorption and desorption isotherms according to Freundlich. As the fly ash content increases, the bound chloride in relation to the CSH content rises. The increase in the level of bound chloride in the presence of fly ash may be accountable to the increase in the gel surface area due to the formation of additional CSH phases from the pozzolanic reaction, which promotes the sorption of chloride. Tang and Nilsson have found a larger gel surface area in cement paste containing 30 wt.% fly ash than in mixes containing pure Portland cement (Tang and Nilsson, 1991). The influence of the larger adsorbent surface on the physiosorptive binding of chloride can be largely factored out by relating the bound quantity of chloride to the gel surface area (Tang and Nilsson, 1991). Although the influence of an increased adsorbent surface area in mixes containing fly ash was compensated for by selecting the gel surface area as the reference basis for the quantity of bound chloride, the authors nevertheless discovered around twice as much bound chloride in the mix containing fly ash as in the cement paste containing pure Portland cement. This is assumed to be due to the higher content of aluminium oxide and iron oxide in the fly ash in comparison to the Portland cement, as a result of which the chemisorptive and/or chemical chloride binding of the cement paste is increased.

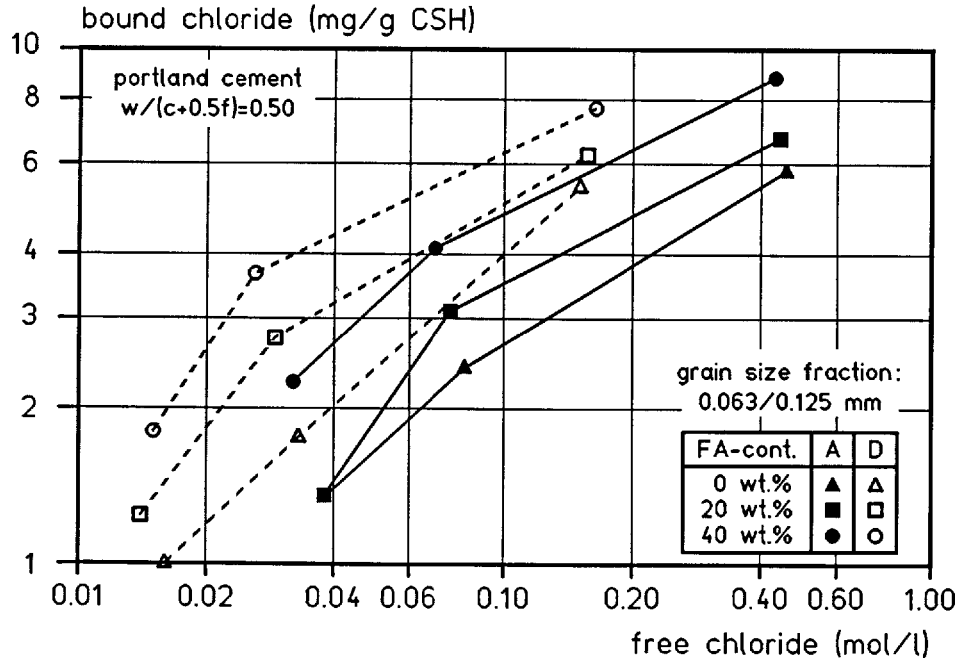

Figure 5: Ad- (A) und desorption isotherms (D) for chloride; cement paste with and without fly ash (fraction: 0.063/0.125 mm; w/(c+0.5·f) = 0.50)

This assumption is supported by X-ray diffraction analyses of the cement paste specimens containing 100 wt.% Portland cement and 40 wt.% fly ash, which were carried out after completion of the desorption experiments in this investigations. The mix containing 40 wt.% fly ash revealed more or better-crystallised Friedel's salt than the cement paste without fly ash. The results of the desorption experiments also indicated stronger chemisorptive and/or chemical

chloride binding in cement paste containing fly ash. In mixes containing 20 and 40 wt.% fly ash, an average level over all the examined concentrations of 91 and 85 % respectively of the chloride bound during adsorption remains in the cement paste after the end of the desorption process, while in the mix containing 100 % Portland cement by weight only around 80 % of the chloride from the adsorption process remains, i.e. around 20 % of the chloride is released again (desorbed).

CONCLUSIONS

On the basis of the completed experiments, it has been possible to derive models to explain the chloride binding of cement containing fly ash. The marked increase in the resistance of cement paste and mortar containing fly ash to penetration by chloride in comparison to the resistance of pure Portland cement is accountable primarily to the increase in physio- and chemisorptive binding capacity as a result of additional sorption surfaces (CSH phases) and the largely irreversible binding of chloride in and on hydrate phases. The high aluminium and iron oxide fractions in the fly ash, which are able to bind chloride in the form of the not readily soluble Friedel's salt, are assumed to be responsible for the increased chemisorptive and chemical binding capacity.

Beyond the increased chloride binding capacity, the transport rate of chloride is reduced as a result of the reduced permeability of the pore system in concretes containing fly ash. The reduced permeability of mixes containing fly ash results primarily from the effective interruption of the capillary pore system and the refinement of the pore structure by CSH phases, which occur as a result of the pozzolanic reaction („pore blocking effect").
The stated mechanisms result in a substantial prolongation of the period which elapses before a critical corrosion-inducing level of chloride content is attained on the reinforcing steel (so-called „incubation time"). It is possible to incorporate the results into an estimation of the lifetimes of concrete structures in environments containing chloride, taking due account of the employed binding agents. In the absence of appurtenant results, binding processes are often neglected in calculations to determine the time-dependent penetration of chloride. The established sorption isotherms can be employed to help render the calculation methods for chloride transport more precise.

Beyond the influence of fly ash on chloride binding in mixes containing Portland cement, it is also planned to include blast-furnace slag cement in combination with fly ash in the investigations into chloride binding. The appurtenant tests have largely been completed and are to be published in the near future.

SULPHATE ATTACK OF CARBONATED AND UNCARBONATED PORTLAND AND BLENDED CEMENT MORTARS

ABSTRACT The influence of the binder's gypsum and C_3A content, both on carbonation and on resistance to sulphate attack, has been evaluated on a series of Iso standard mortars containing Portland,with 6% and 10% C_3A and blends of the same Portland cements with 70% blast furnace slag or with 35% true pozzolana, with gypsum addition varying from 1% to 5% as SO_3. The mortar carbonation process depends on type of cement and SO_3 content and improves response to sulphate attack.

Key-words: blended cement, carbonation, gypsum, porosity, sulphate resistance.

INTRODUCTION

It is well known that the carbonation of concrete can have both positive and negative effects (Taylor, 1990) The aim of the present paper is thus to evaluate the effects of the carbonation of Portland and blended cement mortars on the behaviour of sulphate attack, as part of a wider-ranging project to investigate the durability of cement structures. Permeability is predominantly affected by the presence of large pores and is thus typically the key factor in all durability problems; therefore, response to chemical attack was studied in conjunction with the determination of total porosity and pore size distribution in the carbonated and uncarbonated specimens, as there are some differences in the opinions to be found in literature (Mangat and Khatib, 1995).

These values were determined using mercury intrusion porosimetry which, although it has a number of limitations including over-estimation of the volume of the smaller pores as a result of the "ink-bottle" effect (Kjellsen et al., 1990), nevertheless measures a pore structure that can be reliably referred to the same factors that affect the penetration of fluids and ions (Roy, 1989).

This structure is essentially influenced by the following factors: fineness, water/cement ratio, chemical composition, product curing conditions and pozzolanic reaction. In general the addition of mineral additives to Portland cement reduces pore size or increases the porosity fraction for the smaller pores (Bakker, 1983).

For instance, the low permeability of blast furnace slag pastes has been attributed to differences in pore size distribution compared to Portland cement pastes (Feng et al., 1989) (Malek, et al., 1989). Furthermore, it must be taken into consideration that the smaller pores, which make up the main fraction of total porosity, tend to become unconnected, thus significantly reducing permeability.

Carbonation speed is also affected by the type of cement. In the experimental conditions adopted (Gebauer and Torrent, 1989) it can be seen that cement containing a high percentage of blast furnace slag (70%) shows a faster carbonation speed.

The strength of concrete prepared with ordinary Portland or blended cements is considerably affected by the curing conditions, and in particular by temperature and relative humidity (Mangat and Khatib, 1992) Moreover, the presence of a carbonate layer on the surface of the concrete has been shown to provide a greater resistance to sulphate attack, although numerous exceptions to this have been found. Whereas matrix pore structure and volume seem to have no direct influence on the concrete's resistance to sulphate attack.

This resistance increases when mineral additives are incorporated and after a carbonation process has been carried out. This increased resistance has been evaluated on the basis of the reduction of

calcium hydroxide in the surface layers and the resulting smaller volume of the products of reactions, which expand with sulphate ions.
These and other results found in the literature gave rise to the experimental research reported in this paper.

EXPERIMENTAL

Two samples of type I Portland cement were used with 6% and 10.8% C_3A. Their chemical and mineralogical composition according to Bogue are reported in **Table 1.**

These two samples were then used to prepare the corresponding blended cements by adding 70% granulated blast furnace slag (CEM III/B; CEN ENV 197-1) and 35% true pozzolana (CEM IV/B; CEN ENV 197-1), respectively. A quantity of natural gypsum (98% $CaSO_4 \cdot H_2O$ varying from 1% to 5% as SO_3 was then added to each of these cements in order to take into account its influence on the pore size distribution of the corresponding products, as already extensively verified in our previous investigations (Sersale et al., 1992).

Table1 Chemical and mineralogical composition of the clinkers, wt%.

	Chemical composition	
SiO_2	21.70	21.50

C_2S	8.4	21.5
C_3S	71.4	53.2
C_3A	6.0	10.8
C_4AF	9.8	8.6

The above cements were used to prepare prismatic samples (40x40x160 mm^3) of standard mortars (ISO-RILEM, 1968) which were moist-cured for one day and then cured in water for six days. At the end of this period the mortars were divided into three groups.
The first group was stored in water for six months, after which each specimen was immersed into equivalent strength sodium (0.35M) and magnesium (0.42M) sulphate solutions.
The second group was kept for six months (protected from rain) in air containing 400 ppm CO_2 at 70÷80% R.H. and 10÷30°C so as to facilitate the completion of the carbonation process in conditions similar to those actually encountered in the real world. At the end of the prescribed period the specimens were immersed into the same sulphate solutions.
Similarly, the third group was exposed for the same period of time to the same industrial atmosphere but without being subsequently immersed into the sulphate solutions in order to determine the carbonation depth reached.

RESULTS AND DISCUSSION

Table 2 reports the carbonation depth and mechanical strength values of the studied mortars reached after six months exposure to the above-mentioned industrial atmosphere. It can be seen

that the carbonation phenomenon affects the blended cements much more than Portland cement, and also that as the proportion of SO_3 in the blast furnace slag cement increases, the carbonation depth likewise increases, whereas the pozzolanic cement is affected to a much lesser extent by the SO_3 content.

Table 2 Compressive strength and carbonation depth of the mortars.

	"	3	45.6	5.0
	"	4	41.4	5.2
	"	5	39.2	5.5

The compressive strength values of the pozzolanic cement mortars considered are concentrated within a small range which makes it impossible to identify a predominant trend. However, there are significant differences in the carbonation depth values between the mortars made with Portland cement and those made with blended cements for the same compressive strength (50 MPa).

Table 3 reports the results of the chemical resistance tests conducted on the samples of mortars that were exposed for six months to an industrial atmosphere or were stored in water for the same period of time before both types were kept in the sulphate solutions for a total of twenty-one months.

With the cement samples used, the carbonation depth increases as the C_3A content increases both for blast furnace slag and pozzolanic cements. Furthermore, the carbonation depths of the Portland cement mortars after six months exposure to the industrial atmosphere turns out to be less than

one millimeter, which would make any differentiation relatively insignificant, nor does the trend of this phenomenon appear different after twenty-four months exposure to the same atmosphere. This suggested that it would be of no use to report the carbonation depths after twenty-four months, also because only the mortars carbonated for a six-month exposure have currently been subjected to sulphate attack.

**** Disgregated; *** Very demaged; ** Poorly demaged; * Not sensibly demaged.

Furthermore, it can also be seen that as the Portland cement mortars are not carbonated, they have higher compressive strength values, which are however determined partly by the cement's gypsum content (Sersale et al., 1992).

For the blast furnace slag cement considered, the carbonation depth values were concentrated in an interval that was fairly large according to the variation in the SO_3 content, and the compressive strength of the corresponding mortars is a function of the values of this depth.

Once this period of time had elapsed, the only specimens of uncarbonated mortars that were still intact after immersion in the sodium sulphate solution were the ones made with pozzolanic cement

containing 6% C_3A. The mortars that suffered the greatest attacks were, in order: those made with Portland cement containing 10.8% C_3A; those made with Portland cement containing 6% C_3A; those made with blast furnace slag cement containing 10.8% C_3A. The attack is initially manifested with low SO_3 contents and diminishes as this value increases, within the limits adopted.

As regards the behaviour of the mortar specimens carbonated through exposure to the industrial atmosphere and subsequently immersed for the same period of time in the sodium sulphate solution, at the end of the test the following specimens had not been attacked: the specimens of pozzolanic cement containing 6% C_3A; those made with blast furnace slag cement containing 6% and 10.8% C_3A. For low SO_3 values, the specimens were attacked in the following order: the specimens of pozzolanic cement mortar; those of Portland cement containing 6% C_3A; and, to a much higher degree, those of Portland cement containing 10.8% C_3A.

Therefore, the factors that most decisively regulate sulphate attack in the experimental conditions adopted seem to be as follows: the mineral additive, the content of C_3A and SO_3 in the binder, and the degree of carbonation.

Identical tests conducted using magnesium sulphate as the attacking solution showed that all the specimens of uncarbonated mortars made using the cements examined here had been attacked by the end of the test. The C_3A content of the cements seems to be main promoter of attack while the SO_3 content and the mineral additive do not seem to play a determining role.

Whereas, the carbonated mortar specimens that do not appear to be attacked by the end of the test are: those made with blast furnace slag cement containing 6% and 10.8% C_3A and those made with Portland cement containing 6% C_3A. The mortars made with Portland cement containing 10.8% C_3A turn out to be only slightly attacked while the specimens that suffered the greatest attack were those made with pozzolanic cement.

The SO_3 content in the binder does not seem to have a particular influence, while carbonation depth and content of C_3A, for Portland cement only, seem to be the main parameters involved.

Therefore, in the magnesium sulphate solution the mortars made with blast furnace slag cement seem consistently to resist well, whereas those made with pozzolanic cement are always attacked, although not to a great extent. The Portland cement mortars are only slightly attacked and varies according to the cement's C_3A content. For the two blended cements the C_3A and SO_3 content does not seem to have a determining influence. However, the magnesium sulphate solution turns out to be much more aggressive than the sodium sulphate for all the types of cement considered. This behaviour can be justified by considerations regarding the combination of a number of different factors: chemical, steric, electrical, and so forth.

Table 4 reports the pore size distribution values. It must first be pointed out that no comparison can be made between the carbonated and the uncarbonated Portland cement mortars as their carbonation depth at the end of the period of exposure to the industrial environment was consistently lower than 1 millimeter.

A comparison of the carbonated and the uncarbonated specimens of mortars made with blast furnace slag cement points out that the carbonation process causes a reduction in the percentage of pores smaller than 1000 Å, with a consequential increase in the larger ones, while the total porosity value on the whole remains unchanged. In the carbonated mortars the percentage of smaller pores increases as the content of SO_3 in the binder increases.

At the current stage of research, these results do not appear to be immediately correlatable with the results of the chemical strength tests and it must therefore be assumed that the carbonation process

and the SO_3 content of the cements considered here have different effects on pore size distribution. Future investigations will aim to shed more light on this issue.

TABLE 4 Pore size distribution of blast furnace slag-cement mortars.

Percentage of total cumulative of pores - Rp < 1000 Å			
% SO_3	2	3	4
BFS 6% C_3A			
Uncarbonated	70.28	78.88	89.67
Carbonated	67.37	76.79	84.73
BFS 10% C_3A			
Uncarbonated	76.10	88.79	89.21
Carbonated	71.38	77.69	82.10
Percentage of total cumulative of pores - 1000<Rp<10000 Å			
% SO_3	2	3	4
BFS 6% C_3A			
Uncarbonated	21.34	13.26	5.61
Carbonated	23.35	15.63	8.08
BFS 10% C_3A			
Uncarbonated	17.17	5.26	8.45
Carbonated	19.98	16.29	10.98
Percentage of total cumulative of pores - 10000<Rp<100000 Å			
% SO_3	2	3	4
BFS 6% C_3A			
Uncarbonated	8.38	7.86	4.72
Carbonated	9.13	7.59	7.19
BFS 10% C_3A			
Uncarbonated	6.73	5.95	3.35
Carbonated	8.64	6.02	6.92

CONCLUSIONS

The experimental results and the deductions that can be reasonably inferred from them indicate that:

- the mortar carbonation process improves response to sulphate attack both for the mortars prepared with Portland cement and those made with the blended cements used;
- the mortar carbonation process for all the cements examined is facilitated by their SO_3 content;
- the increase in the carbonation depth as the cement's SO_3 content increases is more evident for the blast furnace slag cement examined in this paper. This may partly explain the increase in resistance to sulphate attack as the SO_3 content increases, as can be seen with the blast furnace slag cement.

INFLUENCE OF LIMESTONE POWDER FILLER ON MICROSTRUCTURE AND MECHANICAL PROPERTIES OF CONCRETE UNDER SULPHATE ATTACK

Wojciech G. PIASTA, Zbigniew SAWICZ, Grzegorz KOPROWSKI, Zdzisława OWSIAK, Technical University of Kielce, Institute of Concrete Technology, Poland

ABSTRACT The paper deals with the effect of limestone and quartz powders on the changes in phase composition of cement paste and on their sulphate resistance. There was also studied the qualitative and quantitative dependence of concrete properties and its sulphate resistance on the three factors: amount of limestone powder, w/c-ratio and level of simultaneous sustained stress. The results confirmed much better sulphate resistance of all the OPC composites with limestone fillers mainly due to the formation of phase $C_3A.CaCO_3.H_{12}$.

Key-words: sulphate attack, creep, limestone powder, ettringite, X-ray powder diffraction

INTRODUCTION

Although the mechanism of ettringite expansion in concrete under sulphate attack is controversial, it is accepted that the formation of ettringite produces harmful swelling (Kurdowski, 1991, Roy, 1986). Susceptible phases of OPC paste to sulphate attack are CH, unhydrated C_3A, hydrates C_4AH_n, C_3AH_6, $C_3A.CaSO_4.H_{12}$ and their solid solutions $C_3A(CH,CaSO_4,CaCO_3)H_n$ (Kurdowski, 1991, Mehta et al., 1992). The resistance of the phases to sulphate solutions depends on their degree of crystallization, pore structure and pore size distribution in their internal microstructure (Piasta et al., 1989, Sawicz et al., 1996). The most resistant phase among aluminate hydrates is $C_3A.CaCO_3.H_{12}$. This phase is formed from limestone powder in the whole bulk paste and it is stable and strength-bearing (Kuzel et al., 1991, Polmann, 1992). Also when compared with other mineral fillers, the beneficial effect of coarse limestone aggregate is due to tighter and stronger transition zone (between grain and bulk paste) resulting from lower degree of orientation of portlandite and ettringite crystals (Mehta et al., 1992) and their smaller size, dissolution of calcium carbonate and its reaction on aluminates to carboaluminates (Maso, 1980).The positive influence of limestone aggregate on concrete properties was confirmed by its fine performance(Uchikawa et al., 1996) and resistance under hard and complex condition of sustained load and simultaneous sulphate attack (Piasta, 1992, Sawicz et al., 1996).

EXPERIMENTAL

The OPC with 12.1% C_3A content was used to make: 1) paste with 20% limestone powder, quartz powder and without addition; 2) concretes (with 350 kg/m^3 of OPC) and with different addition of limestone powder for a part of aggregate and different w/c-ratios. After 28 days of curing the cement pastes were immersed into 5% (35.1 mM) Na_2SO_4 solution The pastes were used to explain changes in phase composition under sulphate attack with the help of XRD. They were tested after 28 days. The concretes were previously loaded under sustained compressive stress of different levels (σ/R_{28}). Then the loaded concretes were also immersed into 5% Na_2SO_4 solution for one year. Concrete performance and resistance to sulphate attack was tested with respect to the three factors of following values: amount of limestone powder L (%) = 0, 7, 14, 21, 28; w/c = 0.50, 0.55, 0.60, 0.65, 0.70; compressive stress level σ/R_{28} = 0.25, 0.35, 0.45, 0.55, 0.65. The results were calculated as a quadratic response-surface at one factor of constant value and presented by contours of the surface.

RESULTS

Phase composition

Plain OPC paste

As it is shown in the X-ray diagram (Fig.. 1a) at d=4.91Å calcium hydroxide (CH) is a predominant well crystallized phase of the plain cement paste at the age of 28 days. There can also be detected large amounts of well crystallized ettringite (E) and it is represented by the X-ray reflection centered at d=9.75Å. The X-ray reflection R_1 at d=9.20Å is probably a metastable and disordered solid solution that is a constituent of the extended solid series between monosulphate (Ms) and hemisulphate (Hs).A broad X-ray reflection centered at d=8.50Å is probably caused by the fact that monosulphate is not stable in the presence of atmospheric CO_2 and a metastable compound or solid solution containing OH^-, CO_3^{-2} and SO_4^{-2} ions may be formed.(Kuzel et al., 1991).

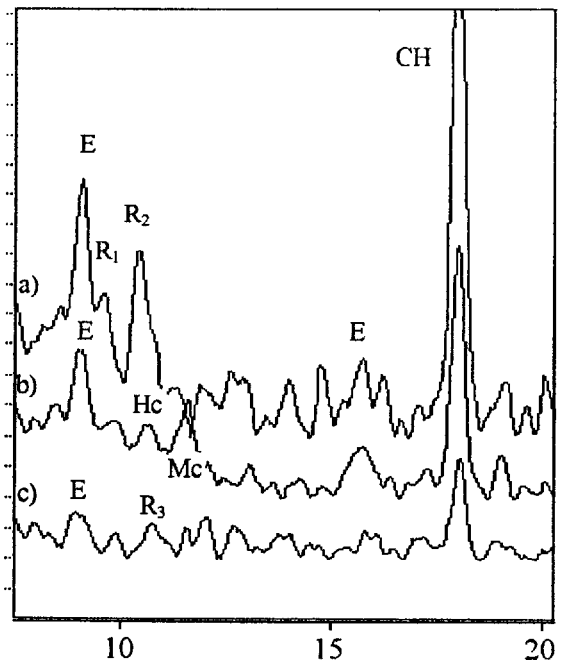

Figure 1 X-ray diffraction plots of pastes under standard condition after 28 days hydration

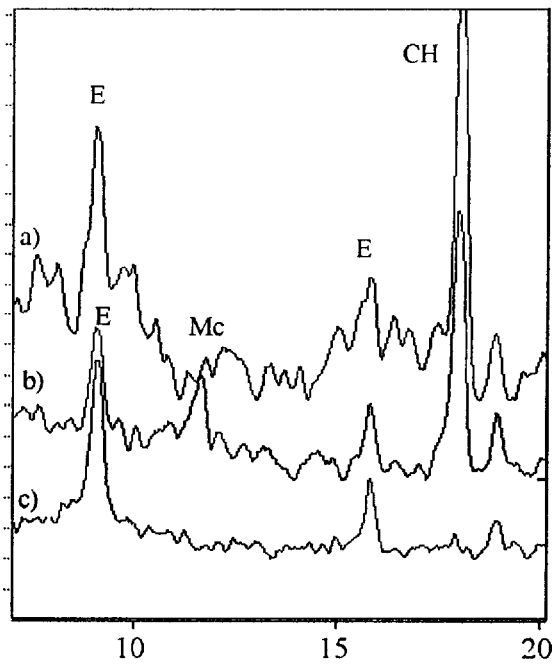

Figure 2 X-ray diffraction plots of pastes subjected to sulphate attack for 120 days.

a) without powder; b) with 20% limestone powder; c) with 20% quartz powder.

After 60 days of sulphate attack on plain paste, metastable phases R_1 and R_2, formed in time of curing under standard conditions, were transformed to hemisulphate (Hs) [d=8.70Å]. The amount of low-crystalline ettringite remained almost unchanged. After 120 days of the attack (Fig. 2a), the peak of the monosulphate (Ms) disappeared. The amount and degree of crystallization of ettringite increased in comparison with the paste after 60 days.

OPC paste with quartz powder

Well crystallized hydroxide phase and poor crystallized ettringite canbeseen in the cement paste with quartz powder at the age of 28 days (Fig. 1c). Some amount of monosulpate (Ms) and carboaluminate phases present were confirmed by the peaks at d=7.62Å and d=7.30Å. A broad reflection centered at d=8.20Å probably is a result of reflection interference (superposition) of peaks connected with hemicarbonate and poor ordered structure of solid solutions $C_3A.CaSO_4.H_{12} - C_3A.Ca(OH)_2.H_{12}$ and $C_3A.CaCO_3.H_{12} - C_3A.Ca(OH)_2.H_{12}$ (R_3).

An increase in crystallized ettringite and disappearance of solid solutions and carbonated phases resulted from the sulphate attack for 60 days. Their easy transformation in direction of secondary ettringite formation confirmed their low resistance to sulphate attack. All the metastable phases disappeared after 120 days in a Na_2SO_4 solution attack (Fig. 2c) and an increase in amount and crystallization degree of ettringite was observed. Thus, it was confirmed that the decrease in sulphate resistance of OPC paste was affected by the application of quartz powder.

OPC paste with limestone powder

Apart from calcium hydroxide (CH) and ettringite (E) the well crystallized monocarboaluminate (Mc) at d=7.60Å, small quantities of hemicarboaluminate (Hc) at d=8.20Å and trace of monosulphate (Ms) at d=8.92Å were found in the cement paste with limestone powder (Fig. 1b). After 60 and 120 (Fig. 2b) days of sulphate attack, the changes in phase composition of the paste with limestone powder are insignificant. Only small amounts of Hc and Ms, were slowly converted to ettringite (E). The monocarbonate phase stays at the same level as that formed in air conditions. Upto 120 days of sulphate attack, the monocarboaluminate phase (Mc) remained at the same level as that at the age of 28 days. The increase in amount of ettringite resulted from the chemical attack of SO_4^{-2} ions on the metastable solutions of monoaluminate phases. The quantitative and qualitative assessment of phase composition indicated much better durability of $C_3A.CaCO_3.H_{12}$ and in the same way it was confirmed that the paste with limestone addition is more stable and resistant to sulphate attack than the plain paste and the one with quartz powder.

Linear expansion of concretes

The investigation results of concrete swelling after one-year storage in 5% (35.1 mM) Na_2SO_4 solution are shown in the dependence on limestone powder amount L and w/c -ratio (Fig. 3). The influence of both independent variables on the expansion was significant even though the effect of any increase in the w/c-ratio, particularly in its interval from 0.60 to 0.70 , was much greater. The lowest expansion ($\varepsilon \cong 485 \cdot 10^{-6}$) of concrete was determined when the limestone addition was 14% and 21% and the minimum ($470 \cdot 10^{-6}$) of response-surface was calculated for the limestone addition of 16 percent.

Time-dependent deformations

The time-dependent free expansion and creep-related deformations results of concrete (w/c = 0.60) under the sustained compressive stress $\sigma = 0.45R_{28}$ indicated (Fig. 4) significant effects of limestone addition amount on the resistance to 5% Na_2SO_4 solution. The lowest magnitudes of deformations related to both simultaneous factors of sustained compression and sulphate attack were stated for concrete with 14% limestone addition. During the latest 3 months some decrease in creep-related deformations of all the concretes was noted. Normally no decrease in creep of concrete stored in water is observed. The lowering of all the creep curves confirmed an increasing effect of sulfate in time expansion. The free expansion of concrete with the 14% limestone addition was also the lowest in comparison with the others (Fig. 3). Thus, it was quantitatively assessed that the 14% amount of limestone powder addition affected the most stable performance of concrete under complex condition of sulphate attack.

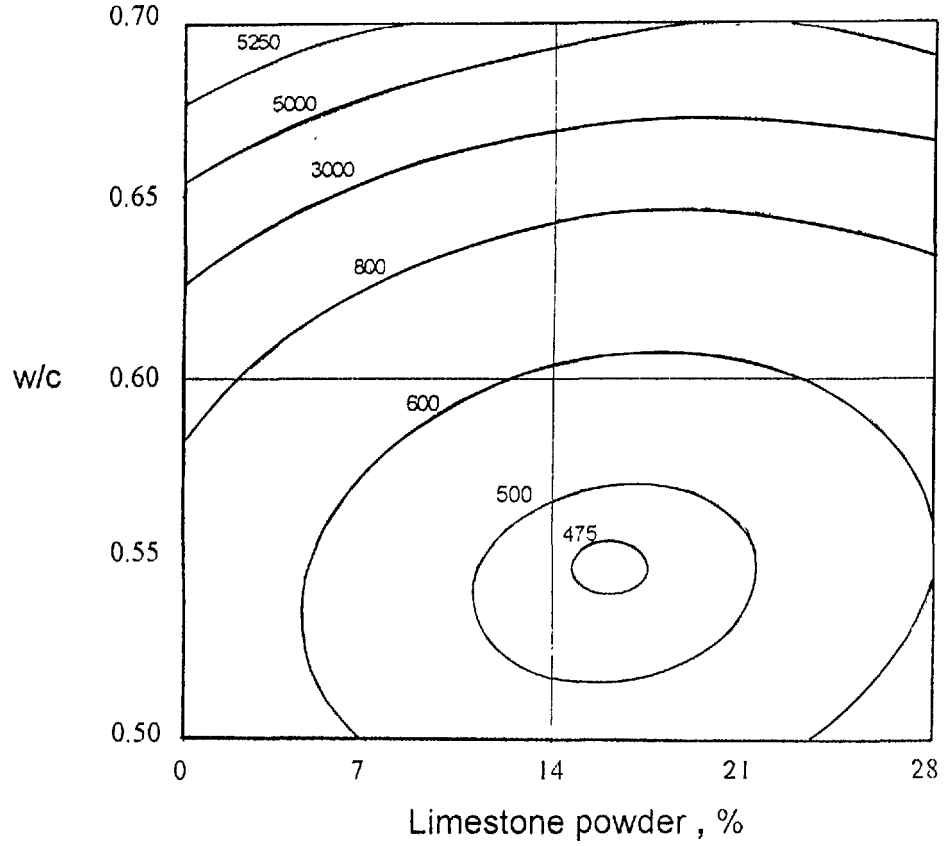

Figure 3 Expansion of concrete under 5% Na_2SO_4 attack as a function of w/c-ratio and limestone addition amount L.

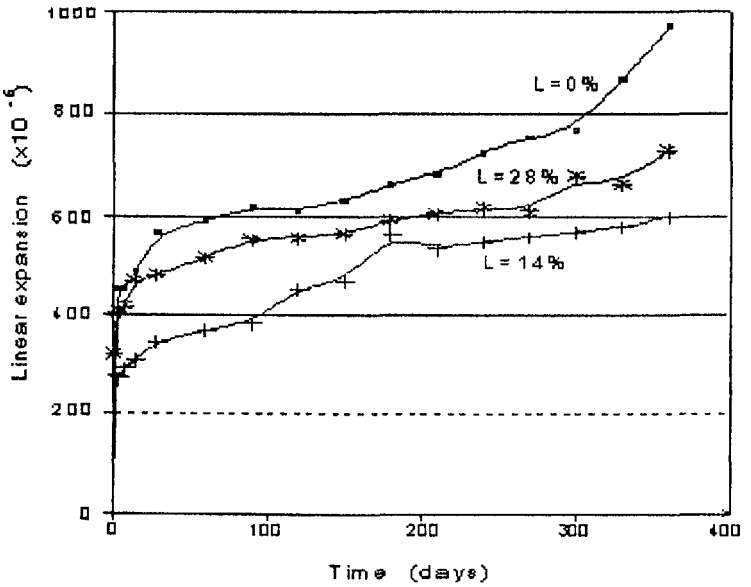

Figure 4 Effect of limestone addition amount L on time-dependent deformations of concrete under 5% Na_2SO_4 attack.

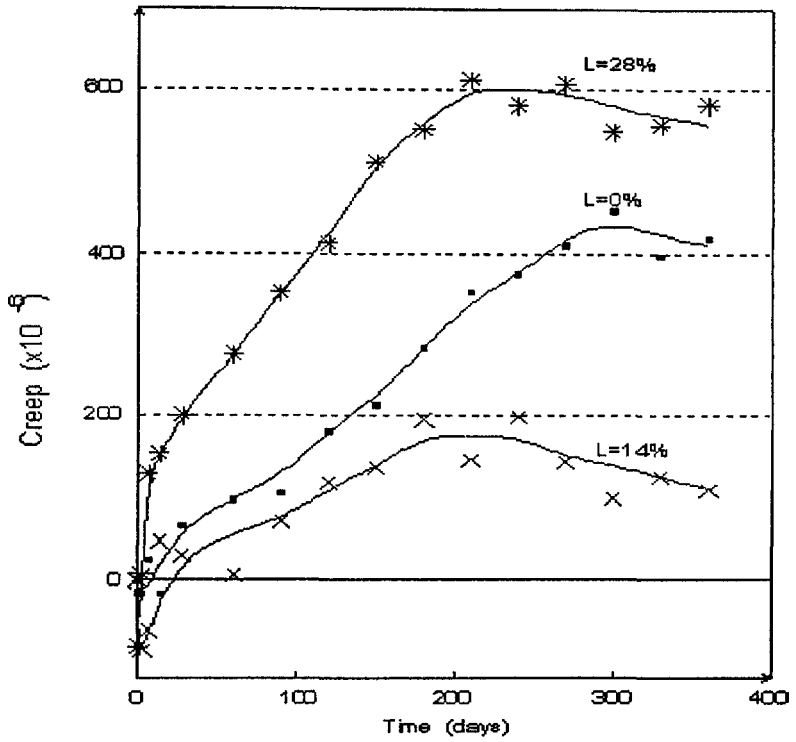

Figure 5 Effect of compressive stress level (σ/R_{28}) on the time-dependent deformation of concrete (w/c=0.60 ; L=14%).

Performance of concretes with limestone fillers was observed under combined condition of 5% Na_2SO_4 attack and simultaneous sustained compression of different levels. The creep- and sulphate attack-related deformations are shown for concrete with 14% limestone addition at the stress levels of 0.25, 0.45 and 0.65 in Fig. 5. The magnitude of deformation under the combined conditions was the highest at the stress level of 0.65 but it was the lowest at the level of 0.45 but not at the level of 0.25. Such a performance of concrete is not known under any conditions of moist air (RH = 100 per cent) or water. Also the decrease of deformation magnitudes found for the latest four months was directly connected with the sulphate swelling that is high in a later age contrary to creep.

Compressive strength of concretes

Compressive strength was determined for the concretes that had been previously loaded for one year under sustained compressive stress and immersed in 5% Na_2SO_4. The strength of the concretes is presented in the Figs 6a, 6b, 6c by the surface contours as values of strength function of w/c-ratio and σ/R_{28}-level for a constant amount L. The highest strength of concrete without addition (L=0%) was nearly 60 MPa (Fig. 6a) and it was found at w/c=0.56 and σ/R_{28}=0.35. Any higher w/c-ratio and σ/R_{28}-level decreased the strength of this concrete and caused even its failure at w/c≥0.65. When the amount of the addition was 14% (Fig. 6b) the strength properties of concrete under sulphate attack were much better and the highest strength (R ≅ 77MPa) was found at w/c=0.54 and σ/R_{28}=0.45, thus the optimum level of sustained stress was higher than that when L=0%. No failure of the concrete with 14% addition was noted at any w/c-ratio and σ/R_{28}-level. For the amount L=28% (Fig. 6c), the highest strength was only about 67 MPa but it was found at the higher level σ/R_{28}=0.55. In general, the lowest strength values were determined when the w/c-ratio was 0.70 and addition amount L was 0% or 28%.

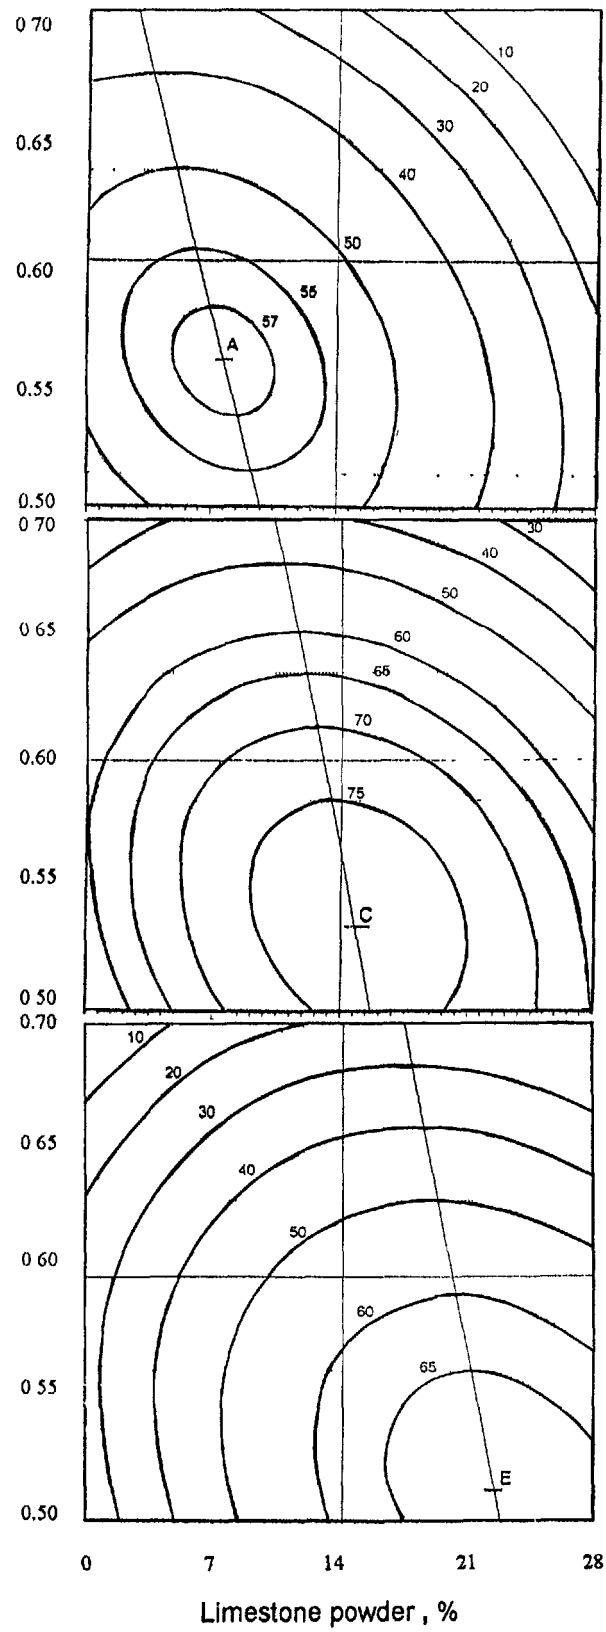

Figure 6 Effect of compressive stress level σ/R and w/c-ratio on compressive strength of concrete after one-year loading and immersion in 5% Na_2SO_4.
a) without limestone addition, b) with 14%, c) with 28%.

The highest values of compressive strength (Fig. 7) of concretes with all the amounts of lomestone powder stored under different complex conditions of one-year loading and sulphate attack are indicated by the points A, B, C, D and E. The points are related to the values of three independent factors L, σ/R and w/c.

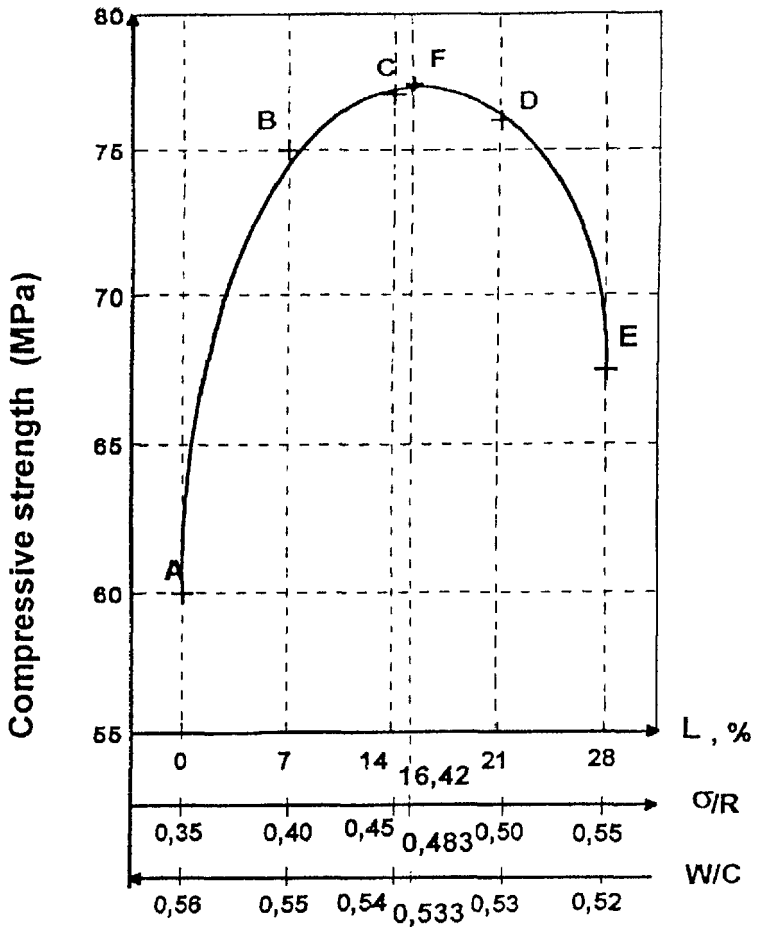

Figure 7 The maximum compressive stregth of concretes with different amounts of limestone addition L and optimum values of level σ/R and w/c-ration determined after one-year sustained loading and 5% Na_2SO_4 attack.

The maximum strength is equal to 78 MPa. It is indicated by point F for all the factors of their following optimum values L=16.4%, σ/R=0.48, w/c=0.53 that are pointed out on their axes. The intervals of the factors σ/R and w/c are indicated on the axes for the region of their optimum interaction (i.e. the best performance and the highest sulphate resistance) with the whole interval of limestone powder amount studied. It should be taken into consideration that higher stress level σ/R demands increase in the limestone powder amount in order to maintain the optimum strength of concrete. The optimum w/c-ratio was not the highest one among the investigated concretes.

CONCLUSIONS

1. The formation of ettringite under Na_2SO_4 attack is the main reason for any expansion, leading to the deterioration or failure of OPC composites.
2. Hydration of OPC with limestone powder addition results in formation of monocarboaluminate hydrate instead of monosulphoaluminate and aluminate hydrates. Ettringite remains unchanged. Formation of monocarboaluminates improves sulphate resistance and mechanical properties of hardened cement paste.
3. The influence of three independent factors (limestone powder amount, w/c-ratio, compressive stress level) on concrete performance and sulphate resistance is quantitatively assessed. The optimum values of the factors are following (as follows) L=16.4%; w/c=0.53; σ/R_{28}= 0.48.

SULPHATE RESISTANCE OF CEMENTS WITH MINERAL ADMIXTURES

Zbigniew GIERGICZNY, Institute of Mineral Building Materials, Opole, Poland

ABSTRACT The effect of aggressive sulphate containing environment on the compressive strength of cements with active mineral admixtures, such as low-calcium fly ashes, high calcium fly ashes, silica fume and ground, granulated blast furnace slag was studied. The corrosion resistance of standard mortars was evaluated basing on the compressive and flexural strength decrease within the 2 year observation period.

Key-words: characterization, fly ash, strength retrogression, sulphate resistance

INTRODUCTION

The mineral admixtures have been widely used in cement technology for many years. Their properties and dosage are the subject of standards in many countries; in some types of cements the blends of admixtures can be added [Peukert, Garbacik 1995]. These cements should ensure fairly good durability of concrete at later age. The mineral admixtures in cement cause the reduction of calcium hydroxide with the simultaneous C-S-H increase in hardened material. It is clearly visible particularly in the presence of silica fume [Giergiczny 1995]. The modification of phase composition is accompanied by the change of porosity. Owing to the modified pore structure the permeability of paste decreases and the strength of mortar increases. Only in the case of the low calcium fly ash the effects are observed at longer time of curing. In this work the strength of cements with mineral admixtures, stored in H_2SO_4 and $MgSO_4$ solutions is discussed. The tests were carried out within 2 years.

EXPERIMENTAL

Materials

Two portland cement clinkers of the following phase composition (in weight %) were used: clinker A: C_3S-49,5; C_2S-24,6; C_3A-8,8 and clinker B:C_3S-40,6; C_2S-30,1; C_3A-14,1 respectively. A low calcium fly ash from the black coal combustion, a high calcium fly ash from the brown coal combustion, silica fume and ground, granulated blast furnace slag were used as mineral admixtures. The chemical composition of admixtures is given in Table 1. The proportions between the particular components of cement blends are given in Table 2. The standard 40x40x160 mm mortar bars (cement/sand -1:3, water/cement - 0.5) were cured in water for 28 days and immersed in corrosive media. Some samples were stored in water for longer time as reference. The corrosive solutions were: sulphuric acid at SO_4^{2-} concentration 4800 mg/l and magnesium sulphate at Mg^{2+} concentration 3000 mg/l.

Strength tests of hardened mortars

The hardened mortars were subjected to the compressive strength tests after 90, 180, 360 and 720 days curing in corrosive media. The results are given in Table 3.

RESULTS AND DISCUSSION

The cements cured in the corrosive environment differ with the type and percentage of mineral admixtures. The corrosion resistance of cements was estimated basing on the compressive

strength decrease in relation to the values for reference samples within the 2 year observation period (see Table 3). The two different portland cement clinkers were used to produce cements with admixtures. The clinkers showed different C_3A contents: 8,8% for series of samples A and 14,1% for series of samples B respectively. The clinkers used were not sulphate resistant materials.

Table 1 Chemical composition of mineral additives.

Component	Percentage [wt.%] in admixtures			
	low calcium fly ash	high calcium fly ash	silica fume	granulated blast furnace slag
L.O.I.	2,9	1,9	2,1	0,1
SiO_2	52,2	44,8	90,4	39,8
Fe_2O_3	7,2	8,7	2,8	1,9
Al_2O_3	27,2	22,6	1,0	7,2
CaO	2,6	16,2	0,2	41,2
SO_3	1,6	2,1	---	---
MgO	1,6	1,9	---	7,0
Na_2O	0,3	0,1	0,6	---
K_2O	2,6	0,3	1,9	---
CaO_{free}	---	0,6	---	---

Table 2 Composition of cements.

Component	Percentage [wt.%] in particular cements							
	cement 1	cement 2	cement 3	cement 4	cement 5	cement 6	cement 7	cement 8
clinker	96	66	56	66	56	36	46	16
gypsum	4	4	4	4	4	4	4	4
low calcium FA	---	30	30	---	---	50	50	---
high calcium FA	---	---	---	30	30	---	---	---
silica fume	---	---	10	---	10	10	---	---
slag	---	---	---	---	---	---	---	80

One can notice that the progress of corrosion was more evident in the magnesium sulphate solution. The pastes from clinker B without admixtures totally collapsed between 6 and 12 months. The bars from clinker A showed only the surfacial fissures. The compressive strength after 2 years was relatively high - 37,6 MPa, though the 37% reduction as compared to the control samples stored in water was found (table 3). In the sulphuric acid environment the bars from cement B without mineral admixtures were totally destroyed between 12 and 24 months of curing. The bars from cement A showed a compressive strength 32,4% lower than the reference.

The mineral admixtures used in this work improved the resistance of cement mortar to the sulphate or magnesium sulphate aggressive environment. The silica fume was added together

with fly ash; the percentage of admixtures in cement was in the range from 30% to 80% (seeTable 2). One should underline that the same cements with admixtures attained higher strength at later age than the reference (see Table 3). The change of compressive strength in the corrosive media is discussed below.

Table 3 Compressive strength of mortars cured in aggresive solutions and in water.

Cured in	Sample No	Compressive strength in MPa at age							
		90 days		180 days		360 days		720 days

*- produced from clinker A, **- produced from clinker B

Sulphate resistance

The compressive strength decrease in the sulphuric acid environment is not too high, usually lower than 10% of reference value for cements containing 50% low calcium fly ash, stored 2 years in the corrosive solution. The highest strengths were observed for cement with 30% high

calcium fly ash and 10% silica fume (cement 5; Table 3). The beneficial effect of pozzolanic admixtures on the sulphate resistance results from the calcium hydroxide consumption in pozzolanic reaction and subsequently from the reduction of porosity due to the presence of calcium silicate hydrates and calcium aluminate hydrates, as well as from the delayed ettringite formation in the pores with no expansion. The calcium aluminate content decrease in cements with admixtures is also not without importance [Irassar, Batic 1989].

Magnesium sulphate resistance

This environment was more harmful for the mortars. The compressive strength decrease was in the range from 5% to almost 33% of reference value. Such a significant reduction took place after 1 year storage. The substantial strength lowering for cements with silica fume should be attributed to the decomposition of calcium silicate hydrates by magnesim sulphate [Kurdowski 1991]. The gypsum formed as a product in the reaction between magnesium sulphate and pozzolanic cement mortar is easily seen on the XRD pattern in Fig.1. $MgSO_4$ acts both as magnesium and sulphate corrosive medium.

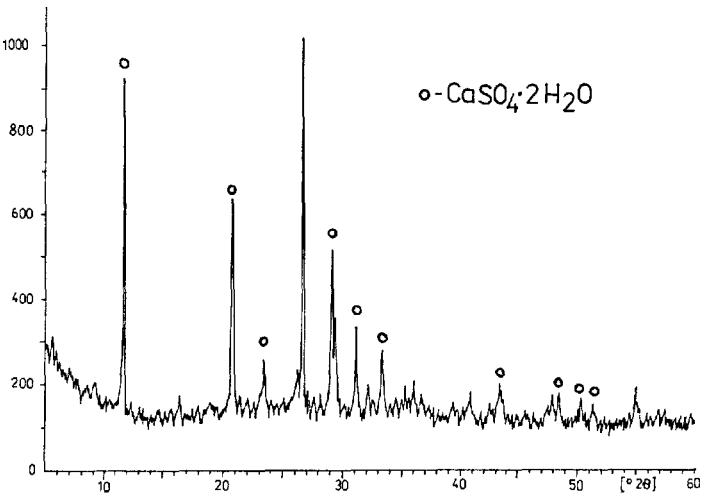

Figure 1 XRD pattern of "cement 6" mortar after 360 days in $MgSO_4$ solution.

CONCLUSIONS

1. Mineral admixtures improve the sulphate resistance of cements.
2. The samples stored in $MgSO_4$ solution show lower compressive strength than those cured in H_2SO_4.
3. The cements with mineral admixtures show higher compressive strength than reference samples without admixtures.

RESISTANCE OF FLY-ASH BLENDED CEMENT MORTARS TO SULPHATE ATTACK

Darko KRIŽAN, The IMS Institute, Belgrade, Yugoslavia
Branislav ŽIVANOVIĆ, Centre for Multidisciplinary Studies University of Belgrade, Yugoslavia

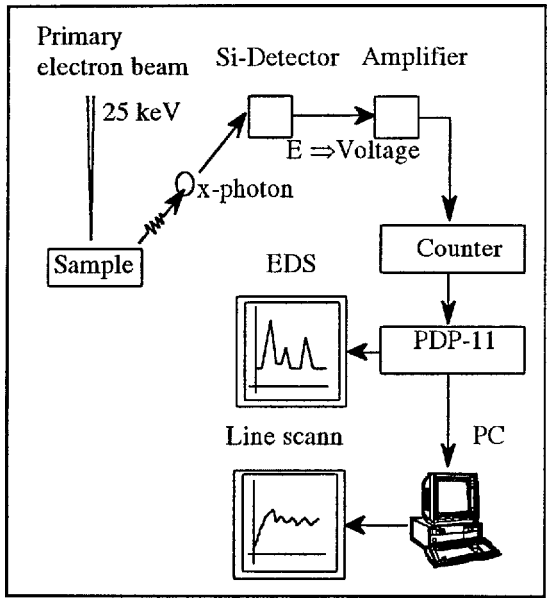
ABSTRACT This paper considers the influence of different aggressive environments (10% Na_2SO_4 and 10% $MgSO_4$ solutions) on ordinary Portland cements and blended cements. Ordinary Portland cement with middle content of $C_3A = 7.20\%$, and high content of $C_3A = 12.35\%$, are utilised. On the other side, blended cements of the above clinkers with 50 and 70% mechanical activated fly ash (specific surface $Sp \cong 700 m^2/kg$ and $1000 m^2/kg$), are prepared.
The measurements of flexural strengths were carried after 35, 49 and 77 days, and as a contribution of corrosion resistance we are followed the penetration of the aggressive ions using by energo-dispersive spectrometry (EDS).

Key-words: Fly-ash, Blended cement, Corrosion, Sulphate attack.

INTRODUCTION

In phenomenon of chemical corrosion of concrete the main part have a water, due to the fact that the solid and gas matters although aggressive, corrosion effect is present only if they are in water solution. Besides to content of C_3A in cement, resistance against water with sulphate ions, depends of cement content, W/C ratio and compact of hardened concrete. It is well-known that on the nature and rate of reaction, during sulphate attack, grate influence has cations, as the constituents of aggressive solutions. It was established, that all Portland cements are succumb to corrosion influence of $MgSO_4$, but in many cases, there is not an influence of sulphate ions, in reference to sulphoaluminate corrosion, that happened because of decomposition of binder caused by chemical effect of $MgSO_4$. This salt are react with hydrated silicates and formed $Mg(OH)_2$ and $CaSO_4$, but the free SiO_2 will precipitate. This kind of destruction's caused by chemical decomposition of cement constituents inside of dense hardened concrete and mortar are slow process if compared with pernicious influence of calcium sulphoaluminat hydrate ($C_6AS_3H_{32}$) or gypsum ($CaSO_4 \cdot 2H_2O$). As concentration Mg^{2+} ions in presence of SO_4^{2-} ions influence magnesium-gypsum or sulphoaluminate corrosion, in such a way concentration of SO_4^{2-} ions influence sulphoaluminate or only gypsum corrosion.
Reason for the work regarding with this problem, we are found, in long time ago established fact, that sulphate attack of concrete is one of the most dangerous corrosion, and also the running water in Yugoslavia are rich in aggressive sulphate ions. From the other side, amount of fly ash which are produced in combustion process of poor quality of coal with high amount of mineral admixtures is about cca 10 million tons per year.

EXPERIMENTAL



The programme for researching resistance of cement to the impact by sulphate attack envisaged characterisation of Portland cement clinker and fly ash. Corrosion resistant of homogeneous cements are obtained using by Steinegger-Koch method, as well energo-dispersive spectrometry (EDS).

Method for testing the influence of aggressive environments

Steinegger-Koch method for testing of cements in aggressive sulphate environments is used. According to this method, for resistance evaluation is made at the base of change on flexural strengths after 77 days (after 35, 49 and 77 days). This time is calculated from moment of the samples are prepared. As criteria for the resistance against sulphate attack on cement, coefficient Ks_{56} is used. This coefficient are obtained as rate of flexural strengths of samples

carried after 56 days in aggressive solutions, and same ages samples carried in the distilled water. The value of this coefficient above 0.7 gives a positive estimate of the constancy of cement in the given aggressive environment. Test samples, with the dimensions 1x1x6 cm, were made of a mixture of cement and quartz sand, in mass ratio 1:3 and with water/cement ratio 0.6. After preparing, the test samples were left to age for 24-40 hours in humid air, and then 21 days in distilled water. Flexural strength was tested. Other test pieces were left to age, in a certain number, in distilled water and in the specified solutions (10% $Na_2SO_4 \cdot 10H_2O$ and 10% $MgSO_4 \cdot 7H_2O$), until the end of periods 35, 49 and 77 days.

EDS method as qualitative estimate of corrosion resistance

Energo-disperzive spectrometry was obtained using by scanning electron microscopy, SEM PHILIPS 515 and EDS device EDAX 9900 (Fig. 1). The test samples were evaporate by Pt/Au alloy, thickness 0.1μm. Evaporated layer was made with aim to provide a conductivity of the sample, without disrupting the morphology of the sample. The analysis was made as line scan. That is 1024 dotted analysis, on the half length of cross section of the prism (5mm). In each point, simultaneously was made 10 analysis, and medium value present one dot on the graph. Examination was made with 25 keV primary electron beam. With the increase of the energy of primary electron beam, we are reduce the measure resolution, and whole measuring range is covered.

Figure 1 Schematic survey of EDS method

RESULTS AND DISCUSSION

The potential mineralogical analysis of clinkers for ordinary and blended cements is given in Table 1.

Table 1 Mineralogical composition of clinkers

Material	Clinker for cement OPC 1	Clinker for cement OPC 2
C_3S	72.27	58.76
C_2S	6.95	12.35
C_3A	7.20	12.77
C_4AF	9.31	8.92

Results exhibit that two used kind of clinkers are with differ on percentage content of C_3A: clinker for OPC-1 contains 7.20%, and for OPC-2 contains 12.77%.

Chemical analysis of fly ash, obtain by combustion of soft brown coal-lignite, shows a rather large percentage of CaO and sulphates (CaO = 22.65%, SO_3 = 4.82%).This high percentage indicate on presence of the mineral ingredients (kaolinite type clays and schistose parts), which are overlap inside of coal. Pozzolanic activity with lime, of mechanical activated fly ash (Table 2) are very high. This is an agree with the fact that the mechanical activation is increased, not only free by surface of materials but also by increased surface reactivity. Tested chemical content of fly ash is: SiO_2 = 37.05%, Al_2O_3 = 21.02%, Fe_2O_3 = 5.83, MgO = 1.52%, Na_2O = 0.24%, K_2O = 1.20%, CO_2 = 0.72%, lost of ignition = 4.48% and insoluble residue = 20.49%.

The main physic-mechanical properties of fly ash is shown in Table 2.

Table 2 Physic-mechanical properties of fly ash

Pozzolanic activity with lime, MPa after 7 days	Activated fly ash Sp≅700m^2/kg	Activated fly ash Sp≅1000m^2/kg
a) Flexural strength	5.3	5.3
b) Compressive strength	20.1	21.1
Specific surface Sp [m^2/kg]	676	1021

Well known fact, that with increase amount of C_3A the corrosion resistant of ordinary Portland cement (OPC) decrease against aggressive sulphate solutions. This is on the Fig. 2 - 5.

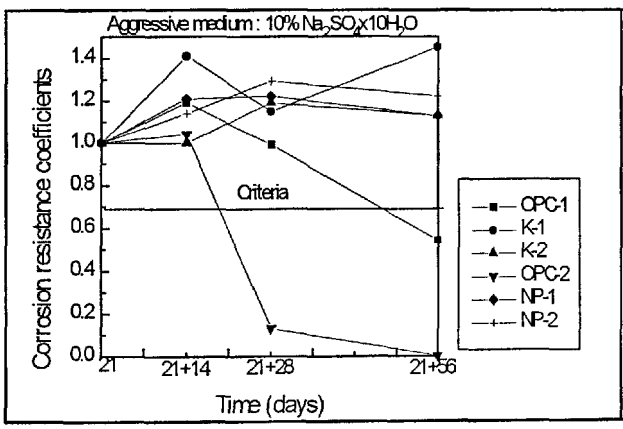


Figure 2 Corrosion resistance coefficients in 10% $Na_2SO_4 \cdot 10H_2O$ solution

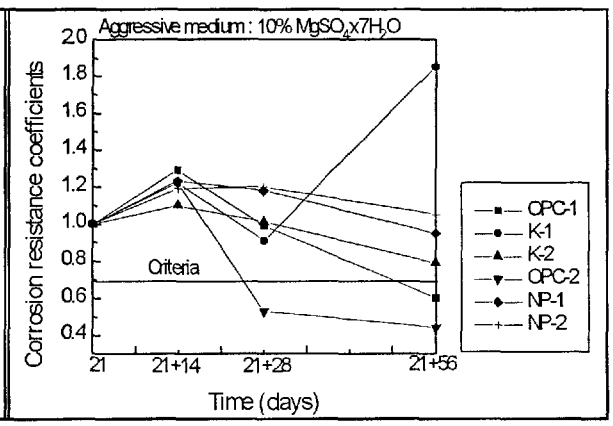

Figure 3 Corrosion resistance coefficients in 10% $MgSO_4 \cdot 7H_2O$ solution

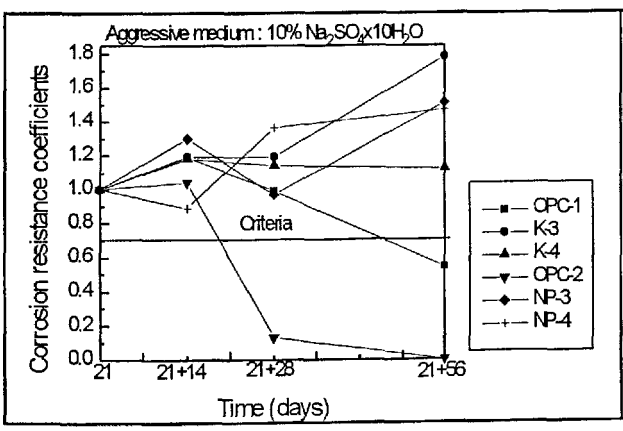

Figure 4 Corrosion resistance coefficients in 10% $Na_2SO_4 \cdot 10H_2O$ solution

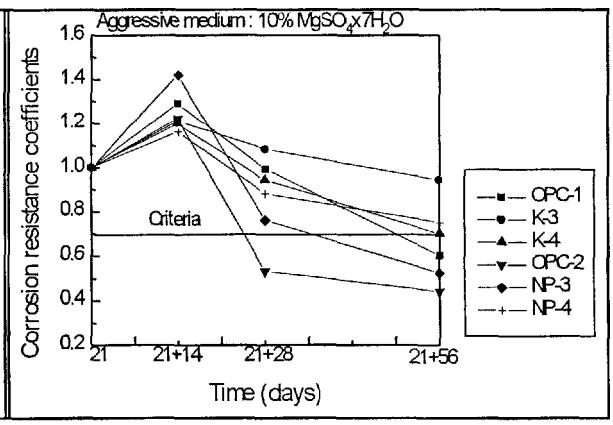

Figure 5 Corrosion resistance coefficients in 10% $MgSO_4 \cdot 7H_2O$ solution

Ordinary Portland cement (OPC-2, C_3A = 12.77%) became vulnerable after 56 days exposition in aggressive solution while samples after 77 days was completely destroyed. Ordinary Portland cement with decreased amount of this mineral (OPC-1, C_3A = 7.20%), also was a week, but this cement after 56 days was corrosion resistant. Explanation for this, we are found in fact that this cement has high amount of mineral C_3S, which increase high early strength and dense structure of microconcrete. Cements with lower content of C_3A, homogenised with 50% of fly ash (Sp≅ 700m^2/kg and

Sp ≅ 1000m^2/kg), K-1 and K-2 respectively, as cements with high amount of C_3A homogenised with same amount of fly ash, NP-1 and NP-2 respectively (Fig. 2 and 3), show a very good resistance to the aggressive sulphate ions as well as on the sulphates in presence of Mg^{2+} ions. Resistance coefficients for ordinary Portland cements and cements based on the same clinkers and 70% of fly ash are on , Fig. 4 and 5. K-3 and K-4 are the blended cements with lower content of C_3A, and NP-3, NP-4 are cements with higher content of C_3A. The better corrosion resistant of the blended cements is obvious.

From spectrogram (Fig. 6, OPC-1, sample of the ordinary Portland cement with lower content of C_3A after 56 carrying in to the 10% $Na_2SO_4 \cdot 10H_2O$), we can seen that the amount of Ca^{2+} ions from the plane of prism up to 2mm deep is decreased. That was result of the desolvation of $Ca(OH)_2$. The concentration of SO_4^{2-} ions are highest on the outside plane of prism and decreases into the bulk. Spectrogram of blended cement homogenised with same clinker and 50% of fly ash Sp ≅ 700m^2/kg (K-1), after 56 days caring in to the 10% $Na_2SO_4 \cdot 10H_2O$) is on Fig. 7. Solubility of main compounds decrease (relatively uniform amount of Ca^{2+} ions). But, concentration of sulphate ions are also low due to the fact that the prepared microconcrete with fly ash is very compact and penetration of aggressive ions into a bulk is minimised.

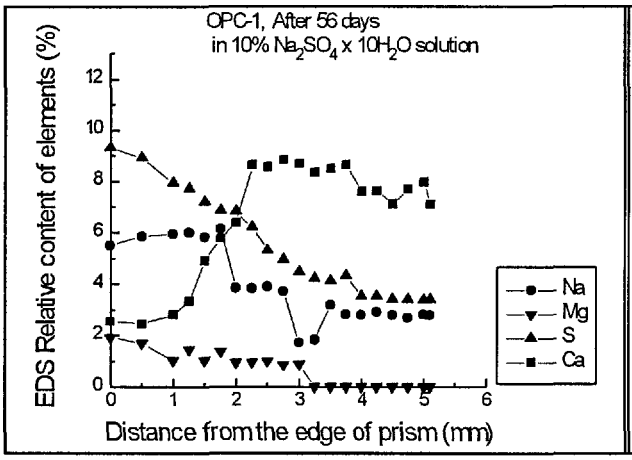

Figure 6 Spectrogram of sample OPC-1; Portland cement with middle content of C_3A

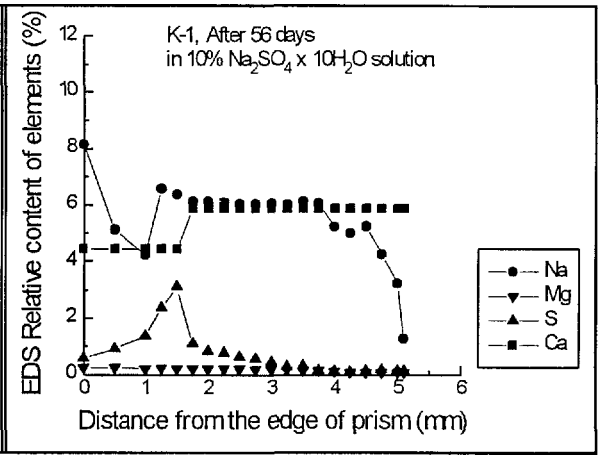

Figure 7 Spectrogram of sample K-1; Blended cement with middle content of C_3A and 50% of fly ash Sp ≅ 700m^2/kg

CONCLUSIONS

Corrosion resistance of cement against aggressive sulphate impact can be estimate only after researching on mortar or concrete in aggressive environments. The amount of aggressive ions in such case must be approximately equal to concentration of ions in real operating conditions. This kind of researching consider long-time tests, and cement estimating according to this methodology is without practical importance. According to this, quick method on small samples of microconcrete have a great significance.

With the sufficient amount of hydraulic admixture (good pozzolana activity) cement resistant against sulphate impact , no matter what amount of alumina in to the clinker or admixture, can be obtained.

DEFORMATION AND MICROCRACKING OF CONCRETE LOADED IN SULPHATE ENVIRONMENT

Dimitre NAZARSKY, University of Architecture. Civil Engineering & Geodesy, Sofia, Bulgaria

ABSTRACT It has been found that the process of microcracking (lower boundary R_t^o) of concrete test samples in water starts at a stress of 0.45 R_b while for samples in an aggressive environment this boundary is about 0.35 R_b. The upper boundary of microcracking (R_t^v) of concrete test samples decreases from 0.70 R_b to 0.55 R_b in 1% ammonium sulphate solution. Finally, conclusions are made about the impact of an aggressive sulphate solution on the deformations and the boundaries of microcracking of concrete.

Key-words: Sulphate, Ammonium, Attack, Deformation, Microcrack

INTRODUCTION

A large part of the concrete and reinforced concrete structures in the industry, agriculture, hydraulic and transportation construction operate in aggressive environments, being liquid, aerosol or gaseous.

The state of stress with a parallel action of aggressive environment has an effect on the change of vvstrength and deformability properties of the concrete in the time, the extent of this effect being dependent first of all on the type and the magnitude of the stresses (Nazarsky, 1979). The mechanism of the combined effect of stresses and aggressive environment is related to the structural changes and the microcracking in the concrete, the latter being regarded as one of the most important processes in the deformation of the concrete under external loading.

Berg (1961) has found that in case of exerted pressure on the concrete, processes like compaction, decompaction and structural degradation occur. With the increase of stresses above certain boundary microdegradations appear that turn into microcracks and macrodegradations in case of further increase of the load. During the process of deformation two parametric points that characterise the transition from the one to the other state can be fixed: boundary of beginning of microdegradations R_t^o and upper boundary of microcracking R_t^v.

Absorption-active environments have an essential effect on the solids deforming in a certain environment as well as on their structure in case of loading. In the reduction of the strength due to absorption and the relief of deformations (Rebinder effect) the main role is played by the smallest hidden microcracks that are formed at certain value of the stresses. The surface-active substances, and also the solutions of acids, alkali and salts quickly penetrate into the microcracks formed whereby prevent their full closure after eliminating the load.

METHOD OF APPROACH

The specific nature of the durability of the concrete and reinforced concrete structures operating in liquid aggressive environments assumes investigation of the effect of similar environments on the boundaries of microcracking of the concrete R_t^o and R_t^v.

The investigated concrete was based on sulphate-resistant cement, produced by the cement plant "Devnia" with water-to-cement ratio w = 0.45. The selected component ratio was cement:sand:gravel = 1 : 1.9 : 3.3.

The test samples were prisms measuring 10/10/40 cm which, after the stripping were put under water for up to 7 days and afterwards exposed to air at normal temperature and humidity. The

prism strength of the concrete samples determined at the age of 90 days in an aerial dry condition was 275.10^5 Pa.

1% solution of ammonium sulphate $(NH_4)SO_4$ with sulphate ions content (SO_4^{II}) 7273 mg/dm^3 and ammonium ions - 2727 mg/dm^3. Besides, water from the water supply network was also chosen as a liquid environment that has to simulate molecular absorption or absorption of a non-electrolyte. Samples that have stayed in open air with relative humidity φ = 60 - 65% have been used as check series.

For measuring the longitudinal deformations of the samples deformers of indicator type with accuracy of 0.001 mm and 200 mm base have been used, and for transversal deformations - with 50 mm base. The deformations (longitudinal and transversal) have been measured at the two opposite sides of each sample.

Before the short-term compression load the samples stayed in the aggressive environment of 1% solution of ammonium sulphate and in water respectively. It was found that in the first 4 days their saturation with the solution or the water is most intensive whereby for the solution the amount of the absorbed liquid was 2.76% by mass, and for the water - 2.41%. The moisture of the samples of the check series that have stayed in open air during the tests was 1.84%.

For expression of the relation "stress - deformation" (σ - ε) one-side relation is usually made between the stresses, invoked by the external loading and the longitudinal deformation (ε_l). With the concrete as an elastic-plastic material the module of the elasticity E and the factor of Poisson μ are constants only in case of comparatively low levels of the state of stress. With the stress increase over a certain level the experimental data do not correspond any more to the law of elastic change of the volume.

According to Berg (1961) the properties of the concrete are clearly manifested through the investigation of its volumetric deformations at different load rates: change of sample volume - $\Theta = \varepsilon_l + 2\varepsilon_t$ and the differential coefficient of the transversal deformation - $\Delta\nu = \Delta\varepsilon_t / \Delta\varepsilon_l$.

In the course of investigations the volumetric deformations of the samples being in contact with the aggressive solution and the water as well as those of the check samples in open air were calculated by the experimentally received values of the longitudinal and the transversal deformations.

During the test of the samples saturated within the liquid environments (1% solution of ammonium sulphate and water) the levels of the state of stress were defined as part of the actual values of their prism strength R'_b which is smaller compared to that of the check samples because of the reduction of the strength due to absorption.

RESULTS

The changes of the volume Θ and of the differential coefficients of the transversal deformation $\Delta\nu$ of the concrete samples in the various environments depending on the magnitude of the stresses (σ/R_b) are shown on Fig 1 and Fig 2 respectively.

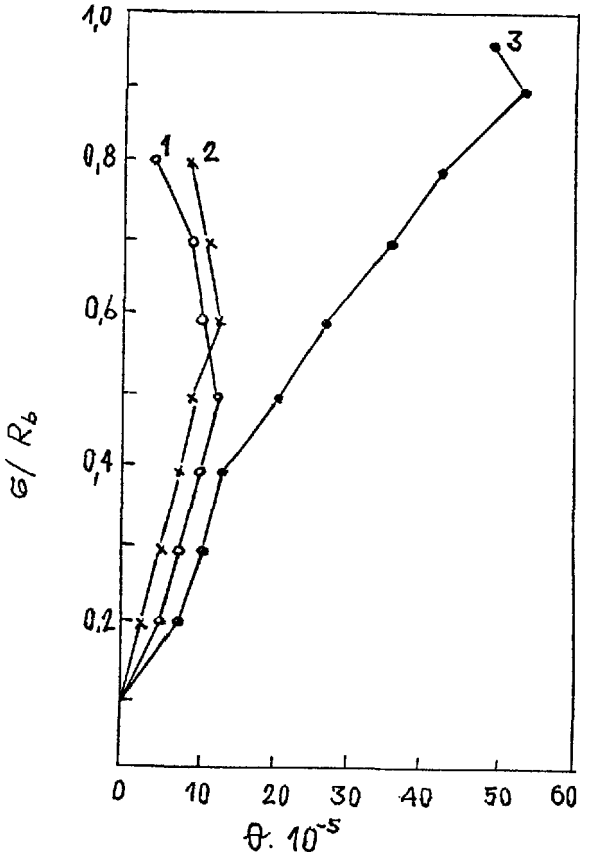

Figure 1 Volume Θ change depending on the magnitude of the pressure stresses
1 - in 1% solution of ammonium sulphate;
2 - in water; 3 - in open air

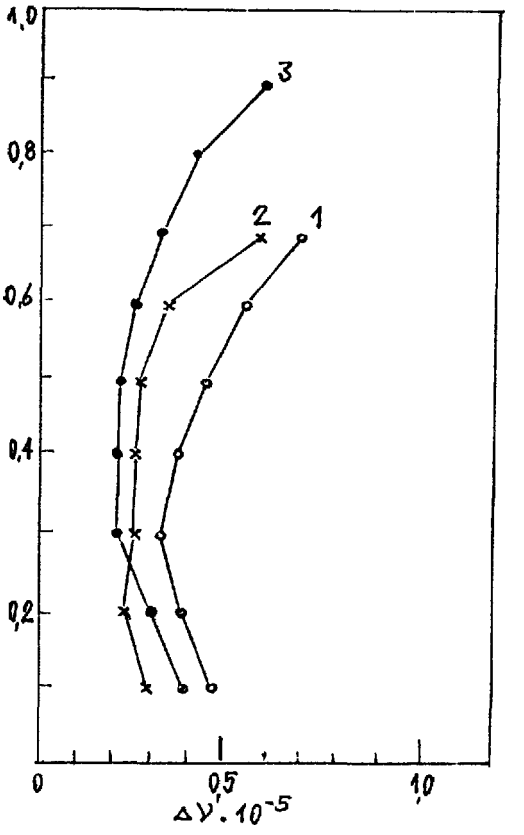

Figure 2 Change of differential coefficient of the transversal deformation Δν depending on the magnitude of the pressure stresses
1 - in 1% solution of ammonium sulphate;
2 - in water; 3 - in open air

The concrete deformations analysis under the combined action of compressed load and liquid aggressive environment shows the total longitudinal deformation of the check samples is considerably greater compared to the samples staying 4 days in 1% solution of ammonium sulphate and in water. The longitudinal deformations for loads closed to the degradation ones are around 120.10^{-5} for the samples exposed to air, and for the samples in the liquid environments the values do not differ essentially - they are around $55\text{-}60.10^{-5}$. The transversal deformations in contrast to the longitudinal ones are almost not influenced by the moist condition of the concrete and their values are within the range $51\text{-}56.10^{-5}$ but the nature of change of those deformations in the process of loading the concrete saturated in liquid environments is rather different. For stresses 0.45 - 0.5 R'_b the transversal deformations of the moist concrete significantly increase while for the check samples this process is observed for stresses above 0.7 R_b.

The reduction of the volume Θ (Fig 1) is most strongly manifested with the samples in open air (58.10^{-5}) and with the samples in aggressive environment it is in average 17.10^{-5}.

The changes in the differential coefficient values of the transversal deformations Δν (Fig 2) with the load increase show that the processes of structure decompaction of the concrete (R_t^o)

stayed in aggressive environment begin with stresses 0.3 - 0.4 R'_b , in water - with 0.40 - 0.45 R'_b , and for the check series in open air - with 0.5 = 0.55 R_b.

The action of the liquid aggressive environment reduces the magnitude of the upper boundary of the microcracks formation (R_t^v) at which the transition from decompaction to degradation of the structure occurs. For the check samples in open air R_t^v = 0.90 - 0.93 R_b , in aggressive environment R_t^v = 0.55 - 0.60 R'_b, and in water R_t^v = 0.65 - 0.70 R'_b.

CONCLUSIONS

1. There is a difference between dry and exposed to open air concrete, and such one immersed and saturated in liquid aggressive environment of 1% solution of ammonium sulphate which can be explained with the liquid filling the porous structure of the concrete takes part also in the deformation of the moist concrete. Under the compressed load impact a pressure of the liquid is created in the pores that obstructs the development of longitudinal deformations. Besides, this pressure causes an increase of the deformations in transverse direction of the acting pressure force whereby creating a possibility for increasing of the transversal deformation (ε_t). As a result the differential coefficient of the transverse deformation $\Delta\nu$ is greater for the concrete being in contact with the liquid aggressive environment.

2. The reasons for the influence of the liquid aggressive environments on the strength and deforming properties of the concrete under load are diverse and first of all related to the structural changes in the concrete. Corrosion-active environment is absorbed in the pores of the cement stone by the way of the surface diffusion through macro- and micro-capillaries. First of all the environment fills in the macro-capillaries without breaking the unity of the structure but relieves those points which are essential for the strength of the cement stone under the action of external load. Besides, the environment disrupts the unity of the concrete structure in the contact zone between the cement stone and the aggregates.

3. In the design of reinforced concrete structures operated in liquid aggressive environments it is necessary to take into account the reduced strength and the reduction of the values of the parametric points R_t^o and R_t^v of the concrete through introduction of a certain coefficient for work conditions by help of which the normative resistance of the concrete to be reduced.

The Microstructure of Concrete Subjected to High-Magnesium and High-Magnesium Sulfate Brine Attack

David Bonen
USG Corporation, Research Center
700 North Highway 45, Libertyville, IL 60048, USA

Abstract

A microstructural study of three suites of concrete subjected to the attack of brines is reported. The first suite was exposed to the action of simulated magnesium sulfate brine for three years. The second category represents in-situ field concrete nine years in service that was recovered from the Waste Isolation Pilot Plant (WIPP) located in a formation. The third one represents an overcored grout that was placed in a borehole over than 20 years ago.

The specimens of the first category were markedly corroded due to magnesium sulfate attack. Massive deposits of gypsum were formed on the surface and within the paste. The C-S-H of the paste was altered to M-S-H at a rate ranging from 0.009 to 0.02 mm/day. In contrast, there was no sign that the field concrete specimens from the WIPP were chemically corroded by brines. Aside from near-surface deterioration, the specimens analyzed have been found to be compatible with the halite host rock. Along the contact with the host rock abundance of halite was deposited within the concrete as layers and as discrete crystals. Other near-surface degradation is related to carbonation, mainly associated with fractured zones.

Of interest is the uncommon mineralogy that has been observed in the grout. The alteration and secondary products include brucite, M-S-H, magnesium chloride hydrate, halite, sylvite, and Friedel's salt. The intact portion of the grout is characterised by the occurrence of large phenograins displaying a mosaic texture and abundance of portlandite. The grout, however, displayed a lower rate of deterioration than that of the first suite. This is attributed to the absence of sulfate in the sodium and potassium-rich brine.

Keywords: Durability, magnesium sulfate, magnesium chloride, and sodium chloride attacks on concrete.

1. Introduction

One of the on-going research efforts to secure safe disposal of radioactive waste considers burial and a lasting isolation of the waste in geological evaporite strata. Because of the aggressive environment and functional lifetime, the common usage of concrete as a solidification/stabilization agent does not necessary apply, rather its role lies in sealing man-made penetrations, such as shafts and boreholes that provide access to the repository. Under these conditions, aside from being structurally sound, the concrete has to be chemically compatible with the surrounding, durable, and possesses low permeability.

For almost two decades the US Army Engineer Waterways Experiment Station in cooperation with Sandia National Laboratories (SNL) has developed cement-based grouts and concrete for the WIPP (Waste Isolation Pilot Plant) repository facility. The WIPP is a research and development facility of the Department of Energy (DOE) established for demonstrating the safe disposal of defense-related transuranic waste generated by various facilities. The WIPP repository facility is located in a thick sequence of bedded evaporite rocks about 660 m below the ground surface, near Carlsbad, New Mexico. The evaporite rock in the WIPP repository horizon is mainly composed of halite (NaCl) with minor amount of anhydrite ($CaSO_4$), magnesite ($MgCO_3$), polyhalite ($K_2Ca_2Mg(SO_4)_4{\cdot}2H_2O$), quartz, and clay. The concrete at the WIPP is required to withstand attacks derived from brines and be compatible with surrounding salt beds. These brines display a wide compositional range(1) and contain magnesium-bearing solutions that are regarded as detrimental to concrete. A simulated high magnesium-bearing brine designated as H-1RSCM has a composition of 54.95 gram/liter (g/l) of sodium, 16.82 g/l potassium, 42.29 g/l magnesium, 209.88 g/l chlorine, and 18.24 g/l of sulfate as SO_4^{2-} (2). For comparison, the corresponding composition of sea water is about 10.5, 0.38, 1.28, 19, and 2.56 g/l, respectively. The concentration factors of Na, K, Mg, Cl, and $SO_4$2- in H-1RSCM brine over sea water are, therefore, 5, 44, 33, 11, and 7, respectively. It is evident that H-1RSCM brine is not a simple derivative of evaporation of sea water, and indeed considerable variations in K/Mg ratio were noted in the

natural brines(1).

Previous studies on the performance of companion specimens were conducted by the US Army Corps of Engineers at the Waterways Experiment Station(3-6). This paper summarizes the microstructural work that was carried out at ACBM, Northwestern University under contract to Sandia National Laboratories with the objectives of establishing the mechanism of the attack, characterizing alteration processes, and determining rates of deterioration, if any.

2. Materials, Exposure Conditions, and Examination Technique

Specimens representing three categories were examined. The first category comprises two specimens of concrete core 10 cm in diameter that were immersed in H-1RSCM brine for 3 years(7). The second category includes a number of field concrete specimens that were recovered from the Small-Scale Seal Performance Tests (SSSPT) after 9 years in service. Among these specimens one with the enclosing salt host rock was also included, thus permitting an examination of the contact between the concrete and the host rock. The other specimens were sampled from a fractured concrete zone some distance away from an old crack plane. The third category comprises 25 cm overcored halite host rock with an internal 9.8 cm grout plug that was placed over 20 years ago in a borehole next to a potash mine near the top of the Salado formation.

Formulation of concrete for underground disposal of defense-generated radioactive waste for the WIPP has been carried out for a number of years by the US Army Corps of Engineers, Waterways Experiment Station. The rational for this formulation and concrete properties are given elsewhere (e.g.,8). This concrete is made of ASTM Type H oil-well cement with a composition similar to ASTM Type V sulfate-resistant cement, Class C fly ash, a number of admixtures, and at water-to-solids ratio of about 0.33. Among the admixtures are Chem Comp III (a mixture of portland cement and calcium sulfoaluminate), and Cal-Seal anhydrite plaster. The latter two ingredients were incorporated to lend expansivity to the mixtures thus providing a good contact between the concrete and the salt rock. For a similar reason, granular NaCl salt constituting about 35% of the mixing water by mass was also introduced to the solid ingredients. This measure was taken in order to saturate the mixing water with respect to sodium chloride, thus eliminating a potential dissolution of the salt bed during placing and securing a good contact between the concrete and the host rock.

Unfortunately, there is no available information on the composition of the grout placed in the borehole. However, based on the appearance of large phenograins (distinct grains embedded in a finer groundmass in the paste, see nomenclature in ref(9)), it appears that the grout was also made of Type H cement, but in contrast to the other specimens it did not contain fly ash particles.

Aside from the specimens of the first category that were immersed in H-1RSCM solution, all the other specimens were exposed to the natural environmental condition of the surrounding salt beds with the possibility of being subjected to the action of brines.

Examinations were carried out in Hitachi S-570 Scanning Electron Microscope equipped with both G.W. backscatter detector and Tracor Northern EDXA (energy-dispersive X-ray analysis) system. Supplementary XRD analyses were carried out in a Philips X-Ray machine. Much of the SEM examination was conducted in a backscatter electron mode, although fractured surfaces were also viewed in secondary electron mode. Specimens analyzed in a backscattered electron mode were prepared by impregnating sliced specimens with an epoxy mix, reslicing and polishing with successively finer grades of diamond grit. The flat surfaces so produced were sputter coated with a thin layer of gold. In general, examination in a backscatter electron mode is preferred as it provides representative, unbiased surfaces, and permits a detailed appreciation of the spatial relationships and juxtapositions of the viewed features.

3. Features of Magnesium Sulfate Attack

It is well recognized that magnesium sulfate attack on concrete is associated with a severe degradation and ultimately may bring about complete disintegration. To date, a large body of literature documented various aspects of the attack. Microstructural studies have shown that at high magnesium sulfate concentration the main features that characterized the attack are secondary mineralization of brucite ($Mg(OH)_2$) and gypsum along with decalcification of the C-S-H and formation of M-S-H (e.g., 10-14).

The detailed microstructure may vary due to compositional changes, effects of mineral admixture, duration of the attack, etc. A "classical" microstructure, however, involves the formation of a double surface layer composed

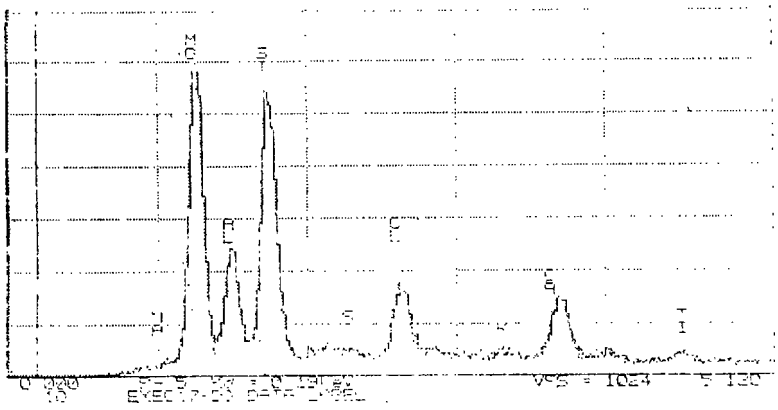

Figure 1(left): A backscatter electron image (BEI) micrograph of a number of gypsum layers (g) deposited in the paste at some 800 μm from the corroded surface. The low gray level of the previous C-S-H is due to strong decalcification and conversion to M-S-H. Ferrite is the only clinker phase that survived the attack.

2. Figure 2(right): X-ray pattern of the paste about 1 cm below the surface. The paste is mainly composed of M-S-H. The chlorine is either incorporated into the latter phase or chemisorbs on it.

of amorphous external brucite layer and an inner well-crystallized gypsum layer. Further inwards, the cement paste is intercepted by a few gypsum bands/layers that run parallel to the outer surface resembling Liesegang band formation involving rhythmic precipitation(10). This is accompanied by a distinct decalcification of the C-S-H from the intact core to the surface in which the Ca:Si of the former C-S-H continuously decreases as the surface is approached(11). The spatial distribution of this secondary mineralization is the result of the formation of two counter diffusion patterns in which hydroxide ions diffuse from the paste outward to produce insoluble brucite on the outer surface, and sulfate ions diffuse inward to form gypsum. The calcium needed for gypsum formation is first supplied by the decomposition of the CH ($Ca(OH)_2$), and subsequent to the consumption of local CH, additional Ca^{2+} is provided by the decalcification of the C-S-H.

It has been shown that the C-S-H is not readily transformed to M-S-H. First, the C-S-H undergoes a distinct decalcification and only at low Ca:Si this transformation takes place(15). Incorporation of aggregate and mineral admixture (e.g., silica fume and slag) modify to some extent the microstructure. Frequently, neither the outer surface double layer, nor the inner gypsum layers are continuous. Rather, gypsum forms discontinuous deposits, lines aggregate, fills voids, and the total amount of gypsum and brucite formed appears to be smaller(12,16). Gollop and Taylor(16) have suggested that the lower content of gypsum and brucite is due to the lower amount of portlandite formed in pozzolanic concrete. The latter microstructural changes appear to be related to a modification of the transport properties of the paste due to an increase of tortuosity and a refined pore microstructure. If so, it is expected that a decrease of the w:c would have similar effects. Nonetheless, it has been reported that the course of the attack is essentially the same even at a high mineral admixture dosage, and brucite, gypsum, decalcified C-S-H and M-S-H, all are formed(16).

4. Microstructure of SMC Stored in H-1RSCM Brine

Salado Mass Concrete (SMC) specimens were immersed in H-1RSCM solution for three years. The outer surfaces of the specimens are markedly corroded and extremely soft. The surface is characterized by a pitted corrosion in which loose-bonded quartz aggregates appear on the surface and are interbedded with well-crystallized, idiomorphic gypsum. Many quartz grains are barely cemented and a great part of their circumferences is exposed. Other phases viewed are small halite crystals and some amorphous materials. The depth of this highly corroded zone ranges from about 1 to 2 mm inward. XRD analyses yield similar results: the two main constituents are quartz and gypsum with minor amounts of halite. Other two unidentified phases appear as shoulders on the main peaks of gypsum and quartz at about d-spacing of 7.83 and 3.39Å, respectively.

It is worth mentioning that the pitted corrosion indicates disintegration and removal of materials. In agreement with a previous study(7), neither SEM nor XRD examinations recorded presence of brucite at the outer

corroded zone, nor at the subsurface. The absence of brucite might indicate that either brucite was not deposited, or it had been lost due to spalling or other reasons (handling and sample preparation). The latter interpretation cannot be overlooked. In fact, the exposed aggregate on the surface suggests that the outermost concrete surface, at least a few hundred microns thick was completely removed and lost because of expansion and spalling, thus destroying any evidences of brucite deposition.

Apart from the absence of the surface double layer, a characteristic microstructure of magnesium sulfate attack is viewed in Fig. 1. Several gypsum layers are deposited parallel to the outer surface and interbedded in highly decalcified C-S-H. The former C-S-H has lost its characteristic microstructure and possesses a typical low gray level (in a backscatter electron mode examination) due to the decalcification of the former C-S-H. Ferrite (C_4AF) is the only clinker phase that has survived the attack. Other typical features of sulfate attack are the formation of thick gypsum deposits around aggregate, within the paste, and in air voids. The depth of the interbedded gypsum layers extends some 800 μm from the present outer surface. Further inwards up to about 1 cm from the surface, the amount of gypsum precipitated decreases, and it appears as a partial lining of aggregates, in voids, and as disseminated grains all across the paste.

X-ray spot and area analyses (Fig. 2) show that the former C-S-H was converted to M-S-H. It may be argued that some of the chlorine is taken up to form Friedel's salt ($Ca_4Al_2Cl_2 \cdot 10H_2O$). However, as viewed in Fig. 2, a considerable amount of chlorine is either chemisorbed on the M-S-H or actually incorporated into its structure or is taken by other phases. In this respect, Burkes(7) reported the occurrence of magnesium chloride hydroxide hydrate ($Mg_2(OH)_3Cl \cdot 4H_20$) in the brine-affected zone of companion specimens. Wakeley et al.(3) also reported the formation of this phase at the interface of the halite host rock and a concrete plug. By contrast, Poole et al.(4) studied the effects of various brines on the paste composition. They noted that the affected pastes gained a small amount of magnesium, but no magnesium-bearing phase could be identified within the pastes.

X-ray spot analysis of a well-recognized feature is highly valuable as any change in the supposed chemical composition of the original feature may be directly related to alteration processes. This technique was employed in this study to identify the depth of alteration by spot-analyzing large phenograins. Several traverses normal to the outer surfaces have been made. In the first specimen, the diminishing effect of the aggressive solution is recognized at a depth of 1 cm below the corroded surface and it is manifested by the occurrence of partially reacted phenograins and limited amount of gypsum formation. Analyses at a greater disclose an unaltered paste with a common gray level, and a common Ca:Si of C-S-H. Area analysis conforms with the previous conclusion and the X-ray pattern fail to show high signals for sulfur and magnesium.

Examination of the second specimen yields similar results, but the paste is affected to a greater depth. Decalcification of the C-S-H and magnesium-bearing phases are identifiable as deep as 2 cm below the surface. At a depth of about 2.5 cm intact concrete is observed. The depth of alteration of the SMC varies, therefore, from about 1 to 2.2 cm. As the specimens were immersed for 3 years, the corresponding calculated linear rate of alteration ranges from 0.009 to 0.02 mm/day. This estimate conforms well with a previous one that is based on strength loss in which the rates of deterioration range from 0.015 to 0.03 mm/day(5). Despite the similar estimates, it is doubtful whether degradation advances inward linearly with respect to time.

Expansion and cracking are probably the main failure mechanisms associated with sulfate attack in which ettringite is formed. The above specimens, however, neither disclose ettringite formation nor any cracking pattern that can account for the measured strength loss(5). In fact, the total amount of gypsum precipitated is smaller than that of neat paste, probably due to the presence of pozzolans(16). It appears that degradation is not necessarily related to cracking associated with volume instability. Rather, as has been suggested(15), the decalcification of the C-S-H plays a major role in the degradation process. This is consistent with other studies pointing at this conclusion(17). SMC is made of cement with a composition similar to ASTM Type V sulfate-resistant cement and a high amount of Class C fly ash in part to grant a better resistance against $MgSO_4$ attack. These remedial measures may slow the attack but not prevent it. In the few studies documenting the degree of decalcification, it has been shown that mineral addition brings about extensive decalcification(11,12,16).

5. Microstructure of Field Concrete from the WIPP Site

Chloride attack on concrete has been extensively studied over the years, primarily because of its adverse effect on the depassivation and corrosion of reinforcing steel. However, there is little data relating to the effect of chloride on the paste performance.

The specimens of the second category exhibit a different microstructure. To the naked eye the contact between the halite host rock and the concrete is smooth and no specific spalling or physical deterioration is observed. Under SEM examination, however, some secondary mineralization did take place. Though the concrete was made with salt-saturated water, an abundance of NaCl crystals were deposited to a depth of 100-150 μm from the interface. A halite layer up to 50 μm thick was deposited in the interfacial transition zone along aggregates and across the paste. Figure 3 shows that the individual crystals are euhedral, and many of them have a distinct rhythmic zoning-a clear indication that they grew over time. Figure 4 exhibits X-ray maps for Cl (upper left), Na (upper right), Si (lower left) and the backscatter electron image of the analyzed area (lower right). The bar displayed at the top of the sodium map designates 60 μm. The image viewed extends from the salt host rock (white at the top) to about 350 μm below the interface. A distinct continuous layer of NaCl a few microns thick accompanies the interface at a depth of between 100 to 200 μm. This layer rims aggregate and runs across the paste. However, further away, except for the appearance of some sulfur-rich nodules, the X-ray maps fail to show any appreciable amount of secondary mineralization. A few disseminated signals for sodium and chlorine up to 300 μm from the surface correspond to relatively small halite grains within the paste. Similarly, a few signals of magnesium correspond to disseminated small dolomite particles and not to Mg-bearing alteration products.

In accord with the X-ray maps, the microscopical examination shows that apart from gypsum grains encountered within the paste there is no evidence for secondary mineralization either along aggregate boundaries or within the paste and cracks. The C-S-H has a typical gray level and Ca:Si. Large gypsum grains, some as large as 80 μm are embedded within the paste. Frequently, they lie along open cracks or are associated with open cracks. The crack widths range from 1 to 5 μm, but they are empty and clear from any deposits. The microstructure of the concrete 6 cm away from the interface is similar to that next to the interface. Apart from dispersed gypsum grains, no other mineralization is observed. Of interest is the occurrence of small gypsum that display sodium X-ray signals suggesting that such grains were precipitated from sodium-rich pore solutions. At this depth the concrete is cracked to about the same extent as described above.

That the gypsum grains are associated with cracks but none are deposited in cracks suggests that the cracking is post gypsum deposition, and cracks are more likely to propagate along gypsum boundaries rather than across the C-S-H. The origin of these gypsum grains is unclear. It might be related to an external sulfate ingress.

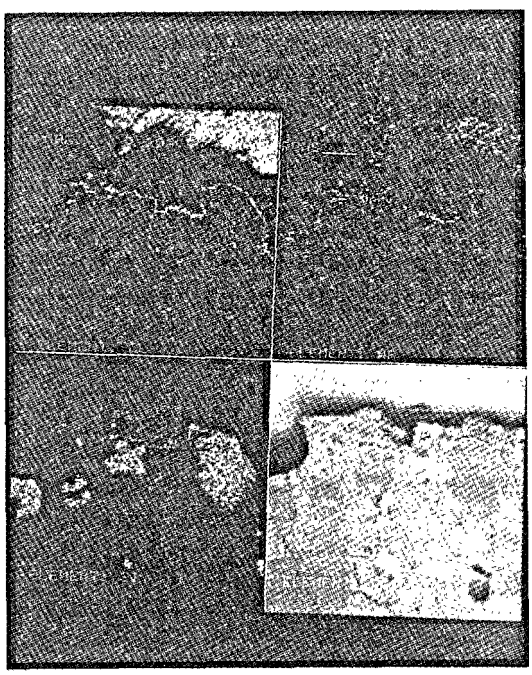

Figure 3(left): BEI micrograph of idiomorphic, cubic NaCl crystals deposited as a layer along aggregate (bottom) and within the paste (center). Note the distinct zoning of some of the NaCl crystals.

4. X-ray maps of Cl (upper right), Na (upper left), Si (lower left) and the BEI of the analyzed area that extends from the halite host rock at the top down to 350 μm below the interface. A distinct layer of NaCl a few microns thick was deposited along the aggregate as is delineated by the Si map and across the paste.

However, in view of the uniform distribution of gypsum irrespective to the distance from the host rock, and the absence of any other signs of brine ingress, it is more likely that the gypsum was deposited from the oversulfated pore solution of the original mixtures or, at least in part, the grains are residue of an incomplete reaction of the Cal-Seal anhydrite plaster.

Examination of a macro crack plane at the top shows abundance of surface deposition of NaCl embedded in corroded paste. Below the crack plane, the best part of the paste is carbonated to a depth of about 20-25 μm. Further inward, the paste retains a common microstructure and a common gray level. At the top, relatively wide open cracks run across aggregate and paste. Nonetheless, no secondary mineralization has been observed within the cracks. The same applies to the interior and except for the occurrence of large gypsum grains within the paste and voids, the paste had not experienced chemical alteration and deterioration. Similarly, there are no evidences that relate the cracking to chemical attack.

It appears that portland cement paste is chemically compatible with NaCl beds and the subsurface deposition of halite crystals observed has little effect. Lea(18) and recently Glasser(19) have made similar conclusions.

6. Microstructure of Grout Plug from the Borehole

Of much interest is the degree of alteration of the grout plug placed in an abundant borehole over 20 years ago. This grout has been clearly affected by brine and exhibits diversified mineralogy. Aside from the original main phases C-S-H and CH, it includes halite, sylvite (KCl), brucite, M-S-H, magnesium chloride hydroxide hydrate and/or magnesium chloride hydrate, and Friedel's salt. It is evident that the grout was influenced by Mg-bearing solution. The intimate association of halite and sylvite in the grout favours the suggestion that the aggressive solution derived from brine from a potash mine intersects the borehole.

Figure 5 exhibits the microstructure next to the contact with the halite host rock. At the interface brucite about 80 μm thick is formed and followed by numerous small halite and sylvite crystals in which the former is the preponderant phase. The brucite is distinguishable by a low gray level and its amorphic appearance. EDX analysis shows that it contains very little calcium and chlorine. Further inward, the C-S-H is converted to M-S-H that is associated with abundant salt crystals. However, the brucite layer is not continuous and in other areas M-S-H appears immediately at the interface. As previously noted, the M-S-H contains substantial amounts of chorine and calcium.

Two other magnesium-chloride-bearing phases are observed. Figure 6 presents a rare occurrence of a bundle of needle-like crystals with X-ray signals that correspond to $MgCl_2$ or $MgCl_2 \cdot nH_2O$. Of a greater importance is the occurrence of another amorphic, low-gray level phase that is associated with M-S-H. An interpretation of spot analyses as well as the low gray level suggests that this phase corresponds to magnesium chloride hydroxide or magnesium chloride hydroxide hydrate with Mg:Cl of 2:1 or 3:1.

Salt crystals appear in all the fields examined though their content is highly variable. Usually, halite is the predominant phase, followed in a decreasing order by sylvite, CH, and Friedel's salt. Sylvite is almost always associated with halite. They are idiomorphic and range in size from sub-micron to about 10 μm. Sylvite is distinguishable from halite by its somewhat higher gray level.

The depth of conversion of C-S-H to M-S-H in not uniform and extends up to about 1.8 mm from the interface. Further away, the unreacted paste has a mosaic texture in which large phenograins are accompanied with a notable amount of CH grains having amoebic appearance. Most of the phenograins are completely hydrated, but a few retain a sizable unhydrated C_3S core. Additional uncommon feature is the appearance of clusters of CH composed of large idiomorphic to sub-idiomorphic grains up to 50 μm across. The outlines of these CH grains display no corrosion despite that the grains are located in the altered paste zone.

As the halide crystals appear all across the grout to its interior, if the sodium and potassium originated from brine, the whole cross-sectional area of the plug was affected by external solutions. However, if the depth of alteration of the C-S-H is considered, the influence of the brine is markedly smaller. Nonetheless, despite the magnesium attack, the high amount of CH recorded indicates that the grout has retained its high alkalinity-the single most important factor for the chemical stability of the C-S-H.

The rate of alteration of the grout is not readily predictable as neither the actual exposure time to the action of the brine is known, nor the brine flux and composition. Provided the grout was exposed for a several years to brine, it displays a lower rate of deterioration than do the specimens immersed in H-1RSCM solution. One

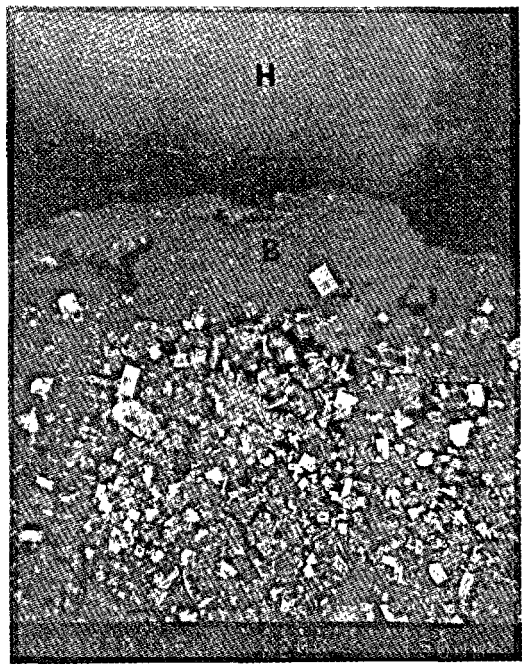

Figure 5(left): BEI micrograph showing the contact of the grout with the halite host rock (H). At the contact brucite (b) about 80 μm thick was formed. Further inwards the C-S-H was converted to M-S-H. Numerous small crystals (white)of halite and sylvite are embedded in the paste.

Figure 6(right): BEI micrograph of needle-like crystals with a composition of $MgCl_2$ or $MgCl_2 \cdot nH_2O$.

conspicuous feature is the absence of gypsum in the alteration products of the grout. This suggests that the sulfate content of the brine was low enough to permit any meaningful precipitation of gypsum. Thus, the grout was mainly exposed to the action of $MgCl_2$ rather than $MgSO_2$ solutions. In fact, it was long ago recognized that $MgCl_2$ corrosion is less destructive than $MgSO_4$ one(20). Lea(18) noted that solutions of 2% $MgCl_2$ and upwards gradually degrade the strength and concentrated solutions, e.g. 3M destroy portland cement concrete.

Unlike magnesium sulfate attack in which degradation is due to the combined action of magnesium and sulfate, in $MgCl_2$ attack the corrosion is because of a base exchange reaction in which:

$$MgCl_2 + Ca(OH)_2 \rightleftharpoons Mg(OH)_2\downarrow + CaCl_{2\,(sol)} \qquad (1)$$

Brucite is practically insoluble and deposits on the surface, whereas $CaCl_2$ is readily soluble and either leaches out or forms other compounds such as Friedel's salt:

$$C_3A + CaCl_2 + 10H_2O \rightarrow C_4A \cdot Cl_2 \cdot 10H_2O \qquad (2)$$

Biczok(20) attributed the higher resistance of portland cement to $MgCl_2$ attack to the formation of impermeable surface layer of brucite that suppresses the rate of ingress and subsequent degradation. However, since the brucite layer in the grout is not continuous it is doubted whether this explanation fully applies. Alternatively, the occurrence of M-S-H and magnesium chloride hydroxide hydrate may offer another explanation. Accordingly, the high concentration of Cl gives rise to:

$$Mg(OH)_2 + Cl^- \rightarrow Mg(OH)Cl + (OH)^- \quad \text{or} \quad 2Mg(OH)_2 + Cl^- \rightarrow Mg_2(OH)_3Cl + (OH)^- \qquad (3)$$

Suppose that the Ca:Si of C-S-H is 1.5, and the Mg:Si of M-S-H is close to 1(15), then a reaction that accounts for the formation of M-S-H and $Ca(OH)_2$ can schematically be described as:

$$C\text{-}S\text{-}H + MgCl_2 + (OH)^- \rightarrow M\text{-}S\text{-}H + CaCl_{2\,(sol)} + 0.5Ca(OH)_2\downarrow \qquad (4)$$

It should be mentioned, however, that an attempt to draw a stoichiometric reaction for eq. 4 is not readily attainable as the Ca:Si of C-S-H is usually greater than 1.5(21) and the M-S-H contains calcium. Nevertheless, eqs. 1-4 provide an explanation for the occurrence of the phases observed, and especially to the appearance of clusters of large CH grains in the altered C-S-H zone just 250 μm away from the surface.

7. Concluding Remarks

Analysis of the data shows that the Salado Mass Concrete is chemically compatible with evaporite beds. The halite rock or any other sodium chloride solutions originated from it exerted minor deleterious effects. This implies that sealing-off man made penetrations into evaporite rock with concrete is a viable solution. However,

satisfactory service life of the concrete is considerably shortened in the presence of $MgSO_4$ brine. Remedial actions in the forms of ASTM Type V sulfate resistance portland cement and addition of pozzolans do not prevent the attack. In the present study continuous exposure to the latter solution resulted in an alteration rate of 0.009 to 0.02 mm/year. Exposure to $MgCl_2$ solutions has been proven to be less detrimental.

EFFECT OF AMMONIUM-SULPHATE CORROSION ON THE STRENGTH OF CONCRETE

Saša R. MILETIĆ and Marina R. ILIĆ
IMS Institute, Bul. vojv. Mišića 43, Belgrade
Yugoslavia

ABSTRACT This paper considers the sulphate corrosion of Portland cement with content of C_3A from 5.45% to 11.84% and the same Portland cement with 30% of fly ash. The test samples were prepared and then exposed to the influence of aggressive environment (solutions with SO_4^{2-} ions as well as NH_4^+ ions). The measurements of flexural strengths were carried out after 1, 2, 4 and 6 months. The results were analyzed and a correlation among the resistance factor was suggested.

Key-words: composition, corrosion, durability, fly ash, sulphate resistance

INTRODUCTION

Corrosion of concrete, as well as the related protection and ensuring of concrete structures against aggressive impacts by chemical agents, regardless whether this concerns liquid, gas or even solid phase under certain conditions, represents a complex problem of utmost importance for the economy in general, and especially for building construction and the construction industry.

This paper shows the influence by the composition of Portland cement clinker, that is, of Portland cement, on the resistance of cement stone to the impact by the aggressive environment. Solutions of sodium and ammonium sulphates with various concentrations were selected as the representatives of the aggressive environment, bearing in mind that in nature these ions are most frequently encountered in underground waters which come into contact with concrete.

The results show that there is a considerable influence by certain components of the mineral composition of Portland cement clinker, that is, of Portland cement, on the resistance to the impact by the aggressive sulphate and ammonium ions. This results in the need that in the course of designing concrete which will be exposed to the impact by aggressive ions, special attention be paid to the selection of cement according to Biczok (1972), Mehta (1983) and Mitrović, Dučić (1985).

Most of the exploited natural aggressive waters with which concrete comes into contact are sulphate waters, and thus the concept of chemical corrosion of concrete most often regards sulphate corrosion. This is certainly the reason why the problem of sulphate corrosion is dealt with by a large number of researchers from all over the world according to Moskvin et al (1980), Regourd (1980) and Taylor (1973).

Chemical corrosion of concrete is the consequence of reactions between the constituents of cement stone, i.e. calcium silicates, calcium aluminates and above all calcium hydroxide, as well as other constituents, with certain substances from water, solutions of soil, gases, vapours, etc. The most important aggressive agents are: SO_4^{2-}, Mg^{2+}, NH_4^+, Cl^-, H^-, HCO_3^-.

When we speak about sulphate corrosion, we primarily think of the impact by sulphate ions on cement stone. The sulphate ion is the cause of one of the most dangerous corrosions - the corrosion of expansion and swelling - because it causes the occurrence of expansive compounds, first of all ettringite- $C_3A{\cdot}3CaSO_4{\cdot}32H_2O$, in the shape of prismatic crystals.

For the process of concrete corrosion under the impact of sulphates, it is essential which cation is linked with the sulphate ion. Namely, cations linked with sulphate ions can be divided into three characteristic groups. The first group includes alkali metals Na^+ and K^+, which give extremely soluble hydroxides, while the second group comprises metals such as Mg^{2+} and Fe^{2+}, which give poorly soluble hydroxides, and the third group consists of cations such as NH_4^+ and H^+, which give volatile or neutral hydroxide. The third group of sulphates, that is $(NH_4)_2SO_4$ and H_2SO_4, covers the most aggressive compounds. In case of impact by these compounds on concrete, neither balancing nor creation of protective gel takes place. The destruction of concrete, in this case, occurs not only due to expansion, but also because of intensive dissolution of cement stone.

Bearing in mind all the above-mentioned, the basic idea and motivation for the work on this paper is to widen the knowledge about the overall effect of corrosion processes in microconcrete, and it is thus the continuation of several-year research in this field of Miletić, Ilić (1995) and (1996).

EXPERIMENTAL

The programme for researching resistance of cement to the impact by sulphate corrosion envisaged characterization of Portland cement and Portland cement with the addition of 30% of fly ash manufactured in Serbia:
- Portland cement (C11) and Portland cement with the addition of 30% of fly ash (C15)
- Portland cement (C21) and Portland cement with the addition of 30% of fly ash (C24)
- Portland cement (C31) and Portland cement with the addition of 30% of fly ash (C32)

Complete testings of the chemical composition of all materials were carried out, same as the testings of mechanical properties of cements, and the potential mineralogical analysis of clinker and Portland cement was given. In the second part, the testings of the influence by the selected aggressive solutions on cement products were carried out. On the basis of results of the implemented testings, the first estimate was given for the resistance of cements to sulphate corrosion, as well as their classification in this sense according to Ranogajec et al (1996) and Miletić et al (1996).

Description of aggressive environments

The solutions of sodium sulphate and ammonium sulphate were used as the aggressive environments, to which cement was exposed. Concentrations of sulphate solutions used are presented in **Table 1**:

Table 1 Concentrations of sulphate solutions

SO_4^{2-}, mg/l	Na_2SO_4,%	$(NH_4)_2SO_4$,%	NH_4^+,mg/l	Solution
1000	0.1478	-	-	I
2000	0.2956	-	-	II
1000	-	0.1375	320	III

The temperature of sulphate solutions was maintained at 20±1°C. In the course of the testings, the solutions were not changed. The concentration of the solution was kept constant. The solutions were renewed every 30 days.

Methods for testing the influence of aggressive environments

V.V. Kind's method, which is standardized (GOST 4798), was selected as the basic procedure in studying the influence of aggressive environment, that is, determining corrosion resistance of cements. The essence of the procedure in V.V. Kind's method is that it uses cement mortar prisms, with the dimensions 1x1x3 cm, prepared in a special way and then submerged parallelly into the solution whose influence is tested and into potable water. The ratio between values of flexural strengths of prisms in the aggressive solution and in potable water, gives the numerical value of resistance coefficients, which is used as the characteristic of corrosion resistance of cement to aggressive impacts. The value of the coefficient of corrosion resistance above 0.8 gives a positive estimate of the durability of cement in the given aggressive environment.

The adopted method for testing the resistance of cements to the impact by sulphates, according to previous researches, proved to be suitable especially when testing composite cements.

Test samples, with the dimensions 1x1x3 cm, were made of a mixture of cement and quartz sand with particle-size distribution of 0.4-0.5 mm, in mass ratio 1:3.5 and with water-cement ratio 0.4. After casting, the test samples were left to age for 24 hours in humid air, and then 14 days in potable water. Flexural strength was tested. Other test pieces were left to age, in a certain number, in potable water and in the specified solutions, until the end of periods of 1, 2, 4 and 6 months (without counting the above-mentioned 15 days).

Other testing methods used in this work

1. Determining the strength (EN 196-1)
2. Chemical analysis (EN 196-2)
3. Calculating the potential mineralogical analysis (ASTM C 150)

RESULTS AND DISCUSSION

The selected aggressive environments represent very strong aggressiveness which is most often present in underground waters in the territory of the Republic of Serbia (**Table 1**).

The potential mineralogical analysis, for all clinkers and Portland cements is given in **Table 2**. It can be seen that the cement used differ in C_3A content - C11 contains 11.84% of C_3A, C21 contains 9.74%, and C31 contains 5.45% of C_3A, which has its impact on sulphate resistance. The ordinary Portland cement is not resistant to the influence by sulphates because it has a considerable content of tricalciumaluminate - C_3A, whose hydrates react with sulphate ions, forming expansive compounds. Portland cement with increased resistance to sulphates must have a low content of C_3A.

Table 2 Mineralogical composition

Material	Clinker			Portland cement		
	K1	K2	K3	C11	C21	C31

Table 3 presents the chemical composition of fly ash. Fly ash, by its chemical composition, shows traditional ash of lignite, which makes it relatively unsuitable for use in concrete (low content of the sum of oxides SiO_2, Al_2O_3 and Fe_2O_3, but the content of CaO is also low).

The chemical composition of cements is presented in **Table 4**. As regards the chemical composition, all the cements satisfy the conditions for quality of the Yugoslav standard JUS B.C1.011. The characteristic feature is an increased content of insoluble residue in cements with the addition of fly ash.

Table 5 Mechanical characteristics of Portland cement and Portland cement with the addition of 30% of fly ash

Cement	Flexural strengths, MPa				Compressive strengths, MPa			
	1day	3days	7days	28days	1day	3days	7days	28days
C11	5.1	6.6	7.8	8.7	20.6	36.5	43.1	55.5
C15	4.9	6.3	7.4	7.5	14.9	30.8	39.8	51.2
C21	3.2	5.7	7.2	8.0	11.8	24.3	33.0	42.6
C24	2.9	5.2	6.5	8.9	10.9	23.1	34.8	50.3
C31	2.8	5.0	6.2	8.3	11.1	22.6	33.9	50.8
C32	2.0	4.6	6.7	7.8	7.2	21.0	34.0	48.7

Table 5 gives values for flexural and compressive strengths of cements after 1, 3, 7 and 28 days. The addition of fly ash generally contributes to the increase in strengths, especially in the later phases of curing (above 28 days), which is its most important contribution. This can best be seen in cement C24.

In this way, complete characterization was implemented regarding all the cements used in this work. The results of testings of the impacts by aggressive solutions, that is, the resistance to sulphate corrosion of cements, carried out in line with V.V. Kind's method, are presented, by way of coefficients of corrosion resistance, in **Figs 1-3**.

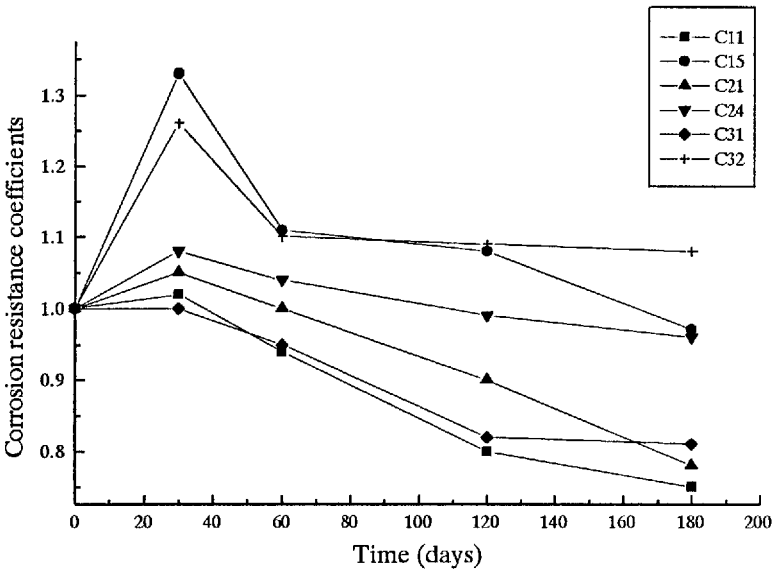

Figure 1. Corrosion resistance coefficients in solution I

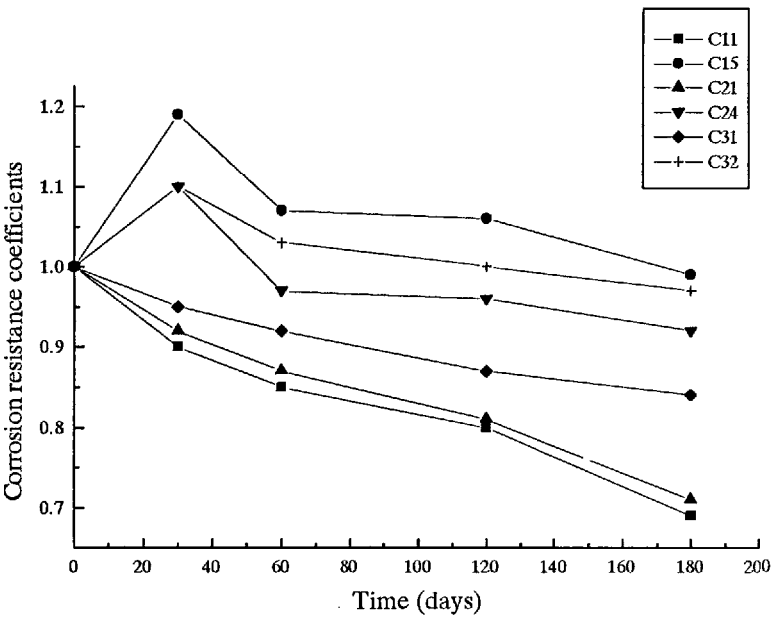

Figure 2. Corrosion resistance coefficients in solution II

Figs 1-3. presents coefficients of corrosion resistance of cements. From the diagrams, it can be clearly seen that cements with the addition of 30% of ash, show distinctly best characteristics in all the three aggressive solutions used. The increase of corrosion resistance in the very begining for all the cements is a normal phenomenon, because the formation of expansive compounds closes the pores and makes cement paste impervious to aggressive ions. However, further increase in the volume within the paste very quickly results in cracking.

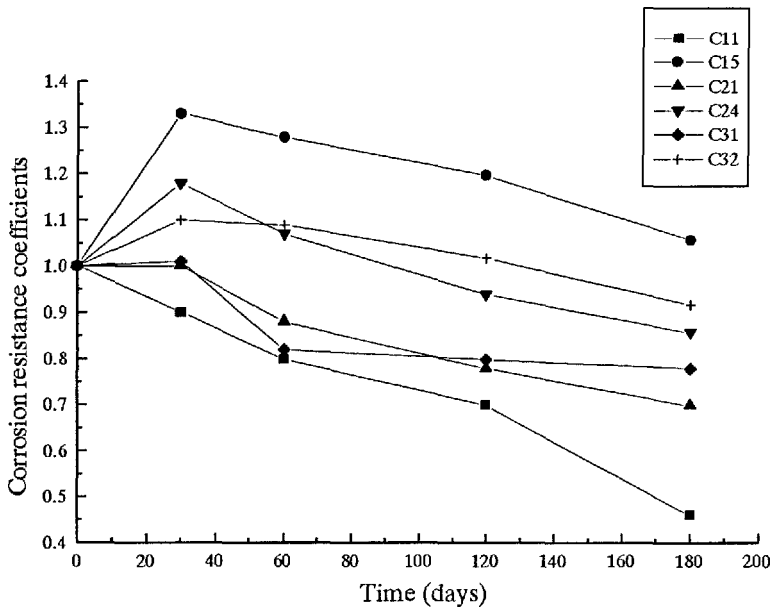

Figure 3. Corrosion resistance coefficients in solution III

The researches are evidently encouraging, because the addition of fly ash has pointed to realistic prospects for its positive effect. Therefore, cement C11 with the addition of ash (C15) shows very good resistance to the aggressive impact by sulphate solutions, although this cement is, due to its mineralogical composition, very unsuitable. When sulphate solutions of different cation compositions were compared, the ammonium sulphate solution showed considerably stronger effect than the corresponding sodium sulphate solution.

Adding fly ash to Portland cement C21, makes this cement become resistant to the sulphate aggressive environment. This is for both sodium sulphate and ammonium sulphate solutions. Adding fly ash to Portland cement C31, increases its durability in the solutions of sodium sulphate, used in this study, it also makes it resistant in the ammonium sulphate solution.

It is evident that the resistance of cement to sulphate aggression, regardless whether it concerns sodium sulphate solutions or ammonium sulphate solutions, is directly related to the content of C_3A in them.

CONCLUSION

On the basis of the tests done, following conclusions are drawn:

1. When comparing different sulphate solutions, it turns out that the aggressiveness of ammonium sulphate is of a higher degree than the solution of sodium sulphate.

2. The best resistance to sodium sulphate and ammonium sulphate solutions, was shown by cement with a lower content of tricalciumaluminate in clinker (C31), and especially by cements with the addition of fly ash, C15, C24 and C32.

3. The addition of fly ash to Portland cements was very efficient regarding their resistance to aggressive sulphate impact. The addition of ash in the quantity of 30% (replacement 30% of clinker with fly ash) improves to a considerable degree the durability of Portland cement to such influences.

4. Portland cements whose tricalciumaluminate content is high (C11 and C21), cannot be used even in the case of sulphate solutions with low concentration.

The above-cited testings of cements from the current production of the domestic cement industry, provided the basis for classification of these products regarding resistance to sulphate impact with various degrees of aggressiveness. This offers the possibility that in certain cases the ensuring of structures and their elements, which lie in contact with aggressive environment, be implemented by way of applying the selected cement with adequate composition and quality of concrete, thus avoiding special measures for protecting concrete by using expensive coatings, films and linings.

REACTION BETWEEN SIMULATED SULPHATE RADIOACTIVE LIQUID WASTE AND CEMENT BASED MATERIALS

Ana Mª GUERRERO, MªSoledad HERNANDEZ and Sara GOÑI. Institute of Construction Science Eduardo Torroja (CSIC). C/ Serrano Galvache, s/n 28033 Madrid, Spain.

ABSTRACT The durability of a specific backfilling pozzolanic cement mortar, which is employed in Spain, in concrete containers for the storage of low and medium level wastes (LLW) (MLW), has been studied by means of the Köch-Steinegger test at the temperature of 40°C during a period of 365 days. Mortar samples were immersed in a simulated radioactive liquid waste very rich in sulphate (0.68M), phosphate (0.89M) and chloride (0.51M) ions. The changes of the microstructure were followed by X-Ray Diffraction (XRD), Mercury Intrusion Porosimetry (MIP) and Scanning Electron Microscopy (SEM).

Key-words: Waste material utilization, sulphate attack, porosity, X-ray diffraction analysis, strength development.

INTRODUCTION

Studies on the durability of matrices made with the cement and the liquid radioactive wastes are numerous, specially those concerning leaching and diffusion of radioactive ions towards the biosphere (Rahman and Glasser, 1987, Komarneni and Roy, 1981, Macphee and Glasser, 1993, Hills et al., 1993, Glasser, 1992, Serne, 1989, Goñi et al., 1996, Hernández et al., Goñi et al., 1994, Guerrero et al., 1994, Hernández et al., 1996). But minor attention has been paid to the implications of the concentrated salts which accompanied the radioactive liquid wastes from the point of view of the durability of cement materials and concrete barriers employed in its storage (Li et al., 1996). Such concentrated solutions may contain a great amount of sulphate, phosphate, borate, chloride etc.. The aggressivity of sulphate to cement-based materials is well established, nevertheless, the degree of the attack depends to a great extension on the other accompanying ions. For example, the aggressivity of sulphate is lower in sea water, although its concentration is still sufficient to cause severe damage to concrete.

A very recent paper of Li et al. (Li et al., 1996) reported the formation of a new mineral designated "U" phase (a sodium substituted AFm phase, very aggressive), that only occurred in the simulated cemented low level wastes containing high amounts of Na_2SO_4 (10-15%). The authors pointed out that this phase can form only at very high alkali concentrations, not compatible with traditional cement paste. This phase transforms into ettringite when the alkalinity of the pore solution decreases for example by a water leaching process.

The present work deals with the durability of a pozzolanic backfill cement mortar (employed in Spain to assure the immobilization of the radioactive cemented matrices inside concrete containers), in a specific simulated radioactive liquid waste (SRLW), a mixture of sulphate (0.68M), phosphate (0.89M) and chloride (0.51M) ions. The study was carried out according to the Köch-Steinegger, (1960) test at the temperature of 40°C during a period of 365 days. The durability was evaluated from the changes of the flexural strength of the backfill mortar, immersed in the simulated solutions, which were compared with those obtained in similar samples immersed in deionized water. The changes of the microstructure were followed by X-Ray Diffraction (XRD), Mercury Intrusion Porosimetry (MIP) and Scanning Electron Microscopy (SEM).

EXPERIMENTAL

The backfill mortar was prepared at an aggregate to cement ratio of 1.75 and deionized water to cement ratio of 0.4. An organic additive was used at an additive to cement ratio of 0.012. The cement was pozzolanic (Spanish type IV) which is a mixture of Portland clinker (55%), pozzolanic fly ash (40%) and calcitic filler (5%). The chemical analyses of the cement components appear in Table 1.

Table 1 Chemical Analyses of the Pozzolanic Cement Components (% weight)

	I.L.	I.R.	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	Na_2O	K_2O
Clinker	0.20	-	21.6	2.64	4.2	66.8	1.68	2.05	0.13	0.50
Fly Ash	2.0	-	53.2	27.0	9.5	3.3	1.50	0.1	0.40	1.74
Filler	43.9	-	1.0	0.30	0.1	53.0	1.0	0.05	-	-

I.L. = ignition loss
I.R. = insoluble residue

In Fig. 1, the XRD analyses of both cement and aggregates are shown. The aggregates were a mixture of α-quartz and calcite. The percentage of calcite determined by thermogravimetric analyses, was 6%.

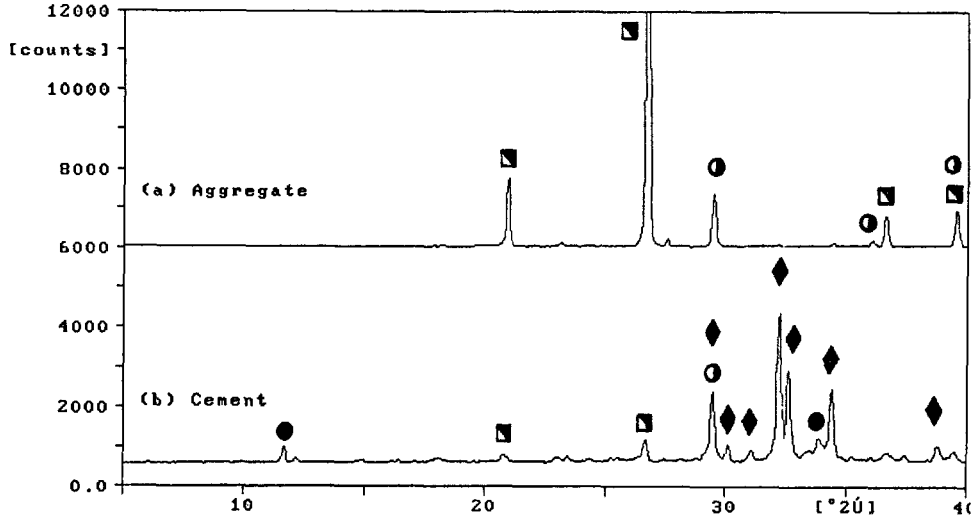

Figure 1 XRD patterns of cement and aggregate: ● C_4AF; ♦ C_3S; ◘ α-SiO_2; o Cc

After mixing, different portions were molded into 1 cm x 1 cm x 6 cm, specimens and compacted by vibration. After 1 day at 100% rh, the samples were demolded and cured in deionized water at 20°C ± 1 during 21 days. After this curing period, groups of 6 samples were immersed in the simulated radioactive liquid waste (SRLW) whose chemical composition is shown in Table 2. The samples were stored in sealed plastic bottles at the temperature of 40°C during a period of 365 days. The volume of SRLW was 800 ml per 6 samples. Similar groups of 6 samples were stored in deionized water as reference.

Table 2 Chemical composition of simulated radioactive liquid waste (g/l)

pH	Density (g/cc)	Na_2SO_4	NaH_2PO_4	Na_2HPO_4	$CaCl_2.6H_2O$	$FeCl_3.6H_2O$
5.5	1.2	96	30	60	8.8	39

X-ray diffraction patterns were recorded using a Philips PW-1730 diffractometer, graphite monochromator and Cu $K\alpha_1$ radiation. Porosity and pore-size distribution were investigated by mercury intrusion porosimetry carried out with a Micromeritics Pore Sizer 9310. SEM analysis was performed with a Jeol JSM 5400 microscope with an Oxford EDS microanalysis ISIS model. The samples were coated with C by sputtering.

RESULTS AND DISCUSSION

Flexural Strength Analysis

The flexural strength changes of the hydrated mortar immersed in deionized water and in the SRLW are shown in (Fig 2).

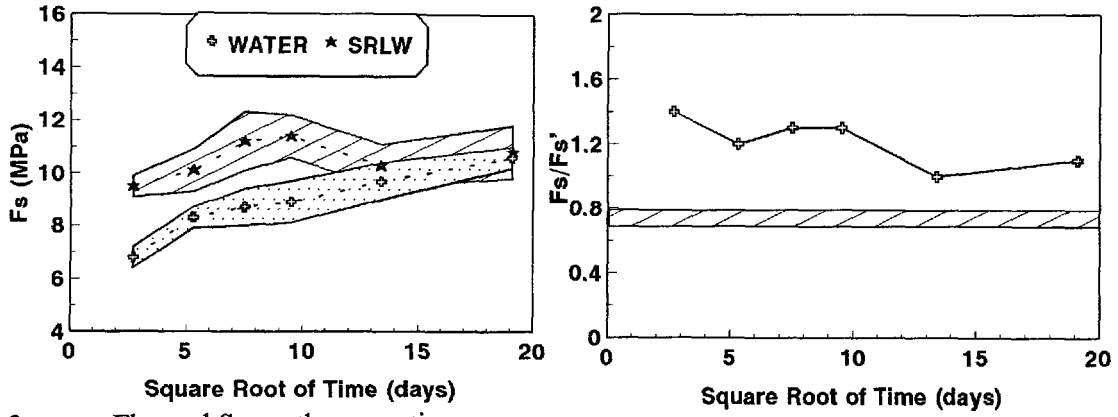

Figure 2 Flexural Strength versus time

Each value represents the average of 6 measurements; the dashed area is the standard deviation of the mean values. For the samples immersed in deionized water a remarkable increase of the flexural strength value is observed between 7 days and 28 days remaining afterward more or less constant. In contrast, the samples immersed in the SRLW during 7 days have a flexural strength value considerably higher than that of samples immersed in deionized water, progressively increasing during 90 days of immersion. The flexural strength starts decreasing thereafter up to the end of the experiment, when similar values independent of the medium are obtained.

The mechanical behaviour of the mortar immersed in deionized water could be related to the pozzolanic reaction of the flyash-cement which is activated at 40°C. Consequently, decreasing porosity of samples is associated with an increase of flexural strength.

The higher flexural strength values reached by the mortar samples, when immersed in the SRLW, could be due to the microstructural changes produced by the diffusion of ions and precipitation of new compounds, mainly of brushite type, within pores, as observed through XRD and SEM analyses. That precipitation process decreased the porosity causing a higher mechanical strength of the samples. According to the Köch-Steinegger test (Köch-Steinegger, 1960), the criterion to classify a material as durable in a specific aggressive medium is that the relative strength of aggressive-stored samples to water stored ones should be higher than 0.7-0.8. In all the cases, the relative strength is below the aforementioned threshold (Fig. 2).

X-Ray Diffraction Analysis

The main change detected for the samples immersed in deionized water is the decrease of the intensity of the portlandite ($Ca(OH)_2$) reflections, indicating the pozzolanic reaction of the fly ash-cement (Fig

3). In the case of samples immersed in the SRLW, new strong reflections appear after 7 days, which could be attributed to both brushite ($Ca(PO_3)(OH).\ 2H_2O$) and gypsum ($CaSO_4.\ 2H_2O$) (see Fig 3 (a)). The crystallographic similarities between gypsum and brushite, both compounds have a monoclinic structure with nearly identical cell dimensions, makes differentiation difficult (Beevers, 1958, Sakae et al., 1978).

The intensity of the reflections of those possible compounds strongly decreases after 90 days. Besides, the intensities of the portlandite reflections also strongly decrease. The ettringite reflections are very weak, but it seems that they slightly increase with time. These results indicate that phosphate and sulphate ions from the SRLW easily combine with Ca^{2+} ions. Nevertheless, brushite is not stable and dissolves over time as observed from SEM analysis, favouring the ingress of Na^+ and SO_4^{2-} ions, and increasing the porosity of the samples. This fact could explain the decrease of the flexural strength (see Fig 2). The intensity of the (001) reflection of portlandite at 18.0 2θ angular zone, is higher than the maximum intensity of the reflection at 34.1 2θ zone, which seems to show prefered orientation of the portlandite, as confirmed from SEM analyses.

Porosity and Pore-Size Distribution Analysis

The pore-size distribution curves of mortar samples immersed in deionized water and in the SRLW are presented in (Fig 4). Cubes about 1 cm^3 were previously degasified under vacuum. As shown, the majority of pores have a diameter minor than 0.05 μm for samples immersed in deionized water. The total porosity decreased from 5.4% at 7 days to 3.0% after 365 days of immersion. For samples immersed in SRLW, the porosity decreased from 5.0% at 7 days to 4.4% at 365 days; nevertheless, the percentage of pores of diameter >0.05μm increased.

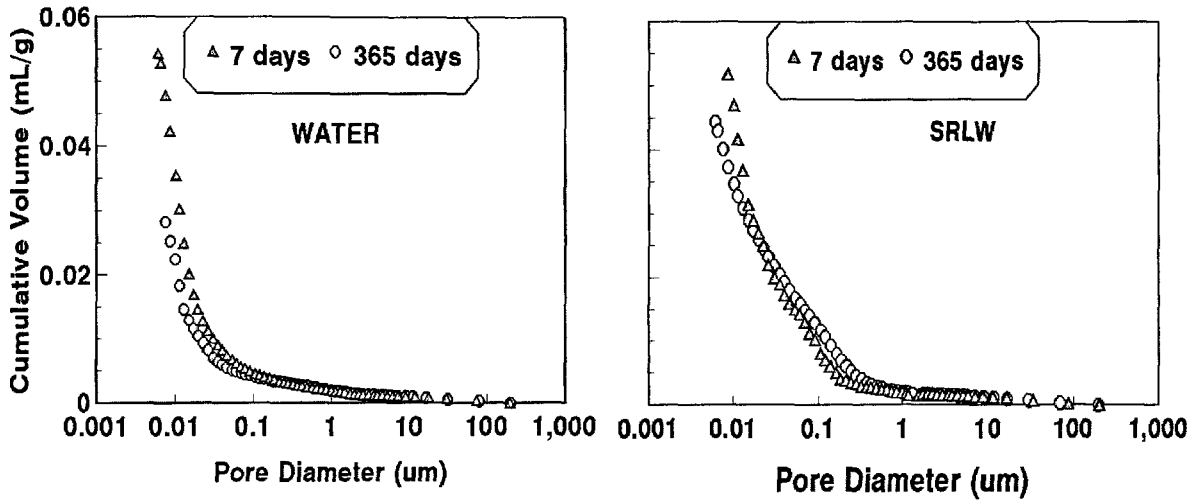

Figure 4 Pore size distribution curves of the backfill mortar

The main pore-size distribution changes for samples immersed in deionized water are produced in the range of pores of diameter < 0.05μm the volume of which strongly decrease between 7 days and 28 days (Fig 5).

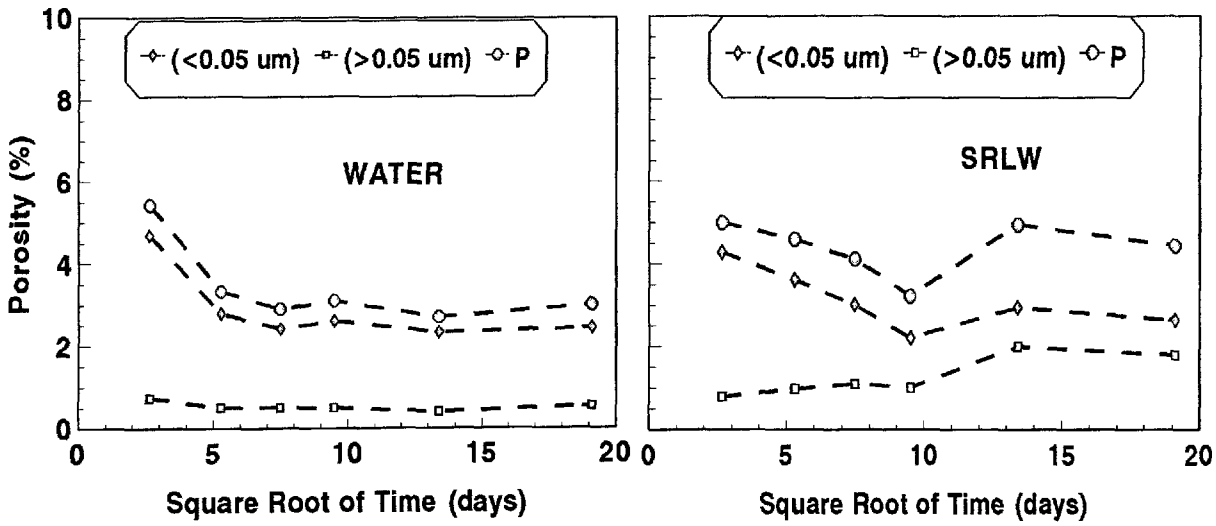

Figure 5 Percentage of pores of diameter > 0.05μm and < 0.05μm vs time

This is due to the pozzolanic reaction of the fly ash that generates hydrated calcium aluminate and silicate gels densifying the microstructure of the backfill mortar. When the mortar samples are immersed in SRLW, between 7 days and 90 days a progressive decrease is observed in the percentage of pores of diameter < 0.05μm. This could be related to the precipitation of brushite and gypsum within the pores. After 90 days an increase is observed, mainly in the percentage of pores of diameter

>0.05μm, which could be due to the dissolution of brushite and portlandite accompanying the decrease of the flexural strength (see Fig 2).

CONCLUSIONS

Despite of the high concentration of sulphate ion in the SRLW (0.68M), its potential aggressivity to the backfill mortar is avoided by the presence of phosphate ions. Phosphate ions easily combine with Ca^{2+} and OH^- from the pore solution forming brushite $Ca(PO_3)(OH).2H_2O$.

The external layer of brushite is very compact, impeding diffusion of sulphate and protecting the microstructure of the backfill mortar. Brushite is dissolved over time, increasing the porosity of the mortar, particularly pores of diameter >0.05μm. Consequently the diffusion of the ions; SO_4^{2-}, Na^+ and Cl^- was enhanced.

The flexural strength values of the backfill mortar are maintained below those of the samples immersed in deionized water throughout the experiment. Accordingly, the backfill mortar can be considered as a durable material in this specific simulated sulphated liquid waste.

In opinion of the authors, more extensive long term studies would be recommended, due to the partial dissolution of the protective brushite layer.

MICROSTRUCTURAL INVESTIGATION OF CALCIUM ALUMINATE CEMENT CONCRETE FROM STRUCTURES

Karen L. SCRIVENER*, Matthew LEWIS, and Justine HOUGHTON
Imperial College, London, UK

ABSTRACT Three structures built from calcium aluminate cement were examined. Two of the structures were 60 years old, had w/c ratios around 0.6-0.7 and had been exposed to sea water. These exhibited a dense surface layer, containing a complex mixture of hydrates, extending some 5 cm into the concrete, then there was a gradual transition to a porous internal microstructure. The third structure, 25 years old, was made at w/c=0.4. This had a dense microstructure throughout, characterised by a fine distribution of C_3AH_6 and AH_3.

Key-words: Calcium aluminate cement, concrete, microstructure, structure, sea water

INTRODUCTION

Calcium aluminate cements (CACs) are made from limestone and bauxite and contain calcium mono aluminate, CA, as the principal reactive phase. These cements were originally developed at the beginning of the century in response to the need for cements which were durable under exposure to calcium sulfate solutions. The good performance of these cements in such conditions lead to their use in marine environments.

Calcium aluminate cements also came to be used for their rapid hardening qualities, the long term strength being achieved in as little as 6 to 8 hours. The long term strengths of CACs, due to the stable hydrates C_3AH_6 and AH_3, are similar, or somewhat lower, than those or Portland cement concretes at equivalent water/cement ratios. Transient high early strengths (>80 MPa) may be achieved in small sections cured at ambient temperatures, due to the formation of metastable hydrates (CAH_{10} & C_2AH_8). The inevitable transformation of these metastable hydrates to the stable ones with time is known as conversion. Design should be on the basis of converted strengths and current guidelines stress the importance of keeping the water/cement ratio below 0.4 and the cement content above 400 kg/m^3 to ensure adequate long term strength. In large sections the heat evolved during hydration will lead to self heating of the concrete to 70°C or higher, at such temperatures the stable hydrates are formed directly during hydration, so the material is converted from the beginning.

In the UK, in the early 1970s three catastrophic failures of prestressed roof beams made with calcium aluminate cement occurred. In only one of these cases was loss of strength due to conversion found to be a significant factors in the collapse, but consequently calcium aluminate cements have not been permitted for use in structural applications in many countries. Nevertheless, many structures of calcium aluminate cement concrete continue to exist and perform well, including around 50,000 prestressed structures in the UK.

The work presented here details a microstructural study of three structures from 25 to 60 years of age which have shown good durability. Two of these, built in the 1930s, Dagenham and Halifax, had water/cement ratios well in excess of the now recommended maximum and were exposed to sea-water, the other was built in 1969 to comply to the current guidelines. All of these structures are of such a size that significant self heating and immediate conversion would occurred during curing.

* present address, Lafarge, Laboratoire Central de Recherche, 95 rue du Montmurier 38291 St Quentin Fallavier, France.

STRUCTURES

Factory Piling's, Dagenham, UK

Calcium aluminate cement was chosen for this application due to sulfate contamination of the ground. Reinforced piles 0.4 m in diameter by 25 m in length were cast with mix proportions, cement:sand:aggregate of 1:2.5:4. The w/c ratio was not recorded, but to give an adequate slump for this mix is likely to have been around 0.6 and measurement from cores gave values of 0.65-0.8.

The rapid strength gain allowed the piles to be driven at an age of 24 hours. The piles originally supported a power station, this was recently demolished, but the piles are still in good condition. The cores were taken from a pile in contact with water from the adjacent Thames estuary.

Ocean pier, Halifax, Nova Scotia, Canada

This site is an ocean port, which experiences around 100 freeze/thaw cycles a year. CAC was chosen for the construction of hollow concrete cribs 32 × 16 × 16 m, which were then filled with gravel. The mix design was 1:2.28:3.35 (cement:sand:aggregate) and the w/c is estimated to have been 0.55-0.7.

The surfaces were sprayed with water during curing, but even so the surface temperatures were recorded as reaching 40°C, 8 hours after curing. The core examined in this study was taken from below the water line of the pier which is still in service today.

Bridge at cement factory, Frangey, France

Calcium aluminate cement was used for the construction of this bridge, which consists of a post tensioned deck (cement content of 500 kg/m3 and w/c = 0.32) and reinforced concrete piles with w/c of 0.4. The internal temperatures reached in trail blocks 2.6 × 1 × 1 m, cast in insulated form work were recorded at between 63 and 85°C. Cores were taken from both concrete types.

Further details of the mix design and construction of the field structures are given in George and Capmas (1994). Some results of the microstructural examination of the Dagenham sample are reported by Houghton and Scrivener (1994).

EXPERIMENTAL

For each structure sections were cut perpendicular to the surface, at the surface of the cores and near the end of the core furthest from the surface. The sections were resin impregnated and polished to ¼ μm with alumina grit and diamond paste. These polished sections were examined in a JEOL 35CF scanning electron microscope (SEM) in the backscattered electron (BSE) mode. The chemical composition of microstructural features was studied by energy dispersive spectroscopic (EDS) X-ray microanalyses. The porosity was measured by image analysis on 20 images at ×540 magnification.

RESULTS

Halifax and Dagenham

Due to the similarity between the microstructures of these samples they are presented together.

Examples of the interior microstructure of these samples are shown in Figure 1 and 2. Both have a very high porosity, which was measured as 14% and 15% for the Dagenham and Halifax samples respectively, nevertheless the cores were found to have a strengths of 17 - 22 MPa (Crammond 1992, Aitcin et al 1995). The relics of the original cement grains are still identifiable although most of the anhydrous phase have reacted. In some grains a reaction rim is visible surrounding still unreacted material (Fig. 1). Some remnants of iron containing phases

can be seen, identifiable by their bright appearance, but most of these phases have also reacted, which, by analogy with pastes hydrated at known temperatures, suggests a high temperature of hydration (Houghton and Scrivener 1994). The hydrates are very intermixed and difficult to analyse. However, three general types of hydrate could be identified: Dark isotropic areas, bright granular areas and regions of a platy phase. The dark isotropic areas were very high in alumina with varying lower amounts of other elements and are thus identified as AH_3 with other elements in solid solution or other phases intermixed. The analyses of the bright granular areas indicate hydrogarnet, C_3AH_6 although with indications of Si substitution. The compositions of the platy phases were very variable, with some analyses including chloride, in addition to calcium aluminium and silicon. The composition and morphology of these regions suggest they are intermixed AFm hydrates based on strättlingite (C_2ASH_8), Friedel's salt ($C_3A.CaCl.H_{12}$) and C_2AH_8.

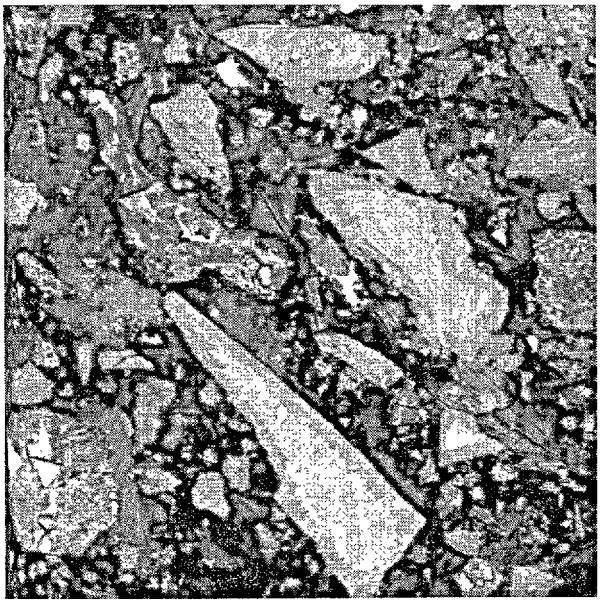

Fig. 1 Interior microstructure of core from Ford's Dagenham

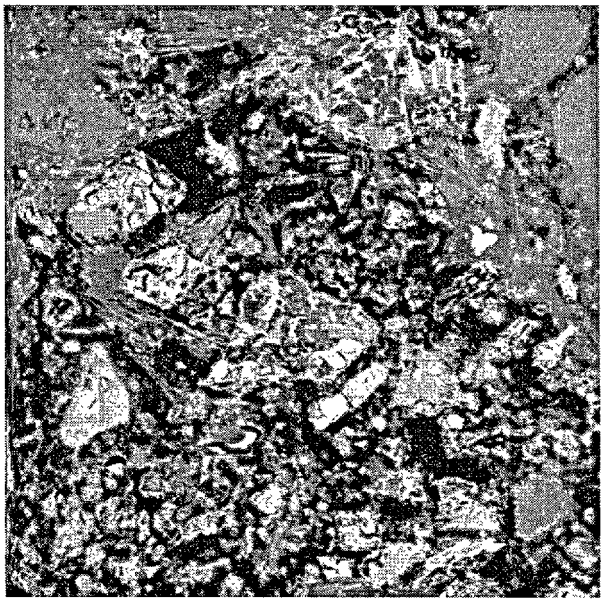

Fig 2. Interior microstructure of core from Halifax

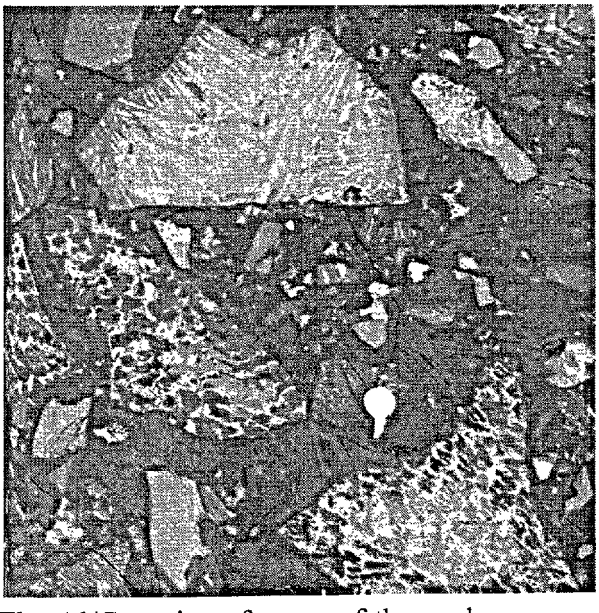

Fig. 3. Microstructure near surface of Dagenham sample

The microstructure near the surface of the sample from Dagenham is shown in Figure 3. It is immediately apparent that the level of porosity is much lower, this was measured as 1.7% by image analysis. The relics of the original cement grains are very clear and their appears to be little reaction of the iron containing phases. The matrix is filled with a darkish isotropic phases and a platy phase. As in the interior, the darker phases is very high in alumina, but here contains a significant concentration of chloride and some sulfate. The Al/Ca ratios of many of the analyses suggest the presence of CAH_{10} rather than AH_3. The

analyses of the platy phase again suggest intermixed AFm phases. The presence of metastable hydrates is unexpected, as significant heating, even at the surface would have been expected during the initial hydration. The metastable hydrates may have formed from the continuing reaction of the anhydrous phases at lower temperatures over time, or by reaction with ingressing ions, such as chloride, or sulfate, or a combination of the two processes.

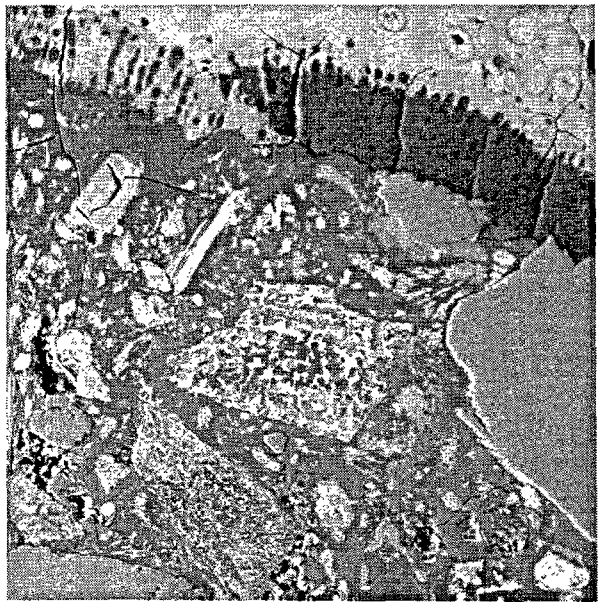

Fig. 4. Exterior microstructure of core from Halifax

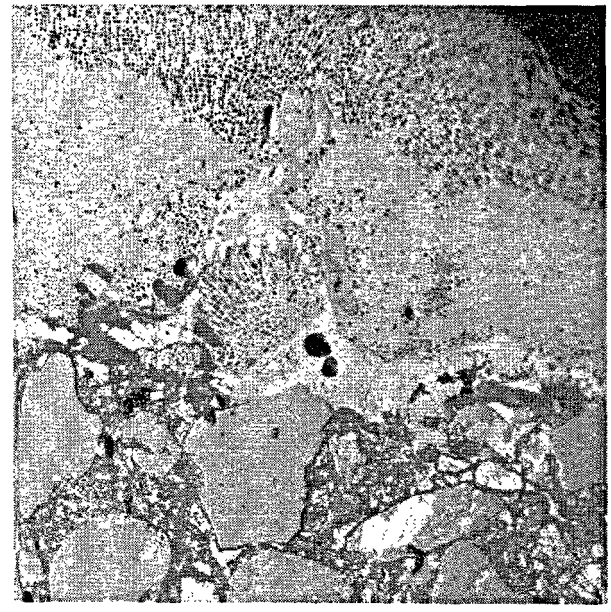

Fig 5. Exterior microstructure of core from Halifax

The microstructure at the surface of the Halifax core is shown in Figure 4 & 5. On the surface there are calcareous deposits from marine animals, directly below these, there is a layer of magnesium oxide, brucite, as has been found in Portland cement concretes exposed to seawater (Buenfeld 1986). Below the brucite layer the microstructure is similar to that of the Dagenham sample. There is a considerable amount of chloride in the analyses of the isotropic phase, which varies with depth as shown in figure 6.

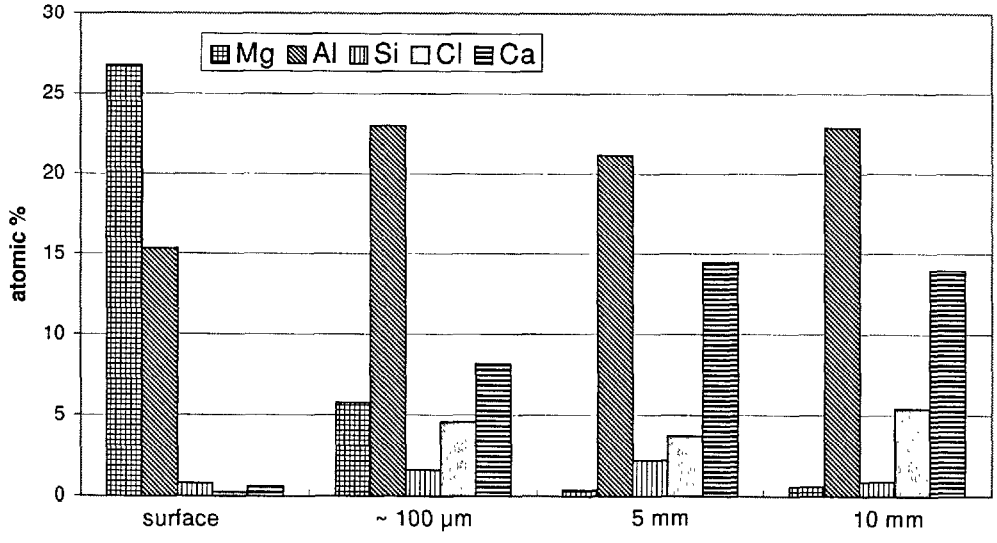

Figure 6. Average analyses of matrix isotropic phase at different depths for the Halifax sample.

The examination of both these samples shows a considerable variation of the microstructure with depth. In both a dense layer is present at the surface. The different properties of this surface region have been confirmed by measurements of O_2 permeability (Dunster 1995), which found the permeability of the surface 50 mm to be almost two orders of magnitude lower than that of the interior. The rapid decrease in chloride and sulfate concentrations reported in the same paper, suggest that this dense surface layer has played a significant role in the good durability of these structures.

Frangey Bridge

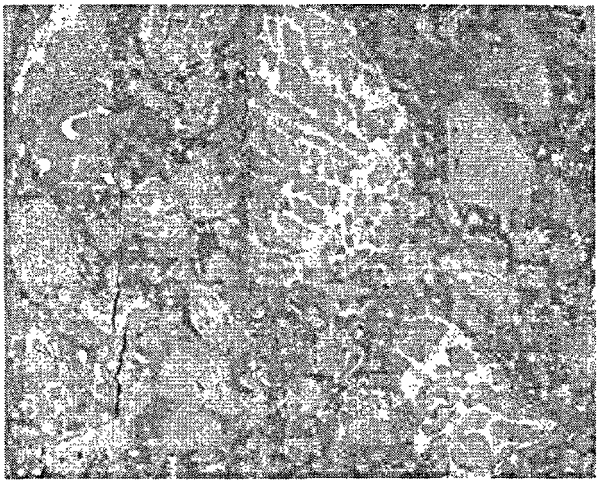

Fig. 7. Microstructure of near surface of Frangey core, column

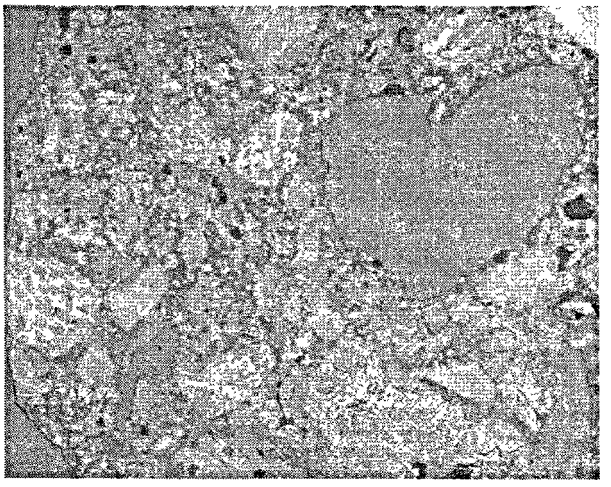

Fig 8. Microstructure 10 mm from surface

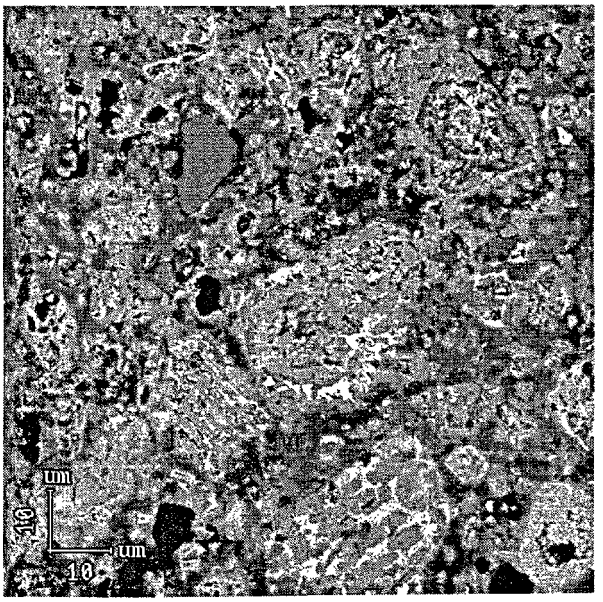

Fig. 9. Microstructure of interior of core from Frangey

Fig 10. Microstructure of interior at higher magnification

Figures 7 to 10 show the microstructure of the Frangey sample at various depths. The images shown are from the reinforced concrete column, although those from the prestressed bridge deck are very similar.

Unlike the two earlier samples with a relatively high w/c ratio, in these samples, with w/c<0.4, there was little noticeable difference between the surface and interior microstructures. All are very dense, the porosity level of the interior sample being measured at 2% by image analysis. The matrix consists of a finely divided mixture of a brighter, granular phase in a darker matrix (Figure 10). Microanalyses clearly indicated that these phases were C_3AH_6 and AH_3 respectively, although the scale of intermixing was too fine for accurate analyses to be obtained for either phase. Although the microstructures are very similar, the sequence of Figure 7-9 moving in from the surface, indicates that there is more reaction of the iron containing phases with greater depths, probably corresponding to greater maximum temperatures.

The O_2 permeabilities were measured at $0.1\text{-}0.7\times10^{-17}m^2$ (Dunster 1995) and the compressive strengths at 48-63 MPa (Marcdargent 1995). There was no clear difference between the two qualities of concrete for the bridge deck and the piles in terms of strength or permeability.

GENERAL DISCUSSION

The three structures examined in this study provide examples of good durability of CAC concrete. The two older samples were made at w/c well in excess of the current guidelines and the interior of these samples is very porous. However, the formation of a dense surface layer appears to be responsible for the relatively low penetration of chloride and sulfate ions over 60 years. This dense surface layer appear to contain 'unconverted' hydrates, which may be stabilised by the ingressing ions or by the low temperatures of exposure.

The third structure, made in accordance with present guidelines has a dense microstructure throughout, consisting of stable 'converted' hydrates. This converted microstructure almost certainly formed during the initial period of curing, due to the high degree of self heating.

As observed for pastes hydrated at different temperatures (Houghton and Scrivener 1994, Houghton 1996) the degree of reaction of the iron containing phases appears to increase at higher temperature, as experienced within concretes of large section.

ALKALINE HYDROLYSIS WITH CARBONATION IN HIGH ALUMINA CEMENT CONCRETE BEAMS

Andrew M DUNSTER and Norah J CRAMMOND
Building Research Establishment, Garston, Watford, WD2 7JR, UK.

ABSTRACT The authors have investigated a case of suspected alkaline hydrolysis with carbonation in a building constructed during the 1960's. Samples were analysed chemically and examined using optical and electron microscopy. The beams in locations with evidence of water penetration showed signs of deterioration at the lower (soffit) surfaces. The deteriorated samples contained granular carbonates and needle-like gibbsite in voids, giving a microstructure which was quite distinct from that normally associated with atmospheric carbonation.

Key words: Calcium aluminate cement, carbonation, chemical attack, durability

INTRODUCTION

Concrete made from High alumina cement (HAC), also known as calcium aluminate cement, was used extensively in the UK from the 1950's to the early 1970's in the manufacture of precast, prestressed concrete beams. Although the importance of carbonation in such concretes has been highlighted by BRE in recent years (Crammond and Currie, 1993), chemical attack under damp conditions, as reported in the present paper, is less common.

Alkaline hydrolysis with carbonation is a form of carbonation in which sodium and/or potassium salt solutions interact with atmospheric carbon dioxide (Taylor, 1990) to attack the hydrated calcium aluminates in the hydrated cement to form calcium carbonate and hydrated alumina. When alkaline hydrolysis with carbonation takes place there is a total lack of cohesion of the bonding cement paste, and the binder crumbles to a powder. This means that part of the concrete loses all strength. Although the interior of the concrete has not lost strength, there is still potential for it to do so as the depth of the cover concrete is progressively reduced. The usual representation of the reactions is given by the action of alkali carbonate on the hydrated calcium aluminates to give hydrated alumina and calcium carbonate. For C_3AH_6, the overall reaction may be represented as:

$$3CaO.Al_2O_3.6H_2O + 3CO_2 \xrightarrow{K_2CO_3 \text{ or } Na_2CO_3} 3\,CaCO_3 + Al_2O_3.\,3\,H_2O + 3\,H_2O \qquad (1)$$

It is important to realise that normal carbonation in HAC concrete in the absence of alkalis also produces $CaCO_3$ and $Al_2O_3.\,3\,H_2O$ (AH_3) as the final reaction products, although this is accompanied by an increase in strength (Raask, 1976). Alkaline hydrolysis with carbonation is relatively rare in practice and only a few cases have been identified by BRE.

The authors have investigated a case of alkaline hydrolysis with carbonation in the chemistry laboratories of a two-storey school building constructed during the 1960's. The building frame supports the flat roof of the building. There is also a suspended false ceiling. Together, the roof and false ceiling form the ceiling for the laboratories. The roof construction comprises precast HAC concrete 'T' beams, woodwool slabs and roof covering (Fig 1). There had been a history of water ingress due to roof leakage which had been remedied in the early 1990's. A routine visual inspection of the underside of the roof structure in early 1995 had revealed degradation of the

cement paste matrix on the underside (soffit) of one of the beams (Fig 1). This gave the building owners cause for concern and a detailed investigation involving BRE's Materials Diagnostic Unit was therefore initiated.

SAMPLING AND MATERIALS ANALYSIS

Sampling

The more detailed phase of visual inspection was accompanied by the collection of lump samples from the HAC concrete for materials analysis (Table 2). Lump samples of concrete were collected from the soffits of four beams in areas of the roof where staining of the ceiling tiles and supporting frame provided evidence of water entry. Two "control" samples were collected from beams in one of the laboratories and in an adjacent corridor where there was no evidence of water penetration. Several additional lumps of mortar-like material and scrapings of soft material were also collected at some locations adjacent to the main concrete lump samples. The sampling locations are numbered from 1 to 6. Concrete lump samples have been designated by the suffix "L", mortar-like lumps or scrapings by "S". Visual signs of deterioration on the surface of the concrete were invariably restricted to those areas of the building showing evidence of water penetration. The erosion of material was limited to the soffit surfaces of the beams (approx. 1 mm to 2 mm depth) and in the majority of cases, the bulk was relatively hard and dense. On one of the beams, however, a soft sandy material (immediately adjacent to concrete lump sample 4) was present in a discrete narrow area surrounded by normal dense concrete. This observation, which is consistent with a mortar having been applied to the surface of the beam at some locations, was pursued in the subsequent laboratory investigations.

Materials Analysis

The samples were examined in BRE's laboratories using optical microscopy (to establish the extent of chemical attack) and chemical analysis (Table 1). Differential Scanning Calorimetry (DSC) and X-ray diffraction (XRD) were carried out on selected samples to check for the products of alkaline hydrolysis with carbonation. Several of the thin sections which were examined optically were polished, gold coated, and examined under the scanning electron microscope (SEM).

Samples were analysed chemically for total alkalis (sodium and potassium) by nitric acid extract and flame emission to check for alkaline hydrolysis with carbonation. Alumina was determined to establish cement content as well as total sulphate by LECO carbon sulphur analyser to check for sulphate attack. In these tests, a ratio of alumina to total equivalent alkalis of much less than 70, together with visual evidence of surface deterioration would indicate that a concrete has suffered alkaline hydrolysis with carbonation (BRE, 1994). Sulphate levels above the 0.2 % SO_3 normally present in HAC would imply ingress of sulphate from a source external to the cement.

RESULTS OF MICROSTRUCTURAL EXAMINATION AND CHEMICAL ANALYSIS

Undeteriorated beams

The samples 5(L) and 6(L), taken from nominally dry areas, showed the presence of dense calcium carbonate under the optical microscope. There were no signs of disruptive chemical attack or other forms of deterioration. There was, however, evidence from optical microscopy of a thin crust (< 200 microns thickness) of sulphate minerals on the soffit of both these beams and this was confirmed by electron microscopy.

The presence of sulphates in these nominally dry areas was surprising as migration of external sulphates from adjacent Portland cement materials in the absence of water would be unlikely. The presence of sulphates implies that some minor moisture movement and mobilisation of sulphates have occurred, possibly as a result of less severe dampness or water penetration than that which affected the deteriorated beams. There was no evidence for the use of repair mortar on these beams.

Deteriorated beams

In the deteriorated beams (sample locations 1 to 4, in areas of obvious roof leakage), the soffits of the beams had typically lost some of the cement paste matrix and were heavily eroded. Optical microscopy revealed granular calcium carbonate and needle-like crystals of AH_3 in voids (these were initially misidentified as gypsum which has a similar appearance optically). The open microstructure was thus distinctly different to the dense matrix associated with normal atmospheric carbonation . In addition, sulphate minerals (ettringite and gypsum) were present in cracks and voids or they formed a crust on the surface. The presence of needle-shaped crystals of secondary AH_3 was confirmed using SEM in combination with X-ray microanalysis. These needles were commonly associated with granular recrytallized calcite which had a "feathered" appearance (Fig 2). It is significant that the AH_3 in the apparently unaltered portion of the HAC

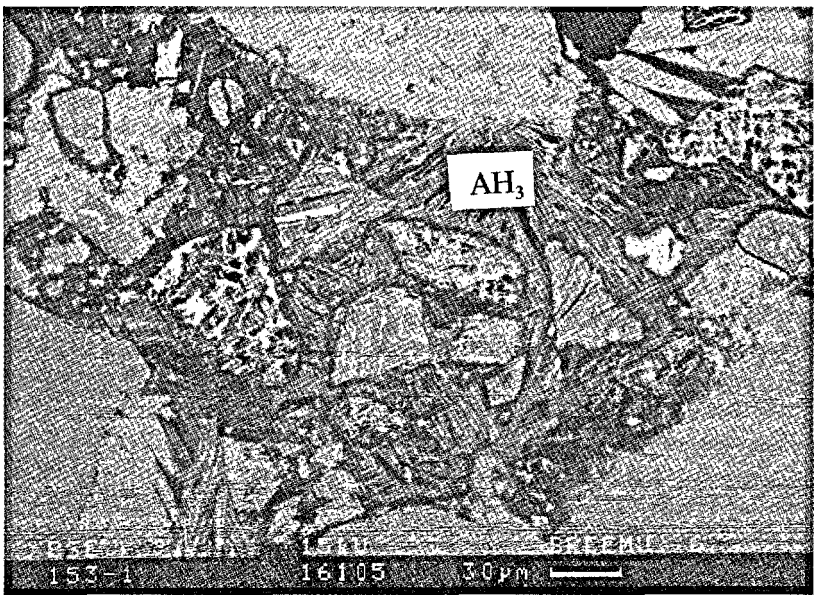

Figure 2 Electron micrograph showing needle like crystals of AH_3 (scale bar, 30 microns)

concrete was not needle-shaped. This implies that the needle-like AH_3 found in the deteriorated samples is a product of alkaline hydrolysis with carbonation.

In the deteriorated samples analysed chemically (samples 1 to 3), the ratios of alumina to total equivalent alkalis (Table 3) were well below the lower limit of 70 stipulated by BRE as an indicator of alkaline hydrolysis with carbonation (BRE 1994). This confirmed the presence of alkaline hydrolysis with carbonation. The high total sulphate values (in excess of 0.6% by weight of cement) in these samples implied that sulphates may also be involved in the deterioration. However, there was no evidence of disruption or cracking caused by sulphate attack and any sulphate minerals (ettringite and gypsum) were restricted to infilling voids or forming a crust on the surface.

RESULTS OF X-RAY DIFFRACTION AND THERMAL ANALYSIS

XRD (Table 4) showed that the unaffected beams contained two polymorphs of AH_3 (gibbsite with traces of bayerite) and that calcium carbonate was present predominantly as aragonite and vaterite with only traces of calcite. Similarly, the affected beams also contained AH_3 but as gibbsite with subordinate nordstrandite. Calcite as well as vaterite and aragonite were also present.

In all the samples examined (affected as well as unaffected), DSC clearly showed the presence of a strong AH_3 endotherm (approx. 250 to 270 °C). Smaller endotherms at approx. 110 °C and 150-170 °C were attributed to CAH_{10} and C_2AH_8 respectively. In all samples the absence of C_3AH_6 (which typically gives a distinct exotherm at approx. 300 to 310 °C) was confirmed by

✓ = present, x = not detected, tr = trace, nd = not determined.

XRD. There were no significant differences between the DSC thermograms of the undeteriorated sub-sample (which was highly carbonated) and the thermograms of beams affected by alkaline hydrolysis with carbonation. The results imply that the stable hydrate C_3AH_6 in these samples has been degraded by normal atmospheric carbonation, alkaline hydrolysis with carbonation, or by a combination of the two, with a small residue of meta-stable CAH_{10} remaining uncarbonated. The presence of CAH_{10} also shows that even after some 30 years complete conversion of the hydrate phases had not been achieved.

The sample of mortar-like powder scraped from the soft area of the soffit (sample 4(S)) contained principally sand with a very low cement content and was shown to contain HAC using DSC. There was no evidence for the presence of sulphate minerals.

DISCUSSION

In the presence of alkalis and excessive and persistent penetrating water, progressive deterioration of HAC concrete is possible due to alkaline hydrolysis with carbonation. In this instance it appeared that there were three main ingredients involved in the deterioration: alkalis derived from Portland cement, possibly in the roof screed but more likely binding the woodwool slabs; sulphates (also derived from Portland cement); and finally leaks around roof outlet gullies providing the water. Erosion of the cement paste, and consequent loss of material from the soffits of beams in the deteriorated areas, made it difficult to diagnose the exact role of the alkalis and the part played by the sulphates (if any) in the deterioration process. However, visual and microscopic examinations together with chemical analysis proved that the beams in areas of obvious water penetration had been attacked locally at the surface by alkaline hydrolysis with carbonation. This attack was associated with deposition of sulphates in the voids which formed as a result of degradation of the cement paste. It is unclear, however, if the sulphates contributed

to the deterioration or if they were only deposited in the cracks and voids created by alkaline hydrolysis with carbonation.

Investigations of other buildings by BRE have shown that the presence of high alkali levels and moisture does not inevitably lead to alkaline hydrolysis with carbonation. Several cases have been identified where, in the presence of high alkalis and dampness or moisture, disruptive alkaline hydrolysis with carbonation of HAC concrete has not occurred. Laboratory studies currently in progress by the authors (unpublished) have shown that progressive erosion of HAC concrete surfaces can occur due to alkaline hydrolysis with carbonation if very wet alkaline conditions are allowed to persist over a period of several months. In good quality concretes, however, the rate of deterioration appears to be low. The presence of "mortar-like" material on one of the beams examined in the present study provides evidence that a relatively poor quality repair mortar may have been applied in the precasting factory to fill voids, etc. This would provide an explanation for the severity of attack at the soffits since mortar would be more porous, and thus more readily attacked, than the dense HAC concrete which appears to be in a good condition.

CONCLUSIONS

The HAC concrete beams, examined in locations which had been subjected to penetrating water, have shown evidence of deterioration at the soffit surfaces due to alkaline hydrolysis with carbonation. Alkalis for the reaction have probably been provided by prolonged roof leakage through the overlying woodwool slabs. Sulphates, which may also be involved, may have been derived by leaching from adjacent Portland cement-based materials or from a repair mortar applied at the surface. The presence of a mortar would provide an explanation for the severity of attack at the soffits since mortar would be more porous, and thus more readily attacked, than dense HAC concrete. Prolonged water leakage in combination with poor quality concrete appear to be prerequisites for damaging alkaline hydrolysis with carbonation and this may explain why cases are relatively rare in the UK.

Both alkaline hydrolysis with carbonation and normal atmospheric carbonation in HAC concrete produce AH_3 and $CaCO_3$ as the principal reaction products. However, each produces a distinctly different microstructure.

ACKNOWLEDGEMENTS

The authors wish to acknowledge Kelvin Pettifer, Simon Lane, David Rayment, Mike Bowley and Freda Halliwell of BRE for help with the microscopy and chemical analysis.

BEHAVIOUR OF THE PASTE RICH IN HYDROGARNET AND GIBBSITE IN CHLORIDE SOLUTION

Wiesław KURDOWSKI, Sylwester DUSZAK, Barbara TRYBALSKA
University of Mining and Metallurgy, Kraków, Poland

ABSTRACT

Paste composed mainly of gibbsite and C_3AH_6 was immersed in the solutions of $MgCl_2$ (150 g/l), $CaCl_2$ (175 g/l) and salt mine water (164 g/l $CaCl_2$ and 272 g/l $MgCl_2$). After several days of immersion the X-ray and SEM analysis showed the diminution of the hydrogarnet phase with the formation of Friedel salt and basic magnesium chloride in case of solutions containing $MgCl_2$. The presence of basic calcium chloride was also confirmed in salt mine water. In all solutions the samples revealed expansion which, however, was considerably lower in the $CaCl_2$ solution.

Key words: aluminate phase, chloride, corrosion, Friedel's salt, high alumina cements,

INTRODUCTION

The corrosion of the cement paste in chloride solution is not fully understood, and only few papers are devoted to the investigation of the phenomena connected with the reaction of chlorides with the cement paste (Smolczyk, 1968, Chatterji, 1978, Monosi et al., 1989, Conjeaud, 1982, Riedel, 1973 and Suzukawa, 1980). Nevertheless the problem is very important, not only with respect to concrete used in the underground salt mine but also for the durability of the containers for hazardous waste deposition and, finally, with the action of de-icing salts on concrete pavements.

For several years in our laboratory we have been investigating the corrosion of cement paste in strong chloride solutions (Kurdowski et al., 1989, 1990, 1994a and 1994b). Out of different types of cement examined, the best durability was presented by HAC and slag cement, activated with sodium salts (Kurdowski et al., 1990 and 1994b).

To obtain further information about the corrosion of calcium aluminate a special paste was prepared which contained mainly gibbsite and, in smaller quantities, hydrogarnet C_3AH_6. This paste was immersed in three different chloride solutions and the process of corrosion followed. The paper describes the results of these investigations.

MATERIAL AND METHODS

In order to obtain the paste rich in $Al(OH)_3$ a pure CA_2 phase were used. This phase was prepared by burning the mixture of suitable stechiometry of calcium carbonate and alumina hydroxide, both pure AR materials. CA_2 during reaction with water will give the paste rich in AH_3, namely:

$$3CA_2 + 21H_2O \longrightarrow C_3AH_6 + 10\,AH_3 \qquad [1]$$

The calcium aluminate CA_2 reacts very slowly with water and in order to accelerate this reaction and to obtain pure hydrogarnet (without admixtures of other calcium aluminate hydrates), the hydration was carried out in the saturated water vapour at the temperature of 80°C. The paste was made at w/c ratio of 0.54, from the ground powder of CA_2 of which small prism elements with dimensions 10×10×80 mm were prepared. These prism elements were then submitted to hydration in the saturated water vapour at 80°C during 72 hours and next stored in water at 20°±1°C during 7 days. The X-ray examination of the paste after this treatment showed that it was composed of gibbsite and hydrogarnet and contained also a very small amount of unhydrated

CA_2. The results of observation of this starting sample under SEM are presented on Figs 1 and 2, in which the crystals of hydrogarnet and the spherical agglomerates of platy crystals of gibbsite can be seen.

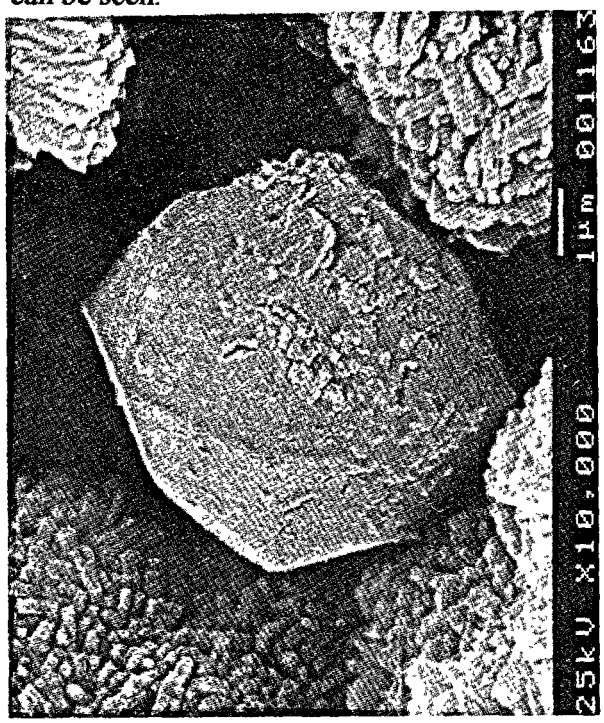

Figure 1 Starting paste. Crystal of hydrogarnet and agglomerates of platy crystals of gibbsite

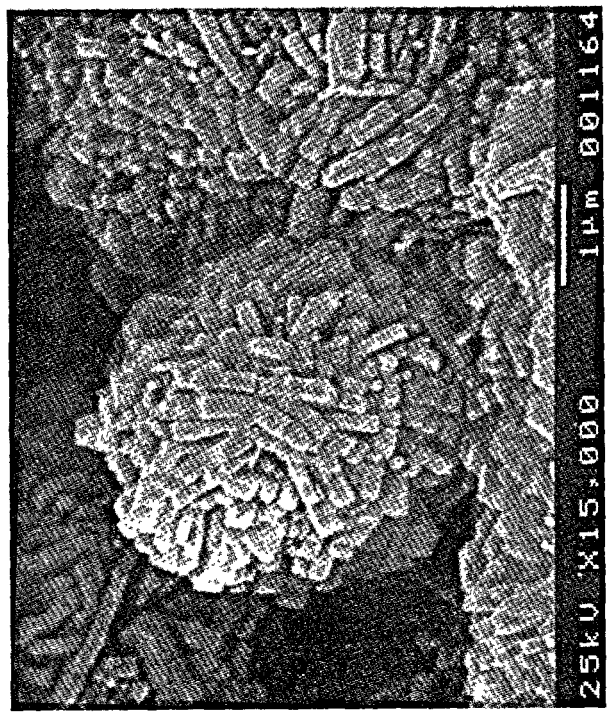

Figure 2 The agglomerates of gibbsite (the same as in Fig 1)

Table 1. Chemical composition of solutions

Solution	1	2	3
	Concentration in g/l		
$MgCl_2$	150	-	272
$CaCl_2$	-	175	164
NaCl	-	-	14
KCl	-	-	10
KBr	-	-	4

The elements of the paste of this composition were then immersed in three chloride solutions, namely: the solution of $MgCl_2$, the solution of $CaCl_2$ and, finally the solution imitating the salt mine water. The composition of these solutions are given in Table 1. For the sake of comparison one series of elements was stored in distilled water. After several days of immersion the change of phase composition of the samples was followed by X-ray, SEM and, for selected samples, also by DTA. In some cases the classical chemical analysis was also done.

EXAMINATION OF SAMPLES

The samples revealed expansion in all the solutions, which was the highest in the solution of $MgCl_2$ for 600 days. In this solution the expansion rises very quickly during the first 200 days, then quickly for 400 days. Then after 400 days a stabilisation of dimension of the samples is observed (Fig 3). In the salt mine water the change of dimension of the samples started with small shrinkage which was transformed into expansion after 30 days. The acceleration of expansion took place between 340 and 420 days. After this period the expansion became slow but took place till the last measurement after 762 days when it reached the highest value for all the

solutions. The expansion in the solution of $CaCl_2$ is relatively very small and reached about 2 mm/m after 762 days, and was about three times larger than in water.
The first examination of the phase composition of the samples took place after 200 days of immersion and then after 400 days and, finally, after 762 days. The X-ray examination of the samples immersed for 200 days in the salt mine water revealed the diminution of the intensity of lines of hydrogarnet and the appearance of the lines of Friedel salt. As another product of corrosion, the basic magnesium chloride $Mg_2(OH)_3Cl{\times}2H_2O$ gave strong peaks. The lines of gibbsite remained as strong as in the starting sample. The X-ray pattern of these samples after 400 days of immersion showed no substantial differences. All the time the peaks of hydrogarnet were present but evidently weaker, as well as strong lines of gibbsite. The lines of basic magnesium chlorides became stronger and new lines appeared, namely at 0.813, a diffuse band at 0.688÷0.641 and at 0.406. Also the increase of intensity of peaks of Friedel salt has to be noted. After 762 days of immersion the sample, according to the X-ray examination, was composed of gibbsite, Friedel salt and basic magnesium chloride. No lines of hydrogarnet could be found on the X-ray pattern.
The examination under SEM gave very similar results. A small quantity of basic calcium chloride was the only difference which can be found in the external layer of the sample (Fig 4). Also in the external part the platy crystals of basic magnesium chloride were abundant (Fig 5).
The phase composition of the samples immersed in the magnesium chloride solution was quite similar. In the function of time of immersion on the X-ray patterns the intensity of the lines of hydrogarnet decreased and these of gibbsite remained unchanged. As new formations, the peaks of Friedel salt and basic magnesium chloride appeared.

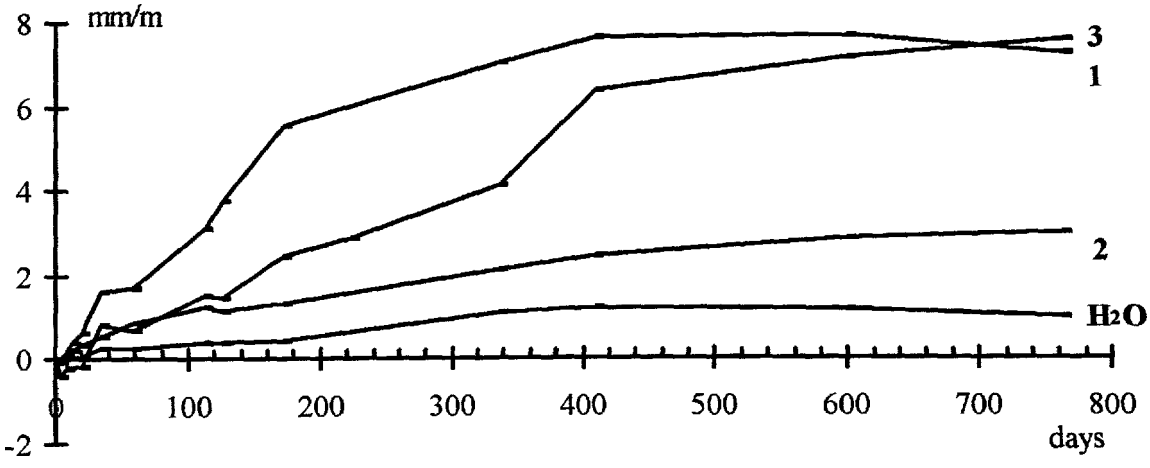

Figure 3 Expansion curves, the number of solutions as in Table 1

The smallest changes of phase composition were noted for the samples immersed in the solution of calcium chloride. Friedel salt is the only product of corrosion. It is preferentially formed in the outer layer of the sample, whereas the core remained unchanged. The porous region can be seen under the compact external layer (Fig 6) which is probably connected with the dissolution of hydrogarnet and the crystallisation of Friedel salt in the external layer. No basic calcium chloride could be found either by the X-ray examination or by the SEM observations.
The SEM examination after 762 days showed only very small quantity of hydrogarnet crystals with the corroded surface (Fig 7). Also the cracked crystal with the layer, probably of Friedel salt, was found (Fig 8). Very small hexagonal crystal of this phase can be seen under large magnification.

Figure 4 Crystals of basic calcium chloride, solution 3, 400 days of immersion

Figure 5 Crystals of basic magnes. chloride solution 3, 400 days of immersion

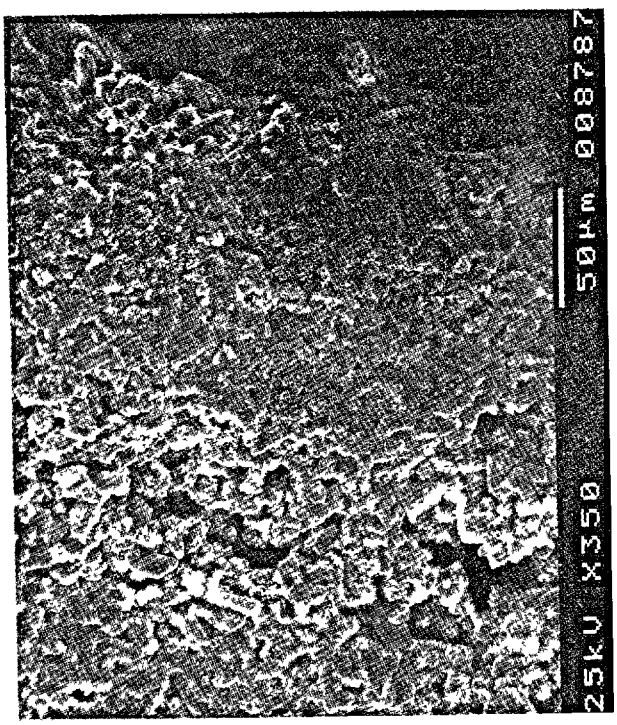

Figure 6 Three layers: external - compact, intermediate - porous and unchanged, solution 2, 400 days of immersion

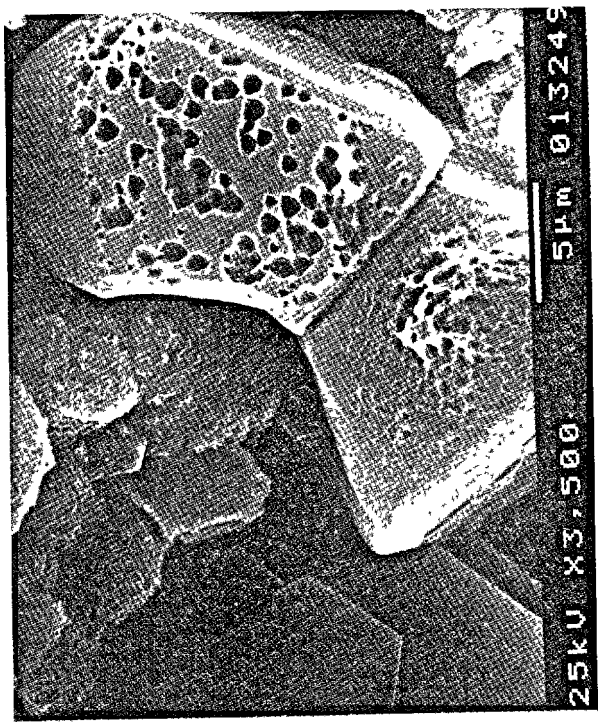

Figure 7 Corroded crystals of hydrogarnet, solution 2, 762 days of immersion

The chemical composition of the external layer of the sample (about 20% of total volume), obtained from the prism element by extracting the core, proves also the total decomposition of

hydrogarnet. This analysis is shown in Table 2 and when we compare with the calculated composition, according to the formula:

$$C_3AH_6 + CaCl_2 + 4H_2O \longrightarrow C_3A{\times}CaCl_2{\times}10H_2O \qquad [2]$$

we can see good conformity of both compositions. The only difference is in the lime content whose value found experimentally is too small. The excess of chlorine may depend on the adsorption of these ions by AH_3 gel.

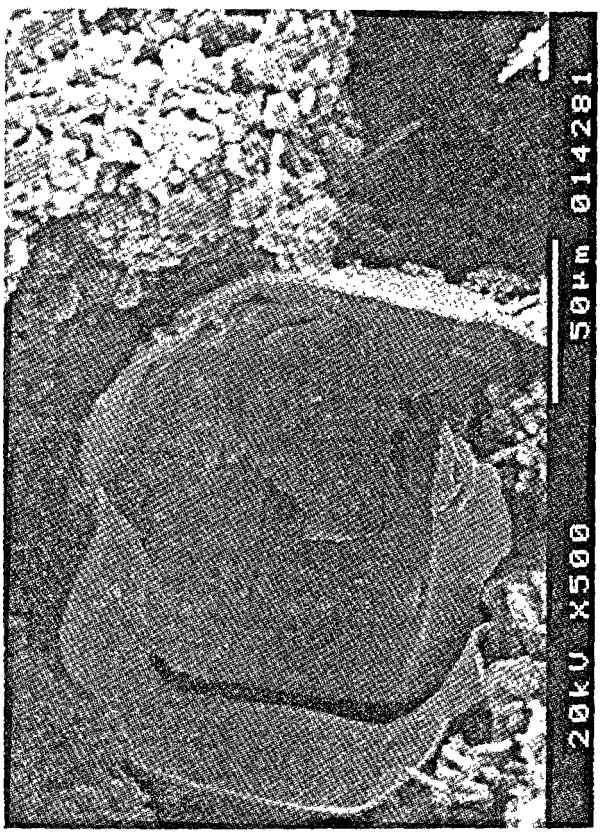

Figure 8 Cracked hydrogarnet crystal with of layer of Friedel salt on the surface, solution 2, 762 days of immersion

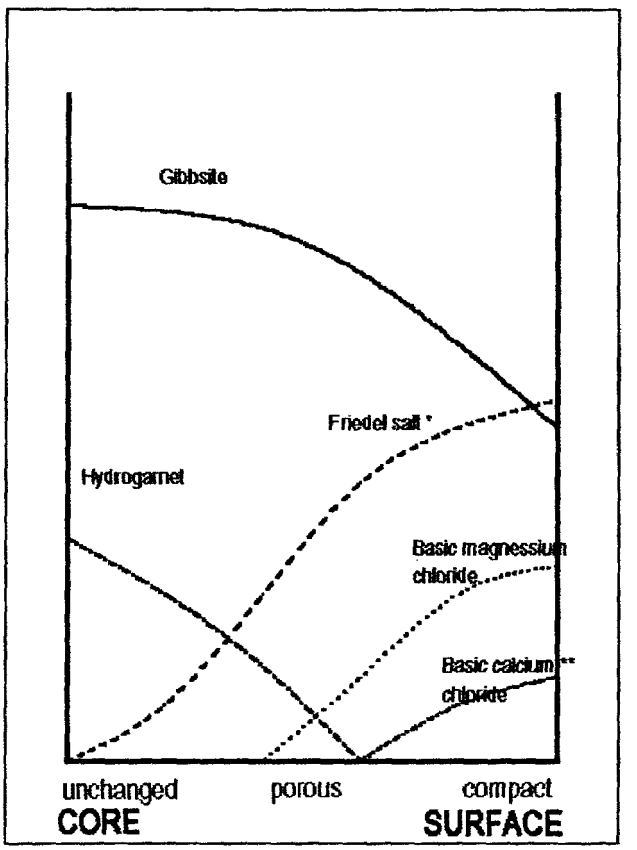

Figure 9 Model of phase composition of samples during corrosion
*) in case of solution 2 only Friedel salt
**) only in case of solution 3

The samples cured in water also show small changes in their phase composition. The intensity of hydrogarnet lines on the X-ray pattern became somewhat weaker and some lines of hexagonal hydrate C_4AH_{13} appeared. Doubtlessly, it is the product of the reaction of remaining CA_2 with water. This hydration process causes a small expansion of the elements cured in water.
The hydration process practically ended after 400 days which was expressed in the stabilisation of dimensions of the samples (Fig 3). Also under the influence on CO_2 from atmosphere the calcite crystals were formed which gave their peaks on X-ray diagram and which can be found with SEM and on the DTA curves (Fig 10).
As it can be seen on DTA curves (Figs 10 and 11), each sample contains some gel which may be principally AH_3 gel. This gel can be formed, among others, during the reaction of magnesium chloride with hydrogarnet:

$$4MgCl_2 + 1^2/_3\ C_3AH_6 \longrightarrow MgCl_2{\times}3Mg(OH)_2{\times}4H_2O + C_3A{\times}CaCl_2{\times}10H_2O + 1^1/_3\ AH_3 \qquad [3]$$

The presence of basic magnesium chloride gel in solutions containing magnesium chloride cannot be excluded, especially because in case of salt mine water this gel was found in the SEM observations.

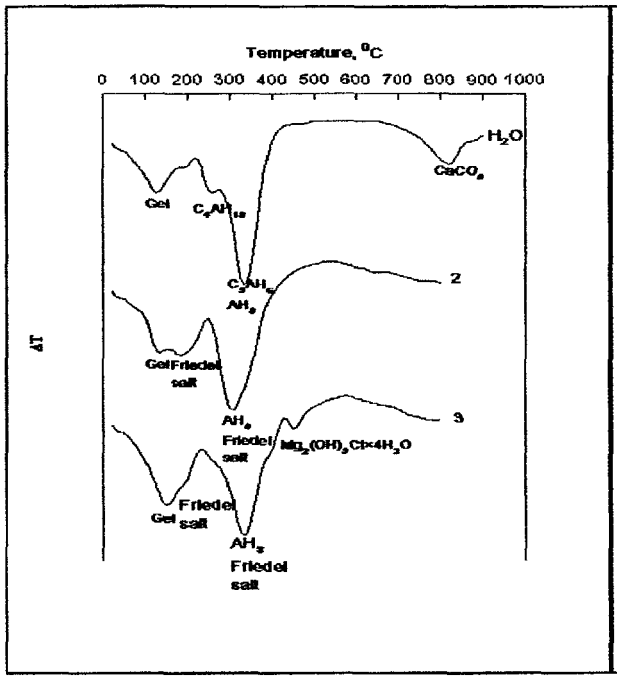

Figure 10 DTA curves, samples after 400 days of immersion, number of solutions as in Table 1

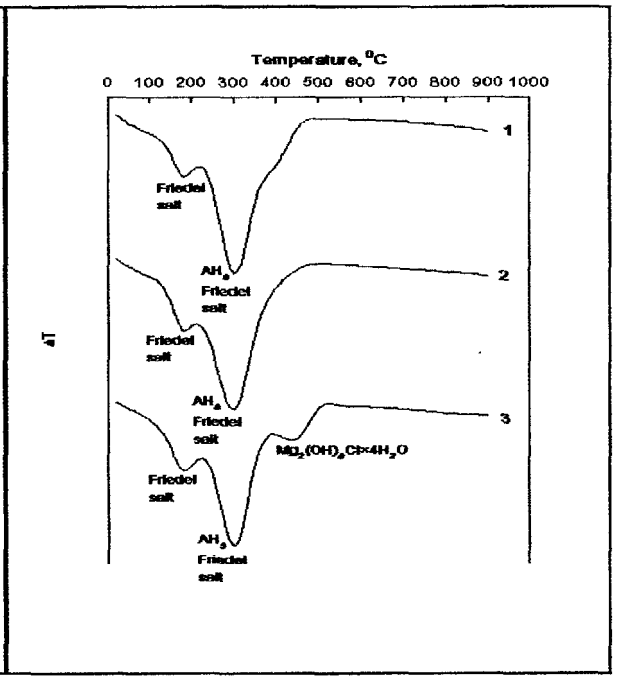

Figure 11 The same as in Fig 10 but after 762 days of immersion

Gibbsite and C_3AH_6 give the strongest peak at about 320°C and in case of samples immersed in chloride solutions this peak is also linked with the decomposition of Friedel salt.
Finally, for the sample cured in water, C_4AH_{13} gives a small peak at 240°C on the DTA curve and on the curve of the samples cured in solutions containing magnesium chloride basic magnesium chloride gives peak at about 440°C. The intensity of this peak is the highest for the sample cured in salt mine water after 762 days of immersion (Fig 11, curve 3) and much more weaker for the sample immersed in $MgCl_2$ solution (Fig 11, curve 1).

DISCUSSION OF THE RESULTS

In the paste gibbsite is stable in the chloride solution and hydrogarnet reacts with this solution giving new compounds which are: Friedel salt in all chloride solutions and basic magnesium chloride in salt mine water and $MgCl_2$ solution and, finally, basic calcium chloride in salt mine water. The formation of Friedel salt is accompanied by a very limited expansion so the paste will be rather stable in the $CaCl_2$ solution. The formation of basic magnesium chloride leads to a high expansion which must end with the destruction of the paste. The formation of basic calcium chloride was only found in salt mine water which contains a high concentration of both chlorides, i.e. of calcium and of magnesium.
Basing on the X-ray examinations and the SEM observation the model of phase composition and the microstructure of the samples can be presented (Fig 9). The external corroded layer is rather compact and contains all new phases, chiefly Friedel salt and basic magnesium chloride. Under the external layer comes a porous layer which is caused by dissolution of hydrogarnet.Gibbsite is the main phase in this region. Under the porous layer the microstructure is transformed gradually into an unchanged core, with small concentration of adsorbed chlorine. This higher content of

chlorine in the core as compared to magnesium is caused by much higher velocity of diffusion of Cl^- in comparison with magnesium (Ushiyama and Goto, 1974).

Table 2 Chemical analyses of external layer of samples after 762 days of immersion

Solution	Content in wt. %

3	7.1	9.0	44.1	13.3

*) calculated according to Eq 2

Several conclusions can be drawn from the chemical analysis shown in Table 2. It can be well seen that aluminium is not leached and its quantity remains stable in the samples and the Friedel salt is crystallised in the pores of the samples. The confirmation of this hypothesis can be found in the porosity measurements, executed for all samples after 762 days of immersion (Fig 12). This porosity is the highest for the sample cured in water. The sample immersed in salt mine water has the smallest total porosity. The samples immersed in magnesium and calcium chloride solutions have the same total porosity, yet the content of the big pores, between 100 and 2000 nm is the largest in case of the sample immersed in the calcium chloride solution.
On the contrary, lime is leached from the samples and this process is the most intensive in case of salt mine water.

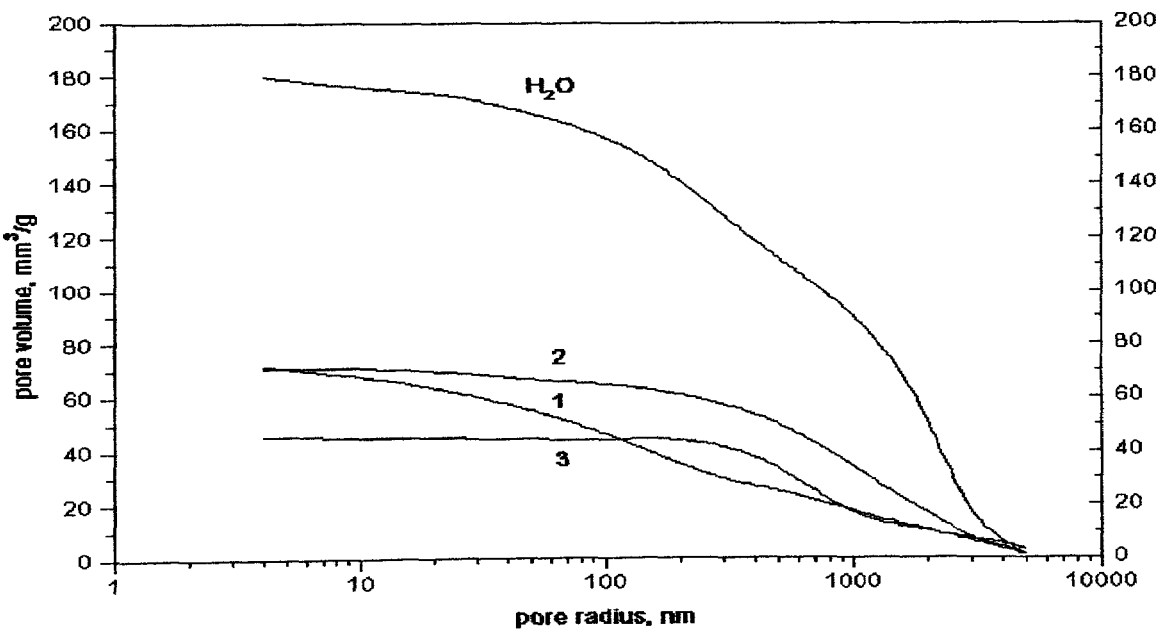

Figure 12 Porosity of samples immersed 762 days in chloride solutions, number of solutions as in Table 1.

The content of chlorine in the external layer of the samples depends strongly on the concentration of chlorine ions in the corrosive solution. In case of magnesium and calcium chloride solutions which are of equal ionic force the content of chlorine is practically the same.
In case of salt mine water whose ionic force is twice larger the content is also about twice the value for two other solutions.

When we compare the corrosion process of the HAC cement (Kurdowski et al., 1990) with the gibbsite/hydrogarnet paste, we can see substantial differences. In case of the HAC paste the skin is formed on the surface of the samples and this skin is composed of brucite and basic magnesium chloride. In case of gibbsite/hydrogarnet paste we did not observe the skin formation and we did not find brucite.
This behaviour is due to the differences of the microstructure of the paste. In case of the HAC paste we have a very dense microstructure with an amorphous AH_3 gel. The densification of the gel, accompanied by shrinkage, causes strong decrease of porosity of the external layer of the paste. Also the skin, when stable, can be regarded as a protecting barrier. In our samples, which are much more crystalline, the shrinkage is very limited and took place only in case of elements immersed in salt mine water (Fig. 3). The diffusion of chlorine and magnesium ions is much quicker in case of the gibbsite/hydrogarnet paste. However, because of the durability of gibbsite phase, the corrosion is limited and the destruction of the paste is slow. The skin is not formed because the simultaneous diffusion of magnesium and chlorine prevails over the countercurrent diffusion of Cl^- and OH^- ions.

CONCLUSIONS

1. Basic magnesium chloride is the main corrosion product in chloride solutions with magnesium ions and the largest expansion of the paste is connected with the formation of this phase.
2. The calcium chloride solution causes only the transformation of hydrogarnet into Friedel salt which is accompanied by a small expansion of the paste.
3. Gibbsite is stable in magnesium and calcium chloride solutions
4. In case of solution containing magnesium and calcium chlorides simultaneously, the basic calcium chloride is also formed
5.The investigation of paste rich in gibbsite proves that HAC will be not destroyed in calcium chloride solution

RESISTANCE TO CHEMICAL ATTACK OF HIGH PERFORMANCE FKJ CONCRETE *

LU Changgao, LI Ruihua, Suzhou Concrete and Cement Products Research Instiute State Adiministration of Building Materials Industry, 215004, P. R. CHINA

ABSTRACT In this paper, the study of the resistance of high performance fly ash slag-alkali concrete (namely FKJ * * Concrete) to chemical attack and durability in the H_2SO_4, HCl, HNO_3, NaCl, $MgCl_2$, Na_2SO_4 solutions, seawater etc attack agents as well as in the atmosphere are highlighted respectively. Simultaneously, the mechanism of resistance of FKJ concrete to chemical attack and its suitable application scope are also advanced.

Key – Words: Alkali, Chemical Attack, Corrosion, Mineral phase, Zeolites.

INTRODUCTION

On the basis of the author's inventive pantent(Lu, 1988), the high performance of FKJ concrete is the scientific research achievements we have contributed to for many years. Nowadays, we have developed FKJ corrosion resistance sewer pipe which was used in sewer pipeline systems of Shanghai Municipal Engineering and Chemical plant. In order to fully understand the resistance ability of FKJ concrete to chemical corrosion, we have carried out the study of its resistance to the above acids, alkalis, salts, seawater as well as in the atmosphere in recent years. On the one hand, by means of macroscopic tests of corrosion resistance for FKJ concrete, We get the understanding of its corrosion resistance degree and work out the suitable application scope of FKJ concrete by combining safety and reliability of its application in an engineering project. On the other hand, by means of microscopic analysis (including X – Ray, SEM, EDAX and po ım
such as ıa-
nism o

THE STRENGTH DEVELOPMENT AND LONG – TERM STABILITY OF FKJ CONCRETE UNDER AMBIENT TEMPERATURE

The mortar specimens and concrete specimens are exposed to naturel curing(atmosphere in a room). The strength development and long-term stability are shown in Fig 1. It can be seen from the curves that the FKJ concrete is featured with early strength. Their R_{1d} strength of it under ambient temperature is more

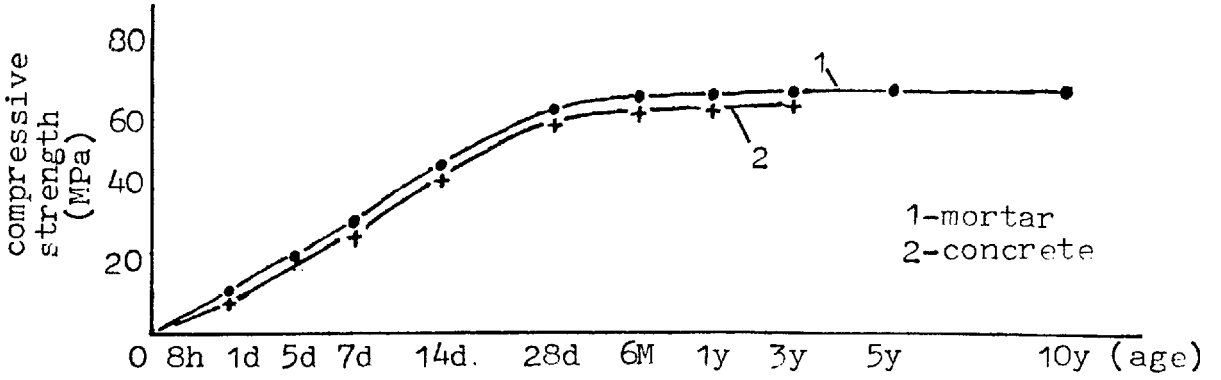

Fig 1 The strength development and long-term stability of FKJ concrete under conditions of ambient temperature.

* This is the aid financil project of national science foundation of China.

* * FKJ refers to the abbreviation of Chinese spelling.

than 10MPa, their R_{28d} strength is more than 55MPa. It is indicated from the data determined in 1, 3, 5, 10 years that the strength of FKJ concrete is slightly increased. which means that mineral phase formed is stable and has fine resistance to weathering(Lu, 1995).

THE RESISTANCE OF FKJ CONCRETE TO ACIDS

According to our analysis, the main mineral phase of FKJ binder is silicoaluminate of Zeolite type and we think the sodium silicoaluminate hydrate of analcite type is the main mineral phase in the system. The fine resistance to chemical corrosion of FKJ concrete is due to the existance of this mineral. viewing from the characteristic of natural zeolite, it is featured with strong acid resistance. After natural zeolite is treated with 2N, 4N, 6N HCl for 2 hours under 90℃, no corrosion failure phenomenon is shown in the crystal structure(Lu, 1994).

Futhermore, we carried out acceleration acid resistance testing for FKJ mortar specimens, that is, immersing and bathing the specimens into 6N HCl solution, heating them up to 90℃ and keeping this for 2 hours, no chemical reaction can be observed during testing. The strength of specimens after testing remained 50. 6MPa, without any decreasing. Whereas the ordinary blastfurnace slag cement mortar specimens(1:3 cement mortar) with oringinal strength of 30 MPa treated with the similar way was severely corroded and pulverized. measured remaining strength of specimens was less than 3 MPa.

In order to highlight the acid resistance degree of FKJ concrete, three strong acids commonly used (H_2SO_4, HCl, HNO_3) were selected as the attack medium and four different concentration were used, which the PH = 2 acidity was chosen in account of the application of a project. During the tests, their acidities were adjusted regularly. The testing results are shown in Table 1. It must be indicated that the ordinary concrete specimens were severely corroded in chemical reaction under the action of strong acid

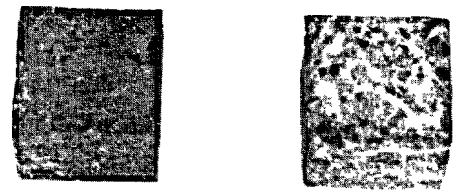

Table 1 The testing results of acid resistance of FKJ concrete

type of medium name	corrosive acidity	age (day)	after corrosion strength (MPa)	apperance	strength of compara. (MPa)	coeffi. of corr. resista.
H_2SO_4	2%	365	39.3	microcrack	57.0	0.69
	1%	365	52.5	fine	57.0	0.92
	0.5%	365	57.1	fine	57.0	1.00
	PH=2	365	62.0	fine	64.3	0.96
HNO_3	10%	365	44.0	fine	57.0	0.77
	5%	365	54.7	fine	57.0	0.96
	1%	365	58.0	fine	57.0	1.02
	PH=2	365	67.0	fine	64.3	1.04
HCl	10%	365	30.7	fine	57.0	0.54
	5%	365	47.6	fine	57.0	0.84
	1%	365	57.3	fine	57.0	1.01
	PH=2	365	62.3	fine	64.3	0.97
H_2SO_4 + HNO_3 + HCl mixed acid	10%	365	32.3	microcrack	57.0	0.57
	5%	365	47.8	fine	57.0	0.84
	1%	365	56.5	fine	57.0	0.99
	PH=2	365	65.3	fine	64.3	1.02

with high concentration(>2%), those specimens were obviously destroyed after testing.

It can be seen from the testng results in Table 1 that the corrosion degrees of specimens to the different acids are dissimilar. The corrosion resistance of specimens to H_2SO_4 and mixed acid with high concentration is relatively poor. Nevertheless, we think if the corrosion resistance coefficient of the specimens to acids after tested for one year is bigger than 0.8, then their corrosion resistance to acid is up to standard. Therefore, the limit of resistance of FKJ concrete to acid is as follows: H_2SO_4—1%, HNO_3—5%, HCl—5%, mixed acid—5%.

In order to incorporate its application with an engineering project and compare it with ordinary concrete, we put FKJ concrete specimens and ordinary concrete (OPC) specimens into (H_2SO_4 + HCl + HNO_3) mixed acid solution of PH = 2. After 1 year the strength of OPC specimens decreased by 43% (from 59.0 MPa down to 34.0MPa) and it was severely corroded; while the strength of FKJ specimens did not decrease (from 64.3MPa up to 65.3MPa) and apperance is fine, as shown in Fig 2. Consequently, the test indicated that the resistance to acid of the FKJ concrete is fine and greatly exceeds that of the ordinary concrete, increased about 20 – 30 times.

FKJ OPC

Fig 2 The Specimen apperance in mixed acid solution of the PH = 2 (H_2SO_4 + HCl + HNO_3) after 1 year.

THE RESISTANCE OF FKJ CONCRETE TO ALKALI

We put FKJ concrete specimens into 10%, 5%, 1% and NaOH with PH = 13 and $Ca(OH)_2$ dense solution respectively, the reason we selected PH = 13 alkality was in account of its application of a project. The testing results of specimens after 1 year are shown in Table 2. It can be seen from testing results

Table 2 the testing results of resistance to alkali of FKJ concrete

type of medium name	corrosive alkality	age (day)	after corrosion strength (MPa)	apperance	strength of compara. (MPa)	coeffi. of corr. resista.
NaOH solution	10%	365	33.5	microcrack	64.3	0.52
	5%	365	54.0	fine	64.3	0.84
	1%	365	65.0	fine	64.3	1.01
	PH = 13	365	65.2	fine	64.3	1.01
Lime solution	PH = 13	365	63.7	fine	64.3	0.99

that the corrosion resistance of specimens to NaOH solution with high concentration is relatively poor. we think that if the coefficient of corrosion resistance of the specimen to alkali is greater than 0.80 after 1 year, its corrosion resistance to alkali is up to standard. Therefore, the limit of resistance of FKJ concrete to alkali (NaOH) is 5%, its alkaline resistance is similar to that of the ordinary pordland cement concrete.

THE CORROSION RESISTANCE OF FKJ CONCRETE TO SALTS

We put the FKJ mortar specimens into seawater, $MgCl_2$ solution with 25 – 30° Be', NaCl solution with 26%, (NaCl + $MgCl_2$) mixed silution with 25% and pure chemical $Na_2SO_4 \cdot 10H_2O$(the concentration of sulfate ion in solution is 2500mg/1) respectively. The testing results are shown in Table 3. It can be seen from the testing results that the corrosion resistance of FKJ specimens is strong, no matter they were put into seawater, $MgCl_2$, NaCl, NaCl + $MgCl_2$ mixed solution or $Na_2SO_4 \cdot 10H_2O$ solution after

immersed for three years, their appearance remained fine and the strength were not decreased, but increasing a bit. Their coefficient of corrosion resistance are more than or equal to 1.

Table 3 The testing results of resistance to salts of FKJ mortar specimens.

type of medium name	corrosive concentra.	age (year)	after strength (MPa)	corrosion apperance	strength of compara. (MPa)	coeffi. of corr. resista.
seawater	manual preparation	1	54.0	fine	52.5	1.03
		3	57.9	fine	54.6	1.06

		3	54.6	fine	54.6	1.00
Na_2SO_4 solution	2500mg/1	1	53.1	fine	52.5	1.00
		3	59.3	fine	54.6	1.00
NaCl solution	26%	1	53.6	fine	51.5	1.04
NaCl + $MgCl_2$ mix. solu.	25%	1	55.2	fine	51.5	1.07

THE REINFORCEMENT PROTECTION PROPERTY OF THE FKJ CONCRETE

In the corrosion tests of above acids, akalis, salts, ø6 × 20mm reinforcements were put in the FKJ specimens. After the specimens were cut apart, all cover of concrete protecting reinforcement was more than 5mm, the reinforcement surfaces were not rusted, so their reinforcement protection property is fine.

THE MECHANISM OF RESISTANCE OF FKJ CONCRETE TO CHEMICAL CORROSION

Microstructural aspects of the hardened FKJ binder paste

The FKJ binder is a new type of non-clinker cement which was worked out by author according to mineralization conditions of natural zeolite mineral. Based on our research and determination, in the FKJ binder the main hydrate products and mineral phases possibly produced are sodium silicoaluminate hydrate of analcite type; the secondary products are calcium silicoaluminate hydrate of scolecite type and sodium-calcium-silicoaluminate hydrate of thomsonite type, meanwhile a small amount of low-alkaline calcium silicate hydrate are also produced(Lu, 1992).

Author consider that the reason why the FKJ binder concrete has fine durability and resistance to chemical attack is due to its relation to the microstructure of its silicon(aluminium)-oxygen tetrahedron. For instance, the sodium-silicoaluminate hydrate of analcite type forms tetrogon-triakisoctahedron crystal, the pore passage in silicon(aluminium)-oxygen crystal lattice mainly consist of hexatomic ring. It forms one-dimensional tube pore pasage, pore diameter is about 2. 6Å and unifmly distributed. Its crystal lattice energy is higher (21214.4KJ/mol), while its solubleness is lower (about 0.02 Kg/m^3). Therefore, its this one mineral phase and microstructure that determines a series of fine characteristics, specially its stronger resistance to chemical corrosion.

Pore structure of the hardened FKJ binder paste

It's well known that many big or small pores are distributed in concrete. By means of changing pore-size distribution in the concrete (specially in the cement paste), some of characteristics of concrete can be improved (Ramachandran et al, 1981) The pore-size distribution of the hardened FKJ binder paste were determined by using mercury porosimetry, as shown in Table 4. It can be seen from the values in Table 4

Table 4 The pore-size distribution of the hardened FKJ binder paste

w/c	total pore (cc/g)	pore-size distribution (%)			
		$>14^4$Å	10^4-10^3Å	10^3-10^2Å	$<10^2$Å
0.4	0.1184	6.0	36.5	18.0	39.5

that there are many <100Å pore-size distribution(amount up to 39.5%), which more than the hardened OPC paste, usually its pore-size distribution of the <100Å is about 20% (w/c=0.4). These pores are not only non-harmful but also can increase the impermeability of concrete. So from the viewpoit of pore structure, the resistance to chemical attack of FKJ concrete is strengthened.

The mechanism of resistance of FKJ concrete to acids

It's well known that acid attack to ordinary concrete is the most serious corrosion among the different corrosion types. Normally, in the acidic environment (PH≤6.5), ordinary cement concrete is unstable

Fig 5 The EDAX of FKJ binder specimen.

on the thermodynamics and may be corrosively damaged sooner o later (Knofel, 1978). However, the degree of resistance to acid of the FKJ concrete is stronger. We put FKJ binder paste specimen into 5% (H_2SO_4 + HCl + HNO_3) mixed acid solution after one year, we carried out X－Ray, SEM and EDAX examination respectively, as shown in Fig 3, 4, 5 and in Table 5. By comparing Fig 3 and Table 5, it can be seen that in FKJ system the sodium-silicoaluminate hydrate of analcite type remained existing without being corroded ($2\theta = 16.51, 26.35, 29.25$; correspondently $d = 5.36, 3.38, 3.05$Å). Its crystal form (Fig 4) is complete and the element quantity of EDAX is also correct (Fig 5).

But, the calcium silicate hydrate in the FKJ system was basically corroded. Its chemical corrosion reaction are as follows:

$$2CaO \cdot SiO_2 \cdot nH_2O + 4HCl \rightarrow 2CaCl_2 + SiO_2 + (n+2)H_2O;$$
$$2CaO \cdot SiO_2 \cdot nH_2O + 2H_2SO_4 \rightarrow 2CaSO_4 + SiO_2 + (n+2)H_2O,$$
$$CaSO_4 + 2H_2O \rightarrow CaSO_4 \cdot 2H_2O;$$
$$2CaO \cdot SiO_2 \cdot nH_2O + 4HNO_3 \rightarrow 2Ca(NO_3)_2 + SiO_2 + (n+2)H_2O;$$

Among which the $CaCl_2$ and $Ca(NO_3)_2$ products were dissolved, while the $CaSO_4 \cdot 2H_2O$ products were not dissolved and remaining in the body, as well as the silicon gel produced also remaining in the body. In the recorded diffracto-spectrogram (Fig 3, Table 5), $d = 7.52, 4.26, 3.33$Å, it belongs to gypsum; $d = 2.20, 1.99, 1.52$Å, it belongs to silicon gel.

Increasing acidity, means increasing H^+ ion concentration in the system, its damaging intensity to the FKJ binder is strengthened. It can be seen from testing results (Table 1) that when the concentration of acid was increased from 5% to 10%, after one year, the crystal lattice of the silicoaluminate hydrate of zeolite type begun to corrode.

It must be pointed out that in the 2% concentration of H_2SO_4 solution although the silicoaluminate hydrate of zeolite type was not corrosively damaged, but since the calcium silicate hydrate was corrosively damaged, producing more expansive salts (gypsum) and leading to the expansive corrosion of sulphate. Therefore, the resistance to sulfuric acid of FKJ concrete is lower, its limit only 1%.

The mechanism of resistance of FKJ concrete to alkalis

It can be seen from the data in Table 2 that the limit of resistance of FKJ concrete to alkali (NaOH) is 5%. Increasing from 5% to 10% , its resistance to alkali is not up to standard. Therefore, FKJ binder was attacked by the concentrated solution of alkali. Its attack mechanism is as follows:

As the FKJ specimens were corroded by high concentration of NaOH solution for a long time. part of sodium silicoaluminate hydrate of analcite type was corrosively changed into the sodium zeolite ($Na_2O \cdot Al_2O_3 \cdot 3SiO_2 \cdot 7H_2O$), and in the X-Ray diffracto-spectrogram (Fig 6 and Table 6): d = 14.36, 8.76, 5.71Å. It can be seen from the SEM crystal morphology in Fig 7 that it formed fibrous cluster crystal, and intergrowth with the sodium silicoaluminate hydrate of analcite type. Fig 8 shows the results of EDAX of this micro area. Its summary of element concentration (weight %) conforms to the actual situation. In

Fig 8 The EDAX of FKJ binder specimen.

the process of corrosive change, the crystal lattice is rearranged, forming internal stress in the structure, Hence the whole strength of the system is weakened.

The alkaline solution can reacts with calcium silicate hydrate to form products which poor cementing power and easily separating out by alkaline solution:

$$2CaO \cdot SiO_2 \cdot nH_2O + 2NaOH \rightarrow 2Ca(OH)_2 + Na_2SiO_3 + mH_2O.$$

Similar to the ordinary concrete, when the alkaline solution permeates into the pores of FKJ concrete, it reacts with CO_2 in atmosphere to form $Na_2CO_3 \cdot 10H_2O$ crystal. Its volume is 2.5 times bigger than the original sodium hydroxide. Therefore, producing greater crystallization pressure and leads to the damage of cement stone structure.

The mechanism of resistance of FKJ concrete to salts.

It can be seen from Table 3 that the resistance of FKJ concrete to salts is fine. Its corrosion resistance mechanism is as follows:

The ordinary concrete contains more $Ca(OH)_2$, whereas the FKJ concrete almost does not contain $Ca(OH)_2$, which blocks the source of the corrosion.

The ordinary concrete contains a number of calcium aluminate hydrate which can corrosively reacts with sulphate. However , the FKJ concrete does not exist this hydrate products which blocks the source of the corrosion.

Part of calcium silicate hydrate is included in FKJ system, though magnisum sulphate in seawater can corrosively react with it:

$$2CaO \cdot SiO_2 \cdot nH_2O + MgSO_4 \cdot aq \rightarrow CaSO_4 \cdot 2H_2O + Mg(OH)_2 + SiO_2 \cdot aq.$$

As the amount of this product is quite less, so unfavorable effect to the system will not be occurred.

SUITABLE APPLICATION SCOPE OF FKJ CONCRETE

we think that the resistances of FKJ concrete to acids and alkalis are the two important aspects in the corrosion resistance and also the criterion to decide its application scope of FKJ concrete. According to our research results and practical conditions of engineering application in concerning the safety of its application in an engineering project, we think FKJ concrete is suitable to be used in the corrosion resistance constructional engineering project with PH = 2 – 13 (including the urban corrosion protection sewer pipeline, the concrete structures in saline-alkali zone and marine structure etc).

ABSTRACT The third cement series (TCS) comprises cement clinkers identified by their content of $C_4A_3\bar{S}$ and giving ettringite in hardened pastes. In this paper, we essentially discussed TCS' outstanding durability performances, such as the long-term strength, permeability, anti-freezing, thermostability and the resistance to chemicalattack, carbonation, rusting and alkali-aggregate reaction, etc., according to over 20 year of experience in China.

Key-words : durability, sulfoaluminate, ferroaluminate

INTRODUCTION

Sulpho-aluminate cements (SAC) and Ferro-aluminate cements (FAC) are two new cement series developed by China Building Materials Academy (CBMA). These two cement series were formally put into industrial-scale production in 1974 and 1983 respectively and the Chinese standards for SAC and FAC were issued in 1987 and 1991.

Due to the similarities in the principal minerals in clinkers, in the major hydrates and in the performances, SAC and FAC are called by a joint name -- the third cement series (TCS), to be distinguished from ordinary Portland cement (OPC) and calcium aluminate cement (CAC), which may be named as the first cement series and the second cement series, respectively.

TCS is a type of hydraulic cement made by heating mixtures of limestone, bauxite and calcium sulfate up to a temperature of about 1325℃with one more form of calcium sulfate added during grinding. TCS can be classified by performance into five main types as rapid-hardening cement, high-strength cement, expansive cement, self-stressing cement and low-alkalinity cement.

With major content of $C_4A_3\bar{S}$ and/or C_4AF in clinker, TCS was sharply distinguished from the other two main cement series, OPC and CAC. For the same reason, TCS was found to have low energy-consumption in cement manufacture. It was also found to have many other advantages, for example, high early strength, good impermeability, good freezing-resistance, outstanding chemical corrosion resistance, satisfactory strength development and low-temperature application, low dry-shrinkage and low alkalinity of its hydration solution, etc.

After more than 20 years of industrial production and development, annual output of TCS has reached 800,000 tones in 1995 and will be over 1.5 million tones at 2005 in China. TCS had been successfully used in a wide range of general and specialized applications, such as winter construction, underground structure, marine construction, corrosion-resisting application and in production of a wide range of building elements.

An increasing importance has been attaching to the durability of TCS along with the expansion of its application area, especially increasing concrete strengths (the strength of cast-in-place concrete has reached 80 MPa). As the durability of concrete is very complicated, each application has different

Table 1 Mineral compositions of the third cement series clinker

	$C_4A_3\bar{S}$	C_2S	C_6AF_2 (C_4AF)
SAC clinker	50-70%	10-25%	3-10%
FAC clinker	45-60%	10-20%	15-25%

requirements. To answer all the question about the durability of TCS, a relatively new cement series, a series of researches have been and will be done for each type of the in each application. This paper focuses on only two types of TCS, rapid-hardening and expansive cements. Some initial results are reported.

MANUFACTURE OF TCS RAPID-HARDENING AND EXPANSIVE CEMENTS

Rapid-hardening and expansive TCS cements are produced by pulverizing respectively by SAC and FAC clinker consisting essentially of $C_4A_3\bar{S}$, C_2S and C_6AF_2 (or C_4AF), usually containing gypsum and limestone as interground additions. The amount of gypsum added for rapid-hardening cement is about 10-15%, but for expansive cement it is about 20-25%. The typical mineral constituents of the two clinkers are shown in Table 1.

Comparing the two, there is a notable difference in the ratio of $C_4A_3\bar{S}$ to C_6AF_2 (or C_4AF). Since the hydraulic minerals in SAC and FAC clinkers are similar, the two cements have similar hydration products, mainly AFt, AFm, (mostly present in rapid-hardening cement), C-S-H gel, aluminum oxide gel and iron oxide gel (mainly present in FAC cement). TCS performance and its hardened paste structures differ considerably from those of OPC and CAC.

PRINCIPAL SPECIFICATIONS FOR TCS RAPID-HARDENING AND EXPANSIVE CEMENTS

Physical properties

Under the Chinese Standard (ZB Q11005-87, JC435-91), the standard strength of TCS rapid-hardening cement is the compressive strength determined according to GB177-85 (Standard Test Method for Strength of Hydraulic Cement Mortars) at 3 days. Three classes of standard strength for the commercial products are covered: Class 425, Class 525 and Class 625, shown in Table 1 and Table 2.

The commercial TCS expansive cements are categorized as mini-expansive and expansive cements according to unrestrained mortar expansivity under Chinese standard ZB Q11007-87 and JC436-91. Only one class of the expansive cement is commercially available at present, Class 525, which standard strength is determined at 28 days (Table 3). TCS expansive cements have a relatively high early strength, especially for mini-expansive types.

Minimum W/C ratio for complete hydration

Compared with OPC, TCS paste has a comparatively high minimum W/C ratio for complete hydration. The principal hydration products of hydrated TCS are $C_3A \cdot 3C\bar{S} \cdot 32H$ (AFt), $C_3A \cdot C\bar{S} \cdot 12H$ (AFm), AH_3 gel, and FH_3 gel; all have fairly high levels of chemically bound water. According to a theoretical calculation the non-evaporable water per unit mass of cement of a fully hydrated paste for TCS rapid-hardening and mini-expansive types is in the range of 0.40-0.45; the typical value for OPC is only about 0.23-0.24. Comparing TCS and OPC concretes if the amount of water is fixed to constant slump, quantity of chemically bound water for TCS is much higher than for OPC, whereas

Table 2 Physical and mechanical indexes of the rapid hardening cement

Clinker	Class	Setting time	Compressive strength (MPa)			Flexural strength (MPa)		
			12h	1d	3d	12h	1d	3d
SAC	425#	Initial ≤25min	29.4	34.4	41.7	5.9	6.4	6.9
	525#	Final ≥180min	36.8	44.1	51.5	6.4	6.9	7.4
	625#		39.2	51.5	61.3	6.9	7.4	7.8
			1d	3d	28d	1d	3d	28d
FAC	425#	Initial ≤25min	34.5	42.5	49.0	5.9	6.4	6.9
	525#	Final ≥180min	44.0	52.5	59.0	6.9	7.4	7.8

Table 3 Physical and mechanical indexes of the expansive cement (Strength: MPa)

Clinker	Class	Setting time	Comp. strength			Flex. strength			Free expansion ratio	
			1d	3d	28d	1d	3d	28d	1d	28d
SAC	Mini-expansive	Initial ≤30min	31.5	41.0	52.5	4.9	5.9	6.9	≤0.05%	≥0.5%
	Expansive	Final ≥180min	27.5	39.2	51.5	4.4	5.4	6.4	≤0.10%	≥1.00%
FAC	425#	Initial ≤30min	31.5	41.0	52.5	4.9	5.9	6.9	≤0.05%	≥.0.5%
	525#	Final ≥180min	27.5	39.2	51.5	4.4	5.4	6.4	≤0.10%	≥1.00%

the evaporable water for TCS was obviously less than for OPC. This is one of the main reason why TCS has relatively lower porosity than OPC and why TCS concrete has excellent impermeability, carbonation resistance, freeze-thaw resistance and high resistance to many forms of chemical attack.

Evolution of hydration heat

The total quantity of heat evolved by TCS rapid-hardening cement and expansive cement at 7days (when most of hydration is finished) is typically 190-210 kJ/kg, somewhat less than ordinary Portland cement (400-480 kJ/kg) and calcium aluminate cement (325-400 kJ/kg), but due to the speed of the reaction, nearly all this heat is produced within 24 hours, as shown in Figure1.

This special feature of heat evolution on hydration gives TCS rapid-hardening cement a very useful advantage — so call "self-steam curing". Therefore, the steam curing procedure sometimes used in concrete work may be omitted, with decreased energy consumption. On the other hand, TCS is suitable for low temperature. It can concreted as usual at subzero temperature (0℃ to -25℃) by adding an appropriate amount of anti-freezing agent and adopting some simple heat loss prevention measures, for its 3 days strength can reach 80% of its ultimate strength. In massive concrete construction, special attention should be attached to the absolute temperature rise inside the structure and the temperature gradient between the structure and ambient conditions. If the difference exceeds 20℃, thermal cracking may occur and if the absolute temperature exceeds 100℃, the expansion produced upon cooling by ettringite reformation causes the concrete to crack. Thus temperature effects could lead to serious deterioration of TCS concrete.

Pore structure of the hardened cement paste

The pore structures for rapid-hardening cement and expansive cement are quite different from those of

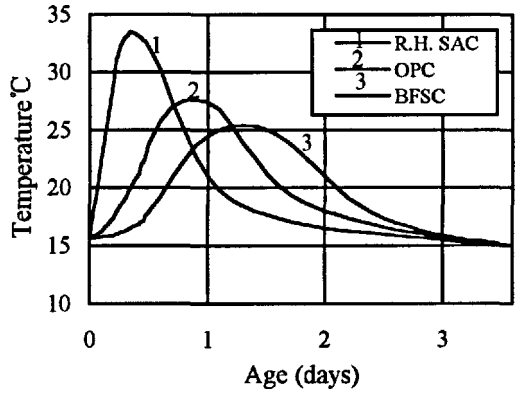

Fig. 1 The heat evolution on hydration for rapid-hardening SAC. (R.H SAC — Rapid-hardening Sulfo-aluminate cement; BFSC — Blast furnace slag cement. The results are tested according to the Chinese Standards concerned)

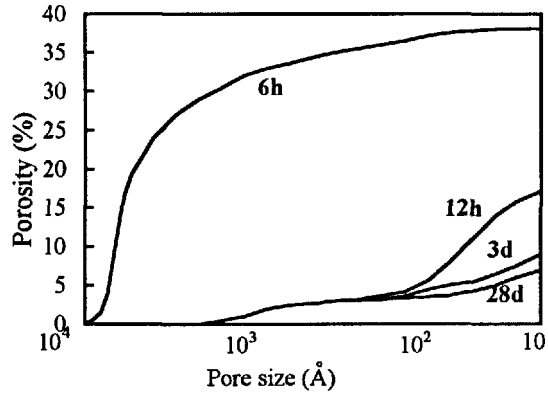

Fig. 2 The general porosity of TCS paste, w/c = 0.30, ambient temperature, the specimens were continuously evacuated to the constant weight at 100-160 mmHg.

50-25 Å	0.0036	8.64	0.0056	11.39	0.0101	36.95
Total porosity	0.0417		0.0492		0.0295	
Position of peak (Å)	458		246		<25	

OPC. Mercury intrusion porosimetry (MIP) results are shown in Table 4, for 1:1 mortar under uniaxial restraint. According to MIP results and other from helium pyknometry, pore structures of TCS rapid-hardening cement and expansive cement have the following features:

(1)The total pore volume for TCS is significantly lower than for OPC (see Table 4).

(2)The average pore radius is relatively small: most are less than 300 (see Figure 2) and the maximum-lickhood of pore radius less than 25Å (Table 4).

(3)The morphology of most pores had an ink-bottle sharp.

These features contributed to the performances of TCS concrete, notably to freezing resistance, impermeability, corrosion resistance, anti-carbonization and reduced dry-shrinkage, etc. All these advantages will be beneficial to durability.

Table 5 Strength development of the FAC and OPC concretes

Cement	Comp. strength(MPa)/Ratio to the 28 days' strengths				
	0.5d	1d	3d	28d	180d
525# rapid-hardening FAC	20.0/0.38	36.0/0.60	51.6/0.86	60.3/1	68.5/1.14

Compressive strength	44.6	61.9	69.2	80.7	81.0
Splitting strength	2.85	4.24	5.38		5.74
Flexural strength		7.23	8.70		8.81

Note: ZB-1 is a kind of compounded superplasticiser specially used for adding in TSC concretes to reduce water and control their setting time and workable time. It is a proprietary product.

MAJOR PROPERTIES INVOLVED WITH TCS CONCRETE DURABILITY

Physical properties for TCS rapid-hardening cement and its concrete

The development of strength of Class 525 TCS rapid-hardening and Class 525 OPC are compared in Table 5, and splitting and bending strengths in Table 6. The early strengths of TCS were higher and the splitting and bending strengths for TCS concrete grew in pace with its curing time and compressive strength.

Impermeability of TCS concrete

As mentioned above, the evaporable water in TCS, rapid-hardening and expansive, are less than in OPC, so the former were more dense than OPC. Therefore, it was found that the former had better impermeability, especially the mild-expansive concrete; results are shown in Table 7 and 8. This advantage is believed to be of benefit to resist corrosion of embedded steel reinforcement in the concrete and to improve the durability.

Freezing-thaw resistance

TCS rapid-hardening and expansive concretes showed outstanding anti-freezing performance. Experimental results by China Building Materials Academy (CBMA) as well as from Ssangyong Group, South Korea, a common conclusion derived was that the strength decreases were slight after 270-300 cycles of freezing and thawing (Tables 9 and 10). There was few if any strength loss for TCS casting concrete under the ambient temperature changed alternatively normal and minus (see Figure 3).

Carbonation resistance

Table 11 shows that comparatively shallow penetration of CO_2 into TCS concrete at 28 days thus indicating that the concrete will protect reinforcement.

Table 7 Impermeability of the rapid-hardening cement concrete

28 days' comp. Strength (MPa)	Water pressure (kg)	Permeability	Osmotic height (mm)
40.7	30	impermeable	38
35.3	30	impermeable	75

Cement type	Slump (cm)	Air con-tent (%)	Comp. Strength at 28 days(MPa)	Variation of comp. strengths after the following cycles (%)						
				0	30	60	90	150	210	270
R.H. SAC	16.0	3.0	56.1	100	99.7	100.7	99.6	99.6	99.7	97.0
M.E. SAC	14.5	2.5	28.0	100	98.7	99.0	98.7	99.9	99.4	95.1
OPC	15.6	2.4	53.1	100	93.7	84.7	88.7	72.3	59.9	/

Note: R.H.SAC—Rapid-hardening Sulfo-aluminate cement; M.E.SAC—Mini-expansive Sulfo-aluminate cement; Extreme temperatures of freeze-thaw cycle are -20℃and +20℃.

Chemical-attack resistance

TCS cements were found to have excellent resistance to sulfate attack and many other forms of chemical attack, especially to their combinations on site. Tables 12,13,14 and 15 give some results of the chemical resistance test completed by China National Lab for Railway Construction, which indicate that TCS has a relatively greater coefficients of corrosion resistance (corroded strength/control strength) compared with other types of cement. Most of the TCS specimens showed increased strength after a certain time in corrosive solution. It was also found that TCS has a very good resistance to recrystallization damage.

Table 11 Carbonation resistance of FAC concrete

Cement	Admixture	W/C	Slump (cm)	Carbonated depth (mm)
FAC from Tangshan plant	\	0.52	7	1.29
FAC from Tangshan plant	ZB-1	0.40	18	0.98
FAC from Lengshuitan plant	ZB-1	0.30	5	0.26

Note: The results in the Table were obtained from the specimens carbonated for 28 days under the standard condition (CO_2: 20±3%; T: 20±5℃; RH: 70±5%). Because different raw materials were adopted, the proportions of $C_4A_3\bar{S}$ and ferrite phase in clinker have some differences between the FAC's from Lengshuitan plant and Tangshan plant.

Note: The characteristics of Luntai water: Na^+ and K^+=83,800mg/l, Mg^{2+}=8,400mg/l, Cl^- =143,000mg/l, SO_4^{2-}=14,600mg/l; The characteristics of Ruoqiang water: Na^+ and K^+=100,800mg/l, Mg^{2+}=12,566 mg/l, Cl^-=127,090mg/l, SO_4^{2-} = 71,040mg/l.

Resistance to alkali-aggregate reaction

Damage caused by alkali-aggregate reaction (AAR) has occurred in many concrete structures. Finding the best cementitious material to limit AAR is a goal of researchers and customers. We found that TCS can effectively restrain the expansion caused by the reactions of alkali with the silica in highly active quartz glass and especially with the carbonate in highly active dolomite.

10×10×40mm mortar specimens and 20×20×60mm concrete specimens were tested to determine expansion features of alkali-silica and alkali-carbonate reactions (ASR and ACR) respectively. A high alkali content OPC (1.0%) was employed as the control specimen and three curing temperatures (20 ℃, 60℃and 75℃) were used.

The result showed that the specimens of SAC, FAC and those with 30% fly ash added remained dimensionally stable with age but marked expansions and cracks occurred in the controls. According to the Arrherius formula and the activation energy (91.4 kJ/mol) of ACR, the age of the concrete cured for 80 days at 75℃and for 160 days at 60℃are equivalent to about 120 years cure at 20℃. Therefore, it can be concluded that TCS will be alternative to deal with the AAR problem, especially ACR.

Rusting resistance

A sufficient importance has been attached to the corrosion of steel reinforcement in SAC and FAC concretes. During the last 25 years, a series of examination have been done under the different environments in which the concretes have to serve and by different testing methods, for instance, accelerated tests, examining specimens buried in moist ground and those placed in tidelands. The conclusions from these examinations are consistent. Steel reinforcement in SAC concrete had some slight rust spots at early age (up to 3 days), but further attack was effectively inhibited. The alkalinity 11.5-12.0 in SAC is somewhat less than in OPC. A passive film, therefore, is established and stabilized with difficulty. This is considered to be the major reason why slight spots rusting occurs in early curing. However, as the hydration of SAC proceeds, the cathodic reaction of the rusting process will soon be

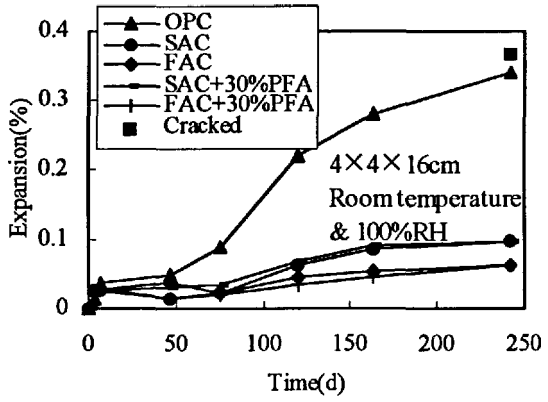

Fig. 7 The development of expansion caused by alkali-aggregate reaction (ACR), active aggregate: Dolomite; alkali content in the OPC = 1.0%.

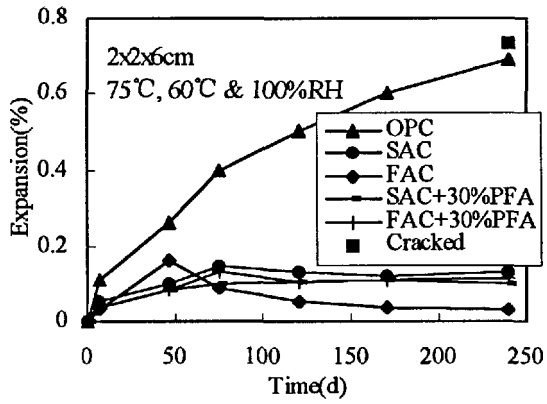

Fig. 8 The relationship between the expansion caused by ACR and the curing time, curing temperature: at 75℃for 80 days and consequently 60℃ for 160 days; active aggregate: Dolomite; alkali content in the OPC = 1.0%.

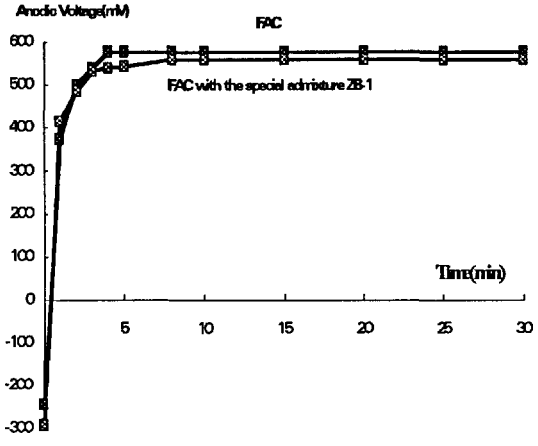

Fig. 9 The anodic polarization curve for the hardening paste of FAC

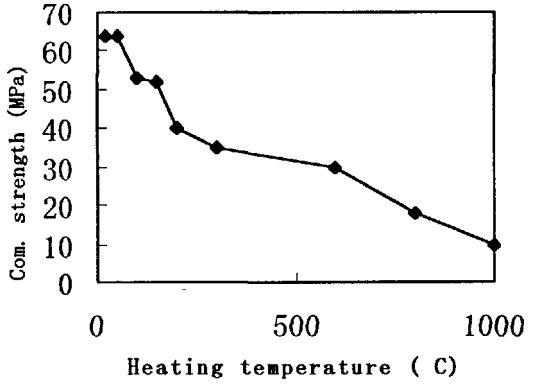

Fig. 10 The strength losses for TCS by heating at different temperatures

restrained because the pores do not contain the water necessary to promote the reaction and the extent of penetration by O_2 is small in dense SAC concrete. This conclusion is strongly supported by an examination on a 13-year-old SAC pipe placed in tidelands on the coast of East China Sea.

In addition to having a similar density to SAC, FAC presents a higher alkalinity (pH 12.5 -13.0) in its pore solution than SAC and is close to that of OPC, so a passive film can be stabilized on the surfaces of the steel bar in FAC concrete. FAC, therefore, will have a better rusting resistance than SAC or OPC.

Long-term strength development

The main hydrates in TCS system are AFt, AFm, C-S-H gel and alumina gel, which are all stable minerals under ordinary temperature. Unlike calcium aluminate cement, there is no so-called

Table 16 Long-term strengths of the rapid hardening cement

Concrete proportion	Compressive strength (MPa)					
	1m	3m	6m	1y	2y	6y
1:1.33:2.81:0.42	41.5	45.0	49.0	51.9	52.3	55.1

Table 17 Long-term strengths of high-strength FAC concrete with the special admixture

W/C ratio	Slump (cm)	Compressive strength (MPa)			
		3d	7d	28d	3.5y
0.25	4		82.9		122.6
0.28	6	72.2		80.5	111.9

conversion problem in TCS systems. Proved to the hilt by over 20 year's experience in China, its long-term strength is stable and a certain increase with time has been observed. During last 20 years, over 8 million tones of TCS have been produced and used in a variety of building constructions and concrete products. There is no any report on the structural accident caused by strength loss. Some laboratory results about the long-term strength of TCS concrete are shown in Tables 16 and 17.

Thermostability

TCS' thermostability had been being attached an increasing importance considering the principle hydration products is ettringite (around 40 to 60%). We have intensively investigated the strength loss of TCS paste. The conclusions may be initially derived as in the following:

(1)After heating for 24 hours, TCS' compressive strength will keep in a relatively steadfast value and does not change with the heating time.

(2)The strength falls off as the temperature increases. At 100℃-150℃, the strength loss was relatively small, about 15%; at 300℃, the strength loss would reach 45%. The strength loss curve is shown in Figure 10.

(3) XRD results shown that there is no decomposition product yielded by the dehydration was detected before 600℃. The decomposition productions above 600℃ are $C_4A_3\overline{S}$, $C_{12}A_7$, $CaSO_4$, $\beta - C_2S$ and $2C_2S \cdot CaSO_4$.

(4) As opposed to OPC, ettringite, C-S-H and alumina gel will be reformed on subsequent curing in water after the heating. TCS' strength is, therefore, restored and may even be somewhat higher than that before. It was also found that the higher is the heating temperature, the higher is the restored strength (see Figure 11).

CONCLUSIONS

The third cement series, consisting of Sulpho-aluminate and Ferro-aluminate cement, has been developed in China since 1972 and over 8 million tones of TCS produced in industrial-scale, which all

used in a great variety of building constructions and concrete products.

Its excellent performances were the main reasons to attract architects, concrete engineers and customers, such as rapid setting and hardening, impermeability, freezing resistance and alkali-aggregate resistance, etc.

The research on the durability for a relatively developed cement is a slow and complex task. We have done a lot of work and started joint researches with groups form the U. K., Japan, France, South Korea and Germany, but these are just initial steps to establish new cement binders.

SULPHO-ALUMINATE CEMENT WITH LOW ALKALINITY

WANG Yanmou, LI Shaozheng, SU Muzhen, XU Jingjun, ZHANG Fengqin

ABSTRACT A new type of low alkalinity cement with pH value of 10.5 was described, which is composed of sulpho-aluminate clinker and some amount of additions. SIC method was adopted to study the strength reservation rate of glass fibre in this kind of low alkalinity cement and the corrosion of glass fibre was investigated by SEM. All the results show that this cement has a very slight corrosion to glass fibre and confirm that the service life of the GRC products with it will be over 100 years .

Key-words: Corrosion Durability Sulphoaluminate Glass

INTRODUCTION

The composite of glass-fibre and cement or concrete is known as glass fibre reinforced cement or concrete (GRC) . It is obviously that the strength and toughness of GRC, using concurrently alkali-resistant glass fibres and ordinary Portland cement, are reduced quickly with time. The reasons are mainly that alkali-resistant glass fibres are still attacked with very high alkalinity (pH=13 ~ 14) in hardened ordinary Portland cement paste. Since 1980s, in order to improve the durability of GRC a lot of works have been done by many researchers in china and abroad. Low alkalinity sulphoaluminate cement that will be introduced in this paper is a new type of low alkalinity cement developed specially for improving the durability of GRC. We own the invention patent.

EXPERIMENTAL AND RESULTS

Composition and property of low alkalinity sulphoaluminate cement (LSAC)

The major mineral components are $C_4A_3\bar{S}$ and C_2S in sulphoaluminate clinker, and based on it we have developed the low alkalinity cement by adding just right amount of some additives and anhydrite. The annual output will be up to 200,000 tons by 1997. The chemical composition and properties of the low alkalinity cement are presented in Table 1, 2 and 3.

Table 1 Chemical composition of LSAC

Composition	Si_2O_3	Al_2O_3	Fe_2O_3	CaO	SO_3
(%)	3 ~ 7	19 ~ 22	1 ~ 2	41 ~ 44	14 ~ 16

Table 2 Strength and setting time of LSAC (Curing in 20 ± 2 ℃ water)

425#	0.42	1:2.5	32.0	42.5	4.5	6.0	≮ 25	≯ 180
525#	0.42	1:2.5	39.0	52.5	5.0	6.5	≮ 25	≯ 180

Table 3 Drying shrinkage rate of cements

Type of cement	C/S	Drying shrinkage rate (%)							
		1d	3d	7d	14d	21d	28d	42d	56d
RSAC	1:2.5	0.03	0.04	0.06	0.06	0.06	0.06	0.06	0.07
LSAC	1:2.5	0.01	0.02	0.03	0.04	0.04	0.04	0.04	0.04
RSAC	1:0.5	0.04	0.06	0.07	0.07	0.08	0.08	0.09	0.10
LSAC	1:0.5	0.03	0.05	0.05	0.05	0.07	0.06	0.06	0.08

NOTE : RSAC — rapid-hardening sulphoaluminate cement ; C/S — cement sand ratio
Curing in 20 ± 3 ℃ water ; Relative humidity=60 ± 5%

Besides, the free expansion rate of LSAC at 28 days is 0.00 ~ 0.10%; and the pH value of its suspension (cement-water ratio is 1:10) at 1 hour is about 10.5.

Experiment of LSAC attack on glass fibre

The method of fibre remaining strength in cement mortar (SIC) was used in this experiment. The sample size of SIC is shown in Figure 1.

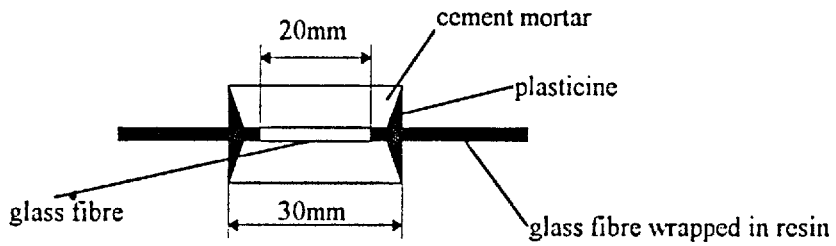

Figure 1 A SIC specimen

The results of accelerated ageing test were presented in Table 4, 5 and Figure 2, 3, in which specimens were immersed in 80 ℃ water.

Table 4 SIC results (immersed in 80 ℃ water)

Cement	Glass fibre	Tensile strength of fibre (KN)							
		Prim.	Demould	1d	3d	7d	14d	21d	28d
LSAC	Cem-fil I	4.28	4.16	3.68	3.73	3.01	3.24	2.70	2.38
OPC	Cem-fil I	4.28	3.28	2.29	1.71	1.33	1.08	1.31	0.91

NOTE : LSAC — Low Alkalinity Sulphoaluminate Cement ; OPC — Ordinary Portland Cement

Table 5 SIC results (immersed in 80 ℃ water)

Cement	Glass fibre	Retained tensile strength of fibre (%)							
		Prim.	Demould	1d	3d	7d	14d	21d	28d
LSAC	Cem-fil I	100	97.20	85.98	87.15	70.33	75.70	63.08	55.61
OPC	Cem-fil I	100	76.64	53.50	39.95	31.07	25.23	30.61	21.26

NOTE : LSAC — Low Alkalinity Sulphoaluminate Cement ; OPC — Ordinary Portland Cement

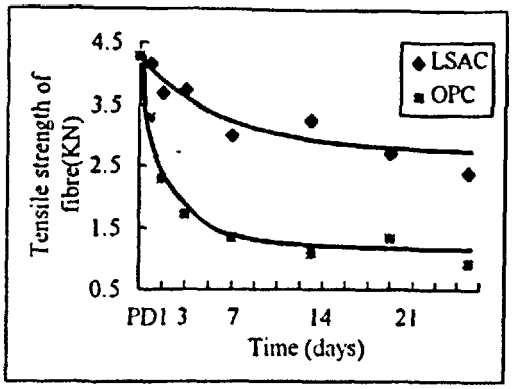

Figure 2 Variation of tensile strength of fibre with time

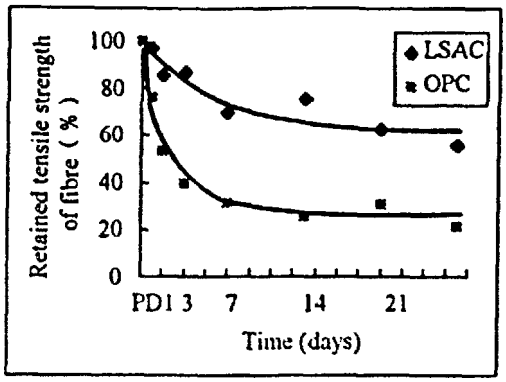

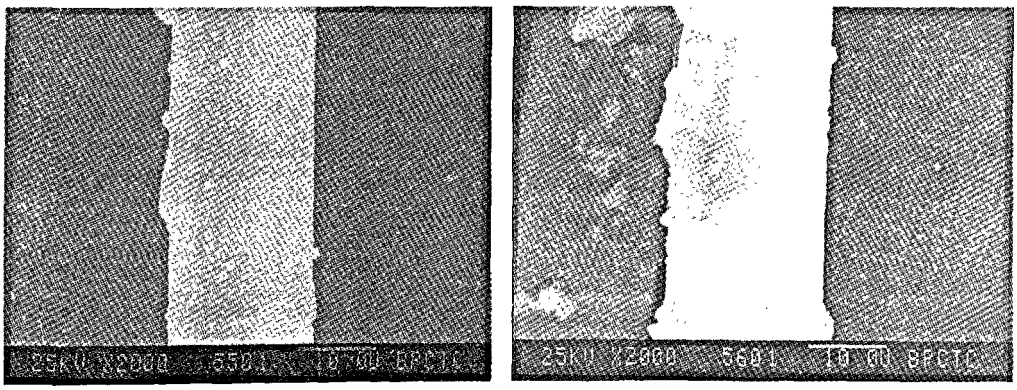

Figure 3 Variation of retained fibre's tensile strength with time

(P — initial ; D — after demoulding)

It may be seen from Table 5 that the glass fibre strength retention ratios at 1 day were 85.98% and 53.50% as using LSAC and OPC respectively; and they were 55.61% and 21.26% at the age of 28 days. Because there is a correlation between the accelerated ageing test with specimens curing in 80 ℃ water and the natural ageing test with specimens exposing to the air, and 1 day accelerated ageing corresponds to 4 ~ 5 years natural ageing. If the fibre strength retention ratio is suggested to be 50% the demarcation point for judging whether or not the durability of materials is satisfactory. Clearly the service life for Cem-fil I glass fibre reinforced LSAC will exceed 100 years, and that for OPC GRC will be only 4 ~ 5 years.

In the mean time, SEM results (Figure 4) confirm that LSAC has a very slight corrosion to glass fibres.

(a) Reinforced LSAC (b) Reinforced OPC

Figure 4 SEM photographs of glass fibres taken from SIC specimens(immersed in 80 ℃ water for 7 days)

DISCUSSION

The low alkalinity sulphoaluminate cement has very little corrosion to glass fibres, affecting mainly by the mineral compositions and hydration characteristics of LSAC. As to sulphoaluminate cement system, the major hydration reactions are as follows :

$$C_4A_3\overline{S} + 2CaSO_4 + 38H_2O \rightarrow C_3A \cdot 3CaSO_4 \cdot 32H_2O + 2AH_3 \quad [1]$$

$$C_2S + 2H_2O \rightarrow C-S-H + Ca(OH)_2 \quad [2]$$

$$3Ca(OH)_2 + 3CaSO_4 + AH_3 + 26H_2O \rightarrow C_3A \cdot 3CaSO_4 \cdot 32H_2O \quad [3]$$

It can be seen from Eqs1 — 3 that there is only temporarily $Ca(OH)_2$ present in the system. So sulphoaluminate cement is a kind of low alkalinity cement developed on the basis of sulphoaluminate cement by adding some additive. Thus the LSAC system possesses much low alkalinity and less corrosion to glass fibre. According to above results, we have achieved the goal of increasing greatly the durability of GRC. Heidelberger Zement AG in Germany researched the durability of GRC produced with Cem-fil II alkali resistance glass fibre and LSAC. The results were exciting as presented in Table 6.

Table 6 Results of accelerated ageing test

Conditions	Limit of proportionality		Modulus of rupture		Elongation (ε)	
	MPa	Relative value (%)	MPa	Relative value (%)	%	Relative value (%)
Before immersion in 80 ℃ water	9.96	100	35.2	100	10.2	100
Immersion in 80 ℃ water for 3 days	9.79	98.3	31.0	88.1	9.73	94.7
Immersion in 80 ℃ water for 7 days	8.33	83.6	29.4	83.5	9.52	92.7

NOTE : Glass fibre — Cem-fil II ; Cement — Chinese low alkalinity sulphoaluminate cement

CONCLUSION

1. The low alkalinity sulphoaluminate cement is of low alkalinity, high strength (especially early strength), small free expansion and small dry shrinkage.
2. The service life of GRC made of LSAC and alkali-resistance glass fibres will exceed 100 years.
3. Due to possessing various excellent properties, the low alkalinity sulphoaluminate cement would be a more ideal cement for GRC.

INVESTIGATION OF COMPATIBILITY OF CEMENTS WITH SEVERAL SALTS

by J. STARK and S. STÜRMER, Bauhaus-University Weimar

ABSTRACT During their service life mortars are often exposed to salt solutions. Most methods described in literature determine the resistance of mortar immersed in salt solutions, that means only external attack. The described method determines the compatibility of cement mortars with salts. This way the cements are in contact with salts from the beginning of hydration. The point of this paper is not the damage by hygroscopicity of salts and their cristallization or hydration pressure, but the possibility of reactions of salts with certain compounds of the cements.

Key-words: Air entraining,Chemical attack,Differential thermal analysis,Ettringite,volume change

CHARACTERISTICS OF CEMENTS AND SALTS The binding materials used in the investigation are 3 commercially used cements according to German Standard DIN 1164-1, part 1: a low C_3A high-sulfate resistant Portland cement (PC) CEM I 42.5 R-HS, a high C_3A PC CEM I 42.5 R, a high sulfate resistant cement rich in granulated blastfurnace slag CEM III 32.5 - NW/HS and a binding material consisting of granulated blastfurnace slag, anhydrite and cement (SSC) similar to the former standardized sulfate slag cement.

Chemical, physical and phase-analytical investigations were carried out to characterize the binding materials used. The chemical analyses of the cements is given in Table 1.
Sulfates, nitrates and chlorides were used as salts which are detrimental to buildings. Two different sulfates and two different nitrates were included in the investigations, because the degree of danger to building materials caused by salts is not only dependent on the kind of anions but also on the kind of cations.

Calcium sulfate dihydrate can be found as a salt inherent in various building materials but it can also penetrate into the building material from outside: SO_2 in the air or sulfate attack from water, soils and gases. Magnesium sulfate will often be found in its hydrate stages where sulfates e.g. from plaster mortars attack dolomite-containing building materials in the presence of moisture. Sodium chloride in coastal regions, however, can only penetrate from outside. Possible sources are: atmospheric attack, splashing water containing de-icing salt solutions, ground water and mixing water containing chloride and acification agents based on hydrochloride acid. Nitrate attack in buildings is also due to outside factors. A possible source is the presence of nitrifying bacteria. Nitrates are also formed by chemical reaction of ammonium and NOx compounds with building materials containing lime and alkali in presence of oxygen from the air.

EXPERIMENTAL To test compatibility in periods which lend themselves to investigation it is important to bring the systems to be investigated in close contact and to avoid too high dilution of the reacting components. For this reason cement paste, usually employed for injections, were used instead of mortars containing aggregates. For storing the specimens you should find conditions which favour the formation of hydrous expansive minerals, i.e. low temperatures and high humidity. To investigate the influence of pore space on the compatibility of above mentioned systems air pores were entrained into the cement paste by means of a tenside. These mixtures are called foam pastes (fp). Production and properties of foam mortars have already been reported elsewhere [Stürmer et al. 1994]. For all experiments the water/binder ratio was 0,5. A cement paste/foam volume ratio of 2:1 was used in any case. The parameters of hardened cement paste (hcp) and foam paste are given in Table 2.
For the simulation of the internal attack the salts with contents of 10 % related to the weight of cement were dissolved in mortar mixing water. The simulated attacking mechanism occurs in restoration practice, e.g. if salts on the surface of building materials like natural stone surfaces are dissolved when getting into contact with fresh mortar in the case of injection.

n.i. ... not investigated

The change in length which took place when the systems came into contact and its progress during the test period were taken as a measure of compatibility [Stürmer et al. 1993]. In addition the change in weight was measured. If the change in length was high, a sample was taken and examined by X-ray diffraction and diffential thermoanalysis (DTA) in order to detect the cause.

The specimens were stored at 10°C and 85 % relative humidity (values that are relevant to historical buildings [Garrecht et al. 1991]) an at 10 °C under water. All cement/salt mixtures were stored separately, whereby all specimens were immersed in the same water volume. Immersion in water was to support the formation of hydrous expansive minerals so that changes in the microstructure of specimens can be observed as soon as possible. Storage in water can result in dissolution of salts in the surrounding water or in the alkaline environment which corresponds to a combined internal and external attack. The change of weight served as an indication of possible dissolution process.

RESULTS AND CONCLUSIONS The results of length measurements as the difference between hcp and fp samples with salts and without salts (zero specimens) immersed in water are given in Table 3 a-e. To evaluate compatibility the progress of change in length after 2 years in contrast to the zero specimen and also the state of the specimens (cracks, scaling and bending) were checked. The results of this evaluation can be found in column 4 and 5 of Table 3 a-e.

- incompatibility + good compatibility
* moderate compatibility C formation of cracks

In contact with KNO_3 SSC and CEM III/B 32,5 NW/HS specimens with foam show a good compatibility. C_3A-rich CEM I 42,5 R was observed to be incompatible with KNO_3. Up to now new phase formation could not be detected.

In the presence of NH_4NO_3 higher changes in length were found, both with the specimen bars without and with foam. As soon as water was added ammonia was released from all binding materials with NH_4NO_3, which lasted for several days. In the case of SSC no length measurement was possible as there was a distinct hardening defect. X-ray diffraction did not show any crystalline changes compared to the sample without salts. By DTA, however, two dehydration peaks were detected which could be an indication of the formation of calcium nitrate. According to equation (1) the reaction between ammonium nitrate and the $Ca(OH)_2$ of hcp results in the formation of calcium nitrate and ammonia which escapes as a gas:

(1) $2\ NH_4NO_3 + Ca(OH)_2 + H_2O \rightarrow 2\ NH_3 + Ca(NO_3)_2 * 4\ H_2O$

As this reaction occurs in all of binding materials tested, it is impossible to elucidate, why it is only in SAC that the hardening defect takes place, only by relating the phenomenon to calcium nitrate formation. Both PC showed the same distinct incompatibility, whereby the presence of a larger pore space only slightly influenced the change in length. DTA also showed these two

dehydration peaks and a small increase of ettringite. According to [Hoffmann 1991] in the presence of binders containing calcium aluminate not only the reaction of the nitrate with the portlandite is possible, but also with the C_3A which may lead to the formation of Tricalciumaluminate mononitrate hydrate. This can be formed, only if there are still distinct quantities of reactive C_3A after the formation of ettringite taking place during hardening of cement paste.
The C_3A-rich PC and the CEM III/B 32.5 NW/HS show with and without foam in the presence of $CaSO_4$ strong changes in length due to higher ettringite formation. SSC shows very good compatibility with $CaSO_4$. Increased porosity of foam mortars limited the length increase of binders CEM I 42.5 R and CEM III/B 32.5 NW/HS in contact with $CaSO_4$, but not to an extent to speak of compatibility. The use of C_3A-poor PC in structures attacked by $CaSO_4$ is possible, if inert aggregates and/or mineral additives are used to „dilute" the cement content.

Only SSC could resist the internal attack of $MgSO_4$, although hardening was retarded when hydration started. In contact with $MgSO_4$ the highest expansions connected with crack formation were observed. Even foam pores could not prevent them. The increase of ettringite in C_3A-rich cement can be compared with that after contact to NH_4NO_3, though much lower expansions were registered. The negative effect of $MgSO_4$ is based both on the reaction of $CaSO_4 * 2\ H_2O$ with C_3A and on the possible reaction whith strength-forming C-S-H phases according to equation (2), which is connected with a weakening of microstructure and an increase in diffusion rate of sulfate:

(2) $MgSO_4 + Ca(OH)_2 + 2\ H_2O \rightarrow Mg(OH)_2 + CaSO_4*2\ H_2O$

$C_3A + 3\ CaSO_4*2\ H_2O + 26\ H_2O \rightarrow C_3A*3\ CaSO_4*32\ H_2O$

$3\ CaO*2\ SiO_2*n\ H_2O + MgSO_4 \rightarrow 3\ CaSO_4*2\ H_2O + 3\ Mg(OH)_2 + 2\ SiO_2*n\ H_2O$

Foam paste made with SSC was well compatible with NaCl. Foam pastes made with C_3A-rich PC and CEM III 32.5 NW/HS showed moderate compatibility, while the hcp of C_3A-rich PC and slag-rich CEM III/B 32.5 NW/HS could not resist the internal NaCl attack. Increased porosity resulted in a marked reduction of the change in length.

SUMMARY $MgSO_4$ showed the greatest damaging effect among all salts relevant to buildings. The highest changes in length were measured in this system leading in some cases to the complete destruction of the samples already after 56 days. Until now only SSC could resist this attack in our investigations. KNO_3 did the least harm to hcp and fm specimens. The increase in porosity of hcp by addition did not improve the compatibility in any case. This can be explained by the fact that even though the porous structure offers additional pore space for new phase formation, fp has a lower resistance to the high pressure that the thin borders of hcp between the air pores are subjected to. The reaction with $MgSO_4$ leads not only to ettringite formation but is also harmfull to strength-forming C-S-H phases which affects the less strong microstructure of the fp more severely. Best results in contact with salts were found with SSC and C_3A-poor PC.

CONCRETE DETERIORATION DUE TO PHYSICAL ATTACK BY SALT CRYSTALLIZATION

YANG Quanbing WU Xueli HUANG Shiyuan
(Wu Dong Road Campus at Tongji University, 100 Wu Dong Road, Shanghai 200433, China)

ABSTRACT Under the various conditions, the length and strength changes caused by sodium sulfate crystallization were measured and compared with those by chemical attack of sodium sulfate. Results showed that: 1)for concrete exposed to the wetting-drying cycle with sodium sulfate solutions, the expansion and damage by salt crystallization were much larger than those by chemical attack of salt, especially for a high concentration of sodium sulfate; 2) the higher the air content of concrete was, the smaller the expansion and damage by salt crystallization were; 3)some improving methods were suggested according to the test results.

Key-words: Air-entraining Expansion Sulfate attack

INTRODUCTION

Geologists have long since studied the phenomena of salt damage in rocks, and have used various terms for them, such as salt weathering, salt crystallization damage and salt decay. ASTM C 88, Soundness of Aggregate by Sodium sulfate or magnesium sulfate, uses the physical attack mechanism of salt for evaluating the durability of aggregate. However, physical attack on concrete by crystallization has received little attention because it seems that the problem is often misidentified as other common damages, such as sulfate attack and deicer scaling due to frost.

Physical damage to concrete from salt crystallization manifests itself in the form of surface scaling and its mass loss is progressive, similar in appearance to freeze-thaw damage, and for poor quality concrete the distress can cause total disintegration.

Reading(1984) showed examples of structural elements from a dam that were damaged only by physical attack of sodium sulfate. Tests showed that chemical sulfate attack was not present. Stark(1989) observed that badly deteriorated specimens had the bottom portions of the beams in excellent condition, but the exposed upper portions of the beams where drying occurred were deteriorated. Controlled specimens in the laboratory, which were continuously immersed in sulfate solution, showed no evidence of deterioration.

Salt solution enters concrete due to capillary action, permeation and diffusion when exposed to the environment abounded with salt solution. However, salt concentration becomes enough high to cause crystallization when pore water evaporates from concrete surface due to changes in ambient temperature and relative humidity. Repeated cycles of dissolution and crystallization can cause deterioration of concrete if the salt crystalliztaion is accompanied by a volume expansion, but this concept needs further study and clarification.

EXPERIMENTAL PROCEDURE

Mix proportions

Concrte specimens with the size of 4 × 4 × 16cm were used. The proportion is W:C:S:G= 0.60:1:1.72:3.19. In order to investigate the effect of air-entraining agent on the salt crystallization, a mixture with the air content of about 3.2% was prepared. Slump was 20±2 cm for all mixes.

Ordinary portland cement with about 15% slag, quartz sand as fine aggregate, 5~12mm marble stone as coarse aggregates were used to make concrete. All specimens were cured in water (20±2 ℃) for 28 days.

Test method

In this paper, crystallization of sodium sulfate was accelerated by drying-wetting cycles. Specimens were dried at 105±5 ℃ for 4 hours and soaked in Na_2SO_4 solutions (0, 10, 20%Wt) at 25~30 ℃, which constitutes one cycle. Companion specimens were immersed in these solutions all the time, which were dried before immersed in order to accelerate concrete soaking the solution. Wet and dry specimen lengths were measured after every cycle, and the mass loss and strength were measured after several cycles.

RESULTS AND DISCUSSION

Expansion

Expansion results under various conditions are shown in Figs 1 and 2. From Fig 1 it can be seen that the effect of drying and wetting in water cycles on the length of specimens is little, and the wet length is always larger than that after drying. However, for the specimens under drying and wetting in Na_2SO_4 solutions cycles, the length of specimen increases continuously after every cycle, and the wet length before drying is always smaller than the dry length after drying. It means that the drying process also causes the expansion of specimen saturated with Na_2SO_4 solution, especially for a Na_2SO_4 solution of high concentration. The expansion by drying-wetting cycles increases with the increase in the concentration of Na_2SO_4. The expansion by 20% Na_2SO_4 is very high, about 0.4% and is 3.5 times as that by 10% Na_2SO_4 after 21 cycles.

For the specimens immersed in solutions all the time, the expansion by sodium sulfate crystallization can be ignored, and therefore is mainly caused by chemical attack of sulfate and moisture expansion. Fig 2 shows that the specimen expansion in solutions increases slowly. It is interest that the expansion in 10% Na_2SO_4 increases more quickly than that in 20% Na_2SO_4, but their final expansions are similar, about 0.04%. Due to low aluminate in cement, the amount of SO_4^{-2} in these solutions is much more than that needed for chemical reaction of sulfate, and therefore the final expansions by chemical attack of these solutions are similar. From Fig 3 it can be seen that the weight of specimens in water increases more quickly than that in Na_2SO_4 solutions, and the amount of water in specimens in 20% Na_2SO_4 is much lower than that in 10% Na_2SO_4 and in water, which may be a reason for these phenomena.

Fig 3 Weight changes of specimens immersed in Na_2SO_4 solutions

From above results it can be seen that the expansion (Esc) by salt crystallization (or drying-wetting cycles) is much larger than that by chemical attack of sulfate (Eca). Esc is about 10 times as Eca for 20% Na_2SO_4, and about 3.5 times as Eca for 10% Na_2SO_4. Therefore, for the environment where water in concrete evaporates easily, the deterioration of concrete is mainly caused by salt crystallization.

Scaling and strength

From Table 1 it can be seen that the strength of concrete immersed in Na_2SO_4 solutions decreases a little, and that after 21 drying-wetting cycles decreases a lot for 20% Na_2SO_4, but increases a lot for 10% Na_2SO_4. In fact, compressive strength is not a good index to evaluate the damage of concrete by salt crystallization, because a little of salt crystallization can make concrete denser and therefore enhance compressive strength. Compressive strength decreases of course when the expansion by salt crystallization is high enough. Tensile strength is sensitive to the damage, but measured values are very dispersive.

The scaling of concrete is a good index to evaluate the damage by salt crystallization. Table 1 shows that drying and wetting in water doesn't cause scaling, but in Na_2SO_4 solutions, it causes severe scaling. The scaling of concrete increases quickly with the increase in the concentration. It is observed that some aggregates scale off. The scaling by 20% Na_2SO_4 is 1240 g/m^2 after 21 cycles, about 9 times as that by 10% Na_2SO_4. However, for concrete immersed in solutions, the scaling is very small, only about 120 g/m^2 even in 20% Na_2SO_4.

These results confirm the conclusion obtained from the expansion test again, i.e., the deterioration of concrete by salt crystallization of Na_2SO_4 is severer than that by chemical attack of sulfate.

Effect of air content

The expansion from physical attack of Na_2SO_4 under drying-wetting cycles is caused by salt crystallization pressure of Na_2SO_4. Does air-entraining agent have the same effect on the damage by salt crystallization as on that by frost action ? From Fig 1 it can be seen that the air-entraining content of about 3.2% significantly reduces the expansion by salt crystallization. The expansion

Table 1 Scaling and strength of concrete under various conditions

Na_2SO_4	Air content	Immersed in solutions for 25 days		21 drying-wetting cycles	
%	%	Strength, MPa	Scaling, g/m^2	Strength, MPa	Scaling, g/m^2
0	0	45.4	0	42.4	0
	3.2	37.3	0	36.7	0
10	0	44.2	56	49.6	150
20	0	43.4	120	37.2	1240
	3.2	36.8	38	34.5	420

Note: The time immersed in solutions for 25 days is equal to that after 21 drying-wetting cycles

is 0.29%, about 70 percent of that of concrete without air-entraining after 21 cycles. Table 1 also shows that the application of the air-entraining agent lessens the scaling and strength loss of concrete by salt crystallization, and the scaling of concrete with the air-entraining agent is 420 g/m^2, only about one third of that without the air-entraining agent. However the air-entraining agent retards the expansion by salt crystallization, the expansion of concrete with air-entraining agent still increases quickly with the increase in the number of cycles. Therefore the application of air-entraining agent doesn't solve this problem completely.

The main reasons that air-entraining agent mitigates the damage by salt crystallization are that a lot of air bubbles entrained by air-entraining agent can receive more salt crystals and retard concrete soaking salt solutions.

SUMMARY

Under drying-wetting cycles, the expansion and scaling due to physical attack by salt crystallization of Na_2SO_4 are much larger than those by chemical attack of sulfate, and the deteriorated surface has an appearance similar to that of damage by freezing-thawing cycles. The air-entraining agent obviously mitigates the damage of concrete by salt crystallization.

Concrete of high permeability is most susceptible to this deterioration. The main methods in preventing the deterioration are to produce concrete of low water-cement ratio and with air-entraining agent.

DILATION AND PHASE TRANSITIONS IN MORTAR DURING COOLING

Vesa PENTTALA, Helsinki University of Technology, Concrete Technology, Espoo, Finland

ABSTRACT Simultaneous dilation and heat evolution of mortar samples were measured from +20 to -70° C in a low temperature calorimeter. Both normal and air-entrained mortars were studied. In the mortar samples preserved in the highest relative humidity (94-96%) expansion was observed during the first freezing of the pore water while the mortars preserved in the lower relative humidity (89-90%) were detected to contract after the first freezing. All mortars expanded when the major portion of gel water freezes in the temperature range -40 to -45° C.

Key-words: Mortar, dilation, phase transition, freezing, thawing, heat capacity

INTRODUCTION

There are presented several theories of the freezing phenomena of wet pastes, mortars, and concrete but relatively few dilation tests of freezing-induced strains and simultaneous ice evolution in porous solids have been performed. In this presentation test results of small mortar prisms cooled in a low temperature calorimeter will be discussed. The compressive strengths of the mortars were 30.4 MPa and 34.6 MPa (air-entrained) measured by 100 mm cubes. The mortar prisms were cooled from +20 to -70° C and thereafter heated back to +20° C with a cooling rate of 3.0° C/h and a heating rate of 4.2° C/h. Mortar prisms were stored in different relative humidity (89-96%) and therefore possessed different pore water amounts filling their pore system.

A CONCISE LITERATURE REVIEW

Four different research groups or scientists have presented freezing theories of wet porous solids. The first important group to study concrete paste was T. C. Powers (Powers 1945,1949) together with his coworkers T. L. Brownyard and R. A. Helmuth (Powers et al. 1947, 1953). Powers started his deduction from the physical fact that during freezing water expands about 9% and if the pore structure was water filled over 91% freezing caused deterioration of the matrix. Later his theory of hydraulic pressure was refined to take into consideration the fact that during cooling the water in the largest pores freezes first and only after the smaller pores have been frozen would the expansion be hindered causing large hydraulic pressures and subsequent paste destruction.

Powers and his coworkers observed also another freezing mechanism: The growth of the bodies of ice in the capillary cavities or air voids by diffusion of water from the nanometer-sized gel pores. However, they assumed that also this mechanism always caused expansion in hardened Portland cement paste. Their experiments showed that empty air voids limit the hydraulic pressure and shorten the period during which ice in the cavities can increase. The closer these entrained air voids are to each other the more effective they are in controlling the two freezing mechanisms. They also noticed the effects of the freezing rates. At low freezing rate the diffusion of gel water is dominant feature causing drying shrinkage in the gel structure while at fast freezing rate diffusion of the gel water has not time to evolve and hydraulic pressure governs the freezing deterioration and induces cracks into the matrix. They were also able to show that osmotic pressures have a role in freezing of cement paste especially when considerable amounts of salts are present in the pore liquid.

Based on thermodynamics, generalized Gibbs-Thomson's equation, and Laplace's equation D. H. Everett and J. M. Hayes (Everett 1961; Everett et al. 1965) showed that ice in a larger pore could expand or grow to a smaller, water-filled pore only when the interface between ice and the water in the connecting tube between the large and smaller pore would be curved. Due to this curvature a lower pressure would be induced into the smaller, unfrozen pore water which would draw water from the smaller pores to the ice crystal until ice could not expand any more because of lack of space.

The third important theoretical impact on the freezing theories of porous solids was done by C. G. Litvan (Litvan 1971, 1973; Sidebottom et al. 1971). According to Litvan's model the surface forces of pores have an important effect during the freezing of the pore liquid. These surface forces hinder ice crystal formation and the water layer situating few molecular diameters from the surface remain structurally oriented during the freezing of the rest of the pore water. According to Litvan the vapor pressure of these meta-stable, undercooled structural water layers exceed the vapor pressure of the solid phases of ice and matrix causing a moisture transport from the pores to the outer surface of the test sample. Similarly, according to Litvan if the cooling rate of the sample is faster than the rate of the before mentioned transport process freezing damage occurs.

M. J. Setzer (Setzer 1977) criticizes Litvan's assumptions of constant surface stresses in the adsorbed interface between vapor and the capillary condensed liquid where Litvan assumes zero angle between liquid meniscus and pore surface. Due to Litvan's simplified assumptions for example gel water could not freeze. Setzer presented a revised thermodynamic model based on Litvan's basic assumptions but taking into consideration the changes in surface stresses in the adsorbed water layer on the pore surface during the thickness changes of this adsorbed, structurally oriented water layer. This structurally oriented, superficial water layer freezes only in very low temperature around -90...-100° C. In his presentation Setzer is the first one to derive an approximate equation for the pressures caused into a porous material during freezing. Setzer's linear relationship is of a very approximate nature because of the rather crude assumptions Setzer has had to do regarding the coefficients of surface tension which has been assumed constant while it really is a function of pore size.

Actual empirical freezing tests with porous solids were performed by T. C. Powers and T. L. Brownyard (Powers et al. 1947), Powers and R. A. Helmuth (Powers et al. 1953), A. A. Antoniou (Antoniou 1964), C. G. Litvan (Litvan 1971, Sidebottom et al. 1971), and B. V. Enüstün, H. S. Sentürk, and O. Yurdakul (Enüstün et al. 1978). Antoniou's tests and Enüstün's and his coworkers tests were done with porous glass specimens while the others used hardened Portland cement pastes.

The first tests of Powers and Brownyard with crushed cement paste samples were rather inaccurate due to the indirect measuring method of liquid solution but the second method done together with Helmuth using tubular, saturated paste specimens provided more accurate results. According to the test results they explained the freezing mechanisms to be a combination of the generation of hydraulic pressure as water freezes in the capillary cavities and the growth of the bodies of ice in the capillary cavities or air voids by diffusion of water from the gel pores. Litvan noticed in his tests two expansion freezing temperatures, around -8° C and another around -40° C which he considered as anomality. Antoniou was the first one to do calorimetric measurements together with simultaneous observations on length changes in saturated Vycor glass. During the tests temperature cooled from +20 to -40° C and he noticed two volume expansion temperature

ranges: One from -9 to -15° C and another from -20 to -26° C. The apparent heat capacity of the phase transformations could also be detected. Enüstün and his coworkers used a mercury dilatometer equipped with a capillary stem. Saturated Vycor rod expanded at -17° C . The lowest temperature measured was -25° C.

TEST SPECIMENS AND ARRANGEMENTS

Two mortar samples were produced for the cooling tests. The composition of the mortars was chosen to represent the ingredients of normal concrete where the aggregate fractions from 2 to 16 mm have been omitted. This explains the large binder amounts of the test mortars presented in Table 1. Test mortar M30 was a normal mortar where no air entraining admixtures were used while in test mortar M35A extra air was introduced into the mix with an air-entraining agent. The air content of mortar M30 was 0.7% and of mortar M35A 8.4%. The binder was rapid hardening

Portland cement CEM52,5 of local origin produced by Finnsementti Oy, Table 2. The aggregates were sieved into 4 fractions and their petrographic composition was mostly granite. The air-entraining admixture was a vinsol resin.

After mixing for 4 minutes the test mortars were poured into 2 dl polyethylene bottles which were rotated for 5 hours to prevent any segregation. At the age of 3 days the bottles were cut open and 10•10•55 mm^3 prisms were cut. Two strain gauges were glued on the opposite sides of the prisms and they were placed into vessels where the relative humidity was held constant by saturated salt solutions. Four relative humidity levels were studied, 89, 90, 94, and 96%. The humidity level was checked by special humidity meters produced by Vaisala Oy. A comparison prism was dried in oven at 105° C temperature for 5 days before the dilation test. At the age of 32 days two strain gauges were glued on the dry comparison sample, wires were soldered to the strain gauges and it was placed into the reference chamber of a low-temperature calorimeter. At the same time the wet sample was taken from the storage environment and wires were similarly soldered to the strain gauges and the sample was placed into the other measuring cell of the calorimeter. The wiring procedure of the wet sample lasted from 7 to 10 minutes and during this time considerable amount of water evaporated from the wet mortar prisms.

During the cooling test the strains of the wet and dry samples were measured every 40 seconds. The strain values of the strain gauges were calibrated by steel samples from which the coefficient of temperature expansion was known. The difference in the heat capacities of the wet and dry test samples was measured by the low-temperature calorimeter produced by Setaram. The cooling rate of the test was 3° C/hour and the following heating rate 4.2° C/hour. The test started from +20° C and the temperature dropped linearly to -70° C and again increased back to +20° C after a few hours waiting at -70° C.

TEST RESULTS

The dilation strain results of the test samples and ice evolution are presented in Figures 1-5. Heat capacities of the wet test mortars are presented in Figure 6. The relative water and ice amounts of the test prisms are presented in Table 3.

Table 3 The relative water and ice amounts compared to the wet weights of the test prisms.

Test mortar/relative humidity (%)	Weight of water / weight of the wet prism	Weight of ice at -70° C / weight of the wet prism
M30/RH96	0.0777	0.0284

DISCUSSION

As can be seen from Figures 1,3,5, and 6 when the test mortar has been stored in the environment of 96% relative humidity the first freezing of pore water causes a large, stepwise expansion in the mortars irrespectively of the air-entrainment. According to the fusion dilation in Figures 1 and 3 this expansion strain of $1.2 \bullet 10^{-5}$ does not seem to cause irreversible cracking in the test samples. This is quite understandable because this expansion causes in the mortar prisms a smaller than 0.4 MPa tensional stress which is well below the tensional strength of the mortars in question. The contraction and expansion of the test mortars stored in 96 and 94% relative humidity during the cooling from +20° C to the temperature of the first freezing expansion are caused by the evaporation of the water and subsequent shrinkage of the wet test samples during the sample preparation before they were transferred into the calorimeter chamber. During the temperature decrease part of the evaporated water amount is returned into the test mortars and part of the shrinkage is retained.

The dilation results of both mortar types M30 and M35A stored in the two lowest relative humidity environment behave quite differently compared to those stored in the relative humidity of 94 and 96%. When ice formation was first detected, thereafter the test prisms contracted until the temperature fell to -40° C when an expansion took place. The expansion of the test prisms stored in 96% relative humidity was surely caused by the generation of hydraulic pressure as water freezes in capillary cavities as Powers has predicted. The contraction after ice formation was detected from the heat capacity curves presented in Figure 6 in the specimens stored in the two lowest relative humidity percents has another physical explanation. When ice is first forming into the largest water filled pores there is enough space for the free expansion of the ice crystal without any restraints from the binder matrix. The chemical potential of the ice surface is smaller than the chemical potential of the unfrozen pore water in the smaller pores and this causes a lower pressure in pore system and a diffusion of pore water to the ice crystals. When gel water is expelled from the gel structure which has a large specific surface area remarkable shrinkage strains will be expected and this will also contribute to the contraction of the mortars. What part of the contraction is caused by the lower pressure and what portion by the shrinkage of the gel matrix cannot be evaluated by these test results but judging from the expansion strains after the test (Figures 2 and 4) the permanent dilations are larger compared to specimens stored in larger relative humidity. Therefore, severe cracking of the gel structure due to shrinkage seems to be at least partly responsible for the contraction. The dilation behavior of the mortars in this situation differs from the propositions of Powers and Litvan. Powers assumed that an expansion would result from the water diffusion and Litvan presented that pore water would diffuse on the outer surface of the specimen and freeze there.

It should be noticed that the dilation curves below -40° C of all test specimens seem to be almost identical. Studying the heat capacity curves of Figure 6 it can be seen that during the freezing of gel water between -40 and -50° C the heat capacities follow the order of the storage relative humidity. One cannot draw very far fetched conclusions from this neither to the gel water amount nor to the amount of how much gel water has diffused away from the gel structure because in these heat capacity values is summed up also the freezing of the superficial, unfrozen layer of adsorbed water between the ice and the pore wall in the larger pores.

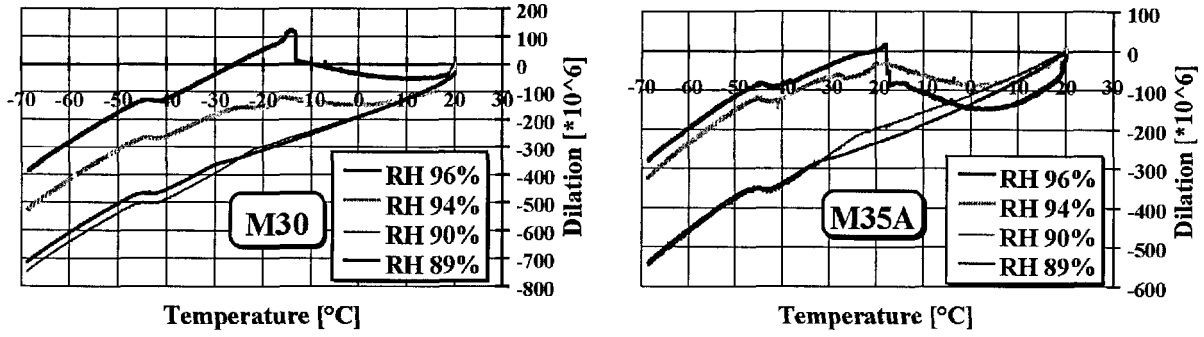

Figure 5 Dilations of the test prisms.

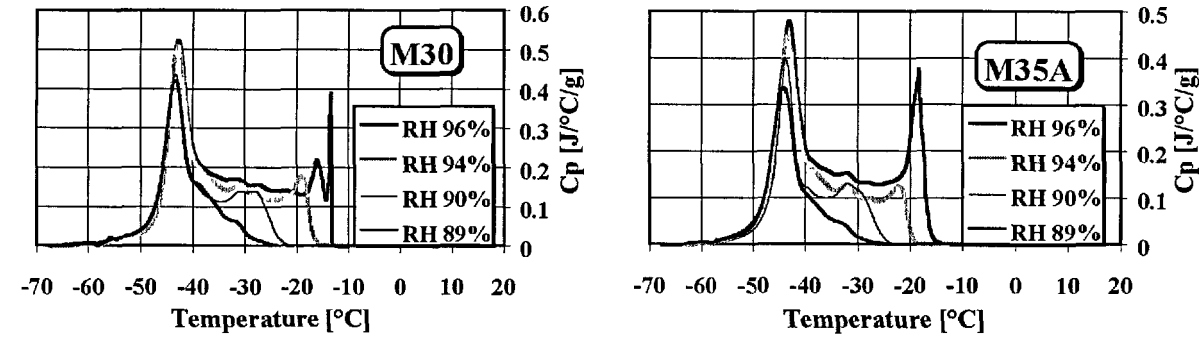

Figure 6 The heat capacities of the wet test specimens.

Comparing the first freezing temperatures to the storage relative humidity of the test prisms one can notice that in mortars M30 they were -13.3, -15, -22, and -24° C in the descending order of the storage relative humidity. For air-entrained mortars M35A the similar first freezing temperatures were -14.4, -18.5, -24, and -25.5° C. These rather small differences can be due to the larger cement amount and somewhat higher compressive strength of the air-entrained mortar M35A and not due to the larger protective pore amount caused by the use of the air-entraining admixture. Actually, in comparing the results of the air-entrained mortars to those of normal mortars very small differences can be noticed. It seems that in the environment below 96% relative humidity air-entrainment has a very small effect on the freezing durability of mortars.

CONCLUSIONS

1. The theory of hydraulic pressure where freezing pore water causes expansion in mortar is valid only if it has been stored in nearly hundred percent relative humidity. In mortars of 30-35 MPa compressive strength this expansion takes place only if storage environment humidity exceeds 95-96%.
2. When the storage environment humidity is below 90-92% the mortar specimens contract after pore water freezes. This is caused by the diffusion of pore water from the smaller, unfrozen pores onto the ice surfaces in larger pores. If there is enough pore space for the additional ice growth the gel structure shrinks due to gel water diffusion. The other reason for the contraction is the lowering of the pressure in the pore system caused by the thermodynamic water and moisture diffusion.

3. In the temperature range -40...-50° C a major portion of gel water freezes and this causes expansion in the mortars. From temperature -40° C downward the dilation of all the test mortars was nearly identical.
4. When 30-35 MPa mortars were stored in and under 96% relative humidity no differences in the dilation behavior could be noticed between air-entrained and normal mortars where no air-entraining admixtures were used.

INFLUENCE OF C_3A CONTENT ON FROST AND SCALING RESISTANCE

Jochen STARK, Bauhaus-University Weimar, Germany
Horst-Michael LUDWIG, Bauhaus-University Weimar (today Schwenk Zementwerke KG, Karlstadt), Germany

ABSTRACT The effects of chemical transformation processes on the frost and frost-deicing salt resistance of concrete are by far not of the same order as the physical effects, but they are nevertheless significant. Our investigations showed that monosulphate (AFm phase) is particularly instable and will transform to ettringite (AFt phase) under frost and also under frost-deicing salt attack. This formation of secondary ettringite, which is supported by thermodynamic conditions at low temperatures, may reduce considerably the frost and frost-deicing salt resistance of concretes without air-entrainment.

Key-words: Aluminate phase, AFm, AFt, Phase transformation, Freeze-thaw damage.

INTRODUCTION

Practical experience of many years has shown that it is possible to produce Portland cement with a high frost and scaling resistance - independent of the types of phases of the cement -, if favourable air void parameters are created by air-entraining agents, if the water-cement ratio is kept low, and if frost and deicing-salt resistant aggregates are employed. On the other hand, however, it is well-known that Portland cement concretes and mortars without air-entrainment which differ only in the type of Portland cement used may vary considerably in their frost and scaling resistance. This is the reason why already for decades attempts have been made to discover a relationship between the types of phases in Portland cements and the frost and scaling resistance of the respective concretes. In the discussions on the influence of cement on frost and scaling resistance the evaluation of the clinker phases of Portland cements is of particular interest.

Most publications deal with the influence of the C_3A content on the frost and scaling resistance of concrete. Still there are completely different opinions held on this question.

Some authors hold the view that the C_3A content has a favourable influence on frost and scaling resistance (Joosting, 1968; Stark et al., 1991; Rasmussen, (1985). Other authors conclude from their test results that frost and scaling resistance is adversely affected by the C_3A content (Jackson, 1955; Rose et al., 1989; Peterson, 1993).

Schrämli (1978) compared the varying statements on the C_3A content and supposed that the differences had been caused by different test conditions. In his opinion the influence of the C_3A content on frost and scaling resistance can only be understood if the basic mechanisms are revealed. The C_3A content in itself cannot be a factor directly influencing frost and scaling resistance because there is hardly any non-hydrated C_3A left when the frost and/or freeze-deicing salt attack begins. It can only be of importance if there is a direct relationship between the C_3A content of the cement and the physical and/or chemical factors of influence (pore size distribution, degree of hydration etc.) Any correlation of C_3A content and frost and scaling resistance is only an attempt to predict the influence of the cement by means of the clinker phase composition without knowing the cause of a possible influence of the C_3A.

The aim of the investigations described in this paper was to find out whether hydrate phases are formed from C_3A that show a different stability under frost and/or freeze-deicing salt attack than hydrate phases from C_4AF. Basic studies were made to find out which phase transformations in calcium sulpho-aluminate and/or calcium sulpho-aluminate ferrite hydrates may occur under frost attack and what the differences between these hydrates are. In a second step the question was considered whether these phase transformations have an effect on the frost and scaling resistance of concrete and which role the C_3A content of the cements may play in this connection.

BASIC INVESTIGATIONS - FROST ATTACK

In the basic investigations into frost attack synthesised C_3A in a stoichiometric mixture with gypsum was hydrated to monosulphate and ettringite respectively, stored for 28 days and then subjected to 28 freeze-thaw cycles (+ 20°C / - 20°C). The comparison of these specimens with other non - frozen specimens showed the different stability of monosulphate and trisulphate under the specific humidity and temperature conditions of a freeze-thaw attack. Whereas ettringite proves very stable, part of the monosulphate is transformed to ettringite during freezing (Fig. 1).

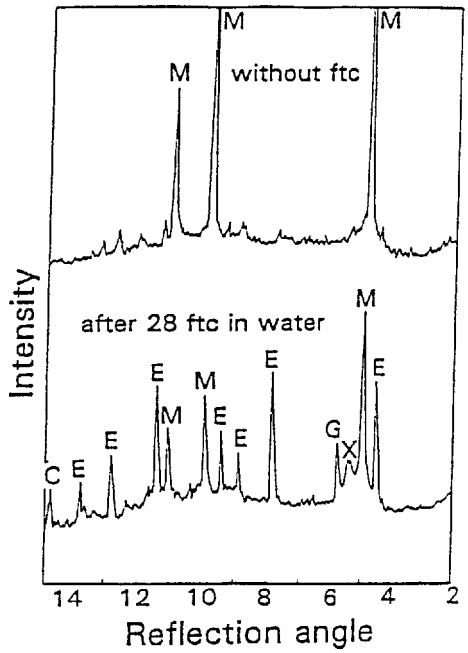

Figure 1 XRD patterns of monosulphate (frost) - M-monosulphate, E-ettringite, G-gypsum, X-monocarbonate.

The main cause of these transformation processes is the change in the thermodynamic stability conditions at low temperatures. Compared to monosulphate, there is an increasing probability that trisulphate - expressed as a negative free formation enthalpy - will form with a drop in temperature, so that at low temperatures the formation of trisulphate is supported by thermodynamic conditions.

The XRD-diagram of the non-frozen monosulphate shows that after pre-storage the added gypsum has almost completely been transformed. That means that, prior to freezing, there was no sulphate available for the transformation of monosulphate to ettringite, which is supported by thermodynamic conditions at low temperatures.

The results of the investigations lead to the conclusion that the sulphate required becomes available through the partial decomposition of the monosulphate due to carbonation. The gypsum formed in this process may then form ettringite with the non-carbonated mono-sulphate. An indication of this reaction mechanism is given by the phase analysis of the reaction products of the carbonation of monosulphate. Both gypsum and calcite (XRD, DTA) as well as aluminium hydroxide (DTA, SEM) could be detected as new formations in addition to ettringite. The reaction proceeds as follows:

$$3\ C_3A{\cdot}C\bar{S}{\cdot}12H + 6CO_2 + 2H_2O \rightarrow C_3A{\cdot}3C\bar{S}{\cdot}32H + 6CaCO_3 + 4Al(OH)_3$$

The results achieved in an examination of AFm phase made from C_4AF correspond to those of the monosulphate tests. The AFm phase also proved instable under frost attack and was partly transformed to AFt phase, gypsum, calcite and aluminium hydroxide.

The morphology of the secondarily formed trisulphate is similar for C_3A and C_4AF (REM). In both cases needle-shaped trisulphate of comparable size is formed. Taking into account the x-ray results and the thermoanalytical tests, the TG curves of the thermoanalysis allow the quantities of both phases to be estimated by means of the dehydration temperatures which are different for ettringite/AFt phase and monosulphate/AFm phase. The quantities determined by this method (Table 1) confirm the results of the x-ray tests. We see that the rate at which AFm phase is decomposed and AFt phase is secondarily formed is nearly identical to the decomposion of monosulphate and the secondary formation of ettringite in C_3A.

Table 1 Monosulphate (AFm) and ettringite (AFt) contents approximately determined by means of TG curves

	monosulphate from C_3A in % by weight		AFm-phase from C_4AF in % by weight	
	monosulphate	ettringite	AFm-phase	AFt-phase
initial sample	95.8	0.0	91.6	0.0
28 ftc/ H_2O/ 14 d	42.9	37.4	35.2	37.6

The formation of the possibly expansive secondary ettringite depends on how much SO_3 is produced by the decomposition of the monophases. If the rate of decomposition of the monophases is the same it should be possible by means of the amount of monosulphate before freezing to predict the new formation of ettringite (AFt phase) and also the potential of the cement for a later damage.

BASIC INVESTIGATIONS - FREEZE-DEICING SALT ATTACK

During the freeze-deicing salt test which consisted of 28 freeze-thaw cycles in a 3 % NaCl solution, the monosulphate was totally transformed into Friedel's salt and ettringite (Fig. 2). After 28 freeze-thaw cycles (ftc) no phase transformations were found in the ettringite examined.

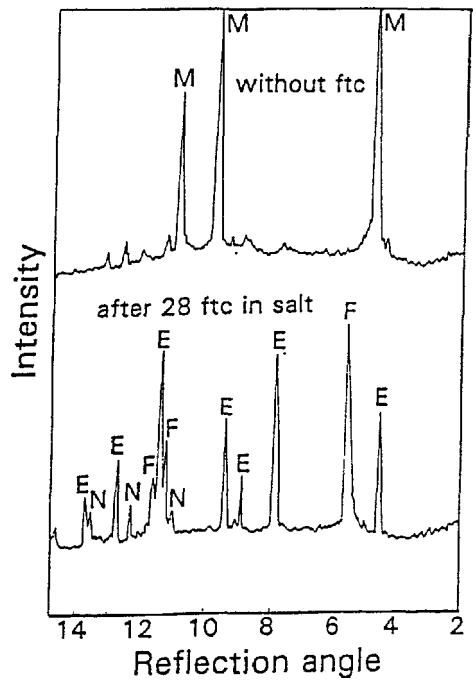

Figure 2 XRD patterns of monosulphate (frost + salt) - M-monosulphate, E-ettringite, F-Friedel's salt, N-sodium chloride.

Contrary to freezing in pure water the combined freeze-deicing salt attack gave no indication of a carbonation of the monosulphate. Obviously the lower solubility of CO_2 in the presence of chlorides leads to a slow-down of the carbonation reaction. It may be concluded that the SO_3 which is required for the formation of ettringite is set free by the partial transformation of monosulphate to monochloride. This hypothesis is supported by investigations by Dorner (1986) who found out that in the presence of NaCl solution a transformation of monosulphate to ettringite will take place even if the work is done in an atmosphere of nitrogen and with nitrogen-saturated water.

The transformation processes which occurred in the AFm phase under freeze-deicing salt attack are comparable in quality to those in the monosulphate from C_3A. Also here AFm phase was decomposed and AFt phase and Friedel's salt were formed. As under frost attack the secondarily formed trisulphate shows again a needle-shaped morphology. The size of the needles is again similar in both C_3A and C_4AF mixes. The decomposition of AFm phase proceeds, however, much more slowly than that of monosulphate. After 28 days only about half of the AFm phase has transformed to other phases (Table 2).

Another source of sulphate than that occurring under frost attack may be assumed to be the reason for the slower decomposition of AFm phase compared to monosulphate. The notoriously bad bonding of chlorides in ferritic phases (Neroth, 1985; Smolczyk, 1984; Lukas, 1983) does not only lead to a reduced formation of monochloride but also to the fact that in comparable periods of time less SO_3 may be provided for the secondary formation of trisulphate than in pure monosulphate from C_3A. The different rate of transformation of monophase under freeze-deicing salt attack indicates that by means of the monosulphate amount (AFm amount) before freezing statements on the potential of the cements for a later damage will not be possible without taking the Fe-content of these phases into consideration.

Table 2 Monosulphate (AFm), ettringite (AFt) and monochloride contents approximately determined by means of TG curves

	monosulphate from C_3A in % by weight			AFm-phase from C_4AF in % by weight		
	mono-sulphate	ettringite	mono-chloride	AFm-phase	AFt-phase	mono-chloride

EFFECTS ON FREEZE-THAW AND FREEZE-DEICING SALT RESISTANCE OF CONCRETE

The phase transformations of synthetically produced aluminate-containing hydrate phases which had been observed in our basic investigations were found by some other authors also in mortars and concretes (Kukko, 1993; Illgner et al., 1991; Ghorab et al., 1981). However, the significance of these phenomena for the real damage by frost and/or freeze-deicing salts has hardly been evaluated as yet.

Within the context of technological investigations into cement and concrete at the Bauhaus-University Weimar it was studied to what extent the new formation of trisulphate may influence the freeze-thaw and freeze-deicing salt resistance of concrete. For this a total of 16 cements with C_3A contents ranging from 0.4 % to 13.7 % were used. With those cements concretes were produced (z = 350 kg/m^3 , w/c ratio = 0.50) with and without artificial air voids, which were then tested by CF test in pure water as well as by CDF test in 3-percent NaCl solution (RILEM, 1995) for their freeze-thaw and freeze-deicing salt resistance.

It was found that concretes without air voids showed big differences in the degree of damage in both tests which has to be attributed to the different cements because mixtures were kept identical and curing was the same for all concretes tested (Fig. 3). Differences in scaling were extreme; under freeze-deicing salt attack the amount of scaled material ranged from 770 g/m^2 up to 5212 g/m^2. Even under frost attack alone where normally only minor scaling can be observed different amounts of scaled material occurred (from 97 g/m^2 to 1079 g/m^2) depending on the cement used.
Damages of concretes with artificial air voids proved not to be dependent on the cements used. All of those concretes showed a high freeze-deicing salt resistance with very small amounts of scaled material.
Evaluating the results from tests with freeze-thaw and freeze-deicing salt attack no clear relationship exists between the composition of clinker phases in portland cements - in this case C_3A content - and their freeze-thaw and freeze-deicing salt resistance. Physical as well as physical-chemical parameters like the degree of hydration of cement or pore size distribution in the concrete also fail to explain the influence of the different cements in concretes without artificial air voids on their freeze-thaw and freeze-deicing salt resistance. Following hypothesis was formulated: the formation of secondary ettringite, which is supported by thermodynamic conditions at low temperatures, as found in basic investigations, influences damage of concrete.

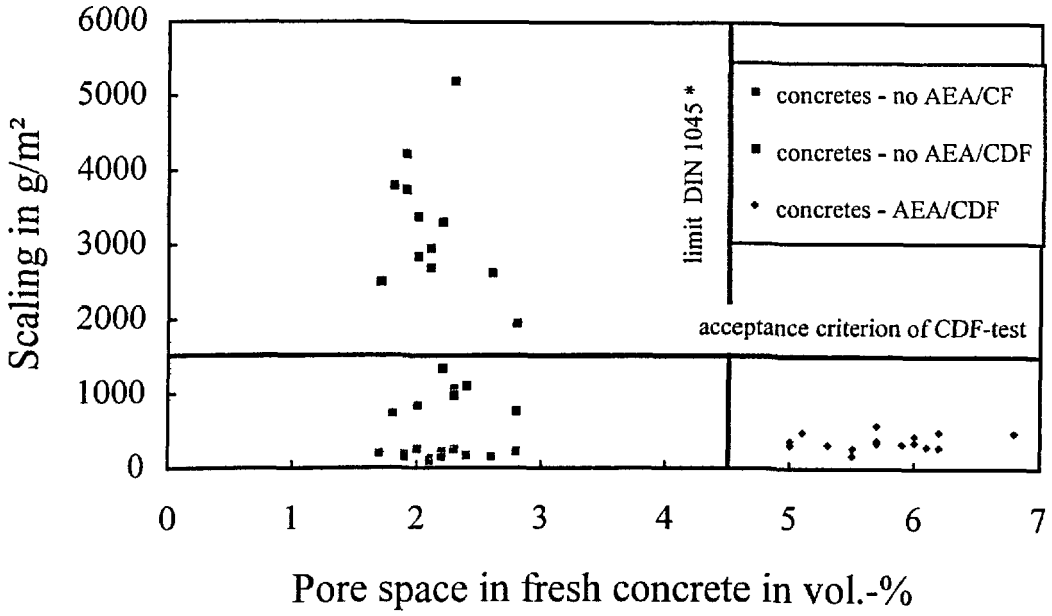

Figure 3 Amount of scaling of concretes with and without air-entrainment (AEA) in dependence on the pore space in fresh concrete in the frost test (CF) and the freeze-deicing salt test (CDF)

After the respective attacks a new formation of ettringite was observed in all concretes, mainly in cracks or at the interface of hydrated cement and aggregate. Obviously some aggregate was forced out of the texture due to the formation of secondary ettringite. A quantification of the newly formed ettringite was not possible because of the diluting effect of the aggregate.
Now it was investigated which aluminate and/or aluminate-ferritic hydrate phases are formed by the 16 cements after 28d hydration and to what extent these hydrate phases are transformed during the CF and/or CDF tests. For this purpose the aluminate-containing clinker phases, the sulphates and the alkalis of the cements were enriched by means of salicylic acid extraction and then hydrated in saturated calcium hydroxide solution. The procedure applied is described in

detail in the literature (Stark et al., 1994, 1992). After 28 d hydration the extractions were subjected to frost and/or freeze-deicing salt attack.
The formation of secondary ettringite (AFt formation), which occurred during freezing the hydrated extraction residues in CF and CDF test, was quantified by thermoanalysis and then correlated to the freeze-thaw and freeze-deicing salt resistance of the concretes tested. The results hint towards a close statistical relationship between the phase transformation as observed and the freeze-thaw and freeze-deicing salt resistance of concretes without artificial air voids (Fig. 4).

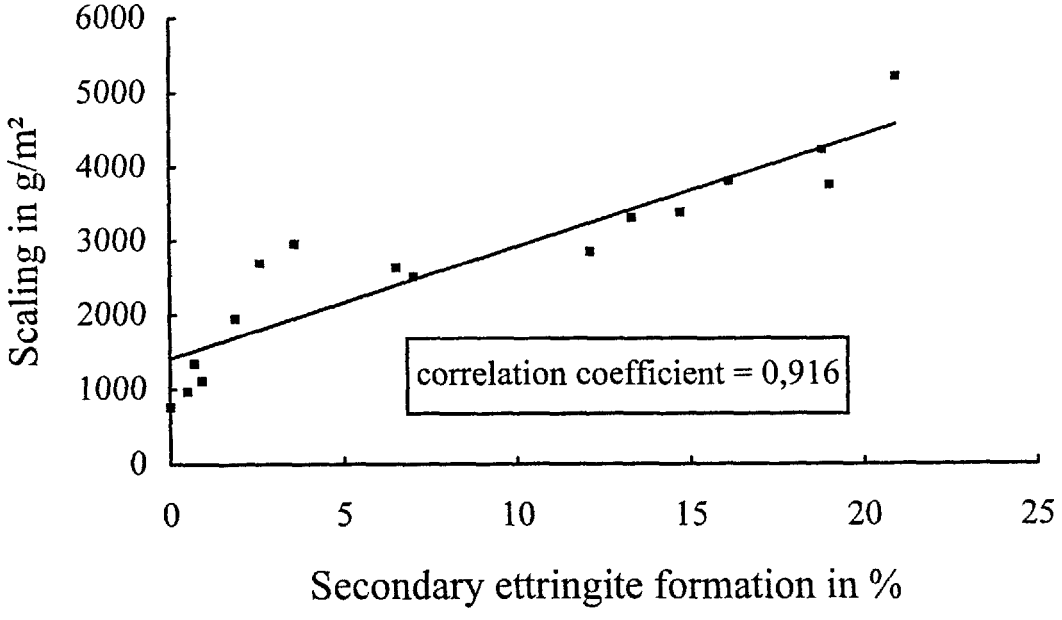

Figure 4 Amount of scaling of concretes in depence on the formation of secondary ettringite in the freeze-deicing salt test (CDF)

Between the formation of new ettringite (new AFt formation) and the amount of scaled concrete material a correlative factor was established of 0.886 under freeze attack and of 0.916 under freeze-deicing salt attack.
The potential of the cement for a later damage, i.e. the formation of new ettringite (new AFt formation), obviously depends on the amount of monosulphate (AFm phase) existing prior to freezing. In addition to that the Fe-content of the monosulphate and AFm phase is important under combined freeze-deicing salt attack. As it is not yet possible to say how the original cement composition influences the content of monosulphate (AFm-content) prior to freezing nothing can be predicted from the clinker phases concerning the potential of the cement for a later damage. A direct relation between the amount of monosulphate (AFm-amount) prior to freezing and the C_3A-content does not exist.
The aim of future investigations should be to determine the factors influencing the increase in the formation of monosulphate (AFm). Then specific measures may be taken to improve the freeze-thaw and freeze-deicing salt resistance by optimising the cement composition.

The importance of the influence of chemical transformation processes is shown in Fig. 5, where the concretes made of two different cements without air-entrainment are compared to air-entrained concrete. It may be seen that these phenomena play a minor role compared to the physical influencing factors such as air-entrainment.

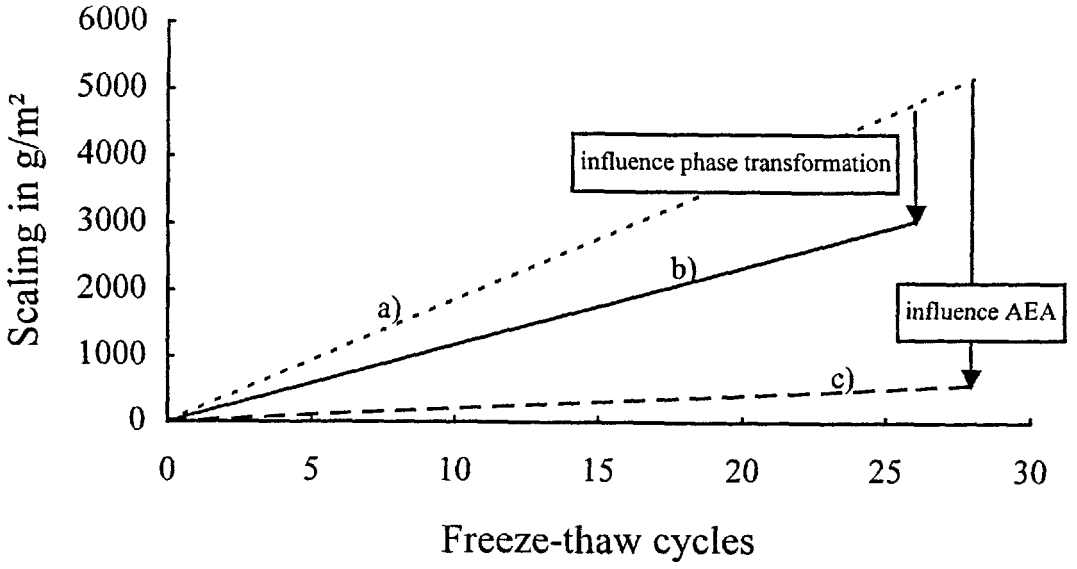

Figure 5 Effect of physical and chemical factors of influence on the freeze-deicing salt resistance (CDF test)
a) concrete with cement A (great amount of newly-formed ettringite)
b) concrete with cement B (small amount of newly-formed ettringite)
c) concrete with cement A and with air-entraining agent (AEA)

The results show that it is possible to produce concretes with a very high freeze-thaw and freeze-deicing salt resistance, independent of the clinker composition. The new findings may, however, be of importance for the future optimisation of concrete with regard to high requirements on its freeze-thaw or freeze-deicing salt resistance. Furthermore phase transformations, as observed in latest investigations, play an important part when the damage of high performance concrete without artificial air voids under freeze-thaw and freeze-deicing salt attack is concerned.

FREEZE-THAW AND FREEZE-DEICING SALT RESISTANCE OF CONCRETES CONTAINING CEMENT RICH IN GRANULATED BLAST-FURNACE SLAG

Jochen STARK, Bauhaus-University Weimar, Germany
Horst-Michael LUDWIG, Bauhaus-University Weimar (today Schwenk Zementwerke KG, Karlstadt), Germany

ABSTRACT Whereas blast-furnace cement concretes have proved successful in structures subjected to freeze-thaw attack, their use in structures subjected to freeze-deicing salt attack is still a problem. It was found out that the freeze-deicing salt resistance of blast-furnace cement concretes is closely related to the carbonation of the surface area. The carbonation of blast-furnace cement concretes does not only lead to an increase in capillary porosity but also to metastable calcium carbonates soluble in NaCl. Based on the results of investigations ways of improving the freeze-deicing salt resistance of blast-furnace cement concretes are proposed.

Key-words: Blast furnace slag, Concrete, Carbonation, Freeze-thaw, De-icing salts

INTRODUCTION

This paper presents the results of several years research work in the field of freeze-thaw and freeze-deicing salt resistance. It should help to clarify the contradictions between the high frost resistance of concretes rich in granulated blast-furnace slag (content > 60%) on the one hand and their low freeze-deicing salt resistance in laboratory tests on the other.

FROST RESISTANCE OF BLAST-FURNACE CEMENT CONCRETE

The problem of frost attack is a problem of the volume, i.e. in addition to surface scaling the interior microstructure may also be destroyed. This fact is reflected in the frost resistance testing criteria of concretes, which consider not only the change in mass and/or the amount of scaling but also characteristics describing the state of the microstructure within the concrete (decrease of the dynamic modules of elasticity, of the ultrasonic speed, of the compressive strength etc.). Because density of the concrete microstructure plays a predominant role in frost resistance, the degree of hydration of the cement at the beginning of freezing is of great importance. Nearly all characteristics relevant to damage such as pore size distribution, total porosity, compressive and tensile strength will depend on the degree of hydration.

There was a test program carried out on how the different degrees of hydration of blast-furnace cements and portland cements at the beginning of freezing will influence pore size distribution and frost resistance. The freeze tests were made according to procedure A of TGL 33433/06. The degree of hydration of blast-furnace cement was determined by using the method of selective solution (by employing methyl-alcoholic salicylic acid, Stark et al. 1990). Comparing portland and blast-furnace cement studies show opposite tendencies. Blast-furnace cements form a considerably denser microstructure than portland cements at the same degree of hydration. For example, in contrast to portland cements blast-furnace cements show a high gel porosity and only a small content of capillary pores, at a degree of hydration of 60 %. On the other hand the rate of hydration of blast-furnace cement is slower than that of portland cement. Thus the portland cement achieved the degree of hydration mentioned above after only 3 days, whereas the blast-furnace cement took 28 days for the hydration of the same amount of cement.

For freeze-thaw resistance the degree of hydration and thus the state of the microstructure at the moment of freezing (test usually after 28 days standard storage) is a decisive factor. After 28 days standard storage (7 days in water and 21 days in the air at 20°C and 65 % relative humidity) the degree of hydration of the portland cements studied was between 85 and 90 %. Depending on the quality of the granulated blast-furnace slag (F2 = $[CaO + MgO + Al_2O_3]/SiO_2$ = 1.1 - 1.8) and

the fineness of cement (Ao = 2000 - 5000 cm^2/g) degrees of hydration from 30 to 65% were established in the blast-furnace cements (slag content c. 65 %) after the same storage time. Fig. 1 (pore classification acc. to Romberg, 1978) shows the effects that different degrees of hydration have on the microstructure.

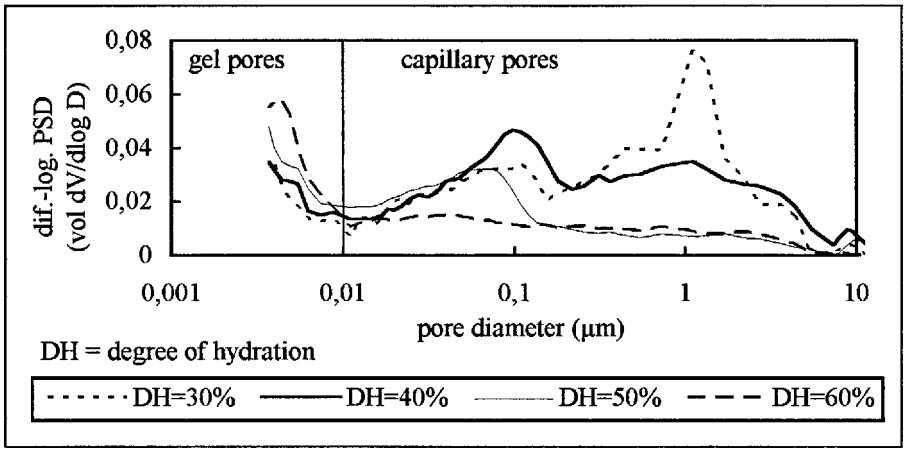

Figure 1 Pore size distribution (PSD) of blast-furnace cement mortar at different degree of hydration after 28 days hydration time

With increasing degree of hydration, the microstructure clearly becomes denser, which becomes apparent through an increase in gel porosity and a decrease in capillary porosity. The peak of capillary pores moves from larger to smaller pore diameters.
A comparison of the pore size distribution between portland (OPC) and blast-furnace cements (BFC) shows that the slower hydration of blast-furnace cement may be compensated for by the denser microstructure which occurs at a degree of hydration from 50 % on. Blast-furnace cement with a degree of hydration of 50 % has a pore size distribution similar to that of portland cement with a degree of hydration of 90 %. High-quality blast-furnace cements with a degree of hydration of more than 50 % develop a denser microstructure than portland cements, regardless of the much lower degree of hydration.
The degree of hydration had a strong influence on the frost resistance of mortars and concretes in laboratory tests. For determining the relationship between the degree of hydration and frost resistance we used the above mentioned cements for the production of concretes without air-entrainment, which were afterwards tested for their frost resistance (cement content = 350 kg/m^3, water-to-cement ratio = 0.5).

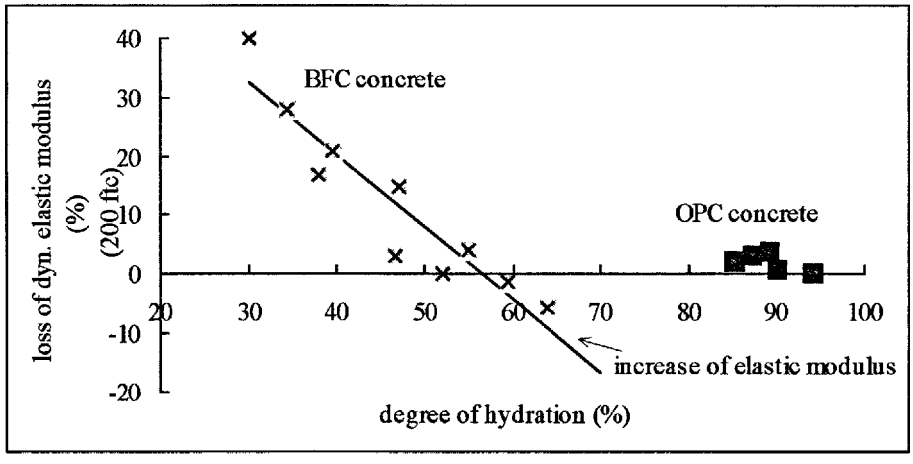

Figure 2 Dependence of frost resistance on the degree of hydration of the cements

As may be seen in Fig. 2, there is a linear relationship between frost resistance and degree of hydration of blast-furnace cement.
Compared to portland cement blast-furnace cements may be subdivided into three ranges, which depend on pore size distribution:

$\alpha_H < 50$ % - the lower degree of hydration leads to a highly capillary-porous microstructure; frost resistance is lower than that of portland cement mortars and concretes

$\alpha_H = 50$ % - the low degree of hydration may be compensated for by the denser microstructure, frost resistance corresponds to that of portland cement mortars and concretes

$\alpha_H > 50$ % - the formation of a very dense microstructure results in a frost resistance which is higher than that of portland cement mortars and concretes

The studies of frost resistance show that a general assessment of blast-furnace cement concrete is not possible. The frost resistance differs greatly, depending on the cement quality, particularly on the quality of the granulated blast-furnace slag, and the curing. In this context it has to be emphasised that all blast-furnace cements examined contained slag which was in accordance with the requirements of DIN 1164 (1990) for an F2 value of ≥ 1. However, an F2 value of at least 1.5 was required to achieve a high frost resistance.

FREEZE-DEICING SALT RESISTANCE OF BLAST-FURNACE CEMENT CONCRETE

As already stated, the freeze-deicing salt resistance of blast-furnace cement concretes is generally considered to be worse than that of comparable portland cement concretes.
Again there was reason to suppose that the degree of hydration is responsible for the different freeze-deicing salt resistance of blast-furnace and portland cement concretes. To verify this assumption the concretes without air-entrainment described in the passage above were not only tested for their freeze-thaw resistance, but also for their freeze-deicing salt resistance by means of the CDF procedure. The CDF procedure developed by Setzer and Hartmann is descripted in RILEM (1995).
In contrast to the pure freeze test the results of the freeze-deicing salt tests showed no relationship between the freeze-deicing salt resistance and the degree of hydration. This becomes apparent if it is taken into account that, unlike pure frost attack, freeze-deicing salt attack causes damage primarily to the surface of the concrete. Studies showed that, even with great surface scaling, no significant interior damage of the concrete could be observed, Siebel (1992). Therefore almost all procedures of determining the freeze-deicing salt resistance of concrete are confined to determining the loss in weight and/or the amount of scaled material. Freeze-deicing salt tests conducted using the CDF procedure at the Bauhaus-University resulted in amounts of scaling between 90 g/m^2 and 6000 g/m^2 after 28 cycles of freezing and thawing, depending on the quality of the concretes. If, assuming a bulk density of 2300 kg/m^3 various scalings are expressed in terms of an average depth of scaling the result will be a layer of 0.04 mm to 2.6 mm in depth.
The above considerations lead to the conclusions that the degree of hydration and the state of the microstructure of the concrete as a whole are of minor importance to whether a concrete exhibits sufficient freeze-deicing salt resistance or not. The properties of a thin concrete surface layer are decisive.
To understand the different freeze-deicing salt resistance of blast-furnace and portland cement concretes, it is important to know in which stage of freezing differences will occur. Whereas in tests for frost resistance under water the scaling of both blast-furnace and portland cement concrete is linear (Fig. 3), heavy initial scaling is observed in tests for the freeze-deicing salt resistance of concrete containing cements rich in granulated blast-furnace slag (content ≥ 60 %) in 3 % NaCl solution (Fig. 4).

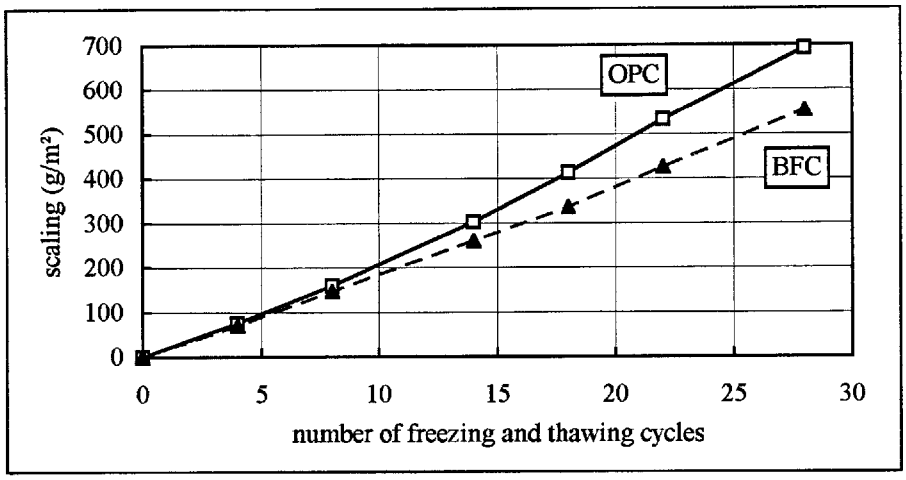

Figure 3 Typical courses of scaling of portland cement concrete and blast-furnace cement concrete (without air-entraining agents) under frost attack (CF test)

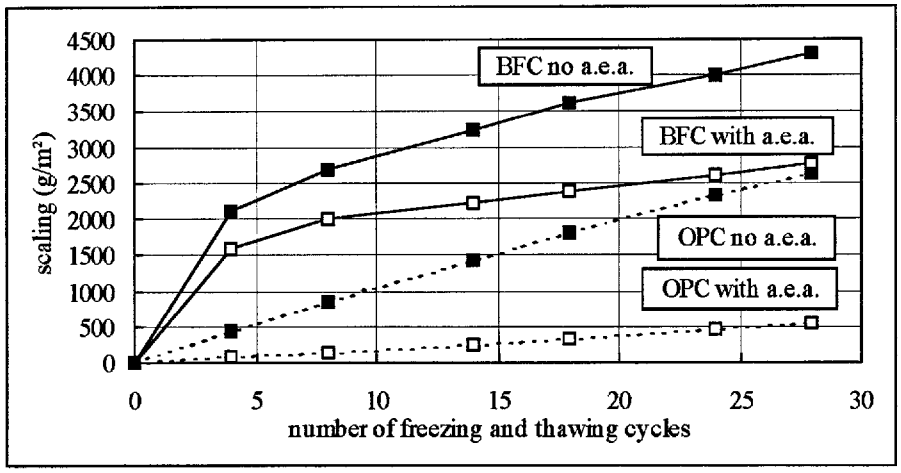

Figure 4 Typical courses of scaling of portland cement concrete and blast-furnace cement concrete with and without air-entraining agents (a.e.a.) under freeze deicing salt attack (CDF test)

This heavy initial scaling occurs both in concretes with and without air-entrainment and is responsible for the fact that in many cases blast-furnace cement concretes show a lower freeze-deicing salt resistance than comparable portland cement concretes and that air-entraining agents are less effective in cements rich in granulated blast-furnace slag. After the initial scaling in the first 4-8 cycles of freezing and thawing the curve changes appreciably and - as a rule - indicates in the second phase a similar or even lower intensity of damage compared to portland cement concretes. The reasons for the heavy initial scaling of blast-furnace cement concretes are not yet known. As the material scaled at the beginning of the damage is identical to the surface layer of the concretes it may be assumed that the initial scaling is influenced by the carbonation of the concrete.

TESTS FOR THE INFLUENCE OF CARBONATION

In order to find out whether the heavy initial scaling of blast-furnace cement concretes is related to the carbonation, the depth of carbonation of different blast-furnace cement concretes prior to freezing was compared to the calculated depth of scaling at the break point of the curve of scaling. The results of these studies (Fig. 5) show conclusively that the decrease in the intensity

of damage (break point of scaling curve) occurs precisely when the damage proceeds from the carbonated to the non-carbonated zone of the blast-furnace cement concretes.

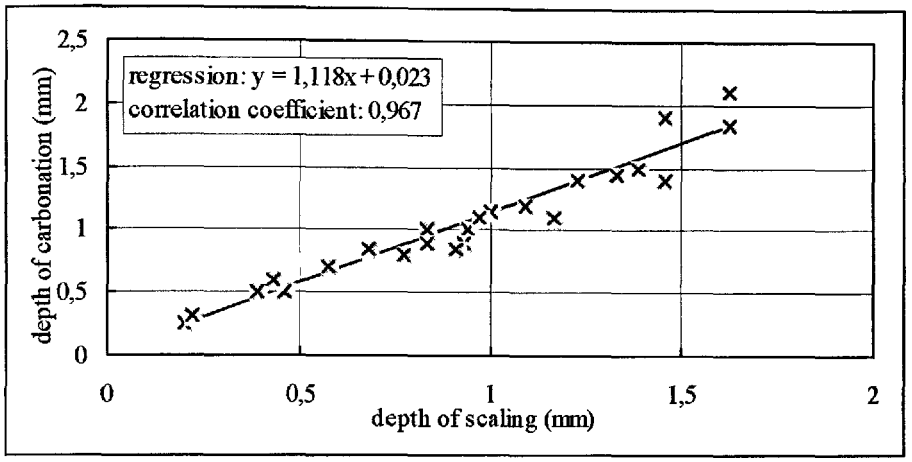

Figure 5 Relationship between depth of initial scaling and depth of carbonation of blast-furnace cement concrete with and without air-entraining agents

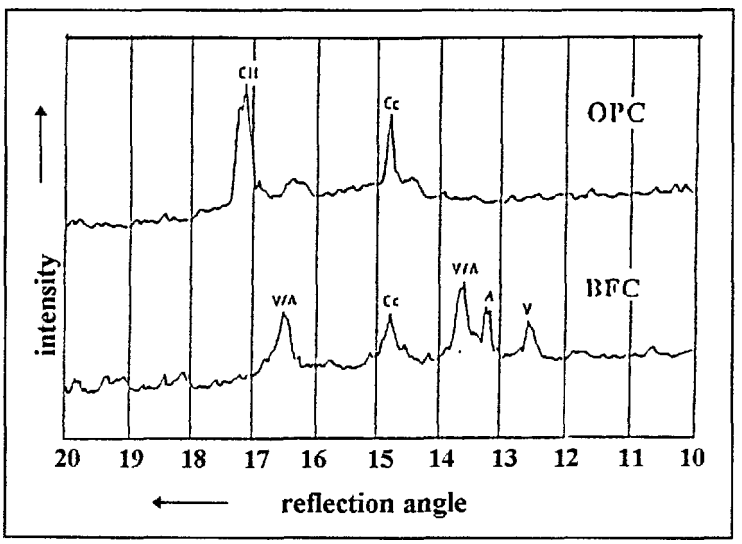
Furthermore, the scaled material was subjected to thermoanalysis and the amount of calcium carbonate in the material was determined by means of the DTA/TG curve for each phase of freezing. The comparison of the calculated amounts of calcium carbonate with the behaviour of the curves of scaling shows, in accordance with the studies into the depths of carbonation, that exactly at the break point of the curve of scaling the content of carbonate in the scaled material decreases considerably. That means that heavy scaling will occur only in the carbonated surface area, whereas the non-carbonated core shows sufficient resistance to freeze-deicing salt attack.
Investigations on blast-furnace cement concrete stored in different CO_2 concentration confirm the strong influence of carbonation. Specimens stored without CO_2 under nitrogen showed no progressive initial scaling and exhibited the best freeze-deicing salt resistance. The freeze-deicing salt resistance of the concrete stored in increased CO_2 concentration (3 % CO_2) was the worst of all concretes. The initial scaling covered a longer period of time and reached greater depths. In all cases the depth of carbonation corresponds to the depth of initial scaling.

RESEARCH INTO THE CAUSES OF INFLUENCE OF CARBONATION

In order to study the causes of the adverse effect of carbonation on the initial scaling of blast-furnace cement concretes, basic investigations into cement pastes (phase-analytical investigations) and concretes (investigations into the microstructure) were carried out.
Differences between blast-furnace and portland cement concrete became apparent through the effect of carbonation on the microstructure. While carbonation led to a slight densification of the microstructure in portland cement concrete, the microstructure of blast-furnace cement concrete became coarser. In fact, the total porosity decreased also in this case, at the same time the portion of capillary pores increased. Nevertheless, it occurred after an even smaller degree of carbonation than that of portland cement concrete. The coarser microstructure of blast-furnace cement concretes due to carbonation has already been stated by Manns and Zeus (1979), Bier (1987), Hilsdorf et al. (1984). The increase of capillary pores due to carbonation, however, cannot be the main reason for blast-furnace cement concretes behaviour under freeze-deicing salt attack, since in this case also under frost attack a higher intensity of damage in the carbonated surface area should have been expected. In contrast to the freeze-deicing salt attack, no break point is observed for the pure freeze-thaw attack under water when the damage proceeds from the carbonated to the non-carbonated zone of the concrete (Fig. 4).

The different course of scaling of blast-furnace cement concretes under frost attack in water and in NaCl solution indicates that there is a chemical cause.
Phase analyses of the carbonated surface area (by XRD) prior to freezing showed in blast-furnace cement that in addition to calcite two other $CaCO_3$ modifications, aragonite and vaterite, occur in considerable amounts (Fig. 6). In portland cement, however, only calcite could be detected. The causes of the occurrence of different calcium carbonate modifications in blast-furnace cement are to date not completely clear. Possibly the different carbonate phases found in portland cement and blast-furnace cement are due to the fact that $Ca(OH)_2$ carbonates to calcite whereas the C-S-H phases or AFm and AFt phases carbonate to aragonite and vaterite (Suzuki and Nishikawa 1992, Nishikawa et al. 1992).



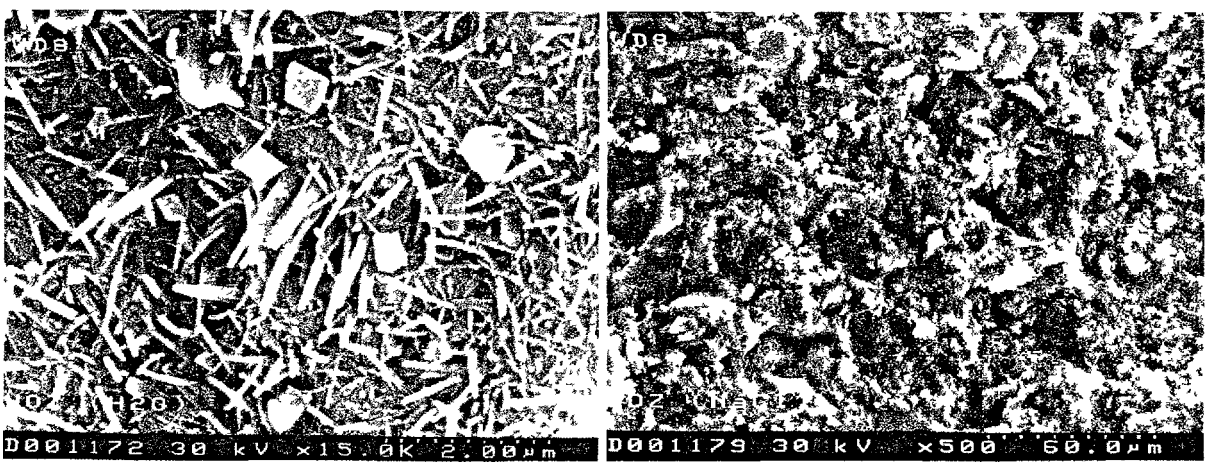


Figure 6 XRD of carbonated surface area of portland cement pastes and blast-furnace cement pastes; CH = portlandite, Cc = calcite, A = aragonite, V = vaterite

Thermoanalyses showed that in all cases the decarbonation temperature of the $CaCO_3$ was between 800-900°C. During the DTA test heating period the metastable $CaCO_3$ modifications are transformed to calcite at about 300-400°C. Examinations of the scaled material and the damaged surface area after the freeze-deicing salt attack showed that large amounts of $CaCO_3$ had already decomposed at about 650°C. It was proved by mass spectrometry that this reaction is indeed a decomposition of $CaCO_3$. According to Cole and Kroone (1960) a lower decomposition temperature indicates badly crystallized calcite. X-ray analysis showed that the new formation of this calcite is accompanied by an intense reduction of aragonite and vaterite. These observations coincide with the existing publications on stability and transformation of calcium carbonate modifications. According to them the solubility constants of the metastable modifications are larger than those of the calcite, and these differences increase considerably in chloride solutions (Schröder 1962, Richter 1993). From the order of solubilities CS (calcite) < CS (aragonite) < CS (vaterite) it follows that a solution which is saturated with respect to vaterite and aragonite is always over-saturated with respect to calcite. Under certain conditions the decomposition of vaterite and aragonite is followed by formation and growth of calcite nuclei.
Based on the test results the following hypothesis about the heavy initial scaling of concretes rich in granulated blast-furnace slag may be proposed: The metastable modifications of $CaCO_3$ - vaterite and aragonite - are dissolved by the combined attack of frost and chloride. This leads to an extensive erosion of the concrete surface. In the deeper carbonated layers the dissolution of vaterite/aragonite may lead to the new formation of calcite in the microstructure. The change in volume implied may further aggravate the damage initiated by the dissolution processes. After the

entire carbonated layer has been scaled in this way the speed of damage decreases appreciably - a clear break point is to be observed in the curve of scaling (Fig. 5).
Additional SEM and EPMA tests confirm the results of the phase analysis and support the above hypothesis about the mechanism of damage. Figure 7a and 7b show the microstructure of the cement paste before and after the freeze-deicing salt attack. In addition to rhombohedrally calcite, well-crystallised aragonite needles and vaterite spherolites can also be recognized before freezing. But after the cycles of freezing and thawing only calcite is still visible in a crystalline form. The metastable $CaCO_3$ modifications have been decomposed almost completely.

Figures 7a and 7b Surface layer of blast-furnace cement pastes prior to freeze-deicing salt attack (left side) and after freeze-deicing salt attack (right side)

WAYS OF REDUCING THE INITIAL SCALING OF BLAST-FURNACE CEMENT CONCRETES

There are two ways of improving the frost and freeze-deicing salt resistance. On the one hand, it would be desirable to reduce carbonation and/or the rate of carbonation by technical means. On the other hand, it should be explored whether the formation of the metastable calcium carbonate modifications may be minimized or even prevented by modifications concerning the materials used.
As a technical means the use of draining formwork material proved successful. In this way the surface area will be densified so that the carbonation of this thin surface area will be reduced considerably. Furthermore, the effect of curing agents as another way of improving the frost and freeze-deicing salt resistance is being investigated and seems to be promising. On the other hand the addition of small amounts of $Ca(OH)_2$ might stabilise the C-S-H phases of the blast-furnace cement (higher C/S ratio) and thus form an additional impediment to the carbonation. The effects of the use of draining formwork material and of an addition of $Ca(OH)_2$ on the initial scaling of blast-furnace cement concretes were at first tested by means of the CDF procedure on concretes without air-entrainment.
The results show (Fig. 8) that the use of the newly developed formwork material (Zemdrain) increases the freeze-deicing salt resistance of the blast-furnace cement concrete considerably. The extreme reduction in the depth of carbonation made the initial scaling disappear completely. Also the addition of 10 % $Ca(OH)_2$ to the concrete led to a reduction in initial scaling from 1500 to 1000 g/m², the prevention of initial scaling was by no means possible. Compared to the use of Zemdrain this method is considered as less effective.

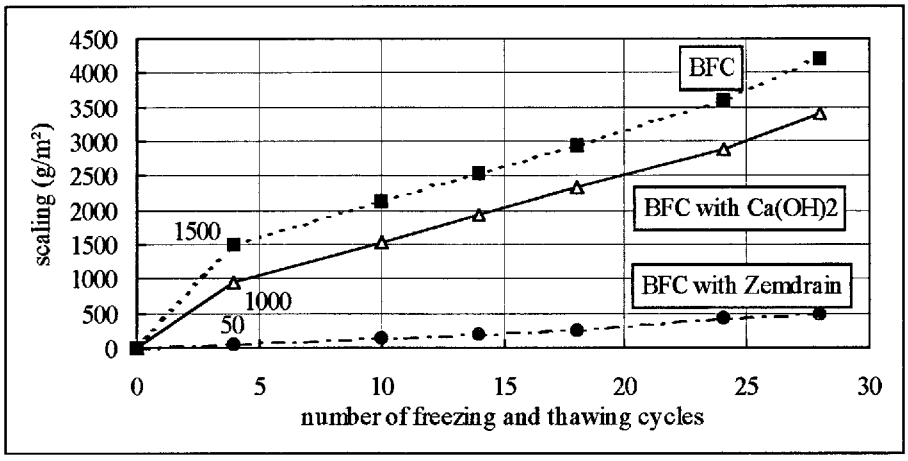

Figure 8 Initial scaling of blast-furnace cement concrete

CONCLUSIONS

The investigations show that the freeze-deicing salt resistance of concretes rich in granulated blast-furnace slag is strongly influenced by the carbonation of the surface layer. The coarser microstructure due to carbonation as well as the existence of metastable carbonates (vaterite, aragonite) lead to a freeze-deicing salt resistance of the carbonated layer which is lower than that of the concrete core. In order to achieve a high freeze-deicing salt resistance it is therefore necessary to minimize the carbonation of these concretes. Draining formwork material is particularly suitable.

NON SHRINKAGE FROST RESISTANT POZZOLANIC CEMENT

Serguei A. ZOUBEKHINE, Boris E. IOUDOVITCH
NIICement, Moscow, Russia

ABSTRACT Modified pozzolanic cement (MpC) with accelerated pozzolanic reaction has been designed and produced on the base of oversaturated-by-lime ferrous special Portland cement clinker (SPCC), natural sedimentary (ns-) pozzolana and gypsum.

Key-words: Clinker composition. Free lime. Pozzolanic cement. Shrinkage. Steam curing.

INTRODUCTION

Pozzolanic reaction degree (p.dg., % by weight) in water hardening (during 1 month) pozzolanic cement (pC) paste with ns-pozzolana is usually under 15. Shortcomings of pC properties are connected with low p.dg. and existence of contour pores around pozzolanic particles (Entine, 1993). Said pores can be filled in when p.dg. reachs 70 (from percolation theory by Chizmadjev et al.,1971). Attempts of p.dg. raising are known, e.g. by: 1) leaving C_{free} in PCC under 10% (Druzhinin, 1934); p.dg. raises by 10, but coarse C_{free} grains in clinker deteriorates pC properties; 2) raising of pC fineness; p.dg. grows by 10-15 (Rabilero, 1988); this is not enough for said pores filling; 3) adding of anhydrous lime to pC (10%, Volzhensky et al.,1991); p.dg. growth is abt 10; 4) two-clinker based pC, in which the 1-st clinker (40%) is alitic, the 2-nd clinker (20%) is belitic with free lime in it under 25% relating to 2-nd clinker weight, ns-pozzolana 35%, gypsum 5%. In this case p.dg. after 1 month is 30-40; this level is not enough for frost resistance (Zoubekhine, Ioudovitch et al.,1994). The results of next attempt of p.dg. raising are written down here.

EXPERIMENTAL AND METHODS

On the plant stage 3 wet process gas fired (3000 m^3/h) rotary kilns (3.6 x 70 m) were used for SPCC burning with throughput (Q.) about 11t/h as in ordinary PCC burning without changes of kiln conditions. Raw materials are chalk, Jurassic black clay and pyrite ores. Pozzolana is weathered kieselgur from Volsk (Russian name - opoka) with activity level 180 - 240 mg of lime absorbed by 1 g of opoka during 30 days (std. min.60 mg/g). SPCC(60%) + opoka(40%) + gips (5% over) were ground jointly in 3-chambered mill (2.6 x 13 m, open cirquit) with Q. for MpC 18 t/h versus(v.) 16 t/h for pC (based on PCC, other the same) upto the fineness: 2-3% of residue on sieve No. 008 (80 mkm), Blaine number under 800 m^2/kg, and v. Q. = 12 t/h for ordinary PC (OPC, type II/A-P) ground to Blaine number 550 m^2/kg. Chemical and phase compositions were analysed by ethyl-glycerate, X-ray fluorescence, diffraction (XRD) and selective chemical (SC) methods. SC analysis (Panina et al.,1992) based on 10% alcohol (alc.) maleic acid solution (calcium silicates solubility [s.,%] 98-99, aluminates and alumino-ferrites s.$\leq$ 1), 0,4% acetoacidic mannite alc. solution (aluminates s.> 99, aluminoferrites s.$\leq$ 0.5) and 3% orthonitrophenol alc. solution (alite s. $\geq$ 99, belite s.$\leq$1). Impurities are determined from solutions. DTA (with parallel wet analysis of CH in pastes) was used for p.dg. determination. Hydration and hardening of MpC and comparing pC were studied with microscopy, XRD, std. physical and mechanical methods.

RESULTS

Raw mix composition was projected with lime saturation factor [LSF=(C - 1,65A - 0,35F)/2,8S] 1.15÷1.45,silicate[S/(A+F)] and aluminate (A/F)moduli 1.7$\pm$0.2; 0.7$\pm$0.2. Chemical compositions of 1) raw mix, 2) SPCC, 3) opoka, by main oxides (%) are next: 1): L.O.I.33-40, S 12-14.5, A 0.5-2.5, F 2-5.5, C 44-50; 2): S 14-21, A 1-3.8, F 3.3-8.5, C 69-80, free C 5-11; 3): S 75-78, A

5-6.6, F 3.5-4.5, C 4.5-5. Powder XRD pattern of SPCC shows reflexes of alite, all in polyplicate form (e.g. profile of peak at d=1.76.10^{-10}m is quadriplicate), and of $C_2(A,F)$ mainly. Phase composition of SPCC sample by SC and limites of that by XRD methods are shown in Table 1.

Table 1. Phase composition of special Portland cement clinker (SPCC)

Notes: [1] With C_2S inclusions probably; [2] Abt 5 ÷ 15 by slightly modified microchemical method

This results testifies that in SPCC: 1) there is *hyperalite* with C/S higher than 3.17 for max. dense alite lattice (Taylor, 1994). Hyperalite has also much higher hydration rate: in neat PC and MpC micropreparations with water/solid ratio 10 by Astreeva`s method (1959) hyperalite hydration degree (h.dg.,%) is estimated as 60 and 80 at 24-28h, 80 and 100 at 48h v. 10/15 and 15/20 for alite in OPC/pC micropreparations. In mortars cured in 100% R.H. air h.dg. of hyperalite in MpC is 20-30 at 1 d., in water 40-50 at 7 d., 70-90 at 28 d. v. 5-10, 25-30 and 50-60 for alite in pC. In water keeping neat PC paste samples 1,41[3] cm h.dg. for hyperalite is 30 and 80 - 100 at 1 and 7 d. v. 15 and 50 for alite. C/S ≥3.3 may be result of lime endotaxy along boundaries of mosaic alite blocks during burning; 2) there is much of S in calcium ferroaluminate and S+F in aluminate. It *does not mean* that any quaternary compounds present in system C-A-F-S, seems to be the result of C_2S-submicroresidues in interlayer spaces of *calcium ferroaluminate* and silicate inclusion in *aluminate glass. Slow hydration* of *both* (h.dg. is 5-10 by month) supports this point of view and *inverses the phases sequence* in hardening cements to the first CH/C-S-H formation and AFt-/AFm-phases much later on; SO_4^{2-} (not CO_3^{2-}) partly goes to C-S-H; 3) free C is amorphous as partly in PCC from marl mix. So the fineness of SPCC raw mix was lowered v. usual level for PCC in connection with raising solution rate and solubility of S in C-supersaturated ferrous melt. Said amorphous free lime under 15% *does not* cause the unsoundness of i)neat PC from SPCC and ii) MpC, and *does not* irritate personnel` mucous membranes. After 3 months SPCC nodules (5-15 mm) kept in the open air are fell to grains (0.5-2 mm in size without dust). Kept over 2 year without alterations grains have the same hydraulic activity as initial SPCC. Average CH content in MpC hardened paste is only slightly more than in pC one, because the essential increasing rate of pozzolanic reaction. So in 1,41[3] cm MpC samples p.dg. is 70-75 at 1 and 90-100 at 2 months v.15 and 25 in pC. Thus amorphous free C of SPCC and more reactive hydrolytic CH (than in pC and OPC pastes) accelerates the pozzolanic reaction in MpC paste and said contour pores around any pozzolana particles can be filled in with the reaction products.

PROPERTIES OF MODIFIED POZZOLANIC CEMENT

Cement strength (GOST 10178) *v. content of pozzolana* or std. blastfurnace *slag* is shown in Fig. 1. Designations: *black triangles*: neat PC and MpC based on SPCC+opoka+gyps; *empty squares*: the same based on alitic PCC+opoka+gyps; *empty rings*: alitic PCC+slag+gyps. Hardening conditions:**a**)in moist air 1 d.,further keeping in water); **b**) after std. steam curing (2 h - exposure, 3 h-raising of temperature,6 h-isothermal curing at 80°C,2 h-cooling;further keeping in moist air).

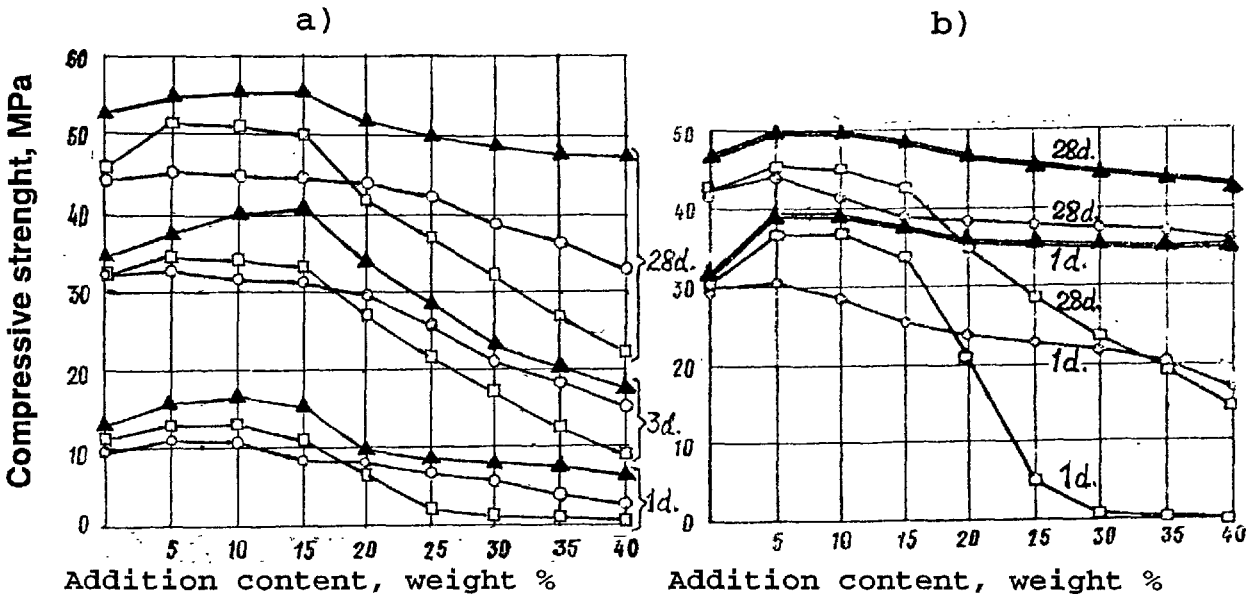

Figure 1. Cement strength versus active mineral additions content

It is evident that the strength of MpC is higher than pC and slag base cement at all hardening times. After steam curing this effect is larger and seen upto 40% addition; it connects with higher temperature stability of C-S-H/hydrogarnets v. AFm-/AFt-phases. The properties of concretes made with MpC and OPC (type IIA-P, opoka content 10%) are shown in Table 2.

Results have shown that the shrinkage of MpC is much smaller than that of OPC. Besides it is stable from 28 to 180 days (0.01 to 0.12 mm/m). In despite of equality of std. strength classes MpC is better than OPC responds to steam curing. So the products have the greater strength and resistance to different environmental conditions though the clinker part in MpC concrete is only 0.57 of OPC concrete. The adducing data testify that *MpC is practically non-shrinkage, frost- and sulphate resistant cement* owing preferentially to clinker composition and high p. dg. MpC is good to use in fine grained concretes with clay rich sands which shortcomings are decreased.

[5]GOST 10050; F-decrease in compare with OPC is caused by smaller cement consumption in concrete.[6]Frost resistant class of blastfurnace cement (Eurotype IIIA) is F30 and of pC is F < 10.

MICROBIOLOGICAL IDENTIFICATION OF MICROORGANISMS RESPONSIBLE FOR DEGRADATION OF CONCRETE

Moema RIBAS SILVA, ENC-FT, University of Brasília, Brasília-DF, Brazil
Lenise Aparecida Martins GARCIA, BIOCEL, University of Brasília, Brasília-DF, Brazil

ABSTRACT Techniques to study the microstructure of building materials as well as microbiological methods have been used in order to try to identify microorganisms responsible for biodeterioration of cement and aggregates of concrete taken from structures of Brasília. The presence of Thiobacillus has not been detected but colonies of Bacteriae and Fungi have been counted. Some images observed at the scanning electronical microscope are presented.

Key-words: Microstructure, Durability, Scanning Electronic Microscopy, Thermogravimetry.

INTRODUCTION

Concrete structures are frequently deteriorated by several agents which act in different ways. Among these, biodeterioration of concrete have been studied recently but the researches did not yet lead to final results. The first phase of the research was related to the role of the environmental conditions on concrete biodeterioration. Next, a tentative was initiated, through microbiological techniques, in order to identify some of the several microorganisms observed by scanning electronical microscopy at the proximity of corroded crystals of concrete. In this phase, now in progress, the presence of Thiobacillus (absent) is searched and colonies of heterotrophic Bacteriae and Fungi have been counted. The aim of this paper is to present some of the results obtained through scanning electronical microscopy and microbiological techniques.

APPLIED TECHNIQUES

The scanning electronic microscopy (SEM) followed by energy dispersive analyser (EDS) applied on fractures are the best techniques to verify the presence of microorganisms in concrete (Ribas Silva, 1990). Besides the presence of microorganisms, the SEM has been used in order to detect deterioration products as well as the corrosion of compounds of concrete (cement and aggregates). The use of SEM allows also the identification of most of mineral compounds of concrete.

However, the SEM is not sufficient to study the biodegradation of the material (Ribas Silva, 1990). To complete the study, the following techniques must to be applied: complete chemical analysis (CA), differential thermal analysis (DTA), thermogravimetry (TG) and X-ray diffraction (XRD). In addition, a mineralogical calculation (MC) will be used to process the results of chemical analysis and thermogravimetry. The application of these techniques, now in progress, will help on identifying and studying biodeterioration mechanisms.

In order to verify the presence of microorganisms in concrete as well as to identify them, microbiological methods are required.

CETESB Standard L5.217 (1991) has been applied to detect the presence of *Thiobacillus* (Hutchinson et al., 1969; Milde at al., 1983); the heterotrophic Bacteriae and Fungi have been counted using Standards CETESB L5.201 (1986) and CETESB L5.204 (1988), respectively.

METHODOLOGY

In a previous study, it has been verified which environmental conditions could be responsible for the development of microorganisms. Concrete from structures submitted to three different climates (long periods of dryness and humidity, with a relatively stable temperature; high temperatures and high relative humidity; and low temperatures and high relative humidity) have been studied (Ribas Silva, 1995 and 1996).

The phase concerning this paper is related to samples taken from the same structures of the first part of the research (low humidity and high temperatures), but the microbiological analysis have been added to the applied techniques, in order to identify the microorganisms.

The verification of the presence of *Thiobcillus*, has used different medium of culture: Medium 9K modified, for *Thiobacillus Ferrooxidans* (simple and double concentration); Medium of Postgate modified for *Thiobacillus thioparus* (simple and double concentration); Medium Postgate modified with green of bromocresol for *Thiobacillus thiooxidans* (simple and double concentration).

Samples from the same concretes have been observed at the SEM in order to verify the presence of microorganisms, but the results of the complementary techniques, now in progress, are not yet completed.

OBTAINED RESULTS

The first phase of the study leads to conclude that climate is not so important on the development of microorganisms but it influences the kind of microorganisms present in concrete. However, the same components of cement and aggregates appear solubilized in the concrete submitted to the three studied climates (Ribas Silva, 1991 and 1995). In other words, the kinds of microorganisms were variable but the solubilization of concrete compounds were similar. This leads to think that many microorganisms can be responsible for the same kind of deterioration.

The deteriorated compounds most frequently observed at the SEM were: calcic products from cement, such as portlandite (Fig. 1) and calcium carbonates; siliceous products from aggregates, such as quartz, feldspars, micas (Fig. 2) and other unidentified crystals (Fig 3). But many other crystals appeared corroded.

Besides the deteriorated compounds of hydrated cement and aggregates, the microscopy showed also the presence of microorganisms such as Algae (Fig. 4), Fungi (Fig. 5), Bacteriae (Fig. 6) and Protozoa. Thermogravimetry and differential thermal analysis are able to confirm the presence of microorganisms. The deficiency of silica can be detected by the mineralogical calculation (Deloye, 1986) and the crystalized compounds are detected by DRX.

Figure 5 Unicel Fungi ($\phi \cong 4\mu m$) probably responsible for deterioration of mica and feldspars.

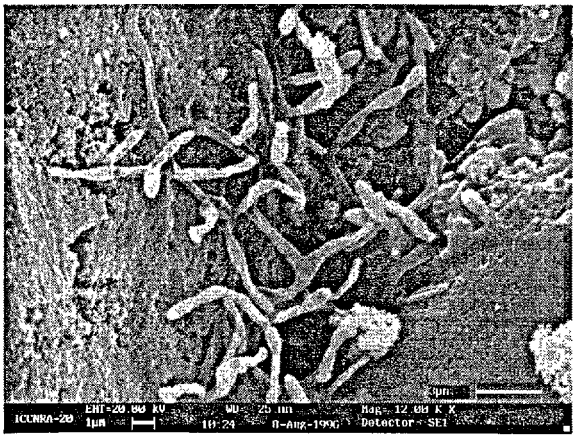

Figure 6 Morphology which seems to be Bacteria, observed in concrete.

CONCLUSION

The mechanisms of the biodeterioration of concrete are not well known but since the mineralogy of soil and natural stones of monuments are similar to concrete, the study of the two first materials, today much more developed, can be extended to concrete.

Taking in account this similarity, the solubilization of calcic products can be explained by the production of acid by microorganisms such as two kinds of Nitrificant Bacteriae which oxyde ammonium in azotic acid and this substance combines with calcium, resulting in a soluble calcium nitrate which is transported out of the concrete (Bock, 1986).

The solubilization of micas and feldspars could be due to the action of Thiobacillus, by the acidification of the medium and realeasing of K but, in this study, this kind of microorganism has not been detected by the applied techniques (Berthelin, 1988).

In this case, the K could be released as a result of the action of fungi, detected by microbiological techniques. Another way to have mica destroyed is through the production of acids (by Bacteriae), when pH can drop under 3, solubilizing the micas (Berthelin, 1988).

Next step will be to identify the Bacteriae and the Fungi which have been counted through microbiological techniques.

STABILITY OF CONCRETE AGAINST BIOGENIC SULFURIC ACID CORROSION- A NEW METHOD FOR DETERMINATION

Dr. Klaus HORMANN; Dr. Fritz-J. HOFMANN; Dr. Michael SCHMIDT; Heidelberger Zement AG, Dept. of Research, Development and Consulting, Leimen, Germany

ABSTRACT Biogenic sulfuric acid corrosion (BSAC) is responsible for damages on cement based sewer systems all over the world. For an economic development of more resistent concrete mixtures, the Department of Biotechnology of Heidelberger Zement AG created a new test system to simulate this BSAC attack, which lasts normally 5- 10 years in the sewer system, within 3 to 5 months. Using the microorganism *Thiobacillus thiooxidans*, responsible for the sulfuric acid synthesis, a differentiation between various concrete mixtures was possible.

Key-words: Bacterial attack, corrosion, high alumina cements, sewage, acid attack

INTRODUCTION

Biogenic sulfuric acid corrosion (BSAC) is a serious problem in particular parts of sewer systems. After first reports from warmer regions like South Africa or Australia (Gilchrist, 1953; Thistlethwayte, 1972), in the last decades damages were found also in temperate zones like north or central Europe (Holmström and Hultman, 1978; Milde et al., 1983).

In anaerobic parts of the sewer system, e.g. in pressure pipes or in deeper zones of biofilms coating the surfaces of pipes and construction buildings, sulfate-reducing microorganisms degrade sulfur containing compounds to hydrogen sulfide (H_2S). These compounds like some amino acids from proteins or sulfate are found in public as well as industrial sewage in significant amounts.

Due to a decrease of the pH-value or by turbulences of the sewage H_2S is emitted into the atmosphere of the sewer pipes or buildings (Thistlethwayte, 1961). Oxygen oxidizes H_2S to elementar sulfur, which is deposited on the concrete surfaces above the sewage. This sulfur is a preferred substrate for microorganisms of the genus *Thiobacilli*. The biochemical activities of these organisms result in a permanent decrease of the surface pH of the concrete down to values below 1.0 (**Eq 1;** Kelly, 1989). At least only *Thiobacillus thiooxidans* previously called *T. concretivorus* (Parker, 1945) is able to live under these extreme conditions. Sulfuric acid, the end product destroys the cement stone and chalky aggregates (Wierig and Nelskamp, 1982).

$$S_8 + 8\,H_2O + 12\,O_2 \text{ -------> } 8\,H_2SO_4 \qquad [1]$$

BSAC in the sewer net work of Hamburg, Germany, with repair expenses of about DM 50 Mill. in the seventies (Flemming, 1994) led to extensive research activities by members of the University of Hamburg (Milde et al., 1983, Sand et al., 1983). The amount of *T. thiooxidans* cells on the surface of the concrete was correlated with the corrosion rate (Sand and Bock, 1984). A breeding chamber with a controlled H_2S atmosphere to simulate BSAC was established (Sand et al., 1983). Using optimized growth conditions for *Thiobacilli* the normal corrosion period of about 8 years, measured by test blocks inserted in the sewer system of Hamburg, was reduced to 1 year in the laboratory (Sand, 1987).

Nevertheless for an economic development of more resistent concrete mixtures against BSAC investigation cycles of 5 to 10 years in a sewer system as well as 1 year in a breeding chamber seems to be to long.

BIOGENIC SULFURIC ACID CORROSION - SIMULATION SYSTEM

The Research, Development, and Consulting Departement of Heidelberger Zement AG developed a BSAC-simulation system giving results within 3 to 5 months. *Thiobacillus thiooxidans* is grown under optimal growth conditions. Elemental sulfur serves as substrate in analogy to the sewer, where emitted H_2S is oxidized to sulfur prior to the utilization by *T. thiooxidans* (Milde et al., 1983). Although *T. thiooxidans* is able to decrease the pH on concrete surfaces below 1.0, pH for optimal growth is about 3.0 (Rao and Berger, 1971). Therefore our test system is separated into a growth and a reaction part. In a 25 l fermentor *T. thiooxidans* was cultivated to give maximal cell counts and biochemical activity. A separate testreactor contained various mortar specimens (1 x 1 x 6 cm) in stainless steel holders. Controlled by a programmable logic controller (PLC) these specimens were flooded periodically for 5 min by an aliquot of the fermentor content, including *T. thiooxidans* cells and sulfur, followed by an 1 hour break. This procedure simulates events in the sewer system, e.g. after a rainy day. Sulfur, which is normally very hydrophobic, is wetted by *T. thiooxidans* through secretion of surface active agents into the medium. These agents are nescessary for the cells to attach and oxidize the sulfur to sulfuric acid (Rao and Berger, 1971). After a few flooding cycles a biofilm was established on the surface of the specimens, built by cells of *T. thiooxidans* together with little amounts of wet sulfur. The principle of this test system is shown in Fig. 1.

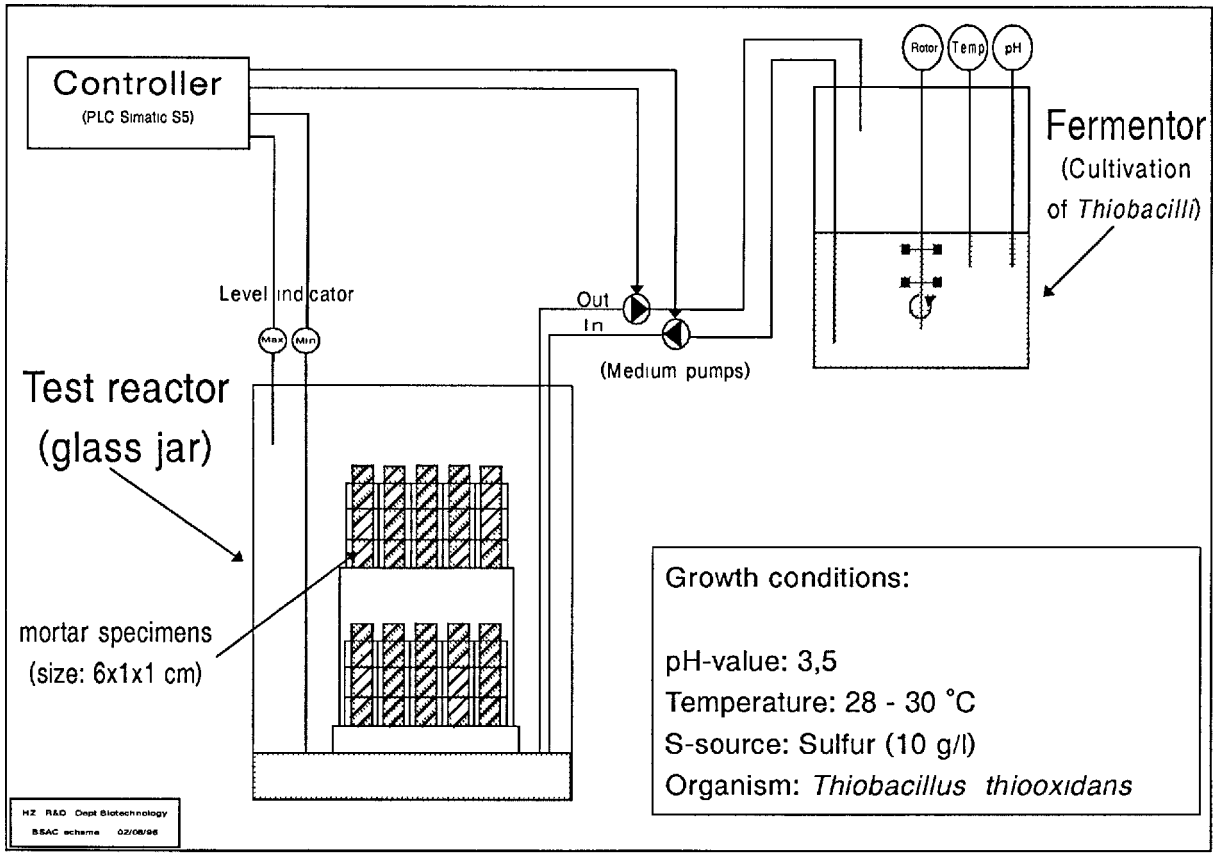

Figure 1: Test sytem for demonstration of biogenic sulfuric acid corrosion

MATERIALS AND METHODS

The test specimens were made of 40 g cement and 120 g aggregates. The water to cement ratio was 0.40. 70 % (w/w) of the aggregate particels were between 0.50 and 1.00 mm, the remaining 30 % (w/w) between 0.25 and 0.50 mm. German CEM I 32,5 R and US Type I-II were used as reference for ordinary Portland cement (OPC). Further specimens were made using high calcium aluminate cement (HAC) with different amounts of Al_2O_3. American traprock, HAC clinkers, limestone, and quartz were used as aggregates. All specimens were stored under water for 28 d and weighed prior to incubation in the test reactor. After 30, 60, 90, 120, and 150 d specimens of each mixture were removed from the reactor. Determination of cell counts on the surface were done according to Sand et al. (1994). To remove remaining loose material from the surface the specimens were treated in an ultra sonic water bath. After a final weighing the loss of weight could be calculated for each specimen.

RESULTS

The behaviour of different cement mixtures regarding their loss of weight is shown in Fig. 2. Whereas the HAC based specimens showed good resistance (3 to 4 % b.m. loss of weight) the OPC based specimens lost under the severe sulfur acid attack 18 and 31 % (b.m.), respectively, of their prior mass. A tendency could be shown already after 30 d, when most of the HAC based specimens showed no loss of weight in contrast to the OPC mixtures (Fig. 2). Regarding the different aggregates HAC-clinker (unmilled material) gave best results, although quartz and broken traprock had only litte higher values. The measurement of the cell counts on the surface of OPC as well as HAC based specimens gave values of about 10^8 cells/ cm^2.

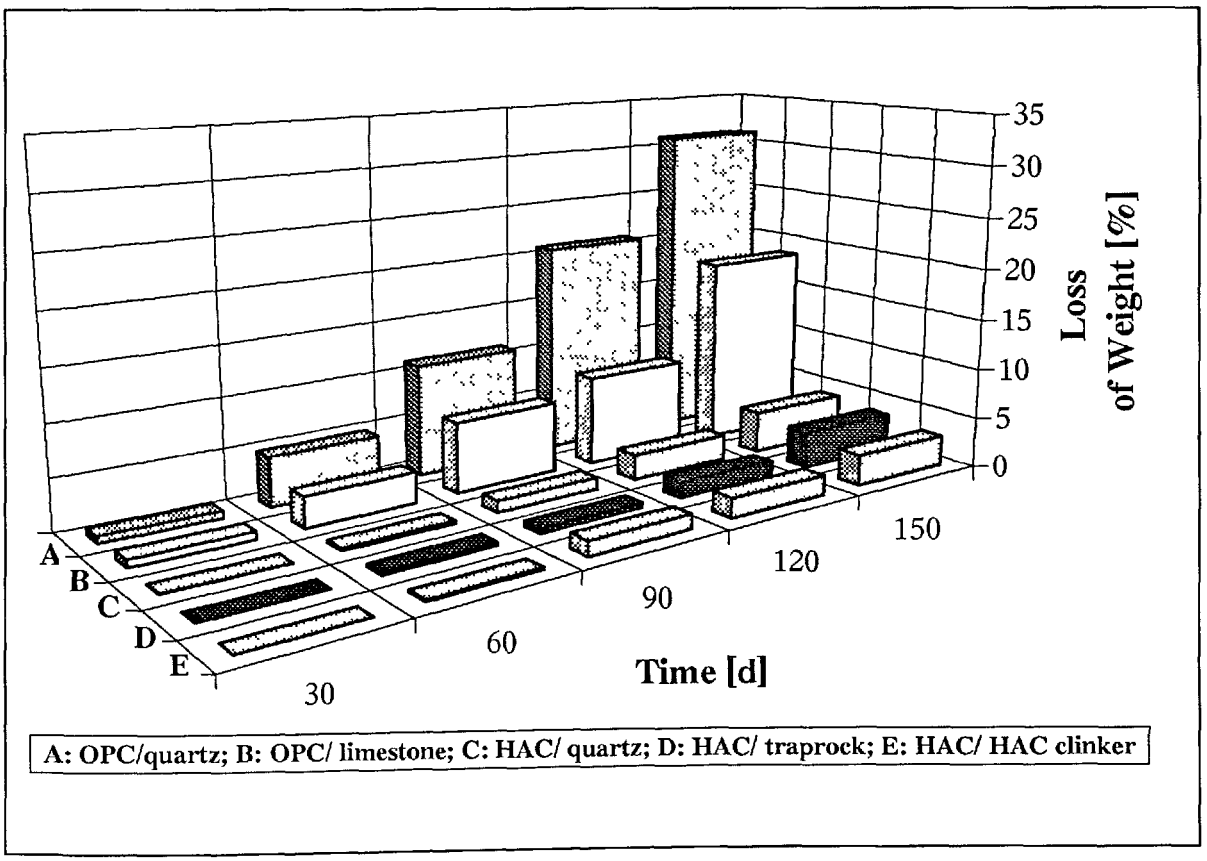

Figure 2: Loss of weight for different cement mixtures

CONCLUSIONS

Using this new test system for BSAC only very short investigation cycles to get information about the resistance of concrete mixtures against this attack are nescessary. In comparison the group in Hamburg reported corrosion rates for OPC from 1 to 4 % within 9 to 12 months (Sand et al, 1983; Sand and Bock, 1984; Sand et al. 1987) whereas with this new system loss of weight values of 18 to 31 % were measured after 5 months. 3 to 5 % loss were found already after 2 months for both the OPC mixtures, showing a further significant reduction of the nescessary investigation time for monitoring BSAC in laboratory. In comparison with OPC, HAC based concrete seems to have a several times higher resistence against BSAC, which correlates with previous data (Sand et al., 1994). Our results should taken into consideration planning or maintaining sewer pipes or buildings. Particular for parts of the system, where high amounts of H_2S are emitted into the sewer atmosphere the use of HAC may be a very good alternative to normal concretes.

CONCRETE OF SEWAGE COLLECTORS AND THEIR PROTECTION: CORROSION MECHANISMS

Vladimir I. BABUSHKIN, Andrei A. PLUGIN, Dmitry Yu. ZELENSKY
Kharkov State Technical University of Construction and Architechture, Ukraine
Gennady Ya. DROZD, Donbass State Academy of Construction and Architecture, Makeevka, Ukraine

ABSTRACT The analysis of investigations aimed at the study of chemical and biochemical processes taking place in sewage collectors is performed. The mechanism of concrete corrosion in above-water part of the sewage collectors is explained. The measures of their protection and durability providing are developed.

Key-words: Sewage, Bacterial attack, Acid attack, Corrosion, Thermodynamics.

INTRODUCTION

The total length of city sewage networks in Ukraine is a few tens of thousands kilometers. The 40% of them are made with the use of reinforced concrete tubes. One failure per each 10 km of the collectors happens every year. Approximately 70% of the failures is caused by the corrosion decay of concrete in the above-water part of the collectors.

THE CORROSION STUDY

The authors investigated a few free-flow collectors made of reinforced concrete in Kharkov. The collectors were the most typical ones by the composition and types of the industrial and domestic wastes transported. When the investigation started, they have been in service more than 30 years. One could notice the multiple corrosion damages in the above-water vault part of the collectors. The damages became more noticeable after connection of the pressure pipelines from the industrial enterprises to the sewage network. Particularly, it was concerned with the drop (relief) wells and the legs with the flow rates more than 1-1.2 m/s. The damages were absent in the under-water flume parts of the collectors and in the vault part of them in the legs with high level of filling up and the flow rates not exceeding 0.6 m/s. The vault corroded across of whole width of the walls here and there, which caused repeated collapses of the vault and ground.

The results of investigations of the concrete and cement paste samples taken from the typical elements of collector are given in Table 1. The results of analysis of the sewage water composition and gas-air containment of sewage collectors as well as the results of calculations of concentrations of the components are shown in Table 2. Here, the data on concentration of substances and ions in sewage water and partial pressure of the gases and vapors in the gas environment were obtained with the use of both Yakovlev's (1975) and own data. The hydrogen pH index of sewage water was 6-9 and more (the mean value is 7.5). The pH in the moisture on the above-water surface of collector is considerably lower than the one in the effluent stream. It can fall to 1 and less values in the moisture. The data obtained by Drozd (1986) and our recent results on micro-biological analysis of sewage water samples and samples scraped off the concrete surface allowed to establish the species of bacteria which live in the effluent stream and on the above-water surfaces of the collector.

THE CHEMICAL REACTIONS ANALYSIS

The complex chemical and biological processes proceed in the sewage collectors. Mainly, they are caused by vital functions of various species of bacteria living in the effluent stream and on both the

above-water and under-water surfaces of the walls of the collector. Proceeding from the composition analysis of the effluent stream and the gas-air containment, the authors analyzed a lot of chemical reactions which could take place in the collectors with participation of the bacteria and without them. Besides, we studied balance equations of the reactions at pressure equal to 1 atm and temperature 25° C. The most important processes and reactions as well as the names of the bacteria which caused the ones are given in Tables 3 and 4. But in some cases we did not consider the intermediate reactions leading to the formation of intermediate products. In these cases the general reaction schemes of the end products formation are presented. For example, in principle, during a sulphate reduction, a sulfate ion may form not only hydrogen sulphide but elementary sulphur and sulphur oxides as well. But, anyway, the latter compounds oxidize into sulphuric acid later on.

In our opinion, the oxidizing-reducing reaction of the sulphate reduction and the reactions of sulphur

and carbonic acids formation out of hydrogen sulphide and carbonic acid gas correspondingly, determine the corrosion risk of collector environment. An analysis of the balance equations of the reactions, given in Table 4 showed as follows:

1) the sulphatereduction reaction in sewage water will proceed at collector conditions in section with high concentration of SO_4^{2-} and low partial pressure of H_2S, in case decreasing pH and increasing oxidizing potential Eh this reaction become more active;

2) it is necessary to have so high concentration of sulphuric acid in moisture to provide equilibrium

of sulphuric acid and hydrogen sulphide that the reaction of the hydrogen sulphide oxidizing in collector is thermodynamically irreversible even at insignificant partial pressures of oxigen inherent to the containment;
3) the equilibrium of carbonic acid gas and carbonic acid in the moisture of collector establishes at the concentration values of the order of 10^{-2} mole/l.

THE MECHANISM OF THE CORROSION ENVIRONMENT FORMATION

An analysis of the above-stated shows that a sewage collector is a sort of a biochemical reactor where complex processes proceed. It is possible to distinguish three main steps in the processes. These steps determine the corrosion environment formation process. They are as follows:
1) the biochemical formation of hydrogen sulfide in the effluent stream given necessary concentration of sulphate-ions, decrease of pH, increase of Eh of the stream as well as the formation of carbonic acid gas, hydrogen sulphide, etc., as a result of organics fermentation;
2) the hydrogen sulphide, carbonic acid gas, etc., extraction out of the stream into the gas containment of collector in the places where the flow behavior and rate change sharply;
3) the biochemical formation of sulphuric acid out of hydrogen sulphide in moisture on the surface of vault and the chemical formation of the carbonic acid out of carbonic acid gas, that damages concrete of the vault.

Thus, the main causes of decay of the vault and other above-stream elements of the free-flow collectors (wells, shafts, etc.) made of concrete and reiforcd concrete are the biogenic sulphuric acid and carbonic acid corrosions. The mechanism of these kinds of corrosion is described in details by Babushkin (1989) and other authors.

THE CORROSION PROTECTION

The authors analysed the equilibriums of the components present in corrosion environment of collector and the mechanism of cement paste, concrete and reinforced concrete corrosion as a whole. As a result, the authors developed a number of construction and organizational measures on corrosion protection of both the newly built and currently operational sewage collectors. The measures are directed towards the decrease of sulphates content in the stream, the aerobic conditions in the effluent stream ensuring, the decrease of gas extraction out of the stream, the use of bactericidal construction, repair and protective materials, including the new ones, resisting attacks of sulphuric acid. The percularity of work of the materials in the collectors is the simultaneous action of neutral sewage water in the flume part and of highly concentrated acid in the vault part. The authors developed acid-proof binding compositions, mortars and concretes based on acid-proof filling agents, sodium liquid glass, sodium silicofluoride and some other special agents which increase waterproofness and provide bactericidal properties. The samples of the materials have been successfully tested in the sewage collectors during 2 years. The application of the measures offered allows to increase the durability of the sewage collectors, to decrease the running costs and to eliminate the negative effect of the failures on ecological situation.

DURABILITY OF ORDINARY PORTLAND CEMENT AND GROUND GRANULATED BLAST FURNACE SLAG CEMENT IN ACID MEDIUM

Julio MADRID, Jesús María DIEZ, Sara GOÑI and Angeles MACIAS, Institute of Construction Science Eduardo Torroja (CSIC), Madrid, Spain.

ABSTRACT The durability of an Ordinary Portland Cement (OPC) and a Blast Furnace Slag (BFS) blended cement in buffered acetic/acetate medium was studied by means of the Köch-Steinegger test. Changes on the solid phases were evaluated by X-ray diffraction, scanning electron microscopy, mercury intrussion porosimetry and measuring the flexural strength. Finally, Ca^{2+}, K^{+}, Na^{+}, $SO_4^{=}$, OH^{-} and Ac^{-} concentrations were measured in the extracted pore solutions. Results show that both materials undergo a corrosion attack, more severe for OPC/BFS blended cement, in the acid medium that is not correctly evaluated through flexural strength measurements.

Key-words: Acid attack, blastfurnace slag, durability, porosity, pore solution.

INTRODUCTION

The highest durability of portland cement with pozzolanic additions is well stated (Douglas, 1987, Feng and Glasser, 1990, Malek et al., 1989 and Malhotra, 1987). This superior durability is based on the decrease of porosity resulting from the active pozzolanic addition that lowers the permeability of the paste impeding the ingress of potential aggressive agents from the environment.Thus, blast furnace slag cements are regarded as superior to portland cement with respect to resistance against penetration of chloride ions and resistance to sulphate attack when the slag content of the cement exceeds 65% (Osborne, 1989 and Wiebenga, 1987). Nevertheless, due to the pozzolanic reaction of active additions, both the lower portlandite content (Hinrichs and Odler, 1989) and lower pH of pore solution (Canham et al., 1987 and Andersson et al., 1989) could negatively affect its behaviour in acid environment.

Sulphate resistance and sea water resistance of concrete are mostly discussed under chemical durability of concrete whereas acid attack has not traditionally attracted much attention, even when cement composites are severely attacked by acids. The acids completely decompose the hydrated and unhydrated cement paste components: calcium hydroxide is dissolved and the hydrated silicate and aluminate phases are decomposed, with removal of Ca^{2+}.

The lack of standard methods to assess the performance of cements in acid environments together with the different aggressiveness of the acid which depend on its pH and nature (those giving insoluble products tend to be less aggressive), make difficult to correlate the results of the few systematic chemical studies found in the literature (Kong and Orbison, 1987, Spirin et al., 1987, El Hakim, 1987 and Chandra, 1988). Pavlik (1994a,b and 1996) makes a remarkable work on acid attack of cement pastes in a series of papers in which he studied the rate of corrosion of hardened cement paste in solutions of nitric, hydrochloric, sulfuric, acetic and formic acid. He concluded that the rate of corrosion of cement paste in acids giving easily soluble Ca-salts depends, to a large extend, on the acid's dissociation constant. He also analysed the chemical composition of the layer of corrosion products covering the undamaged cement paste and found a mathematical relation to express the depth of hydrated cement paste corrosion as a function of the water/cement ratio, the concentration of the aggressive acid solution and the duration of attack.

The behaviour of slag blended cement in acid solution is still less studied than this of plain portland cement. Samarin and Roper (1987), based on the results of the weight loss test, suggested that the

short term HCl resistance of portland blast furnace slag cement containing 35% OPC was mainly influenced by the cement content. De Ceukelaire (1992) working also in hydrochloric acid attack of mortar came to the conclusion that a blast furnace cement mortar proves to be more resistant to acid attack than pure portland cement mortar, due to only part of the cementing skeleton in the outest layer is destroyed by the acid attack, although the depth of the affected area is rather larger.

The need of further studies of acid attack, specially for slag blended cements, and the influence of the degradation of cement in acid environment that takes place in the tests used to characterize the immobilization of toxic wastes in cement matrices (accelerated test involves acetic medium of different pH values) have encouraged the authors to analyse the durability of portland cement and blast furnace slag blended cement in buffered acetic/acetate medium (pH=4.5).

EXPERIMENTAL

Materials

The chemical composition of the Ordinary Portland Cement (OPC) and the ground granulated Blast Furnace Slag (BFS) used are shown in Table 1.

Procedure

Cement pastes with and without addition of 80% (by weight of mixture) were prepared at a W/C of 0.4. Specimens of 1x1x6 cm were molded and compacted by vibration. After 1 day at 100% r.h. the specimens were demolded, put in insulated bags and submitted to a curing period of 21 days at 100% r.h.. After curing, groups of six samples were immersed in an acid buffer solution of 0.87M AcH/AcNa (pH=4.5) and in distilled water. In all cases, the samples were stored in sealed bottles and kept at room temperature for different periods of time. The volume of liquid was 800 ml per 6 samples.

After removing the specimens from the solutions, they were submitted to pore extraction using a high pressure compression device (Barneyback and Diamond, 1981). The extracted pore solution was partly used for determination of OH^- concentration by titration. The Na^+, K^+ and Ca^{2+} concentrations of the remaining pore solution were determined by atomic absorption spectroscopy (using Model 1100B, Perkin Elmer Corp.), and those of sulphate and acetate by ion chromatography (using a Model 2000i/SP, Dionex Corp.). The pH was also measured with a combined electrode for the pH range 0 to 14.

X-ray diffraction patterns were recorded using a Philips PW-1730 diffractometer, graphite monochromator, Cu $K_{\alpha 1}$ radiation. Porosity and pore-size distribution were investigated by mercury intrusion porosimetry carried out with a Micromeritics Pore Sizer 9320. SEM anlysis were performed with a Jeol JSM 5400, equiped with an EDAX Oxford Link System ISIS model.

Table 1 Chemical composition of OPC and BFS (In Wt%).

Oxide	CaO	SiO_2	Al_2O_3	Fe_2O_3	SO_3	MgO	Na_2O	K_2O	S^{2-}	L.I.	I.R.
OPC	65.3	20.1	5.3	2.9	3.1	1.3	0.2	1.6	-	1.5	0.8
BFS	40.2	37.6	12.5	1.2	-	8.2	0.2	0.6	1.2	1.4	0.1

RESULTS AND DISCUSSION

Attack by buffered acetic-acetate (pH=4.5) solution

As it is well established, a soft and porous layer of corrosion products is developed on the surface of cement pastes as a consequence of the chemical attack of the acid solution. The thickness and colour of this layer are different in the two materials used, OPC and OPC/BFS.

For plain OPC samples after 1 day immersion in acetic/acetate buffered solution, an external white layer with perpendicular cracks, easily removable, could be seen in a cross section of the sample. Underneath this layer is also possible to observe another internal light grey layer of altered, more amorphous and porous cement. After seven days, the external layer has a yellowish colour attributable to the precipitation of iron products, as other authors have pointed out (Pavlik, 1994b and De Ceurkelaire, 1992) and in the interface between the internal layer and the undamaged core of the sample a white front of ettringite crystals appears, as analysed and detected by SEM and X-ray techniques. After 28 days, the massive precipitation of crystals in this white front causes the scaling off of the coat disclosing another internal degradation coat of altered material.

In the case of OPC/BFS samples, it is only possible to see an external degradation layer in the cross section observation. The surface of the sample has an orange-yellowish colour and the external corrosion layer is white changing to yellow in its center and then dark grey near the interface with the unaltered core. The white precipitation front seen in plain OPC samples is not present in OPC/BFS ones.

In Fig 1 the values of the corrosion depth are presented versus the square root of time. There is a linear relationship ($y = a + bt^{0.5}$) that confirms a diffusion controlled mechanism for the acid attack. The relationship found for the external layer is similar to that reported by Pavlik (1994) ($d=0.163 \cdot t^{0.525}$) for acetic acid solution of pH= 3.73.

In Fig 1 it is also shown that although the growing of external layer follows the same law with time its thickness is twice for OPC/BFS than for plain OPC samples.

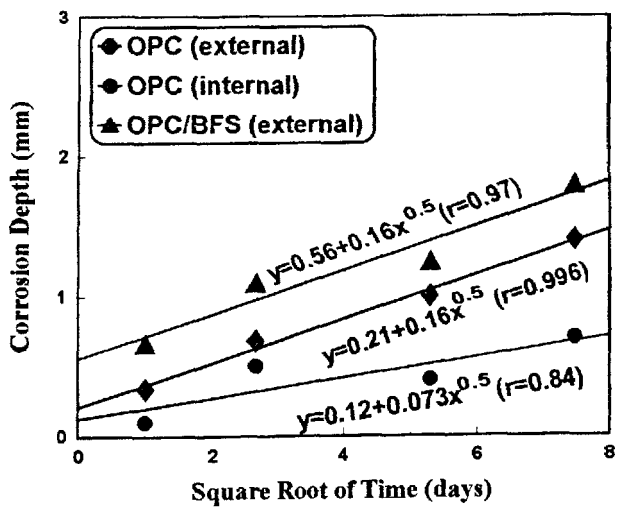

Figure 1 Depth of corrosion layers vs time.

The slope value in the equation expressing the time dependence for the internal layer thickness in plain OPC samples is less than a half for the external layer. This means a deceleration of the acid attack in this layer that can be explained on the basis of a protection of the material by the external coat (difficult to explain due to his high porosity and cracking), or by a change in the core microstructure of the paste that make them less permeable difficulting the entry of acid solution as it can be proved later.

Analysis of the pore solutions

The results of pore solution analysis from OPC and OPC/BFS samples are presented in Tables 2 and 3 respectively. The

columns Σz^+ and Σz^- are the calculated mass-charge balances of ions. The overall charge balances are in reasonable agreement.The 0 days on the table correspond to samples cured during 21 days at 100% r.h.

The pH value of OPC samples immersed in distilled water decreases from an initial value of 13.89 to a final value of 13.20 at 56 days of immersion. This decrease of pH is due to the leaching of alkalis (mainly K^+) from the cement paste. The quantity of $Ca(OH)_2$ detected by XRD stays the same at the different ages tested.

When the samples are immersed in acetic/acetate buffered solution of pH 4.5, the decrease of pH is more acute, being measured pH values about 11 at the end of the test. In this case, the decrease of pH is also due to the destruction of $Ca(OH)_2$ by attack of the acid medium. The quantity of portlandite diminishes with the time of immersion in acid medium as can be inferred from the X-ray diffractograms; nevertheless, at 56 days a significative amount is still present in the pastes. K^+ ion is leached out into the solution whereas Ac^- and Na^+ penetrate from the acid solution reaching already at seven days values that are almost in equilibrium with the concentrations of these ions in the acid medium ($[Ac^-]$ = 870 mM and $[Na^+]$ = 174 mM). Ca^{2+} concentration is always higher than that corresponding to the thermodynamic solubility product of calcium hydroxide at the pH values measured on the pore solutions. The Ca^{2+} concentration increases in order to balance the negative charges of Ac^- present in the pore solution.

The pH values of pore solutions for OPC/BFS samples immersed in distilled water do not vary with time of immersion (pH values stay around 13) and K^+ ion leaches only moderately from the pastes. This behaviour of OPC/BFS samples agrees with his lower permeability compared to plain OPC.

On the other hand, when OPC/BFS samples are immersed in acetic/acetate buffered solution, a high

decrease in the pH value of pore solution occurs very quickly: at seven days pHs bellow 7 are measured, that are in equilibrium with this of the surrounding acid solution (see Table 4). Ac^-, K^+ and Ca^{2+} concentrations follow a similar pattern to that previously described for plain OPC samples. In this case, XRD analysis reveals $Ca(OH)_2$ depletion after seven days in the solid phase.

Porosity and pore size distribution analysis

The pore size distribution curves of plain OPC and OPC/BFS samples immersed in both distilled water and acid aggressive solution appear in Fig 2.

As shown, at 0 days OPC/BFS sample has a porosity value about 50% higher than the plain OPC one, nevertheless, the pore size distribution is shifted to a lower pore diameter value. The total porosity decreased over time from 17.8% at 0 days to 12.4% at 56 days of immersion in distilled water for the OPC/BFS samples, and from 10.1% to 9.1% for the plain OPC ones. The remarkable decrease of porosity in OPC/BFS samples suggests the pozzolanic activity of the addition which, as known, produces hydrated calcium silicate and aluminate gels which densify the microstructure.

As previously indicated, when the OPC samples were immersed in the acid aggressive solution, two different corrosion layers developed at the acid/sample interface: the so called external corrosion layer with almost no adherence, and the internal one. To make the porosity analysis, the external

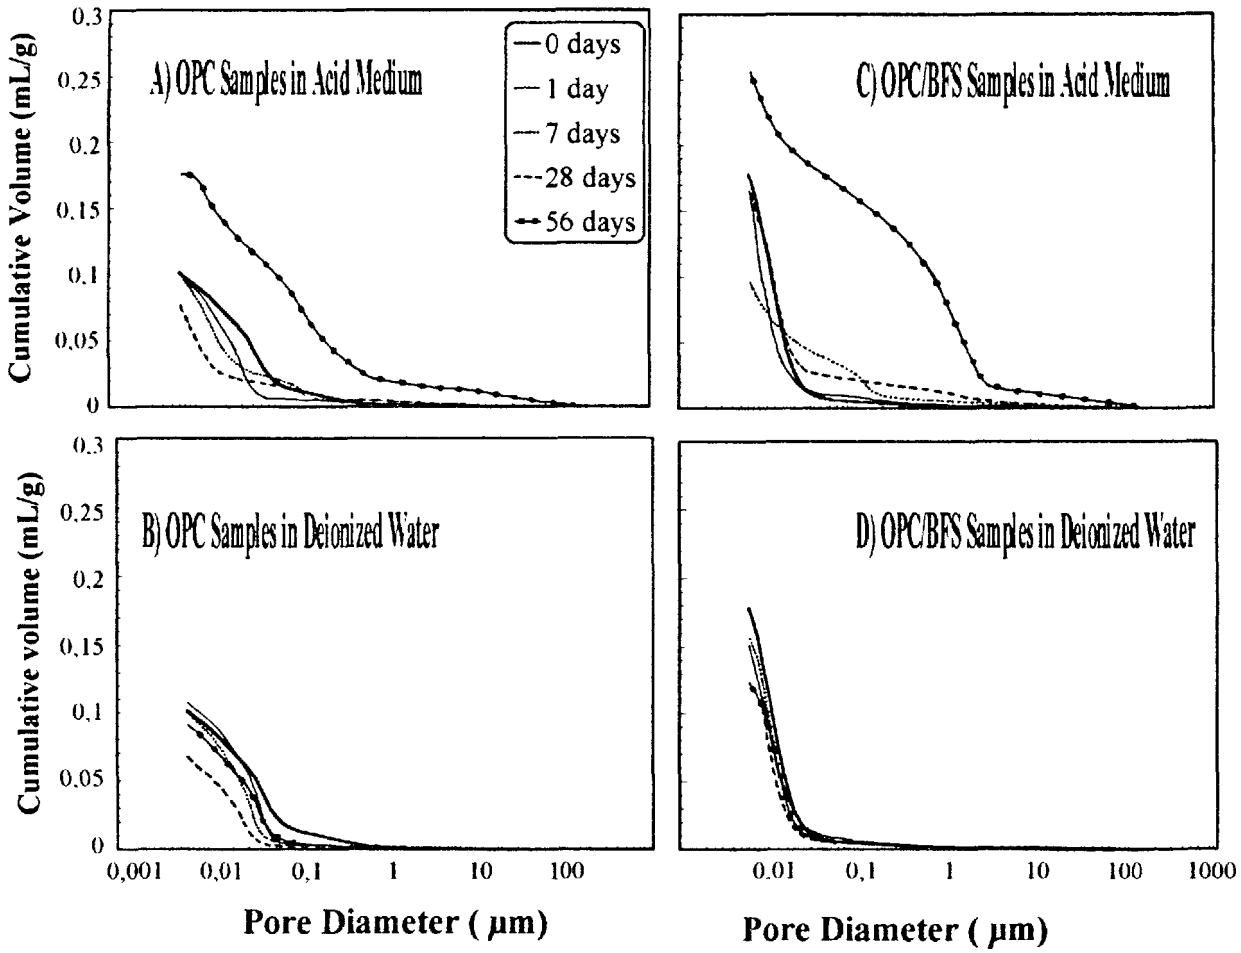

Figure 2 Pore size distribution curves for OPC and OPC/BFS samples.

corrosion layer was removed in all of the samples except those immersed during 56 days in the acid aggressive solution, due to the small dimensions of the core.

The evolution of OPC curves from 0 to 28 days shows a decrease of the porosity from 10.1% to 7.8% and a shift of the pore size distribution to lower pore diameter values. These results seem to suggest that the core of the samples is being densified. This densification was verified by SEM examination of the samples. In the samples stored in acid medium the C-S-H gel has a lower pore content, a lower Ca/Si ratio and higher content of Na than that of C-S-H gel formed in OPC samples immersed in distilled water. This densification of the gel was also found by Kurdowsky and Duszak (1995) in strong chloride solution. If so, consequently, the flexural strength will increase, as it will be seen later.

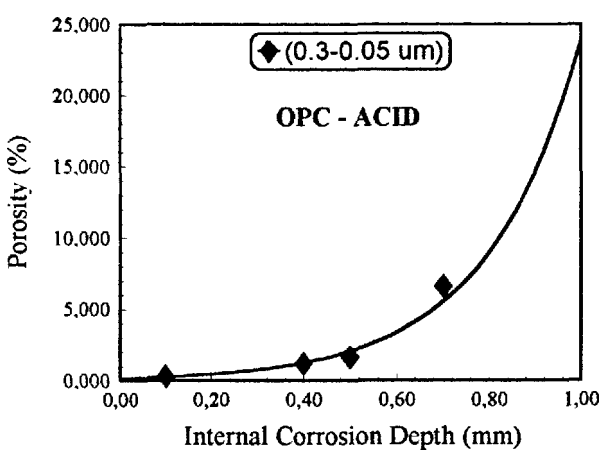

Figure 3 Volume of pores of diameter between 0.3-0.05 μm vs internal layer depth.

On the contrary, the percentage of pores with diameter ranging from 0.3 μm to 0.05 μm

increased. This increase is related to the internal corrosion layer of the samples, as shown in Fig 3 where an exponential correlation is obtained between both parameters.

The more relevant feature for the OPC/BFS samples is the increasing percentage of the pores with diameter >0.02 μm, that could be related to remaining zones of the external corrosion layer not easily removable, due to its better adherence.

The curve profiles of the samples immersed in the acid during 56 days are very different to the rest of the samples. The porosity increased remarkably as well as the percentage of pores with diameter higher than about 0.05 μm. These results are strongly related to the corrosion layers which, for the plain OPC samples, are denser than for those of OPC/BFS.

Finally, it is interesting to note that, the different porosity data obtained are a function of the kind of the corrosion layer. So, the external layer is very porous, as the porosity data after 56 days of immersion indicated, being the results in agreement with those previously reported by Bajza (1992) who used formic acid solutions instead of buffered acetic/acetate ones. Also it is interesting to note that the external corrosion layer is considerably denser in the case of OPC samples. This fact points out the difference of resistance degree to the acid attack between the two cement materials used.

Flexural strength analysis

The evolution of the flexural strength (F_s) versus the square root of time is given in Fig 4, each value representing the average of 6 measurements. The dashed zone is the standard deviation of the mean

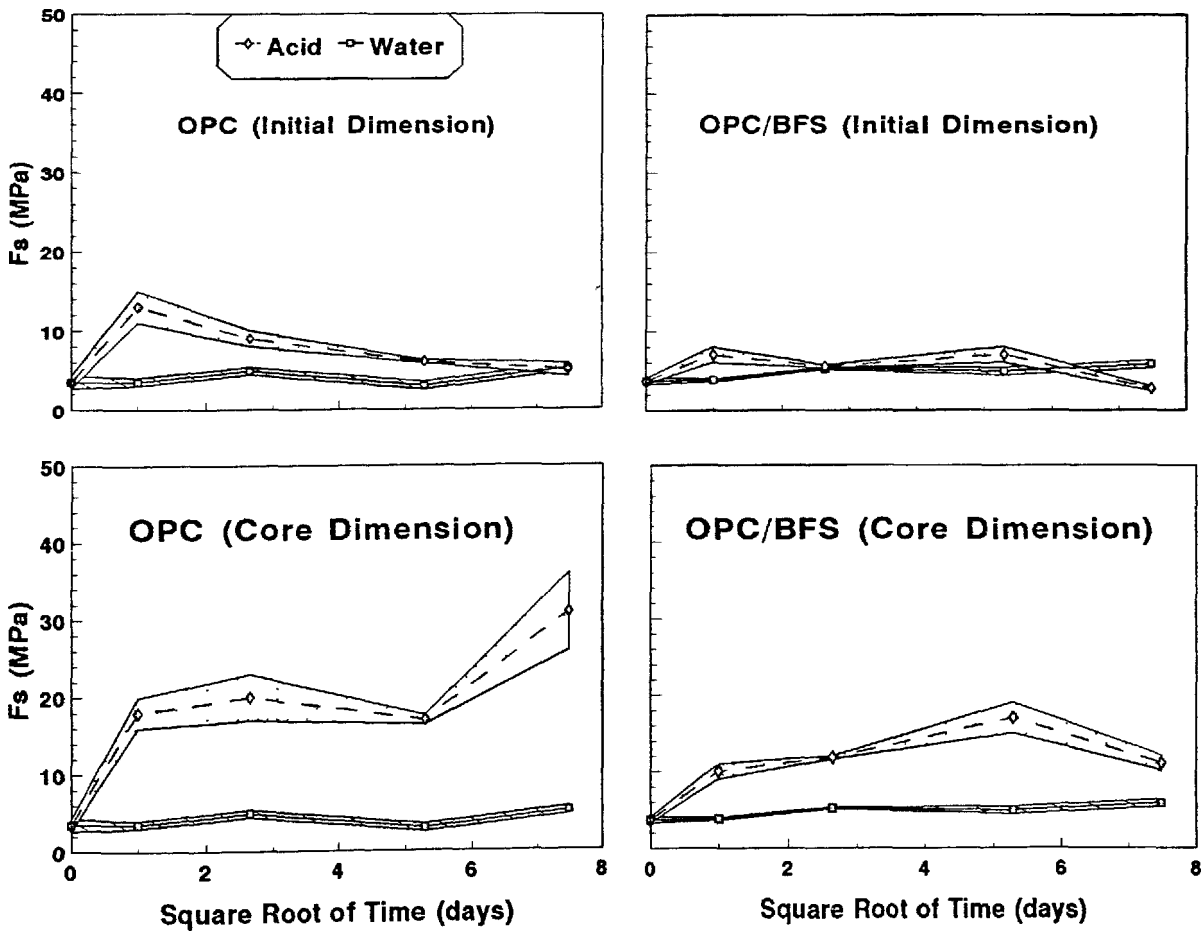

Figure 4 Evolution of flexural strength vs square root of time.

value. When both samples OPC and OPC/BFS were immersed in distilled water, the flexural strength values were very similar. In the case of the acid aggressive medium, the flexural strength strongly increased after 1 day for the plain OPC samples and in a minor extension for the OPC/BFS ones. Afterwards, the values started to decrease until reaching a plateau for the plain OPC. The behaviour for the OPC/BFS samples is more regular, as it can be seen data only have slight variations over time.

The aforementioned decrease of the flexural strength observed after 1 day for the OPC samples could be related to the corrosion layer (more porous than the core). If the flexural strength is measured on the core dimensions, the corresponding values increased with time, showing that the core is being densified (in agreement with the porosity data).

For the OPC/BFS samples and taking into account the core dimensions, the flexural strength values increased in a minor proportion than those of equivalent OPC, suggesting that the core is densified in a minor extension.

From these results and according to the test employed, both samples of plain OPC and OPC/BFS seem to be resistant to the buffered acid acetic/acetate, in the conditions here studied, and in a great measure for the plain OPC samples. But, as we previously proved, both materials are chemically attack by the acid medium been degradated and loosing sections. The simultaneous process of C-S-H gel densification that takes also place in acid medium compensates the loss of strength due to cement destruction in the corroded layers. These results are not in agreement with those reported by De Ceukelaire (1992), who concluded that blast furnace cement mortar was more resistant to hydrochloric acid attack than plain OPC one based on its superior mechanical behaviour.

CONCLUSIONS

The durability tests based on flexural strength measurements are not suitable to characterize the attack of the cement in acid medium. The densification of cement C-S-H gel that takes place in acid medium compensates the loss of strength produced by lost of section due to cement deterioration in the corrosion acid layers.

OPC/BFS pastes are less durable in acid medium than OPC plain samples: the decrease of pH in the pore solution, the consumption of $Ca(OH)_2$ and the depth of the degradation coat are higher for OPC/BFS samples than for OPC, being consequentely more severely attacked by the acid medium.

MECHANISTIC CONSIDERATIONS FOR THE EFFICIENCY OF PORTLAND CEMENT IN WASTE STABILIZATION

F. MacGregor MILLER, Construction Technology Laboratories, Inc., Skokie, IL, U.S.A.
Waldemar A. KLEMM, Construction Technology Laboratories, Inc., Skokie, IL, U.S.A.

ABSTRACT Portland cement has found increasing use in the solidification and stabilization of hazardous wastes containing regulated heavy metals such as Cd, Cr, Pb, and As. Multiple metals hydroxide sludge, with Cd, Cr(III), and Pb(II), were all well-stabilized both in cement pastes and in soil-cement matrices. Three different stabilization mechanisms were in effect, pH control, AFt formation, and C-S-H substitution. As(V) was stabilized better than As(III) in soil-cement mixes containing large additions of $FeSO_4 \cdot 7H_2O$. Iron-arsenic complexes appeared to be responsible.

Key-words: Stabilization; AFt phase; CSH; Heavy metals; Leaching

INTRODUCTION

The process of solidification/stabilization (S/S) is a widely accepted treatment/disposal process for a broad range of wastes, particularly those classified as toxic or hazardous which are not suited for normal methods of disposal and where special treatment is necessitated. Generally, for inorganic wastes, the hazard resides in the toxic and heavy metals content. Portland cement is the material found to be most useful for the purpose of S/S due to its ability for fixation and immobilization of a broad range of heavy metals. As categorized by Weitzman (1990), two of the major S/S processes which have the most value for conditioning inorganic hazardous wastes containing heavy metals include, a) cement-based binders, including portland cement and cement kiln dust (CKD), and b) lime-based binders, including lime, lime kiln dust, and lime-fly ash mixtures. Cements are uniquely suited to the task, as they not only provide the alkaline pH conditions for the precipitation of many heavy metals as insoluble hydroxides, but also provide a strong chemical bonding as well as physical encapsulation. The hydration process results in a high surface area C-S-H reaction product for immobilization of many hazardous constituents, matrix strength development, and formation of metals-substituted calcium aluminate hydrates such as AFt phases. During the solidification process, large quantities of water are incorporated into the hydration products. Regulations under the Resource Conservation and Recovery Act (RCRA) prohibit land disposal of wastes containing free liquid, and a minimum compressive strength of 0.345 MPa (50 psi) in treated waste is the usual guideline for industrial practice.

A number of investigations, relevant to the present work, on the stabilization of metals-containing waste using S/S techniques have been carried out previously. Conner et al (1992), Bishop (1988), and Zamorani and Serrini (1992) have investigated the mechanism of metal fixation in S/S systems using portland cement. Bishop (1988) also studied leaching characteristics of selected S/S systems. Glasser (1992, 1994) and Macphee and Glasser (1993) have analyzed the chemical aspects of portland cement interactions with hazardous wastes, including the effects of oxidizing and reducing agents in cement to modify its redox behavior and the incorporation of soluble oxyanions into the ettringite structure.

CADMIUM, CHROMIUM, AND LEAD — MULTIPLE METAL SLUDGES

Introduction

In previous work, Bhatty and West (1993) investigated the solidification/stabilization of cadmium (Cd), chromium (Cr), lead (Pb), and mercury (Hg) in both ASTM Type I and Type V portland cement matrices. The metals, as Cd(II), Cr(III), Pb(II), and Hg(II) were added individually as single insoluble oxides or as salt solutions, and in concentrations as high as 3% CdO, 3% Cr_2O_3, 5% PbO, and 0.05% HgO, by mass of cement. The addition of metals as oxides or metal salt solutions decreased the workability of Type I cement significantly more than Type V cement. The addition of chromium (III) salts accelerated both setting time and strength development, whereas both variables were retarded with lead(II) additions. Although these metals influenced early hydration reactions, ultimate cement hydration was as complete as the control samples. When added as either oxides or salt solutions, all four metals were well stabilized as determined by the

U.S. EPA's Toxicity Characteristic Leaching Procedure (TCLP). The stabilization of cadmium and chromium was particularly good, but some high pH leachability of lead was observed. Inasmuch as metals in wastes usually occur as hydroxide sludges, or are rapidly converted to that form by lime or portland cement, future work utilized multiple metal sludges prepared in that way.

Materials and Methods

A Type I portland cement was used for all experimental work, which had the composition of 55% C_3S, 19% C_2S, 9% C_3A, 7% C_4AF, 0.01% Na_2O, 0.62% K_2O, 3.10% SO_3, and 1.31% LOI.

Multiple metal hydroxide sludges were prepared using $CdCl_2 \cdot 2.5H_2O$, $Cr(NO_3)_3 \cdot 9H_2O$, and $Pb(NO_3)_2$. The salts were dissolved in about one litre deionized water, and $Ca(OH)_2$ powder was added until the pH reached 10.0 and remained at that value for at least 30 minutes. The precipitates were vacuum-filtered using a Büchner funnel. A small sample was removed and oven-dried at 110° C to determine the moisture content. The remaining sludge was retained in a sealed container over water until used in a cement paste mix within the next 36 hours. Cement pastes were prepared at a 0.6 water/cement ratio, which includes water from the sludge. Pastes were cast into 25.4 mm (1-in.) cube molds, and removed after three days. Compressive strength measurements were made at 3, 7, 28, and 90 days. Two series of mixes were prepared. The first mix contained Type I portland cement, with an added multiple-metal sludge containing cadmium, chromium, and lead, each at 1% (10,000 mg/kg) concentration in the total paste by mass on a metal basis. The second mix contained a similar multiple-metal sludge, each metal at a 0.1% (1,000 mg/kg) concentration by mass in the total paste.

Leaching solutions consisted of acetic acid leaching solution, and synthetic acid rain. The acetic acid leaching solution was prepared by diluting 114 mL glacial acetic acid with deionized water to a volume of 20 litres, giving a pH of 2.88. The synthetic acid rain was prepared by adding 6 mL concentrated sulfuric acid (18 M) and 4 mL concentrated nitric acid (12 M) to deionized water and diluting to 1 litre. A 100 mL aliquot was further diluted with deionized water to a final volume of 20 litres and a pH of 3.0. Paste cubes were prepared for leaching by curing for 90 days, followed by crushing to pass a 74 μm (No. 200 mesh) sieve and dried with acetone. They were subjected to sequential batch leaching of 28.01 g of high metals (1%) concentration paste and 26.39 g of low metals (0.1%) concentration paste, in 450 mL of the appropriate leaching solution. For each one-day leaching step, the 500 mL HDPE plastic leaching bottles were slowly rotated, overnight, for 16 to 20 hours. At the end of the leaching period, the bottles were removed and the contents filtered through a Büchner funnel containing a 0.7 μm pore size acid-washed glass filter. The resulting final leachate pH was measured, and the leachate was then acidified and submitted for analysis of the three multiple metals, as well as the concentrations of calcium, silicon, aluminum, and iron. The solid on the filter was subsequently returned to the original leaching bottle, which was then filled with a fresh 450 mL quantity of leaching solution for the next day of leaching.

Compressive Strength of Multiple Metals Pastes

Compressive strength measurements of two cement pastes, containing cadmium, chromium, and lead multiple hydroxide sludges, are shown in Table 1.

Table 1 Compressive strength measurements of multiple metal cement pastes.

	Compressive Strength, MPa (psi)			
Metals Addition Level	3 days	7 days	28 days	90 days
0.1% (1,000 mg/kg)	24.7 (3580)	35.2 (5100)	55.5 (8050)	61.0 (8850)
1% (10,000 mg/kg)	31.6 (4580)	36.9 (5350)	52.6 (7630)	56.4 (8180)

Acetic Acid Leaching of Multiple Metals Pastes

Sequential batch leaching, using the nominally 0.1 M acetic acid leachant for the first 7 steps and then 0.05 M acetic acid from the eighth step until the end of the sequential batch leaching, was carried out on mature pastes which had been cured for 90 days. Fig 1 shows the cumulative leach of the three metals as a function of decreasing pH for the 1% concentration mix. Each pH value plotted represents the final leachate pH after a specific leaching step. Cadmium does not begin to

leach until the pH is below about 9.5, but increases rapidly thereafter. At high multiple metals concentration, lead is leached to a slight degree at high pH, but then is well stabilized to below pH 6. Chromium has a low but finite solubility from high pH down to pH 6. It is increasingly leached below this pH value. Again, cadmium solubility seems to be nearly exclusively dictated by the pH. It is interesting to note that there appears to be a degree of suppression of leachability of all three metals apparently related to their combined presence. For the paste mix containing the 0.1% metals concentration, similar leaching behavior was observed. Compared to earlier studies of single metal leaching behavior, the solubility of the multiple metals system is somewhat lower. Lead, particularly, is less soluble at any given pH in the multiple metals leaching system. However, small but potentially significant levels of lead do leach out in the early batch leaching steps when the pH is high. In order to avoid the high pH conditions, ancillary experiments were conducted (Bhatty et al, 1996) in which silica fume was added to the multiple metal cement paste system in an amount stoichiometrically equivalent to all the $Ca(OH)_2$ to be formed by C_3S and C_2S hydration. Sequential batch leaching tests showed a reduction in the high pH leachability of lead, and no additional leachability down to pH 4.

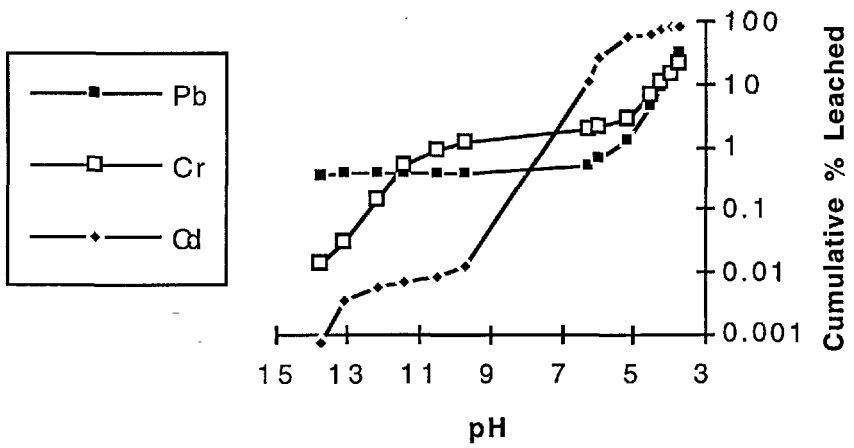

Figure 1 Summary of Pb-Cr-Cd multiple metals (1% each) leach with acetic acid.

As another means of comparing the effectiveness of portland cement stabilization of cadmium, chromium, and lead, their solubilities as a function of pH for the various leaching steps were compared to corresponding calculated solubilities from Conner et al (1992). The multiple metals in a cement matrix showed significantly lower solubilities than predicted by their theoretical hydroxide solubilities. The situation is most dramatic for lead, in that over a broad pH range, lead was found to be nearly three orders of magnitude less soluble than would be predicted by the solubility of $Pb(OH)_2$.

Cumulative % leach quantities of lead and aluminum from the 1% metals paste with acetic acid are depicted in Fig 2. The very close correspondence suggests that there is mutual synergy in the leaching of these two elements. It appears that a significant fraction of the lead may be associated with the alumina in ettringite or ferrite, since it only begins dissolving when the alumina also becomes solubilized. At pH values greater than about 11.5, lead shows some leachability due the formation of the plumbite ion, $Pb(OH)_3^-$. This oxyanion, however, has not been confirmed as forming a substituted ettringite, although the capacity of the ettringite structure to accommodate a wide variety of oxyanions is well known. In a situation similar to lead and aluminum, there is a strong correlation of leachability and pH between chromium and silica, as also seen in Fig 2. The correspondence is striking, and suggests that some of the chromium may be stabilized in the C-S-H system rather than ettringite. The ionic radii of $Cr(OH)_4^-$ and $Si(OH)_4$ are fairly closely comparable. Bensted and Prakash Varma (1971) showed that it was possible to replace Al in ettringite with trivalent Cr^{3+} and Pöllmann et al (1989, 1993) prepared chromate-substituted ettringites. However, Bensted and Prakash Varma (1972) found that the larger size of hexavalent CrO_4^{2-} oxyanions in ettringite channels appear to sterically hinder the replacement of $[Al(OH)_6]^{3-}$ octrahedra by trivalent metals such as Cr^{3+}. Only trivalent chromium was added in this Cd-Cr-Pb

system, although the possibility of limited oxidation does exist. Due to the close association of chromium leaching with silica in the multiple metal sludge mixes, it is more likely that Cr(III) substituted, in part, for Si in C-S-H as observed by Ivey et al (1990) and Lin et al (1996). It is also possible that a minor amount of Cr(III) has substituted into the aluminate phases.

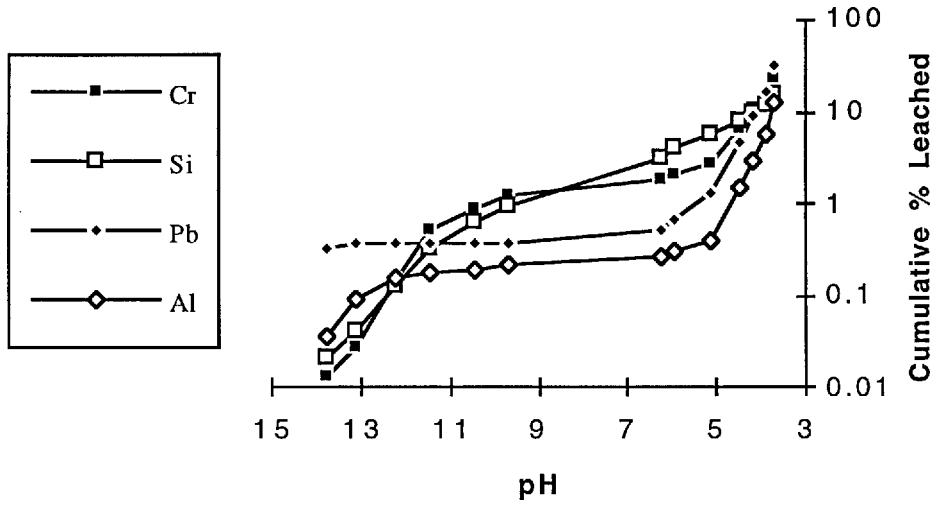

Figure 2 Lead-alumina (1% Pb) and chromium-silica (1% Cr) leaching with acetic acid.

Synthetic Acid Rain Leaching

Synthetic acid rain is a much less aggressive leaching solution than the acetic acid solution. This is not surprising when the actual number of moles of acid (hydrogen ion) available for leaching is calculated for the two systems. The acetic acid solution was 0.10 M, with a pH of 2.88, and the synthetic acid rain contained 0.00024 M nitric acid and 0.00054 M sulfuric acid for a total normality of 0.00132 N and a pH of 3.0. Thus, synthetic acid rain would require 76 leach cycles to furnish an amount of acid equivalent to that supplied by one acetic acid leach cycle. Therefore, with synthetic acid rain as a leachant, the pH never dropped below 13.0, and the degree of leaching experienced was far lower than that observed with the acetic acid leaching solutions. The initial high-pH leachability of chromium and lead was observed to continue for several cycles. The total amount leached, however, was very low for all metals, even after 16 sequential leaches.

LEACHABILITY OF CONTAMINATED SOILS AND OILY WASTE

Materials and Methods

In order to determine the behavior of cadmium, chromium, and lead in soil-cement matrices, with and without the contamination of oil, soil samples were prepared according to a procedure outlined by the U.S. EPA (1988). The soil composition is shown in Table 2. Two soil types were prepared, a) a dolomitic soil (37.14% SiO_2, 14.47% CaO, 9.63% MgO, 26.62% LOI) and b) a siliceous soil (75.27% SiO_2, 1.67% CaO, 0.88% MgO, 7.24% LOI). The silt required in the siliceous mix was prepared by grinding the silica sand to the appropriate fineness.

Table 2 Proportions of materials required for preparation of synthetic soil matrix.

Soil Ingredients	Proportion, mass %	Sources for Soil Types
Gravel (No. 9)	5.7	a) Dolomitic b) Siliceous
Sand	31.5	a) Dolomitic b) Siliceous
Silt	28.3	a) Dolomitic b) Siliceous
Bentonite	5.4	Mississippi
Kaolinite	9.4	Kraft clay
Topsoil	19.7	Local garden shop

Three soil samples were each prepared in 5 kg batches for compressive strength determinations and metals leachability, all containing 8% (400 g) of Type I portland cement and approximately 400 mL of water. The moisture content was estimated (from one experimental test with only soil and cement) to be that required for maximum density by ASTM D 558. All of the soil-cement mixes contained 7.0 g each of cadmium, chromium, and lead. The mixture of metals was added as a freshly prepared wet sludge, as described earlier. For each metal this is about 1% added to a paste of 640 g with a 0.6 w/c ratio.

A soil composition termed "Dry-Calcareous" was prepared as above and contained dolomitic soil constituents, cement, and multiple metals sludge. A second soil was termed "Oily," and was prepared with dolomitic soil, cement, metals sludge, and the further addition of 8% SAE 10-weight motor oil which had been previously aged in an oven at 100° C for 72 hours. This aging process helped to simulate the condition of contaminated oily soils usually found in the field. Additionally, to help emulsify the oil, a combination of two surfactants (31 g of Triton X-45 and 10 g of Triton X100, from Union Carbide Corporation) were added as a replacement for about 30 mL of mix water. The third soil, termed "Siliceous," was also prepared with cement, oil and metals sludge, but contained a siliceous soil composition.

Soil mixes were tamped into standard 50 mm (2-in.) cube molds. The soil specimens were cured at 23° C and 100% relative humidity prior to removal from the molds at 3-days. Cubes were tested to determine compressive strength and, after at least 28 days of curing, were crushed and dried. Soil samples containing oil were air dried and the non-oily soil was dried with acetone, prior to being subjected to the acetic acid leaching procedure described previously.

Compressive Strength of Multiple Metals Soils

Compressive strength determinations, at 7, 28, and 90 days, were subsequently made on the three soil compositions containing cadmium, chromium, and lead multiple hydroxide sludges and are shown in Table 3. Strengths exceed the industry guideline minimum of 0.345 MPa (50 psi).

Table 3 Compressive strength measurements of multiple metal soil-cement cubes.

	Compressive Strength, MPa (psi)		
Sample	7 days	28 days	90 days
Dry-Calcareous (no oil)	1.24 (180)	1.59 (230)	2.55 (370)
Oily (calcareous)	1.17 (170)	1.72 (250)	3.17 (460)
Siliceous (with oil)	1.24 (180)	1.79 (260)	2.34 (340)

Acetic Acid Leaching of Multiple Metals Soils

The three synthetic soil-cement compositions were leached with 0.012 M acetic acid as previously described. Solid leaching samples weighed between 24 and 32 g and were leached using 450 mL of leachant. The results of these sequential batch leaching steps are presented in Fig 3, which shows a comparison of the cumulative % leaching of Cd, Cr, and Pb, over a pH range of 13 to 5, for calcareous soil, oily calcareous soil, and oily siliceous soil. Each metal extracted from all three soil types showed similar leaching characteristics and tended to be grouped together by metal type.

As expected, due to its pH dependence, cadmium showed the greatest insolubility at pH values above 8, but was rapidly solubilized as the pH was lowered. Both chromium and lead were stabilized well over the range of pH 13 to 6, but lead was retained better than chromium. A comparison of leachability between the three soil types reveals some interesting trends. For the stabilization of chromium, the two calcareous soils appear to be significantly more effective in all pH ranges. For cadmium, the calcareous soils outperformed the siliceous soil at pH values above 8, but lagged at lower pH values. In the case of lead, above a pH of 9, both oil-containing soils provided better stabilization against leaching. However, below a pH of 9, the oily calcareous soil performed best. In regard to differences between the calcareous and siliceous soils, for a given amount of acetic acid used, the siliceous soil system attained a much lower pH than its dolomitic equivalent, because of the neutralizing capacity of the dolomite. At a pH of 5.0, there was a

significant amount of unreacted calcium left in samples at the end of 13 leach cycles, in spite of the acidic pH. The calcium was principally in the form of unreacted dolomite.

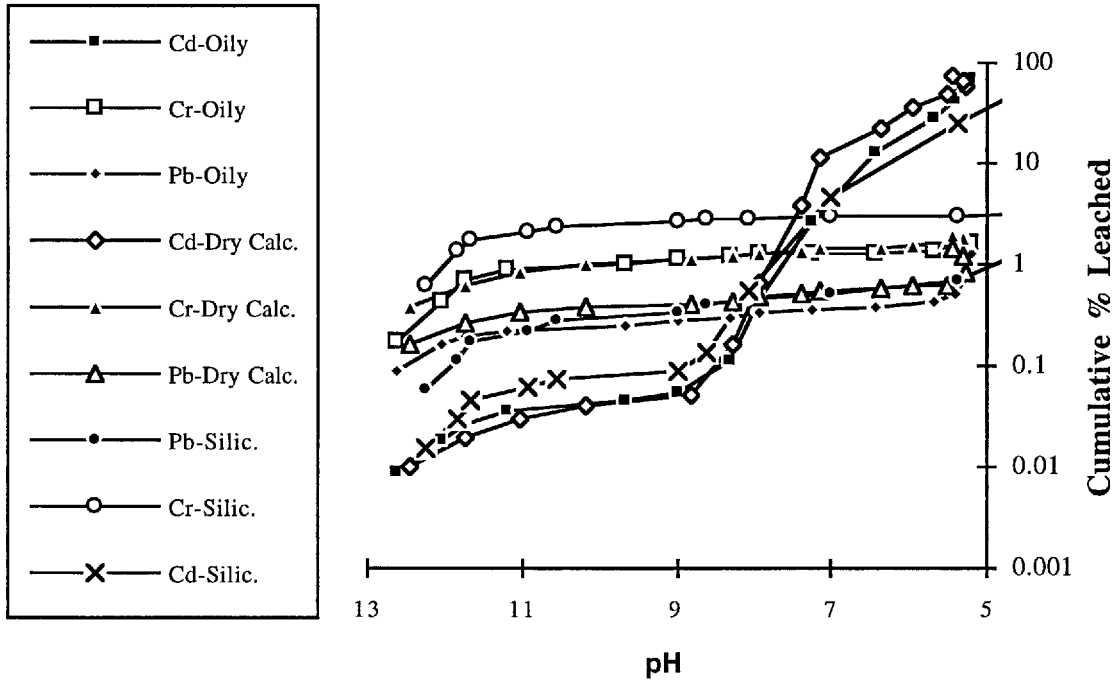

Figure 3 Comparison – cumulative % leach for oily waste, calcareous soil, and siliceous soil.

ARSENIC LEACHABILITY FROM SILICEOUS SOILS

Materials and Methods

Five soil samples were prepared in 4 kg batches for compressive strength determinations and arsenic leachability. The soil mixes, designated ASC1 through ASC5, each contained 15% (600 g) of portland cement in the synthetic siliceous soil composition described previously. Three mixes (ASC1-ASC3) contained As(V) as $Na_2AsO_4 \cdot 7H_2O$ (50 g) and two (ASC4-ASC5) contained As(III) as $NaAsO_2$ (21 g), which gives an arsenic concentration of 2% by mass of cement. Mixes ASC1, ASC4, and ASC5 also contained $FeSO_4 \cdot 7H_2O$ (267 g), which provides a six-fold molar excess of iron(II) over the arsenic. Robins (1988) reports that Fe(II) does not reduce As(V) to As(III), but that it does stabilize the arsenic in a hydrated cement matrix. These soils also required an increase in the amount of water required for proper mixing. Mix ASC2 contained EDTA (20 g), but no ferrous sulfate, in order to chelate lime and perhaps encourage the formation of substituted AFt phases. Mix ASC5 contained 20 mL of 30% H_2O_2 (6 g) in the mix water to oxidize all of the arsenite in the mix to arsenate. Additionally, a paste mix (ACP) was prepared containing cement, As(V), and Fe(II) in the same proportions as in the soil mixes.

The five soil mixes were tamped into 50 mm (2-in.) cube molds, cured, and treated as previously described. The paste sample (ACP) was cast into a 25.4 mm (1-in.) mold and cured. Cubes were tested for compressive strength and, subsequently, crushed, acetone-washed, and leached with 0.03 M acetic acid. Soil samples weighing 32 g were leached with 450 mL of leachant. The ACP sample (26 g) was leached with 0.1 M acetic acid for 7 days and then the leachant was changed to 0.05 M acetic acid for subsequent batch leaching. The change to a more dilute leachant solution at later leaching times served to expand the pH scale for lower pH values. All samples were batch leached for 11 days.

Composition and Compressive Strength of Arsenic Soils

Compressive strength determinations were made at 7 and 28 days on arsenic-containing siliceous soils. The paste sample (ACP) had a 4-day strength of 0.34 MPa (50 psi) and a 28-day strength of 6.34 MPa (920 psi). Mix compositions and soil strength data are given in Table 4.

Table 4 Composition and compressive strength of arsenic soil-cement cubes.

Mix	Additions	Compressive Strength, MPa (psi)	
		7 days	28 days
ASC1	arsenate + $FeSO_4$	0.34 (70)	3.10 (450)
ASC2	arsenate + EDTA	1.31 (190)	3.38 (490)
ASC3	arsenate	1.03 (150)	1.72 (250)
ASC4	arsenite + $FeSO_4$	0.69 (100)	6.00 (870)
ASC5	arsenite + $FeSO_4$ + H_2O_2	0.28 (40)	3.10 (450)

Acetic Acid Leaching of Arsenic Soils and Paste

The five arsenic soil cement mixes (ASC1-ASC5) and the arsenic cement paste mix (ACP) were all subjected to sequential batch acetic acid leaching. Over the 11-day period of leaching, the pH continuously decreased from approximately 13 to a final range between 3.3 and 3.6. A summary of test results showing cumulative % arsenic leached over the 11-day extraction period is given in Fig 4. All mixes had a maximum arsenic solubility at a pH of about 9.5, which corresponds, generally, to the fifth day of batch leaching. The two mixes without ferrous sulfate had excessive solubility at this pH, and eventually over 40% of the total arsenic was extracted.

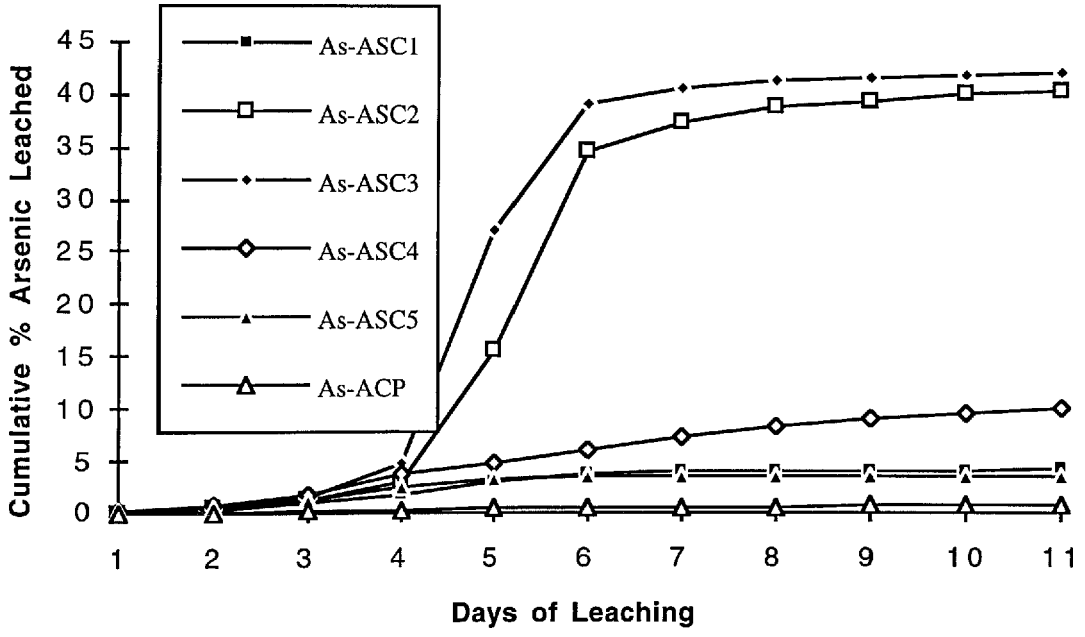

Figure 4 Summary of arsenic leach test results for synthetic soil cement and paste mixes.

The addition of EDTA (ASC2) had no real beneficial effect. At a pH below 4.0 (11th extraction), the soil containing arsenite and $FeSO_4$ (ASC4) had a cumulative loss of 10% As. The two mixes which contained arsenate with $FeSO_4$ (ASC1) and oxidized arsenite with $FeSO_4$ (ASC5) had cumulative losses of 4.1 and 3.5% As, respectively. The paste sample (ACP), containing both arsenate and $FeSO_4$, released only 0.7% of its available arsenic.

The formation of calcium arsenate was the procedure generally used in the past to stabilize arsenic. Recently, however, Taylor and Fuessle (1994) studied the interactions of iron salt precipitants with both As(III) and As(V), as stabilizing agents for arsenic. The validity of this approach was confirmed in the present study. A plausible stabilization mechanism for arsenic also involves the formation of arsenic-substituted ettringites, where the arsenate or arsenite oxyanions may replace sulfate and be incorporated into the channels between structural columns of the ettringite crystal structure. An arsenate-substituted ettringite, as well as ettringites containing B, Mo, Se, and V oxyanions, were synthesized and characterized by Hassett et al (1989) and Kumarathasan et al

(1990). However, in the arsenic cement soil experiments, an X-ray diffraction pattern taken after 28 days of curing (but, before leaching), showed the presence of a significant amount of AFt phase, probably iron-substituted ettringite. The arsenate oxyanion is probably unable to substitute into ettringite due to competition from the high excess sulfate concentration. Further evidence that arsenic is not stabilized to any significant degree in the AFt phases is provided by the low amount of arsenic leached at low pH values during sequential batch leaching when the AFt phases are being decomposed.

SUMMARY

This research was undertaken with the goal of establishing the mechanisms by which portland cement and portland cement-based stabilizing reagents immobilize certain regulated trace metals in inorganic form in S/S systems. The metals studied included Cd, Cr, Pb, and As, with addition levels of usually 1% by mass of cement. Inasmuch as metals usually occur in wastes in the form of hydroxide sludges, Cd, Cr, and Pb were added in that form to cement paste mixes and also to synthetic soil-cement matrices. In paste systems, sequential batch leaching with 0.1 M acetic acid and synthetic acid rain showed, with the exception of early high-pH leachability of lead, that very little of any of the metals were dissolved by increments of these two leachants. The effectiveness of stabilization was, in most cases, orders of magnitude better than would be projected from their respective hydroxide solubilities.

Lead showed the greatest improvement in stabilization, followed by chromium, and then by cadmium. Lead dissolution at low pH values corresponded closely with the loss of alumina, suggesting an ettringite or ferrite stabilization mechanism. In a similar fashion, the increased chromium loss at low pH values was correlated to a corresponding dissolution of silica, which indicates Cr(III) substitution for Si in C-S-H. The leachability of cadmium is continuous as the pH decreases from 9.5 to lower values during the batch leaching steps, and confirms a simple insoluble hydroxide stabilization mechanism and pH-controlled dissolution. Silica fume additions were also found to reduce high-pH lead leachability.

Stabilization in a soil matrix, both dry and oil-contaminated was also studied with additions of the Cd-Cr-Pb multiple hydroxide sludge. Cement (8%) was added to two soils, a dolomitic soil and a siliceous soil. Stabilization of the metals, especially chromium, in a soil matrix was at least as good as in cement paste. Generally, dolomitic soils stabilized the metals better than the siliceous soil. For the oily waste, appropriate emulsifiers avoided phase separation, and leaching results of oily soils were essentially comparable to those without oil. Arsenic (2%), in siliceous soil-cement matrices, was effectively stabilized through the use of ferrous sulfate additions and a Fe/As ratio of at least 6. Arsenate was found to be better stabilized, under these conditions, than arsenite. Stabilization was through formation of an iron-arsenic complex, and not by AFt phases.

ACKNOWLEDGEMENT

USE OF HEAT SIGNATURE IN SOLIDIFICATION TREATABILITY STUDIES

Caijun **SHI**, Julia **STEGEMANN** and Robert **CALDWELL**, Water Technology International Corporation, Burlington, Ontario, Canada

ABSTRACT A computerized Quadrel™ system was used to monitor the setting and structure formation of cement solidified arc furnace dust through the measurement of the adiabatic heat evolution profiles. The setting and structure development of solidified waste could be described using several parameters: initial time of setting; final time of setting, maximum heat evolution rate and total heat evolution. Experimental results indicated that the system could be used for the selection of cementing materials and for the quality control of cement solidified wastes.

Key-words: Arc Furnace Dust, Calorimetry, Heat evolution, Solidification, Structure

INTRODUCTION

The hydration of cementitious materials is accompanied by heat evolution that has been widely used to monitor the hydration and structure formation process of cement concrete [Shi and Day, 1995]. The addition of a waste to cementitious materials usually interferes with the hydration and changes the heat evolution characteristics of cementing materials. Thus, the measurement of heat evolution can be used to monitor the setting and structure development characteristics of solidified wastes. In this study, a computerized Quadrel™ system was used to measure the adiabatic heat evolution of cement solidified arc furnace dust. The purpose of this study was to examine the potential application of this system as a screening test for the selection of cementing materials for the stabilization/solidification of wastes and the quality control of cement solidified wastes.

EXPERIMENTATION

Materials

Two cementitious materials were investigated - alkali-activated slag binder (ASC) and a regular typical Type I portland cement (PC). ASC consisted of 65.9% blast furnace slag, 26.4% hydrated dolomitic lime, 7.7% silica fume and 2% Na_2SiO_3 by mass. The blast furnace slag, hydrated dolomitic lime and silica fume were pre-blended before mixing with the waste. Na_2SiO_3 for the ASC was dissolved in mixing water. The waste was dry electric arc furnace dust (AFD) from a specialty steel production, which contained a high level of B, Cr, Hg, Pb, Ni and Zn. The characteristics of the waste have been described elsewhere [Stegemann, Caldwell and Shi, 1996]. The mixing proportions of different batches are shown in Table 1.

Preparation of Specimens

Solidification mixing was performed at a temperature of 23±2°C using a Hobart mixer. The cementing materials were first mixed with water (for PC) or Na_2SiO_3 solution (for ASC) for approximately 30 seconds first, then with arc furnace dust for approximately 5 minutes. The mixing water was adjusted to produce mixtures with a normal consistency. Once the mixing was finished, the mixtures were cast into plastic cylinder moulds with a diameter of 6 inches and a height of 12 inches, then weighed and placed into a QD0612 Qdrum™ Calorimeter to measure the adiabatic heat signature of the mixtures.

Table 1 Mixing Proportions of Solidified Arc Furnace Dust (by mass)

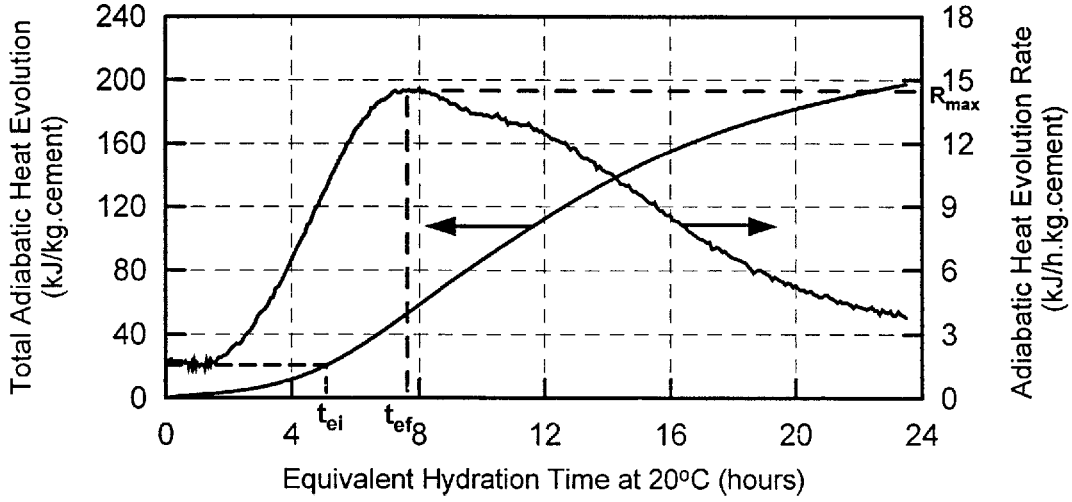
Batch Symbol	ASC (%)	PC (%)	Arc Furnace Dust (%)	Water to Solid Ratio	Water to Cementing Material Ratio
ASC0	100		0	0.43	0.43
ASC30	70		30	0.35	0.50
ASC60	40		60	0.30	0.75
PC0		100	0	0.28	0.28
PC30		70	30	0.26	0.37
PC60		40	60	0.25	0.63

Measurement and Analysis of Adiabatic Heat Signature (AHS)

The computerized Quadrel™ system, which consists of a Qdrum™ calorimeter, QuadLogger™ datalogger and Quadrel™ software, is described in detail in a published report [Radjy et al, 1995]. The datalogger and calorimeter were programmed before mixing and started recording signals once the specimen was placed into the calorimeter drum. Thus, the first recording started approximately 10 minutes after mixing water or Na_2SiO_3 solution was added to the mixtures. The recording was checked every day and stopped when no significant temperature change was observed. The Quadrel™ software analyzed the recorded results and converted the hydration time into equivalent time at 20°C using a maturity approach [Radjy et al, 1995]. Fig.1 illustrates the determination of some parameters, such as: equivalent initial time of setting (t_{ei}), equivalent final time of setting (t_{ef}) and maximum heat evolution rate (R_{max}) by the Quadrel™ software.

EXPERIMENTAL RESULTS AND DISCUSSIONS

Figure 2-a shows the adiabatic heat evolution of ASC0, ASC30 and ASC60. At early ages, the addition of AFD to ASC decreased the heat of hydration. The higher the AFD content was, the lower the total heat evolution was. The cementing materials in ASC0 released heat quickly before



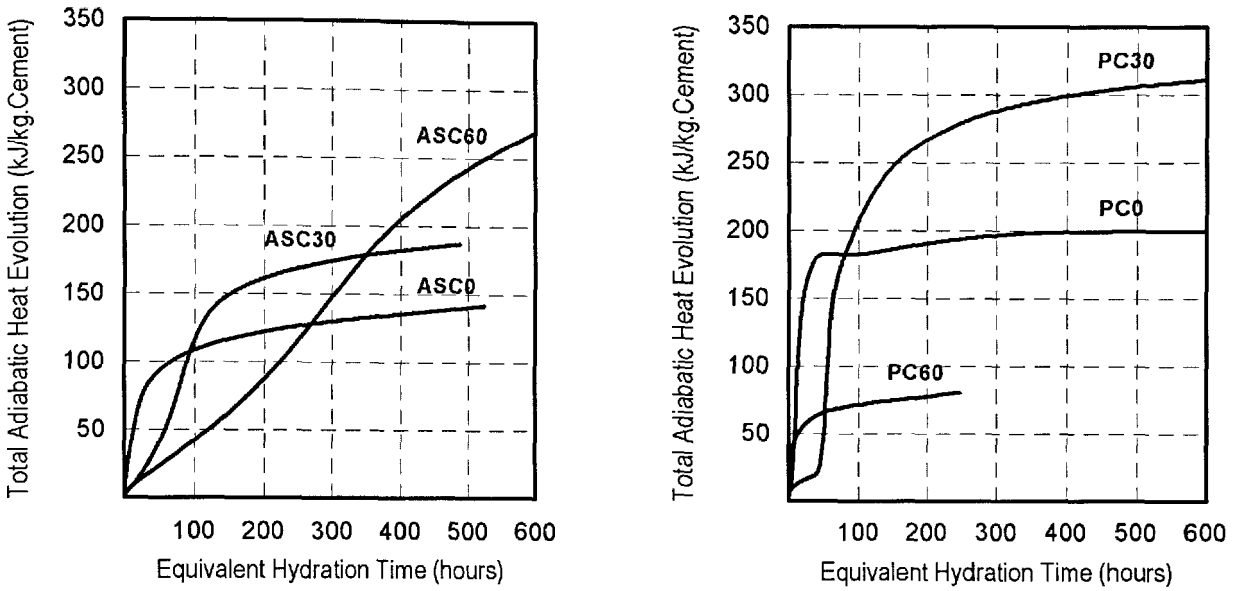


Figure 1 Determination of Setting Times and Maximum Heat Evolution Rate by Quadrel™

(a) ASC Solidified AFD (b) PC Solidified AFD

Figure 2 Effect of AFD Dosage on Adiabatic Heat Evolution of Solidified AFD

70 equivalent hours and very gradually thereafter. ASC30 and ASC60 released less heat than ASC0 before 70 equivalent hours and continuously released heat at a higher rate than ASC0 thereafter. At approximately 100 equivalent hours, ASC30 released more heat than ASC0. ASC60 released more heat than ASC0 after 260 equivalent hours, and. more heat than ASC30 after 350 equivalent hours. It appeared that the presence of arc furnace dust retarded the early hydration but was beneficial to the later hydration of the slag.

The adiabatic heat evolution curves of PC0, PC30 and PC60 are shown in Figure 2-b. PC0 exhibited a very short induction period at the beginning of hydration, then released heat very vigorously until approximately 40 equivalent hours and reached a plateau thereafter. The appearance of the plateau resulted from the shortage of water for further hydration. According to T. C. Powers' theory [Powers, 1958], the minimum water-to-cement ratio for the complete hydration of portland cement under sealed conditions is 0.42. The water-to-cement ratio in PC0 was only 0.28 and therefore sufficient for 67% cement to hydrate. The release of heat from PC30 was retarded for approximately 50 equivalent hours, and then behaved as PC0. However, PC30 released heat gradually at later ages. Although the water-to-cement ratio in PC30 was 0.35 which theoretically enabled 83% cement to hydrate, no plateau was observed in the heat evolution curve of PC30. PC60 did not exhibit any induction period at the beginning, but had a very brief vigorous release of heat and released much less heat than PC0 and PC30 at later ages. The total released heat is closely related to the degree of hydration and strength of hardened cementing materials [Radjy and Vunic, 1994]. It can be expected that PC60 will not have a dense and strong structure due to only a small portion of portland cement being hydrated.

The curves for heat evolution rates are not presented here due to space limitation. Equivalent times of setting and heat evolution characteristics of all batches are summarized in Table 2. The addition of AFD retarded the initial and final setting of the ASC based mixtures. The higher the AFD content was, the more retarded the setting. The addition of 30% AFD retarded initial and

Table 2 Times of Setting and Heat Evolution Characteristics of Solidified AFD

Batch	t_{ei} (hours)	t_{ef} (hours)	R_{max} (kJ/h.kg.cement)	Q_{28} (kJ/kg.cement)	Q_{90} (kJ/kg.cement)
ASC0	3.5	16.5	2.4	146.1	169.0
ASC30	45.3	83.7	1.8	192.8	206.1
ASC60	144.2	336.8	0.6	398.8	544.7
PC0	6.1	9.3	14.0	199.6	201.4
PC30	45.7	53.8	9.7	313.5	329.0
PC60	1.2	214.2	0.1	87.3	90.3

final setting of PC, while the addition of 60% AFD caused a rapid initial setting and a retarded final setting. As the AFD content increased, it reduced the heat evolution rate of PC much more significantly than that of ASC. The predicted heat evolution at 28 (Q_{28}) and 90 days (Q_{90}) was very consistent with above statement.

From the times of setting and heat evolution characteristics of solidified AFD, it could be seen that the increase in AFD content from 30 to 60% showed a much more significant effect on the hydration of PC than on that of ASC. The rapid initial setting of PC60 will affect the mixing and placing of solidified wastes. It could be concluded that ASC was better than the Type I portland cement for the stabilization/solidification of the AFD and was selected for a field solidification study [Stegemann, Caldwell and Shi, 1996]. Extensive experiments have confirmed that ASC60 shows a very dense and durable structure after 28 days of curing, while PC60 specimens are still very weak and porous after more than one year of curing at room temperatures.

CONCLUSIONS

The Quadrel™ system could monitor and determine the hydration and structure formation of cement solidified wastes using parameters, such as equivalent times of setting, maximum heat evolution rate and total heat evolution. Based on the adiabatic heat evolution measurement, it could be concluded that ASC was better than the commercial Type I portland cement for the stabilization/solidification of the AFD because the former was less sensitive to AFD content than the latter.

STUDIES ON IMMOBILIZATION OF HEAVY METALS IN CEMENT PASTE - - C-S-H LEACHING BEHAVIOUR

Wiesława NOCUŃ-WCZELIK, University of Mining and Metallurgy, Kraków, Poland
Jan MAŁOLEPSZY, University of Mining and Metallurgy, Kraków, Poland

ABSTRACT The effect of heavy metal containing compounds, such as $Zn(NO_3)_2$, $Pb(NO_3)_2$, $CdCl_2$ and Na_2CrO_4 on the phase composition, microstructure and leaching behaviour of calcium silicate hydrates cured at ambient temperature and in hydrothermal conditions was investigated. In the presence of heavy metal compounds the highly disordered C-S-H formation is accelerated and recrystallization is retarded. A high degree of Zn, Pb and Cd stabilization in C-S-H has been shown; Cr(VI) is immobilized with lower effectiveness.

Key-words: CSH, heavy metals, immobilization, leaching, structure

INTRODUCTION

Application of cementitious systems in heavy metals immobilization has been widely reported for a few years [Glasser 1992, 1994; Grutzeck 1992]. The Cr, Pb, Cd and Zn compounds are succesfully immobilized in normal portlan cement matrix [Reinhardt 1993; Tamas, Csetenyi, Tritthart 1992]. The C-S-H produced as a result of processes occurring in cement pastes plays a decisive role of "cut-off wall" (when cement concrete is used to surround the area of waste storage) or stabilizer (when waste sludge is mixed with cement and thus solidified), forming a physical barrier due to special physical and chemical properties (microstructure, high pH value of residual liquid, high specific surface etc.) [Glasser 1994].

EXPERIMENTAL

Materials

The mixtures of calcium hydroxide (analytically pure), silica-gel (pure) and water with CaO to SiO_2 molar ratio equal to 0.83 and 1.5 respectively were prepared. Apart from the reference samples without admixtures, the following heavy metal containing compounds of analytical purity, calculated as 2 wt.% of anhydrous $CaO+SiO_2$ substance, were introduced to the batches: $Zn(NO_3)_2$, $Pb(NO_3)_2$, $CdCl_2$ and Na_2CrO_4.
The samples, thorougly homogenized with w/c=1.5 were subsequently sealed in polyethylene bags and stored at ambient temperature for several months or subjected to 24 hours thermal treatment in a laboratory autoclave, at 200°C. After treatment the hardened samples were ground and washed with acetone before drying in a laboratory drier (60°C); pieces of fractured samples were kept in acetone for SEM observations.

Methods

The effect of heavy metal compounds on the phase composition of hydrating mixtures was studied by XRD, DTA and TG analysis (determination of bound water content and carbonates). The microstructure was characterized through the SEM observations and EDS measurements. The leaching behaviour of calcium silicate hydrates cured at ambient temperature as well as in hydrothermal conditions was investigated on the leachates obtained by the liquid phase separation from the suspensions prepared at water to solid ratio of 50 - the powdered samples were mixed with water and shaken for 1 hour period. Finally, the silicate anion structure before and after the lixiviation was evaluated by the molybdate complexing method [Thilo, Wieker, Stade 1965].

RESULTS - CaO/SiO_2=0.83

Results from the XRD and DTA-TG experiments, at ambient temperature, in the presence of heavy metal compounds show that a highly disordered C-S-H formation is accelerated, but the transformation of the structure or its recrystallization during hydrothermal treatment is retarded. The strong peaks corresponding to d=0.307nm (nearly amorphous C-S-H) and d=0.490; 0.2628nm ($Ca(OH)_2$)are visible on XRD patterns of the samples stored at room temperature. The patterns for the autoclaved samples show no $Ca(OH)_2$ peaks and some further small ones attributed to the calcium silicate hydrate C-S-H (see Fig.1). Only in two cases: the product without additive and that synthesized with $Pb(NO_3)_2$, the 1.1nm peaks corresponded to the more ordered, tobermorite-like structure: these two materials seem to be better crystallized.

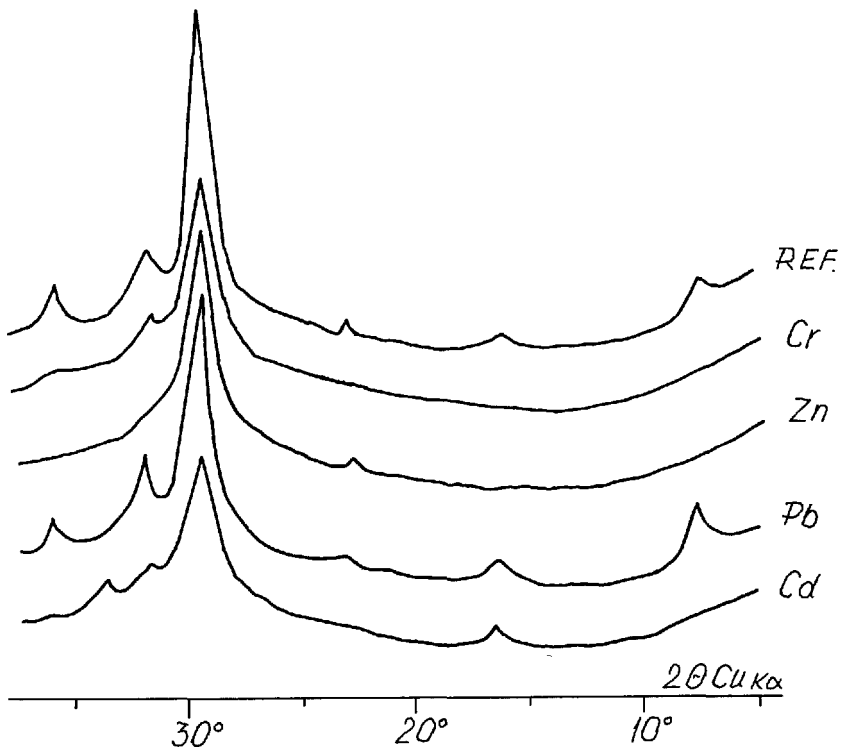

Figure 1 XRD patterns of the autoclaved samples (200°C/24h). CaO/SiO_2=0.83.

Results from the DTA-TG measurements given in Table 1, disclose thet samples synthesized at room temperature with heavy metal compounds have higher water release contents during C-S-H decomposition in the range 100-200°C and simultaneously lower $Ca(OH)_2$ contents.

Table 1 Results of DTA-TG studies. CaO/SiO_2=0.83.

Sample	Reference	Na_2CrO_4	$Zn(NO_3)_2$	$Pb(NO_3)_2$	$CdCl_2$
cured at room temperature for 6 months					
H_2O in C-S-H	8,9 %	13,6 %	13,6 %	12,6 %	13,9 %
$Ca(OH)_2$	13,5 %	10,0 %	2,0 %	5,2 %	3,0 %
$CaCO_3$	14,9 %	9,2 %	12,7 %	3,2 %	17,5 %
autoclaved 200°C/24 hours					
H_2O in C-S-H	8,3 %	14,9 %	10,0 %	10,3 %	11,0 %

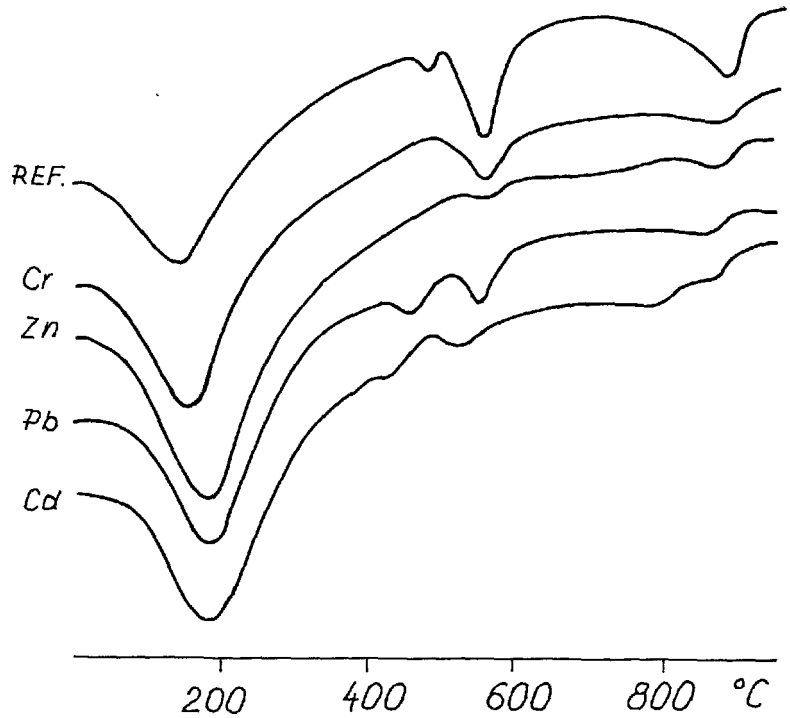

Figure 2 DTA curves for the samples cured at room temperature for 6 months. C/S=0.83.

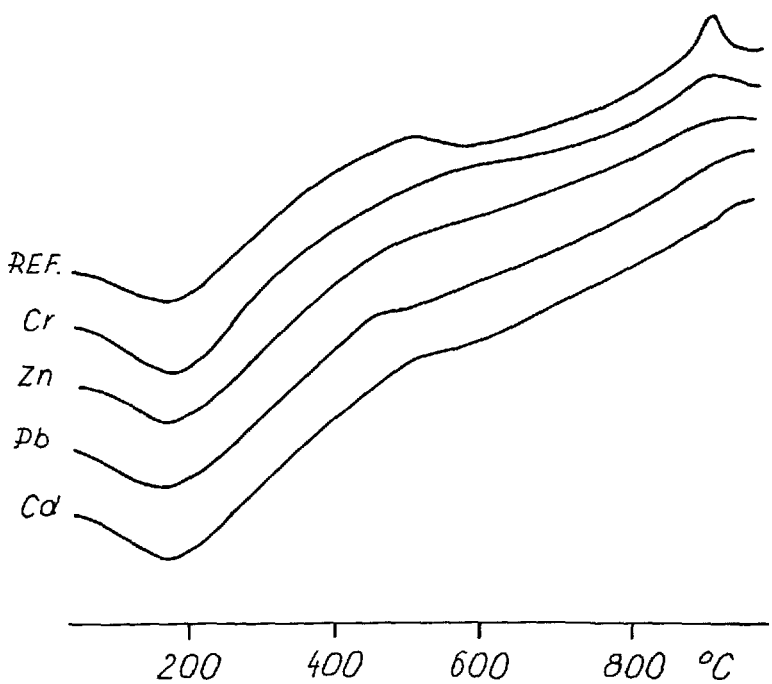

Figure 3 DTA curves for the samples autoclaved at 200°C/24h. C/S=0.83.

There are also some small effects which can be attributed to the decomposition of the heavy metal hydroxides and salts (see Fig.2), not detectable by XRD. The DTA curves for the autoclaved samples show only the dehydration effect at 100-200°C (see Fig.3). Up to about 800°C the curves exhibit no peaks - which would suggest that the calcium hydroxide and

additives have been totally consumed and incorporated to the structure of calcium silicate hydrates. Only in the cases of the sample with no admixture and that of Na_2CrO_4 the peak usually attributed to wollastonite synthesis is visible. This may mean that some amount of the chain silicate anions has been formed in in the precursor hydrates. The autoclaved calcium silicate hydrates doped with heavy metal compounds, as well as those cured at ambient temperature, show a significantly higher water content. This may be as a consequence of their highly disordered, more "open" structures. The samples stored for a long time at room temperature also show the presence of carbonates (DTA - TG results) but it is rather difficult to find a relationship between the admixture, calcium hydroxide and carbonate contents. The CO_2 content in the sample with $Pb(NO_3)_2$ is the lowest.

Results from the SEM observations, which were the subject of a more detailed report [Nocuń-Wczelik, Trybalska and Rakowska 1994], show that the C-S-H phase produced with heavy metal compounds is generally poorly crystallized, composed of small grains or flakes. The autoclaved material with no admixtures shows the presence of well developed plate-like and lath-like morphologies. A similar morphology is observed also in the autoclaved material with Pb compound. The examples of microstructures are presented in Figs 4 and 5.

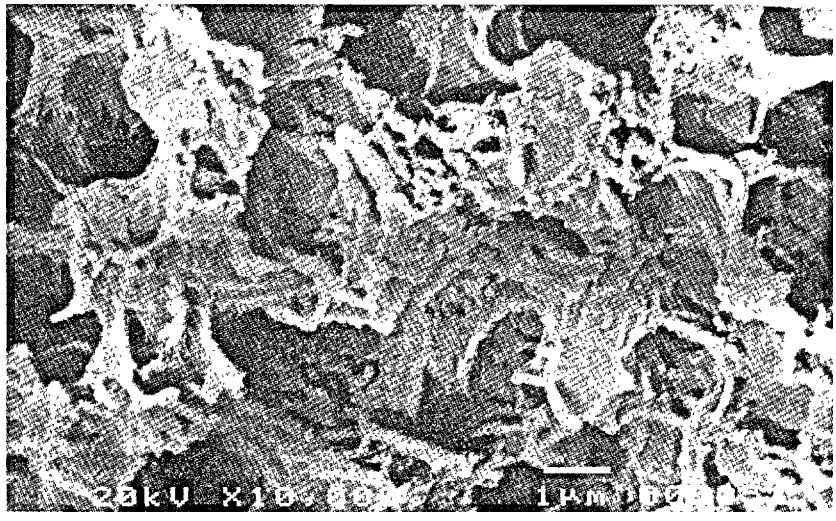

Figure 4 SEM. Microstructure of autoclaved (200°C/24h) sample. 2% $Zn(NO_3)_2$. C/S=0.83.

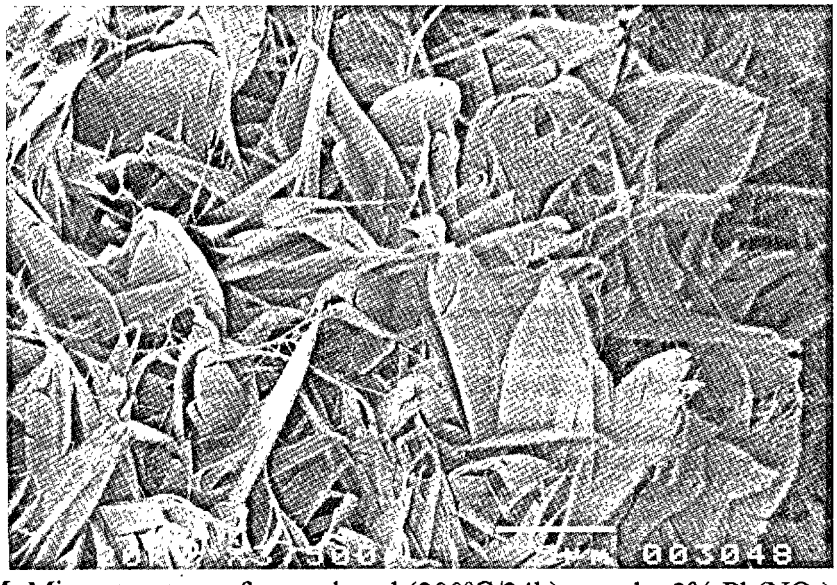

Figure 5 SEM. Microstructure of autoclaved (200°C/24h) sample. 2% $Pb(NO_3)_2$. C/S=0.83.

The EDS studies showed the homogenous distribution of the metallic elements introduced with admixtures.
The results of leaching tests are shown in Table.2. The high degree of Zn, Pb and Cd stabilization (exceeding 99.8%) in C-S-H formed both at room temperature and in hydrothermal conditions has been shown; Cr(VI) is immobilized with lower effectiveness.

Table 2 Results of leaching tests. Water to solid =50. CaO/SiO_2=0.83.

Sample curing	Cr [immobilized]	Zn [immobilized]	Pb [immobilized]	Cd [immobilized]
20°C/6 months	95,15% (498 ppm)	99,91% (48 ppm)	99,87% (138 ppm)	99,97% (18 ppm)
200°C/24h	95,85% (451 ppm)	99,96% (28 ppm)	99,97% (34 ppm)	99,96% (23ppm)

RESULTS - CaO/SiO_2=1.50

In all the samples cured at room temperature, irrespectively of the additive used, the strong d=0.307 nm peaks corresponding to the poorly crystallized C-S-H are observed, together with the strong d=0.490; 0.2628 nm peaks of unreacted calcium hydroxide. The XRD patterns are very similar. In the autoclaved samples (200°C/24h) the tobermorite occurring together with C-S-H (I) are found. This C-S-H shows a significantly ordered structure as it can be derived from the sharp peak d=1.25 nm. Only in the sample with Na_2CrO_4 can unreacted $Ca(OH)_2$ be detected by XRD. Analyzing the XRD data one also notes that the structural order slightly decreases from the sample without admixture and with $Zn(NO_3)_2$ through those with $CdCl_2$ and $Pb(NO_3)_2$ to the Na_2CrO_4 doped hydrating mixture respectively (see Fig.6). In both series of samples, neither the admixture nor the other phases formed with these admixture were detected by XRD. The presence of $CaCO_3$ cannot be totally excluded because of the coincidence of carbonate peaks with those of C-S-H and $Ca(OH)_2$.

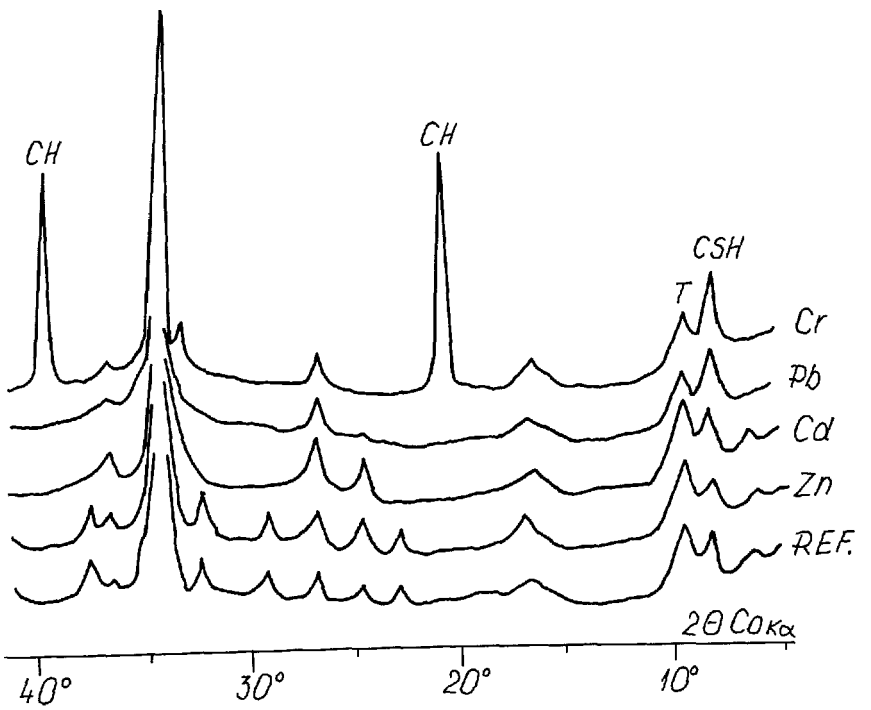

Figure 6 XRD patterns of the autoclaved samples (200°C/24h). CaO/SiO_2=1.50.

The DTA-TG measurements add some new information to the results. On the DTA curves the peaks of hydrate decomposition in the range up to over 200°C, as well as the peaks corresponding to the calcium hydroxide dehydration at 400-600°C and those relating to the $CaCO_3$ decarbonation are visible. On the basis of the TG results the bound water, calcium hydroxide and carbonate contents were calculated (Table 3).

Table 3 Results of DTA-TG studies. CaO/SiO_2=1.50.

Sample	Reference	Na_2CrO_4	$Zn(NO_3)_2$	$Pb(NO_3)_2$	$CdCl_2$
cured at room temperature for 9 months					
H_2O in C-S-H	3,8 %	3,6 %	5,2 %	5,3 %	4,7
$Ca(OH)_2$	10,5 %	8,2 %	3,3 %	6,2 %	7,8 %
$CaCO_3$	7,1 %	14,1 %	12,9 %	10,8 %	10,9 %
autoclaved 200°C/24 hours					
H_2O in C-S-H	1,0 %	0,9 %	0,9 %	4,2 %	2,3 %
$Ca(OH)_2$	-	1,8 %	-	-	-
$CaCO_3$	4,2 %	3,6 %	2,2 %	2,3 %	4,5 %

The sample without admixture, stored at room temperature has the highest $Ca(OH)_2$ content. In the admixtured samples the amounts of unreacted hydroxide are lower but the contents of carbonate increase, presumably in finely dispersed form, as one can conclude from the lowered decomposition temperature. The formation of carbonates with cations introduced to the mixtures cannot be excluded. Undoubtedly, the presence of accompanying acid anions promotes the carbonation of pastes [Fournier, Fournier, Bellaoui, Pit 1995]. The TG studies confirm that the calcium hydroxide is consumed in hydrothermal conditions; apart from the sample with Na_2CrO_4, the carbonation is low.

From the SEM observations, the C-S-H phase produced with heavy metal compounds at room temperature is poorly crystallized, composed of sponge-like aggregates and crumblyd flakes. The autoclaved material with and without admixtures shows more or less platelike and fibrous morphologies (C-S-H, tobermorite); an example of microstructure is given in Fig 7.

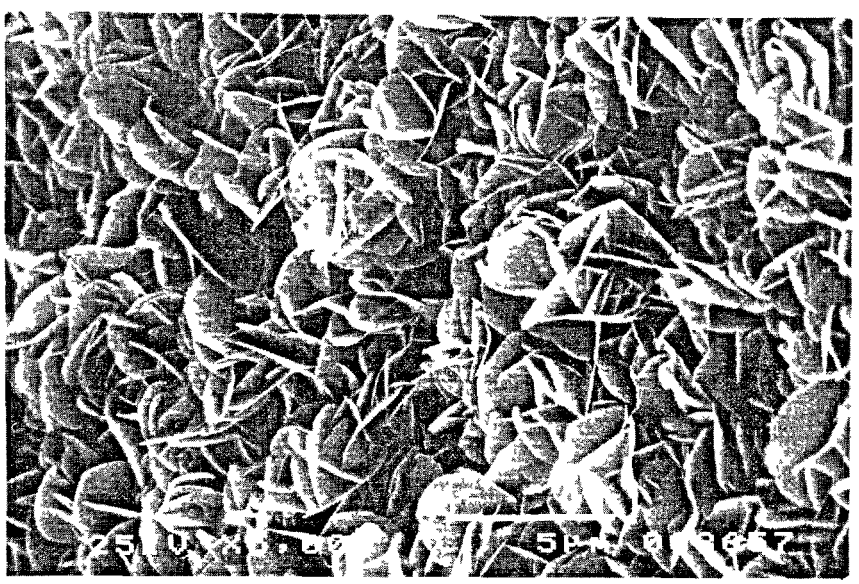

Figure 7 SEM. Microstructure of autoclaved (200°C/24h) sample. 2% $CdCl_2$. C/S=1.50.

The results of leaching tests are shown in Table.4. The high degree of Zn, Pb and Cd stabilization (exceeding 99.8%) in C-S-H formed both at room temperature and in hydrothermal conditions has been shown; as one could expect Cr(VI) is immobilized with lower effectiveness. These data are in good agreement with the earlier results and reports.

Table 4 Results of leaching tests. Water to solid=50. CaO/SiO_2=1.50.

Sample curing	Cr [immobilized]	Zn [immobilized]	Pb [immobilized]	Cd [immobilized]
20°C/9 months	83,28% (20 ppm)	99,99% (11 ppm)	99,96% (54 ppm)	99,99% (7 ppm)
200°C/24h	81,83% (22 ppm)	99,93% (89 ppm)	99,96% (44 ppm)	99,98% (138 ppm)

For the series of samples cured at room temperature the degree of silicate anion condensation before and after leaching was evaluated by the molybdate complexing method and plotted in Figs 8 and 9 as percentage of silica complexed vs. time.

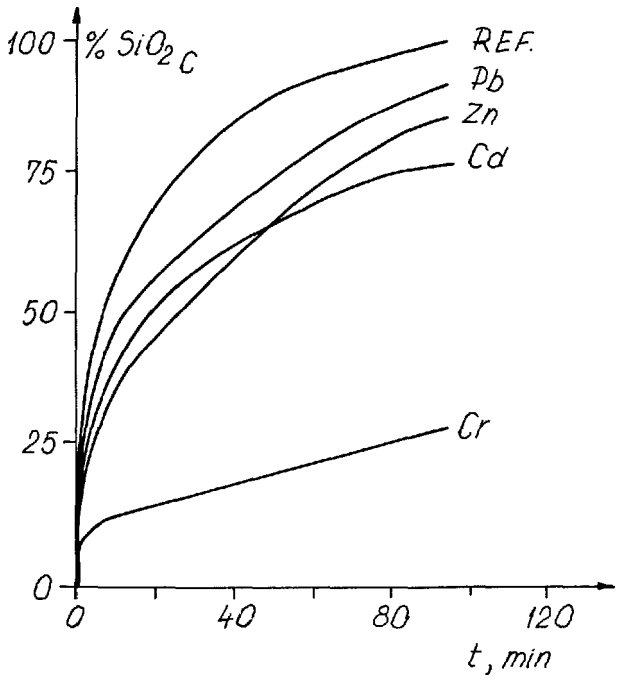

Figure 8 Molybdate complexing curves. CaO/SiO_2=1.50. 20°C/9 months. Before leaching.

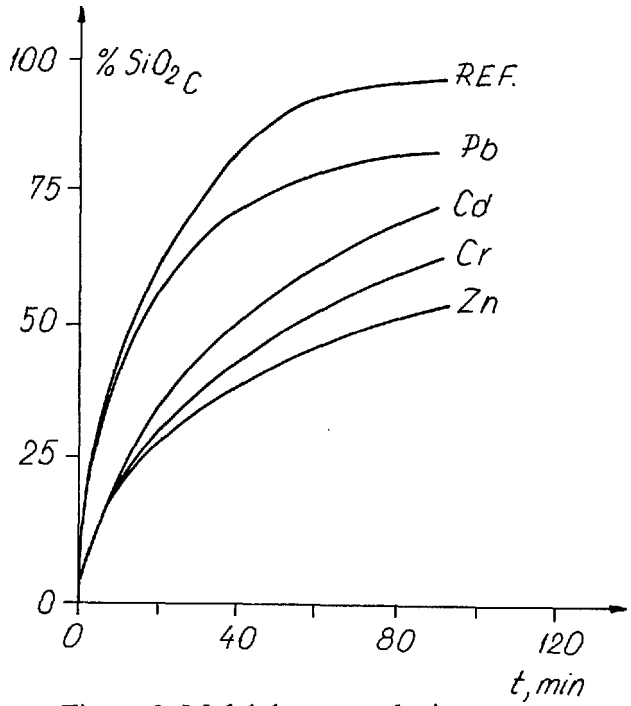

Figure 9 Molybdate complexing curves. CaO/SiO_2=1.50. 200°/24h. After leaching.

The results of the molybdate complexing studies can be summarized as follows:
- the admixtures introduced to the hydrating batch bring about an increase in the fraction with higher silicate anion condensation degree: this effect is particularly strong for the sample with Na_2CrO_4,
- the lixiviation by water destroys the structures formed on hydration, the changes observed for the reference sample with no admixture are not so evident as for the other samples,
- in the samples produced with $Zn(NO_3)_2$, $Pb(NO_3)_2$ and $CdCl_2$ the condensation of the silicate anion after leaching is generally observed; in turn, the silicate anion structure in the presence of Na_2CrO_4 decomposes on leaching.

The course of molybdate complexing curves depends on many factors. The admixtures introduced to the hydrating mixtures play a decisive role. The higher condensation degree in

the presence of admixtures results from the better dissolution of initial components and acceleration of calcium silicate hydrates formation; the carbonation of paste favourizes also this process. Subsequently, the mobile, acidic anions accompanying the cations immobilized as hydroxide or complex compounds in the matrix, are removed on leaching from the pore water or from the structure, thus promoting the condensation. The reverse situation in the presence of Na_2CrO_4 can be explained by the presence of sodium cations which strongly accelerate the dissolution of silicate component during the formation of hydrates and the simultaneous action of chromate components reinforcing the polymerized structure. This "competition" mechanism results in the condensation degree decrease on leaching.

CONCLUSIONS

1. Calcium silicate hydrates formed at room temperature in the presence of heavy metal compounds are poorly crystallized; admixtures accelerate the calcium hydroxide consumption and carbonation of pastes.
2. The silicate anion structure is significantly affected by the presence of heavy metal compounds - the fraction of high condensation degree increases.
3. In hydrothermal conditions the crystallization of hydrates is accelerated but generally the retarding action of heavy metal compounds on the structural transition to more ordered forms is observed.
4. Zn, Pd and Cd are immobilized in C-S-H with very high, exceeding 99.8% effectiveness, irrespectively of curing conditions and CaO/SiO_2 ratio in the matrix. Cr (VI) is immobilized with lower effectiveness. The degree of Cr immobilization becomes lower as CaO/SiO_2 ratio in C-S-H increases from 0.83 to 1.50.

ABSTRACT

Samples containing HAC, OPC, and different aggregates were mixed with a composition of different pollutants. The long term physico-chemical stability was investigated by a weathering cycle lasting five month. The development of strength, further phase crystallization, elution behavior, structural change and element distribution on the surface was evaluated. The results are giving a good stability for waste immobilizates in different solution when the mixtures are attuned for specific applications.

Key-Words: Immobilization; solidification; life cycle analysis; leaching; heavy metals;

INTRODUCTION

The accumulation of polluted, non-reusable industrial waste products (flue gas desulfurization products, fly-ashes (PFA), contaminated sludge etc.) requires environmentally acceptable disposals. Immobilization and solidification of these pollutants can be achieved by adding cement to the waste products or by mixing adequate proportions of different industrial waste products. The resulting stabilized product of this treatment is containing different reservoir minerals (AFm phases, AFt phases) intimately intergrown with non reactive material. The solidified waste containing the immobilized pollutants itself can be used as an „Inner Barrier System" of a waste dump. For this application the immobilizates have to be resistant against atmospheric conditions and also have to be stable under the geochemical conditions in the waste dump.

Object of this study was the investigation of two different cement mixtures with the same content of pollutants, which comply with the requirements of homogenizing, with the specifications of the pollutants and aggregates, specific gravity and strength, and to determine if further crystallization of phases occurs.

Both mixtures were classified according to the German environmental legislation „TA-Siedlungsabfall" with three different elution processes.

In the next step the physico-chemical long term stability of the solidified waste products was evaluated. Therefore the weathering conditions in a waste dump were simulated by a five month weathering cycle (Fig. 1).

In the course of weathering, phase changes and structural changes occur: strength, leaching and the distribution of environmentally relevant elements on the surface of the immobilizates was observed.

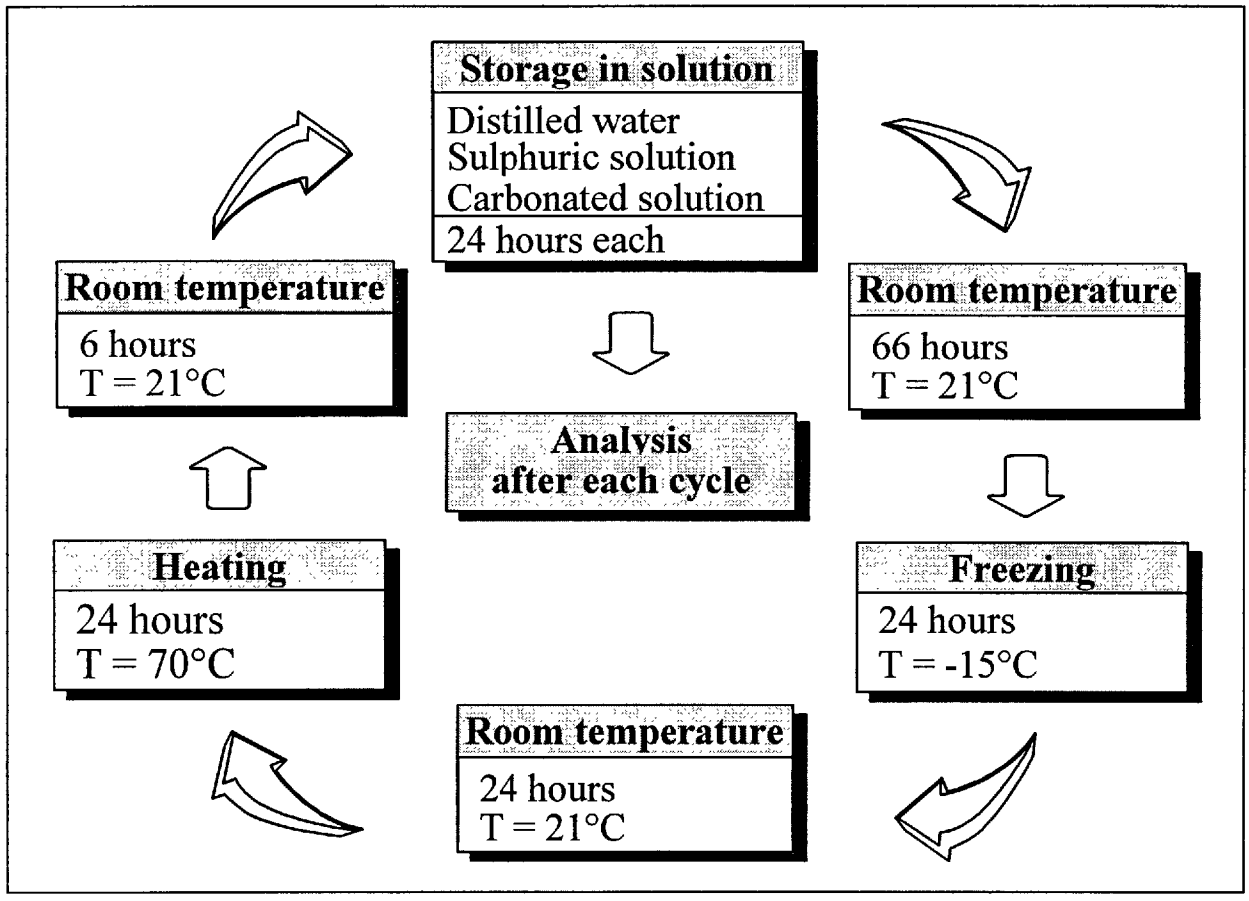

Figure 1: Weathering cycle

EXPERIMENTAL

After investigation of different mixtures in an accelerated weathering test, only two stabilized waste products (enough strength for further studies) could be formulated: one consisting a Portland cement - High alumina cement mixture with the ratio 1:1 (*HAC/OPC-mixture)* and the other using only High alumina cement (*HAC-mixture*). Quartz sand was used as filling material. In order to increase strength, part of cement was substituted by PFA. The pollutant content of 20% was achieved by adding a mixture of calcium chromate, cadmium sulfate, copper sulfate, lead sulfate (poorly soluble) and sodium hydrogen arsenate. The water/cement-ratio for each sample was 0.6 (Table 1).

The constituents were mixed in a concrete standard mixer with water for 10 minutes. The mass was filled into a standard mortar prism with 4*4*16 [cm]. The consolidation and degasing was done with a table vibrator. The prism was cut with a diamond saw cooled with isopropanol to get a 4*4*4 [cm] sized cube. The heating and freezing time during the five month weathering cycle was realized in a climatic cabinet under atmospheric conditions; storage in solution (sample weight/solution volume = 1/10) was investigated with three different solvents:

- distilled water
- saturated CO_2-solution (pH=4-4,5)
- H_2SO_4-solution (starting pH=4)

The solvents were renewed after each weathering cycle.

Table 1: Composition of the samples

Constituents	HAC-mixture weight- [%]	HAC/OPC-mixture weight- [%]	
High alumina cement	30	16,5	**Cement**
Portland cement		16,5	
PFA	20	20	**Aggregates**
Quartz sand	20	20	
CaO	10	7	
$CaCrO_4$	5	5	**Pollutants**
$CuSO_4 \cdot 5H_2O$	5	5	
$CdSO_4$	2,5	2,5	
$CdCl_2$	2,5	2,5	
$PbSO_4$	3	3	
Na_2HasO_4	2	2	
w/c-ratio	0,6	0,6	

RESULTS

XRD-Analysis

In both mixtures a similar phase formation was observed after seven days hydration time: AFt phases, AFm phases, and calcite could be determined beside the added quartz. Reflection lines of remaining alite occur in the *HAC/OPC-mixture*.

In course of weathering alite in the *HAC/OPC-mixture* reacts to give CSH-phases. The amount of AFt-phases increases inside the *HAC-sample*, when delayed crystallization of ettringite leads to cracking. Additionally the penetrated solution causes formation of calcite in the cracks.

In the *HAC/OPC-mixture*, cracking could not be observed; because of the lower amount of aluminate phases, less AFm and AFt phases formed, and alite persisted.

The XRD of the surface showed mainly calcite as the detectable product in all of the specimens examined (Figs. 2 and 3).

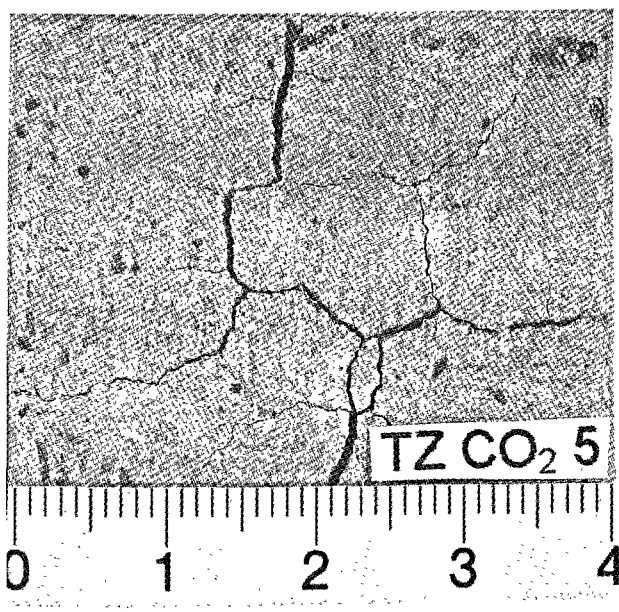

Figure 2: Cracking by the HAC-mixture after five month weathering with CO_2-solution

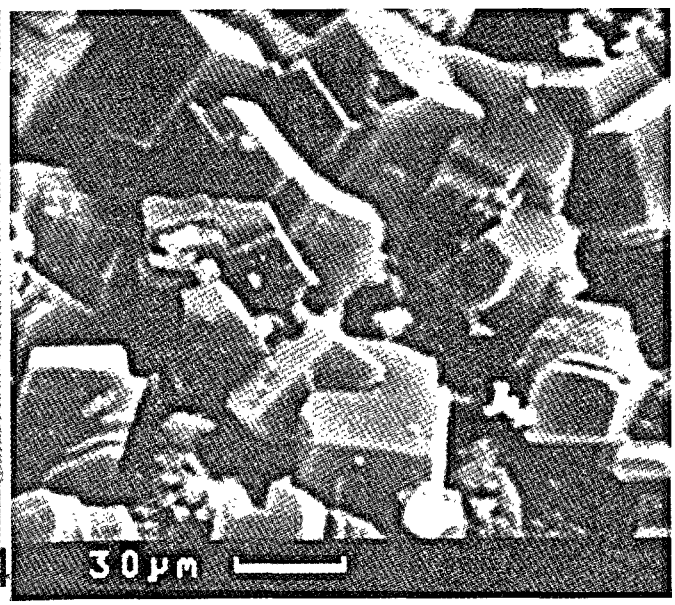

Figure 3: Calcite at the surface of the HAC-mixture

Transmitted-light microscopy, EDX-Detection

The microstructural analysis by transmitted-light microscopy showed the effects of weathering in the surface region (Fig. 4) of both different mixtures. The effects are nearly independent of the way the samples were stored in solution. On the surface, a covering layer (calcite) with the dimension of 0.5 [mm] was determined; beneath lies a leached zone (1 [mm]). In the deeper parts the matrix of both mixtures were not influenced by weathering.

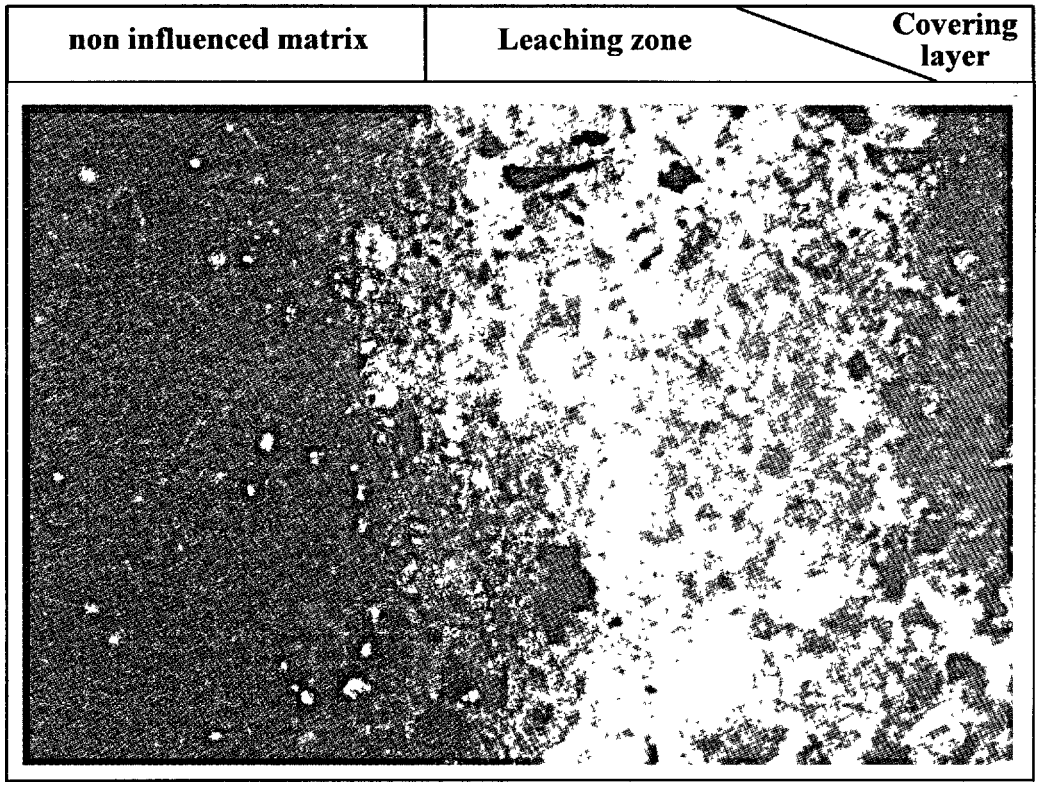

Figure 4: Transmitted-light microscopy of the HAC-mixture after five month weathering with saturated CO_2-solution; image width: 3 [mm]

The transmitted-light-microscopy-samples were also used to investigate the distribution of the environmentally-relevant elements in the surface by EDX-detection.

Sulfur and heavy metals are depleted in the covering layer. Calcium, carbon and oxygen are enriched in these region. In the transition between the covering layer and unaltered matrix the distribution of the elements is reversed: calcium, carbon and oxygen are depleted while sulfur and the heavy metals are enriched.

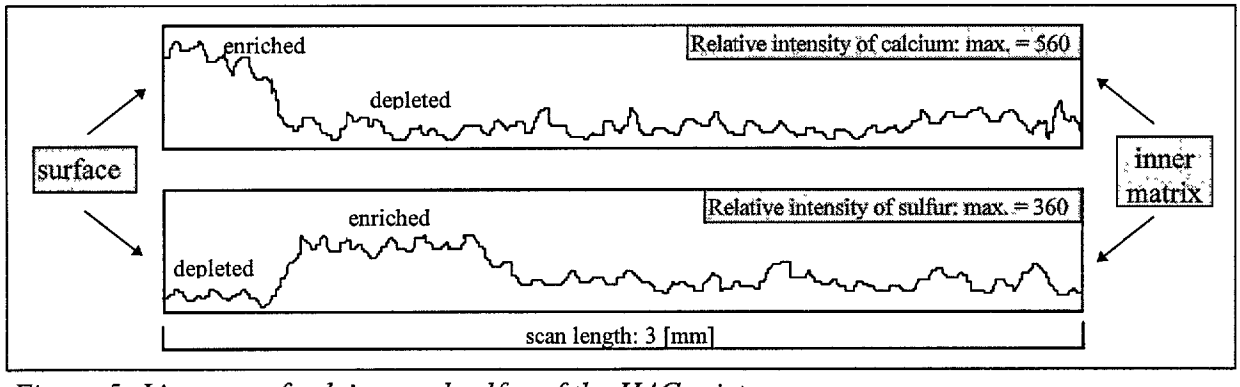

Figure 5: Linescan of calcium and sulfur of the HAC-mixture

Strength development

The compressive strength of the two specimen types depends on the composition of the mixtures and on the type of leachant solution. After five month the *HAC-mixtures* had lost about 25% of its 7 day strength during storage in sulfuric and in carbonated solution. No further reduction in strength was found by storing in distilled water. The decrease of strength results from cracking the *HAC-mixtures* by delayed crystallization of ettringite combined with thermal cycling: freezing and thawing.

The 7 day strength of the *HAC/OPC-mixtures* reached with 20 [N/mm^2] the same value as the *HAC-mixtures*. After five month weathering the cubes showed a corresponding high strength: between 24 and 29 [N/mm^2]. The reaction of remaining alite to CSH-phases during weathering could be responsible for the increased strength and for compensating the effects of thermal cycling (Table 2, Fig. 6).

Table 2: Development of compressive strength after five month weathering (5 measurements per specimen; maximum deviation from average value for each sample: 1.8 [N/mm^2])

HAC-mixture			
7 day strength	**sulfuric solution**	**carbonated solution**	**distilled water**
20 [N/mm^2]	16 [N/mm^2]	15 [N/mm^2]	19 [N/mm^2]
HAC/OPC-mixture			
7 day strength	**sulfuric solution**	**carbonated solution**	**distilled water**
20 [N/mm^2]	29 [N/mm^2]	25 [N/mm^2]	24 [N/mm^2]

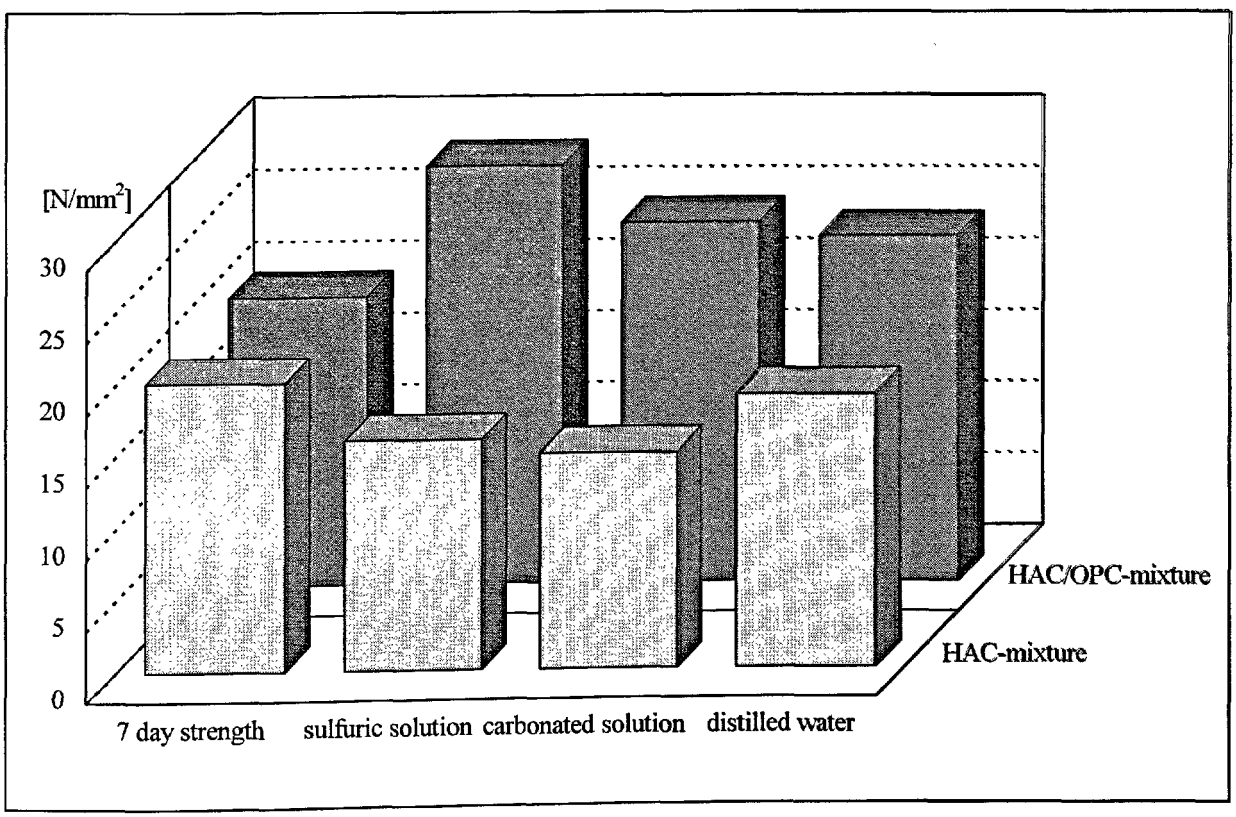

Figure 6: Compressive strength after five month weathering

Elution behavior

The measurement of pollutants in solution during the five month weathering cycle showed the maximum concentration of leached elements in this period of time. As well the elution behavior as a function of weathering time could be observed. The measured concentrations ([mg/l]) of the different elements after each storage in solution were compared to the limiting values of the German environmental legislation „TA-Siedlungsabfall". This legislation regulates the limit values of waste deposits to classify different „deposit classes".

In the course of weathering the determined concentrations of arsenic are in accordance with the requirements for „deposit class 1" for both mixtures stored in distilled water, sulfuric solution and carbonated solution (Table 3). By elution with sulfuric solution and distilled water the copper concentrations lie within the limits of „deposit class 1" and cadmium within the limits of „deposit class 2". Both elements could not fulfill the requirements for „deposit class 2" by storing in carbonated solution. Chromium(VI) was never below the limiting values of the legislation after storing in any solution. The immobilization of Chromium(VI) in AFm phases was hindered, caused by the insufficient homogenizing and the great agglomeration of added calcium chromate during mixing the specimens.

Table 3: Evaluation of the leached elements

Elements	German legislation [mg/l]		This study
	„deposit class 1"	„deposit class 2"	
Chromium(VI)	0.05	0.1	higher values
Cadmium	0.05	0.1	lower „deposit class 2" except carbonated solution
Copper	1	5	lower „deposit class 1" except carbonated solution
Arsenic	0.2	0.5	lower values

Generally the *HAC-mixture* showed higher leaching values than the *HAC/OPC-mixture*. During weathering, carbonation of the *HAC/OPC-sample* surfaces caused a conspicuous reduction of elution (Fig. 7). This reduction could not be observed for the *HAC-mixture*. The formation of cracks regards a higher soluble surface and therefore leaching values did not decrease.

A model calculation for a weathering depth of 2 [mm] (transmitted-light microscopy) demonstrated, that in the *HAC-mixture* only 0.15% and in the *HAC/OPC-mixture* 0.10% of the added pollutants were totally leached during weathering time.

The process of leaching Chromium(VI) with carbonated solution as a function of time is plotted for both mixtures in Fig. 7. The initial leaching values are equal for both samples. A decrease caused by carbonation can be observed in the first 5 weeks by weathering the *HAC/OPC-mixture* and after 10 weeks for the *HAC-mixture*. Increasing Chromium(VI) concentrations after 12 weeks are due to the formation of cracks in the *HAC-sample*. The Chromium(VI) leaching concentrations of the *HAC/OPC-mixture* after 6 weeks of weathering are nearly constant.

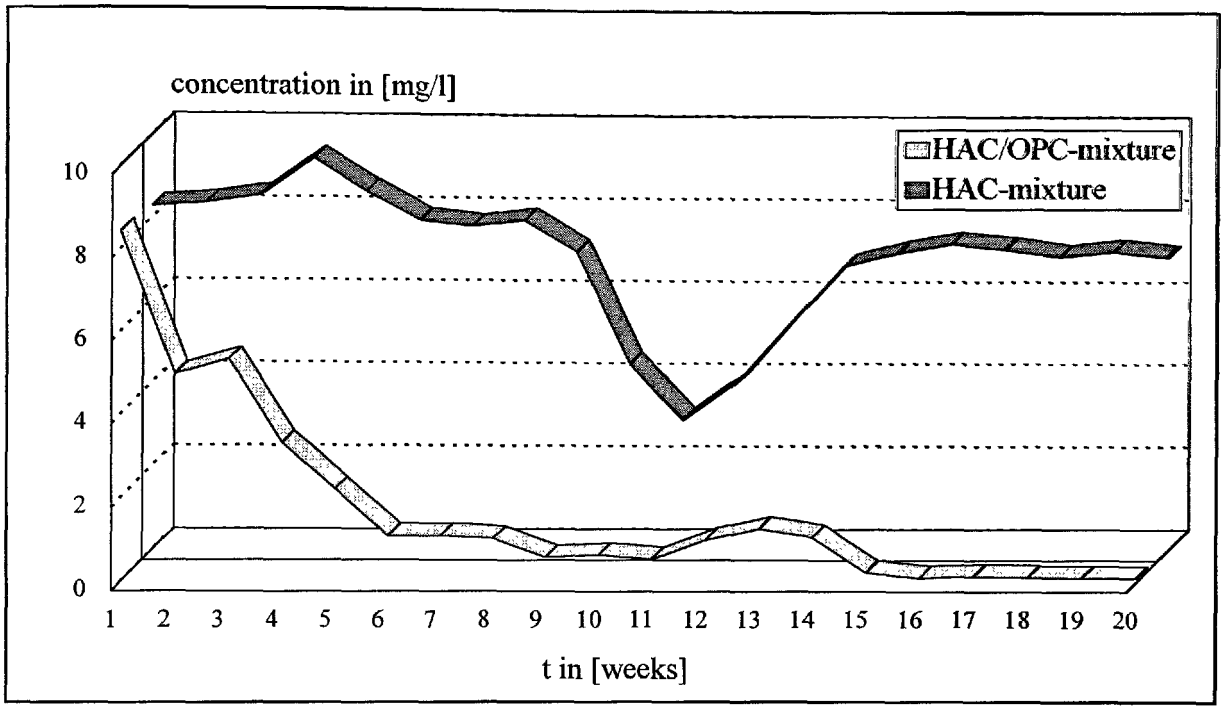

Figure 7: Elution behavior of Chromium(VI) stored in carbonated solution

DISCUSSION OF THE RESULTS

The influence of atmospheric and geochemical conditions in a waste dump on the stability of a immobilized waste model composition based on OPC and HAC has been investigated. The results give a good stability for waste immobilizates in various solutions, when the mixtures are attuned for the specific application.

The combination of calcium silicates with calcium aluminates for immobilization of waste materials is represented with the HAC/OPC-mixture. The slowly hydration of silicates during weathering leads to an „inner physical barrier" by compensating the effects of thermal cycling and possible delayed ettringite crystallization. The silicates are able to increase strength about a long time comparable with a self-heeling-process. The hydration of aluminates forms AFm and AFt phases, which are responsible for the „inner chemical barrier" (immobilization of pollutants in reservoir minerals). Particular high leaching values of added heavy metals are caused by an insufficient homogenizing of the mixtures and partly agglomeration of the pollutants. However carbonation of the surface leads to a decreasing elution by this physically stabilized immobilizates and to an accumulation of soluble elements in the transition of carbonated surface to unaltered cement matrix.

The very low content of silicates from added PFA in the HAC-mixture has a negative effect on the strength development and the leaching values. The high alumina content is responsible for cracking during the weathering time caused by continuously delayed ettringite formation and thermal cycling. This cracks are enlarging the leachable surface and decreasing the physical stability of the immobilizates. Carbonation of the surface and the cracks would reduce the leaching values, but more and more forming cracks are leading to higher elution of the heavy metals.

Fortunately the application of valuable cement should be substituted in further investigations by using industrial waste products with similar physical and chemical attributes. Also the quality of

the physical and chemical stability of immobilizates could be optimized by testing different ratios of aluminates/silicates. Additionally the leaching of the environmental relevant elements could be reduced by reducing the ratio of surface/volume.

IMMOBILISATION OF Cs-LOADED ION EXCHANGE RESINS IN ZEOLITE-CEMENT BLENDS

Sandor BAGOSI, Laszlo J. CSETENYI
University of Veszprem, Department of Silicate and Materials Engineering
H-8200 Veszprem, P.O. Box: 158, Hungary (Phone/Fax: +36 88 423 091)

ABSTRACT Water leaching of caesium-loaded cemented ion exchange resin and the mechanism of Cs-immobilisation were studied in the cement-resin-zeolite system as a whole as well as, for simplification, in parts as all three constituents are porous structure complex materials interconnected by the pore fluid. Present work focuses on reduction of significant Cs leaching (in terms of the total Cs adsorbed on the resin) by blending natural and chemically treated zeolites to the cement. Addition of natural zeolites decreased the Cs-release by 70-75% the course of a three year leaching period.

Key-words: immobilization, leaching, zeolites, ion exchange resin

INTRODUCTION

In several countries radioactive waste immobilisation strategies are based on cementitious materials (Glasser, 1992). Exhausted ion exchange resins from the primary cooling circuit of pressurised water reactor systems are favourably cemented for disposal. Heavy metals readily precipitate in the high pH environment of cements, but alkali metals, such as ^{137}Cs, remain substantially soluble. Cementation of Cs-loaded resins is important from two main aspects: (i) Cs accumulates in the resin during operation of the reactor, (ii) Cs-loaded resins, when cemented, show one or two orders of magnitude higher leach rates than on their own.
Because of the high leaching of Cs from a preliminary set of cemented samples in comparison with that from uncemented cesium-loaded resins, development of a matrix material was targeted which can significantly reduce this leachability. To comply with this aim, admixing zeolite seemed to be an obvious solution since zeolites have large occurrences in Hungary. Thus, release of isotopes from specimens, prepared using zeolite in natural and in various chemically treated forms, was investigated. The optimum composition (cement/zeolite ratio) was worked out by strength measurements, capacity and selectivity studies of zeolites and ion exchange resins, the migration of ions in solid phase was assessed by diffusion experiments with cements and zeolite admixed cement samples.

MATERIALS AND THEIR PERFORMANCES

Solutions

In practice, final storage time of radioactive wastes is usually determined by the ^{137}Cs isotope ($t_{1/2}$=30 yr.). In present study the shorter half life isotope, ^{134}Cs was instead used ($t_{1/2}$=2.05 yr.). For the saturation of ion exchange resins, for the distribution and selectivity measurements as well as for the leaching tests, CsCl solutions in various (chemical and radiochemical) concentrations were employed, which contained the active isotope ^{134}Cs. All determinations of caesium were carried out by radioisotope tracing techniques except for the Cs-containing inactive solutions equilibrated with resins and zeolites, where flame emission spectroscopy was used. Activities of the liquids were detected by a scintillation detector equipped with a NaI(Tl) cluster crystal.

Cement

For preparation of specimens to be used in leaching experiments, 350-10 coded Ordinary Portland Cement (OPC) containing 10% PFA was used. Chemical composition of the cement is given in Table 1. The caesium adsorption potential of hardened cement paste and caesium distribution ratios between solid and solution phases, calculated with the help of Eq. 1, are demonstrated in Table 2: for test conditions, see the relevant Table footnote.

Zeolite

The zeolite used originates from the Tokaj Hills (Hungary) occurrence. For the mineralogical composition, assessed by XRD, XRFS and morphometric studies, as well as for the chemical composition of tuff see Table 1. The 0.5...1.0 mm fraction of the zeolite was used in the sample preparation. Since ion exchange properties alter on replacing the mobile ion in the zeolite (Bish, 1988), the ground mineral was pre-treated by various methods (Na^+-form(1): Szász (1977); NH_4^+ and H^+-form: Valyon et al (1979); Na^+-form(2): Hlavay et al. (1987)) to obtain different exchangeable cation contents. Characterisation of one natural and the above mentioned four modified zeolites was performed by a radioisotopic method, their break-through and saturation capacities were determined by a dynamic method (Table 3, Fig. 1). The caesium adsorption potential of untreated zeolite and caesium distribution ratios between solid and solution phases are demonstrated in Fig. 4, for test conditions see the Table footnote.

volume of saturating solution: 100 cm^3, mass of zeolite: 1 g, grain size 0.5-1.0 mm, contacting time: 2 weeks

Out of the four variously treated zeolites, the one in hydrogen form showed inferior ion exchange capacity and selectivity to the natural zeolite, therefore the H^+-form zeolite was excluded from subsequent cement addition experiments. A reason for the unsatisfactory behaviour may be that the zeolite looses part of its crystal water content and thus significant changes occur in its structure (Olaszi, 1982).

Ion Exchange Resin

In the course of leaching studies, for the preparation of specimens, a high purity ion exchange resin (VARION KS-N) was used.This resin, in combination with VARION AT-N resin, is also used for the water cleaning system of Nuclear Power Plant Paks (Hungary). Saturation of the pre-treated resins was done by a static method, whose essence is that a known quantity of the resin to be saturated is contacted for prolonged time (1 week) with a know concentration of

saturating solution (solution/resin volume ratio 2.08). The advantage of the method is that it results in resin beads of nearly similar saturation. In the course of the one week saturation period the caesium solution contacting the resin was shaken several times every day. The quantity of caesium ions bonded in the resin was determined from the difference of the signal frequencies (cps) of 1 ml samples taken before and after the saturation procedure. For saturation data of used ion exchange resins for leach sample preparation see Table 5. The caesium adsorption potential of ion exchange resin and caesium distribution ratios between solid and solution phases are demonstrated in Table 6; for test conditions, see the Table footnote.

Selectivity measurement of ion exchange resin for Cs^+ - Ca^{++}

Selectivity ratios of ion exchange resins for Cs^+ - Ca^{++} were determinated by following a static method. 10-10 cm^3 quantities of E_c, termed saturated resin, were weighed into airtight polythene vessels and contacted with 100 cm^3 $Ca(OH)_2$ solutions of different Ca^{++} concentrations. Equilibration was accelerated by shaking the sealed vessels for 2 weeks. After this, 1 cm^3 sample each were taken from both the standard CsCl solution and the calcium hydroxide solutions. Signal frequencies of these samples were determined. By knowing the saturation degree of ion exchange resin samples, the signal frequency of a 1 cm^3 sample of known concentration CsCl standard solution, from which solution samples for resin saturation purposes were previously taken, the differences between signal frequencies (cps) and the quantity of caesium washed off by the $Ca(OH)_2$ solutions one can calculate selectivity ratios with the help of Eq. 2. Calcium concentrations were determined by titrimetry before and after $[Ca^{2+}]$ phase contaction, by the difference of which one could calculate the concentration of Ca on the resin (Ca^{2+}). (Values of R_s (selectivity ratio) are to be found in Table 7. The given equation (see Table 7 for symbol definitions) refers to the exchange of Cs^+ and Ca^{++} ions and gives selectivity ratios for Ca^{++}: the more Ca^{++} is bonded in the resin, the higher the value of R_s.

$$R_s = \frac{[Cs^+] \cdot (Ca^{++})}{[Ca^{++}] \cdot (Cs^+)} \qquad [2]$$

Preparation of leach test samples

There were three series of leaching tests performed in this study. The first series comprised uncemented resin samples, the second investigated cemented samples, whereas the third series determined behaviour of resins in zeolite admixed cements.

In order to assess the leaching character of uncemented resins, resin samples, previously saturated to various degrees (A_u...E_u), were placed in 45 mm diameter 4.4 mm high (70 cm^3 volume) perforated polythene walled vessels also equipped with a lid (Goór, 1989). For the second series of leach tests resin samples were first saturated to the required degrees (A_c...E_c) and then cemented by mixing 24 cm^3 resin, 93.2 g cement and ion free water to achieve a paste of W/C = 0.3. For the third series, the suitable cement/zeolite ratio was selected by also considering the results of strength tests (Bagosi, 1992), *i.e.* the highest zeolite content still ensuring sufficient strength was chosen. From compressive and tensile strength tests, as well as the water/solid ratios, a zeolite/cement ratio of 40/60 (by weight) was found to be the optimum. The zeolite containing samples (either with Natural B, Na^+(1)B, NH_4^+B or Na^+(2)B) were prepared by mixing 24 cm^3 resin (A_c), 55.9 g cement, 37.3 g zeolite and ion free water to achieve a paste of W/C = 0.3. These were prepared as reference samples (B) similar in composition to the samples of the second test series.

Leach tests

In the course of the leach tests, specimens were stored in 1 liter volume airtight PVC vessels filled with 750 cm^3 ion free water and covered with a lid. The perforated ring on the bottom of the specimens and the size of the vessels ensured that the samples were surrounded with at least 20 mm of water on each side. The leach tests were done without renewal of leachant, that is, the sampled leachants were returned to the vessel after measurement. The equipment used is illustrated in Fig. 2. During the first week of investigation, samples were taken daily, for the next month weekly, then at longer periods. The activites of the sample solutions (500 cm^3 each time) were measured in a Marinelli vessel which, due to its unusual shape, enabled the detector to be surrounded by the

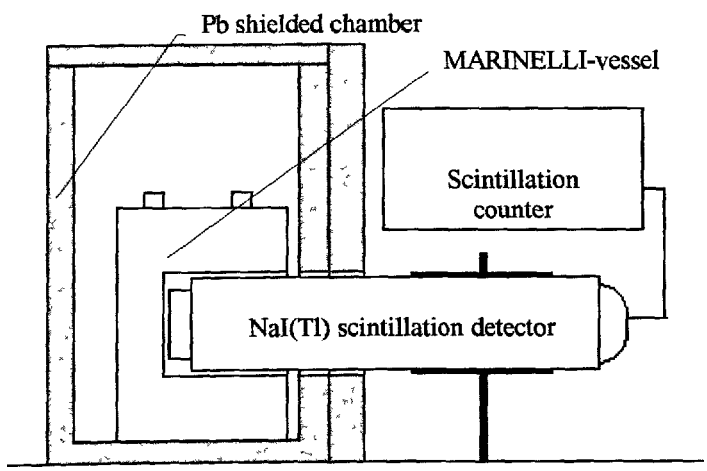

Figure 2 Measuring system to detect activities of leachates

solution. The effect of background radiation was reduced by a 50 mm thick lead jacket around the measurement assembly.
From the CsCl stock solution, previously used for making solutions to saturate the resins, a standard solution of 10^{-3} mol/dm^3 concentration was prepared by dilution. Signal frequency (activity) of this solution was determined before and after each series of measurements. This was done for two reasons, first, to compensate for probable instabilities of the measuring system, and second, to determine the absolute Cs concentrations of the leachates by taking the actual activity of a standard solution as reference.

RESULTS AND DISCUSSION

On comparing leaching of Cs from uncemented and cemented ion exchange resins (1st and 2nd series), it can be seen that Cs-concentrations of leachates are more than one order of magnitude higher for the 2nd series samples. Considering the effect of increasing saturation degrees of the resins, the amount of leached Cs decreases for the uncemented resin. In a cementitious environment, however, on increasing the resin saturation the amount of leached Cs increases (Fig. 6). Removal of Cs from the uncemented resin is low, not exceeding 0.06 - 0.88 % of the initially bonded ions. As a consequence of cementation, these values change between 6.4 - 41.6 % depending on the saturation degree of the resin (Table 8.).
Due to Ca^{2+} ions liberated during hydration reactions as well as readily soluble alkali, Cs^+ ions bonded on the resin are washed out at a significant degree (Table 7, R_1...R_5 1.9, 14.0, 37.2, 54.3 and 75.3 %, resp., of the initially bonded quantities depending on the concentration within the resin). Cs retaining capacity of the cement/resin system on its own is rather low, as is that of the pure OPC used (Table 2.). In order to suppress leaching, *i.e.* to lower the relatively high Cs concentration within the pore fluid of the cement when cementing resins, the 3rd series of samples were prepared by mixing cement, resin and zeolite in selected compositions. The connection between the three constituents, each being porous also on their own, is established by the pore fluid interconnecting elements of the system. Therefore, the overall behaviour of the matrix is dependent on several equilibration processes (ion exchange, sorption, hydration etc.). Zeolites, especially those containing clinoptilolite, show excellent Cs-retention (Table 4.), which can be further improved by simple chemical treatments.

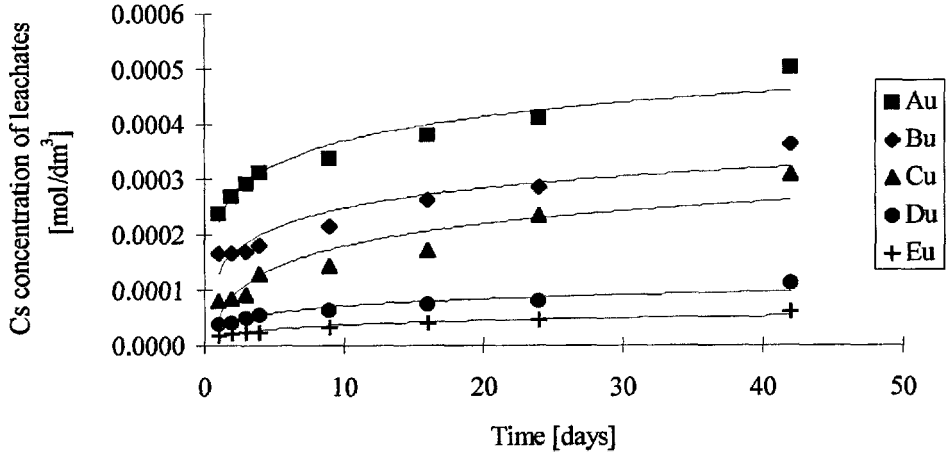

Figure 3 Caesium concentration of leachates in time for uncemented ion exchange resin samples (1st series)

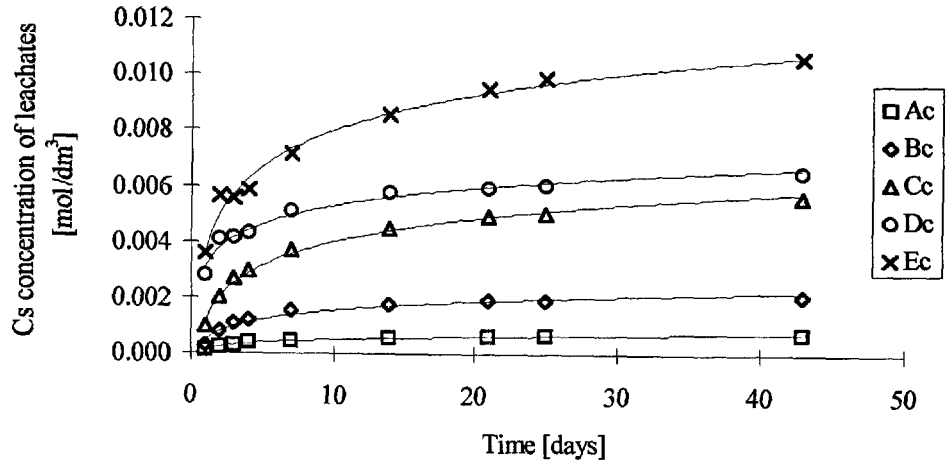

Figure 4 Caesium concentration of leachates in time for cemented ion exchange resin samples (2nd series)

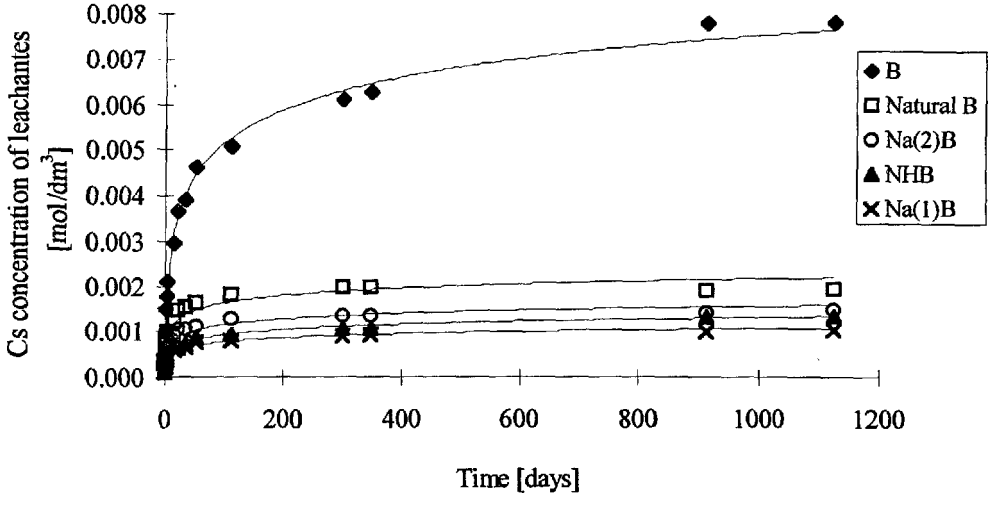

Figure 5 Caesium concentration of leachates in time for zeolite admixed cemented ion exchange resin samples (3rd series)

Table 8 Distribution ratios (R_d) of caesium between resin and liquid phases as well as exclusion of caesium from ion exchange resins in percentage [%] of the original amount

1st series			2nd series			3rd series		
Sign of samples	R_d	[%]	Sign of samples	R_d	[%]	Sign of samples	R_d	[%]
A_u	1207	0.88	A_c	454.9	6.4	B	1.3	70.4
B_u	1986	0.54	B_c	147.9	17.4	Natural B	14.9	17.3
C_u	2610	0.41	C_c	79.5	28.2	Na^+(1)B	20.4	13.3
D_u	8478	0.13	D_c	75.9	29.2	NH_4^+B	22.5	12.2
E_u	18947	0.06	E_c	43.8	41.6	Na^+(2)B	30.4	9.3

In the 3rd series the saturation degree of the resin was set to a relatively low value to simulate conditions in nuclear power plants, where, due to operation safety reasons, ion exchange columns of the water treatment system are allowed to saturate to a moderate degree only.

On examining leaching for more than three years, one may conclude that the cemented resin containing no zeolite has lost 70.4 % of its originally bonded Cs content (Table 8.), nevertheless the major part of the caesium was removed within the first 100 days of leaching. With the presence of natural zeolite in the matrix, the amounts leached fell to one quarter. With previous treatment of the zeolite to obtain Na^+ or NH_4^+ forms, further decreases in Cs leachability can be achieved. In the last two years of leaching, increase of Cs concentration of the leachates is lower for the zeolite containing samples.

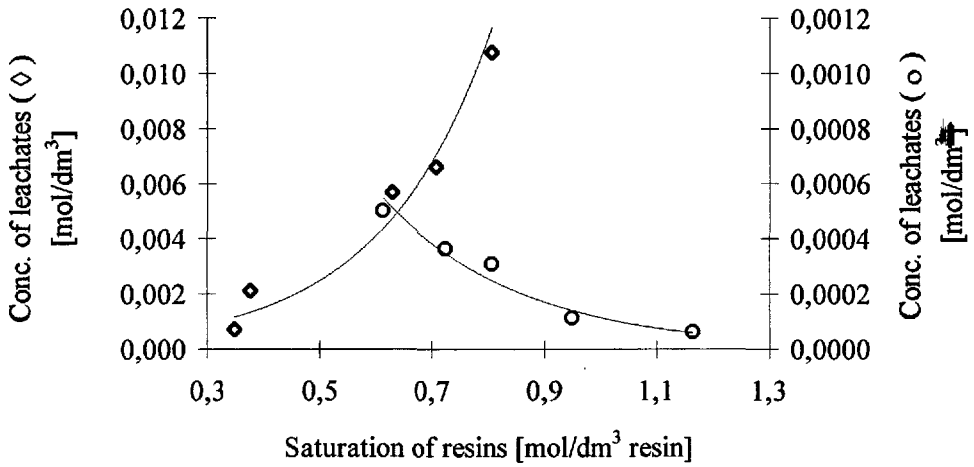

Figure 6 Comparison of leach behaviour of cemented (◊) and uncemented (o) resin samples. Change of caesium concentration of leachates as a funcion of resin saturation after 40 days.

CONCLUSIONS

The oldest and most often used technique for stabilisation/solidification of radioactive wastes, *i.e.* cementation is not satisfactory for immobilisation of Cs-containing spent resins.
For suppressing the leaching from the repository after the unlikely event of soil water intrusion, the cement/zeolite matrix gives better performance.
Admixing zeolites to the backfill between the solidified waste packages could further increase the safety of disposal.

TOPIC IV.C

Cement aggregate compatibility and structure↔performance relationships

ALKALINE CEMENTS: TERMINOLOGY, CLASSIFICATION, ASPECTS OF DURABILITY

Pavel KRIVENKO, Scientific Research Institute on Binders and Materials, Kiev, Ukraine

ABSTRACT The questionable problems arising from inadequate views on role the alkalis perform in producing hydraulic properties by mineral binder systems and terminology in the field of alkaline cements are dealt with and discussed. A classification of alkaline cements based on theoretical regularities of these cements synthesis has been suggested. Taken as a main distinguishing feature was a phase composition of hydration products of cement stone since it was found to be a determining factor affecting service properties, first of all, durability.

Key-words: alkaline cement, aluminosilicate, classification, durability, terminology, zeolites

INTRODUCTION

The investigations of Professor V.D.Glukhovsky and associates demonstrated and proved that alkalis and alkali metal salts, under condition of required concentration and ability to create high values of pH in a disperse medium, interact with glassy and crystalline aluminosilicate compounds of natural and artificial origin (Glukhovsky, 1959: 1965; Glukhovsky et al, 1979; Glukhovsky et al, 1979; 1983; Krivenko, 1986). Water- resistant alkaline and alkaline-alkali-earth alumino- and ferrosilicate compounds, analogous to naturally occurring minerals of zeolite and mica type, are found to be the interaction products (Glukhovsky et al, 1983). Some researchers restrict the role of alkaline compounds only to activators but not as constructive elements of the cement stone phases. That's why these systems are called "alkali-activated cementitious systems", what seems to be somewhat incorrect and does not reflect the true role of the alkalis in producing hydraulic properties (Feret, 1939; Purdon, 1940; Kuhl, 1958; Roy et al, 1993; Jolicoeur, 1993; Shi, 1993; Wang et al, 1995).

TERMINOLOGY

Theoretical fundamentals of possibility to produce and use of alkaline cements in construction have been laid supported by geological data on conditions of occurrence of sedimentary and metamorphous silicate rocks and constitutional composition of main rock-forming minerals (Glukhovsky, 1959; 1965). Due to the fact that at the initial stage of development of the alkaline cements, substances of natural origin were involved as raw materials, these cements were called "soil cements" (Glukhovsky, 1959; 1965), and materials based on them- "soil silicates". In 1976 Professor Davidovits was granted first patents for analogous alkaline cements in which sintering products of kaolinite and limestone or dolomite were used as aluminosilicate constituent (Davidovich, 1976: Davidovits and Sawyer, 1986; Davidovits, 1988). These cements were called "geopolymers" and have been put into practice under trademarks Pyrament, Geopolymite, Trolit, Geopolymere, Geopolyceram, etc. The cements of this type were called "SKJ-binder" in China (Changgo, 1991), "F-cement" in Finland (Forss, 1991) and "geocements" in Ukraine (Krivenko et al, 1991) to underline the presence within the hydration products of analogues to natural minerals. The interest to alkaline aluminate(Krivenko et al., 1984), portland (Glukhovsky et al., 1990) cements and their varieties (Krivenko et al., 1991) in which alkalis act as activators and structure-forming elements has grown steadily for the last 10-15 years.

CLASSIFICATION

The classification of alkaline cements, depending upon the phase composition of hydration products, which, in its turn, is caused by both the type of aluminosilicate constituents used and quantity of the alkali introduced, was developed (Fig 1). As it follows from Fig 1, the alkaline cements may be divided into two groups. The main hydration products of the cements belonging to the first group are the alkaline and alkaline- alkali-earth zeolite-like hydroalumino- and ferrosilicates, and low basic calcium, magnesium, strontium hydrosilicates serve as auxiliary hydration products, and vice versa: the main hydration products of the cements of the second group are the low basic calcium, magnesium, strontium hydrosilicates, and the alkaline and alkaline- alkali-earth zeolite-like hydroalumino- and ferrosilicates serve as auxiliary hydration products. The zeolite-like hydration products resulting from their more slower crystallization, are detected in cement stone at later stages. Being formed, predominantly, in pores they fill them and promote the formation of strong crystallization bonds between primary phases of hydrosilicates and hydroaluminosilicates of calcium.

ASPECTS OF DURABILITY

Durability is associated in many aspects with the structure and properties of cement stone and concrete, the phase composition of hydration products being the determining factor. The hydration products of conventional cements are known to be presented by calcium hydrosilicates and hydroaluminates which possess increased basicity at initial stages lowering with time, leading to destructive processes occurring in the cement stone. Free and bound calcium as well as aluminates are capable to come into cation-exchanging processes with atmospheric reagents easily promoting corrosion of cement stone. Such formations are not found in nature proving their instability.

A characteristic feature of the alkaline cements is that free lime and calcium hydroaluminates are not found in them, the basicity of calcium hydrosilicates is lower, and their hydration products contain within them more stable and less soluble zeolite-like new formations analogous to naturally occurring ones (Glukhovsky, 1959; 1965; Glukhovsky et al, 1979; Krivenko, 1986).

Professor Davidovits concluded that extremely high durability of ancient structure (pyramids, etc.) may be attributed to zeolite-like new formations of analcime type which had been detected in the concrete of ancient structures (Davidovits and Sawyer, 1985; Davidovits, 1986). The comparative testing of ancient and modern concrete structures demonstrate that under similar weather conditions the specimens made from conventional portland cement failed earlier the period specified by the standards for shelf life (50 years), while the ancient concretes remained undamaged over thousands of years. Extremely high durability of the ancient structures as well as similarity of their compositional build-up to alkaline cements suggested to draw a conclusion that the latter should also possess the same high durability as compared with that of known cementitious systems.

PRACTICAL EXPERIENCE

The geocements are widely used in composite materials to replace organic polymers. They possess high fire-, heat- and acid resistance and may be effectively used as a matrix in the immobilization of hazardous wastes such as heavy metals, radioactive nuclides, etc., as glues and adhesives for concrete, glass, ceramic, metal, wood, etc., hydro-insulating mastics, as binder in the production of mineral wool articles, heat-, sound-insulating, decorative, constructive materials, including those with organic aggregates.

Figure 2 Practical Experience

The slag and flyash alkaline cements in their properties are superior to conventional portland and high alumina cements. Of great advantage is a set of special properties they have allowing their use not only in construction, but in machine-manufacturing, foundry, etc.

The alkaline portland and high alumina cements surpass considerably the conventional cements in strength gain, including of at subzero temperatures, the greater activity, higher density, fire- and corrosion resistance, wear resistance, etc. resulting in great energy saving due to possibility to introduce a larger quantities of fillers without loss in quality as well as to involve industrial wastes.

High durability of the alkaline cements is proved by the vast experience gained by the scientific school of Professor Glukhovsky from manufacture, and use of the alkaline cements in constructional and non- constructional special and common fields of application (Fig 2)(Krivenko, 1986; 1992). Although this experience is not as large as that gained from ancient concretes, it may be of special interest, especially when these concretes were in service under severe conditions.

THERMAL ACTIVATION OF ALKALI SILICA REACTION IN CONCRETE

Ajoy K MULLICK, George SAMUEL, Ramesh C WASON, Surendra K SINHA
National Council for Cement and Building Materials, New Delhi, India

ABSTRACT Linear expansion tests on mortar bar or concrete prism specimens made with slow/late expanding aggregates showed strong dependence on test temperature upto 80°C. Continuous exposure of aggregate pieces to KOH with or without $Ca(OH)_2$ solution at 80°C comprised a severe test, leading to cracking and fracture of samples.

Key-words: Activation, Alkali Silica Reaction, Microstructure, Temperature

INTRODUCTION

Deleterious chemical reactions between certain types of 'reactive' silica in concrete aggregates and alkalies from the cement have been reported for the last fifty years. The reactivity of silica could be due to its amorphous metastable state as in Chert, Chalcedony, Opal etc., or due to defects in the crystal lattice of quartz (Brown, 1955, Mielenz, 1958, Mullick, 1987). In practice, the reaction takes long time to manifest and still longer to come to completion (Tuthill, 1982). Accelerated tests are, therefore, resorted to in assessing the potential reactivity of concrete aggregates so that meaningful guidance can be obtained in days (ASTM C-289), or within a period upto 6 months (ASTM C-227). The acceleration is achieved by either increasing the amount of reactant i.e. exposing the aggregate to abundant presence of alkali solution (Oberholster and Davies, 1986) or increasing the temperature of reaction (Mullick, Wason and Sinha, 1992) or both.

In order that the short-term accelerated tests are useful in predicting long-term behaviour, the dependence on the accelerating medium as well as the resultant mechanism of attack should be understood (Mullick, 1984). This paper investigates the role of temperature in accelerating alkali-silica reaction in concrete with aggregates, whose reactivity is due to the presence of strained quartz and not any metastable silica mineral. Such aggregates are commonly referred to as 'slow' or 'late' expanding type (Mullick, 1994). The findings of the investigation are relevant to concrete constructions in tropical countries where the temperature inside mass concrete could be quite high. The results also allow a critical evaluation of various accelerated tests employing storage temperature upto 80°C.

SCOPE OF EXPERIMENTAL PROGRAMME

In all, 25 naturally occurring aggregate samples were evaluated. The description of the aggregates including modal composition are reported elsewhere (Mullick, 1994). The aggregates did not contain conventionally known reactive silica minerals like Chert, Chalcedony, Opal, Tridymite etc. On the other hand, quartz grains showed strain effect indicative of disorder in crystal lattice. The undulose extinction angle, measured as per the procedure of Dolar-Mantuani (1983) ranged from 11° to 40° and the percentage of quartz showing strain effect 15 in Dolerite to 90 in Quartzites.

The evaluation of aggregates was carried out in mortar bars or concrete prism specimens as well as singly in rapid chemical test, and continuous immersion in KOH, with or

without $Ca(OH)_2$ solution. In the latter case, observations were made using Scanning Electron Microscopy and Optical Microscopy techniques.

MORTAR BAR TESTS

One of the most widely used methods of assessment of concrete aggregates for potential alkali-silica reactivity is measurement of linear expansion in mortar bar specimens. The size of the specimens, mix proportions and test procedures are described in ASTM C-227. These tests, either at 38°C or 60°C, take upto six months to give meaningful results. In order to cut down the time of observation further, procedure evolved at National Building Research Institute of South Africa (NBRI test) envisage storage of mortar bar specimens in 1N NaOH solution at 80°C and expansion after 14 days form the criteria (Oberholster and Davies, 1986). In order to assess the effect of test temperature, mortar bar tests were carried out at 27°C, 38°C, 60°C and 80°C. The results are presented in **Fig 1.**

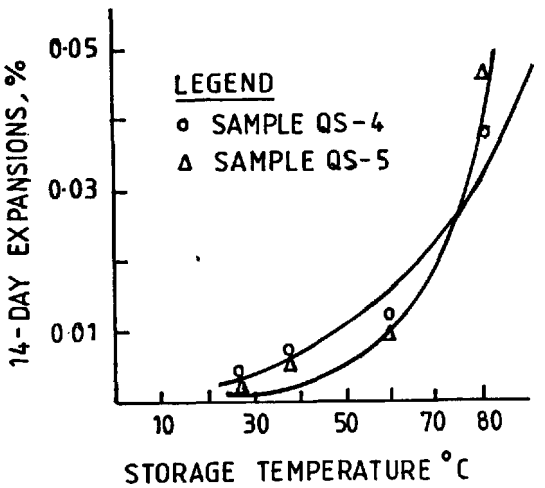

Figure 1 Effect of Temperature on Mortar Bar Expansion

It is observed that linear expansion of mortar bars increased exponentially with test temperature. In the authors' opinion, the accelerating effect of temperature on the slow/late expanding aggregate containing strained quartz was greater than in 'classical' reactive aggregates. To substantiate this, the mortar bar expansions at 38°C and 60°C using high alkali cement in case of aggregate samples containing strained quartz obtained in this investigation and those in case of classical reactive aggregate, as reported in the literature are compared in **Fig 2**. Although the results are only indicative, the regression equations imply that ratio of expansions at 60°C and at 38°C are greater in case of strained quartz type aggregate.

Mortar bar expansions at 80°C, both in 1N NaOH solution (NBRI test) and over water (as in ASTM C-227 test) were compared (Mullick and Wason, 1996). Results in **Table 1** indicate that presence of external alkali solution accelerates the expansion in addition to

that of temperature. Accordingly, combination of presence of external alkalies and increased temperature comprise a severe tests regime for aggregate containing strained

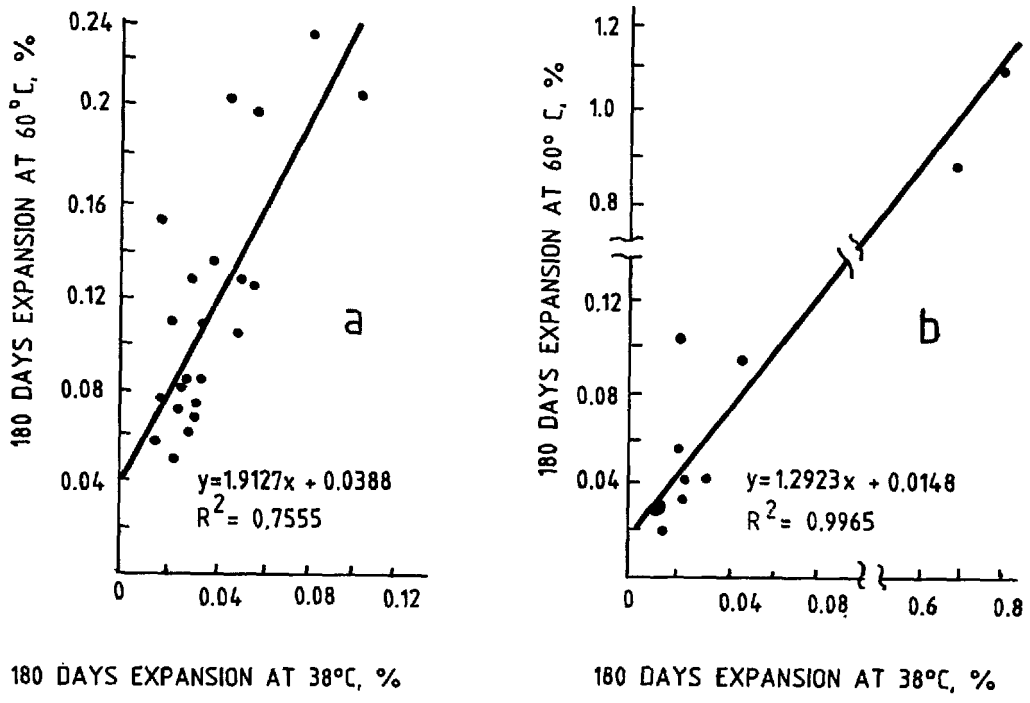

Figure 2 Correlation between Mortar Bar Expansion for (a) Aggregates Containing Strained Quartz and (b) Classical Reactive Aggregates

quartz, which may make NBRI test not discerning enough (Mullick and Wason, 1996). This aspect is examined further in exposure tests of aggregates reported later.

CONCRETE PRISM TEST

Candian Standard CAN 3-A23.2-14A prescribes a method for determination of potential expansion of cement-aggregate combination in concrete specimens of size 75x75x350 mm. With slight modification of the CSA method, storage temperatures of 38°C and 60°C were used in the present investigation. Cement contents (having alkali content of 1.0 percent as Na_2O equivalent) in the concrete mixes were varied so as to result in total alkalies to be 5, 6 and 8 kg per m^3 of the mix.

Table 1 Comparison of Expansions in NBRI and ASTM C-227 Tests at Same Temperature

Sl No	Aggregate Sample	14-day Expansion, %	
		NBRI Test+	ASTM C-227 Test+
1	QS-4	0.1524	0.0380
2	QS-5	0.1884	0.0464

+Test Temperature 80°C in both cases.

Results of linear expansion upto 400 days are shown in **Fig 3**. The ratio of expansions at 60°C and at 38°C generally varied between 2.04 to 1.35, with one value as high as 5.61. For any particular aggregate, the ratio was greater, when the total alkali in the concrete mix was the lowest i.e. 5 kg/m^3.

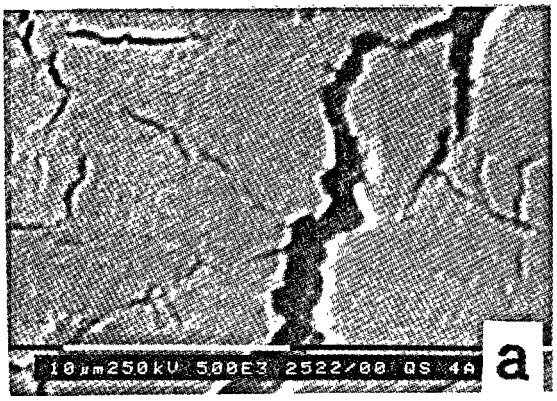
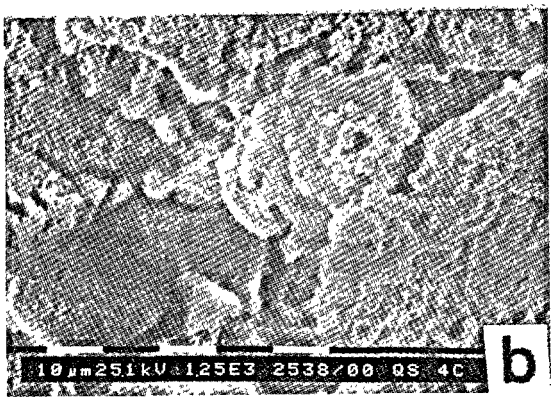
EXPOSURE TESTS ON AGGREGATES

Apart from testing in mortars and concrete mixes, aggregates are also assessed by immersion in alkali solution. Rapid chemical method as per ASTM C-289 is one such method in which the aggregate samples ground to sand fineness are immersed in 1N NaOH solution at 80°C. The dissolution of silica and reduction in alkalinity of the solution after 24 hours form the basis of assessment. The method is not regarded to be reliable for aggregates such as Graywacke, Quartzite, Granite etc. (Oberholster, 1994).

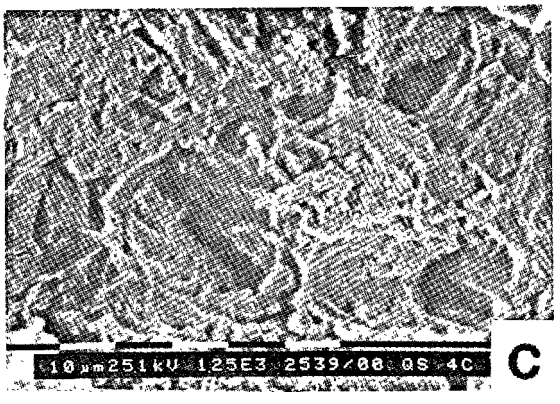
Assessment of the aggregate samples used in this investigation by ASTM C-289 Chemical method has been reported earlier (Mullick, Wason and Sinha, 1992, Mullick, 1994). After 24 hours' exposure, the aggregates were found to be 'innocuous' (**Fig 4**); however, more and more aggregates fell in the 'potentially deleterious' category, as the period of exposure increased to 3 days (**Fig 5**) and 7 days (**Fig 6**). This pattern is consistent with what is expected of slow or late expanding aggregates, where the kinetics of reaction could be different from that of 'classical' reactive aggregates (Mullick, 1994).



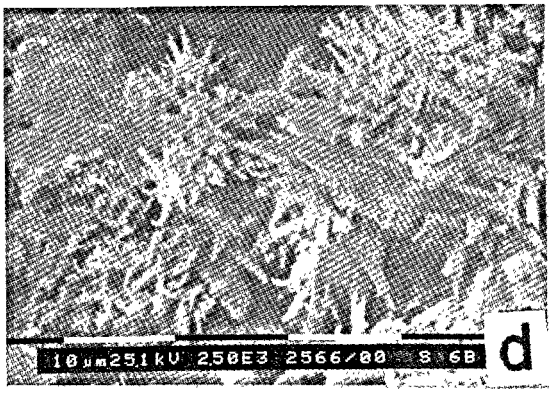
To assess the behaviour under exposure to alkali solution for longer time, three aggregate samples containing strained quartz were chosen. The rock types were Quartzite, Graywacke and Diorite. A small chip of each aggregate sample was cut with a diamond saw and stored in a container in 1N KOH solution. In view of the importance of the presence of $Ca(OH)_2$ for occurrence of expansive alkali silica reaction (Diamond, 1989), samples were also stored in solutions of KOH and $Ca(OH)_2$. The containers were kept in oven at 80°C. After continuous exposure of 55 days, the samples were washed and examined under Scanning Electron Microscope and Optical Microscope. The salient results are described below.



SEM + EDAX Study



SEM and EDAX studies were conducted on a Philips SEM 515 with EDAX PV 9900. A typical example of a Quartzite grain after treatment in KOH solution is in **Fig 7(a),** which shows typical cracks associated with disintegration of grains. After treatment with KOH and $Ca(OH)_2$ (50:50) the crumbling of grains and cracking were observed as shown in **Figs 7(b)** and **7(c)** respectively. **Fig 7(d)** shows typical features of reaction products. **Fig 7(e)** shows a representative EDAX spectrum of the reaction products. The elemental analysis of reaction products was quite similar to those reported in case of ASR occurring in concrete structures in service (Samuel, Mullick, Ghosh and Wason, 1984; Mullick and Samuel, 1986) and can be described as lime-alkali-silica gel; so aptly identified and described by Regourd et al (1978) and Thaulow and Knudsen (1975). These tests showed exposure to KOH solution at 80°C led to severe distress to these aggregates, which was further aggravated in presence of $Ca(OH)_2$.



Optical Microscopy

Aggregate samples after prolonged exposure to KOH and $Ca(OH)_2$ solution at 80°C were examined under a Zeiss Polarising Microscope. Thin sections of treated and untreated rock samples were prepared using Canada Balsam for fixing on the glass slide. The grain sizes were determined using occular micrometer. For samples exposed to KOH solution, development of cracks on quartz grains and crumbling and deposition of foreign materials were noticed **[Fig 8(a)]**. For samples exposed to both KOH and $Ca(OH)_2$, severe crumbling of quartz grains and deposition of foreign materials in voids, with some

faint fractures were visible **[Fig 8(b)]**. However, in no case any change in the percentage of quartz grains showing strain effect and undulatory extinction, as compared to untreated samples, were noticed.

CONCLUSION

Like many other chemical reactions, alkali-silica reaction can be thermally activated. In mass concrete construction in tropical countries, where the temperature inside concrete pour could be of the order of $60^{o}C$ due to heat of hydration, the incidence of ASR could be higher. This fact, and the need of quick results in accelerated tests justify adoption of higher temperatures upto say $60^{o}C$ in testing. However, in presence of abundant alkali solution and storage temperature of $80^{o}C$, the attack on aggregates could be severe and such testing regimes may give unreliable results.

THE INFLUENCE OF CARBONATION ON THE ALKALI-AGGREGATE REACTION MECHANISM

Yushiro KIHARA, Brazilian Association of Portland Cement and São Paulo University, São Paulo, Brazil

ABSTRACT Experimental studies on reactive aggregates (pyrex glass, chalcedony and mylonitic granite) with different reaction rates on NBRI accelerated test allowed us to investigate the influence of carbonation on reducing cement mortar expansion due to alkali-aggregate reaction. The intensity of reaction regulated the quantity of expansive gels in the following order: pyrex glass>chalcedony>mylonitic granite. Carbonation reduced $Ca(OH)_2$ availability to form expansive gels. Porosity was greatly reduced in samples with low expansion rates but little changes occurred in those with high expansion rates.

Key-words: carbonation, durability, alkali-aggregate reaction, porosity

INTRODUCTION

The increasing occurrence of alkali-aggregate reaction affecting concrete structures has motivated interest on studying the reaction kinetics and factors which could minimize expansion effects.

GASKIN (1947) on investigating the effect of CO_2 on the expansion of mortar bars using an alkali-react
minimized
the Moxot
(CAVALCANTI et al., 1989) showed, after regular measurements over a period of 180 days, that injection of CO_2 in a $1m^3$-concrete block decreases expansion rate significantly.

The influence of carbonation on the alkali-aggregate reaction mechanism and on mortar microstructure makes up the subject of this paper.

EXPERIMENTAL PROCEDURES AND RESULTS

Starting Materials

For the experiments, mortar bars were made using ASTM Type I portland cement (with 4% gypsum, 1.37%-Na_2O equivalent) and three potentially alkali-reactive aggregates: pyrex glass, chalcedony gravel and deformed quartz-bearing mylonitic granite.

Experimental Techniques and Results

NBRI South African Accelerated *Alkali-Aggregate Reaction Test and Carbonation Test*.

After demoulding the mortar bars, two bars were cured in water for 28 days and two others were cured for the same period in a carbonation chamber with 10% CO_2. Later on all the bars were immersed in a 1N NaOH solution at 80°C and daily measurements of the bars'length were made. Results are given in Figure 1 and Table 1.

Mercury-Intrusion Porosimetry

Mercury-intrusion porosimetry was conducted with a MICROMERITCS Autopore II-9215 model. Results are listed in Table 1.

Ultraviolet Fluorescence Analysis

The insitu identification of alkali-aggregate reaction was made using the technique described by NATESAIYER & HOVER (1988). The samples were soaked in a uranyl acetate solution and then placed under a short wave ultraviolet lamp and the presence of gels was indicated by the characteristic greenish yellow fluorescence of the uranyl ion selectively adsorbed onto the gel surface. Results observed are showed in Table 1.

Table 1 Results of mortar bar accelerated test, porosimetry and *insitu* fluorescence test.

Mortar bar nr.	Materials	Mortar bar expansion NBRI Test 28 days (%)	Porosimetry (%)	Observation of alkali-aggregate reaction products by fluorescence test
1	Pyrex glass	0,511	23,50	Fluorescence spots disperse and frequent in all samples
2*	Pyrex glass	0,012	23,20	Fluorescence spots distributed preferentially at the borders and rare at the core of the sample
3	Chalcedony	0,200	23,46	Fluorescence spots disperse and common in all samples but less frequent than in nr. 1
4*	Chalcedony	0,019	20,86	Fluorescence spots limited to the borders of the bar, preferentially at the apex
5	Granite	0,056	20,24	Rare fluorescence spots
6*	Granite	0,018	14,06	Fluorescence spots not observed

(*) Carbonated

X-Ray Diffraction Analyses (XRD)

XRD analyses were carrried out using a RIGAKU, DMAX 1.100 with CuKα radiation. XRD-peak patterns emphasizing the carbonation rate are presented in Figure 2.

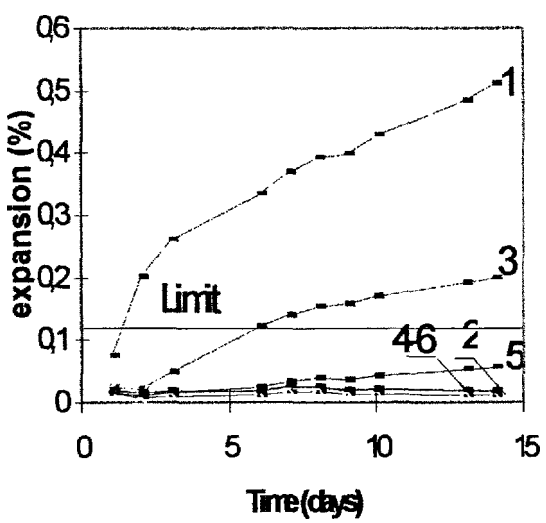

Fig. 1: Expansions of mortar bars.

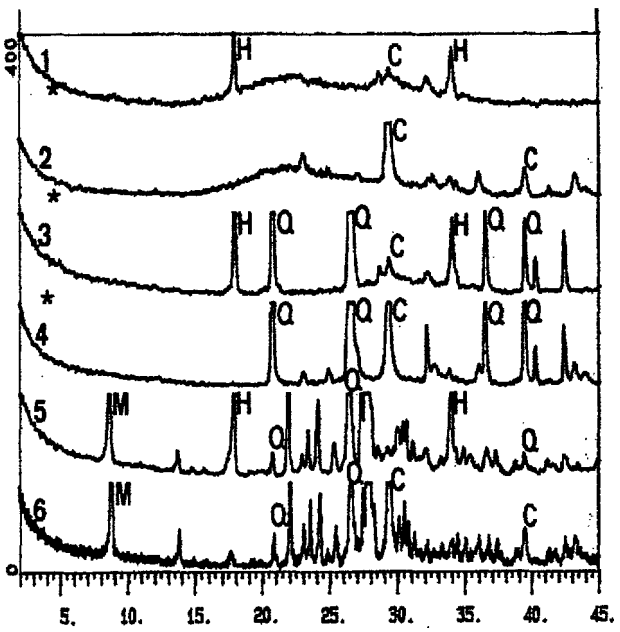

Fig. 2: XRD pattern of mortar bar (H=portlandite, C=calcite,Q=quartz, M=mica).

Scanning Electron Microscopy with Energy-Dispersive X-Ray (EDX)

The scanning electron microscopy (SEM) studies of the microstructure and gel phases found in reaction product were made with a JEOL T300 model SEM photographs are presented in Figures 3, 4, 5 and 6.

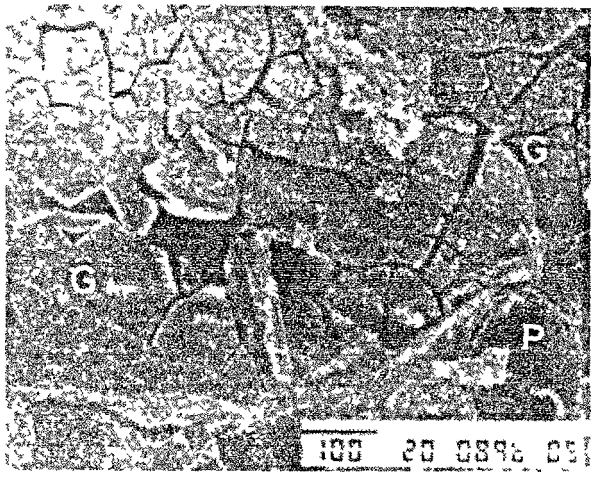

Fig.3: Microcraked pyrex glass (G) with abundant grated gel (sample 1).

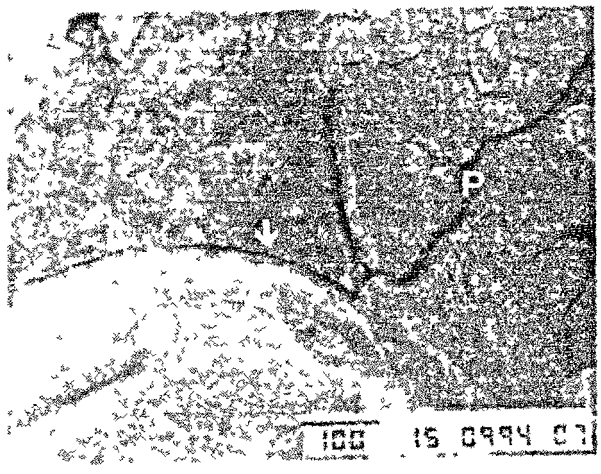

Fig.4: Chalcedony (Q) (sample 3) with reaction border and pore (P) filled with expansive gel

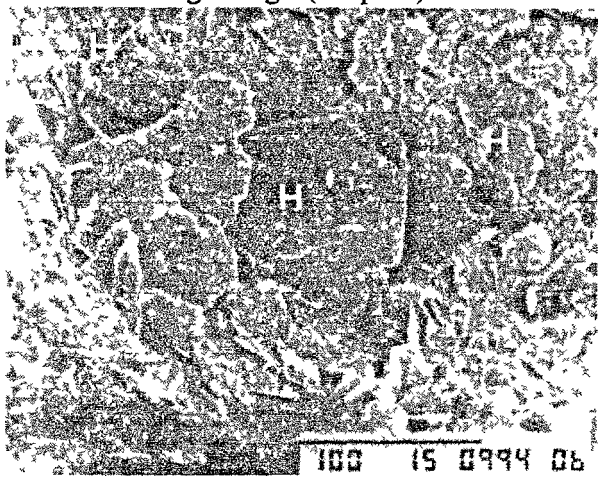

Fig.5: $Ca(OH)_2$, crystals (H) filling void (sample 5, pyrex glass).

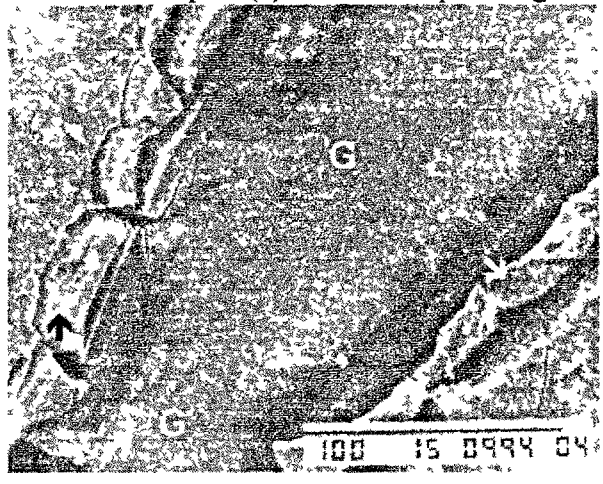

Fig.6: Reaction border with little developed expansive gel (carbonated sample 2, pyrex glass).

DISCUSSION AND CONCLUSIONS

The potentially alkali-reactive aggregates developed distinct expansions in the mortar bars. The pyrex glass showed to be the most reactive on the NBRI accelerated test with mortar bar expansion of 0 511% at 14 days. The mylonitic granite mortar bar presented the lowest expansion (0.019%) and chalcedony mortar bar gave intermediate values (0.20%). Carbonation reduced the expansion of mortar bars made with pyrex glass, chalcedony and mylonitic granite 96%, 86%, and 44% in average, respectively.

Quantity and distribution of expansive gels (Table 1) is regulated by the intensity of reaction which in turn depends on the different kinetics of reaction of silica in the aggregate crystal structure (in this case lower for the strained quartz structure in mylonitic granite, higher for the amorphous silica in pyrex glass and microcrystalline silica in chalcedony). Sample 1, with the

highest expansion rate, presented highly fractured pyrex glass and abundant expansive gel distributed on the grain interface with the paste (transition zone), filling voids and fractured surfaces. Gels were less frequent in sample 3 although reaction borders in some chalcedony grains were observed (Fig. 4). In sample 5 the occurrence of gels was rare and restricted to the mortar pores.

The products of the alkali-aggregate reaction were massive gels, alkali-chalcosilicate in composition with the presence of very small amounts of K and Na, as observed from the EDX spectra. Typical reaction products (DAVIES et al. 1988) were not found and botrioidal gels were rare. $Ca(OH)_2$ hexagonal plaques were encountered on transition zones and in a few pores in the mortar (Fig. 4), their occurrence being more frequent the lower the gels contents, in the following order: pyrex glass < chalcedony < mylonitic granite. Carbonation reduced $Ca(OH)_2$ availability to form gels (Fig. 6) and therefore strongly curbed cement mortar expansions due to alkali-aggregate reaction. Reaction products were limited to the outward regions with a higher concentration at the apex of the mortar bars made with chalcedony and pyrex glass and apparently did not form in the mortar bars with the less reactive mylonitic granite. The abscence of $Ca(OH)_2$ XRD peaks and low expansions in samples 2, 4 and 6 (Table 1) testify for the efficiency of carbonation.

The effect of carbonation on porosity of mortar bars varied according to the intensity of expansion reaction. The mylonitic granite mortar bars with lower expansion, less intense microcracking and higher $Ca(OH)_2$ availability, had porosity 44% reduced while mortar bars made with chalcedony and pyrex glass, with higher expansions, more intense microcracking and lower $Ca(OH)_2$ availability had porosity reduced 12,5% and 1%, respectively. The present measures to minimize the effects of alkali-aggregate reactions on concrete structures are costly and of limited efficacy. Although a controvert issue, studies on the use of carbonation to curb expansion provoked by these reactions are justified in view of the limitations of existent methods and the results obtained in this work.

ACKNOWLEDGMENT

ABSTRACT Alkali silica reaction leads to cracking of concrete. It results from an interaction between reactive silica included in the aggregate particles and the hydroxide ions of the pore solution. Following are the consequences :

- the partial dissolution of the silica and to the ionization of the residual silica,
- the formation of hydrated calcium silicate alkali products by reaction,
- the creation of sufficient stress to generate the cracking of concrete.

The aim of this paper is to improve the understanding of the chemical and physical phenomena involved in the stress creation. It has been demonstrated from a simple model system simulating concrete that the presence of calcium, reactive silica, alkali and hydroxide ions are sufficient to generate cracking of concrete. Silicate solution, residual silica and the product precipitated may be involved. The cracking appears to result essentially from the product reaction formation. The residual silica contribution is not excluded.

KEY-WORDS : Alkali silica reaction, stress, reaction products, residual silica, alkali silicate solutions, osmotic pressure, crystallization pressure.

INTRODUCTION

Alkali silica reaction leads to cracking of concrete and to the formation of a reaction product localized in the cracks and at the aggregate / paste interface. It results from an interaction between reactive silica included in the aggregate particles and the hydroxide ions of the pore solution. As three of the direct consequences of this interaction:

- the reactive silica and the hydroxide ions react together. This leads to the partial dissolution of the silica, thus to the presence of alkali silicate entities in solution, and to the ionization of the residual silica,
- a hydrated calcium, silicate, alkali products is formed by reaction between the alkali-silicate entities in solution and the calcium ions provided by the calcium phases of the cement paste,
- sufficient stress to generate the cracking of concrete are created.

The first two consequences are quite well known. However, the third consequence requires further study. Concerning the latter, some people claim that the residual silica is the major source of the stress creation, whereas some others holds the reaction product is responsible for this. Following are the hypothesis proposed :

- The residual silica would swell by solution absorption (Struble, 1987; Wang and Gillott, 1991; Poole 1992).
- The reaction products would swell by absorbing solution (Wen, 1989). If the products are in confined spaces, stress will be generated.

- The formation of reaction products, by reaction between the calcium ions provided by the cement paste and the alkali silicate entities in the solution resulting from the silica dissolution, and their growths in a confined space would generate stresses. It has been demonstrated by thermodynamics that the formation of a product can create pressure (Ping and Beaudoin, 1992). This pressure known as crystallization pressure would be generated by the better crystallized hydrates calcium alkali silicate reaction products (C-N-S-H and C-K-S-H) (Dron and Brivot, 1993).

These propositions have not been evaluated. In the first two cases, the expansion is commonly associated to osmotic phenomena (Hansen, 1944; Powers and Streinour, 1955; Krogh, 1975; Dent Glasser, 1979; Dent Glasser and Kataoka, 1981; Diamond, 1989). However no real scientific arguments have been brought forward to define the origin of the process and the pressures have never been quantified. Only one experimental work initiated by Krogh (1975) and followed up by Struble and Diamond (1981) has been conducted. The aim was to measure the pressures exerted by water absorption by either reaction products or residual silica; it was not precisely specified. The solid was simulated by synthetic silico-alkali and calco-silico-alkali solids. Nevertheless, although the measured pressures reached in some cases 10 MPa, no conclusion can be drawn from these experiments because :

- the measured pressures were not reproducible,
- the experimental conditions were far from the real ones. The solution absorbed by the solid was pure water and the products had been synthesized by exchange of sodium silicate solution on a resin to obtain a silicilic acid to which hydroxide ions have been added.

The purpose of this paper is to shed some light on the chemical and physical phenomena involved in the stress creation during alkali silica reaction by :

- determining the constituents responsible for generating sufficient stresses leading to concrete cracking.
- making an inventory of the different possible stress sources.
- making an attempt to determine the stress associated to each of these sources.

To reach these objectives, model systems were elaborated.

WHAT ARE THE CONSTITUENTS WHICH ARE SUFFICIENT TO MAKE CONCRETE CRACK BY ALKALI SILICA REACTION ?

The simplest model system representative of a concrete portion, i.e. silica aggregates coated by cementious materials submerged in the pore solution, has been reconstituted and is shown in Fig 1. The components have been chosen to promote alkali silica reaction. The system under study consists of a pellet composed of reactive silica coated with porous cementious matrix composed only of C-S-H and portlandite, submerged in a rather high sodium hydroxide solution concentration (1 mol/kg). The composition of this solution corresponds to that of the pore solution in a cement paste prepared from cement with about 1 % Na_2O eq.

The silica pellet was made by compacting powder silicagel. The porous C-S-H and portlandite matrix were obtained by hydrating C_3S in saturated calcium hydroxide solutions for more than 28 days to hydrate most of it; following is the C_3S hydration reaction :

$C_3S + H_2O \rightarrow C_{(\approx 1.8)}\text{-S-H} + 1.2\ Ca(OH)_2$.

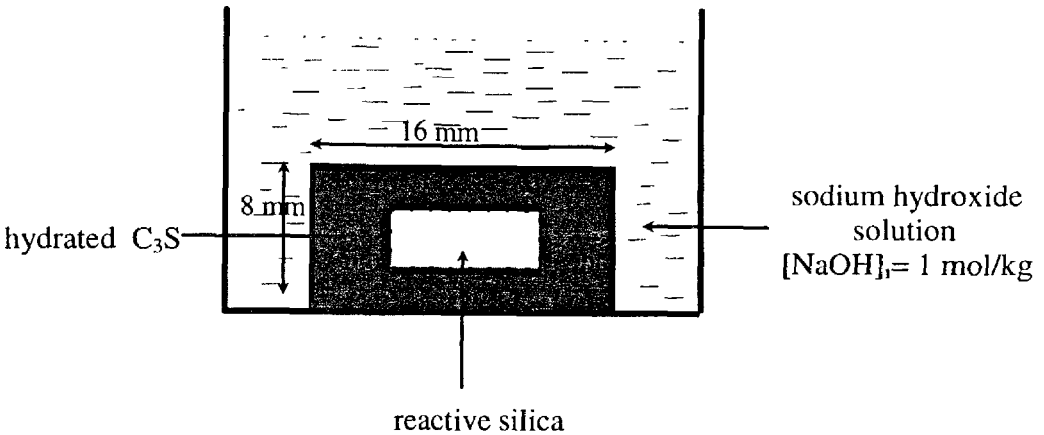

Figure 1 Transverse section of the experimental model which permits the simulation of concrete susceptible to alkali silica reaction.

The state evolution of the "sandwich" was followed up. After 3 or 4 weeks, the "sandwich" was cracked in the silicagel pellet plane (Fig 2).

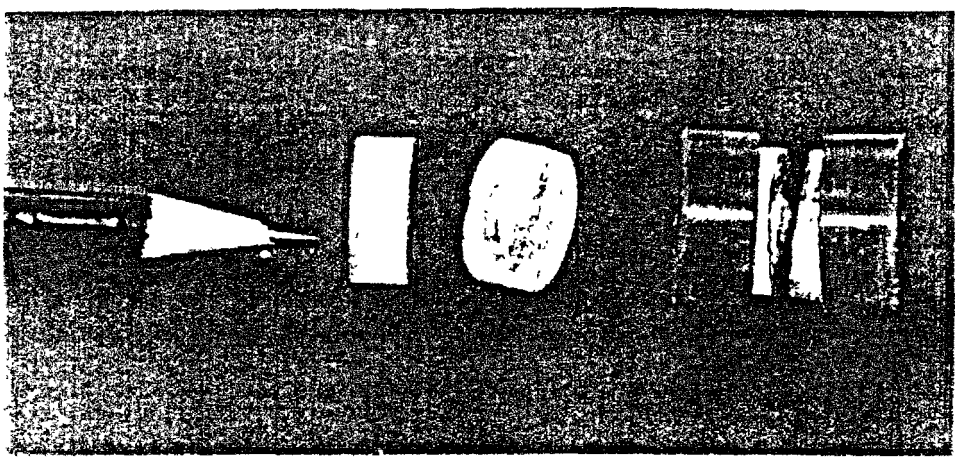

Figure 2 Photograph of the sample composed of a pellet of reactive silica coated with porous cementious matrix (hydrated C_3S) after being submerged in a sodium hydroxide solution with a concentration 1 mol/kg.

Therefore, the sole presence of calcium, reactive silica, alkali and hydroxide ions is sufficient to generate concrete cracking.

WHAT ARE THE DIFFERENT POSSIBLE STRESS SOURCES IN THIS "SANDWICH" AND THE STRESS ASSOCIATED TO EACH OF THEM ?

The system simulating the concrete portion is composed of an alkali solution and silica separated by a porous cement paste. The hydroxide and alkali ions of the alkali solution can therefore diffuse through the cement paste. The hydroxide ions will react with the silica which will lead to the dissolution of part of the silica, therefore to the formation of alkali silica solution in contact with the silica. Consequence of this reaction is the ionization of the residual silica as well.

The reaction between the alkali silicate entities in the solution and the calcium ions provided by the portlandite in the cement paste will lead to the formation of a hydrated calcium, alkali, silicate reaction product.

Consequently, alkali silicate solution, residual silica and reaction product may be involved in stress creation.

It was examined if each of these possible expansion source could generate stresses and if so by what mechanisms. An attempt has been made to quantify the pressure exerted by each of them.

Can stresses be generated by the alkali silicate solution ?

It is well known that alkali silicate solutions are composed of alkali silicate entities with different sizes, varying from monomer to polymer ions when the silicates concentration is quite high, even colloidal particles if it is very high.

Referring to the previously mentioned system, two solutions with different compositions, a sodium hydroxide solution and a sodium silicate solution, are separated by a porous barrier (the cement paste). These two solutions can not be completely mixed together because polysilicate entities can not migrate through the barrier. For reaching equilibrium state, the chemical potential of the solvent (water) have to be equal on both side of the barrier. The chemical potential of the solvent is a function of the activity of the solute which composes this solution and of the pressure exerted on the solution at a given temperature. Since the biggest polyions can not migrate, if the initial activities of the constituents of the alkali-silicate solution is higher than the initial activities of the constituents of the sodium hydroxide solution, in order to equalize the water chemical potential on each part of the barrier, water will diffuse from the sodium hydroxide solution towards the alkali silicate solution to dilute it, until the pressure exerting on the alkali silicate solution compensates the difference of activity of the constituents which compose the solution on each side of the barrier. The resulting pressure will be as high as the difference of activity is high.

Therefore, in this way, the alkali silica solution can generate pressure.

The existence of this pressure has been confirmed with a classic dialysis experiment. The experimental conditions were chosen such that the measured osmotic pressure was maximum. The experimental device is shown in Fig 3.

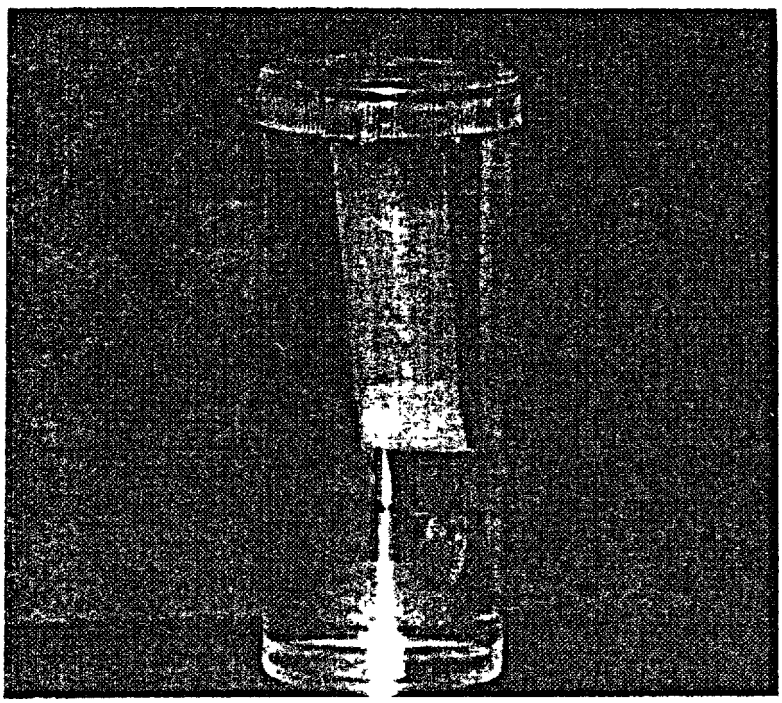

Figure 3 Experimental model used to determine if the alkali silicate sols may generate stresses

A dialysis membrane was filled with an alkali silicate solution composed of large size particles (a colloidal solution) in order to avoid most of the silicate particles going through the membrane. Therefore, a very concentrated alkali silicate solution ($[Na^+]$=0.84 mol/l and $[SiO_2]$ = 1.8 mol/l) was used here. This membrane was submerged in water in order to maximize the difference of solvent chemical potential in the solution inside and outside of the membrane. After 2 hours, the membrane had swollen.
The swelling results from the equalization of the chemical potential of the solvent in the solutions on each side of the membrane by diffusion of water towards the inside of the membrane. The diffusion is also accompanied by a diffusion of a low proportion of the sodium and silicate ions (small-size ions) towards the outside of the membrane. The diffusion stops as the pressure exerted by the membrane on the solution compensates for the difference between the activity of the solute in the solution inside and outside the membrane.

The pressure exerted by the system initially composed of alkali silicate solution and water separated by an osmotic membrane, has been measured by comparison with that exerted by polymers. For the latter, the pressure can be calculated and the relation between the pressure and the concentration is effectively known. The pressure is very low, about 1 kPa.

Can stresses be generated by the residual silica ?
If residual silica is the cause of stress creation, the process involved is osmotic as well. Contrary to the previous case, the presence of a membrane is not necessary to generate osmotic potential.
It is well known that the negative charges of the residual silica are compensated by the positive charges of the alkali ions, and that a part of these latter ions is not condensed.
Therefore, very schematically, if two silica surfaces are facing each other (two surfaces which belong either to the same particle or to two different particles), some alkali ions are not condensed and behave as ions in solution between the two surfaces. Nevertheless, they remain necessary localized between the two surfaces in order to compensate the negative charges of the ionized silica. The alkali ions, which are not condensed on the silica, participate therefore to the activity of the localized solution between the two silica surfaces. This solution is in equilibrium with the one which has a different composition outside the two surfaces. Therefore, if the activity of the solute in the solution between the two surfaces is higher than the activity of the solute in the solution outside of two surfaces, the system will evolve to dilute the solution between the two surfaces until the pressure exerted on the two surfaces compensate for the difference of activity of the solute in the solutions when the system is at the thermodynamic equilibrium.
This pressure has not been measured. No model system has been successfully conceived to isolate the pressure which would be exerted by the residual silica from that exerted by the alkali-silicate solution and the reaction product formation.

Can stresses be generated by the formation of the calcium, alkali, silicate reaction product?
As it has been proposed previously, it can be postulated that the formation of a reaction product from calcium ions and sodium silicate entities, which result from the silica dissolution, and their growth in a confined environment can generate stress.
A model system which permits the formation of a reaction product in a confined environment by avoiding the presence of residual silica was conceived. It was composed of a source of calcium ions and an alkali silicate solution and is presented in Fig 4. Two cementious paste pellets (hydrated C_3S) were in contact to each other and submerged in an alkali silicate solution with a

high silicate concentration ([SiO_2] = 3 mol/l and [Na^+ or K^+]=0.84 mol/l). In this condition, the portlandite resulting from the C_3S hydration constitutes the source of calcium ions.

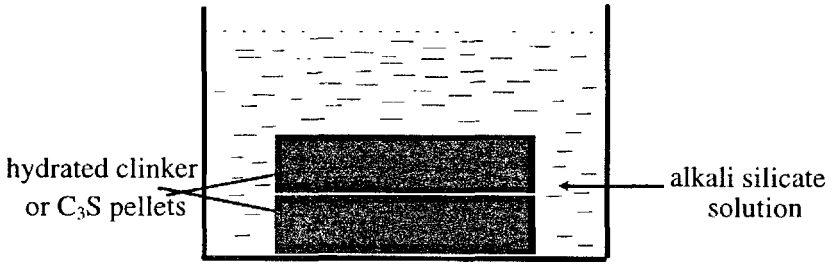

Figure 4 Experimental model which permits the formation of the hydrated calcium alkali silicate reaction product in a confined environment.

The formation of a white reaction product has been observed at the interface between the two pellets. As shown in the Fig 5, its morphology is very similar to that of the of the alkali silica reaction products observed in damaged constructions.

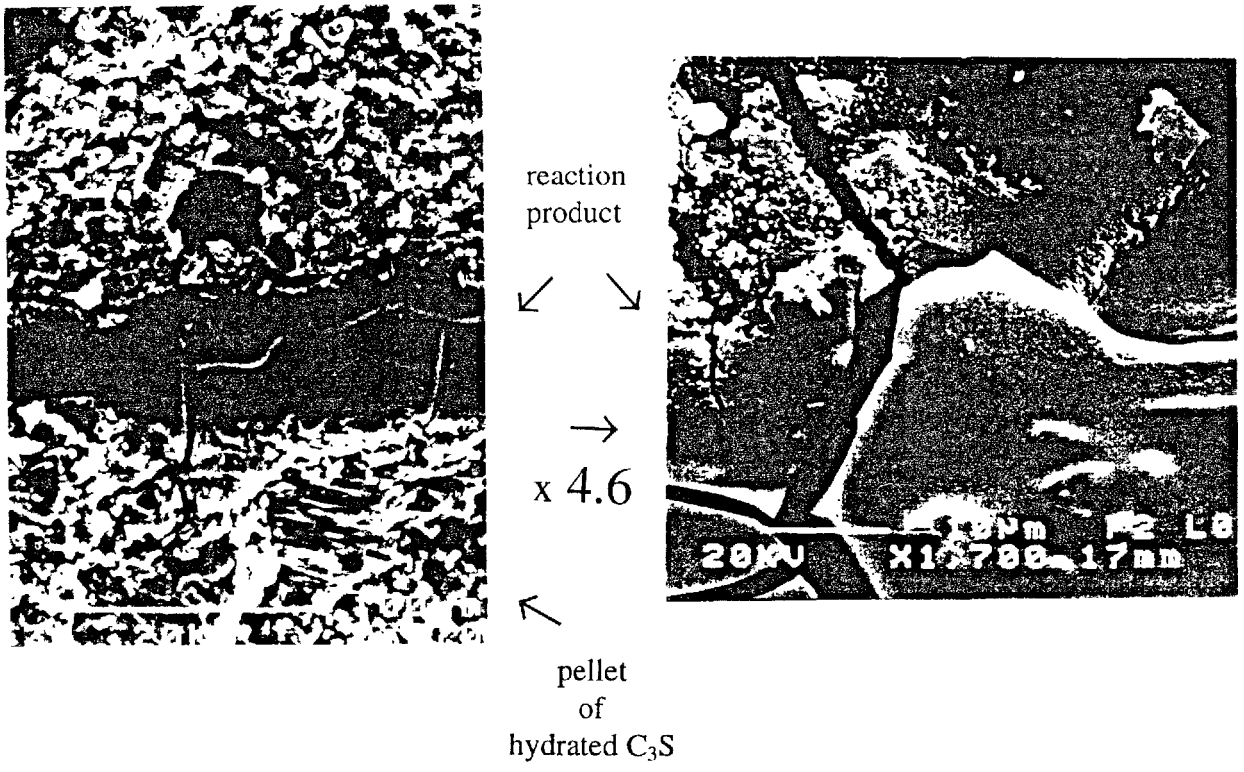

Figure 5 S.E.M. Photographs of the reaction product at the interface of two hydrated clinker paste pellets.
The two pellets initially were in contact to each other and submerged in a sodium silicate solution with alkali and silicate concentrations of 1 and 3 mol/kg respectively.

The changes in pressure exerted by the formation of this product with time was followed with a specially conceived experimental equipment and described below.

Experimental equipment designed to follow the pressure evolution with time generated by the formation of the calcium, alkali, silicate reaction product.

To quantify the pressure exerted by the formation of the calcium, alkali, silicate reaction products, it was necessary to keep the two pellets in contact to each other in a confined environment by preventing any displacement of the pellets and to measure the exerted pressure with time. In this way, the measured pressure would refer to that of the reaction product.

The experimental equipment which was conceived is shown in Figs 6 and 7.

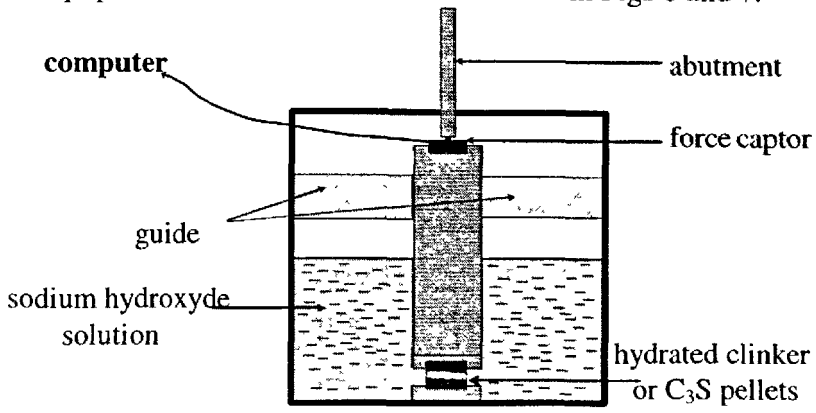

Figure 6 Transverse section of the experimental equipment designed to follow the pressure evolution with time generated by the formation of the calcium, alkali, silicate reaction product.

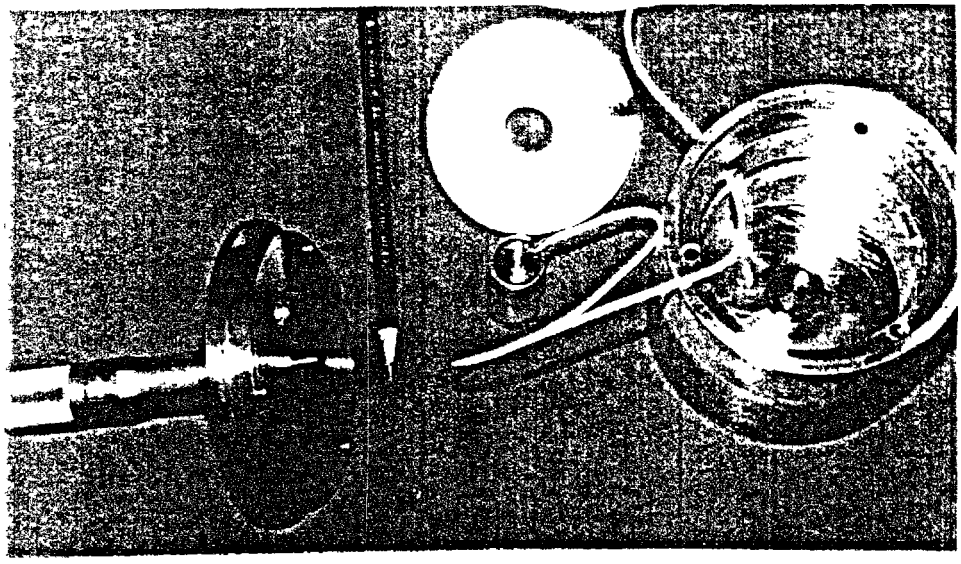

Figure 7 Photograph of the experimental equipment designed to measure the pressure exerted by the system simulating a portion of concrete composed of calcium - silica - alkali and hydroxide ions.

It consists of a stainless steel tank. Each pellet is placed in a support in P.V.C. By attaching one of the supports to the bottom of the tank and the other to a stainless steel shank, the two pellets are in contact to each other. To prevent any movement of these pellets, an abutment is attached to the cover, which is tied to the tank by screws. The pressure exerted by the sample is measured by a pressure captor consisting of a stress guage placed between the top of the shank and the bottom of the abutment [Entran ELM-16A-50].

Actually, the design of the stress guage does not permit to quantity the pressure exerted by the reaction product for two reasons :

- deformation is not totally prevented. The stress guage is effectively composed of a membrane which has a low deformation when effort is exerted on it. Therefore, this equipment permit only to provide an evolution profile of the pressure with time.
- the geometry of the system does not prevent any flow of the reaction product out of the two pellets interface. Therefore, the measured pressure would probably be underestimated.

Evolution profile of the pressure generated by the reaction products

The changes in pressure with time are shown in Fig 8.

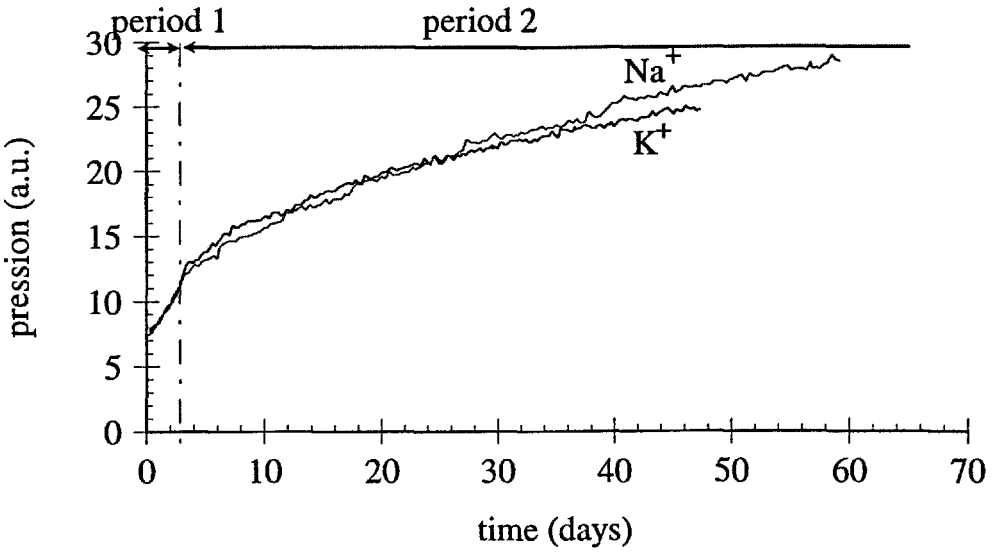

Figure 8 Evolution profile with time of the pressure exerted by the experimental model composed initially of two pellets in contact to each other and submerged in a alkali (sodium or potassium) silicate solution with alkali and silicate concentrations of 1 and 3 mol/kg respectively.
The initial pressure corresponds to the one exerted to maintain the pellets in contact to each other.

The profile of the pressure in time is reproducible and similar whatever the alkali ions nature (K^+ or Na^+) in the alkali silicate solutions. Two periods are distinguished; an initial one characterized by a sigmoidal increase, following by a second one during which the pressure increases slower.
Conductimetry experiments showed that for the first period the increase of the pressure is mainly due to the formation of the reaction products.

CONCLUSIONS

The present study shows that the sole presence of calcium, reactive silica, alkali and hydroxide ions generate a sufficient pressure to make concrete cracking.
Alkali silicate solution can generate pressure but its value is too low to contribute to the disruption of concrete.
Residual silica and reaction product can generate pressure as well. For the former, osmotic phenomena would be the cause. The ability of the reaction product to generate pressure has been confirmed by following pressure with time.

The pressure exerted by the last two sources has nevertheless not been quantified, thus their respective contributions has not been determined.
It is important to keep in mind that the pressure which is necessary to make the concrete cracking can be very lower than the resistance of the concrete. Defects are always present in concrete; therefore, to make the concrete cracking it is not necessary to initiate defects what requires high pressure, but only to propagate the cracks, what requires a very lower pressure.

INTERFACIAL LONG AGE REACTIVITY OF SLAG/CLINKER COMPACTS

Bernardo MARCHESE, Dipartimento Ingegneria Materiali e Produzione, Facolta' Ingegneria Universita' di Napoli, Italy
Giuseppe FRIGIONE, Dipartimento di Ingegneria Chimica e dei Materiali, Facolta' di Ingegneria, Universita' della Calabria, Italy

ABSTRACT Reactivities of blast furnace slag, ground to 370 m^2/kg, in contact with different aqueous solutions are reported. Disks of slag, clinker and slag+clinker (50+50), five centimeters in diameter, were obtained by cold compaction. Pairs of discs: slag/slag, slag/clinker and (slag+clinker)/(slag+clinker), were separated with filter paper hanging saturated lime solution or distilled water. Each pair was stored in a closed box at room temperature for ten years.
Composition and microstructure modifications of the matching layers of compacts were determined by Scanning Electron Microscopy (SEM), X-ray Diffraction (XRD), Differential Thermal Analysis (DTA) and Thermogravimetry (TG).
A low reactivity resulted in slag in contact with lime solution, while medium reactivity in contact with the alkaline solution from hydrating clinker. Highest reactivity was shown by slag in touch with hydrated phases from clinker. A special reactivity of the slag grain, when activated topochemically by the unique pore solution of hydrating clinker, can be hypothesized.

Key-words: Slag, Reactivity, Interfacial zone, Microstructure, Long age.

INTRODUCTION

The hydration of blast furnace slag is activated by lime of different origins. According to Nurse, Nurse (1964), there is a substantial difference between the activation promoted by $Ca(OH)_2$ saturated solution or by the portlandite liberated by the hydration of Portland clinker silicates. In contrast, Krüger has suggested that the slag hydration reaction is the same whatever is the origin of lime, Krüger (1976).

In slag cements, the slag hydration occurs very slowly in the first stage and with a higher speed then, Hooton (1987). This behaviour has been explained by a mechanism involving the development of a semi-protective layer of hydrates that quickly envelopes the surface of slag grains, decreasing hydration rate of the slag. At the same time, the hydration of clinker grains proceeds increasing in turn the CH content. Then, the CH accumulated outside the slag grains develops a chemical potential between the cores of the unhydrated slag grains and the hydrated cement matrix. "The membrane of hydrated products enveloping the slag grain acts as an ion pump : water diffuses inward to maintain the hydration reaction, while mobile hydrophilic ions (Ca, Si, etc.) migrate in the opposite direction into the more hydrous outer regions", Fig. 10 Glasser (1990).

As the hydration progresses, on the other hand, the clinker grains transform in a cellular matrix of interconnected pores and small particles. In the matrix there are immersed larger grains - phenograins - composed of: CSH, with different crystallinity; calcium hydroxide; and residual unhydrated clinker constituents, Diamond and Bonen (1993).
In the present work the effect on the slag activation due to different source of CH is described.

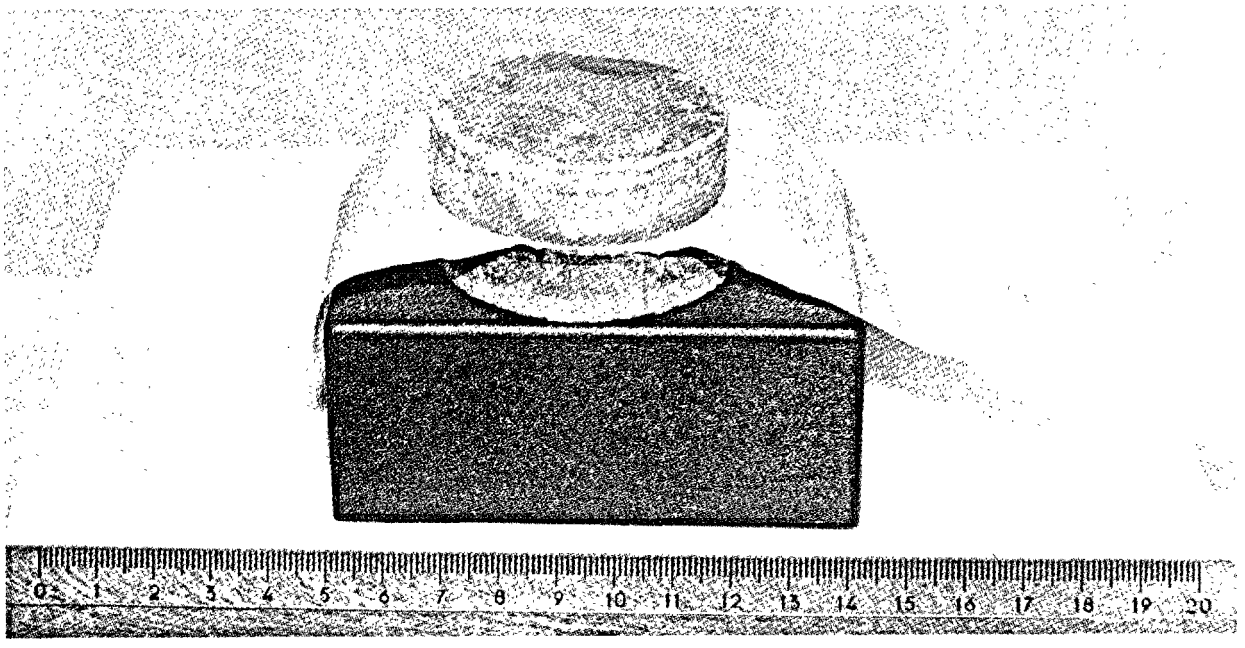

Figure 1 Surfaces of a pair of specimens hydrated by solution permeating through interposed filter paper.

EXPERIMENTAL

Cylindrical specimens, 50 mm in diameter and 15 mm in height, of ground slag, clinker and a mixture of 50slag+50clinker were obtained by cold compaction. Compositions were reported previously, Frigione and Marchese (1996).In different laboratory containers three pairs of discs: slag/slag (L/L), slag/clinker (1L/1K) and (50slag+50clinker)/(50slag+50clinker) (L+K)/(L+K) were kept in contact for ten years through an intermediate filter paper. The filter paper of the first couple was immersed in an oversaturated solution of calcium hydroxide and the one of the others two couples in distilled water. By capillarity the solutions were able to reach the surfaces of specimens.

For the examinations by SEM thin transversal slices of samples were fractured and the two halves were put on the same specimen holder and coated with Au. A Stereoscan Cambridge 240 SEM was used.

XRD patterns were obtained from both the external surface and the internal one obtained by lapping after remotion of a layer of about 200 μm of thickness, for each sample. A Philips PW1710 Series automatic diffractometer was used with a X-ray source of $CuK_{\alpha 1}$ radiation (λ = 1,5406 Å).

The powdered samples obtained by grinding were kept in oven at 60 °C for 24 hr to remove the most of the evaporable water, and submitted to thermal analysis using a Stanton Redcroft STA-780 series simultaneous analyser with an N_2 fluent atmosphere and heating of 10 °C/min.

Actually carbonation does not occur because of the rapid lack of water during the oven-drying, Bakker (1988).

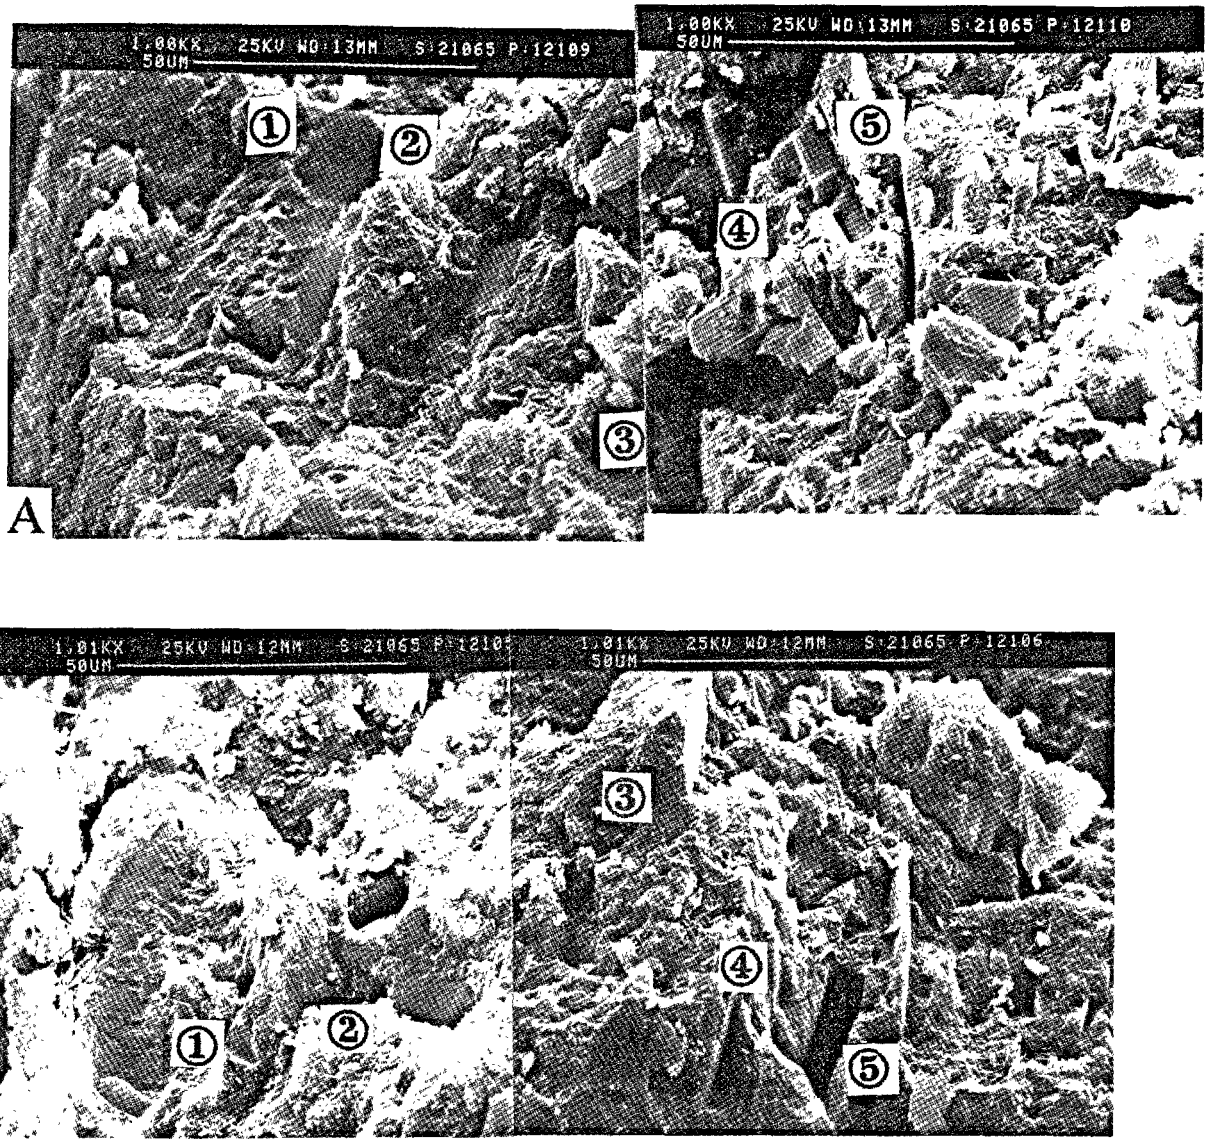

Figure 2 SEM of matching fracture surfaces, A and A', of the slag compact, L. The CH solution was penetrating from the left. Magnification 700x.

RESULTS AND DISCUSSION

SEM Observations

Micrographs in Figs 2, 3 and 4 show selected images of fracture surfaces normal to the external surface in contact with aqueous solution.

In Fig 2 the matching or "twin" surfaces of a slag compact L, show the high porosity of the whole mass. At left in micrographs, large masses, as those marked with 1, were originated by slag grains permeated by the CH solution. However, hydrated products were not able to occupy all the intergranular volume. Isolated grains, like 4 and 5, remain visible with evident smooth surfaces. Areas like 3 are voids left by the slag grains, signed also as 3, visible in the other matching micrograph.

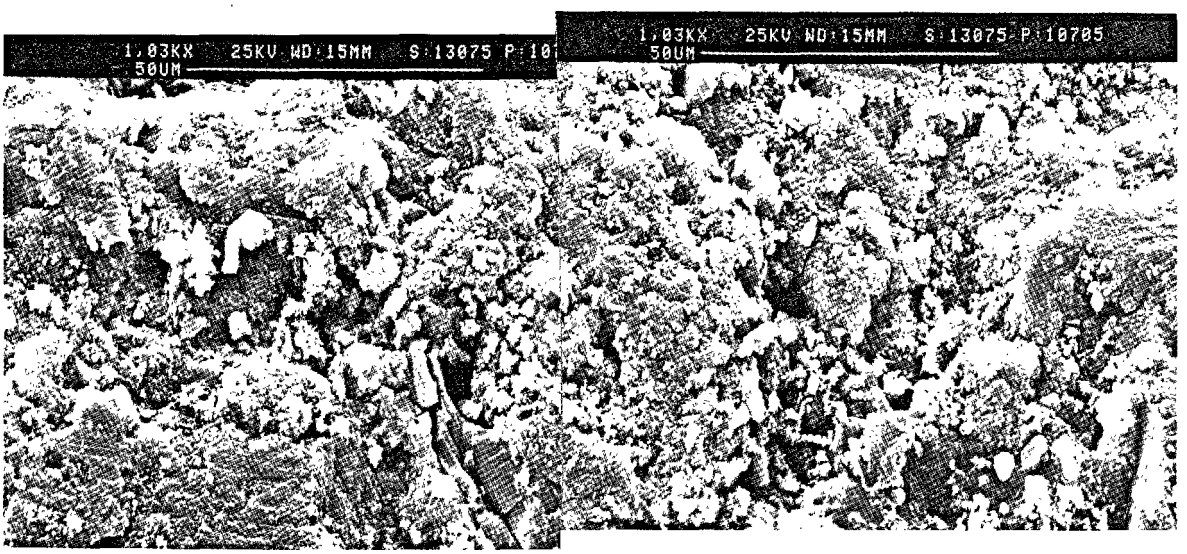

Figure 3 SEM of fracture surface of the slag compact, 1L. The solution from hydrating clinker was penetrating from the right. Magnification 700x.

In Fig 3 the internal mass of the slag compact, 1L, appears composed of slag grains covered by the hydrated products originated by the highly alkaline solution originating from the opposite clinker specimen, 1K. The resulting mass seems less porous than the mass in Fig 2.

Micrographs of matching surfaces reveal instead the very dense mass of the (L+K) compact, Fig 4. Aqueous solution hydrates quickly the clinker grains producing voluminous C-S-H gel which has a tendency to fill the interstitial space and to adhere to the surface of surrounding slag grains. On the other hand a layer of hydrates, just formed on slag surface, operates as a membrane which permits diffusion of OH ions into grain core and diffusion of Ca, Si, Mg, and other mobile ions, in opposite direction, Glasser (1990).

The very high specific surface of C-S-H along with the permeating solution rich in OH^- and other ions make the attack of slag very active controlling at the same time the oversaturation and the precipitation of solid phases.
The hydrated products from both clinker and slag grains are now interconnected and the solution moves freely through their porosities, Bourdette et al (1995). However in some zones, presented by number 3, lamellar CH was evident. Conchoidal smooth surfaces and their impressions, marked 4 and 5, reveal slag grains. The final mass may be described as pseudomorph phenograins surrounded by hydrated products, Diamond and Bonen (1993).

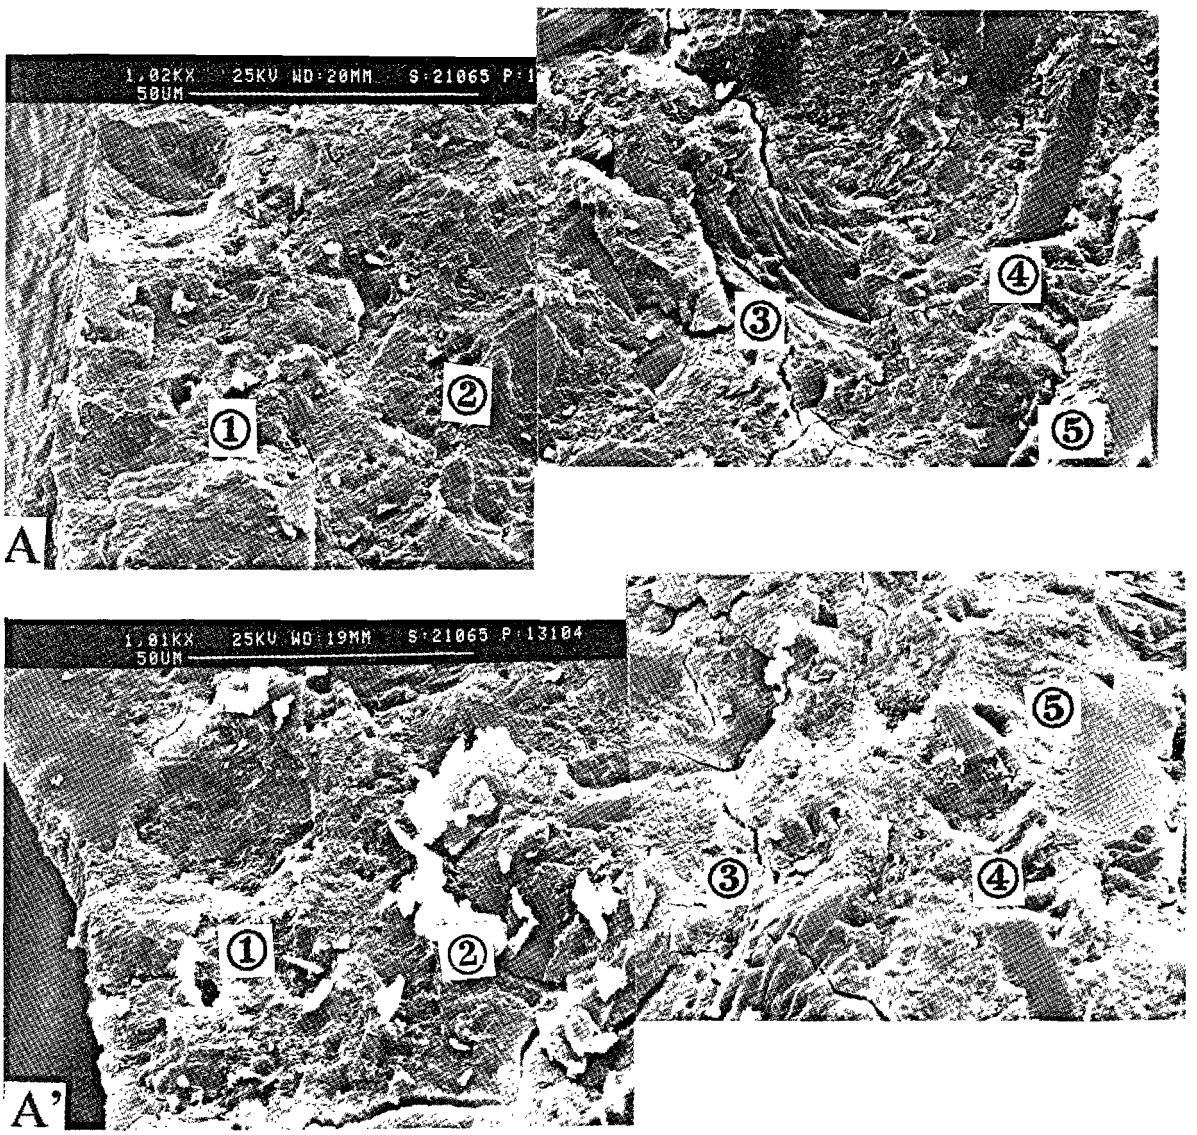

Figure 4 SEM of matching fracture surfaces, A and A', of the 50slag+50clinker compact, L. Aqueous solution was penetrating from the left. Magnification 700x.

X-ray Diffraction

In Fig 5A the broad peak around 28-32 °2θ denotes the vitreous structure of slag. The permeating CH solution originates calcium carbonate and calcite peaks appear in XRD traces of the surface layer. Hydrotalcite-type phases are not well observed due to their low amount, Wang and Scrivener (1995). C-S-H reflexes near the very strong calcite peak confirm the alkaline activation of slag. The XRD trace for underlying surface, at about -180 μm, shows less intense peaks of crystalline phases whereas remains the broad peak of slag for the reduced presence of CH solution.

In Fig 5B the XRD trace of surface of slag (1L) presents intense peaks of calcite due to contact with solution originating by the opposite clinker specimen. They disappear on the intermediate internal surface at -80 μm because the calcite layer was very thin and impermeable.

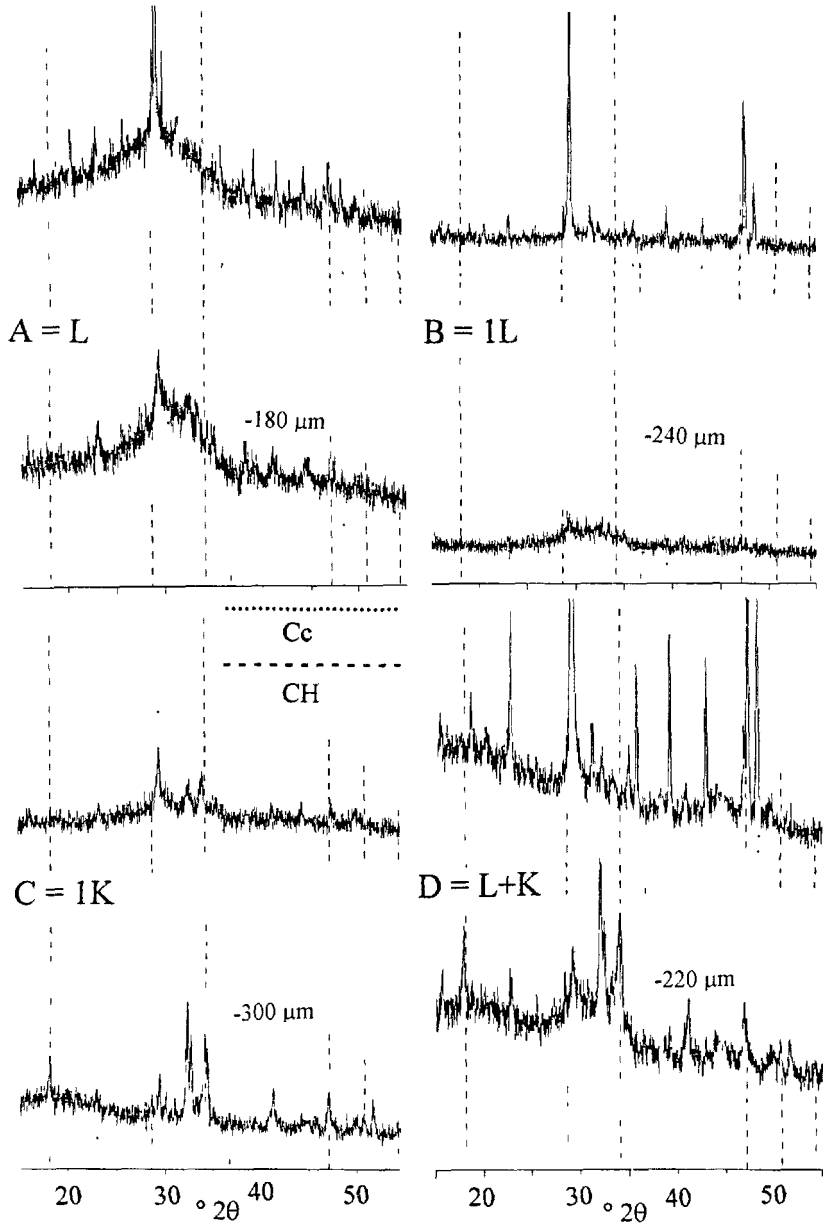

Figure 5 XRD patterns for external surfaces of the specimens and internal ones resulting after remotion of the external layer. A = slag (L), B = slag (1L) at contact with C = clinker (1K), D = 50slag+50clinker (L+K). Calcite (Cc) and calcium hydroxide (CH) lines with intensities from JCPDS index are overimpressed.

In Fig 5C the XRD pattern of the 1K clinker surface reveals peaks of calcite (Cc) with intensities different by the corresponding JCPDS card. They disappear on the internal surface meanwhile the CH, 32 -33 °2θ of C-S-H and also the anhydrous clinker reflexes are visible.

The highest reactivity of 50slag+50clinker sample is evidenced from diffractogram in Fig 5D. On the external surface numerous peaks of the crystalline phases are observed. On the internal surface the carbonation is less evident and the CH peaks with the clinker ones are now emerging.

Thermal Analysis

Aqueous solutions furnished by intermediate filter paper were able to penetrate in the two facing specimens for capillary absorption controlled initially by nature, particle-size distribution and porosity of compact and then by hydrated products of the superficial layers.
From the surfaces previously in contact, two samples of each specimen were removed by lapping and collected. Their hydrated and carbonated phases were detected by simultaneous thermal analysis.
DTA profiles and TG data were used to measure the effects of three endothermal decompositions: (a) C-S-H decomposition and water loss in the 20 - 170 °C range; (b) CH dehydroxilation and water loss in the 400 and 500 °C interval; (c) Calcite (Cc) decarbonation and CO_2 loss in the 550 and 740 °C range, Frigione and Marchese (1996).

Table 1 Weight losses and ratios between weight losses and residues at 900 °C, at two temperature ranges. In (CH) there is added the stoichiometric amount from Cc. Initial mass = 20 mg.

sample	thickness μm	20-400° (C-S-H)	400-740° (CH)	$R_{900°}$	20-400° (C-S-H)/ $R_{900°}$	400-740° (CH)/ $R_{900°}$
L	0 - 90	1,16	0,89	17,73	6,5	5,0
	90 - 180	1,13	0,68	18,06	6,3	3,8
1L	0-80	1,30	1,08	17,32	7,5	6,2
	80-240	1,05	0,41	18,35	5,7	2,2
1K	0-110	1,45	1,60	16,40	8,8	9,8
	110-300	1,38	0,74	17,70	7,8	4,2
L + K	0 - 150	2,92	0,78	13,94	20,9	5,6
	150 - 220	1,75	0,64	17,43	10,0	3,7

Residues at 900 °C are to be considered inversely proportional to the total content of thermolable phases. In fact it is evident that external layers have a hydrated products amount higher than of the internal layers of each specimen. The higher figure was shown by the (L + K) specimen.

Two approximations can be made. The first one was to attribute the weight loss up to 400 °C, indicated as (CSH), to the water of hydrated products, namely CSH, monosulphate and ettringite, Rahman and Glasser (1989). The second one concerns the weight loss between 400 °C and 740 °C, indicated as (CH), which has been considered as due to decomposition of free CH and the CH stoichiometrically equivalent to the Cc content. This latter represents the amount of $CaCO_3$ formed by carbonation of only CH. As a matter of fact the carbonation affects both CH and CSH, Rahman and Glasser (1989).
The first ratio, (C-S-H)/$R_{900°}$, show the highest values for (L + K) samples that is the highest content of hydrated phases. That means that the slag fraction present as 50% in initial mixture, contributed actively to hydrated product. The figure appears even higher than the corresponding of the plain clinker, 1K.
Compared to Portland cements pozzolanic cements have lower portlandite content and higher CSH content (Massazza, 1991).

Also the ratios (CH)/ $R_{900}°$ may indicate the reactivity of mixtures. For the L and 1L slag specimens their values indicate that some solution was penetrating and originating some of CH and/or Cc solid phases.
For the (L + K) sample the low figure for the inner layer means that part of the CH produced by clinker fraction was consuming by the slag fraction resembling the pozzolanic reaction.

CONCLUSIONS

Different hydration degrees have been shown by the cold compacted slag grains after ten years. A low reactivity was shown at contact with the oversaturated CH solution and a medium one with the solution produced by the clinker grains hydration. Highest reactivity was reached in the 50:50 by mass slag:clinker mixture with formation of a well compacted hydrated mass.
Highest reactivity appears to be attributed to the slow transformation of the clinker grains into phenograins which allows the development of chemical potential and increase the hydration of surface layers around the slag grain.
A topochemical attack of the slag grains by cooperation both of the special solid phase formed by the cellular matrix of cement paste and the permeating CH-rich solution could be hypothesized.

Authors would like to thank Mrs A. Annetta and G. Mocci for valid technical assistance.

ABSTRACT Mechanical properties of high carbon ferrochromium (FCr) slag mortar were investigated. Strength of FCr slag mortar was greater than the mortar with natural river sand, especially in later ages Fluorescence microscopy and SEM examination revealed that failure occurred in the matrix at a distance away from the real interface. Rough surfaces of the slag particles were found to be filled with cement paste matrix. Better performance of FCr slag mortar can be attributed to the greater bond strength due to the reaction of glassy phase with cement paste matrix and the improved mechanical interlocking due to rough surfaces of the grains.

INTRODUCTION

Utilization of various industrial by-products as construction materials has been of great interest from the standpoint of saving of energy in the world. By-products such as blast furnace slag and silica fume have already been quite important materials to provide concrete with improved properties. Recently, the ferronickel slag of by-products in the electric furnace has been standardized as aggregate for concrete in Japanese Industrial Standard (JIS) since the quality of ferronickel slag was confirmed to be comparable to that of blast furnace slag. High carbon ferrochromium slag (FCr slag) is also a by-product at the production of ferroalloy. This FCr slag is expected to be used as aggregate for concrete since its mechanical strength is high enough for concrete aggregate. Furthermore, the slag may have additional effects to improve mechanical properties of concretes if the quenching process of the slag leads to the formation of a glass phase. The purpose of this study is to reveal mineralogical compositions of FCr slag in relation to the alkali reactivity with a cementitious matrix. Effects of their reactivity on mechanical properties of the mortar with FCr slag are also discussed in terms of the crack path and microscopic failures around FCr slag grains.

EXPERIMENTAL

Materials and Mix Proportions

The cement used was ordinary Portland cement. Alkali reactivity of FCr slag was determined by chemical method of ASTM C 289. Its Rc and Sc are 37mmol/l and of 73mmol/l, respectively. Physical properties of FCr slag and the natural river sand used as aggregate are shown in Table 1. Water:cement ratios of mortars for compressive strength and wedge-loading compact tension tests were 0.35 and 0.55. The mortar for expansion tests was prepared at a water:cement ratio of 0.50 and a cement : aggregate ratio of 2. In the mortar for expansion

Table 1 Physical Properties of Aggregates

	Specific Gravity	F.M.
Coarse FCr Slag	2.90	6.85
Fine FCr Slag	3.09	3.36
River Sand	2.64	2.49

Table 2 Mix Proportions of Concrete for Expansion Test

Unit Content (kg/m^3)					
C	W	Fine Slag	Coarse Slag	Super-prasticizer	NaOH
400	86	1079	973	4	77.4
500	127	962	868	5	77.4
600	167	847	764	6	77.4

tests, the replacement level of FCr slag varied. Mix proportions of concrete prisms for expansion tests are given in Table 2.

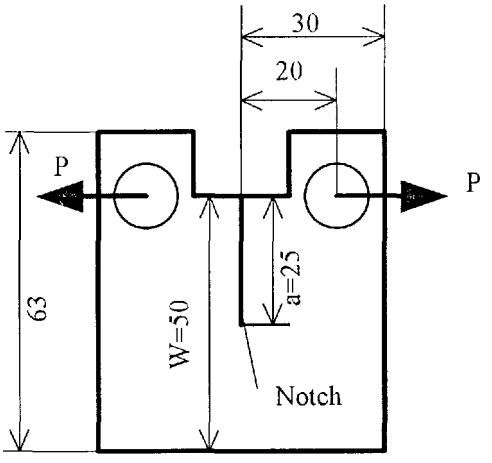
Characterization of FCr Slag

Chemical and mineral compositions of the FCr slag were determined by X-ray diffraction, chemical analysis (JIS A-5011, JIS M-8209～8266, JIS R-5202), polarizing microscopy and SEM-EDXA examinations for the polished surface of the slag grains.

Expansion Test

The mortar bars of 40×40×160mm and concrete bars of 75×75×400mm prisms were stored in a fog box maintained at 40±2℃. The length changes of the bars were measured according to JIS A 5308.

Compressive Strength and Wedge Loading Compact Tension Tests



40 × 40 × 160mm prisms and compact tension specimens (Fig.1) were produced. FCr slag aggregate of which grading was adjusted to have the same grading curve as the river sand, was used in the specimens for the wedge loading compact tension test. All specimens were stored in water at 20℃ for prescribed time. Compressive strength tests for the mortars were carried out according to JIS R 5201.

A crack from a notch was forced to extend by wedge loading. Fracture toughness of the mortars was calculated using Eq.(1). Experimental procedure was described in detail elsewhere (Igarashi and Kawamura, 1995).

$$K_{eff} = \frac{P}{B\sqrt{W}} Y\left(\frac{a}{W}\right) \qquad [1]$$

Fluorescence Microscope and SEM Examination

Cracked specimens after compact tension test were impregnated with the epoxy resin containing a fluorescence die. After the resin hardened, the surface of specimens was polished for fluorescence microscopy (Igarashi and Kawamura, 1995) and SEM examinations.

RESULTS AND DISCUSSION

Mineral Compositions of FCr Slag

XRD patterns and polarizing microscopic examination showed that FCr slag had two crystalline phases in a glass matrix. Those crystalline phases were identified

Table 3 Chemical and mineral compositions of FCr slag

Constituent Phases	Chemical Content(wt%)					Mineral Content
	SiO_2	MgO	Al_2O_3	Cr_2O_3	others	(wt%)
Spinel		3.9	11.4	1.4		16 7
Forsterite	11.8	17 2		0.8	4 3	34.1
Glass Phase	22 9	5 5	13.3	2 3	5 2	49.2
Total	34.7	26.6	24.7	4.5	9.5	100.0

as spinel and forsterite. The constitution of the slag was clearly seen in the BEI micrograph (Fig.2). The compositions of the FCr slag determined by chemical analysis are given in Table 3. It is found that the slag mainly consists of SiO_2, MgO and Al_2O_3, and contain other minor components such as Cr_2O_3. EDXA analysis showed that the glass phase was similar to the cordierite of which the formula is $2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$. Analytical results of the mineral compositions given in Table 3 were compared with the phase diagram of SiO_2-MgO-Al_2O_3 system. As expected, the composition of the slag falls in a triangle of spinel-forsterite-cordierite. The mineral contents calculated from EDXA analysis were consistent with those in the phase diagram. Furthermore, it was confirmed that the glass phase was preferably formed since it was hard to crystallize under the condition of the constitution of FCr slag. Consequently, it seems that the constitution of mineral compositions of the FCr slag was controlled by the chemical composition of SiO_2-MgO-Al_2O_3. The characteristics of the slag as an aggregate for concrete was related to the formation of glass phase and its composition.

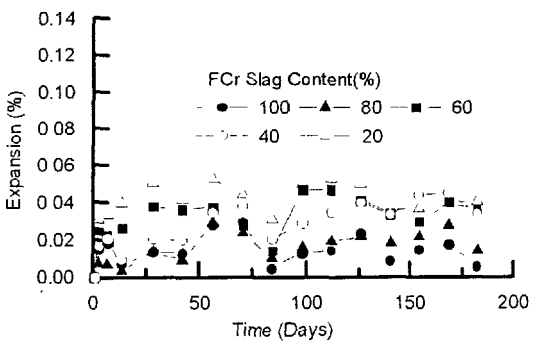

Fig. 3 Expansion of mortars with FCr slag.

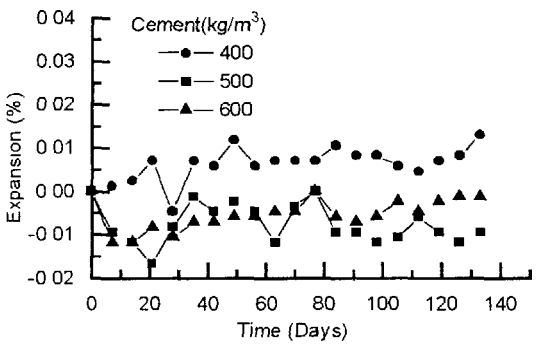

Fig.4 Expansion of concretes with FCr slag.

Alkali Reactivity of FCr Slag

The plot of the value of Rc and Sc for the FCr slag falls in the region of "Deleterious". However, the expansion of the mortar bars with the FCr slag was far lower than the critical value of 0.1% at 6 months (Fig.3). Expansion of the concrete prisms with much added NaOH was also small (Fig.4). Therefore, the use of the FCr slag as an aggregate for concrete is considered not to give rise to the deterioration of concrete due to the alkali silica reaction.

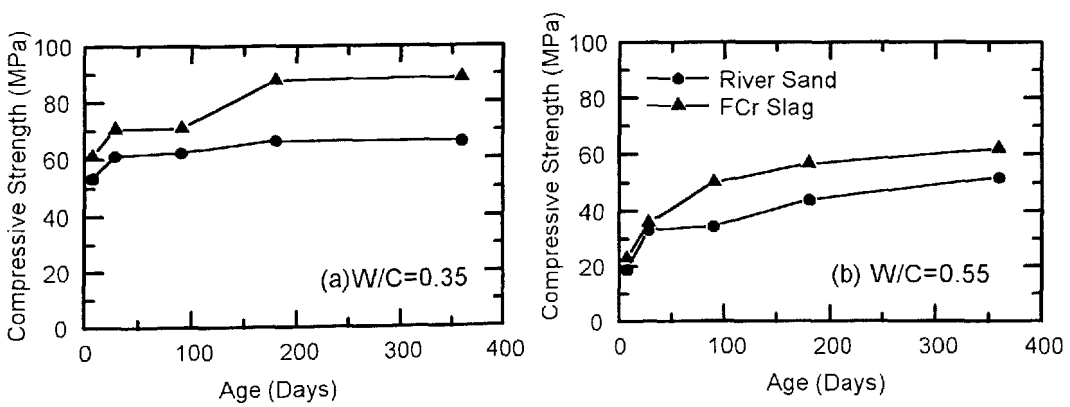

Fig. 5 Comparison in compressive strength between the FCr slag mortar and the control.

Mechanical Properties of FCr Slag Mortar

Fig.5 shows the comparison in compressive strength between the FCr slag mortar and the control. The compressive strength of the FCr slag mortar was greater than the control. The compressive strength of the FCr slag mortar steadily increased with time even after 28 days, while the gain of

strength in the control at later ages was relatively small.

Fracture toughness of FCr slag mortar and the control is shown in Fig.6 At the age of 28 days there was little difference in the values of K_{eff} between both mortars. However, a considerable difference in fracture toughness between both was found at the age of 180 days.

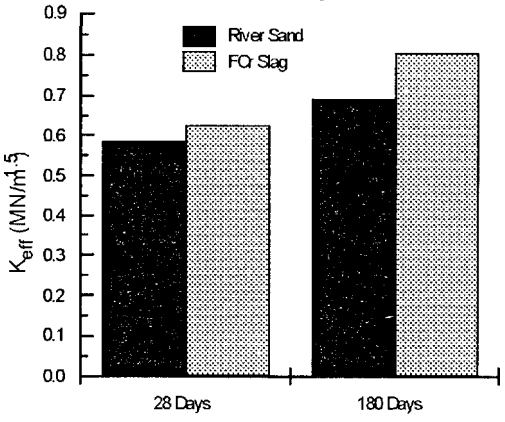

Fig. 6 Fracture toughness of mortars.

Fig.7 shows the crack path of a main crack around the slag particles. A crack propagating toward the slag grain deflected at the interfacial zone. The path of the crack after deflection was apart from the real interface between the slag particle and the cement paste. A bright rim, which is a portion of the matrix seems to be attached to the surface of the slag. Namely, debonding has not occurred in the real interface, but in the weak interfacial transition zone formed apart from the real interface. As mentioned earlier, the FCr slag is reactive to some extent. It seems that chemical interaction took place to form a stronger bond across the real interface, and a crack shifted into porous areas (Bentur, 1990).

Fig.8 also shows the crack propagating in the vicinity of FCr slag particles. A crack appears as a dark gray area at the center of the micrograph, because cracks were filled with the epoxy resin. The main crack appears to have passed about 50 μm away from the aggregate surface. The FCr slag particles have irregular shape and uneven surface. However, cement paste fully penetrated into the concavities of the surface of the slag particle. These geometrical effects also lead to the greater bond by mechanical interlocking. It is suggested from Figs. 7 and 8 that greater strength and toughness of the mortar with the FCr slag can be attributed to the increase in bond strength due to those chemical and mechanical functions between the slag particles and the cement paste matrix.

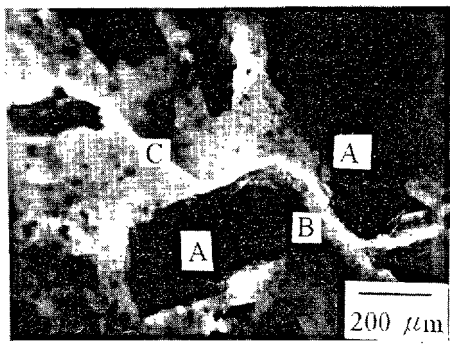

Fig. 7 Crack path around FCr slag particles. (A:aggregate B:original surface C:crack)

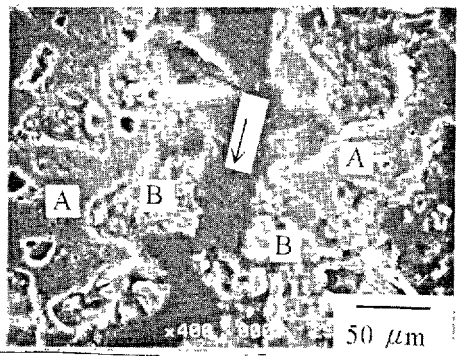

Fig.8 Mechanical interlocking by rough surfaces of the FCr slag particles. (A:aggregate B:cement paste ↓ :crack path)

CONCLUSIONS

The FCr slag has the potential reactivity with cement paste matrix. However, the reaction does not result in the deterioration of concrete due to the alkali silica reaction. On the contrary, the reactivity of the FCr slag contributed to the increase in bond between aggregate and cement paste. Irregular geometry of the slag particles also contributed to the increase in bond strength and crack growth resistance. Those interactions can enhance the function of aggregates as reinforcement and crack arresters.

ABSTRACT. The cement hydration equation is applied to determine the equation of the compressive strength of concrete. The equations of the compressive strength of fourteen concrete mixtures, prepared with different blended cements and silica and limestone aggregates, were defined. Based on these equations the influence of the pozzolana content and of the aggregate's type on the compressive strength is examined.

Key-words: Cement hydration equation, concrete strength development, blended cements.

INTRODUCTION

Concrete's compressive strength is one of the material's properties affecting the safety of the structures. During the last decates several reasons forced the Cement Industry at the production of pozzolanic cements. In most cases these cements develop the major part of their compressive strength after the age of 28 days (Figs 1 and 2) , due to their different mineralogical composition.

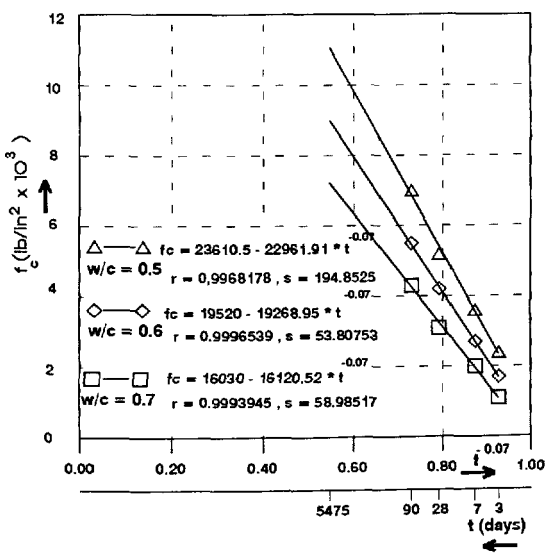

Figure 1: Compressive strength of concrete versus modified time scale. [measured values taken from Lea (1970)].

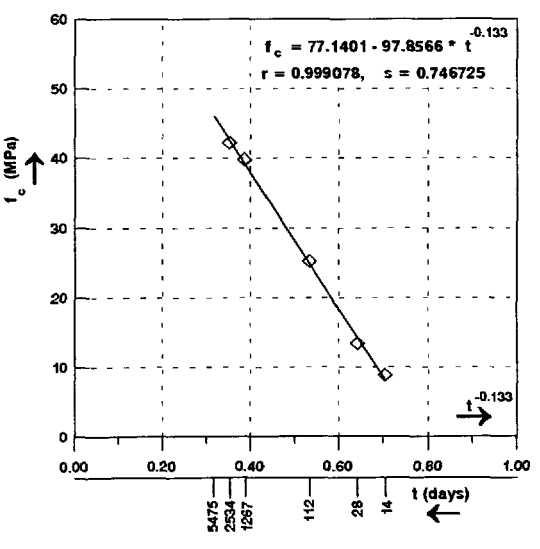

Figure 2: Compressive strength of concrete versus modified time scale. [measured values taken from Hansen (1990)].

This observation led several investigators to perform long-term laboratory tests in order to compare the performance of blended cement concretes with this of Portland cement concrete (OPC concrete). Most of these tests stopped at the age of 2 or 3 years, mainly because of the difficulties of the long-term studies.

In this work the final compressive strength of fourteen concrete mixtures, made with silica and limestone aggregates, is experimentally investigated. The calculation of the concretes' compressive strength at older ages was obtained with the use of the cement hydration equation $K= K_{\infty} \pm b*t^{-p}$ according to Sideris (1993). When the hydration criterion K of the concrete's compressive strength is examined, this equation takes the form:

$$\mathbf{f_c = f_{c\infty} - b*t^{-p}},$$

where: f_c: the concrete compressive strength at any age t (days)

$f_{c\infty}$: a constant, determined with the aid of linear regression

b : is the slope of the straigth line determined with the aid of the linear regression

t: is the age of hydration (days, t>>0)

p: is the hydration number depending only on the chemical composition of the cement type used.

The cement hydration equation was applied to the compressive strength of concrete which determined for a hydration time up to 90 [Karayannis (1994), Sideris K.K. et al (1994), Sideris K.K. et al (1995)], 365 [Sideris K.K. et al (1994)], 730 [Sideris K.K. et al (1994), Sideris K.K. et al (1995), Sideris K.K. et al (1996)], 840 [Sideris (1993)], 1095 [Sideris et al (1994)] and 2534 days [Hansen (1990)]. For the above examples (Figs 1, 2) the measured values of the concrete compressive strength were taken from Lea (1972) and Hansen (1990). In the second case long term laboratory tests were performed up to 2534 days (7 years).

EXPERIMENTS

The blended cements used in this research were prepared by the replacement (wt%) of OPC by three different pozzolanas: one natural pozzolana (Santorini earth - SE) and two lignite fly ashes, a high-calcium fly ash (Ptolemaida fly ash - PFA) and a low-calcium fly ash (Megalopoli fly ash - MFA) (Table 1).

Evaluation of the hydration number p

In order to determine the hydration number of the seven cements used, cement paste specimens were prepared. These specimens were prisms 4X4X16 (cm) which were prepared and cured according to DIN 1164. The water to binder ratio was 0.45 and the specimens were crashed and tested at the ages of 3, 7, 14, 28, 60 and 90 days. Using linear regression for the pairs (β_{Dmeas} - t^{-p}), the hydration number p was estimated for each case, according to the procedure described by Sideris (1993) and Sideris K.K. (1996). The estimated p values are shown in Table 2.

Compressive strength of concrete

Fourteen concrete mixes -twelve blended cement concretes and two OPC concretes- were prepared as it is shown in Table 1. A binder (cement + pozzolana) content of 300Kg/cm^3 and a water to binder ratio (w/(cement + pozzolana)) = 0.60 was used in each case. Broken silica stone and limestone aggregates of the area of northern Greece were used. The aggregates' grading curve was equal to the curve B32 of the standard DIN 1045.

The concrete specimens were cubes 15X15X15 (cm) which were cured at 20±2° C in a room with a relative humidity of 95-98° C. Crash tests were performed at the ages of 3, 5, 7, 14, 28, 60 and 90 days. The compressive strength for each age was calculated as the mean strength of the experimentally measured values of three cubes. Results are shown in Table 1.

Defining the concrete compressive strength equations

Based on the measured concrete compressive strength for each age and the hydration number p estimated above, linear regression was performed for the pairs ($f_{c,meas(t)}$ - t^{-p}), for each mixture. The method of drawing up the compressive strength equations is explained in Table 3 with the aid of the measured values of concrete mixture 1. Using the results of the linear regression, the equations of the compressive strength for each mixture were deduced (Table 2). With the use of these equations, the accurate estimation of the concrete compressive strength at the ages of 7, 28, 60, 365 and 5475 days (final hydration time) was possible. The so calculated values are shown in figures 3-8. The end of the hydration was estimated to be at the age of 15 years (5475 days), according to Sideris (1993).

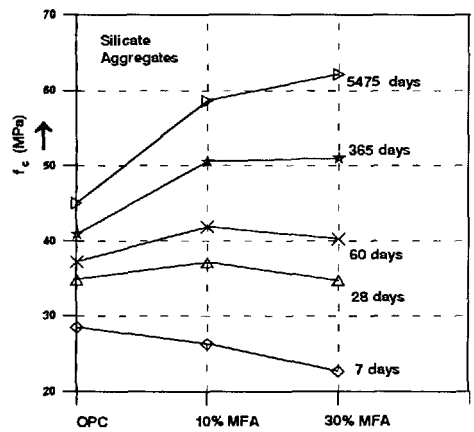

Figure 8: Compressive strength of different MFA concretes for various hydration ages.

The influence of aggregates' type and of the pozzolana content on the compressive strength is shown in figures 3-8. In the case of OPC concrete the ratio $f_{c,5475}/f_{c,28}$ is greater for the concretes prepared with silicate aggregates (1.285, Table 4) than to the concretes with limestone aggregates (1.221, Table 4). This greater development of strength from 28 to 5475 days is the proportion of the bond strength (cement-aggregate bond), which is higher in the case of concrete prepared with silicate aggregates (Schwiete, 1968/69).

CONCLUSIONS

The equation which correlate the compressive strength of concrete mixtures with time, can be formulated by the application of the cement hydration equation. Using this equation, the compressive strength of concrete can be reliably estimated at any age, up to the end of the hydration, without performing long-term laboratory tests. The formulation of the compressive strength equation can easily be obtained using values of the concrete compressive strength, measured at the early ages of the hydration (up to 28 days for OPC concrete and 28-365 days for blended cement concrete depending on the pozzolana content).

The influence of pozzolana's content and of aggregates' type on the compressive strength of concrete can be examined by the determination of the degree of hydration and the ratio $f_{c,5475}/f_{c,28,calc}$ (Table 4). These results indicate that blended cements, due to the pozzolanic reactions, develop a greater part of their strength after the age of 28 days, than to portland cements.

In spite the fact that the condensation of the mixtures was better for the concretes prepared with limestone aggregates, the final compressive strength of blended cement concretes is higher when silica broken aggregates were used (Figs 3-8).

EFFECT OF ALUMINOUS CLINKER AS AGGREGATE ON MICROSTRUCTURE OF INTERFACIAL ZONE IN REFRACTORY CONCRETE.

Olga RYBAKOVA, Alecsander KRIVOBORODOV, JSC "Concern Cement", Moscow, Russia

ABSTRACT The effectiveness of refractory concrete depends on the properties of cement and aggregate. This paper presents a study of formation of interfacial zone between hydrates and initial compounds. The usage of hydraulic aggregate permits to obtain concrete with high refractory performance.

KEY-WORDS: Aggregate, interfacial zone, microstructure,refractory

INTRODUCTION

There are numerous studies of the contact zone between aggregates and cement paste in concrete (Butt, et.al., 1985; Dhir and Sangha, 1974; Kouznetsova, 1986;). According to most of them, the bond between aggregates and cement paste has dramatic impact on mechanical performance of concrete.Maso (1980) shows that the bond plays a major role in the crack propagation process and the failure of concrete. Then bond strength is higher, the strength in traction is higher. Scrivener and Gartner(1988), Zilbermann (1985) showed that the main constituent of the contact zone is calcium hydroxide which is also mainly responsible for the cement-aggregate bond. The bonding region is the result of the adhesion between cement paste and aggregates due to epitaxial growth of calcium hydroxide on the aggregate surface. The microstructure of the contact zone is characterized by porosity, composed of relatively large pores and large crystals of calcium hydroxide. Monteiro and Mehta (1986) used expansive cement with the aim to reduce porosity of the interfacial zone . In this case the modified interfacial zone contains a higher amount of ettringite and discontinuous calcium hydroxide crystals. This zone in expansive concrete resists crack propagation and therefore is stronger than typical interfacial zone in portland cement concrete. However, the interfacial zone in refractory concrete is caused both by hydration process and dehydration under high temperature, therefore a great attention is to be attributed to the interaction between aggregate and cement matrix. This paper presents the investigation of contact zone between aluminate cement hydrate products and initial compounds.

EXPERIMENTAL

Materials and techniques

For the investigation the samples on the basis of aluminate cement with corundum and hydraulic active aggregate were prepared. Cement-to-aggregate ratio was 1:3 and water-to-cement ratio (W/C) was 0.38.

The samples cures at standard conditions and at the air conditions under heating to 100-800°C, because refractory concrete is characterized by strength after drying at 100°C and after heating at 800°C. All samples were examined by optical and electron microscopy, X-ray diffraction and infrared spectroscopy.

Results and discussion

The samples up to 28 days old were examined. Optical microscopy of the samples shows that corundum grains are surrounded by hydrate products of aluminate cement. The thickness of contact zone is about 10-15 μm. Probably contact zone is formed due to epitaxial growth of crystals of calcium hydroaluminate on the surface of corund grains without chemical reaction.

Contact zone between hydraulic active aggregate (technical calcium aluminates - TCA) and cement paste is hardly observed. There is a layer of hydrates on TCA grain surface which is an evidence of its by their various structure because aluminate cement as well as TCA are presented by calcium monoaluminate (CA) and dialuminate (CA_2) phases having different crystal growth rate.

The investigation of the samples containing corundum as the aggregate shows that microcracks appear along the aggregate grains, i.e. by surface of contact zone. In case of aluminate cement with TCA very densety interface zone developed both along initial unhydrate crystals, gel phase and TCA grains. SEM analyses shows that interaction between TCA aggregate and cement matrix leads to appearance of dense contact zone, thus provide a high strength of the samples. It is also promoted by the rise of hydration degree of cement and aggregate leading to reduction of the structure porosity.

The experimental data shows that contact zone between cement paste and TCA aggregate is 30-40 μm and represented by aluminium hydroxide and calcium hydroaluminate crystals of which growth from both cement paste side and from TCA aggregate grains. In case of corund use as aggregate the adhesion of cement paste to the aggregate is essentially due to physical forces. These results explain the different behavior of concrete contained the various aggregates.

Table 1 shows the compressive and bending strength of the samples cured at standard conditions for 28 days. According to the given data the strength of the samples with TCA aggregates much greater than with corund ones.

Tadle 1. Strength of cement stone with different aggregates

Cement	Aggregate	Strength, MPa	
		bending	compressive
High alumina cement	Corundum	6.7	53.6
High alumina cement	TCA aggregate	11.2	78.8

Investigation of hydration of the above mentioned mixes shows that the liquid phase becomes supersaturated during the first minutes of hydration and crystallization of hydrate products is occured on the surface of aggregates. Nuclear on active centres during further growth promote the appearance of intergrowth with the starting sheet. Intergrowth with other surface zones is restricted by the decrease of migration activity of crystal nuclears, leading to the unability of their growth. During further hydration cement grains are covered by the layer of the reaction products which lead to decrease of ion migration into the liquid phase the degree of supersaturation.

On of the main properties of refractory concrete is the compressive strength after heating up to 800°C. In Table 2 the strength of concrete obtained by the use the different aggregates is given. Table 2 data shows that compressive strength of refractory concrete with TCA aggregate is higher than one of concrete with corundum aggregate at the various temperature. These values are equal to 63.3-71% of the strength after the drying by 100°C while the similar value of corundum concrete is only 35-47%.

Table 2. Compressive strength of refractory concrete

Concrete number (Aggregate type)	Compressive strength, MPa, %					
	standard curing, days			after heating, t°C		
	1	2	3	100	800	1200
1.TCA aggregate	27	36	50	40/100	28/71	26/63
2.Corund	15	20	36	34/100	16/47	12/35

Heat resistance is very important for refractory concrete.It provides the stability of concrete under influence of high temperature. The results show that this value is in the range of 40 cycles of heating and cooling.

Temperature deformation under loading of 0.2 MPa promotes the ability of concrete to withstand against high temperature and loading simultaneously. Table 3 presents the data of these properties of concrete.

Table 3. Heat resistance and deformation of concrete

Heating-cooling,	Temperature deformation, °C		
	beginning of softening	4%	40%
40	1350	1520	1610
35	1400	1600	1650

CONCLUSION

The contact zone in refractory concrete depends on the type of aggregate. In case of corund aggregate the contact zone is formed due to adhesive cement paste to the aggregate. Compared to the contact zone in TCA aggregate concrete, it is obvious that contact zone is formed due to chemical reaction and crystal growth. This leads to crack propagation and good performance of refractory concrete.

**Inorganic Materials Eng. Hanyang Univ. Seoul, Korea.

ABSTRACT The microstructure of calcium silicates-fibers composites were studied. The reactivity of the silicates was important for lighting the weight and increasing the performance of composites. The C/S molar ratio, reactivity of silicates, pressure and fibers were main factors determining physical properties because these conditions affect the porosity, crystal shapes and bending strength of hydrates-fibers composites. The higher the reactivity of silicates increases, the higher the properties of performance, lightness, the crystal size of crystalline and physical properties increased.

Key-words : Calcium silicate, Autoclavation, Porosity, Strength development

INTRODUTION

Calcium silicates-fibers composites are mainly produced by applying pressure in an autoclave after gel synthesis using various materials. The performance and physical properties of the composites are affected by the reactivities of silicates, the shapes of the hydrates and the contents of fibers because different shapes of hydrates have different point of contact, and optimum fiber volume is determined according to the properties of both matrix and fibers(Okada, 1994 ; Talor, 1965 ; Mitsuda, 1989). This report was studied how to change the the microstructure of hydrates with various silicates and conditions of manufacture, and how to control physical properties under these conditions.

EXPERIMENTAL PROCEDURE

Starting Materials ; The raw materials used were shown in Table 1.

Table.1. Chemical compositions of the starting materials

No	Materials	Chemical composion (%)								Remark
		SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O	L.O.I	(m^2/kg)

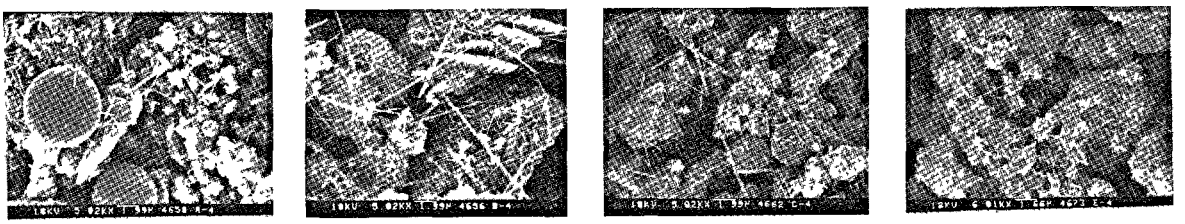
VII	ARG	50.7	16.7	0.8	21.6	0.3	0.25	0.16	0.9	L:13mm
VIII	Pulp	Solid / Water : 5 %								L:4mm



※ ARG : Alkali Resistance Glass Fiber(Density : 2.7g/㎤)

Mix Designs ; The mix designs were (I + II + III + VI)/IV=1, VI/(I + II + III)=0.11 using raw materials as shown in Table 1, CaO/SiO_2 mole=0.67, 0.77, 0.87, 0.97 Water/Solid=3.0 Fibers (pulp, ARG) were added into the composites about 2.0, 3.5, 5.0%.

Process ; Gel synthesis was first initiated at 90-100℃, for 2-4hrs in a water bath and compressed at 10, 25, 40kg/㎠. Subsequently, it was autoclaved at 180℃ for 8hrs. It was cut into 2x2x4cm pieces for compressive strength tests, and into 2x2x5cm pieces for bending strength tests. These samples were analyzed by XRD, DT-TGA, SEM and porosimeter.

RESULTS AND DISCUSSION

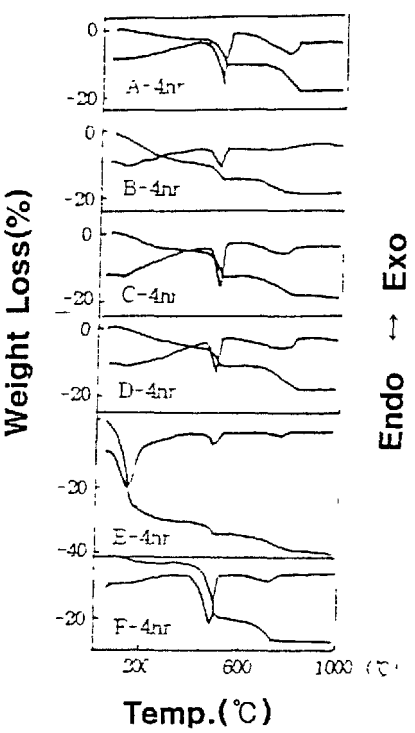
Gel Synthesis and Hydrates The gel reaction was very slow for A mix (fly ash) but for B mix(slag) or E mix(diatom earth) the reaction rate was fast, and C-S-H, ettringite and monosulfate were detected. Especially, for E mix (diatom earth), gel synthesis was almost over in about 4hrs and the hydrates were mainly C-S-H gel with spongiform structures. In DT-TGA, the rates and contents of reactions were in sequence, E mix>B mix>A mix (Fig 1 and Fig 2).

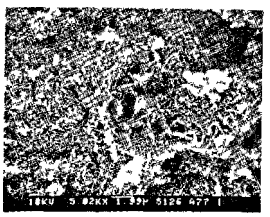
<Fly ash> <Slag> <Fly ash+Slag> <Diatom earth>

Fig.1. SEM micrographs of hydrates after gel synthesis(4hrs) used the various silicates

Casting and Gravity The higher the content of gels were increased, the higher the castability was improved. The castability of mix designs were, in sequence : E mix>B mix>A mix. Average gravity of composites were, in descending order : E mix(0.73) <B mix(0.78) <A mix(1.05). The lower C/S mole became, the lower the gravity because of the increasing content of gel.

Porosity and Physical property C/S mole and casting pressure of hydrate non-adding fibers were decreased to increase the porosity to the 1-0.02㎛ range, and increase the size of crystals. When size of crystals and porosity were decreased, bending strength/gravity increased because of the increasing number of contacts. Compressive strength/gravity was more affected by porosity than by the size of crystal(Fig 3). Here, diatom earth was superior to the other silicates in gel reaction, performance, lightness and physical property.





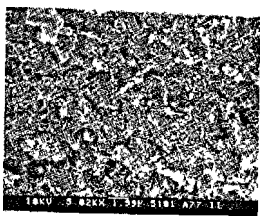


Fig.2. DT-TGA results of hydrates after gel reaction(4hrs)

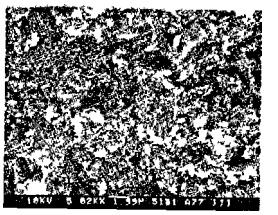

Physical property and Microstructure of Calcium Silicate Hydrates-Fibers Compositions These changes in the shape of crystals and physical properties for adding fibers can result in a reduction of compressive strength, but also in reduced weight and greater bending strength(Table 2, 3 and 4).

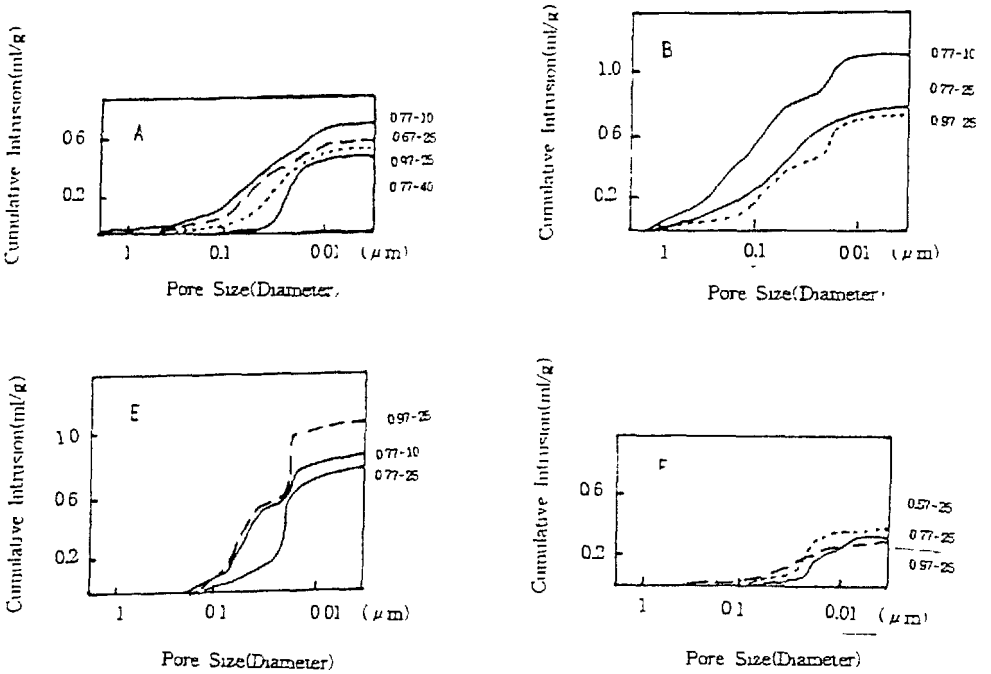
Fig.3. Physical properties and microstructures of hydrates made with the various silicates



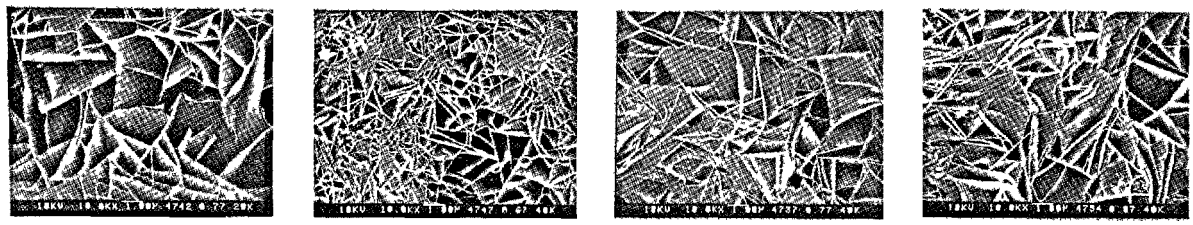


Fig.4. Porosities of hydrates applied with the various manufacturing conditions

On the other hand, decreased C/S mole in mix design and pressure leads to increasing strength due to decreasing the shape of crystals, increasing the point of contact and decreasing the corrosion of ARG (Fig 5 and 6). Increased activity of silicates led to the composites being lightened and increased strengths and performance, but strength was least for B mix because it developed cracks after autoclaving. For these reasons, we determined the optimum conditions of the composites using diatom earth as : C/S 0.67, pulp 5%, glass fiber 2%, pressure 10kg/㎠.

CONCLUSIONS

The influence of the shapes of hydrates and fibers in composites using various silicates was investigated. The conclusion are :

(1) The activity of silicate is important for lightness, high performance and the strength of the composite. Diatom earth is the best of all materials for these purposes, and this gel reation was over in 4hrs.

(2) Decreased C/S molar ratio and increased pressure promotes reductions in crystal size and matrix porosity, which leads to increased bending strength. Compressive strength is mainly affected by porosity, rather than by crystal size.

(3) ARG has little effect on strengths improvement because of the corrosion of glass fibers in the autoclave. Increasing the C/S molar ratio and casting pressure of composites increases the corrosion of ARG and decreases the strength of composites. The optimum condition are C/S 0.67, press 10kg/㎠, ARG 2% and pulp 5%.

THE MECHANICAL PROPERTIES OF ALKALI RESISTANCE GLASS FIBER REINFORCED CONCRETE UNDER DIFFERENT CURING CONDITIONS

Moon-Young JEONG and Jong-Taek SONG
Dept. of Materials Science & Engineering, Dankook University, Cheonan, Korea

ABSTRACT The mechanical properties of alkali resistance(AR) glass fiber reinforced concrete(GFRC) under different curing conditions are investigated in this study. The specimens were formed by extrusion process, and then steam cured and autoclaved. An autoclaved specimen showed the elastic-brittle behavior up to 4% of fiber volume fraction. But it was found that the fracture behavior for steam cured specimen was changed to the elastic-plastic with crack branches fracture from 3 vol% of fiber.

KEY WORDS Alkali, Glass, Curing, Strength development, Microstructure

INTRODUCTION

Cement-based materials have a good compressive strength, durability and cost competition for building materials. But they have a poor flexural strength and ductility. Especially thin products(e.g., board and panel), flexural property is more important than other mechanical ones. In order to improve flexural performance, fiber reinforcement is employed in various concrete structure(Shah, 1991). Reinforcement effects depend on the individual materials constituent(fiber, matrix, and interface), fiber geometry(aspect ratio) and fiber orientation(Toutanji and Katz, 1993).

As for GFRC, it has been known that the mechanical property degraded(Bijen, 1983, Kosa et al, 1991) after long-term exposure to weathering because glass fibers were damaged by the reaction with the highly alkaline cement matrix(Yilmaz and Glasser, 1991). But most of previous reports the results when the samples were moist cured between 20-65℃. In this paper, test was conducted at a relatively high temperature.

EXPERIMENTAL PROCEDURE

The proportion of the matrix and fibers is shown in Table 1. All of mixing is represented by weight. AR-glass fiber was mixed with cement using Omni mixer, followed by mixing with other ingredient for 2 minutes. Then dry mixed composite was thoroughly mixed with water by kneader for 3~5 minutes. At that time, small amounts of water and kneading time were varied with fiber content.

Table 1 Batch Proportions (by wt.%)

Fiber volume fraction (%)	Cement [1]	Silica powder[2]	ARG [3]	HPMC [4]	Water(%) [5]

2	96.89		2.39	0.72	28.6
3	95.62		3.62	0.76	29.8
4	94.36		4.83	0.81	31.3

(1)Ordinary portland cement (type I) (2)About 93% of SiO_2 in composition and blaine value is 2,750cm^2/g (3)Length is 6 and 12mm, diameter is 14㎛ (4)Hydroxy Propyl Methyl Cellulose =viscosity 30,000 cps. at 20℃ of 2% aqueous solution(RV type 20 r.p.m. with No.6 spindle) (5)Proportions of water is based on the total amounts of dry raw material.

The board-shape specimen having the size of $450\times80\times10mm^3$ were made by vacuum extruder. All specimens were steam-cured at 60℃ for 8 hours and half of them were autoclaved at 180℃ for 8 hours. And then all samples were aged for about 1 week before testing. The mechanical property was tested with a three-point loading employing the computer controlled testing machine(Autograph AG-10TE) with a span of 300mm and a cross head speed of 5mm/min.

RESULTS and DISCUSSION

Fracture Behavior

The plain matrix(i.e, without fiber) cured by steam or autoclave are very brittle but their flexural strength were different(Mobasher and Shah, 1989). The flexural strength increased with fiber volume fraction used both for an autoclaved specimens(ACS) and steam-cured specimens(SCS) (Fig 1). The load-deflection curve shown in Fig 2 depicted the sudden loss of strength after crack formation at the peak load(Ho and Woodham, 1982). ACS also showed the elastic-brittle behavior up to 4% of fiber volume fraction. While the fracture behavior for SCS was changed to the elastic-plastic with crack branches from 3 vol.%. It was thought that the adhesion strength between fiber and matrix was not sufficient, so the fracture behavior of SCS was not affected by ultimate strength of fiber(Bentur and Diamond, 1984). AR-glass fiber had a brittle character because it had a very short elongation at rupture. This implied that the post-cracking zone for SCS was caused by fiber pullout. The critical pullout of glass fiber for this matrix was found for fiber of 12㎜ length.

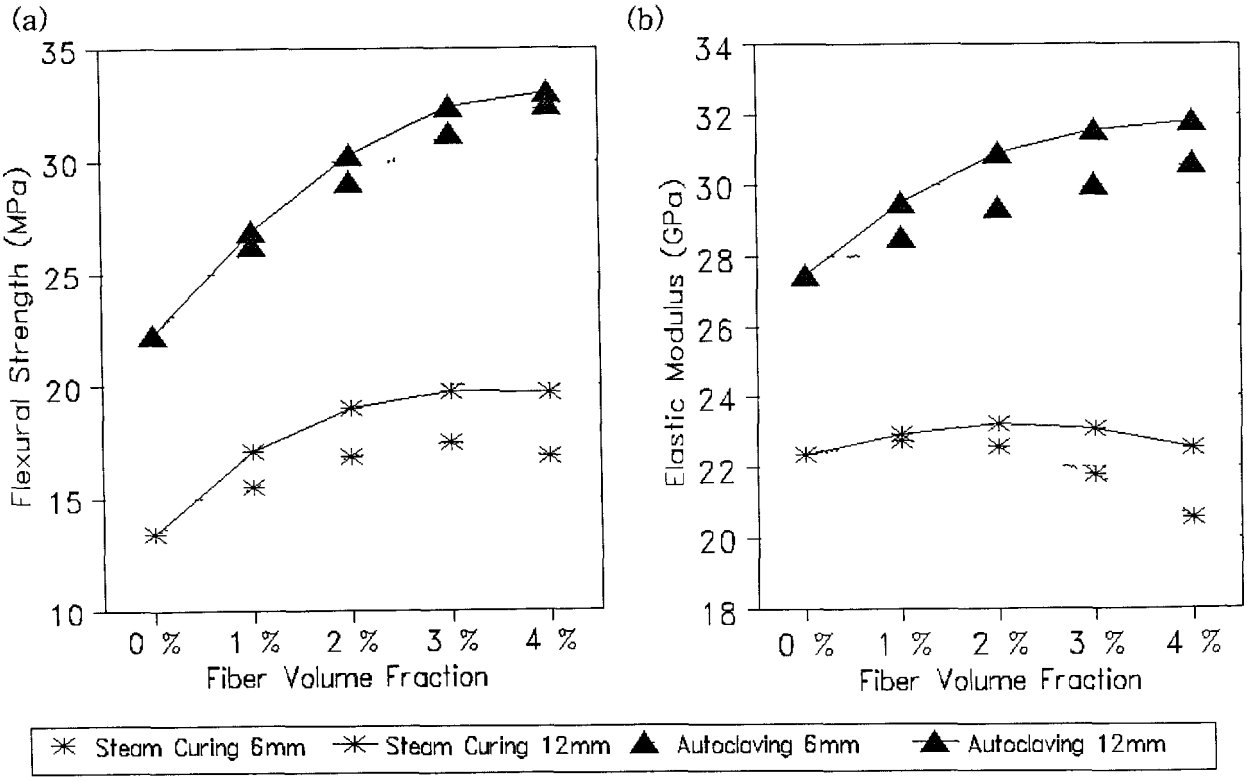

Figure 1 Effect of fiber volume fraction on flexural strength(a) and elastic modulus(b) of steam cured and autoclaved GFRC.

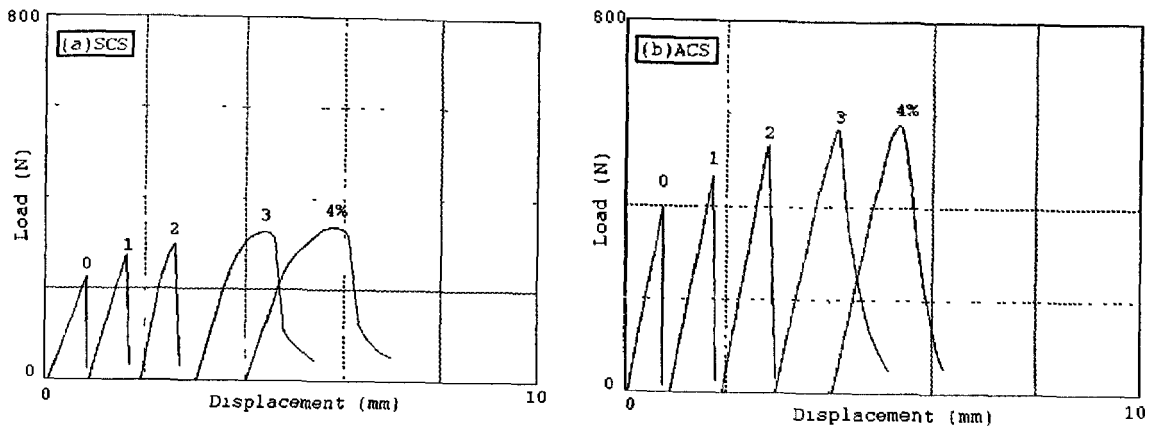

Figure 2 Load-deflection curve of SCS(a) and ACS(b) with varing fiber content

Fiber Orientation

The flexural strengths of line direction are increased with fiber content. However those for the cross direction are slightly decreased with fiber content (Fig 3). These showed that the fiber was arranged with 2-dimensional orientation. The 3-dimensional oriented fibers were rearranged into extrusion direction because this direction received relatively small shear stress of fluidity during extrusion.

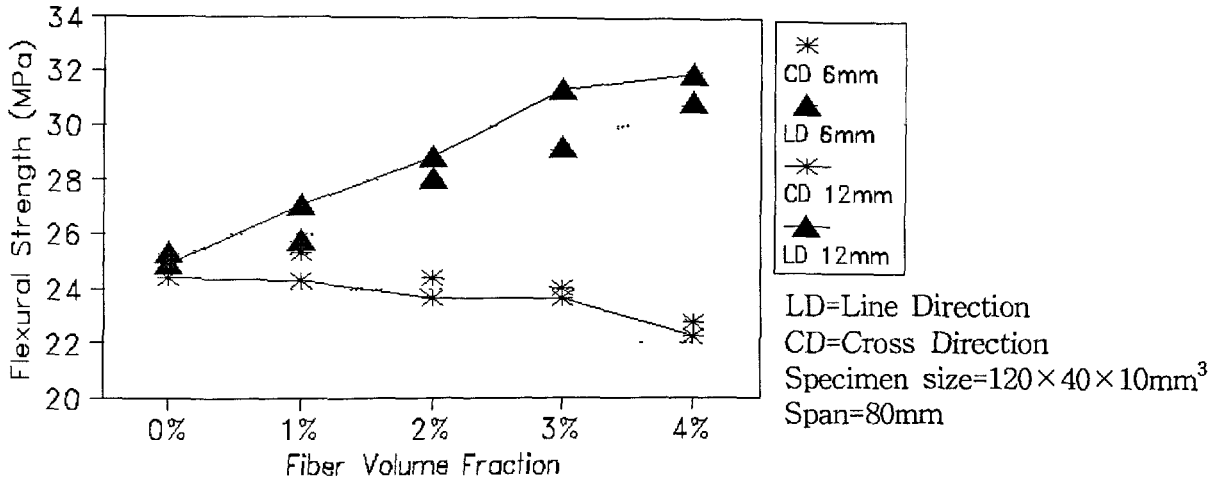

Figure 3 Flexural strength of LD and CD in various fiber content

Corrosion of Fiber

Fig 4 is the SEM photographs of surface of glass fibers. It showed that no visible corrosion of glass fiber occurred at the interface for SCS. But there were small amount of cement hydrate formed at the interface between fiber and matrix. On the other hand, the fibers in the ACS clearly show the corrosion of the surface. It might be thought that the cement hydrates formed were tenaciously bonded to the glass fiber at the interface. As a consequence of surface corrosion, glass fibers became weaker with the curing temperature. The chemical stability of the interfacial zone was important, but the improved properties of ACS are to be retained.

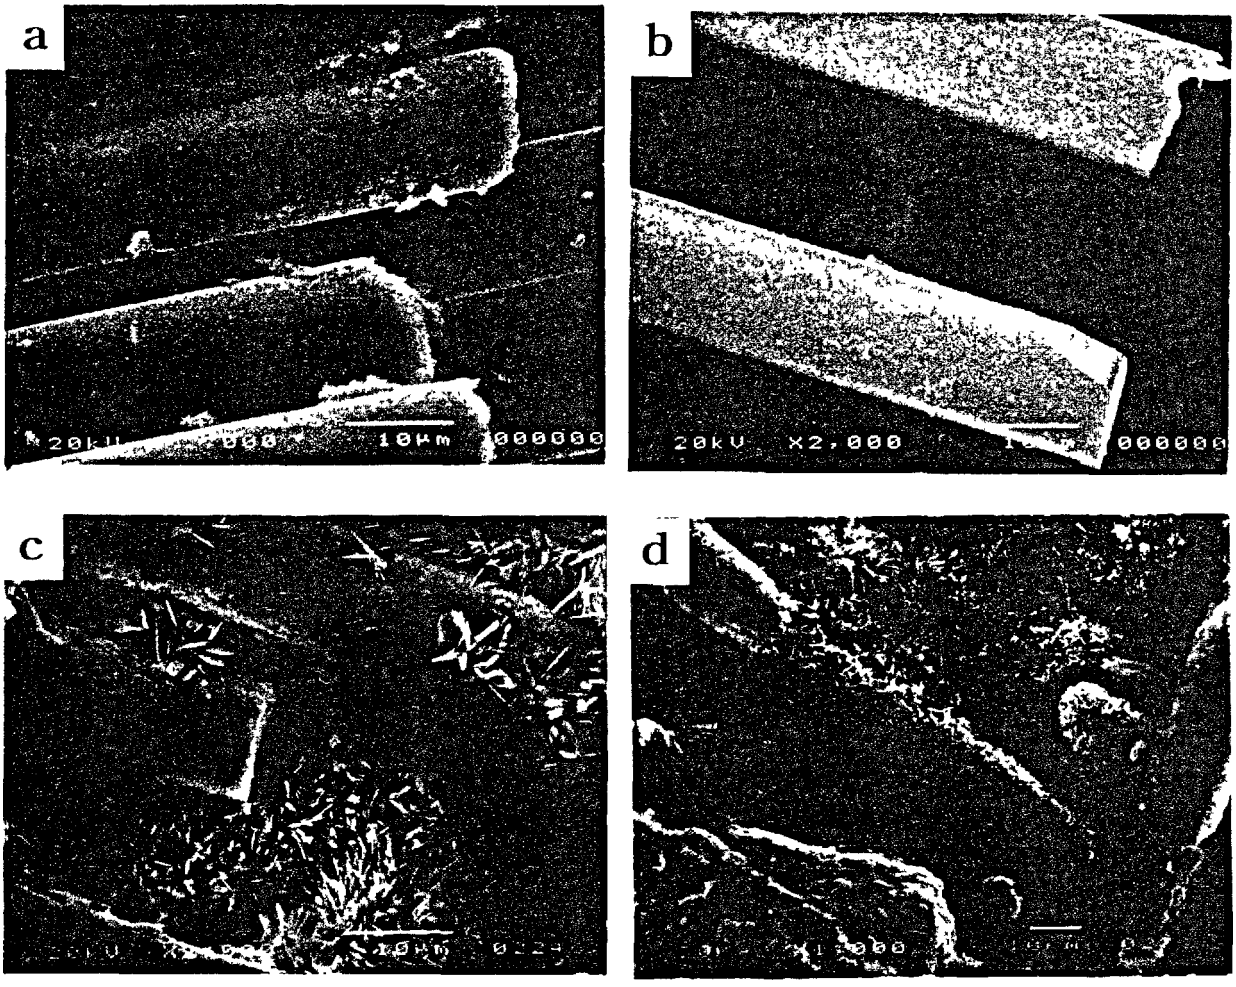

Figure 4 SEM of AR-glass fibers of SCS and ACS. virgin fiber(a), SCS(b), ACS(c) and E-glass fiber as reference(d).

PECULIAR FEATURES OF CONTACT ZONE FORMATION BETWEEN CEMENT PASTE AND VITREOUS SILICATE FILLER

Vladislav GLUKHOVSKIY, Yury BIRYUKOVICH, Nina MIKHAILISHINA, Tatyana DASHKOVA, Technical University of Ukraina"Kyiv Polytechnical Institute", Kyiv, Ukraine

ABSTRACT The results of investigations of the processes occurring in a contact zone between the hardening cement and the vitreous silicate filler, carried out with taking matrix shrinkage induced stresses arising inside such contact zone into account, are presented.

Key-words: Diffusion, Filler, Interfacial zone, Shrinkage, Strength development.

RESULT

The investigations of peculiar features of contact zone formation between the products of the cement hydration and the silicate filler revealed occurrence of chemical processes in a contact zone. Thus, in particular case, the strength decrease of composites on the base of portland cement (or other binders) and reinforcing component in the form of glass fibers with different compositions (see Table 1) may result from such chemical interactions.

It is known that if glass fibers are used as a component, the film of newly formed compounds resulting from the chemical interactions between the filler and the matrix may precipitate on the surface of glass fibers (Pashchenko et al, 1988, Pashchenko et al, 1979, Budnikov et al, 1966, Majumdar et al, 1977, Stucke et al, 1976). Still, the authors observe no changes of the optic properties of fiber cores providing the prolonged period of their interaction with the binder (Budnikov, Slobodianik et al, 1966), same the value of Young's modulus remains constant (Majumdar et al, 1977).

The investigations of such new compounds layers formed on the fiber surface, which have low-basic calcium hydrosilicates prevailing in their composition, have shown that the microhardness of these layers with a thickness of 0.1 - 0.6 μm amounts to 350 - 4100 MPa, the microbrittleness reaches 200 - 1780 pJ, the minimal load on microhardness tester penetrator resulting in cracking of a layer of newly formed compounds (P_t) makes 1.1 - 9.9 cH. These characteristics are lower then such of initial fibers: in 1.4 - 8.0 times for microhardness values, in 1.4 - 8.0 times for microbrittleness values, in 3.2 - 45.0 times for values of a minimal load on microhardness tester penetrator resulting in a layer cracking. Besides, it was found, that stabilization of the major properties of new compounds layer continues for 150 hours of mix's hardening, whereas the deformation of the shrinkage matrices may be observed within 300 - 360 days.

It was found in the course of kinetics study of the strength changes in mixes that the mostly explicit dependence exists between the rate of strength drop on a proper stage of mix's hardening and the mean size value of the opened capillary pores (λ) (Brusser, 1971, Turkestanov, 1964) estimated at the beginning of this period (see Figure 1), which is the evidence that such processes occur in a diffusion-controlled area. The existence of the new compounds layer completely formed after 150 hours of its hardening and the process of intensive decrease of mix's strength continuing during more then 360 days in diffusion-controlled area, allows to assume the possibility of processes, resulting in destruction of a new compounds layer, inside the contact zone. The process of matrix shrinkage, the maximal intensity of whereof takes place within the first 300 ... 360 days of hardening, may be one of the possible causes of such destruction.

Table 1. Kinetics of the strength changes in mixes on the base of portland and alumina cements.

Type of reinforcing component	The limit bending strength (MPa) after mix's hardening during a period of (in months)					
	1	3	6	12	60	180
			Gypsum-alumina cement			
alkali-free fiber	29.0	29.2	29.3	25.4	20.5	20.1
same with protective coating	29.0	31.5	33.4	31.7	33.0	33.0
			Portland cement			
alkali-free fiber	38.0	26.5	20.3	13.7	11.2	11.1
same with protective coating	33.5	28.5	26.2	23.3	21.0	20.0
			Simulated terms of service (in months)*			
	12		24	60		120
alkali-free fiber	17.5		14.2	12.2		11.4
same with protective coating	25.1		22.5	18.0		16.7

* Pashchenko A.A.(1988)

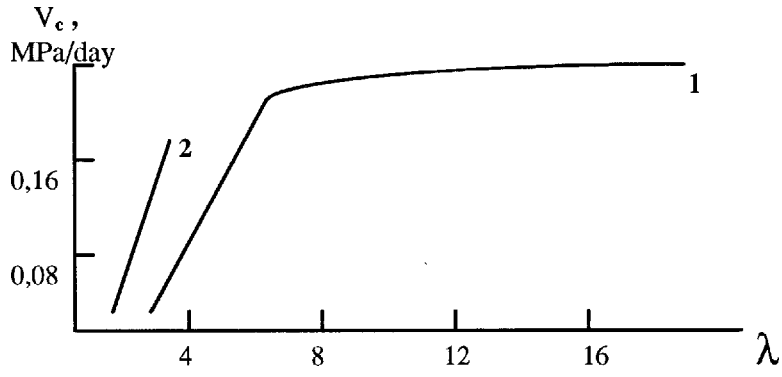

Figure 1. Dependence of the rate of bending strength decrease (U_c) from the pore mean size value (λ) for the mixes of portland cement and glass fibers with (1) and without (2) the protective coating.

The calculations of the values of stresses (P_y) arising due to the matrix shrinkage, which were carried out for the purposes of these values comparison with the values of minimal load resulting in the cracking of a layer of new compounds (P_t), were based on the following data:

· It was found by the electronic microscopy study that the cement paste and the layer of new compounds on the glass fiber surface do contact through the sites with diameter of 1 - 10 μm, separated by the distances of 10 - 100 μm (Pashchenko et al, 1988).

· The value of a pressure bearing upon a layer of new compounds due to the matrix shrinkage was estimated on the base of a known solution of Lamé-Gadolin task (Bezukhov, 1953), in assumption of hexagonal arrangement of fibers in a mix:

$$q = \frac{0{,}952\varepsilon_m E_f}{\sqrt{V_f}\left[(1-\nu_f)+\frac{E_f}{E_m}\left[\frac{0{,}906+V_f}{0{,}906-V_f}-\nu_m\right]\right]} \qquad [1]$$

Here, ε_m is the relative deformation of matrix shrinkage; V_f is the volume ratio of fibers in a composite; E_f, E_m, ν_f and ν_m are the values of elasticity modulus and Poisson's ratio for fibers and matrix, respectively.

In this case, in assumption that within the i- length of a fiber it contacts with a matrix, at least, in two points symmetric about the fiber axis, the value of a matrix shrinkage stress in the contact zone will be: $P_y=\pi qiD_f/4$. Here, q is defined in accordance with Eq.1, D_f is the fiber diameter.

The calculated values of matrix shrinkage stresses (P_y) are presented in Fig. 2 versus the age of a mix with taking the experimentally defined inherent deformation of portland cement matrix into account.

As it is known, the anomalistically high strength level of glass fibers, which was put into foundation of the idea of mixes, depends on the state of fiber surface. Just this factor determines the dependence of mix's durability from the state of surface of reinforcing component, which may undergo changes during a long enough period due to the physico-chemical and physico-mechanical processes taking place in a contact zone. One of the methods to prevent the unwanted influence of such contact zone processes at the final strength of mixes is to use the silicate glass fibers as the reinforcing components, as far as the strength of such fibers doesn't depend on the state of their surface. The physico-chemical characteristics of such mixes are presented in Table 2.

It was found in the course of complex physico-chemical investigations of the contact zones of such mixes, carried out using derivatography, X-ray, IR - spectroscopy and electronic microscopy methods of analysis, that the process of interaction of new compounds produced by the binder with the surface of reinforcing component is accompanied by the decrease of calcium hydroxide content

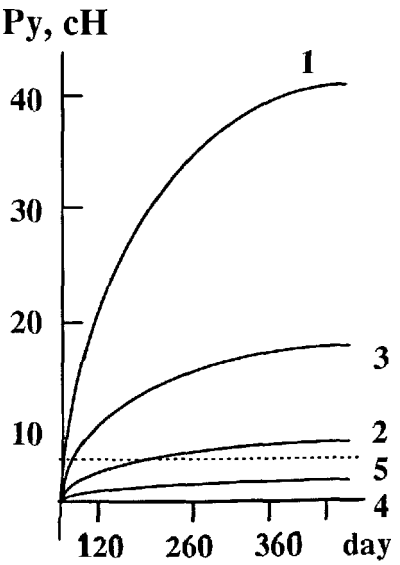

Figure 2. Kinetics of the strength changes in a new compounds layer versus the shrinkage of cement (1,2) and sand cement (3,4) matrices, calculated for the i = 100μm (1,3) and i = 10μm (2,4) length of fiber in comparison to P_t (5).

Table 2. Kinetics of the strength changes in mixes on the base of portland cement.

Ratio of reinf., in %	The limit bending strength (MPa) after mix's hardening during a period of (in months)					
	1	6	12	24	60	90
	Natural hardening in a water					
10	20	32.3	36.8	38.4	41.2	48.2
20	26.5	46.4	52.7	53.8	55.9	58.1

	After wet thermal treatment					
10	---	32.7	33.1	40.3	---	---
20	---	41.0	47.2	56.2	---	---
30	---	55.3	56.4	60.7	---	---

inside the contact zone. The fiber surface layer of new compounds similar in its composition and physico-mechanical properties to such of the mixes studied earlier was shown to exist in these mixes as well. Yet, in this case a growth of intensity of interaction processes inside the contact zone results in a growth of mix's strength.

CONCLUSIONS

Formation of a new compounds layer at the vitreous silicate filler inside the hardening portland cement is a result of chemical interactions of filler surface with reactive components of hydrating binder (mainly of calcium hydroxide).

The shrinkage deformations of a matrix cause stresses in a zone of contact between the new compounds layer and the matrix. Mostly it is accompanied by microcracking providing the possibility of reactive components diffusion to the "fresh" surfaces of a filler. These processes are just a reason, why mix doesn't undergo stabilization within the first 150 hours of its hardening after formation of a new compounds layer.

One of the possible ways of obtaining mixes with a long term of service on the base of portland cement is to use the glass fibers as reinforcing component, as far as the physico-chemical charcteristics of such component doesn't depend on the state of its surface.

EFFECT OF ADDITION OF PHOSPHATE BEARING MATERIALS ON STRENGTH DEVELOPMENT CHARACTERISTICS OF HIGH TEMPERATURE REFRACTORY CONCRETE

S C SHARMA and S CHATURVEDI

National Council for Cement and Building Materials
New Delhi, India

ABSTRACT In the present study, an attempt has been made to investigate the effect of addition of phosphate bearing materials to various aggregates & also to optimise the type of aggregate, their particle size distribution & dosage,etc on strength development characteristics of high temperature refractory concrete. The refractory concrete so made had the bulk density 3.150 g/cm^3, thermal expansion , CCS and MOR : + 0.62 %, 450 kg/cm^{2}and 115 kg/cm^2 respectively at 1300^{o}C .

KEY WORDS : Refractory, Aggregate, Phosphate, Binder, Strength .

INTRODUCTION

Phosphate bonded refractory concretes are characterised by excellent abrasion and spalling resistance, high modulus of rupture and high crushing strength at elevated temperatures. The main constituents of these types of refractory concretes are refractory aggregates and phosphate binders. The auxiliary constituent used is setter /inhibitor required to control setting behaviour. Two types of refractory concretes are normally available based on their setting characteristics i.e. air setting and heat setting types. In case of air setting type of refractory concretes, setting takes place at room temperature and in case of heat setting type the setting takes place at elevated temperatures only. Orthophosphoric acid and Mono aluminum phosphates (MAP) are the normally used phosphate binders.

Dry binders are preferred over wet ones owing to their distinct advantage of easy mixing and longer shelf life. The quality of a phosphate binder, to be used in refractory concrete, is determined by its P_2O_5 content, which determines the ultimate binding propeties. It has been reported that with the increase in P_2O_5 content, both Hot MOR and Hot crushing strength increase and porosity is reduced but simultaneously unstability is introduced at high temperature. On the other hand, reduction of P_2O_5 leads to insufficient strength development.

MECHANISM OF PHOSPHATE BONDING

It has been reported that the end products of all the reactions, in case of phosphate bonding are generally $AlPO_4$, $CrPO_4$, $Mg_3(PO_4)_2$ or Na_3PO_4. Their composition depends largely on the nature and type of aggregates, binders and setters used. The mechanism of formation of tertiary phosphates is based on physico-chemical transformation followed by neutralization process. In case of orthophosphoric acid as binder with high alumina aggregate, the probable sequence of reactions, which has been reported (Petzold & Rohrs, 1970) without incorporating any setter, are as follows :

i) At room terperature $Al(H_2PO_4)_3$ is formed;
ii) Around 250°C, polymerization of $Al(H_2PO_4)_3$ takes place along with the formation of aluminium pyrophosphate;
iii) At 500°C, pyrophosphate melts and aluminium metaphosphate is formed ;
iv) At higher temperatures, formation of crystalline $AlPO_4$ bonding phases take place resulting in lower strength;

EXPERIMENTAL WORK

Raw Materials Evaluation

Two types of aggregates viz. fireclay and fused alumina were selected initially. The chemical and mineralogical characteristics of these are as given in **table 1.**

Table 1 Chemical and Mineralogical Characteristics of Aggregates

Characteristics	Fireclay	Fused Alumina
Chemical Comp.(%)		
Al_2O_3	48.59	93.51
Fe_2O_3	5.52	0.38
SiO_2	42.11	-
Mineralogical Comp. %		
Corundum	Moderate	Most predominent
quartz	Predominent	Traces
Mullite	Predominent	-
Crystobalite	Most predominent	-

Orthophosphoric acid (H_3PO_4) and mono-aluminium phosphate (MAP) were initially selected as binders. The P_2O_5 content of orthophosphoric acid was 48.90% and that of mono-aluminium phosphate was 55.57%. Mag-chrome powder (60:40) was used as a setter.

Sample Preparation

The dry aggregate and setter were blended in the required proportion. The binders were added slowly to the dry materials and mixed for 5 minutes. The mix was than cast into (50x50x50) mm molds with 100 nos. of fixed strokes. After demolding, the specimens were dried at 110°C. For determination of strengths at 600°C, the specimens were heated first at 400°C for 5 hrs and then at 600°C for another 5 hrs. The heating rate was kept 2°c /min. (approx.) in both the cases.

Choice of Aggregates

Fire clay and fused alumina were mixed separately with orthophosphoric acid (10% by wt.). Strength of specimens made was determined at 400°C and 1050°C. While the specimens made from

fire clay showed very low strength development at 400oC which further droped at 1050°C. The specimen of fused alumina showed remarkably high strength development and was selected for further investigation. The results are given in **table 2.**

Table 2 Effect of type of aggregate on strength development

Temperature (°c)	Average strength (kg/cm^2)	
	Fireclay	Fused Alumina
400	112	220
1050	69	533

Optimisation of grain size distribution of aggregate

The specimens were prepared by mixing varying proportions of fine and coarse fractions of fused alumina and the strength were determined after firing at 600°C. For this experiment, 12% orthophosphoric acid and mag-chrome powder (25% by wt. of aggregate) were added to the aggregate. The results are as shown **Table 3.**

Table 3: Effect of grain size distribution of fused alumina

Mix Proportioning (%)		Avg. Strength at
Coarse (-14+325 mesh)	Fine (-325 mesh)	600°C (kg/cm^2)
75	25	940
50	50	1235
35	65	1240
25	75	1240

It is obvious that with increase of fine fraction of fused alumina from 25% onward, strength increases but beyond 50% it did not gain strength considerably. Therefore fused alumina with 50% coarse fraction and 50% fine fraction were optimised for further studies.

Choice of Binders

Orthophosphoric acid and MAP were mixed seperately with fused alumina of the optimised grain size as shown above. The dose of binders were varied from 6% to 20% (by wt.). Mag-chrome powder was used as setter and the specimens were fired at 600°C. It was observed that development of strength with H_3PO_4 as binder is much higher when compared with that of MAP. The strength development in case of H_3PO_4 increased progressively on increasing its dose. Hence use of MAP was discarded and orthophosphoric acid was used for further investigations. From the above investigations. The following observations were made.

1. Fused alumina was preferable over fire clay aggregates.
2. Orthophosphoric acid was preferable over MAP as binder.
3. Mag-chrome powder was an effective setter

Optimisation of Binder Percentage

Taking the aggregate with optimised grain size distribution and setter, the % of addition of H_3PO_4 as binder was optimised on the basis of higher modulus of rupture.It was observed that the optimum value of binder was 8 % by vol. or 13.68 % by wt.

HIGH TEMPERATURE PROPERTIES OF OPTIMISED REFRACTORY CONCRETE

The specimen with the optimised proportions of various constituents were prepared and were evaluated for various properties such as chemical composition, Bulk density, CCS, MOR, PCE, etc. The properties are as given in **Table 5.**

Table 5 Properties of Phosphate Bonded Refractory Concrete

Characteristics		
Al2O3 (%)		78.86
SiO2 (%)		1.95
Fe2O3 (%)		0.88
Service temperature (Max.)		1600°C
Pyrometric Cone Equivalent (°C) PCE		1804°C
Bulk Density (110°C) kg/m^3		3150
Thermal expansion (% at 1300°C)		(+) 0.62
MOR (kg/cm^2) at	110°C	173
	600°C	230
	1300°C	115
CCS (kg/cm^2) at	600°C	600
	1300°C	450

CONCLUSIONS The investigations carried out revealed that the fused alumina is preferred as an aggregate on account of its improved chemico-mineralogical characteristics as compared to fireclay and the addition of orthophosphoric acid as binder has a positive effect on strength development of refractory concrete. The refractory concrete so developed has exhibited the improved values of physical and thermal properties viz. Bulk density, thermal expansion, cold crushing strength and MOR.

PHYSICO-MECHANICAL AND DEFORMATION PROPERTIES OF CEMENTLESS FINE-GRAINED ASH-SLAG CONCRETE OVER A 5-YEAR PERIOD

Yury BAZHENOV, Building University of Moscow, Russia
Stanislav PAVLENKO, SSAMM, Novokuznetsk, Russia

ABSTRACT Physico-mechanical and deformation properties of a cementless fine-grained ash-slag concrete (patent of 21.01.93) developed by the SSAMM have been studied for 5 years in order to predict its future performance. The compressive strength of the concrete was 5 to 20 MPa which is suitable for the construction of cast in-situ low-rise building and the production of silica brick. Over the 5-year period, the concrete improved its characteristics: compressive strength, modulus of the elasticity, compressibility, extensibility, prism-to-cube strength ratio of the concrete increased by 1.53 (from 15.2 to 23.3 MPa), 1.58 (from 12.1 to 18.64 MPa), 1.22 (from 0.87 to 1.07 mm/m), 1.5 times (from 0.12 to 0.18 mm/m), and 1.54 (from 12 to 19 MPa), respectively.

INTRODUCTION

In this work, the main physico-mechanical and deformation properties of the concrete developed were studied over 5-year period. The concrete was entirely made of waste products from thermal power plants (ash and slag) and ferroalloy plant (silica fume). High-calcium ash from burning brown coals of Kansko-Achinsky Power Complex and silica fume were binding materials. Two-stage heat treatment was applied to the concrete: the use of hot water (60-80 °C) for mixing and then curing concrete in stream-curing chambers (for concrete articles) or heating concrete in formworks (for cast in-situ structures).

MATERIALS

High-Calcium Fly Ash

The ash from Abakanskaya thermal power plants, burning brown coals of the Irsha-Borodinsky deposit, was used. Physical properties and chemical analysis of the ash are given in Table 1 and 2, respectively.

Table 1 Physical Properties of Fly Ash, Slag Sand and Silica Fume

Properties	Fly Ash	Slag Sand 0...5 mm	Silica Fume
Fineness-passing 45 mm, %	92.50	0.25	100
Blaine, m^2/kg	240	-	2900
Specific Gravity	2.76	2.68	2.25
Bulk Density, kg/m^3	1120	1580	245
Setting Time, h : mm			
-Initial	0.56	-	-
-Final	5.48	-	-
-Colour	grey	black, green	light grey

As shown by the investigations of the Siberian branch of the Russian Academy of Sciences (Savinkina and Logvinenko, 1979), SibZNIIEP (Ignatova, 1990) and by our study (Pavlenko, 1995), binding properties of high-calcium ash can be determined by the so-called coefficient of quality (C_q) according to the formula:

Table 2 Chemical Analysis of Fly Ash, Slag Sand and Silica Fume

Oxides, %	Fly Ash	Slag Sand 0...5 mm	Silica Fume
SiO_2 total	39.45	51.47	90.11
including free SiO_2	14.20	14.57	82.00
CaO total	31.20	29.92	0.71
including free CaO	8.96	-	-
MgO	6.31	3.50	0.97
Al_2O_3	7.11	8.16	1.93
FeO	0.87	8.20	1.82
Fe_2O_3	9.92	1.43	-
MnO	0.18	0.17	0.20
P_2O_5	0.06	0.05	1.18
SO_3	0.86	0.01	0.89
TiO_2	0.90	-	0.02
Na_2O	0.40	-	0.87
K_2O	0.70	-	1.16
Loss on Ignition	1.85	-	2.05

$C_q = (CaO + Al_2O_3 + MgO) / SiO_2 = (31.20 + 7.11 + 6.31) / 39.45 = 1.13$

If the coefficient is more than 1, then the ash has good binding properties. In our investigation, the coefficient was 1.13. However, C_q of this ash is considerably lower then that from Novosibirskaya thermal power plant, and has to be ground in a ball mill to the fineness of 400 to 450 m^2/kg. The grinding activates strength of the ash, makes it possible to use free silica of fly ash (14.2%) and silica fume (82%) for binding free calcium oxide (8.96%) as well as activates minerals containing magnesium.

Granulated Slag

Slag sand from Abakanskaya thermal power plant was studied in accordance with the requirements of State Standard 26644-85 (1991). The date are given in Table 1 and 2. Testing for oxides contents was carried out according to State Standard 5382-91 (1994) and 25583-83 (1983). A system of slag removal at the thermal power plant is based on the principle of granulation (removal of the fiery liquid slag with hydrocooling) (Panteleyev et al, 1985). Granulated slag is then ground to sand with a particle size of 0 to 5 mm (Pavlenko, 1989). Testing of the slag for silicate and ferruginous decomposition and frost resistance was done according to State Standard 9758-86 (Pavlenko, 1991). Losses of weight of the slag during the testing for silicate and ferruginous decomposition were up to 6.7 and below 4%, respectively, as compared with 8 and 5% according to State Standards. Frost resistance of the slag was 235 cycles versus 200 cycles according to State Standard.

Silica Fume

Silica fume from Kuznetsk Ferroalloy plant was a super dispersed powder (5-6 times finer than cement) of a light grey colour with a fineness of 2200 to 3000 m^2/kg. The data on test results are given in Table 1 and 2. X-ray diffraction and DTA showed the presence of silicon mostly in the amorphous form which increased the hydraulic of the silica fume while reacting with lime and binding free lime of high-calcium ash. The hydraulic activity was evaluated by determining the

amount of lime absorbed by silica fume from a saturated solution at 85 °C. It was 102 mg CaO/g.

OPTIMUM MIXTURE PROPORTIONS OF CEMENTLESS CONCRETE

As a result of previous investigation of the process of structure formation and strength characteristics of cementless concrete using the method of experimental planning and a computing technique (Pavlenko, 1991 b, Pavlenko, 1992, Pavlenko and Oreshkin, 1992, Pavlenko and Chayka, 1993), optimum mixture proportions of the fine-grained ash-slag concrete were developed which are given in Table 3. Main physical and deformation properties of the concrete developed were studied for the period of 5 years (1990 to 1995).

Table 3 Mixture Proportions of Cementless Concrete

Quantities, kg/m^3				Mix	Mix	Compressive
Fly Ash	Silica Fume	Slag Sand	Water	Slump, cm	Density, kg/m^3	Strength at 28 days, MPa
650	70	720	480	8-10	1920	15

EXPERIMENTAL PROCEDURE

Test cubes, 100*100*100 mm in size, and prisms, 100*100*400 mm in size, were cast for studying physico-mechanical and deformation properties of the fine-grained cementless ash-slag concrete. Mixture were made in a laboratory positive mixer using hot water (70-80 °C), vibrated, cured for 4 hours at room temperature steam-curing chamber at 85-95 °C using 3+10+3h cycle.

Strength Characteristics

Compressive strength was determined on 100-mm cubes and prism strength on 100*100*400 mm prisms in accordance with the methods of NIIZHB (1976, a) at the following ages: 24h, 28, 365, 730, 1095, 1460 and 1825 days. The data are given in Table 4. It is evident from the data that the cementless fine-grained ash-slag concrete increased its compressive and prism strength by 53 and 58%, respectively, over a 5-year period. The highest strength gain was at 28 to 365 days (18 to 26%), beyond this period the strength development was slow (5% and lower). Ordinary concrete showed increase in strength by 10% during the first year, and by 15 to 18% at the age of 5 years. The modulus of elasticity was also determined in accordance with the NIIZhB methods (1976, b). It increased by 54% over the 5-year period which exceeded the requirements of the Building Code for fine-grained concretes (Gosstroy USSR, 1985 a) by 15 to 20% (Table 4).

Table 4 Main Physico-Mechanical Characteristics of Cementless Concrete

Concrete Characteristics	Period of testing, days						
	1	28	365	730	1095	1460	1825
Compressive strength, MPa	10.80	15.20	18.00	19.80	20.96	22.08	23.30
Prism strength, MPa	8.10	11.96	15.07	16.63	17.61	18.55	18.96
Prism-to-Cube strength Ratio	0.75	0.78	0.83	0.84	0.84	0.84	0.85
Initial Modulus of Elasticity, MPa	9.50	12.10	17.60	17.72	17.96	18.03	18.64
Compressibility, mm/m	0.85	0.87	1.04	1.05	1.06	1.07	1.07
Extensibility, mm/m	0.09	0.12	0.16	0.17	0.17	0.18	0.18

Shrinkage and Creep Deformation

Drying shrinkage and creep tests were performed using the methods of NIIZhB (1976, c). Prism specimens, 100*100*400 mm in size, were cured at 18 to 22 °C and 50 to 75% relative humidity. Shrinkage strains were determined by a dial type indicator with 0.001 mm scale. The measurements were made in the following periods: immediately after cooling of the specimens; at 30 min, 2, 4, 12 and 24 h; once a day between 2 and 6 days ; once a 2-day period between 7 and 14 days and once a week beyond this period until the complete stabilization of the shrinkage. The shrinkage strains were 0.3 mm/m and 0.6 mm/m at 24 h and 28 days, respectively. Between 28 and 180 days, they increased up to 0.65 mm/m and stopped beyond this period. At 5 years, the shrinkage strain was 0.66 mm/m which exceeded the requirements of the Building Code (Gosstroy USSR, 1985 b) for fine-grained concretes (up to 0.75 mm/m). The drying shrinkage of the ash-slag concrete developed smoother than that of a sand concrete (Fig. 1) which was attributable a lower bleeding of the first. Due to the lower bleeding and higher strength gain as compared to the cement sand concrete, the ash-slag concrete attained a higher crack resistance.

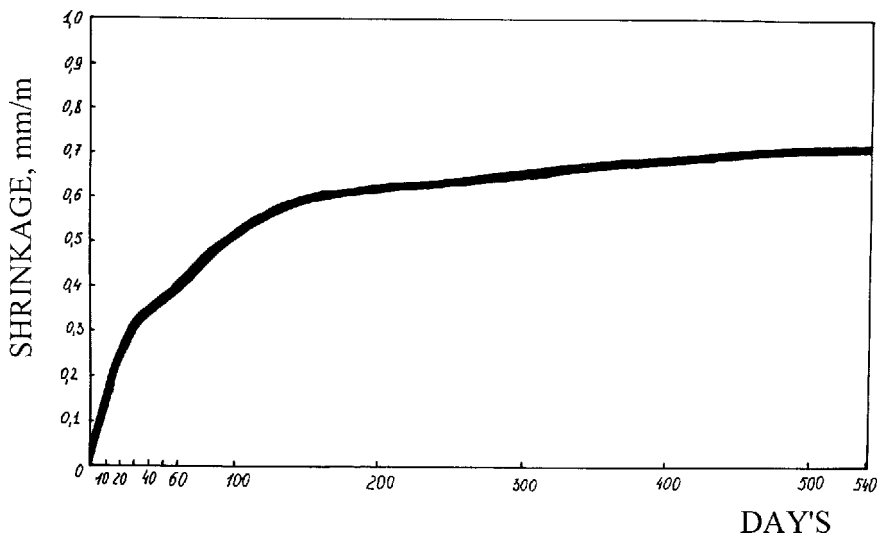

Figure 1 Relative shrinkage of fine-grained concrete

Creep tests were started at 28 days. Prisms were subjected to a long-term loading at the applied stresses constituting 50% of the prism strength (0.5R prism). The measurements were taken in the following peroids: at 30 min, 1, 3, 6 and 12 h, once a day between 2 and 6 days, once a 2-day period between 7 and 15 days, twice a week beyond this period and once a month after the stabilization. It can be seen that the creep strain of the cementless ash-slag concrete achieved 0.8 mm/m at 20 days, and the magnitude of the creep increased insignificantly between 20 and 180 days (up to 0.94 mm/m) stopping beyond this period (Fig. 2). The concrete showed 12 to 15% less creep than data reported for a fine-grained sand concrete (1985 c).

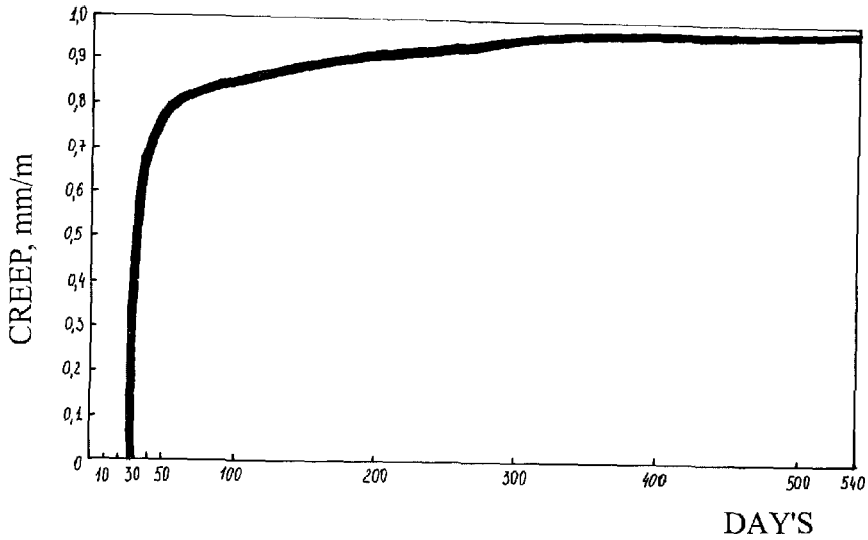

Figure 2 Relative creep of fine-grained concrete

CONCLUSIONS

The conclusions arrived at from this work may be stated as follows:

1) Cementless ash-slag concrete produced from waste products of the thermal power plant and ferroalloy plant based on high-calcium ash may be used as a replacement for ordinary cement sand concretes of B10-15 classes (15 to 20 MPa).

2) The main physico-mechanical and deformation properties of the concrete meet the requirements of State Standard and Building Code of Russia for concretes of this strength and, in some respect, exceed them.

3) The concrete developed seems to be a promising material for the twenty first century. Excluding the use of both natural and artificial energy consuming materials permits to solve economic, ecological and social (housing construction) problems.

Influence of physico-chemical aspects during early material history on durability

PLAUSIBILITY OF DELAYED ETTRINGITE FORMATION AS A DISTRESS MECHANISM - CONSIDERATIONS AT AMBIENT AND ELEVATED TEMPERATURES

Waldemar A. KLEMM, Construction Technology Laboratories, Inc., Skokie, IL, U.S.A.
F. MacGregor MILLER, Construction Technology Laboratories, Inc., Skokie, IL, U.S.A.

ABSTRACT Recent debate on delayed ettringite formation (DEF) as a distress mechanism for ambient- and steam-cured concrete has inspired this paper, which examines relevant data from the literature and from the authors' laboratory. DEF can be associated with distress in high temperature concrete, but not for ambient-curing in the absence of external SO_3 sources, or an aggregate sulfate source. The two internal SO_3 sources cited as potentially responsible—anhydrite in clinker and high SO_3 concentrations in the silicate phases—are shown to be absent or fundamentally innocuous.

Key-words: Anhydrite; Delayed ettringite formation; AFt phase; Sulphate attack; Curing

DELAYED ETTRINGITE FORMATION

Introduction

Delayed ettringite formation is one form of what will here be termed Internal Sulfate Attack (ISA). ISA in concrete may occur through the presence of sulfate in aggregate, or from the deliberate or inadvertent inclusion of high levels of gypsum in the system. These varieties of ISA will not be dealt with here.

The two forms of concrete distress to be treated here will be those in which the sulfate and aluminate are furnished by the cementitious materials. These are expansion and cracking in concrete that has been cured at high temperature (>70°C), caused by formation of ettringite in mature concrete. Also considered are expansion and cracking reported in concretes that have been cured under ambient conditions. The high-temperature effect is usually termed delayed ettringite formation, while the ambient temperature hypothesis has been given the title "late" ettringite formation. Taylor (1996) has given a very good description of the process of ettringite formation under various conditions.

Taylor (1996), Scrivener (1996), Kelham (1996), Fu and Beaudoin (1996) and others have established that when concrete is cured at temperatures over 70°-80°C, ettringite which may have been produced in the initial pre-curing period is decomposed, and the formation of new ettringite is impeded. Early thinking seemed to favor the stability of monosulfoaluminate ($C_3A{\cdot}CaSO_4{\cdot}12H_2O$) under these conditions, but it now appears that a more likely explanation involves adsorption of the sulfate by the C-S-H gel phase. The alumina is also adsorbed, and it is believed (Fu and Beaudoin, 1996) that the sulfate and alumina are held more tightly if curing temperatures are high. Subsequently, when the concrete is cooled, it is postulated that the sulfate and alumina desorb from the C-S-H and can potentially reform ettringite. The slow desorption of sulfate from the C-S-H occurs well after the strength of the concrete has developed.

However, the desorption of sulfate from the C-S-H does not necessarily lead to concrete distress. Scrivener's work (1996) has established that the tendency toward expansion of the system depends upon the sulfur-to-alumina ratio of the C-S-H. If the molar ratio is close to three, there is expansive stress, but if it is near unity, no such expansion is observed. Kelham (1996) has stated that there must be juxtaposition of several factors for steam curing to lead to distress:

- sulfate-resisting cements (with low C_3A) are not susceptible to DEF
- there is a pessimum in the SO_3 level for any given clinker
- increases in cement fineness, alkali level, and MgO level all appear correlated to increased expansion

Johansen and co-workers (1995) have explained that the effect of alkalies seems to relate to the temperature of instability of ettringite. The higher is the alkali content, the lower this temperature limit becomes.

Another issue with respect to internal sulfate attack is the issue of temperature and service conditions of concrete cured at ambient conditions. Stark and co-workers (1992) concluded that in addition to the temperature of heat treatment, the temperature attained during the utilization of hardened concrete has great influence on the durability of the concrete, especially in concretes with a dense structure (low w/c ratio), a cement SO_3 content of >3.3%, and exposure conditions consisting of drying temperatures of ≥60°C combined with longer wetting periods. Under these conditions structural deterioration may result . They also note that deterioration first becomes apparent in small specimens.

The test of Grabowski and co-workers (1992) probably measures both delayed ettringite formation and ISA from this kind of thermal cycling. Their conditions (very short pre-cure, very high temperature with fast ramp, short time at temperature, slow cooling) would largely maximize the probability of problems, if any could occur, and exacerbate their severity. The Duggan test itself "...involves measuring length changes in concrete cores, 22 mm in diameter, 50 ± 5 mm long. After soaking in water for 3 days, the cores are subjected to 3 cycles of heating and cooling over a period of 7 days. The cores are then placed in distilled water and length change measurements are taken for 20 days. Trials indicate that cores which expand by 0.05% or more after the 30 days are from concretes with a potential for deleterious expansion."

Fu and Beaudoin (1996) distinguish between DEF and the exposure-induced distress, terming the latter "secondary ettringite formation" (SEF). In the case of SEF, severe drying decomposes the sulfoaluminate hydrates. When re-wetting occurs, the calcium sulfate dissolves and reacts rapidly with aluminates to form ettringite. They indicate that the Duggan test, which is designed to assess the potential for DEF, may be showing SEF potential instead. It appears to the present authors that the Duggan test measures both mechanisms.

The third mechanism, that of sulfate becoming available only after the concrete has developed strength, in samples cured under ambient conditions, has been discussed by Hime (1996a, 1996b, 1996c) and Mielenz et al. (1995). Hime (1996a) states that,

"If the precast concrete is not air-entrained, and exposure to water will be frequent, then DEF may occur if either: a) the concrete temperature during curing or in service reaches a temperature high enough to decompose ettringite. Depending on cement composition, this temperature may be as low as 140°F (60°C); or b) the clinker contains a substantial amount of slowly soluble sulfate. Clinker sulfate levels may be as low as 1.5% to cause DEF. For high-alkali cements, the lower SO_3 limit may be 2% or more."

In another paper, Hime [1996b] indicates that ambient DEF can be avoided by keeping *clinker sulfate below 1%.* The position is that if the belite crystals contain very high levels of sulfate, this sulfate will not become available until the belite hydrates, which is well after the development of rigidity in the concrete. Furthermore, according to this hypothesis, there is the possibility that high-sulfur fuels will cause large accumulations of anhydrite in the clinker, which will not be exposed by grinding, and which will become available only slowly, after the development of concrete rigidity. The results obtained in the present studies are not consistent with this hypothesis, and the balance of this paper will address this issue.

"Slowly Soluble Sulfate"

As mentioned above, recent literature references hypothesize that sulfate which is "slowly soluble" in ambient curing scenarios can cause distress. One of the goals of the present work was to try to discover what sulfated clinker phases might be slowly soluble, and what their effect might be on volume stability due to late ettringite formation. One of the chief difficulties in trying to measure this elusive parameter is that the measurement techniques themselves may alter the form of the sulfate.

As an example, one may consider the adaptation, for determination of water-soluble sulfate in cements, of the ASTM procedure for determination of water-soluble alkalies (C 114). This method uses a high ratio of water-to-cement and a relatively short duration of exposure of the cement to the water. Irrespective of the short exposure period, there is a good possibility that rapidly soluble sulfate, such as hemihydrate, soluble anhydrite (γ-calcium sulfate), or alkali sulfate, will go into solution and immediately be taken out of solution again by reaction with the aluminates. This sulfate will therefore be measured as slowly soluble or insoluble, when in fact it is highly soluble. Furthermore, using ASTM Method C 265 for determination of unreacted calcium sulfate is also unrepresentative of field conditions, because it uses a low ratio of water to mortar, a coarse specimen to be leached, and a very short duration of exposure (2 minutes), followed by filtration. As such, it is unlikely to result in the dissolution of any "slowly soluble" sulfate.

Recently, Jøns (1996) published a method for determination of soluble and insoluble sulfate in clinker and cement, based on the use of a dilute solution of sodium carbonate. His work shows that the results of the water extraction method indicate high levels of insoluble sulfate even when there is no clinker sulfate, (i.e., when all sulfate is furnished by gypsum or hemihydrate). The soda extraction method measures insoluble sulfates which correlate well with the level of sulfate in the silicate phases determined in the residue of extraction of clinker or cement using KOH-sucrose extraction solution (Gutteridge, 1979). Jøns' method seems applicable to the determination of soluble and insoluble sulfate during early hydration. It seems to be inapplicable to the determination of slowly soluble sulfate in hydrated samples, because it may partially decompose ettringite and monosulfate.

EXPERIMENTAL PART

Distribution of Sulfur in Modern North American Clinkers

The present research has been focused on the determination of how sulfur is distributed in present-day clinkers. For this study, 33 clinkers with SO_3 contents ranging from 0.03-3.00% were received from participating cement plants. These samples were subjected to chemical analysis by X-ray fluorescence (XRF) with results organized in order of increasing SO_3/alkali ratio, as shown in Table 1.

Table 1 Selected Chemical Analytical Results, 33 Industrial Clinkers.

The mineralogy of the sulfur-containing phases in clinker was determined using powder X-ray diffraction (XRD) spectrometry combined with selective extraction techniques. Methanolic salicylic acid (Takashima, 1958) was used to extract the free lime and calcium silicates from the aluminates, ferrites, and the sulfate salts. The residues were analyzed by XRF and subjected to XRD examination. This selective dissolution technique concentrated these salts by about a factor of 5, and facilitated interpretation of the XRD spectra. Potassium hydroxide/sucrose solution (Gutteridge, 1979) was used to extract the aluminates, ferrites, and sulfates from the calcium silicates, free lime, and periclase in the parent clinkers. These residues were also studied using XRF and XRD.

The sulfate phases were readily observed on the salicylic acid/methanol extraction (SAMX) residues by XRD. Results of the analysis for alkalies and sulfur, and the XRD findings, are given in Table 2, in order of increasing molar SO_3/alkali ratio:

Table 2 Salicylic Acid/Methanol Residues-Chemical & XRD Analyses.

The chemical analysis of the KOH/sugar residues permits determination of their sulfur content, and thus the potential for slowly soluble sulfate from belite. The results were in line with expectation, and indicate that the sulfate in modern North American clinkers is distributed in the following mineralogical forms:

- Arcanite (K_2SO_4)
- Aphthitalite (a solid solution series, nominally $3K_2SO_4 \cdot Na_2SO_4$)
- Calcium langbeinite (usually designated $2CaSO_4 \cdot K_2SO_4$)
- Sulfate substituted in silicates (probably chiefly in belite)

The arcanite, aphthitalite, and calcium langbeinite are readily identified using XRD. The sulfate incorporated in belite (and alite) appears in the analysis of the KOH/sugar solution residues, from material balance calculations subtracting the sulfate in the SAMX residues from the total clinker sulfate, and from the appearance of "soluble anhydrite" (γ-$CaSO_4$) in the SAMX residues. In no case does this represent more than 0.85% SO_3 in the silicates, or 0.68% for the clinker as a whole. No natural β-anhydrite was found in any clinkers, either in the whole clinkers or in the SAMX residues. (Detection limits for the

presence of anhydrite are estimated at 0.5% in whole clinker and 0.1% in the SAMX residue on a whole clinker basis.) (It should be pointed out that γ-$CaSO_4$ has an XRD pattern very similar to that of hemihydrate, and completely different from that of β-$CaSO_4$. There can be no mistaking what the phase identified is, and that its formation can only be understood on the basis of small quantities of water present in the methanolic salicylic acid. Our experience indicates that only trace quantities of water are required to form this phase.)

The Gutteridge method for KOH/sugar extraction makes no mention of the efficiency in extraction of sulfur- containing phases other than silicate-lattice sulfate. For this reason, an experiment was performed to establish whether any other sulfur-containing phases might be present in the extraction residue, leading to inaccuracies in the determination of the silicate sulfur. Two such residues, from high sulfur clinkers (Nos. 9 and 21) were subjected to DSC examination for the presence of ettringite and/or syngenite (the clinkers had contained substantial quantities of calcium langbeinite). The derivative of the heat curves (rate of change of endotherm or exotherm) was also plotted. Evidence for small amounts of C-S-H phase were found, but no endotherm for ettringite or syngenite was found. The evidence of the derivative curve was particularly convincing; the addition of 1% ettringite to the sample gave a strong inflection at 100-110°C.

As further confirmation of the efficiency of extraction, a one-gram sample of pure synthetic ettringite was subjected to extraction with KOH/sugar. The sample was extracted and filtered, and the filtrate was subjected to chemical analysis for sulfate ion. 98.6% of the sulfate content of the original ettringite was found in the filtrate. In view of the very low solubility product for ettringite (of the order of 1×10^{-40}), it is clear that the sugar is very effectively chelating the calcium ion and ensuring the solubility of sulfate sources other than those incorporated within the calcium silicate phases.

Correlation of SO_3 Insoluble in the "Soda Method" and SO_3 in the Silicates

The sulfate contents in the silicate phases would be expected to be similar to the SO_3 content in the clinker that might be "slowly available"; the rest of the sulfate might be anticipated to dissolve in the dilute sodium carbonate solution utilized by Jøns (1996). To check this hypothesis, seven of the clinker samples (samples 1, 3, 9, 11, 19, 21, and 26) were extracted with Jøns' solution at two finenesses: passing 147 μm (100 mesh), and passing 45 μm (325 mesh). Figure 1 illustrates the correlation for the finer clinker; the correlation is quite good, with an R^2 value of 0.87. Figure 2 gives the same information for the coarser sample, with a correlation coefficient of 0.88.

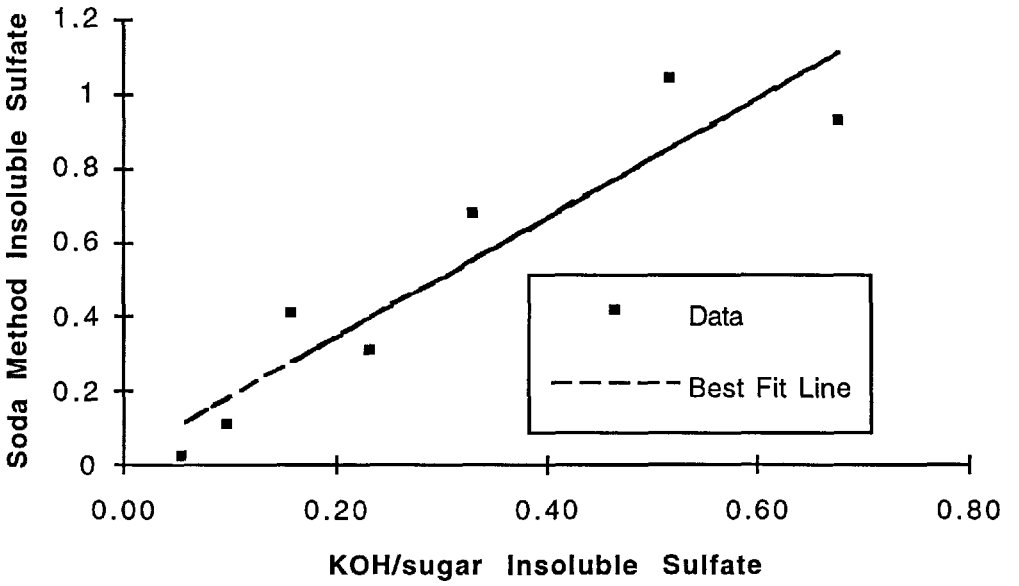

Figure 1 KOH/Sugar Insoluble SO_3 vs Soda Method Insoluble SO_3 - 45 μm Clinker.

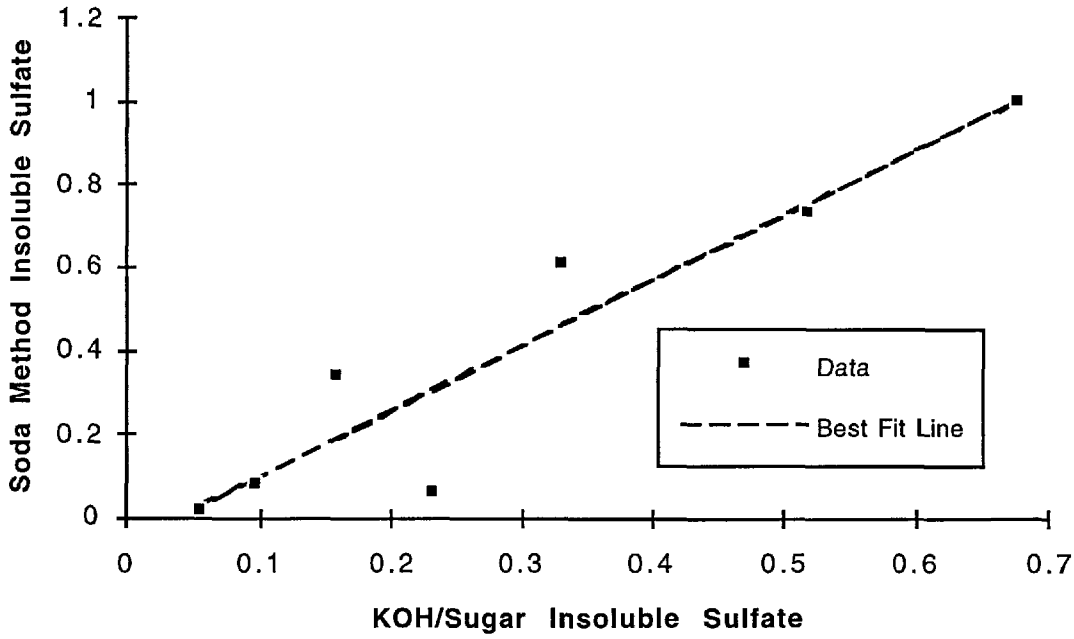

Figure 2 KOH/Sugar Insoluble SO_3 vs Soda Method Insoluble SO_3 - 147 μm clinker.

It will be noted that, although there is a good correlation, the sulfate content of the residue from the soda method extraction is generally higher than that of the residue from the KOH/sugar extraction. It seems likely that there may be a small amount of ettringite, or perhaps syngenite, formed during the process of extraction with soda; further work would be needed to verify this hypothesis.

Rate of Release of Sulfate from High Sulfate Clinker

It was considered of interest to determine the fate of the sulfur compounds in a cement made from a clinker with high sulfate level. The XRD pattern for clinker no. 9 had shown the presence of relatively large amounts of calcium langbeinite, together with aphthitalite and some γ-$CaSO_4$. The formation and disappearance of phases was followed using differential scanning calorimetry (DSC). There was particular interest to determine whether calcium langbeinite hydrated to syngenite, how fast the endotherm corresponding to the decomposition of syngenite disappeared from the DSC trace, the rate of formation and disappearance of peaks attributable to gypsum or hemihydrate, and the rate of formation of ettringite. The authors' laboratory has recently developed a useful, reproducible semiquantitative method for separating the endotherms attributable to ettringite, monosulfoaluminate, gypsum, hemihydrate, syngenite, and calcium silicate hydrate, so that the abundance of these phases can be at least approximated.

Table 3 shows the rate of appearance and disappearance of the phases of interest, and the % of each as a function of time.

Table 3 DSC Results, Cement Made from High Sulfur Clinker (Clinker #9)

Sample ID	Ettring.,J/g	Gypsum, J/g	Syngnte,J/g	% Ettringite	% Gypsum	% Syngenite
Cement	-	8.21	-	-	1.8	-
2 min paste	34.37	12.31	2.62	5.3	2.7	1.6
5 min paste	37.88	13.46	2.87	5.9	3.0	1.7
10 min paste	38.71	11.99	4.11	6.0	2.6	2.5
30 min paste	41.96	13.01	3.17	6.5	2.9	1.9
1 hr paste	45.80	13.85	1.60	7.1	3.0	1.0
2 hrs paste	49.12	13.92	1.41	7.6	3.1	0.8
3 hrs paste	57.62	13.24	0.48	8.9	2.9	0.3
24 hrs paste	213.59	-	-	33.1	-	-

Immediately after mixing with water, syngenite began to form. It was measured at 2 minutes, 5 minutes, and reached a maximum at 10 minutes. Thereafter, the endotherm at 270°C began to decline, and three hours after mixing the cement and water, the syngenite was almost completely gone. Gypsum increased also for a period of 2 hours, but declined thereafter, and was gone after 24 hours. The most important change noted was in the ettringite peak, which increased steadily, until after 24 hours, the peak corresponded to 33.1% ettringite. This ettringite quantity is equivalent to an amount of SO_3 greater than the total sulfate content of the cement. Not only did all sulfur incorporated within the calcium langbeinite, gypsum, and aphthitalite become converted to ettringite, but by 24 hours, even the sulfur associated with the silicate phases, 0.52% as SO_3 in the clinker, had hydrated. This finding provides strong evidence that even for clinkers with high sulfur levels, and with high sulfur/alkali molar ratios, all the sulfur is rapidly available to form ettringite while the paste is still plastic.

Discussion of Silicate SO_3 and Anhydrite

It should not be surprising that β-anhydrite was not found in any of the clinkers. Anhydrite is unstable at cement kiln burning zone temperatures. It has been found in mineralized clinker made with additions of calcium sulfate and calcium fluoride (Borgholm et al, 1995), but these are burned at temperatures of approximately 1350°C. Even here, however, the SO_3/alkali ratios necessary for anhydrite to form result in unstable kiln operation. The SO_3/alkali ratios which are maintained in production of the mineralized clinker are such that anhydrite does not occur in the commercially available cement. Pollitt and Brown (1968) provide microscopical evidence of clinker anhydrite; however, the photomicrograph of an anhydrite-containing clinker sample they show was almost certainly a laboratory clinker with a very high sulfur/alkali ratio, burned at low temperature. They provide a table of "works clinkers", in which almost all the sulfate content is shown to be water-soluble. Furthermore, they make no mention of sulfur incorporation into the clinker phases, and provide complete sulfur balances without allowance for this possibility. The anhydrite they generated proved to be very water-soluble, and some of it may have been γ-$CaSO_4$. Dreizler et al (1985) were unable to find evidence for anhydrite even in clinkers rich in sulfate but of low alkali content. Hanic et al (1985) have provided useful information on its decomposition in the range of 1170-1450°C, which shows that the calcium oxide generated by decomposition can form an eutectic melt with calcium sulfate. This effect inhibits the ability of lime to deter the decomposition; hence anhydrite normally decomposes very readily at cement kiln clinkering temperatures. The removal of CaO by reaction with C_2S or by dissolution in the clinker melt would tend to further accelerate the decomposition. Pliego-Cuervo and Glasser (1979) show a decomposition pressure at about 7.6 mm Hg at 1200°C, and indicate further that anhydrite is not stable in the presence of C_3A, but only in the presence of $C_4A_3\bar{S}$. Further insight into this issue is provided by Demoulian et al (1980). The authors refer to two different kinds of alite--one with smooth borders, and the other with corroded edges. They interpret the former, for clinkers with excess or equivalent alkali, as resulting from the slow vaporization of K_2SO_4, and condensation of the same. The vaporization is slow and does not disturb the cohesion, which in fact is aided when it condenses again. By contrast, in high sulfur environments, the compounds present are the Klein ternary, $C_4A_3\bar{S}$, and anhydrite ($CaSO_4$). Both of these compounds normally decompose rapidly at temperatures above 1350°C, and rapidly perturb the internal structure and the surface of the grains of clinker. Therefore, although anhydrite may be present in clinker manufactured with mineralizers that permit alite formation at reduced temperatures, one would not normally anticipate finding anhydrite in clinker samples produced in kilns operated at temperatures above 1400°-1450°C. An exception to this rule applies when the alkali content of high-sulfur clinker is very low; in such a case, small amounts of anhydrite may occasionally be found in clinker burned at normal temperatures.

As a practical matter, the amount of sulfate dissolved in the calcium silicate phase is self-limiting. This fact results from the inhibiting effect of calcium sulfate on the reaction of belite and lime to form alite. Work done by Gutt and Smith (1968), Odler and Abdul-Maula (1982), and Christensen and Johansen (1980) indicates that calcium sulfate (especially in the presence of alumina) strongly inhibits the conversion of belite to alite. In practice, high free lime values cause the kiln operator to increase the temperature; this would tend even more to volatilize the stoichiometric excess of sulfur over alkali. The solubility of calcium sulfate in belite is cited by Gutt and Smith (1968) as 1.1 mole % at 1200°C and 1.7 mole % at 1000°C. Taylor (1996) cites the work of several authors who report that real or "works" clinkers may have SO_3 levels as high as 2.5-3.4%; alite SO_3 levels are lower, but less than 0.9%. In production, however, he claims that silicate sulfur will probably never exceed 1% as SO_3, and that half of this will be in the alite phase. Gartner and Tang (1987) also point out that magnesia reduces the solubility of SO_3 in the belite. These findings are in agreement with the earlier work by Gutt and Smith (1968). Since magnesia reduces the incorporation of sulfate into belite, it will counteract the inhibition of belite's conversion to alite.

CONCLUSIONS

The intent of this paper has been to investigate internal sulfate attack, in systems that contain no aggregate sulfate. The mechanisms may include delayed ettringite formation, when the concrete has been cured at high temperature, or subjected to severe temperature or moisture cycles. However, ambient internal sulfate attack in the absence of aggregate sulfate appears inconsistent with the results obtained in these studies, as only very minor amounts of clinker sulfate appear to be insoluble in the first day of hydration, and when such more slowly soluble clinker sulfates do dissolve, they do so in the presence of stoichiometric excess of alumina. To ensure reasonable, accurate, and defensible explanations of expansion and cracking of mortars or concretes in service, hypotheses should be supported by appropriate analytical data, not simply microscopical pictures showing the presence of a phase or phases without confirming supporting data from other measurement techniques.

ACKNOWLEDGEMENT

The research reported in this paper (PCA R&D Serial No. 2079) was conducted by Construction Technology Laboratories, Inc., with the sponsorship of the Portland Cement Association (PCA Project Index No. 95-10). EFFECTS OF CEMENT COMPOSITION AND HYDRATION TEMPERATURE ON VOLUME STABILITY OF MORTAR

Steve KELHAM, Blue Circle Technical Centre, Greenhithe, Kent DA9 9JQ, UK

ABSTRACT Mortar prisms were cast from >70 laboratory ground cements prepared from 7 production clinkers with a range of chemistries. After initial curing at various temperatures up to 90°C the prisms were stored in water at 20°C. Expansions of 20°C control prisms were <0.1%, decreased with cement surface area and increased with cement SO_3. Expansions after 90°C curing increased with surface area and were greatest at SO_3 contents of ~4%. Addition of KOH or K_2SO_4 accelerated and increased expansions after 90°C curing and led to expansion after 80°C curing.

Key-words: Expansion, Ettringite, Composition, Fineness, Temperature

INTRODUCTION

The volume stability of heat treated mortars and concretes has been studied widely in recent years. Expansion during subsequent moist storage is often observed, associated with delayed (or secondary) ettringite formation (DEF). The ettringite is found filling voids and cracks, particularly around aggregate particles. The paste/aggregate interface appears to be important, since the nature of the aggregate affects expansions, but expansions have also been reported in paste samples. A full explanation of the expansion process is not yet available.

The published data indicate a critical early age temperature of ~70°C below which no expansions are observed. Higher temperatures may lead to subsequent expansion but some cements do not expand even after prolonged initial curing at 100°C. It has recently been suggested that certain clinkers may lead to expansion through a similar process in the absence of high temperatures during or after hydration. The present study is an attempt to clarify the influences of temperature and cement composition and fineness on expansions associated with DEF. A set of laboratory prepared cements has been used to allow controlled variations of the factors believed to be important. Knowledge of the factors which determine the relative susceptibility of cements will assist in the development of models of the expansion process.

MATERIALS

Seven clinkers were used to produce the cements tested. The chemical analyses of the clinkers are given in Table 1 together with phase compositions from Bogue calculations. Clinker A is high in C_3A, clinker B high in K_2O, clinker C high in MgO and low in Na_2O eq. and clinker D low in SO_3. Clinker E is low in C_3A and suitable for producing sulfate resisting cement to BS 4027 or ASTM C 150 Type V. Clinker F has moderate levels of all parameters and clinker G is a mineralised active clinker produced at the same works as clinker F. The Bogue analysis for clinker G assumes that all the sulphate is present as $CaSO_4$. Three sources of added SO_3 were used:- a natural gypsum, a natural anhydrite and a flue gas desulfurisation (FGD) gypsum. The natural anhydrite was used blended with a small proportion of natural gypsum, giving 20% of the SO_3 present as the dihydrate. Limestone was used in some grinds. The limestone meets the requirements in ENV 197-1 for the production of Portland Limestone Cements. The cements prepared with clinkers A to E were ground in a 450 mm diameter laboratory mill. The grinding was carried out cold and the cements then heat treated at 105°C for four hours to produce a similar degree of gypsum dehydration to that found in production cements. The grinds carried out are summarised in Table 2. The limestone was used at 5% and 15% levels in grinds with clinker A and natural gypsum. The target specific surface areas

(SSA) are given as 350 and 450 m^2/kg but the grinds were actually designed to give a similar clinker fineness to that in the equivalent grind without limestone, as indicated by the 45μm residue. The actual SSAs were therefore higher, particularly for the 15 % limestone grinds. The cements prepared from clinkers F and G were ground in a pilot scale closed circuit ball mill equipped with a high efficiency separator (REMA). Target SO_3 contents were 3.5% and target SSAs 400 and 550 m^2/kg.

METHODS

Mortars (3:1:0.5 sand:cement:water) were prepared as described in EN 196-1. The standard silica sand used was German 'Normensand' supplied in pre-weighed bags. 16 x 16 x 160 mm prisms were cast with stainless steel studs in their end faces. Up to four moulds, each containing three prisms, were used for each mortar mix. The prisms were cast in a single layer and compacted with 60 jolts. After striking off excess mortar a top-plate in each prism compartment provided essentially sealed curing conditions. Each mould was further sealed in a polyethylene bag together with a water soaked cloth to ensure 100% rh during curing. Samples were either maintained at 20°C or subjected to a heat treatment regime. 70° and 80°C cures were carried out in environmental cabinets. After a 20°C pre-cure for 4 hours the temperature was increased by 20°C/hour up to the required maximum temperature, which was maintained for 12 hours. Cooling was also at 20°C/hour. 90°C curing was carried out in an accelerated curing tank. The moulds were held ~50 mm above the surface of the water. After the 4 hour pre-cure at 20°C the water was heated to 95°C in 1 hour and maintained at this temperature for 12 hours. Calibration with sand filled moulds showed that this gave a sample

temperature of 90°C. Unforced cooling to 20°C took ~6 hours. All prisms were demoulded at 24 hours and subsequently stored in water at 20°C. Lengths and weights were measured at regular intervals. Data for up to 5 years of water storage are available. All cements were tested with 20°, 70° and 80°C curing. Those also tested at 90°C are indicated in Table 2. Some additional mortars were prepared with K_2SO_4 or KOH dissolved in the mixing water to raise the SO_3 and/or Na_2O eq. levels. The cements used are also indicated in Table 2.

RESULTS

Control prisms

Length changes of prisms maintained at 20°C were always <0.1%. The data for cements based on clinker D are plotted in Fig 1. The data for the other cements are similar. Any expansion takes place during the first 28 days and the prisms are then stable within the accuracy of the present tests. The expansions of prisms cured at 20°C are plotted against cement SO_3 content in Fig 2. The plotted values are the means of the data for times greater than 600 days in order to reduce the scatter. The lines in the plot connect data points for cements which were ground from the

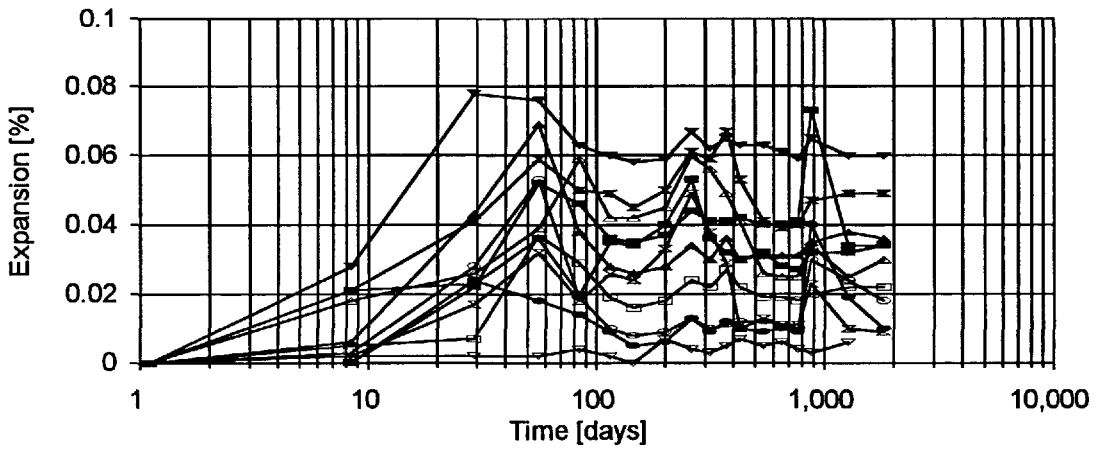

Figure 1. Expansion of mortars cured at 20°C (Clinker D cements).

same clinker and sulfate source to the same target SSA and thus differ only in SO_3 content. It can be seen that generally the expansion increases as the sulfate content increases. Cements based on clinker C appear to expand more than the others at the same sulfate content which may be due to the high MgO content. Fig 3 shows the same data plotted against cement surface area. The lines connect data points for cements with the same clinker, sulfate source and target sulfate content. There is a clear decrease in expansion as the surface area increases. In both plots vertical lines connect results for repeated measurements and indicate the reproducibility of the method.

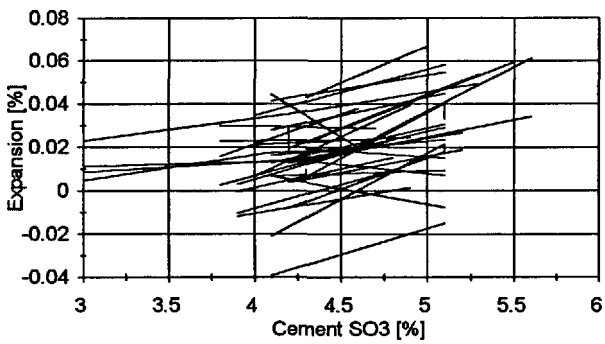

Figure 2. Dependence of expansion of mortars cured at 20°C on cement SO_3 content.

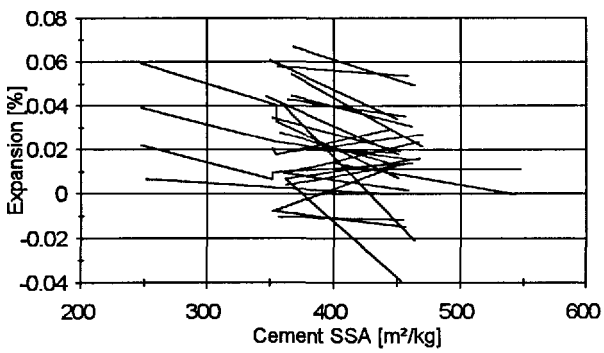

Figure 3. Dependence of expansion of 20°C cured mortars on cement surface area.

Heat treated mortars

The mortars cured at 70° and 80°C normally gave no significant expansion while most 90°C cured mortar expanded by ~1% between 56 and 200 days. A typical set of curves is shown in Fig 4. The only mortars to expand after curing at 80°C were those containing added K_2SO_4 or KOH. No expansions were observed with cements containing the sulfate resisting clinker (E). Where initial rapid expansion took place continued water storage gave further slow expansion but, in order to analyse the effect of various parameters on the expansion, plots such as Fig 4 have been used to estimate a value for the ultimate long term expansion for each set of prisms. Expansions were associated with increases in weight, 1% expansion corresponding to ~1.5% weight increase.

Fig 5 shows the dependence of the ultimate expansion on the cement surface area for mortars cured at 90°C in the same format as Figs 2 and 3. It can be seen that in all cases where expansion takes place an increase in surface area gives an increase in expansion. The results for cements based on clinker E are not included. The cements with low expansions at ~450 m^2/kg are based on clinkers B and D and have SO_3 contents >5%.

In Fig 6 the dependence on cement sulfate content is plotted. The expansions pass through a maximum at sulfate contents near 4%. Only clinker C gives expansion at 3% SO_3. The results for cements based on clinker E are not included. The cements giving low expansions at ~4% SO_3 are ~350 m^2/kg grinds based on clinker D. The vertical lines on the plot again indicate results from repeated tests.

The grinds containing 5% or 15% limestone gave similar ultimate expansions to the equivalent grinds without limestone, although the expansion occurred earlier.

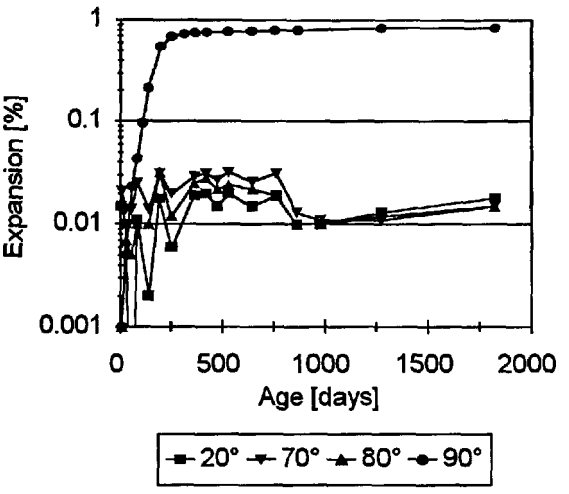

Figure 4 Typical expansion data for mortars cured at different temperatures.

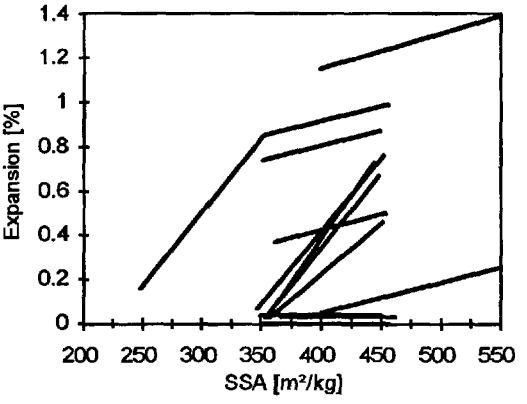

Figure 5. Effect of cement SSA on expansion after curing at 90°C.

Effect of added alkali

The tests with added K_2SO_4 were carried out on cements prepared from clinkers A, B and C with target SO_3 contents of 4% as indicated in Table 2. The quantity of K_2SO_4 used was calculated to give the same sulfate content in the mortar as in that containing the equivalent cement with a target sulfate content of 5%. Control and 70°C prisms were cast only for the cement prepared from clinker A. The added alkali had no effect on the expansion of these prisms. After curing at 80°C all the mortars with added K_2SO_4 gave significant expansions of ~0.5% while after curing at 90°C the expansions were very large, ~2%. Adding sulfate in the form of $CaSO_4$ during grinding thus leads to a lower expansion after curing at 90°C while adding the same quantity of sulfate as K_2SO_4 dissolved in the mixing water leads to much higher expansions. The expansion data are given in Table 3.

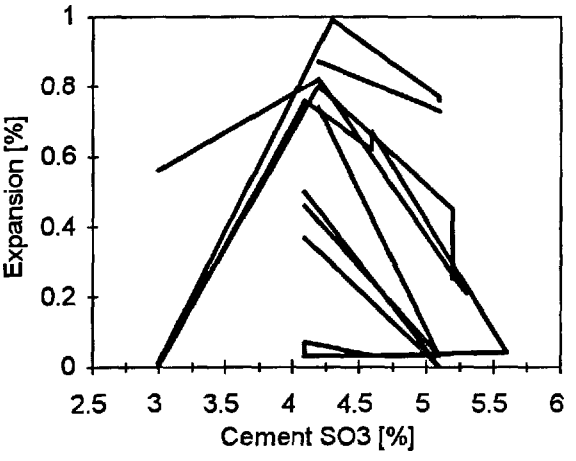

Figure 6. Effect of cement SO_3 content on expansion after curing at 90°C.

KOH was added to mortars prepared with a clinker C grind with a target sulfate content of 4%

Table 3. Expansions [%] of mortars with added K_2SO_4.

		Curing temperature [°C]			
Clinker	Sulfate [%]	20°	70°	80°	90°
A	4.3	0.015	-0.011	0.008	1.00
	5.1	0.013	0.014	0.020	0.82
	4.3+0.8 as K_2SO_4	0.022	0.019	0.550	2.20
B	4.2	0.018	0.015	0.015	0.84
	5.2	0.028	0.030	0.015	0.29
	4.2+1.0 as K_2SO_4	-	-	0.41	1.74
C	4.2	0.040	0.026	0.032	0.78
	5.3	0.059	0.032	0.026	0.22
	4.2+1.1 as K_2SO_4	-	-	0.375	1.80

(see Table 2) at various levels to increase the effective Na_2O eq. from ~0.4% to 0.6%, 0.8% and 1.2%. As with the K_2SO_4, the KOH was dissolved in the mixing water. The expansion data are plotted in Fig 7. The alkali level has no effect on the expansion after curing at 20°C or 70°C but the high alkali mortar expands after curing at 80°C. Curing at 90°C gives large expansions with all the mortars and the expansion increases as the alkali content increases.

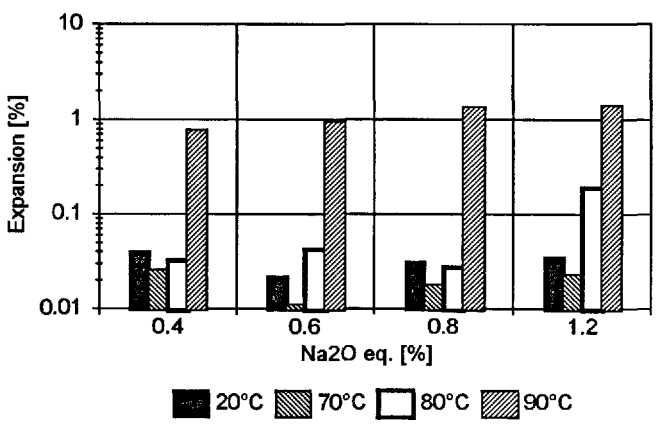

Figure 7. Effect of alkali content on expansions after curing at various temperatures.

DISCUSSION

The short term expansion data of the mortars cured at 20°C are similar to data obtained by Hobbs (1978) who also observed increasing expansion with increasing cement SO_3 content and decreasing fineness. The precision of the present data is not sufficient to make a detailed analysis worthwhile but expansions appear to increase with clinker C_3A and MgO contents.

It has recently been suggested that cements with high clinker sulfate contents, particularly when linked with low alkali contents, may give long term expansions due to 'late' ettringite formation (Diamond, 1996; Hime, 1996). It is proposed that the clinker sulfate may be unavailable during early hydration, either because it is in an insoluble form or is incorporated in the clinker minerals. Clinker sulfate is normally present as alkali sulfates and calcium langbeinite ($K_2SO_4.2CaSO_4$) and is readily soluble. As the sulfate content increases the proportion of potassium present as calcium langbeinite increases. An estimate of the 'excess' SO_3 in a clinker can be calculated by assuming that all sodium

in the clinker is present as Na_2SO_4 and all potassium as calcium langbeinite. Such 'excess' sulfate would be expected to occur as $CaSO_4$ or in solid solution in the C_2S (Taylor, 1990). Applying this method to the clinker analyses in Table 1 gives excess SO_3 contents of 0.4% in clinker C and 1.6% in clinker G. Only alkali sulfates and calcium langbeinite would be expected in the other clinkers. Despite this excess SO_3 the cements based on these clinkers behaved in the same way as all the other cements, with no signs of continuing or late expansions.

The curing temperature is clearly the dominant factor in determining whether large mortar expansions are observed. Expansions after curing at 70°C are the same as those obtained with no heat treatment. Curing at 80°C, for high alkali mortars only, or 90°C for most of the mortars leads to large expansions. These results are in agreement with other published data (e.g. Day, 1992; Lawrence, 1995). No large expansions are observed with curing temperatures below some critical value, typically ~80°C, unless other expansion mechanisms are also present such as alkali silica reaction (Shayan and Ivanusec, 1996; Diamond et al., 1994). Long delays have been observed before significant expansion takes place in the case of heat treated pastes (Lawrence, 1995) but no such delayed expansions have been reported with heat treatments below the critical temperature giving expansions in the usual time scale.

The evidence from laboratory investigations thus indicates that a temperature above ~70°C is necessary for subsequent expansion due to DEF. The reports of expansions not associated with high temperatures during curing have all involved investigations of field concretes. Analysis of crack patterns and the distribution and form of ettringite may be argued to be consistent with cracks having developed through the late formation of ettringite but the large number of unknown factors makes definite identification of the cause of damage very difficult. It is generally accepted that ettringite will be deposited in cracks caused through some other mechanism but the extent to which the growth of such crystals can contribute to crack growth and damage to the concrete is still not clear.

The expansion data for mortars cured at 90°C have been analysed previously (Kelham, 1996). The expression

$$\text{Exp}(90°C) = 0.00474*SSA + 0.0768*MgO + 0.217*C_3A + 0.0942*C_3S + 1.267*Na_2O \text{ eq.} - 0.737*ABS[SO_3 - 3.7 - 1.02*Na_2O \text{ eq.}] - 10.1$$

was found to give good agreement with the data, as shown in Fig 8. The factors involving SSA, SO_3 and Na_2O eq. are consistent with the data presented in Figs 5, 6 and 7 and Table 3. The model is generally consistent with the published data (Heinz et al., 1989; Day, 1992; Lawrence, 1995; Odler and Chen, 1995). The factors SSA, C_3S and Na_2O eq. suggest that the rate of early silicate hydration is important. Kelham (1996) noted a correlation between early strength and expansion.

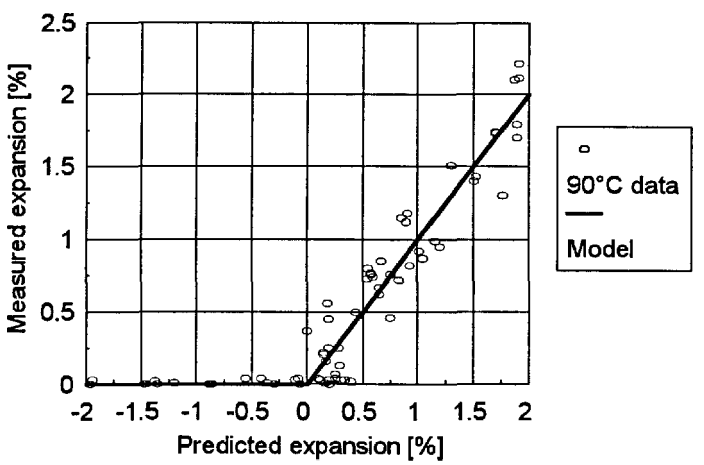

Figure 8. Comparison of predicted and measured expansions.

CONCLUSIONS

The dominant factor in determining expansions is the curing temperature. Curing at temperatures below 70°C would seem to be safe for current UK cements.

The small expansions observed in mortars maintained at 20°C increased with cement SO_3 content and decreased with cement surface area.

Cements prepared from clinkers containing 'excess' sulfate showed no abnormal expansions.

For mortars cured at 90°C expansions :-

increase with

- Cement fineness (SSA)
- Alkali (Na_2O eq.) content
- C_3A (Bogue) content
- C_3S (Bogue) content
- MgO content.

show a maximum at a cement SO_3 of ~4%, increasing with cement alkali content.

A MICROSTRUCTURAL AND MICROANALYTICAL STUDY OF HEAT CURED MORTARS AND DELAYED ETTRINGITE FORMATION

Karen SCRIVENER* and Matthew LEWIS, IMPERIAL COLLEGE, London, England

ABSTRACT Cements with various sulfate levels were prepared from a production clinker. Mortars from these cements were cured at 20, 80 and 90°C. The dimensional variation of the mortars was followed along with their microstructure and microchemistry. It was found that the evolution of X-ray microanalyses made in the C-S-H gel around anhydrous grains, was characteristic of the expansion behaviour of the mortars. This finding supports the view that expansion in heat cured mortars occurs due to ettringite formation within the C-S-H gel matrix.

Key-words: AFm phase, C-S-H, Delayed ettringite formation, Backscattered electron image.

INTRODUCTION

The phenomenon of expansion of concretes and mortars cured at elevated temperatures and subsequently exposed in wet or humid conditions has achieved much attention in recent years. The most characteristic feature of this type of expansion is the formation of gaps around aggregate particles, usually, but not always, filled with massive deposits of ettringite. In addition, it is generally agreed that the amount of ettringite formed during hydration decreases with temperature of curing, such that above a temperature of 70-90°C (depending on the characteristics of the cement) no ettringite is present in the paste after curing at elevated temperature. Subsequently, in moist conditions at lower temperatures (around 20°C), ettringite reforms over time in pastes, mortars and concretes which expand and also in those which do not. These observations have led to the use of the term 'delayed ettringite formation', DEF, even though the relationship between ettringite formation and expansion is still the subject of considerable controversy.

Field and laboratory studies of this phenomenon and possible mechanisms of expansion have been reviewed elsewhere (Lawrence, 1995 and Taylor, 1996). This paper summarises the results of an extensive laboratory programme to study the effect of various parameters on the expansion of mortars (Lewis, 1996). These parameters included sulfate level of the cement, temperature of curing, alkali content and additions of blast furnace slag. Throughout the expansion process the mortars were subject to detailed microstructural and microanalytical study. Preliminary findings of this study have been published previously (Lewis et al, 1994; Lewis and Scrivener 1995).

EXPERIMENTAL

The cements were prepared from a production clinker whose composition is given in Table 1.

Table 1 Chemical composition of clinker used.

SiO_2	Al_2O_3	Fe_2O_3	Mn_2O_3	P_2O_5	TiO_2	CaO	MgO	SO_3	LOI	K_2O	Na_2O
20.7	6.0	2.4	0.07	0.08	0.24	66.8	0.7	1.5	0.4	0.59	0.22

The clinker was ground in the laboratory with a natural anhydrite to give cements with total sulfate contents of 3, 4 and 5 wt% at specific surface areas of 450m^2/kg, and a cement with 4% sulfate at a specific surface area of 350m^2/kg. These cements were used to produce mortars at w/c = 0.5 and sand/cement=3. Eleven heat cured mortars were produced as detailed in Table 2; for each of these a control mortar cured at 20°C was also produced. The mortars were cast as

* Present address, Lafarge, Laboratoire Central de Recherche, France

25mm cubes and 16×16×160mm prisms. After a 4 hour precure they were brought to the relevant temperature (90, 80 or 20°C) over 1 hour, maintained at this curing temperature for 12 hours and then allowed to cool to room temperature. The samples were then demoulded and placed in water.

In the majority of cases expansion data was already available (Kelham, 1996), therefore characterisation times were chosen at equivalent points during expansion, i.e.:

1) one day after heat treatment
2) just before the start of expansion
3) midway through the expansion
4) at the end of expansion
5) extended period after the end of expansion, ~ 500 days.

Mortars which did not expand, including the control samples cured at 20°C, were characterised at the same time as the most closely analogous samples which did expand.

* surface area 350 m^2/kg

expansion started after about 500 days and is still continuing at 1050 days

The main characterisation techniques used were X-ray diffraction (XRD), observation of baskscattered electron (BSE) images of polished surfaces in the SEM and X-ray energy dispersive spectroscopy (EDS) microanalyses in the SEM.

RESULTS

Expansion

The ultimate expansions of the heat cured mortars are given in Table 2. None of the mortars cured at 20°C expanded measurably, even at the high sulfate content of 5%. Amongst the heat cured mortars, the degree of expansion is not a linear function of sulfate content; at 3% SO_3 there was no expansion, at 4% a considerable expansion of 9.8mm/m and at 5% a slightly lower expansion of 7.6 mm/m. The addition of alkali appears to increase the ultimate expansion, while it is reduced for a lower surface area of the cement. The mortars with additions of blast furnace slag, even when the overall sulfate content was increased to 4%, did not expand.

The mortar made with a limestone aggregate did not start to expand until after 500 days, but at 1050 days has expanded 1.3mm/m and shows no signs of levelling off.

X-ray diffraction

Fig 1(a) and (b) show the typical development of the x-ray diffraction curves with time for a room temperature cured and a heat cured mortar respectively. In the room temperature cured mortar significant ettringite can be seen in the paste immediately after the heat cure (period 1) and remains throughout the period of study. Significant quantities of monosulfate are only detected at later ages alongside hemi-carbonate.

In the heat cured pastes there is virtually no evidence of ettringite at period 1. Over the subsequent periods the formation of ettringite can be clearly observed, this pattern of delayed ettringite formation was similar both in mortars which did and in those which did not expand.

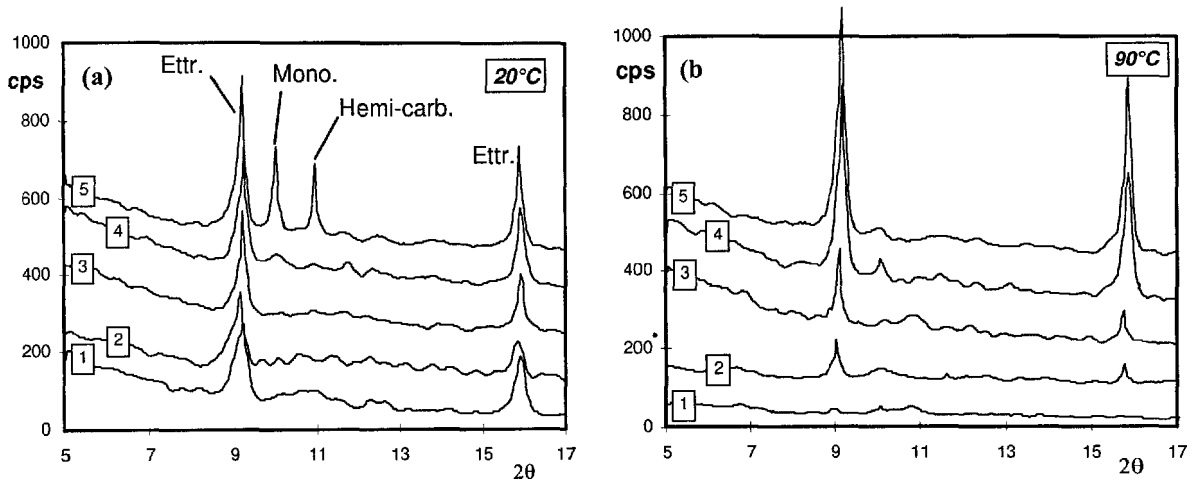

Figure 1 XRD pattern development over the five periods for, (a) room temperature cured, and (b) 90°C cured mortar, mortar 2.

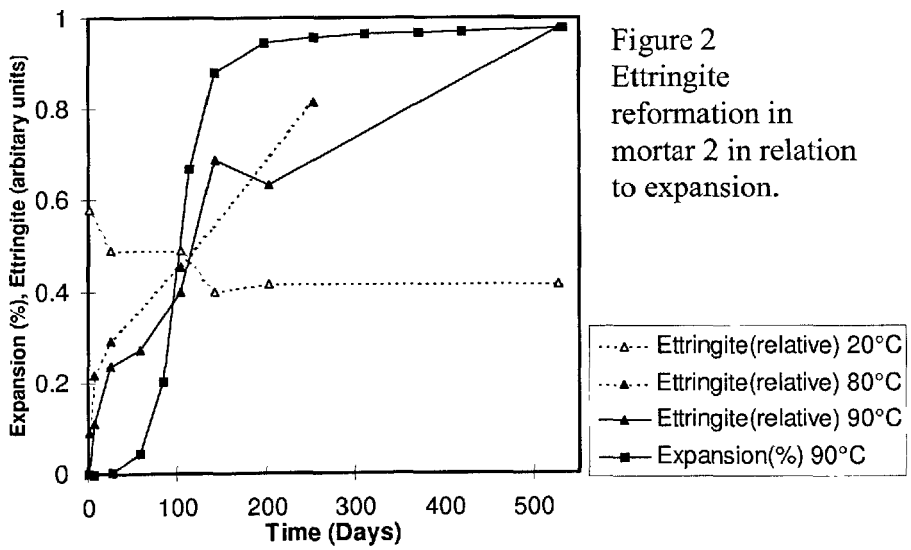

Figure 2 Ettringite reformation in mortar 2 in relation to expansion.

Figure 2 shows the development of ettringite measured semi-quantitatively by XRD and the expansion curves for the mortars made with the 4% sulfate cement cured at the three temperatures, 90, 80 and 20°C. The formation of ettringite is virtually identical in the specimens cured at 80 and 90°C, despite the fact that one expands and the other does not. There is also a considerable increase in the amount of ettringite detected in the samples cured at 90°C between period 4 and 5, despite the fact that no further expansion occurs between these two times. These observations indicate that the ettringite detectable by XRD is not directly responsible for the

expansion of the mortars. The continued increase in the amount of detected ettringite after the end of expansion suggests that ettringite continues to recrystallise, by a process of Ostwald ripening, in the space made available by the expansion of the paste.

Scanning Electron Microscopy (SEM)

The microstructural development of the mortars has been more fully described elsewhere (Lewis, 1996; Lewis and Scrivener, 1995). In the expanded mortars, bands filled, completely or partially with ettringite and, in some cases, calcium carbonate were observed around the sand particles. The relics of the original cement grains exhibited C-S-H with two grey tones (Scrivener, 1992) corresponding to C-S-H formed during the heat curing and that formed later at room temperature; Fig 3 shows a typical example of this. In those pastes which expanded an additional feature was observed at later ages shown in Fig 4. Here the outer, originally lighter product appears to have expanded away from the originally darker cores, leaving a gap between the two and the C-S-H now appears to be of uniform grey level. This feature has also been reported by (Patel et al, 1996), although they provided a different explanation of their formation.

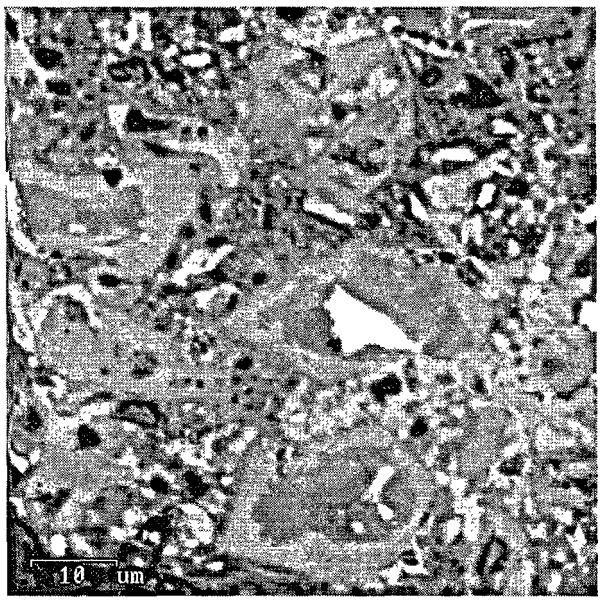

Figure 3 Relic of original cement grain showing two toning of the C-S-H.

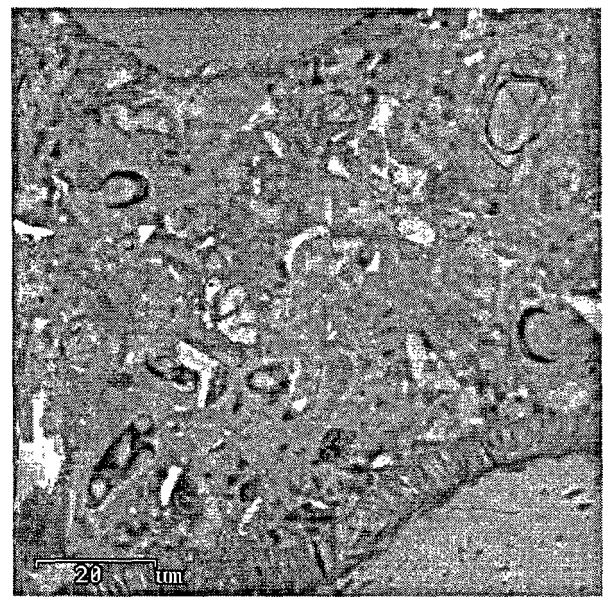

Figure 4 Localised C-S-H expansion away from inner cores.

X-ray microanalysis, EDS

In cement paste microstructures, phases are generally very finely intermixed on the submicron scale. As each microanalysis samples a region approximately one micron in volume, microanalyses taken at random will vary widely one from another. Therefore to study differences between the different mortars at the different time periods it was decided to carry-out the analyses on the C-S-H of homogeneous appearance around the partially hydrated clinker grains, often referred to as 'inner product'. In cases where two tones of C-S-H were present, the brighter outermost region was the area analysed in this study. In each sample some twenty or more analyses were made on different grains widely dispersed throughout the specimen in order to obtain a representative group of analyses. The most useful way of depicting the microanalyses was found to be on plots of S/Ca versus Al/Ca. On these plots tie lines are drawn between AFt (ettringite) and the origin and between AFm (monosulfate) and the origin. Mixtures of 'C-S-H' and AFt and of 'C-S-H' and AFm would be expected to fall along these lines, but definite identification of the mineralogy of the phases present cannot be made in the SEM.

The development of the C-S-H microanalyses followed a pattern corresponding to the expansive behaviour of the samples. These can be classified into groups described below:

1) Heat cured mortars which do not expand.
2) Heat cured mortars which do expand.
3) Heat cured mortar containing limestone aggregate.
4) Room temperature cured mortars.

1) Heat cured mortars which do not expand

These were the mortars 1 (3% sulfate); 3 (4% sulfate, cured 80°C); 10 & 11 (with slag substitution). Figure 5 shows the typical evolution of microanalyses for this groups of samples. In these mortars the microanalyses at period 1 fall between the two tie lines for C-S-H-AFt and for C-S-H-AFm. The lack of any definite ratio between the sulfate and aluminate ions suggests that they are not combined in a crystalline phase but sorbed in the C-S-H gel. Over time the sulfate and, to a lesser extent, aluminate content in the C-S-H gel fall until the analyses lie around the C-S-H-AFm tie line. At the same time ettringite is seen to form in pores and voids in the mortar, but there is no expansion.

2) Heat cured mortars which do expand

These were the mortars 2, 4, 6, 7, 8 and 9. The typical evolution of the microanalyses for this group of samples is shown in Figures 6 and 7. At period 1 the microanalyses fall around the C-S-H-AFt tie line, or, as in the case of the example shown in Figure 6 slightly below. However, the form of the sulfate and aluminate ions is unlikely to be as ettringite due to the heat curing and as with the other samples the ions are probably sorbed in the C-S-H gel. At period 2 (just before expansion) there is a marked shift of the analyses up to the C-S-H-AFt tie line which indicates that a phase with a definite stoichiometry, i.e. ettringite, has formed within the C-S-H gel. At subsequent periods the analyses points drop down towards the C-S-H-AFm tie line as with the none expanding samples. This may indicate that mixtures of C-S-H and microcrystalline AFm are quasi-stable. The plot of Al/Ca versus Si/Ca indicates that calcium also leaves the C-S-H gel during the expansion process.

Figure 8 shows the analyses of all the mortars at period 1 on the same plot, indentified as coming from expanding or non-expanding mortars. This graph shows a clear difference between the two sets of analyses, which has been indicated by an arbitrary threshold level. This threshold may indicate the level above which the potential for the formation of microcrystalline ettringite within the C-S-H exists.

3) Heat cured mortar containing limestone aggregate

The analyses for the mortar containing limestone aggregate are shown in Figure 9. This mortar had not expanded at the end of the original study, 400 days, but at that time the analyses were in the same position as at period 1, immediately after the heat cure. Thus, if the interpretation of Figure 8 is correct, this mortar should still have a potential for expansion. At the age of 860 days this mortar had started to expand and the analyses had dropped towards the C-S-H-AFm tie line.

4) Room temperature cured mortars

At period 1 at 20°C the degree of hydration is very low and clear rims of 'inner product' do not exist. Analyses made at this period inevitably include normal ettringite intermixed in the outer product and thus are very variable with some points lying on the C-S-H-AFt tie line, but at much higher sulfate and aluminate levels, Figure 10. At later ages when clearly defined rims exist the analyses fall below the threshold line.

DISCUSSION

In a previous publication (Scrivener and Taylor, 1993) it was proposed that, after curing at elevated temperatures, the delayed formation of ettringite takes place within the C-S-H gel matrix and that this ettringite subsequently recrystallises to give the large deposits seen in pores and voids and in gaps around aggregate particles. The formation of even and sometimes empty or partially filled gaps around aggregate particles, whose width is proportional to the size of the aggregate (Johansen et al, 1993) indicates that the expansion occurs relatively evenly throughout the cement paste component and that ettringite subsequently recrystallises 'opportunistically' in these gaps. Several features of the present work support these views and further indicate that the expansive processes is localised in the C-S-H gel.

First, the change in microanalyses between period 1 and 2 (Fig 6) for the expanding mortars indicates the formation of ettringite within the regions of C-S-H gel. If this is the case, this initial formation of ettringite could well be microcrystalline, perhaps poorly ordered and possibly with a low or variable water content. In such circumstances this ettringite would not be detected by X-ray diffraction.

Secondly, the difference between the microanalyses at period 1 for the expansive and non expansive mortars (Fig 8) strongly suggests that this potential for formation of ettringite within the C-S-H gel matrix determines the expansive behaviour of the mortar.

Thirdly, the appearance of the cement grain relics in the microstructure of the specimens after expansion (Fig 4) indicates that the C-S-H formed during heat curing expands relative to that formed at ambient temperatures.

Fourthly, the increase in ettringite measured semi-quantitatively by XRD (i.e. that which is seen in pores, voids and gaps) between periods 4 and 5, when no further expansion occurs, supports the view that the recrystallisation of ettringite by a process of 'Ostwald ripening' occurs after the gaps have been formed by expansion occurring throughout the paste.

Several aspects of this proposed mechanism remain to be clarified. The exact state of the aluminate and sulfate ions in the C-S-H gel after the heat curing are not known. Also there is no direct evidence for the formation of microcrystalline ettringite within the C-S-H gel. However, it is not unreasonable to suggest that such a reformation of ettringite in the C-S-H gel matrix leads to the imbition of water and so a volume increase and hence expansion. The imbition of water may be directly by uptake from the pore solution to form ettringite or indirectly as ettringite takes water locally from the surrounding C-S-H which in turn imbibes water from the pore solution (as suggested by Taylor).

If assumptions are made as to the probable composition and density of C-S-H, it can be calculated that if all the sulfate present in the C-S-H at period 1 were transformed locally to ettringite with the imbition of the requisite amount of water a volume increase of the C-S-H gel of roughly 10% would occur. In the present work linear expansions of ~1% (equivalent to ~3% volume) were observed. Considering that somewhat over 50% on the volume of cement paste is C-S-H gel and that not all of this potential increase would be realisable, the calculated figure is consistent with the experimental observations.

A major finding of the present work is the clear difference between microanalyses of mortars which subsequently expand and those which do not. One must be cautious in extrapolating this finding to other clinkers without further experimental work, but nonetheless this method of characterisation could have practical implications for providing information in a very short time period on the expansive potential of a system. Furthermore the finding that at the end of expansion all the C-S-H in all the mortars tends toward the same composition might prove diagnostic of a dimensionally stable situation in a mortar or concrete. The aforegoing relate to mortars which have been heat cured; the generalisation of these conclusions to mortars cured at ambient temperatures is difficult due to problems in applying the analysis techniques.

While the above may provide an explanation of whether or not expansion occurs, further work is necessary to explain the magnitude of expansion and the relationship of the process parameters (including cement composition) to the composition of the C-S-H gel formed during heat curing.

CONCLUSIONS

1. The present work support the hypothesis of delayed ettringite formation within C-S-H gel.
2. Evidence was found for expansion of the C-S-H which would lead to the relatively uniform expansion of the cement phase and so to the formation of even gaps around aggregate particles with a width proportional the to aggregate size.
3. The microanalyses (and so potential for ettringite formation) within the C-S-H gel after heat treatment differentiate between expansive and non-expansive mortars for the series studied.

ETTRINGITE FORMATION - A DURABILITY PROBLEM OF CONCRETE PAVEMENTS

Jochen STARK, Bauhaus University Weimar, Germany
Katrin BOLLMANN, Bauhaus University Weimar, Germany

ABSTRACT The formation of ettringite in hardened concrete is not only a problem of heat treatment. It also occurs in not heat-treated concrete, which is exposed only to normal varying climatic conditions. In some cases the mechanism of damage in concrete pavements correlates with this ettringite formation in the hardened concrete. The ettringite formation itself as well as the combined action of frost and de-icing salt after filling the artificially entrained air voids with ettringite crystals may cause damages.

Key-words: Delayed ettringite formation, Durability, Ettringite, Expansion, Moisture

INTRODUCTION

The durability of concrete pavements is still an unsolved problem. Sometimes crack formation with different appearances occurs even after a short time of utilization. Cracks with a network pattern on the surface have to be caused by internal stresses for instance as consequence of physical processes like differences in temperature and moisture or by chemical reactions like the alkali-silica reaction (ASR) as well as the recrystallization of ettringite. The recrystallization of ettringite in a hardened concrete in form of the so-called "delayed ettringite formation" (DEF) during moist storage as a result of heat treatment is known to be followed by expansion and possible cracking of the concrete (Ghorab, 1981, Heinz and Ludwig, 1982, Heinz, 1986, Sylla, 1988, Neck, 1988, Ludwig, 1991, Seyfarth, 1991, Johansen, 1993, Stark, 1995, Glasser, 1996, Diamond 1996). This mechanism occurs because of the primary ettringite being unstable above a temperature of approximately 60-70°C due to the amount of alkalis in the pore liquid. Thus, if the concrete is exposed to such temperatures, primary ettringite will not be formed and that which was formed prior to such heat treatment will decompose. But also in many of the samples taken from damaged aged concrete pavements, which are in general not heat treated, a conspicuous ettringite formation was found in the interface between cement paste and aggregate and in cracks and voids, which were originally empty (Bollmann, 1991, Stark, 1992 , 1995, Springenschmid, 1993). An additional external supply of sulfate is excluded. This leads to the conclusion that another mechanism has to take place. Also the primary cause of damage and the chronological development of the destructive mechanism have not been completely determined. It has not been proved whether the ettringite formation in the hardened concrete itself is the cause of crack formation or whether the cracks in microstructure as a result of stress due to other influences like temperature, moisture, frost and de-icing salt are enlarged by the crystallization pressure of ettringite crystals. This paper deals with the ettringite formation in normal hardened concrete which was exposed to normal environmental and climatic conditions.

LABORATORY EXAMINATIONS

To find out what the reason is for accumulation of ettringite in larger spaces a laboratory program of alternating temperature and moisture conditions was developed to simulate the climatic conditions during utilization like sun-radiation, varying temperatures, rain and frost. Three levels of stress differing in the temperature of drying were investigated. The samples exposed to the 1st level of stress (drying at 20°C) are used for comparison. The 2nd and 3rd levels of stress include a higher drying temperature up to 60°C and freeze-thaw cycles. The temperature of 60°C in the surface of concrete panels was found to be realistic under intensive sun-radiation by measuring the temperature in open air stored concrete panels in the upper concrete layer. A minimum of 3 cycles at each level was necessary to create clear results (Table 1).

Table 1 Program of alternating temperature and moisture conditions.
(only 1 cycle is described for each level)

level of stress	time		temperature	humidity
1st level of stress (1 cycle)	2 weeks	permanent	**20°C**	65 %
	8 weeks	permanent	20°C	water
2nd level of stress (1 cycle)	2 weeks	24 hours	**60°C**	→ 0 %
		24 hours	**20°C**	<40 %
	8 weeks	permanent	20°C	water
	24 hours	4 hours	20°C → -20°C	water saturated
		3 hours	-20°C	
		4 hours	-20°C → 20°C	
		1 hour	20°C	
3rd level of stress (1 cycle)	2 weeks	permanent	**60°C**	→ 0 %
	8 weeks	permanent	20°C	water
	24 hours	4 hours	20°C → -20°C	water saturated
		3 hours	-20°C	
		4 hours	-20°C → 20°C	
		1 hour	20°C	

drying storage in water freezing

To investigate changes in microstructure due to varying temperature and moisture conditions different measurement methods were applied to get suitable characteristic values. During the laboratory treatment bulk density, porosity, compressive strength, expansion, variation in mass, in ultrasonic pulse velocity, and in the modulus of elasticity were determined and microscopical as well as phase-analytical investigations were carried out. In addition to this the change of frost/ de-icing salt resistance due to laboratory treatment was determined by the CDF test.
In concrete samples exposed to the described alternating climatic conditions, a conspicuous ettringite formation in the hardened concrete and damages in the microstructure became evident in some cases depending on the concrete composition (Fig 1).

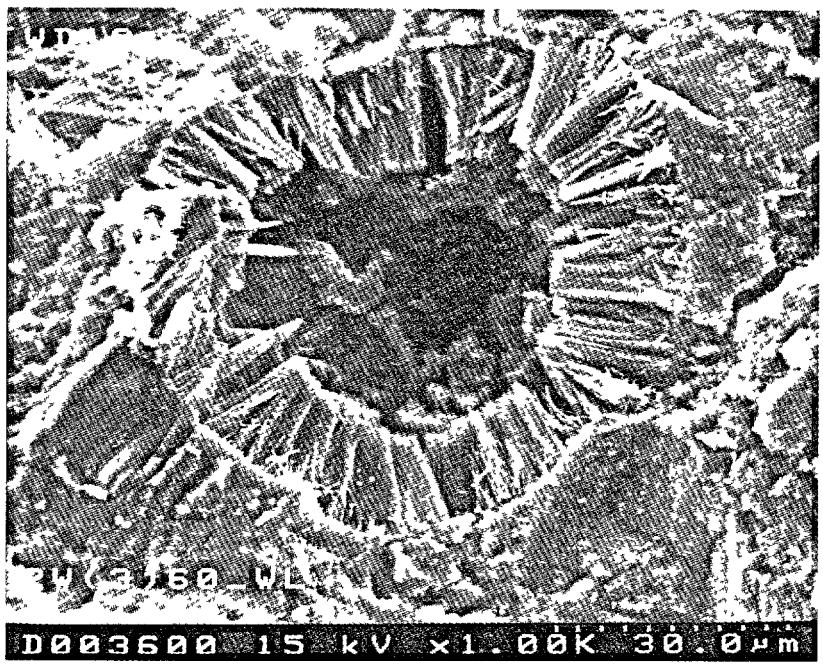

Figure 1 SEM micrograph of a concrete with entrained air: Ettringite formation in an air void after 2 cycles of laboratory treatment at the **3rd level of stress.**

That means it is possible to create the same processes in concrete in the laboratory in a relatively short time under conditions relevant to practice as under natural climatic conditions (Fig 2).

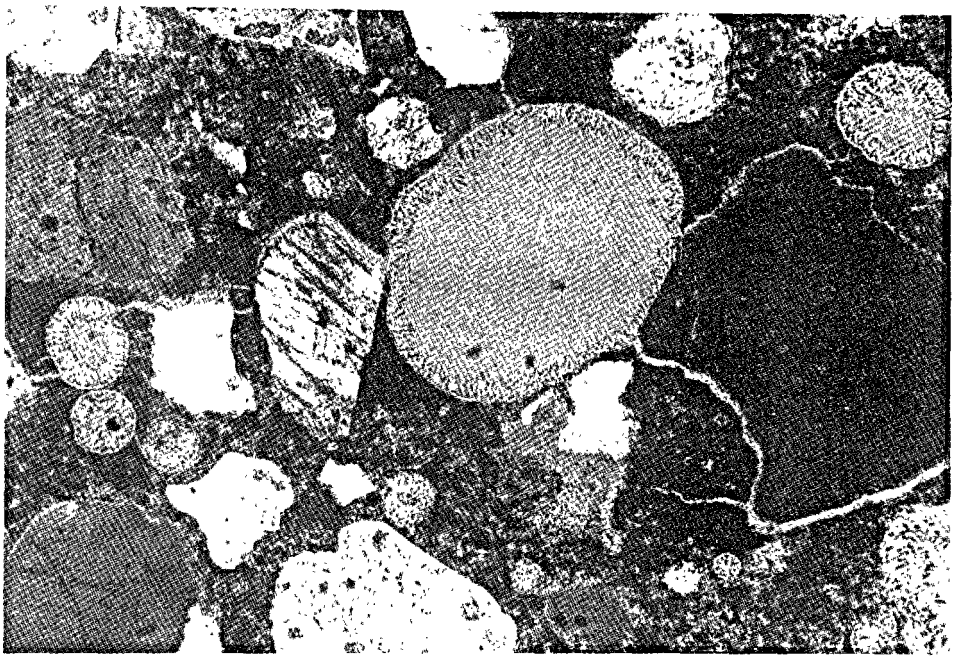

Figure 2 Polished thin section micrograph of a "naturally" aged concrete pavement: Ettringite formation in air voids.

The following results were received from a concrete pavement with a minimum compressive strength of 35 N/mm² and 340 kg/m³ of cement CEM I 32.5 R (SO_3 content = 3.2 %, Na_2O-äquiv. = 0.79%), w/c < 0.45 as well as an air void content of 5.5 %. Beams of 100mm x 100mm x 400mm were taken from a hardened concrete pavement within 2 weeks after placing. These samples were treated in the laboratory according to the described program of alternating cycles. The results of the different stress levels were compared. Furthermore the data which were received from comparable concrete samples produced in the laboratory (same water/cement ratio) without air-entraining agent were taken into account.

RESULTS

The changes of concrete microstructure, such as accumulation of ettringite and cracks caused by the laboratory treatment, became visible by optical microscopy, scanning electron microscopy (SEM) and microanalysis on fractured surfaces and polished sections and were reflected by expansion of the samples, decrease in ultrasonic pulse velocity and deterioration of the microstructure transmission behaviour.

The higher the level of stress the higher the increase of expansion during the laboratory treatment. The total expansion of samples during the alternating temperature and moisture conditions is among other things attributed to changes in microstructure and fractures. Expansion of more than 0,5 mm/m are generally expected to be associated with possible defects. But it should be taken into consideration, that the total expansion consists of the expansion due to microstructural change as well as the expansion due to change in moisture content, which is reversible to a large extent and exists independent of defects in microstructure. The expansion taken place at the 1st level of stress can be attributed to changed moisture contents and is reversible to a large extent.

The 2nd and 3rd level of stress leads to an increase of expansion in tendency. The difference in expansion between the 1st and 2nd level of stress and the 1st and 3rd level of stress reflects the change in microstructure caused by different treatment in the laboratory (Fig 3).

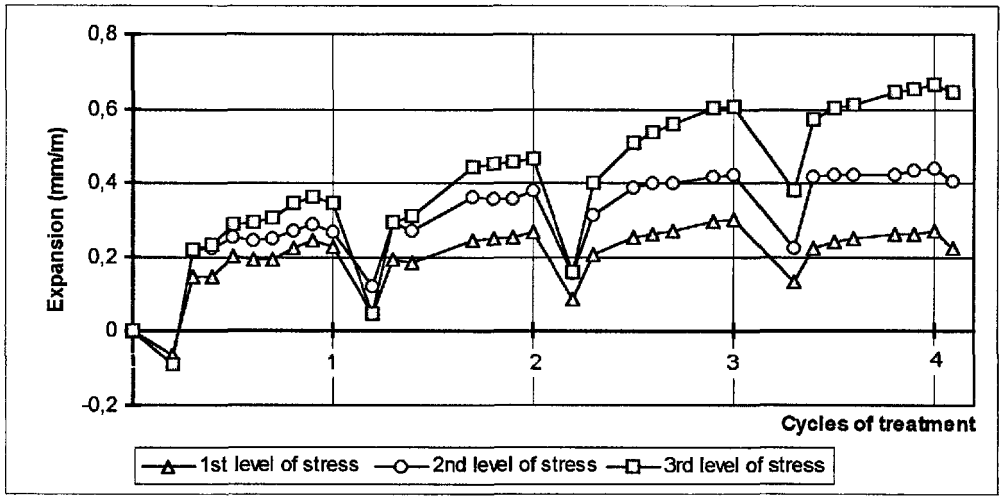

Figure 3 Expansion of samples from pavement concrete (100mm x 100mm x 400mm; same composition) during the laboratory treatment at 3 different levels of stress.

The change in microstructure induced by the different levels of stress becomes obvious by SEM. In each case at the end of the storage in water the formation of new compounds on the inside of air voids is observed (Fig 1, 4).

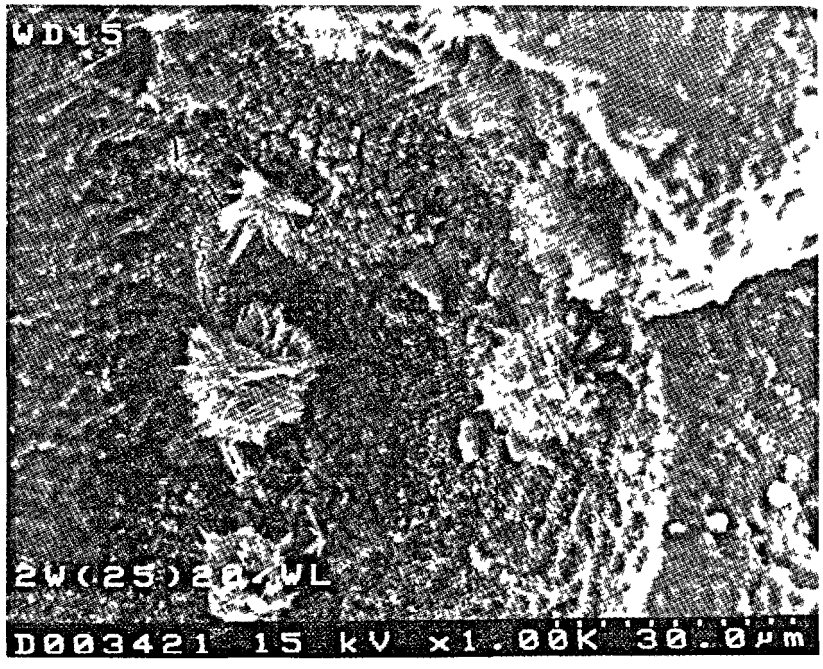

Figure 4 SEM micrograph of a concrete with entrained air: Bundles of ettringite crystal formations on the inside of an air void after 2 cycles of the laboratory treatment **(1st level of stress)**

In samples treated at the **1st level of stress** sporadically placed small bundles of ettringite crystal formations detected on the inside of air voids probably close to capillary voids (Fig 4) become

larger at each cycle of treatment. They arise probably by mobilization of phase forming components in the pore liquid and their local accumulation in weak areas and defects of the microstructure like the interface between paste and aggregate, voids or cracks where the capillary transportation is interrupted. Because the concrete remains moist during drying periods (20°C), the moisture movement and the resulting amount of transported reactants is small and only some new ettringite formations arise.

In samples treated at the **3rd level of stress** the insides of air voids are predominantly evenly covered with greater amounts of needle-shaped or compact ettringite crystals (Fig 1). With the number of alternating cycles in laboratory treatment the degree of filling of voids with new phase formations increases up to the complete filling. Due to the intensive drying (60°C) during the cycles of the 3rd level of stress the movement of moisture and thus the amount of transported reactants in the microstructure is considerably larger in comparison with the 1st level of stress. Therefore it is possible that an essentially larger amount of typically shaped ettringite in air voids can be formed.

Johansen (1993) also agrees that the ettringite formation in microstructure defects is obviously promoted by frequent drying and repeated wetting. The higher the amount of water passing the capillary system and the possible resulting transport of reactants during the changing moisture conditions, the higher the apparent amount of ettringite in pores detected by SEM and micro-analysis. Because of the lower stability of small crystals compared to larger crystals, it is possible that the small ettringite crystals within the paste may dissolve in the pore liquid and recrystallize as larger crystals in available larger spaces, such as pores and cracks (Johansen, 1993). This occurs mainly in microstructure defects like voids and microcracks caused by environmental effects. The mechanism of this ettringite formation is promoted and accelerated by the temperature effect up to 60°C, which may occur under using conditions in the upper concrete layer. The temperature of 60°C itself is not the only reason for the mechanism of damage. It has been detected by SEM that ettringite crystals arising in the voids are stable up to 60°C. It was also found that the SO_3 content of the cement (alkali content < 1%) is not of great importance for the formation of ettringite in the hardened concrete, because it also occurs in concrete made with a cement of a SO_3-content of 2.3 % (Stark and Bollmann, 1992, 1995).

In all represented samples of pavement concrete after 4 cycles no obvious damages were found in spite of the different behaviour in expansion due to laboratory treatment. The compressive strength and the ultrasonic pulse velocity show in each case the same level or an increasing tendency. During the first moisture cycles the air voids in concrete, which contains artificially entrained air voids but has a dense mortar matrix, offer expansion space for ettringite to accumulate without impediment. Therefore in these concretes with entrained air also at the highest level of stress by the laboratory treatment no essential decrease in the typical properties of hardened concrete was discovered. On the contrary comparable concretes with the same water/cement ratio without artificial entrained air voids show at the same level of stress considerable defects in microstructure like cracks, reflected by considerable expansion up to 10 mm/m and more. However, the laboratory treatment at the 1st level of stress causes for both concretes, with and without air voids, a change in length of the same level (0.3 mm/m) exclusively caused by moisture (Stark and Bollmann, 1995).
What is the correlation between the conspicuous ettringite formation in air voids of pavement concrete and the observed damages in concrete pavements?

The frequent drying and wetting in addition to higher temperatures up to 60°C may cause a complete filling of the air voids (Fig 5) whereby a frost/ de-icing salt resistance can no longer be guaranteed.

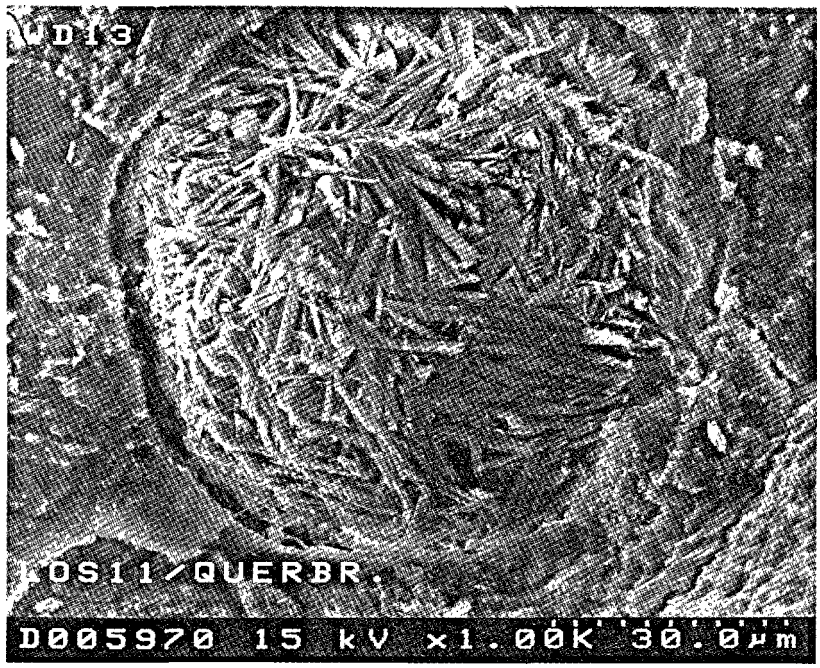

Figure 5 SEM micrograph of a "naturally" aged pavement concrete: Air void completely filled with ettringite crystals.

The frost/de-icing salt resistance test (CDF) of pavement concrete, exposed to 4 cycles of the laboratory treatment, shows the influence of microstructural changes on the frost/de-icing salt resistance. Already the increased capillary suction of NaCl solution of the samples treated at the 3rd level of stress points to detrimental changes in microstructure before CDF test (Fig 6). The influence of 28 cycles of freezing and thawing induces an exponential increase of scaling development (Fig 7). The considerable structural defects after 28 cycles of freezing and thawing were reflected by the poor transmission behaviour of the microstructure. The ultrasonic frequency spectrum analysis indicates the destruction of microstructure in concrete treated at the 3rd level of stress (Fig 8). A pavement concrete resistant to frost and de-icing salt at the age of 28 days looses its resistance as a result of microstructural changes as a consequence of the alternating temperature and moisture conditions. It decomposes during the frost/de-icing salt resistance test (CDF).

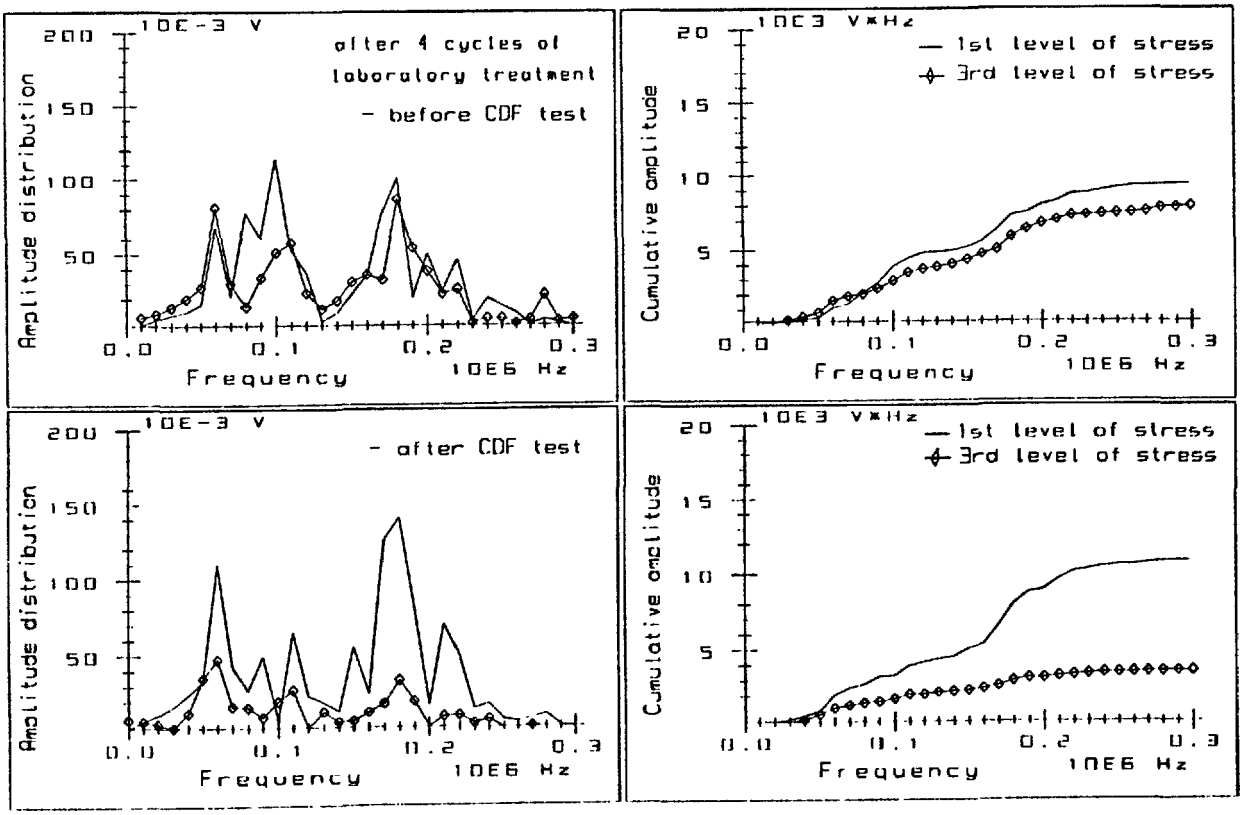

Figure 8 Ultrasonic frequency spectrum *(left)* and integral curve *(right)* of a pavement concrete after 4 cycles at the 1st and 3rd level of stress before *(upper)* and after *(below)* 28 cycles of freezing and thawing

CONCLUSIONS

Structural changes due to ettringite formation are caused above all by varying moisture conditions and by resulting transportation of moisture and substances within the concrete structure. That means that primary ettringite from the cement paste may dissolve in the pore liquid and recrystallize in larger available spaces like pores and cracks. The mechanism of this ettringite formation is just promoted and

accelerated by the temperature effect up to 60°C because of the intensive drying. However, microstructural defects like microcracks may also be created at this temperature and later on filled and widened by ettringite crystals. The expansion of the concrete is reduced by the entrained artificial air voids, because of the larger available space for ettringite formation. In concrete pavement samples no well defined indications were found for ettringite to be the primary cause of crack formation. The cracks can be caused by stresses as a result of ettringite formation itself, but also another mechanism of failure may occur: Artificial entrained air voids can be completely filled by ettringite crystals and are subsequently not available to guarantee the frost/de-icing salt resistance. Consequently damages by frost and de-icing salt such as cracks cannot be excluded, and these cracks may also be filled and widened by ettringite crystals.

DELAYED ETTRINGITE FORMATION IN STEAM CURED OPC AND SLAG CEMENT PASTES AND ITS EFFECTS ON MORTAR COMPRESSIVE STRENGTH

Gladis CAMARINI, State University of Campinas - UNICAMP, Campinas - SP, Brazil
Maria Alba CINCOTTO, University of São Paulo - USP, São Paulo - SP, Brazil

ABSTRACT Steam curing at 60°C, 80°C and 95°C were applied to ordinary Portland cement and slag cements (35%, 50% and 70% of slag) totalizing 60 complete curing cycles. After the heat treatment their mortar presented a compressive strength loss from 28 to 90-days. XRD and SEM techniques showed delayed ettingite formation at these ages, which can contribute for the strength loss.

Key-words: blastfurnace slag, delayed ettringite formation, steam curing, strength development.

INTRODUCTION

Steam curing is a suitable technique for precast mortar and concrete products in order to accelerate early strength development. This procedure follows curing cycles with various periods. As slag hydration is slower than that of clinker it could be advantageous to employ thermal activation in precast industry with slag cements. The aim of an experimental work was to observe the performance under steam curing of ordinary Portland cement (OPC) and slag cements (35%, 50 and 70% of slag), according to the Brazilian Standards. The specimens (pastes and mortars) were steam cured at 60°C, 80°C and 95°C, in five different curing periods, resulting 60 complete curing cycles (Camarini and Cincotto, 1996a). The results already available are about the effects of curing temperature on compressive strength (Camarini and Cincotto, 1996a), selection criterion of best steam curing condition (Camarini and Cincotto,1996b) and characteristics of early hydration of slag cements (Battagin et al., 1996c). In this paper are presented the results of delayed ettringite formation and its probable effect on compressive strength decrease after 28 days.

EXPERIMENTAL PROCEDURE

Materials

Cements

Four cements from the same clinker were employed in this study, one OPC and three slag cements. Their clinker and slag proportions are presented on Table 1, and their chemical compositions and physical properties are reported on Table 2.

Table 1 Weight Proportions of Clinker and Slag on Cements

Cement	OPC	AF-1	AF-2	AF-3
Clinker+Gypsum (%)	100	65	50	30
Slag (%)	0	35	50	70

Pastes and Mortars

Paste specimens were cylinder (ϕ 100 mm, h = 10 mm) and cast with cement;water proportions equal to 1;0,40. Mortar specimens were cylinder (ϕ 50 mm, h = 100 mm) and cast according to

the Brazilian Standards, that is cement:sand:water proportions equal to 1:3:0,4. Pastes were analysed by X ray diffraction (XRD) and secondary electrons image (SEI) in SEM. Mortar specimens were tested under compressive strength.

Curing Conditions

The control specimens were cured in standard conditions, that is, they were kept in their molds for 24 hours at room temperature (20°C); after demolding they were maintained in a water bath at 20°C for different periods of time: 2, 28 and 90-days, until the date of testing. In steam curing, each cement followed a complete curing cycle with a presteaming period equal to the initial set of cement, temperature rise and cooling periods of 20°C/hour and steaming periods of 3:00, 4:30, 6:00, 7:30 and 9:00 hours. The maxima temperatures employed were 60°C, 80°C and 95°C. After steam curing, some of the specimens were tested immediately after the steam cycle (RIC), and others maintained in water bath at 20°C until the dates of testing, that is, at 2, 28 and 90-days.

RESULTS AND DISCUSSION

Compressive Strength

Statistical analysis of compressive strength showed that during the studied periods, the highest strength was attained at 28-days. At 90-days, the compressive strength were equal to or lower than that, and the results did not indicate a relationship with the steaming period and its maximum temperature. Table 3 presents the compressive strength losses occured in OPC and slag cements and indicates the correspondingly steaming periods. It is observed that each cement

has its own performance after steam curing and all of them can lose compressive strength, being the higher values those with 50% of slag (AF-2). This performance can be explained by its chemical composition after steam curing, obtained by XRD and SEM analysis.

Table 3 28 and 90-days Strength (MPa) (and Strength Loss, Percent) in Steam Cured Mortar (in Different Steaming Periods)

T (°C)	CEMENTS			
	OPC	AF-1	AF-2	AF-3
60	45,2 - 43,5 (3,8) 40,2 - 38,2 (4,5) 39,9 - 34,5 (13,5)	52,9 - 48,7 (7,9)	57,4 - 47,6 (17,1) 52,1 - 48,2 (7,5) 54,7 - 40,1 (26,7)	58,6 - 47,2 (19,5) 52,2 - 47,6 (10,5) 53,6 - 48,7 (9,1) 48,0 - 42,7 (11,0)

X Ray Diffraction

In anhydrous slag cements, as the clinker phase diminished, the peaks corresponding to its anhydrous phases also diminished, corresponding to its proportion present in these cements. And as slag content increased a diffuse band appeared from about 28° to about 32° 2θ. In standard curing, by 2-days, the slag cement AF-1 hydrates the same way of OPC, with lower peaks due to clinker substitution by slag. AF-2 and AF-3 presented few peaks showing that the hydrated compounds were not well crystallized. By 28-days and 90-days, the anhydrous peaks disappeared and the calcium hydroxide peaks in OPC were the highest and in slag cements they diminished, indicating their consumption by slag reaction. It is interesting to observe that the slag cements showed few peaks of both anhydrous and hydrated phases, but their compressive strength were higher than OPC.

After the heat treatment, OPC specimens presented several peaks of hydrated compounds and as curing temperature increased, their quantity and intensity also increased. In slag cements as slag content increased the peaks of hydrated compounds diminished and even with temperature increase they did not became more intense. The Portlandite peak at 0,490 nm for all slag cements presented an intensity decrease with the increase of slag content and curing temperatures. Peak of C-A-H phase at 0,820 nm was clear for all cements cured at 60°C in all ages, but at 80°C and 95°C it was found only in advanced ages. Gypsum peaks appeared in OPC at 0,756 nm and were not present in slag cements; for these cements it was identified at 0,427 nm only at 95°C. With the presence of gypsum and aluminate phases after steam curing, its is possible the formation of delayed ettringite at advanced ages. Etringite peaks at 28 and 90-days were clear slag cements steam cured at 95°C.

It is known that elevated temperature enhances the rate of gypsum consumption by C-S-H (Fu et al., 1995) (Scrivener and Wieker, 1992), which is liberated with age, which was identified in XRD for all ages and temperatures in this study. Moreover, EDS analysis of paste specimens showed considerable sulphate present in C-S-H gel of all cements steam cured specimens. This

phenomenon occuring between 28 and 90-days can be the reason for the mortar compressive strength loss. For this reason, as shown in Fig 1, delayed ettringite was observed at 28-days, in steam cured OPC paste at 60°C for 4:30 hours, which were standard cured after the heat treatment.

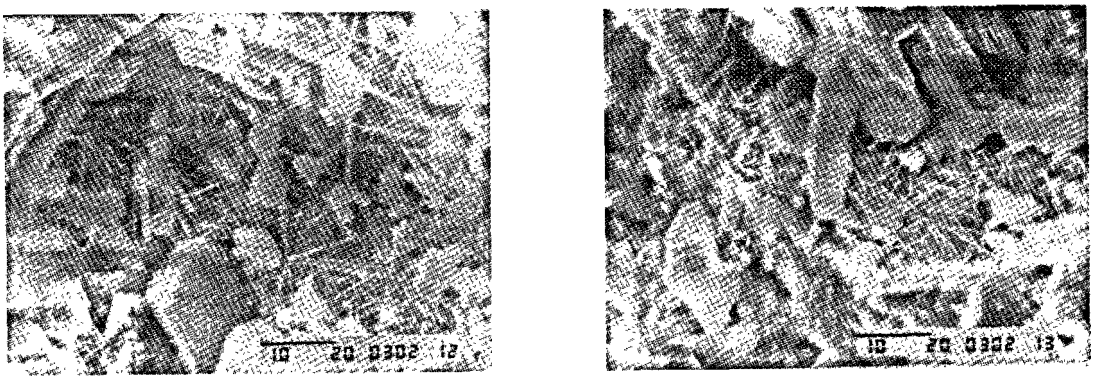

Figure 1 SEI in SEM of delayed ettringite formation in OPC pastes steam curing at 60°C, plus standard curing, at 28-days.

CONCLUSIONS

The present results permit to conclude that, in fact, thermal activation is more advantageous to slag cements than to OPC. In spite of XRD does not present many peaks, compressive strength of slag cements improves. In most cases, for longer curing cycles and higher temperatures the compressive strength decreases with age. After steam curing, free gypsum and aluminate phases are ready to react to form delayed ettringite, observed by XRD and SEM, which may be the reason for mortar compressive strength loss. Its formation was favored by standard curing after the heat treatment.

DURABILITY PROBLEMS RELATED TO DELAYED ETTRINGITE FORMATION AND /OR ALKALI AGGREGATE REACTIONS

Inger MELAND, Harald JUSTNES, Jan LINDGÅRD, SINTEF Civil and Environmental Engineering, Cement and Concrete and Sverre SMEPLASS, Dept. of Structural Engineering, Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT SEM- examination of concrete - and mortar prisms cured at elevated temperatures and stored in water for 1 - 2 years indicates that their volume expansions and loss of compressive strength may be caused by delayed ettringite formation. Delayed ettringite formation may also be the reason why abundance of ettringite has been observed by thin section analyses of concrete cores taken from dam structures and investigated for alkali aggregate reations, which indicates that the hydration temperature in the structure may have reached about 70° C or more.

Key - words: Expansion, Delayed ettringite formation, Scanning Electron Microscopy

INTRODUCTION

Expansion and degradation of mortars and concretes hydrated at elevated temperatures (≥ 70° C) and subcequently stored under moist conditions have been studied by quite many researchers (Heinz and Ludwig, 1986), (Scrivener and Taylor, 1993), (Hammer et al., 1995), (Beaudoin et al, 1995), (Glasser et al., 1995). It has been shown that the reason for this kind of expansion / degradation is delayed ettringite formation (DEF). Ettringite is voluminous crystals normally formed during the early hydration period between sulphates and calcium aluminate (C_3A) or ferrite (C_4AF) and causes no problem. Contrary, delayed ettringite formation takes place in hardened concrete and is associated with voids and cracks filled with ettringite, particularly around aggregate particles. In recent years the simultanous occurance of alkali aggregate reactions and delayed ettringite formation has been observed and studied (Pettifer and Nixon, 1980), (Shayan and Quick, 1992), (Johansen et al., 1993).

This paper presents data on compressive strength, volume and linear expansions of laboratory concrete cured at elevated temperature and stored under water at 20°C for 2 years. Microstructural appearance and characteristics of secondary ettringite have been studied, using Scanning Electron Microscope (SEM) and Wave Dispersive Analysis of X-rays (WDAX) . It is also shown that addition of silica fume prevents the formation of secondary ettringite (DEF). The possibility of delayed ettringite formation in dam structures showing alkali aggregate reactions is discussed as well.

EXPERIMENTAL.

Materials and Methods

Concretes of normal density were made using Ordinary Portland Cement (OPC) with - and without addition of slilica fume. Chemical analysis and mineral composition of the cement are given in Table 1. Compositions and handling of the mixes investigated are given in Table 2.

Table 1 Chemical composition of OPC (% of cement)

Oxides							Minerals

* Na_2O-ekv.

Table 2 Composition and handling of concrete mixes

Mix no.	w/s	Silica fume % of cem.	$D_{max.}$ (mm)	Cement type	Resting time (h)	Max. temp. (C°)	Test / analysis
1	0,45	0	16	OPC	1,5	20 / 85	Compress. strenght, Linear expansion, Microscope
2	0,40	0	16	OPC	6	20 / 70 / 85	Volume change, Microscope
3	0,40	8	16	OPC	6	85	Volume change, Microscope

From mix no. 1 10 x 10 x 10 cm^3 cubes were cast for compressive strength measurements. From the same mix prisms of 40 x 40 x 160 mm with partly embedded knobs were cast for linear expansion detections. Cylinders with Ø = 100 mm, h = 300 mm were cast from mixes 2 and 3 for measuring volume expansion. Volume expansion was determined according to Archimedes law by weighing the cylinders in air and water. The casting of specimens was performed within 20 - 60 minutes after addition of water. The specimens were placed in temperature controlled water baths within 1 - 2 hours after mixing and precaution were taken against leaching of materials. After a hydration time of 1.5 hour for the specimens of mix 1, and 6 hours for those of mixes 2 and 3, the specimens were cured at elevated temperatures (see Table 2). Temperature was raised 10° C / hour for the specimens of mix 1, and 12° C / hour for the specimens of mixes 2 and 3. At the end of curing period (72 hours) at elevated temperatures the specimens were stored in water of 20° C until testing.

For examination of alkali aggregate reactions in a 50 years old dam, concrete cores were drilled from the dam crest. The samples were investigated by thin section analyses at 3 levels, at both sides and in the middle of the cores.

Microscopical examinations

After being cured at different temperatures and stored in water of 20° C for 1 year, laboratory samples were prepared for microscopical examinations. Slices for macro examination were cut from mix 2 and 3, impregnated with flourescent epoxy, plane polished and studied in ultra-violet light (UV-light). Further, samples from all 3 mixes were impregnated with epoxy, plane polished to a micro level before subjected to investigation by Scanning Electron Microscope (SEM) in Back Scattered Electron - (BSE) and/or Secondary Electron mode (SE) and Wave Dispersive Analysis of X-rays (WDAX).

Test Procedures, SEM / WDAX and thin section analysis

Using Secondary Electron modus (SE) in Scanning Electron Microscope (SEM) gives the opportunity to study the surface topography of a preparation, and in this case to observe cracks on the mortar surfaces. Using Back Scattered Electron modus (BSE) for examination of mortar gives the possibility to distinguish between different phases and their distribution. It is important that the sample is properly plane polished. The backscatter process depends strongly on the average atom number of the sample, sample density and the energy of the primary electrons. Phases with high average atom number and / or samples with a dense structure will have bright colours on a BSE image. On the other hand, phases with low average atom number and samples with porous structures will appear dark.

Together with a SEM-investigation, WDAX diagrams may be recorded. WDAX gives semiquantitative compositions of solids. The principle for the method is based upon the exitement of the electrons of each atom in the sample. When the electrons return to their stable energy level, the atoms in the sample will emit X-rays of a certain energy specific for each chemical element. The results will appear as peaks in a diagram with variation of energy as X-axis. The position (X) determines the element, while the height (Y) of the peaks gives the amount of the spesific elements in the sample. By use of WDAX small volumes ($\approx$ 1 μm^3) of a sample are analysed with respect to chemical composition.

For thin section analysis of the concrete from the dam, samples were cut from the cores, impregnated with flourescent epoxy, ground to a thickness of 20 - 25 μm and examined in polarizing Optical microscope. Alkali reactions and growth of crystals like ettringite can easily be observed by thin section anlysis.

RESULTS AND DISCUSSION

Compressive strength and linear expansion, Mix 1

The compressive strength development and linear expansion of mix 1 cured at 20° C and 85° C are shown on Figures 1 and 2, respectively. The compressive strength has been followed for 1 year, and the result shows a considerable strength reduction between 90 days and 1 year for the concrete exposed to curing temperature 85° C compared to that exposed to a curing temperature of 20° C, which coincides with a pronounced length expansion in the prisms cured at 85° C (Fig. 2). Both linear expansion and loss in strength of mix 1 are assumed to be caused by the elevated curing temperature.

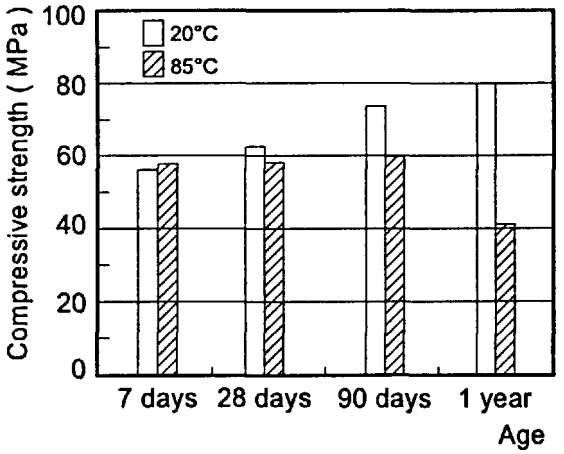

Figure 1 *Compressive strength development, mix no 1, w/s = 0.45, curing temperature 20°C and 85°C*

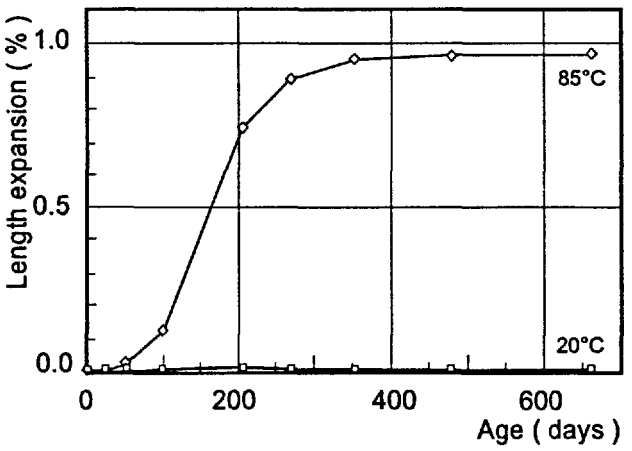

Figure 2 *Length Expansion for mix no 1, w/b = 0.45, P30 cement*

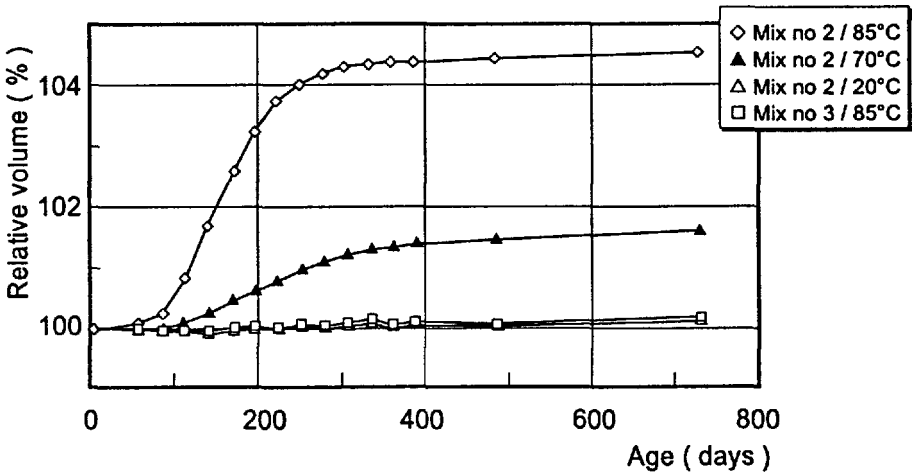

Figure 3 *Relative volume expansion for mixes no 2 and no 3 w/s = 0.4*

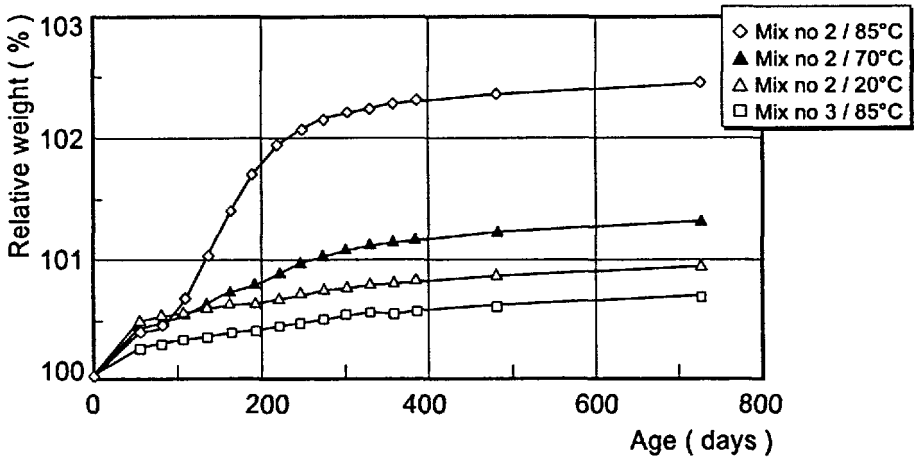

Figure 4 *Relative weight increases for mixes no 2 and no 3*

Volume expansion, Mixes 2 and 3

Volume expansions for samples of mix 2 cured at 20, 70 and 85° C respectively, and for mix 3 with 8 % silica cured at 85° C have been followed for about 2 years. The results as relative changes in volume are shown on Figure 3. When measuring changes in volume, the corresponding changes in weight of the samples were observed, calculated as relative changes in weight as shown on Figure 4. Figure 3 shows an extensive volume increase taking place from 50 days till 1 year for samples of mix 2 cured at 85° C. Also the specimens cured at 70° C showed a significant volume expansion in the same period compared to the samples cured at 20° C. In his experiments Kelham (1996) found 70° C to be a safe curing temperature for the current UK cements. As can be seen from figure 3, our experiments indicate a critical curing temperature < 70° C to avoid DEF. As a matter of fact the Norwegian Standard, NS 3420 claims a curing temperatur ≤ 65° C.

The increase of weight is due to penetration of water (ρ = 1.0 kg/l) and weight increase / unit volume may therefore be compared with the measured volume expansions and give informations as the fraction of cracks are filled with water or water-bearing products. The increases in weight for the samples of mix 2, after 2 years storage in water of 20° C, have been calculated as % of concrete volume and set up in Table 3 together with the results from the measured volume expansion. The results indicate that all cracks may be filled with water / water-bearing products. In addition the samples contain some absorped water due to the porosity of the concrete.

Table 3 Mix no. 2 - weight increase and volume expansion

Curing temperature	85 ° C	70° C	20° C
Weight increase (W / V) %	5.7	2.8	2.2
Volume expansion (V / V) %	4.5	1.2	0.05

Microstructural examinations

The macro examination of fluorescent impregnated cores revealed a normal shrinkage crack pattern for all specimens cured at 20° C. Specimens containing silica fume also showed this micro crack pattern, notwithstanding curing temperature. These cracks, which are due to self desiccation shrinkage, radiating from the aggregates into the matrix could not be observed in samples without silica fume with curing temperatures of 70° C respectively 85° C. Typical for the last mentioned specimens were cracks in the transition zone between aggregate and matrix (i.e. typical for expanding matrix), and the extent of cracks clearly increased by increasing curing temperature. The results from these macro structure examinations were further confirmed by micro structure analyses. On studying the micro structure of the surface of specimen from mix 1 cured at 85°C, using SEM (SE-mode), numerous cracks could be observed in the transition zones. This is shown on Figure 5. SEM (BSE-mode) and microanalyser indicated that these cracks to a large degree were filled with calcium sulpho-aluminate hydrates of the AFt-modification (SO_3 / Al_2O_3 ≈ 2.04), shown on Figure 6. Crystals of the AFt-modification were also observed in the matrix of these samples. Also in samples cured at 70° C the AFt-modification of the sulpho-aluminates could be observed in some cracks. But analyses of sulpho-aluminate crystals found in the matrix of these specimens as well as in the specimens cured at 20° C, and in samples containing silica fume, the ratio SO_3 / Al_2O_3 indicated sulpho-aluminate crystals more like the AFm-modification (SO_3 / Al_2O_3 = 0.75).

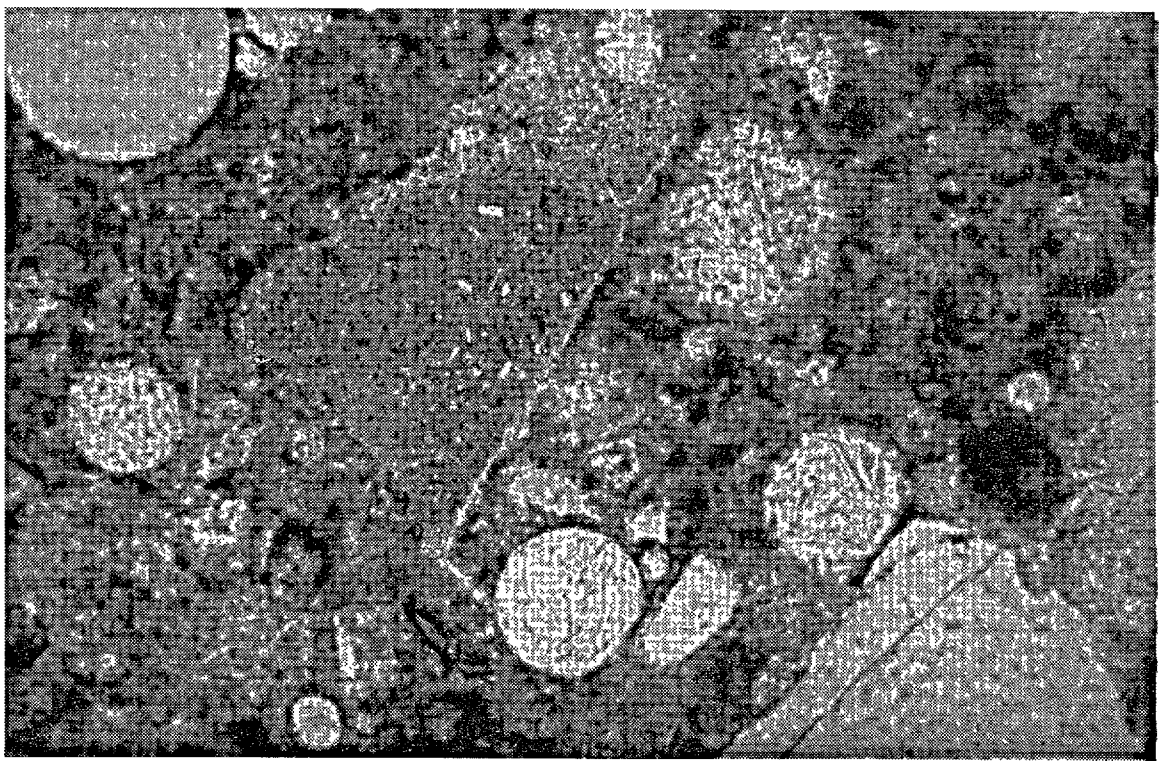

Fig. 7 Alkali-gel and ettringite filled pores in concrete.

The reason why silica fume seems to prevent or postpone DEF is not quite understood. According to Barnes (1983) addition of active silica might accelerate the formation of ettringite and increase the conversion to monosulphate in sulphate-poor systems. This may be the reason why the AFm-modification was observed in the specimen containing silica fume. Glasser et al. (1995) and Kelham (1996) found that increasing of alkali content in the clinker, or alkalis added with the mixing water affected DEF leading to increased expansion of mortar prisms. In addition to a reduced alkali content in silica-substituted cement, the alkalis also react with silica fume, and a reduced alkali content in the pore fluid of silica-blended paste may also be a reason why DEF seems to be overcome by use of silica fume. Whilst Hammer, T. A. et al. (1995) suggested that the lack of DEF in concrete containing silica fume, most likely is due to chemical reactions between aluminate phases and the active silica forming more stable silicon rich aluminate phases (C_3AH_6-C_3AS_3).

Delayed ettringite formation and alkali-aggregate reaction

Many petrographic examinations [Pettifer and Nixon (1980), Shayan and Quick (1992), Johansen et al. (1993)] of thin sections of concrete in which alkali-aggregate reaction is to be expected, also reveal large quantities of ettringite. Simultaneous existence of these two chemical reactions has first and foremost been observed in precast concrete cured at elevated temperatures. In a condition survey of Norwegian dams, concrete cores from several dams were examined for alkali aggregate reactions. The cores refered to in this paper were taken from the crest of the dam. Thin sections analyses of these concrete cores showed alkali-silica gel in specimens taken from the interior of the cores and very often pores in the vicinity of alkali reactive aggregates were quite filled with ettringite crystals as shown on Figure 7. Neither alkali-aggregate reactions nor an abnormal content of ettringite crystals could be observed in samples taken from layers near the exterior sides of the cores. Thus it may be supposed that the abundance of ettringite observed in pores and cracks of these cores, is due to delayed ettringite formation caused by the hydration temperature in the middle of the dam structure. There were no indications that delayed ettringite formation, in this case, had lead to any formation of cracks or similar degradation of the concrete. However, if delayed ettringite formation is observed in concrete damaged by alkali reactive aggregates, it has to be taken into consideration when evaluating the damages.

CONCLUSIONS

* Initial curing temperature at elevated temperatures causes delayed ettringite formation.
* Critical curing temperature in order to avoid DEF is below 70° C.
* High initial curing temperatures give an extensive formation of cracks in the transition zone between aggregate and matrix.
* Addition of silica fume prevents or postpone delayed ettringite formation.
* Sulpho-aluminates observed in concrete cured at elevated temperatures, were of the AFt-modification. Sulpho-aluminates in concrete cured at 20° C and in concrete containing silica fume and cured at any temperatures were of the AFm-modification.
* Delayed ettringite formation may cause linear - and volume expansion and loss in strength.

EXPERIMENTAL SIMULATION OF THE STABILITY OF ETTRINGITE IN ALKALI SILICA SOLUTIONS, PRODUCED BY ALKALI-SILICA REACTION, IN CONCRETE.

V. MICHAUD , LAFARGE CANADA INC., C.T.S., Montreal, Quebec, Canada
A. NONAT, C.N.R.S., Laboratoire de Recherches sur la Reactivité des Solides, Dijon, France
D. SORRENTINO, LAFARGE, Laboratoire Central de Recherche, Saint Quentin Fallavier, France

ABSTRACT Ettringite formation after the setting period of cement is often blamed for generating cracking of concrete. The objective of this study is to determine if the crystallization of secondary ettringite in an hardened paste is promoted while subjected to alkali-silica reaction. Experimentally, the pore solution surrounding the aggregates was simulated by synthetic solutions with various silica and sodium hydroxide concentrations. Ettringite or various proportions of C_3A and gypsum were mixed with these solutions until the system reached the thermodynamic equilibrium state.
The experiments show that hydrated calcium sulphoaluminate phases are not stable in silicate solutions. They all evolve towards the formation of amorphous or semicrystalline phases, depending on the initial composition of the mixtures, including calcium, silicate, aluminate and alkali ions. Their characteristics are similar to A.S.R. products. Sulphate ions are not incorporated in the solid phases. They are available in the pore solution and can migrate towards areas where the silica concentration is low enough to react with calcium and aluminate, and subsequently ettringite crystallizes.

KEY-WORDS : Alkali-silica reaction, secondary ettringite formation, ettringite stability, alkali silicate solution, durability, pH, silicate concentration.

INTRODUCTION

Ettringite and alkali aggregate reaction gel are often simultaneously observed in damaged concrete. The frequent simultaneous occurrence of sulfate and alkali reaction attacks raises the questions : are these two attacks interconnected and can they promote each other.

So far this state is neither known nor wholly understood. The several studies conducted to verify this aspect only provide hypothesis rather than certitudes. Some of them are based on empirical arguments only.
Now, several authors (Brown and Bothe Jr, 1993; Ebied, El-Didamory, Amin and Mosalamy, 1993; French, 1986; Mehta, 1978; Pettifer and Nixon, 1980; Shayan and Quick, 1991/92, 1992) agree and support the suggestion that "sulfate attack" and alkali aggregate may be interconnected. Brown and Bothe Jr (1993), French (1986), Jones and Poole (1987), Shayan and Quick (1991/92) suggested the proposal that ASR creates conditions favouring ettringite formation. Following are the prevailing arguments :

1. According to Jones and Poole (1987), the ettringite nucleation would occur preferentially in the ASR gel and that latter would offer an advantageous growth medium
2. The formation of ASR gel consumes locally alkali and hydroxide ions of the pore solution. This will lower the pH of the solution and subsequently will promote ettringite formation (Brown and Bothe Jr, 1993).
3. The extensive microcracking due to ASR increases the access of moisture to the interior of the concrete promoting ettringite precipitation.

Whereas Pettifer and Nixon (1980), Regourd, Hornain and Poitevin (1981) and Shayan and Quick (1992) have blamed ettringite formation for promoting ASR because it would liberate hydroxide ions in the pore solution.

The aim of this study is to shed some light on this state by examining if alkali reaction may promote secondary ettringite formation.

It is well known that the alkali reaction results from an interaction between reactive silica phases of aggregate particles and the hydroxides ions of the pore solution. That leads to the partial dissolution of the silica. Therefore, the pore solution around an aggregate including reactive silica can be very concentrated in silicate ions. If the hydrated paste is prepared from a cement containing 1% eq. Na_2O, the alkali concentration in the pore solution will be about of 0.7 mol/kg and the silicate concentration may reach locally around the aggregate a value as high as 1.5 mol/kg (Dent Glasser and Kataoka, 1981).
So far, the behaviour of ettringite which would be locally in contact with the pore solution is unknown. The influence of the presence of silicates ions in the pore solution on the stability of ettringite and more generally of the hydrated calcium sulphoaluminate phases has not been examined. This is the purpose of this paper.
The thermodynamic stability of hydrated calcium sulpho-aluminate phases in the system CaO-Al_2O_3-Na_2O-SO_3-SiO_2-H_2O has been experimentally determined.

EXPERIMENTAL CONDITIONS AND METHODS

This study has been conducted using pure phase materials. Either gypsum and C_3A (S.S.B. equal to 330 m^2/g) or ettringite were mixed at 25°C in diluted suspension with sodium silicate solutions. The compositions of the sodium silicate solutions are representative of those of the pore solution in contact with aggregate containing reactive silica when the cement has an equivalent Na_2O level of about 1%. Once the system had reached its thermodynamic equilibrium (4 weeks), the solid and liquid phases were separated by filtering. The solid phases, after being washed with acetone and ether, were analyzed by X.R.D. The calcium, silicates, sodium, aluminate concentrations in the filtrate were measured by atomic absorption spectroscopy, the sulfate ions by turbidimetry with a Hach 300 colorimeter and the hydroxide activity by pH-measurement with a high alkalinity electrode.

The compositions of the alkali silicate solutions used for this study are : $[Na^+]$ = 0.7 mol/kg, $[SiO_2]$ = 0.035, 0.525 and 1.05 mol/kg. They have been chosen using the results of Dent Glasser and Kataoka (1981). In this study and as shown in Fig 1, it was demonstrated that the composition of the pore solution around an aggregate containing reactive silica depends on the quantity of the reactive silica.
The compositions of the solutions used here are similar to those for the mixtures shown with black dots in Fig 1 upon reaching thermodynamic equilibrium.

Different initial gypsum and C_3A quantities and gypsum / C_3A ratios were used. Different ettringite amounts were used as well.

Firstly, we will discuss the evolution of gypsum and C_3A in sodium silicate solution with the average initial silicate concentration (0.525 mol/kg), and later with the low (0.035 mol/kg) and the high (1.05 mol/kg) silicate concentrations. Then the evolution of ettringite in the same solutions will be examined.

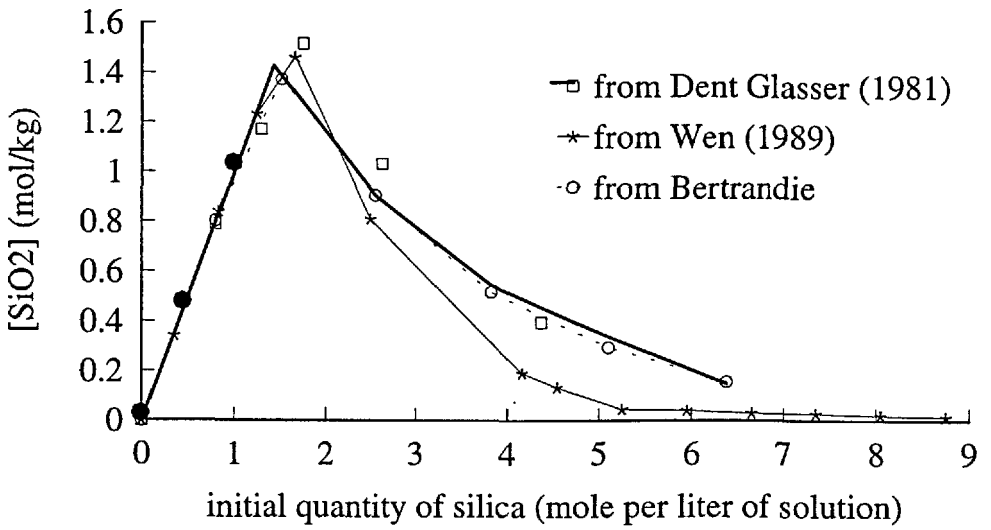

Figure 1 Evolution of the silicate concentration of the solution with the initial quantity of silica per liter of solution once the mixture composed initially of various quantities of silicagel (reactive silica) and a sodium hydroxide solution at 1 mol/kg is at the thermodynamic equilibrium,.
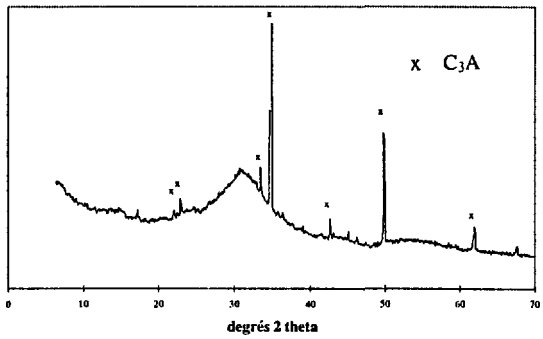
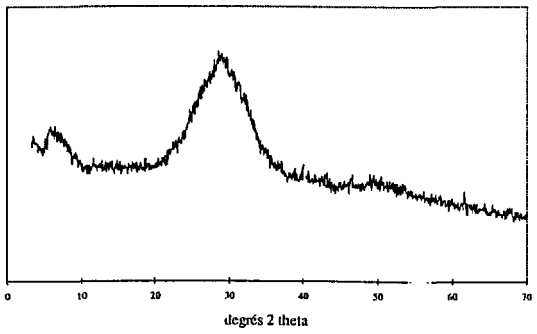
The test solutions have the same composition than the residual solutions of mixtures marked with a black dot.



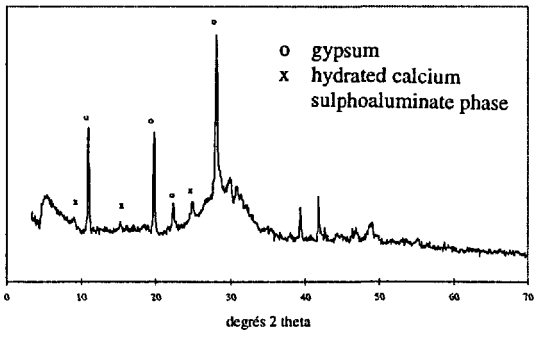
RESULTS AND INTERPRETATION

Evolution of gypsum and C_3A in sodium silicate solutions

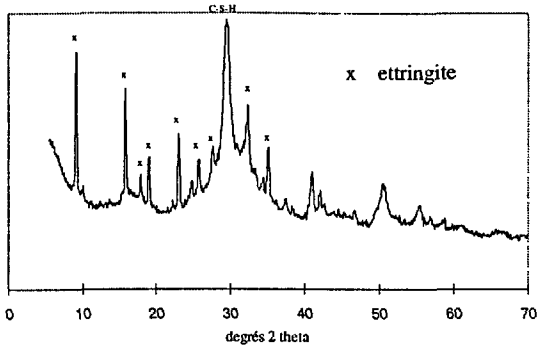


Alkali silicate solution with initially an average silicate concentration (0.525 mol/kg)
The silicate solution was mixed with 0.01 mole per liter of C_3A and different quantities of gypsum varying from 0 to 0.4 mole per liter, also with 0.05 mole per liter of C_3A and 0.30 mole per liter of gypsum.

Ettringite or other hydrated calcium sulphoaluminate phases do not precipitate when the initial quantities of calcium phases are low. It has been confirmed by analyzing the residual solids by X-Ray diffraction and ^{27}Al N.M.R. spectroscopy.
From the X-Ray patterns, presented in Fig 2, only the hydrated calcium sulphoaluminate phase has been detected and in very little amount when 0.01 mole per liter of C_3A was mixed with at least 0.33 mole per liter of gypsum, and when 0.05 mole per liter of C_3A has been mixed with 0.30 mole per liter of gypsum. In this last case, ettringite was detected.
The ^{27}Al N.M.R spectra showed that the aluminate sites are different in ettringite and in the synthesized compounds. In ettringite, and more generally in all of the hydrated calcium sulfoaluminate phases, the aluminium core structure is octahedral and it is mainly tetrahedral in the residual solids.

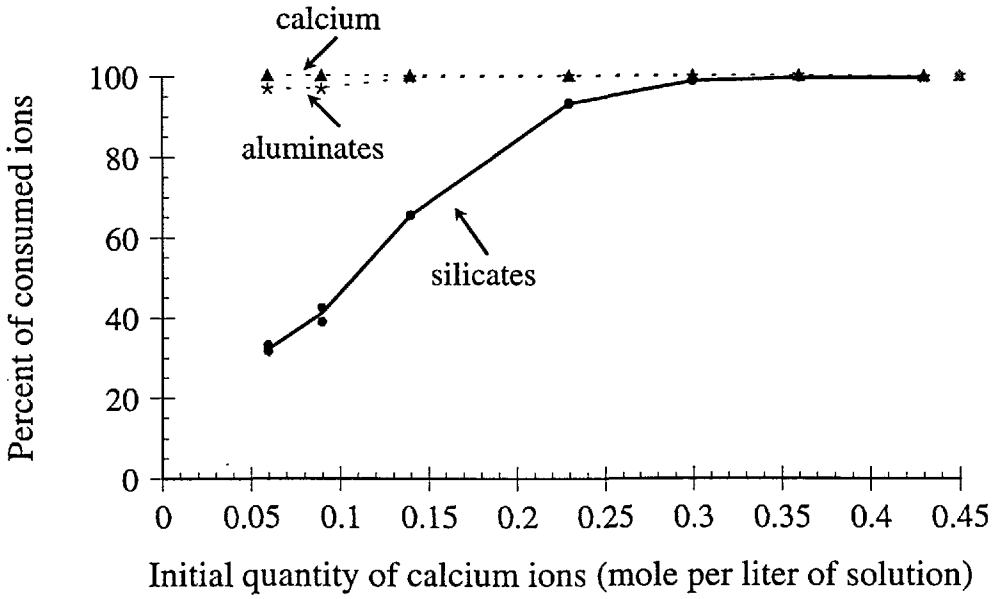


Independent upon the initial mixture, amorphous or semicristalline phases are being precipitated from gypsum, C_3A and the alkali silicate solution.



C_3Ai = 0.01 mole + $CaSO_4i$ = 0.03 mole per liter of solution

C_3Ai = 0.01 mole + $CaSO_4i$ = 0.06 mole per liter of solution



C_3Ai = 0.01 mole + $CaSO_4i$ = 0.33 mole per liter of solution

C_3Ai = 0.05 mole + $CaSO_4i$ = 0.30 mole per liter of solution

Figure 2 X-ray patterns of the solids formed from various quantities of C_3A and gypsum and a sodium silicate solution ($[SiO_2]$=0.525 mol/kg, $[Na^+]$=0.7 mol/kg).

gypsum + C_3A 0.01mole per liter of solution

gypsum 0.30 mole + C_3A 0.05 mole per liter of solution

Figure 3 Proportion of calcium, aluminate and silicate ions present in the initial mixtures incorporated in the final solids. The final solids have been precipitated from various quantities of C_3A and gypsum and a sodium silicate solution ($[SiO_2]$=0.525 mol/kg, $[Na^+]$=0.7 mol/kg).

Analysis of the residual solution shows that the precipitates are composed of calcium, sodium, silicates and aluminate ions, and do not contain any sulphate ion. According to the Fig 3, they incorporate the total calcium and aluminate ions of the initial mixture, and the totality of the silicate ions when the initial quantities of calcium phases are high as well. As long as the initial quantity of calcium ions is below 0.23 mole per liter of solution, the silicates ions are shared between the solid and the liquid phases.

Fig 4 shows a decrease in pH value of the residual solution with the increase in the initial quantities of calcium phases.

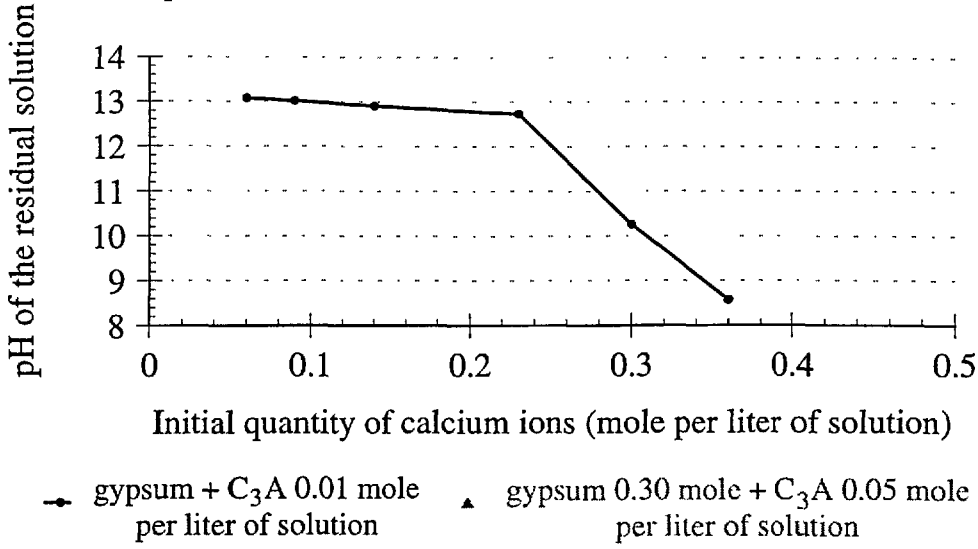


Figure 4 pH in the residual solutions of the mixtures composed initally of various quantities of C_3A and gypsum and a sodium silicate solution ($[SiO_2]$=0.525 mol/kg, $[Na^+]$=0.7 mol/kg), versus the initial quantity of calcium ions.

Residual gypsum is also present only when the initial quantity of gypsum was equal or higher to 0.33 mole per liter.

This shows that gypsum and C_3A are not stable in a sodium silicate solution. Calcium and aluminate ions in solution react preferentially with the silicate ions of the solution to precipitate an amorphous hydrated calcium, silicate, aluminate, sodium reaction compounds which has a structure and a stoechiometry close to those of alkali-reaction products, rather than along with the sulfate ions to form an hydrated calcium sulphoaluminate phase. The sulfate ions do not take part in the formation of the amorphous solid phases. They remain in solution.
Hydrated calcium sulphoaluminates were observed only for mixtures with a high initial amount of calcium phases, that is for the mixtures whose final solution has both a very low final silicate concentration (around 1 mmol/kg) and a low pH value. Mixtures with a low silicate concentration are those for which all of the silicate ions initially present were consumed by the calcium and the aluminate ions to form the amorphous hydrated calcium, sodium, silicate, aluminate reaction compounds.

Therefore, the hydrated calcium sulphoaluminate phases appear to be stable only in solutions with a very low silicate concentration and low pH value. The previous experiments do not permit to determine if rather the silicate concentration or the pH value has the greater influence on the stability of hydrated calcium sulphoaluminate phases. This is the purpose of the next parts.

Alkali silicate solution with initially a high pH (13.7) and a low silicate concentration (0.035 mol/kg)

The silicate solution was mixed with 0.01 mole per liter of C_3A and different quantities of gypsum varying from 0 to 0.2 mole per liter.

The nature of the precipitated phases for the different test mixtures are given in Fig 5.

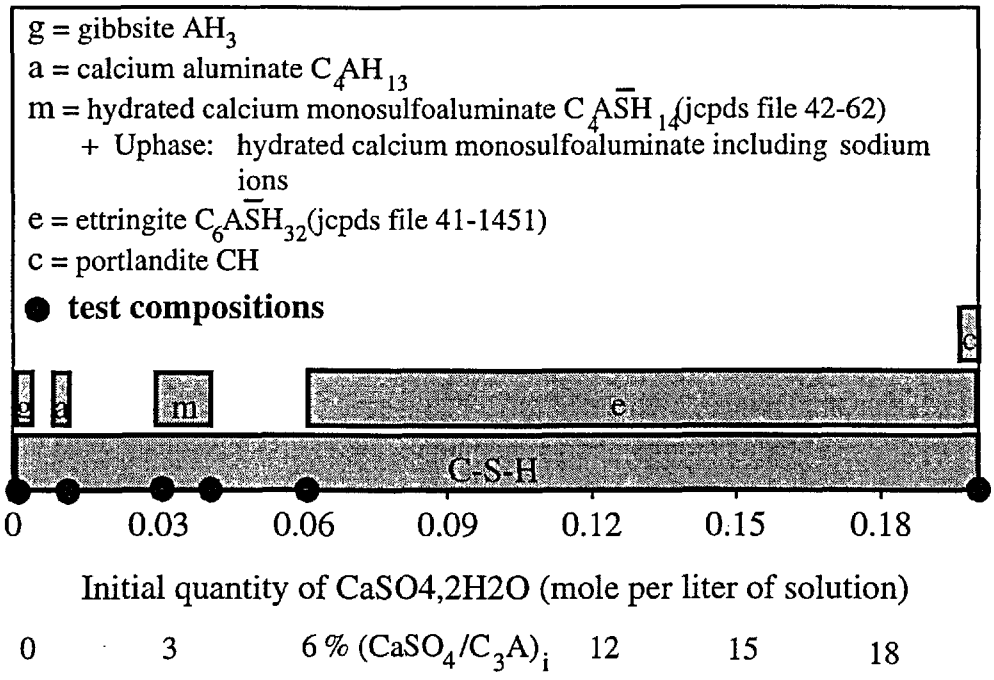

Figure 5 Phases precipitated from the mixtures initially composed of 0.01 mole per liter of C_3A, various quantities of gypsum and a sodium silicate solution ($[SiO_2]$=0.035 mol/kg, $[Na^+]$=0.7 mol/kg), versus the initial quantity of gypsum.

The proportions of silicates, aluminate and calcium ions precipitated from the initial mixtures are shown in Fig 6 and the pH values of the residual solutions in Fig 7.

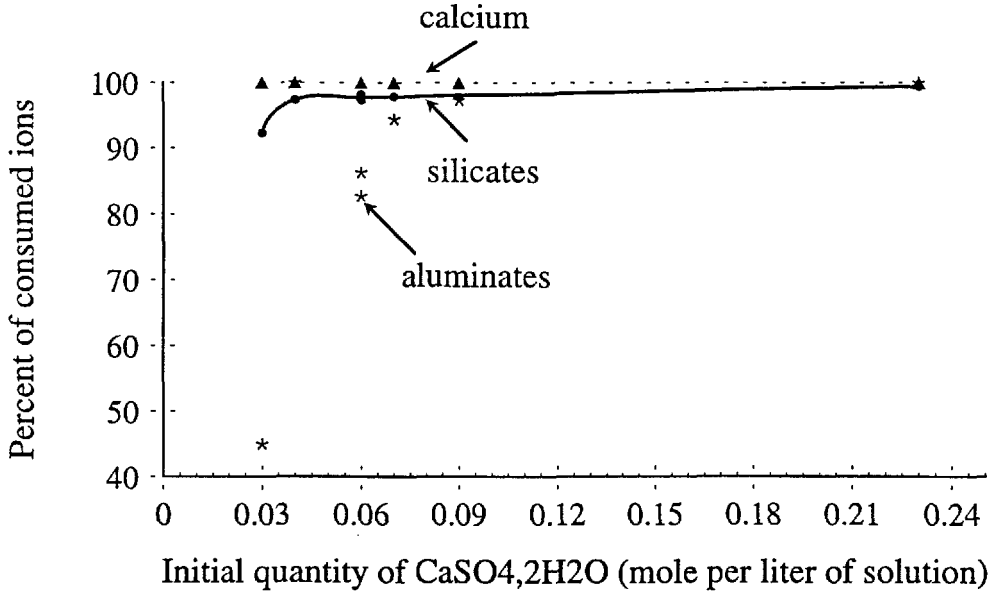

Figure 6 Proportion of calcium, aluminate and silicates ions present in the initial mixtures incorporated in the final solids. The final solids have been precipitated from 0.01 mole per liter of C_3A, various quantities of gypsum and a sodium silicate solution ($[SiO_2]$=0.035 mol/kg, $[Na^+]$=0.7 mol/kg).

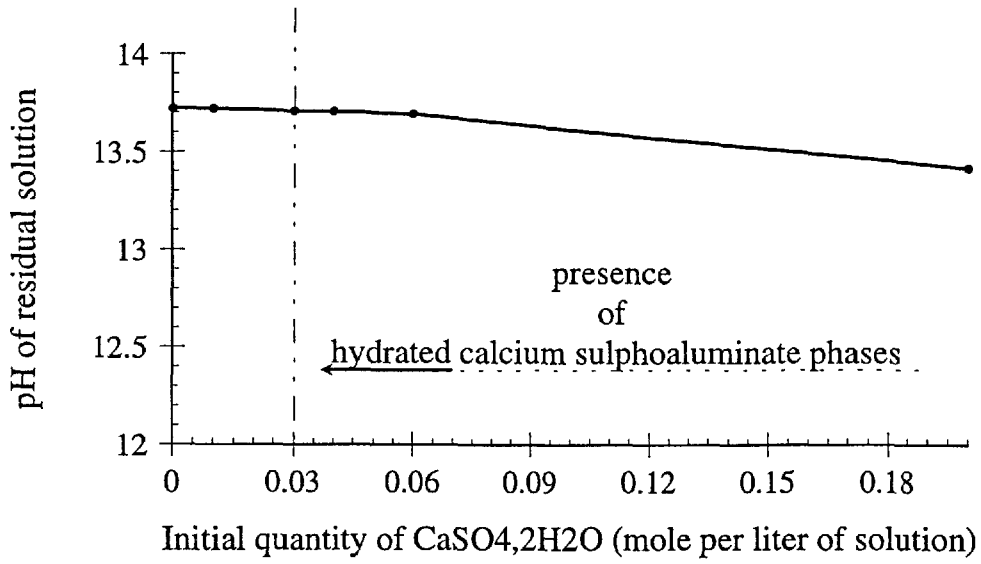

Figure 7 pH evolution in the residual solutions of the mixtures initally composed of 0.01 mole per liter of C_3A, various quantities of gypsum and a sodium silicate solution ($[SiO_2]$=0.035 mol/kg, $[Na^+]$=0.7 mol/kg), versus the initial quantity of gypsum.

As seen before, gypsum and C_3A react preferentially with the sodium silicate solution to precipitate hydrated calcium, silicate, sodium reaction compounds (C-S-H phase in the present case) rather than to form hydrated calcium sulphoaluminate phases. These phases were observed only when all of the silicate ions initially present in the solution were consumed to form C-S-H phase, whereas the pH value of the final solution was equal to 13.7.

Alkali silicate solution with initially a low pH (11.4) and a high silicate concentration (1.05 mol/kg)

The silicate solution was mixed with 0.03 mole per liter of gypsum and 0.01 mole per liter of C_3A. After 4 weeks all C_3A and gypsum have reacted to form only amorphous phases. As before, all the calcium and aluminate ions are incorporated in the final solid. The silicate concentration and pH value of the final solution are equal to 0.74 mol/kg and 11.4 respectively.

These results show that the stability of the hydrated calcium sulphoaluminate phases is governed rather by the silicate concentration of the solution in thermodynamic equilibrium with the solid than by its pH value. Hydrated calcium sulphoaluminate phases are not stable in silicate solution, even when the solution pH value is quite low. Nevertheless, they may be stable at high pH values if the silicate concentration is low.

Evolution of ettringite in sodium silicate solutions

The evolution of ettringite in sodium silicate solutions was studied for two silicate concentrations of 0.035 and 1.05 mol/kg.

Ratio of 0.016 mole and 0.010 mole per liter of ettringite were mixed with these sodium silicate solutions.

For the sodium silicate solution with the lower initial silicate concentration, 97% of the silicate ions initially present in the solution reacted to form a C-S-H phase after 4 months, and residual ettringite was observed. In the second case, all the ettringite had reacted after 7 weeks and the final compositions of both the solid and the solution were similar to those of the mixture with a similar initial composition composed of gypsum and C_3A.

CONCLUSIONS

This study clearly shows that ettringite and more generally hydrated calcium sulphoaluminate phases are not stable in contact with alkali silicate solutions with a silicate concentration higher than very few mmol/l. Therefore, in a concrete with aggregates containing reactive silica, and cement with a high proportion of alkali ions (at least 1% eq. Na_2O), locally, around aggregates which include reactive silica, the solution will be concentrated in silicates ions. If hydrated calcium sulfate, aluminate or sulfoaluminate are in contact with the pore solution concentrated in silicate ions, these phases will be destabilized. The calcium, aluminate and silicates ions will react together to form an amorphous or semicrystalline hydrated calcium, silicate, sodium, eventually aluminate reaction compounds, depending on the initial composition of the mixtures. Their structures and compositions will be similar to those of alkali-reaction products.

These products do not include any sulfate ions. These ions remains available in solution and can diffuse through the pore solution. If locally the silicate ions concentration is low enough and calcium and aluminate ions are available, the ions may react together to form ettringite.

In this way, alkali-silica reaction may promote secondary ettringite formation.

This study also provides indications on ettringite stability in alkaline solution. It shows that ettringite may be stable at high pH values contrary to what is sometimes suggested. Therefore, ettringite formation is not likely to be promoted by alkali silica reaction due to the decrease of the hydroxide ions of the pore solution as suggested by Brown and Bothe Jr. (1993) but the decrease of silicate concentration.

THERMODYNAMIC INVESTIGATION OF THE $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ SYSTEM AT 25°C AND THE INFLUENCE OF Na_2O

Denis DAMIDOT, Department of Chemistry, University of Aberdeen, Scotland.
Frederik P. GLASSER, Department of Chemistry, University of Aberdeen, Scotland

ABSTRACT Phase equilibria in the $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ system at 25°C have been calculated: sixty seven stable solid assemblages coexist with the aqueous phase, nine of which define invariant points. Ettringite and calcium monochloroaluminate hydrate coexist stably and the range of aqueous solution compositions over which they coexist at equilibrium has been defined. Conditions under which calcium monochloroaluminate hydrate transforms into ettringite and vice-versa have been defined. Preliminary calculations of the influence of alkalis on equilibria in the system are presented.

Thermodynamics, Aluminate phase, Phase diagram: $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$, Alkalis.

INTRODUCTION

Cement paste is unstable in contact with saline waters. Many phenomenological investigations report the rate of ingress of chloride and of the mineralogical zonation which results. These studies are valuable qualitative indicators but to progress further, it is desirable to develop and apply thermodynamic methodologies for the study of complex equilibria. These are described and applied in the course of this paper.

Ettringite, $3CaO.Al_2O_3.3CaSO_4.32H_2O$, is a commonly-occurring constituent of cement paste: Its stability domain has been refined by thermodynamic investigation of the $CaO-Al_2O_3-CaSO_4-H_2O$ system with and without alkalis: Damidot and Glasser (1993, a, b). Changes to the stability of ettringite are also expected to occur as a consequence of adding additional soluble constituents to the $CaO-Al_2O_3-CaSO_4-H_2O$ system: for example, chloride. However the behaviour of chloride is more complex than that of alkali. Study of the $CaO-Al_2O_3-CaCl_2-H_2O$ system at 25°C indicates that the calcium monochloroaluminate hydrate, $3CaO.Al_2O_3.CaCl_2.10H_2O$, is a stable phase: Damidot et al (1994). Thus the relative amounts of sulphate and chloride in solution should determine whether ettringite and/or calcium monochloroaluminate hydrate are stable in contact with a permeating solution. Experimental results seem to indicate that three cases can occur: ettringite and monochloroaluminate occur together: Ftikos et al, (1980), monochloroaluminate transforms to ettringite: Zhang et al, (1980) and ettringite is converted to monochloroaluminate: Zhang et al, (1980).

The aim of this study is to define more precisely the boundary conditions in terms of aqueous solution compositions corresponding to these three cases. This is achieved by calculating the equilibrium diagram of the $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ system. This system includes three main sub-systems: $CaO-Al_2O_3-CaSO_4-H_2O$, $CaO-Al_2O_3-CaCl_2-H_2O$ and $CaO-CaSO_4-CaCl_2-H_2O$. The first two have already been reported: Damidot and Glasser (1983), Damidot et al (1994); the third is calculated for this paper. Finally, the modifying role of Na_2O on phase stability is examined.

METHOD OF CALCULATION

The method used is based on the calculation of the stable invariant points of a given chemical system by minimisation of the free energy. For calculations, we use solubilities previously

determined for the $CaO-Al_2O_3-CaSO_4-H_2O$ and $CaO-Al_2O_3-CaCl_2-H_2O$ systems (Table I). For the $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ system, no solid phases exist containing all five components:

Table 1 Calculated composition of the solution in equilibrium with selected solids dissolved in water at 25°C

solids	[Ca] mmol/kg	[Al] mmol/kg	[SO_4] mmol/kg	[Cl] mmol/kg
C_3AH_6	3.711	2.474		
CH	21.95			
AH_3 (gibbsite)		3.25e-6		
ettringite	1.651	0.550	0.826	
gypsum	15.20		15.20	
FS*	6.575	3.287		3.287
3-1-15*	146.10			73.08
1-1-2*	1997.1			2997.1
$CaCl_2.6H_2O$	4000.5			8001.0

*3-1-15=$3CaO.CaCl_2.15H_2O$: 1-1-2=$CaO.CaCl_2.2H_2O$
FS = calcium monochloroaluminate hydrate, or Friedel's salt.

thus no additional phases have to be considered. Each potentially stable phase assemblage is then defined by linear combinations of the solids contained in the system and the composition of the aqueous phase in equilibrium is calculated using a program derived from PHREEQE: Parkhurst et al (1980). Activity coefficients are calculated using Pitzer's relations: Pitzer (1973), Pitzer and Mayorga (1973). The coefficient used in Pitzer's relation for alumina have been taken from Reardon (1990). This program also enables calculation of the saturation index of the solids (the saturation index of phases at equilibrium is equal to 0). If calculation discloses that no solids occur having a positive saturation index, (i.e., the solution is supersaturated with respect to these solids), the phase assemblage thus defined is stable. Once all the stable invariant assemblages have been defined, phase assemblages with $F \neq O$ but having fewer solid phases than the maximum, are determined by a simple linear combination of the solids defining each invariant point. If the dimension of the system is less than 5, it is practicable to represent the results graphically: a schematic phase diagram can be drawn simply by linking the related invariant points by straight lines. The position of the boundaries thus sketched is not precise, but this simplified phase diagram contains much of the same information as one which has been completely calculated.
The pH of a cement paste is unlikely to be less than 7, so, to simplify the presentation, we have not considered low pH regions. As a consequence, the phase diagram relevant to cement can be shown diagramatically.

RESULT OF CALCULATIONS

The $CaO-CaSO_4-CaCl_2-H_2O$ system at 25°C

The $CaO-CaSO_4-CaCl_2-H_2O$ system has five solids stable at 25°C: $Ca(OH)_2$ (CH), $3CaO.CaCl_2.15H_2O$ (3-1-15), $CaO.CaCl_2.2H_2O$ (1-1-2), $CaCl_2.6H_2O$ and gypsum ($CaSO_4.2H_2O$). The phase diagram (Fig 1), contains three invariant points at 25°C:

- CH + $3CaO.CaCl_2.15H_2O$ + gypsum + aqueous phase
- $3CaO.CaCl_2.15H_2O$ + $CaO.CaCl_2.2H_2O$ + gypsum + aqueous phase

- $CaO.CaCl_2.2H_2O + CaCl_2.6H_2O$ + gypsum + aqueous phase

Solution compositions at these invariant points are given in Table 2. Phases containing essential chloride appear at high aqueous chloride concentrations; note that $3CaO.CaCl_2.15H_2O$ appears only at [Cl] > 3.25 mol/kg. On the other hand, the sulphate concentration in equilibrium with gypsum is considerably reduced by the presence of chloride, typically by more than one order of magnitude, i.e., gypsum solubility decreases as [Cl] increases

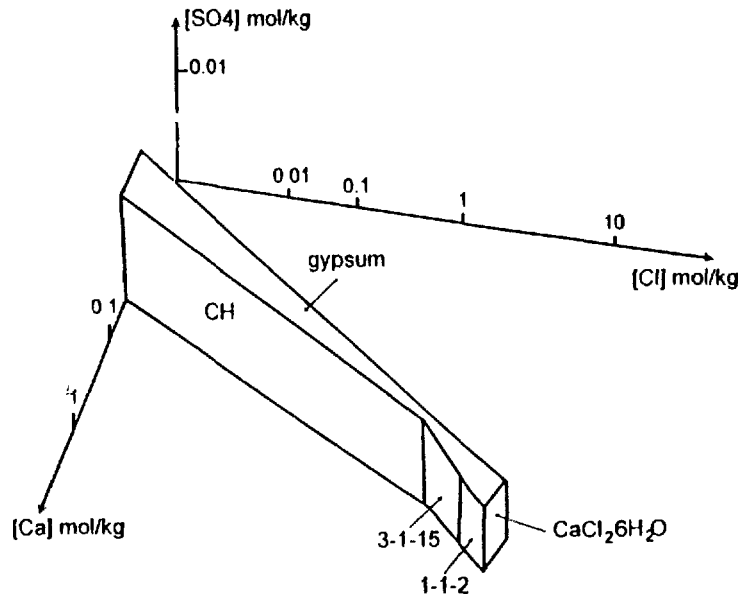

Figure.1.Three dimensional representation of the $CaO-CaSO_4-CaCl_2-H_2O$ system at 25°C. A non-linear graduation, fifth root of the concentration, is used for this and following figures.

Table 2. Calculated compositions or invariant points in the $CaO-CaSO_4-CaCl_2-H_2O$ system at 25°C

Solids in equilibrium with aqueous phase	[Ca] mol/kg	[SO_4] mol/kg	[Cl] mol/kg
CH + 3-1-15	1.641	-	3.220
3-1-15 + 1-1-2	3.248	-	6.424

1-1-2 + $CaCl_2.6H_2O$ + gypsum	4.025	7.14E-4	8.015

$CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ system at 25°C

From a knowledge of the sub-systems $CaO-Al_2O_3-CaSO_4-H_2O$, $CaO-Al_2O_3-CaCl_2-H_2O$ and $CaO-CaSO_4-CaCl_2-H_2O$ and the experimentally-determined absence of additional solid phases, the number of stable solids can be determined as nine: CH, AH_3 (crystalline, gibbsite), C_3AH_6,

gypsum, ettringite, $3CaO.CaCl_2.15H_2O$ (3-1-15), $CaO.CaCl_2.2H_2O$ (1-1-2), $CaCl_2.6H_2O$ and calcium monochloroaluminate hydrate (or Friedel's salt, abbreviated FS). As explained previously during investigation of the $CaO-Al_2O_3-CaCl_2-H_2O$ system, chlorine-ettringite is not stable at 25°C (3). Quaternary hydrates containing all the constituents of the system have been reported (10): solid solutions between calcium monochloroaluminate hydrate and calcium monosulfoaluminate ($3CaO.Al_2O_3.CaSO_4.14H_2O$) exist. The maximum substitution is equal to ~50%: $3CaO.Al_2O_3.0.5CaSO_4.0.5CaCl_2.yH_2O$. The evolution of the value of the solubility product of calcium monochloroaluminate hydrate as a function of chloride: sulphate ratio can be assessed using the approach developed by Tardy and Fritz (11) in which the end members of the solid solution are used, in which case the expression of its solubility product,
for $X\ SO_4$ ($X \leq 0.5$), is:
$\log K_{FS+X\,SO4} = (1-X) \log K_{FS} + X \log K_{monoS} + X \log X + (1-X) \log (1-X)$
where "monoS" is monosulfoaluminate.
At X=0.5, the variation of the value of log K for calcium monochloroaluminate is equal to -0.82. As a consequence, calcium monochloroaluminate partially substituted by sulphate is slightly more stable than FS itself. The modification of the log K value when calculating the phase diagram is, however, within limits of error and solid solutions have not been taken into account in calculations reported in this paper.

The results of the calculation indicate the presence of nine stable invariant points (Table 3). From the solids coexisting at the invariant points, it is possible to determine all the stable phase assemblages of lower dimensionality; 25 stable assemblages of 3 solids and 24 stable assemblages of 2 solids coexist in equilibrium with an aqueous phase:

ett., gyps.: ettringite & gypsum

A geometric representation of the system is difficult if water is in excess due to its dimensionality of four. It is however possible to decrease the dimensionality of the system by fixing the concentration of one or more constituents. If, for example, the chloride concentration

is kept constant, the dimensionality of the system at constant temperature is reduced to three and projections can be drawn of selected isopleths. Fig. 2 shows the isopleth at 0.2mol/kg at which AH_3, CH, gypsum, ettringite and calcium monochloroaluminate hydrate are stable in contact with solution. Ettringite and calcium monochloroaluminate are in equilibrium along a range of aqueous compositions corresponding to the boundary curve defining their equilibrium surface. Compared to the $CaO-Al_2O_3-CaSO_4-H_2O$ system, crystallisation of C_3AH_6 is suppressed; it reacts at the invariant point: CH + C_3AH_6 + FS + ettringite + aq, for which [Cl]= 9.58E-3 mol/kg.

Table 3. 25°C invariant solution compositions for in the $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ system.

Solids in equilibrium with aqueous phase	[Ca] mol/kg	[Al] mol/kg	[SO_4] mol/kg	[Cl] mol/kg	pH
CH , C_3AH_6 , FS , ettringite	2.59E-2	7.18E-6	7.29E-6	9.58E-3	12.50
AH_3 , C_3AH_6 , FS , ettringite	1.05E-2	2.79E-4	8.21E-6	1.18E-2	11.86

1-1-2 , gypsum , $CaCl_2.6H_2O$, FS	4.025	4.7E-11	7.14E-4	8.015	10.73

Ettringite is stable over a wider range of sulphate concentrations compared to calcium monochloroaluminate hydrate. However, higher chloride concentrations increase the stability domain of calcium monochloroaluminate relative to ettringite, as shown in Fig. 3, for the isopleth at [Cl]=4.5mol/kg. In this case, CH is no longer stable in contact with an aqueous phase and is replaced by $3CaO.CaCl_2.15H_2O$. Relative to the previous isopleth, the saturation surfaces are progressively shifted towards higher calcium concentrations as the chloride concentration increases: this is necessary to maintain electroneutrality of the solution, with its high solubility for both OH^- and chloride. This chloride concentration - 4.5mol/kg - is close to the invariant point: 3-1-15, gypsum, FS, ettringite, aq and is the highest chloride concentration at which ettringite is stable. Experimentally, the chloride content of ettringite at this point is negligible.

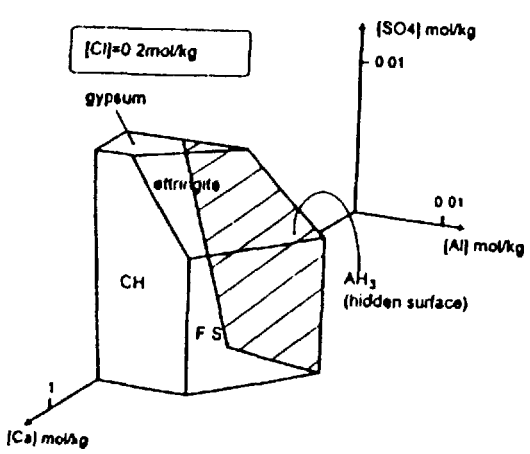

FIG.2 Three dimensional representation of the $CaO-Al_2O_3CaSO_4-CaSO_4-H_2O$ system at 25°C: [Cl] = 0.2mol/kg.

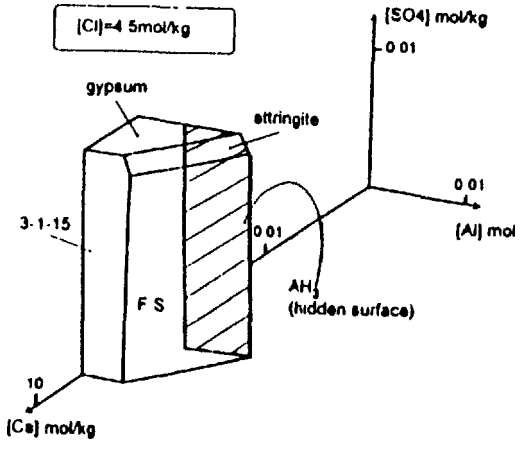

FIG.3 Three dimensional representation of the $CaO-Al_2O_3CaSO_4-CaSO_4-H_2O$ system at 25°C with Cl fixed at 4.5mol/kg.

DISCUSSION OF THE RESULTS

Ettringite and calcium monochloroaluminate domains of stability

The system of nine solids contains 67 stable assemblage coexisting with an aqueous phase: 24 assemblages of 2 solids, 25 assemblages of 3 solids and 9 assemblages of 4 solids (invariant points). This complex pattern of stable coexistence may explain the scatter of the experimental results and apparently contradictory conclusions reached in the literature: most previous studies describe only portions of the system. Contrariwise, phase assemblages that are not included here must be unstable; the calculations confirm the results of experiments cited in the introduction: ettringite and calcium monochloroaluminate hydrate can form a stable pair of solids and, depending on the relative sulphate to chloride ratio in the aqueous phase, either ettringite can be transformed into calcium monochloroaluminate or vice-versa. The region of coexistence of these two hydrates depends on the chloride and sulphate concentrations in solution. Geometrically, the region is a surface that is defined by two boundaries: the first starts from the invariant point: CH, C_3AH_6, FS, ettringite, aq, follows the boundary curve: CH, ettringite, FS, aq, passes through the invariant point: CH, 3-1-15, FS, ettringite, aq, thereafter following the boundary curve: 3-1-15, ettringite, FS, aq and terminates at the invariant point: 3-1-15, gypsum, FS, ettringite, aq. The second boundary also starts from the invariant point: CH, C_3AH_6, FS, ettringite, aq and follows the boundary curve: C_3AH_6, ettringite, FS, aq, passing: AH_3, C_3AH_6, FS, ettringite, aq, follows the boundary curve: AH_3, ettringite, FS, aq, passes through: AH_3, gypsum, FS, ettringite, aq, follows the boundary curve: gypsum, ettringite, FS, aq, eventually terminating at the same invariant point as the first boundary. The two boundaries appear to be close in projection on the sulphate-chloride plane (Fig.4) but a phase transformation requires uptake or release of anions, so the system is buffered with respect to change and the boundaries, although closely spaced on a $\sqrt[5]{}$ scale, have real physical significance.

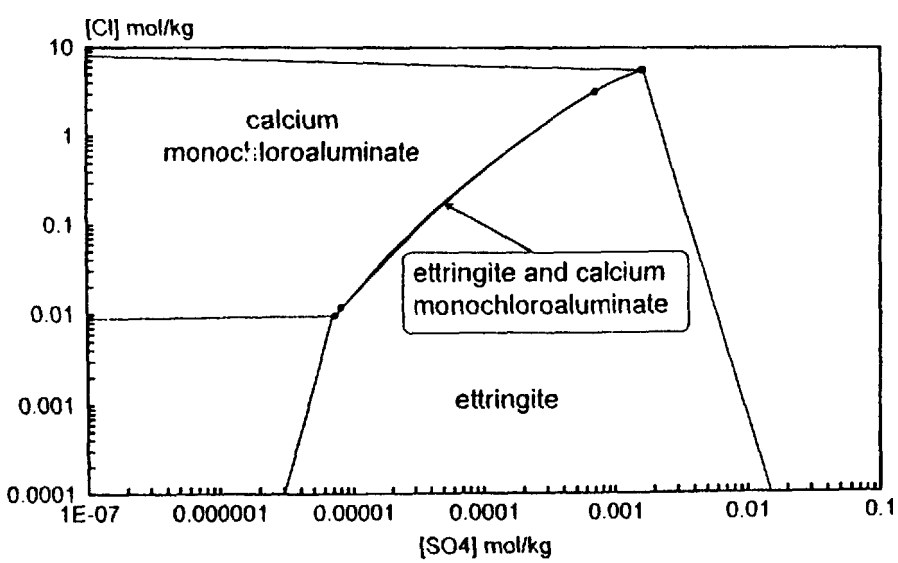

FIG.4 Stability fields of ettringite and monochloroaluminate projected onto the sulfate-chloride plane: temperature = 25°C.

Compared to the $CaO-Al_2O_3-CaSO_4-H_2O$ system, high aqueous chloride concentrations stabilise ettringite to lower pH: as low as pH=9.5, compared with a minimum of 10.5 in the system $CaO-Al_2O_3-CaSO_4-H_2O$.

Evolution of the System with Added Na_2O: The $CaO-Al_2O_3-CaSO_4-CaCl_2-Na_2O-H_2O$ System

Readily soluble constituents added to the system modify the equilibrium domains but, at low concentrations, do not generate additional stable solids. Since sodium is commonly encountered as the charge balancing soluble cation for chloride and sulphate, parts of the $CaO-Al_2O_3-CaSO_4-CaCl_2-Na_2O-H_2O$ system have been calculated. Although NaCl is formally the component added, i.e., [Na] = [Cl], the two components react differently with cement substance: Na is weakly removed while Cl reacts more strongly with aluminates, forming Friedel's salt. As a consequence, and to help predict mineral zonation, Na and Cl contents have to be treated as independent variables. With increasing sodium concentration, NaCl is the first sodium-containing solid to become stable at the invariant point: gypsum, NaCl, FS, $CaCl_2.6H_2O$ 1:1:2: aq. Aqueous concentrations at this point, are [Na] = 1.014mol/kg, [Cl] = 8.4mol/kg, $[SO_4]$=7.7E-4 mol/kg, [Ca]=3.704mol/lkg and [Al]=5E-11mol/kg. With increasing sodium concentrations, the region of NaCl crystallisation expands and NaCl precipitates at progressively lower chloride concentrations. The other sodium-containing phases, $Na_2SO_4.10H_2O$ (mirabilite), Na_2SO_4 and NaOH, are calculated to be stable only at high sodium concentrations, beyond the limits of our confidence in ionic strength corrections.

As a consequence, at sodium concentrations lower than 1mol/kg, solid phase formation in the $CaO-Al_2O_3-CaSO_4-CaCl_2-Na_2O-H_2O$ system is comparable with the $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ system previously described: phases containing essential sodium are not stable. But the addition of sodium modifies the location of the phase regions; a decrease in calcium concentration occurs but aluminate, chloride and sulphate concentrations increase: the evolution of chloride and sulfate concentrations of the assemblage: CH, C_3AH_6, ettringite, FS., aq. is shown in Fig. 5 as a function of added sodium. As sodium increases, saline solutions have to be progressively more concentrated in sulfate and chloride in order to stabilise ettringite or/and calcium monochloroaluminate hydrate.

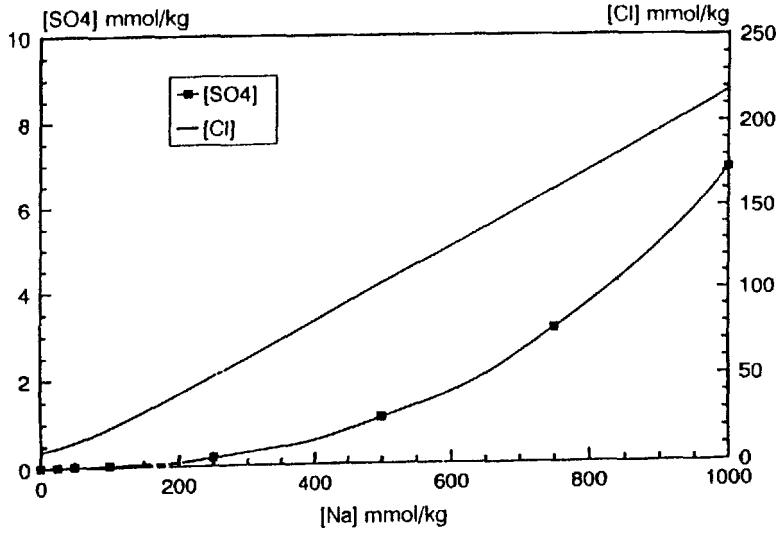

Figure.5.Evolution of the sulfate and chloride concentration at the invariant point CH, C_3AH_6,, ettringite, calcium monchloroaluminate hydrate (Friedel's salt), aq. as a function of the concentration of added Na^+: temperature = 25°C.

CONCLUSION

The calculation of the $CaO-Al_2O_3-CaSO_4-CaCl_2-H_2O$ system at 25°C has demonstrated the ability and power of computational thermodynamics applied to aqueous cement systems . The stability domains of ettringite and calcium monochloroaluminate hydrate have been defined. Ettringite and calcium monochloroaluminate hydrate are in equilibrium with solutions having compositions starting at the invariant point: CH, C_3AH_6, ettringite, calcium monochloroaluminate hydrate, aq. and extending to the invariant point: $3CaO.CaCl_2.15H_2O$, gypsum, ettringite, calcium monochloroaluminate hydrate, aq. In the presence of sodium, more chloride and sulphate must dissolve in order to stabilise calcium monochloroaluminate hydrate and ettringite. The phase equilibria thus determined can be applied flexibly to a wide range of problems of mineral stability and cement deterioration in aggressive chemical environments. The data tables and diagrams presented are often sufficient for qualitative calculations but recourse to the computer-based routines may be necessary for more quantitative approaches.

ABSTRACT A parametric study on concrete cubes prepared from the cement of known chemical,mineralogical and physical characteristics and fired to various temperature regimes has been carried out using DTA/TGA and XRD, to correlate the effect of temperature on changes occurring in the mineralogical composition of cement hydration products and the compressive strength.Such a correlation can be used to determine fire conditions and the consequent expected deterioration in compressive strength of the damaged concrete.

Key-words: Calcium hydroxide,Fire damage,High temperature,Curing

INTRODUCTION

Harmathy (1968) demonstrated the use of differential thermogravimatric technique for gauging the temperature to which concrete could have been exposed during the fire.Raina et al (1978) and Handoo and Agarwal (1993) reported the application of DTA/TGA technique for assessing fire damaged concretes.A number of specific case studies on rehabilitation of fire damaged concrete buildings have been carried out by National Council for Cement and Building Materials (NCB) (1987 ,1993). However , no systematic study has so far been reported to simulate the conditions of temperatures generally experienced in concrete structures exposed to high temperatures such as an accidental fire and to correlate with the physico-chemical and mineralogical characteristics of the damaged concrete with the extent of damages.

EXPERIMENTATION

Concrete grade M-20,with cube compressive strength of 20 N/mm^2 at 28 days was designed as per Indian standard IS:10262-1982 using standard aggregates and OPC having performance characterictics as listed in Table 1.The concrete cubes of 100 mm size were prepared and cured under water at ambient conditions for 28 days.Each set of three cured cubes was dried in air and exposed to temperature regimes upto 1000^{o}C in the steps of 100^{o}C in a hot air

Table 1 PHYSICAL CHARACTERITICS OF ORDINARY PORTLAND CEMENT

Comp.stregth (N/mm^2)	36	37	36	36	35	32	16	15	13	10	nil

oven/muffle furnace for a constant retention period of 5 hours.The fired cubes after cooling to ambient temperature were immerersed in water for 48 hours before testing for compressive strength.The change in average compressive strength of three cubes with temperature is given in Table 2. The DTA/TGA and XRD studies were carried out on the mortar part of the cubes drawn at areas representing the exposed surface and the core at the depth of 50mm,using simultaneous Mettler Thermo analyser TA 1 and Rigaku's X-ray diffractometer with $CoK\alpha$ radiation.

RESULTS AND DISCUSSIONS

The average compressive strength of concrete cubes after curing in water for 28 days was found to be 36 N/mm^2.The concrete cubes exposed to a temperature regime for a constant period of 5 hours have negligible effect on their compresssive strength upto 400^oC. The concrete suffered a significant loss of strength,nearly 45 percent in the temperature range of 400^o to 600^oC due to the loss of crystal water resulting in decrease in $Ca(OH)_2$ content besides due to the changes in the morphology and microcracks formations.The concrete cubes showed distinct distress beyond 800^oC. Similar pattern of reduction in strength of concrete specimens has also been reported by Orchard (1979) and Neville (1995).

DTA/TGA study on the mortar samples drawn depthwise representing the surface and the core indicated that concrete at surface suffered more damage compared to the core at all temperatures (Fig 1a).The change in $Ca(OH)_2$ content determined by corresponding TG loss in mortar samples of the fired concrete cubes reveals that at 700^oC it is reduced to 80 percent of its content at ambient temperature.Beyond 700^oC,$Ca(OH)_2$ was not detected by DTA in the exposed surface samples of the concrete.The rate of dehydration in the core at the depth 50 mm of the cubes was rather slow due to a temperature gradient from the surface. Consequently the residual $Ca(OH)_2$ in the core samples of the cubes fired upto 900^oC was still found to be 13.2 percent of its content at ambient temperature.

XRD studies on the matured concrete cubes have shown the presence of normal hydrated phases such as ettringite,calcium silicate hydrates, $Ca(OH)_2$, $Mg(OH)_2$ in few cases and $CaCO_3$. The diffractograms of exposed surface and core of the fired cubes (Fig 1b) confirm the change in mineralogy and gradual reduction in $Ca(OH)_2$ content with increase in temperature as evaluated by DTA/TGA as well.

The decrease in the $Ca(OH)_2$ content in the core as well as the exposed surface of the concrete cubes with the increase in temperature has been correlated with the decrease in the compressive strength. This correlation (Fig 2) can possibly be

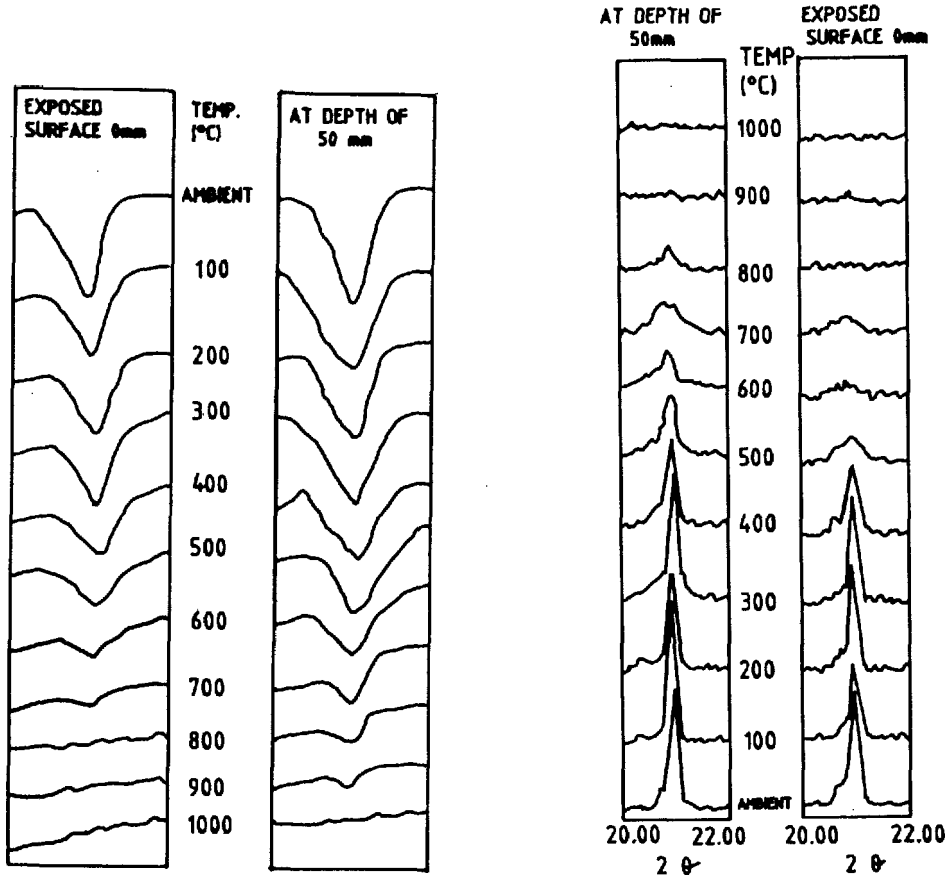

Figure 1 : (a) DTA Curves showing the dehydration of $Ca(OH)_2$ and corresponding XRD patterns (b)

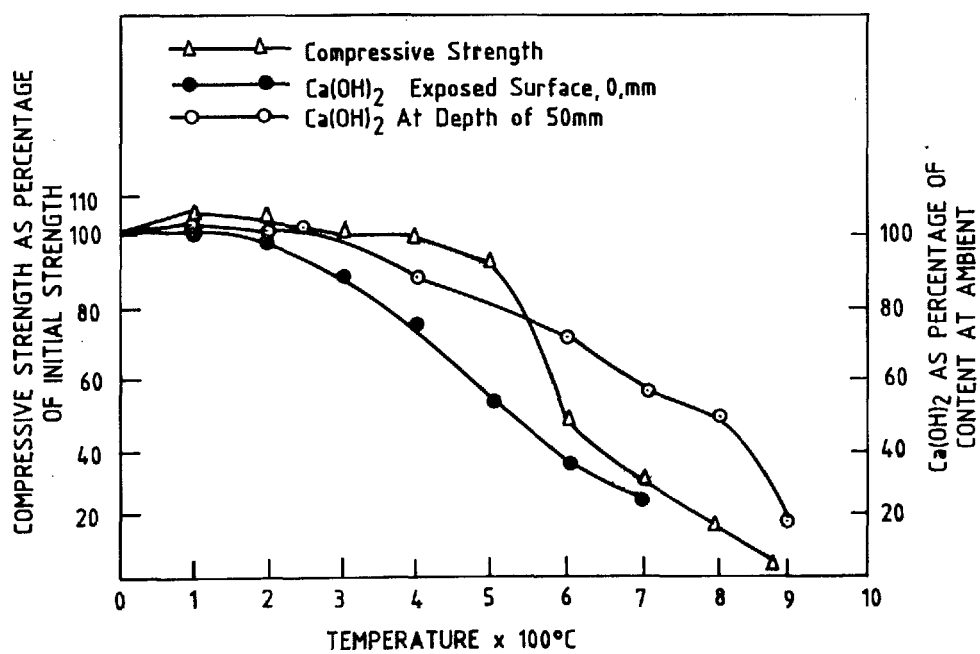

Figure 2 : Variation of change in compressive strength and $Ca(OH)_2$ content in concrete cubes with temperature

used for determining the temperature to which a concrete has got exposed to and consequent reduction in its compressive strength during the exposure to temperatures like in accidental fire. This data can provide information for making the recommendations for possible rehabilitation of the damaged concrete structure.Further studies are being carried out to establish the reliability of the correlation vis-a-vis the actual deterioration in concrete.A large number of investigations on the extent of fire damage in the structures have been carried out at NCB and the application of these techniques for assessing the extent of damage have proved useful.

CONCLUSIONS

1. The effect of temperature on the compressive strength of concrete cubes is negligible upto 400°C.Subseqnently there is a rapid fall in the strength of the cubes fired upto 600°C after which the rate of loss of strength becomes lower.

2. The content of $Ca(OH)_2$ in the concrete is reduced in a definite pattern with the increase in temperature.At 700°C, it is reduced to 80 percent of its content at ambient temperature under the conditions of the experiment.

3. The correlation derived between simultaneous reduction in compressive strength and content of $Ca(OH)_2$ in the concrete with increasing temperature can be used to predict qualitatively the temperature to which a concrete has got exposed during the fire.

MICROSTRUCTURAL CHANGE OF CALCIUM SULPHOALUMINATE CEMENT PASTE DUE TO TEMPERATURE

Choon-Keun PARK, Byung-Kwon KIM, Sung-Yoon HONG, Gyoo-Youn SHIN and Hee-Kap OH
Research Center of Ssangyong Cement Ind. Co., Taejon 305-345, Republic of Korea

ABSTRACT

Ettringite formed from C_4A_3S and/or calcium sulphoaluminate cement loses water in its structure when heat was applied. The ettringite changes to amorphous phase at greater than 120°C, even though the framework of ettringite texture still remains at above 400°C. The amorphous calcium sulphoaluminate phase decomposes above 600°C, forming C_4A_3S, $CaSO_4$ and CaO. The dehydration causes changes in microstructure and specific surface area of ettringite.

INTRODUCTION

Calcium sulphoaluminate cement (hereafter CSA cement), comprising calcium sulphoaluminate, calcium silicate and calcium sulphate, has many desirable properties, such as high early strength development, less drying shrinkage, good durability etc. Calcium sulphoaluminate mineral, C_4A_3S ($4CaO \cdot 3Al_2O_3 \cdot SO_3$), reacts with water and forms ettringite at an early hydration stage. The ettringite, $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31\text{-}32H_2O$, causes high early strength development and expansion of hardened structure.

Many researches have been conducted to produce the C_4A_3S and explore its properties.

Teoreanu and Georgescu (1988) studied the C_4A_3S - $CaSO_4$ - CaO - H_2O system and suggested that the hydration rate of C_4A_3S would depend on concentrations of Ca^{++}, SO_4^{--} and chemically bonded water in the calcium sulpoaluminate hydrate also would vary with these ion concentrations. The ettringite structure has also been reported that combined water molecules are dependent on environmental conditions, such as $Ca(OH)_2$, $CaSO_4$ atmosphere by Bannai and Nakakawa(1968). They suggested that the ettringite would be similar to zeolitic structure. The ettringite contains zeolitic water in the channel of column of its structure and the zeolitic water is evaporable(Moore and Taylor, 1970). The status of water plays an important role to develop physicomechanical properties and durability of the hardened cement structure.

In this paper, calcium sulphoaluminate mineral and calcium sulpho-aluminate cement containing calcium sulphoaluminate, calcium silicate, calcium aluminoferrite and calcium sulphate were hydrated, and status of water and microstructural change of hydrates due to temperature up to 1000 °C were investigated.

EXPERIMENTAL

Materials

The calcium sulphoaluminate mineral was prepared with molar mixes corresponding to C_4A_3S using pure grade chemicals, $CaCO_3$, Al_2O_3 and $CaSO_4$. The mixes were sintered at 1280 °C for 3 hours and the sintered specimens were ascertained to be composed of C_4A_3S by using the XRD method. The CSA cement comprising 60% C_4A_3S, 18% C_2S, 6% C_4AF and 16% $CaSO_4$, was synthesized at 1300 °C for 3 hours.

Specimen preparation and experiment

Pure ettringite was prepared with molar mixes corresponding to $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O$ using synthesized C_4A_3S, pure grade CaO, $CaSO_4$ and water as shown equation (1) in the later Ettringite part. Specimens were prepared at W/C=0.4 and cured at 20°C in a constant humidity cabinet with R.H 90% for characterizing properties. The status of water in specimens was analyzed using a weight loss by heat treatment method and DT-TGA. Hydrates and heat treated specimens were examined by means of XRD, BET, and SEM for investigating structural change.

RESULTS AND DISCUSSION

Hydration

Figure 1 shows the XRD patterns of hydrated specimens made with CSA cement as a function of curing time. The main reactant, C_4A_3S, decreases with the curing time and remains as an unhydrated form until 28 days even though the intensity of the XRD peak as much decreased, compared with the early hydration time. At an early hydration time C_4A_3S would be reacted with Ca^{++}, SO_4^{--} in aqueous solution, resulting in forming ettringite (AFt), since Ca^{++} and SO_4^{--} are abundant around C_4A_3S particles, and monosulphate (AFm) is identified after 3 days.

Figure 2 presents results of DT-TGA of specimens hydrated for 7 days. Ettringite which was prepared with C_4A_3S, $CaSO_4$, CaO and water shows one big endothermic peak around 130 °C and another very broad endothermic peak around 270 °C. But CSA cement hydrate specimen give three distinguished endothermic peaks, around 130 °C, 200 °C and 270 °C. The first endothermic peak is attributed to decomposition of ettringite, and the second endothermic peak is associated with decomposition of ettringite and calcium monosulphate hydrate, and the last endothermic peak is due to the decomposition of OH^- group from the framework of ettringite and monosulphate hydrate (Bannai et al., 1968; El-Didamony, 1980).

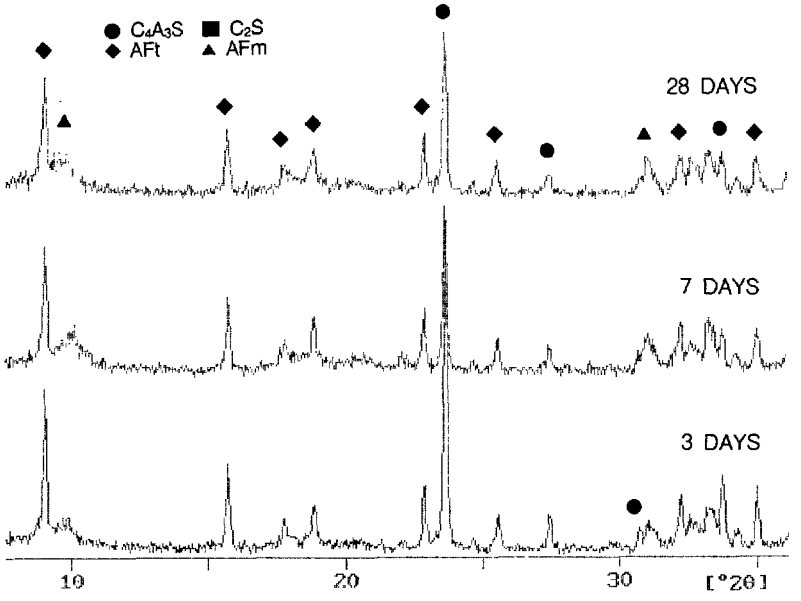

Figure 1. XRD patterns of CSA cement hydrates as a function of curing time. AFt : Ettringite, AFm : Monosulphate

Ettringite

When calcium ion and sulfur ion present in solution, the C_4A_3S reacts with these ions to form ettringite. In the study, the C4A3S was hydrated as follows.

$$4CaO{\cdot}3Al_2O_3{\cdot}SO_3+8CaSO_4+6CaO+96H_2O \text{ in aq. } \longrightarrow 3[3CaO{\cdot}Al_2O_3{\cdot}3CaSO_4{\cdot}32H_2O] \quad \text{--- (1)}$$

Moore and Taylor (1970) suggested the structure of ettringite as shown in Figure 3. Ettringite has the formula $\{Ca_6[Al(OH)_6]_2{\cdot}24H_2O\}{\cdot}3(SO_4){\cdot}2H_2O$, the columns $\{Ca_6[Al(OH)_6]_2{\cdot}24H_2O\}^{6+}$ are based on $[Al(OH)_6]^{3-}$ octahedral running along c axis, each $[Al(OH)_6]^{3-}$ linked to each of its neighbors through three Ca ions which are eight-coordinated by four H_2O molecules and four OH^- groups. There are two H_2O molecules and three SO_4 in the channels of the $[Al(OH)_6]^{3-}$ columns (Wang et al., 1986). Table 2 shows the weight loss and d value for (10·0) plane of hexagonal ettringite due to dehydration. The ettringite loses its combined H_2O molecules rapidly until 100 °C, and then gradually until 270 °C. The combined H_2O molecules were almost decomposed at about 600 °C.

Table 1. Weight loss and change of d value of ettringite as a function of temperature applied to heat.

Items	Trapped water	Temperature (°C) 20	40	60	80	100	110
Wt. loss	4.1	-	3.1	10.6	14.7	26.7	31.1
Combined H_2O mole		31.7	28.6	20.3	16.9	8.7	6.3
Ettringite d value* (A°)		9.7102	9.7131	9.7313	9.7488	9.7588	9.7708

Items	Temperature (°C) 120	190	230	270	400	600	800	1000
Wt. loss	35.0	37.9	39.9	41.9	43.5	44.1	45.0	45.1
Combined H_2O mole	4.3	3.0	2.1	1.3	0.6	0.4	-	-

* hkil = (10·0)

Decomposition of combined H_2O molecules causes the structural change of ettringite texture. The d value of hexagonal structure of ettringite increases until 110 °C. The parameter a of hexagonal crystal increases from 9.71 A° to 9.77 A° as the combined H_2O molecules decompose from 31.7 to 6.3. At temperature greater than 120 °C the ettringite crystal changes to an amorphous phase. The change of ettringite structure which had been characterized by XRD method was given in Figure 4. The dehydration of ettringite causes characteristic XRD peak position shift to low angle (refer to the change of d value in Table 2). This result is accounted that the framework of ettringite changes with dehydration. At 120 °C or higher temperature the characteristic peak of ettringite completely disappeared even though calcium sulphoaluminate hydrate still contain little amount of water in the structure. The remained water seems to be water of octahedral $[Al(OH)_6]^{3-}$ differently from the decomposed water below 120 °C. As the temperature increases greater than 600 °C no portlandite is identified and the amorphous calcium sulphoaluminate start decomposing, and begins to form $CaSO_4$. At temperature greater than 800 °C the amorphous phase of dehydrated calcium sulphoaluminate vigorously decomposes, so that $CaSO_4$, CaO and C_4A_3S, which are start materials in this system, increase quantitatively.

When the combined H_2O molecules decomposes, change of specific surface area of ettringite accompanied. The change of specific surface area in ettringite as a function of temperature

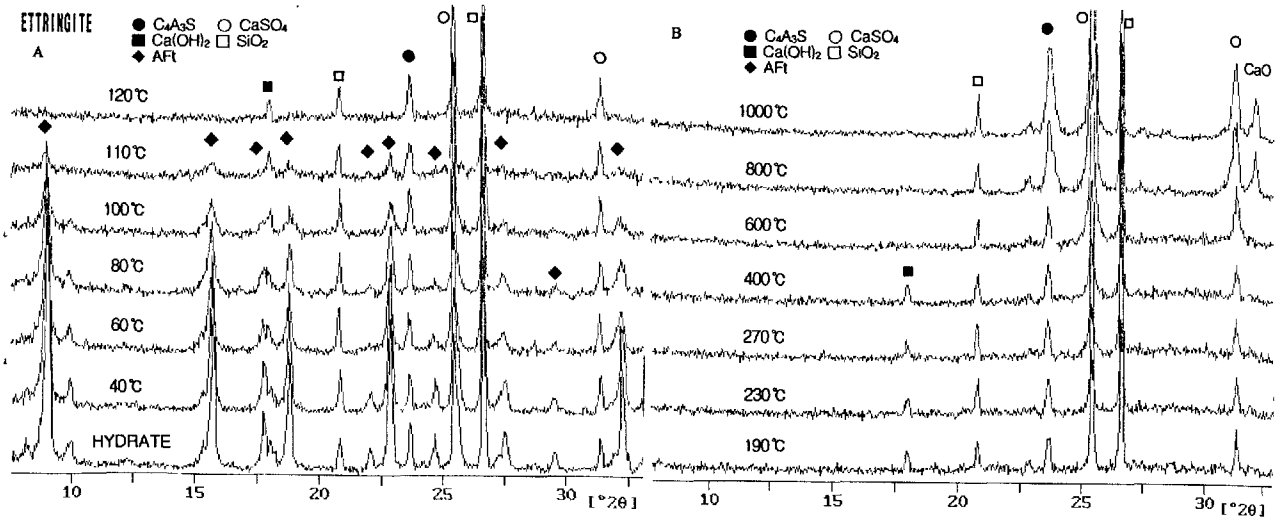

Figure 4. X-ray diffraction patterns of ettringite as a function of temperature applied to heat. A : XRD patterns from room temperature to 120 °C, B : XRD patterns from 190 °C to 1000 °C. AFt = Ettringite

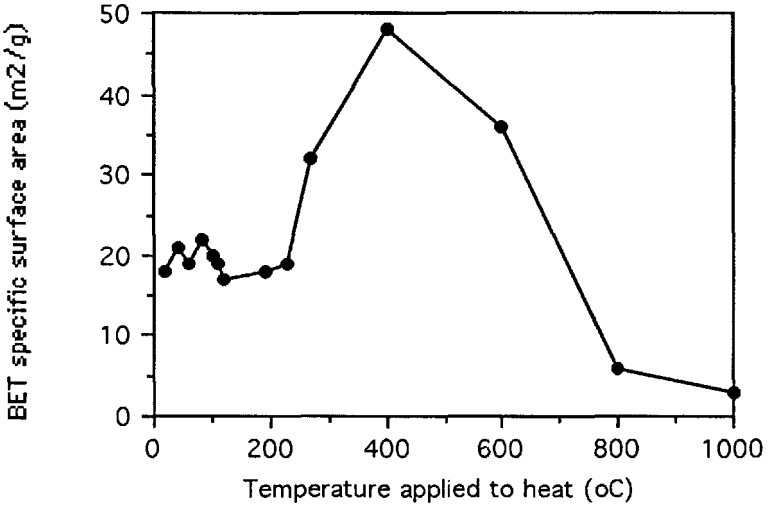

Figure 5. Specific surface area of ettringite as a function of temperature applied to heat measured BET method using N_2 gas.

measured by BET using N_2 gas is given Figure 5. BET specific surface area slightly increases until 100 °C and then decreases about 18 m^2/g until about 200 °C. At greater than 200 °C the BET specific surface area abruptly increases and presents maximum value at 400 °C. And then, the BET specific surface area value decreases steeply to 1000 °C which shows minimum BET specific surface value. The result agrees well with the result of weight loss in ettringite structure. That is, when combined water in the channels and columns between octahedral $[Al(OH)_6]^{3-}$ decompose no big structural change occurred [$2H_2O$ and $24H_2O$, respectively in the ettringite formula $\{Ca_6[Al(OH)_6]_2 \cdot 24H_2O\} \cdot 3(SO_4) \cdot 2H_2O]$, but decomposition of the OH^- group of the base framework $[Al(OH)_6]^{3-}$ causes microstructure change.

Figure 6 shows the microstructure change of ettringite due to dehydration observed by scanning electron microscope. The pure ettringite is a long needlelike crystal at room temperature, but the long axis become short as the temperature increased to 80 °C. No big shape change of dehydrates occur until 190 °C, but the radius and length are more shorten at about 400 °C. Therefore, it seems that the number of short needlelike particle and the amount of micropore to be maximized at

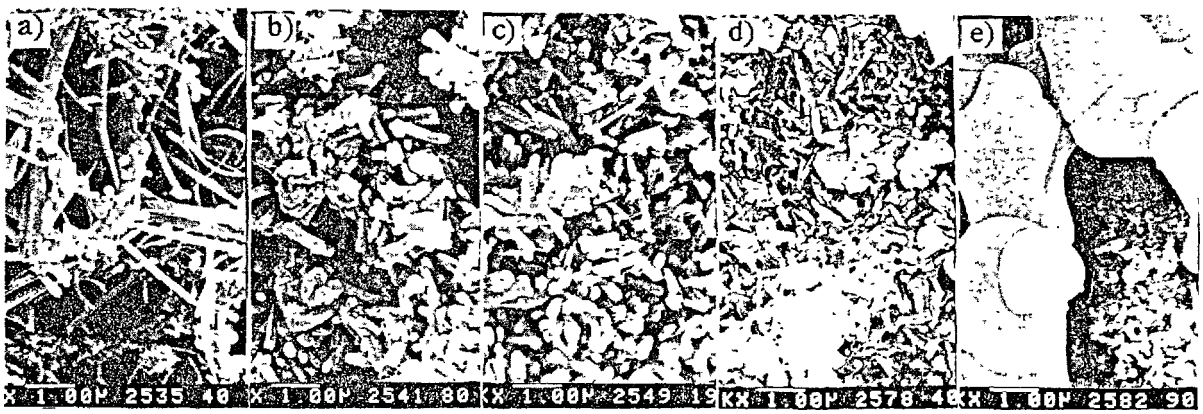

Figure 6. SEM photographs of ettringite paste as a function of temperature applied to heat
a) 40 °C b) 80 °C c) 190 °C d) 400 °C e) 900 °C

about 400 °C. As the temperature increases needlelike texture collapse. At 900°C, sintered grains observed,which are grown to few micrometers. These results related to the trend of BET specific surface area changes.

Cement hydrate

Figure 7 shows the weight loss and BET specific surface area as a function of temperature for the calcium sulphoaluminate cement paste. The trend is similar to that of ettringite. The water decomposes abruptly until 270 °C and then gradually to 1000 °C.
The decomposition of water in the cement paste causes microstructure change, resulting in showing different BET specific surface area as shown in Figure 7(B).

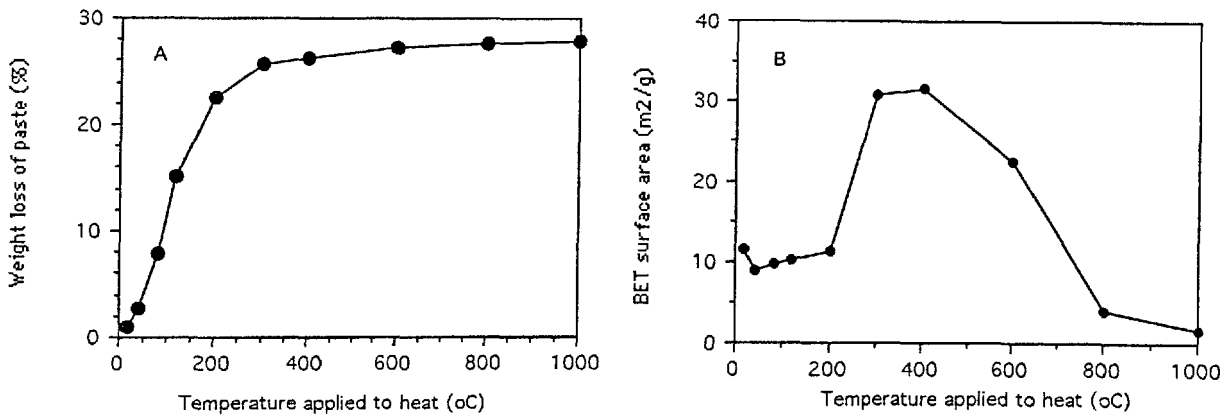

Figure 7. Weight loss and BET specific area of CSA cement paste cured for 7 days as a function of temperature. (A: Weight loss, B: BET specific surface area)

Figure 8 shows the XRD patterns of cement pastes hydrated for 7 days as a function of temperature. The trend of decomposition of cement paste is similar to that of ettringite. The ettringite formed in this system is considered as a solid solution of ettringite since the d value of XRD characteristic peak (10·0) is 9.748 A°, compared with d = 9.710 A° of pure ettringite as shown in Table 2. The ettringite decomposes H_2O molecule with increasing temperature, resulting in changing its structure from hexagonal crystal to amorphous phase. The ettringite, main hydrate of cement paste, appears at less than 120 °C. At greater than 120 °C no crystalline ettringite is noted even though calcium sulphoaluminate hydrate still contains little amount of water in the structure. When the remained water decomposes at high temperature, the BET specific surface area increases because the decomposition of water offer more spaces which small size N_2

gas can enter into. In this system, monosulphate hydrate is identified, and unidentified phase is noted at around d=8.0 A° in the specimens heated at 80 °C and 120 °C. This unidentified phase, which seems to be modified calcium sulphoaluminate hydrate with 7~10 mole H_2O formed from monosulphate (Turriziani, 1964), appears and increases its intensity of XRD peak as ettringite and monosulphate hydrate decrease. As the temperature increases greater than 600 °C the calcium sulphate forms due to the decomposition of calcium sulphoaluminate hydrate. At greater than 800°C the increases in quantity. This sintering process decreases BET specific surface area.

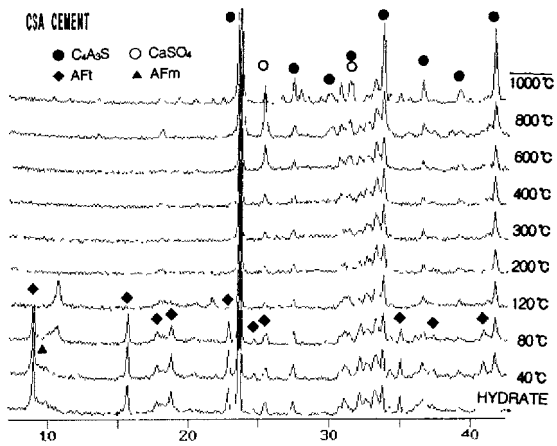

Figure 8. XRD patterns of CSA cement hydrates as a function of temperature applied to heat.

SUMMARY AND CONCLUSIONS

1. The ettringite formed from the C_4A_3S-CaO-$CaSO_4$-H_2O system contains 31.7 combined H_2O moles. The combined H_2O moles are decomposed from the structure of ettringite with increasing temperature.

2. When decomposition occurs, the water bound in the channel and column between octahedral $[Al(OH)_6]^{3-}$ dehydrates first, and then the OH- group of the base $[Al(OH)_6]^{3-}$ framework dehydrates. Furthermore, the ettringite changes its structure from crystal to amorphous phase at greater than 120 °C.

3. The amorphous phase of calcium sulphoaluminate hydrate decomposes at greater than 600 °C, resulting in forming CaO and $CaSO_4$. At 800 °C C_4A_3S forms from ingredients which were decomposed of calcium sulphoaluminate hydrates.

4. The dehydration causes change the specific surface area of ettringite. The BET specific surface area slightly changes until 200 °C, and then abruptly increases to 400 °C. At greater than 400 °C the BET specific surface area decreases.

EFFECT OF TEMPERATURE ON CHLORIDE INGRESS AND CHLORIDE BINDING IN HARDENED CEMENT PASTE

Claus K. LARSEN, Norwegian Road Research Laboratory, Oslo, Norway
Josef TRITTHART, TVFA, University of Technology, Graz, Austria

ABSTRACT: Pure and blended cement pastes were stored in chloride solutions at 5, 20 and 40°C for up to 100 days. Chloride ingress and chloride binding decreased as the temperature increased from 5 to 20°C. The effects were reversed from 20 to 40°C. The observed effects were most likely complex interactions between temperature, degree of hydration and microstructure. Silica fume decreased chloride ingress and binding.

Key-words: Chloride Binding, Pore solution, Temperature, Silica fume

INTRODUCTION

Chloride initiated reinforcement corrosion is the predominant form of concrete deterioration in most highway bridges. Chloride sources are usually sea spray or de-icing salt. In cold climates where de-icing salts are used, concrete is in many cases exposed to chlorides only at low temperatures. This is the case, for instance, in Central Europe. In coastal areas, concrete can be exposed to chlorides at relatively high temperatures during summer. In the Scandinavian countries, with both cold winters and warm summers, concrete along the coast is exposed to chlorides at both low and high temperatures. Due to solar radiation temperatures on the concrete surface can be relatively high. Most of the research work on chloride ingress and binding is, however, done at room temperature.

The present work is a collaboration between the Norwegian Road Research Laboratory in Oslo and TVFA at TU-Graz in Austria. The reason for this collaboration is partly based on different opinions regarding the effect of silica fume upon chloride binding in blended cements (Byfors, Hansson and Tritthart, 1986; Page and Vennesland, 1983).

EXPERIMENTAL

Cement

Two types of cement were used, one Austrian and one Norwegian. The Austrian cement EZ375 is a normal OPC while the Norwegian HS65 is a high strength low alkali OPC. They are both commonly used in their respective countries. Cement composition is shown in Table 1.

Table 1 Cement composition, in %

	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	K_2O	Na_2O	SO_3	$L.o.i.$

HS65	21.41	5.57	3.34	0.35	63.27	1.40	0.79	0.33	2.8	0.98
"Bouge" composition	C_3S	C_2S	C_3A	C_4AF						
EZ375	57.2	12.5	8.2	8.7	Calculated values					
HS65	44.6	27.7	9.1	10.2	Calculated values					

Silica fume

Silica fume (SF) from Elkem AS in Norway was used. The chemical composition of the SF is not exactly known, but on average it contains 95% SiO_2 and 2% C. Surface area as measured by N_2-sorption was 16.3 m^2/g.

Sample preparation

The cement pastes were prepared using a high-speed mixer (8000 rps), to ensure a complete dispersion of cement and SF. Codes for the pastes used are listed in Table 2. SF dosage, when used, was 10% of binder weight as cement replacement. All pastes had a water binder ratio (w/b) of 0.60. After mixing for four minutes, small plastic bottles (100 ml, Ø50 mm) were filled and rotated at room temperature for 24 hours to prevent segregation. Half of the samples were then wet-cut in 5 mm thin discs and without drying immersed in the storing solutions. The second half were stored at 21°C for 27 more days prior to cutting and immersion.

At each exposure temperature; 5±0.2, 20±1 and 40±2 °C; two different chloride solutions were used. Soft chloride-free tap water and NaCl were used to make the solutions that had chloride concentrations of 18 and 54 g/l. The discs were placed on racks with a spacing of 10 mm, to ensure that each disc was surrounded with an adequate amount of chloride solution. The volume of solution in each container was about seven times greater than the paste volume. All storing solutions were stirred from time to time to ensure an even chloride concentration within the container. Chloride concentrations in the solutions were checked regularly and found to be sufficiently constant.

Sets of two discs made up the test samples. One disc was used for pore solution expression, the other one for total chloride determination. All discs were removed from the storing solution just before testing. They were kept wet in a plastic bag and, immediately before testing, all excess solution was wiped off using a clean wet cloth.

Pore solution expression

To determine chloride concentrations in the pore solution of the pastes, the pore solution was expressed. The technique described by Tritthart (1991) was used. The disc to be tested was broken in about 1 cm big pieces and put into the test cylinder, with as little contact with the air as possible. Each disc "produced" about 1.5 ml pore solution, which was collected in small glass or plastic containers, and sealed with a cap. Chloride concentrations were determined using automatic potentiometric titration with 0.01M $AgNO_3$. This was done the same day the pore solution was expressed.

Total chloride determination

The discs were dried at 105°C for one day. They were then ground to a fine powder, passing 9μm sieve, to ensure a total decomposition in the heated concentrated acetic acid. Chloride concentration was determined using the procedure mentioned in the section above. Parallel control tests were made using nitric acid to check that the acetic acid was able to decompose the paste powder completely. All tests showed that there were practically no differences. Acetic acid was preferred because nitric acid sometimes caused difficulties in the titration. The reasons for this are not known.

XRD and electron microprobe analysis

The discs investigated with XRD and electron microprobe were taken from their respective solutions after 37 days of storage. After drying over Silica-gel ("blue gel") in vacuum for two days, the XRD samples were ground and sieved (9 μm).

The samples for EDXA were cut to ensure a plain clean surface for the investigation. To prevent the chlorides from being washed out during cutting, no cooling water was used. All samples were then dried over P_2O_5 in vacuum at room temperature for two more days before investigation. XRD scans were performed using the Cu-anode, a count time of 2.0 seconds per step, a step size of 0.02° and scanning from 5 to 42° (2θ). A Philips SEM 505 electron microscope and the EDAX-DX4 (ultrathin window) X-ray spectrometer was used for the electron microprobe analysis. The samples were coated with a thin layer of carbon and count-time was 100 seconds.

Chloride profiles through the discs were determined by scanning along lines, four mm long and one μm wide, parallel to one of the exposed surfaces, as shown in Fig 1. The outer scan was approximately 0.05 mm from the one exposed surface, with the following scans in 0.5 mm steps into the center of the disc. It was assumed that the chloride profile would be symmetrical around the center line, leaving half the profile unexamined. In three cases the whole profile was examined, with the conclusion that this assumption was correct.

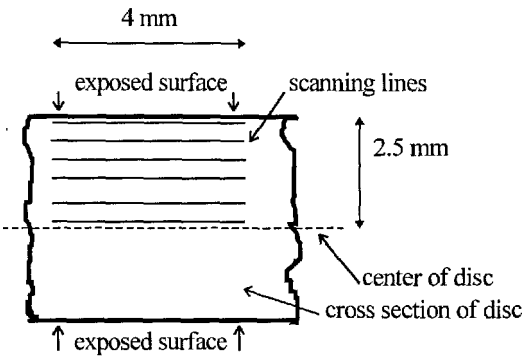

Figure 1 Setup for chloride profile

RESULTS AND DISCUSSION

"State of equilibrium"

When considering the inaccuracy of the microprobe analysis, four of the seven investigated discs had gentle chloride profiles (Fig 2). This indicates that the chloride ingress was more or less homogeneous through these discs. The two PA- pastes and one of the PN- pastes (20°C, 1d), however, had a steeper gradient. The "state of equilibrium," that is the difference between chloride content at the surface and in the center of the disc, is therefore questionable in these three discs. It must be pointed out that these investigations were done on samples exposed for 37 days. It is therefore likely that the pastes after exposure for 100 days, even for the PA- samples, will be close to equilibrium, in the sense of practically no chloride gradient through the disc.

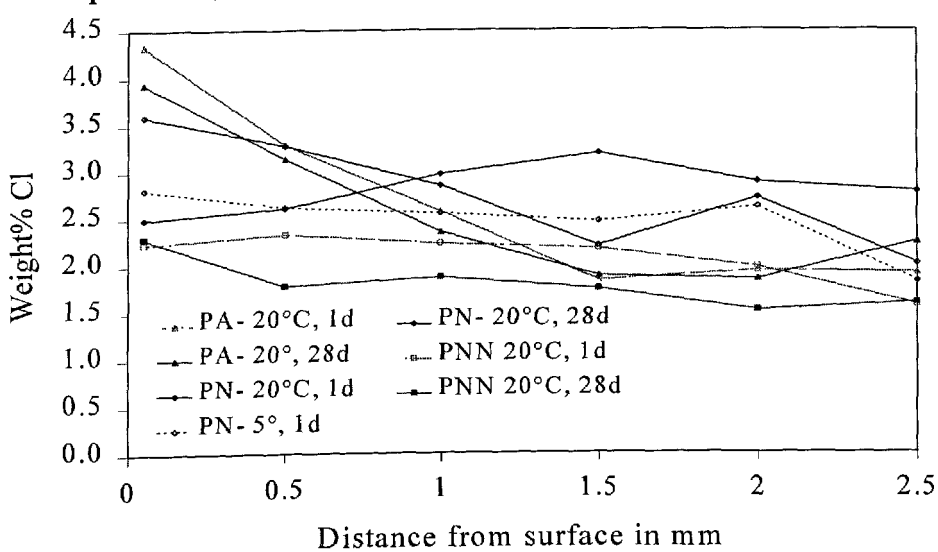

Figure 2 Chloride profile through the disc. Pastes cured for one and 28 days before exposed in a 18 g/l chloride solution for 37 days.

Total chloride content

All individual results from the total chloride determination are given in Table 3. Generally, the chloride ingress was highest in the pure cement pastes and lowest in the pastes containing SF. With decreasing chloride content the general ranking was: PA-, PN-, PAN and PNN.

Table 3 Total chloride content in % of dry sample mass.

Statistically one can calculate the effect of each experimental parameter on the chloride ingress. Using the method described for a two-level factorial design (Box, Hunter and Hunter, 1978) the results are summarised in Table 4. The listed effect is an average response for the indicated parameter changing from one level to the other over all conditions of the other experimental parameters.

Table 4 Effect of the experimental parameters on total chloride content. % of dry sample mass

Sample combinations			Parameter changed					
		From:	5°C	20°C	HS65	0% SF	18 g/l	37 days exp.
		To:	20°C	40°C	EZ375	10% SF	54 g/l	100 days exp.
Curing time	Temperature °C	Grand average*)						
1 day	5 and 20	3.12	-0.35		0.34	-0.24	1.19	0.48
1 day	20 and 40	3.02		0.14	0.43	-0.47	1.28	0.39
28 days	5 and 20	2.57	-0.14		0.41	-0.29	1.50	0.28
28 days	20 and 40	2.71		0.42	0.52	-0.52	1.47	0.29

*) Average of total chloride content for all parameters for the indicated sample combinations.

As an example, pastes cured for 28 days and exposed at 5 and 20°C have an average chloride content of 2.57% of dry sample mass. For this combination of samples the effect of replacing 10% of the binder content with SF was that the chloride content decreased on average 0.29% of dry sample mass (minus means a decreased chloride content in the pastes).

It is interesting to notice that for paste cured one day and exposed 37 days, as presented in Fig 3, all samples at 5°C, independent of type of binder and exposed to the same concentration, had about the same chloride content. The reason for this is most likely the slow cement hydration at low temperature, so that the various binders approximately hydrated equally. At the higher temperatures, the hydration was accelerated. The binders therefore hydrated differently and caused the distinct chloride content between each paste. This is seen by the scattered curves.

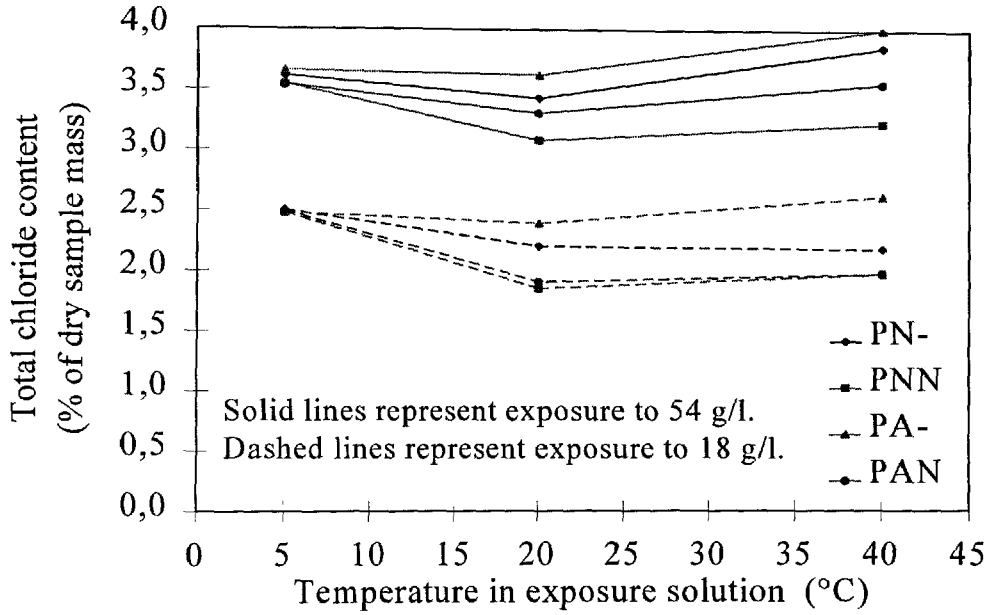

Figure 3 Total chloride content versus exposure temperature.
Paste cured for one day and exposed for 37 days.

When looking at the effect of temperature on chloride content, the picture seems a bit confusing. It is, however, obvious from Table 4 that an increase from 5 to 20°C decreased the chloride ingress. This can be seen as negative effects for both one day (-0.35) and 28 days curing (-0.14). The effect for samples cured one day was 2.5 times greater than for samples cured 28 days. One reason for this is probably that the pastes cured for one day at 20°C developed a denser microstructure faster than at 5°C. This caused, in spite of the increased temperature itself, less chloride diffusion. Another reason might be a shift in the adsorption/desorption equilibrium as the temperature increased. Besides a shift of the equilibrium towards desorption caused by the increased kinetic ion energy, a shift in the same direction is accompanied by the decreased (positive) ζ-potential of the hydrated cement (Ludwig and Singh, 1986) as temperature is increased. Less chloride ions are therefore adsorbed on the surface of the hydrated cement as the temperature increases. On the other hand the surface area of the samples cured for one day, must be much higher at 20 than at 5°C, due to the higher degree of hydration. It is therefore hard to believe that the observed differences are caused by adsorption effects only. Another factor of greater influence on the chloride uptake is the chloride concentration of the pore solution. This will be discussed later. For the only disc exposed at 5°C investigated with EDXA, the observed chloride content at the surface was lower than that of the corresponding disc exposed at 20°C, although the total chloride content of the 5°C sample was higher (Tab 3). In the centre of the disc the increased temperature had little effect.

From Table 4 it is also clear that an increased temperature from 20 to 40°C led to an increased chloride ingress. The average responses for the samples cured for one and 28 days, were 0.14 and 0.42, respectively. The increased chloride content was 3 times greater for the samples cured for 28 days. A possible reason might be that hydration at 40°C, after one day pre-curing, densified the microstructure even more than at 20°C. At 40°C the densified microstructure in the samples one day counteracted the effect of the increased ion mobility and thereby the diffusion rate of chlorides in the pastes. This is in agreement with Dhir et al. (1993). The pastes cured for 28 days were already well hydrated and had a highly developed microstructure when exposed in the chloride solutions. The increased temperature affected the microstructure insignificantly in these samples, so that the increased diffusivity was not counteracted. All this shows the strong influence of the microstructure of cement based materials upon chloride ingress, and it clearly points out that curing prior to exposure has a major influence on chloride uptake.

As expected, the use of SF decreased the chloride ingress. An increase in both exposure concentration and time, also as expected, increased the content of chlorides in the samples.

Chloride binding

The free chloride content was calculated using measured values of evaporable water (from the disc used for total chloride determination) and chloride concentration in the pore solution. The chloride binding was then found by subtracting the free content from the total content of chlorides. As for chloride ingress, the statistical effects on binding were calculated (Table 5).

Table 5 Effect of the experimental parameters on chloride binding. % of dry sample mass

Sample combinations			Parameter changed					
		From:	5°C	20°C	HS65	0% SF	18 g/l	37 days exp.
		To:	20°C	40°C	EZ375	10% SF	54 g/l	100 days exp.
Curing time	Temperature °C	Grand average*)						
1 day	5 and 20	1.57	-0.50		0.06	-0.28	0.05	0.11

28 days	20 and 40	1.18		0.22	0.43	-0.53	0.16	0.14

*) Average of bound chloride content for <u>all</u> parameters for the indicated sample combinations.

A discussion of the chloride binding results is difficult as neither the chloride concentration of the pore solution nor the total chloride content was constant and thereby not directly comparable. The inaccuracy of the calculated binding values depend strongly on the chloride concentration of the pore solution as well as the amount of pore solution itself. However, as can be seen from Table 5, the chloride binding decreased on average from 5 to 20°C for the samples cured for one day and was practically unchanged for the samples cured for 28 days. From 20 to 40°C the binding increased. One would expect, in equally hydrated pastes, a decreased binding as the temperature is increased. The reasons for this are the decreased ζ-potential, as discussed before, and the decomposition of Friedels salt (Maslehuddin et al., 1996). Why the present results are in contradiction to this is possibly explained by the likely interactive effects as the degree of hydration, and thereby surface area and microstructure, is changed. These combined effects will probably affect the various binder types differently, and thereby causing an even more complex situation. Dhir et al. (1993) have also pointed out that "the effects of temperature on different binder types is not consistent."

Further, the chloride binding was higher in the EZ375-containing pastes, in the samples exposed to the highest chloride concentration and in samples exposed for 100 days. The use of SF decreased the chloride binding. The latter is in agreement with the findings of Page and Vennesland (1983), but in contradiction to Byfors et al. (1986). The reason Byfors et al. found an increased chloride binding in SF-containing pastes, might be in connection with the particular cement used (a Swedish OPC). Pure cement pastes made of this cement, had a much higher chloride concentration in the pore solution than pastes made of the other two OPCs investigated (an Austrian and a Danish). The actual concentration was in the range normally obtained in pastes made of sulphate resistant cement (Tritthart, 1989).

Chloride concentration of the pore solution

All individual chloride concentrations are given in Table 6.

Surprisingly, the chloride concentration in the pore solution was found to be higher at 5°C than at both 20 and 40°C, in the samples cured for one day and exposed for 37 days in the 18 g/l solution (solid lines in Fig 4). A possible explanation of this observation is that equilibrium had not yet been reached in 37 days. Another reason might be that weakly bound chlorides at 5°C were pressed out during pore expression. The picture seems more complex when considering the same samples after 100 days of exposure (dashed lines in Fig 4). Now, the concentrations at 5 and 40°C were approximately equal, but there had been a major increase in the 20°C-concentration. The reason cannot be explained at the moment, but the above discussed interactive effects might be important in this matter. However, it must be pointed out that the chloride concentrations of the exposure solutions were checked regularly, and used-up chlorides replaced.

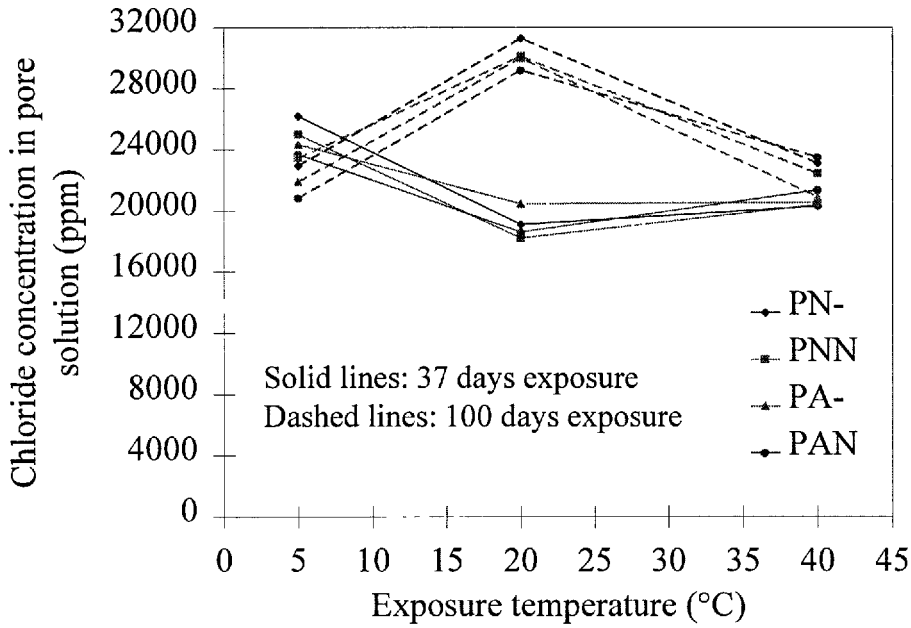

Figure 4 Chloride concentration in pore solution versus exposure temperature. Paste cured for one day and exposed in a 18 g/l solution.

XRD

The pastes made of Austrian cement contain more Friedel's salt than the pastes made of Norwegian cement. This can be seen in Figs 5 and 6. Friedel's salt can be identified as peaks at 11.2°, 22.8°, 30.9° and about 39° (2θ). This was not expected because the Norwegian cement contained a bit more C_3A than the Austrian. A possible reason for this might be that the amount of sample investigated was not completely the same. Other investigations not discussed in detail here, gave no indication that SF affects the formation of Friedel's salt. They showed further that longer curing before exposure to chlorides and higher chloride concentration, will tend to decrease the formation of Friedel's salt. These results were not significant, but there was a clear trend for curing time and a weak trend for concentration.

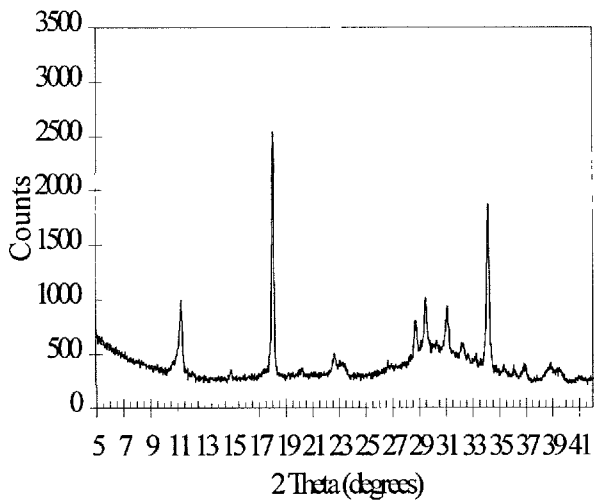

Figure 5 XRD-spectra from PA-. Exposed 37 days in 18 g/l at 20°C. Cured 28 days.

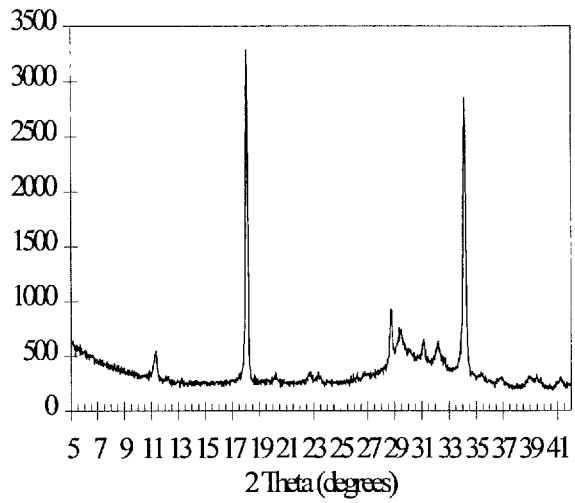

Figure 6 XRD-spectra from PN-. Exposed 37 days in 18 g/l at 20°C. Cured 28 days

SUMMARY AND CONCLUSIONS

In this investigation, the influence of temperature on chloride ingress and binding in pure and blended cement pastes was evaluated. The results showed that some of the 5 mm thin discs investigated with EDXA after 37 days exposure were not at equilibrium, in the sense of no chloride gradient through the disc. Both total chloride content and chloride binding decreased from 5 to 20°C and increased from 20 to 40°C. The observed effects were most likely complex interactions between temperature, degree of hydration and microstructure. Silica fume decreased chloride ingress and binding.

The results show the strong influence of microstructure on chloride ingress, and they clearly point out that curing, age and temperature have a major influence on the speed and degree of chloride uptake. It follows from the results that young concrete exposed to chlorides at low temperatures might experience not only a greater chloride uptake, but also a greater penetration depth. Further research is needed to clarify this.

ACKNOWLEDGEMENT

The present paper is part of the "OFU Bridge Repair Project" financed by the Norwegian Public Roads Administration (NPRA), Rescon AS and The Norwegian Industrial and Regional Development Fund (SND). The project is managed by NPRA.
The electron microprobe analysis was performed by energy-dispersive X-ray spectrometry (EDAX-DX4) at the Institute for Electron Microscopy at TU-Graz. This device was sponsored by the "Jubiläumsfonds der Österreichichen Nationalbank."

Modelling and mechanisms of degradation processes

NEURAL NETWORKS FOR MODELLING THE INFLUENCE OF CEMENT CHEMISTRY ON CONCRETE DURABILITY

Nick R. BUENFELD,)

London, UK

ABSTRACT Neural networks (NNs) are introduced as a method of analyzing cement/concrete performance data to quantify the effects of individual cement components on concrete deterioration mechanisms. NNs developed to predict chloride binding and carbonation depth are presented as examples.

Keywords: carbonation, chloride binding, durability, modelling

INTRODUCTION

Cement chemistry is expected to influence most concrete deterioration mechanisms. There are numerous papers in the literature describing the performance under particular test/exposure conditions of concretes of specified mix proportions and binder composition. However, such studies have rarely allowed the effects of any but the most dominant chemical constituents to be quantified because a large number of variables are required to characterize cement and it is very unusual to find cements of almost identical composition with the quantity of only one or two constituents varying to allow a direct comparison. Consequently, despite large amounts of apparently relevant data, it is rarely possible to accurately predict the performance of a cement of known composition, necessitating the expense and time commitment of further testing.

This paper shows how neural network (NN) analysis of cement/concrete performance data can be used to isolate and quantify effects to provide insights not possible with conventional methods. A brief introduction to NNs is presented. This is followed by two examples of NN analysis of durability data; these relate to chloride binding and carbonation. The wider applicability of NNs in this field is then discussed.

NEURAL NETWORKS

A NN consists of a number of processing units (neurons) grouped together in layers and connected to form a complex net-like structure (e.g. Fig 1). An input layer consists of neurons describing the influencing factors, ideally with each variable that is thought to possibly influence the output represented by an input neuron. An output layer gives the response to the set of inputs. In addition, there are usually 1 to 3 *hidden* layers. Neurons receive the output signal from many other neurons. A neuron calculates its own output by determining the weighted sum of its inputs, generating an activation level and passing it through a *transfer function*. Two neurons communicate via a *connection* and the strength of the connection between two neurons is its *weight*.

NNs are trained by presenting a series of inputs and the desired output. The most popular learning method is by example and repetition; the NN is presented with a set of facts and each time an input is presented the NN sends back an answer of what it thinks the output should be. This is compared with the correct output. If the output is incorrect, the NN makes corrections to the weights. This training process is repeated until the discrepancy is minimised. The NN is then tested to determine its accuracy by presenting it with sets of input data (not previously seen by the NN) and comparing the outputs with the known correct outputs. Finally, the NN

is used, i.e. it is presented with input combinations of interest data and predicts unknown output values. The NNs described in this paper were developed using the back propagation algorithm, delta learning rule and sigmoid ($(1+e^{-x})^{-1}$) transfer functions with NeuralWorks Professional II/PLUS (NeuralWare, 1993).

CHLORIDE BINDING

All cements bind a proportion of any chloride present. This reduces the depth of chloride penetration from an external source, but results in higher chloride levels nearer the exposed surface than if binding did not occur. Chloride binding may also influence the threshold level required for corrosion. Numerous experimental studies of chloride binding have been reported, with some of the findings being contradictory. No individual study has encompassed all of the influencing variables. A major attraction of NN analysis was to assimilate data from a number of independent studies to allow the most accurate possible prediction of chloride binding.

The output was chosen as free chloride concentration, avoiding errors associated with estimating pore solution volume to convert published data to percentage bound. A total of 18 input variables (listed in Table 1) were used, including total chloride content, the phase composition of the cement, Na_2O equivalent and SO_3 contents, pore solution OH^- concentration, replacement levels of PFA, GGBS and silica fume (SF), free water/cement ratio (w/c), sand/cement ratio (s/c), chloride ion source (internal or external) and cation (Na or Ca). Two different methods have been used to determine free chloride content: extraction of pore solution from a chloride contaminated sample (*pore pressing*) and equilibration of the pore solution with an external solution (*equilibrium method*). Method was included as an input variable to allow any discrepancy to be isolated. Only room temperature data from pastes and mortars (not concretes) were included.

Approximately 500 datapoints drawn from 21 papers (listed in Glass et al, 1996) were used to develop the NN. An indication of the distribution of variable values in this data is provided by the typical ranges given in Table 1; although more extreme values were present, predictions outside of the typical ranges are likely to be less accurate.

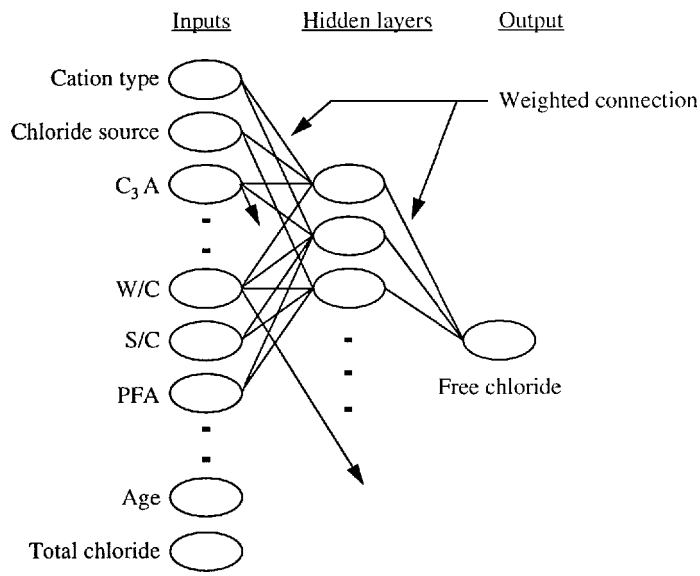

Figure 1 Schematic diagram of chloride binding neural network.

Table 1 Chloride binding NN input variables and their individual effects on free chloride concentration (typically 0.313M) at a total chloride content of 1%.

Variable			Free chloride	
Type	Typical range	Typical value	Concentration (M)	Change
Total Cl^- (%)	0 → 2.5	1		
C_3A (%)	2 → 14	8	0.495 → 0.192	97%
C_3S (%)	42 → 68	55	0.415 → 0.241	56%
SF (%)	0 → 20	0	0.313 → 0.474	52%
w/c	0.4 → 0.7	0.55	0.398 → 0.243	50%
GGBS (%)	0 → 65	0	0.313 → 0.160	49%
OH^- (M)	0.03 → 0.77	0.4	0.251 → 0.390	45%
Cation	$Na^+ \rightarrow Ca^{2+}$	Na^+	0.313 → 0.193	38%
C/S	2.9 → 3.3	3.12	0.260 → 0.375	37%
Na_{eq} (%)	0.3 → 1.2	0.75	0.289 → 0.343	17%
s/c	0 → 2	0	0.313 → 0.265	15%
Method	pp → eqbm	pp	0.313 → 0.270	14%
Cl^- source	int → ext	int	0.313 → 0.348	11%
PFA (%)	0 → 35	0	0.313 → 0.284	9%
SO_3 (%)	2 → 4	3	0.299 → 0.327	9%
Age (days)	10 → 250	130	0.323 → 0.303	6%
C_4AF (%)	7 → 14	10.5	0.317 → 0.310	2%
Conditioning	wet → sealed	sealed	0.309 → 0.313	1%

There is no widely applicable systematic means of determining the optimal number of hidden layers, number of hidden neurons and other NN parameters. This was achieved largely by educated trial and error involving the development and testing of over 100 NNs. NN accuracy was assessed according to the average percentage error for chloride concentrations above 0.05M This was a compromise between assessing absolute error which would have attributed too much importance to the larger values and percentage error applied to the entire data set which would have given undue weight to the unresolvable differences at low values and presents difficulties at the origin. In addition, the relations generated by each NN were compared with well-established relations in the literature. It was encouraging to observe that the same relations were predicted for nearly all of the NNs assessed in the process of optimization.

The optimised NN had 8 neurons in the first hidden layer and 3 in a second. It predicted the training set with an error of 19.4%, the test set (drawn from the training set papers, but not used in training) with a error of 19.0% and a validation set (4 independent data sets not used in training) with an error of 20.2%. Significant variations (up to 50%) have been reported in the determination of both free and total chloride contents by different laboratories (Byfors et al, 1986 and Grantham and van Es, 1995). The closeness of the error in the prediction of these data sets implies that the *noise* (variations uncorrelated with either inputs or output) in the training data did not significantly affect the NN predictions. The relative importance of each variable was assessed by predicting the change in free chloride concentration (expressed as a percentage of the typical concentration) when the variable was assigned the minimum and maximum values in its typical range, all other variables being held at their typical values. The variables are listed in Table 1 in order of importance at the 1% total chloride level; it should be recognised that the relative importance assigned to variables depends on the range of the variable which in practice

may differ from that in this study. The NN was able to separate the effects of factors that are otherwise difficult to assess individually in a laboratory environment. For example, the strong effect previously attributed to PFA was shown to be largely due to accompanying changes in OH^-. Including test method as a variable indicated that there is negligible difference in binding between internal and external chlorides, the effect attributed to chloride source in the literature probably being due to errors in the determination of the total chloride content originating from an external source. The somewhat surprising effects attributed to C_4AF, C_3S and C/S largely result from the assumption in the above analysis that all the variables are independent. However, variables which depend on the oxide composition of the cement are partially dependent due to both the requirement that the sum of these compositions cannot exceed 100% and other interactions. The influence of phase composition was investigated further by varying pairs of variables, constrained by the Bogue equations. In practice an increase in C_3A content is generally accompanied by a decrease in the C_4AF content. The predicted effect of C_3A did not change significantly when combined with variations in C_4AF. However, the combined effects of C_3S and C/S partially cancelled with a marginal increase in binding occurring when both C_3S and C/S increased.

The NN provides a method of estimating chloride binding data in a manner which reduces the effect of unexplained variations present in individual measurements. The NN is now used to predict binding isotherms for use in numerical models of chloride transport (Buenfeld, 1996a). See Glass et al (1997) for a detailed description of the development and application of this NN.

CARBONATION

A literature search located over 100 papers containing carbonation depth data. These were reviewed to identify the variables believed to affect carbonation. Papers with many key variable values missing were discarded. The vast majority of the studies measured carbonation depth using phenolphthalein; data based on other methods were discarded. This left around 7000 carbonation depth measurements from 88 papers (listed in Buenfeld et al, 1996b). NNs were then formulated, based on training with data from 68 of the papers and testing with data from the other 20. The final stage of development involved assessing the performance of 30 NNs, involving different NN parameters.

The optimum NN, described here, used 39 inputs (indicated by • in Table 2). Cements were defined according to type and Bogue composition, plus alkali content. If cement composition was not provided in a paper, information in the paper concerning the source of the cement was used to estimate the composition; accuracy trials showed that this approach was preferable to allowing the mean or mid-range value to be adopted and was effective for other variables too. To ensure that the NN had every opportunity of learning the effect of free water content, cement content and w/c, all three were included as neurons, even though any two of these factors effectively define the third. Curing was characterized by temperature, moisture state at the surface of the concrete and duration. Moisture state was described on a scale of 0 to 10, defining water immersion as 10, >95% RH (e.g. sealed curing) as 8, 90-95% RH as 6, <90% RH as 4 and no curing as 0. Curing duration was entered as a logarithmic value to assist the NN in identifying the diminishing effect of prolonged curing. Such transformation of important variables allows expert knowledge to be used to advantage in developing NNs. A major complication of modelling carbonation in relation to the chloride binding study was the number of variables required to describe the exposure environment. Ideally exposure environment would be specified entirely in terms of well-defined environmental parameters. The difficulty is that in most natural exposure environments, these vary with time in an unpredictable fashion.

Average temperature, average ambient RH and annual rainfall were included as *quantitative neurons*. *Qualitative neurons* were used to identify whether exposure was internal, external and sheltered or external and unsheltered and to indicate from which of five world-wide regions the data originated. Data from elevated CO_2 laboratory studies were included in the NN to allow correlation between natural and accelerated carbonation.

Table 2 Carbonation NN input variables.

	Defaults		Defaults
CEMENT		**CONDITIONING**	
• Rapid hardening portland (Y/N)	No	**(only applies to accelerated**	
• Sulphate resisting portland (Y/N)	No	**tests)**	
• C_3S (%)	63%	• Cond. RH (RH-40%)	
• C_2S (%)	20%	• Cond. period (log(days))	
• C_3A (%)	8%		
• Na_2O equiv. (%)	0.6%		
ADDITIONS		**EXPOSURE**	
• PFA (% replacement)	0%	**(applies to all cases)**	
• PFA *CaO content (%)*	0%	• Temperature (°C)	9°C
• PFA passing 45μm (%)	0%	• Relative humidity (RH-50%)	78% RH
• GGBS (% replacement)	0%		
• SF (% replacement)	0%		
MIX PROPORTIONS		**NATURAL EXPOSURE**	
• Water content (kg/m^3)	180	Region: • UK (Y/N)	Yes
• Cement content (kg/m^3)	325	• Scandinavia (Y/N)	No
• Water/cement (ratio)	0.55	• Japan (Y/N)	No
• Maximum aggregate (mm)	20	• Germany (Y/N)	No
• Coarse/fine aggregate (ratio)	2	• Gulf (Y/N)	No
• Air content (%)	1%	• External (Y/N)	Yes
		• Sheltered from rain (Y/N)	Yes
		• Rainfall (mm/year)	60mm
		Exposure period: • (years)	Stated
		• (√years)	
CURING		**ACCELERATED EXPOSURE**	
• Moisture state (0-10)	8	CO_2 concn: • (%)	0
• Curing/conditioning temp. (°C)	20°C	• (log(%))	
• Duration (log(days))	3 days	Exposure period: • (weeks)	Stated
• Maturity after curing (log(°Chr))		• (√weeks)	

The optimum NN had 39 neurons in the first hidden layer and 19 in a second. Different methods of monitoring training and assessing NN accuracy were investigated. The least root mean square (RMS) absolute error achieved in training was 0.0245, but this NN was overtrained in that it learned some of the noise in the data. The optimum NN was trained up to an RMS of 0.029. The average error (absolute error/measured value) over the entire testing file was 27.5% and the error was smaller for the more critical cases where carbonation depth was large. Predictions for real structures were as accurate as for naturally exposed specimens (see Fig 2). The error can be partially attributed to factors that influence carbonation that are rarely reported

in papers, such as mould oil application and micro-environmental factors such as wind direction. Error is also due to the variability of concrete, with samples tested not being truly representative.

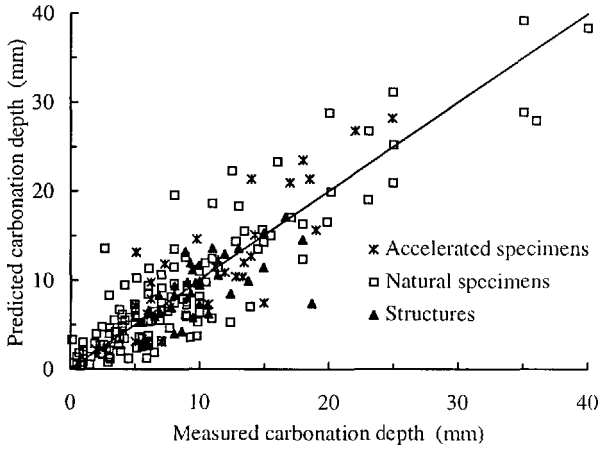

Figure 2 Predicted vs. measured carbonation depths.

The NN was used to predict the effects of concrete and environmental variables on carbonation. In the following examples, unless indicated to the contrary, the input neurons were set to the values listed in the righthand column of Table 2. Relatively well-established relationships were replicated; for example, Fig 3 shows the effects of w/c, cement content and exposure type. Fig 4a shows the time dependence of carbonation for typical levels of cement replacement; it should be recognised that these mixes are compared on the basis of similar mix proportions and that the strengths would be different. The NN allows the effect of factors that are not normally varied in a single study to be investigated. Fig 4b shows the effect of world location and involved selection of appropriate values of average temperature, RH and annual rainfall, as well as region neuron; this may be useful when considering the applicability of particular national codes in other parts of the world. When varied independently, both C_3S and C_2S were found to reduce carbonation depth. When varied dependently, according to the Bogue equation $C_2S = 2.87S - 0.754C_3S$, the predicted influence of C_2S is reversed (Fig 5).

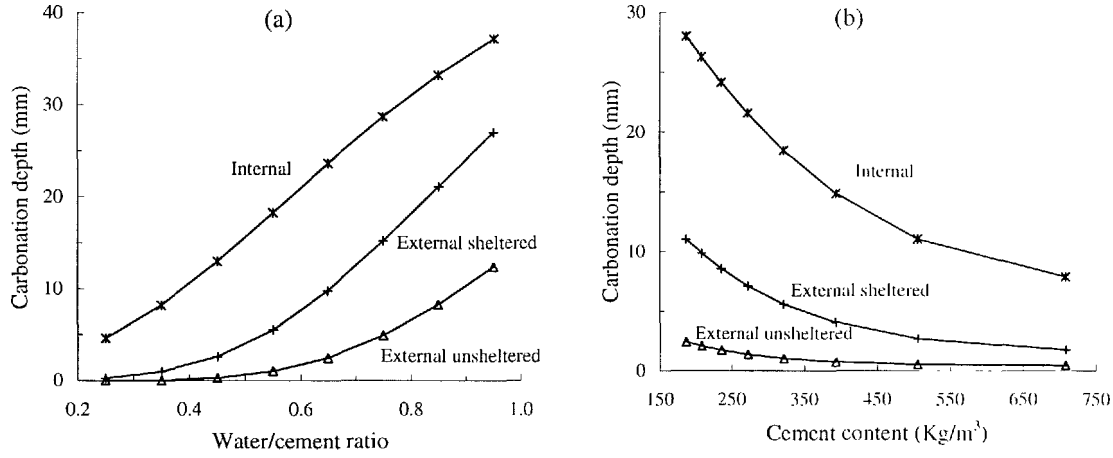

Figure 3 Carbonation depth vs. (a) w/c at constant cement content and (b) cement content at constant w/c, for 3 exposure conditions.

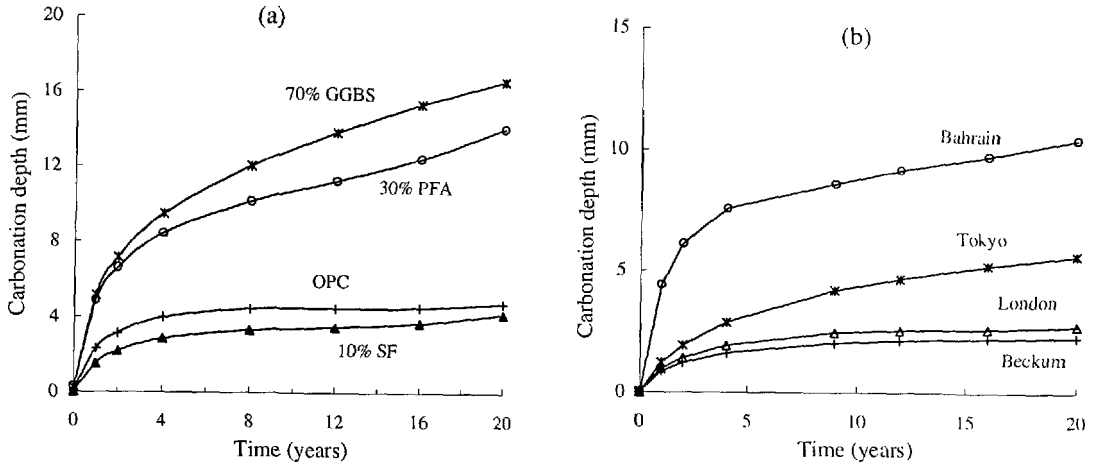

Figure 4 Carbonation depth vs. time for (a) cement replacements and (b) world location.

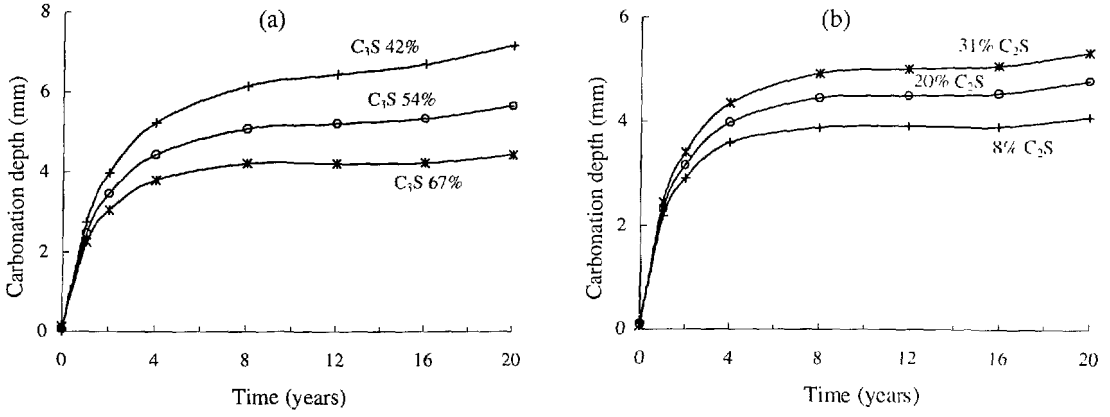

Figure 5 Carbonation depth vs. time for different levels of (a) C_3S and (b) C_2S.

There was very little carbonation depth training data for exposure periods beyond 20 years and it would therefore have been unwise to use the NN directly to predict to longer times. Long-term predictions are best achieved by using the NN to determine the time dependence of carbonation depth within the time range of the training facts then fitting a function (e.g. $A + Bt^n$) to allow extrapolation to longer times. See Buenfeld et al (1996b) for a more detailed description of the development and application of this NN.

CONCLUSIONS REGARDING APPLICABILITY OF NNs TO DURABILITY MODELLING

Deterioration processes affecting concrete structures are influenced by many variables including those relating to cement composition, concrete mix proportions and environmental exposure. NNs can cope with the large numbers of variables involved and do not require the effects of secondary variables to be overlooked when considering the effects of the main variables. NNs are able to generalise, i.e. to draw conclusions about something that has not been observed before, by learning of the effects of the input variables in other situations. This is essential when dealing with a topic involving so many variables. However, a NN is only as good as the data on which it is trained. A moderate amount of training data spread across the whole domain of interest is more valuable than a vast amount of data limited to only a subset of all of the

variables of interest. Incomplete input sets can be accommodated and in some cases where data are missing for an influential input, a separate NN can be developed to predict the missing values (e.g. Hills et al, 1995).

The NN approach requires knowledge of the variables that may be important, but does not require prior understanding of the relationships between each variable and the output of interest; for example, a NN has been developed to predict chloride profiles without the assumption of Fick's Law compliance (Hassanein, 1996). Once trained, the NN can be used to quantify these relationships. Non-linear relationships are common in the concrete durability field; for example, the effect of curing regime on carbonation depth is dependent upon binder type. It is difficult to identify and quantify such interactions with conventional analytical methods; NNs are well-suited to this kind of problem, but care should be taken when assessing the effect of cement chemistry inputs to ensure that dependent inputs are also varied appropriately. This is an argument against using concrete properties (e.g. strength) as well as concrete constituents and proportions as inputs.

Individual laboratory studies and natural exposure trials necessarily only investigate subsets of the influencing variables. NNs can be used to combine and analyze such data; this approach tends to average out noise and is recommended as a means of synthesizing previous research, identifying what remains uncertain, prior to undertaking a new study. A NN may also be a practical method of encompassing results from a large number of different studies to validate or modify design code durability recommendations.

THE INVESTIGATION OF CEMENT CONCRETE CORROSION BY AN IMITATION MODEL.

V.L.CHERNYAVSKY, V.Y.DUBNITSKY.
Kharkiv State Technical University of Building and Architecture

ABSTRACT A structural functional model of cement concrete is proposed to be used in numerical simulation of processes taking place in it at all stages of its life cycle, including corrosion actions. The model consists of a system of Kolmogorov-type linear differentional equations for Markov's processes with a discrete condition and continuous time. The model identification has been made.

Key words: Corrosion, Design life, Hardening, Hydration, Modelling

INTRODUCTION.

In corrosion of cement materials (hardened paste, concrete) taking place under interaction of their structural components therebetween and strongly influenced by environment some complicated processes are involved hardly describable in an analytical form for a number of reasons (presence of clinker, slag, ash and other relicts, polymineral composition of hydration and corrosion products, time-changing role of creative and destructive processes in structure formation) defines a non-monotorous nature of cement hardened paste property alteration and makes impossible a formal extrapolation of the concrete properties as a whole.

To study cement structure formation under the action of environment we proposed an imitative model of cement hardened paste (the most corrosion-sensitive part of concrete) structure based on grouping its structural components by common functional properties. The basic principles of grouping cement hardened paste structure components into model elements were described by Mchedlov-Petrossyan et al. (1970).

OBJECT OF WORK.

The object of this work is to create an imitative model for quantitative study of alteration with time of structural and functional characteristics of cement materials (hardened paste, concrete) acted upon by environment of any type and aggressiveness, taking into consideration creative and destructive process emerging in those materials in the course of long-term operation of building constructions.

Hypotheses taken in model building.

For simulation a concept has been received about the structure of cement hardened paste in concrete based on grouping its component into blocks (model components V_i, **i=1,4**) by common functional properties.

Relative content of non-hydrated cement particles is designated as V_1; relative content of hydrate formations as V_2; relative content of voids ($r > 10^{-5}$ m) as V_3; relative content of corrosion products as V_4. In constructing connections between model elements the following assumptions were made:

-in every unit volume all model components Vi are present and disposed uniformly along all coordinate axes, their ratios corresponding in average to the ratios of structural components in the actual material;

-the condition

$$\sum_{i}^{4} Vi = 1 \qquad [1]$$

is met along the whole time interval of model functioning;
-all components V_i within a unit volume for which the condition [1] is met are equally accessible to the rest of model elements, a connection of each element V_i to any element $V_j(\alpha_{ij})$ being a continuous one;
-only such processes can proceed in the model: hydration of component V_i, "extraction" of components V_1, V_2, V_4 "accumulation" of components V_3, V_4 or linear combinations of these processes;
-alteration intensity of components V_1, V_2, V_4 for a given medium is independent from mineral composition of their actual prototypes;
-the liquid phase in cement hardened paste is represented by chemically bound, crystallisation, adsorption, capillary and gravity forms and is taken into consideration during construction and evaluation of each of the model components. The relations between model components are presented in the from of an oriented weighted graph

$$G=g(V_i,\alpha_{ij}),\ i=\overline{1,4},\ j=\overline{1,4}. \qquad [2]$$

Apices Vi correspond to model components having the same subindices, arcs show transition directions, arc weight α_{ij} corresponds to intensity of transition $V_i \rightarrow V_j$, i.e. to the part of element V_i that passed into element $V_i\left(i=\overline{1,4}\right) V_j$ for unit time Δt. Then, according to the sense of model , transitions $V_1 \rightarrow V_2$; $V_3 \rightarrow V_2$ would describe creative processes, whereas transitions $V_1 \rightarrow V_4$; $V_2 \rightarrow V_3$; $V_1 \rightarrow V_4$; $V_2 \rightarrow V_4$; $V_3 \rightarrow V_4$ refer to destructive ones.
The graphs corresponding to each of the models considered are shown in *Fig.1.*

EXPERIMENTAL RESEARCH

The object of our study were cement hardened paste specimens from concrete's mode using 13 cements in which the content of basic clinker mineral were (in %): $C_3S-41\ldots67$; $C_2S-15\ldots33$; $C_3A-4\ldots9$; $C_xA_yF_z-10\ldots15$. The following external actions were assumed: normal storage in a moist air medium, filtration of mild water with pH≈5, action of a sulphate - containing aqueous solution with pH≈7.5, cyclic action of sulphate - containing aqueous solution and heating at 60°C. The duration of laboratory studies was 10...12 years. Numerical values of model components Vi were obtained at an optical microscope by quantitative petrographic analysis of flat parallel sections (Mchedlov-Petrossyan et al., 1974). It has been distribution of model component Vi is normal by monofactorial dispersion analysis it is shown that the time alteration of cement hardened paste model component content is statistically connected to the change in the concrete strength properties which may be considered as a confirmation of the model adequacy.

REASONING OF MODEL EQUATION

For each apex of any graph shown in Fig.1 an equation is composed of the type:

$$\frac{dV_i}{dt} = -\sum_{i=1}^{P}\alpha_{ij}V_i + \sum_{j=1}^{P}\alpha_{ji}V_j, i=\overline{1,P} \qquad [3]$$

$$j=1,2,\ldots,i-1,i+1,\ldots,P$$

For cement hardened paste with hydration processes taking place in it the system of differential equations has the form

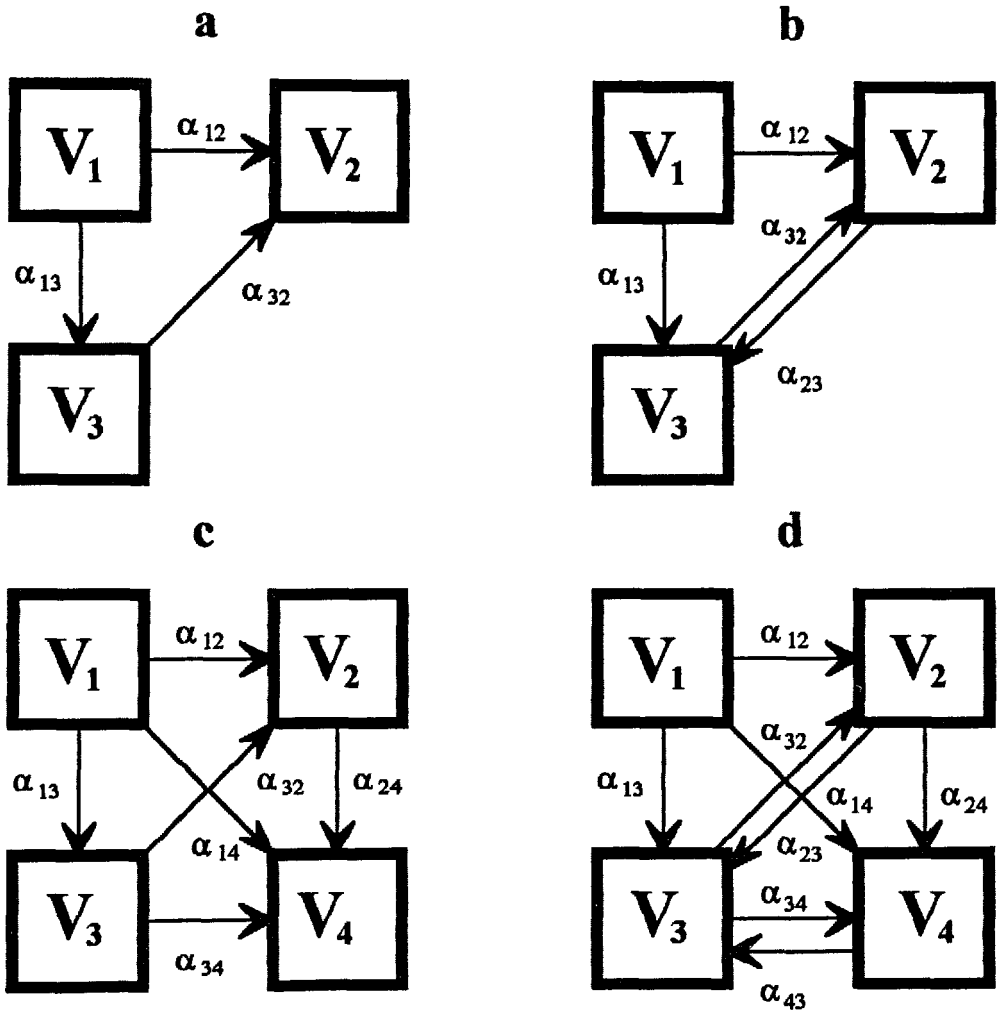

Figure 1 Model graphs
1a) cement hardened paste corrosion absent
1b) extraction of cement hardened paste components
1c) accumulation of corrosion products in cement hardened paste
1d) joint development of processes 1b, 1c in cement hardened paste

$$\begin{cases} \frac{dV_1}{dt} = -\alpha_{12}(t)V_1 - \alpha_{13}(t)V_1 \\ \frac{dV_2}{dt} = \alpha_{12}(t)V_1 + \alpha_{32}(t)V_3 \\ \frac{dV_3}{dt} = \alpha_{13}(t)V_1 - \alpha_{32}(t)V_3 \end{cases} \quad [4]$$

a graph corresponding to this system being shown in Fig.1a.

A system of equations for cement hardened paste with processes of hydration and extratplace in it has the form

$$\begin{cases} \dfrac{dV_1}{dt} = -\alpha_{12}(t)V_1 - \alpha_{13}(t)V_1 \\ \dfrac{dV}{dt} = \alpha_{12}(t)V_1 - \alpha_{23}(t)V_2 + \alpha_{32}(t)V_3 \\ \dfrac{dV}{dt} = \alpha_{13}(t)V_1 + \alpha_{23}(t)V_2 - \alpha_{32}(t)V_3 \end{cases} \quad [5]$$

its graph being shown in Fig.1b.

A system of equation for cement hardened paste with processes of hydration and accumulation of corrosion products taking place in it has form

$$\begin{cases} \dfrac{dV}{dt} = -\alpha_{12}(t)V_1 - \alpha_{13}(t)V_1 - \alpha_{14}V_1 \\ \dfrac{dV}{dt} = \alpha_{12}(t)V_1 - \alpha_{24}(t)V_2 + \alpha_{32}(t)V_3 \\ \dfrac{dV}{dt} = \alpha_{13}(t)V_1 - \left(\alpha_{32}(t) + \alpha_{34}(t)\right)V_3 \\ \dfrac{dV}{dt} = \alpha_{14}(t)V_1 + \alpha_{24}(t)V_2 + \alpha_{34}(t)V_3 \end{cases} \quad [6]$$

its graph being shown in Fig.1c.

A system of equation for cement hardened paste with processes of hydration, extraction of structural components and accumulation of corrosion products taking place in it has form

$$\begin{cases} \dfrac{dV_1}{dt} = -\alpha_{12}(t)V_1 - \alpha_{13}(t)V_1 - \alpha_{14}(t)V_1 \\ \dfrac{dV_2}{dt} = \alpha_{12}(t)V_1 - \alpha_{23}(t)V_2 - \alpha_{24}(t)V_2 + \alpha_{32}(t)V_3 \\ \dfrac{dV_3}{dt} = \alpha_{13}(t)V_1 + \alpha_{23}(t)V_2 - \alpha_{32}(t)V_3 - \alpha_{34}(t)V_3 + \alpha_{43}(t)V_4 \\ \dfrac{dV_4}{dt} = \alpha_{14}(t)V_1 + \alpha_{24}(t)V_2 + \alpha_{34}(t)V_3 - \alpha_{43}(t)V_4 \end{cases} \quad [7]$$

its graph being shown in Fig.1d.

IDENTIFICATION OF MODEL.

In Eqs 4...7 the value of αij(t) is to be defined using the data of numeric values of elements V_i ($i = \overline{1.4}$) found experimentally. Let us consider the identification of model elements at an example of the most complicated system, Eq.7

By transition from infinitely small values to finite increments, assuming that $\Delta t = 1$ we obtain a system like Eq. 8

$$\begin{cases} \Delta V_1^{(m)} = -\left(\alpha_{12}^{(m-1)} + \alpha_{13}^{(m-1)} + \alpha_{14}^{(m-1)}\right)V_1^{(m-1)} \\ \Delta V_2^{(m)} = \alpha_{12}^{(m-1)}V_1^{(m-1)} - \left(\alpha_{23}^{(m-1)} + \alpha_{24}^{(m-1)}\right)V_2^{(m-1)} + \alpha_{32}^{(m-1)}V_3^{(m-1)} \\ \Delta V_3^{(m)} = \alpha_{13}^{(m-1)}V_1^{(m-1)} + \alpha_{23}^{(m-1)}V_2^{(m-1)} - \left(\alpha_{32}^{(m-1)} + \alpha_{34}^{(m-1)}\right)V_3^{(m-1)} + \alpha_{43}^{(m-1)}V_4^{(m-1)} \\ \Delta V_4^{(m)} = \alpha_{14}^{(m-1)}V_1^{(m-1)} + \alpha_{24}^{(m-1)}V_2^{(m-1)} + \alpha_{34}^{(m-1)}V_3^{(m-1)} - \alpha_{43}^{(m-1)}V_4^{(m-1)} \end{cases} \quad [8]$$

In construction of system Eq. 7 and similar ones the following assumptions have been made. The whole type of process development T is divided into M unit length intervals. Within each interval, i.e. at $t^{(m-1)} < t \le t^{(m)}$, $m = \overline{1.4}$, the value of V_j ($j = \overline{1.4}$) and αij $\left(j = \overline{1.4}\right)$ are constantly changing spasmodically in response to changing index **m** which confirm the hypothesis of a first continuous approximation of the elements forming Eqs. 4 -7.

Using condition in Eq. 1 let us exclude one of the variables, say V_j, and the **j**-th equation corresponding to it. The variables may be always renumbered so that the first variable and its respective equation be never taken into consideration.

Then instead of variable V_1, using Eq. 8 we introduce

$$V_1^{*(m)} = 1 - \sum_{j=2}^{p} V_j^{(m)},\ j = 2,3,\ldots P;\ m = \overline{1, m} \quad [9]$$

Hereafter we shall commit the symbol [*] in order to simplify the record unless it causes ambiguities. The system of model equation has some peculiarities caused by its structure:

- each **j**-th line contains $p'_j < p$ variables;
- coefficients at the variables are either monoials (αij) or their linear combinations $C_l\left(\alpha_{jk_1}, \alpha_{jk_2}\ldots\alpha_{jk_u}\right),\ l = 1,2,\ldots, z.$
- all coefficients forming a **l**-th linear combination separately come into other lines of the system different from the **j**-th line.

Then a **j**-th line may be presented in the form

$$\Delta V_j^{(m)} = \sum_{k\neq 1}^{p_j} d_{jk}^{(m-1)}\tilde{V}_j^{(m-1)} + \sum_{l=1}^{z} C_l^{(m-1)}\left(\alpha_{jk_1}, \alpha_{jk_2}, \ldots, \alpha_{jk_u}\right)\tilde{V}_j^{(m-1)},\ m = 1,2,\ldots, M \quad [10]$$

Let $\Delta\tilde{V}_{ji}^{(m-1)}, \tilde{V}_{ji}^{(m-1)}$ mean respective values obtained in i-th (i=1,2,...,N) experiment.
Then using a standard least square procedure and solving a problem like

$$\left(L_j^{(m)}\right)^2 = \sum_{i=1}^{N}\left(\tilde{\Delta}V_{ji}^{(m)} - \Delta V_{ji}^{(m)}\right)^2 \rightarrow \mathbf{min} \qquad [11]$$

at **j=2,3,...,(p-1),p; m=1,2,...,M**

we obtain estimated $\hat{\alpha}_{jk}^{(m-1)}$ and $\hat{G}_l^{(m-1)}$ of values $\alpha_{jk}^{(m-1)}$ and $G_l^{(m-1)}$.

As these estimates are obtained for each **j**-th line independently at a fixed **m**, some additional limitations cuoght to be introduced.
Let $\hat{\alpha}_{jkh}^{(m-1)}$ mean the least one and $\hat{\alpha}_{jkb}^{(m-1)}$ the largest one of estimates of $\alpha_{jk}^{(m-1)}$ obtained at **m**-th step and belonging to different lines of system Eqs. 7 of equations. To estimates $\hat{G}_l^{(m-1)}$ of linear combinations it is required that

$$\hat{G}_l^{(m-1)}\left(\alpha_{jk_1}, \alpha_{jk_2}, \ldots, \alpha_{jk_u}\right) = \sum_{S=1}^{u}\alpha_{jk_S} \qquad [12]$$

Finally, the problem of identification of the model system of equations is formulated as:

$$\sum_{j=2}^{P}(L_j^{(m)})^2 + \sum_{l=1}^{Z}\left(\hat{G}_l^{(m-1)} - \sum_{S=1}^{k}\alpha_{jk_S}\right)^2 \rightarrow \mathbf{min}$$

[13]

at limitations

$$\hat{\alpha}_{jkh}^{(m-1)} \le \hat{\alpha}_{jk}^{(m-1)} \le \hat{\alpha}_{jkb}^{(m-1)};\ j \ne k = 2,\ldots p;\ m = \overline{1, m} \qquad [14]$$

In Connotation Eq. 11 symbol $\hat{\Delta V}_{ji}^{(m)}$ means a calculated value of $\Delta V_j^{(m)}$ obtained by substitution into the system equations of optimal estimates $\alpha_{jk}^{(m-1)}$ defined by solution of problem Eq. 6, where ΔV_{ji} exp is an experimentally found value.

To evaluate the quality of results of identification of models proposed a special two-stage procedure is used. All specimens that served as a source of numerical values of components V_i were divided into two equal groups. Using sources forming the first group of models in Eqs. 4 - 7 that were identified according to algorithms in Eqs. 10 - 14 and then the adequacy of equations obtained was evaluated at every step of discretization by **F** criterion, the number of degrees of freedom in the numerator being diminished by so many units how many common elements α_{ij} there were in all lines of corresponding systems in Eqs. 4 - 7.
The specimens forming the second group were used to evaluate predictability of the models obtained.
To this end the value

$$\xi = \|\hat{V}\| / \|\tilde{V}\| = \left[\sum \hat{V}_i^2\right]^{1/2} / \left[\sum \tilde{V}_i^2\right]^{1/2} \qquad [15]$$

was calculated where $i = 1, 3$ for model in Eq. 4, $i = 1,3,4$ for models in Eqs. 5 - 7. Index (^) means that a corresponding value of V_i was obtained by calculation whereas index (~) means that the corresponding value of V_i was obtained using experimental data. Index $i = 2$ was committed by the condition Eq. 1.

The mean relative error of the norm of vector $\|\hat{V}\|$ relative to vector $\|\tilde{V}\|$ was 14.7% for system in Eq. 4, 15.1% for system in Eq. 5, 12.8% for system in Eq. 6, 11.6% for system in Eq. 7.

Actually all aggressive actions of inorganic media, especially heat and moisture actions of constant and cyclic nature, create emergence of constructive and destructive processes in cement concrete. Basing on the model proposed it became possible to describe the endowment of constructive component

$A^{(m)} = \alpha_{12}^{(m)} V_1^{(m)} + \alpha_{32}^{(m)} V_3^{(m)}$ and destructive component $B^{(m)} = \alpha^{(m)}{}_{13} V^{(m)}{}_1 + \alpha^{(m)}{}_{23} V^{(m)}{}_2 + \alpha^{(m)}{}_{14} V^{(m)}{}_1 + \alpha^{(m)}{}_{24} V^{(m)}{}_2 + \alpha^{(m)}{}_{34} V^{(m)}{}_3$ as well as to define the resulting characteristic $C^{(m)} = A^{(m)} - B^{(m)}$

In this connection a stagewise character of $G^{(m)}$ was obviously fixed as well as actual independence of intensities of $A^{(m)}$ and $B^{(m)}$ from mineral composition of the binder at the final stage of concrete interaction to the active medium.

The first stage is predominantly constructive when $A^{(m)} \geq B^{(m)}$, whereas the second stage is predominantly destructive, $A^{(m)} < B^{(m)}$.

By this modelling the transitions $V_1 \rightarrow V_2$ and $V_1 \rightarrow V_4$ were quantitatively separated for the first time, i.e. the percentage of cement relicts transiting into products of hydration and products of corrosion were defined. Up to this time nobody managed to do it experimentally. It has been found that at the beginning of such common maintenance actions at steel works as a cyclic action of sulphate-containing aqueous solutions of industrial origin under elevated (up to 100°C) temperatures, the values of α_{12} are two-three times larger than those of the sum $(\alpha_{13} + \alpha_{14})$. Later on the dependence is gradually altered and the values of said intensities become roughly equal until the number of cement relicts reaches $V_1^{(m)} \leq 0.15...0.3$ relative units.

The validity of choice of model components as characteristics that sufficiently completely describe the cement hardened paste and the processes taking place in it (transitions $V_i \rightarrow V_j$) has been proved by an obvious statistical connection between the model components and certain properties of cement concrete. Particularly, there exists a sufficiently stable correlation between critical levels of the percentage of faulty areas $V_3 + V_4 > 0.25$ and the ratio $R^{(m)} / R^{(0)} < 0.7$. It is also found that the structures of cement hardened paste made of portland cements having different mineral compositions become statistically indistinguishable at the moment of destruction as to components V_1 and $V_3 + V_4$ in spite of different duration of test time (Mchedlov-Petrossyan et al., 1972).

To define the area of values of initial parameters of cement hardened paste structure (components $V_i^{(0)}$) that provide for continuation of maintenance properties of concrete (strength, deformation resistance,

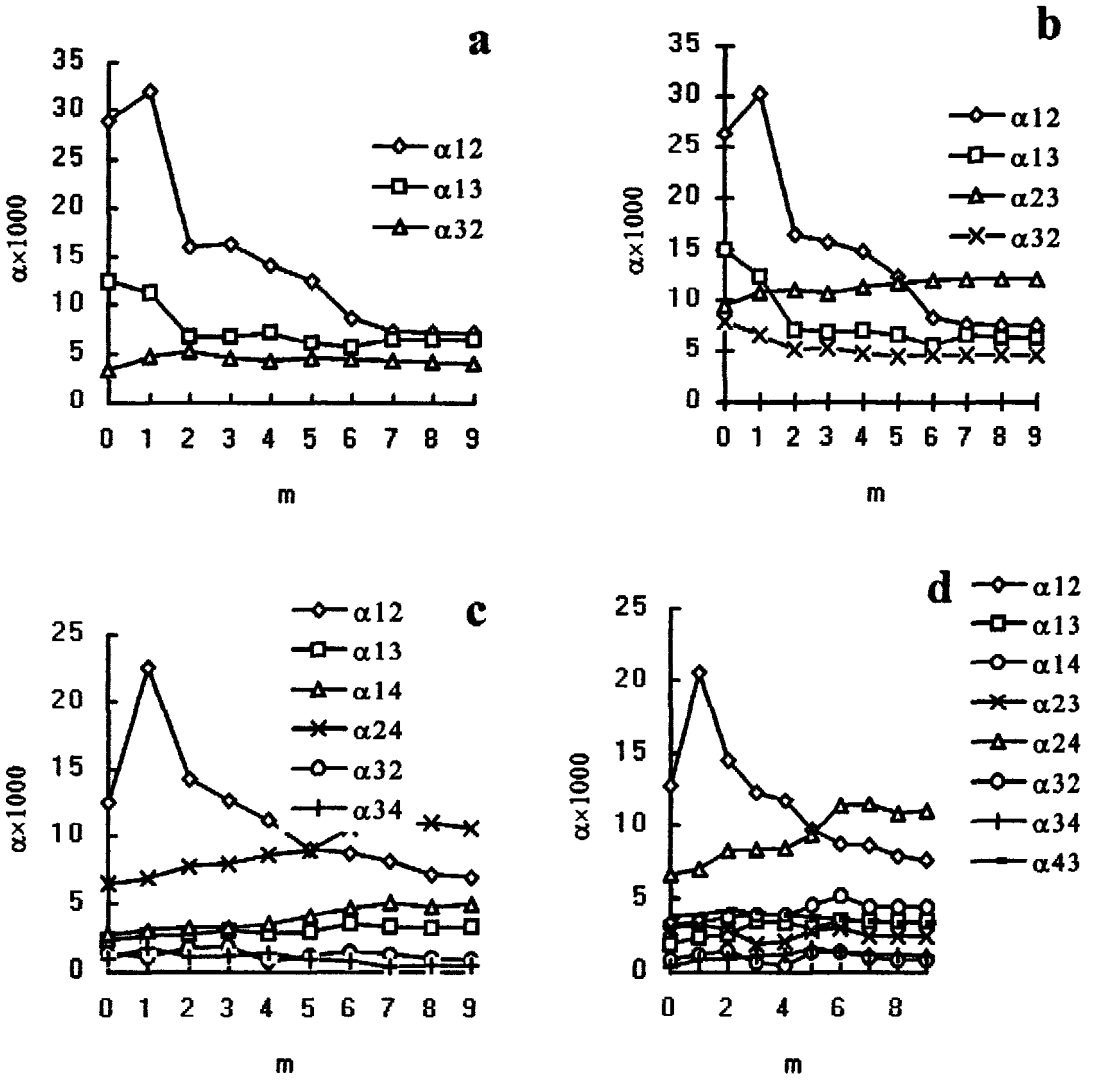

Figure 2 Results of model identification
2a) for system in Eq. 4, graph shown in Fig. 1a)
2b) for system in Eq. 5, graph shown in Fig. 1b)
2c) for system in Eq. 6, graph shown in Fig. 1c)
2d) for system in Eq. 7, graph shown in Fig. 1d)

protection) at an efficient level a problem of optimisation of initial condition of cement hardened paste has been solved for a necessary degree of binder hydration (in terms of the model $r_f = V_1^{(0)} / V_2^{(0)}$). It has been shown that the longest period of concrete resistance has a corresponding value of $r_f = 1$

Thus, all speculations relating to acceleration of the degree of cement hydration in concrete at the stage of construction manufacture by way of increased fineness of cement grinding may be annulled.

CONCLUSION

A structural and functional model of cement concrete under prolonged action of an aggressive medium is described. Numerical values of the model parameters have been defined. Optimisation tasks of structural change imitation in cement hardened paste under four types of corrosive actions have been solved. A substantial role of constructive processes connected to hydration of clinker relicts in cement hardened paste is shown which explains a temporary improvement of concrete properties at early stages of corrosive destruction.

The data obtained allow to regulate the properties of cement hardened paste by stimulation of its adaptability.

SIMULATION MODEL FOR TEMPERATURE RISE AND EVOLUTION OF THERMAL STRESS IN CONCRETE BASED ON KINETIC HYDRATION MODEL OF CEMENT

Fuminori TOMOSAWA, The University of Tokyo, Tokyo, Japan
Takafumi NOGUCHI, The University of Tokyo, Tokyo, Japan
Cheol HYEON, Dea Dong Corporation, Seoul, Korea

ABSTRACT As an application of a newly proposed hydration model of cement, a simulation for heat liberation, temperature rise and thermal stress of concrete was made. These characteristics were calculated on the every finite element, where the rate of hydration and the development of strength and elastic modulus were affected by its own temperature, and hence the differences of these time -dependent changes in each element were calculated and the distribution of thermal stress could be predicted.

Key-words: Hydration, Heat evolution, Adiabatic temperature rise, Thermal stress

INTRODUCTION

Hydration-induced temperature rise of concrete and subsequent thermal cracking cause serious problems for high strength or mass concretes. To cope with these problems, it is necessary to estimate accurately the temperature in members and assess the risk of thermal cracking before the start of construction. However, most conventional techniques of estimating temperature have the irrationality of expressing the test results of adiabatic temperature rise in the form of an equation and applying it to portions which are not in adiabatic conditions. It has therefore been difficult to adapt the histories of temperature distribution in members to actual situations. Tomosawa developed a hydration model of cement (1974, 1997) modifying the unhydrated core model. This paper reports on the application of this model to the estimation of heat liberation rate of cement hydration and adiabatic temperature rise of concrete, as well as temperature distribution and thermal stress in members. The comparison between the estimation and the measurements is reported as well.

OUTLINE OF HYDRATION MODEL

The hydration model of cement, **Eq1**, expresses the rate of hydration as a function of the degree of hydration. It was derived by assuming that as the hydration proceeds the initial protective layer is formed and destructed around spherical cement particles, and that the hydration rate of cement is determined by the rate of the inward diffusion of external water equivalent to the outward diffusion of reaction products and the chemical reaction rate on the core surfaces.

$$-\frac{d\alpha}{dt}=\frac{3C_w}{\nu\rho r_0^{\,2}}\cdot\frac{1}{\dfrac{1}{k_d r_0 \alpha^{2/3}}+\dfrac{\alpha^{-1/3}-(2-\alpha)^{-1/3}}{D_e}+\dfrac{1}{k_r r_0 \alpha^{2/3}}} \qquad [1]$$

where α = unhydrated percentage of cement, ρ = density of cement
ν = stoichiometric ratio of water to cement (by mass)
r_0 = radius of unhydrated cement particles at the beginning of hydration
k_d = mass transfer coefficient within initial protective layer ($k_d=B/\alpha^{1.5}+C\cdot\alpha^3$)
D_e = effective diffusion coefficient of water in hydration products
k_r = coefficient of hydration rate per unit area of cement
C_w = water concentration outside hydration products
If $1-\alpha \leqq m$, then $C_w = 1$
If $1-\alpha > m$, then $C_w = \exp\{-n(1-\alpha-m)\}$
where $m = p\cdot(W/C)^{1/3}$, n and p = constants, W/C = water-cement ratio

As the hydration of cement proceeds, D_e decreases due to the decreasing pore diameter in the gel as follows:

$$D_e = D_E[\ln\{1/(1-\alpha)\}]^2 \quad [2]$$

B, C, D_E, and k_r are affected by temperature, following the Arrhenius's law as follows:

$$\begin{aligned} B &= B_{20} \cdot \exp[-\beta_1(1/T-1/293)] \\ C &= C_{20} \cdot \exp[-\beta_2(1/T-1/293)] \\ D_E &= D_{E20} \cdot \exp[-\beta_3(1/T-1/293)] \\ k_r &= k_{r20} \cdot \exp[-E/R(1/T-1/293)] \end{aligned} \quad [3]$$

where B_{20}, C_{20}, D_{E20}, and k_{r20} = values of B, C, D_E, and k_r at 20℃
T = absolute temperature (K)
β_1, β_2, β_3, and E/R = coefficients determined for each cement type and W/C

HEAT LIBERATION RATE OF CEMENT

To ensure that the above model expresses the changes in the heat liberation rate of any cement independently of the temperature of the hydration environment, the heat liberation curve of each cement given in **Table1** was actually measured with a conduction calorimeter and each coefficient was calculated by means of repetitive calculation, so that the model coincides with the measured curve. Four levels of temperature were selected: 10, 20, 40, and 60℃. The water-cement ratio was fixed at 50%. In the case of ordinary portland cement (OP), the use of a high-range water-reducing agent was also investigated with a water-cement ratio of 35%.

Table2 gives the calculated coefficients, and **Fig1** shows the comparison between the heat liberation rates actually measured and those calculated from the model. This figure shows that the calculation appropriately expresses not only the peak values of heat liberation rate but also the extended induction periods due to the addition of a high-range water-reducing agent. In other words, the model was found to be capable of adequately describing actual hydration of cement.

ADIABATIC TEMPERATURE RISE OF CONCRETE

In order to confirm the applicability of the model to the estimation of adiabatic temperature rise of concrete, the adiabatic temperature rise of four types of concrete was actually measured, and the measurements were compared with the calculation by the model as shown in **Fig2**. The specific heat of concrete, Θ_c, was assumed to change in the course of hydration as expressed by **Eq4**. The calculations and the measurements are found to agree well with each other. Accordingly, the model is considered to be capable of estimating adiabatic temperature rise of concrete by using the coefficients given in **Table2** with an accuracy sufficient for practical use.

$$\Theta_c = \frac{1}{W + C_e + S + G}(W + 0.904C_e + 0.796S + 0.771G)\alpha + 1.17(1-\alpha) \quad [4]$$

where W,C_e,S and G=unit mass of water, cement, fine aggregate and coarse aggregate (kg/m^3)

THERMAL STRESS OF CONCRETE MEMBERS

To confirm the applicability of the model to the estimation of temperature distribution and thermal stress in real concrete structures, the authors examined the changes in the temperature and thermal

strain over time of reinforced concrete columns shown in **Fig3** with water cement ratios of 0.395 and 0.33 at the points shown in **Fig3**. The measurements were compared with the calculations using the model. Ordinary portland cement was used and the temperature of concrete at the time of placing was 26℃. The temperature and thermal stress were analyzed using difference calculus and FEM, respectively, regarding a quarter of the section. The heat transfer coefficient of the concrete surfaces, heat conductivity of concrete, and specific heat of concrete were assumed to be 33.5kJ/m²h℃, 7.12kJ/mh℃, and 1.17kJ/kg℃, respectively. The external restraint was

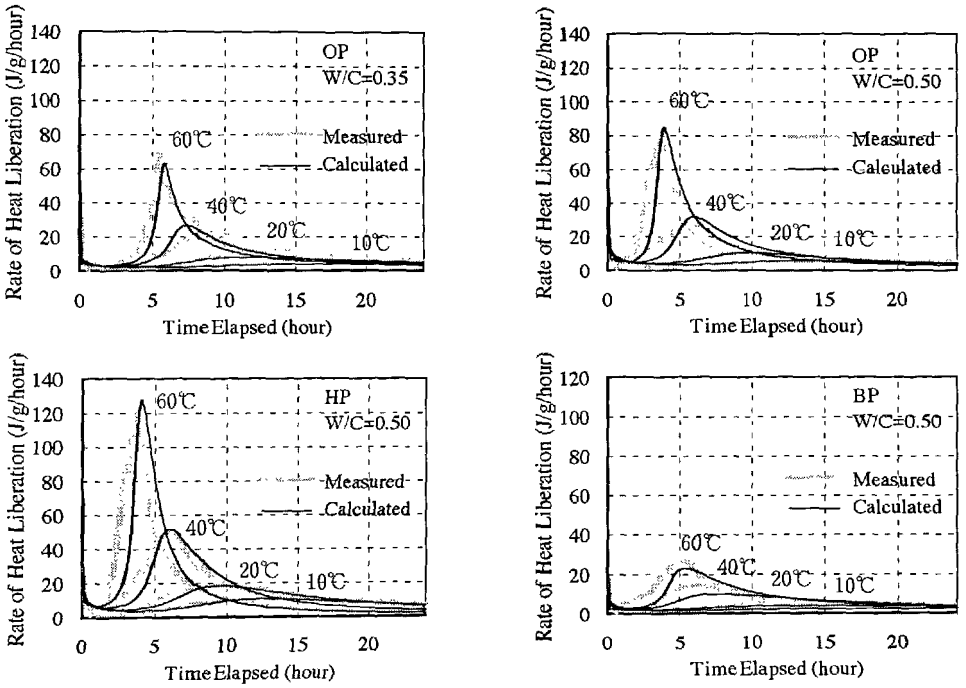

Figure 1 Heat Liberation Rate of Various Cements

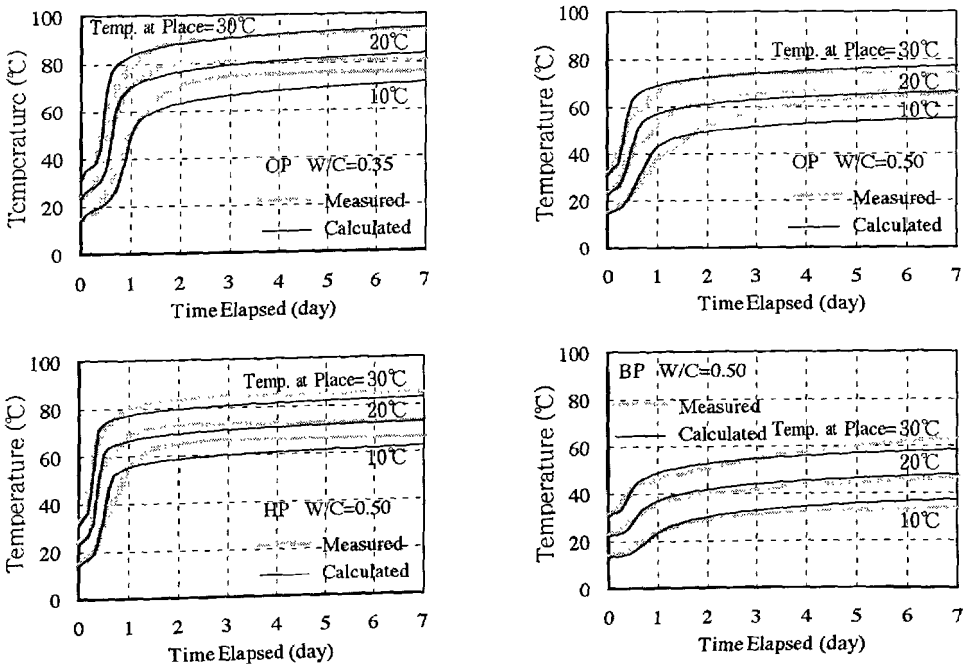

Figure 2 Adiabatic Temperature Rise of Concrete with Various Cements

disregarded and only the internal restraint was taken into account for the thermal stress analysis.

Figure4 shows the comparison between the measured temperature histories and those calculated using the model. The calculations by the model are found to be capable of estimating the peak temperature, time of peak, and ascending and descending temperature slope with an accuracy sufficient for practical use both deep in the concrete and near the surfaces. **Figure5** shows the comparison between the thermal stress histories calculated on the basis of the measured strain and those calculated on the basis of the model. The tensile strength curves in the figure are those near the surfaces. In this study, tensile strength is assumed to be 1/13 of compressive strength calculated by Powers's method (1958) based on the degree of hydration determined from **Eq1**. The estimation of thermal stress based on the model agrees well with the measured values, suggesting the effectiveness of the model for the estimation of thermal stress of members.

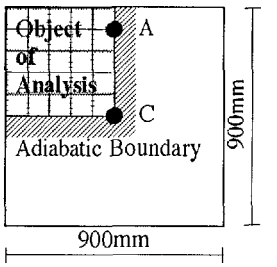

Figure 3 Dim. of Column

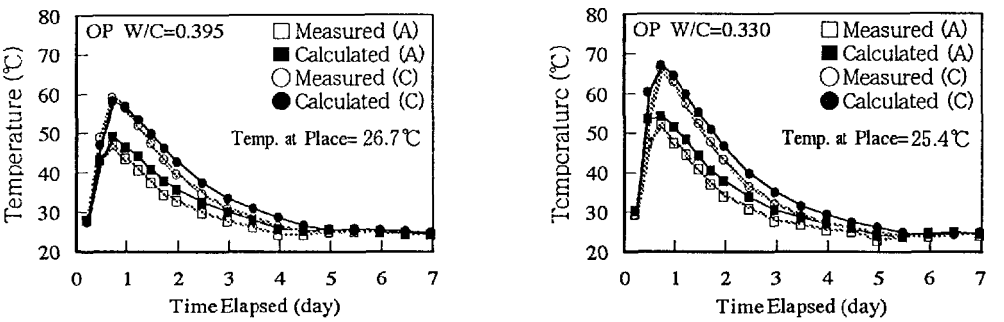

Figure 4 Temperature History in Reinforced Concrete Column

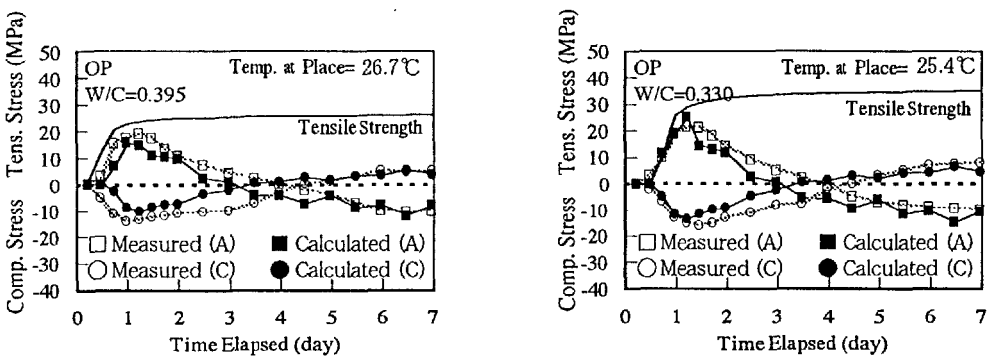

Figure 5 Thermal Stress in Reinforced Concrete Column

CONCLUSION

The coefficients for the cement hydration model were calculated from the measured data of heat liberation rate curves of cement. The model was found to be applicable to the estimation of the adiabatic temperature rise of concrete as well as temperature distribution and thermal stress of real structures under any environmental conditions with an accuracy sufficient for practical use.

COMPUTER MODELLING OF THERMAL PERFORMANCE OF REINFORCED CONCRETE SUBJECTED TO FIRE

Andrew PLATTEN, Zhaohui HUANG, and John ROBERTS
Department of Built Environment, University of Central Lancashire, Preston, PR1 2HE, U. K.

ABSTRACT A theoretical analysis of heat and moisture transfer in concrete was made which incorporated the simplifications that energy transfer by convection and diffusion in concrete could be neglected. Based on this analysis a non-linear finite element procedure was proposed to predict the temperature distribution history in the cross section of structural members in fire conditions.

KEYWORDS: Concrete, Fire, Performance, Modelling

INTRODUCTION

There has been a number of studies on using non-linear finite element procedure to predict the temperature distribution history in reinforced concrete subjected to fire conditions Bizri (1973), Becker et al (1974). The objective of this study is to develop a computer model which, based on the theoretical heat and mass transfer in concrete, predicts the temperature distribution history in reinforced concrete subjected to fire conditions.

THE THEORETICAL BACKGROUND OF THE MODEL

Since concrete is a capillary-porous material, the thermal analysis of reinforced concrete in fire conditions is complicated by the presence of moisture. Sahota (1976) proposed a theoretical model which takes into account mass diffusion, convection, evaporation, and condensation. No dry-wet interface was postulated. Based on the literature review the theoretical model developed by Sahota [1976] was adopted as the theoretical foundation in this research.

One-dimensional energy equation

In one dimensional form the energy equation can be expressed as, Sahota (1976),

$$\frac{\partial T}{\partial t}=\alpha\frac{\partial^2 T}{\partial x^2}+\left\{\frac{1}{\rho C_p}\frac{\partial k}{\partial x}-C_r\left[u_m+\frac{D(C_{p,v}-C_{p,a})}{C_{p,m}}\frac{\partial w_a}{\partial x}\right]\right\}\frac{\partial T}{\partial x}-\frac{1}{\rho C_p}\left[h_{fg}\Gamma_m-\frac{\partial}{\partial t}(\rho_m R_m T)\right] \quad [1]$$

Sahota (1976) carried out an order of magnitude analysis for the various terms in the governing equation. Sahota's analysis provides guidelines to determine the range of parameters required to describe the general result and the following simplifications may be made in the Eq 1: the orders of magnitude of terms $C_r u_m$ and $C_r[D(C_{p,v}-C_{p,a})/C_{p,m}](\partial w_a/\partial x)$, which respectively represent energy transfer by convection and mass diffusion, are <<1. For the term $\partial(\rho_m R_m T)/\partial t$, which is the result of the difference between the enthalpy and internal energy of air-vapour mixture, the order of magnitude is also << 1. Compared to the conduction terms for which the orders of magnitude are unity, the three terms noted above may be neglected. Thus the simplified energy equation can be written as:

$$\frac{\partial T}{\partial t}=\alpha\frac{\partial^2 T}{\partial x^2}+\frac{1}{\rho C_p}\frac{\partial k}{\partial x}\frac{\partial T}{\partial x}-\frac{1}{\rho C_p}h_{fg}\Gamma_m \quad [2]$$

Which is the ordinary conduction equation with a heat sink term due to evaporation of water. If one is interested only in the temperature field, Eq 2 can be solved for T with initial and boundary conditions if Γ_m is known. The following assumptions are made to evaluate Γ_m: (1) The energy transfer due to mass diffusion is negligible compared to that by conduction. This implies that the contribution due to evaporation of water is unimportant as long as liquid water does not start to boil. (2) The boiling point of water in concrete is seen to be in range from 100 to 140 ^0C, Haksever and Anderberg (1981/82). In this study it is assumed that water boils at 120^0C; for the purpose of calculating the temperature field the average pressure is taken as two atmospheres. (3) Movement of the liquid water is neglected. As a result of assumption (1), Γ_m in Eq 2 is put equal to zero at each point in the wet region in the interior of the concrete elements where temperature is less than 120^0C. Γ_m is also zero in the dry region. As the temperature at a wet node approaches 120^0C, it cannot increase further according to assumption (2) until all the liquid water at that node is evaporated. Therefore, Eq 2 can be used to calculate the value of Γ_m:

$$\Gamma_m = \frac{1}{h_{fg}}\left[k\frac{\partial^2 T}{\partial x^2} + \frac{\partial k}{\partial x}\frac{\partial T}{\partial x}\right] \qquad [3]$$

As $\partial T/\partial t = 0$. Once Γ_m is known, a new liquid density is calculated at that node using continuity equation for the liquid. That is, $\partial \rho_l/\partial t = -\Gamma_m$.Once the liquid density becomes zero, the temperature increases again with $\Gamma_m = 0$.

Two-dimensional energy equation

From Eq 2, the two-dimensional energy equation can be expressed as follows:

$$\rho C_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) + H \qquad [4]$$

where, H is internal heat generation, for concrete: $H = -h_{fg}\Gamma_m$, for steel: $H = 0$. Eq 3 can be used for calculation of Γ_m in the two-dimensional analysis, that is

$$\Gamma_m = \frac{1}{h_{fg}}\left[\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right)\right] \qquad [5]$$

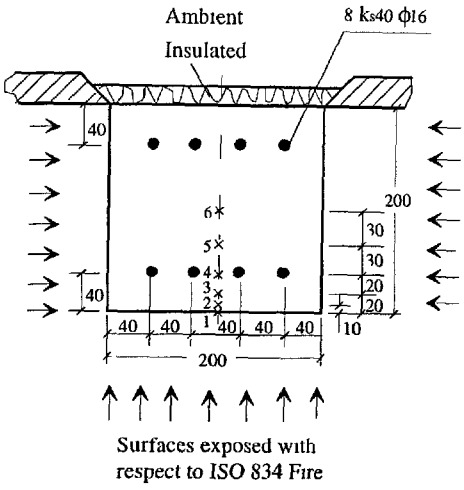
MATERIAL PROPERTIES AND NUMERICAL PROCEDURE

In this study the thermal properties of concrete have been considered as temperature and moisture dependent and the properties of steel is temperature dependent. The details of the models used can be found in Huang (1995). The finite element method has been used as the solution technique. A non-linear fire boundary condition was used to model the heat transfer between fire and concrete surface. The temperature of a pseudo-fire is represented by a standard fire curve. The detail numerical procedure used in this paper can be found in Huang (1995).

PROVING TESTS

In this study, there are a actual test data sets, Haksever and Anderber (1981/82), with which the predictions of the analytical method are compared. The schematic diagram of cross-section of the column (2 m in length) is shown in Fig 1. The concrete used for the column specimens had a cube

strength of about 46 MPa with a testing age of 110 days. The moisture content of the concrete was measured on cubes $(0.15\times0.15\times0.15)\ m^3$ and was about 6%. The other values of parameters of normal weight concrete used in this calculation are listed in Table 1.



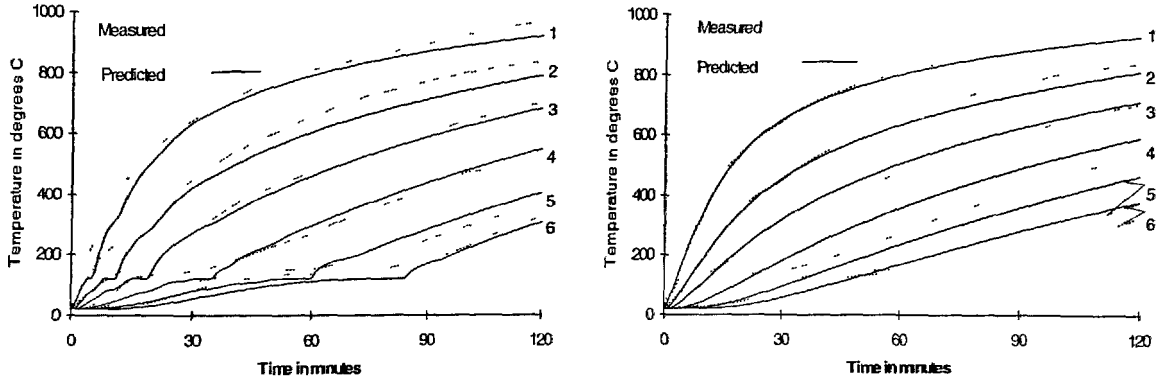


Figure 1. Schematic diagram of cross-section of column for proving tests (dimensions in mm)

(a) (b)

Figure 2. Comparison of predicted and measured temperatures at mid-section of the column exposed to ISO 834 Fire (flame emissivity of fire = 0.75), (a) $w=6\%$, (b) $w=0$.

Results and discussion

The results of the tests are shown in Fig 2. It can be seen from both the sets of measured points and the prediction curves that the presence of moisture has a significant effect on the temperature histories in concrete during fire conditions. It is seen that, overall, the model proporsed produces a fairly good agreement with test data. To improve the accuracy of prediction the thermal properties of material at elevated temperature are required further investigation. Conclusions derived from the work include the following: (1) The model proposed in this study is capable of predicting the temperature distribution histories of cross-section of reinforced concrete structural members subjected to fires with a reasonable good accuracy, the total deviation observed over the range of parameters examined was found to be 6% to 13%. (2) The effect of moisture is significant on the temperature distribution histories in concrete during fire conditions, especially for higher initial moisture content which should be taken into account in the thermal analysis of reinforced concrete. (3) The temperature distribution histories in reinforced concrete are sensitive to the value of the flame emissivity of fire, ε_f, used. It appears reasonable to use values in the range of 0.75 ~ 0.85 for the ε_f.

MECHANISM OF THE ALKALI-SILICA REACTION

Roger DRON, Françoise BRIVOT and Thierry CHAUSSADENT
Laboratoire Central des Ponts et Chaussées
58 Bd Lefebvre - 75732 Paris Cedex 15 - France

ABSTRACT The Le Chatelier principle of through-solution processes suffices to completely explain the ASR mechanism. The essential steps (dissolution of reactive silica in the alkaline pore solution and formation of reaction products from silicate solutions and solid calcium hydroxide) were studied separately *in vitro*. The properties of the system K_2O-CaO-SiO_2-H_2O are represented in a two-dimensional projection of the chemical potential diagram μ_{KOH}-μ_{SiO2}-μ_{CaO}. The formation conditions for two kinds of products (precipitates and gels) are examined.

Key-words: Alkali silica reaction, CSH, Gel, Mechanism, Phase diagram

INTRODUCTION

Most authors attribute the degradation known under the name of alkali-silica reaction (ASR) to the belated formation, within concrete made with sensitive aggregates, of masses of hydrated compounds visible under the scanning electron microscope and containing silicon, calcium and alkalis in poorly defined proportions (Dent Glasser and Kataoka, 1981, Davies and Oberholster, 1988).

Research aimed at determining the mechanism of this reaction has a practical purpose. The objective is less to describe than to provide a key for understanding what takes place in order to suggest ideas capable of preventing disorders or remedying them. If such means are effective, the proposed mechanism will stand some chance of corresponding to reality.

The experimental study of the mechanism can rarely be accomplished on the real or simulated system. The difficulty is due to the fact that, *in vivo*, the stages are not separated in time so that, at a given instant, it is possible to find simultaneously products formed at different stages and not reveal those that have only a transient or brief existence. Therefore it is necessary to begin with a hypothetical scheme based on a guiding principle and to try to obtain separately, *in vitro*, the assumed main stages, removing the reagents which intervene only in the next stages or using, as reagent, products supposed to have formed during the preceding stages. In this way, it can be shown that such stages are plausible.

THE LE CHATELIER PRINCIPLE

Based on the new vision introduced by the Gibbsian revolution, the great French scientist Henry Le Chatelier considered that cement also obeyed the essential laws of chemistry, as they were established in the early 1900. He had perfectly assimilated the subtle concepts of phase and chemical potential and knew that, at ordinary temperature, transfer of matter is practically nonexistent in the solid state. Thus he drew the conclusion that the aqueous solution, that filled the pores of cement paste, was the surface dissolution agent of the anhydrous phases, as well as the vehicle of the resulting ions and the mother liquor of the hydrates.

In connection with this aspect of Le Chatelier's work, one should not speak of theory. What was involved was simply a scientific attitude, let us say a principle, more general than the crystalloid theory that he deduced therefrom. We shall use this unique guiding idea as our support.

SOURCES AND RESERVOIRS OF REAGENTS

Alkalis come mainly from the cement itself. Initially present in the diffuse state in the anhydrous phases, during hydration they go to the liquid phase under the form of K^+OH^- and Na^+OH^- and, as they do not take part in the formation of normal cement hydration products, they accumulate in the interstitial solution until a concentration of about 1 $mol.l^{-1}$. The quantity present in solution is thus, approximately proportional to the degree of advancement of the hydration reaction but the concentration grows slightly faster, owing to the partial consumption of water. As both asymptotic behaviours are approached simultaneously, it may be said, roughly, that the first condition of the alkali-reaction is met only when hydration comes to an end. The alkali reserve is then totally in a dissolved form.

Reactive silica of interest to us is, by definition, that of the aggregates. Every variety of silica is practically insoluble in pure water but, because of the acid nature of SiO_2 , some may dissolve in anionic form in aqueous solutions of strong bases. The action of such a dissolution process in the alkali reaction is altogether plausible since, in hardened concrete, the requisite conditions are met by the accumulation of alkalis. The equilibrium to which it leads depends on both the final pH and the reacting solid variety. To this component of the reactivity, of a thermodynamic nature, should be added the kinetic component which, in practice, may turn out to be more important.

The most accessible source of the CaO constituent is portlandite present in the hardened paste under the form of microcrystals dispersed in a rather uniform manner. However, its dissolution is problematical because the law of the solubility product, $K_s = [Ca^{2+}].[OH^-]^2$, applies to the equilibrium of dissolution. In the very basic medium resulting from the accumulation of alkalis, the Ca^{2+} ions have an extremely low concentration level. They can initiate a reaction but they do not enable it to be maintained considering that their available amount in solution is very weak. However, even partial, their consumption in any reaction is sufficient to make the solution undersaturated, thus leading to a dynamic shifting of the dissolution equilibrium. Due to this coupling, the solution can take, as it requires, the calcium hydroxide from the solid reserve.

In the absence of any diffusion, the silica and calcium hydroxide dissolution process would be located in the vicinity of the liquid-reagents solid interface. Diffusion alone can ensure the transfer of matter beyond, and only in dissolved form, in this case ions. Indeed it is by diffusion that the Ca^{2+} and OH^- ions coming from the dissolution of the portlandite as well as the silicate ions resulting from the attack of the silica can move away from the interface. Diffusion also allows, in the opposite direction, the supply of OH^- ions necessary for this attack and the movement that brings these ions into contact with each other.
It is thus possible to find, within the solution, under certain conditions and in varied forms, at certain locations and at certain moments, in addition to water, which is omnipresent, the ingredients necessary for the formation of hydrated compounds including lime, silica and alkalis if two fundamental acts take place *in vivo*:
- changeover to solution in the form of anions of reactive silica by hydroxyl attack.
- reaction of these anions with the cation Ca^{2+}, coupled with the dissolution of the portlandite.

EXPERIMENTAL PART

The research consisted in reproducing separately *in vitro* the two acts considered above. Silica attack by alkaline solutions was investigated in the absence of calcium hydroxide and, in the study

of the reaction between calcium hydroxide and the dissolved silicates, we used synthetic solutions similar to those resulting from the attack of the silica.
The basis of this research and the results were published in several articles to which it may be useful to refer (Dron *et al.* 1992, 1993, 1994, 1996). In the present general article, we shall explain the approach, summarise the essential findings, develop the interpretation and draw the consequences.

Dissolution of silica in alkaline solutions

The principle and the operating conditions were those of the ASTM C 289-71 test. Three parameters (contact time, temperature and sodium concentration) were varied in relation to the standard version. In the present study, 50 ml of sodium solution was allowed to act on 25 g (160-315 μm grains) of the tested aggregate. An original apparatus makes it possible to maintain the suspension.
The measurement is based on the analytical determination of the amount of silica going into solution for a given time. We worked on different varieties of silica, in particular an opal from central France. Its high reactivity enabled us to complete the entire process in 24 hours, the composition of the solution did not show any further change after that time.
The existence of an induction period of about one hour is noted. A steady state is then established, with the rate decreasing gradually towards zero as the silica concentration approaches the sodium concentration (0.5 $M.l^{-1}$ or 1 $M.l^{-1}$).
The dissolution rate, measured at the inflexion point, is approximately proportional to the OH^- concentration (kinetic order near 1). It is divided by 2.8 when the temperature drops from 67 to 57°C, which corresponds to an activation energy, taken from the law of Arrhenius, of 96 $kJ.M^{-1}$.
It is deduced that the standard ASTM test, conducted at 80°C, is accelerated by a factor of the order of 400 in relation to what it would be at 25°C.
This rate depends essentially on the variety of silica. For the solution at 1 $M.l^{-1}$, the rate, expressed in moles per litre and per hour and referred to 25°C, was found to be equal to 7.10^{-7} for quartz, 9.10^{-5} for silex and 5.10^{-3} for opal, representing a progression by a factor of about 100.

The gradual slowing of the attack is explained quite easily by the conventional calculation of species in solution. When the solution becomes richer in silica, the Na^+ ion concentration remains constant while the pH and the anion charge decrease in a related manner.

Difficulties related to the presence of polymer forms are avoided by considering the species S^0, S^1 and S^2, defined by a silicon site linked to zero, one or two charged oxygen carriers, or HO-Si-OH for S^0, HO-Si-O^- for S^1 and $^-$O-Si-O^- for S^2. For the couples S^0/S^1 and S^1/S^2, the values of pK_a are taken equal, namely 9.8 and 12.6, to the corresponding monomer couples ($H_3SiO_4^-$ for S^1 and $H_2SiO_4^{2-}$ for S^2).

Fig 1 summarises the results of these calculations. It shows that the form S^1 becomes exclusive (average anionic charge per atom of silicon tending towards -1) as the pH tends towards 11.2.
At the maximum amount of S^1, the pH has fallen to the theoretical value of 11.2 so that, for kinetic as well as thermodynamic reasons, the attack can no longer continue further.
It is in fact the electroneutrality of the solution that fixes the final concentration of silica at a level near that of the alkaline ions, which remains constant throughout the attack.
In our experiments, such a limit was reached only in the case of opal. The time required for this saturation in an agitated medium depends only on the liquid/solid ratio.

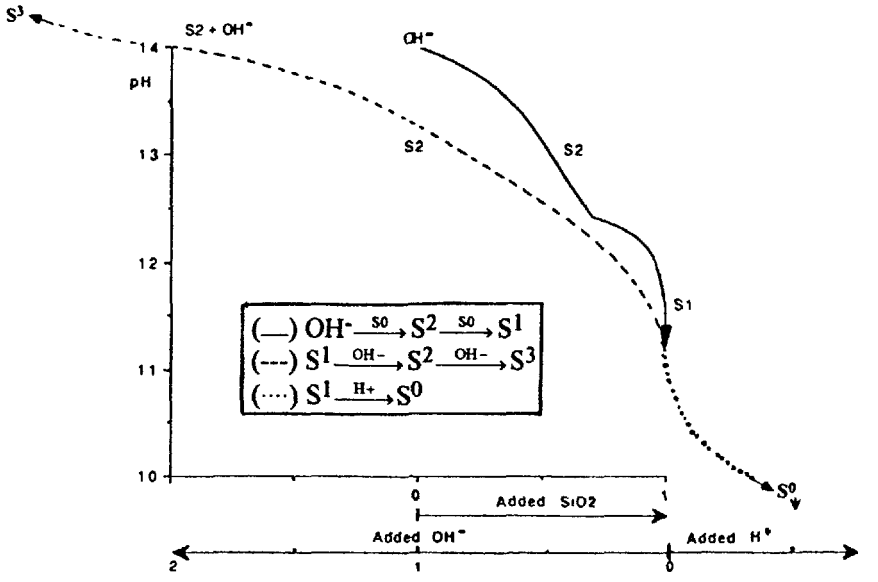

Figure 1 Acid-base reactions with silica entities in solution

In the real system, diffusion occurs, and the saturation time depends in particular on the thickness of the film in which the produced solution is confined. Considering the liquid-volume/reactive-surface ratio allows this thickness to be estimated. In the ASTM test, it is of the order of one millimetre and would be about ten times smaller for concrete containing 1,250 kg of a reactive aggregate exhibiting an area of 0.5 $m^2.kg^{-1}$.
The orders of magnitude found in the case of silex would allow the approach of saturation with time of the scale of a year, and even less if the attack liquor remained confined in the vicinity of the reactive surface.

Interpretation in light of NMR spectroscopy of ^{29}Si

This research technique provides precise information on the distribution of the many siloxane bonds, from 0 to 4, around silicon atoms (sites Q^0, Q^1, Q^2, Q^3 and Q^4) and thus enables the interpretation of experimental facts on the scale of atomic arrangements.
Differences in reactivity between the various varieties of silica are thus explained to a great extent by differences in structure: practically inert forms such as quartz are made up only of Q^4 entities, i.e. each silicon atom is bound to four others by siloxane bridges. They are partially replaced in the reactive forms by Q^3s, the fourth bond being occupied by a hydroxyl (silanol group). The induction period may be related to the breaking of the Q^3s prior to the Q^2s one which would then take place during the actual attack phase. This would also explain the loss of alkalinity observed during the attack of large specific surface materials, such as silica gel, by chemisorption of the K^+OH^- couple at the breaking place of the Q^3.
Also very instructive are the studies of NMR of ^{29}Si relative to alkaline silicate solutions. Engelhardt and Michel (1987) investigated the distribution of Q^n entities on solutions of various silica concentrations, on the one hand, and various $R_m = [SiO_2]/[M_2O]$ on the other.
We adjusted these data on semi-empirical expressions, i.e. forms such that, upon approaching the limit values, they are rigorous for theoretical reasons (Dron, 1994). Thus we were able to

calculate the relative abundance of each Q^ns for any composition and, especially for the fixed concentration $[Na^+] = 1$, the percentage of each form as a function of the concentration $[SiO_2]$.
Monomers, which correspond to the Q^0s, represent the majority in low concentrations of silica and become a very small minority upon the approach of $[SiO_2] = 1$ mol.l^{-1}, whereas Q^3s begin to appear. Neglecting the contribution of Q^3s, it is possible to deduce the average length of the linear polymers.
Monomers are predominant as long as the SiO_2 concentration does not exceed 0.4 mol.l^{-1}. Above this concentration, linear-chain polymerisation becomes dominant. Then, branched-chains appear, revealed by the presence of Q^3 sites. We shall consider that, at the start of the attack, the only silicate anions compatible with the high alkalinity are monomers, essentially the $H_2SiO_4^{2-}$ species, whereas, as we approach saturation, the linear-chains having about five patterns become the predominant form. The branched-chains, revealed by the Q^3s, become significant only upon approaching the limit concentration level at 1 mol.l^{-1}.

Reactions between calcium hydroxide and alkaline silicate solutions

We used an extensive experimental framework bringing together, under agitation, a fixed amount (1 g) of finely dispersed calcium hydroxide and a fixed volume of potassium silicate solutions (100 ml).
These synthetic solutions were prepared by mixing commercial silicate (ratio $K_2O/SiO_2 = 3.8$), potash 4 M.l^{-1} and water. thus it was possible to vary, as desired and independently (in steps of 0.25 M.l^{-1}), the silica and potassium concentrations. Work based on very similar principles had been undertaken independently by Way and Shayan (1992) who, reaching the same conclusions as we did, published the results before us. We have noted their priority (Dron and Brivot, 1993) and stressed the points of agreement which appear to be essential, and which we are repeating below, namely:
"The existence of two fields in the space x = [K], y = $[SiO_2]$ at equilibrium when a fixed amount of calcium hydroxide has been added to solutions of KOH and SiO_2 in various proportions. The lower field corresponds to precipitates + mother liquor. The upper field corresponds to macroscopically homogeneous gels impregnated by a serum. The precipitates are characterised by XRD as similar to C-S-H(I) and the gels are amorphous systems with a broad band centred at 0.305 nm. There exists a definite relation between the composition of each washed solid and the composition of the corresponding mother liquor or serum."
We pointed out in the same discussion the most important of our observations:
"The system, obtained by mixing up to 1.85 g of calcium hydroxide and 100 ml of potassium silicate solution [K] = 2 M.l^{-1}, $[SiO_2]$ = 1.5 M.l^{-1}, exhibits the surprising behaviour of complete dissolution of the particles and leads to a clear and fluid solution, as if Ca^{2+} were complexed, as it is by EDTA in high pH media."
Our NMR studies of ^{43}Ca (Nieto *et al*, 1995) have demonstrated a very close kinship of the Ca's present in the complex and the gel, very different from the Ca^{2+}s. The coagulation could result from a rearrangement of the Si-O···Ca···O-Si intra-ionic bridges into inter-ionic bridges.

Diagram of chemical potentials governing equilibria

On the occasion of the International Congress on Cement Chemistry which was held in Moscow in 1974, we pointed out the great interest for cement chemistry of the representation of ternary and quaternary systems in equilibrium by chemical potential diagrams in bidimensional projection (Dron, 1974). Then we then applied this to the $CaO-Al_2O_2-SiO_2-H_2O$ system and stressed its advantages over former representations. Those findings apparently did not come to the attention of Gartner and Jennings (1987) who later developed the same idea.

In our opinion, the value of these diagrams is not of a descriptive nature but rather of an explanatory, and even pedagogical nature. They contain all the thermodynamic information available and their remarkable simplicity results from the use of variables which are linear by construction. The relative arrangement of the phase domains and the slope of the straight lines which generally separate them are of greater importance than their exact position. Thermodynamic tables have, in the best of cases, only data relative to the compounds with fixed and integer stoechiometric coefficients, which is almost the exception in cement chemistry. For the others, the only data available are those of the chemical analysis of the solid phases and of the solutions. They can be translated by means of conventional formulae into solubility products and, more generally, into ionic products whose logarithm is an affine magnitude of the chemical potential. Taking into account the activity coefficients changes nothing in the general configuration and very little in the position of boundaries. They may be omitted without detriment and only what is essential may be considered. What is essential, in the present problem, is relative to the variance.

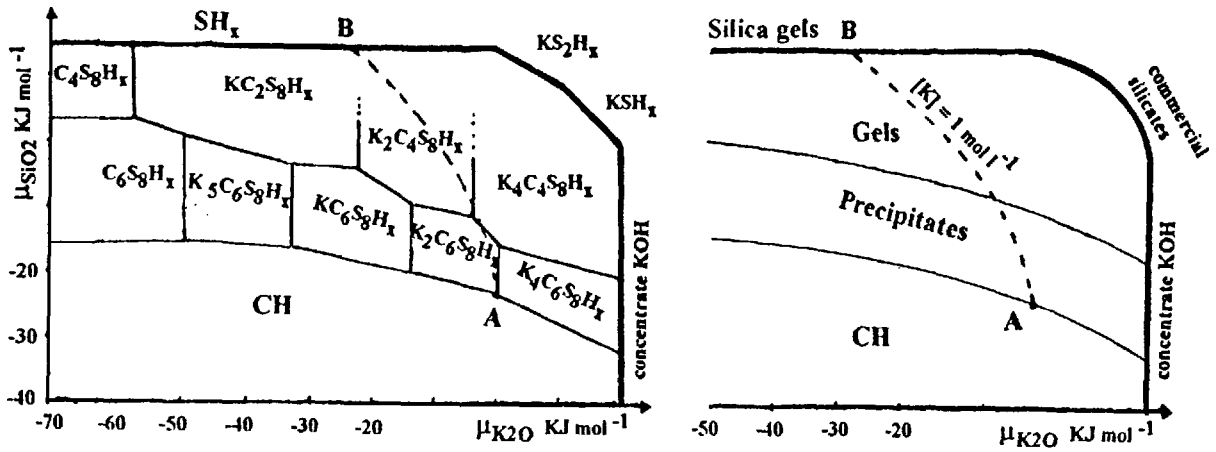
The K_2O-CaO-SiO_2-H_2O system has four independent constituents. The aqueous phase is always present. At constant pressure (1 atm) and temperature (298°K), the variance is $V = 4 - \Phi$. Let $\Phi' = \Phi - 1$ be the number of solid phases. Then we have $V = 3 - \Phi'$.

The number of solid phases in equilibrium, always at least equal to one, is thus at most equal to three ($V = 0$). A first version of the chemical potential diagram based on this conventional vision is represented in Fig. 2a.

The calculations were carried out on the basis of usual rules of the chemistry of solutions: conservation of matter, electroneutrality, action mass law applied to concentrations. They include an important innovation: they make use, not of silicate ion concentrations, which is not possible given the polymerisation, but those of S^0, S^1 and S^2 entities as we defined them earlier.

The chemical potentials are calculated by means of the following relations:

$$\mu_{K2O} = 2.R.T.\ln[K^+].[OH^-] \quad \mu_{SiO2} = R.T.\ln[S^1]/[OH^-] \quad \mu_{CaO} = R.T.\ln[Ca^{2+}].[OH^-]^2$$



Within a given domain, the orientation of the level lines of the chemical potential of CaO is obtained by applying the Gibbs-Duhem relation (taking $d\mu_{CaO} = 0$) for the local stoechiometry. The slope of the frontier between two contiguous domains is obtained by elimination of μ_{CaO} between the equations of the two corresponding plans.

Determined by establishing the coherence of all our analytical results, this version is true only as a first approximation. The difference with reality is not so much the result of simplifications which were made during the calculation, but is due rather to the fact that no account is taken of two basic characteristics resulting from our experimentation:

a) Monovariant lines (phase domain boundaries) and the supposed invariant points are formally contradicted by the absence, at the expected locations, of any link between the two composition variables [Si] and [K] of the liquid phase.

b) The composition of solid matter, which is expressed by the couple (K_2O%, SiO_2%), varies in a strictly continuous manner within a given domain.

In the μ_{K2O}-μ_{SiO2}-μ_{CaO} space, the diagram 2a would be represented by a polyhedral whose sides intersect two by two on straight edges, converging at the invariant points. For most of them, these edges have no existence. They are rounded off and we go strictly in a continuous manner from one domain to another, to the extent that one can still speak of domains.

a: Idealized diagram

b: General features of the true diagram

Figure 2 Chemical potential diagram

The correct orientation (Fig 2b) of the level lines μ_{CaO} = cte was determined, for each of the experimental points, by using, in the application of the Gibbs-Duhem relation, the effective composition of the solid phase.

CONCLUSION

Chemical potential is a local, instantaneous and evolutive magnitude. It is thus possible to characterise an element of active volume, in local equilibrium, by a point on the diagram. For this, we shall initially use the approximate version of Fig 2a, more pedagogical and easy to transpose later mentally on the more correct version of Fig 2b.

At the "zero" instant of the ASR, which we take towards the end of the hydration of cement, the interstitial liquor is roughly the same throughout. It contains about 1 mol.l^{-1} of OH^- and is saturated in $Ca(OH)_2$, which places it at point A.

The interstitial liquor in strict contact with the portlandite has no reason to evolve, but the one in contact with the reactive silica tends to equalise its potential with that of the solid phase so that evolution takes place in the direction of point B.

This situation would remain in the absence of any diffusion, but its occurrence will upset this precarious equilibrium, the course of events being determined by the choice of the limiting stage.

a) <u>If the limiting stage is the attack of the silica:</u> The diffusion assures the evacuation of the rare silicate ions formed, first in the surrounding alkaline liquor, where they depolymerise into $H_2SiO_2^{2-}$ monomers and co-precipitate with the rare Ca^{2+} ions, renewed immediately after being consumed, in the presence of many K^+ ions. The figurative point will separate from point A only what is necessary for adjusting the dissolution flux of the portlandite. The neo-formed product will be a precipitate, and in any case a crystalloid, because it is made up of ions which are sufficiently small so as not to be arranged randomly. This product does not have two phases as diagram 2a would suggest, but a single phase (continuous solid solution) of intermediate composition in conformity with diagram 2b. This calm precipitation in quasi-equilibrium does not involve a high energy level and hence is of no great danger for the structure.

b) <u>If the limiting stage is diffusion:</u> The process described in (a) is restricted to the immediate vicinity of the solution-reactive aggregate interface and takes place until the depletion of the immediately accessible portlandite. The figurative point moves in the direction of point B following the line [K] = 1 mol.l^{-1}. A radical dissymmetry is established in the concrete:
- in contact with the aggregate, we find a solution saturated in silica represented by point B. The silicate ions forming it are mostly polymers.
- throughout the rest of the paste, including portlandite, the solution is represented by point A.
It is at the interface between the two antagonist domains that the destructive reaction occurs. This means the complexation of the Ca^{2+} ion by the silicate polyanions which take it from the surface of the portlandite crystals, inexorably gnawing at them. The representative point of the solution of the complex, as long as a solid phase does not form, is free to escape over the surface (flat or curved) which will be assigned to it *in fine* by the return to equilibrium. The level of μ_{CaO} can rise up to that of the portlandite. The break of this metastable equilibrium takes place in the form of a coagulation, in which the disorder increases as the difference increases between the present system, at a very high lime potential, and the biphase stable system (matrix + serum, gel in the sense of colloid chemistry) to which it is transformed. The free energy made available by this sudden break can cause irreversible mechanical damage, especially as it occurs in a sector made fragile by voids resulting from the dissolution of the portlandite. It can be understood why the solid which forms under such conditions and from very disparate and partially branched polyanions is completely amorphous. This gel moreover has properties liable to attract pure water by an osmosis phenomenon.

THE MECHANISM OF WATER AND IONIC PERMEABILITY OF CONCRETE

Arkady N. PLUGIN, Irina G. PROKOPOVA, Kharkov State Academy of Railway Transport, Ukraine
Stan WILD, University of Glamorgan, United Kingdom
Andrei A. PLUGIN, Kharkov State Technical University of Construction and Architecture, Ukraine

ABSTRACT The durability and serviceability of concrete structures are resulting from deformation and filtration properties of concrete and construction. Mechanism of these properties and tensile strength are described by fundamental aspects of Colloid Chemistry and Physico-Chemical Mechanics and corresponding equations are given. New methods of concrete composition calculation, new methods of concrete water permeability measurements, new methods and materials for concrete protection are developed with help of the new theoretical concept.

Key-words: structure, durability, permeability, water, ions.

INTRODUCTION

Insufficient durability and serviceability of concrete structures are resulting from imperfection of theoretical concepts about concrete structure, concrete deformation and filtration properties and imperfection of assessment and diagnostic methods too. Our theoretical concepts on these aspects are based on fundamental aspects of Colloid Chemistry and Physico-Chemical Mechanics of dispersed systems and materials developed by us with allowance for electrosurface properties, phenomena and interactions in cement-water systems (Plugin, 1989; Plugin and Plugin, 1995; Plugin et al, 1995).

When heavy concrete is compressed the stress is transferred in a form of two components - the uniformly distributed one between broken stone and mortar and the concentrated (contact) stress in the interphases between them. It is considered that the stone grains are incompressible in comparison to the mortar component of concrete. At this condition, the relative deformations and stresses in the interlayers between the grains are much higher than in the space between the stone grains. The analogous situation on the distribution of relative deformations and stresses takes place between the grains and particles (structure forming elements SE) in the mortar component and the cement paste of concrete. Accordingly, the destruction of concrete, mortar and cement paste begins with the deformations in the compressed contacts and the subsequent destruction of the stretched contacts between the SE at different structure levels. Depending on the concrete structure, redistribution of stress between matrix and structure forming elements in all the levels takes place under the influence of gel water filtering from the matrix into the pore space.

The above-stated predetermines that the structure, strength and deformations of the interlayers and the filtration properties of cement paste play leading role in demonstration of strength and deformation properties by cement paste and concrete as a whole.

THE STRENGTH THEORY. THE WATER FILTERING FROM GEL

Concrete is a polydispersed system, in which different levels - macro-, mezo-, micro-, submicro- and supermolecular of structures are combined. These levels are characterized by medium sizes of the structure forming elements (SE), accordingly large aggregate - 10-15mm, sand - 0.2-0.5mm, unreacted cement particles - 10-50μm, microcrystalline hydration new formations - 250-500nm, hydrosilicate gel particles - <50nm. Since the structure is a multi-level one, matrix is disperse and

consists of its structure forming elements - matrix particles (PM) (sand particles in concrete, cement particles in mortar, new formation particles in cement paste). The experiments and calculations show that the width of matrix layer in each level is comparable to the sizes of the structure forming particles of the matrix (PM). It allows to represent a generalized model of the matrix in interlayer in a form of three possible patterns of the matrix particles packing between the SE, Fig.1. The packing optimal by the average number of the contacts, density, tensile strength and deformability is the one shown in the Fig.1b,c. The coefficient of the structure forming elements (particles) extension (removing) is the generalized characteristic of the particles packing in the structure:

$$K_r = V_m / V_{pse}, \qquad [1]$$

where V_m - matrice volume, m^3; V_{pse} - volume of a pore in the skeleton, produced by structure forming elements, m^3.

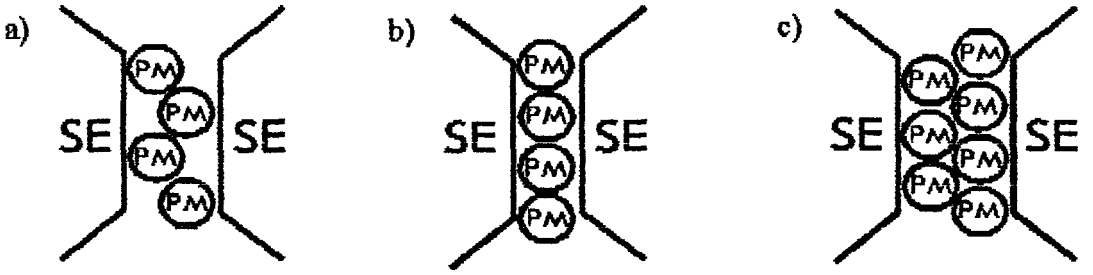

Figure 1 The generalized model of matrix in interlayer.

Among the hydration products microcrytalline hydration products have positively charged surfaces (positive electrosurface potential). The rest - negatively charged (except carbonate aggregates) (Plugin,1989; Babushkin and Novikova,1973). The electrosurface potentials ψ of some minerals are shown in Table 1.

Table 1 The electrosurface properties of some materials

Materials	ψ_0, v	ψ_{pH12}, v	n_c, $1/m^2$	n_e, $1/m^2$	a, nm	z_{pdi}	d, nm
quartz SiO_2	-0.55	-	$4 \cdot 10^{15}$	$4 \cdot 10^{15}$	6.0	4	0.152
portlandite $Ca(OH)_2$	-	+0.54	$9.8 \cdot 10^{15}$	-	10.2	2	0.240
tobermorite-like hydrosilicates $C_5S_6H_n$	-	-0.44- -0.56	$7.6 \cdot 10^{15}$- $-9.6 \cdot 10^{15}$	-	11.7- -10.4	2	0.405

According to our concepts about electroheterogeneous hardening of the cement paste, mortar and concrete structure is resulting from electroheterogeneous contacts EHC (between opposite charged surfaces of the structure forming elements). EHC determine strength, water resistance and hydraulic properties of portland cement concretes. An equivalent scheme of the EHC is presented in Fig.2 where a positively charged crystallohydrate block forms contact with a negatively charged surface of crushed stone or sand surface or with particles of hydrosilicate gel. The latter ones can be spherical, scaly or fibrous. The equivalent scheme of EHC type presented allows to apply the Physico-Chemical theory of dispersed systems strength by Rehbinder-Schukin (Rehbinder et al, 1964) and the formula of tensile strength of such systems modified by us (Plugin et al, 1995) to qualitative analysis of tensile strength of concrete, mortar and cement stone:

$$R_t = P \cdot n \cdot \gamma, \qquad [2]$$

where P- strength of bonding between the active centers (potential determining ions PDI); n - surface

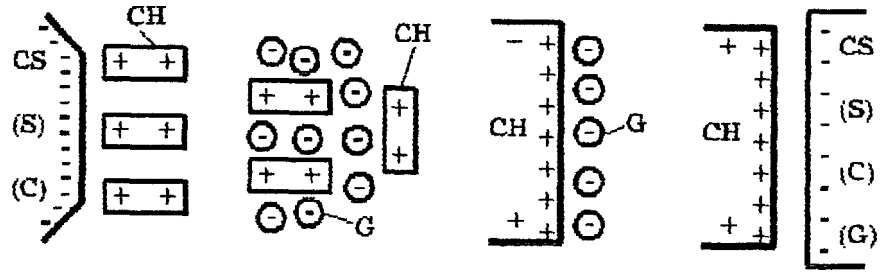

Figure 2 The equivalent scheme of the electroheterogeneous contacts (EHC): CS, S, C, CH, G - particles of crushed stone, sand, crystallohydrates, gel. CS-S-CS - macro-level; S-C-S - meso-level; C-CH,G-C - micro-level; CH-G-CH - submicro-level.

concentration of the active centers; γ -share of surface occupied by structure forming elements SE in tension cross-section.

Surface charge q, Kl/m^2, surface concentration of the charges (PDIs) n, 1/m^2 and electrosurface potential ψ, v are connected by equation for flat double electrical layer DEL:

$$n = \frac{q}{ze} = \frac{\varepsilon\varepsilon_o\psi}{4\pi dze}, 1/m^2, \qquad [3]$$

where ε, ε_0 - relative dielectric permeability and absolute dielectric constant (ε_0=8.85×10^{-12}); d - distance between potential determining ion PDI and anti-ion AI (counter ion) in dense DEL (between cation and anion), m; z - valence of ion; e - electron charge, 1.6×10^{-12} Kl. Quantity d is determined with the help of the crystallographic characteristics, i.e. the length and ionic bond direction. The calculated quantities of the surface concentration of the potential determining ions n_c and experimental n_e - of the active centers for the quartz SiO_2, for the portlandite and calcium hydrosilicate $C_5S_6H_n$ (tobermorite-like) are shown in Table 1.

The bonds between structure forming elements in different levels are determined by interactions between surface active centers, t. i. between potential determining ions and the total strength of solids in addition to it is determined by their concentration. The attractive force in this bond is determined by equation:

$$P = \frac{z_1 z_2 e^2}{8\pi\varepsilon\varepsilon_o h^2} + \frac{2z_{1(2)}\psi_{1(2)}\mu_d}{4\pi\varepsilon\varepsilon_o h_\mu^3}, N, \qquad [4]$$

where h - distance between the interacting ions (centers), m; μ_d - dipole moment of water molecule, (6.1×10^{-12} Kl·m). The tensile strength of such bond R_t=P/S_{ion} (S_{ion} - area of ion) is equal to 10^4-10^5 MPa. It is in accordance to theoretical tensile strength of solids. Real tensile strength of solids may be determined by the next formula:

$$R_t = \left(\frac{z_2 e\psi_1}{32\pi^2 d_1 h^2} + \frac{z_2\mu_d\psi_1}{8\pi^2 z_1 d_1 h_\mu^3}\right)\cdot\gamma = \left(\frac{508 z_2\psi_1}{d_1 h^2} + \frac{773 z_2\mu\psi_1}{z_1 d_1 h_\mu^3}\right)\cdot\gamma, Pa, \qquad [5]$$

where 1, 2 - correspond to the opposite charged ions.

The main structure forming elements in portland cement are the positively charged portlandite and hydrosulphoaluminate microcrystals, but the gel-like products are represented mainly by hydrosilicates. The submicrocrystalline hydrosilicate particles of xonotlite and tobermorite compounds of $C_5S_6H_n$ type, where n = 0,5-2,4 for 9-14 A° tobermorites, are the most imposing ones accordingly to (Ilukhin, 1979). Lets assume 14 A° tobermorite to be basic one. Its electrosurface potential ψ = -0,44 V. The parameters of bonding in active center are: d=2.4A°, h=5.2A°, h_μ=2.8A°, z_i=2. According to Eq.5 strength of cement stone (at γ=1) R_t=13.3MPa. Having assumed that compres-

sion strength exceeds tensile strength 10 times ($R_c \approx 10R_t$), which is inherent to concretes and other stone materials, we obtained $R_c^c \approx 133$MPa , which corresponds with experimental data $R_c \approx 140$MPa.

The γ value which determines concentration of the electroheterogeneous contacts in a unit of stretched cross-section, is calculated as a product of concentration of crystallohydrates γ_{ch} in cement paste and concentration of gel γ_g in water.:

$$\gamma = \frac{2CA\alpha_h \cdot 1.5}{\rho_{ch}\left[(C/\rho_c) + W - W_{cc}\right]} \times \frac{CB\alpha_h \cdot 1.5}{\rho_g W} = k\frac{(C/W)^2}{C/W + \rho_c\left[1-(W_{cc}/C)/(W/C)\right]}, \quad [6]$$

where $k=6.6\alpha_h^2AB$; A and B - stoichiometric mass correlation of crystallohydrate and gel products of cement hydration; α_h - hydration pitch. The coefficient 2 is to take into account that the electro-heterogeneous contacts form in both surface of break of cement stone. The coefficient 1.5 is surface concentration-to-volum concentration ratio. At A=0.57, B=0.67, α_h=0.5, W_{cc}/C=0.25 quantity k=0.26. The results of calculations γ^c and R_c^c and the corresponding experimental data received by Sitnikov and Vandone (Italy) independently and presented in (Kireyenko,1961) are given in Table 2.

Table 2. The calculated and experimental data on γ and R, MPa.

W/C	C/W	Experimental data		Calculated data		
		R_c^e	γ^e	γ^c	R_c^c	$\gamma^{sp}=\gamma^c R/138.7$
0.1	10	42	0.3	0.35	46.7	0.34
0.2	5	105	0.75	0.74	98.7	0.71
0.25	4	140	1	1.04	138.7	1
0.3	3.33	100	0.71	0.75	100	0.72
0.4	2.5	60	0.43	0.44	58.7	0.42
0.5	2	40	0.29	0.29	38.7	0.28
0.6	1.67	26	0.19	0.21	28.0	0.2
0.7	1.43	17	0.12	0.15	20.0	0.15
0.8	1.25	12	0.09	0.09	12.0	0.09
0.9	1.11	9	0.07	0.08	10.7	0.08
1.0	1	7	0.05	0.07	9.3	0.07

The calculated values of strength R_c^c and specific coefficient $\gamma^{sp}=\gamma^c R/138.7$ are very close to the experimental data. Therefore it is very difficult to evaluate the difference between the calculated and experimental data in graph (Fig.3). This fact demonstrates the correctness of the theory and the cement paste strength formula offered, which allows to explain nature of strength of cement stone, mortar and concrete on this basis.

Strength of cement paste, mortar and concrete is determined by the number of electroheterogeneous contacts EHCs in the stretched cross-section. The influence of W/C on strength is connected with decrease of crystallohydrates concentration. The compression strength exceeds the tensile strength because the compression force is taken not only by stretched EHC but by the compressed EHC and electrohomogeneous (with the same charged surfaces between gel particles) ones as well. The latter one favors uniform distribution of load all over the volume of cement paste and concrete, because hydrosilicate gel is the finest dispersed component of hydrate new formations. The gel specific surface ($S_g \approx 200 m^2/g$) is considerably higher the one of crystallohydrates ($\approx 2\text{-}5 m^2/g$). Therefore, it is possible to obtain that whole physico-chemical combined water ($W_{pcc} = W - W_{cc}$, where W - initial water, W_{cc} - chemical combined water) belongs to hydrosilicate gel. The electron microscope

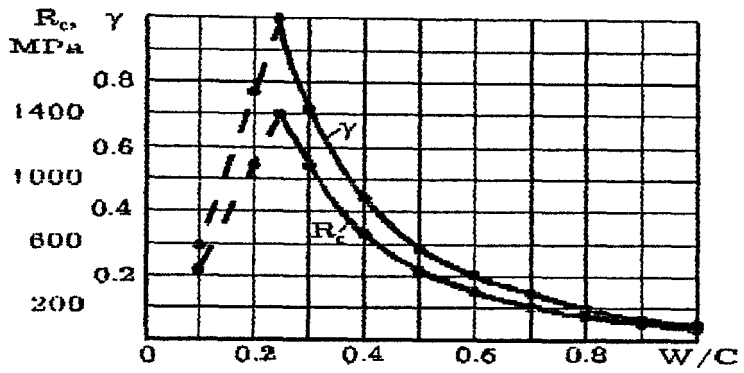

Figure 3 Depending calculated and experimental quantities strength R_c and coefficient γ^{ep} from W/C

photos made by Wild et al (1990) are the convincing demonstrations of moisture capacity of hydrosilicate gel.

Submicrostructure and microstructure of the cement paste will be optimum if $(W/C)_{opt}=0.25$. In this case hydrosilicate gel particles of different forms are connecting crystalline particles by electroheterogeneous mechanism in optimum dence crystallohydrate skeleton. There is forming of openwork skeleton filled with floaded gel and there are conditions for the extrusion of water from gel and for the concrete deformations in case $W/C>(W/C)_{opt}=0.25$. The skeleton is porous if $W/C<(W/C)_{opt}$.

Hydrosilicate gel under load at W/C>0.25 compresses at the expence of water filtering out of it but into pore space. As it is compressed the load is taken by crystallohydrate frame by means of its compressing EHCs, and as these contacts are compressed the load is transferred to the stretched EHCs. In the limiting state, which corresponds to strength of cement paste and concrete, water molecule is removed out of the elementary contacts and the contacts move together till the Ca-O chemical bonding formed between potential determining ions in active centers. In this case, the d and h distances become equal to the length of chemical bonding d=h=2,4A° and the contact in each active center of portlandyte is realised. In case of absence of water in the contact, its electrosurface potential becomes equal to ψ_0=+1.25v.The pressure needed for such contact formation is equal to R_{cc} = 91.9MPa.

The structure of crystallohydrate frame with the EHC compressed till the chemical bonding formed correponds to the structure of cement paste with limiting strength and W/C=0.25. The width of water layer in hydrosilicate gel h_g and gel resistance R_g, Pa in this case are equal:

$$h_g = \frac{W_{pcc}}{S_g} = \frac{W - W_{cc}}{BC\alpha_h S_g / \rho_g} = 4.23nm, \qquad R_g = \frac{q\psi}{2h_g} = \frac{\varepsilon\varepsilon_o\psi^2}{8\pi d h_g}, \qquad [7]$$

For ε=40 and ψ=+1.25v R_g=22MP and the resulting compression strength $R_c = R_{cc} + R_g + R_t = 91.9 + 22.0 + 13.3 = 127.2$ MPa. Accordingly $n=R_c/R_t=127.2/13.3=9.5\approx10$, which corresponds with real values.

The γ value in the strength equation and, therefore, the number of electroheterogeneous contacts and, correspondingly, strength and durability of cement paste and concrete depend not only on W/C but on composition of products of cement hydration. Here, the maximum strength will be reached if the optimum ratio between the number of positively charged particles of crystallohydrates and all other negatively charged particles will take place. The curves in Fig.4 confirm this statement. They are the

curves for two-component silicate systems and aluminate binders. One can see sharp extremums at the points of the optimum ratio beween mass of crystallohydrate products of hydration and mass of gel hydration products.

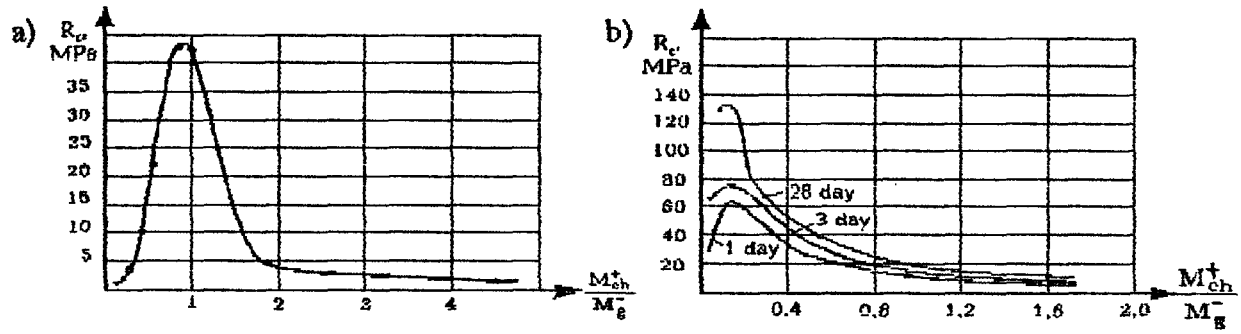

Figure 4 Depending R_c from ratio between the mass of positively charged crystallohydrate products M_{ch}^+ and the mass of negatively charged gel products M_g^- for silicate (a) and aluminate (b) binders.

THE GEL WATER FILTERING UNDER LOAD AND DURABILITY OF CONSTRUCTIONS

Lets consider the quantitative aspect of the process of water filtering caused by compression stresses. In principle, this process is close to the process of filtering caused by pressure. However, this mechanism is considered here taking into account electrosurface phenomena (Plugin, Wild et al, 1995). The extrusion of water from the gel, induced by the concrete compression of its own weight or because of the concrete prestress, may be described by an equation for filtration coefficient K_f:

$$K_f = \frac{\Delta V_w L}{S \Delta\tau \Delta P}, \qquad [8]$$

where ΔV_w - water volume filtered throught the concrete, m^3; $\Delta\tau$ - duration of filtration, s; ΔP - pressure of filtration, N/m^2; L - length of the filtration way, m.

From here:

$$\Delta\tau = \frac{\Delta V_w L}{S \Delta P K_f}. \qquad [9]$$

The extrusion of water from gel is the major reason of the concrete creep. In this case the duration of filtration of water $\Delta\tau$ throught the concrete and the filtration coefficient are the major characteristics of the concrete creep and of the concrete durability, when sagging of the construction, induced by the creep f, is more of tolerate f_{tol}. The quantity of the construction creep f are defined from the water volume extruded from the concrete:

$$\Delta V_{ex} = C(W/C - 0.25)\left(1 - \mu_{opt}/\mu\right)\left(1 - \alpha_{opt}/\alpha\right), \qquad [10]$$

where μ, α - coefficients of the sand and large aggregate removing, which may be determined by Eq.1; μ_{opt}, α_{opt} - optimum coefficients of removing, which may be determined $(K_r)_{opt} = 2.1\,(1+D_{pm}/D_{se})^3 - 1.1$ with accordance the particles sizes (Plugin et al, 1995).

The quantity of tension N causes by its own weight for the beam construction is determined by:

$$N = \frac{3\rho L^2}{4H}, \qquad [11]$$

where ρ - concrete density with the accounting of the static load, t/m^3; H, L - height and length of the construction, m.

With regard to Eq.9:

$$\Delta\tau = \frac{2C(W/C - 0.25)}{3\rho K_f}\left(\frac{H}{L}\right)^2\left(1 - \mu_{opt}/\mu\right)\left(1 - \alpha_{opt}/\alpha\right). \qquad [12]$$

The example: $C = 0.45 t/m^3$; $W/C = 0.5$; $K_f = 10^{-11} m/s$ (not high water resistance); H=1m; L=10m; $\mu = 1.97$, $\alpha = 1.35$ for S(sand)$= 600 kg/m^3$; LA(large aggregate)$= 1200 kg/m^3$; $\mu_{opt} = 1.28$; $\alpha_{opt} = 1.1$; $\rho = 2500 kg/m^3$

(of reinforsed concrete). For this data by Eq.9 $\Delta\tau=1.4\cdot10^6$s=3.2years. For $K_f=10^{-13}$m/s (water resistant concrete) $\Delta\tau$=320years. The quantity of the specific sagging h^s may be calculated by $h^s=0.125\Delta V_{cr}/H$. For H=1m by this formula and Eq.10 $h^s=1/208$. This quantity limits of the tolerate sagging quantities h_t^s=1/200-1/1000. The latter shows that the above mentioned aspects are principally correct.

THE ELEMENTS OF CONCRETE FILTERING THEORY

As it is known, in case of water filtering through concrete takes place leach of the less stable in water environment crystallohydrate products, particularly, portlandite $Ca(OH)_2$. As a result, accordingly to the curves in Fig.4 , the ratio between masses of crystallohydrate and gel products will deviate from the optimum. Besides, it will cause the decrease of the number of the electro-heterogeneous contacts and, correspondingly, strength and durability of concrete will degrade. The other kinds of chemical instability of concretes are connected with water filtering together with either aggressive salts and acids or agressive gases from air solved in water. However, filtration characteristics of concrete determined in the standard way by pressing water through a sample do not reflect real filtration properties of concrete in real constructions, where pressure is absent, but concrete is leaking. Water goes through concrete not only because of outer pressure ΔP but mainly because of internal pressure. The internal pressures are the ones connected with the well known in colloid chemistry fenomena: capillar rise pressure P_{cr}, osmotic pressure P_{os}, electro-capillar pressure P_{ec}, capillar-osmotic pressure P_{co} (Fig.5) and flow potential pressure P_{fp} (for ΔP) (Plugin et al, 1995; Plugin, Babushkin, 1996). The equality of all the forces causes stationary mode of flow: $F+P_{fp}=\Delta P+P_{cr}+P_{ec}+P_{os}+P_{co}$, or:

$$\frac{2l\eta V}{r\delta_{dl}}+\frac{\varepsilon^2\varepsilon_o^2\psi\zeta\Delta P}{4\pi^2 dr\eta k}=\Delta P+\frac{2\sigma}{r}+\frac{\varepsilon\varepsilon_o\psi^2\delta_p}{\delta_{dl}\pi r^2}+RT\frac{\varepsilon\varepsilon_o\psi}{2\pi drF}+\frac{4\varepsilon\varepsilon_o\zeta\psi\delta_p}{\pi r^3(1-h_o/r)^2}, \quad [13]$$

where r-capillar radius; δ_p-size of particles in capillar wall; δ_{dl}-width of double electric layer inside capillar; σ-water surface tension; l - capillar length; η – water viscosity; V - water flow rate in capillar. The DEL width should be assumed to be the distance along which the rate drops to zero.

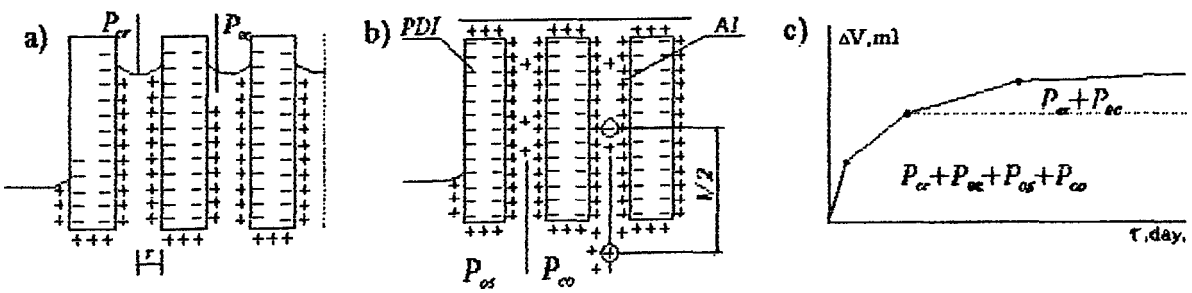

Figure 5 The filtration characteristics of concrete and water filtering at free-flow conditions (without ΔP).

The capillar and electro-capillar pressures predominate in case of water saturation when condensate or rain moisture accumulates on concrete surface. The osmotic pressure is caused by difference of concentrations ΔC of electrolyte outside and inside capillars of concrete.The flow rate V is constant if the flow is stationary. It allows to derive V and coefficient filtration K_f:

$$K_f=\frac{Vl}{\eta\Delta P}=\frac{r\delta_{dl}}{2\eta^2}+RT\frac{\varepsilon\varepsilon_o\psi\delta_{dl}}{4\pi dF\eta^2\Delta P}+\frac{2\varepsilon\varepsilon_o\zeta\psi\delta_p\delta_{dl}}{\pi\eta^2r^2(1-h_o/r)^2\Delta P}-\frac{\varepsilon^2\varepsilon_o^2\psi\zeta\delta_{dl}}{8\pi^2 d\eta^2 k}, \quad [14]$$

Calculations show that the internal pressure in capillars with radius up to 1000A° (the capillars in hydration products of cement) is higher than the outer one used in standard methods of filtration properties of concrete evaluation. The internal pressure can reach up to tens and hundreds of MPa.

As one can see, filtering properties, particularly, filtration coefficient of cement stone and concrete, depend on radius of capillar and its electrosurface properties. It allows to efficiently control the filtering properties and ensure durability of concrete in constructions.The easiest way to do it is to optimise concrete structure (when manufacturing constructions) at micro- (W/C), meso- (μ) and macro- (α) levels with the use optimum structure of concrete (Fig.1) with maximum strength, water-resistance and minimum deformability by (Plugin, 1989; Plugin et al, 1995).

CONCLUSION

Thus, concrete destruction, particularly, in the protective layer of the stretched zone, is caused by creep in compressed zone. The creep is caused by the filtration desplacement of physico-chemically combined water of hydrosilicate gel in concrete with in optimal structure. It is followed by subsequent loss of density of cement paste and concrete in the stretched zone. It favors gradual destruction of the electoheterogeneous contacts and subsequent complete destruction of concrete. It appears especially active in the stretched zone of concrete because the electroheterogeneous contacts break down in tension only. In the conditions of flooded constructions or in case of their hydroisolation break this process is aggravated by leach of concrete. It leads to decrease of the number of the electroheterogeneous contacts, strength degradation and porosity rise. Based on the above-stated views, successful research works and practical recommendations development on durability providing to reinforced concrete constructions, including the measures on protection, repair and rebuilding of the currently operational and destructing constructions, are carried out.

THE DEGRADATION OF CALCIUM SILICATE HYDRATES (CSH): A KINETIC STUDY

Christa R. SCHWEIZER, Annette C. JOHNSON, and Peter BACCINI
Swiss Federal Institute for Environmental Science andTechnology (EAWAG), 8600 Duebendorf Switzerland

ABSTRACT

For the assessment of the long-term behavior of cement stabilized and municipal solid waste incinerator products, an understanding of the degradation of calcium silicate hydrates is needed. The series CSH- tobermorite- xonotlite were chosen to determine the relationship between ageing crystallinity and stability. Initial dissolution experiments were conducted with xonotlite in a through-flow reactor. The dissolution rates were calculated and interpreted in terms of surface complex theory. The dissolution rates of xonotlite in the pH range 9-11 were found to range 25 $\mu mol.g^{-1}.h^{-1}$ - 3.5 $\mu mol.g^{-1}.h^{-1}$. The rates were compared to those of naturally occurring minerals. They appear to be faster than those of aluminosilicates but slower than calcite. Supporting evidence from field studies suggest that CSH dissolution could be controlled either by kinetic or thermodynamic factors in a field situation depending on the hydrology of the system.

Key-words: CSH, Kinetics

INTRODUCTION

The use of cement to stabilize wastes containing heavy metals or radioisotopes has been widely considered or applied because of the propensity of cement to immobilize inorganic constituents such as heavy metals. The mobility of heavy metals via leaching is influenced by two factors, the geochemistry of the waste material and the hydrology of the deposit. The composition and the pH of the leachate are controlled by the interaction of the solid material with the leachate water. Minerals which are sufficiently soluble can buffer the solution pH, as is known for CSH or $CaCO_3$. The pH in turn controls the mobility of heavy metals retained by various mechanisms such as adsorption, precipitation and ion exchange. Though ideally cement stabilized products should be virtually impermeable to water, investigations in deposits filled with cement stabilized filter ash from municipal solid waste incinerator (MSWI) show that water can enter such systems (IMRA, 1991).The leachate water contains low concentrations of heavy metals (in the range of µmol/l) at present but over long time periods when buffering minerals are no longer present, the chemical environment can change causing lower pH values. In such a situation the metals cations will become more mobile (Johnson et al., 1995). For the assessment of the long-term behavior of cement stabilized products, an understanding of the important mineral water interactions is needed.

Thermodynamic studies provide evidence on reactions at equilibrium conditions. However, in field situations equilibrium is often not achieved, especially in systems with high permeabilities such as landfills of MSWI bottom ash. In such cases, kinetic studies of dissolution rates permit the estimation of the composition of a

leachate. The understanding of the dissolution reaction mechanism can give additional information on the long-term behavior. The dissolution rates of mineral-water interactions depend on the presence, amount and residence time of water. Recent studies of weathering processes in geological systems have clearly demonstrated that the rates of these reactions are strongly dependent of the surface structure of the mineral and that the kinetic mechanism is mainly controlled by formation of the surface complexes (e.g. Aagaard and Helgeson, 1982; Casey et al., 1988).
From synthesis studies it is known that amorphous CSH exposed to hydrothermal conditions forms tobermorite and then xonotlite (El-Hemaly et al, 1977; Glasser, 1995). We have decided in an initial step to investigate dissolution kinetics of on xonotlite in order to set up the methodology. In a second step the dissolution rates of tobermorite and CSH, which are presumably faster, will be investigated. In this paper we present results of dissolution experiments carried out on the crystalline CSH mineral xonotlite in a flow-through reactor. These are interpreted in terms of surface complexation theory and the rates compared with other minerals and with field results.

MATERIALS AND METHODS

Starting Material Xonotlite

The minerals used in the experiments were synthesized according to the method of Glasser (1995). $CaCO_3$ (Merck) was calcined at a temperature of 1000°C for 2 hours. A quantity of the resulting product (3.73g) and SiO2 (4.00g, Aerosil 300, Degussa) was mixed with ~100ml bidistilled water boiled under argon. This mixture was shaken (125rpm) for 24h. The reactants were then autoclaved at 200°C for 1 week and subsequently freeze dried. XRD analysis showed the product to be pure. The xonotlite was crushed in an agate mortar and sieved. The size fraction between 100-200μm was separated and used for the experiments. The total external surface area (BET method, N_2) was found to be $24.4 m^2 g^{-1}$. Raster electron microscopy photograph of the product showed nearly spherical particles.

Dissolution Experiments

Experiments were conducted in a continuously stirred polycarbonate flow-through reactors (250ml, Fig 1). The reactor was placed on a balance (Mettler PM6000) connected via an interface to a peristaltic pump. Another pump was used to remove reactor solution at a rate of approximately 20ml/h. The weight of the reactor was kept constant by a feed solution which was pumped from a 2 liter polyethylene reservoir via the peristaltic pump into the reactor. The outlet solution passed through a 0.45μm filter as it exited the reactor. In order to maintain a constant solution pH value, a computer-controlled Dosimat (Metrohm 665) was used to add acid or base. In order to minimize the influences of CO_2 from air all experiments were carried out under argon atmosphere. The argon was passed through a NaOH (Merck) solution and presaturated with the eluent. Unless otherwise stated, the temperature was kept constant at 298K and the ionic strength was fixed at 0.1 with NaCl (Merck) solution. The pH values during the experiment were measured with a Ross Sure-Flow Electrode (81-72BN) and automatically

registered every three minutes. The pH electrode was calibrated by titration before and after every dissolution experiment.

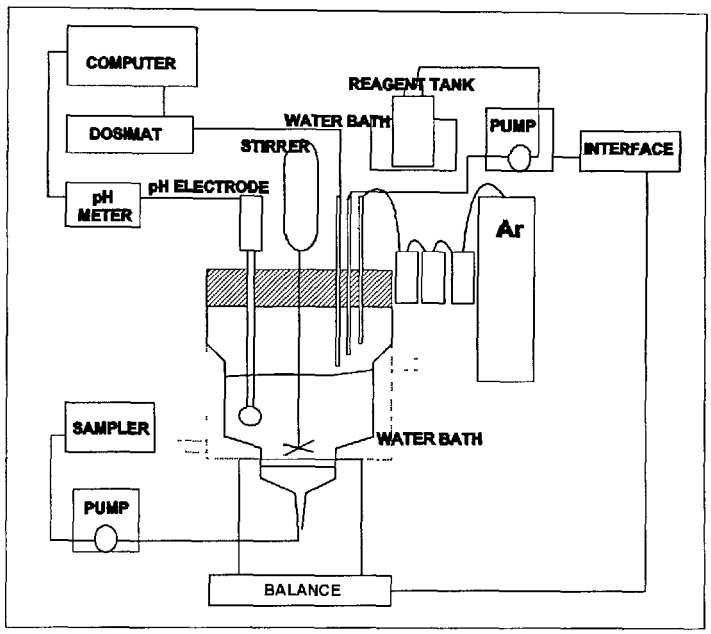

Figure1 Schematic representation of the flow-through reactor.

The experiments were conducted with xonotlite under variable pH conditions to investigate the pH dependence of dissolution rate and reaction stoichiometry.
A 100-200μm fraction of xonotlite powder was suspended in the 0.1M NaCl solution (0.5g/50ml) added to the reactor and was stirred with a hanging stirrer (Metrohm 722). At pH 9 the computer controlled Dosimat (Metrohm 665) added 1M HNO_3 at pH 10.5 0.1M NaOH, at pH 11 1M NaOH, at pH 10.18 no acid or base were added. HNO_3 and NaOH solutions were prepared from Titrisol (Merck) from bidistilled water boiled under argon. These solutions were also stored under argon. The dissolution experiments required ~300 hours.
Outlet solutions were continuously collected and were examined for silicon and calcium. Calcium was analyzed by atomic absorption spectroscopy (Varian SpectrAA) and silicon was analyzed by the molybdate blue colorimetric procedure (ASIA, Ismatec). Analytical detection limits for silicon were 0.02ppm and for calcium 0.2ppm.

Calculation of Dissolution Rates

The dissolution rates R were calculated according to the method proposed by FURRER et al. (1993) with Eqn. 1

$$R = c/(\tau^* c_s) \qquad [1]$$

The average of the steady-state concentrations c ($mol.l^{-1}$) were divided by the mean residence time τ (h) of the solution in the flow-through reactor and by the particle concentration c_s ($g.l^{-1}$). The residence time τ (h) is the quotient of the reactor volume V (ml) and the flow rate of the effluent r ($ml.h^{-1}$) (Eqn. 2).

$$\tau = V/r \qquad [2]$$

This method is based on the assumption that all particles are of the same size and remain spherical throughout the dissolution experiment.

RESULTS AND DISCUSSION

Concentrations versus Time

Fig.2 shows the calcium and silicon concentrations in function of time in the pH range 9-11.

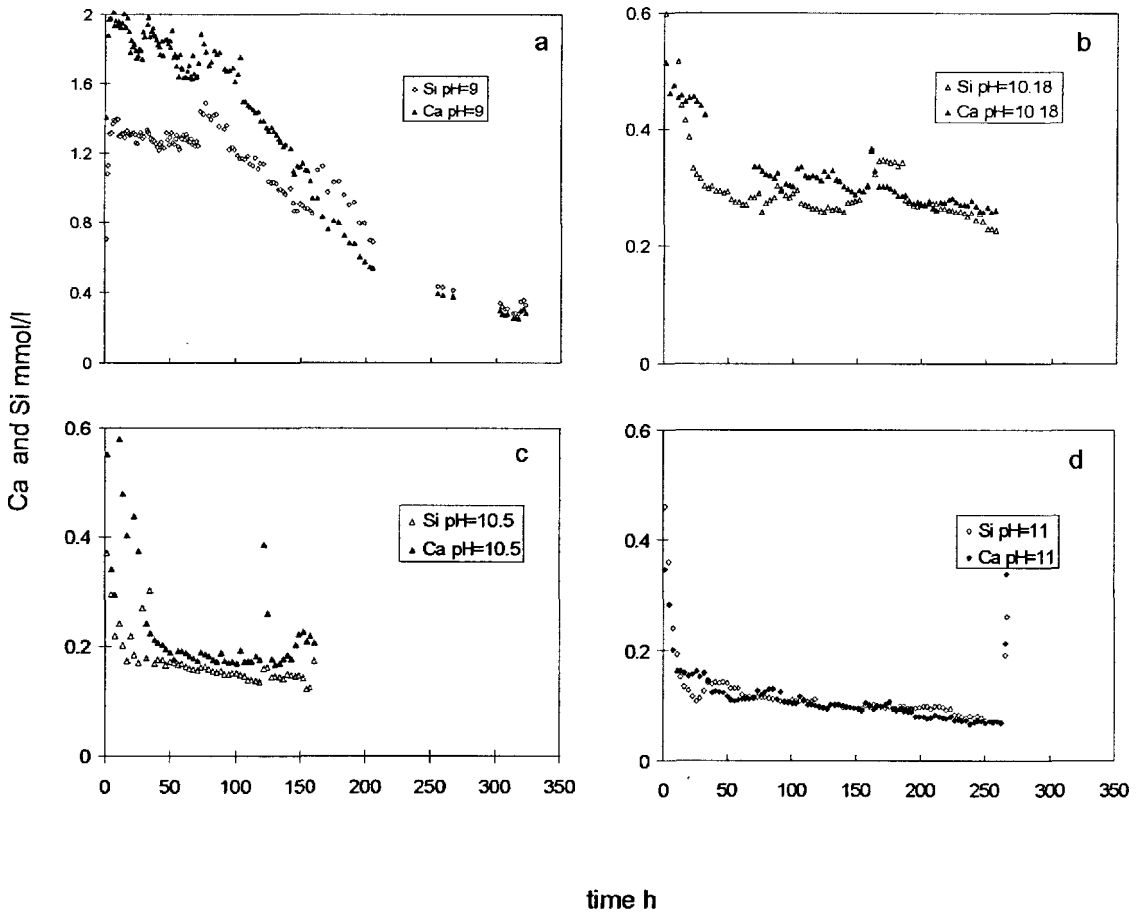

Figure 2 Silicon and calcium concentrations of xonotlite (mmol.l^{-1}) in 0.1 M NaCl at 25°C and at different pH a.) pH 9, b.) pH 10.18, c.) pH 10.5 and d.) pH 11.

In all experiments outlet solution chemistry follows the trend noted by other flow-through reactor studies (e.g. Chou and Wollast, 1984; Mast and Drever, 1987, Stilling and Brantley, 1995): an initial, rapid increase in solute concentration which gradually decreases with time to a nearly constant value (steady state). The steady-state silicon concentrations are more rapidly reached at lower pH, namely after 10 hours at pH 9, 50 hours at pH 10.5 and after 60 hours at pH 11. The

calcium and silicon concentrations increase with decreasing pH. After 10 hours at pH 9, the silicon concentrations attain a value of 1.3 mmol.l^{-1} . At pH 10.18 the steady-state concentrations are 0.28 mmol.l^{-1} at pH 10.5 0.18 mmol.l^{-1} and at pH 11 0.1 mmol.l^{-1}. The stoichiometric ration Ca/Si varies from 1.4 to 1. Dissolution tends to be stoichiometric at more basic pH values. In more acidic conditions calcium concentrations are initially greatly enhanced but stoichiometry is attained at steady state.

Preferential release of calcium cations or ionic exchange with protons during the initial stage of dissolution with acid suggests the early development of a calcium-depleted surface layer. This phenomenon is well documented and has been illustrated in a conceptional model by Schnoor (1990). Adopting this model, initial dissolution is characterized by rapid, outward diffusion of calcium from within the mineral through a calcium-depleted surface layer. As the thickness of the surface layer increases, diffusion of calcium slows until at steady state, the transport rate of calcium through the surface layer equals the dissolution rate silicon. After this point, dissolution will proceed congruently where the detachment of the surface complex silicon is the rate-determining step.

Dissolution Rates vs. pH

The dissolution rates of these experiments are evaluated according to Eqns. 1 and 2 and have been calculated from the silicon steady-state part (see Fig 3). At pH 9 the first plateau concentration has been used.

The pH dependence of the xonotlite dissolution is shown in Fig 3. The silicon dissolution rate decreases with increasing pH values. The measured points in the curve suggest a linear dependence of the dissolution rate in the pH range 9 to 11. Although for an accurate verification more measurements are needed. We estimate the error in the flow rate of the eluent to be ±2% - ±5% and the error in c to be ±5 - ±10%. Therefore the estimated error in R can range from ±7% to 15%. In these calculations the decrease of surface area was not considered.

Various conceptional models have been proposed in order to interpret the pH dependent dissolution of soluble minerals (Lasaga, 1981; Stumm and Furrer, 1987). The models are based on experimental observations that the dissolution of most oxides and silicates at low temperature is controlled by surface chemical processes. Transition state theory (TST) has been used as a theoretical framework to establish kinetic rate laws for surface controlled dissolution reactions. Far from equilibrium, the elementary step in such a dissolution is the detachment of an activated complex. Furrer and Stumm (1986) and Wieland et al. (1988) propose the coordinative chemical model of mineral dissolution and combine the TST and the surface coordination model. The dissolution rate of most oxides increases both with increasing surface protonation and with decreasing deprotonation (or hydroxylation). The overall rate of the dissolution can be calculated using

$$R = k'_H (C^s_H)^j + k_{OH}'(C^s_{OH})^i + k'_L (C^s_L) + k'_{H2O} \qquad [3]$$

with R the sum of the individual reaction rates, assuming that dissolution occurs in parallel at different metal centers. k'_H and k_{OH}' denote the experimental rate constant for proton and hydroxide-promoted and k'_L the experimental rate constant for ligand-promoted dissolution. C^s_H or C^s_{OH} the surface concentration of protons or

hydroxides and C^{s}_{L} the surface concentration of ligands (Stumm et al, 1990). The values of the exponents j and i represent the order of the overall reaction with

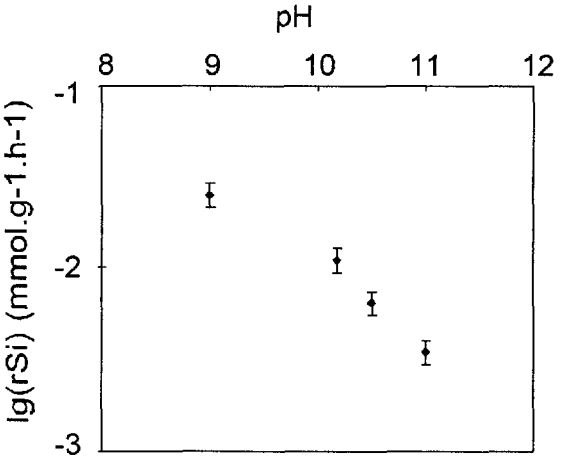

Figure 3 Silicon dissolution rates of xonotlite in $mmol.g^{-1}.h^{-1}$ as a function of pH at 25°C.

respect to surface charge and are the key parameter used to interpret the stoichiometry of proposed activated complex. This model shows that the protonation or deprotonation of detachable surface sites could explain the pH dependence of dissolution rates for simple oxides. Rates are compared in terms of surface concentrations of protons and hydroxides and not solution chemistry. The pH of zero point of charge is approximately 10.1. The surface of xonotlite in acidic conditions has a predominately positive charge below pH 10 and according to the dissolution model described above, the rate is a function of the first term $k'_{H}\ (C^{s}_{H})^{j}$ and corresponds according to the leached layer model (see before) with regard to the release of silicon. Reactions in solutions above pH 10 are controlled by the term $k'(C^{s}_{OH})^{i}$. The discrepancy between surface charge and the dependency of dissolution rate on pH had yet be clarified with further experiments.

The dissolution rates of xonotlite are compared to naturally occurring minerals (Fig 4). It should be noted, that with the exception of wollastonite ($CaSiO_3$), quartz and calcite the minerals are all aluminosilcates. All these minerals with the exception of quartz can engage in acid/base buffering reactions in field conditions. Dissolution rates limit the efficiency of these processes. The dissolution rates of xonotlite is between the two extremes calcite and quartz followed by the dissolution rates of aluminosilcates. There could be a relationship between aluminosilicates structure and dissolution rate. The dissolution rate of the chain silicate enstasite is approximately one order of magnitude higher than the framework silicates anorthite, albite and bytownite. These in turn are around one order of magnitude higher than that of the sheet mineral muscovite. In parallel fashion the sheet mineral tobermorite might also have a slower dissolution rate than that of xonotlite. The least crystalline CSH can be expected to have the most highest rates comparing with tobermorite and xonotlite.

The dissolution rates of the minerals depend on the presence, the residence time and the composition of the percolating water. Equilibrium could be achieved if conditions are favorable. In the lysimeter study with cement stabilized municipal solid waste incinerator filter ash (IMRA, 1991), in which 20% of rainwater infiltrates

the waste material, thermodynamicaly calculations (Schweizer, 1996) show that the leachate is saturated with respect to CSH or tobermorite and gypsum.

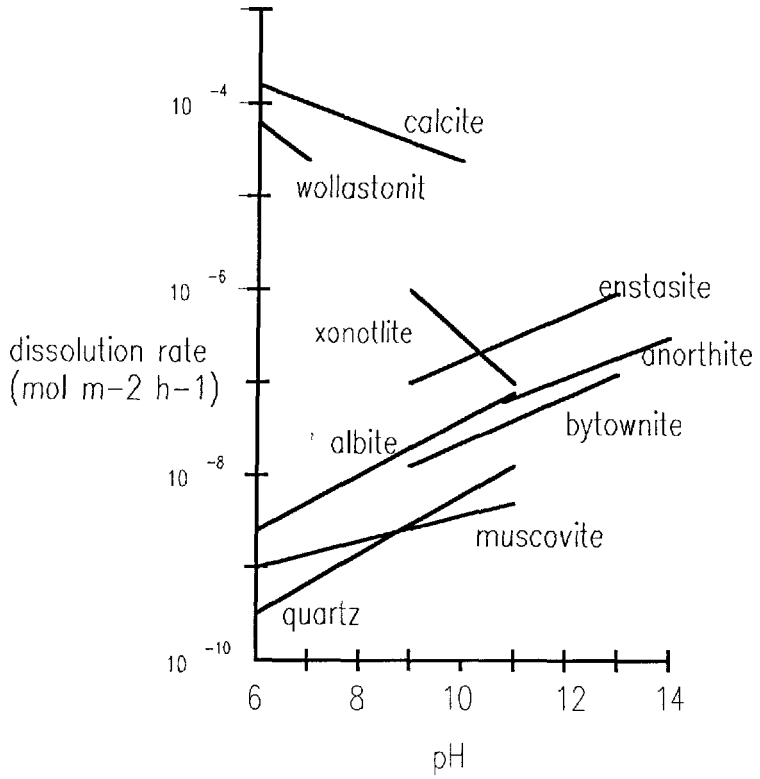

Figure 4 *Dissolution rates in mol.m^{-2}.h^{-1}of different minerals as a function of pH* at 25°C. (**Quartz:** Wollast, R. and Chou, L.; **muscovite:** Kalinowski, B.E. and Schweda, P.; **bytownite, anorthite and enstasite** Brady, P.V and Walther, J.V.; **albite:** Chou, L. and Wollast, R.; **calcite:** Chou, L. and Wollast, R.; **wollastonite:** Rimstitdt, J.D. and Dove, P.M.)

In contrast leachate concentrations of calcium and silicon of a MSWI bottom ash landfill are undersaturated (Schweizer and Johnson, 1996). Since water residence times are approximately ten time greater in the example, hydrological factors could play an important role.

CONCLUSIONS

The dissolution rates of xonotlite lie within the large range of naturally occurring minerals. They appear to be faster than these of aluminosilicates but slower than calcite. The dissolution kinetics can be described by the surface complex model. Evidence from field studies indicate, that depending on water residence time either thermodynamic equilibrium or kinetically controlled dissolution calculations must be applied to describe CSH dissolution. It is therefore necessary to obtain a depth

understanding of the least crystalline CSH minerals to be able to more accurately model these reactions in field systems. We are presently working on the dissolution behavior of tobermorite and CSH.

ACKNOWLEDGMENT

We would like to thank Christian Ludwig and Felix Ziegler for their encouragement and discussions. In addition, we would like to thank Madeleine Langmeier, Hermann Mönch and Sandro Brandenberger for their technical advice and assistance.

ADSORPTION ISOTHERM OF CONCRETE

Aimin XU, STK Inter Test AB, S-254 67 Helsingborg, Sweden

ABSTRACT The multi-layer adsorption theory, BET equation is discussed in this paper. On the evidence of more energy level change occurring between the adsorbed layers than that originally assumed by BET isotherm which empirically valid only in a small relative pressure range, a new isotherm equation is obtained which can be applied in a much greater range. The analysis of the moisture adsorption character of concrete containing fly ash, using this isotherm, has shown that the indices provided by the new function are closely related to the concrete parameters.

Key-words: Adsorption, Drying, Fly ash, Pore size distribution, Sorption isotherms

INTRODUCTION

Adsorption of molecules on a solid material is a phenomenon occurs in various situations. The most common cases in building materials include the moisture and ions adsorption/desorption, which affect the building environment and the gaseous/ionic transport process related durability of concrete structures.

In a comprehensive exposition of adsorption methods for the assessment of the surface area of the solids, Gregg and Sing (1982) showed that the adsorbed amount is governed by the energies of solid surface and the molecules, the size of surface area and presence of pores in the solid. The multi-layer adsorption isotherm by Brunauer-Emmett-Teller (BET) (1938, 1943), and the relation between meniscus and pore size by Kelvin equation, are the fundamentals for the most widely applied methods, in spite of that earlier experimental data only confirmed BET isotherm in the low relative pressure (of gaseous adsorbed molecules) range, e.g. $x = p/p^\circ < 0.35$.

The dependence of moisture / length change on the relative vapor pressure (or relative humidity, $RH = 100p/p^\circ$) is a primary interest to concrete scientists. Numerous investigations have been carried out since the1940s as summarized by Powers (1960). The fact that concrete or cement paste is a porous material containing capillaries of micro-meter size (excluding the entrapped air voids) down to micro-pores of inter-lattice distance, has led to several complicated phenomena in desorption-adsorption (or sorption, in general) isotherms, e.g. difference in surface area measured by N_2 compared to that by water, and the hysteresis between the desorption and adsorption, especially that at low p/p° range attributable to some inter-lattice water loss and reenter as addressed by Feldman (1968) who thus questioned the reversibility of the water isotherms. Considerable effort has been made by researchers to estimate the pore size distribution of porous solid, which in concrete science is represented by work of Mikhall *et al* (1968), Radjy and Sellevold (1972) on relationships between micro-pore filling and adsorbed layer thickness.

However, the calculation of thickness of the adsorbed layer by BET equation still presents a problem, as mentioned earlier that BET equation predicts a too high uptake value even at moderate dry conditions. Therefore in practice, other equations, such as Halsey equation (1948) was used for the calculation. From the view point of both theory and practice, it is important to re-examine the basic assumptions, the validity and applicable range of the BET theory.

The weakness of BET equation in fitting the experimental data, and some of its theoretical assumptions, have led to debates and several refinements (Hill, 1952). Halsey (1948) pointed out that the hypothesis: $E_2 = E_L$ (the heat of adsorption at the second and higher layers is equal to the heat of liquefaction) leads to erroneous indications for the theory itself, however no modifications have been followed in this line.

The modifications of BET equation did extend the application range, best represented by that made Brunauer himself and co-authors (1969), that the volume of the adsorbed molecules V relates to the relative pressure x by:

$$V = \frac{V_m ckx}{(1-kx)(1-kx+ckx)} \qquad [1]$$

where V_m is the monolayer capacity, c is a coefficient depending upon energy and temperature. Compared to the original form, this equation introduces a factor $k < 1$, on the hypotheses that the number of adsorbed layer is infinite at a pressure exceeds the saturation pressure, which determines the isotherm shape at $x > 0.4$. $k = 0.57$ to 0.79 was reported for nitrogen adsorption isotherm of various adsorbents. Several earlier and later research works on sorption theory, e.g. Anderson (1946) and Hillerborg (1985), presented forms essentially identical to Eq.1.

It is reasoned by Brunauer *et al* on the thickness of the adsorbed layer built up at the saturation vapor pressure, that k is a measure of the attractive force field of the adsorbent. However, this is only a speculation. It will be shown here that the discarding the hypothesis $E_2 = Q_L$ leads to a new form of multi-layer adsorption isotherm. Its application in analyzing water sorption isotherms of concrete samples is demonstrated with a discussion about influences of pore size, change or aging of hydrates on the sorption.

A MODIFIED MULTILAYER ADSORPTION ISOTHERM

Although the theory can be applied to both the adsorption of ions (solid in solution) and gas molecules, it is convenient to take the latter case for discussion. On a solid surface, gas molecules that collide with it will stay for a moment then leave. When the rates of the coming and going (i.e. *adsorption* and *desorption*) become equal, an equilibrium occurs. The rate of adsorption is proportional to the concentration of the molecules, and to the surface area which has not yet been covered by adsorbed molecules, assuming the surface has uniformly distributed adsorption sites. Furthermore, molecules can stack upon one another at an adsorption site, resulting in the multi-layer adsorption. The total number of the adsorbed molecules is

$$Z = Z_m(A_1 + A_2 + ... + A_n) \qquad [2]$$

where A_1, ..., A_n are the fractions of the surface covered by 1 to n layers of molecules respectively. It is defined that $A_0 + A_1 + ... + A_n = 1$. Z_m is the total number of adsorption sites, which is unchanged during the process. This assumption, in drying of cement paste, is only conditionally satisfied, thus it is important to clarify this before proceeding further.

Surface area and dry state

Formed by cement hydrates of various shapes, such as foils (e.g. C-S-H), needles (e.g. ettringite) and plates (e.g. $Ca(OH)_2$), the surface of cement paste is far from flat. With drying, water between layers of hydrates, e.g. C-S-H gel, may exit at low relative pressures, resulting in close-down of this part of area. In terms of sorption isotherm, it shows a hysteresis between the desorption and adsorption, such as that demonstrated by Feldman (1968) on moisture and length change isotherms of cement paste degassed at 80°C. He thus questioned the validity of using

water adsorption data to measure the surface area of cement paste, since a part of the area is only available to water but not to other molecules, e.g. N_2.

Powers (1960) showed that a substantial reduction in surface area of cement paste with drying (to 0.00002 p/p°) and re-wetting cycles, i.e. more than 30% reduction occurred after 8 cycles. Powers speculated that gel particles are brought together by shrinkage forces, though he also doubted on extent of this effect. To clarify this, it may help mentioning that the specific surface can be expressed as (Gregg and Sing, 1982)

$$S = \frac{f}{L} \qquad [3]$$

where L is a characteristic length, and f is a coefficient approaching to 6, 4, and 2 for uniform size particles of sphere (or cube), rod, and plate respectively. This implies that it is possible to have a significant surface area reduction by partial fusion of gel particles, e.g. joining spheres to plates may lead to a 1/3 surface area reduction.

Nevertheless, during one drying process, surface area change is not significant. In experiments of drying cement mortar samples at 20°C, it was observed that the hysteresis between desorption and adsorption in small range (at about 10% intervals) is so small that it can be accounted for by the evaporation of capillary water; and the desorption and adsorption between 11% and 33% RH was practically reversible (Xu, 1992). The large hysteresis shown by Feldman (1968) can be due to the severe drying condition used, i.e. > 80°C. Cong and Kirkpatrick (1995), by using ^{29}Si and ^{1}H MAS NMR technique, showed that C-S-H dried at 9% RH had somewhat higher local structure disorder and lost some water in C-S-H, compared to the samples dried at 51 or 71% RH; whereas drying at 110°C resulted in a significant change in the NMR signals indicating that heating removes both inter-layer water and gel water, the loss of C-S-H water is evidenced by a stronger ^{1}H-^{29}Si coupling for Q^1 peak. In fact, it is well known that many hydrates are unstable during prolonged drying at 80°C, e.g. ettringite, gypsum, etc.

Therefore, the sorption isotherms determined at moderate temperatures, e.g. 20°C, and the drying to about 10% RH can be considered to be thermal dynamically reversible. And the sorption site is so assumed to be constant.

Equilibrium

With the on-going desorption and adsorption, the equilibrium on a solid surface for the first layer of adsorbed gaseous molecules established when:

$$a_1 v p A_0 = Z_m A_1 \nu_1 e^{-E_1/RT} \qquad [4]$$

where a_1 is the fraction of the collisions resulting in adsorption, v and p are the speed and pressure of the gas, ν_1 the oscillation frequency of molecules at the first layer, and E_1 is the difference in energy between the molecules at the 1st layer and the 'hard' adsorbed state, i.e. *the heat of adsorption.*

The equilibrium at the higher adsorption layers can be similarly written by changing subscripts (Eq.4) i to $i+1$. The heat of adsorption approaches that of liquefaction with more stacked layers. The original hypothesis of BET equation is: $E_1 \neq E_2 = E_3 = \ldots = E_n = Q_L$. However, this is not true in many cases, such as that shown by Harkins and Jura (1944) that for water adsorption on anatase the heat of adsorption between the 2nd and 3rd layers was still quite significant.

We can go a little further by letting $E_1 \neq E_2 \neq E_3 = ... = E_n = Q_L$,, thus make a slight modification for BET equation. Introducing parameters $\alpha = A_1/A_0$, $\beta = A_2/A_1$, $c = \beta/\alpha$, and $k\beta = A_{i+1}/A_i$ for i = 2, 3, ... n, one obtains $A_i = cA_0k^{i-1}\beta^i$. Substituting these into Eq.2 (when n is large, or assuming that $n = \infty$ for simplicity) and rearranging yield:

$$\frac{Z}{Z_m} = \frac{c\beta\left[1-(1-K)(1-K\beta)^2\right]}{K(1-K\beta)\left[1-K\beta+c\beta(1-K\beta+\beta)\right]} \qquad [5]$$

At saturation pressure $p°$ when condensation occurs, the coverage of the second layer is equal to that at the first layer, that is $A_1 = A_2$, which results in $\beta = p/p°$. Note that $A_1 = A_2$ is not a necessary condition, it can be a certain ratio due to the configuration influenced by the geometry (e.g. a curved surface) and the nature of the adsorbed molecules / ions. This clearly indicates that the adsorbed layer may be limited even at $\beta = 1$. Considering $V/V_m = Z/Z_m$, (though configuration of adsorbed molecules may involve lateral distribution as well as stacking which will lead to a slightly higher V/V_m ratio,) and writing $\beta = x$, one obtains the relative adsorbed thickness:

$$\Theta = \frac{V}{V_m} = \frac{cx\left[1-(1-k)(1-kx)^2\right]}{k(1-kx)\left[1-kx+cx(1-kx+x)\right]} \qquad [5a]$$

where V_m is the monolayer capacity, c and k are parameters depending on temperature and the difference in adsorption heat of molecules at different layers: $c \propto exp[\,(E_{ad} - E_2)/RT]$, and $k \propto exp[-\,(E_2 - Q_L)/RT]$. At k=1, Eq.5a reduces back to the original BET equation. The form of Eq.5a with limited n (max. adsorbed layer) is provided in Appendix. I showed previously (1992) that Eq.5a is numerically similar to Eq.1, thus the definitions of c and k given here can also be applied to BET equation, (Eq.1). Figure 1 illustrates this isotherm function at various parameters.

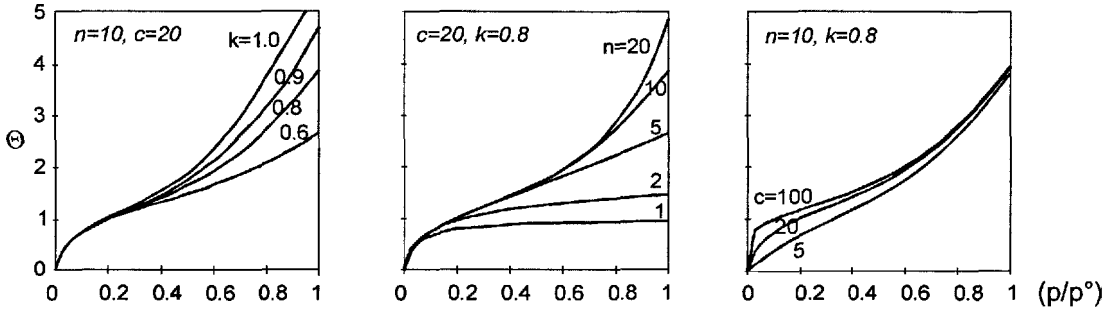

Figure 1. Modified BET isotherm varying with parameters n, k and c.

Some comments

Although Eq.5a has a singular point at (1- kx) = 0 which apparently indicates that when $p/p° = 1/k$ the adsorbed layer is infinite, one should *not* take it so, since this is simply because of the assumption n=∞. (It can be proven that $V/V_m \,|_{1-kx\to 0} = (n+1)/2$, for $n >> 1$. c.f. Appendix) Unfortunately, this singular point was used by previous researchers as one of major arguments in deriving their adsorption equations, which led to confusions.

To obtain V_m, c and k from experimental data, Eq.5a can be written to a $y = b_0+b_1x+b_2x^2$ form:

$$\frac{x}{1-kx}\cdot\frac{1+2(1-k)x-k(1-k)x^2}{V} = \frac{1}{cV_m}(1+(c-k)x+c(1-k)x^2) \qquad [5b]$$

try k values for the left hand side of Eq.5b, and calculate the coefficients by: V_m=1/(c b_0), $k = (1 - b_1/b_0 + \sqrt{(b_1/b_0 - 1)^2 + 4(b_1 - b_2)/b_0}\,)/2$, $c = b_1/b_0 + k$, until the k value converges. It may be noted that Eq.5b is very sensitive to the small change in k value, and a great care is needed in the trial calculation.

The extent of drying, as discussed before, though for the validity of application in cement / concrete study should not include very low RH condition, however, it is convenient to use traditional drying methods, i.e. D-drying and 105°C oven drying, to obtain the total evaporable moisture content for desorption, or a defined "dry" condition for adsorption. For the former, the error induced due to the gel water loss would not be large (the mass fraction of this part of water in the gel or crystals is very small); for the latter, the surface area alteration renders the specific surface under study only a comparative value, be it determined by H_2O or by N_2 adsorption.

MOISTURE SORPTION ISOTHERMS OF CONCRETE

Concrete contains large capillaries and micropores. The adsorption of moisture on walls of pores contributes a part of its total moisture content during drying, and a major part of moisture uptake during wetting to approximately 75-85% RH (at which capillary condensation occurs for my experimental results). Since that hydrated cement which has a great specific surface dominates the adsorption, and the majority of pores are formed in cement paste, the sorption isotherms are better expressed as the moisture per mass of cement (or cement + pozzolanic admixtures).

As an example, sorption isotherms of a concrete containing 30% fly ash replacing cement, with water to binder (cement + fly ash) 0.465 are shown in Figure 2. The adsorption was measured on samples dried at 105°C. Apparently the adsorption branch is much lower than the desorption, attributable to a number of differences, such as capillary meniscus curvatures and large pores connected with smaller pores for the high RH range; and the surface area for the low RH part.

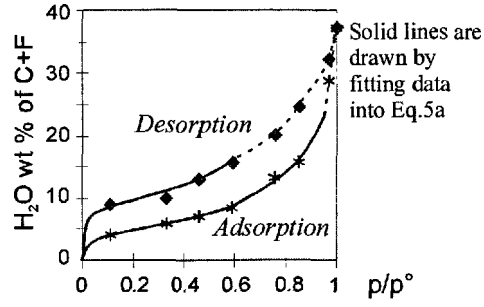

Figure.2. Desorption and adsorption isotherms of concrete, average of six specimens.

Desorption isotherm influenced by pore size distribution

The analysis of pore size distribution by desorption isotherm is based on the fact that, the moisture in pores (radius r) starts to evaporate when the curvature of the meniscus meets the criterion expressed by the *Laplace-Kelvin equation*:

$$\frac{2\gamma}{r} = \frac{RT}{M_V}\ln(x) \tag{6}$$

where γ is the surface tension (note: in micropores, it is a function of curvature, Gregg and Sing, 1982) and M_V the molecular volume for water. The adsorbed film on the wall (thickness $t_f = \Theta d$, d is the diameter of adsorbed molecules) in the mean time, will make the meniscus curvature slightly smaller and new equilibrium will then be established for the pores whose radius of the *core* satisfies Eq.6, that is, $r = r_{pore} - t_f$. The moisture loss is mainly due to the core water and thinning of the adsorbed film. Strictly speaking, the pore solution contains various ions thus has a lower chemical potential than the pure water, and its saturation vapor pressure is lower as well. But this effect is practically intermingled with the experimental error, and rarely observable.

The relation between volume of water in pore (V_p) and water in the core (V_c) is $V_c=V_pQ$, where $Q= 1- t_f / r_{pore}$ for the parallel slit-like pores, and $Q= (1- t_f / r_{pore})^2$ for the cylindrical pores. By setting a model of pore shape, the pore size distribution can be estimated (Xu, 1992). During calculation, it is necessary to adjust the parameters of the adsorption isotherm, i.e. c and k in Eq.5a. Figure 3 demonstrates pore size distribution of concrete, obtained by the moisture desorption, analyzed on the assumption of slit-like pore shape. No attempts were made in further evaluating the micro-pores, so the pore volume corresponding to the smallest pore size in Figure 3, is a sum of all smaller pores. It can be seen that the pure cement mortar has a higher micro-pore fraction than its fly ash containing counterparts. And mortars with higher $w/(c+f)$ ratios contain higher volume of large pores (r > ca. 80 Å).

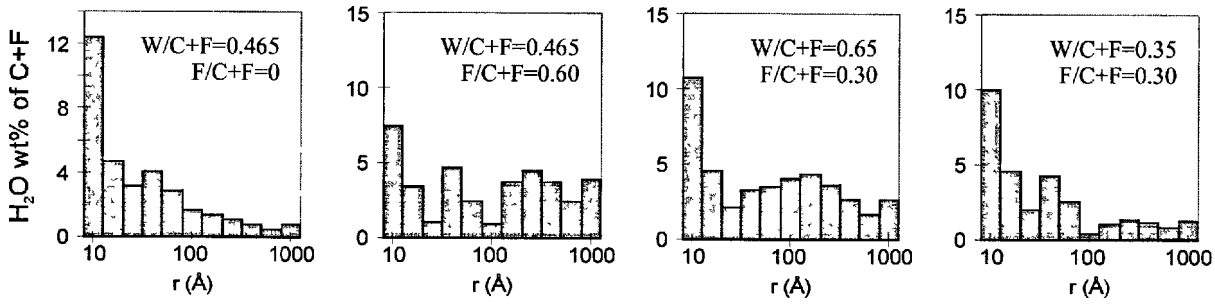

Figure 3. Pore size distribution of concrete determined by moisture desorption.

Surface area and sorption characteristics

Analysis of the isotherms in Figure 2 by Eq.5a results in V_m= 152 m^2/g of binder (4.3 g H_2O /g of binder), c= 38 and k=0.85 for adsorption (dried at 105°C before re-wetting); and V_m= 284 (8.0 g H_2O/g), c=145 and k=0.80 for desorption. The adsorption isotherm is lower than that of desorption, largely because of the drying induced surface area change for the low p/p° part as discussed before and indicated by the values of V_m; and in a given pore size the mean meniscus curvature may be smaller at adsorption; other reasons including the difference in liquid-solid contact angels for drying and wetting, presence of "ink-bottle-like pores", etc. are discussed elsewhere (Gregg and Sing, 1982).

In particular, the presence of "ink bottle" pores, pores having a narrower entrance than the body, may be responsible for a quite abrupt moisture loss between about 42% and 33% RH sometimes observed (Fig.4). Powers (1968) showed, at p/p°=0.40 the tension caused by lowering in p/p° is about 1200 atm (111 MPa), the limit of cohesion strength between water molecules. Thus there would be no meniscus exist at lower RH, and water formerly enclosed in the "bottles" is released.

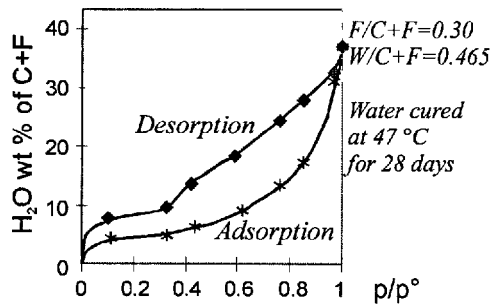

Fig. 4. Desorption at about 40% RH leads to an abrupt drop, Xu (1992).

It is observed that the coefficient c is lower for the adsorption compared with desorption, whereas k is slightly higher. By definition, as derived here, these imply a reduction in adsorption heat between molecules at the first and second or higher adsorption layer. It can be speculated that the apparent reduction in V_m is due to that the surface energy of the cement hydrates changes with drying, and number of adsorption sites reduces.

Concrete parameters, such as *w/c*, partial replacement of cement by pozzolanic material, and the factors that affect concrete properties, such as carbonation, aging etc., significantly influence the sorption isotherms. For example, large replacement of cement by fly ash (Class F) results in a decrease in V_m and lower c and k values. The latter was also seen for the effect of *w/c*, which however does not influence V_m (thus the specific surface) determined at adsorption.

CONCLUDING REMARKS

The adsorption function presented in this paper describes the adsorption isotherm of cement paste / concrete over the range about 10% to 80% (restricted to the stability of cement paste and presence of pores). The modification of BET equation, by assuming that $E_2 \neq E_3$ based on experimental evidences, introduces a parameter k which allows the application of this equation to 100% RH for non-porous material. It clearly shows, the relative thickness of adsorbed molecules at 100% RH (or rather, at $1 - kx = 0$) is about half of the probable highest layer.

Pores in cement paste influence the desorption isotherm, which in turn can be used for estimating the pore size distribution. Empirically, the desorption curve can also be expressed by the equation presented here, provided that the curve is smooth.

It should be pointed out, that the derivation of the adsorption equation in this paper is not restricted to the type of adsorbed substances. The adsorption isotherm function, i.e. Eq.5, can be applied to the ion sorption on solid in solution.

$$\frac{Z}{Z_m} = \frac{c\beta\left[1-(n+1)(K\beta)n+n(K\beta)^{n+1}-(1-K)(1-K\beta)^2\right]}{(1-K\beta)\left\{(1-K\beta)K+c\beta\left[(1-K\beta)K+K\beta-(K\beta)^n\right]\right\}}$$

At $1\text{-}k\beta=0$:

$$lim\frac{Z}{Z_m} = \frac{c((n+1)n-2(1-K))}{2(c(n+k-1)+K^2)}$$

MODELLING OF CHLORIDE INGRESS INTO CEMENT-BASED MATERIALS DUE TO CAPILLARY SUCTION

ABSTRACT
To forecast the ingress of chloride ions by capillary suction of salt solutions, we simulate the pore structure of mortars by a monodimensional porous network with randomly distributed radius sizes. This model associated with a simplified suction theory and the knowledge of chloride binding isotherms shows good correlation with experimental data, provided that binding kinetics is quite slow. However, experimental binding is almost instantaneous. We must then assume that suction induces a delay in chloride binding.

Key-words: chloride, chloride binding, water suction, porosity, modelling.

MAIN NOTATIONS

r :	pore radius	g :	gravity
t :	time	C :	volume concentrations
ρ :	mortar density	C_s :	surface concentrations
K :	maximum suction height	N :	number of pore families

INTRODUCTION
Salt transport in unsteady state porous media is complex because of the coupling between transport phenomena. On the one hand, salt ingress is linked to moisture flows inside the material and on the other hand, salt influences water phase changes.

In order to study such transports, we performed suction tests on mortars with sodium chloride solutions. These tests led to the building of a network porosity model which can be used to predict profiles of both water and chloride content.

After presentation of the model and its performances, we deal with the required parameters and above all with the kinetics of chloride binding.

MATERIAL MODEL

Geometrical description
Following-up of water content in mortar during capillary suction shows that there is no real water front and that the material can be in an unsteady state, even when imbibition is ended (Perrin, 1995).

We consider N families of pores, with different radii and as a result different suction kinetics. Pores of various sizes are thus distributed randomly in the model in order to respect porosity, porometric distribution and specific area. We finally obtain a porous network constituted of vertical cylinders whose radii are varying along the suction direction (Fig 1).

With such a method, we are able not only to correlate very well with experimental results but also, which was our initial aim, to have unsteady state in the upper layers of the specimen.

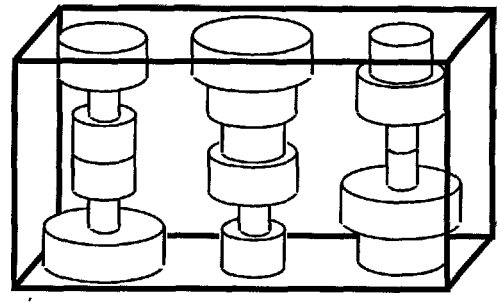

Figure 1: schematics of porous network

Model inputs

Our model requires two main parameters:

- Porosity and porometric distribution of the material provided by Mercury porometry. The experimental porometric distribution is discretized in a finite number of representative families.

- Chloride binding isotherm.
  It was measured and calibrated by a Freundlich expression (Bigas, 1994):

$C_{s\infty} = a\, C^{\gamma}$ $C_{s\infty}$: bound chloride at equilibrium (weight% of cement paste)
C : equilibrium chloride concentration of porewater (kg/m^3)
In our case, $a = 2.32\times10^{-3}$ and $\gamma = 0.36$.

Moreover, we make some hypotheses concerning:

- Kinetics of capillary suction.
  In one of the model's pore i, the final height K_i is given by balancing the weight of the water column and the vertical capillary force:

$$\lambda \frac{2\pi}{r(K_i)} = \int_0^{K_i} \rho g \pi r(h)^2 \, dh \qquad [1]$$

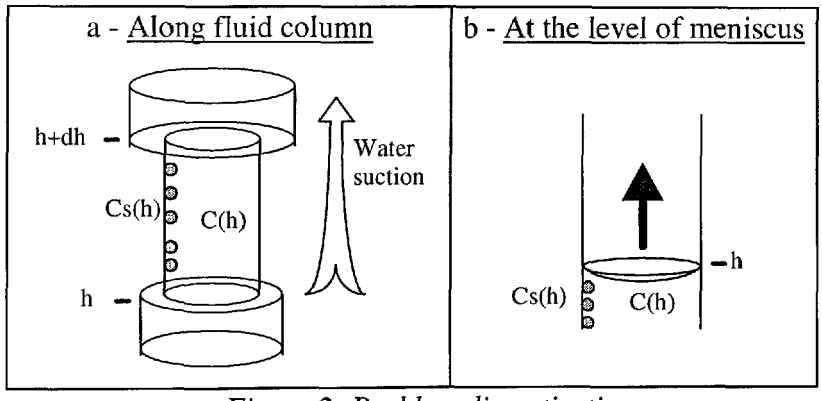
λ depending on: surface tension of water,
porosity,
tortuosity of medium.

Suction height in pore N° i is then given by:

$$h_i(t) = K_i \frac{\sqrt{t}}{\sqrt{t + z_i}} \qquad [2]$$

According to the first results, z_i can be taken equal to 1, whatever the pore radius and its variation. Otherwise, the kinetics should vary with the suction height. This simple

kind of kinetics shows good correlation with both experience and suction theory in cylindrical pores (Volkwein, 1993) and facilitates the numerical part.



- Kinetics of chloride binding.
  For a first approach, we choose a simple kinetics based on first-order chemical reactions (Fripiat, 1971):

$$C_s(t) = C_{s\infty} (1 - e^{-\eta t}) \qquad [3]$$

η depending on the material.

Such an evolution proves quite close to experimental measures (Tang, 1993).

Mathematical resolution

C(h): Cl vol. concentration of porewater at h

Cs(h): bound Cl surface concentration at h

Figure 2: Problem discretization

We can write the mass balance equations along the fluid column and at the level of the meniscus during capillary suction.

Along the column between t and t+dt (Fig 2a):

$$\pi\, r(h)^2\, dh\, C(h) = \pi\, r(h)^2\, dh\, dC(h) + \pi\, r(h+dh)^2\, dh\, C(h+dh) + 2\,\pi\, r(h)\, dh\, dCs(h)$$

$$r^2C(h+dh) - r^2C(h) = - r^2\, dC(h) - 2\, r\, dCs(h)$$

$$\frac{\partial\, r^2C}{\partial\, h}\, dh = - r^2\, \frac{\partial\, C}{\partial\, t}\, dt - 2\, r\, \frac{\partial\, Cs}{\partial\, t}\, dt \qquad [4]$$

$$\frac{\partial\, Cs}{\partial\, t}(h,t) = a\,\gamma\,(1 - e^{-\eta(t-th)})\, \frac{\partial\, C}{\partial\, t}\, C^{\gamma-1} + a\,\lambda\, C^{\gamma}\, e^{-\eta(t-th)}$$

th: time when water reaches h

and $$dh = \frac{K}{2}\left[\frac{1}{\sqrt{t}\,\sqrt{t+z}} - \frac{\sqrt{t}}{\left(\sqrt{t+z}\right)^3}\right] dt \qquad [5]$$

At the level of the meniscus between h et h+dh (Fig 2b):

$$\pi\, r(h)^2\, dh\, C(h) = \pi\, r(h+dh)^2\, dh\, C(h+dh) + 2\,\pi\, r(h)\, dh\, dCs(h+dh)$$

$$r^2C(h) - r^2C(h+dh) = -2r\frac{\partial Cs}{\partial t}(h+dh)\,dt$$

Keeping first order terms: $$\frac{\partial r^2C}{\partial h}dh = -2r\frac{\partial Cs}{\partial t}dt \quad [6]$$

and $$dt = 2zK^2\frac{h}{(h^2-K^2)^2}dh \quad [7]$$

MODEL VALIDATION

Experiments

Vertical suction tests were made on two kinds of mortar: cement CEM I 42,5 , W/C=0.38, sand volume content resp-. 19% (M1) and 57% (M2). Specimens were 70 mm-high prisms initially dried at 50°C with only a few percent of RH kept by silica-gel. Then, they were put in contact with salt solutions of various concentrations ([NaCl] = 0, 20 and 80 g/l). Their lateral faces were made watertight by a polymer resin in order to keep a monodimensional moisture flow. Water concentration profiles were recorded thanks to the gammaray attenuation technique (Perrin, 1995).

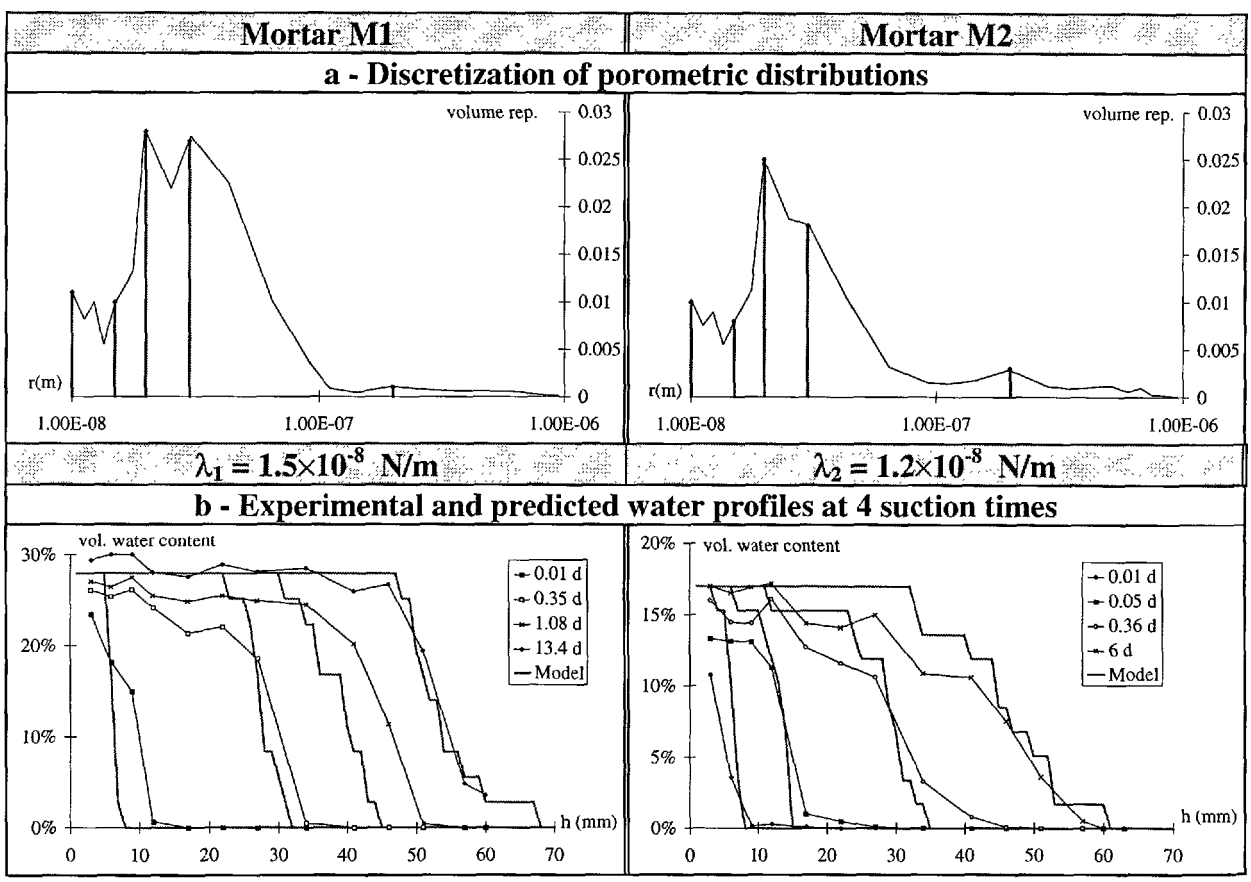


Figure 3: discretization of porometry results and compared water profiles for mortars 1 and 2

Salt concentration showed poor influence on height and kinetics of capillary suction which greatly simplifies our work. But, as expected, binding of chloride ions (essentially on C-S-H) induces a decrease of chloride content along the suction direction.

Water profiles prediction

First of all, we have to build the porous network. Experimental porometric distribution (Bigas, 1994) is discretized into N pore families (Fig 3a). The radii of those families are equal for the two mortars and only their distributions vary from one mortar to the other.

As we can notice, simulations provide good results (Fig 3b). Let us outline that, in these simulations, porous networks are only constituted of ten vertical major pores, which makes the calculation faster but resulting profiles not very smooth.

Chloride binding kinetics

Chloride binding kinetics was investigated by immersing 20 g of mortar powder (particles size inferior to 2 mm) into 50 ml of basic chloride solution (NaOH: 1 g/l, KOH: 4.65 g/l, NaCl: 32.96 g/l) and recording the solution concentration from the earliest times. Powder was previously vacuum-dried at 20°C for 3 days in a desiccator filled with silica gel and then kept in a decarbonized air at 11% RH imposed by a saturated LiCl solution for 7 days (Tang, 1993). Solutions were agitated and concentration measured by a chloride-selective probe.

Chloride binding seems to end after 4 hours and solutions show no change for 15 days (Fig 4). Between 15 and 30 days, the amount of bound chloride seems to increase but on the one hand, dispersion of measures prevents us from making such an assumption and on the other hand, all our imbibition tests last less than 15 days.

If we keep a first-order chemical kinetics to describe the phenomenon (Fig 4), such an evolution can be modelled by the following equation: $C_s(t) = C_{s\infty} (1 - e^{-40\,t})$

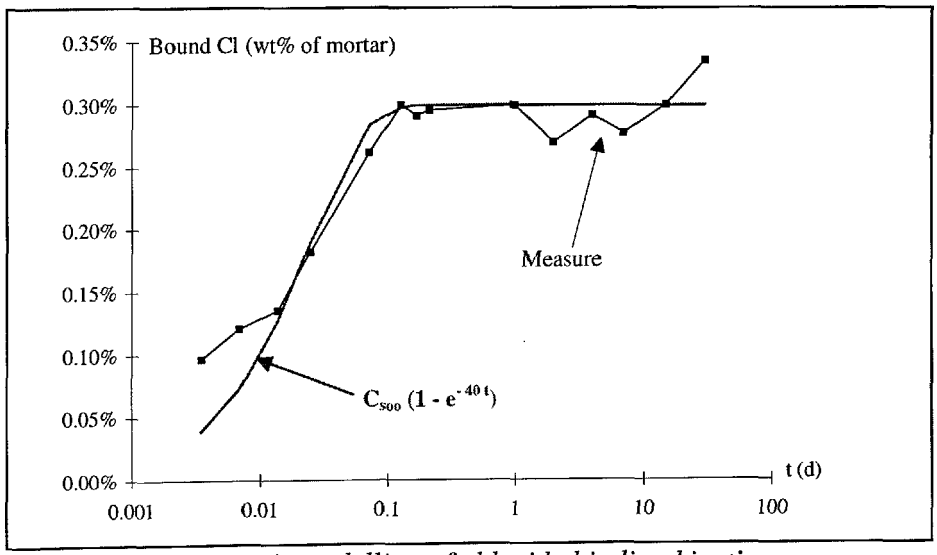

Figure 4: modelling of chloride binding kinetics

We could suppose that binding kinetics is linked to solution concentration. But binding isotherms measured (at present time in the LCPC Paris) on synthetic C-S-H demonstrated the poor influence of chloride concentration upon binding kinetics. However, kinetics is too fast and dispersion too important to quantify this influence.

Chloride profiles simulations

If we simulate the chloride profiles obtained by salt solutions suction with our experimental

chloride binding kinetics, the predicted profiles appear to be very far from reality. To correlate quite well with experience results, the value of η has to be decreased from 40 to 0.4 (Fig 5). Moreover, as pore radii are randomly distributed, the porous network does not remain exactly the same for every simulation. As a result, we studied the model dispersion which never exceeds 0.0012 g Cl / g mortar (Fig 6).

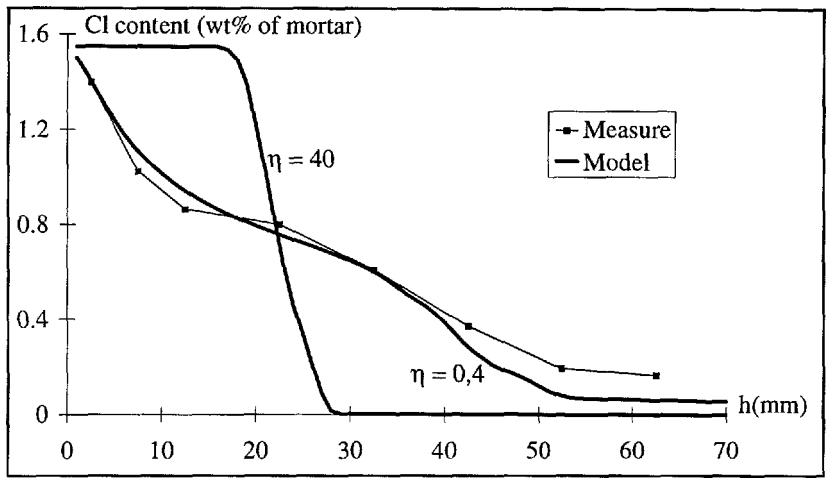

Figure 5: Influence of parameter η upon chloride profiles for M1 - 80 g/l

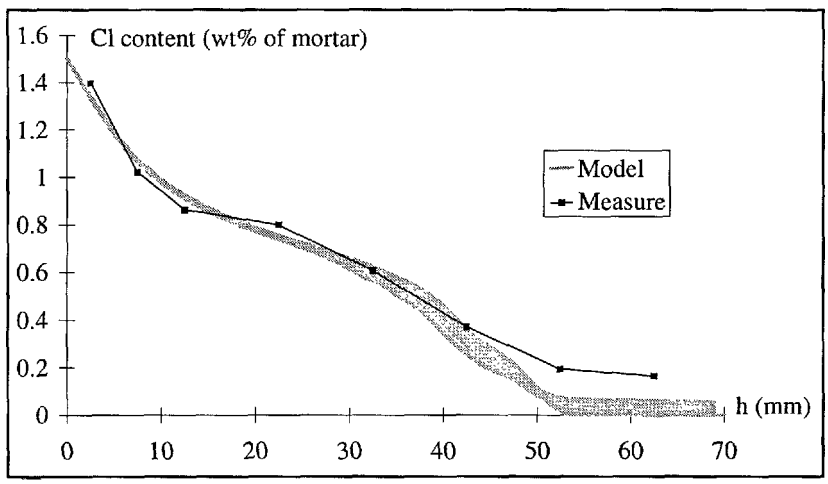

Figure 6: Model dispersion for M1 - 80 g/l and η = 0.4 (10 simulations)

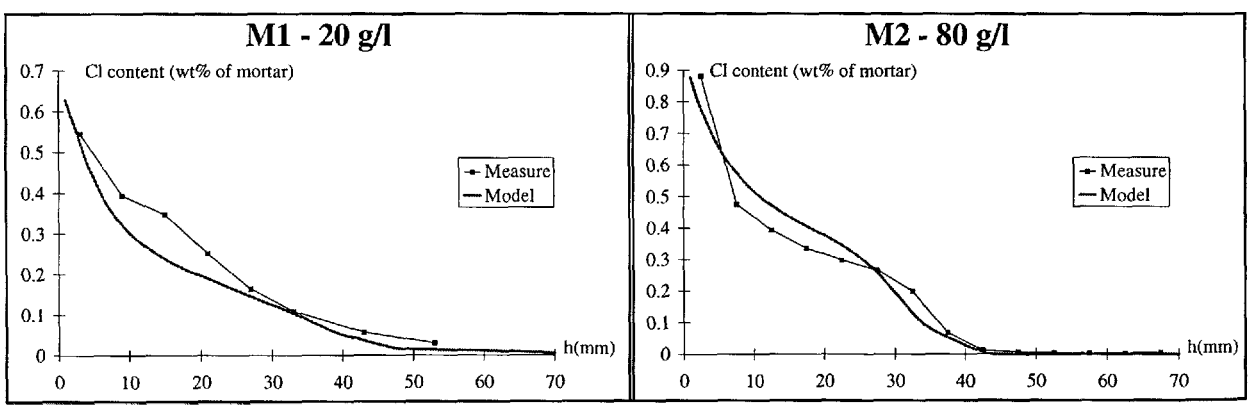

Figure 7: Compared experimental and predicted chloride profiles for 2 other tests

Besides, the value of 0.4 provides a good correlation between measured and predicted profiles

for all other tests (Fig 7).

Discussion about chloride binding

As a result, why should chloride binding be delayed during capillary suction? We can find many explanations to this problem but each one is very difficult to quantify. The only thing we can positively state is that the liquid flow is dragging ions and preventing them from binding as quickly as usual.

Even if pores are very thin, liquid flow in the porous media remains faster than the binding equilibrium. Consequently, some of the chloride ions initially likely to bind (according to the porewater concentration) are dragged away before equilibrium is reached. In fact, the flow prevents them from accessing some minor pores or from finding instantly a free site on the pore walls (Fig 8).

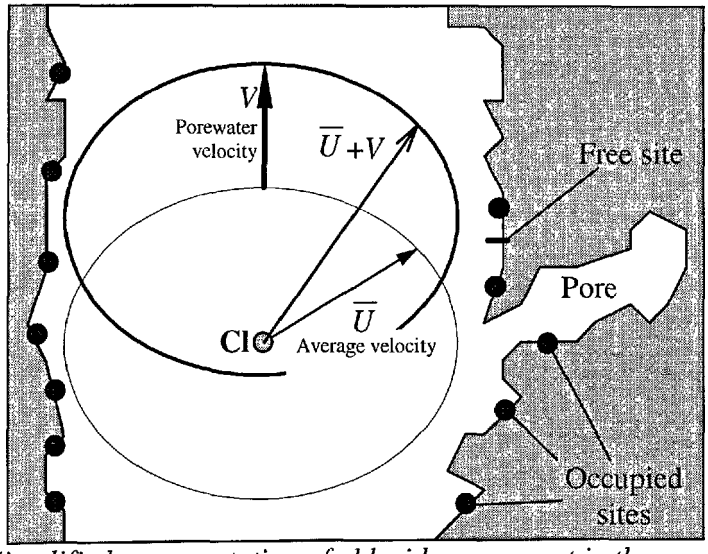

Figure 8: Simplified representation of chloride movement in the porous medium

We can try to quantify those effects with simple numerical considerations.

Let dM_∞ be the total weight of Cl that might be bound (for a given concentration) over one discretization step dh.

$dM_\infty = C_{s\infty} (\rho\ S\ dh)$

For a 20 g/l concentration, $dM_\infty = 0.0141$ dh and $dM_\infty = 1.41\times10^{-2}$ g for dh = 1 mm

The evolution of occupied sites is then: $dM = dM_\infty (1 - e^{-\eta t})$

Because of porewater flow, each chloride ion spends $\tau = \frac{dh}{V(h)}$ within the distance dh and for instance: $\tau\ (\frac{K}{100}) \approx \frac{2\ z}{100\ K}$ dh (Eq 5)

For a maximum suction height of 60 mm and dh = 1 mm, $\tau\ (\frac{K}{100}) = 0.33\times10^{-3}$ s

Such a time is required to occupy the first 1.3% of the total number of sites which represents less than 2×10^{-4} g and correlates well with our need to decrease η by a hundred times.

CONCLUSION

With a simple geometrical model, we were able to predict quite perfectly the combined transport of water and chloride ions during capillary suction tests. We have also highlighted the abnormal binding kinetics of chloride ions during such a test since the velocity of liquid flow prevents some part of the ions from binding instantly on pore walls.

Of course, we could hesitate about using mercury porometry results to build such a model as such an experiment does not provide true information on the internal structure of the material. But, as we only consider intrusion phenomena (Winslow, 1988) and since the model has shown its efficiency in predicting water profiles, we can be quite trustful.

ELECTRICAL PROPERTIES OF CEMENTS

Anatoly F. BERNATSKY, Siberian Research Institute of Energetics.
Novosibirsk, Russia

ABSTRACT Electrical properties of main portland cement clinker minerals, products of hydration of portland cement (hydrosilicates, hydroaluninates, hydroalumoferrites of calcium) and solidified cement in dry and water saturated states were investigated. Power analysis of main products of clinker minerals hydration on calculation of electrical strength was carried out.

Key-words: Electrical, Properties, Drying, Humidity, Ions.

INTRODUCTION

Investigations of electrical properties of cements and concretes based on cement have been carring out at the Siberian Research Institute of Energetics for thirty years, and constructions for power building have been developing too. Thus, knowledge of electrical properties of solidified cement is of practical importance.

Cement stone is a total combination of hydratic new formation with clinker minerals which haven' t reacted with water. Portland cement clinker minerals have extremely irregular crystal lattices with vacancies in points of lattice and varied ions in sites between points. The bonds of these ions are weaker than those in regular crystals, that affects physical and chemical properties of clinker minerals and their electrical conductivity too. Joint action of thermal motion and electrical field can lead to a situation when this or that ion can become a carrier under certain conditions. Thus, electrical conductivity of clinker minerals can be classified as ionic type. The importance of electrical conductivity in many respects depends on ordering of ions in a crystal lattice.

DISCUSSION

The introductionary remarks are confirmed by researches of electrical conductivity of main clinker minerals in temperature ranges from 20 to 1150 °C (Mackenzie,1978). It was found that temperature coefficients of β- C_2S , C_3S and CaO are proportional among themselves. It makes possible to come to a conclusion that electrical conductivity of above mentioned minerals is caused by diffusion of ions Ca^{2+}. Conductivity of C_3A is close to conductivity of pure Al_2O_3, but can be changed to a great extent in the presence of ions Ca^{2+}. Conductivity of C_4AF and pure Fe_2O_3 are close. It means that carrying of electrical charge in C_4AF is realized by ions Fe^{2+} and Fe^{3+}.

Electrical conductivity of hydrated compound of cement stone in many respects depends on quantity of percentage of water in it and on forms of bonds of liquid phase with a solid body. The part of water used for mixing concrete ingredients with water is used directly for formation new compounds of crystalline hydrates, the remaining part is adsorbed or is kept in pores of cement stone, firstly in pores of cement gel. Electrical conductivity of cement gel as a colloid system is connected with existence of water in it, the full removal of which leads to destruction of crystalline hydrates at high temperature. Crystalline hydrates of cement stone contain molecules of water in chemically connected state which were included in the crystal lattice. The part of electrical conductivity related to gel is to a great extent more than the part related to crystalline hydrates. This is confirmed by data given in Table 1.

Table 1 Specific volume electrical resistance of crystalline hydrates of cement stone.

Compound	Resistance, Ω · m
(0.8-1.5) $CaO \cdot SiO_2 \cdot$ (0.5-2.0) H_2O	$9 \cdot 10^4$ - $5 \cdot 10^7$
$3CaO \cdot Al_2O_3 \cdot 6H_2O$	$8 \cdot 10^6$ - $2 \cdot 10^7$
$4CaO \cdot Al_2O_3 \cdot 12H_2O \cdot 3CaCl_2 \cdot 12H_2O$	$8 \cdot 10^6$ - $2 \cdot 10^7$
$4CaO \cdot Al_2O_3 \cdot nH_2O$	$1 \cdot 10^6$ - $3 \cdot 10^6$
Hydrated C_4AF	$1 \cdot 10^6$
$3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O$	$6 \cdot 10^4$
(1.7 - 2.0) $CaO \cdot SiO_2 \cdot nH_2O$	$1.2 \cdot 10^4$ - $6.7 \cdot 10^4$

High-based hydrosilicates and hydrosulphoaluminates of calcium have minimal resistance but one-based hydrosilicates, tricalcium hydroaluminate - maximal. Specific electrical resistance of cement stone is not reduced lower than 10^4 Ω·m in air-dry state and can reach values of 10^9-10^{10} Ω·m.

Electrical conductivity of water saturated cement stone is increasing. Electrical resistance of wet cement stone and its humidity are connected together by a following relationship (Bernatsky, 1980):

$$\rho = \frac{K}{W^{2.6}},$$

where ρ - specific volume electrical resistance of cement stone (Ω·m);
K - coefficient of proportionality, depending on structure of cement stone;
W - absolute humidity of cement stone (%).

The removal of free and partially adsorbed moisture on inner surface of cement stone is the result of its drying. It affects an increase of electrical resistance of cement stone to values equal to 10^9-10^{12} Ω·m. The degree of cement stone dehydration is determinated to a considerable extent by temperature at which the drying is carried out. The higher the temperature of drying the lower balanced humiduty of cement stone can be achieved. Free moisture from capillary-porous body can be removed as a resullt of drying at 105 °C. The temperature of drying must be higher for removal of adsorbed moisture. Thus, electrical conductivity of dried concrete and other electrical characteristics connected with conductivity must be determined to a considerable extent by temperature of drying . This is corroborated completely by the results of experimental investigations given in Table 2.

Table 2. The influence of temperature of drying on electrical characteristics of cement stone.

Type of cement, the conditions of hardening	Temperature of drying, °C	ρ , Ω·m	tgδ
Portland cement, steaming	105	10^7	more 1.0
Sand portland cement, autoclave	140	$2.7 \cdot 10^{10}$	0.16
The same	150	$5.0 \cdot 10^{10}$	0.15
The same	200	10^{11}	0.07

Considerable quantity of new formation in sement stone, its structural and crystal chemical variety, difficulties in their synthesis and identification are the main reason of that electrical properties of these components are little known nowadays. It is related in particular to its electrical strength. The method of power analysis (Bernatsky,1980) was developed for definition of electrical strength of cement crystal hydrates. The results of calculations of electric strength of cement stone components are given in Table 3.

Table 3 Power characteristics of crystalline hydrates of cement stone.

The name of compound	Crystal chemical formula	Calculated values of impulse dielectric strength, kV/sm
	Hydrosilicates of calcium	
Hyrolite	$Ca_2[Si_4O_9(OH)_2] \cdot 3H_2O$	76.5
Tobermorite	$Ca_5[Si_6O_{18}H_2] \cdot 4H_2O$	145
Hillerbrandite	$Ca_{12}[Si_6O_{17}] \cdot (OH)_4 \cdot 12Ca(OH)_2$	148
C_3SH_2	$Ca_4[Si_2O_7] \cdot (OH)_2 \cdot 2Ca(OH)_2$	149
Xonotlite	$Ca_6[Si_6O_{17}] \cdot (OH)_2$	154
Hydrate α -C_2S	$Ca_2[SiO_3 \cdot (OH)] \cdot (OH)$	167
Phasa Y	$Ca_6[SiO_4] \cdot [Si_2O_7] \cdot (OH)_2$	173
	Hydroaluminates of calcium	
C_2AH_8	$2[Ca(OH)_2] \cdot 2[Al(OH)_3] \cdot 3H_2O$	76.5
C_3AH_6	$3[Ca(OH)_2] \cdot 2[Al(OH)_3]$	119.5
C_4AH_{13}	$[Ca_2Al(OH)_7] \cdot 6H_2O$	80
C_4AH_{19}	$2\{Ca_2[Al(OH)_7] \cdot 6H_2O\}$	41
	Hydrosulphoaluminates of calcium	
$C_3A \cdot Cs \cdot H_{32}$	$Ca_6Al_2[(SO_4)(OH)_4]_3 \cdot 26H_2O$	66
$C_3A \cdot Cs \cdot H_{12}$	$Ca_4[Al(OH)_6]_2 \cdot (SO_4) \cdot 6H_2O$	85
	The other compounds	
β-C_2S	Ca_2SiO_4	199
C_3S	$Ca_2[(SiO_4)(CaO)]$	181
C_3A	$3CaO \cdot Al_2O_3$	190

CONCLUSION

Analysing the data received we can stress that electrical strength of starting clinker minerals is higher than that of the products of its hydration. Hydrosilicates of calcium have higher electrical characteristics than hydroaluminates and hydrosulphoaluminates of calcium.

Life cycle analyses and input parametres

THE MYTHS AND MISCONCEPTIONS OF CHLORIDE PENETRATION INTO CONCRETE

Narayan SWAMY, University of Sheffield, Sheffield, England

ABSTRACT This paper examines the conventional tests used to determine the amount and process of chloride penetration into concrete. It is shown that chloride penetration into concrete is a time-dependent process involving physical processes and chemical interactions, and that chlorides penetrate not only in the direction of gravity i.e., depth, but also in a direction lateral to the depth. One dimensional models of chloride diffusion are thus inapplicable to concrete. A two-dimensional model for chloride diffusion is proposed.

Key-words: chloride, penetration, Friedel's salt, pore structure, diffusion

INTRODUCTION

Conventional tests to determine the penetration of chloride into concrete are fundamentally of limited value in terms of the amount of chlorides penetrating the concrete, and the process of chloride ion intrusion into concrete. The standard diffusion cell test, for example, which involves the flow of ions due to a difference in ion concentration to measure the chloride diffusion coefficient, although well established, assumes that chloride penetration is a one-dimensional process, and the unique coefficient of diffusion derived from the test does not represent what happens in practice (Swamy et al 1994).

Accelerated chloride diffusion tests, on the other hand, rely either on increasing the concentration of the chloride solutions, or testing at elevated temperatures in order to accelerate the chloride intrusion. The most widely used accelerated test is the application of an electric field to a test specimen to drive chloride ions through the concrete towards an anode. A potential difference across the test specimen is applied, and the chloride diffusivity is expressed in terms of the total charge in coulombs passed over a period of six hours. Many variations of this test are reported in literature, with the electrical field ranging from a potential difference of 2 volt dc to 60 volt dc. A number of factors influence the results of these tests, such as, the temperature rise during the test, migration of all of the ions present and not just the chloride ions, and the application of Fick's first law of diffusion, which ignores the effects of the electrical field. The value of the results of these tests is thus highly dubious; at best, the test gives a comparative chloride diffusion index, and at worst, the test alters the physical processes of chloride penetration through changes in the chemical structure and porosity of the medium, such that the mechanism of chloride intrusion is totally different to what happens in real life.

The aim of this paper is to establish a better understanding of the amount and chlorides that diffuse through concrete, and to obtain data based on processes and mechanisms that are realistic and relevant to real life situations.

EXPERIMENTAL BACKGROUND

To achieve these objectives, the test specimens chosen for this study were reinforced concrete slabs, 1000 x 1000 x 150mm, or 1000 x 500 x 150mm, with fairly large exposed surface areas, simulating pavements and bridge decks. The slabs were subjected to chloride penetration by cyclic ponding with 4% sodium chloride solution for 7 days, and drying in ambient air for 3 days. At intervals, the concrete slabs were exposed to a drying environment, similar to what occurs in

practice, to enable carbonation processes to occur. The acid-soluble chloride contents, and chloride profiles, were determined indirectly by Volhard's method described in BS 1881, 1988.

To establish the direction of chloride penetration, some of the slabs were partially coated with an acrylic-based surface coating system with extensive test evidence of very high resistance to chloride penetration (Swamy and Tanikawa, 1990, 1991a, 1991b, 1995). Cores were taken from the uncoated and coated parts of the slabs to determine the chloride concentration profiles using Volhard's method.

TEST RESULTS AND DISCUSSION

A large amount of data has been collected from these tests on chloride penetration into concrete slabs. The main variables investigated are water-binder (w/b) ratio, amount and type of mineral admixtures, time of exposure to the chloride penetration regime, and duration of test. Currently, the tests have been in progress for about 9 years, and typical selected data are presented here to highlight the main theme of this paper.

Time-dependency of chloride penetration

The results of chloride concentration profiles for two sets of slabs with a water-binder ratio of 0.60, and containing cement replacements of 30% fly ash, or 65% ground granulated blastfurnace slag after 10, 20 and 50 cycles of exposure to chlorides are shown in Figs 1 and 2 respectively. These results are typical of other data obtained in this study with concretes containing portland cement only, or, those containing other mineral admixtures or combinations of mineral admixtures. These results show conclusively the following:

1. The amount of chlorides penetrating concrete, and the depths of their penetration are dependent on the structure of the concrete mix i.e. the type of concrete mix.
2. The process of chloride penetration is a time-dependent phenomenon, implying that short-term tests do not represent what happens in practice.
3. The surface concentration of chlorides in a concrete element is not constant, but varies with the duration of exposure, and inevitably, with the severity of exposure i.e. chloride concentration in the environment.

Directions of chloride penetration

To obtain conclusive proof of the direction of penetration of chlorides, one-half of 1000 x 1000 x 150mm slabs was coated with an acrylic-based coating system, and the other half left uncoated, and then, the entire slabs were subjected to the cyclic chloride penetration regime described earlier. However, the ability of the coating part to resist chloride penetration needs to be completely reliable to validate the directions of chloride transportation. To confirm this, 1000 x 500 x 150mm slabs, made of portland cement only, but with three different water-cement ratios, and fully coated with the acrylic system, were then exposed to cyclic chloride penetration regimes. In both cases, three water-cement ratios of 0.45, 0.60 and 0.75 were used, and only normal portland cement was used in these slabs.

The chloride penetration profiles in the three fully coated slabs 1000 x 500 x 150mm, after 70 cycles of exposure, are shown in Table 1. The data in this table give conclusive proof that no chlorides have penetrated the acrylic surface coating, even after long-term exposure to a salt-laden environment, justifying the test methodology adopted in using the partially coated slabs.

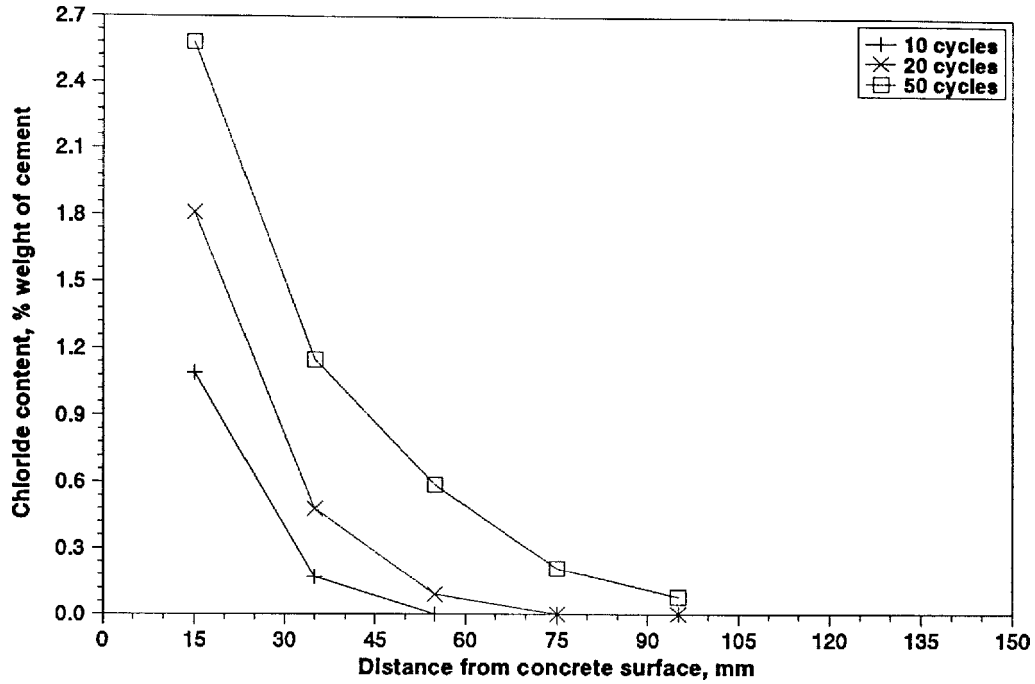

FIG 1 Chloride profiles in slag concrete after different cycles of exposure (w/b = 0.60)

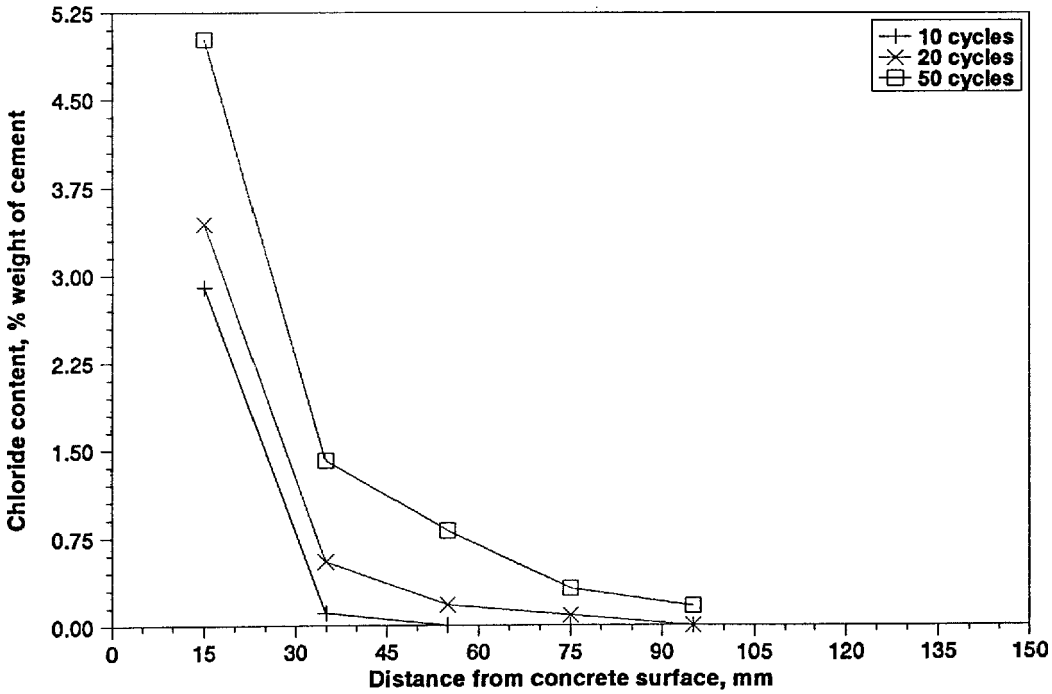

FIG 2 Chloride profiles in fly ash concrete after different cycles of exposure (w/b = 0.60)

Table 1 Acid soluble chlorides by percentage weight of cement

Slab number	w/c ratio	Depth intervals (mm)					
		0-5	5-25	25-45	45-65	65-85	85-105
S4, S5and S6	0.45, 0.60 and 0.75	0.00	0.00	0.00	0.00	0.00	0.00

The results of the chloride concentration profiles of the partially coated slabs 1000 x 1000 x 150mm are shown in Figs 3, 4 and 5. In these slabs and figures, the chloride concentration was determined in the uncoated parts, and at three locations in the coated parts - along lines X1, X2 and X3 at distances of 70, 210 and 350mm from the junction between the coated and uncoated parts as shown in Fig 6. The data in Figs 3 to 5, bearing in mind the results shown in Table 1, prove conclusively the following:

1. Chlorides diffuse both in the direction of depth, i.e. gravity, and in a direction lateral to the depth of the concrete. The amount of chlorides that diffuse in the lateral direction, and the depth they diffuse to laterally, are a function of the w/b ratio, duration of exposure, and obviously, the severity of exposure concentration of chlorides.
2. In practice, the lateral transportation of chlorides will take place in all concretes, irrespective of their w/b ratio, because of continuing duration of exposure, and cracking, arising from various processes, such as, wetting/drying cycles, freezing and thawing, thermal movements, and of course, external loads.
3. The surface concentration of chlorides on a concrete element is again shown to be not a unique constant, but a highly variable parameter which has implications to the diffusion model applicable to concrete.

Other implications

The data shown in Figs 1 to 5 give rise to many implications, which, lack of space will not permit full discussion here. However, these are briefly referred to below:

1. The time-dependency of chloride transportation into concrete implies changes with time, of the physical processes and chemical interactions involved in the chloride transportation process.
2. The stability of Friedel's salt formed due to the interactions between the penetrating chlorides and the C_3A phase in the cement is a function of the alkalinity changes of the concrete arising from atmospheric carbonation. The dissolution of Friedel's salt will increase the free-chloride ion concentration in the concrete (Swamy and Suryavanshi, 1996).
3. The presence of mineral admixtures will have an influence on the dissolution of Friedel's salt present at the concrete external surface.
4. Ettringite will also become unstable in severely carbonated concrete.
5. Prolonged exposure to a carbonating environment after chloride penetration can enable the formation of well-crystallised and amorphous calcite below the exposed surfaces, and the presence of acid-soluble chloride appear to have no influence on the mechanism leading to their formation (Suryavanshi and Swamy, 1997).
6. Penetrating chlorides will change the pore structure of the cover concrete. Extensive microstructural studies show that voluminous chloride-bearing compounds such as Friedel's salt, and calcium chloride, preferentially precipitate in the coarser pores, which results in a significant reduction in the number of coarser pores (> about 30nm in diameter) with reductions in both total accessible pore volume, and porosity of the chloride contaminated concrete (Swamy and Suryavanshi, 1996). Chloride contamination of the outer surface layers of exposed concrete can thus lead to reduced permeability of the cover concrete to further ingress of chlorides.

Chloride diffusion models

The data presented in Figs 1 to 5 question the validity of one-dimensional chloride diffusion models, and in particular, of the diffusion coefficients calculated on the basis of Fick's second law of diffusion for one-dimensional non-steady state, namely,

$$\frac{dc}{dt} = D\left\{\frac{d^2c}{dx^2}\right\} \tag{1}$$

A more realistic model representing the two-dimensional diffusion process is given by

$$\frac{dc}{dt} = D\left\{\frac{d^2c}{dx^2} + \frac{d^2c}{dy^2}\right\} \tag{2}$$

Research is currently in progress to analyse the data presented here on the basis of the above two-dimensional model, and the results will be reported when this work is completed .

CONCLUSIONS

This paper critically examines the current conventional tests to determine the chloride concentration profiles when concrete is exposed to a salt-laden environment. Test results derived from concrete slabs subjected to a cyclic chloride solution ponding and drying regime are then presented to show that chloride intrusion into concrete is a time-dependent phenomenon, involving both physical processes and chemical interactions, and that, the chloride diffusion process involves chloride transportation both in the vertical and lateral directions. A two-dimensional diffusion model is proposed to represent chloride intrusion into concrete.

CHLORIDE ION DIFFUSION COEFFICIENTS FOR CONCRETE - A REVIEW OF EXPERIMENTAL METHODS

Harald JUSTNES and Eva RODUM, SINTEF Civil and Environmental Engineering, Dept. Cement and Concrete, N-7034 Trondheim, Norway.

ABSTRACT The mathematical theories for determining diffusion coefficients from experiments based on pure diffusion or migration in an impressed electrical field, both under steady state and non-steady state conditions, have been reviewed. Literature data from comparative studies of the relation between theory and experimental results support the validity of the calculation of pure diffusion coefficients from migration experiments. Diffusion coefficients obtained by steady and non-steady state methods can not be interchanged, due to the dependence on chloride binding of the latter. Thus, diffusion coefficients to be used in for instance service life analyses should be obtained by non-steady state methods since this is the diffusion mode in practice, although in some cases suction may dominate over diffusion as transport mechanism.

Key-words: Chloride, diffusion, methods.

INTRODUCTION

There is a number of accelerated methods for determination of chloride diffusion coefficients in concrete in the literature, and there is still a great confusion with respect to the fundamentals of the applied equations and the validity of the methods, although some recent papers have clarified some of the matter. The present paper is a review of the different available methods and the theories they are based on. In order to ease the comparison, uniform symbols have been used throughout, although they may deviate from the symbols used by the original authors.

MATHEMATICAL THEORIES

Laboratory methods for determining the rate of chloride ion penetration into concrete may be classified into four categories: Steady state diffusion, non-steady state diffusion, steady state electrical migration and non-steady state electrical migration.

Steady State Conditions

The calculation of diffusion coefficients from laboratory experiments has to be based on the fundamentals of transport processes in solutions. The general equation for transport processes in a solution is named Nernst-Planck equation, which can be written as (Andrade, 1993 and Bockris and Reddy, 1970):

$$-J_j(x) = D_j \frac{dC_j(x)}{dx} + \frac{z_j F}{RT} D_j C_j \frac{dE(x)}{dx} + C_j v(x) \qquad [1]$$

where:

$J_j(x)$ = unidirectional flux of species j [kg/m^2·s]
D_j = diffusion coefficient of species j [m^2/s]
dC_j = variation of concentration (e.g. in compartment 2, Fig 1) [kg/m^3]
dx = variation of distance [m]
z_j = electrical charge of species j (z_{Cl} = - 1) [equivalent/mol]
F = Faraday number = 96,500 [C/equivalent]
R = gas constant = 8.314 [J/mol· K]
T = absolute temperature [K]

C_j = bulk concentration of species j (e.g. in compartment 1, Fig 1) [kg/m^3]
dE = variation of voltage across specimen [V]
v = artificial or forced velocity of ion [m/s]

which means that the unidirectional (x) flux of a particular ion (J_j) is governed by the sum of its diffusion, migration and convection components. Convection does not operate inside the concrete, so the last term of Eq 1 is to be omitted when chloride ion transport in concrete is considered.

Diffusion

The classic steady-state diffusion experiment can be carried out with an equipment as sketched in Fig 1, but without electrodes.

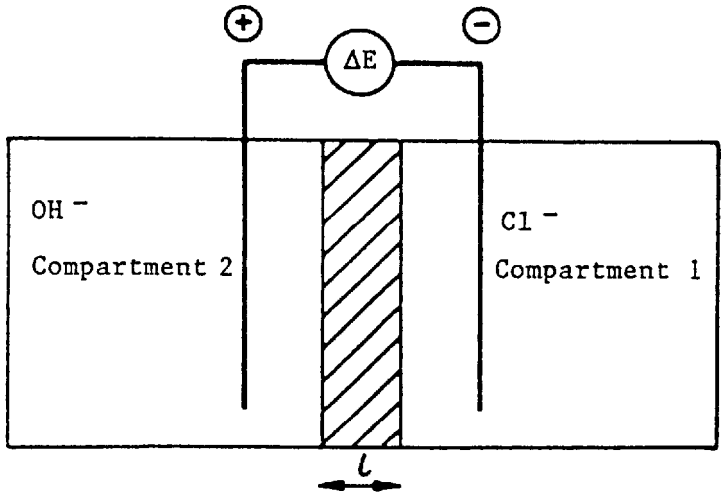

Figure 1 Sketch of cell for testing of chloride flux through porous materials.

The results from the steady-state experiments may be expressed graphically as increasing chloride concentration in compartment 2 (C_2) with increasing time (t), as shown schematically in Fig 2.

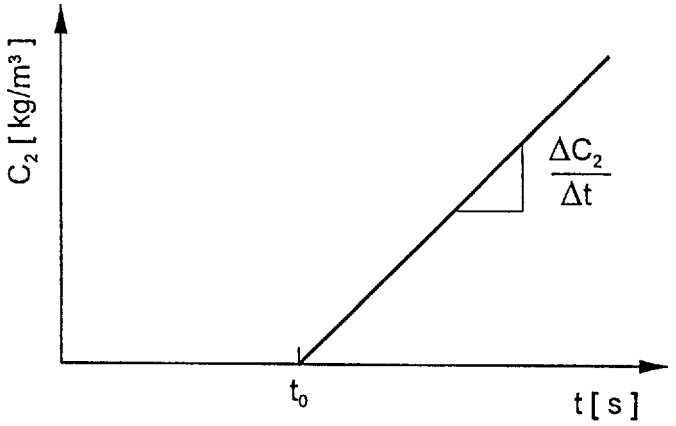

Figure 2 Schematical plot of chloride concentration in compartment 2 versus time.

The rectilinear plot of C_2 versus t, $\Delta C_2/\Delta t$, may be extrapolated to $C_2 = 0$ which corresponds to the initiation time, t_0, for penetration of chlorides. The diffusion coefficient, D [m^2/s], can then be expressed according to Eq 2 (Fick's 1. law, e.g. Page et al, 1981) since the flux $J = \Delta C_2 \cdot V_2/\Delta t \cdot A$:

$$D = \frac{l}{C_1} \cdot \frac{V_2}{A} \cdot \frac{\Delta C_2}{\Delta t} \qquad [2]$$

where:

C_1 = chloride concentration in compartment 1 [kg/m^3] or [mol/ℓ]
l = concrete disk thickness [m]
V_2 = volume of compartment 2 [m^3]
A = cell cross-sectional area [m^2]
$\Delta C_2/\Delta t$ = increase in chloride concentration in compartment 2 with time (slope of the plot on Fig 2) [kg/m^3·s] or [mol/ ℓ· s]

Migration in electrical field

Andrade (1993) has proposed a procedure to calculate the diffusion coefficient, D [m^2/s], from the total chloride flux recorded according to Eq 1 utilizing electrical field experiments (e.g. with set up as sketched in Fig 1). Andrade (1993) measures the reduction of chlorides in compartment 1, but for a steady state this flux should be equal to the increase in chlorides in compartment 2, since $C_1 \cdot V_1 = C_2 \cdot V_2$. Assuming that the contribution of diffusion is negligible compared with migration when an electrical field high enough (> 10 V) is applied to the concrete specimen, and since convection does not operate inside the concrete, Eq 1 can be reduced to (Andrade, 1993, Andrade et al, 1994), remembering that the flux $J = \Delta C_2 \cdot V_2/\Delta t \cdot A$:

$$D = \frac{RTlV_2}{z_{Cl}F\Delta E\gamma_{Cl}C_1A} \cdot \frac{\Delta C_2}{\Delta t} \qquad [3]$$

where:

γ_{Cl} = activity coefficient of chloride
ΔE = voltage drop across specimen [V]

It should be noted that the voltage drop across specimen, ΔE, is less than the applied voltage, ΔU, given by:

$$\Delta U = \Delta E + E^{rev}_{H_2O} + \eta \qquad [4]$$

where:

E^{rev}_{H20} = reversible dissociation potential of water [V] (= 0.463 V at 25 °C and pH=13).
η = polarization effects [V]

McGrath and Hooton (1996) described recently a method of setting the potential ΔE over the sample length by using reference electrodes and Luggin capillaries. They measured the difference ΔU-ΔE to vary from 1.91 to 2.36 V for an impressed potential, ΔU, ranging from 6 to 30 V. Or in other words, the "driving force" ΔE ranged from 68 to 92 % of the nominal voltage. Thus, a higher impressed voltage is preferred if the potential drop over the specimen can not be measured, as long as the temperature rise in the specimen is taken into account.

The NORDTEST method (1989) utilized Eq 2 to obtain a "chloride permeability factor" until 1996 in spite of being a steady state experiment accelerated by an electrical field, but is recently revised to give a chloride diffusion coefficient in accordance with Eq 3.

Zhang and Gjørv (1994) deduced an equation equivalent to Eq 5 based on a theoretical evaluation of steady state migration in an electrical field. β_0 is a correction factor for ionic interaction, ranging from 1.22 for 0.1 N NaCl to 1.70 for 0.5 N NaCl, while the other symbols are defined in the preceding text. Appart from the ion interaction correction factor, it is worth noting that Eq 5 is simply the solution of the Nernst-Planck equation for diffusion (Eq 2) multiplied with the term RT/zFΔE. Thus, it is not in accordance with the solution of the Nernst-Planck equation (Eq 1) for migration of ions in an electrical field when the diffusion term is neglected (Eq 3).

$$D = \beta_0 \cdot \frac{RT}{zF\Delta E} \cdot \frac{lV_2}{C_1 A} \cdot \frac{\Delta C_2}{\Delta t} \qquad [5]$$

Non-Steady State Conditions

Gau and Cornet (1985) formulated the following equation, based on Nernst-Planck (Eq 1), for non-steady state transport processes when D is concentration independent, where the time dependent concentration flux can be expressed as the sum of diffusion and migration terms (convection is omitted):

$$\frac{dC}{dt} = -\frac{dJ}{dx} = D\left(\frac{d^2C}{dx^2} + \frac{zF}{RT}\cdot\frac{dE}{dx}\cdot\frac{dC}{dx} + \frac{zFC}{RT}\cdot\frac{d^2E}{dx^2}\right) \qquad [6]$$

Diffusion

The classic non-steady state diffusion experiment is carried out by immersing a concrete specimen, sealed on all sides except the surface to be exposed, into a NaCl-solution (e.g. the APM302 method developed at the AEC Laboratory in Denmark). Uni-directional transport of chloride ions by pure diffusion (non-steady state) is expressed by Fick's second law (first term in Eq 6 when D is assumed to be concentration independent):

$$\frac{dC}{dt} = \frac{d}{dx}\left(D\frac{dC}{dx}\right) \qquad [7]$$

The solution of Fick's second law for a concentration independent diffusion coefficient gives the chloride content as a function of exposure time, t, and the distance from exposure surface (AEClaboratory, 1991):

$$C_x = C_0 - (C_0 - C_i)\ erf\left(\frac{x}{2\sqrt{D\cdot t}}\right) \qquad [8]$$

where:

C_x = chloride concentration, measured at the depth x at the exposure time t [mass %]
C_0 = boundary condition at the exposed surface (calculated surface concentration, x=0) [mass %]
C_i = the initial chloride concentration in the sample [mass %]
x = depth below the exposed surface [m]
t = exposure time [s]
erf = the error function

Migration in electrical field

Luping and Nilsson (1992, 1993) utilized Eq 6, assuming linear electric field over the specimen with $dE/dx = \Delta E/l$ and $d^2E/dx^2 = 0$ (may be doubtful in the case of non-steady state);

$$\frac{dC}{dt} = D\left(\frac{d^2C}{dx^2} - \frac{zF\Delta E}{RTl}\cdot\frac{dC}{dx}\right) \qquad [9]$$

in the development of their rapid penetration method. For the actual boundary conditions, and neglecting the pure diffusion term, the exact analytical solution of Eq 9 can be found as:

$$C = \frac{C_0}{2}\left[e^{ax}\, erfc\left(\frac{x + aDt}{2\sqrt{Dt}}\right) + erfc\left(\frac{x - aDt}{2\sqrt{Dt}}\right)\right] \qquad [10]$$

where $a = zF\Delta E/RTl$ and other symbols as defined earlier.

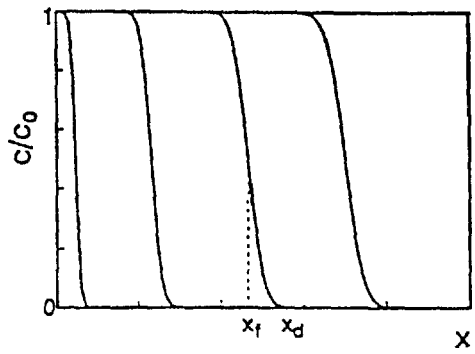

Figure 3 Theoretical concentration profiles according to Eq 10 (Luping and Nilsson, 1992).

Fig 3 illustrates the concentration profiles of Eq 10, and shows that there is an apparent concentration front in each profile. This implies the possibility of calculating diffusivity from the penetration depth. In fact, it can be found from Eq 10 that the profile has an inflection point at x_f:

$$x_f = \frac{zF\Delta E}{RT\,l}\,Dt \qquad [11]$$

Although it is difficult to determine x_f, the penetration depth x_d can be measured by using a colorimetric method based on chlorid precipitation by silver nitrate. The relationship between x_f and x_d can be obtained by using a numerical solution;

$$x_f = x_d - \alpha \cdot x_d^{\beta} \qquad [12]$$

where α and β are regression coefficients depending on the experimental conditions. The diffusion coefficient, D, can then be found by combining Eq 11 and Eq 12:

$$D = \frac{RTl}{zF\Delta E}\left(\frac{x_d - \alpha x_d^{\beta}}{t}\right) \qquad [13]$$

where t is testing time in hours.

Sha'at et al (1994) presented a solution to Eq 9 which can derive the diffusion coefficient, D [m^2/s], from a migration experiment with impressed voltage, ΔU, with a set-up as sketched in Fig 2 by measuring the chloride concentration in chamber 2, C_t, at a given time, t:

$$C_t / Co = erfc \{ [l - (D \cdot z \cdot F \cdot \Delta U \cdot t / R \cdot T \cdot l)] / 2\sqrt{D} \cdot t \} \quad [14]$$

where: erfc = (1 - erf), the complement of the error function
C_t = the outflow concentration in chamber 2 at time, t.
C_0 = inflow concentration in chamber 1 at t = 0
and the other symbols as explained for previous equations

Sha'at et al (1994) showed that calculations by Eq 14 gave diffusion coefficients of chlorides comparable to those obtained by pure diffusion tests. They applied voltages of 10, 30 and 60 V. The obtained D decreased only slightly with increasing ΔU, and was in fact closer to the pure diffusion coefficient for the highest ΔU when the temperature rise in the sample was taken into account. This might be due to the relative difference between ΔE (should replace ΔU in Eq 14) and ΔU (see Eq 4) being less for higher ΔU.

Andrade et al (1994) deduced using an analogy with natural diffusion experiments, when the pure diffusion is neglible compared with migration in an electrical field, that the equation for a non-steady state migration can be formulated as

$$\frac{dC}{dt} = \frac{zF\Delta E}{RT} \cdot D \cdot \frac{d^2C}{dx^2} \quad [15]$$

where $zF\Delta E/RT$ is simply the accelerating factor. The solution of Eq 15 can be achieved analogously to pure diffusion under non-steady state conditions to:

$$C = C_0 \, erfc \left(\frac{x}{2\sqrt{\frac{zF\Delta E}{RT} \cdot D \cdot t}} \right) \quad [16]$$

which is similar to Eq 8 for pure diffusion (since erfc = 1 - erf). Eq 16 is a much simpler solution than Eq 10. Their comparison between acceleration in electrical field with pure diffusion placed the diffusion coefficients of the two concretes in the same order, but the magnitudes were 2-3 times higher for the pure diffusion (lowest Cl^- concentration in concrete).

Crank (1975) showed that the non-steady state diffusion coefficient, D, independent of concentration can be calculated from the intersection of the steady state line with the abscissa in Fig 2, t_0, for porous materials:

$$D = \frac{l^2}{6\tau_0} \quad [17]$$

The factor 6 in Eq 17 is called the "time lag" and may depend on the material characteristic, which make the formula too uncertain for practical use in concrete technology.

DISCUSSION

It is important to notice that diffusion coefficients deviated from steady state (D_{ss}) and non-steady state (D_{ns}) conditions can not be compared directly, since the ratio between them depend both on the porosity and the chloride binding capacity of the material. In a recent model for chloride penetration, Tang and Nilsson (1996) used the following expression;

$$\frac{D_{ss}}{D_{ns}} = \epsilon + K_b \cdot W_{gel} \qquad [18]$$

where:

ε = porosity of the concrete,
K_b = chloride binding constant [m^3 solution/kg gel]
W_{gel} = hydrated gel content [kg gel/m^3 concrete]

Apparently Tang and Nilsson (1996) assumed in Eq 18 that chloride binding is dominated by adsorption on the CSH-gel, which may not be true for systems with high contents of calcium aluminate hydrates (e.g. HAC, fly ash blends and slag blends). In the calculations of D_{ns} it has until recently been assumed that the ratio between free and bound chlorides are independent of the chloride concentration, which is not correct neither for chemical binding (e.g. Friedel salt formation) nor adsorption. Tang and Nilsson (1996) used a Freundlich isoterm and terms correcting for OH^- concentration and temperature variations when calculating the bound (i.e. adsorbed) chloride content in their numerical model (chemical binding neglected). A high chloride binding capacity will lead to a steeper profile of total chlorides and thereby a smaller D_{ns} than in reality (i.e. when binding is saturated or reversed by sulphates or carbonation), which may create significant errors in service life predictions. In spite of the fundamental difference between D_{ss} and D_{ns}, many obtain diffusion coefficients by steady-state experiments and use them in life cycle calculations for structures where chloride diffuses in a non-steady manner, but other uncertainties are larger.

McGrath and Hooton (1996) compared D_{ss} and D_{ns} for the same concrete in the same experiment similar to the set-up sketched in Fig 1. D_{ss} was calculated from Eq 3 after obtaining steady state flow, while D_{ns} was calculated directly from Eq 10 utilizing a "break through" time, t, defined as $C/C_0 = 0.03$, after the methodology of Halamickova et al (1995) who used $c/c_0 = 0.005$. McGrath and Hooton (1996) realized that the D_{ns} is related to pore solution concentrations and porous area fractions, and they divided D_{ss} by a simple approximated area fraction prior to comparison with D_{ns}. Furthermore, chemical binding will slow down the "break through" time thus reducing D_{ns} relative to D_{ss}. The D_{ns} was quite constant at all voltages (ΔU = 6, 12, 20 and 30 V), and the D_{ss} quite comparable at the two lower voltages, but increased substantially for the two highest voltages. The latter might be due to temperature effects that did not seem to be taken into account in the study.

To complicate the matter further, suction may dominate over diffusion as the transport mechanism in tidal and splash zones in marine environment as pointed out by for instance Volkvein (1993). He also claimed that the suction due to underpressure created by the contraction of the continued hydration also plays a role in the transport process of fluids in young concrete. Roelstra et al (1996) also modelled chloride penetration taking into account important effects of moisture migration and cement hydration. Jones et al (1996) discussed chloride ingress into unsaturated concrete in terms of sorptivity and capillary diffusivity. Note that the preceding methods of obtaining diffusion coefficients rely on the assumption of

saturated pores.

A third matter that must be taken into account when diffusion coefficients are going to be applied in calculations, is their time dependence. This aspect has been discussed thoroughly the later years by Poulsen (1993, 1996), while Mejlbro (1996) recently presented the mathematical solution of Fick's second law of diffusion with time-dependent diffusion coefficient and surface concentration. The particular importance of this aspect for slow reacting binders like fly ash has been pointed out by Thomas and Jones (1996). However, if a diffusion coefficient obtained for say a 60 days old concrete is treated as constant in modelling, the resulting service life will be underestimated, which leaves one at the safe side of the uncertainty. Nevertheless, if not the time dependence of the diffusion coefficient for the particular concrete mix is determined, a single determination on a mature concrete (e.g. 1 yr moist curing) is recommended.

A fourth important matter, the concentration dependence of the diffusion coefficient, seems to have been neglected. All methods for determination of non-steady state diffusion coefficients rely on that it is independent of the concentration. This topic should be focused on in future studies.

The preceding electrical migration methods rely on that the potential drop over the concrete specimen is linear ($dE/dx = \Delta E/l$ and $d^2E/dx^2 = 0$) which may not be true in particular for non-steady state experiments. In addition, the applied theory of electro-migration is developed for dilute electrolytes. The latter has been tried to be counteracted by the activity coefficient, γ_{Cl}, in Eq 3 or the ion interaction factor, β_0, in Eq 5. The concept of an activity coefficient is the deviation from ideal behaviour, which in the case of an electrolyte of ionic strength, $I = \frac{1}{2}\sum c \cdot z^2$ (mol/ℓ), mainly is due to the ionic interaction, but also ion-solvent (water) interaction. The average ion activity coefficient for an electrolyte may be estimated by advanced Debye-Hückel limiting law modified by a linear correction term;

$$\log \gamma_{\pm} = -\frac{A \cdot z_+ \cdot z_- \cdot \sqrt{I}}{1 + B \cdot a \cdot \sqrt{I}} + b \cdot I \qquad [19]$$

where in the case of NaCl ($z_+ = z_- = 1$), the experimental coefficients a = 0.4 nm and b = 0.055 ℓ/mol, while the temperature dependent constants A = 0.50925 $\ell^{1/2}/mol^{1/2}$ ($\propto T^{-3/2}$) and B = 3.2864 $\ell^{1/2}/mol^{1/2}\cdot nm$ ($\propto T^{-1/2}$) for water at 25°C. Thus, in the case of NaCl, $0.68 < \gamma_{\pm} < 1.00$ with a minimum at a concentration of ≈1 M. Note that in the actual diffusion or migration process, iteraction between the moving ions and the solids of the concrete, and/or the additional ions of the pore water, may lead to a different "activity coefficient". However, choosing a correct activity coefficient may be a minor adjustment compared to the preceding discussed fundamentals.

CONCLUSIONS

From the evaluation of the different methods for determining chloride diffusion coeffisients, the present authors recommend the following;

1) The determination of *steady state chloride diffusion coefficients* should be performed by an experiment utilizing acceleration by electrical field and relying on Eq 3. The activity coefficient for chlorides could be calculated according to Eq 19. If the imposed potential exceeds 10 V, the temperature rise in the specimen should be determined and applied in Eq 3 instead of the ambient temperature. The true potential drop over the

specimen should be used instead of the impressed potential in Eq 3. This method will be a revised NORDTEST NT Build 355 method in 1997.

This method is mostly useful for determining material parametres when the chloride binding is saturated in order to compare different concrete qualities or recipes. The steady state chloride diffusion coefficient can not be used directly in service life calculations for structures where chlorides in practice is transported in a non-steady state manner.

2) The determination of *non-steady state chloride diffusion coefficients* should be performed by the diffusion method describe by AEClaboratory (1991), relying on Eq 8, and accelerated by concentration (16.5 % NaCl). The method has lately (November 1995) been accepted as NORDTEST NT Build 443 method. The method could easily be further accelerated by an electrical field requiring a set-up as in Fig 1, but this needs to be documented.

   This method is most relevant for submersed concrete structures (e.g. lower part of bridge pillars). Due to the influence of sulphates on chloride binding, and the dependency of D_{ns} on chloride binding, the exposure liquid should be enriched, artificial sea water rather than the prescribed NaCl.

3) The determination of an *apparent non-steady state chloride diffusion coefficient* should rely on Eq 8, but the eposure to the chloride source should be cyclic in terms of ponding or salt-spray in order to simulate tidal zones or splashing of sea water at the coast. Such an experiment should give apparent (since the transport is a mix of diffusion and suction) diffusion coefficients more relevant to practice and better suited for service life predictions.

In all three situations, the concrete should be mature (>90 days water cured) prior to testing, unless the time-dependency of the obtained diffusion coefficients are determined.

THE INFLUENCE OF THE ELECTRICAL POTENTIAL IN THE CHLORIDE THRESHOLD FOR REBAR DEPASSIVATION

Cruz ALONSO, Carmen ANDRADE and Marta CASTELLOTE, Institute of Construction Science "Eduardo Torroja", Madrid, Spain.

ABSTRACT Chloride/hydroxide threshold is considered as the most representative parameter to determine rebar depassivation. The influence of the electrical potential exhibited by the rebar when chlorides arrive has been studied by a statistical treatment. A mean value of Cl^-/OH^-=0.82 and % Cl free= 0.56 was found, although a big scatter appears which has been related to the nature of the passivating layer.

Key-words: chloride, corrosion, durability, steel

INTRODUCTION

Chlorides are known to be the most dangerous aggressive towards the steel passivity. When they reach the rebar in a certain proportion, a localized attack is developed. Chloride threshold to produce reinforcing steel corrosion varies according to several parameters and it is expresed in terms of free or total chloride as well as Cl^-/OH^- ratio.

Although Kaesche (1959) and Baumel (1959) were the first to try to determine a chloride limit for rebar corrosion in alkaline solutions, Lewis (1961) was the first to give a value (3000 ppm Cl^-) for corrosion initiation. Later on, Haussman (1967) and Gouda (1970) established that the threshold is related to the amount of hydroxides. They gave a mean value for Cl^-/OH^- of 0.63 and 0.4 respectively. Further studies from Goñi (1990) in solutions simulating pore solution indicated a Cl^-/OH^- threshold between 0.25-0.8 and found a correlation between rebar corrosion rate and Cl^-/OH^- values.

Less agreement between authors is found in the case of mortar and concrete, thus Gouda (1970) gave values from 0.15 to 0.75%of NaCl by weight of cement depending on the type of cement and surface of the rebar, Hope (1987) 0.2 to 0.4 and Page (1991) found a value of 1.5% Cl^- and also a Cl^-/OH^- = 3. Recently, Petterson (1994,1996) has obtained variations from 2-8 when testing under different conditions.

All these research have pointed out that the disagreement between authors on a single value for Cl^-/OH^- is due to the numerous variables that influence the threshold: Type of cement, w/c, porosity, temperature, chloride addition or penetration, quality of passivation layer and the electrical potential of the rebar. Among those variables, that less studied is the potential exhibited by the rebar when chloride arrive (Ishikawa,1969, Tuutti, 1982, Bertolini, 1996). In present paper results of Cl^-/OH^- are given in the region of potentials from -250 to +250mV SCE. The study has been made in a numerous set of mortar specimens in order to obtain statistically relevant results.

EXPERIMENTAL METHODOLOGY

Specimens Preparation

200 mortar specimens of 2x2x8 were fabricated with w/c=0.5 and c/s=1/3. Each had embedded a corrugated rebar with a exposed area of approx. 60 mm^2. The electrical contact was made in the emerging part of the rebar. The cover was of 5 mm. The specimens were kept in a chamber at 95%RH and 20°C until testing. Six types of cement were used:

1. OPC-I, with low C_3A (1.1%) and low alkali content (0.43% Na_2O eq.).
2. OPC-I, with high C_3A (9.7%) and high alkali content (0.84% Na_2O eq.).
3. OPC-I, low C_3A + 35% fly ash class F.
4. OPC-I, high C_3A + 35% fly ash class F.
5. Aluminous cement.
6. Portland-II with filler addition.

Testing Procedure

The surface in which the rebar is protuding, was covered with epoxy resin to avoid preferential entrance of chloride by the steel concrete interface. A set of identical specimens made of the same batch were immersed in 0.5M NaCl solution.

The passivation state of the rebar was tested before the penetration of chloride. Thus the measurements of corrosion potential indicated values more positive of -250mV (Vs.SCE) and corrosion rates <0.2 $\mu A/cm^2$ in all cases.

A mesh of stainless steel or titanium were employed as counter electrodes. As reference electrode a Mn/MnO_2 was used. The rebars of each specimen, were all connected in parallel as working electrode. A constant potential was then applied (potentiostatic test) and maintained in each specimen along the test. The potential tested were: +100,0,-100,-200,-300 and -400mV (Mn/MnO_2) or +250, +150, +50, -50, -150 and -250 mV (SCE).

The current flow was monitored at each rebar.When a sharp increase was observed,the specimen was taken out off the testing arrangement, and the Ecorr and Icorr was measured to check the rebar depassivation. Free and total chloride and hydroxide concentration at the rebar level were determined after depassivation.

RESULTS

When the steel depassivates under potentiostatic conditions a sharp increase of current is noticed. Fig 1 shows an example for the case of OPC-I high C_3A content and +150 mV (SCE).

The chloride content at the moment of rebar depassivation is represented in Fig 2 for the case of +50 mV (SCE) and the various cement tested. A scatter in the results is noticed for each cement type. The type II OPC is that showing higher Cl^- contents. The scatter widens when the plot is based on the Cl^-/OH^- ratio as Fig 3 depicts for -150 mV (SCE) test.

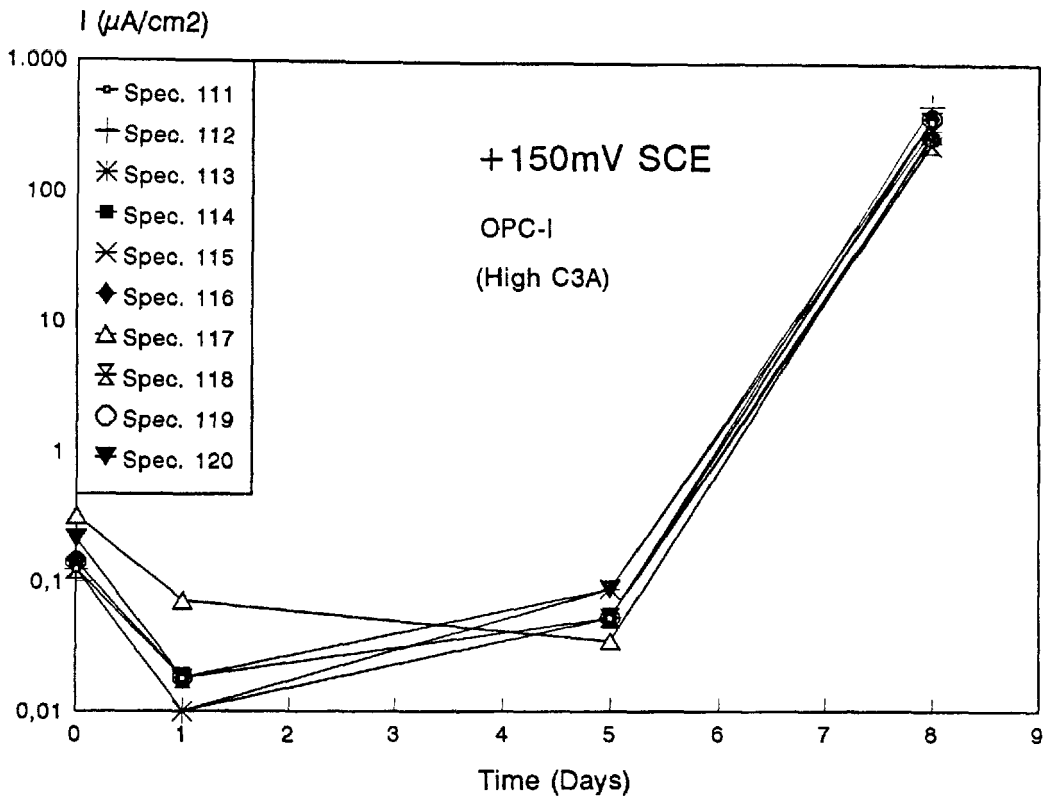

Figure 1 Current flow (in $\mu A/cm^2$) measured during rebar depassivation test at +150 mV (SCE).

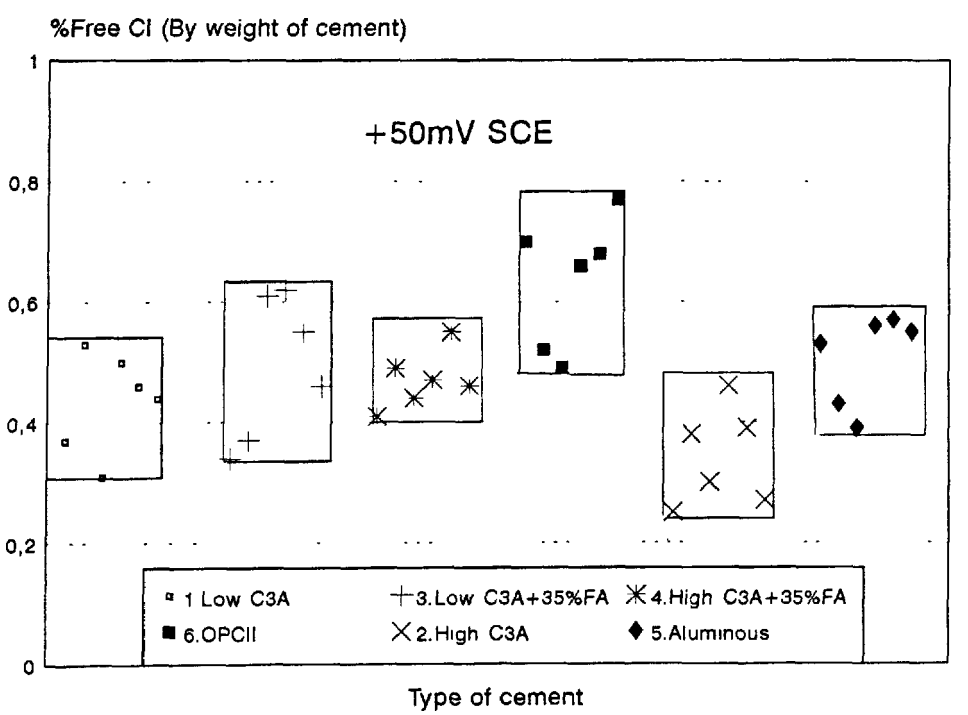

Figure 2 Percentage of free chlorides by weight of cement for rebar depassivation embedded in various cement types and polarized at +50 mV (SCE).

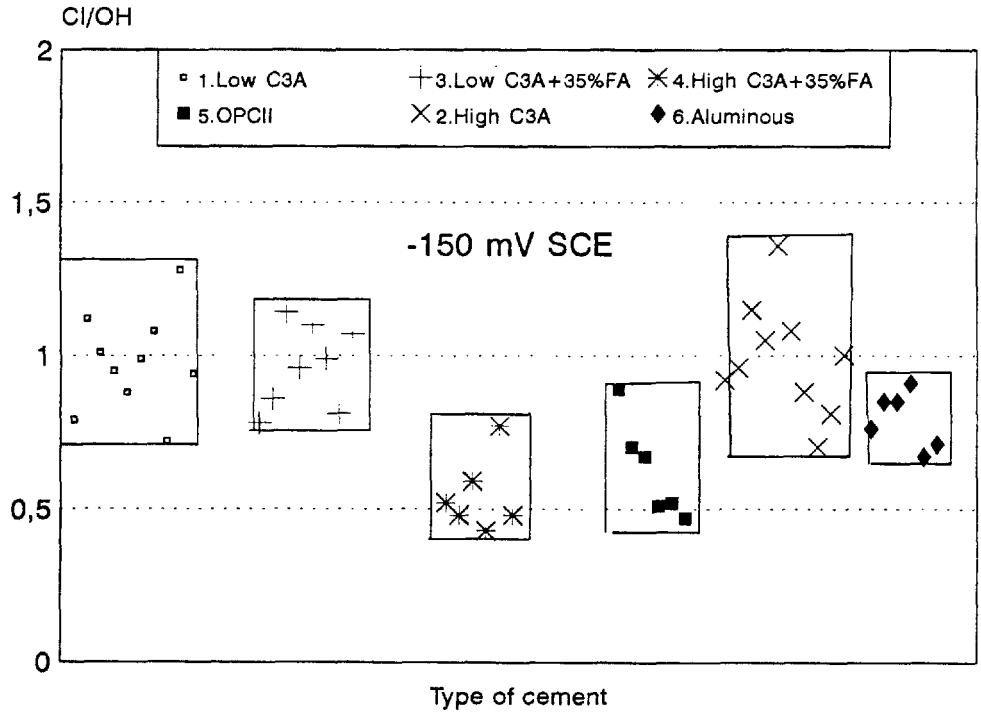

Figure 3 Cl^-/OH^- threshold for varios cement types. Polarization at -150 mV (SCE).

Statistical Study

The scatter found led to the need of an statistical treatment. As first approach a normal distribution law was considered. Thus, the determination of the mean and the standard deviation of the chloride and Cl^-/OH^- ratio at each potential was made. Fig 4 represents the mean for the %Cl free. A relationship with the C_3A content was not defined. This was attributed to the fact that the cover is too thin (5mm) to allow differences. Similar results were found for Cl^-/OH^- ratio.

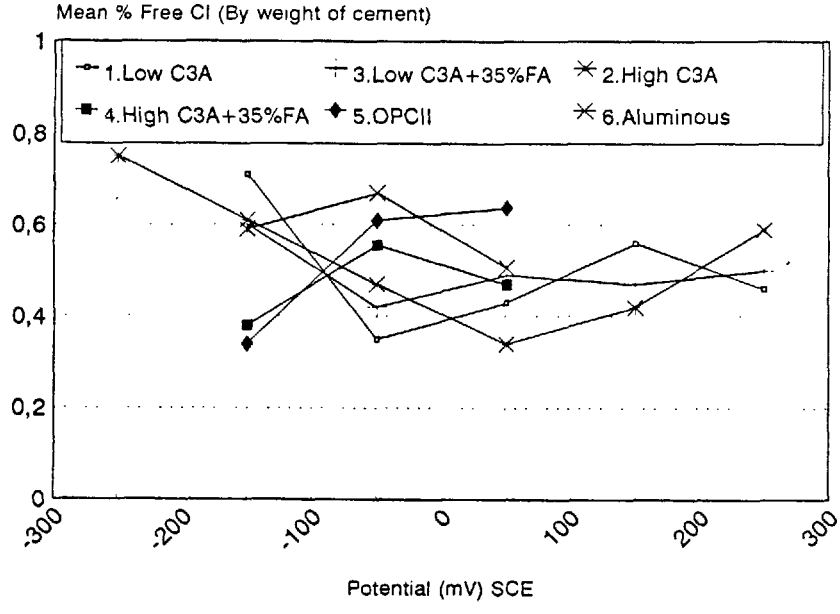

Figure 4 Mean critical chloride for the six types of cement in the range of potentials: +25 to -250mV (SCE).

As the type of cement was not a determinant parameter in present research, another treatment was made in funtion of the electrical potential. Fig 5 and Table 1 show the mean and the standard deviation. The mean of the mean at each potential resulted: 0.56 ± 0.17% Cl free and 0.73 ± 0.02 Cl total by weigth of cement and Cl^-/OH^- = 0.82 ± 0.018. These are the thresholds for rebar corrosion initiation found in present work.

Table 1 Results of the mean threshold for total chlorides and Cl^-/OH^- ratio.

Pol.Potent. (SCE)	Total chlorides %		Free chlorides %		Cl^-/OH^-	
	Mean	Stand.Dev.	Mean	Stand.Dev.	Mean	Stand.Dev.
+250 mV	0.73	0.06	0.516	0.054	0.78	0.075
+150 mV	0.76	0.05	0.483	0.058	0.77	0.04
+50 mV	0.70	0.12	0.480	0.09	0.74	0.15
-50 mV	0.741	0.16	0.513	0.11	0.79	0.16
-150 mV	0.743	0.17	0.54	0.13	0.83	0.19
-250 mV	-	-	0.70	0.11	1.026	0.176

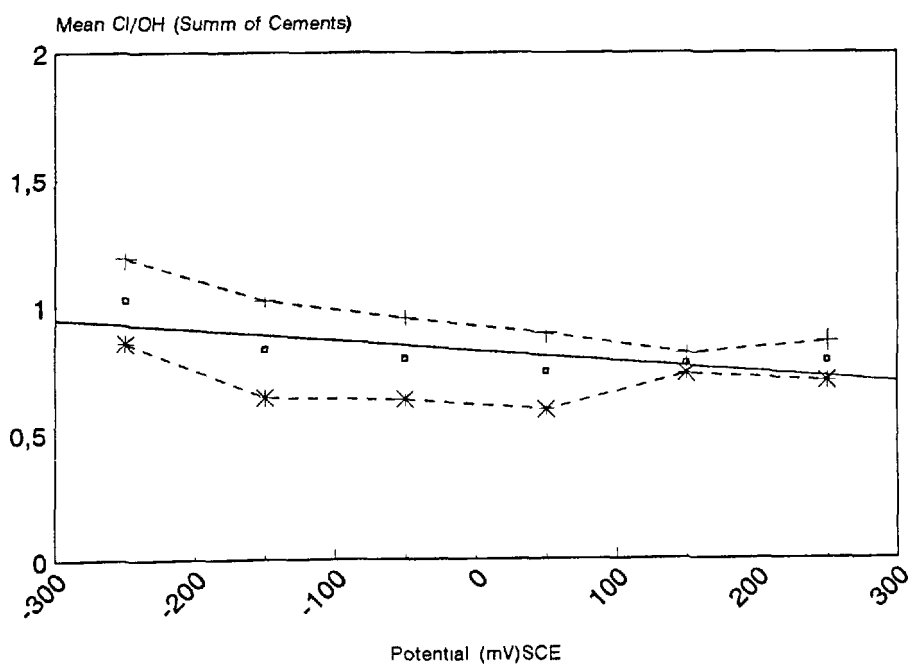

Figure 5 Mean and standard deviation of Cl^-/OH^- threshold in the range of potential: +250 to -250mV (SCE).

DISCUSSION

Type of cement in Cl^-/OH^-

The type of cement is considered a factor that influences rebar corrosion. It is well known that chloride combines with aluminates of cement forming a solid phase named Friedel salt. This ability of aluminates to remove free chlorides from the pore solution decreases the risk of corrosion for the rebars. The final effect is a delay in the time for depassivation. The reactivity of aluminates depends on: pH of pore solution, changes of temperature, origing of

the aluminates (e.i. from OPC, fly ash or aluminous cement) and also varies whether chlorides are present during setting or penetrate from outside.

In present experimentation no influence of the type of cement was found. Chloride and OH^- in the pore solution resulted very similar in all cements with a wide scatter. No particular reason has been found to explain this circumstance, as the values of the potentials applied were in the natural range of the rebars, and therefore any artificial acceleration in the penetration has been induced, except that of the cover too thin to allow the C_3A to efectively combine chloride before reaching the rebar surface.

On the other hand it is worth to point out that, the value in terms of free chlorides per weight of cement resulted slightly higher than that given in the standards (0.4% of cement weigth). Similarly the Cl^-/OH^- value is higher than that found in solution simulating the pore solution (0.6). Higher values were also found by other authors as Fig 6 shows (Hansson,1990, Page,1991, Petterson,1994,1996).

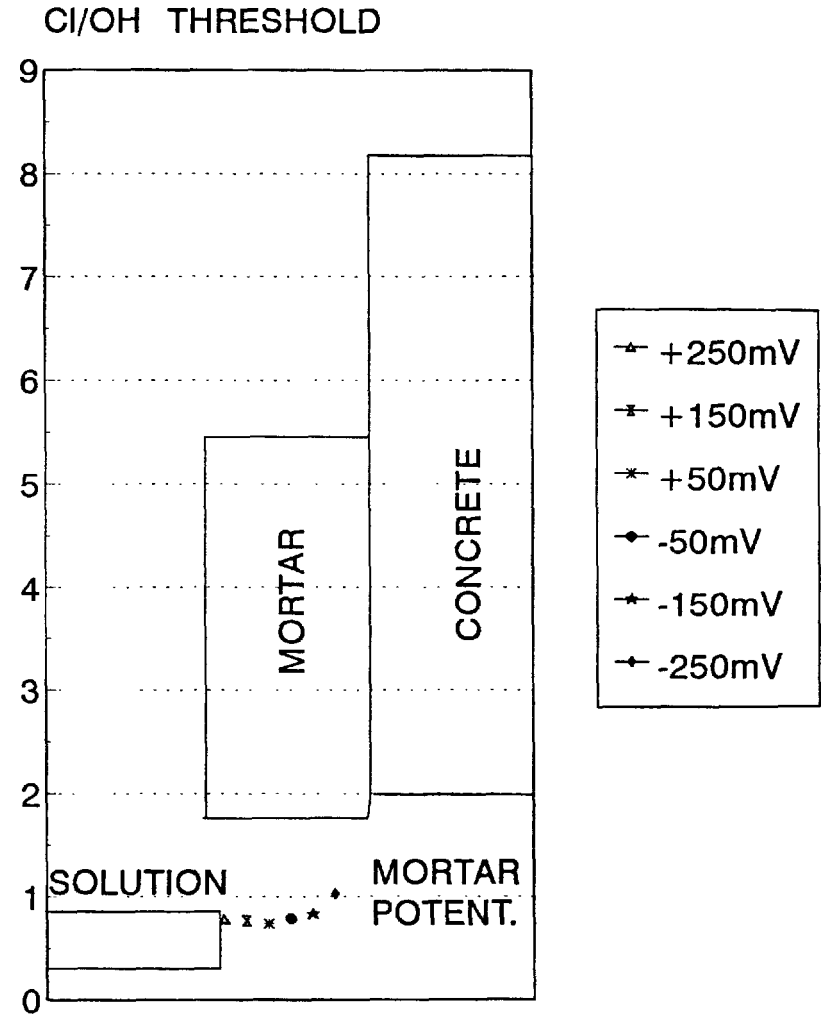

Figure 6 Cl^-/OH^- threshold at different potentials (+250 to -250mV SCE). Comparison with other authors (Hansson, Page, Petterson).

Electrical potential of the rebar in Cl^-/OH^-

As no systematic trend with the potential has been found present results indicate that, in the natural range of potential exhibited by passive rebars, the variations in the Cl^-/OH^- threshold is due to the normal scatter of the breakdown process of the passive layer. In consequence, cathodic prevention which is claimed (Bertolini, 1996) to increase the chloride threshold do not seem to make its influence at least in the range of potential values tested here >-250mV SCE.

CONCLUSIONS

Statistical determination of Cl^-/OH^- values (free chlorides) for rebar depassivation has given a threshold of 0.82 ± 0.018. This threshold ha not been found to vary in the range of values of potential between +250mV to -250mV (SCE). A mean value of 0.73% Cl total by weight of cement for rebar depassivation has also been found.

SINGLE ION ACTIVITIES OF UNASSOCIATED CHLORIDES IN NaCl SOLUTIONS BY ION SELECTIVE ELECTRODE POTENTIOMETRY

Ana HIDALGO, Carmen ANDRADE, Sara GOÑI and Cruz ALONSO, Institute of Construction Science Eduardo Torroja (CSIC), Madrid, Spain

ABSTRACT Ion-selective electrode (ISE) potentiometry is a useful technique for the determination of free ion activities. One of the causes of the break down of the steel reinforcement passivity is the attack by free chloride ions; so solution speciation in concrete aqueous phase is very important to determine the equilibrium state of such solutions. In this paper, activity coefficients of chloride ions are measured and compared with the calculated by different theoretical models. Finally a discussion about structural effects of ions in aqueous solutions and their influence on thermodynamic properties, is made.

Key-words: activity coefficients, chloride, ionic association, mobility, potentiometry.

INTRODUCTION

Solution speciation or the knowledge of aqueous species that are produced when water comes in contact with grouts, concrete or cement, is very important to determine the equilibrium state of such solutions. The use of mathematical models to calculate activity coefficients of these aqueous species (hydroyisis products, ion pairs or complexes) can thus considerably simplify the solution speciation, and consequently the calculation of chemical equilibrium states. Nevertheless experimental methods that involve the introduction of electrodes into natural media without contamination, are most appealing. Ion selective electrode (ISE) potentiometry has proved to be a useful technique for the determination of stability constants, because the potential of these electrodes depends mainly on the ion activity in the surrounding electrolyte and therefore it should be possible to use them as a non-destructive method of obtaining ion activities in cement and concrete structures. For instance, in-situ measurements of chloride activities in concrete can help to the early detection of risk of corrosion in existing structures allowing to follow the variation of the different aqueous species with time.

In this work, chloride activities in NaCl solutions up to 5 molal (m) using a chloride ISE, were made. Experimental results of chloride activity coefficients (γ_{Cl^-}) were compared with calculated values, trying to explain briefly the structural effects and the different types of interactions in aqueous electrolyte solutions, and how they can affect to the charge and mobility of the different species, and their influence on thermodynamic properties.

EXPERIMENTAL

Solutions were made up with NaCl Merck of analytical grade in deionized water; they were maintained at 25±0.1°C and stirred by magnetic stirrer. The following electrodes were used: Orion Research Inc., Cl^- selective (94-17) with a double-junction reference electrode (90-02-00) wich contained a 10% (w/v) KNO_3 outer filling solution. Measurements were made with an Orion 920 pH meter with a precision of ±0.1 mV.

RESULTS

Stable values of emf were attained within 1 minute (drift less than 0.1 mV/15 min).The measured potential corresponding to the level of chloride ion in solution is described by the Nernst equation:

$$E=E_{AgCl;Ag}-E_{ref}-\frac{RT}{F}\ln(m_{Cl^-}\gamma_{Cl^-})+E_a+E_j=E^{o'}-k\ln(m_{Cl^-}\gamma_{Cl^-}) \quad [1]$$

where $E^{o'}$ is the algebraic sum of the potentials of the internal Ag/AgCl electrode, $E_{AgCl;Ag}$, the reference electrode potential E_{ref}, the liquid junction potential, E_j, and the potential established at internal membrane surface, E_a.

In theory, the algebraic sum of these terms: $E_{AgCl;Ag}$, E_{ref}, E_j and E_a should be relatively constant with time and relatively independent of the test solution composition; so $E^{o'}$ would be a constant determined in a solution of unit chloride ion activity at 25°C. However, in relatively concentrated solutions, the magnitude of the liquid-junction potential is affected by the ionic strength of the test solution in addition to the pH, the structure of the liquid-liquid boundary and the temperature; so for rigorous measurements, a cell without liquid junction, where the other electrode is reversible to a cation in the test solution, must be used (Butler, 1969). Orion model 90-02 double junction reference electrode, use equitransferent filling solution; that is, the speed with which the positive and negative ions in the filling solution diffuse into the sample should be as nearly equal as possible. When the rate at which positive and negative charge is carried into the sample solution is equal, then no junction potential must result.

In practice the magnitude of the liquid junction potential changes and $E^{o'}$ must be measured from the results of an accurate electrode calibration, or using the method of known addition. Known addition is a convenient technique for measuring $E^{o'}$ and the slope of the Nernst equation, k, by adding known amounts of the same species to the sample solution, and recording the change in potential of the ion-selective electrode pair (Bruton, 1971).The observed emf values are listed in Table 1; also a comparison with literature values is shown.

Table 1 Comparison of the observed emf with some literature values.

Experimental values of chloride activity coefficients, in molality scale, versus NaCl molality, are showed in Figure 1. In the same figure, chloride activity coefficients calculated by hydration theory (Robinson-Stokes, 1948), are drawn.

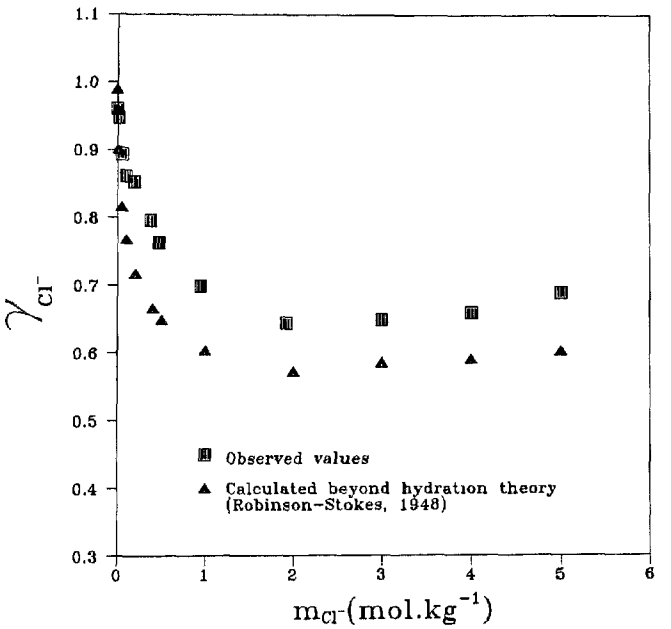

Figure 1. Experimental and calculated chloride activity coefficients

Mean activity coefficients in NaCl solutions from theoretical models

In Figure 2 experimental and calculated mean activity coefficients of NaCl versus molality, are drawn. Activity coefficients were calculated with MathCAD 4.0 program, and beyond: a extension of the Debye-Hückel equation (Davies, 1938), the hydration theory equations (Robinson-Stokes, 1948, 1959), and the specific ionic interaction equations (Pitzer, 1973, 1974, 1977, 1978).

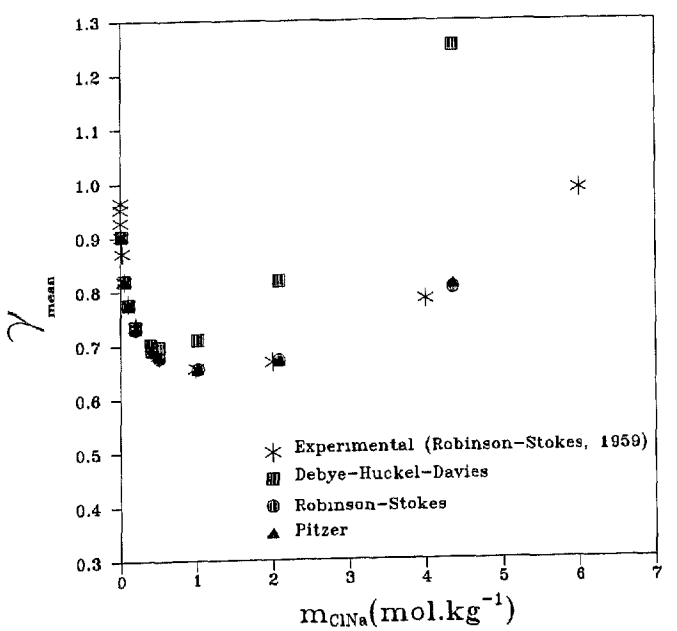

Figure 2. Mean activity coefficients in NaCl solutions

Debye-Hückel-Davies equation

The Debye-Hückel equation is a limiting law, correct in the limit at zero ionic strength, which predicts that the activity coefficient of an ion depends only on its charge and the ionic strength of the environment; that the identity of the other ions in the solution is unimportant beyond the specification of their charge; and that γ will decrease uniformly as I increases. All these predictions are true at extremely low ionic strength (Debye-Hückel, 1923).

At ordinary concentrations, for example at 0.1 m, the behaviour of real electrolytes deviates from the relatively simple predictions of the Debye-Hückel limiting law. Several more or less empirical extensions have been proposed; they fit the data with varying success at moderate values of the ionic strength, I. It is always possible to fit any set of empirical data with an equation which contains a large number of adjustable empirical parameters; such equations are not generally satisfactory, since they require the measurement and tabulation of otherwise meaningless constants for each ion studied. Davies (1938) propose the empirical equation:

$$\log\gamma\pm = -0.50|z_+z_-|\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.2I\right) \qquad [2]$$

where I is the ionic force in molalities, and z_+, z_- are the cation and anion charges.

Experimentally a minimum in the activity coefficient occurs, followed by a more or less rapid rise of it at high concentrations. Davies's equation usually fails to give a reasonably accurate representation of observed activity coefficients at ionic strengths much greater than unity. To overcome this, further arbitrary terms in higher powers are sometimes introduced, but such equations are of no theoretical value.

The hydration theory

This theory (Stokes-Robinson, 1948) introduces the effect of ion-solvent interaction in terms of "hydration". There are spectroscopic evidences (Gmelin Handbuch, 1976) that the kinetic unit of the solute in many electrolyte solutions is an ion with several relatively firmly attached water molecules. One of the equations that this model proposes to calculate mean activity coefficients is:

$$\log\gamma\pm = -\frac{0.5092|z_+z_-|\sqrt{\mu}}{1+0.3286a\sqrt{\mu}} - \frac{n}{\nu}\log a_w - \log(1-0.018(n-\nu)m) \qquad [3]$$

where μ is the ionic strength in volume units (molarities), a_w is the water activity, m is the solute molality, υ is the number of ions that a mol of solute gives in solution, and the three terms on the right are: the Debye-Hückel term (D-H), the solvent term and the scale term. The D-H term is refered to the coulombic forces between solvated ions, and the solvent term to the ion-solvent forces.

This model certainly comes closer to the physical reality and it takes into account the observed lowering of the bulk dielectric constant by ionic solutes which arises from effects in the first layer of water molecules around the ion. Eq.3 is the simplest treatment of the effect of ionic solvation on the activity coefficient. This expression contains only two parameters: n or the number of moles of

"bound" water per mole of solute, and a or the dimensions of solvated ions. It has been extensively tested for aqueous solutions (Robinson-Stokes, 1959), and it is remarkably succesful with poorly associated electrolytes as NaCl or in general, electrolytes 1:1.

In this form, Eq.3, is capable of representing observed activity coefficients with accuracy in a wide range of concentration, extended in many cases to an ionic strength of 5. In very concentrated electrolyte solutions, there is a transition from a freely flowing solution to semi-solid gels and these phenomena suggest the possibility that the system could be treated as an adsorbent (solute) and an adsorbate (water).

The specific ionic-interaction: ionic association

As it have been seen, the effect of long-range electrostatic and the ion-solvent interactions, is not enough to predict accurate activity coefficients for most electrolytes. The Pitzer approach (Pitzer, 1973, 1974, 1977, 1978) initially developed by Guggenheim (1935) take into account long-range (attractive and repulsive) and short-range electrostatic forces, the net effect of solvation, London's dispersion forces, and any other effects of similar range; for instance, permanent dipoles or multipoles. General equations are derived from statistical mechanics for electrolyte theory, that yields thermodynamic functions from knowledge of the interionic potentials of mean force and the radial distribution functions; so activity coefficients are expressed in virial expansion.

In a solution of a single electrolyte MX, the simplest Pitzer's equations are reduce to (Pitzer and Mayorga, 1973):

$$\ln\gamma_{MX} = |z_M z_X| f^{\gamma} + m\left[\frac{2\nu_M\nu_X}{\nu}\right]B^{\gamma}_{MX} + m^2\left[\frac{2(\nu_M\nu_X)^{\frac{3}{2}}}{\nu}\right]C^{\gamma}_{MX} \qquad [4]$$

where υ_M and υ_X are the numbers of M and X ions in the formula ($\upsilon = \upsilon_M + \upsilon_X$), z_M and z_X give their respective charges in electronic units, and m is the conventional molality. B^{γ}_{MX} define the second virial coefficient, that represent the short range interaction between a pair of ions; C^{γ}_{MX} define the third virial coefficient, that represent the short range interaction between triplets of ions; and f^{γ} is a Debye-Hückel funtion that represent the electrostatic interactions. These quantities have the form:

$$f^{\gamma} = -A_{\Phi}\left[\frac{\sqrt{I}}{1+b\sqrt{I}} + \frac{2}{b}\ln(1+b\sqrt{I})\right.$$

$$B^{\gamma}_{MX} = 2\beta^{(0)}_{MX} + \beta^{(1)}_{MX} \times g_1(\alpha_1\sqrt{I}) + \beta^{(2)}_{MX} \times g_1(\alpha_2\sqrt{I})$$

$$C^{\gamma}_{MX} = \frac{3}{2}C^{\phi}_{MX}$$

Aϕ: Debye-Hückel coefficient for the osmotic function. It is related with the constant A from the Debye-Hückel expression by: $A_{\phi} = A/3 = 0.392$ at 25°C.

b: a constant, having a given value of 1.2 for all electrolytes.

α_1 and α_2: constant values that depends only from the electrolyte type 1:1, 1:2, 2:2, etc. (Pitzer and Mayorga 1973, Pitzer and Mayorga 1974, Pitzer and Silvester 1978).

$g_1(x)=2[1-(1+x-(1/2)x^2)e^{-x}]/x^2$.
$\beta_{MX}^{(0)}$, $\beta_{MX}^{(1)}$ y $\beta_{MX}^{(2)}$ are specific coefficients for every studied salt, they describe the second virial coefficient and C_{MX}^{ϕ} describe the third virial coefficient. $\beta_{MX}^{(0)}$, $\beta_{MX}^{(1)}$ y $\beta_{MX}^{(2)}$ and C_{MX}^{ϕ} can be calculated from osmotic coefficient data (Pitzer and Mayorga 1973).

One advantage of the ion association theory is that it can be applied to solutions of different salinities; for instance, brines or seawaters, for the speciation of constituents and the calculation of stability constants (Pabalan and Pitzer, 1988).

DISCUSSION

The measurement of single-ion activity coefficients is very convenient for complex mixtures, because these values can then be combined easily to obtain the mean activity coefficient for any of the numerous neutral species represented in the mixture.

From Figure 1 it can be seen that experimental activity coefficients of Cl^- are higher than the calculated from the hydration theory; maybe because in these calculations authors assume that chloride ions are not hydrated; but if the electrochemical process at an ion-selective electrode is characterized by n=1 in the Nernst equation, an uncertainty of 1 in the hydration number corresponds to an error of aproximately 0.5×m mV in the electrode potential (Bates et al. 1950). In Figure 2 we can see that mean activity coefficients of NaCl calculated by hydration theory and Pitzer equations, are in good agreement with experimental values from Robinson-Stokes, 1959. On the other hand, if we compare ionic activity coefficients of chloride ions with mean activity coefficients of NaCl (see Figure 2), and we assume that $\gamma\pm = \gamma_{Na+}$ (Hyman, 1962), we can say that in a non associated electrolyte as NaCl, the differences between γ_{Cl-} and γ_{Na+} are due to ion-solvent interactions. Nevertheless, it is important to make a difference between ionic association: stable ionic pairs, complexes or poli-ionic species, charged or uncharged, and electrostatic ionic interactions. In NaCl solutions, there are ion-solvent and ionic interactions, and the minimum in the curves can be explained in terms of changes in the "real" ionic strength resulting from the removal from the bulk solvent of water bound to the ions, and also in terms of an increasing of ionic interactions.

In the immediate vicinity of the ion, there is a primary solvation shell of water molecules that are essentially immobilized by the ionic charge and move only as a single unit with the ion.This region, sometimes termed *electrostrictive* because the water is compressed by the field of the ion, is more highly structured than bulk water (Bates and Pinching, 1950). There is an intermediate disordered or structure-broken region, in wich water is less structured than bulk water (Bell, 1958). In the outer region, the normal structure of bulk water exist. An interesting ion classification (Samoilov 1965, 1972) is based on the relative residence times of a water molecule in the vicinity of an ion. If on the average, the exchange of water molecules in the vicinity of an ion, is less frequent than the exchange of nearest-neighbor molecules in pure water, the phenomenon is termed positive hydration (structure-maker ions). If the reverse is true, that is, exchange more frequently than in pure water, the ion is said to undergo negative hydration. Positive and negative hydration correspond to hydrophilic structure making and to structure breaking, respectively (structure-breaker ions).

Na^+ ion is a typical structure maker and Cl^- ion is a structure breaking ion. This large monovalent ion is surrounded by a relatively weak electric field which may be comparable with the competing forces of normal dipole-dipole interactions between water molecules. These competing influences tend to cancel, so the hydration picture is one of little structural order. Around ions like Cl^- ion, water may be immobilized and electrostricted at most only in the first hydration shell; then a disordered structure

broken region predominates. Hydrophilic structure-making ions, like Na^+, undergo electrostrictive hydration; that is, the water molecules in the primary hydration shell, wich are oriented by the ionic field, are packed more tightly than in bulk water. Thus water in the vicinity of the ions becomes compressed owing the electric fields of the ions. Electrostrictive hydration produces three basic effects, all of which tend to reduce the mobility of an ion:

- The permanent tightly bound hydration shell, which moves as a single kinetic unit with the ion, increases the effective size of the ion in solution. Thus the Stokes radii of structure-making ions are greater than the corresponding crystallographic radii.
- The local viscosity of water in the vicinity of these ions increases.
- An additional retarding force acts on the moving ion owing to the relaxation effect of the water dipoles. This relaxation force arises because water dipoles that were originally oriented in the field of the ion require a finite time to return to their random orientation once the ion has passed.

These are the reasons why the limiting equivalent conductances of the electrostrictive ions are relatively low (λ°_{Na+}, 25°C = 50.20).

Very interesting is the mobility behavior of the structure breakers, such as the halide ions which have relatively high mobilities (λ°_{Cl-}, 25°C = 76.39) and for which the solvated radii calculated from the Stokes equation (Stokes 1948, 1957) turn out to be smaller than the corresponding crystallographic radii. The current explanation for this phenomenon is that structure breakers decrease the local viscosity of the solvent, thus increasing their mobility.

According to a rough calculation (Robinson and Stokes, 1959), the average separation between ions in a solution of a 1:1 electrolyte is 20Å at 0.1 M and 9.4 Å at 1.0 M concentration. At the same time, electrical fields due to ionic charges may perturb water up to distances of 7 Å or more from the center of an ion. Thus, when dealing with the concentration dependence of thermodynamic properties beyond the concentration of about 0.1M, it becomes necessary to consider ion-ion interactions resulting from the overlap of two such zones of water perturbed by the ionic fields (Robinson-Stokes 1948, 1959, Guggenheim, 1935, Frank and Robinson, 1940). According to Gurney (Gurney, 1953) the behavior of the activity coefficients of the alkali metal salts until 1.0m concentration can be explained in term of the overlap of their cospheres, which generates additional forces of either attraction or repulsion that are superimposed on the usual coulombic forces. Additional forces of attraction arise between ions like Na^+ and Cl^- whose structural influences are mutually compatible, leading to a decrease in the free energy.

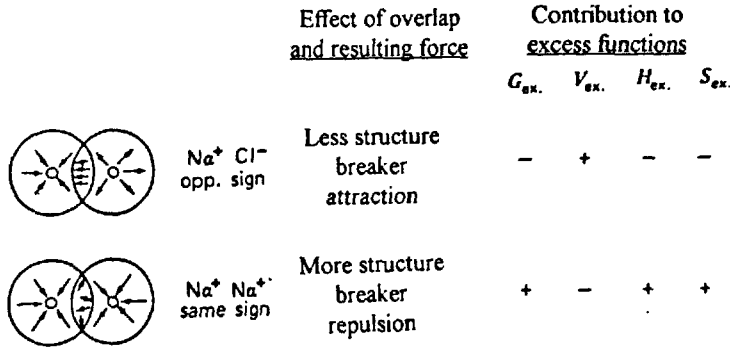

Figure 3.Structural hydration interaction model (Desnoyers et al., 1969)

Vaslow (1963) postulated that small structure-making ions, such Na^+, can fit into the holes of water structure without disrupting it and with the formation of a relatively stable uncharged ion pair and a lowering of the activity coefficients. From the concentration at which the minimum occurs, the activity coefficient increases, and this fact can indicates that there is a transition from the water structure in solution, to the crystal structure where the water molecules can be considered as adsorbed; that is to say, at high concentrations charged poly-ionic species are formed and an incresing of activity coefficients is observed.

CONCLUSIONS

Structure breaker ions such as Cl^- ions, have relatively high mobilities. This phenomenon can be explained with the hydration theory: around the Cl^- ion a disordered structure broken region of water molecules predominates (around Cl^- ions water may be immobilized at most in the first hydration shell) and the local viscosity of the solvent decreases. When the concentration increases ionic-interactions appear and the mobility results to be lower.

Around small structure-maker ions like Na^+, the water molecules are compressed and a ordered structure region predominates; thus the local viscosity of water in the vicinity of these ions increases.The ion moves with the bound hydration shell as a single kinetic unit and its mobility is reduced. When the concentration increases the ionic-interactions disturb the ordered structure, and the mobility results higher.

In NaCl solutions the minimum in the mean activity coefficient curves can be explained in terms of an increasing of the concentration of uncharged [Na^+Cl^-] ion pairs. From the concentration at which the minimum occurs, charged poly-ionic species are formed and activity coefficients increase.

CORROSION OF STEEL IN CARBONATED CONCRETE

Anastasia G. CONSTANTINOU* and Karen L. SCRIVENER†, Imperial College, London, UK.

ABSTRACT The behaviour of steel in carbonated concrete was investigated. The initial microstructure of the concrete around the steel was studied by the use of a scanning electron microscope (SEM) in the backscattered electron (BSE) mode and by image analysis. This technique was also used to study the microstructural development during corrosion. The corrosion of the steel was monitored by the linear polarisation resistance technique.

Key-words: Interfacial zone, Image analysis, Microstructure, Carbonation, Corrosion.

INTRODUCTION

In earlier work, image analysis of backscattered electron (BSE) images was used to characterise the microstructure of cement paste around aggregate particles in concrete (Scrivener et al, 1988, Crumbie 1994). The aim of the current work was to extend these techniques to the study of the interfacial zone around reinforcing steel in concrete and to the study of the active corrosion process in carbonated concrete.

The results presented here relate to three fairly independent aspects of the study:

- characterisation of the interfacial transition zone (ITZ) before carbonation;
- carbonation of the specimens and discussion of the similarities between the accelerated method used and natural carbonation;
- study of the ITZ after a period of active corrosion.

After a general section on the preparation of the samples these aspects are presented separately.

EXPERIMENTAL

Concretes were produced at three different w/c ratios, varying the cement content to achieve approximately constant slump:

1. w/c = 0.47, cement content 373 kg/m^3;
2. w/c = 0.56, cement content 315 kg/m^3 and
3. w/c = 0.65, cement content 275 kg/m^3.

These were cast into cylindrical moulds 100 mm in diameter by 200 mm in length, with steel reinforcement bars (8 mm diameter) at cover depths of 11 mm and 20 mm. The samples were demoulded after one day and then half were air dried and half were cured for a further 7 days under damp sacks. A set of samples was then sectioned at 28 days to study the ITZ. The remaining samples were carbonated and then placed in different humidity regimes.

CHARACTERISATION OF STEEL ITZ

Little work has been done to characterise the microstructure of the interfacial transition zone (ITZ) around reinforcing steel in concrete. Qualitative studies based on the examination of fracture surfaces (Page 1975, Monteiro 1985, Sagoe-Crensil and Glasser, 1990), discuss the

predominance of a layer of calcium hydroxide adjacent to the steel surface. Some work on image analysis of the ITZ around reinforcing steel in concrete was also reported by Zayed and Slater-Haase (1992).

Sections of the reinforced samples were cut using a slow speed precision saw. The sections were then resin impregnated, lapped with 9 μm alumina powder, polished with diamond pastes, to ¼ μm and then carbon coated. A JEOL-35CF scanning electron microscope (in the backscattered electron, BSE, mode) was used to examine the samples. Forty images were collected around the steel interface at a magnification of ×480 (1650 × 1650 μm) for each of two sections. The relative areas of aggregate, anhydrous material, calcium hydroxide and porosity were measured in bands about 5 μm in thickness radiating out from the steel interface. The values were averaged for each band for the eighty images and the percentage area against distance plotted for each phase. A typical image used for image analysis is shown in Fig 1. At the depth of the reinforcement, there was no effect of the different curing regimes used.

Figure 1: The steel / concrete interfacial zone for a sample with w/c = 0.65

Packing of Aggregate Particles

The maximum size of the aggregate used was 10 mm, approximately the same as the steel cross-section, and much larger than the size of the individual images used for analysis. Thus the results obtained for the aggregate distribution are not statistically representative of the overall aggregate distribution. The variability of the results for nominally identical samples and for the different w/c ratios can be seen in Fig 2. Despite the variability, the general trend of increasing aggregate area fraction with distance from the steel is clear. The lack of aggregate particles close to the steel interface is a result of the 'wall effect', whereby large particles cannot pack efficiently against a relatively flat surface.

To compensate for the variability of the aggregate distribution the relative proportions of the other components were calculated relative to the paste volume.

Distribution of Anhydrous Particles

During mixing and placing of the concrete, the anhydrous cement grains pack between the aggregate particles with varying degrees of efficiency. Therefore, even when the volume of anhydrous is normalised relative to the paste fraction, the distribution of aggregate still has an influence. The variation of remaining anhydrous material with distance from the steel is shown in Fig 3 for the three concretes. As with the studies of the ITZ around aggregate particles (Crumbie, 1994), the wall effect results in a depletion of cement grains adjacent to the steel interface. In these mature samples, the amount of unreacted anhydrous material is relatively low. Close to the steel the packing effect dominates and the values for all three concretes are similar, increasing steeply in the first 20 μm and more slowly thereafter to give values in the 'bulk' which increase with decreasing w/c as expected. The effective width of the ITZ relative to the anhydrous distribution of some 50 μm is similar to that found around aggregate particles by Crumbie (1994).

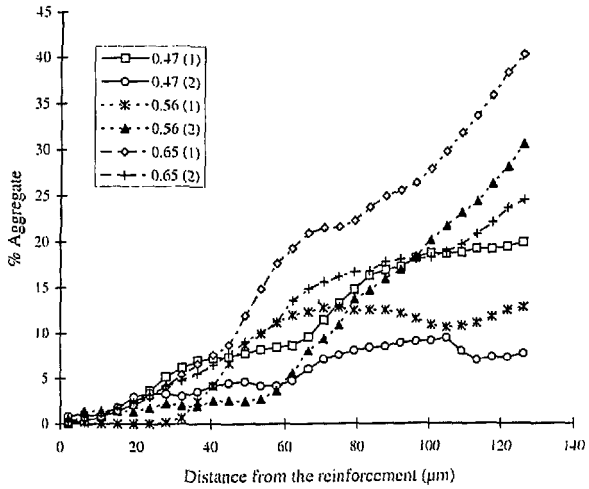

Figure 2: The distribution of aggregates around the steel / concrete interfacial zone.

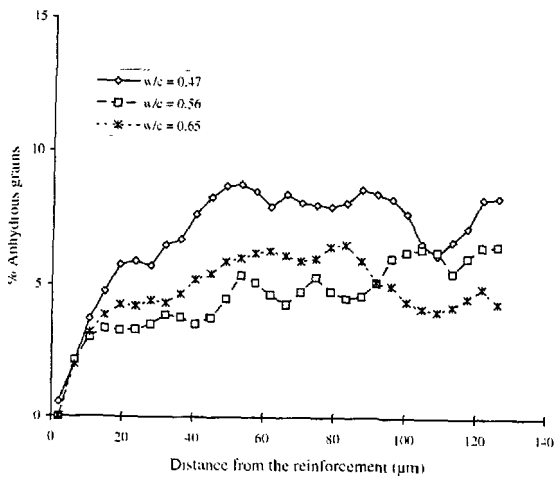

Figure 3: The distribution of anhydrous cement grains at the steel / concrete interface.

Distribution of Porosity

Due to the wall effect on the packing of the cement grains, and as with the ITZ around aggregate particles, the porosity increases in the ITZ around the steel as the interface is approached, Fig 4. The porosity at the interface increases significantly with the w/c ratio from 25% to 35%, and these figures are very similar to those measured around aggregate particles (Crumbie 1994). The porosity drops with distance from the steel over about 45-50 μm to a 'bulk' level which increases with w/c.

Distribution of Calcium Hydroxide

The distribution of calcium hydroxide in the steel ITZ is shown in Fig 5. The most notable feature is the lack of calcium hydroxide at the steel interface in contrast to the elevated level found in the ITZ around aggregate particles and to the expectation that growth of calcium hydroxide should be favoured by the increased porosity.

This result is also different from that reported by Zayed and Slater-Haase (1992), who found a constant value of 14% for the ITZ around steel in a concrete at w/c 0.45. The possibility of some calcium hydroxide removal during specimen preparation cannot be ruled out, although values in the bulk of the concrete are similar to other observations. Nevertheless it is clear that there is no continuous 'layer' of calcium hydroxide around the steel as has been suggested by some workers.

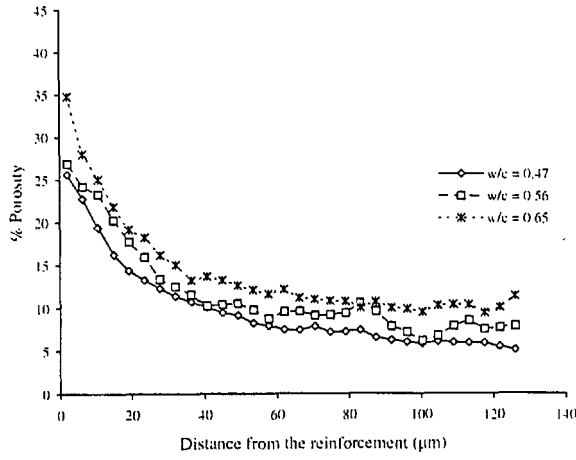

Figure 4: The distribution of porosity around the steel / concrete interfacial zone.

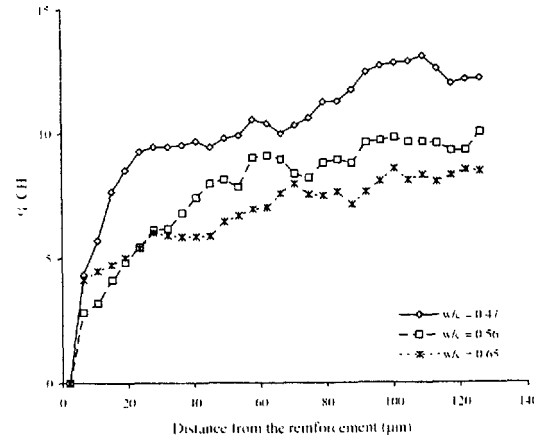

Figure 5: The distribution of calcium hydroxide at the steel / concrete interface.

MICROSTRUCTURE AFTER ACCELERATED CARBONATION

To accelerate the carbonation process in order to induce active corrosion in the reinforcing steel the specimens were placed in an environment of 100% CO_2 and 65% RH at 20° C. The progress of carbonation was checked regularly by spraying phenolphthalein indicator on parallel control samples cast without reinforcement. After carbonation samples were prepared as before.

It was found that the w/c ratio and the curing regime affected the rate of carbonation, but the effects on the microstructure were very similar.

The carbonation regime clearly differs significantly form natural carbonation of a CO_2 concentration of 0.03%. Therefore, the microstructure after carbonation was compared with a naturally carbonated field sample 40 years old.

Fig 6 shows the microstructure of a concrete (w/c = 0.56 and 1 day curing) subject to accelerated carbonation. Comparing this microstructure with the initial microstructure in Fig 1, the most obvious differences are the reduced porosity, due to the deposition of the carbonation products, i.e. $CaCO_3$ in the pores of the concrete and the absence of calcium hydroxide. Another feature of the fully carbonated microstructure is the attack of the anhydrous cement grains by CO_2. The attacked grains are easily distinguishable with the original grains of alite (faceted) and belite (round) parts turning dark grey and the interstitial parts remaining unaffected (white). These dark areas were found by EDS x-ray microanalysis to have high Si/Ca ratios due to depletion of calcium.

Comparison of the microstructure of the concretes subject to accelerated carbonation with that of a naturally carbonated microstructure indicated that they were very similar. Attacked, dark relics of anhydrous grains were observed in both samples although these were more prevalent in the accelerated sample, due to the younger age at carbonation. Overall it was judged that the accelerated carbonation process did not result in differences likely to affect the subsequent corrosion process significantly.

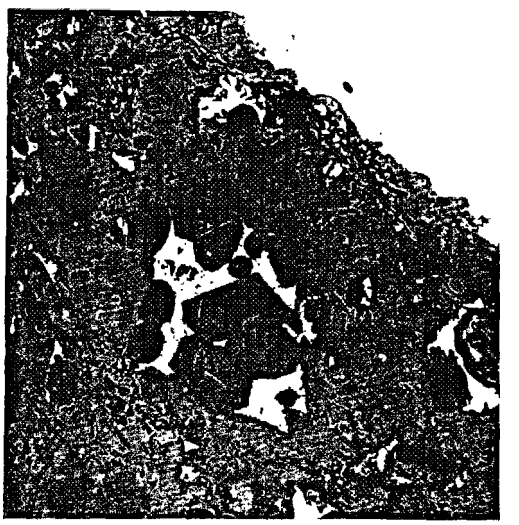

Figure 6: Steel / concrete interface of a fully carbonated sample with w/c = 0.56 and 1 day cure.

STUDY OF THE CORROSION PROCESS

After full carbonation, the samples were placed in two humidity regimes at 90% and 70% RH. The corrosion rate of the steel reinforcement was followed by the linear polarisation technique using a potentiostat. Fig 7 shows the measurements of corrosion rate with time for the w/c = 0.56 sample. The rate was slightly higher at 90% RH than at 70%, when one of the 90% samples was subsequently placed in 43% RH the corrosion stopped, as shown in the figure. The rate of corrosion was slightly higher in the w/c = 0.65 samples.

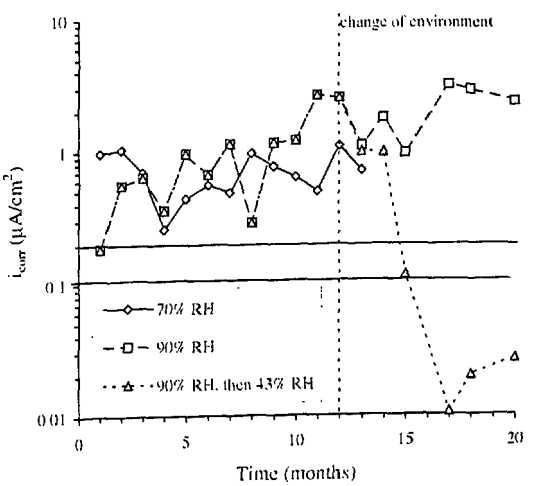

Figure 7: The effect of the various RHs on the corrosion rate of a sample with w/c = 0.56.

One sample from each of the batches at 70 and 90% RH was removed from the tank for microscopical examination after six, twelve and eighteen months. Adjacent images were collected around the interface (between 50-60) to make up a montage of the whole interface at a magnification of x200. The interfaces were examined, the amount of corrosion products traced onto paper and the relative corroding area measured using a planometer. The maximum thickness of the corrosion layer was also measured.

Fig 8 shows the steel / concrete interface of a sample with w/c = 0.56, after 1 year in 90% RH after corrosion has taken place. The layer of cement paste which has been affected by the deposition of the corrosion products is clearly visible. The presence of cement grain relics indicates that the corrosion products have diffused into and deposited in the cement paste. Two discrete layers are apparent. The first layer, closest to the steel interface, is dense and by its high grey level contains a high proportion of iron oxide. In the second layer further out the iron oxide is more diffusely mixed with the cement paste.

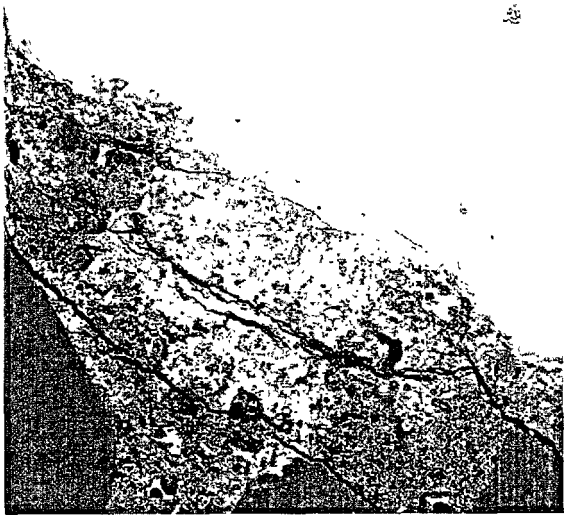

Figure 8: The steel / concrete interface of a sample with w/c = 0.56 after 1 year in 90% RH.

A montage of the entire interface of the sample with w/c = 0.56, after 1 year at 90% RH is shown in Fig 9. The top of the figure represents the side of the steel which is closest to the surface of the steel. It can be seen that the heaviest corrosion is on this side closest to the surface whereas the other side is just starting to corrode. This effect is probably due to the availability of oxygen.

The corrosion processes in carbonated concrete is usually considered to be homogeneous and generalised. At a microscopic level it is clear that the distribution of corrosion products is in fact very heterogeneous, although the scale of heterogeneity is much finer that that found in chloride induced pitting corrosion.

Some cracks are observed in the region most heavily corroded. There may be due to the build-up of corrosion products but could also be caused by the specimen preparation.

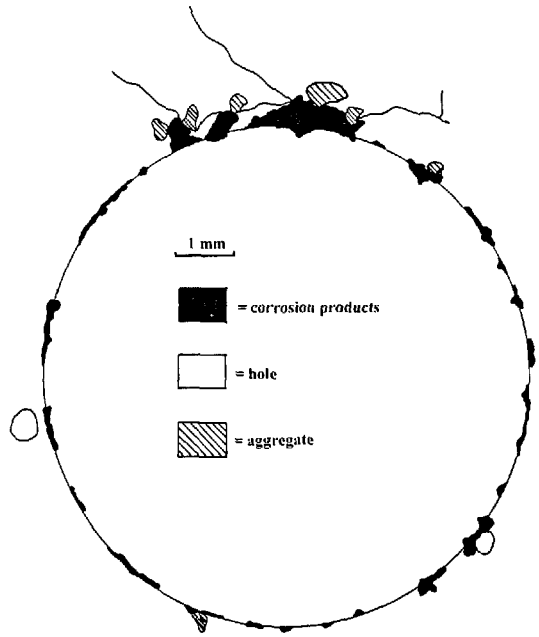

Figure 9: The schematic diagram for the steel / concrete interface of a sample with w/c = 0.56, after 1 year in 90% RH.

CONCLUSIONS

1. The distribution of the various phases around the reinforcement is dominated by the packing of the aggregate particles and to a lesser extent by the packing of the anhydrous particles. The w/c ratio has a slight effect.
2. A region of high porosity in the paste adjacent to the steel was observed in all the samples. The lower the water / cement ratio of the mix, the lower the amount of the porosity.
3. Carbonation led to a more compact microstructure of the concrete paste due to the deposition of $CaCO_3$ into the pores with no visible CH.
4. The humidity regime appears to have little effect on the corrosion rate of steel in carbonated concrete. However, when the sample was placed in 43% RH after 90% RH the corrosion rate dropped to very low values.
5. Corrosion products form two distinct layers. The corrosion was heaviest in the region closest to the surface of the concrete. The corrosion was localised with small "pits" distributed fairly evenly around the steel.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. N.N Dioh for help with the planometer readings. NGC would like to thank the Building Research Establishment (BRE) and W.R. Grace for financing this work.

KEY-WORD INDEX

A

Accelerated test; 3iii033
Accelerators; 3ii103, 3iii005, 3iii012, 3iii014, 3iii022, 3iii027, 3iii032,
Acid attack; 3ii109, 4iv002, 4iv021, 4iv038, 4iv039, 4iv040
Activation; 1i006, 2ii016, 2ii045, 2ii062, 2ii076, 3ii083, 3ii092, 3ii094, 3ii098, 3ii099, 3ii100, 3ii103, 3ii104, 3ii113, 3ii114, 3iii028, 4iv047
Activation energy; 1i053
Activity coefficient; 4iv083
Additives; 1i009, 1i020, 1i035, 2ii003, 2ii009, 2ii045, 2ii074, 3ii116, 3iii017, 3iii032
Adiabatic temperature rise; 4iv072
Admixtures; 2ii012, 2ii034, 2ii036, 2ii047, 3ii087, 3ii095, 3ii097, 3iii001, 3iii002, 3iii004, 3iii009, 3iii018, 3iii019, 3iii023, 3iii024, 3iii025, 3iii026, 3iii029, 3iii030, 3iii031, 3v015, 4iv004
Adsorption; 2ii001, 3iii002, 4iv077
AFm phase; 2ii032, 3iii032, 3ii089, 4iv034, 4iv061
AFt phase; 1i060, 4iv034, 4iv041, 4iv059
Aggregate; 2ii015, 3v024, 4iv053, 4iv057
Air entraining; 4iv031, 4iv057
Air pollution; 4iv002
Alinite; 2ii030, 3ii118
Alite; 1i006, 1i015, 1i041, 1i050, 2ii040, 2ii042, 2ii056, 3ii107, 3ii117, 3iii005, 3iii031
Alkali; 1i002, 1i012, 1i028, 1i035, 1i049, 2ii012, 2ii065, 3ii083, 3ii098, 3ii100, 3ii103, 3ii113, 3ii114, 3ii117, 3iii025, 4iv003, 4iv028, 4iv055, 4iv066
Alkali aggregate reaction; 3iii033, 3v022, 4iv048
Alkali silica reaction; 4iv047, 4iv049, 4iv065, 4iv074
Alkali silicate solutions; 4iv049, 4iv065
Alkaline cement; 4iv046
Alumina; 2ii027, 2ii026, 3iii010
Aluminate phase; 1i001, 1i022, 1i051, 1i056, 2ii041, 2ii060, 3iii010, 3iii015, 4iv027, 4iv034, 4iv066
Aluminoferrite; 1i004, 1i005, 1i055, 2ii031
Aluminosilicate; 1i024, 4iv046
Anhydrite; 1i032, 2ii011, 2ii022, 2ii029, 3ii092, 4iv059
Aragonite; 1i042
Arc furnace dust; 4iv042
Asbestos; 1i027
Ash; 3ii080
Autoclavation; 3ii120, 4iv054
Autoclave soundness; 1i023
Autogeneous shrinkage; 2ii069, 2ii070, 2ii071, 2ii073

B

Backscattered electron image; 2ii014, 4iv061
Bacterial attack; 4iv038, 4iv039
Bamboo dust; 1i019

Barite; 1i036
Barium phases; 1i058
Belite; 1i006, 1i015, 1i018, 1i041, 1i052, 2ii007, 2ii040, 2ii045, 2ii056, 3v009
Belite cement; 1i036
Binder; 1i059, 2ii047, 2ii054, 3ii080, 3ii101, 3iii021, 4iv057
Blastfurnace slag; 2ii068, 2ii074, 3ii082, 3ii093, 3ii095, 3ii096, 3ii098, 3ii099, 3ii101, 3ii102, 3ii103, 3ii104, 3ii115, 3ii122, 3iii009, 3iii017, 4iv001, 4iv005, 4iv009, 4iv015, 4iv035, 4iv040, 4iv063
Blended cement; 1i020, 3ii089, 3ii091, 3ii111, 3ii114, 3ii115, 3ii121, 3v026, 4iv004, 4iv017, 4iv020, 4iv052,
Bogue calculation; 1i039, 3v007, 3v009
Borax; 1i036
Bottom ash; 3ii090
Bound water; 2ii072, 3iii019, 3v019
Brick; 3ii080
Brownmillerite; 1i022, 2ii029, 2ii032,
Burnability of raw mixes; 1i021, 1i030, 1i031, 1i034, 1i040, 1i041, 1i045, 1i048, 1i054
Burning conditions of clinker; 1i018, 1i023

C
Calcium carbonate; 1i042
Calcium aluminate; 2ii022, 2ii025, 2ii050, 3iii022, 3v005
Calcium aluminate cement; 2ii024, 2ii026, 2ii027, 2ii028, 3iii007, 3v018, 4iv003, 4iv025, 4iv026
Calcium aluminate sulphate; 2ii010, 4iv068
Calcium aluminozincates, 1i059
Calcium hydroxide; 2ii049, 2ii059, 3ii082, 3ii106, 3ii107, 3ii108, 3ii112, 3iii031, 3v019, 4iv067
Calcium fluoride; 1i032, 2ii042
Calcium langbeinite; 2ii011
Calcium nitrate; 3iii012
Calcium phosphate; 1i036
Calcium phosphate cement; 2ii063
Calcium silicate; 1i035, 1i055, 2ii055, 2ii050, 2ii062, 4iv054
Calcium sulphate; 1i012
Calorimetry; 2ii021, 2ii025, 2ii041, 2ii066, 3iii032, 3v016, 3v017, 4iv042
Capillary; 2ii048
Carbon dioxide; 1i024, 2ii032, 4iv010
Carbonation; 2ii073, 4iv003, 4iv004, 4iv005, 4iv006, 4iv010, 4iv017, 4iv026, 4iv035, 4iv048, 4iv070, 4iv084
Case studies; 4iv002
Cement; 3ii092
Cement hydration equation; 2ii061, 4iv052
Characterization; 1i008, 2ii062, 3ii088, 3v011, 3v020 3v023, 3v026, 4iv019
Chemical analyis; 3v012
Chemical attack; 4iv015, 4iv026, 4iv028, 4iv031
Chemical prestressing; 3iii016

Chemical shrinkage; 2ii069, 2ii070, 2ii072
Chloride; 1i002, 1i012, 2ii030, 3ii118, 4iv006, 4iv015, 4iv027, 4iv078, 4iv080, 4iv081, 4iv082, 4iv083
Chloride Binding; 4iv016, 4iv069, 4iv070, 4iv078
Classification; 4iv046
Clay; 2ii020
Clinker; 1i048, 1i058
Clinker composition; 1i028, 4iv036
Clinker formation; 1i004, 1i006, 1i008, 1i010, 1i011, 1i026, 1i031, 1i037, 1i043, 1i044, 1i046, 1i049, 1i054, 2ii006, 3ii118
Cluster; 1i003
Coal; 1i047, 3ii090
Composite cements; 1i009, 2ii016, 2ii034, 3ii122
Composition; 2ii007, 2ii071, 3v004, 3v011, 3v026, 4iv007, 4iv023, 4iv060
Concrete; 2ii035, 3ii108, 3iii024, 3iii029, 3v021, 3v022, 4iv025, 4iv035, 4iv073
Cooling of clinker; 3v005
Corrosion; 2ii006, 4iv014, 4iv020, 4iv023, 4iv027, 4iv028, 4iv030, 4iv038, 4iv039, 4iv071, 4iv082, 4iv084
Creep; 4iv018
Cross-linking; 3iii011
Crystal; 2ii015
Crystal size; 1i051, 3iii031
Crystal structure; 1i055, 2ii048
Crystallisation pressure; 4iv049
Crystallography; 2ii054
CSH; 2ii044, 2ii047, 2ii053, 2ii055, 2ii059, 2ii064, 2ii067, 2ii068, 3ii082, 3ii093, 3ii121, 3v001, 3v003, 4iv016, 4iv041, 4iv043, 4iv061, 4iv074, 4iv076
Curing; 2ii037, 2ii078, 3ii091, 4iv055, 4iv059, 4iv067

D

Deformation; 4iv021, 4iv058
Degree of hydration; 2ii051, 2ii053, 2ii062, 2ii077, 3v019, 4iv016
De-icing salts; 4iv006, 4iv035
Delayed ettringite formation; 4iv059, 4iv061, 4iv062, 4iv063, 4iv064
Delayed expansion; 3iii016
Design life; 4iv071
Dicalcium silicate; 1i017, 1i053
Differential thermal analysis; 2ii041, 4iv031
Diffusion; 2ii046, 3ii084, 3ii098, 4iv010, 4iv015, 4iv016, 4iv056, 4iv080, 4iv081
Diffusivity; 4iv008, 4iv009
Dilation; 4iv033
Dispersion; 2ii005
Disposal; 1i027
Dopant; 1i053
Drying; 3iii018, 3v018, 4iv011, 4iv077, 4iv079
Durability; 2ii011, 3ii095, 3iii024, 3v022, 4iv004, 4iv007, 4iv022, 4iv023, 4iv026, 4iv029, 4iv030, 4iv037, 4iv040, 4iv046, 4iv048, 4iv062, 4iv065, 4iv070, 4iv075, 4iv082

E
Economy; 1i036, 3ii114
Ecology; 1i043
Electron microscopy; 1i060
Electron spectroscopy for chemical analyses (ESCA); 2ii044
Electrical conductivity; 4iv011
Electrical impedance; 3ii112
Electrical properties; 4iv079
Electrical resistivity; 3v021
Energy; 2ii046
Environment; 1i003, 3ii093
Equilibria; 2ii057, 2ii058
Ettringite; 1i025, 2ii006, 2ii010, 2ii017, 2ii029, 2ii031 2ii056, 2ii070, 2ii074, 3iii022, 4iv012, 4iv018, 4iv031, 4iv060, 4iv062, 4iv065
Evaporable water; 3v019
Expansion; 2ii006, 2ii074, 3iii017, 3v022, 4iv057, 4iv060, 4iv062, 4iv064
Expansive cement; 1i001, 2ii010
Extraction methods; 3v020

F
False set; 3iii013
Ferrite phase; 1i008, 1i015, 1i060, 3iii005, 3v003
Ferroaluminate; 4iv029
Filler; 1i020, 2ii002, 2ii020, 3ii081, 4iv056
Fineness; 1i007, 2ii001, 2ii002, 2ii018, 2ii043, 2ii060, 3ii088, 3v008, 4iv060
Fingerprinting; 3v010, 3v011
Fire; 4iv073
Fire damage; 4iv067
Flow; 2ii017, 3v024
Flue gas desuphurisation product; 3ii090
Fluidity; 2ii001, 2ii002, 2ii012
Fluoride phases; 2ii043, 3v002
Fly ash; 3ii081, 3ii082, 3ii083, 3ii084, 3ii085, 3ii086, 3ii087, 3ii088, 3ii089, 3ii090, 3ii110, 3ii115, 3ii116, 3ii122, 3v006, 3v020, 3v021, 4iv004, 4iv009, 4iv012, 4iv019, 4iv020, 4iv023, 4iv058, 4iv077
Fracture mechanics; 2ii075
Free lime; 1i016, 1i045, 2ii049, 4iv036
Freeze-thaw damage; 2ii016, 3iii019, 4iv034, 4iv035
Freezing; 4iv033
Friedel's salt; 4iv027, 4iv080
Fuels for clinker making; 1i013, 1i019

G
Gel; 3ii105, 3iii007, 3iii022, 4iv074
Glass; 1i046, 1i051, 3ii088, 3ii119, 4iv030, 4iv055
Grinding aids; 2ii020, 3v014
Grinding technology; 1i009, 1i040

Ground silica; 3ii120
Grout; 2ii005
Gypsum; 2ii040, 2ii044, 2ii060, 3ii093, 3ii115, 3iii025, 3v008, 3v023, 4iv017

H
Hardening; 2ii008, 2ii034, 2ii039, 2ii047, 2ii052, 2ii054, 2ii076, 3ii112, 3v016, 4iv071
Heat capacity; 4iv033
Heat evolution; 2ii021, 2ii035, 2ii051, 2ii076, 2ii077, 3ii102, 3ii105, 3iii029, 3v016, 4iv042, 4iv072
Heavy metals; 1i043, 2ii014, 3v010, 3v013, 4iv041, 4iv043
High alumina cement; 2ii023, 2ii033, 3iii010, 3ii096, 4iv013, 4iv027, 4iv038
High performance; 2ii035, 2ii038, 3ii108, 3v006, 3v021
High strength; 2ii037, 3ii120
High sulphate clinker; 2ii011
High temperature; 3ii111, 3iii020, 4iv067
Humidity; 4iv011, 4iv079
Hydration; 1i022, 1i057, 1i059, 2ii004, 2ii006, 2ii008, 2ii007, 2ii012, 2ii013, 2ii015, 2ii019, 2ii021, 2ii022, 2ii023, 2ii024, 2ii025, 2ii026, 2ii028, 2ii029, 2ii030, 2ii031, 2ii033, 2ii035, 2ii036, 2ii039, 2ii040, 2ii041, 2ii042, 2ii043, 2ii044, 2ii046, 2ii047, 2ii050, 2ii052, 2ii055, 2ii057, 2ii058, 2ii061, 2ii067, 2ii069, 2ii070, 2ii078, 3ii089, 3ii094, 3ii097, 3ii099, 3ii100, 3ii101, 3ii102, 3ii107, 3ii116, 3ii118, 3ii119, 3iii008, 3iii014, 3iii015, 3iii019, 3iii025, 3v006, 3v016, 3v018, 4iv072, 4iv071
Hydrothermal synthesis; 1i017

I
Identification; 3v010
Image analysis; 4iv084
Immobilization; 2ii014, 2ii016, 2ii052, 4iv043, 4iv045
impact prediction; 1i003
Impact evaluation; 1i003
Induction period; 2ii019, 2ii055
Infra red absorption spectra; 3ii104
Inhibitor; 3iii033
Interfacial zone; 4iv050, 4iv051, 4iv053, 4iv056, 4iv084
Interground cements; 1i013, 3v026
Interstitials; 2ii007
Ion exchange resin; 4iv045
Ionic assocoiation, 4iv083
Ions; 2ii036, 2ii046, 2ii065, 3iii012, 3iii013, 4iv075, 4iv079
Iron mud; 1i021
Isomorphism; 1i059

K
Kinetics; 1i005, 1i035, 1i044, 1i052, 2ii019, 2ii023, 2ii028, 2ii043, 2ii055, 3ii098, 3iii008, 4iv076

L
Latex; 3iii008
Leaching; 2ii014, 4iv012, 4iv041, 4iv043, 4iv045
Light microscopy; 3iii031, 3v007
Lignosulphonates; 2ii004, 3iii013, 3iii021
Lime; 2ii049, 2ii074, 3ii084, 3iii005, 4iv010

MICROSCOPY METHODS IN CEMENT AND CONCRETE SCIENCE

Karen L. SCRIVENER,
Lafarge, Laboratoire Central de Recherche, France

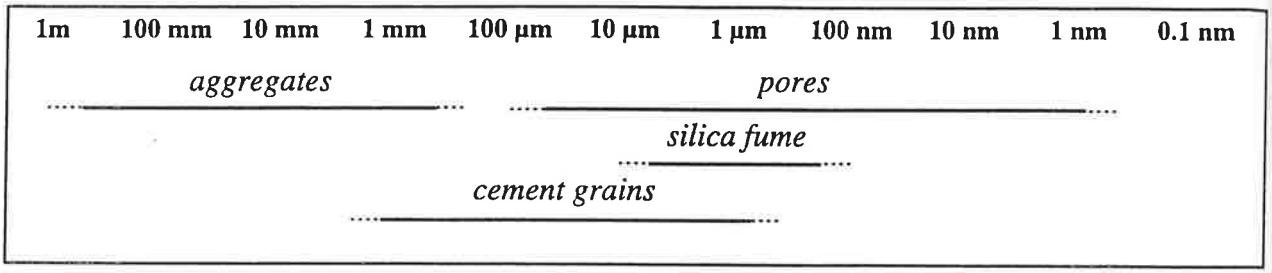
1. Why microscopy?

A rather simple answer to this question might be that cement is a microscopic material — a grey powder whose grains range from around 100μm down to less than 1μm in size. However, its end uses, in concrete, are anything but microscopic and include some of the largest manmade structures. The challenge is to link the microscopic to the macroscopic and here microscopy has a role to play.

The question of what we can hope to achieve by microscopic study has three broad responses :

1. Understanding reaction mechanisms
2. Diagnosis of damage processes
3. Microstructure—Property relationships

In all of these cases microscopy can only supply partial answers, which must be integrated with results from other techniques into a coherent conceptual or theoretical framework. In the first two cases, qualitative examination of the microstructure, perhaps combined with local chemical analysis, may be sufficient to indicate or confirm a mechanism.



The last of these three goals is perhaps the most difficult, as here, some kind of quantitative measure of the microstructure is necessary (Scrivener 1989a). Yet understanding the links between microstructure and properties is the essential precept of materials science, necessary if the development of cementitious materials is to be anything other than empirical. Obtaining numbers from images is the goal of image analysis.

1.1 Why this paper?

The international cement chemistry conferences bring together a wide range of people concerned with the manufacture and use of cement, not all of whom are directly involved in research, and an even fewer who are involved with microscopy on a day to day basis. Therefore I was asked to write something along the lines of a tutorial overview of the current use of microscopy for the study of cementitious materials. It does not aim to be a comprehensive account of the published literature, but rather a personal view of the state of the art. The emphasis is on the use of microscopical techniques, rather than the details of microstructural development (for this see for example Scrivener 1989b). I have tried as far as possible to make it comprehensible to the non-specialist. To put microscopic techniques in context, I felt it useful to bring together many things which are often considered to be 'old hat' and known by 'everyone'. To those of my colleagues who say there is nothing new here, I apologise, but hope that others will find it useful as an introduction to the subject. I have also tried to present some of the difficulties and drawbacks in microscopic study as well as the strengths.

1.2 Microscopy — usage and abusage

Most of us are familiar with the expression, *"the camera never lies"* and fully appreciate the simultaneous truth and irony behind those words. The position for microscopy is analogous — a micrograph is a truthful representation of one particular area of the sample under a particular set of preparation and observation conditions — whether it tells us anything of general value to understanding the original sample is another matter.. Many people have tried to estimate the *total* volume of material (cement and concrete), which have been looked at through a microscope. It is probably something less than 1 mm^3 by TEM, 10,000 mm^3 by SEM and several m^3 by optical microscopy, but none of these are very large in comparison with the amount of cement and concrete produced *annually* (around 2 billion m^3). Microscopy has to be selective and the extent to which it is representative depends on the skill (and luck) of the microscopist. The process of selection is made much more difficult by the highly heterogeneous nature of concrete, with features ranging over some ten orders of magnitude, from several hundreds of millimetres for aggregates to a few nanometers for the smallest pores.

2. Types of microscopy

Figure 1 summarises the different microscopical techniques applied to the study of cement and concrete, before and after hydration.

2.1 Optical

Optical microscopy in both the transmission and reflection modes is widely used for the study of cementitious materials. A principal advantage of this technique is the wide spread availability of equipment, there are probably several hundred optical microscopes used for every electron microscope.

For the study of cement clinker the refection mode is the most common, with the use of suitable etchants (e.g. HF vapour) on polished sections, Figure 2. Generally the silicate phases, alite (impure C_3S) and belite (impure C_2S) are easily identifiable. The ferrite and aluminate phases may be individually identified in more coarsely crystalline interstitial material, found in slowly cooled clinkers, but at rapid cooling rates, these phases may be so finely divided that they are difficult to distinguish. The sulfates present in the clinker may also be seen, although these may be removed during the polishing or etching processes.

The spatial distribution of the phases can reveal much about the clinkering process, but further details are outside the scope of this overview, the interested reader is referred to Campbell (1986). Optical microscopy is very effective for the assessment of clinker and it is used for this purpose in many cement plants.

The relative proportions of the various phases within clinkers may be determined by point counting. A comparative study of optical microscopy, backscattered electron image analysis and x-ray diffraction, indicated that optical microscopy is still probably the most efficient method for this purpose, being more accurate and less time consuming than SEM image analysis

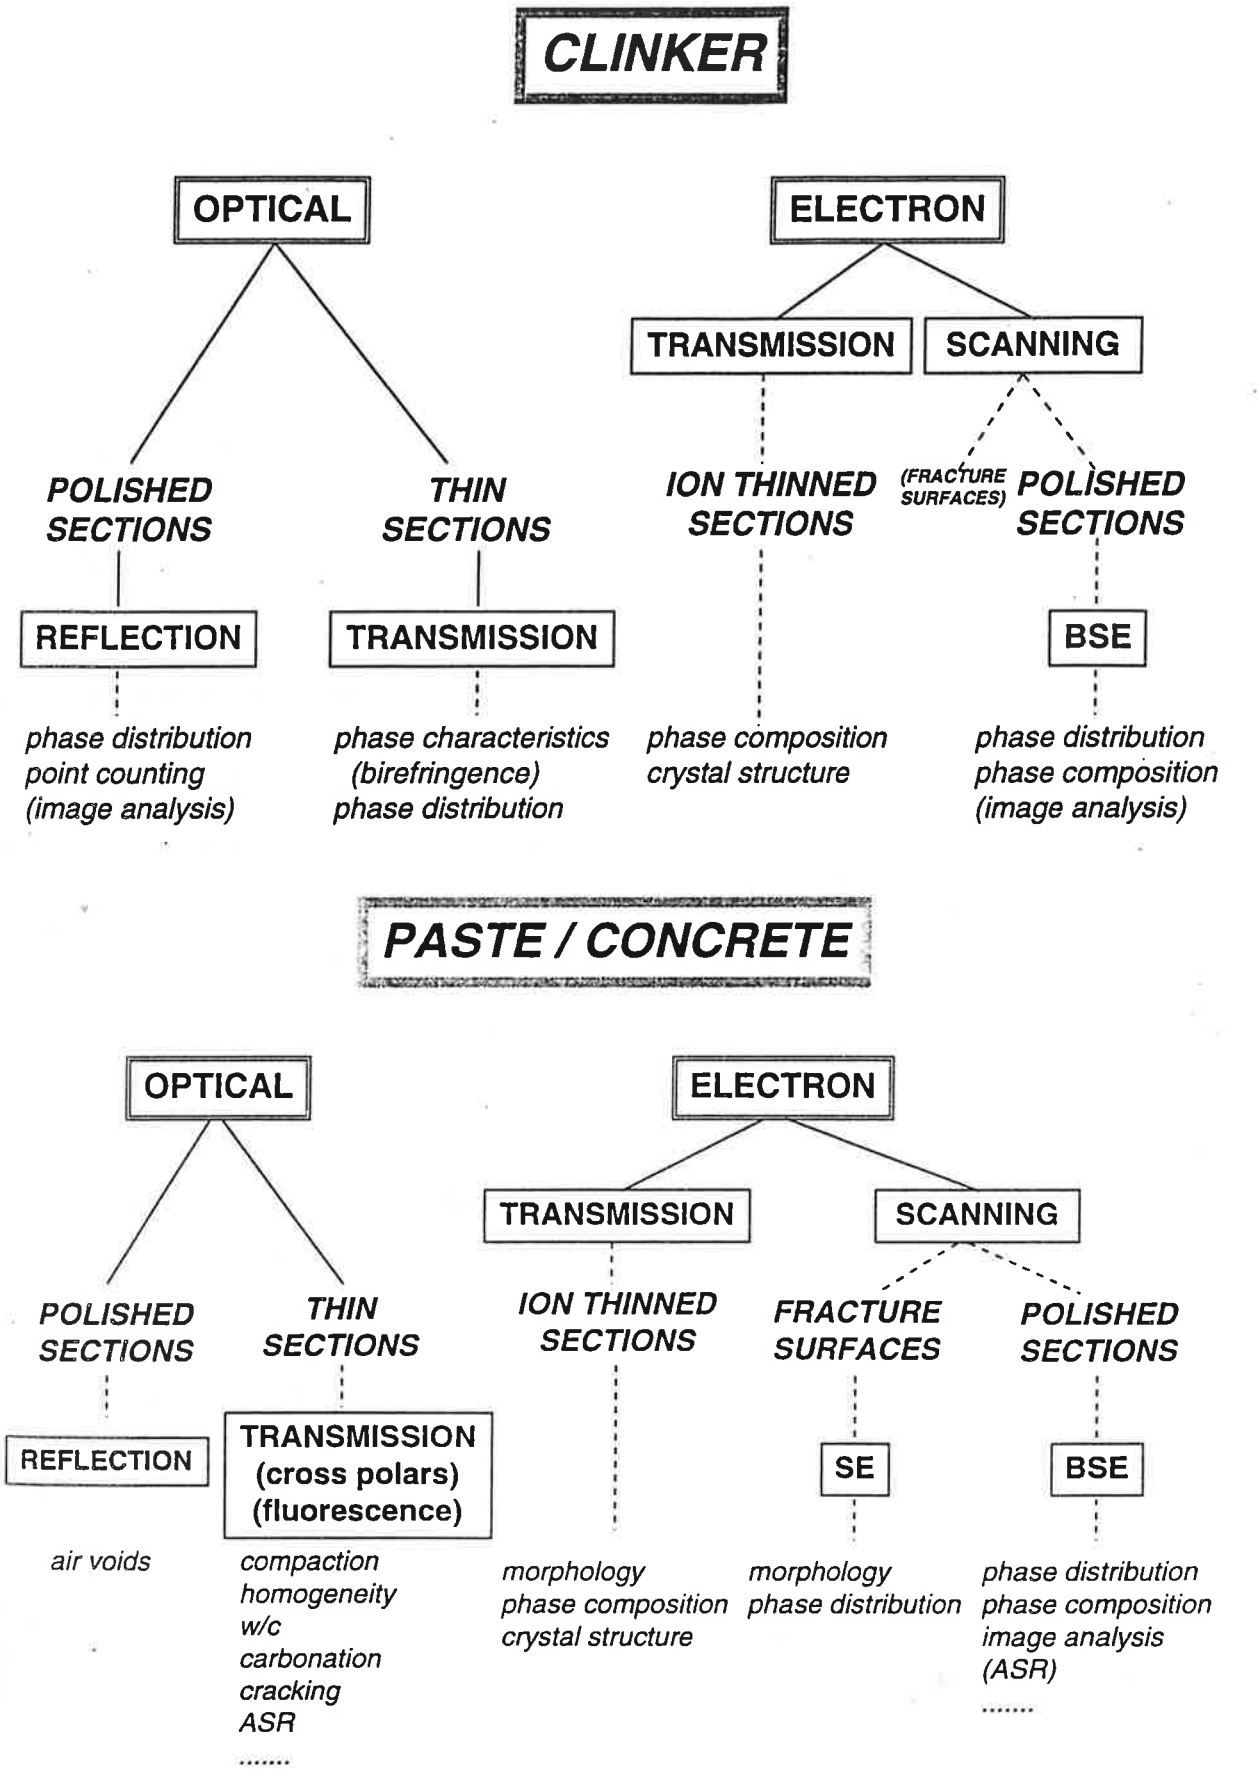


Figure 1. Summary of microscopical techniques and their application to cement before and after hydration

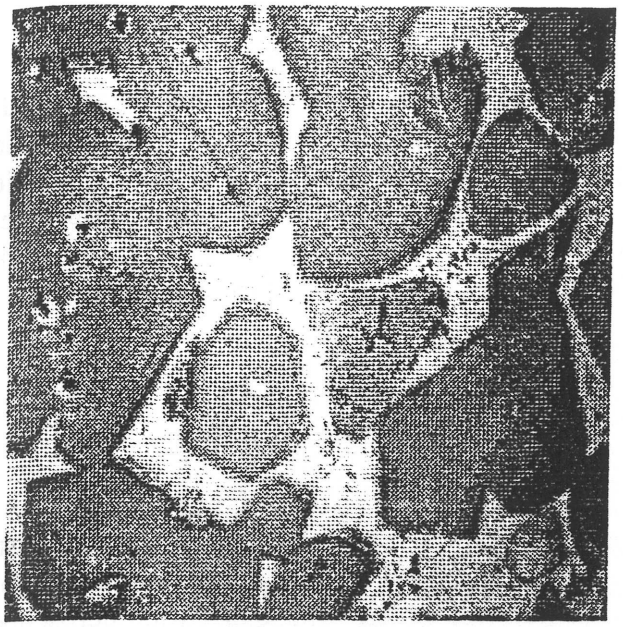
(Stutzman et al. 1989). The variability of the etching process makes this measurement difficult to automate, although progress is being made (e.g. Theisen 1997).

Transmission optical microscopy is also used for the study of anhydrous materials, although less extensively than reflection. The preparation and observation of thin sections permits other features, such as the birefingence of the phases to be determined. Such features can be related to kiln operating conditions according to the Ono method (Ono 1980)



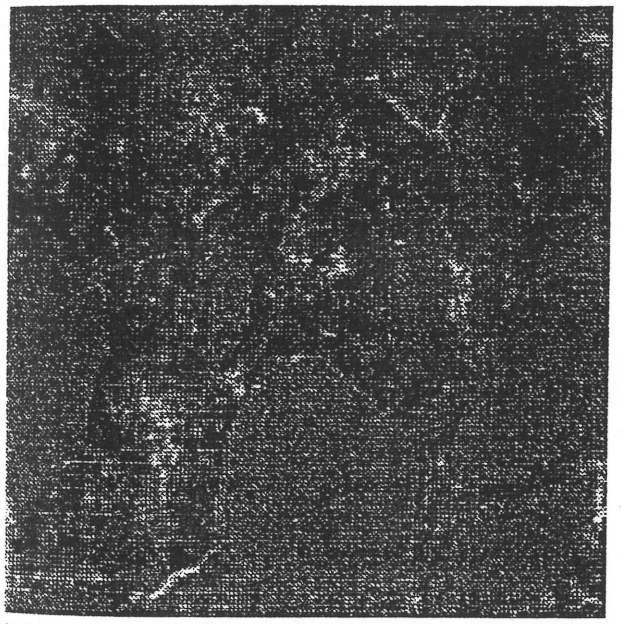
Thin sections are more widely used for the study of hardened concrete, where this is the primary technique for quality assessment and diagnosis of deterioration (e.g. Thaulow and Jackobsen, 1997, Jackobsen et al. 1997). Here the main advantage of optical microscopy is the ability to study large areas. Nevertheless the preparation of thin sections covering a large area is a specialised technique. Sections 100 mm square or larger can be prepared, but a more usual size, would be around 35×45 mm. Even with larger specimen sizes, careful selection of the sections from the macroscopic sample is necessary, to account for possible heterogeneity. Another strength of the technique is that specimens do not need to be pre-dried, so that with careful preparation the crack pattern existing in the original concrete may be studied.

Two important techniques used in conjunction with transmission optical microscopy are cross polars and fluorescence. The use of cross polars, above and below the specimen, is a classic petrographic technique. Highly symmetric (cubic) crystals or amorphous phases are isotropic (have the same properties in all direction) and therefore do not change the direction of polarisation of light, and so appear dark. Other crystals in which the speed of light varies according to direction, may rotate the plane of polarisation and so transmit light through cross-polars. This phenomenon permits different phases to be identified. Examples of the use of this technique are : determination of the depth of carbonation, by the depletion of calcium hydroxide and/or presence of calcite ; identification of alkali-silica gel, formed by reaction of susceptible aggregates, which is non-crystalline and therefore isotropic.

A sample may also be impregnated with resin containing a fluorescent dye, which fluoresces, when viewed under a suitable light source. This technique can enable an estimation of the original water to cement ratio (w/c) of the paste or concrete to be made (e.g. Romer and Dobrolubov 1974, Thaulow et al. 1982, Mayfield 1990). Accurate results depend on the comparison of the unknown, with well prepared standards at known w/c ratios. As the fluorescent dye fades over time, these standards must be remade regularly, but an experienced user can obtain results to within 0.05 or less. This technique is widely used as a quality control measure in Denmark. For important structures, such as the bridge-tunnel links between islands the concrete may be cored at seven days, to ensure correct mixing and placing. This is particularly important in mixes using high quantities of superplasicizer, where there is an increased possibility of segregation.

Figure 3, gives some examples of images obtained by optical microscopy of thin sections (G.M.Idorn Consult 1997)

The main limitation of optical thin section microscopy is the resolution. This is limited more by the thickness of the section, some tens of microns, than the resolution of the microscope itself which is less than 1 μm. The other disadvantage of optical microscopy is that it is not possible to obtain information on the chemical composition of phases. However, it is important to reiterate the primary role of optical microscopy, especially for the diagnosis of deterioration, where damage must be assessed in a wider context. In general the use of electron microscopy should be as a adjunct to and not a replacement for optical microscopy.



Clinker

2.2 Transmission Electron Microscopy (TEM)

With TEM, in terms of resolution we move, from one extreme to the other, but regarding the principals of image formation the TEM is analogous to the optical microscope, with the use of electrons rather than light to image the specimen. In theory, the considerably smaller wavelength of electrons (~ 2 Å) should enable individual atoms to be resolved easily. However, electromagnetic lenses used to focus electrons are far less effective than those for visible light, so near atomic resolution is only realisable under ideal conditions of specimen and instrument.

The TEM can provide a unique combination of information about a specimen :

- imaging,
- crystallographic information and
- local chemical analysis.

The type of imaging relevant to cementitious materials, is called mass thickness contrast. Electrons are absorbed more strongly, by areas of the specimen of higher relative mass or of greater thickness. An example is shown in Figure 4, taken in a high voltage electron microscope with environmental cell, without prior drying of the sample. Here a partially hydrated cement grain can be seen surrounded by hydration products, the unhydrated cement absorbs more electrons and so appears darker. In such images the typical resolution is around 10 nm.

In the TEM it is also possible to observe electron diffraction patterns from local areas. Electron diffraction is analogous to the better known X-ray diffraction, but, in the TEM, can be carried out on features of less than a micron in size. This enables known crystal structures to be *identified*, but the difficulty of obtaining accurate intensity information, means that the technique is of limited value in *determining* unknown crystal structures..

The third type of information is the determination of local chemical composition, from analysis of characteristic X-rays (see 2.3.3). Due to microscope geometry, difficulty of comparison with standards and of determining specimen thickness accurately the chemical accuracy of the analyses are somewhat less than in the SEM, however, the spatial resolution is much higher, around 10 nm in comparison to 1 μm in the SEM. Chemical information can also be obtained by analysis of the electron energies in the transmitted beam (EELS, electron energy loss spectroscopy). As the electrons pass through the specimen some may interact with the atoms of the specimen and some of the energies lost as a result are characteristic of the elements in the specimen. This technique can give chemical information on an even finer scale and can also give information on the local environment of particular atoms. For example, Richardson et al (1994) have used this technique on slag/cement pastes to confirm the presence of aluminium in bridging sites of silcate polymers in C-S-H.

Two factors limit the widespread use of transmission electron microscopy for the study of cementitious materials : availability of equipment and difficulty of specimen preparation. There are perhaps 10 or more scanning electron microscopes (SEMs) to every one TEM.

There are basically three methods of specimen preparation for TEM:

- dispersed particles,
- surface replicas and
- thin sections.

For all these techniques, representativity is a major problem. The sample size for TEM is 3 mm, but the observable area is much smaller than this, as a specimen must be very thin to transmit electrons (~100 nm).

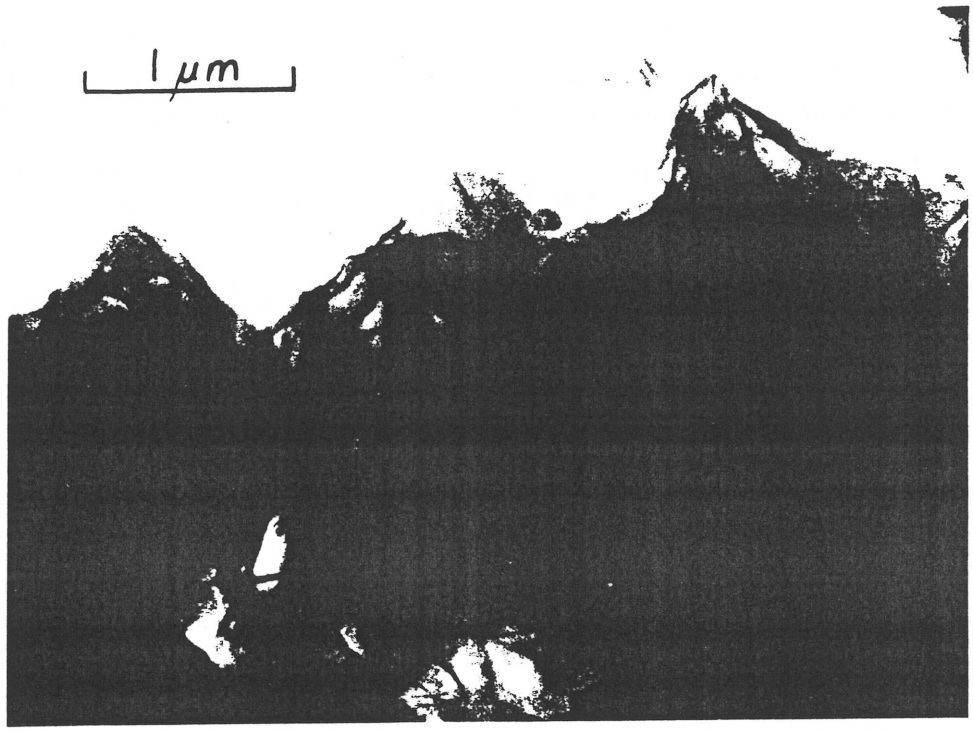

Figure 4. C_3S hydrated for 1day, observed without prior drying in the HVEM. The foil like structure of the C-S-H can be seen.

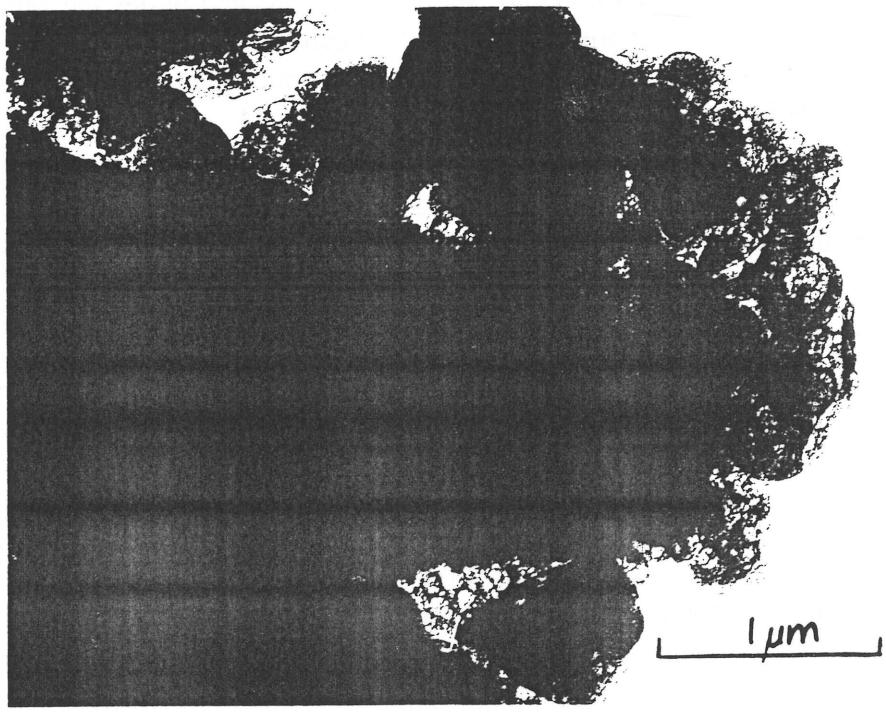

Figure 5. C_3S hydrated for 1 hour. After exposure to the electron beam in the HVEM for a few seconds the product 'bubbles' up.

The simplest technique is to grind a sample to give particles less than a few microns in size. These are then dispersed on a supporting carbon film. This technique was used in early studies of cement (e.g. Grudemo 1960, 1964) and has been used more recently to analyse the chemical composition of hydrates (e.g. Lachowski et al 1980). The main drawback to this technique is that spatial information about the arrangement of phases in the microstructure is lost.

The replica technique, for fracture surfaces was used fairly extensively before the availability of SEMs (e.g. Cottin 1971), but has now being effectively replaced by the direct observation of fracture surfaces in the SEM.

The best technique for observation of microstructure in the TEM is the preparation of thin sections. For cementitious materials these are usually prepared by ion beam milling.. Electron transparent regions are generally obtained by thinning a specimen until a hole appears. There will then be a region around the hole, thin enough to be studied in the TEM. With brittle and fragile cementitious materials this process can be quite difficult and it is almost impossible to control the position of the observable region, further adding to the problem of possible unrepresentativeness.

Another major problem in TEM is the sensitivity of cement hydrates to the electron beam. If the beam is focused on an area for only a few seconds, the products dehydrate and may bubble up. Figures 5 shows an image after beam damage. The electron beam may also lead to preferential volatilisation of some elements, with implications for the accuracy of chemical analyses.

Despite the difficulties, TEM studies have made an important contribution to the understanding of cementitious materials in recent years. The work of Groves and Richardson is particularly notable in this area (e.g. Groves 1986, Richardson and Groves 1990,). The morphology of 'inner' and 'outer' types of C-S-H can be distinguished, as can phases finely intermixed with C-S-H such as hydrotalcite in rims around slag grains. In carbonated pastes the fine intermixing of calcium carbonate and silica gel formed from C-S-H can be resolved (Richardson et al. 1992). More recently lattice images of C-S-H gel, have been published by Viehland et al. (1996). These have a resolution of less than a nanometre and indicate that C-S-H contains nanocrystalline regions.

Probably more than other microscopic techniques, it is important not to use TEM in isolation. However, when the general arrangement of features is well known from the SEM or optical studies, it is of great value.

2.3 Scanning Electron Microscopy (SEM)

The scanning electron microscope is more recent in development than the TEM, the first commercial instruments arrived in the early 1960s. The principal for image formation is radically different from either the TEM or the optical microscope. Essentially images are formed via coupled scanning of the electron beam over the specimen and of the output signal from the specimen on a TV screen, or similar viewing device. The magnification results from the difference in size of the two scans : thus if the scan on the specimen is 400 μm in dimension, and that on the screen is 200 mm the magnification will be ×500. The main advantage of the SEM is its flexibility, a magnification range of more than three orders of magnitude is possible (~×20 to >×50,000), and a range of signals can be used to form the image. The three kinds of signal most commonly used for the study of cementitious materials are:

- secondary electrons,
- backscattered electrons and
- characteristic X-rays.

These signals are generated by the interaction of the incident electron beam with the atoms of the sample, which occurs in a tear drop shaped region, known as the interaction volume, Figure 6. The size of the interaction volume increases with the energy of the incident electrons, which is dependent on the accelerating voltage used. Thus lower accelerating voltages should give better resolution than high ones, but this must be traded against the strength of the signal which decreases with accelerating voltage. For backscattered images a threshold voltage is needed to obtain contrast between phases, for light elements and oxides (as in cements) this threshold is higher than for heavier elements. Also for chemical analysis the energy of the incident electrons must be sufficient to excite the atoms present in the sample. For most SEMs an accelerating voltage of 15 kV is a good compromise, but with more modern instruments it is possible to obtain good images at lower voltages.

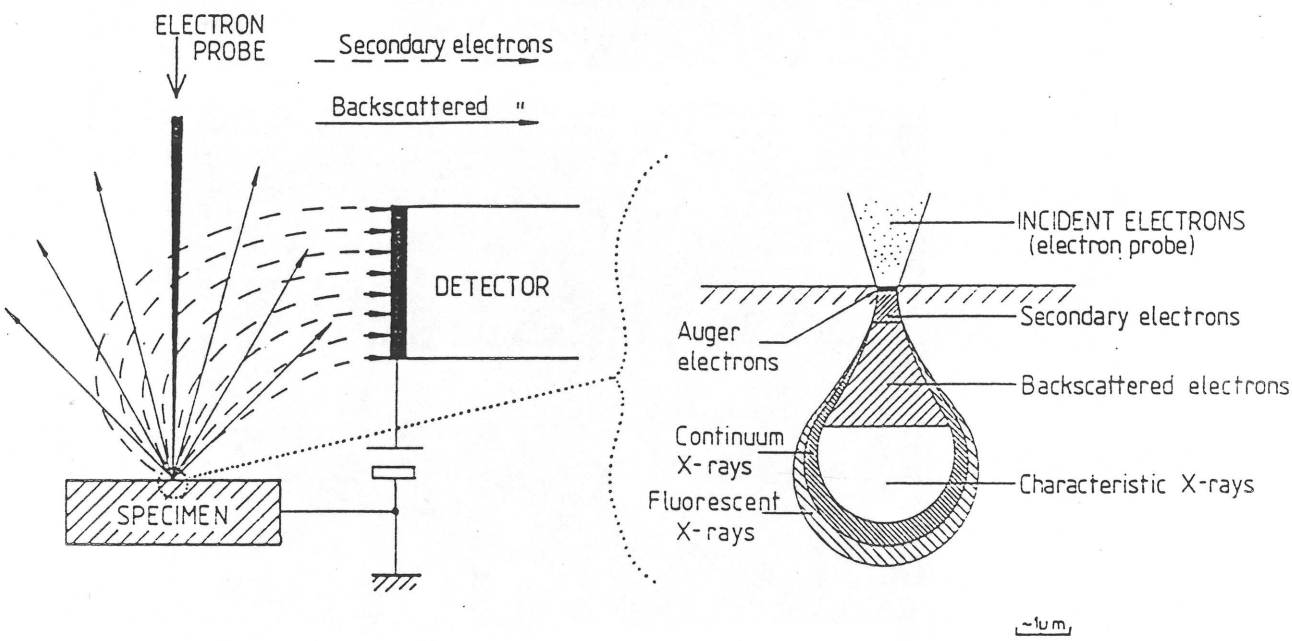

Figure 6. Generation of signals in the SEM

2.3.1 Secondary Electron Imaging of Fracture Surfaces

Secondary electrons result from inelastic scattering processes within the specimen, they have much lower energy than the incident electrons and so only escape from within a few angstroms of the specimen surface. This means that the potential resolution of secondary electron images is higher than that of other signals. The intensity of secondary electrons is influenced to some extent by the local atomic number of the sample, but the major effect on contrast is the inclination of the specimen surface to the horizontal (topography), this makes them ideal for imaging rough surfaces, such as produced by fracture. Secondary electron are collected by a detector with a small positive bias, which enables them to be separated from the more energetic incident and backscattered electrons.

Fracture surfaces are easily produced by smashing a hardened sample with a hammer or chisel. For cement pastes the specimen must first be dried before placing in the high vacuum of conventional electron microscope and coated with of a conducting material such as gold or carbon, to prevent charge build-up from the incident electron being unable to escape from the specimen. In SEMs with a low vacuum facility prior drying may be avoided.

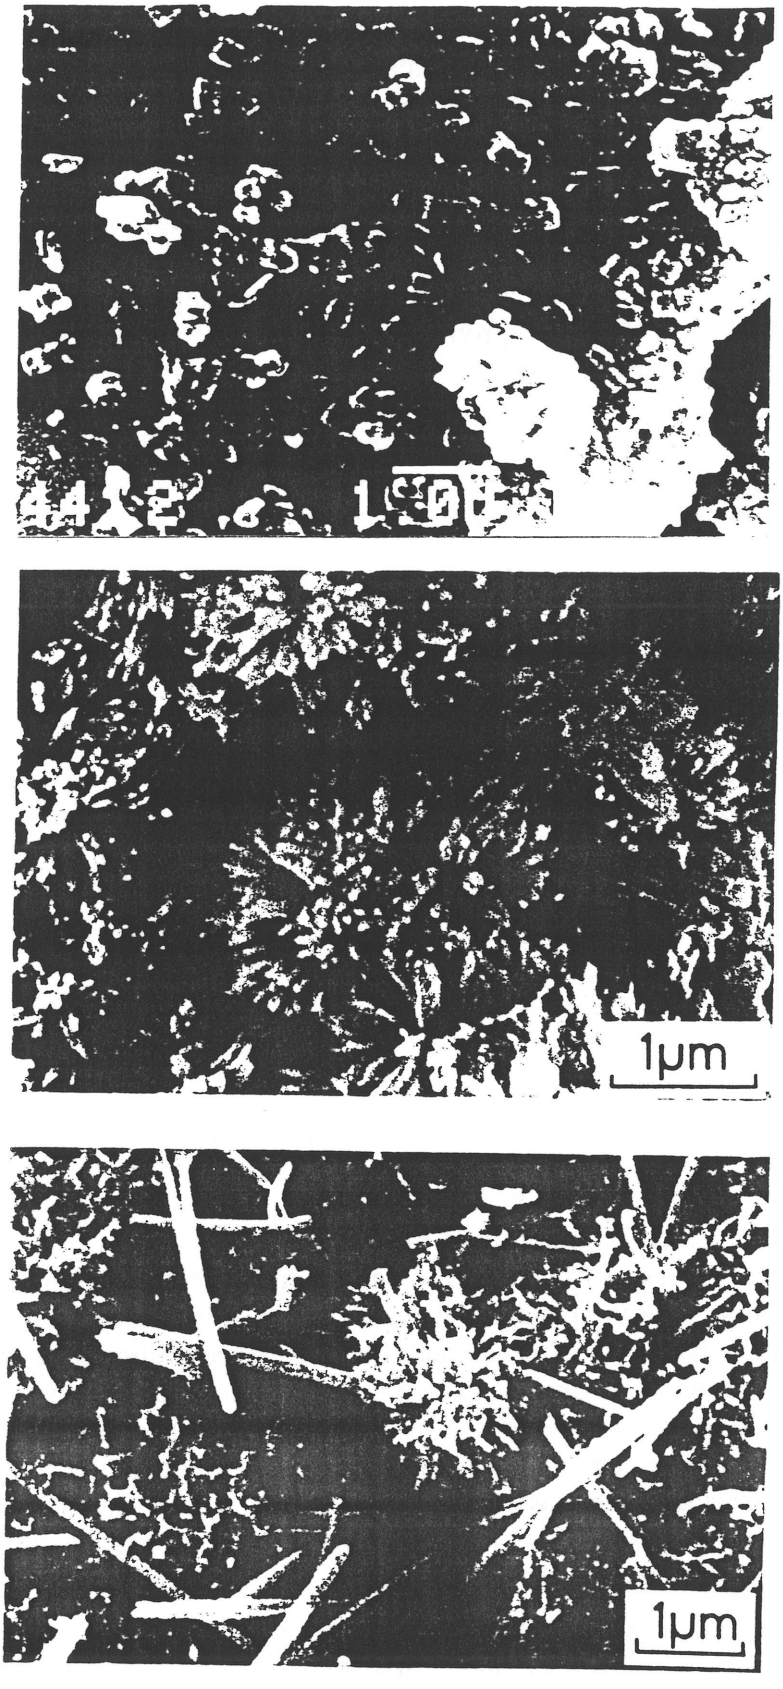

Figure 7. Fracture surfaces of cement paste after 1hr, 10hrs and 24hrs hydration.

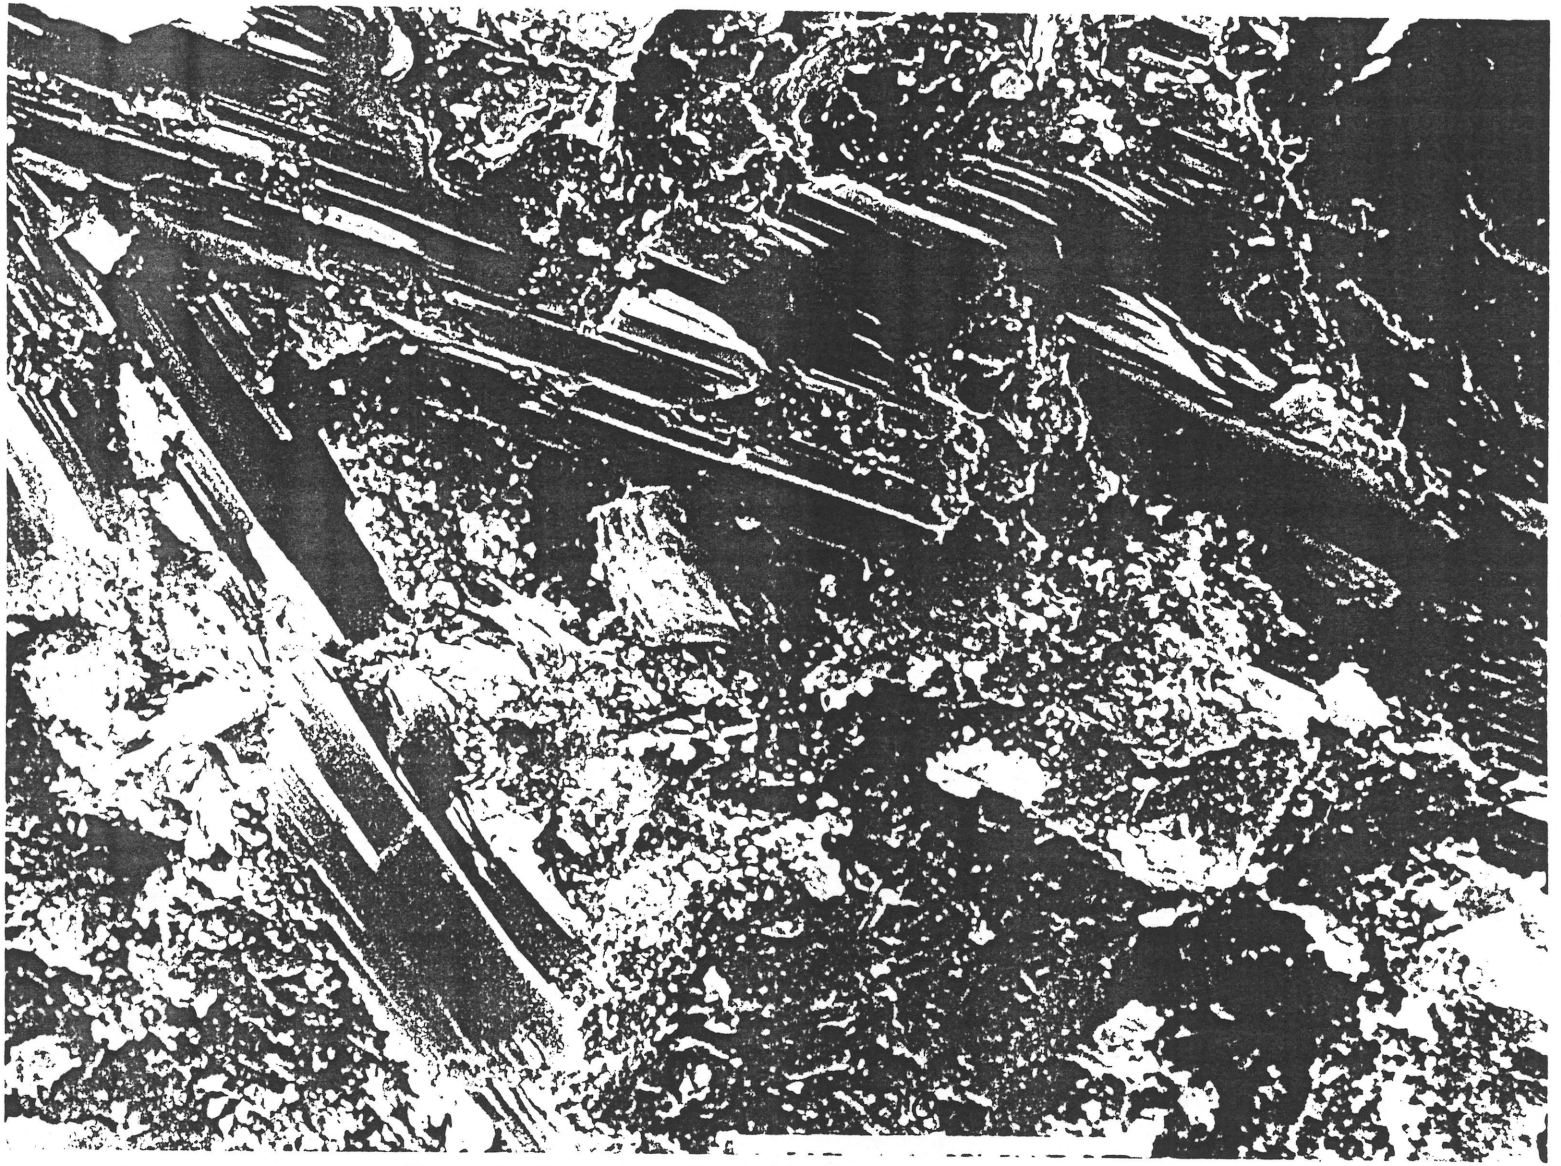

Figure 8. Fracture surface of 28 day old cement paste

As with all microscopical techniques the examination of fracture surfaces has advantages and limitations. The principal advantages are the good resolution and ability to observe the morphology of hydration products. This makes the technique well suited to the study of the early period of hydration. For example, Figures 7 shows fractures surface of a cement paste after 1, 10 and 24 hours of hydration. At 1 hour, small grains of ettringite can be seen on the surface of the cement grains, at 10 hour there has been a significant growth of C-S-H around the grains and at 24 hours both C-S-H and further ettringite are visible. However, these microstructures also illustrate some of the cautions which must be observed when studying fracture surfaces. In the 1 hour microstructure, the presence of the small ettringite crystals on the grain surface is frequently interpreted as their formation close to the grain surface, even as topochemical formation. Such interpretations misleading as other techniques show that the ettringite crystals form in the solution phase away from the grain (Scrivener 1984, 1989b). During the drying process the crystals will fall back onto the underlying grain. Similarly the spiky morphology of the C-S-H in Figure 7b is also accentuated by the drying process. In the undried state, this phase has a less defined, more foil-like morphology, Figure 4.

After about 1day of reaction , the microstructure becomes more dense. The fracture path will run through the weakest areas, which are thus the areas observed. With increasing densification at later ages, it becomes increasingly difficult to interpret the microstructure as a whole (Figure 8) which is dominated, by dense areas of C-S-H and calcium hydroxide. In addition, only relatively small regions of the rough surface will be in focus at any one time. Consequently, the microscopist is drawn to the study of 'interesting', but perhaps unrepresentative features.

2.3.2 Backscattered Electron imaging of Polished surfaces

Polished sections can be prepared to give a representative cross-section of the microstructure. However, these cannot be imaged satisfactorily with secondary electrons, due to the lack to topography. In this case backscattered electrons (BSE) are used for imaging, these are incident electrons which have been scattered through large angles so that they re-emerge from the sample. Their intensity is mainly dependent on atomic number (larger atoms are more likely to cause scattering and produce a high backscattered electron intensity). The resolution of BSE images, a few hundred nanometers, is somewhat less than that of secondary electron images, but this drawback is vastly outweighed by their flexibility. This imaging mode was used on early electron microprobes, but the image quality was poor. The advent of solid state backscattered detectors in the 1980s, enabled high quality backscattered electron images to be obtained and this technique has become more and more widely used for the study of cementitious materials.

In a sample, the intensity is proportional to the local BSE coefficient (C_{BSE}), which is the average of the BSE coefficients of the elements present weighted according to their relative mass:

$$C_{BSE} = \sum C_i m_i \qquad (C_i, \text{ BSE coeff. of } i^{th} \text{ element. } m_i, \text{ mass fraction of } i^{th} \text{ element})$$

Figure 9. shows the relative BSE coefficients of some of the phases found in cementitious materials. Generally the anhydrous phases appear brighter than the hydrates and pores appear dark. A typical image of an hydrated Portland cement is shown in Figure 10. The contrast is complicated by the presence of microporosity, particularly in C-S-H gel, this lowers the BSE coefficient, but the precise relation with the level of porosity is not known.

By and large the images of clinker are very comparable to those obtained by optical microscopy, Figure 11, except the higher resolution and good contrast between the ferrite and aluminate phases, makes the fine detail of the interstitial material clearer. The reproducible contrast between the phases makes BSE images well suited for automated image analysis, however, the

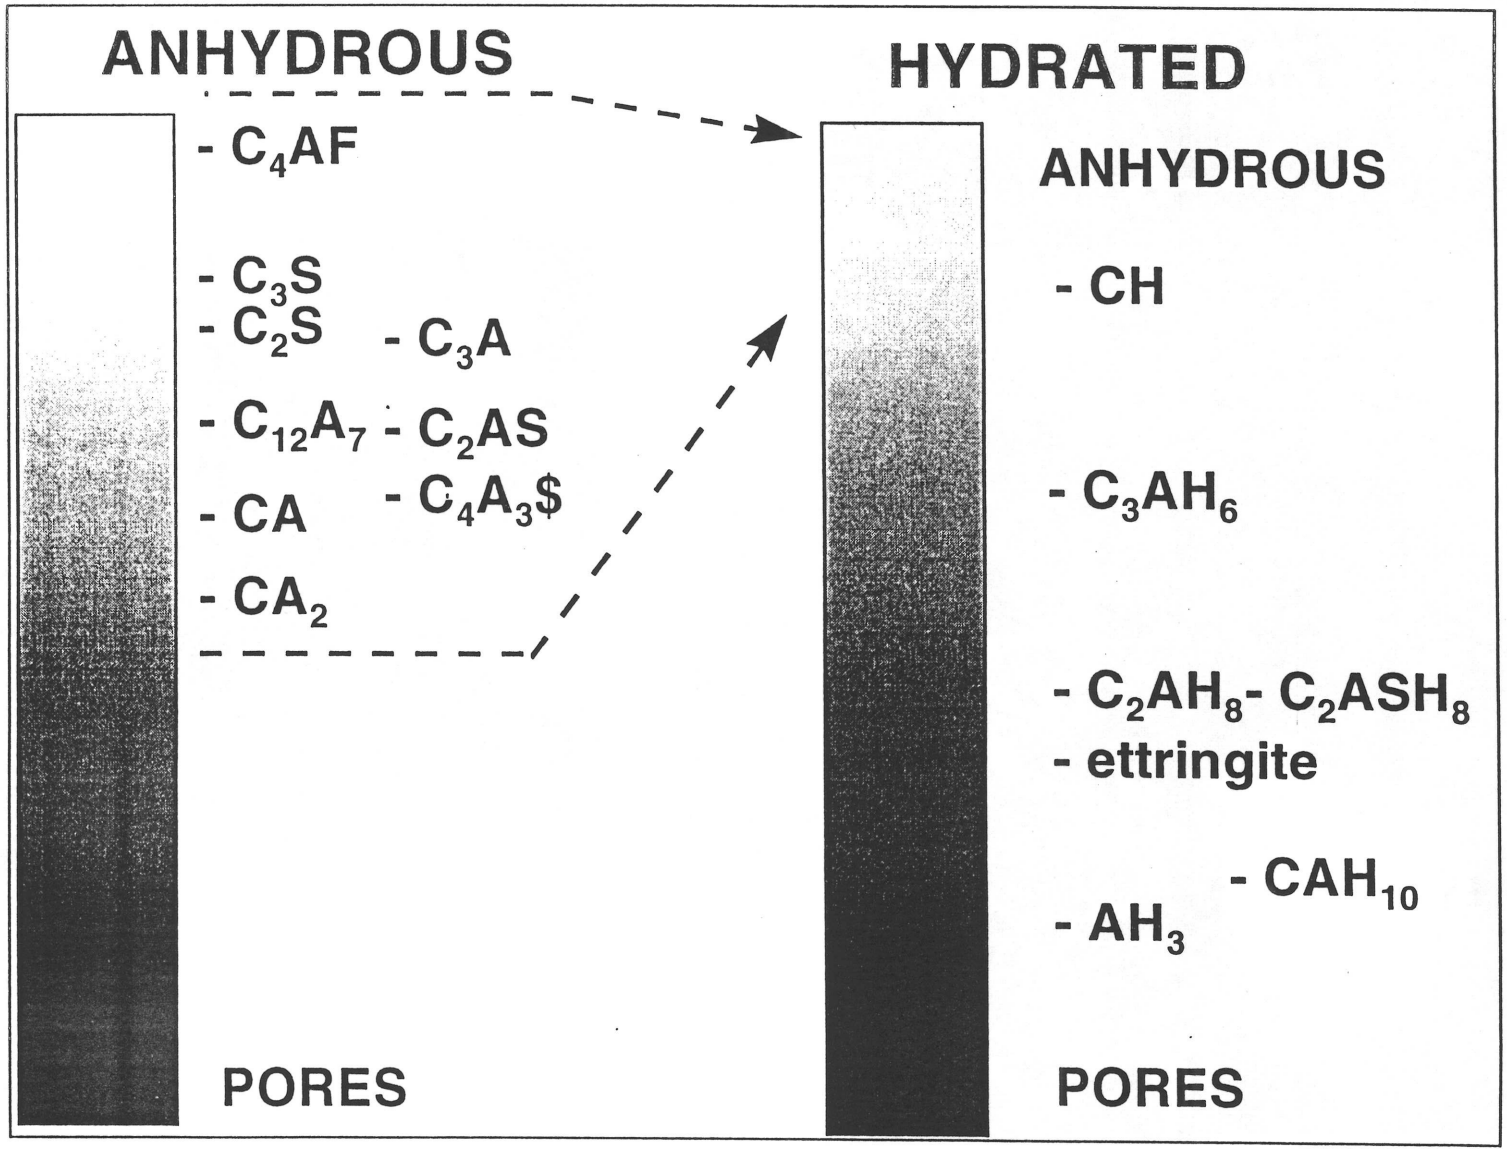

Figure 9. Relative backscattered electron coefficients for cementitious phases

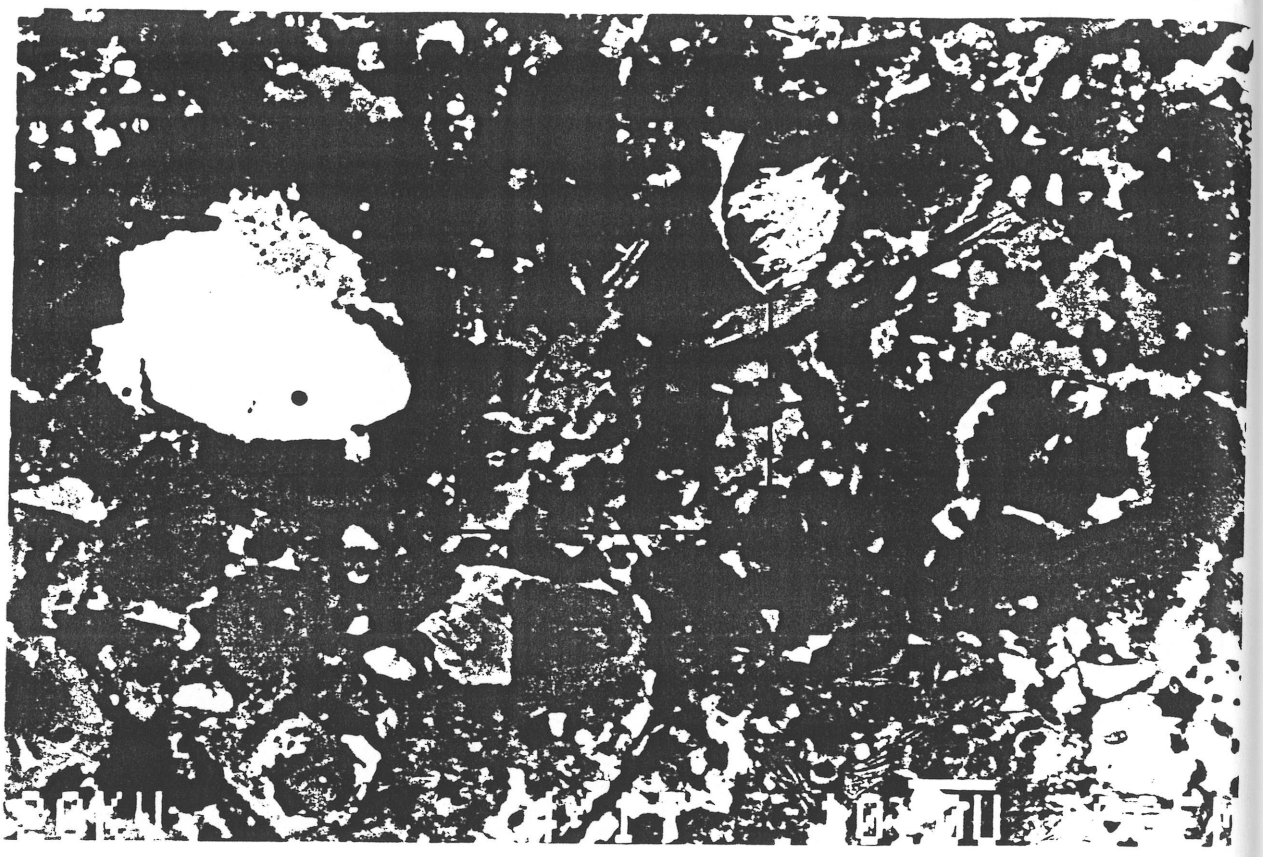

Figure 10. BSE image of polished section of Portland cement paste hydrated for 28 days. N.B. black box indicates similar area to whole image in of fracture surface in Figure 8.

Figure 11. BSE image of polished section of cement clinker.

very similar BSE coefficients of the belite and aluminate phases poses a problem in practice. Several methods have been developed, usually in combination with chemical information from X-ray signals (see 2.3.3), (e.g. Scrivener 1987, Stutzman 1991, Sutter et al, 1997). The technique may equally well be applied to a ground cement, dispersed in resin and polished. Here the improved resolution over optical microscopy is more important, although, quantitative measures cannot be realistically used for grains less than a few microns in size.

For the study of cement pastes, and concretes, the effective resolution of SEM/BSE is considerably greater than for optical thin sections. The major advantages of the technique are the ability to obtain quantitative information by image analysis and the possibility to use the X-ray signal to make local chemical analyses. Both these techniques are described in more detail below.

2.3.3 Characteristic X-rays for chemical analysis.

Some of the scattering events which occur as the incident electron beam penetrates the sample will result in the emission of X-rays, these consist of characteristic X-rays, specific to individual elements, superimposed on a continuous background, Figure 12.

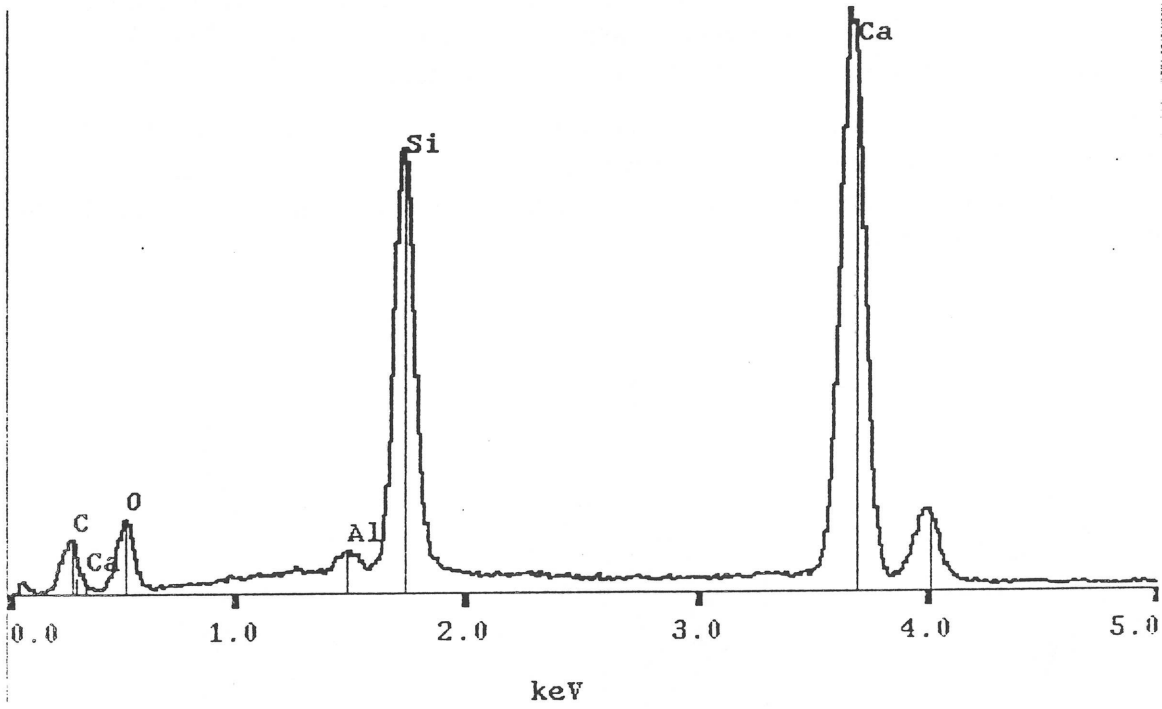

Figure 12. X-ray spectrum emitted from belite grain sample in the SEM.

The characteristic energies correspond to differences between electron energy levels in the atoms. The emitted X-ray may be analysed, either according to their energy (energy dispersive spectroscopy, EDS) or wavelength (wavelength dispersive spectroscopy, WDS).

EDS analysis is by far the most widely available, the whole energy range can be analysed at the same time so that a spectrum can be obtained for qualitative purposes in several seconds, and a spectrum for quantitative analysis in 50-100s. The disadvantage of EDS is the relatively low signal to noise ratio, this means that the detection limit is at best 0.1 wt % absolute and the accuracy between ±0.2 and ±2%, depending on the absolute amount and the analysis procedure. The EDS detector is usually protected by a window, which does not allow elements lighter than sodium to be detected. Thin, ultra thin window and windowless detectors are becoming increasingly common, these allow light elements to be detected down to Boron, but the accuracy in this range is much lower.

WDS is the technique used on specialised microprobes and occasionally on conventional SEMs. The spectrum is acquired by scanning through the range of wavelengths. To obtain a complete spectrum takes considerably longer than EDS, but the technique is usually used to scan a narrow, predefined range to detect a specific element. For quantitative analyses a good signal can be acquired in a few microseconds for each element, a microprobe will usually have at least three detectors to analyse several elements simultaneously. The detection limits and accuracy are about an order of magnitude better than for EDS analysis.

In both cases, accurate quantitative analyses, depend on comparison with spectra obtained from standards of known composition, obtained under identical conditions — accelerating voltage, beam current, specimen height, specimen tilt, etc.. In compounds containing several elements, the signal form one element, will be affected by the presence of the other elements, due to absorption and secondary fluorescence. Commercial analysis software, makes corrections for these effects automatically, 'ZAF' and 'phi-rho-Z' being the mathematical models most commonly used (the phi-rho-Z correction is best adapted to the light elements found in cementitious materials.). Commercial software is designed to give good results across the complete range of materials, e.g. metals and oxides, which are not necessarily optimal for any one class of materials, e.g. cements. Therefore, the analyses from a system dedicated to cements, may be optimised by using cement phases as standards.

Accurate X-ray microanalysis depends on having a flat specimen. The type of artifacts which can be produced by rough surfaces are shown in Figure 13. Therefore X-ray analysis should not be used on fracture surfaces, for anything other than to get a very rough idea of the chemistry of the area being examined.

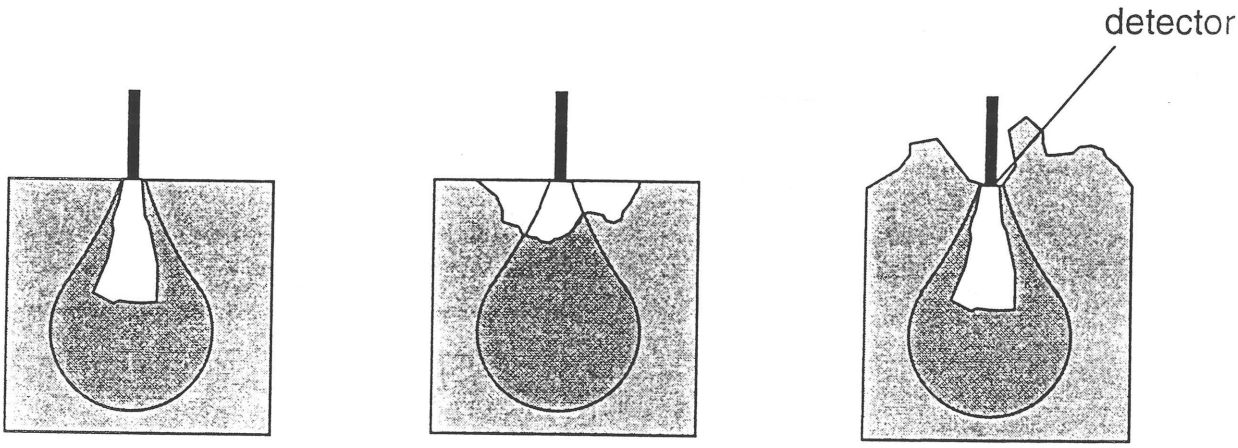

Figure 13. Possible artifacts in chemical analysis

The main limitation to X-microanalysis in the SEM is the size of the interaction volume from which X-rays are collected, this is of the order of 1-2 μm in cementitious materials (Figure 6). In many cases, particularly for hydrated materials, phases are intermixed on a scale finer than this and cannot be analysed separately. In these situation graphical representations of sets of individual analysis points can assist interpretation. This technique was first used by Harrison et al. 1986 to study the composition of hydrates in slag/cement blends.

An example of the use of atom/ratio plots is shown in Figures 14 and 15. This shows analysis of hydrates in a paste of an alkali activated slag (Wang & Scrivener 1995). On the fracture surface (Fig. 13a)) some thin plates can be seen amongst a fairly featureless 'gel', but no sensible analyses can be made by this technique. In the BSE image of a polished surface (Fig.13b)), the plates are difficult to identify and individual analyses cannot be made. When the results of

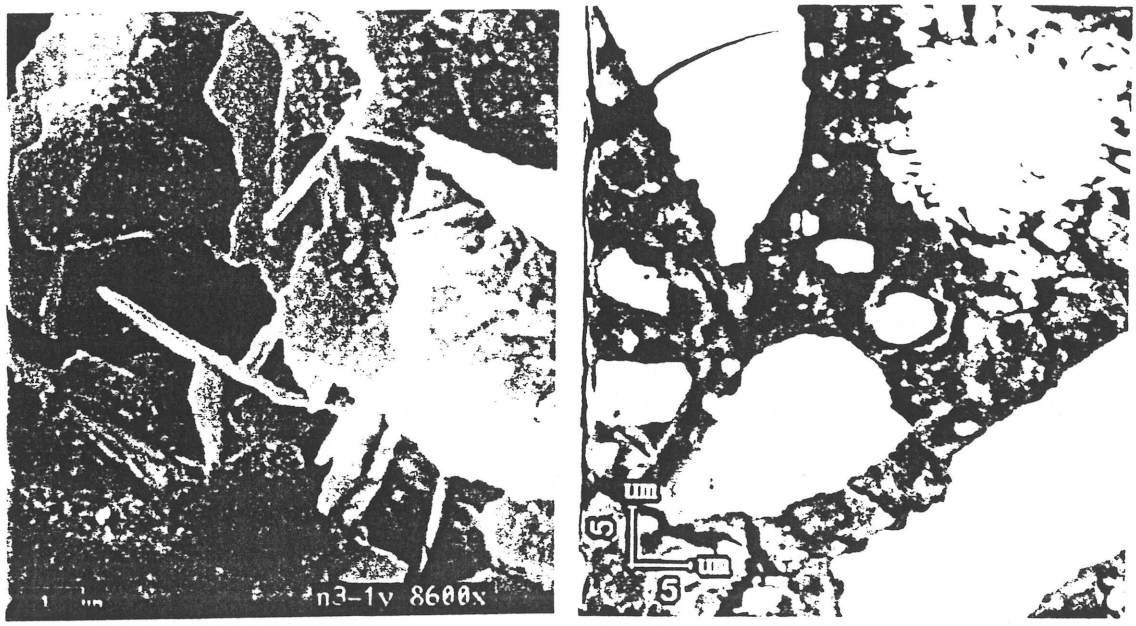

Figure 14. Fracture surface and polished surface of slag activated with NaOH solution hydrated for 1 year

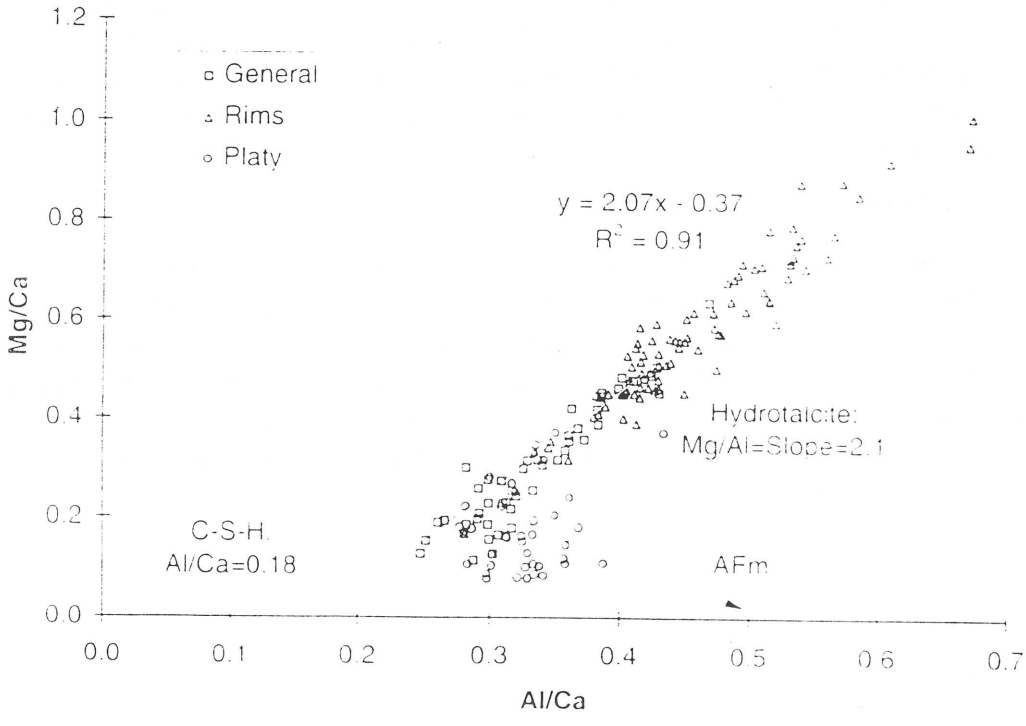

Figure 15. Microanalyses of slag activated with NaOH plotted Mg/Ca against Al/Ca

many point analyses are plotted on a graph of Mg/Ca to Al/Ca, the intermixed phases can be identified. The larger plates visible on the fracture surface are an AFm phase and the analyses centred on these plates fall around a line between a C-S-H and AFm. The featureless 'gel' is a C-S-H, but the distribution of the analyses indicated that there is finely dispersed hydrotalcite within this, which could not be seen in the microscope images. It is also evident that the amount of hydrotalcite in the C-S-H is higher in the 'rims' around the slag grains. These deductions were supported by the results of X-ray diffraction and thermal analysis. Other examples of this type of analysis, for the study of delayed ettringite formation in heat cured pastes can be found in Scrivener and Lewis (1997)

In addition to point analyses, X-ray signals may be used for mapping. Here the intensity of the signal associated with one elemental peak is collected as the beam scans the specimen. Such maps can be very useful in visualising the distribution of an element, but they are time consuming to acquire and the resolution is limited, not only due to the interaction volume, but also by the signal to noise ratio of the x-ray signal.

3. Sample preparation

Before considering the theme of image analysis, it is worth considering the question of sample preparation. The importance of this is often underestimated, but good sample preparation may be far more critical to obtaining good images than skill at operating a microscope, and certainly more important to meaningful image analysis than sophisticated mathematical routines. As electron microscopes operate under vacuum, free water must be removed from samples before examination. Then the sample must be polished (for optical microscopy or BSE in the SEM).

Finally for the electron microscope, measures must be taken to avoid charge build up, as cementitious materials are non-conducting. For fracture surfaces a layer of gold (or other metal) is vapourised onto the surface. The vapourisation process is good for giving a continuous film on rough surfaces and the good electrical conduction of gold means that only a very thin layer is necessary. The disadvantage of gold is that it gives a characteristic X-ray peak in the same position as sulfur, so for polished samples on which chemical analysis is to be carried out, carbon is usually used.

3.1 Drying Techniques

There has been considerable controversy as to the best technique for removing free water from cementitious specimens; inevitably, any technique induces some change in the specimen. The choice of the most suitable technique will depend to some extent on the age of the specimen, the equipment available and the principal features to be observed. In the SEM for example the maximum practical resolution is well above 10 nm, therefore techniques which undoubtedly damage the fine gel pores of C-S-H (~ 2 nm) will not have a visible effect on the specimen. The techniques most commonly proposed are :

- oven drying
- vacuum drying
- freeze drying
- solvent exchange

Oven drying has a very destructive effect on the microstructure, 'blurring' the fine morphology of the hydrate phases and inducing microcracking. Therefore, this is a technique which should be avoided. Otherwise, at least for samples more than a few days in age, there is little discernible difference between the remaining techniques at the microscopic level.

The main advantages of freeze drying are its speed and the minimal damage during water removal. Specimens are dropped into a mixture of solid CO_2 (cardice) and methanol at −80°C (the thermal shock of liquid N_2 can shatter specimens). For small specimens of a few centimetres in size the freezing is almost instant so that early age samples hydrated for as little as a few minutes may be examined. After freezing the specimens are transferred to a cooled chamber under vacuum, where the water sublimes directly from solid to gas so avoiding the destructive effect of a retreating liquid interface. In addition any solutes present in the pore solution, will be simply deposited on the hydrate surface without crystallisation, they are thus 'invisible' at the microscopic level.. The main drawback of freeze-drying is the need for specialist equipment, also for specimens of any size the drying process may be very slow.

Drying under vacuum is a relatively slow process, which will take several days, even for very small samples. It is only suitable for mature specimens (older than about 28 days), which have a fairly low free water content anyway.

Solvents may partially dehydrate phases such as C-S-H and ettringite. However, such dehydration probably has little effect on the outward morphology of the crystals, so is more important from the point of view of X-ray diffraction and thermal analysis than microscopy. The problem with solvent exchange is that it is also a relatively slow process and for samples of a few millimetres the exchange process will take several days. Therefore, it is only suitable for older samples. For younger samples, the hydration may be stopped more rapidly by grinding the sample, but in this case valuable spatial information about the microstructure is lost.

3.2 Polishing

A good polish, without relief, is essential to the examination of samples by BSE. With many materials i.e metals, this is comparatively easy. The preparation of cementitious materials, especially concretes, is somewhat more complex and difficult to achieve. Traditionally clinkers and concretes have been studied by optical microscopy where the use of water and heating during sample preparation is generally acceptable. The impregnation of the pore structure of the material with resin is also less critical for these techniques as the resloution is lower.

Cements and concretes are multiphase materials with complex microstructures. They materials have variable moisture states, and different hardnesses of constituents and within the microstructure. The most important constituents within a concrete are usually the cementitious phases. These are generally softer and more porous than aggregates and need attention for successful preparation.

The basic procedure for the preparation of polished sections involves: initial cutting of the bulk section to a manageable size; impregnation of the pore structure, precision cutting or grinding to expose the material surface, lapping of the surface with abrasive compounds to so it is flat prior to the polishing stages, and finally polishing to a size of 0.5μm or less. The choice of appropriate techniques and equipment for preparation depends on the particular type of sample and on the analyses intended; i.e porosity, surface regions, chemistry.

For impregnation there are many resins commercially available today with different in viscosities and chemical compositions; a lower viscosity resin generally enables better penetration and impregnation of the material but these resins tend to contain significant amounts of chlorine.

The next step is to expose a surface of the material which still has resin within the pore structure. Grinding with diamond discs and silicon carbides, and/or precision cuts are generally employed for this task. The exposed resin impregnated surface is subsequently *lapped* with free abrasives,

corundum (Al_2O_3) or silicon carbide (SiC), and then *polished* with diamond grits on pellon cloths. Generally corundum powders are less aggressive than SiC grits and are more successful with softer materials. If the use of water is undesirable alcohol and/ or oil based lubricants need to be used.

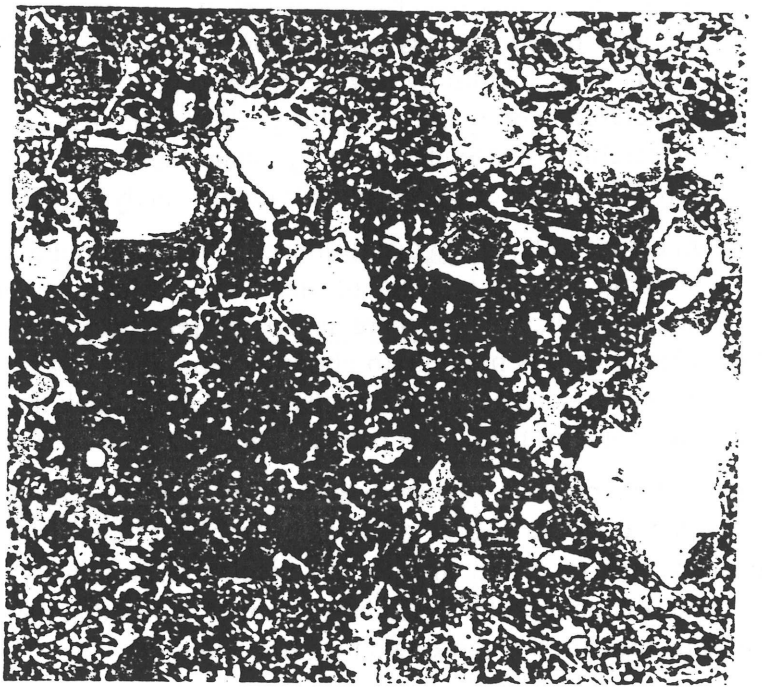
Between each grit size the surface condition should be assessed with optical microscopy to ensure successful completion of one stage before starting the next, and the samples should be ultrasonic cleaned in appropriate solvents. Careful attention to each preparation stage is important for successful results.

It is important to understand the type of material and the sample preparation process in order to avoid and identify artifacts, which hamper or prevent proper microstructural examination. Perhaps the most common artifact is "relief", where one component (e.g, aggregate) is polished and stands 'proud' of the others (e.g. paste) which remains poorly or unpolished. In the worse case this can prohibit polishing of the cementitious phases and therefore BSE microstructural imaging in concrete. On a smaller scale relief can result in both topographical and atomic number contrast which complicates the grey scale/atomic number relationship so that subsequent feature discrimination for image analysis is inaccurate. Relief can also result in the local charging, which affects both imaging and chemical analysis.

Another common artifact is "plucking", whereby softer phases are removed (i.e. calcium hydroxide) to leave pores. Plucking can also significantly distort the pore network, size, shape and total porosity. This problem can be minimised or avoided all together if the pore structure of the material is adequately supported by impregnation with epoxy resin.

Microcracking is also a fairly common artifact which results from the initial stages of sample preparation; either from the removal of the "free" water, or during the coarse cutting and grinding processes. Microcracking can be minimised by removing the water in the least aggressive way possible i.e solvent exchange, and by precision cutting of the surface followed by lapping with corundum powders.

Despite the difficulties it is possible to polish concretes successfully. Each stage must be carefully considered and the time must be taken to do the work necessary, since as for many other techniques there are no easy answers or short cuts.



4. Image analysis

Image analysis is essentially the process of obtaining quantitative information from images. Simplistically the number of different quantities which can be derived from an image is effectively infinite, therefore the problem is to produce quantities which have some use. The process of image analysis can be considered in two stages :

- discrimination of the features of interest from the microstructure;
- measurement of the discriminated features.

4.1 Feature discrimination

The main criterion used to discriminate microscopical features is grey level in BSE images or colour in optical images. [The reproducibility of grey level (determined by average atomic number) in BSE images, as opposed to colours (determined by etching) in optical images makes them better adapted to image analysis.] For a typical Portland cement paste, a histogram of the grey level distribution is shown in Figure 16. From bright to dark, peaks can be identified for

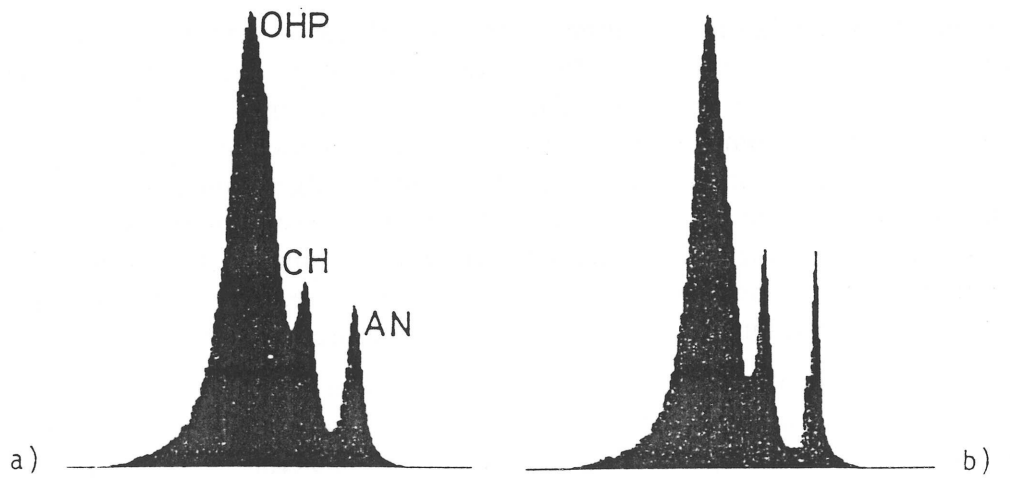


Figure 16. BSE image of 28 day old cement paste for image analysis and associated grey level histogram, a) before and b)after smoothing

the anhydrous cement phases, calcium hydroxide and for the other hydrates (mainly C-S-H). The separation of the peaks can be improved somewhat by smoothing the image.

From this histogram threshold values may be chosen to extracted the anhydrous cement. Comparisons of the anhydrous material measured by image analysis for this phase, compare well with calculations based on loss on ignition measurements (Patel 1987, Scrivener et al. 1987) (Figure 17a)). The calcium hydroxide can also be discriminated, although it can be seen that there is considerable overlap between this peak and that from C-S-H. Generally it is found that measures of calcium hydroxide made by image analysis tend to be slightly higher than measures by X-ray diffraction or by thermogravimetric analysis (Figure 17b)).

The real problem comes in trying to discriminate the pores from the C-S-H. Part of the problem comes from the range of grey levels of the C-S-H and inherent microporosity, but high magnification images indicate that there is no discrete boundary between these two phase. Despite these difficulties it is possible to choose a reproducible grey level threshold, which can be used to make comparisons between samples [Patel 1987, took the point of intersection of the tangents to the lower side of the C-S-H peak and the rising curve of the pores].

The question is often posed — what is the minimum pore size detected by image analysis? Clearly pores integral to the C-S-H gel are not resolved, but what about the 'capillary' pores. The simple answer is to relate this to the pixel size, which is typically 0.3 μm at ×320 magnification and 0.1 μm at ×1000. However, table I shows that there is no significant increase in the pore volume measured at these two magnifications.

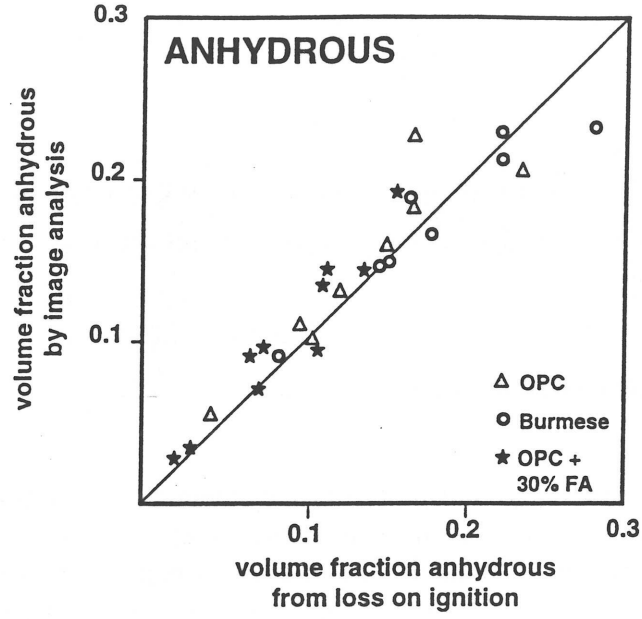

Table I, Porosity measured at three different magnifications of cement paste (w/c=0.5) at two ages (Scrivener 1989), area % (std. error)

	× **110** (4 fields)	× **320** (9 fields)	× **1000** (9 fields)
1 day	17.8 (0.7)	23.2 (0.3)	24.5 (1.2)
28 days	6.8 (1.3)	12.7 (0.3)	14.6 (1.2)

The reason for this lies in the nature of the thresholding — the pixels which are discriminated as 'pores' are in fact those in which the average level of porosity is greater than a certain value, close to, but not equal to 100%. Thus the porosity 'over estimated' in a pixel with an actual porosity of 95% is compensated for by the porosity 'missed' in a pixel containing 5% of pores, which is not included in the measurement of porosity. This compensating effect mean that there is no simple pore size cut off, and in fact the total measure of porosity is very similar to that measured by other methods, which can access much smaller pore sizes. This can be seen in Figure 17c) shows the comparison of porosity measured by image analysis (nominal cut-off 5000Å), with the volume of pores above 368 Å measured by solvent replacement.

In terms of available software a large range of other criteria are available for discriminating features — circularity, aspect ratio, size, etc.. In general, it has been very difficult to find routines which work reproducibly in cementitious materials. For example, it is possible to identify fly ash particles on the basis of circularity in young pastes, but in older pastes the boundary of the particles cannot be reliably discriminated. In addition many fly ash particles are not spherical, and the overall error in measurement is not acceptable.

A particular problem is posed by the discrimination of aggregate particles in concrete. The mineralogy, even of primarily siliceous aggregates, is too variable for them to be reliably discriminated by grey level thresholding, even in combination with other selection criteria. In

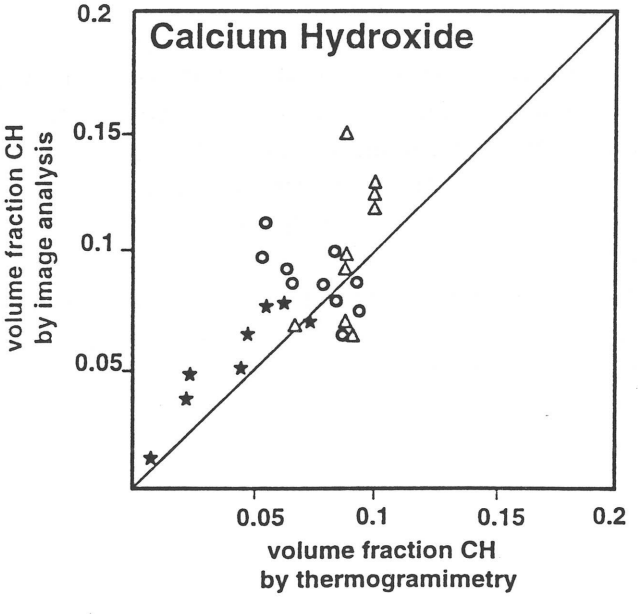

Figure 17
Comparison of anhydrous cement, porosity and calcium hydroxide measured by image analysis of BSE images with measurements by classical techniques, from Patel 1987

general it has been found necessary to draw round the particles by hand, which is somewhat, though not very, time consuming.

4.2 Quantification

The utility of any quantity measured by image analysis is governed by two major concerns:

1. How can a measure made on a two dimensional section be related to a three dimensional microstructure? (Stereological aspect)
2. Is the measure representative of the sample from which it comes? (Statistical aspect)

These two aspects are not independent of each other.

4.2.1 Stereological aspects

A first class of measures are those for which there exist mathematically simple relationships between three dimensional quantities and their measurements in two dimensional sections. There are very few such measures, but fortunately one of these is perhaps the most useful, that of the volume fraction of a phase. The relationship between the volume fraction (V_V), area fraction (A_A), line fraction (L_L) and point fraction (P_P) was found in the 19th century to be:

$$V_V \equiv A_A \equiv L_L \equiv P_P$$

This means that, within the limits of statistical considerations the volume fraction of a phase, can be estimated from the area fraction of that phase on random two dimension sections, or from the intercept fraction of that phase on random lines, or from the fraction of random points falling within that phase (point counting). There are a few important prerequisites for the validity of this identity:

- the phases must be randomly distributed
- the sampling areas, lines or points must be at random
- the measures must be made globally - i.e. the identity does not apply to a subset of area fractions classified by size.

Other quantities which can be uniquely estimated from measures on two dimensional sections are the surface area of a phase per unit volume and the line length (of cracks for example) per unit volume.

A second class of measures are those which can be estimated from two dimensional measures, if some assumptions are made, into this category fall measures of particle size distribution. Exact expressions exist only for very simple geometrical shapes and distributions such as monosized spheres. The problem here is one common to many 'inverse' problems. Given a known three dimensional distribution, the expected two dimensional distribution can be calculated, but from a given two dimensional distribution there is not unique solution for the parent three dimensional distribution — for example a circular section of given size may be the equatorial section, for a sphere of equal size, or the non-equatorial section of larger size, Figure 18. The accuracy of the solution then becomes basically statistical in nature.

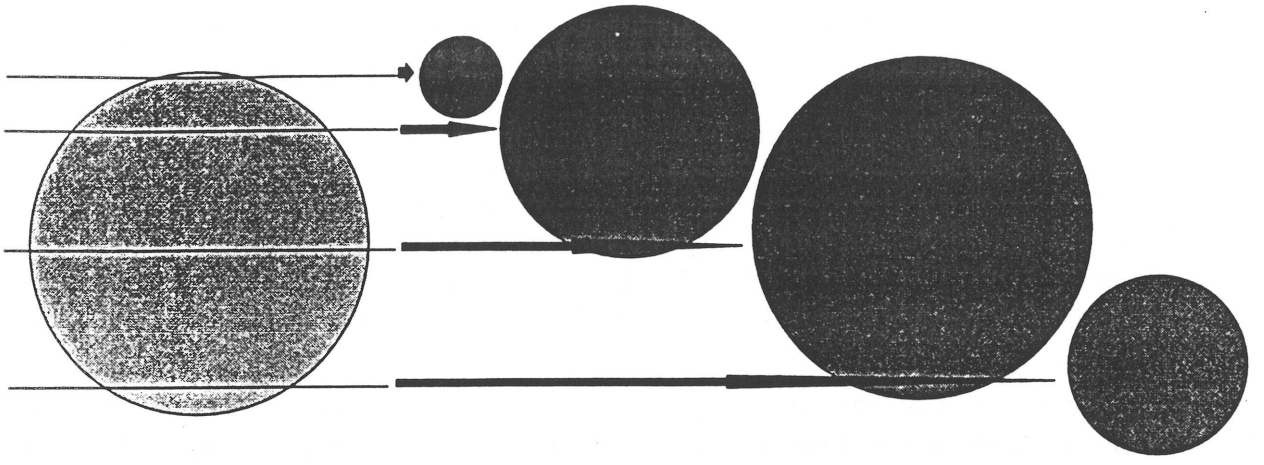

Figure 18. A given *particle* size may give rise to different sized *sections* in a 2D image, also the *sections* in a 2D image may originate from *particles* of different sizes.

Despite the problems, fairly reasonable routines exist for calculating size distributions for discrete, reasonably rounded particles. However, many microstructural features of interested features in cementitious materials do not fall into this category — the prime example being pores. The first question in this context is the meaning of a pore size. Although other measures, such as mercury intrusion porosimetry, also suffer from the problem of what exactly is the 'pore size' measured.

The third class are parameters which cannot be estimated directly from measures on two dimensional sections, the classic example being connectivity, which again concerns the characterisation of pore structure.

4.2.2 Statistical aspects

As in all measurements which can be made to characterise materials, errors arise from bias in the technique or finite precision in the method which have to be analysed by statistical procedures. However in stereological measures by image analysis we are forced by the very nature of measurement process to *sample* the true 3-D structure, the extent to which this sampling reveals the *'truth'* about what is there is fundamentally a statistical problem (Russ 1986)

In microscopic image analysis the area of sample actually measured is very small in relation to a macroscopic sample of concrete or paste. It is also much smaller than the volume sampled in 'bulk' measures such as X-ray diffraction or mercury intrusion porosity. In image analysis it is usual to speak of a measured value as an *estimate* of the actual value for the whole sample. The reliability of this *estimate* depend on the number of measures made and on the heterogeneity of the sample. If the goal of image analysis is to quantify differences between samples

Typically if the measures from N fields are averaged an idea of the variation of this average (compared to that for a different N fields) is given by the *standard error* (=standard deviation/$\sqrt{N}$). Clearly increasing the magnification of an image facilitates the discrimination of the microscopical features, however this reduces area measured in a given field. For example at a magnification of ×1000, four times as many images are needed to cover the same area as at a magnification of ×500. Generally the benefits of analysing a larger area outweigh the advantages of improving feature discrimination, this is encapsulated in the phrase:

Do more less well

The effect in cement paste can be seen in the measures in Table I, where the standard error of the porosity measured from nine fields at ×320 is four times that of the measurement for nine fields at ×1000.

The *error* of a given set of measurements will also depend on the way in which the fields to be measured are chosen. The most efficient sampling strategy (i.e. that giving the lowest error for a given number of measurements) is *uniform random*, in which the first field is chosen at random and then the other fields are chosen in a uniform spacing from this field. Within reason it is also best to space the fields as far apart as possible to have measurements from throughout the specimen.

In cement pastes 10 images at a magnification of ×400, gives an error of around 7% for the estimate of the volume fraction of anhydrous cement, around 4% for the estimate of porosity and around 15% for the measurement of calcium hydroxide (Scrivener et al. 1987). The cement paste fraction in concrete is more variable and it is necessary to measure more than 20 images to get similar levels of accuracy at the same magnification. In the case of concrete it is necessary to 'edit out' the aggregate particles to obtain measurements relative to the cement paste fraction. To give some idea of the meaning of these kind of accuracy levels, the calculated volume fraction of anhydrous materials in a cement paste at w/c=0.4, before any reaction is 45.2% and for w/c=0.45, 42.3%, i.e. a difference of about 7%.

For more complex measures it becomes more difficult to assess the statistical reliability. For example, the distribution of phases in the interfacial transition zone between aggregate and cement paste in concrete varies considerably from place to place. Measurement of the microstructural gradient around one aggregate may be very different from that measured around a second. In order to assess, the average microstructural gradient, many images on different aggregate particles need to be measured. Crumbie (1994, Scrivener et.al. 1988) measured 50 images, but even this was insufficient to confirm that some of the differences between samples were *statistically* significant.

4.3 Progress in image analysis of cementitious materials

With image analysis one moves beyond, 'pretty pictures' with the aim of obtaining 'useful' numbers. It is an area of tremendous potential, but unfortunately one can easily end up with 'pretty', but not very useful numbers'.

In general one can say that the simplest measures are the best — i.e. volume fraction. Despite their simplicity such measurements can be very useful. For example the volume fraction of anhydrous material can be used to calculate the degree of reaction if the original w/c ratio is known. Measurement of the microstructural gradients around aggregate particles at different ages also enables the pattern of deposition of the hydration products to be deduced (Crumbie 1994, Scrivener & Pratt 1996).

The time necessary to make the requisite number of measurements is a major impediment to the further use of image analysis. However, given the time investment necessary it is even more important that the measures made should be those relevant for relating microstructure to properties. Here collaboration is necessary between researchers in different areas.

The big challenge for image analysis is the characterisation of the pores structure, due to the importance of the porosity in the durability of concrete. Here it is possible that progress can be made by linking 3 dimensional computer models of microstructure with real microstructures through measurements on 2D sections (Kunzel et al. 1997).

5. Environmental Microscopy

A major problem with classical electron microscopes is the need to remove free water from a sample before it can be exposed to the high vacuum. Therefore, there is considerable interest in the use of 'environmental' microscopes , in which samples can be kept 'wet', for the study of cement and concrete. The first environmental microscopes were transmission electron microscopes (HVEM) operating at a very high accelerating voltage of 1 million volts, which produced electrons with high enough energy to penetrate thick samples. Two types of 'environmental' cell were produced. In the first 'window' type the cement, and water, were contained completely between two thin windows and could be examined periodically during hydration (Double et al 1978). The disadvantages of this arrangement, was the relatively low resolution, due to the presence of the windows and the high w/c ratios needed for electron transmission. The morphology of hydrates in cement pastes is highly dependent on water cement ratio above about 1. C-S-H can form long thin needle like growths and long ettringite crystals are also favoured.

The second type of cell used was the differentially pumped apertures cell. Here there are two apertures above and two below the specimen, with an independent pumping system between them. The area around the specimen can be maintained at up to 300τ. This arrangement was used by Jennings and Pratt (1980) and by Scrivener (1984) — the micrograph shown in Figure 4 was taken in such a microscope. Here, cements pastes at realistic water cement ratios were used. Carbon coated grids were placed in the pastes and removed specified time intervals. Samples could be studied from very early times, limited only by the time to mix the samples and place the grid in the microscope. As drying is not totally prevented, the samples could only be studied for 10 minutes or so, before the hydrates became damaged by drying. Unfortunately these type of high voltage microscope were very expensive to maintain and the performance deteriorated with age, so they have now been dismantled.

In the late 80s, a totally different type of environmental *scanning* microscope (ESEM) was developed. The area around the specimen is separated from the rest of the microscope by a differentially pumped aperture and fairly high pressures can be maintained in the vicinity of the sample. The microscope uses the ionisation of the gas in the specimen chamber to amplify the emission of electrons from the sample so contribute to the image formation. The specimen stage can be cooled, such that it is possible to condense liquid water on the sample. However, it is misleading to expect that this enables the hydration of cement to be followed 'in-situ'. Firstly, unlike the HVEM, the incident electrons have similar energy to a conventional SEM (~15-25 kV) and so cannot penetrate far through water. Therefore if liquid water is present, one sees the surface of the water and not the cement underneath. Secondly, as discussed for high w/c ratios the microstructural development of cement is a function of the *system* of cement plus water, thus repeated wetting and drying of the sample is not representative of the conditions existing is a normal paste (this phenomenon has been studied by Damidot & Sorrentino 1996).

The main advantage of the ESEM is that samples can be examined without prior drying or coating as for the HVEM with environmental cell. Neubauer & Jennings (1996) have discussed the use of the ESEM for the study of cement paste and concrete. A major area they have developed is the study of shrinkage as a paste is dried in the microscope.

The design of the electron optics in the ESEM are not optimal for the detection of X-rays, so the sensitivity and precision of chemical microanalysis is lower than in an conventional SEM.

6. New techniques

6.1 X-ray microscopy

The refractive index of X-rays in solids is very close to unity. This means that X-rays cannot be focused by conventional lenses and it used to be thought that X-ray microscopy was impossible. However, monochromatic X-rays can be focused by diffraction through Fresnel zone plates. These are circular diffraction gratings comprised of concentric opaque and transparent zones, Figure 19. X-ray microscopy requires an intense source of soft X-rays, which can be produced by a synchrotron. The development of synchrotrons and the increasing precision with which zone plates can be made has led to rapid advances of this technique, which has been widely applied to biological materials. The principal advantage of X-ray microscopy over electron microscopy is that specimens do not need to by dried (can even be immersed in water) and there is much less beam damage. In addition, the X-ray wavelength can be 'tuned', to maximise or minimise the absorption by different elements (e.g; O, N, Fe, Mg, Co, Ni, Ca, F), so permitting a kind of chemical imaging. The best resolution achievable today by X-ray microscopy is about 50 nm (very similar to the resolution of BSE images for cement).

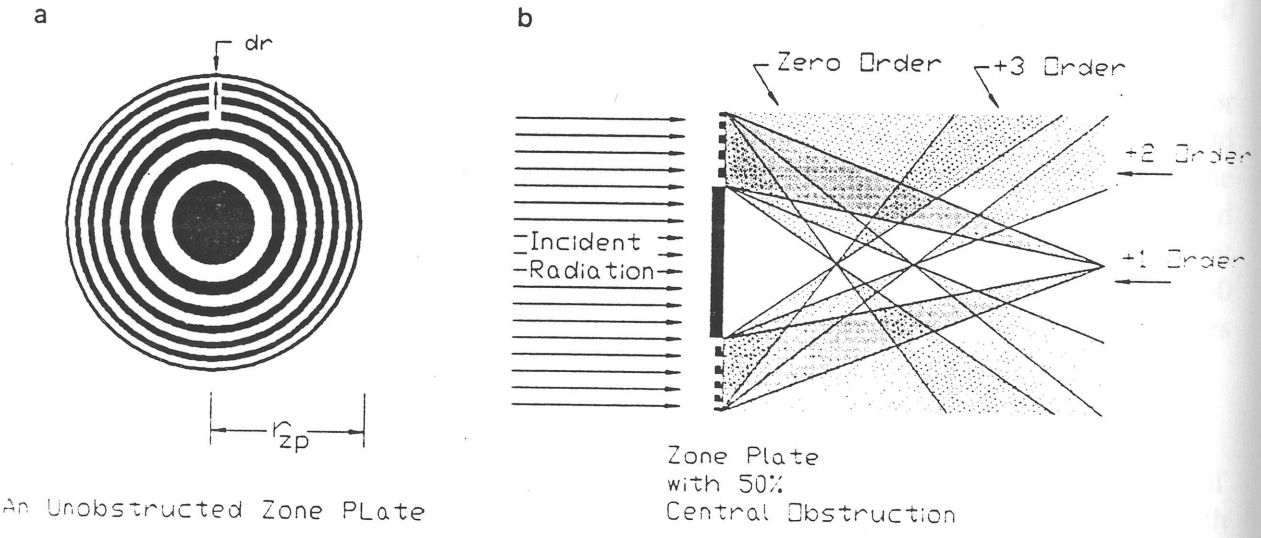

Figure 19. A Fresnel Zone plate and the principal of X-ray focusing with this device.

Soft X-ray transmission microscopy is being used to study cementitious materials by Kurtis et al. 1997, using the ALS (advanced light source) at the Lawrence Berkeley Laboratory in California. Figure 20 shows one of their images of an alkali silica gel in sodium hydroxide solution. The sample is immersed in the solution and the dissolution and repolymerisation can be followed 'in-situ'. This is clearly a technique with considerable potential.

6.2 Atomic force microscopy

In the atomic force microscope (AFM) a sharp tip is scanned over a specimen surface, with a separation between tip and specimen of about 10 Å. A force is generated between the specimen and the tip due to electron tunnelling, which is measured by the deflection of a cantilever on which the tip is mounted. The variation of the force across the specimen surface can be used to produce images of the surface relief, with atomic resolution (~2 Å) for suitable materials. This technique does not need to be operated under vacuum and images of solid surfaces can even be formed under water. Hall (1995) has used this technique, to study the dissolution and growth of gypsum and to image cement clinker under water. Mitchell et al (1996) have also studied the

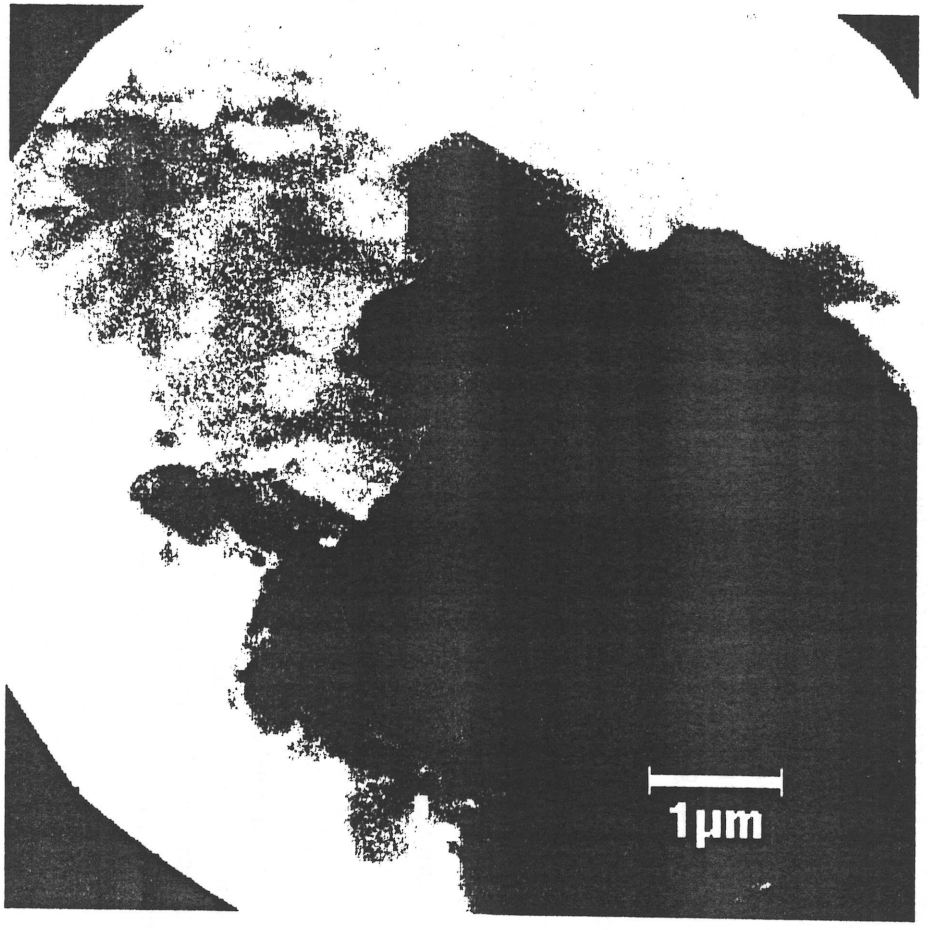

Figure 20. soft X-raytransmission microscope image of alkali silica gel
(courtesy of K.Kurtis and P.J.M. Monteiro, University of California, Berkeley)

surface of cement clinker, hydrated under various conditions. In the case of clinker, where, unlike gypsum atomic resolution, is not yet possible, the interpretation of the images is rather difficult, as there is no means of identifying the phases on the surface, only the overall relief of the surface is seen. Nevertheless this is a very new technique, which is developing rapidly and clearly or interest for the study of cementitious materials.

6.3 Imaging spectroscopies

Rapidly improving imaging capacities are being developed for many spectroscopic techniques — infra-red, Raman, NMR (nuclear magnetic resonance), SIMS (secondary ion mass spectroscopy), etc. As resolution develops these are becoming, in effect, microscopic techniques. The main benefit of this microscopic ability is the possibility to obtain spectra from local regions. At present most of these techniques have a fairly low resolution, typically 5 μm at best, which means that individual phases cannot be distinguished in hydrated cement and much of the advantage is lost. In some cases (e.g. infra-red, Raman) the resolution will be ultimately limited by the wavelength of the probe (as is light microscopy). Nevertheless this is a rapidly evolving field, in which it is clear that much progress will be made. The application of these techniques to cementitious materials is as much hampered by their complexity and lack of knowledge regarding crystal structures, as by the availability of the techniques themselves.

7. Concluding Remarks

The wide range of microscopical techniques available have much to contribute to the study of cementitious materials. Looking back only fifteen years, it is clear that our understanding of hydration and microstructure have advanced considerably in this time, due to improvements in imaging techniques and the wider availability of electron microscopes. However, it is important to remember that looking too closely, one may not be able to see the wood for the trees and that optical microscopy has an important role to play, not only for its convenience, but because larger areas can be studied, without undue drying of damage to the sample microstructure.

In the field of quantification of microstructure, through image analysis, there is tremendous potential, but progress is relatively slow. This is mainly because these techniques are inherently time consuming and the statistical aspects have not yet been extensively studied. Here I think progress must come from co-ordinated collaborative studies.

I have tried to give an idea of the limitations of techniques as well as their advantages, because I believe such knowledge is essential to the proper interpretation of the results. Microscopy is only one tool among a range of characterisation techniques, which can, and should, be used to advance or understanding of these complex materials. Hopefully so as to contribute to improving their performance and durability and to materials development.

DEVELOPMENT OF HIGH SLAG BLAST FURNACE SLAG CEMENT WITH AN IMPROVED EARLY STRENGTH

Andreas EHRENBERG, Eberhard LANG and Jürgen GEISELER
Forschungsgemeinschaft Eisenhüttenschlacken, Duisburg, Germany

ABSTRACT The aim of this investigation was the variation of parameters having influence on the early strength of blast furnace slag cements while the characteristic positive properties of slag cement should be ensured. The separately ground laboratory cements contained granulated slag among 45 and 75 wt.-%. The early strength has been increased by 70% with positive consequences for the early strength of the concrete, too. The relative compressive strength of concrete cubes after 2 days (β_2/β_{28}), which usually is about 20-30%, has been increased to 50%.

INTRODUCTION

Having the same 28-days compressive strength the blast furnace slag cements show, depending on their slag content, lower early strength after 2 days and higher final strength after 91 days (Smolczyk, 1980). This characteristic strength development is desirable and often necessary due to the low heat of hydration. On the other hand an improved early strength is required for some fields of application, for example to reduce the time needed for removing shutterings or prestressing.

AIM OF THE INVESTIGATIONS

In the past a lot of researchs has been carried out to clarify the mechanisms having influence on strength development of blast furnace slag cements and to improve their early strength. During the first half of this century many scientists developed the fundamental knowledge on the hardening behaviour of slag cements (Passow, 1908, Grün, 1924+1928, Lea, 1935, Keil, 1949, Kühl, 1950, Taylor, 1964). On the basis of these results during the second half of the century the knowledge has been further developed. Summarizing the results of these investigations it can be stated that following factors can improve the early strength of blast furnace slag cements:

- increasing lime saturation factor and sulfate content, decreasing alkali content of the clinker (Frigione and Sersale, 1985, Smolczyk, 1981)
- high C_3S, low C_2S content of the clinker (Kollo, 1991)
- increasing contents of CaO, MgO, Na_2O, Al_2O_3 and decreasing contents of SiO_2, FeO, TiO_2, MnO, MnS of the slag (Kollo and Geiseler, 1987, Kollo, 1991)
- high glass content of the slag (Keil, 1963, Erntroy, 1992)
- optimal SO_3 content and initiation conditions for the latent hydraulic granulated blast furnace slag (Ludwig, 1968, Frigione, 1984, Sersale, 1992, Dahlhoff, 1994)
- mixtures of Sulfatetypes (Schwiete, 1963, Ludwig, 1968)
- reactive or inert fine minor additional constituents (Payá, 1995)
- increasing fineness (Dahlhoff, 1994)

Each of these parameters presents a different potential of optimization, but not each of them can be realized within a technical scale. With respect to given raw materials for clinker and iron production changes of the chemical composition are not possible in most cases. Both the material and transport costs and the availability of the materials play an additional important role. Within the frame of the investigations discussed below possibilities should be developed to improve the early strength of blast furnace slag cements *without* decreasing the proportion of granulated slag

and *without* changing the chemical composition of the cement constituents. The proportion of slag has essential importance for a lot of special positive slag cement and concrete properties (Geiseler and Lang, 1994). These properties, like low heat of hydration, high resistance against chemical and sea water attack, high sulfate resistance and resistance against alkali-aggregate-reaction and low conductivity, should be insured. In the same way the transferability of optimized mortar characteristics to the concrete is of high importance. Therefore some concretes using optimized blast furnace slag cements and trade cements should be produced and tested.

EXPERIMENTATION

More than 160 laboratory cements with slag proportions among 45 and 75 wt.-% using 3 clinkers, 7 different slags, 5 sulfatetypes and 2 fine minor constituents have been characterized. The influences of the specific surface of the ground granulated slag and the clinker, of the grain size distribution, of SO_3-content and the types of sulfate have been investigated (Ehrenberg and Lang, 1996). The materials resulted from current industrial production. As reference cements 4 trade cements (1 Portland cement, 3 blast furnace slag cements with different contents of slag) have been chosen. The chemical composition of the slags used in laboratory cements represents the average of German granulated blast furnace slags. The investigations have been performed according to DIN EN 196. Using slag cements with an increased early strength additionally 12 concretes have been investigated. **Table 1** shows the test program.

Table 1: Test program

Parameter	Quantity	Variation
Constituents:		
blast furnace slag	7	Al_2O_3: 11,4 - 14,6 wt.-%, C/S: 1,07 - 1,34
Portland cement clinker	3	C_3S: 56,2 - 69,4, C_2S: 7,3 - 18,4, C_3A: 7,6 - 11,2 wt.-%
type of sulfate	5	anhydrite II (AH), natural anhydrite/dihydrate-mixture, natural gypsum, desulfogypsum (by-product), β-hemihydrate (HH)
Cements:		
ratio slag / clinker	4	0/100, 45/55, 60/40, 75/25 (wt.-%)
sulfate content	3	2, 3, 4 wt.-%
specific surface (slag)	6	2100 - 8000 cm²/g (Blaine)
specific surface (clinker)	5	1700 - 6200 cm²/g (Blaine)
grain size distribution (slag)	6	d' = 42,1 - 8,7 µm, n = 0,92 - 0,85 (RRSB-grid)
grain size distribution (clinker)	5	d' = 48,2 - 8,8 µm, n = 0,89 - 0,80 (RRSB-grid)

Cement characterization:	**Mortar characterization:**	**Concrete characterization:**
water demand	spread	spread and raw density
setting time	compressive strength (prisms)	air pore volume
volume stability	flexural strength	compressive strength (cubes)
	dyn. E-modulus	porosity/pore size distribution
	bound water	carbonation depth

A detailed discussion of all results is beyond the scope of this paper, therefore only some aspects of the investigations carried out will be discussed.

RESULTS AND DISCUSSION

Proportion and composition of granulated blast furnace slag

Independent of the chemical composition of the slags the early strength clearly decreased with increasing proportions of slag. In consideration of constant parameters cements including granulated blast furnace slags with higher contents of Al_2O_3 and higher CaO/SiO_2 (C/S) ratios showed higher early strength. For example, slag cements with a slag/clinker ratio of 75/25, specific surfaces of 4900 cm^2/g (slag) and 4200 cm^2/g (clinker), anhydrite II and a SO_3-content of 4 wt.-% had the lowest 2-days strength using a slag with 11,9 wt.-% Al_2O_3 and a CaO/SiO_2 ratio of 1,07 but the highest 2-days strength using slag with 14,6 wt.-% Al_2O_3 and a basicity C/S of 1,34. However it has to be stated, that the influence of the chemical composition within the investigated frame is lower than the influence of other parameters like the specific surface or the sulfate content.

Proportion of minor additional constituents

As additional constituents Microsilica (slurry) and white lime hydrate (powder) have been used in the range of 1-5 wt.-%. The mean diameter d' (RRSB-grid) of these materials was 1,7 µm (Microsilica) and 9,1 µm (lime hydrate) and the slope of the grain size distribution was 1,12 (Microsilica) and 1,03 (lime hydrate). The use of these materials in slag cements with slag/clinker ratios of 60/40 and 75/25 in all cases led to an improved strength development. Especially the early compressive strength has been increased by about 50-80% (60/40) and 20-60% (75/25) respectively; the relative compressive strength of mortar bars after 2 days (β_2/β_{28}) increased from 0,22 to 0,30-0,34 (60/40) and from 0,30 to 0,34-0,42 (75/25) respectively. Using 5 wt.-% Microsilica the capillary porosity (pores > 30 nm) in the age of 2 days has been decreased from 24 to 17 vol.-%; the matrix of the cement stone showed a higher density. However the use of the fine additions impaired the processing characteristics. For example the spread of mortars including Microsilica decreased from 15,5 to 13,6 cm (60/40) and from 15,6 to 13,2 cm (75/25) respectively; the water demand increased from 26,5 to 29,5 wt.-% (60/40) and from 27,5 to 29,5 wt.-% (75/25). These problems occur in general in the case of mixing cement constituents with additions having very high specific surfaces without a control and modification of the grain size distribution. **Fig. 1** shows the results for mortars using slag cement with a slag/clinker ratio of 75/25 and 5 wt.-% additional constituents.

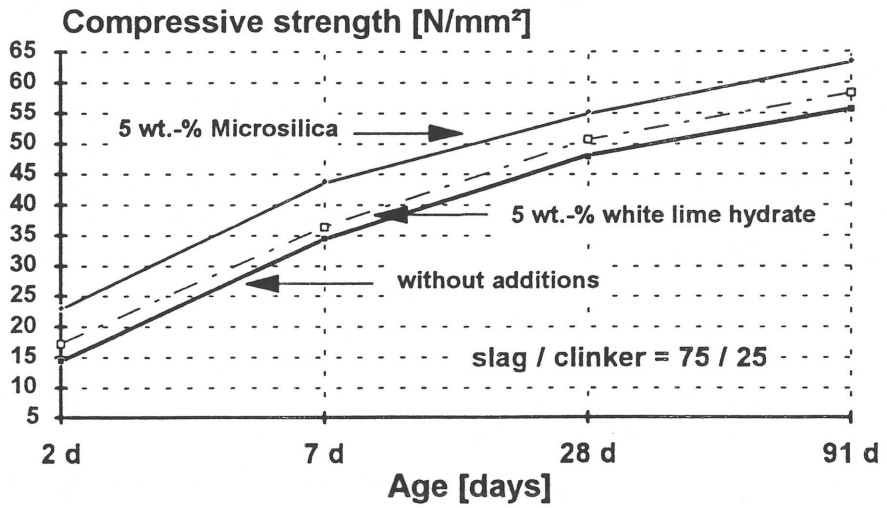

Figure 1: Influence of Microsilica and white lime hydrate on the strength development of blast furnace slag cement

Specific surface of the main constituents

Fig. 2 shows the 2-days compressive strength for different slag/clinker ratios. While the specific surface of the granulated blast furnace slag has been increased from 2100 to 6300 cm²/g other parameters have been left unchanged (4 wt.-% SO_3, anhydrite II, specific clinker surface 4200 cm²/g). Increasing the slag fineness from 2100 to 3500 cm²/g increased the 2-days compressive strength by 11 N/mm² or 20% per 100 cm²/g. But increasing the slag fineness by the same amount of 1400 cm²/g from 4900 to 6300 cm²/g raised the 2-days strength only by 1,6 N/mm² or 1% per 100 cm²/g. These examples make evident, that the possibility to compensate a lower early strength by a higher specific surface is limited mainly to lower and medium surface values. The investigations led to the result, that the aim of a higher early strength of slag cements requires a minimum fineness of the ground granulated slag which should be about 3500 cm²/g. But on the other hand increasing the slag fineness above a upper limit leads to only a small raise of the early strength which often does not justify the higher energy input to grind the slag finer.

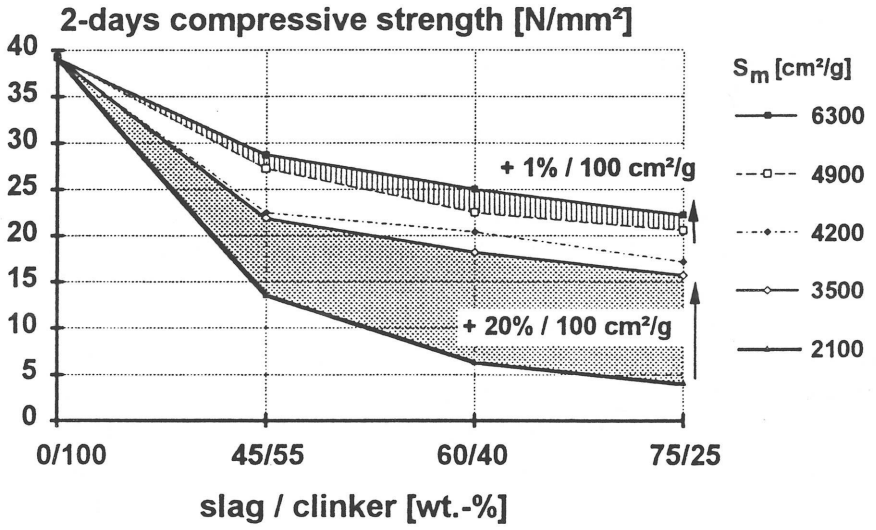

Figure 2: Increase of the compressive strength by increasing the specific surface (S_m)of the granulated blast furnace slag

Grain size distribution of the main constituents

To describe the fineness of a material there are used two methods: Measuring the specific surface (Blaine, BET) and the grain size distribution (laser granulometry, sedimentation analysis). But it is well known, that with a constant specific surface different grain size distributions can be connected. The mean diameter d' and the slope of the grain size distribution n (RRSB-grid) have a big influence on the behaviour of powder materials like cement. Therefore these parameters deliver more informations with respect to the water demand and other properties. The slope of the grain size distribution depends on the individual milling aggregate, the milling conditions like feed material or grinding media filling ratio and the characteristic of the material being ground. The investigations showed, that using one laboratory ball mill for different kinds of material (slag, clinker, sulfates) led to nearly constant values of n in the range of 0,80-0,95. Considering only *one* milling aggregate ($n \approx$ constant) the mean diameter d' and the specific surface are corresponding in an almost linear way. Therefore an increasing early strength as a result of increasing specific surfaces was connected with lower mean diameters. Additionally therefore the grain size distribution has been modified by mixing ground slags from different mills: The mixed slag cements show wider grain size distributions (n = 0,65-0,72) and mean diameters in the range

of 13-25 µm. Using these mixed slag cements it is possible to raise the early strength without any disadvantageous influence on water demand or spread. Summarized it can be stated that a lower mean diameter and a wider particle size distribution of the ground slag and of the cement have a positive influence on the strength development, especially at early age. **Fig. 3** shows one example of the results obtained by these investigations, which shall be continued.

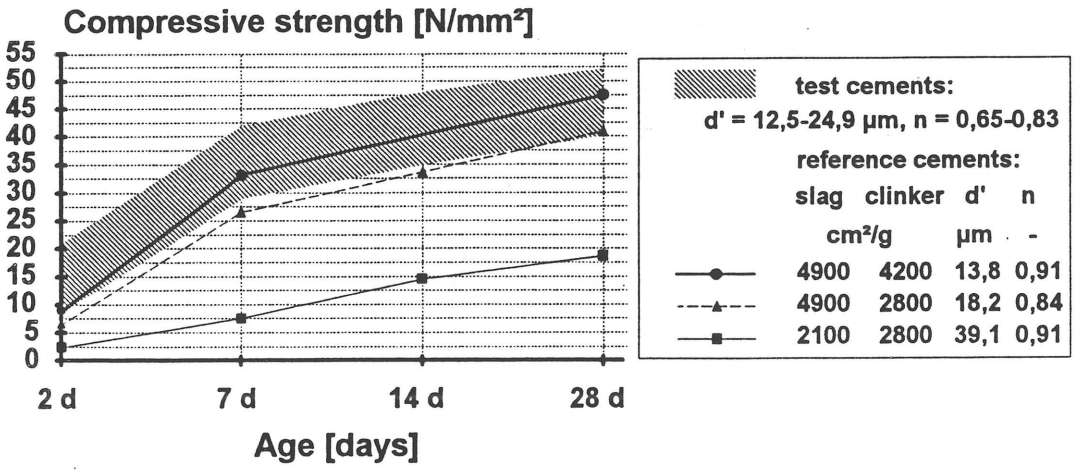

Figure 3: Increase of the compressive strength by variation of the grain size distribution (slag / clinker = 75 / 25, 4 wt.-% SO_3, HH / AH = 15 / 85)

Sulfate content of the cement

The sulfate content is important for regulating the setting and hydration characteristic of cements. Among others the optimal value depends on C_3A-content of the used clinker and the slag/clinker ratio; usually slag cements need a lower sulfate content to delay the setting. But especially for slag cements the early strength development is strongly influenced by the sulfate content, too. So the variation of the SO_3 content in slag cements with different slag/clinker relatios among 2-4 wt.-% showed, that in most cases a sulfate content of 4 wt.-% led to the highest early strength; 2 wt.-% sulfate led in more than 160 laboratory cements to the lowest 2-days strength. In some but not all cases a small decrease of the 28-days compressive strength was connected with the increase of the early strength. The results verify those of Frigione (1984) and Soroka (1986). In **Fig. 4** the change of the 2-days compressive strength by variation of the sulfate content is presented, resulting from 45 different blast furnace slag cements with 5 slags, 2 clinkers and anhydrite II. Only the limit lines of all test results are plotted. The positive effect of increasing SO_3-contents for cements with lower slag contents is evident; with higher slag/clinker ratios the test results deviate more from another. Therefore this effect is not ascertainable in the same extent. This seems to be an indicator for the dominant interaction of sulfate content and clinkerphases like C_3A and C_4AF forming ettringite, monosulfatehydrate and tetracalcium hydroaluminoferrite. With respect to the decrease of the early strength with increasing slag contents (see shifting the strength level of the grey fields within **Fig. 4**) it is possible to partly compensate the strength loss by optimization of the SO_3-content.

Type of sulfate

The solubility and the solution velocity of the sulfates are important for the setting and the early strength. Both are depending on the type of sulfate, the fineness and the distribution in the cement (Soroka, 1984). For example the solubility of sulfate variates, depending on the temperature, between 0,18 g/100 cm³ (dihydrate), 0,38 g/100 cm³ (anhydrite II) and 0,83-1,01 g/100 cm³ (α-, β-hemihydrate). The reactive specific "inner" surface of different types of

sulfate is different, too. Having the same surface according to Blaine the BET surface of hemihydrate is 4times higher than that of anhydrite. The investigations showed, that substituting anhydrite II totally by other types of sulfate led to lower 2-days-strength by up to 30%. But small additions of β-hemihydrate (HH/AH = 15/85 - 35/65 corresponding to 0,5-1,4 wt.-% SO_3 from HH) in cements with higher slag contents led to a raise of the 2-days strength in the range of 3 N/mm². This experience is verified in industrial scale by partly dehydration of natural gypsum during the milling process. Elder investigations have shown, that SO_3 contents more than 2-3 wt.-% resulting from hemihydrate response "false setting". The initial set has been prolonged from 250 min (AH) to 305 min (HH/AH = 15/85), the setting time of 40-45 minutes was not influenced significantly. **Fig. 5** shows an example with results for slag cements with a slag/clinker ratio of 75/25 and a total sulfate content of 3 wt.-% (clinker: 4200 cm²/g, slag: 4900 cm²/g).

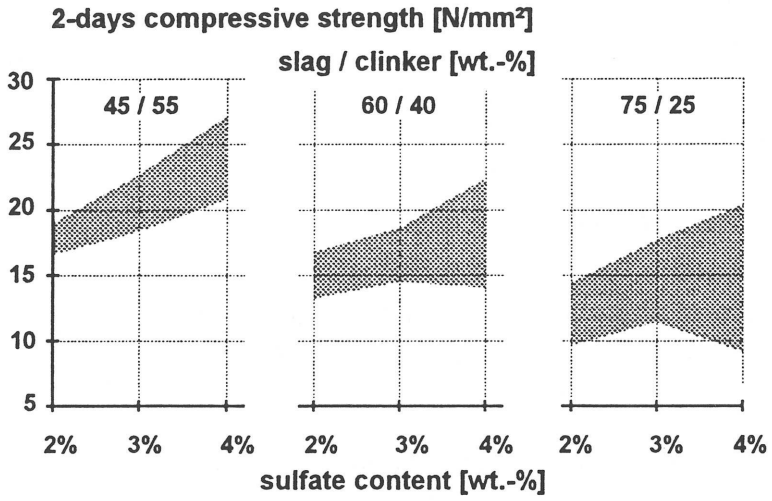

Figure 4: Change of the compressive strength by variation of the sulfate content (results from 5 slags, 2 clinkers and 45 blast furnace slag cements)

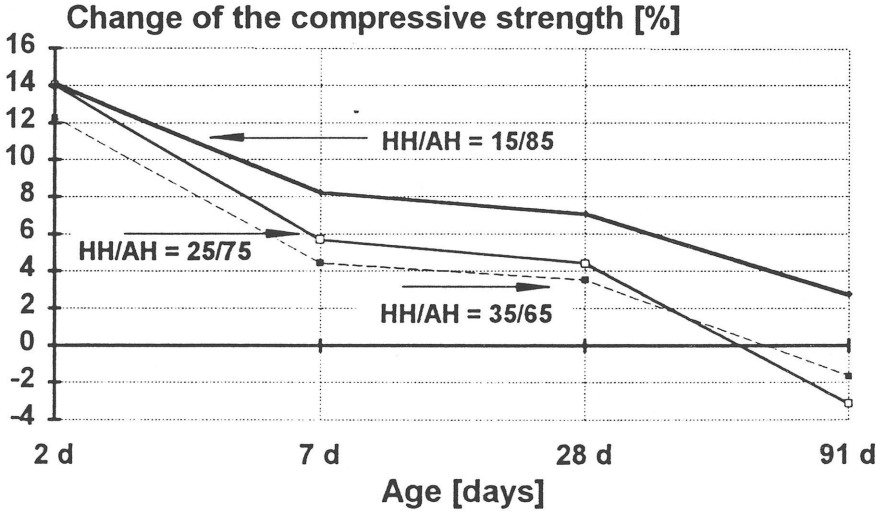

Figure 5: Influence of β-hemihydrate (HH) on strength development (slag / clinker = 75/25, 3 wt.-% SO_3)

Concrete investigations

With 6 slag cements, optimized with respect to their sulfate content and specific surface, 1 Portland cement and 3 trade slag cements using the same clinker and slag like in the laboratory investigations 10 concrete mixtures have been tested in laboratory scale. For the concretes 350 kg/m³ cement, 1850 kg/m³ aggregate (Rhine gravel and sand) and a water/cement ratio of 0,50 have been used. **Fig. 6** shows a good linear correlation of the compressive strength of mortars and concretes (coefficient of correlation = 0,96, standard deviation s = 4,6 N/mm²). This strong correlation is partly based on the constant laboratory conditions. But it is cognizable, that the strength potential of optimized slag cements determined on mortars can be transferred to concretes, too.

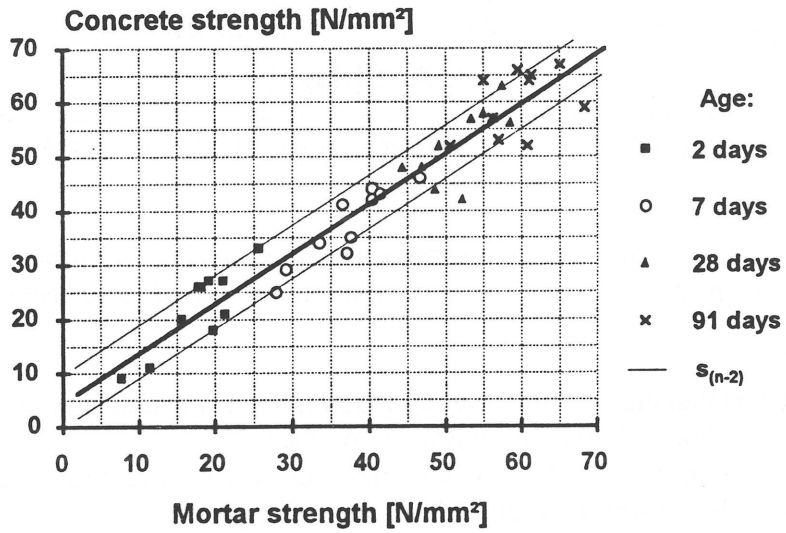

Figure 6: Compressive strength of laboratory mortars and concretes

Compared with trade cements the optimization of slag cements led to an increase of the early strength of mortars in the range of 20-70%. This increase had positive consequences for the early strength of the concrete, too. The relative compressive strength of concrete after 2 days (β_2/β_{28}), which usually is about 0,2-0,3, has been raised to 0,4-0,5, as illustrated in **Fig. 7**. The laboratory slag cements Z 8 and Z 9 have slag/clinker ratios of 75/25, the corresponding trade slag cement of 78/22. The specific surface of the slag and the clinker within both laboratory cements was 4900 cm²/g and 4200 cm²/g respectively; the sulfate content of Z 8 was 2 wt.-% and of Z 9 4 wt.-%. For the production of the trade slag cement CEM III/B 32,5 NW HS (NW: low heat of hydration, HS: high sulfate resistance) and of the laboratory cements the same clinker and slag have been used. The specific surface of the trade cement was 3900 cm²/g, the mean diameter d' was 15,9 µm and the slope n was 1,09; the sulfate content was 1,2 wt.-%. Using higher SO_3-contents, higher specific surfaces, lower mean diameters (Z 8: 13,1 µm, Z 9: 12,8 µm) and a wider grain size distribution (Z 8: 0,94, Z 9: 0,92) a higher early strength of the concrete between 122 and 189% has been realized. The relative 2 days strength (β_2/β_{28}) increased from 0,21 to 0,42 (Z 8) and 0,50 (Z 9). Therefore it can be stated, that the increased early strength of optimized slag cements was transferred to the concrete, too. The investigations will be continued by further optimization of the grain size distribution of slag cements.
