The necessity of obtaining by control insulation that would effectively perform during operation of the concrete structure, brings us face to face with the need to separate the function of the insulation from that of the protected structure (factory stacks, tanks, cooling towers, etc.). This is yet another proof of the imperative *need to approach the solution to the problem of the durability of concrete and concrete structures on a complex basis*, particularly in the presence of strong aggressive media.

Correct sharing in the task by the durability or resistance of concrete, and by the protection of concrete structures must be effected with a view to the given specific conditions.

Role of Maintenance and Repair of Concrete Structures

Maintenance and repair of concrete structures are important factors of both physical and economical durability.

The task of systematic maintenance consists in ensuring for a structure the same conditions as have been considered in its static and technologic solutions. Systematic control and regular, timely maintenance can restrict or completely eliminate the usual cuases of pathologic state of a structure. They include: inappropriate foundation and uneven settlement, inferior quality of components, improper composition and placing of concrete, wrong type and insufficient support of formwork, imperfect curing of concrete during hardening, etc.

From the long-time point of view (durability), even isolated overloading of the structure, producing no effect on its instantaneous strength, can be the cause (cracks) of an unfavourable development of reinforcement corrosion and structure durability. Special care should, therefore, be accorded to concrete structures as regard the state and causes of crack formation in concrete.

The durability of structure—even of a high-quality one—is generally threatened in yet another way, namely by excessive wetting of the structure by rain or other water. This risk becomes particularly serious if the structure is periodically exposed to the action of frost. Regular maintenance and control of the draining system play, therefore, an outstanding role in the durability of concrete and concrete structures thus exposed. Bearing in mind that water in concrete is the cardinal factor of almost all deteriorating processes that occur in it (frost, dissolving, chemical reactions), the speediest possible withdrawal of water should be provided for structures built above the ambient water level.

The object of repairs is to stop the progress of deterioration and to restore the structure to its original safety both instantaneous and long-term, as implied by the required durability.

The efficiency of repairs is to a considerable extent dependent on the quality of the bond between old and fresh concrete. The demands made on the tech-

nique and quality of repairs in this respect are very high indeed. Some of the modern materials, such as epoxy resins, offer us hitherto unheard of possibilities of effective repairs of deteriorating concrete structures.

The Bond and its Significance for the Durability of Concrete

Deterioration of concrete by various agents can essentially take place on three fronts: hardened cement paste, aggregates, and the joints.

Deterioration of the texture of concrete depends on: magnitude of the deteriorating action of the medium (internal stresses produced by freezing of concrete, volume changes, osmotic pressure, crystallization pressure; weakening due to dissolution of components), strength of concrete, the tensile one in particular.

The importance of the bond for the durability of concrete can thus be assessed also indirectly, from the properties of the joint relative to those of hardened cement paste or aggregates (rock). Generally speaking, the effect of the aggregate-cement bond is the greater, the larger the specific surface of aggregate grains.

Effect of the Bond on the Mechanical Properties of Concrete

The case that decides about the failure of the joint is that in which it is stressed by tension with shear also coming unfavourably into effect. The importance of the bond is given by low strength of the joint relative to both hardened cement paste and the currently used rocks of aggregates.

Direct tests of flexural strength of various rocks, hardened cement paste and the joint after 28 days afford us a clear picutre of the bond and of the fractured and the cut joint (Fig. 9) (113). This is one of the reasons why aggregate grains separate from cement in the course of concrete disintegration.

Effect of the Bond on Concrete Permeability

Even though the joints between aggregate grains and cement form no continuous channels for the flow of water through the texture of concrete, they can nevertheless substantially affect penetration of water in concrete. As direct tests of the joint permeability in relation to the permeability of the adjacent rock and hardened cement paste have clearly shown, the permeability of the joint is many times greater than that of the other two components. Equivalent breadth of the joint as expressed by hardened cement

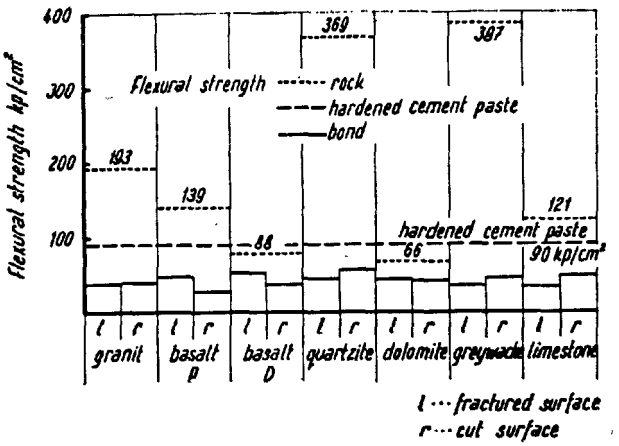

Fig. 9. *Bond of cement with different rocks (113)* .

paste was several cm and grew rapidly by frost action.

Effect of the Bond on the Durability of Concrete

The relatively low strength of the joint and the increased possibility that water can enter it, are the reasons of its low durability whenever moist concrete is exposed to the action of alternate frost.

According to direct durability tests of prisms ($4 \times 4 \times 16$ cm) made in part of rock, in part of cement paste, the frost resistance of the joint under flexure is very low. A typical example of the results obtained for granite is in Fig. 8 (113).

Notwithstanding the fact that in concrete ingress of water in the joint is not so easy as it is in the test prisms, the above is a clear evidence of the important part that the bond between aggregate grains and cement plays as regard the durability of concrete and the mode of its deterioration by alternate frost and other aggressive agents, particularly in the case of aggregate grains with a smooth surface (natural gravel and sand).

The examples of results achieved with various rocks quoted above, bear clear evidence as to the general importance of the aggregate-cement bond and in turn of the necessity of

a) thorough scientific studies of the contact zone and of the conditions for a perfect bond (up to the ultimate strength of one of the components),
b) practical measures that will lead to the creation of favourable conditions for a perfect cement-aggregate grains bond (clean surface, suitable treatment of the surface of grains, etc.).

Analysis of Concrete Deterioration by Aggressive Agents and by Deteriorating Processes

Depending on the purpose for which it is intended and on the local climatic and other conditions, concrete of structures is exposed to the effect of a whole number of aggressive agents and otherwise deteriorating factors. Several such agents combine in their action as a rule. Irrespective of this, a separate analysis of the action of each agent must be made in order to ascertain the basic conditions, kinetics and final effect of each of them on concrete properties in measurable relationships.

The relationships that we are thus attempting to elucidate are both qualitative and—that mostly—quantitative, and we need them to express the degree of deterioration as a function of the intensity and duration of the external action.

External factors of the durability of concrete. Using the main effect on the gradual deterioration of concrete, we can classify them in four groups (Table 1).

Basic Processes of Concrete Deterioration

The effects of various deteriorating factors and processes of mechanical, physical, chemical and biological nature on concrete can be subdivided in three basic categories:

1—*internal or surface stresses* due to non-homogenous volume changes in concrete, or to mechanical action such as impacts, friction, cavitation, etc. This group also includes the effect of temperature and humidity variations, volume changes caused by freezing of water in closed pores.

2—*dissolving and washing away of soluble components*—cement in particular—from concrete. This leads to a loss of strength, especially of tensile strength because of loss of: binder (cement) cross section, and cement-aggregate bond.

3—*chemical reactions and physico-chemical processes* leading to the formation of voluminous salts or to osmotic pressures. Loss of concrete strength mostly in tension is then caused by: reduced strength of concrete components, reduced cement-aggregate bond, and internal pressures (salts, osmotic pressure).

An analysis of deteriorating processes is also important for quantitative observations by appropriate test methods.

Important criteria for the properties of concrete and of its components bearing on the durability, are another of its results. Among them are:

i) tensile strength of hardened cement paste, ii) cement-aggregate bond, iii) permeability (or absorptivity and capillarity) of concrete and iv) chemical resistance of cement (hardened cement paste) to aggressive waters, acids, sulphates, etc.

The processes of concrete deterioration just outlined are related to certain concrete properties that necessarily result from the properties of the components, composition, placing and the resultant mechanical and physical properties of concrete.

It is, therefore, possible to deduce for concrete and its components, the favourable properties they should have and the requirements they shoud meet to resist the above-enumerated basic processes of concrete deterioration (Table 2).

Some of the requirements have general validity and include:

i) homogeneity of concrete, ii) low permeability and absorptivity of the components and of concrete, iii) appropriate system of pores, abundance of binder, air-entrainment, water-cement ratio, compaction, iv) high bond and tensile strength, v) effective protection

Table 1. *Classification of aggressive agents and their action*

Group	Specification	Effect on concrete
mechanical effects	load, overload and shocks	cracks, mainly in binder
	impacts and friction	erosion, crushing
	flow water and air	erosion, cavitation
physical effects	temperature variations and differences	cracks, peeling off, bond failure
	humidity changes and non-uniformity	cracks and bond failure
	frost (alternate)	cracks and bond failure, peeling off
	fire and high temperatures	cracks, chemical changes
	electric current and radiation	reinforcement corrosion, binder dissolution
chemical effects	air and other gases	binder dissolution, H_2S, SO_2, CO_2 and NH_3 reactions
	aggressive waters	binder dissolution, reactions: H_2SO_4 sulphates, carbon waters, chlorides
	chemicals	reactions of acid salts and acids
	soil and soil minerals	reactions of weak acids, sulphate salts, zeolites
biological effects	vegetation	cracks, etching by juices, moisture
	microorganisms (bacteria, microscopic forms of organic life)	formation of sulphates, mechanical weakening of texture

of reinforcement, vi) appropriate curing at the initial stage of hydration (moisture).

Relative Importance of Aggressive Agents

The importance of various aggressive agents or deteriorating processes for the durability of concrete is generally a function of a number of conditions, and after all, of the criterion of evaluation. It is also among others a function of local conditions. Irrespective of this it is necessary to know—from a higher, international aspect—the relative importance of the various causes of concrete deterioration—no matter that they might be evaluated in terms of the extent of failure they produce.

The RILEM Technical Committee for the Durability of Concrete and Concrete Structures in which participate all the principal countries where concrete durability is of major engineering and economical significance, has made an inquiry to determine the

Table 2. *Requirements on the components of durable concrete for different classes of its deterioration*

Concrete	Component	Class of concrete deterioration		
		1 Stresses by mech. effects and nonhomogeneous volume changes	2 Dissolving and leaching	3 Compounds of increased volume, osmotic pressure
Cement	Physical	Reduced fineness	Reduced fineness	—
	Chemical	$C_3S > C_2S > C_3A > C_4AF$	Low CaO content	Low C_3A, C_4AF contents, high C_2S content, low CaO content, low MgO, low alkalies content
Aggregate	Physical	Adequate coef. of thermal volume changes. Low absorption Reduced mica content. Reduced relative volume changes by absorption.	Low permeability and absorption	Low permeability and absorption
	Chemical	—	No soluble components No alterable rocks	No FeS_2 No active SiO_2 (alkali reaction) No $CaMg(CO_3)_2$
Admixtures	Physical	Gas forming admixtures.	Air entraining or combined effect admixtures Waterproofing admixtures.	
	Chemical	Pozzolanas } with air- Blast furnace slag } entrainment	Pozzolanas Blast furnace slag.	Pozzolanas Blast furnace slag, No $CaCl_2$
Hardened cement paste	Physical	Low w/c	Low permeability and absorption	
Bond	Physical		Reduced relative volume changes Rough clean surface, low permeability	
	Chemical	—	—	No active SiO_2 in aggregate No $CaMg(CO_3)_2$
Water			No acid waters, both anorganic and org No polluted waters	
Reinforcement			No chlorides Air entraining or combined effect admix Low permeability and absorption of concrete cover Effective cover thickness Surface treatment of reinforcement—use of corrosion inhibitors	
Composition, placing and condition of hardening of concrete	Physical		Plain concrete with adequate quantity of cement to fill up small pores and cover the grains surface Low w/c for good workability Adequate air content Homogeneity—avoid segregation (in mixing, transport and placing) Impermeable construction joints. Adequate surfacing Avoid loss of water by evaporation (shuttering, impermeable membranes, surface protection) Adequate temperature for hydration	
	Chemical		Avoid excessive carbonation Surface treatment by fluorosilicate	
Mechanical and physical properties of concrete			Homogeneous concrete Low permeability and absorption High tensile strength Adequate air pore system	

relative importance of the various factors. The following criteria were considered:

11 modes of concrete deterioration

alternate wetting	crystallization of salts	sulphates
alternate frost	abrasion	acids
reinforcement corrosion	internal stresses	aggregate reaction
leaching	external stresses	

5 classes of structures according to their exposure
i) indoor concrete with normal atmosphere, ii) indoor concrete with condensation and aggressive vapours or gases, iii) outdoor covered structures, iv) outdoor exposed structures, v) underground structures, structures exposed to chemical effects

3 degrees were used for the classification
0—comparatively little importance
1—some importance
2—general importance

Although this system of the modes of concrete deterioration, the internal and external stresses in structures in particular, could be subject to discussion, the results of the inquiry are of outstanding general significance for the future trend of research and cooperation. This is the sequence of the modes of concrete deterioration resulting from the inquiry:

1 reinforcement corrosion
2 sulphates
3 alternate wetting
4 alternate frost
5 leaching
6 acids
7 internal stresses
8 external stresses
9 crystallization of salts
10 aggregate-cement reactions
11 abrasion

The slight difference between the points given to alternate wetting and alternate frost and leaching is evidently due to the circumstance that the effect of alternate frost like that of leaching is conditioned by the presence of water in concrete.

Physical and Mechanical Properties of Concrete Important for the Durability.

The action of aggressive agents on concrete and its results depend on:

the character of the agents in relation to concrete and its components (chemical nature, concentration, etc.),
the possibility of their action (permeability, porosity, capillarity, etc.),
the resistance of concrete and its components to stresses produced by the majority of disintegrating process (tensile strength, cement-aggregate bond).

The presence of water and the possibility of its ingress in concrete is the decisive factor of most deteriorating processes.

Of the physical properties of concrete (and of its components), the following are the most important: *porosity*, *permeability*, *capillarity* and *absorptivity*.

Porosity of concrete and its components

Porosity of concrete is given by the porosity of concrete components and by pores in the cement paste-aggregate joint. Generally speaking, systems of pores differ one from another and are very closely linked with mechanism of formation of the texture of each component. Considering the possibility of water and gas penetrating in concrete, two general classes of pores (Fig. 10) may be distinguished:
open or accessible pores connected to the remaining pores and to the surface; they may be accessible from one or from both sides;
closed, inaccessible pores, without connection to the remaining pores or to the surface.

Closed pores come into play only in the mechanical properties of concrete. Open pores are a very important factor in permeability, capillarity, absorptivity and durability of concrete.

According to their form and origin, pores can be classified in the following three kinds:
cells (bubbles)—characterized by three roughly equal dimensions,
cracks or lentils—with two predominant dimensions,
channels—with just one predominant dimension.

The way pores affect the mechanical and physical properties (tensile strength, permeability, absorptivity,

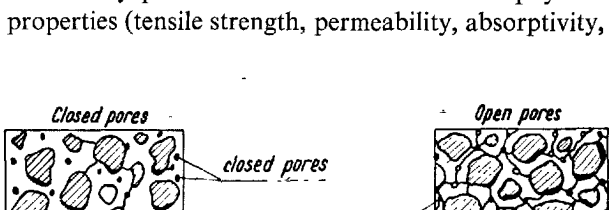

Fig. 10. *Porosity of concrete*

capillarity) essentially differs from one kind to another. The most unfavourable from mechanical aspects are cracks. Continuous channels sometimes linking onto cracks, play the biggest part of all as regard permeability inasmuch as they appreciably facilitate flow of water through the texture. Pores accessible from one side as well as discontinuous channels, exert their effect mostly by air cushions during expansion of freezing water.

To be in a position to exactly estimate the effect of porosity on mechanical and physical properties, we must acquire detailed knowledge of pore morphology, size and distribution. Tests of directional permability, absorptivity and capillarity are likely to afford us at least integrated data on the properties of the system of pores under study; Experimental data of this sort depend, however, also on the effect of applied pressure and accordingly, water pressure, too, becomes an important criterion in pore system studies. The phenomenon is exploited in modern engineering practice of air-entrained concrete. These phenomena should be taken into account in research and test methods which must be based on physical properties independent of those factors whose effect is to be expressed by physical laws of general validity.

Whereas the porosity of aggregates (rocks) can merely be determined and taken in consideration when choosing the aggregates, we are in a position—partially at least—to adjust the porosity of cement paste and the joint. This the basis of the successful technique of air-entrained concrete (90).

If air bubbles are to play a role favourable from the point of concrete frost resistance, they must be connected into the spatial system of capillary channels, be uniformly distributed in the texture of cement paste, have adequate (small) spacing. The length of and the flow conditions in the channels eventually decide about the inner pressure (tension) in concrete and about the suitability of the system of pores, exert highest possible effect at small total air content.

Air bubbles can play their favourable role only in the space taken up by cement paste. As their spacing varies in reality, we should consider that corresponding to a uniform bubble distribution. The size and hence also the number of air bubbles per unit volume of air bubbles is under otherwise identical conditions a function of surface tension and thus of the properties—efficiency—of air entraining admixtures. The total air content of hardened cement paste, and the more so of concrete with aggregates of diverse size, is therefore, not an adequate criterion of efficient air entrainment.

Neither is the total air content of concrete a suitable criterion of the actual degree of air entrainment. T. C. Powers has correctly referred his spacing factor to the volume of cement paste. In this way specification of air entrainment of concretes with different aggregate skeletons could be set on a logical comparable basis.

The main effect of air entraining admixtures and of artificial air entrainment of concrete consists in modification of the system of pores; this has been proved by research work carried out in the United States (6, 7, 90, 91) and resulting in the establishment of the main characteristics of pore systems of ordinary and air entrained concretes (Table 3).

Detailed data on pore distribution from the point of their sizes in air entrained concretes, and the effect of water-cement ratio, nature of the admixture and the effect of vibrations are summarized in Fig. 11.

It is a pity that the tests made in the USA do not contain detailed information on the nature of the pore systems of ordinary and air entrained concretes, which would make it possible to estimate the effect of air entraining admixtures on the pore system still more clearly and specifically.

The predominant size of pores as shown in Fig. 11 indicates the necessity to also elucidate the effect of fineness of cement on the formation of the pore system in relation to those fractions of sand that are designated as most efficient for air entrainment. Several research studies (21, 47, 95, 123) especially those of postwar years have proved sand grain sizes between 0.30 and 0.60 mm to be the decisive ones for the content of entrained air.

It also follows from Fig. 11 that pores larger than 0.120 mm dia. are rather random in occurrence. They are pores of air entrapped in concrete.

Further studies of the effect of a system of pores on the durability of concrete are also fully justified from the point of improving the resistance of air entrained concrete to sulphates, sea water, alkali reactions, and with volume unstable rocks.

Another problem that deserves clarification in relation to the character of the pore system (size of air bubbles at equal total air content) is the loss of mechanical properties of concrete (tensile strength in particular).

Table 3. *Nature of pores in ordinary and air entrained concrete*

Kind of concrete	Air content %		Specific surface of pores cm^2/cm^3		Spacing factor cm	
	Range	Avg.	Range	Avg.	Range	Avg.
Ordinary	0.2–5.7	2.0	42–435	175	0.023–0.155	0.064
Air entrained	2.4–10.6	4.4	242–615	387	0.005–0.020	0.013

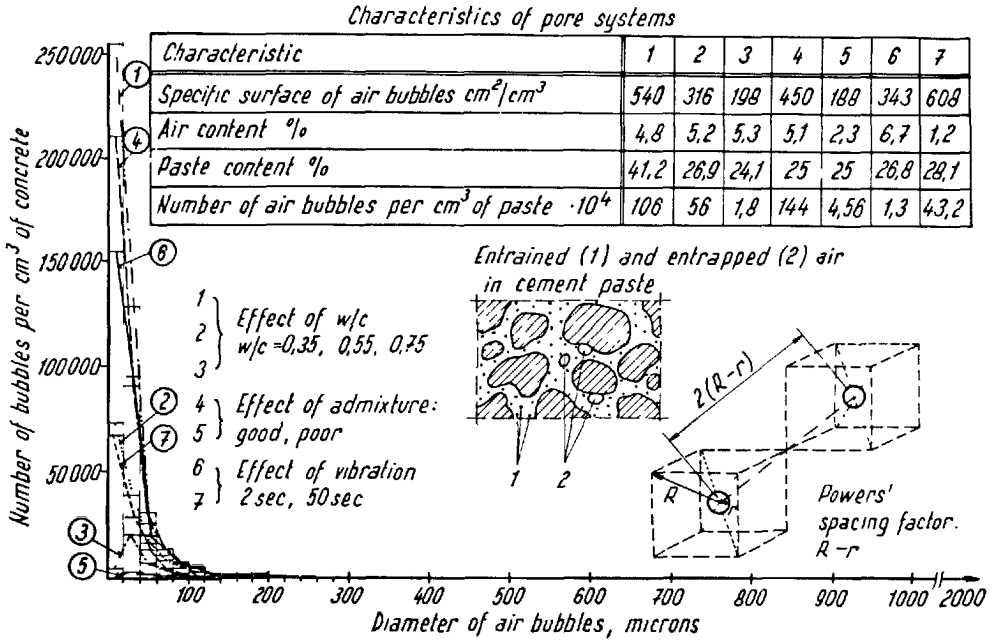

Fig. 11. *Influence of various factors on the quantity and distribution of pores in air-entrained concrete*

Very important for the mechanical and physical properties of concrete are pores contained in the cement-aggregate joint. They are usually larger pores cuased by air adhering to rough surface of the aggregates. In this sphere of research we meet a number of complex problems of utmost theoretical and practical significance.

Relation between porosities of cement paste and aggregates (rocks)

The relation between the properties of the pore system of aggregate grains and that of hardened cement paste bears decisively on the course of physical, physico-mechanical and physico-chemical processes that lead at later stages to deterioration of the texture of the two components and of their joint.

We can judge as to this relationship from the familiar, usually experimentally verified properties: absorption (total), permeability. As only sound, unweathered rocks are employed for aggregates, and from natural gravels the strongly weathered parts are usually eliminated, permeability and absorption of aggregates are relatively low. A proof of this is offered in Table 4 (62, 85).

The unfavourable effect of water-cement ratio and specific surface of aggregates is evident from the case of cement mortar. This phenomenon is clearly in very close connection with high permeability of the aggregate-cement joint, also determined experimentally by direct tests (115). The motion of water in concrete follows the path of least resistance and the relatively high permeability of the joint creates conditions leading to strong action of hydraulic pressures, ice, dissolving effect of waters and acids, as well as to that of aggressive salts in the joints.

It is logical to presume that the nature of the pore system of aggregates (rocks in particular) will be in close connection with their "technology"—process of their formation. We may, therefore, assume essentially different systems of pores in igneous rocks, sedimentary rocks and metamorphic rocks.

The mechanics of frost action in wet rocks undoubtedly follows the same basic mechanico-physical laws, and for this reason it will be necessary to study the basic properties of rocks important for their frost resistance, by the same means.

A certain connection between the system of pores in and the frost resistance of rocks was proved in France (65). The studies have proved the utmost importance of calcite moisture for volume changes (Fig. 12) and deterioration. They have at the same time pointed out the significance of the nature and size of pores for absorptivity and frost resistance of the rock. A mercury porosimeter facilitated the determination of the size distribution of the pores and helped to explain the causes of different frost resistance (Fig. 13) after the unlike nature of the pores became

Table 4. *Permeability and absorptivity of concrete components and mortar*

evident from the rate and degree of relative absorption of two calcites on their immersion in water (Fig. 14). Fine open pores (capillary channels to 5μ dia.) of the Tervoux calcite are the reason for rapid penetration of water in its texture, and hence of the higher relative degree of saturation, decisive for the unfavourable effect of frost.

Concrete permeability

Permeability of concrete decides about the pos-

sibility of water and substances contained in it to penetrate in concrete through interconnected open channels. It is defined by the permeability coefficient k in the Poiseuille-Darcy law for the rate of water flow through a porous medium, viz. $v = kI$. So long as no complete penetration of water through concrete had taken place (Fig. 15), the water head must also include the effect of capillarity. The relative head is then given by the relation

$$J = \frac{h + h_0}{x} \tag{2}$$

where

h—the actual height of water column above concrete surface

h_0—the capillary elevation

x—the thickness of concrete (depth to which water had penetrated).

The permeability coefficient k is not a time constant. It depends on gradual cement hydration and on the effects of water flowing through the capillary channels (swelling of channel walls, clogging with or washing off of fine particles including air bubbles).

At the initial stage larger pores connected to the channels cause by their filling up the flow to decelerate. After water had penetrated through concrete, these pores lose their effect on the apparent (resultant) velocity and outflow (Fig. 16). Surface cracks also cause changes in percolation of water through concrete. This is the reason why the permeability of concrete is usually expressed in terms of completed percolation and of the amount of water that had flowed through. Even though simple such a procedure is usually time consuming. The permeability coefficient however, be determined (with some approximation) from the relation for unsteady percolation

$$k = \frac{x^2}{2th_r} \tag{3}$$

where

x—the actual depth to which water had penetrated,

t—the time,

h_r—the height of water head ($h_r = h + h_0$)

At large enough h, h_0 may be neglected.

The above relation is approximate in that it disregards the time necessary for filling up large pores on the flow channels. Nevertheless, the permeability coefficient k thus obtained is a measure of the possibility of water penetrating in concrete.

Concrete absorptivity

Absorptivity of concrete or of another substance is usually understood to mean the quantity of water that penetrates in the specimen during a certain time of immersion in water (Fig. 17). It is a measure of the open porosity. Penetration of water occurs due to simultaneous action of hydrostatic pressure h and capillary forces that can be expressed in terms of the height of water column h_0, the capillary elevation. So far as specimens completely immersed are concerned, the counterpressure of air contained in

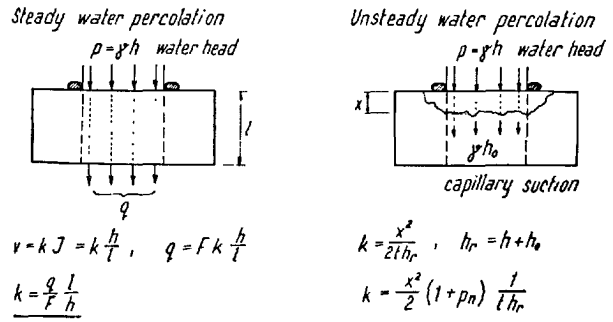

Fig. 15. *Percolation of water through the concrete*

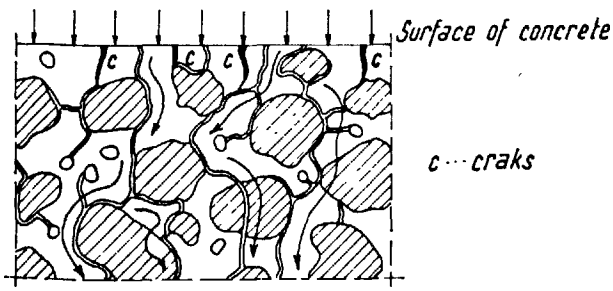

Fig. 16. *Concrete pore system and percolation of water*

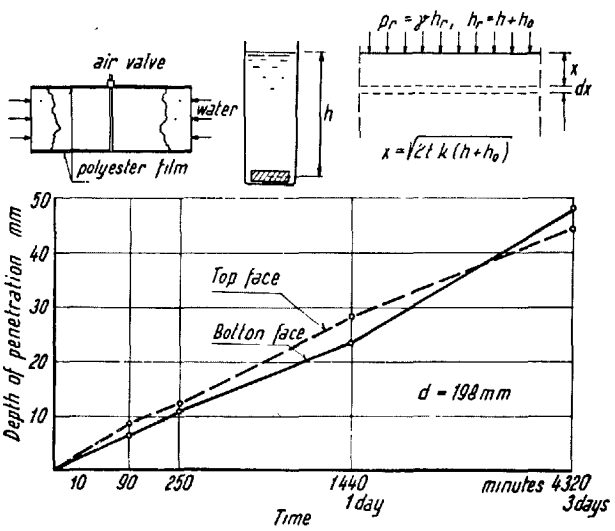

Fig. 17. *Absorption of water by concrete*

concrete pores should be considered, too.

The depth of absorption can be expressed by the relation

$$x = \sqrt{2tk(h + h_0)} \qquad (4)$$

which holds on the assumption that all the pores (channels) are open to flow and directly contribute to water percolation in the principal direction. What actually happens is that water penetrates through transverse channels and simultaneously to no-through channels. The resultant percolation is slowed down by the time necessary to fill the volume of both.

After time t the amount of water that had penetrated in the specimen is given by the relation

$$Q = F_0, x, \pi_0 = F_0\pi_0\sqrt{2tk(h + h_0)} \qquad (5)$$

where

F_0—the free surface of the specimen,
π_0—the (relative) open porosity.

For a statistically homogeneous material the relation between the weight increases of the specimen is given by the relation between percolation depths from the initial state (Table 5).

The linear dependence of the relative percolation depth on $\sqrt{t/t_0}$ ($t_0 = 10$ min in our case) can be used to advantage in the determination of the smoothed value of the permeability coefficient k (Fig. 17).

Capillary elevation

In penetration of water in concrete and its components, capillarity asserts itself as an additional water pressure head. If we wish to express the permeability coefficient k from formula 4, h_0 must be measured by a suitable test (Fig. 18).

Time, permeability coefficient k and capillary elevation are bound together by the relation

$$t = \frac{h_0}{k}\left(lg\frac{h_0}{h_0 - x} - \frac{x}{h_0}\right) \qquad (6)$$

Given experimental values (two at least), both the permeability coefficient k and the capillary elevation h_0 can be determined. Both values can be ascertained more accurately from a larger number of experimental values.

But in all cases the process calls for further analysis.

Table 5. *Rate of water penetration into specimen*

Absorption time	10 min.	40 min.	90 min.	160 min.	250 min.	360 min.	24 hrs.
Relative depth of penetrat. or relat. weight increase	1/12	1/6	1/4	1/3	5/12	1/2	1

While in the action of direct hydrostatic pressure the resultant permeability coefficient k is related to all the pores—no matter what their cross section, the situation changes once capillary forces—also bound to the dimensions of the capillary channels or cracks—come into action. Accordingly, the distribution of water flow among the different size groups of channels will be different (Fig. 18).

This alone is already a good indication of the high demands imposed on a test method capable of determining the fundamental properties of the pore system, and the resistance of the texture to specific aggressive processes.

In all the cases, i.e. unsteady percolation, absorption of water in concrete and capillary elevation, we must furthermore consider the effect of flow-ineffective channels and partially open pores, on the values of: t, x and k.

The possibility of using these physical criteria as a measure of concrete capability to resist the effect of alternate frost or of aggressive substances contained in water in relation to the 10 mins and 24 hrs

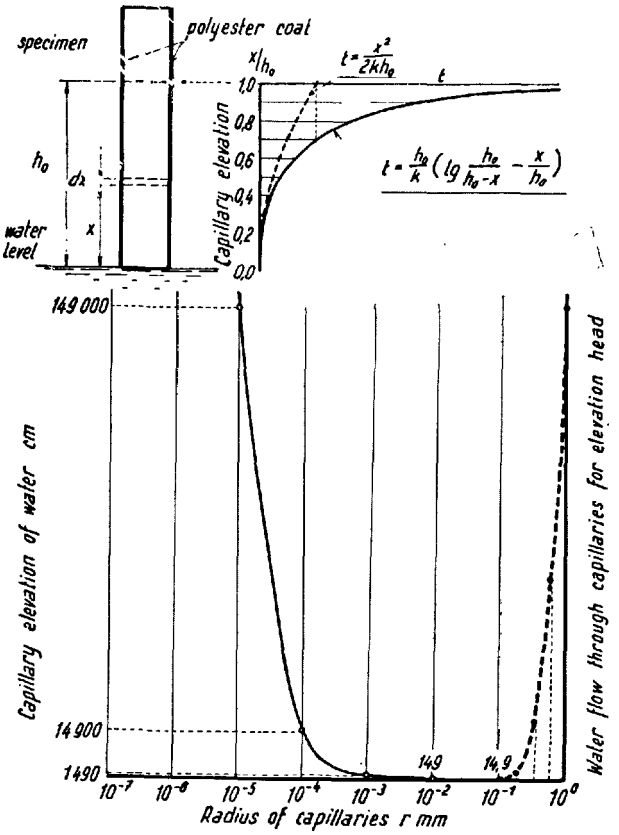

Fig. 18. *Capillary elevation of water in concrete (mortar, paste)*

absorptivity and frost resistance was successfully verified in Great Britain. A characteristic dependence between frost resistance and capillary absorption of standard mortars (ISO- 1/3) was also determined in France (120). Volume changes of the test specimens ($4 \times 4 \times 16$ cm) of various cement mortars used as an index of frost resistance and capillary absorption have proved the importance of the pore system for frost resistance (Fig. 19).

Tensile strength and bond of concrete components

The tensile strength of hardened cement paste and its bond with aggregates are decisive as regard the crack formation and deterioration proper of the texture by internal forces (ice, crystals, etc.). Concrete in the immediate vicinity of a tensile reinforcement is stressed in tension to failure by a system of cracks. In most cases these cracks do not affect the ultimate strength of sections but their effect on unfavourable action of aggressive media on concrete and its reinforcement in particlar, is of a decisive character.

Even though the danger of cracks in the covering layer of reinforcement is reduced by suitable prestress, as little as an isolated overloading there can give rise to harmful cracks.

The tensile strength and high aggregate-cement bond are of essential importance for the mechanical properties and durability of concrete and concrete structures; it is up to research to seek new ways towards their improvement.

The Function of Cement and Hardened Cement Paste in the Durability of Concrete

Hardened cement paste—though occupying but a small fraction (15 to 30%) of the total volume of concrete, holds a decisive position marked out by its task. It is at the same time a component of concrete that can most and best of all be affected by technology. Implied in this is the decisive effect of cement on all the properties as well as on the durability of concrete.

Depending on the circumstances, cement plays a role in the durability of concrete both by its chemical properties (composition) and by the physical and mechanical properties in hardened cement paste. Very important, too, is its relation to aggregates.

The *chemical aspect* involves the relation of cement components to aggressive agents of chemical nature which can either dissolve some of them, or through chemical reactions create new products that give rise to an internal state of stress by physico-chemical processes or crystallization.

The *physical aspect* refers to some of the physical properties that are of importance for:

the possibility of ingress of water and aggressive agents in concrete (chemical, physico-chemical processes),

the magnitude of stress in concrete (aggregates) and its eventual deterioration by cracks.

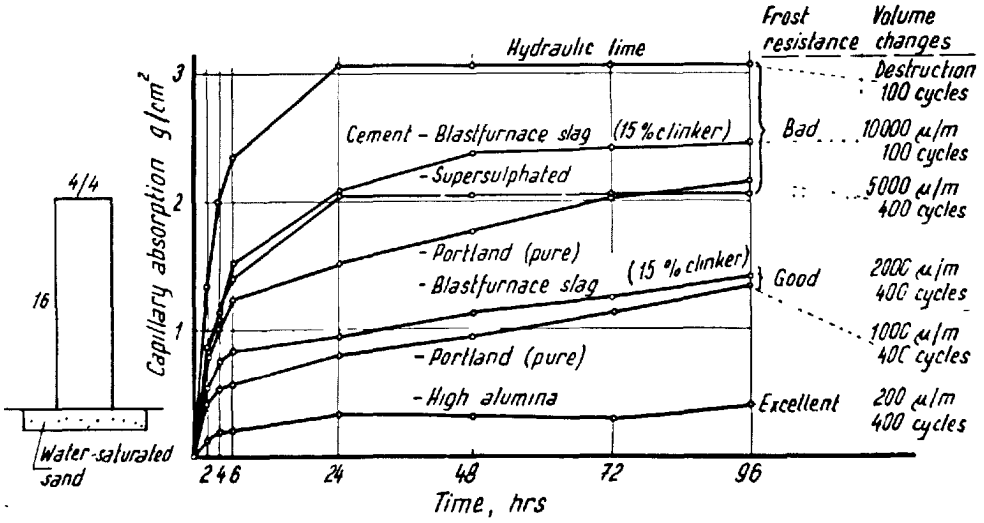

Fig. 19. *Capillary absorption of mortars* ISO (*1/3*) *with different cements* (*120*)

The physical properties in question include: porosity, permeability, absorption capillary elevation.

The *mechanical aspect* is concerned with tensile strength and bond of cement (rock) grains.

So far as the durability of concrete is concerned, the point in question is the relative capability of hardened cement paste and aggregate grains to resist the effect of various factors of the aggressive medium. Deterioration of concrete structure, however, always proceeds along the path of least resistance.

Effect of Cement Properties on the Durability of Cement and Concrete

Cement plays a role in these three ways: chemical and mineralogical composition; the properties of hardened cement paste; its relation to the aggregate, or to its components.

As to the *chemical and mineralogical composition of cement*: we are mostly interested in the relative content of the principal mineralogic components (C_3A, C_3S, C_2S and C_4AF), content of free lime (CaO), MgO and alkalies (Na_2O and K_2O). An important practical role is also played by hydraulic admixtures added to cement, which assert themselves also by their hydraulic capability (blast furnace slag, fly ash, trasses, tuffs, etc.).

The general criteria based on the existing results of world research are reviewed in Table 2. As a general rule it is necessary to verify them experimentally for the given specific conditions. A verification of that sort should start out from the decisive mechanical and physical properties of hardened cement paste: tensile strength, porosity, permeability, absorptivity.

Frost resistance of young, fresh concrete

Young concrete is very sensitive to the action of frost for the following reasons; a) it generally contains in its pores a large amount of chemically free water due to excess mixing water which only gradually combines with cement components or evaporates; b) the bond between the components (aggregate grains and cement) is weak and leads to low strengths, particularly in tension; c) high permeability facilitates motion of water and in turn formation of ice lenses in insufficiently solidified concrete structure.

As regard processes taking place in concrete during its cooling and deterioration by internal stresses: the tensile strength (bond) is the best indicator of the the resultant deterioration in the structure (eventually of its prestress).

The humidity of young concrete is given by mixing water. The water-cement ratio thus becomes a suitable index of the amount of water that is likely to turn to

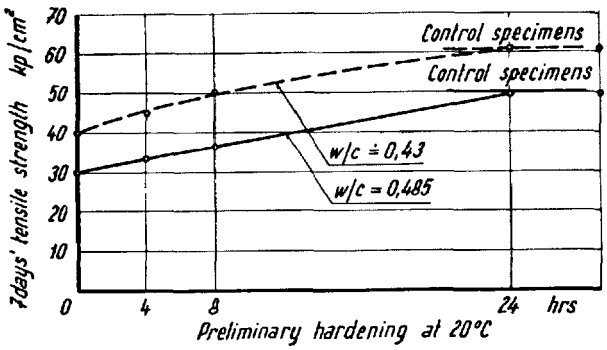

Fig. 20. *Effect of one frost (24 hrs, −14°C) on the 7 days' tensile strength of concrete for different ages at frost (0, 4, 8, 24 hrs) (65)*

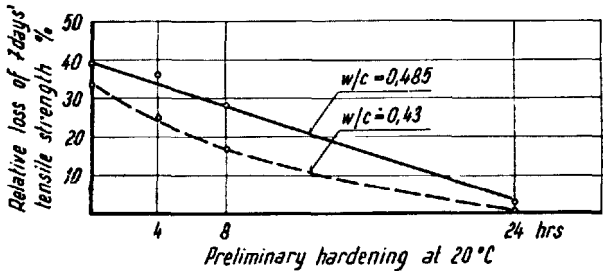

Fig. 21. *Effect of W/C ratio on the relative loss of concrete strength at 7 days by a single frost (−14°C) (65)*

ice in concrete cooled below 0°C. Another such index is the actual tensile strength or cement-aggregate bond at the instant of the first frost. This is corroborated also by the results of work done by M. Mamillan (Fig. 21).

Fig. 21 shows the effect of concrete age (degree of hydration) before the action of frost of −14°C/24 hrs/ on the 7-day tensile strength. The lower the previous temperature (< 20°C), the lower was the degree of hydration achieved and the higher the final loss of concrete strength. Not only the nature of cement (strength, rate of hardening, heat of hydration) but the water-cement ratio, too, come into play here (Fig. 22).

The mechanics of chemically free water contained in concrete and in hardened cement paste in particular, turning to ice under the action of frost continues to remain an unclarified clue to perfect understanding and explanation of the effect of alternate frost on wet concrete and its mechanical properties. Equally unclarified relations and processes accompany the temporarily favourable properties of frozen concrete (high tensile strength especially); their elucidation would help to better understanding of the effect of

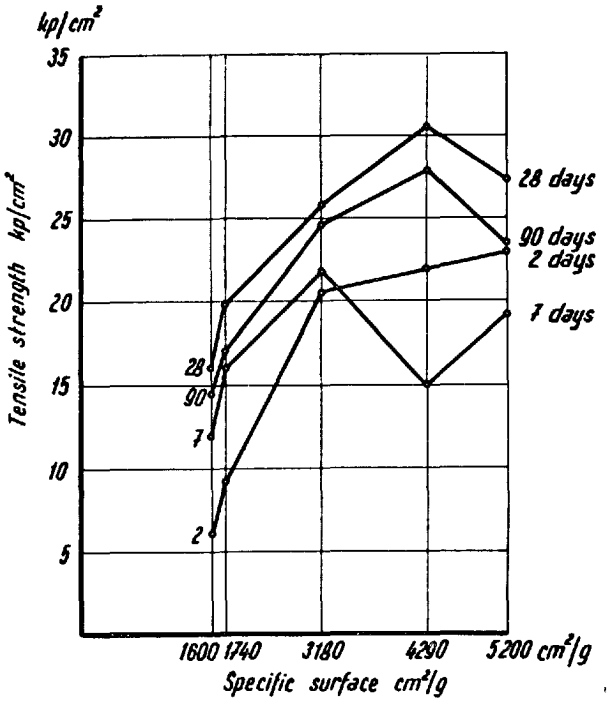

Fig. 22. *Effect of cement fineness on the tensile strength of concrete* ($W/C = 0.51$, 350 kg/m², $v = 50\%$, $T = 20°C$) (*118*)

frost on concrete—wet concrete in particular (116).

The *physical properties of cement*—fineness of grinding, granulometry and the relation surface to water, too, play a part here. These properties assert themselves predominantly through the amount of water bound by the surface of cement grains and through the resultant system of pores.

The favourable effect of greater fineness on frost resistance is clearly conditioned by an adequate increase in the amount of gypsum ($CaSO_4 \cdot nH_2O$) with respect to the extent of the reaction proceeding on the surface of grains (120). Surplus gypsum and coarse grinding (together with cement) act unfavourably on texture formation and limited durability of hardened cement paste, clearly because of these two factors: limited bond and tensile strength, unfavourable changes of the system of pores and higher absorptivity.

These results are at variance with earlier findings which had proved coarse grain cements favourable for concrete frost resistance (13). It is obvious that the relations are more complicated by far, and that next to porosity, the tensile strength—bond with aggregates—and deformability of hardened cement paste assert themselves in them. It we consider hardened cement paste as porous system of grains of partially hydrated clinker, we may assume that there exists an optimum grain size that leads—depending on the degree of intergrowth and the tensile strength of grains—to maximum tensile strength of hardened cement paste.

The size of cement grains influences the size and nature of pores in hardened cement paste in the same way as does the water-cement ratio. A coarse grain, porous texture leads to higher absorption and thus to limited frost resistance. Equally unfavourable will this property assert itself in resistance to aggressive agents and in moisture dependent reactions (e.g. alkali reactions).

The properties of hardened cement paste and mortar should, however, be also judged in relation to aggregates (their size). The fissurability tests signal higher danger of crack formation in case of restrained shrinkage with unfavourable consequences for tensile strength, permeability, absorptivity and hence also durability of concrete. A proof of this is offered by the dependence of tensile strength of concrete on the fineness of cement grinding (Fig. 22).

Cement admixtures

Various cement admixtures employed to obtain most diverse effects must, too, be always evaluated from the point of their influence on long-term properties of hardened cement paste, mortars and concretes. This requirement in itself indicates the necessity of knowing the composition of the various admixtures so as to exclude beforehand any unfavourable secondary effects, especially those on reinforcement corrosion.

Of particular importance are *inorganic components* which in combination with cement act like an active part of the binder: blast furnace slag, various pozzolanes of volcanic or orgaic origin, and a number of artificial pozzolanes such as fly ash, burnt clay, slag, etc.

Considering the durability of concrete, these components exercise the following favourable effects on the properties of cement and concrete:

Increase the resistance to aggressive waters (acidic or sulphatic); this is due to their chemical composition and binding of $Ca(OH)_2$ released by cement (clinker) hydration. The relation between the amount of free lime and the capacity of the pozzolanic component to bind it is of importance. Therefrom results the importance of the composition and relative amount of the two components: clinker and pozzolana;
reduce the permeability and the possibility of lime leaching;
increase the relative tensile strength;
eliminate harmful reactions between cement com-

ponents (Na_2O, K_2O) and some aggregates (SiO_2, dolomitic limestone).

A condition of the development of these favourable properties is sufficient humidity for hardening. Otherwise large volume changes, lower rate of strength increase and reduced frost resistance—unless ensured by suitable air entraining—will come into play on a broad scale.

As to frost resistance: the results of existing studies are not consistent. This has surely something to do with the different composition and nature of natural and artificial pozzolanas.

With respect to the *properties of hardened cement paste*: those mainly involved are:

physical properties—porosity, permeability, absorptivity and capillary elevation, coefficient of thermal expansion, volume changes due to humidity changes; *mechanical properties*—tensile and shear strengths, modulus of compressibility and elasticity, bond with aggregates and reinforcement.

The principal of these properties was analyzed in previous Section (Physical and Mathematical Properties of Concrete Important for the Durability). Next to the properties of cement, their formation is affected by technology (water-cement ratio, admixtures) and conditions of mortar and concrete hardening.

Among the other factors one should include the *water-cement ratio* and the fissurability of hardened cement paste given by the relation between volume changes and growth of tensile strength during cement hydration in mortar or concrete. This cement property is designated as fissurability and verified by a test based on simplified modelling of hardened cement paste on rigid core. Crack formation in the texture of concrete—in cement paste—for various reasons is of decisive importance for the action of deteriorating factors and for the durability of concrete.

The unfavourable effect of a high water-cement ratio on the mechanical and physical properties of cement paste and concrete—its durability under adverse conditions in particular—is generally known today.

Susceptibility of hardening concrete to cracking—fissurability

The fact that hardening and usually also shrinkage of cement paste take place in concrete in the aggregate skeleton and on aggregate grains creates conditions leading to crack formation in cement paste. The spatial system of such cracks unfavourably affects the resultant tensile strength and far more so, permeability and absorptivity of concrete.

A simple test to verify this cement property was introduced in France. The criterion of cement suitability is the occurrence of the first crack during storage (after 24 hrs) in controlled atmosphere ($T = 20 + 2°C$, $v = 50\%$). From the point of their suitability for structures exposed to adverse effects of external agents in liquid or gaseous form, cements are classified according to the interval between mixing and crack formation.

It would be of interest to verify to a greater detail the effect of restricted shrinkage of cement on the formation and properties of the texture of cement paste with respect to both mechanical and physical properties closely connected with the durability of concrete.

As to the relation of cement to aggregates: the hitherto research has mainly been concerned with detrimental reactions leading to concrete deterioration, viz. alkali-silica or alkali-carbonate reactions.

Great attention was given to the alkali-silica reaction by research in countries with natural conditions for its occurrence (USA, Denmark). Its principles were explained and convenient preventive measures stated. Alkali-carbonate reactions are being studied mainly in Canada (35).

Concerning the outstanding importance of bond for the durability of concrete, it seems to the point to study with increased interest the long-time relations between cement and different minerals of rocks used in concrete aggregates.

Formation of Cracks in Cement and Concrete and Their Relation to Concrete Durability

Cracks and their formation are of decisive importance for the durability of all concretes. They reduce the effective strength of concrete (in tension and bond), and facilitate ingress of aggressive agents of liquid and gaseous (but also of solid) nature in concrete and eventually to reinforcement. It is, therefore, necessary to accord due attention to crack formation in concrete structures, study its causes and introduce measures that would eliminate or at least alleviate it. According to their causes cracks in concrete or in hardened cement paste may be classified in four groups, viz.:

a) cracks caused by normal shrinkage and hydration heating,
b) cracks initiated by the effect of normal stresses (flexure, tension, principal tension),
c) cracks due to pathology of concrete structures
d) cracks arising in the texture of concrete by the action of aggressive agents and deteriorating processes.

The danger of cracks for the durability of concrete increases with the humidity of the environment.

Cracks caused by normal shrinkage and hydration heating

These cracks arise in cement paste, mortar and concrete by volume changes during hardening whose natural course is restricted by external and internal conditions such as anchorage, friction (concrete pavement), aggregates, reinforcement, etc. High rate of volume changes at the initial stage of cement hardening caused by loss of water in dry conditions leads to intensive formation of surface cracks (Fig. 23). The ensuing shrinkage of concrete is smaller by far than that of hardened cement paste (Fig. 24), so that local stresses in cement paste near aggregate grains are substantially larger (stress concentration).

This fact has been proved by T. C. Hsu (38) in his studies of the effect of shrinkage on stresses in binder between aggregate grains. As theoretical studies of a model of the texture of mortar and concrete and experimental verifications made on two-dimensional models have shown, the following three kinds of cracks can form in cement paste between aggregate grains:

1 tensile cracks in reduced cross section of cement paste between grains,
2 diagonal tensile cracks in cement paste,
3 tensile cracks in the cement-aggregate joint.

The relation between tensile stresses in cement paste between the grains, and tensile stresses in the joint depends on the spacing of grains (Fig. 25).

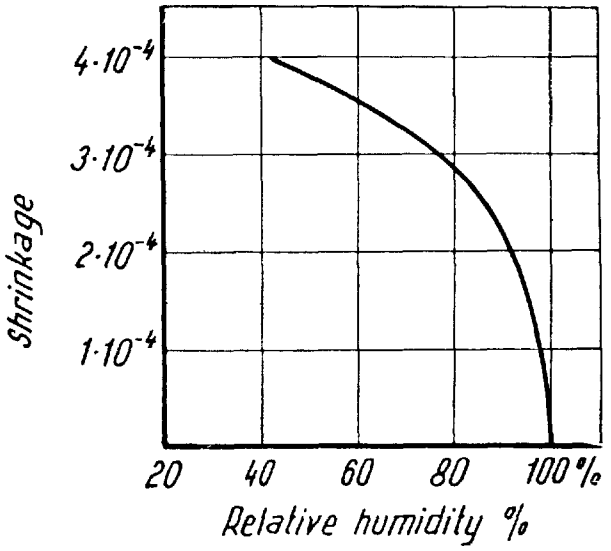

Fig. 23. *Effect of air relative humidity on drying shrinkage.* (58)

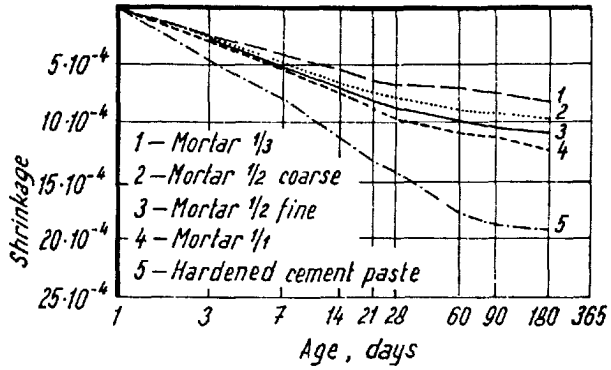

Fig. 24. *Effect of cement content on the shrinkage of mortar* (55)

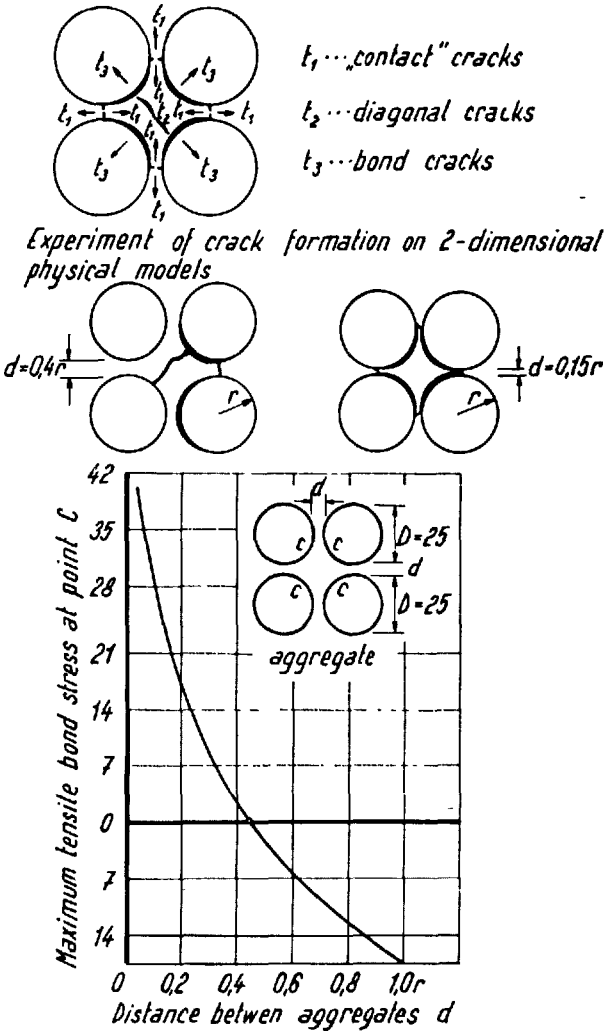

Fig. 25. *Tensile bond stresses and crack formation between aggregate grain skeleton* (38)

Even though the results of Hsu's study must of necessity be considered—from the quantitative aspects—as general indices of conditions, for no account was taken of the deformational, plastic in particular, properties of fresh and hardened cement paste, they clearly point out the principle of this important process.

Microscopic studies of concrete of cylindrical specimens before test and after application of a certain load (deformation 0 to 30×10^{-4}) have proved the existence of a whole system of cracks around the aggregate grains (joint) before loading, and gradual develop of cracks with loading. It was the cracks on the contact surface between binder and aggregate grains (38) that predominated in every case. This is another proof of the importance of the cement- aggregates bond. While development of such cracks may seem favourable from the point of view of stress distribution in the texture of concrete, the situation becomes completely different when judged from the point of concrete capability to resist aggressive factors of a most diverse nature.

Heat of hydration concrete is contingent on the nature and composition of cement, ambient temperature and other factors (admixtures, heat removal, etc.). A change of temperature leads to different thermal expansions of concrete components and thus also to internal stresses whose nature and range are given by the change of temperature, and thermal and mechanical properties of the components. In ternal stresses in concrete are also caused by differences of temperature of the core and the surface of concrete body. Unlike those produced by normal shrinkage, cracks due to temperature changes are much deeper (several m) and wider (1 mm), and spaced farther apart (44). They mostly occur in bulky structures where the temperature differences are greater, and their danger grows with the quantity, fineness and rate of cement hydration.

In this case, too, the relation between cement deformability and tensile strength is of importance for crack formation.

Actual conditions representative of size, stress distribution and concentration in hardened cement paste are highly complex. Even though surface cracks exert no serious effect on static behaviour of concrete, they represent a weakening from the point of the effect of aggressive agents.

Tensile prestressing of hardened cement paste resulting from its shrinking differently that the aggregates is the cause of reduced effective tensile strength of concrete as well as of crack formation on a dried surface. *Restriction of shrinkage-induced stresses is one of the ways toward increased relative strength of hardened cement paste, and above all, of concrete*, not to mention the secondary stresses in structures and the necessity to consider them in structure design.

It is, therefore, imperative from the point of the durability of concrete structures, not only to study the possibilities of reducing shrinkage of cement in its manufacture but also to control this cement property by a suitable test.

Cracks due to normal loading of structure

Structural members or parts of cross sections under tension are always liable to crack formation once the effective tensile strength of concrete has been exceeded. This happens even in cases when all tension is assigned to reinforcement.

Even under normal load crack formation depends on several factors: steel quality (stress in reinforcement), reinforcement bond, rigidity, effective height and shape of section, tensile strength of concrete, thickness of protective concrete layer, etc.

Crack formation due to load of reinforced concrete is of decisive importance mostly because of the possibility of reinforcement corrosion, the depth and width of cracks playing the cardinal role in that.

The possibility of dangerous crack formation is restricted in design by calculation and limitation of the theoretical width of cracks specified by various authors from 0.05 to 0.40 mm according to the environment. Even a minute, narrow crack is a source of locally different moisture of concrete, and at its contact with reinforecement a likely cause of electrochemical corrosion. The question to be tackled is that of under what conditions is it necessary to properly seal the tensile parts of concrete structure sections and thus exclude the possibility of corrosion since it is practically impossible at present to eliminate crack formation in general (except prestress).

In prestressed concrete structures cracks in concrete are unlikely to appear under normal load, and if they do after accidental limited overload, they close up again. So long as such a structure is in no direct contact with water (capillary elevation, permeability) or humid air containing aggressive gases, the cracks spell no danger.

Cracks of pathological character

Cracks of this sort are caused by the difference between the assumed action of the structure and the actual possibilities and conditions of structure behaviour. There are several causes for this: inappropriate foundation of the structure, deficiencies in design and construction, imperfect maintenance and

unsuitable operation of the structure.

As we see, they are all consequences of technical imperfections which though distant by their nature from the complex problem of durability of concrete and concrete structures, are apt to exercise a decisive influence on the durability of an otherwise high-quality structure. It is generally a system of larger, wider and deeper cracks, particularly dangerous in case of reinforced concrete.

In sufficient survey of foundation conditions and *inappropriate foundation* lead to unfavourable settlement and deformation of the structure and thus also to extraordinary stresses, mainly tensile, and in the ultimate stage to crack formation.

Similar consequences are brought about by *deficiencies of design* mainly consisting in selection of an inappropriate structural system, imperfect design, poor structural details and inadequate measures against the effect of external agents (insulation).

Advances in automatic computer techniques offer us the possibility of speedily effecting complicated calculations—but it is up to the designer and researcher to provide the basic conception of a suitable structure and the requisite physico-mechanical data, particularly those relating to long-time behaviour.

Many seemingly minor design details are of importance for concrete durability: *rapid removal of water* (rain or other, especially aggresive) from the structure, suitable position and execution of working joints (Fig. 7), perfect expansion joints, elimination of crack formation by suitably positioned reinforcement, reinforcement of corners of openings (Fig. 26), etc.

Structural design is greatly deficient in the way of preventive and protective measures devised to ensure the durability of concrete structures mainly under conditions of aggressive underground waters and sewage. A design properly conceived from the point of drainage or neutralization of aggressive agents, especially those of gaseous and liquid nature, can substantially contribute to the durability of concrete structures in industrial buildings. Surface insulation of concrete against excessive attack of aggressive agents must be solved within the framework of the complex questions of the durability of concrete structures.

Deficiencies in the execution of concrete structures are caused by: poor quality of the basic materials,

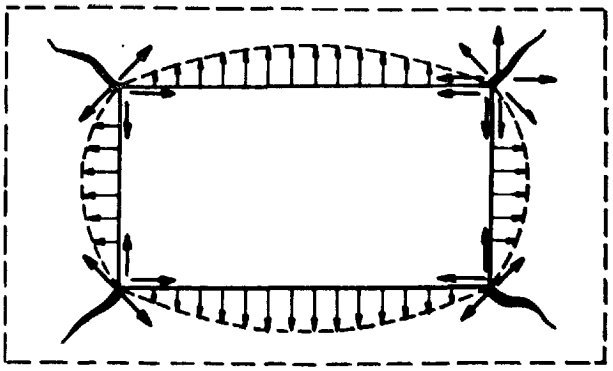

Fig. 26. *Cracks formation in corners of an opening*

inappropriate composition and processing of concrete, defective construction and function of the formwork and supporting structures, improper curing of concrete. Current practice pays no heed to the fact that manufacture of durable concretes calls for somewhat different approach to the selection of basic materials for, and technology of concrete from which high homogeneity and impermeability are required.

Imperfect maintenance and unsuitable operation of a structure are likewise a cause of defects that result in reduced durability be it due to a disproportional effect of aggressive agents when the drainage system has failed, or to crack formation by excessive load. It is in the interest of the durability of a structure in aggressive environment to reliably close all the cracks or renew the original function of continuous concrete.

Cracks due to the action of aggressive factors and deteriorating processes

As pointed out in the foregoing (Section; Effect of Cement Properties on the Durability of Cement and Concrete), aggressive factors according to their action on the texture of concrete may be classified in three groups. Two of those can cause cracks in concrete texture by:

a) producing internal or surface stresses in the texture,
b) giving rise to voluminous salts or to the effects of osmotic or crystallization pressures.

Cracks of this sort can occur either in hardened cement paste or in the cement-aggregate joint.

Methods of Testing Forecasting and Design for the Durability of Concrete

The great importance of concrete durability in numerous cases of concrete application in aggressive environment leads to the necessity of selecting the basic components, designing concrete and ensuring its

correct technology with a *view to the long-time effect of the specified aggressive factors.* This brings about the imperative need for verifying and proving the durability of concrete by accelerated tests. We are thus faced with the necessity of making a quantitative determination of the durability of concrete and an estimate whether or not it will be sufficient for the required safety at the end of the assumed life of the structure. And the tests of the durability of concrete and of its components should be made before the beginning or in the course of construction or on the occasion of any supplementary control—to supply us with reliable data and proofs.

Fundamentals of Test Methods

The requirements imposed on tests methods may be classified in two groups, viz. scientific and technical.

Scientific Requirements

From the scientific point of view every modern test method intended for durability testing must be based on new, advanced findings about the texture of concrete and mechanics of its deterioration, mechanics of its durability even if the technical arrangement of the test makes us seek the simplest possbile ways. These considerations necessarily reveal the fact that every method is subject to development.

Losses of important mechanical and physical properties represent a decisive indication of the durability of concrete and concrete structures. The character and purpose of the structure or of its part, and the type of stressing are then the main factors for the selection of the decisive mechanical or physical characteristics (compressive or tensile strength, modulus of elasticity, permeability, etc).

Al scientific test methods must, therefore, be necessarily *based on a scientific analysis of the individual isolated possible processes and their thorough qualitative and quantitative understanding* with respect to the various components of concrete. It is only on their basis that it is possible to reliably and safely proceed to the study of the complicated interaction between the components of concrete.

The actual processes of concrete deterioration occurring in practice are both very complex and very diverse. This is due to a very large number of possible combinations of the properties of the components of concrete and time sequence or simultaneity of the effect of the most different external factors of aggressive or beneficial character. In particular, structures exposed to weathering or other factors of natural character are practically impossible to compare in this respect.

These facts put the test methods face to face with the important problem of the fundamental approach to the solution of the following complex problems:

a) *Modelling of real conditions*

Test methods based on the endeavour to produce in the test conditions as identical with the actual ones as possible, are fundamentally correct. In the case of the durability of concrete this, however, has one principal drawback: it solves every case separately, independently of the general laws of mechanics, physics and chemistry, and affords, therefore, no generally valid results that could scientifically be applied, approximately in any event, to other at least similar cases. At the same time it cannot by far characterize the complex conditions in actual practice in the case of preliminary tests connected with the design of concrete mix of a suitable durability.

This approach can be compared with an attempt to carry out the structural design of every structure with its particular loading by means of a model without applying generally valid laws of structal mechanics and the strength of materials.

Furthermore, it necessitates costly, long-term tests using even more costly apparatus which can never a priori create a genuine, true-to-life model of reality.

b) *Analysis of deteriorating processes*

This method leads via a consistent analysis of the complex effect of the combined system of various factors, its separation from the point of their character, and an analysis of elementary, basic processes, to simple laws of qualitative and quantitative character.

In connection with an analysis of external conditions based on long-term observations of climatic conditions and considering also the interaction betwen the deteriorating processes in their combined effect, it is possible to acquire scientific data that can be used for an objective and technically true evaluation of the deteriorating effect of the respective environment and its principal factors.

This is seemingly a more complicated and exacting method which, however, offers one *substantial advantage* in that it is *based on the study of basic mechanical, physical and chemical reactions* as regard both the *qualitative and the quantitative aspects* opening the way to a scientific solution of this complex problem.

c) *Use of statistical methods*

The application of non-destructive methods of testing to the inspection of mechanical or physical properties of test specimens and concrete makes the problem easier with respect to the required number of

test specimens and test locations.

At any rate, statistics must help us out in: the determination of the sufficient number of test specimens, measurements or observations on the real structure to ensure the required reliability; the processing of results achieved, particularly in long term observations; the general evaluation of atmospheric or other real conditions of great variability which cannot be processed in any other way.

d) *Use of non-destructive methods*

From the numerous methods of non-destructive testing available for the inspection of the properties of concrete, more than one should be used at the same time. The selection must be based on the following principles:

1. The test method must be simple and quick, must not introduce extraordinary stresses in the test specimen; must be sensitive to the deterioration of structure and afford reproducible results.

2. The test method must not introduce appreciable disturbances in the regime of the durability test (changes of humidity, internal stresses, etc.). Should such changes be used (water absorption, permeability) a suitable procedure must be selected.

3. The use of ultrasonic or sonic methods based on simple measurements of the impulse velocity is not suitable because it is not sensitive enough to the deterioration of the texture of concrete (cracks).

4. For effective studies of the gradual deterioration of the texture of concrete it is necessary to develop new methods, especially such that are based on the damping of energy of ultrasonic or sonic impulses.

5. These methods must be combined with destructive tests for general control.

Technical Requirements

From the technical point of view, every new test method must satisfy a number of requirements including:

a) *Effectiveness*

The condition of effectiveness is given by the same process of concrete deterioration in test specimens and in reality, and by the ability to discern with sufficient sensitivity, between different durabilities due to different character of the components of concrete.

b) *Reliability*

Deterioration of concrete, its state and rate (including that of concrete components) must be controlled by objective methods. In their relation to reality the tests must afford reliable data on the relative durability of tested concretes.

c) *Reproducibility*

The method must ensure high uniformity of test conditions, of humidity in particular, and the rate of heating and cooling.

d) *Acceleration*

Practically all test methods are accelerated. However, they must not introduce new factors in the process of concrete deterioration, and must afford at least informative, reliable results for general information.

e) *Simplicity*

The durability test must be simple, easily checked and capable of mechanization and automation in a relatively simple outfit.

f) *Non-destructive character and effectiveness from the point of view of objective control* of progressive deterioration of concrete in test specimens and structures.

Analysis of the Methods of Testing Concrete Durability

The complexity of the processes of concrete deterioration and the urgent need for timely ensurance of concrete durability lead to an endeavour to utilize experimental results on as large a scale as possible. This brings us logically to an analysis of the test methods used in various countries and to the necessity of their simplification and unification. A suitable comparative test method is the least prerequisite for cooperation.

An analysis of the test methods used or standardized in various countries, made within the framework of RILEM Technical Committee for the Durability of Concrete and Concrete Structures (RILEM-CDC) has shown that:

1 There is generally great inconsistency among the methods used in various countries.

2 No relation exists between the nature of concrete (aggregates, cement paste) deterioration in natural conditions, and the regime of the test method.

3 Generally speaking there is no adequate control of the structural characteristics of test specimens either before or in the course of the tests.

Since the system of pores and its relation to water has a decisive effect on the course of deteriorating processes, and their influence on the texture of concrete depends on other mechanical properties of the material (tensile strength, bond), the nature of the pore system and those mechanical properties must be

ascertained prior to the test proper.

Absorptivity and its rate, permeability and capillary elevation can serve for important indicators of the properties of concrete particularly from the point of aggressive agents action.

4 Greater use should be made of tensile strength together with compressive strength control when testing the durability of concrete and of its components. This also important in relation to the necessary control of concrete durability of structures under actual conditions in case of long term observations.

Determination of the rate of concrete deterioration relative to its specific properties as necessary information for forecasting at least the relative rate of deterioration of concrete in structures should be considered the primary task of laboratory tests of concrete durability under various conditions.

The following important relations should be solved at the same time:

a) between gradual deterioration of concrete in structure and the results of accelerated laboratory tests,

b) between deterioration of concrete of laboratory specimens and of specimens under actual but controlled conditions,

c) between deterioration of concrete in structure and of tests specimens under the same conditions.

An important role in all these cases is played scale. Its formulation requires among others a qualitative as well as a quantitative control of deteriorating processes.

Long-Term Observations and Studies

Long term tests and observations of structures under actual conditions (environment) form an indispensable part of any rational set of methods for testing the durability of concrete, which should be based on the actual mode of concrete deterioration and be systematically verified—as far as its effectiveness and reliability go—by long term tests and scientific observations of structures.

The generally high requirements—be they of scientific, work, material or financial character—*make international cooperation in this field imperative.* This naturally imposes yet higher demands on the perfection of the system both as regard defined conditions of manufacture and placement of specimens or conditions of structures, and as regard the techniques of measurement and observations (of specimens and structures) and the final processing of their results (evaluation, analysis, conclusions).

In either case the essential conditions of success are:

1. Complete documentation concerning the properties of the basic materials, composition, placing and curing of concrete, supplemented by additional tests of mechanical, physical and chemical properties important for long-term effect of external agents (environment);

2. Complete documentation concerning the scope and nature of load, environment and aggressive agents acting on concrete in the course of test or observation;

3. Complete documentation concerning the structure or test specimen from the point of design, testing, overloading, etc.

Besides the usual control tests special tests given by the present-day state of research are used. This makes of the structures under observation long term research objects.

All of this also imposes extraordinary claims as regard the elaboration of a suitable set of methods of controlling concrete in structures and in specimens, which would enable us to continuously deal with a limited number of specimens.

Long Term Field Observations

The task of long term observations of concrete structures from the point of durability consists in part in the determination of the actual rate of concrete deterioration under real conditions, in part in the verification of the durability of concrete made on the basis of short term laboratory tests of durability. Only systematic observations of objects with complete data on concrete, and perfect long term control of external conditions can offer reliable results of scientific nature.

Observations of structures without such a sound basis, without perfect information about the mechanics of concrete deterioration and without modern means for analyzing the mode and degree of concrete deterioration can never furnish us with substantial help in the solution of this complicated problem. If sufficient in number, such observations can only provide data on:

the physical durability of various kinds of structures within a wide range given by the difference in their initial quality;

defects of a general nature which are no functions of the properties of concrete and its components relative to the environment.

The value of the results of an evaluation of the above sort appreciably increases in case of precast standard elements or structures with identical technologic procedure.

Filling of technologic documentation together with design documentation, at least for objects of major economic importance exposed to extraordinary conditions would greatly aid in the evaluation of results of periodic, incomplete inspections.

Main emphasis should be placed on thorough, systematic observations of selected structures using methods based on scientific data on concrete deterioration by various factors and modern means of concrete properties control in suitably chosen time intervals.

Closely connected with this is the need for uniform, clear terminology for phenomenological descriptions of failures that are likely to occur in concrete structures.

And finally, due consideration should be given to properly instructing the inspectors in the way of carrying out inspections, sampling and sample testing, description of phenomena, etc. A system of records should permit machine processing of data.

The high claims of such effective observations of the durability of concrete structures, and the necessity to arrive at reliable conclusions as fast as possible place the need for cooperation on a broad international basis in the forefront of interest.

Long Term Concrete Studies

Long-term tests of concrete and its components are a necessary link in the control of accelerated test methods and deteriorating processes (nature, rate) usually of a slow rate. In every case they offer the possibility of a comparison of concretes of different natures and compositions. Such was for instance one of the conclusions of long term studies of various cements (Long Time Study of Cement Performance in Concrete) organized by Portland Cement Association during the last war: the frost resistance of concrete can substatantially be increased by air entrainment (43).

In concrete cases of large structures long term tests represent an important long in the evaluation of the relation: specimen concrete—structure concrete (effect of scale, different conditions, size and nature of stress).

Long term tests of concrete bodies on exposure sites taken separately, though a good means of concrete and concrete structures control under natural conditions, are not fast enough in affording data for durable concrete technology. Their drawback lies in that the whole process progresses very slowly and thus it is not possible under variable environmental conditions to draw conclusions until after a considerable time. This reason alone would be enough to warrant systematic observations, measurements and recording of the characteristics of external conditions.

Accordingly, it is necessary to establish more such exposure sites to cover the whole scale of climatic and other (industrial) conditions.

This only underscores our justified demand to base research of the durability of concrete and concrete structures on a suitable combination of all the methods, viz. scientific analysis of the mechanics of concrete deterioration by various factors, control of the basic physical, mechanical and chemical properties important for the individual processes, accelerated laboratory tests of the components of, and of concrete, long term studies of concrete specimens and elements on exposure sites, and long term scientific observations of concrete in structures.

Progress of Deteriorating Processes and its Effect on Concrete Durability

Determination of the degree and rate of deterioration of concrete from the point of its effect on the ultimate strength of a concrete section, element and structure, is a fundamental task of great practical importance.

There are two questions involved here:

a) to what depth and extent have deterioration of the texture of concrete and loss of its mechanical and physical properties taken place;

b) what is the effect of this deterioration on the function of the original element or structure.

An important part in this is played by the nature of loading and the main task of concrete. The latter can be static (a section under compression, etc.) or physical, protective (concrete cover of steel).

In the first case—compressive stress—the matter in question is the relative loss of ultimate strength from the point of the whole section (Fig. 27). In the most

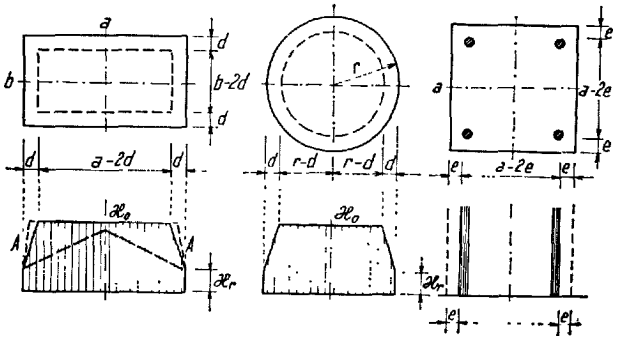

Fig. 27. *Loss of strength of concrete elements and structures*

unfavourable case of an aggressive medium acting from all sides of the element, the weakening of the section is

$$\Delta p = d\frac{a + b - 2d}{ab} \cdot \left(\frac{æ_r}{æ_0} - 1\right) \quad (7)$$

for a rectangular section

$$\Delta p = d\frac{r_0 - \frac{d}{2}}{r_0^2} \cdot \left(\frac{æ_r}{æ_0} - 1\right) \quad (8)$$

for a circular section

The resultant weakening depends on the depth and degree of deterioration, d, $æ_r$, and on the properties of the section (shape and size).

High impermeability of concrete will lead to small d even in the case concrete had completely disintegrated on the surface (A). High permeability, on the other hand, will mean deeper, more dangerous deterioration (B). This again brings out the importance of some of the physical properties of concrete.

In the second case when the main task of concrete is to protect reinforcement against corrosion, it is the ability of concrete to perform such function that is the decisive one. If we disregard the presence of random cracks, the degree of reinforcement protection is a function of the product $(e \cdot 1/k)/k$—the coefficient of permeability. In this case, however, we are not interested so much in the loss of the mechanical as in *the loss of the physico-chemical properties of concrete*: impermeability and chemical nature (pH). Hence *impermeability of protective concrete has double significance*—one, for the gradual deterioration of concrete, same as in the previous case, and two, for the reinforcement corrosion proper.

Taking into consideration the possibility of rapid reinforcement corrosion (pitting corrosion in particular) and very difficult and costly remedial action, the safety requirements must be formulated by excluding the conditions of reinforcement corrosion for the reason of ineffective protection by concrete. This raises the demands on the impermeability of the concrete protective layer, its homogeneity and durability proper relative to the environment.

The time necessary for water to penetrate to reinforcement can be expressed by the relation

$$t_e = \frac{e^2}{2kh} \quad (9)$$

where

k—the coefficient of permeability,
h—the head of water column.

Up to that time no appreciable corrosion should be likely to occur at all.

Otherwise, considering the general reinforcement corrosion (uniformly distributed on the section surface), the relations that come into play here are those deduced for gradual corrosion of circular sections of concrete, and the requirement that a smaller number of larger sections of steel should be preferred from the point of safety.

In structural elements subjected to bending moment or tension the conditions are made worse by the necessity of accounting for cracks in the cover concrete and for the possibility of local corrosion due to different humidity.

As the foregoing notes suggest, the task facing research in the way of ensuring data for a rational solution of the durability of reinforced concrete and reinforced concrete structures is a great one indeed.

Cooperation in Testing and Research

The need for cooperation and coordination of research activities relating to complex problems of concrete durability under conditions concomitant to the broad field of applications and great economic significance of this material, follows logically from the general interest in and the difficulties encountered along the way to a successful solution.

Such cooperation on a national scale in testing frost resistance was realized in practice in the United States under the sponsorship of Highway Research Board, National Research Council and National Academy of Science. Three series of tests were made within the framework of this coordinated research:

a) the first in 1936, with the aim to determine the effect of various portland cements;

b) the second in 1944, with the aim to determine the relation between a comparative test method and the methods employed by various laboratories;

c) the third in 1959, with the aim to compare four ASTM test methods:

C 290–52 T—Rapid freezing and thawing in water,
C 291–52 T—Rapid freezing in air and thawing in water,
C 292–52 T—Slow freezing and thawing in water or brine,
C 310–53 T—Slow freezing in air and thawing in water, using three kind of concrete with both sound and poor aggregates and different degree of air entrainment. Thirteen research institutes participated in these tests. (34)

The International RILEM Symposium held in Prague in 1961—Durability of Concrete and Concrete Structures—has clearly shown the international need for as well as willingness based on mutual interest,

to close organized cooperation in research relating to the difficult problems of concrete structure durability. RILEM Technical Committee for the Durability of Concrete and Concrete Structures which has taken upon itself to carry out this task in a general way, is attempting to gradually ensure its fulfilment on the basis of an analysis of the present state of world research, endeavouring to prepare optimum conditions for an organized international cooperation both in scientific laboratory studies of the basic questions of the mechanics of the durability of concrete and its components, and in providing scientific and technical data for a rational design and manufacture of concretes having specified durability expressed in terms of the physical durability of concrete structures. This preparatory work includes moreover the organization of systematic long term observations of the durability of various concrete structures and exposure sites so that the outlay for this costly work summarized on an international basis would yield maximum possible amount of high-quality findings of a general nature.

The accomplishment of this task will call for close cooperation with all national and international organizations and research institutes engaged in serious studies of concrete durability.

Quick, regular interchange of data, contact between specialists and periodic exchange of opinions at international meetings and conferences are other important conditions for a successful international cooperation.

Conclusions

The durability of concrete structures is a highly complicated problem whose solution must be based on a scientific analysis of and research into the various mechanical, physical and chemical processes that cause gradual loss of the basic physical and mechanical properties of concrete. It should also be ensured on a basis in daily practice, from the design through construction methods to the maintenance of structures.

Similarly as in mechanics where theory has passed from empiric knowledge to calculations based on the understanding of the laws of mechanics, we are facing today the problem of durability in concrete technology, with the need for *conscious, intentional selection of materials, creation of the texture and of the whole technologic process with a view to the specifically required durability of concrete under given conditions.*

The durability of concrete and concrete structures is at the present time a measure of structure quality same as is the strength of concrete. It unquestionably is an expression of a long time quality of concrete given by the required durability of the structure, as well as one of a long term economic solution of concrete and structure technology.

Even though our analysis has indicated how significant is a complex solution of the durability of concrete structures, the crucial point of our task and of the measures to fulfil it continues to lie in concrete proper, its technology in particular.

Air entrainment, a technique introduced in the United States a quarter of a century ago, must be designated a valuable contribution to ensuring the durability of concrete, particularly under the action of alternate frost in humid environment and everywhere elsewhere new voluminous products arise through unfavourable reactions. Further work, above all that relating to *efficient control of the system of pores* produced by various admixtures, will of course be required before the technique is safely established in practice.

Irrespective of the fact that some of the principal questions of durability mechanics, e.g. concrete deterioration by alternate frost have not been fully elucidated so far, we should on the basis of the present-day knowledge endeavour to create conditions for ensuring high durability of concrete, at least for the characteristic, essential exposure conditions of structures. In doing so we must start out from the mechanics of the various deteriorating processes of concrete due to diverse agents, and from its connection with the fundamental mechanical, physical and chemical properties of concrete and its components. *Results of this scientific analysis of the processes should, therefore, be utilized, qualitatively at least, in the technology of concrete structures:* choice of materials, composition, placing and curing of concrete. In the exceptional case of a very strong attack of aggressive agents we should utilize to the full such preventive measures—drainage, protection of concrete—that lead a priori to a limited action of the aggressive agents on concrete.

In close connection with this is the need for a reliable, scientific formulation of provisional recommendations for the production of durable concrete and concrete structures based on the present state of our knowledge. By its nature and urgency, the technique of gradual introduction of ever more perfect

technological procedures and ever more suitable materials for concrete structures under unfavourable conditions imposing high requirements on the durability, combined with systematic control of selected structures and its reciprocal impact on laboratory research, is the only possible way towards a solution of this difficult task.

Despite a number of partial tasks whose object is a complete clarification of the mechanics of concrete deterioration by various agents, especially as it concerns the relation to hardened cement paste and its bond with aggregates, and which pertain to all concrete components, admixtures including, we should direct our activities towards obtaining reliable scientific and experimental data for a rational design of concrete of the required durability.

Present-day findings, above all an analysis of the main deteriorating processes in concrete, already indicate some of the important requirements on the properties of concrete, such as impermeability, absorptivity, capillary elevation, tensile strength of hardened cement paste, cement-aggregate bond. Besides further elucidation—quantitative in particular—of their relations to concrete durability, the matter to concentrate on is the search for suitable technologic measures and cement properties (fineness of grinding) ensuring them. We have to search for new, suitable admixtures, or for new materials that would reliably provide the required properties of concrete.

A speedy and successful solution to this complex of intricate problems should and must be sought in broad but close international cooperation and coordination of reserach work that would ensure maximum effect—basic relations of general validity capable of furnishing reliable data for the technology of durable concretes.

This fact logically leads to the need for suitable, uniform test methods which as the only ones will permit uniform evaluation of concrete durability under laboratory conditions, and for more intensive utilization of results achieved on a world scale.

Quantitative evaluation of laboratory tests, of the accelerated ones especially, in relation to reality and from the point of designing concretes with the required durability under conditions defined in advance, has become a task of first magnitude. Every means—no matter how small—of rendering concrete technology more exact has an enormous economic and engineering significance considering the present day volume of cement and concrete production and the ever growing quantity of cement per inhabitant. Mastering this relation together with a rational technology of durable concretes will provide a sound basis from which to tackle the optimalization of the solution given by minimum overall costs.

Advances in civil engineering and concrete technology bring along some new tasks concerning the long term concrete quality—concrete durability. Among the most important ones we should include the durability of concrete and reinforced concrete prefabricates of all kind, and of structures built of them. Mass production, high degree of technologic control and a broad field of application under most diverse circumstances create conditions highly conducive to the solution of the questions of concrete durability.

It is just in this instance that the properties of cement as a binder play a very important part, and we should exploit to full the possibilities that cement manufacture has to offer by way of improving conditions relative to the deteriorating processes, both from the mechanical (tensile strength), the physical (fineness of grinding, grain size) and chemical aspects. Contradictory requirements, especially under combined effects, will of necessity call for specialization in cements. Great possibilities are offered by new materials of suitable properties, appropriately introduced in the texture of cement paste having already a satisfactory durability of its own.

The scope of the tasks that confront us, their outstanding economic importance and great complexity, as well as the high claims they make on scientific capacity, time and materials, convert them into a fitting subject of wide international cooperation.

Oral Discussion

Hoshagrahar C. Visvesvaraya

May I start by expressing our congratulations to the author for his excellent paper in which he has not only given a vast amount of useful information on the durability of concrete but also brought out very clearly the important issues connected with this highly complicated subject.

The author has rightly divided the principal aspects of durability into two groups—the *physical* and the *economical*. The *physical durability* is expressed in terms of the decisive mechanical and physical properties of concrete; what properties are decisive depends on a given situation and so the physical durability of the same concrete could be different in different situations of use depending on the performance expected of it. Similarly the economic durability expressed by equation 1 in the authors' paper takes into account only the direct costs; the indirect costs such as having to do either without a structure in case of collapse (Ex: collapse of a rail bridge) or with an unsatisfactory structure in case of damage (Ex: damaged highway pavement) as well as the economic consequences of the collapse of a structure have also been kept in view in the overall assessment (Ex: Bursting of dam).

There cannot be any two opinion on the significance of the homogenity of concrete which the author has discussed in the paper; the non-homogeneity of concrete leading to stress concentration should perhaps be qualified as in sections of low deformability in stead of *high* modulus of elasticity and *deformability*.

The importance of a proper understanding of the cracking phenomenon in the durability studies of concrete has already been well emphasised in the paper.

Cracking can occur in concrete when it is still fresh and/or after it has set and hardened. Cracking in fresh concrete could result from a rapid evaporation of moisture leading to excessive plastic—shrinkage, or differential settlement over obstacles such as aggregate particles or the reinforcement, or separation of cement mortar from aggregate caused by local bleeding. These cracks have been variously defined as "plastic", "plastic—shrinkage", "settlement", "presetting" "prehardening" or "surface" cracks and the author appears to be in favour of the last mentioned word. The term "surface cracks" could be misleading, in that, such cracks have been found to be not only on the surface but also extending all the way through slabs. Ravina and Shalon (1), in a very recent report, have mentioned the observation of plastic cracks up to depths of 23 cm. The cracks were of a width of 0.1 to 3.0 mm and had lengths ranging from a few centimeters to 1 or 2 meters.

Cracking of hardened concrete could result from shrinkage restrained internally (when bond cracking between aggregates and mortar may develop) or externally (when larger cracks may form), or from severe fluctuations in the temperature (causing differential expansions of the aggregate and matrix or concrete and steel in reinforced sections) and humidity (resulting in excessive shrinkage on drying and in reduction of surface tension on wetting) or application of stress.

Regarding the development of cracks induced due to shrinkage, the author has rightly considered the result of the investigations of T. C. Hsu (2) in which the possibility of the formation of three types of cracks (viz. tensile cracks in reduced cross section of cement paste between grains, diagonal tensile cracks in cement paste and tensile cracks in the cement—aggregate joint) have been found. In structures of reinforced concrete, the internal stresses developed in a cross-section due to fluctuations in temperature arising from differences in the thermal expansion properties of concrete and steel are not usually accounted for and the resulting simplifications in the analysis appears to be the major reason for this. In the discussions that arose over a paper by Vetter (3), it was pointed out that the thermal coefficient of concrete may vary from 4×10^{-6} to 6×10^{-6} per degree Fahrenheit (depending on the composition), where as that of steel from 6.3×10^{-6} to 6.8×10^{-6} which may give a difference sufficient enough to cause a rather wide variation in the stresses. This appears to be a point which requires a more serious attention and investigation, especially for such conditions which introduce tensile stresses in concrete.

Cracking is also induced in concrete due to the stress which is brought on it by the application of external loads. Hsu, Slate, Sturman and Winter (4) studied the micro-cracking in concrete in relation to the stress-strain curve and the type, location and extent of progress of the cracking with the increasing stress and strain on the cross section. Bond cracks (resulting from shrinkage) were found to exist even before the application of load, and with increase in stress, the cracks increased in length width and number. This increase was negligible up to stresses less than 30 per cent of ultimate stress and above which matrix cracks also developed, and at about 70 to 90

per cent they increcased noticeably and formed continuous crack patterns. Sturman, Shaw and Winter (5) have extended the investigations by Hsu et. al. (4) to the study of the influence of flexural strain gradient on microcracking, by comparing the behaviour of eccentrically loaded specimens with that of concentrically loaded specimens. By observations based on sonic method, Jones (6) also finds that the micro-cracking (from stress) starts in concrete when the stress on it reaches about 30 per cent of the ultimate. The limitations of sonic and ultrasonic methods in these studies which the author has mentioned are also brought out here. The true ultimate strength of concrete when it is subjected to sustained loading represented by the stage at which extensive internal cracking occurs in concrete, is about 70 to 90 per cent of the short term ultimate strength. Estimation of the sustained load strength of concrete from micro-cracking and other methods have been recently reviewed in detail (7). According to Glucklich (8), up to 30 per cent of stress negligible bond cracks occur, between 30 and 50 per cent slow growth of bond cracks occurs, between 50 and 75 per cent slow growth of matrix cracks and bond cracks occurs, and between 75 and 100 per cent fast growth of matrix cracks occurs. Glucklich has also discussed in detail the effect of micro-cracking on time-dependent deformations and the long-term strength of concrete. For an understanding of the cracking and the conditions under which progressive cracking occurs in concrete, the theory of fracture mechanics is also being applied (9).

Research on concrete cracking should ultimately lead to the realisation of the various factors by which cracks in concrete could be minimized if not eliminated altogether. The plastic-shrinkage cracks could be minimized to a considerable extent by taking proper care and necessary precautions as given by Lerch (10). Regarding this aspect, an engineer incharge of a construction job could benefit much from the tips given by Jellic (11) also. The attempts at reducing the shrinkage cracking in hardened concrete could be through the use of expanding cements which is already mentioned in the paper.

Probably the micro-cracking of concrete resulting from stress is the one type of cracking which cannot be avoided in concrete as the concrete section has to sustain a stress. However the extent of this cracking could be minimized by keeping the stress on it to within 30 per cent of the short term ultimate load. This aspect of study becomes more complex because a balance is to be struck between the adoption of smaller stresses and the resulting increased expense or reducing the expenses by using higher stress when the micro-cracking from stress will be more which will affect the durability of the structure. In any case this discussion emphasises the effect of overloading on durability; a structure overloaded over a length of time, having developed micro-cracks, even if the overload is removed could lead to lower durability of the concrete.

The use of prestressed concrete in reducing the cracks that may develop in concrete structures from any occasional overloading is already given in the paper. The closing up of cracks an unloading in a prestressed structure is a well known phenomenon but this is not universally applicable at all sections under all conditions. There are many prestressed structures known to have developed cracks which did not respond to reduction of superimposed load; in fact a case recently brought to our notice in India regarding the cracking observed in the prestressed concrete girders of a railway bridge. Gracks are noticed to have formed in the end blocks of these girders and through these cracks rain and other water has been gaining access to the high tensile and other steel in the ends of the girder. This could have set in the rusting of steel and hence affect the strength and durability of the structure and the problem is now being investigated. Obviously, the prestress acting on the girder cross section has not been of use in preventing these cracks; similarly the prestressing might not be of assistance in so far as microcracking due to stresses caused by overloading are concerned.

The authors conclusions that the complex problem of durability is to be studied on the basis of long-term observations in the laboratory as well as long-term field observations on the basis of uniform test methods should be fully endorsed.

The few comments given above are an only by way of elaboration of certain points briefly brought in the excellent paper presented by the author and not as criticism or comment.

Author's Closure

Oldřich Valenta

Mr. Visvesvaraya has rightly pointed to the high complexity of concrete and concrete structures durability. This state of things led me only to the try of giving to the participants of this symposium a framely picture of actual state of research as well as of general direction for future research and international cooperation in it.

Mr. Visvesvaraya has also rightly pointed to the necessity to consider *also indirect costs* in the analysis of concrete structure durability. Complete analysis of every individual case must be done. Any timely repair of the structure must be covered by the 2nd member of the equation No 1. Increased probability of collapse must be dealt with as probability of collapse admitted and accepted by normal design regulations.

Many causes and effects *of cracks in concrete* have got to be considered when analysing their effect on the durability of concrete and concrete structures.

No complete analysis could be included in the paper. We are actually very far from using at least the same definitions in describing them. When considering the durability of concrete we must concentrate especially on their consequencies: *increased permeability and nonhomogeneity of concrete* when water, aggressive solutions or liquids, vapor and gases may penetrate into concrete easily and rapidly. This refers also to prestressed structures endangered even by isolated overloading. Load carrying capacity has not been necessarily reduced—but penetration to liquids or gases has been increased with due unfavourable effect on corrosion processes and durability of concrete and reinforced concrete.

Homogeneity of concrete has different consequences depending on the forces or agents acitng on concrete: *Concrete section with increased porosity* generally has:

a) *reduced strength and rigidity* (modulus of elasticity or deformation)—leading to reduced stresses,
b) *increased permeability* leading to increased deteriorating action due to easier penetration of agents.

This remark had *to stress the fact that increased care should be given to concrete technology* as to obtained homogeneity in cases of its exposure to aggressive agents than in cases of structures not exposed or protected.

Supplementary Paper III-24 Behaviour of Mortars and Concretes in the Temperature Range from +20°C to −196°C

Giampietro Tognon*

Synopsis

Results of an investigation on specimens of cementitious mortar and of concrete cast with different types of aggregates and cement, as well as on specimens of lapidary materials for comparison, are reported.

Two cryogenic chambers, with temperatures adjustable in the treating cell respectively from +20°C to −100°C and from −100°C to −180°C, were used and for the temperature of −196°C a thermostatic container with liquid nitrogen.

Performed tests showed an increase of compression, bending, tensile strengths and of modulus of elasticity as the treating temperature was decreased.

Strengths are neither influenced by the type of cement nor—it seems— by the nature of aggregates, but by the content of free water in the specimen.

This last fact is the cause of an anomalous behaviour of strength trend which appears about in −35C° and −60°C range.

The trend of the thermal contraction coefficient was also determined and the existence of above indicated the singular zone.

Tests were performed to know the behaviour of concrete to the impact at very low temperatures.

Repeated cycles of freezing and thawing from ambient temperature down to −196°C and vice versa, showed that concretes do not undergo significant degradation.

Then, following direct investigation on water-ice system, and on the ground of thermometric measurements and of distribution of porosity, one tried to explain the behaviour of hardened concrete at lower and very low temperatures through a thermodynamic interpretation and to justify strength values reached with a triaxial stress.

Introduction

Rather recent and still limited in their numbers are the studies about the behaviour of concrete at very low temperature (1) (2).

On the other hand, it is not long since the opportunity has arisen, to bring the concrete into contact with fluids or in ambients that are at temperatures about 180 ~ 200°C below zero. This is the case of tanks used to hold liquid gases: methane for instance, that boils just at −178°C.

This report has the purpose to bring a contribution to the knowledge of the specific physical properties that mortars and concretes hardened in a normal ambients assume, when the temperature of their mass is brought in equilibrium to values decreasing little by little to approximately −200°C.

First Part

At the moment to program the investigation, it has been thought right to soon have an idea about the fundamental characteristics of the phenomenon which had to be studied, to free it from the variables which might have proved to have no influence on it and to bring it, if possible, back to its essence.

Consequently, the first plan of research was made, to establish the influence of the type of cement on the behaviour of the respective hardened concrete subjected to extremely low temperature.

*Central Chemical Laboratory, Italcementi S. p. A., Bergamo, Italy.

Materials

Cements and Pozzolanas

As far as cements are concerned, it seems to be useful to point out the reasoning which led to choose, for this first investigation, pozzolanic cements rather than portland cements.

As everybody knows, the Italian pozzolanas, which constitute with the clinker the fundamental component of our pozzolanic cements, consist of a vitreous mass containing crystals (of feldspar, leucite, augite, and so on) and they had their origin, according to the most accepted hypotheses, in an explosive volcanic eruption, during which, the gases, when liberated pulverized the melted magma and impeded by the sudden cooling that followed, its complete crystallization. The evolution of dissolved gases produced a fine texture of canals or bubbles so that the consolidated vitreous particles have a high internal surface area. This particular physical state is called "aerogel", namely a gel in which the liquid phase has been replaced by a gas (3) (4).

With reference to the physical characteristics of pozzolanas and in particular to their constitutional porosity and to their large internal surface, it was deemed important to verify, whether the hardened concretes of pozzolanic cements could results more suitable than concretes of portland cement, to stand the mechanical stress arising when the free water turns into ice during the tests.

In conclusion, three groups of cements, all of industrial production, have been chosen:

I Group—consisting of No. 19 pozzolanic cements, Class 325 (plastic mortar according to the recommended project ISO 771–775) with an average percentage of pozzolana equal to 36%. These 19 cements were produced in as many works, and consequently with clinkers having different chemical composition. On the contrary, the types of pozzolana are three and their origin, as well as the corresponding values of their average porosity and internal surface are indicated in Table 1. The strengths at 20°C of the respective concretes for which we give the composition at the following point, vary in a range included between 270 and 390 kg/cm²;

Table 1. *Physical properties of the pozzolanas*

Denomination of the pozzolana and origin	Average porosity cm^3/g measured on 58 mm granules	Specific surface m^2/g measured on $< 200\ \mu m$
(BC) Bacoli (Campania)	0.3528	9.300
(BR) Barbarano (Lazio)	0.4090	10.500
(SL) Salone (Lazio)	0.0547	38.700

II Group—consisting of No. 11 cements, still of the pozzolanic type, Class 425, that is high strength cements. The average percentage of pozzolana of the qualities already described, is equal to 30%. The clinkers are included in the set of the first group. The strengths of concretes at 20°C vary between 380 and 450 kg/cm²;

III Group—consisting of No. 4 high strength portland cements, Class 425, which have given, in concrete, strengths included between 480 and 550 kg/cm².

Concretes

The cubes, having 10 cm of side, and 10 × 10 × 50 cm prisms were cast, settling by vibration concretes having the following compositions:

aggregate: of siliceous and calcareous nature consisting of sand and gravel after the Fuller's ideal curve with max 30 mm;
cement: of different types as already described, in the quantity of 300 kg/m³
w/c ratio: 0.5 (constant).

The concretes differed therefore with the difference of the cements.

After curing for two months in conditioned room at 20°C and 100% R. H. (fog), from the 10 × 10 × 50 cm prisms, specimens of the following dimensions were obtained by cutting: 4 × 4 × 16 cm and 2 × 4 × 25 cm. The curing in room has been protracted for 6 months and then the treatments and tests were started.

Experimental Procedures

The experimental procedures adopted at this first stage of the research have been simplified; in particular, the conditions of temperature and humidity, chosen for the treatment of the specimens, were as follows:

+100°C—in climatic cabinet until a constant weight is reached, in order to obtain specimens having the same % value of residual humidity;

+20°C—R.H. 85%—in climatic cabinet for 48

hours:

+10°C—R.H. 85% in climatic cabinet for 48 hours; at the end of this treatment the free water contained in the specimens is around an average value equal to 3.72% (see Table 2, forward);

−78°C—in thermostatic container in constant contact with dry ice for 48 hours;

−196°C—in thermostatic container, steadily immersed in liquid nitrogen, for 48 hours.

The compressive strength have been determined for each type of concrete and for each of the above mentioned conditions, on three cubic specimens having sides of 10 cm, as well as on the couples of pieces obtained after breakage by bending of three $4 \times 4 \times 16$ cm prisms, which as already said, had been previously obtained in their turn, by cutting, from $10 \times 10 \times 50$ cm prisms. Before the breakage by compression, care was taken to bring the pieces again to the pre-established temperature.

The dynamic Young's modulus was measured on three specimens, for each type of mix, in the dimensions of $2 \times 4 \times 25$ cm, using the flexural resonance method.

Moreover: on three specimens having the dimensions just given above and conveniently provided with pins, the linear variations for thermal contraction were executed by means of an apparatus equipped with a comparator having a sensibility of ± 5 μm.

Experimental Results

Table 2 groups the values of the strengths, shrinkage, and the Young's modulus of elasticity obtained on the basis of the tests already described. Some additional remarks are given on this subject.

Mechanical Strengths

a) The compressive strength are rising as the temperature of treatment falls, as it appears from the diagrams of Fig. 1, which were drawn with the average values for each group of cements.

It is to notice, that the increase in strength is higher for the first drop in the temperature (+20°C, −78°C), than for the second one (−78°C, −196°C). The pertinent ratios are diminishing as the initial strengths of concrete rise, owing to the fact that the increases remain pratically constant in each interval, independently from the initial strengths of the concrete.

In the case of bendings the test was made only for the greater drop in the temperature, obtaining trends corresponding to those of compression.

b) As the increases of strength of the concretes due to the fall in temperature result to be pratically constant, at least in each of the two intervals taken into consideration, and as it is the case of concretes that differ only with the characteristics of the cement, the deduction is that the type of cement does not influence the trend of the phenomenon which is being considered. In particular, also the type of pozzolana as well as its quantity in the pozzolanic cement do not modify the above mentioned conclusion. The only thing that could be said is, that the pozzolana of Salone, which has an average porosity of one time and a half lower and a specific surface B. E. T., almost four times higher than those of the remaining two types, causes increases tending to be inferior to those that may be found with the pozzolanas of Bacoli and of Barbarano, which result to be less finely porous.

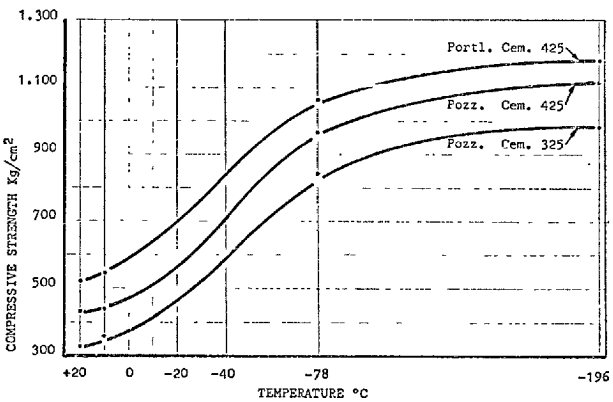

Fig. 1. *Relation between compressive strength of concretes with different types of cements and treatment temperature*

c) Independently from the group of cements, the set of the values of the compressive and bending strengths of the concretes at +20°C can be statistically put in correlation with the corresponding set of values obtained at −78°C and −196°C. This constitutes a further confirmation, in quantity terms, of the fact that the increases are connected with the values of the initial strengths of the concretes and of the fact that, surely such increases do not depend, at least in the sense of a connection of significant probability

on the type of cement and therefore on its composition; and they also do not depend on its components: clinker and pozzolana chosen of different origin and having different chemical and mineralogical characteristics.

Young's Modulus of Elasticity

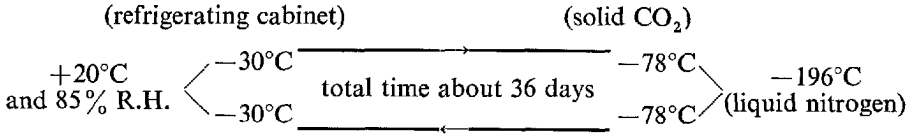
The dynamic modulus of elasticity that, as everybody knows, is bound to the mechanical strengths of the concrete, shows as increase in value included between 14–19% as the temperature is decreased from +20°C to −196°C. By returning to the normal temperature, values are found, on average, slightly lower than the values measured at the beginning.

Thermal Contraction

The thermal contraction measured for the greatest drop in the temperature (+20°C, −196°C) is around 1250 μm/m in the concretes with pozzolanic cements as well as in those with portland cements. By returning to the normal temperature, the presence of a residual deformation (hysteresis) is revealed, sometimes of positive sign and sometimes of negative sign.

Thermal Cycles

It appeared to be useful to investigate already at



this first stage of the research, about the behaviour of concretes after they have been submitted to the repetition, for ten times, of the thermal cycle, the scheme of which is given hereunder:

The time of stay of the specimens at each stage of the cycle was varying, owing to technical necessity, from 5 to 7 days; this period of time was of course more than enough to obtain the equilibrium of temperature; the passage from a temperature value to the other one took place suddenly.

The concretes on which the investigation has begun, after two months of curing in a room at +20°C and 100% R. H. and after that they had been put subsequently in equilibrium at +20°C and 85% R. H., had the composition already described and different for the type of their cement: nine of them have been made with normal strength pozzolanic cements (type 325) and three were made with high strength portland cements (type 425).

Strengths

The Table 3, that follows, shows the single values and the average values of compressive and bending strength determined on the respective types of concrete on completion of the tenth cycle. For the comparison, also the strengths are shown, which were obtained by testing twin specimens, not submitted however to the cyclic treatments and that during the whole corresponding period have been cured in conditioned room.

The results obtained, and above all the comparison between the two series of data prove, that the concretes have not suffered a significant degradation, as a consequence of the cyclic treatment. It may be stated in addition that, on the 10 × 10 cm cubes, after they had been subjected to the cycles, an increase may be found of about 6% in the strengths, in comparison with the strengths measured on the untreated specimens. On the contrary, the bending strength determined on specimens having a thinner section: 4 × 4 × 16 cm, have likewise a reduction of about 14%. It must be taken into account on the other hand, that for all the time the specimens remain at low or very low temperature (about 80% of the total employed for the cycles) it is not possible to think that the strengths may increase, contrary to what is to be expected for specimens cured in a normal ambient. This last comment is not valid in the case it is deemed

Table 3. *Strengths of concretes submitted to cycles of freezing and thawing*

$\bar{X}$ general			443.5	417.2	56.4	65.6

that it is possible to justify increases or anyhow not excessive decreases in strength in connection with the effect called "hibernation", consisting of the fact that a concrete cured for some time in an ambient with a temperature lower than normal, when brought again in a normal ambient shows, at the end, higher strengths than a concrete cured uninterruptedly in a normal ambient.

Finally it is to mention that on completion of the cyclic tests and before breakage tests were carried on, it was not remarked in spite of a scrupulous visual inspection any deformation, cracks, breakage of edges or any other damage on the surfaces of the specimens.

Trend of the Young's Modulus of Elasticity

The dynamic modulus of elasticity has been measured at the beginning (+20°C) and half-way through each cycle (−196°C); the average trends, in connection with the number of cycles, are represented

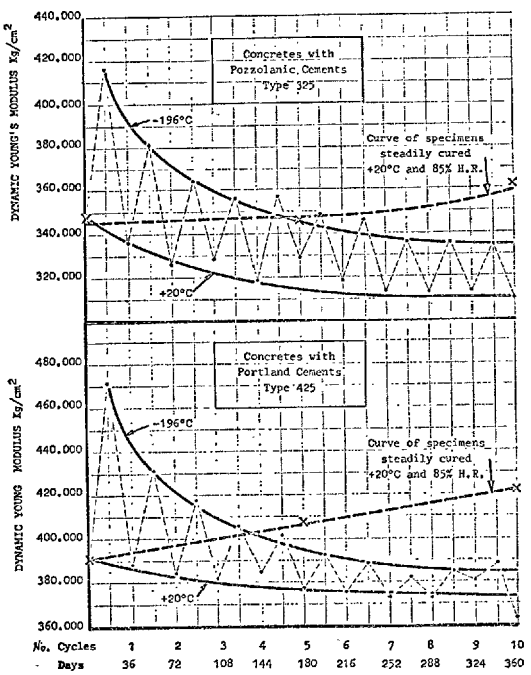

Fig. 2. *Trend of Young's modulus with cycles of freezing and thawing*

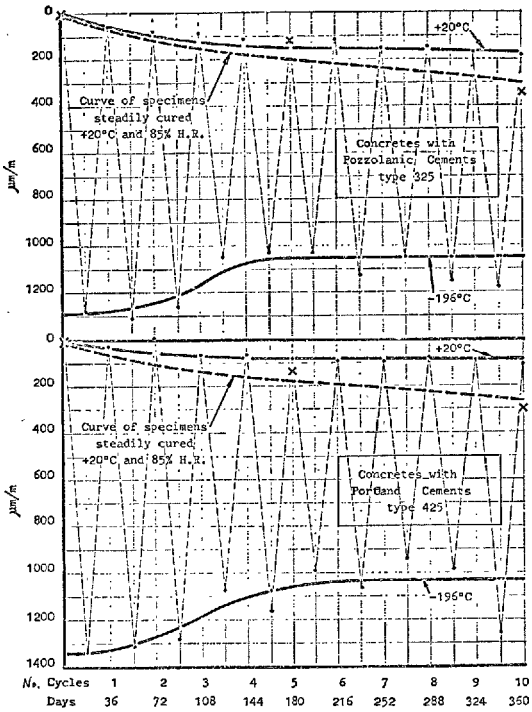

Fig. 3. *Trend of thermal contraction with cycles of freezing and thawing*

respectively for the group of pozzolanic cements and the group of portland cements, in the diagrams of Fig. 2.

In conclusion, on the specimens submitted to cycles it has been observed, when they were each time in equilibrium with the normal conditions, that there was a progressive slow decrease of the modulus of elasticity, whereas on the specimens cured steadily at +20°C and 85% R. H., it has been verified on the contrary (see again Fig. 2), in a corresponding time, an equally slow increase: on an average equal, in absolute value, to the above mentioned decrease.

The modulus of elasticity measured on the specimens, when half-way through each cycle they were in equilibrium with the temperature of −196°C, is rapidly decreasing up to the fourth or fifth cycle, and then it decreases very slowly for the subsequent cycles, until it reaches a trend parallel to the one of the +20°C.

Trend of the Contraction

The trends are shown on the diagrams of Fig. 3.

About the specimens subject to cycles, at the moment they were at +20°C, is noted a progressive increase of the contraction, but this increase is inferior to the one that can be measured on the specimens which have been cured for a corresponding time in a conditioned room.

It is therefore evident that the linear variations measured on the specimens brought again to a normal temperature are not ensuing only from the cyclic treatment, but they are the result due to the addition on another effect, in spite of the handicap constitution by the curing at low temperature, that is, the effect of hygrometric shrinkage still acting due to the relatively limited age of the specimens (2 months) at the beginning of the test.

The measurements taken at −196°C show, going towards the third and fourth cycle, a reduction of the contraction which seems then, to fix itself, although with a great dispersion of values, on a trend which remains parallel to the one of the +20°C.

Second Part

What we reported in the first part confirmed that the cement concrete is a material fit for being usefully

employed also when it is brought down to extremely low temperatures. In particular we established:

—that the type of cement, as regards the nature both of the clinker of origin and of the pozzolana as a possible component of the mix, does not influence the behaviour of the concrete at the very low temperatures;

—that the concrete can support, without any degradation, the effects of repeated cycles of freezing down to temperatures reaching −196°C and warming to room temperature.

Consequently we went on with our research, investigating on concretes with different characteristics. So we made plans for additional types of tests, as well as refining the testing procedures, and explain the causes of its characteristic trend.

Materials

Cements

Six types of cement have been taken into consideration and their characteristics are shown in Table 4, hereunder (the numbers correspond to those of Table 2).

It is to point that the cements, within each group, have mechanical strength comparable with one another. The clinkers of origin result, on the contrary to have rather different mineralogical compositions, particularly as regards the C_3A contents; the pozzolanas are present in the three types already described.

Table 4. *Properties of the cements*

Cements	No.	Specific surface Blaine cm²/g	Mineralogic composition of respective clinkers				Strengths of plastic mortars kg/cm² at 28 days, 20°C	
			C_2S	C_3S	C_3A	C_4AF	flexion	compression

	3	3790	23.5	53.6	9.3	9.8	82	470

Aggregates

Cubes having 10 cm of side and 4 × 4 × 16 cm prisms were cut from blocks of 5 mineralogically different types of aggregates. Table 5 indicates their main mineralogical and physical characteristics.

The materials in question can be considered as non porous, that is very compact, and having consequently a very reduced possibility of absorbing water.

Tests were made also with light aggregates, that is, with granular roundish products, obtained by expansion, through thermic treatment of schistous clays.

Such aggregates (complying with ASTM C330) have a density included between 600 kg/m³ for the size 0–3 mm and 450 kg/m³ for the max. size 8–15 mm.

Table 5. *Physical properties of the aggregates*

Type of aggregate	Petrographic features		Density g/cm³	Cumulative pore volume cm³/g	Adsorbed water content % by wt	Strength tests kg/cm² at 20°C	
	Type of rock-texture	Mineralogic composition				flex	compress
Limestone	Sedimentary microcrystalline with light diagenetical alteration	calcite	2.684	0.0009	0.16	180	1870

Silica	Sedimentary microgranulatic	quartz, with amorphous cement	2.622	0.0082	0.72	The material was crumbly and no strength test was allowed	

Concretes

$10 \times 10 \times 50$ cm prisms were made for each of the 6 types of aggregate, employing 6 types of cement. The composition of concretes was:

aggregate: obtained by means of crushing and then subdivided by a sieve, in four granulometric sizes, in order to obtain the Fuller's continuous line with max. 20 mm;

cement: quantity: 300 kg/m³;

water: w/c ratio: 0.5 (constant).

We made a set of concretes differentiated by the type of aggregate, which are putting themselves on two classes of strength, considering that as already said, the cements, in their respective type show pratically equal strengths.

After 5–6 months of curing in conditioned room at 20°C and 100% R. H. (fog) from the $10 \times 10 \times 50$ cm specimens, cubes of 10 cm of side and prisms having the dimensions $4 \times 4 \times 16$ and $2 \times 4 \times 25$ cm were obtained by cutting. Before starting the treatments and the tests, we protracted the curing of the specimens in that room for another year, owing to necessities of program.

Two types of light concrete were made with the aggregates of expanded clay: one of them consisting of light aggregate only (divided into three sizes) and the other consisting of light aggregate completed by a certain quantity of fine siliceous sand, in order to make it more compact.

The mix proportions of the dry aggregates in % of weight, are as follows:

	Concrete "A"	Concrete "B"
sand 0.4–0.6	—	22
aggregate 0–3	45	35
aggregate 3–8	30	23
aggregate 8–15	25	20

The quantity of cement (portland type 425) has been 300 kg/m³, while the w/c ratio was 0.66 and 0.50 respectively for concrete "A" and concrete "B" to obtain mixes equally workable.

As regards the curing and the shape of the specimens, all we said for the normal concretes is confirmed.

The specific weights at the moment of breakage resulted to be: 1100–1150 kg/m³ and 1300–1350 kg/m³ respectively for the concretes "A" and "B". Considering the object of this work, it is interesting to point out that, whereas for the concretes containing the different aggregates taken into consideration, having anyhow a normal specific weight, the coefficient of thermal conductivity λ is ranging around 2.0 kcal/m, h, °C (oven dry specimens), for the concretes of expanded clay it may be mentioned a value about four times lower, that is $\lambda = 0.5$ kcal/m, h, °C (oven dry specimens).

Plastic Mortar

In order to reduce the effects due to the variability of the peculiar characteristics of materials, and in particular of concretes, we decided to test also specimens of plastic mortar, the mix of which results to be evidently more homogeneous than the mix of a concrete. In this way we intended to use an additional means to improve the research in particular situations and particular test, in the case the experimental trends could appear doubtful or at least not in accordance with the expectation.

Consequently homogeneous sets of $4 \times 4 \times 16$ cm specimens were made in plastic mortar, using the same portland cement type 425. Sets of specimens in the figure of "eight" were prepared with the same type of mortar, suitable for breakage by a simple tensile stress.

Equipment and Test Conditions

For the execution of the second part of the work, the most important apparatus employed in addition to those already mentioned, consisted of:

—*a thermostatic unit* for low temperatures consisting of No. 3 boxes. The temperature of the box No. 1 may be regulated between +20 and −100°C. The temperature of the box No. 2 may range down to −180°C. The box No. 3, made in cupper, consists of a hollow space, where is possible the storage of liquid nitrogen, so to fix the temperature at −196°C. The sensitivity of regulation of the temperature, within the respective fields in the three boxes is ±3°C. The real test temperature was measured by means of a thermometric feeler, sensitive at ±0.5°C, immersed in a witness specimen having physical and geometrical characteristics similar to those of the specimens on which the investigation was made.

—*an equipment for shock tests:* at the first we used an impact machine similar to the one used for testing

toughness of steels. The results were unsatisfactory and it seemed that this might depend on the technique of the test. Tests of shock strength, were therefore carried out using another equipment (8) (9). The apparatus consists of a frame on which a hammer of 25 kg, with a terminal of hemispherical shape, is free to fall from a changeable height, striking the upper face of the cubic specimen.

The height of fall increased each time by 1–2 cm until the specimen submitted to this test breaks.

The above mentioned test has been made for each value of temperature, on 3 specimens: from the first one we obtained the indication of the most probable height of fall to cause breakage; on the remaining two specimens the most approximate value of the height of breakage was determined and confirmed, by making a reduced number of shocks in order to avoid damage of the specimen.

The breakage by shock is considered to have taken place when the falling hammer does no more rebound on the specimen. Planes of breakage subdivide the specimen into two or more prisms.

—*we covered the specimens* with layers of expanded polystyrene in order to avoid losses of temperature. The time necessary to carry out the tests varied from 30 to 90 seconds. The departures of temperature at the surface of the specimen could be contained around 0.5–2.5°C under the worst conditions.

—*the specimens submitted* to special curing in order to maintain a pre-established degree of humidity, were jacketed with polyethylene film.

—*the specimens were maintained* in the box at test temperature for about 24 hours; this time has proved to be more than sufficient to reach the equilibrium value.

Test Results

Mechanical Strength

The aggregates, as the temperature decreases, show increases both in bending and in compressive strength as indicated by the diagrams of Fig. 4.

The trend of the curves is regular enough, taking into account the difficulty to find samples of stones free from defects, like microcracks. We don't indicate the bending strengths of the different aggregates in the range of temperature −60 and −80°C. The diagrams would have announced, in this range, a particularly irregular trend. The compressive strength shows, in correspondence, except for the basalt, a regular increasing trend also within that field.

The concretes, made with different types of aggregates show both at compression and at bending strength trends, on the average, an increase (about 45% at compression and 50% at bending, changing from +20 to −180°C) as the temperature is lowered (see Fig. 5).

We find a certain dependence, that we cannot call a correlation, between the strength of concretes and the corresponding aggregates, on the contrary, we note a clear dependence between strengths of concretes and the relative cements. We point out an interesting trend in bending of concretes: there are some irregularities, and exactly a decrease in strength, when a temperature about −50 ~ −60°C is reached. We note again an increase, after the minimum correspondence to −80 ~ −90°C has been reached.

We cured for 3 years in fog-room a set of concrete samples. These were made with calcareous aggregate and high ratio in cement (450 kg/m³); this is a rapid hardening and high strength cement. Half of them were submitted to a drying treatment in a stove at

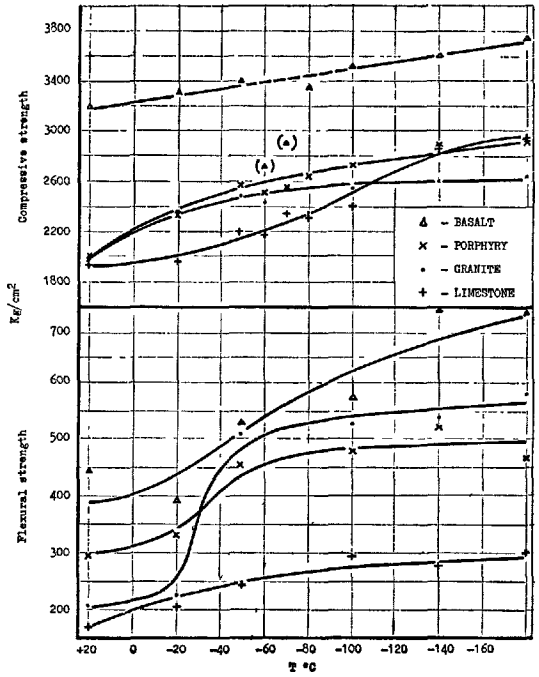

Fig. 4. *Relation between strength of stone and temperature of treatment*

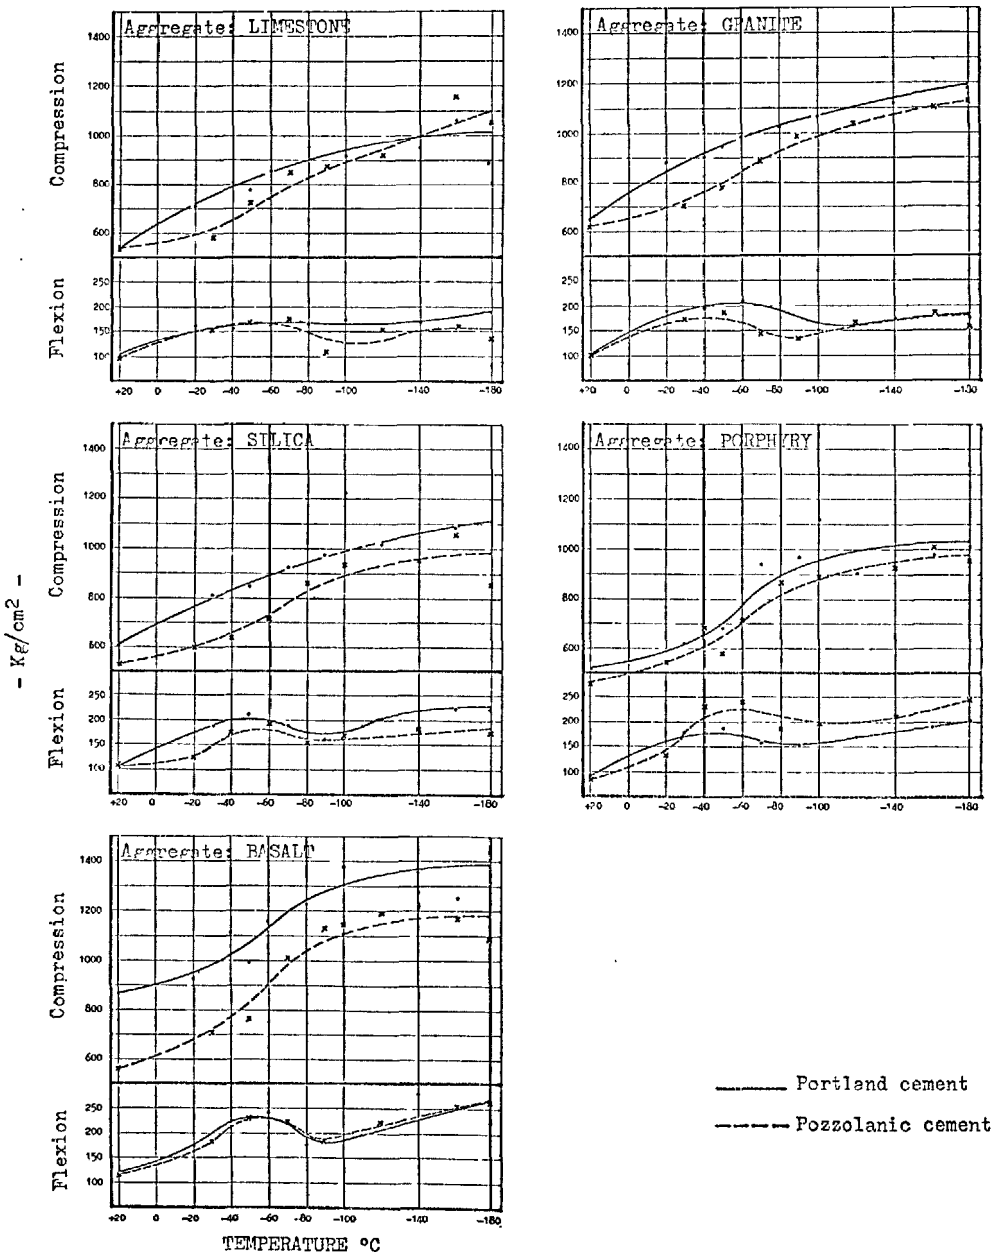

Fig. 5. *Strengths of concretes made with different aggregates and two types of cement at various temperatures*

110°C. Then they were treated together with the specimens at the moist state, at low temperatures. The results of the compression strengths are shown in the diagram of Fig. 6.

In this diagram is put in evidence the influence of the quantity of the free water contained in the concrete on the trend of the strength as the temperature decreases.

We notice increases of strength of concretes containing expanded clay, previously cured in fog-room, when the temperature decreases (see Fig. 7).

Plastic Mortar

The availability of a large number of specimens having homogeneous characteristics gave us the possibility to carry out a particularized investigation on the trend of the strengths. In this test, we put down

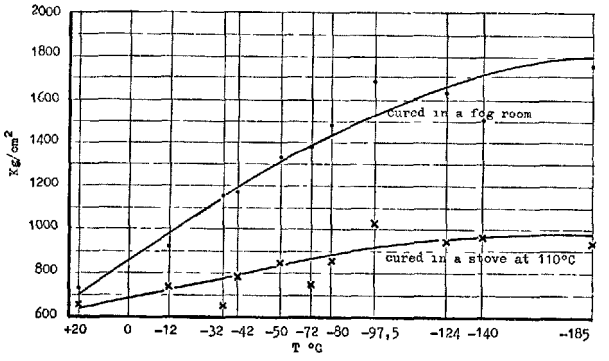

Fig. 6. *Relation between compressive strength of concrete and temperature of treatment*

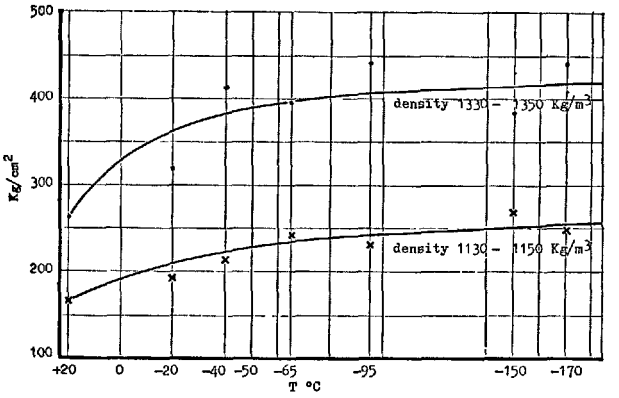

Fig. 7. *Relation between compressive strength of concrete made with expanded clay and temperature of treatment*

the temperature 5°C every time. The diagrams of Fig. 8 indicate the trends of tensile, bending and compressive strength of specimens cured in water up to the moment of the test. In the same diagram we indicate the strength found on specimens dried in a stove at 110°C. It is evident that the presence of free water in the specimen is necessary for increasing strength.

We notice, as it is evident in the Figures, an inflection in every types of strength of the saturated specimens in the range of temperature from −50°C to −100°C. We have hatched in Fig. 8 the area included between the interpolated line and that of the experimental values to lay particular stress to the phenomena.

Shock Strength

The results with the impact machine on samples made with plastic mortar have been very dispersed and we don't think opportune to relate them. The apparatus provided with a beating hammer has been

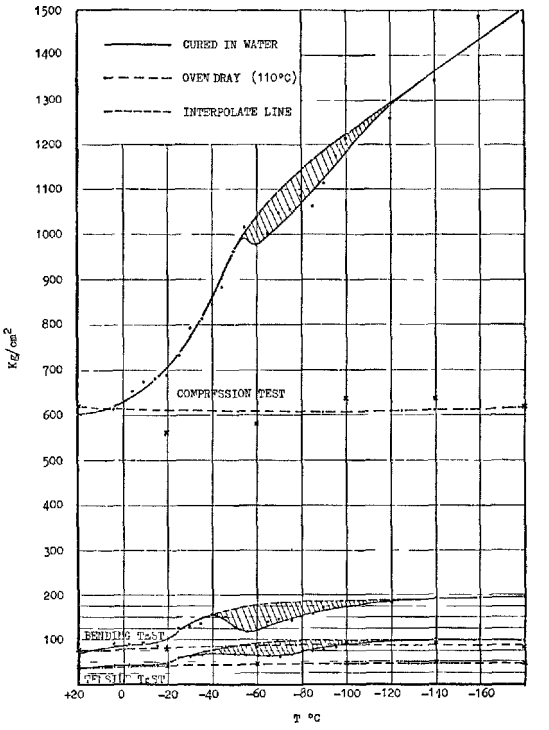

Fig. 8. *Relation between strength of plastic mortar and treatment temperature*

used on shock tests on concrete made with various aggregates. Fig. 9 shows the respective diagrams.

The procedure of the test justifies the dispersion of results. We think the shock strength of concretes, brought to very low temperature, to be strongly bound to their behaviour at bending and compression.

Dimensional Variations due to Thermic Effect

The investigation about thermic contraction, very characteristic for the materials that now we consider, has been made by some authors (2) (10) (11), but they did not include very low temperatures, and different types of cement mixes. Our results on testing lead to find some anomalies in behaviour.

Thermic Contraction

Aggregates

The curves representing the trend of linear thermal contractions are parabolic (see Fig. 10a), and consequently the respective contraction coefficient changes linearly with the temperature.

The respective average values in the field from +20 to −180°C are shown hereinafter in Table 6,

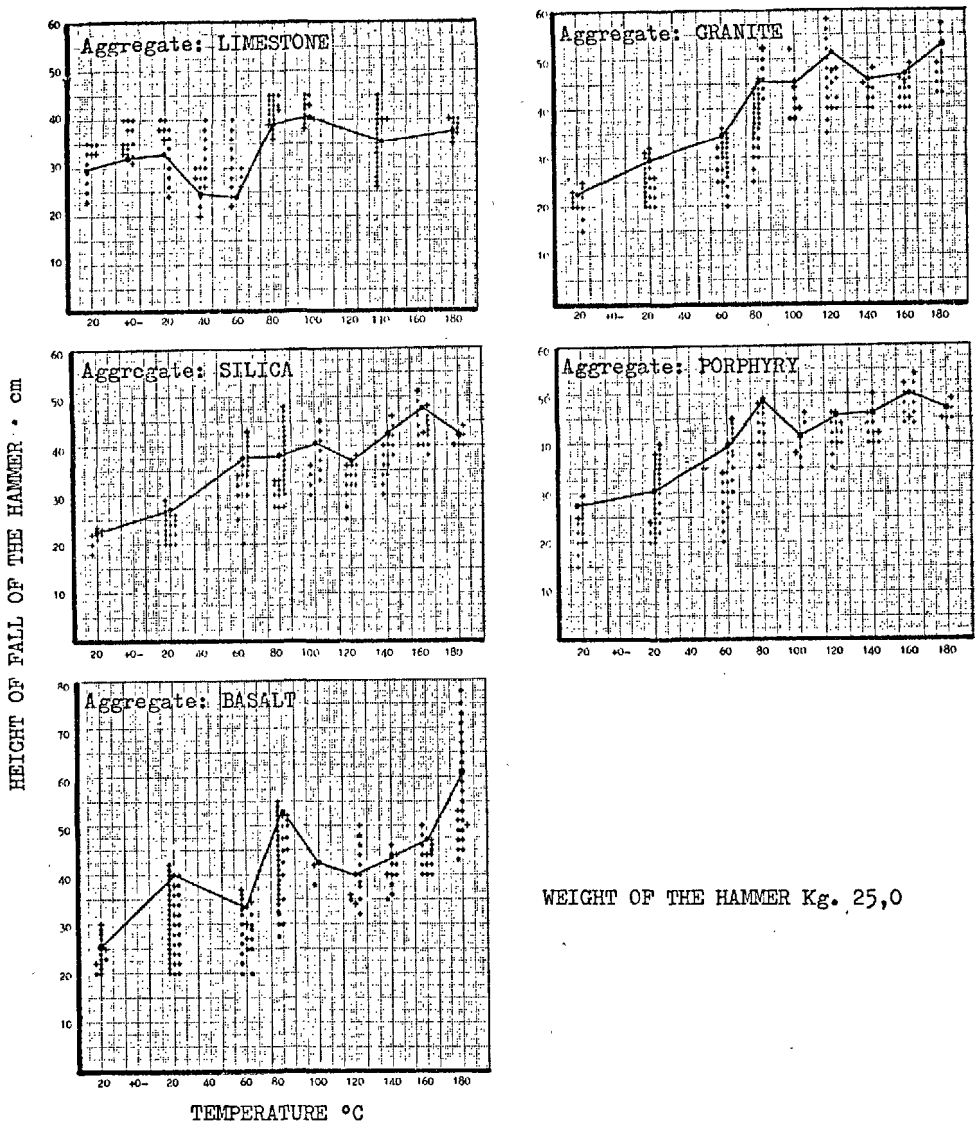

Fig. 9. *Relation between shock strength of concretes with different types of aggregates and treatment temperature*

Table 6. *Thermal contraction ($\cdot 10^{-6}/°C$) of aggregates and respective concretes for $0 < T < -160°C$*

	Aggregate			Concrete		
	$\lambda = \lambda(T)$	λ T = 0°C	λ T = −160°C	$\lambda = \lambda(T)$	λ T = 0°C	λ T = −160°C
Limestone	5.224 + 0.030T	5.224	0.424	6.901 + 0.036T	6.901	1.141
Granite	4.395 + 0.018T	4.395	1.515	5.195 + 0.028T	5.195	0.715
Porphyry	8.740 + 0.026T	8.740	4.580	8.875 + 0.030T	8.875	4.075
Basalt	8.480 + 0.026T	8.480	4.320	9.571 + 0.032T	9.571	4.451

On account of their very low coefficient of water imbibition, negligible are the differences between the linear deformations of specimens cured in a humid and in a dry room.

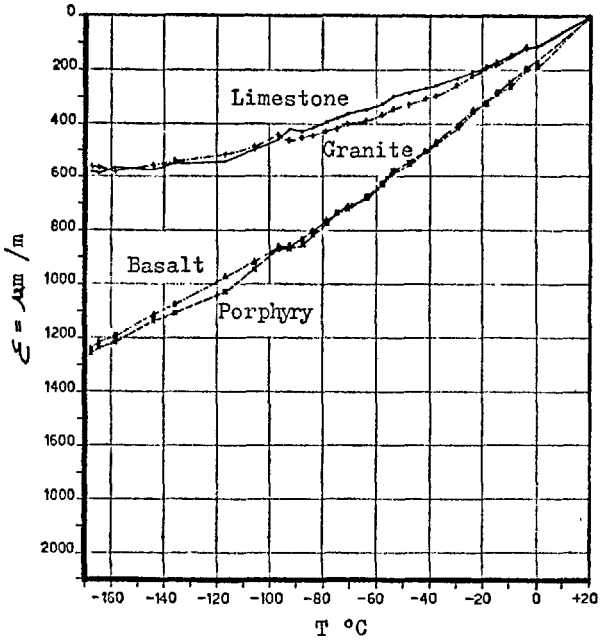

Fig. 10a. *Linear deformations of aggregates*

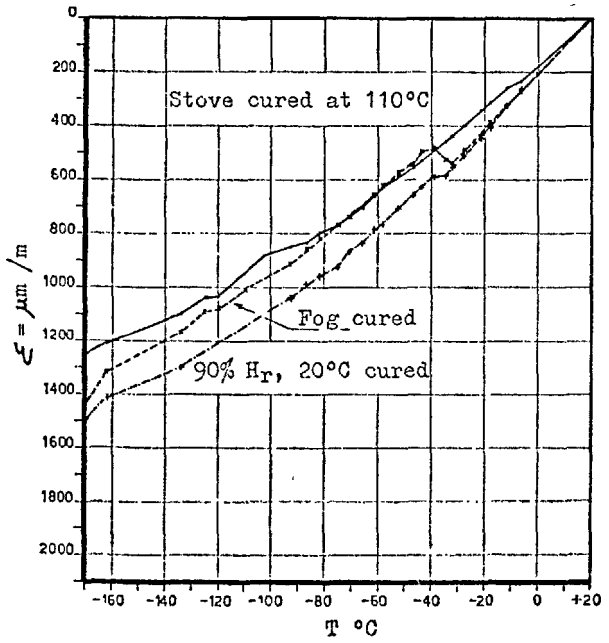

Fig.10b. *Linear deformations of concrete made with porphyric aggregate*

Concretes

Before carrying out tests, some specimens were dried in a stove at 110°C, others were stored in a room almost saturated with water (90% R.H., 20°C), others were stored in a fog-room (20°C).

The thermic contraction of the dried concretes has a regular trend and the respective average shrinkage coefficients are indicated in Table 6.

The specimens cured at 90% R. H., 20°C, shrink since the beginning more than the dried specimens and go on, with the exception of a slight interruption at about −37°C, with a regular trend. In Fig. 10b it is shown the trend of the concrete made with porphyritic aggregate.

The specimens stored in a fog-room, and therefore saturated with water, shrink at first as much as those which were brought in equilibrium at a humidity of 90%. But at a little below −10°C, their curve deviate upwards in comparison with the curve of 90%, at first slightly, then rapidly, at a little below the temperature of −30°C, owing to a rather sudden expansion, the curve continues with a variable trend till −60°C ~ −65°C, and then puts itself, till the end, along a line parallel to the line of the non-saturated samples.

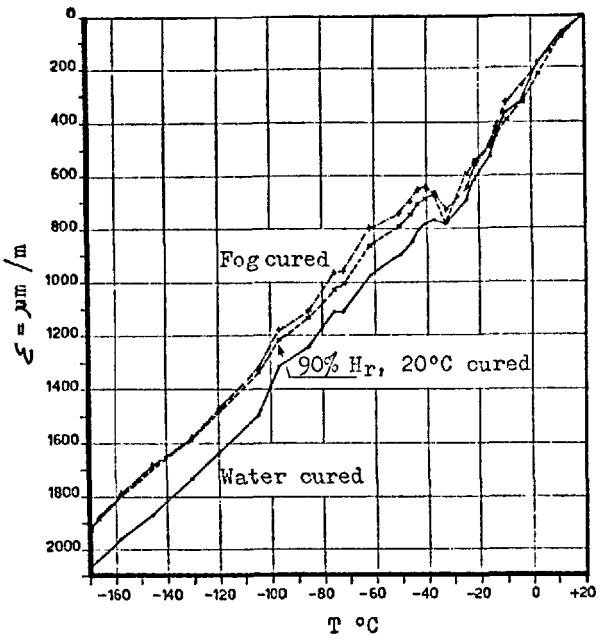
Paste and Mortar

The dried paste takes a trend of contraction almost rectilineal. If it is moist, the average coefficient of shrinkage is greater and it reaches $19.6 \cdot 10^{-6}$/°C, in comparison with the $10 \cdot 10^{-6}$/°C, reached when it is dry. The phenomenon of expansion is noticed also for plastic mortar, as found for the paste, when the specimen had been stored in a room having a humidity $\geqslant 60 \sim 70\%$ R. H. (20°C). In Fig. 11a, the curves refer respectively to the specimens immersed in water, cured in a room having 90% of R. H., 20°C and cured in a fog-room.

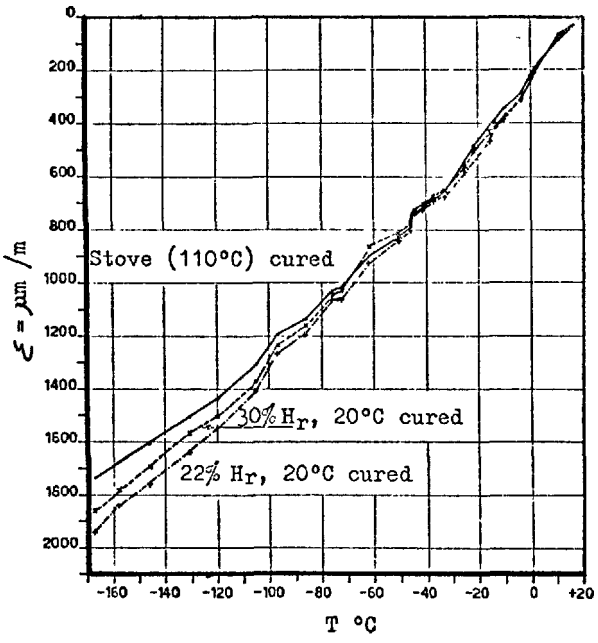
The effect of expansion becomes stronger when passing from a type of curing to the other one as the specimen absorbs more water, or is able to fill those porosities on which the expansion is depending. The filling of porosities is more full in moist atmosphere rather than in water.

The curves in Fig. 11b which correspond to specimens dried at 110°C, cured in rooms having 22 and 30% of R. H., 20°C, confirm by their trend that only the presence of free water can cause the expansion in question.

The experimental results show concordantly that the specimens previously dried, contract less than the corresponding moist specimens as the temperature decreases, from the beginning of the test. On the first ones the test is started after the samples have already undergone the shrinkage, characteristic of the loss of humidity, ensuing the drying treatment. The changes in length, continuously measured on them, are exclusively due to contraction on account of the thermic effect.



(a)



(b)

Fig. 11. *Linear deformations of mortars*

On the moist specimens, there is the superimposition of the thermic contraction on the hygrometric shrinkage. The nature of this shrinkage is quite different from the one due to the evaporation of the free water.

Table 7. *Thermic contraction of ice*

Temper. °C	μm/m	Temper. °C	μm/m
−25	673	−65	2248
−30	1043	−70	2371
−35	1273	−75	2584
−40	1523	−80	2745
−45	1554	−85	2892
−50	1636	−90	2052
−55	1839	−95	3222
−60	2104		

In a cement paste the freezing of the free water takes place at first in the coarsest porosities, which are not, in general, at critical filling, so it does not arise an expansion of the mass. At the same time, some additional water migrates from the finer, completely filled porosities, towards the coarsest ones. This water freezes, in its turn. The capillaries undergo, thus, a loss of water, and consequently a hygrometric shrinkage arises.

As the temperature decreases more and more, also the water contained in the capillaries freezes (about −30°C). As this temperature we observe stopping of the shrinkage and the appearance of the sudden expansion; when all the free water has frozen (about −70°C) the contraction continues as the thermic effect.

The Water-Ice System

Owing to the fundamental influence of water and ice on the appearance and trend of the phenomena under consideration, we wanted to measure the coefficient of contraction of ice. The results, which are in good accordance with those of the literature (12), are shown in Table 7.

In Fig. 12 it is also shown the trend of the specific volume of the water-ice system.

Hysteresis Curves

Concretes and Mortars

Specimens of these materials containing different quantities of humidity, have been submitted to cooling and warming cycles and their respective variations in length were observed.

Fig. 13 indicates the trends referring to concretes submitted for three times consecutively, without any interval, to changes in temperature with start from +20°C down to −150°C and vice-versa. The fog cured specimens show a very clear hysteresis effect; such an effect is very little noticeable on specimens having 90% of R. H. and it is pratically inexistent on specimens dried at 110°C.

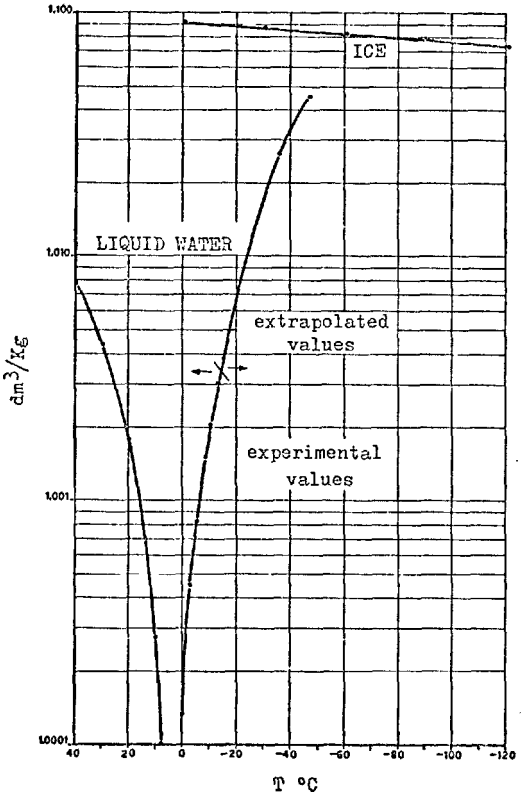


Fig. 12. *Relation between specific volume of water and temperature*

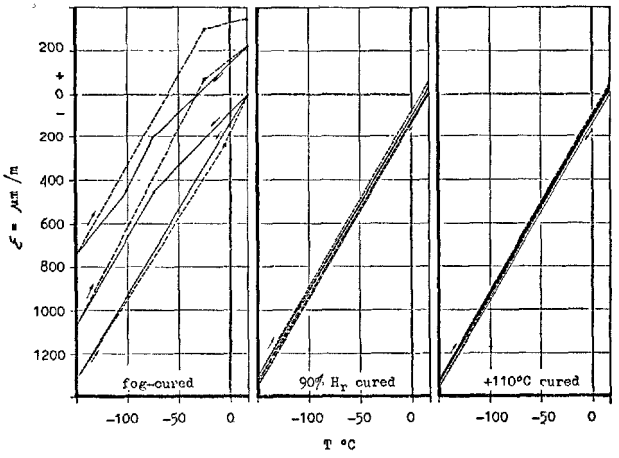

Fig. 13. *Relations between linear deformations of concrete and temperature for three cycles of freezing and thawing*

The results of tests made on specimens of plastic mortar, are indicated in the diagram of Fig. 14 and fully confirm the existance of the hysteresis as well as its trend.

It is necessary to point out, that for cooling and warming cycles between −50 and −90°C no hysteresis effect was noticed. The moist cement paste undergoes a deformation beyond its elastic limit, owing to water freezing in the capillaries. If a warming happens, some water will migrate from the coarse porosities to the deformed capillaries. So, at the room temperature, we will find an hysteresis, that is an increase of dimensions in comparison with the ones measured at the beginning.

On repeating the freezing, the process of subsequent expansion in the capillaries happens again, at least as long as there is sufficient water in the coarse pores for their previous saturation. There will be, at the end, a further increase in the permanent deformation.

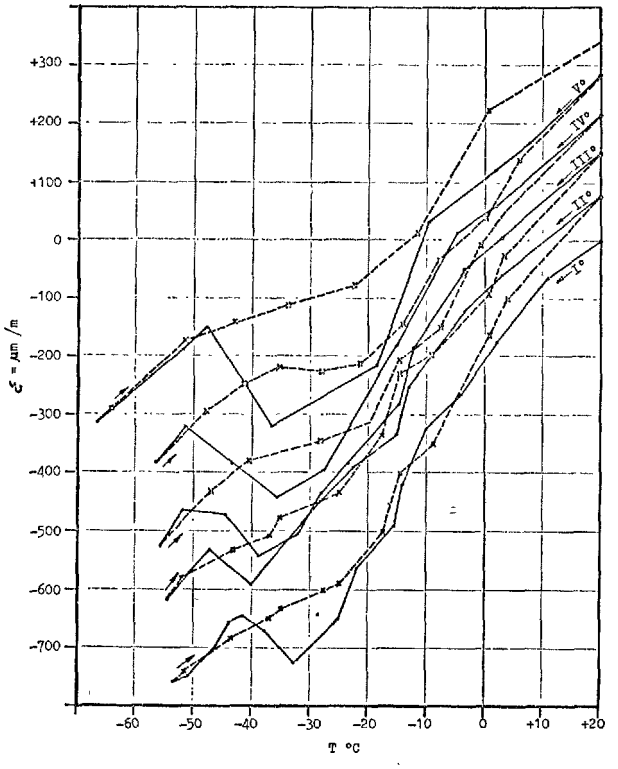

Fig. 14. *Relation between linear deformations of fog cured mortar and temperature (for five-cycles of freezing-thawing)*

Complementary Investigations

Calorimetric Tests

The object of this investigation is the research, through calorimetric tests, of the temperature or of the interval of the temperature at which the water contained in a paste freezes.

Choice and Preparation of Samples

Samples of pure paste, prepared with high strength cement, w/c = 0.45, cured for 300 days in water were used.

The samples were heated in a stove at 110°C, after cooling in a drying container, and were weighed on an analytical balance. Some samples were tested in this condition and their water content (determined as loss of ignition) was 0.1139 g/g of dried paste equal to 16.56% (this accords with the theoretical value of the non evaporable water, wn) (12).

Other samples cured after having been put in water for 24 hours, were kept into a box, saturated with water at 20°C, for 48 hours. The absorption of humidity was examined, by weighing again the samples on an analytical balance.

After the treatment described above, the average value of the content of water of the samples determined as loss on ignition was: 0.18056 g/g of moist paste $w_0 = 31.62\%$ of which 16.56% non evaporable water (wn) 15.06% evaporable water (we).

Equipment

For cooling samples, different freezing apparatus were employed according to the interval of temperature under examination.

The temperatures of the cooled samples were measured with I/RO thermocouple connected with a millivoltmer (Class 0.1). A multiple jackets calorimeter was used. The proper calorimetric container is plastic made, tightly jacketed with copper (shield against convective movements), contained in a stainless steel jacket. The whole is immersed in a thermostatic bath at a temperature of 25.2 $\pm$0.01°C.

The thermometer consists of a thermometric feeler provided with platinum resistance connected with a branch of a Wheatstone's bridge. The loss of balance of the bridge, which is proportional to the variation of the temperature, is continuously registered by means of a galvanometric recorder with a sensitivity of 0.00758°C per mm.

Results

The warming of the samples from the initial temperature T_i to the final one T_f involves a variation of enthalpy ΔH_0

$$\Delta H_0 = \frac{\Delta a \times c}{P}$$

where:

Δa = thermic change in mm

c = calorimetric equivalent of the calorimeter cal/mm

P = weight of the samples in grams

Tables 8 and 9, respectively for wet and dried samples, give the values of ΔH_0 and the values of $\Delta H_{corr.}$, because the temperature T_f show a dispersion of 22°C $\pm$ 1.5°C and for this reason a correction is made, in order to refer always to a final temperature of 22°C.

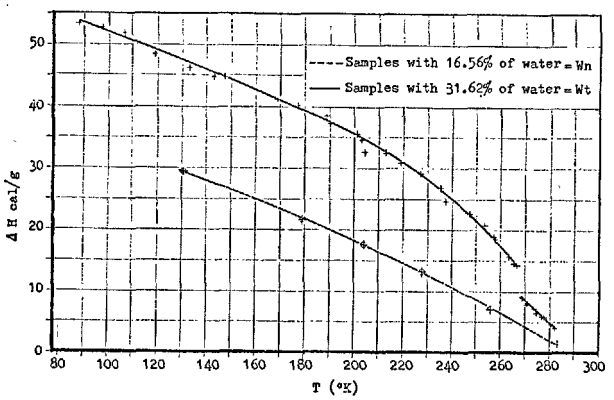

Fig. 15. *Enthalpy changes of cement pastes with variable water content from 295°K to T °K*

It is possible to draw the diagram of the $\Delta H = \Delta H(T)$ of the dried samples showing a water content (determined as loss of ignition) equal to 16.56% and of the wet samples showing water content (determined as loss of ignition) equal to 31.62% (Fig. 15).

As it may be noticed, the trend $\Delta H = \Delta H(T)$ is regular and continuous for the dried specimens and it may be well represented by a parabola:

$-\Delta H_{295°K}^{T_i°K} = 42.00662 - 5.9079 \cdot 10^{-2} T - 3.00173 \cdot 10^{-4} T^2$

It is now to consider the trend of ΔH of the moist specimens.

It is possible to see a clear discontinuity for $T = 269.16$°K which is attributable to the change of the state from ice to water. Following to this transformation, the calories involved are:

$\Delta H = 5.1$ cal/g

Referring to the melting heat of water under normal conditions $\Delta H_m = 79.71$ cal/g, the result obtained is, that at this temperature, 0.0639 g of water freezes per g of paste, which is equivalent to 35% of the evaporable water.

The decrease of the freezing point may be attributed to the presence of dissolved salts.

If we want to evaluate the temperature at which all the water is frozen, we can usefully examine the diagrams $C_p = C_p(T)$.

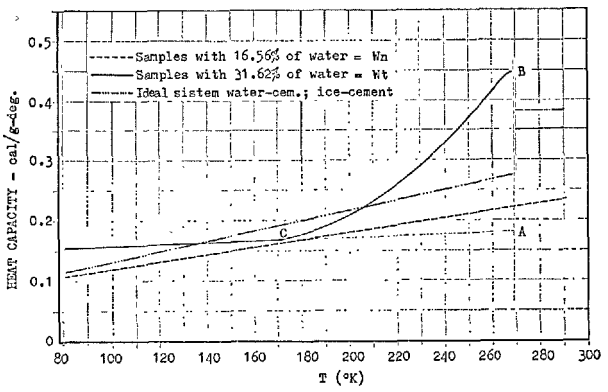

Fig. 16. *Heat capacity of cement pastes with variable water content from 80°K to 290°K*

Such diagrams (14) can be obtained by derivation: $C_p = \partial \Delta H / \partial T$

The trend $\Delta H = \Delta H(T)$ for the wet samples can be analytically represented by three parts of curve:

for $80 < T_k < 170$

$-\Delta H_{295°K}^{T_i°K} = 67.2300 - 0.14788T - 5.28293 \cdot 10^{-5} T^2$

for $170 < T_k < 269$

$-\Delta H_{295°K}^{T_i°K} = 101.812 - 0.77023T + 3.76696 \cdot 10^{-3} T^2 - 7.89380 \cdot 10^{-6} T^3$

for $269 < T_k < 282$

$-\Delta H_{295°K}^{T_i°K} = 103.220 - 0.35070T$

and the $C_p = C_p(T)$ will be respectively:

for $80 < T_k < 170$ $C_p = 0.14788 + 1.05658 \cdot 10^{-4} T$

for $170 < T_k < 269$ $C_p = 0.77023 - 7.53393 \cdot 10^{-3} T + 2.36814 \cdot 10^{-5} T^2$

for $269 < T_k < 282$ $C_p = 0.35070$

The quantities of water that freeze at temperatures inferior to the transition point (269.16°K), lead to an excess of specific heat.

The difference between the behaviour of wet samples and the behaviour of the dried samples may be attributed to a progressive change in the state of water.

At this point, we represent graphically the trends of $C_p = C_p(T)$ (Fig. 16).

In addition to the experimental behaviour, the graph represents also the trend of the specific heat of the ideal system of "ice-dried paste" and "water-dried paste".

By extrapolating the trend of the curve of the specific heats valid for $T < 170$°K down to the temperature of $T = 269.16$°K (which is equivalent to the admission of a total freezing at this temperature) the area ABC is isolated. This area, when measured in

heat terms, represents the calories involved in the progressive freezing of water for $T < 269.16°K$. The measurement of the area graphically executed has given a value of 10.2 cal/g of paste.

Supposing as a first approximation, that the latent heat of melting does not change considerably with the temperature, by the following ratio we obtain:

$$\frac{10.2 \text{ cal}}{79.62 \text{ cal/g.}} = 0.1278 \text{ g.}$$

which means that 0.1278 g., that is about 70% of the evaporable water, freeze in this interval.

The change of state of such a system is quite different from a normal one for the reason that the water absorbed by the paste is contained in microcapillaries.

Other authors have studied similar effects (15); for instance, water absorbed by the gel of silica, nitrogen by dioxide of titanium. Thermodynamic explanations have been put forward, but the incomplete knowledge of the superficial conformation of the paste and the presence of collateral effects do not allow to reach a whole explanation of the phenomenon.

We can affirm consequently by this peculiar investigation, that evaporable water freezes gradually from $-4°C$ to $-95°C$.

Some anomalies in the trend of concretes in this range of temperature are so explained.

Triaxial Tests

The concraction phenomena help us to explain the increase of strengths as temperature decreases.

Freezable water is essential for the increment of strength.

The ice in the capillary net raises a state of stress in the surrounding mass because its contraction coefficient is the highest among the coefficients of the other materials. We think it is not right to consider ice like an inert solid filling porosities. In mechanical terms we can figure it like a diffused reinforcement pre-stressing the surrounding material.

We deemed interesting to identify the internal stress state with the stresses produced it in a specimen when submitted to triaxial stress and where $\delta_x = \delta_y \neq 0$. The δ_z of breakage increase on increasing of the stresses acting on the plane x,y. The results of the tests are shown in Fig. 17. In the same figure we put in relation the value of the lateral stress and the consequent value of the δ_z with the value of the temperature at which the same compressive strength is corresponding.

It appears finally opportune to point out the varia-

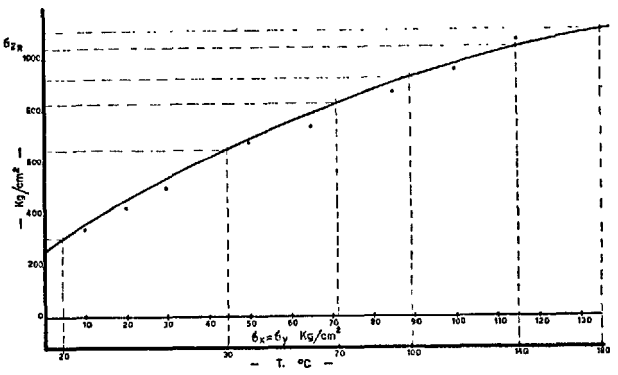

Fig. 17. *Relation between the temperature of treatment and $\delta_x = \delta_y \neq 0$ stress of a triaxial test*

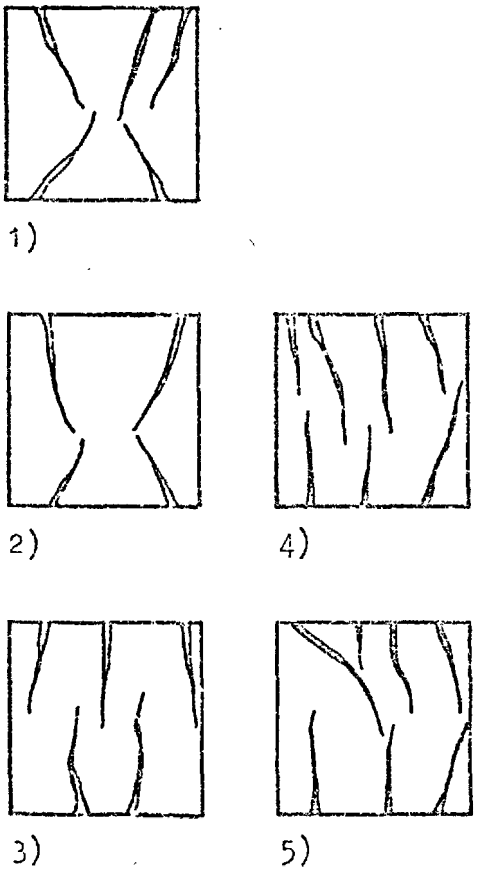

Fig. 18. *Breakage lines of concretes with different water contents at different temperatures*

1) Test at +20°C (cured at R.H. 100%, +20°C) $\delta R = 356$ kg/cm²
2) Test at −70°C (cured at R.H. 100%, +20°C) $\delta R = 820$ kg/cm²
3) Test at −180°C (cured at R.H. 100%, +20°C) $\delta R = 1125$ kg/cm²
4) Test at +20°C (dried at +110°C) $\delta R = 384$ kg/cm²
5) Test at −160°C (dried at +110°C) $\delta R = 474$ kg/cm²

tion of fracture planes in which specimens break as temperature decreases (see Fig. 18).

The kind of fracture is pointed out by some authors (16) (17) as a peculiar characteristic of the strength values.

Conclusions

—The fog-cured, hardened concrete, increases its mechanical strengths when it is cooled from room to low temperatures, even down to −196°C.

—The concrete, cured at 110°C so to eliminate its free water, when cooled doesn't show increases in strength.

—Cement type and nature of the pozzolana, in the case of pozzolanic cement, do not modify trends of the phenomenon. The same can be said in regard to the seven different types of aggregates with which the concretes were made (including also the aggregates of expanded clay). The highest strength, found at low temperatures, is bound to the room temperature strength of the concrete; so it depends on all the variables which condition a concrete (strength of the cement, its quantity, type of aggregate, curing, and so on).

—The shock strength of cooled concretes depends on their respective bending and compressive strength.

—Degradation of no significance was found in the physical and mechanical characteristics on concretes treated cyclically from +20 to −196°C with a long curing at the test temperature.

—The dynamic modulus of elasticity, that at room temperature follows the trend of strengths, increases as temperature decreases.

—The thermal contraction coefficient of concrete at low temperatures, depends on the type of aggregate and feels the effects of the respective water contents. In connection with water content hysteresis curves appear on specimens submitted, without interruption, to warming and cooling treatments.

—The enthalpy variation referred to cooling temperature on cement paste specimens, indicates that the free water freezes progressively from −4°C down to −90°C.

—Inflections on mechanical strengths in the range −10°C ~ −60°C can be explained on the basis of what written at the preceding point. In the moist specimens, the migration of water, during the freezing, from the capillaries to the coarsest porosities causes a hygrometric shrinkage, in addition to the thermal contraction; the corresponding dried specimens are subject only to the effect of thermal contraction. The progressive and complete freezing of the water contained in the porosities causes a deformation: hence the hysteresis.

—The freezing of the water contained in the capillaries induces in the mass of the paste an internal stress, more and more diffuse and intense. When all the free water is frozen and the temperature still falls down, paste and ice go on with their thermal contraction. The contraction coefficient of ice is higher than the one of paste and of the aggregate, and consequently the ice contained in the porosities and in the capillaries consists of a sort of pre-stressed reinforcement immersed in the paste. By means of triaxial compressive tests, we found the values of the lateral stresses, to which the values of the temperature are corresponding, to obtain the same monoaxial breakage strengths in the cooled moist specimens.

Acknowledgements

The author wants to express his gratitude to the Chairman and Managing Director of "Italcementi" S.p.A. Cav. Lav. Dr. Ing. Carlo Pesenti, who understood widely and deeply the problem of scientific research and encouraged the Central Laboratory of the Company in its activity of study and practical and technical experimentation.

He is grateful also to Prof. Dr. F. Massazza, director of the Laboratory for the contribution he gave in the discussions concerning this work. He thanks Dr. Ing. P. Ursella for the very help he performed during the experimentation and the interpretation of the results, as well as during the drafting of the present paper, and finally he thanks Dr. Costa, Mr. Martinelli and Mr. Morlotti for their co-operation.

Oral Discussion

Rolf F. Feldman

The experimental results of the author are very interesting. The result that the specimens which were dried before cooling contract less than the corresponding moist specimens should, however, be further discussed.

The resultant length change that occurs when a saturated sample of hydrated portland cement is cooled may involve many factors and it is the purpose here to discuss a few of them separately with the view of further understanding the results.

We will initially consider hydrated portland cement as a relatively inert high surface area material and consider it as saturated with water at 0°C. As cooling takes place (We assume that equilibrium is maintained, kinetic effects not playing a role.), one of the effects we might except is a change in the surface free energy change due to interaction of the adsorbate (H_2O) with the adsorbent (hydrated cement).

The above phenomena is considered here as small and more so because the amount of physically adsorbed water in cement is not very large. However, in the above case, we have ignored any effect due to menisci forces and freezing. When cooling takes place to temperatures below 0°C and water in some large pores freezes, a new equilibrium will be set up; the vapour pressure required to maintain the saturated state of the sample will be that of supercooled bulk water at the temperature of the sample. Below zero, and in the presence of bulk ice, this will be impossible to maintain and the system will attain equilibrium at a new p/p_0 value, where p is the vapour pressure of bulk ice at the temperature of the sample and p_0 is the vapour pressure of bulk water at the same temperature. Thus there will be an effective reduction in vapour pressure as the sample is cooled and a shrinkage due to menisci forces in the small pores of the specimen.

In the discussion above, we have considered the solid (hydrated portland cement) to be inert, but immediately we can see that this assumption is not correct. When hydrated is first dried, an irreversible

shrinkage is obtained and it has already been shown how cooling can effectively reduce the relative humidity of the specimen. At −15°C the relative humidity would be 86 per cent, and it is considered here that the irreversible shrinkage phenomenon would represent a larger portion of the shrinkage observed on cooling than capillary effects which have been observed on stabilized cement paste (1, 2).

One last area of importance is the effect of the cooling on the interlayer hydrate water. It has been shown (1) how this water plays a very important role in length change phenomena at low vapour pressures and one might wonder if the low temperatures could cause a further change in order and mobility of this water, resulting in a length change.

Author's Closure

Giampietro Tognon

The results of the experiment, set forth in our supplementary paper and further demonstrations on the same subject, are still being worked out.

We therefore agree that a thorough examination thereof would be well-advised; and we deem of interest and, moreover, useful the suggestion put forth by Mr. Feldman regarding break-down of the components of the basic occurrence, i.e., the lower contraction taking place further to cooling applied to previously dryed test specimens, as compared to contraction noted on comparable moist test specimens.

In the first place, it is important to bear in mind that, in the part of testing where we would observe freezing effects most accurately, the test specimens are to be considered, at least theoretically speaking, immersed in a closed system. Their mass has certainly achieved the temperature levels that we have pointed out, without having the possibility, though, of reaching the point of equilibrium at the respective temperatures, as like as the necessary adsorptions or desorptions of water.

It therefore arises that any consideration as regards equlibrium adjusted by the Gibbs' equation, the menisci forces and the effects on the interlayer hydrate water may be well applied in the case of a system in a condition of well definable equilibria, but in our investigation method, we would work out them in a particular way in order to put them valid.

The type of investigation according to procedures recommended by Mr. Feldman, a result of his importand works, is definitely to be applied.

Supplementary Paper III-25 The Influence of Temperature on Sulphate Attack on Portland Cement Mortars

J. H. P. van Aardt*

Synopsis

The paper discusses various aspects concerning corrosion of portland cement products in sulphates. Some reactions at 5°C and 25°C of the relevant calcium aluminate hydrates are considered with special reference to early ages. Various calcium sulpho-aluminate hydrates are dealt with in relation to rate of reaction at the two temperatures and the various products formed when both the sequence of mixing of the reactants and their quantities are varied. The stability of calcium aluminate hydrates and calcium sulpho-aluminate hydrates at these temperatures is considered with a view to explaining some of the observations in practice as regards sulphate attack on portland cement products. Experiments with mortars and observations on their behaviour in sodium sulphate solutions at 5°C and 22°C are considered. Two of the important findings are:—(1) cubic calcium aluminate hexahydrate is unstable at low temperatures and more so in the presence of $Ca(OH)_2$; (2) under some circumstances a calcium mono-sulpho-aluminate with a basal spacing at 8.5 Å is the reaction product of C_3AH_6, $Ca(OH)_2$ and $CaSO_4 \cdot 2H_2O$ at 25°C.

Introduction

The entire issue of sulphate corrosion of portland cement products is complicated by physical factors such as the density and the permeability of the product. In other words, durability depends also on the cement content, the grading and type of aggregate, the degree of compaction, the water/cement ratio and the thoroughness of curing; in short the higher the quality of a cement product, the better its resistance to sulphates. The influence of these physical factors can be so marked that in some instances they may obscure the influences on corrosion of differences in chemical composition of various portland cements. Nevertheless, the chemical composition of portland cement, especially the alumina content, determines to a large extent its resistance to the sulphate ion. Although much is known about sulphate attack there are still some doubts about certain aspects of the mechanism involved when calcium aluminates react with sulphate to cause deterioration in portland cement products. It is known, for instance, that the reactions are affected by temperature but there is as yet no clear understanding of the matter. In this contribution, experiments concerning the nature and behaviour of some calcium aluminates at 5°C and 25°C are described; reactions at early ages are considered. The behaviour of portland cement mortars in sulphate solutions at these temperatures is also discussed.

Some Reactions of Tricalcium Aluminate Hexahydrate and Tricalcium Aluminate at 5°C and 25°C

Working with suspensions of C_3AH_6 in water and of C_3A in water, van Aardt and Visser (1) have shown that both the substances behaved differently at 5°C and 25°C. In the presence of $Ca(OH)_2$, the two aluminates gave the same reaction product at 5°C. Fig. 1 shows that the reaction product at 5°C of (i) C_3AH_6 (1.89 g) plus $Ca(OH)_2$ (0.37 g) plus H_2O (50g) and (ii) C_3A (1.35 g) plus $Ca(OH)_2$ (0.37 g) plus water, has *d*- spacings at 10.6 Å and 5.3 Å, similar to C_4AH_{19} described by Jones and Roberts (2). This indicates that C_3AH_6 is unstable at 5°C and more so in the presence of $Ca(OH)_2$. Furthermore, C_3AH_6 plus $Ca(OH)_2$ at 25°C seemed to react partially to form a compound

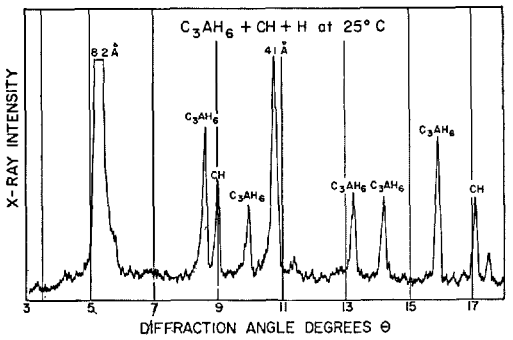

Fig. 2. *X-ray diffractogram of* C_3AH_6 *and* $Ca(OH)_2$ *in water at* 25°C

with *d*- spacings at 8.2 Å and 4.1 Å. The 10.6 Å compound was unstable above 30°C; at this temperature, the suspension showed *d*- spacings for C_3AH_6, $Ca(OH)_2$ and the 8.2 Å compound. The filtered wet 10.6 Å compound behaved in a similar way on heating to 50°C in an enclosed space, the silky appearance of the paste disappeared and it was changed into a very wet paste; water was clearly set free. Fig. 2 is an X-ray diffraction diagram of the substance obtained in this way; it is similar to a diagram of a suspension of C_3AH_6 plus $Ca(OH)_2$ at 25°C, i.e. the 8.2 Å, 4.1 Å substance plus $Ca(OH)_2$ plus C_3AH_6. When the suspension containing the 8.2 Å substance was kept at a temperature above say 70°C for a period, only C_3AH_6 and $Ca(OH)_2$ were detected on the X-ray diffraction diagram .

The course of the reactions when C_3A was added to water can be summarized as follows:

$$2C_3A + H_2O \xrightarrow{\text{approx. } 25°C} C_4AH_{19} + C_2AH_8 \qquad (1)$$

The two types of hydrates could be detected by the basal spacings at 10.6 Å and 10.7 Å. Two types of

Fig. 3. *X-ray diffractogram of cubic* C_3AH_6 *in water at* 25°C

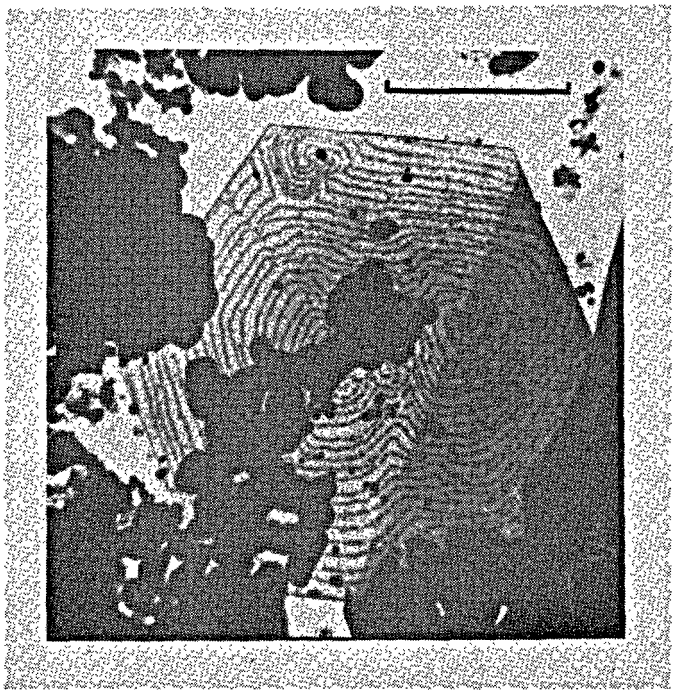

Fig. 4. *Electron micrograph showing zoning during reaction between* $C_2AH_8 + Ca(OH)_2$

hexagonal plates could also be observed under the electron microscope. When the temperature was raised, the aluminates were converted to cubic C_3AH_6 and some hexagonal substance with a basal spacing at 7.6 Å. The X-ray diffractogram was identical to that of a suspension of C_3AH_6 in water at 25°C (see Fig. 3).

When $Ca(OH)_2$ was added to the suspension at 25°C, the C_2AH_8 reacted with it and C_4AH_{19} was produced.

$$C_4AH_{19} + C_2AH_8 \text{ (eqn. 1)} + 2Ca(OH)_2 \xrightarrow{+H_2O,\ 25°C \text{ and lower}} 2C_4AH_{19} \qquad (2)$$

When (2) was heated to about 50°C it changed into cubic C_3AH_6 and a hexagonal substance with a basal spacing at 8.2 Å, (see Fig. 2). On cooling to 5°C, this again formed the 10.6 Å substance.

When $Ca(OH)_2$ was added to the suspension (1) above and the mixture was examined under the electron microscope soon after the addition, hexagonal crystal showing the zoning as in Fig. 4 were observed. It is assumed that this was a reaction between C_2AH_8 and $Ca(OH)_2$. A similar observation but with the zoning even more pronounced was made when C_3A and C_3S were mixed in water and the temperature of the suspension kept in the vicinity of 25°C. The zoning disappeared on storage.

Reaction Products at Early Ages of C_3A and of C_3AH_6 with Calcium Sulphate

Having established the behaviour as described above of C_3A and of C_3AH_6 in water and in the presence of $Ca(OH)_2$ in water at 5°C, and 25°C, the reactions of $CaSO_4$ with the calcium aluminate hydrates were investigated.

Reactions at 25°C

Suspensions containing essentially the 10.6 Å hexagonal hydrate and the 8.2 Å substance were prepared as follows:

C_3A (1.35 g) or C_3AH_6 (1.89 g) was reacted for seven days with $Ca(OH)_2$ (0.37 g) in water (100 g) at 5°C to give the 10 .6 Å hydrate and C_3AH_6 (1.89 g) plus $Ca(OH)_2$ (0.37g) in water (100 g) was used at 25°C to give the 8.2 Å substance.

The reaction products obtained when one mole or three moles $CaSO_4 \cdot 2H_2O$ was added to these calcium aluminate hydrates and the reaction mixtures kept at 25°C were described by van Aardt and Visser (3). The addition of one mole of sulphate to the 10.6 Å compound produced a phase with *d*- spacings 9.6 Å, 4.77 Å at early ages, i.e. one hour to seven days (see Fig. 5(A)).

This substance changed to a phase with *d*- spacings 8.9 Å, 4.4 Å at equilibrium. When three moles of sulphate were added, only the 9.6 Å compound and $CaSO_4 \cdot 2H_2O$ were observed at one hour: the equilibrium phase was ettringite. The presence of excess $Ca(OH)_2$ tended to retard the reaction rate. In brief:

$$10.6\text{ Å} \xrightarrow{+1\ CaSO_4 \cdot 2H_2O} 9.6\text{ Å} \xrightarrow{Ca(OH)_2 + \text{time}} 8.9\text{ Å}$$

$$10.6\text{ Å} \xrightarrow{+3\ CaSO_4 \cdot 2H_2O} 9.6\text{ Å} + CaSO_4 \cdot 2H_2O \longrightarrow \text{ettringite}$$

One mole of sulphate added to the 8.2 Å compound, produced a phase with *d*- spacings 8.5 Å, 4.23 Å and ettringite: gypsum was also present at an early age, i.e. one hour, but was not detected at seven days (see Fig. 5(B)). The 8.5 Å compound changed to ettringite and finally at equilibrium the 8.9 Å compound was observed; the change from ettringite to 8.9 Å appeared to pass through the 9.6 Å substance. When three moles of sulphate were added the 8.5 Å phase and gypsum were observed at one hour; the equilibrium phase was ettringite. The presence of $Ca(OH)_2$ tended to retard the reaction rate. In brief:

$$8.2\text{ Å} \xrightarrow{+1\ CaSO_4 \cdot 2H_2O} 8.5\text{ Å} + E \longrightarrow E + \text{aluminate} \longrightarrow 9.6\text{ Å} \longrightarrow 8.9\text{ Å}$$

$$8.2\text{ Å} \xrightarrow{+3\ CaSO_4 \cdot 2H_2O} 8.5\text{ Å} + CaSO_4 \cdot 2H_2O \longrightarrow \text{ettringite}$$

In the presence of gypsum, a suspension containing both the 10.6 Å and 8.2 Å compounds gave the intermediate phase 9.6 Å and 8.5 Å at early ages (see Fig. 5(C)).

When all the reactants, i.e. C_3A (1.35 g) or C_3AH_6 (1.89 g) and $Ca(OH)_2$ (0.37 g) and $CaSO_4 \cdot 2H_2O$ (0.86 g) were added at once, C_3A and $CaSO_4$ rapidly formed ettringite; the latter then reacted with more calcium aluminate to form the 9.6 Å compound within one day. C_3AH_6 reacted with the $CaSO_4$ to again produce ettringite; in this instance the ettringite was only slowly changed to the 9.6 Å substance. The equilibrium phase was again the 8.9 Å compound in both instances. Three moles of sulphate gave only ettringite at early ages while unreacted sulphate and aluminate were present.

With one mole of calcium sulphate and C_3A, in the absence of added $Ca(OH)_2$, the 9.6 Å phase was predominant after one day (see Fig. 6(A)), but with C_3AH_6, ettringite was predominant (see Fig. 6(B)); at later ages both suspensions contained the 9.6 Å compound. In the presence of saturated $Ca(OH)_2$

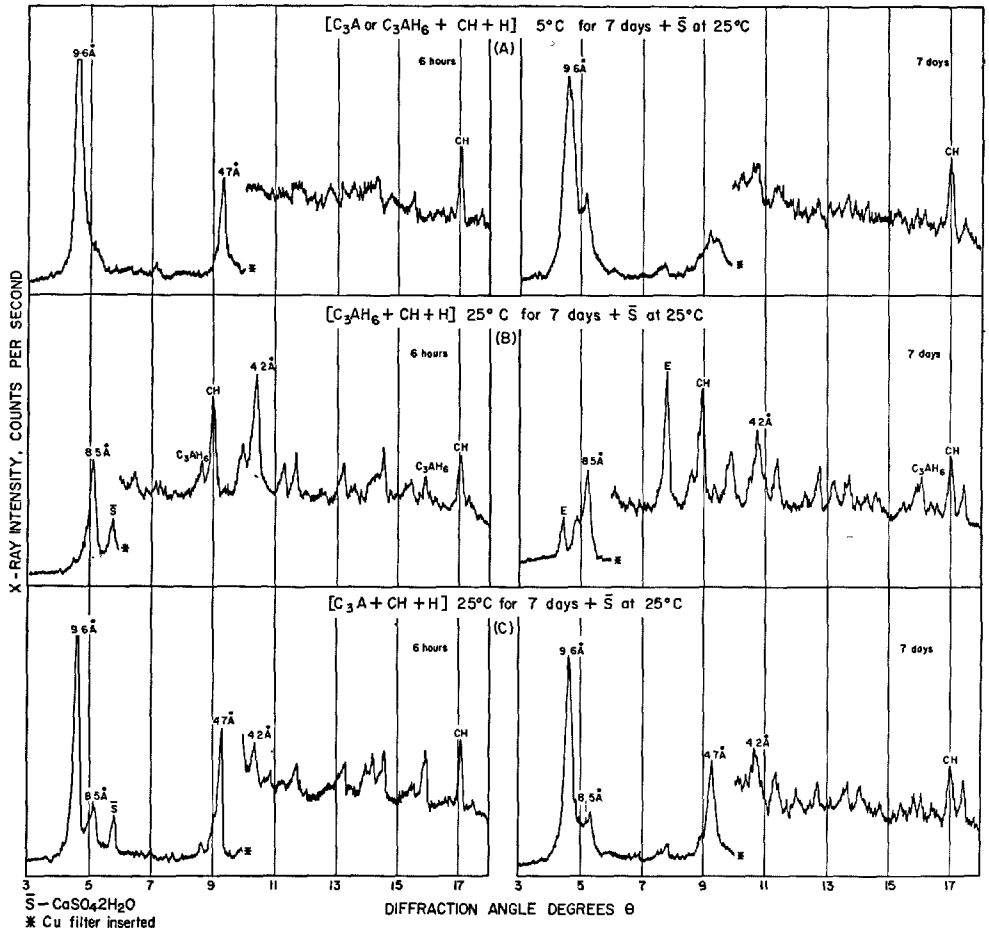

Fig. 5. *X-ray diffractograms of various calcium sulpho-aluminate hydrate at* 25°C

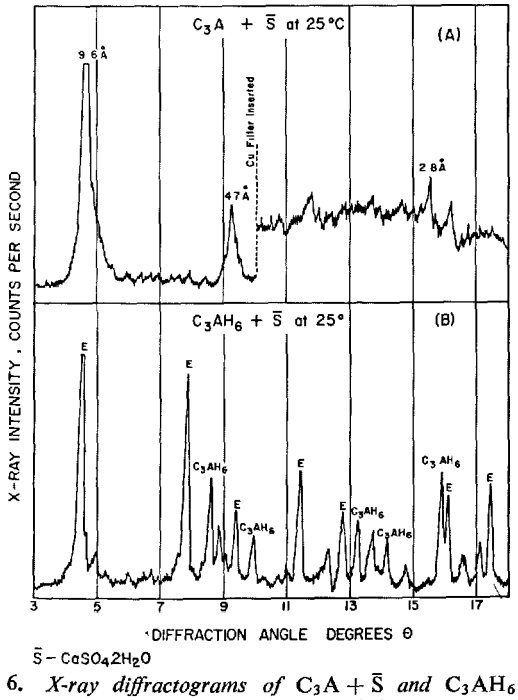

Fig. 6. *X-ray diffractograms of* $C_3A + \bar{S}$ *and* $C_3AH_6 + \bar{S}$ *after one day in water at* 25°C

solutions, the 8.9 Å phase was detected at equilibrium. Ettringite was the only phase observed when three moles of gypsum were added to the aluminates.

Reactions at 5°C

The following reaction mixtures in the form of suspensions in 100 g of water were examined:

(1) C_3A (1.35 g) plus $CaSO_4 \cdot 2H_2O$ (0.86 g)

(2) C_3AH_6 (1.89 g) plus $CaSO_4 \cdot 2H_2O$ (0.86 g)

(3) C_3A (1.35 g) plus $Ca(OH)_2$ (0.37 g) plus $CaSO_4 \cdot 2H_2O$ (0.86 g)

(4) C_3AH_6 (1.89 g) plus $Ca(OH)_2$ (0.37 g) plus $CaSO_4 \cdot 2H_2O$ (0.86 g)

(5) C_3A (1.35 g) + $Ca(OH)_2$ (0.37 g) reacted at 5°C for 7 days } plus $CaSO_4 \cdot 2H_2O$ (0.86 g)

(6) C_3A (1.35 g) + $Ca(OH)_2$ (0.37 g) reacted at 25°C for 7 days } plus $CaSO_4 \cdot 2H_2O$ (0.86 g)

(7) C_3AH_6 (1.89 g) + $Ca(OH)_2$ (0.37 g) reacted at 25°C for 7 days } plus $CaSO_4 \cdot 2H_2O$ (0.86 g)

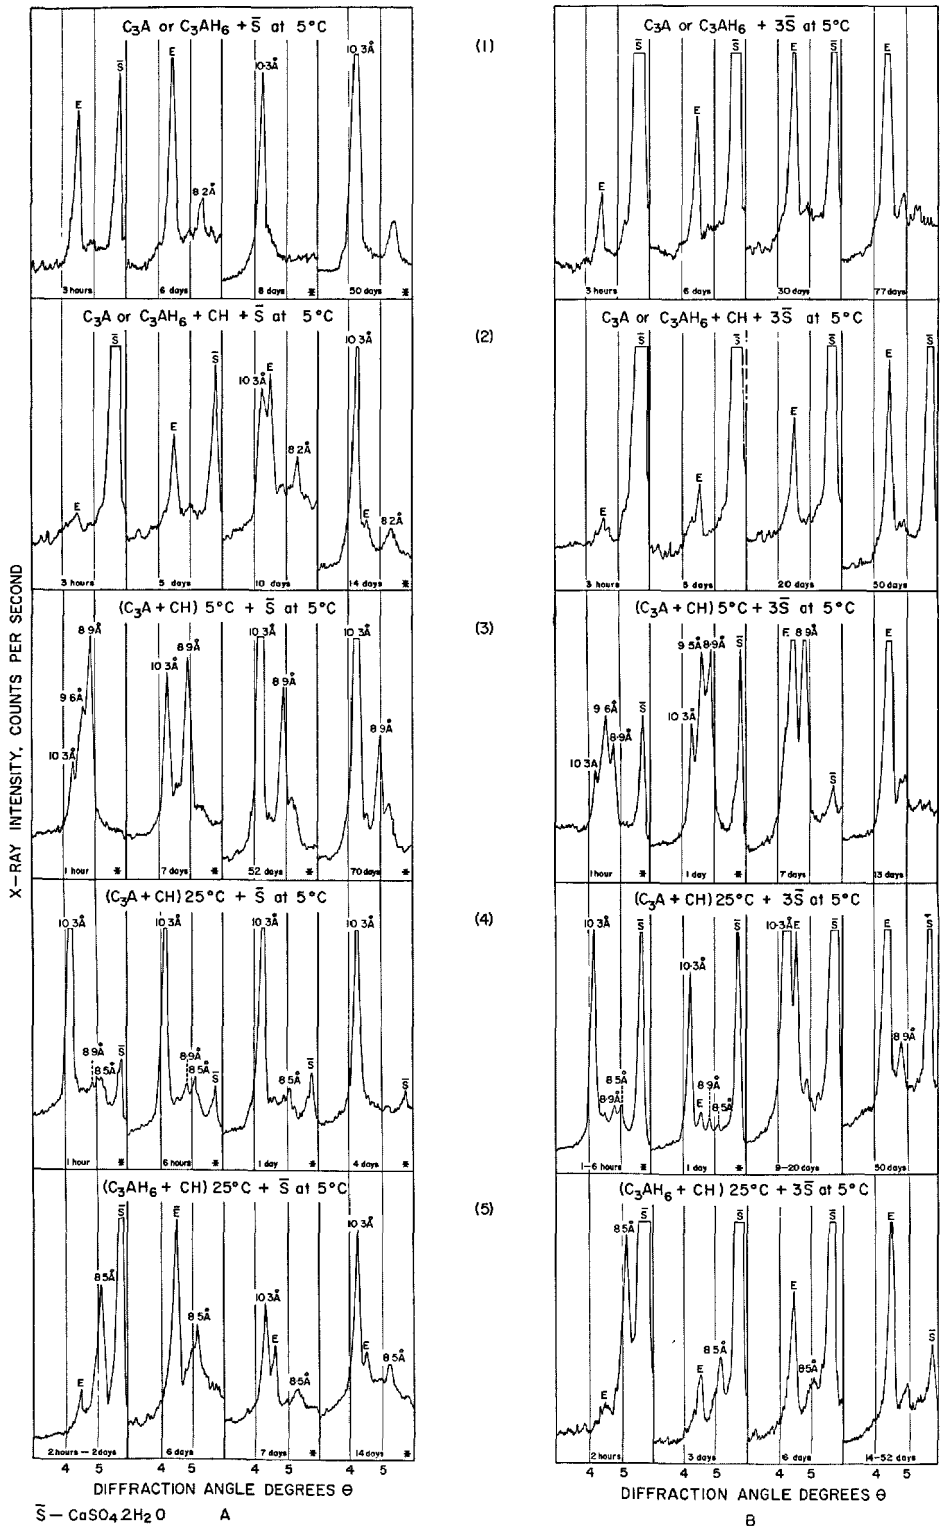

Fig. 7. *X-ray diffractograms of various calcium sulpho-aluminate hydrates at* 5°C

These experiments were repeated with three moles of $CaSO_4 \cdot 2H_2O$ added instead of one mole.

It was observed that when either C_3A or C_3AH_6 was mixed with one mole of $CaSO_4 \cdot 2H_2O$ and sus-

pended in water the first reaction product was ettringite and at a later stage some 8.2 Å substance was also present. Hydrated aluminates then reacted with ettringite to produce a substance with a basal spacing at 10.3 Å. This reaction appeared to be faster with C_3AH_6 than with C_3A. Thus with ettringite as an intermediate product the final product was the 10.3 Å substance. A similar position existed when $Ca(OH)_2$ was also present in the suspension, but the $Ca(OH)_2$ appeared to retard the rate of reaction as can be seen from Figs. 7A(1) and 7A(2).

When C_3A (and also C_3AH_6) was first reacted with $Ca(OH)_2$ for 7 days at 5°C before the addition of $CaSO_4 \cdot 2H_2O$ the course of the reactions was quite different, little ettringite was formed, gypsum appeared to react fast with the aluminate, which in this instance was C_4AH_{19}, to produce the monosulphate compounds 9.6 Å and 8.9 Å. These changed to the 10.3 Å calcium monosulpho-aluminate, i.e. the stable calcium, mono-sulpho-aluminate hydrate at 5°C. Eventually after a few months, only this substance and $Ca(OH)_2$ were detected in the suspension (see Fig. 7A(3)).

When C_3A plus $Ca(OH)_2$ were first reacted for seven days at 25°C before the addition of $CaSO_4 \cdot 2H_2O$ at 5°C, a complex mixture of calcium sulpho-aluminate hydrates formed rapidly (see Fig. 7A(4)). Little ettringite was produced and the 10.3 Å substance formed soon after the addition of $CaSO_4 \cdot 2H_2O$.

As was expected the conditioned mixture at 25°C of C_3A and $Ca(OH)_2$ contained both the 10.6 Å and some 8.2 Å calcium aluminate hydrates and these reacted with $CaSO_4 \cdot 2H_2O$ as described under the reactions at 25°C, but the reaction products then changed to the 10.3 Å material which is a stable phase at 5°C.

When C_3AH_6 and $Ca(OH)_2$ were mixed and kept at 25°C for seven days before the addition of $CaSO_4 \cdot 2H_2O$ at 5°C, the reaction follows a completely different course (see Fig. 7A(5)). Much of the substance with a basal spacing at 8.5 Å was formed in the initial stages and much of the 8.2 Å calcium aluminate hydrate and C_3AH_6 were present. Large quantities of ettringite were formed and there were no 9.6 Å and 8.9 Å materials. The 8.5 Å substance, the ettringite and aluminate hydrates slowly reacted finally to produce the 10.3 Å material.

As was expected, the use of three moles of $CaSO_4 \cdot 2H_2O$ instead of one gave only ettringite at equilibrium. The 10.3 Å calcium mono-sulpho-aluminate was an intermediate phase when the three moles of $CaSO_4 \cdot 2H_2O$ were added to the C_4AH_{19} hydrate. Figs. 7B(1)–7B(5) gives an indication of the course of the reactions.

The Influence of Heating and Cooling on the 10.3 Å, the 9.6 Å and the 8.9 Å Calcium Mono-Sulpho-Aluminate Hydrates

Turriziani and Schippa (4) have reported the existence of a 10.3 Å hydrate at 1°C and a mixture of 9.6 Å and 10.3 Å hydrates in the 12–17°C region. As can be seen from Fig. 8 this is the stable phase when suspensions formulated to give the mono-sulphate hydrates were cooled and kept at 5°C for long periods. These suspensions were filtered and the solid X-rayed in a damp condition out of contact with carbon dioxide. During the X-ray work the sample was at a relative humidity of 100 per cent. By merely raising the temperature of the solid on the X-ray machine to above 20°C, it was possible to change the substance into the 9.6 Å hydrate, and when ice water was passed through the cell containing the solid, (the water did not come in contact with the sample) the 9.6 Å hydrate was immediately changed back to the 10.3 Å hydrate; this conversion 10.3 Å $\underset{\text{(cool, ice water)}}{\overset{\text{heat 20°C}}{\rightleftharpoons}}$ 9.6 Å could be performed repeatedly at will (see Fig. 9).

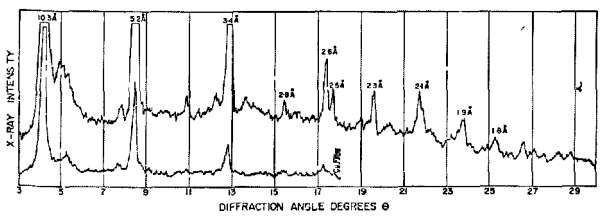

Fig. 8. *X-ray diffractogram of the* 10.3 Å *calcium mono-sulpho-aluminate hydrate at* 5°C

However, when a wet solid consisting essentially of 9.6 Å, prepared from aluminates and $CaSO_4 \cdot 2H_2O$, was cooled on the X-ray machine, it did not change rapidly to 10.3 Å as described above; the 8.9 Å substance appeared and this changed only slowly to 10.3 Å. The 8.9 Å substance appeared to be formed from 9.6 Å preferably in the presence of $Ca(OH)_2$ at temperatures between 15°C and 25°C. When a sus-

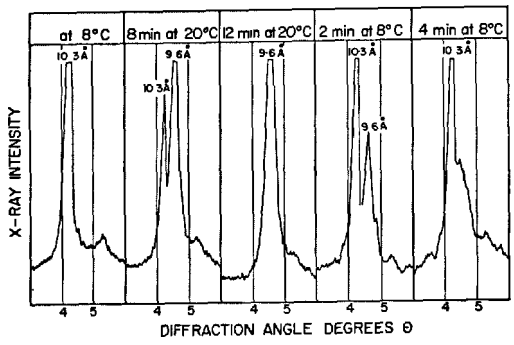

Fig. 9. *X-ray diffractogram showing the behaviour of the* 10.3 Å *and* 9.6 Å *hydrate during heating and cooling*

pension containing the 8.9 Å hydrate was heated to above 30°C, it was changed to the 9.6 Å hydrate. On cooling, the 9.6 Å hydrate apparently changed through the 9.8 Å hydrate to the stable 10.3 Å hydrate at 5°C.

The relationships between the 8.9 Å, the 9.6 Å and the 10.3 Å hydrates is not clearly understood at this stage; it is not clear why, when once the 10.3 Å hydrate was formed, it could be easily changed to the 9.6 Å hydrate and back to the 10.3 Å hydrate, but when fresh 9.6 Å hydrate (not obtained by heating the 10.3 Å hydrate) was cooled, it changed slowly through the 8.9 Å hydrate to the 10.3 Å hydrate.

The Influence of Temperature on the Sulphate Resistance of Portland Cement Containing Tricalcium Aluminate

It has long been known that the resistance of concrete and mortar made with portland cement containing C_3A can be improved or rendered immune to attack by the sulphate ion if they are autoclaved in saturated steam at temperatures above 100°C; higher temperatures are beneficial but even relatively low temperatures, say from 40°C upwards, appear to induce some resistance although not rendering the products completely resistant to attack by the sulphate ion (see for instance the work by Richards (5)).

It is, however, not quite clear why autoclaving should render the aluminates resistant to sulphate attack, because the stable cubic calcium aluminate hexahydrate phase, produced at the temperatures normally used, is also attacked by sulphates and changed into ettringite, the substance generally accepted to be responsible for the expansion of cements containing C_3A. It is often argued that the resistance is due to the reduction of the $Ca(OH)_2$ content as some $Ca(OH)_2$ which aids expansion, reacts with silica in the mortar or concrete to form hydro-calcium-silicates, which are resistant to sulphate attack. Some investigators are of the opinion that during autoclaving some complicated hydrogarnets are produced and that they are resistant to sulphate corrosion. Furthermore it is likely that the physical state of the autoclaved product and the nature of the calcium silicate hydrates have some influence on the matter; it is known that the gel-like tobermorite normally found in water-cured cement products is changed somewhat to a more crystalline state in the autoclaved product. There are many arguments for and against these theories, for example, in connection with the reduction of the $Ca(OH)_2$ content due to reaction with silica. It has been found (6) that when an aggregate that contains no silica is used for concrete or mortar and the material is autoclaved, the resultant product is also resistant to sulphate attack. In this instance there is no question of a reduction of the $Ca(OH)_2$ content due to reaction with silica.

Recently Chatterji and Jeffery (7), (8) have put forward a new hypothesis as regards sulphate attack, in which they doubt the accepted theory that the mere formation of ettringite is responsible for the sulphate expansion. Their hypothesis has since been criticized by other workers in this field (9), (10). Whatever the mechanism of the deterioration or expansion one should not lose sight of the fact that expansion need not necessarily be the prime cause of deterioration. There can be breakdown of the structure before actual expansion takes place and, once breakdown or deterioration has occurred, only a small force is required to produce expansion. However, the forces involved, when a portland cement contains alumina or aluminates and calcium sulphate, can be tremendous; Fig. 10 shows how a steel mould was ruptured when portland cement was mixed with a few per cent of kaolinite and gypsum. Note that although much expansion has occured, there is little lowering of the quality of the hydrated product. It has been shown (6) that the rate of expansion has a marked influence on the quality of the expanded product; a slow expansion of a homogenous body can be considerable without disintegrating the body, but a rapid expansion leads to distintegration. Furthermore it is possible to limit or stop the expansion of a body containing ingredients that cause sulphate expansion by means of steaming; the expansion of expanding cements can be controlled

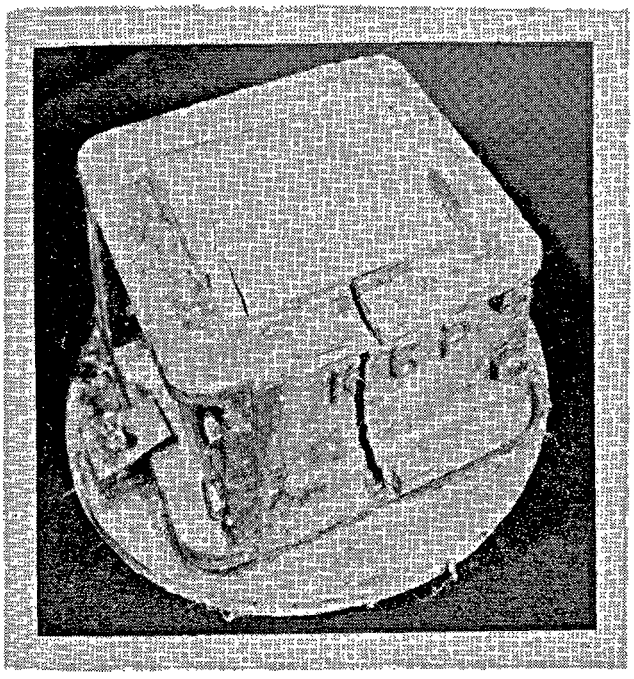

Fig. 10. *Large forces develop during the formation of calcium sulpho-aluminates (4 in cube steel mould)*

somewhat by steaming at atmospheric pressure at the appropriate time after casting.

The above discussion deals with the influence of temperature during the curing period on the subsequent sulphate resistance of portland cement products, but it is also conceivable that temperature changes after curing and during the use of cement products could have an effect on their durability; temperature changes can be of importance by causing changes in the aluminate hydrates and sulpho-aluminate hydrates already in the product, or it can determine the type of sulpho-aluminate hydrate produced when sulphate enters the product from an external source. One is inclined to get the impression that sulphate corrosion of portland cement products is more common and serious in colder climates than in warmer regions. Freezing and thawing may be one of the reasons for this because it is likely that freezing and thawing will weaken the structure and create favourable conditions for further deterioration by sulphate attack. However, the fact that different aluminates and sulpho-aluminates are the stable phases at different temperatures, and that there is a backwards and forwards shift of equilibrium, may have a considerable influence on durability. This may be of much importance in products such as expanding cements that could contain appreciable quantities of aluminates and sulpho-aluminates. It appears that if sufficient sulphate is present to change all the aluminates into ettringite, no trouble would be experienced because ettringite is stable also at low temperatures in the absence of aluminates, but should mono-sulpho-aluminate hydrates and free aluminate hydrates be present, the equilibrium will change with temperature changes at the low level. That such equilibrium shifts are likely is clearly indicated by the work described in the former half of this paper.

In an attempt to investigate the influence of low temperatures on the sulphate resistance of portland cement mortars, experiments were undertaken in which mortars were exposed to sulphates at 5°C and 22°C. In these experiments the following variables were examined:

1. C_3A-content;
2. high pressure steam curing;
3. water curing;
4. exposure in sodium sulphate at 5°C;
5. exposure in sodium sulphate at 22°C.

Specimens were prepared, exposed and examined by procedures described by van Aardt (11).

Crushed, fresh dolomitic rock was used as aggregate in the mortars with a view to eliminating possible pozzolanic reaction in the autoclave between $Ca(OH)_2$ and fine silica; the intension was to prevent the lowering of the $Ca(OH)_2$-content of the specimens during autoclaving. Some specimens were cured under water for 28 days while others were autoclaved at 150 lb/in² saturated steam pressure for 3 hours. The portland cement used had a C_3A-content of approximately 7 per cent and, where it was increased to 14 per cent in the specimen, finely ground C_3A prepared separately was mixed in a mechanical mixer with the required quantity of cement.

After curing, the specimens were immersed in 5 per cent sodium sulphate solution as follows:

1. A set of specimens was stored in the solution at 22°C;
2. A set of specimens was stored in the solution at 5°C.

Table 1 reflects the condition of the specimens after storage for 300 days in the sulphate solution. It can be seen that the autoclaved specimens stored in sulphate solution at 5°C deteriorated rapidly while those stored at 22°C remained sound and unaffected. Fig. 11 illustrates the nature of the deterioration of the specimen in the foreground, i.e. the one that was stored in a sulphate solution at 5°C, while the other one, stored at 22°C in the solution, was unaffected

Table 1. *The influence of temperature on corrosion*

Description of specimen		Treatment during immersion in 5% Na_2SO_4 solution	Period of storage in Na_2SO_4	Observations as regards expansion and deterioration
C_3A content %	Curing			
7	Water-cured	kept at 5°C	300 days	Very rapid deterioration
7	Water-cured	kept at 22°C	300 days	Rapid deterioration
7	Autoclaved	kept at 5°C	300 days	Cracking started after 200 days, bad cracking after 300 days
7	Autoclaved	kept at 22°C	300 days	No cracking or expansion after 300 days of exposure
14	Water-cured	kept at 5°C	300 days	Very rapid deterioration
14	Water-cured	kept at 22°C	300 days	Very rapid deterioration
14	Autoclaved	kept at 5°C	300 days	Expansion started after 100 days, complete disintegration at 300 days
14	Autoclaved	kept at 22°C	300 days	No cracking or expansion after 300 days of exposure

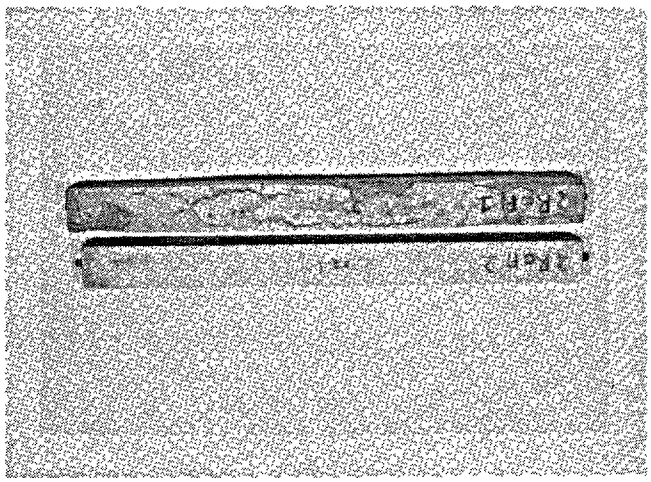

Fig. 11. *Specimens showing the influence of temperature of the sulphate solution on the behaviour of outclaved specimens* ($1'' \times 1'' \times 11\frac{1}{4}''$)

and sound in every respect. These mortars are generally of very high quality and of low permeability and it normally takes a considerable time for liquids to penetrate to the interior. For this reason the ones under consideration were dried, evacuated and the sulphate solution admitted under vacuum. It is not known at this stage whether specimens made with quartzitic aggregate would behave in a similar way or not as the latter experiments have been started only recently. However, the indications are that a similar trend can be expected.

Working with portland cement mortar specimens to which C_3A, C_3AH_6, the 10.6 Å hydrate and the 8.2 Å hydrate were added when the mortars were prepared for moulding and curing, it was observed that in sodium sulphate solutions, the ones containing C_3A or the 10.6 Å hydrate appeared to deteriorate much more rapidly than the ones to which C_3AH_6 or the 8.2 Å hydrate was added.

The work on mortars appears to substantiate the belief that if portland cement products are subjected to sulphate solutions at low temperatures, i.e. temperatures below say 10°C, there is a likelihood of more severe deterioration than at higher temperatures and that autoclaved products are not immune to sulphate attack at low temperatures especially if the portland cement contains much alumina or calcium aluminates.

Supplementary Paper III-30 The Frost Resistance of Cement Grouts for Prestressed Concrete Applications

Cameron MacInnis*

Synopsis

This paper is a summary of an extensive, three-stage experimental program carried out to study the factors affecting the frost resistance of cement grouts for prestressed concrete applications.

In Part I, the expansive tendencies, during a freezing cycle, of seventeen different cement grout mixtures (at a variety of maturities) were investigated. The length change patterns exhibited in the Part I tests are grouped into a number of categories and a short theoretical section is devoted to the interpretation of these patterns. The Part I experimental results provided a good comparative picture of the frost resistance of the various cement mixes at different maturities.

In Part II, a limited number of mixes were subjected to a freezing cycle in a restrained condition ("tube" tests) and resultant pressures were measured. In Part II experimental results provided an indication of the pressures developed by the various grout mixtures during freezing (at different maturities) and these were found to correlate very well with the various expansion patterns exhibited in the Part I tests.

In Part III, selected mixes were chosen for freezing tests in grouted beams of various dimensions. These tests demonstrated in a practical way the validity of the findings in Parts I and II and showed that only mixes exhibiting continuous expansion after freezing starts can produce enough pressure to crack beams.

The estimated curing periods required, for both air-entrained and non-air-entrained cement grouts of various water-cement ratios, to achieve frost-resistance, are presented. Cement composition was found to be of minor importance compared with the provision of air-entrainment and low water-cement ratios for the achievement of frost resistance.

Introduction

The factors affecting the frost resistance of grouts for prestressed concrete applications are to a large extent the same as those which apply to concrete in general, i.e. (a) water-cement ratio, (b) maturity of grout, (c) cementing materials and (d) admixtures, especially air-entraining agents. Provided that the general quality of the cementing materials being used is satisfactory, there is no doubt that frost-resistant grouts can be produced by the use of a low water-cement ratio and purposely entrained air voids of adequate spacing, together with the provision of favourable curing conditions for a sufficient period of time before the grouts in question are subjected to frost action. However, although there is considerable knowledge and agreement about the various factors affecting the frost-resistance of grouts, little attempt has previously been made to assess the relative importance of these factors. This, therefore, was the purpose of this program of studies.

Outline of Investigation

The frost-resistance of a given post-tensioned prestressed member will be a function of the frost-resistance of the grout itself plus what might be called "beam factors", e.g. amount of restraint, dimensions of beam, duct sizes, maturity of concrete in the beam, strength. Because of the large number of "beam factors" involved in the frost-resistance of a grouted member it was decided that initially

*University of Windsor, Ontario, Canada.

the studies should be limited to the grout itself—to be followed later with studies of grouted beams. A three-stage approach, as follows, was adopted:

Part I—Evaluation of the relative frost-resistance of a variety of grout mixes in an unrestrained condition, by obtaining an accurate measurement of expansive tendencies during a freezing cycle.

Part II—Study of a limited number of selected mixes (and maturities) in a restrained condition to measure the forces involved and, if possible, the effect of restraint on the pressure generated.

Part III—Study of a limited number of selected mixes (and maturities) in freezing tests of grouted beams of various dimensions. These should demonstrate in a practical way the validity of the findings of Parts I and II.

Test Programme—Part I

Since sand is not commonly used in grouting mixtures for prestressed concrete because of the danger of segregation and blockages during the grouting operation it was decided to deal only with non-sanded grouts in this study. The various factors to be investigated were dealt with as follows in the experimental program:

Maturity of Grout

The frost resistance of all mixes investigated were studied at six different maturities—1, 2, 3, 4, 7 and 28 days of standard laboratory curing.

Cements

Although ordinary portland cement is most commonly used in grouting mixtures it was decided because of their potential beneficial effect on frost-resistance, to include air-entraining and rapid-hardening portland cements as well. In all, three ordinary portland cements, one air-entraining portland cement and two rapid-hardening portland cements were included in the program.

Admixtures

Preliminary tests were conducted to evaluate the effectiveness of a number of water-reducing and air-entraining agents, as a result of which one agent from each class was chosen for the main test programme. The water reducing agent chosen was a lignin type and was utilized in grout mixes with each class of cement in the program. The air-entraining agent chosen was a neutralized Vinsol resin and was used in mixes with ordinary portland cement and in one mix with rapid-hardening portland cement.

Water-Cement Ratios

The minimum water-cement ratio will largely be governed by the fluidity required for pumping and will therefore, in the absence of a water-reducing agent be more or less fixed for a given cement. This forms a lower limit to the experimental values. Thus, a fluidity of 30-40 sec (using the German Immersion Apparatus) served as a guide for the minimum water-cement ratio mix made up with each cement. Higher water-cement ratio mixes were also included using both the ordinary portland and air-entraining portland cements.

In all, seventeen different mixes were included in the Part I experimental programme, as shown in Table 1, Summary of test results.

Table 1. *Summary of test results—Part I*

Freezing Test Procedure—Part I

The freezing test procedure used in the Part I program is based on the premise that "length measurements can be used to tell whether or not at any given time a specimen is vulnerable to frost action. If it shrinks normally in the freezing range it is immune; if it dilates it is not immune—the process that eventually causes disintegration has begun" (1). Also it has been pointed out that test conditions fundamentally different from field conditions must be avoided if valid results are to be obtained in freezing tests (1). The freezing cycle chosen, therefore, was a relatively slow lowering of temperature from 65°F to 5°F (+18°C to −15°C) over a period of nine hours. Length measurements were made on the specimens (in the freezing chamber) at regular intervals during the freezing cycle using a mechanical length comparator which could be read to 0.0005 in.

The freezing test specimens were prisms, 1-1/2 × 1-1/2 × 10 in., which had a suitable stainless steel insert embedded in each end to facilitate the taking of length measurements. The specimens were cured at a temperature 65°F (18°C) from time of casting until *subjected* to the freezing test. Suitable precautions were taken to prevent the loss or gain of moisture from the time specimens were cast until *completion* of the freezing test.

Interpretation of Freezing Test Results

On examining the length change patterns exhibited by the specimens from the various mixes when subjected to the freezing test, it was possible to detect a range of patterns which could conveniently be grouped into a number of categories. It seems appropriate therefore, before dealing with the merits of the various mixes, to discuss briefly the interpretation of these patterns, which are presented in idealized form in Fig. 1.

In Case A (Fig. 1) there is a normal thermal contraction until the freezing temperature is reached, followed by a distinctive continuous expansion as the temperature is lowered further, This obviously represents a great vulnerability to damage by frost.

In Case B, there is a sudden expansion at the freezing point followed by a transitory contraction and then expansion at a lower rate as the temperature is reduced further. Case B, it is felt, also represents a serious vulnerability to damage by frost.

In Case C there is transitory expansion at the freezing point followed by contraction at an increased rate. This latter phenomenon was also noted by Powers (2) and is claimed to occur after ice crystals begin to form in the air voids of the paste. Once crystals have formed, they tend to attract water from the cement gel pores on further cooling, causing the cement gel to shrink. As long as the ice crystals have space available for expansion in the air voids the net result is a contraction at a rate greater than that due to the thermal coefficient alone. If the transitory expansion in a case such as C were very great it is believed that this would represent a considerable vulnerability to frost action.

In Case D, normal thermal contraction is followed by a period of no length change and then contraction at an increased rate. The period of no expansion is,

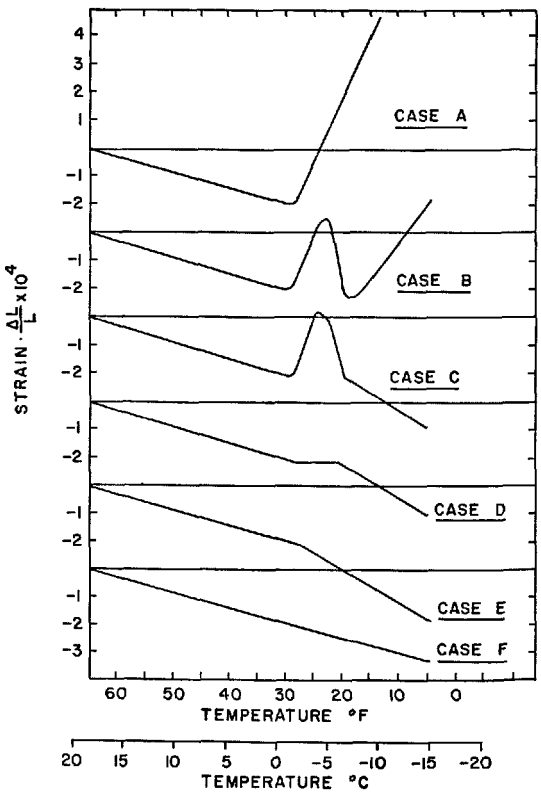

Fig. 1. *Typical "Idealized" length change patterns exhibited during freezing cycle*

according to Powers (2), due to a cancelling out of opposite effects, i.e. "the tendency to expand from the freezing of water in capillary cavities is about equal to the thermal contraction plus the tendency to contract due to diffusion of water from the gel pores to the ice bodies". The explanation of the subsequent increased rate of contraction is the same as for Case C. Case D, it is believed, represents a frost-resistant condition. Although a tendency to expand exists in some regions during the no length change period, no irreparable damage is likely to occur to the grout.

In Case E there is normal temperature contraction followed by increased contraction after freezing starts. The explanation for the increased rate of contraction is the same as for cases C and D. This also represents a frost-resistant condition.

In Case F there is a constant rate of contraction throughout the thermal range. Only in virtually dry grouts will the relationship be constant over the whole range of temperature. This also represents a frost-resistant condition.

To summarize, it would appear that A and B represent grouts that would be vulnerable to frost action; D, E and F represent grouts that would be frost-proof. Condition C is the doubtful one and the magnitude of the transitory expansion should be taken into consideration when assessing the possibility of frost damage.

Discussion of Test Results—Part I

The experimental results are presented in Table 1 and Figs. 2 to 8. It is proposed in this discussion to deal in turn with the various factors investigated. The important effect of maturity of grout on frost-resistance was well demonstrated by all mixes and need not be discussed separately as it will come up in discussion of the other factors.

Type of Cement

The first three mixes investigated (0–1, RH-1 and AE-1) demonstrated the effects of these different types of cement and the duration of curing, on frost-resistance. These three mixes were all made to the same consistency. The average freezing test results for these mixes are presented in Fig. 2.

As would be expected, the air-entraining cement performed most satisfactorily, producing a length change pattern similar to Case C at an age of one day. Even this cement, however, showed a significant amount of transitory expansion and it was not until the age of 7 days that the transitory expansion was eliminated. The rapid-hardening cement produced intermediate results, showing a Case C length change pattern at the age of 4 days while at 7 days it no longer exhibited the transitory expansion. In the case of the ordinary portland mix (0 –1) it was not until the age of 7 days that both the transitory expansion at the start of freezing and the ultimate expansion at the lower temperature were eliminated.

In mix 0–2 the use of the water reducing agent, allowed reduction of the water-cement ratio from 0.45 (mix 0–1) to 0.40 without affecting the fluidity, Table 1. This in turn reduced the age at which expansive tendencies were no longer exhibited from 7 days to the 3-day age.

Using the water-reducing agent with the rapid-hardening cement, however, it was possible to reduce the water-cement ratio only from 0.52 (mix RH-1) to 0.51 (RH-3) and still achieve the same fluidity, Table 1. Nevertheless, this did appear to have a significant affect on frost resistance, reducing the age at which ultimate expansion was no longer exhibited from four days to three days. However, if mixes 0–2 and RH–3 are now compared (Fig. 3) it is seen that their performance in the freezing test are practically identical, both indicating immunity from frost action after 3 days curing.

Water-Cement Ratio

The effect of water-cement ratio is demonstrated very well in Fig. 4 where No. 1 -OPC is used in mixes of 0.40, 0.45, 0.50 and 0.55 water-cement ratios. It can be seen that the 0.40 water-cement ratio mix indicated frost-resistance at the 2-3 day age, the 0.45 mix at the 7-day age, and the 0.50 and 0.55 mixes at the 28 day age. To demonstrate better the difference in frost-resistance of the 0.50 and 0.55 water-cement ratio mixes it would have been desirable to have freezing tests run between the 7 and 28 day ages; however, even at the 28 day age the 0.55 water-cement mix exhibited a case D length change pattern compared with a case F pattern for the 0.50 mix.

The effect of water-cement ratio can also be seen in the mixes made with No. 2-OPC, i.e. 2-0-1 and 2-0-2, also in the rapid-hardening cement mixes RH-1 and RH-3 (see Table 1). In the air-entraining cement

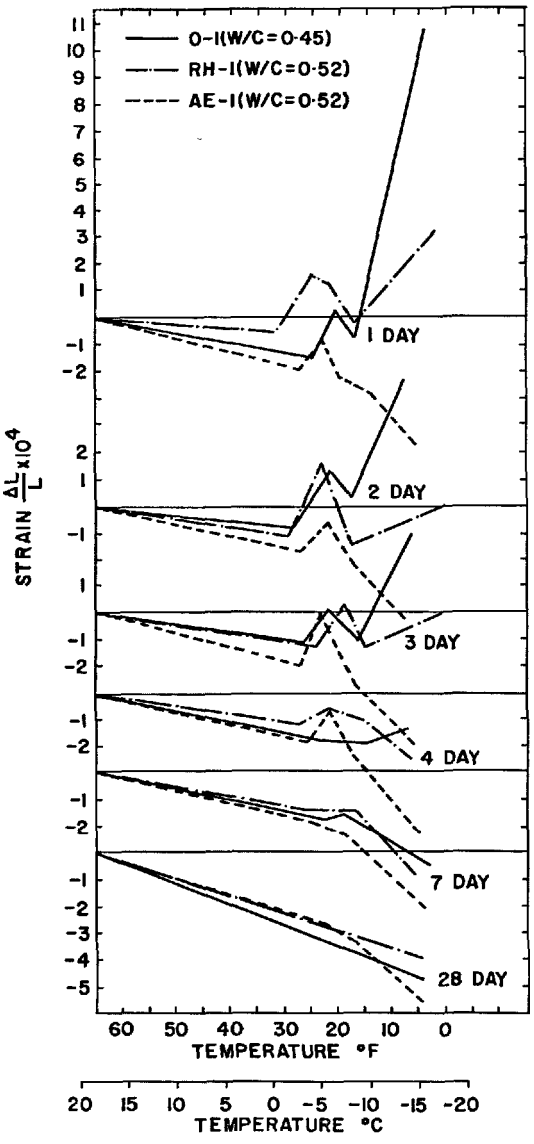

Fig. 2. *Effect of type of cement on length change patterns exhibitad during freezing cycle*

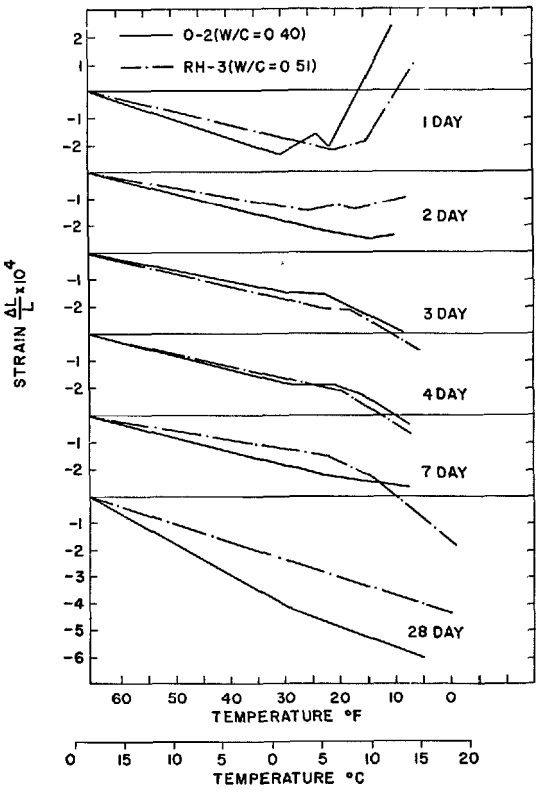

Fig. 3. *Effect of water-reducing agent on length change patterns of both ordinary and rapid-hardening portland cement mixes*

mixes (AE-1, 3, 4) the effect of the water-cement ratio on frost-resistance seems to be clouded by the much greater effect of the entrained air itself, so that there was no significant difference in frost-resistance indicated by air-entrained mixes of 0.40, 0.45 and 0.50 water-cement ratios (see Table 1).

Differences between Cements of Same Type

In addition to the differences in performance between the various types of cement there was significant differences shown by the cements within each group. In Fig. 5, for example, freezing test results are presented for 0.50 water- cement ratio mixes made with each of the three ordinary portland cements used in the programme. It can be seen that mixes 0-4 and 3-0-1 exhibited strong expansive tendencies up to and including the 7-day age which were equivalent to patterns exhibited by mix 2-0-2 specimens at the age of 2 days. Similarly, significantly different freezing test results were exhibited by the two 0.45 water-cement ratio mixes, 0-1 and 2-0-1.

It is interesting to note in Fig. 6 that if the cements 1-OPC and 2-OPC are compared at the same fluidity (but different water-cement ratios, 0.45 and 0.50) there is little difference in frost behaviour. Similarly, the two RH cements, when compared at the same fluidity, are very similar in frost resistance although the water requirements are vastly different (0.52 versus 0.69 water-cement ratio for mixes RH-1 and 2RH-1 respectively).

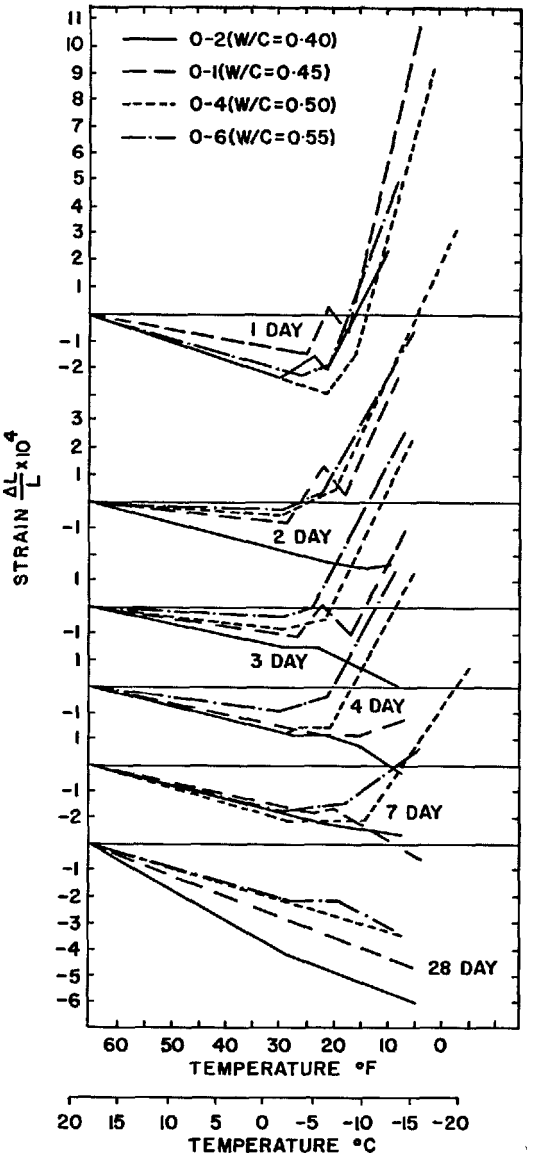

Fig. 4. *Effect of water-cement ratio on length change patterns exhibited during freezing cycle*

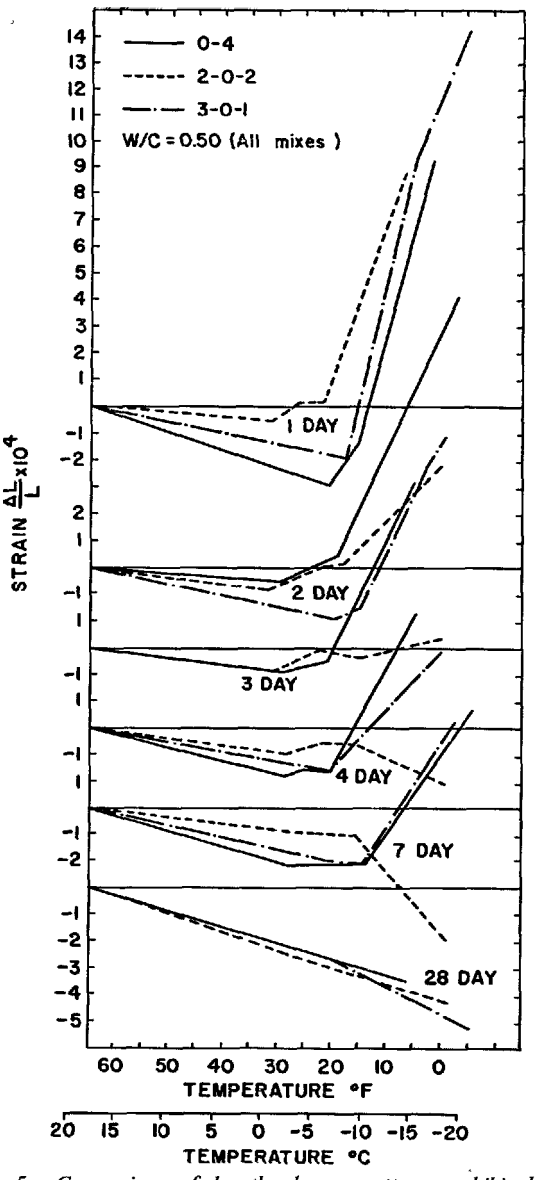

Fig. 5. *Comparison of length change patterns exhibited by different ordinary portland cements during freezing cycle*

Air-Entrainment

The significant effect of entrained air on frost-resistance was already indicated when the performance of the air-entraining cement was compared with normal and high-early portland cements. Similar results were produced by using an air-entraining agent in the ordinary and rapid-hardening cement mixes. In Fig. 7 a plain mix at a water-cement ratio of 0.50 is compared with mixes of the same water-cement ratio containing 5.5 and 13.5% air respectively. Both of the air-entrained mixes eliminate the ultimate

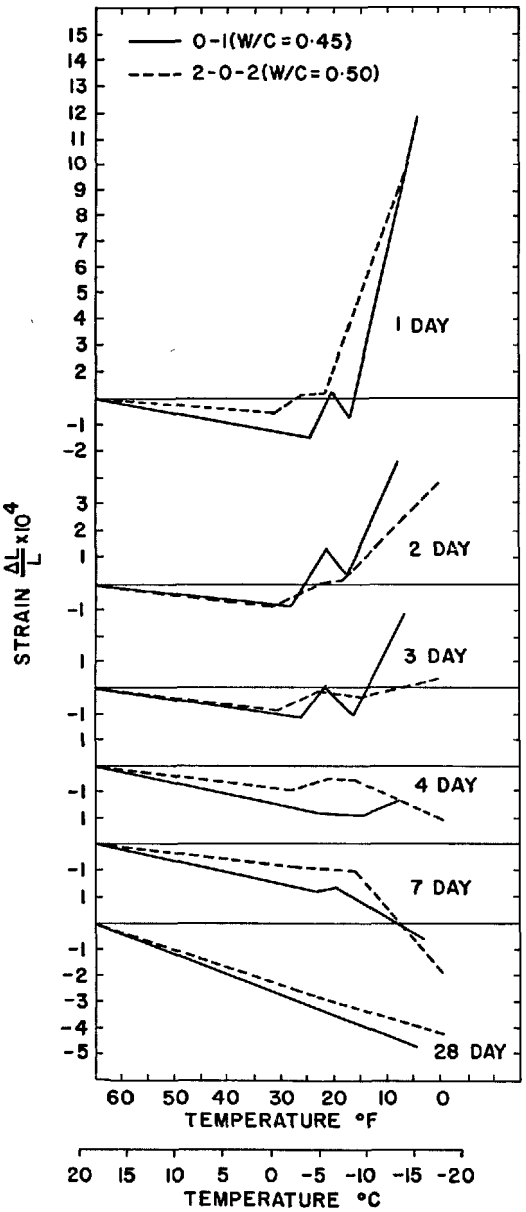

Fig. 6. *Comparison of length change patterns exhibited by different ordinary portland cements at same fluidity*

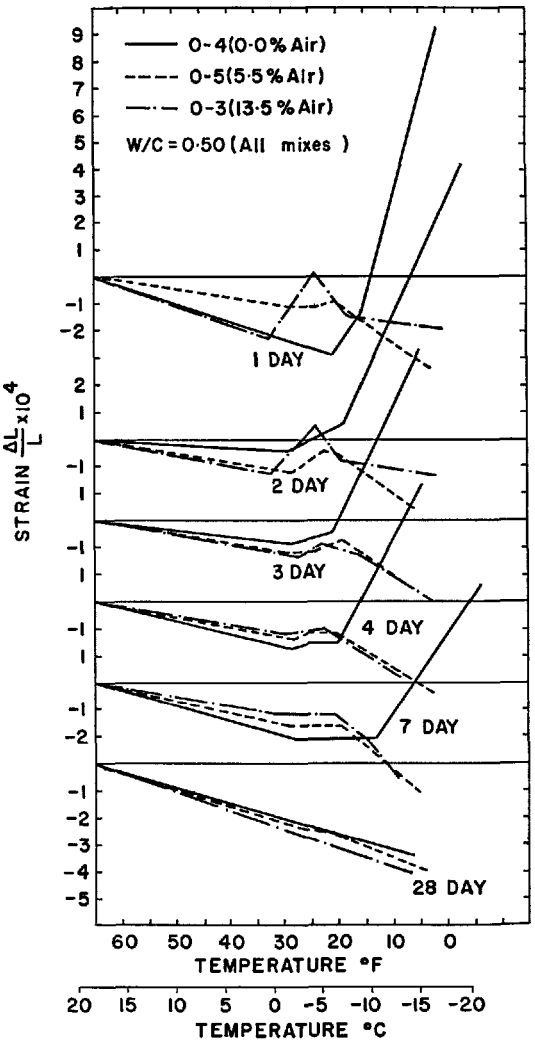

Fig. 7. *Effect of air-entrainment on length change patterns exhibited during freezing cycle*

expansive effects at all test ages, although transitory expansions are noticeable up to the age of 4 days. Probably of most significance is the fact that the 5.5% air mix appears to be equally as effective as the 13.5% air mix. In the air-entrained high-early cement mix ultimate expansions were eliminated at all ages, but some transitory expansions were noted up to the 4-day age. This same pattern of performance also holds for all mixes made with the air-entraining cement (mixes AF-1, 2,3 and 4).

It is interesting to compare mixes AE-2, AE-1 and 0-3. In Fig. 8 it can be seen that mix AE-2 containing

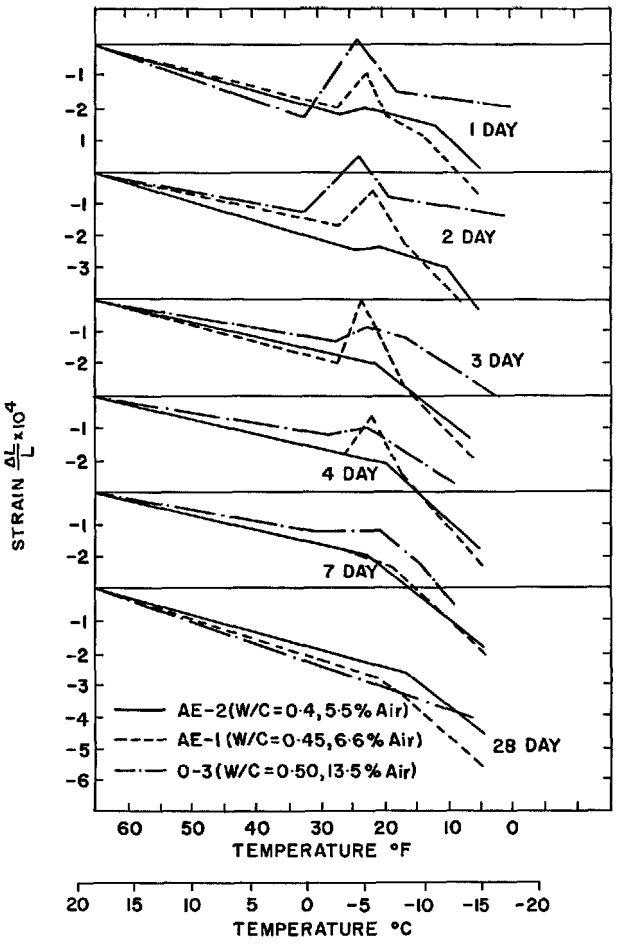

Fig. 8. *Effect of air-entrainment and W/C ratio on length change patterns exhibited during freezing cycle*

5.5% air at a water-cement ratio of 0.40 exhibited smaller transitory expansions and for a shorter period than either mix AE-1 containing 6.6% air at a water-cement ratio of 0.45 or even mix 0-3 containing 13.5% air at 0.50 water-cement ratio. Thus, providing a mix contains a certain minimum of entrained air (say 5 per cent) a lower water-cement ratio seems more effective than additional air in increasing frost-resistance.

Test Programme—Part II

The test method used in Part I (unrestrained tests) provides a sensitive assessment of the expansive tendencies during freezing of a grout specimen. However, it was realized that a completely quantitative assessment of the frost resistance of the various grouts was not provided; and there was some difficulty in interpreting some of the data, especially mixes that showed transitory expansions during the freezing test. Also, this data was obtained on unrestrained specimens, whereas, in practice, the grout is contained in ducts in the prestressed member.

As a next stage, therefore, the effect of freezing on restrained grout specimens was studied by measuring the strains developed in grouted steel tubes during a freezing cycle. Aside from providing information on the effect of restraint, this test procedure has the advantage of ensuring no moisture loss and provides data which can be related to potential damage to a prestressed member.

The aims of Part II can be briefly summarized as follows:

1. To determine the magnitude of the forces developed by the freezing grouts.
2. To determine if there is a direct relationship between the results of tests on restrained and unrestrained grouts.
3. To determine if the degree of restraint affects the magnitude of the forces developed by the freezing grout.

Selection of Mixes for Investigation

The results obtained in Part I were taken into account in deciding which mixes and maturities to

test in Part II. mix 0-1 was a natural choice since in the Part I experimental programme it exhibited excessive expansions for maturities up to 3 days, minor expansions for the 4 and 7 day maturities and complete immunity to frost action at 28 days. It was also decided to test a mix of a higher water-cement ratio (mix 3-0-1 at water-cement ratio of 0.50) and to include an air-entrained mix at a relatively high water-cement ratio (AE-4 at water-cement = 0.50).

To determine the effect of restraint on the generation of expansive forces three different tube wall thicknesses were included in the program, i.e. 0.128 in., 0.09 in., and 0.06 in. An outline of the program carried out is shown in Table 2.

Test Procedures—Part II

Selection and Preparation of Tubes

The tubes used in this part of the programme were solid drawn steel tubing of similar interior diameter to the ducts provided in prestressed concrete members and the wall thicknesses chosen were such that strains would be in the same range as that exhibited by concrete in service. Tubing of 1-3/4 in. O.D. and 10 gauge (0.128 in.) thickness was chosen for the maximum size. Wall thicknesses of 0.09 in. and 0.06 in. for the other two sizes were obtained by machining the 10 gauge tube down to these values.

The tube specimens were cut to 2 ft. lengths, which was considered to be long enough to eliminate end effects. The ends of the specimens were threaded to accommodate an end cap and adaptor required in the pressure calibration of the tubes.

Strain Measurement of Grouted Tubes

One-quarter inch foil strain gauges were used for strain measurement of the grouted tubes during the freezing test. Six gauges were mounted at approximately the centre of each tube-four circumferentially and two longitudinally, diametrically opposite each other. As a preliminary, pressure-strain relationships were established for each tube, so that the strains recorded in the subsequent tests could be related to pressures being generated by the grouts during the freezing cycle. The tubes of 0.128 and 0.09 in. wall thickness were calibrated to a maximum pressure of 3000 lb/in^2 while the tubes of 0.06 in. wall thickness were calibrated to a maximum pressure of 2000 lb/in^2.

Freezing Regime

The freezing regime was similar to that used in Part I except that the minimum temperature of 0°F was maintained for 8-10 hours. Strain readings were taken on the grouted tubes at regular intervals during the freezing cycle. Prisms (as used in Part I) were provided for subjection to the freezing test at the same time as the grouted tubes. This was to assist correlation of the restrained and unrestrained tests.

Disccuion of Test Results—Part II

Comparison of Different Mixes

In Table 2 a summary is provided of the average maximum pressures indicated by the gauges for all mixes (and maturities) tested in the program. It can be seen that in the restrained tests, mix 3-0-1 (water-cement = 0.50) produced the highest pressures, mix 0-1 (water-cement = 0.45) intermediate values and mix AE-4 (water-cement = 0.50) the lowest pressures. With mix 0-1, increasing maturity in the grout resulted in decreasing pressures being developed in the grouted tubes, ranging from 1500 to 2000 lb/in^2 at the 1 day maturity down to zero lb/in^2 for the 28 day maturity. On the other hand, mix 3-0-1 exhibited a consistent level of pressure (in the range of 2000 to 2200 lb/in^2) for all maturities up to 7 days, and the relatively small pressure of 90 lb/in^2 at 28 days. Mix AE-4 exhibited the relatively low level of 200-270 lb/in^2 pressure for all ages tested (1, 7 and 28 days).

Effect of Degree of Restraint on Pressures Developed

It can be seen from Table 2 that four sets of grouted tubes (three wall thicknesses) were provided for studying the effect of degree of restraint on the generation of expansive forces. In general, the greater the restraint, the lower is the pressure developed, but this

Table 2. *Summary of test results—Part II*
Pressure measurements of grouted tubes during freezing

Age of grout before freezing	Average maximum pressures produced in grouted tubes — lb/in.²								
	Mix 0–1 W/C = 0.45			Mix 3–0–1 W/C = 0.50			Mix AE–4 W/C = 0.50		
	Tube wall thickness-in.			Tube wall thinkness-in.			Tube wall thickness-in.		
	0.128	0.09	0.06	0.128	0.09	0.06	0.128	0.09	0.06
1	1750	1525	1965	1340	2170	2695	50	260	205
2					2000				
3	760	630	890						
7		165			2250			205	
28		0			90			270	

pattern is by no means consistent. With mix 3-0-1, this pattern of decreasing pressure for increasing wall thickness was most pronounced. The tube of 0.06 in. wall thickness exhibited an average maximum equivalent pressure of 2695 lb/in² followed by 2170 lb/in² for the tube of 0.09 in. thickness and 1340 lb/in² for the tube of 0.128 in. thickness. With mix 0-1 tubes at both the 1 and 3-day maturities it can be seen that the thin-walled tubes exhibited higher pressures than the thick-walled tubes, but in both cases the tubes of intermediate thickness exhibited the lowest pressures. It is also significant that the differences in pressures between the different tubes were much smaller for mix 0-1 than for mix 3-0-1. With mix AE-4 tubes, the thin-walled tube exhibited a higher pressure than the thick-walled tube, but the tube of intermediate thickness exhibited the highest pressure. However, all pressures for the AE-4 tubes were relatively low (50 to 260 lb/in²).

Correlation between Restrained and Unrestrained Test Results

It is interesting to compare the test results for the grouted tubes with the length change patterns exhibited in the freezing test by unrestrained prism specimens of the same mixes.

Mix 0-1 in the unrestrained tests, Fig. 2, exhibited case "A" length change patterns (normal temperature contraction initially, followed by distinctive continuous expansion as the temperature was lowered further) for the 1 and 3-day specimens, a case "D" length change pattern (normal temperature contraction, followed by a period of no length change, then contraction at an increased rate) for the 7-day specimens and a case "F" length change pattern (practically constant rate of contraction throughout the thermal range) for the 28-day specimens. Corresponding to these in the restrained tests, Table 2, were pressures of 1500–2000 lb/in² for the 1-day tests, values of 600–900 lb/in² for the 3-day tests, a value of 165 lb/in² for the 7-day test and zero pressure for the 28-day test. The tube test has thus served to provide an indication of pressures corresponding to the expansion patterns exhibited by this mix at various maturities in the unrestrained test. It is interesting to note that although the three-day test on the unrestrained prisms exhibited expansions somewhat less severe than the 1-day specimens, the pressures in the 3-day tubes were less than 50 per cent of the 1-day test values.

Mix 3-0-1 in the unrestrained tests, Fig. 5, exhibited case "A" length change patterns (normal temperature contraction followed by distinctive continuous expansion as temperature was lowered further) for maturities of 1, 2, 4 and 7 days. It will be noted, however, that the magnitude of the expansions exhibited decreased with increasing maturity of grout. In spite of this, the pressures indicated in the tube tests, Table 2, remained the same, i.e. about 2000–2200 lb/in² for all 0.09 in. tubes tested up to the age of 7 days. The 28-day unrestrained specimens showed a case "F" length change pattern (continuous contraction rate throughout) and the 28-day tube test produced the relatively low pressure of 90 lb/in².

Mix AE-4 in the unrestrained tests exhibited case "C" length change parterns (transitory expansion at freezing point, followed by contraction at an increased rate) for both the 1 and 3-day maturities and case "E" length change patterns (normal temperature contraction followed by increased contraction after freezing starts) for the 7 and 28-day maturities. In the tube tests, however, there was little difference in the pressures generated at maturities 1, 7 and 28 days, Table 2. Indeed, the pressures indicated at all maturities of AE-4 tested (ranging from 200 to 270 lb/in²) are so small that they are not likely to be of practical importance.

Conclusions—Part II

The test results for the restrained grout specimens ("tube" tests) have provided an indication of pres-

sures developed by the various grout mixtures during freezing and hence, serve as a calibration for the expansion patterns exhibited by the unrestrained grout specimens in the freezing test (Part I). Probably the most interesting aspect of the test results for the restrained specimens is the extent to which they correlate with the freezing test results for the unrestrained grout prisms. The main conclusions follow:

1. The test results for the restrained grout specimens have confirmed the usefulness of length change measurements on unrestrained specimens as a means of determining the probable frost resistance of a given grout mix.

2. The restrained tests confirmed the benefit of air-entrainment for frost resistance. Only relatively low pressures (50 to 270 lb/in^2) were exhibited by the tubes grouted with AE-4 (6.2% air) which had a relatively high water-cement ratio (0.50).

3. Only those mixes (and maturities) that exhibited a case "A" length change pattern (normal temperature contraction initially, followed by continuous distinctive expansion as the temperature was lowered further) in the unrestrained prism tests produced significant pressures in the tube freezing test. Mixes exhibiting transitory expansions in the unrestrained test did not produce significant pressures in the tube test.

4. The test results indicated that the importance of water-cement ratio in determining the frost behaviour may be even greater than was indicated in the unrestrained test. This is because higher water content mixes tend to expand slightly as hydration proceeds and hence at later maturities fit more tightly into the grout duct than would a lower water-cement ratio mix. Hence expansive pressures are exerted immediately freezing starts provided there is still free water available to freeze.

5. In general, the greater the restraint (the thicker the wall of the tube) the lower was the pressure developed in the tube; but this pattern was not consistent and more testing would be required to confirm this pattern.

Test Programme—Part III

In Part III, selected mixes were chosen for freezing tests in grouted beams. The basic aim of these studies was to demonstrate in a practical way the validity of the findings of Parts I and II.

The three mixes studied in Part II (mixes 0-1, 3-0-1 and AE-4) were included in the programme of freezing studies on grouted beams. A rapid-hardening cement mix (2-RH-1) was also included. The maturities at which each mix was tested were determined as the programme proceeded, on the basis of the results obtained from the first beams tested, and taking into consideration the performance of these mixes in Parts I and II. In all, 15 sets of grouted beams were subjected to the freezing test, as shown in Table 3.

Table 3. *Freezing test results on grouted beams*

Design and Fabrication of Beams

Beams were used which had three different thicknesses of concrete cover over the grouted tubes, i.e. 1 in. 1-1/2 in. and 2 in. Ducts were formed with thin-wall rigid plain steel tubing with lock joint seams, 1-5/8 in., I.D. The beams were 2 ft. long and 6 in. in depth; the ducts were centrally spaced so that the minimum cover was at the sides of the beams.

The concrete for the beams was designed to provide a nominal minimum 28-day strength of 6,000 lb/in^2 at a "very low" degree of workability. The moulds were stripped from the beams after 1 day and the beams were cured in water (at 65°F) for 7 days, and then remained in the laboratory for approximately 6 months before being grouted and subsequently subjected to the freezing tests.

Test Procedures—Part III

The freezing regime was the same as that used in Part II. In fact for some of the early maturities, the tube specimens (of Part II) and grouted beams were subjected to the freezing test at the same time.

To confirm that freezing temperatures were being attained in the grout of the beam specimens, temperature records (using thermistors) were obtained for one set of beam specimens (mix 0-1, 1-day maturity) during the freezing test. The temperature readings were obtained in the centres of the grouted ducts.

Discussion of Test Results

The results of the freezing tests on the grouted beams are presented in Table 3. An "X" denotes that the beam cracked during the freezing cycle; an "O" indicates that no cracking occurred.

Grout mix 3-0-1, it can be seen, produced cracks in beams of 1 in. and 1-1/2 in. concrete cover for maturities up to 7 days, but produced no cracks at the 14 and 28-day maturities. Mix 0-1 produced no cracks beyond the 1-day maturity. Mix 2-RH-1 procuced no cracks at the two maturities tested. Mix AE-4 produced no cracks even when the beams were subjected to the freezing cycle immediately after the grout was injected in the beams. However, the concrete cover afforded a significant protection for the grout so that it was about 12 hours old before freezing temperatures obtained in the grout.

After the freezing test, several beams (including some that showed cracking externally and some that did not) were sawn in two. In all cases where a crack showed on the surface it extended to the grouted duct, and where no crack was visible on the surface no cracking was noted in the sawn cross-section.

Correlation between Unrestrained Tests and Beam Tests

If the beam test results are compared with the length change patterns shown by the unrestrained grout prisms, it is seen that only those mixes (and maturities) that exhibited case "A" length change patterns (continuous expansion after freezing started) in the unrestrained freezing tests, produced cracks in the grouted beams. And *not all* mixes that exhibited case "A" length change patterns produced enough pressure to cause cracks. For example, mix 2-RH-1 exhibited case "A" expansive patterns at maturities up to 3 days, but did not produce cracks in the beams at either the 3-day or 1-day maturities. Similarly mix 0-1 exhibited case "A" expansive patterns at the 3-day maturity, but did not produce beam cracks at this maturity. Nevertheless, if a criterion of frost-resistance is desired on the basis of length change tests during the freezing cycle, then any mix (and maturity) that does not produce a continuous expansion as the temperature is lowered below the freezing point can be considered not dangerous.

Correlation between Tube Tests and Beam Tests

By comparing the results obtained in the tube tests with those obtained on the grouted beams an indication of the pressure required to produce cracks can be obtained, as well as an indication of the correlation between the two test methods. Mix 0-1 at the 1-day maturity exhibited equivalent pressures of 1500–2000 lb/in^2 in the tube test (Table 2), and produced cracks in the beams having 1 and 1-1/2 in. of concrete cover but not in the beam of 2 in. concrete cover (Table 3). At the 3-day maturity this mix exhibited equivalent pressures of 630 to 890 lb/in^2 in the tube test, but produced no cracks in the beam tests.

Mix 3-0-1, at the 1-day maturity, exhibited pressures ranging from 1340 to 2695 lb/in^2 in the tube tests and produced cracks in all three beams. At the 2 and 7-day maturities the tube tests exhibited average equivalent pressures of 2000 and 2250 lb/in^2 and produced cracks in the beams having 1 and 1-1/2 in. of concrete cover but not in the 2 in. concrete cover beams. Hence, there appears to be a reasonable correlation between the tube and the beam tests. Indicated pressures of 1340 lb/in^2 or higher in the tube tests represented mixes (and maturities) that produced cracks in grouted beams. Indicated pressures as high as 890 lb/in^2 represented mixes and maturities that did not produce cracks, even in beams of 1 in. concrete cover.

No tube tests were conducted on the AE-4 mixes at the zero and 12-hour maturities, but the pressures produced in the beams were not great enough to produce cracks, and hence would probably be less than 1000 lb/in^2.

Conclusions—Part III

The results obtained in this section demonstrated in a practical way the potential danger from frost action on grouted beams and provided a yardstick for interpretation of the test methods in Parts I and II. The main conclusions are:

1. The beam tests confirmed the validity of the unrestrained test method used in Part I and showed that only mixes exhibiting case "A" length change patterns (continuous expansion after freezing starts) can produce enough pressure to crack beams. Transitory expansions do not appear to be serious.

2. There was also a good correlation between the tube tests and the beam tests. It would appear that equivalent pressures in excess of 1000 lb/in^2 as determined in the tube test are required to cause cracks in beams of minimum concrete cover (1 in.).

3. The beam tests demonstrated that with certain grout mixes (3-0-1, at water-cement = 0.50 e.g.) it is possible to crack beams even when they possess concrete cover in excess of that often required by Codes of Practice for Prestressed Concrete.

Final Discussion and Conclusions

In this research programme the basic aim has been to find out how to produce frost-resistant cement grouts for use in prestressed concrete applications. On the basis of the results obtained in Parts I, II and III, it is possible to draw several conclusions of general application.

Danger of Frost Damage

Beams cracked with a grout of 0.50 water-cement ratio, cured for 7 days at 65°F. Thus, frost damage can be a real danger, even in the absence of free water —and hence a much greater danger exists if free water is available in the ducts.

Air-Entrainment

Air-entrainment was found to be the most effective method of preventing expansion and cracking by freezing temperatures. The introduction of entrained air, even at a low percentage (5%) in a mix of high water-cement ratio (0.50) was effective in eliminating all but transitory expansions at all maturities tested. It also prevented cracks in the grouted beams, even when the beams were subjected to the freezing cycle immediately after injection of the grout. Thus air-entrainment is effective as a protection against frost even in fresh grout; however, this is considered to be mainly of academic interest, for it would seem unwise to grout beams if there was danger of early frost and no protective measures were undertaken for at least the first 24 hours after injection.

Five percent air appeared to be just as effective as air contents as high as 13.5 per cent in producing frost-protection.

Water-Cement Ratio

Water-cement ratio is next in importance to air-entrainment in providing frost-protection for grouts. Provided a mix contains 5% of entrained air, a lower water-cement ratio seems more effective than additional air in increasing frost-resistance.

Curing Period

If no entrained air is employed, the estimated curing periods required for mixes of various water-cement ratios to achieve adequate protection to prevent cracks in a beam (of 1-1/2 in. concrete cover) are given below for two curing conditions.

Cement	Water-cement ratio	Curing period required—days @ 65°F (18°C)	Curing period required—days @ 40°F (4°C)
Ordinary portland	0.40	3	6
〃 〃	0.45	7	14
〃 〃	0.50	14	28
〃 〃	0.55	14+	28+
Rapid-hardening	0.52	2	4
Fine grained RH	0.69	2	4

The indicated curing period required for curing at 65°F (18°C) are based on the results of this research programme; the indicated periods required at 40°F (4°C) were calculated according to a maturity factor relationship due to Saul (3).

Type of Cement

Type of cement used is of minor importance compared with air-entrainment or water-cement

ratio in the achievement of frost-resistant grouts. Although, one can normally expect the development of frost-resistance at an earlier age with rapid-hardening portland cement than with ordinary portland cement, it has been shown that a water-reducing agent can so reduce the water requirement of an ordinary portland cement mix to make its performance equal to that of rapid-hardening cements in frost-resistance.

Recommendations

On the basis of results obtained in this research programme, the following recommendations are made regarding the achievement of frost-proof grouts for prestressed concrete.

1. The use of an air-entraining or gas-forming agent to provide at least 5 per cent voids is strongly recommended for grouts injected in the winter time. Even with the provision of such an agent the grout should not be injected if the air temperature is below freezing or is likely to fall below freezing during the next 24 hours, unless suitable precautions are taken to protect the fresh grout for at least 24 hours.

2. If entrained air is used the water-cement ratio of the mix will not be critical. However, if for some reason there is objection to the use of void-producing agents then the water-cement ratio should be the minimum possible consistent with achieving adequate fluidity; and if grouting is carried out during freezing weather adequate measures should be taken to provide curing in line with the requirements laid down in the final conclusions.

Acknowledgements

The author wishes to thank Professor W. Fisher Cassie, Head of the Department of Civil Engineering, University of Newcastle-upon-Tyne, for his advice and encouragement and for providing the facilities for carrying out this research; Professor J.D. Geddes of the Welsh College of Advanced Technology (formerly Senior Lecturer at Newcastle-upon-Tyne) for helpful discussions and suggestions throughout the research program; the Cement and Concrete Association who awarded a fellowship to the author for three years; and G & T Earle Ltd., of Hull, for generously providing the cements used in the investigation and particularly Mr. Hunter Rose, their Technical Manager, for his interest and assistance.

Supplementary Paper III-31 Chemical Reactions of Strong Chloride-Solutions with Concrete

Heinz G. Smolczyk*

Synopsis

For the purpose of filling a gap within the numerous investigations on resistance against chemical attack and to suggest new points of view concerning seawater action and deicer scaling, the behaviour of concrete in strong chloride-solutions has been investigated.

Test specimens: Small concrete cubes 4 × 4 × 4 cm, quartz aggregate 0/5 mm, w/c 0.5 and 0.7

Cements
Z 1 = blastfurnace slag cement with 75% slag
Z 2 = portland cement with <1% C_3A
Z 3 = portland cement with 12% C_3A

Solutions:
Solution I = $MgCl_2$ 3 mol/l
Solution II = $CaCl_2$ 3 mol/l
Solution III = NaCl saturated
Solution IV = H_2O (for comparison)

The changes in the visible conditions and, after a period of 2 years, the compressive strengths were measured. Furthermore the reaction products were investigated by a special method of X-ray analysis.

All the three chloride solutions reacted chemically with all concrete cubes.

Nevertheless, only I and II attacked the concretes with Z 2 and Z 3 seriously which were destroyed within different periods, each of less than 16 weeks. At this the denser concrete (w/c 0.5) did not behave better than the poor quality (w/c 0.7). The expanding reaction products of Z 2 and Z 3 were

in Solution I: $MgO \cdot Mg(OH)Cl \cdot 5H_2O$

in Solution II: $CaO \cdot CaCl_2 \cdot 2H_2O$

which formed out of the reaction with free $Ca(OH)_2$ followed by a total loss of the alkalinity of paste.

In all other cases the concrete was not attacked and the alkaline reaction with phenolphthalein was not reduced although the afterhardening in IV was always stronger than in I and III.

With III all three cements formed

$$3CaO \cdot (Al, Fe)_2O_3 \cdot CaCl_2 \cdot 10H_2O$$

which had very little if any affect on the very strong afterhardening of Z 1, whereas the other two cements did only obtain about 60% of their full strengths.

Even with I and II the blastfurnace slag cement did not show any visible alterations. The strengths have been measured with only I so far. They had remarkably increased during 2 years of immersion and reached about 40% (w/c 0.7) and even about 70% (w/c 0.5) of the very strong afterhardening in III and IV.

The results of X-ray investigation stood in full agreement with the other test results.

Introduction

Papers about the resistance of concrete against aggressive waters mostly deal with the attack of strong aggressive chemicals in relatively low concentrations. Well known are the numerous tests with diluted sulfate-solutions which have been leading to the development of sulfate-resisting cements (portland cements without C_3A, blastfurnace slag cements with more than 70% slag, supersulfated cements and high alumina cements).

*Forschungsinstitut für Hochofenschlacke, Rheinhausen, West Germany.

In solutions of higher concentration, however, the chemical reactions in many cases are of different types: e.g. seawater already reacts much less than a sulfate solution of equal concentration. On concrete exposed to the daily tidal range, however, seawater action is very strong. Under this severe condition in several long time tests blastfurnace slag cements with more than 60% slag have shown very good performance without exception (1), (2), (3), (4), (5). This high resistance against seawater attack cannot be explained neither by the higher sulfate resistance only, nor by a higher resistance against frost action. Other causes must be present in addition.

Substances known as rather uneffective can eventually become very aggressive if their concentrations are high enough. Only few papers deal with this matter (6), (7), (8), (9), (10). In this field strong chloride solutions are of special interest. They certainly have a far greater importance on seawater action and also on frost-deicer action than is generally assumed.

Experimental Part

Experiments

For completion and control of earlier investigations (13) the behaviour of small concrete cubes (4 × 4 × 4 cm) should be compared in

Solution I:	$MgCl_2$	3 mol/l
Solution II:	$CaCl_2$	3 mol/l
Solution III:	NaCl	saturated
Solution IV:	H_2O	

The following 3 cements bought from commercial sources were tested:

Z 1: Blastfurnace slag cement "Z 275" with 75% slag
Z 2: Portland cement "Z 275" with < 1% C_3A
Z 3: Portland cement "Z 375" with 12% C_3A

The legend of concrete was

Aggregate: Quartz 0/0.2 mm = 15%
" 0.2/1 " = 25%
" 1/3 " = 32%
" 3/5 " = 28%
Mix: Cement/aggregate = 1/3
Water: w/c = 0.5 good quality
w/c = 0.7 poor quality

Curing conditions

before immersion: 10 days water (Cond. D)
3 days water + 7 days moist air (Cond. E)

The changes in the visible conditions of the concrete cubes and their compressive strengths were measured. Furthermore the reaction products were investigated by X-ray analysis.

Test Results

The changes in the visible conditions of the concrete cubes in the $CaCl_2$-solution up to 16 weeks are shown in Fig. 1. The two different precuring conditions (10 days water or 3 days water + 7 days moist air) had no significant if any influence on their behaviour. After 16 weeks the cubes have not suffered any further deteriorations since 1½ years. Cement Z 1 shows no alteration. The two other cements Z 2 and Z 3 are seriously attacked. At this the poor quality (w/c 0.7) has proved slightly better than the dense concrete (w/c 0.5).

A very similar behaviour was observed with the $MgCl_2$-solution, as is shown in Fig. 2.

Fig. 3 is a photograph of these small cubes after 4 months immersion in 3 mol $MgCl_2$. This picutre had not changed until the strength-test was taken after 2 years.

Immersion in saturated NaCl-solution up to 2 years did not create visible alterations on any concrete cube.

After 2 years of immersion the compressive strengths of the cubes were measured and compared with the compressive strengths measured after 10 days of water curing. Table 1 shows the results for H_2O, NaCl and $MgCl_2$. (The time of immersion in $CaCl_2$-solution has not reached 2 years yet.)

Evidently in all cases after 2 years' water curing the compressive strengths were higher than after 2 years' immersion in the chloride-solutions. With the cements Z 2 and Z 3 no compressive strengths could be measured after 2 years' immersion in $MgCl_2$. (And also after immersion in $CaCl_2$. See Fig. 1, Fig. 2 and Fig. 3.)

On the other hand, compared with the compressive strengths immediately before chemical attack (10 days water), the cements Z 2 and Z 3 showed in NaCl-solution no loss in strength, and Z 2 even showed increases of 60% to 80%. The very large increase in the compressive strength of Z 1 after 2 years NaCl-immersion was nearly as high as by curing in water and even after $MgCl_2$-immersion increases of 40% to 70% were measured

Reaction Products

The causes of these great differences were investigated by X-ray analysis. On this behalf small mortar specimen were made with w/c 0.5 and plastic-sand as aggregate. Plastic-aggregate is very advantageous for this purpose because it can very easily and completely be separated from the hardened paste. Thus an X-ray diagram of pure paste is performed without disturbing residues of quartz (11).

These plastic-cement-mortars were also cured in water for 10 days and then stored in the chloride solutions. They were investigated by X-ray analysis for different times of immersion. For control X-ray diagrams of the pastes of the concrete cubes and of several reaction products were taken after 2 years of immersion.

All the powder specimens for X-ray analysis were prepared in the same way according to earlier publications (11), (12):

Drying of paste at 20°C and 1 Torr = mmHg—grinding 40 min in cyclohexane—drying 2 min in faintly streaming air—firm pressing of the very fine powder ($\sim 5\mu$m) into the specimen holder.

This method constantly results in a homogeneous and very dense surface of the powder specimen. No precautions were taken against preferred orientation.

Among the X-ray diagrams more than 50 could be evaluated accurately and this work resulted in rather a clear picture of the chemical reactions. Here only those diagrams shall be shown that are essential and sufficient for understanding the problem.

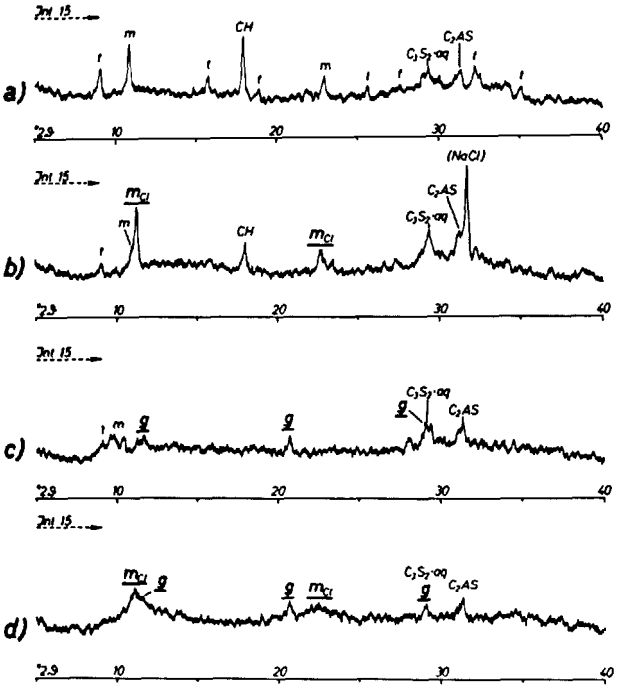

Fig. 4. *Reaction of blastfurnace cement (75% slag) with chloride solutions*

Curing condition: 10 days in H_2O

a) H_2O—10 days
b) NaCl—saturated—8 weeks
c) $CaCl_2$—3 mol/l—8 weeks
d) $MgCl_2$—3 mol/l—1 year

Hydration products:
$C_3S_2 \cdot aq$ = Tobermorite
C_2AS = Trace of crystallized slag
$CH = CaO \cdot H_2O$
$t = 3CaO \cdot (Al, Fe)_2O_3 \cdot 3(CaSO_4, CaO) \cdot aq$
$m = 3CaO \cdot (Al, Fe)_2O_3 \cdot (CaO, CaSO_4) \cdot aq$

Reaction products:
$m_{Cl} = 3CaO \cdot (Al, Fe)_2O_3 \cdot CaCl_2 \cdot 10H_2O$
$g = CaSO_4 \cdot 2H_2O$

Fig. 4 clarifies the behaviour of the blastfurnace slag cement in water and in the three chloride solutions. The least alterations are visible in the NaCl solution. Here by partial inversion of the already present AFm-phase (m) only the adequate chloride-containing member (m_{Cl}) of the solid solution is formed. Simultaneously the AFt-phase (t) and the free calcium hydroxide are decreasing slightly.

In the other two solutions the alterations are slightly more distinct. The calcium hydroxide disappears totally, and the sum of calciumaluminate-

d) $MgCl_2$—3 mol/l—1 year

Hydration products:
C_3S_2·aq = Tobermorite
CH = $CaO \cdot H_2O$
k = rest of klinker
t = $3CaO \cdot (Al, Fe)_2O_3 \cdot 3(CaSO_4, CaO) \cdot aq$
m = $3CaO \cdot (Al, Fe)_2O_3 \cdot (CaO, CaSO_4) \cdot aq$

Reaction products:
m_{Cl} = $3CaO \cdot (Al, Fe)_2O_3 \cdot CaCl_2 \cdot 10H_2O$
O_C = $CaO \cdot CaCl_2 \cdot 2H_2O$
O_M = $MgO \cdot Mg(OH)Cl \cdot 5H_2O$

hydrates decreases. Moreover some gypsum (g) is formed. On the average the alterations of the slag cement mortar are small and all observed reaction products are well known products of cement hydration, too (11).

Compared with these results the reactions of the portland cement mortar are much stronger, as is shown in Fig. 5. In NaCl-solution the same amount of chloride-containing AFm-phase (m_{Cl}) has formed as with the slag cement, although in the portland cement mortar before immersion only very little C_4AH_{13} (m) was present. In the two other solutions about 20% of calcium hydroxide disappear totally and as for cement paste odd reaction products very distinctly appear by immersion in $CaCl_2$-solution appears

$$CaO \cdot CaCl_2 \cdot 2H_2O$$

and by immersion in $MgCl_2$-solution

$$MgO \cdot Mg(OH)Cl \cdot 5H_2O$$

The portland cement with $< 1\%$ C_3A behaved similarly and the same reaction products were observed as are to be seen in Fig. 5.

The X-ray diagrams of the concrete cubes were less distinct but otherwise in full agreement with Fig. 4 and Fig. 5.

Comparison and Summary of Results

The behaviour of the concrete cubes and the results of X-ray investigation add up to the following picutre:

In water storing all the three cements show a strong afterhardening from 10 days to 2 years. With the portland cement with $< 1\%$ of C_3A and with the blastfurnace slag cement the compressive strengths of the concretes with w/c 0.5 increase by nearly 150% and the compressive strengths of the concretes with w/c 0.7 by more than 200%. Since after 10 days of hydration the blastfurnace slag cement shows no residues of clinker phases any more, its very strong afterhardening can only be due to hydration of the slag. The afterhardening of the portland cement with 12% of C_3A (and higher early strength) is less than half as strong in all cases. These facts are important for valuating the further results.

By immersion in NaCl-solution the high alkalinity of paste remains unchanged and all the three cements form

$$3CaO \cdot (Al, Fe)_2O_3 \cdot CaCl_2 \cdot 10H_2O$$

well known as "Friedel'sches Salz".

This reaction has practically no influence on the concrete with blastfurnace slag cement, for it obtains nearly the same strength as by water-curing. The hydration of the slag is not disadvantageously influenced because similar hydration products are formed by water-curing, too.

In case of the two portland cements, however, it seems that rather a constant proportion of the clinker is hampered with respect to its hydration. Although the strengths of the concretes increase in NaCl-solution too, all test specimens reach, in a rather equal degree, only about 60% of their maximum strength they obtained when cured in water for 2 years.

Fundamentally different are the reactions of the two other chloride solutions. By reaction with the free $Ca(OH)_2$ they form expanding oxychlorides which within a short time destroy concretes with high contents of $Ca(OH)_2$. This reaction is accompanied by a total loss of the high alkalinity of paste. Unexpectedly this danger appears slightly greater in case of dense concrete than in case of less dense concrete. Similar observations during several experiments with various strong salt-solutions are already reported by W. H. Kuenning (7) and also by H. Berndt and E. Würth (10).

Although even the test specimens with the blastfurnace slag cement show greater alterations of their X-ray diagrams in $CaCl_2$-solution and $MgCl_2$-solution than in NaCl-solution, they do not form expanding oxychlorides and thus remain sound. This result stands in full agreement with earlier experiments (13):

6 blastfurnace slag cements with slag contents of 47% to 80% remained unaffected during 2 years immersion in 3 mol $MgCl_2$-solution. Furthermore, a steady increase in the resistance of the small mortar specimens was measured with increasing slag contents.

Using concrete cubes, moreover, in the $MgCl_2$-solution within 2 years all the strengths increase in case of the blastfurnace slag cement. At this they obtain with w/c 0.7 about 140% and with w/c 0.5 even about 170% of the compressive strengths before immersion. Furthermore the alkaline reaction with phenolphthalein is not reduced. The normal very strong afterhardening of this cements, however, is disturbed in any case. The concretes with w/c 0.5 reach about 70% and the concretes with w/c 0.7 only about 40% of their maximum strength they obtained when having been cured in water for 2 years. As there is no expanding influence, the dense concrete in this case behaves definitely better than the less dense concrete.

It can be assumed that in the case of the $CaCl_2$-solution the strengths of the concretes with blastfurnace slag will show similar tendencies.

Final Conclusions

Strong solutions of NaCl, $CaCl_2$ and $MgCl_2$ react chemically with concrete.

Nevertheless, destroying chemical attacks occur only with $CaCl_2$ and $MgCl_2$ if the concrete possesses too much free $Ca(OH)_2$. At this a higher density of the concrete does not pay out in a much better protection as otherwise has been proved in most of the other chemical attacks.

In all other cases the concrete will not be attacked, but its afterhardening will at worst be only reduced, whereas the alkaline reaction with phenolphthalein is not reduced.

Blastfurnace slag cements with more than 60% of slag are resistant against all the three chloride-solutions. e. g. a blastfurnace slag cement with 75% of slag proved, when immersed in saturated NaCl-solution, the same very strong afterhardening as it did by curing in water.

These unexpected facts are apt to provide new points of view with respect to the resistance of concrete against deicer scaling, to the durability against seawater action and also to connected problems especially the qualification of suitable concretes to protect the reinforcement against steel corrosion.

Supplementary Paper III-39 A Durability Study of Concrete Using Monte Carlo Simulation

Kenneth R. Lauer and Callin W. Gray*

Synopsis

This paper deals with a durability study of a hypothetical bridge deck. The durability study is accomplished by employing the Monte Carlo method of analysis utilizing a digital computer. It consider such stochastic variables as compressive strength, air content, curing, freeze-thaw cycles, and salt scaling. Laboratory data was used to establish the relationships used in the study.

The ultimate goal of this study is to be able to predict how long a bridge deck will be in service before resurfacing or rebuilding of the deck is necessitated.

Air-entrained and non-air-entrained concrete are used in different cases of the bridge deck. The influence of air-entrained concrete on durability is observed.

The bridge deck is placed in a climatic environment comparable to that of South Bend, Indiana. Consideration is given to placing the bridge deck in April and in August and the effects of placement time are observed.

Introduction

The purpose of this paper is to introduce the Monte Carlo method of analysis as a valid approach in studying the durability of concrete in service.

The majority of concrete technology research in the last twenty five years has been orientated toward laboratory experiments. Traditional methods of reach have been to compare similar concretes or comparison of dissimilar concretes for similar purposes. While the above mentioned research was good, it gave only qualitative results. For example, in the late 1940's and early 1950's, many investigators showed that air-entrained concrete is much more frost resistant than non air-entrained concrete. Investigators studied, in the laboratory, one or two variables at a time holding all other parameters constant.

The investigators have payed little or no attention to what actually happens to the concrete when it is in service. That is to say, what happens to the concrete when the combined effect of temperature, chemical attack (interor and exterior), freezing and thawing, traffic, etc. are acting on the concrete simultaneously? Since many of these factors which influence the durability of concrete are stochastic variables, the formulation of an exact mathematical expression for durability becomes impossible. In order for an analysis to be meaningful, a mathematical approach such as Monte Carlo simulation must be utilized.

In this paper, the mathematical simulation has been formulated on the basic ideas of durability obtained predominantly from laboratory investigations and some field investigations. The temperature and precipitation data are from the South Bend, Indiana area.

Monte Carlo Method

Historical

As the name implies, Monte Carlo involves a system or process which concerns an element of chance (1). That is, the input to the system is random variables.

Monte Carlo was first called "model sampling" before 1948 when Fermi, Metropolis and Ulam used the method for obtaining estimates of the eigenvalues associated with the Schrodinger equation (2).

The use of the Monte Carlo method at the end of the second world war in relation to problems concerned

*Department of Civil Engineering, University of Notre Dame, Notre Dame, Indiana, U.S.A.

with random neutron diffusion in fissionable material brought to light the mathematical power of the method (3). Computers were used to carry out the computation of the above mentioned problem.

The method came into prominence about 1957 with the advent of the high-speed digital computer. The method without a high-speed computer would be impractical because of the time involved to carry out the numerous simulations.

Scope

Definition

Monte Carlo simulation is a technique which utilizes the probabilities of possibilities of occurrence of the pertinent stochastic variables by imitating the occurrence of the states of nature that interact with the different designs under investigation through the use of random number generation. Each simulated design is observed until it fails to meet the requirements for which it was originally intended. After a number of simulations have been completed for one design, that design's life may be predicted.

The probabilities of the possibilities of occurrence of the various stochastic variables are usually grouped in a two-dimensional matrix notation. This two-dimensional ordered array is used when one dependent variable is known to be essentially a function of one stochastic variable. A three-dimensional matrix may be used if one dependent variable is known to be a function of two stochastic variables.

The probabilities of the possibilities of occurrence of the various stochastic variables are determined from field and/or laboratory investigations.

Types

Problems to which this method of analysis is applicable are of two types: deterministic and probabilistic.

The deterministic type has no direct association with random processes; but when theory has exposed the underlying structure of the problem, it may be possible to recognize that this structure or formal expression also describes some apparantly unrelated random process, and, therefore, the solution of the deterministic problem is accomplished numerically by Monte Carlo simulation of an accompanying probabilistic problem.

The probabilistic type of Monte Carlo problem is essentially the observation of random numbers chosen in such a way that they directly simulate the physical random process of the original problem and infer the desired solution from the behaviour of these random numbers.

This direct simulation of a probabilistic problem is the type of Monte Carlo used in studying the durability of concrete in this paper.

Random Number Generation and the Computer

Random numbers may be obtained from random number tables or they may be pulled out of a hat full of slips of paper with various numbers on them. But the quickest method which can be used to generate a sequence of numbers, one at a time so devised that no reasonable statistical test will detect any significant departure from randomness is by the congruential or midsquare method using the digital computer. The numbers generated on the computer by either of the above methods are called pseudorandom numbers since the next number to be generated can be predicted from the last number which the computer generated. La Russo (4) has thoroughly checked out the congruential pseudorandom number generator at the University of Notre Dame Computer Center and has reported it satisfactory. This subroutine was used for generation of the "random" numbers for the simulation model.

Application of the Monte Carlo Method to a Concrete Durability Study

Introduction

Durability of concrete has been defined as its resistance to deteriorating influences which may through inadvertence or ignorance reside in the concrete itself or are inherent in the environment to which it is exposed (5).

Of the many factors influencing the durability of concrete in service, the following major ones are considered: (1) probability of occurrence for compressive strength, (2) probability of occurrence for air content, (3) compressive strength loss due to air-entrainment, (4) loss in compressive strength due to improper curing and compaction, (5) time, and temperature effects on gain in strength, (6) dynamic modulus of elasticity and freeze-thaw cycles, (7) compressive strength and dynamic modulus of elasticity, (8) compressive strength and pulse velocity, and (9) de-icing scale rating

and the number of scale cycles. These factors are considered primarily because of their importance relative to the durability of concrete bridge decks and because of the data available in these areas for the simulation model.

The concrete mix used in the model represents the most homogenous data available. In some instances relationships were adjusted to be more applicable. The following mix proportions and properties were used.

	Non-air entrained mix	Air entrained mix
W/C, wt	0.50	0.50
Cement factor, bags/cu yd	6.4	6.0
Slump, inches	2–4	2–4
Max. aggregate size, inches	1	1
Air content, % entrained	0.0	4.5

The variables in the model are assumed to be linearly independent thereby making the principle of superposition applicable.

The model has been formulated in the same sequence as the various parts of the model are explained.

Compressive Strength

The variability of the strength of the concrete is characterized in the relationship of probability of occurrence for a given strength versus strength. Implicitly implied in the above mentioned curve is all the possible variations in the concrete mix before it is placed in the field.

For reasonable field control, and no radical changes in mix proportions, the curve of percentage frequency of occurrence versus strength is approximately bell-shaped. That is, if a bar chart or histogram of per cent frequency of occurrence versus strength is plotted, see Fig. 1, the histogram or "parent" distribution may be approximated by the theoretical Gaussian or "normal" distribution curve.

Two significant properties of the normal curve are the following. The total area under the normal curve is equal to one and the area under the curve between any two points A and B is the probability of occurrence of a value in that interval. Therefore, if the specific strength distribution for a certain mix being produced at a certain batch plant is known, then, for that certain mix, the probability of a certain strength being produced at that plant can be determined.

It is assumed in this study that the probability curve is a normal curve and is given in Fig. 1. The concrete is non-entrained. The average 28 day compressive strength is assumed to be 4500 psi. From the data in

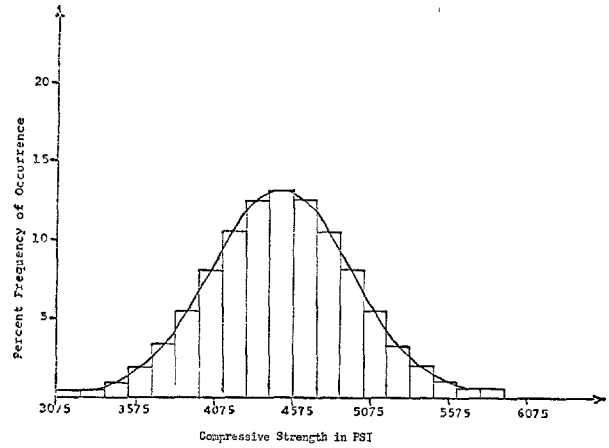

Fig. 1. *Percent frequency of occurrence versus compressive strength for 4,500 psi non-air-entrained concrete*

Newlon's (6) paper, the standard deviation for 4500 psi concrete is approximately 450 psi. This gives a coefficient of variation of 10%. A coefficient of variation of 10% infers good quality control procedures.

One way of using the normal curve in the simulation model is to approximate the curve by its corresponding histogram as in Fig. 1. A cell interval of 150 psi and nineteen cells were used in order to approximate the normal curve. Theoretically, the furthest extents of the ordinates of a normal curve never terminate on the abscissa axis. Therefore, some of the values of compressive strength, even though they may have a very, very small probability of occurrence still have a chance of occurring. If the range of strength varies from a value of three times the standard deviation in either direction from the average strength, then 99.73% of all the strength values will lie in this range.

In Table 1, the average cell strength values are

Table 1. *Average cell strength values, their probabilities of occurrences, and their specific number designations*

Average cell strength psi	Probability of occurrence, per cent	Specific number designation
3150	.3	1–3
3300	.4	4–7
3450	.9	8–16
3600	1.8	17–34
3750	3.3	35–67
3900	5.5	68–122
4050	8.1	123–203
4200	10.6	204–309
4350	12.5	310–434
4500	13.2	435–566
4650	12.5	567–691
4800	10.6	692–797
4950	8.1	798–878
5100	5.5	879–933
5250	3.3	934–966
5400	1.8	967–984
5550	.9	985–993
5700	.4	994–997
5850	.3	998–1000

listed with their probabilities of occurrence and their specific number designations for indicating what strength the concrete will have when the random number selection is made. The range of random numbers is 1 to 1000 inclusive.

Now, the computer picks a random number which will determine what non-air-entrained strength the concrete will have. If the computer picked 501, the strength of that batch of concrete would be 4500 psi.

Air Content

Air content has a very marked effect on the durability of concrete. The lack of sufficient entrained air in concrete can considerably decrease the durable life of a structure exposed to frost action.

Klieger (7) has shown that the "optimum" air content for a given mix is a function of the maximum size of the aggregate, workability of the mix, and the cement factor for the mix. Optimum air content is considered by Klieger (7) to be that minimum air content beyond which further increases in air result in only a small decrease in expansion due to freezing and thawing.

Since the exact relationship between strength and air content probability distribution has not been fully investigated, it is assumed that the probability distribution of air content remains constant for the whole range of strength variation. That is to say, one air content probability curve is used for the whole range of strength variation, 3150 psi to 5850 psi. The average air content was chosen as the optimum air content according to Klieger's (7) work. For the specific mix under study, the optimum air content is 4.5%. The air content probability curve is assumed to be a normal curve. From Newlon's (6) work the average standard deviation for air content is assumed to be 0.70%. This gives a coefficient of variation for air content of about 15.6%. A cell interval of .30% was used for the approximation of the normal curve.

In Table 2, the average cell values are given with their probabilities of occurrence and their specific number designations. These values and the previously mentioned strength values were calculated using a mathematical probability table.

It may be shown from Klieger's (7) results that the average percentage change in strength for each 1% of entrained air for total amounts of entrained air up to 6% is approximately linear. This is true if the cement factor, slump, and maximum size of aggregate are maintained constant.

For the specific mix in question the plot of loss in strength versus the air content is given in Fig. 2. This relation is used in the model.

Table 2. *Average cell air content values, their probabilities of occurrences, and their specific number designations*

Average cell air content, %	Probability of occurrence, per cent	Specific number designation
2.4	.1	1
2.7	.7	2–8
3.0	2.8	9–36
3.3	3.0	37–66
3.6	7.6	67–142
3.9	11.8	143–260
4.2	15.5	261–415
4.5	17.0	416–585
4.8	15.5	586–740
5.1	11.8	741–858
5.4	7.6	859–934
5.7	3.0	935–964
6.0	2.8	965–992
6.3	.7	993–999
6.6	.1	1000

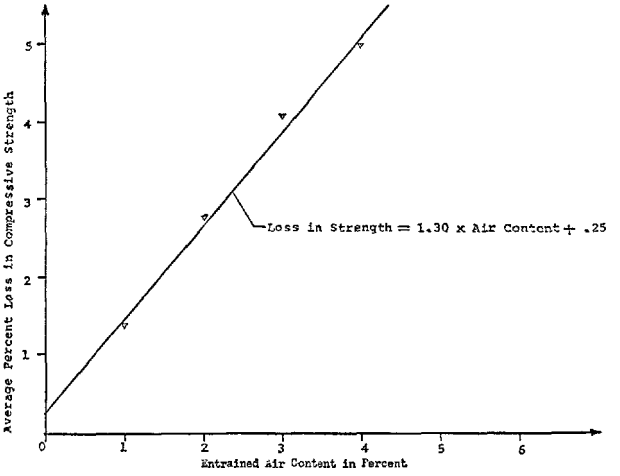

Fig. 2. *Loss in strength versus percentage entrained air content (Points plotted are from Klieger's (7) data)*

After a strength is selected an air content is picked by having the computer choose a random number. Suppose this number is 200. From Table 2, the air content for the previously selected 4500 psi batch is 3.9%. One per cent of air is deducted from 3.9% to take into account the entrapped air content. The assumption of one per cent entrapped air was used for all air-entrained simulations. The computer calculates the loss in strength due to air entrainment by the equation in Fig. 2. The loss in strength is subtracted from the original compressive strength to give a new compressive strength.

The above steps are omitted in the simulation model for the non-air-entrained concrete.

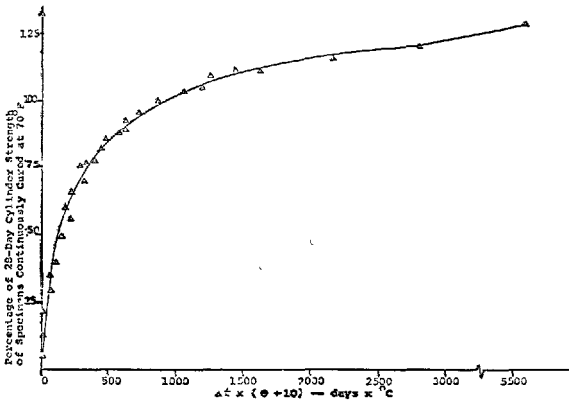

Fig. 3. *Percentage compressive strength as a function of age and temperature (Saul and Nurse (8))*

Moisture Loss and Compaction

The computer, next, modifies the compressive strength in order to account for moisture loss due to less than perfect curing conditions and imperfect compaction of the concrete in the field. A loss in strength of five per cent is deducted from the compressive strength to give the updated compressive strength of the concrete.

In the non-air-entrained case, the five per cent loss is computed with respect to the non-air-entrained strength which the computer chose first.

A loss of five per cent would indicate good compaction in the field and a relatively good membrane type of curing method. For some jobs, the loss due to the above mentioned factors may be as high as 20 per cent.

When the effect of compaction and moisture loss on compressive strength are better understood, these relationships may be incorporated into the simulation model.

Time, Temperature, and Strength Gain Relationship

The relationship of temperature to the rate of concrete hardening and gain in strength is of importance in concrete durability. As a rule, for moist curing conditions, high temperatures accelerate strength gain and low temperatures reduce strength gain.

Most investigators (8, 9, 10) agree that strength gain is proportional to the product of time and temperature. The approach of Saul and Nurse is a good method of estimating strength gain from time-temperature relations (8, 9).

This relationship using Price's data is shown in Fig. 3. Price's (11) data is for concrete cured in a moist environment at 100°F, 73°F, 50°F, 33°F and 16°F and tested in compression at 3, 7, 14, 28, 90 and 180 days. In Fig. 3, it may be seen that the gain in strength, after a certain time-temperature period, approaches the constant value of approximately 128% of the 28 day, 73°F, moist cured laboratory test specimen strength.

For this study it is assumed that the concrete gains compressive strength according to the above mentioned curve. Also, the maturity factor, $\Delta t \times (\theta + 10)$, is assumed to be the summation of the individual maturity factors. The average temperature effect on the concrete is assumed to be equal to that of the average daily temperature of the air everyday for 90 days after the concrete is placed. That is to say, the concrete is observed to see what gain in strength due to temperature occurred during the first 90 days of its existence. Then, the concrete is observed on a monthly average temperature basis in order to calculate the further gain in strength of the concrete. If and when the concrete reaches the value of 128% of the laboratory strength, the concrete is not permitted to gain any more strength.

In order to use this relationship some means of obtaining temperatures which are most likely to occur in the field is necessary. Since temperature is also a random variable, it was necessary to determine the probability of occurrence of temperature on a daily and monthly basis. The South Bend, Indiana, area weather data (12) was used for the analysis. For the daily basis, twenty-seven years of continuous records were available and analyzed. For the monthly data, sixty-seven years of data was available and was analyzed. The method of analysis was to sort the temperatures out according to a predetermined number of cell sizes. The cell sizes used were 10, 11, 12, 13, 15 and 20 cells. In order to conserve computer time, only the 10, 15 and 20 cell data was used in the simulation study.

In Table 3, the analyzed average daily temperature data for May third, for ten cells, is given.

Now, the computer picks a random number, 401, and for example, if the concrete was placed on May third, then the average daily temperature for that day was 54.5°F. Therefore the maturity factor for that day is calculated by the equation, Maturity Factor $= \Delta t \times (\theta + 10)$ where $\Delta t = 1$ day and $\theta =$ the average daily temperature determined by the random number selection, in degrees centigrade.

The above process is then repeated using the temperatures and specific number designations of

Table 3. *Average daily cell temperature values, their probabilities of occurrences, and their specific number designations for May 3rd. 10 cells*

Average daily cell temperature °F	Probability of occurrence, per cent	Specific number designation
39.2	7.4	1–74
43.0	11.1	75–185
46.7	11.1	186–296
50.5	3.7	297–333
54.5	14.8	334–481
58.0	11.2	482–593
61.8	14.8	594–741
65.6	7.4	742–815
69.3	11.1	816–926
73.1	7.4	927–1000

Table 4. *Precipitation probabilities and their specific number designations for the first ten winter days*

Winter day	Precipitation probability, per cent	Specific number designation
1	30.8	1–308
2	34.6	1–346
3	26.9	1–269
4	19.2	1–192
5	19.2	1–192
6	26.9	1–269
7	30.8	1–308
8	42.3	1–423
9	30.8	1–308
10	26.9	1–269

May fourth, May fifth, etc. until 90 days have been observed. The cumulative maturity factor is constantly being updated during this process.

After ninety days, the concrete is studied on a monthly average temperature basis in a similar manner. Then, after the winter months are over the concrete's gain in strength is computed and added to the former compressive strength to give the updated compressive strength. The gain in strength is computed from the equations of the straight line relationships obtained when the percentage strength gain is plotted against the log of the maturity factor using Price's data.

Freezing and Thawing Cycles and Compressive Strength Relationship

In order to simulate the freezing and thawing cycles which occur in nature it was necessary to analyze the daily low and daily high temperature values for the winter months in the same manner as the daily average temperatures and the monthly average temperatures were analyzed as described in the previous section. The winter days in this study were assumed to be 150 in number and extended from November first to March thirtieth, inclusive.

To have a freezing and thawing cycle in nature which will damage the concrete to some degree structurally, precipitation in the form of melting snow or freezing rain is essential to provide the required saturation in order to cause hydraulic pressure to build up in the capillary cavities when the temperature of the concrete drops below freezing. The amount of precipitation necessary to cause frost distress was assumed to be .20 inches of snow or greater and/or .05 inches of freezing rain or greater. The precipitation probabilities for the winter days were computed from twenty-six years of continuous record for the South Bend area. In Table 4, the precipitation probabilities for the first ten winter days are listed along with their corresponding specific number designations.

First, the computer pulls a random number which corresponds to some specific high temperature for the given day. Then, the computer pulls another random number corresponding to a specific low temperature for the same day. It is assumed that this temperature occurs after the high temperature and at night before 12 o'clock midnight. Then the computer chooses another random number and this number specifies whether a sufficient amount of precipitation was available to cause frost distress. For example, suppose on the third day of winter, the computer pulled the random number 300. Then it did not rain or snow, see Table 4, in sufficient amounts to cause frost distress in the bridge deck even if the concrete was beginning to freeze. If the computer had pulled the random number 200 for the third winter day instead of 300, from Table 4, the concrete was exposed to sufficient moisture that day to be damaged by frost distress provided that the high and the low temperatures of that day were sufficient to cause a freezing cycle.

It is generally aggreed that $E_D = Kf^n$ where $E_D =$ the dynamic modulus of elasticity, $K =$ a constant depending on the mix components, $n =$ an exponent, and $f =$ the compressive strength of the concrete (13, 14, 15, 16, 17, 18).

Laboratory freezing and thawing tests are based on an "accelerated" freeze-thaw cycle. The measure of deterioration is loss in dynamic modulus of elasticity after a prescribed number of cycles have been completed or linear expansion or weight loss of the specimen after a prescribed number of cycles have been completed.

The loss in dynamic modulus of elasticity indicates a structural weakening of the concrete due to frost distress. Conventionally, a plot of relative dynamic modulus of elasticity in per cent versus number of freeze-thaw cycles is made. See Fig. 4. If the concrete

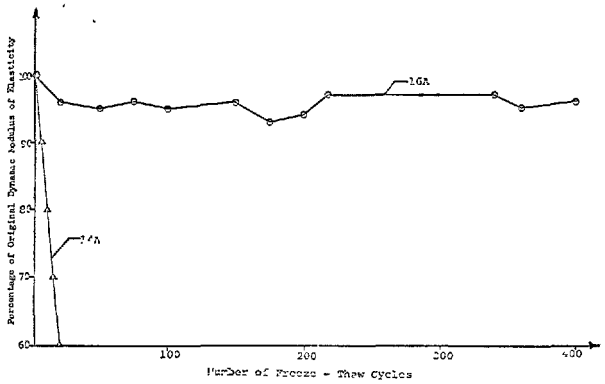

Fig. 4. *Relative dynamic modulus of elasticity as a function of freeze-thaw cycles (Hussell (21))*

is fairly frost resistant, the curve will resemble curve 16A. If the concrete is fairly non-front resistant, it will resemble curve 14A. If a core sample was taken from a structure exposed to frost action with concrete in it like that of curve 14A, the compressive strength of the core would be significantly less than that of a core taken from a structure made with concrete, exposed to frost action, of the type of curve 16A. Therefore, a correlation should exist between strength and dynamic modulus of elasticity when concrete has been subjected to frost action. Whitehurst (19) and Cheesman (2) report good correlation between laboratory resonance frequency measurements of the modulus of elasticity and that calculated from the pulse velocity which was obtained in the field. The equation relating the pulse velocity to the dynamic modulus of elasticity is

$$E = \frac{V^2 d(1 + u)(1 - 2u)}{(1 - u)}$$

where

E_D = the dynamic modulus of elasticity of the concrete
V = the pulse velocity
d = the density of the concrete
u = Poisson's ratio

Now if the calculation of the dynamic modulus of elasticity from the field data corresponds to that measured in the laboratory on a core of the field concrete and there is a correslation between the laboratory modulus of elasticity and compressive strength, then the following is most likely to be true.

Let

$$E_R = \frac{E_p}{E_0}$$

where

E_R = relative dynamic modulus of elasticity
E_p = the present dynamic modulus of elasticity
E_0 = the original dynamic modulus of elasticity before the "accelerated" freezing and thawing cycles commenced

Since $E_D = Kf^n$, and assuming K to remain constant

$$E_R = \frac{(Kf_p)^n}{(Kf_0)^n} = \frac{f_p^n}{f_0}$$

where

f_p = the present compressive strength
f_0 = the original compressive strength before the freezing and thawing cycles commenced.

Also, the part of the original compressive strength which the concrete presently possesses $= f_p/f_0 = E_R^{1/n}$ or the present loss in strength due to freezing and thawing in per cent of the original strength of the concrete $= (1.0 = E_R^{1/n}) \times 100$.

The ordinates of the curves given in Fig. 4 were converted by the last equation stated above. Fig. 5 shows the linear least squares fit plot of the converted data points.

It would be possible to measure the approximate loss in strength of concrete exposed to frost action if the exposure cycles in the field were comparable to those of the "accelerated" freeze-thaw tests. In the simulation model, an adjustment of the requirements for a frost deteriorating freeze-thaw cycle in the field is used in order to utilize the "accelerated" laboratory freeze-thaw cycle results. It is felt that the "accelerated" laboratory freeze-thaw test which most nearly approximates the freeze-thaw cycles in the field is ASTM Designation C291–57T. This procedure is based on rapid freezing in air and thawing in water. In order to assure that at least the top 1 inch of concrete is thawed out, it was considered necessary that the high air temperature of any given day be at least 35°F. A low air temperature at night of at least 29°F and sufficient precipitation had to have fallen before the computer tailed a freeze-thaw cycle. A low temperature of 29°F was also chosen to insure that the top 1 inch of concrete was frozen. By using the above two temperatures as part of the criterion for a frost deteriorating cycle, the laboratory "accelerated" freeze-thaw test is approximated as much as is possible. The major fault of the field criterion for tailing freeze-thaw cycles is the fact that the intensity of the cycles in the field are not uniform as they are in the laboratory. No way was devised to take into account the variable intensity of the freeze-thaw cycles in the field.

After the computer goes through all the winter days tabulating the number of frost deteriorating cycles, the loss in compressive strength due to freeze-thaw cycles is computed from the equations which are repre-

sented graphically in Fig. 5.

After the loss in compressive strength due to freeze-thaw cycles is calculated, for the air-entrained mix, the air content of the concrete of the particular simulation run is compared to the air content of the mix from which the equations were approximated. In this case, the air content is 5.0%. If the air content of the particular run is between 4 to 6%, it is assumed, considering Klieger's optimum air content of 4.5% for this concrete, that no adjustment in the loss in strength due to frost deteriorating cycles is required. Also from Klieger's work (7), if the air content of the particular batch is greater than 6.0%, the loss in strength due to freezing and thawing is decreased by 5% of the previously computed loss. If the air content of the batch is less than 4.0% then the originally computed loss in strength is increased by 10% of the original value.

Finally, the loss in strength is subtacted from the present compressive strength and the new updated compressive strength is tabulated.

In the non-air entrained concrete model, the loss in strength due to deteriorating freeze-thaw cycles is calculated and immediately deducted from the present compressive strength.

Pulse Velocity, Dynamic Modulus of Elasticity and Compressive Strength Relationships

Klieger's work (22), presents the relationship between compressive strength and dynamic modulus of elasticity, as measured by the resonance method, for different types of cements for a non A/E mix having a cement factor of 6 bags/cu. yd. The test ages were 1, 7, 28 days, 3 months, 1 and 3 years. The ordinates of this curve were reduced by 6% in order to approximately convert this curve to the 6 bags/cu. yd., air-entrained mix curve having an average air content of 4.5%.

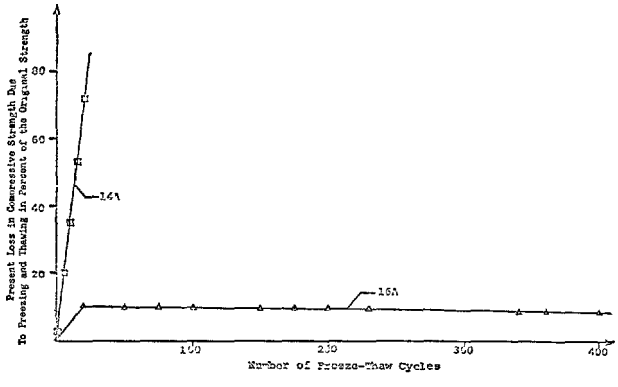

Fig. 5. *Loss in strength due to number of freeze-thaw cycles*

The values of the non-air entrained case and the air entrained case were then plotted on 2 × 2.4 cycle logarithmic paper (Fig. 6). On this paper, the curves were straight lines in the area which was applicable to the simulation model. The equations of the straight line relationships are of the form

$$E_D = Kf^n$$

where E_D, K, f and n are as previously defined.

It was then assumed that the value of the dynamic modulus of elasticity of the concrete under study at any instant of time may be approximated by one of the above equations.

The computer then calculates the present value of the dynamic modulus of elasticity. This step simulates the obtaining of a core sample from the bridge deck and the subsequent laboratory resonant testing of the core in order to ascertain the dynamic modulus of elasticity of the concrete.

Again, Klieger's work (22) presents the relationship between compressive strength and pulse velocity for a

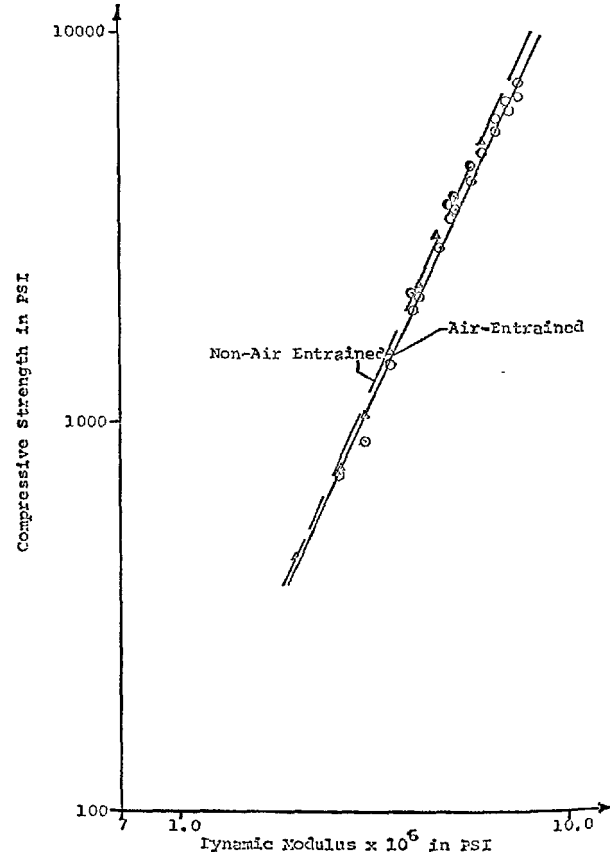

Fig. 6. *Compressive strength—Dynamic modulus of elasticity relationship on log- log paper (Points plotted are from Klieger's (22) data)*

6 bags/cu. yd., non-air entrained, mix using different types of cement. Test ages for this relationship were the same as the above mentioned dynamic modulus-strength relationship. The pulse velocity was determined by the soniscope. If these points are plotted on 2×2.4 cycle logarithmic paper, the relationship is found to be linear (Fig. 7). It is assumed that the pulse velocity of the concrete at any time may be computed from the equation of the linear portion of the logarithmic plot.

The computer, now, calculates the pulse velocity of the batch of concrete in the deck. The calculation of the pulse velocity simulates the taking of a core sample from the specifically placed batch in the bridge deck and determining the pulse-velocity in the laboratory or using the soniscope directly in the field in order to determine the pulse velocity for the specific area of the deck in which the batch was placed. It is further assumed that in either of the just mentioned interpretations the pulse velocity is determined on a specimen of concrete in which the reinforcement steel, either longitudinal or tranverse has no effect on the value of the measured pulse velocity. This asumption was made because the data used for the pulse velocity—strength relationship was for plain concrete. The pulse velocity is higher in reinforced concrete due to the fact that steel is denser than concrete.

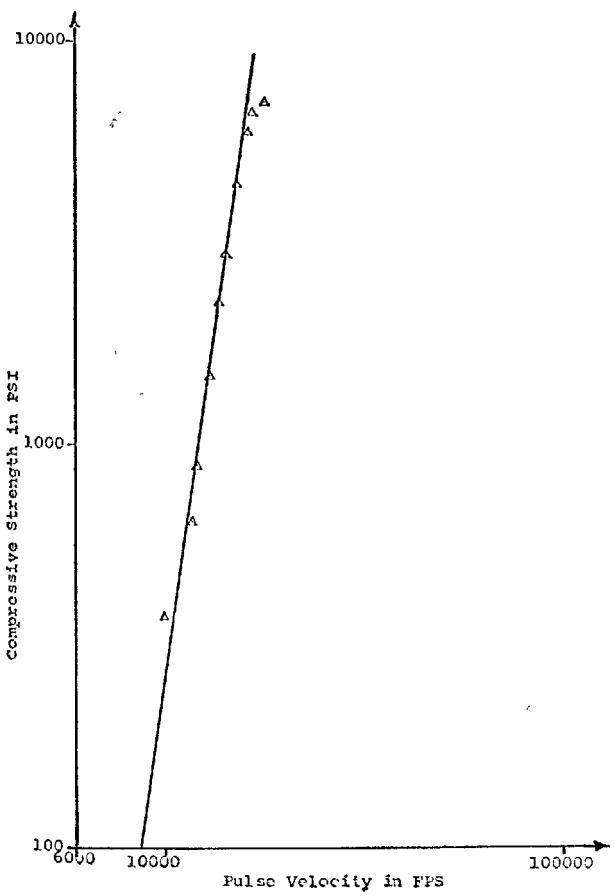

Fig. 7. *Compressive strength-pulse velocity relationship on log-log paper (Points plotted are from Klieger's (22) data)*

In both the dynamic modulus-strength and pulse velocity-strength relationships, the compressive cube strength was used in Klieger's original work (22). The compressive cylinder strength was obtained by multiplying the compressive cube strength by 0.75 after the suggestion by Jones (23) and the British Standard 1881, 1952.

Structural Failure Criteria

The propagation of an ultrasonic wave through concrete, either in the field or in the laboratory, and the subsequent calculation of the velocity of propagation or pulse velocity is a means of evaluating the overall quality of the concrete. If the concrete is of good structural quality it will be dense and the pulse velocity will be high. If the concrete is structurally poor its pulse velocity will be low.

According to Leslie and Cheesman (24), the quality of concrete in service may be rated from the following pulse velocity measurements.

Pulse velocity, ft per sec	General condition
above—15,000	excellent
12,000—15,000	good
10,000—12,000	questionable
7,000—10,000	poor
below— 7,000	very poor

The above listed pulse velocities give an indication of the structural integrity of the concrete. Whitehurst (25) reports that the above categories are based on normal concrete having a unit weight of approximately 150 lb/cu ft. Cheesman (20) states that although concrete having a pulse velocity between 16,000 to 12,000 f.p.s. is generally structurally sound, some tranverse cracking, a very few popouts, and non-progressive light scaling may be present on the surface. The above is possible since the concrete just below the surface probably is in excellently good condition. If the pulse velocity is less than 12,000 f.p.s., the concrete is probably not in good structural condition.

It is assumed that a structural failure is imminent if the pulse velocity calculated by the above mentioned equation is less than or equal to 12,000 f.p.s.

The computer then checks the computed pulse velocity of the concrete against the value of 12,000

f.p.s. If the value is less than or equal to 12,000 f.p.s. the computer prints out the life of the present concrete batch in years, its failure pulse velocity, the dynamic modulus of elasticity at failure, the average life of the concrete which is equal to the summation the individual lives of the previous batches including the present batch divided by the number of simulations just completed, the compressive strength of the concrete at failure, and the average compressive strength of the concrete at failure which equals the summation of the individual compressive strength at failure up to and including the most recent simulation divided by the number of simulations just completed. The computer also prints out the scale rating when the concrete failed and the non-air entrained strength which the concrete theoretically possessed at its inception.

The computer then begins the next simulation by choosing a random number corresponding to the non-air-entrained strength of the next batch of concrete. The previously mentioned steps are then repeated.

If the computed pulse velocity is greater than 12,000 f.p.s. then the numerical scale rating is calculated as described below.

Relation of Salt Scaling to Durability

The problem of salt scaling of bridge decks is probably the primary cause why most bridge decks need resurfacing (26).

In the salt scale test, the salt solution is placed on the specimen and frozen and then thawed for a specific length of time. Sometimes water is placed on the specimen and salt pellets or flakes are placed on the specimen and allowed to remain there for a prescribed time period before the specimen is allowed to be frozen. After a certain predetermined number of scale cycles, the surface of the specimen is rated qualitatively on the percentage of surface area scaled and the depth of scaling. The scale cycles are repeated until a specific scale rating is reached or until a certain number of cycles is achieved. Then a plot of numerical scale rating versus the number of scale cycles is made. Fig. 8 is one such plot for a scale resistant concrete (curve 46A) and a scale susceptible concrete (curve 26A). According to Klieger (27) classification, the numerical scale ratings are as follows:

0—no scaling
1—very slight scaling
2—slight to moderate scaling
3—moderate scaling
4—moderate to bad scaling
5—severe scaling

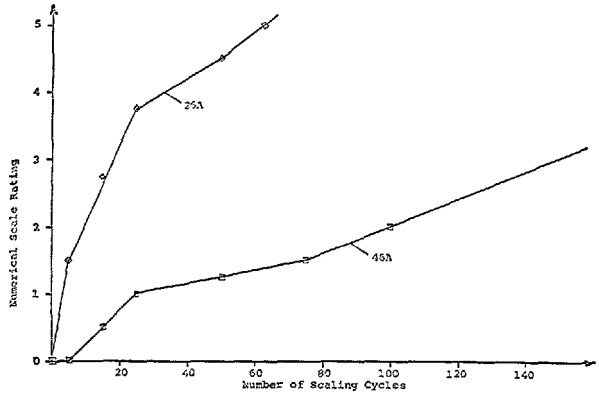

Fig. 8. *Scale rating versus number of scaling cycles (Hussell (21))*

Scaling Failure Criteria

Good maintenance practice would dictate that the time to resurface a bridge deck would be before the scaling and cracking becomes too severe, approximating the numerical scale rating 3.

It is assumed that everytime the conditions necessary to cause a frost deteriorating freeze-thaw cycle are satisfied; a salt application is also made on the bridge deck. This assumption also supposes fairly good maintenance practices. If is further assumed that 3 per cent sodium chloride solution (by weight) is placed on the deck everytime the salting is done. This assumption is not entirely correct since the rate of salt application is variable. Three per cent sodium chloride was used in the laboratory salt scaling tests which are used as the data (21) in this study. It is further assumed that the numerical scale rating expected in the field may be calculated from the equations of the straight line segments in Fig. 8. These curves are based on 14 days moist plus 21 days dry curing, then freezing with the salt solution on the surface of the slab. This procedure and specific salt concentration presents the most severe condition possible and a condition which may exceed field conditions. The curing conditions of the salt scaling tests are not the same as those assumed for the bridge deck, but the mix proportions of the concrete with the above mentioned curing came closer to the rest of the mix properties of the other relationships which were utilized in the study.

The computer calculates the scale rating in real number form from one of the above mentioned equations. The scale rating, for the air-entrained concrete, is modified to take into account the actual air content of the concrete. The measured air content for the air-entrained curve 46A is 4.1%. Using Klieger's work (27, 28) as a guide, it is assumed that if the actual air content is greater than or equal to 3.1% and less than

or equal to 5.1% no adjustment in scale rating is necessary. If the actual air content is greater than 5.1%, then the scale rating is decreased by 30%. If the actual air content is less than 3.1%, the scale rating is increased by 50% of its computed value.

For the non-air-entrained case, no modification of the initially computed rating is made.

In order to use Klieger's (27) numerical integer scale rating the computer rounds off the real number form of the scale rating to the nearest whole integer value. The computer, then, compares the computed scale rating with the scale rating of three. If the scale rating is less than three, the computer continues to calculate the cumulative maturity factor for the concrete and the compressive strength is updated and additional freezing and thawing cycles are taken into account. The constant updating of the cumulative maturity factor, compressive strength, and the age of the concrete batch is repeated until the concrete fails structurally, or failure is caused by moderate salt scaling. After a failure by scaling occurs, the same parameters at failure as those listed after a structural failure are printed out by the computer.

Expected Simulation Results

A number of simulations are run in the manner described. The specific number of simulations which are run corresponds to the number of simulations which are needed to cause the average life of the concrete to approach and maintain a relatively constant value. This expected value is then predicted as the average life of the concrete bridge deck before it will have to either be rebuilt or resurfaced. The average life of the bridge deck may be obtained by observing what happens to a number of the randomly placed batches of concrete in the deck, since the average life is the summation of the lives of each batch of concrete in the deck including that of the most recently completed simulation divided by the cumulative number of simulations completed.

The average compressive strength at failure should also approach and maintain a relatively constant value after a specific number of simulations. This value of average compressive strength at failure should approximately equal the compressive strength of a core sample taken from the bridge deck when its expected average life is reached.

Results and Discussion

Introduction

Air-entrained and non-air-entrained concrete with approximately the same mix proportions were studied.

The effect of the placement time was studied by placing the concrete, hypothetically, on April first and on August first.

Since an exact analysis was not attempted to determine the theoretical probability curves for the temperature data, the effect of varying the cell number was observed. Only the results for 10 cell temperature data are shown in this paper.

Average Life—Number of Simulation Results

In Fig. 9 and 10 the plots of the average life of the bridge deck versus the number of simulations completed may be seen for the air-entrained concrete and the non-air-entrained concrete. In the above mentioned plots the first value of the average life and every tenth value of the average life is plotted thereafter.

It may be seen that the non-air-entrained cases damp out or approach a relatively constant value after a fewer number of simulations than the air-entrained cases. This is due to the greater complexity of the air-entrained model.

It is, also observed that the air-entrained concrete

Table 5. *Expected average life parameters of the bridge deck depending on placement date*

Air entrained concrete		
	Placement date	
	April 1st	August 1st
Expected average life, years	16.9	16.2
Number of simulations	501	501
Standard deviation, years	3.8	3.7
Variance, years squared	14.7	14.0
Coefficient of variation, per cent	22.8	23.1
Predominant method of failure	Salt scaling	Salt scaling
Computer time utilized	1h 8m 59s	1h 7m 42s

Table 6. *Expected average life parameters of the bridge deck depending on placement date*

Non air-entrained concrete		
	Placement date	
	April 1st	August 1st
Espected average life, years	2.6	2.1
Number of simulations	501	501
Standard deviation, years	.6	.6
Variance years squared	.4	.3
Coefficient of variation, per cent	24.2	27.5
Predominant method of failure	Salt scaling	Salt scaling
Computer time utilized	0h 13m 10s	0h 12m 28s

has an average life of about 8 times that of the non-air-entrained concrete.

Tables 5 and 6 list the expected average life parameters of the bridge deck for the various cases.

The predominant method of failure for all cases is scaling. This is reasonable since bridge deck concrete with a mean 28 day laboratory strength of 4500 psi will most likely not fail structurally.

The concrete placed in April lasted approximately 7 months longer than the concrete placed in August because both fail after approximately the same number of winters of exposure. The above statement is true for both the air-entrained and non-air-entrained concrete cases.

Average Compressive Strength—Number of Simulation Results

The plots of the average compressive strength of the bridge deck versus the number of simulations completed are of the same general shape as the plots of the average life of the bridge deck versus the number of simulations completed.

In Table 7 the expected average compressive strength of the bridge deck, is given at the average life expectancy.

The expected value of the average compressive strength should be approximately equal to the compressive strength of a core sample taken from the hypothetical bridge deck when it reaches a state of structural deterioration or moderate salt scaling.

It may be seen from Table 7 that the date of placement has a marked effect on the value of the expected average compressive strength for the air-entrained mix. It is observed that the value of the expected average compressive strength for the April first placement

Table 7. *Expected average compressive strength of the bridge deck when the average life expectancy is reached*

Air entrained concrete	
Placement date	Compressive strength psi
April 1	3610
August 1	4650
No. of simulations (Same for both placement dates)	501
Non air-entrained concrete	
Placement date	Compressive strength psi
April 1	2640
August 1	2230
No. of simulations (Same for both placement dates)	501

data is approximately 1000 psi lower than that of the August first placement date.

For the air-entrained cases, the 90 days following the August first placement date are generally on an average daily temperature basis for the South Bend area considerably warmer than those 90 days following the April first placement date. This implies that there will be a considerable greater strength gain after the August first placement data than the April first placement date provided that an adequate continuous moist curing procedure is employed as assumed in this analysis.

It can be seen from Table 7 that the values of the expected average compressive strength for the air-entrained cases are between 1000 and 2400 psi greater than the expected values of average compressive strength for the non-air-entrained concrete. This difference is due to the dissimilarity in the loss in strength—number of freeze-thaw cycles relationship for the air-entrained and non-air-entrained cases as shown in Fig. 5.

For the non-air-entrained cases, it may be seen that the April first placement date yields a higher value of expected average compressive strength than the August first placement date. No plausible explanation is apparent to explain the greater value of approximately 350 psi in the expected average compressive strength of the April first placement date in relation to that of August first. Since the difference is only about 2 times the probability distribution for strength cell width of 150 psi, it may be possible that this difference is due to the random fluctuations of the variables in the simulation model.

The results of the study show that the expected average compressive strength of the air-entained concrete is much greater than that of a similar non-air-entrained concrete if both are exposed to the same type of climatic conditions.

It also appears that the placement date has a marked effect on the expected average compressive strength of the air-entrained concrete bridge deck; whereas the placement date does not have as great an effect on the expected average compressive strength of the non-air-entrained concrete bridge deck.

Conclusions

The most important conclusion to be drawn from the analysis is that the Monte Carlo simulation approach to a concrete durability study is highly feasible. However, to make the results of the mathematical model most meaningful, it is imperative to have the proper combination of laboratory and field data available for input to the model. At present all of the essential knowledge for the most meaningful use of the simulation model has not been thoroughly developed. As this knowledge becomes available the simulation model can be readily modified to incorporate the findings.

It may also be concluded that, since the values of the expected average life of the bridge deck appears to be of the proper magnitude, the initial assumption of the application of the principle of superposition to the many variables involved in the durability of concrete may not be in serious error.

The simulation model is very flexible. As a result if enough time, money and effort are expended on the procurement of input data for the simulation model, the results will make possible the most durable type of concrete for a given structure in any given environmental situation for given economic considerations.

Supplementary Paper III-59 Measuring Gas Diffusion for the Valuation of Open Porosity on Mortars and Concretes

Hans E. Schwiete, H. J. Böhme and Udo Ludwig*

Introduction

Together with water, cement and its aggregate (sand, gravel and broken material) form mortar or concrete which is damp to plastic in consistency, according to the amount of water added, and which hardens by the reaction of the water with the cement.

The denseness of hardened mortar or concrete depends upon

1. the ratio of cement : aggregate : water
2. the quality of the cement
3. the type and particle size distribution of the aggregates
4. the degree of compaction
5. and upon the type and duration of subsequent treatment of the fresh mortar or concrete.

Cement in combination with water increases the denseness of the mixture because the hydration products (calcium silicate hydrate, calcium aluminate ferrite hydrate, calcium aluminate ferrite sulphate hydrate and free calcium hydroxide) have a higher specific volume than the unhydrated cement.

Measurement of the Gas Diffusion

The amount of gas which diffuses independant of time through samples of mortar or concrete was measured by the application of Fick's first law:

$$\dot{S}_0 = -D_0 \cdot q \cdot \frac{dc}{dx}$$

The amount of the substance ($\dot{S}_0$) which in the time (t) diffuses through a cross-section (q) is proportional to the diffusion gradient (dc/dx), and the proportionality factor is D(cm²/sec.). In the case of porous media the sum of the permeable cross-sections (Σq) should be introduced into the diffusion equation, however only the cross-section of the sample (F) is known. The texture of the material must also be taken into account, i.e. the pores are variable in width and length. However only the thickness (L) of the investigated body is known. Furthermore if the pore width is equal to or smaller than the free path length of the diffusing particles, the normal volume—or gas type of diffusion is replaced by Knudsen's capillary diffusion (molecular diffusion). One must also reckon with the effect of Volmer's surface diffusion particularly in the case of hydration products with highly active surfaces. Thus it seems appropriate to define an effective diffusion coefficient (D_{eff}), as Wicke (1) has done. This is:

$$-\dot{S} = D_{\text{eff}} \cdot F \cdot \frac{dc}{dx}$$

If one relates the concentration gradient to the measurable thickness L, the following equations define the diffusion coefficient:

$$D_{\text{eff}} = \frac{S \cdot L}{F \cdot t \cdot (C_0 - C_L)} = \frac{V \cdot p \cdot L}{F \cdot t \cdot (p_0 - p_L)}$$

The "specific permeability" is defined according to Manegold (2):

$$\psi = \frac{D_{\text{eff}}}{D_0}$$

It should be noted that D_{eff} and D_0 refer to the same conditions of temperature and pressure.

Measurement of the Effective Diffusion Coefficient

To determine the diffusion coefficient we built a simple apparatus (3) which uses oxygen as the measuring medium (Fig. 1). The paramagnetism of oxygen is used to determine the oxygen content in a stream of nitrogen. The apparatus consists essentially of two measuring tubes, a sample container with sample, a differential manometer and a gas analyser. In addition there is a burette to calibrate the volume of the measuring tubes. Subsequently another apparatus was built in which the total pressure could be lowered to 150 Torr so that it was possible to distinguish the various types of diffusion (volume, molecular and surface diffusion), qualitatively at least, by their different

*Institut für Gesteinschtenkunde, Technische Hochschule Aachen, Aachen, West Germany.

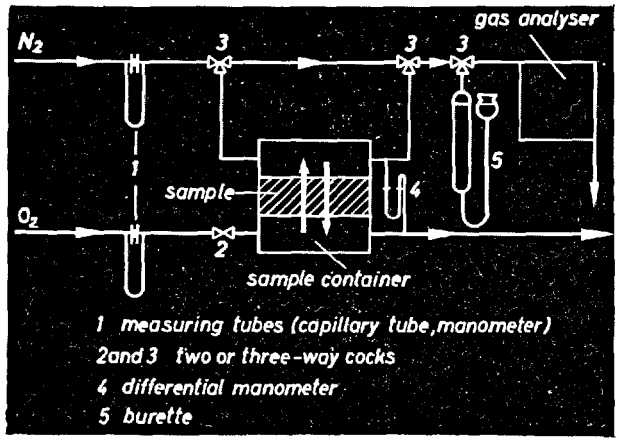

Fig. 1. *Measurement of gas diffusion*

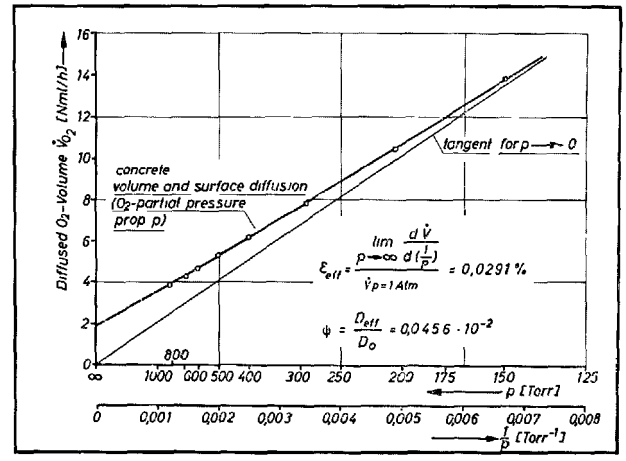

Fig. 2. *Diffusion measurement on concrete*

response to pressure. The gas analyser uses electrochemical principles and allows measurement in the range from 0 to 0.1, 0.01 and 0.001% oxygen. With four different sample holders cylindrical samples 3, 6, 5, 8 and 15 cm in diameter and 1 to 3 cm high could be measured.

Interpretation of the Measurements

As the gas diffusion measurements are "stationary" i.e. independant of time, the oxygen content can be given the value 1 where the gas enters the sample and the value 0 where it leaves it.

Thus:

$$D_{eff} = \frac{\dot{S} \cdot L}{c \cdot F}$$

where

D_{eff} = effective diffusion coefficient in cm²/sec.
L = thickness of the sample in cm
F = cross section of the sample in cm²
$\dot{S}$ = the amount of oxygen in cm³/sec. which diffuses through the sample

As the analyser gives the oxygen content in % and as the amount of the transporting medium, nitrogen, is measured in cm³/sec., this yields

$$\dot{S} = \frac{n \cdot \%\, O_2}{100}$$

with n = the amount of nitrogen in cm³/sec.

Thus:

$$D_{eff} = \frac{n \cdot \%\, O_2 \cdot L}{F} \quad (cm^2/sec.)$$

The diffusion coefficient of N_2–O_2 without specimen has been determined as 0.203 cm²/sec. (between 11.7°C and 13.1°C and 756 – 761 Torr) and using this value the specific permeability at 20°C and 760 Torr is

$$\psi = \frac{D_{eff}}{D_0} = \frac{D_{eff}}{0.211}$$

Mean Error of the Measurements

The mean error comprises the individual errors in determining the sample dimensions, the amount of nitrogen present and the concentration of oxygen. We estimate this error to be in the range $\pm 3 - 7\%$. For large samples with a high specific permeability it is small, and in the case of small samples with a low specific permeability, it is large. Žagar (4), who investigated the method for determining the "apparent diffusion coefficient" reckons with a relative error of $\pm 5\%$. We remounted the specimens repeatedly and found, in agreement with Žagar, that the reproducibility lies below this limit of error. Furthermore the error is affected by uneven or insufficient drying of the specimens. We dried ours at 50°C to constant weight. This ensures sufficiently quick drying but does not alter the hydration products too much.

Results of the Measurements

Analysis of the Types of Diffusion Occuring in Concrete

Normally, Knudsen and Volmer diffusion can be distinguished by their characteristic response to pressure. Following the experiments of Wicke and Kallenbach (5) we carried out similar measurements on concrete samples and have established that even in dense concretes volume diffusion is predominant (Fig. 2). At pressures up to 150 Torr molecular diffu-

sion was not observed.

The curves, however, show that surface diffusion is present. The curve for $p \longrightarrow \infty$ does not run through the origin but instead cuts the ordinate. If one eliminates the effect of Knudsen diffusion by applying infinitely high pressure, and the effect of Volmer diffusion by a parallel shift of the curve measured, one arrives at a definition for the "effective porosity" which shows, quantitatively, in the slope of the curve, only the stereometric influence of texture. The effective porosity can therefore be formulated mathematically as follows:

$$\varepsilon_{\text{eff}} = \frac{\lim\limits_{P\to\infty} \dfrac{d\dot{S}}{d\left(\dfrac{1}{P}\right)}}{\dot{S}_0\,(P = 1\ \text{atm.})}$$

If neither Knudsen nor Volmer diffusion contribute to material transport, then the specific permeability (ψ) is equal to the effective porosity ε_{eff}:

$$\psi = \frac{D_{\text{eff}}}{D_0} = \varepsilon_{\text{eff}} \quad \text{for} \quad \begin{cases} D_{\text{eff}} \sim \dfrac{1}{P} & \text{and} \\ \dfrac{d\varepsilon_{\text{eff}}}{d\left(\dfrac{1}{P}\right)} = \dfrac{D_{\text{eff}}}{D_0} \end{cases}$$

It is apparent from the results above that one must reckon with an appreciable amount of surface diffusion in cemented building materials and therefore

$$\psi \neq \varepsilon_{\text{eff}}$$

In the case of these materials, however, there is the possibility that a proportionality exists between ψ and ε_{eff} and this means that to a given permeability a certain effective porosity can be assigned.

In contrast to the measurements of Wicke and Kallenbach, in our case the partial pressure of oxygen was not kept constant. As it varies with the total pressure one can approximately determine ε_{eff} from the tangent to the curve at $p \longrightarrow 0$, and from the difference

$$\psi_{\text{total}} - \varepsilon_{\text{eff}} = \psi_0$$

the contribution of surface diffusion can be calculated.

For concrete we determined:

$$\left.\begin{aligned} \varepsilon_{\text{eff}} &= 0.028\,\% \\ \psi_{\text{total}} &= 0.044 \cdot 10^{-2} \\ \psi_{\text{surface}} &= 0.016 \cdot 10^{-2} \end{aligned}\right\} \quad 760\ \text{Torr},\ 0°\text{C}$$

Laminar flow was observed during the gas permeability measurements. Thus from the equation

$$\vartheta_s = \frac{r_{\text{eff}}^2 \cdot \varepsilon_{\text{eff}}}{8}$$

the value of r_{eff}^2 can be calculated. When $Ds = 11 \cdot 10^{-2}$ cm^2 and $\varepsilon_{\text{eff}} = 2.8 \cdot 10^{-4}$, $r_{\text{eff}} = 5.5 \cdot 10^{-4}$ cm $= 5.5\ \mu$m.

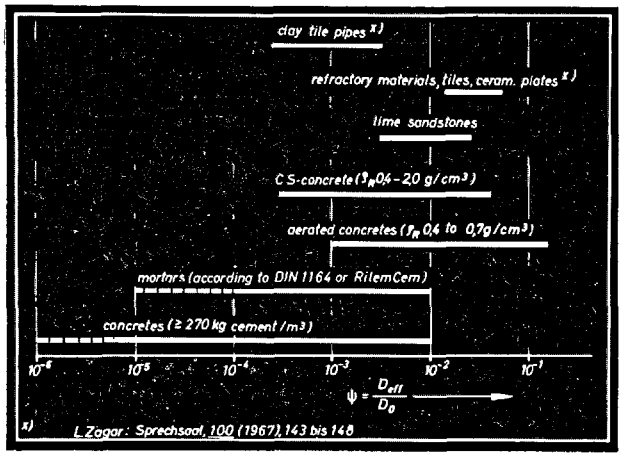

Fig. 3. *Specific permeability of inorganic building materials*

Žagar (4) made comparative measurements of the electrical conductivity, the ionic diffusion, the gas diffusion and the replacement of air by water in ceramic tiles, roofing tiles, earthenware pipes and refractory bricks (chamotte, silica and magnesite) and he found that the later two methods were a reliable means of determining the effective porosity of fine-pored ceramic materials.

The Specific Permeability of Sintered and Cement-Bonded Building Materials

Fig. 3 is a compilation of the specific permeabilities of some inorganic building materials which have been determined by the gas diffusion method. The values for mortar and concrete show a wide spread which ranges from 10^{-2} to 10^{-6} or 10^{-5} respectively, depending upon the age of the samples, the composition of the mixture and the degree of compaction. It should be noted that only those mortars and concretes which can be drilled (with a compressive strength of more than about 100 kg/cm^2) have been tested. This means that in the very early stages of hardening the specific permeability is probably 10 to 100 times higher. The practical application of these results shows the importance of a sufficient duration for the after-treatment of concrete in order to prevent premature drying-out.

Normal aerated concretes or lime sandstones do not reach denseness of high-grade mortars and concretes.

For comparison, Žagar's values (4) for sintered ceramic building materials have been listed. For them

$$\varepsilon_{\text{eff}} = \psi \cdot 100(\%)$$

In the following it is shown on the basis of measurements, that, at least partially, a good proportionality must exist between ε_{eff} and ψ for mortars and concretes. Otherwise the relationships which have been found in investigations of the material strength, frost resistance and carbonation would not be so pronounced.

Influence of the Specific Permeability on Compressive Strength and Frost Resistance

A further example shows the influence of specific permeability on the compressive strength and the freeze-thaw resistance for cement mortars in which the cement fraction is replaced by cement raw material up to a value of 30%. The raw material was made up of 15% montmorillonitic, kaolinitic or illitic clay components, 10% quartz and 75% limestone.

Fig. 4 shows that there is a nearly linear relationship between the compressive strength measured and the specific permeability of the mortar, irrespective of the time of ageing. This means that the compressive strength measured after 3, 7 and 28 days can be directly correlated with the specific permeability measured at these intervals.

In order to determine the resistance to freeze-thaw action the linear expansion and the resonance frequency were used. After being stood for 28 days in water the samples were frozen at −15°C for 4 hours and then thawed for 1 hour in a water bath at 20°C.

Fig. 5 shows the relationship between the linear expansion of the mortar samples, measured according to Rilem-Cem, after 30 freeze-thaw cycles, and the specific permeability after 28 days in water. It can be seen that with increasing amounts of raw material the specific permeability and the linear expansion increase. It appears that the differences arise from the constituent clay components. Thus with even 10% of raw material the unfavorable influence of the clay minerals becomes apparent. As one would expect, the montmorillonite-bearing material are worse in effect than the kaolinitic ones.

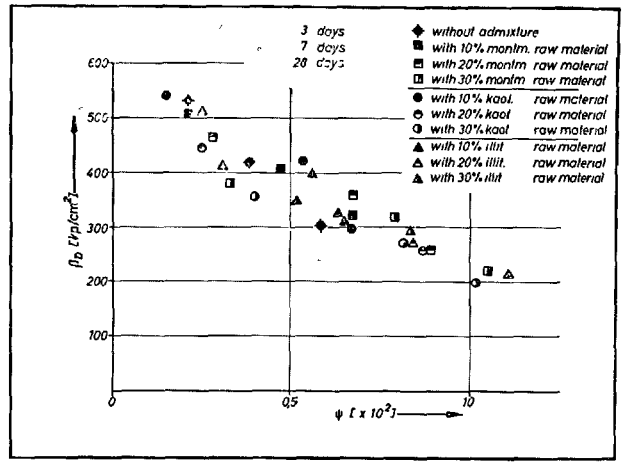

Fig. 4. *Specific permeability of mortars and compressive strength according to Rilem-Cem*

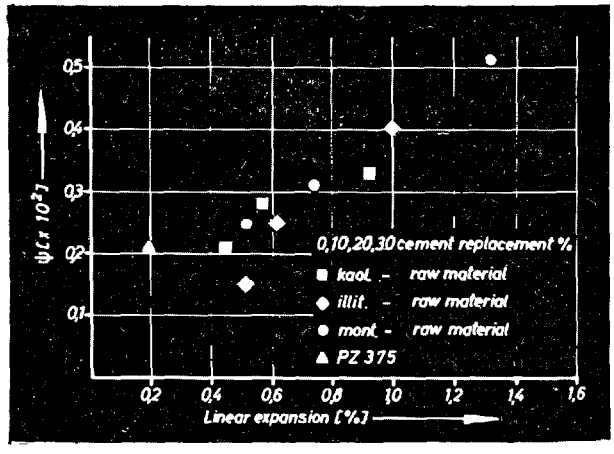

Fig. 5. *Influence of specific permeability on freeze-thaw-resistance*

Influence of the Specific Permeability on the Carbonation of Concretes

To study the carbonation we had 7-year old samples from bending strength tests and section of the same age taken from beams for measuring shrinkage. These are samples left over from the sea water experiments carried out by the German Committee for Reinforced Concrete. The bending strength samples were kept moist for one day and then stored in water up to the day of investigation. The bending test was carried out at earliest after 7 days, and at latest after 90 days of preliminary storing. Thus all the samples were stored in water for different lengths of time. The beams for measuring shrinkage were kept wet for one day and subsequently stored in an air conditioning chamber for one year at 20°C and a relative humidity of 65%. Then the samples were kept in a bunker for $4\frac{1}{2}$ years at about 8°C and 62% relative humidity. Thus this beams suffered a very rapid drying so that, at least at the surface, sufficient strength could not develop and the closing of the open pores by the formation of hydrates could not take place. Fig. 6 shows the relationships obtained between the average depth of carbonation (determined with phenolphthalein) and the specific permeability for the two kinds of concrete. The minimum specific permeability for the beam is 0.1% and at most 0.9% and the corresponding

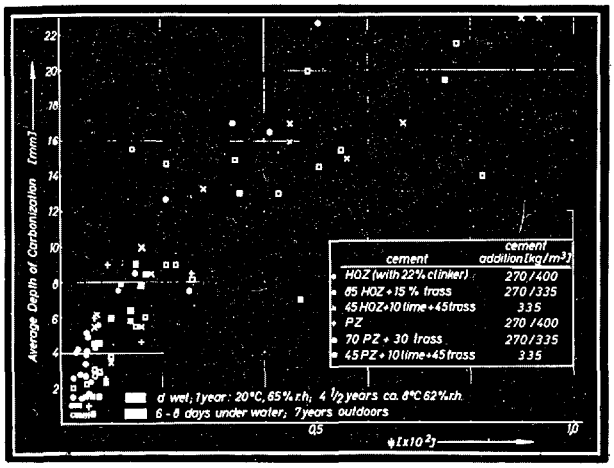

Fig. 6. *Influence of the specific permeability on the depth of carbonation of concretes*

depths of carbonation are 2 mm and 23 mm respectively. The specific permeabilities for the bending test samples are only 0.02 and 0.26% with a maximum average carbonation depth of only 10mm. This means, however, that the carbonation depth for the bending test samples fall on one line with those for the beams for measuring shrinkage.

These results show that the measurement of the specific permeability of mortars and concretes can give an important indication about what depth of carbonation can be expected after a given time. As the carbonation is purely a diffusion process accompanied by ad—and absorption, the amount of lime available, and the kind and amount of the bonding medium which is added, must also exert an influence, apart from that of the specific permeability.

It should be added that we have successfully used the specific permeability to estimate the influence of the addition of plastic dispersions and puzzolanic materials on the properties of mortars.

Furthermore gas diffusion measurements have shed light on the following problems: the waterproofing of concrete with skins of plastic, the chemical resistance of cement mortars and concretes, and hydrate alterations in aluminous cements.

Summary

From the data presented it is apparent that besides normal gas diffusion surface diffusion also occurs in cement-bonded building materials. Only with further measurements of the gas diffusion at varying total pressures it will be possible to determine the effective porosity which plays a role in any transportation effects in the material, and hence allow the labyrinth factor (χ) and the effective pore radius (r_{eff}) to be calculated, using the equation

$$\chi = \frac{\varepsilon_{eff}}{P_{total}} \quad \text{and} \quad D_S = \frac{r_{eff}^2 \cdot \varepsilon_{eff}}{8}$$

Measurements of the gas diffusion at normal pressure have already shown a close connection between the texture and useful technical properties.

Supplementary Paper III-99 The Behaviour of Concrete Subjected to Freezing and Thawing as a Reference for Frost Resistivity of Concrete

Yoshiro Koh and Eiji Kamada*

Synopsis

The length change of concrete during freezing and thawing was recorded continuously and automatically with the aid of differential transformers. Test specimens were 10 by 25 cm cylinders under oven-dry and saturated conditions and sealed with water proofing paint after storage in water for four weeks. The tensile strength and moisture content of the specimens were measured after 13 alternate freezing and thawing cycles within the range from 20°C to −30°C.

Four water-cement ratios were applied to concrete mix. Coarse aggregates were gravel, crushed stone and several kinds of artificial lightweight aggregates.

Oven-dry specimens give uniform thermal expansion, however, saturated specimens show different behaviors on the length-temperature curve. The saturated specimens using high water absorptive aggregates show abnormal expansion during freezing, and the residual expansion after 13 alternate freezing and thawing cycles is about 0.1 to 0.3 per cent. In this case, the decrease in the tensibl strength exceeds 50% of the initial strength. In case of low water absorptive aggregates, no expansion during freezing is observed, and increase in the residual expansion and decrease in the tensile strength are very small.

The grade of transitional and residual expansions depends upon the difference of water-cement ratio and degree of moisture content of concrete due to absorptive aggregates.

The residual expansion will suggest the grade of frost damage of concrete, as there is a relation between the residual length change of specimens and the decrease of splitting tensile strength.

To make clear the relation between frost resistivity of concrete and transitional and residual expansion, we made slow and rapid freezing and thawing tests for finding out the relation between the residual expansion and the behavior of decrease of dynamic elastic modulus, and water permeability test.

Introduction

The durability of concrete is always one of the important properties as well as the strength of concrete for structures and the workability of concrete at a time of placing. We have to make effort to clarify what is the best way to know the behavior of concrete exposed to natural weathering.

Many researchers made the freezing and thawing test of concrete according to the standard methods such as ASTM Designation C290 or C291 to make clear the behavior of concrete exposed to freezing and thawing action. A few of them carried out their special investigations on the behavior of concrete, especially on the volume change of concrete during freezing. There are, for example, Valore's paper in 1950 and Wills' study in 1963 according to Powers' proposed method in 1955.

In Japan, many papers on the resistance to freezing and thawing were presented at the General Meetings of the Japan Cement Engineering Association in recent ten years from 1957 to 1966. Almost of all researchers turned their investigations to the effect of cements, aggregates and admixtures on the resistance to freezing and thawing comparing the properties of concrete with each other by applying ASTM C290 or C291 methods. The remainder aimed at investigating the resistance of green concrete to freezing and thawing soon after placing, as a reference to winter concreting.

The investigation herein described was intended to study the expansion when concrete was exposed to severe freezing action, however, our method will also be a measure for the resistance to freezing and thawing.

Test method by Powers (1) and a paper written by Valore (2) encouraged us to start our effort to study the behavior of concrete frozen down to −30°C. Up to

*Hokkaido University, Sapporo, Japan.

this time we made various freezing and thawing tests of concrete in accordance with the method defined in our laboratory or ASTM C290. The freezing temperature was fixed to $-15 \sim -20°C$ or $-7 \sim -10°C$, the latter was mainly applied to the study on the frost resistance of early age concrete as a reference for winter concreting.

We intended to clarify the abnormal expansion of concrete expected during freezing and thawing, when concrete was made with undesirable aggregates with soft particles such as so-called "bad" aggregates, either artificial or volcanic lightweight aggregates, which might show rather low resistance to frost action.

Description of the Investigation

Test Procedure

The investigation consisted of measuring the resistance to freezing and thawing of concretes made with two natural aggregates and seven artificial lightweight aggregates and with or without air entraining agent. Three moisture conditions were applied; (1) oven-dry, (2) wet and (3) supplying water. Another test series was carried out as preliminary test in 1966 for two moisture conditions of oven-dry and wet. The three freezing and thawing methods were our new method, described in detail later and hereafter referred to as the "medium cycle", our conventional method of slow freezing and thawing, shown in the second line of Table 1 and hereafter called the "slow cycle", and the ASTM Designation C290, hereafter called the "rapid cycle".

We know that fast cooling and lower temperature cause severe damage to concrete or mortar, as mentioned in papers of many researchers and mine. However, we made an attempt to prepare an apparatus for "medium cycle" capable to cool air temperature down to $-40°C$ and to heat air up to $40°C$.

Medium Cycle

The medium cycle consisted of cooling of the $10\phi \times 25$ cm cylinder specimens from $20°C$ to $-30°C$ for a period of about 6.5 hours and heating up to $20°C$ for a period of about 5.5 hours (Table 1). Temperature at the center of the specimens was measured and recorded by thermocouple, which was embedded when concrete was placed, and by recorder. This medium cycle was repeated 13 times and 5 times in the principal test and the preliminary test respectively.

Subject to moisture conditions, the specimens were prepared for the test before freezing. In case of oven dry condition, five or two days before freezing and thawing test, the specimens were removed from water and dried in oven at $105°C$ for four days in the principal test and for one day in the preliminary test respectively. In both cases of wet and water supplying conditions, the specimens were removed from water one day before the end of curing period.

The length and weight of the concrete cylinders were measured before preparing the specimens for the test. The cylinders first had been applied with neoprene water proof paint, then were wrapped in non-woven fabric made from polyvinylalcohol to minimize drying through pin-hole of the paint, and they again had the paint applied except on two tiny dented round areas in the center of the both ends of cylinders, where the measuring rods were adhered with epoxy-resin adhesive. The measuring rod was made of quartz glass and the diameter of the rod was approximately 12 mm. The length of the rods was 250 mm and 50 mm at the top and bottom ends respectively. An additional

*Preliminary test

thermocouple was fixed on the surface of concrete for measurement of temperature during freezing and thawing at the surface of the specimens (Fig. 1). Ring shape foam polystylene insulations were attached to both ends of the concrete to minimize the cooling of the concrete along vertical axis and the temperature effect to the quartz glass rods. The depth of the insulations was 4 cm and the diameter was the same as that of concrete specimens. The clearance between the measuring rods and the insulation was greased to avoid restriction due to the frost by cooling of the surface of rod. And then the specimens were wrapped by two layers of butyl rubber sheet, 33 cm in width, to eliminate the difference between the temperatures at the surface and the center of the cylinder (Figs. 2 and 3).

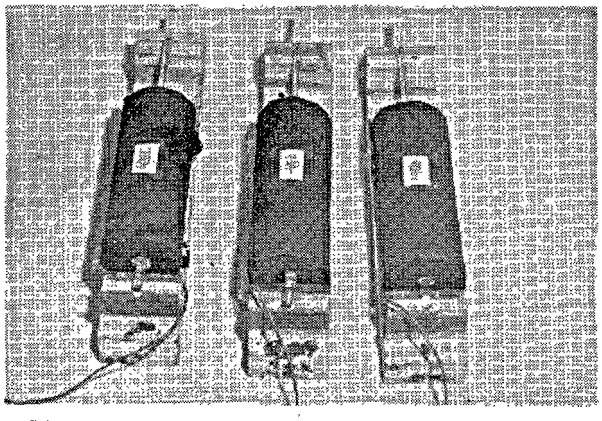

Fig. 1. *Specimens after waterproofing by paint and fabric*

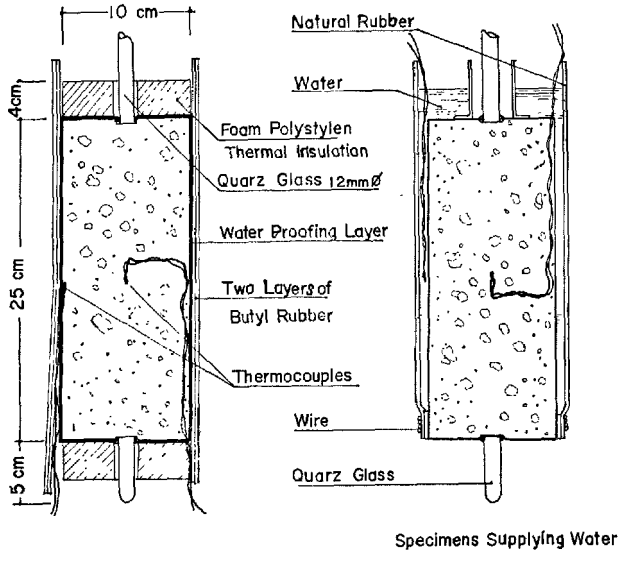

Fig. 2. *Specimens for medium cycle*

In case of the specimens for water supplying condition, no foam insulation and waterproofing layers of paint and non-woven fabric were applied. The concrete cylinder was put in a rubber pipe and the bottom was tightly bound with wire. We made a narrow space for pouring water around the cylinder by using rubber strips (Fig. 4). When set up in the testing chamber, sufficient water to cover the top end of cylinder was poured into the space.

The specimens were placed on a vertical electric comparator in the freezing chamber. The ambient air temperature was controlled at 20°C before cooling. The specimens were cooled down to −30°C and warmed up to 20°C by air in chamber. No program control of temperaure was applied in this test. Temperature (Fig. 5), expansion and contraction were recorded automatically.

Slow Cycle

The slow cycle of freezing and thawing in water, which was conventional in our laboratory, was made

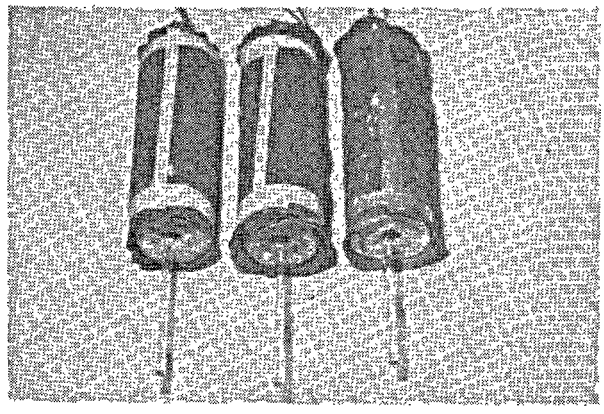

Fig. 3. *Specimens wrapped with butyl rubber sheet*

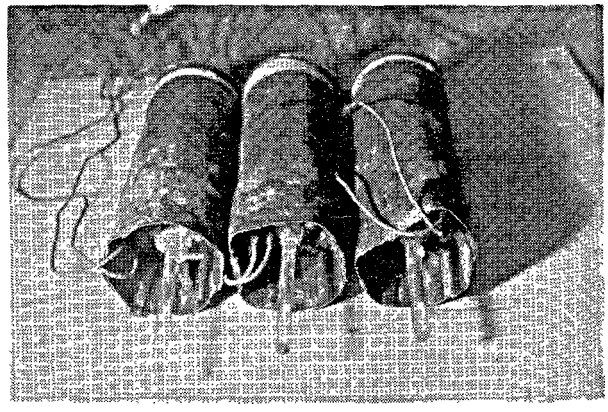

Fig. 4. *Specimens for test under condition supplying water*

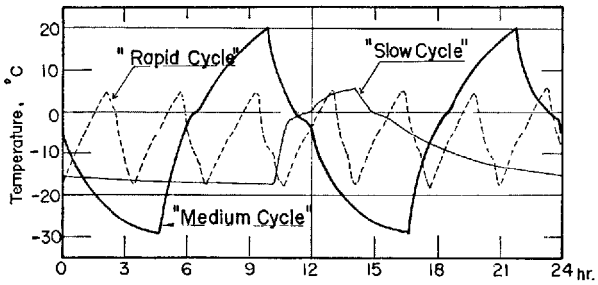

Fig. 5. *Typical temperature curves*

by using 7.5 × 7.5 × 40 cm square beam type specimens as shown in Table 1. Specimens were frozen in water at—18°C for 22 hours and thawed in water at 5°C for 2 hours in this test (Fig. 5). That is one cycle of freezing and thawing per day. Freezing and thawing was started after curing in water for 28 days at 20°C and was terminated when specimens had lost more than 50 per cent of their initial dynamic modulus. Two brass gage plugs were embedded at each end along the longitudinal axis, and the dynamic modulus of elasticity, the total residual length change and weight loss were measured at every six or ten cycles of freezing and thawing. However, in the preliminary test, slow cycle was started after curing in water for 14 days at 20°C, and no gage plug was embedded for the measurement of length change. And three types of beam specimens were used, i.e. 10 × 10 × 40 cm, 7.5 × 7.5 × 40 cm and 4 × 4 × 40 cm.

Rapid Cycle

The conventional rapid cycle of freezing and thawing in water was made in accordance with ASTM Method C290 at the laboratory of the Hokkaido Building Research Institute. Specimens were the same with those of slow cycle and were frozen and thawed in water with approximately seven or eight cycles per day (Fig. 5 and Table 1). Weight loss and fundamental frequency measurements were made on all specimens. No rapid cycle was carried out in the preliminary test.

Materials

The coarse aggregates were a diluvial gravel, a crushed andesite and seven kinds of artificial lightweight aggregates including some trial products as shown in Table 2. The diluvial gravel contains considerable per cent of soft particles, however, it is used in our district due to the lack of good aggregates in the vicinity of Sapporo city. In the preliminary test,

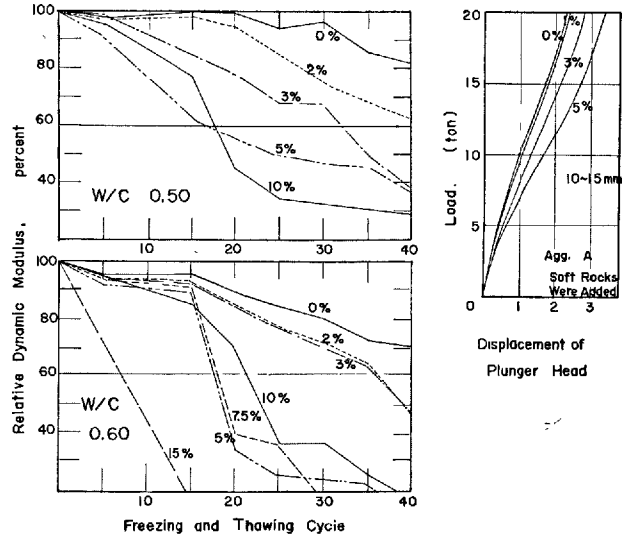

Fig. 6. *Hattori's test results*

only the gravel was used without any treatment (content of soft particles is approximately 5% by volume, i.e. 3.6% by weight), however, the soft and light particles were picked out by hand to avoid the effect of them on the frost resistance of concrete in this test, and the content of them was considered less than 2% by volume.

The content of soft particles shows a considerable effect on the resistance of concrete to freezing and thawing, and the curves of displacement of plunger versus load, obtained by crushing test of coarse aggregates, are not only a measure of hardness but also of the quality of aggregates for durable concrete, as shown in Fig. 6 and mentioned in my previous paper with aid of Hattori (5) for the RILEM Symposium on the Durability of Concrete held in Prague in 1961. In the conclusion of the paper, I mentioned that the soft particles should be less than 3% by volume based on the test results considering frost action.

Fig. 7 shows the crushing test results of the artificial coarse aggregates by Hashimoto (4), by using Hattori's apparatus (5), consisted of cylinder, of which inside diameter is 10 cm and effective depth is 20 cm, and plunger.

Well graded diluvial sand from the same source was used as fine aggregate. A little effect of soft and light particles in sand on the strength of concrete is inevitable. Aggregates in surface dry condition were used for making concrete.

A normal portland cement used widely in our district was used. A neutralized Vinsol resin solution was used as air entraining agent for a part of concrete mixes.

Concrete

Concrete mixes were decided after trial mix to have a slump of 18 cm. Three kinds of water cement ratio were chosen to apply to the principal test, i.e. 0.50, 0.70 and 0.90 by weight. Three kinds of slump, 8, 18 and 22 cm, and five variations of water-cement ratio, i.e. 0.4, 0.5, 0.6, 0.7, 0.9, and 1.1, were chosen for the preliminary test (Table 3).

Four $10\phi \times 20$ cm cylinders and one $10\phi \times 25$ cm cylinder for the medium cycle were made from the same batch. The former was used for testing compressive and splitting tensile strengths at the end of curing period, when freezing and thawing was started. The splitting tensile strength and moisture content were also measured after defined repetitions of medium cycle by using $10\phi \times 25$ cm specimens. Three $7.5 \times 7.5 \times 40$ cm square beam type test specimens for slow or rapid cycle and three $10\phi \times 20$ cm cylinders for compressive strength test were made from each batch. The compressive strength test was made at the end of curing period (Table 4).

When concrete was placed in molds, thermocouples were installed in the geometric center of each of the cylinder specimens for medium cycle and of the specimens for measuring temperature for slow or rapid cycle (Fig. 3).

All specimens, except those tested under oven-dry conditions, were cured in water for 28 days and 14 days, respectivley for the principal and the preliminary, at 20°C, including the first day in molds in room air and the final day for preparing of the medium cycle specimens in air.

System of Apparatus for "Medium Cycle"

Fig. 8. *Apparatus for "medium cycle"*

Testing Apparatus

The parts of measuring apparatus for medium cycle were composed of electric comparator and recorder (Fig. 8). Three differential transformers were installed in a stand with three quartz glass legs to eliminate the effects of temperature on the comparator (Fig. 9).

Three 10 by 25 cm cylinder specimens (Figs. 2 and 3) were placed on the comparator, and the expansion and contraction during freezing and thawing in air chamber were continuously recorded with the aid of differential transformer and recorder. From the record we can find the relation between temperature and linear expansion of the specimens. Freezing and thawing procedures at the center of the specimens are shown in Fig. 5.

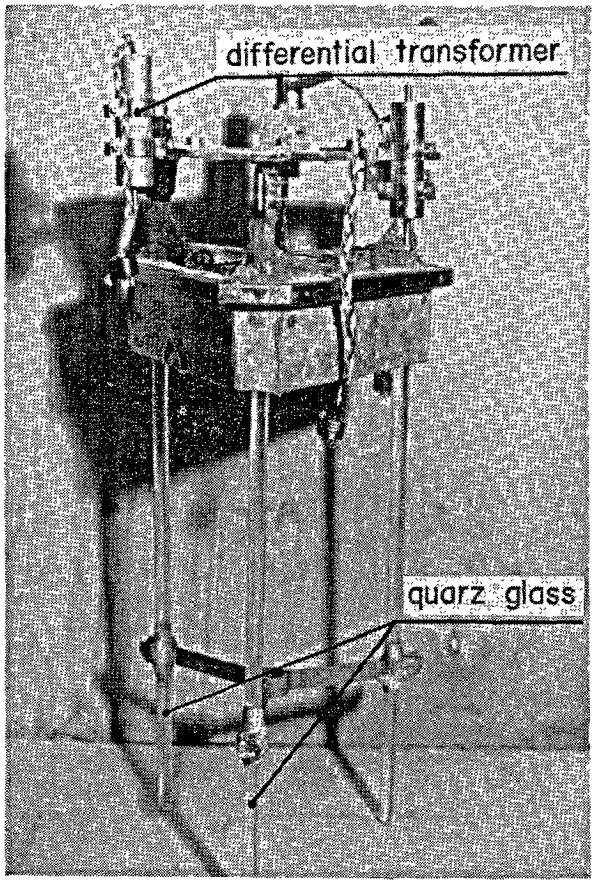

Fig. 9. *Electric comparator*

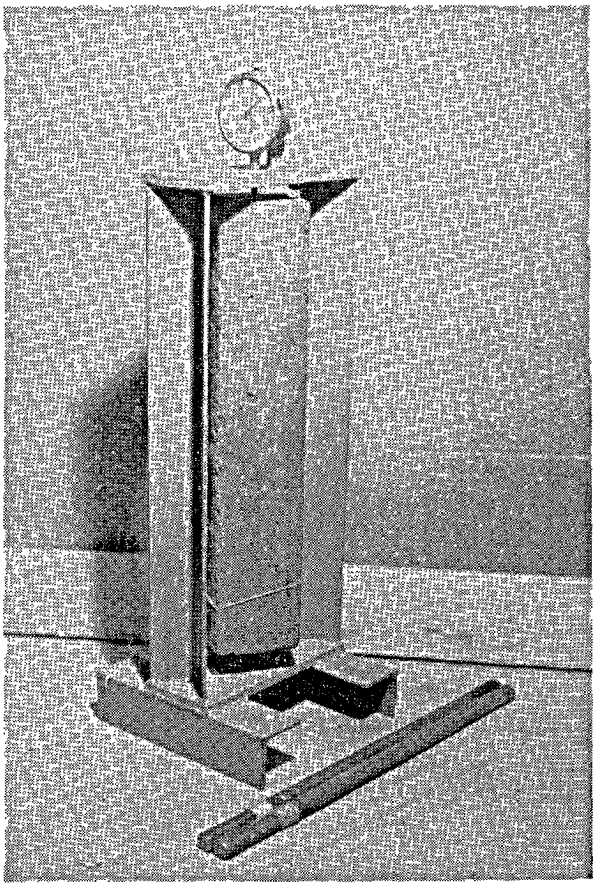

Fig. 10. *Comparator for measurement of total residual expansion in "slow cycle"*

Both the apparatus at the laboratory of Hokkaido Building Research Institute, capable to test according to ASTM C290, and our apparatus were used for rapid and slow cycles respectively.

And we prepared another comparator for the slow cycle, consisting of a dial gage with 1/1000 mm divisions mounted on a stand designed to hold the specimen vertical along its longitudinal axis. All parts of the comparator were made of mild steel as the comparator was used only in room air where the air temperature was controlled at 20°C (Fig. 10).

Discussion of Data

Preliminary Test

A part of the results obtained by the preliminary test is shown in Figs. 11 and 12. As shown in Table 3, the aggregates were limited to diluvial sand and gravel, and concrete mixes were chosen so those that water-cement ratio might vary from 0.4 to 1.1 and the value of their slump was changed as to give 8, 18 and 22 cm. Only non-air-entraining concrete was applied and wet and oven dry conditions were compared.

The fluctuation of data, we observed, was probably caused by use of diluvial coarse aggregate in the vicinity of Sapporo, which contained about 5% of soft and light particles by volume as mentioned above.

Fig. 11 shows the results of our conventional slow freezing and thawing test. In this test, we intended to compare the effect of the size of specimens by using $4 \times 4 \times 40$ cm, $7.5 \times 7.5 \times 40$ cm and $10 \times 10 \times 40$ cm prisms.

In the same repetitions of freezing and thawing, 4 cm square beam specimen give the largest reduction of dynamic modulus. Our conventional $7.5 \times 7.5 \times$

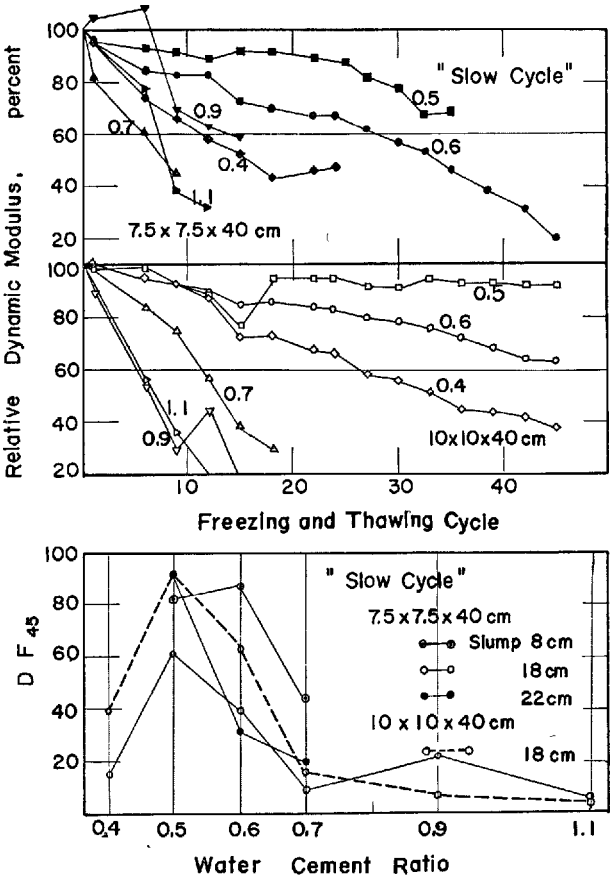

Fig. 11. *Results of preliminary test (slow cycle)*

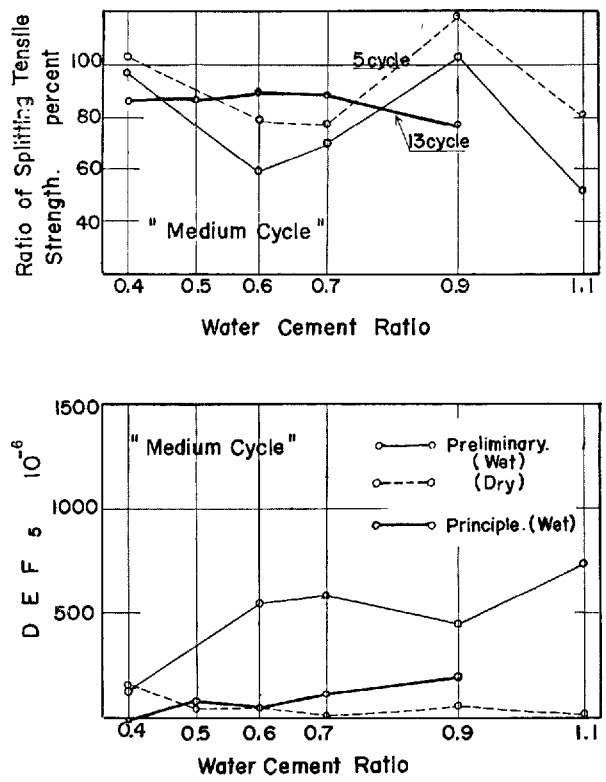

Fig. 12. *Results of preliminary test (medium cycle)*

40 cm prism gives moderate results between the results of 4 cm and 10 cm square beams as shown in Fig. 11. Specimens, of which the water-cement ratio is 0.40, show rather bad results in spite of the low value. The reason for the inversion of order by water-cement ratio seems to be that the age of concrete at the start of test was insufficient for comparison of the effect of water-cement ratio, as the test was started after 14 days of water curing. The recovery of strength during thawing period will be considerable for specimens of higher water-cement ratio, however, as for the low water-cement ratio, such as 0.40, the growing of dynamic modulus was not considered even at the young age of concrete such as 14 days. Moreover, the high content of soft particles in the coarse aggregate might have an influence on the above mentioned inversion of order by water-cement ratio and on the different results derived from the size of specimen.

In Fig. 12, we compare the results by medium cycle of the preliminary test by using coarse aggregate without treatment and those of the principal test by using treated aggregate. There is a difference of the cycle of freezing and thawing between the preliminary and the principal test. However, the ratios of splitting tensile strength after freezing and thawing to the initial strength and the relation between the DEF by the medium cycle and the water-cement ratio were largely affected by picking out of the soft particles. The remarkable role played by soft particles on the frost resistance is again recognized by these results (Figs. 12 and 6).

Principal Test

The data obtained by the principal test are presented in Table 4 and Figs. 13 ~ 22. The concrete mixes tested and their data of compressive and splitting tensile strengths at age of 28 days, when freezing and thawing cycles started, are shown in Table 4.

Concrete, of course, contracts as it is cooled. When highly saturated concrete is cooled to low temperature, however, the formation of ice results in expansion which may exceed the contraction due to cooling as mentioned in several papers published in USA. This expansion has been called dilation in Powers' paper (1).

The typical curves of contraction and expansion are shown in Fig. 13. They have a tendency different from

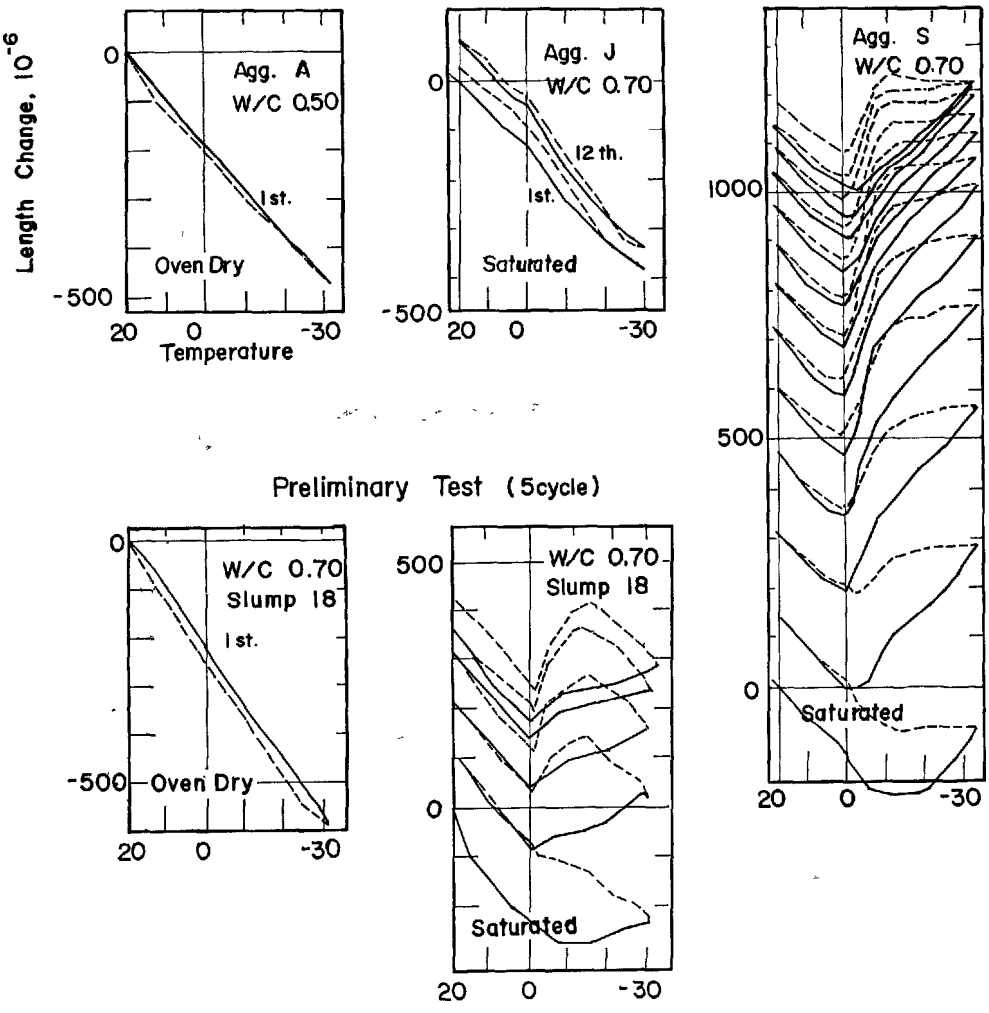

Fig. 13. *Typical curves of contraction and expansion*

that shown by the typical cooling curves for limestone concrete in the Powers' slow cycle carried out by Wills et al (3). There are many different factors such as aggregates, water-cement ratio, slump, cooling rate and range of temperature, curing conditions etc., between Wills' test and ours, however, it seems, the cooling rate will be the most effective factor.

The specimens under oven-dry condition in the preliminary test and made from diluvial gravel without treatment showed no dilation and left no residual length change. However, we observed abnormal expasion and contraction during freezing and thawing respectively, and considerable total residual length change after five repetitions of medium cycle in case of the specimens under saturated conditions as shown in Fig. 13.

The similar behavior was observed in case of the artificial lightweight aggregates which showed high water absorption, Aggregate S, as seen in Fig. 13. Aggregate J, which was low water absorptive one, showed little total residual length change after thirteen repetitions of medium cycle. This total residual length change is called by us "the degree of expansion by frost". As the notation to simplify the words, we used DEF for this new term. The designation of this term is the degree of expansion caused by freezing and thawing, and expressed by the ratio of total residual length change of the specimens subjected to medium cycle in millionth of the initial unit length. Another similar notations are used in this paper hereafter. They are,

DEF_n: Degree of expansion caused by n cycles of medium cycle,

DEF_s: Degree of expansion caused by slow cycle.

The former is calculated from the record of electric

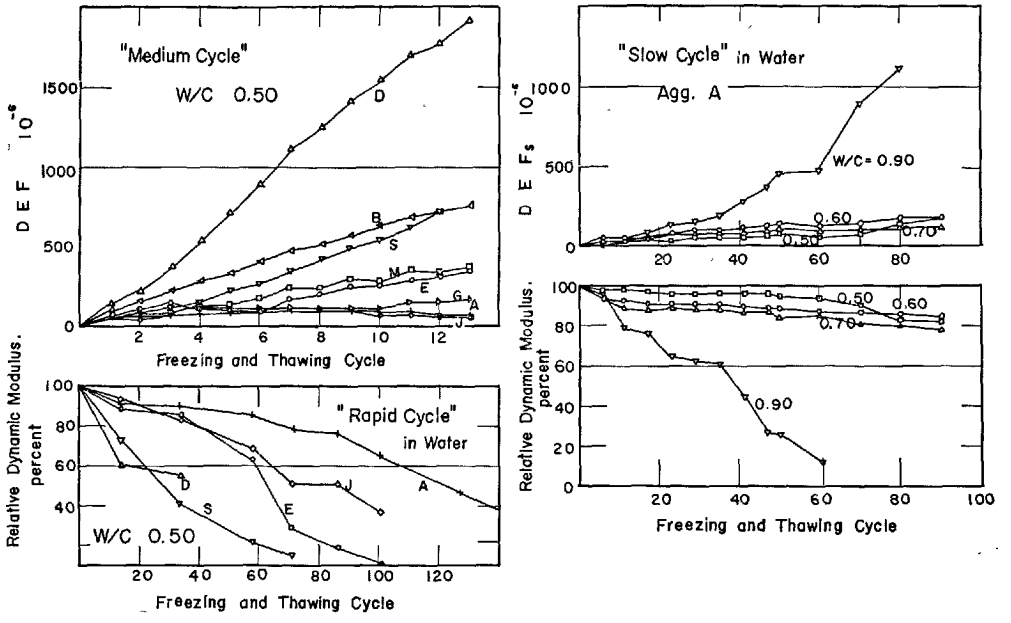

Fig. 14. *DEF, DEFs and rapid cycle*

comparator and the latter is measured by any suitable comparator after any cycle of thawing of the slow cycle.

Fig. 14 shows that the larger the DEF of medium cycle, the larger the reduction of dynamic modulus of elasticity tested by rapid cycle. The left half of the figure shows the different behavior of aggregates, of which water absorption vary as shown in Table 2. The effects of soft particles in the diluvial coarse aggregate, aggregate A, are eliminated by picking out of the soft particles before mixing concrete as mentioned above (Fig. 12). The right half of the figure shows the difference of concrete mix, i.e. the difference of water-cement ratio. The higher the value of the water-cement ratio, the weaker the resistance to freezing and thawing.

DEF versus Splitting Tensile Strength

The splitting tensile strength is reduced by freezing and thawing. There is a good relation between the value of DEF and the corresponded ratio of tensile strength as shown in Fig. 15. This means DEF_n will be one of good measure for the decrease of strength by freezing and thawing action. Fig. 16 shows the relation between DEF and moisture percent in concrete by volume when the test by medium cycle was terminated. It seems, DEF is not distinctly in proportion to moisture percentage of concrete by volume.

DEF by Medium Cycle, DEF_s and Relative Dynamic Modulus by Slow Cycle

DEF_n, DEF_s of each cycle and the relative dynamic modulus are shown together in Fig. 17 to compare with each other. The similar tendency is shown in both DEF and DEF_s by medium cycle and slow cycle respectively. The medium cycle accelerate the expansion compared with slow cycle. The reduction of dynamic modulus is proportional to DEF_s as shown in Figs. 17 and 18.

Moisture Condition of Test Specimens

The growing behavior of DEF of sealed specimens under wet condition by medium cycle is compared with that of specimens under the condition supplying water in Fig. 19. The termination of medium cycle is only 13 cycles in the test, however, we can observe the different tendency of growing expansion expressed by DEF. The residual length change under moisture condition supplying water is more than that of specimens under wet condition in each medium cycle. The DEF curves of the former turn upwards as the number of cycle by repetitions of freezing and thawing increases, however, the curves of the latter show gentle slope and it seems to approach a definite value. In case of air-entraining concrete, the DEF curves goes

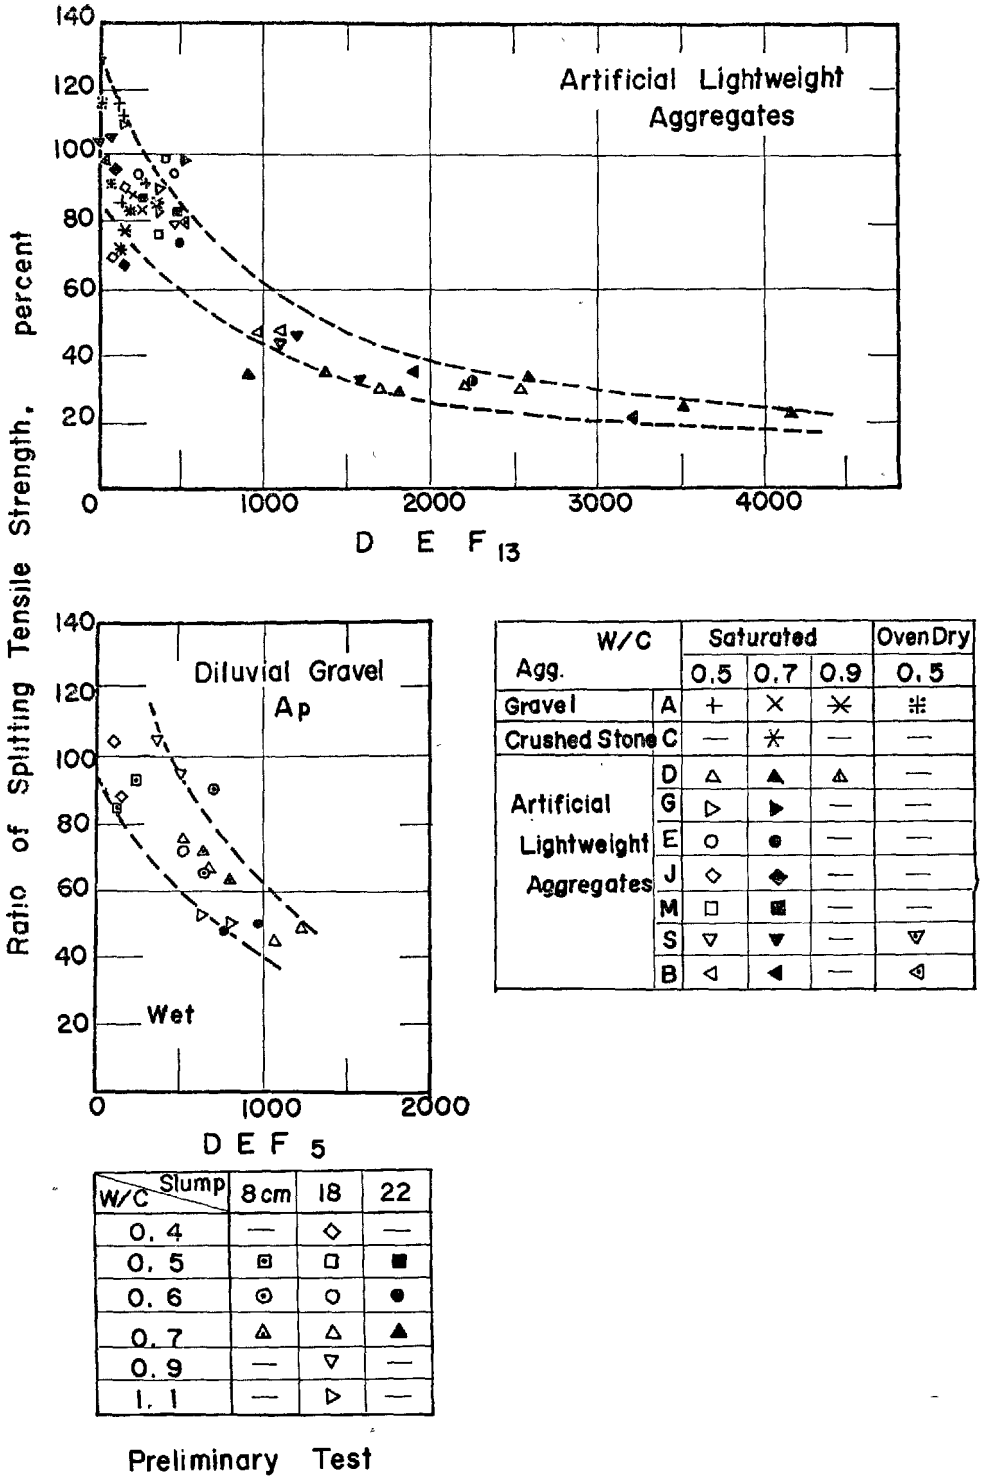

Fig. 15. *Splitting tensile strength and DEF*

up gradually and their total values are small compared with non air-entraining concrete,

Wills' Slow Cycle versus Our Slow Cycle

Fig. 20 compares the Willls' and our methods of

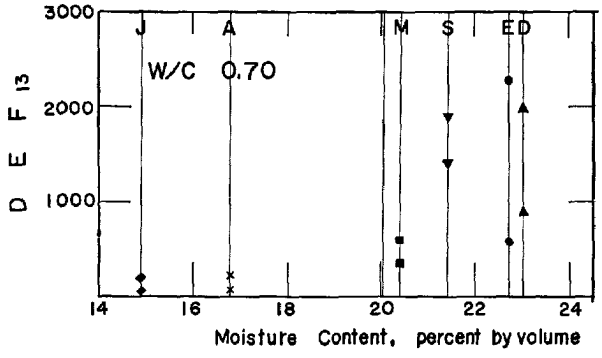

Fig. 16. *Moisture content and* DEF_{13}

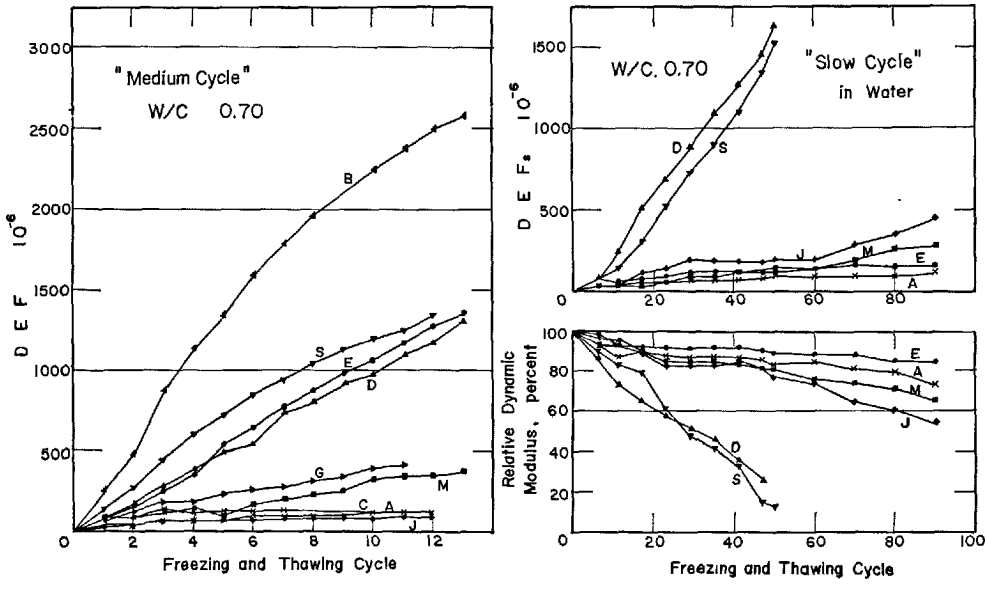

Fig. 17. *Comparison between "medium cycle" and "slow cycle"*

slow cycle. The results of our test by slow cycle (DEF_s) is remarkably similar to the relation between Wills' cumulative length change and reduction in dynamic modulus, in spite of the difference of test method, aggregates, water-cement ratio and cooling rate of both "slow cycle" methods.

Water Permeability Test

Water absorption of concrete is considered as an important factor to the resistance of concrete to freezing and thawing. We made water permeability test after four weeks of water curing followed by oven drying for 7 days in air at 80°C, by using $15\phi \times 4$ cm disc specimens. Water pressure of 2 kg/cm² was applied to the round area of 5 cm in diameter on the center for 1 hour. The quantity of permeable water is shown in Fig. 21. After the permeability test followed by drying again at 80°C, we made vacuum water absorption test of the specimens. Both results are shown in Fig. 22. The difference between vacuum saturated water absorption test results and moisture content after curing for four weeks is small in case of the diluvial gravel, however, all concretes made with artificial lightweight aggregates show large difference, probably caused by internal pores of coarse aggregates.

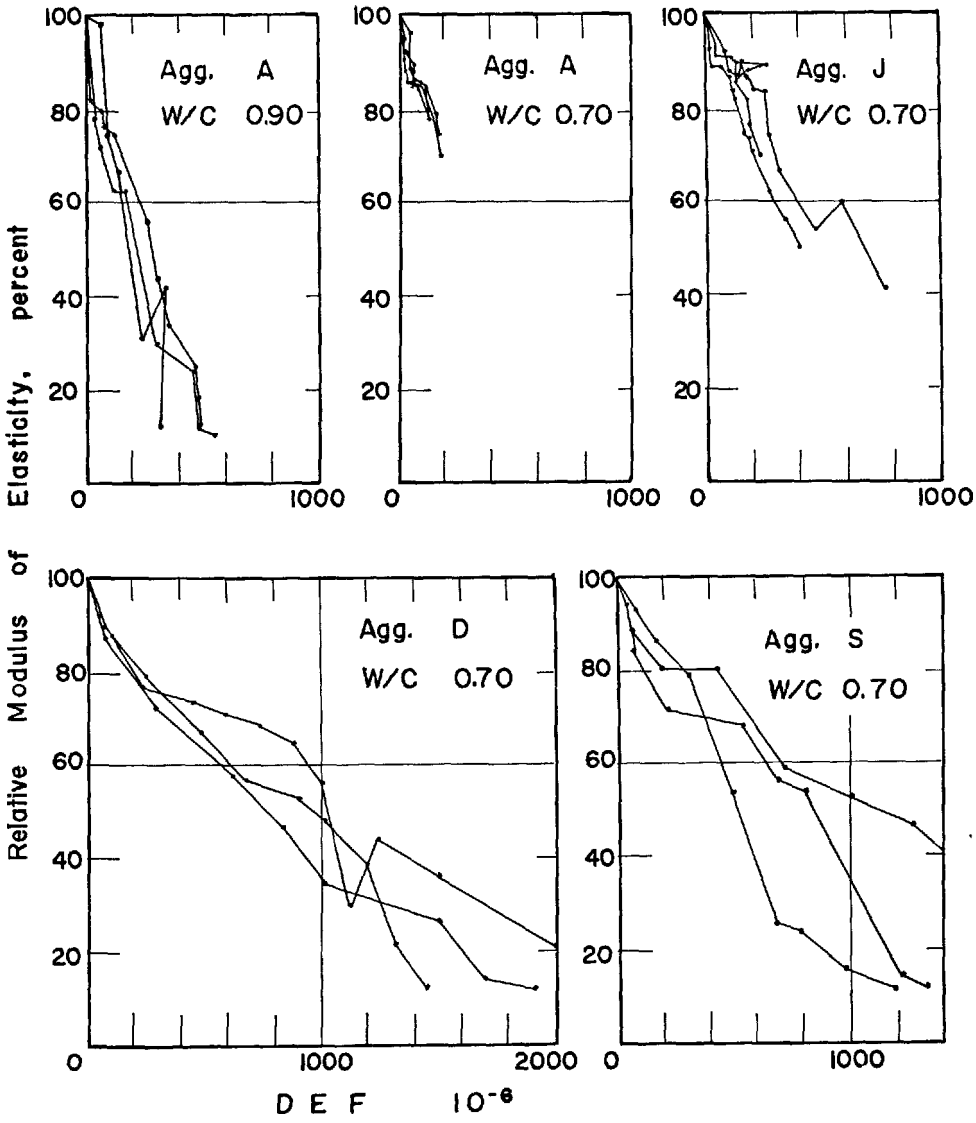

Fig. 18. *Relative dynamic modulus and degree of expansion caused by "slow cycle"*

Conclusion

These data, based on the tests of concretes made with several kinds of artificial lightweight aggregates which show various resistance to freezing and thawing, appear to support the following conclusions:

1. The degree of expansion by frost, either DEF or DEF_s, which is designated in this paper, is a good measure of the resistance of concrete to freezing and thawing action. Medium cycle reduces the period of getting the same order of DEF and is easy to test compared with slow cycle.

2. The measurement of total residual length change of the specimens used in slow cycle test is a good measure of the reduction of dynamic modulus of elasticity when the definite concrete mix is used for the test. It appears the measurement of the length change will be also a good measure for the rapid cycle.

3. How many repetitions of medium cycle will be a good measure for proper judgment of the resistance of concrete to freezing and thawing is to be decided by studies in future.

Supplementary Paper III-123 Effect of Conversion on Properties of Concrete Using High-Aluminous Cement

Ryuichi Tsukayama*

Synopsis

Properties of high-aluminous cement concrete after conversion were investigated by accelerated test. The following two methods to accelerate the conversion of hydration product were employed:

(1) curing in water at 50°C after the age of 1 day,
(2) placing large specimen in which temperature rise of concrete due to heat of hydration is permitted.

Two kinds of cement were used. The percentage of Fe_2O_3 in cements were 2.5% and 16% respectively. Both cements were free of SO_3.

As the result of test, it was observed that the following changes in the properties of high-aluminous cement concrete took place due to conversion.

(1) Strength lowers to some value at which it would be kept for long period.
(2) Durability of freezing-thawing action is remarkably deteriorated.
(3) Permeability is increased.
(4) Secondary temperature rise and expansion is produced during conversion.

To make clear the cause of these phenomena, the distribution of open pores was measured by Mercury Pressure Porosimeter. The total volume of pore increased and the peak of pore distribution moved from about 100 Å (radius of pore) to about 1000 Å. This means that conversion multiplies the quantity of larger pores. This increase of pore seems to have a close relation to the change of properties in converted high-aluminous cement concrete.

From the practical point of view, the above experimental results lead to the conclusion that the concrete of satisfactory strength after conversion can be obtained by selecting smaller water-cement ratio. But it is not suitable to decide mix proportion on the strength base only, when durability of concrete is required.

Introduction

Although high-aluminous cement is a very useful material for rapid work of construction, the amount of consumption is far less than portland cement. Besides an economical reason, this is mainly because of such an unfavorable properties as reduction in strength with age due to conversion.

A number of researches gave knowledge on these properties. For example, beneficial summarization was given by Robson (1), and comprehensive data from laboratories and fields were collected and analysed by Neville (2). But a lack of the decisive testing method which affords a reliable estimation of final or residual properties is, even now, responsible for the very limited consumption.

In this report, an accelerated conversion test method by curing at higher temperature was investigated. Since the effect of higher temperature differs according as whether a specimen gets warmed after suffiecient hydration period under normal temperature or soon after mixing, two methods corresponding to each condition were examined.

Properties of concrete with high-aluminous cements which were studied by these methods include porosity, heat of hydration, and volume change. Tests were also conducted to determine the effect of conversion on compressive strength, bending strength, tensile strength, permeability, and resistance to freezing and thawing action. Concrete mixes for the tests contained two different types of high-aluminous cement.

*Research Laboratory, Nihon Cement Co., Ltd., Tokyo, Japan.

Materials

Concrete was prepared from two different types of high-aluminous cement, domestic cement produced by sintering in a rotary kiln (cement A), and one imported cement produced by fusion (cement B). The chemical compositions, shown in Table 1, were quite different in both cements. Cement A contains more than 50 per cent of Al_2O_3 and less than 3 per cent of Fe_2O_3, whereas cement B less than 40 per cent of Al_2O_3 and more than 15 per cent of Fe_2O_3. Natural sand and gravel from a river were used for all concrete mixes, and the maximum size of gravel was 25 mm.

Table 1. *Chemical composition of cement* (%)

	cement A	cement B
ig. loss	0.2	+0.5
insol.	4.8	0.2
SiO_2	2.3	3.4
Al_2O_3	56.2	39.8
Fe_2O_3	2.8	16.6
CaO	35.0	37.7
MgO	0.4	0.9
TiO_2	2.3	1.9

Accelerated Coversion Test Procedure

In trying to investigate the effect of conversion on several properties of concrete, it was necessary to find out the conditions of curing, so as to get fully-converted concrete in a short period. For this purpose, the curing at temperature above normal seemed suitable, because the conversion of high-aluminous cement hydration product has a tendency of being accelerated with increasing temperature. The details of the curing conditions in the following two methods were determined by experiments.

Method-1; Curing in water at higher temperature,

Method-2; Curing at raised temperature caused by heat of hydration,

Method-1

This method aimed at converting the sufficiently hydrated concrete in water at higher temperature. In this method, compressive strength was mainly examined. Specimens were 10 cm in diameter and 20 cm in height.

Fig. 1 shows the effect of the length of standard curing under water at 20°C prior to curing at higher temperature. The concrete mixes were designed for a 40 per cent water-cement ratio and a 10 cm slump. The initial temperature of concrete was controlled at 20°C. The specimens were removed from the mould in 3–4 hrs. after casting, placed in water at 20°C till the age of 6 hrs., 1 day and 28 days, respectively, and then stored in water at 50°C. By curing in water at 50°C, the strength of concrete fell to a stable lower value in 7 days, irrespective of the duration of the pre-curing at 20°C.

The effect of curing temperatures is clearly shown in Fig. 2. Concrete mixes of two different water-cement ratios, that is, 40 per cent and 60 per cent were used in this test. Specimens were cast at 20°C and cured in water at the same temperature for 1 day, thereafter they were stored in water at 40, 50 and 60°C, respectively. The higher the temperature, the more rapid the reduction of strength. It took 28 days for the concrete cured at 40°C, 7 days at 50°C, and 2 days at 60°C until it reached the minimum value. Hereafter, the strength showed a little gain and then maintained a constant level. This slight

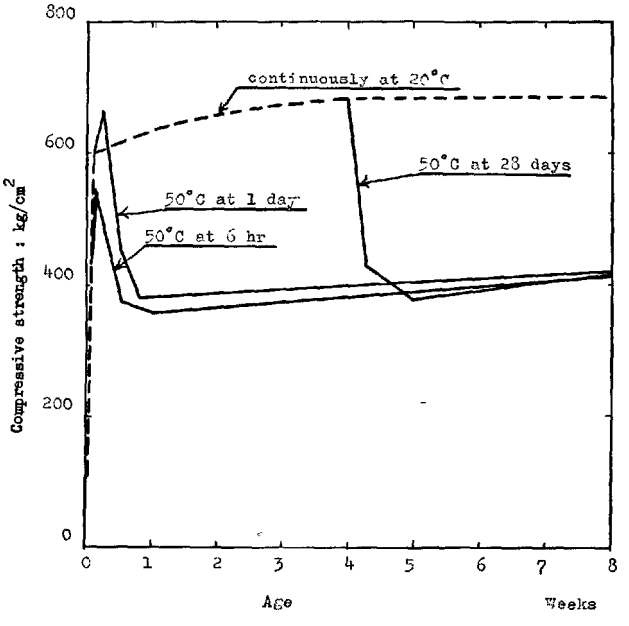

Fig. 1. *Effect of duration in water at 20°C before placing at 50°C*

increase in strength is to be ascribed to hydration of unhydrated cement. Increased pore and dehydrated water due to conversion seemed to provide a favourable condition for this delayed hydration.

To find out any difference of strength at higher temperature between continuous curing and alternate one, concrete specimens were stored in each water at 20°C and at 50°C for 7 days, reciprocally. The result of strength tests, in Fig. 3, shows that there is no difference between them.

Based on the above tests, the following details of the test method seemed to be suitable:

initial temperature of concrete is controlled at 20°C;

for 1 day after casting, cure in water at 20°C;

from 1 day to 7 days, cure in water at 50°C.

X-ray analysis of neat cement paste cured by this method is shown in Table 2, indicating nearly complete change, taken place as below.

Therefore, fully-converted specimens of

$$3CAH_{10} \longrightarrow C_3AH_6 + 2AH_3 + 18H$$

concrete can be obtained by this method from the concrete initially cured at normal temperature. However, the fully-converted concrete which had been at a higher initial temperature or in which a greater temperature rise due to heat of hydration occured, showed a lower strength. Method-2 was devised for such cases.

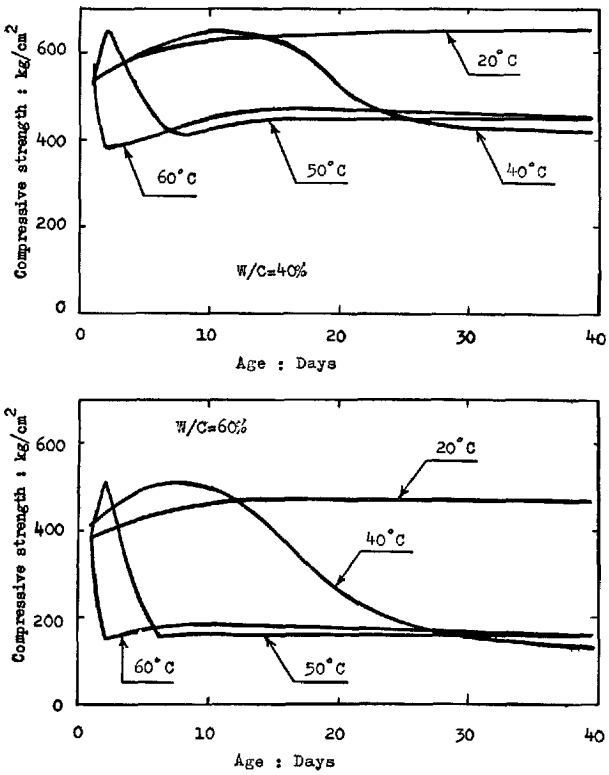

Fig. 2. *Effect of curing temperature*

Method-2

Owing to a very rapid rate of heat generation in a initial stage of hardening, the concrete made from high-aluminous cement often shows a remarkable temperature rise.

In this method, concrete was cast in a cylindrical container, 34 cm in diameter and 32 cm in height, and then placed in a adiabatic calorimeter. The heating equipment in a calorimeter was not operated, so that a natural curves of temperature rising and falling similar to an actual change in a structure could be obtained. Since the conditions of heat leakage of the calorimeter were constant, checking of repeated tests showed a good agreement. As typical examples, temperature curves are shown in Fig. 4.

Table 2. *Result of X-ray analysis of hydrated cement paste*

	Method-2	×	×	×	×	×	×	◎	◎

◎: strong, ○: moderate, △: weak, ×: none

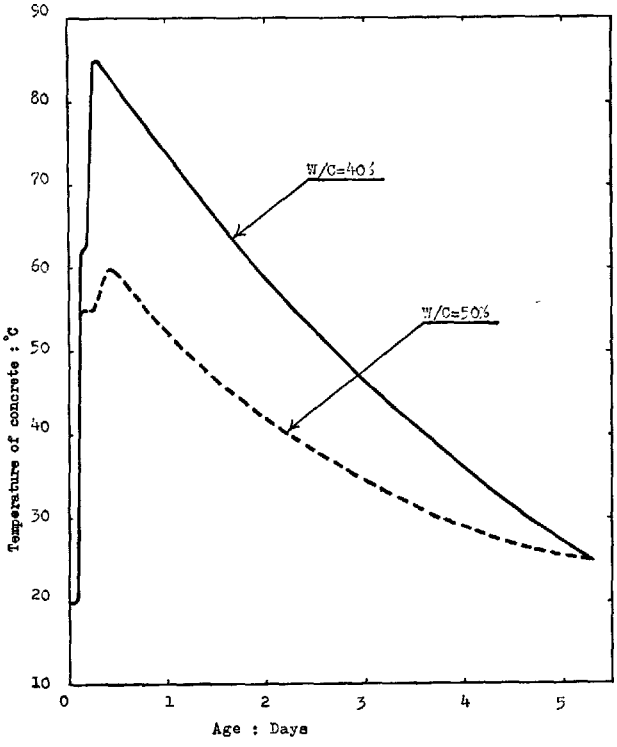

Fig. 4. *Typical temperature change of concrete in Method-2*

Table 4. *Comparison of strength between Method-1 and Method-2 (cement B, W/C = 40%)*

Curing condition of specimen	Age in days	Compressive strength (kg/cm²)
in water at 20°C	1	614
for 1 day at 20°C and then for 6 days at 50°C (in water)	7	402
core specimen cured by Method-2	2	312
	4	303
	6	310

Concrete specimen was taken out at the age of two days, from which two or three specimens of core were cut. By X-ray detection, it was confirmed that the concrete had been completely converted (Table 3). A result of strength test indicated that the strength did not vary with a longer storage in the calorimeter than two days. The fully-converted strength by this method was a little lower than that obtained by Method-1.

Pore Size Distribution

Many previous publications have pointed out an increase in porosity due to conversion and a close relationship between the reduction in strength and the increase in porosity.

Lea (3) determined densities of high-aluminous cement hydration product cured at normal and higher temperature. Neville (2), based on Lea's data, deduced the increase in porosity corresponding to conversion from hexagonal CAH_{10} to cubic C_3AH_6. Schwiete and Ludwig (4) verified the close relation between porosity measured by gas penetration method and several properties such as resistance to chemical action,

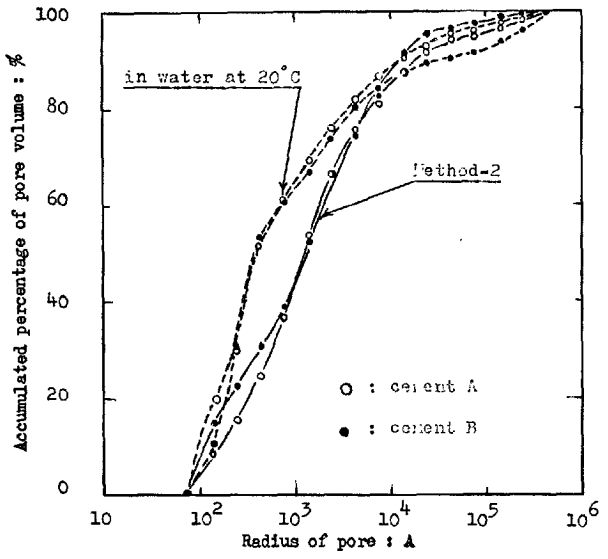

Fig. 5. *Pore size distribution curve, W/C = 50%*

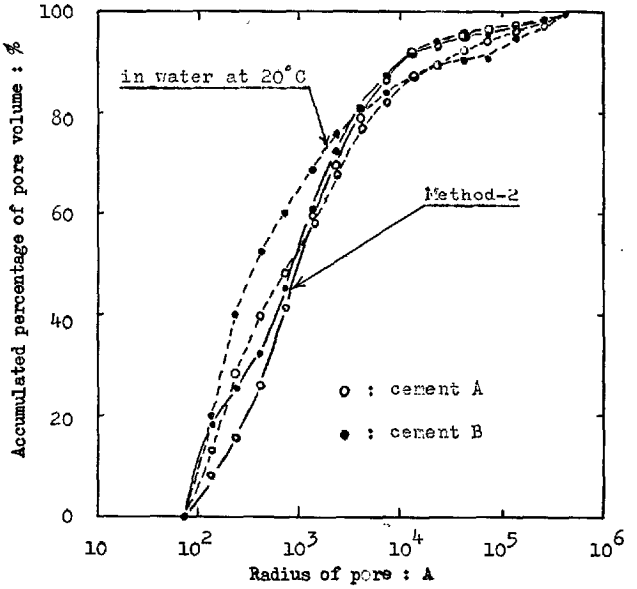

Fig. 6. *Pore size distribution curve, W/C = 40%*

resistance to freezing and thawing action, and carbonation due to air, on mortar and concrete. In the recent symposium on structure of portland cement paste and concrete, there were many presentations concerning to porosity and its effect (5, 6, 7). But all these works contained no result on high-aluminous cement.

Since the measurement of porosity provides a useful means for investigation on the effect of conversion, distribution of open pores in high-aluminous cement concrete was tried to measure by a mercury pressure porosimeter. As the size range of pores by this apparatus is limited between 75 Å–75000 Å, the result includes no gel pores (8). Samples were taken from concrete cured at normal temperature and at higher temperature (Method-2). Gravels in concrete were removed.

In Table 5, increase in porosity due to conversion can be seen. Further, the distribution of pores shifted to a larger side as shown in Figs. 5 and 6. The changes in the distribution occurred mainly between 100 Å–1000 Å. The average radius at 50 per cent point was around 400 Å for cured at normal temperature and around 1000 Å for cured at higher temperature. The distribution curves showed no difference for the two types of cement. These changes in the distribution of pores seemed to have a conclusive effects on properties of concrete made from high-aluminous cement, especially concerning to conversion, but insufficient data were obtained to establish relationships between them.

Table 5. *Porosity in concrete measured by mercury pressure porosimeter*

Cement	W/C %	Curing condition	Porosity $\times 10^{-4}$ cm³/g.
A	40	20°C, in water	284
		Method-2	476
	50	20°C, in water	472
		Method-2	488
B	40	20°C, in water	300
		Method-2	534
	50	20°C, in water	459
		Method-2	620

Micro-structure in hardened high-aluminous cement paste were observed with the aid of electron microscope. Broken surface of the paste was reproduced by replica method. The surface texture of the paste cured in water at 60°C for 5 days (Fig. 7.2) formed outstanding contrast to that cured in water at 20°C for 1 day (Fig. 7.3). The former had very ragged surface with many small granules, while the latter had flat surface. The details of the former can be observed in Fig. 7.3. In such a granular system, porosity of hardened paste should be greatly increased. The capillary pore existing in paste cured in water at 20°C for 1 day is shown in Fig. 7.4. In converted paste, capillary pore could not be found out clearly, because of the very granular texture of the surface.

(4) capillary pore in normaly cured cement paste W/C = 60%

Fig. 7. *Electron micrograph of hydrated high-aluminous cement paste* (*cement A*)

Temperature Rise and Volume Change

Temperature Rise

As one of the method for determining the effect of conversion Method-2 was proposed. By this method of curing, concrete showed a remarkable temperature rise during the earlier stage of hardening. Although the general tendency could be observed in Fig. 4, more details of the temperature curves are to be examined in Fig. 8. The most conclusive features for the curves were that there existed two steps in the course of the temperature rise. Beginning the evolution of heat in 2–3 hrs after mixing, the temperature of concrete increased very rapidly. In about 4–5 hrs the speed of temperature rise abruptly slowed down, and then showed again the second step of rising. For concrete with a water-cement ratio of 60 per cent, even a temporary fall in temperature was observed at this point. Similar features were found in a previous publication, but any explanation was not given. Probably, this is due to the hydration of unhydrated cement, and this secondary hydration could not occur until the early hydration product was converted.

When concrete was cooled positively, a curve of temperature rise has only one step. These phenomena were likely to give certain influence on the strength of concrete, but enough data have not been obtained at present.

Volume Change

Volume change of high-aluminous cement concrete cured under water at normal and higher temperatures were tested. For measurement, Carlson Strain Meter was embedded within a concrete specimen, which was 10 cm in diameter and 20 cm in height. Specimens were removed from molds in about 4 hrs after casting, and placed in water at 20°C for 7 days, thereafter in water at 50°C. This procedure

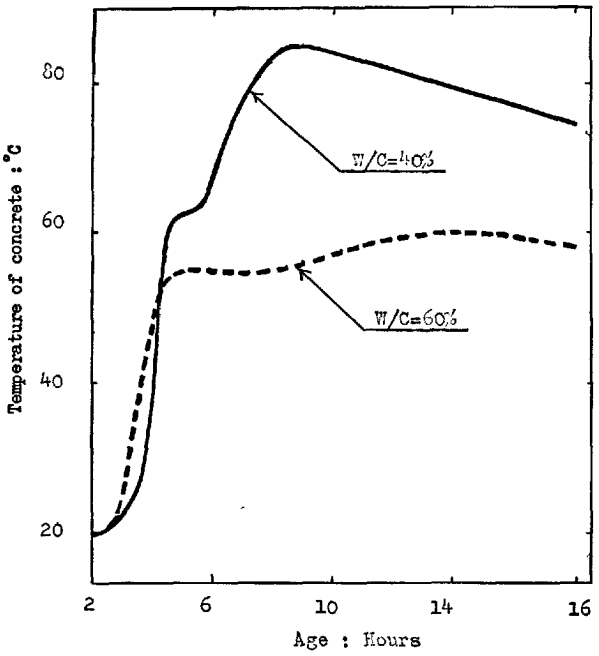

Fig. 8. *Distinctive feature of temperature change*

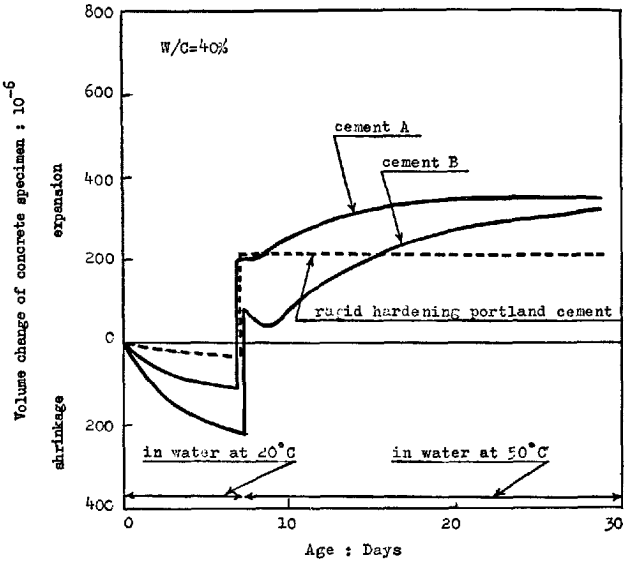

Fig. 9. *Volume changes of concrete during conversion in water*

was just the same as Method-1. Volume change was measured from soon after casting. Results are shown in Fig. 9. During the initial curing in water at 20°C, some shrinkage took place, while after moved into water tank at 50°C considerable expansion occurred. The expansion did not ceased until 23 days after placing at 50°C for cement A and 15 days for cement B. The tendency quite differed for a reference specimen made from rapid-hardening portland cement. The volume of the latter was invariable in water at 50°C.

This behavior of high-aluminous cement does not appear to have been sufficiently well known. The conversion might be contributory factor in the expansion of concrete.

Effect of Conversion on Properties of Concrete

Strength

Compressive strength, bending strength, and tensile strength of concrete were tested with specimens which were cured under two different conditions. One group of the specimens were cured in water at 20°C for 1 day, and another group was cured for 1 day under the same condition as the former and then in water at 50°C for 6 days (Method-1). The temperature of concrete at placing was 20°C. Mix proportions were selected to give the three different slumps, 3, 10 and 18 cm for each water-cement ratio of 37, 43, 49 and 55 per cent.

Test data indicating the relationship between cement-water ratio and strength are shown in Figs. 10, 11 and 12. Because of a small variation between mixes having different value of slump, all of the data were expressed in a single linear function. Almost all the functions were calculated with a small error of correlation.

In every kind of strength test a reduction in strength due to conversion became greater with the increase in water-cement ratio. If the ratio was 40 per cent or less, the reduction was fairly small, and at 40 per cent of the water-cement ratio, concrete with compressive strength over 300 kg/cm², bending strength over 40 kg/cm², and tensile strength over 30 kg/cm² seemed to be safely obtained. These values would satisfy the designed strength for wide range of purposes.

The difference in strength resulting from types of high-aluminous cement appeared to be more distinctive for converted strength than for normally cured strength.

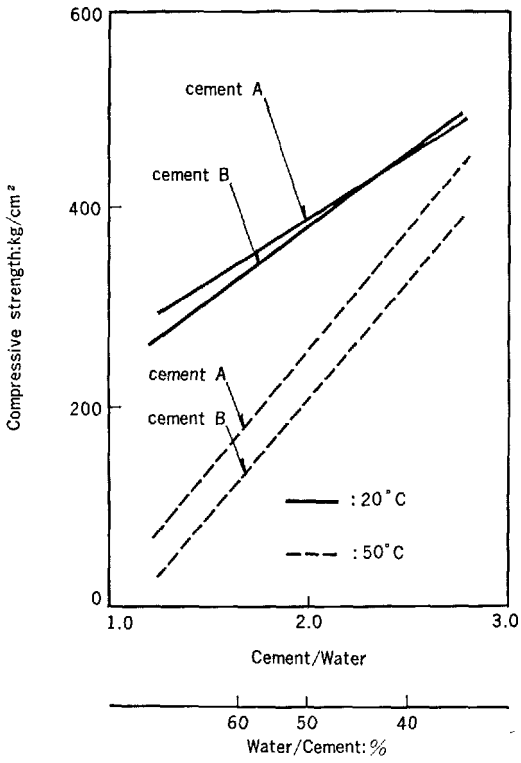

Fig. 10. *Relation between water-cement ratio and compressive strength*

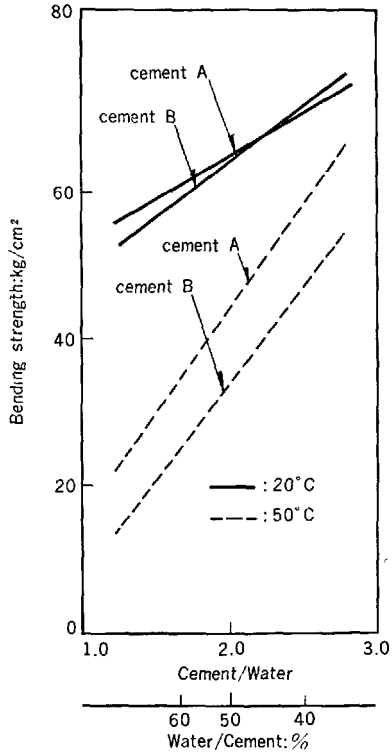

Fig. 11. *Relation between water-cement ratio and bending strength*

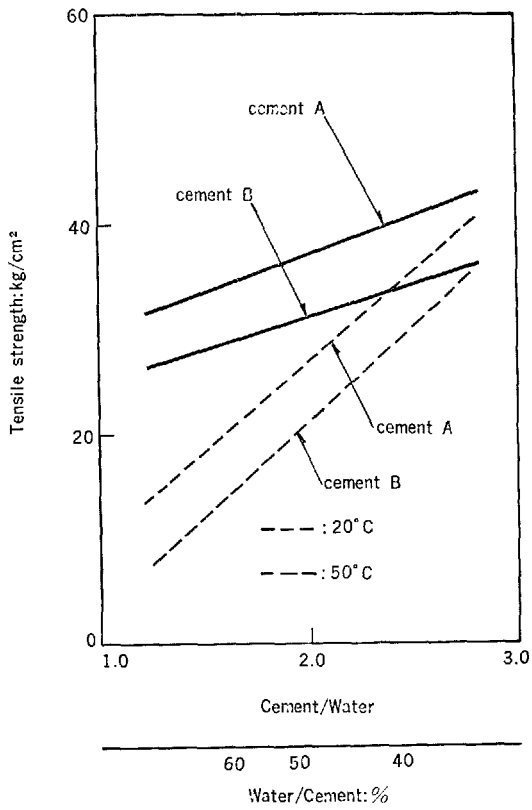

Fig. 12. *Relation between water-cement ratio and tensile strength*

Permeability

Effect of conversion on permeability of concrete with water-cement ratio of 35, 45, 55 and 65 per cent was tested. A cylindrical specimen, 15 cm in diameter and 30 cm in height was cast and cured under water at 20°C for 1 day, and was divided into six disks of 4 cm thick by concrete saw. After curing in water at 50°C for 6 days more, specimens were dried in a room of constant humidity at 55 per cent. Drying was continued for 35 days till the weight became nearly constant. The reference specimens were dried for the same period just after dividing. Under the pressure of 3 kg/cm², water was forced into a disk for 30 minutes. Permeability was indicated by the difference in weight before and after adding pressure.

Fig. 13 shows a percentage loss in weight after drying for 35 days. Converted specimens gave greater loss of weight than reference specimens. The relationship between water-cement ratio and an amount of water penetrated into concrete are plotted in Fig.14. However, the permeability of converted specimens did not differ so greatly from that of normally cured,

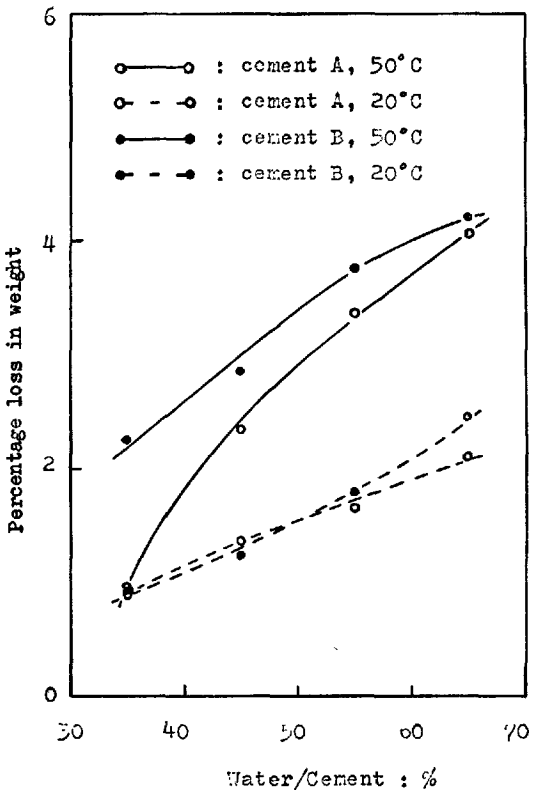

Fig. 13. *Percentage loss in weight after drying for 35 days*

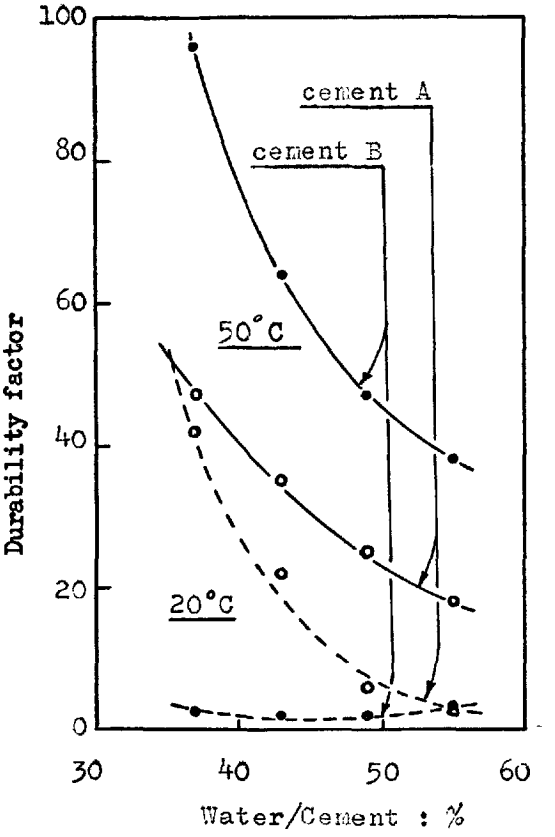

Fig. 15. *Result of freezing and thawing test*

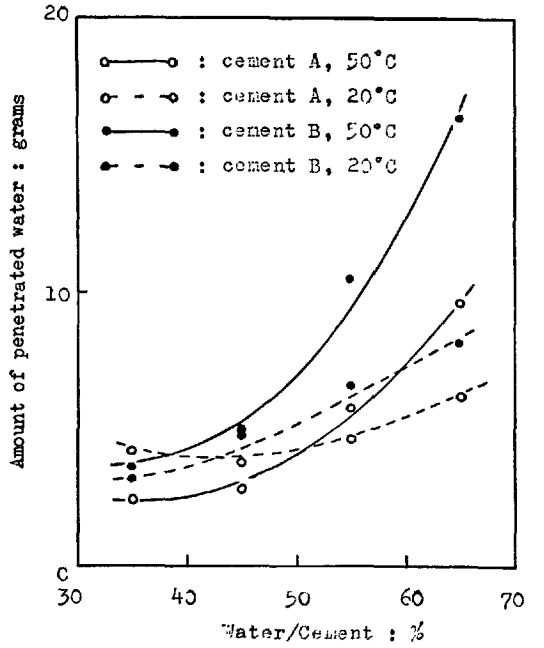

Fig. 14. *Amount of water penetrated into concrete under pressure of 3 kg/cm² in 30 minutes*

there seemed to be a general tendency of the increase in permeability due to conversion. In this result, the increasing amount of capillary pores may be implicit.

Resistance to Freezing and Thawing Action

Freezing and thawing tests were performed on 7.5 × 10 × 40 cm beam specimens. After casting, specimens were cured in water at 20°C for 2 days and then in water at 50°C for 7 days. Reference specimens were cured in water at 20°C for 9 days. The accelerated freezing and thawing test procedure consists of subjecting saturated specimens to 2 hrs freezing at −17°C and 1 hr thawing at 5°C. Dynamic modulus of elasticity and weight change were often measured. Durability factors were calculated when percentage of elasticity dropped to 60 per cent of the initial or at 300 cycles of freezing and thawing.

In Fig. 15, significant decrease in durability of

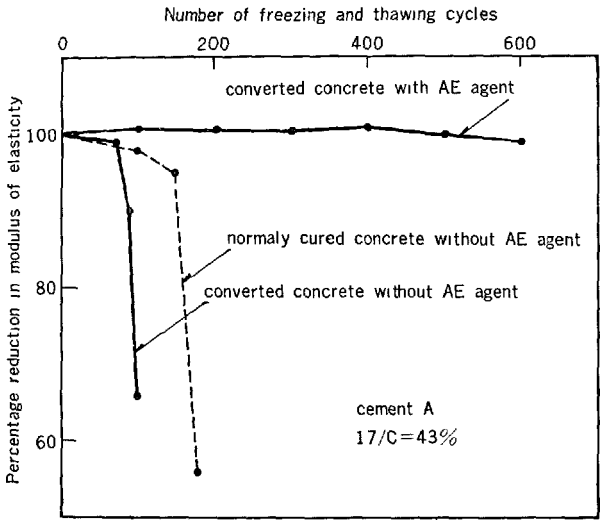

Fig. 16. *Effect of AE agent on durability of high-aluminous cement concrete*

converted concrete was observed. But, as with portland cement, air entraining agent enabled the converted concrete to withstand 300 cycles and over of freezing and thawing. Fig. 16 clearly shows this effect. The variation of durability with the type of cement, as shown in Fig. 15, seemed to imply the difference in characteristics of pores. Further research should be needed for this problem.

Effect of Conversion Observed in Field Test

To investigate the long term behavior in field, high-aluminous cement concrete was placed in a part of concrete pavement. In order to make a test under the severest condition, the placement was conducted in summer, the temperature of concrete at placing being about 30°C.

Table 6 gives the mix proportion used in this test. The size of the test slab was $0.2 \times 0.8 \times 3.4$ m For each type of cement, two slabs were cast, one being cured by watering on the surface, and one being left without watering. A Carlson Strain Meter was embedded in concrete. Core specimens for compression test, 10 cm in diameter and 17 cm in height were cut out at the age of 1, 7, 28, 91 and 182 days.

Among these four slabs, two showed gradual reduction in strength (cement A without watering and cement B with watering), one showed no reduction till 182 days (cement A with watering), and one showed remarkable reduction from 1 day (cement B without watering). The test result of the first two are shown in Figs. 17 and 18. The maximum temperature caused by heat of hydration within 1 day after placing,

Table 6. *Mix proportion of concrete used in field test*

Cement	Slump (cm)	Max. size of aggregate	W/C (%)	Unit weight of materials (kg/m³) C	W	S	G
A	2–5	25 mm	40	368	147	703	1201
B	2–5	25 mm	40	365	147	773	1163

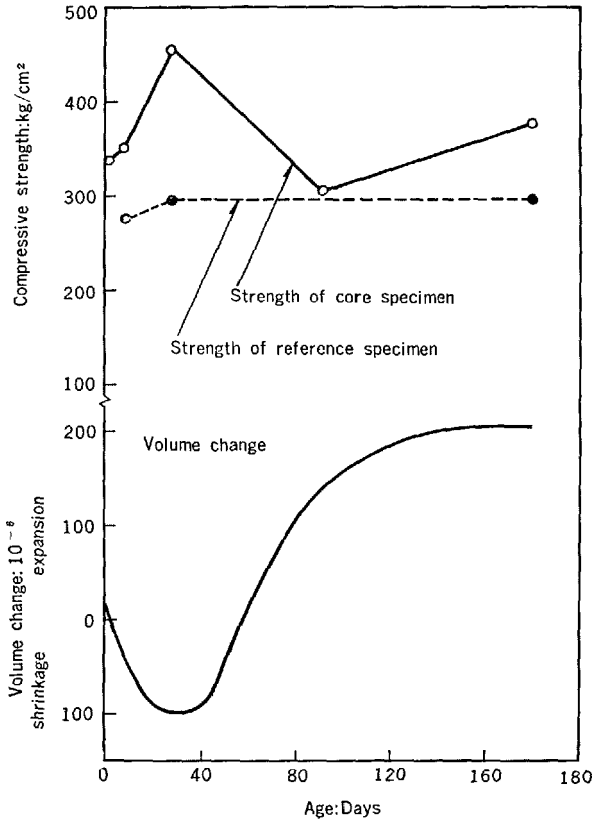

Fig. 17. *Results of field test*
(1) cement A, without watering

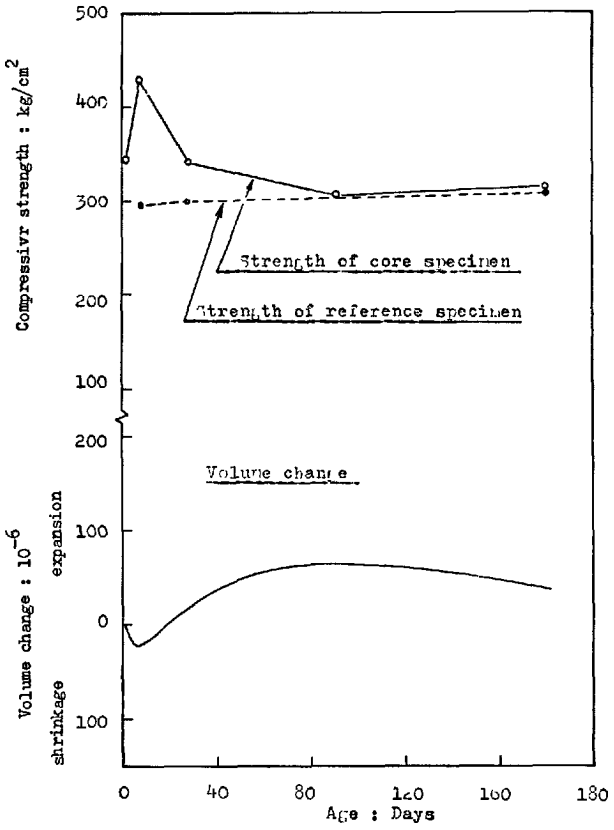

Fig. 18. *Results of field test*
(2) cement B, with watering

was 76.5°C for cement A without watering (Fig. 17) and 62.0°C for cement B with watering (Fig. 18). The strength of core specimen reduced gradually and reached the minimum in 90 days. Comparing with the strength of reference specimen which was cured at the site of the test slab, and then immersed in water at 50°C for 7 days before testing, the minimum value of the core was nearly equal to the reference specimen. From the age of 91 days on, the strength showed slight increase similar to the result in Fig. 2.

In their lower part, Figs. 17 and 18 contain the results of volume change testing. Volume change was calculated by subtracting thermal volume change from apparent volume change, on the assumption that the coefficient of thermal expansion of concrete being 10×10^{-6}. The parallelism between the reduction in strength and the expansion of concrete was observed. The same phenomena as this were observed in laboratory and already shown in Fig. 9.

Conclusion

As early as 1930, it was of common knowledge that the deterioration of concrete using high-aluminous cement was caused by conversion. To keep the damage at a minimum, use of low water-cement ratio has been recommended. But any decisive method to test residual or final strength has not been established. And the effect of conversion on properties of concrete other than strength has not been well known.

At the start of this study, the proposed method of accelerated conversion test, which covers two typical cases of conversion, was examined. One method is for conversion in concrete placed and cured at normal temperature, and the other is for conversion due to heat of hydration in concrete soon after placing. It was made clear that residual or final strength can be estimated in a short period by these methods. Further study is still needed to clarify the effect of placing temperature of concrete.

As a result of applying these method to some other properties than strength, it was observed that permeability and resistance to freezing and thawing are much influenced by conversion, and that, even if strength of converted concrete is nearly equal, there is considerable difference in above mentioned properties resulting from type of cement. One of them showed very low resistance to freezing and thawing action whereas the proportion of concrete was selected for a mix with a water-cement ratio less than 40 per cent.

In order to study the mechanism of deterioration caused by conversion, micro-structure in hydrated high-aluminous cement was surveyed by a porosimeter and an electron microscope. Increase in porosity and change in pore size distribution were found. Also outstanding transformation in internal structure produced by conversion was recognized. The average radius of pores was about 400 Å for specimen cured at normal temperature and about 1000 Å for cured at higher temperature. The texture of broken surface in hydrated cement paste cured at higher temperature was more ragged than that cured at normal temperature. Aggregation of many small granules, which seemed to be products of conversion, was observed

on the surface.

Summarizing the results of X-ray analysis, electron microscope observation, heat of hydration, volume change, and strength test, the phenomena of conversion could be explained as follows: The transformation, $3CAH_{10} \rightarrow C_3AH_6 + 2AH_3 + 18H$, leads to the increase in porosity and free water, which easily make residual unhydrated cement hydrated. By this secondary hydration, C_3AH_6 is directly produced and a slight gain in strength and generation of heat occurred. Expansion of concrete taken place at the same time may be ascribed to the pressure of water derived from dehydration of CAH_{10}. Micro structure of converted hydration product becomes ragged aggregation of C_3AH_6 embedded in crystallized AH_3. At the boundary between them, greater amount of pore may exist.

Supplementary Paper III-124 Influence of Chloride and Hydrocarbonate on the Sulphate Attack

Friedrich W. Locher*

Synopsis

Earlier storage tests have shown that concrete is attacked less by sea water than by pure sodium- or magnesium sulphate solutions of the same concentration. Therefore it has been examined if chloride and hydrocarbonate which are contained in sea water as active substances beside sulphate, are responsible for the decrease of the sulphate attack. For that purpose storage tests have been performed in solium- and magnesium sulphate solution with 2500 mg SO_4^{2-}/*l* without and with additions of 30 g NaCl/*l* or of 0.19 g $NaHCO_3$/*l*. Small prisms (1 × 1 × 6 cm) and flat primss (1 × 4 × 16 cm) of mortar according to the German standard specification have been used as test specimens. Three portland cements with calculated contents of tricalcium aluminate of 12%, 8% and 0% as well as three blast-furnace cements with 50%, 65% and 77% granulated blast-furnace slag have been chosen as cements. It is shown more clearly by the expansion of the flat prisms than by the decrease in relative bending strength of the small prisms, that magnesium sulphate attacks more intensely than sodium sulphate. The sulphate attack is generally increased by the addition of chloride to the sulphate solution, whereas it is clearly reduced by the addition of sodium hydrocarbonate. X-ray diffraction analysis and microscopic investigations indicate that the formation of calcite on the surface of the test specimens may be responsible for this result.

Introduction

Experiences and tests have shown that concrete is attacked less by sea water than by pure sodium- or magnesium sulphate solutions of the same sulphate concentration. This is generally attributed to the influence of the high concentration of chloride. It effects, that less trisulphate (ettringite), $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O$, is formed, because its solubility is increased by chloride (1) and a part of the aluminate is combined as monochloride (tricalcium aluminate monochloride hydrate, Friedel's salt), $3CaI \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ (2). Besides, there is assumed that the trisulphate crystallizes from the solution when chloride is present, because of the higher solubility of trisulphate in chloride containing solutions and so it does not cause expansion. But our own tests which attended to the examination of the sulphate resistance of cement, have shown, that the sulphate attack is not diminished by an addition of chloride to sodium- or magnesium sulphate solutions, but it is often strengthened. These tests have shown, that fibrous and nodular separations of calcite, aragonite and vaterite are formed on the surface of concrete prisms, which were exposed to the attack of synthetic sea water.

The composition of synthetic sea water in which the concrete prisms were stored, is given in Table 1. It corresponds to the composition of natural sea water with a total salt concentration of 33.25 g/*l*. Therefore the small concentration of hydrocarbonate is responsible for the formation of calcium carbonate on the surface of the concrete. Although the carbonate concentration of sea water cannot influence the reaction between the aluminate of the cement and the sulphate of the sea water, it is to assume that the penetration of the sulphate is restrained by the calcium carbonate, formed on the surface of the concrete.

Table 1. *Composition of the artificial sea water for the concrete storage tests*

calcium, Ca^{2+}	410		

*Forschungsinstitut der Zementindustrie, Düsseldorf, West Germany.

Accordingly the chemical influence of the components of the solution on the reaction between aluminate and sulphate is not important to the degree of attack of the sea water on concrete, but the increasing of the resistance against diffusion by separation of calcium carbonate on the surface and in the pores of the hardened cement. It results from tests about the sulphate resistance of cement (3) that the resistance of the hardened cement against diffusion has a decisive influence on the sulphate resistance of the cement. It appears that portland cement, poor in tricalcium aluminate, has a high sulphate resistance, because its hydration products cannot react with sulphate. During the hydration of blast-furnace cements there are always formed hydration products which are susceptible to sulphates. Nevertheless, blast-furnace cements with at least 65% granulated blast-furnace slag are sulphate resistant, because their hardened paste is so impermeable that neither sulphate nor other non aggressive ions can penetrate into it (4).

In order to confirm if the hydrocarbonate concentration of sea water is significant for the attack of sea water on concrete there were carried out storage tests with 6 cements, i.e. 3 portland cements with different contents of tricalcium aluminate and 3 blast-furnace cements with different contents of granulated blast-furnace slag. The hydrate phases and the compounds which are formed in the reaction thereof with the different sulphate solutions were identified by X-ray analysis. In addition the changes on the surfaces of the mortar specimens were tested microscopically.

Tests

For the investigation 6 cements of the type Z275 were chosen, i.e. 3 portland cements with 12%, 8% and 0% tricalcium aluminate and 3 blast-furnace cements of 50%, 65% and 77% granulated blast-furnace slag. The composition and the specific surfaces of the cements are given in Table 2. The phase composition of the portland cements are calculated from the chemical analysis. The slag contents of the blast-furnace cements are ascertained by microscopic counting of the sieve fraction 30–40 μm and correction of the counting results by analytically determined concentrations of CaO, MnO and S^{2-} in the sieve fraction and in the whole cement. The specimens for storage tests—small prisms 1 × 1 × 6 cm (5) and flat prisms 1 × 4 × 16 cm (6)—are made of mortar in accordance with DIN 1164 with 1 part by weight of cement, 1 part of standard sand I (fine), 2 parts of standard sand II (coarse) and 0.6 parts of water. The prisms have been cured for 1 day in moisture saturated air and then suspended in water. Some remained in water until they were tested for flexural strength. Other at the age of 21 days were suspended in the different sulphate solutions. After a sulphate storage of 4, 8, 12, 18, 26, 38 and 52 weeks the flexural strength (B_s) of the small prisms was examined and compared with the flexural strength of water stored test specimens (B_w) of the same age. The expansion of the flat prisms was measured in time intervals of 4 weeks. The length change of adequate water stored prisms was taken into account. The relative flexural strength B_s/B_w of the small prisms and the expansion of the flat prisms were taken as a criterion for the aggressive effect of the different sulphate solutions.

Pure sodium- and magnesium sulphate solutions with the same sulphate concentration of 2500 mg SO_4^{2-}/l (0.026 m) are chosen as aggressive solutions. Besides, sodium- and magnesium sulphate solutions of the same sulphate concentration with additions of sodium chloride or sodium hydrocarbonate are included in order to test the influence of chloride and hydrocarbonate on the sulphate attack. The concentrations of the additions corresponded with 18.200 mg Cl^-/l and 140 mg HCO_3^-/l to the concentration of sea water.

4 small prisms produced in the same kind and tested at the same time, were stored in a solution of 600 m*l* and adequate 6 flat prisms were stored in a solution of

4000 ml. The solutions of the small prisms were restored every 4 weeks, of the flat prisms every 8 weeks.

The X-ray diffraction analysis which should give informations about the influence of the chloride and hydrocarbonate additions on the formation of trisulphate were carried out on mortar prisms (1 × 1 × 16 cm) as already described (3). Plastic sand which consisted of polyethylene globules with an average diameter of 0.7 mm was used as aggregate instead of quartz sand. The small prisms were produced of mortar with 1 part by weight of cement, 1.33 parts of plastic sand and 0.6 parts of water. After 1 day of moist curing and further water curing they were exposed to the attack of sulphate solutions at the age of 21 days. After 8 weeks of sulphate storage the test specimens were crushed, the plastic sand was separated by sieving and portion of the cement was investigated by X-ray diffraction analysis (CuK_α-radiation).

The microscopic test should give informations about alterations on the surface of the prisms. For that purpose the phase composition and the nature of surface layers were examined with a polarisation microscope on thin sections cut parallel to the 1 × 1 cm top area of the small prisms with quartz sand and as aggregate after 28 days of sulphate storage.

Results

Storage Tests

The results of the storage tests are compiled in Tables 3 and 4. The Tables 3a and 3b contain the relative flexural strength of the small prisms and the Tables 4a and 4b the expansion of the flat prisms.

The flexural strength of the small prisms composed of portland cement (Table 3a) indicates the known influence of the content of tricalcium aluminate. The prisms composed of portland cement with 12% tricalcium aluminate disintegrate after 12 weeks at the latest, the prisms of portland cement with 8% tricalcium aluminate after 1 year, whereas the prisms of portland cement free of tricalcium aluminate even did not change after one year. An essential difference in the effect of sodium- and magnesium sulphate is not to realize. The additions of sodium chloride and sodium hydrocarbonate do not have a remarkable influence on the degree of attack of the sulphate solutions.

The small prisms consisting of blast-furnace cement with 65% and 77% granulated blast-furnace slag (Table 3b) are not attacked by sulphate solutions. Differences in the effect of the various solutions are only to observe at prisms of blast-furnace cement with 50% slag, which are destoryed after 18 weeks of sulphate storage. In this case the addition of sodium hydrocarbonate does reduce the aggressive effect of the sodium sulphate solution, but not the aggressive effect of the magnesium sulphate solution.

The expansion behaviour of the flat prisms which are shown in Table 4 reveals more clearly than the decrease in strength of the small prisms, the influence of the sulphate resistance of the cement as well as the differences in the aggressive effect of the sulphate solutions. Nevertheless both methods yield nearly the same sequence in sulphate resistance of the 6 cements.

The test specimens of all cements are attacked much more by the magnesium sulphate solution than by

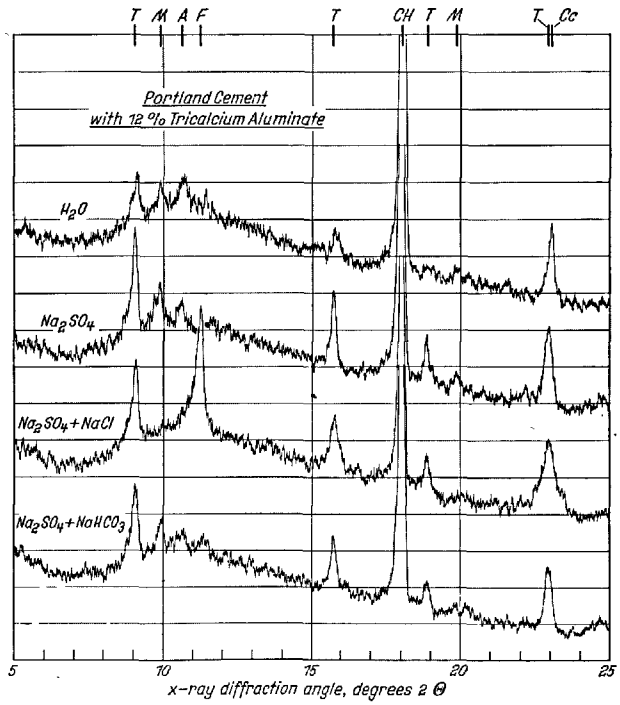

Fig. 1a. *X-ray diffraction diagrams of the hardened portland cement with 12% tricalcium aluminate after a storage of 8 weeks in distilled water and in sodium sulphate solutions without and with additions of sodium chloride and of sodium hydrocarbonate.*

the sodium sulphate solution. The addition of sodium chloride has a small reducing effect, but only when test specimens of portland cement with 8% tricalcium aluminate are stored in a magnesium sulphate solution. In any other case the aggressive effect of the sulphate solution does not change or even it is intensified. An addition of hydrocarbonate reduces the aggressive effect of the sulphate solutions, especially on the prisms of cement with a smaller sulphate resistance.

X-ray Tests

The X-ray investigations are limited on the cements with the smallest sulphate resistance, i.e. the portland cement with 12% tricalcium aluminate and the blast-furnace cement with 50% granulated blast-furnace slag. The corresponding X-ray diffraction diagrams are shown for portland cement on Fig. 1a and 1b and for blast-furnace cement on Fig. 2a and 2b.

The water cured prisms consisting of portland cement contain trisulphate (ettringite), monosulphate

and tetraclacium aluminate hydrate as aluminate bearing hydration products (Fig. 1a, diagram uppermost). After storage in sodium sulphate solution the trisulphate content has increased (Fig. 1a, 2. diagram). If the solution contains sodium chloride in addition to sodium sulphate, monochloride (Friedel's salt), $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ (Fig. 1a, 3. diagram), is formed besides the trisulphate. The addition of sodium hydrocarbonate results in a diminution of trisulphate content in comparison with storage in a pure sodium sulphate solution (Fig. 1a, 4. diagram). Aluminate carbonate hydrates could not be identified, calcite only in small quantities because the carbonate is precipitated only in a thin surface layer so that the calcite concentration of the total sample remains small (see microscopic investigations).

The prisms stored in the magnesium sulphate solution contain much bigger quantities of trisulphate (Fig. 1b), because the prisms containing portland cement with a high content of tricalcium aluminate are vigorously attacked and damaged within 8 weeks and consequently the magnesium sulphate solution could react with the compounds of the hardened cement without any difficulties. Accordingly the calcium hydroxide concentration, originally very high, has been nearly completely consumed. Probably the magnesium sulphate solution has reacted with the calcium hydroxide to form solid magnesium hydroxide and calcium sulphate solution which on its side reacts with the still available aluminate hydrate to trisulphate (7). Additions of sodium chloride (Fig. 1b, 2. diagram) or sodium hydrocarbonate (Fig. 1b, 3. diagram) do not have any influence on the course of the reaction perceptible by X-ray diffraction. Nevertheless the stronger calcium hydroxide line on the 3. diagram points out, that in presence of sodium hydrocarbonate the reactions are not so far advanced. The high calcite content of the specimen stored in the magnesium sulphate solution with sodium chloride is due to its rapid disintegration and subsequent precipitation of the liberated lime by the carbon dioxide of the air which is permanent dissolved in the sulphate solution.

In the hydration of blast-furnace cements the same aluminate hydrates are formed as in the hydration of

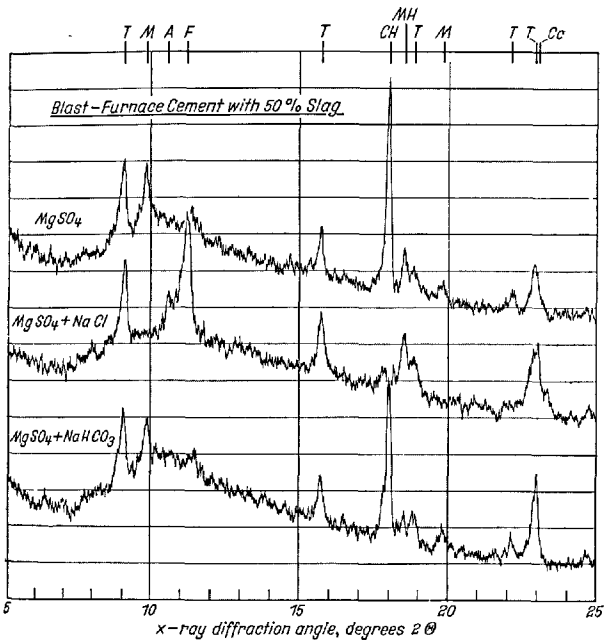

Fig. 2b. *X-ray diffraction diagrams of the hardened blast-furnace cement with 50% granulated blast-furnace slag after a storage of 8 weeks in magnesium sulphate solutions without and with additions of sodium chloride and of sodium hydrocarbonate.*
T = *trisulphate (ettringite)*, M = *monosulphate*, A = *tetracalcium aluminate hydrate*, F = *monochloride (Friedel's salt)*, CH = *calcium hydroxide*, MH = *magnesium hydroxide*, Cc = *calcite*

portland cement, but there is much more monosulphate and less trisulphate (Fig. 2a, diagram uppermost). The trisulphate content is increased a little by storage in the sodium sulphate solution (Fig. 2a, 2. diagram). But the evident decrease in calcium hydroxide content indicates that a reaction with the sulphate solution took place. When sodium chloride is present, the monochloride is formed (Fig. 2a, 3. diagram), analogous to the behaviour of the portland cements. Besides, the diagram exhibits an increased formation of trisulphate and a complete consumption of calcium hydroxide. An addition of sodium hydrocarbonate (Fig. 2a, 4. diagram) does not yield any alteration compared with the pure sodium sulphate solution, excepting a further decrease in calcium hydroxide content.

In the case of magnesium sulphate attack (Fig. 2b) trisulphate is formed to a greater extent. But there is no difference between the influence of the pure magnesium sulphate solution (Fig. 2b, diagram uppermost) and the magnesium sulphate solution with addition of carbonate (Fig. 2b, 3. diagram). In the presence of chloride monochloride is formed again (Fig. 2b, 2. diagram), without any influence on the trisulphate content and with complete reaction of the calcium hydroxide.

Microscopic Inspections

During storage in water or in various sulphate solutions coatings are formed on the surfaces of the small prisms. The microscopically determined composition of the coatings depends on the kind of solution but not on the type of cement. When stored in water or in sodium sulphate solution the coating is composed of calcite, $CaCO_3$, and when stored in magnesium sulphate solution it consists of brucite, $Mg(OH)_2$ with only a very small admixture of calcite.

The surface coatings of the water cured prisms with a mean thickness of 2 to 3 μm are very thin compared with the 15 to 20 μm thick coatings on prisms stored in the various sodium sulphate solutions. An addition of sodium chloride has no influence on the thickness of the calcite coating, an addition of sodium hydrocarbonate effects a small increase only.

The brucite coating formed during storage in magnesium sulphate solution, has an average thickness of 5 μm. It increases significantly up to 30 μm, when sodium chloride is present in the solution. If the magnesium sulphate solution contains sodium hydrocarbonate, the surface coating has a thickness of 2 or 3 μm and is composed of a mixture of brucite and calcite.

Discussion

The storage tests especially those by the flat prism method, mainly indicated that

1. solutions of magnesium sulphate attack the mortar prisms of all cements more vigorously than solutions of sodium sulphate,

2. an addition of sodium chloride to the sulphate solution does not diminish the rate of attack but even increases it in some cases and

3. an addition of sodium hydrocarbonate diminishes the rate of attack of the sulphate solution.

These results agree with those of the X-ray diffraction investigations, that means that the test specimens

which are more vigorously attacked, show the higher content of trisulphate. That is particularly valid for the attack of magnesium sulphate solution too.

When chloride is present trisulphate has an increased solubility according to investigations mentioned by W. W. Kind (2), consequently it is to crystallize either in a small quantity only or in the harmless formation in the pores of the hardened cement paste. The above-mentioned X-ray diffraction investigations indicate however, that the formation of trisulphate is not hindered by addition of chloride. Moreover monochloride is formed but always by consumption of monosulphate and tetracalcium aluminate hydrate. The fairly large quantities of monochloride indicate that the sodium chloride added to the solution, also reacts with the nonhydrated tricalcium aluminate.

Furthermore it is remarkable that the prisms which were not heavily attacked, contain much more monochloride than the disintegrated prisms. Hence it follows that the chloride ions penetrate the hardened cement more quickly than the sulphate ions and react there with monosulphate, tetracalcium aluminate hydrate and probably with the nonhydrated tricalcium aluminate, too, forming monochloride. But as the monochloride is not stable in presence of sulphate, it gets converted later on into trisulphate when sulphate attack proceeds. Hence it is unlikely that in a sulphate solution containing chloride less trisulphate is formed than in a sulphate solution without chlorides. The assumption that in presence of chloride the harmless form of trisulphate crystallizes in the pores of the hardened cement does not correspond to results of the storage tests. In sulphate solutions containing hydrocarbonate the trisulphate is formed significantly slower than in solutions without carbonate. As there is no difference in the kind of the chemical reaction the retarded formation of the trisulphate can only be attributed to the increase of the diffusion resistance. So it can be assumed that the hydrocarbonate together with the calcium hydroxide forms calcite, which grows upon the surface and in the pores near the surface of the hardened cement and hinders penetration of the solution. The microscopic inspections show, however, that in solutions of sodium sulphate without addition of hydrocarbonate coatings of calcite are formed, too, but which, as the results of the storage tests show, do not diminish sulphate attack. So it seems to be important that the solution always contains a sufficient quantity of carbonate to form a calcite coating also on the surface in cracks arisen by sulphate expansion. In solutions without admixture of carbonate, the supply of carbon dioxide dissolved from the air, obviously is very slow and consequently the calcite coating is formed not quickly enough to prevent penetration of sulphate when sulphate susceptible cements are used and the sulphate attack proceeds quickly.

The brucite coatings of various thicknesses formed during storage in magnesium sulphate solutions with and without chloride have no influence on sulphate attack. The aggressive effect is significantly diminished however, when the coating consists of a mixture of brucite and calcite.

The results of the investigations point out the fact that the high content of chloride in the sea water has no essential effect on the sulphate attack. A significantly greater influence is exerted by the content of hydrocarbonate. But it is still doubtful, whether the comparatively weak aggressive effect of the sea water can be explained in this way only.

Summary

Experiences and investigations showed that sea water has a significantly less aggressive effect on concrete than pure sodium or magnesium sulphate solutions of the same sulphate concentration. So it has been examined whether chloride and hydrocarbonate, the other efficaceous components in the sea water besides sulphate, are responsible for the diminution of the sulphate attack. For that purpose storage tests have been performed with solutions of sodium and magnesium sulphate with 2500 mg SO_4^{2-}/*l* with and without additions of 30 g NaCl/*l* or of 0.19 g $NaHCO_3$/*l*. Small prisms (1 × 1 × 6 cm) and flat prisms (1 × 4 × 14 cm) of mortar according to the German standard specification with 3 portland cements with calculated contents of tricalcium aluminate of 0%, 8% and 12% and 3 blast-furnace cements with 50%, 65% and 77% slag were used as test specimens. The decrease in bending strength of the small prisms and the expansion of the flat prisms tested in certain time intervals were taken as a criterion for the aggressive effect of the solutions. Microscopical inspections of the small prisms gave informations about the character of the surface coatings formed during the sulphate storage, and the nature of chemical reactions between the hydration products and the consistuents of the solutions were illustrated by X-ray diffraction analysis. The expansion of the flat prisms showed more significantly than the decrease in strength of the small pri-

sms, that magnesium sulphate is a more aggressive media than sodium sulphate. The sulphate attack is either not changed or increased by an addition of chloride to the sulphate solution, whereas it is clearly reduced by the addition of sodium hydrocarbonate. X-ray diffraction investigations reveal that in any case the formation of trisulphate (ettringite) is the cause for the detrimental effect of all sulphate solutions tested. The formation of trisulphate is not diminished by sodium chloride, retarded however by sodium hydrocarbonate. Microscopic examinations showed that on the surface of the prisms coatings are formed, which are composed of calcite ($CaCO_3$), when prisms have been in water and in sodium sulphate solutions and the coatings are composed of a mixture of brucite ($Mg(OH)_2$) and calcite when the prisms have been stored in magnesium sulphate solutions. An addition of hydrocarbonate increases the formation of calcite. Thus the assumption has been made that the calcite crystals grow upon the surface and in the pores near the surface of the hardened cement and hinder the penetration of the sulphate solutions.

Oral Discussion

Arthur W. Brown

Dr. Locher will be interested to know that in similar work in connection with sodium chloride contaminated aggregates, it was found that the incorporation of sodium chloride in an ordinary portland cement mortar mix, at a level of 2% on the cement, imparted considerable sulphate resistance to the O.P.C. based specimens in solutions containing up to 24,000 mg. SO_4^{2-}/litre. Could this perhaps be due to the appearance of sodium as bicarbonate, following the complexing of some chloride as chloro-aluminate? I feel that in view of his findings this may well be the case. Using sulphate resisting portland cement no differences due to the incorporation of sodium chloride have been detected up to date, that is in 9 months.

Author's Closure

Friedrich W. Locher

The reduction of the sulphate attack by an addition of chloride to the cement is perhaps to be attributed to the quick formation of aluminate chloride hydrates during the early hydration reactions. At lower chloride concentrations the monochloride is formed, at higher chloride concentrations the trichloride, too, according to recent results of W. Richartz (will be published). The monochloride reacts with the later penetrating sulphate solutions to ettringite, but it does not generate a crystallization pressure. The trichloride is resistant against sulphate. An addition of chloride to cement effects that a bigger quantity of aluminate will be already bound as aluminate chloride hydrates during the setting of the cement and consequently less aluminate can react to form trisulphate.

Supplementary Paper III-138 Mechanisms of Sulphate Expansion of Hardened Cement Pastes

Susanta K. Chatterji*

Synopsis

The expansion of cement motars or concrete due to sulphate attack can be ascribed to (i) the formation of sulphoaluminate, (ii) the formation of gypsum, and (iii) other reactions catalyzed by the sulphate ions. It has been shown that of the two sulphoaluminates which may form, monosulphate formation form C_4AH_{13} explains the observed expansions under different conditions better than the formation of ettringite. This mechanism of sulphate expansion also opens up a method of improving the sulphate resistance of ordinary portland cement by adding finely ground calcium carbonate. The formation of gypsum may lead to an expansion of the concentration of sulphate solution is such that a supersaturated solution of gypsum is formed. It has been proposed that recrystallization of X-ray amorphous calcium hydroxide, which is catalyzed by sulphate ions, may lead to some expansion. The cations, present though not contributing to expansion directly, may influence the rate of sulphate attack.

Introduction

It has been observed by the earliest users of portland cement that structures made with portland cements are not very stable when exposed to water containing sulphate ions. A large number of research workers have studied this problem in order to elucidate the mechanism of the deterioration, arriving at different conclusions. The action of water containing sulphate ions on the hardened cement pastes or mortar etc. had been followed either by measuring the rate of expansion or loss of strength (tensile or compressive) or by ultrasonic resonance vibration. It has generally been agreed that the main reason for the deterioration of structures is due to the expansion of the hardened cement and that the alteration of mechanical properties occurs as a result of this expansion. In recent years a series of papers has been published from this laboratory on the volume stability of cementitious pastes. The main object of this paper is to collect together the various ideas, put them in perspective and compare them with other theories.

The reactions between hardened cement paste and sulphate ions (disregarding the effects of cations for the present) can be broadly divided into three categories, in order of descending importance:

(i) formation of sulphoaluminates,
(ii) formation of gypsum,
(iii) other reactions catalyzed by the sulphate ions.

The effects of these reactions on the volume stability of hardened cement pastes will be discussed in the following sections. At the end, the effects of different cations on the rate of sulphate attack on hardened pastes will be discussed.

*Department of Crystallography, Birkbeck College, London, United Kingdom.

Formation of Sulphoaluminates

There are two types of sulphoaluminates that can form by the reaction between C_3A and sulphate ions in the presence of excess Ca^{2+} ions; these are $C_3A \cdot 3CaSO_4 \cdot 32H_2O$ (ettringite) and $C_3A \cdot CaSO_4 \cdot 11H_2O$ (monosulphate). In both the structures part or the whole of the Al^{3+} ions can be replaced by Fe^{3+} ions. Of these two sulphoaluminates, ettringite is stable in the presence of excess sulphate ions. Monosulphate forms when the sulphate ion concentration falls below the value at which ettringite is stable.

Two theories have been proposed connecting the formation of different sulphoaluminates with the volume expansion of hardened cement pastes. According to the earlier theory of Lafuma (1) the volume expansion is due to the formation of ettringite. It has been assumed that the ettringite formation can take place by two mechanisms. If the liquid phase containing sulphate ions is saturated with respect to $Ca(OH)_2$, the ettringite formation occurs through a solid state reaction between C_3A and SO_4^{2-} and Ca^{2+} ions from solution. A simple molar volume calculation shows that this reaction is accompanied by a volume increase of about 815% calculated on the basis of C_3A volume. But if the liquid phase is unsaturated with respect to $Ca(OH)_2$ the reaction goes through the liquid phase and the ettringite crystallization occurs in the pores present in the structure without causing any expansion. Until recently this was the only accepted theory of sulphate attack involving sulphoaluminate formation.

In 1963 another mechanism of sulphate attack was proposed, which does not involve ettringite formation as the cause of expansion (2). In this mechanism the expansion is attributed to the conversion of *pre-existing* C_4AH_{13} to monosulphate by reaction with SO_4^{2-} ions present in the liquid phase. The main experimental basis of this mechanism was an observation that in a $C_3A + Ca(OH)_2 + CaSO_4 \cdot 2H_2O$ paste, expansion had occurred when ettringite was disappearing and monosulphate was forming. This observation is very difficult to explain on the basis of Lafuma's theory. This observation has recently been confirmed by Seligmann and Greening (3). In a paste of $C_3A + Ca(OH)_2 + CaSO_4 \cdot 2H_2O$, having gypsum to aluminate molar ratio of $\frac{1}{4}$, they observed that most of expansion occurred during the disappearance of ettringite and formation of monosulphate.

The new mechanism can be put in the following terms. During hydration of cements the alumina bearing compounds first go into solution and then precipated out as hydrated compounds. The actual nature of the hydration compounds depends on temperature and concentrations of other ions present in the liquid phase. Taking the case of freshly ground portland cement, containing no CO_2 and hydrating at room temperature, the main alumina bearing compound will be ettringite as long as the sulphate ion concentration is high. When the sulphate ion concentration falls below the value necessary for ettringite formation, monosulphate may be precipitated if the sulphate ion concentration is high enough for monosulphate stability otherwise C_4AH_{13} will be precipitated. As the above reactions proceed through the liquid phase the reaction products will form in the pores present in the structure without causing any expansion. If the structure containing C_4AH_{13} is subsequently exposed to sulphate solutions, sulphate ions will start to diffuse inwards. When the sulphate ion concentration reaches a critical value monosulphate will start to form from C_4AH_{13} by an ion exchange process. This mode of monosulphate formation leads to volume expansion. On further increase in sulphate ion concentration, monosulphate will be converted to ettringite by a 'through-solution' process. These secondary ettringite crystals will be precipitated in the pores present in the structure without causing any significant expansion.

The volume expansion due to the formation of monosulphate from C_4AH_{13} may or may not be accommodated in the structure depending on the $Ca(OH)_2$ concentration in the liquid phase. If the $Ca(OH)_2$ concentration is low a part of the expanding C_4AH_{13} crystals will dissolve (being under compression) and diffuse out to other parts of the structure, thereby accommodating the expansion. If the concentration of $Ca(OH)_2$ is high in the liquid phase the solubility of C_4AH_{13} will be depressed, thereby making the accommodative process inoperative, and as a consequence there will be disruptive expansion.

It is to be noted that the formation of monosulphate by itself does not necessarily give rise to volume expansion. Volume expansion occurs only when it forms from C_4AH_{13} by an ion exchange process. It seems that some confusion has arisen by not noting this distinction (4). It follows from the above discussion that an anhydrous compound with SO_3/Al_2O_3

molar ratio 1 or less, e.g. C_4A_3S, will form monosulphate during dissolution and precipitation processes without causing any expansion.

One of the basic assumptions of this new mechanism is the formation of C_4AH_{13} in the paste, instead of C_4AH_{19} as is found in the phase equilibrium studies (5). The validity of this assumption has been confirmed by taking X-ray diagrams of moist clinker pastes in which the proportion of aluminate phase had been increased by adding C_3A. The X-ray diagram of these pastes showed the existence of C_4AH_{13} in the pastes (6).

Another assumption is that the formation of monosulphate from C_4AH_{13} is an ion exchange process. If this assumption is true then it should be possible to replace the SO_4^{2-} ions from the monosulphate structure by other ions / by placing the monosulphate crystals in a suitably concentrated solution of the appropriate ion. Take the case of portland cement paste containing both ettringite and monosulphate, in $CaCl_2$ solution of fairly high strength. Soon after placement of the paste in the chloride solution, the chloride ions will start to diffuse inwards from outside. When the concentration of chloride ion has reached the appropriate value monosulphate will be converted to monochloroaluminate, thereby releasing sulphate ions in the liquid phase. These freshly released sulphate ions can then migrate to other places and can convert any C_4AH_{13} crystals available to monosulphate causing further expansion; provided the sulphate ion concentration can reach the appropriate value. The chances of reaching this sulphate ion concentration will be more in a low w/c paste than in a high w/c paste, simply because the amount of diluting liquid phase present in the paste is less in the former than in the latter. In other words, the richer paste is expected to expand more, notwithstanding its higher strength, than the lean paste when placed in $CaCl_2$ solution. Recently, Heller and Ben-Yair (7) have published some results which seemed to corroborate the above expectations. In this work the authors exposed paste prisms made from (a) ground clinker and (b) portland cement to 3.5% calcium chloride solution and also to distilled water. They also made prisms from portland cement with w/c ratios of 0.3 and 0.5 which were also exposed to 3.5% calcium chloride solution. The authors found that "expansion of cement clinker exposed to chloride solutions ... resemble that in distilled water. Bars of normal portland cement, however, expand more in chloride solutions than in distilled water." From this they concluded that "addition of gypsum to ground clinker causes increased expansion in chloride solutions". Thus the chloride solutions, though themselves not giving rise to any expansion, cause expansion in the presence of sulphate. Furthermore, they also found that the portland cement prisms with low w/c expanded more than those with higher w/c ratio. Both these observations are in accordance with the proposed mechanism.

It follows from the proposed mechanism of sulphate expansion that if C_4AH_{13} can be converted to a more stable compound with a lower basal spacing then monosulphate, which changes directly to ettringite when exposed to sulphate solution, this should result in lower expansion. Monocarboaluminate (monocarbonate) seems to fulfil all these requirements (8,9). It is expected that the addition of finely ground $CaCO_3$ to portland cement will result in the formation of monocarbonate at the expense of C_4AH_{13}, and this should result in lower sulphate expansion on subsequent exposure to sulphate solutions. This corollary of the proposed mechanism has been verified recently (10).

It is evident that none of the above results are easily explained by Lafuma's theory. Another observation, which is also difficult to explain from the ettringite formation theory is that the same amount of ettringite formation in sulphate resistant cement causes less expansion than in the case of ordinary portland cement (11). This is easily explained by the proposed mechanism as a monosulphate type of compound does not seem to form in sulphate resistant cement (6).

Taking all the evidence it is clear that if sulphoalminate formation has anything to do with sulphate expansion, then monosulphate formation explains the observations better than ettringite formation.

Formation of Gypsum

Portland cement always liberates $Ca(OH)_2$ during its hydration. Matured portland cement pastes generally contain about 14% $Ca(OH)_2$. When these pastes are exposed to sulphate solutions, if the concentration of Ca^{2+} and SO_4^{2-} ions exceed the solubility product of gypsum, gypsum will be precipitated. As the

gypsum crystals are surrounded by a supersaturated solution they will grow even when they are under constraint, provided the constraining force is not higher than the 'crystal growth pressure' (12). The crystal growth pressure is a function of supersaturation. Thus if the conditions are appropriate, i.e. the supersaturation is high, the formation of gypsum may lead to expansion. Lea has earlier discussed the possibility of cement expansion due to gypsum formation on the tacit assumption that the gypsum formation is a reaction between solid $Ca(OH)_2$ and sulphate ions present in aggressive solutions (13). The assumption of a reaction between solid $Ca(OH)_2$ and SO_4^{2-} ions from solution is questionable in view of the fact that the structures of $Ca(OH)_2$ and $CaSO_4 \cdot 2H_2O$ are so different and the explanation in terms of crystal growth pressure seems preferable. This type of expansion assumes importance in the presence of magnesium sulphate solution, because of the low solubility of $Mg(OH)_2$.

Other Reaction Catalyzed by Sulphate Ions

From the above discussion it will appear that mortar prisms made from pure C_3S should not expand when exposed to gypsum solution. But Thorvaldson has found that even these mortars expand when exposed to gypsum solution for a long time (14). This result is rather difficult to explain as there is no possibility of any sulphoaluminate or gypsum formation. One possible explanation has been suggested by an observation that $Ca(OH)_2$ crystals grow more readily in the presence of gypsum (15). It is known that during C_3S hydration a certain amount of X-ray amorphous $Ca(OH)_2$ forms (16). In the presence of SO_4^{2-} ions these X-ray amorphous $Ca(OH)_2$ will start to recrystallize into bigger crystals, at the same time developing an expansive force (12). As this recrystallization process depends on double diffusion of SO_4^{2-} and $Ca(OH)_2$ it will be slow. It seems probable that in the case of portland cements similar expansion will also occur.

It is possible that other reactions may contribute to expansion under certain circumstances and investigation of this field is far from exhausted.

Effect of Cations

So far only the effects of sulphate ions have been discussed. Though these provide the basic reasons for expansion, the course of reaction is also effected by the cations. These cations can be divided into three general classes: (i) those forming very soluble hydroxides, e.g. Na^+, K^+ (ii) those forming sparingly soluble hydroxides, e.g. Mg^{2+}, Fe^{2+}, and (iii) those forming volatile or neutral compounds e.g. NH_4^+ or H^+.

The metal sulphates of the first group will form gypsum and highly soluble metal hydroxides. Depending upon the initial concentration of the metal sulphate, formation of gypsum may or may not develop an expansive 'crystal growth pressure'. But the formation of metal hydroxide will increase the OH^- ion concentration in the liquid phase; in a closed system equilibrium will soon be reached. This increase in OH^- ion concentration will firstly depress $Ca(OH)_2$ concentration in the liquid phase thereby bringing the expansion accommodative process into play. Secondly, this increase of OH^- ion concentration may attack other constituents of the structure thereby decreasing the strength of the whole. Thus two opposing forces will be brought into play if the system is a closed one. If on the other hand, the system is an open one, i.e. there is a continuous flow of sulphate solution, the concentration of OH^- ion in the liquid phase may not reach a high value and as a consequence the expansion accommodative process will not be operative and expansion may be severe.

The second group of metal sulphate solutions are very corrosive. None of the cementing materials is stable in their presence, the final products being gypsum, sparingly soluble metal hydroxide, silica and aluminium hydroxide gels. As against this extreme corrosiveness, these metal hydroxides form a protective coating by being precipitated all over the structure and thereby hindering further transport of ions to the reacting surfaces. Thus in the case of rich pastes this type of metal sulphate may be less aggressive than the other two types.

The third group of sulphates consist of $(NH_4)_2SO_4$ and H_2SO_4. In this case neither the accommodative process nor the protective coating formation can

occur. The attack is very vigorous and is not limited only to expansion but also includes weakening the strength of the paste by dissolving out the cementing components.

Acknowledgements

The author would like to thank Professor J. D. Bernal for his continued interest and encouragement in cement research. It is a pleasure for the author to acknowledge the help, advice and encouragement from Dr. J. W. Jeffery.

Oral Discussion

Arthur W. Brown

Dr. Chatterji proposes the theory that he and Dr. Jeffery initiated some 5 years ago, and does so with considerable supporting evidence.

Nevertheless I do not find it possible to accept this theory in the light of our experience to date. I would ask Dr. Chatterji what mechanism he suggests for sulphate attack on the many cements with tricalcium aluminate contents around 8% or less, where, after ettringite formation and its conversion to the mono-sulphoaluminate during hydration, there is little or nothing left to form the C_4AH_{13} as a basis for his mechanism of attack?

Our experience is that serious specimen damage occurs only after the appearance of ettringite in significant quantity.

After disagreeing with Dr. Chatterji I feel I must perhaps suggest some evidence in favour of his theory. We have found, as I believe have others, that the longer a specimen is cured in water before immersing in sulphate solutions, the more decisive is the effect of the sulphate. We also know that cements with high C_3A and therefore a good potential for the formation of C_4AH_{13} are attacked much more in relation to their C_3A contents than the O.P.C.'s with lower C_3A contents mentioned earlier. Is this perhaps significant?

Author's Closure

Susanta K. Chatterji

It is unfortunate that Mr. Brown did not specify either the nature of sulphate solution used in his experiments or the type of damage that resulted. As I have tried to show in my paper, there may be more

than one type of mechanism operation in any given situation. Without any further information it is impossible to suggest which mechanism was operative in the experiments carried out by Mr. Brown.

I would like to thank Mr. Brown for supplying me with some evidence in favour of one of the proposed mechanisms.

SESSION III-3 CARBONATION OF CONCRETE

Principal Paper Neutralization (Carbonation) of Concrete and Corrosion of Reinforcing Steel

Minoru Hamada*

Synopsis

Reinforced concrete structures have extremely long lives, but there have been cases of the reinforcing steel being corroded even in ordinary atmospheric environments. The purpose of this paper lies in defining the phenomena related to life spans of reinforced concrete structures, providing a guide for building high quality structures of long life and contributing to the sound development of reinforced concrete structures. The contents of the paper consist of a summarization of long-term studies carried out by the author and its group. The paper begins with a description of the experiments which motivated this research and with the theme presented by the author that neutralization (carbonation) of concrete has a relation with corrosion of reinforcing steel as the basis, considers the various factors influencing the rate of neutralization of concrete, describes through experiments the methods of determining neutralization connected with rusting of steel, introduces surveys made of actual buildings and further comments on the result of studies on special cases which have an effect on the life spans of reinforced concrete structures.

1. Purpose and Significance of the Study

Reinforced concrete structures, barring cases of dynamic failure or special types of chemical corrosion, are generally said to be of a semi-permanent nature.

In looking at actual reinforced concrete buildings, the first of which date back to about 70 years age, corrosion of steel has been noticed in recent years in relatively old buildings which have existed in normal atmospheric and other environmental conditions. It is desirable that the causes of such phenomena be pursued, if possible to place a numerical evaluation on the so-called semi-permanent life, and if occurrence of such phenomena is the fate of reinforced concrete, to find a method of prolonging the life.

In Japan, as a result of investigations of the Great San Francisco Earthquake of 1906, it became to be considered ideal for future buildings to be of reinforced concrete. However, in a country like Japan where the humidity is high, especially in the hot summer months, there is a question regarding the susceptibility of reinforcing steel to rusting, and therefore, durability tests under the conditions of natural exposure as described later were begun. The author, after twenty years of outdoor exposure tests, investigated the results obtained up to that time, the first study of its kind in the world.

From the results, it was ascertained that over the years the alkali of concrete is neutralized from the surface by carbon dioxide gas in the atmosphere, rusting beginning to take place when the neutralization reaches the reinforcing steel. Having determined that neutralization of concrete has a great influence on rusting of reinforcing steel, numerous studies were carried out centered around this problem. Method of evaluating the life of a building and of prolonging that life have been suggested to contribute to the sound development of future reinforced concrete structures. This paper is a summary of these many studies.

*Tokyo University of Science, Tokyo, Japan.

2. Origin of Studies

The experiments were motivated by the reasons stated in the preceding section and consisted of two groups.

2.1 Experiment No. 1 (1)

This experiment first began in the autumn of 1907 by the late Dr. Riki Sano. Specimens consisted of untreated steel and steel coated with rust preventive material. Also, these steels were embedded in concretes of various mix proportions and with varying coverages. These specimens numbered in the hundreds were placed outdoors in the atmosphere, indoors, in the earth and in ponds, and rusting of the steel was examined.

Unfortunately, there were a number of the specimens lost in later years and those which will be described hereafter were mainly specimens which had been placed outdoors in air.

Place of Exposure: A corner of a spacious inner court of a two-storied brick building of the Department of Architecture, Faculty of Engineering, University of Tokyo.

Steel: Round bars of 1/2-inch diameter, polished and embedded in the centers of various concretes.

Concrete: The mix proportions used were the six varieties given in Table 1 and the concrete was cast in prisms 15 cm × 15 cm × 60 cm. Some of the 1:3:6 mixes were 6 cm × 6 cm × 60 cm and 60 cm × 60 cm × 90 cm.

The mix proportions were by volume and although the concrete was relatively stiff no detailed records such as kept today were taken as this was in the early days of concrete technology. Neither was compaction of the concrete complete.

Survey: Of the several specimens, of each type remaining 20 years after manufacture, three or four each were broken and examined. The remainder were left for further long-term tests and presently a number of them still exist after 60 years.

Table 1. *Types of concrete in corrosion test*

No.	Mix proportion				
	Cement	Lime	Sand	Gravel	Cinder
1	1	0	1	2	0
2	1	0	2	4	0
3	1	0	3	6	0
4	1	0	5	10	0
5	1	2	4	8	0
6	1	0	2	0	4

Rusting: Results show that richness or leanness of concrete mix proportions and the degree of compaction have an important relation with the outcome.

2.2 Relation between Alkalinity Retained in Concrete and Rusting

It was well known at that time that steel would not rust if its environment was alkaline, but if this environment were neutralized, the steel would tend to rust. As it was readily assumable that the alkali of the concrete would gradually be neutralized from the surface inward by penetration of carbon dioxide gas in the atmosphere, the fractured surfaces of all of the specimens tested were examined by application of phenolphthalein reagent. This examination showed there was no rust to be seen when concrete in contact with steel was colored red while rusting had occurred without fail when the concrete in contact did not become colored. Table 2 shows that after 20 years the steel was mainly rusted in parts where compaction of concrete was inadequate and neutralization had progressed deep into the interior of the concrete at such parts.

Estimation of Time of Rusting of Steel in Reinforced Concrete: Judging from the above, even should

Table 2. *Rusting of steel in reinforced concrete at 20 years*

No. of type of concrete	Width of concrete prism		
	6 cm	15 cm	60 cm
1	—	No corrosion except for partial rusting at voids caused by poor compaction.	—
2	—	Ditto	—
3	Completely rusted concrete cracked longitudinally by expansion.	Ditto	Approximately 10% of surface of steel covered with red rust. Rusting where honeycombing existed.
4	—	Approximately 30% of surface of steel rusted. Mostly at parts of poor constitution.	—
5	—	Approximately 10% of surface of steel rusted. Mostly at parts of poor constitution.	—
6	—	Completely rusted.	—

Note: indicates no applicable test specimen.

the compaction of concrete be complete, when penetration of carbon dioxide gas reaches the steel, it is thought possible that rust can form at this time, a fact which provides an important basis for evaluation of the life of reinforced concrete.

The average depths of neutralization of 15-cm prisms included in the above-mentioned group of specimens are given in Table 3.

With rich mixes, the concret tends to be dense so that penetration of carbon dioxide gas is lessened and since the content of calcium hydroxide in the concrete is greater, the depth of neutralization is naturally less.

As the above specimens were not adequately compacted, it is assumable that the depth of neutralization would have been less if complete compaction had been obtained.

In the following, theorizing simply with the inclusion of some bold assumptions that for a given concrete the quantity of carbon dioxide gas reaching a depth, x, in a given time is proportionate to $\frac{1}{x}$, then the time, t, required for the depth, x, to be neutralized is $t = kx^2$, with k a constant based on mix proportions and placing practices. Considering water-cement ratio to be 0.60 in normal cases of concrete for buildings, and determining the constant, k, from results of concretes of the same quality as those in the specimens of the before-mentioned tests, $t = 7.2x^2$ (t: years, x: coverage in centimeters) is obtained. This, of sorts, is the equation for estimating life of reinforced concrete. (2)

Table 3. *Concrete mix proportions and depth of neutralization at 20 years*

Mix proportion	Depth of neutralization (cm)
1 : 1 : 2	0.65
1 : 2 : 4	1.4
1 : 3 : 6	3.3
1 : 5 : 10	4.3

2.3 Experiment No. 2 (3)

Since compaction of concrete in the above test had been unsatisfactory, Prof. Shozo Uchida, five years later, began similar tests in which placement of concrete was carried out as perfectly as possible. The results of these tests were extremely good and a similar equation, $t = 167x^2$, was formulated based on these tests. In other words, at the same water-cement ratio, merely the difference in constitution produces a life $167/7.2 \fallingdotseq 23$ times longer showing how much it is necessary to improve the constitution.

3. Test Studies of Neutralization of Concrete

3.1 Test Studies in Taiwan (4)~(9)

In Taiwan, corrosion of steel in reinforced concrete is more rapid than in Japan and the author upon conducting a survey pointed out high temperatures and influence of salt air as external conditions, and poor gradation of sand and use of too much water as internal conditions for this phenomenon. Later, the author planned and directed the making of 15 cm × 15 cm × 30 cm prisms of various mix proportions which were placed in the vicinity of Takao (Kaoshun) Lighthouse and in the city of Taipei upon which 1-year, 4-year and 9-year results were studied.

Table 4. *Tests in Taiwan*

Test location		Takao (Kaoshun)			Taipei			
Test period (yrs.)		1	4	9	1	4	9	19
Depth of neutralization (mm)	Portland cement	1.5–2.5	1.1–3.3	2.5–6.5	0.5	0–0.8	1–3.5	2–9.5
	Blast furnace slag cement	2.0–4.5	1.8–5.3	5.0–14.5	1–2.5	0.8–3.5	1.5–7.5	2.5–6.5*

*Maximum depth 36 mm

The results summarized are as follows:

a. The depths of neutralization of specimens at Takao were greater than those at Taipei, i.e., the rate of neutralization differs with climate.
b. Neutralization was considerably retarded in the case of dry-consistency concrete adequately compacted, i.e., neutralization progresses along voids.
c. Depth of neutralization is increased the greater the water-cement ratio.
d. A comparison of blast furnace slag cement and portland cement showed depth of neutralization of concrete using the former to be about twice that using the latter. This is due to less free $Ca(OH)_2$ in blast furnace slag cement.

These tests in Taiwan were carried out after thorough planning and were conducted on a very large scale. The carefully collected data provided valuable

information for later studies.

However, the specimens at Takao were evidently lost at the end of World War II and only those at Taipei now remain. Measurements of depths of neutralization after 19 years were recently carried out by Chinese engineers (10). It is reported that depths of neutralization have increased and the neutralization of blast furnace slag cement concrete has become extremely irregular.

3.2 Comparative Study of Various Concretes in Relation to Neutralization under Accelerated and Natural Conditions (Part 1) (11)

Outline

These experimental studies were conducted with the purpose of comparing various reinforced concrete specimens neutralized under identical conditions.

Accelerated tests were carried out along with natural exposure tests. The acceleration of neutralization was secured in an apparatus containing 15% carbon dioxide gas. Results of one year of accelerated tests and 4 measurements during $6\frac{1}{2}$ years of natural exposure tests establish the appropriateness of this method of accelerated testing which closely approximate the results obtained from exposure in the atmosphere.

It was also ascertained that use of surface-active agents markedly reduced the rate of neutralization and also that use of these agents in lightweight concrete made it possible to restrict neutralization in this type of concrete to about the same degree as in normal concrete.

Test Specimens

Test specimens were 40 cm × 40 cm × 15 cm in size each having three parallel ϕ — 9 mm steel bars covered with mill scale embedded in it. In order to be able to measure neutralization from the direction of the steel bars only, all surfaces of the specimens other than the surfaces perpendicular to the reinforcing steel were thoroughly coated with an asphalt-based paint. The types of specimens are listed in Table 5.

Method of Testing

The testing room was an air-tight chamber as shown in Fig. 1, into which carbon dioxide gas was directly introduced. The air inside the chamber was agitated with a fan. Regulation of the concentration of carbon dioxide gas was performed manually once every day. Outdoor exposure tests were carried out in the open air on the roof of the building of the Department of Architecture, Faculty of Engineering, University of Tokyo.

Table 5. *Types and general descriptions of test specimens*

Code	Type of concrete	General description
A I	Normal	W/C = 75% } Slump 21 cm, gravel 20 mm
A II	Ditto	W/C = 65% } sand 0.6 mm and under
A III	Ditto	W/C = 55% }
B I	Pozzolanic cement	W/C = 65%, other conditions same as above
C I	Air-entrained	AEA pozzolith } Other conditions
C II	Ditto	AEA vinsol resin } same as A II
D I	Pumicite	Asama pumicite, slump 21 cm, gravel 20 mm, sand 2.5 mm, diotomaceous earth 25 kg/m³
F I	Pumicite air-entrained	AEA pozzolith } Same as D I, no diotomaceous earth
F II	Ditto	AEA vinsol }
G I	Cinder	According to standard mix proportions for pumicite concrete, sand 2.5 mm, gravel 20 mm

F II	10.0	4.0	6.2	Slightly irregular, neutralization through aggregate
G I	26.0	7.0	14.2	Extremely irregular, neutralized portion slightly whitened

6 months and 1 year for the accelerated tests, and at 6 months, 1 year and $6\frac{1}{2}$ years for the outdoor tests. The results given here are for 1 year of accelerated tests and $6\frac{1}{2}$ years for the outdoor exposure tests. Tables 6 and 7 give the results of measurement of neutralization. Comparisons of depths of neutralization between accelerated-test specimens and exposure-test specimens are given in Table 8. A study of these comparisons shows the following:

a. Normal concrete is more readily neutralized the greater the water-cement ratio. Specimen AI, especially, showed extremely irregular depth of neutralization indicating the non-uniform constitution of the concrete. It was noticeable that neutralization had progressed along the surfaces of gravel which was probably because the cement paste at the undersides of gravel was more porous than at other parts due to bleeding and other causes.

b. The depth of neutralization of pozzolanic cement concrete was naturally greater than that of portland cement concrete because of less free $Ca(OH)_2$, being one and a half to two times greater. Concrete containing surface-active agents showed extremely small depth of neutralization. This was probably because of smaller water-cement ratios and consequently denser cement paste and also because of dispersion of cement particles. In lightweight aggregate concrete, neutralization was extremely great when diatomaceous earth was contained. Especially, in concrete using coal cinders, the neutralized portions had reached the reinforcement and rust had already formed. It was found that addition of surfactants to lightweight concrete will provide improvements to a level equal to or better than normal concrete.

In considering the acceleration rate in tests using carbon dioxide gas it is generally necessary to know the acceleration rate over the natural exposure tests.

Table 8. *Neutralization ratios of specimens (1-year acceleration, 6 1/2-year natural exposure)*

Type of concrete	Code of concrete compared

FII (Pumicite, AE concrete, vinsol resin)	0.68 0.83	0.95 2.06	1.42 4.13	0.77 1.00	2.83 4.13	1.42 3.44	0.43 0.48	1.42 1.35		0.38 0.11
GI (Cinder)	1.80 1.90	0.25 4.74	3.75 9.45	2.04 2.29	7.50 9.45	3.75 7.89	1.12 1.09	3.75 3.09	2.65 2.29	

Note: Upper figures neutralization ratios for tests in carbon dioxide chamber. Lower figures for outdoor exposure tests. Examples of comparisons: Depth of neutralization of pumicite concrete (DI) in carbon dioxide is 1.6 times AI, 2.22 times AII, in open air 1.73 times AI, 4.33 times AII, etc.

The relation between the rate of neutralization in air containing 15% carbon dioxide gas adopted for these

tests and that of open air containing 0.02 to 0.05% was thus investigated. In regard to this, there was a formula induced by the author with the assumption that the rate of neutralization is proportionate to the concentration of carbon dioxide gas. This formula may have been appropriate when the concentration was low, but in accelerated tests such as considered, in which the concentration of the gas would be high, the formula was thought to be inapplicable. Interpolating linearly to obtain the results for 2 months from the accelerated test data for 1 month and 6 months and comparing with the results of $6\frac{1}{2}$ years of natural exposure a good approximation can be seen. In other words, in these accelerated tests with carbon dioxide gas, it was found there was an acceleration of approximately 40 times expressed in terms of the period required for neutralization. Since natural exposure tests of this kind require a long time the practical significance of accelerated tests is great.

3.3 Comparative Study of Various Concretes in Relation to Neutralization under Accelerated and Natural Conditions (Part 2) (12)

Outline

Following on the tests conducted as described in 3.2, various concretes were similarly tested for neutralization under identical conditions and compared. This time, the condition of exposure indoors was added and neutralization of concrete under the three conditions of accelerated tests, outdoor tests and indoor tests were measured.

The accelerated tests were conducted for 6 months and the outdoor and indoor tests for 5 years. The results were generally the same as those described in 3.2. It was noted that there was considerable difference in neutralization occurring indoors and outdoors and the ratios of depth of neutralization for the different conditions were studied.

Table 9. *Comparison between estimated and natural exposure value of neutralization*

Type of concrete	AI	AII	AIII	BI	CI	CII	DI	FI	FII	GI
Estimated value of neutralization at 2 month acceleration	5.6	4.1	2.2	8.6	1.8	2.7	13.2	4.0	7.0	12.6
Neutralization at 6 1/2 years of outdoor exposure	7.5	3.0	1.5	6.2	1.5	1.8	13.0	4.6	6.2	12.5

Materials

Four types of cement were used. These were normal portland cement, high-early strength portland cement, blast furnace slag cement and pozzolanic cement.

The aggregates used were river sand, volcanic pumicite and coal cinders. Among other materials, 4 types of surface-active agents, Pozzolith, Lissapol, Vinsol Resin and Darex were used, each in standard amounts.

Test Specimens

The test specimens were 15 cm × 15 cm × 30 cm prisms each with a ϕ–13 mm steel bar embedded in the center. Mill scale was removed from the steel bars with sandpaper after which the bars were thoroughly washed with hydrochloric acid and again with water before they were embedded. The varieties of specimens tested are given in Table 10. The specimens were cured for 4 weeks in moist sand and for another 4 weeks indoors in the air. The tests began from the age of 8 weeks. To measure neutralization only from the top and bottom surfaces of the concrete placed, polyvinyl chloride paint was applied to the sides of the specimens to prevent neutralization from these two surfaces.

Methods of Testing

a. Outdoor Exposure: Rooftop of Building. No. 1,

Department of Architecture, Faculty of Engineering, University of Tokyo. (Concentration of carbon dioxide gas: 0.02–0.03%)

b. Indoor Exposure: Interior of room facing inner court of Building No.1, Faculty of Engineering, University of Tokyo, not too frequently entered by people. (Concentration of carbon dioxide gas: 0.04–0.05%)

c. Accelerated Carbon Dioxide Gas Test: Accelerated neutralization test chamber described in 3.2, 15% carbon dioxide gas concentration, 85% humidity, normal temperature.

Test Results

The depths of neutralization at 6 months of acceleration were as shown in Table 11. The results of outdoor and indoor exposure for 5 years are given in Table 12. The results of accelerated tests as clearly shown in the table indicate that:

a. The general trend of the extent of resistance to neutralization was approximately the same as the results described in 3.2.

b. Concretes containing surface-active agents, both normal and lightweight, had slow neutralization rates indicating their high resistance to neutralization. There were differences according to the types of surface-active agents, those with high dispersing effects producing better results than those which were simple foaming agents.

c. There were no differences in depths of neutralization between surfaces which were at top and bottom of concrete at the time of placement. This was because the height of the placement was not very great.

The comparison of rate of neutralization caused by outdoor and indoor exposure is as given in Table 13. The following may be said from the results:

a. The neutralization rate of various normal concretes using river sand and gravel as aggregates were approximately the same for outdoor, indoor and accelerated tests. On the other hand, in the case of lightweight concrete, the rate was approximately the same for indoor and accelerated tests whereas in outdoor testing there were many cases where the rates were higher. This is considered to be because lightweight concrete is porous and absorptive, and therefore, in the case of these tests in which no cover was provided on the concrete against the outdoor exposure, such things as the leaching of lime from the concrete by rainwater were disadvantageous in respect to neutralization.

b. From the above, it can be said that in the case of normal concrete, the accelerated tests using carbon dioxide gas agree well with both outdoor and indoor tests, but in the case of lightweight concrete the accelerated test agrees well with indoor tests, but not always with outdoor exposure tests. However, with lightweight concrete containing a surface-active agent with good dispersing qualities, the results of carbon dioxide gas accelerated tests agree well with both outdoor and indoor test results.

c. Throughout the three types of tests, the concretes in order from the slowest rate of neutralization were normal concrete containing a surface-active agent, high-early strength cement concrete, normal concrete for dry consistency, normal concrete, lightweight concrete with a surface-active agent, blast furnace slag cement concrete and pozzolanic cement concrete.

d. In general, blended cements are neutralized more quickly than portland cements. Although the ratio of neutralization depth differs according to tests, it is roughly between 1.1 and 2.3 depending on the type of cement and the various conditions of the concrete.

In comparing neutralization from outdoor and indoor exposure, it was found the neutralization indoors had progressed more than that outdoors, being 1.0 to 3.0 times deeper. This is because of the influence of rainwater in the case of outdoor natural exposure in which the voids in the concrete are filled with water making it difficult for carbon dioxide gas to penetrate the concrete, and also because the concentration of carbon dioxide gas indoors is slightly higher. This tendency has been found in investigations of neutralization in actual buildings.

From the above, the following conclusions are obtained:

Table 11. *Depth of neutralization at 6 months acceleration*

* "Top" and "Bottom" indicate top and bottom surfaces respectively at time of concrete placement.
**Figures in ( ) indicate ratio of average of two surfaces.

a. In normal concrete, there is less tendency of neutralization the lower the water-cement ratio and the higher the cement content.

b. Surface-active agents for concrete markedly reduce the rate of neutralization. However, the effect will differ according to the type of agent, the results being better the higher the dispersing action.

c. Neutralization occurs more rapidly with blended cements than with portland cements. The ratio of the depth of neutralization differs considerably according to the variety of cement and the conditions under which the cement is used.

d. The neutralization of plain lightweight concrete is rapid, but when surface-active agents are used, the resistance is greatly improved. The surfactants are better the higher the dispersing qualities.

e. The neutralization of cinder concrete is rapid. Considerable improvement can be obtained by use of a dispersing agent, but even this is not sufficient. Also, there is fear of corrosion of reinforcing steel from sulphur compounds contained in the aggregate.

f. The neutralization ratios of various concretes under the three conditions, acceleration, natural exposure and deposit indoors, roughly approximate each other in the case of normal concrete, but with lightweight concrete, the ratio is somewhat different for natural exposure.

g. In the case of natural exposure, neutralization is more rapid indoors than outdoors.

3.4 Tests of Influence of Fly Ash on Neutralization of Lightweight Aggregate Concrete (13)

Outline

The poor workability of lightweight concrete can be improved by the use of fly ash. However, it is conceivable the calcium hydroxide produced by the hydration of cement will react with the fly ash to form an insoluble compound. The tests conducted were for the purpose of studying this point. It was found that the use of a water-reducing agent along with the fly ash would result in neutralization of roughly the same extent as lightweight concrete without fly ash, but from the viewpoint of durability it is desirable to use a water-reducing agent alone for the improvement of workability of lightweight concrete.

Test Specimens

The specimens were 15 cm × 15 cm × 30 cm prisms with ϕ–13 mm polished steel bars embedded at a depth to obtain a 3-cm coverage. The concretes were as shown in Table 14. Normal portland cement was used as cement, Asama natural pumicite as lightweight aggregate both fine and coarse, and Pozzolith as a water-reducing agent. The specimens were cured for 2 weeks in water after which they were air-cured to the ages of 4 and 13 weeks.

Method of Testing

As described previously, measurements were made at 1 month and 6 months of accelerated testing with carbon dioxide gas and at 4 years of outdoor and indoor testing.

Test Results

The test results are shown in Tables 15 and 16. These tables give the results of 4 years of natural outdoor exposure, 4 years of deposit indoors, 1 month and 6 months of acceleration. The neutralization ratios obtained from the study of these data are given in Table 17, while the comparison by condition in order to see the difference according to conditions of the test is shown in Table 18. As is clearly seen from the

Acceleration (18 mos) Neutralization in progress	4.0	4.8	3.3	4.3	8.9	5.3	3.0	4.2	4.7
Acceleration (6 mos)	0.9	1.1	0.9	0.8	1.2	0.7	0.6	1.0	0.9

results:

a. When fly ash is added without the use together with a water-reducing agent, the rate of neutralization is 1.1 to 2.3 times more rapid than plain lightweight concrete for all conditions.

b. When both fly ash and a water-reducing agent are added, the rate of neutralization is slightly slower. This indicates the beneficial effect of the water-reducing agent. However, when cement content is reduced, the neutralization is great.

c. Compared with the case of addition of a water-reducing agent only, the addition of fly ash with the water-reducing agent results in more rapid neutralization under all conditions.

d. Parenthetically, when fly ash is to be used, the use of a water-reducing agent together with the fly-ash will slow down neutralization to an extent.

e. The depths of neutralization for 6 months of acceleration and 4 years of outdoor exposure are about the same. Therefore, the acceleration factor for lightweight concrete is 8. The neutralization of specimens left standing indoors is more rapid than those subjected to outdoor exposure, being approximately 2.2 times faster.

3.5 Relation between the Factors of Concrete Materials and Mix Proportions and the Rate of Neutralization (14)

Various combinations of factors are now studied centered about the experiments of the author.

Variety of Cement and Neutralization

As contemplated in 3.1 to 3.4, the rate of neutralization differs considerably between portland cement and blended cement. The comparison of neutralization of these cements as obtained from various test results is as shown in Table 19. When blended cement or a pozzolanic admixture is used, the neutralization is rapid so that for the improvement of durability of reinforced concrete structures, portland cement should be used. Of portland cements, high-early strength portland cement produces slower neutralization than normal portland cement for even better results.

Variety of Aggregate and Neutralization

Of the aggregates used for concrete, normal river sand, river gravel and crushed stone are dense and hard so that they are less air-permeable than the cement paste and neutralization will therefore progress through the paste. However, in the case of lightweight aggregate for lightweight concrete, the aggregate itself has large voids and the permeability is great so that neutralization will progress through the aggregate also. Therefore, neutralization is generally more rapid than in normal concrete. The test results may be summarized as shown in Table 20. It is seen that neutralization of lightweight aggregate concrete is extremely more rapid than normal concrete and that the use of pozzolanic admixtures is of great disadvantage from the standpoint of durability. However, this neutralization can be slowed down by the use of water-reducing agents and air-entraining agents.

Table 19. *Scopes and averages of depths of neutralization ratios using mixed cement*

Test condition	Portland cement		Blast furnace slag cement		Pozzolanic cement	Fly ash mixture (Cement replacement 15–20%)
	Normal	High-early strength	Slag (30–40%)	Slag (60%)		
Carbon dioxide gas acceleration	1	0.4	1.1–2.3 1.8	2.1–2.2 2.2	1.2–2.8 1.9	1.6–2.8 2.3
Outdoor exposure	1	0.6	1.1	—	1.3–2.1 1.7	1.9–2.4 2.2
Indoor deposit	1	0.7	1.3	—	1.4	1.1–1.2 1.2
Average	1	0.6	1.4	2.2	1.7	1.9

Types of Surface-Active Agents and Neutralization

There are various advantages of using surfactants such as airentraining agents and water-reducing agents. The water-cement ratio is reduced, cement particles are dispersed and dense concrete is obtained to slow down neutralization so that the use of a surface-active agent would be highly beneficial in improving the durability of reinforced concrete buildings. A gross summarization of these studies would be somewhat as given in Table 21. In other words, when a surface-active agent is used, the neutralization of normal concrete and lightweight concrete both become slower by about the same ratio. Compared with plain concretes, it may be considered the ratio is 0.6 for air-entraining agents and 0.4 for waterreducing agents. Therefore, if a high-performance water-reducing agent is used, concrete of good durability can be obtained even with reduction in cement content.

Water-Cement Ratio and Neutralization

In general, neutralization of concrete is slower the lower the water-cement ratio. This is because the cement paste is more dense. This is clearly seen from Tables 22 and 23 which summarize the relation between water-cement ratio and neutralization ratio.

The author, from the tests described in 2.1 and from some amount of theoretical considerations, has induced the following formula for progress of neutralization. (2)

Table 20. *Scopes and averages of depths of neutralization ratios of lightweight concrete (Cement used; normal portland)*

Test condition	Normal concrete (plain)	Lightweight concrete (Pumicite fine and coarse aggregate)			
		Pumicite, plain or with diotomaceous earth	Cinder, plain	Pumicite, AEA	Pumicite, dispersing agent
Carbon dioxide gas acceleration	1	2.2–4.0 2.9	2.5–4.0 3.1	0.9–2.0 1.6	0.7–1.5 1.1
Outdoor exposure	1	3.0–4.3 3.6	3.0–5.2 4.3	1.5–3.2 2.5	1.0–1.5 1.2
Indoor deposit	1	2.3	2.6	1.4	1.0
Average	1	2.9	3.2	1.8	1.1
			River sand, pumicite gravel, AEA 0.8

0.55	AEA	10 (0.7)	12 (0.7)	1.5 (0.8)	1.8 (0.6)

Note: Cases of use of dispersing agents not included.

Table 23. *Ratios of depths of neutralization according to water-cement ratios*
(Normal concrete, depths of neutralization in mm, figures in parentheses denote ratio to water-cement ratio of 60%)

Type of concrete		Test condition		
W/C	Admixture	6 mos. carbon dioxide gas acceleration	5 yrs. outdoor exposure	5 yrs. indoor deposit
0.71	None	13.5 (1.4)	2.8 (1.1)	7.8 (1.1)
0.60	None	10.0 (1)	2.6 (1)	6.9 (1)
0.52	None	3.5 (0.4)	1.6 (0.6)	3.8 (0.6)
0.54	AEA	3.0(0.3)	1.5 (0.6)	3.3 (0.5)
0.55	AEA	6.5 (0.7)	1.8 (0.7)	5.3 (0.8)
0.54	AEA	4.0 (0.4)	1.7 (0.7)	3.3 (0.5)

Note: Cases of use of dispersing agents not included.

$$t = kx^2$$

where

$$k = \frac{0.3(1.15 + 3w)}{(w - 0.25)^2}$$

for plain concrete using portland cement and normal aggregates,

w: water-cement ratio
t: period of time (years)
x: depth of neutralization (cm)

Ratio of Neutralization according to Factor of Concrete

The effects on neutralization of various materials used in concrete obtained from the tests of 3.2 to 3.4 and expressed as ratios are as shown in Table 24.

Introducing these in the equation in 3.5, the following is obtained:

$$t = \frac{k}{R^2}x^2$$

where

$R = r_c \times r_a \times r_s$ (see Table 24)

This may be used to calculate the depths of neutralization and the periods required for neutralization of various concretes.

Table 24. *Depth of neutralization ratio by factor*

4. Investigations of Reinforced Concrete Buildings

4.1 Case No. 1 (A Bank Building) (14)

The building in this investigation was well built with adequately thick surface finish and appreciately great coverage provided for the reinforcing steel. A period of 37 years had elapsed since completion during which time maintenance and upkeep of the building had been satisfactory. The concrete had been proportioned by volume at a ratio of about 1: 2: 3.3 and had been of a wet consistency causing a great amount of laitance to occur at construction joints.

Table 25. *Outline of investigations*

Case investigated		1	2	3	4	5
Outline of building	Use	Bank	Apartment house	Elementary school	Office	(Various)
	Scale	Reinforced concrete, 5 stories, 1 basement	Reinforced concrete, 3 stories, 1 basement	Reinforced concrete, 3 stories	Reinforced concrete, 3 stories, 1 basement	22 buildings
	Floor area m²	4451	446	1246	3580	
	Location	Tokyo	Tokyo	Yamagata	Hokkaido	Tokyo
	Completion	1921	1924	1937	1938	1912–1940
Year of investigation		1958	1958	1947	1959	1950–1952
Years from completion		37	34	10	21	10–38
Portions of buildings investigated		Entire building	Basement	Above ground level	Entire building	Columns, walls
Investigator		K. Kishitani	K. Kishitani	M. Hamada	T. Nishi, T. Koh	S. Takenouchi
Remarks		Concrete containing silicate admixture $F_c = 200 - 300$ kg/cm² Mix ratio by volume, 1:2:3.3 Good workmanship in finish	$F_c = 320$ kg/cm² Adjacent to river estuary	Lean mix containing pozzolanic cement Structural strength inadequate Dimensions of members less than designed Heavily snowbound	Use of building frequently altered	Various buildings subjected to fire damage

The depths of neutralization of concrete at various parts of this building were as are shown in Table 26. The summarization according to thickness of finish is given in Fig. 2. Generally speaking, columns, partition walls and interior surfaces of outer walls showed less neutralization the greater the thickness of the finish. The considerable scatter in the values is thought to be due to the quality of surface finish (for example, whether or not painting had been performed), the quality of concrete, and the conditions under which the building was used.

The exterior surfaces of outer walls were covered with polished granite slabs so that the thickness of the finish was not less than 30 mm. In this case, the depth of neutralization was only 10 mm regardless of the thickness so that it may be said the finish was good for durability. However, wherever neutralization had progressed to reinforcing steel, the steel in almost all cases showed formation of rust.

4.2 Case No. 2 (The Basement of an Apartment House) (14)

The building investigated had a road in front and a levee wall of the Sumida River estuary approximately 1.5 meters behind the back wall. There was evidence of river water (salt water) having entered the basement during floods.

The depth of neutralization of the interior concrete was of an ordinary degree as seen from a comparison of the measurement values in Table 26 with an average value of about 21 mm* for a period after completion of approximately 34 years. No rusting at all could be observed on the steel in concrete above ground, but in the basement, the corrosion of steel in columns and ends of undersides of beams was severe with large cracks formed in the concrete coverage. Upon measuring the salt content in the finish plaster and concrete, it was found to be extremely high as shown in Table 27. In general, the allowable limits for salt contained in concrete materials are 0.04% for water and 0.01% for sand. This converted to salt in oven dry concrete is 0.004%. Therefore, it was seen in the basement of this building that although the neutralization was of a normal extent, there was severe rusting of reinforcing steel due to salt.

The thickness of the plaster coating was from 10 to 20 mm which is considered to have been relatively ineffective in preventing neutralization of concrete.

4.3 Case No. 3 (An Elementary School Building)

The building in this case was constructed in a snowy region and already after 10 years from construction the concrete had been neutralized to depths of 50 to 90 mm. The mortar on the outside was loosened, the reinforcing steel was rusted to push the concrete cover outwards and cracks could be seen everywhere. However, the main reinforcement in the frame, even where the concrete was almost entirely neutralized, was not rusted on the inner side. The reasons for such extremely rapid neutralization are thought to be the following:

1) Use of pozzolanic cement in the concrete mix
2) Extreme infiltration of water from snowfall

*$t = 7.2x^2$; when $t = 34$ years then $x = 2.1$ cm.

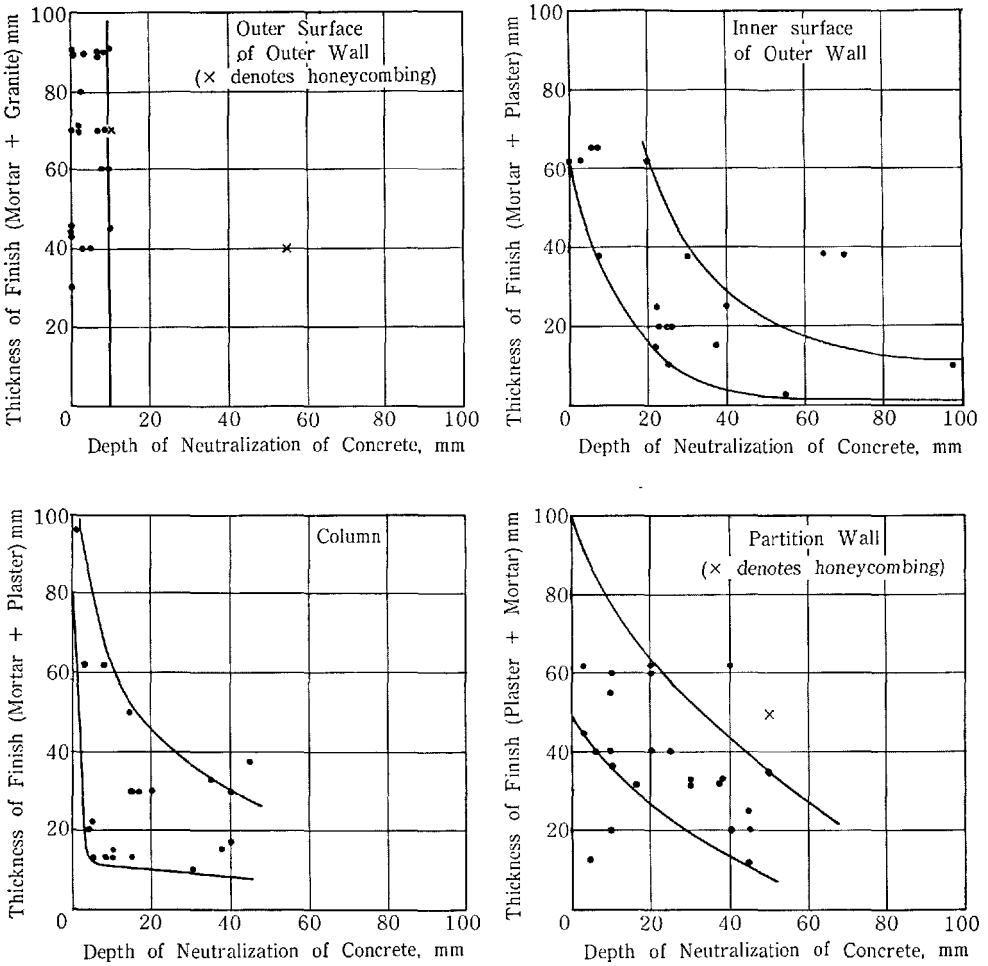

Fig. 2. *Relation between depth of neutralization of concrete and thickness of finish*

4.4 Case No. 4 (An Office Building) (15)

The building in this case had been constructed in Hokkaido, an area of cold climate.

The purposes for which the rooms in the building had been used had been frequently changed during the 21 years from completion. The average depth of neutralization was 34.5 mm with averages of the various rooms ranging between 21.7 mm and 47.5 mm.

The depths of neutralization by purpose of use of room are given in Table 28. According to the investigation, the rooms with histories of use with a great many prople working in them tended to show greater neutralization. Due to the geographic conditions, this building was heated for long periods in the wintertime so that the air in the interior was dry while ventilation was inadequate and it is considered concentrations of carbon dioxide were high. Therefore, the depth of neutralization was great overall. It was indicated that such methods of finish as coating plaster with paint of low air-permeability or covering concrete with air-tight material are effective in hindering neutralization.

4.5 Case No. 5 (Fire-Damaged Buildings) (16)

Twenty-two reinforced concrete buildings subjected to fire in World War II were selected at random and about 10 parts of each building on the average, mostly interior columns and walls, ranging from undamaged by fire to heavily damaged by fire were measured for

Table 26. *Depths of neutralization of concrete in buildings investigated, cases 1 to 4*

depth of neutralization.

As a result of the investigation, the items described below were brought to light.

Fire-Damage and Neutralization

The black dots in Fig. 3 indicate portions of concrete considerably damaged by fire. The finish coat on

reinforced concrete such as mortar or plaster, if damaged to some extent during a fire, will be loosened from the concrete and will then drop off in many cases. Most of the black dots represent portions of concrete where this had happened so that the concrete surfaces were directly subjected to fire and heat to a considerable degree becoming discolored and crazed with hair cracks. These portions were distributed over wide areas and in every building the neutralization at these portions had distinctly progressed to a much greater extent than portions unharmed by fire. Since the investigation was conducted several years after suffering damage, and the buildings had been left in fire-gutted condition, it should be considered that the damaged portions were even more neutralized during this time.

The dots crossed with bars represent portions which had been subjected to some degree of fire damage with the surface finishes still existing so that fire damage to concrete was extremely light. The neutralization was extremely light compared to the black dots.

The open dots indicate portions completely escaping fire damage and in general neutralization had occurred to an even lesser degree than the portions represented by dots crossed with bars.

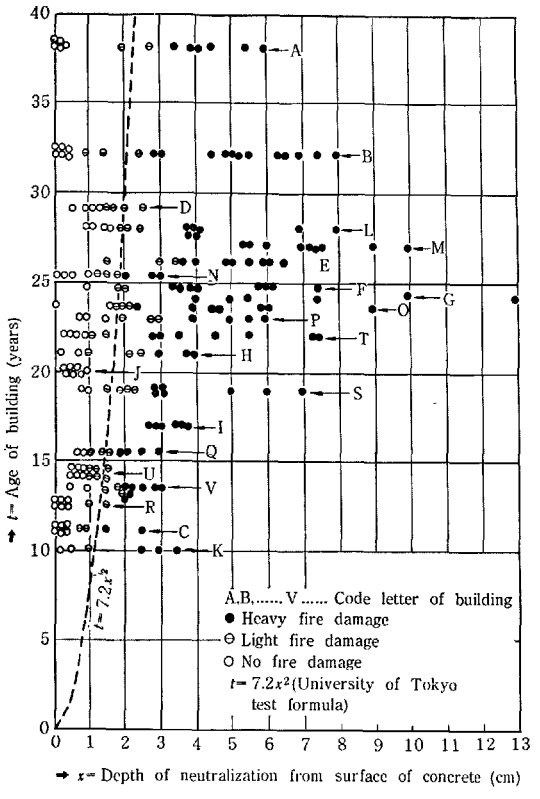

Fig. 3. *Fire-damage and neutralization*

Neutralization and Lapse of Time

The relation between depth of neutralization and age based on Fig. 3 on concrete completely escaping fire damage modified to neglect the thicknesses of surface finishes would be as is given in Fig. 4. It should be kept in mind, however, that the protective effect of the same thickness of surface finish will differ according to the material and the quality of the work. Almost all of the buildings investigated had concrete covered with ordinary finishes, mortar or plaster. The trend in the case of finish thicknesses of 1 to 2 cm was as is indicated by the broken lines in the figure.

Corrosion of Reinforcing Steel

Little corrosion of steel could be seen in parts which had escaped fire even when the depth of neutralization had progressed to near the location of the steel. In portions subjected to fire damage, since neutralization had progressed to considerable depths and because concrete had been cracked and made porous by fire, formation of rust could be seen in many cases. It appeared that in portions exposed to rain and wind the rusting was especially rapid.

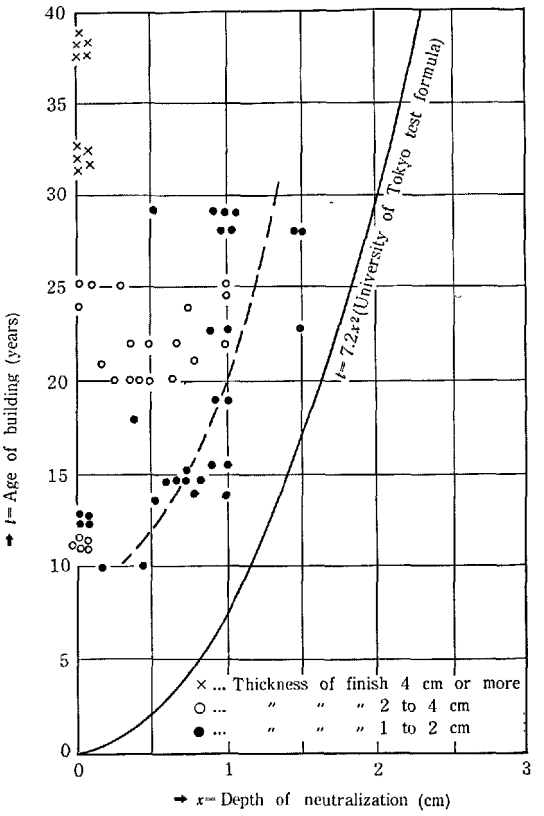

Fig. 4. *Relation between depth of neutralization and age on concrete escaping fire damage*

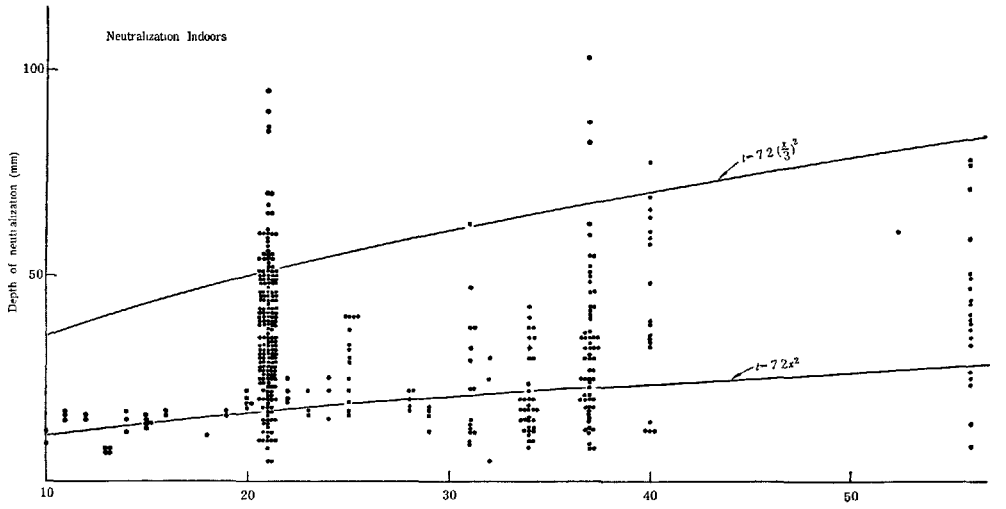

Fig. 5. *Relation between depth of neutralization indoors and age*

In investigations conducted by other researchers, which are not many, there was a case of an office building constructed in 1910 which was well-built for that time and was maintained in good condition. Although there were portions on the interior which had been neutralized to depths of 25 to 80 mm, it is reported no formation of rust could be recognized.

4.6 Neutralization of Concrete and Rusting of Reinforcing Steel as seen from Cases Investigated

1) Neutralization is rapid when the concrete is of a poor mixture. Neutralization of concrete containing blended cement such as pozzolanic cement is especially rapid.

2) Plaster is not effective against neutralization while mortar is effective.

3) When concrete is covered with materials impermeable to water or air, such as tile and stone, the rate of neutralization is reduced.

4) Neutralization occurs more rapidly indoors than outdoors.

5) The relation between depth of neutralization indoors and age according to the investigations and other references can be illustrated as in Fig. 5. It is readily seen that neutralization is 1 to 3 times greater indoors than outdoors as described in Chapter 3.

6) As special cases, when there is action of salt, reinforcing steel in concrete will be heavily rusted without regard to neutralization, and when the concrete is subjected to fire, neutralization is accelerated and the steel will be rusted.

7) When concrete is neutralized, the reinforcing steel in the neutralized portion is rusted in many cases, but this is not always true depending on the conditions. These conditions are, for example, that the concrete is relatively dense and of low air-permeability and furthermore faces a relatively dry interior of a building.

5. Functions of Neutralization and Steel Corrosion

5.1 Function of Neutralization

In order to study the function of neutralization of concrete it would appear first necessary to consider the constitution of hardened concrete. Meyers (17) stated that certain types of aggregates will release alkalis when subjected to the action of carbon dioxide to raise the possibility of alkali-aggregate reaction. However, since most aggregates are inert against carbon dioxide, it may be said that of the components of concrete, only the hydration products of cement have a relation with neutralization. According to Copeland and Kantro, (18) calcium hydroxide, tobermorite gel, ettringite, calcium aluminate monosulphate hydrates, calcium aluminum hydrates, calcium ferrite hydrates, hydrogarnets, etc. are contained in hydration products

of portland cement. Of these hydration products, calcium hydroxide, when subjected to action of carbon dioxide in the presence of a suitable amount of moisture, will readily react with the carbon dioxide to produce calcium carbonate and water. Although it may be thought that the hydration products other than calcium hydroxide are relatively unaffected by carbon dioxide, according to the studies of Meyers, Lieber and Blakey (19), and Verbeck (20), it was indicated that all hydration products of portland cement will react with carbon dioxide subjected to pressures of one atmosphere or more. Also Steinour (21) concluded from results of experiments and physicochemical considerations it is possible for the hydration products of portland cement even in normal atmosphere to be decomposed by minute quantities of carbon dioxide contained in them to be changed into calcium carbonate, hydrous silica, alumina and ferric oxide.

However, the degree and rate of carbonation of concrete will depend not only on the concentration and pressure of the carbon dioxide in the surrounding atmosphere, but also very much on such factors as the cement content, moisture content, porosity, permeability, internal relative humidity, etc. of the concrete.

Verbeck, using $1 \times 1 \times 1\frac{1}{4}$ inch mortar specimens in studying the relation between relative humidity and the rate of carbonation, reported that rate of carbonation is extremely high at relative humidities of 50 and 75% and low at 100 and 25%. He explains the low rate of carbonation at relative humidity of 100% to be because the pores of cement paste are filled with water at such high humidity so that carbon dioxide must first be dissolved in the water and then gradually be dispersed into the interior, this dispersion being slower than when the pores are not filled with water so that carbon dioxide is able to be dispersed into the interior in the form of gas. As for the low rate of carbonation at relative humidity of 25%, this is explained by the scarcity of relatively free water necessary for carbonation.

Powers (22) states that when the moisture in hydrated cement paste is 45% or less the water in the paste loses the characteristics of liquid water so that it is incapable of dissolving calcium hydroxide making it impossible for the latter to be spread through the gel pores thus slowing the rate of carbonation. Powers also assumes that the hydration products other than calcium hydroxide in hydrated cement paste contain two kinds of calcium ions, one of which is relatively susceptible to the action of carbon dioxide and the other relatively insusceptible to such action, and the relatively susceptible calcium ions at the outer parts are combined topochemically with carbon dioxide, but are not broken off from the gel structure.

The question of whether one of the components of the hydration products of cement in concrete reacts with carbon dioxide or whether many components react in parallel is answered by Powers that calcium hydroxide easily reacts with carbon dioxide, but only part of the other hydration products is reactive while the remainder does not readily react, so that at the beginning of carbonation calcium hydroxide and a part of the other hydration products react with carbon dioxide.

5.2 Neutralization and Steel Corrosion

The author, as one method of learning of the formation of rust on steel in reinforced concrete, studied whether rusting could be predicted by spontaneous electrode potentials immersing steel bars in calcium hydroxide solutions of differing hydrogenion concentrations and measuring the spontaneous electrode potentials and amounts of corrosion of the steel. The steels used were ϕ–5 × 100 mm bars polished with emery paper and washed thoroughly with alcohol and ether to remove adhering organics and ϕ–9 × 100 mm unpolished bars with mill scale from which organics were removed in the same manner.

The polished bars were immersed in 10 different solutions varying between pH of 7.0 to 12.0 adjusted with calcium hydroxide and the spontaneous electrode potentials were measured. The unpolished bars were immersed in 7 different solutions varying between pH to 7.0 to 12.0 and again the spontaneous electrode potentials were measured.

The amount of corrosion was measured only on polished bars. The method of measurement was to take out the polished bars from the solutions at the designated ages, wash them in hot solutions of 10% ammonium citrate, washing again with alcohol and

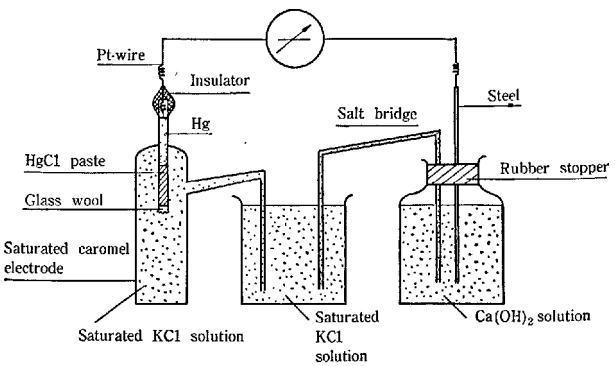

Fig. 6. *Spontaneous potential measuring apparatus*

drying to measure the weight loss. The amount of corrosion was expressed by the weight loss per unit area.

Test Results and Considerations

The changes in electrode potentials of polished steel in calcium hydroxide solutions of different hydrogen ion concentrations are given in Table 29 and Fig. 7 while the changes for unpolished steel are given in Table 30 and Fig. 8. In looking at the electrode potential variation of polished steel, no drop could be seen in calcium hydroxide solution with pH of 12.0; even after 96 hours the electrode potential still had not dropped. In solution of pH 11.0, there was a slight rise at 30 minutes after which the potential began to drop and a clear tendency of the steel to corrode could be seen. In solution of pH $\leqq$ 10.5, there was a very rapid drop in electrode potential with elapse of time. To summarize, in solutions of pH $>$ 11, there was no corrosion of steel, in solutions of 10 $<$ pH $\leqq$ 11 a slight trend of corrosion could be seen, while in solutions of pH $\leqq$ 10 the corrosion of steel was extremely great. In the case of unpolished steel, since there was corrosion at spots where the mill scale was broken the results of measurements of spontaneous electrode potential were roughly the same as for polished steel. Looking at Table 31 and Fig. 9, the tendency of corrosion agrees quite well with the tendency for rust formation as seen from the spontaneous electrode potential.

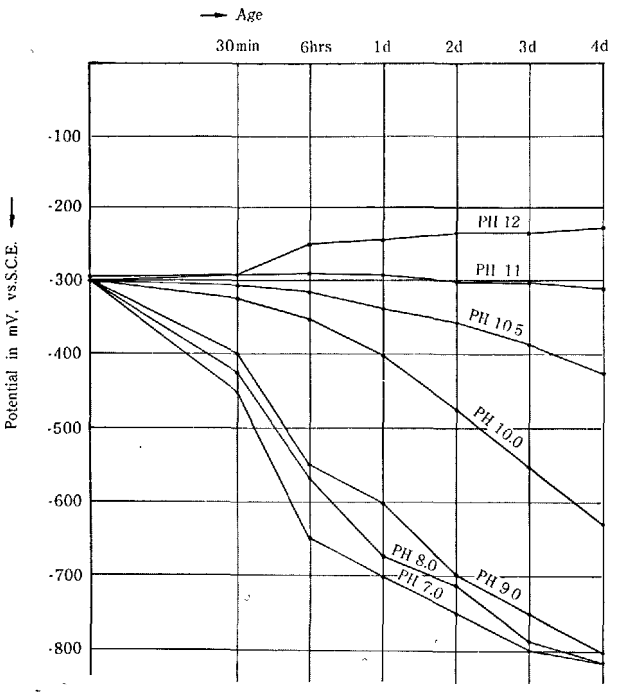

Fig. 8. *Time-potential curves of various corrosion testing solutions (unpolished steel)*

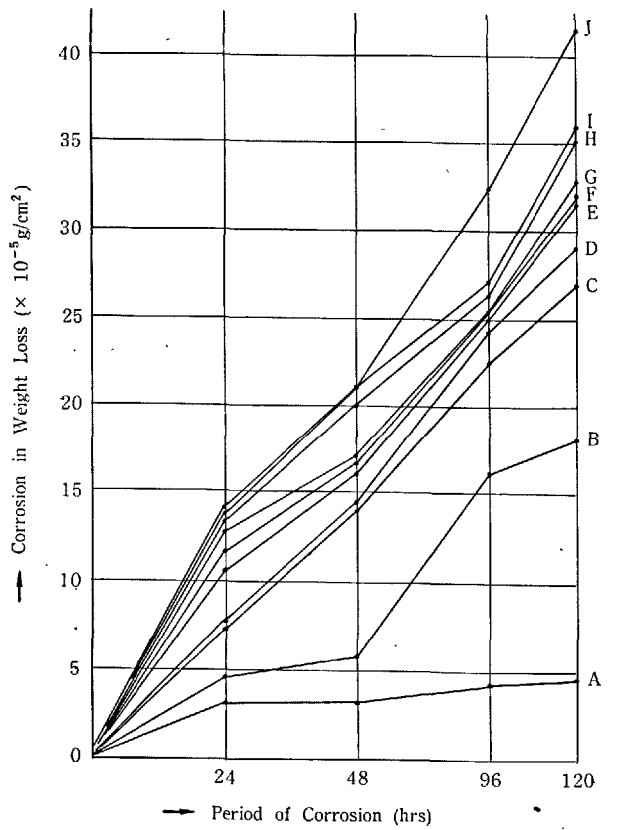

Fig. 9. *Corrosion in weight loss of polished steel in various testing solutions*

Summarizing the above, the corrosion of steel in reinforced concrete has a close relationship with neutralization of the concrete. Empirically, it had been said from the past that reinforcing steel in neutralized parts of concrete was liable to be corroded. From the foregoing conclusion and the conclusion obtained from measurements of hydrogen ion concentrations in neutralized and unneutralized parts of concrete described later—the hydrogen ion concentration of neutralized portions is 10 or less and there is a great difference with the concentration in unneutralized portions—it is further concluded that the reinforcing steel in concrete in the presence of oxygen and water will be corroded in neutralized areas while it will not be corroded in unneutralized areas substantiating the concept which had been recognized empirically.

5.3 Considerations on the Method of Determining Neutralization by Phenolphthalein

Measurement of the depths of the so-called neutralized layers of mortar and concrete is generally performed by spraying phenolphthalein solution on the specimens and determining the thicknesses from the surfaces of the specimen remaining uncolored which are considered as the depths of neutralization. However, contemplating on the above method from a common sense point of view, a question will arise whether there would not be considerable differences in the depth of neutralization values depending on the moisture content of mortar and concrete and the variety of phenolphthalein solution which may or may not contain water. The present circumstances are that no quantitative measurement is made of calcium carbonate and calcium hydroxide in the neutralized and unneutralized portions of specimens and there is no certain proof that phenolphthalein is appropriate for use in determination of neutralization of mortar and concrete. The author's cooperators carried out various studies on whether or not the phenolphthalein was appropriate for use in concrete neutralization determination tests. Firstly, regarding the phenolphthalein solution to be used in the determination of neutralization, 1% anhydrous phenolphthalein solution and 1% hydrous solution (5% of ethyl alcohol replaced with water) were prepared and painted on non-autoclaved cellular concrete of 15% moisture content. The results were that hydrous phenolphthalein indicated great coloring capability immediately after painting which in a few minutes changed to the same degree of coloring as the anhydrous phenolphthalein so that there was no difference in respect to determina-

tion of depth of neutralization. Therefore, it can be said there would be no difference in the results whether hydrous or anhydrous phenolphthalein solution is used for determination of depth of neutralization.

Next, the quantitative measurements of calcium carbonate and calcium hydroxide and the measurements of hydrogen ion concentrations in neutralized and unneutralized portions of specimens with varying moisture contents are described below.

Non-Autoclaved Cellular Concrete

The specimens consisted of 20 cm × 20 cm × 50 cm cellular concrete left outdoors for 10 years and divided into 4 equal parts with the procedure below followed for each of the specimens.

Specimen 1 was immersed 48 hours in water of 20°C temperature, Specimen 2 was immersed 10 hours in water of 20°C temperature, Specimen 3 was left in the same condition as when cut up and Specimen 4 was dried 24 hours in vacuum. After this, each of the specimens was cut in two at the middle, wiped thoroughly with a dry cloth and painted with 1% anhydrous phenolphthalein. Samples were taken from each of the specimens from the 4 portions indicated in Fig. 10 and quickly ground roughly in a porcelain mortar. In order to prevent carbonation of the samples, they were immediately vacuum-dried and after drying removed to an agate-mortar and pulverized to an extent that particles could not be sensed with the finger-tips and then placed in a tube-bottle and stoppered tightly to be used as samples for quantitative measurement of calcium carbonate and calcium hydroxide.

The quantitative measurement of calcium carbonate was calculated by using a Schrötter carbon dioxde measurement apparatus and measuring the quantity of carbon dioxde gas formed from decomposition by hydrochloric acid.

As for the methods of quantitative measurement of calcium hydroxide, there are the Lerch-Bogue Method, (23) Schlöpter-Bukowski Method, (24) Fujii Method, (25) Franke Method, (26) etc., but all of these methods have their disadvantages along with the advantages and it cannot be considered that quantitative measurement values of high reliability can be obtained.

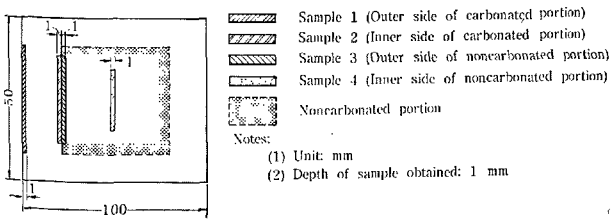

Fig. 10 *Portions of specimens from which samples were obtained*

In these tests, as quantitative measurement values of high accuracy are required because comparisons must be made of the calcium hydroxide from the same specimen, it was thought to make combined use of the Lerch-Bogue Method and X-ray diffraction. In the Lerch-Bogue Method the completion time of extraction is not clear and has the fault of also measuring the calcium hydroxide loosely combined in the hydration products. By using the combination method, the extraction completion time is accurately determined by X-ray diffraction to minimize the error from overmeasurement of calcium hydroxide so that quantitative measurements of high accuracy are obtained.

In this combined method, the sample was dispersed in a solvent and calcium hydroxide extracted for a given period and measured quantitatively. After extraction for the given time the extraction residue was thoroughly washed with ethyl alcohol and ether, vacuum-dried and used as the sample for X-ray diffraction. The extraction was performed over a hot water both of 90 to 95°C, titrating every 15 minutes. At the same time, X-ray diffraction was performed on the extraction residue and the calcium hydroxide quantity obtained from the quantitative measurement value of the Lerch-Bogue Method at the point when calcium hydroxide reflection at the surface (001) could no longer be recognized.

The measurement of hydrogen ion concentration was performed by using the extraction completion time of the respective samples determined by the combined Lerch-Bogue and X-ray diffraction method, extracting the calcium hydroxide in the samples using glycerin ethyl alcohol, quickly filtering after completion of extraction, diluting the filtrate 4 times with distilled water and measuring with a pH-meter.

On one hand, 50 g each were taken from the samples before vacuum drying and these were vacuum-dried, weighed after drying and the moisture contents of the samples before drying were calculated from the equation below.

$$\text{Moisture content } (\%) = \frac{\text{Weight of sample before drying (g)} - \text{Weight of sample after drying (g)}}{\text{Weight of sample after drying}} \times 100$$

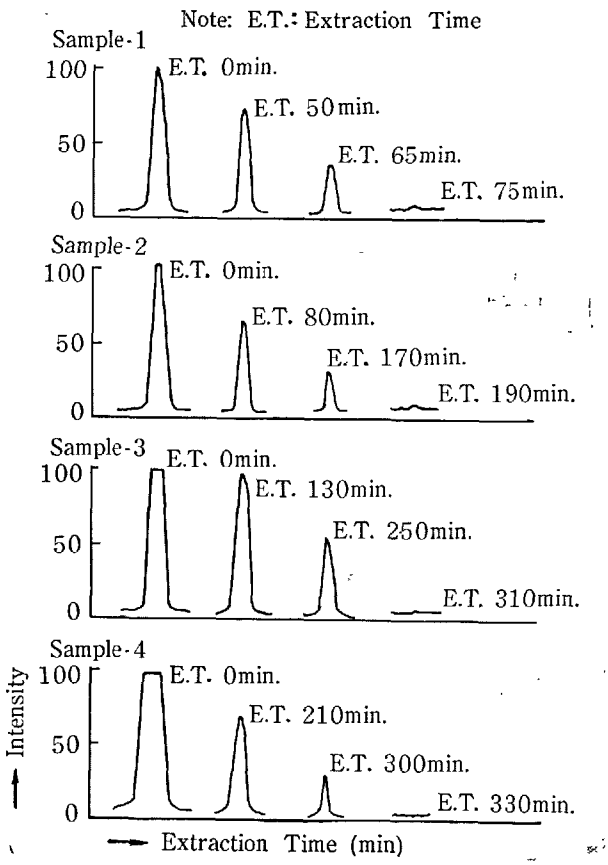
5.3.2 Ordinary Concrete

The specimens were taken from ordinary concrete

60 cm × 60 cm × 90 cm placed outdoors for 60 years, cut in half at the middle and painted with 1% anhydrous phenolphthalein with samples taken from each of the specimens from the 4 portions indicated in Fig. 10. In preparing the samples, aggregate was removed as much as possible and the procedure for preparation and the methods of quantitative measurement were according to the preceding paragrapy. However, before making the quantitative measurements of calcium hydroxide and calcium carbonate, the insoluble residue and the calcium oxide of the samples were measured quantitatively, the cement portion in the samples accurately calculated, and the analysis values of the calcium hydroxide and the calcium carbonate converted into equivalent of cement and tabulized.

Test Results and Considerations

The results of quantitative measurement in the case of cellular concrete are given in Table 32. The result of X-ray diffraction on extraction residues of major points on various samples from Specimen 3 are indicated in Fig. 11. The results of quantitative measurement on ordinary concrete are given in Table 33. As can be seen from Tables 32 and 33, when the moisture content of the specimens is comparatively high being 20 to 30%, it becomes difficult to discern the neutralized and unneutralized portions using phenolphthalein due to the dispersion phenomenon of the calcium hydroxide at the surface of the specimen. Even when straining to distinguish the neutralized portion by the shade of the area colored by phenolphthalein, as can be seen from the analysis results in Table 32, a great amount of calcium hydroxide was measured from the neutralized area and thus, in this case, it cannot be considered that the neutralized area is correctly indicated chemically. However, when the moisture content of the specimen is 15% or less, it is possible to clearly define between the neutralized and unneutralized areas with phenolphthalein, while a considerable difference between neutralized and unneutralized areas is seen in the quantitative measurement results. On one hand, as seen in Fig. 12, there is a great difference in the hydrogen ion concentration on either side of the borderline between the neutralized and unneutralized areas, and as described in 5.2, since the corrosion of reinforcing steel depends greatly on the before-mentioned hydrogen ion concentration, it may be considered that neutralized and



Conditions of Diffraction:

6. Special Cases

6.1 Reinforced Concrete Chimneys (Influence of High Temperatures and Gases)

Reinforced concrete chimneys are subjected to the actions of heat and gases so that from a durability standpoint these chimneys are placed at a disadvantage. The author, in order to clarify the condition of this type of chimney investigated 7 chimneys which fell down in the First Muroto Typhoon of September 1934 and 2 chimneys at public bath-houses in Tokyo. For instance, a factory chimney 15 years after construction was completely neutralized for 10 cm on

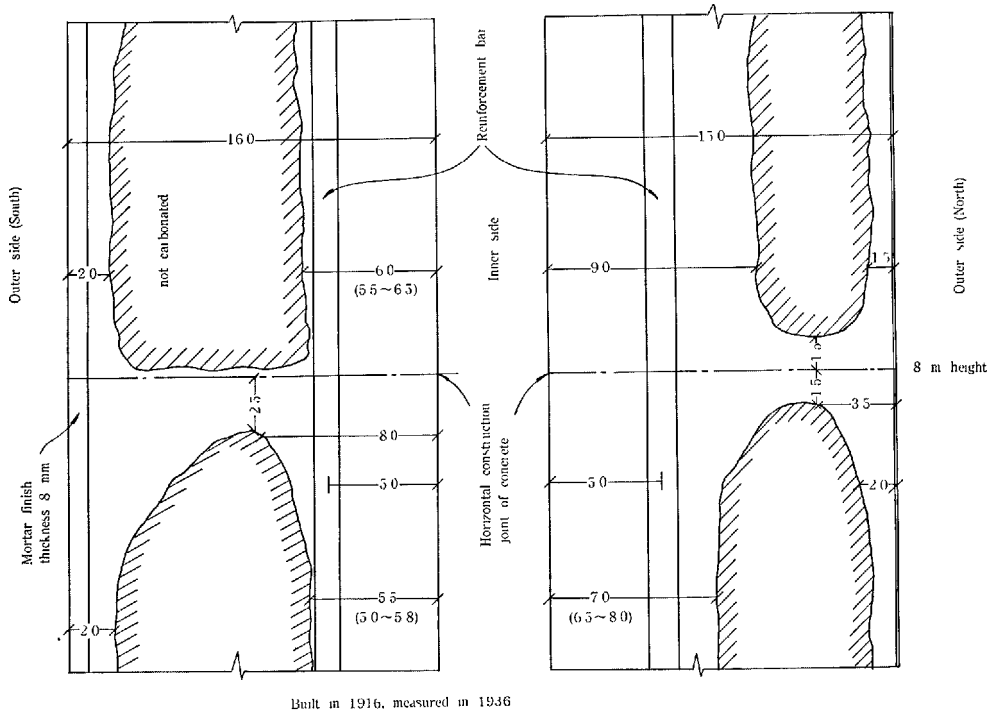

Fig. 13. *Chimney for heating wooden dormitory building in Tokyo*

both outer and inner sides, and the main reinforcement, ϕ–9 mm bars, had been reduced to less than half their diameters. In the case of the bath-house chimneys, such results as $t = 6.2x^2$ for exterior surfaces and $t = 1.7x^2$ for interior surfaces were seen, while at construction joints the conditions were even worse and the reinforcing bars had become rusted at 10 to 20 years. (Fig. 13)

The concrete of almost all reinforced concrete chimneys are uncovered and although a great deal depends on the lining, the interior concrete is exposed to heat and smoke with high concent rations of carbon dioxide and sulphur dioxide gas while the exterior is subject to some extent of concentrated gases and to minute cracking caused by temperature stresses. Therefore, the life of a reinforced concrete chimney is short, especially at construction joints. After experimental and theoretical studies, it was pointed out that special care should be exercised in design and construction, and that it would be beneficial to use high early strength portland cement. (27), & (28)

Later, in 1936, the author ascertained the weak points of construction joints in a study of a chimney for heating of a dormitory. In 1950, in an investigation of 2 chimneys at Sapporo Thermal Power Station conducted by Koh, (29) the difference in neutralization depending on height and the relation with the interior lining were studied and it was found that the coverage on the interior for several meters from the top was insufficient.

In 1956 to 1958, Fukuchi (30) investigated 9 chimneys damaged by earthquake and 14 chimneys which went undamaged at public bath-houses in Tokyo and it was indicated that the coefficient of x^2 in the beforementioned equation should be selected at 1.0 or less. This figure substantiates to a considerable extent the appropriateness of the 0.77 coefficient induced in 1937 for cases of good concrete workmanship in which considerations were given to the concentration of gas.

The results of investigation on a chimney at a hospital in Sapporo carried out by Koh in 1961 also show that chimneys which are continuously used are neutralized rapidly, that interior lining is necessary and that concrete mixtures must be improved. It was indicated that the top portion of a chimney is especially liable to be damaged, The investigations by the author on a locomotive shed in Niigata Prefecture in 1948 and by Nishi on a locomotive shed in Hokkaido in 1955 also point out examples of corrosion by smoke from locomotives and show the durability of dense concrete of a good quality mix.

In the case of thermal power plants, there are cases in which the coefficient of x^2 must be taken at 0.1.

In summary, although depending on various conditions, the corrosion of reinforcing steel in chimneys is fairly rapid and there is a need for close observation.

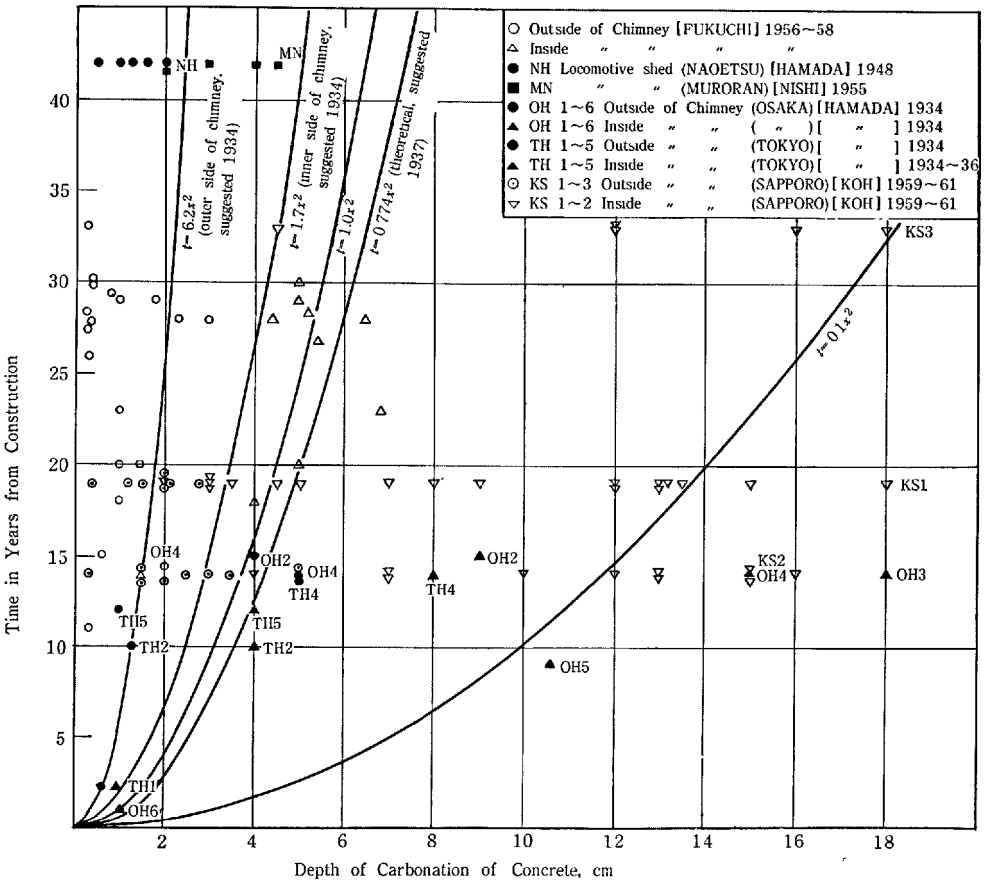

Fig. 14. *Depths of carbonation measured on chimneys and locomotive sheds. Curved lines with formulae are suggested by Hamada based on measured date and hypothetical studies*

Fig. 14 gives an illustrative summary of the relation between age and depth of neutralization and indicates that a diagnosis of deterioration should be made within 20 years.

6.2 Fire-Damaged Buildings

The investigation by Takenouchi in 1952 on buildings damaged by fire during the war conducted mainly on neutralization of interior columns and walls produced the result that neutralization progresses greatly from fire damage. (16) According to Kimura, (31) up to 600°C, neutralization is not different from that at normal temperature, but from 700°C and above, the situation changes completely and neutralization progresses 2.5 cm or more in 2 hours of heating.

6.3 Cold Weather Regions

In regions of cold climate, the neutralization is considerably different from that seen in other regions. When concrete is dry, the air-permeability is raised so that it would appear neutralization would become accelerated. The neutralization indoors would be severer than in warm regions because of drying occurring from heating throughout half the year. The results of experiments for a 3-year period on specimens placed outdoors in the cold and in the corridor of a heated building showed about 2.5 times neutralization indoors over outdoors.

Comparing this neutralization with the data on neutralization according to thickness of finish obtained by the beforementioned Takenouchi on portions of buildings not subjected to fire damage, it is found to be considerably greater.

Even when there is a finish on the exterior, the concrete at corner portions of a building will become more air-permeable from frost damage so that examples of some acceleration of neutralization have been seen.

6.4 Rusting of Reinforcing Steel under Special Conditions such as Chemical Factories and Countermeasures

Tatsumi (32) carried out a number of experiments in 1934 having noticed the corrosion of concrete at factories which have electrolytic processes and the electrolytic corrosion from direct current in subways, etc. With the same point of view, the author conducted tests (33) in 1938 on concrete containing electrolytic materials such as calcium chloride which are used as accelerators in cold weather concreting.

In such cases the rusting of reinforcing bars is severe. This is because when small amounts of electrolytic material enter the concrete, although there may be little difference in the specific resistance, the rusting of steel is extremely severe due to the Cl^- gathering at the anode.

In chemical plants, there is much corrosion of concrete from sulphur dioxide gas and various other acids and in 1955 a guide to prevention of corrosion of reinforced concrete (34) was prepared by the Committee on Countermeasures for Corrosion of Concrete based on both previous studies and a new survey which had been conducted.

Also, Nagano (35) reported in 1958 on a systematic study on electrolytic corrosion affected by type of cement, concrete mix proportion and whether or not admixtures had been used.

Acknowledgements

The author wishes to express his deepest gratitude to Dr. Tadao Nishi, Professor, University of Tokyo, Dr. Koichi Kishitani, Associate Professor, University of Tokyo, Dr. Yoshiro Koh, Professor, Hokkaido University, Dr. Katsuro Kamimura, Building Research Institute, Ministry of Construction, Mr. Hideo Teramoto, Research Laboratory, Nihon Cement Co., Ltd., and Mr. Tsuruyoshi Saito and Mr. Koretoshi Hitotsuya of the Central Research Laboratory, Onoda Cement Co., Ltd. for their invaluable cooperation in preparation of this paper.

Written Discussion

Heinz G. Smolczyk

Synopsis

In addition to the widely interesting part of Mr. Hamada's paper on the very extensive Japanese long time studies on carbonation the results of five years' experiments of three German laboratories are described, evaluated and compared with various publications of other authors.

The evaluation proved the following results for mortars and concretes with dense aggregate:

a) Carbonation does not depend on the quantity of free $Ca(OH)_2$ in the paste.

b) Carbonation increases the strength of normal concretes in any case. Exceptions are the supersulphated cements.

c) The equation

$$\text{carbonation} \sim \sqrt[2]{\text{time of carbonation}}$$

is an approximation, which becomes suitable for extrapolation only after a longer period of carbonation i.e. with older concretes.

d) Carbonation of older mortars and concretes with portland cements and with ortland blastfurnace slag cements can be expressed in terms of the formula

$$\text{carbonation} \sim (1/\sqrt{\text{compressive strength}}) \times \sqrt{\text{time}}$$

e) Following d) carbonation must decrease with an increase of afterhardening of concrete. Thus greater differences in initial carbonation between cements with lower initial strength and high afterhardening and cements with higher early strength and low afterhardening gradually disappears with growing age of the older concretes.

f) With respect to carbonation it is safer to use rich mixes with normal hardening cement than leaner mixes with higher early strength cement.

The Problem

The principal paper of Mr. Hamada especially the first part "Carbonation of Concrete" is a widely interesting summary mainly of the very extensive Japanese work on this field, which represents the basis of our knowledge of the carbonation of various types of concrete (1) and (2). Thus the impression could occur that nearly all the questions are answered, and the supplementary papers also seem to confirm this opinion.

But there are also other tests and facts, which clearly do not agree with some of these theories: e. g. distinct differences to the $\sqrt{\text{time}}$—relation, carbonation of calciumsilicatehydrates and calciumaluminatehydrates in the paste, cases with stronger carbonation of lime-rich cements than those lower in lime, extremely strong influence of the precuring conditions on carbonation rate etc. Many of these observations have already been reported in (3), (4), (5), (6), (7), (8), (9), (10), (11), (12) and (13).

Our Laboratory has evaluated these questions for about seven years (14). The experiments and long-time studies will not be finished in the near future, but it nevertheless seems to be necessary to report on part of these tests which are apt to put another point of view on the subject and could possibly clarify some apparent contradictions (15).

Test Results (Experimental Results)

Cements

The following studies have been carried on by several laboratories (14) with

3 "Hochofenzementen" (HOZ): slag cements > 30% slag

2 "Eisenportlandzementen" (EPZ): slag cements < 30% slag

4 "Portlandzementen" (PZ): portland cements

1 "Sulfathüttenzement" (SHZ): supersulphated cement

All the cements were bought from commercial sources and selected in such manner that specimens with all variations in strength could be compared.

Three laboratories made mortar-prisms 4 × 4 × 16 cm and labor "F" also mortar-prisms 5 × 5 × 25 cm and concrete-prisms 5 × 5 × 25 cm with aggregate 0~15 mm. Up to now, for five years the progress in carbonation has been tested with phenolphthalein and partly the maximum binding of CO_2 and furthermore some compressive strengths of carbonated specimens.

The interesting data of the cements and of the test specimens are to be seen in Table 1. The compressive strengths of the concretes were only measured after 7 days and 28 days. The strengths after 14 days are interpolated according to the formula of G. Sadran (16).

$$\frac{1}{B} \sim \frac{1}{t_w} \qquad [1]$$

B = compressive strength

t_w = time of water-curing

The mortar have been stored indoors (65% RH, 20°C) after 28 days of water-curing, the concretes in a seldom used room (50% RH, ~ 20°C) after 7 days of moist treatment.

Some further tests (prestressed piles, heat treatment, outdoors storage, CO_2 storage) (14) shall not be reported here.

Results of the Carbonation of Mortars

In this report the test results of each experimental step are generally shown in tables.

With respect to the mortars, however, the number of single tests has been so great that the exact equations of carbonation progress could be established.

For this purpose the measured depths of carbonation 'X_v' and the time of carbonation 't' were drawn to double logarithmic scale as is to be seen in Fig. 1 (cement Z8) and Fig. 2 (cement Z1). The logarithms

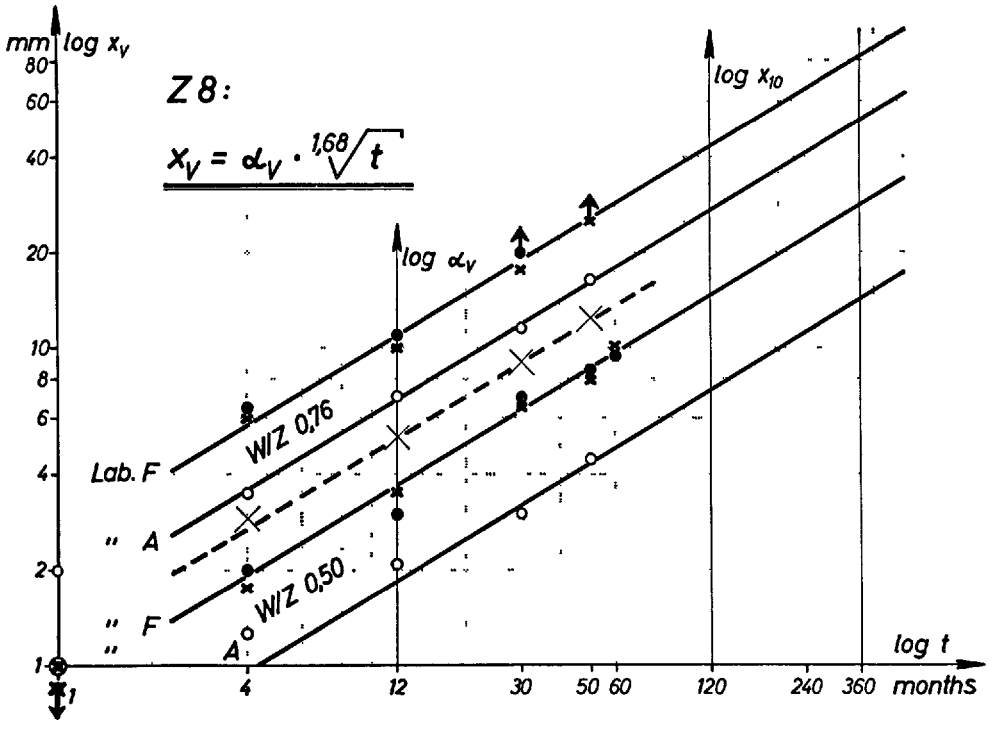

Fig 1. *Calculation of genuine carbonation progress for portland cement Z 8*
– – – × – – –trend line of overaged log-values

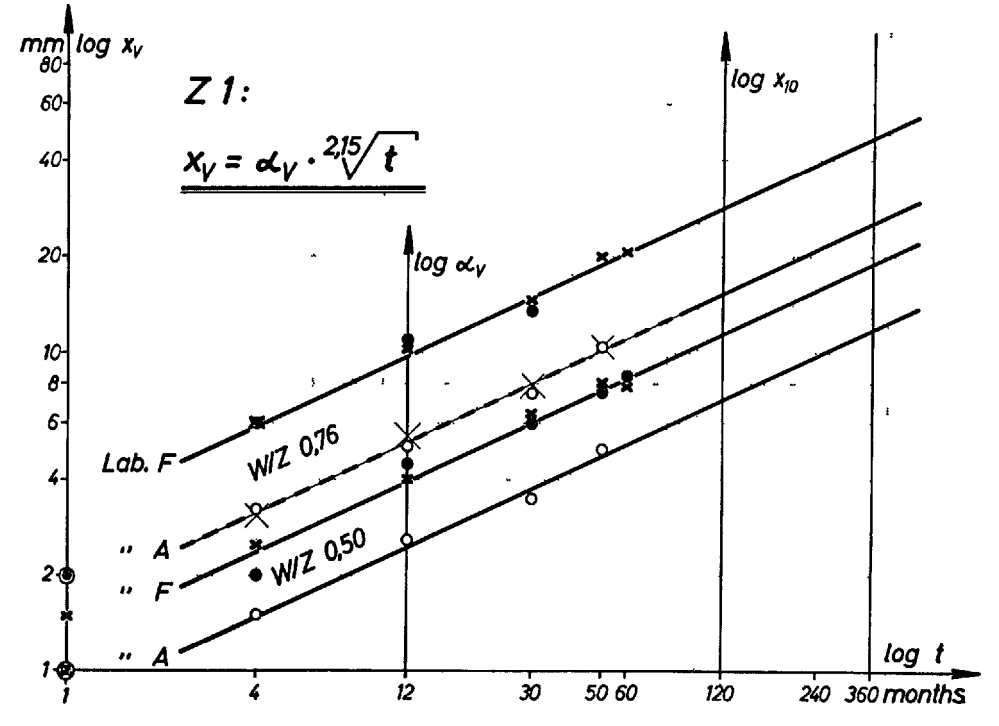

Fig 2 *Calculation of genuine carbonation progress for portland blastfurnace slag cement Z 1*
– – – × – – –trend line of averaged log-values

of all the 6 test series were averaged at 4, 12, 30 and 50 months. The slope of the average values (---- in the diagrams) then equals the value 'v' in the general equation

$$X_v = \alpha_v \sqrt[v]{t - t_0} \qquad [2]$$

't_0' being a relative short period of retardation

Equ. [2] becomes [3] already within 4 to 6 months

$$X_v = \alpha_v \cdot \sqrt[v]{t} \qquad [3]$$

Knowing the 'v' for a given cement, it is possible to calculate for each tested mortar of this cement the exact speed constant 'α_v' and to interpolate or also extrapolate carbonation depths 'X_v'. Table 2 shows these values 'v' and 'α_v' and also the carbonation 'X_{v10}' after 10 years as results for further evaluating.

The carbonation depth after 10 years was chosen, because only after this period an approximaitve formula

$$X \sim \sqrt[2]{t}$$

is possible, as is to be seen in Fig. 3. Here, for mortars of w/c 0.76 (Laboratory F) the experimental carbonation-curves (see Table 2)

of $\quad Z1: X_v = 9.7 \cdot \sqrt[2.15]{t}$

and $\quad Z9: X_v = 7.6 \cdot \sqrt[1.74]{t}$

are drawn on a graph with $\sqrt{t}$-axis in thick curves. The thin lines show that even after 1 year a linear adjustment can lead to very great deviations by extrapolating (14).

The best adjustment is possible in case of 't' being great enough according to the formula

$$X_q = X_o + \alpha_q \cdot \sqrt[2]{t} \qquad [4]$$

This function (— — — — — in the diagram) does not start from the origin. But X_o only represents a mathematical correction and must not be mistaken for the experimental time of retardation or induction period 't_o' in equ. [2].

This 'X_o' is very awkward with respect to further calculations and it is possible to calculate within the range from 5 to 30 years with only little divergence by using the formula

$$X \cong \alpha \cdot \sqrt[2]{t} \qquad [5]$$

Table 2. *Carbonation of mortars with $\sqrt[v]{time}$ (experimental) and $\sqrt[2]{time}$ (calculated)*

provided that 'X_v' in equ. [2] and 'X' in equ. [5] are taken the same value not earlier than after 10 years.

This approximative adjustment [5] is also drawn in Fig. 3. It is in case of Z1 and Z9 very nearly the same (— · — ·). Likewise in Table 2 besides the experimental values 'v', 'α_v' and 'X_{v10}' according to equ. [3] also the adjusted values 'α' according to equ. [5] are calculated and further the deviations

$$\frac{X_{30}}{X_{v30}} = \frac{\alpha}{\alpha_v} \cdot 30^{v/2} \qquad [6]$$

which are to be expected after 30 years.

Additional Test Results

Table 3 shows the carbonation depths and the compressive strengths of the corresponding concrete prisms after 5 years. The evident test deviations are put in parenthesis. Nevertheless, even the other results show that exact values of carbonation of a precisely defined concrete are not to be obtained easily.

In Table 4 the compressive strengths of completely carbonated mortars (in normal air and in 3% CO_2) are compared to the initial strengths after 28 days of water-curing. The columns "S_A/S_W%" and "S_C/S_W%" show the strengths after carbonation given in % of the strengths immediately before carbonation.

Of numerous sufficiently carbonated mortar prisms (normal air and 3% CO_2) the CO_2-contents of the carbonated paste were analyzed, chemically and by X-ray analysis. Of several just slightly carbonated specimens the CO_2-contents of the thin carbonated layer could be measured with X-ray analysis only. For this purpose the contents of calcite and vaterite of the mechanically enriched paste were measured quantitatively. Fig. 4 shows the X-ray diagrams of the completely carbonated mortars of Z7 and Z2 (enriched paste).

All CO_2-contents were calculated as carbonated CaO/cement and are listed in Table 5.

bonation changes also the strength—probably the permeability too—and the composition of the paste.

Table 3 and especially Table 4 show that the compressive strengths of all the HOZs and PZs and remarkably increased. An exception is the SHZ (also the high alumina cements!), which behaves differently in many respects. Therefore the SHZ must not be compared to the other cements.

The binding of CO_2 of the mortars is drawn on a graph "carbonated CaO versus CaO-content of the cements" in Fig. 5 (see Table 5). Obviously the capacity of the slag cements to neutralize CO_2 increases linear with their CaO-content and is far greater than the free $Ca(OH)_2$ of the paste could be accounted for. On the average HOZs carbonate in air as long as there is left more than 25% noncarbonated CaO in the paste. Only then they can be called "completely carbonated". The PZs reach this point with 30% noncarbonated CaO already. Nearly all of the carbonated mortars without any alkaline reaction showed rests of free $Ca(OH)_2$.

Theories, based upon a neutralization of CO_2 or a resistance against carbonation only by the free $Ca(OH)_2$ of paste are disproved by these experimental results! (17)

After carbonation in 3% CO_2 the chemical analysis results in 5%~10% more carbonated CaO though the X-ray analysis proved nearly the same $CaCO_3$-contents as after carbonation in normal air. Up to now

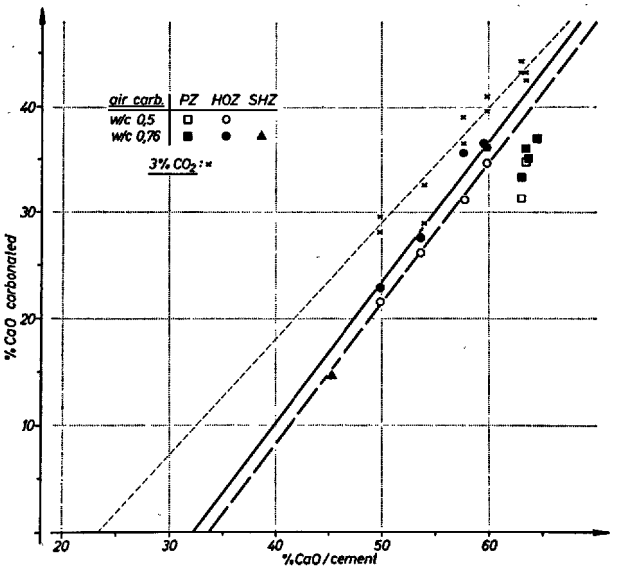

Fig. 5. *Carbonated* CaO *of completely carbonated cements (paste of mortars) versus total* CaO *of cements*

this "missing CO_2" could not be explained.

Rate of Carbonation

In the approximative function [5]

$$X \cong \alpha \cdot \sqrt{t}$$

α determins the speed of carbonation which depends on the storage or weathering conditons and on the properties of the concrete.

The Tables 1, 2 and 3 show that constant ratios X_{HOZ}/X_{PZ} or $X_{W/C=0.76}/X_{W/C=0,50}$ do not exist. Other tests have meanwhile proved that these ratios can be altered at pleasure just by varying the precuring conditions. For this reason the parameters 'storage condition', '*w/c*-ratio' and 'type of cement' do not suffice to postulate the progress of carbonation and this way of representation requires too many exceptions and therefore is far too complicated (14).

Surely, the decisive parameter is the permeability (18). But the permeability is difficult to measure and even more difficult to predetermine. As, however, the easily measurable compressive strength is to a certain extent connected with the porosity and permeability of a concrete, an empirical relation was detected after thorough investigations and numerous evaluation tests (19).

In Fig. 6 for all the PZs, EPZs and HOZs and for *w/c* 0.76 and *w/c* 0.50 the carbonation depths 'X_{10}' of the mortars and their factors '$1/\sqrt{B}$' are drawn on a plot (see Tables 1 and 2). B is the compressive strength after 28 days of water-curing i. e. at the begin

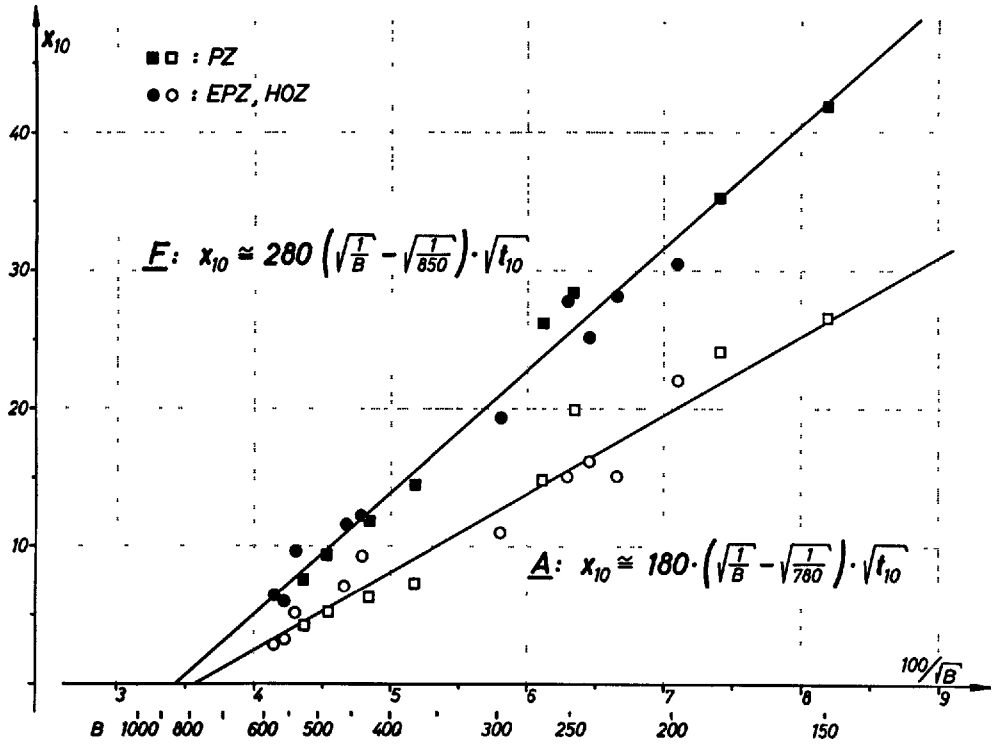

Fig. 6. *Carbonation of mortars "Indoors"*
X_{10} = *carbonation after 10 years in mm*
B = *compressive strength after 28 days of water-curing in kg/cm²*
t_{10} = *10 years*

of carbonation. With these straight lines the speeds of carbonation for the different conditions of Laboratory A and Laboratory F can be calculated and equ. (5) becomes

$$X \cong a \cdot \left(\frac{1}{\sqrt{B}} - \frac{1}{\sqrt{B_G}}\right) \cdot \sqrt{t} \qquad [7]$$

This equation has only the two constants 'a' and 'B_G' which depend on the storage conditions alone:

'a' is the speed constant

'B_G' is the strength limit of carbonation i. e. a concrete with a compressive strength $>$ 'B_G' does not carbonate.

This diagram is based on ~200 test values (Labor. F) and. ~100 test values (Labor. A) respectively.

Inquiries proved that the storing room of Laboratory Fhad been used more frequently than the one of Laboratory A. Thus the CO_2 content of the air was in Labor. F somewhat higher than in Labor. A. The relative humidity had been ~65% RH in both cases. It is clearly to be seen that little differences such as these result in a strong influence on the rate of carbonation.

Fig. 7 is a similar diagram of the concrete prisms after 5 years storage indoors at 50% RH (see Tables 1 and 3). Because of the still very steep strength increase at the beginning of carbonation (7 days), in this case the 14 days' strengths were put in as 'B'.

The constant 'B_G' for the concretes is greater than it is in the case of the mortars, according to the lower relative humidity of the room. This diagram is based on 14 test values only.

Comparison with Other Published Data

The carbonation of all the alkaline components of paste and not only that of the free $Ca(OH)_2$ is based on a fundamental chemical law and this fact was published by several authors (5), (8), (9), (12), (14), (17), (19), (20) and (21).

Meanwhile only few authors report on the altera tion of strength due to carbonation. A. Meyer, H.-J. Wierig and K. Husmann investigated tiny cylinders (12 mm) which are undoubtedly not suitable for comparisons with concretes or even mortar prisms (15).

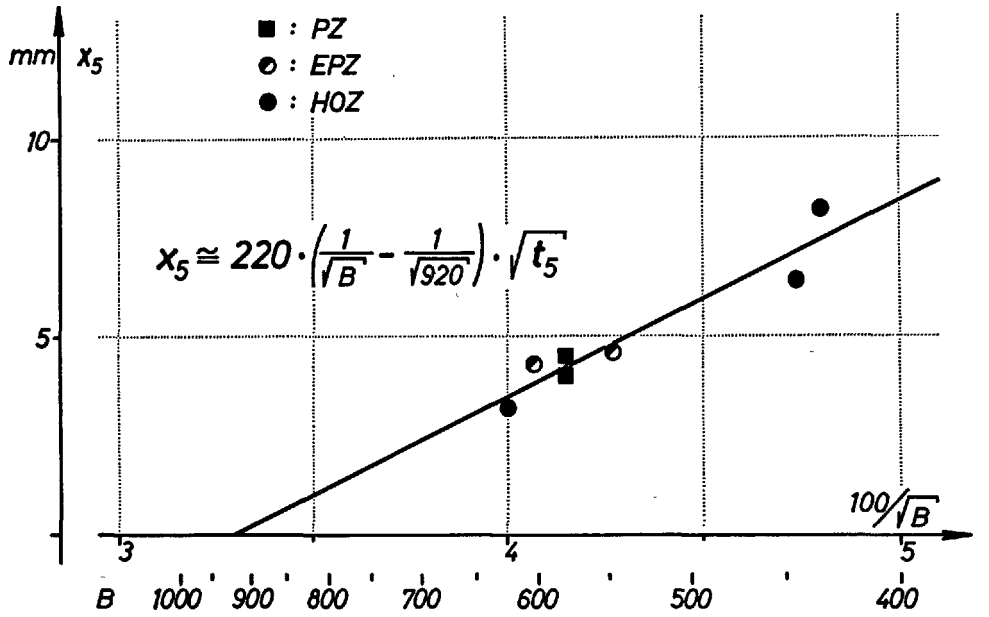

Fig. 7. *Carbonation of concretes "Indoors"*
X_5 = *carbonation after 5 years in mm*
B = *compressive strength after 14 days of moist treatment in kg/cm²*
t_5 = *5 years*

W. Manns and O. Schatz investigated the carbonation of completely dried mortar prisms 4 × 4 × 16 cm in 9% CO_2 and report on losses of strength not only with SHZ but also with HOZ containing more than 60% slag (22).

As with the exception of the SHZ and the PZ these experiments disagree completely with our results, we searched for the cause:

In Fig. 8 for 5 PZ, 7 HOZ and 2 SHZ all the available compressive strengths 'B' and flexural tensile strengths 'F' measured by the Laboratories A, F and H and by Manns and Schatz (Laboratory I.f.B.) are drawn to double logarithmic scale. Only those specimens are represented which has been water-cured or completely dried (40°C and 105°C) or completely carbonated.

According to a well known formula (24) the strength characteristic of mortars 4 × 4 × 16 cm is

$$F = B^{0.70-0.73}$$

Fig. 8 shows that the following specimens fit well in this equation

a) Water-cured prisms (3 to 91 days) of all the laboratories.
b) All the dried prisms (40°C and also 105°C each) and all the carbonated prisms of Laboratories A, F and H.

On the other hand the dried prisms and the carbonated prisms of Laboratory I.f.B. do not obey this law any more. Using the 4 mean values of the dried specimen (7 single results) and the 4 mean values of the carbonated prisms (39 single results) a compensating computation resulted in the (trend line) average equation

$$F \cong 0.0005 \cdot B^{1.9}$$

The drying conditions in Laboratory I.f.B. had completely destroyed the strength characteristic of normal mortars. For this reason these results can not be compared with the results of the other laboratories. Moreover, they cannot be brought in any relation to the behaviour of a normally treated concrete structure which will never be completely dried at 40°C or 105°C.

The relation between the rate of carbonation and the initial compressive strength has not specially been reported yet, but many published results provide an excellent proof.

A. Meyer, H.-J. Wierig and K. Husmann tested the carbonation of mortars 4 × 4 × 16 cm after 7 days' water-curing using 4 different cements and 5 different *w/c* factors (Test series 4) (15).

Here again—as in the case of our own concrete prisms—not the 7 days' but the 14 days' strength

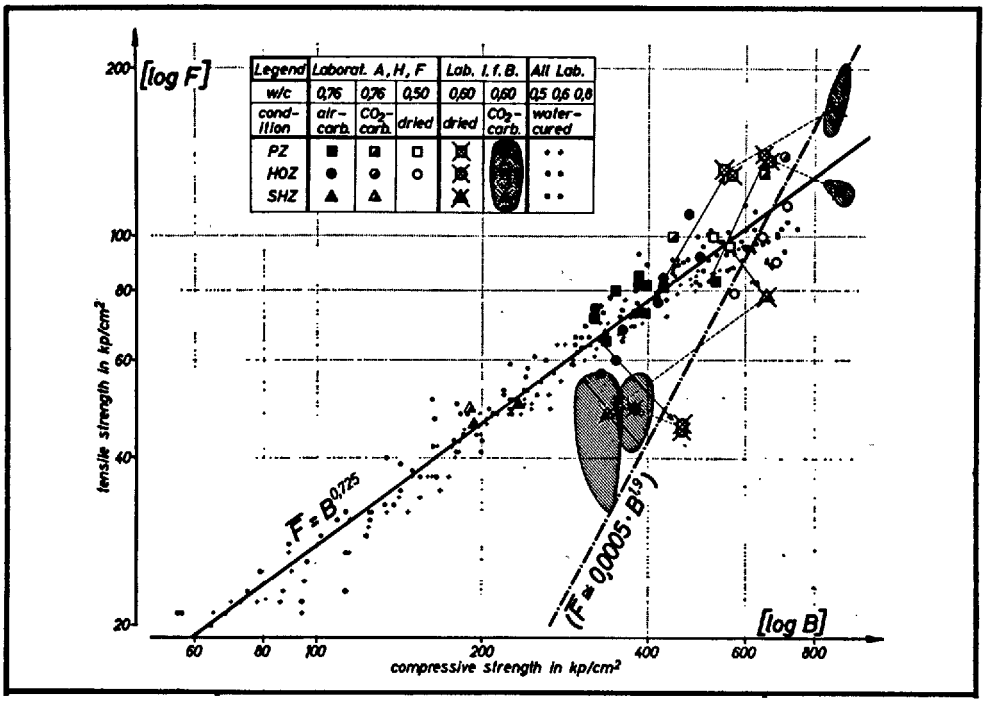

Fig. 8. *Relation between compressive strength and flexural tensile strength of mortars 4 × 4 × 16 cm after various treatments. Well knownstatistic equation of normal treated mortars:*

must be set for 'B'. With use of the published 7 and 28 days' strengths (Test series 3) these 14 days' strengths have been calculated and were together with the also published carbonation after $2\frac{1}{2}$ years specified in Table 6. Fig. 9 proves that the relation

$$X \sim 1/\sqrt{B}$$

is excellently confirmed. Furthermore it is to be seen that the carbonation conditions had been extremely strong in this laboratory (50% RH).

With tests on old structures this accuracy cannot be expected due to the lack of information about the exact weathering conditions during the length of time (14).

The concretes being best comparable must be those which had been stored outdoors sheltered from rain and which are old enough for a statistical survey without inaccurate extrapolation of carbonation

depths.

Using the reports given by G. Rehm and H. Moll (25) by H.-J. Kleinschmidt (26) and A. Meyer, H.J. Wierig and K. Husmann (15) in Table 7, all the concrete structures (without exception) are listed which firstly met this storage condition, secondly were older than 20 years, and thirdly were published with strength data. The carbonation after 25 years was calcu-

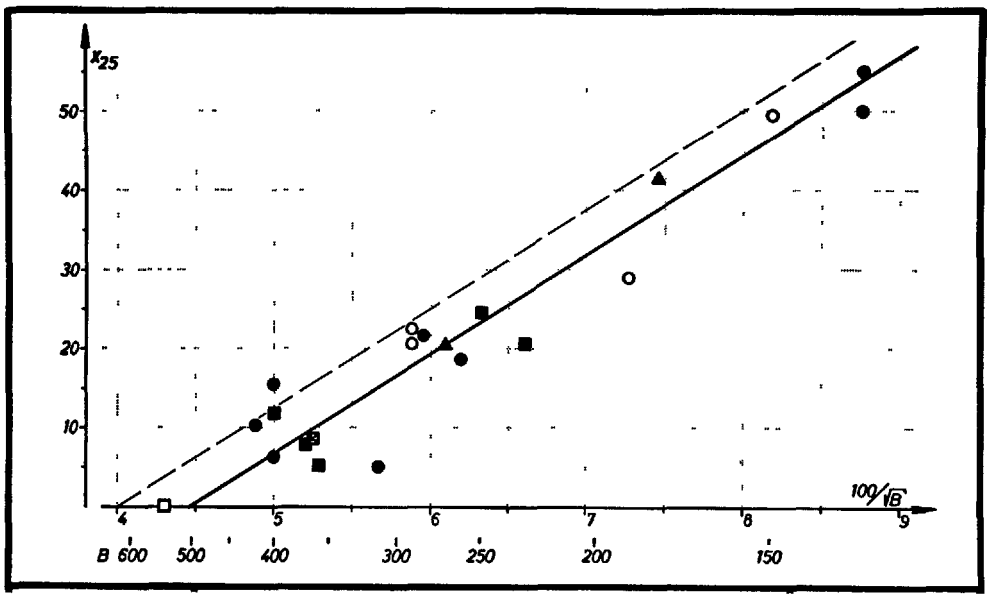

Fig 10 *Carbonation of old concrete structures "outdoors sheltered from rain" (age > 20 years)*
x_{25} = *reduced carbonation after 25 years in mm*
B = *published compressive strength in kg/cm²*
■⊠□ = *PZ* ●○ = *HOZ* ▲ = *Cement unknown*
(According to A Meyer, H-J. Wierig, K Husmann ■●▲, *G. Rehm, H Moll* □○ *and H-J Kleinschmidt* ⊠)

lated according to the formula

$$X_{25} \cong X_t \cdot \sqrt{\frac{25}{t}} \qquad [8]$$

Though the strength data are probably not very exact, even these concretes show the same tendency as Fig. 10 proves. The dotted line in this diagram is calculated according to results of another very comprehensive German longtime study with > 15 cements and three *w/c* factors.

These examples sufficiently demonstrate the fact that the so far recommended—and several exceptions including—parameters "type of cement" and "*w/c* factor" and "precuring condition" are to be represented much better by the single summarizing factor $1/\sqrt{B}$ (23).

Conclusions

By comparing numerous carbonation studies in several laboratories for the storage condition "outdoors without rain" the average constants

$$a \cong 250 \quad \text{and} \quad B_G \cong 625$$

were estimated. Thus equ. [7] becomes

$$X \cong 250 \cdot \left(\frac{1}{\sqrt{B}} - \frac{1}{\sqrt{625}}\right) \cdot \sqrt{t} \qquad [9]$$

This relation is drawn on a graph in Fig. 11 for

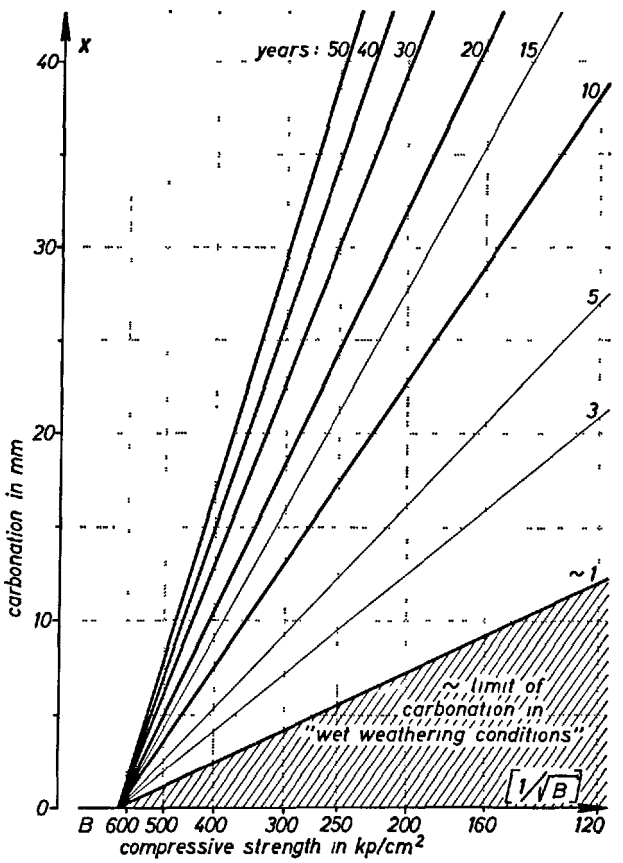

Fig 11. *Approximative carbonation of concretes "outdoors sheltered from rain" without afterhardening*

carbonation periods up to 50 years. This diagram stands for the very unfavourable case that the concretes have only little if any afterhardening.

$$X = 250 \cdot \left(\frac{1}{\sqrt{B}} - \frac{1}{\sqrt{625}}\right) \cdot \sqrt{t}$$

On the other hand it is well known that concretes with slowhardening cements generally develop slow but high afterhardening (27)

$$N = B_\infty - B_w$$

even in air of natural humidity conditions. In this case equ. (1) can be slightly altered in

$$\frac{1}{B} = \frac{1}{B_\infty} + \left(\frac{1}{B_w} - \frac{1}{B_\infty}\right) \cdot \frac{n \cdot t_w}{t + n \cdot t_w} \qquad [10]$$

B_∞ = final strength
B_w = strength after water curing (= B_0)
t_w = time of water curing
n = retarding factor
t = time of air storage (and carbonation)

The calculation of the relation between equ. [9] and equ. [10] is only possible by means of a rather difficult integration. Nevertheless the problem can be solved accurately by graphical constructions. As a final result Fig. 12 shows the carbonation progress of concretes "B 250" (kg/cm²) with afterhardening 'N = 250' (kg/cm²) and 'B 350' (kp/cm²) with afterhardening 'N = 100' (kp/cm²). (Constants of afterhardening according to [10] are $t_w = 1$ month and $n = 4$.)

It is to be seen that after 30 to 40 years the two concretes will reach quite the same carbonation as a 'B 425' without afterhardening. Furthermore this diagram demonstrates clearly another fact: It is impossible to calculate or extrapolate the carbonation of an old concrete by only using the carbonation of the present young concrete and without at least knowing its strength development (14) and (19).

Fig. 13 is a similar diagram like Fig. 11 for carbonation periods from 10 to 30 years without afterhardening (N = 0) and also taking into consideration two slow ($n = 4$) afterhardenings N = 100 kg/cm² and N = 250 kg/cm². This diagram provides an explanation for the experience that the relation

$$X \sim \frac{1}{\sqrt{B}} \cdot \sqrt{t}$$

is to be proved less accurately with old concretes

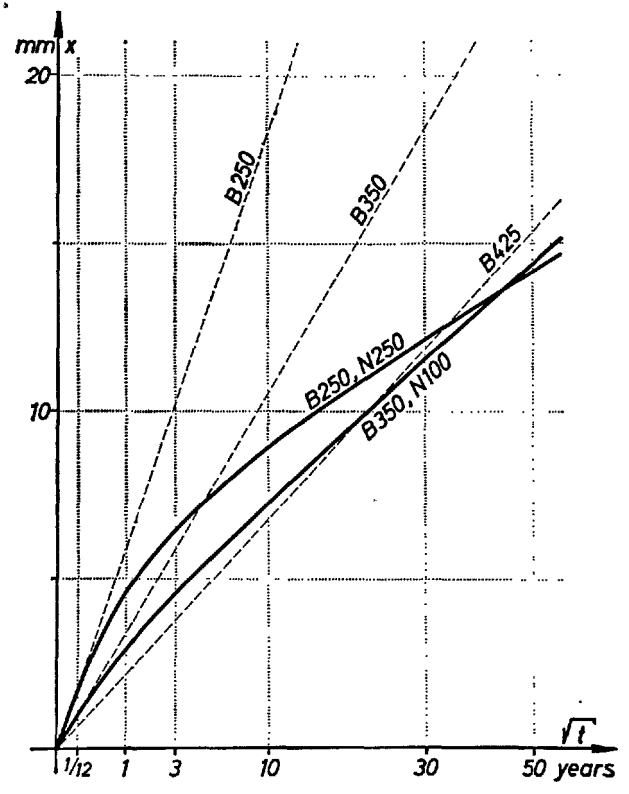

Fig. 12. *Approximative carbonation progress of different concretes with different afterhardening*
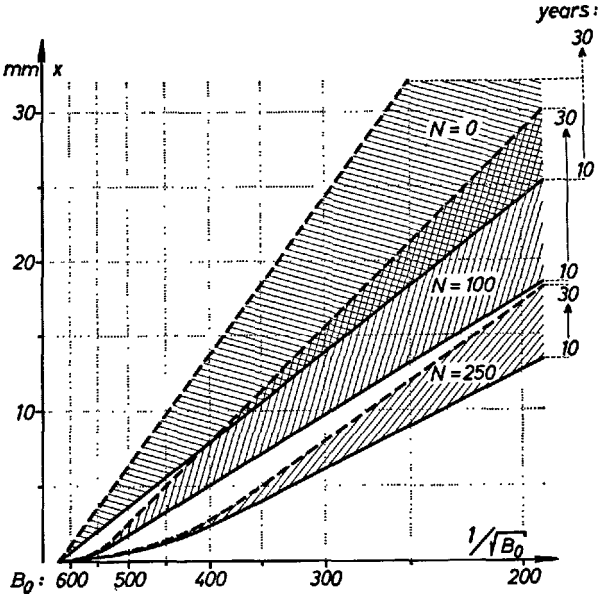
B = initial compressive strength in kg/cm²
N = afterhardening in kg/cm²
($a = 250$, $B_G = 625$, $n = 4$)



B_0 = initial compressive strength in kp/cm²
N = slow afterhardening in kp/cm²
x = carbonation depth in mm

Fig. 13. *Approximative carbonation of concretes "outdoors sheltered from rain" with afterhardening*
($a = 250$, $B_G = 625$, $n = 4$)

(see Fig. 10) than with mortars in a laboratory.

Following Fig. 12 and Fig. 13 grater differences in initial carbonation between cements with lower initial strength and high afterhardening and cements with higher early strength and low afterhardening will gradually disappear with growing age of older concretes. This corresponds exactly with the general results of extensive studies on old and very old concrete structures (4), (6), (11) and (14).

Summary

A high content of free $Ca(OH)_2$ cannot protect any concrete against carbonation.

In case of portland cements and blastfurnace slag cements the carbonation progress is practically entirely determined by the permeability of the concrete. Thus under constant storage conditions the entire carbonation behaviour can be calculated in first approximation by means of the initial strength and the afterhardening of the concrete only.

For this, not the knowledge of the chemical composition of the cement is necessary but the knowledge of the complete strength development of the concrete under certain distinct storage conditions.

At any rate it is safer to make a concrete with a sufficiently high content of normal or even with slow hardening cement than a concrete with similar initial strength but a lower content of high early strength cement.

Oral Discussion

Heinz G. Smolczyk

At first sight a direct relation between strength and carbonation rate (see my written discussion) seems to be strange, but this fact is proved by too many experimental results—once again by the supplementary papers III-16 of W. Manns and K. Wesche (see Fig. 1) and III-52 of A. Meyer (see Table 1).

And there is a theoretical explanation for this surprising result because of the relation between compressive strength B and capillary porosity ε_c in connection with the chemical composition of the cement. The tendency of this very relation is partly being reported of at this Symposium.

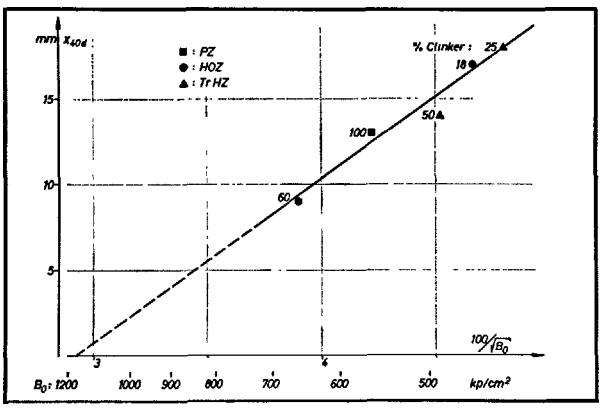

Fig. 1. *Carbonation of completely dried mortars after 40 days' storage in 9%CO_2*
B_0 = *compressive strength after heat-treatment (40°C or 105°C)*
x_{40d} = *carbonation depth*
(According to test results of K. Wesche)

According to R. Helmuth and G. Verbeck—principal paper III-1—compressive strength is proportional to 1-capillary porosity. We found an even better linearity—also with the test results of Helmuth and Verbeck—by plotting compressive strength against 1-capillary porosity, but the difference is only slight.

The results of R. Mills—supplementary paper III-46—show an increase in capillary porosity with increasing CaO/SiO_2—ratio at constant strength.

The studies of our laboratory with a mercury porosimeter showed the same tendency. Some results are to be seen in Fig. 2, where compressive strengths after 90 days' watercuring. Four cements with very different chemical composition and two water-cement

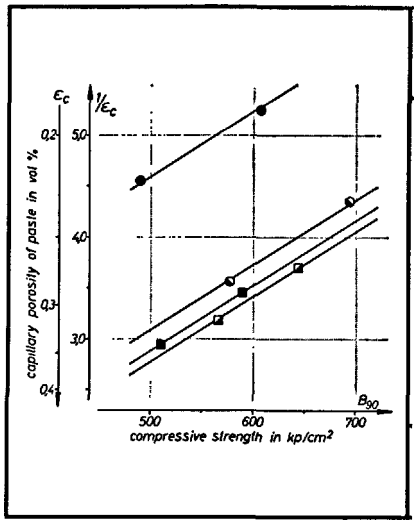

Fig. 2. *Relation between capillary porosity and strength Mortar prisms 4 × 4 × 16cm, w/c 0.50 and 0.60, 90 days' watercuring*

Chemical data in %

	slag	C/S	CaO	CO_2 max
■	0	3.3	66.4	~29
◪	25	2.7	60.4	~28
◓	50	2.2	54.5	~22
●	75	1.7	48.5	~16

ratios were tested, see the table beside the diagram. The general slope of the curves is the same for all cements, but the porosity decreases distinctly with decreasing clinker content, CaO/SiO_2 ratio, CaO content or maximum amount which could be expected after complete carbonation.

All these results lead to the tendency

$$\text{strength} = \frac{\text{f(CaO)}}{\text{f(capillary porosity)}}$$

and the empirical formula

$$\text{carbonation} \sim \sqrt{\frac{1}{\text{strength}}}$$

receives the theoretical explanation

$$\text{carbonation} \sim \sqrt{\frac{\text{f(capillary porosity)}}{\text{F(CaO)}}}$$

And this—on the other hand—corresponds very closely to the formula of R. Kondo, M. Daimon and T. Akiba—supplementary paper III-116.

Many precise experimental studies will be necessary to establish the exact mathematical relation but I think the validity of the general tendency is proved sufficiently by the great number of quite different test results published by quite different authors.

Author's Closure

Minoru Hamada

First of all, I wish to thank Dr. Smolczyk for having gone to the trouble of reading the many Japanese papers on the subject in order to prepare his very detailed discussion.

Dr. Smolczyk's opinions are based on tests carried out for 5 years at 3 research institutes in Germany, using portland cement, eisenportland cement and blast furnace slag cement.

I first with to explain that my standpoint is research has been to take reinforced structures above ground to clarify the relationship between rusting of steel and carbonation of concrete, as a reference for producing structures of long life, and therefore my ovservations are based on a broad point of view.

1. Very broadly speaking, I am in general agreement with his opinion that carbonation is unrelated to the free $Ca(OH)_2$ in paste. In other words, there are in the range of concrete of extremely high strength using high-early strength cement to concrete which is very porous such as cellular concrete, and taken as one group, it may be said that free $Ca(OH)_2$ and carbonation are unrelated.

Dr. Smolczyk's pinpointing of gross CaO rather than free $Ca(OH)_2$ is no doubt one way of considering the matter. However, the quantity of free $Ca(OH)_2$ resulting from hydration of CaO depends greatly on the degree of hydration, and the prevention of rusting of steel with which I am concerned is dependent on free $Ca(OH)_2$.

Further, the comment that there is $Ca(OH)_2$ remaining in neutralized portions is quite correct, but the question is whether this amount of $Ca(OH)_2$ will contribute towards prevention of rusting of steel.

I am not discussing whether or not free $Ca(OH)_2$ exists as a chemical component. My viewpoint is that steel in the portion of concrete which is not colored by phenolphthalein will rust.

2. It has been pointed out that carbonation will increase strength. This is naturally so, and I have no arguments against this.

3. Dr. Smolczyk states that depth of carbonation proportional to the root of the time of carbonation is suitable only with very old concretes. My concern is with the rusting of steel in concrete and therefore, naturally considers long-time age, and limited to this regard, both Dr. Smolczyk and I are basically in agreement.

4. Dr. Smolczyk suggests a method of expressing

depth of carbonation for various cements by a formula with not only age in years, but also early strength as factors. In contrast, I am of the thought that it would be more commonly applicable to indicate depth of carbonation with concrete materials-cement, aggregates, admixture—and water—cement ratio, cement paste quantity, etc. which are deeply related to the structure of concrete, as factors.

5. The depth of carbonation when using high early strength cement and long-term strength-gaining cement are discussed and an interesting analysis of data has been made. However, without going into the case of underground structures, it may be said that long-term strength gain at concrete in ordinary building structures cannot be expected.

In short, as to substantiate the point I emphasize in my paper, Dr. Smolczyk mostly aptly states at the end, manufacture of a dense and impermeable concrete comes before all else.

Supplementary Paper III-16 Variation in Strength of Mortars made of Different Cements Due to Carbonation

Wilhelm Manns and Karlhans Wesche*

Synopsis

By carbonation strength is varied in the area of the concrete surface: in the case of portland cement strength is increased, on the other hand, it was suggested that with slag sulphate cement strength is reduced by carbonation.

This has been confirmed by researches on structural concrete at an age of 4 to 10 years. Due to the considerable decrease in strength of concrete made of slag sulphate cement caused by absorption of atmospheric carbon dioxide which must be equalized with the known phenomenon of concrete corrosion, it should be considered whether this corrosion is confined to the slag sulphate cement only or whether it can be observed with other cements. Therefore, researches on the carbonation of mortar prisms made of six types of cements were carried out, namely on specimens of 1 portland cement, 1 slag sulphate cement, 2 blast furnace cements, 2 trass blast furnace cements.

The specimens were cured after drying in an air current enriched by 9% CO_2 and their strengths were compared with specimens cured at 20°C at a relative humidity of 65%. The influence of the absorption of carbon dioxide proved to be dependent on the type of cement, essentially on the content of portland cement clinker and thus on the content of $Ca(OH)_2$ produced by hydration: at a content over 40% clinker strength increased by up to 70%, at a content below 40% of clinker it decreased by up to 50%. The variation in strength is accompanied by a variation in the modulus of elasticity and in weight. The variation in weight is linear to that in strength so that it is possible to estimate by the variation in weight whether carbonation will induce an increase or decrease in compressive strength. The investigations will be continued.

Introduction

By carbonation, i.e. the reaction of carbon dioxide of the air, the alkalinity of cement paste and thus the rust protection of the reinforced and prestressed concrete structures is reduced. Particular attention has been devoted to this question and to the researches interconnected with the carbonation depth and the rate of carbonation in Japan and the Federal Republic of Germany during the last years. The question whether the strength characteristics of concrete will be changed and to which extent has not been followed, however, on a larger scale so far.

Previous Investigations

According to the American researches by Leber and Blakey (1), Kroone and Blakey (2), and Cole and Kroone (3) strength of concrete made of portland cement (PC) is increased by carbonation by about 40 to 100% which, according to Toennis (4), can be economically utilized for production of concrete blocks.

Mußgnug (5) found, however, that concretes made of slag sulphate cement (SSC) stored at room temperature developed strengths reduced by about 30 to 40% compared with those stored under water or in open air. Gaede (6) also observed on long term tests on 10 cm concrete cubes of blast furnace cement (BFC) and of SSC considerable decreases in strength which are, however, statistically verified for SSC only with about 20 to 35%, whereas for PC the already stated increase in strength could be deter-

*Institut für Bauforschung Technische Hochschule Aachen, Aachen, West Germany.

mined although somewhat reduced.

Basing on the results of Gaede, investigations have been made on 4 to 10 years old SSC concretes. For this purpose, cores with a diameter of 10 and 15 cm were taken from buildings and, if possible, three test specimens were made thereof. A height of 4 cm of the upper specimen was chosen to prevent an influence of the carbonated layer on the results of the successive specimens. The mean specimen had the usual specimen size with a slenderness ratio of $h/d = 1$, the height of the lower specimen was chosen with 4 cm to compare the strengths of the upper and lower specimens. The test results are summarized in Table 1.

Table 1. *Strength results of test specimens made of cores of SSC concrete*

	Slenderness ratio	Strength (mean value) kg/cm²	Standard deviation kg/cm²	Sample size
upper specimen	0.25–0.40	636	106	20
mean specimen	1	580	59	19
lower specimen	0.25–0.40	798	106	14

Because of the influence of the specimen height the strengths of the upper and lower layers can be compared only. A statistical check of the characteristic values of the random test showed that the compressive strength values of the two random tests differed significantly. The difference between these compressive strengths is given with a statistical safety of S = 95% within a range of 85 to 235 kg/cm².

If the compressive strengths of the surface layer, i.e. specimens with carbonated concrete, are plotted against the carbonation depth the correlation coefficient points to a significant relation between the two variables, so that it can be assumed that the significant difference in strength between external and internal concrete is also due, besides other influences, to the influence of carbonation causing decrease in strength.

Manns and Sasse (8) found by ball penetration tests according to DIN 4240 that, on 20 cm concrete cubes made of SSC, the penetration measuring instruments indicating the strength of the surface layer only could be assigned to a strength which had a mean value of about 30% below the destructively tested strength.

Induced by the somewhat contradictory behaviour of PC and SSC reported of in previous papers, Manns and Schatz (14) carried out carbonation tests on cement mortar prisms of different cements in the Institute of Building Research of the Technical University Aachen.

Tests

Six cements of different compositions were tested and the magnitudes influencing carbonation such as there are temperature, humidity, cement content, water/cement ratio, compaction, and surface of specimen were kept invariable. The following cements were chosen: 2 blast furnace cements (BFC I and II), 2 trass blast furnace cements (TBFC I and II), 1 slag sulphate cement (SSC), and 1 portland cement (PC).

Some cement characteristics are shown in Table 2.

Table 2. *Several characteristics of cements used for carbonation tests*

[1] without calcium sulphate
[2] values which do not belong to the Institute of Building Research

For the tests according to DIN 1164 standard cement prisms were made and cured for 28 days according to the Standards and then dried at 40°C up to constant weight (By mistake, the PC prisms were dried at 105°C.).

The storage temperature of 40°C was chosen for two reasons: firstly to prevent a liberation of crystalline bound water, and secondly to anticipate a postponed hardening of the mortar. Storage of water saturated cement mortar prisms at 40°C has accomplished this effect since the compressive strength values given below of specimens stored under constant air conditions did not indicate any tendency to an increase in strength.

After drying part of the specimens was stored under constant air conditions at 20°C and at a relative humidity of 65% (air curing). The remaining test specimens were cured in a CO_2 apparatus. The CO_2 apparatus consisted of two superimposed sheet steel boxes connected on their ends by semi-circular tubes. Circulating air was provided by a built-in ventilator, a thermostat was adjusted for an equal temperature of 25°C, the relative humidity measured by a hygrometer varied between 65 and 70%. Through test gas meters 3.3 l air/min. and 0.33 l CO_2/min. were supplied to the CO_2 apparatus. The test gas meters were adjusted semi-diurnally to exclude any irregularities in the supply of air and CO_2 so that the air was enriched by an average of about 9% CO_2. The apparatus was not gas tight so that an excess pressure could not arise (CO_2 curing).

In given intervals, two specimens, each of which was taken out of the CO_2 apparatus and one specimen out of the air-conditioning room and, after determining the weight, were tested for modulus of rupture and compressive strength according to DIN 1164. Between the modulus of rupture and compressive strength tests the common phenolphthalein test was carried out. With the exception of PC, the phenolphthalein test distinguished colourless zones sharply from coloured ones. If a specimen showed no longer a red colouring, it was designated as completely carbonated. The carbonation depth of PC could presumably not be clearly determined since the hydration of PC was abruptly stopped by drying at 105°C and continued by CO_2 curing so that calcium hydroxide was freed continuously over the whole section also influenced by CO_2.

Test Results

Compressive Strength

In Fig. 1 the compressive strength is plotted against the time by determining the terminated drying as starting point. It can be seen that strength development of

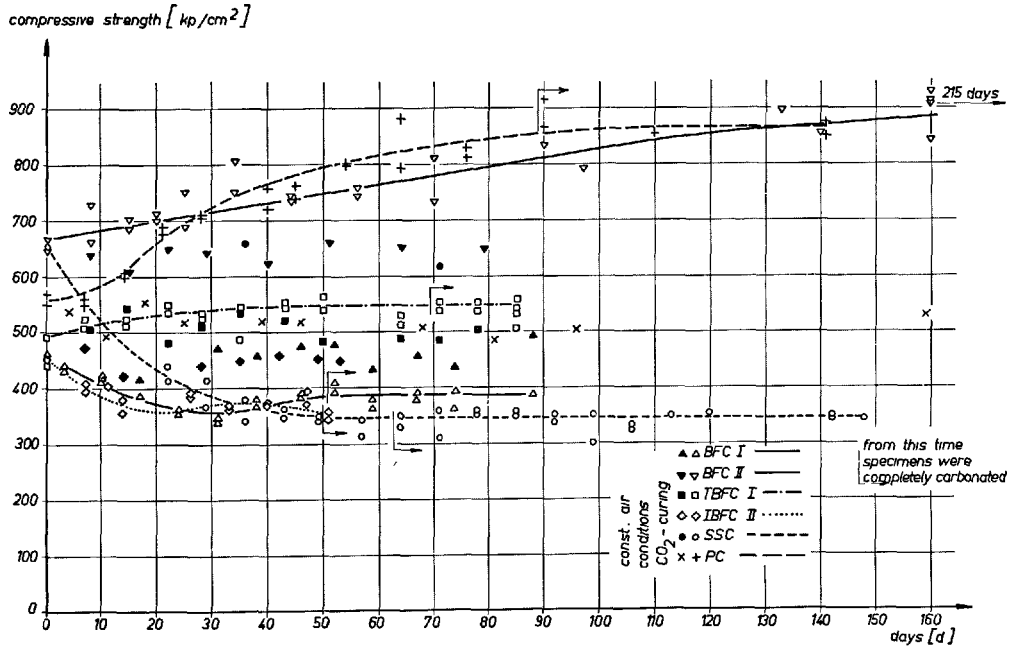

Fig. 1. *Relation between compressive strength and the duration of CO_2 curing and under constant air conditions resp.*

the individual cements differed considerably. This is still more obvious when instead of the absolute strength values the relative strength values are chosen as percentages of the compressive strength upon starting the CO_2 curing and curing under constant air conditions respectively (Fig. 2). The strength values

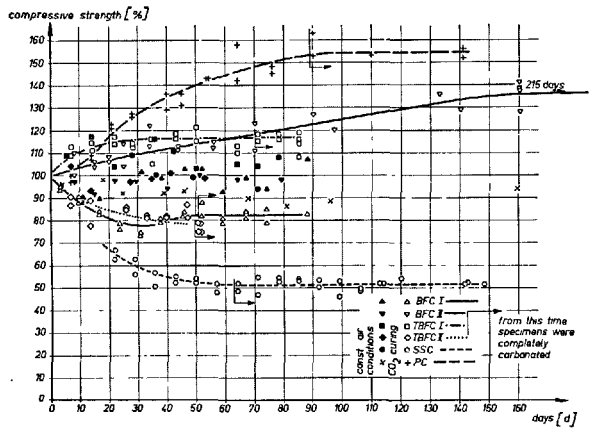

Fig. 2. *Change in compressive strength at CO_2 curing and under constant air conditions resp.*

under constant air conditions do not show any tendency: they vary in accordance with the natural scattering about the mean value of 100%. The strength values of the CO_2 curing have either an increasing or a decreasing tendency for the individual cements, however, they change any more after reaching a limit value different for each cement. This limit value was attained when carbonation of the specimen was completed and for PC specimens the first remarkable change in colour became obvious in the centre of the specimen. For PC, BFC II and TBFC I test specimens compressive strength values of carbonated mortar were above and for BFC I, TBFC II and SSC test specimens below the strengths upon starting the CO_2 curing.

A further insight into the relationship between compressive strength and carbonation provides the relation of the compressive strength as a function of the carbonation depth. The tendency of the relations is the same for the individual cements as shown in Fig. 1. The values, however, form a S-shaped curve. It should be added to this that a change in compressive strength cannot be discovered up to a carbonation depth of 5 mm and at a carbonation depth of about 15 mm, strength does not increase nor decrease any

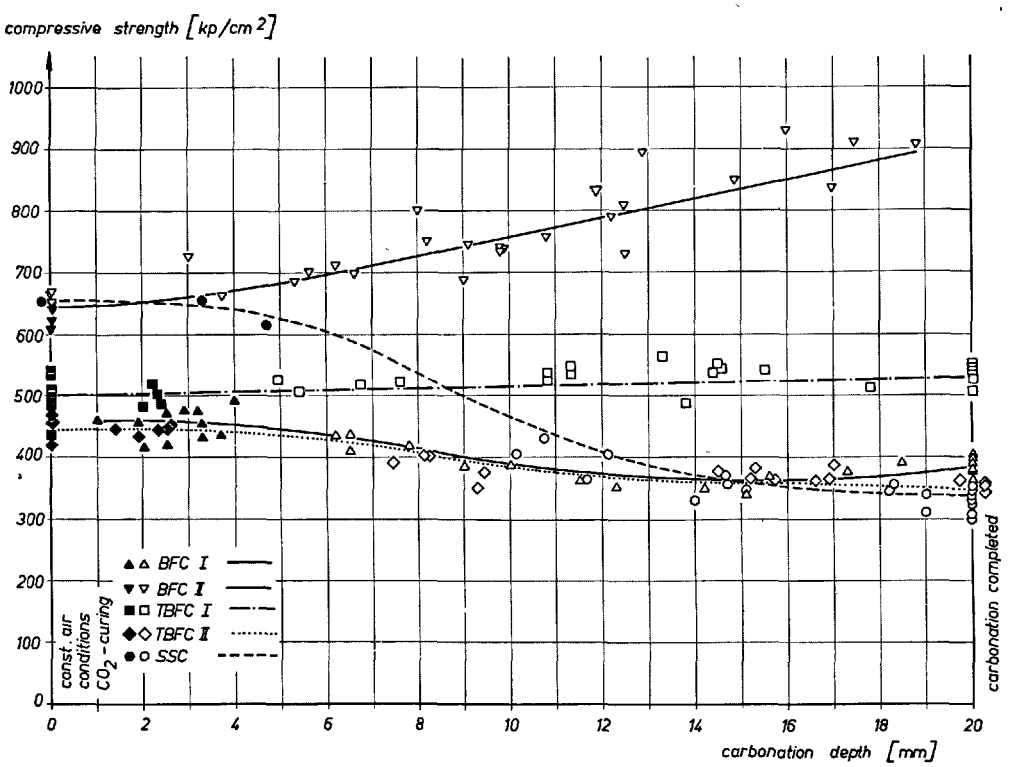

Fig. 3. *Relation between compressive strength and carbonation depth*

more. Since the latter can be presumably explained by the form of the fracture of the specimen it is difficult and not logical to draw up a mathematical relationship between compressive strength and carbonation depth which is based on these tests. The compressive strength as a function of carbonation is, however, well expressed if the absolute strength values are substituted by those refering to CO_2 curing and curing under constant air conditions respectively (Fig. 4).

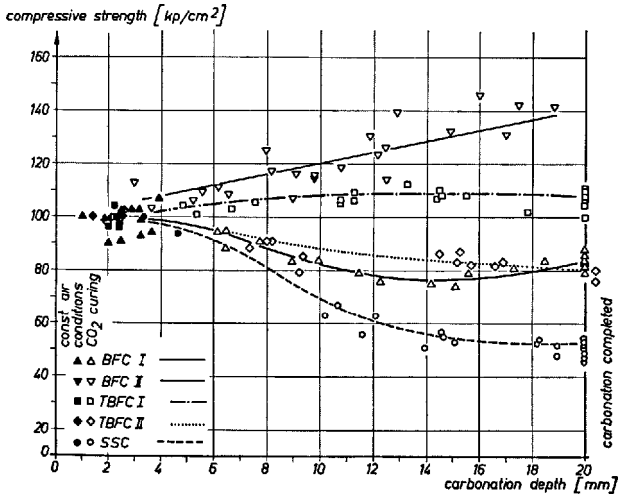

Fig. 4. *Relation between compressive strength and carbonation depth (at K = 0 mm, β_D = 100%)*

Modulus of Rupture

In Fig. 5 the modulus of rupture is plotted as a function of the time and in this diagram the end of drying is given as the starting point. At first, the modulus of rupture of all cement types decreases considerably during CO_2 curing and it increases after some time of storage to a greater or lesser extent to adjust, after the specimens are completely carbonated, to a value which is above or below the initial values depending on the type of cement. A still better insight into the relationship between modulus of rupture and carbonation is given by plotting the modulus of rupture against the carbonation depth (Fig. 6). Here is also shown the decrease of the modulus of rupture of all cements, however, for a carbonation depth up to 6 to 10 mm only, thereupon the modulus of rupture increases in a greater or lesser extent up to the completed carbonation of the specimens. This irregularity in the development of the modulus of rupture can be explained by the shrinkage process caused by carbonation which has been investigated by Powers (9), Leber and Blakey (1), and Verbeck

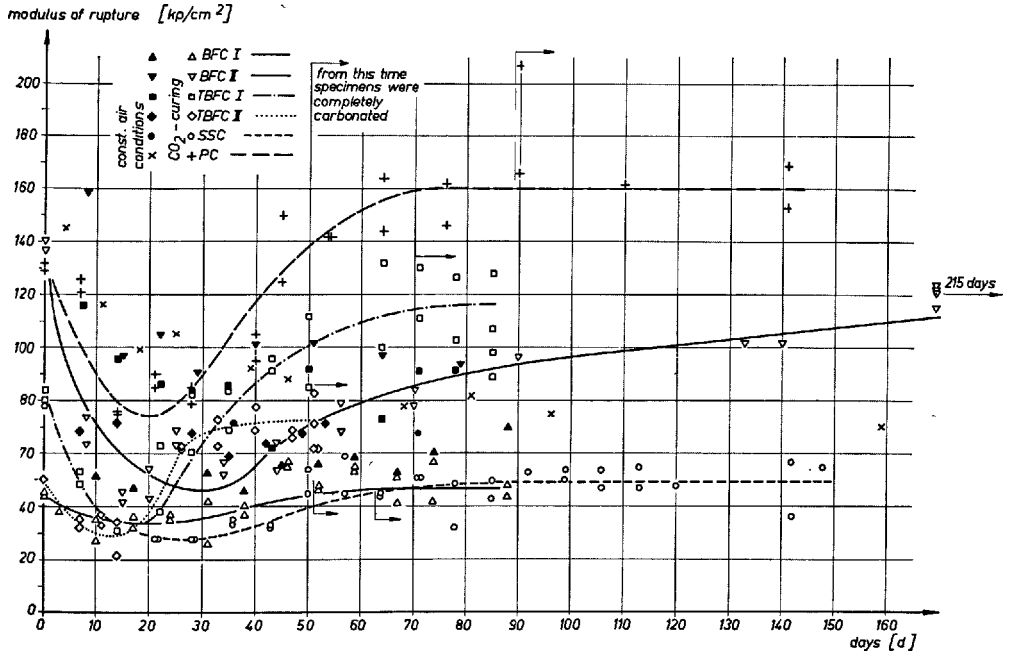

Fig. 5. *Relation between modulus of rupture and time of CO_2 curing and under constant air conditions resp.*

(11). Hereby, compressive stresses occur in the core and tensile stresses in the carbonated zone which reduce the modulus of rupture determined by the flexural test. This initial tensile stress of the tensile zone reaches probably its highest value at a carbonation depth of 6 to 10 mm which is then reduced with progressing carbonation and which will become zero when the carbonation process is completed. Then, the modulus of rupture determined in this phase cannot be falsified by shrinkage stresses caused by carbonation. The internal stresses caused by the carbonation process can be estimated from Fig. 6, however, it must be taken into account that the elastic behaviour may be changed with carbonation. Tests give rise to assume that changes in strengths and in the elastic behaviour are alike.

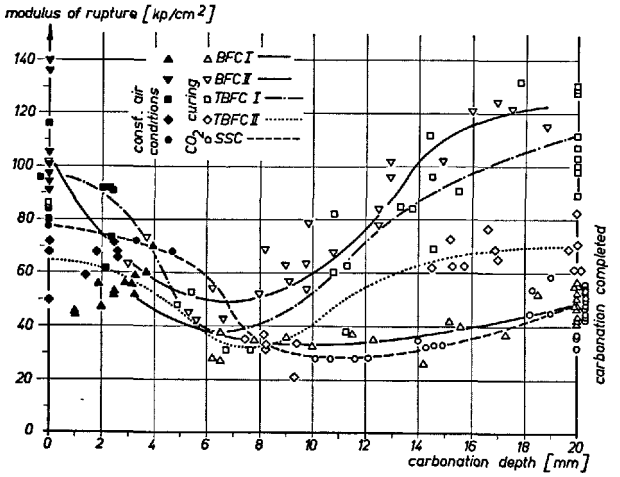

Fig. 6. *Relation between modulus of rupture and carbonation depth*

Change in Weight

In Fig. 7 the change in weight is plotted as a function of the time with the end of drying as zero point. It can be seen that the mortar prisms of PC, BFC II and TBFC I have increased in weight, those of SSC, however, decreased in weight, those of BFC I and TBFC II first increased in weight and afterwards decreased. When carbonation is completed, a considerable change in weight does not occur emphasizing that the chemical process is finished. In comparing the time behaviour of the change in weight and the compressive strength (Fig. 2) it can be noted that both follow the same tendency and that the termination of weight change nearly coincide with the change in compressive strength. It is, therefore, obvious that there is a correlation between change in weight and

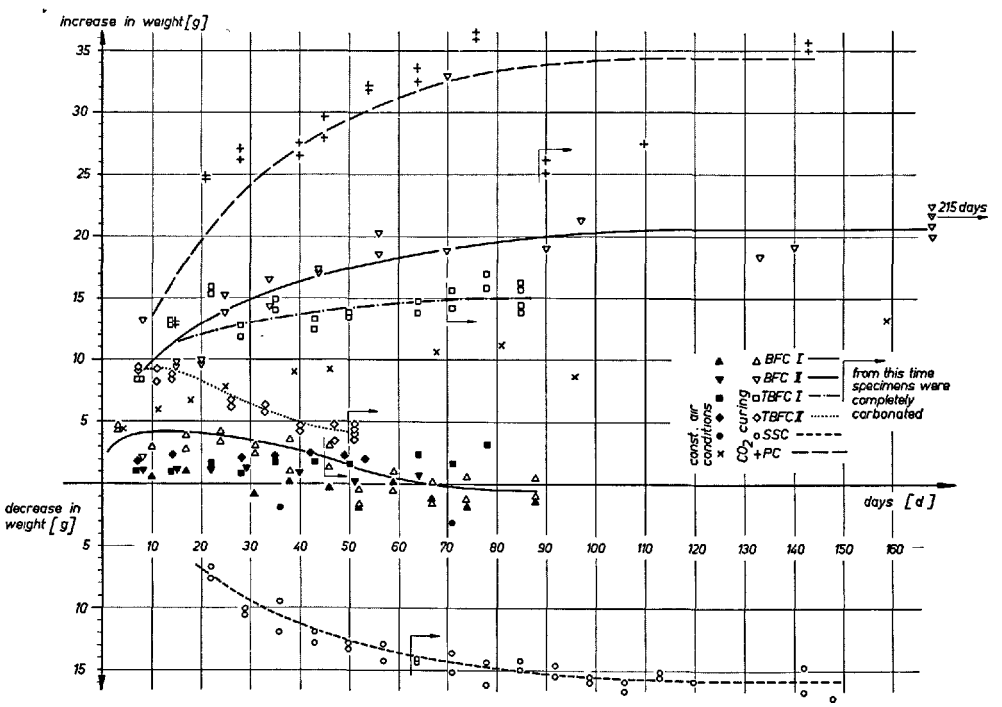

Fig. 7. *Change in weight at CO_2 curing and under constant air conditions resp.*

change in compressive strength. It should be considered, however, that the test specimens increase in weight after drying at 40°C (specimens of PC at 105°C) in the CO_2 apparatus at a relative humidity of 65 to 70% up to reaching equalized moisture. PC specimens increased in weight by about 11 g, all other specimens by 1 to 2 g. Thus two processes were interacting at the change in weight: the increase in weight caused by taking up humidity and the change in weight caused by carbonation. This fact explains the course of curves for specimens of TBFC II and BFC I. In plotting the relation between change in weight and change in compressive strength in Fig. 8, the change in weight caused by taking up humidity is eliminated up to equilibration. By the method of least error squares the correlation line was determined in the form of

$$\Delta\beta_D = a \cdot \Delta G_K + b$$

The following equation was developed with $a = 13.0$ and $b = -15.1$:

$$\Delta\beta_D = 13.0 \cdot \Delta G_K - 15.1$$

$\Delta\beta_D$ = change in compressive strength in per cent
ΔG_K = change in weight in per cent caused by carbonation.

The confidence limit of the determined straight line was also calculated and is shown in Fig. 8. The precision equivalent for the equation was $B = 0.84$. It can be seen from the diagram that the values for PC deviate somewhat from the straight line which probably depends on the different drying method. However, a valuable information is given by this unintentional difference in treatment that probably different preliminary treatment, even though unessential, may modify the found relation. The test for linearity, i.e. the evidence whether the assumption of a linear relation is justified, resulted in a statistical security of S = about 95% if the PC specimens were included, if they were excluded, however, it resulted in S = about 99% (Fig. 9). If the PC specimens were not considered, the values resulted in $a = 10.8$ and $b = -18.5$ for the constant of the straight line equation at a precision equivalent of $B = 0.92$.

The change in weight due to carbonation may be caused by

a) the carbonation of the calcium hydroxide in releasing 1 mol H_2O from 1 mol CO_2. Even if it is assumed that the water is completely evaporated, a considerable increase in weight remains;

b) the carbonation of crystal and gel connections. Some mols H_2O are released by 1 mol CO_2 from which at least one part must evaporate since the specimens had an equilibration humidity. D'Ans and Eick (12) for instance, give for carbonation of ettringite the following reaction equation:

$$C_3A \cdot 3CaSO_4 \cdot 32H_2O + 3CO_2 \longrightarrow$$
$$3CaCO_3 + 2Al(OH)_3 + 3CaSO_4 \cdot 2H_2O + 23H_2O$$

According to this reaction 4 mols CO_2 are taken up whereas 23 mols water are released. Even if it is assumed that only part of the water is diffused out and changed over into the evaporable form, a considerable decrease in weight is still remaining.

This assumption is strengthened by the fact that PC specimens released considerable more calcium hydroxide in hydration, contrary to the other tested specimens, and developed the highest increase in weight, whereas SSC specimens developing less free calcium hydroxide but containing large quantities of ettringite showed the highest loss in weight. It is uncertain whether the decrease in compressive strength along with a loss in weight may be connected with the reduced strength of the forming products or

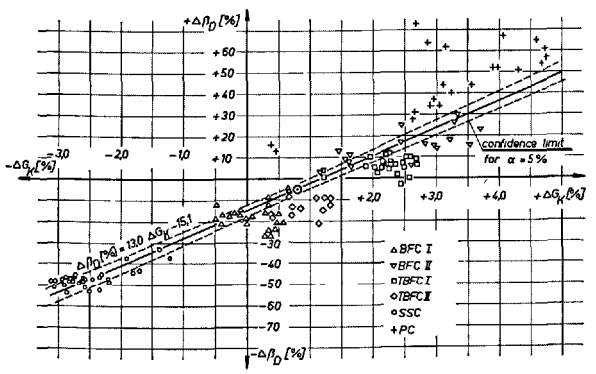

Fig. 8. *Relation between change in compressive strength* ($\Delta\beta_D$) *and change in weight* (ΔG_K)

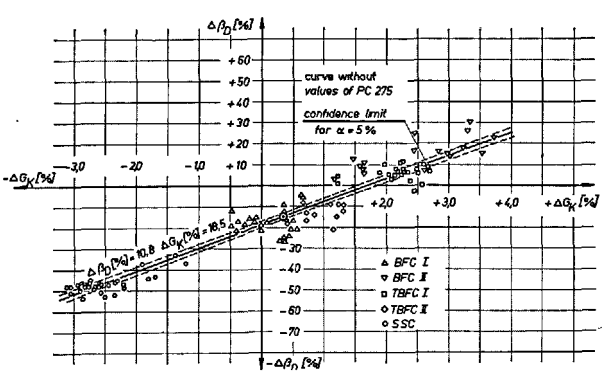

Fig. 9. *Relation between change in compressive strength* ($\Delta\beta_D$) *and change in weight* (ΔG_K)

with an inferior density of cement paste.

Change in Compressive Strength and Clinker Content

The assumption that change in compressive strength depends on the quantity of released calcium hydroxide which is highly affected by the clinker content of the cement, points to the conclusion that there is a regression between clinker content of cement and changes in compressive strength. Change in compressive strength after completed carbonation in relation to the strength at 28 days (upper values) and the strength after heat treatment (lower values) is shown in Fig. 10 as a function of the clinker content. Mean values were plotted only. It is noted that regression of these test values can be approximated by a straight line, even so, if the value of the change in strength of SSC in relation to the 28 days strength deviates considerably. For calculation of the regression straight lines mean values only were used, since the number of the individual values for each cement was different. In using the equilibration calculation, the following equations and precision values can be given:

$$\frac{\beta_{DK}}{\beta_{D28}} = 1.44\,A + 76.5 \quad \text{with } B = 0.94$$

$$\frac{\beta_{DK}}{\beta_{D\infty}} = 1.16\,A + 54.8 \quad \text{with } B = 0.96$$

β_{DK} = compressive strength in the state of completed carbonation

β_{D28} = compressive strength prior to drying

$\beta_{D\infty}$ = compressive strength after drying (this strength corresponds nearly to the ultimate strength)

A = clinker content in % (PC = 100%)

β_{DK}/β_{D28} and $\beta_{DK}/\beta_{D\infty}$ resp. = 100 give the clinker content, a falling below of which results, following these tests, in a decrease in strength which gives in the first case about 20% and in the latter ab. 40%.

Rate of Carbonation

In practice, the rates of carbonation determined by these tests cannot be assigned to atmospheric conditions nor can be used for a prediction of carbonation depths, nevertheless they should be given for completion's sake. In Fig. 11 carbonation depths are a linear function of the time. In Fig. 12 they are given on a double logarithmic scale. It may be of interest, however, to note that the rates for specimens of BFC I, TBFC I and II and SSC do not differ considerably, the specimens of BFC I, however, is carbonated at a much slower rate.

Conclusions

As stated, conditions of temperature and humidity, cement content, water/cement ratio, compression, surface of specimens, and CO_2 enrichment were kept constant so that the results relating to other conditions have limited validity only. Further researches are being made in the Institute of Building Research and are directed to the above mentioned magnitudes. The compressive strength results correlate well with American results (1, 2, 4, 10, 11, 13). The difference in strength observed by the authors on 4 to 10 years old SSC concretes of partly carbonated and non carbonated specimens can, according to the test results, be fully related to decrease in compressive strength caused by carbonation. Similar results have been found by investigators (1, 2, 4, 11) for flexural tensile strength and increase in weight.

The conclusion of Toennis (4) that weight control is a solid method in determining the magnitude of carbonation can be supplemented in so far as for all cements the change in weight is linear to the change in compressive strength and that it allows an estimation whether carbonation affects an increase or decrease in compressive strength.

Furthermore, it is questionable whether the problem of a decrease in compressive strength is of any significance in practice. If under normal conditions the carbonation processes at such a slow rate that a structural member cannot completely be carbonated, due to its life or due to its dimensions, or even if carbonation is stopped because of environmental conditions after reaching a maximum depth, it cannot be expected, in general, that a building may loose its stability. This statement can, however, be considered as secured only by profound investigations into all questions, the more as with thin bending members the carrying capacity determining the compression zone is only some centimeters in height. If, however, surface requirements are to be met as to hardness and wear, the test results will give valuable hints for practical works. Linear regression between PC clinker content and change in compressive strength caused by carbonation resulted in an increase in strength at a clinker content $>40\%$ and a decrease in strength at a clinker content $<40\%$. Whether this limit of 40% of the clinker content will be also confirmed under other conditions must be clarified by further researches.

Supplementary Paper III-52 Investigations on the Carbonation of Concrete

Adolf Meyer*

Synopsis

Tests carried out on concrete and mortar under defined conditions showed that the age, the composition of the concrete and the conditions of storage are to be considered as the main factors influencing the progress of carbonation. An investigation of concrete samples taken from 53 old building constructions had longly confirmed the tendency of the interdependence found under definrd conditions. The test results allowed, to predict approximatively the depth of carbonation for a certain concrete. The carbonation resistance of a fully compacted and normal cured concrete is essentially determined by its water/cement ratio and by the type of cement used.

Introduction

Concrete exposed in air will release more or less of its free water. This drying process involves primarily the layers next to the surface. The progress and the degree of the evaporation depend upon the conditions of storage and the structure of the concrete. During the evaporation the pore-water in the concrete is replaced by air, and from this time on, carbon dioxide can react with the alkaline compounds of the concrete. This transformation that reduces the initial alkalinity of the concrete is called carbonation. The carbonation may have an undesirable influence on the protection of the steel in reinforced concrete against corrosion. It is therefore interesting to know under what conditions a profound carbonation of the concrete will occur, and what depth the carbonated layer will reach.

In the present paper tests made in the Laboratory of the Westphalian Cement Industry are briefly dealt with. In these tests Dr.-Ing. H.J. Wierig and Dr.-Ing. K. Husmann took part besides the author.

Methods to Demonstrate the Reaction of Carbon Dioxide in Concrete

The depth of the carbonated layer in mortar and concrete can be determined by various methods. The microscopic detection of the calcium carbonate is a precise method. As a rule, a distinct border between the unchanged hydrated phases of clinker and the newly formed calcium carbonate is clearly to be seen in thin sections. The calcium carbonate with its pronounced double refraction in polarized light differs clearly from the almost isotropic cement gel and the less double-refractive calcium hydroxide.

In serial tests, the use of pH-indicators has proved well. These indicators do not allow to determine the exact pH of the concrete, they merely indicate the depth of the modified concrete layer. Comparative tests made on thin sections have confirmed that a 2% solution of phenolphtalein in ethyl-alcohol makes visible the border zone between the carbonated and the not carbonated concrete. Besides phenolphthalein thymolphthalein and alizarin yellow R are used as indicators. The zones dyed by these indicators are virtually identical to those coloured by phenolphthalein, see Fig. 1. However, in practice the colouring properties of these indicators are often less distinct than those of phenolphthalein.

The concrete to be tested should be broken or cut two days before the determination of the depth of the carbonation by pH-indicators take place. In cutting the concrete not hydrated cement particles are layed bare, that might interfere with the determination of the carbonation level.

Due to the presence of porous aggregates, cavities and cracks in the concrete, the carbonation level seldom appears as a straight line parallel to the surface

*Portland-Zementwerke Heidelberg AG, Forschungs und Beratungsstelle Heidelberg, West Germany.

of the concrete. One observes irregularities of that borderline that render difficult the precise determination of the depth of carbonation. Fig. 2 shows our definition of the depth of carbonation. In the cases *a* and *b* only the measured value *k* is indicated, in case *c*, the maximun value k_{max} is stated additionally.

Properties of Concrete Affected by Carbonation

Protection of the Reinforcement against Corrosion

It has been found out by appropriate tests that the passivation ensuring the protection of the steel against corrosion is neutralized by carbonation (1, 2). As a result, the steel in a carbonated concrete will undergo corrosion as soon as two other conditions are present: access of oxygen and of moisture. In a dairy we have had some years ago the opportunity to study the effect of the passivation of steel in reinforced concrete. In this dairy the steels of a reinforced beam were partially embedded in carbonated concrete and partially in non-carbonated concrete, see Fig. 3. The depth of the carbonation was after about 40 years 26 mm. The steel was covered with 15 mm of concrete. In the near of the wall the concrete cover was thicker. Here in the non-carbonated zone—red coloured by phenolphtalein—the steel showed no sign of corrosion while in the grey carbonated zone severe corrosion had

occurred.

Strength

The influence of carbonation on the strength was studied by cylinders 11.3 mm in height and in diameter. The mix of the mortar was cement: sand: water 1: 3: 0.4 by weight. The small cylinders were made from 11 different cements and stored as follows:

a) 56 days under water
b) 28 days under water, 21 days exposed in air at 10% CO_2 and 80% of relative atmospheric humidity, then 7 days under water.

In storage a non-carbonation of the mortar occurred. In storage *b* all samples were completely carbonated. The results of the strength tests after 56 days are summarized in Table 1.

The effect of carbonation was by no means identical in all cases. In mortars of portland cement and of portland blastfurnace cement the compressive strength increased significantly, while in mortars of blastfurnace cement containing approx. 50% of blastfurnace slag and in mortars of aluminous cement the increase was not significant. The strength of mortars made from blastfurnace cement with a high slag content remained almost unchanged. In mortars made from supersulphated cement the strength decreased clearly.

Permeability

Cores of 15 cm in diameter were extracted from 6 concrete building constructions presenting a rather deep carbonation. Slices of 3 cm were cut out from the carbonated and the non-carbonated zones of these cores. These specimens were tested as to their permeability for water vapour by the method described in (3). In these tests the carbonated specimens were almost as impermeable as the non-carbonated ones.

Similar results were obtained in partially carbonated mortar specimens stored 4 months in water and then exposed to an atmosphere enriched with for carbon dioxide. In these tests the differences of the permeability of the carbonated and the non-carbonated specimens remained within the limits of the margin of error.

As far as the progress of carbonation is concerned, an eventual difference of permeability between non-carbonated and carbonated zones would be of minor importance since the carbon dioxide of the air will always pass through carbonated concrete on its way from the surface of the concrete to the level of carbonation.

Moisture Movement

3 concrete specimens 15 cm in diameter and 2 cm thick, were extracted from the carbonated and the non-carbonated zones of a 43-year old concrete. The sides and the bottom of the specimens were sealed and the specimens were saturated several days with water. Then the specimens were stored in air 20°C, 65% of relative humidity. In Fig. 4, the loss of water in kg/m² is plotted as a function of the time. It was found out that the carbonated concrete dried faster at the beginning than the non-carbonated concrete.

Shrinkage

We did not perform tests to study the shrinkage of mortar and concrete due to carbonation. We refer however to the numerous papers dealing with this subject (4) (5). The carbonation results in a slow ir-

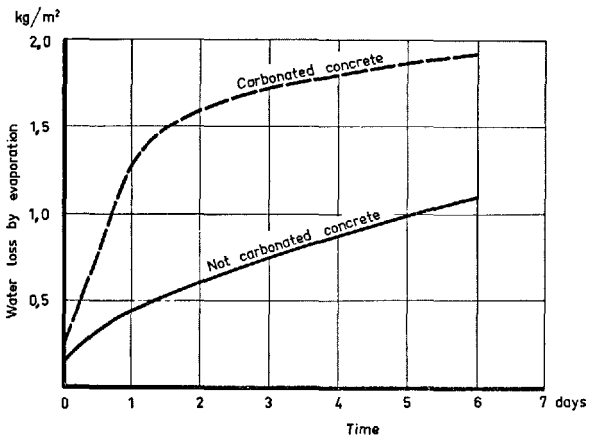

Fig. 4. *Water loss of wet concrete in air (20°C and 65% relative humidity)*

reversible contraction.

Test Series

The main factors bearing on the progress of carbonation are being studied in 5 test series. Moreover, we have determined the depth of carbonation in 60 different concretes, the age, the composition and the storage conditions of which were known to us. These tests are called "test series 6".

In all the test series the depth of carbonation was determined by spraying the breakage or cutting surface with phenolphtalein. All the concretes and mortars described in the following part were stored in normal atmosphere.

In some tests carried out simultaneously in an atmosphere enriched with carbon dioxide the progress of carbonation was considerably accelerated. However, this result is true only as long as the progress of the carbonation is determined by the diffusion of carbon dioxide, while it does not apply to the progress due to the migration of the evaporation level. It is therefore advisable to dry the samples prior to the exposure to air enriched with carbon dioxide, so that the level of humidity is almost the same in all samples. By the way, it is well possible that other chemical equilibria will occur when mortar and concrete are exposed to higher pressures of carbon dioxide. This fact might disturb the interpretation and the evaluation of the results.

Influences on the Progress of Carbonation

Test series 1

Specimen: Concrete beams $10 \times 15 \times 50$ cm
Cement : aggregate : water = 1 : 5.4 : 0.53 per weight (mix)
Type of Cement: 4 Portland cements, 3 Blast-furnace cements
Storage condition: 4 weeks wet, then placed on the small side and submerged to half its height in water, the other half being exposed to normal room air.
Age: 8 years up to now

Test series 2

Specimen: Concrete cubes $10 \times 10 \times 10$ cm
Water/cement ratio: 0.4 to 0.8
Type of Cement: Portland cement Z275
Storage condition: a) 1 day wet, then exposed to normal room atmosphere
b) like a), but once a week submerged in water for 1 hour
Age: 4 years up to now

Test series 3

Specimen: Concrete beams $10 \times 15 \times 70$cm
Water/cement ratio: 0.4, 0.5, 0.6, 0.7 and 0.8
Type of Cement: 1 Portland cement, 3 Blast-furnace cements, 1 Pozzolanic cement
Storage condition: 7 days wet, then in an airconditioned room: 18°C/50% of relative atmospheric humidity
Age: 3 years up to now

Test series 4

Specimen: Mortar prisms $4 \times 4 \times 16$ cm
Water/cement ratio: }
Type of Cement: } see test series 3
Storage condition: }
Age: 3 years up to now

Test series 5

Specimen: }
Water/cement ratio: } see test series 3
Type of Cement: }
Storage condition: like in test series 3, but once a week submerged in water for 2 minutes
Age: 3 years up to now

Effect of Age

Fig. 5 shows the average depth of carbonation in % as related to the age (test series 1 and 2). The depths of carbonation measured on the last day of the test were considered as 100%. These values are medium values for different concretes, the values of each concrete differ more or less from the average. The measuring points of each test series form almost a straight line. Since on the abscissa the age is plotted as a radical value, an almost quadratic function exists between the depth of carbonation and the age of the concrete stored in air. Theoretically we get the same relation between depth of carbonation and age by using Fick's first diffusion law for the diffusion of carbon dioxide in concrete.

The two curves of Fig. 5 do not cross the abscissa at the end of the curing period, but somewhat later. Obviously, carbonation starts after a certain induction time, but this time is of minor importance when long periods are considered. The relations between the depth of carbonation and the age apply only to concretes in which the evaporation of the free water is faster than the diffusion of the carbon dioxide into the concrete. In concretes exposed to atmospheric precipitations, the progress of carbonation is slowed down by the absorption and evaporation of water. In this case the depth of carbonation may be limited by the depth of drying.

Effect of Composition of Concrete

In a fully compacted concrete with dense aggregates and without air-entraining admixture the progress of carbonation depends largely upon the water/cement ratio and the type of cement used.

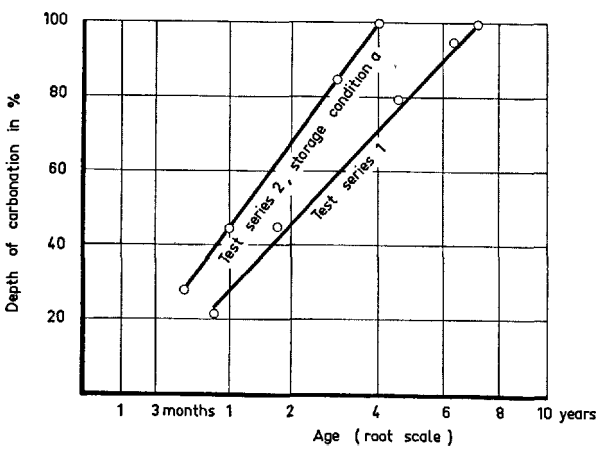

Fig. 5. *Effect of age on the progress of carbonation*

Water/Cement Ratio

Fig. 6 interprets the test series 3, 4 and 5. The depth of carbonation in concrete and mortar $2\frac{1}{2}$ years old having a water/cement ratio of 0.6 is = 100%. The depths of carbonation measured at different water/cement ratios are related in percent to that value. Between the water/cement ratio and the depth of carbonation existed nearly a linear function. In trials made at a relative atmospheric humidity of 65%, the depth of carbonation depended more on the water/cement ratio when the latter was low. That means, that the curve in Fig. 6 is a little steeper geometrically.

Type of Cement

In Fig. 7 the results of test series 1 are indicated, in

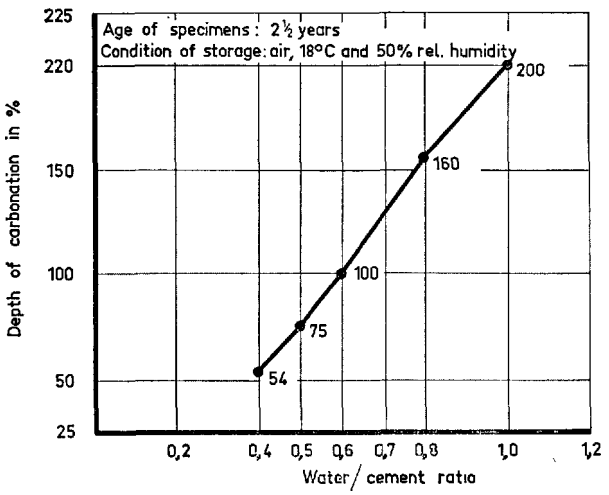

Fig. 6. *Effect of water/cement ratio on the progress of carbonation (results of test series 3, 4 and 5)*

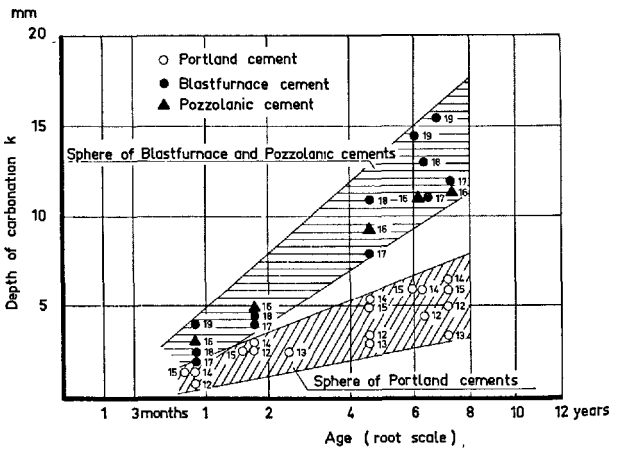

Fig. 7. *Effect of cement type on the progress of carbonation (results of test series 1)*

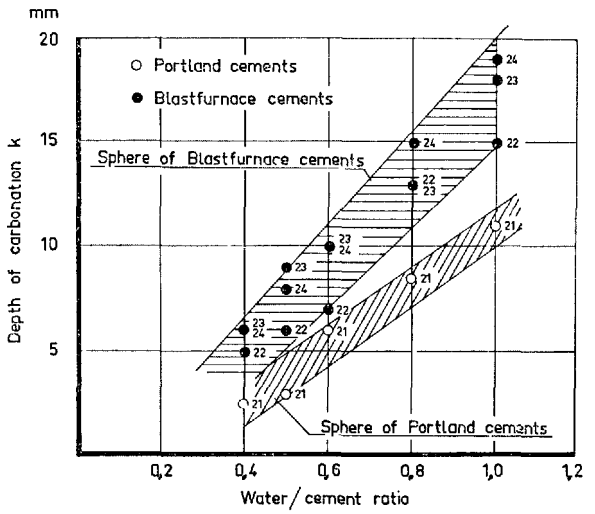

Fig. 8. *Effect of water/cement ratio and cement type on the depth of carbonation of concrete 2 1/2 years old (results of test series 3)*

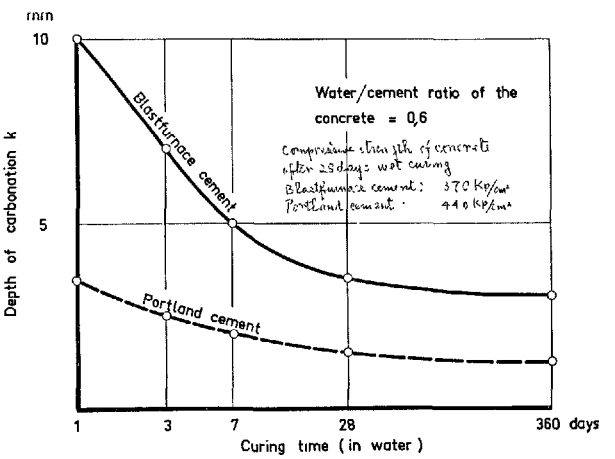

Fig. 9. *Effect of the curing time on the depth of carbonation. Concrete storaged after wet curing for 1 year in open air protected from rain*

Fig. 8 those of test series 3. The concretes made of portland cement showed lower depths of carbonation under the same conditions, than the concretes made from blastfurnace cement and pozzolanic cement. In concrete made of blastfurnace cement, the depth of carbonation increased with an increasing percentage of blastfurnace slag. At a percentage of approx. 50% of blastfurnace slag the carbonation was 1.5 times as deep as in portland cement concrete, while it was 2 times as deep when the percentage of blastfurnace slag amounted to 70%. In mortar tests (test series 4 and 5) the influence of the type of cement used upon the depth of carbonation was less pronounced than in concrete trials. That difference might be due to the fact that the shrinking behaviour of small mortar prisms is not identical to that of concrete test cubes.

The fact that the resistance of a concrete to carbonation is a function of the cement type used, seems to be due to the difference in the percentage of carbonatable substances and especially of free calcium hydroxide. Owing to the high diffusion resistance of the concrete, only limited quantities of carbon dioxide can diffuse through the concrete in the unit of time, thus transforming carbonatable substances. This is the reason why the progress of carbonation depends upon the presence of carbonatable substances, all other conditions being identical.

Storage Conditions

Concrete *constantly stored under water or away from the air* will not carbonate.

Concrete *constantly exposed in room air* after curing will release the free water. Simultaneously the air penetrates into the concrete. Concrete constantly stored in air will undergo the strongest carbonation. As long as the level of carbonation did not reach the drying level under those storage conditions an approximately quadratic function exists between the depth of carbonation and the age of the concrete. In concrete cured under water for a longer period the progress of carbonation is reduced, see Fig. 9.

*Concretes *exposed to open air* and *moistened* from time to time in their shell zones by precipitations will carbonate less rapidly. In this case the depth of carbonation will not surpass the two uppermentioned limits. The progress of carbonation depends primarily upon the chronological order of the periodical moistening and drying of the concrete. In the test series 2 the depth of carbonation in concrete specimens 4 years old, moistened regularly once a week, amounted only to 30–60% of the depth of carbonation in concrete stored in the air.

Fig. 10 shows the influence of the storage conditions upon the progress of carbonation generally.

Results of Test Series 6

The 60 concretes of test series 6 differ from each other as to their age and their composition. On the other hand they were stored under almost identical

*The portland cement used for these concrete tests was a nomal portland cement with appr. 12% C_3A. The slag content of the blastfurnace cement was appr. 70%.

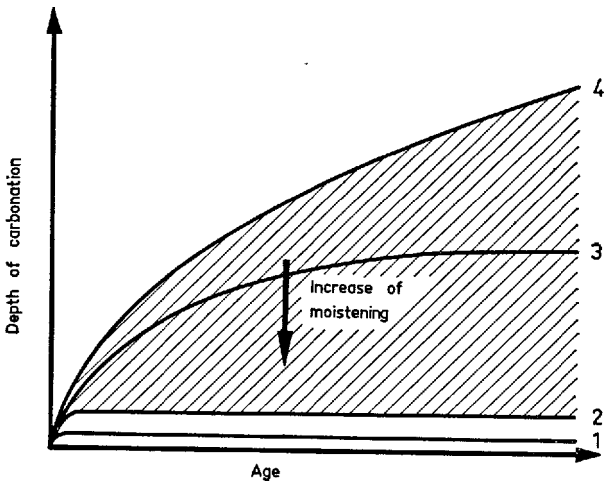

Fig. 10. *Effect of storage conditions on the progress carbonation (model)*

1. Constantly under water or in moist air
2. Horizontal concrete surfaces out door in wet climate
3. Out door in air not protected from rain and snow
4. Constantly exposed in room air or out doors protected from rain and snow

conditions, that means that all these concretes were stored to normal room air after a short moist curing.

Different types of cements were used for the concrete specimens. The ages of the concrete specimens ranged from 1 to 12 years, medium age approx. 5 years. In Fig. 11 the depth of carbonation $k'_t = 10$ related to the age of 10 years is plotted against the water/cement ratio. It was calculated on the base of the quadratic function between the depth of the carbonation k and the age t indicated in the test series 1 to 5 by equation

$$k'_{t=10} = k \cdot \sqrt{\frac{10}{t}}$$

Fig. 11 shows clearly that there exists a linear function between the depths of carbonation related to an age of 10 years and the water/cement ratio in concretes made from portland cement, although concretes of different consistency and different granulometry of the aggregate were compared. In concretes made from blastfurnace cement the linear function between the depth of carbonation and the water/cement ratio is less clearly visible due to the fact that the percentage of blastfurnace slag has not been taken into consideration.

Investigations on Old Building Constructions

In 1962 and 1963, 53 old concrete or reinforced concrete building constructions were examined in

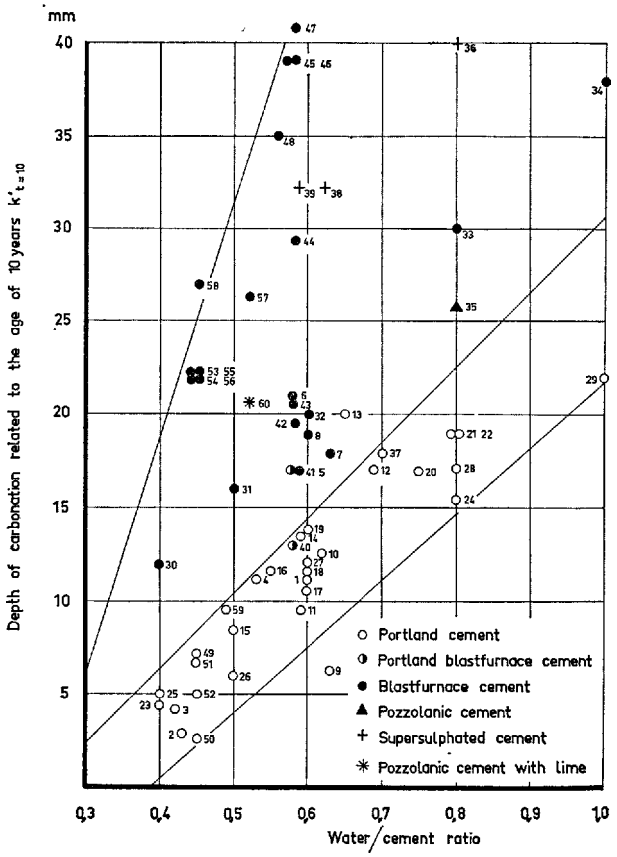

Fig. 11. *Effect of water/cement ratio and cement type on the depth of carbonation related to the age of 10 years (Results of test series 6–60 different concretes)*

order to determine the depth of carbonation in the concrete as a function of the age, the composition of the concrete and of the storage conditions. The building constructions has been erected between 1910 and 1955. The results of these investigations are published already (6).

63 concrete samples were tested. It was found out that the depths of carbonation in these concretes depended essentially on the age and the composition of the concrete as well as on the storage conditions.

The relations stated in the chapter "Influences on the progress of carbonation" existing between these values and the depth of carbonation could be confirmed as a whole in the samples taken from these old building constructions. Some marked variations are due to the fact that the technical data of the concretes could not be reproduced exactly, and that the conditions of storage were not fully known as far as their nature, their intensity and their chronological order are concerned.

Summary and Conclusions

Concrete and mortar tests made under well known conditions have proved that the age and the composition of the concrete as well as the conditions of storage are the main factors that act on the progress of carbonation.

Effect of Age

In concretes stored in air but protected from rain and snow the depth of carbonation increased more rapidly in the beginning than later on. A simple relationship between the depth of carbonation and the age could be established that applied to the period of the investigations of about 10 years. Supposing that this relationship is also applicable to older concretes, the depth of carbonation reached after 10 years will have doubled in at least 50 years. Concrete is carbonated less rapidly, if his outer zone is moistened from time to time for instance by rain.

Effect of Concrete Composition

In concretes having a water/cement ratio of 0.50 the depth of carbonation is only approx. half the depth of carbonation in concrete stored under the same conditions but having a water/cement ratio of 0.80. The depth of carbonation of concrete of portland cement having a water/cement ratio of 0.50 stored 50 years in open air protected from rain will be probable 10 — 15 mm. In concretes made from blastfurnace cement or pozzolanic cement greater depths of carbonation could be measured than in concrete made from portland cement, all other conditions being identical.

Effect of Storage Conditions

Concrete soaked with water is practically free from carbonation. In concretes stored at normal room atmosphere the greatest dephts of carbonation were measured. Periodical moistening of the concrete for instance by rain hampers the progress of carbonation noteworthily. In this case the depth of carbonation can be limited by the depth of evaporation.

Investigations in Building Constructions

The investigation of 63 concrete samples taken from old building constructions have largely confirmed the results of our tests as to the relation existing between the depth of carbonation, the age, the composition of the concrete and the storage conditions.

Carbonation and Reinforcement

In case the steel in reinforced concrete is endangered by corrosion due to unfavorable environmental conditions, care must be taken to prevent the carbonation from reaching the steels. In this respect are important the thickness of the cover and its resistance against carbonation. The carbonation resistance of a fully compacted and normal cured concrete is essentially determined by its water/cement ratio and by the type of cement used.

Supplementary Paper III-116 Mechanisms and Kinetics on Carbonation of Hardened Cement

Renichi Kondo, Masaki Daimon and Tokuji Akiba*

Synopsis

Carbonation of mortar or concrete is the reaction between cement components, either unhydrated or hydrated, and carbon dioxide in the air. Studies were made on carbonation under simplified and accelerated experimental conditions to clarify the mechanisms and kinetics. These are discussed in regard to the data of carbonation, neutralized depth and also the pore size distribution. Carbonated products are concentrated especially near the surface at shorter period, but distributed afterward to the deeper part. The slope of the degree of carbonation to the deepness becomes gradually more gentle with the lapse of time. While neutralization does not occur immediately even at the surface in contact with CO_2 gas. The length of the induction period which appear in the neutralization varies with the type of specimen, and these differences are mainly dependent on lack of uniformity in the pore structure. The rate of neutralization can be expressed as $L^2 = kt$ or $(L + l)^2 = kt$ in the first approximation where L is the neutralized depth and t is the time of carbonation. On this rate the water-cement ratio and curing time show the greater effect, and the greater the pore volume, the faster the rate. The above equations suggest that the rate determining process is diffusion. Nevertheless a boundary between parts, carbonated and un-carbonated, is ambiguous, carbonation is assumed to occur at a boundary which corresponds to the neutralized depth. Thus we can apply the following equation:

$$k_t = \frac{2D_0\varepsilon\Delta P T^{0.75}}{273^{1.75}RC_0\rho},\quad k_e = \frac{k_t}{f}$$

Then, the rate constant of neutralization is calculated in consideration of the material transfer of either CO_2 or H_2O in order to determine which diffusion controls the rate of reaction. In consideration of the magnitude of the f value, the species of diffusion which controls the rate of neutralization is infered to be CO_2, H_2O or both of them depending on the pore structure of the specimens. Thus the above rate equations seem to be reasonable to the rate of neutralization in assumptions, and applicable to the practice.

Introduction

Studies on the carbonation of cement mortar and concrete have been made mainly in connection with shrinkage and cracks in European countries, and in connection with corrosion of reinforcing steel in Japan. Studies of carbonation has been made by chemists on each pure cement hydrated or unhydrated compound, while on the rate of neutralization of concrete by building engineers. Some studies seem necessary to fill the gap between them.

As the cement mortar and concrete are porous materials consisting of cement hydrates, carbonation seems to be unavoidable. However, its resistivity should be taken into account. Carbonation is regarded as an example of the reaction of porous solid with gas or liquid which diffuses into the former. Metal refining by the pellet method, sulfate attack on concrete, etc., are also reactions of this type. One of the authors has studied the rate of oxidation of carbonaceous matters contained in shale or clay, in relation to the bloating mechanisms of lightweight aggregates, and found a relationship between the rate and the pore structure.

In a similar way, studies were made on carbonation under simplified and accelerated experimental conditions to make clear the mechanisms and kinetics. As carbonation is concerned with the diffusion of CO_2 gas, examination of the pore size distribution must be important. As the pore size distribution of concrete other than lightweight concrete can be estimated from that of mortar, specimens in the form of mortar were prepared.

*Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Tokyo, Japan.

The degree of carbonation, neutralized depth and pore size distribution were measured under accelerated conditions. In this experiment portland cement and portland blastfurnace cement were used in comparison. The rate of neutralization and the carbonation mechanisms were discussed.

Carbonation and Neutralization

Nevertheless, the carbonation of mortar or concrete is unavoidable because the hydraulic cements and their hydrates are calcarious and reactive with CO_2, the rate of reaction is the most important aspect to be investigated in practice.

Carbonation is the reaction of cement hydrates or unreacted cement with carbon dioxide, and it is a kind of gas solid reaction. However, the existence of adsorbed water or the drying condition influences the rate of carbonation. Maximum rate was found by Hunt and Tomes (1) in a certain drying condition. Accurate control in the relative humidity is, accordingly, important in the carbonation experiment.

Although the mechanism of carbonation of hydrated cement is complex, one molecule of water should be liberated by the reaction of one molecule of carbon dioxide with calcium hydroxide. Hunt and Tomes (1), however, found experimentally that the decreasing of non-evaporable water is less than the increasing of carbon dioxide in carbonation of hardened cement, so that other phases also react with carbon dioxide while calcium hydroxide is still present.

Inoue and Asano (2) found that not only calcium hydroxide but also unhydrated C_3S decreased in carbonation, and that hydrated C_3S tends to produce calcite, but unhydrated C_3S produces vaterite. Formation of vaterite was also reported by Schröder (3) to form by a topochemical reaction between moist CO_2 gas and calcite in the surface layer of concrete.

On the other hand, cement hydrates are originally basic, but neutralized by the carbonation. The neutralization of mortar or concrete is expressed with the depth of the neutralized layer or its rate of increase, which is described by Hamada (4) in this symposium. It is, however, difficult to distinguish a spot in a specimen as neutralized or not, because the carbonation advances continuously; for example, it is probable that only certain species are reacted while others are not, or only the surface of each particle of reactant is carbonated, while the core remains unchanged. The depth of neutralization of specimens is determined conveniently by phenolphthalein as an indicator in connection with the fact that the reinforcing steel in concrete is reported (5) in a passive state when the latter maintains an alkalinity greater than 10.5 in pH value. In the later part of this paper, the relationship between the depth of neutralization and carbonation will be discussed.

Experimental

Preparation of Specimens

In this experiment, portland cement and portland blastfurnace cement of compositions as shown in Table 1 are used in comparison, while the sands put to use are of different fineness, as illustrated in Fig. 1. Both sands were previously treated with 10% HCI for 2 hrs to remove the carbonates. The conditions of the mortar preparation are given in Table 2. The size of the specimens molded is 2 cm × 2 cm × 8 cm. After being cured in saturated $Ca(OH)_2$ solution for 7 or 28 days, the specimens are dried with a rotary pump for 24 hrs and then put into a desiccator maintaining RH 44% for more than 7 days to approach an equilibrium. Five surfaces of each specimen are sealed with the epoxy-resin and one surface, 2 × 2 cm in size, is exposed to CO_2 gas. The specimens previously cured are exposed to CO_2 gas to carbonate

at 20 ± 1°C. The specimens are laid to avoid contact with each other in a desiccator of sufficient size. CO_2 gas is led from a bomb through 3 bottles to the desiccator. And the saturated $Zn(NO_3)_2$ solution is put in 2 of the 3 bottles, and the desiccator is put to maintain CO_2 gas at 44% relative humidity.

Analytical Methods

Carbonated specimens are cut lengthwise with a diamond cutter and the neutralized depth is determined with 1% phenolphthalein solution. Some of the carbonated specimens were sliced into 1 mm thickness perpendicularly to the direction of diffusion, using a grinding wheel of 0.5 mm thickness. And each slice is crushed for such tests as the quantification test by X-ray diffraction, fixed CO_2 by the micro diffusion method (6) and free $Ca(OH)_2$ by a modified Franke method (7) using isopropanol as the solvent. The pore size distribution of several specimens were also measured with a mercury pressure porosimeter.

Results

Results of Carbonation

The degree of carbonation was determined by various methods such as X-ray diffraction analysis, chemical analysis for fixed CO_2 and free $Ca(OH)_2$. The analytical results are given in Fig. 2. The amount of calcium hydroxide quantified by X-ray diffraction is in good accordance with the results by the Franke method. But the amount of calcite estimated by X-ray diffraction does not correspond to the fixed carbon dioxide chemically obtained. This discrepancy is remarkable in the sample taken from the deeper position from the surface. This result is an evidence that amorphous carbonate is likely to form in the deeper part. X-ray diffraction intensity of calcite also decreases steeply especially near the surface of specimens carbonated for a long period, due to the formation of vaterite. The modification of $CaCO_3$ produced is calcite in the early stage of carbonation, but is vaterite in the later stage where carbonation of unhydrated cement components must take place as reported by Inoue and Asano (2). At the early stage, the carbonation occurs only near the surface, but in the deeper part at the later stage. In comparison of A2 and C2, the slope of the carbonation ratio is steeper in case of A2 than in case of C2, and the rate of C2 is larger than of A2. This difference is important in view of the rate of neutralization in connection with the pore size distribution.

The amounts of free $Ca(OH)_2$ of uncarbonated specimens are 0.038, 0.019 and 0.033g CaO/g specimen for A2, A4 and C2 respectively. The amount of free $Ca(OH)_2$ is larger in portland cement mortar than in portland blastfurnace cement mortar. In a comparison between A2 and A4, in which portland cement and portland blastfurnace cement are used respectively, fixed carbon dioxide in the specimens carbonated for 7 days are 0.00303 and 0.00267 mole/g specimen. Therefore, these values are equivalent to 0.645 and 0.547 each of the total CaO of cement. It is considered from these results that all of the CaO in cements is effective for the fixation of CO_2.

The molar ratio of fixed carbon dioxide to free $Ca(OH)_2$ are about 0.2 regardless of different depth from the surface. This result reveals that the there is no great difference in the case of carbonation between the calcium hydroxide and the other phases.

In Fig. 2, the arrow shows the neutralized depth, where some free $Ca(OH)_2$ still remains.

Results of Neutralization

The neutralization rate of the specimens are shown in Fig. 3. An explanation of why the neutralization could not be detected in such specimens as D3, D4 and E is that the carbonation takes place imperfectly and unneutralized part remains even near the surface, in spite of the carbonation progress in the deeper part at the same time. Though the slope of the lines in Fig. 3 tends to become steeper in the later stage, the rate of neutralization can be expressed as $L^2 = kt$, in the first approximation, where L is the neutralized depth, t is time and k is a constant. Therefore, the value k shows the ease of neutralization. The difference in sands and the addition of A. E. R. seem to have no significant effect. The curing time and

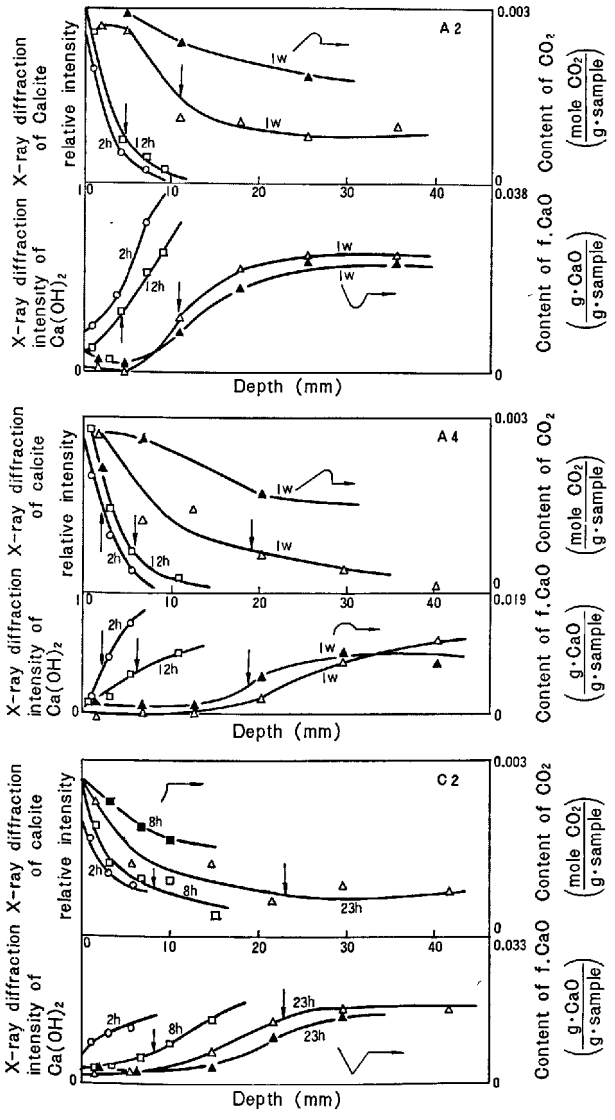

Fig. 2. *Experimental results on carbonation*

Time of carbonation is taken as parameter

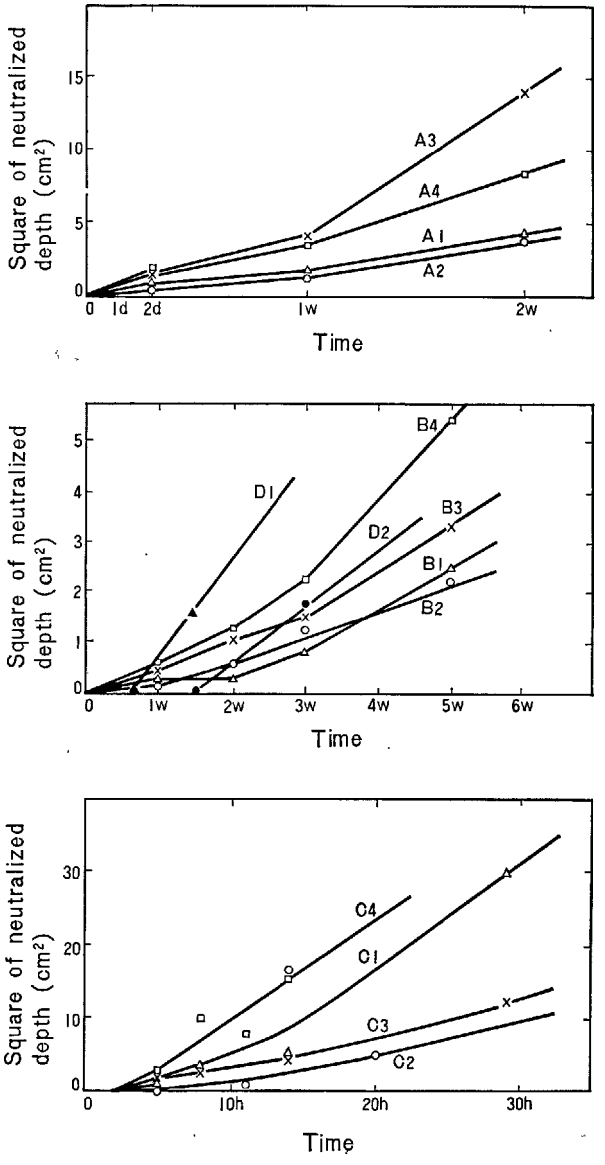

Fig. 3. *Relationship between neutralized depth and time of carbonation*

the water-cement ratio show the greatest effect and portland blastfurnace cement seems to be easily neturalized at least in this accelerated conditions.

Pore Size Distribution

The determination of the pore size distribution is useful in consideration of the rate of neutralization. The pore size distribution of various samples are compared in Fig. 4. The shorter the curing time, the larger the size and total volume of pores. The pores existing at the beginning must be gradually filled with produced hydrates. But this trend is not clearly observed in the cases of B2 and D2, in which the W/C ratio is as low as 0.5 and cement particles are compactly packed. Even though in the case of D4 the W/C ratio is 0.5, it has a large pore volume. This seems to be due to the low degree of hydration of portland blastfurnace cement not filling the pores enough with hydrates, in the case of curing for 7 days. While in the specimens cured for 28 days, even with such a high W/C ratio as 0.65, the total of the pore volume is nearly equal in both case of portland cement and portland blastfurnace cement. As the pore volume of C specimen is greater than that of B, the rate of neutralization is faster in case of the former. E2 is the specimen containing portland cement, with W/C = 0.65 and sand-cement ratio of 1 : 3, cured for 28 days. The rate of neutralization of such specimens as D3, D4 and E could not be measured as inducated previously. This fact seems to be due to the existence of large pores where CO_2 gas preferentially diffuses and carbonation takes place at the peripheries of large capillaries. As some reduction in pore volume is generally observed, accompanied by carbonation, it suggests that the volume of reaction procucts including carbonate is increased.

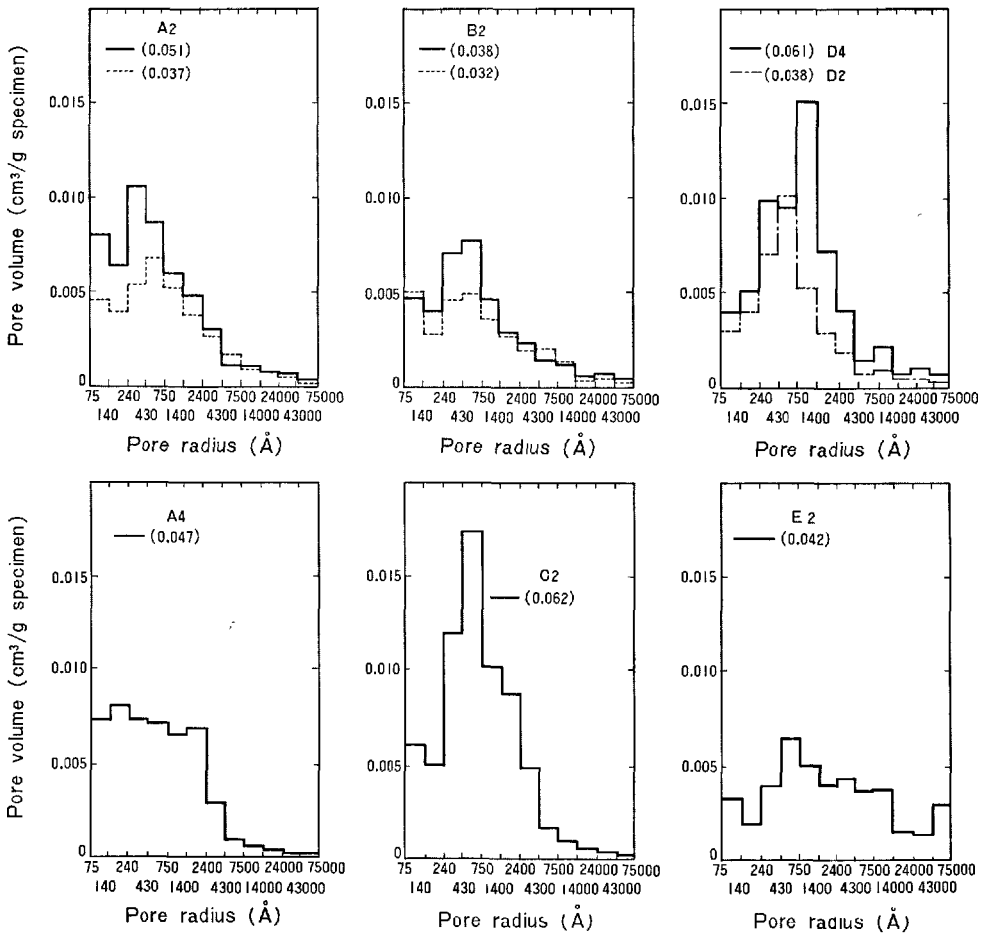

Fig. 4. *Pore size distribution of specimens*
—, —·—: *showing the unneutralized part*
·····: *showing the neutralized part*
( ): *showing the total pore volume*

Induction Period in Neutralization

Neutralization does not occur immediately even on the surface which is in direct contact with CO_2 gas. The length of the induction period varies with the type of specimen as follows: almost 0 hr for A group; about 15 hrs for B group, 2 hrs for C group and even several days for D1 and D2. These differences occur depending chiefly on their pore structure. The induction period is considered to be attributable to the lack of uniformity in the pore structure. The induction period of the specimens cured for 7 days are longer than those for 28 days. This fact seems to be partly due to the existence of unhydrated cement components which react more slowly with CO_2 gas than the hydrates. In other words, the pore structure must be more uniform and the cement components must be more extensively hydrated in the case of the specimens cured for 28 days than in those for 7 days.

Rate Equation on Neutralization

The rate of neutralization of various specimens are shown in Fig. 3. In the first approximation, the rate can be expressed by the equation,

$$L^2 = k_e t \tag{1}$$

or

$$(L + l)^2 = k_e t \tag{2}$$

where

- L: the neutralized depth
- t: the carbonation time
- k_e: the neutralization rate constant experimentally obtained
- l: the constant to be related with induction period

These equations suggest that the rate determining process is diffusion, because this type of equation can be derived when the rate of reaction is controlled by diffusion. The rate of diffusion is shown as

$$N_0 = \frac{D\Delta C}{L} \tag{3}$$

and thus the rate of reaction is expressed as

$$\frac{dL}{dt} = \frac{N_0}{C_0 \rho} = \frac{D\Delta C}{C_0 \rho L} \tag{4}$$

Therefore, the following equations result:

$$L^2 = kt, \quad k = \frac{2D\Delta C}{C_0 \rho} \tag{5}$$

where D is the diffusion constant, ΔC is the difference in concentration, C_0 is the amount of reactant in unit weight of specimen and ρ is the density.

Nevertheless, the boundary between the two parts, neutralized and unneutralized, can not be clearly distinguished, carbonation is assumed to occur at the boundary. In Fig. 5, an idealized model of neutralization is shown. Thus, we can apply the following equations, in view of counter diffusion, inward and outward, and that diffusion coefficient of gas is written as $D_T = D_0 \times (T/T_0)^{1.75}$

$$k_t = \frac{2D_0 \varepsilon \Delta P T^{0.75}}{273^{1.75} R C_0 \rho} \tag{6}$$

where

- D_0: the diffusion constant at 0°C (cm^2/sec)
- ΔP: the difference of pressure (atm)
- C_0: the maximum amount of fixed CO_2 or produced H_2O (mole/g specimen)
- ρ: the density of the specimen (g/cm^3)
- T: temperature (°K)
- R: gas constant (= 22400/273),
- ε: the porosity of the specimen (cm^3/cm^3)
- k_t: the theoretical neutralization rate constant

$$k_e = \frac{k_t}{f} \tag{7}$$

where f is the tortuosity.

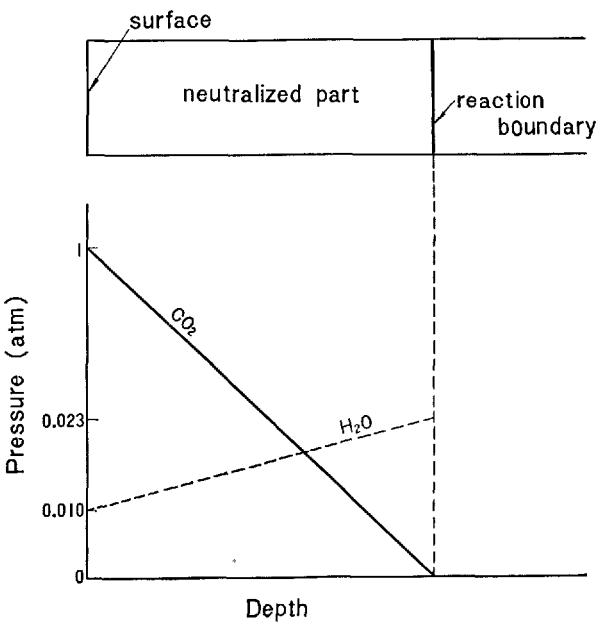

Fig. 5. *The model of neutralization in which the rate determining process is assumed to be the diffusion of* CO_2 *or* H_2O

Rate Constant of Neutralization

In this system, there are three kinds of gas species. CO_2 diffuses inward the specimen, and air and H_2O produced by carbonation diffuse outward. The rate constant of neutralization is calculated in consideration of the material transfer of either CO_2 or H_2O, in order to determine which diffusion controls the rate of reaction. Calculated values for specimens A2, B2, C2 and D2 were shown in Table 2.

Experimental values of ε/ρ in Fig. 4 are not to be used because the diffusion constant of diffusion in the smaller pore than the order of mean free path decreases proportionally to the radius according to Knudsen's Law. Therefore the experimental values were corrected and the effective values obtained were 0.0394, 0.0299, 0.0583 and 0.0320 for the unneutralized specimens of A2, B2, C2 and D2 respectively.

The partial pressure of CO_2 and that of air varies from 0 to 1 atom, where as in case of H_2O it varies only between 0.010 atom (= RH 44%) and 0.023 atom (= RH 100%). Thus, the value, ΔP in equation (6) is 1.0 for CO_2 diffusion, and 0.013 for H_2O diffusion.

Diffusion of CO_2 gas in air must be considered in the neutralization under atmospheric condition. However, the diffusion of CO_2 in H_2O is taken into account in the case of accelerating condition, in which diffusion of H_2O in CO_2 gas must also be considered. Regardless of the kind of diffusions concerned, their diffusion coefficients are approximately the same value, $D_0 = 0.14$, which is then used in the calculation.

Table 3. *Rate constant and tortuosity*

In the case of CO_2 diffusion (ΔP = 1 atm)

	A2	B2	C2	D2
C_0	0.0030	0.0027	0.0024	0.0024
k_e	0.25×10^{-5}	0.041×10^{-5}	4.7×10^{-5}	0.16×10^{-5}
k_t	1.8×10^{-4}	1.5×10^{-4}	3.3×10^{-4}	1.8×10^{-4}
f	72	370	7.0	110

In the case of H_2O diffusion (ΔP = 0.013 atm)

	A2	B2	C2	D2
C_0	0.0015	0.0014	0.0012	0.0012
k_e	0.25×10^{-5}	0.041×10^{-5}	4.7×10^{-5}	0.16×10^{-5}
k_t	4.7×10^{-6}	3.9×10^{-6}	8.6×10^{-6}	4.7×10^{-6}
f	1.9	9.5	0.18	2.9

As for the value of C_0, analytical data were adopted. In the case of H_2O diffusion, however, analytical value is multiplied by 0.5, because the molar ratio of reduced non-evaporable water to increased carbonate is about 0.5 according to Hunt and Tomes. In spite of this, the ratio must be 1 in the carbonation of $Ca(OH)_2$.

In consideration of the magnitude of the f value, the type of diffusion which controls the rate of neutralization seems to be both of CO_2 and H_2O for A2, H_2O for B2, CO_2 for C2, and CO_2 and H_2O for D2 respectively, as the f value is empirically expected to be approximately in the order of 5 to 10.

Discussion

Carbonation occurs partly in the deeper position caused by diffusion through large pores, while the degree of carbonation is not greatly increased until the smaller pores are filled with CO_2 gas in spite of the peripheries of the large capillaries being rapidly carbonated. The degree of neutralization is expressed in terms of the depth where a small amount of $Ca(OH)_2$ still remains. All components of the cement, not limited to $Ca(OH)_2$, either hydrated or unhydrated, react with CO_2 gas, and the easiness of carbonation of $Ca(OH)_2$ is not greatly different from that of the other phases.

The tendency of the lines in Fig. 2 becoming steeper at the later stage seems in part to be due partly to an experimental error, if any, caused by some permeation of CO_2 gas through the epoxy-resin coating and also to the following facts: the pore size has a distribution, the rate of carbonation of every components can not be neglected in the diffusion of CO_2 gas, and the size of specimen is limited.

The rate of neutralization of concrete was measured by Hamada (4) and formulated as follows;

$$t = \alpha x^2$$

where,

t: expressed in years
α: a constant and determined as 7.3
x: the depth of neutralization in cm

The value, k_e can be derived as 0.043×10^{-7} from the value α. While, the value $k_t = 0.54 \times 10^{-7}$

is calculated from equation (6), if A2 mortar is to be carbonated in the air. In this case, the value f is to be about 13, but it must be reduced to about 10 for the mortar part in consideration of the difference in the proportion of specimens. Thus, the equations (6) and (7) seem to be applicable in practice and also reasonably assumed as the rate equations of neutralization.

SESSION III-4a HYDRATION OF PORTLAND CEMENT PASTE AT HIGH-TEMPERATURE UNDER ATMOSPHERIC PRESSURE

Principal Paper Hydration of Portland Cement Paste at High Temperature under Atmospheric Pressure

Gunnar M. Idron*

Synopsis

Literature of the hydration of portland cement at elevated temperatures under atmospheric pressure is reviewed. The discussion is broadly introduced in pointing to the increasing importance in practice of accelerated hardening of concrete. Principles applied in studies of slow hydration at low temperatures are briefly mentioned.

Heating shortens the induction period of the course of hydration, and increases the rate of the early hydration. There are indications that temperatures above 80 ~ 90°C may result in decreased ultimate degrees of hydration. Studies of volume change, strength and elasticity mostly point to the same direction. Ultrasonic velocity measurements have proved useful. Measurements of heat evolution at high temperatures seem to have met considerable difficulties, but improvements are under way.

The detailed steps of reaction in the hydration process have not been found described in available papers. Adsorption, dissolution, mass-transfer and crystallization are emphasized with reference to room-temperature hydration, as useful subjects of studies to elucidate the kinetics of high temperature reactions. Empiric models of the overall reaction kinetics for hydration at varying temperatures are mentioned, but much more work is avowedly needed before the decisive features are revealed.

High temperature hydrates evidently differ from room-temperature hydrates, particularly in that the CaO/SiO_2 ratio is greater, and that less separates of aluminates, ferrites and sulphoaluminates are formed at high temperatures. Small amounts of crystalline calcium silicates have been found to result from heat curing. Considerable uncertainties remain in interpreting hydration of pure compounds with regard to cement-water systems.

Heat curing has been found to influence the morphology and agglomeration of the hydrates in cement paste; recent studies point towards increased heterogeneity. This effect may be utilized to gain ultimate strength. The need is emphasized for considering temperature a paramount parameter in future studies of cement hydration.

Introduction

The hydration of portland cement paste at high temperatures at atmospheric pressure is a topic of current interest as steam curing of concrete has proved an important innovation in the establishment of the manufacture of large precast concrete units for house-building and civil engineering purposes in many countries, although so far predominantly in Eastern and Western Europe.

The immense market demand has enforced the introduction and development of accelerated manufacture of concrete in factories as replacement for traditional curing at ordinary temperature of concrete

*Concrete Research Laboratory, Karlstrup, Denmark.

cast in situ, and heating with low pressure steam has been found an easy and cheap way of achieving the accelerated hardening, strength development etc.

It may be found surprising, that hydration at elevated temperatures has not been the subject of comprehensive studies in the past. However, 'room-temperatures', i.e. 18°C to 25°C, was considered a convenient and almost universal standard condition in cement and concrete research laboratories, and in most respects the field behaviour of concrete in structures was not significantly different from the behavious found by measurements under simplified laboratory exposure. Moreover, the important development took place in north-temperate, climatic regions without excessive exposures, and development of research and practice had the character of a harmonious evolution, in the 'thirties even involving the introduction of both high-early-strength, rapid-hardening and slow-hardening, low-heat portland cements. The long-sighted, fundamental studies on the basic nature of the hydration of portland cement paste at room-temperature commenced in the same period and was advanced particularly in the USA.

The first studies announcing the benefit of temperature as a parameter in research concerning cement hydration appeared in the late 'forties, if we exclude a few eclectic pre-war studies, particularly referring to block manufacture problems in some countries. In the introduction of this new era the hydration in the temperature range 0°C to 20°C attracted much more interest than acceleration by means of heating. This is due to the immense post-war demand for building at all seasons, that is to say, also throughout the winter. By research it was demonstrated that this could be done by means of precautions in winter-concreting based upon the then sufficiently established understanding of the nature of hardening and hardened cement paste, including the influence of varying temperature on the rate of hydration etc. The applications were especially helpful for practice in countries with moderate winter climates, where site construction proved possible and economic in the 0°C to minus 20°C range.

In regions of more severe winters the tremendous demand for housing etc. in the same period created the prefabrication concrete industry, where plant manufacture of large concrete units was speeded up by means of accelerated hardening, predominantly by means of hydration of portland cement paste at elevated temperatures under atmospheric pressure. The breakthrough of this industry came in the USSR and other Eastern countries in the 'fifties, and the development was excellently reviewed and summarized during the RILEM symposium: *Accelerated hardening of concrete in manufacturing precast reinforced concrete units* in 1964 in Moscow.

Today, prefabrication of concrete is neither confined to particular climatic regions nor to house building, but is an integral part of the magnificent growth of the building industry all over the world. Low-pressure steam curing has become one important possibility among others for increasing the rate of production. But the basic technology of accelerated hydration of portland cement is still much in the dark, in contrast to the situation when concreting about 20 years ago needed and obtained the application of knowledge of the hydration at ordinary and low temperatures.

This paper attempts to summarize the present state of knowledge and to outline some important fields of further studies which may counteract the unsatisfactory economy of an empiric development. In this concept, it seems appropriate to mention that an adequate theoretical understanding of the technology of hydration at elevated temperatures will enable systematic applications in the dry polar regions as well as in the humid-temperate regions, and also in excessively moist and arid warm belts of the earth. Without the support of a scientific approach, practice will still need expensive and incompatible field experi ences under each of these different conditions, which are all becoming important for future building activity.

Steam curing of concrete has been found to influence the strength development and the final strength level of concrete. Various authors have discussed how the different thermal expansion of the solid, liquid and gaseous phases results in the development of internal stresses in the concrete, thus possibly creating interior fracturing. These problems are merely touched upon in the present paper. A discussion in more detail of the mechanics of the fracturing by steam curing of concrete, and therefore also of the beneficial effects of prehardening or other precautions which can prevent expansive forces from causing internal disruption and other mechanical effects, is considered to be beyond the scope of this paper which concentrates upon the influence of temperature ($20 \sim 100$°C) on the hydration of portland cement.

It is appropriate to examine whether high temperature (up to 100°C) treatment might possibly change the characteristics of the cement compounds. However, the transformation temperature of the polymorphs concerned are orders of magnitude higher than 100°C, and no evidence has been found of significant transformation below 100°C. Therefore, the cement compounds are considered unaltered within the range of

reaction temperatures dealt with. Gypsum, however, which is a constituent part of ground cement may be altered into hemihydrate as described by among others W.C. Hansen and J.S. Offutt (1). This alteration will affect the initial hydration reactions as the different types of calcium sulphate have different solubilities. Moreover the solubilities are affected differently by the temperature as shown in Fig. 1. For the sake of completeness, it must also be mentioned that K. Takemoto, M. Kanaya, T. Tashiro and T. Shimoda (2) described changes of cement during high-temperature storage. They concluded that the gypsum will dehydrate when cement is stored for a long time at 55°C to 85°C, and that the cement minerals will hydrate, taking water from the gypsum. (This observation may well deserve attention in modern cement storage practice).

When temperature at first was considered a parameter in studies of cement hydration it was assumed that the reaction process was not influenced by temperature except with regard to the rate of the reactions. On this basis maturity functions were made an important aid in calculations of strength development etc. A.G.A. Saul (3) defined the maturity of concrete as its age multiplied by its average temperature above 0°C, and concluded that concrete of the same mix will have approximately the same strength at the same maturity, whatever combination of time and temperature produced that maturity. Modifications of this principle and applications on other characteristics than strength, e.g. heat of hydration, have been worked out by S.G. Bergstrøm (4), E. Rastrup (5), (6), A. Nykänen (7) and others. These studies proved to be important for investigations of the physical properties of concrete, see e.g. P. Nerenst (8), and for the establishment of the optimum technological conditions for the manufacture of concrete under special conditions, RILEM symposium 1956 (9), J. Jessing (10) and other authors.

In more recent investigations the approximations necessary for the calculation of maturity functions have been found to possess much uncertainty, see e.g. K. M. Alexander and J. H. Taplin (11), and (12). U. Danielsson (13) examined maturity functions by means of the conduction calorimeter and recommended caution with regard to their use as more than rough approximations. Thus, it is not to be expected that maturity functions covering the 20°C to 100°C range of hydration temperatures can readily be established, despite their proved validity for practical purposes in the 0°C to 20°C range of hydration temperatures. In fact, it seems more fruitful to search for descriptions in more detail of hydration phenomena in the 20°C to 100°C range in order to ascertain how the processes involved change with temperature with regard both to the rate of hydration and to the compositions and the characteristics of the reaction products.

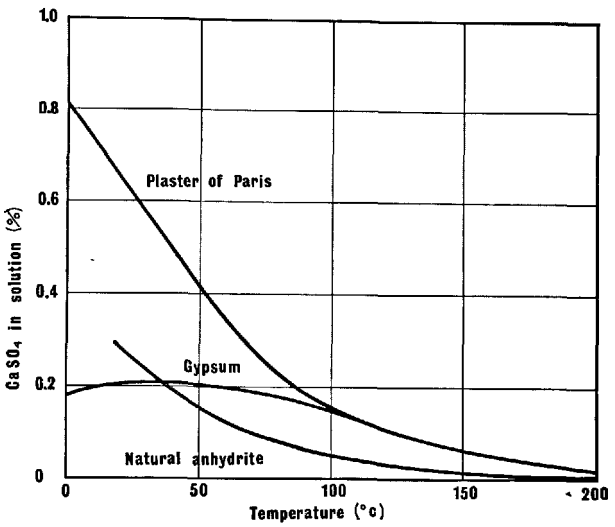

Fig. 1. *Water solubility of different forms of calcium sulphate. From L. E. Copeland and D. L. Kantro (57)*

Rather much of the information referred to below has been found in studies referring to concrete as the experimental material. Such studies are discussed when observations regarding the hydration process and the reaction products have been found, but evaluations with regard to the technology of steam curing of concrete have been omitted, because this topic is treated elsewhere. This limitation covers also the influence of surrounding atmosphere on the hydration, for instance of the relative humidity and of carbon dioxide.

The Course of Hydration

The hydration of portland cement is accompanied by phenomena like i) conversion of reactants (cement and water) into hydration products; ii) heat evolution; and iii) formation of a solid structure exhibiting strength and rigidity. Continuous recording of these phenomena has been used in many investiga-

tions to describe the course of hydration.

The Conversion of Reactants

The amount of cement and water converted into hydration products at any given stage of hydration are determined in various ways, for instance by the intensity of a significant peak in an X-ray diffractogram, by the amount of non-evaporable water, etc. In the literature, either of these characteristics has been used to define what is termed the 'degree of hydration'. For the sake of convenience this term will be used in the following:

The effect of temperature on the temporal changes in the degree of hydration was studied by G. Verbeck (14) (in the temperature range 50°C to 80°C), J. H. Taplin (15) (in the range 5°C to 82°C), D. L. Kantro, S. Brunauer and C. H. Weise (16) (in the rage 5°C to 50°C), U. Danielsson (13) (in the range −2°C to 40°C), P. P. Budnikov, S. M. Royak, J. S. Malinin and M. M. Mayants (17) (in the range 20°C to 90°C), P. P. Budnikov and E. Erschler (18) (at temperature levels 20°C and 80°C), and J. Gebauer and I. Odler (19) (at temperature levels 20°C and 80°C).

From these studies it may be concluded that the rate of hydration increases with increasing temperature level at the early stages of hydration and at moderate hydration temperatures (below 60 ~ 80°C). However, G. Verbeck (14), J. H. Taplin (15) and N. C. Ludwig and S. A. Pence (20) found that curing of higher temperatures (above about 80°C) results in a reduction of the degree of hydration at later age as compared with degree obtained by curing at room-temperature. This phenomenon is illustrated in Fig. 2 (unpublished data obtained at the Concrete Research Laboratory Karlstrup (21)). The tests reported by J. Gebauer and I. Odler (19) on cement pastes with a water-cement ratio of 0.30 and cured at 20°C and 80°C, however, did not reveal a similar reduction.

The possible reason for the reduction will be discussed later on, but the following observations are of interest in this respect:

1. L. E. Copeland, D. L. Kantro and G. J. Verbeck (22) showed that at room-temperature, the quantity of hydrated cement was proportional to the amount of non-evaporable water. No data have been found in the literature to illustrate whether this is true also at higher temperatures.

2. The 'degree of hydration' curve is strongly influenced by the water-cement ratio as demonstrated among others by J. H. Taplin (15), and by the chemical and mineralogical composition of the cement as shown among others by P. P. Budnikov and E. Erschler (18).

The conversion of portland cement and water into hydration products is accompanied by a contraction which is due to the fact that the total volume of the hydrates formed is less than the sum of the volumes of the anhydrous phases and the water involved in the reaction.

W. Czernin (23) used a volumenometer to measure the contraction as a function of time and illustrated the course of hydration by means of data obtained in this manner. As shown also by J. S. Malinin, L. J. Lopatnikova, V. I. Guseva and N. D. Klishanis (24), contraction vs. time curves at room-temperatures are characterized by an initial period (lasting a few hours) of low contraction rate. Then the rate increases, passes through a maximum, and then decreasing slowly towards zero.

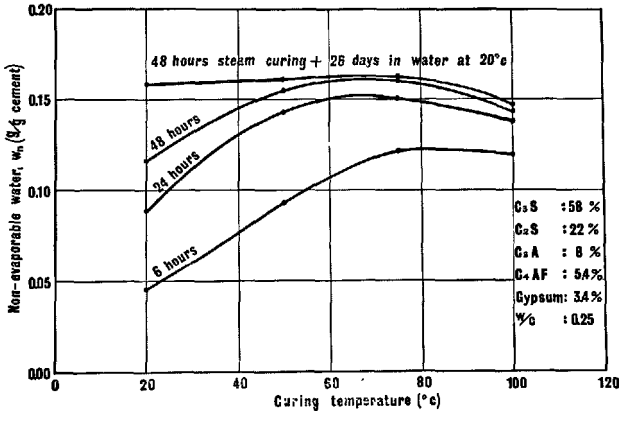

Fig. 2. *Non-evaporable water content in portland cement pastes as a function of curing temperature, measured at the indicated ages (from water addition). Data from (21), not published*

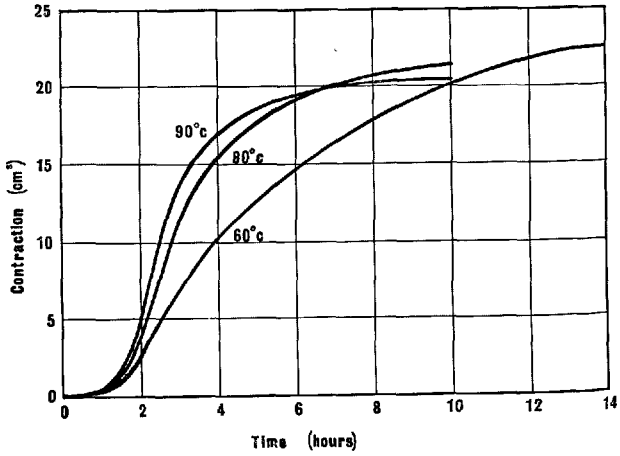

Fig. 3. *Contraction of portland cement mortars versus curing time under isothermal conditions. From L. A. Sil'chenko, M. V. Mikhailov and P. A. Rehbinder (26)*

R. Malinowski (25) used the same technique as Czernin to measure the volume changes of cement paste hydrating at 80°C. L.A. Sil'chneko, M. V. Mikhailov and P. A. Rehbinder (26) described an ingenious but simple apparatus which allowed them to study the effect of temperature on the contraction of hydrating portland cement mortars. As appears from Fig. 3, they observed that the rate of contraction, in the early hydration stages, increased with increasing temperature. The total contraction, however, at an age of about 12 hours, was higher with a curing temperature of 60°C than with temperatures of 80°C and 90°C. (The contraction dealt with above does not imply that a hydrating specimen of cement paste undergoes a decrease in its outer dimensions during hydration. On the contrary, a slight expansion of moist-cured specimens is usually observed).

Heat Evolution

Various calorimeter techniques have been applied to measure the heat which is liberated during the the hydration of portland cement. The heat of solution method is used to obtain figures of the total heat of hydration at the later age stages. The conduction calorimeter technique provides information on the rate of heat evolution and is particularly suited for investigations of the early stages of hydration. Thus, this latter technique is also best suited for studies of temperature effects, since in such studies the early hydration stages are of particular importance.

W. Lerch (27) and others in studies at room-temperature found that the rate of heat evolution curve has two or more peaks. The first peak occurs a few minutes after mixing with water and represents, according to Lerch, initial rapid dissolution of aluminates and rapid crystallization of hydrated calcium aluminates. This peak is followed by a period of low activity, lasting usually 2 to 3 hours and named the induction or 'dormant' period. At the end of the induction period, the rate increases again, passes through a maximum (second peak) and decreases then slowly towards zero. The second peak usually occurs 6 to 10 hours after mixing. Mainly, it represents heat evolution associated with the reaction of calcium silicates with water to form calcium silicate hydrates. A third peak may occur, depending generally on the contents of C_3A, gypsum, and alkalies in the cement as well as on the ratio between them.

Data on the effect of the temperature level under isothermal curing conditions on the heat evolution during hydration are presented by a number of authors. In the low temperature ranges (below about 40°C), the temperature effect was studies by H. Yokomichi (28), E. Rastrup (5), (6), L. E. Copeland, D. L. Kantro and G. J. Verbeck (22), H. Lehmann and W. Roesky (29) and U. Danielsson (13) and others. Some of Danielsson's results are reproduced as Figs. 4 and 5. Studies of the effect of higher temperatures (in the 40°C to 100°C range) were reported by N. C. Ludwig and S. A. Pence (20), L. E. Copeland, D. L. Kantro and G. J. Verbeck (22), Jo Gebauer and I. Odler (19), (30), and P. P. Budnikov and E. Erschler (18).

From these studies it appears that the temperature level strongly influences the evolution of heat of hydration. In general, the effect of increasing temperature consists in a reduction of the induction period and an increase of the rate of heat evolution, As seen in Fig. 4, this effect manifests itself as a displacement of the main peak towards zero time and as an increase of the height of the peak.

In the low-temperature range (below about 40°C), L. E. Copeland, D. L. Kantro and G. J. Verbeck (22), H. Lehmann and W. Roesky (29), and U. Danielsson (13) found that the total heat of hydration, at any stage of hydration, is proportional to the degree of hydration as defined above, irrespective of the temperature level. However, J. Gebauer and I. Odler (30) in their experiments found the ratio between non-evaporable water and heat of hydration to be less in pastes cured at 20°C than in pastes cured at 80°C, this difference being particularly pronounced at later ages (28 days).

As appears from the above, only a few data are reported on isothermal heat evolution at high temperature levels (above about 60°C). This may be due to

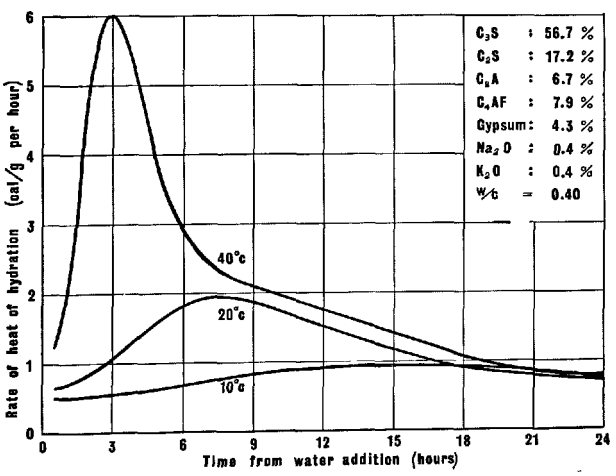

Fig. 4. *Rate of heat of hydration for portland cement pastes cured continuously at 10°C, 20°C, and 40°C, respectively. From U. Danielsson (13)*

experimental and instrumental difficulties. However, for future investigations, the microcalorimeter developed by E. Calvet (31) and used by M. de Tournadre in his studies of the hydration of calcium aluminates (32) and calcium sulphate (33) seems to be a suitable instrument for accurate measurements of heat evolution under isothermal conditions.

Strength and Elasticity

With a given cement and with given mix proportions, the development of strength and stiffness in cement paste and concrete proceeds in a manner similar to that of the degree of hydration.

Thus, as shown for instance by R. Malinowski (25), the rate of strength growth increases initially, then it passes through a maximum, after which it decreases slowly towards zero. Unfortunately, however, rather few experimental data are reported in the literature on the strength development during the very early stages of hydration.

Early changes in elasticity, on the other hand, were studied by means of ultra sonic methods by A. E. Whitehurst (34), J. Andersen and P. Nerenst (35), L. Palotas, D. Balazs and I. Gemesi (36), M. Lystbæk (37), and others who calculated the dynamic modulus of elasticity from continuously measured values of the ultrasonic velocity.

Numerous test series are reported in the literature concerning the effect of the level of curing temperature on the strength and stiffness development. They all show that the rate of strength (and stiffness) growth at the early stages of hydration increases strongly with increasing curing temperature. With increasing age, however, this effect of temperature becomes less pronounced, and it is even frequently observed, see e.g. J. A. Hanson (38), that strength and modulus of elasticity at later ages (for instance at 28 days) are greater for specimens cured at moderate temperatures (below about 40°C to 50°C) than for specimens cured at the highest temperature (about 80°C to 100°C). This applies whether high temperature curing was used continuously during the whole curing period or only during the first few hours of curing. This phenomenon is demonstrated in Fig. 6 (data from J. Gebauer and I. Odler (19)).

The ultrasonic technique has been taken in use at the Concrete Research Laboratory Karlstrup (see Fig. 7) to study the effect of temperature on the growth of modulus of elasticity during the very early stages of hardening of concrete. Preliminary results are presented in Fig. 8. The plateau which is observed on both curves has not yet been interpreted.

The reduction of strength at later ages which is often observed with steam curing, has not been fully explained. W. Czernin (39), J. A. Hanson (38), H. H. Bache and P. Dragsholt (40), and P. P. Budnikov and E. Erschler (18) showed that structural disintegration, due to different thermal expansion of solid material and water and vapor phases, could occur under certain unfavourable conditions. This would be expected to cause strength losses. H. H. Bache and P. Dragsholt (40), however, concluded from their results that structural disintegration could account for only part of the strength reduction observed. It is worth mentioning in this connection that P. P. Budnikov, S. M. Royak,

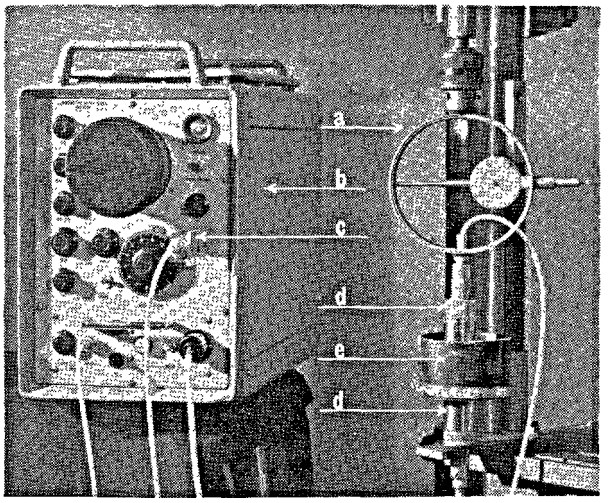

Fig. 7. *Setup for continuous measurement of ultrasonic velocity in cement paste, mortar or concrete during hardening: a) pressure device with dynamometer (it is often useful to apply a certain pressure to the specimen in order to facilitate the propagation of sonic pulses through the specimen, particularly at the early stages of hydration); b) ultra sonic apparatus; c) switch by means of which the transmission of pulses may be switched off between readings; d) transducers (the upper transducer is in direct contact with the surface of the specimen); and e) mould containing the concrete specimen (the bottom is made of steeel, the cylindrical shaft of rubber, while the part of the upper surface of the specimen, which is not in touch with the transducer, is covered with a steel plate). From M. Lystbæk (37)*

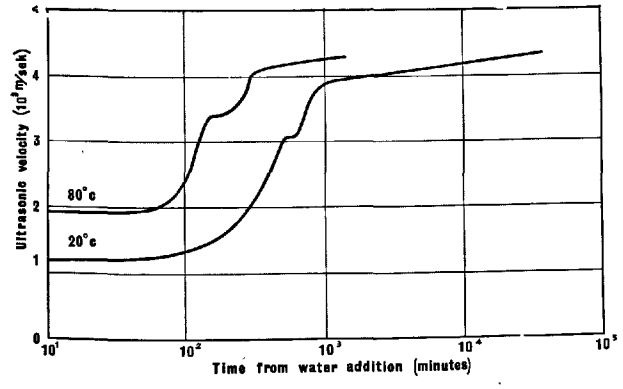

Fig. 8. *Ultrasonic velocity in portland cement concrete cured permanently at the temperature levels indicated. Preliminary data from the Concrete Research Laboratory Karlstrup*

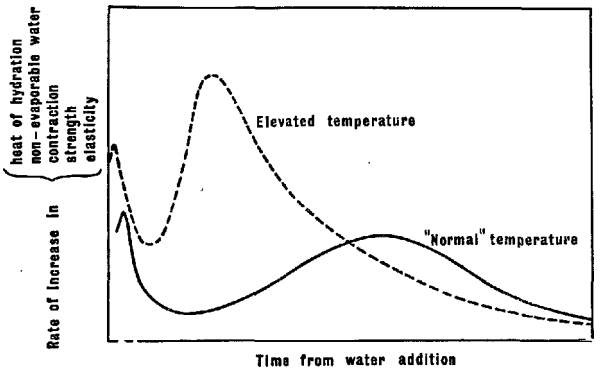

Fig. 9. *Qualitative picture of the effect of a temperature increase on the rate of development of the phenomena indicated*

J. S. Malinin and M. M. Mayants (17) in experiments with pure C_3S pastes found that with equal degree of hydration, specimens hydrated at about 50°C obtained much less strength than specimens hydrated at temperatures below and above 50°C. They attributed the phenomenon to the formation of a special, metastable hydration product which formed only at about 50°C.

The various methods mentioned provide a somewhat indirect and incomplete picture of the hydration process, and observations on hydration at elevated temperature levels must accordingly be interpreted with singular caution. With reasonable certainty, however, the following can be said:

1. Whether degree of hydration, volume change, heat of hydration, strength or elasticity are used to characterize the hydration process, a temperature increase manifests itself in the same manner: The length of the induction period decreases and the early stage rate of hydration increases with increasing temperature. This is qualitatively illustrated in Fig. 9.

2. At later ages, curing temperatures above about 60°C to 80°C are frequently found to result in a reduction of the degree of hydration, contraction, strength, and modulus of elasticity as compared with what is obtained at lower temperature levels. However, there is also experimental evidence pointing in the opposite direction.

Mechanisms of Reaction

The hydration of portland cement is a heterogeneous, stepwise reaction.

From numerous investigations of hydration at room temperatures it appears that the reaction steps should be sought within such topics of physical chemistry as adsorption, dissolution, mass-transfer, and crystallization. Several models have been suggested to describe the individual steps or combinations of steps

involved in the hydration process. A few examples of such models are presented in the following:

Adsorption

W. C. Hansen (41) suggested a hydration mechanism of C_3A, C_2S, and C_3S based on the chemi-sorption of OH^- and H_2O^+ ions from water by Ca^{2+} and O^{2-} ions in the surfaces of crystals. A. K. Chatterji and R. S. Rawat (42) stated that the reaction between cement clinker and water is a semiconducter surface reaction, and the hydration of clinker minerals therefore is a chemi-sorption process occuring on the surface of clinker crystals. Whether physical adsorption occurs is not mentioned.

Dissolution

S. A. Greenberg and T. N. Chang (43) in investigations on the hydration of C_3S at 30°C considered dissolution of calcium silicate to be one of the processes occuring. N. Kawada and A. Nemoto (44) in a detailed description of mechanisms of the reaction between C_3S and water showed that the initial step is a dissolution of approximately half of the calcium from the surface of the C_3S particles. This mechanism is in agreement with the one suggested by J. S. Malinin, L. J. Lopatnikova, V. I. Guseva and N. D. Klishanis (24).

Mass-Transfer

Diffusion of hydrated ions away from surfaces of unhydrated minerals is one of the steps discussed by S. Brunauer and S. A. Greenberg (45). V. B. Ratinov and A. P. Lavut (46) derived an equation which describes the hydration kinetics assuming convection and diffusion to take place. N. Kawada and A. Nemoto (44) described transfer through solution, of the amorphous coating formed on unhydrated calcium silicate to nucleii of more crystalline calcium silicate hydrate.

Mass-transfer (either by diffusion or by Poiseuille flow) through coating of hydration products on surfaces of unhydrated minerals is described by H. N. Stein (47), H. zur Strassen (48), T. C. Powers (49) and others.

Crystallization

S. A. Greenberg and T. N. Chang (43) demonstrated that after the initial surface reaction between C_3S and water the solution was only slightly supersaturated with respect to hydrated calcium silicate but highly supersaturated with respect to calcium hydroxide, and they stated that the rate of crystallization of the hydrated silicate was much faster than the rate of hydration. H. E. Schwiete, U. Ludwig and P. Jäger (50) suggested that the topochemically formed ettringite coating on C_3A grains later on is bursting off due to crystallization pressure. V. YA. Khaimov-Mal'kov (51) derived an equation for crystallization pressure.

In order to elucidate the reaction kinetics at elevated temperatures it would be desirable to establish i) the steps involved in the hydration, and ii) the influence of temperature and degree of hydration upon the reaction scheme and the velocity of the steps. Hence, the various 'rate determining steps' could possibly be found.

However, since no model, accounting in detail for the complete course of the hydration process, has so far found sufficient support in experimental data to be generally accepted and since no indication of the effect of temperature on the particular reaction steps possibly involved was found in the literature reviewed, the following literature survey is limited to investigations dealing only with measurements of the overall rate of reaction and its variation with temperature. In some of these investigations, calculation-models have been used to correlate experimental data to kinetical theories; these models, naturally, are more or less realistic. For instance, the fact that the individual cement grains consist of a mixture of the cement minerals is rarely taken into consideration, see Fig. 10.

V. B. Ratinov, A. P. Lavut (46), V. B. Ratinov, G. D. Kucheryaeva, G. G. Melent'eva and S. M. Pimenova (52), and V. B. Ratinov, T. I. Rozenberg and I. A. Smirnova (53) stated that the kinetics of hydration may be divided into two stages. In the earliest stage (1 ~ 3 days), transfer of materials proceeds through convection and diffusion. In the second stage, which occurs after the formation of a rigid skeleton, the transfer of materials is a diffusion only. They derived equations describing the hydration kinetics within the first stage, and they presented experimental

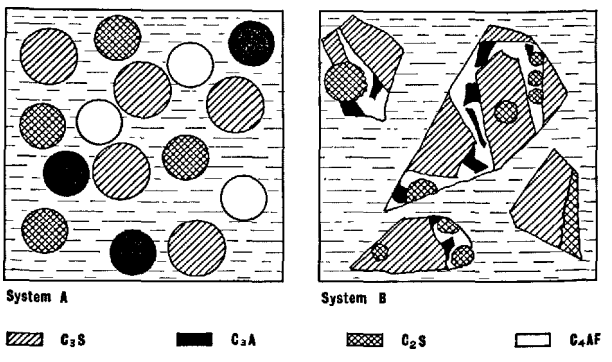

Fig. 10. *Models of water-cement systems. System A contains grains of pure clinker minerals. System B contains grains of a mixture of clinker minerals*

evidence for the validity of the equation:

$$m_\tau^{1/3} - m_0^{1/3} = -K \cdot D^{2/3} \cdot C \cdot \tau,$$

where m denotes the amount of unhydrated material at time τ and $_0$, respectively, K a constant, D the diffusion coefficient, and C the solubility of the anhydrous phase. The temperature affects the solubility C and $K \cdot D^{2/3}$. The theoretical and experimental results were used to calculate the ratios of the hydration rate and the dissolution rates of C_3S and β–C_2S at various temperatures. It was shown that increasing temperature results in increasing solubility of β–C_2S and C_3S, and a decrease in the ratio between the reaction rates of C_3S and β–C_2S. Some of the data are presented in Table 1.

P. P. Budnikov, S. M. Royak, Y. S. Malinin and M. M. Mayants (54), (17) measured the degree of hydration (by means of X-ray investigations) of cement minerals and mixtures of them at various ages and at various temperatures. For all the materials investigated they found that the empiric equation

$$L = K \cdot \log\tau - B$$

covered the test results with reasonable accuracy within the range $20\% < L < 80\%$, see Fig. 11. In this equation, L denotes the degree of hydration, τ time, and K and B constants which depend on the type of clinker mineral or mineral mixtures and the temperature. B is related to the induction period. The effect of temperature was described by the following equations:

$$\log B = A - n \log T,$$

and

$$K = cT + d,$$

in which T is the absolute temperature in °K. A, n, C, and D are constants distinctly related to each kind of binding materials.

T. M. Berkovltch, D. M. Kheiker, O. I. Grachva, O. S. Volkov and E. S. Mikhalerskaya (55) concluded from their investigations that the kinetics of the hydration process can be described by the first order

Table 1. *The effect of temperature on hydration rates and on solution rates of* C_3S *and* β-C_2S. (*From V. B. Ratinov and A. P. Lavut* (46)).

Temperature °C	Ratio between hydration rates of C_3S and β-C_2B		Ratio between solution rates of C_3A and β-C_2S
	24 hours	72 hours	
20	4.1	4.7	2.4
35	3.7	2.8	2.0
50	2.5	2.4	1.9
65	2.4	2.4	1.8

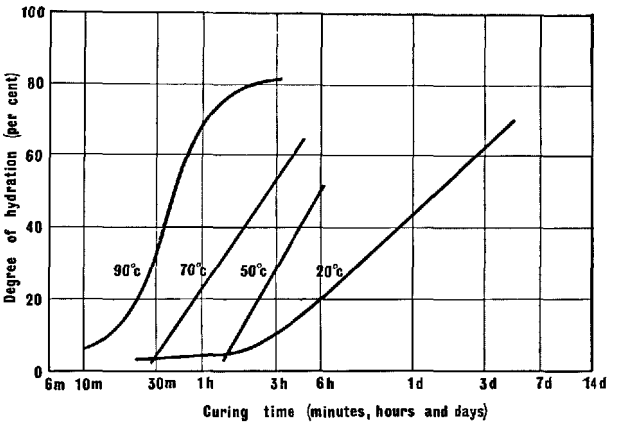

Fig. 11. *Kinetics of hydration of the clinker mineral* C_3S *at different temperatures. From P. P. Budnikov, S. M. Royak, Y. S. Malinin and M. M. Mayants* (54)

equation:

$$-\log c = K \cdot \tau + \text{const},$$

where c is the amount of unhydrated cement, τ time, and K a rate constant. Plots of $\log c$ versus τ showed two rectilinear portions corresponding to two different values of the rate constant K. Thus, they suggested the hydration process to be divided into two periods. The effect of temperature was said to consist in an increase of the rate of hydration, but the fundamental regularities of the process were not considered to be greatly affected. Data were presented for the hydration of C_3S and β–C_2S within the range $25° \sim 175°C$, and it was demonstrated that the rate constants vary with temperature according to Arrhenius' law within each of the two periods.

Values of the activation energy which is a constituent part of Arrhenius equation, have been used to describe the effect of temperature on cement hydration. G. Verbeck (56) showed that the Arrhenius equation is valid within the temperature range $4° \sim 110°C$. The activation energy found has the same value for different types of cement. L. E. Copeland and D. L. Kantro (57) on the other hand showed that the activation energy depends on the degree of hydration. H. E. Schwiete, H. Knoblauch and G. Ziegler (58) found in investigations on the kinetics of hydration of C_3S and β–C_2S that the hydration of C_3S is a reaction of third order with an activation energy of 2.1 Kcal/mol, and that the hydration of β-C_2S is a reaction of 1.5 order with an activation energy of 1.8 Kcal/mol. J. H. Taplin (59) found, however, activation energies of about 10 Kcal/mol for the hydration of C_3S and 18 Kcal/mol for the hydration of β–C_2S. In investigations on composition of the

liquid phase during the hydration of cement, C. D. Lawrence (60) found the activation energy for the reaction between C_3A and sulphate to be 9.0 Kcal/mol.

R. F. Feldmann and V. S. Ramachandran (61) studied the effect of temperature (from 2°C to 52°C) on the hydration of C_3A/gypsum mixtures. They concluded, that gypsum decreases the reactivity of C_3A by sorption of SO_4^{2-} ions and that gypsum reduces the rate of conversion of hexagonal to cubic hydroaluminate by sorption of SO_4^{2-} ions. At the highest temperature (52°C), a large amount of gypsum may have an accelerating effect, as the gypsum prevents the growth of impermeable C_3AH_6 films on the surface of C_3A.

Hydration Products

Observations on the influence of the temperature upon rate of hydration and on the final strength of cement paste indicate that the hydration products formed at elevated temperatures differ from those at room temperature. The identification of the various hydration products is not simple, as the type of hydration products found depends on the identification-criteria (chemical composition, X-ray pattern, DTA-temperatures, IR-traces, etc.) and on the conditions (relative humidity, CO_2-concentration, etc.), under which the investigations are carried out. This may explain the fact that a distinct picture of the phase-composition of cement hydrated at elevated temperature has not been found in the literature.

System $CaO–Al_2O_3–Fe_2O_3–CaSO_4–H_2O$

Equilibria in the ternary system $CaO–Al_2O_3–H_2O$ was reviewed by F. E. Jones (62). He concluded that the only aluminates appearing in the temperature range 20 ~ 100°C are C_4AH_{19} and C_2AH_8 which, however, both are metastable with respect to C_3AH_6. O. P. Mchedlov-Petrosyan (63) used calculated values of thermodynamic functions to predict the components which might be expected to form under various hydration conditions and to predict the energetics of the reactions involved. These included reaction of formation of the various hydrated components from solutions, hydration reactions of anhydrous cement compounds, and transformation reactions. Concerning the system $C_3A–H_2O$ and the system $CA–H_2O$ as well, he concluded that the only thermodynamically stable compound in the temperature range 25 ~ 125°C is C_4AH_{19}. M. de Tournadre (32), (64) and P. Longuet and M. de Tournadre (65) studied the hydration of calcium aluminate by means of a microcalorimeter. They found that C_3A at 30°C hydrated into C_3AH_6 only.

E. T. Carlson studied the hydration of calcium aluminate ferrites (66) and properties of the hydrates (67). He concluded that the hydrogarnet phase $C_3(A, F)H_6$ is a stable phase above 35°C. At 70°C a solid solution of C_3AH_6, in which one-tenth of Al_2O_3 is replaced by Fe_2O_3, is precipitated. Moreover, he found that all the aluminoferrite hydrates reacted with calcium sulphate solution forming mixtures of the monosulphate and the trisulphate types, the latter predominating at later stages.

O. P. Mchedlov-Petrosyan (63) concluded concerning the system $CaO–Al_2O_3–CaSO_4–H_2O$ that trisulphate is the thermodynamically stable product up to 70°C, and that monosulphate is the stable compound above 70°C. H. Kühl (68) considered that the formation of ettringite above 40°C is not possible, whereas W. Lieber (69) obtained ettringite from aqueous solutions up to 90°C. This is in agreement with Y. M. Butt, A. A. Maier and B. G. Varshal (70), who found transformation temperatures for ettringite to monosulphate in the temperature range 125°C to 175°C. On the other hand, they found monosulphate to be stable in contact with its saturated solution in the temperature range 50°C to 200°C.

System $CaO–SiO_2–H_2O$

O. P. Mchedlov-Petrosyan (63) treated the hydrothermal main-reactions and side-reactions in the system $Ca(OH)_2–SiO_2–H_2O$ from a thermodynamical point of view as previously described. He found that amount the compounds having C: S = 2: 1 (and 3: 1, 4: 1, 5: 1, and so on) hillebrandite ($2CaO \cdot SiO_2 \cdot 1.17H_2O$) is the stable phase. For compounds having C: S between 3: 2 and 4: 3 foshagite ($4CaO \cdot 3SiO_2 \cdot 1.5H_2O$) is the stable one. With a C: S ratio of 1: 1 14 Å tobermorite ($5CaO \cdot 6SiO_2 \cdot 10.5H_2O$) is stable up to about 80°C, 11 Å tobermorite ($5CaO \cdot 6SiO_2 \cdot 5.5H_2O$) up to about 100°C and above that xonotlite ($6CaO \cdot 6SiO_2 \cdot H_2O$) is stable. 14 Å tobermorite is the stable phase by C: S = 5: 6 up to 50°C, xonotlite stable above 50°C. With a C: S ratio of 2: 3, 1: 2, 1: 3, 1: 4, and so on, gyrolite ($2CaO \cdot 3SiO_2 \cdot 2.5H_2O$)

is the stable phase. Using an isothermal solution calorimeter J. E. Taylor (71) determined the heats of formation of a number of calcium silicate hydrates. The results obtained were very close to those calculated by O. P. Mchedlov-Petrosyan (63).

O. P. Mchedlov-Petrosyan (63) in a description of the thermodynamics in the hydration of β–C_2S and C_3S concluded that the most stable endproduct up to 100°C in both cases is hillebrandite. Other products, however, such as for instance foshagite and tobermorite are possible endproducts due to kinetical and structural conditions.

D. L. Kantro, S. Brunauer and C. H. Weise (72) reported that calcium hydroxide and a tobermorite-like product is found during hydration of β–C_2S at the temperatures 5°C, 25°C, and 50°C. They found an increase in the final CaO/SiO_2-ratio with increasing temperature. Such increase in CaO/SiO_2-ratios are also found in products hydrated at temperatures up to 100°C, as described by H. Funk (73). D. L. Kantro, S. Brunauer and C. H. Weise (72) moreover found an increase in H_2O/SiO_2-ratios with increasing temperatures. Concerning hydration of C_3S they found no unidirectional changes with temperature in the ultimate ratios of CaO/SiO_2 and H_2O/SiO_2. H. Funk, B. Schreppel and E. Thilo (74) found that hydrated intermediate products with water contents up to $H_2O/SiO_2 = 1.5$, and β–C_2S-like structures occur. The intermediate products are also formed by interaction between β–C_2S and gaseous water at 100°C. In this case the porous final products have compositions of $1.8 \sim 2CaO \cdot SiO_2 \cdot 1 \sim 2H_2O$, and structures which are still similar to that of β–C_2S.

P. P. Budnikov, S. M. Royak, S. J. Malinin and M. M. Mayants (17) found that the 'basicity' of the hydrosilicate phase in specimens of hydrated C_3S increases up to a temperature of about 50°C and decreases slightly in the range 50 ~ 90°C. At 90°C, however, the 'basicity' is still higher than at 20°C. Specimens of hydrated C_2S showed no change in 'basicity' by change in temperature.

E. R. Buckle and H. F. W. Taylor (75) showed that when C_3S is hydrated at temperatures above 50°C small amounts of tricalcium silicate hydrate are formed together with tobermorite gel and calcium hydroxide.

H. Funk and F. Zimmermann (76) stated that below a hydration temperature of 120°C only the ill-crystallized phases of calcium silicate hydrate exist.

Natural Minerals

Investigations on the characteristics of the cement paste are difficult due to small size and low order of crystallinity of the components. Larger pieces of natural minerals, which are more or less identical to the cement paste components have sometimes been examined and their characteristics have been compared with the cement paste components. Recently two such investigations, which are of interest to the present problems, have been published.

V. C. Farmer, J. Jeevaratnam, K. Speakman and H. F. W. Taylor (77) studied the thermal decomposition of 14 Å tobermorite from Crestmore. The composition is considered to be $Ca_5Si_6O_{18}H_2 \cdot 8H_2O$ with small amounts of CO_2 and B_2O_3. At 55°C there is a sharp change to 11.3 Å tobermorite $Ca_5Si_6O_{18}H_2 \cdot 4H_2O$. The 11.3 Å tobermorite looses most of its water gradually, at 55°C to 200°C, apparently without undergoing fundamental change in structure.

At Crestmore a new mineral has been found. The mineral was described by K. Speakman, R. A. Chalmers, J. A. Gard, H. F. W. Taylor and A. B. Carpenter (78) and it was named jennite. Jennite seems to be very similar to the C–S–H I phase found in cement paste (H. F. W. Taylor (79)). Jennite has a composition $Na_2Ca_8(SiO_3)_3(Si_2O_7)(OH)_6 \cdot 8H_2O$.

On heating, jennite remains stable up to 70°C, but at 70°C to 90°C there is a sharp loss of water, which amounts to about 7% of the initial weight. The product thus formed is called meta-jennite; its composition is thought to be $Na_2Ca_8(SiO_3)_3(Si_2O_7)(OH)_6 \cdot 5H_2O$.

It is of interest in this connection that T. Yoshii and G. Sudoh (80) in studies of the system Na_2O–CaO–SiO_2–H_2O at 20°C found, that when C_3S and C_2S initially hydrated in contact with a Na^+-containing liquid, the hydrated solid phases after 98-days are $N_{0.26}C_{1.60}SH_n$ and $N_{0.15}C_{1.40}SH_n$.

Hydration Products in Cement Paste

Study of pure few-component-systems can give an idea of the compounds which would be expected to appear during the hydration of cement. Cement paste, however, is a multi-component system in which formation of meta-stable compounds and solid solution series is possible, and as equilibrium is possibly not reached, the hydration-pattern obtained from pure-system investigations may very well be very much different.

A. E. Sheikin and N. I. Oleinikova (81), in X-ray investigations of steam cured cement paste, found the presence of low intensity lines of trisulphate and lines of monosulphate of much higher intensity, as well as

lines of C_2AH_8 and diffuse lines of C_4AH_{13} and gypsum. The presence of C_3AH_6 was not established. They concluded that the hydration products of steam cured cement paste are similar to those of ordinary cement paste at long duration of hydration, which may point out the formation of more stable compounds at steam curing.

P. P. Budnikov and E. Erschler (18) concluded from studies of low pressure steam curing of concrete that in the course of steam treatment, formation of hydrosulpho-compounds in cement paste takes place up to 60°C. At higher temperatures these are transformed into compounds of lower sulphate content, and free calcium sulphate is released.

L. Hjorth (82) found monosulphate to be present and ettringite to be absent in a cement sample initially hydrated 7 hours at 100% RH and 80°C, and thereafter stored for two months at 100% RH and room-temperature. The ettringite phase seems to disappear at about two hours of hydration. The presence of ettringite and the absence of monosulphate was found in a similar sample cured at room-temperature and 100% RH for two months.

G. L. Kalousek (83) investigated by means of DTA the amount of the different SO_3-containing compounds in cement hydrated at the temperatures 24°C, 55°C, and 82°C. He found that some SO_3 was 'missing' and he suggested that SO_4^{2-} is incorporated in the tobermorite gel substituting SiO_4^{4-}. The solid solution formed is called phase X. The effect of the temperature is considered to be an acceleration of the reaction: Ettringite → monosulphate → solid solution of monosulphate and calcium aluminate hydrate → phase X. He found it reasonable to assume that the constituents Al_2O_3, SO_3, and Fe_2O_3 have solid solution saturation levels in phase X. Once the saturation values are exceeded, such constituents would become parts of other phases.

In X-ray investigations of cement hydrated at 100°C, A. Aitken and H. F. W. Taylor (84) found no hydrated aluminate or sulfoaluminate phases. P. P. Budnikov, S. M. Royak, J. S. Malinin and M. M. Mayants (17), however, found monosulphate by means of DTA in a cement hydrated 24 hours at 90°C.

From electron microscopic observations Å. Grudemo (85) stated that there is no fundamental change in the C–S–H gel phase at temperatures of about 100°C or a little higher.

There are some indications that small amounts of crystalline hydrated silicates are formed during the hydration of cement at elevated temperature besides the formation of tobermorite gel. A. Aitken and H. F. W. Taylor (84) found that some tricalcium silicate hydrate was formed at 50°C to 75°C, and G. L. Kalousek and A. F. Prebus (86) reported that hillebrandite was formed at 50° to 120°C.

I. Odler and J. Gebauer (19), (30) found in an investigation of cement hydrated at different temperatures that a phase characterized by a DTA-peak at 450°C occured in cement paste hydrated at 80°C. This phase was considered to be α–C_2SH.

P. P. Budnikov, S. M. Royak, J. S. Malinin and M. M. Mayants (17) in a review of literature mentioned that the presence of C_2SH_2, $C_2SH_2 + C_3S_2H$, and C_3SH_3 in high-temperature hydrated cement has been reported.

It can be concluded that the reaction products of cement hydrated in the temperature range 50°C to 100°C differ from the products formed at room-temperature as follows:

1. The calcium silicate gel obtained probably has a higher content of Al^{3+}, Fe^{3+}, and SO_4^{2-} ions. By analogy with results from investigations on pure clinker minerals the calcium silicate gel, moreover, is considered to have a higher CaO/SiO_2-ratio and a different H_2O/SiO_2-ratio.
2. Small amounts of some other, more crystalline calcium silicate hydrates may be formed.
3. Less amounts of separate hydrated aluminate, ferrite or sulfoaluminate phases will be formed, if formed at all. The ratio between the amounts of trisulphate and monosulphate will probably be lower.

Moreover, it seems well established that increasing temperature does not promote the transformation of hexagonal calcium aluminate hydrates into cubic calcium aluminate hydrates when these products are present in cement paste.

The Structure Formation

Many authors have stated that curing of concrete at elevated temperatures results in lower ultimate strength than curing at room-temperatures. Studies reporting curing at elevated temperatures without loss of ultimate strength have appeared only exceptionally, see e.g. R. Malinowski (87). Thus, a certain loss of ultimate strength is often considered the payment for the acceleration of hardening of concrete.

However, recent experiments at the Concrete Research Laboratory Karlstrup have demonstrated that under certain conditions more than 50 % increase of ultimate strength can be achieved by means of steam curing. These apparently contrasting observation call for a brief discussion of the nature of the strength determining factors and their dependence on temperature.

The strength of cement paste, mortar and concrete is controlled by the building up of a structure composed of hydration products (here designated the *microstructure*) and their interaction with grains of unhydrated cement and fillers, which together with the microstructure constitute the *macrostructure*, as shown schematically in Fig. 12. The strength and rigidity of the macrostructure is influenced by the temperature through its influence upon:

1. Interatomic forces within the individual particles which are formed during the hydration.
2. Interfacial atomic forces which bind the individual particles together and to grains of hydrated cement and fillers.
3. Size and morphology of the hydrated particles as well as their intergrowth and agglomeration.
4. The distribution of microstructure, i.e. its geometrical arrangement and its density distribution.

The contribution of intrinsic particle strength and interfacial forces to the strength of the microstructure was discussed by S. Chatterji and J. N. Jeffery (88) who explained the difference between tensile and compressive strength on the basis of a model of the structure of set cement, provided through examinations of electron micrographs. The effect of temperature on crystal growth was discussed by P.P. Budnikov and E. Erschler (18) who suggested that the ratio between the amount of crystalline hydration products and the amount of gel increases and that the crystal size increases with increasing temperature. They further suggested that this temperature effect on the microstructure would lead to decreasing strength with increasing temperature. The same effect was suggested by F. Keil (89) in his review on the hardening of hydraulic binders. Measurements of the specific surface area of hydration products rather consistently show that the specific surface area decreases with increasing temperature at the late age stages of hydration (see e.g. N. C. Ludwig and S. A. Pence (20), P. P. Budnikov, S. M. Royak, Y. S. Malinin and M. M. Mayants (17), O. Matsuda and S. Ishimura (90), and S. Brunauer and D. L. Kantro (91)) indicating that coarser particles are formed at elevated temperatures than at room-temperatures.

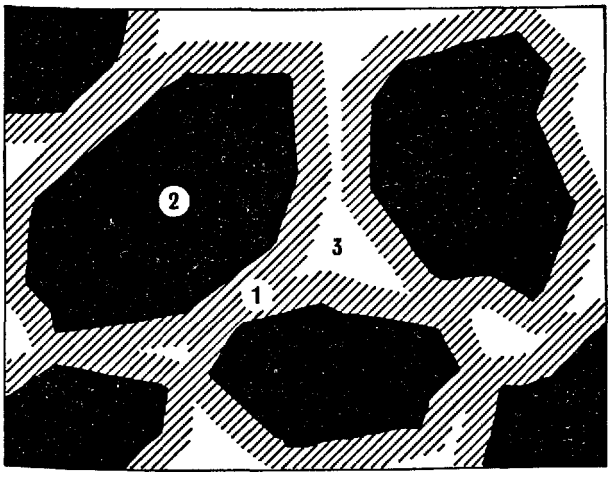

Fig. 12. *Model of structure of hardened cement paste. The microstructure (1) consisting of particles of hydrated compounds of varying shape and size (typical size 10–100 Å) is located in the space between particles of unhydrated cement and filler (2), gluing these solid particles together to form a solid macrostructure. The pore space in the macrostsucture is marked (3).*

Unfortunately, the available information about these matters is insufficient to provide a synthesis by means of which the influence of curing temperature on the strength of cement paste may be interpreted. However, some comments concerning the microstructure distribution shall be made in the following.

Studies of hardened cement paste in the electron microscope have demonstrated that the microstructure is of a complex and highly heterogeneous character, see e.g. Å. Grudemo (85) and Portland Cement Association (92), and recent observations on fracture surfaces of hardened cement paste by means of the scanning electron microscope, see Fig. 13, have similarly demonstrated the heterogeneity of the microstructure. The possible significance of this fact, as regards the strength of the macrostructure, does not seem to have been recognized in many earlier investigations.

G. Verbeck (14), however, suggested a heterogeneous distribution of the microstructure of cement paste to be the cause of the decrease of ultimate strength which is generally observed with steam curing. He assumed, thus, that in the case of curing at elevated temperatures, a condensed coating of hydrates is formed on unhydrated grains, leaving the remaining structure relatively open, while in the case of curing at room-temperatures a more homogeneous microstructure is formed, see Fig. 14 (1 and 2). According to Verbeck's theory, the relatively open microstruc-

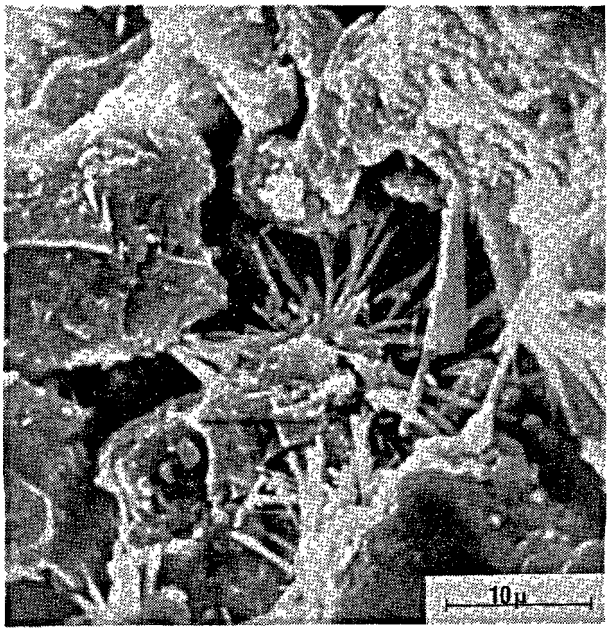

Fig. 13. *Scanning electron micrograph showing fracture surface of steam cured cement paste. The cement paste has been cured under water for 24 hours at 90°C and then cured under water for 28 days at 20°C prior to examination. The specimen was prepared by pressing in almost dry condition followed by impregnation with water. The porosity of the paste prior to hydration was 0.40. A portland cement of 3740 cm²/g Blaine was used. Investigation by the Concrete Research Laboratory Karlstrup.*

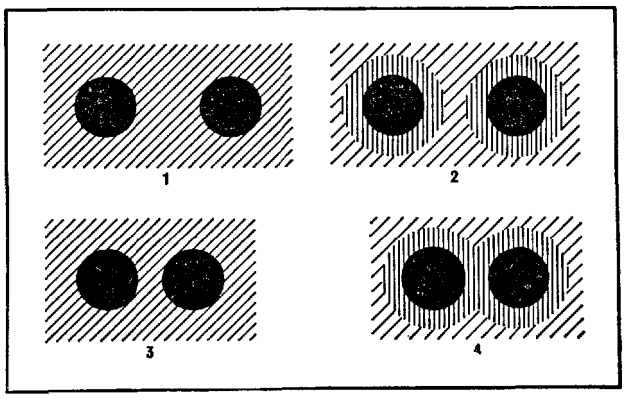

Fig. 14. *Effect of heterogeneity of microstructure on the strength of cement paste. Particles of unhydrated cement (black) are surrounded by a microstructure, which in case (1) and (3) is uniformly distributed. In case (2) and (4) the microstructure is heterogeneous as the cement grains are surrounded by a denser coating. With loose packing (1) and (2), the cement paste is strongest, when the microstructure is homogeneous, while the opposite is the case with dense packing (3) and (4). In the latter case the dense microstructure coatings (4) around the cement particles glue the particles together.*

ture around the denser zones which is formed at elevated temperatures is responsible for the lower strength of the macrostructure. In experiments at room-temperature, P. A. Rehbinder (93) found that cement paste adjacent to aggregate particles exhibited much higher strength (measured as microhardness) than paste forming the mass of matrix in between particles.

From these studies it seems reasonable to expect that improvement of the strength of hardened cement paste may be achieved by condensation of the agglomerate of the solids of fresh paste, thus utilizing the higher strength of the microstructure adjacent to hydrating cement grains or inert fillers. In fact, this principle has, for room-temperature hydration, already been applied successfully in the USSR, see G. M. Khutortsov, N. V. Mikhailov and P. A. Rehbinder (94) and N. B. Ur'ev, N. V. Mikhailov and P. A. Rehbinder (95). This beneficial effect of the heterogeneity of the microstructure, obtained in the case of densely packed pastes or mortars, should probably be even more pronounced with curing at elevated temperatures, as shown schematically in Fig. 14 (3 and 4).

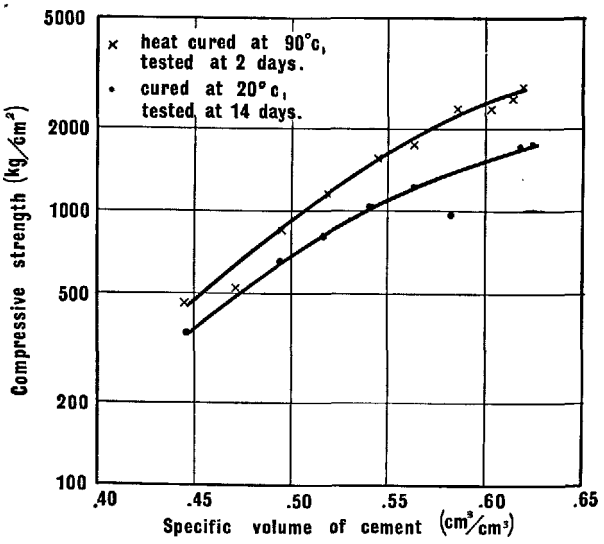

Fig. 15. *Compressive strength (log scale) of Portland cement paste specimens cured at 20°C and 90°C, respectively, versus fractional cement content (by volume). The specimens were small cylinders (11.3 mm high and 11.3 mm in diameter), prepared by pressing. Specific surface area of cement: 5100 cm²/g Blaine. The heat cured specimens were cured under water at 90°C for approximately 24 hours; during the next 24 hours they were air dried at 90°C, cooled down to 20°C, and then tested. The specimens cured at 20°C were cured under water for 7 days, dried in 65% relative humidity for 7 days, and then tested. Data from the Concrete Reseach Laboratory Karlstrup.*

Experimental evidence which is in agreement with this conclusion has been obtained at the Concrete Research Laboratory Karlstrup, where studies have been commenced on the effect of temperature on the strength of portland cement paste and mortars prepared with finely ground quartz sand. Small cylinders (11.3 mm by 11.3 mm) are prepared by mechanical compaction of almost dry mixtures followed by impregnation with water. Compressive strength levels up to five times of those obtained with traditional preparation methods have been obtained. The effect of steam curing (90°C) is an overall increase of approx. 50% in ultimate strength, see Fig. 15. It is believed that this strength gain is due to the existence of a condensed microstructure which glue together the closely packed solid particles (cement and filler) into a strong macrostructure.

It seems promising by means of further experimental and theoretical research to pursue these possibilities for utilizing steam curing, not only to accelerate the hardening of concrete, but also—contrary to practice of today—to increase the quality of the manufactured products considerably.

Concluding Remarks

The importance for the building industry of acceleration of the manufacture of concrete by means of curing at elevated temperatures has been stressed in the introductory remarks. The presented survey of knowledge on the hydration of portland cement paste at high temperature under atmospheric pressure shows that much fundamental knowledge on this subject is still lacking. This means that technical progress in the coming years to a large extent must still rely upon empiric development work, to be advanced by means of modern instrumentation and data processing methods.

The hydration of portland cement has been found strongly influenced by temperature. It has not been possible to establish a synthesis of the interdependence which has proved to be widely varying with different cement-water systems. Moreover, most of the information available concerns rather incommensurable investigations, and in many studies elevated temperatures have been a factor of only minor emphasis.

In the writer's opinion the hydration temperature ought to be considered a paramount parameter in future investigations, and room-temperature should be referred to as a special, modified condition in the broader picture.

It is a challenge to further development, that recent studies have shown a considerable gain of final strength as the result of heating during hydration.

The writer is indebted to his associates Messrs H. H. Bache, L. Hjorth, P. Nepper-Christensen and N. Thaulow for valuable assistance and co-operation by the compilation of literature and the preparation of this paper.

Written Discussion

Roman Malinowski

Synopsis

The influence of various heat curing conditions on temperature increase, irreversible expansion and contraction of cement paste and of strength was studied. Mortar of proportion cement: sand: water = 1: 1: 0.3 was used. Various holding periods of 0, 3 and 6 hours, curing temperatures of 60°, 80° and 98°C and various curing times of 1 1/4, 3 1/4, 5 1/4 and 6 hours were proved. In additional tests the influence of higher temperature of concrete (when placing), heating immediately by higher ambient temperature, the influence of the pressure of closed forms on the strength and the influence of various water-cement ratios (0.25, 0.35, and 0.45) was proved. The relations strength: irreversible expansion: contraction were analysed and general remarks presented.

Introduction

The contraction is a fundamental phenomenon in the hydration process of cement (1) and in the creation of the structure of the cement paste (2), (3).

The chemically bound water (Wn) decreases its volume about 1/4 (2) creating the contraction pores in the gel. The contraction water which fills the pores can be checked by simple volumenometric test (2), (3).

Many authors connect the properties of hardened cement paste and concrete such as strength, drying shrinkage, water permeability and durability, with contraction (2), (3). The contraction is actually a

resultant of simultaneously occurring internal (in the microstructure of cement paste) and smaller external (in the dimensions of tested specimens) volume changes (4), (5).

The contraction is accelerated in higher temperatures, especially in the first heating period and increases insignificantly after a heating period of 10~14 hours (6, 7, 8). The likeness of both processes: as well of contraction as of increasing of strength enables to fix the optimal heat curing procedure for concrete based on contraction tests (9).

In the above mentioned works (6)~(9) the connection between the contraction and the thermal expansion was not analysed. This problem seems to be of great importance because of the volume changes caused by higher temperatures (10), (11), (12).

Experiments

Testing Conditions and Procedure

Expansion, contraction and strength of mortar were tested simultaneously during and after the heat curing process. Changes of temperature were recorded.

The volumenometer for the expansion and contraction test consisted of a glass bottle (200 cc) with a measuring pipe and a rubber stopper (Fig. 1). The temperature of mortar was recorded in cubes 10^3 cm cast in steel forms. For strength tests mortar prisms 2.5 × 2.5 × 16 cm were prepared in steel forms.

The mortar was made of standard portland cement, sand of fineness modulus 1.8 in a proportion 1: 1. The water-cement ratio in the main series was 0.3.

The mortar was mixed in a RILEM laboratory mixer, then placed and compacted on a Vebe vibration table.

The specimens for expansion—contraction tests were cured in a heating vessel in water. The specimens for strength tests were cured in steam in steel forms without covering.

The curing cycle consisted of:

—rising of temperature

—heating at constant temperature

—cooling in water to 20°C and then water curing up to 28 days.

The expansion and contraction were measured by changes of the water level (above the mortar) in the volumenometer.*

The irreversible expansion of the fresh mortar ($\varepsilon_{m.\,ir.}$) is

$$\varepsilon_{m.ir.} = \varepsilon_{\Sigma} - \varepsilon_{w} - \varepsilon_{m.r.} \text{ in cm}^3/100 \text{ g cement}^{**}$$

when ε_{Σ} — is the total expansion of the volumenometer (water + paste)

ε_{w} — the expansion of the water (above the mortar) in the volumenometer

$\varepsilon_{m.r.}$ — the thermal expansion of the mortar measured by deflectometer

$\varepsilon_{m.r.} = \alpha_{m} \cdot \Delta t^{\circ}$

α_{m} = thermal expansion coefficient of fresh mortar (approximately 0.0001 in volume)

The contraction (C) is

$$C = V_0 - V_x \text{ in cm}^3/100 \text{ g cement}^{**}$$

When V_0, V_x is water level before curing and after cooling (at 20°C).

The contraction was tested for each curing cycle immediately after cooling, at the age of 1 and 28 days.

Scheme for the expansion-contraction tests is given in Fig. 1.

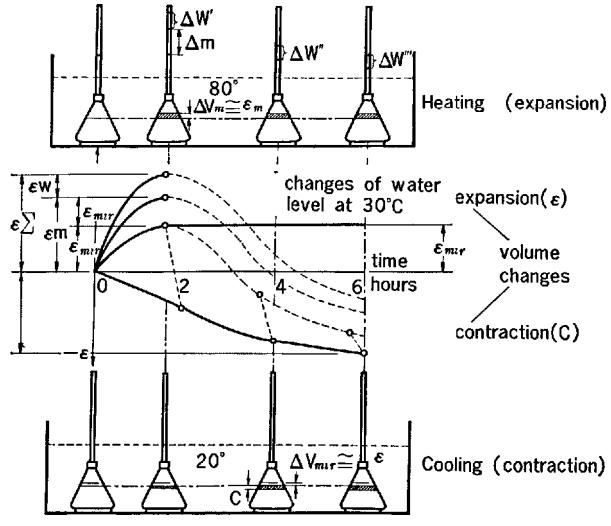

Fig. 1. *Scheme for the expansion—contraction test of heat cured mortar*

Symbols: Δw^{1}, Δw^{11}, Δw^{111}-*expansion of the water in cm³/100 g cem.** ΔV_{m}, $\Delta V_{m.r.}$, $\Delta_{m.ir.}$—*expansion of mortar total, reversible, irreversible in cm³/100 g cement.** ε_{Σ}, ε_{w}, ε_{m}, $\varepsilon_{m.r.}$, $\varepsilon_{m.ir.}$—*expansion in % (volume) total in the volumenometer, of water, of mortar-total, -reversible, -irreversible.*

*or in % (volume) when multiplying by $\frac{1}{1/3.1 + w/c}$ for the main serie × $\frac{1}{0.623}$.

* Additionally the expansion was controlled by deflectometer in the cubes for temperature records.

**For the main series (mortar 1: 1: 0.3) this value is approximately cm³/100 cm³ mortar (% in volume) or cm³/62.3 cm³ cement paste.

The changes in the water level measured during the isothermal and the cooling periods show besides contraction an additional absorbtion of water by mortar (Fig. 1).

Strength was tested for each curing cycle immediately after cooling of the specimens in water and at the age of 28 days. Contraction and strength tests of the same mortar cured after remoulding (in water—20°C) were also made.

Results

Series No. 1—The influence of various holding periods, curing temperatures and curing times on expansion, contraction and strength Table 1.

The results of the expansion-contraction tests and the compressive strength of mortar are presented in Fig. 2.

The temperature in the center of the specimens 10^3 cm becomes after 1 1/2 ~ 2 hours higher than the external heating temperature. For the external temperature 98°C about 15°C after 1 1/2 hour, for 80°C about 12°C after 1 3/4 hour and for 60°C about 10°C after 2 1/4 hour. Similar results were achieved for all holding periods.

The irreversible expansion takes place only under the first 90 minutes of heating. It increases at higher temperatures (80°C and 98°C) and decreases when adapting a holding period. There were not noticed any significant changes in the external dimensions after achieving the maximum expansion.

The contraction is accelerated remarkably at higher curing temperatures. The contraction immediately after curing at 98°C was much higher than at other temperatures. At longer curing time, at later age (1 and 28 days), especially when adapting longer holding periods the differences between the contraction values diminish.

Higher temperature accelerates the strength in-

crease. The strength at the age of 28 days diminishes by rapid heating, especially at higher temperatures (98°C). After adapting a suitable holding period the 28 days strength heat cured mortar was only insignificantly less than of the normally cured.

Estimated optimal conditions (for minimum expansion, high-, early- and 28 days strength) in the tests were:holding period of 3 hours, temperature 80°C and curing time 5 1/4 hours.

Series No. 2—Influence of different initial temperatures of the mortar (20°C and 60°C) and of the environment (20°C and 98°C) on expansion contraction and strength (Table 2).

Mortar 1: 1: 0.35 (cement: sand: water) was used. The specimens were cured without holding period 1 1/4 and 4 1/4 hours at the temperature of 98°C.

There was observed increased expansion by rapid heating and when using hot mortar.

Also a remarkable contraction of rapidly heated specimens and of hot mortar was noted immediately after curing, at the age of 24 hours and at the age of 28 days.

A significant decrease of strength for heated specimens and for warm mortar was noted, especially when the surfaces of specimens were uncovered. In closed forms the losses in strength were less.

Series No.3—The influence of different water cement ratios (0.25, 0.35 and 0.45) on expansion, contraction and strength (Tables 3 and 4).

Mortar 1: 1 (cement: sand) was cured at 80°C during 4 and 6 hours (heating time 2 hours, cooling time 1/2 hour).

Higher expansion was noted at higher water-cement ratios.

The contraction of paste in % (volume) is higher immediately after curing for less water-cement ratios, approximately the same for all water-cement ratios at the age of 24 hours and higher at 28 days for high water-cement ratios.

Similar tendencies are notified for the strength tests.

and increase in strength have great influence on the structure and strength of the cement paste at the cement paste at the later age.

2. The irreversible expansion which lasts 1 ~2 hours is caused mainly by the thermal expansion of the fluid and gas phase of the paste. The thermal expansion coefficient of water is approximately 10 and that of air and steam 100 times higher than of the solids of mortar (sand). The rapidly hardened

paste makes this increased volume of pores stable (Fig. 3), (11), (12).

3. The irreversible expansion is increased by higher temperature and is diminished by longer holding periods (Figs. 2 and 3). During the holding period the binding forces, the contraction and the strength are growing. Other factors and conditions which diminish the expansion under the heat curing process are: less water-cement ratio (stiff consistency) external hydraulic pressure or the form pressure (14), (15).
4. The function strength: contraction valid for normal curing conditions (water—20°C) (3) shows irregularities and discontinuities in heat curing. Different strength: contraction values are noted for various curing conditions and at various age of the tested mortar (Fig. 2c).

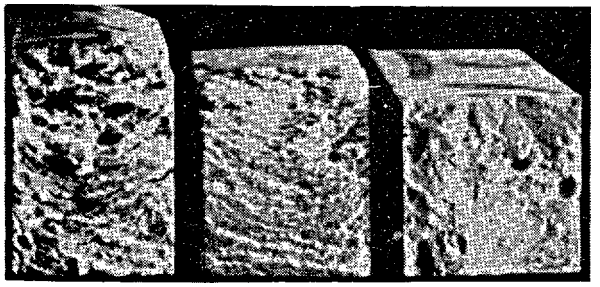

Fig. 3. *Irreversible expansion of cement paste (W/C = 0.3) cured immediately without holding period at 98°C. a—in closed form, b—in open form, c—warm paste placed in form before heating. Section 2.5 × 2.5 cm.*

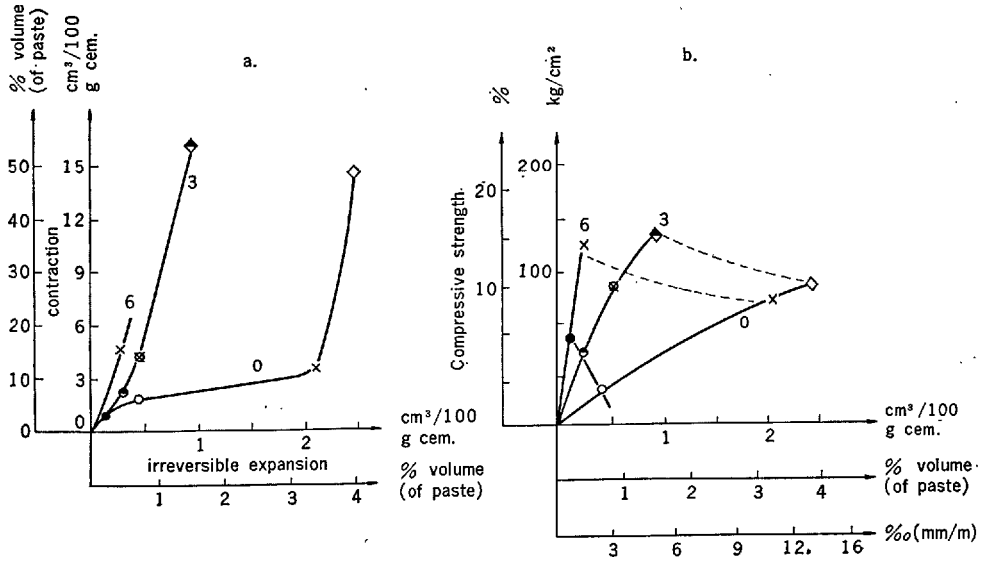

Fig. 5. *The relation contraction: irreversible expansion (a) and the relation strength: irreversible expansion (b) at the time of maximum expansion after approximately 1 1/4 hour heat curing. Various curing temperatures:*

60°C—○ ◓ ● holding period 0, 3, 6, hours
80°C—× × × " " 0, 3, 6, "
98°C—◇ ◈ — " " 0, 3 – "

100% is the contraction and strength of the normally cured mortar at the age of 28 days.

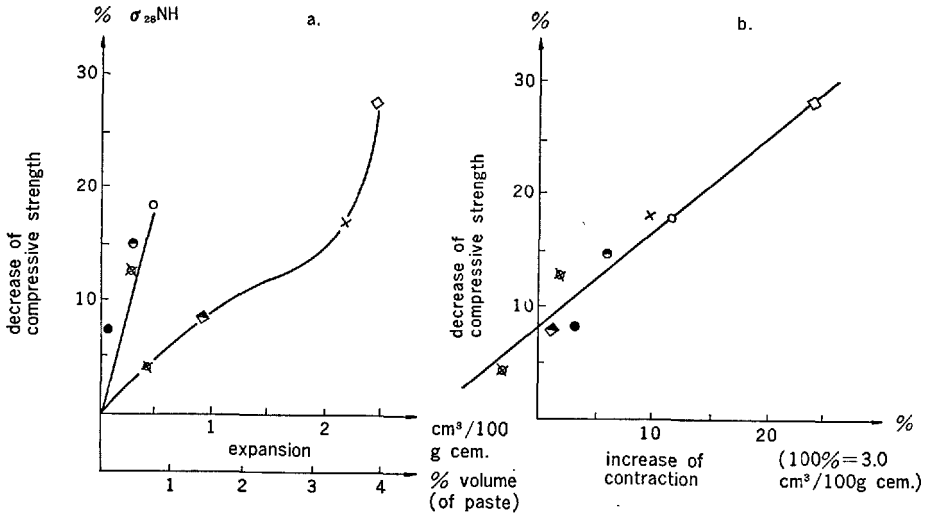

Fig. 6. *The relation decrease of strength: expansion (a) and the relation decrease of strength: contraction (b) for the heat cured mortar at the age of 28 days.*
Various curing temperatures:
60°C—○ ◓ ● holding period 0, 3, 6 hours
80°C—× × × " " 0, 3, 6 "
98°C—◇ ◈ — " " 0, 3 – "
100% is the contraction and strength of the normally cured mortar at the age of 28 days.

The relation early strength: contraction for mortar immediately after curing in 60°C and 80°C without holding period is approximately similar to the normally cured. At 100°C higher contraction occurs and no significant changes in strength are noted (Fig. 2c). For longer holding periods at 80°C the strength is higher for the same contraction (Fig. 2c).

The relations the expansion: contraction and the strength: contraction after 1 1/4 hour heat curing (at the moment when maximum expansion occurred) are not synonymous.

For both the expanded and not expanded mortar approximately the same contraction for a constant temperature was achieved. The contraction was for 100°C much higher than for 80°C while the strength was approximately the same (Figs. 5a and 5b).

At the age of 28 days the relation strength: contraction is mostly influenced by the expansion which takes place during the curing process. The relative decrease in strength (in %) corresponds with the relative increase of the contraction.* Both are caused by expansion (Fig. 6).

5. Presented tests show general tendencies for the relation expansion—contraction—strength of heat cured pastes and mortars. For more complete analyses there should also be used other cement types, mortars of different water-cement ratios. Further tests should include measuring of changes in porosity and pressure in the paste during and after the expansion—contraction test and be completed by microscopical investigations.

This work was carried out at the Construction Division of Chalmers University of Technology by grant of the Swedish Governmental Building Research Committee.

SESSION III-4b HIGH TEMPERATURE CURING OF CONCRETE UNDER ATMOSPHERIC PRESSURE

Principal Paper High-Temperature Curing of Concrete under Atmospheric Pressure

Yu. M. Butt, V. M. Kolbasov and V. V. Timashev*

Synopsis

The curing of concrete with saturated water steam at atmospheric pressure and the temperature range of 60–100°C is now a basic and most wide accelerated method for concrete hardening in commercial scale. This method, which is widely used in many countries to intensify the process of manufacture, optimal use of plant equipment and plant facilities, is based on the acceleration of the hydration reactions of portland cement clinker. This acceleration, in its turn, brings to the accelerated hardening of the hardened cement paste in concrete. Along with, the hydration chemical reactions, taking place during hydrothermal curing of concretes, are followed by a number of physico-chemical and physical reactions, which assert a complicated influence on the properties and the structure of the concrete. The way the sequence and the degree of completeness of the said processes, the way these factors influence both on the formation and the resulting qualities of the concrete are due to a lot of factors-primary due to the chemical and compound compositions of the cementing material in concrete, W/C ratio, the rate of homogenization, the rate of the concrete tamping, the quality of aggregates, the hydrothermal curing of the concrete (including the precuring time, the rate of temperature rise, the isothermal curing and its temperature, the excess pressure, the rate of cooling), as well as the conditions of consequent hardening of concrete articles (temperature, humidity, gaseous composition of the environment etc).

The strengthening of the hardened cement paste during the steam curing of a concrete lies in the process of the structure forming, this process are caused by the hardening of cement. Meanwhile the destructive processes, bringing about decreasing of the concrete strength, are connected with the physical change, alteration of its structure due to the heat— and moisture transfer, and to the expansion of the concrete forming components depend on the influence of temperature. The efficiency of the present ways of accelerated concrete hardening depends on the optimal ratio of forming and destructive processes these ways provide, since it is known (1), that destructive processes do always follow the hardening of the cement paste, though in various degree and in various stages.

Introduction

The curing of concrete with saturated water steam at atmospheric pressure and the temperature range of 60–100°C is now a basic and most wide accelerated method for concrete hardening in commercial scale. This method, which is widely used in many countries to intensify the process of manufacture, optimal use of plant equipment and plant facilities, is based on the acceleration of the hydration reactions of portland cement clinker. This acceleration, in its turn, brings about the accelerated hardening of the hardened cement paste in concrete. Along with, the hydration chemical reactions, taking place during hydrothermal curing of concretes, are followed by a number of physico-chemical and thermo-physical reactions, which assert a complicated influence on the properties and the structure of the concrete. The way the sequence and the degree of completeness of the said processes, the way these factors influence both on the formation

*The Moscow Mendelleyev's Institute of Chemical Technology, Moscow, U.S.S.R.

and the resulting qualities of the concrete are due to a lot of factors primary due to the chemical and compound compositions of the cementing material in concrete, W/C ratio, the rate of homogenization, the rate of the concrete tamping, the quality of aggregates, the hydrothemal curing of the concrete (including the precuring time, the rate of temperature rise, the isothermal curing and its temperature, the excess pressure, the rate of cooling), as well as the conditions of consequent hardening of concrete articles (temperature, humidity, gaseous composition of the environment etc.)

The strenthening of the hardened cement paste during the steam-curing of a concrete lies in the process of the structure forming, this process are caused by the hardening of cement. Meanwhile the destructive processes, bringing about decreasing of the concrete strength are connected with the physical change, alteration of its structure due to the heat—and moisture transfer, and the expansion of the concrete forming components due to the influence of temperature. The efficiency of the present ways of accelerated concrete hardening depends on the optimal ratio of forming and destructive processes these ways provide, since it is known (1), that destructive processes do always follow the hardening of the cement paste, though in various degree and in various stages.

The Mechanism and the Kinetics of Cement Hydration

The Mechanism of Hydration

The mechanism of portland cement hydration at elevated temperatures is just the same as at 20–25°C. It is but the kinetics of the process, the sequence and the completeness of the phase transformations suffer the change. The ions, forming up a crystal dissolving when interacted with water, during the fluctuations periodically take positions, in which the strength of their bond with the lattice is of the least value. The ions of the surface layer of crystals, especially those on the edges and the apexes of the crystals more easily (as to compare with the ions inside the crystals) enter into chemical interaction with water and hydrate, i.e. "catch" attract H^+ or H^- ions. Partially hydrated ion is in a less strong bond with the lattice and almost immediately transfers into solution where its hydration ends. The outcome of a part of ions out of the lattice brings to deformation of a surface layer of crystals. Then a destruction of a surface layer of crystals comes, this lessening the "break-out" energy of the break-off of the rest of crystals from the remnants of the lattice. Since such fluctuation migrations are constant, the process of water "corrosion" of a crystal should run consequently and constantly. The depth of the reaction frontage depends on the crystal density and—in case of an "ideal" crystal might correspond to the depth of the monomolecular layer of water. The ions, hydrated on the surface of a crystal immediately transfer to the solution. During the destruction of a surface layer of a crystal there might happen a break-off of not only separate single crystals, but so well the "blocks" of them—counting hundreds and thousands ions. Hydration of such "blocks" in the solution is similar to that of a "starting" crystal. Most of the workers admit now the possibility of a reaction by means of a joint of anhydride grains with water with consequent precipitation of the particles, transferred into the solution (2~7).

The process of cement grains corrosion by water is of a decreasing rate, this being excited both with the formation on their surface of protecting films consisting from reaction products and with the decrease of dimensions of hydrating particles in the course of time. One of the reason of the quick formation of protecting films on hydrating grains is the exfoliation of some ions "blocks" from a crystal and these "blocks" can not easily move in a liquid phase and group together near the surface of a "matrix" crystal. Their consequent hydration brings to the consolidation of the film. The formation of the film is also contributed by a various speed of the diffusion of the ions in the solution, this variance bringing to the selective expulsion from the reaction zone of some moleculae (e.g. of calcium oxide hydrate) and to the concentration of other moleculae (e.g. of orthosilicic acid) on the surface of a crystal. As a result of such an incongruent dissolution of the compounds in the zone of reaction, low basic crystallic hydrates form at first; further these hydrates can increase their basicity due to subsequent recrystallization in the environment, saturated with the calcium hydroxide.

Development of the surface reaction of the direct joining of water to anhydrides greatly depends on the energetic state of the rigid body surface. It is possible that the lessening of the chemical bond in the lattice of dissolving crystals and the increase of the rate of the electrolytic association on the H^+ and OH^- ions

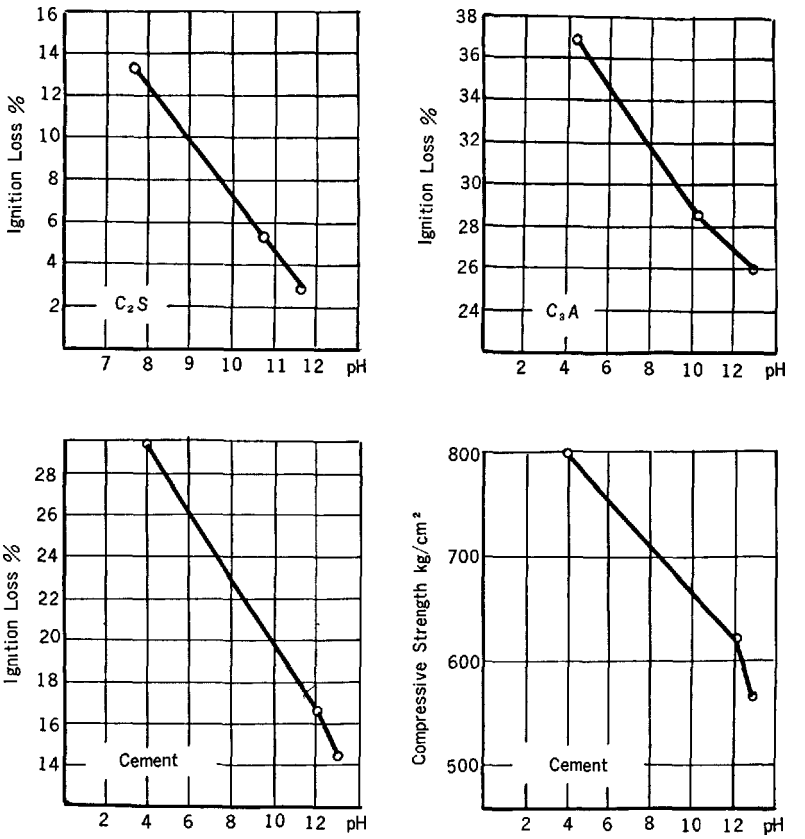

Fig. 1. *Hydration rate and the strength values of compounds and cement depending on pH of water solution*

should bring up to the acceleration of the hydration processes. And indeed, the increase of the H^+ ions concentration in the water solution, obtained by adding of the salts-electrolytes, was accompanied with an increase of hydration rate of separate compounds and of the cement as a whole (Fig. 1). The change of the rate of water moleculae dissociation (decrease of $(H_2O)_n$ groups), taking place in the magnetic field, this being of 2000–2500 ersted intensity, might attain such a rate of hydrogen bonds' break-up, when their break-off is possible. The change of the physical features of water, the breaking up its associates and the appearance of some amount of free H^+ and OH^- ions, positively affected both the rate of the cement hydration and the strength of units made from this cement (Fig. 2). Such a positive influence was also observed when water was influenced by the X-rays and slow neutrons' stream. The water temperature increase at the 0–100°C range evenly decreases down the viscosity of water. The change of the features and the qualities of water as the temperature rises, influences hydration and hardening kinetics of the compounds

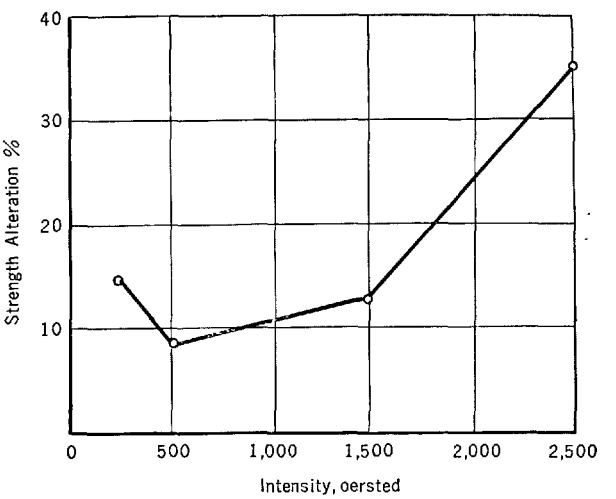

Fig. 2. *The influence of a constant magnetic field intensity on relative values of the strength of a hardened cement paste of 1:0 composition; 7 days age*

mixed with water of different temperature. The highest C_3S hydration rate and strength are found

when this compound was mixed with water of 60°C (Fig. 3). C_3S and C_4AF hydration rate increased 1.5–2.0 times mixed with water of 20 and 40–80°C respectively. The strength of samples made from these compounds practically didn't rise, however. The portland cement with Saturation Factor SF = 0.96; Silicate Modulus = 2.00; Alumina Modulus = 1.3 mixed with water of 60–80°C temperature also has higher hydration rate and strength (Fig. 4).

The Kinetics of Hydration

The kinetics of polycompounded cement grains' hydration, which is of a heterogenodiffuse character, is limited by the inner mass transfer through the shells of hydrated products, appearing around these grins in the course of time. The exact quantity description of the speed of this process is rather difficult, though its general regularities have been described elsewhere (8 ~ 14). Some of the offered equations of the kind $dV/d\tau = f(V)$, (where $dV/d\tau$—hydration speed, V—hydration rate and τ—hydration time), listed in the Table 1. The constant coefficients in these equations do not reveal the process nature and, therefore cannot find out which features of the "matrix" material define the hydration kinetics. The use of these equations brings about various results, and this shows that they could be used just for description of some separated stages but not the process as a whole.

A more satisfactory description of the kinetics process is given by the equations of A. Polak (15, 16),

V. Ratinov and A. Lavut (17) and K. Schiller (18). These authors make following assertions. The dissolution process of the binding material and the growth of crystals of the newly formed compounds run simultaneously and both these processes are connected with each other by the mass balance conditions. The surfaces of the binding material and of its hydrates are not constant ones, though the powders are of a monodisperse nature. The "nuclei" of hydrates appear just during the beginning of the process (during the induction period) and the time counting starts from the moment the nuclei formation ends. During the initial period of hydration the process speeds up; in the range of $V = 0.4 - 0.6$ it attains its maximum value and then decreases. The absolute values of the reaction rate depend on the concentration and the oversaturation on the depth of diffusion layers of the dissolving grains, on the constants both of the dissolution rate and of the crystal growth and on many other factors.

The rise of the process temperature rises up the rate of the process, though doesn't change the basic phenomenae of its run (Fig. 5). As well as at the normal temperature, there are two distinct periods of the process: a quick and a slow one. With the increase of the temperature, the duration of all the hydration periods decreases, while the hydration rate of the binding material increases—at the main stage of the process (Table 2). The activation energy of a given compound is similar at 40–80°C temperature range (Fig. 6). C_3A and C_4AF strongly respond the temperature rise and at 50°C they are almost completely hydrated to 1–3 days age. At these conditions both C_2S and C_3S hydration rates increase.

The coefficient of the reaction temperature (γ) decreases with the temperature rise: $\lg \gamma^{\tau} \simeq 10E/2.3RT^3$ showing the lowering of the influence of the temperature on the hydration rate of the binding material at the increasing of the time of hydrothermal treatment. Decrease of the γ-value with the temperature increase is specific to heterogeneous processes. The retardation of the binding material hardening and hydration during its hydrothermal curing at the second period of the process can be explained by the

formation of a compact protecting film consisting from a well crystallized products of hydration. This film serves as a protective shell of unhydrated grains of the cement and prevents the access of water molecules to such grains. So, the film decreases the rate of the inner mass transfer.

The Phase Composition of the Newly Formed Compounds, the Structure of the Hardened Cement Paste and of the Concrete

Phase Composition of the Newly Formed Compounds

It is widely known, that hydrothermal curing of cements up to 100–200°C shows no any serious influence on the phase composition of the newly formed compounds. According to some authors (19~22), the hydration products, forming at the steam curing, do not differ from the hydrate compounds appearing when hardening of cements at normal temperature conditions. That is why different features of the cement paste hardened at normal and elevated temperature can not be explained just only by the change of the composition of the newly formed compounds.

The present data concerning the change of calcium silicates' basicity during the hydrothermal curing of the hardened cement paste (23~24, 37) as well as concerning the stability of the high sulphate form of calcium sulphoaluminate hydrate and its role in the hardening process (35~40) are quite contradictory and unsufficient. Therefore on the base of these data one cannot judge the influence of this change on the strength and durability of the hardened cement paste.

In any case there is but a few data to consider the change of the silicate hydrates' composition to be the main reason of the hardened cement paste qualities change. We can count one of the recent work in this field—the work of J. Gebauer and I. Odler (41). These authors point out the appearance of a noticeable amount of $C_2SH(A)$ in the cement hydration products (6 hours, 80°C), this hydrate being identified on the thermograms by endothermal effect at 450°C. The presence of this hydrate instead of silicate hydrates having fibrous pattern (C_2SH_2, CSH(B)) results to a very serious disattaintment of strength of the hardened systems (42). At the same time there are some data (38) proving the possibility to intensify the process of the cement paste hydration during the steam curing

through a desired formation of calcium sulphoaluminate hydrates.

It is possible, however, just when special cements are used, these containing admixtures of alumina compound. For it is found, that a considerable fraction of alumina in the portland cement clinker cannot be used to form calcium sulphoaluminate hydrates in the course of the first stage of hardening, when the appearance of this compound aids the strengthening of the hardened cement paste. Beside this, it is known that the frame, consisting of calcium sulphoaluminate hydrates, is the base of an early strength gain of the hardened cement paste even at the normal temperature of hardening. That is why this factor cannot be considered as responsible for the quality changes of the hardened cement paste, these changes resulted hydrothermal treatment. Up to the present, there is not yet any generally accepted and well grounded opinion concerning the real strength making factors of the hardened cement paste forming at 30–100°C. Silicate hydrates C_2SH_2, CSH(B), aluminate hydrates C_3AH_6, C_4AH_{11-19} and $Ca(OH)_2$ with $CaCO_3$ are considered to be the main products of portland cements hydration in this temperature range. Following compounds have been revealed in the systems: afwillite, xonotlite, calcium aluminate hydrates and various complex salts based on aluminum oxide hydrate. It is necessary to stress that the formation of hydrates of any composition, in the strict meaning of it, does depend on the temperature and humid conditions of the environment of the hydration process. First of all, the temperature of the environment determines the solubility of the binding material in water. Along with it determines the concentration and the oversaturation rate of the liquid phase, the correlation of the oxides dissolved in it (CaO, SiO_2, Al_2O_3 etc.), the viscosity of water, the rate of association of water moleculae, the quantity and the pattern of the newly formed crystallization nuclei. And, at last, the temperature of the environment influences the character of the processes in the solid phase, these processes taking part on the surface of the hydrated binding material. However, the phase composition changes of the hydrates which form at 30–100°C temperature range due to the reasons listed, bring to both the minor calcium silicate hydrates basisity and to some changes of the quantitative correlation of the forming phases, this leading to neither any serious change of the structure nor to the structure and the features of the hardening cement paste.

It is rather possible to make some changes of the phase composition of the newly formed compounds by bringing into the mixing water electrolytes preventing the polymerisation of the silicic acid. Indeed, in the presence of Na^+, K^+ and Li^+, in the "$C_3S + H_2O$" system at 100°C highly basic calcium silicate hydrates—$C_2SH(B)$ and $C_2SH(A)$ more readily formed than low basic ones. Alkali cations by themselves can serve as crystallization "nuclei". N. V. Belov (44) has shown that there are active hydrate "areas" of a certain form in the liquid phase and these "areas" might serve as crystallization nuclei. It is necessary to say that cations Ca^{2+}, Mg^{2+}, Ma^+, K^+, Li^+ as well as the water moleculae associates play an important role in forming these areas. Such active areas often define the type and the structure of the resulting compounds in the hardening material, since for every given concentration of these ions in the solution, there are crystallization areas of definite geometric and crystallic forms.

Crystalline Structure

The first stage of forming of a crystalline structure of a hardened cement paste new compounds presents the appearing of various areas ("nuclei") of crystallization. These are as follows: 1—hydration areas; 2—crystallization nuclei of a new phase—due to the accumulation of the pertinent ions, and—3—crystallization areas on different colloid films used for being "dusted" with a compound under investigation. The nuclei appeared tend to grow and to coalesce.

The process of a consequent coalescence of crystals is yet not a clear one. Even concerning the base limiting factor of this process the oversaturation rate of the water media—there are quite contradictory opinions. Some workers suppose that, in accordance with thermodynamic data, the coalescence should take place even at the lowest oversaturation rates of the solution (16). However, some others workers (45, 46) think that the coalescence of crystals can take place just only at the highest oversaturated rates of the solutions, at a great amount of crystals in the newly formed compounds. In these conditions the probability of the appearing of contacts when growing crystals draw together, increases and is the more, the higher is the oversaturation rate and the longer its "lifetime". The coalescence takes more vigorous character after the inductive period is over (during this period the solution oversaturation reaches its highest peak). Afterwards, as for as the surface of new hydrate phase increases and the oversaturation decays, hydration process takes even higher rate though it is already followed not by the crystals coalescence but by their dimensional increase. In other words, the crystalline framework appeared during the first stage of the process, overgrows. If to break down the crystallic con-

struction, the crystals of which have exceeded its critical dimensions, then the crystals developing during the further hydration, would not coalesce any more, forming but coagulation compound of relatively small strength.

So the crystals of gypsum having two H_2O moleculae and attained approximately one millimeter size practically did not form coalescent "buildups". So well the formation of contacts bringing to such "buildups" to form, slows down in the case if both the form and dimensions of the crystals of a hydrate have attained the equilibrium of a given conditions. And indeed, various types of crystals of calcium silicate hydrates, which grew up at hydrothermal synthesis with $P = 2000$ atm. both at normal and steam curing, made no "buildups" during a prolonged storing in different solutions. This was true for the two groups of samples—for a non loaded group and for a constantly compressed one—with an approximate charge of 100 g/mm².

Besides, regular crystalline "buildups" can form only at some very definite conditions necessary for isomorphism to display. Theoretically, not all the crystalline hydrates of a hydrated cement paste can make regular "buildups" with each other since a lot of them belong to different structural pattern. The highest ability in this respect belongs to crystalline hydrates of the same pattern, though practically it might occur that, in forced conditions, crystals of different pattern make contacts.

The picture of a buildup, forming between the crystalline hydrates of a similar pattern might be as follows: In a narrow gap between some crystals, neared together due to some reasons (e.g. crystalline pressure, convective shifts etc.) the concentration of an entrained solution arises, this bringing to oversaturation, and the crystallization occurs. Active parts of the surface of coalescing grains play the role of the new crystals growth. The direction of the growth of crystals is parallel to the surface of an opposite grain. The crystals reach this surface and make a "buildup" with the body of a matrix crystal. The heat released during this process is being spent to make up for the decrease of the solution concentration, this being done by bringing of some ions from the surface layers of coalescing crystals into a dissolved state. Resulting such a transfer of the substance, takes place the filling up the gap between the crystals closing together. The crystalline lattice of an appearing "seam" is nearly similar to the lattices of the both coalescing crystals, though the zone of contact might contain a number of dislocations lessening the strength of the "seam".

When crystals of the different structural pattern are coalescing, the structure of the "seam" serves as a transfer zone between one lattice and another one—and is of quite a larger dimension as to compare with the contact zone between the isostructural crystals.

The contacts of coalescing were studied in preparations consisting from calcium sulphoaluminate and silicate hydrates. These hydrates, obtained through the hydrothermal recrystallization, were put in ampules made from molybdenum glass with an oil lock. In order to bring the crystals up to the distance of hk minim at which the coalescing takes place, the crystals were being compressed with the force of 100 g/mm². The liquid phases of real hardening cements were used as a media. The temperature of the test was 20–80°C.

Fig. 7 shows the "buildup" of a hexagonal ($a = 11.43$ Å) and a prismatic ($a_0 = 10.98$ Å) crystals of calcium aluminate hydrate. The closeness of the cells parameters of the two coalescent crystals, found by the microdiffractography method, shows that in this case the coalescing can run along the flat nets similar by their form and almost equal by their dimensions (at parameters difference of the coalescing crystals lattices up to $\Delta = 15 - 16$ per cent). In this

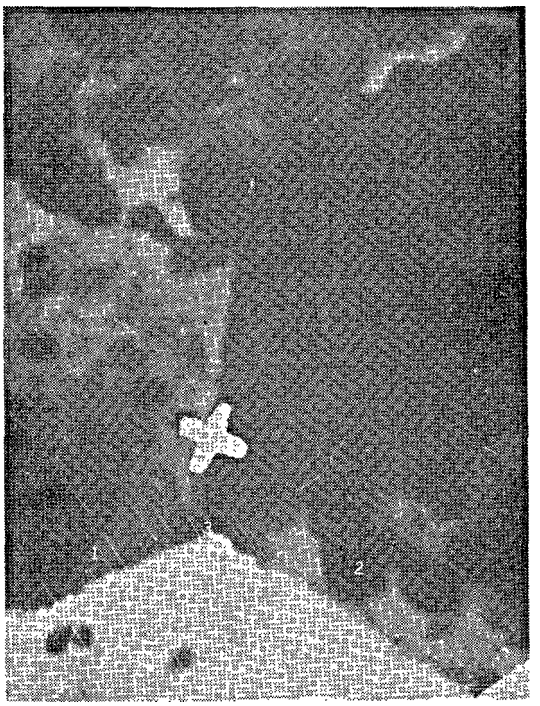

Fig. 7. *Electron microscopic picture of two coalescent crystals of calcium aluminates hydrates* (×9,000); *x—the point, where microdiffractogram was taken.*

case $\Delta = 4.5$ per cent. The analysis of the microdiffractogram obtained in the point located in the zone of the coalescence of crystals (Fig. 8) shows that $a_0 = 11.11$ Å. The proximity of a_0 values for all the three zones shows that the process of coalescence runs without any noticeable change of the parameters of coalescing crystals lattices in the plane of their conjugation. In other words, an isomorphous mixing takes place, this resulting from the crystallographic similarity, from the closeness of the composition and from the ability of aluminate hydrates to form isostructural phases of changeable composition. Table 3 shows possible planes and angles of coalescence between the crystals. The angle of the turn of plane nets of the coalescing crystals in the plane of conjugation is 22°.

Calcium silicate hydrates formed some accumulation of fine crystals of the same habitus (needles, fibres, prisms). It was not possible to obtain any

valuable microdiffaction from the contact zones in such conglomerations. The possibility of coalescence of needle-like, fibrous and prismatic calcium silicate hydrates of the same structural pattern is evident. The composition of the phase on Fig. 9a, is C_6S_3H–$C_2SH(C)$. Probably the coalescence between calcium silicate hydrates of differen habitus is also possible (Fig. 9b).

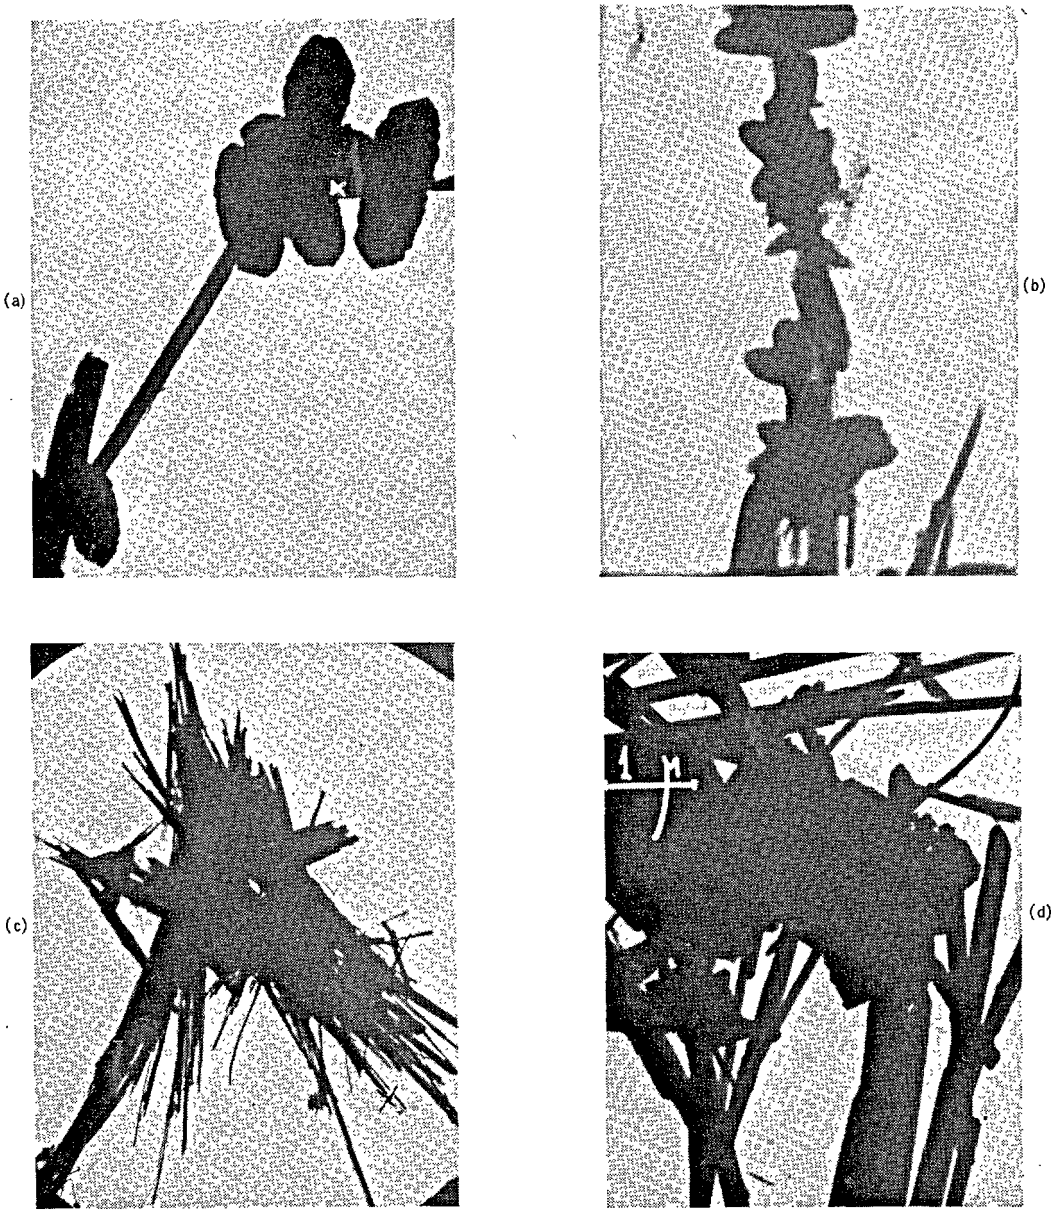

Fig. 9. *Electron microscopic pictures of crystals of calcium silicate hydrates*
a, b) C_6S_3H–$C_2SH(C)$ (×6,000); c) hillebrandite; d) xonotlite (×7,5000)

Distinct coalescences between calcium silicate hydrates and calcium aluminate hydrates were not found. The coalescence process between calcium silicate hydrates and portlandite runs easily.

The investigation of the influence of crystalline hydrates of various kind on the kinetic of portland cement hardening was conducted in the following manner. Plate-like crystals of $Ca(OH)_2$, of tobermorite and of calcium aluminate hydrate C_4AH_{12}, acicular crystals of $CaSO_4 2(H_2O)$ and of calcium aluminate sulphate, and cubic crystals of C_3AH_6, synthesized by a well known methods, were added to the binding material in dry form, 15 per cent by weight. In the most of the cases, the introduction of the said crystalline hydrates was not accompanied with an increase of an initial strength of the hardening samples. Therefore, the admixture to the cement of various preliminary synthesized crystalline hydrates, which form during the hardening of the binding material, not always brings to the formation of a rigid crystalline frame in the hardened cement paste. The efficiency of the influence of various crystalline hydrates as the "centres" of crystallization depends on the type of a given crystalline hydrate, on the size of its crystals, on the amount of the admixture and on the way this admixtures is being introduced.

Calcium silicate hydrate having $C/S \simeq 1$ and with the particle size nearly 10^{-7} cm, and the same hydrate but having $C/S \simeq 2$ with the particle size $10^{-6} - 10^{-5}$ cm, brought to a considerable acceleration of the portland cement hardening at 100°C steam curing (Fig. 14). Calcium silicate hydrates precipitation was used just immediatelly after it had been prepared—without drying—and was added into a ready cement paste, this mix was additionally mixed. Positive influence of calcium silicate hydrate of both dispersity values results from a minor size of the crystals and from their ability to grow.

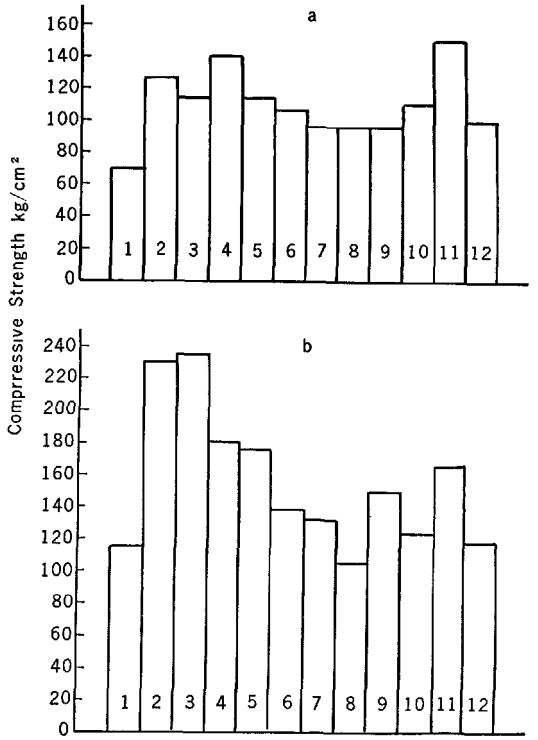

Fig. 14.a, b. *The effect of various crystalline and non-crystalline compounds on the strength of a cement mortar (1: 3, W/C ratio = 0.3) immediatelly after the steam-curing (a) and at the age of 28 days after the steam-curing (b). (The steam-curing pattern: 1.5–8–1.5; 90°C; sealed moulds).*

Physical Structure and the Factors of Destruction

Hydrothermal treatment of a concrete at atmospheric pressure shows a considerable influence on its physical structure. It brings about the change of a general porosity, pore structure of the hardened cement paste, and to the change of both the dispersity and the rate of crystallizing of hydrate phases.

The components of the concrete: solid (cement, aggregate), liquid (mixing water) and a gaseous one (entrained air) tend to expand in various degree under the influence of heat. The distortion of the primary structure of a freshly—laid concrete first of all is due to a volume expansion both of free water and entrained air (47 ~ 51). This expansion is many times larger than that of solid components of the concrete. By S. A. Mironov and L. A. Malinina (52), common concrete contains 2–4 per cent of air entrained during the making of the concrete mix, its placing and tamping. The water content of a freshly made concrete mix is usually many times higher. Taking into consideration that the temperature expansion of water and air (53) is dozens and hundreds times higher than that of solid components of a concrete, the cardinal role of these phases in both reversible and non-reversible deformations of the hardening cement paste at the steam curing is quite clear. Non-reversible volume changes of

concrete resulting its expansion after the steam curing proves a destructive process in the structure of the hardened cement paste (54, 55). The amount of residual expansion of a steam—cured concrete depends not only on the rate of expansion of liquid, solid and gaseous phases of concrete. It also depends on the intensity of the heat—and mass exchange processes. In capillary—porous colloid bodies, to which concrete also belongs, the phenomenon of the moisture transfer, resulted from the gradients of temperature and humidity, follows the main law of the transfer of a substance (56). Migration of water is a typical factor during the process of the concrete structure formation during its steam curing. Migration of water and the changing capillary pressure in the hardening concrete turn to be, at some definite conditions, the main reason of the so called "directed" porosity formation of the hardened cement paste. In the upper layers of concrete units, where the highest change of temperature and of conditions in moisture take place, these processes have very intensive character (47).

The microstructure of the hardening cement paste is different, this resulted from the change of dispersity of the newly formed hydrate compounds—depending on the hardening temperature. This difference is described elsewhere (1, 2, 3, 57 ~ 60). At the steam curing the number of geleous components in the products of hydration decreases, while the amount of crystalline phase and the size of its crystals regularly increases. The compactness of the hydration products forming at the steam curing is 15–20 per cent higher as to compare with normal hardening (1). With the increase of both the duration and the temperature of isothermal heating of concrete units at the steam curing, appearing of newly formed compounds having even more coarse disperse pattern is noticed (58, 59, 61). In this connection it is necessary to remind that physical and physicochemical patterns of the structures, formed during the hardening of a binding material in many respects do depend on the dispersity of the particles of the newly formed compounds and on their concentration in a unit of volume (43). The higher is the dispersity and the concentration of hydrate particles in a unit of volume, the more contacts appear between them—and the higher their interconnection resulted from the actions both of van der Waals and friction forces. Therefore the higher is the strength of the system as a whole. One of the reasons of unsufficient strength during the steam curing as to compare with those of common hardening is the enlargement of hydrate particles (along with simultaneous decrease of contact points)—due to the dissolution of the said particles from their being the most unstable elements of the structure. Due to the reasons listed, the lessening of adhesion between the newly formed crystalline formations and between the said formations and other structural components of the hardening cement paste, the appearance of inner stretching forces resulted from the pressure of the crystals growing at the a steam treatment might be accompanied by the change of the structure and by its weakening. So, the structure of the hardened cement paste is constantly changing during the steam curing of concrete. And these changes have both positive effect (the strengthening of the hardened paste) and a negative one (formation of defects in the paste and decrease of its strength).

Formation of defected structure at the hydrothermal treatment of concretes lies in the influence of some physico-chemical factors, these being as follows disintegration and the transformation of the metastable phases formed earlier, re-crystallization of hydrated products and packing and re-packung of the particles of the hardening system—this accounted for more quiet crystals growth condition at the decrease of the liquid phase oversaturation, contraction shrinkage of the hardening system, osmosis etc.

The most of these processes and their role in the hardened cement paste destruction have not yet been studied enough, however, due to the complexity and versatility of the processes, and their manysided influence on the qualities of cements and concretes.

One of the displays of the physical constitution of a hardened cement paste, this constitution depending on the conditions of hydration, is the formation of the pore structure. During the recent years there appeared a considerable number of scientific works (22, 62–76), devoted to the study of the influence of hydrothermal treatment at atmospheric pressure on the pore structure of the cement paste.

A sound means to appraise the physical structure of a material is its both the general and differential porosity. And indeed, the above mentioned destructive process of the cement paste, recrystallization and the size-enlargement of hydrated phases, contraction shrinkage of the system, specific to the hardened cement paste, distinctly reveal in the form of the changes of both the general porosity; and the faults of the structure of the paste. It also takes the form of re-distribution of the general pore structure and pore sizes. So, by measuring these parameters, one can trace the character and the rate of destruction of the cement paste in a hardening concrete this revealing in the change of its pore structure. It is experimentally proved (68), that the physical features, and durability of concretes are directly related to the general pore volume and to the porosity pattern of hardened ce-

ment paste. Table 4 shows the composition of the cements investigated.

Table 5 shows the connection between the general amount of pore volume and the compressive strength of a steam—cured cement paste made on cements of various chemical and compound compositions. As seen from Table 5, the general amount of pore volume is one of the most important factors influencing the strength of the hardened cement paste and the rate of the change of the strength in the course of time.

It is also known that the pore volume of the hardened cement paste in a steam—cured concrete as a rule is higher than that in a commonly hardened concrete. The relation between these two porosities depend on the compound composition of the cement, the pattern of hydrothermal treatment, the character subsequent hardening and W/C, Table 6 contain the data concerning the influence of a steam—curing and of subsequent hardening on the general porosity of the hardened cement paste made from clinkering compounds and cements.

Hydrothermal treatment shows also great influence on pore size distribution and it is of great importance for the durability, strength and for the thermophysical features of concrete. On the data available one cannot draw a conclusion concerning the pore structure change of the hardened cement paste due to the hydrothermal treatment, since these date are scare and contractionary. Some workers (62, 66) assert, that the hardening of cement paste at elevated temperature (80–100°C) brings to the pore volume increase to increase of the macro-pore fraction ($r > 1 \cdot 10^{-4}$ cm) and, quite naturally, to decrease of micro-pore fraction ($r < 5 \cdot 10^{-5}$ cm). Other works (22, 67) contain the data showing the increase of micropore fraction—along with an increase of the general volume of porosity.

The investigations of the authors of work show that the steam-curing tends to a preferable increase of the porosity of the hardened cement paste along with a decrease of micropore phase (r = less than 100 Å). However, the change of the hardened cement paste pore structure at the hydrothermal treatment depends on some other factors—first of all the composition and the properties of cements.

The Influence of the Binding Material Composition on the Structure and the Properties of Hardened Paste and of Concrete

One of the main ways to increase the efficiency of the concrete steam-curing is the use of cements having

optimum properties, which provide formation of a necessary composition and the structure of the cement paste this giving both necessary qualities and the durability of concrete. In this respect of the main importance are the compound composition and crystallic pattern of the clinker, the composition and the fineness of a given cement.

Compound Composition

It has been found (68), that the chemical and compound compositions of binding material shows a considerable effect on the strengthening of a hardening system—since the very beginning of the process. Figs. 10 and 11 show the kinetics of the strength gain of various hardening cement pastes of normal consistency during the first hours of hardening. The samples are prepared from separate compounds and from polycompounded cements of various chemical and compound composition (Table 4). These data show that both structural and mechanical properties of the cement paste of a concrete do depend during an early term of hardening, on the chemical and compound compositions of cement. It is necessary to say that there are great variations in the kinetics of developing systems' hardening. And in its turn all this shows a great influence of compound composition both on developing structures strength and on the rate of a hardening cement paste destruction during the temperature rise when hardening. All the aforesaid shows the necessity to consider, (when choosing the optimal duration of a pre-curing before steam-treatment) the structural and rheological properties of cement pastes in concretes, these properties being defined by the chemical and compound compositions of the binding material.

As far as steam-curing is considered, cements of high hydraulicity with an increased C_3S content are referred to as having optimum compound composition.

The reason of this point of view is, firstly, the higher physical test data of steam-cured concretes made on such cements and, secondary, the optimum structural and rheological properties of alite cements as to liability of being heated.

Figs. 10 and 11 show that tricalcium silicate and cement with higher alite content have retarded gain of plastic strength at the first hours of hardening and it does conform with an induction period at the kinetics of tricalcium silicate hydration process (69).

Keeping the paste made from tricalcium silicate and cements with higher content of said silicate in the plastic, non-consolidated, "form-filling" state for a short period of time before steam-curing, can serve as one of the reasons to weaken the destruction of the

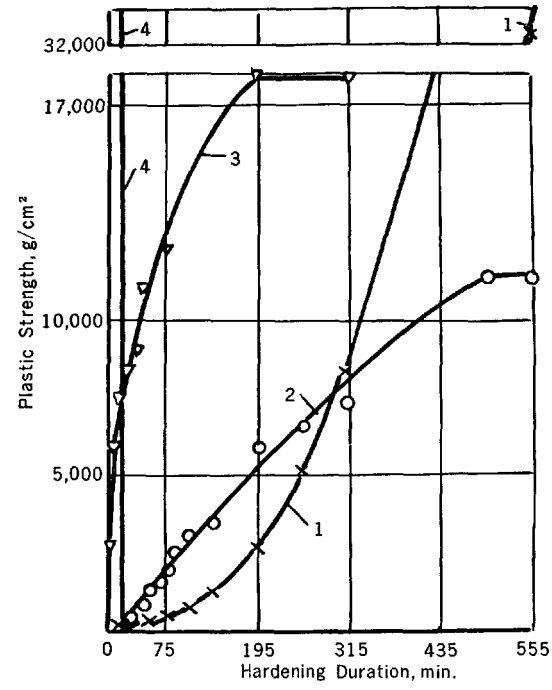

Fig. 10. *The kinetics of the plastic strength gain of a normal consistency paste made from clinker compounds at normal hardening*

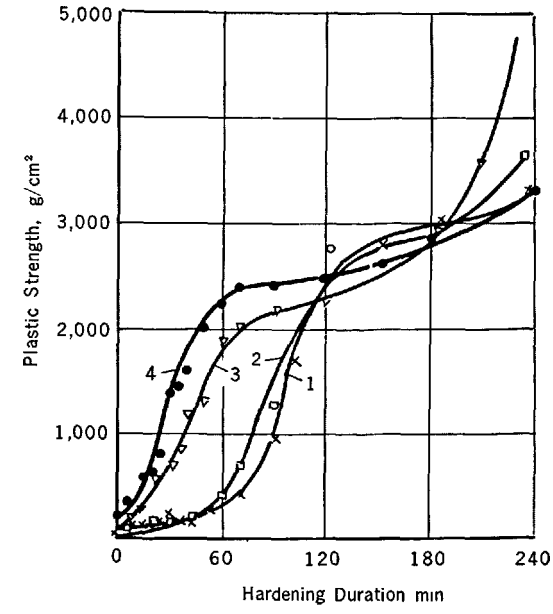

Fig. 11. *The kinetics of the plastic strength gain of a normal consistency paste made from cements of various compound composition; temperature—20°C*

hardening system when heated during the steam-curing. Despite this, the increase of pre-curing of the paste made from tricalcium silicate up to 12–30 hours (69) increases the strength of hardened samples. The reasons of these are as follows. During the pre-treatment at normal temperature, the products of hydration of higher dispersity have more points of coalescence. This, in its turn brings to the formation of an optimum structure, providing higher strength after the steam-curing and during the subsequent normal hardening.

Table 7 shows the data of strength and hydration rate tests of samples made from separate compounds and from cements of various compound composition. Hydration rate tests were conducted on an "ignition loss" basis. The samples hardened in normal conditions as to the temperature and humidity. The heating pattern was 1.5 + 8 + 1.5 hours; isothermal temperature of 90°C. Pre-treatment of moulded specimens before steam-curing was 10–12 hours. Tests were conducted on specimens 1.41 × 1.41 × 1.41 cm made from normal consistency paste. The specimens of normal hardening were kept in air-humid environment at room temperature. Steam-curing was performed in forms covered with metallic plates. Cements No 3,5 and 7 were burned on a pilot rotary kiln from the same raw materials and the same conditions, while cement No. 8 was a commercial one. Cements and separate compounds were ground in laboratory mills up to 3,000 cm²/g (by air-permeability method). When grinding, gypsum was added to cements and to alumina-bearing compounds. Tables 8 and 9 contain the porosity data of the same samples, the data being obtained by means of a hydrargyrum porosimetry. This method was used to measure the pore volume in the range of 20 microns—40 Å. For convenience to discuss the results, the pores are divided into four subdivisions as to their sizes. Pores having $r_1 > 10^4$ Å —"coarse" pores; those having 10^4 Å $> r_2 > 10^3$ Å—capillary macropores; those having $r = 10^3$ Å $> r_3 > 10^2$ Å—"intermediate" pores and those having r 10^2 Å $> r_4 > 40$ Å—micropores.

Table 7. *Compressive strength (kg/cm²), and hydration rate (ignition loss, %) of samples made from separate compounds and from cements of normal hardening and steam-cured at 1.5 + 8 + 1.5 hours, at 90°C*

Cement 8	—	—	900	10.3	540	9.9	630	11.4

These data show that the strength value of tricalcium silicate is next to that of tricalcium aluminoferrite. However, to distinct from C_3AF, the steam-curing of C_3S brings to unsufficient use of its binding properties, and the steam-cured samples of C_3S are of 2–2.5 times lesser strength as to compare with 28 days' normal hardening.

Subsequent hardening of C_3S steam cured samples at normal temperature and humid conditions brings about a noticeable strength gain; the kinetics of this process depends on the pattern of hydrothermal

curing. The softer are the conditions of hydrothermal during, the more efficient the subsequent hardening is, and the more complete is the use of the binding features of this compound. However it is necessary to say, that the softer is the hydrothermal curing, the lower is the strength gain of C_3S samples just immediatelly after the steam-curing (see Tables 7 and 10). The strength data of C_3S samples attained at different conditions hardening, well correlate with their cumulative porosity and the pore size distribution (by sizes). So, the less strength corresponds to increased values of cumulative porosity and to relative more coarse pore structure. All this well agrees with the present views. Concerning the coarse crystallization of new hydrated compounds during the steam-curing of cements. It is quite naturally that C_3S samples having nearly the same porosity have similar cumulative porosity and the same distribution of pore volumes (by their radii).

As to compare with β-dicalcium silicate, the tricalcium silicate just after the steam-curing gives the structure of lower porosity and higher strength. This is probably the answer of why so many workers preferably recommend alite cements for steam-curing. It is necessary to say however, that the efficiency of hydrothermal curing, β–C_2S—as to compare with common hardening,—has quite distinct advantages over tricalcium silicate (3), since it is belite cements, which more completely reveal their binding qualities when steam-cured, especially when to consider their kinetics of their subsequent hardening. As seen from Tables 7 and 10, steam-cured samples of dicalcium silicate show maximum relative strength gain during the subsequent hardening; the strengthening of the "β–C_2S + water" system corresponds to the sharp

Table 10. *Strength of specimens made from separate compounds, hardened at various conditions (by S. A. Mironov and L. A. Malinina (52))*

drop of the cumulative porosity (this drop being one and half times during 28 days) and redistribution of the pore volume resulting to the decrease of their sizes (Table 8). Similar regularity is observed in case of polycompounded cements (Table 7 and 9). Though this regularity is of less distinct character through mutual influence of all hydrating compounds. Intensive hardening after steam-curing, typical for concretes made with alite cements in many cases brings these concretes to attain (at 28 days) the strength values of concretes of similar composition but hardened in common condition. This is rarely observed in case of concretes on alite cements. Nevertheless one can agree with the opinion (70–72), that higher β–C_2S content in cements destined for steam-curing, is undesirable since these cements give just after the steam-curing, low strength values—especially at shortened periods of hydrothermal treatment. The strength increase of such concretes is possible through a more prolonged pre-curing (at shortened steam-curing) and through a prolonged isothermal heating. In the last case the strength of belite cements amounts

to 70 per cent of a standard compressive strength (73) or lower—depending on the content of other compounds—first of all C_3A (Table 7). Higher C_3A content sharply lowers the strength of steamed alite cements (No. 5 and 8) and belite cements (No. 6 and7) and practically doesn't influence their strength when hardening at normal temperature and humid conditions. Immediately after the steam-curing, the strength of low-alumina cements No. 5 and 6 amounted 73–75 and of high-alumina cements—50–60 per cent of the strength of 28 days normally hardened samples. After 28 days of steam-curing, the relative strength of these cements amounted respectively 90–98 and 70–79 percent of the said strength. As a rule, the steam-cured concretes with higher C_3A content have increased porosity. The above said is in accordance with the recommendations (70, 71, 73) concerning the perferable use of alite cements with lower content of tricalcium aluminate (up to 4–5 per cent) for hydrothermal treatment, the lowest content of C_3S in these cements being 45 $\sim$ 60 per cent. Hydrothermal treatment of low alumina cements along with sufficient isothermal curing provides for high strength with a well pronounced trend to a subsequent strength gain at normal temperature and humid conditions. The use of these cements is obligatory when it is necessary to fabricate concrete articles of higher durability and of higher resistance to the influence of the environment.

However, at accelerated steam-curing of concretes one would recommend the use of cements with higher content of tricalcium aluminate along with moderate or higher content of alite (1, 30, 37, 70, 72). In this case tricalcium aluminate can be referred to as a compound, increasing the speed and the rate of C_3S hydration (57). From another point of view, C_3A can also be referred to as a phase taking an independent part in making high strength of the hardening cement paste—at the condition of an optimum increased as to compare with usual content of sulphuric anhydrid in the cement of a sufficient fineness (72).

There are some works (74, 75) in which the allowed tricalcium aluminate content in cements able to efficient hardening when steam-cured, is considered in connection with alite content. The authors (74) think, that for the steam curing at 100°C during 3 hours, cements having more than 55 per cent of C_3S and up to 4–5 per cent of C_3A are suitable. If the alite content is near 50 per cent, then the C_3S content might be increased up to 11 per cent. In other words some increase of C_3A in clinker to some extend allows to decrease the alite content in a concrete subjected to a short-termed steam-curing (75).

The most harmful changes give the steam-curing of samples made from neat tricalcium aluminate. In this case the steam-curing brings to sharp decrease of strength of the compound-this being of a lower strength even without steam-curing. It cannot be explained by a lesser hydration rate, basing on the amount of combined water in samples (Table 7), since the cubic calcium aluminate hydrate makes loose structures and can not form dense protective films around the remnants of unhydrated grains, these films preventing the further hydration of the said grains. The increased amount of combined water in C_3A samples of natural hardening is probably the result of the presence in them of some hexagonal crystalline hydrates containing some higher amount of water. This supposition can be proved by a higher content of micropores in normally hardened C_3A samples—as to compare with steam-cured samples. Low strength of C_3A samples corresponds to their higher (as to compare with other compounds) cumulative porosity and to their prevailing content of coarse and macropores ($r_1 + r_2$). Hydrothermal treatment aids a considerable change of the pore structure of tricalcium aluminate. In these conditions the content of coarse and macro-pores (over 90 per cent in steam-cured samples as to compare with 70 per cent in normally hardened samples). It is necessary to say that pore sizes in steam cured samples are 10 times larger and the general value of the cumulative porosity is 25 per cent higher as to compare with C_3A samples of normal hardening. Therefore the low strength of C_3A and detrimental influence of hydrothermal curing might be well explained through the structural features of hydrated phases of this compound.

And indeed, the main reason of the low strength of this compound lies in the formation of a coarse crystalline frame composed from the cubic tricalcium aluminate hydrate (having six moleculae of water) of a higher homogenity of pores and in the loose bond between its separate crystals. The cases when said compound is of any noticeable strength coincide with the presence in the hydration products of hexagonal crystalline hydrate phases, these providing the formation of a more strong crystallic structure.

Subsequent storing of steam-cured samples of C_3A at air-humid conditions does not bring about any noticeable changes in the structure developed during the steam-curing.

The highest strength during the steam-curing of clinkering compounds gives the C_4AF (Table 7 and 10). The strength of steam-cured samples made from this compound turned to be some lower as to compare with the normally hardened samples. This is in

accordance with the most of the earlier data. High strength of C_4AF samples well agrees with minimum cumulative porosity and with minimum pore fraction having radius more than 10^3 Å ($r_1 + r_2$)—as to compare with other compounds. The pores of the said dimension ($r > 10^3$ Å) might be considered as a factor lowering the strength of the hardened cement paste. In any case it refers more to the said pore dimension rather than to the smaller pores. It has been found (76) that destructive phenomenae during the steam-curing bring to the pore sizes' enlargement.

It is specific for C_4AF steamed samples that they, as to compare with those of normal hardening, have increased content of micropores (10^2 Å $> r_4 >$ 40 Å) and of combined water. It agrees well with the supposition that iron component of C_4AF hydrates more completely, this being accompanied—as it is known—by the formation of geleous products. These products can contribute to the compensation and healing of structural defects of aluminate carcass which appear at C_4AF steam-curing. Our ealier data show that at C_4AF steam-curing, the newly formed compounds are of more disperse pattern as to compare with those of normal hardening. It agrees with the supposition expressed. Specific surface data obtained by low temperature adsorption of nitrogen were 12.4 and 9.6 m^2/g respectively—i.e. two times higher than that for newly formed phases of the samples of other compounds. Table 9 shows that there is no unfavourable change of C_4AF structural porosity as a result of hydrothermal curing of this compound. It is necessary to say however that the presence of this compound in clinker (10–15 per cent usually) makes no material influence on the strength of a steam-cured concrete (72, 77). Moreover, there are some data (77) that at higher C_4AF content in clinker (20 per cent), the strength of a steam-cured concrete lowers significally.

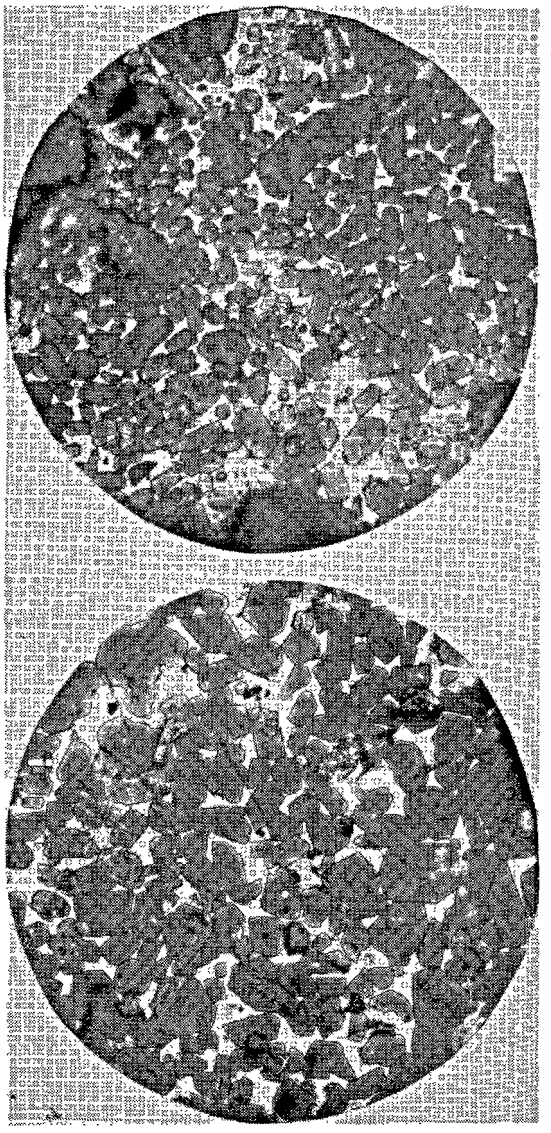

Fig. 12. *Microscopic structure of a laboratory burnt clinker; the structure is near to an optimum one. (Reflected light, ×400)*

Crystalline Structure

Considering that the form of crystals and the crystalline structure of alite and belite, these being main phases of portland cement, strictly depend on their crystallic lattices, one can judge the hydraulicity of a cement by the crystalline pattern of said compounds in it.

Based on a long year experience in the quality control of clinkers and cements of the USSR, the authors (78–80) came to conclusion that regular form of crystals of the main compounds of clinker corresponds to higher quality of cement. Fig. 12 shows the optimum microstructure of clinker. However, if either distorted or partly broken crystals prevail, then the cement made on this clinker would have decrease strength. This dependence has been traced by the authors on clinkers of 80 cement plants. Cements made with these clinker hardened in usual steam-curing on 1.5–3–1 hours pattern—at 95–96°C.

Polyhedral and poorly developed crystals of alite and granular or strongly hatched crystals of belite more oftenly bring about lower hydraulicity. The presence on alite crystals of a "boarder" consisting from the secondary crystals of belite and appeared as a result of C_3S disintegration, is also both the reason and the sign of a slow hardening of cement—during the first period at least. However, the macrodefects cannot

Table 11. *Compressive strength of specimens made from cement consisting from a clinker with various admixtures*

	2.0	48	88	125	128	116	171

be considered as a sufficient sign of the hydraulicity of cement. The main role in changing the hydraulicity of crystals of compounds and of the binding material as a whole belongs to the structure of crystalline lattices of separate compounds. Depending the character of the change in lattice composition, defects can result to either decrease or increase of the hydraulicity of a compound. For example, the defects appeared during the occlusion of aluminium oxide, titania, sulphuric anhydride and of some other compounds into the C_3S lattice, contribute to the acceleration of the surface reaction and to the strength gain of the system. Of course, besides providing for pertinent defect, it is necessary to provide for their optimum concentration in crystals. The excess of different (by type) and opposite (by sign) defects in a crystal can bring about the lowering of its interconnection with H^+ and OH^- of water. Table 11 contains data showing complex character of the hardening of cements containing the admixtures which deform crystals at 20–100°C temperature range. So, 0.5–2.0 per cent of Cr_2O_3 results to a small decreased of samples' strength immediatelly after steam-curing; at the age of 28 days the articles of cements, having 0.5 and 2.0 per cent of chromium oxide show higher strength. The addition of 2 per cent of Cr_2O_3 is of the most efficient influence. For normal conditions of hardening L. D. Yermakov (81) and M. M. Sychev (82) recommend 0.15–0.30 per cent of Cr_2O_3 admixture. The addition of 1.0–1.5 per cent of P_2O_5 and 0.5–1.5 per cent of SO_3 also positively influence the steam-curing.

When providing for the conditions in clinker to form alite and belite crystals, optimum as to their size and structure, it is also helpful to provide for the conditions to form these phases as particles of a definite size. Some articles (83–84) point out positive influence of fine crystalline pattern of clinker on the hydraulicity of cement. Along with there are some works (78) mentioning about the obtaining of high-strength cements from coarse-crystalline clinkers. Such contradictory data are conditioned by the fact that the researchers, when studying the influence of alite crystals on the properties of cement, considered neither the structure of crystals nor the fineness of clinker ground. It is rather probable, that the conclusion concerning influence of alite crystals' size on the properties of cement can be drawn just in case when the particle size of the given cement is commeasurable with the size of C_3A crystals. In all other cases it is necessary to consider many attendant factors—for example: 1) the character and the rate of a coarse crystals grinding; 2) aggregative character of fine crystals in the particles of cement; 3) the rate of coverage of alite crystals' surface with the interstitial phase; 4) compound composition of separate cement particles; and some other factors.

At the steam-curing, the hydraulicity of cements having nearly the same compound compositions, and made with clinkers of some 3,000 cm^2/g specific surface, these clinkers consisting from different sized crystals of alite and belite, was commeasurable. 3—hours steam-curing at 95–100°C of cements of the like compound composition, made from clinkers having approximately 3,000 cm^2/g fineness and consisting from alite and belite crystals of various sizes, showed very similar strength. Therefore size of alite and belite crystals is not the factor of a noticeable influence on the strength of steam-cured units. It is at 4,500–6,000 cm^2/g fineness of cement the positive influence of the clinker fine crystalline pattern reveals more distinctly. 20–40 microns are optimum for the change of the size of alite crystals for the similar conditions.

Fineness of Cement

Hydration kinetics of cement rises as its fineness increases. Table 12 contains data showing the hydration rate of various fractions of clinker powder.

The rise of hydration rate when their fineness increased, brings about some higher density of the forming hardening cement paste due to the formation of a great amount of hydration products. Further increase of the fineness of cement over a certain limit brings, however, to a decrease of the hardened cement paste density due to the increase of both the water consump-

tion of the binding material and of contraction shrinkage of the "water—cement" system.

The study of a hardened cement paste physical structure shows its some definite relation to the fineness of cement. The increase of the specific area of cements within the range of 3,000–6,000 cm^2/g tends to some decrease of the summary porosity and to the re-distribution of the hardened cement paste pores volumes, namely—to the increase of the coarse pores volume—on the account of the volume of micropores. Table 13 shows that the change of properties of a steam-cured hardened cement paste, this change being connected with the fineness of these cements, is also defined by the compound composition of said cements. The fineness increase of belite cements proved to be more efficient than that of alite cements.

The fineness of cement shows noticeable effect on the character of structural changes in the steam-cured hardened cement paste at its subsequent hardening at normal temperature and moisture conditions. In this case the increasing of cement fineness brings to a more coarse-voided structure of the hardened cement paste to form. The process of the re-distribution of the pore structure of the hardened cement paste during its ageing is probably connected with the crystallization process and with the densification of the geleous phase of hydration products. The influence of a cement fineness on the process of the re-distribution is in accordance with the pertinent changes of cements hydration rate.

The Material Composition of Cement

The problem of using cements containing finely ground mineral for making concretes subjected to steam-curing is a disputable one. Some authors think (85, 86) that for such concretes only "netclinker" cements should be used, which contain no any mineral admixtures but gypsum. Such an assertion is based on the fact that the addition of more oftenly used admixtures such as ground silica sand, blast-furnace slags and hydraulic products lowers the strength of concrete, though in separate cases the improvement of some other features is noticed—e.g. the resistance

against agressive solutions etc. At the same time many studies in the recent years (87 ~ 89) have shown that the use of a high quality blast-furnace portland cement for steam-curing gives a concrete of high technical values and excellent durability.

Table 14 contains data considering the efficiency of the steam-curing of concretes with various cements. These data show that the steam-cured portland blast-furnace slag cement is not much inferior to a "neat" portland cement—as their absolute strength values and the strength gain are concerned.

The study of the hardening of the portland blast-furnace slag cement at steam-curing (88) has shown that the best results are obtained when this cement is steam-cured at elevated temperature. The increase of duration of the steam-curing is more favourable for the blast-furnace portland cement rather than for portland cement (See Table 15).

It is specific for portland blast-furance slag cement concretes that they have a less shortage of the strength gain during the steam-curing and at subsequent hardening as to compare with portland cement concretes.

Table 14. *The influence of a kind of cement on the steam-curing effect of concrete (1.5 + 8 + 1.5 hours, at 80°C) (by S. A. Mironov and L. A. Malinina data (52))*

Cement, kind	Compr. strength, 28 days norm. hard., kg/cm²	Cement consumption, kg per m³ concrete	W/C	Compressive strength, kg/cm²	
				Compressive strength, kg/cm²	age 28 days
Pozzolanic portland cement	446	340	0.42	233 / 68	326 / 95
Portland blast-furnace slag cement	412	320	0.42	330 / 72	424 / 93
Portland cement	430	275	0.4	333 / 74	485 / 107

Note: numerator: compressive strength, kg/cm²; denominator, per cent of the standard strength.

The main difference between the portland blast-furnace slag cement and the portland cement—both having hardened at the steam-curing—is that the portland blast-furnace slag cement contains less of hydrolytic calcium hydroxide and more of low basicity silicate hydrates. These silicate hydrates in the hardening blastfurnace portland cement paste are mainly represented by a unibasic silicate hydrate of the tobermorite group with a trace of silicate hydrate, C_2SH/A/(89).

To obtain portland blast-furnace slag cement of an efficient hardening while steam-cured, it is advisable to use clinker of increased C_3S and C_3A contents. The contents of clinker, granulated blast-furnace slag and of gypsum should be designed in consideration of the features of these materials. Blast-furnace portland cement should have higher fineness.

Good results to intensity the hardening of concretes while steam-curing are obtained (38) by designing the material composition of cement, The authors of this work have advanced an idea that cements whose hardening is mainly based on the formation of calcium aluminate sulphates, should increase their strength at steam-curing more rapidly than the portland cement whose hardening is mainly based on the formation of silicate hydrates bond. On this idea the authors have offered a "four-component" cement consisting from portland cement (58 ~ 65) per cent, aluminous cement (or high alumina metallurgical slags) (3–7 per cent), $CaSO_4 \cdot 2H_2O$ (7–10 per cent) and hydraulic admixture (23–28 per cent).

Both aluminous compound and increased amount of $CaSO_4 \cdot 2H_2O$ are added to increase the amount of calcium aluminate sulphate hydrates during the first stage of hardening. It is known that this crystalline hydrate forms at the hardening of portland cement but its amount is not sufficient to provide for a substantial strengthening of the hardened cement paste while its steam-curing. Calcium aluminates contained in portland cement clinker reveal insufficiently during

Table 15. *The influence of a kind of cement on the efficiency of various steam-curing pattern (W/C = 0.56; cement consumption—280 kg/m³) (by S. M. Royak, A. F. Cherkasova and E. T. Yashina data (88))*

Cement, kind	Amount of additions in a cement slag (tripoli earth)	Compressive strength, 28 days norm. hard., kg/cm², "GOST 310-41"	Compr. str. (kg/cm²), 1 hour age after the heating by patterns, hours								
			3 + 4 + 2			3 + 6 + 2			3 + 8 + 2		
			Isothermal heating, t, °C								
			80	90	100	70	80	90	70	80	90

Portland blast furnace slag cement	33/15	436	144	161	176	134	161	184	140	171	185

the grinding of cements and therefore the main amount of these aluminates can react with gypsum only at the later stages of the hardening. According to some data (38) only 30–50 per cent of alumina content of portland cement can be used for calcium aluminate sulphate to form during the first period of hardening.

The solubility of calcium aluminates in the liquid phase is suppressed by the calcium oxide hydrate, formed at the C_3S hydrolysis. Hydraulic admixture introduced into the above-mentioned cement aims to lower the CaO concentration in the mortar, thus increasing the solubility of calcium aluminates and—therefore—increasing the rate of formation of calcium aluminate sulphate hydrate.

The Influence of Various Technological Factors on the Structure and on the Properties of the Hardened Cement Paste and of Concrete

Water-Cement Ratio and the Method of Moulding

The water content in a moulded concrete article is of the primary influence as to the quality of concretes of both normal hardening and even in a grater rate at steam-curing. The presence of water is necessary for a normal hydration and hardening of the cement in a concrete; the content of water immensely influences the kinetics and the completenes of these processes (91 ~ 94). It also influences the workability of a concrete mix. Besides, water is a concrete mix component, which takes part in destructive processes of a concrete during its hydrothermal treatment. Considering this, it is necessary to obtain maximum lessening of the water content in a concrete mix. The free water, which evaporates during the hardening, as well serves as the main factor of the pore structure of the hardened cement paste along with the entrained air and with the pores of contraction. When steam-curing, the W/C ratio influences the qualities and the durability of concrete. It also influences the optimum duration of separate periods of hydrothermal treatment. The lowering of the W/C ratio allows to shorten the pretreatment and to increase the rate of temperature rise during the steam-curing of the concrete. It also provides for the possible shortening of an isothermal heating of concrete and increasing its temperature (95). When freshly moulded concrete is being heated, the role of water in increasing the porosity of the hardened cement paste depends on the thermic expansion of the water. It also depends on the migration of highly disperse droplets and vapours through the capillary pores as a result of the temperature and moisture gradients of the concrete body. W/C ratio is also of a great importance for the kinetics of the structural and mechanical consolidation of the hardened cement paste. Accelerated consolidation of the hardened cement paste structure at lowered W/C (Fig. 13) is one of the reasons permitting to intensify hydrothermal treatment.

There is a spread opinion (52) that high strength concretes with low W/C made from stiff concrete mixes can be steam-cured using shorter time-patterns as to compare with low-strength concretes of plastic consistency. But even in case of stiff mixes the lowered rate of temperature rise is possible. The lowering of W/C in a concrete mix increases its absolute strength and provides for its more rapid hardening (75). When considering the W/C ratio, it is necessary to remember that its change brings about the change of the workability (stiffness) of a concrete mix and, therefore, it defines the method of tamping when moulding the concrete articles. In commercial scale the use of lean concrete mixes is restricted with the difficulty of their tamping. Efficient tamping of stiff concrete mixes requires for special equipment; along with, it complicates the technological process and rises up its

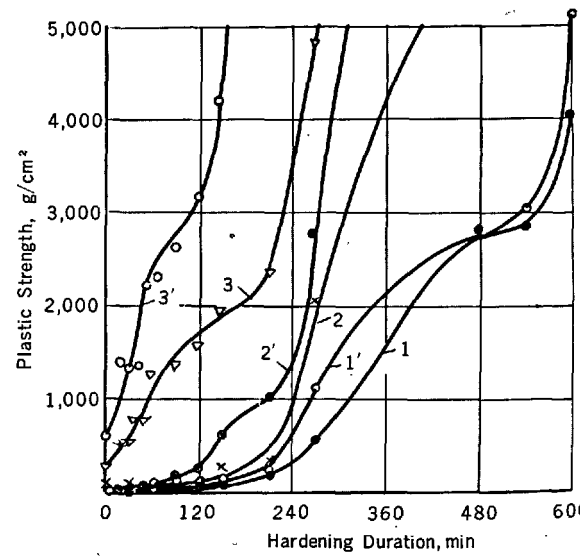

Fig. 13. *The effect of the W/C ratio on the cements plastic strength. Curves 1, 2, 3—cement 1, W/C ratio—0.4, 0.3, 0.2 respectively.*

cost. Therefore a commercial concrete should be not lower than 0.3.

Table 16 shows the influence of the W/C ratio and of the method of concrete tamping on the strength and physical data of a steam-cured hardened cement paste. One can see from these data that the lowering of W/C ratio brings to the sharp of the hardened cement paste strength, to a favourable change of its general porosity, of its bulk weight, of its moisture content after the steam-curing. In other words, the parameters, reflecting the structure of the hardened cement paste immensely and favourably change.

It is of a great importance that the increase of W/C ratio immensely changes the structural porosity of a steam-cured hardened cement paste. In such a case the volume of coarse capillary pores increase (Table 17) and this is one of the main reasons of lower durability and lower frost resistance of steam-cured concretes made at high W/C ratios. High content of coarse pores and macropores in a hardened cement paste of higher W/C ratio is, as it was previously said, due to the fact that during the steam-curing, free water increases the pores' sizes in a steam-cured hardened cement paste. Moreover, B. G. Skramtaev, T. I. Gorchakov and M. M. Kapkin (76) show that the pattern of the change of a hardened cement paste during the steam-curing is greatly defined by the W/C ratio. In other words the hardened cement paste of low W/C ratio (0.3–0.4) is turning to be more dense during the steam-curing, while that of higher W/C (0.5–0.6) is turning to be more porous.

The W/C ratio greatly influences the residual water content (i.e.—after the steam-curing) of a hardened cement paste (Table 16) which, in its turn, greatly defines the hardening of the paste at normal temperature and humid conditions. Table 18 contains data showing the strength gain of steam-cured cements

Table 17. *Pore size distribution in cement specimens at 100°C by "0 + 2 + 0 hours" pattern 1*

0.15	16.4	19.0	11.5	

Table 18. *The W/C ratio effect on the strengthening of a steam-cured hardened cement paste at subsequent hardening at normal temperature-humid conditions*

W/C	Rate of the strength gain, age 28 days, multiplicity factor		Mode of moulding	Notes
	cement 1	cement 3		
0.60	3.9	—	Pouring	The strength of specimens, age 30 minutes after the steaming, is taken for the rerefence
0.50	4.2	—		
0.40	3.7	4.9	Jolting, 100 times	
0.30	1.7	2.82		
0.25	1.60	2.3	Vibration, 30 sec.	
0.20	1.52	2.14		

during the subsequent air and humid curing-depending on the W/C ratio. Great difference in strength correlations shows some more intensive strengthening of steam-cured hardened cement pastes of higher water content during subsequent hardening. But even more rapid strength gain of the steam-cured samples of higher W/C ratio does not allow them to attain strength level of cement samples at lower W/C.

Practically to obtain rapid hardening of steam-cured articles, as well as to obtain more complete use of binding features of the binding material, in some cases one can provide for an additional wetting of the steam-cured articles (96~97). It allows to obtain intensive hardening of the article after their steam-curing without any increase of the W/C ratio. For an efficient use of this method an additional amount of water supply is necessary—at a definite moment, namely prior to the appearing of solid diffusion shells on the grains of clinker—but after the forming of a minimum strength structure, which is able to withstand washout (96). At the same time it is necessary to take into consideration, that in many cases technical standards limit the residual moisture content of the steam-cured articles. In such cases the low W/C concretes are highly desirable.

So, the W/C ratio increase in steam-cured concretes, despite making favourable conditions for an intensive hydration of the binding material, negatively influences the strength, the hardening kinetics of the cement paste especially on the early stages of the process.

Conditions of Hardening

At present there is not yet a generally accepted opinion concerning the optimum pattern of a concrete steam-curing. There is a spread trend to shorten the steam-curing of concrete in order to speed-up the manufacturing process and for this one would use strictly shortened pattern of steam-curing. However, the physical defects thus appearing in the structure of the cement paste, lower the concrete strength and durability. This in turn calls for an additional cement consumption per cubic meter of concrete.

The efficiency of the steam-curing depends on the duration of separate periods of the process and of their respective conformity, to the properties, and the composition of the cements used and on the composition of the concrete, on the W/C ratio as well as on some other factors. Hydrothermal treatment of concrete consists of the following cardinal periods.

1. Pre-treatment, which starts from the time of mixing of a concrete components with water up to the temperature rise of a moulded article due to an external heating.

2. The period of the temperature rise, during which the article is being heated from the temperature of the environment up to the temperaure ordered.

3. Isothermal heating, during which the article is being kept in a steam environment at the constant temperature ordered.

4. The period of temperature lowering, during which the article cools down the environment temperature.

Each of the said periods plays its important role to form the qualities of the hardened cement paste and of the concrete.

a) Pre-Treatment

One of the ways to increase the stability of the hardened cement paste during the temprature increase and, therefore, improving the qualities of the steam-cured concrete, is the pre-curing of the concrete mix prior to the steam-curing. This pre-curing is performed prior to and after the moulding of articles (75~98). There are some ideas (91, 98~101) that during a long pre-curing at normal temperature, an intensive hydration of cement particles, the lessening of uncombined water amount (which most readily evaporates during the heating), the formation of geleous hydration products and the filling of "free water zone" with the said products. Higher concentration of calcium hydroxide in the liquid phase is also of some importance due to its higher solubility at normal temperature, as to compare its solubility at the steam-curing temperature. Packed structure of the hardened cement paste formed during the temperature rise, prevents water migration in concrete thus preventing its loosening and warping which otherwise would lead to the strength disattainment. Besides, during a prolonged curing the concrete attains its initial strength, sufficient to withstand temperature deformations and stresses, developing in a steam cured articles. According to V. A. Fedorov (55), increasing the pre-treatment before a steam-curing at 80°C from 15 min to 24 hours admitted to lower the residual deformation of a hardened cement paste from 3 mm/meter down to 0.2 mm/meter. It can be of a great importance that during a pre-treatment, highly disperse hydrates of well developed surface form, these sorbing water in capillary pores thus preventing its untimely evaporation during a steam-curing. There is also some opinion (91) that untimely temperature rising of a hardening concrete helps to a hardening of shells around the particles of cement. These shells made from newly formed compounds can lead to the retardation—and even to the full cessation—of "water-cement" chemical interaction. According to the aforesaid, certain prolongation of a normal temperature pre-treatment of concrete articles before they are steam-cured, is helpful. Some other authors think however, that the prolongation of a pre-treatment above a definite short term is not only disadvantageos but even can bring about negative results. It has been found (102) that the

strength of a concrete of 2 hours pre-treatment was higher than the same concrete of 4 hours pre-treatment. The steam-curing after a short termed precuring brings about a relatively higher deformations though does not bring about a serious strength drop. According to the authors, feeble structure in an early age and at new conditions of hardening is able to get a "self-healing" of the defects appeared. It does not take place however after the 4 hours pre-treatment, when more rigid and less plastic structure form.

Some authors also think (103, 104) that for articles made from a cement mortar it is advisable to have a 3-hours pre-curing before steam-curing. According their data, however (103), the strength of mortar specimens with cement having 3,800 cm^2/g and steamed without a pre-curing, is similar to those steamed at 3 hours and made of mortar with cement having 3,300 cm^2/g surface. It has also been shown (101) that concrete steam-cured at 85°C without a pre-curing was of equal strength with that one which had a 6-hours pre-curing before the steam-curing.

All the abovesaid proves that there is no generally accepted opinion concerning the optimum time for a pre-curing of a concrete prior to its steam-curing. It is quite understandable to take into consideration that the efficiency of a pre-treatment of a concrete with normal temperature and destined for a steam-curing also depends on the composition of the concrete and cement, on the W/C ratio, on the environment temperature etc. According to some data (52), the optimum time of a pre-curing of concretes made from portland cement can vary in the range of 2–10 hours—depending on the above listed factors. Some authors think (105, 106) that optimum duration of a pre-curing period of concretes prior to their hydrothermal curing corresponds to the moment of transition of a coagulated structure of a "mortar" part of these concretes (i.e.—"cement-sand-water") into a crystallo-coagulated phase. Other authors assert (107, 108) that hydrothermal curing of a concrete should be coordinated with the kinetics of the cement heat release and the beginning of this process should not coincide with the period of maximum heat release.

The beginning of a concrete setting can be considered as the optimum time of pre-curing (52).

There are some data of a considerable interest (109, 110) showing that the breaking down of a cement paste structure during its formation does not influence the hardened cement paste strength. Meanwhile the break down of the structure during its consolidation lowers down the specimens' strength sharply. All this admits to think that the most dangerous structure during the temperature rise is—(considering defects' formation and hardened cement paste strength lowering)—such a structure which has already lost its plasticity and ability to "self-healing", but has not yet attained the necessary strength to withstand stresses arising from the volume change of the components of a concrete and from the mass-transfer. In other words, optimum time for pre-curing of a concrete depends on its structural and mechanical state, attained to the beginning of hydrothermal curing. It is due to the difference in these properties (Figs. 10 and 11) that alite cements admit a shorter pre-curing time as to compare with belite cements. Table 19 shows the change of strength and of other properties of various compound composition, depending on the pre-curing period of samples prior to their steam-curing.

Duration of a pre-curing, as well as duration and temperature of isothermal heating influence the hardening of a cement paste after the steam-curing. The shorter the stages of hydrothermal curing and the lower its maximum temperature, the more efficient is the subsequent hardening and the more strength gain is obtained to 28 days after the steam-curing (Table 20). This corresponds to the data concerning the structure formation of a hardening cement paste during the hydrothermal curing (76). These data show that the most efficient hardening and hydration products accumulation take place at the

first period of the steam-curing, i.e.—during 4 hours. After this period hydration process retards and the processes of re-crystallization prevail. One can naturally suppose that the structures, formed by less crystallized newly formed compounds, are more liable to an additional structure at subsequent hardening due to their greater mobility and greater solubility of highly disperse hydrates. Therefore, reduced steam-curing on account for a shortened pre-curing and-mainly-on · account for shortened isothermal heating seem to be more advantageous to avoid (or to reduce) the strength disattainment, which is specific to the steam-cured concretes.

The principal ways to reduce the pre-curing of concrete articles prior to their steam-curing are either the use of high early strength alite cements or the use of concrete mix with reduced W/C ratio. It is also possible to perform pre-curing of the concrete mix prior to its moulding and the use of rigid, tightly sealed moulds in order to prevent temperature expansion of the concrete and to restrict the moisture exchange with the environment.

b) The Rate of Temperature Rise

Main defects and distortions of a hardened paste physical structure arise during the heating of concrete articles, when the hardened cement paste has not yet attained the strength necessary to absorb thermal stresses without any change of monolithic character of the structure. Destruction of a hardened cement paste during the temperature rise takes the form of a developing and increasing of the volume of capillary and coarse pores, this resulting from the migration of highly disperse water and steam-air mixture, which is filling the pores.

The said migration in its turn results from a temperature and humid gradient in a concrete and this gradient attains its maximum value during the heating of the concrete. Temperature expansion of water and of an entrained air also of a great importance for the defects and tensile stresses to appear. The negative influence of free water and of entrained air increases as their amount increases. It also increases with the temperaure rise. At the negative influence of these factors destructive processes of moisture migration and of temperature expansion of liquid and of gaseous phases of the hardened cement paste develop more strongly. During the same period, hydration process of a cement runs most vigorously. This process, as it is known, is being accompanied with contraction phenomenae, which condition contracting stresses in the hardened cement paste. That is why the period of the temperature rise at a concrete hydrothermal curing is one of the cardinal factors of this process.

There are various points of view concerning the rate of the temperature rise. According to our opinion, the most grounded of these points of view are those which can coordinate the heating rate of a concrete mix with its rheological and structural properties during the heating. In connection with this, the coordination of the rate of temperature rise with the duration of a concrete pre-curing prior to its steaming is evident. There are some interesting data (III) showing that, irrespective of the kind of a cement, the pre-curing at slow temperature rise does not give the effect necessary. In other words, the slow temperature rise prior to the steam-curing can compensate the absence of a pre-curing. However, quick temperature rise (up to 80°C of isothermal heating) can lead, at the conditions of insufficient pre-curing, to a considerable loss of strength of a concrete.

To obtain a least stressed but most dense structure of a hardened cement paste of a concrete while steam-cured, the temperature rise should have such a rate so as an additional pore volume, appeared as a result of air and water migration and temperature rise, be compensated, rather than supplemented by a pore volume formed as a result of the contraction shrinkage of a hardening system "cement-air". To achieve this, it is necessary to express quantitatively and to bring to conformity the hardened cement volume changes resulted from the said phenomenae. So, the rate of a hardened cement paste destruction during the temperature rise when steam-crued, depends on structural and mechanical features of the paste at the start of heating of a concrete, on the rate of the temperature rise, on the water content of the concrete mix and on the content of the entrained air. In their turn, the structural and mechanical features of a hardened cement paste depend on material and compound compositions of the cement, on its fineness and on a pre-treatment duration. A concrete mix water content can be reduced by means of the reduction of mixing water. The amount of an entrained air depends on the amount of an air-entraining agent and on the rate of a concrete mix tamping when moulding the concrete articles.

In order to speed up the temperature rise when steam-curing, one can use rigid moulds with covers (better with sealed ones). Such forms fix the dimensions of a moulded article, prevent its surface from evaporation by condensing steam and from residual expansion. Use of well-tamped (and therefore having

minimum of an entrained air) stiff mixes of low W/C ratio is also helpful. The so called "step-by-step temperature rise" during the steam-curing of a concrete (52) is a vey effective one. This method consists of an accelerated temperature rise up to 35–40°C. Then comes the curing at such temperature during 1.5–2.5 hours, which is followed by further accelerated rise up to the isothermal temperature ordered. Such a method provides for no any serious temperature deformation or the deformation of a concrete structure during an accelerated heating up to 35–40°C. The curing at such temperature provides a concrete for the strength necessary to remain dense with a least defects at subsequent heating up to the temperature of an isothermal curing. The efficiency of a low temperature rise at a steam-curing of concrete can be probably explained similarly.

c) The Temperature and Duration of an Isothermal Heating

At the isothermal heating of concrete, the hydration process of a cement continues. During this the structural defects, appeared at some earlier stages of hardening of a concrete, turn to be more stable. At the same time, the process of re-crystallization of hydrate phases takes place, this being accompanied with further "reconstruction" of the newly formed compounds, which, in its turn, can stipulate either strengthening or weakening of a hardened cement paste. The alteration of the properties of a concrete during the isothermal heating when steam-curing depends on the temperature and duration of this period. Practically the isothermal heating runs at various temperatures ranging from 60 to 100°C. It also has various duration —from 0 to 24 hours. Both these parameters show independent influence on the hardening kinetic and on the features of steam-cured concrete articles.

With the increase of isothermal curing temperature, the maximum strength of any given condition is mostly attained for a shorter period. According to S. A. Mironov and L. A. Malinina data (52), in order to attain 70 per cent of the standard strength of a concrete having W/C ratio of 0.4, the duration of isothemal heating, amounted to: at 60°C–9 hours, at 80°C–5 hours and at 100°C–4 hours respectively. However, the absolute value of maximum strength at elevated temperatures, is less as to compare with lower temperature of steam-curing. According to the studies conducted by the authors of this work and at the conditions they have chosen, the steam-curing at 60°C would give maximum compressive strength of 360 kg/cm² after 16 hours of isothermal curing; however the "steaming" of a concrete of similar composition at 100°C reduces both the time to attain maximum strength (up to 2 hours) and absolute compressive strength (up to 290 kg/cm²). The data of Table 21 show that even at similar duration of the steam-curing, a more higher temperature of isothermal curing results to the higher strength disattainment at subsequent hardening. These phenomenae can be explained with the increase of defects of a hardened cement paste at higher temperatures of the steam-curing, due to a higher volume alterations of its water and entrained air, an immense role in this respect can play following factors: a) lower rate of hydration at elevated temperature due to a more complete crystallization and to a more "packing" of the newly formed compaction, these making "shells" around unhydrated grains of cement; b) strong evaporation of a concrete mixing water (up to 60–70 per cent) (102).

With the increase of isothermal curing duration, the strength gain of a concrete sharply lowers (113) and the higher the isothermal temperature, the more sharp is the drop of the strength gain. Table 22 shows that the prolongation of isothermal curing ever 4 hours does not give any sufficient rise of a concrete strength. During a prolonged isothermal curing even at 80°C, the drops of a hardened cement paste strength are observed. Probably this is a result of the formation of a low strength calcium silicate $C_2SH(A)$ (52) and of the

denominator—% of the standard strength

change of the structure of newly formed compounds. All this is accompanied with the weakening of an "intercrystallic bond" and with a developing crystalline pressure and inner strain forces.

Practically the duration and the temperature of the steam-curing should be such as to fit the given conditions of manufacture. It is necessary to remember that the efficiency of these parameters of the hydrothermal curing depend on the chemical and compound compositions of the cement, on its hydraulicity and hardening kinetics, on the concrete water content and its consistency, on the composition and the compactness of the concrete, on the thickness of the concrete article etc. When choosing the steam-curing patterns, the isothermal curing should be the shorter, the higher is the temperature of the process.

The Rate of the Temperature Drop and the Subsequent Hardening

Unfavourable effect of the sharp cooling of concrete units, i.e. the temperature gradient in the body of concrete, brings about the formation of stretching stresses in the surface layers of the unit. At some definite conditions (big difference between the unit temperature and that of its environment, draughts etc.) it is accompanied with disturbance of the monolithic structure of the unit and with the formation of micro- and macrocracks. These defects lower both the strength and the durability of a concrete units. According to some various authors, the maximum admitted difference between the temperature of a surface of a steam-cured article and that of its environment varies in the range of 40–75°C (52, 114, 115). S. Reinsdorf (114) shows that the cooling pattern after the hydrothermal curing greatly influences the strength of concrete unit at early ages of the hardening. Too rapid cooling intensifies the drying of a steam-cured concrete (112) and this is mostly considered to be the negative factor, resulting to a retarded hardening of such a unit. Some loosening of a concrete due to the intensive evaporation of sharp water cooling of the units is probable. However, the degree of this loosening on this stage of the steam-curing is negligible, since to this time the hardening cement paste attains sufficient strength. Therefore, the main deformations and disturbance of a concrete structure taking place at this period, can be regarded as a result of internal stresses, arising from the temperature gradient while its cooling. A steam-cured concrete, having residual water in its pores, is able to the further hardening. The kinetic of this process depends on the hydraulic properties of the cement used, on the temperature and humid conditions of the environment and on the pattern of a preceded hydrothermal curing. At shortened isothermal curing, the slow cooling of concrete units is, as a rule, an effective one, since in these conditions the "maturing" of the concrete occures on account of the heat this concrete has accumulated.

The humidity of the environment is of a great importance for the hydrothermal curing of a concrete unit and for its subsequent hardening. After the steam-curing, at the conditions of humid environment, the process of a concrete hardening is of rather intensive character. According to some data (116), the strengthening of a steam-cured hardened cement paste while

its subsequent storing in a humid-air environment results from several factor such as: the compacting of its structure, the lowering of its general porosity and the re-distribution of its pores' volume, thus forming a more favourable structure (Table 23). This is very interesting, since it shows the possibility of a considerable reconstruction of a hardened cement paste structure formed during the hydrothermal treatment at atmospheric conditions favourable for hardening. It is also interesting, that the hardened cement paste structure attains its respective greater value when steaming at an accelerated pattern (2 hours at 100°C) and at shorter terms of the pre-curing. As we have already said, it can be explained by less crystallinity and metastability of a hardening cement paste structure, forming at these conditions.

Written Discussion

Jørn Jessing and Poul Nerenst

In the principal paper by Butt, Kolbasov and Timashev (1) it is clearly demonstrated, that data from practice or research on accelerated hardening of concrete often are conflicting. This is not surprising, as experience has only been collected during a relatively short period. It shall be attempted in the following to perform a systematic discussion of these factors, even if it is not based on experimental research.

Rate of the Hydration Process

The curing of concrete at elevated temperature results in an acceleration of the hardening, i.e. the physical and chemical reactions in the cement-water-aggregate system proceed at a higher rate. The direction and rate of reaction are in general controlled by the driving potentials of the system. The hydration of cement depends primarily on

the chemical potential,
the temperature and
the pressure.

The chemical potential is determined by the nature and concentration of the reacting components, i.e. of the cement type and of the ratio of water to cement. For a given concrete mix these parameters will be constant.

The temperature history of the system (temperature as function of time) will depend on several factors: the initial temperature of the concrete mix, the amount of heat generated by hydration, the temperature difference between the system and its sur-

roundings and the thermal characteristics of the system.

As to the pressure, we are concerned only with thermal curing at temperatures below 100°C, i.e. the pressure is considered constant and equal to the atmospheric pressure, unless the curing takes place in closed, rigid forms.

It seems an established fact, that the course of the hydration reaction and the end products are substantially the same within a temperature range from 20°C to 100°C (1), (2). Although the temperature might influence the habit of the hydrated compounds (size and form of particles etc.), these problems have only in part been clarified, and we shall in the following assume identical hydration products at all temperatures below 100°C.

Destructive Processes

The mechanical properties of hardening concrete depend on the new structure formed during the hydration. Changes in the thermodynamic potentials may give rise to other physical processes, which may damage the formation of new structure in cement paste.

Two causes of harmful processes in concrete hardening at elevated temperatures are considered:

a. changes of temperature,
b. cnanges of water vapour pressure.

Changes of Temperature

A temperature change will cause volume changes in concrete. As the concrete components have rather different coefficients of thermal expansion (water about 10 times those of solids), they dilate differently. The resulting strain differences may damage the structure of concrete, if its internal cohesion and adhesion have only attained low values.

If the temperature change occurs, because the ambient temperature is higher than that of the concrete body, heat will be transferred to concrete, predominantly to its surface layers. This may cause temperature gradients and an uneven stress distribution, leading to crack formation.

If the temperature of the surrounding atmosphere is below the concrete temperature, heat transfer from concrete may reverse the mechanism just described, which in a similar way could damage the concrete.

Changes of Water Vapour Pressure

Changes in the pressure of water vapour may have detrimental effects, when cement paste or aggregate contain air-filled pores or bubbles of entrained air. In that case water may change phase within the system, i.e. evaporate or condense, which in turn entail consumption or liberation of heat.

Pressure changes caused by differences between the external and the internal vapour pressure may have more serious consequences:

If the relative pressure of water vapour is higher in the surroundings than in concrete, vapour will condense on its surface. Directly this may only be an advantage, but as condensation liberates heat, it may be harmful indirectly, by increasing the surface temperature and producing temperature gradients in the concrete body.

If vapour pressure is higher in concrete than in the curing medium (as it will be, if both are saturated, but the temperature of concrete the highest one), evaporation will take place at the concrete surface. This produces gradients of vapour pressure within the concrete and lead to transport of water (by flow or by diffusion) through the structure. The displacement of water will produced a hydraulic pressure, which the paste may not be able to resist.

Classification of Variables

In order to understand the physical processes and treat them mathematically, it is necessary to discuss the factors, which determine the temperature history of the concrete body and those, which determine the vapour pressure history. In practice it is possible to accelerate the hardening process by varying a great number of factors. Some of these are given by the characteristics of the materials and their mix proportions, i.e. the chemical and geometrical properties and the state of the concrete. Other factors are inherent with the curing conditions, i.e. the resistance to heat and moisture flow through the boundary of the concrete body and the temperature and humidity of the surrounding medium. The variables are listed systematically in Table 1.

Discussion of Variables

Among the parameters in Table 1 those directly related with the structure will be treated separately. Air content and aggregate content are omitted as they can be considered constant. The parameters directly influencing heat and mass transfer are dealt with more comprehensively.

Cement Types

Cements differ with respect to clinker compound

Table 1. *Classification of variables*

Materials	Chemical and physical properties of the system: Cement type (compound composition and fineness) Volume fraction of cement, Volume fraction of water } initial paste* porosity Volume fraction of air Volume fraction of aggregate Geometrical characteristics of the system: Volume of concrete body, Surface of concrete body } shape factor Initial state of the system: Temperature Vapour pressure
Curing	Boundary conditions: Heat insulation of concrete Moisture insulation of concrete External conditions: Initial temperature of surrounding medium Initial vapour pressure of surrounding medium Temperature changes as function of time Vapour pressure changes as function of time

*paste defined in accordance with T. C. Powers.

composition and fineness. It is rather well known how the hydration rate may be increased by selecting a optimal combination of these characteristics. Whether it may also be possible to obtain cement types especially suitable for thermal curing seems not sufficiently clarified; there are indications, that C_3A becomes unfavorable as temperature is raised (3), but this may result also indirectly from excessive temperature differentials due to the rapid hydration and heat development of the aluminate compounds.

The Volume Fraction of Cement

The cement content if of importance absolutely as well as in relation to the amount of water. A high cement content will generate more heat (and vice versa) and a high *w/c* ratio will in general accelerate hydration (4). The *w/c* ratio on the other hand will also change the mechanical properties of the paste, which may or may not enable the structure to withstand destructive forces.

The Volume Fraction of Water

The volume fraction of water shall initially and during hydration be sufficient to make continuous reaction with cement possible. The amount of free water will change due to chemical and physical adsorption during gel formation. The content of free water, its temperature, and the structure of the cement-water system determines the water vapour pressure in concrete, which in turn is responsible for a possible vapour transfer to or from environments. The increasing fineness of the structure connected with the gel formation will lead to lowering of the vapour pressure (self-desiccation).

The Temperature History

The temperature of a concrete member as function of time is determined by its geometrical and thermal properties and the heat development during hydration. Under certain assumptions the rate of temperature changes within a body placed at an environmental temperature different from its own can be calculated by means of the time constant defined as

$$\tau = \frac{V \cdot c_b \cdot R_b}{\Sigma k F}$$

when V = volume of concrete member
c_b = specific heat of concrete
R_b = density of concrete
$k \cdot F$ = coefficient of heat transmission multiplied by surface area

A method for a successive computation of the concrete temperature was developed by Nerenst, Rastrup and Idron (5):

$$N = N_b + \frac{C}{c_b \cdot R_b}(Q - Q_0) - \sum_0^t \frac{1}{\tau}(N - N_u)\Delta t$$

where N = concrete temperature
N_b = initial concrete temperature
N_u = temperature of surroundings
C = cement content
t = time
Q = heat development of cement $Q(t)$

The heat development must be known (as a table or a curve) $Q = Q(t)$ at constant temperature. By means of a time-temperature function it is possible to convert curing time at one (constant or varying) temperature into curing time at another (constant) temperature, see e.g. Rastrup in (6).

The Vapour Pressure History

The history of vapour pressure in concrete will depend on its water content in relation to its changing pore volume (coefficient of saturation). The pore volume comprises capillary capacity of paste, the possible porosity of aggregate and the content of air. As water is consumed by hydration and, simultaneously, the capillary capacity of paste is changing, a mathematical formulation of the vapour pressure history will be rather difficult to arrive at.

The problems of moisture transfer are in many ways analogous with heat transfer. It might, therfore, be possible to use an approach similar to that referred to above in connection with the temperature history, in order to calculate the vapour pressure history. Several important aspects of moisture transfer in connnection with the drying of concrete have been

treated by Pihlajavaara (7), (8). For the moisture loss by evaporation, for the moisture loss due to fixation of water by hydration and for the moisture gain due to carbonation expressions are derived, which might be used for calculation under certain conditions.

Protection against Destructive Processes

Whether a potentially destructive mechanism will actually damage the mechanical properties of the concrete will depend on the newly formed structures ability to accommodate the stress and strain produced by the mechanism in question. As paste structure is gaining in strength and rigidity, it seems possible to avoid or disminish the adverse consequences if the harmful processes can be delayed or postponed to a later stage of the hydration. At a certain degree of hardening damage is prevented because the mechanical properties have reached a sufficiently high level, i.e. the concrete has become immune against the destructive processes. This is also in agreement with the empirically established rules of maximum heating rates and necessary preheating periods (9), (10).

On the other hand it should be noticed that some properties of cement paste will develop in a direction, which will not make it easier for the solid structure to accommodate the influences which may be exerted. Flow or diffusion of water through the paste caused by vapour pressure differences may thus be met with increasing resistance as the permeability of cement paste decreases during hardening. The pressure gradient will become greater and the hydraulic pressure in paste may grow to a value, which leads to rupture.

The negative effects can, however, also be counteracted by external means, in the first place by using different form types. The form of the concrete member will always mean that concrete and curing medium is separated, i.e. a certain isolation against heat and moisture transfer is obtained. As most of the damaging processes are caused by temperature and vapour pressure differences the mould will provide some protection. In principle 4 different cases can be met with as shown in Table 2.

It shall be mentioned, that the application of a highly effective heat insulation has little sense as we are dealing with hardening of concrete at elevated temperatures.

Further, it will be possible to avoid harmful processes by using closed, rigid forms, which show no thermal expansion. By this means the water vapour exchange is excluded and the damage due to the too rapid and different dilations of the components under temperature rise in concrete can largely be avoided.

Table 2. *Influence of form type on heat and mass transfer*

		Heat	
		exchange	no exchange (adiabatic)
Moisture	no exchange	impermeable elastic covering	impermeable heat insulation
	exchange	no form	vapour permeable heat insulation

Combined Effect of Accelerating and Destructive Processes

It will appear from the above, that the temperature history of concrete is controlling both the rate of hydration and destructive processes; the vapour pressure within the concrete is decisive for another potentially destructive mechanism. The combined effect of accelerating and destructive processes may be illustrated by using a superposition principle introduced by Nerenst and Plum (11) in a discussion of the effect of freezing on green concrete:

The increase in hydration rate, which may be obtained at elevated (constant) curing temperatures, is illustrated in part (a) of Fig. 1. As the reactions are supposed to be the same in all cases, an identical degree of hardening will eventually give the same mechanical properties, if destructive processes are prevented.

In Fig. 1b is shown, how the hardening proceeds, if the temperature is increased from e.g. 20°C to 80°C after a preheating period of some hours. If the temperature is raised at rate of 20 deg/hour, it is assumed that the actual temperature history can be substituted by a stepwise temperature increase of 20 deg. every hour. We may now construct the resulting hardening curve by using parallel bits of the appropriate hardening curves valid for constant curing temperatures. We are still assuming the absence of harmful processes.

In practice such processes are often difficult to avoid. According to the foregoing discussion they may be avoided if curing takes place in impermeable, rigid forms. At the time of form removal, however, the energy stored in concrete, because expansion was suppressed, will be released, and damage may occur, if the strength is not sufficient to prevent it. This is depicted in Fig. 1c, where the different curves show, that different reductions in mechanical strength must

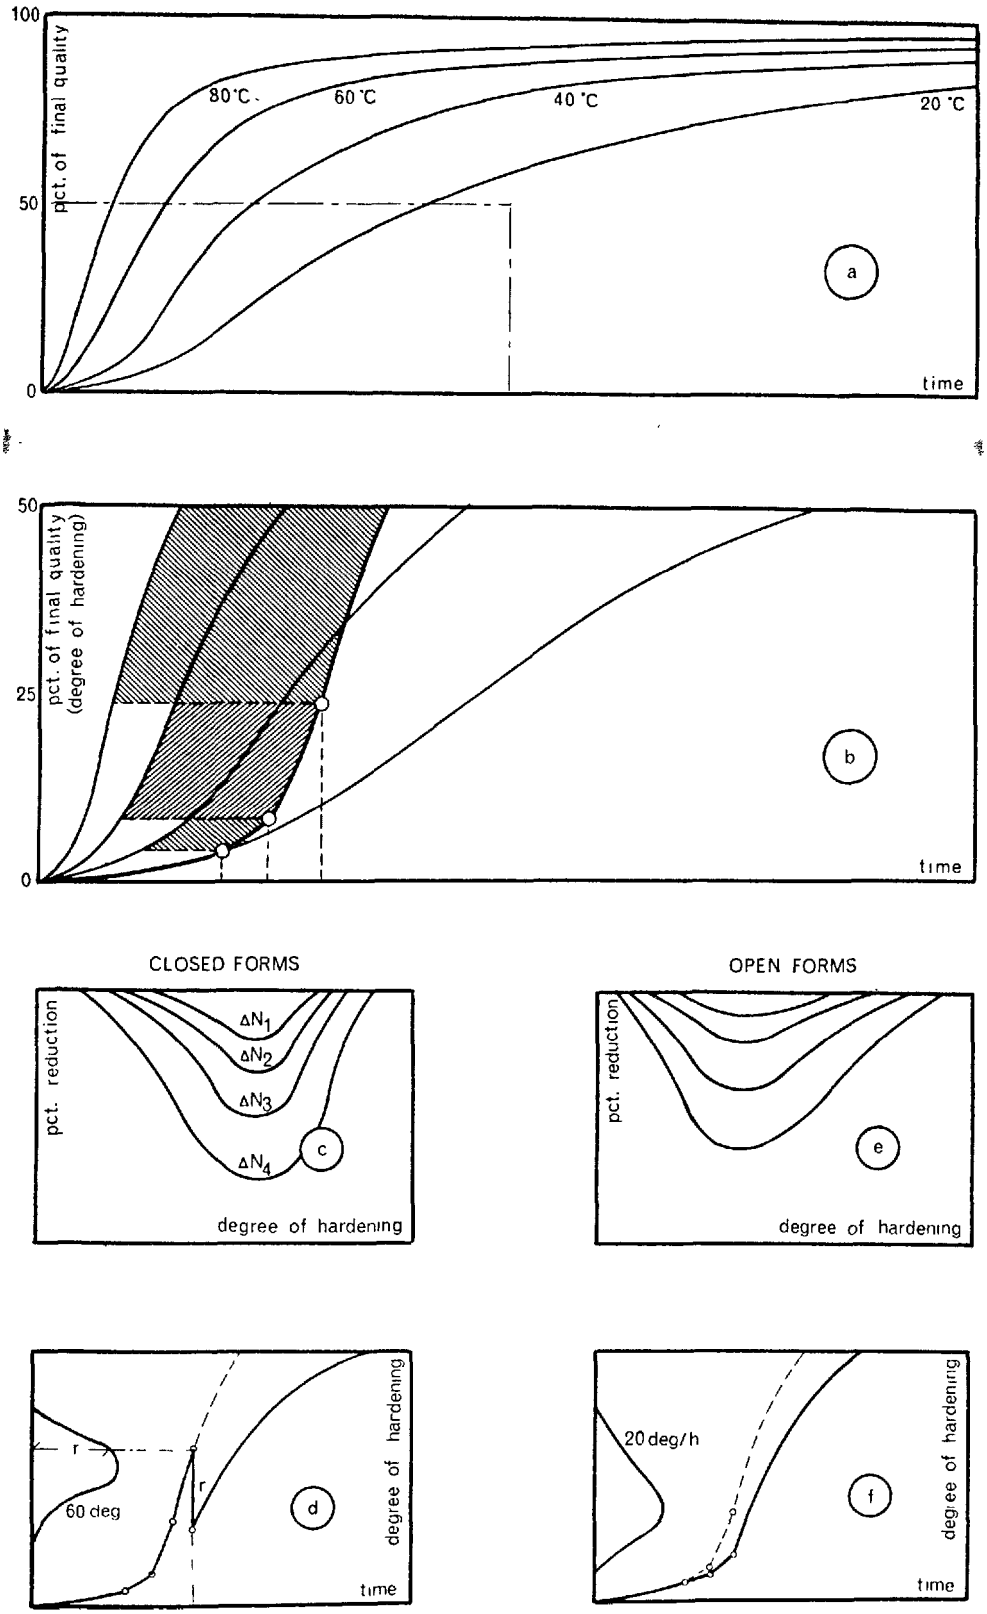

Fig. 1. *Combined effect of accelerating and destructive processes*

be expected in dependence of the total temperature increase (ΔN) during the heat treatment. The reduction will further be a function of the degree of hardening obtained at the moment of form removal. The point at which the reduction becomes zero, indicates, the degree of hardening, at which the concrete has obtained immunity to destructive processes. In a rather formal way Fig. 1c may be used to predict the final part of the hardening curve after moulds have been removed: The curve corresponding to the actual temperature increase (ΔN) from Fig. 1c is placed along the abscissa in Fig. 1d. At the time for form removal the reduction r is to be expected. The hardening curve is then lowered a corresponding amount and may after this procese after the appropriate curve from Fig. 1a.

Concrete moulds will normally be open or partly open. In this case the amount of destruction will depend on the rate of temperature increase. In Fig. 1e is shown how the quality reduction will depend on the heating rate and be a function of the degree of hardening attained, when heating starts. The construction of a resulting hardening curve is in this case more complicated, as the quality will be reduced continuously during the whole period of temperature raise. An example is shown in Fig. 1f.

Conclusion

The inconsistency of the great amount of information, which is available on high temperature curing of concrete, might in the authors opinion be overcome, if the many parameters are dealt with according to the physico-chemical nature of their influence. It might even be possible to handle the problem mathematically, if the development of certain properties can be established at different temperatures (isotherms) and if it can be proved, that these properties are identical, when destructive processes are prevented, e.g. by hardening in impermeable, rigid moulds. It is further a necessity, that temperature functions are formulated for the range $20°C \sim 100°C$, and to clarify the effect of harmful mechanisms.

The increasing use of prefabricated concrete elements makes it important, that research within this field is carried out with a similar intensity as earlier in the field of concreting at low temperatures.

Authors' Closure

Yuri M. Butt, V. M. Kolbasov and V. V. Timashev

I consider the material of this written discussion to be a very important and interesting addition to our investigations as it is closely connected with problems of our paper. I have no other remarks.

Supplementary Paper III-65 Influence of Cement Characteristics on Mix Proportion for Steam Cured Prestressed Concrete

R. K. Lewis and Frank A. Blakey*

Synopsis

In the production of prestressed concrete it is required in Australia that a minimum strength of 4000 lb/sq.in. on cylinders be obtained before transfer of prestress is permitted. Where steam curing is used the concrete is proportioned to give this strength at the end of the steam-curing cycle. For a given steam treatment variations in the cement characteristics result in a wide range of cement factors necessary to achieve this strength.

This report relates the cement factor required to satisfy the above strength requirement to the phase composition of the cement used.

An empirical relation is also obtained between the cement properties and the rate of development of strength under fog curing for up to 91 days, and the gain in strength of steam-cured concrete with subsequent fog curing to 28 days.

Introduction

Previous papers (1, 2, 3) have reported the results of a study of the optimum steam-curing conditions for high strength concrete. In the latter paper (3) the influence of cement characteristics was reported. To obtain a predetermined compressive strength after a particular steam-curing cycle it was found necessary to adjust the mix proportions to suit the cement used. It was also found that the 28-day compressive strength of concrete cured with steam, then with fog ranged from 98 to 124 per cent of the strength of concrete continuously fog cured.

An estimate of the cement factor necessary to meet the specification requirements was obtained from the standard 7-day tests for cement strength. A more accurate relationship was desired and to this end an analysis was made of the rates of strength development in relation to the chemical properties of the cement.

Mix Proportions of Concrete

Table 1. *Chemical and phase composition of the cements tested* (%)

	Chemical composition										Phase composition			
Cement No.	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	Na_2O	K_2O	Loss on ignition	Total alkalies	C_4AF	C_3A	C_2S	C_3S

Tables 1 and 2 show the chemical and physical properties of the cements tested. These represent cements from four Australian States.

The target compressive strength at the end of the steam treatment chosen was the minimum transfer strength of 4000 lb/sq.in. on cylinders, (5000 lb/sq.in. on 4-in. cubes), as required by the Code of Prestressed

*Division of Building Research, C. S. I. R. O., Highett, Victoria, Australia.

Concrete CA 35 (Standards Association of Australia 1963). The slump of these mixes was maintained at around 2 in. The steam cycle chosen had a delay period of 4 hr from mixing, a 10 degC/hr temperature-time gradient, and an isothermal (constant temperature) period of 6 hr at 80°C.

Table 3 sets out the compositions of the mixes that satisfy the above requirements. The cement factor ranged from 575 to 842 lb/cu.yd. The former value was that obtained for a "high early strength" cement and the latter for a "low heat cement".

The specimens were compacted for 10 sec on a table vibrator having a frequency of 3000 cycles/min.

It is usually considered desirable to reduce the sand content as the cement content is increased. Fig. 1 shows the relationship between the absolute volumes of the cement and sand used in this work, where a unit increase in the absolute volume of cement was balanced by a unit reduction of the sand content.

Table 3 also shows the grading of the sand and basalt aggregate used, and the compresseve strength of the concrete at the end of the steam treatment.

*Average of two replicates

Fig. 2 shows the development of compressive strength with fog curing up to 91 days for three of the cements tested. These results are tabulated in the previous report (3). With up to 7days of fog curing there was little difference between the compressive strengths obtained from each cement, but with longer periods wide variations occurred. Inspection of the plotted results suggested that they could be represented by two straight lines on a log-linear plot, except for cement No. 5 for which the graph was one straight line to 91 days. The two cements high in C_2S (No. 3, 6) have a second gradient steeper than the initial gradient. That is, they gained strength faster than if the initial gradient had continued, but because the function is a log-linear one, the absolute gain in strength in a given time interval is lower than that obtained during the early period.

The prediction of the strength at any age is dependent on the knowledge of these gradients, the age at which one gradient is replaced by the other, and the strength at particular age. In Table 4 the actual values of the parameters of the concrete strengths are set out for each of the six cements tested.

Abrams (4) made predictions of the 28-day compressive strength based on the ratio $K/7^w$, where w was the water/cement ratio by apparent volume. Taylor (5) suggests that nowadays the relationship is closer to $K/5^w$. The terminology of apparent-volume is not completely satisfactory and it is more appropriate to think of the exponent as 1.5 W, where W is the water/cement ratio by weight.

From trial mixes, and also from those reported in this paper, the value of K was found to vary from 21,200 to 30,600 lb/sq.in. depending on the cement used, strength being determined from 4-in. cubes. The variation for any one cement was of the order of ± 1000. A correlation between the value of K and the chemical composition of the cement was sought, but there appeared to be no unique relationship. This could be expected from the strength-age relationships,

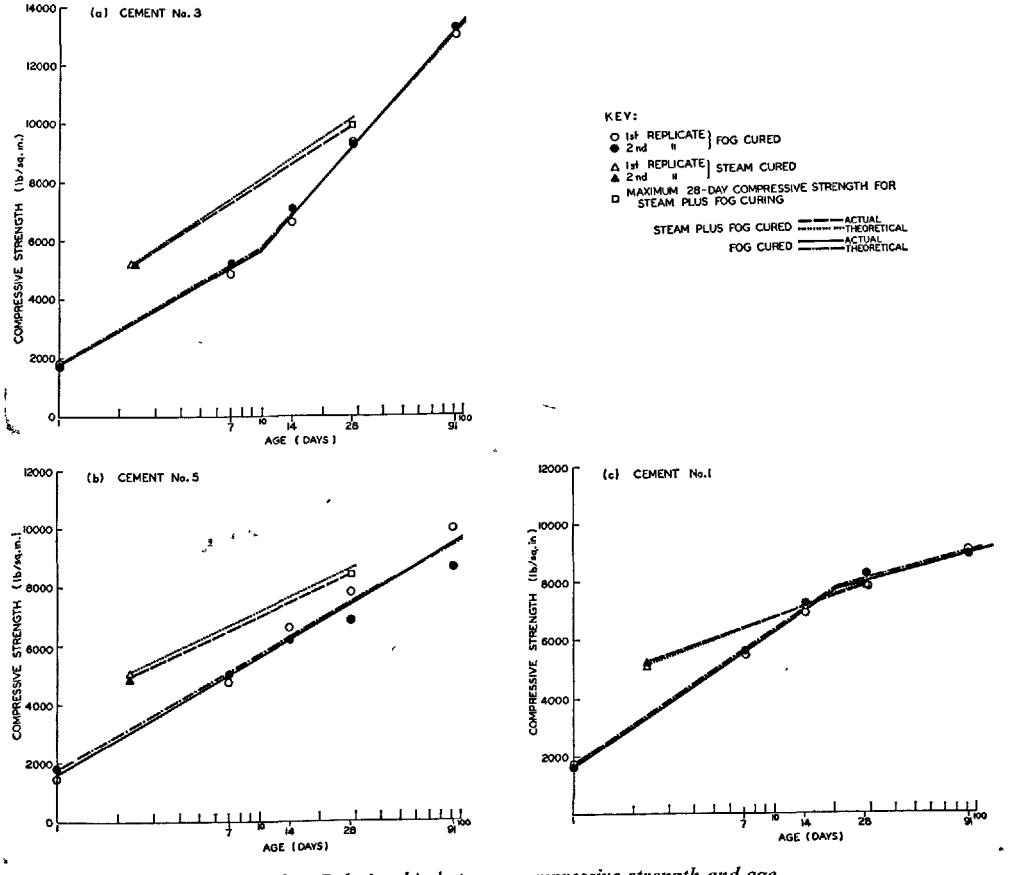

Fig. 2. *Relationship between compressive strength and age*

in that the 28-day strength lies sometimes along the initial gradient portion and sometimes along the second gradient portion.

Table 4. *Values of parameters in concrete strength relations*

Cement No.	$5^{1.5W}$	Compressive strength (lb/sq. in.) A (1 day)	Compressive strength (lb/sq. in.) B (91 day)	K_1 (lb/sq. in.)	$\sqrt{\frac{S}{3500}}$	SO_3/C_3A	Gradient constants L (Initial)	Gradient constants M (Second)	Gradient constants F (Steam & Fog)

6	2.79	1770	10140	4940	0.926	1.07	4130	4730	4050

Compressive Strength at 1 Day

It was therefore assumed that the above form of relationship between strength and water/cement ratio should be related to a time prior to the change of gradient, and the strength at 1 day was chosen. Values of K_1 were obtained from the expression $K_1 = A5^{1.5W}$, where A is the compressive strength at 1 day, and these values were systematically compared to the other characteristic parameters. The best correlation was established between K_1 and the initial gradient constant, the straight line obtained (Fig. 3) having the form:

$$K_1 = 2.25L - 4300 \qquad [1]$$

where L is the initial gradient constant.

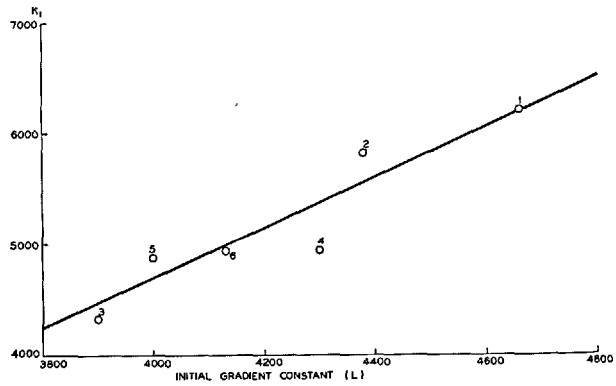

Fig. 3. *Relationship between* K_1 *and initial gradient constant*

Further investigation was then done to relate this gradient to the phase composition.

Lerch (6) studied the influence of additions of SO_3 to mortar mixes made from a wide range of cement types in order to establish optimum SO_3 contents. The optimum amount depended not only on the amount of C_3A present, but also on the alkali content of the cements. As the SO_3 content was increased up to the optimum, the compressive strength at 1 day and subsequent ages increased.

The SO_3 contents in the cements used in this work were close to optimum values. The results obtained must be considered with this in mind. Deviations in SO_3 content from those given in this report may vary Equation [1]. In normal cement manufacture it is unlikely that large deviations would in fact occur and therefore the formula should generally hold for the grade of concrete made in this work.

Another fact arising from the work of Lerch is that the ratio of the optimum SO_3 content to the C_3A content varies in his work from 0.21 for a C_3A content of 14.3 per cent, to 0.79 for a C_3A content of 2.4 per cent. That is, as the C_3A content decreases, the optimum SO_3 content decreases at a slower rate.

Initial Gradient Constant

The initial gradient constant was believed to be related to the proportions of C_3S, C_3A, C_2S, and to the specific surface area of the cement. By successive variations in the constants appropriate to each

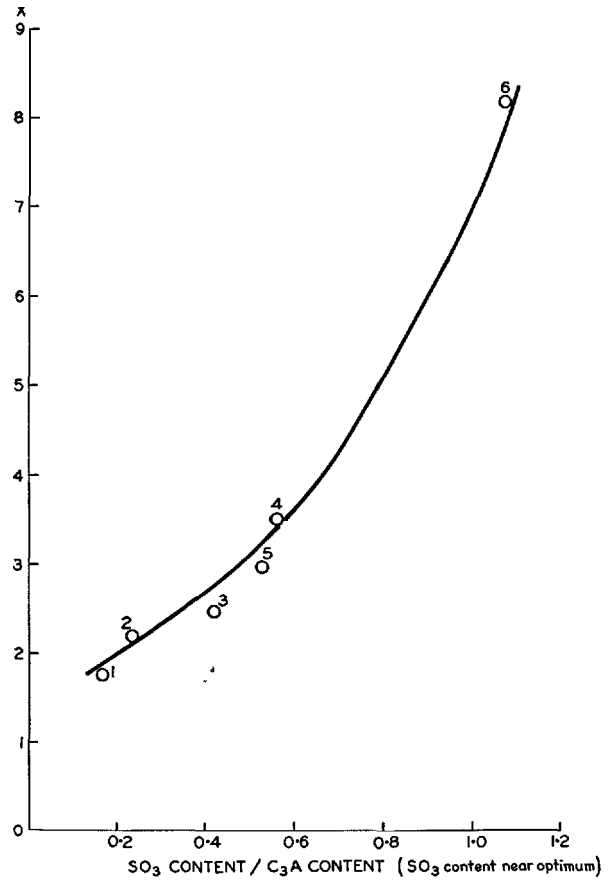

Fig. 4. *Relationship between* X *and* SO_3/C_3A *ratio*

phase component, the following was obtained.

Initial gradient constant =

$$L = 50(C_3S + (X)C_3A + 0.75C_2S)\sqrt{\frac{S}{3500}} \quad [2]$$

where (X) is a function, (see Fig. 4), of the ratio of SO_3 to C_3A, (for optimum or near-optimum values of SO_3 content), and S is the specific surface area, measured by Rigden air-permeability apparatus.

The formula is a 'rate' expression and as such the coefficients of the components do not mean that only a portion of the constituent is acting, but rather that the activity of the various constituents differs. Thus the most active phase is the C_3A (since (X) is greater than 1), followed by the C_3S and then the C_2S.

Second Gradient Constant

A direct relationship between the second gradient constant and the chemical phase composition was not immediately found. When the ratios of the second/initial gradients were compared with the cement composition, however, a linear relationship was established, as shown in Fig. 5.

$$\text{Gradient ratio, } M/L, = 6R - 2.36 \quad [3]$$

where

$$R = \frac{50(C_2S + 0.5C_3S)\sqrt{\frac{S}{3500}}}{L}$$

Expanding the above expression, and substituting for L from Equation [2] we obtain:

Second gradient constant =

$$M = 300\frac{S}{3500}(C_2S + 0.5C_3S) - 2.36\left\{50\sqrt{\frac{S}{3500}}(C_3S + (X)C_3A + 0.75C_2S)\right\}$$

$$= 50(0.64C_3S + 4.23C_2S - 2.36(X)C_3A)\sqrt{\frac{S}{3500}} \quad [4]$$

Thus for the second stage of the strength development the activity of the C_2S is seven times as large of the C_3S, whilst the influence of C_3A is negative.

Although the initial and second gradient constants, and the 1-day compressive strength may be calculated from Equations [1], [2] and [4], it is impossible to predict the strength development completely since the time at which the former gradient gives way to the latter is still unknown. Various attempts to relate the change-over point directly to the phase composition failed. Another approach was to relate the ratio of the 91-day and 1-day compressive strengths to the phase composition.

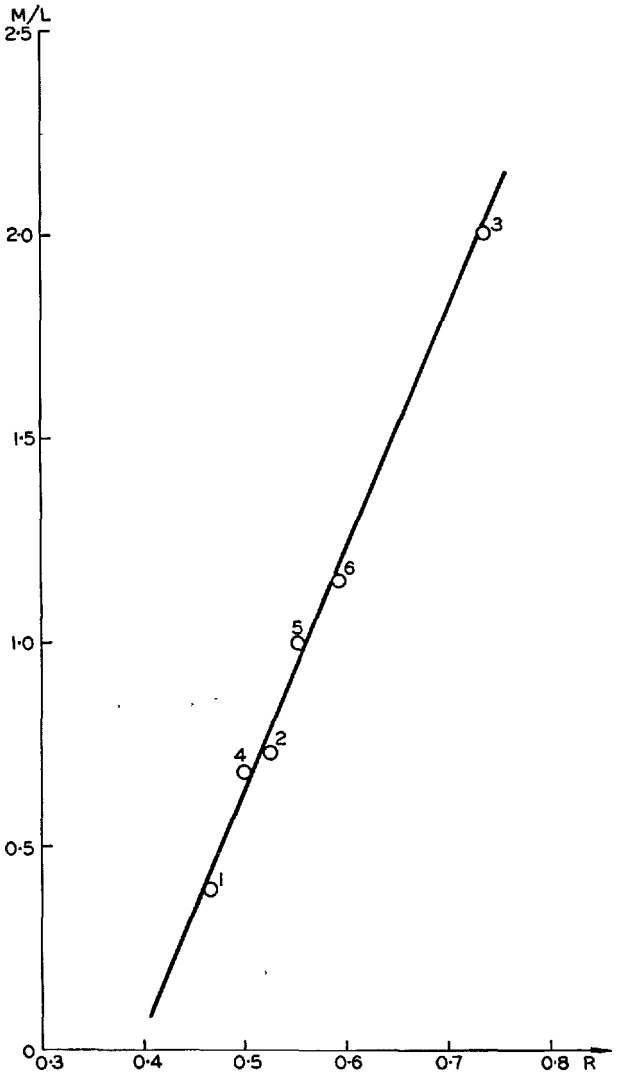

Fig. 5. *Relationship between* M/L *and* R

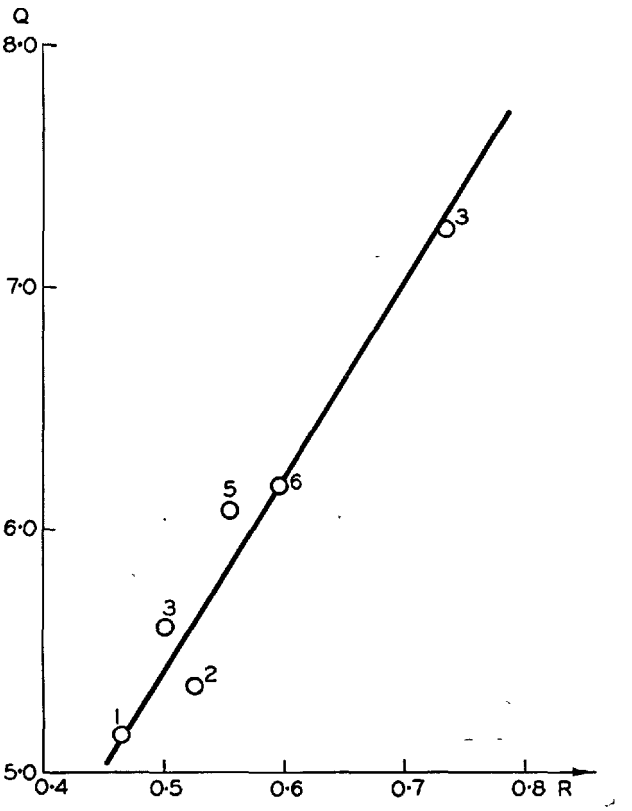

Fig. 6. *Relationship between* Q *and* R

Compressive Strength at 91 Days

To obtain a relationship it was necessary to first divide the ratio of 91-day to 1-day compressive strength, B/A, by the term $\sqrt{S/3500}$. The result is designated by Q. It was found (Fig. 6) that Q is related to R by the expression:

$$Q = 8.2R + 1.3 \qquad [5]$$

where R is as defined above. Thus, substituting for Q, the 91-day compressive strength, B, was found to be:

$$B = A(8.2R + 1.3)\sqrt{\frac{S}{3500}} \qquad [6]$$

where A is the compressive strength at 1 day.

Prediction of Cement Factor

Fig. 7 shows the relationship between the cement factor and the initial gradient constant. The higher the initial gradient, the lower the cement factor necessary to achieve the grade of concrete specified in the

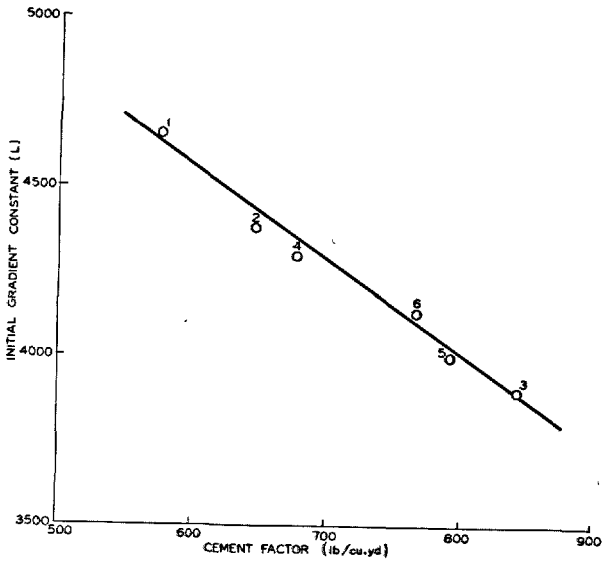

Fig. 7. *Relationship between initial gradient constant and cement factor*

work. The equation of the straight line relationship is:

$$\text{Cement Factor} = 2230 - 0.357L \qquad [7]$$

Prediction of Water/Cement Ratio

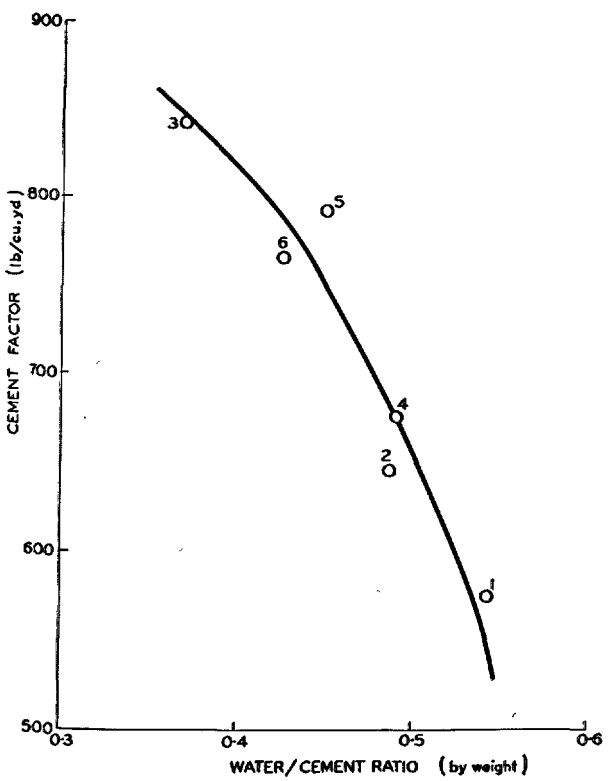

Fig. 8. *Relationship between cement factor and water/cement ratio*

From Table 3 it can be seen that as the cement factor increases the water/cement ratio required (under the circumstances of decreasing sand content) is decreased. This relationship is shown in Fig. 8. For mixes having a cement factor of 800–900 lb/cu.yd, a decrease of 100 lb/cu.yd in cement resulted in an increase of about 0.1 in the water/cement ratio, whereas for the leaner concretes (600 lb/cu.yd cement factor) a similar decrease necessitated an increase of only 0.05 in the water/cement ratio.

From the information on the chemical composition of the cement it is possible, using the above expressions, to calculate the cement factor and water/cement ratio necessary to produce a concrete having the properties specified for this work.

Compressive Strength of Steam-Plus-Fog-Cured Concrete

As mentioned earlier in the report, the 28-day compressive strength of steam-plus-fog-cured con-

crete ranged (depending on the cement) from 98 to 124 per cent of the strength of concrete continuously fog-cured for 28 days.

The steam-cured concrete had a steam maturity of about 1200 deg Chr (based on 0°C) which is equivalent to about 2.3 days at 21°C. If the compressive strength following steam curing is plotted on Fig. 2 at this age, then the rate of development of strength during the subsequent fog-curing to 28 days is, for cements No. 1, 2 and 4 approximately the same as the secondary rate development of the continuously fog-cured specimens. For those cements high in C_2S (No. 3 and 6) the rate of development during the fog curing is lower than the secondary rate of development of continuously-fog-cured specimens, but higher than the initial rate. The gradient constant for the steam plus fog curing condition has been designated by F.

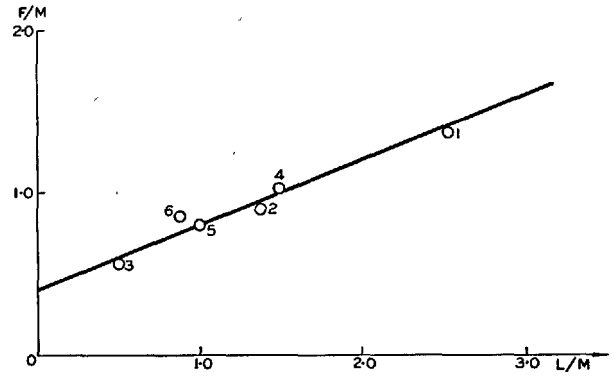

Fig. 9. *Relationship between F/M and L/M*

Fig. 9 shows the relationship between F/M and L/M, from which Equation [8] has been obtained.

$$F = 0.4(L + M) \qquad [8]$$

Accuracy of Strength Prediction

Table 5 sets out the various physical constants of the mixes used in this work, calculated from the above equations. Comparison with the actual values used shows that the prediction of the concrete properties is very good. The cement factor was predicted to within ±5 per cent, the 1-day compressive strength to within +11.2, −6.1 per cent, and the 91-day compressive strength to within +7.1, −4.8 per cent.

The greatest difference between the theoretical and the actual strength values occurred in the case of cement No. 4. In Table 3 it will be noted that the compressive strength after the steam curing is 280 lb/sq.in. below the average value of 5100 lb/sq.in, taken in this work. Thus if in this case the original mix proportion had been adjusted to obtain the higher "ex-steam" compressive strength, then the difference between the theoretical and actual strength development would have been less.

6	4110	−0.5	5010	+5.9	3650	−11.0	4950	+0.05	1690	−4.6	9650	−4.8	760	−0.8

Limitations of Empirical Formula

The expressions obtained in this work apply only to concrete mixes having the same type of ingredients. Variations in the grading of the sand aggregate, the maximum particle size of the stone, the strength level after steam curing and the workability desired will all affect the relationship.

Although the six cements tested cover a wide range of chemical and physical properties, they all have one

aspect in common and it is that the change-over point, from the initial to the second gradient, occurs at ages later than one day. If a cement is so chemically constructed to produce a rapid early strength growth in the first 24 hours, followed by a lower rate of strength growth thereafter, then it is anticipated that such a cement would not follow the pattern of results outlined in this report.

Conclusions

Although the expressions are purely empirical, it is believed that they may provide the basis for some theoretical explanations at a later date.

It is possible to predict with reasonable accuracy the strength-age relationship of fog-cured concrete, proportioned to give a compressive strength of 5100 lb/sq.in. after a steam cycle giving a maturity of about 1200 degChr. Prediction can also be made of the development of strength of steam-cured concrete with subsequent fog curing to 28 days.

The cement factor necessary to produce the above strength can be predicted from the chemical characteristics.

The important characteristics of the cement, from the point of view of the above predictions, are the proportions of C_3S, C_3A, C_2S, the specific surface area and the SO_3/C_3A ratio.

Supplementary Paper III-91 Heat of Hydration of Portland Cement during Steam Curing under Atmospheric Pressure

Hideo Teramoto and Naoya Kawada*

Synopsis

The hydration processes of cement during steam curing are so complicated that it has not been made clear as yet. As a clue for solving the problem, the authors tried to measure the rate of heat liberation of cement paste taking place during steam curing.

The calorimeter used for this purpose consisting of a pair of conduction calorimeters; one for sample and other for dummy. As both calorimeters are equal in heat capacity, effects on change of curing temperature can be canceled and only the heat of hydration of cement paste during steam curing can be measured.

Using the calorimeter, the influence of various curing cycles on the rate of heat liberation of cement was investigated. The relation between peaks of heat liberation and strength, and the mechanisms of hydration at every peak were studied.

Introduction

As the steam curing of concrete is one of the methods effective for hardening acceleration, for obtaining the high strength at early ages, for reducing drying shrinkage and so on, it has become popularly employed in the manufacture of precast concrete. The properties of steam cured concrete are affected by many factors, e.g. time of presteaming, rate of heating, etc. At present, the conditions of steam curing process are determined only by experience alone. While physical properties of steam-cured concrete have been described in detail by many authors, hydration process of cement during steam curing has not been made clear as yet. In order to find suitable steam curing conditions for manufacturing concrete products of excellent quality, it is necessary to clarify the hydration process of cement taking place during steam curing.

The conduction calorimeter is a very useful apparatus for studying hydration process at room temperature, but it cannot be used during steam curing because it is so designed as to determine the heat of hydration at a constant temperature. In order to measure the rate of heat liberation of cement during steam curing, two twin-type calorimeters were designed and tested.

The heat liberation curves were obtained by the calorimeters and the characteristics of reactions occurring at every step of steam curing were investigated.

Calorimeter

The conduction calorimeter developed by Lerch (1) has such a structure as is shown in Fig. 1 and it is useful for studying the kinetics of hydration of cement at early ages.

A sample container made of copper was packed with fresh cement paste, placed on a conduction tube and it was then covered with a Dewar's vessel. The heat of hydration evolving in the sample container flows down through the conduction tube and is released subsequently into the water which is kept at a constant temperature by means of thermo bath. At the top side (A) and the bottom side (B) of the conduction tube, thermodetectors were placed and the difference of temperatures between A and B, which is in proportion to the rate of heat evolution of cement, was determined.

When the curing temperature rises during steam

*Research Laboratory, Nihon Cement Co., Ltd., Tokyo, Japan.

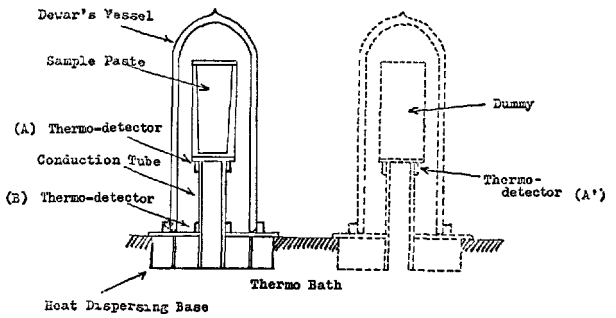

Fig. 1. *Schematic structure of conduction calorimeter and twin-type conduction calorimeter*

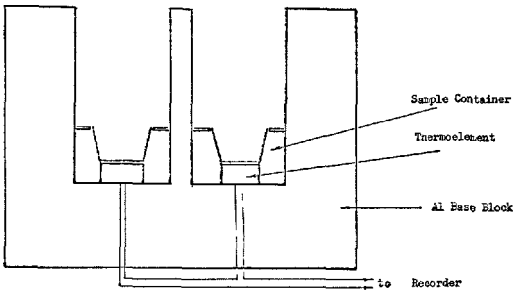

Fig. 2. *Microcalorimeter*

curing, which is the rise of the temperature of water in the thermo bath, heat flows from B to A. Hence, it gives us false information as if endothermic reaction is occurring in the cement paste during the heating period.

In order to remove the structural defect of the conduction calorimeter, an additional conduction calorimeter having the same thermal properties was set in parallel. The container was packed with inactive substance which was equal to the sample in heat capacity, and this was used as a dummy. By detecting the diference of temperature between A and A', the rate of heat liberation of the cement can be obtained without being disturbed by the temperature change. Twin-type calorimeters such as Calvet's calorimeter, the conduction calorimeter designed by Danielsson (2) and the microcalorimeter designed by the Oyo-Denki Lab. (3) are reported. The authors, however, designed two kinds of twin-type calorimeters as follows:

(1) The Oyo-Denki Lab.'s microcalorimeter of special design

The Oyo-Denki Lab.'s microcalorimeter consists of (1) an Al base block about 28 kg in weight similar to the block of DTA apparatus, (2) an insulator to keep the block at uniform temperature and (3) covers with mixing parts. The authors' microcalorimeter consists of only an Al block as shown in Fig. 2. Sample containers are ϕ 54 $\times$ 35 mm in size and are made of copper. The one for a dummy was filled with about 27 g of fly ash paste and the other was filled with about 25 g of cement paste. Each containers were placed on each thermoelement in the Al block. The calorimeter was set in a steam curing bath. As measurement was disturbed by water drops falling on the containers, which condensed on the ceiling of the steam curing bath, covers were placed over the openings of the Al block to shut out water drops.

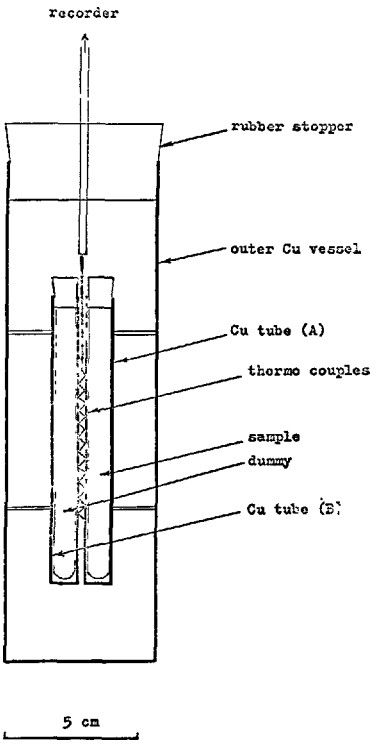

Fig. 3. *Structure of twin-type calorimeter*

This calorimeter, however, has one weak point. Water condenses on the sample container and thermoelement during cooling period of steam curing and disturbs the measurements of the heat liberation.

(2) Twin-type calorimeter devised by the authors

Another twin-type calorimeter as shown in Fig. 3 was designed and tested.

A glass test tube was filled with cement paste, sealed with a rubber stopper and placed in a Cu tube (A). Another glass test tube was filled with

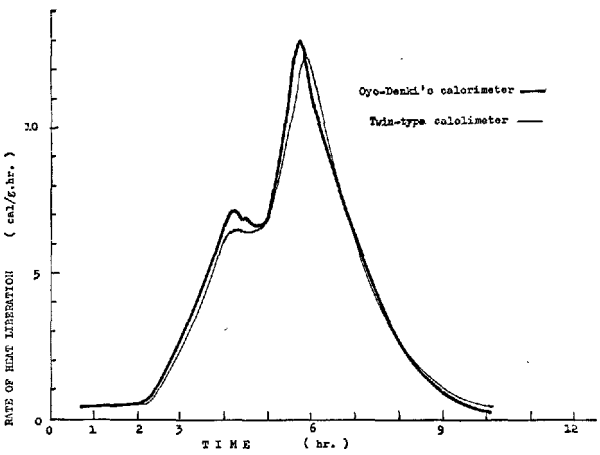

Fig. 4. *Comparison between the two calorimeters*

an inert substance used as a dummy, which had almost the same heat capacity as the cement paste, and was placed in a Cu tube (B). At the space between the Cu tubes (A) and (B), 10 thermocouples arranged in series were installed and were connected with a recorder. The Cu tubes were set in an outer large Cu vessel. The relation between electromotive force of the thermocouples and the rate of heat liberation was determined by standardized electric heater and it showed linear relation up to about 500 cal/hr., but lost its linearity when over 500 cal/hr. This is probably due to the temperature difference between the tube B and the outer vessel, which is caused by the accumulation of heat in tube B, into which much more heat flows from the tube A than that which flows from the tube B to the outer vessel when the heat generation in the tube A is high.

At the period in which curing temperature rises at high rate, e.g. at the rate of 40°C/hr, the temperature difference between the outer and the inner Cu vessel reaches as much as 2°C. If the diameter of outer vessel can be decreased, the temperature difference between the outer and the inner vessels being reduced, the relation between the electromotive force of the thermocouples and the rate of heat liberation can be improved.

(3) Comparison between both calorimeters

Curves of the rate of heat liberation shown in Fig. 4, were obtained by each calorimeters using the same program of steam curing. The results obtained were almost the same. According to the test results, whether the air surrounding the cement paste is saturated with water vapour or not seems to be of little importance to the rate of hydration of cement.

Measurement of Volume Changes of Cement Pastes during Steam Curing

Much has been reported on the volume change of cement paste at early ages during constant temperature curing, but there are only a few reports on that occurring during steam curing.

The volume of cement paste decreases by early hardening process, which is called "intrinsic shrinkage" or "autogenous shrinkage". But, the volume increases with the rise of curing temperature. As both shrinkage and expansion take place during steam curing, complicated volume changes were noted.

Homma's method (4), which is available for determining volume changes of cement paste at constant temperature, was applied to obtain the informations on the volume changes taking place during steam curing. Fresh cement paste was filled in a thin rubber container having a capacity of about 20–30 ml, taking cares not to bring air bubbles into the container, and this was sealed tightly with a bakelite stopper having a curved surface so as to prevent occurrence of void between the stopper and cement paste, as shown in Fig. 5. The sample thus prepared was suspended in water kept at a given temperature and was connected with a chemical balance, and its weight in water was measured. When the sample paste shrinks, its weight in water increases. The contracted volume of cement paste can be obtained by multiplying density of water at a given temperature by the increased weight of sample in water. During steam curing, the surface of water in the thermo bath was

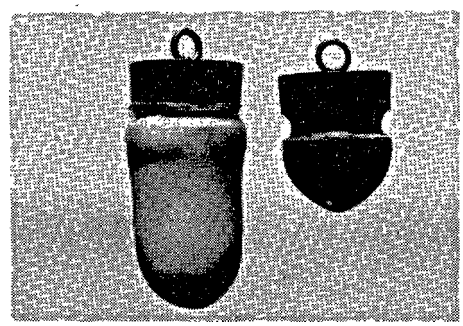

Fig. 5. *Rubber container and bakelite stopper for measuring volume change*

Fig. 6. *Apparatus for measuring the rate of heat liberation and the volume change*

covered with liquid paraffin so as to keep it at constant level. Water which had been boiled to expel dissolved air was filled in the thermo bath, so as to prevent the clinging of air bubbles on the sample by heating and causing thereby a decrease of weight of the sample in water. By an automatic recording thermal balance reconstructed for this purpose, changes of weight in water were determind. The apparatus is shown in Fig. 6.

Effects of SO_3 Contents in Cement on the Heat Liberation Curves during Steam Curing

By mixing gypsum with normal portland cement clinker, cements having various SO_3 contents (1.8, 2.3, 2.8 and 3.3%) were prepared. The fineness of the cements was about 3600 cm^2/g by the Blaine method. After the cement paste with W/C = 0.4 was cured at 25°C for 5 hours, it was heated at the rate of 20°C/hr up to 75°C and cured at this temperature thereafter.

The results are shown in Fig. 7.

The heat liberation curve of the sample cured at 20°C is also shown for reference. As the cements of four kinds gave nearly the same heat liberation curves at 20°C, the curve representing them is that of the cement with 1.8% SO_3 content.

Just after beginning of heating, the rates of heat liberation curve showed lower values than the one cured at 20°C, but a little later it increased rapidly in every case of cements.

Eleven hours after mixing, the rate of heat liberation of cement paste cured at 20°C reached the highest peak and this figure was 2.2 cal/g.hr. During steam curing, the peaks of heat liberation curve appeared at the hours 8 to 9 after mixing, and their heights were about 12 or 13 cal/g.hr., which were 5 to 6 times higher than that of sample cured at 20°C.

After passing the peaks, the rate of heat liberation of steam cured sample decreased rapidly and fell below 0.5 cal/g.hr. at 15 hours.

Sample paste prepared from cement with 1.8% SO_3 showed two peaks of heat liberation at 7 and 9.5

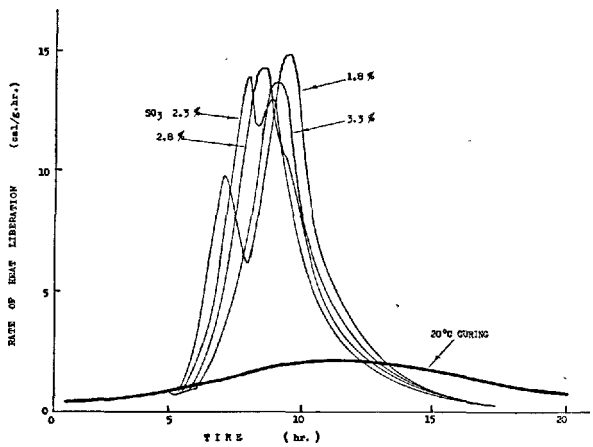

Fig. 7. *Effects of* SO_3 *contents in cement on the heat liberation curves during steam curing*

hours after mixing, and that with 2.3% SO_3 also showed two peaks at 8 and 9 hours after mixing. They had two different hydration steps. The first peak may be dependant on rapid hydration of aluminate phase in cement and this will be discussed later. The latter peak depends on hydration of alite. The samples prepared from cement with 2.8% and 3.3% SO_3 showed only one peak, because the two hydrations occurred almost simultaneously.

Effects of Time of Presteaming on Strength and Heat of Hydration

The time of presteaming is one of the most important factors which affects the strength of steam cured concrete products. O.P. Mchedlov-Petrosyan, A.G. Bunakov and Ju. L. Vorodyov (5) stated that the optimum preheating time would be determined from the heat liberation curve of concrete, and that the time immediately after the curve passes the peak should be chosen. In this section, the relation between

the rate of heat liberation and compressive strength of specimens cured at various presteaming times and by the same steam treatment is discussed.

Specimens for strength test ($\phi 5 \times 10$ cm) were prepared by molding a mixture of 1241 g of portland cement, 2308 g of natural sand and 517 ml of water, and for the calorimeter test the same mixture was filled in a test glass tube. The specimens for strength test in molds and the specimens for heat liberation test placed in the twin type calorimeter mentioned above were cured at 20°C for a given period of time, and then heated in a steam curing bath. Conditions of steam curing were as follows;

Temperature of presteaming	20°C
Time of presteaming (hours)	1/4, 1/2, 1, 2, 4, 8 and 16 (7 levels)
Rate of heating	20°C/hr.
Temperature of isothermal curing	85°C
Time of isothermal curing	5 hr.
Rate of cooling	20°C/hr.

When the temperature fell to 30°C in the cooling period, the specimens were brought out of the steam curing bath, taken out of the molds and then cured in water at 20°C. The compressive strength was examined 1 hour after the specimens were brought out of the steam curing bath and 28 days after mixing.

Fig. 8 shows the results of the strength test and Fig. 9 gives the rate of heat liberation.

The thick line in Fig. 9 shows a heat liberation of cement hydrated at 20°C. According to the view of Mchedlov-Petrosyan et al., the presteaming time of 8 to 9 hours seems to be most appropriate, because the heat liberation curve at 20°C shows the maximum at 8 hours. Compressive strength at 28 days increased with the increase of presteaming time up to 4 hours, and decreased when presteaming time was longer. Compressive strength at 1 hour after steam curing showed higher value with the increase of the presteaming time. Considering the above results, it may be concluded that the presteaming time should be determined in accordance with the conditions necessary for practical performances instead of heat liberation curve of concrete.

The heat liberation curves of the test samples cured with presteaming time shorter than 4 hours had two sharp peaks appearing at a intervals of 1 to 2 hours, the first peak being due to the hydration of aluminate and the second due to the hydration of silicate. With 4 hours' presteaming, both reactions occurred almost

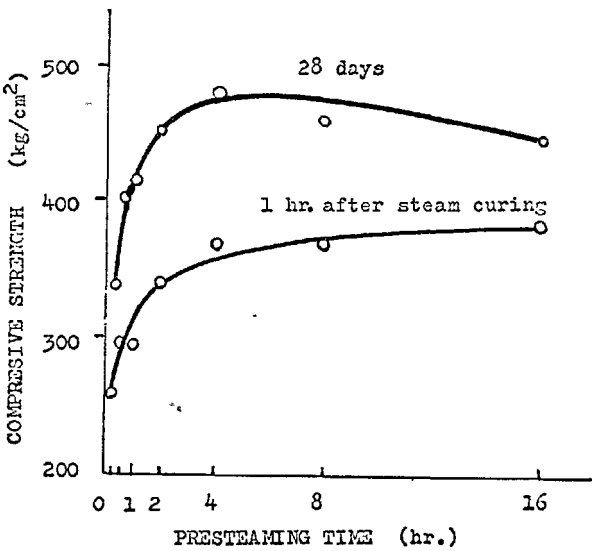

Fig. 8. *Effect of the time of presteamig period on strength*

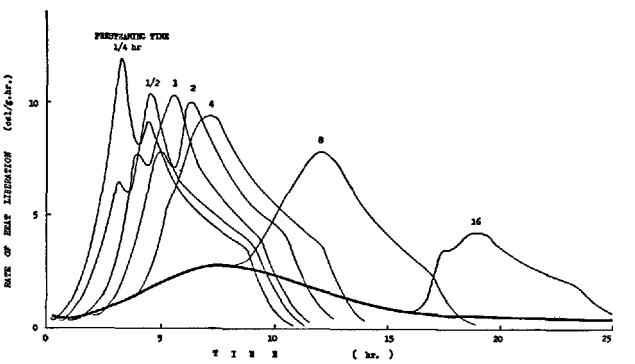

Fig. 9. *Effect of time of presteaming period on the rate of heat liberation*

at the same time. With longer presteaming period, a low and gentle peak appeared. With 16 hours curing at 20°C, the hydrated products covered the surface of the unhydrated cement particles, the rate of diffusion of water through the film of the hydrated products fell, and the rate of heat liberation of cement decreased to almost zero. When the sample was heated at this condition, the diffusion of water through the film of hydrated products was activated by rising temperature and the hydration became active again. But the rate of heat liberation decreased again in a short time, presumably due to filling up of the capillary pores of cement paste with hydration products appearing as a result of the hydration. This may be the reason why a steam cured mortar showed high strength immediately after steam curing, but exhibiting relatively low strength development at the later stage.

Hydration of C_3S during Steam Curing

C_3S used in this investigation was made from the mixtures of chemical reagents heated repeatedly in an electric furnace until free CaO content fell below 0.1 %. It was pulverized to the fineness of 3600 cm^2/g by the Blaine method, and the sample paste was prepared with $W/C_3S = 0.4$. The pastes were cured under following conditions;

No.	1	2	3	4	5
Presteaming period (hr)	cured at 20°C	2	5	2	5
Rate of heating (°C/hr)		20			
Temperature of isothermal curing (°C)		60		80	
Time of isothermal curing (hr)		17.5	14.5	15.5	12.5
Rate of cooling (°C/hr)		20			

The results are shown in Figs. 10-14.

The rate of heat liberation of C_3S cured at 20°C (No. 1), began to rise from about 3 hours after mixing, passed through the maximum about 10 hours after and decreased gradually thereafter. The volume of C_3S-paste continued to shrink until 24 hours after mixing and it was high in proportion to the rate of heat liberation.

The rate of heat liberation in curing No. 2 was closely equal to that of No. 1 until 1.5 hours after start of heating. It may be concluded from the results that nucleation process of calcium silicate hydrate is not accelerated by heating. After the paste had reached the potential sufficient for nucleation, the hydration of C_3S was accelerated by the rising temperature and the rate of hydration increased rapidly. At 4.9 hours after mixing, the rate of heat liberation reached the maximum and its peak was 18.1 cal/g.hr., which was 3 times as high as No. 1. The rate of heat liberation then dropped rapidly and 9 hours after mixing it was less than 2 cal/g. hr. The C_3S-paste expanded after the beginning of heating, but shrank after the end of the dormant period.

With longer presteaming time, (No. 3 and No.5) the rate of heat liberation increased as soon as the heating began.

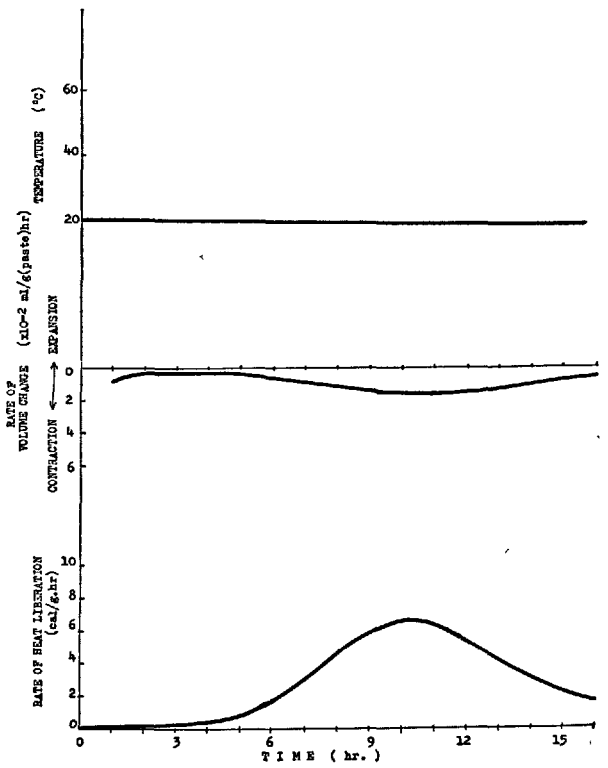

Fig. 10. *Hydration of C_3S cured at 20°C (No. 1)*

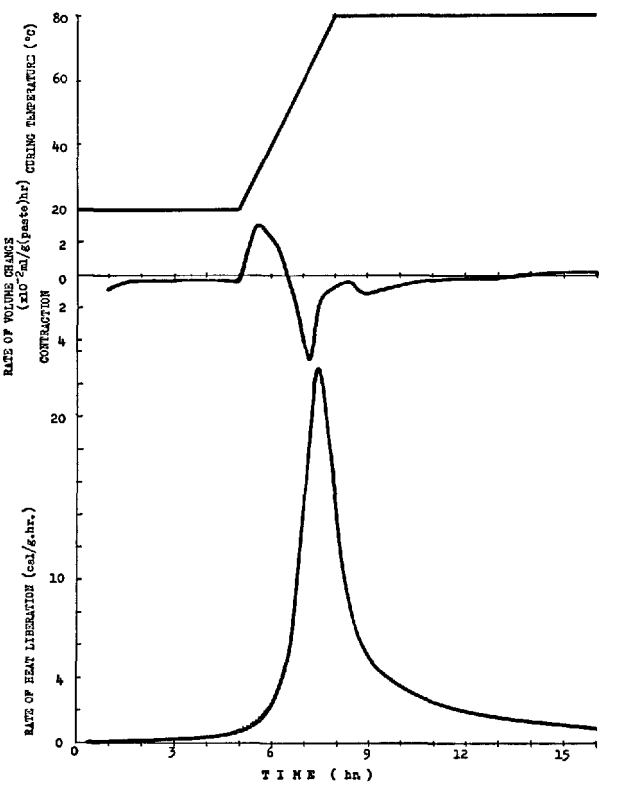

Fig. 14. *Hydration of* C_3S, *presteaming time 5 hrs, curing temperature 80°C (No. 5*

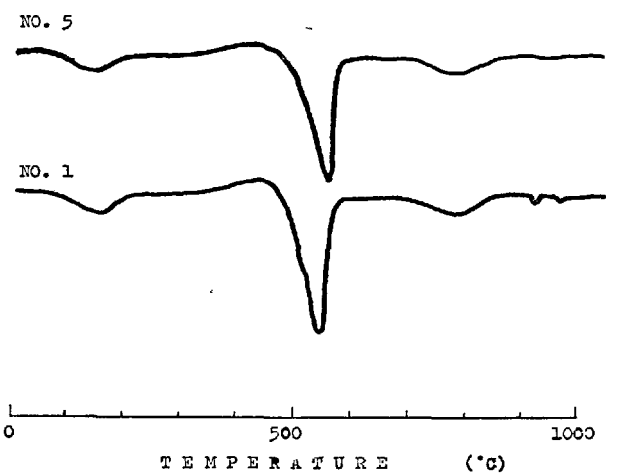

Fig. 15. *DTA curves of* C_3S *paste curves at 80°C (above) and 20°C (below) (24 hours aftermixing)*

The highest rate of heat liberation was 23.0 cal/g.hr. of No.5. The height of the peak of No.3 was nearly equal to that of No.2. With isothermal curing at 60°C, the height of the peak of heat liberation curve de-

creased proportionally to the length of presteaming time, but the situation was quite contrary at 80°C.

Amounts of nonevaporable water of C_3S-paste at 24 hours after mixing were as follows, and practically no difference was observed among them; No. 1 10.5%, No. 2 9.1%, No. 3 10.1%, No. 4 11.2% and No. 5 11.6%.

The hydration products in the pastes occurring when cured at the raised temperature were thought to be of the same kind as those occurring when cured at 20°C according to DTA (see Fig. 15).

Hydration of β–C_2S during Steam Curing

β-C_2S having 1% Cr_2O_3 content as stabilizer was prepared by heating a mixture repeatedly until free CaO disappeared and was ground to the fineness of 2800 cm^2/g by the Blaine method. Sample paste prepared with $W/C_2S = 0.4$ was cured in accordance with the program shown in Fig. 16.

It shows that the rate of heat liberation was increased by heating but it did not reach 1 cal/g.hr. even when heated at 80°C, and that the sample pastes did not harden in 24 hours. It may be concluded therefore that the steam curing has only a small effect on the rate of hydration of β-C_2S.

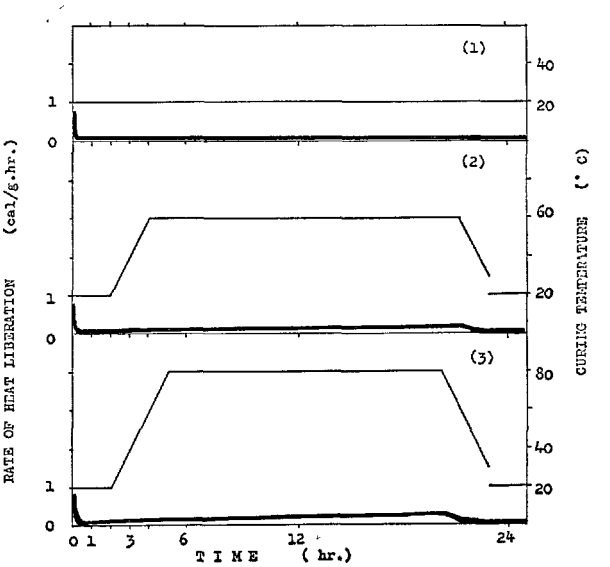

Fig. 16. *Rate of heat liberation of* C_2S *at various curing conditions*

Hydration of C_3A during Steam Curing

C_3A prepared by burning a mixture of chemical reagents in an electric furnace was ground to the fineness of 3100 cm^2/g by the Blaine method. Mixing of 800 g of C_3A and 160 g of gypsum (88μ under) was made. In consideration of the fact that low W/solid-ratio may possibly hinder perfect hydration owing to lack of water, the sample pastes were prepared with W/solid = 1. The prepared samples were cured at 20°C (Fig. 17) and treated in accordance with the programs shown in Fig. 18 and Fig. 19.

The reaction of C_3A with gypsum was accelerated with the rising temperature and all gypsum in the mixture were spent at early ages. After the gypsum in the mixture were totally consumed, the hydration proceeded rapidly and the paste hardened. Results of DTA (Fig. 20) shows that the hydration product formed before the disapperance of gypsum was trisuphate hydrate and this later became monosulphate and C_3AH_6. W. Lieber (6) reported that C_3A reacts with gypsum at high temperature and forms trisulfate hydrate. The results of DTA show that the formation of trisulphate hydrate will take place as long as gypsum remains in paste.

The paste was expected to expand with the formation of trisulphate hydrate, but it showed contraction through the curing period except at the time of 10 hours after mixing. This may be due to the presence of large amount of water in the paste.

The paste expanded at the beginning of steam curing because of the expansion of free water in the paste. When the rapid hydration occurred with the disapperance of gypsum, the volume of paste contracted at a high rate. After that, the rate of contraction gradually decreased in case of 60°C curing, but the paste expanded in case of 80°C curing and the rate of expansion gradually decreased with the

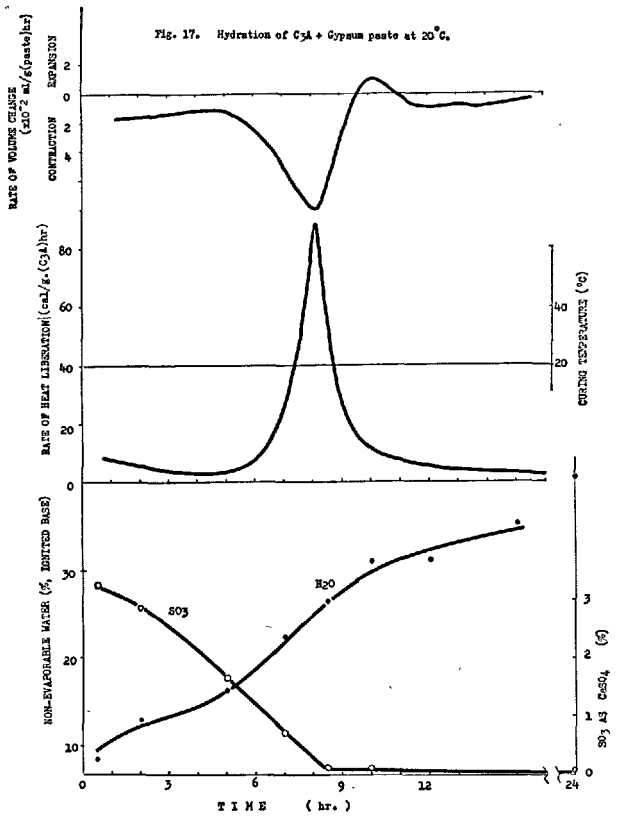

Fig. 17. *Hydration of* C_3A + *Gypsum paste at 20°C*

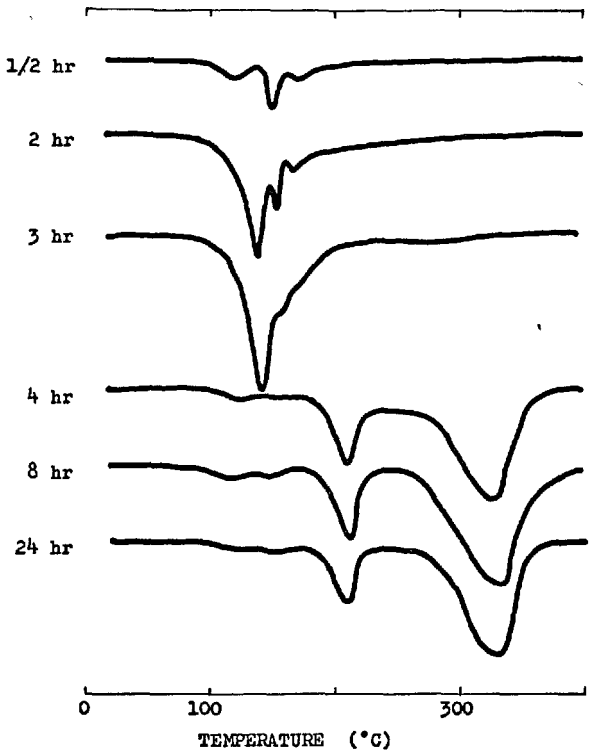

Fig. 20–3. *DTA curves of* C_3A + *Gypsum cured at 80°C*

lapse of time.

The degrees of hydration of C_3A after 24 hours were 75, 65 and 63% with curing temperatures of 20, 60 and 80°C respectively. It shows that the rate of hydration of C_3A after 24 hours decreases with the rise of temperature. The amount of non-evaporable water has the same tendency as the rate of hydration; 40.7% for 20°C, 31.4% for 60°C and 30.1% for 80°C (on ignited base). The difference between the amounts of non-evaporable water for 20°C curing and that for 60°C and 80°C was probably due to the difference in ratios of monosulphate-C_4AH_n solid solution to C_3AH_6 of these samples.

Hydration of C_4AF during Steam Curing

C_4AF prepared by burning a mixture of chemical reagents in an electric furnace was ground to the fineness of 4200 cm^2/g by the Blaine method.

In the hydration of system C_4AF + gypsum, the formation of trisulphate hydrate decreases the calcium concentration in the liquid phase. It seems that the hydration of C_4AF in portland cement was different from that of the mixture of C_4AF and gypsum, because the former proceeded in the solution of high calcium concentration and the latter in low concentration. For this reason, 360g of C_4AF was mixed with 54 g of $Ca(OH)_2$ and 108 g of gypsum ($<88\mu$).

The sample pastes were prepared with W/solid = 0.5. The prepared samples were cured under three kinds of heat treatment as shown in Figs. 21-23.

The rate of heat liberation for curing temperature of 20°C is small until 24 hours, except for a certain period after mixing when rapid reaction takes place. The pastes contracted at nearly constant rate. The DTA curve of the paste at 24 hours shows that large amount of gypsum still remains (see Fig. 24) (endothermic peaks at 150° and 180°C).

The rate of heat liberation of paste cured at 60°C increased as soon as heating started. When it reached to 6 or 7 cal/g.hr., the heat liberation curve kept a constant level until 10 hours. At 11 hours, a steep peak appeared. It was caused by the rapid hydration of C_4AF taking place immediately after the gypsum

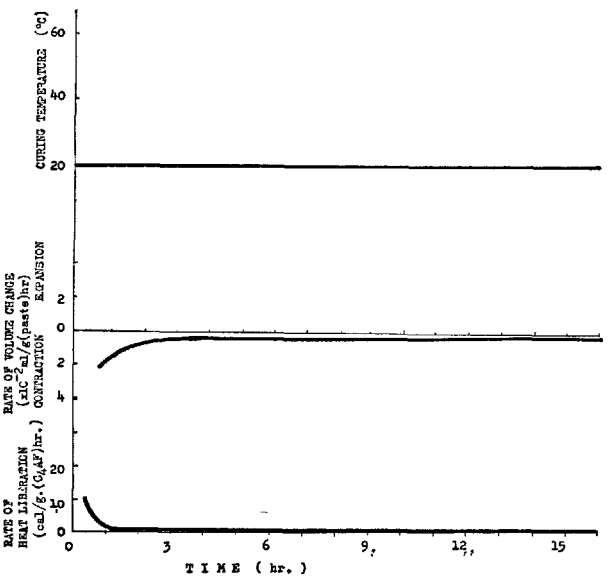

Fig. 21. *Hydration of* C_4AF + *Gypsum* + $Ca(OH)_2$ *cured at 20°C*

in the mixture had been spent for the formation of trisulphate hydrate. The paste hardened at this hydration. While the gypsum remained in the paste the

hydration product was trisulphate hydrate, but after the disappearance of gypsum trisulphate hydrate was decomposed and formed $C_3(A, F)H_6$ and monosulphate-$C_4(A, F)H_n$ solid solution. The paste expanded during the heating period and shrank at the early period of isothermal steam curing. The rate of volume contraction decreased gradually with the lapse of time and at 8.5 hours the paste began to expand. It may have been caused by the formation of trisulphate hydrate. The rapid hydration of C_4AF caused by the disappearance of gypsum brought about the volume contraction of the paste. After the peak of heat liberation, the rate of volume contraction fell rapidly to almost zero.

The reaction of C_4AF with gypsum was more accelerated at 80°C than at 60°C curing, and the peak of heat liberation closed by the disappearance of gypsum in the paste occurred at early ages. After the appearance of the peak, the rate of heat liberation fell down to 1 or 2 cal/g.hr. The hydration product was trisulphate hydrate at first but after reaching the peak monosulphate-$C_4(A, F)H_n$ solid solution hydrate and $C_3(A, F)H_6$ resulted. The paste expanded during the heating period and contracted after the rapid reaction owing to the disappearance of gypsum in the mixture took place. The cycle of contraction and expansion and contraction occurring in 60°C curing, expansion first by heating and contraction caused by rapid hydration, did not take place in 80°C curing. After reaching the peak of heat liberation the paste expanded. After the disappearance of gypsum in the paste, the hydration of the phase containing alumina caused contraction of the paste by 60°C curing and expansion of the paste by 80°C curing.

Hydration of Normal Portland Cement during Steam Curing

Studies of hydration process of normal portland cement during steam curing were made from the scopes of the heat liberation and volume change. It was studied in relation to the results of hydration of each compounds mentioned above.

Normal portland cement used for the experiments had components of 48% C_3S, 28% C_2S, 9% C_3A, 9% C_4AF and 3.1% $CaSO_4$ according to Bogue's formula. Sample pastes were prepared with W/C = 0.4 at 20°C. The pastes were cured by 8 kinds of heat treatments as follows;

No.	1	2	3	4	5	6	7	8
Time of presteaming (hr)	cured at 20°C	2	5	1/2	1	2	5	10
Rate of heating (°C/hr)		20						
Temperature of isothermal curing (°C)		60		80				
Time of isothermal curing (hr)		17.5	12.5	17.0	16.5	15.5	12.5	7.5
Rate of cooling (°C/hr)		20						

The heat liberation of sample No. 1 cured at 20°C, was small during the dormant period which lasted for about 2 hours, but it increased after that period and reached the maximum at 9.5 hours. Its peak was 2.8 cal/g.hr. The rate of heat liberation decreased gradually thereafter. The sample contracted continuously up to 24 hours after. When the rate of heat liberation reached the peak, the contraction rate of volume also reached the maximum. SO_3 as calcium sulphate contained in the cement paste decreased with the lapse of time and was almost completely spent for the formation of trisulphate hydrate at 12 hours. In the paste of C_3A + gypsum mentioned above, the rapid hydration occured when gypsum in the paste was totally spent for the formation of trisulphate hydrate. In the paste prepared from portland cement, however, a peak which should have been caused by the disappearance of gypsum did not appear.

In the heat treatment of No. 2, the heat liberation curve of the cement paste showed that the hydration

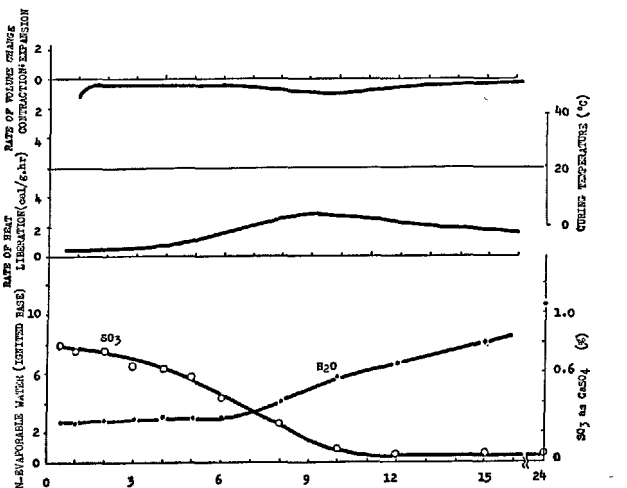

Fig. 25. *Hydration of normal portland cement cured at 20°C (No. 1)*

of cement still remained in the dormant period after the beginning of heating.

The paste expanded due to the thermal expansion of water. After 3 hours, curing temperature rose to above 40°C, the rate of heat liberation increased rapidly and the hydration of cement changed from the dormant period to the active period. The change of volume altered from expansion to contraction. At 5 and 6.5 hours after the mixing two peaks of heat liberation occurred. The first was the sharp and high peak (17 cal/g.hr.) accompanied by the contraction of the paste. It appears to be that this peak of heat liberation was caused by the hydration of aluminate owing to the disappearance of gypsum. Gypsum in the cement paste decreased rapidly during the period of 2 to 5 hours after mixing and SO_3 as calcium sulphate dropped to only 0.05% at 5 hours (as shown in Fig. 26). The latter peak was gentle and shaped like a shoulder of the first. It seems that this peak arose from the hydration of silicate. The hydration of silicate in C_3S-paste caused the volume of paste to contract as described above, but in the case of portland cement paste, it caused a slight expansion. Results of DTA show that before the appearance of the first peak, trisulphate hydrate (endothermic peak at 120°C) was formed, but this product decreased in course of time to form monosulphate-C_4AH_n solid solution hydrate (endothermic peak at 220°C). Both of the endothermic peaks became broad and indistinct after 1 week.

In case of No. 3, the rate of heat liberation and the rate of volume change showed the same tendency as those in No. 2. The height of earlier peak caused by absence of gypsum was lower than that of No. 2.

A notable difference between hydration processes at 60°C curing and at 80°C curing is shown by the heat liberation curves of No. 2 and No. 6. Three peaks appeared in the heat liberation at 80°C curing, the first at 4.8 hours, the second at 5.1 hours and the last at 6 hours. The former two were not so sharp as the last, and these peaks appeared successively one after another. As free $CaSO_4$ dropped to the minimum at 4.5 hours, it seems that the first peak came to appear by the rapid hydration of aluminate owing to the absence of gypsum. SO_3 as calcium sulphate increased again at 5 hours. At this time the temperature of curing was 80°C. DTA curves show that trisulphate hydrate was found formed up to 4.5 hours and at 5 hours trisulphate hydrate and monosulphate hydrate appeared. After 5.5 hours, endothermic peaks became indistinct. P.P. Budnikov and Ya. Erschler (7) reported that the transition of hydrosulpho-

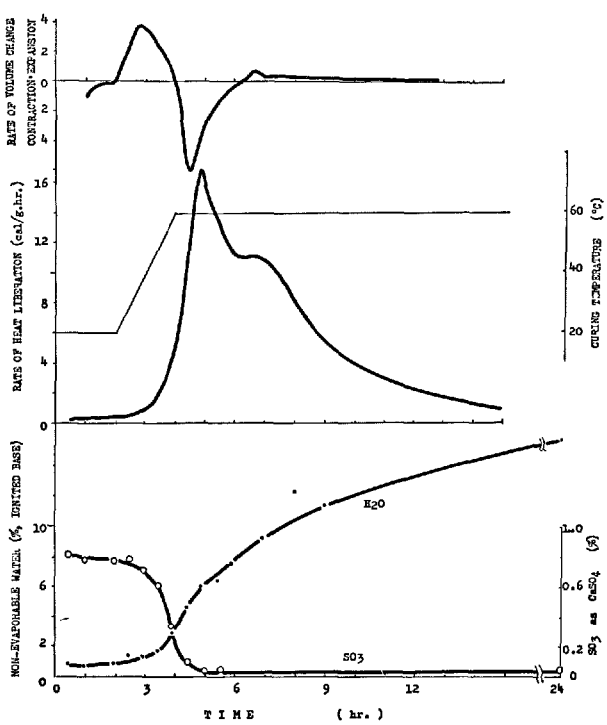

Fig. 26. *Hydration of normal portland cement. presteaming time 2 hrs, curing temperature 60°C (No. 2)*

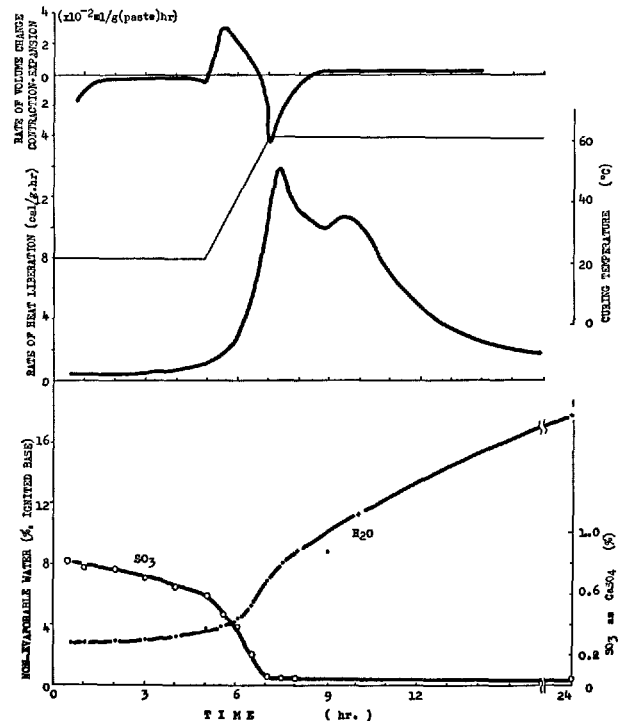

Fig. 27. *Hydration of normal portland cement, presteaming time 5 hours, curing temperature 60°C (No. 3)*

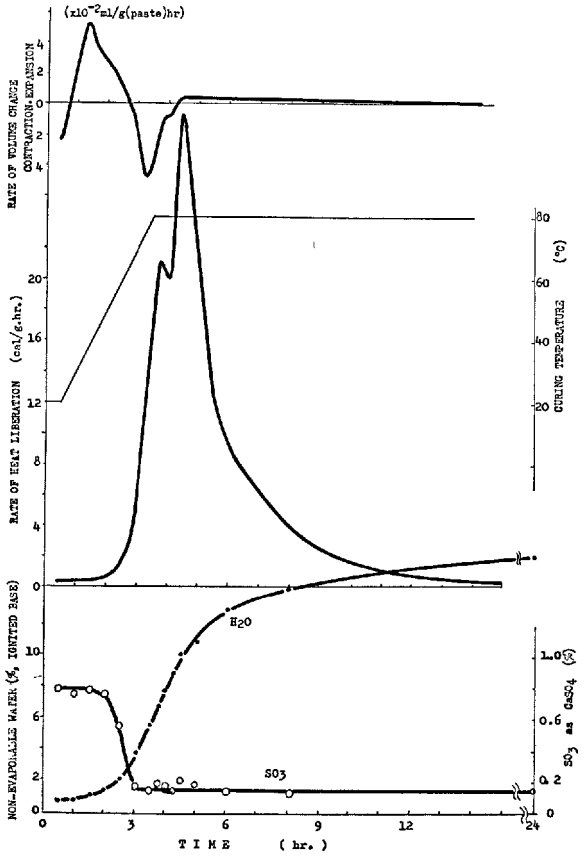

Fig. 28. *Hydration of normal portland cement, presteaming time 0.5 hr, curing temperature 80°C (No. 4)*

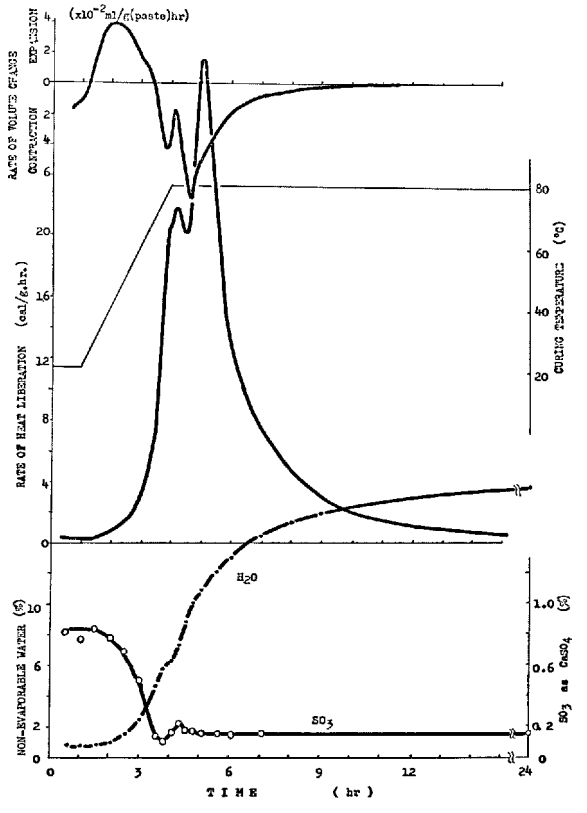

Fig. 29. *Hydration of normal portland cement, presteaming time 1 hr., curing temperature 80°C (No. 5)*

compounds into the low sulphate takes place; this was accompanied with the release of free $CaSO_4$ under the influence of high temperature and a liquid phase saturated with $Ca(OH)_2$. From the facts of increase of free $CaSO_4$ and disappearance of tri-and mono-sulphoaluminate hydrates as shown by DTA, it may be concluded that the second peak appeared owing to the partial decomposition of aluminate hydrates.

The third peak was the highest of all and it was caused by the accelerated hydration of silicate phase.

At every step of hydrations, the volume contracted in high rate. After the occurrence of the third peak, the volume expanded for a while, but thereafter the paste maintained its constant volume.

In both cases of shorter and longer presteaming period than that of No. 6, two peaks appeared. With shorter presteaming period (No. 4 and No. 5), the amount of SO_3 as gypsum decreased with the lapse of time, but as the release of SO_3 occurred before SO_3 in cement was spent for the formation of trisulphate hydrate, a peak of heat liberation due to the disappearance of gypsum did not appear. Therefore, the first peak is considered as showing the hydration owing to the release of SO_3 and the second as showing the hydration of silicates.

With longer presteaming period (No. 7 and No. 8), gypsum in cement was used up for the formation of trisulphate hydrate during the heating period and a peak of heat liberation caused by the rapid hydration of aluminate appeared. When the curing temperature was raised up to 80°C, trisulphate hydrate formed should have decomposed, as was shown in the case of No. 8, that is, SO_3 as gypsum dropped to the amount less than 0.1% at 12 hours and increased to 0.2% at 13.5 hours. The peak of heat liberation was accompanied with the decomposition of trisulphate hydrate, perhaps overlapped with a large and sharp peak caused by the hydration of silicate.

In all of the cases except No. 7, the paste con-

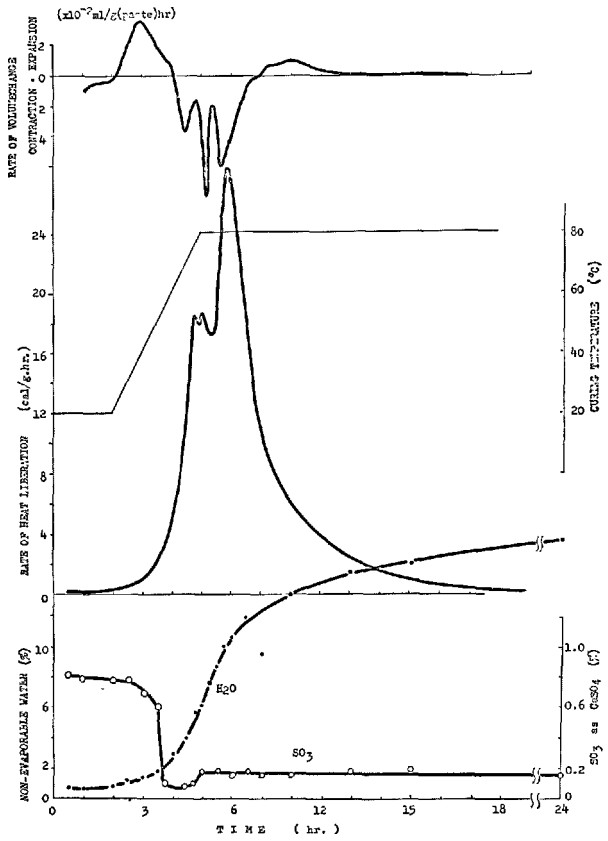

Fig. 30. *Hydration of normal portland cement, presteaming time 2 hrs, curing temperature 80°C (No. 6)*

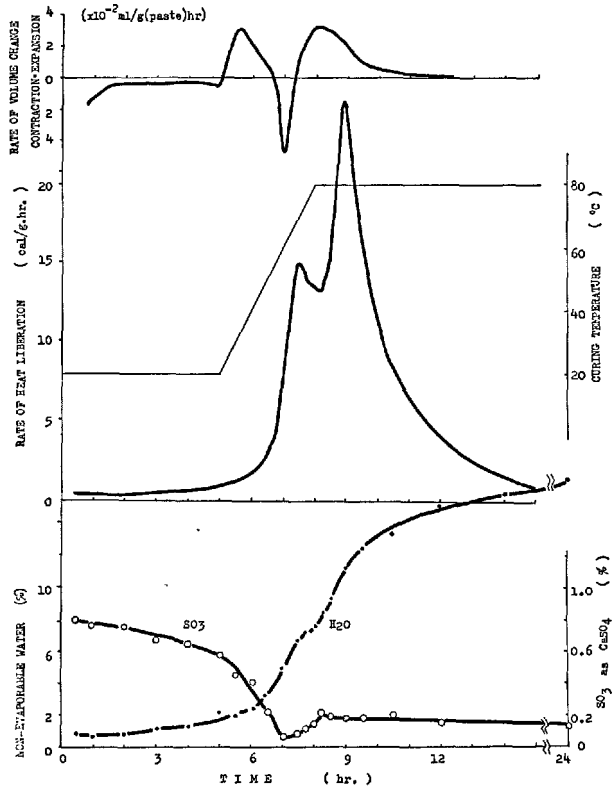

Fig. 31. *Hydration of normal portland cement, presteaming time 5 hrs, curing temperature 80°C (No. 7)*

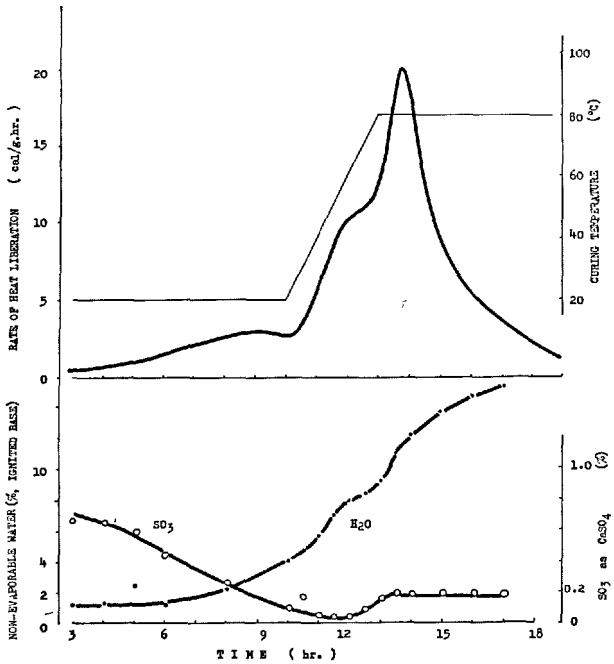

Fig. 32. *Hydration of normal portland cement, presteaming time 10 hrs, curing temperature 80°C (No. 8)*

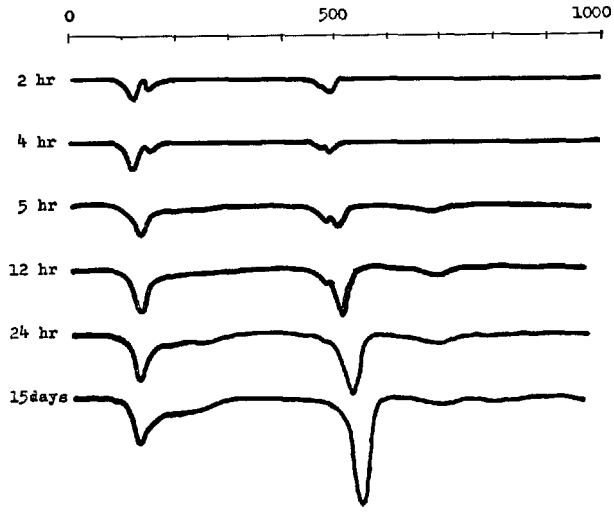

Fig. 33–1. *DTA curves of normal portland cement paste cured at 20°C (No. 1)*

tracted when the hydration of silicate took place, and in case of No. 7, it expanded. This expansion may be attributed to the hydration of silicate taking

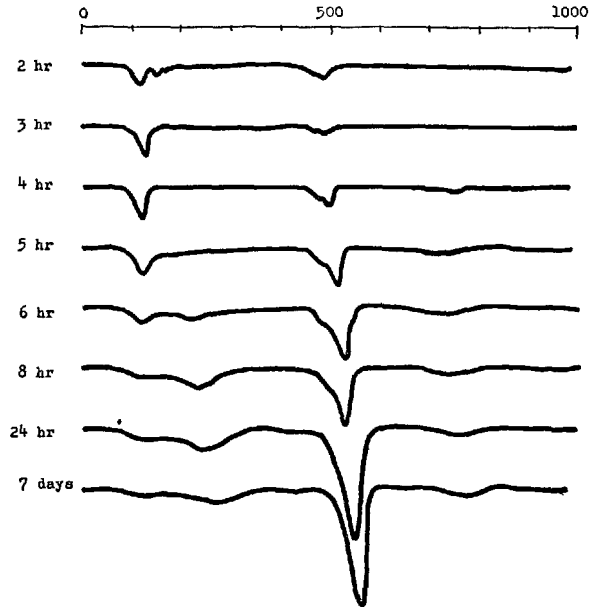

Fig. 33–2. *DTA curves of normal portland cement paste cured at 60°C (No. 2)*

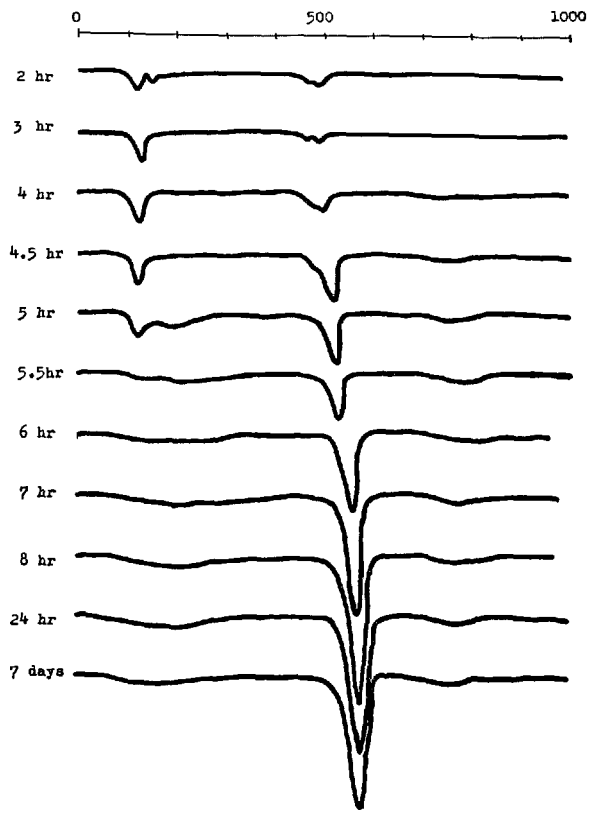

Fig. 33–3. *DTA curves of normal portland cement paste cured at 80°C (No. 6)*

place after the hardening of the paste.

Shorter presteaming time brought about a heat liberation curve with a sharp and eminent peak, but sharpness and height of the peak decreased with length of presteaming time. This may be due to the extent of early hydration of cement.

By 60°C isothermal curing, a heat liberation curve having one sharp and high peak and another gentle peak were obtained, the first owing to the disappearance of gypsum and the latter due to the hydration of silicate. At the temperature of 80°C, a heat liberation curve having a low peak, due to the disappearance of gypsum, and a high peak, due to the hydration of silicate, were obtained.

General Conclusion

For a better understanding of the hydration process of cement taking place during steam curing under atmospheric pressure, the authors tried to determine the rate of heat liberation, and were able to obtain useful informations on the effects of steam curing on the rate of hydration, the steps of hydration and so on. For this purpose, twin-type calorimeters were designed and tested. In addition, they tried to determine the volume change taking place during steam curing.

The rates of heat liberation were measured under various conditions of steam curing, and the hydrations occurring during process which caused to reveal peaks of heat liberation were studied.

Generally speaking, one or two peaks of heat liberation took place. These peaks were caused by the hydration of silicate, which was accelerated by heating 3 or more times higher than when cured at 20°C, and by the hydration of aluminate which was caused by the disappearance of gypsum. In some cases, these hydrations took place simultaneously. In the case of isothermal curing at 80°C, another peak of heat liberation appeared by the hydration of aluminate which may have been caused by a partial decomposition of trisulphate hydrate into an unknown phase.

The paste cured at 20°C continued contracted at a low rate for 24 hours. During the steam curing period, it expanded as soon as heating started, but it again began to contract with the appearance of

the first peak of heat liberation. The rate of volume change during steam curing was greater than that when cured at 20°C.

Supplementary Paper III-108 Physical and Chemical Properties of Cement Mortar Cured at Elevated Temperatures

P. Freisleben Hansen, John Jessing, Karen Mønsted and Erik Trudsø*

Synopsis

In order to investigate the laws governing the acceleration of concrete hardening at elevated curing temperatures, the course of a number of physical and chemical properties of cement mortar was followed. At four levels of curing temperature, the compressive strength, sound velocity, internal damping, electrical resistance, alkalinity, and content of non-evaporable water were determined intermittently or continuously at ages from ½ hour to 24 hours.

The data obtained show that the effect of temperature on the development of mechanical properties can with moderate accuracy be accounted for by means of concrete maturity, but only within certain intervals. When the curing temperature exceeds 45°C, the mechanical properties seem to be impaired and after 24 hours lower values than those obtained by curing at 25°C can result.

The rates by which physical and chemical properties develop have been examined by differentiating the basic curves. This has revealed certain relations between the hydration processes and the mechanical properties and has permitted identification of the reaction of water with C_3S and C_3A, respectively. The methodology applied appears promising for future studies of concrete hardening.

Scope

The use of curing methods, which accelerate the hardening of concrete, becomes increasingly important for the building industry. For ordinary concrete, acceleration is most frequently achieved by an increase in the curing temperature. The investigation reported in this paper was undertaken in order to obtain knowledge on the influence of temperature on the course of the hardening process, especially as regards such properties which are of immediate practical importance.

Four temperature levels were chosen: 25°C, 45°C, 60°C, and 80°C, as it was desirable to cover as wide a range as possible with the equipment at hand.

For practical production, the most pertinent properties are the workability of fresh concrete, the setting time, and the strength and rigidity of the hardening concrete. As no apparatus for measuring strictly reological properties was available, one settled for determining the dynamic modulus of elasticity as well as the internal damping immediately after mixing and moulding and intermittently during the rest of the experiment. Strength was measured at certain intervals by compression tests of cylinders.

The intension was to explain the effect of the curing temperature by the changes it produces in the chemical and physical processes during hydration; therefore, it was attempted to follow these by different means. The content of non-evaporable water was determined in two ways: 1) by subtracting the content of evaporable water found by drying and weighing of broken pieces of test cylinders from the original content of water and 2) by intermittent observation of volume contractions caused by the chemical fixation of water. Temperature and electrical resistance were recorded continuously during the whole test. Also the pH-value was recorded continuously, but only during the first stages of hydration.

*Danmarks Ingeniørakademi, Bygningsafdelingen Copenhagen, Denmark.

Materials and Techniques

Materials

A cement mortar, made as specified by RILEM-Cembureau in the method of testing strength of cement (1), was used in the investigation. The cement was of the rapid-hardening portland type with a fineness of 3930 cm^2/g (Blaine) and a chemical composition as shown in Table 1. Setting time determined by the Vicat method was about 180 min (initial set) and 290 min. (final set). The mechanical strength of prisms made of standard mortar (according to RILEM-Cembureau) is shown in Table 2. Danish standard sand and destilled water was used. The ratio of water to cement was 0.5, and the ratio of paste to sand also 0.5 (by weight).

Mixing and Curing

The ingredients were mixed in accordance with the specification, and the mortar was introduced directly from the mixing bowl into the moulds, which were mounted on a vibrating table. The mortar was placed in three layers, each being compacted by a steel rod under simultaneous vibration. Moulding lasted about. 4 min. The acrylic moulds consisted of 14 cylinders ($4\phi \times 8$ cm) and a rectangular box ($5 \times 10 \times 20$ cm).

age, days	1	3	7	1	3	7
mean value, kg/cm²	38.6	71.4	74.8	139	357	453
standard deviation	1.6	0.8	1.3	4	6	4

The 14 cylinders were used as follows (Fig. 1): 12 for the determination of compressive strength at ages from 30 min to 24 hours, 1 for measuring the electrical resistance between two copper electrodes mounted at top and bottom, and 1 cylinder finally for temperature recording by means of a thermistor inserted into the center of the cylinder. The box was used to determine wave velocity and damping, but also a thermistor was introduced, because the bigger dimensions of the box would make it more difficult to avoid deviations from the prescribed temperature level. All cylinders and the box were placed in a waterfilled tank (see Fig. 2), where the temperature

was held constant by a thermostat. Mixing, moulding, mounting and placing in the bath was completed within 15–17 min. after cement and mixing water was brought into contact.

Compressive Strength

When the mortar cylinders had reached the prescribed age, they were taken out of the curing tank, demoulded with care, and subjected to compression at room temperature within 2–3 min after the end of the curing period. A beam testing machine with the loading brought about by shot flowing into a pan (see Fig. 3) was used to determine compressive strength values below 5 kg/cm²; the loading rate was about 10 kg/cm² per sec. At failure, the flow stopped automatically, and the compressive strength was calculated by weighing the amount of shot. When cylinders had attained higher strength, a hydraulic Mohr and Federhaff compression machine was used, ajusted to the same loading rate as above. The cylinders failed distinctly in shear, even at very early ages.

Wave Velocity and Damping

Fig. 4 shows two electro-acoustic transducers lowered 20 mm into the rectangular moulding box to which were glued on both sides hollow cylindrical liners, closed against the mortar by a "window" of 1.0 mm thick acrylic sheet. One transducer acts as a transmitter, the other one as a receiver, both of them operating by virtue of the piezo-electric effect of barium titanate. 50 times per second, an electrical condenser is discharged across the crystal of the transmitter, the resonant frequency of which is 100 kc per sec. A short train of longitudinal waves of this frequency is thereby transmitted through the mortar and, on the arrival to the receiver, forces the crystal here to vibrate in its fundamental frequency, identical with that of the transmitter, thus producing an electrical signal in step with the short wave train.

On the electrically produced time scale of an oscilloscope, this signal is used repeatedly (50 times a second) as a trigger of an arrival mark, and the distance, in micro-seconds, is read from here to a starting mark, caused on the same scale by a signal at every one of the repeated onsets of the transmitter crystal.

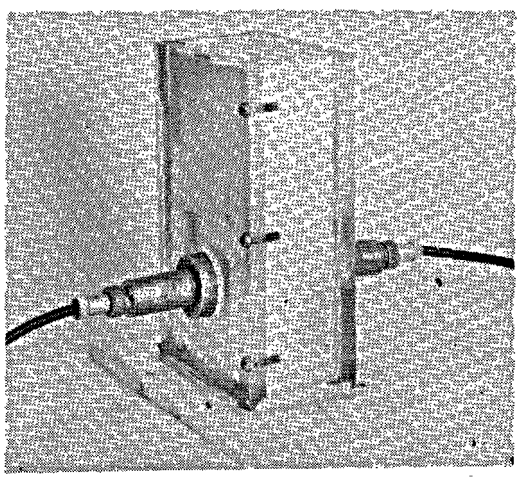

Fig. 4. *Electro-acoustic transducers in contact with mortar in acrylic box*

By subtracting from this figure the passing time of a wave directly from the transmitter to the receiver and with only two thin acrylic sheets, as those forming the windows of the box, placed in between—the net passing time through the mortar is found. Dividing this passing time into the local thickness of mortar ($26\frac{3}{4}$ mm), yields the sound velocity c, which is related to the dynamic modulus of elasticity E_{dyn} by the equation

$$c = \sqrt{\frac{E_{dyn}}{\rho}}$$

where ρ is the mass of a unit volume of mortar. Figs. 8 and 11 below show E_{dyn}, calculated on this basis, versus curing time. Intervals between readings of passing times were of 5–15 min. in the beginning; later on they were increased to $\frac{1}{2}$–1 hour or more.

As a basis for relative evaluation of damping capacities was measured the strength of the electrical signal from the receiver, the transmitter being at all times driven with one and the same fixed voltage of the apparatus (Cawkel).

Provided that the maximum receiver voltage V is proportional to the amplitude of the first wave of the arriving wave train, the parameter $\log(1/V)$ should be a growing function of the damping which this wave has undergone by passing through the mortar, and eventual changes in it should be ascribed to gradual hardening of the cement paste. Now, certain contributions to total internal damping will be constant and independent of the mortar such as: the resistance against transmission of acoustical energy from transmitter through contact with vaseline to thin acrylic sheet, from here to mortar, and from this material to the corresponding layers on the receiver side. In this brief investigation, no correction has been attempted for these complications, and as is seen from Fig. 11, rather sudden and characteristic changes are obvious in "damping expression" $\log(1/V)$ as a function of curing time.

When possible, the damping capacity of the mortar was measured and calculated at the same times as the sound velocity.

Alkalinity (pH-Value)

The alkalinity of the cement mortar was determined by means of the cell:

Glass electrode | mortar pH | saturated calomel electrode.

The sample was taken directly from the mortar mix and put into an acrylic tube ($3\phi \times 5$ cm). On the pH-meter, single values are read to calibrate indications on the recorder (see Fig. 5).

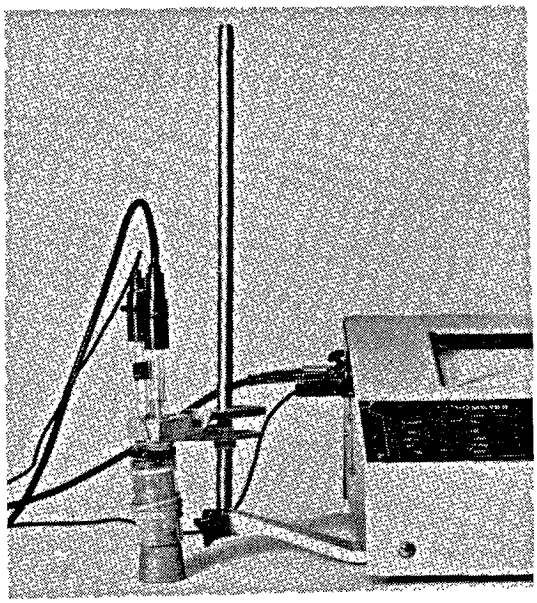

Fig. 5. *Electrodes inserted in mortar for registration of pH-value*

The curves cannot be used for an absolute determination of the alkalinity, as the pH-meter was not stable during the entire experiment. In order to save the electrodes, the recording was switched off after a few hours, when the mortar had set.

Non-Evaporable Water

The content of non-evaporable water in the cement paste was calculated on the basis of evaporable water content in the mortar.

From the center of cylinders crushed in the strength test two samples of about 10 g were taken and their weight determined by means of an analytical balance. The sample was pounded if necessary and immersed in alcohol to stop hydration. After evaporation of water and alcohol, the sample was dried for 24 hours at 105°C and the weight loss determined.

Volume Contraction

It has been suggested by W. Czernin (2) that the degree of hydration in cement paste may be determined by observation of the contraction which results from the increase in density accompanying the chemical fixation of water. To avoid the volume changes of water, which may be difficult to control during the temperature rise, the original procedure was modified and a special device developed.

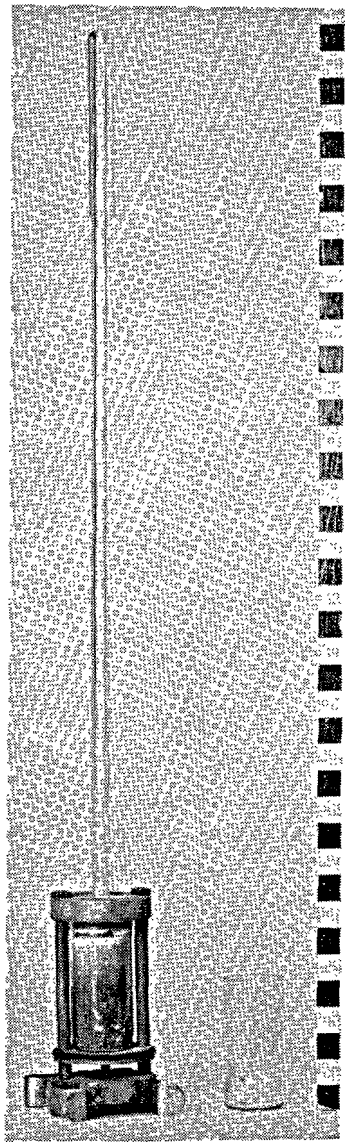

Fig. 6. *Device for determination of volume contraction in cement paste*

Water and cement was mixed by hand with a w/c-ratio of 0.5. Paste with 20–25 g cement was filled into a glass cylinder, evacuated during 15 min. hand compacted, and weighed. The cylinder was mounted in a holder with a graduated dilatometer tube (see Fig. 6), and submerged in water, the temperature of which was controlled by thermostat and did not deviate more than 1/10–1/20°C from the curing temperature aimed at (in the 80°C test, however, differences about 1/2°C occurred at the end of the curing period). The tube was loosely covered with a glass cap to reduce evaporation. It was calibrated along its length in hundredths of a ml, which allowed estimation of thousandths by means of a magnifying glass.

Observations

For each temperature level, three identical test series were carried out in order to ensure reproducibility. For those measurements which were undertaken at fixed times (strength and evaporable water), the three results were averaged, and mean values are used in the diagrams. For other quantities, which were recorded continuously or read at convenient intervals, averages have been formed when appropriate; in illustrations, however, typical curves selected among the three possibilities at hand have been used. Mean curves would not have been suitable, as interesting details might escape by the procedure.

Compressive Strength

Mortar cylinders were tested for compressive strength at the following ages: $\frac{1}{2}$, 1, $1\frac{1}{2}$, 2, $2\frac{1}{2}$, 4, 6, 8, 10, 12, 16, and 24 hours. At curing temperatures 60°C and 80°C the 8 and 10 hours measurements were omitted, and tests were made at 3 and 9 hours' age instead. In Table 3 are presented mean values and standard deviations from a statistical treatment, and the means are plotted in Fig. 7. It appears for curing at all 4 levels that after initiation of the strength development, the early stages of the hardening process

may fairly well be approximated by exponential growth curves (straight lines in diagram with logarithmic abscissa). At first the lines are parallel, but for the specimens cured at 60°C and 80°C the curves deflect, which results in strength values at 24 hours' age not much higher than those obtained by curing at 25°C.

Dynamic Modulus of Elasticity and Damping

Readings of the travelling time for sound waves were carried out with regular intervals as soon as a signal transmitted through the mortar could be picked up. As is seen in Fig. 11 it was possible at the lower temperatures to take readings of passing times as early as 15–25 min. after mixing. At the higher temperatures it lasted somewhat longer before signals from the transmitted wave were strong enough to affect the arrival mark trigger. This difference in sensibility may be explained by the decreased piezoelectric effect of the transducers at elevated temperatures; if this physical explanation were not realistic, it would look paradoxical that quicker hardening, as a result of higher temperature, should give increased internal damping in the mortar. After a relatively short period the readings gave a constant value, probably because contact failed between hardening mortar and form. Curves of the damping capacity

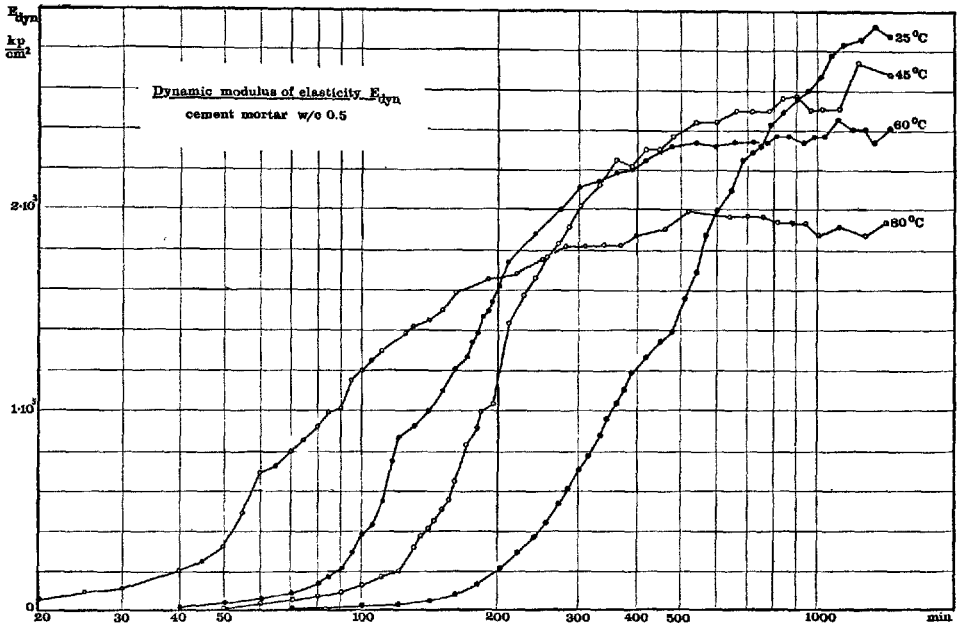

Fig. 8. *Typical curves for the development of dynamic modulus of elasticity at different curing temperatures*

are presented in a later section of this paper.

Typical curves of the development of E_{dyn} at the four temperature levels are shown in Fig. 8 (because of their abundance, not all observations are marked). From the 25°-curve it may be noticed, that the growth is rather regular within the first 24 hours, but the development, maybe, takes place within two separate periods: before and after curing in about 400 min. (this graduation is discernible in all three identical test series). The depicted curves for higher curing temperatures show similar features. Moreover, all of the curves seem simply to be parallel in the beginning. The transition from the first to the second part of the E_{dyn} development occurs at still earlier ages and at still lower values of E_{dyn} as the temperature rises. The second part of the elasticity increase, further, seems to be less intense at higher temperatures, which results in an obviously lower modulus at 24 hours' age.

Electrical Resistance

From typical graphs of the electrical resistance of the mortar cylinder, as produced by the recorder for each temperature level, a number of single points were selected and plotted in Fig. 9a-d as resistivity (ohm cm).

The four curves show some common characteristics: an initial slight decrease of the resistance is superseded by an increase, which becomes less and less pronounced as the curing temperature is raised. The subsequent local maximum appears to occur at a time which is particularly sensitive to temperature changes: it moves from about 450 min. at 25°C to 180 min at 45°C, 90 min. at 60°C and about 60 min. at 80°C. The decrease in resistance following the maximum point, results in a second minimum, and a final increase covers the rest of the examined curing period.

Volume Contraction and Non-Evaporable Water Content

Typical curves for the volume contraction in cm^3 per 100 g cement is shown in Fig. 10 for the 4 temperature levels. At 25°C the readings were continued beyond the 24 hours' period in order to facilitate comparison. It is noted that the curve at 45°C show a perceptible parallelism with that at 25°C, but this is not the case for those at 60°C and 80°C. The 60°-curve is roughly parallel with the foregoing for curing times below 150 min., but turns off and is at times beyond 1000 min. lower than the 45°-curve.

The 80°-curve hardly shows any tendency to parallelism at all, at the most during the first 50 min. The

Fig. 9. *Typical curves for the variation in electrical resistivity of cement mortar*

increase is then impaired during the next 50 min, is again intensified for a period, but merges slowly with the 60°-curve along the rest of its course.

The volume contraction can be used as a measure of the degree of hydration. According to Powers and Brownyard (3), the specific volume of the non-evaporable water is reduced by 24 per cent. The amount of non-evaporable water is, therefore, related directly to the volume contraction; the reduction of the specific volume of adsorbed water is negligible in comparison. The amount of non-evaporable water at complete hydration can be calculated from the clinker composition of cement as indicated by Copeland, Kantro and Verbeck (4):

$$\frac{w_n}{c} = 0.226(C_3S) + 0.194(C_2S: 0.982) + 0.510(C_3A) + 0.097(C_4AF) + 0.149(CaCO_4) = 0.219 \text{ g water per } g \text{ cement}$$

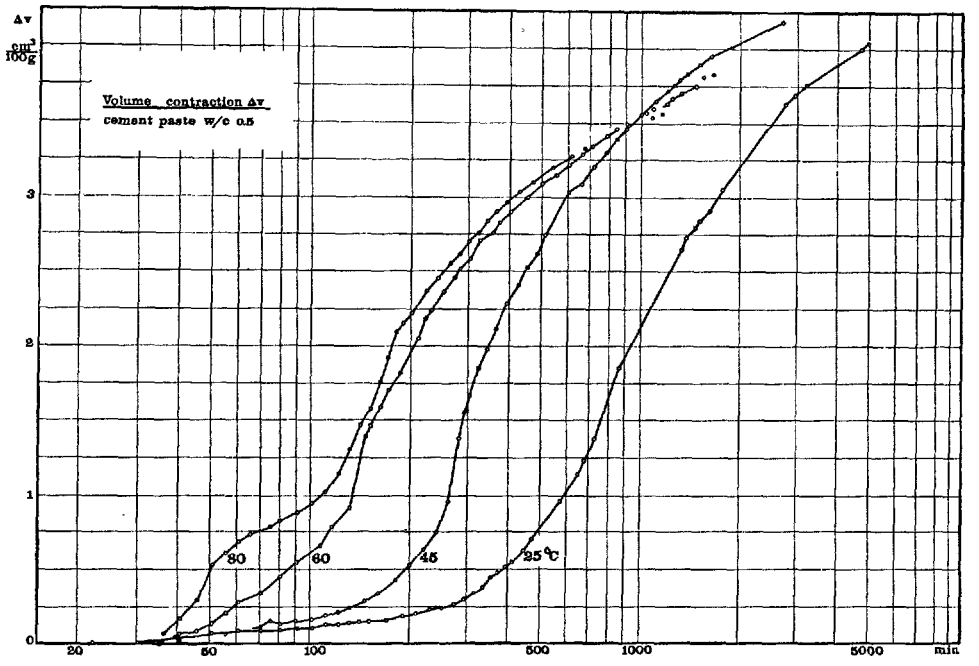

Fig. 10. *Volume contraction of cement paste cured at different temperatures*

age	25°C		45°C		60°C		80°C	
(hours)	*m*	*s*	*m*	*s*	*m*	*s*	*m*	*s*
½	0.62	0.09	0.82	0.18	0.92	0.15	1.75	0.32
1	0.69	0.10	0.42	0.09	0.83	0.11	1.53	0.17
1½	0.66	0.03	0.51	0.14	0.79	0.07	1.87	0.22
2	0.46	0.08	0.45	0.12	1.61	0.09	2.40	0.15
2½	0.55	0.08	0.48	0.14	1.90	0.24	3.07	0.21
3					2.22	0.15	2.79	0.12
4	1.24	0.08	0.67	0.30	2.82	0.16	3.39	0.36
6	1.22	0.18	1.98	0.07	3.03	0.31	3.38	0.28
8	1.23	0.06	2.73	0.14			3.98	0.24
9					3.61	0.29	3.43	0.09
10	2.11	0.13	2.64	0.09			3.22	0.60
12	2.02	0.19	2.58	0.19	3.38	0.11	3.93	0.18
16	2.20	0.14	2.65	0.25	3.75	0.22	3.38	0.23
24	3.69	0.15	3.70	0.10	4.03	0.17	4.45	0.23

This corresponds to a volume contraction of 5.25 cm³ per 100 g cement. The y-axis in Fig. 10 could therefore have been calibrated also in degree of hydration, with curves aiming at an asymptote $\Delta v = 5.25$ cm³ per 100 g.

The content of non-evaporable water determined by weighing and drying mortar samples, ought to result in values comparable with those obtained indirectly by the volume contraction. The sources of error inherent in the later method are, however, so significant that only the magnitude in general and the main tendency can be confirmed. Average values and standard deviations are presented in Table 4. The amount of non-evaporable water in the units used in the table (per cent by weight of fresh mortar) should at complete hydration be 4.87 per cent.

Discussion and Results

The methods used in this investigation have brought about some novel features of the hardening process and the effect of temperature. The determination of initial set, the development of mechanical properties in consequence of the chemical reactions during hydration, and time-temperature functions for concrete cured at temperatures between 20°C and 100°C, are particularly interesting and seem to indicate fruitful fields of future research.

The Setting Time

The development of rigidity in cement paste or mortar is usually characterized by the setting time determined e.g. by the Vicat needle or a similar penetration test. Physically, the initial set may be interpreted as the emergence of a continuous solid structure from the original dispersion of coarse solid particles in an aqueous solution.

Therefore, a determination of wave velocity and damping was aimed at as soon as possible after mixing, in order to detect early changes in these properties. Typical curves are shown in Fig. 11a-d, and it appears that the dynamic modulus of elasticity in the beginning remains on a low, fairly constant level corresponding to the low rigidity of water. The moment, when the rigidity with certainty starts to grow, can be determined rather precisely, and it is believed that a through network of solid matter exists in the paste at that time.

The internal damping is plotted in the same figures. As long as setting has not begun, the mobility of the system causes a considerable loss of energy. When continuity is established in the paste by formation of hydrates, this should be reflected by a decrease in the damping curve, as is actually the case in Fig. 11a and b, where the deflection points of damping are even more distinct than those of the elasticity. As damping became smaller with rising temperature it was increasingly difficult to obtain a discernible early signal, which is evident in Fig. 11c and d.

Another interesting detail may be observed from the damping curves: in the interval observed, the decrease markedly takes place at two different rates. The age at which the rate changes is 140 min at 25°C, 105 min at 45°C, and 70 min at 60°C (at 80°C the point could not be determined).

Chemical Reactions and Mechanical Properties

As concrete hardens, several chemical reactions are in progress in the cement paste. The reactions result in the formation of new solid compounds with mechanical properties depending on the structure of the hydrates. Because of the complex nature of the hydration, it has been considered rather difficult to interprete the mechanical properties of hardening cement paste in detail as regards the processes going on between water and single clinker compounds. Usually, the broader concept of relations between net fractions of reacted cement and physical properties is accepted. In order to throw some light on these matters, the principle of comparing rates was put to use. As readings for a number of properties had been made continuously or with short intervals, it was possible to calculate differentials with respect to time for the dynamic modulus of elasticity, for the electrical resistivity, and for the volume contraction. Maxima and minima on the differentiated curves will correspond to inflection points on the basic curves.

The results are interesting.

Firstly, the differential curves are reproducible. This is demonstrated in Fig. 12, where the changes in resistance, for the three parallel test series run at 45°C are shown as an example. It should be noticed that all the main features are repeated in each of the 3 curves. For the volume contraction, the reproducibility was only ascertained by a few duplications.

Secondly, it is possible to identify several chemical reactions and establish their connection with the development of mechanical properties. In the identification, also the observations of mortar temperature (see Fig. 13) and of alkalinity proved useful.

The Differential of the Dynamic Modulus of Elasticity

The differential of the dynamic modulus of elasticity is at 25°C clearly developing during two stages (A and B) separated by a minimum, approximately 450 min after mixing (Fig. 14a). The first stage (A) is subdivided with a local minimum at about 230 min and peaks after curing in 210 and 300 min. One may further notice that the beginning of the temperature rise (which occurs somewhat later in the box than in the cylinders due to the size effect) coincides with the second maximum after curing in 590 min.

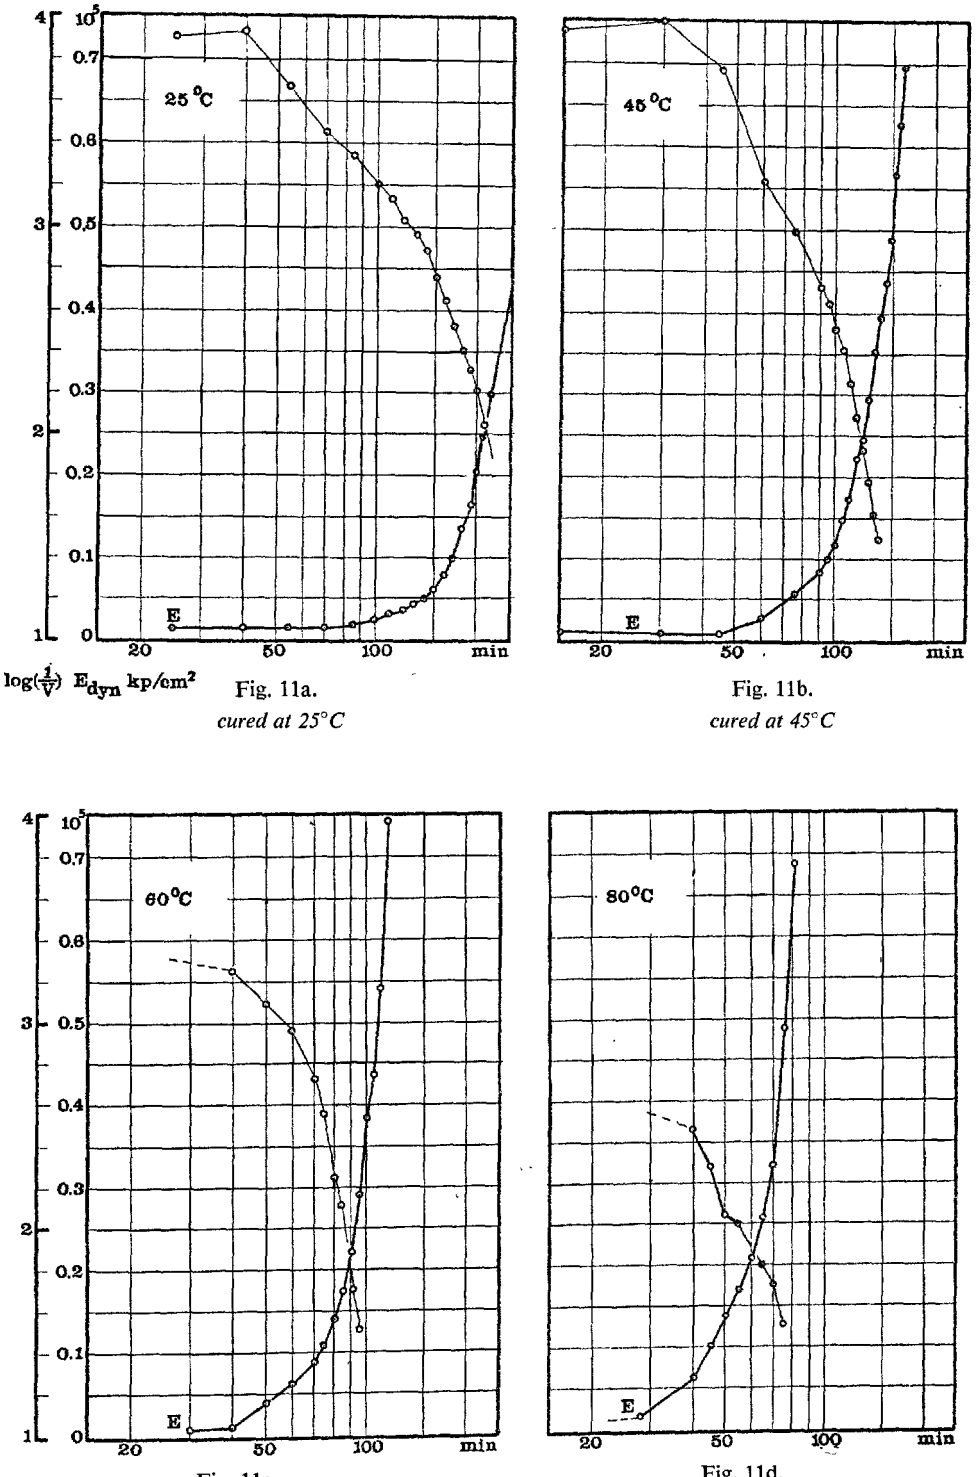

Fig. 11a. *cured at 25°C*

Fig. 11b. *cured at 45°C*

Fig. 11c. *cured at 60°C*

Fig. 11d. *cured at 80°C*

Fig. 11. *Typical curves of dynamic modulus of elasticity and internal damping of cement mortar*

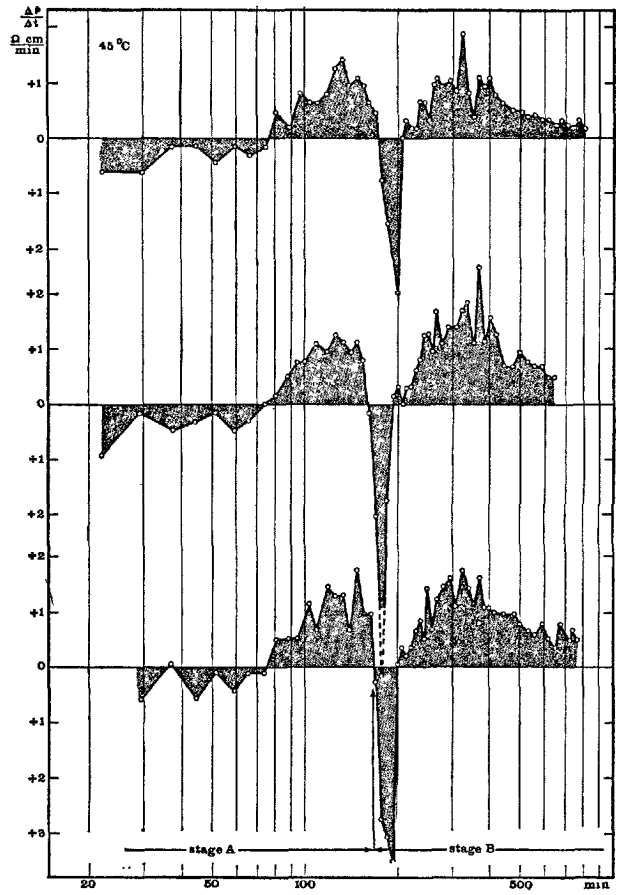

Fig. 12. *Differentials of the electrical resistivity as determined in three mortar cylinders cured at 45°C*

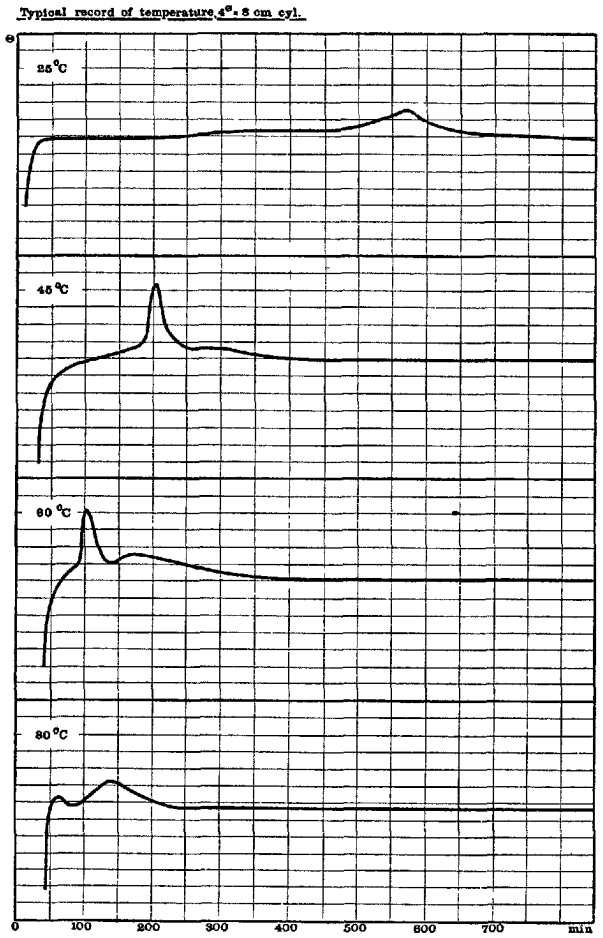

Fig. 13. *Typical recordings of temperature in mortar cylinders cured at different temperatures*

At 45°C the picture has not changed principally, the events only happen a little earlier, and peaks are more pronounced (Fig. 14b).

The first stage (A) has its maxima approximately after 125 and 165 min.; the separating minimum arrives after 185 min., and the peak in the second stage (B), which is now the highest one, comes after 200 min. Here, again, it seems that the temperature rise starts shortly after the highest peak. A very early peak (about 100 min.) and a rather late one (about 350 min) may be distinguished.

Important changes are noted at 60°C (Fig. 14c): the highest peak (in stage B) occurs after curing in only 115 min. That this peak actually corresponds to the one about 200 min at 45°C, is substantiated by its position relative to the temperature peak. The two stages are divided by the minimum at 125 min., and the second stage (A) is still characterized by 2 peaks, situated at app. 150 and 180 min. The final decrease now precedes a second, rather faint peak on the temperature curve.

The early peak and the late secondary one may still be discerned.

At 80°C (Fig. 14d), the first peak occurs after 75 min., the separating minimum after 85 min, and the two smaller peaks after 115 and 170 min. The two temperature maxima arrive shortly after the declines of the differential curves.

The curves shown in Fig. 14a-b are typical, and the values mentioned above refer to these curves. The ages at which the extreme values of elasticity differential and temperature occurred are summarized in Table 5. These times are averages of 3 observations, if available.

The Differential of the Electrical Resistivity

The differential of the electrical resistivity at the four temperature levels is illustrated in Fig. 15a-d, on which recordings of the pH-value are also shown.

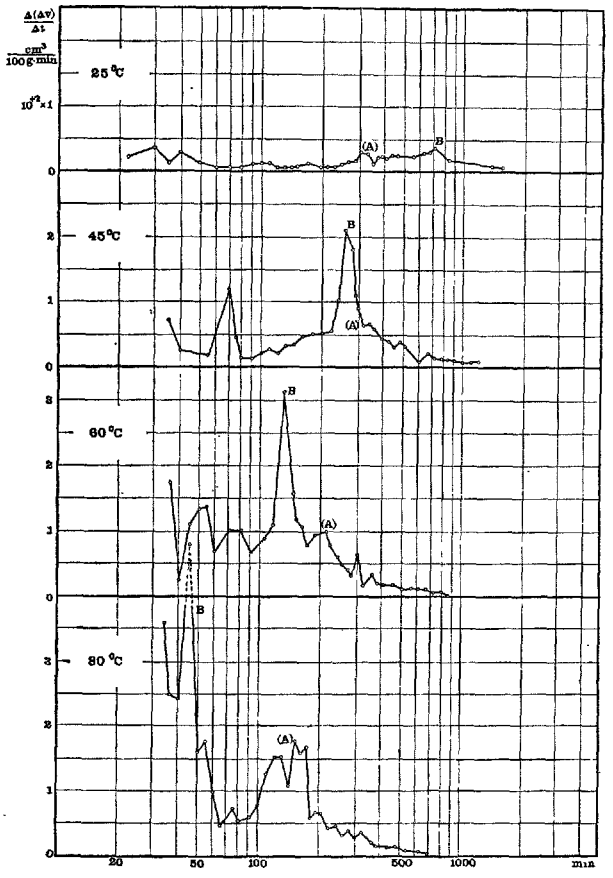

Fig. 14. *Differentials of dynamic modulus of elasticity for cement mortar cured at different temperatures*

Table 5. *The occurrence of characteristic values of the elasticity differential; temperature in mortar box and strength indicated for comparison (min after mixing)*

	Curing temperature	25°C	45°C	60°C	80°C
Stage A	Start of $\frac{\Delta E}{\Delta t}$	100	60	37	38
	Start of temperature rise	(165)	(130)	110	90
	Maximum 1 of $\frac{\Delta E}{\Delta t}$	203	128	153	112
	Minimum 1 of $\frac{\Delta E}{\Delta t}$	223	138	183	148
	Maximum 2 of $\frac{\Delta E}{\Delta t}$	285	163	201	164
Separating minimum of $\frac{\Delta E}{\Delta t}$		470	183	138	90
Stage B	Strength = 10 kg/cm²	390	190	150	105
	Start of temperature rise	450	210	125	75
	Peak of $\frac{\Delta E}{\Delta t}$	585	212	122	75
	Temperature maximum	610	250	145	90

The curve for curing at 25°C consists of 4 parts in which indications of the two stages A and B may be found. The resistivity is reduced during the first 125 min., but some change is perceived a little earlier (after curing in 100 min.); this is approximately at the same time as the first increase in elasticity is noticed. The resistance subsequently grows untill an age of 460 min. (A), but the change starts some 80 min. before and leads to a second negative area (i.e. falling resistivity) with a marked peak (B) at 540 min, which coincides with the temperature maximum. The resistivity increases once more during the rest of the observed period, but the differential seems to fall off at an age about 960 min. In this case the recording of alkalinity was discontinued rather early and does not supply much information.

At 45°C, the course is largely the same, but some acceleration is obvious. The negative part ends at 76 min. and the first maximum is reached at 130 min. The negative peak (B) covers the period from 170 to 205 min. and corresponds to the temperature maximum. The second maximum is situated at 330 min. and is more pronounced. The pH-value increases as the differential decreases and assumes negative values, i.e. corresponds to rising conductivity.

At 60°C, the first negative differential comes to an end after 56 min., and the positive area (A) hardly starts to build up, at 73 min., before the steep decline begins and results in a peak (B) at about 96 min.; again coincidence with the temperature maximum is noted. In the second positive region, a faint deflection point (or perhaps a secondary minimum separating A and B) is observed after curing in 170 min., and at this age the second temperature maximum is found. In the positive region a first maximum lies at 210 min and maybe a second one at 270 min. The pH-value rises as the negative peak occurs, i.e. from 90 to 110 min.

Finally, for curing at 80°C, the resistivity differential starts with low negative values at a minimum about 45 min after mixing, but increases rapidly to a narrow positive maximum at 52 min. The negative peak (B) is broader and less intense, setting in from 58 to 76 min. The second positive area shows two distinct maxima (B and A) and maybe more. The negative peak (B) corresponds still to the first temperature maximum and the relative minimum in the positive area to the second temperature maximum.

The alkalinity increases at the peak after (45 min and) after 60 min. Averages of the extreme values for the three curves at each temperature level is presented in Table 6.

The Differential of the Volume Contraction

The differential of the volume contraction is shown

cured at 45°C

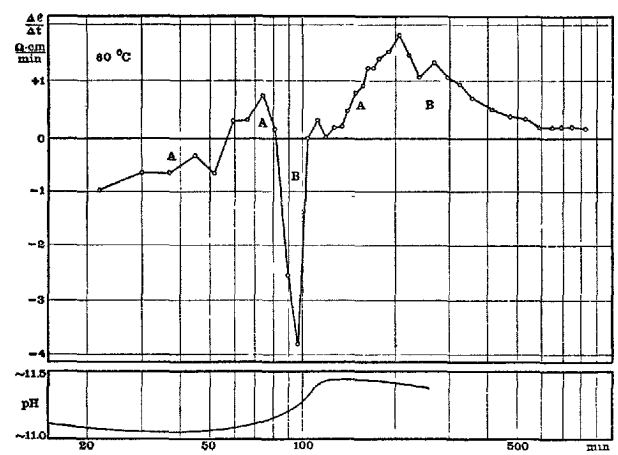

Fig. 15c.
cured at 60°C

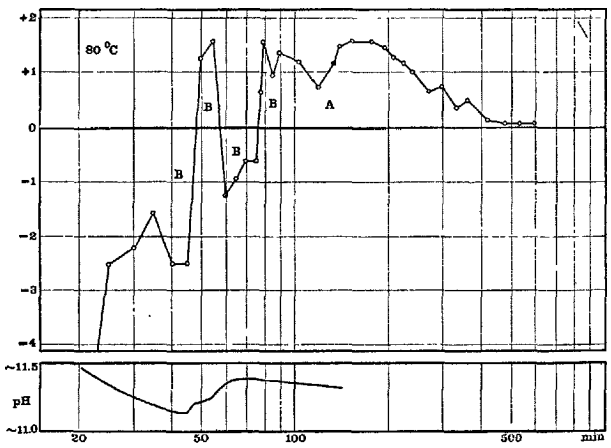

Fig. 15d.
cured at 80°C

Fig. 15. *Differentials of the electrical resistivity and the alkalinity both determined for cement mortar*

Table 6. *The occurrence of characteristic values of the resistivity differential; temperature in mortar cylinder indicated for comparison (min. after mixing)*

	Curing temperature	25°C	45°C	60°C	80°C
Stage A	$\frac{\Delta\rho}{\Delta t} = 0$	120	76	59	50
	Start of temperature rise	140	85	75	70
Stage B	Start of temperature rise	470	165	83	68
	$\frac{\Delta\rho}{\Delta t} = 0$	465	169	83	55
	Negative peak of $\frac{\Delta\rho}{\Delta t}$	555	192	96	64(42)
	Temperature maximum	585	202	105	57
	$\frac{\Delta\rho}{\Delta t} = 0$	585	203	104	74

in Fig. 16 for the four curing temperatures. They are perhaps—at least with the technique used in this investigation—less informative than the previous differentials, but some remarkable features were found.

At 25°C, the most intense hydration produces a peak at 710 min (stage B). The most distinct peak is at 45°C after 170 min., at 60°C after 130 min. and at 80°C after 45 min. This peak seems to move from right to left across a region (stage A) with a relatively high hydration rate. The region is probably characterized by two smaller peaks, which also increase

	Maximum temperature	380	270	175	145
Stage B	Peak of $\frac{\Delta(\Delta v)}{\Delta t}$	710	260	135	45
	Maximum temperature	585	202	105	57

somewhat in intensity and also move from right to left, but more slowly than the highest peak. The region in question is, at 25°C, found after curing in 300–350 min., at 45°C after 150–350 min., at 60°C after 100–250 min., and at 80°C after 90–180 min. In Table 7 are presented the times when the maximum and the peak occur at the four curing temperatures.

Interpretation

Interpretation of the findings is based on Copeland and Kantro's account of the early reactions in cement paste (5): When cement is mixed with water, the "immediate" heat of hydration causes a temperature rise, which is not observed in this experiment, as mounting etc. lasted about 15 min. After a period extending from 1 to 3 hours (presumably at room temperature), 1 or 2 subsequent temperature peaks may be expected, caused by the hydration of the clinker minerals.

It was possible in the three differentiated curves to ascertain at least two different stages or processes, each characterized by its maximum rate and with a certain sensitivity to temperature changes. This is illustrated by Fig. 17 which shows in one diagram five curves obtained by curing at 45°C.

Considering first the course of events at 25°C, it may be assumed, that the first reaction at the end of the dormant period takes place between C_3A and water; this will cause a heat development, which can

be perceived as a slight, but lengthy temperature increase (Fig. 13). The formation of hydrates gives the system some rigidity, which is seen from the modulus of elasticity (Fig. 14), but the solid matter will decrease the mobility of ions, i.e. the electrical resistivity will increase (Fig. 15a). When C_3S begins to react, calcium hydroxide is formed, i.e. the alkalinity will grow (which is not covered by Fig. 15a), the temperature shows a marked peak (Fig. 13), the electrical resistivity falls rapidly in consequence of the ion activity, but increases again as new solid matter is formed (Fig. 15a), which is also reflected in a second, different increase in the modulus (Figs. 8 and 14) and in the strength increment, manifest only at this age (Fig. 7).

As the temperature is raised this sequence of the processes changes. At 45°C, the order is largely the same (see Fig. 17), but at 60°C the C_3S reaction appears prior to the C_3A reaction. This picture is repeated at 80°C, but there are indications of three reactions: the resistivity shows 2 negative minima, one at 40–45 min. and another at 60–70 min. (Fig. 15d). As both C_3S and C_2S produces calcium hydroxide during hydration, this seems a reasonable explanation also of the small changes in the pH-curve, which can be distinguished. Hereby may further be explained, why the temperature rise (start to maximum) in stage B, which for curing at lower temperatures coincides almost exactly with the negative peak in the resistivity differential (See Table 5), at 80°C seems to be somewhat displaced to the left—as it ought to be because the hydration of C_3S and C_2S will both release heat.

Time-Temperature Functions and Reaction Rates

By definition a time-temperature function is a variable $f(\theta)$ by which the duration t of a process at one temperature θ can be converted to the duration t_a of the same process at another temperature Θ_a:

$$t_a = f_a(\theta) \cdot t$$

For concrete hardening at low and normal temperatures, the effect of the temperature level on concrete properties is often taken into account by the use of time-temperature functions, and this has also been attempted for accelerated hardening at curing temperatures not exceeding 100°C. Different forms of time-temperature functions have been proposed, some empirical (6) and some based more or less on the Arrhenius equation (7). Much seems to indicate, that at least two processes govern the early stages of hydration; therefore, a time-temperature function derived from the Arrhenius equation cannot be expected in detail to give an accurate description of properties dependent on these processes.

If one wants, nevertheless, to apply a time-temperature function, it is necessary either to consider only phenomena resulting from a single process or to accept certain deviations. Both approaches have been tried on data obtained in the present investigation.

It was attempted to find the reaction rates by applicating the Arrhenius equation on such characteristics of the hydration process which seemed to depend on only one reaction. Characteristic points belonging to three different properties, but depending, presumably, on the same reaction (C_3S hydration) were chosen: the peak of the E_{dyn}-differential, the peak of the ρ-differential, and the peak of the Δv-differential. At the higher curing temperatures, some of these events occurred before the mortar temperature had reached the presupposed level. It was decided in such instances to transform the periods, during which acceleration was achieved at all, in time at the proper temperature, by means of the Nurse-Saul maturity concept, and to discount the period, when no acceleration took place. In Tables 8–10 are shown the observed time, the correction and the "reaction rate" taken as the reciprocal of the time.

Table 8. *Determination of reaction rate by means of the E_{dyn}-differential peak*

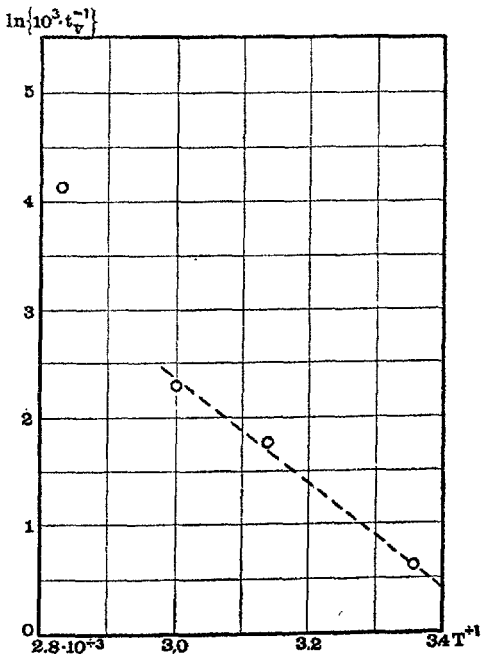

Fig. 18c.
peak of volume contraction differential

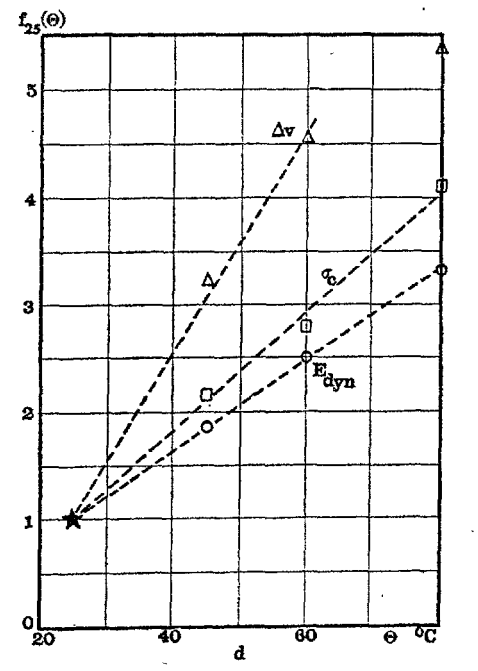

Fig. 18d.
different maturity functions

Fig. 18. *Reaction rates and time-temperature functions*

The logarithms of the rates are plotted in Fig. 18 versus the inverse of the absolute temperature. The almost straight lines obtained indicate a fairly good agreement with the Arrhenius formula

$$\text{rate} = \text{constant} \cdot e^{-Q/RT}$$

in which Q is the activation energy, R is the gas constant and T is the absolute temperature.

The elasticity line and the resistivity line give by calculation the same slope from which the activation energy is found to $Q = 29.6$ kcal/mol. The three points from the volume contraction, which forms a straight line, gives $Q = 28$ kcal/mol. This is not inconsistent with the reaction energy of C_3S.

In the following, a range of variation about 25% ($\pm 12.5\%$) is regarded as acceptable.

For the compressive strength it is possible to convert the curing times at 45°C, 60°C and 80°C to curing time at 25°C within limited ranges of the compressive strength (see also Fig. 7):

25°C: $f_{25}(25) = 1.00$ (by definition)
45°C: $f_{25}(45) = 2.15$ (valid for all observed values)
60°C: $f_{25}(60) = 2.81$ ($\sigma_c < 120$ kg/cm²)
80°C: $f_{25}(80) = 4.15$ ($\sigma_c < 110$ kg/cm²)

The values of the time-temperature function are shown in Fig. 17d.

For the dynamic modulus of elasticity, the following values of a time-temperature function may be found under the same conditions (see also Fig. 8):

45°C: $f_{25}(45) = 1.87$ ($E_{dyn} < 2.35 \cdot 10^5$ kg/cm²)
60°C: $f_{25}(60) = 2.47$ ($E_{dyn} < 2.05 \cdot 10^5$ kg/cm²)
80°C: $f_{25}(80) = 3.30$ ($E_{dyn} < 1.60 \cdot 10^5$ kg/cm²)

Finally, it was attempted to apply the principle in the same way on the volume contraction, but with less success because only intermediate intervals could be used without excessive variations:

45°C: $f_{25}(45) = 2.76$ ($1.1 < \Delta v < 3.7$ cm³/100 g)
60°C: $f_{25}(60) = 4.52$ ($0.5 < \Delta v < 2.8$ cm³/100 g)
80°C: $f_{25}(80) = 5.35$ ($0.8 < \Delta v < 2.6$ cm³/100 g)

Also the time-temperature functions obtained by the modulus of elasticity and by the volume contraction are depicted in Fig. 18d.

With good approximation, the calculated points are on a straight line, with the exception of the one corresponding to Δv at 80°C. This confirms that the development of concrete properties by curing at temperatures from 25°C to 80°C can be described by means of maturity functions (sum of products time and temperature).

Conclusion

It was possible to establish a series of facts, which allow the following interpretations:

1. Curing at elevated temperatures below 100°C accelerates the development of mechanical properties. The acceleration can be accounted for by means of the concrete maturity, but at ages of about 24 hours the quality obtained by curing above 45°C may be impaired due to other influences.

2. By curing at temperatures above 45°C it seems that the hydration of C_3S is accelerated in particular, and in cases where this process starts before the hydration of C_3A, the mechanical properties may be injured.

3. A comparison of the development of physical and chemical properties during the hardening of concrete—according to the applied rather simple methods—already appears promising. Further detailed insight in hydration processes will no doubt result from a more refined technique based on the same principles.

Additional Investigation

The investigation reported in supplementary paper III-108 has been supplemented with a test series carried out by Mrs. Karen Mønsted, in which the gypsum content of the cement was increased. This retarded and flattened peak B. The original interpretation of the reactions A and B as, therefore, not correctly. When peak B occurs later with higher gypsum contents, it must represent a reaction with C_3A. This interpretation provides, in addition, an explanation of the strength decrease at high curing temperatures: the formation of solid structure by the hydration of C_3S might be disturbed, because the ettringite is not stable at high temperatures, but is transformed into monosulphate.

Oral Discussion

Hideo Teramoto

Generally, before high-temperature curing to accelerate hardening of concrete, pre-curing is performed at normal temerature for several hours. Also, the temperature rise is made to be gradual. It is considered raising temperature without precuring or suddenly raising temerature will have adverse effects on strength and other properties of concrete.

The authors cure mortar specimens immediately after molding by placing them in water tanks maintained at 25°C to 80°C. It is wished to know the reason or purpose of these tests in which curing methods which are rarely used in actual practice were adopted.

Author's Closure

John Jessing

The remarks by Mr. H. Teramoto touches upon a important question, and I am happy for this opportunity to discuss it.

The purpose of our investigation was *not* to imitate curing conditions in practise, because the procedures which are used generally will confuse the different influences on the hydration process. Our purpose was—as a first step—to investigate the influence of the temperature *level* on the hydration process and mechanical properties. The next step might be to find the influence of temperature *changes* on the hydration process and mechanical properties. A more detailed presentation of the principal point of view is given in the written discussion in session III by Jessing and Nerenst, and I beg to refer to this.

SESSION III-5 HIGH-TEMPERATURE CURING OF CONCRETE UNDER HIGH PRESSURE

Principal Paper High-Temperature Steam Curing of Concrete at High Pressure

George L. Kalousek*

Synopsis

H. F. W. Taylor reviewed the science of hydrous calcium silicates and, more recently, some practical applications of the findings. With this background, this paper is developed partly around the results of examinations of 24 commercially produced autoclaved products. The binders were strongly to poorly crystallized tobermorite, $C_5S_6H_5$. Some contained a low lime tobermorite gel designated $C_{5-6}S_6$ Hn for given reasons. Laboratory tests to explain the difference between Taylor's C–S–H(I) and $C_{5-6}S_6$ Hn lead to a tentative conclusion (with reservations) that C–S–H(I) is a poorly to well-crystallized variety of tobermorite. On the other hand, $C_{5-6}S_6$ Hn is the precursor of the Lock Eynort tobermorite, the phase found as a binder in the commercial products.

The gel-crystal phase composition of the binder relates to physical properties of the products. This is an area of future fruitful research. The possible important effects of ion (Al^{3+}, Fe^{3+}, SO_4^{2-}, etc.) substitution in the lattice of tobermorite on properties is discussed. Possible techniques of differentiating between gel and crystal phases in a binder are reviewded.

Introduction

The chemistry of autoclave curing of concrete is essentially the chemistry of the reaction of CH with S and/or silicates in high-temperature steam at high pressure. Portland cement may supply all the C and part of the S or silicates. Any additional S required is supplied as ground quartz or other reactive siliceous materials such as fly ash, shale fines, oil shale ash, aggregate fines, etc. The CH for production of sand-lime brick, fine grain (sand) concrete, and similar products is available as quicklime, hydrated lime, by-product lime including nepheline slurry (largely βC_2S), etc. The principal requirements of lime and S are that both be sufficiently reactive to yield binders of satisfactory quality and at competitive costs.

Autoclave curing according to Bessey (1) was first applied in Germany in 1898 for curing sand-lime brick. The new industry grew rapidly in several countries. About two to three decades after this start, autoclave curing extended into commercial production of concrete block and products, asbestos-cement products, cellular concrete, thermal insulation and structural light weight calcium silicates, calcium silicate fillers and other products. Concrete now being developed for the upper temperatures of evaporator chambers in sea water desalting plants is another autoclaved material.

The growth of the industry, worldwide, was especially rapid in post World War II years. A large variety of products made from several different raw materials are being produced in large volume in the Soviet Union. The status of the industry there was reported in a Rilem Symposium (2). A review of that symposium including comparison of the autoclave curing industries in the Soviet Union and the United States was published (3). Proceedings of a symposium (4) in London in 1964 documents the status of the autoclaved calcium silicates especially of sand-lime brick. The report of ACI Committee

*Concrete Department of the Interior, Bureau of Reclamation, Denver Federal Center, Denver, Colorado, U.S.A.

516, High Pressure Steam Curing (5), describes modern practices and properties of autoclaved products mostly in the United States and Canada. Taylor (6) reviewed the importance of the chemistry in the industry. Important relations between properties and chemical nature of the binders were summarized by Hansen (7). Volzhensky (8) reported on the impact of autoclave curing on the structural concrete industry in the Soviet Union. These relatively recent reports reflect the strong sustained growth of, and progress within, the industry. Bessey (9) predicted further extensive increase in use of autoclave curing in the field of concrete structural products.

Undoubtedly chemistry will play an increasingly important role in the advances to be made. During the first three to four decades of the industry, chemistry made only small contributions. In 1929, Thorvaldson and Shelton (10) discovered αC_2SH in autoclaved cement pastes, but the significance of the discovery remained obscure for over 20 years. The earlier attempts to identify the binders of sand-lime brick by optical microscopy and XRD (11, 12) were unsuccessful. These research tools lacked sufficient resolution. Also, reference phases prepared under controlled laboratory conditions were not always available. In 1952, Taylor (13) identified by XRD the binder of a commercially produced sand-lime brick which later was recognized as tobermorite. This and other investigations were the forerunners of the chemistry of autoclaved products.

The early practical advances were achieved almost entirely through empirical approaches. Correlations of physical properties, generally strength and shrinkage, with the kinds and compositions of the raw materials and conditions of autoclaving supplied information applied in the production. The contribution of chemistry to the technology, however, has made sizable advances during the past 10 to 20 years. Projections based on these accomplishments indicate increasing usefulness of basic chemical research in the industry. This paper is a review of the contributions of chemistry to the technology. An attempt is made to direct attention to areas of chemical research which appear to have considerable promise.

The rather extensive basic chemical research on hydrated calcium silicates conducted during the past 20 years, and areas of related technology, is given in excellent review reports by Taylor (6, 14, 15, 16) and by Heller and Taylor (17).

A new mineral addition to the family of hydrous calcium silicates is jennite, $NC_8S_3H_{11}$, recently described in detail (18).

Background Relating to Binders

The first laboratory experimental results showing effects of high-pressure steam on strengths of portland cement specimens were published in 1911 by Wig (19). Several similar studies on cement with and without additions of silica (20, 21, 22, 23, 24, 25) were conducted. Woodward (21) and Menzel (24) demonstrated that drying shrinkage was markedly reduced by autoclaving. Miller (20) and Thorvaldson (23) reported that specimens cured in the autoclave had significantly better resistance to sulfate attack than normally cured products. Menzel (24) developed the optimum silica replacement for cement for maximum strength and minimum shrinkage, this being about 40% silica and 60% cement by weight. Mironov and Malinina (25) reported extensive results of tests on various proportions of different cements and pure clinker phases with silica for different steam pressures and times of curing. Their results showed that the binders having highest strengths had C/S ratios of 0.9 to 1.0. They demonstrated that the optimum $\bar{S}$ content of specimens autoclaved at 175°C was 1.0 to 1.5%. With exception of results by Bozhenov and Kavalerova (26), to be discussed, the binder compositions most frequently reported were 0.9–1.0 C/S. The mineral of the binder was generally not identified.

The XRD reexamination of tobermorite from Tobermory, Scotland, by Claringbull and Hey (27) supplied data on a most important reference standard. Data like Taylor's (13) showed the binder of an industrial product was tobermorite. The XRD data on a lime-silica product disclosed in a U.S.A. patent (28) was in complete agreement with the Claringbull-Hey data. The exact formula, $C_5S_6H_5$ was deduced by McConnell (29). The average values of complete analysis of several preparations (showing the complete tobermorite pattern) for C,S,$\bar{C}$, free C and free S (30, 31) gave a C/S ratio of 0.83 in excellent agreement with the 5C:6S (0.833) value reported by McConnell.

An application of chemistry was made (32) in the interpretation of the minimum and maximum

strength in Menzel's strength vs silica replacement relation. The low strength was attributed to αC_2SH and the maximum strength to a phase of 0.9 to 1.0 C/S. Butt and Krzheminski (33) and Butt, Rashkovich, and Danilova (34) reported similar findings on autoclaved calcium silicates made of calcium silicates and silica. Malinina (35) associated low strength with αC_2SH and high strength with a phase of 0.8–1.0 C/S.

The C/S ratio, generally reported 0.9–1.0, is substantially higher than the 0.83 C/S ratio of tobermorite. Further, the 0.9–1.0 C/S binder reported in one investigation (32) exhibited an exotherm at about 830–840°C which pure tobermorite does not show. These inconsistencies were reconciled by studies (31), to be discussed, showing that 1.18% S was replaced by 1.00% A in the tobermorite lattice. In a 1.0 C/S raw mix containing 4.0% A the actual C/(S+A) ratio is close to 0.83. The A-substituted tobermorite, unlike pure C-S tobermorite, exhibited an exotherm at about 830–840°C. The XRD patterns of tobermorite and A-substituted bobermorite were identical except for a small increase of the basal spacing at 11.3Å to about 11.5–11.7Å by A substitution.

In order to develop reference standards from raw materials used commercially, pastes of cement and ground quartz, shale, pumice or slag fines were autoclaved (36) following a plant cycle with 8 hours at 175°C. The sample having C/(S+A) ratios of 0.8–0.9 gave satisfactory XRD patterns for tobermorite. It was, therefore, assumed that the commercially produced counterparts also contained tobermorite as binder.

The most readily synthesized calcium silicate using CH and ground quartz is xonotlite, C_5S_5H. It forms rapidly at 200°C and higher temperatures. At temperatures around 200°C, xonotlite would be expected to be the binder in many commercially produced products. Most raw materials contain sufficient Al_2O_3 to stabilize tobermorite, and only a few tenths of a percent of Al_2O_3 retard xonotlite formation. Tobermorite forms first and is stabilized by the Al_2O_3 in the lattice. Xonotlite has very low drying shrinkage compared to tobermorite (37) and has been patented (38) as a high-temperature thermal insulation. Xonotlite may form in sand-lime brick made with pure silica sand and pure CH and cured at temperatures around 200°C. Bessey (1, 39) reported some very low drying shrinkage of samples of sand-lime brick in which he found microscopically long needle-like crystals (morphologically similar to xonotlite crystals). Based on similar observations including XRD, it was suggested the binder was xonotlite (40).

Other calcium silicate hydrates beside tobermorite and xonotlite have capabilities as binders and were discussed by Taylor (6). Bozhenov and Kavalerova (26) autoclaved nepheline slurry, CH and $C\bar{S}H$ mixtures of 2.3 C/S. At temperatures of 225°, 265°, 310°C they reported presence of tobermorite gel, gyrolite, xonotlite, αC_2SH and C_3SH_2, with highest strength obtained on products autoclaved at 265°C. It is not known if so high a temperature (265°C) is economically feasible using cement and quartz.

The equilibria involving gyrolite and the related phase truscottite (or reyerite), Z-phase of Assarsson (41) and other phases as xonotlite and tobermorite were described by Harkins (42). Taylor (6) reported that gyrolite and the Z-phase can be synthesized at pressures used commercially. It may be speculated, however, that a relatively high silica concentration in solution would be required (6, 40, 42, 43, 44).

The high costs of silica gel or silica glass to supply silica for solution may militate against gyrolite and related phases as binders for commercial products. Taylor (6) discussed other possible related binders but technological results are still too limited to permit drawing conclusions about practical use of these.

Identification of Binders in Commercial Products

Results of XRD examinations of binders of 22 commercially produced autoclaved products, two deep oil well cements autoclaved in the laboratory and several reference samples have been published (45, 46). Out of the total of 24 commercial products, the binders of 22 were reported to be tobermorite in different degrees of crystallinity and some contained $C_{5-6}S_6Hn$ (the formula, CSHn, previously used has been modified for reasons to follow). The two unidentified binders might have been poorly crystallized tobermorite and $C_{5-6}S_6Hn$ but interference of aggregate and calcite lines in the XRD patterns precluded positive identification.

Only two of the samples contained a phase other than tobermorite or $C_{5-6}S_6Hn$ in more than trace amounts. One asbestos-cement product contained

in the order of 7–12% αC_2SH. A sand-lime brick contained a significant, but not major, amount of $C_3SH_{1.5}$. Information was not available on raw materials, and proportions, or autoclaving conditions and, therefore, no explanation can be advanced for the presence of these extraneous phases. Other phases were present in some of the samples but on basis of very weak intensities of the strongest XRD lines of such phases, the amounts were regarded as traces generally less than 1%. Among these were cement clinker phases, CH (0.0–0.7%), gyrolite, $C_3SH_{1.5}$, αC_2SH and perhaps others. The hydrogarnets were not detected. The trace amounts of CH, coexisting with residual silica (which always was present as excess fines or aggregate), may appear surprising. It has been observed (47) that residual clinker phases persisted in autoclaved asbestos-cement samples immersed in saline water for 20 years. The explanation is that the residual clinker phases are completely surrounded by impervious hydration products. This explanation may also apply to the presence of the phases named above, and still others. Aitken and Taylor (48) detected several phases in cement or cement-silica pastes autoclaved for different periods of time. The time of autoclaving was less for some samples, and more for others, than usually used in commercial production. Kennerley (49) examined nine grout samples exposed to temperatures up to 225°C in geothermal bores. Exclusive of $C\bar{C}$ and CH, the binders of the cement grouts were largely αC_2SH and, of cement-pozzolan grouts, one or more of the "tobermorite family" depending on C/S ratio. Xonotlite, hillebrandite, and γC_2SH were detected in lesser amounts.

The identification (45, 46) of tobermorite was based on the three strongest XRD lines of this phase, 11.3, 3.07, and 2.97Å. A second parameter, the ratio of intensities of the 2.97/3.07Å lines, was introduced for purpose of differentiating between Taylor's C–S–H(I) (intensity ratio equal to 0.0) and tobermorite (intensity ratio equal to 0.70–0.80). Also this parameter was useful in identifying tobermorite in samples containing calcite. Low-lime tobermorite gels were described by Kalousek (50, 30) and Neese (51) as a series of solids of composition C_4S_5Hn (actually revised later to C_5S_6Hn), CSHn, C_5S_4Hn, and C_4S_3Hn. The C_4S_3Hn, synthesized only at room temperature, decomposed into C_5S_4Hn and αC_2SH in an autoclave at 175°C (52). Not being a stable autoclave product, it is not considered further in this paper.

The C_5S_6Hn and CSHn were prepared as separate solids characterized only by composition and an exotherm at 830 ± 5°C. The only difference between the two, detectable instrumentally, was in the much stronger intensity of the exotherm exhibited by CSHn. The intensity difference is of little diagnostic value in the examination of samples under consideration. Because of the uncertainty relating to separate identification of these two phases, and because they frequently coexist, the formula $C_{5-6}S_6Hn$ has been adopted for use in this paper. The possibility of a solid solution between the two has not been established but cannot be excluded.

C_5S_4Hn exhibits a characteristic exotherm at 860 ± 5°C and is readily detected when present with the other gel phases of the series. Furthermore, the 3.0–3.1Å spacing was exhibited at 3.02–3.03Å by C_5S_4Hn and at 3.04–3.05Å by $C_{5-6}S_6Hn$, both products having been synthesized hydrothermally. In the earlier report (30) attention was not directed to this difference because of the coincidence of the strong 3.035Å line of calcite with the corresponding line of $C_{5-6}S_6Hn$. A compilation of XRD data by Glen (53) for tobermorite and related phases shows the 3.0–3.1Å spacing at 3.06–3.08Å for tobermorite and C–S–H(I), and at 3.02–3.03Å for related gel-like phases. The hazard and uncertainty of differentiating between C_5S_4Hn and $C_{5-6}S_6Hn$ by XRD are recognized. However, because of the extensive DTA results characterizing these two solids, it seemed desirable to direct attention of possible application of XRD for this purpose. This differentiation applies explicitly to samples prepared by autoclaving.

In recent tests (54), CH and tripoli in a 0.83 C/S were used in following the sequence of reactions starting with C_5S_4Hn and terminating with tobermorite at 175°C. In another series, the formation and crystallization of C-S-H(I) was followed using a Type I portland cement and tripoli mix, the C/(S + A) ratio was 0.83 in most tests and the mixes were autoclaved at 175° and 205° C for different periods of time.

The DTA results of the representative samples of the CH-tripoli mix are included in Fig. 1 (curves 1, 2, 3, 4) and the XRD results are given in Fig. 2. The 5-hour sample (curve 1, Fig. 1) exhibited an exotherm at 860°C and an XRD spacing at 3.02Å. The binder was considered to be essentially C_5S_4Hn. In Fig. 2, XRD curve 1 is of a 4-hour sample and curve 2 is of a companion 4-hour specimen made with a mix containing 2% added $C\bar{C}$. The XRD curves are the same except for a small peak of calcite at 3.035Å. The 3.02Å spacing is that of C_5S_4Hn, the presence of which was confirmed by DTA (the curve being nearly the same as that of the 5-hour sample). The 6-hour

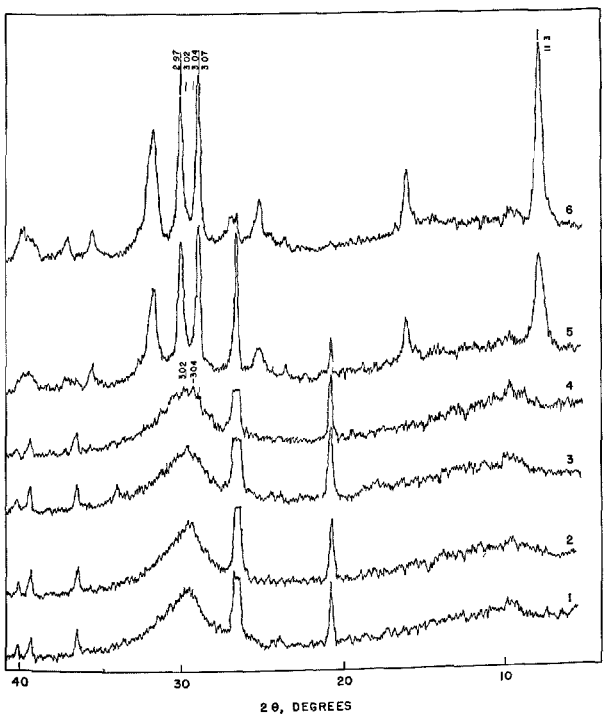

Fig. 2. *XRD tracings on* CH–S *mixes No. 1, 2, 3, 4, 5, and 6 autoclaved at 175°C for 4, 4, 5, 6, 6-1/3, and 8 hours, respectively. No. 2 contained 2 percent* $\overline{CC}$

sample showed exotherms at 860° and 835°C indicating presence of both C_5S_4Hn and $C_{5-6}S_6Hn$. This result was confirmed by the 3.02Å and 3.04Å peaks in the XRD patterns. In an attempt to obtain essentially pure C_5S_6Hn, the mixes were removed from the autoclaves at 20-minute intervals. The 6-1/3-hour sample was essentially well-crystallized tobermorite, not C_5S_6Hn. DTA indicated presence of a little C_5S_6Hn and XRD measurements revealed 4.5% quartz. The composition of this tobermorite, corrected for the free S, was 0.92 C/S. The 8-hour sample contained no residual C_5S_6Hn and only a trace of quartz and, therefore, the sample was essentially pure tobermorite.

The Type I cement-tripoli mix autoclaved at 175°C showed early formation of C–S–H(I) gel as indicated by the 3.09Å line in the XRD pattern (curve 1, Fig. 3). The C–S–H(I) persisted as a phase over broad variations in autoclaving conditions, 175°C for 4 to 96 hours and 205°C up to 96 hours, with change of C (S + A) from 0.83 to 0.60, with increase in W/S ratio to 0.8 from 0.6, and with replacement of tripoli by quartz. The only variation was changes in intensities of the XRD spectrum, the line intensity increased with increase in time and temperature of autoclaving. Representative XRD patterns are compiled in Fig. 3. The DTA results are included in Fig. 1 as curves 5, 6, 7, and 8. Only Sample 8 (curves at 205° for 96 hours) showed a small endotherm at

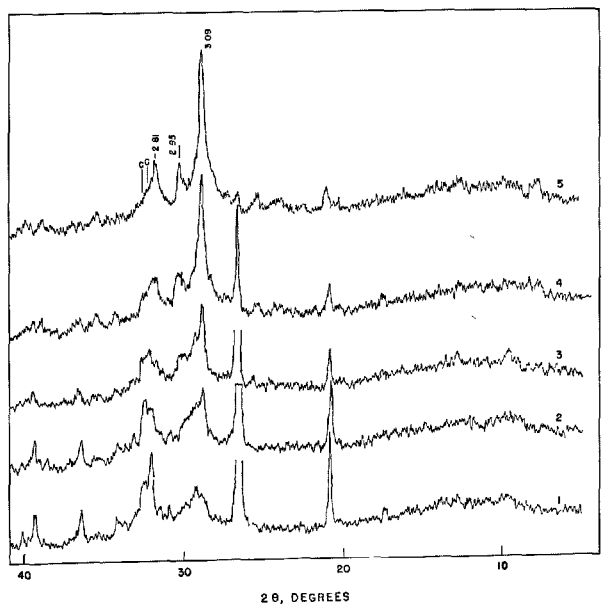

Fig. 3. *XRD tracing on cement-S, mixes No. 1, 2, and 3 autoclaved at 175°C for 4, 8, and 24 hours and No. 4 and 5 at 205°C for 24 and 96 hours*

200°C, compared to the 260-270°C endotherm of tobermorite. The exotherm at 850°C in the 4-hour sample (curve 5) decreased to 835°C after 8-hour curing at 175°C. This behavior is also shown by well-crystallized A-substituted tobermorite.

Present results showing that $C_{5-6}S_6Hn$ is a precursor of tobermorite of the Lock Eynort type substantiate the earlier results (30). The C–S–H(I) in present tests appeared to be a sinlge phase occurring in different degrees of crystallinity, depending on curing conditions and other variables mentioned.

Applying the above considerations, representative results on the commercially produced products and reference sample made with a Type I cement-ground quartz mixes are discussed. In Fig. 4 are presented XRD results on a 62.5% cement: 37.5% S samples autoclaved for 8 and 16 hours at 163°C by tracings No. 1 and 2, respectively. Samples No. 3 and 4 are commercial asbestos-cement products showing the weakest (No. 3) and strongest (No. 4) XRD patterns on these products. (These combinations of cement and quartz caused nucleation of tobermorite crystals unlike the combinations discussed in previous paragraphs in which C–S–H(I) was formed. All attempts, some already mentioned, to determine the cause of nucleation of C–S–H(I) were unsuccessful.) Sample No. 5 is a laboratory product made with a 50% Type I cement: 50% S mix and No. 6 is the same mix with 20% asbestos fiber replacement. The more intense XRD lines of Sample No. 6 suggests that asbestos promoted crystal growth. All six samples (1-6) were considered to be tobermorite, No. 1 and 3 being poorly crystallized and also probably contained significant amount of $C_{5-6}S_6Hn$.

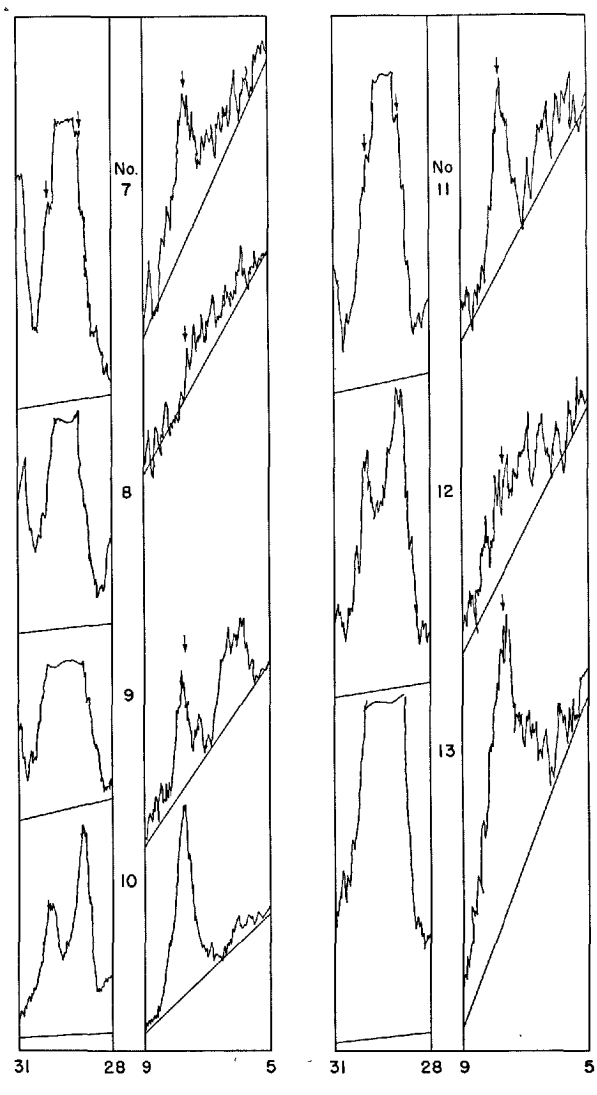

Fig. 5. *XRD tracings of concrete block (No. 7 and 8), concrete brick (No. 9), cellular concrete (No. 10), sand-lime brick (No. 11) and calcium silicate thermal insulation (No. 13)*

Present results on the 3.04Å line permits some modification of previous interpretations on the phase compositions of the binders. In laboratory samples prepared with care to prevent carbonation, it may be assumed that the 3.04Å line was due to $C_{5-6}S_6Hn$, not $C\bar{C}$. On this basis, Sample No. 1 contained a relatively large amount of $C_{5-6}S_6Hn$ which is not surprising, considering the relatively mild extent of autoclaving, 8 hours at 163°C. The XRD result on Sample No. 3 (commercial product) compared to that of No. 1 suggests that $C_{5-6}S_6Hn$, probably in significant amount, was also present in Sample No. 3, provided that the latter was not contaminated with $C\bar{C}$. At the present state of knowledge it may be assumed that if tobermorite is poorly crystallized, some $C_{5-6}S_6Hn$ may be present. However, before any conclusion to this effect can be drawn, more critical methods of testing for the crystalline tobermorite and $C_{5-6}S_6Hn$ will be required.

In Fig. 5, the patterns of concrete blocks (No. 7 and 8), concrete brick (No. 9), cellular concrete (No. 10), sand-lime brick (No. 11), deep oil well cement (No. 12) and calcium silicate thermal insulation (No. 13) are representative of autoclaved products. Large calcite contaminations in most samples tended to mask, or masked, the 3.07 and 2.97Å lines. Samples exhibiting the 11.3Å line, such as Sample No. 13, were considered to contain tobermorite even though the 3.07 and 2.97Å lines were completely submerged in the strong calcite line. In this pattern other lines of tobermorite were apparent. The binder of Sample No. 8 could not be even tentatively identified because of absence of the 11.3Å line and the masking of the 3.07 and 2.97Å lines, if present.

Application of the intensity ratio, 2.97/3.07 of 0.70-O.80, as a test for tobermorite, assuming absence of C–S–H(I), is misleading on "over autoclaved" CH–S products. A partial transformation of tobermorite to xonotlite causes a drop of this ratio to values of 0.5 and less as illustrated by results of Soo-Lee and Gon-Chen (55).

The apparent absence of C–S–H(I) in the group of 24 commercial products is surprising. Its occurrence as a binder should not be precluded in other products. Still incomplete current studies on binders (for possible commercial application) made with cement and fly ash showed presence of C–S–H(I). C–S–H(I) is apparently another modification of tobermorite. Another modification was reported by Grothe, Schimmel, and zur Strassen (56) in a laboratory produced sand-lime brick. As mentioned, attempts to ascertain cause of nucleation of C–S–H(I) were unsuccessful. This may not be due to the R_2O_3 in the cement or fly ash. Sauman (57) obtained C–S–H(I) in autoclaved mixtures of βC_2S and quartz powder.

Ionic Substitutions in Lattice of Tobermorite

Basic Studies

In studies of substitution of Al^{3+} in the lattice of tobermorite, the compositions of the mixes were computed generally to a 0.83 C/(S + A) ratio. On a weight basis 1.00% A replaced 1.18% S. The tobermorite with substituted A exhibited the same XRD pattern as the A-free tobermorite except for a small increase in values of the basal spacing with increasing amounts of A. Up to 5–6% A was substituted before a hydrogarnet, C_3ASH_4, was detected by XRD as a second phase. Diamond (58) in similar experiments reported A substitution up to 10%; A in excess of 10% and up to 15%, however, did not appear as a hydrogarnet. In autoclaved pastes, made from CH and shale, a hydrogarnet was not detected with 10% addition of A (36). Glenn (53) reported A substitution in tobermorite made with CH and bentonite.

Diamond (58) also substituted several percent of F, using goethite as source of F, into tobermorite. Later experiments (59) with new starting materials of same apparent descriptions lead to substitutions of less F than in the previous tests. Unpublished results by the writer on samples prepared with C_2F and C_4AF (the latter supplying equal amounts of A and F) led to a tentative conclution that F was substituted in tobermorite. Reproducibility of results, however, was poor. Furthermore, using mix compositions computed on assumption that the F substituted for the C yielded indirect evidence that some of the Fe^{3+} assumed octahedral coordination and occupied Ca^{2+} positions. The difficulty in attempts to substitute F may be due to the larger ionic radius, 0.64Å, of the Fe^{3+} compared to 0.50 and 0.41Å of Al^{3+} and Si^{4+}, respectively. More recent tests (60) on pastes made of CH, tripoli and goethite in C/(S + F) ratio of 0.83 and autoclaved at 175°C for 8 and 16 hours again yielded uncertain results. More intensive curing,

72 hours at 200°C of a mix having a 0.83 C/(S + F) which was equivalent to a C/S ratio of about 1.0, resulted in formation of well-crystallized xonotlite and goethite. In this experiment the F did not stabilize the tobermorite lattice as A does. The F-bearing tobermorite or the precursor gel which presumably formed was entirely decomposed by the prolonged autoclaving at 200°C. The DTA tracing showed no exotherm at 835°C, a result previously reported (59).

At room temperature, Copeland, Bodor, Chang, and Weise (60) reacted high-lime tobermorite gel with aluminates, ferrites, and sulfates. The F substituted in amount of 7.1% and the product had a C/S ratio of 1.52. A in amount of 5.0% substituted in a solid of 1.50 C/S ratio. It is apparent that tobermorite and high-lime tobermorite gel have approximately the same capacities for Al^{3+} but different capacities for Fe^{3+}. On basis of present knowledge on substitution of F, it may be speculated that the F enters the lattice of the intermediate gel in the course of the reactions. In the recrystallization of tobermorite gel to low-lime gel and then to tobermorite some or all of the F, depending on intensity of autoclaving may be expelled. Obviously, no definite conclusion may be drawn, and more research is required on Fe^{3+} substitution.

Diamond (58) reported substitution of several percent of M into tobermorite. The results (58, 59) tended to be somewhat erratic, perhaps for some such reason as relates to F substitution.

At room temperature, Copeland, Bodor, Chang, and Weise (60) substituted 7.4% $\bar{S}$ into high-lime tobermorite gel and the product had a C/S ratio of 1.76. Studies (61) on autoclaved pastes of CH, tripoli and $C\bar{S}H$ cured at 175°C and 205°C for 8 to 72 hours indicated that 1.2 to 1.9% $\bar{S}$ (presumably as SO_4^{2-} substitution for SO_4^{4-}) entered the lattice. The average amount was 1.6% S.

Phases other than Tobermorite in the Pastes

The A, etc., in a paste not substituted in the tobermorite lattice obviously appears as some other phase. The most probable second phase with A and F is a member or members of the hydrogarnet solid solution of composition, $C_3((A_{1-x}\cdot F_x)(H_{6-2y}\cdot S_y))$. As mentioned, C_3ASH_4 formed as the second phase with substituted tobermorite of composition $C_5(S + A)_6H_5$ and another unidentified hydrogarnet (31) formed in pastes having a composition of 6C/6 (S + A). A hydrogarnet was not detected in any of the 24 commercially produced products (45, 46). Akaiwa and Sudoh (62) autoclaved pastes of Type I cement, 55% Type I cement: 45% slag, and Type I cement: 40% quartz flour. Hydrogarnet was found only in the pastes made with slag and autoclaved at 250°C. Aiken and Taylor (48) detected hydrogarnet sporadically and in small amounts in autoclaved cement and cement-silica pastes. Kalousek, Curtis, and Schmertz (63) and Kalousek (52) reported only a trace amount of hydrogarnet in one clinker paste cured at room temperature, as a metastable phase. Copeland, Kantro, and Verbeck (64) detected a hydrogarnet in small amount in a Type V cement paste cured for 14 years at room temperature.

The distribution of F in autocalved products is not definitely known because of uncertainties about the amounts substituting. The possibility that some of the F may appear as goethite of hematite has been indicated in scattered tests. Further experimental evidence is required for ascertaining distribution of this constituent in autoclaved products.

The conclusion that hydrogarnets do not form in autoclaved products except sporadically and in small amounts may be made with one exception. A hydrogarnet can generally be expected in products made with fly ash, slag, etc., of high A content and used in relatively large amount.

The $\bar{S}$ in excess of about 1.6% has been observed to appear as either anhydrite or a substituted apatite in pastes autoclaved at 120° to 200°C (61). The apatite is the mineral ellestadite with composition of $C_{10}S_3\bar{S}_3H$.

Applied Studies

Published data on the effects of substituted ions on properties of tobermorite are still small in number. The results on optimum $\bar{S}$ content of steam-cured products has been reviewed (61). The amounts of $\bar{S}$ for optimum strength have not been published, but scattered results including extrapolation indicate that less than 1% $\bar{S}$ might be the amount for optimum performance.

Noorlander (65) reported data showing that drying shrinkage of autoclaved sand-lime brick decreased progressively with increasing amounts of kaolin or gibbsite added to the raw mix. Based on experience described in this report, it may be assumed that the A substituted in the lattice of tobermorite. The data are reproduced in Fig. 6 as drying shrinkage vs A content computed as percentage of tobermorite using a value of 9% of C added to the sand. The

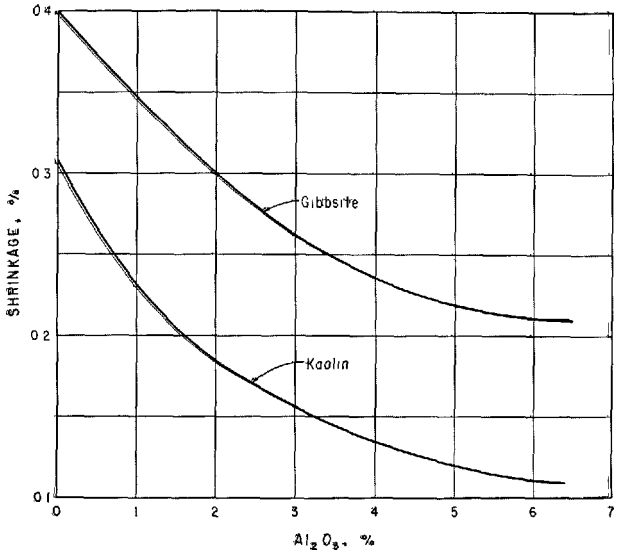

Fig. 6. *Drying shrinkage vs* Al_2O_3 *content in tobermorite (Noorlander (66))*

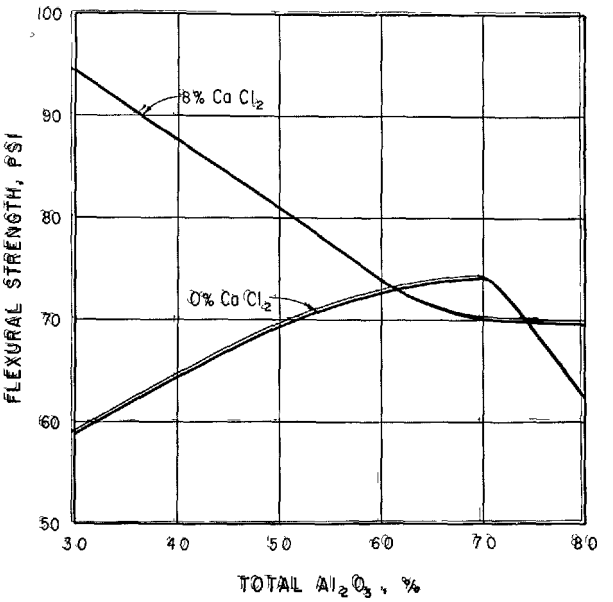

Fig. 7. *Flexural strength vs* Al_2O_3 *content with and without added* $CaCl_2$

shrinkage decreased with increasing amount of A. The lowest shrinkage reported occurred at 6% A on basis of the assumed composition. This result suggests that minimum shrinkage may be associated with an optimum A content. The shrinkage reduction from 0.3% (zero A) to 0.11% with an optimum A addition is significant.

Data reported in a patent (66) on effect of A substitution on reduction of drying shrinkage at high temperatures (108° to 649°C) of calcium silicate thermal insulation are reproduced in this paper. The results, in turn, are compared with results of similar products containing chloride. The experiments were designed on the assumption that drying shrinkage at these high temperatures might be reduced by substitution of $C\bar{l}$ for the $O\bar{H}$ in the crystal lattice. The mixes made of CH, diatomite, tripoli, kaolinite and $CaCl_2$ had a C/(S + A) ratio of 0.83. The amount of $C\bar{l}$ was not counted, it being assumed that $C\bar{l}$ replaced $O\bar{H}$. Autoclaving was at 186°, 192°, 198°, 203°, and 208°C. Only at 208°C was drying shrinkage reduced. This reduction amounted to 50% for specimens containing a total A content of 7% and $C\bar{l}$ of 5.1%. Tests for free $CaCl_2$ were negative. XRD patterns were the same for samples with and without added $CaCl_2$.

The flexural strength (Fig. 7) was at an optimum value at 7% A content in specimens containing no $CaCl_2$. The strength of the sample containing 5.1% $C\bar{l}$ and 7% A was about the same as that without $C\bar{l}$ (the variations are apparent in Fig. 7). Drying

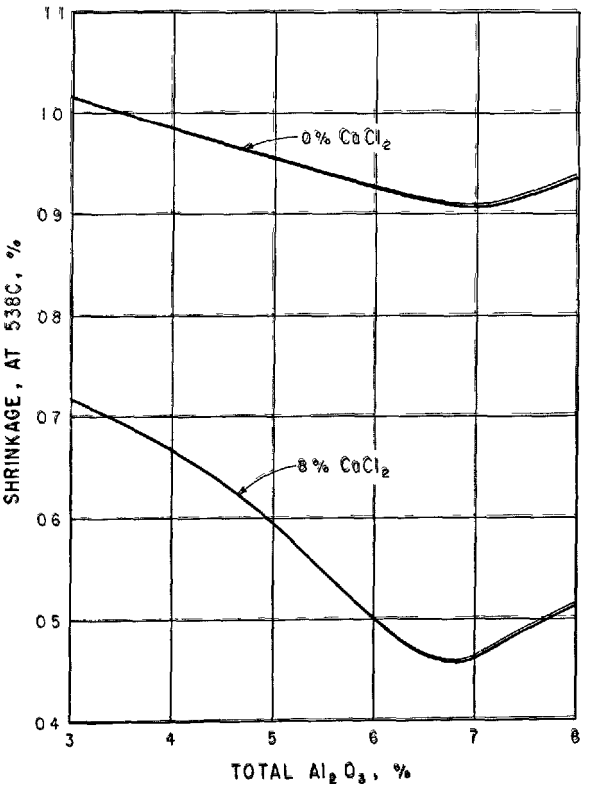

Fig. 8. *Drying shrinkage at 538°C vs* Al_2O_3 *content, with and without added* $CaCl_2$

shrinkages at 538°C of the 0.0 and 5.1% $C\bar{l}$ specimens cured at 208°C are shown in Fig. 8. Shrinkage

of the 0.0% $\bar{Cl}$ specimens decreased only slightly with increasing A contents to 7.0% and then increased slightly with more added A. The 5.1% $\bar{Cl}$ addition caused a large shrinkage reduction compared to the 0.0% $\bar{Cl}$ samples. The lowest shrinkage occurred with 7% A addition.

Actual proof was not developed, nor is such conclusion drawn, that the $\bar{Cl}$ substituted for the $\bar{OH}$. The unusual effect of $\bar{Cl}$ on drying shrinkage at elevated temperature appears to merit further study.

The probable modification of properties of tobermorite products by lattice substitution to obtain optimum properties appears to be a potentially rich area for basic and applied research.

Kinetics

In an aqueous dispersion of CH and S, the CH dissolves rapidly and Ca^{2+} are available immediately for reaction. The S dissolves slowly at room temperature but the rate of solution increases with increasing temperatures. Greenberg (67), and Halstead and Lawrence (68) used solubility data of CH and S in studying the kinetics of the reaction. Both reached the conclusion that rate of solution of S, or more specifically the availability of the silicate ions in the reaction zone, was the rate-determining step.

The manner of deposition of films of reaction products on the S grains and properties of such encapsulating deposits have been studied in recent years. Moorehead and McCartney (69) exposed large crystals of quartz to a solution saturated with CH in an autoclave at 235° and 335°C. They deduced the following sequence of reactions: (1) The S dissolved as $H_3SiO_4^-$, (2) the silicate and Ca^{2+} formed a deposit of a calcium silicate hydrate on the quartz surface, (3) xonotlite crystals nucleated on the reaction product film and the deposit of this phase grew outwardly into the liquid phase, and (4) the rate of reaction was governed by the rate of diffusion of the silicate ions through the deposit surrounding the quartz crystal. The solution of the quartz finally destroyed the initial quartz-calcium silicate hydrate interfacial bond and the residue of the quartz crystal was likened to a nut in a shell. Kondo (44) reacted quartz and silica glass of 5–10 micron size with CH at temperatures of 80° to 216°C. From analytical data collected, he computed the thickness of the films to be 0.5 and 1.0 microns for the silica glass and quartz, respectively. The rate of diffusion of the ions through the deposit was considered to be the rate-determining step. Krzheminski, Rashkovich, Sudina, and Varlamov (70) using a specially designed XRD spectrometer placed over the CH–S mixture in an autoclave obtained a continuing record of the reaction. The nature of the calcium silicate hydrate was reported to vary with increasing distance from the surface. Only at later periods of reaction did the rate of diffusion through the film of reaction product become the rate-determining step. Logginov, Rehbinder, and Abrosenka (71) reported that the rate of formation of the reaction products decreased with increasing thickness of the film deposit. After a certain lapse of time the thickness of the film became uniform and the rate of reaction was then governed by the rate of diffusion. Assarsson (72) autoclaved CH with S, silica gel and different silicate minerals. He reported the films of reaction products nucleated on the surface of the silica and silicates. The subsequent rate of reaction depended on the availability of the Ca^{2+} and silicate ions to the surfaces of the reaction products already formed.

There is general agreement that the rate-determining step in the reaction of CH and S is the diffusion of ions through the reaction products surrounding the S grains. Direct evidence of the occlusion of CH crystals by surface deposits is not so well documented as is that of S grains. Kalousek (73) compared the relative rates of reaction of large crystals of CH, up to 85 microns across, to freshly slaked C (the crystals being submicron in size) with sodium silicate at 25°C. The small crystals reacted rapidly, but the reaction with the large crystals proceeded to completion very slowly. Microscopic examinations revealed that the large CH crystals, although etched, remained surrounded by presumably nearly impervious reaction products for months. Dry mixtures of C and S, with subsequent addition of mixing water were compared (74) to mixtures prepared by addition of the S to CH suspensions freshly prepared by slaking C in hot water. The latter gave more uniform and reproducible results in autoclave curing. These and similar experiences indicated that unless the CH is thoroughly dispersed, it tends to form agglomerates. Such CH agglomerates may become surrounded by deposits of reaction products and behave like large individual crystals of CH. The Soviets practice (2) of fine grinding of CH with silica sand for improving quality of fine grain concrete may relate to a greater

availability of CH for reaction by preventing the occlusion of agglomerates of CH by deposits of reaction products.

It has been observed (6, 30, 44, 50, 51, 70, 75, 76) that reaction of CH and S at temperatures of about 125°C to 200°C proceeds through stages. The first reaction product is a lime-rich phase generally called lime-rich tobermorite gel of probable composition of C_7S_4Hn (30, 51, 52, 77). The phase reacts with residual S to form C_5S_4Hn and further reactions with residual S results in formation of CSHn followed by C_5S_6Hn provided the raw mix had a 5C:6S composition. If the C:S is less than 5:6, residual silica remains. Kalousek (30) using a 0.83 C/S (5C/6S), 4.0 W/S mix and curing at 175°C, and Neese (51) with a 0.33 C/S, 1.85 W/S mix, and curing at temperatures of 140° to 200°C reported highly similar results. The sequence of reactions was: $7C + 4S + Hn \longrightarrow C_7S_4H_3 \xrightarrow{S} C_5S_4Hn \xrightarrow{S} CSHn \xrightarrow{S} C_5S_6Hn \longrightarrow C_5S_6H_5$, Neese's final product coexisted with S. The time of formation of the different compositions varied between the two investigations. This difference is attributed to effect of W/S ratio. The lower the water content, the slower is the rate of formation of the products. Others (30, 55, 78) have reported similar effects of W/S on rate of reaction. In CH–S mixes of 0.8 C/S made with 4.0–20.0 W/S, compared to a 1.0 W/S, the rate of reaction was markedly increased (55). The effects of W/S have not been as systemically studied on CH–S as with portland cement pastes. A W/S ratio of 1.0 using CH and S gives a stiff paste due to the large surface area of the CH and such value of W/S would be considered low. An early attempt (36) to produce lime-cement-sand and gravel block on a concrete block machine was unsuccessful due to high water requirements with attendent low strengths. The Soviets (2) have surmounted this problem by using dead burnt lime and retarders to prevent hydration of the C until after the products were molded and heat applied to the forms.

The preceding discussions do not apply fully to silica gel, compared to quartz. Replacement of silica gel for quartz in a 0.8 C/S mix (30) increased the time of formation of tobermorite to 72 hours, compared to 8 hours for quartz. Increasing the C/S to 0.83 of the silica gel mix reduced the time from 72 hours to 24 hours. It was postulated that C_5S_6Hn, the precursor of tobermorite, was stabilized by the higher silica concentration in solution in the 0.8 C/S mixes due to persistence of free silica gel. Soo-Lee and Gon-Chen (55) using C/S ratios of 0.80 and 0.85 obtained essentially the same results mentioned for silica gel. Gaze and Robertson (79) in parallel experiments using ground quartz in one mix and diatomite in the other obtained tobermorite and $C_{5-6}S_6Hn$, respectively. The difference could have been due to a higher silica concentration in the CH-diatomite mix.

Nucleating agents are surfaces of solids possessing cell-size domains of about the same size as that of the solid to be nucleated. As already discussed, quartz surfaces (69) may become a substrate on which nucleating points may form, such as those for xonotlite. The number of nucleating points in such case would be obviously proportional to the surface areas of the quartz.

Funk (80) measured qualitatively the rate of hydration of βC_2S with and without addition of lime-rich tobermorite gel and αC_2SH at temperatures of 25° to 120°C. The mixture of βC_2S with the added gel hydrated more rapidly than in absence of the gel and the product was high-lime tobermorite gel. The mix containing the added αC_2SH also hydrated more rapidly and the product of hydration was only αC_2SH. Funk reported that hydration of βC_2S without addition was a solid-state reaction; and with the additions a through-solution mechanism applied. Sauman (57) reported marked acceleration of the hydration of βC_2S in a 50% βC_2S: 50% quartz powder by additions of CH, C_3S and γC_2S. He offered no explanation, but it may be inferred that the CH, as such or originating from hydrolysis of C_3S, reacted with the quartz to form the lime-rich gel, and this, as in Funk's test, served as nucleating agent. It is not apparent how γC_2S accelerated hydration unless its lattice as such served to nucleate the reaction product. The simplest explanation of the acceleration of hydration of βC_2S by nucleating agents is the diffusion of the Ca^{2+} and silicate ions away from the surfaces of the βC_2S crystals. The thickness of reaction deposit around the βC_2S crystals would thereby be decreased. The dissolving ions with a thinner deposit to permeate, would diffuse from the residue crystals of βC_2S at a faster rate with attendant acceleration of hydration.

The formation of αC_2SH by hydrothermal reaction of CH and S is erratic and unpredictable; other lime-rich products frequently form (74). A patented process (81) describes selective formation of αC_2SH by additions of NaOH or NaF to the raw mix. The mechanism was not described, but both additions decrease concentration of CH in the solution, and this may be a factor in formation of αC_2SH.

The mechanism of nucleation, either spontaneously from super-saturated solution or by epitaxial crystallization, of the different calcium silicate hydrates is not understood. The process may be governed by

the species of the ions formed and their concentrations under the conditions of the experiments. Information on concentrations of both ions at room temperatures has been published. Very little is known definitely of the species of the ions formed at hydrothermal temperatures. Taylor advanced some speculative interpretations which merit mention here as a guide to further research in a neglected area. The Ca^{2+} may exist as such, or as $Ca(OH)^{+}$ or $Ca(H_2O)(OH)^{-}$. The silicate ions may be present as $H_3SiO_4^-$, $H_2SiO_4^{2-}$, $HSiO_4^{3-}$ or condensed polysilicates. The species of ions and concentrations of these undoubtedly have an effect on the type of phase that uncleates either spontaneously or epitaxially. Taylor's (6) suggestions on relations between kind of silicate ion in solution and types of product are presented diagrammatically in Fig. 9. For example, $H_3SiO_4^-$ forms the intermediate products which recrystallizes to gyrolite. The methods of analysis for kind and amounts of silicate ions developed by Lentz (82), and Funk and Frydrych (83) would appear to be means for testing Taylor's hypothesis.

Only at temperatures up to about 200°C, the phase C_7S_4Hn forms initially in reaction between CH and S. At temperatures above 200°C, this phase may no longer form. Bozhenov and Kavalerova (26) reported formation of gyrolite at 225°C from a 2.3 C/S mix. Kondo (44) observed gyrolite formation at 216°C as the initial reaction product. The experimental data are still too few to define the temperature above which the CH and S form species of ions favoring the nucleation of a product other than C_7S_4Hn.

The preponderance of evidence relating to the kinetics of reactions of CH and S points to through-solution mechanisms. Solid state reactions in hydrating cements were discussed by Hansen (8) and of βC_2S by Funk (80). Steinour (85) and Mielenz and Peppler (86) critically reviewed Hansen's hypothesis, particularly the improbability of diffusion of such ions as H_3O^+ and OH into the structures of the solid reactants.

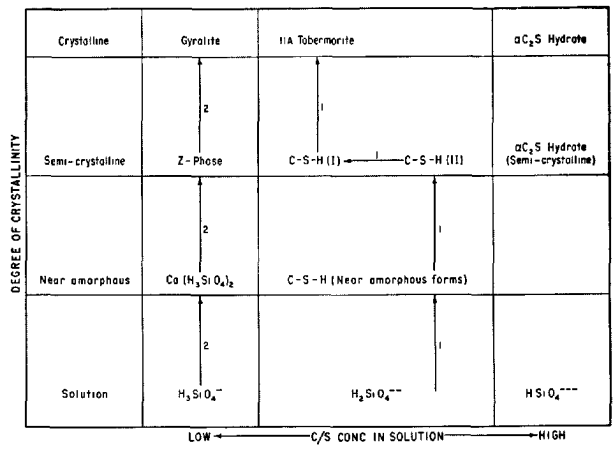

Fig. 9. *Taylor's (6) diagrammatic relation between degree of crystallinity and* C/S *ratio of solution*

Most generally the binders in commercially autoclaved products are metastable phases. The only exception appears to be xonotlite. Peppler (87) in study of the system C–S–H at 180°C allowed up to 6 months for attainment of equilibrium starting with both saturated and undersaturated solutions of the starting materials. He concluded that only two ternary phases were stable, xonotlite and hillebrandite. Roy and Harker (88) presented compatibility diagrams of the system C–S–H at temperatures up to 1,000°C. They cautioned about the uncertainties on the attainment of equilibrium, especially at the lower temperatures used in commercial autoclaving.

The preceding discussions were concerned with the kinetics of CH and S. No comparable research results are available on cement and S. This system is more complex because the cement clinker grains become encapsulated by reaction products. Further the calcium silicates form initially as lime-rich phases which later become reactants with S so long as it is available. When S availability for reaction is decreased, as it appears to be at times, the lime-rich gel may crystallize as αC_2SH.

Relation of Binders and Properties

Most of the commercially prepared samples which were examined were made with cement and ground quartz or perhaps some other siliceous fines. Mixes prepared with cement require substantially less water than those made with lime. This larger water requirement for CH–S mix may be surmounted partly by forming the stiff mixes under high pressure.

Taylor, Moorehead, and Cole (78) compressed CH–S mixes with 0.23 W/S under high pressures and obtained very high strengths. XRD and electron microscopy revealed the binder to be possible $C_{5-6}S_6Hn$ (89) of fibrous habit. Very dry mixes, 0.06 W/S, of CH and S contained (90) some free CH and some C_5S_4Hn (as suggested by reported DTA

results) and other phases after curing at 180°C for 16 hours. In such very dry mixes, water may be exhausted by self-desiccation and, therefore, the hydration reactions may stop.

Very little data appears to have been published showing the effects of $C_{5-6}S_6Hn$ in a binder consisting partly of tobermorite on strength of dense products. Sanders and Smothers (91) published results indicating increasing strength with increasing amount of tobermorite formed in dense products made with cement and S. In highly watered suspensions of CH and S, 3.0 to 6.0 W/S, used in manufacturing lightweight thermal insulation and structural products, strength was markedly higher with tobermorite as binder compared to $C_{5-6}S_6Hn$ (92). No reason can be advanced to explain why a highly compacted product with $C_{5-6}S_6Hn$ has high strength and the same phase in a product of low density gives inferior strength, far less than due to effect of increased water content.

Strength results were not available on the commercial products examined (45, 46). Because all products were marketed, many under specifications, there was no reason to believe that any had poor strengths independently of binder phase composition. Sauman (93) on basis of detailed tests concluded that optimum strength was obtained for product containing a binder consisting of tobermorite and "CSH" (presumably $C_{5-6}S_6Hn$).

Correlation of type of binder with strength of product requires attention to possible "overautoclaving" of the product. Prolonged autoclaving of dense products may cause strength reduction from an optimum value. Bessey (94) suggested that either a change in crystal form of the tobermorite or an inversion of one phase into another (for example, tobermorite to xonotlite) could cause strength reduction. The destruction of the quartz-calcium silicate hydrate interface through solution of the S and diffusion outwardly of the silicate ion (69) would be another factor causing strength loss. This effect has not been established for quartz-tobermorite or other aggregate-binder interfaces. However, until proven or disproven, the Moorehead-McCartney effect is a factor suspect of causing strength reduction of "overautoclaved" products.

The beneficial effect of increasing autoclave temperature for accelerating formation of binder of satisfactory strength in the approximate temperature range of 140–200°C is well documented. Much less is known about the effect of increasing temperatures between 200–225°C to 350°C on cement-silica or lime-silica products. Binders prepared by autoclaving a raw mix of 2.3 C/S gave maximum strength at 265°C (26). At temperatures above 265°C, the phases were more strongly crystallized, and those below this temperature were more gel-like. The reaction products differed in phase makeup at different temperatures. The two effects mentioned by Bessey (94) and that by Moorehead and McCartney (69) may have contributed to the strength decreases at temperatures above 265°C. It does not necessarily follow that a given binder if well crystallized may have lower strength than if poorly crystallized. Xonotlite may be such an example. On the other hand, the composition of the tobermorite—$C_{5-6}S_6Hn$ binder may relate to the relative amounts of these two phases present.

Effects of temperatures at 260° to 300°C have been reported (95) on a 1:2 mix of hydrated lime and quartz fines mixed with 8% of water. Time to temperature (300°C) in the autoclave was 20 minutes. After holding times of 1 minute and 100 hours at 300°C, the compressive strengths were 23,800 and 18,500 psi, respectively. The CH was combined in the total autoclave time of 21 minutes at this temperature. XRD revealed no recrystallization of the binder in 100 hours. Strength loss was attributed to the Moorehead-McCartney effect.

Another factor which will have to be considered in relating strengths to degree of crystallinity will be the amounts of substituent ions in the lattice. Properties may relate to amount of substituent ions while the binder retains approximately a constant crystal size so far as differentiation between gel-like and crystalline phases is concerned.

Frost resistance relates to porosity of autoclaved products. The Soviets (2) report that binders consisting of gel and crystals, or gels alone, have lower porosities, and therefore higher frost resistance, than well-crystallized binders. Control of porosity is amenable through control of intensity of autoclaving.

The markedly better resistance of autoclaved products to sulfate attack compared to normally cured products, has been recognized for some time (23, 96, 97). Such improvement is of a particular interest in application of asbestos-cement and concrete pipe in soils containing sulfate. The improvement in part has been attributed to removal of CH by combination with the S or silicates during autoclaving. The inactivation of the A-bearing phases to reaction with $\bar{S}$ to form ettringite has been attributed to several mechanisms, no one of which has been substantiated experimentally. Autoclaved Type I and Type V cement products tend to show equal resistance to sulfate attack. The assumption that hydrogarnets,

known to be immune to sulfate attack, are formed does not appear to be tenable. It is doubtful that hydrogarnets are usually present in significant amount, if at all. It is well established that sulfate resistance is increased by decreased permeability of the cement paste. If the A-substituted tobermorite, as such, is resistant to $\bar{S}$ attack low permeability of the autoclaved product or concrete would not be a requirement. Some of the samples of autoclaved asbestos-cement pipe that were examined contained well-crystallized tobermorite and others contained poorly crystallized tobermorite with some $C_{5-6}S_6Hn$. It would be interesting to compare such products for sulfate resistance and also for strength.

In the United States and Canada, autoclaving as a method of curing gained favor because of drying shrinkage reduction (4). Tobermorite shrinks about one-half as much as tobermorite gel.

A further improvement due to autoclaving, and inferred from Noorlander's (66) results, is the shrinkage reduction by substitution of A in tobermorite. The effects of optimum $\bar{S}$ and F for minimum shrinkage and maximum strength remain to be explored experimentally. Tobermorite is not the binder of lowest shrinkage among autoclaved calcium silicate hydrates. αC_2SH undergoes much less shrinkage but at the cost of sizable strength loss. The effects of reactive siliceous additions, W/C ratios, and curing time and temperature may be summarized in a generalization (4): "Those factors which increase strengths of cement-silica pastes also increase drying shrinkage."

Effects of autoclaving on other properties (creep, porosity, adsorption, etc.) have been described in the Rilem (2) and ACI reports (4).

Determination of dependable relations between nature of the binder, principally gel-crystal composition, and physical properties of the products should prove highly useful in advancing the technology. The gel-crystal composition should be amenable to control through predetermined autoclave cycles and choice of starting materials. No single method is yet established for this purpose. XRD appears to give a qualitative indication of degree of crystallinity. Usefulness of this method should increase as differentiation between gel and crystals is more fully resolved by other methods in conjunction with XRD. BET nitrogen surface areas of 38, 38, 45, 70, and 86 m^2/g were reported (98) for binders of autoclaved blocks made with pumice, sintered shale, shale, cinders and silica sand and gravel, respectively. The nitrogen surface areas were 43 (36) and 50 m^2/g (30) for tobermorite, and about 160–180 m^2/g (30) for $C_{5-6}S_6Hn$. The surface area results suggest that the binder of the sand and gravel, and cinder blocks contained some high surface area phase, presumably $C_{5-6}S_6Hn$. A substituted tobermorite exhibits a higher surface area than pure tobermorite (59) and this factor would have to be considered in application of surface area results for the suggested purpose.

DTA might prove useful only in examining products containing little or no A. The A-substituted tobermorite shows an exotherm at about the same temperature as $C_{5-6}S_6Hn$.

Uncertainties still exist on usefulness of electron microscopy for defferentiation between gel and crystals on the grid collected from liquid suspensions of the test sample. The sample on the grid is not necessarily representative of the major phase. This difficulty may be subject to correction by application of the scanning microscope (99) in conjunction with a replication method (60). Techniques of preparing the surface for replication offer opportunities for innovations. An earlier report (30) that $C_{5-6}S_6Hn$ was of fibrous morphology was later revised on bases of new results (92) that the morphology was of a crinkled foil variety in agreement with observations by Grudemo (100). Now recently, (89) the crystal habit of this phase was reported to be fibrous. It is not certain which of the two habits represent $C_{5-6}S_6Hn$. Perhaps both are present and method of sample preparation for examination is a factor as to which is collected. On the other hand, excessive illumination, even though of minimal intensity required for resolution, may account for the crinkled foil habit. Examinations of various phases (92) using minimal and intensive illumination showed the crinkled foil crystals unaffected by intense illumination while other were altered, some significantly. The possibility that the crinkled foil may be an artifact cannot be excluded. Budnikov and Strelkov (101) discussed similar difficulties experienced in electron microscopic examination of cement pastes.

Summary

1. A large background of scientific information has been developed on hydrous calcium silicates as binders of concrete products during the past 20 years.

2. Results on 24 autoclaved commercial products indicate the binder to be well to poorly crystallized tobermorite. The latter (in some samples) coexists with $C_{5-6}S_6Hn$ gel, proposed to be the precursor of tobermorite.
3. Lattice substitution in tobermorite of Al^{3+}, Fe^{3+}, SO^{2-}, etc., may significantly affect the properties.
4. The gel-crystal composition of the binders appears to be an important area for research for explaining and controlling properties.
5. Kinetics of the reactions of CH and S are closely dependent of the rate of diffusion of the ions through the reaction products encapsulating the S grains.
6. More remains to be learned about the effects of W/S ratios on properties of CH-S products.
7. Results suggest that Taylor's gel, C–S–H(I), may differ from the low-lime gels described by Kalousek and Neese.

Written Discussion

Waldemar C. Hansen

This is to be limited to a discussion of through-solution reactions and the reactions which have been referred to, by various authors, by such terms as topochemical, solid-state, solid-liquid and in situ reactions. Kalousek, concludes that the preponderance of evidence points to a through-solution mechanism for the reaction of silica with calcium hydroxide and he refers to a paper published by me in 1959 pertaining to solid-state reactions in portland cement pastes. Two, more recent, papers (1 and 2) review some of the literature on such reactions. From these reviews, and from other literature which was not included in those papers for example (3 and 4), it seems that one must conclude that compounds such as silica and the cement minerals cannot dissolve in an aqueous medium without undergoing a reaction with the ions of water and possibly other ions from the medium. That is, a reaction must occur at the surface of the solid particle which overcomes the ionic forces that bind the ions to one another in the solid. For example, when sllica reacts with water the surface of the particle is converted to a silicic acid. The ions of this acid, probably by further hydration, can separate from the unreacted solid and diffuse into the liquid. In other words, the silicic acid dissolves in the water and any silicic acid that precipitates from the solution was formed by a through-solution mechanism. However it was not formed by the dissolution of silica which, after dissolving, reacted with the water to form silicic acid.

The evidence in the literature points to the conclusion that compounds such as calcium oxide and the cement minerals, which form reaction products with water having relatively low solubilities, become coated with a layer of the reaction product; which, after reaching some thickness, ruptures or spalls forming a number of small particles or crystallites. This exposes fresh surfaces of the reactant to the liquid phase. These colloidal sized particles, because of their size and probably because of an almost amorphous nature, have higher solubilities than the solubility of larger and more nearly perfect crystals of the reaction product. Hence they tend to dissolve and recrystallize as relatively large and perfect crystals. It seems reasonable to assume that some of these colloidal

particles act as nuclei for the crystallization of the dissolved material.

According to Kalousek, Funk found that additions of either a lime-rich tobermorite gel or alpha-C_2SH to pastes of beta-C_2S accelerated the rate of hydration of the C_2S. Also that the final product in each case was the same as the added material. It seems that this acceleration can be explained on the basis that the solubility of the topochemical product formed on the surfaces of the C_2S grains was greater than that of either of the additives. Accordingly these materials acted as nuclei to remove the dissolved calcium silicate and prevented the solution from becoming saturated with respect to the topochemical coating. It seems that under such conditions the coating might be dissolved almost as rapidly as it formed, whereas, in the absence of added nuclei, no nuclei were present until the topochemical layer formed its own, probably after a layer ruptured.

According to Vyrodov, supplementary paper, "On some aspects of theory of solidification and strength formation of cement-stone and concrete," Baikov believed that the cement minerals reacted topochemically with water and that these more or less amorphous reaction products were the binder of the cement paste. Some dissolution and recrystallization of these products occurred, but this was not essentially a part of the mechanism which caused hardening and the development of strength.

Taylor, principal paper, "The calcium silicate hydrates," suggests the following in the formation of C-S-H. A high C/S product is formed on the surfaces of the crystals of C_3S and C_2S. This probably is composed initially of Ca^{2+}, $H_2SiO_4^{2-}$, and OH^- ions and H_2O molecules and has a C/S ratio close to that of the starting material. A second product is formed by dissolution and reprecipitation of this product. Further anion condensation may occur within this material, either by *in situ* transformation or by repeated dissolution and reprecipitation. It is seen from this that Taylor believes that it is possible for these reaction products to develop better crystallinity without dissolving and recrystallizing from solution. It seems that there may be no need to postulate that the original topochemical product has to dissolve before it can improve its crystallinity. When the cement minerals react in the presence of relatively large amounts of water and possibly also under high-pressure steam curing much of the topochemical reaction product probably dissolves and recrystallizes, but with W/C ratios of practice and at atmospheric temperatures probably very little of this product dissolves. However there might be considerable in situ rearrangement of the structure as the cement paste ages.

It seems that cement technologists should accept the conclusions that (a) the cement minerals react topochemically with water and possibly other ions from the liquid phase of the cement paste, (b) these reaction products will dissolve to some limited extent to yield relatively large and nearly perfect crystals and (c) the second step is of relatively little importance in the development of the properties of the hardened paste cured at atmospheric pressure but may be of greater importance for pastes cured at elevated pressures.

Synopsis

The aim of the research project discussed in this paper was to find a relationship between phase constitution and strength of hardened cementitious pastes. Specimens of

hardened pastes containing different types of binding new-formations were used for the investigation. These cementitious pastes were made of mixes of $Ca(OH)_2$, C_3A and C_3S with ground siliceous materials and were left to harden for different periods of time at temperatures 20°C, 80°C and 175°C.

The phase constitution of hardened cementitious pastes was studied by X-ray phase analysis, by a complex thermal analysis, by electron microscopy and by chemical analysis. Over-all porosity and compressive strength of specimens were determined by usual methods.

The results have shown that the strength of hardened cementitious pastes is given by the type and the volume of binding new-formations developed in the pastes.

Among the pastes containing the same volume of binding new-formations the highest strength was developed by those, in which the tobermorite—like phases were found as binding new-formations. The drop of relative strength (P) of pastes, depending on the type of binding new-formations developed in the pastes, is characterized by the following sequence:

Tobermorite-like phases (100% P) → CSH I (56 to 62% P) → mixture of 70 to 80% gehlenite hydrate and 20 to 30% CSH I (28 to 32% P) → mixture of 70 to 80% of hydrogarnet phase and 20 to 30% of CSH I (13 to 20% P) → C_3AH_6-hydrogarnet phase (3 to 4% P).

The strength of pastes containing the same type of binding new-formations is given by a power function of volume-θ occupied in the paste by the binding new-formations and may be expressed by the general formula:

$$P = a\theta^3 + b\theta^2 + c\theta$$

The relationship between the strength and the phase constitution of cementitious pastes may be in practice biased by internal flaws of their macrostructure developing, as a rule, in the early stage of their hardening.

Introduction

In his principal paper "High temperature steam curing of concrete at high pressure" (Part III, Session 5) G. L. Kalousek (1) discusses the present knowledge of interrelations between the type or constitution of the binder, developed in autoclaved products and their physico-mechanical properties. The results of research work made by W. H. Taylor, D. R. Moorehead and N. F. Cole (2), further by W. F. Cole and D. R. Moorehead (3), by D. L. Sanders and W. J. Smothers (4), by G. L. Kalousek and A. F. Prebus (5), by Z. Šauman (6) and by others justify the opinion that the value of strength of autoclaved products depends to a considerable extent on the development and contents of tobermorite as well as on the relative presence of tobermorite and $C_{5-6}S_6H_n$ in binding new-formations, developed in these products in the course of autoclave treatment. G. L. Kalousek points out in this connection several factors, which may influence the strength of autoclaved products—it is above all the overautoclaving, the degree of crystallinity and the surface area of the binding new-formations, the amounts of substituent ions in the lattice etc. At the same time Kalousek stresses the fact, that the determination of dependable relations between the constitution of the binder and/or the binding new-formations and the physico-mechanical properties of autoclaved products is of great importance for further progress in the technology of their production.

The statements, pronounced in the general report are in principle correct, however they should be supplemented by the statement that the elucidation of interrelationships between the over-all phase constitution and the physico-mechanical properties becomes an important presupposition of the future improvement of technology of production not only of autoclaved products but also of cementitious pastes and concretes, hardening at normal temperature, and/or under higher temperature, and under normal pressure.

Among the other papers, dealing with these problems, it is necessary to recall the work of T. C. Powers (7, 8, 9), who found that the strength of cement paste is a power function of the volume of hydration products developed in the paste and summarily denoted as cement gel, and that with increasing volume of cement gel the strength of the paste increases too approximately according to the cubical relationship. Similar results have been obtained by Giertz—Hedström (10), J. Jambor (11, 12), F. M. Lea and F. F. Jones (13) and others.

Owing to the importance of this problem, the presented paper contains some new data concerning the relationship between crystallo-chemical phase consitution and strength of hardened cementitious pastes, which supplement the data of principal paper report presented by G. L. Kalousek and elucidate

further this problem. These data have been determined by a long-time research program carried out by the Institute of Construction and Architecture of the Slovak Academy of Sciences in the course of the recent years.

Methods Used

For the purpose of study of relationships between the phase constitution of hardened cementitious pastes and their compressive strength a selection has been made from a large number of test specimens which had been used for the study of the influence of different curing on the strength of cementitious pastes of different composition. But for insignificant exceptions, all specimens showing visible cracks or other damage capable of influencing the compressive strengths were excluded from the selection.

Preparation of Test Specimens

For the preparation of cementitious pastes homogenized mixes of convenient siliceous powdered materials with 34%, 50% and 64% by weight of powdered $Ca(OH)_2$ were used. Further, mixes of the same siliceous materials with 50% by weight of C_3A and/or of C_3S were used. The mixing water was added in a quantity necessary to prepare a paste of normal consistency (according to the Czechoslovak standard CSN 72 2110). After a 3 minute homogenization cube specimens with 2 cm edge were moulded. These specimens were compacted by rodding and were left to set in moist air of 97 to 100% relative humidity and under the temperature of 20°C. The subsequent curing of the specimens proceeded in one of the following three ways.

a. The test cubes were demoulded and left to harden in water at the temperature 20–21°C for a period 90 and/or 180 days. In the case of some of the pastes it was necessary to prolong the period of humid atmosphere curing of specimens before their immersion in water.

b. The test cubes (in moulds) were put into a steam chamber and cured in a saturated steam medium at the temperature 80°C. The temperature rise was controlled so as to let the temperature attain the value of 80°C during 120 minutes. The total period of steam curing was 24 hours.

c. The test cubes (in moulds) were put into a pressure vessel and cured in a saturated steam medium at the temperature 175°C and under the overpressure about 8 atm. The heating process was controlled so as to let the temperature attain the value of 175°C in the pressure vessel in the course of 120 minutes. The total period of high temperature steam curing was 24 hours.

After the conclusion of the curing period 6 test specimens of each paste were dried at 100°C and their bulk density (unit weight) and compressive strength were determined. The crushed specimen fragments were further disintegrated, homogenized and used for determination of the true density (specific weight) and of the over-all phase constitution of the hardened paste.

Testing Methods

The chemical composition and the approximate specific surface of the initial materials, used for the preparation of cementitious pastes, as well as the compressive strength, the bulk density and the true density specimens were determined by usual methods.

In order to determine the over-all crystallo-chemical phase constitution of hardened pastes a combination of the following methods was used:

a. X-ray powder diffraction (XRD) analysis, used for the determination of the type of binding new-formations contained in the hardened paste, of the presence of unbound $Ca(OH)_2$ and $CaCO_3$ and of the contents of nonhydrated C_3A and/or C_3S.

b. Complex thermal analysis used for the determination of the contents of the free $Ca(OH)_2$ and $CaCO_3$ in the hardened paste and at the same time as a check of the XRD analysis.

c. Electron microscopy used as a check of the XRD and thermal analyses.

d. Chemical analysis used for the determination of the approximate content of the unreacted siliceous admixture and in combination with the previously listed methods for the determination of the approximate over-all content and the composition of the binding new-formations.

Diffractograph Micro 111 made by the company C. H. F. Müller in Hamburg was used for the XRD analysis. The apparatus consists of a strictly stabilized source of X-rays, of a precision goniometer with a proportional counter and of a transistorized measuring and registration equipment. Quantitative determination of non-hydrated C_3A and C_3S in the hardened pastes was obtained by the method of the internal standard.

Thermal analyses were made by means of a complex thermoanalytic equipment, namely the Derivatograph, delivered by the company MOM, Budapest. This equipment allows a simultaneous differential thermal analysis (DTA), a thermogravimetric analysis (TG)

and a derived thermogravimetric analysis (DTG) on the same specimen. The equipment includes a precision registration device allowing a reliable quantitative evaluation of the thermogravimetric analysis. A sufficiently accurate determination of the weight reduction due to the decomposition of $Ca(OH)_2$ or $CaCO_3$ was possible owing to a simultaneous evaluation of the DTG record.

The electron microscope used for the microscope analysis was a Czechoslovak Tesla BS-242 table model. Specimens were prepared by the normal techniques from dilute water suspensions of finely ground samples on collodium films. Ultrasound treatment was chosen for perfect disintegration of the samples in suspension.

Modified Steopoe's method (14) was used for the chemical analysis of hardened pastes. This method is based on the fact that when solving a hardened paste in HCl with $d = 1.12$ (under simultaneous cooling) the unreacted siliceous admixtures separates in the form of an unsoluble residue whereas the other components of the specimens enter into the solution. From the contents of CaO, SiO_2 and Al_2O_3 assessed in the solution the share of the above mentioned oxides bound in $Ca(OH)_2$, $CaCO_3$, C_3A and C_3S was subtracted. The remaining parts of soluble CaO, SiO_2 and Al_2O_3 give the approximate composition and over-all contents of the binding new-formations, contained in the paste. This method is not perfectly accurate due to the fact that in solving the finely ground paste in HCl a certain share of the unreacted siliceous admixture mainly R_2O_3 enters into the solution too. This must be taken into account mainly in the case of cementitious pastes made of siliceous admixtures with higher R_2O_3 content and with low contents of the binding new-products.

Materials Used

The following siliceous materials were used for the preparation of the cementitious pastes:

1. dacite tuff (pozzolanic material of high activity);
2. fly ash (pozzolanic material);
3. activated kaolin made by burning for 2 hours at 650°C of washed kaolin (pozzolanic material of high activity);
4. ground washed siliceous sand (practically pure β-quartz).

All the used siliceous materials were ground to the maximum grain size of 90 microns.

The following binders were used for the preparation of the pastes:

a. Powdered calcium hydroxide-$Ca(OH)_2$ made of selected lumps of pure quicklime slaked with 45% of water and passed through a 200-micron aperture sieve;

b. Tricalcium aluminate—C_3A—prepared by five times repeated burning of granules pressed of chemically pure $CaCO_3$ and Al_2O_3 mixed in molecular proportion 3: 1. The burning temperature was 1380°C

c. Tricalcium silicate–C_3S–prepared by five times repeated burning of granules pressed from a mixture of chemically pure $CaCO_3$ and SiO_2 mixed in molecular proportion 3: 1, to which 0.5% admixture of fine CaF_2 was added as mineralizer. The burning temperature was 1380°C.

After the last burning of C_3A as well as C_3S were ground to the maximum grain size of 90 microns and their composition was checked both by chemical and XRD analysis.

The results of the chemical analysis as well as of the XRD analysis and of the microscope examination of the original samples of materials used for the preparation of the pastes are given in Table 1.

Results and Discussion

Phase Constitution of Hardened Pastes

The results of the study of phase constitution of hardened pastes, as well as the approximative composition of binding new-formations, calculated on the basis of chemical analysis, are given in Tables 2 to 5.

Among the non-binding phases in the studied pastes in the first place the unreacted residue of the siliceous admixture and $CaCO_3$ were identified. In most of the pastes the free $Ca(OH)_2$ was found, too. This free $Ca(OH)_2$ was, however, not identified only in pastes prepared of mixes containing C_3A and was present only in smaller quantities in pastes prepared of a mix of activated kaolin with 34% by weight of $Ca(OH)_2$, as well as of a mix of activated kaolin and C_3S. In the pastes made of mixes of siliceous materials and clinker minerals residues of non-hydrated C_3A and/or C_3S have been identified in addition to the above mentioned non-binding phases. Exceptions were only pastes made with C_3A which were subjected to autoclave treatment (pastes No. 133, 233, 333 and 433). In these pastes no non-hydrated C_3A has been found by XRD—analysis and hence its perfect hydration may be assumed.

The binding new-formations identified in pastes of similar constitution and subject to the same treatment have mostly shown considerable similarity. Disregarding some secondary binding phases, which were present in some of the pastes in smaller quantities, the

* In the case of these pastes the calculation is subject to relatively great error.

marizing name of "tobermorite-like phases", gave diffractometer traces showing in addition to the CSH I diffraction lines also distinct characteristic diffraction lines of tobermorite, especially 11.3 Å; 3.07 Å and 2.97 Å, and/or diffraction lines 5.5 Å; 2.27 Å and 2.14 Å. The binding new-formations of this type have been identified even in pastes prepared of mixes of siliceous materials with $Ca(OH)_2$ and with C_3S and subjected to autoclave treatment under a pressure of 8 atm. and at 175°C for 24 hours. Exceptions were pastes prepared of activated kaolin (i.e. No. 304, 314, 324 and 343) in which the tobermorite-like phase have not been found.

Type II. The binding new-formations were mostly produced by CSH I and/or by its mix with CSH II. This type of binding new-formations has been identified by the characteristic diffraction lines 3.02–3.06 Å; 2.76–1.81 Å; 1.82 Å and other as well as by differential thermal analysis and electron microscopy. CSH I and/or its mixture with CSH II has been identified as the principal binding phase in most of the studied pastes hardening at the temperature of 20°C and 80°C, except the pastes prepared with C_3A as well as pastes made with activated kaolin.

Type III. The binding new-formations, which were mostly constituted by a mixture of about 70 to 80% of gehlenite hydrate-C_2ASH_n and 20 to 30% CSH I. In the diffractometer traces this type of binding new-formations was characterized by diffraction line of gehlenite hydrate 12.4 Å; 6.2 Å; 4.16 Å; 2.48 Å etc. in addition to the CSH I diffraction lines. The presence of gehlenite hydrate in binding new-formations was proved by electron microscopy, too. The binding new-formations of this type have been identified only in hardened pastes made of a mix of activated kaolin with 34% of $Ca(OH)_2$ and hardening at 20°C and 80°C (paste No. 301, 302, 303) as well as in the paste made of activated kaolin with 50% of C_3S hardening at 20°C (paste No. 341).

Type IV. The binding new-formations, which were mostly constituted by a mixture of about 70 to 80% of hydrogarnet phase $C_3AS_nH_{6-2n}$ with 20 to 30% CSH I. This type of binding new-formations was characterized by the diffractometer traces, apart from CSH I diffraction lines, by diffraction lines approximately 9.8 Å; 5.0 Å; 3.31 Å; 3.01 Å; 2.77–2.71 Å; 2.26 Å; 2.01 Å and other. It may be inferred from the foregoing values, that the constitution

of the hydrogarnet phase varied between the constitution of C_3AH_6 and that of plazolite-$C_3AS_2H_2$ and hence its approximate constitution may be assumed to be C_3ASH_4. The binding new-formations of this type have been established in all pastes prepared of mixes of activated kaolin with 50% and 66% by weight of $Ca(OH)_2$ and further, in the paste made of activated kaolin with 34% of $Ca(OH)_2$ autoclaved at 175°C (No. 304), as well as in pastes made of activated kaolin with 50% of C_3S, hardening at 80 and 175°C (No. 342 and 343).

Type V. The binding new-formations, which were mostly constituted by C_3AH_6 and/or the hydrogarnet phase with a small contents of SiO_2 the constitution of which came very near C_3AH_6. This type of binding new-formations has been identified by the characteristic diffraction lines 5.09–5.13 Å; 4.41–4.44 Å; 3.32–3.25 Å; 3.12–3.14 Å; 2.78–2.80 Å; 2.28–2.30 Å; 2.026–2.04 Å and 1.67–1.68 Å. The lowing of the above values of spacings were established for pastes prepared of active siliceous materials whose SiO_2 took a more pronounced part in the reaction processes and further in pastes hardening under higher temperatures. The binding new-formations of this type were identified in all pastes in which C_3A was used as the cementitious substance.

Typical instances of diffractometer traces of pastes containing individual types of binding new-formations, as described above, are shown in Fig. 1. and 2. The complex thermoanalytic records of some pastes are shown in Fig. 3 to 6.

In the pastes prepared of mixes consisting of siliceous sand with $Ca(OH)_2$, hardening at the temperaure 20 and 80°C (pastes No. 402, 403, 412 and 413) the identification of the type of the binding new-formations could not be carried out quite reliably. The results of the XRD-analyses justify, however, even in this case the opinion, that the new-formations in question are a mix of CSH I and CSH II.

Some diffraction lines in the diffractometer traces of the studied pastes as well as the results of electron microscopy have shown that in addition to the above mentioned main types of binding phases even some secondary binding phases are found in most of the studied pastes in smaller quantities. In the pastes made of mixes with C_3A the presence of C_2AH_8 as well as of the gel-like $Al(OH)_3$ could be found. In the pastes made of mixes with fly-ash and hardening at a temperature of 20°C solitary crystals of ettringite have been identified. In a number of cases the identification of these secondary phases was not feasible owing to their low content.

The results of chemical analyses as well as the composition of binding new-formations and their over-all contents in the pastes, as obtained by calculation on the basis of the former, are in good agreement with the above described results of XRD, microscopic and thermal analyses. Certain differences of the calculated over-all composition of the binding new-formations from the theoretical values should be accounted for by the limited accuracy of the applied chemical analysis and further by the fact that the eventual presence of secondary phases was not taken into consideration. For the same reasons it is necessary to admit certain error of the calculated values of the over-all contents of the developed binding new-formations. These errors do not have, however, any relevant influence on the conclusions of the investigation.

Compression Strengths and Their Relation to the Phase Constitution of the Hardened Pastes

The obtained values of bulk density, true density and compression strength of the studied hardened pastes are given in the first part of Tables 6 to 9.

Compressive strength as well as bulk density of individual pastes vary within wide limits depending on the composition and method of curing of these pastes. Highest values of strength have been attained by pastes made of mixes of siliceous materials with C_3S and on the contrary the lowest were the values of strength of the pastes made with C_3A. Strength of the pastes autoclave-treated at 175°C exceed in most cases highly the values of strength of corresponding pastes hardening at a temperature of 20°C or 80°C. In the case of pastes made of mixes of siliceous materials with $Ca(OH)_2$ and hardening at a temperature of 20°C their strength is usually proportional to the activity of the siliceous admixture. All these statements show that compressive strength of hardened cementitious pastes essentially depends on the same factors as their phase constitution.

In order to clarify the mutual relation between the phase constitution and compressive strength of hardened cement pastes, the over-all porosity of individual pastes was computed and their phase constitution expressed in % by weight has been converted to % by volume, with respect to their over-all porosity and/or to their over-all volume of solid phases. The following values of true density were used for the calculation of volume occupied by individual solid phases contained in the pastes: $C_3A = 3.00$ g/cm³, $C_3S = 3.13$ g/cm³, $Ca(OH)_2 = 2.23$ g/cm³, $CaCO_3 = 2.71$ g/cm³, unreacted residue of dacit tuff 2.16 g/cm³, fly-ash = 2.13 g/cm³, activated kaolin = 2.46 g/cm³,

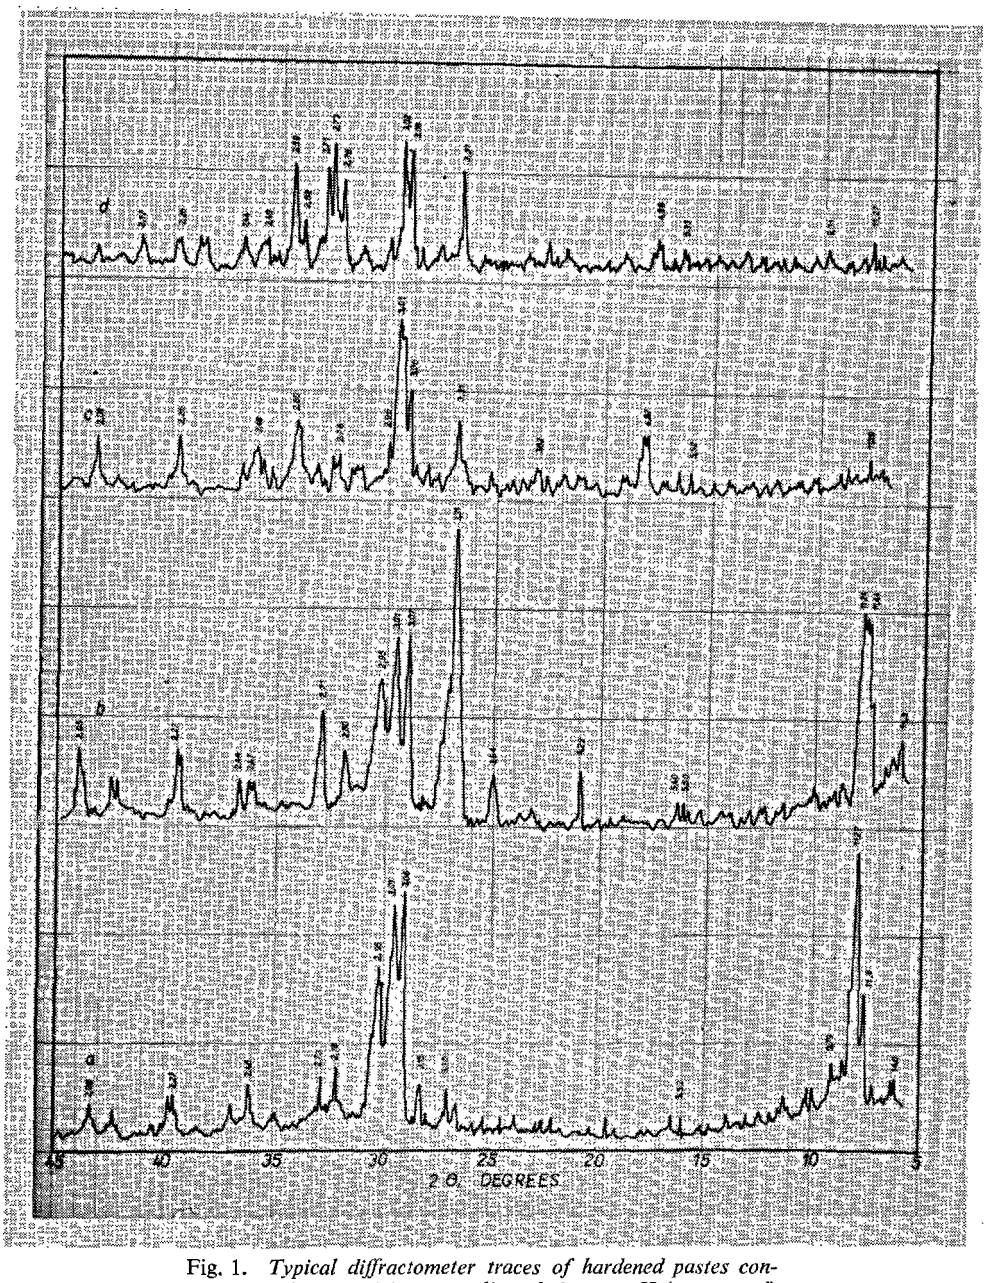

Fig. 1. *Typical diffractometer traces of hardened pastes containing the type I (traces a, b) and the type II (traces c, d) of binding new-formations:*
a—paste No. 104; b—paste No. 404; c—paste No. 203; d—paste No. 241.

β-SiO_2 sand = 2.62 g/cm³, CSH I = 2.25 g/cm³, tobermorite-like phases = 2.45 g/cm³, mixture of gehlenite hydrate and CSH I = 2.32 g/cm³, mixture of hydrogarnet phase and CSH I = 2.50 g/cm³ and the C_3AH_6-hydrogarnet phase = 2.52 g/cm³. The over-all constitution of the studied pastes, expressed in % by volume is shown in the second part of Tables 6 to 9.

As a result of mutual comparison of values presented in Tables 6 to 9 and apparent relationship may be found between the compressive strength and the type as well as volume of the binding new-formations developed in the studied pastes. This relationship is represented in Fig. 7 in which the values of compressive strength of all studied pastes are given in dependence on the over-all volume of the binding new-formations developed in the pastes. If the negative influence of macrostructure flaws in the hardened paste (e.g. cracks) is disregarded the obtained results

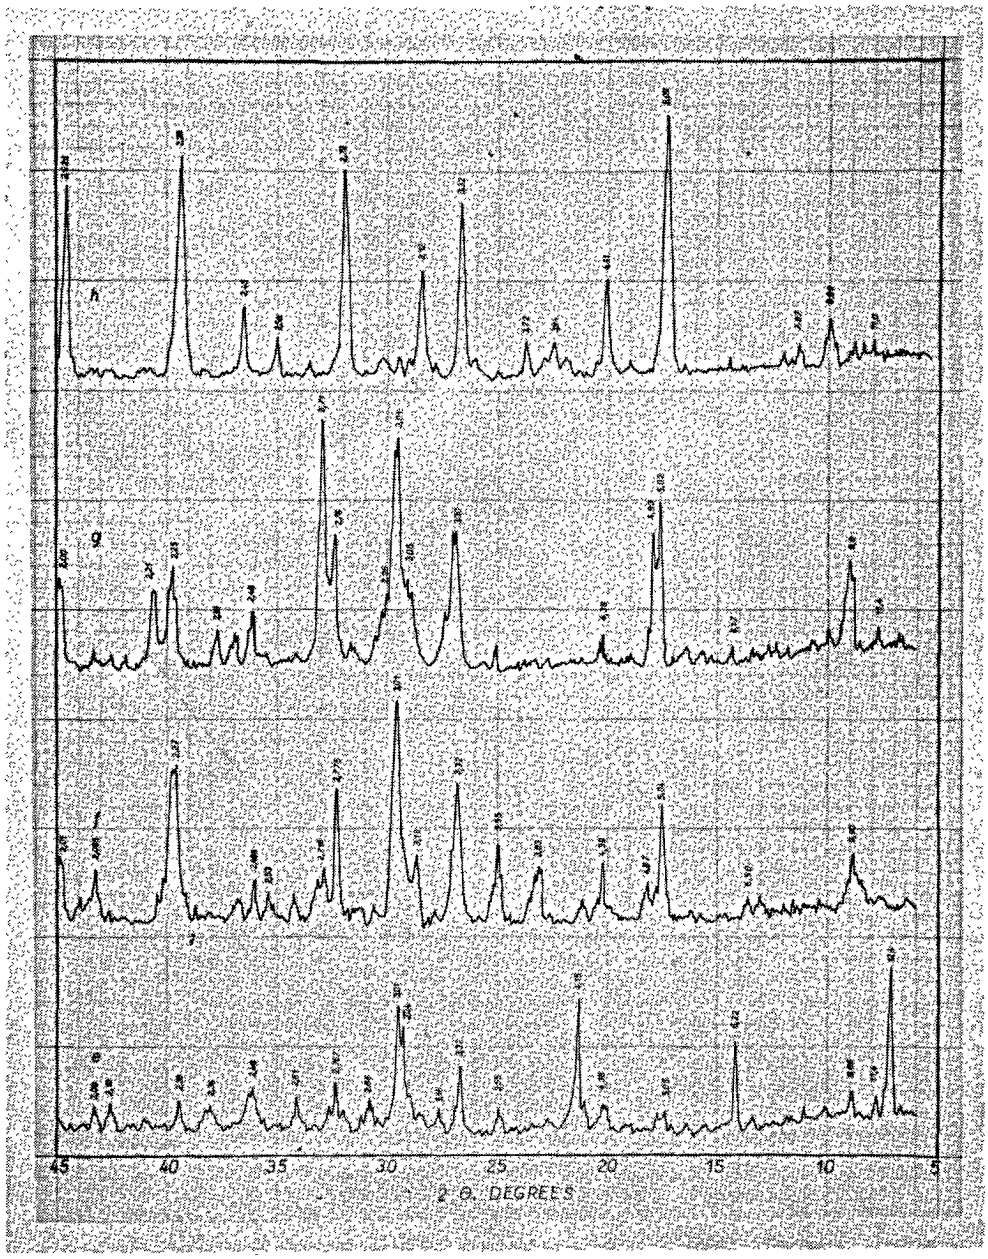

Fig. 2. *Typical diffractometer traces of hardened pastes containing the type III (trace e), the type IV (traces f, g) and the type V (trace h) of binding new-formations:*
e—paste No. 302; f—paste No. 313; g—paste No. 314; h—paste No. 133.

entitle to the opinion, that the compressive strength of a hardened cementitious paste is given only by the type and by the over-all volume of the binding new-formations contained therein, regardless of the initial composition of the paste and of the method of its curing.

An intensive influence of the type of binding new-formations developed in the paste on its compressive strengths is shown by the comparison of compressive strength of pastes having almost the same over-all contents of binding new-formations, only of different type. The highest values of strength have been obtained

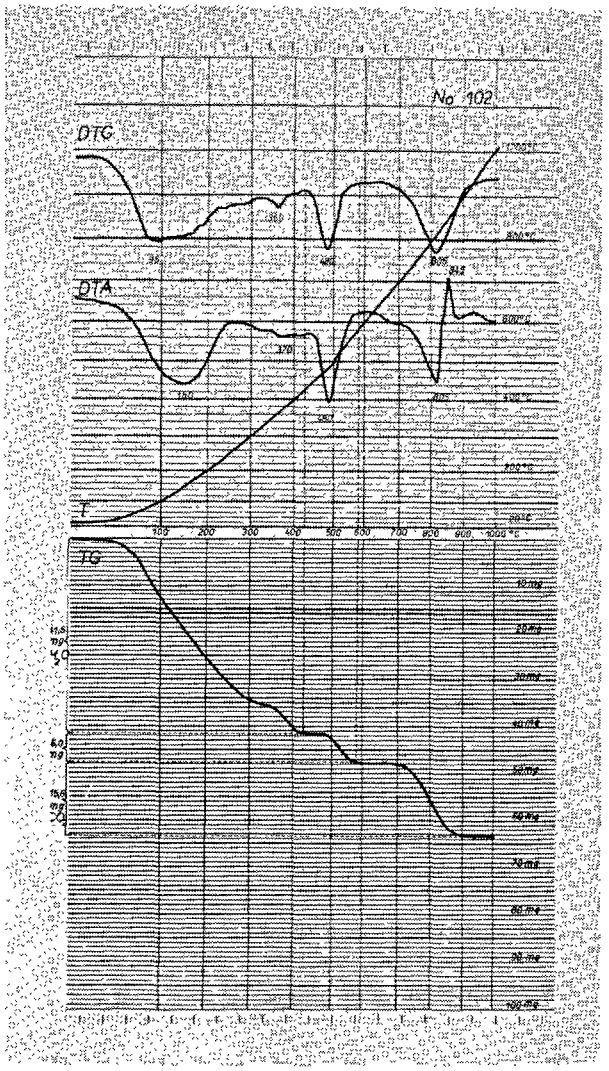

Fig. 3. *Original derivatograph trace of paste No. 102 (dacite tuff 66% + $Ca(OH)_2$ 34%—cured for 180 days at 20°C)*

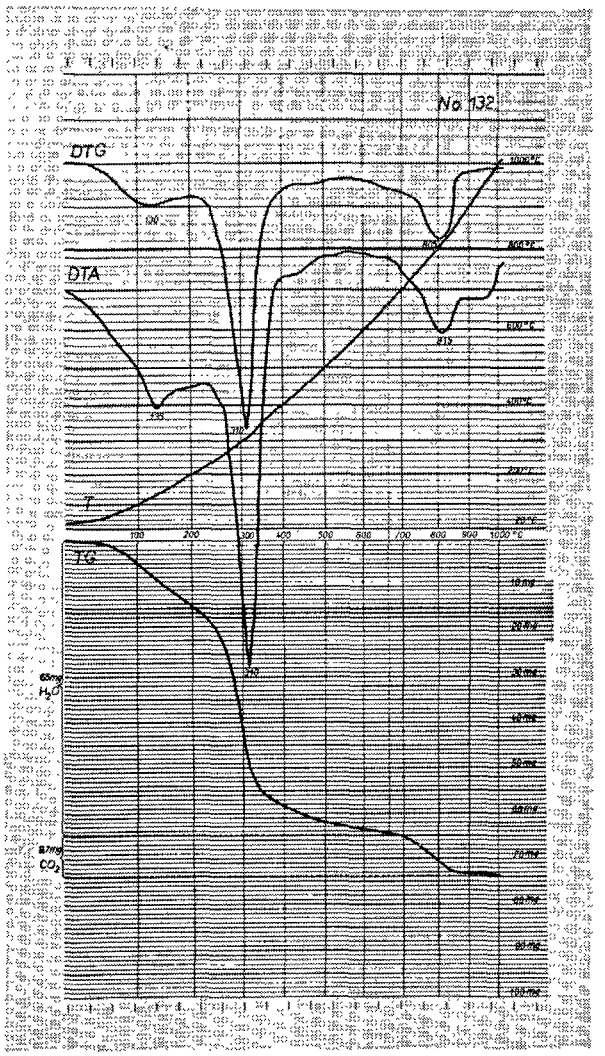

Fig. 4. *Original derivatograph trace of paste No. 132 (dacite tuff 50% + C_3A 50%—steam-cured for 24 hours at 80°C)*

for pastes, in which tobermorite-like phases have been identified as the binding new-formations. If strength of this type of pastes is taken as basis and evaluated by 100%, then the pastes containing approximately the same over-all volume of binding new-formations, only of different type, have the following values of compressive strength.

Type of binding new-formations developed in the paste:	Compressive strength (per cent):
Type I. Tobermorite-like phases	100
Type II. CSH I	56–62
Type III. Mixture of about 70 to 80% gehlenite hydrate and 20 to 30% CSH I	28–32
Type IV. Mixture of about 70 to 80% of hydrogarnet phase and 20 to 30% CSH I	13–20
Type V. C_3AH_6-hydrogarnet phase	3–4

The above given values of strength of pastes with different types of binding new-formations apply only to pastes containing an over-all quantity of binding new-formations up to about 30% by volume. It is, however, probable that the same relative values of strength would result for pastes with a higher over-all content of binding new-formations. The presented comparison proves anyway a fundamental influence of the type of binding new-formations developed in the paste on its strength. The clarification of the proper cause of the different influence of individual types of

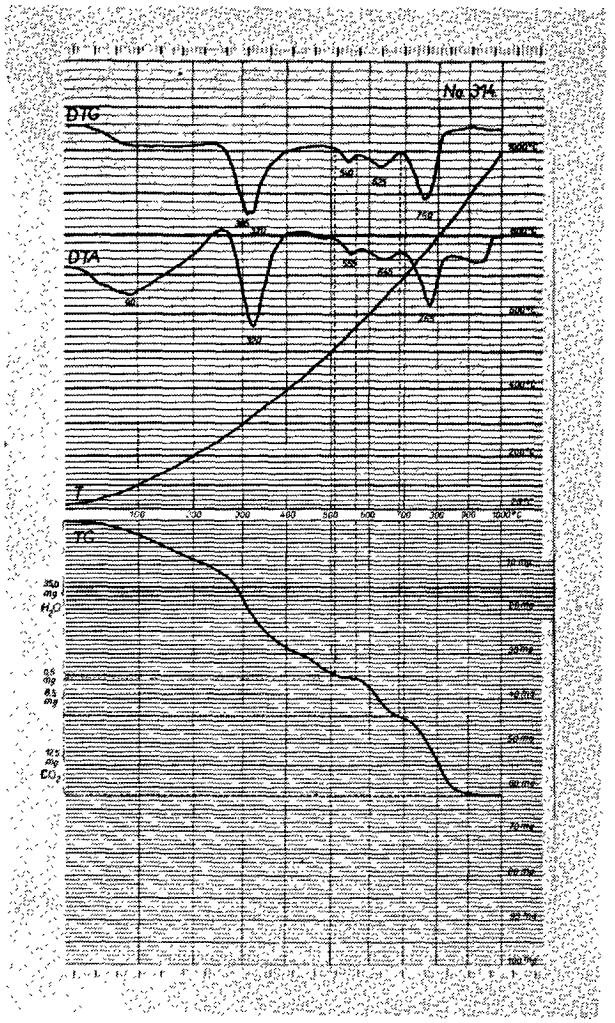

Fig. 5. *Original derivatograph trace of paste No. 314 (activated kaolin 50% + $Ca(OH)_2$ 50%—autoclaved for 24 hours at 175°C)*

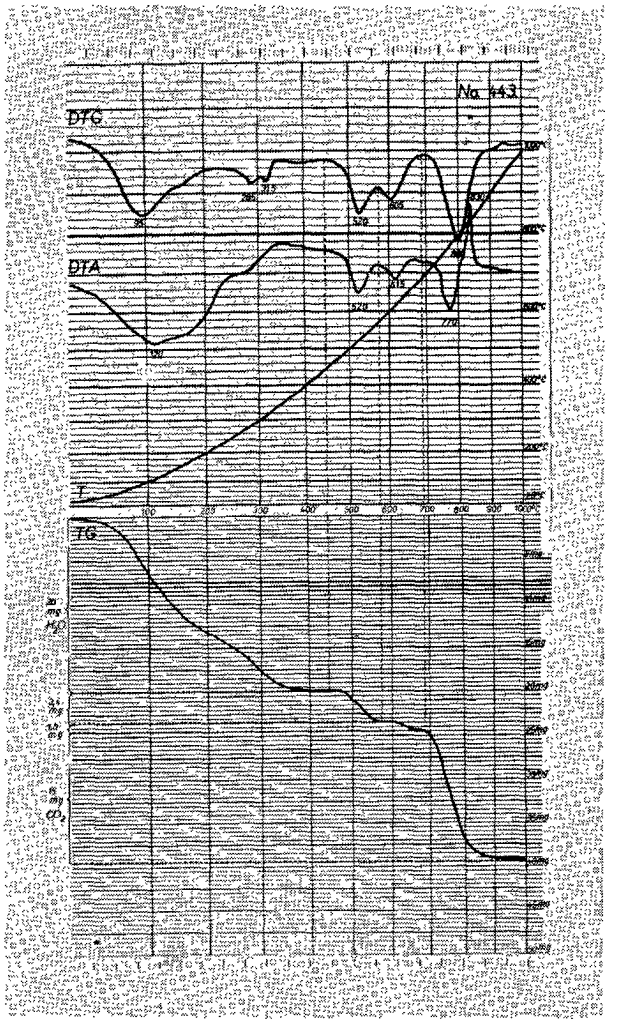

Fig. 6. *Original derivatograph trace of paste No. 443 (β-quartz sand 50% + C_3S 50%—autoclaved for 24 hours at 175°C)*

binding new-formations on strength of hardened cementitious pastes exceeds the frame of this paper and will be discussed in a special paper.

The strength of pastes, containing the same type of binding new-formations is in the first place a function of volume occupied by the binding new-formations in the paste. The functional relationship of the compressive strength and the volume of binding new-formations is different for pastes with different type of binding new-formations. Fig. 7 shows characteristic curves plotted by graphical fitting of values corresponding to pastes, containing the same type of binding new-formations. These curve express functional relationships of compressive strength depending on volume of binding new-formations of Type I to V, as specified above.

Although the functional relationships of compressive strength and volume of binding new-formations differ from each other for pastes with different types of binding new-formations, the relationships in general may be expressed with sufficient accuracy by a function of third degree

$$P = a\theta^3 + b\theta^2 + c\theta$$

where P = compressive strength

θ = volume of binding new-formations developed in the paste, expressed as a percentage of volume of the paste

a, b, c = constants describing the variation of the curve, the value of which depends of the type of binding new-formation.

After substitution of the corresponding values the following formulae have been derived for the suggested functional relationships and/or for the calculation of strength of pastes with binding new-formations of Type I to V:

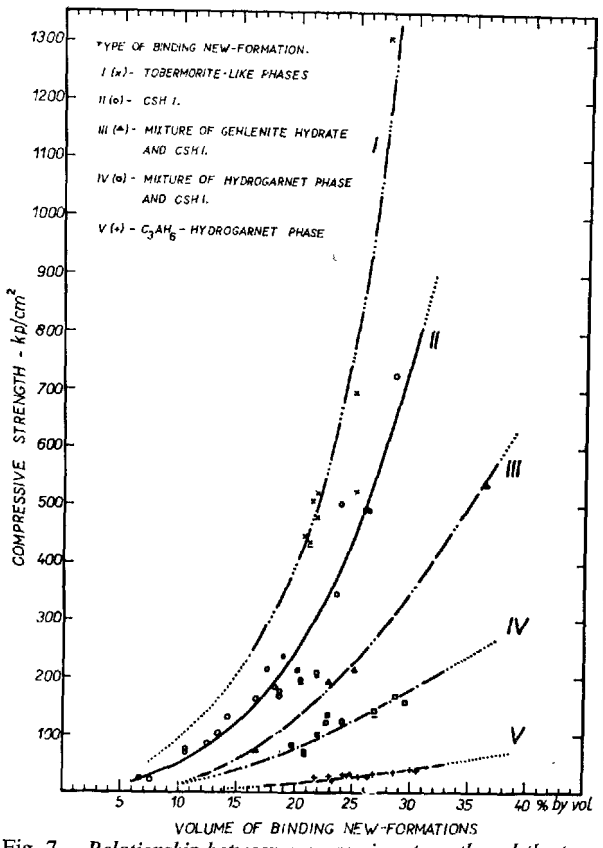

Fig. 7. *Relationship between compressive strength and the type as well as volume of binding new-formations developed in the pastes*

I. For pastes containing binding new-formations of type I (tobermorite-like phases);

$$P = 0.18\theta^3 - 5.093\theta^2 + 50.15\theta$$

II. For pastes containing binding new-formations of Type II (CSH I);

$$P = 0.0275\theta^3 - 0.05\theta^2 + 2.25\theta$$

III. For pastes containing binding new-formations of Type III (mixture of about 70 to 80% of gehlenite hydrate and 20 to 30% CSH I);

$$P = 0.0011\theta^3 + 0.4675\theta^2 - 3.54\theta$$

IV. For pastes containing binding new-formations of Type IV (mixture of about 70 to 80% of hydrogarnet phase and 20 to 30% CSH I);

$$P = -0.005\theta^3 + 0.475\theta^2 - 3.75\theta$$

V. For pastes containing binding new-formations of Type V (C_3AH_6-hydrogarnet phase);

$$P = 0.00327\theta^3 - 0.1252\theta^2 + 2.146\theta$$

The determined values of strength of most of the studied pastes correspond to the reported functional relationships of the compressive strength and the volume of the binding new-formations. Some deviations from these relationships may be explained by the

limited accuracy of methods used for the determination of the phase constitution of the pastes and/or for the determination of the over-all volume of binding new-formations developed in the paste. The second cause of some of the deviations may be internal microscopic flaws (cracks) in the macrostructure of hardened pastes. These flaws did not appear visibly on the specimens, but their existence and their eventual negative influence on the obtained values of compressive strength of some of the pastes cannot be excluded.

Conclusion

The reported results of studies concerning the influence of the type and volume of binding new-formations developed in the cementitious paste on its compressive strength explain and overcome to a certain extent the differences of opinion of various authors as to what is the proper cause of high strength of hardened cementitious paste and what are the measures to be taken to attain this strength.

The statement that the type of binding new-formations developed in the paste is of a decisive influence on their strength and that the values of strength (P) of various pastes decrease depending on the type of the developed binding new-formations according to the sequence: tobermorite-like phases (100% P) → CSH I (56–62% P) → mixture of gehlenite hydrate and CSH I (28–32% P) → mixture of hydrogarnet phase and CSH I (13–20% P) → C_3AH_6-hydrogarnet phase (3–4% P), is in good agreement with the results obtained by G. L. Kalousek, M. Adams, A. F. Prebus, L. D. Sanders, W. J. Smothers, W. H. Taylor, Z. Šauman and others (1, 2, 3, 4, 5, 6). Most of these authors attribute the decisive influence on the strength of hardened paste precisely to the type of the developed binding new-formation, usually to tobermorite.

On the other hand, the statement that the strength of the cementitious paste, the type of the binding new-formation being the same, is a power-function of volume occupied in the paste by the binding new-formations and which may be expressed by the

general formula

$$P = a\theta^3 + b\theta^2 + c\theta$$

which is in good agreement with the results of T. C. Powers as well as other authors who have considered the increasing quantity and hence the volume of the binding new-formations as the principal cause of the strength's growth of hardened cementitious pastes (7, 8, 9, 10, 11, 12, 13).

The obtained results have confirmed that both groups of opinions are justified, although their validity is limited by certain conditions. The statement that the strength of hardened cementitious paste is given both by the type and by the over-all volume of the binding new-formations contained therein, is in full agreement with the theory of P. A. Rehbinder (15, 16, 17).

The obtained results concerning the relationship between the phase constitution and the strength of hardened cementitious pastes apply, as stated earlier, only to pastes in which no apparent or hidden flaws of macrostructure are present, capable of affecting negatively the values of strength. According to our experience these internal flaws of macrostructure of cementitious pastes made in practice appear very frequently. They appear usually as a consequence of internal stresses developing in hardening pastes in the course of recrystallization of phases, under thermal shocks and often also as a consequence of an inconvenient control of hydration kinetics of binders, etc. An important influence on the possibility of propagation of cracks in macrostructure of hardened cementi-

tious paste due to the developing internal stresses is exerted by the contents, by the character and the distribution of the non-binding phases present in the paste. The possibilities of a spectacular restriction or even elimination of flaws development in the macrostructure of hardened cementitious pastes will require further research.

Written Discussion

Surinder K. Chopra

Kalousek's excellent review bring out important gaps in the existing knowledge on the relations between binders and strength properties of autoclaved products prepared from lime and siliceous fines. A study on this topic is reported below and a probable mechanism of strength development in autoclaved products moulded under pressure has been suggested.

Five different mixes of lime and fines, designated as E, F, G, H and I were prepared from pure hydrated lime and a high purity ground quartz sand, raw and calcined fly ash samples, granulated slag (Indian) and foamed slag (British) respectively. The two samples of fly ash, raw and calcined, had a fineness of 2763 and 3466 sq. cm. per g. (Blaines) respectively while the remaining three materials had a specific surface of 3200 ± 50 sq.cm per g. The ratio of hydrated lime to fines in the mixes E, F, and G was 30: 70 parts by weight. In the other two mixes, e.g. H and I, the ratio of lime to slag fines was 10: 90. These mix ratios had been selected in the light of the earlier work of Midgley and Chopra (1) except that a ratio of 10: 90, instead of 5: 95, was chosen for lime-slag mixes as the Indian slag has a CaO/SiO_2, ratio lower than that of the British granulated slag.

In order to analyse the respective effects of factors such as porosity, degree of hydration, and nature of hydration products etc. on the strengths of mixes of lime with fines, preparation of cylindrical compacts from the moist mixes at a uniform porosity was considered desirable. Earlier Midgley and Chopra had moulded their specimens from different lime-fines mixes at a uniform pressure of 2 tons per sq.in. Since this process does not ensure a uniform degree of compaction of the different lime-fines mixes, which in turn may influence the strengths of autoclaved specimens, the effects of moulding pressure on deformation (i.e. degree of compaction), density and porosity of cylinderical compacts prepared from the moist mixes at varying W/S ratios were studied after Lecnazar (2). Relationships between moulding pressure and deformation, and porosity were determined for each of the five mixes at varying W/S ratios (0 to 0.24) and were interpreted in the form of curves. The moulding pressure for each mix corresponding to a W/S ratio of 0.12 (commonly employed in practice for sand-lime bricks) was chosen from the curves so that all the moulded compacts (3 in. ht $\times$ 2 in. dia), were at the same final porosity. The data in Table I show that the average final porosity was $0.33 \pm .02$ (a lower variation in porosity was not found practicable). The data further revealed that if a uniform pressure of 2 tons per sq.in. is employed for moulding compacts from these moist mixes at a W/S ratio of

Table 1.

Mix No.	Mix composition by wt.	Porosity (before autoclaving)	Properties of compacts after autoclaving			
			Porosity	Non-evaporable	Surface area of solids	Density of solids
		Average	Average	mg/g	sq m/g	g/cc
E	30 L*: 70 Quartz sand	0.32	0.318	0.059	78	2.49
F	30 L: 70 Fly ash (R)	0.35	0.341	0.122**	71	2.51
G	30 L: 70 Fly ash (C)	0.32	0.354	0.089	68	2.64

I	10 L: 90 Slag (f)	0.31	0.38	0.025	18	2.93

* L stands for lime, R for raw, C for calcined, g for granulated and f for foamed slag.
** Not reliable because of presence of unburnt carbon.

0.12, the porosity of the compacts may vary within wide limits i.e. 0.193 to 0.319 in the series under consideration.

The green compacts were autoclaved in a laboratory autoclave (Cenco) at a pressure of 160 psi for 16 hours and were tested for water absorption, compressive and tensile (splitting) strengths. Compacts were crushed and lightly pounded to prepare a granular sample passing No. 30 and retained on No. 80. U.S. Sieves. The granular samples were dried under vacuum (3) for the determination of non-evaporable water by determining loss in weight up to 650°C in a thermogravimetric balance. The other determinations made on the granular samples were density using Kerosine oil and B. E. T. surface areas by water vapour absorption after Ludwig and Pence (4). The autoclaved products were also examined with the help of X-ray powder diffraction and differential thermal analyses for identifying the hydration products formed.

The data on compressive strengths, non-evaporable water contents, surface areas, porosities etc. of compacts of different autoclaved lime-fines mixes are summarized in Tables 1 and 2 and show that strength development does not bear any simple relationship either with the B. E. T. surface areas or nonevaporable water contents. Though the data in Tables 1 and 2 indicate in a general way that strengths are low when total porosity is higher, the explanation of strength development in terms of porosity values also suffers from limitations as shown little later.

11.4 Å-tobermorite was the main cementitious phase in lime-fly ash mixes F and G; and poorly crystallized tobermorite was present in lime-quartz and lime-granulated/foamed slag mixes in order of decreasing amount. Xonotlite was detected only in lime-quartz mixes. Some CSH (probably $C_5S_4H_n$ according to Kalousek) was also present in lime-quartz and lime-granulated slag mixes. α C_2SH was present in both mixes (H and I) of lime and slag; the quantity being more in lime and foamed slag mix. A hydrogarnet, C_3ASH_4, was formed in both the mixes of lime and fly ash (F and G). The composition of hydrogarnet phase in the lime-slag mixes was $C_3AS_2H_2$ thus confirming earlier results of Midgley and Chopra. In all the mixes $Ca(OH)_2$ had been consumed almost completely.

As in the past, it is difficult to correlate strength with the formation of calcium silicate hydrate phases except that poor strengths of lime-foamed slag mix are probably due to the formation of αC_2SH. The problem of choosing between tobermorite and "CSH" phase for high strengths has been discussed by Kalousek in the principal paper and the data of this study is also not conclusive. Interpretation has to wait till more is known about the gel-crystal composition of the binders. The densities of the C_3ASH_4 and $C_3AS_2H_2$ are 3.00 (by calculation) and 3.13 g/cc respectively (5) and are higher than those of lime and fly ash or slag fines from which they are formed. If hypothetical equations are written after Hansen (6), it is found out that their formation from their components results in an increase in porosity of the compacts which could affect strengths adversely. Since according to Satava (7) porosity is a more important factor than the nature of solid phase formed by a hydrothermal reaction, the final total porosities of the autolcaved compacts were calculated on the assumption that the specific volume of combined water is not different from that of evaporable water and are reported in Table 1. The data show that an increase in porosity on autoclaving is probably an important cause of lower strengths in lime-fly ash/foamed slag mixes.

The principal stress, which in the case of unconfined compression is the compressive strength, is known to increase rapidly with an increase in cohesion and also with an increase in the friction angle. Cordon and Gillespie (8) believe that in high strength concrete the total bond strength between aggregate particles and

paste controls the cohesive value and as the quality of paste increases, failure in bond controls the strength of concrete.

Mixes of lime and aggregate fines could be likened to those of cement and fine aggregate. Presence of smaller-sized particles is known to increase both cohesion and angle of friction. On application of high moulding pressure little water was found to squeeze out from lime-fines mixes even at water/solid ratios above 0.12 and lower than 0.24. It may therefore be inferred that most of the added water was held tightly by lime (having internal surface as well) and therefore its contribution towards promoting deformation and thereby adhesion could be a variable factor. Since the compacts for compressive strength test were prepared at a W/S ratio of 0.12 and different loads were applied for achieving the same value of porosity, and adhesion between particles is improved by application of pressure, differences in degree of adhesion could have arisen at the stage of moulding the compacts themselves. All the above mentioned factors account for the green strength of the compacts.

As a result of hydrothermal reactions the strengths of compacts increased manifoldly. For example, the compressive strength of compact H(10 lime: 90 slag) was about 950 psi after curing in 99 per cent relative humidity for 28 days and 9,203 psi after autoclaving at 160 lbs per sq. in. for 16 hours, the increase being ten times. Similarly, Midgley and Chopra had found the strengths of compacts containing 95–100 parts of slag fines with 0 to 5 parts of lime ranging between 3,780 to 8,589 psi. Surely, presence of this small quantity of lime cannot result in the formation of hydration products in any large quantity and it alone cannot account for this manifold increase in strength. The increase in strength could be primarily due to the strengthening of the primary bonds resulting from bridging between particles in contact, where surfaces are under pressure or deformed, and hydrate or react more readily. Solid state reactions are postulated for the formation of primary bonds. The formation of Bernal's welds by intergrowth of the lattices of crystals in contact due to some re-arrangement of the lattice as postulated by Lea (9) in explaining bond of cement to aggregate is also quite likely. The adhesional strength of the interparticulate bridges (10) and the number and strength of welds seem to be important factors in governing the strength and other properties of the compacts. Though difficult to assess, some information on this was obtained by subjecting the cylindrical compacts to direct tensile stresses by performing the splitting test (11). The results are reported in Table 2, together with the ratios of compressive to splitting strengths under columns 5. The ratios in mixes F, G and H are different from those of E and I.

Table 2. *Water absorption and strength of cylindrical specimens (Autoclaved for 16 hours at a pressure of 160 psi)*

Specimen designation		Water absorption after 48 hours per cent	Crushing strength lb/in²	Splitting strength lb/in²	Ratio 3/4

A lower ratio (Table 2) indicates comparatively a better adhesion of cementitious phase particles to other particles in the system (excluding those of calcium hydroxide if present). Because in the present study, the fineness of reactants, W/S ratio and porosity etc. of the compacts were nearly the same, the major factors responsible for differences in adhesional strengths would be the nature of surfaces, shape and surface texture of particles and their mutual orientation etc. It is therefore not surprising to find better adhesional strengths of reactive solids i.e. two samples of fly ash and a granulated slag against ground quartz and foamed slag. The reason of the relative inactivity of the latter has been explained earlier by Assarson (12). Briefly, the explanation of strength development in pressure-moulded lime-fines products could be as follows:

Application of pressure improves the adhesion between particles by formation of primary interparticulate bridges. Strengthening of the latter forms an initial framework during early periods of autoclaving. Increase in strength can take place by a further conversion of the reactants into reaction products of high specific surface i.e. by increasing the cohesion. Alternatively, the strengths can also be increased by increasing the number and strengths of welds i.e. working through adhesion, through a judicious choice of materials and methods both the approaches can

lead to high strengths. However, the practical limitation in either case is the aggregation which beyond a certain degree will reduce strength through an increase in porosity.

Author's Closure

George L. Kalousek

Dr. Jambor has presented a remarkable paper. The numerous quantitative results on kinds and amounts of binder phases, densities, etc. (and the compounding of these data for construction of Fig. 7), is a monumental achievement. The results either supply, or suggest, answers to several important questions on relation of type and volume of binder to strength.

Curve I in Fig. 7 representing tobermorite, or tobermorite plus some C–S–HI, shows this binder to have higher strength than the poorly crystalized C–S–H of Curve II for the "binder-space ratios" studied. (The term binder-space ratio is analogous to Power's gel-space ratio and is adopted for this discussion as a matter of simplification and consistence with Powers' term.) Dr. Jambor's equations relating strength to binder-space ratio shows that strength is approximately proportional to the cube of the binder-space ratio (expressed in percent). In this respect his relations' are in argument with that of Powers and Rehbinder. Type II binder, mostly poorly crystalized C–S–H, is more closely related to cement gel than the other four binders under discussion. A direct comparison (not made) of the curves for Type II binders and cement should prove interesting and informative. Allowance would have to be made for the volume of CH and small amounts of other hydrates per cent with C–S–H in cement gel. Jambor included only the binding phases in computing the binder-space ratio.

The Type II binder is C–S–HI or C–S–HI plus some C–S–HII. Presence of $C_{5-6}S_6Hn$ in some of the samples is suspect but not in others. The presence of $C_{5-6}S_6Hn$ in the pastes of low binder-space ratios seems improbable on basis of strength results (zero or near zero) discussed in the principal paper. Comparable strength of C–S–HI at binder-space ratios of 7.5- to 15.0-per cent range from 20 to 100 kg/cm^2. On the other hand, extraordinarily high strengths have been reported (references 78 and 95 in P. P. III-5) for lime-silica specimens formed under high pressure

of which the binder was probably $C_{5-6}S_6Hn$. It follows that $C_{5-6}S_6Hn$ is a binder of superior strength in dense products and an inferior one in products of low density.

It is possible that Curve II is a composite of several curves, one not differing much from the other except as mentioned for $C_{5-6}S_6Hn$ and C–S–HI. A direct comparison of C–S–HI—space ratio curve with the C–S–HII—space ratio curve and in turn with the gel-space ratio curve (the latter corrected for free CH, etc.) should prove informative. The techniques developed by Sereda and associates at the Division of Building Materials, National Research Council of Canada using compacts with controlled porosities should be found highly effective.

Comparison of Curve IV (C–S–HI—hydrogarnet) and Curve V (hydrogarnet) permits evaluation of additiveness of strength of the two binders. Hydrogarnet (Curve V) is a binder of very low strength. The values presented in related tables of data, and which were applied in construction of Curve IV, were used to compute the C–S–HI—space ratio of the Type IV binders; these ranged from about 5 to 8 per cent. Similarly the hydrogarnet-space ratios had computed values of about 15 to 20 per cent. Over these binder-space ratios, the strength of C–S–HI ranges from about 20 to 50 kg/cm², and hydrogarnet from about zero to 20 kg/cm². The sums of the strengths of these binders at any given binder-space ratio are only a small fraction of the strengths shown by Curve IV. This observation is interpreted to mean that the C–S–HI binds together the particles of the hydrogarnet.

Dr. Jambor's technique should prove especially usedul in clarifying the relation of binder-space ratio to strength of calcium aluminate cements. These cements form two composite binders: The metastable CAH_{10}–C_2AH_8 which possesses high strength, and the equilibrium hydrogarnet-alumina gel/gibbsite composite which is generally thought to be of low strength. Manufactures urge lowest possible water content to avoid strength retrogression due to transformation to the stable phase. Limited data obtained by the writer indicate that using very low-water contents and curing at relatively high temperature, the pastes contained the stable phases as binder and had superior strength. The question arises: Did not many structures made with calcium aluminate cement with low-water content undergo transformation or partial transformation to the stable phases without serious strength loss?

Dr. Chopra's results on binders of different porosities and consisting of different phases are an interesting addition to the data already reported. His hypothesis on the effects of pressure forming for securing high strength is also of interest.

Drs. Soroka and Sereda (supplementary paper No. III-34) studies on pressure molding of hydrated cement and gypsum compacts, and corresponding in situ hydrated samples of different porosities appear to contribute much to the understanding of interparticulate bonds. The hypotheses presented are expected to be useful in explaining the third power increase in strength with increasing values of binder-space ratio.

The technology of pressure forming, long known to the sand-lime industry, should become increasingly more sophisticated and important to the industry as knowledge of the fundamentals of high binder-space ratios is increased. The opportunities in the field of autoclave curing of precast ware, allowing a variety of single and composite binders, appear especially bright.

Dr. Hansen's discussion directs attention to an apparent contradiction of through-solution vs topochemical reactions. The term through-solution is often used loosely in the sense that it does not include steps in the overall reaction between a solid and solution such as quartz and CH solution. The following hypothesis is mentioned, not as an explanation, but rather to direct attention to a sequence of reactions which may occur.

The Si^{4+} in quartz is a part of a crystalline lattice and is strongly bonded to 0^{--}. The surface of a quartz grain is disordered to some depth due to breakage of interionic bonds during grinding and subsequent redistribution of surface charges. According to Weil the disordered surface consists of 0^{--} screening the Si^{4+}. A solution of CH supplies Ca^{2+} to combine with the 0^{--} and OH^- with the Si^{4+}. This may be regarded the first step of the reaction. Some of the Si–O bonds in the surface "layer" of the quartz would not yet be broken. The surface complex of randomly orientated Ca^{2+}, Si^{4+} and OH^-, called the "quartz-CSH complex," would be firmly bonded to the quartz through the still unbroken Si–O bonds. As the reaction continues with the Ca^{2+} and OH^-, the remaining Si–O bonds in the surface layer are broken. A C–S–H, possibly C_7S_4Hn is formed. During the formation of this hydrate, a new layer of the quartz-CSH complex is formed. The C_7S_4Hn remains bonded through surface charges to the underlying layer of the quartz-CSH complex. Partial hydrolysis of the C_7S_4Hn would supply silicate ions to solution. The reactions in the two suggested steps would continue with Ca^{2+} and OH^- diffusing inwardly through the reaction products.

The presence of free CH assures high Ca^{2+} concentration and continued formation of C_7S_4Hn. After the free CH is depleted, the reaction of the residual quartz continues. The C_7S_4Hn becomes the supply of Ca^{2+} ions.

The C_7S_4Hn in the interior of the reaction products and at the interface with the quartz-CSH complex supplies through solution the Ca^{2+} and OH^- to continue the reaction with the quartz. Eventually in this zone, which extends outwardly, the composition of the C–S–H reaches the stable ratio of 5C: CS and supply of Ca^{2+} is depleted. At this stage actual solution of the quartz may begin.

This alternate reaction of direct solution of the quartz is suggested by studies of Moorehead and McCartney (reference 69, p. p. III-5). The silicate ions diffuse outwardly through the reaction products to continue formation of C–S–H of successively lower C/S ratios. This reaction would occur through solution.

It is recognized that the model just presented is highly speculative even though consistent in gross features with results on kinetics studies. Some evidence in the literature supports a through-solution mechanism, others a topochemical reaction. It is probable that the condition of the test and stage of the reaction are factors determining the type of reaction occurring. Obviously, more direct evidence (which is difficult to obtain) will be required for an entirely acceptable conclusion.

Dr. Hansen's explanation of the mechanism of Funk's seeding experiments appears logical to the writer.

Supplementary Paper III-80 Hydroxyl Ellestadite Produced by Hydrothermal Reaction Containing Calcium Sulphate

Kunihiro Takemoto and Hajime Kato*

Synopsis

Mechanical strength of hydrated calcium silicate cured in autoclave is affected by the contents of calcium sulphate in the raw mixtures and the optimum content was around 2% of SO_3. The possibility of introduction of sulphur into tobermorite at the elevated temperatures was examined.

Sulphur tends to be separated from the substituted tobermorite gel to form $CaSO_4$.

In the hydrothermal reaction products of the hardened mass of which raw mixture contains calcium sulphate, there exists a mineral, hydroxyl ellestadite $Ca_{10}(SiO_4)_3(SO_4)_3 \cdot (OH)_2$, known as a mineral of apatite group.

The condition in which hydroxyl ellestadite is formed was revealed. When the CaO/SiO_2 molar ratios of mixtures exceed 1, hydroxyl ellestadite is produced coexisting with xonotlite, hillebrandite, portlandite and anhydrite according to the chemical composition of the mixtures.

However, when the ratios were less than 1, anhydrite was the only SO_3-bearing phase coexisting with quartz, xonotlite and gyrolite. Some properties of the synthesized hydroxyl ellestadite were measured by means of optical, X-ray and thermal analysis and so on, and compared with the results of the earlier investigators. Formation of hydroxyl ellestadite and its relation with the coexistence with alumina were discussed. Chemical composition and thermal decomposition of this mineral were also discussed.

Introduction

Calcium sulphate is usually added to portland cement clinker as a form of gypsum to control its setting time.

When cement is mixed with water at ordinary temperatures below 100°C, the calcium sulphate reacts with tri-calcium aluminate to form calcium sulphoaluminate hydrates, $C_3A \cdot 3CaSO_4 \cdot 32H_2O$ and $C_3A \cdot CaSO_4 \cdot 12H_2O$. Kalousek (1) reported that the SO_3 content calculated from both calcium sulphoaluminate hydrates determined by D. T. A. could not account for all the SO_3 in the paste and suggested the introduction of sulphur into tobermorite gel in the paste, perhaps as SO_4^{2-}.

Copeland, Bodor, Chang and Weise (2) observed the formation of substituted tobermorite in the reaction of tobermorite gel with aluminate, ferrite and sulphate after bottle-shaking and ball-milling. The measured maximum amount of substitution was one atom of substituents, such as Al, Fe and S, to 6 atoms of Si.

Above 100°C, calcium tri-sulphoaluminate hydrate decomposes to monosulphoaluminate hydrate and calcium sulphate hemi-hydrate and at higher temperatures to calcium aluminate hydrate and anhydrite.

However, the influence of SO_3 on the mechanical strength of autoclaved building materials and the reaction of SO_3 in the autoclave hydration are not clear so far (3, 4).

The present authors (5) tested the mechanical strength of the autoclaved mass of various mixes of portland cement, quartz sand, slag and gypsum and examined the SO_3-bearing phases in the mass by X-ray diffraction, D.T.A., I. R. and so on. The authors made clear the conditions of formation of hydroxyl ellestadite in the hydrothermal reaction in this paper.

*Central Research Laboratory, Onoda Cement Co., Ltd., Tokyo, Japan.

Mechanical Strength of Autoclaved Concrete

In the course of the investigation of autoclaved concrete, the authors (5) examined various mixes, considering many factor such as CaO/SiO_2 molar ratio, alumina content, SO_3 content, curing temperature and time, etc.

The authors found that the SO_3 content affected the mechanical strength of the hardened mass, and discovered that the optimum content of SO_3 was around 2% in the raw mixture.

A few examples are shown in Fig. 1.

The materials used and the treating conditions were as follows:

Materials:

White portland cement clinker—pulversized to the fineness of Blaine 3870 cm^2/g.

Quartz sand—pulverized to the fineness of Blaine 5260 cm^2/g.

Gypsum—chemical reagent calcium sulphate di-hydrate.

Table 1. shows chemical compositions of these materials.

Treating Condition

Specimens of 10 × 10 × 70 mm. were set in a 17*l* autoclave. The temperature was raised to 179°C (saturated steam pressure 10 kg/cm^2) in 2 hrs., and then kept at the same temperature for the following 5 hrs. and lowered to room temperature in the next 2 hrs.

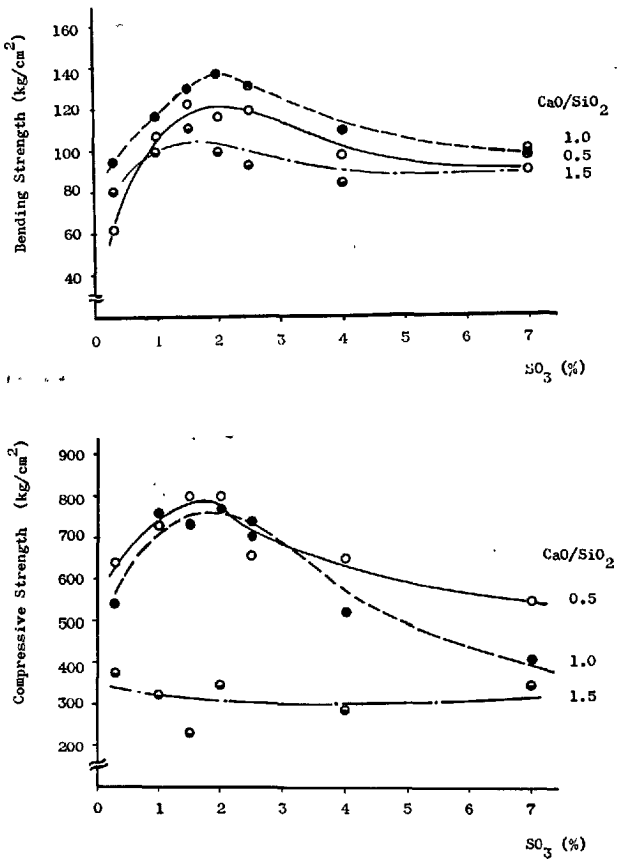

Fig. 1. *Mechanical strength of the autoclaved mass in connection with* SO_3 *content*

Table 1. *Chemical compositions of raw materials*

Material	Chemical composition (%)									Fineness Blaine (cm^2/g)
	ig. loss	insol. res.	SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	SO_3	Total	
white cement clinker	0.9	0.3	24.1	0.2	4.8	67.1	1.5	0.3	99.2	3,870
quartz sand	−0.4	—	96.1	2.2	1.3	—	—	—	99.3	5,260
gypsum	20.99	—	—	—	—	32.52	—	46.59	100.10	—

Introduction of Sulphur into Tobermorite Lattice

Tobermorite gel of which CaO/SiO_2 molar ratio was 1.2 prepared from burnt lime and silica gel at 60°C, then the mixture of the gel and about 6% of gypsum was ball-milled with 9 parts of distilled water for 6 days, as previously stated (2). Then the product was filtered and dried in a vacuum desiccator.

X-ray examination shows no crystal other than tobermorite gel. According to the chemical analysis this tobermorite contained the SO_3 of 6.08% on ignited base, i.e., SO_3/SiO_2 molar ratio was 0.156. The substituted gel was treated at 133°C, 158°C and 179°C respectively in an autoclave. X-ray diffraction patterns of the treated gel were shown in Fig. 2.

From these experiments, at the elevated temperatures, sulphur seems to be separated from the substituted tobermorite gel to form $CaSO_4$.

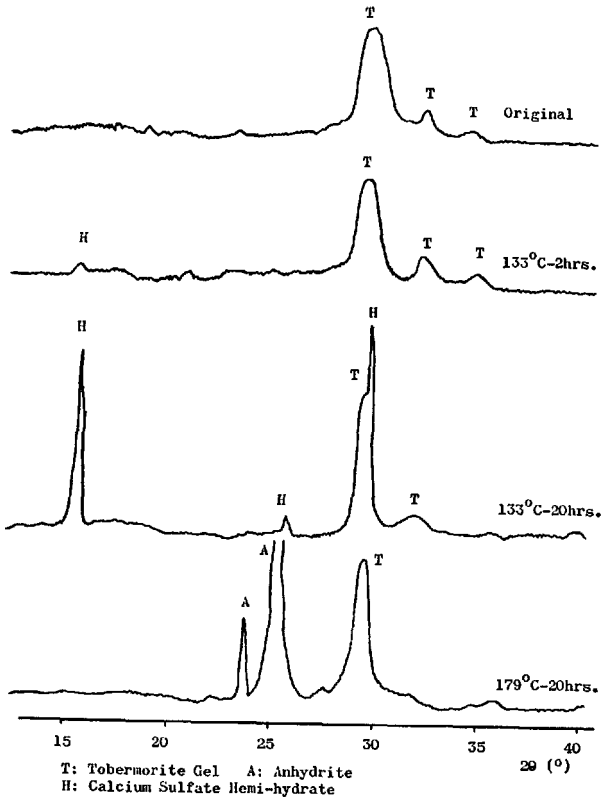

Fig. 2. *X-ray diffraction patterns of the substituted tobermorite gel, original, and after autoclaved at 133°C, 179°C, respectively*

Formation of Hydroxyl Ellestadite

In the preliminary experiments of hydrothermal reaction, starting with any combination of raw materials containing calcium and silica, such as portland cement clinker, C_3S, C_2S and calcium oxide or calcium hydroxyde with quartz or silica gel, and one of calcium sulphates, such as gypsum, hemi-hydrate and anhydrite, hydroxyl ellestadite is easily formed if the chemical composition of the raw mixture and the reaction temperature are suitable. So, the present authors conveniently used the followings as raw materials for determining the conditions of formation of hydroxyl ellestadite.

Lime: Analytical grade chemical reagent calcium carbonate was burnt at 1200°C for 20 hrs.

Silica: Two kinds of silica were used. One was fine quartz ($<2\mu$) and the other was silica gel. The main difference is that the quartz requires higher temperature than silica gel to react. The quartz was mainly used because of its easy detection by X-ray. Table 2 gives analytical data of these silica.

Gypsum: Chemical reagent calcium sulphate di-hydrate.

The raw mixtures, composition of which were stoichiometric to those of the circles shown in Fig. 3, were kept in Ni-crucibles with small amounts of distilled water and treated in a 17*l* autoclave.

Hydrothermal Treatment

It was recognized by the present authors that hydroxyl ellestadite was formed at temperatures a little higher than 100°C, but not at just 100°C even

Table 2. *Chemical composition of silica*

Material	Chemical composition (%)				
	ig. loss	SiO_2	$Al_2O_3 + Fe_2O_3$	CaO	$K_2O + Na_2O$
quartz	1.55	97.00	0.18	trace	—
silica gel	11.23	86.12	0.58	trace	0.55

by the long treatment of 2 months.

It is difficult to establish the phase equilibrium under 200°C, because of the slow rate of formation of the minerals appearing in the system CaO–SiO_2–$CaSO_4$–H_2O at such temperatures.

Therefore, a temperature of 235°C (saturated steam pressure 30 kg/cm²) was chosen with the reaction time of 100 or 200 hrs. The reaction temperature of the autoclave was controlled within ±1°C.

Detection

The reaction products obtained were dried in vacuum desiccator. Detection of the phases in the products were made by X-ray diffraction analysis and infrared absorption analysis.

Results

The results are shown in Fig. 3. The SO_3-bearing phases detected are as follows:

Anhydrite, when the CaO/SiO_2 molar ratio of the raw mixture is below 1.

Hydroxyl Ellestadite, when the CaO/SiO_2 molar ratio of the raw mixture is larger than 1. This mineral is known as a mineral of apatite group (6).

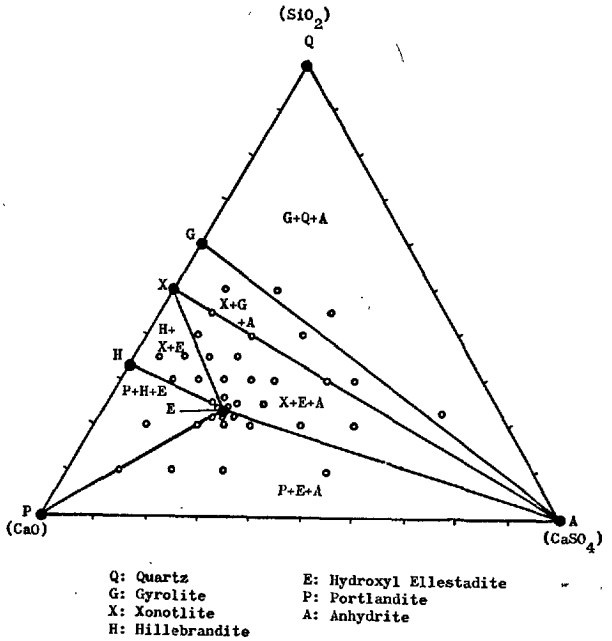

Fig. 3. *Hydrothermal reaction products in the system* CaO–SiO_2–$CaSO_4$–H_2O *at 235°C*

Properties of Hydroxyl Ellestadite

A sample of hydroxyl ellestadite was prepared from the raw materials mentioned before.

According to the X-ray diffraction examination, it contained a small amount of residual quartz. The properties of this synthesized sample were as follows:

Optical and X-ray Properties

Average refractive index: $\bar{n}_D = 1.632 \pm 0.002$
Birefringence: $B \leqq 0.002$
Shape: hexagonal prism with pyramidal ends
Extinction: parallel extinction
Elongation: negative
Space group: C^2_{6h}, $P6_3/m$
Unit cell: $a = 9.48^4$ Å
$c = 6.92^7$ Å

Table 3 shows X-ray data of hydroxyl ellestadite synthesized by the authors.

Density

$d = 2.96 \pm 0.01$ g/cm³

Chemical Composition

Table 4 gives the analytical data of the sample.

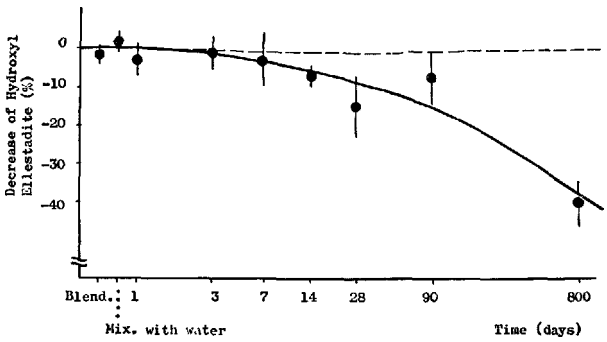

Fig. 4. *The stability of hydroxyl ellestadite in hydrating cement*

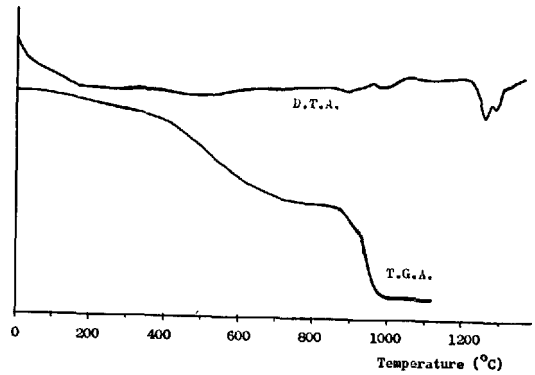

Fig. 5. *D.T.A. and T.G.A. curves of the synthesized hydroxyl ellestadite*

Stability in the Hydrating Cement

The mixture of portland cement, 16% of the synthesized hydroxyl ellestatite and 4% of quartz (5–10μ) was hydrated at room temperature. Quartz was used as an internal standard. The water-cement ratio was 0.5. After various length of time, hydroxyl ellestadite, in the hydrating mixture, was pursued by X-ray diffraction analysis. The results are shown in Fig. 4.

Thermal Properties

Fig. 5 shows D. T. A. and T. G. A. curves of the synthesized hydroxyl ellestadite.

Discussion

Mechanical Strength

Almost all of the specimens measured of their mechanical strength, contained 11 Å tobermorite, CSH(I), or tobermorite gel, Of course, the conditions at which the specimens were treated were far from the equilibrium. As a result, unreacted clinker minerals, quartz and slag remained in the hardened mass.

The reason why the strength showed a maximum of around 2% of SO_3 content in the raw mixtures was not clear. But, the formation of hydroxyl Ellestadite tends to reduce the strength of the specimens.

Hydroxyl Ellestadite in CaO–SiO_2–$CaSO_4$–H_2O

At the saturated steam temperature of 235°C, hydroxyl ellestadite coexists with portlandite, hillebrandite, xonotlite and anhydrite, but not with gyrolite and quartz, while anhydrite coexists with gyrolite, xonotlite, portlandite and hydroxyl ellestadite, but not with hillebrandite. At lower temperatures, hydroxyl ellestadite will coexist with tobermorite, CSH(I), CHS (II), tobermorite gel and α–C_2S hydrate, as seen in the hydrothermal products (5) the mechanical strength of which were measured.

Hydroxyl Ellestadite coexisting with Hydrogarnet

(i) A synthesized hydroxyl ellestadite was treated with C_3A in an autoclave at the temperature of 235°C for 100 hrs. The phases detected were hydroxyl ellestadite, hydrogarnet and a small amount of anhydrite.
The cell dimension of the hydrogarnet type mineral shows little substitution of SiO_2 occured.

(ii) The mixture of silica gel, burnt lime, gypsum and C_3A the stoichiometry of which is the same as that of the former experiment, was also treated in the same way.
The reaction products were anhydrite, hydrogarnet portlandite and hydroxyl ellestadite.
The cell dimension of the hydrogarnet shows the composition of about $C_3AS_{0.7}H_{4.6}$
From these results, it is concluded that hydroxyl ellestadite is considerably stable coexisting with hydrogarnet, and both minerals could exist in the autoclaved mass of raw materials which contain Al_2O_3 and SO_3 components.

Stability in the Hydrating Cement

Experiments about the stability of hydroxyl ellestadite in the hydrating cement at room temperature up to 800 days show that this mineral is unstable in the hydrating cement.

X-ray Diffraction and Chemical Composition

The properties of the synthesized hydroxyl ellestadite should be compared with those reported by the previous investigators.

Dihn and Klement (7) reported the unit cell dimension as $a = 9.54$ Å $c = 6.99$ Å. These values are somewhat different from those measured by the authors.

The density calculated from the cell dimension and the ideal formula of $Ca_{10}(SiO_4)_3(SO_4)_3(OH)_2$ is 3.07 g/cm³.

The formula calculated from the chemical composition of the sample synthesized by the authors is $Ca_{9.4}(SiO_4)_3(SO_4)_{3.1}(OH)_{4.2}$

The deviation from the ideal formula is commonly observed in the formations of hydroxyl apatite $Ca_{10}(PO_4)_6(OH)_2$ (8).

Thermal Properties

D.T.A. Curve of the hydroxyl ellestadite is smooth as usually observed on the mineral of the apatite group.

From the T. G. A. curve of the synthesized hydroxyl ellestadite, two types of water seem to exist.

At the temperatures from 200°C to 800°C, this mineral loses progressively one of two types of water, and loses the other at 860°C. X-ray diffraction patterns and infra-red absorption of the original sample of the synthesized hydroxyl ellestadite and the sample heated at 800°C, 900°C and 1,300°C, respectively are shown in Fig. 6.

The comparison between the infra-red absorption of the original sample and that of the sample heated at 800°C shows slight difference in the regions around 1,450 and 3,400 cm^{-1}. The former is related to the contamination of CO_2. The later is related to OH vibration and the absorption of the original seems broader than that of the other.

The second stage in the T.G.A. curve is of course the thermal decomposition of this mineral as seen in Fig. 6. Hydroxyl ellestadite decomposes on heating in the air to $Ca_nSi_2O_{n+7}$ ($n = 5 - 6$), anhydrite and water at 860°C, then to dicalcium silicate and anhydrite with or without calcium oxide at 1230°C.

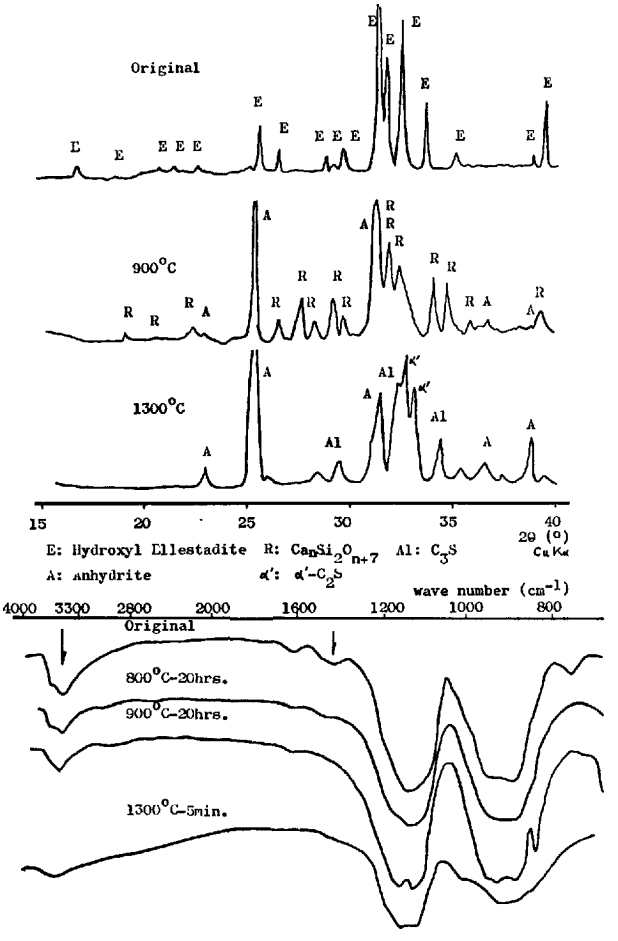

Fig. 6. *X-ray diffraction patterns and infra-red absorption of the synthesized hydroxyl ellestadite, original and heated at 800°C, 900°C and 1300°C*

$$Ca_mSi_3S_3O_{m+15}(OH)_2 \rightarrow Ca_nSi_2SO_{n+7} + 3CaSO_4 + H_2O$$

$$Ca_nSi_2SO_{n+7} \rightarrow Ca_2SiO_5 + CaSO_4(+CaO)$$

$Ca_nSi_2O_{n+7}$ is a mineral which is commonly observed in sulphate ring of the rotary kiln for cement burning (9), (10).

Supplementary Paper III-87 Some Physical Properties of Aerated Concrete under Autoclave Process

Koh-hei Ono and Kōzō Ojiri*

Synopsis

The physical properties of aerated concrete under the autoclave process were investigated on the basis of (i) heat transfer (ii) linear changes and (iii) mechanical properties.

The apparent thermal diffusivities K were derived from the measurement results on temperature profile of a cylinder by using Fourier's heat flow equation. The average value of K during the heating-up period with a rate of 0.75 ~ 1.0°C/min to 180°C and the early stage of soaking at the temperature was approximately 4 times as large as that determined for the final product.

The values of K and their variation with the autoclave time schedule and with the position in the specimen suggested that heat transfer in concrete was promoted both by the presence of liquid water and by the movement of vapor or liquid in the specimen.

By the application of these values to Fourier's equation again, the temperature profiles of a slab of 20 cm thickness at successive time were determined. The temperature difference between surface and center was 120°C when the surface was heated up to 180°C with a rate of 1°C/min. Seven hours soaking at this temperature was required for this difference to become less than 5°C.

A simple apparatus by the "Differential Optical Lever Method" was devised for successive measurement of linear change of specimen under autoclave process.

In a specimen without additives, almost the same expansion-shrinkage phenomena were observed for various compositions (cement-siliceous sand-blastfurnace slag), Specimen sizes (2.5 cmϕ × 10 cm and 20 × 20 × 60 cm) and bulk densities (0.5 g/cm^3, 1.8 g/cm^3), and the mean coefficient of expansion during heating-up period to 180°C was 9 ~ 10 × 10^{-6}/°C.

Augmented expansion was observed in the heating-up period for the specimen added with light-burnt MgO, but it was observed in the soaking period when dead-burnt MgO was added. This tendency was irrespective of other factors, whereas the amount of expansion somewhat influenced by compositions, sizes and bulk densities of the specimen. The excessive addition of MgO led to disruption of the specimen.

In view of thermal stress, it is concluded that the thickness of 20 cm was approximately estimated to be the upper limit for a slab to be securely produced under the autoclave condition carried out in this study.

Introduction

The use of autoclaves is an essential process in the manufacture of aerated concrete.

Many difficulties during this process are encountered which are ascribed to the fact that young age concrete is subjected to water vapor having high temperature and high pressure and their comparatively rapid changes with time. Unsuitable conditions produce various kinds of defects in the product i.e., cracks of various shapes within or on the surface of the product and nonhomogeneity of mechanical strength in its inside. For purposes of improving such phenomena, and in addition, determining the best autoclave time schedule, it is essential to investigate chemical and physical properties through the autoclave process.

There have been many reports about the chemical reactions, especially hydration mechanisms and their equilibriums. In the case of physical properties, however, only a few papers have been written. The reasons seem to be as follows:

1) Difficulties in the measuring technique under the condition of saturated steam at high temperature filled in an autoclave.
2) The effect of the material size is one of the important factors to measure these properties. The specimen of fairly large size must be subjected to the

*Research Laboratory, Asahi Glass Co., Ltd., Yokohama, Japan.

test so that the results are applied to concrete of manufactured size.

The gradients of temperature, vapor pressure and moisture content along a cross-section of concrete, which are very important problems for manufacturing, are developed only when the specimen is large enough. Size effect on the volume change also must be discussed.

Physical properties concern with the problems on defects of product and determination of best autoclave condition on the basis of the relationships in the following categories:

i) Mechanical properties
ii) Volume change
iii) Heat transfer
iv) Movement of moisture

Several investigations concerned with these subjects were recently reported.

N. I. Dybrovna, et al. (1) and C. A. Mironov, et al. (2) followed the volume changes due to hydraulic movement during the autoclave process by the differential voltage transformer (DVT). Weight changes were measured by also N. I. Dybrovna, et al. (1) and K. F. Lomunov, et al. (3) by using a balance equiped to an autoclave.

A. I. Avakov, et al. (4) followed also the volume changes by strain gauge buried in concrete.

In addition, temperature profiles were determined by the C–A thermocouple for a cubic or a slab in these investigations.

The relationships of these informations to the mechanical properties were discussed by C. A. Mironov (2) and A. I. Avakov (4).

P. Smallwood (5) calculated temperature distributions for a brick during autoclave process assuming that the relevant properties of the specimen are constant during autoclaving.

Also at the Research Laboratory of Asahi Glass Co., Ltd. some studies of these subjects under steam curing condition have been carried out in these few years. Then some ideas of the methods for measurement will be submitted and the several results obtained will be discussed in this paper.

Heat Transfer in Concrete

Most of the products at factories are slabs and blocks of various sizes. The slabs are not suited to laboratory work due to their large width and length. Therefore any expedient experimental method must be devised.

Heat transfer in concrete under steam curing depends on two mechanisms, i) heat conduction in solids and ii) the movement of moisture. Either can be dealt with by Fourier's equation. The latter is, however, more complicated because of the condensation—vaporization mechanism of water in concrete. Therefore, one way is, as a first approximation, to assume only the mechanism i) for heat transfer phenomena observed experimentally. Then, by the deviations from the theory, mechanism ii) might be presumed.

The testing results from a long cylinder can be applied to the treatment of a large slab and satisfactory results may be derived. The reason is that the thermal diffusion is unidirectional in a cross-section perpendicular to a longitudinal direction for both cases. On the basis of such a concept, the heat transfer phenomena are investigated in this paper.

Method of Measurement

A cylindrical specimen of 20 cmϕ × 60 cm was moulded which was designed so as to be a product with bulk density of 0.5 g/cm^3 after autoclave curing. At the same time C–A thermocouples were buried in concrete, along the longitudinal axis and the center cross-section perpendicular to the axis (Fig. 1). This specimen was preliminarily cured at 40°C, and above 90% R. H. for 15 hrs.

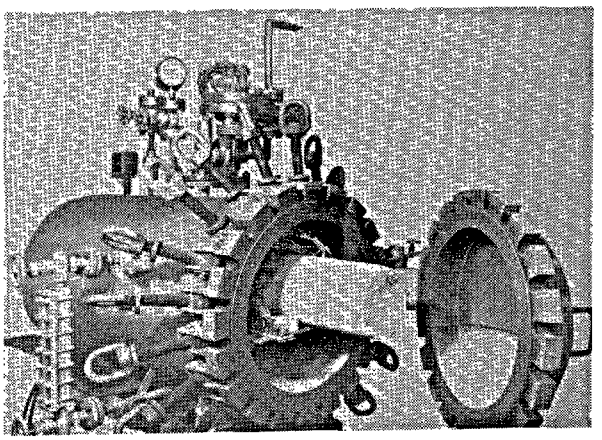

Fig. 1. *Long cylindrical specimen of aerated concrete set in autoclave having 200 lit. in content. CA-thermocouples are buried in concrete and drawn out of autoclave through flange*

The joints through which the thermocouples are drawn out of the autoclave had to be of the same material as the thermocouples to prevent the development of a contact potential.

Before heating-up, the autoclave was evacuated to −500 mmHg.

The specimen was heated in the autoclave to a temperature of 180°C and a vapor pressure of 10 atm (heating-up period) and kept under this condition for 8 hrs (soaking period). Then the water vapor in the autoclave was blown off through a leakage value in order to cool to 100°C and atmospheric pressure in approximately 30 min (blow-off period), and the autoclave was opened and the specimen was immediately removed from the autoclave in the atmosphere at 20°C (cooling-period). Variations in temperature over this whole cycle was recorded.

Computation Procedure

From the data on the temperature distribution along the longitudinal direction, it was confirmed that thermal diffusion along that direction near the center cross-section was completely negligible.

The apparent thermal diffusivities K were computed as a function of the time, the temperature and the position along the radial direction of the cylinder by the analytical solution of Fourier's heat flow equation (6). The values of K obtained were applied again to the analytical solution of Fourier's heat flow equation for a infinite slab of 20 cm thickness, so that the temperature profile of the slab under the autoclave process was derived.

The values of K were computed by the application of the respective datum on temperature at a desired time and position in the cross-section to heat flow equation under the following initial conditions for each period.

Heating-up period: Temperature in the whole body is constant (25°C) at initial time ($t = 0$).

Soaking period: The initial temperature distribution is adapted in itself to be parabolic in a range of $r = 0 \sim 7.5$ cm at initial time ($t = 0$).

Cooling period: Temperature in the whole body is constant (100°C) at initial time ($t = 0$).

Therefore the results given in Table 1-a, b, c, mean the average values from each initial time to the desired time.

The reason why such computations were carried out are as follows:

1) Heat flow equation is analytically solved only for the cases of simple initial conditions.
2) Average value of K has the advantage for the practical application.
3) The results by this method give suggestions for one of the purposes of this study which is to know qualitatively the mechanism of heat transfer.

Most of these computations were carried out by IBM 360.

The values of film thickness of heat transfer were derived from the experimental data by the following ordinary procedure:

This value is equal to a distance from the surface of a cylinder or a slab to the point at which the tangent line of temperature-distribution curve at the surface intersects with a horizontal line showing ambient temperature.

Results

The results of measurement of temperature distri-

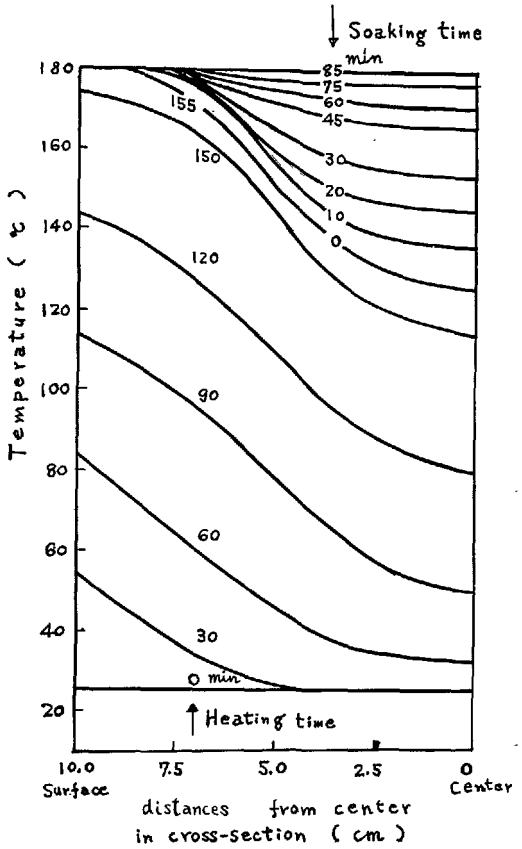

Fig. 2a. *Temperature profiles during heating-up and soaking period when long cylinder of 20 cmϕ is heated at rate of 1°C/min*

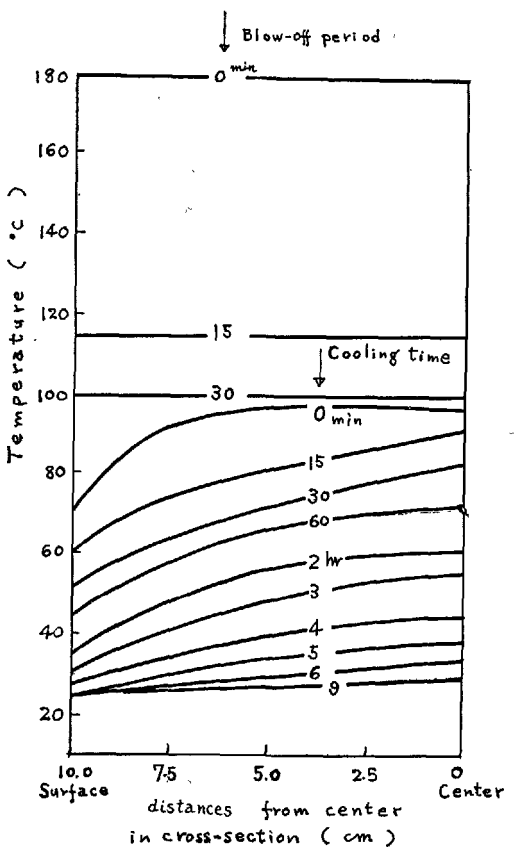

Fig. 2b. *Temperature profiles for long cylinder of 20 cmϕ during blow-off and cooling period*

bution for a cylindrical specimen are illustrated in Fig. 2-a, b. The surface temperature of the cylinder was equal to that of ambient saturated steam at any time of heating and soaking period, whereas for cooling period it was higher than the ambient temperature. Therefore the film thickness of heat transfer was treated as zero for heating and soaking period, and for cooling period it was determined to be approximately 2.0 cm as a mean value for this period by the method described before. It should be noticed, however, that this value would be largely varied by the ambient condition of cooling.

During the heating-up period, K increased with the temperature or with the time and was larger near the surface than at the center of the cylinder. The average value of K for the whole cross-section during heating-up period with a heating rate of 1°C/min was 0.40 cm^2/min as shown in Table 1-a.

Heating rate of 0.75°C/min resulted in approximately the same values of K and the same tendency of the variation.

At the initial stage of the soaking period, K decreased once, but gradually increased again to reach 0.42 cm^2/min (Table 1-b).

For the blow-off period no temperature difference in the cylinder was observed. Then K value is considered to be infinite. After the specimen was removed from the autoclave, however, temperature gradient in a specimen developed again.

The values of K at the initial stage of the cooling period were relatively high and gradually decreased with time.

For an infinite slab of 20 cm thickness the following results were computed.

1) The heating-up period and the early stage of the cooling period: Assuming that heating rate = 1°C/min from room temperature to 180°C and average thermal diffusivity K = 0.40 cm^2/min, temperature at the center reaches 60°C at the end of heating period, and 7 hrs soaking at 180°C is required for the temperature difference to be less than 5°C.

2) The cooling period: Assuming that $K = 0.6$ cm²/min at 30 min after the specimen is removed from the autoclave, temperature difference between the surface and the center is 40°C, which is a maximum temperature difference during this period.

Discussion

Thermal diffusivities K of the final product having a bulk density of 0.5 g/cm³ have been determined to be 0.10 cm²/min at room temperature, and it somewhat increases with temperature to a value 0.13 cm²/min at 200°C (7). Therefore the average values of K in a specimen during heating-up period obtained above corresponded to 4.0 times of the value of the final product. Their variations with time, temperature and location are also extraordinarily large.

The moisture movement phenomena which consist of the three mechanisms shown below may be assumed from such a tendency.

i) The driving force for the movement of water vapor is its pressure gradient attributed to temperature gradient which has been at first originated from the time lag of heat conduction in solids.

The water vapor which reaches lower temperature field condenses there to raise the temperature by the heat of condensation.

ii) If the heat is transfered to any low temperature field by the heat conduction process, the liquid water which had been stored there evaporates for the reestablishment of the equilibrium water vapor pressure, thus the rate of temperature rise is reduced by the heat of vaporization.

For the above two cases the condensed liquid water may also diffuse in a specimen due to the gradient of water content and play a role of heat transfer.

iii) If at any time, capillaries connecting a pore to the others are sealed with condensed water to some degrees and in addition temperature of that region rises further, the pressure of the air which has permeated into the pores by that time increases, and forces condensed water to come out of the capillaries or of the pores.

During the heating-up period, the mechanism i) is superior to ii), whereas at the early stage of the soaking period ii) is superior to i). The water content in the specimen gradually increases up to 180°C. On the contrary at the early stage of the soaking period mechanism ii) plays a significant role, since only inside temperature increases with time.

In addition, the moisture movement from inside to outside of the specimen will be derived from the mechanism iii) at the later stage of the heating-up period and the early stage of the soaking.

These movements of moisture will appear more distinctly near the surface than at the center because of a larger temperature and pressure gradient at the surface. Therefore values of K vary more significantly there.

The phenomena of the inside pressure increase and the weight diminution at the end of the heating period or at the early stage of the soaking period have been observed by K. F. Lomunov, et al. (3). The differences in K along the radial direction decrease as the temperature differences disappear after a few hours' soaking at 180°C.

During the blow-off period, a violent movement of water vapor from inside may also be suggested by the fact that no temperature difference in a specimen was observed. At an early stage of cooling, relatively high values of K indicate that the water vapor continue to move towards the outside.

Then, values of K approach to that of the final product as the specimen continue to be cooled and dried for long hours.

The violent moisture movement in concrete may have a influence upon the mechanical properties under autoclave process.

Linear Change during Autoclave Process

As mentioned in the "Introduction", two kinds of methods have been reported on the continuous measurement of linear change during the autoclave process. The DVT method is rather simple and precise, whereas the method by straingauge needs a special adhesive agent having an endurance for moisture at high temperature, and a correction for such a condition. Common difficulty for both methods lies rather in their expensiveness as equipment.

The linear changes during steam curing are a function of i) thermal expansion of solid part of concrete, ii) hydraulic movement and iii) hydration reaction. Linear changes by hydration reaction of usual silicates are not so large as compared with ther-

mal expansion or hydraulic movement, but some hydration reactions, for example the reaction of MgO + H_2O = $Mg(OH)_2$ dealt with in our investigation, are known to show extraordinarily high expansion. If such a reaction is contained in the usual system of silicates, it sometimes becomes an origin of fracture.

Augmented expansion of this reaction, however, can be used effectively for balancing the expansion of the concrete part with that of the reinforcement part or sometimes for manufacturing prestressed concrete.

In this section a simple apparatus for measurement of linear change is presented and some results are discussed concerning the above problems.

Apparatus and Method

An apparatus was devised by which the linear change of concrete in an autoclave could be measured successively on the basis of the principal "Differential Optical Lever Method". Fig. 3-a, b, c show this apparatus, Its principal features are as follows:

The linear change of the specimen placed horizontally in a quartz tube is transfered to the rotation angle of a mirror through a quartz rod and a stainless steel part. At the same time, the linear changes of the quartz rod and the stainless steel part are cancelled by those of another quartz rod and stainless steel part with same lengths. This dilatometer is set in an autoclave.

A small pyrex-glass window is attached through the flange of the autoclave. Light is allowed to come into the autoclave through this window, to be reflected by the mirror and to focus on a scale placed outside. The location of the light spot on the scale is recorded automatically by taking a photograph at regular intervals.

The mirror was made of the Pt-Rh alloy, which was the only material that could withstand corrosion by water vapor at high temperature. Both the mirror and the window glass were heated by two nichrome heaters which were fitted inside and outside the window glass.

Before the measurements, the accuracy of this apparatus was calibrated by a rod of steel of which expansion coefficient was already known. The linear change of the specimen of 2.5 cmϕ × 10 cm in a whole cycle of autoclaving was measured by this dilatometer. The same method can be applied easily to a specimen of larger size. In our investigation, however, only a maximum expansion of the larger specimen of 20 × 20 × 60 cm during the autoclaving cycle was measured by the simple method of recording

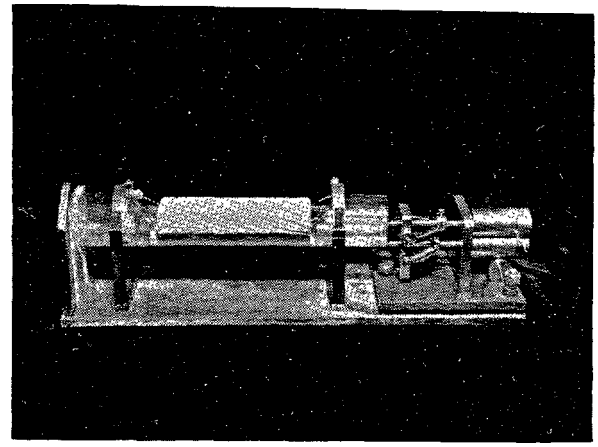

Fig. 3a. *Dilatometer in which specimen of 10 cm in length is inserted. It is consisted of quartz tube and rod, stainless steel part and Pt-Rh minor*

the linear change of the specimen on a ground glass plate by a carbon rod previously attached to the specimen. By this method, the information on the size effect of the specimen could be obtained satisfactorily. The specimens for both methods were previously stored under 40°C above 90% R. H. for 12 hrs. Autoclaves of 5.0 liters and 200 liters content were used for a small size and a large size specimen respectively. The specimen in an autoclave was heated to 180°C, 10 atm vapor pressure at a rate of 1°C/min, soaked under this condition for the desired period and cooled to room temperature.

The influences of the addition of MgO on volume change were investigated both for batch compositions (cement-siliceous sand-blastfurnace slag) and for bulk densities (0.5 g/cm^3, and 1.8 g/cm^3). The starting materials were ground to approximately 3000 cm^2/g. The bulk densities were controlled both by the additives and by water-cement ratio. Two kinds of MgO were used, one was light-burnt MgO (900 ~ 1000°C), another was dead-burnt MgO (1700°C).

Results and Discussion

Characteristic of Expansion-Temperature Curve

As seen in Fig. 4 the expansion-temperature curve without MgO during heating-up period is almost linear, but has a slightly S-shaped characteristic. The average coefficient of expansion is 12.5 × 10^{-6}/°C for the temperature range of 80° ~ 150°C, whereas it is 8.0 × 10^{-6}/°C for both in lower and higher temperature range.

The average value up to 180°C from room temperature is 10 × 10^{-6}/°C (9 × 10^{-6}/°C for cement-sand system), which is almost the same order as the coefficient of thermal expansion of the starting material, i.e., that for cement 14 × 10^{-6}; siliceous sand 11 × 10^{-6}; concrete with crushed slag 10.6 × 10^{-6} (9).

From these data it may be said that the expansion-temperature relation depends mainly on the thermal expansion of the solid part in concrete and secondarily is slightly deformed to an S-shaped characteristic by the other mechanisms. To account for this characteristic, it seems necessary to describe the hydraulic movement in concrete.

The effects of the moisture behavior on thermal expansion of concrete have been investigated by several authors. According to them, there is a maximum of the thermal coefficient at an intermediate state of wetness, which is 70% R. H.. Powers (8) explained this mechanism by saying that there are capillary water and a water fixed in the gel that is constituted

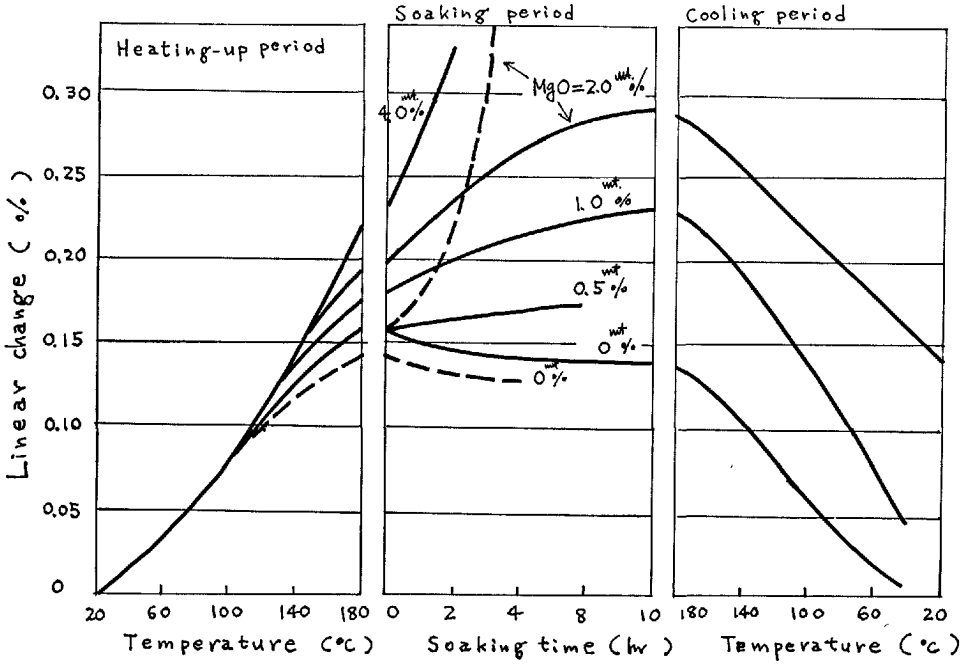

Fig. 4. *Linear change during a whole autoclave cycle Conditions: heating rate 1°C/min; specimen size 2.5 cmφ × 10 cm; bulk density 0.5 g/cm^3; burning temperature of* MgO, *dead-burnt* MgO *(1700°C); composition, slag rich system (——) and siliceous sand or cement rich system (- - - -)*

by the hydration phase; a change in temperature destroys the equilibrium between two kinds of water, then requires a transfer of water between the two phases. The delay in this transfer results in the additional dilation that disappears after reestablishment of the equilibrium.

L. Hermite (9) and Honma (10) suggested that the reduction of the surface tension of the capillary water with the temperature increase diminishes the shrinkage pressure which results in additional expansion.

In the present study, the specimens absorb water to achieve a highly humid situation in their interior in the heating period as previously mentioned and, in addition, continuously change their quality by hydration reaction. These conditions seem to be explained by the several theories above.

The slight shrinkage in the early stage of the soaking period also seems to be connected with the moisture movement in concrete.

The Effect of bulk Densities and Sizes

The amount of expansion and its tendency to vary with time elapsed during the autoclave process were almost the same for the specimen of density of 0.5 g/cm³ and 1.8 g/cm³ in the case of no addition of MgO (Fig. 6). The larger size specimen of 20 × 20 × 60 cm also showed the same amount of expansion and variation tendency as the smaller one (2.5 cmϕ × 10 cm) (Fig. 5). The following assumptions are based on these informations.

i) Moisture movement in concrete has scarcely any significant role for expansion phenomena in the autoclave process, although it should be remembered that there may be a little influence of it as mentioned in the former section, namely overall linear change in autoclave process depends on the thermal expansion coefficient of the solid part of concrete.

In other words, it can be said that the concrete under autoclave process has permeability and Young's modulus large enough for moisture movement and its force in concrete respectively.

ii) The summed-up length of the solid parts along the linear direction is a base length for calculating the amount of expansion or shrinkage as long as the solid parts are continuously linked. Then the amount of expansion or shrinkage is independent of the porosity of the concrete.

The Effect of the Addition of MgO

Augmented expansion effect of dead-burnt MgO was observed mainly in the early stage of the soaking period at 180°C. This tendency was irrespective of the various compositions, bulk densities or the specimen sizes, but the sensibilities of MgO were somewhat different for each case. In the case of the speci-

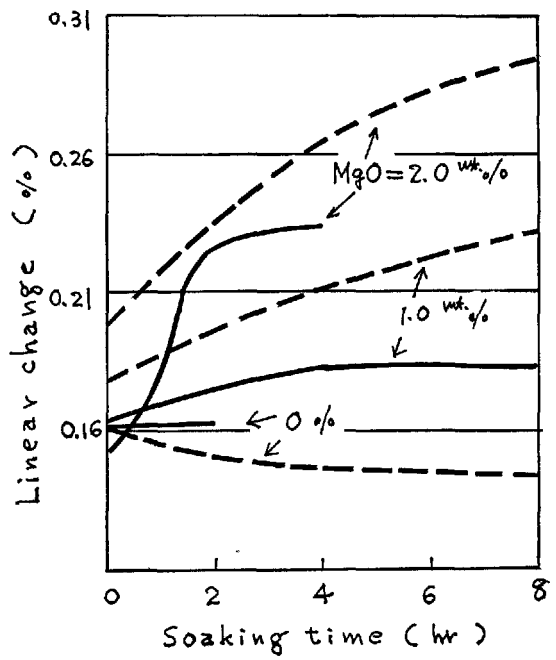

Fig. 5. *Size effect developed during the soaking period Conditions: composition, slag rich system; specimen sizes, 20 × 20 × 60 cm (——) and 2.5 cmϕ × 10 cm (- - - -) the others are the same with Fig. 4*

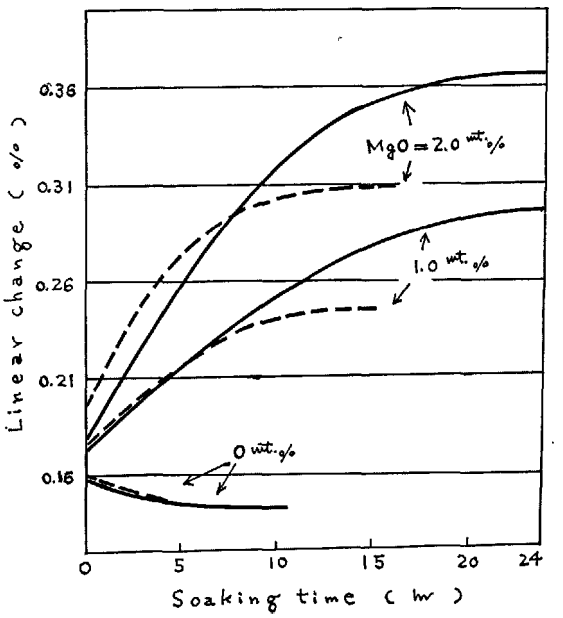

Fig. 6. *Influences of bulk density during the soaking period Conditions: composition, slag rich system; bulk densities 1.8 g/cm³ (——) and 0.5 g/cm³ (- - - -); the others are the same with Fig. 4*

men having a bulk density of 0.5 g/cm³, the addition of more than 2% of MgO led to extraordinarily high expansion. An addition of 4% of MgO caused fine cracks across each other or disruption, and 10% of MgO caused dusting (Fig. 4). These are typical damages arising from the differences in the expansion characteristics of the different phases. In view of compositions, the specimens having a large percentage of blastfurnace slag showed a higher resistibility to expansion effect by MgO than siliceous or cement rich compositions (Fig. 4). Compared with that of 0.5 g/cm³, the expansion of MgO in the specimen having a bulk density of 1.8 g/cm³ continued to develop for a longer period of 20~24 hrs (Fig. 6).

A large size specimen reduced the expansion effect of MgO (Fig. 5).

The expanding effect by light-burned MgO was completed during the heating-up period to 180°C as seen in Fig. 7.

From the above data, some practical and useful informations could be drived.

1) The time when augmented expansion of MgO develops is controlled mainly by the selection of its burning temperature.
2) The amount and type of MgO has to be changed with the compositions, densities and dimensions of the specimen.
3) Too much addition of MgO causes cracks due to difference in the expansion characteristics of different phases.
4) The coefficient of shrinkage during the cooling period is approximately equal to that of the specimen without addition of MgO irrespective of the amount of MgO added to the specimen.

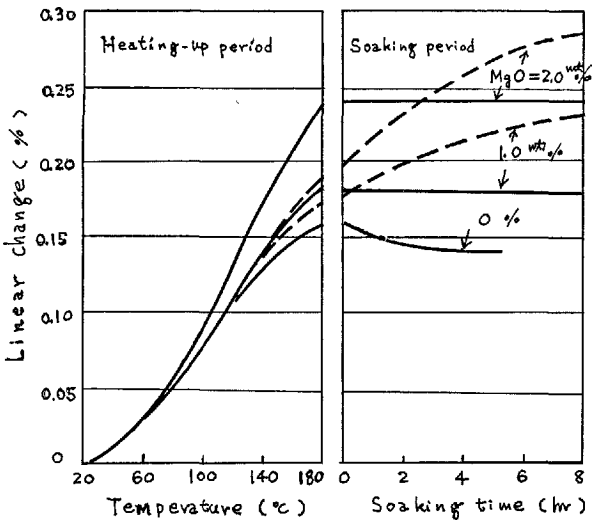

Fig. 7. *Influences of burning temperature of* MgO
Conditions: composition, slag rich system; burning temperatures of MgO, *light-burnt* MgO (*900–1000°C*) (——) *and dead-burnt* MgO (*1700°C*) (- - - -)*; the others are the same with Fig. 4*

There develops, then, the accumulated compressive stress due to the augmented expansion of MgO in the case of a reinforced concrete product.

It is considered to be advantageous also in reducing the tensile stress which develops during the cooling period due to thermal stress.

Mechanical Properties and Thermal Stress

Investigation of the process of development of mechanical properties during autoclave reaction is conclusively important for determining the time schedule of autoclaving.

Moreover determination of the actual stress in a concrete material under a given condition of heat transfer requires data on mechanical properties. In the previous sections we treated heat transfer and linear change of concrete. Therefore in this section the problem of thermal stresses will be discussed by using the some results of measurement on Young's modulus and mechanical strength.

Experimental Method

The blocks having the same shape and dimensions as that used for the test on the temperature distribution were subjected to measurement of mechanical properties in room condition. The blocks had been soaked for 0~8 hrs at 180°C and 10 atm.

The test pieces of 3.5 × 3.5 × 16 cm were cut at several locations along the radial direction in an original block so that direction of the longitudinal axis of the test piece coincides with that of the original block and also the center cross-section perpendicular to the longitudinal axis of the test piece coincides with that of the original block.

Young's modulus and mechanical strengths of these test pieces were determined. Sound velocities were measured and from the data, Young's modulus E (kg/cm²) was calculated by the following equation.

$$E = \rho u^2/g \qquad [1]$$

where, ρ = bulk density of specimen (kg/cm³)
u = sound velocity in concrete (cm/sec)
g = acceleration of gravity (cm/sec²)

The strengths for 0 hr soaking specimens were estimated from the experimental data on the Young's modulus by the empirical equation [2], since the specimen was too fragile to subject to usual mechanical strength test.

$$E = 4500\sqrt{0.9Fc} \qquad [2]$$

where, Fc = compressive strength (Kg/cm²)

This equation was obtained by the revision of Purins's empirical equation for ALC products (7), $E = 3000\sqrt{0.9Fc}$, on the basis of the experimental data on E and Fc of 2 hrs soaking specimens. Tensile strengths Ft (kg/cm²) were calculated by the Kano's equation (7) for concrete.

$$Fc = 2.66Ft^{1.44} \qquad [3]$$

This equation has been shown to be in good coincidence with ALC products.

From the data on expansion coefficient, temperature distribution and Young's modulus, the thermal stress both in a cylinder of 20 cmϕ and in a large slab of 20 cm thickness were estimated by the equation given in Table 2, where Poisson's ratio was assumed to be 0.3.

In the case of the initial stage of cooling period, the possibility of the surface crack due to sudden change in temperature was discussed also on the basis of the values of Biot's modulus and nondimentional time.

Table 2. *Computation equation for surface and center stresses.*(11)

Shape	Surface	Center
Long cylinder	$\frac{E\alpha}{1-\mu}(Ta - Ts)$	$\frac{E\alpha}{2(1-\mu)}(Ta - Tc)$
Infinite slab	$\frac{E\alpha}{1-\mu}$	$\frac{E\alpha}{1-\mu}$

E = Young's modulus.
α = coefficient of thermal expansion.
Ta, Ts, Tc = average, surface and center temperature, respectively.
μ = Poisson's ratio.

Results and Discussion

Mechanical Properties

Experimental and calculated results are given in Table 3-a, b, c, d. Variations in mechanical properties (Young's modulus and mechanical strength) along the cross-section were most distinct in the block soaked for 2 hrs at 180°C after the end of the heating-up period. It should be remembered that temperature difference in like size specimen disappeared at 1.5 hrs' soaking (Fig. 2-a). These variations decreased in the specimen at longer soaking time. This tendency means that the time lag for heat transfer in concrete is accompanied by that for the development of mechanical properties.

Thermal Stress and Failure

If the specimen was perfectly elastic, the inner tensile stress of 0.8 kg/cm² for a cylinder (20 cmϕ) and 1.8 kg/cm² for a slab (20 cm thickness) should be developed at the end of the heating-up period, which were considerably larger than the tensile strength of the material at that time (0.35 kg/cm² for cylinder as seen in Table 3-a). Then the inner crack might be predicted to arise for both shapes.

The stress, however, must be relaxed more or less during hardening process, then the values of 0.8 kg/cm² and 1.8 kg/cm² may be somewhat reduced.

The surface tensile stresses of the cylinder and the slab at the initial stage of the cooling period, 6.0 kg/cm² and 9.0 kg/cm², respectively, were approximately comparable to the tensile strength at that time.

If the stress is completely relaxed only during heating-up period and after that the specimen is perfectly

elastic, the surface tensile stress of 0.8 kg/cm² for the cylinder and 1.8 kg/cm² for the slab should be developed at the time at which the temperature distribution in the specimen disappear. These values are certainly noticed to be lower than the tensile strength at that time (4.2 kg/cm² for cylinder). Therefore the possibility of the inner crack during hardening process (heating-up and early stage of soaking period) is reduced. In addition, these tensile stresses are accumulated to the tensile stresses developed at cooling period and the possibility of the surface crack slightly increases.

On a basis of these approximate estimation concerning thermal stress, it is concluded that the thickness of 20 cm is the upper limit for a slab to be securely produced under the autoclaving condition carried out in this investigation.

Furthermore it should be noticed that failure phenomena under autoclaving process might be affected also by the drastic movement of moisture in concrete, or heterogeneous linear changes due to the different phases contained in concrete as pointed out in previous sections.

Summary

(1) For a cylindrical specimen of 20 cmϕ, average value of apparent thermal diffusivity K during the hardening process (the heating-up period and the early stage of the soaking period) under the heating rate of 1.0~0.75°C/min in autoclave process was determined to be approximately 4 times as large as that determined for the final product.

(2) From the values of K and their variation with autoclave time schedule and the position in the specimen, it was presumed that heat transfer in concrete was affected both by the presence of liquid water in concrete and by movement of vapor or liquid in concrete.

(3) The temperature profiles of a slab of 20 cm thickness at successive times were determined. The temperature difference between surface and center was 120°C when the surface was heated up to 180°C with a rate of 1°C/min. Seven hours soaking at this temperature was required for this difference to be less than 5°C.

(4) By the application of the principal "Differential Optical Lever Method", a simple apparatus was devised for successive measurements of linear change of specimen under autoclave process.

(5) Almost the same expansion-shrinkage phenomena in the case of no addition of MgO were observed for various compositions (cement-siliceous sand-blastfurnace slag), specimen sizes (2.5 cmϕ × 10 cm and 20 × 20 × 60 cm) and bulk densities (0.5 g/cm³ and 1.8 g/cm³).

(6) Augmented expansion was observed in the heating-up period for the specimen added with light-burnt MgO, but it was observed in the soaking period when dead-burnt MgO was added. This tendency was irrespective of other factors, whereas the amount of expansion somewhat influenced by compositions, sizes and bulk densities of concrete. Excessive addition of MgO caused disruption of the specimen.

(7) In view of thermal stress, it is concluded that the thickness of 20 cm was approximately estimated to be the upper limit for a slab to be securely produced under the autoclaving condition carried out in this study.

Supplementary Paper III-111 Influence of Minor Components on the Strength of Calcium Silicate Hydrate Synthesized by Hydrothermal Reaction

Gunji Shikami*

Synopsis

In the present investigation, it was studied about the influence of the addition of the foreign components, such as beryllium, zinc, and alkaline compounds, on the strength and the reaction rate of hydrothermal synthesized products.

Addition of beryllium and zinc even in quantities up to 0.1–0.4 per cent, can appreciably delay the progress of hydrothermal reaction, deteriorating seriously the development of the strength of the reaction product at the usual hydrothermal condition (160–180°C, 3–6 hours). They, however, do not entirely stop the hydrothermal reaction, but merely lower the rate of the reaction. The manner of the hydrothermal reaction does not be changed substantially by the addition of the poisoning compounds, as recognized from the molar ratios of the hydrated substances.

The addition of alkali in minor quantities can promote the reactivity as well as the strength development of the product. The promotion of the strength may be explained by the increased reactivity of quartz and the formation of a compound of system R_2O–SiO_2–H_2O in the hardened product. Alkalies added in quantities above 0.3 per cent, however, generally tend to retard the reaction and deteriorate the development of the strength of the reaction product. Addition of alkali causes a marked decrease of the water absorbing capacity of the hydrothermal product.

Introduction

Many investigators have studied about the factors affecting the strength of hydrothermally synthesized calcium silicate hydrate (1), namely,

i) CaO/SiO_2 molar ratio
ii) the temperature and the duration of an autoclaving
iii) the physical properties of the starting materials, especially crystalline modifications, crystallinity, and fineness of the siliceous material
iv) the compacting pressure and the amount of mixing water applied at the moulding
v) the addition of some foreign components

Of these, we were interested particularly in the factor (V). Since these were already some studies on the influence of Al_2O_3 (2) and MgO (3), the present investigation was undertaken to determine the influence of the addition of beryllium, zinc, lithium, sodium and potassium on the strength of the hydrothermally synthesized products. The presence of them even in minor quantities was known to have rather remarkable influence, either favourable or unfavorable, on the strength of the products of hydrothermal synthesis. The results of these experiments are reported below.

Methods and Conditions of Experiment

Material

The principal components, CaO and SiO_2, were obtained from slaked lime of analytical reagent and high-purity quartz respectively, whose chemical compositions and physical properties are shown in Table 1. By X-ray and thermal analysis, it was shown that this slaked lime was contaminated with a little amount of calcium carbonate.

Preparation of Specimen

Autoclaved specimens were prepared by the follow-

*Osaka Cement Co., Ltd., Osaka, Japan.

Table 1. *Properties of raw materials*

[2] by water vapour adsorption.

ing method. Slaked lime and quartz powder were weighed out in quantities corresponding to a CaO/SiO_2 molar ratio of 0.60 and these were thoroughly mixed up with prescribed amounts of the selected foreign components, e.g. BeO, ZnO. Then water was added to the mixed powder in a quantity corresponding to a water-powder ratio of 0.55, followed by thorough kneading.

The paste thus prepared was placed into a mould $2 \times 2 \times 8$ cm. After 8 to 12 hours the paste was autoclaved under the prescribed conditions, followed by demoulding.

Analysis of Free Lime and Quartz

Quantitative Analysis for Free Lime

According to the method of quantitative analysis for free lime in portland cement clinker, the specimen prepared by the procedure described above was treated in glycerine-ethanol solution with $Sr(NO_3)_2$ as catalyst and titrated with ammonium acetate solution. Thus the amount of unreacted lime in the specimen was determined.

Quantitative Analysis for Unreacted Quartz

In the analysis for unreacted silica, following the method of Steope, a pulverized sample was rapidly dissolved in 1 N HCl solution containing 5 per cent NaCl, then washed with a solution of 5 per cent Na_2CO_3 and 5 per cent NaCl by weight, and finally washed in succession with 1 per cent HCl solution and hot water. The ignited residue represented the amount of unreacted silica.

Analysis in a blank test of slaked lime-quartz mixture prior to hydrothermal synthesis gave a result of 56.9 per cent which was considered to be satisfactory against the calculated value of 57.5 per cent.

Determination for Combined Water of the Hydrate

In the determination for combined water of hydrothermal hydrate, there are three factors which make the result inaccurate, namely the crystalline water due to unreacted slaked lime, the error due to contamination with carbon dioxide and the water physically adsorbed by calcium silicate hydrate. Therefore, for accurate determination of combined water in the hydrate, the errors resulting therefrom had to be corrected against the result of a thermal gravimetric analysis. Namely, the loss due to slaked lime at 500°C and that of calcium carbonate over the range of 690 to 850°C were deducted from the weight loss over the temperature range of 100 to 850°C and the remain was recorded as the amount of combined water. The correction of physically adsorbed water was carried out by keeping the specimen in vacuum for 8 to 10 hours. In a thermal analysis (DTA and TGA) the temperature was raised at a rate of 10°C/min.

Influence of Addition of Beryllium and Zinc

The presence of beryllium or zinc compounds in the system even in minor amounts or trace can rather seriously retard the progress of hydrothermal synthesis, as seen from Table 2 showing the result of synthesis 180°C—6 hours. As seen from the tabulated data, beryllium and zinc, added in quantities up to 0.1–0.4 per cent either in the form of oxide or sulphate, retard the hardening reaction and lower the development of the strength. The lowering effect, however, depends on the conditions of the hydrothermal treatment, as it is shown in Fig. 1.

To clarify the retarding effect due to such components, an experiment was made with some zinc compounds, whose result is shown in Table 3. To make easy identifing the reaction product, the experiments were carried out with a CaO/SiO_2 ratio of 1.0 and

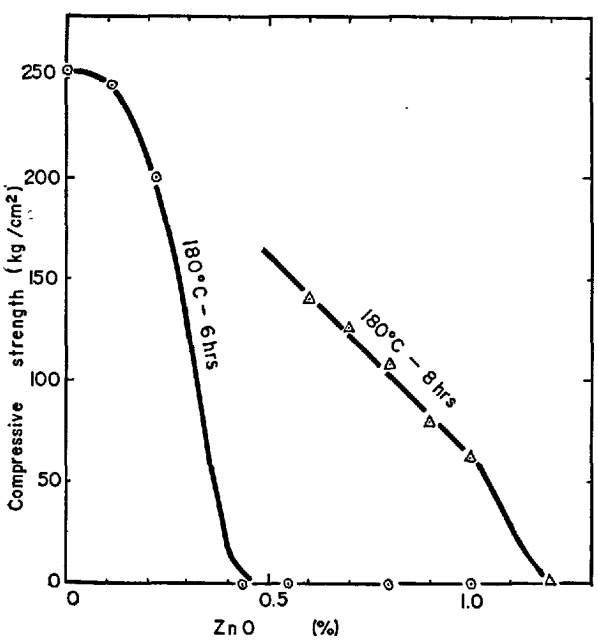

Fig. 1. *Effect of adding zinc oxide on the strength of autoclaved products*

with a larger proportion of mixing water (water/solid = 1) in a stainless steel container.

The amount of unreacted silica in the products synthesized at 200°C was difficult to be determined, because there were many troubles in the filteration called for by the Steope method. According to the results from X-ray analysis, some amounts of quartz (unreacted silica) were recognized in the products at 200°C-6 hours, but in the case of 200°C-12, 24 hours treatments the trace of quartz was not found. These results were also confirmed from the curve in Fig. 2. The compositions of the hydrates formed at 200°C-6 hours were not calculated, because the amount of unreacted quartz could not be estimated by X-ray analysis from the point of accuracy.

The progress of hydrothermal reaction can be discussed from the amount of the reacted silica and tobermorite gel formed, the degree of crystallization of tobermorite, the converting rate of tobermorite into xonotlite, and the surface area etc., the data of which were shown already in Table 2 and 3. The details of such findings are summarized in Fig. 2 to Fig. 8 and will be explained below.

Fig. 2 shows the influence of a presence of zinc compound on the reaction rate. From Fig. 2 it is noted that the reactivity of quartz is lowered remarkably when the reaction temperature is lower and reaction time shorter. These results are important from the industrial point, because these conditions are usual in autoclaved concrete industry. These lowering effect, however, decreases with increasing maturity of autoclaving. The dependence of silica's reactivity on the kind of zinc compound added has not been confirmed yet.

The typical change of hydrate phase with increasing maturity of hydrothermal treatments ,determined by X-ray analysis, is shown in Fig. 3. The diffraction pattern by X-ray alters from (1) through (2) and (3) to (4) with increasing hydrothermal treatments. In the figure, (1) is the X-ray pattern of tobermorite gel

(near amorphous tobermorite), (2) that of semi-crystalline tobermorite with the peak of 11 Å, (3) that of crystalline tobermorite in coexistence with xonotlite and (4) that of xonotlite. The results of identification of hydrate are tabulated in the final column of Table 3. From Table 3 it is known that the addition of zinc compound results in delaying the crystallization of tobermorite and conversion of tobermorite into xonotlite.

In a differential thermal analysis, as seen from Fig. 4, the formation of tobermorite in hardend product is indicated by a characteristic peak, resulting from the exothermic reaction due to β-wollastonite. The said peak appeared at a temperature range 810–830°C. The peak grows higher with increasing amount of tobermorite. Then the peak drops rather sharply with conversion of tobermorite into xonotlite and continues dropping until the said conversion is completed. The analysed results of DTA, not shown here, well agreed with that of X-ray analysis.

The evolution of the combined water in a thermal gravimetric analysis is plotted in Fig. 5. The gradual

loss of weight over the range of 100 to 800°C increased with increasing amount of tobermorite formed and begins to decrease as the formed tobermorite is converted into xonotlite. Since, as shown later in Fig. 8, CaO/SiO_2 ratios intimately relate to the amount of hydrated silica, it can be used as a measure for the progress of the reaction. But, when the conversion of tobermorite into xonotlite begins, H_2O/SiO_2 ratios change sharply, while CaO/SiO_2 ratios are indifferent to the progress. It is clear that a progress of synthesis can be known reasonably from both ratios, as shown in Fig. 6. Considering these ratios tabulated in Table 3,

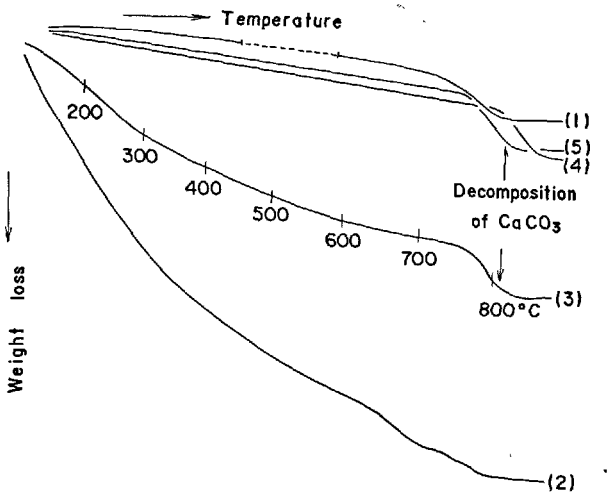

Fig. 5. *Thermogravimetric curves of hydrothermal products not containing posioning compounds. Molar ratio of the starting mixtures is* CaO: $SiO_2 = 1$. *Autoclaved conditions as follows;* (1) *140°C — 6 hrs,* (2) *160°C — 12 hrs,* (3) *200°C — 6 hrs,* (4) *200°C — 12 hrs,* (5) *200°C — 24 hrs. Dashed line was extrapolated by substracting the weight loss due to* $Ca(OH)_2$ *from the original one*

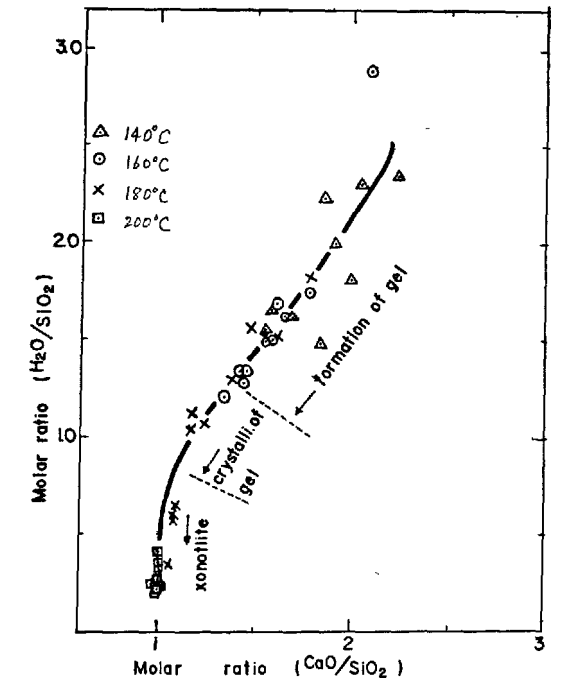

Fig. 6. *Change in morlar ratio of the hydrates with the progress of the reaction. These results were obtained with the autoclaved products containing or not containing zinc compound*

it is also concluded that an addition of zinc lowers the rate of hydrothermal reaction and conversion of tovermorite into xonotlite.

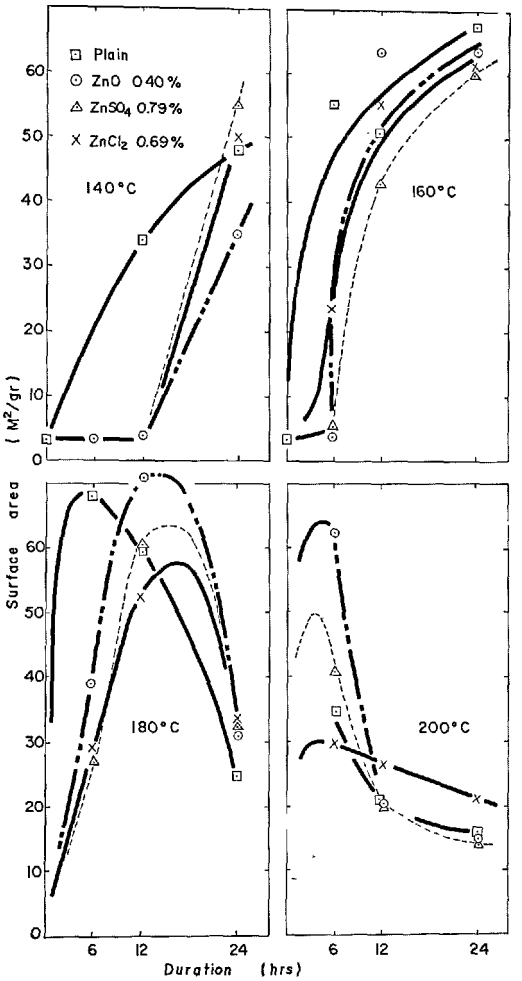

Fig. 7. *Change in surface area of the products. Surface area was determined by vapour adsorption with the aid of BET equation*

Fig. 7 shows the change in the surface area of the hardened product. Comparing these results with that of the X-ray analysis and differential thermal analysis, it is known that the surface area of the hardened product increases with progressive formation of tobermorite and starts decreasing sharply as it is converted into xonotlite.

Fig. 8 shows the relationship between CaO/SiO_2 ratio of the formed hydrates and the amount of hydrated silica in the product. It is recognized that this relationship can be plotted in a curve regardless of a presence of zinc and beryllium compounds. Since either CaO/SiO_2 ratios or H_2O/SiO_2 ratios of the hydrate formed are not influenced by the addition of zinc compounds, it comes to the conclusion that zinc compounds do not have any effects on the composition of the hydrates formed in the products. Only to be noted is that the result of differential thermal analysis

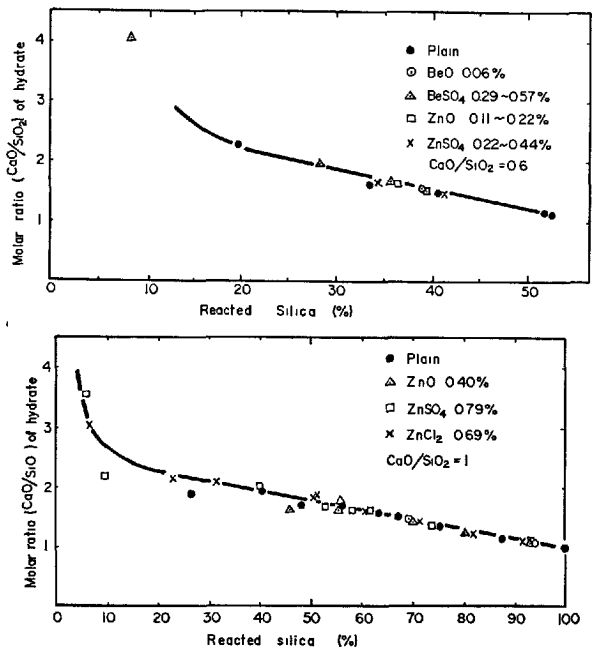

Fig. 8. *Relation between the reacted silica and molar ratio of the hydrate. Molar ratios of the starting mixture are* CaO: $SiO_2 = 0.6$ *in upper experiment and 1.0 in lower one respectively*

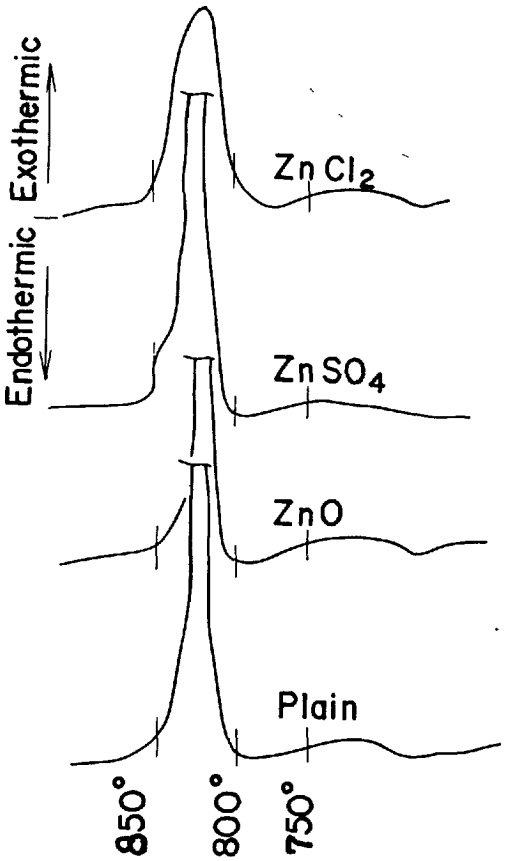

Fig. 9. *Change in the DTA curve caused from the kind of the added compounds. Broader peak is recognized in the case of* $ZnCl_2$

of the products containing $ZnCl_2$ indicated a somewhat broader peak at 820°C compared with the hardened products of other systems (Fig. 9) and the change in surface area was of somewhat different pattern, suggesting somewhat different physical properties of the formed hydrates.

From the results of the experiments above mentioned, it is known that by addition of zinc or beryllium compounds

i) the rate of the reaction between CaO, SiO_2, and H_2O is decreased appreciably with resultant drop in strength of the reaction product under usual hydrothermal condition,

ii) but the substantial pattern of the reaction and the compostion of the hydrate are not affected,

iii) and the growth of tobermorite and xonotlite as well as crystal phase conversion thereof is interfered in some degrees.

Influence of Addition of Alkali

The addition of alkalies shows remarkable influence on the properties of the hydrothermally hardened products as well as zinc and beryllium compounds. To be noted, however, is that alkalis, unlike beryllium or zinc, can promote the hydrothermal synthetic reaction in some cases.

Table 4 shows the results of this series of experiments. In this experiments lithium was added in a form of oxide, sodium and potassium in a form of hydroxide, which were prepared in a form of aqueous solutions of fixed concentrations, for the convenience of the procedure.

The influence of an addition of alkalies on the reactivity of quartz is as illustrated in Fig. 10. While the addition of alkalies in minor quantities can somewhat promote the reactivity of quartz, but it lowers reactivity if it is added in larger quantities (above 0.3 per cent). The lowering effect is least significent with lithium and becomes stronger with potassium and sodium. As already mentioned above, important is the fact that the addition of alkalies in minor quantities can promote reactivity between CaO and SiO_2.

[1] Not corrected values as to CO_2 contamination. Molar ratios of CaO/SiO_2 and H_2O/SiO_2 will be lowered by the correction up to 0.01–0.03.

Fig. 11 shows the relationship between the bulk density and the apparent specific gravity (by an immersing method in water) of the hardened products. A marked difference between the products containing and not containing alkali is noted from the figure. While the bulk densities increase progressively with increasing addition of alkali (see Table 4), the tendency is reversed with regard to the apparent specific gravities which decrease with increasing addition of alkali. This phenomenon comes from the fact that the alkali containing products are more compact and less water permeable (less absorbent). As seen from Fig. 12, the apparent specific gravities of the hardened products decrease with increasing amount of alkali added and with increasing amount of the reacted silica. Therefore, this tendency may be attributed to the formation of the hydrate in the system R_2O–SiO_2–H_2O, which is likely to impart water impermeability to the

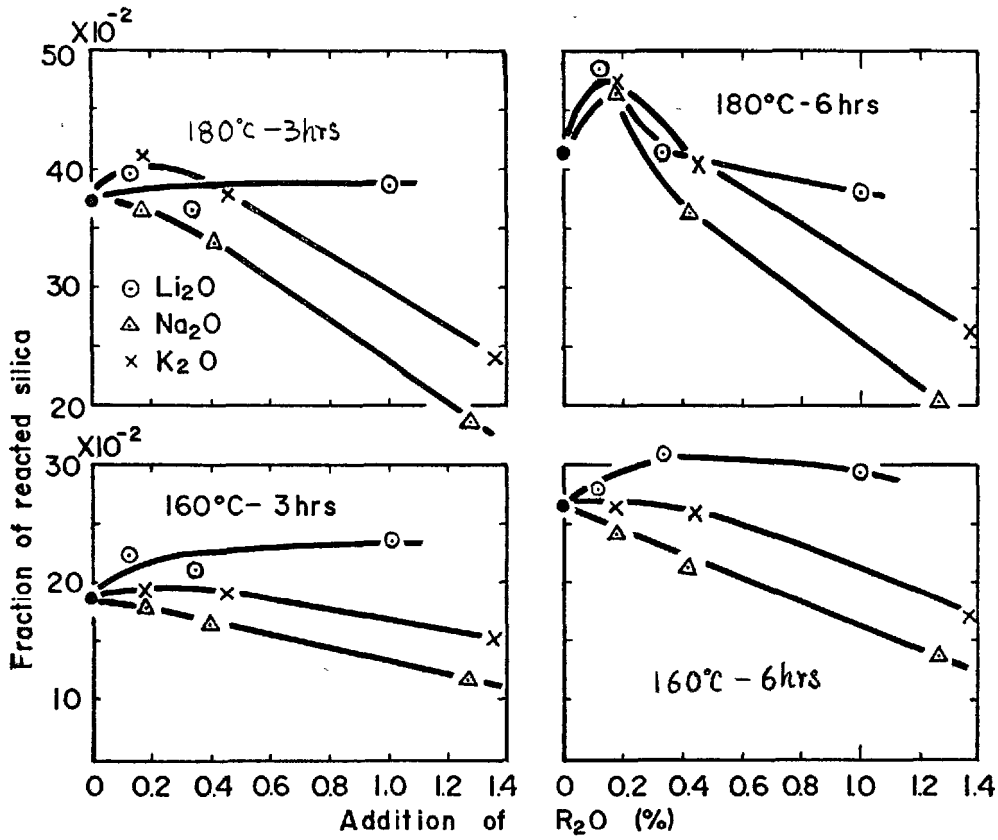

Fig. 10. *Influence of adding alkalies on the reactivity of quartz*

product. (see also Fig. 14).

From Table 4 it is clear that alkali containing products have substantially higher strength than expected from the amount of reacted silica. For instance, Na_2O containing product synthesized under condition of 180°C-3 hours is stronger than plain product, although the amount of reacted silica is smaller than that of the corresponding ones. Supposing that this phenomenon had something to do with the apparent specific gravity or bulk density of the hardened product, we plotted in Fig. 13 the strength of the hardened products as function of the ratio of the amount of reacted silica by apparent specific gravity. Since apparent specific gravity intimately relates to the bulk density (see Fig. 11), the said relation may as well be plotted with the product of reacted silica and bulk density on the axis of abscissa.

Judging from the results of Fig. 12, Table 4 and Fig. 13, it is clear that an addition of alkalies has considerable influence on the physical properties of the product synthesized by hydrothermal reaction.

The curve in Fig. 14 is the relationship between the CaO/SiO_2 ratio of the formed hydrate and the amount of reacted silica in the products. It is noted from the figure that the CaO/SiO_2 ratios of the hydrate formed in the products containing alkali are $0 \sim 0.2$ lower than that of the hydrate not containing alkali at the same amount of reacted silica. These differences are larger with potassium, sodium and lithium in this order and also with increasing amount of alkali added. This means that the said differences are roughly proportional to the molar fraction of alkali in the products. It is then apparent that the hydrate of the system R_2O–SiO_2–H_2O, in addition to calcium silicate

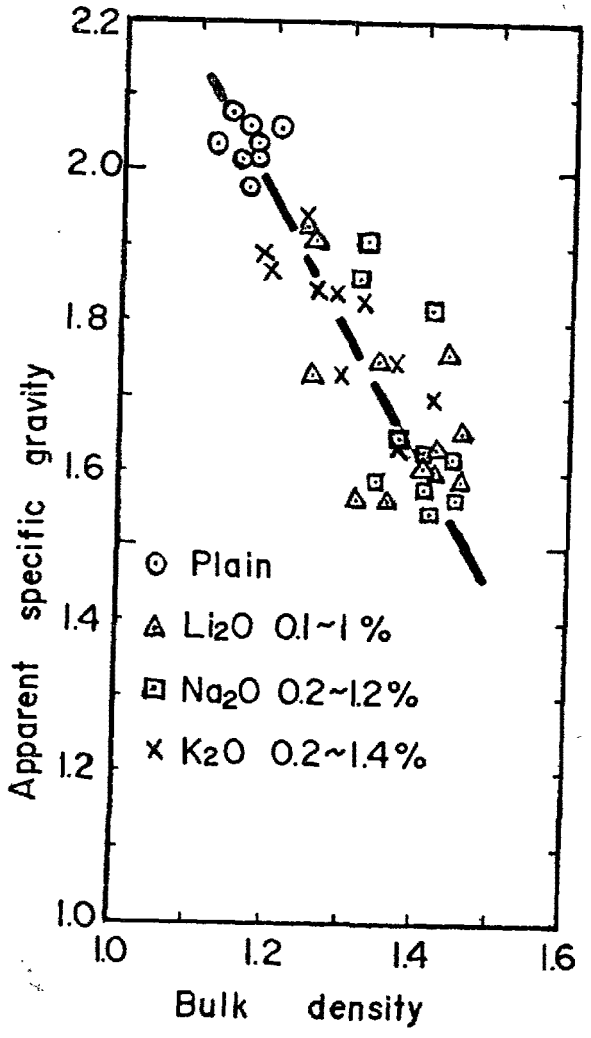

Fig. 11. *Relation between bulk density and apparent specific gravity of the products*

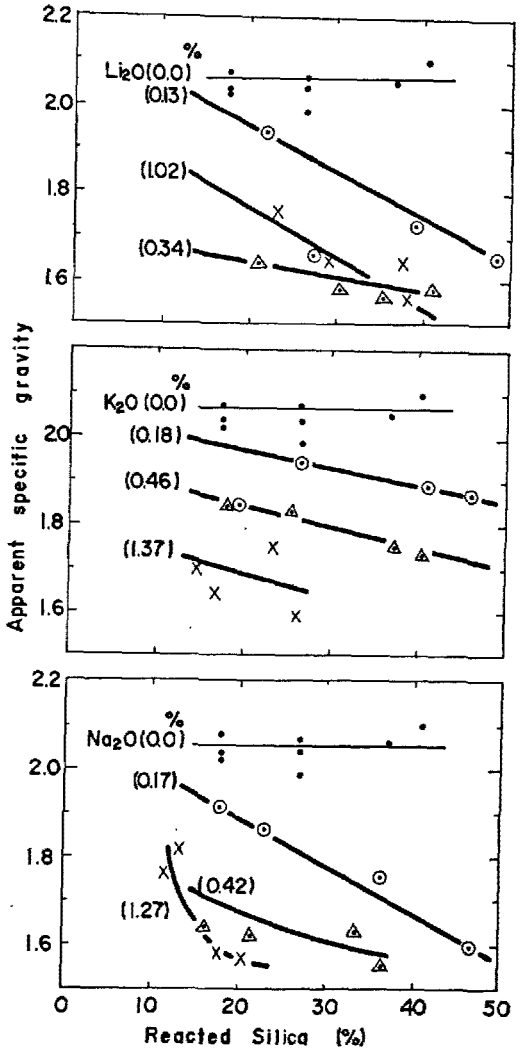

Fig. 12. Decrease of apparent specific gravity caused from the increasing addition of alkalies and the increased amount of reacted silica

hydrate, is likely to be formed in the products.

Assuming the formation of alkali silicate hydrate, there rises the suspicion that the increase of silica's reactivity by addition of alkali in a minor quantity, as shown in Fig. 10, is due to the reaction of R_2O on SiO_2. This suspicion, however, can be denied on the ground that the reactivity of silica decreases with increasing addition of alkali beyond a certain limit and that the increase of silica's reactivity with addition of minor amounts of alkali is by far more remarkable than might be expected from the reaction with the added alkali.

So, taking all these into consideration, it is concluded that an addition of alkali up to 0.3 per cent:

i) promotes silica's reactivity,

ii) imparts a high degree of water impermeability to the hardened products, substantially improving the strength of the products even if the amount of reacted silica remains the same,

iii) appears to give rise to formation of a hydrate of system R_2O–SiO_2–H_2O, besides calcium silicate hydrate, in the hardened products and accordingly results in lower CaO/SiO_2 ratios of the hydrate compared with that of the hydrate not containing alkali.

An addition of alkali in larger quantities above 0.3 per cent, however, is generally detrimental, causing a drop of the strength of hardened product.

Discussion

Reaction in the Presence of Beryllium and Zinc

Oxides of beryllium and zinc are almost insoluble in water (solubility of BeO and ZnO are 5–20 $\times$ 10^{-6} g/100g water and 4.2 $\times$ 10^{-4} g/100g water respectively) but are soluble as hydroxide in alkaline solutions. On the other hand their salts are water soluble but react with base quantitavely precipitating their hydroxide. For instance, according to Hazel et al (4), zinc sulphate titrated with sodium hydroxide or sodium silicate produces the precipitation of hydrated zinc oxide. Under the conditions of his study, no zinc silicates were formed, but peptizing effect of silica on the zinc precipitates was observed, and also observed the mutual coagulation of hydrated zinc oxide and silica. A similar example of reaction is observed by Britton (5). When 0.02 M $BeSO_4$, 0.02 M $ZnSO_4$, and 0.02 M $CaCl_2$ solution were titrated with 0.102 N Na_2O: 2.16 SiO_2 solution, precipitation of their hydroxide took place at pH 5.31, 5.25 and 10.07 respectively. As may be seen from these examples, oxide or sulphate of beryllium and zinc is converted in the alkaline solution containing silica into the corresponding hydroxide which precipitates at lower pH of 5 to 6 compared with calcium. At the beginning of hydrothermal reaction, hydroxide of beryllium or zinc is supposed to be adsorbed in a form of insoluble colloid onto the surface of quartz prior to the reaction between lime and silica and thus seriously interfers with dissolving of quartz. There appears no chemical reaction to take place between zinc hydroxide and silica, the apparent combination accounted for by mutual adsorption. It is presumed that the progress of the hydrothermal reaction is apparently retarded by a thin film of hydroxide formed by said mutual adsorption and the normal reaction rate is restored when this thin film has been destroyed under progress of reaction. The facts that the drop in reactivity of quartz appeared seriously in low temperature and short duration and decreased with rising temperature and prolonged duration (see Fig. 2), is reasonably understood by the hypothetic film of hydroxide mentioned above.

Acceleration of Reaction by Addition of Alkali

According to Kalousek (6), there is a close relation between Na_2O concentration and the solubility of

CaO and SiO_2 in the solution. For instance, in aqueous solution containing 20 g Na_2O/l, the solubility of CaO is lowered to 0.02–0.03 g/*l* compared to 0.5–0.6 g/*l* in lime water. On the other hand, the solubility of SiO_2 increases gradually as Na_2O concentration of the solution increases. This tendency is maintained essentially even at still higher temperatures.

In the present series of experiments, the addition of alkali amounted up to 1.5 per cent which corresponds to about 15 g/*l* mixing water. Within this range the solubility of CaO decreases sharply with increasing addition of alkali, whereas the solubility of SiO_2 increases slightly. The observed influence of the addition of alkali on the rate of hydrothermal reaction may, therefore, be explained by the fact that the solubility of silica is raised by addition of alkali in minor quantities (up to 0.3 per cent), whereas addition in larger quantities of alkali retards the rate of the reaction through lowering of the solubility of lime.

As to hydrates of system R_2O–SiO_2 formed with addition of R_2O, it is reported by Kalousek (6) that Na_2O/SiO_2 ratios can vary from 0 to 0.25 according to Na_2O concentration. While accurate molar ratios of R_2O/SiO_2 could not be obtained from the present series of experiments, it was observed that R_2O/SiO_2 molar ratios were almost common with Li_2O, Na_2O and K_2O, in most cases ranging from 0.0 to 0.2.

It has been already pointed out that the strength of the hardened product is promoted rather remarkably by addition of alkali and this may be attributed to the binder-like function of sodium silicate hydrate, resulting from addition of alkali, for calcium silicate hydrate.

Conclusion

By the present study on the influences of the addition of beryllium, zinc and alkali compounds on the rate of hydrothermal synthetic reaction of calcium silicate hydrate, it is concluded as follows:

i) An addition of beryllium and zinc even in quantities up to 0.1–0.4 per cent, can appreciably delay the progress of hydrothermal reaction, deteriorating seriously the development of strength of the reaction product at the usual hydrothermal condition (160–180°C, 3–6 hours). The deteriorating effect is not affected by the kind of the compounds e.g. oxide or sulphate.

ii) An addition of beryllium and zinc, however, does not entirely stop the hydrothermal reaction, but merely delay the progress of the reaction. This is supported from the results that the mixtures containing the poisoning compounds can hydrate as well as the one not containing them at an increased autoclaving. The hydrothermal reaction is not changed substantially by the addition of the poisoning compounds, as known from the molar ratio of the formed hydrate. But from the identification of the existing phase by X-ray analysis, it is found that the addition of them has some retarding effects on the crystallization of tobermorite and the conversion of tobermorite into xonotlite. Its retarding effect on the reaction rate may be attributable to its tendency to form hydroxide over quartz surface and to interfere with the dissolving of quartz. This will explain the fact that the said retarding effect is less significent when the reaction temperature is higher and the reaction time is longer.

iii) The addition of alkali in minor quantities can promote the reactivity as well as the strength development of the reaction product. The promotion of the strength of the product by addition of alkali may be explained by the increased reactivity of quartz and the formation of a compound of system R_2O–SiO_2–H_2O in the hardened product. Added alkali in quantities above 0.3 per cent, however, generally retards the reaction, deteriorating the strength development of the product. In this case, the retardation of the reaction is explained by the effect of added alkali to lower the solubility of CaO.

iv) The addition of alkali causes a marked decrease of the water absorbency of the hydrothermal reaction product, while the bulk density of the product increases with its addition. This fact is very interesting from the point of view of the autoclaved product which is less permeable to the water than the conventional one.

Explanatory Notes

Abbreviations.

The following symbols, which have been universally recognized by cement chemists for formulating more complex compounds, are used interchangeably with the respective oxide formulas throughout this book:

$C = CaO$, $S = SiO_2$, $A = Al_2O_3$, $F = Fe_2O_3$, $M = MgO$, $N = Na_2O$, $K = K_2O$, $H = H_2O$,

Less common abbreviations of this type are defined as they occur.

Commonly used abbreviations of more general nature are as follows:

DTA = differential thermal analysis
EPMA = electron probe micro analysis
IR = infrared
NMR = nuclear magnetic resonace
psi (or p.s.i.) = pounds per square inch

SESSION IV-1 USE OF SURFACE ACTIVE AGENTS IN CONCRETE

Principal Paper Use of Surface-Active Agents in Concrete

Richard C. Mielenz*

Synopsis

This report summarizes use of surface-active organic substances in portland cement concrete to cause air entrainment, reduce water requirement, control rate of setting and hardening, and otherwise modify properties of the fresh and hardened product. Surface-active substances causing air-entrainment are positively adsorbed at air-water interfaces and may be adsorbed at water-solid interfaces, particularly on granules of cement. Widely used air-entraining admixtures are anionic. Complex relationships determine the efficiency of air entrainment, void size distribution, and effects on viscosity in fresh concrete. Data show the importance of interchange of air among bubbles prior to stiffening of the concrete. A separate relationship of durability factor and air-void spacing factor occurs for each cement-admixture combination in air-entrained concrete as water-cement ratio and water content are varied.

Water-reducing, set-controlling admixtures employed to substantial extent in concrete construction are salts of sulfonated lignin, water-soluble hydroxy acids and their salts, and carbohydrates. They can be combined with accelerators, catalysts, air-entraining compounds, or other substances for specific purposes. Water-reducing, set-controlling admixtures modify the properties of fresh and hardened concrete primarily by activity at the interface of mixing water and cement, but the mechanisms are not understood completely. Engineering properties of concrete containing water-reducing, set-controlling admixtures can be evaluated by standard testing procedures. Expanded research on use of surface-active organic substances as admixtures is recommended as a part of continued progress in the technology of portland cement concrete.

Introduction

Technical and scientific application of organic, surface-active additives and admixtures in portland cement mixtures was initiated about 1936 with the introduction of air-entraining agents and organic materials that reduce water requirement for given consistency, change time of setting, and modify other properties of concrete (1). These materials are surface-active agents. This paper summarizes knowledge of their function and use in concrete. Most applications of these agents are based on empirical tests and experience because basic data and theory are too sparse to permit quantitative prediction of the effects that will be produced in concrete. Ultimately, research data should provide a quantitative basis for their selection and control as additives and admixtures for concrete.

The scope of this paper is as follows: Application of water-soluble organic materials to entrain air or to reduce water requirement and control setting and hardening of portland cement concrete through physical-chemical activity at air-water and water-solid interfaces.

Air-Entraining Admixtures for Concrete

Materials for Air Entrainment

Air-entraining agents for concrete are organic substances that promote formation of minute air bubbles in concrete during the mixing operation and subsequently inhibit coalescence, dissolution, or escape of the bubbles until stiffening of the matrix has occurred. The active constituents of the agents are positively adsorbed at air-water interfaces and may be adsorbed or chemisorbed at the surface of portland cement and aggregate in an aqueous medium. Air-entraining admixtures marketed in the United States of America have been classified into seven groups (2):

Group A—Salts of wood resins
Group B—Synthetic detergents
Group C—Salts of sulfonated lignin
Group D—Salts of petroleum acids
Group E—Salts of proteinaceous materials
Group F—Fatty and resinous acids and their salts
Group G—Organic salts of sulfonated hydrocarbons

Surface-active agents in general may be classified as follows by their physical-chemical properties (3):

1. Anion-active compounds
2. Cation-active compounds
3. Nonionic compounds

In the first class, the hydrocarbon structure contains negatively charged hydrophilic groups, such as COO^-, SO_3^-, and OSO_3^-, so that large anions are released in water. Conversely, if the hydrocarbon ion is positively charged, the compound is cation-active. Compounds composed of positively and negatively charged organic ions are said to be amphoteric. Nonionic compounds release no ions into aqueous solutions. Surface-active compounds of all these classes can cause air entrainment in concrete, but their efficiency and the characteristics of the air void system vary widely.

Use of Air-Entraining Admixtures

Anionic surface-active agents are the most widely used as air-entraining admixtures in concrete mixtures for general construction. All of the products tested by the Bureau of Public Roads (4) are of this type. In concrete mixtures at plastic consistency, anionic surface-active agents are used at rates about 0.002 to 0.5 per cent by weight of the cement content[1] to produce air content of 5 to 6 per cent, or a cement paste-air void ratio of about 3.5 to 6 by volume. Salts of wood resins, synthetic detergents, salts of fatty and resinous acids, and organic salts of sulfonated hydrocarbons, which are most widely used as air-entraining agents, typically are employed at rates of 0.002 to 0.06 per cent, based upon the active constituents of the admixture. In tests of diverse anionic detergents, including both sodium and organic salts, in concrete with water-cement ratio about 0.45 by weight[2] and slump of 3 to 4 in., air content of 5 to 6 per cent was achieved by use of the admixture at rates of 0.002 to 0.006 per cent.

When an air-entraining admixture is used in concrete simultaneously with a water-reducing admixture, the rate of use of the air-entraining agent is less than that otherwise required to produce the same air content, even when the water-reducing admixture does not cause air entrainment when used alone. For example, in tests of water-reducing retarders, Grieb, Werner, and Woolf (5) found that the requirement for the air-entraining admixture was reduced 14 to 100 per cent at constant cement content and slump.

So far as the author is aware, no commercial air-entraining admixtures for concrete are based upon cationic surface-active compounds; data on their effects in concrete are scanty. Bruere (6) gives data on dodecyl trimethyl ammonium bromide as an air-entraining agent in cement pastes. Satisfactory void systems were developed with its use at rates of 0.010 to 0.075 per cent. Unpublished data are available on a group of seven cationic surfactants tested in concrete with a calcium lignosulfonate used at the rate of 0.16 per cent. Water-cement ratio was 0.47 and slump was 3 to 4 in. The air content of concrete containing the lignosulfonate as the only admixture was 3.0 per cent. When the cationic agents were added at rates of 0.0015 to 0.0067 per cent, air content was 5.2 to 5.7 per cent. The agents were a fatty amide, a fatty amine, dodecylamine acetate, dodecyl trimethyl ammonium chloride, and hexadecyl trimethyl ammonium chloride. The air-void system was not evaluated microscopically, but the properties of the fresh concrete indicated that the air bubbles were stable. Conversely, cationic n-alkyl dimethyl amines from two sources produced air content of 1.7 to 3.2 per cent when used at rates as high as 0.033 per cent.

---

[1] Rate of use of the admixture will be expressed as per cent by weight of the cement content unless otherwise noted.

[2] Water-cement ratio is expressed by weight throughout this report.

Nonionic surface-active agents comprise natural products, condensation products of fatty substances and their derivatives with ethylene oxide, products obtained by condensation of phenolic compounds having side chains with ethylene oxide, and miscellaneous nonionic compounds possessing solubilizing polar groups (3). Condensation products of phenolic compounds having lateral chains with ethylene oxide have been used as admixtures for concrete, especially in non-plastic mixtures, such as are used in the molding of concrete products, to which they impart a plasticizing effect without substantial entrainment of air. However, nonionic surface-active agents generally are not effective as air-entraining agents for concrete because of instability of the bubbles in the fresh mixture (6–8).

Bubble Formation and Dissolution

Because of the presence of hydrophobic and hydrophilic portions in the molecule of the surface-active compound, an air-entraining compound is concentrated at air-water interfaces, with the hydrophobic portion preferentially oriented toward the air (9, p 68; 10, p 99). The process is a dynamic one during and following mixing of concrete because the volume of bubbles increases as air is supplied from several sources, and the air-water interface is subject to many influences (11). The amount of air originally incorporated in the mixture can be decreased by escape of bubbles, and Landgren (12) detected consumption of a part of the oxygen by oxidation reactions, such as with metallic iron, ferrous iron, or sulfide sulfur in the cement.

As each air-water interface develops, the surface-active agent is concentrated there at a rate characteristic of the substance, its concentration in solution, and environmental conditions, such as temperature. The adsorbed film decreases surface tension, possibly by 20 dynes/cm or more, decreasing the rate at which the bubbles dissolve, the tendency of bubbles to coalesce, and the work necessary to produce bubbles of given surface area.

However, the stability of the bubbles is not related directly to the surface tension, at least as measured at equilibrium. Maximum stability is obtained at a concentration of surface-active substance such that the ratio of instantaneously developed surface tension to the equilibrium surface tension is at a maximum (13). Important factors in foam stability are low equilibrium surface tension, moderate rate of attainment of surface tension, and high viscosity. Important also in determining the rate of coalescence of bubbles is the like electrostatic charge that exists at the interface containing ionic surfactants; the charge tends to repell such bubbles from one another (14). These factors have not been related quantitatively to air entrainment in concrete. Examination of a series of three concrete mixtures that differed only in the proportion of an anionic surface-active agent necessary to produce nominal air content of 3.0, 6.5, and 8.8 per cent showed that air content increased with increased concentration of the agent, and specific surface (α) of the void system increased from 603 to 737 to 1112 $in.^2/in.^3$ (8). The increased concentration of agent allowed increased bubble formation and stabilized more very small bubbles.

In water solution, the surface-active agent is soluble to varying degree in the bulk of the liquid and individual molecules are interchanged between the adsorbed film and the liquid (9). When the surface of the bubble is stretched, as with distortion of the bubble, surface tension is increased and additional molecules of the agent move into the interface. Because this process is not instantaneous, the increased surface tension tends to restore the bubble to its original surface area. Hence, the bubbles can sustain short-time loads. The adsorbed film formed in water at concentrations ordinarily used in production of air-entrained concrete is highly permeable to air (11); hence, in an air-water system, bubbles dissolve at rates related to the excess of pressure to which the air is subjected. At diameters less than 50μ, the rate of dissolution is very rapid. In solutions containing a high concentration of calcium ion, many anionic surfactants will precipitate as calcium salts. Such salts precipitated in the adsorbed film further stabilize bubbles and, if present in sufficient concentration, may prevent the complete dissolution of the bubble.

Although the principles stated above are universally accepted for water-air systems, their application to air-entrained concrete has been questioned on the basis that distances between bubbles in air entrained concrete are too great and solubility of air in water is too low to allow transmission of appreciable amounts of air between bubbles. Bruere (15) concluded that cement pastes mixed at a water-cement ratio of 0.45, using a high-speed (1000 rpm) electric mixer, showed no evidence of rearrangement of bubbles of air after cessation of mixing. The void system was compared among pastes with normal stiffening time, pastes caused to stiffen in about three minutes by addition of ammonium carbonate, and pastes caused to remain fluid for four hours by addition of citric acid. Similar pastes prepared in an atmosphere of nitrous oxide contained a coarser void system than that produced

by air entrainment, but the specific surface did not vary significantly with two hour variation in the period during which the pastes remained fluid. Bruere concluded that interchange of nitrous oxide occurred among bubbles of nitrous oxide during mixing but not following fabrication of specimens. He concluded also that the differing results obtained with nitrous oxide and air relate to the higher solubility of nitrous oxide in water.

The latter conclusion is not justified inasmuch as the transmission of gas between bubbles is controlled by the rate at which the gas molecules diffuse through the aqueous solution and the surface tension relationship characteristic of the two gas-liquid systems, rather than by the solubility of the gases in water. In both instances, the aqueous phases in the cement pastes prepared by Bruere were saturated for nitrous oxide or for air, respectively; hence, rearrangement of bubble sizes is controlled by net transfer of gas, rather than by net uptake of gas by the solution.

Several factors distinguish cement pastes from concrete. Most important are the relatively low water-cement ratio (0.45) used by Bruere, the mixing procedure, and the lack of aggregate to entrap bubbles large enough to escape from cement pastes. The relationship establishing the rate of interchange of air is (11):

$$\frac{dB}{dt} \alpha \frac{aD\gamma}{T}\left[\frac{1}{d_1} - \frac{1}{d_2}\right] \qquad (1)$$

where d_1 and d_2 are respective diameters of a small bubble losing air and a large bubble gaining air, B = mass of air transported, a = area of the surface of the small bubble, D = a diffusion coefficient, γ = surface tension at the gas-solution interface, and T = average distance between the surface of the bubbles.

Hence, significant transfer of air requires juxtaposition of small bubbles possessing high internal pressure and large bubbles, such as those greater than 100μ in diameter, in which excess pressure is negligible. Values of α observed by Bruere in rapidly stirred pastes are 1900 to 2500 in.^{2}/in.^{3}, magnitudes that are not observed in normally compacted concrete and that show the virtual absence of large bubbles that could effectively produce high values for the factor $\left[\frac{1}{d_1} - \frac{1}{d_2}\right]$.

On the contrary, α in neat cement pastes mixed in a drumtype concrete mixer at water-cement ratio of 0.30 to 0.60 was 570 to 1330 in.^{2}/in.^{3} and spacing factor ($\bar{L}$) (16, 17) was 0.0127 to 0.0063 in., values that are common in concrete of that water-cement ratio (11). Air content determined microscopically was always higher than that indicated by pressure meter to be in the fluid cement paste and the difference in these values increased as the water-cement ratio increased. These relationships indicate significant interchange of air between bubbles following casting of the specimens, since transmission of air from a small bubble of high internal pressure to a large bubble of lower internal pressure causes an increase in air-void volume. Any change of level of the top of the fresh specimen before hardening might be partially or wholly offset by bleeding and settlement. In fact, such increase of air-void volume may be a mechanism by which air entrainment decreases bleeding and settlement of concrete.

To examine these concepts on bubble rearrangement, two series of three air-entrained concrete mixtures were prepared using Type I portland cement, crushed dolomite coarse aggregate of nominal 1-inch maximum size, and neutralized Vinsol resin as an air-entraining admixture to entrain 5–6 per cent of air as determined by pressure meter on the fresh concrete (Table 1). Water-cement ratio was 0.41—0.49, 0.61—0.67, and 0.81—0.87, respectively. Each series included four mixtures as follows: Concrete with no other admixture, concrete with calcium chloride added at the rate of two per cent by weight of the cement, and two mixtures containing mucic acid to achieve retardation of setting as determined by bond pin pull-out procedure (18). In the intermediate series, the desired retardation was not achieved. In two of the series, extended retardation was achieved at the higher rate of use of the mucic acid, but the concrete was hard at 24 hr. and developed strength normally thereafter.

Parameters of the air-void system were determined by the modified point-count procedure (17) on small slabs sawed from 6-inch cube specimens (Table 1.). As has been established previously (8) α decreases markedly as water-cement ratio increases (Fig. 1.). So strong is this relationship that other factors influencing α can be discerned only at relatively constant water-cement ratio.

The series prepared at the lowest water-cement ratio shows a relationship of α and rate of hardening that is consistent with qualitative predictions of the air-diffusion concept. α for the accelerated concrete was 930 in.^{2}/in.^{3}, whereas that of the reference mixture was 851 in.^{2}/in.^{3}, in contrast to a value of 690 in.^{2}/in.^{3} for the two retarded mixtures. Conversely, the other two series show essentially constant values of α regardless of time of setting,[3)] the values being 580 to 625 in.^{2}/in.^{3} for the intermediate series and 373 to 444 in.^{2}/in.^{3} for the series of highest water-

cement ratio. These relationships appear to relate to the magnitude of $\frac{dB}{dt}$ in equation 1, particularly as it is influenced by the pressure gradient, namely, the factor $\left(\frac{1}{d_1} - \frac{1}{d_2}\right)$. This effect is most notable for the third series for which very low values of α prevail, indicating values of bubble size in which excess pressure is virtually nil. An α of 400 in.^{2}/in.^{3} corresponds to an average bubble diameter of about 300μ. In void systems of this specific surface diffusion of gas is very slow even in gas-water systems because of the limited pressure gradient. In these concrete mixtures, the stable end value of α appears to be about 600 in.^{2}/in.^{3} at a water-cement ratio of about 0.65 and about 400 in.^{2}/in.^{3} at a water-cement ratio about 0.85.

Tests along similar lines were conducted by O'Neill (20) and by Zipparro (21). The air-entraining admixtures used by Zipparro were sodium dodecyl sulfate (anionic), cetyl trimethyl ammonium bromide (cationic), and a polyethyleneoxy derivative (nonionic); supplementary tests were performed on concrete containing purified saponin, Vinsol NVX, and Darex AEA. Some of Zipparro's data are shown in Tables 2 and 3.

The specific surface (α) of the air voids in concrete

[3] *Data for the reference mixture in the high water-cement ratio series (Mix III B) are not considered (and are not include in Fig. 1.) since the desired air content was not achieved and α is anomalously high for the indicated water-cement ratio.

containing the two non-ionic or the cationic agents decreases immediately with vibration or after initial vibration but for the concrete containing the anionic agent increases consistently with vibration. Whether these effects are characteristic of these classes of admixtures cannot be stated on the basis of the available data. Increasing α or decreasing void size is the trend that would be expected from prior work on anionic agents (23). The contrary change observed in the mixtures containing the non-ionic or the cationic agent can be explained only by coalescence of bubbles (an unlikely possibility) or differential dissolution of small bubbles and passage of the air into larger bubbles.

Table 3 shows the effect of retardation of setting upon α, namely, an increase in average void size.

[1] 3/4-in. nominal maximum size sand and gravel aggregate.
[2] Acceleration achieved by use of ammonium carbonate at the rate of 0.60 per cent; retardation obtained by use of citric acid at the rate of 0.275 per cent (w/c = 0.49) or 0.395 per cent (w/c = 0.75). Time of initial setting 4 hr. without set-controlling admixture and 15 hr. with the retarder (ASTM C 403) (19); setting time of accelerated mixture was not reported.
[3] ASTM C 457. (17)

This effect is not observed with use of saponin, possibly because of the extraordinarily thick adsorbed film at the air-water interface (6).

O'Neill (20) compared air-void parameters among concrete mixtures in which varying time of setting was achieved by use of ammonium carbonates as an accelerator or citric acid as a retarding admixture. He reports that air content determined gravimetrically on the fresh concrete was consistently lower than that determined microscopically. He concludes that this effect relates to diffusion of air from small bubbles to larger bubbles before setting of the cement paste matrix.

Using the diffusion rate relationship (equation 1) and surface tension values determined on filtrates extracted from the fresh concrete mixtures, O'Neill gives estimates relative to rates of diffusion of air for four of his mixtures (Table 4), but the results cannot be expressed as weight or volume of air involved in the diffusion process for any given quantity of concrete. The parameters of the air-void systems in the hardened concretes are shown in Table 5. The effect of type of agent upon chord size distribution is shown in Fig. 2 and the effect of retardation or acceleration is shown in Fig. 3 for representative mixtures.

The data are consistent with the concept that diffusion air from small bubbles to large can effect a significant change in the parameters of the air-void system. Apparently, α about 600 in.^{2}/in.^{3} at a water-cement ratio of 0.49 is a stable end value. In other words, interchange of air apparently occurs at an insignificant rate if the average void size is larger than about 250 μ at this water-cement ratio. O'Neill found (Table 4) that the average diameter of air bubbles gaining air was 220 to 254 μ. Hence, if the average size of all the voids is in this range, further transfer of air is extremely slow.

The values found by O'Neill for the diameter of bubbles losing air (58 to 70 μ), corresponding to α of 2630 to 2180 in.^{2}/in.^{3}, may be compared with α found by Bruere (15) for rapidly stirred cement pastes in which no diffusion of air was indicated. His values were 1500 to 2500 in.^{2}/in.^{3} at water-cement ratio of 0.45. This comparison supports the conclusion that the range of void sizes in those cement pastes was insufficient to permit measurable transfer of air under the conditions of testing. A conclusion that diffusion of air between bubbles of various sizes can occur in concrete under ordinary conditions is consistent also with some of the findings of Larson, Mangusi and Radomski (23), who observed decrease in specific surface of the voids with retardation of setting in two of three series of tests. The stable end value of α achieved after a 35-hr delay in setting was 641 in.^{2}/in.^{3} at a water-cement ratio of 0.397.

The extent to which α at cessation of mixing is controlled by water-cement ratio in contrast to interchange of air among the air bubbles is undecided. Moreover, any quantitative evaluation of these factors presents a difficult experiment inasmuch as they are not independent. High water-cement ratio and water content of concrete contribute to reduction of α because shearing action during mixing is less and they likewise facilitate diffusion of air through the matrix. These factors are considered in detail by Powers (24).

Adhesion of Bubbles to Cement and Aggregate

The three classes of air-entraining agents cause generation of bubbles having differing ionic charge relationships: anionic surface-active agents produce bubbles that are negatively charged; cationic agents cause bubbles to be positively charged; and nonionic agents do not induce an appreciable charge on the bubble. Development of an ionic charge is considered to be an important factor promoting resistance of bubbles to coalescence (14).

Moreover, various types of surface-active agents respond differently to surfaces of cement granules or particles of aggregate that carry ionic charges. Anionic surface-active agents are positively adsorbed at the surface of particles of cement (11, 25, 26). Those including a large hydrophobic anion free from closely spaced polar groups are bound to the surfaces, probably through calcium ions that in turn are held ionically in the silicate or aluminate structure of the cementitious compounds. As a result, the surface is rendered hydrophobic and adherence of air bubbles is facilitated. Mielenz, Wolkodoff, Backstrom and Flack (11) reported contact angles of 46°00′ and 81°30′ for bubbles formed in aqueous slurries of portland cement in the presence of either of two common anionic air-entraining agents of this type.

Surfaces of aggregate particles may carry either net positive or negative charge in aqueous suspensions, depending upon the composition and molecular structure of the constituent minerals, the pH of the aqueous phase, and any contamination of the surfaces, but a net negative charge is typical of quartz and common rock-forming silicates (9). Bruere (6) has shown that finely ground quartz does not adsorb sodium dodecyl sulfate or sodium abietate from water solution, but adsorption was observed in the presence of calcium hydroxide and the quartz adhered to entrained air bubbles. This effect is thought to be the result of adsorption of calcium ions onto negatively charged locations on the mineral surfaces, followed by interaction of the calcium ions and the organic anions.

Unlike the anionic organic ions just discussed, in which closely-spaced polar groups are absent, the anion of some anionic surface-active agents includes or is composed of polar groups that can interact with charged sites in surfaces of cement granules or constituents of aggregates (26). In fact, the adsorption or chemisorption so effected may dominate, leaving a net residual negative charge at the surface of the solid particles (27). The like charge causes a decrease in interparticle attraction and possibly a net repulsion, which in turn causes a decrease in degree of flocculation or dispersion of the finely divided solids. Air bubbles in such a slurry do not adhere to particles of cement because the adsorbed organic anion is likewise negatively charged. Also, with sufficient concentration of polar groups within the anion, the surfaces of the affected solids are hydrophilic and so are not conducive to preferential displacement of water by air. The outstanding surface-active agents in this class from the standpoint of wide use are salts of sulfonated lignin.

Bruere (6) demonstrated that the cation from cationic surface-active agents likewise is adsorbed by portland cement in aqueous mixtures, presumably at negatively charged sites in the surface. Tetradecyl ammonium bromide and some alkylamine hydrochlorides effect flotation of finely ground quartz in aqueous slurries, freshly ground quartz being negatively charged in neutral or alkaline media (9). When Bruere used tetradecyl ammonium bromide at rates less than 0.05 per cent, the surfaces of cement were rendered hydrophobic. At higher concentration, a second layer of cations apparently is adsorbed, with the polar end oriented toward the aqueous phase. The cement granules then are hydrophilic and adhesion of bubbles decreases as the concentration of the agent is increased.

Nonionic surfactants may or may not be adsorbed on particles of cement or aggregate. Bruere (6) found that saponin is adsorbed by cement in aqueous mixtures whereas a condensation product of ethylene oxide with a nonionic alkyl phenol apparently was not adsorbed appreciably. The cement granules remained hydrophilic and no bubble adherence occurred.

Adsorption and bubble adherence modify viscosity and bleeding of cement pastes. Anionic surface-active agents that make cement hydrophobic increase viscosity of the paste even in the absence of air entrainment apparently because of an increase in interparticle attraction (6). This effect is more pronounced in the presence of air bubbles in part because of the linkage that is established between cement granules and air bubbles. The increase in viscosity is greater than is expected from the increase in surface area of the system resulting from the entrainment of air. A cationic air-entraining agent increased the paste viscosity to a maximum as its concentration increased, but at higher concentration the viscosity decreased. These effects apparently were caused by initial formation of a hydrophobic surface, followed by development of hydrophilic surfaces when a second layer formed. In the absence of air entrainment, both saponin and calcium lignosulfonate decreased paste viscosity

because of the development of hydrophilic surfaces and decrease of interparticle attraction; this effect was overcome by entrainment of air. The factors that contributed to increased paste viscosity likewise decreased bleeding of pastes.

Except for anionic air-entraining agents that render cement hydrophilic, most notably soluble salts of sulfonated lignin, which are usually used at rates of 0.10 to 0.50 per cent, air-entraining admixtures appear to effect insignificant change of hydration reactions because of the low rate at which they are used relative to the cement content. Kelly and Bryant (18) noted small differences in rate of hardening of concretes containing either of two anionic air-entraining agents. Kreijger (28) detected small changes in heat of hydration for both C_3S and C_3A in the presence of anionic agents. He observed no significant change in heat of hydration with use of nonionic surface-active agents.

Geometry of the Air-Void System

The bulk of air voids in air-entrained concrete mixed to a plastic consistency are spherical or nearly so, especially in sizes less than about 1000 μ, because the air bubbles were enclosed within the viscous matrix that was under hydrostatic head imposed by the superimposed concrete. In well proportioned concrete of plastic consistency, voids of irregular shape molded against particles of aggregate are infrequent.

Air voids are retained within unhardened concrete by viscosity of the cement paste matrix, adherence to granules of cement and, to some extent, to particles of aggregate, and mechanical entrapment. Comparing the air void system in concrete with that of cement paste at the same water-cement ratio and compacted similarly, Mielenz, Wolkodoff, Backstrom and Flack (11) concluded that over half of the air content of entrained air concrete may be retained by entrapment among the aggregate. For two anionic agents of good quality, the average void size in the hardened concrete and hardened cement paste was the same or nearly so, whereas for an anionic agent of intermediate quality, the average void size in the concrete was significantly greater than that found in the cement paste. Hence, for these agents, air entrainment depended to differing degree upon the entrapping effect of aggregate.

The average size of air voids is affected by other factors, notably the kind and concentration of surface-active agent, water-cement ratio, and the kind and amount of compaction (6, 11, 8, 22, 29). Increased roughness of surface of aggregate, increased temperature, and decreased slump are reported to decrease average void size (22). Bruere (30) showed that mixing time and speed are important factors; mixing time, type of cement, and presence of calcium chloride did not greatly modify void size in pastes. Grading of fine aggregate produced minor change of average air void size in concrete, although the effect in mortars undoubtedly is appreciable.

Bruere (29) studied the effect of combinations of surface-active agents upon air entrainment in rapidly stirred cement pastes. He concluded that particular combinations could be employed to produce bubble systems of especially high α under given conditions of mixing. However, the findings are not applicable directly to concrete mixtures because of the high proportion of air bubbles that are retained in concrete by entrapment among the aggregate.

Contrary effects can be produced by introduction of surface-active chemicals that decrease the stability of adsorbed films of air-entraining admixtures. Table 6 comprises data on three concrete mixtures containing an air-entraining portland cement (ASTM Type IA) (31). Addition of a water-reducing admixture based upon calcium lignosulfonate (0.266 per cent) and reduction of cement content increased air content of the fresh concrete as indicated by the pressure meter from 6.8 to 8.6 per cent and that of the hardened concrete as determined by the microscopical point-count procedure from 9.49 to 11.98 per cent. An aliphatic alcohol 1-decanol was added to an equivalent concrete mixture at the rate of 0.008 per cent, the air content being reduced to 6.4 per cent as determined by the pressure meter or 6.25 per cent as determined by the point-count procedure. α was decreased (average void size increased) and spacing factor ($\bar{L}$)

increased, although not critically. A higher rate of use to further reduce the air content might increase $\bar{L}$ above the range that should correlate with satisfactory freezing and thawing resistance of concrete.

Data show that within narrow limits $\bar{L}$ is an inherent characteristic of a given air-entrained concrete mixture following completion of mixing (8, 22). Little change in the $\bar{L}$ is observed in concrete mixtures sampled before application of any compactive effort and after differing modes of compaction, even though the air content is decreased substantially. In concrete that was vibrated internally for 2 and 50 seconds, Backstrom, Burrows, Mielenz and Wolkodoff (8) found that air content was decreased from about 7 per cent to 6.60 and 1.20 per cent, respectively. The decrease was accomplished by reduction in the number of air voids in all sizes from 20 to 4000 μ; there was no evidence of disruption of large bubbles into smaller ones. Since bubbles whose diameter after 2 seconds of vibration is less than 80 microns are unlikely to escape from concrete, the data appear to show that the internal vibration promoted dissolution of the smallest bubbles.

Effect of Air Entrainment on Some Engineering Properties of Concrete

Air entrainment is employed for two main reasons in modern construction: (1) improved resistance of the concrete to freezing and thawing and (2) improved working qualities of the fresh concrete. Optimum use of air entrainment requires change in the proportioning of the mixture. Powers (24, 32) recently dealt with the factors influencing the proportioning of air-entrained concrete. Consequently, no detailed discussion of these matters is required here. Using data from actual concrete mixtures containing neutralized Vinsol resin, Powers (32) shows that the change in water content effected with change of air content at constant consistency and aggregate grading is a linear function of the cement content. At cement content less than about 835 lb per cubic yard, each one per cent of air replaces 20 to 25 per cent of that volume of water (about 3.4 to 4.2 lb), the remainder being compensated by a decrease in the aggregate content. Warris (33) found that air entrainment reduces water content of concrete at given consistency at an average rate of 0.3 times the increase of air content. The change decreases as cement content increases, becoming nil at 400 kg per cu. m. (674 lb per cu. yd.) or above.

Powers (32) contrasts such behavior in equivalent mixtures in which air entrainment is effected by use of calcium lignosulfonate, showing that the relative volume of water displaced at given consistency is increased 6 to 50 per cent over that effected by neutralized Vinsol resin. The net reduction in water requirement increased with increased cement content. Independent data obtained in a large series of concrete mixtures containing a Type I portland cement (about 440 lb per cu. yd.) and 1-inch nominal maximum size sand and gravel aggregate together with a calcium lignosulfonate water-reducing admixture (0.266 per cent) show a consistent reduction of water content with increasing air content, the typical value being about 8.3 lb per cubic yard for each one per cent of air entrained by any of a wide variety of air-entraining admixtures.

Powers (32) notes that the water-content *vs* air content relationship for the mixtures containing neutralized Vinsol resin is like that characterizing the mixture containing no air-entraining agent, whereas the locus representing concrete containing the calcium lignosulfonate is displaced from the position representing the mixture containing no surface-active agent. He concludes that the effect is caused by adsorption of lignosulfonate and change of interparticle attraction. The findings do not deny adsorption of neutralized Vinsol resin; rather, the adsorption does not modify the water-cement-air content relationship to appreciable degree.

The kind and extent of the changes produced in concrete mixtures by air entrainment depend upon many factors. To evaluate some of these effects in a particular combination of cement and aggregates, three series of concrete mixtures were prepared, as follows:

Series I	Constant slump (3 to 4 in.) and air content (5.5 ± 0.5 per cent by pressure meter) with varying cement content and water-cement ratio (nominally 0.44 to 0.62).
Series II	Nominally constant cement content (about 525 lb per cu. yd.) and air content (5.5 ± 0.5 per cent by pressure meter) with varying slump (2 to 7 in.)
Series III	Constant proportion of air-entraining admixture and cement content (about 525 lb per cu. yd.) and varying slump (2 to 7 in.)

Each series comprised eight concrete mixtures:

Air-entraining admixture	Water-reducing admixture
1. Neutralized Vinsol resin*	None
2. Neutralized Vinsol resin*	Calcium lignosulfonate
3. Alkyl aryl sulfonate	Calcium lignosulfonate

*12 per cent solution

Each group of mixtures included two concretes containing neutralized Vinsol resin as the only admixture, three concretes containing neutralized Vinsol resin and the calcium lignosulfonate, and three concretes containing the alkyl aryl sulfonate and the calcium lignosulfonate (Table 7). All of the concrete mixtures contained a Type I portland cement from a single source, nominally 1-in. maximum size, crushed and graded dolomite coarse aggregate, and natural sand, all meeting applicable specifications of the American Sosiety for Testing and Materials. Specimens were prepared from each concrete mixture as follows:

3- by 4- by 16-in. prism	3	Freezing and thawing resistance (ASTM C 290) (19)
4- by 6- by 6-in. prism	1	Microscopical determination of the air-void system (ASTM C 457) (19) (magnification 150 dia.)

Series I shows the effect of air entrainment when water-cement ratio and cement content vary over a wide range (Table 8). Durability factor (DF) and compressive strength decline as water-cement ratio is increased. For the concretes containing the calcium lignosulfonate, spacing factor ($\bar{L}$) decreased greatly as water-cement ratio increased from about 0.44 to about 0.53, this change being related mainly to a simultaneous increase in specific surface (α) of the voids. As the water-cement ratio increased to about 0.62, α decreased and $\bar{L}$ increased. However, these changes were not reflected in the DF. The effect of varying water-cement ratio upon the void system in the concrete containing neutralized Vinsol resin as the only admixture cannot be discussed as well because only two concretes were prepared in this series. However, the results demonstrate that $\bar{L}$ decreased slightly as water-cement ratio increased from about 0.44 to about 0.62, whereas DF decreased significantly.

No general correlation is indicated between $\bar{L}$ and

Table 8. *Air-void parameters and freezing and thawing durability factor for concrete relating water-cement ratio, water content, and air-void parameters*[1]

[2] Modified point-count procedure, ASTM C 457 (17)
[3] Rapid freezing-thawing in water, ASTM C 290(19); durability factor computed after 250 cycles; average of 3 specimens except as noted. The specimens in each series were tested simultaneously.
[4] Difference obtained by subtracting air content of fresh concrete determined by ASTM C 231 (19) from air content of hardened concrete determined microscopically.
[5] Average of two results; for Mix II-B one specimen having durability factor of 2 and for Mix II-F one specimen having durability factor of 6 were disregarded.
[6] One specimen only; two specimens broken in handling.

DF such as would be predicted from the theory covering the function of air voids during freezing of concrete (34). Rather, each combination of admixtures produces its own relationship between $\bar{L}$ and DF. Any value of DF correlates with values of $\bar{L}$ which are least for concrete containing neutralized Vinsol resin alone, maximum for concrete containing the alkyl aryl sulfonate and the calcium lignosulfonate, and intermediate for concrete containing neutralized Vinsol resin and the calcium lignosulfonate.

Another interesting phenomenon is the relationship of air content of the fresh concrete as determined by the pressure meter to that of the hardened concrete determined microscopically. For the concretes at a water-cement ratio close to 0.44, the hardened concrete contains less than 0.4 per cent less air than is indicated by the pressure meter test of the fresh concrete. At water-cement ratio of about 0.62, the hardened concrete contains 0.2 to 1.2 per cent more air than indicated by the presure meter in the fresh concrete. The relationship of these factors at water-cement ratio of 0.53 is intermediat .

In Series II, slump was fixed at about 2, $4\frac{1}{2}$, and $6\frac{1}{2}$ in., whereas the proportions of the air-entraining admixture were adjusted to produce air content of 5.5 ± 0.5 per cent while cement content was held nominally constant. The desired air content was not achieved for the concrete containing the alkyl aryl sulfonate with the calcium lignosulfonate when the slump was 2 in. Water-cement ratio ranged from 0.42 to 0.53.

In Series II, water-cement ratio and water content increased as the slump was increased from 2 to 6–3/4 in. Air content of the hardened concrete and the difference between the air content of the fresh concrete indicated by the pressure meter and that of the hardened concrete also increased (Fig. 4). The latter effect was more pronounced than in Series I. Again, the maximum divergence was found in the mixtures containing neutralized Vinsol resin. As slump increased, α decreased when neutralized Vinsol resin was used (with or without the calcium lignosulfonate) but increased slightly in the concrete containing the alkyl aryl sulfonate and the calcium lignosulfonate. Simultaneously, $\bar{L}$ for the concrete containing the calcium lignosulfonate decreased, whereas that for the concrete containing neutralized Vinsol resin as the only admixture increased slightly.

As slump increased, DF in each group of concretes changed, increasing when the concrete contained the calcium lignosulfonate and decreasing when neutralized Vinsol resin was the only admixture. Again, no general relationship was exhibited between $\bar{L}$ and DF (Fig. 5). Within each group of mixtures containing the same admixtures, a consistent correlation is indicated, DF increasing with decrease of $\bar{L}$. For the concrete containing the alkyl aryl sulfonate and the calcium lignosulfonate and gauged to a slump of 2 in., the air content was 4.3 per cent as determined by pressure meter in contrast to the specified range of 5.5 ± 0.5 per cent and the air content determined microscopically was only 2.82 per cent.

Series III simulates a condition in which water content and slump are increased without purposeful modification of cement content or rate of use of the air-entraining admixtures. The quantity of air-entraining admixture employed was that necessary to produce air content of 5.5 ± 0.5 per cent when slump was $4\frac{1}{2}$ in. Water content was increased 33 lb to increase the slump of the concrete containing neutralized Vinsol resin as the only admixture from 1–3/4 to $6\frac{1}{2}$ in., whereas the increase required for similar change of slump when the calcium lignosulfonate was present was only 14 to 17 lb per cubic yard.

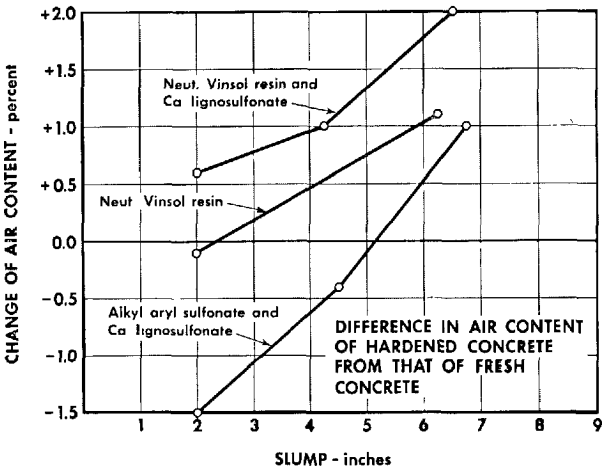

Fig. 4. *Difference in air content of hardened concrete from that of fresh concrete.*

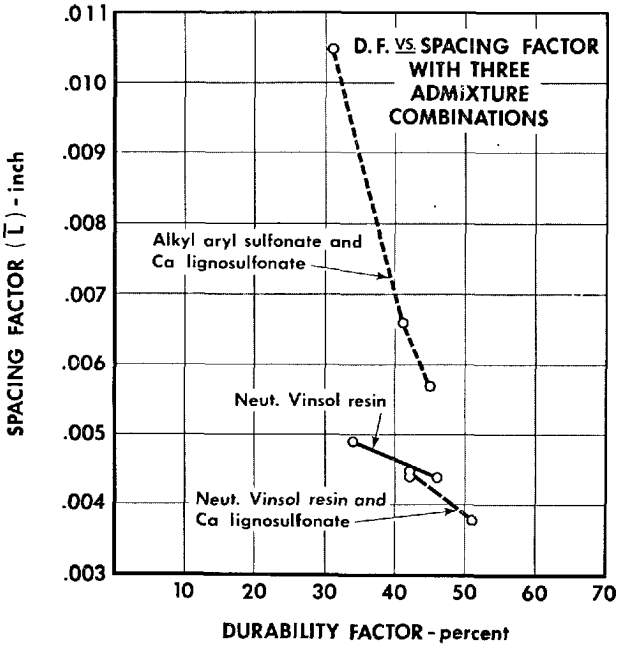

Fig. 5. *D.F. vs. spacing factor with three admixture combinations.*

As the water content and slump were increased, air content indicated by the pressure meter increased. However, no consistent increase occurred in the difference between the indicated air content of the fresh concrete and that determined microscopically on the hardened concrete. With increase in slump under the stipulated conditions, $\bar{L}$ tended to decrease, in part because of the increase in air content. α tended to increase when the calcium lignosulfonate was present, whereas no change was observed when neutralized Vinsol resin was used as the only admixture. Compressive strength decreased considerably as the slump was increased.

DF remained essentially constant over the range of slump when neutralized Vinsol resin was used as the air-entraining admixture, regardless of the presence or absence of calcium lignosulfonate. Conversely, DF of the concrete containing the alkyl aryl sulfonate and the calcium lignosulfonate decreased linearly as slump was increased, although DF at the highest slump was essentially equal to that of the concrete containing neutralized Vinsol resin as the only admixture. Again, individual relationships were established between $\bar{L}$ and DF for each admixture system.

Water-Reducing and Set-Controlling Admixtures for Concrete

Hansen (35) concluded that organic water-reducing retarders include the configuration H–C–OH and that their effect results in large part from adsorption of the molecule or large anions on exposed surfaces of cement granules. He suggested that the anions may be adsorbed by Ca^{++} ions in the solid surfaces, and that large anions and molecules of appropriate structure and composition also may be adsorbed by hydrogen bonding through OH groups to O^- ions in the solid surfaces (36). He proposes that salts analogous with the $C_3A \cdot 3C\bar{S} \cdot 32H$ and $C_3A \cdot C\bar{S} \cdot 12H$ can form with substitution in their crystal structure of organic molecules, such as salts of hydroxy acids and lignosulfonates (36, 37). Although such action probably occurs for retarding compounds of smaller molecular size, such isostructural analogues of the sulfoaluminates cannot develop by intracrystalline accommodation of lignosulfonates, whose molecular weights range from about 2,000 to 100,000 (38).

According to Steinour (39, 40), the effective molecular configuration is a stable OH group that is not subject to ionization or ionizes only slightly, and he found a relation between degree of retardation and the number of un-ionized or undissociated OH groups per molecule of the admixture. He concluded that their action in retarding hydration of cement is mainly or entirely adsorption by hydrogen bonding on both the calcium silicates and tricalcium aluminate. In a study of cement pastes containing each of 13 calcium salts of simple organic acids, Danielsson (41) concluded that retardation of setting is the result of adsorption of molecules on surfaces of the cement and that the

retarding capacity increases exponentially with the number of groups capable of forming hydrogen bonds with surfaces of the cement grains.

According to Taplin (42), the group HO–C–C = O is an important compound of some organic substances that retard hydration of portland cement. He concluded that for an organic substance to retard portland cement hydration and setting the molecule must contain at least two oxygen atoms each bound to a single but different carbon atom in such a way that the oxygen atoms can approach each other. Conversely, a few organic substances, such as oxalic acid, were found not to retard hydration of portland cement even though the specified atomic grouping is present. Effectiveness of the individual components varied widely with location and arrangement of the OH groups in the molecule. Kennerley, Williams and St. John (43) concluded that retardation of setting appears to be associated with presence of OH groups, particularly if two carboxyl groups are present also. They note that when the carboxyl groups of tartaric acid are changed to alcohol groups, an accelerating action is produced. They suggest that at least four carbon atoms are necessary in order that significant retardation will be effected.

A widely used classification of water-reducing and set-controlling admixtures for concrete comprises four groups (44) based upon hydroxylated, organic substances.

1. Lignosulfonic acid and its salts
2. Modifications and derivatives of lignosulfonic acid and its salts
3. Hydroxy acids and their salts
4. Modification and derivatives of hydroxy acids and their salts

To these classes may be added:

5. Carbohydrates and polyols
6. Modifications and derivatives of carbohydrates and polyols

Classes 1 and 2 constitute the largest volume of use in construction to this time. The products are based mainly upon calcium or sodium, less commonly, magnesium or ammonium, salts of sulfonated lignin resulting from the sulfite process of paper manufacturing. Calcium lignosulfonates are the most common. The lignosulfonate usually will have been processed by any of several methods to partially or completely remove wood sugars that are a constituent of raw sulfite liquor. However, the lignosulfonates used as admixtures for concrete are a complex mixture of many substances resulting from the degradation of the wood. Kennerley, Williams, and St. John (43) concluded that a large part of the set-retarding action of lignosulfonates is due to the presence of wood sugars, and they found that unrefined lignosulfonates often produce excessive air content.

Products of Class 3 include organic acids and their salts, such as sodium, calcium, potassium, or triethanolamine salts of gluconic acid. Hydroxyacetic acid, hydroxylated adipic acid, tartaric acid, citric acid, mucic acid, and the like, together with their water-soluble salts, are included in this class.

Class 5 includes such substances as simple sugars, disaccharides, and water-soluble polysaccharides as well as some sugar derivatives, such as sorbitol.

Classes 2, 4, and 6 are modified by processing or are blended with organic or inorganic accelerators, catalysts, air-entraining agents, or, rarely, air-detraining agents. Accelerators or catalysts can completely overcome the retarding effect of the main constituent so that the admixture performs in concrete as a water-reducing agent or water-reducing accelerator (Types A and E, respectively, of ASTM Designation: C 494) (19).

This classification does not include materials that have been used to limited extent in concrete as water-reducing and set-controlling admixtures for concrete, such as hydroxyethyl cellulose and related polymers and various water-soluble silicones, such as salts of methyl- and ethyl-siliconates. These materials are not discussed because of the meager information that is available. Some data on silicone admixtures are given in the recent International Symposium on Admixtures for Mortar and Concrete (45–48), and elsewhere (49).

Mechanism in Cement Hydration

The mechanism through which water-reducing, set-controlling admixtures modify the hydration, setting, and hardening process in hydraulic cement mixtures is believed most widely to be adsorption or chemisorption of the organic molecule at the solid-water interface on particles of cement and products of hydration (35, 36, 39). This action is accompanied by others if the admixture includes supplementary materials and, moreover, the modification of the course of cement hydration effected by the formation of the adsorbed film at the solid-liquid interface will itself generate secondary changes in the hydration and setting process. Suzuki and Nishi (50) concluded that organic substances that retard hydration of portland cement do so by reaction with the cement to form insoluble compounds that precipitate in the cement paste and on surfaces of the cement granules. Differences in effects of various compounds were thought to arise in differing stability, solubility, and mor-

phology of the precipitated substances. Those substances whose calcium salts are only slightly soluble delay or stop hydration and retard setting of concrete as a result of formation of an insoluble layer on the cement grains. Organic substances whose calcium salts are highly soluble do not cause substantial change in hydration and setting of portland cement. They recognize the possibility of adsorption or chemisorption of the organic compound or ions on surfaces of cement or hydration products. In reality, the processes of adsorption and precipitation are hardly separable if the organic phase interacts with intact surfaces of the solid phases.

The effects that are to be expected from adsorption or chemisorption of hydroxylated organic compounds or precipitation of insoluble organic compounds on cement granules include:

1. Change of rate of hydration of constituents of the cement.
2. Change of rate of interaction of sulfate with constituents of the cement.
3. Change of concentration of substances in the mixing water, including change of pH value.
4. Change of rate of formation of hydration products.
5. Change of particle size and crystal habit of hydration products.
6. Formation of products of reaction of the admixture and the cement or the hydration products.

The hydroxylated admixtures are adsorbed to differing degree by the constituents of portland cement. For example, Blank, Rossington and Weinland (51) show maximum uptake of calcium lignosulfonate from water solution by C_3A and much smaller uptake by C_4AF, C_3S, and C_2S, the amounts decreasing in that order. Seligmann and Greening (52) found that 99 per cent of sucrose was removed from 5 cc. of one per cent aqueous solution in seven minutes by one gram of C_3A. Similar conclusions and data are given by other workers (27, 51, 53, 54).

The results obtained in water differ from those obtained in other media, such as alcohol, wherein no hydration of the cement has occurred. The preferential order of uptake of salicylic acid in ethyl alcohol solution is

$$C_3S > C_2S > \text{Type I portland cement} > C_3A = C_4AF = 0 \quad (51).$$

Addition of small amounts of water to the alcohol solution greatly increases the uptake in the presence of the aluminates, showing that the adsorptive power of the aluminates in water is caused primarily by the hydration products. The amount of salicylic acid taken up in the presence of C_4AF increases as the proportion of water increases, presumably because more hydration product is formed in given time. With C_3A, C_2S and C_3S, maximum uptake of salicylic acid occurs with minor proportions of water in the alcohol solution, from which Blank, Rossington and Weinland (51) concluded that water and salicylic acid compete for adsorption on calcium aluminate hydration products, C_3S, and C_2S. They state: "Certain modified properties of cement due to admixture addition are a result of preferential adsorption of the admixture by the hydration products of tricalcium aluminate and tetra-calcium aluminoferrite, thereby rendering them inactive and allowing the main cementing compounds (C_3S and C_2S) to control the reaction."

Manabe and Kawada (55) found that the amount of lignosulfonate removed from solution in aqueous suspensions of portland cement increased as the concentration of the lignosulfonate increased. Equilibrium was established rapidly when the lignosulfonate was used in amounts less than 0.5 per cent, but the uptake continued over the course of 30 minutes at high concentrations. Multimolecular adsorption occurred, the amount of calcium lignosulfonate adsorbed being 350, 470, 510, and 540 mg per 100 g. of cement at water-cement ratio of 0.4, 0.5, 0.6, 0.7, and 1.5, respectively. The amount easily adsorbed as a monolayer is provided by use of calcium lignosulfonate at the rate of 0.3 per cent; at higher concentrations the monolayer is completed and multimolecular layer adsorption occurs with still higher concentrations of the lignosulfonate.

Crepaz and Raccanelli (54) and Russian workers (53, 56–58) also emphasize the uptake of hydroxylated admixtures by hydration products. Any such action must be an important factor in cement hydration since it will slow down crystallization, alter the extent of supersaturation of the solution phase, and change the form of the hydration products. Crepaz and Semenza (59) and Young (60) show by electron microscopy change of habit of hydration products of C_3A in the presence of a lignosulfonate and the former show that the calcium-aluminoferrite phase in the presence of the admixture characteristically produces small agglomerations of crystals. Earlier work in this field is reviewed by Young. Crepaz and Raccanelli (54) postulate that these changes result from preferential adsorption of the lignosulfonate on certain crystallographic planes of the crystals.

Feldman and Ramachandran (61) suggest that the rate of hydration of C_3A is decreased by adsorption

of SO_4^{-2} ions on exposed surfaces of the crystal, and further that adsorption of SO_4^{-2} ions on hexagonal hydroaluminates inhibits their conversion to cubic hexahydrate. Both of these mechanisms will retard the hydration of C_3A. They correlate these concepts with earlier conclusions of Russian workers (62–64), who studied the effect of surface-active agents on hydration of C_3A, and the observation by Sersale (65) that, at room temperature, a small amount of calcium lignosulfonate retards the conversion of the hexagonal hydro-aluminates to C_3AH_6.

Roberts (66) found that sucrose (0.1 per cent) decreased the amount of calcium and alkali hydroxide released in cement pastes initially, but a slight increase was observed at one day and no change thereafter. A slight increase in concentration of Al_2O_3 and Fe_2O_3 was detected at six hours (with one per cent addition of sucrose appreciable quantities of these substances were found in solution), suggesting formation of a soluble complex with the sucrose. Similar results have been reported for saccharose (50). The concentrations of calcium and sulfate were increased significantly to age 7 days, except that at 7 days the concentration of calcium was slightly decreased relative to the filtrate from the reference paste.

Seligmann and Greening (52) observed great acceleration of the reaction of gypsum with C_3A in an aqueous mixture with sucrose, causing formation of large amounts of the high-sulfate calcium sulfoaluminate. They concluded that solid C_3A sorbs sucrose to produce a surface that does not permit formation of an impermeable layer of the sulfoaluminate. Thus, the usual immediate retarding effect of gypsum on the reaction of C_3A did not occur. After the initial accelerated reaction, further reaction of gypsum and C_3A was somewhat retarded.

Calcium lignosulfonate increases calcium and sulfate concentration during the early period of hydration of cement; supersaturation with respect to $Ca(OH)_2$ and $CaSO_4 \cdot 2H_2O$ commonly occurs (66–68). With delay in time of addition of the admixture to the paste during mixing, the composition of the solution is intermediate between that obtained from the untreated cement paste and that obtained from the paste to which the admixture was added at the start of mixing (66, 68). Similar results are reported by Farkas and Dodson (68) and by Goetz (69) for a salt of a hydroxy acid.

Seligmann and Greening (52) examined pats of pulverized C_3S and water containing small proportions of lignosulfonate admixtures by X-ray diffraction to determine the rate of calcium hydroxide formation. Hydration was delayed indefinitely. In the presence of alkalies, delayed set occurred. The alkali appeared to react with the lignosulfonate on surfaces of C_3S to destroy the hydration-inhibiting effect. Such an action is consistent with Swenson and Thorvaldson's observation (70) of early degradation of lignosulfonate in cement pastes and concrete.

Study of mixtures of sodium calcium aluminate, C_3S, CaO, $Ca(OH)_2$, and gypsum provides valuable information on the action of a calcium lignosulfonate admixture (52). The particular commercial admixture selected by the authors is reported elsewhere (71) to include about 12 per cent of residual wood sugars. The effect of the lignosulfonate anion in contrast to the effect of the sugars is not distinguishable in the data. The ability of the admixture to inhibit release of Ca^{++} from C_3S was found to be an important factor in its effect on hydration of the aluminate. In the presence of $Ca(OH)_2$, the admixture produced only slight retarding effect initially and substantial retardation at 17 hr. Substitution of C_3S for $Ca(OH)_2$ resulted in acceleration of hydration of the aluminate in the presence of the admixture, and the acceleration was increased greatly by agitation of the mixture, presumably because of exposure of fresh surfaces of the aluminate to continued reaction. This acceleration was accompanied by considerable heat generation.

The author concludes that C_3S will not produce setting in the presence of a lignosulfonate unless some minimum quantity of sodium or potassium is present. In the absence of appreciable concentration of dissolved $Ca(OH)_2$ lignosulfonate produces accelerated hydration of C_3A comparable to the initial effect of sucrose. The immediate acceleration is decreased by delayed addition of the admixture so as to permit initiation of the hydration reactions, and the setting of the mixture typically is retarded more than would result from earlier addition of the same proportion of the admixture.

Available data show that water-reducing, set-controlling admixtures do not change significantly the nature of the hydration reactions or the composition of the reaction products (44). The rates of the reactions are modified, the reactions of the calcium aluminates being accelerated or retarded initially as outlined above, and the silicate hydration and setting retarded unless the retardation effect is compensated, as by use of accelerating chemicals or application of heat.

The relative importance of interaction of the hydroxylated admixtures with anhydrous constituents of portland cement in lieu of interactions with hydration products is conjectural. The data of Blank,

Rossington and Weinland (51) indicate the importance of the latter reactions whereas others emphasize uptake of the admixture by the unhydrated cement, especially C_3A. Bruere (72) explained the increased effectiveness of water-reducing, set-retarding agents when added to portland cement mixtures after a preliminary mixing period as being the result of diminished availability of anhydrous surfaces upon which adsorption could be accomplished because of accumulation of immediately-formed hydration products. Contrariwise, sorption of the admixture upon the hydration products formed on surfaces of the cement granules might be more effective in delaying additional hydration than is their direct adsorption on anhydrous surfaces, and sorption on separate particles of hydration products may modify the development among the hydration products of the adhesive forces that otherwise would lead to setting.

Effect of Cement Composition

Chemical and compound composition of the cement influences the effects that are produced by hydroxylated admixtures in concrete (43, 73–75). The factors involved are not well understood nor are they quantitatively predictable. Consequently, concrete containing the proposed materials should be tested to select the admixtures and rate of use that will yield optimum results in the work. Such testing should be conducted in concrete, preferably utilizing the mixing facilities that are proposed for use in the construction.

The content of aluminates is the most important factor influencing the effectiveness of hydroxylated admixtures in terms of water-reduction, retardation, and strength development of concrete (58, 73, 74). The effectiveness generally decreases as the content of C_3A increases. However, inasmuch as the content of C_3A in commercial cements typically decreases as the content of the calcium-aluminoferrite phase increases, and *vice versa*, tests performed upon cements of varying Al_2O_3/Fe_2O_3 ratio do not permit easy determination of the relative significance of the content of C_3A and of the ferrite phase. Crepaz and Raccanelli (54) conclude from tests of ground clinkers of varying Al_2O_3/Fe_2O_3 ratio that the effect of a lignosulfonate admixture on hydration of C_3S in producing extended retardation relates more to the amount of the ferrite phase than to the amount of C_3A. They believe the ferrite phase produces gelatinous hydration products that accumulate on surfaces of the calcium silicates under some conditions, with resulting prolonged retardation of setting in the manner described by Lerch (76) for under-sulfated low alkali cements of high C_4AF content. This process may explain the prolonged retardation produced by a lignosulfonate admixture on setting of concrete containing a low-alkali cement of high C_4AF and low C_3A content that caused problems in tunnel lining construction in California (71).

Kawada and Nishiyama (77) show that C_2F takes up much less calcium lignosulfonate from aqueous solution than does C_4AF, except at concentrations of the admixture less than about 100 mg/cc.

The efficiency of hydroxylated admixtures in water reduction and retardation depends also upon alkali content of the cement, their effectiveness decreasing with increased alkali content (74). However, Seligmann and Greening (52) conclude that some, as yet undetermined proportion of alkalies must be available to overcome the retardation of hydration and setting that otherwise could be caused among the calcium silicates. Apparently, the alkalies promote breakdown of the adsorbed film of the hydroxylated compounds so that hydration can proceed. The admixture can control the availability of alkalies to the extent that sodium is combined in calcium aluminate or sodium and potassium are components of the silicates; if hydration of these compounds is retarded, the concentration of alkalies in the solution phase will be decreased.

The effect of hydroxylated admixtures upon early hydration reaction and setting is influenced also by the type and amount of calcium sulfate that is present in the cement as an interground addition. The relationships are complex (37, 78). In a cement-water mixture, the immediately developed concentration of sulfate can be low because of deficient quantity of calcium sulfate or because the calcium sulfate is in the form of the slowly-soluble natural anhydrite. Conversely, the immediately developed concentration of sulfate can be higher than the saturation concentration for gypsum because of the presence of substantial amounts of the hemihydrate or soluble anhydrite phases. The excessive concentration of calcium sulfate will lead to false setting tendency of the mixtures if precipitation of gypsum occurs following cessation of mixing and prior to completion of placing of the concrete. The time of precipitation depends not only upon the degree of supersaturation but also upon the presence of gypsum crystals or other particles that can serve as crystallization nuclei. With complete destruction of original gypsum during the cement manufacturing operation, no nuclei suitable for immediate precipitation of gypsum remain so that the precipitation and consequent stiffening may be delayed until after removal of the concrete from the mixer, with resulting

problems in handling and placing of the concrete (72). Conversely, if suitable nuclei of gypsum remain, the precipitation usually will occur in the mixer, stiffening will be overcome by continued mixing, and no ill effects or only some increase in water requirement for given consistency may be the practical result. Manabe (67) concluded that granules of portland cement might also serve as crystallization nuclei for gypsum, and Hansen (37) suggested that crystallites of calcium sulfoaluminate might serve a similar role.

Addition of a hydroxylated admixture to the cement-water system can effect any of several changes relative to these phenomena. The previously noted increase in concentration of calcium sulfate that typically occurs in the presence of a lignosulfonate and (at least some) salts of hydroxy acids may lead to premature stiffening or an aggravated degree of stiffening as the result of precipitation of gypsum in the cement paste matrix. Loss of slump of concrete associated with use of these admixtures has been reported by several authors (52, 79, 80). In other instances, these admixtures may decrease or eliminate loss of slump; Goetz (69) shows for a particular combination of cement and a salt of a hydroxy acid that false setting of the cement paste is delayed, apparently because the admixture reduced the ability of solids in the mixture to serve as nucleii for precipitation of gypsum. Seligmann and Greening (52) show the effectiveness of sucrose in decreasing false set of cement paste, this result being due to consumption of calcium sulfate in an accelerated production of high-sulfate calcium sulfoaluminate from C_3A.

Seligmann and Greening (52) and Palmer (81) cite an instance of early stiffening that is akin to flash set of the C_3A induced in a low-sulfated cement as a result of early depletion of the available calcium sulfate; this action is apparently the result of acceleration of initial reaction of C_3A by a lignosulfonate. In this instance, as is reported above, setting of the silicates did not occur normally, possibly because of insufficient alkalies to remove adsorbed lignosulfonate from the silicates or because of precipitation of iron-bearing hydration products on the silicates. Their data suggest that sucrose would produce an effect similar to that of the lignosulfonate. But a salt of hydroxy acid apparently did not cause abnormal retardation of setting under these conditions (91).

Reduction of Water Requirement

ASTM Specifications C 494 (19) require that a water-reducing admixture for concrete reduce water requirement by five per cent or more with respect to the water requirement of the comparable concrete mixture not containing the admixture. At rates of use typically employed in construction, commercially available water-reducing admixtures allow 5 to 12 per cent of water reduction at equal air content, the average being 6 to 8 per cent.

The physical-chemical causes for reduction of water requirement are not completely understood, apart from the mechanical results of entrainment of air bubbles. Powers (32) concluded that it is a consequence of adsorption of the admixture upon surfaces of the cement grains. Bruere (6) shows that calcium lignosulfonate used at rates ranging from about 0.020 to 0.080 per cent progressively reduces viscosity of cement pastes in which air entrainment was avoided by imposition of a vacuum during the mixing operation. He believed this effect to be the result of adsorption of the lignosulfonate on the cement granules with consequent development of hydrophilic surfaces.

Ernsberger and France (27) described the uptake of lignosulfonate anions by portland cement and the development in dilute aqueous suspensions of a high degree of dispersion of the cement as indicated by increased time of sedimentation. Maximum dispersion was obtained with 0.5 g of calcium lignosulfonate per 100 g of cement, and amounts ranging from 0.2 to 0.4 g/g were highly effective. Electrophoretic observation of cement-water suspensions demonstrated that cement particles in distilled water did not migrate in an electrical field whereas cement particles suspended in a calcium lignosulfonate solution moved toward the anode, indicating existence of a negative charge on the particles. They attributed the negative charge to adsorbed lignosulfonate anions, and the dispersion of cement to mutual repulsion of the particles. Similar observations were made with respect to salts of hydroxy acids in unpublished work. Scripture (82) concluded that reduction of water requirement results from the dispersion; mixing water that otherwise would be trapped among the flocculent cement is made free to contribute to fluidity of a mortar or concrete mixture.

Prior and Adams (44) point out that acquisition of an electrical potential by a particle with adsorption of an ion will orient water dipoles around the particle to form a sheath which acts mechanically to prevent close approach of adjacent particles. In concrete mixtures, the adsorption may effect only a reduction of interparticle attraction, rather than development of forces of repulsion. Hence, each cement particle is not free to act independently of others but the decrease in interparticle attraction permits greater mobility of particles. They conclude that water freed from the

flocculated system is available to lubricate the mixture. Another or a supplementary concept may be that to achieve the same level of interparticle forces of attraction, a lesser distance of separation is required when the forces of attraction are reduced through adsorption of the hydroxylated admixture; hence, a lesser proportional volume of interstitial water is required for given viscosity.

Cordon (83) shows that a lignosulfonate admixture reduces the amount of water that is required to change slump of concrete to given extent, as was discussed previously in this report (Table 7). That is, by introduction of the admixture, the concrete mixture is made more sensitive to water content in relation to consistency.

Workability

Workability of concrete cannot be measured by a single parameter since it is an expression of diverse properties, namely, (1) compactibility, (2) mobility, and (3) stability of the fresh mixture (84). An evaluation of workability should consider not only the magnitude of these properties, but also the relationship of their magnitude to time after completion of mixing and to the properties of the hardened concrete.

By use of a retarding admixture, the period of time following completion of mixing and preceding the onset of setting can be extended (85). Purposeful retardation in excess of a week has been produced by use of a water-reducing retarder so as to permit continuity of placing operations under special conditions. Wallace (86) concluded that a lignosulfonate water-reducing retarder "appeared to loosen the mix and improve mobility of the concrete during vibration. However, the greatest benefit from a workability viewpoint was obtained through lengthing the hardening period. This kept underlying layers alive longer and enabled them to be knitted together with subsequently placed concrete."

Whether use of a water-reducing admixture will improve workability of concrete as apart from effects of delay of setting and aside from the effects of accompanying air entrainment has been the subject of critical discussion (79) even though numerous reports of observations of such effects in practice have been published (87). Pertinent technical data are meager.

Desov (46) found that a lignosulfonate greatly reduced viscosity of cement paste relative to that of cement paste without a chemical admixture. The effect considerably exceeded that produced by soaps of wood resins used as an air-entraining admixture. Nishi (7) shows that for concretes of equal slump and water-cement ratio, with and without a lignosulfonate admixture, mortar screened from the concrete containing the admixture had substantially greater flow than did mortar screened from the reference mixture, even at equal air content and lower cement paste content of the mortar. Ashworth (75) reported that sucrose improved workability of concrete as measured by compacting factor when used at the rate of 0.05 per cent.

Conversely, as is noted above, consistency of concrete as measured by slump can decrease more rapidly with use of a water-reducing admixture, regardless of its effect on time of setting, than occurs in an equivalent mixture without such an admixture. To the extent that slump is a measure of workability in these instances then workability will be decreased, at least after some period of time during which the concrete has been handled. Hughes and Bahramiam (88) concluded that the Vebe test (89) is a very satisfactory measure of the ease with which the concrete can be vibrated into place, this method being superior to the slump test for this purpose. Della Libera (90) reported that slump loss of concrete containing a water-reducing admixture may be more or less than that of the equivalent concrete without the admixture, but loss of workability as indicated by the Vebe apparatus is less. He illustrates observations for a concrete containing a lignosulfonate admixture for which slump loss during the first two hours after mixing was about 3 cm whereas no appreciable change occurred in the Vebe measurement of workability.

Skeen (91) evaluated workability of concrete containing each of four surface-active agents: (1) an anionic air-entraining agent, (2) a nonionic agent consisting of condensation products of polyethylene oxide with substituted phenols, (3) an air-entraining agent consisting of a triethanolamine salt of sulfonated hydrocarbons, and (4) an impure calcium lignosulfonate. Mixing of the concrete was conducted under reduced atmospheric pressure to hold air entrainment at a minimum. Workability was measured as a "compacting factor", that is, the ratio of the weight of the fresh concrete in a test vessel after compaction in a standard manner to the maximum weight attainable by vibration (92). Skeen concluded that agent 2 above, improves the working qualities and agent 4 provided marked improvement in working qualities of the concrete when used at rates of 0.15 and 0.30 per cent.

Heat of Hydration

Forbrich (73) experimented with mixtures of cal-

cium lignosulfonate, orthohydroxy benzoic acid, and calcium chloride to determine their effect upon hydration of C_3A, C_3S, and portland cement. He classified orthohydroxy benzoic acid and other substituted hydroxy benzoic acids as catalysts in the hydration and setting of portland cement mixtures inasmuch as the small rates of use to achieve such action preclude the possibility that the effect is a consequence of direct combination with any phase of the cement.

Calcium lignosulfonate used alone delayed the time of rapid heat evolution by C_3A and greatly retarded heat liberation from C_3S. Orthohydroxy benzoic acid slightly retarded heat liberation of portland cement and C_3S, whereas that of C_3A was slightly accelerated. Calcium chloride increased the maximum rate and amount of heat liberated by portland cement and C_3S during the first 24 hours, but had little effect on C_3A. By combination of the three agents in various proportions, early heat liberation of portland cement could be controlled in almost any direction.

Combinations containing calcium chloride typically had little effect upon total heat liberation from a group of portland cements after seven days. Conversely, a combination of calcium lignosulfonate and the catalyst, used at the rate of 1.065 per cent, slightly decreased heat release at three days but at 28 days six of seven cements showed increased heat generation up to 12 per cent with respect to heat evolved by the cement without admixture. Moreover, Forbrich observed that use of the formulated admixtures increased compressive strength of concrete at given age and increased the ratio of strength of concrete to heat released from cement pastes. That is, the admixture appeared to increase the efficiency of the cement in producing strength per unit of hydration as expressed by heat generation.

Danielsson (41) found that heat of hydration at 28 days was not notably altered by the use of a group of calcium of simple organic acids, in spite of retardation of setting and initial heat release.

Polivka and Klein (74) concluded that setting time of mortar as determined by a penetration test can be calculated as a function of the time required for a paste of the same cement to reach maximum heat of hydration. Kennerley, Williams and St. John *et al* (43) found also that the maximum rate of increase in temperature of cement paste correlates with physical hardening of the paste. Consequently, setting of portland cement mixtures with and without water-reducing, set-controlling admixtures seems to be determined by the degree of hydration attained. In view of the interaction of chemical admixtures and hydration products of cement, the rate of hydration and the rate of setting could be quite different.

Bleeding and Settlement

Water-reducing, set-controlling admixtures influence the rate and capacity of fresh portland cement mixtures to bleed and settle under the influence of gravity. Lignosulfonates typically reduce the rate and capacity of bleeding even when the air content of the test mixture is equal to that of the reference mixture not containing a chemical admixture (93, 94). Conversely, hydroxy acids and their salts commonly increase the rate and capacity of portland cement mixtures to bleed and settle at given air content and degree of retardation of setting (91, 93, 94).

Kreijger (28) studied the effect of surface-active agents on the bleeding properties of cement pastes and mortars. He concluded that at given water-cement ratio anionic water-reducing, set-controlling admixtures reduce bleeding rate more than can be accounted for by air entrainment, whereas anionic air-entraining admixtures reduce bleeding rate and capacity in closer relation to the effect of air content as deduced by Powers (95). Kreijger gives the following equations for cement pastes at water-cement ratio = 0.5.

For anionic, water-reducing admixtures:

$$\frac{Q_x}{Q} = 1 - 10x \qquad (2)$$

$$\frac{H_x}{H} = 1 - 10x \qquad (3)$$

For anionic air-entraining agents (rendering cement granules hydrophobic) and nonionic water-reducing admixtures:

$$\frac{Q_x}{Q} = 1 - 4.0x \qquad (4)$$

$$\frac{H_x}{H} = 1 - 4.0x \qquad (5)$$

where:

Q and Q_x are respectively bleeding rate for cement pastes without and with the admixture; H and H_x are respectively bleeding capacity of cement pastes without and with the admixture; and x is the air content. Equation 4 is considered to be valid to maximum air content of 14.5 per cent, whereas equation 2 is considered to be valid to air content of 4.1 per cent.

Equations 2 and 4 are compared by Kreijger with that calculated for his cements from the theoretical formula given by Powers (95) in which no account is taken of any physical-chemical effects of the admix-

tures. The resulting formula is stated as

$$\frac{Q_x}{Q} = 1 - 2.45x \qquad (6)$$

Hence, for the cement admixture combinations used by Kreijger both types of admixtures produced effects other than mere incorporation of air bubbles. In view of other data, it is questionable whether Equations 2 and 3 can be applied to the broad spectrum of hydroxylated anionic water-reducing compounds.

Kreijger (28) concluded also that bleeding rate of concrete can be calculated from bleeding rate of cement paste when an admixture is employed, provided the same concentration of admixture is used in each mixture.

Manabe and Kawada (55) found that portland cement is dispersed by addition of calcium lignosulfonate to aqueous suspensions in amounts up to 0.3 per cent, this concentration corresponding to that necessary to produce the readily formed portion of a monomolecular layer over the cement granules. At this concentration, maximum stability of the suspension (10 g. cement in 15 ml. of aqueous solution) was attained. At higher concentrations further dispersion of the cement occurred and coarse particles separated from the suspension, causing progressive decrease in volume of the suspension at given time following cessation of shaking.

Bruere and McGowan (96) evaluated several polyelectrolytes that produce flocculation through increased particle attraction in cement pastes, mortars, and concrete. Discussion of admixtures of this type is outside the scope of this paper.

Stress-Strain Relationships

When used at rates that provide reduction of water requirement and the time of setting appropriate for general construction, water-reducing, set-controlling admixtures typically increase compressive strength of concrete significantly (97). Unless setting is unusually retarded, the increase in compressive strength is apparent at 24 hours and at 7 and 28 days the increase is in the range from 10 to 20 per cent, and may be substantially higher. The strength increase, expressed in proportion to the strength of the reference concrete not containing the admixture, usually is greater at 3 and 7 days than at 28 days and later. The improvement in compressive strength is related in part to the reduction in water-cement ratio, but the increase in strength typically exceeds that expected from change in water-cement ratio (98). The effect of calcium lignosulfonate used at 0.266 per cent is shown in Table 7 for air-entrained concretes of differing cement content, water-cement ratio, air content, and slump. Based upon analysis of data obtained by testing of a lignosulfonate admixture in concrete in combination with 26 portland cements and 36 combinations of aggregates, Mielenz (87) adduced the following relationships of 28 day compressive strength and void cement ratio:

$$Sa = 8518 - 1830Va \qquad (7)$$

$$Sp = 8190 - 1992Vp \qquad (8)$$

Where Sa = 28 day compressive strength of the admixture concrete, psi; Sp = 28 day compressive strength of the concrete without admixture, psi; Va and Vp = void-cement ratio by volume of the concretes. These relationships indicate that on the average, at constant air and cement content, an increase of 19 per cent in 28 day compressive strength can be expected even if the water reduction effected is only 5 per cent. If a water-reducing retarder is used at rates sufficient to effect extended retardation, early strength may be decreased but later strength will be increased, provided the concrete is properly cured and protected and provided the air content is in the proper range.

Flexural strength of concrete at given cement and air content typically is increased by use of water-reducing, set-controlling admixtures, but the improvement is proportionally less than that effected in compressive strength. Similar conclusions may be reached relative to their effects upon tensile strength, shearing strength, and modulus of elasticity (80). Abrasion resistance of surfaces and bond with reinforcement are related to compressive strength of concrete, and so typically are likewise improved.

Only very limited data are available on the effect of water-reducing, set-controlling admixtures on creep of concrete. Some recent data are given by Hope, Neville and Guruswami (99) for normal weight concrete and by Jessop, Ward and Neville (100) for concrete containing lightweight aggregate. Each report is based upon tests in which only one portland cement (Type III, high early strength) was used. Use of a water-reducing retarder based upon either lignosulfonate or salts of a hydroxy acid was found apparently to cause an increase in creep of the normal weight concrete. In the tests of the lightweight concrete, a lignosulfonate retarder appeared to increase creep whereas a retarder based upon a salt of a hydroxy acid seemed to reduce creep under most of the conditions applied. The authors recommend caution in generalization of their observations in consideration of other cement-admixture combinations.

Available information on the effect of hydroxylated admixtures upon the structure, texture, and composition of the cement paste matrix of concrete and upon development of bond of cement paste to aggregate particles is insufficient to explain quantitatively the observed changes in stress-strain relationships that are induced. Except for changes in the composition of calcium aluminate hydration products that may occur under some circumstances, such as formation of analogues of the high-sulfate calcium sulfoaluminate (36), the hydration products of portland cement appear to be the same in spite of the presence of the surface-active admixture, but rates of hydration of the several constituents, sequence of formation of the hydration products, and crystal habit and size distribution of the hydration products are changed. Therefore, the change in properties of concrete may arise in large part in the altered texture and structure of the hydrated cement paste. This concept is consistent with conclusions of several workers who observed by electron microscope change of crystal size and habit of hydration products of tricalcium aluminate and of calcium aluminoferrites and changes in the morphology of hydration products of C_3S and C_2S (54, 57, 60, 101–103). Hope, Neville and Guruswami (99) cite the observation of change in size and shape of crystals formed by hydration of C_3A in the presence of lignosulfonate to account for the indicated changes in magnitude of creep of concrete.

Although these modifications within the matrix undoubtedly affect stress-strain relationships in hardened concrete, the possibility of modification of boundary relationship among the hydration products and between the hydration products and aggregate particles should not be overlooked.

Drying Shrinkage

The effect of water-reducing, set-controlling admixtures upon drying shrinkage of concrete is a matter of concern with respect to performance of the concrete in service. Standard tests of drying shrinkage, such as ASTM Designation: C 157 (19), typically specify use of unrestrained specimens of small size that are cured initially in moist air in the molds, then briefly in moist air or lime water, and then are dried in air, usually at 23.0 $\pm$ 1.1°C. and 50 $\pm$ 4 per cent relative humidity. These conditions cause more rapid drying and greater shrinkage than occurs in structural members and slabs in service, and they produce an optimum environment for shrinkage of the cement paste matrix by carbonation (104). Moreover, such procedures neglect any internal cracking that would be an important manifestation of shrinkage stress yet will reduce the indicated shrinkage strain. Della Libera (90) reported lesser cracking of concrete pavements and structures with use of a lignosulfonate admixture.

Water-reducing, set-controlling admixtures produce varying results in such accelerated tests. For no admixture of these types is any substantial reduction of drying shrinkage shown consistently. Some hydroxylated admixtures cause an increase in drying shrinkage even when water content is reduced. At early periods, the increase may be 100 per cent or more relative to the length change of the reference concrete. However, the changes are most pronounced at early ages and they decrease with passing time, possibly with reversal of the relationship to the reference concrete after several months of drying. Increases in early drying shrinkage are greatest when the admixture includes constituents that accelerate the hydration and setting process, so as to partially or completely overcome the set-retarding action of the hydroxylated component. The resulting change in drying shrinkage depends on many factors, most important of which are the characteristics of the cement and aggregate (105).

Bruere and Newbegin (106) determined the effect of various water-reducing, set-controlling admixtures on accelerated drying shrinkage of concrete beam specimens. The admixtures included calcium lignosulfonate, mixtures of calcium lignosulfonate and calcium chloride, mixtures of calcium lignosulfonate and triethanolamine, sodium gluconate, and sucrose. After seven days of drying at 50 $\pm$ 3 per cent relative humidity, the drying shrinkage of the concrete containing the admixtures was increased 30 to 110 per cent (for one cement-aggregate combination) and 0 to 50 per cent (for a second cement-aggregate combination), whereas after 168 days of drying the respective changes in drying shrinkage were -6 to 6 per cent and -8 to 0 per cent. The authors conclude that "the effects of admixtures on shrinkage (of concrete) after 14 days of drying are not indicative of their effects after longer periods of drying."

Helmuth and Turk (107) showed that drying shrinkage of portland cement pastes in a carbon dioxide-free atmosphere is dependent upon how the drying is carried out and how long the pastes were stored moist after hydration was substantially complete. For example, ultimate drying shrinkage at a low relative humidity was greatly reduced by prior storage at intermediate relative humidity, rather than direct exposure to the low humidity following curing. Also, they found that prolonged moist curing can substantially reduce the shrinkage that occurs on first drying at low relative

humidity. They conclude that irreversible changes occur in the structure of the hydration products during moist curing with the result that shrinkage upon drying is reduced. These results indicate the error that can arise in extrapolation of results obtained in accelerated drying of small specimens to predict performance of structures and pavements in service. An important contribution would result if the Helmuth-Turk studies were repeated to evaluate the effect of water-reducing, set-controlling admixtures on the magnitude of delayed drying shrinkage.

The cause of any increase in drying shrinkage that may relate to use of a water-reducing, set-controlling admixture is not understood completely. The effect may result from increased proportion of cement that is hydrated at given time, this possibility being most pertinent to performance of admixtures containing an accelerator or catalyst. The magnitude of shrinkage does not correlate directly with loss of water when concretes with and without a water-reducing, set-controlling admixture are compared. For example, in a series of concrete mixtures containing 511 to 516 lb of cement per cu. yd. and 5.4 to 5.8 per cent of air with slump of $3\frac{1}{2}$ to 4 in., drying shrinkage during 180 days was 0.045 per cent linearly for the concrete containing no water-reducing admixture whereas that of five concretes containing lignosulfonate water-reducing retarders was 0.054 to 0.058 per cent; yet weight loss was 3.31 per cent for the reference concrete and 3.04 to 3.20 per cent for the specimens containing the water-reducing admixtures. The ratio of lineal shrinkage to weight loss increased consistently as the water-cement ratio decreased. The test was performed in accordance with ASTM Designation: C 157 (19), using 3- by 4- by 16-in. beams.

The relationship appears to be like that shown by Roper (108) for cement pastes with water-cement ratio of 0.35 and 0.50, respectively. For given weight loss expressed as a percentage of the weight of the paste at given relative humidity, substantially greater shrinkage occurs in the paste of lower water-cement ratio. The loss of weight occurring at relative humidity down to about 90 per cent is accompanied by little shrinkage. At relative humidity from 90 to 40 per cent, a substantial increase takes place for each increment of weight loss. Roper concludes that the first type of water is that contained in macropores of the cement paste, whereas the second type of water is held by capillary condensation so that its loss creates capillary compression of high magnitude.

In other words, considering the case in which the water-reducing admixture is incorporated in the concrete mixture without reduction of cement content, the water-cement ratio is reduced thereby. Presumably, the excess of water that is present in the reference concrete to provide the specified consistency, will exist in larger openings (Roper's macropores) in the cement paste. Loss of this water will effect little shrinkage and the time required for its movement through and out of the concrete will delay the initiation of loss of water from the small capillaries in which significant capillary tension can develop. Meanwhile, the relative smaller proportion of water that is present in macropores of the cement paste within the concrete containing the admixtures is lost sooner and loss of water within capillaries is initiated quickly, with resulting early development of relative humidity within the concrete at levels in which high capillary tension can develop. In tests of water-reducing and air-entraining admixtures Kondo and Hideshima (109) found that drying shrinkage of concrete is less with use of water-reducing admixtures based upon calcium lignosulfonate than for the reference concrete or concrete containing conventional air-entraining admixtures; in these tests drying was accomplished at an ambient relative humidity of 70 to 80 per cent.

If the use of the admixture is accompanied by a reduction of cement content so as to maintain the water-cement ratio constant or nearly so, decrease of relative humidity within the concrete still will be more rapid than within the reference concrete because of the higher water content of the latter concrete.

Although the above conditions and processes are qualitatively valid and germane to explanation of the effect of hydroxylated admixtures on drying shrinkage of concrete, they cannot afford a complete comprehension of the mechanical and physical-chemical processes involved because of the effects of such admixtures upon the texture and structure of the cement paste as well as upon its physical properties such as permeability, tensile strength, and creep characteristics. For example, Stupachenko (47) studied pore size distribution and porosity of hardened cement pastes and mortar by absorption of benzol and use of the mercury porosimeter. He reported that use of a lignosulfonate admixture at the rate of 0.25 per cent did not significantly change the total porosity, but the volume proportion of pores with radius of 500 to 1000 Å was decreased 8 per cent in the mortar (water-cement ratio = 0.5) and 30 per cent in the cement paste (water-cement ratio = 0.25) whereas the proportion of pores measured by the mercury porosimeter (radius = 100 to 65,000 Å) was increased about 11 per cent in each instance. For the reference mortar without admixture, pores with diameter greater than 1 μ constitute about 21 per cent of the total porosity

in contrast to 25 per cent for the mortar with the lignosulfonate admixtures, and pores having diameter greater than 1000 Å constitute 40 per cent and 52 per cent of the two mortars. Stupachenko concluded that the cement paste containing the admixture should be more permeable to water and other fluids than is equivalent cement paste without the admixture; this conclusion would not necessarily relate to the concrete as a whole. These factors also will influence the rate and magnitude of drying shrinkage under given conditions of exposure.

Wallace and Ore (80) found that so-called autogenous shrinkage of concrete, that is, shrinkage occurring in sealed specimens for which no moisture loss is permitted, is reduced by use of a lignosulfonate admixture. The reduction was observed at all periods to an age of five years.

Resistance to Freezing and Thawing

Resistance of concrete to the effects of freezing and thawing depends mainly upon the air content, distribution of air voids in the cement paste matrix, and the degree of saturation of the aggregate and the matrix (34, 110). However, the quality of the cement paste as defined by water-cement ratio and extent of hydration is an important factor both because of the physical properties of the hardened matrix and because of the influence of the fresh cement paste upon the geometry of the air-void system. Also, as has been noted (Table 8), the specific relationship of the parameters of the air-void system, such as the air-void spacing factor, and resistance to freezing and thawing is affected by the composition and rate of use of the air-entraining agent and any chemical admixtures that may be present. Wallace and Ore (80) found that the average freezing and thawing resistance of concrete containing any of several water-reducing, set-controlling admixtures was 39 per cent greater than that of comparable reference concretes. In studies by the Bureau of Public Roads (5), concretes containing each of 22 water-reducing retarders were about equally resistant or more resistant to freezing and thawing as were the comparable reference air-entrained concretes without a water-reducing admixture. Concretes containing each of the three remaining admixtures of the 25 tested showed somewhat less resistance to freezing than did the reference concretes. Other reports also show reduced resistance to freezing and thawing of concrete containing individual water-reducing admixtures (111, 112). So far as the present author is aware, such instances of reduced resistance to freezing and thawing correlate with deficiencies of parameters of the air-void system, such as excessive spacing factor (or unprotected paste volume) and deficient air content.

Additional research is necessary to establish quantitatively the parameters of the air-void system and the cement paste matrix that control the resistance of the matrix of concrete to effects of freezing and thawing. Larson, Cady and Malloy (113) concluded that Philleo's protected paste volume concept (114) evaluated by a new procedure that they propose, provides the best indication of resistance to freezing and thawing. Price (115) found that total air content determined microscopically does not correlate significantly with dilation of concrete in a freezing and thawing test but that air content based upon voids less than 1000 μ in diameter correlates at the 90 per cent confidence level, and a higher degree of correlation results with elimination of all voids larger than 500 μ.

Warris (116) emphasizes the importance of the degree of saturation of concrete at time of freezing, including the partial or complete filling of air-voids, as a basic factor in the resistance to distress. This condition is not contemplated in the several analyses noted in the previous paragraph. Moreover, consideration should be given to the ease with which air voids of differing size are filled by water under conditions of capillary absorption and hydraulic flow. Bache, Idorn, Nepper-Christensen and Nielson (117) show from observation of deposits of calcium hydroxide in air voids that voids near surfaces in contact with water can readily fill with water; however, the deposits were virtually restricted to voids larger than 50 μ in diameter. Noting that small voids should fill with water faster than do larger voids because of the pressure-solubility relationship of air contained in a bubble (11), these authors suggest that the cement paste adjacent to large voids may be less dense and more permeable than that close to small voids. Slate (118) suggests that the hydrophobic film at the interface of entrained air bubbles impedes entry of water into the voids after hardening of the concrete. These are matters for further study.

Considering the above factors, it appears that air voids that are most important for protection of the cement paste of concrete from damaging effects of freezing are those of intermediate size, such as 50 to 500 μ, that are less likely to fill with water prior to freezing than are smaller voids, yet are small enough to provide efficient distribution of the available air volume and a relatively large specific surface for entry of water into the voids during freezing.

Urgently Needed Research

Air-Entraining Admixtures

1. Techniques for measurement of bubble size, proportional volume, and distribution in fresh concrete.

2. Further evaluation of factors controlling the proportional volume and geometry of the air-void system in hardened concrete, including effects during mixing and following mixing, particularly bubble dissolution and enlargement.

3. Evaluation of parameters determining the freezing and thawing resistance of concrete that is saturated with water or nearly so, including geometry of the void system in relation to the cementitious matrix of the concrete and properties of the matrix.

4. Determination of properties and composition of air-entraining admixtures that will provide optimum effects on workability, bleeding, and settlement of fresh concrete and yet will produce a satisfactory air-void system in hardened concrete.

5. Discovery of the properties and composition of air-entraining admixtures that will produce air-void systems of optimum efficiency in hardened concrete, that is, adequate protection of the matrix at minimum air content.

6. Evaluation of factors controlling the rate and degree of filling of air voids prior to freezing, including such factors as void size, structure of the cement paste and its variation with proximity to voids, and the nature of the void-cement paste interface.

7. Determination of the mechanism by which air entrainment in concrete affects permeability and absorption of water, such as improved uniformity by reduction of bleeding and segregation, change of capillary structure of the matrix, and properties of the interface between air voids and the matrix.

Water-Reducing, Set-Controlling Admixtures

8. Development of water-reducing admixtures that accelerate setting and early strength development of concrete, without introduction of adverse effects on other properties.

9. Development of water-reducing admixtures to further improve and maintain working qualities of fresh concrete, including avoidance of undesirable stiffening, control of time of setting, minimizing bleeding and settlement, and improvement in placing and finishing qualities.

10. Development of water-reducing admixtures that will reduce appreciably the volume change of hardened concrete, including drying shrinkage and creep.

11. Evaluation of the effect of water-reducing admixtures on bond of the cement paste matrix and the surface of aggregate particles.

12. Definitive studies on effects of admixtures upon stress-strain phenomena in concrete, including such properties as strength, elasticity, creep, and resistance to cracking, in relation to changes of composition, texture, and internal structure of the matrix and physical-chemical processes at matrix-aggregate boundaries.

Oral Discussion

Norihiro Kudo

Dr. Mielenz states that the activity of surface-active agents as set-controlling agent is due to the formation of insoluble film by their adsorption or chemisorption to the surface of cement grains.

There is a set-retarding agent, on the Japanese market, which is the mixture of water-soluble silicofluoride and some acids. It is probable that this retarder also makes insoluble film or layer on the surface of cement grains by the reaction of its ingredients and Ca-ion of cement, and the thickness of this laver is proportional to the dosage, subsequently the retarding effect of this retarder is proportional to the dosage.

Fig. 1 shows the initial set of concrete containing three types of retarding agents. The silicofluoride type retarder indicates the proportional retarding action, which is quite preferable property as set-controlling agent. Though the retarding effect of these retarding agents reduces slightly, this inclination does not change at 30°C.

Compressive strength of these concretes at 7 days is shown in Fig. 2. This tendency does not change at 28 days of age. As shown in this figure, the overdosage of the organic type retarding agents, say, more than 1.0% of cement weight, makes fatal defect in concrete structure.

Since surface-active agents are originally used as water-reducing and/or air-entraining agent, it must be thought that their set-retarding effect is a sort of "side-effect", that is to say, there are some doubts and anxiety to use such kind of surface-active agents as set-controlling agents. I'd like to ask Dr. Mielenz for some comments on this point.

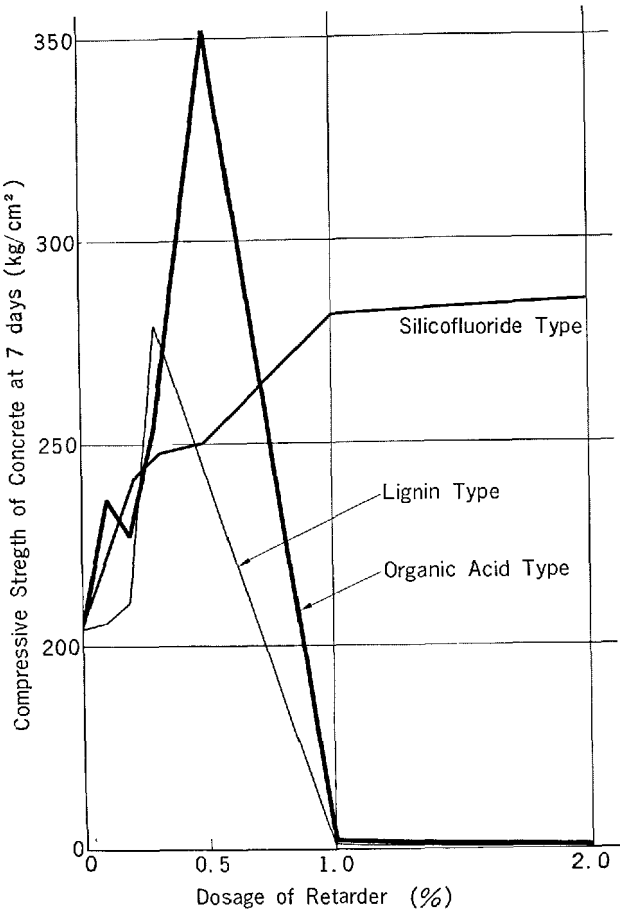

Fig. 2.

Oral Discussion

Udo Ludwig, Hans E. Schwiete and K. Seiler

1. During the study on the reaction mechanism of some special retarders we found out that with silicofluorid type retarders after short time the reaction products with lime ($Mg(OH)_2$, CaF_2 and $C_{2-3}S \cdot aq$) had a surface area that is equal to that of the unhydrated cement. Therefore we are in the opinion that in this case the retardation is due to a coating of reaction products on the surface of the clinker grains or on the active centers of the clinker surface.

2. With organic additives (hexites and polyhydroxy carbonic acids) lime reacts in solutions under formation of less solid phases with less surface area (Table 1). Therefore we assume an addition reaction of the organic molecules on the clinker surface or on the active centers. Proving this idea we mixed the portland cement with optimum addition of retarder and W/C = 0.35. As a function of the time we made a suspension with a total water content of 200 ml. By filtration the water was seperated from the solid phase. The organic substances were determined by a method from Springer (2). The results are given in the following Table 2.

From Table 2 you see the rapid initial decrease of the retarder concentration and here with the fixation of retarding molecules on the clinker surface. The general aspect of the retardation on the beginning of cement hydration is for the silico-fluorid and the organic retarders the same: less lime liberation and sulphate and water fixation. From special interest is that retarded mortars and concretes must be wetted thoroughly for a longer time for they have initially a higher open porosity.

The chemical measurement of fixation of organic molecules by Springer-method was conducted by Dr. K. D. Pohl.

Oral Discussion

Richard A. Kuntze and P. Hawkins

Dr. Mielenz has indicated that several effects must be expected when hydroxy compounds are added to portland cement. For example, a change in the rate of interaction between sulfate and C_3A may result in an increased or decreased formation of calcium sulfoaluminate (ettringite). This is of particular interest with respect to false set, since our own work has indicated that ettringite contributes to this type of early stiffening of cement paste (1).

Seligmann and Greening (2) reported that the formation of ettringite is increased by sucrose whereas ligonsulfonates have a negligible effect. In contrast, Goetz (3) has found that hydroxy acids decrease the formation of ettringite even if hemihydrate is present in the cement. Our own work has shown that some hydorxy acids are capable of delaying the crystallization of gypsum by direct retardation of the hydration of hemihydrate (Fig. 1). Consequently, false set of cement may be affected by these materials by reducing the amount of ettringite formed and by delaying the crystallization of gypsum.

Hydroxy acids differ widely in their effect on the crystallization of gypsum depending not only on their molecular configuration, but also on the concentration of $Ca(OH)_2$ (Figs. 2 and 3). Therefore, if the effect of the hydroxy acids is just sufficient to produce gypsum crystallization after the mixing is completed, false set may be obtained with a cement that otherwise does not show this behaviour. Alternatively a false setting cement may appear to behave normally, if the crystallization of gypsum is delayed until testing is completed.

In contrast to hydroxy acids, little or no effect on the crystallization of gypsum has been observed with sucrose or lignosulfonates. In view of this difference in the behaviour between hydroxy acids and other hydroxy compounds such as lignosulfonates, we would like to ask Dr. Mielenz if observations made in prac-

tice support or disagree with the results obtained by us.

Oral Discussion

Geoffrey J. Frohnsdorff

Since the understanding of the mechanism of hydration of C_3S and alite is of great interest to us all, I would like to make some comments on this subject and to ask Dr. Mielenz if he agrees with them.

Since C_3S, unlike C_3A, does not normally react rapidly and continuously on being mixed with water, it seems reasonable to consider its hydration to be "self-retarded". This suggests that an understanding of the mechanism of the self-retardation is a prerequisite to understanding the retarding or accelerating effects of surface active agents and other additives.

The study of the mechanism is difficult because it appears that a number of consecutive and concurrent reactions are involved and, even when present in minute amounts, the products of the reactions may have large retarding effects on the reactions in which they are formed. A continuing need in studying the effects of additives on the hydration of C_3S or cement is to design experiments which, at least partially, separate the reaction steps. Some ways in which this may be done are illustrated by:

1) The work of Dr. Kondo (1) in which the hydration of C_3S in water extracted from a C_3S paste was compared with the hydration carried out in distilled water.
2) The work of Drs. Dolch and Compbell (2) in which they studied the earliest reactions of C_2S in a very large quantity of water or aqueous solution (W/C = 2000) so as to avoid the complications caused by formation of new solid products; this technique might prove valuable in studies of surface active agents or other

admixtures by helping to show their effects on initial rates of hydrolysis of cement compounds.

3) The work of Dr. Bruere (3) who showed the effects on cement hydration of delayed additions of retarders.

I would like to suggest that understanding of the effects of the retarders and accelerators would be significantly aided by extensions of methods to which I have just referred. I would like to ask Dr. Mielenz if he agrees with this point of view.

Oral Discussion

John H. Taplin

Would Dr. Mielenz care to make a comment on the suggestion that I made to Dr. Lieber in session II, namely, that retarders may act by delaying the nucleation of a calcium silicate hydrate and that the adsorption of retarders on anhydrous clinker mineral surfaces may be unnecessary for retardation.

Author's Closure

Richard C. Mielenz

Mr. Kudo has provided data on time of setting and compressive strength of concrete containing each of three types of set-retarding chemical admixtures that are identified as silicofluoride, organic acid, and lignin types, respectively. By their nature water-soluble salts of hydroxy acids and of lignosulfonic acid are water-reducing retarders for portland cement mixtures; hence, it is not appropriate to designate their set-retarding action as a "side-effect." Although the retardative action of these types of organic admixtures can be partially or completely overcome by suitable intermixture with accelerating agents, salts of hydroxy acids and lignosulfonates are widely and successfully employed as set-retarding admixtures in construction.

In his tests, Mr. Kudo extended the rate of use of the organic admixtures well beyond the proportions in which they normally are used in portland cement mixtures for general construction. Unfortunately, he has not identified the chemical composition of the two organic admixtures so that it is not possible to state an optimum rate of use for these products to meet the requirements of typical construction. In particular, note should have been made as to whether the rates of use indicated are for the active constituent or an aqueous solution. However, calcium lignosulfonates usually are used at rates in the range 0.15 — 0.40 and salts of hydroxy acids in the range 0.05 — 0.10 percent by weight of the cement content of concrete.

The low maximum strength reported for the concrete containing the lignosulfonate relative to that for the concrete containing the organic acid type admixture probably relates to air entrainment. The air-entraining efficiency of differing lignosulfonates varies widely and may be a basis for selection of a product for use in concrete. In any event, comparative tests like those shown should be conducted at equivalent air content or the air content and proportioning of each concrete mixture should be stated for the reader.

Mr. Kudo refers to "doubts and anxiety" about use of organic surface active agents in concrete. There is no basis for such concern provided the product approved for use conforms with carefully prepared specifications, such as A.S.T.M. Designation: C 494, Standard Specifications for Chemical Admixtures for Concrete, and provided proper dispensing procedures are employed so as to control the rate of use of the admixture within close limits, usually ± 3 percent of the amount required.

Kuntze and Hawkins have summarized valuable information on the effect of various hydroxy acids on time of setting of plaster of Paris, and they apply this information to an interpretation of reactions of calcium sulfate in portland cement mixtures. They note the report of Seligmann and Greening (52)* on accelerated ettringite formation in the presence of sucrose. Not noted is the observation by Seligmann and Greening of similar behavior in the presence of a lignosulfonate in the absence of appreciable amounts of calcium hydroxide. These latter authors also confirm the observation of others that calcium lignosulfonate retards the setting of plaster by delaying the precipitation of gypsum.

In any event, as is stated in the principal paper,

*Numbers in parentheses refer to references appended to the principal paper.

numerous factors influence the development of a stiffening tendency (or lack thereof) in concrete. Practical experience is in accord with the findings of scientific work in this field. The C_3A content and alkali content of the cement, the form and amount of calcium sulfate addition, any aeration of the cement, the composition and rate of use of any chemical admixtures and the sequence of addition of the concrete-making materials and the mixing cycle employed in preparation of the concrete, ambient conditions, such as temperature, and job conditions, such as distance of haul and timing of placing and finishing operations—all together determine whether loss of working qualities will occur in specific concrete construction. Under particular circumstances, either a hydroxy acid salt or a lignosulfonate may alleviate or aggravate premature stiffening of concrete. If the action is a false setting tendency, the problem may arise either because early precipitation of gypsum that otherwise would occur during mixing of the concrete is delayed to the interval when the concrete is being handled and worked, or because precipitation of gypsum that otherwise would be delayed until after completion of placing is caused to occur during the period when the concrete is being handled and worked. Inordinate delay of stiffening, combined with premature finishing of unformed surfaces, can lead to unsoundness of the surfaces because of interference with normal process of bleeding and settlement of the concrete (93). In cements that are deficient in available calcium sulfate, either because of low SO_3/Al_2O_3 ratio or because the calcium sulfate is in the form of slowly soluble anhydrite, a flash setting related to inadequate retardation of C_3A may induce an irreversible stiffening of the concrete prior to completion of placing. These matters have been discussed by Seligmann and Greening in relation to practical problems.

The data supplied by Ludwig and his coworkers are interesting but they cannot be discussed in detail because they do not provide complete information on the systems and procedures utilized in the investigation. Presumably, the mixtures referenced in Table 1 do not include portland cement or ground portland cement clinker, but the text of the discussion is confusing in this respect. The condition of dryness of the solids should be known in order that the significance of the reported weight of precipitated material can be established. Likewise, their statement that the specific surface of reaction products of lime and magnesium silicofluoride is equal to that of unhydrated portland cement is surprising considering their reported values of $100 - 116\ m^2/g$ in contrast to usual values of $0.3 - 0.5\ m^2/g$ for commercial portland cement. I am unable to identify the substance designated as "hexite." Can it be a hexose or hexatol?

Ludwig *et al* conclude from their data that the retardative action of the silicofluoride and of the organic agents arises from deposition or interaction at the anhydrous surfaces of granules of portland cement. On the contrary, the data provided with the discussion do not separate such effects from those that would arise if the admixtures interact with hydration products that either are plated over the surfaces of the clinker components or are dispersed in the mixing water. Such distinction requires carefully developed experiments that involve delayed addition of the admixtures, use of non-aqueous media, and detailed study of the composition and morphology of the resulting cement paste matrix. Such procedures have been explored, as is noted in the principal paper, and such work is now in progress in several laboratories.

I agree with the comments of Dr. Frohnsdorff relative to the techniques that should be applied in the study of hydration of C_3S or alite. The recommended procedures should be supplemented by study of cement-admixture reactions in non-aqueous or partially aqueous systems, as was initiated by Blank *et al* (51). Moreover, the solid products and solutions should be studied chemically and the morphology of the solid products should be established, as by scanning electronmicroscopy.

I agree with Dr. Taplin's suggestion that chemical retarders may act by delaying the nucleation of a calcium silicate hydrate. However, the reactions and physical-chemical effects of the surface-active agents are considerably more complex than can be explained by a single mechanism.

Likewise, adsorption of chemical retarders on anhydrous surfaces of clinker compounds may not be an essential aspect in the cement-admixture interaction. However, this concept does not deny the probable significance of uptake directly upon such anhydrous surfaces. Data by Blank *et al* (51) indicate that water molecules and molecules of hydroxylated chemical admixtures compete for sites on anhydrous surfaces, a situation that will always give water the statistical advantage in a practical concrete mixture. In this connection it is worthwhile to recall the independent work of Polivka and Klein (74) and of Kennerley *et al* (43), who found close correlation between release of heat of hydration and time of setting of portland cement pastes, regardless of the presence or absence of a water-reducing, set-controlling admixture. Their data indicate that setting is determined largely by the

quantity of hydration products produced, a conclusion that, if confirmed, will depreciate the significance of any action of chemical retarders on nucleation of the products of hydration.

Supplementary Paper IV-5 Possible Mechanisms of Influence of Admixtures on Creep of Cement Paste

Emlyn L. Jessop, Michael A. Ward* and Adam M. Neville**

Synopsis

Creep data under conditions of drying of neat cement pastes with two water-reducing and set-retarding admixtures are presented. To find the possible mechanism of action of the admixtures the following factors have been investigated experimentally and are discussed: the magnitude and rate of loss of water from the given pastes at higher temperatures, density of hydrated cement paste, surface tension of the solution of admixture in water, and morphology of the hydrated paste as revealed by electromicrographs. Some relation between the ease with which water can move within and out of the paste and creep is shown to exist, but it is suggested that all the other factors be further studied, too.

Introduction

Admixtures have been used in concrete for some time with many beneficial effects (1, 2). Not all the effects are, however, understood or even well-known: among these is the influence of admixtures on creep, a property of considerable, and indeed increasing, importance in the design and performance of concrete structures.

At the 1967 RILEM International Symposium on Admixtures for Mortar and Concrete there were presented two papers (3, 4), arising from work at The University of Calgary on the influence of water-reducing and set-retarding admixtures on creep of concrete made with lightweight and normal weight aggregates. Little other work in this area has been published. The earlier two papers (3, 4) dealt with the creep behaviour of concrete at the phenomenological level. In the present paper, an attempt is made to study the mechanism through which two selected water-reducing and set-retarding admixtures affect the creep of neat cement paste under conditions of drying.

There is an important limitation of the present work that should be mentioned. The behaviour of admixtures, insofar as influence on the properties of concrete is concerned, is not simply related to the ASTM classification (1) of the admixture and is often sensitive to the properties of the actual cement used. As far as creep is concerned, earlier work (3, 4) showed that admixtures, even when belonging to the same ASTM classification, vary widely in their influence. Thus no generalization from the present experiments is possible: the paper describes no more than the effects of the particular admixtures.

Previous Work

In earlier tests (3, 4) creep of concretes containing four water-reducing and set-retarding admixtures was studied. The effects of an admixture were determined by a comparison with an admixture-free, or plain mix, which had the same workability and the same compressive strength at the time of application of the sustained load; such mixes were termed corresponding mixes. Thus the concrete with an admixture had a reduced cement content as well as a reduced water content compared with the corresponding plain mix. As a result, the volumetric content of cement paste in the concrete with an admixture was lower, too.

*Department of Civil Engineering. The University of Calgary, Alberta, Canada.

**Department of Civil Engineering. The University of Leeds, Leeds, United Kingdom.

Now, the influence of cement paste content on creep is such that a concrete with a lower paste content (i.e. with an admixture) would be expected (5) to exhibit less creep than the corresponding plain mix. In fact, in nearly all the tests the opposite was the case. Thus the quantity of the cement paste per unit volume of concrete cannot account for the influence of admixtures on creep. Furthermore, tests on four admixtures have indicated that there is no simple correlation between creep and the chemical group to which the admixture belongs. It appears, therefore, that an explanation of the influence of admixtures on creep must be sought in the quality of the paste, viz. the physical structure of the gel or the properties of the water.

Theoretical Considerations

Cement paste has been shown to be the seat of creep in concrete, the influence of the aggregate being mainly a restraining one (6). Although creep occurs under conditions of hygral equilibrium between the concrete and the ambient medium, such creep being known as basic creep, additional creep takes place if moisture is lost from the concrete while under sustained load; this is known as drying creep (7). While the exact mechanism of creep is still under discussion, it seems likely that creep is closely associated with movement of moisture in the cement gel, this movement being induced by the applied load. Support to this statement is lent by the fact that cement paste containing no evaporable water does not creep (8).

Powers (9) suggested that diffusion of moisture within the cement gel gradually dissipates mechanically induced swelling. The situation is that within the gel there exist voids of different sizes, on the surfaces of which there are formed films some 13Å thick, providing wide enough space is available between adjacent solid surfaces. When this is not the case, adsorption is hindered, and when a compressive stress is applied to a cement paste specimen, the films in the areas of hindered adsorption are subjected to an additional pressure which is brought to a state of equilibrium by diffusion of water from these wedge-shaped crevices into wider spaces. A part of creep can be explained by this diffusion process.

It could be postulated that if moisture movement is the essential element in creep, then the speed or ease of this movement is a factor in creep. It follows that changing the characteristics of moisture movement in cement paste might change its creep behaviour. One way of effecting such a change is to alter the properties of water in the cement paste, e.g. the surface tension of the water. Another way would be to alter the physical structure of the gel in which the moisture movement takes place, i.e. of the solid-water interface. It should be explained that the term water is taken to mean in reality a solution of salts such as exists in hydrated cement paste.

The presence of admixtures can affect the surface forces existing between the water and the gel, with the result that, under an applied sustained stress, the movement of moisture will be facilitated. It is known that some admixtures reduce the surface tension of water, and this could result in an increased magnitude and rate of creep. However, it is also possible that admixtures affect the morphology of the gel so that the surfaces along which moisture has to move are changed.

A morphological change was observed by Young (10) in the case of hydrated C_3A when calcium lignosulphonate was added: instead of the usual hexagonal platey structure there were acicular interwoven crystals. This behaviour was, however, not confirmed (11) in the case of hydration of C_3S with the same admixture.

Even if the behaviour of C_3A with an admixture were the same under conditions existing in a hydrating cement paste as in Young's tests on pure C_3A, the presence of an acicular crystal structure of C_3A may not be important. Tamas (12) points out that aluminates represent only a minor part of portland cement and their hydration products are not only small in absolute amount but also have a specific surface negligible in comparison with the products of hydration of the silicates. He believes, therefore, that it is the hydration of the silicate phase that is changed by admixtures. More specifically, there is activation or de-activation of the reaction between the silicate phase and water, so that with a retarder there is a lower amount of tobermorite gel formed at a given time. Such behaviour represents a change in structure which may be responsible for a variation in creep characteristics of the paste.

Another type of structural change which could occur in hydrated cement paste due to the presence of an admixture is that associated with the geometry and distribution of pores. These properties influence

permeability and strength and may well affect drying creep, which involved movement of moisture from the gel. If this is correct, then the paste with a higher creep should also show a higher loss of water due to a sustained load than a nominally similar paste without an admixture and with a lower creep. Furthermore, high-temperature drying should lead to a differential loss of water in the two pastes, if the admixture indeed affects the size and distribution of pores in the hydrated paste.

To resolve the mode of influence of admixtures on creep, it would be useful to answer the following questions.

1. Do the admixtures used in the previous tests on concrete (3) alter the surface tension of the mixing water?
2. Do the admixtures alter the structure of the cement gel in a manner likely to influence creep? Specifically,
   (a) do they affect the density of the gel?
   (b) do they affect the morphology of the gel?
3. Does either of the changes under 1 or 2, or both, lead to a more rapid or a higher loss of moisture from the specimen of hydrated paste?

Experimental

The tests consisted basically of a comparison of the properties of 6 by 12 in. cylinders of neat cement paste with and without an admixture; two admixtures were used. The properties involved were: the modulus of elasticity of the paste, creep under conditions of drying, density of the hydrated paste, morphology as revealed by a scanning electron microscope. In addition, the surface tension of the mixing water for a series of admixture concentrations was determined.

The same cement was used as in the previous investigation (3); this was a Type III high early strength portland cement, whose properties are given in Table 1. Two commercially produced admixtures were used. According to the ASTM classification, they are water-reducing and set-retarding. Admixture A belongs to Class 3 (hydroxylated carboxylic acid) and admixture B to Class 1 (lignosulphonic acid). The descriptions A and B refer to the same admixtures which were used in the earlier investigations (3, 4). The admixtures were used in amounts prescribed by the manufacturers to achieve normal water-reducing and set-retarding effect.

The mixing water was ordinary tap water at a temperature of approximately 21°C.

The water-cement ratio of the plain mix specimens was 0.4. For the specimens containing an admixture the ratio of the weight of water plus admixture to the weight of the cement was 0.4.

All the specimens were demoulded at the age of 24 hours and thereafter stored in water at a temperature of 21°C. The creep specimens were loaded at the age of 28 days, the nominal stress-strength ratio at loading being 0.50. The load was applied in a testing machine incorporating a load-maintaining device and sustained for 12 hours. The test environment had a relative humidity of 50 ± 5 per cent and a temperature of 21°C. Thus the specimens were drying while undergoing creep so that both basic and drying creep took place. The extent of the latter is, however, not known as the water first lost from a specimen exposed to load and to drying for so short a time (12 hours) is capillary water. Such removal of capillary water may, however, facilitate the movement of gel water, pos-

sibly by inducing a state of tension in the liquid.

The results of the creep tests are given in Table 2. Table 3 lists the strength, the actual stress-strength ratio at application of load, and the secant modulus of elasticity at a stress-strength ratio of 0.50, determined at the same time.

In the moisture loss tests, specimens cured in fog at a relative humidity of 100 per cent for 28 days were dried in an oven at 105°C. The results are presented in Table 4.

Additional tests were made on the density of the fresh cement paste. Here a known volume of compacted fresh paste, 25 minutes old, was weighed with a sensitivity of 10^{-5}. The results are presented in Table 3.

Table 5 gives the surface tension of water with the admixtures in different concentrations. An arbitrary scale is used in which the surface tension of pure water is 100 and that of benzene is 39.7. The surface tension was determined using a capillary rise and fall technique.

Discussion of Results

From Table 2 it can be seen that, compared with the plain mix, admixture A decreases and admixture B increases creep for the 12-hour period under test. When the same admixtures were used in concrete (3, 4) a qualitatively similar effect was observed for periods under load up to 150 days.

Table 5 shows that for the concentration of admixtures used in the present tests the effect of admixture B is to reduce the surface tension of the water by about 3 per cent; admixture A appears to have no effect. While the creep of the paste with admixture B is higher than that of the plain mix, in the case of admixture A there is no accord between the effect of the admixture on the surface tension and on creep. It seems thus that the surface tension effect can do no more than contribute to the influence of the admixtures on creep.

The data on density (Table 3) are of interest: both admixtures cause a decrease in the density of the hydrated paste: about 3 per cent in the case of admixture A, and approximately 4 per cent for B. The difference between the two admixtures may be due to the slight air-entraining properties of admixture B (about 1 per cent in excess of the plain mix). A reduction in density can be interpreted to mean a less well-packed gel which may permit easier movement of moisture, and hence a higher magnitude or rate of creep. However, the decrease in density was not accompanied by a decrease in strength, compared with the plain mix, and may mean increased hydration of the mixes with an admixture. Since the main product of hydration—gel—is responsible for creep, the presence of more gel could account for higher creep. This possibility does not, however, explain the difference between the creep behaviour of mixes with admixture A and B. In any case, the amount of gel present should be checked by measurement of the degree of hydration—a test which was not performed.

The electron micrographs showed no significant morphological difference between the mixes with and without an admixture. The magnification was 15,000 times, which is inadequate to resolve the changes in the gel structure; for this, a magnification ten times greater would be necessary. An indirect indication of the structure of the hydrated paste is

obtained from the values of the secant modulus for the different mixes. Specifically, in comparison with the plain mix, the mix with admixture A has a higher secant modulus and a lower creep; the converse is the case with admixture B. This behaviour was previously found also to exist in concretes with and without the same admixtures, both with lightweight and normal weight aggregates (3, 4).

Perhaps the most significant results obtained in the present investigation concern the moisture loss from the different mixes when subjected to higher temperature. Table 4 shows that, relative to the plain mix, the mix with admixture A loses less moisture (and exhibits less creep); the opposite is the case with admixture B. As pointed out earlier, the water actually lost is probably mostly capillary water but its movement may well affect the internal movement of gel water—a factor in creep.

Summary of Possible Effects of Admixtures

It is possible that the increased creep of the mix with admixture B, compared with the plain mix, can be accounted for by a greater ease of moisture movement within and out of the paste and a lower surface tension of water with this admixture. These two phenomena are likely to be related to one another. There is also a possibility of a change in the gross morphological structure when this admixture is used.

In the case of admixture A, the creep is lower than in the plain mix. The moisture loss of the mix with the admixture was lower than for the plain mix, but the rate of loss was higher in the former case. If this trend continues, it is possible that the ultimate loss of water will be higher in the mix with the admixture. There is no comparable rate-effect in the creep of the two mixes, but it is interesting to recall that in the earlier tests (3, 4) on concrete with admixture A, the rate of creep decreased only slowly with time so that the long-term creep was in most cases higher than for the plain mix. It is conceivable, therefore, that the presence of admixture A leads to a similar increase in creep as in the case of admixture B but with a delay. The reason for this still unconfirmed behaviour of cement paste with admixture A is not known.

Tentative Conclusions

1. There appears to exist a relation between the ease with which water is lost from hydrated paste on heating and the magnitude of creep of mixes with and without the admixtures used in the present tests.
2. The influence of admixture B on the surface tension of water appears to be in accord with the influence on the magnitude of creep; there is, however, no such relation in the case of admixture A. It is, therefore, not possible to correlate the surface tension effect with creep.
3. The density of paste 25 minutes old and creep are related in the case of the mix with admixture B, as compared with the plain mix, but again no such relation exists for admixture A. Thus, the density and creep cannot be correlated.
4. It is possible that admixtures affect the gross morphology of the hydrated paste, and therefore the shape of the stress-strain curve and the creep. A confirmation at the level of gel particle size is still required.
5. It seems from the above that the mechanism through which admixtures influence creep is still uncertain. The present paper has suggested some of the possible mechanisms, which it is proposed to examine in more detail in the future.

Supplementary Paper IV-45 Effects of Organic Compounds on the Hydration Reactions of Tricalcium Aluminate

Kenneth E. Daugherty and Milton J. Kowalewski, Jr.*

Synopsis

At one time it was believed that the hydroxyl-carbon groups found in many organic admixtures might be responsible for the retardation of the reaction of water molecules with cement compounds. It was theorized that the reduced rates and the associated set-delays were a result of hydrogen bonding of the hydroxyl-carbon groups to cement compound surfaces.

A more modern theory stated that the α-hydroxyl carbonyl groups was responsible for the set-delay produced in portland cement on the basis that many set-retarding agents contain or hydrolyzed to give this functionality.

In order to investigate reactions of compounds containing α-hydroxyl carbonyl groups with cementitious materials, the effects of 13 well-characterized, interrelated organic compounds on the hydration reactions of tricalcium aluminate were examined at 25°C. The organic compounds contained various types and numbers of hydroxyl groups and carbonyl groups. The compounds were: acetic acid, glycolic acid, DL-mandelic acid, glyceric acid, ketomalonic acid di-sodium-salt, ethylene glycol, glycol aldehyde, sucrose, D-(+)-trehalose, D-(+)-glucose, fructose, mannitol and sorbitol.

The principal means of investigation was to study the disappearance of tricalcium aluminate and the appearance of new hydrated phases by X-ray diffraction. The method employed in this paper of using a C_3A-C_3AH_6 calibration curve appeared to be a useful method for quantitatively following the course of the hydration of C_3A, both in the presence and absence of organic compounds. For each organic compound, results were obtained covering the period from 22 minutes to 64 days. Sucrose was investigated more intensively as compared to the other organic compounds.

It was found that the hydroxyl groups tend to retard the hydration of tricalcium aluminate and carbonyl groups tend to accelerate the hydration of tricalcium aluminate. The α-hydroxyl carbonyl group itself does not appear to be important in retarding the hydration of tricalcium aluminate though it may be for other cement compounds. Various effects of the blocking action of organic compounds preventing the hexagonal hydroaluminates from forming the cubic hexahydroaluminate are discussed.

Possible mechanisms for the hydration of tricalcium aluminate in the presence of hydroxyl and carboxyl groups are considered.

It has been shown in many investigations that compounds containing hydroxyl and carbonyl groups are important factors in influencing hydration rates and possibly the hydration products of portland cement and its constituents. This paper is concerned with the effects of organic compounds on the hydration reaction of C_3A, and also the role of hydroxyl and carbonyl groups on the hydration of C_3A to the hexagonal hydroaluminates, C_2AH_8 and C_4AH_n, and then subsequent conversion to the cubic hydroaluminate, C_3AH_6.

This paper examines the effects of 13 well-characterized, interrelated organic compounds on the hydration reactions of C_3A in the absence of other ions such as sulphate and calcium. The organic compounds contain various types and numbers of hydroxyl and carbonyl groups. The compounds studied were: acetic acid, glycolic acid, DL-mandelic acid, glyceric acid, ketomalic acid di-sodiumsalt, ethylene glycol, glycol aldehyde, sucrose, D-(+)-trehalose, D-(+)-glucose, fructose, mannitol and sorbitol. Sucrose was investigated more intensively than the other organic

*Technical Center, American Cement Corporation, Riverside, California, U.S.A.

compounds.

The hydration of C_3A in the absence of organic compounds was also studied to provide a control against which to measure the effects of organic compounds. Reactions in which C_3A hydrated more rapidly than C_3A alone were considered to be accelerated by the organic compound. Conversely, those in which C_3A hydrated more slowly than C_3A alone were considered to be retarded by the organic compound.

This investigation is part of a broader study aimed at understanding the interaction of selected organic compounds with inorganic compounds found in cementitious materials.

Forbrich (1) stated that calcium lignosulfonates delayed the time of rapid heat evolution of C_3A, and that orthohydroxybenzoic acid (salicylic acid) had a slight accelerating effect on the hydration of C_3A. Prior and Adams (2) listed some categories of set-retarding admixtures such as lignosulfonic acids and hydroxylated carboxylic acids that are designed to delay initial and final set in a controlled manner. Vivian (3) found that carbohydrates such as sugars, starches, cellulose and hydroxylated carboxylic acids had marked retarding actions on the hydration of portland cement.

Stein (4) observed that in the early stages of the hydration of C_3A at normal temperatures, the formation of C_2AH_8 and C_4AH_{13}, rather than of C_3AH_6, was favored. The conversion of the hexagonal hydroaluminates (C_2AH_8 and C_4AH_{13}) to C_3AH_6 could accelerate the hydration of C_3A by removal of the layer of products formed around the C_3A grains by a solution mechanism. The rate of reaction at the surface and passage of H_2O through the layer of hexagonal hydroaluminates controls the overall reaction. Stein indicated that dislocations intersecting a surface have a significant influence on the hydration rates.

Segalova, Selovéva and Rebinder (5) observed that polar ions in solution can retard the reaction by adsorbing on sites formed by defects and dislocations in the crystalline structure.

Blank, Rossington and Weinland (6) found that calcium lignosulphonate and salicylic acid in aqueous solution were more strongly adsorbed on C_3A and C_4AF than on C_3S and C_2S. This also confirmed the previous work of Ernsberger and France (7).

According to Young (8), lignosulphonates favored the formation of C_2AH_8 and C_4AH_{13} with respect to C_3AH_6 and modified their crystal habit. Such a morphological change can be regarded as a physical consequence of adsorption as postulated by Rebinder (5). Young demonstrated that lignosulphonates definitely inhibited the change from the hexagonal hydroaluminates to C_3AH_6 under normal conditions. Additions of gypsum and lime did not alter the sequence of reactions.

Chatterji (9) has commented that (i) pure salts of lignosulphonic acids were inferior retarders to commercial lignosulphonates; (ii) the reducing sugars were the main active ingredients of the commercial calcium lignosulphonates; and (iii) a mixture of reducing sugars and the pure lignosulphonates was a better retarder than either of the compounds alone. Chatterji also found that higher strength development and a lower rate of hydration went hand in hand with the thinness of hexagonal hydroaluminates.

Feldman, Ramachandran and Sereda (10,11) studied the influence of gypsum and calcium carbonate upon the hydration character of C_3A. They found that the degree to which gypsum retarded the hydration of C_3A at a particular temperature was affected by (i) the concentration of SO_4^{2-} ions on and around the surface of the C_3A; (ii) the rate of reaction of SO_4^{2-} ions with the hexagonal hydro-aluminates; and (iii) the reaction of the hexagonal hydroaluminate layer around the C_3A grains. They have also observed that during hydration the C_2AH_8 and C_4AH_{13} are stabilized if the temperature was low and that increased amounts of $CaCO_3$ progressively inhibited C_3AH_6 formation.

Van Aardt and Visser (12) have shown that C_3AH_6 is unstable at low temperatures and, in the presence of $Ca(OH)_2$ at 5°C, a metastable compound thought to be C_4AH_{19} was formed.

Hansen (13) pointed out that the organic materials used for prolonging the period during which a cement slurry remains sufficiently fluid for transporting by pumps at elevated temperatures generally contained one or more hydroxyl carbon groups. Hansen (14) also suggested that these organic compounds were adsorbed on the cement surfaces so that they retarded the adsorption of hydronium ions on the cement mineral surfaces and slowed down the setting reaction.

Steinour (15) suggested that the activity of retarding was due to hydrogen bonding of the hydroxyl groups. Hydroxyl carboxylic acids such as tetrahydro-adipic acid may undergo intermolecular association by hydrogen bond formation whereby a hydroxyl group in one molecule may react with a hydroxyl group in another molecule. Steinour also suggested that compounds with several hydroxyl groups appeared generally to be strong retarders in portland cement pastes.

Stein (17) concluded that all polyalcohols exhibited a retarding action on portland cement hydration. With the use of gypsum, ettringite coatings on the C_3A were replaced by C_4AH_{19} formations that created

heat. Eventually the C_4AH_{19} formation dissipated and more hydration occurred toward the final C_3AH_6 phase.

Seligmann and Greening (16) have found that materials which cause retardation of set, such as sucrose or lignosulfonates, can also produce a large initial acceleration of the hydration reactions of portland cement paste. They found that 1 g of C_3A will remove 99% of the sugar from 5 cc of a 1% sucrose solution within 7 minutes. Gypsum or $Ca(OH)_2$ did not interfere with the process. They also showed that if the C_3A were allowed to hydrate for several minutes in the absence of sucrose and then sucrose was added, the sorption of the sucrose was reduced.

Taplin (18) studied a wide range of set-retarding agents on portland cement. Surprisingly, he found that they nearly all contained the α-hydroxyl carbonyl group.

Bruere (19) found that α, α-trehalose (D-(+)-trehalose) possessed only weak retarding properties in portland cement pastes whereas all of the other sugars studied in his investigation were powerful set-retarding agents. D-(+)-trehalose did not contain the α-hydroxyl carbonyl group nor did it form this group in an alkaline medium. Bruere found that the other sugars either contained the α-hydroxyl carbonyl

Table 1. *List of the organic compounds used.*

#	Compound name	Empirical formula	Compound structure	Molecular weight
1	Acetic acid	$C_2H_4O_2$		60.05
2	Glycolic acid	$C_2H_4O_3$		76.05

13	Sorbitol	$C_6H_{14}O_6$		182.17

group or were capable of forming it in an alkaline medium, such as exists in portland cement paste. Bruere (20) supported Taplin's (18) beliefs that the α-hydroxyl carbonyl group was the active adsorbing group in many set-retarding agents in portland cement paste.

From a review of the literature mentioned above, it was thought that the adsorption of α-hydroxyl carbonyl groups on C_3A might play a major role in governing the effectiveness of retardation. Also, it was of interest to the authors to determine the relationships of carbonyl and hydroxyl groups relative to the set-retardation of C_3A hydration in the absence of sulphate and calcium ions. With this in mind, the effects of simple, well-characterized, interrelated, water-soluble organic compounds containing varying numbers and types of hydroxyl and carbonyl groups were studied in the hydration reactions of C_3A. (See Table 1). Special emphasis was placed on sucrose because it is the best characterized and best known of the common retarders.

Reagents

C_3A Preparation

Many methods have been suggested for the preparation of C_3A. Among them are those of Van Aardt and Visser (20), and Seligmann and Greening (21). However, the following method was found to be more effective in yielding high purity C_3A with little difficulty:

Two moles of $Al(OH)_3$ and a 1/1000 mole excess of $Al(OH)_3$ and 3 moles of $CaCO_3$, all of Baker analytical reagent grade, were blended in a ball mill for approximately 12 hours. The blended powder was transferred to platinum crucibles (100 gram capacity) and heated in an electric furnace for 2 hours at 900°C. The crucilbes containing the calcined material were then transferred to a Leco electric furnace for at least 6 hours at 1455°C. The material was air-cooled to room temperature and ground to −200 mesh (−74 microns) in an agate ball mill. It was felt that the use of a glove box was unnecessary. Some material was also ground to −325 mesh (−43 microns). The sieves used throughout this investigation were Tyler Standard Screen Scale Sieves.

The X-ray powder diffraction analysis showed no trace of CaO or $C_{12}A_7$ or other impurities. (Fig. 1). The pattern was in excellent agreement with the C_3A pattern of Swanson, Gilfrich and Ugrinic (22). The C_3A was also analyzed by Diamond (23) and his analysis was in excellent agreement with the authors. The free lime chemcial analysis by the method described by Lea and Desch (24) showed less than 0.1% CaO.

The C_3A was stored under desiccation using Ascarite and Anhydrone. The C_3A is believed to be of the highest purity available. The −200 mesh C_3A had a surface area of 0.46 m^2/g. The surface areas were determined by N_2 adsorption using a Perkin-Elmer-Shell Model 212 Sorptometer (BET method). The −200 mesh material was used throughout the investigation unless otherwise noted.

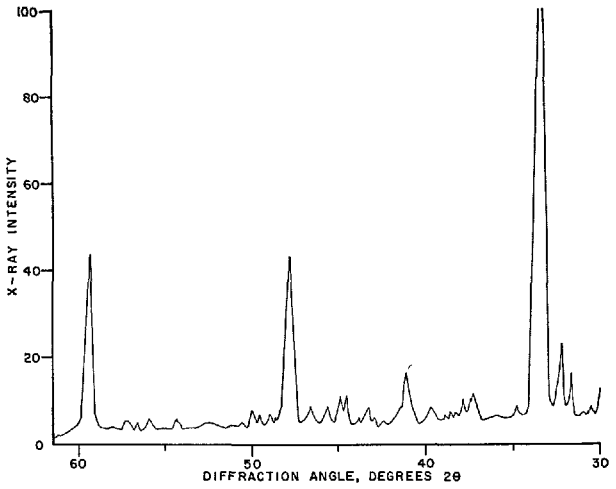

Fig. 1. *X-ray powder diffraction pattern of pure* C_3A.

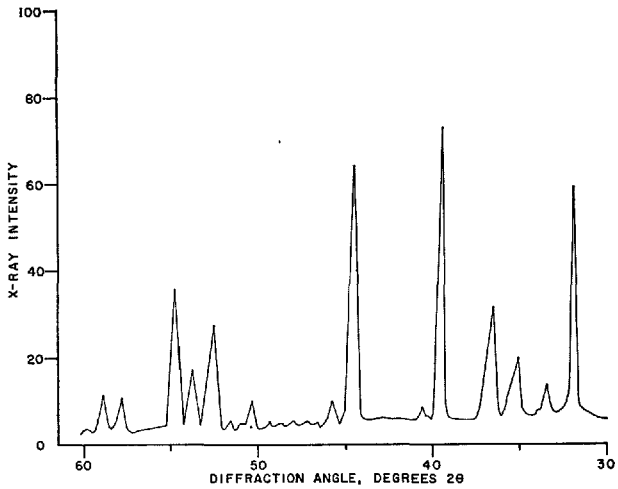

Fig. 2. *X-ray powder diffraction pattern of pure* C_3AH_6.

C_3AH_6 Preparation

A number of methods have been suggested for the preparation of C_3AH_6 including those of Stein (25), and Van Aardt and Visser (26). The following method was found to be particularly effective in yielding high purity C_3AH_6 with little difficulty:

C_3A was mixed with distilled H_2O and ice chips at a H_2O/C_3A ratio of greater than 10 for 60 minutes at 25°C in a Spex mill. The ice had melted by this time and the container was placed in a 15°C chamber for 16 hours. The samples, which were completely hydrated, were then heated to 150°C for 2 hours in order to drive the intermediate metastable C_2AH_8 and C_4AH_n compounds to C_3AH_6.

X-ray powder diffraction analysis showed that the material was completely hydrated with no detectable traces of C_3A, C_2AH_8, C_4AH_n or other impurities. The X-ray pattern was in excellent agreement with the pattern described by Thorvaldson, Grace and Vigfusson (29) (Fig. 2).

The C_3AH_6 had a surface area of 1.7 m^2/g as determined by N_2 adsorption.

Organic Compounds

The compounds used in this study were well-characterized and of reagent grade purity (See Table 1). Acetic acid (No. 1), glycolic acid (No. 2), glyceric acid (No. 4), ketomalonic acid di-sodiumsalt (No. 5), ethylene glycol (No. 6), D-(+)-trehalose (No. 9), mannitol (No. 12) and sorbitol (No. 13) were obtained from Aldrich Chemical Company. DL-mandelic acid (No. 3) and fructose (No. 11) were obtained from Matheson, Coleman and Bell. Glycol aldehyde (No. 7), sucrose (No. 8), and D-(+)-glucose (No. 10) were obtained from Allied Chemical Corporation.

Instrumentation

X-ray Diffraction Analysis

The X-ray diffraction analyses conducted throughout this investigation were at 25°C using nickel-filtered copper Kα radiation at 45KV and 35 mA and a Norelco proportional counter and diffractometer. The X-ray scanning was conducted at a rate of 2° 2θ/min with a 2° divergence slit, a 2° scatter slit, a 0.006 inch receiving slit and a time constant of 4 seconds. An automatic sample changer described in the paper by Berger, Frohnsdorff, Harris and Johnson (28) was employed for routine sample analysis.

Method of Analysis

Preparation of Standard Calibration Curves

A series of 16 samples (Table 2) were prepared ranging from 100 mole % C_3AH_6 and 0 mole % C_3A to 0 mole % C_3AH_6 and 100 mole % C_3A. The samples were weighted to a 1/10 of mg, blended in an agate mortar, funneled to produce a homogeneous material, blended again, funneled again, and blended again in order to produce the samples for X-ray powder diffraction analysis. The loss in the overall preceding operation was less than 1%.

X-ray diffraction patterns were run on each smaple. An example of the pattern produced with 35.27 mole % C_3A and 64.73 mole % C_3AH_6 is found in Fig. 3. The intensities were determined for the 33.3°2θ, 47.7°2θ and 59.7°2θ peaks of C_3A and the 39.3°2θ, 44.4°2θ and 54.6°2θ peaks of C_3AH_6. The preceding

100% C_3AH_6 and 0% C_3A and 100% C_3A and 0% C_3AH_6. The theoretical curve can be seen as a dotted line in Fig. 4.

C_3A/C_3AH_6 ratios were then calculated from the intensity ratios $^{1}33.3°2\theta/^{1}39.3°2\theta$, $^{1}47.7°2\theta/^{1}44.4°2\theta$, and $^{1}59.3°2\theta/^{1}54.6°2\theta$. The three ratios were then averaged and, for convenience, multiplied by a constant 3.333 in order to produce a graph of per cent unhydrated C_3A vs ratio of C_3A/C_3AH_6 with 0.01 in the lower left hand corner (Fig. 4). The calculations were greatly facilitated by the use of a time-sharing computer which saved many hours of calculations.

The calibration curve (Fig. 4) was then used for computing from X-ray diffraction data the per cent hydration of C_3A in samples hydrated in the presence of the organic compounds.

The calibration curve agreed well with the theoretical curve based on mass absorption coefficients for peaks were selected because of their high intensities and little interference.

Preparation of C_3A Samples with Organic Compounds

A series of 7 samples was prepared for each organic compound (Table 1). Each sample contained 10 mg of organic compound, 1 g of C_3A and 0.6 ml of distilled H_2O. A standard solution was prepared for each organic compound containing 167 mg of organic compound and 10 ml of distilled H_2O. A volume of 4.2 ml of this solution was added to 7 g of C_3A in a 25 ml beaker and mixed by hand for 2 minutes with a glass stirring rod.

The resulting mixture had a H_2O/C_3A ratio of 0.6 and contained 1% by weight of organic compound to C_3A. A H_2O/C_3A ratio of 0.40 is the stoichiometric ratio necessary to hydrate C_3A to C_3AH_6. The samples were divided immediately into 7 equal-sized portions and placed in 7 ml glass vials and capped with plastic snap-top lids. The samples were then transferred to an environmental chamber held at 25°C. The quantity of H_2O evaporated from these vials was less than 1.5 weight % of sample in the first 5 days.

The samples were stored in the chamber for 22 minutes, 90 minutes, 6 hours, 24 hours, 4 days, 16 days and 64 days. The samples were desiccated immediately upon removal from the chamber using a Welch vacuum pump, a glass vacuum desiccator and an Anhydrite drying tower. The samples were desiccated for 12 hours and the hydration reactions were

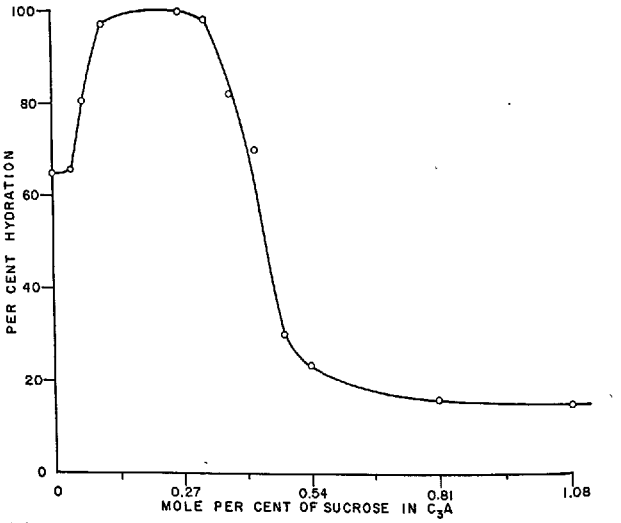

Fig. 7. *Effect of varying concentrations of sucrose on the hydration of* C_3A *after 24 hours hydration at 25°C.*

arrested. The samples were ground to —325 mesh in an agate mortar and analyzed by X-ray diffraction. The samples before and after grinding were kept in the glass vials with the lids in place. The samples in the glass vials with the lids removed were then heated to 160°C in an oven for 12 hours in order to convert any hexagonal hydro-aluminates to the stable

cubic C_3AH_6. Lea and Desch (29) have stated that the metastable hexagonal hydroaluminates convert more rapidly with rising temperature to the stable cubic C_3AH_6. The samples were again analyzed by X-ray diffraction without grinding. The extent of the hydration of the C_3A to C_3AH_6 after the heat treatment is found in Fig. 5 and 6. The hydration of C_3A in the absence of other organic compounds is also plotted in Figs. 5 and 6. These curves were obtained in an identical manner as the C_3A samples containing organic compounds.

Preparation of C_3A Samples with Sucrose

The effect of sucrose on the hydration of C_3A was studied in greater detail than for the other compounds because of wide interest in this particular compound.

Sucrose was dissolved in distilled H_2O and added to C_3A in a series of different molar concentrations at a H_2O/C_3A ratio of 1.0. This was done in the manner described in the previous section.

The samples were stored for 24 hours in the chamber at 25°C, vacuum desiccated as described previously, heated as described previously and analyzed by X-ray diffraction. (Fig. 7).

Results and Discussion

Quantitative X-ray diffraction has been found to be a convenient method for following the hydration of C_3A with time (Fig. 4). The results following these hydration reactions have been found to be reproducible to within $\pm 3\%$ of the quantity present.

The results of the data in Fig. 5 and Fig. 6 are self-explanatory for the per cent hydration of various organic compound-C_3A mixtures with time on a log 4 basis. However, it should be pointed out that during the first 22 minutes the hydration of the organic compound-C_3A mixtures was very rapid. C_3A hydrated 43%, the sugars and sugar derivatives hydrated less than 10% and a couple of the acids hydrated better than 50%. It is interesting that mandelic acid which contains an α-hydroxyl carbonyl group is an accelerator and sucrose which forms an α-hydroxyl carbonyl group as an alkaline medium (19) is a retarder of C_3A hydration.

The hydration of C_3A is believed to proceed through the initial formation of the metastable phases of C_2AH_8 and C_4AH_n followed by their subsequent transformation to the more stable phase, C_3AH_6, which is the only stable aluminate hydrate existing over a wide range of temperatures (30).

$$2C_3A + (n + 8)H_2O \longrightarrow C_2AH_8 + C_4AH_n \longrightarrow 2C_3AH_6 + (n - 4)H_2O$$

Some of the organic compounds block the hydration at the metastable phases while others permit the reaction to proceed to C_3AH_6. In general, the accelerators (acids) permit the hydration to proceed to C_3AH_6 while the retarders (sugars and sugar derivatives) block the reaction at the metastable phases. Table 3 lists the organic compounds and indicates their effectiveness in blocking the hydration of C_3A at 1 day of hydration and at 64 days of hydration.

Table 3. *Interpretation of data listed for compounds in increasing effectiveness of blocking the formation of C_3A hydrates based on data taken from X-ray powder diffraction patterns at a H_2O/C_3A ratio of 0.6 and a temperature of 25°C.*

$$2C_3A + (n + 8)H_2O \longrightarrow C_2AH_8 + C_4AH_n \longrightarrow 2C_3AH_6 + (n - 4)H_2O$$

Based on effectiveness of hydration evaluated in 2 ways:
(1) at 1 day
(2) at 64 days

Compound No.	Compound name	1 Day	64 Days
3	DL-mandelic acid	–	–

13	sorbitol	+	+
9	D-(+)-trehalose	+	+

Symbols:
+ Organic compound blocks the hydration of C_3A at the metastable phases C_2AH_8 and C_4AH_n.
– Organic compound does not block the hydration of C_3A at the metastable phases C_2AH_8 and C_4AH_n and the stable phase C_3AH_6 is formed.

The −325 mesh C_3A hydrated more rapidly than the −200 mesh C_3A. The hydration increase was on the order of 7%.

Fig. 7 clearly demonstrates that sucrose in small concentration acts as an accelerator and in higher concentration acts as a retarder. Sucrose in a concentration of 0.27 mole % corresponds to 0.34 weight %. Sucrose was found to effectively retard the hydration of C_3A at concentration levels as high as 20 mole %

in C_3A.

The initial acceleration effect in Fig. 7 for sucrose has been observed for all of the sugars and sugar derivatives found in Table 1 at concentration levels of 0.25 mole % relative to C_3A.

Additions of 0.2 mole % free lime relative to C_3A to the sucrose-C_3A samples shifted the curve in Fig. 7 to the right.

A possible explanation for the preceding results might be the following: In concentrations of 0.3 mole % or less relative to C_3A the organic materials complex or chelate with available calcium ions (and other cations) in solution and on the surface of the C_3A. These reactions might affect the rates of solution of C_3A and the solution, precipitation or nucleation of the hydration products in a manner which accelerates hydration.

After the available calcium is tied up, the organic material is adsorbed on the surface of the C_3A. This adsorption may be chelation with calcium in the C_3A, complexation, or surface adsorption depending upon the type of organic molecule. In general, chelates and complexes at high pH levels are stable and have low solubilities in water if they are relatively free of groups that can be hydrated. The greater the size of the hydrocarbon groupings, the lower will be the solubility in water (31). These concepts might prove useful in determining the effectiveness of organic compounds as retarders and accelerators.

Organic compounds with more insoluble calcium salts would be expected to form more closely packed, more impervious sheaths around the C_3A. This might prevent H_2O from further attacking the C_3A. The organic layers could prevent the intermediate products, C_2AH_8 and C_4AH_n, from transforming to C_3AH_6. Retardation of hydration would be the result.

Sucrose can form many different complexes with calcium and similar organic molecules can be expected to behave similarly. Among the calcium complexes of sucrose that can form in lime solutions are $C_{12}H_{22}O_{11} \cdot CaOH$, $(C_{12}H_{22}O_{11})_2$ Ca and $(C_{12}H_{22}O_{11})$ Ca–O–Ca$(C_{12}H_{22}O_{11})$ (32).

Some compounds such as ethylene glycol appear to be effective retarders in early hydration reactions and accelerate hydration in later stages.

The mechanism of retardation and acceleration of organic compound-C_3A systems is open to speculation and further work is aimed at examining these phenomena. It is without question that the type of organic compound and the rates of solution, nucleation and precipitation of the various species in the hydrating system are important.

Various instrumental means of investigating organic compound-C_3A reactions were considered. For this particular study X-ray diffraction was found to be more directly applicable, however, it is to be expected that the supplementary use of calorimetry, electron microscopy, and other techniques will lead to a better understanding of the mechanism of hydration of organic-cementitious materials.

Conclusions

The following conclusions apply to a temperature of 25°C, a H_2O/C_3A ratio of 0.6 and 0.1 weight % to 1.0 weight % additions of organic compounds to C_3A:

1. Water-soluble organic compounds containing hydroxyl, carboxyl or carbonyl groups act as either accelerators or retarders for the hydration of C_3A depending upon their concentration levels and composition.
2. The α-hydroxyl carbonyl group itself does not appear to be especially important in the hydration of C_3A, though it may be for other cement compounds.
3. The carboxyl group (acids) tends to accelerate C_3A hydration and the hydroxyl group (sugars) tends to retard hydration.
4. Mandelic acid is a strong accelerator for the hydration of C_3A.
5. Of the compounds examined, sorbitol is the most effective retarder of C_3A hydration on a weight basis.
6. Some organic compounds appear to block the conversion of C_2AH_8 and C_4AH_n to C_3AH_6 while others permit the C_3AH_6 to be formed readily:
   (a) In general, the organic acids permit the hydration of C_3A to proceed to C_3AH_6.
   (b) In general, sugars and their derivatives, block the hydration reactions at C_2AH_8 and C_4AH_n.
7. A simple organic compound containing a carboxylic acid group and zero or one hydroxyl group will accelerate C_3A hydration and a simple organic compound containing two or more hydroxyl groups will retard C_3A hydration.

Oral Discussion

Shigeaki Koide

A discussion of influences of some organic groups on the hydration process of tricalcium aluminate is of much interest. The actions of the groups, however, for the hydration of CA are different from that just mentioned in the paper. We have found that the carboxyl group has always retarded the hydration process of CA irrespective of its concentration and the species of compounds, and lowered the heat liberation during hardening. The effect is especially marked when the group were contained in the chelate compounds, for instance, EDTA which produces the sexadentates with a high stability constant. On the other hand, such chelate compounds that produce tetradentates or sexadentates with rather low stability constants have been less effective. On the basis of the results, the retarding action of the group is considered to be due to the ligand compounds temporarily produced between Ca^{++} or aluminum ion and carboxyl group.

On the retarding or accelerating mechanism of the hydration process of tricalcium aluminate in the presence of the organic groups, we should like to ask the author's opinion.

Authors' Closure

K.E. Daugherty and M.J. Kowalewski, Jr.

We appreciate the comments of Mr. Shigeaki Koide.

We agree that the reactions of various organic groups are different for monocalcium aluminate (CA) as compared to tricalcium aluminate (C_3A). In this paper, only the results of our studies with C_3A are described. The work that we have done with CA also indicates that the carboxyl and hydroxyl groups generally retard hydration. We have some evidence, however, that this is not always true.

The retarding action of the organic functional groups on C_3A, CA and other similar compounds is considered to be due to the ligand compounds produced between the calcium ions, aluminate ions and the organic groups. The concentration and type of hydroxyl and carboxyl groups will determine the stability constants, as well as complex or chelate formation.

In our paper we have considered complexes to be those which are produced when a metal ion combines with an electron donor. A chelate is a substance that has combined with a metal and contains two or more donor groups so that one or more rings are formed. Our views on the retarding and accelerating mechanism of the hydration process of C_3A in the presence of organic groups are found in the results and discussion section of our paper. We have found no reason to alter our views and they correlate well with the thoughts of Mr, Shigeaki Koide.

Supplementary Paper IV-51 Abnormally Delayed Setting of a Low-Heat Portland Cement with Calcium Lignosulphonate Admixtures

René J. Bauset*

Synopsis

Abnormally long setting times occurred in the concrete at two sites of the Quebec Hydro-Electric Power Commission's project on the Manicouagan River. The project was supplied at the time with a low-heat portland cement from three manufacturers.

Data is presented showing field performance tests and preliminary tests undertaken for acceptance of the admixture. Data outlining the history of cement supply is reviewed.

A conclusion is reached that the slow setting was due to an overdosage of calcium lignosulphonate admixture with a low SO_3 type of portland cement.

Introduction

Full development of the Manicouagan and Outardes rivers was begun in the autumn of 1959. These rivers flow parallel and close to one another, emptying into the Gulf of St. Lawrence near Baie-Comeau, a seaport located about 400 miles' northeast of Montreal, Canada. The development comprizes seven power-houses with a total installed capacity of 5.5 million kW.

Manicouagan 5 is a multiple-arch dam requiring over 2,900,000 cubic yards of high strength concrete for its construction. The Manicouagan 2 dam is a hollow-joint gravity structure requiring a little under 1,000,000 cubic yards of lean concrete in its mass, and 3,000 psi concrete on its faces.

Because of the logistics of the entire development project, the same low-heat portland cement was used for both dams.

Field Observations at Manic 2

In September 1963, the green-cutting crew noticed that sections of a 1,000 cubic yard monolith had not yet set. Inspection indicated that concrete had stopped hardening at the initial set while adjacent concrete had hardened normally. Field laboratory tests showed that with the cement we had in stock in the laboratory, long delays in the time of set were obtained only by quadrupling the dosage of the water reducing retarder (Table 1).

Table 1. *Effect of a calcium lignosulphonate admixture on the compressive strength development of an air-entrained concrete made with a low-heat portland cement (LAB No 631017)*

*Cylinders not taken.
Field tests at Manic 2, September 1963.

*Hydro-Quebec, Montreal, Canada.

Since the field personnel were positive that no more than double dosage had occurred, investigations were then directed to the cement. Attention was also directed to a similar case of slow-hardening concrete reported by Tuthill (1).

Further studies made during the winter slack season showed that difficulties corresponded to arrivals of cement from one of the three suppliers.

Field Observations at Manic 5

The commercial grade, de-sugarized, calcium lignosulphonate type of water-reducing agent used at Manic 2 having been proved unsatisfactory, a proprietary mixture with a long history of successful application was accepted for use at this site. Batching of concrete with this admixture started on the 18 th of May, 1964.

On the 20th, it was noticed that standard cured samples of concrete were not setting. But the accelerated cured concrete sample showed normal results averaging 4,995 psi after 48 hours in a water bath maintained at 170°F $\pm$ 2°. At the end of two weeks, all the standard-cure cylinders showed a potential strength of almost 4,200 psi.

The concrete placed in the field was observed for the next 9 days with no apparent development of set. Because production delays were becoming intolerable, the field staff proceeded to remove 620 cubic yards of "soft" concrete at a total cost (direct cost and lost production time) of six times the original in-place cost.

Performance Tests, Manic 5

The first series of tests evaluated the admixture in mixes used for compressive strength testing of cement (2). Results are shown in Table 2. It can be seen that mixes prepared with cement A had a long hardening period and the compressive strength after 5 days was extremely low. But a reduction of dosage to 0.15% of admixture restored considerably the rate of strength gain. The compressive strengths with the reduced dosage for cement A were similar to those with 0.3% addition to cement B. Subsequently, tests were done on over 50 samples of cement A that were taken from three 6,500-ton shipments received from manufacturer A during the period under review. All showed excess retardation of around $4\frac{1}{2}$ days with relatively low compressive strength obtained at 7 days. But the 90-day strengths were all well above our specified values.

Table 2. *Effect of a calcium lignosulphate proprietary admixture on compressive strength development for two different low-heat cements*

Discussion

Performance tests prior to these setting "failures" had shown that low-heat cement showed excess retardation with admixtures. One potential supplier of admixtures had reported early in 1963 that his product, although satisfactory from the standpoint of strength benefit, would not be acceptable on the basis of the rate of hardening results. His graph of Proctor penetrometer results with cement No. 630110 shows an 8-hour retardation for the final set.

Further studies on 5 different admixtures were done and it was found that all retarded the hardening of concrete for approximately the same period. Since this retardation was acceptable to the field staff, one of the admixtures reported on Fig. 1 was accepted and was the one eventually involved in the excess retardation reported at Manic 5.

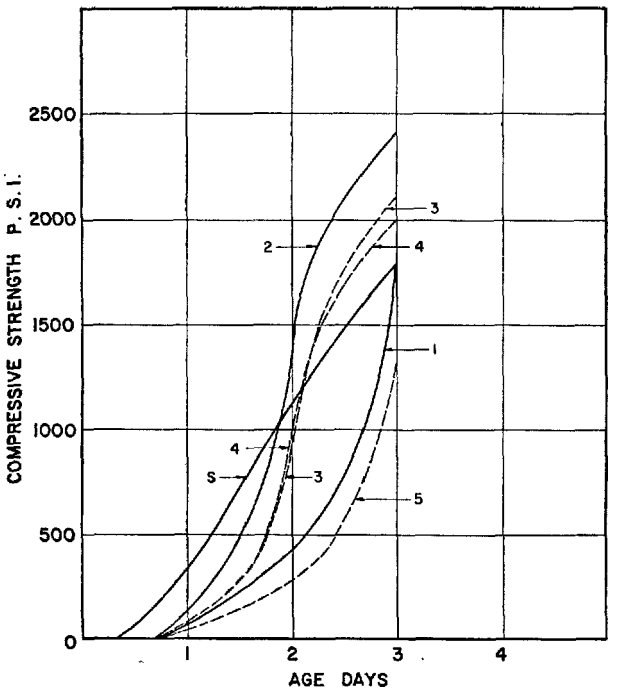

Fig. 1. *Effect of five different lignosulphonate admixtures on early age strength development.*

When the admixtures were tested in 1963, the characteristics of cements were as shown in Tables 3 and 4. All are low C_3A, moderately-high alkali cements ground to an average 3290 cm²/gm fineness. The low heat of hydration requirement combined with high strength also dictates low additions of gypsum to the clinker (3). It is therefore probable that the time for initial set is determined by the exhaustion of the gypsum (4). Fig. 2 shows the effect of gypsum on the setting time of a cement made by manufacturer A. In order to stay within the specified setting times, lower percentages than needed for optimum performance were most probably used, as is indicated by the physical data of these cements shown in Table 5.

Effect of Calcium Lignosulphonate on the Setting Characteristics of Low Heat Portland Cement from Plant A.

Further tests on the setting characteristics of cements P–143–1–to–6 showed that the retarding effect of the admixture was very pronounced for cements contain-

ing 1.1% SO_3. It was concluded that the dosage of the admixture should not exceed 0.2% for cements containing less than 1.6% SO_3 and that the normal dosage of 0.3% could be used with cements around 2% SO_3.

Having discounted the possibility of a high sugar content lignosulphonate being used, and the possibility of overdosage of the admixture and delayed addition of the admixture, then the SO_3 content of these cements determined the dosage of the retarding admixtures. Seligmann & Greening (5) reported that, for the similar case reported in California (1):

"The observed excessive retardation resulted from a combination of factors and a chain of events that ultimately caused a lack of sufficient alkali release during the early hydration of the cement."

Table 4 illustrated a significant drop in alkalies for cements A-1 and A-2, which could be a contributory factor in this instance.

Table 5. *Physical characteristics of cements from manufacturer A used in laboratory investigation of effect of gypsum content*

Conclusion

Whenever preliminary studies show a tendency for an admixture to retard excessively the set of a cement, careful consideration should be given to its use in the field. If used with low C_3A and low SO_3 cements, each shipment of these sensitive cements should be checked in order to avoid delays in construction due to excessive retardation.

When very long retardation periods are required, the effect of overdosages of the retarder should also be tested in order to establish a limit. The required dosage should be well within this limit in order to allow for field errors.

Post Scriptum

Both of these dams were completed without the use of retarding admixtures. The cement specification was also changed to allow wider latitude in setting times, thus permitting optimum addition of gypsum. This cement has since been used successfully in concretes with admixtures.

Supplementary Paper IV-89 Investigations on the Method of Test for Setting Time of Concrete Especially of Concrete Containing Water Reducing Admixture

Jiro Okabe, Koji Nakajima and Takuji Yoshihara*

Synopsis

Time of setting is one of the most important properties of concrete. Setting time of concrete depends upon the hydration velocity of the cement in concrete. Therefore, the rate of the setting of cement has a much significance for the use of cement in mortar and concrete. However, the setting time of cement is determined by the tests on cement paste and have not much significance for the estimation of the setting time of concrete.

In order to determine the setting time of concrete, the penetration resistance method is being used widely. This method requires concrete whenever the setting time is determined. For convenience, use of mortar in lieu of concrete is being tried sometimes. However, it has not been clarified whether or not the mortar sieved from concrete and the mortar prepared by a mortar mixer give the same setting time.

In order to establish the testing method by using mortar in lieu of concrete, the accuracy of this method is examined and the effects of the change in proportion, mixing condition and temperature on the setting time are studied. The following results are obtained.

(1) The setting time of concrete can be determined by using the mortar prepared by a mortar mixer.

(2) The setting time of the mortar is influenced by various factors, especially when the admixtures are used.

(3) Therefore, the test should be performed as follows: 1) The water-cement and sand-cement ratio shall be identical with that of the concrete, 2) The same materials as in the concrete shall be used, 3) The same mixting sequence shall be used, 4) The mixing period of the mortar shall be determined depending upon the kind of the mixer used.

The effects of various factors on the setting time of the concrete or the mortar containing the admixture are also discussed.

Introduction

Time of setting is one of the most important properties of concrete. The acceleration of the time of setting and hardening of concrete is required in the precast concrete industries, and in cold weather concretings, while the retardation of the time of setting and hardening of concrete is also required for the manufacture of the massive concrete and in hot weather concretings. Consequently, set controlling admixtures for accelerating and retarding the setting time have been widely used in concrete manufacture.

Setting time of concrete depends upon the hydration velocity of the cement in concrete. Therefore, the rate of the setting of cement has a much significance for the use of cement in mortar and concrete. In the specification of cement, the requirements for the initial and final set of cement are prescribed. Initial and final set of cement are defined by the methods of testing that determine the time when neat cement paste shows an arbitrary defined resistance to a particular deformation (1). However, setting time of cement is determined by the test on cement paste made with a water-cement ratio and a mixing condition which are completely different from that of concrete. Indeed, this test is normally made for the purpose of finding out the false set of cement. Therefore, the setting time of cement have not much significance for the estimation of the setting time of concrete. Especially for the concretes containing water reducing and set controlling admixtures, it is impossible to know the time of setting of concrete from the test for cement paste (2). The reaction velocities of the process of setting can be determined by many other methods. These include the measurements of change in electrical conductivity (3), electrical potential (4), heat evolu-

*General Research Laboratory, Sanyo Pulp Co., Ltd., Iwakuni, Japan.

tion (5), etc. However, these are not being used as the practical method to determine the setting time. In order to determine the setting time of concrete, the penetration resistance method (6) is being used widely. This method provides a procedure for determining the times of initial and final setting of concrete by measuring the penetration resistance of the mortar sieved from the concrete mixture (Concrete method). Unfortunately, the concrete test requires great quantities of materials and a long time. And the results obtained vary widely with the change in the places and dates of testing, materials used and mixing conditions.

As a more convenient method, use of mortar in lieu of concrete has been tried occasionally (Mortar method). However, it has not been clarified whether or not the mortar sieved from concrete and the mortar prepared by a mortar mixer give the same setting time. It was observed in our laboratory that, when water reducing admixtures are used, the setting time of the concrete differed widely from that of mortar prepared by a mortar mixer.

Hence, the investigation on the use of mortar in lieu of concrete is carried out when lignosulphonate water reducing admixture, water reducing and retarding admixture and water reducing and accelerating admixture are added to cement.

Furthermore, the effects of various factors on the setting time are investigated by using mortar test.

Experimental

Materials

Cement

Normal portland cement is used. The quality conforms to the specification of normal portland cement in JIS (Japan Industrial Standard) R 5210 (7). In Table 1, the composition and the physical properties of the cement is shown.

Table 1. *Composition and physical properties of cement*

Ignition loss (%)	Tricalcium silicate (%)	Tricalcium aluminate (%)	Initial set (hr-min)	Final set (hr-min)
0.6	50.0	9.0	2–40	3–58

Fine Aggregate

River sand at Nishiki river (Iwakuni, Japan) is used. Specific gravity, absorption, fineness modulus and maximum size of the sand is 2.59, 1.80%, 3.04 and 5.0 mm, respectively.

Coarse Aggregate

River gravel at Nishiki river is used. Specific gravity, absorption, fineness modulus and maximum size of the gravel is 2.64, 1.20%, 7.10, 25 mm, respectively.

Admixtures

Three kinds of lignosulphonate water reducing admixtures which conform to the specifications of Type A (Normal), Type D (Retarding) and Type E (Accelerating) water reducing admixture in ASTM C494–65T, respectively, are used.

Test for Setting Time of Concrete (Concrete Method)

The initial and final setting time of concrete are determined with the penetration resistance apparatus (Proctor penetration resistance needle) according to ASTM C403–65T.

Test for Setting Time by Using Mortar in Lieu of Concrete (Mortar Method)

The mortar mixer used is of the ASTM C305 type (8). Mortar is mixed by the following methods.

1. Saturated surface dry fine aggregate, cement and water or an admixture solution are placed in the bowl, then mixed at the slow speed (140 rpm) for three minutes (Method M1).

2. Saturated surface dry fine aggregate and cement are placed in the bowl and premixed at the slow speed for 1 minute, the mixer is stopped and water or an admixture solution is added to the mixture, then mixed again at the slow speed for three minutes (Method M2).

The initial and final setting time of the mortar are determined by the method prescribed in ASTM C403–65T.

As the amount of the mortar prepared by this mixer is not enough to prepare the specimen, the mixing is performed twice and the first mortar mixture is placed in the lower part of the test container.

Preparation of Concrete

A revolving drum tilting mixer (size is 2 ft^3) is used. Proportions of the concretes are indicated in

Table 2. The concretes are mixed by two methods as follows.

1. Fine aggregate, coarse aggregate and cement are placed in the mixer, then water or an admixture solution is added. After all the materials have been introduced into the mixer, the concrete is mixed for three minutes (Method C1).

2. Saturated surface dry fine aggregate, dry coarse aggregate and cement are mixed for 1 minute without water addition, then water or an admixture solution is added and mixed for three minutes (Method C2).

Table 2. *Proportions of concretes*

Kind of admixture	Slump (cm)	Air (%)	Water/Cement (%)	Sand/Aggregate (%)	Sand/Cement (%)	Cement (kg/m³)
none	7.3	2.0	52.7	40	254	300
Type A	7.9	4.8	45.0	37	233	300
Type D	8.7	4.2	45.0	37	233	300
Type E	7.9	4.2	45.0	37	233	300
none	18.4	1.3	63.3	44	268	300
Type A	18.1	3.8	53.1	41	250	300
Type D	18.0	4.4	53.1	41	250	300
Type E	17.3	4.0	53.1	41	250	300

Results and Discussions

Applications of the Testing Method by Using Mortar in Lieu of Concrete

It was observed occasionally that the setting time determined by using the mortar in lieu of concrete (Mortar method) was not identical with that determined by using the mortar sieved from the concrete (Concrete method). Therefore the factors affecting the setting time was studied. After the extensive work, it is concluded that both methods give the same results when the same proportion, mixing sequence, mixing period and temperature are used.

The initial and final setting times of concretes are determined by testing mortars sieved from the concrete mixtures in accordance with ASTM C403–65T. The proportions of concretes are shown in Table 2, and the times of setting are shown in Table 3.

In this method, the mixing of concrete is carried out according to the Method C1. That is, after all the materials has been introduced into mixer, the mixing is started. The mixing is continued for 3 minutes. The materials are kept at 20°C and the experiment is carried out at 20°C.

The setting time of mortars is determined by the Mortar method. The same cement and fine aggregate, the same water-cement, sand-cement ratio and the same temperature as those used in the Concrete method are used, and after all the materials have been introduced into the mortar mixer, the mixing is started and continued for 3 minutes. The results are shown also in Table 3.

In order to find out the causes of discrepancies which were observed occasionally between the setting times in both methods, the effects of proportions, mixing sequence, mixing period and temperature on the setting time of the concrete are investigated in details.

Influence of Mixing Sequence

The influence of the mixing sequence on the setting time of concrete is studied. In Table 4, the results are shown.

Table 3. *Setting time of concrete determined by the concrete method and mortar method*

Kind of admixture	Slump (cm)	Time of setting (hr-min) concrete method initial	concrete method final	mortar method initial	mortar method final
none	7.5	5–16	7–17	5–20	7–15
Type A		5–18	7–10	5–10	7–10
Type D		6–26	8–30	6–35	8–40
Type E		4–15	6–05	4–15	6–05
none	18.0	5–45	7–35	5–50	7–45
Type A		6–00	8–05	6–03	8–10
Type D		7–10	9–25	7–10	9–15
Type E		5–00	7–00	5–30	7–00

Concretes and mortars are mixed by the Method C1 and M1.
Proportions of concretes are shown in Table 2.
Proportions of mortars are the same water-cement and sand-cement ratios as that of corresponding concretes.

Table 4. *Influence of mixing sequence on the setting time of concrete.*

Kind of admixture	Mixing method	Slump (cm)	Air (%)	Time of setting (hr-min) initial	Time of setting (hr-min) final
none	C1	7.2	2.1	5–16	7–17
	C2	8.0	1.9	5–23	7–20
Type A	C1	5.5	4.7	5–18	7–10
	C2	8.0	5.0	7–10	9–00

Proportions of concretes are the same as that shown in Table 2.

The change in the mixing sequence brings about an unexpected remarkable effects on the setting time. That is, when the cement and the aggregate are premixed before the admixture solution is added, the setting time of the concrete is delayed by two hrs. for the Type A admixtures.

The effect of the mixing sequence on the setting time of mortar is shown in Table 5.

Table 5. *Influence of mixing sequence on the setting time of mortar.*

Kind of admixture	Mixing method	Water/Cement (%)	Sand/Cement (%)	Time of setting (hr-min) initial	final
none	M1	52.7	254	5–55	8–30
	M2			6–40	9–05
Type A	M1	45.0	233	6–25	9–05
	M2			9–20	11–50
Type D	M1	45.0	233	7–50	10–20
	M2			12–10	15–10
Type E	M1	45.0	233	5–05	6–45
	M2			6–40	8–40

In the Mortar method, the same phenomena as in the Concrete method are observed. When the cement is premixed with fine aggregate before the admixture solution is added, the setting time of the mortar is delayed by two to five hrs. depending upon the kind of admixture used.

In our preliminary experiment, the same delaying phenomena are observed for the mortar containing other kinds of Type A admixture (β-naphthalene sulphonic acid-formaldehyde condensation product) and retarders (sugar, glucose etc.). V. H. Dadson and E. Farkas studied (9) on the delayed addition of set retarding admixtures to the concrete. The addition of lignosulphonate and hydroxylated carboxylic acid to concrete two minutes after the mixing has been started, increases their efficiency as retarder. G. M. Bruer studied (10) on the set retarding effects of calcium lignosulphonate and citric acid in cement paste made with water-cement ratio of 0.35 by weight, and showed that when the cement was premixed with water, then mixed again with the retarder solution, the setting time of the paste were considerably longer than when the retarder was added to the dry cement with the mixing water. These authors pointed out that the effect of delayed addition is much greater in cement with higher tricalcium aluminate content. Bruer explained these phenomena as follows. When cement was premixed with water for a few minutes, gypsum in cement had ample time to dissolve and coat the tricalcium aluminate. Consequently, when the retarder was added to the premixed cement, the tricalcium aluminate is unable to absorb it and a large amount of the retarder was available to retard the silicate hydration reaction. Dadson and Farkas also supported this theory.

The delaying phenomena observed in this study may relate to the delayed addition. During the premixing, the cement reacts with a small quantity of water which is absorbed in the sand. This can be proved by the fact that when the oven dry sand is used in place of the saturated surface dry sand, no delaying phenomenon is observed. It is very interesting that such a minute amount of water brings about the delayed addition phenomenon and not only retarding admixture but Type A and Type E admixtures also exhibit the delaying of the setting time.

In the performance of the testing by the method using mortar in lieu of concrete, the effects of the mixing sequence on the setting time should be recognized. This premixing method (Method M2) is being used as the mixing method for the preparation of mortar in JIS R5201 (11). But this mixing method should be avoided in the test for the setting time by using mortar, if the concrete is not prepared by the premixing method (Method C2). It is concluded that, as concretes are usually mixed by Method C1, the mortar used in the Mortar method shall be mixed by Method M1 in order to know the setting time of the concrete.

Influence of Mixing Period

Influence of mixing period on the setting time is studied. The concrete is mixed by the Method C1 for three and six minutes. The results shown in Table 6 indicate that the extension of the mixing period brings about a decrease in the setting time by about 25 to 45 minutes.

Table 6. *Influence of mixing period on the setting time of concrete*

Kind of admixture	Mixing period (min)	Slump (cm)	Air (%)	Time of setting (hr-min) initial	final
none	3	7.2	2.1	5–16	7–17
	6	6.8	2.1	4–55	6–45
Type A	3	5.5	4.7	5–18	7–10
	6	6.8	4.8	4–50	6–55

Proportions of concrete are the same as that shown in Table 2. Concretes are mixed by the Method C1.

The effect of the mixing period on the setting time is also studied by the Mortar method. The results are shown in Table 7.

In the Mortar method (Method M1), the mixing period shall be decided so that the setting time of the mortar may reach to the same setting time as that obtained by the Concrete method. In our experiment, the same mixing period as in the concrete mixing is necessary for the Mortar method (three minutes). This period, however, shall be varied depending upon the kind of the mixer used.

Table 7. *Influence of mixing period on the setting time of concrete*

Kind of admixture	Mixing period (min)	Time of setting (hr-min) initial	final
none	1	5–55	7–55
	3	5–10	7–10
	6	4–50	6–30
Type A	1	5–55	8–10
	3	5–10	7–10
	6	4–50	6–35
Type D	1	7–50	10–35
	3	6–35	8–40
	6	5–35	7–30
Type E	1	5–05	6–50
	3	4–10	6–05
	6	3–50	5–20

Proportions of mortar: W/C = 52.7%, S/C = 252% for no admixture mortar
W/C = 45.0%, S/C = 233% for admixture mortar
Mortars are mixed by the Method M1.

Influence of Proportions of Concretes

Table 3 indicates that the setting times of concretes vary with change in the proportions and the concretes with higher consistencies give longer setting times.

The influences of the changes in water-cement ratio and sand-cement ratio of the mortar on the setting time are studied by the mortar test. The results are shown in Fig. 1.

The setting time varies widely when the proportions of the mortar are varied. It seems to be seen a linear correlation between the setting time and the consistency of the mortar.

In the Mortar method, the proportions of the mortar shall be identical with that of the concrete.

Influence of Temperature

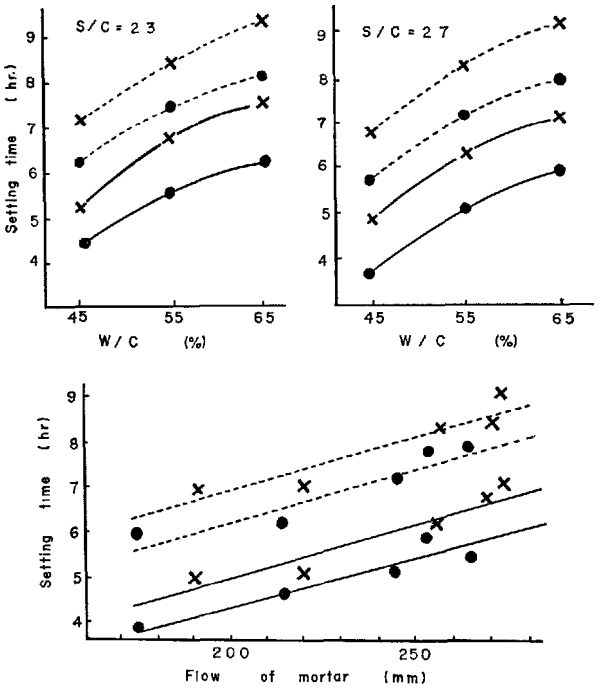
Influence of temperature on the setting time is studied by the Mortar method. The results are shown in Fig. 2.

The effect of the temperature on the setting time of the mortar is remarkable. The mortars containing the type D and E admixtures exhibit greater deviation in the setting times from the mortar without admixture when the temperature of the mortars is lowered.

In the Mortar method, the same temperature shall be used as in the Concrete method.

Effects of Various Factors on the Setting Time of the Concrete or the Mortar Containing the Admixtures

In Table 8, the specified requirements for the setting times of the concretes containing various types of admixtures are summarized.



—●— Initial setting time of the mortar without admixture
—×— Initial setting time of the mortar containing type A admixture
--●-- Final setting time of the mortar without admixture
--×-- Final setting time of the mortar containing type A admixture

Fig. 1. *Influence of the proportion and concistency of mortar on the setting time.*

min.	...	...	−1	...	...	...	...

Figs. in the Table indicate the deviations of the setting time from reference concrete without admixture, in hr.
* see reference (12)
** see reference (13)

In these specifications the setting time of concrete is determined as prescribed in ASTM C403–65T. Proportions and mixing methods are specified in the respective specification. The effects of the retarding and accelerating admixtures are expressed as the deviations of the setting time of the concrete or mortar containing the admixtures from the standard concrete or mortar without admixture. As the setting time of concrete is affected by the various factors as mentioned above, the deviation of the setting time is also affected by the factors such as proportions, mixing sequence, mixing period and temperature. In order to exhibit the effect of the proportions, the deviations of the setting times of the concretes containing the admixtures from concrete without admixture are calculated from Table 3 and shown in Table 9.

With increasing the slump of the concrete, the deviation of the setting time increases for Type A and D admixtures and decreases for Type E admixture. This fact indicates that the efficiency of the set accelerating admixture decreases with increasing the consistency of the concrete.

The effect of the mixing sequence is very important as shown in Tables 4 and 5. When the concrete is mixed by Method C2, the setting time of the concrete containing the admixture is delayed by more than 2 hrs. than that of the concrete mixed by Method C1. While, the concrete without the admixture is affected by the change in the mixing method to a much smaller extent. Accordingly, when the concrete is mixed by Method C2, the qualities of the admixtures expressed as the deviation of the setting time do not conform to the requirements in the specification.

The effect of the mixing period is shown in Fig. 3.

When the mixing period is varied, the deviations of the setting times of the mortars are constant for the Type A and E admixtures, but for the Type D admixture, the deviation decreases with the extension of the mixing period.

The effect of the temperature is also remarkable as shown in Fig. 2. The Type E admixture can be used more effectively in the lower temperature.

Table 9. *Deviation of the setting time from no admixture concrete.*

Slump of concrete	Deviation of the setting time of the concrete (hr-min) containing					
	Type A admixture		Type D admixture		Type E admixture	
	initial	final	initial	final	initial	final
7.5	0–02	0–07	1–10	1–30	1–01	1–12
18.0	0–15	0–28	1–25	1–48	0–45	0–37

Proportions of concretes are shown in Table 2.

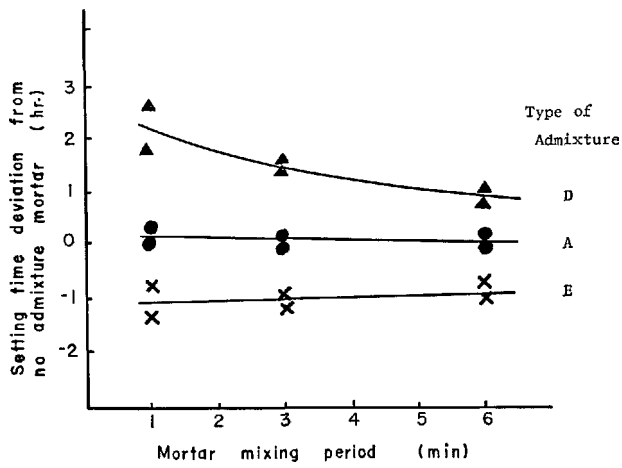

Fig. 3. *Influence of the mixing period on the deviation of the setting time of the mortar containing various admixtures from the mortar without admixture.*

These results indicate that the efficiency of these admixture varies with the change in the various factors mentioned above. In establishment of the specification for chemical admixture, the testing method for the setting time should be decided under the consideration of these factors.

On the other hand, in the use of the admixture it must be recognized that the efficiency of the set con-

trolling admixture varies with the change in the proportions, mixing method and temperature in actual job condition and in some case, the quality of the admixture may not conform to the requirement in the specification.

Conclusion

In order to determine the setting time of concrete, especially of the concrete containing various types of admixtures, the method using mortar in lieu of concrete (Mortar method) is studied.

When the admixtures are used, the results obtained by this method are influenced profoundly by various factors. Therefore, the mortar test should be performed as follows.

1. The proportions of the mortar for the test shall be identical with that of the concrete.
2. The same materials as in the concrete shall be used.
3. The same mixing sequence as in the concrete shall be used.
4. The mixing shall be continued until the setting time of the mortar reaches to the setting time obtained by the concrete test.

This method is more convenient than concrete test and gives the practical information on the setting time of concrete, and gives more accurate and reproducible results than concrete test. This method can be used for determining the effects of various variables such as cement, mixture proportion, mixing method, temperature and admixtures upon the setting time of the concrete.

The effect of the retarding and accelerating admixture on the setting time of the concrete are investigated and it is clarified that the efficiency of these admixture varies with the change in proportions, mixing sequence, mixing period and temperature. The significance of the effect of the mixing sequence is pointed out.

Therefore, in establishment of the specification for chemical admixture, the testing method for the setting time should be decided under consideration of these factors.

Supplementary Paper IV-107 Study on the Admixture for Aerated Concretes Including Maleic Anhydride Modified

Kenji Akutsu*

Synopsis

Various kinds of surface active agents are now used as air-entraining agent (AE agent) or dispersant for cement, but there are few which are effective as foaming agent, one of admixtures for aerated concrete. Various basic tests have been performed on the foaming agents, in which a maleic anhydride modified resin, a product of recent synthetic chemistry, is utilized.

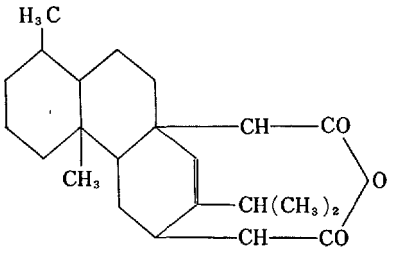
Utilization of Maleic Anhydride Modified Resin in Foaming Agent

Well known as surface active agents for the cement admixture are salts of resin acids, salts of alkylbenzene sulphonic acids, salts of lignin sulphonic acids, non-ionic agents, etc., but since the foaming agent is different from the ordinary air-entraining agent (AE agent) and thus requires introduction of a large amount of air (5% to 80% larger than the air-entraining agent requires), the foaming agent must have a high foam stability and consequently must have a good effect in reducing the bleeding of concrete. For this purpose it seems that, if there is a higher surface activity in the cement paste and further, if there is a group of atoms capable of forming a primary bondage with calcium ion, Ca^{2+}, in the paste, the stability of foam film would be more effective.

On the basis of the foregoing concept, an attempt has been made to utilize as a foaming agent a maleic anhydride modified resin prepared by adding maleic anhydride to abietic acid, a main component of resin acid of the anionic surface active agent, to introduce carboxyl groups (–COOH), that is, hydrophilic groups, into a molecule.

That is, total three carboxyl groups (–COOH) are involved in a molecule by the maleic anhydride modification, and thus the electronegativity is increased and the ability for bonding Ca^{2+}, Al^{3+}, etc. is enhanced.

Maleic anhydride modified resin



In that case, it is also possible to allow the abietic acid to react with other unsaturated polybasic acid than maleic anhydride, for example, fumaric acid.

Said resulting maleic acid copolymer is saponified, and after addition of a foam stabilizer thereto, is uniformly emulsified, whereby an admixture is prepared.

Heretofore used as foaming mixtures have been a glue-resin mixture, saponine-resin mixture, protein-hydrolysate, etc.

In addition, a foam stabilizer, such as sodium silicate, has been added thereto, but there have been problems in the stability and storability of the product. However, the foaming agent of maleic anhydride modified resin is hardly deteriorated in quality even if it should be stored for a long time, for both main component and additive are the products of synthetic chemistry.

*Taisei Construction Co., Ltd., Tokyo, Japan.

Basic Property Test

The basic property tests of maleic anhydride-modified resin (M.R.) foaming agent were conducted according to the test procedure for the surface active agent for concrete. That is, these tests were to determine the correlation of the foaming agent with its utility by conducting the tests as itemized below prior to the concrete test.

(i) Quantitative determination of solid matters (evaporation residue)
(ii) Specific gravity
(iii) pH (hydrogen ion concentration) of dilute solution
(iv) Viscosity
(v) Surface tension (specific surface tension and specific boundary tension)
(vi) Foaming capacity and stability
(vii) Dispersibility (rate of bleeding)

Among the foregoing items, the solid matters, specific gravity, viscosity, etc. relate to workabilities, such as dilution, mixing, etc., and the surface active actions has an important correlation with foaming, wetting, emulsification, dispersion, etc. Further, as to the hydrogen ion concentration, the pH that is very far from the neutral point (pH-7) must be avoided. The concentration, at which the AE agent or foaming agent can demonstrate its characteristics to a maximum as a cement admixture, resides around the so-called critical micelle concentration (C.M.C), which can be inferred from a surface tension-concentration curve. In the testing procedure for the surface active agent for concrete the specific surface tension or specific boundary tension is determined according to the testing procedure for the synthetic detergent, JIS K3362 (drop count meter), but in the present test, Du Noüy's surface tension balance (Photo 1) was used. To determine the viscosity viscotester (Photo 2) was used.

Fig. 1 shows a surface tension-concentration curves obtained by testing 4 kinds of commercially available typical surface active agents for cement.

Resin acid chloride, non-ionic agent, alkylbenzene suphonic acid chloride, and lignin sulphonic acid chloride were used as said four kinds of surface active agents.

As to the relations between concentration and surface tension, the M.R. foaming agent has a large percentage decrease in surface tension next to the non-ionic agent, and salt of alkylbenzene sulphonic acid, and its normal applicable concentration as foaming agent ranges between 0.05 and 0.2%.

As to the dispersibility test, Fig. 2 shows a result of determination on the amount of water separated from the cement paste having a water-cement ratio, w/c, of 65%.

The result reveals that the M.R. foaming agent has the least bleeding capacity.

Results of the research for basic properties of maleic anhydride modified resin and other commercially available surface active agents are shown in Table 1.

Viscosity (c.p)	30	92	5	600	10

Setting Test

Admixture for aerated concrete, either foaming agent or gas forming agent, must not contain any substance that retards the setting of lime or cement, because if the setting or hardening is retarded, there is a fear of disintegration of the formed foams.

Influences of M. R. foaming agent and said four kinds of surface active agents for concrete upon the setting time of the cement were comparatively studied. The result is shown in Fig. 3.

In addition, change in setting time when the M. R. foaming agent was employed together with calcium chloride or sodium fluoride as accelerating agents, and the influence of methylcellulose (MC) water-soluble polymer, which has been recently used as an admixture for cement, and further the influence of organic acid (succinic acid) when used as a retarder, were studied. The results are shown in Figs. 4–7.

The setting test was conducted according to the cement physical test procedure, JIS R 5201. The

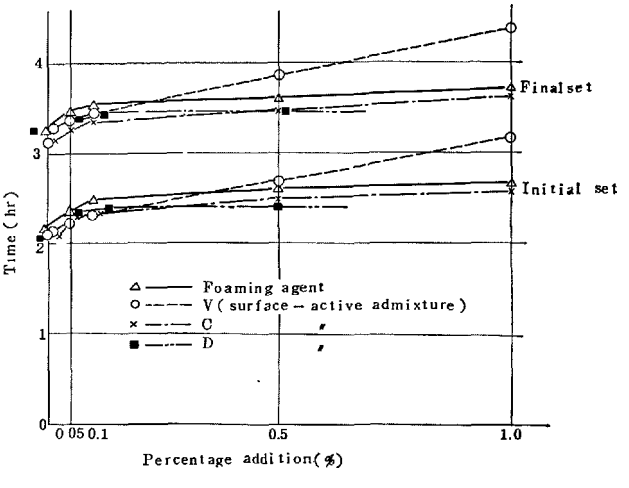

Fig. 3. *Relation between percentage addition and setting time*

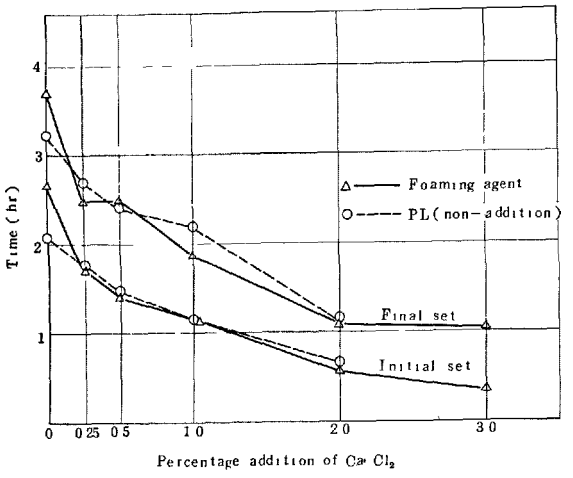

Fig. 4. *Influence of calcium chloride on set.ing tme*

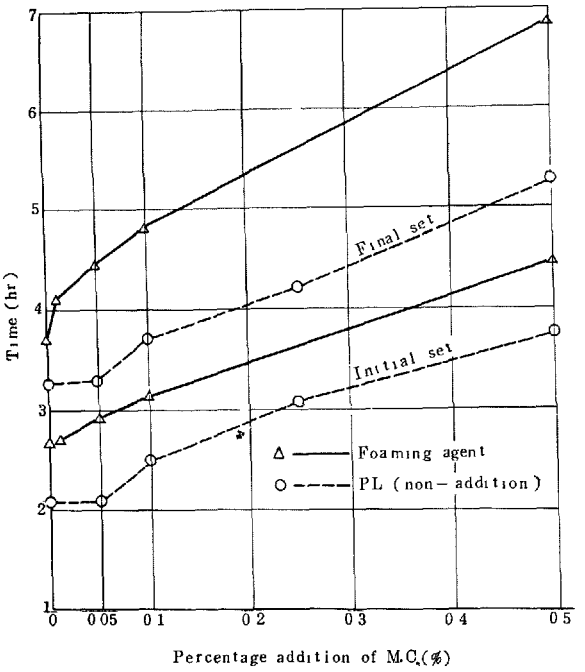

Fig. 6. *Influence of methylcellulose on setting time*

result of quality test of the cement used is the same as that of the cement used in the following section 4, aerated Mortar Test.

As shown in Fig. 3, when the M.R. foaming agent and other commercially available surface active agents for concrete were used alone one by one, the relations between percentage addition, % wt. (percent by weight of cement) and setting time did not greatly influence the setting phenomena of cement in more or less normally usable amount, except for the lignin sulphonic acid agent.

At 1% addition, both the initial and the final setting

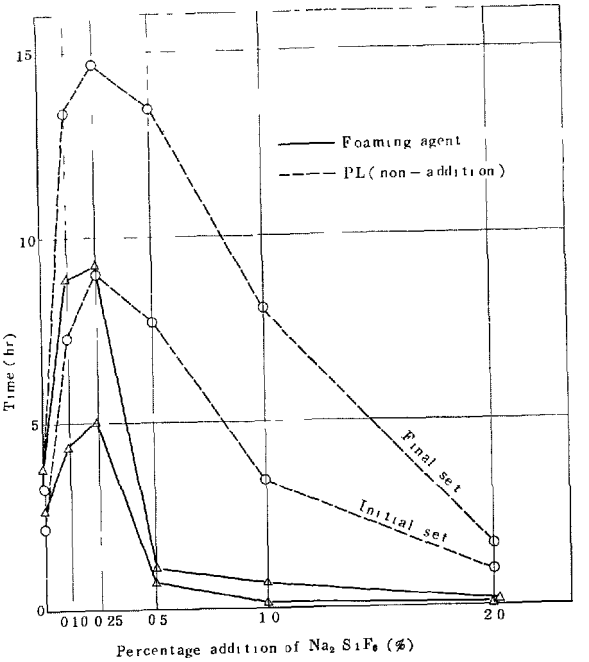

Fig. 5. *Influence of sodium silico-fluoride on setting time*

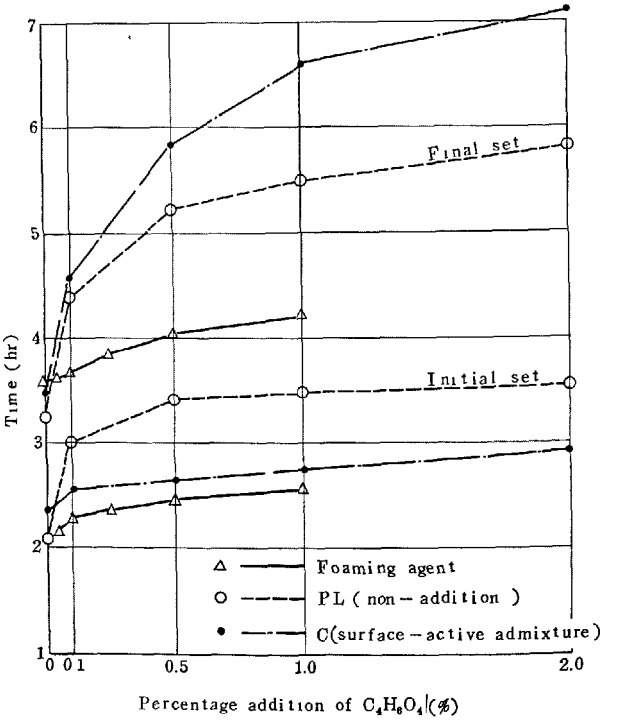

Fig. 7. *Influence of succinic acid on setting time*

were about 30 minutes retarded by use of the M. R. foaming agent as well as the C and D surface active agent, but when the V surface active agent was used, the setting was further retarded.

In the case where the M.R. foaming agent was used together with an accelerating agent, the initial and the

final setting were accelerated by increasing the percentage addition when calcium chloride, $CaCl_2$, was used, but in case sodium silico-fluoride was used, considerably retarded setting was observed, to the contrary, up to 0.5% addition and an almost instantaneous setting was attained with increasing the percentage addition. Further, when succinic acid, $C_4H_6O_4$, $\begin{matrix}CH_2\text{–}COOH\\ |\\ CH_2\text{–}COOH\end{matrix}$, was added as an organic retarder, the retarded setting was observed with the increase of the percentage addition. When succinic acid was used together with non-ionic surface active agent, a more retarding effect was obtained than that when the M.R. foaming agent was used.

When methylcellulose, M.C., which has been recently used especially as an admixture for masonry mortar, was added, somewhat retarded setting was observed as shown in Fig. 6, but such a phenomenon is a general trend observable when a hydrating substance is added. As an exception, an abnormal setting reaction was observed when the lignin surface active agent was simultaneously used. In addition, when the foaming agent was used together with silicate material bentonite as a pouring material, no influence was observed up to about 2% addition.

Aerated Mortar Test

The maleic anhydride modified foaming agent can be used both in an aerated concrete, wherein the lightweight aggregates are used (the ordinary aggregates may be used together), and in a heat-insulating aerated mortar, wherein only fine aggregates are used. But the amount of the maleic anhydride modified foaming agent to be added must be decided in view of the specific weight or strength of the desired concrete or mortar, and a required amount of air must be introduced therein.

In the present test, a M.R. foaming agent was added to the standard sand mortars in various mixing proportions, and the amount of M.R. foaming agent to be added was varied from 0.01 to 1.0% wt. Bending strength, compressive strength, drying shrinkage, air amount, etc. were studied as a basic test for aerated concrete for concreting at site or precasting.

Materials Used

Cement: ordinary portland cement (quality test result is shown in Table 2).
Fine aggregates: standard sands obtainable at Toyoura, Yamaguchi-prefecture, Japan
Admixture: maleic anhydride modified resin foaming agent

Mixing

Mix proportion used in the present test is shown in Table 3.

Table 3. *Mixing proportions of aerated mortar*

Mixing proportion	Cement (g)	Standard sand (g)	Water (cc)	W/C (%)	Percentage addition of foaming agent (%)
1:2	520	1,040	312	60	0, 0.01, 0.05 0.1, 0.2, 0.3
1:3	400	1,200	320	80	0.1, 0.2, 0.3 0.5, 1.0
1:4	350	1,400	350	100	(Total 8 kinds)

Testing Procedure

The test was conducted according to the cement physical testing procedure, JIS R 5201, and an asphalt mixer (experimental use; volume: about 10 l) was used for mixing. After determination of flow value,

Table 2–1. *Chemical compositions of cement used*

	Ig. Loss (%)	MgO (%)	SO_3 (%)	$3CaO\cdot SiO_2$ (%)	$3CaO\cdot Al_2O_3$ (%)
Ordinary portland cement	0.7	1.5	2.0	45	9

Table 2–2. *Physical properties of cement used*

Specific gravity	Fineness		Setting times			Flow	Bending strength (kg/cm²)			Compressive strength (kg/cm²)		
	Blaine's specific surface (cm²/g)	Residue on 88μ sieve (%)	Water content (%)	Initial (hr-min)	Final (hr-min)	(mm)	3 days	7 days	28 days	3 days	7 days	28 days
3.16	3,350	2.0	27.2	2–16	3–20	243	31.6	47.6	70.2	130	232	409

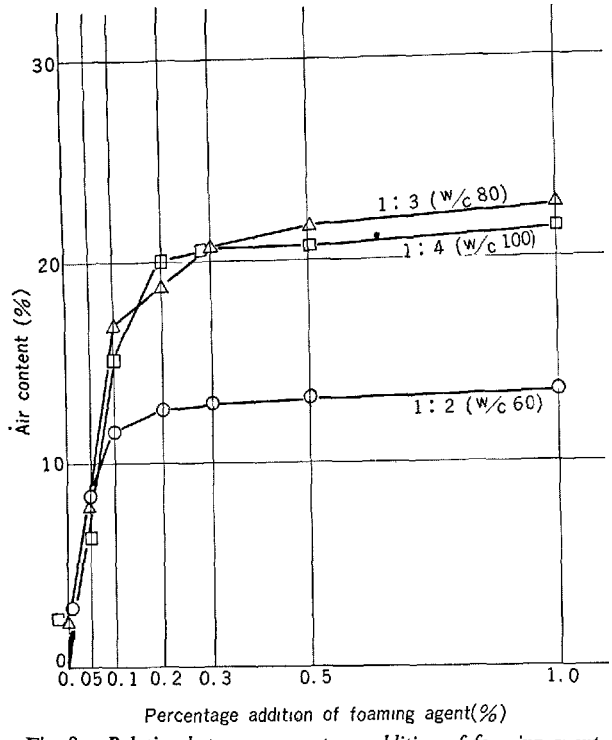

Fig. 8. *Relation between percentage addition of foaming agent and air content*

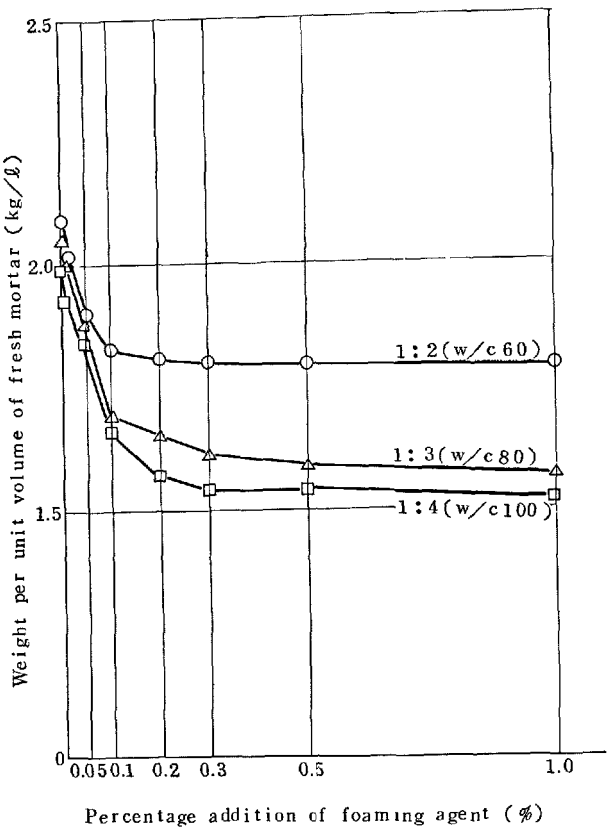

Fig. 9. *Relation between percentage addition of foaming agent and weight per unit volume of fresh mortar*

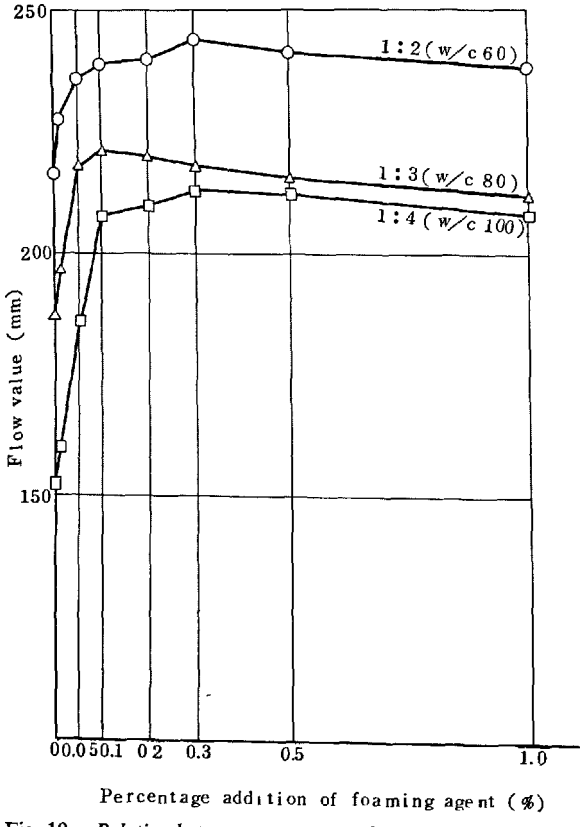

Fig. 10. *Relation between percentage addition of foaming agent and flow value*

a standard mortar specimen ($4 \times 4 \times 16$ cm) was prepared. As to the curing, both high humid air curing (humidity: 80%, temperature: 20°C) for the strength test and low humid air curing (humidity: 50%, temperature: 20°C) for the drying shrinkage test were carried out.

Results and Discussion

(i) The relation between the amount of added foaming agent, amount of air, and the weight per unit volume of fresh mortar are shown in Figs. 8 and 9.

With the increased amount of M.R. foaming agent, the amount of air was increased, and a point of flection corresponding to the critical micelle concentration (C.M.C.) was observed around 0.1 — 0.2% addition of M.R. foaming agent. The relation between the percentage addition (concentration) of the M.R. foaming agent and the amount of air was in an exponential curve, and the increase in the amount of air was in proportion with the amount of adsorption at the boundary and accorded with the Freundlich's adsorption isotherm formula.

(ii) As to the relation between the amount of M.R.

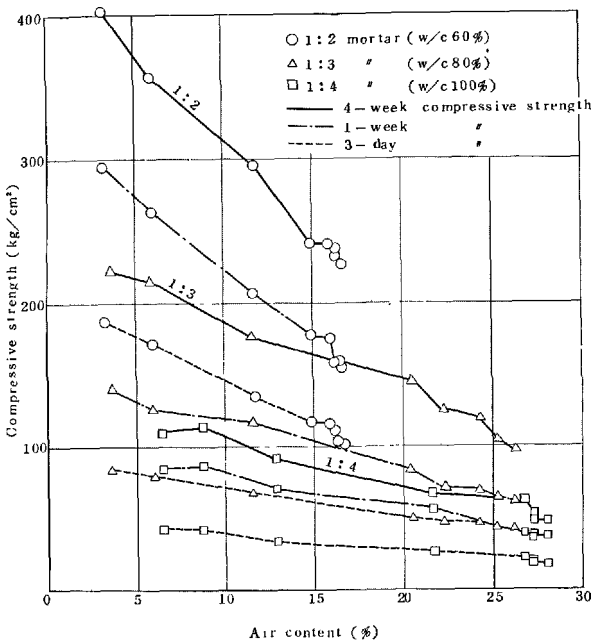

Fig. 11a. *Relation between air content and compressive strength*

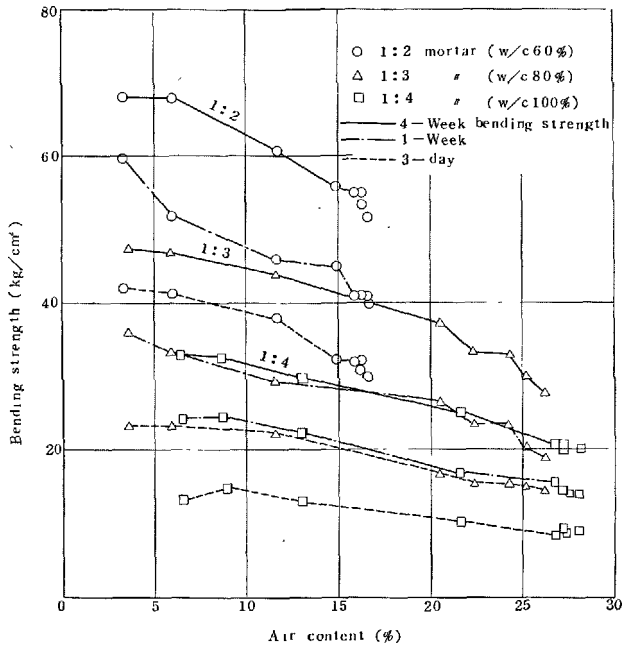

Fig. 11b. *Relation between air content and bending strength*

foaming agent and the flow value, the flow value considerably increased with increasing amount of M.R. foaming agent up to 0.1 — 0.2%, but on the contrary decreased with further amount of M.R. foaming agent, as shown in Fig. 10. Such a phenomenon seems to be due to an increase in viscosity of cement paste with increasing amount of foaming agent.

(iii) The relation between the change in the amount of air and the compressive or bending strength are shown in Fig. 11-a, 11-b.

In every mixture, the strength decreased with increasing amount of air. The higher the amount of air, the higher the percentage decrease in strength. However, the change in strength was small when the percentage addition of M.R. foaming agent exceeded 0.1%.

(iv) As to percentage drying shrinkage and percentage decrease in weight, the larger the amount of cement used, or the larger the amount of air in the mortars at the same mixing proportion, the higher the percentage shrinkage in proportion with the amount of M.R. foaming agent added, as shown in Figs. 12–14.

(v) One example (1: 3 mortar) of the test result of percentage water absorption is shown in Fig. 15. The standard mortar specimen was dried until it reached a constant weight, and was dipped into water at a constant temperature of 20°C, whereby the relation between the time and the percentage water absorption was determined. The results reveal that at not

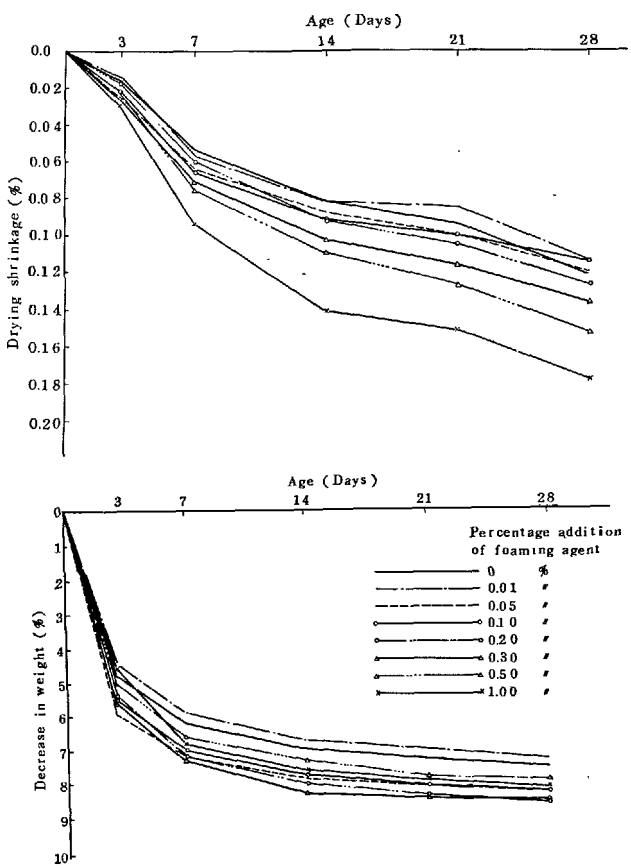

Fig. 12. *Drying shrinkage and decrease in weight of aerated mortar (1: 2)*

less than 0.5% addition of M.R. foaming agent,

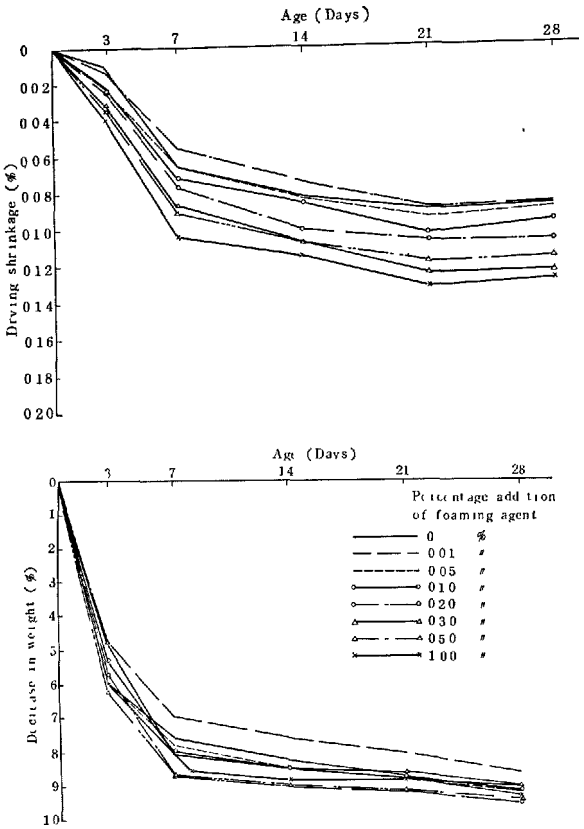

Fig. 13. *Drying shrinkage and decrease in weight of aerated mortar (1: 3)*

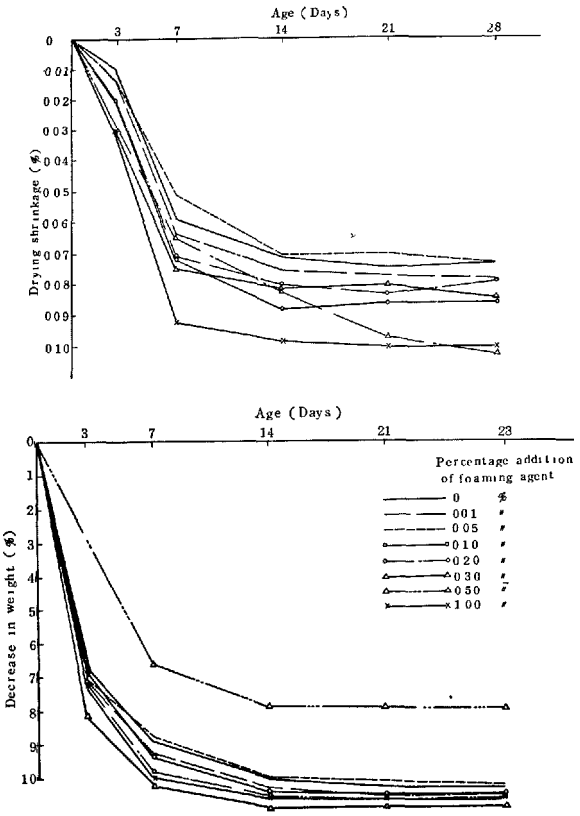

Fig. 14. *Drying shrinkage and decrease in weight of aerated mortar (1: 4)*

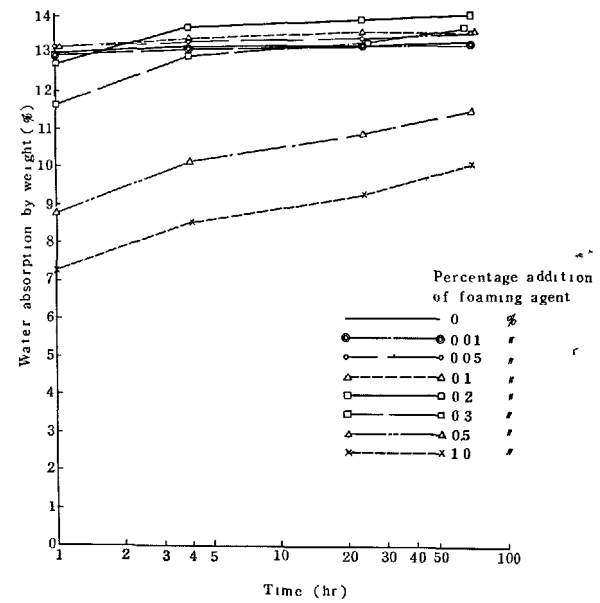

Fig. 15. *Relation between dipping time and water absorption of aerated mortar (1: 3)*

a considerable water proof effect was obtained. Further, the mortar having 0.05 — 0.2% of foaming agent, when about 10 — 20% of air was introduced, shows the same percentage water absorption similar to that of the plain mortar where no foaming agent was added. Such a phenomenon seems to be due to the fact that insoluble metal salts are formed between maleic anhydride modified resin and calcium hydroxide in the paste as mentioned above.

Conclusion

As discussed above, the results of research of the basic property, setting and mortar tests of maleic anhydride modified resin having a special molecular structure when the maleic anhydride modified resin is utilized as a foaming agent reveal that it is effective as an admixture for aerated concrete.

SESSION IV-2 FLY ASH AND FLY ASH CEMENT

Principal Paper Fly Ash and Fly Ash Cement

Masatane Kokubu*

Synopsis

Classifying various researches regarding fly ash, the author first describes the chemical composition and physical properties such as particle shape, specific gravity and fineness of various fly ashes and discusses the influence of fly ash on workability, strength, volume change, heat of hardening, watertightness, durability, abnormal expansion due to alkali-aggregate reaction, etc. of concrete and establishes the practical limits of the effect of fly ashes in improving these properties of concrete. Next, as a result of summarization taking into consideration the various studies of chemical behavior of fly ash, it is found appropriate to theorize that the superior characteristics imparted to concrete by fly ash are due not only to the smooth, spherical particle shape, fine grain size and pozzolanic activity, but also to the acceleration of hydration reaction caused by replacement of fly ash particles in the floc structure of cement particles.

Although pozzolanic reaction is extremely complicated, it was possible to ascertain that the glass phase is the chief part of the phase composition contributing to pozzolanic reaction, the latter being governed by the surface area of the glass phase, and that increase in concrete strength from pozzolanic reaction has a close relationship with the $SiO_2 + Al_2O_3$ content of fly ash, while other fruits of research which offer clues to the explanation of pozzolanic reaction are recognized. Also, the reasons for the marked effect in increase of long-term strengths of concrete even with pozzolanic reaction of a degree not reflected in test values of non-evaporable water and heat of hydration are discerned.

Further, from results of studies, practical methods of solving the problems involved in actual use of fly ash such as pack setting during storage, fluctuation of air content in air-entrained concrete, etc. are suggested. The problems relevant to fly ash cement are also discussed.

Introduction

The idea of using the ash produced at the time of combustion of finely pulverized coal as a pozzolan for concrete has been in existence for a long time, research results having been published as early as 1914. (1) The term "fly ash" first appeared in literature in 1937 (2) and it is from this time that research related to this material began to be actively conducted. Parenthetically, as it became possible to collect fly ash of high fineness, greater pozzolanic effect could be expected and the use of fly ash in concrete began to be seriously studied.

With the progress in research on facilities for economically collecting good quality fly ash (3)(4)(5) the studies became even more intense, almost all of them being conducted in the United States. After the performance data of fly ash used at Hungry Horse Dam were published by the U.S. Bureau of Reclamation, (6) the use of fly ash in concrete for hydraulic structures and various other structures spread all over the United States and in 1954 an ASTM standard on fly ash (See Appendix 1) was established.

In Japan, studies on fly ash were begun around 1950. This was a period when the demand for electric power showed a sudden growth and along with this there was great activity in constructing both hydroelectric and thermal power stations so that studies connected with fly ash were advanced rapidly. In 1958 a standard on fly ash (See Appendix 1) was established. The utilization of fly ash in European countries came at

*Faculty of Engineering, The University of Tokyo, Tokyo, Japan.

about the same time as in Japan. In France, a standard on fly ash cement (See Appendix 2), in the U.S.S.R. and Great Britain, standards on fly ash (See Appendix 1) were approved in 1963 and 1965 respectively.

Fly ash, besides being used as an admixture for cement and concrete, is used in considerable quantities as an additive in celluar concrete, artificial lightweight aggregate, refractory materials, brick, in soil improvement and in asphalt as well as in abrasives, purifiers for polluted water, fertilizer and medicines, and there has been data from research in these fields published, but it is not within the scope of this paper to discuss these subjects.

It is difficult to say how much fly ash is being used as an admixture for cement and concrete in various countries of the world, but it is estimated the annual consumption in recent years has been around 1,500,000 tons in the U.S.A., 1,000,000 tons each in Japan, France and Germany and 500,000 tons in Great Britain.

Since fly ash is a by-product of the combustion of pulverized coal, it is first necessary to have facilities for collection which will economically assure uniformity of quality in order for the advantages of the material to be truly demonstrated. The advantages of good quality fly ash are the improvement of workability of concrete, improvement of strength, watertightness and durability of concrete at advanced ages, alleviation of heat of hardening of concrete and reduction of drying shrinkage, although probably, the foremost advantage of fly ash lies in the economy resulting from reduction of cement. When considering the fact that thermal power stations are going to great expense in disposing of the material as waste, the advantages of utilizing fly ash are even more marked.

These advantages of fly ash can be said to offset the shortcomings of portland cement. In concrete work, the qualities most desirable for the cement to possess will differ somewhat with the type of structure and peculiarities of the work. However, when it is attempted to obtain special portland cements which will completely satisfy the requirements of each project, it will generally be extremely uneconomical.

Under such circumstances, it is possible to obtain the properties desired of a concrete by modifying its nature through the use of a good quality fly ash as an admixture. Therefore, the true worth of a good quality fly ash is in economical improvement of the qualities of cement.

It is natural that fly ash cement should appear on the market for the reasons stated above. "Fly ash cement" is a term not yet generally accepted internationally, but since "portland-pozzolan cement" would allow pozzolans other than fly ash to be included, this term will be used purposely according to the custom in Japan in order to avoid confusion in the discussions here.

It is natural for the quality of fly ash to differ according to quality, fineness and method of burning of the pulverized coal, collecting facilities, etc., and the chemical composition of fly ash varies considerably according to country. Still, it is extremely interesting that papers from various countries all list the beforementioned advantages of fly ash.

Past research on pozzolans has been summarized and introduced by Lea (7) at the International Symposium on the Chemistry of Cement in 1938, theASTM Symposium (8) of 1949 and the symposium of 1953 of the Italian Chemical Society. Malquori (10) also introduced such research at the International Symposium on the Chemistry of Cement of 1960. These naturally include researches on fly ash.

The purpose of this paper is to summarize the results of research published in various countries, list the physical and chemical properties of fly ash, endeavor to solve the problems involved and clarify the various precautions to be taken in using the material.

There are almost 700 research reports on fly ash which have been published to date. As it will be impossible to cover all of these reports in this paper, only the representative ones of each topic discussed here will be referred to. It should be mentioned there do exist excellent papers which are not referred to due to lack of space.

Chemical Composition of Fly Ash

In the standards on fly ash of the U.S.A., Japan, U.S.S.R. and Great Britain, there are provisions for the amounts of silica (SiO_2), moisture content, loss on ignition, etc. Although it is said the active portion of fly ash consists of silica and alumina, the pozzolanic activity cannot be judged by chemical composition alone. On the other hand, it is a fact that pozzolanic activity differs greatly with the SiO_2 content and it is natural for the quantity of SiO_2 to be specified in the various countries. In the ASTM standard, the total amount of $SiO_2 + Al_2O_3 + Fe_2O_3$ is specified.

Examples of chemical composition of fly ash in various countries are given in Table 1 which shows there are great differences according to the country. These are only isolated examples, the data coming from different periods so that there may be little significance in making detailed comparisons. As far as Table 1 is concerned, the average values by country are 58–40% for SiO_2, 27–21% for Al_2O_3, 17–4% for Fe_2O_3 and 6–4% for CaO. These variations are due to the great difference in quality of coal between the various countries, the fly ash of Japan being conspicuously high in SiO_2 content compared with

Note 1. The fily ashes listed in Table 1 are identical to those in this table. The 10 varieties, A to J, are representative fly ashes widely marketed in Japan for use in concrete.
2. The trace elements of fly ashes were quantitatively analysed by the method proposed by Funato (91)
3. The quantitative analysis method of phase composition was as follows:
Quartz and Mullite: directly measured by intensities of X-ray diffraction tests.
Iron compounds : calculated from chemical components.
Glass : 100—(Quartz + Mullite + Iron compounds)

the fly ash of the U.S. and European countries.

The SO_3 exists mainly in the form of calcium sulfate and according to recent studies, it has been ascertained that the pack setting of fly ash during storage is due to the influence of calcium sulfate.

It is thought the reason the MgO content is specified in the ASTM standard is the considerations of harmful effects as in cement. Also, the alkali content is specified in ASTM, but in Japan there is almost no aggregate which may cause alkali-aggregate reaction and therefore there is no provision for alkali in the Japanese standard.

The loss on ignition is a measure of the carbon content and in this respect also there is a great difference according to the country, the average values ranging between 10 and 0.7%. In the early reports, the necessity for moderately low carbon content is emphasized, but the effect on the properties of hardened concrete is negligible even when the carbon content of fly ash is high to a certain extent. However, when fly ash of high ignition loss is used for air-entrained concrete, control of air content becomes difficult in many cases and for practical reasons the amount of ignition loss must be carefully considered.

Along with chemical analysis, quantitative measurement of the phase composition of fly ash has been given importance in recent years.

The major phases composing fly ash are quartz,

mullite and a comparatively large amount of glass. Of the chemical components, SiO_2 exists in the form of quartz and glass phases while part of the Al_2O_3 exists as mullite and the remainder is contained in the glass phase. Needless to say, the mineral composition will differ in a complex manner according to the quality and fineness of the pulverized coal, method of burning and other factors.

The results of analyses of 10 representative fly ashes now being marketed in Japan and 2 coarse fly ashes are given in Table 2. Table 2 also gives the phase compositions. A comparison of these with 7 out of 14 British fly ashes reported by Watt and Thorne (11) is given in Table 3.

Table 3. *Example of comparison of phase composition of Japanese and British fly ashes*

	Japanese fly ash	British fly ash
Quartz	11.8–5.4%	8.5–2.2%
Mullite	18–8%	14–6.5%
Glass	84–69%	88–71%

Physical Properties of Fly Ash

Particle Shape of Fly Ash

Although the particle shape of fly ash differs somewhat with size, the great part consists of spherical glass, in which quartz, small needle-shaped fragments of mullite and minute quantities of hematite or magnetite are contained. In some cases the spheres exist linked together.

Most fly ash consists of fine and dense spherical particles, but there are cases of relatively large particles having voids in the interiors. Some of the large particles are hollow spheres with openings which on occasion contain minute spherical particles resembling the form of fish eggs. There are also shell forms and other irregularly formed particles interspersed in the fly ash.

It will be convenient to discuss particle shape of fly ash by the 4 classifications of spherical and rounded, rounded, irregular, and angular.

Fig. 1 shows fly ash photographed by Terrier and Moreau (12) with an ore microscope while Fig. 2 shows fly ash photographed by a scanning electron microscope.

The ratio of the mixture of porous particles with internal voids and irregular shaped particles differs with the fly ash. One Japanese fly ash contained approximately 12% porous particles while a coarse fly ash contained approximately 20% (13). In any case it is an outstanding feature of fly ash that most of the particles are spherical, something which is not seen in other pozzolans. This is thought to be the principal reason for the improvement of workability of concrete obtained with fly ash.

Specific Gravity of Fly Ash

The results of measurement of specific gravities of

fly ash in the U.S., Japan and Great Britain are given in Table 1. Naturally, the specific gravity is higher the higher is the Fe_2O_3 content and the average values by country range between 2.10 and 2.40.

There is a report that the specific gravities of individual particles differ according to particle shape with apparent specific gravity being higher the smaller the particle (14). This substantiates the fact that porous particles are distributed in the fly ash. However, there is a report of greater specific gravity in the case of coarse-particled fly ash (15).

Fineness of Fly Ash

As fineness of fly ash is an important factor governing pozzolanic activity along with the SiO_2 content and also greatly affects the workability of concrete, all of the countries have attached importance to this aspect and specified limits and uniformity of fineness.

Regarding the procedure for determining fineness, there has been great discussion on whether sieving or the specific surface method measured by the air permeability apparatus should be used. At present most researchers use the specific surface method. This is because of the simplicity of this method and because it is possible to estimate the mean particle size (See Appendix 1, ASTM). When discussing the quality of fly ash from one plant, the specific surface area obtained by the air permeability method is highly reliable. However, when comparing with other fly ashes, it is thought there is a necessity for examining the reliability of the values as there are cases of deviation of test values due to differences in specific gravity, particle distribution, particle shape, carbon content, etc. There are a number of papers reporting it difficult to recognize a correlation between pozzolanic activity of fly ash and test values obtained by the air permeability method of measuring fineness (16)(17)(18). However, Brink and Halstead (17) state there is a relation between the quantity passing 44μ sieves and pozzolanic activity, while Watt and Thorne (11) surmise there may be a close relationship between fineness measurement values and pozzolanic activity in the case of disagglomerated ashes. Fig. 3 gives the results of tests on the 10 fly ashes listed in Table 2, these fly ashes considerably resembling each other in chemical composition. The compressive strength ratios obtained on mortar specimens at the age of 13 weeks and the fineness values (See Appendix 1, JIS) present a comparatively clear correlation except for one fly ash.

Although there is disagreement on the above, there is no question that the fineness value of a fly ash is one guide to its quality. Also, the standard value of fineness is significant in providing a criterion in planning fly ash collecting facilities.

Table 1 also gives examples of the specific surface areas of fly ashes in various countries. In this case also, a wide difference is seen between countries, the average values being between 5,180 and 3,090 cm^2/g.

Japanese coal is generally high in content of ash and volatile matter while low in coking properties. Therefore, when this is burned in the form of pulverized coal, thermal explosion occurs within the flame and combustion gases and there is a tendency for the individual particles to become finely divided. It is thought that in the case of Japan, fly ash of high fineness and low carbon content can be obtained comparatively readily because of this. On the other hand, it might be considered that coal of other countries are higher in coking properties compared with Japanese coal with less volatile matter so that the abovementioned fine division does not occur when the pulverized form is burned and there is a smaller ratio of finely divided powder to be contained in the ash. This and the fact that the SiO_2 content is high as mentioned before are the distinguishing features of Japanese fly ash and as a result there are cases when there is considerable difference in the influence of fly ash on the properties of concrete between Japan and various other countries.

Therefore, it is conceivable there would be considerable differences in the fly ashes of other countries which will complicate the discussions, but since fly

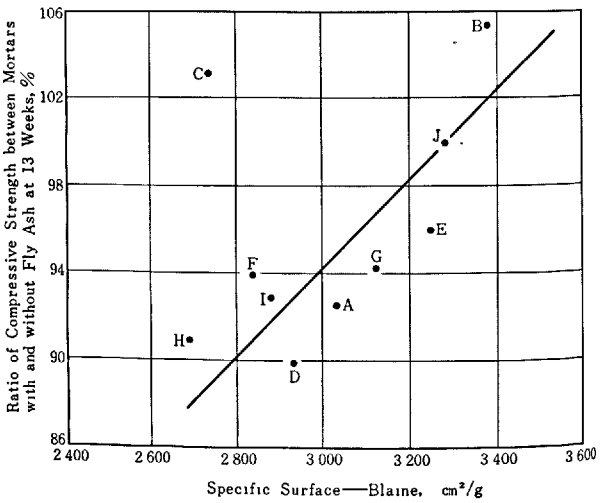

Fig. 3. *Relation between specific surface of fly ash and relative compressive strength of mortar at 13 weeks. Relative compressive strength indicates ratio to compressive strength of mortar without fly ash. Fly ash replacement ratio, 25%.*

ash is after all a by-product, this is inescapable.

The comparatively close resemblance of the Japanese fly ashes is because of identical periods of formation of coal strata and identical component plant material so that all coal mined in the country are the same in quality and also since only the portions meeting JIS specifications are sold on the market except in the case of coarse fly ash.

Strength and Other Properties

When discussing the physical properties of fly ash it is highly necessary to have test values of unit water content and strength when the fly ash is used in mortar or concrete, and all of the countries clearly designate the standards for these aspects (See Appendix 1). However, since the testing methods differ, direct comparison of the values will be avoided here.

Influence of Fly Ash on Various Properties of Concrete

Influence of Fly Ash on Workability of Concrete

That replacement of a portion of the cement with a suitable amount of fly ash when mixing concrete would improve workability was made clear in a paper by Davis et al (2) as early as 1937. It was suggested in this paper that suitable replacement ratios would be 30% or less for ordinary construction. Viewed in the light of present day common knowledge, however, the paper attributes surprisingly little to fly ash for the reduction in unit water content necessary to obtain a concrete of a given consistency. This probably is due to the fact that fly ash in those days were inferior to present day fly ash in quality and especially in fineness.

It is though that with the use of fly ash in the great volume of concrete in Hungry Horse Dam (arched-type concrete dam, construction begun in 1948, height 172 m, concrete volume 2,360,000 m^3) as an impetus, exceptional progress was made in the techniques of collecting and producing fly ash in the United States. The interior concrete of this dam was a lean air-entrained concrete with a unit cement content of 111 kg/m^3, unit fly ash content of 56 kg/m^3 (a replacement ratio of 33% of cement with fly ash), air content of 3.7% and slump of approximately 5 cm and the unit water content was only 88 kg/m^3 (19). The reduction in unit water content was of course due to entrained air to a great extent, but nevertheless this was an epoque-making project in the use of fly ash in concrete.

The rate of reduction in the unit water content necessary for a given consistency obtained by replacing a part of the cement with fly ash will differ depending on the mix proportions of the concrete, the particle shape and fineness of fly ash, the fly ash replacement ratio, gradation of fine aggregate, etc. The results of tests on 20 varieties of fly ash marketed in Japan with a replacement ratio of 25% ranged between 11 and 4% water reduction or an average of 7% (18).

It was not possible to ascertain the unit water content reduction ratios for fly ashes of the various countries, but it is thought that a reduction of about 5% can well be expected if the fly ash is of a suitable fineness.

The shape and surfaces condition of particles, and fine particle size are some of the reasons which can be thought of for the reduction of unit water content due to fly ash. It has been said from before, citing examples of microscopic photographs, that the main reason was the smooth spherical shape (6). Yamazaki also conducted studies of these factors (20) and applying the immobile water factor proposed by Powers (21) and Steinour (22) regarding cement particles, or the factor related to the amount of water lying immobile on the surfaces of finely divided particles, rearranged the test results of bleeding rates of fly ash slurries to indicate the relation between shape and surface condition of fly ash and other finely divided particles and the water retention factor in discussing the effects of fly ash, and ascertained that the smooth spherical shape was the most important reason for the improvement of workability of concrete due to fly ash. When the fineness of fly ash increases, the effect of reducing unit water content of concrete is generally great. This is thought to be due to the higher rate of spherical particles with smooth surfaces the higher the value in fineness.

Yamazaki further states that the particles of fly ash in a dry state often present a floc structure from the mutual attraction of the particles, while some fly ashes are agglomerated, and establishes that when concrete is mixed using fly ash which present floc structures or agglomerates, the particles of fly ash are floculated and difficult to disperse (20). (See Fig. 4) If this flocculation were to be prevented, it is conceivable the effect of fly ash on the workability of concrete would be improved further. As a practical means of prevention, there is the method of using fly ash in slurry form by mixing vigorously with water beforehand instead of using it as a powder. This method is

described later. There are many reports that state bleeding of concrete is reduced by replacement of a part of the cement with a good quality fly ash, but there are cases when rather the bleeding is increased.

Influence of Fly Ash on Strength of Concrete

Although with some difference in degree, the pozzolanic effects of fly ash, or the improvements in long-term strength, watertightness and durability, have been described in almost all reports since the advent of the material, which fact has been instrumental in causing it to be used in dam concrete and other concrete. These pozzolanic effects of fly ash will not only differ extremely according to the quality of the fly ash and the amount used, but also with the quality of cement, the mix proportion, the age and curing conditions, but when about 25% of normal portland cement is replaced with good quality fly ash and the concrete is cured at normal temperature in the presence of adequate moisture, it is not seldom that the strength of the concrete will become greater than that of concrete without fly ash within the age of 6 months.

It is a characteristic of concrete containing fly ash to demonstrate strength increases over long periods, and especially, it appears there is a tendency for tensile strengths to be improved. (23) Fig. 5 is an example of the relation between compressive strength and tensile strength of concrete containing fly ash correlated to age (24) which shows tensile strength to be improved over that of concrete without fly ash at advanced ages. This can be said to be an advantage of fly ash offsetting to some degree the defects of normal portland cement.

One disadvantage of fly ash when cement content is reduced is that the strength of concrete at early ages is reduced. One method of covering this disad-

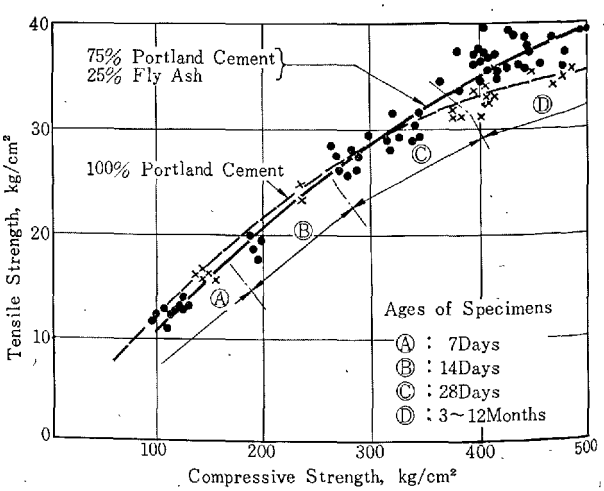

Fig. 5. *Example of relation between tensile strength and compressive strength of concrete (Max. size coarse aggregate, 25 mm; cement factor, 300 kg/m³; slump, 6–7cm; specimens cured in water maintained at 21°C; test ages, 7 days–12 months).*

vantage is to use more fly ash than the amount of cement reduction, the unit cement content and unit fly ash content being selected in a manner to obtain the required strength at the designated age (25). This is done in many cases in concrete pavements and other members, although of course the concrete mix must be selected in consideration of cost.

When fly ash is used for ordinary members, the members, unlike hydraulic structures, will gradually become dried and there will be a fear that strength increases at advanced ages cannot be expected. Stingley and Peyton (26) have reported on 1- to 10-year test results of beam specimens job-cured in exactly the same manner as concrete of an experimental pavement in Kansas in which flexural strengths of beams reached maximum values at about 1 year in the case of concrete without fly ash, while for concrete with fly ash, the strength increased for 3 to 4 years exceeding 70 kg/cm^2 after 3 years.

Tsukayama and Miyoshi (27) have reported on tests of cores and beams cut out of test pavement slabs at the age of 10 years. When the amount of fly ash used was adjusted to obtain 28-day compressive strength (curing in water at 21°C) equal to that of concrete without fly ash (curing in water at 21°C), the compressive strength of the fly ash concrete pavement slab which was approximately 100% of that of the concrete pavement slab without fly ash at 3 months, had increased to 120% at the age of 10 years. Further, the flexural strength ratio which was approximately 80% at the age of 3 months had increased to approximately 150% at 10 years. In these tests also, it is indicated that the effect of fly ash is more pronounced in flexural strength than compressive strength.

Kokubu and Ito (28), on testing compressive strength of core specimens taken from concrete pavement slabs of first class national highways with 30% replacement of cement with fly ash have reported that strengths which were 370 kg/cm^2 at 3 months had increased to 610 kg/cm^2 at the age of 9 1/2 years.

However, Legg (29) has reported that as a result of testing compressive strengths of core specimens cut out from concrete pavement slabs at ages of 28 days to 5 years, the strength of concrete with fly ash which was more than 250 kg/cm^2 at 28 days increased to more than 400 kg/cm^2 at 5 years, but were still poorer than the strength of concrete without fly ash.

The strength of concrete containing fly ash is accompanied by complicated factors as described previously and it is not surprising that uniform results cannot be obtained in field tests. However, it is thought there have been no reports that the use of fly ash in an actual project has had bad effects, except in cases of especially high water-cement ratios of concrete.

The pozzolanic reaction of fly ash differs greatly with the temperature of the concrete, being more active the higher the temperature. Therefore, when fly ash is used for massive concrete the strength of concrete will be considerably greater than in the case of curing at normal temperature making fly ash advantageous from the viewpoint even of only strength. (2) Takano (30) on testing compressive strengths when a part of normal portland cement was replaced with fly ash and mixing and curing of the concrete was performed at temperatures of 10°C, 21°C and 30°C, states that strengths at 3 months or later are lower the higher the curing temperature in the case of concrete without fly ash whereas they are higher the higher the curing temperature in the case of concrete containing fly ash. In other words the use of fly ash alleviates the drop in the long-term strength gain ratio produced by high-temperature curing of concrete.

Stolnikov and Kind (31), in consideration of precast concrete, has reported on normal pressure steam curing of concrete containing fly ash. This research was conducted with the thought to augment the reduction in short-term strength when fly ash is used. In the intake pressure tunnel of Kurobegawa No. 3 Power Station which passes through hot bedrock of temperatures 100°C or higher, the cement in the tunnel lining concrete was replaced 25% with fly ash and excellent results were obtained (32).

Influence of Fly Ash on Volume Change of Concrete

There is an extremely great number of papers which report that by replacing part of the cement with good quality fly ash, drying shrinkage of mortar and concrete is reduced. Blanks (33) for example, has obtained test results as shown in Fig. 6. Blanks also states that autogenous shrinkage is somewhat reduced. These are features of fly ash different from other pozzolans which are said to be due to the reduction in unit water content necessary for the required consistency. There are, however, reports (34) which say that drying shrinkage increases somewhat more than for concrete without fly ash when fly ash of high carbon content and low fineness is used.

In performing tests of drying shrinkage with concrete specimens, it is normal for reduction in the amount of drying shrinkage not to be very pronounced in proportion with replacement of cement with fly ash, even when the fly ash used is of good quality. When beams of 10 cm × 10 cm cross sections are dried severely for 6 months and more, the reduction

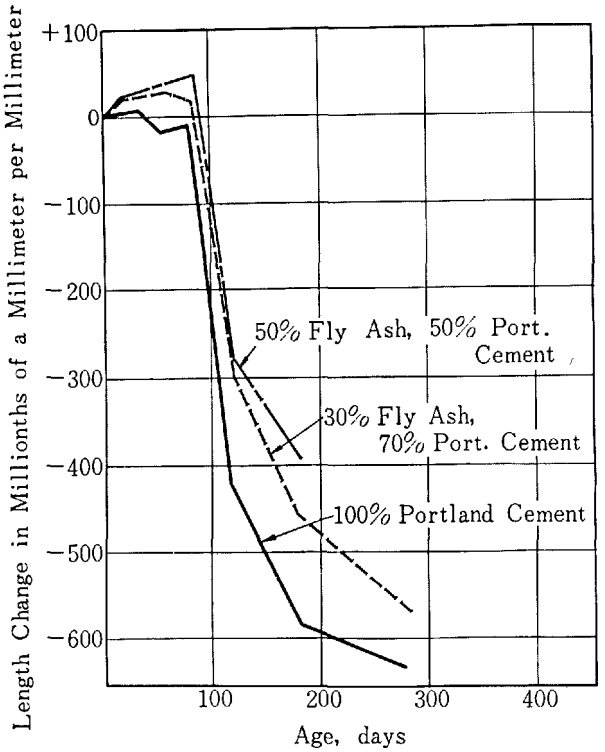

Fig. 6. *Drying shrinkage of concretes. Measurements made on 10 × 10 × 75 cm beams fog cured 90 days, then dried at 50% humidity, 21°C.*

in drying shrinkage barely reaches 15 to 20%. For a shorter period, at about a month of drying, there is very little difference seen, the reduction in drying shrinkage of concrete containing fly ash being only about 5% of that of concrete without fly ash. It is not possible for concrete members exposed to outdoor air to be dried as severely as in the above tests. Nevertheless, it is clearly seen in experience with projects using fly ash that cracks accompanying drying are reduced. In other words, the degree to which the detrimental effects of drying shrinkage are reduced is much more prominent than indicated by the drying shrinkage values obtained with concrete specimens. One of the reasons for this is that in almost all tests the shortening in length of a specimen due to drying shrinkage is measured along the central axis of the specimen. When this is done, it is impossible to obtain the shrinkage at the surface portion occurring with the drying.

Davis et al (2) sealed off 15-cm cube specimens on five sides allowing drying to occur from only one surface and measured shrinkage not only at the central axis, but also along an axis near the surface in discussing shrinkage in the interior of the specimens. Nagataki (35) also sealed five sides of beam specimens and measured shrinkage at each of the surfaces that accompanied drying. Nagataki also studied tensile stresses occurring when drying shrinkage is restrained. As a result he has ascertained that when concrete with part of the cement replaced with fly ash is dried at relatively early ages, the difference in moisture content between surface portion and interior is alleviated and the tensile stresses produced by drying is reduced. This is thought to happen because in young concrete containing fly ash, the free water slightly to the interior from the surface is in a readily evaporable condition. Therefore, it is thought even if the effect of fly ash in concrete indicated by drying shrinkage values obtained in normal methods of testing is small compared with the effect in cement paste or mortar, the role that good quality fly ash plays in preventing cracking of concrete is surprisingly great.

The above is an indication that it will often be reasonable to use fly ash not only for concrete in hydraulic structures, but also in various members in general.

Influence of Fly Ash on Heat of Hardening of Concrete

When concrete is made replacing a portion of the cement with fly ash, the rate of evolution of heat of hardening of the concrete is retarded. The U.S. Bureau of Reclamation has conducted numerous experiments concerning heat of hardening of concrete containing fly ash. (19) Davis et al (2) state that the value of the rate of reduction in heat of hardening of concrete at 28 days when fly ash is used is equal to approximately one-half of the percentage figure of fly ash replacement. The reason that the rate of reduction does not equal the percentage figure of fly ash replacement is the finely divided powder effect of fly ash, a matter to be discussed later.

One of the reasons for the extensive use of fly ash in dam concrete is this alleviation of heat of hardening, which makes it easier to regulate the temperature of the concrete reducing the fear of cracking from thermal stresses (24)(36).

Influence of Fly Ash on Watertightness and Durability of Concrete

Unless curing conditions are especially poor, the watertightness of concrete containing fly ash is improved. This is only natural when pozzolanic activity is considered. Davis (34) compared permeability coefficients of concretes of unit cement contents of 225 kg/m³ at the age of 6 months, and states that the coefficient of concrete with 30% of cement replaced

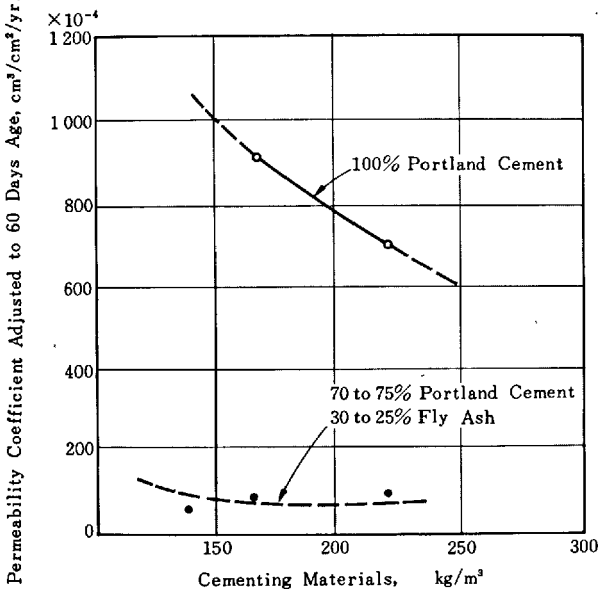

Fig. 7. *Permeability of concrete with and without fly ash.*

with fly ash was 1/5 of that of concrete without fly ash, while with 50% replacement, the coefficient was reduced to 1/12. The U.S. Bureau of Reclamation and the Corps of Engineers have tested watertightness of lean concrete containing large-sized coarse aggregate and both have shown the effectiveness of fly ash in this respect. Fig. 7 illustrates the test results reported by Higginson (37) which indicate the marked improvement in watertightness obtained by use of fly ash. Yoshikoshi (38) has also carried out wide studies of fly ash, and especially in regard to watertightness, originated a simple method of testing permeability in which a concentric hole of small diameter was provided in a cylinder to obtain a thick-walled specimen and hydraulic pressure was applied from outer surface, and discusses in detail the effect of fly ash on watertightness of concrete. Going by this method, the same relation between the direction of concrete placement and the direction of permeation of water as seen in the field is obtained.

Fundamentally, the watertightness and durability of concrete structures depend a great deal on defects in workmanship at joints and other parts of concrete whenenver these defects exist. Therefore watertightness of a concrete structure will be greatly affected by whether or not workability of concrete is good. Other than in cases of grossly inferior quality of concrete or especially severe exposure conditions, the quality of concrete does not necessarily determine watertightness. When a good quality fly ash is suitably used, workability of concrete is improved to aid in reducing defects occurring at the time of concrete placement so that it is thought watertightness of concrete members will be improved even more.

By proper use of pozzolans in concrete, resistance to various kinds of aggressive waters is improved. It is even said that this is the principal reason for pozzolans to have become used so actively. From the viewpoint only of resistance to action of aggressive water, there are other pozzolans which are superior to fly ash. However, there are many reports which state that this type of durability was improved by replacement of a part of the cement with fly ash (2)(23)(39)(40).

Even when workable concrete is carefully consolidated, about 1% of air bubbles is generally contained in the concrete, and depending on the cement and aggregate, the air may be as high as 2% or more. These bubbles of air are not entrained air, but are effective to some degree in providing durability against freezing and thawing. When concrete is mixed with the addition of fly ash, the air bubbles are reduced due to the influence of the fine particles so that the air content of the concrete is reduced to about 0.5% after consolidation. Therefore, when fly ash is used in concrete which is not air-entrained, it is customary for the performance of the concrete in freezing and thawing tests to be somewhat impaired. (23) However, there is a report saying that at an age of 5 months better results were obtained in freezing and thawing tests with a non air-entrained concrete containing fly ash compared with non air-entrained concrete without fly ash (41). This is believed to be due to the influence of pozzolanic effect of the fly ash.

It is needless to say that durability of concrete against freezing and thawing action will be vastly improved by entrainment of a suitable amount of air using a good quality admixture. Larson (42) established that this principle can be applied to concrete containing fly ash. Parenthetically, as a result of measurement of the size and distribution of air voids on the surface of a sawed section of concrete containing fly ash and from results of freezing and thawing tests, Larson states that fly ash has no ill effects on air voids of hardened concrete and in comparison of concretes of equal strength and air content there was no difference between concretes with and without fly ash.

The freezing and thawing tests mentioned above are an extremely severe test of concrete differing greatly from the meteorological conditions to which concrete in the field is exposed. As the correlation between the results of these laboratory tests and durability of field concrete is a great problem which has not yet been solved, no attempt will be made here to discuss this

matter. Even limiting the discussion to comparison tests for estimating the effect of fly ash, there are problems remaining regarding test methods such as the age of concrete at which freezing and thawing should be commenced, the method of curing during this period, and the moisture conditions of specimens during freezing and thawing (34)(43).

Influence of Fly Ash on Alkali-Aggregate Reaction

Alkali-aggregate reaction is mostly considered a problem in North America and apparently in Australia there has been some trouble (44), but it appears there have not been many cases in other parts of the world which have been reported.

The use of pozzolans to prevent alkali-aggregate reaction has been recommended by Stanton (45), Hanna (46), Lerch (47) and others. In many studies that have followed, it has been indicated that certain natural or artificial pozzolans are effective in reducing alkali-aggregate reaction while some other pozzolan have almost no effect.

Meissner, as a result of comparative experiments of the effect of fly ash and 10 other pozzolans in controlling alkali-aggregate reaction, reported that fly ash, although not as much as opal and calcined shale, had considerable merit (48). Blanks (49) and Lerch (50) have also produced results of experiments which enable comparison to be made of the effect of fly ash versus other pozzolans.

Brinks and Halstead (17) experimented with 10, 20, 35 and 50% replacements respectively of cement using 17 out of 34 varieties of fly ash listed in Table 1. Fig. 8 is an example of the test results which shows that a high percentage of replacement with fly ash (e.g., about 35% replacement of cement) is effective in controlling expansion from alkali-aggregate reaction in the case of all fly ashes. However, it is indicated at the same time that there is a pronounced difference according to the fly ash in the relation between the fly ash content and the effect in controlling expansion.

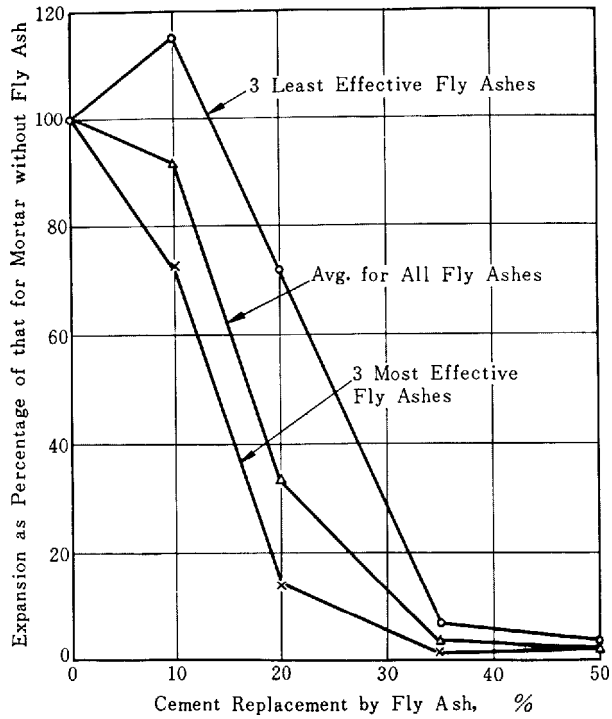

Fig. 8. *Effect of fly ash on expansion of alkali-reactive mortar at age of one year.*

As described above, although fly ash is not the most suitable admixture for prevention of alkali-aggregate reaction, there is no question that it has a practical effect. It is a fact, however, that the effect of fly ash on alkali-aggregate reaction differs to some extent not only according to the aggregate and cement, but also the quality and the amount of fly ash used.

In testing the effect of admixtures in controlling alkali-aggregate reaction, the ASTM method (51) is widely used. However, this is an accelerated test using mortar specimens so that there are many questionable points remaining and it is desirable that progress be made in studies regarding correlation to concrete in the field.

Chemical Behavior of Fly Ash in Concrete

Chemical Characteristics of Fly Ash in Concrete at Early Ages

The chemical composition and fineness of fly ash, as described previously, differ greatly according to country and even within the same country there are considerable differences according to the plant. Therefore, it is difficult to accurately describe the chemical characteristics of fly ash within concrete and it is especially so at early ages.

Yamazaki (52) disclosed that in concrete with fly ash cured at normal temperature, the strength of the concrete estimated from the void-cement ratio calculated considering fly ash not to be part of the cement

is somewhat higher even at early ages when hardly any pozzolanic reaction has occurred. For example, Fig. 9 shows the results of compressive strength tests of concrete made to a given consistency adding fly ash while maintaining unit cement content at 290 kg/m³. Although water-cement ratio is slightly increased with increasing addition of fly ash, the concrete strength is clearly greater at the age of 7 days when very little pozzolanic reaction has occurred. Also, similar increases in concrete strengths are found when adding limestone powder which has no pozzolanic reactivity at all. The same phenomenon was seen with finely divided powders of gray wacke and silicious sand which too are considered to cause hardly any chemical reaction in cement paste. Yamazaki further experimented on the non-evaporable water in the cement paste portion of mortar in which finely divided mineral powders were used and pointed out these mineral powders, even when hardly causing any chemical reaction within the cement paste, brought about an increase in non-evaporable water per unit amount of cement equivalent to the increase in strength, in other words increased the amount of cement hydrated from early ages. Regarding the reason for this, Yamazaki theorizes that replacement by fly ash or other finely divided mineral powders in the floc structure constructed of cement particles expands the available space in which hydration products are precipitated to increase the hydration of cement. This effect was named "finely divided powder effect."

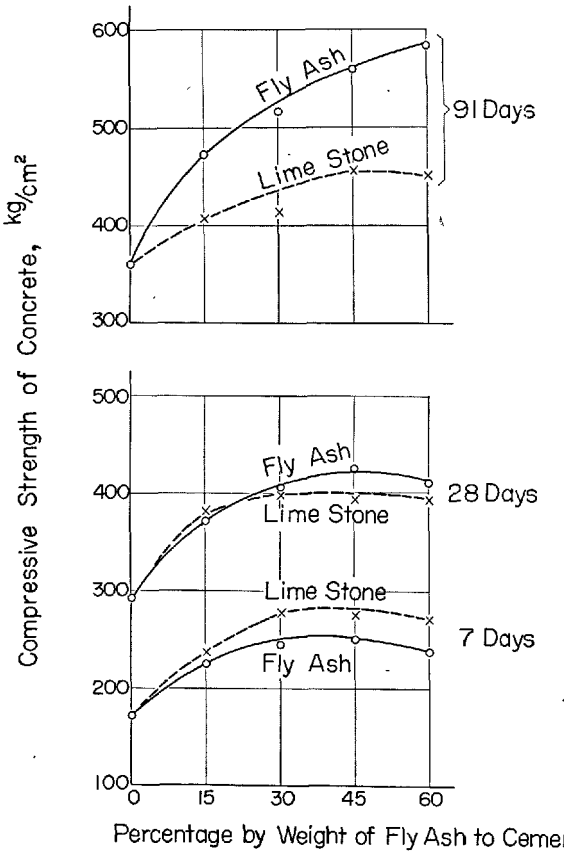

Fig. 9. *Compressive strength of concrete made by replacing part of fine aggregate with fly ash. (Unit cement content of concrete maintained at 290 kg/m³, and therefore finely divided powder was added and was not replacement for cement.)*

Kawada (53) studied the hydration of cement paste at early ages when fly ash is added. As the actual water-cement ratio is changed by replacement of cement with fly ash, Kawada measured the rate of heat evolution of cement pastes (without fly ash) at various water-cement ratios for reference (See Figs. 10 & 11). According to the results, there is no great change in the time required for the rate of heat evolution curve to reach a peak according to water-cement ratio, but the rate of heat evolution per gram of cement is higher the lower the water-cement ratio. Further, up to one hour of addition of water, the amount of hydration heat shows almost no change with variation in water-cement ratio, but at 24 hours, the amount of heat is reduced when the water-cement ratio is increased. Next, Kawada took pastes with a constant water-cement and fly ash ratio of 0.4 in which a part of the cement was replaced with fly ash from which soluble components were removed by washing with water and measured the rate of heat evolution and the amount of heat evolution per gram of cement (See Figs. 11 & 12). With the increase in the fly ash replacement ratio, the time at which the rate of heat evolution reaches a peak is somewhat quickened and also the peak is at a higher point. The fact that the heat of hydration per gram of cement is constant at one hour regardless of the amount of fly ash indicates that the amount of hydration reaction occurring within a short period of time after addition of water is not governed by the quantity of water or fly ash. The heat of hydration of paste without fly ash becomes lower with increased water-cement ratio at 24 hours, but in paste in which there is a replacement of cement by fly ash, the heat of hydration per gram of cement is conversely greater with the increase in the amount of fly ash. This appears to substantiate the appropriateness of Yamazaki's theory of finely divided powder effect of fly ash.

In the above experiments, fly ash washed with water was used to exclude influence of the soluble components of fly ash. In the case of unwashed fly ash, the peak of heat evolution is only heightened a little and the time at which the maximum is reached is slightly retarded (See Fig. 12). The soluble components of fly ash consist mostly of calcium sulphate, but the

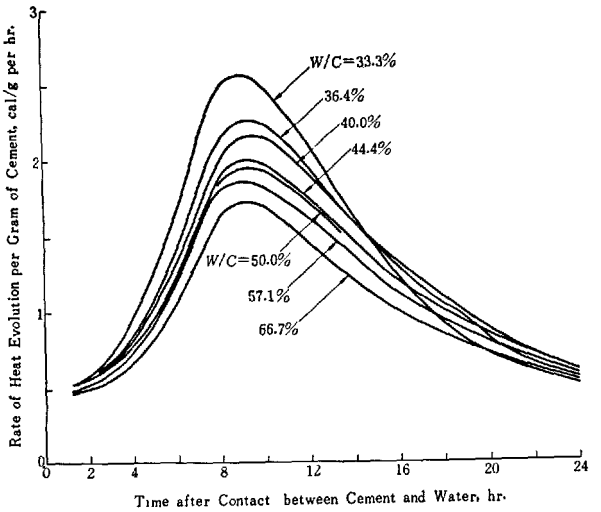

Fig. 10. *Effect of water-cement ratio on rate of heat evolution.*

content is extremely small while the rate at which they are leached out is slow, so that it is assumed the influence of the soluble components on initial chemical behavior of fly ash in concrete is of a negligible degree. Therefore, it is thought the effect of fly ash on cement hydration at early ages, is limited to the finely divided powder effect or the increase of cement hydration through the increase of available space for hydration products.

Method of Testing Pozzolanic Activity

Methods of testing pozzolanic activity of pozzolans have been studied by many researchers for more than one hundred years. However, since the varieties of pozzolans used in concrete are so myriad with pronounced differences in quality, and since the purposes of use of these pozzolans are also varied, it is extremely difficult to establish an appropriate test method for pozzolanic activity.

Lea (7) summarized and discussed the various methods of testing pozzolanic activity at the International Symposium on the Chemistry of Cement held in 1938, while Malquori (10) also discussed test methods at the Fourth International Symposium on Chemistry of Cement held in 1960. These reports and the discussions thereof all comprise information of great value, part of which are useful guides to research on methods of testing pozzolanic activity even today.

Moran and Gilliland (54) have discussed methods of testing pozzolanic activity dividing their studies into the 3 categories of tests on pozzolan alone, tests on pozzolan-lime mixtures and tests on poz-

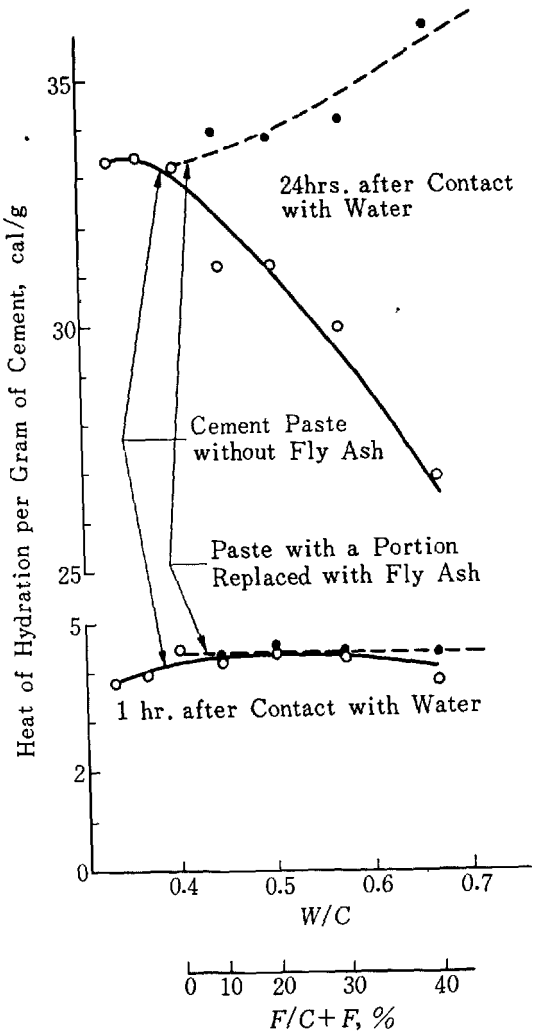

Fig. 11. *Heat of hydration per gram of cement per various water-cement and fly ash ratios. Thoroughly washed fly ash with water-cement fly ash ratio maintained at 0.4.*

zolan-portland cement blends. Although today, when research and testing techniques have progressed further and methods have been suggested which are combinations of various methods so that establishing of distinct classifications is difficult, if an attempt were to be made to classify the methods of testing pozzolanic activity which can be considered to be commonly used, it would result in the form given in Table 4.

Forest and Demoulian (60) compared Steopoe's method, (62) the method suggested in AFNOR P 15-301, (65) the method in ASTM Designation: C 379-56T (61) and the method of Poliet and Chausson (60) using 6 pozzolans including 4 fly ashes. As a result, they have pointed out that the AFNOR

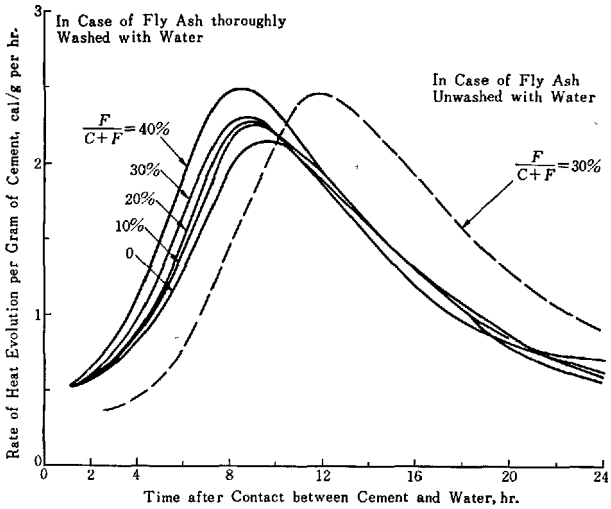

Fig. 12. *Rate of heat evolution for cement per gram in paste with portion of cement replaced with fly ash. Water-cement fly ash ratio maintained constant at 0.4.*

Table 4. *Classification of methods of testing pozzolanic activity considered to be relatively frequently used*

Classification		Example of test method
Method testing strength by accelerated curing of pozzolan-lime mortar or pozzolan-portland cement mortar		ASTM C 593–66T(55) ASTM C 402–65T(56)
Method adding pozzolan to lime solution	Quantitative measurement of lime	Chapelle's method(57) Moran and Gilliland's method(54)
	Quantitative measurement of lime and alkali	AFNOR P 15–462(58) Italian standards ISO recommendation No 1156(59)
Method treating pozzolan or pozzolan-lime mixture with acid or alkali	Quantitative measurement of SiO_2	Florentin's method(60)
	Quantitative measurement of $SiO_2 + Al_2O_3$	ASTM C 379–56T(61) Poliet and Chausson's method(60) Austrian standards Charisius' method(66)
	Quantitative measurement of $SiO_2 + Fe_2O_3$	Steopoe's method(62)
	Quantitative measurement of $SiO_2 + Al_2O_3 + Fe_2O_3$	Sestini and Santarelli's modification of Baire's method(11) Feret-Florentin method(63)
	Quantitative measurement of insoluble residue	Guillaume's method(64) AFNOR P 15–301(65)
Method measuring development of dissolution heat of pozzolan		Jambor's method(66)

Remarks Besides the above, there are Lea's method(67) of measuring electrical conductivity of pozzolan-lime solutions, a method of combining insoluble residue and development of dissolution heat of pozzolan (66) and Devillard's method (68) of quantitatively measuring lime by exposing mixtures treated with carbolic acid to ultra-violet rays. Also, petrographic analysis, X-ray analysis and differential thermal analysis are sometimes effective.

P 15–301 method is a method of quantitatively measuring insoluble residue, and due to a portion being dissolved by acid at the beginning, it is not effective in predicting pozzolanic activity, that the method of ASTM Designation: C 379 is not sensitive enough for comparison of pozzolanic activity between various pozzolans, while the method of Poliet and Chausson showed a good correlation with results of strength tests.

Jarrige and Darques (69) examined Devillard's method (68) in regard to fly ash and state that a good relation was obtained with results of strength tests at 3 months.

Watt and Thorne, (11) using the 14 fly ashes listed in Table 1 carried out detailed tests with the Feret-Florentin method (63) and the lime solution method, an application of the Feret-Florentin method to lime solutions. At the same time they compared testing methods using Sestini and Santarelli's modification of Baire's method, (11) Lea's electrical conductivity method (67) and Moran and Gilliland's method. (54) As a result, they found the Feret-Florentin method and the lime solution method to have good reproducibility and the best correlation with strength results of lime mortars at equal ages and curing temperatures. The correlation with strength at the age of 3 months was especially good. However, it is stated that no correlation could be seen at advanced ages of one year or more. As one means of acceleratedly testing pozzolanic activity within a short period of time, it is conceivable to raise curing temperatures, but in the two methods above, there was very little relationship between 28-day to 1-year strengths of lime mortars tested after accelerated curing at temperatures maintained at 50°C and at 20°C, and it is stated that there is hardly any correlation between short-term chemical testing methods and long-term strengths of mortar. Watt and Thorne further concluded that chemical methods of testing were not suitable for estimating long-term strengths when fly ash is used in construction.

In the widely used standards of various countries, chemical methods of testing pozzolanic activity are specified, but these would more be criteria for judging acceptability of various pozzolans. Because of the extremely great number of pozzolans, it cannot be helped if the standards are inadequate in some respects.

The values of SiO_2, Al_2O_3, Fe_2O_3, etc. often specified in standards are provided as a first-line limit of the chemical components necessary for a pozzolan and cannot be considered as having much significance in evaluating pozzolan and cannot be considered as having much significance in evaluating pozzolanic

activity.

Needless to say, the value of a method of testing pozzolanic activity of a pozzolan does not depend only on reproducibility, speed and simplicity; the correlation with strength of standard-cured concrete or mortar is an important yard-stick.

Taking fly ash into consideration, since it can be thought it is used more frequently in concrete when strength is important compared to other pozzolans, the correlation with long-term strength especially becomes even more important. Thinking in such terms, the most effective method of testing pozzolanic activity of fly ash would be a method based on strength of mortar or concrete obtained by accelerated curing. Even were this method of testing strength to be adopted, a problem remains regarding the relationship with strength of concrete cured at normal temperature. For example, in ASTM Designation: C402–65T, (56) the pozzolanic activity index with portland cement is tested with accelerated curing, but it is noted that the index is for evaluating the degree to which fly ash contributes to longer strength development of concrete and is not a measure of the compressive strength of concrete containing the fly ash.

The purpose of using fly ash is not solely to increase long-term strengths, but at times it will be to increase resistance of concrete to sulphate attack or to decrease leaching by soft water. Needless to say, it will then be necessary to perform pozzolanic activity tests which are in accordance with such purposes.

The Pozzolanic Reaction of Fly Ash

The pozzolanic reactions of various pozzolans have been studied by a great number of researchers from quite some time ago (7)(8)(9)(10). Regarding these studies, reference has already been made, but it is worthy of note that Malquori cites the crystalline chemical soundness of glass as governing pozzolanic activity of natural pozzolans. The major reports on pozzolanic reaction of fly ash made public since the Fourth International Symposium on the Chemistry of Cement may be summarized as in the following.

Guillaume (70) quantitatively measured CaO produced by hydration in cement paste containing fly ash, discussed the relationship between decrease in CaO with age and progress of pozzolanic reaction and suggested that pozzolanic reaction of fly ash began from an age of about 14 days.

Jambor (66) states that pozzolanic reaction is defined as an reaction of SiO_2 and Al_2O_3 in fly ash with $Ca(OH)_2$ to form calcium silicate hydration products and calcium aluminate hydration products and that evaluation of pozzolanic reaction must take into consideration not only the fixing capacity of CaO, but the process of reaction between fly ash and $Ca(OH)_2$.

Shikami (71) tested reactions of various fly ashes added to CaO and $CaSO_4$ suspensions and together with results of tests by Florentin's method and other factors, demonstrated that fly ash was most reactive in a combined solution of lime and gypsum and also that besides calcium silicate hydration products, other reaction products, such as aluminates like $C_3A \cdot 3CaSO_4 \cdot 32H_2O$ also can be considered to be produced. The production of calcium sulphoaluminate hydrates have been proven in electron microscope observations by Saji as will be described later (See Fig. 19).

Pyachev (72) shows the results of strength tests on mortars made by adding fly ash to C_3S, C_2S, C_3A, C_5A_3 and C_4AF respectively and states that the extent to which fly ash contributes to strength is governed by the C_3S and C_2S content in cement. Among other things, Pyachev also states that the reaction between C_3S or C_2S with fly ash differs greatly with curing conditions and that the amount of addition of fly ash to obtain maximum strength will be markedly different for standard curing and steam curing.

Terrier and Moreau (12) stated that pozzolanic reactivity of fly ash is governed by the latent heat of devitrification of fly ash in differential thermal analysis and at the same time suggested that EPMA (Electron Micro-Probe Analyzer) would be a suitable apparatus to determine the composition of pozzolanic reaction products at fly ash surfaces.

Venuat (73) conducted wide-scale experiments using 2 different clinkers, 3 different fly ashes and gypsum in various mix proportions corresponding to F/(C + F) ratios of 20, 30, 40, 70 and 90%. Applying Feret's coefficient (equation below) to strength test values of 1:3 mortar in discussing pozzolanic reaction of fly ash, he has stated that pozzolanic reaction begins to appear from about the age of 28 days.

$$S = K\left(\frac{C_V}{C_V + V + A}\right)^2$$

$$K \fallingdotseq S\left(\frac{\frac{C}{W} + \rho_c}{\frac{C}{W}}\right)^2$$

where K: Feret's coefficient
S: Compressive strength
$\frac{C}{W}$: Cement-water ratio by weight
ρ_c: Specific gravity of cement
C_V: Absolute volume of cement

V: Volume of water

A: Volume of air

An example of the relation of the addition rate of fly ash to compressive strength is given in Fig. 13 in which it is shown that in comparison to strength in the case when fly ash is considered inert, the strength of mortar is slightly higher at 7 days and greatly higher at 90 days.

Ducreux and Jarrige (74) separated fly ash by sieving to obtain several fractions according to particle size and further in some cases crushed these fractions to obtain fly ashes of various finenesses. Using these fly ashes the strengths of 1:3 mortars were investigated and the respective pozzolanic reactions were discussed by application of Feret's coefficient and as a result it is stated among other things that fly ashes of 5 to 30μ particle size were highest in acitivity.

Sakurai et al (13) tested compressive strength of 1:2 mortras made using 12 fly ashes listed in Table 1 with 25% replacement of cement by weight as well as the reactivity of fly ash to lime saturated solutions in which case the mol values at various ages of SiO_2, Al_2O_3 and Fe_2O_3 which had reacted with lime solutions were measured.

From the test results, Sakurai showed that Feret's coefficient at ages of 28 days to 6 months had a close relationship with the mol values of $SiO_2 + Al_2O_3 + Fe_2O_3$ as illustrated in Fig. 14 and that the calculated value of the specific surface area of the glass phase, computed by multiplying the specific surface area of the fly ash obtained by the air-permeability method by the ratio of the glass phase content, also had a close relationship with Feret's coefficient (See Fig. 15). Further, comparing the results of X-ray analysis of the residue after removal of reaction products from samples in which reaction with lime had occurred with results of X-ray analysis on the original fly ash, it was found that the ratios between quartz contents and mullite contents were exactly identical in both, but the percentages of the quartz and mullite contents were markedly higher in the residue than in the original fly ash (See Fig. 16). Similar tests were conducted on pulverized quartz sand in which case only 1.9% of the SiO_2 reacted with lime.

These test results demonstrate that the glass phase is the major part of the phase composition of fly ash contributing to pozzolanic reaction in concrete with very little reaction on the part of the crystalline phases. It has also been ascertained that the SiO_2/Al_2O_3 value of the glass phase in the original samples of fly ash is very close to the ratio in the reaction products. This suggests that the products of pozzolanic reaction of fly ash contain not only calcium silicate hydrates

Deviation of Feret's coefficient at same age and specific surface area of glass indicates difference of reactivity of each glass.*

but also calcium aluminate hydrates.

Thorne and Watt (11) tested crushing strength of lime mortar using 14 varieties of fly ash listed in Table 1 (proportions by weight: fly ash 2.50, sand 2.0, lime 1.0) as well as the amount of acid-soluble material ($SiO_2 + Al_2O_3 + Fe_2O_3$) by the lime solution method. Prior to the tests, the fly ashes were all washed exhaustively with water. This was in consideration of prevent-

ing increase in error from agglomeration of fly ash particles.

As a result of the tests, little relationship was seen between increase in crushing strength from 28 days to 91 days and the silica content, alumina content, glass content, carbon content and density of fly ash, while the best correlation was found with the specific surface as determined by particle size analysis. On the other hand, no relationship whatsoever was recognized with the specific surface determined by the air-permeability method (See Fig. 17). It is also stated there was a close relationship between acid-soluble increments and specific surfaces and it is concluded that pozzolanic reaction occurring during this period is dependent on the surface area of the fly ash contributing to reaction.

It was also shown that the relationships between specific surface and acid-soluble increments with crushing strengths at advanced ages of 1 to 2 years were weakened, these strengths being closely related to the SiO_2 content or the $SiO_2 + Al_2O_3$ content of the original fly ash (See Fig. 18) and that pozzolanic activity was governed by the content of reactive components in the fly ash.

Saji (75) broke hardened cement-fly ash pastes at certain designated ages and preparing replicas by deposition from the fractured surfaces at which fly ash particles were exposed, made observations using electron microscopes. Fig. 19 shows electron microscope photographs of specimens cured in water at 20°C with the left photographs indicating the surfaces of fly ash particles and the right photographs the surfaces of cement hydration products with which fly ash had been in contact. These photographs clearly show the progress of pozzolanic reaction with elapse of time, but it is worthy of note that before 140 days, the surfaces of fly ash particles are comparatively simple while the concave surfaces on the side of the hydration products in contact with the fly ash present a complex condition so that there is little symmetry in appearance

Age	Fly ash particles embedded in cement paste	Hydrated cement substances in contact with fly ash
28 days		42 days		140 days		
Fig. 19. *Electron micrograph of ruptured surface of hardened cement paste containing fly ash.*

between the two. This is thought to be because at early ages there is a rim between fly ash particles and cement hydration products, with pozzolanic reaction taking place in this rim, it being filled with reaction products as pozzolanic reaction progresses.

When concrete containing fly ash is adequately cured, there is marked increase in long-term strengths, but normally, even in these cases there are surprisingly little increases in non-evaporable water and heat of hydration. As an explanation for this, Yamazaki (52) points out that the products of pozzolanic reaction at advanced ages are formed in the thin rim between fly ash particles and cement hydration products, so that even with reaction of an extent which does not affect the non-evaporable water and heat of hydration values, the pozzolanic reaction will serve to strengthen the bond between fly ash particles and cement hydration products. Fig. 20 shows the increase in strength accompanying increase in nonevaporable water to be higher the greater the age, which agrees with the abovementioned theorization. Yamazaki suggests that in discussing the relationship between mix proportions and strengths of mortars, if the volume of the solid phase of a unit volume of the cement paste portion is taken as a parameter, the latter's relationship with strength may be expressed with a single curve regardless of whether different types of cement are used, whether admixtures are used or whether curing temperatures and ages differ. It is stated that when fly ash particles and cement hydration products are strongly bound together, it is more reasonable to consider the unreacted portion of fly ash as a solid phase which governs the strength of mortar just as the unreacted portion of cement.

Homma and Kikuchi (76) tested flexural strengths, compressive strengths, and non-evaporable water at various ages of 1 : 2 mortar made with 10 to 30% replacement of cement with fly ash cured at temperatures of 20° and 40°C and also performed X-ray diffraction of hardened mortar. They also took hardened specimens of cement paste mixed at a ratio of 70 (cement) to 30 (fly ash) and conducted tests by the BET Method for specific surface area to which N_2 was adsorbed and for non-evaporable water. The Feret's coefficient corresponding to the mortar strengths at various ages were obtained and the respective ratios to the Feret's coefficient corresponding to strengths of mortar without fly ash were calculated in discussing the influence of fly ash on the strength

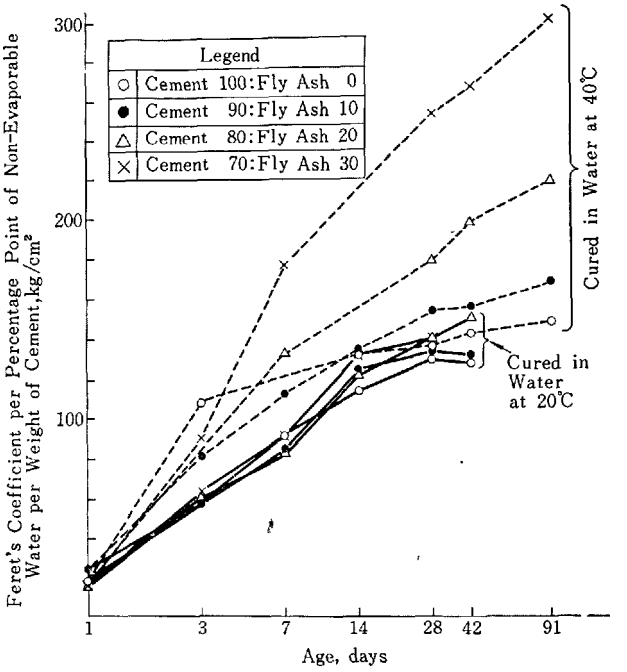

Fig. 20. *Development of Feret's coefficient per non-evaporable water of hardened cement paste.*

of mortar. It is stated that the age at which the Feret's coefficient ratio exceeds 1 is around 20 days for curing at 20°C and around 5 days for curing at 40°C. The specific surface area of the hardened cement paste increased slowly with age when fly ash was not used, but when fly ash was added it reached a maximum value at a certain age and thereafter grew smaller. The age at which the maximum value is reached agrees generally with the age at which the effect of fly ash on strength began to appear as indicated by the Feret's coefficient. It was also demonstrated that the quantity of non-evaporable water was increased when fly ash was used and that the increase was greater in the case of curing at 40°C than at 20°C. The Feret's coefficient per percentage point of the non-evaporable water is as given in Fig. 20 showing that the strength gain per percentage point is greater when fly ash is used. The results of these experiments offer a key to the search for the structure of pozzolanic reaction products. However, it should be mentioned it is thought that at the beforementioned ages at which the effect of fly ash becomes pronounced, the finely divided powder effect of the fly ash plays a part along with the pozzolanic effect.

Problems in Use of Fly Ash as a Concrete Admixture

Influence of Carbon Content of Fly Ash

As mentioned before, even when a certain amount of carbon is contained in fly ash, so long as the carbon particles are not weak, it is not thought the difference in carbon quantity will have much effect on the various properties of hardened concrete.

Fedynin (77) tested 5 varieties of fly ash with ignition loss of 6, 12, 15, 25 and 28%. The results showed very little influence of high carbon content on strength, durability, wear resistance, etc. of concrete and Fedynin explains the reason for this to be the semi-coking or coking of pulverized coal so that the fly ash itself is strong and hard. Also, there is an example of a test pavement in the U.S.A. on which it is reported a fly ash of approximately 13% ignition loss was used without any trobule. (29)

The reason the use of fly ash of small carbon content has been emphasized in a great number of reports in the past is probably because as the combustion in boiler furnaces is incomplete in the case of fly ash of high carbon content, the proportion of minute and smooth spherical particles is low and the effect on the various properties of concrete is weakened.

However, when air-entrained concrete using fly ash is made, a considerable amount of the air-entraining agent is adsorbed on the active carbon in the fly ash during mixing of concrete so that the effect of the agent is reduced. As a result, in order to obtain the required air content, it becomes necessary to increase the unit quantity of agent and it is not rare for this quantity to become several times the quntity sufficient when fly ash is not used (18)(23). There is an example of a project in which this quantity was increased by 11 times (29). Fine mineral powders have the characteristic of adsorbing admixtures by nature so that the increase in unit admixture content required is not restricted to the case of fly ash, but with the latter, the influence of active carbon is added to the abovementioned effect.

The ignition loss of fly ash has a close relationship with carbon content and there is a report which states that ignition loss and required unit admixture content are proportionate and suggests a method of calculating required unit admixture content from ignition loss test values (42). However, the carbon content and required unit admixture content are not necessarily proportionate when the source plant of fly ash differs. When pulverized coal is burned and fly ash is produced, it is thought that in the uncombusted portion of coal maintained at high temperature the carbon will have been changed to various forms in which there would be portions with weak adsorption even in uncombustioned portions. Also since the fineness of uncombustioned carbon is not uniform, carbon content and required unit admixture content would not necessarily be proportionate.

A further inconvenience is that the amount of air-entraining agent adsorbed by carbon differs with slight fluctuations in carbon content, which increases fluctuation in air content and in turn workability to make the control of air-entrained concrete difficult. There are countries in which adsorption quantities of methylene blue are measured by colorimetric tests to obtain an indication of admixture to be adsorbed by fly ash during mixing of concrete (18). Since adsorption of methylene blue and required unit AEA content are roughly proportionate, this method has proved useful in control of air-entrained concrete construction.

Pack Setting of Fly Ash during Storage

There are fly ashes which become pack set during storage. This tendency is stronger in the case of fly ash of high fineness. When pack setting occurs during storage, conveying and weighing is made difficult in the case of bulk fly ash, while in the case of bagged fly ash weighing is difficult. This is the second of the problems involved in the use of fly ash. Since Japan is a country of high humidity, the tendency for pack setting is pronounced, but it is unlikely that this is a problem limited to Japan. The pack setting of fly ash is a complicated phenomenon, hardening occurring with some fly ashes while not occurring with others.

Homma and Taniguchi (78) and Nagasako Homma (79) investigated the causes of pack setting in the case of various fly ashes and discovered that pack setting occurred because minute quantities of calcium sulphate existing on the surfaces of fly ash particles absorbed moisture from the atmosphere to act as a binder. Nagasako and Homma (79) also state that with the addition to fly ash of minute quantities of water of about 0.1%, calcium sulphate adhering to the particle surfaces is transformed into gypsum which will prevent pack setting, and that crushed coarse fly ash also would not pack set. Furthermore, it was found that fly ash blended with 20%

or more of crushed coarse fly ash is not readily pack set.

Use of Fly Ash in Slurry Form

Since fly ash is after all a by-product of combustion of pulverized coal, it is conceivable there is fear of some fluctuation in quality. Therefore, there are many standards of fly ash which contain provisions for uniformity of quality. When such provisions are not clearly understood, some fluctuation in quality of fly ash will occur and this will constitute a cause of fluctuation in the quality of concrete. This is the third problem encountered when fly ash is to be used as an admixture.

Even when the quality of fly ash meets the requirements on uniformity, as previously described, some amount of fluctuation in carbon content is unavoidable unless the conditions under which fly ash is produced are extremely good and it will be difficult to control air content and workability of air-entrained concrete. These and pack setting during storage pose the difficulties in using fly ash as an admixture.

Testing and research (80) were conducted to overcome these difficulties on the job at Okutadami Dam (gravity dam, height 157 m, concrete volume 1,630,000 m^3, period of concrete placement 1958–1961). As a result it was established that when fly ash was first vigorously mixed with water to form a slurry of a water-fly ash ratio of about 50% for storage in large quantities and then was used as necessary in this slurry form, it was splendidly made uniform to facilitate control of concrete and that even a mixture of two different fly ashes could be used. Also, since pack set fly ash could be readily used, all of the abovementioned difficulties were all nicely overcome. Furthermore, the workability of concrete was improved prominently over the case of use of fly ash in powder form and it was even found that durability was somewhat improved. In addition, when the slurry method was adopted, the equipment required was limited to the slurry mixing tank, slurry storage tank, air compressor, slurry pumps and slurry pipes eliminating the need for such equipment as screw conveyors, air sliders, bucket elevators and fly ash silos so that equipment on the job could be reduced drastically. Also, the concrete batching plant is no longer soiled by scattering of fly ash in the air. Following Okutadami Dam, this method of using fly ash was adopted at a number of dam projects other than gravity-type, such as arched types and hollow-gravity types, all with good results.

The reasons workability and durability of concrete is improved when the slurry method is adopted are thought to be that the individual particles of fly ash are released by the breaking up of agglomerates and that air entrapped in the agglomerates is released. Thorne and Watt (11) demonstrated that crushing strength of lime mortar containing fly ash which was first exhaustively extracted with water was two to three times greater than the case when fly ash was used without treatment after collection and cited the increase in the surface area of fly ash made available for reaction by the breaking up of agglomerates. The ratio of this strength increase cannot be applied immediately to the ratio of strength increase obtained when fly ash is used in slurry form for concrete, but the results of the tests do suggest that the slurry method will at times be effective in increasing strength of concrete.

Problems Involving Fly Ash Cement

Apart from its role as an admixture for concrete, fly ash has been in use for some time as an additive to cement. The U.S. Bureau of Reclamation has been having fly ash cement manufactured under special specifications and has been using it in concrete dam construction. Some of the portland-pozzolan cements presently being marketed in the U.S.A. contain fly ash. In Japan, a Japanese Industrial Standard on fly ash cement was established in 1960 (See Appendix 2), and presently 3 types of such cement are on the market. In France, standards on fly ash cement were established in 1959 (See Appendix 2) and 6 types are now being marketed. The consumption of this type of cement is extremely large and comprises approximately 1/3 of the cement manufactured in France.

The question of whether it would be better for fly ash to be used as an admixture for concrete or in the form of fly ash cement will depend on the economic structure and customary practice and is not a matter to be decided lightly. When in the form of fly ash cement, there is an advantage in that uniformity of fly ash is more easily secured. However, there are many cases in which it is more economical for fly ash to be used as a concrete admixture in power company construction and in other work. Also, since there is considerable difference in the quality of fly ash pro-

duced at various plants, unless as a concrete admixture, it will generally be impossible to use good quality fly ash in the most suitable manner to compensate for defects in portland cement, or to increase or decrease as necessary the amount used according to type of member, dimensions of member, temperature and other factors.

The influence of fly ash on the various properties of concrete is basically the same whether it is used as an admixture when making concrete or whether it is used in the form of fly ash cement. The technical problems involved in fly ash cement can be listed as the chemical composition and fineness of cement clinker and the method of blending the fly ash and the amount to be mixed in the cement.

There are numerous reports which state that the effect of fly ash differs with the type of cement when the fly ash is used to replace part of the cement. Davis (81) states that fly ash is more effective with normal portland cement and moderate heat portland cement than low heat portland cement, the reason being that these two types are high in C_3S content.

Brink and Halstead (17) taking 10 cements of greatly different alkali content, tricalcium silicate content and mortar strength, compared strengths of 1 : 2 mortar made replacing 50% of cement with fly ash and reported that at the earlier ages (e.g., 28 days or less) the alkali in cement appeared to accelerate the reaction between cement and fly ash, but at the greater ages (e.g., one year or more) the strength was higher the higher the C_2S content. Timms and Grieb (23) using two portland cements greatly different in alkali content, tested concretes made replacing part of the cement with fly ashes and reported that the effect of fly ash on strength and durability of concrete differed with cement.

In the studies of Stingley and Peyton (26) and Tsukayama and Miyoshi (27) on pavement concrete, it is reported that the effect of fly ash on strength was less in concrete made with moderate heat portland cement than in concrete made with normal portland cement.

There are reports (82)(83) which have stated that concrete made replacing a part of portland blast-furnace slag cement with fly ash demonstrated long-term strength equal to that of concrete without fly ash when the fly ash used was of good quality.

The chemical reaction in concrete between portland cement clinker and fly ash as mentioned previously is very complicated and differs not only with the quality of fly ash and the chemical composition of the clinker, but also greatly with fineness of the clinker. Judging from the fact that in all countries with the exception of France the production of fly ash cement is far less in comparison to the production of portland cement, it is doubtful that a portland cement clinker made esepcially for fly ash cement is being produced in any of the countries. It is thus natural that research in this direction has not progressed and it is extremely difficult to clarify a chemical composition of clinker suited to fly ash cement. At present, except for special cases, it is believed that so-called normal portland cement clinker is being used as material for fly ash cement.

The second problem of fly ash cement is whether in manufacture fly ash should be blended with ground portland cement clinker or whether clinker and coarse-particled fly ash should be mixed and ground together.

When coarse fly ash is ground, there is a fear that the smooth spherical shape will be lost. However, according to the work by Yoshikoshi (38). the part of the fly ash crushed when ground together with clinker is limited to the relatively larger particles so that the finer fly ash particles retain their smooth spherical shapes. Since the effect of fly ash in improving the various properties of concrete depends on the minute particles, it is believed the features of fly ash are retained even in the case of combined grinding. Actually, in this study by Yoshikoshi, it was shown that at the same degree of fineness, fly ash cement made by grinding coarse fly ash and clinker together, displayed roughly the same behavior as a blend of fine fly ash of the same chemical composition and a clinker ground separately in advance.

Venuat (84) has conducted a detailed study regarding finenesses of portland cement clinker and fly ash when manufacturing fly ash cement. Clinker ground to four different finenesses ranging between 2,500 and 6,400 cm^2/g and fly ash ground to three finenesses between 3,000 and 8,000 cm^2/g were blended to make fly ash cements and mortar specimens were made of the respective strengths in 3 classes of mix proportions. From the results, Venuat points out the existence of a certain fineness of fly ash suited to a given fineness of clinker and that fineness of fly ash has a great influence on strength at early ages, but little on strength, drying shrinkage and durability at advanced ages.

Summarizing the abovementioned and other studies, it appears that the difference in the method of manufacturing, whether by grinding fly ash and clinker separately or together, has a negligible effect on the various properties of fly ash cement. The fineness to be aimed for in grinding or the amount of fly ash to be blended should be determined upon testing to obtain cement of the required quality. In such a case,

it is important that fly ash cement of the required quality should be economically obtained, at times this being the governing consideration in manufacture of fly ash cement.

Conclusions

It is of course a difficult matter to gather every piece of literature throughout the world, and especially, in the case of fly ash which is a by-product and moreover a material which has come into use only comparatively recently, this difficulty becomes even greater. However, summarizing the various researches on fly ash and fly ash cement made public in various countries which it has been possible to obtain up to the present, it is believed the following can be said:

(1) As a result of reviewing the chemical compositions, phase compositions, and physical properties such as particle shape, specific gravity and fineness of various fly ashes, it has been found that this material differs greatly by country and by plant within each country. As examples, in chemical composition, SiO_2 ranged between 63 to 30%, Al_2O_3 between 34 to 11%, Fe_2O_3 between 31 and 3% while CaO ranged between 39 to 1%. Specific surface areas were between 8,100 to 1,200 cm^2/g. This is apparently due to differences in quality of coal, methods of burning, methods of collecting fly ash and other factors.

(2) On making an investigation of researches on the influences of various fly ashes with respect to workability, strength, volume change, heat of hardening, watertightness, durability against freezing and thawing, durability against aggressive waters and abnormal expansion from alkali-aggregate reaction of concrete, it was found that the reports from all countries agree in emphasizing although with some difference in degree, that a fly ash of suitable chemical composition and high fineness, or in other words a good quality fly ash, will influence these properties benefitially. The marked effects with respect to workability, drying shrinkage, heat of hardening, watertightness and durability against agressive waters have already become common knowledge. The age at which the strength of concrete with about 25% of the portland cement replaced with good quality fly ash exceeds that of concrete without fly ash is 3 to 6 months at 20°C moist curing. This age is reduced further when moist curing at higher temperatures is carried out indicating clearly that fly ash is of even greater advantage at high temperatures. It is also shown that the effect of fly ash is more pronounced in tensile strength and flexural strength than in compressive strength.

However, in the reports of all countries, it is pointed out that these effects differ considerably depending on the quality of fly ash and there are even examples cited in which prominent effects were not noted.

(3) It has been made clear that entrained air introduced by the use of an admixture in concrete containing fly ash is the same in size and distribution as entrained air in concrete without fly ash. Therefore, the durability against freezing and thawing of air-entrained concrete with fly ash is governed by concrete strength and air content as in the case of normal air-entrained concrete.

The amount of admixture required to obtain the desired air content often is increased extremely when fly ash is used. The reason for this is the adsorption of the admixture by carbon contained in the fly ash. Since it is impossible to maintain fineness and carbon content of fly ash perfectly uniform, it is stressed that special attention must be given to air content, and in turn workability, when fly ash is used with air-entrained concrete and there are simple testing methods which have been conceived for obtaining criteria for unit admixture content required to yield the specified air content.

However, it has been established by experience that when fly ash is first mixed vigorously with water to form a slurry and is stored in large quantities to be used as necessary instead of using it in powder form, the uniformity of fly ash will not only be maintained surely, but it will pose no difficulty to use pack set fly ash. On top of this, workability of the concrete is improved and also the method will result in more economy in many cases.

As mentioned above, the quantity of carbon content will greatly affect fresh concrete but there is little influence on the various properties of hardened air-entrained concrete.

(4) The excellent properties imparted to concrete by fly ash are not due only to the smooth, spherical particle shape, the high fineness and pozzolanic activity. The theorization that replacement of fly ash particles in the floc structure of the cement particles to increase the available space around the cement particles thus accelerating the hydration reaction also contributes to an extent has been indicated to be appropriate. When a finely divided powder such as fly ash is added, the strength of concrete becomes higher to some extent than the strength corresponding to the void-cement ratio even at early ages when there is

still no pozzolanic reaction. Since it has also been indicated that the soluble components of fly ash are of minute quantity and the rate at which they are leached out is slow, the reason for this strength increase can be explained brilliantly by the above theorization.

(5) Pozzolanic reaction, even when limited to that of fly ash, is an extremely complex phenomenon which has not yet been fully explained. However, it has been clarified that the phase composition of fly ash related to pozzolanic reaction is chiefly the glass phase, that the pozzolanic reaction depends on the surface area of the glass phase, that the strength increase of concrete due to pozzolanic reaction has a close relationship with the $SiO + Al_2O_3$ content of fly ash, and that calcium aluminate hydrates are contained in the pozzolanic reaction products as well as calcium silicate hydrates. These are research results which provide a key to the explanation of pozzolanic reactivity.

(6) The effects of pozzolanic reaction seen in concrete containing fly ash is somewhat different from the effects of other types of pozzolan. In concrete using fly ash, even with pozzolanic reaction of a degree not affecting the test values of non-evaporable water and heat of hydration, the strength of concrete at advanced ages is markedly increased when this reaction occurs. It has been established the reason for this is that the pozzolanic reaction products are formed in the rims between fly ash particles and cement hydration products so that even a weak pozzolanic reaction is extremely effective at long-term ages in causing fly ash particles and cement hydration products to be strongly bonded together.

(7) In regard to the manner of testing pozzolanic activity of pozzolans, there have been a great many methods which have been suggested from the past, each with its special features. In spite of this, at the present stage, there is still no test method with a close relationship to the long-term strengths of concrete or mortar containing fly ash. However, if the objective is limited to fly ash, it is a fact that various studies on the properties of fly ash have progressed to a considerable degree, and there are many actual examples of use of fly ash in the field with results of long-time tests already published, and therefore, in the case of fly ash, there is not very much necessity to discuss the values of the various methods of testing pozzolanic activity from a broad point of view. It should be adequate for a suitable method to be selected and applied in accordance with the circumstances of each country.

(8) Fly ash cement is already widely used practically, and good results have been reported. However, there is no generally accepted theory regarding the problems with respect to the chemical composition and fineness of cement clinker to be used in manufacture of fly ash cement, the method of blending fly ash, the quantity of fly ash to be blended, etc. This may appear strange, but probably is due to the different circumstances of each country.

To summarize, fly ash is already being used in many areas as an important ingredient of concrete, the purpose of its use being not only economy, but also the improvement of the various properties of portland cement concrete. Parenthetically, a good quality fly ash will even augment the defects of portland cement. Therefore, the concept of fly ash as a by-product is already becoming something of the past. It is necessary to seriously consider collecting methods so that good quality fly ash can be made available economically. The day when even greater lustre is added to these pearls born from coal through such efforts is looked forward to with great anticipation.

Acknowledgements

The sincerest gratitude of the author is extended to Dr. Kimbe Chujo, Dr. Junji Yamada and the engineers of the Nihon Cement Company Laboratory for their untiring aid in writing this paper and for their performance of supplementary tests whenever found necessary, and to the engineers of the Ministry of Construction for conducting field tests in connection with this paper.

Appendix 1 Standard Specifications for Fly Ash in Various Countries

1. Specifications

Country	Designation of standard	Year
Japan	JIS A 6201 FLY ASH[a]	1958
U.S.A.	ASTM C350–65T Tentative Specifications for FLY ASH FOR USE AS AN ADMIXTURE IN PORTLAND CEMENT CONCRETE[b]	1965 (First established in 1954)
Great Britain	B.S. 3892 Specifications for PULVERIZED-FUEL ASH FOR USE IN CONCRETE[a]	1965
U.S.S.R.	GOST 6269–63 BINDER ACTIVE MINERAL ADDITIVES	1963
Others	[c]	

a. Methods of sampling and testing are included.
b. Methods of sampling and testing are determined in accordance with the requirements of the ASTM Designation C311 and C402.
c. In the other countries, there exist specifications for fly ash only manufactured in case of artificial pozzolans, and these are not included in this appendix.

2. Chemical Requirements

	Japan JIS A 6201	U.S.A. ASTM C350–65T	Great Britain B.S. 3892	U.S.S.R. GOST 6269–63
Silicon dioxide (SiO_2), min. percent	45	—	—	40.0
Silicon dioxide (SiO_2) plus aluminum oxide (Al_2O_3) plus iron oxide (Fe_2O_3), min. percent	—	70.0	—	—
Magnesium oxide (MgO), max. percent	—	—	4	—
Sulfur trioxide (SO_3), max. percent	—	5.0	2.5[a]	3
Moisture content, max. percent	1	3.0	1.5	—
Loss on ignition, max. percent	5	12.0	7.0[b]	10
Available alkalies as Na_2O, max. percent	—	1.5[c]	—	—

a. Where the weight of pulverized-fuel ash to be used in the mix is equal to or greater than the weight of cement in the mix, a limit of 1.5 percent on the maximum sulphate content of the pulverized-fuel ash to be used shall apply.
b. Unless otherwise agreed between purchaser and vendor.
c. Applicable only when specifically required by the purchase for use in concrete containing reactive aggregate and cement required to meet a limitation on content of alkalies.

3. Physical Requirements

	Japan JIS A 6201	U.S.A. ASTM C350–65T	Great Britain B.S. 3892	U.S.S.R. GOST 6269–63
Fineness:				
Mean particle diameter, microns, max.	—	9.0	—	—
Amount retained when wet-sieved on No. 325 (44-micron) sieve, max. percent	25	—	—	—
Specific surface, (Air permeability test), min. cm^2/g	2700	—	Zone A. 1250[a] up and to and including 2750 Zone B. Above 2750 and up to and including 4250 Zone C. Above 4250, subject to a range not greater than 1500	
Compressive strength of mortar:				
Percentage of control at 7 days, min.	—	100	—	—
Percentage of control at 28 days, min.	63	100	—	—
Percentage of control at 91 days, min.	80	—	—	—
Increase of drying shrinkage of mortar bars at 28 days, max. percent	—	0.03	—	—
Water requirement, max. percent of control	100	105	—	—
Soundness:				
Autoclave expansion of mortar bars, max. percent	—	0.50	—	—
Pozzolanic activity index:				
With portland cement, at 28 days, min. percentage of control	—	85	—	—
With lime, at 7 days, min. psi	—	800	—	—
Reactivity with cement alkalies:				
Mortar expansion at 14 days, max. percent	—	0.020[b]	—	—
Uniformity requirements:				
Fineness and specific gravity	c	d	—	—
Water requirement	e	—	—	—
Air entrainment	—	f	—	—

a. By agreement between the purchaser and the vendor any other range of specific surfaces may be supplied.
b. The indicated test for reactivity with cement alkalies is optional and to be applied only at the purchaser's request. The test need not be requested unless the fly ash is to be used with cement containing 0.60 percent or more of alkalies calculated as sodium oxide and aggregate that is regarded as deleteriously reactive with alkalies in cement.
c. In tests on individual samples, the specific surface shall not vary more than 450 cm^2/g from that of the preceding sample.
d. In tests on individual samples, the specific surface shall not vary more than 15 percent, nor shall the specific gravity vary more than 5 percent, from the average established from the tests on ten preceding samples, or by all preceding tests if less than ten.
e. In tests on individual samples, the water requirement shall not vary more than 5 percent from that of preceding sample.
f. In addition, when air-entraining concrete is specified, the quantity of air-entraining agent required to produce an air content of 18.0 percent by volume of mortar shall not vary from the average established by the ten preceding tests, or by all preceding tests if less than ten, by more than 20 percent.

Appendix 2 Standard Specifications for Fly Ash Cement in Various Countries

1. Specifications

Country	Designation of standard	Year	Year first established
Japan	JIS R 5213 FLY ASH CEMENT	1964	1960
France	NF 15–302 PORTLAND CEMENT WITH SECONDARY CONSTITUENT	1964	1959
Others	a		

a. In the other countries there exist specifications for fly ash cement only manufactured in case of pozzolanic cement, and these are not included in this appendix. The countries are as follows: Bulgaria, China, Czechoslovakia, West Germany, Greece, Hungary, Italy, Mexico, Netherlands, Portugal, Rumania, Spain, U.S.A. (ASTM and Federal), U.S.S.R., Yugoslavia.

Remarks

Preparation of specimens for strength test:

JIS: Natural Toyoura sand to pass 297-μ and be retained on 110-μ sieve. Specimens $4 \times 4 \times 16$ cm. Mix 1:2. Water/cement ratio 0.65. Compressive strength tests on broken prisms from bending strength test. The strength at any age shall be higher than the strength at the preceding age.

NF: Sand from Leucate (Aude) equal parts (tol. 10%). 0.5 – 1 mm, 1 – 1.6 mm, 1.6 – 2 mm. Specimens for tensile strength tests, eight shaped specimens, section 5 cm^2, for compressive strength tests, 5-cm side cubes. Mix 1:3, water according to normal consistency of neat cement paste. Mortar pressed in by means of iron pestle (8 mm diam. by 20 cm) with round end.

Written Discussion

Hirotoshi Abe, Shigeyoshi Nagataki and Ryuichi Tsukayama

The Sub-Committee on Fly Ash was set up in 1957 by Japan Society of Civil Engineers for the purpose of investigating the quality of fly ash and the method of its use. Since 1962, thirteen laboratories of the members in the committee has carried out the long term research upon neutralization of concrete containing fly ash and corrosion of steel bar embedded in the concrete specimens exposed to in natural conditions. The reason the committee took up this problem was because a discussion whether fly ash had a bad effect on neutralization and corrosion or not occured at a period when the demand of fly ash for reinforced concrete structure began to grow rapidly. Some of researchers eagerly stated that neutralization and corrosion would proceed faster in concrete containing fly ash.

This research project is being performed under the leadership of Prof. Kokubu, the chairman of the committee. However, when Prof. Kokubu prepared the P.P. IV-2, this research could not be referred to because the test data had been obtained only up to the age of 2 years. Afterwards, the data at the age of 5 years were studied, and many knowledges about the influence of fly ash on neutralization of concrete were made clear. The object of this discussion is to supplement the principal paper with these new data. Hereafter, the same tests are scheduled to be conducted at the ages of 10 and 20 years.

Materials and Test Method

Cement and Fly Ash

The laboratories joining in the long term test made specimens with two types of cement, normal portland cement and moderate-heat portland cement, each being supplied from the same lot of a factory. Fly ash was also supplied from a single lot. The test results are shown in Table 1 and Table 2, indicating the typical products in Japan used in the test.

Table 1. *Physical and chemical properties of cements (JIS R 5201, 5202)*

Type	Fineness cm^2/g	Bending strength 3d.	7d.	28d. kg/cm^2	Comp. strength 3d.	7d.	28d. kg/cm^2	Chemical composition SiO_2	Al_2O_3	Fe_2O_3	CaO %
N	3220	32.9	48.1	72.8	132	227	416	22.5	5.3	3.0	63.6
M	3250	28.0	41.3	63.3	98	156	283	23.2	4.2	3.3	63.4

N = normal portland cement
M = moderate-heat portland cement

Table 2. *Physical and chemical properties of fly ash (JIS A 6201)*

Fineness cm^2/g	Bend. str. ratio 7d.	28d. %	91d.	Comp. str. ratio 7d.	28d. %	91d.	Chemical composition SiO_2	Al_2O_3	Fe_2O_3	CaO %
3500	79	82	92	74	78	97	56.0	28.5	4.2	4.4

Aggregate

River gravel and sand were used, which were employed for daily work in each laboratory. The maximum size of the gravel was 25 mm. and the fineness moduli of the sands were 2.65–2.79. Specific gravities were 2.62–2.68 for gravels and 2.49–2.69 for sands. Absorptions were 0.8–1.9% for gravels and 1.8–2.7% for sands.

Mix Proportion of Concrete

Sixteen mixtures of concrete proportioned by combining four factors, per cent replacement of cement with fly ash, unit cement-fly ash content, type of cement and slump were used. Besides these factors, concretes containing air-entraining agents or water-reducing agents were also tested in some laboratories. In the case of replacing 30% of cement with fly ash, the reduction of unit water content ranged from 5% to 9% for normal portland cement and from 6% to 7% for moderate-heat portland cement. The amount of reduction depended on unit cement-fly ash content and slump.

Size and Type of Specimen

Cylinderical specimens, 15 cm. in diameter and 30 cm. in height were used. In order to investigate the problem of corrosion, three polished steel bars, 9 mm. in diameter, were embedded in concrete. The coverage of steel bars were 20, 30, and 50 mm., respectively. To keep the coverage accurate during placement of concrete, special metal fittings were used.

Manufacturing of Specimen

Concrete was mixed in a tilting drum type mixer used for daily work in each laboratory. Concrete was carefully placed and compacted so as to keep the correct location of steel, and not to make a defect in upper part of specimen due to bleeding.

Curing

One or two days after placing, specimens were demoulded and then cured in water at 18–24°C till the age of 14 days. Subsequently, the specimens were stored in an outdoor exposing space of individual laboratory. All spaces were in good condition for sunshine and ventilation. The outer part of specimen was temporally moistened by rain, and dried by sunshine. Under these condition, the rate of neutralization of concrete was slower than continuously dry condition. The temperatures in the exposing spaces, although depending on the location, were between −5°C and 35°C.

Neutralization Test

The neutralization of concrete and the corrosion of steel bar were scheduled to be tested at 2, 5, 10, and 20 years. The depth of neutralized part from the outer surface was measured on inner surfaces exposed by cutting a specimen. A specimen was cut along two cross sections, 7 cm. apart from both top and bottom surfaces. Then the middle part was cut again along a vertical section including the center of the cylinder (See Fig. 1). The maximum and the minimum depth of neutralization and the area of neutralized part were determined by means of spraying phenol phthalein solution on the surface. The mean depth of neutralization was calculated according to the following formula.

cross section,

$$d = R - \sqrt{B/\pi}$$

vertical section,

$$d = \frac{1}{2h}(A - B)$$

where,

d = mean depth of neutralization, cm.
R = radius of specimen, cm.
h = height of specimen, cm.
A = total area of section, cm^2.
B = area of colored part, cm^2.

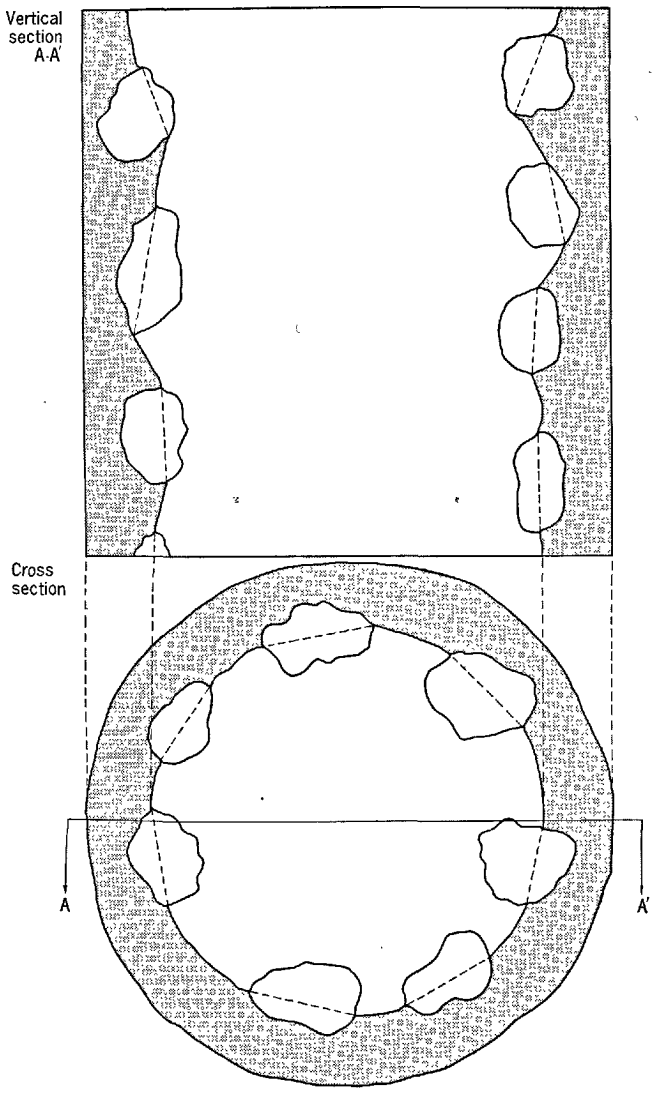

Fig. 1. *Sections of specimen for measuring the depth of neutralization*

Observation of Corrosion

Taking out steel bars from the specimen after measurement of neutralization, the extent of rusting was observed. In case of finding a corroded part, the area was measured and surrounding concrete was carefully investigated.

Compressive Strength Test

Compressive strength was also tested at the age of 28 days and 2 years on specimens manufactured simaltaneously with the specimens for neutralization test. The formers were cured in water at 20°C, and the latters were cured in the same procedure as the specimens for neutralization test.

Effect of Types of Cement, Use of Fly Ash, Cement-Fly Ash Content and Slump

Table 3 shows the test results at the ages of 2 years and 5 years. The clear relation between corrosion of steel and neutralization of concrete was not found out, because only small number of specimen showed the occurence of rust up to the age of 5 years. Accordingly, Table 3 contains only the mean depth of neutralization. Since the difference between laboratories due to the quality of aggregate and the location of exposure space are relatively small, Table 3 shows the average value of all laboratories.

The results show the influence of four factors, that is, type of cement, use of fly ash, unit cement-fly ash content and slump, on neutralization of concrete. Since some of the total combinations of these four factors were omitted, the influence of a special single factor could be known by averaging the data of pairs in which other three factors were kept constant. Fig. 2 shows the effect of each factor. The arrow line indicates the range of the data. Among the four factors use of fly ash and unit cement-fly ash content had major effect on neutralization of concrete. The type of cement and slump had only a slight influences on it.

Effect of Fly Ash

Effect of fly ash on neutralization are shown in Fig. 2–1. The mean depth of neutralization for concrete without fly ash was 0.24 cm. at 2 years and 0.49 cm. at 5 years, while for concrete replaced 30% of cement with fly ash was 0.33 cm. at 2 years and 0.68 cm. at 5 years. By replacing 30% of cement with fly ash neutralization of concrete progressed double as deep as concrete without fly ash.

Effect of Unit Cement-Fly Ash Content

In Fig. 2–2, the depth of neutralization showed marked decrease with the increase of unit cement-fly ash content.

Effect of Slump

Fig. 2–3 shows the effect of slump. The trend of slight increase with slump was observed, however, the increase was merely 0.1–0.2 cm. per 10 cm. variation in slump.

Effect of Cement Type

Fig. 2–4 shows the effect of the type of cement. The concrete which used moderate-heat portland cement showed a little greater increase in the depth of neutralization than the case of concrete which used normal portland cement. But, the difference between them which was less than 0.1 cm., appeared to be no essential importance.

					(50)			

Effect of Water Cement Ratio

The previously described results showed independently the effect of each four factors. The depth of neutralization in an actual concrete mix consisted of the combination of these four factors could not be estimated from Fig. 2. Therefore, the data were analysed again as a function of water cement ratio. In case of using fly ash, the ratio of water to cement (W/C) was adopted instead of the ratio of water to cement and fly ash ($W/C + F$), because of the short period of curing in water.

Between the mean depth of neutralization and water cement ratio (W/C), a strongly linear correlation was verified as in Table 4. (coefficient of correlation ranged from 0.976 to 0.995). The relation between water cement ratio and mean depth of neutralization, and between water cement ratio and the compressive strength at 28 days are shown in Fig. 3.

The trend observed in this figure could be summarized as follows:

(1) The relation between water cement ratio (W/C) and the mean depth of neutralization might be expressed by different straight lines depending on use of fly ash and type of cement.

(2) The mean depth of neutralization was smaller for concrete with fly ash than for concrete without fly ash so long as the comparison was made on the basis of equal water cement ratio.

Table 4. *Experimental formula for the relation between water-cement ratio and mean depth of neutralization of concrete*

Cement	$F/C + F$ %	Experimental formula for neutralization 2 years	5 years
N	0	$d = 2.20\ W/C - 1.00$ (0.984)	$d = 2.89\ W/C - 1.36$ (0.976)
	30	$d = 2.05\ W/C - 1.05$ (0.923)	$d = 3.14\ W/C - 1.68$ (0.976)
M	0	$d = 1.79\ W/C - 0.95$ (0.994)	$d = 1.79\ W/C - 0.62$ (0.978)
	30	$d = 1.78\ W/C - 0.79$ (0.992)	$d = 3.83\ W/C - 2.07$ (0.995)

in parenthesis; coefficient of correlation
d; mean depth of neutralization, cm.
W/C; water-cement ratio by weight,
N; Normal portland cement
M; Moderate-heat portland cement

(3) The difference in the gradient of the line in this figure, which is steeper for the data at 5 years than for the data at 2 years, indicates that the effect of water cement ratio increases with age.

(4) Irrespective as to whether using fly ash or not, the concrete of normal portland cement having the same compressive strength at 28 days showed the nearly equal depth of neutralization. For example, the mean depth of neutralization of the concrete having

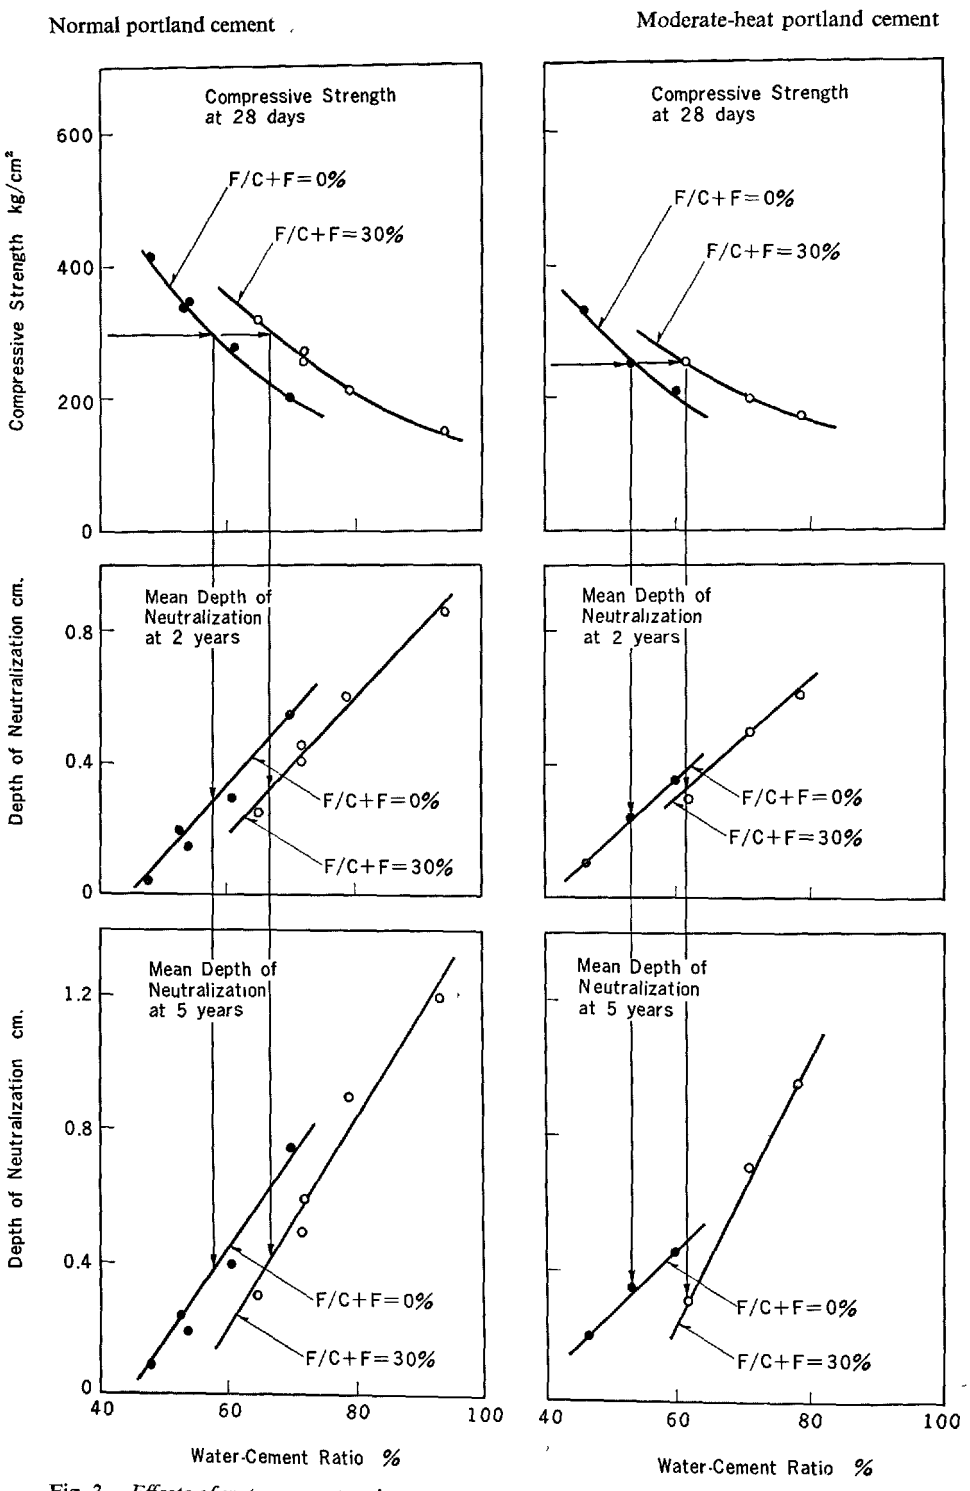

Fig. 3. *Effects of water-cement ratio on compressive strength and mean depth of neutralization*

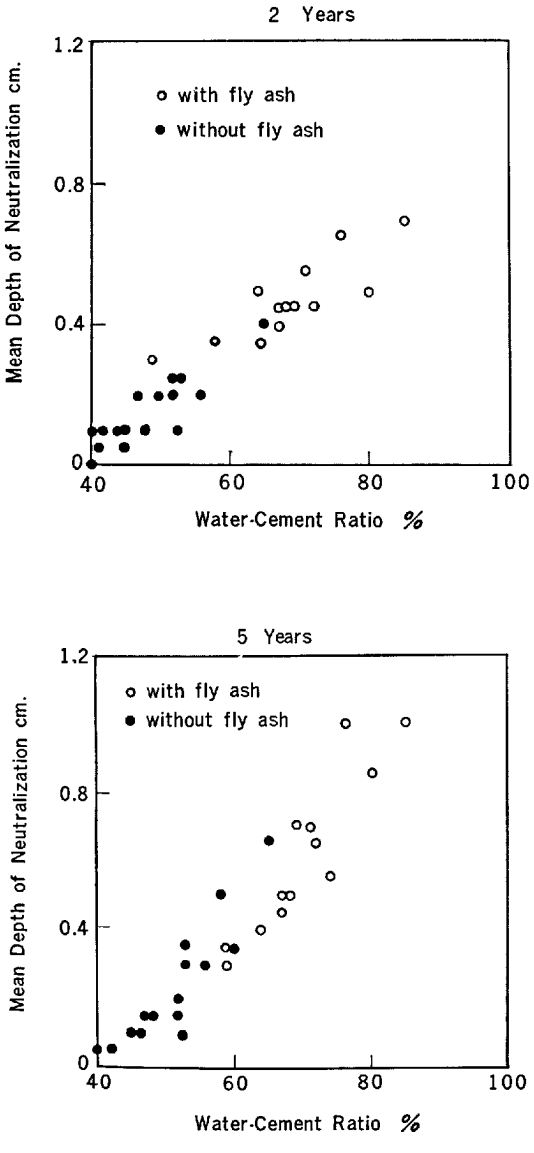

Fig. 4. *Effect of water-cement ratio on mean depth of neutralization of concrete containing air-entraining agent and water-reducing agent*

300 kg/cm² of 28 days strength was 0.30 cm. for concrete without fly ash and 0.32 cm. for concrete with fly ash at 2 years, and at 5 years 0.40 cm. and 0.42 cm. respectively. The data for moderate-heat portland cement demonstrated the similar trend to those shown above.

Effect of Air-Entraining Agent and Water-Reducing Agent

The neutralization test of concrete using air-entraining agent or water-reducing agent are conducted at several laboratories. The tests results at 2 years and 5 years showed that the mean depth of neutralization was slightly reduced by use of air-entraining agent or water-reducing agent. The relation between water cement ratio and the depth of neutralization are shown in Fig. 4. Since the separate data in each of three laboratories are plotted in this figure, some scattering of the data due to the difference in quality of aggregate and in the condition of exposure are observed. Nevertheless, the linear relation can be seen between water cement ratio and mean depth of neutralization. The reason of the reduction in the depth of neutralization by use of these agents is considered to be mainly due to the reduction in water content and water cement ratio.

Neutralization of Concrete Containing Fly Ash

The results of the exposure test described previously indicate that there is a close relationship between water cement ratio and mean depth of neutralization. On the basis of this relationship, the depth of neutralization can be predicted. A survey of the relation between compressive strength and the mean depth of neutralization revealed that there was no essential difference for both concrete with and without fly ash, having the same 28 days strength. Consequently, the restriction to the use of fly ash in a reinforced concrete structure in fear of the increase of neutralization of concrete and corrosion of steel bar appeared to be unnecessary so far as the concrete mix is proportioned on the basis of 28 days strength, regardless of fly ash itself having the character of increasing the neutralization. But, since the above conclusion was obtained from the data on concrete cured in alternately wet and dry condition, different behaviors might appear with concrete placed indoors and kept dry.

Written Discussion

Toshio Sakurai

It was my thesis that pozzolanic reactivity was to be attributed to the solubility of the glass of fly ash (1). Moreover I considered that the strength of mortar or concrete containing fly ash could possibly be due to

the amount and structure of the outer product formed mainly by the dissolution of the glass. In this paper, as an extension of this consideration, I have formulated a conception regarding the relationship between the strength of mortar or concrete and the quantity of glass, that is, the effective surface area of fly ash.

I have attempted to explain the relationship between the Feret's coefficient of mortar containing fly ash K and the curing time t in the following equation:

$$K = A \log t + C$$

According to the result obtained, K vs t is a straight line as is shown in Fig. 1. The sample of higher early strength seems to indicate a higher later strength, with no intersection of the lines. Accordingly, a factor A seems to show the effect of fly ash on the strength.

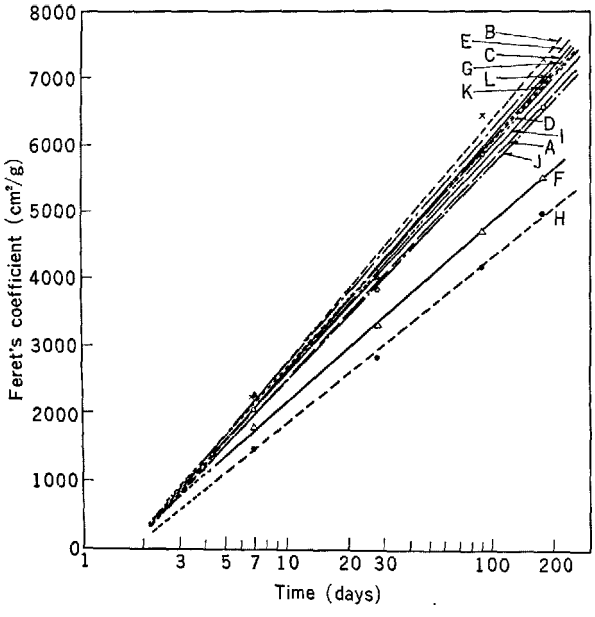

Fig. 1. *Relationship between Feret's coefficient of mortar containing fly ash and curing time.*

Table 1. shows the surface area of each fly ash measured by the air permeability method (second column) and the coefficient of pozzolanic reactivities given by Sakurai et. al. (1) (third column). The fourth column is the product of the second and third columns. This product may be considered to be the effective surface area of fly ash. The relationship between slope A obtained from Fig. 1 and this product, S_{eff}, is indicated in Fig. 2.

These two are in an almost straight line relationship, as is shown in the Fig. Accordingly, it is possible to estimate the mortar strength after an arbitrary curing time if the effective surface area of fly ash is known.

As stated above, it is clear that the properties of mortar or concrete containing fly ash are determined by the effective surface area of the fly ash.

Table 1. *The properties of fly ashes.*

Oral Discussion

Bryant Mather

Kajii and Usui (14) are cited as having found that specific gravity increases with decreasing particle size. I found (1) that by *grinding* fly ash from a surface area of 1855 to 5860 cm^2/g (air permeability) the specific gravity increases as follows:

Surface Area, cm^2/g,	Specific Gravity
1855	2.44
3565	2.70
4250	2.74
4660	2.75
5860	2.78

In other work by Luke (2), where two fly ash samples were separated into size fractions by use of an air classifier, the results were as follows:

	Fly Ash A		
	Specific Gravity	Fineness (a.p.), cm^2/g	Fe_2O_3, %
As received	2.41	2817	24.33
"Fine"	2.47	6061	19.87
"Medium"	2.60	1846	38.23
"Coarse"	2.92	1230	43.46
	Fly Ash B		
	Specific Gravity	Fineness (a.p.), cm^2/g	Fe_2O_3, %
As received	2.52	8,824	19.63
"Fine"	2.53	10.714	16.46
"Medium"	2.64	3,030	37.38
"Coarse"	3.02	1,846	53.35

This reversal of the relationship resulting in increasing specific gravity with increasing particle size is believed to reflect the differences in composition of the fractions, especially the increase in iron content with increasing particle size.

Author's Closure

Masatane Kokubu

Messrs. Abe, Nagataki and Tsukayama, based on results of experiments on concrete of equal compressive strength in which depths of neutralization with time were equal whether or not fly ash was used, have concluded that the depth of neutralization from the surface of suitably placed concrete exposed to the atmosphere is dependent on the quality of the concrete. In other words, they have concluded it is not necessary to restrict the use of fly ash in consideration of rusting of reinforcing steel in the case of suitably placed concrete.

Although only one variety of fly ash was used in this work, since the fly ashes marketed in Japan are all similar, it may be considered the test results are representative of Japanese commercial fly ash.

Since the test period of the above research is still short, it may not be proper to induce a decisive conclusion from the results. However, the author is in complete agreement with the conclusions of Messrs. Abe, Nagataki and Tsukayama and is looking forward with great expectation to the results of these tests which will be carried out for another 15 years.

The effective surface area of fly ash introduced by Dr. Sakurai is a factor which is thought to be useful in estimating the general outline of pozzolanic reactivity of fly ash by mineralogical means and his research work is of interest in this sense.

The author has heard with great interest Mr. Mather's discussion in relation to the particle size and specific gravity of fly ash and agrees with his opinion that when Fe_2O_3 contents of fly ashes differ the specific gravity of the coarser fly ash can be greater. Since the iron contents of Japanese fly ashes are much less than those of other countries, we were unaware of this point.

Supplementary Paper IV-7 Hydrated Phases after Reaction of Lime with "Pozzolanic" Materials or with Blast Furnace Slags*

Riccardo Sersale and Paolo Giordano Orsini*

Synopsis

Products of reaction between saturated lime solutions and several materials, natural or synthetic, have been studied with different experimental techniques for a better understanding of the hydraulic binders hydration process.

Natural glasses (true pozzolanas), artificial glasses (blast furnace slags, industrial or synthetic), zeolites (herschelite, analcite), volcanic tuffs (neapolitan yellow tuff, rhenish trass, which are zeolitized equivalents of the corresponding pozzolanas), have been considered.

Maximum amount of lime fixed by each material has been determined. Reaction products have been identified as follows:

1) Tobermorite-like calcium silicate hydrate and gehlenite hydrate from flegrean pozzolana. 2) Calcium silicate hydrate, tetracalcium aluminate and gehlenite, from neapolitan yellow tuff and rhenish trass. 3) Calcium silicate hydrate and gehlenite from zeolites. From herschelite also tetracalcium aluminate is produced. 4) Tetracalcium aluminate hydrate, calcium silicate, gehlenite and, probably, small amounts of hydrogarnets from blast furnace slags.

As it concerns the evolution of alumina contained in the reactants, an high content of Al_2O_3 and CaO favours hydrogarnet formation. An increase of silica, corresponding to medium contents of SiO_2 and Al_2O_3 favours gehlenite hydrate formation. Tetracalcium aluminate prevails when a silica rich glass, with small amounts of alumina, is used as reactant.

Identification of phases originated from different pozzolanic materials and from basic blast furnace granulated slags, after contact with lime, has been attempted by different investigators (1). It is well known, in fact, that composition, structure and relative abundance of new formed phases, influence technical behaviour of hydrated and hardened pastes.

In our Institute, emphasis has been given to the following topics:

—observation and identification of products;

—influence of reactants on the nature of hydrated phases;

—influence of environment, when reaction is carried either in excess liquid ("suspension") or in conditions comparable with practical use (paste).

In this note we shall refer on the whole of our experimental results and on their interpretation.

Pyroclastic Materials: Products of Reaction with Lime (Suspension)

Reaction between lime and the following pyroclastites, whose analyses are reported in Table 1, has been studied first:

1) Light pozzolana from Bacoli Naples, Italy; (2nd Flegrean volcanic period).
2) Dark pozzolana from Segni (Colli Albani volcanic region, Italy) (2).
3) Yellow neapolitan tuff from Ponti Rossi Naples, Italy; (2nd Flegrean volcanic period); zeolitized equivalent of flegrean pozzolana. Zeolite term prevailing in the groundmass is *herschelite* (3).

*Istituto Chimica Industriale, Fac. Ingegnerio, Università di Napoli, Napoli, Italy.

2) Dark pozzolana.
3) Yellow tuff.
4) Trass.

4) Trass from Krets (Andernach/Rhein, Germany; zeolite term prevailing in the groundmass is *analcite* (4).

These products, powdered to 230 mesh, have been kept in contact, at room temperature, with a saturated lime solution according to a standard procedure already described in a previous work (5). The plot of their lime uptake has been reported in Fig. 1.

In Table 2 are reported hydration products identified with X-ray diffraction analysis; interplanar spacings correspond to the strongest reflections.

Examination of this table confirms the existence of

Table 2. *Products of reaction between pyroclastic materials (see Table I) and saturated lime solution. Interplanar spacings (Å) correspond to strongest reflections.*

a relation between products and reactants. In the case of pozzolanic glass, considering that the excess liquid phase cancels any variation of total alkalinity (due to alkalies released from pyroclastic materials in correspondence with the lime uptake), it can be deduced that, alumina content being constant, an increase of silica favours formation of gehlenite hydrate. This result will be confirmed in the case of synthetic glasses. In the case of zeolitized glasses (numbers 3 and 4 in Table 2) contemporary presence of gehlenite and tetracalcium aluminate among hydration products cannot be explained on the basis of initial composition only (see analyses 1 and 3 in Table 2) but must be ascribed to the role of alkalies, even in dilute solutions. The larger amounts of alkalies released from zeolitic groundmass lowers lime concentration and favours formation of gehlenite hydrate.

Zeolites: Products of Reaction with Lime (Suspension)

Two zeolites, namely *Herschelite* from Aci Castello (Catania, Italy) and *Analcite* from Nova Scotia (North America) (8) have been studied with the same experimental procedure already described. These minerals have been selected because the zeolitic terms are prevailing in the volcanic tuffs previously investigated (yellow neapolitan tuff and Rhenish trass).

Chemical composition of specimens studied has been reported in Table 3. Products after reaction with lime, as identified by X-ray diffraction analysis, have been reported in Table 4. The plot of lime uptake, in Fig. 2, shows that amount and rate of lime fixation are higher for herschelite than for analcite in accordance with the corresponding results already reported in Fig. 1 concerning yellow neapolitan tuff and Rhenish trass.

Considering the nature of hydrated phases, obtained by action of saturated lime solution on pure minerals (Table 4), experimental conditions being equal, no tetracalcium aluminate was formed from analcite. This can be ascribed either to the higher silica content in analcite or to a larger amount of alkalies liberated which reduces lime concentration in equilibrium solution.

Synthetic Glasses: Products of Reaction with Lime (Suspension).

With the same experimental procedure already described, hydration reaction of synthetic glasses with different composition, has been followed in order to ascertain the influence of chemical composition of reactants (only major constituents are involved in this case) on the nature of products.

Attention has been particularly given to the evolution of alumina contained in reactants, which is difficult to follow because reaction products are not easily identifiable (9).

Three synthetic glasses have been prepared, with composition predisposed to formation of different hydration products (10).

Composition of different glasses has been reported in Table 5. Specimen No. 5, with mol ratio SiO_2: Al_2O_3: CaO = 1: 1: 1 is predisposed to formation of gehlenite hydrate, after fixation of suitable amount of "external" lime (lime from the $Ca(OH)_2$ saturated solution).

Specimen No. 6, with a mol ratio 0. 4: 1: 2 is predisposed to formation of terms in the isomorphous series *Grossularite*-Tricalcium aluminate hexahydrate (C_3AS_3-C_3AH_6) (11), after fixation of suitable amount of "external" lime. Specimen No. 7, with mol ratio 0. 6: 1: 3. 5, is predisposed to the formation of terms in the same series, even without fixation of lime.

Lime uptake of three synthetic glass specimens is plotted in Fig. 3. Hydrated phases, identified by means

of X-ray diffraction analysis, formed after reaction of different specimens with water or with saturated lime solution, have been reported respectively in Tables 6 and 7.

Absence of tetracalcium aluminate among these products confirms its formation from alumina poor reactants only (12). High alumina content, on the contrary, causes formation of gehlenite hydrate if silica is correspondingly high, or hydrogarnets if, even at room temperature, lime content (constitutional or external) is high.

Blast Furnace Slags: Products of Reaction with Lime (Suspension)

Three blast furnace specimen have been considered. Their composition is reported in Table 8.

As these specimen show equal lime uptake, only one plot has been reported in Fig. 4.

Compounds, identified by X-ray diffraction analysis, formed during reaction of each specimen with lime are shown in Table 9.

Table 8. *Chemical composition of blast furnace slags examined (wt%; 105°C dry)*

	8	9	10
SiO_2	32.23	29.94	28.57

	3.89	3.87	3.89
	2.86		2.87

Among these products, besides tobermorite like calcium silicate hydrate and tetracalcium aluminate hydrate, it has been possible to identify some terms in the hydrogarnet isomorphous series (reflections at 3.37 to 3.39 Å and 2.29 to 2.30 Å). Presence of these terms cannot be taken as certain. In any case their presence is not fundamental in order to explain the well known resistance of blast furnace cements to sulphate rich waters.

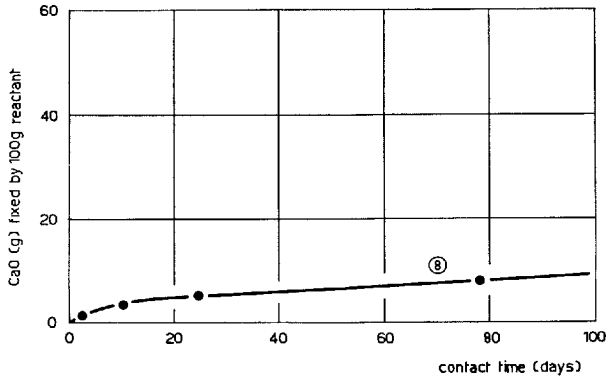

Fig. 4. *Lime uptake of blast furnace slags. Composition reported in Table 8.*

Pyroclastic Materials: Products of Reaction with Lime (Paste)

Same specimen reported in Table 2, mixed with 40% lime, have been used to prepare pastes. 40% water was added to the dry mixture. Homogeneous paste has been formed under pressure into small cylinders. These, after setting in a CO_2 free atmosphere, have been kept at room temperature, under distilled and reboiled water. After five years the core of cylinders, isolated after crushing, has been ground avoiding atmospheric contamination. The powder has been analysed with the methods of X-ray diffraction.

Substances identified have been reported in Table 10. Gehlenite hydrate and calcium aluminate (or

2. Hexagonal thin plates of gehlenite and of tetracalcium aluminate hydrate
3. E.D. pattern from a plate in 2.
4. Isometric crystals of hydrogarnet series term (from synthetic glass No. 6) Carbon replica.

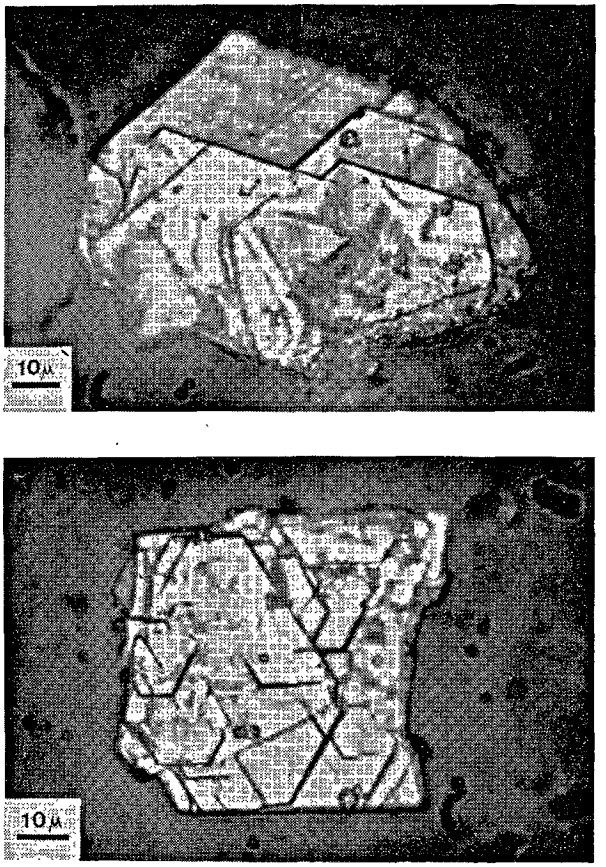

Photo 2
1. Hexagonal plates from pozzolana (reaction in paste)
2. Hexagonal plates from yellow tuff (reaction in paste)

carbo-aluminate) hydrate are constantly present besides tobermorite.

Products in Table 2, corresponding to reaction in suspension, when compared to products in Table 10, corresponding to reaction in paste, reveal a close analogy between the two types of reaction, at least within the limits of specimens and of conditions experienced. A slight difference concerns pozzolanic glasses. Pozzolana from Segni, for instance, reacting in paste has given also gehlenite hydrate (6). This confirms that the relative amounts of gehlenite and calcium aluminate (or carbo-aluminate) besides chemical composition of reacting glass, is influenced by lime concentration in the environment.

Besides X-ray diffraction analysis, specimens have been subjected to microscope observation and to differential thermal analysis. Results obtained with these techniques are reported hereafter.

Microscope Examinations

Micrographs in Photo 1 show solid phase obtained after reaction (in suspension) of some material investigated, with lime solution.

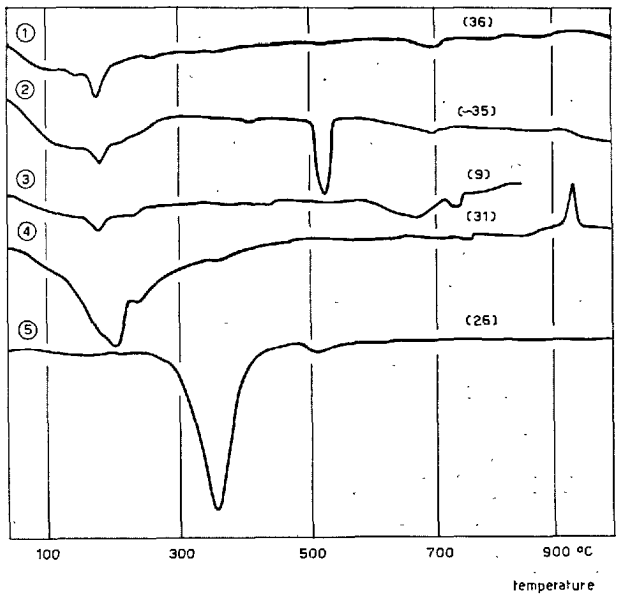

Fig. 5. *Differential thermal curves of:*
1) Pozzolana after reaction in suspension
2) Pozzolana after reaction in paste
3) Blast furnace slag.
4) Synthetic glass No. 5 (Table 5).
5)Synthetic glass No. 6 (Table 5).

Micrograph No. 1 shows crinkly foils of tobermorite, other forms of tobermorite have been observed elsewhere (14).

Micrograph No. 2 shows hexagonal crystals with basal lattice constant (see electron diffraction pattern No. 3) $a_0 = 5.73$ Å (15). This value being common to both gehlenite and tetracalcium aluminate, further discrimination between these compounds, with X-ray analysis, is necessary.

Micrograph No. 4 shows monometric crystals of terms in hydrogarnet series produced after reaction of synthetic glass No. 6 with lime.

In Photo 2, optical micrographs concerning pastes from pozzolana (Bacoli) and from yellow tuff (Naples) are reported. In both cases, No. 5 and No. 6, packed hexagonal plates can be observed at high magnification. Specimens were obtained evaporating on the glass slide a drop of xylene suspension containing small fragment of pastes. Dispersion of fragments in xylene has been achieved by treatment with ultra-acoustic waves.

Differential Thermal Analysis

Differential thermal curves were obtained with a

model D-200 Deltatherm analyzer (Technical Equipment Corp. U.S.A.) (16) on different reaction products and are reported in Fig. 5.

Curves No. 1 and No. 2 refer to pozzolana (Segni, No. 2 in Table 1) after reaction with lime, in suspension and in paste respectively (Numbers between brackets indicate the amount of lime taken up). Their profiles are much alike if the peak at 550°C, due to non combined lime, is not taken in consideration. The most significant thermal effect is the exothermic one with maximum between 150°C and 200°C due to free water and fundamentally to tobermorite. A weaker endothermic effect follows slightly over 200°C, probably due to tetracalcium aluminate (or carboaluminate).

No peak corresponding to terms in the series of hydrogarnets has been found between 300°C and 400°C. Curve No. 3 refers to a blast furnace slag (specimen No. 8 in Table 8) which has taken up around 10% lime. A first endothermic effect due to water, tobermorite and ettringite (17) between 150°C and 200°C is followed by a peak, at 200°C to 220°C, due to tetracalcium aluminate hydrate (or to its solid solution with sulphate). Also in this curve thermal effects due to hydrogarnets between 300°C and 400°C are absent.

Curve No. 4 refers to synthetic glass No. 5 in Table 5. Besides an endothermic effect with maximum at 200°C due to free water, tobermorite and mainly to gehlenite hydrate and a weaker effect with maximum around 225°C probably due to tetracalcium aluminate hydrate (or to the corresponding carbo-aluminate), a third effect, exothermic, with maximum between 900°C and 950°C can be attributed to the crystallization of gehlenite.

Curve 5 of glass No. 6 (Table 5) shows typical shape of terms of hydrogarnet series, considering that endothermic peak at 550°C is due to lime.

Results obtained with differential thermal analysis thus correspond to those obtained with X-ray diffraction and microscope methods.

Conclusions

The whole of experimental results points out that:
—Reactivity of zeolitized glasses (volcanic tuffs) to comparable to that of pozzolanic glasses (true pozzolanas).
—Stable hydrates originated after reaction of all pyroclastic products examined are: tobermorite-like calcium silicate, gehlenite, tetracalcium aluminate (or the corresponding carboaluminate). Formation of one or two alumina containing compounds depends upon composition of reactant and is influenced by the amount of alkalies released in correspondence with lime take up.
—Formation of tetracalcium aluminate hydrate is favoured when alumina poor glasses are used as reactant. Alumina rich reactants produce gehlenite or hydrogarnets. Formation of former or latter product depends upon silica and lime content of reactants.
—Among hydration products of blast furnace slags tobermorite and tetracalcium aluminate have been recognized. Neither gehlenite nor hydrogarnet have been detected via X-ray diffraction so that alumina in reactant slag seems to be in excess to the quantity engaged for reaction products. The problem of alumina collocation after reaction needs thus further investigation.
—Stable hydrated phases after reaction with saturated lime solution are qualitatively the same as obtained after reaction in pasty state. Reaction in suspension has, obviously, an higher rate and an higher degree of completeness, while crystals, better shaped and with regular faces, are more suitable for identification.

Supplementary Paper IV-17 Study of Reactions between CaO or $3CaO \cdot SiO_2$ and β-$2CaO \cdot SiO_2$ and Power Station Fly Ashes under Hydrothermal Conditions

Zdeněk Šauman*

Synopsis

The author investigated the reactivity of ten types of power station fly ashes with CaO in a 3:1 ratio (by weight) under hydrothermal conditions—175°C/8 atm. The character of hydrosilicate, as well as of further reaction components formed during the 16-hour hydrothermal process, was determined. The relative quantity of the tobermoritic phase was compared for the individual fly ash mixtures with the achieved strength values of porous silicate shapes; in the majority of cases an unambiguous relationship was found.

It was shown on the basis of C_3S—fly ash reactions in various weight ratios that the maximum quantity of the tobermoritic phase was formed in the case of equal weights of both starting components. The reaction of β-C_2S with fly ash was stopped at its very beginning due to coating layers of silica gel around the β-C_2S grains or their agglomerations.

The author also studied the reaction of mullite with CaO or C_3S and β-C_2S during the autoclave process, as most investigated fly ashes contain a significant quantity of mullite. In the first case is formed exclusively the hydrogarnet phase, in the second phase the hydrogarnet component with a smaller quantity of tobermorite. It was found that the main factor influencing the hydraulic properties of fly ashes is, beside α-quartz, the quantity and composition of the glass phase, but above all the SiO_2 content.

Introduction

The manufacturing technology of porous concretes employing power station fly ash as one of the main raw materials has until recently been based on empirical methods which made it in certain cases difficult to explain anomalies directly during the production of these materials. The reaction of various forms of SiO_2 with CaO under hydrothermal conditions has received relatively very great attention from many authors during the last 10 or 15 years. The field of the reactions of fly ashes of different compositions with CaO in the course of autoclaving has, however, with regard the narrowly specialized subject, been given substantially less attention. Déry (1) studied the reaction products formed in the autoclaved mixture fly ash—lime exclusively with the aid of X-ray diffraction. Apart from other components, hillebrandite was determined.

Butt, Majer and Varshal (2) studied the phases formed during the autoclaving of fly ashes with lime at 8 and 16 atm. Apart from hydrosilicate components, belonging to the tobermorite group, there was determined at a pressure of 16 atm. a phase corresponding with its composition to the mineral plazolite—$3CaO \cdot Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$.

Tun Soo-lee and Wang Yan-mou (3) investigated, chiefly by means of X-rays, the formation and character of the tobermoritic phase in mixtures fly ash—lime during the autoclave process.

The reactions of clinker minerals, mainly $3CaO \cdot SiO_2$ and β-$2CaO \cdot SiO_2$, with quartz sand in the course of the autoclave process were systematically studied by Bozhenov and Kavalerova (4), Kravchenko et al. (5) and further workers.

Volkov et al. (6) found by comparing the ratios of starting mixtures of alite and β-C_2S with quartz that maximum strength values were obtained—with the application of sand having a specific surface around 3,000 cm^2/g—for the case of a 50% addition of alite and a 20% addition of belite to the sand at 8 atm.

Šauman (7) studied the anomalous hydration of β-C_2S in a mixture with quartz sand of a different

*Research Institute of Building Materials, Brno, Czechoslovakia.

fineness during the autoclave process.

Relatively little attention was given to the reaction of fly ashes with clinker minerals.

Watt and Thorne (8) compared the mineralogical composition of 14 British fly ashes with compressive strength data for their mixtures with lime stored at normal temperature.

Simons and Jeffery (9) and Minnick (10) studied the relationship between the hydraulic properties of power station fly ashes and their mineralogical composition and pointed out the importance of the composition of their glass fraction and of further minerals. The last author determined especially the influence of the carbon content and the ignition loss of fly ashes on their pozzolana activities.

Šauman (11) compared compressive strength values for porous concrete blocks and found that the main factor influencing the strength of these materials is above all tobermorite and the CSH(I) phase, respectively.

Owing to the fact that already in a previous paper (12) of the author it was not possible to find at least an approximate correlation between the obtained strength values of porous concretes with specific surface, granulometric composition, fly ash porosity, combustible fraction content, etc., further factors were studied which could contribute to the evaluation of power station fly ash and which could also explain at least partly some anomalous phenomena in the technology of porous concrete production.

Experimental

Methods and Materials

X-ray Investigations

For the identification of reaction components, as well as for the quantitative determination of the appropriate phases was employed the Müller "Mikro 111" X-ray diffractograph, in all cases with CuKα radiation. The samples were comminuted, passed through a 400 mesh sieve and mixed with 10% $Mg(OH)_2$ used as an internal standard. The lines 2.36 Å or 4.76 Å were used.

To prevent preferential orientation a similar technique of preparation was employed as described by Copeland and Bragg (13).

As far as other physical methods are concerned, use was made of electron microscopy including diffraction, differential thermal analysis, and in certain cases infrared spectral analysis (Perkin-Elmer Infracord 337 instrument).

Chemical Methods

For the determination of uncombined $Ca(OH)_2$ was used the modified Franke method (14). The soluble SiO_2 form was determined by means of the method (15) derived from the Steopoe process.

Synthetic Preparation of Clinker Minerals and Mullite

The preparation of $3CaO \cdot SiO_2$ and β-$2CaO \cdot SiO_2$ has been described in detail by the author in another paper (16).

For studying the reactivity of mullite with CaO and clinker minerals, two samples of the mullite phase were used which were obtained by two different processes: by a solid state reaction from starting materials and by electromelting. In the first case the content of corundum did not exceed 1%, in the second one 2 to 3% in addition to a certain amount of glass phase.

The specific surface of the mullite sample prepared by solid-phase reactions was 4,760 cm^2/g and that of the mullite sample prepared by electromelting was 4,530 cm^2/g. The corresponding values for C_3S were 3,670 cm^2/g and for β-C_2S 3,160 cm^2/g. In all cases the Blaine method was used.

Selection of Starting Materials—Fly Ashes

For the actual experiments was employed a total of 10 types of Czechoslovak fly ashes from 10 Czechoslovak electric power stations, 8 samples being brown coal fly ashes and 2 hard coal fly ashes. The complete chemical analysis is given in Table 1.

The specific surface was determined by the Blaine method, as well as with the aid of the BET instrument. The results are presented in Table 2.

At the same time an X-ray analysis of the given fly ash types was carried out.

Each fly ash contains a fluctuating quantity of α-quartz and mullite, besides a very small quantity of haematite. The ER sample contains anatase and the TI fly ash a smaller quantity of anatase and rutile.

Actual Preparation of Samples for Hydration

To the mixtures intended for the hydrothermal process was added approximately 25% boiled distilled water and using a mould cubes with a 10 mm edge were prepared.

Instead of an autoclave small pressure vessels with an inner diameter of 25 mm were employed; these

were filled to 1/3 of their content with boiled distilled water. Immediately above the water level was placed on a holder the cube of the investigated sample. The pressure vessels of each sample series were placed in an electrically heated thermostat with forced air circulation, usually at a temperature of 175°C (8 atm.), for different periods of time. It took about 30 minutes to reach the given temperature. After the termination of the hydrothermal process, the samples were dried at 100°C in a nitrogen stream for a period of 7 to 8 hours.

Results and Discussions

Hydrothermal Reaction of Power Station Fly Ashes with CaO

The individual fly ash samples were homogenized with CaO in a 3: 1 weight ratio and autoclaved in the form of a moistened mixture in the small pressure vessels for a period of 16 hours at 175°C.

Evaluation of X-ray Measurements

In mixtures with NO fly ash it was possible to determine considerable quantities of tobermorite, since the interference lines of this phase ~11.3, 3.07, 2.97 Å and others exhibit a considerable degree of intensity. Also interferences corresponding to still unreacted α-quartz and mullite can be seen. Visible are also relatively intense diffractions of the hydrogarnet component which are not overlapped by lines of the remaining components—5.04, 2.75, 2.25, 2.00 Å, and others.

The mixture with the ER fly ash already contains a significantly smaller quantity of the tobermoritic component, besides the hydrogarnet phase and the still unreacted components—α-quartz and mullite. The quantity of the hydrogarnet component is somewhat smaller than in the previous case.

In mixtures with the BR fly ash the tobermorite content has again increased approximately to the value of the content of the first mixture. Here can again be seen interferences of the hydrogarnet component and of the still unreacted α-quartz and mullite.

Conditions are similar also in the mixture with the MA fly ash; the differences lie exclusively in the integral intensity of the individual diffractions.

The mixture with the NH fly ash contains approximately the same quantity of the hydrogarnet and of the tobermoritic phase.

The diffraction diagram of the mixture with the TR fly ash exhibits a similar character. In accordance with the integral intensity of the tobermorite diffractions, the content of this component is somewhat lower.

In the mixture with the MO fly ash a steep increase of the tobermorite content was noted; on the other hand, a very small quantity of the hydrogarnet phase is present.

In the next mixture with the PC fly ash was observed a very considerable quantity of tobermorite, besides a relatively small quantity of the hydrogarnet phase.

In the mixture with the PH fly ash is apparent a considerably lower tobermorite content (in relation to the previous case).

It seems that the altogether smallest quantity of tobermorite is present in the mixture with the TI fly ash, since the diffractions ~11.3 Å, 2.98 Å, and others display a minimum degree of integral intensity.

Fig. 1 presents X-ray diffraction diagrams of CaO mixtures with the fly ashes NO, ER, PC and TI.

In the studied mixtures no significant quantities of still uncombined $Ca(OH)_2$ were determined.

Apart from the above experiments, also autoclaving of the fly ashes in the identical weight ratio with CaO was carried out using shorter periods of time—2, 4 and 8 hours at 175°C/8 atm. In the investigated mixtures of the individual fly ashes was formed already in the course of a 2—4 hour reaction a significant quantity of the tobermoritic phase. With a prolonged hydration period (8 hour reaction) the content of this phase rises steeply and reaches in the majority of cases its maximum value, since the difference in the tobermorite content in mixtures autoclaved for 8 and 16 hours is very small.

Apart from tobermorite is formed as the first reaction component the hydrogarnet phase. The formation of this component takes place during the first periods of the hydrothermal process, since already after a 2 hour reaction this phase can be identified reliably by X-ray methods. It can be assumed that this component exhibits a composition which approaches the formula $3CaO \cdot Al_2O_3 \cdot SiO_4 \cdot 4H_2O$. It is, however, possible to speak only about an approximate composition, since in connection with the Fe-ions in the fly ash glass the hydrogarnet phase can contain also a small quantity of iron; its composition is given by the general formula: $C_3A_{1-n}F_nS_xH_{6-2x}$.

It appears that the reactivity during the first two hours of the hydrothermal process is, among other things, influenced by the value of the specific surface; after the above period of two hours, this influence becomes apparently considerably smaller.

Differential Thermal Analysis

The DTA-curves do not exhibit significant anomalies and are therefore not presented here.

Electron Microscopy

The conclusions derived from electron microscopy and electron diffraction correspond to the data obtained by means of micro-structural X-ray measurements. After a 4 hour hydrothermal period it is already possible to determine the typical platy tobermorite crystals, the number of which reaches its maximum after 8 or 16 hours of the reaction. Fig. 2 presents an electronmicrograph of a mixture with the TR fly ash autoclaved for 8 hours.

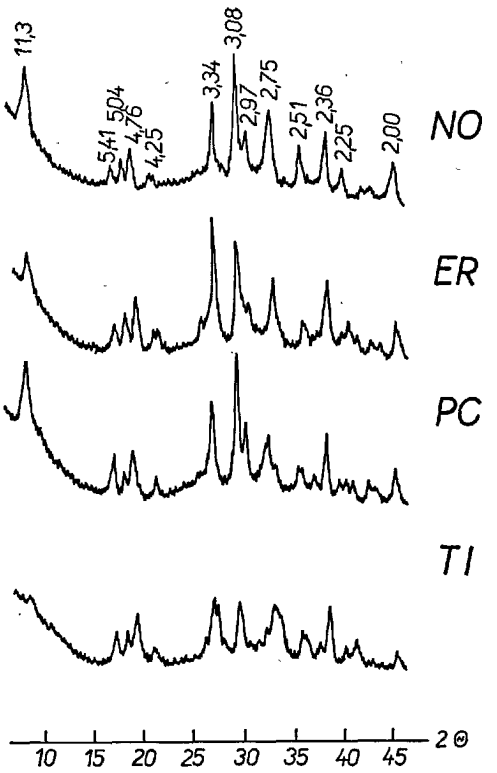

Fig. 1. *X-ray diffraction diagrams of power station fly ash samples with CaO (3: 1) after 16 hours of hydrothermal process (175° C/8 atm.).*

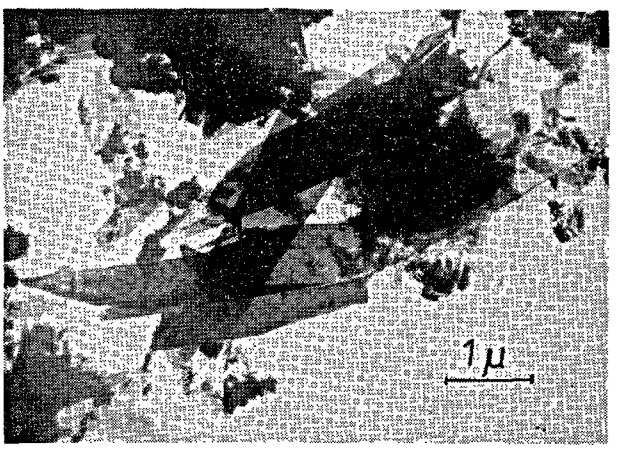

Fig. 2. *Electronmicrograph of the mixture TR fly ash with CaO (3: 1) after 8 hours of hydrothermal process (175°C).*

Evaluation of Fly Ashes with Regard to Formed Tobermoritic Phase

For assessing the quality of the investigated fly ashes will be mainly considered their capability of forming in the course of the hydrothermal process with CaO the maximum quantity of the binding component—the tobermoritic material. It was found on

the basis of preliminary experiments that the actual tobermoritic phase, 11.3 Å—tobermorite, exhibits the highest binding qualities. For the above reasons were prepared mixtures fly ash—lime (3 parts to 1 part) which were autoclaved in the form of moistened samples in small pressure vessels for a period of 12 hours. Each mixture was autoclaved twice, in order to obtain more objective results. The approximate relative quantity of the tobermoritic phase was expressed by the ratio of the integral intensity values of the relevant diffractions of tobermorite and brucite employed as the internal standard: $\frac{I \sim 11.3\,Å}{I\,4.76\,Å}$. This data was compared with the determined strength values for test porous silicate shapes (cubes with a 10 cm edge) prepared from the individual fly ashes (75 parts fly ash, 22 parts CaO, 3 parts $CaSO_4 \cdot 2H_2O$ and a small quantity of Al-powder). The technology of the laboratory production of porous silicate shapes was controlled in such a way as to obtain a minimum scatter of density values. This density fluctuated for the individual types between 680 and 700 kg/m³.

It is readily apparent from the diagram in Fig. 3 that the values of the relative quantity of the tobermoritic phase correspond approximately to the compressive strength data. Only minor differences can be seen for fly ashes BR and PH.

Reaction of Fly Ashes with $3CaO \cdot SiO_2$ under Hydrothermal Conditions

For a more detailed study and clarification of the reactivity of C_3S and β-C_2S with fly ashes was employed the mixture of three fly ash samples—TR, ER and MO. Moistened mixtures were prepared with graded C_3S quantities, as shown in Table 3. Hydration was carried out at 175°C for a period of 16 hours and 72 hours.

X-ray Evaluation

16 Hour Reaction

Mixture 1 contains a very small quantity of the tobermoritic phase with regard to the diffuse interference line ~3.06 Å. The quantity of this component is already substantially higher in mixture 2. This contains a certain quantity of CSH(I) apart from a small quantity of tobermorite, since the ~11.3 Å diffraction almost merges with the background of the X-ray record. In mixture 3 the ~11.3 Å diffraction is already highly pronounced, the further characteristic tobermorite line (2.98 Å) also exhibits a higher degree of intensity.

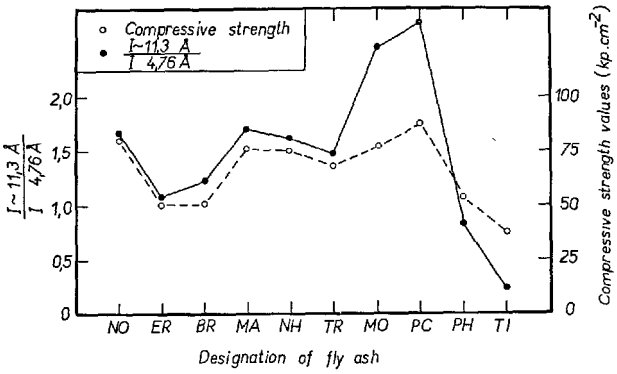

Fig. 3. *Comparison of the relative tobermorite quantity with the achieved compressive strength values.*

Table 3.

Mixture number	Quantity of $3CaO \cdot SiO_2$ or β-$2CaO \cdot SiO_2$ (%)	Quantity of fly ash (%)
1	10	90
2	20	80
3	30	70
4	50	50
5	70	30
6	80	20
7	90	10

In mixture 4 can again be noted an increase of the diffractions which are typical for tobermorite (11.3, 3.08, 2.98, 2.81 Å, and others). The lower intensity diffractions (2.73, 2.23, 1.97 Å) probably correspond to the hydrogarnet phase.

The X-ray diffraction diagram of mixture 5 already exhibits a decreased intensity of tobermorite diffractions. Here is also apparent the presence of a certain quantity of the $C_2SH(A)$ phase. On the basis of the 4.98, 3.25, 2.73 Å and even other diffraction it is possible to assume the formation of the hydrogarnet component.

In the remaining mixtures the contents of the tobermoritic phase are rapidly reduced, whereas the $C_2SH(A)$ quantity is increased. It is possible to determine also a small quantity of unhydrated C_3S besides C_3S-hydrate and liberated $Ca(OH)_2$. The presence of the hydrogarnet phase can be identified only with great difficulties, since the most interferences are overlapped by lines corresponding to the starting minerals or to the newly formed products.

72 Hour Reaction

Mixture 1 contains a very small quantity of the tobermorite group phase. In the other mixtures the tobermorite contents again grow, the maximum being reached in mixture 4, in which there is in the unhydrated, original form the same weight ratio of C_3S and fly ash. The presence of the hydrogarnet phase is indicated by the lines 4.98, 4.33, 2.73 Å, etc. The next

mixture 5 contains already a certain quantity of the $C_2SH(A)$ phase, besides the tobermoritic hydrogarnet component and the uncombined $Ca(OH)_2$ and undecomposed C_3S.

In the previous and also in the following mixtures the tobermorite content rapidly decreases and simultaneously the quantity of the $C_2SH(A)$ component grows. Apart from the liberated calcium hydroxide there is present also a very small quantity of still undecomposed C_3S and C_3S-hydrate.

A comparison with X-ray diffraction diagrams of mixtures hydrated for 16 hours brings out the fact that through further hydration the contents of CSH(I) and tobermorite are increased, besides an increased quantity of the $C_2SH(A)$ component. Conversely, in the course of the prolonged hydration (72 hours), the quantity of C_3S-hydrate and of the unhydrated C_3S fraction is reduced.

Based on the integral intensity degree of the diffraction ~11.3 Å of the tobermorite, it was possible to assess the relative content of this phase in the sample. By plotting along the vertical axis of the diagram the ratios of the integral intensity values $\frac{I \sim 11.3\ Å}{I\ 4.76\ Å}$ and along the horizontal axis C_3S data (%) in the original, unhydrated mixtures, it is possible to express at least theoretically the relative quantity of the tobermorite (Fig. 4).

The curve representing the relative quantity of the tobermorite exhibits in both cases a steep rise and reaches its maximum approximately for a 50% C_3S content in the original, unhydrated mixture.

Reaction of Fly Ashes with β-2CaO·SiO₂

Mixtures with a graded β-C_2S content were prepared by the same method.

During the 16 or 72 hour reaction, no more pronounced hydration of β-C_2S took place, and thus no hydrosilicate components were formed. This phenomenon was also observed with quartz sand of extreme fineness which was the subject of other papers published by the author (7, 17).

It was shown that in the course of hydrothermal reactions of β-C_2S with fly ash, very fine quartz sand (specific surface higher than 4,500 cm^2/g), blast furnace slag, quartz glass, or even other materials with a significant SiO_2 content, the silica gel is liberated and coats the β-C_2S grains or their agglomerations with a protective layer and reduces or almost completely inhibits its own hydration of β-C_2S.

In order to study in greater detail the reactions between β-C_2S and power station fly ash, mixtures of power station fly ash with β-C_2S were hydrated in a weight ratio 65: 35. Samples in the form of moistened mixtures were hydrated for periods of 2, 4, 8, 16, 24, 72 hours and 7 days at 175°C/8 atm. It was found that not even during the 7 day hydrothermal process there occurs a more pronounced hydration of β-C_2S, since the integral intensity of the β-C_2S diffractions exhibits an almost unchanged intensity with respect to the original, unhydrated mixture.

Also the content of the soluble SiO_2 form is increased only slightly in the course of the hydrothermal process, as is clearly shown by the reaction mechanism diagram (Fig. 5). This graphical representation of the approximate reaction mechanism indicates an almost unchanging integral intensity value of the line ~3.04 — 3.06 Å which seems to represent only the β-C_2S diffraction. The slight increase is probably caused by an almost negligible rise of the integral intensity value of this line owing to the formation of a slight quantity of the tobermoritic phase.

It is not without interest that it was found during investigations of the hydration of mixtures β-C_2S—power station fly ash that a quantity of 8—10% power station fly ash, added to β-dicalciumsilicate, prevents its own hydration, and thus also inhibits the formation of binding hydrosilicate components of the tobermorite group. On the other hand, however, an addition of a small quantity of calcium hydroxide (1—3%) to the unhydrated mixture β-C_2S—fly ash causes its own hydration of β-dicalciumsilicate, since the formed silica gel is bound by the present calcium hydroxide to the tobermoritic material. Similar effects were obtained with a small addition of C_3S or the phase $C_2SH(A)$.

Reaction of Mullite with Ca(OH)₂ under Hydrothermal Conditions

Owing to the fact that the employed power station fly ashes contain apart from quartz also a certain quantity of mullite, the reactivity of the latter was investigated with calcium hydroxide and finally with the main clinker minerals—$3CaO \cdot SiO_2$ and β-$2CaO \cdot SiO_2$.

In order to clarify more closely the above type of reactions, mixtures were prepared with graded quantities of both components. The selected weight ratios of the mixtures mullite: CaO are summarized in Table 4.

Apart from a synthetically prepared mullite sample M-S also mullite M-B was used; the latter was obtained by electromelting. Hydration was again carried

out in the form of a moistened paste for periods of 16 and 72 hours at 175°C.

Evaluation of X-ray Measurements

Reaction of Mullite M-B with CaO

The X-ray diffraction diagram of mixture 1 shows relatively intense diffractions of still unreacted $Ca(OH)_2$ besides diffractions 5.04, 2.75, 2.00 Å and others which correspond to the hydrogarnet phase.

In the X-ray diffraction diagram of mixture 2 the diffractions of the hydrogarnet phase display a somewhat lower intensity.

With an increasing quantity of mullite and a decreasing CaO content, the hydrogarnet phase is reduced. In mixture 5 only a very small quantity of this component is present. Similar results were obtained for the mixtures 6—9; the quantity of unreacted $Ca(OH)_2$ increases and the content of the hydrogarnet component is reduced.

The series of samples hydrated for a period of 72 hours contains larger quantities of the hydrogarnet component—with respect to the previous samples. The contents of free $Ca(OH)_2$ and mullite have been somewhat reduced.

Reaction of Mullite M-S with CaO

In the X-ray diffraction diagram of mixture 1 can readily be seen very intense diffractions of the hydrogarnet component 5.03, 4.36, 2.75, 2.25, 2.00 Å and others. The diffractions of unreacted mullite exhibit a relatively very low intensity. Interferences of $Ca(OH)_2$ are no longer apparent, in contrast to the identical mixture with mullite M-B which still contains a significant quantity of this phase.

In further mixtures the quantity of the hydrogarnet phase is gradually decreased, as was shown in the case of the mixtures 2 and 3; the content of unreacted lime does not, however, reach the limiting quantity which is essential for X-ray identification. Similarly also in the further mixtures the contents of the hydrogarnet component are reduced; the lowest quantity of the latter was recorded in the mixtures 5 and 9.

In the course of the 72 hour hydrothermal process the content of the hydrogarnet component is increased in all cases. The highest quantity of this component was again identified in the mixture with CaO in a 1:1 ratio.

It follows from the results of X-ray measurements that the largest quantity of the hydrogarnet phase is contained in mixtures with CaO in a 1:1 ratio in the course of a 72 hour reaction; when mullite M-S was employed, a significantly larger content was noted.

In Fig. 6 are reproduced X-ray diffraction diagrams of mixtures mullite—CaO in a 1:1 ratio after a 72 hour reaction.

Differential Thermal Analysis

The differential thermal analysis curves of mixtures with mullite M-B, autoclaved for 72 hours, are shown in Fig. 7. The thermogram of mixture 1 exhibits two crater-shaped peaks with maxima around 350° and 480°C, the latter corresponding to the decomposition of $Ca(OH)_2$. The peak at the lower temperature is caused by the decomposition of the hydrogarnet component. As can readily be seen from the slope of the difference curves of further reaction mixtures, the period corresponding to the hydrogarnet com-

ponents is gradually reduced, in the 1: 10 mixture it is an almost insignificant bending of the difference curve.

DTA curves of autoclaved mixtures with mullite M-S are of a similar character as has been observed for the case of the previous mixtures. In Fig. 8 are reproduced DTA curves of mixtures after 72 hours of hydration. The sample mullite: CaO = 1: 1 is characterized by a deep valley with a maximum around 360°C which corresponds to the hydrogarnet component. With an increasing mullite content, the content of this phase is rapidly reduced; the lowest quantity in all the studied mixtures can again be noted in the 1: 10 sample. The thermogram of the 3: 1 mixture exhibits two deep valleys with maxima around 340°C and 520°C, the first of which corresponds to the decomposition of the hydrogarnet phase and the second to $Ca(OH)_2$. With an increasing CaO content in the original, unhydrated mixture, the quantity of the hydrogarnet component decreases and the $Ca(OH)_2$ content increases.

From the above observations also follows a substantially lower reactivity of mullite M-B with CaO under the employed experimental conditions.

Reaction Mullite M-S—$3CaO \cdot SiO_2$ Evaluation of X-ray Measurements

16 Hour Reaction Period

Mixture 1 is characterized by intensive diffractions of still unreacted mullite besides relatively pronounced diffractions of the hydrogarnet phase—4.99, 3.26, 3.05, 2.73, 2.60, 2.50, 2.40, 2.23, 1.98 Å and others.

It may not be without interest that a certain quantity of tobermorite is present, i.e. on the basis of diffractions 11.3, 2.98, 2.81 Å and others. Mixture 2 also contains a significant quantity of the hydrogarnet phase besides a smaller quantity of tobermorite. The quantity of both components does not differ too much with respect to the previous case.

In mixture 3 can be observed a reduction of the contents of the hydrogarnet phase and tobermorite. Conditions are similar in the next two mixtures—4 and 5. In the X-ray diffraction diagram of mixture 6 can be seen tobermorite diffractions of a low intensity, beside interferences of the hydrogarnet component.

The X-ray diffraction diagram of mixture 7 is characterized by already less intensive diffractions of the tobermoritic phase, conversely the interferences corresponding to the hydrogarnet component exhibit an increased degree of intensity. The mixture contains also a smaller quantity of the $C_2SH(A)$ phase on the basis of the interferences 4.22, 3.90, 3.54, 3.27 Å and

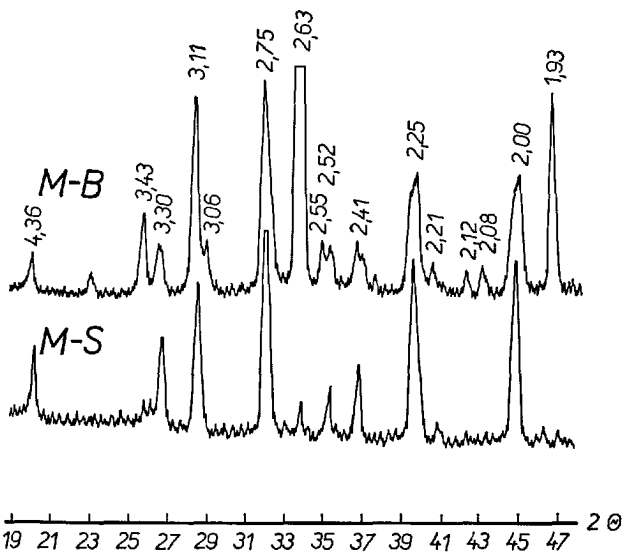

Fig. 6. *X-ray diffraction diagrams of mixtures mullite-CaO (1: 1) after a 72 hour hydrothermal process.*

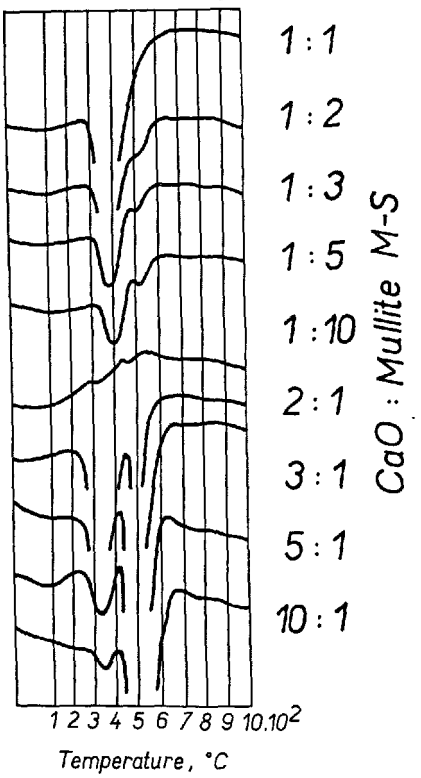

Fig. 8. *DTA curves of the mixtures mullite M-S with CaO; 72 hours/175°C.*

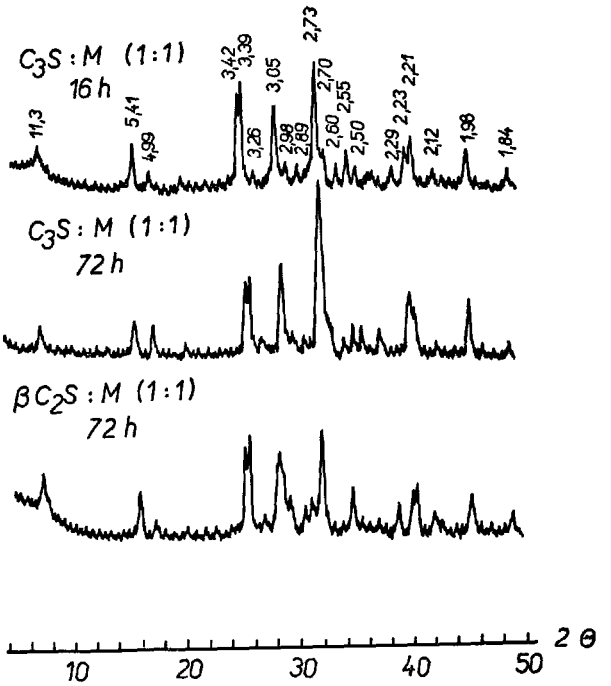

Fig. 9. *X-ray diffraction diagrams of mixtures—3CaO·SiO₂ or β-2CaO·SiO₂ with mullite.*

others.

In the next mixture of mullite with C_3S (1 : 5), the content of the $C_2SH(A)$ phase has risen rapidly; at the same time can be noted a certain quantity of unreacted $Ca(OH)_2$. The content of the hydrogarnet phase has been somewhat reduced. In the X-ray diffraction diagram of mixture 9 can be seen very intensive $C_2SH(A)$ diffractions besides interferences of unreacted $Ca(OH)_2$. The sample contains a small quantity of the hydrogarnet component and of the unhydrated C_3S fraction, besides a small quantity of C_3S-hydrate.

72 Hour Hydrothermal Reaction

Mixture 1 contains a considerable quantity of the hydrogarnet phase which is significantly larger than in the identical mixture hydrated for 16 hours. Apart from a more pronounced tobermorite quantity, there are also present unreacted mullite and a very small quantity of the $C_2SH(A)$ phase.

The maximum content of the hydrogarnet component can readily be seen in mixture 2. In mixture 3 and in the next mixtures 4 and 5, the quantity of the hydrogarnet component decreases rapidly, and simultaneously there is an increase in the contents of the $C_2SH(A)$ component and uncombined calcium hydroxide, besides a small quantity of C_3S-hydrate. The presence of tobermorite can also be noted in mixture 3, in the remaining mixtures the tobermorite quantity is below the limit essential for X-ray determinations.

Mixture 6 contained besides a significant quantity of tobermorite the hydrogarnet phase and a considerable quantity of unreacted mullite. In the next sample 7 it is no longer possible to identify quite positively tobermorite, the content of the hydrogarnet component has been rapidly reduced. The reduction of the quantities of the above reaction components takes place in further mixtures 8 and 9.

Fig. 9 shows X-ray diffraction diagrams of mixture 1 after 16 and 72 hours of hydration.

Differential Thermal Analysis

The DTA curves show endothermal peaks within the temperature range 180°–600°C corresponding to the decomposition of tobermorite, and hydrogarnet phase eventually to that of other components ($Ca(OH)_2$, $C_2SH(A)$).

Reaction Mullite—β-2CaO·SiO₂

Evaluation of X-ray Measurements

In the course of the 16 hour reaction in the mixtures

1 and 2 to 5 none of their own hydration of β-C_2S takes place, and thus no formation of the tobermoritic and hydrogarnet phases can be observed, since the hydration of dicalciumsilicate is suppressed as a consequence of protective layers around the β-C_2S grains or their agglomerations. Only through the addition of 2—3% C_3S or 1—2% CaO to the starting mixture mullite—β-C_2S, or by prolonging the hydration period to 72 hours, there occurs the hydration of β-C_2S and the formation of the tobermoritic and hydrogarnet phases. In the first case this is the consequense of binding the formed silica gel with $Ca(OH)_2$ to the tobermoritic material, in the second case this is due to the ageing of the protective gel layers and thus to an increased diffusion of water molecules to the actual β-C_2S particles.

In Fig. 9 is shown the X-ray diffraction diagram for mixture 1 after 72 hours of hydration.

The DTA curves are of a similar nature as has been observed for the mixtures mullite—C_3S.

Determination of Composition of Hydrogarnet Phase

To an approximate composition at least of the hydrogarnet components were prepared $3CaO \cdot Al_2O_3$ glasses with a graded quantity of SiO_2 (0.5, 1.0, 1.5 and 2.0 mol.). Glass samples were autoclaved at 218°C for a period of 5 hours and after drying and comminution, the process was further repeated another five times.

The obtained values for the edge (a) of the elementary cell approach data published by Locher (18). It was found on the basis of the values thus obtained that the hydrogarnet phase formed by the reaction between mullite and CaO corresponds basically to the component $3CaO \cdot Al_2O_3 \cdot SiO_2 \cdot 4H_2O$, in contrast to the phase formed by the reaction of mullite with C_3S or β-C_2S the composition of which corresponds approximately to the formula $3CaO \cdot Al_2O_3 \cdot 1.5SiO_2 \cdot 3H_2O$.

Influence of Hydrogarnet Phase on Obtained Strength Values

From the moistened mixture of mullite M-S with CaO in a 1 : 1 ratio test cubes with a 20 mm edge were prepared; these were autoclaved at 175°C for a period of 16 hours. It was found that the test cubes practically do not exhibit more pronounced compressive strength values. It can thus be assumed that the hydrogarnet phase (C_3ASH_4) exerts no significant influence on the compressive strength values of porous silicate shapes made from power station fly ash and lime.

Determination of Quantity and Character of Glass Phase of Power Station Fly Ashes

On the basis of a qualitative and semi-quantitative X-ray analysis of the individual fly ashes, as well as with regard to the results in quantity and type of the hydrosilicate and hydrogarnet phases, there can be assumed a considerable influence of the actual petrographic composition of the fly ashes on the character of hydrothermal reactions with CaO. For this reason it appeared essential to carry out a quantitative X-ray determination of the main crystalline components—mullite, α-quartz, haematite, anatase and rutile, and to determine the quantity and character of the glass phase of the fly ashes. The results of the X-ray determinations are summarized in Table 5.

The α-quartz content in the studied fly ashes fluctuates between 4.7% NH and 12.6% ER. Also the mullite content exhibits a considerably wide range: 2.0% NO—29.3% MA.

On the basis of the X-ray determination of both major and minor mineralogical components and from data contained in the overall chemical analysis was calculated the probable composition of the glass phase of the individual fly ashes (Table 6). The glass of the MA fly ash contains the highest quantity of SiO_2, whereas the lowest SiO_2 content was observed in the glass of the fly ash TI. The greatest Al_2O_3 quantity is present in the glass phase of fly ash NO, whereas conversely the lowest Al_2O_3 content was noted in the glass of the fly ash MA.

The knowledge of the SiO_2 quantity in the glass phase of the fly ashes makes it possible to carry out a comparison of the compressive strength values of porous silicate shapes with a glass SiO_2 content. It follows from the enclosed graphical representation (Fig. 10) that there exists in almost all cases a certain proportionality between the compressive strength values and data about the SiO_2 content in the glass. This proportionality is somewhat less pronounced in the case of comparing the contents of glass SiO_2 and the quantity of α-quartz contained in the fly ashes, with the achieved strength values. Analogically it is possible to compare data about the relative quantity of the hydrogarnet phase with the Al_2O_3 content in the glass phase of the individual types of investigated fly ashes (Fig. 11). The relative quantity of the hydrogarnet phase is given by the ratio of the integral intensity of the diffractions $\frac{I \sim 2.75\,Å}{I\,2.36\,Å}$ and $\frac{I \sim 5.05\,Å}{I\,4.76\,Å}$. The numerical data in the numerator of both fractions

correspond to the diffraction of the hydrogarnet component. The values of both ratios follow at least approximately the Al_2O_3 content data in the glass phase of the individual fly ashes. A more significant difference was found only in the case of the integral intensity value of diffraction 5.05 Å of the hydrogarnet component in the hydrated mixture of the MA fly ash.

It appears from the above that the main part of the hydrogarnet component was formed by the reaction of Al contained in the glass phase of the fly ash, with CaO. An already substantially smaller quantity of this component was formed by the hydrothermal reaction of mullite with lime.

Finally were prepared synthetically glasses which approach in their composition the glass phases of the studied fly ashes in which, however, the content of the individual components was graded in suitable ranges.

By autoclaving samples of synthetic glasses with CaO and by the determination of their reaction products, the influence of the individual components on the formation of tobermorite was investigated. It was found that apart from the SiO_2 quantity, which plays a basic part, a growing K_2O content exhibits a certain positive influence on the formation of tobermoritic material.

Conclusion

Reactions of 10 power station fly ashes with CaO in a 3: 1 weight ratio were studied at 175°C (8 atm.) for a period of 16 hours. Apart from tobermorite and probably the CSH(I) phase was determined the hydrogarnet phase—probably C_3ASH_4. By comparing the relative quantities of tobermorite with the achieved compressive strength values of porous silicate shapes was obtained a satisfactory tolerance which indicates that tobermorite exerts on the former a fundamental influence.

By the reaction of fly ash with C_3S is formed besides tobermorite again the hydrogarnet component; the maximum quantity of tobermorite was noted for a starting ratio of 1: 1. β-C_2S does not react with fly ash even in the course of a 7 day hydration as a consequence of protective coating layers of silica gel around the β-dicalciumsilicate grains or their agglomerations which prevent the diffusion of water molecules to the β-C_2S particles.

By the reaction of mullite with $Ca(OH)_2$ is formed the hydrogarnet component, the composition of which probably corresponds to the formula $3CaO \cdot Al_2O_3 \cdot SiO_2 \cdot 4H_2O$, whereas when C_3S or β-C_2S is used instead of CaO, there is formed, besides a smaller fraction of tobermorite, a hydrogarnet phase, whose composition corresponds probably to the formula $3CaO \cdot Al_2O_3 \cdot 1.5SiO_2 \cdot 3H_2O$. On the basis of comparisons of the SiO_2 content in the glass phase of the individual fly ashes with the achieved compressive strength values of porous silicate shapes, as well as with due regard to experiments with synthetically obtained glasses, there appear the content and character of the glass phase as the most important criteria for the assessment of power station fly ashes for the manufacture of porous concretes. It was shown simultaneously that the formed hydrogarnet phase does not significantly contribute to the achieved strength values of autoclaved building materials.

Supplementary Paper IV-63 Investigations on the Behaviour of Natural and Artificial Puzzolans

Hans E. Schwiete, P. Kastanja, Udo Ludwig and Peter A. Otto*

Synopsis

The chemical, mineralogical and physical data of 10 trasses from the Rhineland, 6 from Bavaria, one Austrian trass, 2 puzzolanas from Italy, a calcined molererde from Denmark, and 3 samples of granulated slags from power stations have been determined. The lime bonding and the resulting formation of hydrates has been investigated as well as the reactivity of these stone flours in mixtures with lime, portland- and slag cement.

All the natural puzzolanas were found to contain varying amounts of glassy groundmass which, in the case of the Rhine trasses, was 55 ~ 60% and for the Bavarian trasses constituted 62 ~ 67%. In the Austrian trass and the molererde the amorphous silica-rich groundmass shows signs of adopting the cristobalite lattice. The artificial puzzolanas, namely the slags from power stations, are almost completely glassy. The crystalline components of the puzzolanas have been identified microscopically and by X-rays.

Of the puzzolanas of volcanic origin the Bavarian trasses show the highest content of SiO_2, ranging from 59.2 ~ 66.0%, whilst the Italian puzzolana from Salone only contains 48.1%. The Al_2O_3 content varies between 13.8% for the Bavarian trass to 20.6% for the Italian puzzolana from Bacoli. Accompanying the low SiO_2 content, the puzzolana from Bacoli has the highest amounts of CaO and MgO, namely 10.0% and 5.7% respectively.

The highest loss by ignition was found for the Austrian trass with 15.3%; this sample contains 1.96% SO_3.

The molererde consisting of a mixture of silicified diatoms and clays contained 14.3% SiO_2 and 13.4% Al_2O_3. With smaller silica contents of 47.5 ~ 51.8%, the granulated slags contain larger amounts of Al_2O_3 (26.8 ~ 33.1%) and Fe_2O_3 (6.6 ~ 13.3%).

The specific weights of the puzzolanas have been determined and also their specific surfaces. Whilst the specific surfaces of natural puzzolanas lie between 0.7 and 2.7 m^2/g, according to Blaine, the values obtained by the adsorption method according to BET were between 4.4 and 95 m^2/g. These great differences in the areas are caused by partial alteration of the glassy fraction to zeolites and montmorillonite.

The surface areas of the granulated slags were found to be 0.5 m^2/g by Blaine's method but only 1.01 ~ 1.27 m^2/g by BET.

The combination with lime was determined in suspensions of puzzolanas and lime of which the W/S factor (water/solid) was 5. The greatest affinity for lime was shown by the molererde. After 90 days 591 mg CaO/g molererde were bonded. The lime combination of the artificial puzzolanas lies in the range of the Bavarian trasses and the Italian puzzolanas showing values between 228 and 283 mg CaO/g granulated slag.

After 90 days the newly-formed hydrates in the residues of these samples were examined. CSH phases formed as well as C_4AH_{13} (tetracalcium aluminate), $C_3(A, F)S_nH_{6-2n}$, n = 0 – 3, (these are mixed crystals in the hydrogarnet series), and occasionally C_2ASH_8 (gehlenite hydrate). In addition the formation of $C_3(A, F)Cs_3H_{32}$ (ettringite) was observed for the sulphate-bearing Austrian trass. If extra sulphate was added ettringite and monosulphate hydrate formed from all the puzzolanas.

Investigations of the strengths of lime-rich cements (e.g. trass cement 30/70) showed that the contribution of the natural puzzolanas with a high specific surface (according to BET) is overshadowed in the early stages of hardening by the high requirement of water.

In contrast, for lime-poor bonding materials a contribution to the strength was observed even at an early stage, in particular if anhydrite was added.

If a granulated slag with a low specific surface (after BET) but which has been sufficiently finely ground is used, an improvement in the final and also partly in the initial strength is observed. This occurs even with additions as small as 30% as the water requirement is not increased.

*Institut für Gesteinshüttenkunde, Technische Hochschule Aachen, Aachen, West Germany.

Introduction

This work continues earlier investigations (1, 2) into the properties of natural puzzolanas of volcanic origin (3). We investigated molererde calcined at 800°C, which originated from silicified diatoms; this is a very reactive puzzolana (4, 5). The behaviour of granulated slags from power stations shows that these materials also posses the properties of natural puzzolanas (5).

Chemical, mineralogical and physical data of puzzolanas were determined. The reactivity of these stone flours in mixtures with lime, portland and slag cements have been investigated, as well as their combination with lime and the hydrates thus formed.

The Chemical Composition of Puzzolanas

As Table 1 shows, the chemical composition of puzzolanas varies over a wide range. We investigated 10 trasses from the Rhineland, 6 from Bavaria, 1 from Austria, 2 puzzolanas from Italy, molererde and 3 samples of granulated slag from power stations. Of the puzzolanas of volcanic origin, the Bavarian trasses show the highest content of SiO_2, ranging from 59.17—65.97%, whilst the puzzolana from Salone only contains 48.13%. The Al_2O_3 content varies between 13.77% for a Bavarian trass and 20.58% for the puzzolana from Bacoli. Accompanying the low SiO_2 content the puzzolana from Salone has the highest amounts of CaO and MgO, namely 9.96 and 5.70% respectively. The highest loss by ignition was from the Austrian trass (15.29%); this sample contains 1.96% SO_3.

With somewhat smaller silica contents of 47.46—51.82% the granulated slag contain larger amounts of Al_2O_3 (26.84—33.09%) and Fe_2O_3 (6.60—13.26%).

The Mineralogical Composition of the Puzzolanas

The mineralogical composition was determined by X-ray diffraction. All natural puzzolanas contain varying amounts of a glassy groundmass which, in the case of the Rhine trasses, was 55—60% and for the Bavarian trasses constitutes 62—67%. In the Austrian trass and the molererde the amorphous groundmass consists of opal, which shows signs of adopting the cristobalite lattice. The slag from power stations are completely glassy.

The Rhine trasses contain larger amounts of quartz and feldspar, and varying amounts of chabasite, analcime, mica, illite and kaolinite, whereas for augite and hornblende amounts only up to 1% were determined.

Similarly in the Bavarian trass larger amounts of quartz and feldspar were found. The augite content was in many cases under 1%. In addition amounts of montmorillonite up to 7% were found. The Austrian trass contains cristobalite, alunite, kaolinite, analcime and small amounts of quartz as well as augite. The high ignition loss of this material is explained by the presence of opal, alunite and kaolinite.

Augite, analcime and leucite are the principal crystalline phases in the puzzolana from Salone; in addition, small amounts of quartz and chabasite were found.

The main components of the puzzolana from Bacoli are feldspar and analcime, whilst only small amounts

of augite and quartz were found.

The molererde contains cristobalite, montmorillonite, illite and haematite as crystalline phases.

In contrast to the natural puzzolanas, the artiffcial ones, namely the granulated slags, contain a very small crystalline fraction amounting to 3%, which could not be identified more closely.

The Physical Data of the Puzzolanas

As Table 2 shows, the specific weights of the puzzolanas, with exception of the molererde, lie between 2.42 and 2.69 g/cm³. The specific surfaces of the volcanic puzzolanas, which were determined by the nitrogen-absorption method of BET, show a strikingly wide range. Great differences in surface area are caused by partial alteration of the glassy fraction to zeolites and montmorillonite.

Table 2. *Specific weights and specific surfaces of the puzzolanas*

Puzzolana	Spec. weight (g/cm³)	Spec. surface (m²/g) after Blaine	after BET
Rhine trass	2.42—2.60	0.70—1.18	19.6—95.0
Bavarian trass	2.52—2.63	0.71—0.95	8.3—39.0
Austrian trass	2.44	0.92	60.5
Italian puzzolanas			
Salone	2.69	0.89	17.4
Bacoli	2.45	0.90	4.4
molererde	2.25	2.70	12.0
slag granulated	2.58—2.68	0.50	1.01—1.27

Lime Bonding of Puzzolanas

The combination with lime was determined in suspensions of puzzolana and lime of which the W/S factor (water/solid) was 5. In Table 3 the degree of combination of the various puzzolanas with lime after periods of 56 and 90 days is shown.

Table 3. *The amount of lime combined with puzzolana after 56 and 90 days*

Puzzolana	Combined lime in mgCaO/g puzzolana 56 days	90 days
Rhine trass	264—335	270—373
Bavarian trass	186—241	192—254
Austrian trass	400	417
Italian puzzolanas		
Salone	248	254
Bacoli	262	266
Molererde	570	591
slag granulated (spec. surface = 5000 cm²/g Blaine)	210—272	228—283

The values† show that, among the volcanic puzzolanas, the Bavarian trasses combine with the least amount of lime (192—254 mgCaO/g trass) after 90 days, whereas the Austrian trass combines with the largest amount (417 mgCaO/g trass); this is a consequence of its reactive opal groundmass.

The greatest affinity for lime is exhibited by the molererde with 591 mgCaO/g molererde. This can also be related to the high opal content of this puzzolana. The lime combination of the artificial puzzolanas lies in the range of the Bavarian trass and the Italian puzzolanas, with a lime content of 228—283 mgCaO/g granulated slag.

Formation of New Hydrates in the Puzzolanas

After 90 days the following hydration products were observed in suspensions of CaO and puzzolanas shaken together; the residues were examined by X-ray analysis and in the electron microscope. In the case of the volcanic puzzolanas, CSH phases form as well as C_4AH_{13} (tetracalcium aluminate), $C_3(A, F)S_nH_{6-2n}$ (where $n = 0 - 3$; these are mixed crystals in the hydrogarnet series) and occasionally C_2ASH_8 (gehlenite hydrate). In addition the formation of $C_3(A, F)Cs_3H_{32}$ was observed for the sulphate-bearing Austrian trass.

The hydration products of the molererde were only CSH phases. In spite of the Al_2O_3 content of 13.4% no aluminous phase occurs which indicates that the aluminate is taken into the CSH phase.

In the experiments with granulated slag the formation of CSH phases, hydrogarnet and small amounts of gehlenite hydrate was observed.

If extra sulphate is added, ettringite and monosulphate hydrate occur in all the puzzolanas.

†In order to examine free lime we used Franke-method. This method gives too high values specially if C_4AH_{13} is formed.

The Reactivity of the Puzzolanas with Lime or Cement

For puzzolana-lime mixtures (70: 30) we have observed, in the case of the natural puzzolanas, that the strength of the mortar increases with increasing affinity of the puzzolana for lime. Thus the molererde which has the greatest affinity for lime yields mixtures that have the highest strength (of 127 kg/cm²) despite their greater requirement of water.

For the granulated slags the strength of the mortar is directly dependant on the specific surface.

Even after 4 years the strengths of cements containing up to 30% German trasses were less than that of pure cement. This fact can be explained by their greater internal surface and the correspondingly higher water requirement. However, taking into account the various W/C factors (water: cement) it becomes apparent that the volcanic puzzolanas do contribute to the strength of the mortar.

Mixtures of up to 30% granulated slag with portland cement had a lesser initial strength but after 90 days it was higher than that of pure portland cement if granules with a specific surface of 5000 cm²/g (Blaine) were used.

A considerable increase in strength was observed if puzzolana was added to cement poor in lime. Thus the 3-day strength of slag cement containing 70% slag sand was improved by up to 100% if 15% of the slag sand was replaced by molererde. The role of molererde in the hydraulic hardening could be demonstrated by the combination of lime and sulphate, and also by the earlier appearance of a thermic reaction.

Investigations (6) using mixed bonding materials with trass reveal the same tendency, as the Fig. 1 shows. The influence of the trass on the strength is evident after only 7 days, if anhydrite is used to provide sulphate.

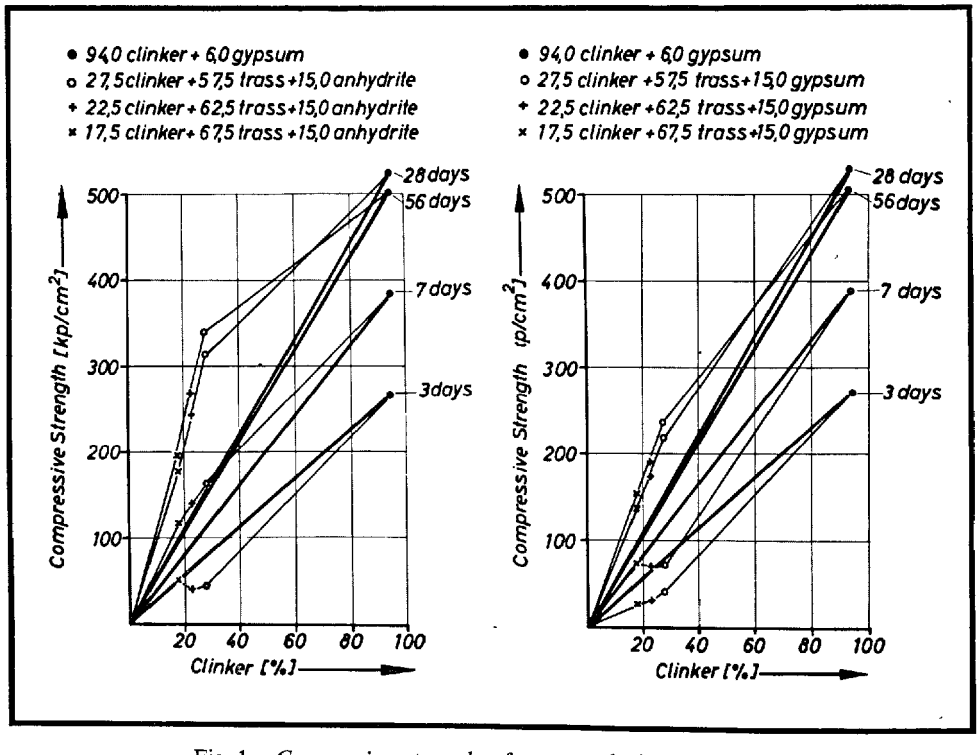

Fig. 1. *Compressive strength of mortars high in trass and sulphate content.*

Summary

All the silicate stone flours which have been investigated form compounds with lime. The pronounced reactivity of natural and artificial puzzolanas is due:

1) to their chemical and mineralogical composition
2) to the high amount of glassy or amorphous phases

3) and to their large reactive surface

The same hydrate phases which occur in the hydration of standard cements appear as reaction products when these puzzolanas react in aqueous solution with calcium hydroxide and calcium sulphate.

In contrast to granulated slags, the contribution that natural puzzolanas make to the strength in the early stages of hardening is disguised by the high requirement of water in the case of the lime-rich cements (trass cement 30/70). In the case of bonding materials poor in lime, an increase of strength is shown even at an early stage, in particular if anhydrite is used.

Supplementary Paper IV-135 The Different Action Mechanism of Pozzolanic Materials and Slags in the Hydraulic Binders

Adriano Celani, Pietro A. Moggi and Arturo Rio*

Synopsis

In order to outline the different action mechanism of pozzolanic materials and slags in the hydraulic binders an investigation was carried out on the equilibrium relations of these materials with lime solutions and free calcium hydroxide from portland cement.

The experimental results point out that the amount of fixed $Ca(OH)_2$ is much higher for pozzolanas than for slags. They show furthermore the different lime retention force of both materials, which force results in a lower lime concentration of the liquid in contact with the solid mass, when its pozzolana amount is sufficient, as well in a greater resistance to the leaching action of an aqueous solution.

Such a different behaviour is due to the different nature of the calcium silicate hydrates formed by reaction between lime and pozzolanas or slags.

Introduction

As it is known, true pozzolanas are materials of volcanic origin which, though not hydraulic in themselves, combine with the lime at ordinary temperature and in the presence of water to give compounds possessing hydraulic properties.

On the contrary, granulated blast furnace slags, which are principally constituted of a vitreous material with variable composition depending on the pig iron production process, possess its own latent hydraulic properties which need only a simple alkaline activation, generally promoted by lime, to reveal themselves.

Whilst pozzolanas combine progressively with lime to give silicate and aluminate hydrates by chemical fixing of its quantities appreciable in respect of their reactive silica and alumina contents, slags, on the other hand, absorb only small amounts of lime, whose main function, as F. M. Lea (1) pointed out, is to promote the hydration. The reaction course does not depend on the further combination with the lime, but on the hydration of the slag itself, though it could not be excluded, in agreement with other authors (2), that there is a moderate reaction with lime when this is present in excess.

However, the quantitative differences in the lime absorption require a different proportioning of these materials when pozzolanic and slag cements are prepared.

Besides the different quantity of lime susceptible to be combined, there is another quantitative point of view of this combination on which the attention should be recalled: the compounds which are formed during the hydration of pozzolanic cements, in consequence of the reaction between the hydrolysis lime of clinker and the constituents of pozzolana, are chemically different from the compounds formed during the hydration of high slag content cements.

In the first case little basic and then chemically more stable compounds are formed: consequentially there is a sharp increase of the chemical resistance with a remarkable improvement of the physical and mechanical characteristics.

In the second case, on the contrary, the reaction between lime and slag gives rise to more basic hydrated compounds which will be more attackable, though their formation is followed by the increase of strengths.

In the literature it is possible to find several works in which comparison is made between the relative lime absorption capacity of pozzolanas and that of slags; on the contrary, as far as we know, never pointed out was the different force by which the above materials fix and retain lime.

In a first stage of our research (3) we studied the quantitative relations between the concentration of

*Soc. Calci e Cementi di Segni, Laboratorio Centrale, Roma, Italy.

lime in solution and the amount of lime combined with pozzolanas and slags, in equilibrium with the solution itself. The tests were performed on mixtures with different lime/material ratio. The experimental results confirmed that the combined lime amount is much higher for the pozzolanas than for the slags. They have furthermore proved the different stability of the compounds formed from the combination of the lime with the examined materials.

Successively the research was extended to the behaviour of pozzolanas and slags towards the lime developed during hydration of portland cement.

The tests, carried out on mixtures with different cement/material ratio, covered the observation of the following characteristics:

—Proportioning of the material, mixed with cement, which is required to absorb quantitatively the hydrolysis lime of portland cement.
—Quantity of the hydrolysis lime fixed by the material in function of the time and of the cement/material ratio.
—Equilibrium relations with the lime concentration of the contact solution.
—Chemical-physical constitution of the hydration products and of the lime combination products with the examined materials.
—Lime retention power of the combination products.

Experimental

Materials and Research Methods

The compositions of the used materials are reported in Table 1. The slags No. 1 and No. 2 come from two different countries and have been chosen from those commonly used for the industrial production of blast furnace cements. The pozzolanas No. 1 and No. 2 also belong to the types commonly used for the production of pozzolanic cements; they differ in the reactive silica amount which highly affects pozzolanic activity. The sand was chosen in order to have comparison value with a material of practically negligible pozzolanic activity.

The clinker, the composition of which is reported in Table 1, is also of usual industrial production. It has been always used mixed with 5% of gypsum. Finally, standard mixture were prepared with an absolutely inert material. To this aim $BaSO_4$, pure for analysis, was used.

Mixtures of the various materials with cement in variable ratio were prepared.

The performed tests, which will be described later in detail, are the following:

—Pozzolanic activity determination.
—Hydrolysis lime absorption.
—Specific surface measurements.
—X-ray analysis.
—Leaching with diluted lime solution.

Pozzolanic Activity Determination

The pozzolanic activity determination was carried out according to the test as specified by Italian Standards 1966, which has been proposed by I.S.O. for international application.

According to this test, which covers the determination of the lime concentration and of the total alkalinity of the contact solution with the cement paste at 40°C after 8 days, are "positive" those cements with their representative points lying under the isotherm of the lime-alkalies solubility (Fig. 1).

The test was carried out on cements with 30, 70 and 80% of one of the two slags, which are similar in their behaviour, (points L_3, L_7, L_8); with 30 and 40% of the pozzolana No. 1 (points P_3, P_4) and with 20 and 30% of the pozzolana No. 2 (points P'_2, P'_3); finally with 30, 70 and 80% of sand (points S_3, S_7, S_8) and on the cement without additions as comparison.

The test results are "positive" only with slag contents above 70%, while addition of 30% of pozzolana No. 1 and of 20% of pozzolana No. 2 are sufficient to reach the same result. The sand, as it was to be expected, does not present any pozzolanic activity.

Hydrolysis Lime Absorption

Cement mixtures were prepared with 20, 30, 50 and 70% of the slags, of the two pozzolanas, of sand and of $BaSO_4$. They were hydrated with a water/cement ratio = 12.5, on keeping them in a polyethylene bottle under agitation in a thermostat at 40°C up to the fixed ages of 1, 7, 28 and 60 days.

At the end of the curing the suspension was filtered in CO_2 free atmosphere, the solid was washed with alcohol and ether and then overdried at 105°C in CO_2 free air stream. On the liquid, the alkalinity was determined by titration with HCl and methyl orange as indicator and the lime concentration by com-

plessometric titration with EDTA and calconcarbonic acid as indicator.

On the solid the free lime was estimated according to the T.V.M. method (4) and the ignition loss at 950°C. The concentration of the lime in solution and of the free lime in the solid phase have been referred as percentage to the anhydrous original mixture.

From the tests performed on the mixtures with $BaSO_4$, the lime available at various ages for each cement/material ratio was derived and then the absorbed lime was estimated by the difference between available lime and the total free lime in solution and in the solid phase, the cement/material ratio being equal.

The diagrams in Figs. 2, 3, 4, 5, 6 plot the lime absorbed by 100 g material versus time and cement/material ratio.

In Tables 2, 3, 4 are reported the percentages of the lime absorbed by the various materials, in function of the cement/material ratio, to the lime-available at different ages, 1, 7, 28 days, respectively.

The obtained results clearly show the different activities of slags and pozzolanas in the absorption of hydrolysis lime.

—Slags present an activity which, on the whole, differentiate very little from that of an inert material

Pozzolana N. 2	71.2	92.1	96.0	99.2
Sand	10.6	12.8	24.5	37.6

such as sand. On the contrary pozzolanas, especially pozzolana No. 2, that results more active than No. 1, present a clearly higher activity.

If a scale should be made for the activity on the basis of the results of this test, it should be somewhat as this:

sand < slag No. 2, slag No. 1 < pozzolana No. 1
1 : 2 : 4
< pozzolana No. 2
: 7

—The two slags have similar behaviour, the slag No. 1 is somewhat more active than the No. 2, and in 28 days they fix 60%, at the most, of the available lime in the mixture with the higher slag content.

—The pozzolana No. 2 can absorb already after 1 day 90% of the available lime in the mixture in which it is contained in higher amount. At 7 days also pozzolana No. 1 attains such a yield and at 28 days the lime absorption is almost quantitative for both pozzolanas, even for the mixture with 50% of pozzolana.

—Likewise the rate of lime absorption is higher for the pozzolanas, specially for the No. 2 than for the slags.

Results of particular interest have been obtained

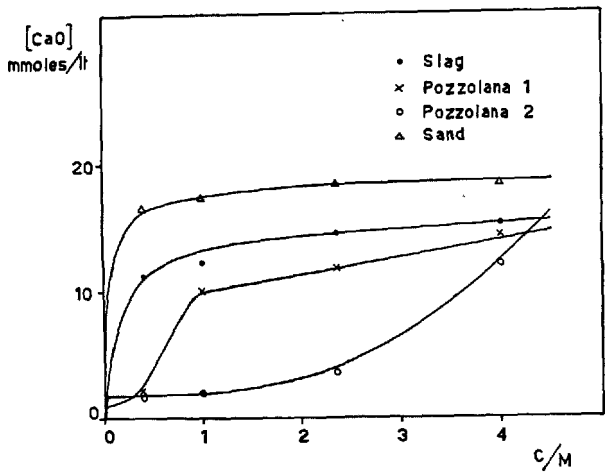

Fig. 7. *CaO concentration in equilibrium with mixtures cement-materials at 7 days*

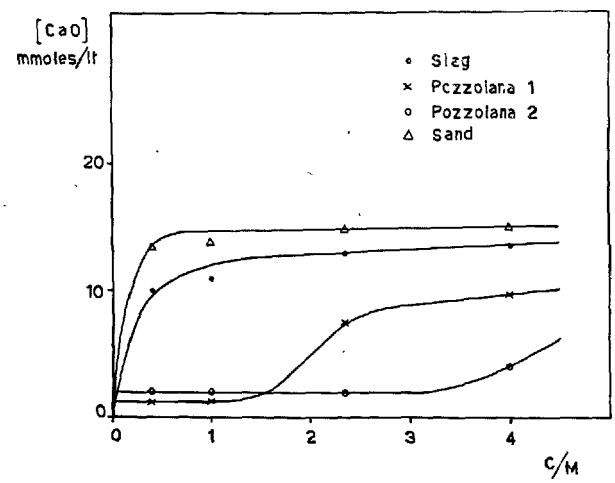

Fig. 8. *CaO concentration in equilibrium with mixtures cement-materials at 28 days*

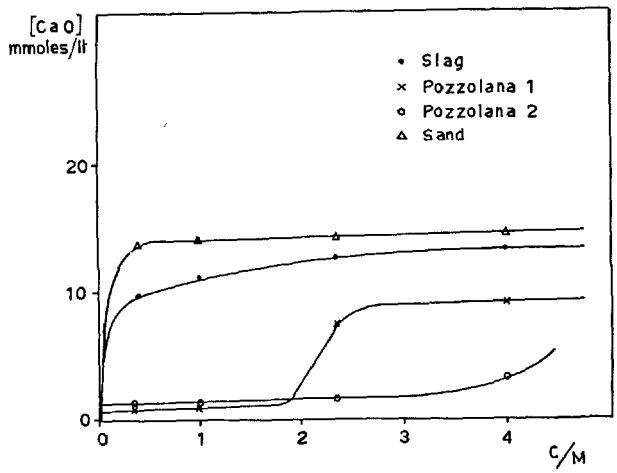

Fig. 9. *CaO concentration in equilibrium with mixtures cement-materials at 60 days*

also from the determination of the lime concentration in the contact solution with the solid.

In the diagrams of the Figs. 7, 8, 9 the concentration in mmols/l of the lime in the contact solution is plotted in function of the cement/material ratio at ages of 7, 28 and 60 days respectively. Because of the similarity of their behaviours, only one slag of the two has been reported, that is the No. 1, a little more active.

The overall development of the curves points out to the different forces with which lime is retained by the reactive silica of the materials under examination. Indeed, the lower is the lime concentration in the contact solution, the stronger is the retention power.

From Fig. 9 it is noted that for sufficiently high pozzolana content in mixture with cement, the lime concentration in the contact solution is under 2 mmols/l. This equilibrium concentration of the lime in solution occurs, in the system $CaO–SiO_2–H_2O$, in correspondence to the coexistence zone among silica, CSH(I) and the liquid phase (5). The value of nearly 9 mmols/l obtained for cements with lower pozzolana content corresponds, on the contrary, to the equilibrium concentration of the lime in the presence of the alkali amount developed from the material.

Slags present a completely different course from that of the pozzolanas, and analogous one to that of the sand. There is no evidence of stable and well defined compounds, not even for mixtures with higher slag cement. In fact the lime concentration of the contact solution is always greater than the equilibrium value corresponding to the alkalinity of the solution.

Specific Surface Measurements

The specific surface of the cements with 30 and 70% of slag No. 1 and of the pozzolana No. 1 after 1, 7 and 28 days of curring according to the test procedure for hydrolysis lime absorption, has been measured.

The measurement was carried out by nitrogen adsorption from nitrogen-helium mixture, after degasing the samples for two hours at 105°C in helium stream: the specific surfaces, calculated according to the B.E.T. method (6), are given in Table 5.

The cements with pozzolana give rise to hydration products of higher specific surface than those containing an equal amount of slag. The difference is more remarkable for the mixtures with much addition

Table 5. *Specific surfaces of hydration products of mixtures cement-slag or pozzolana*

Mixture	Specific surface m²/g		
	1 day	7 days	28 days
70% Cement + 30% Slag	18.06	46.24	110.31
70% Cement + 30% Pozzolana	25.71	69.49	116.87
30% Cement + 70% Slag	23.59	54.63	115.44

25% $Ca(OH)_2$ + 75% pozzolana	24.17	95.80
20% $Ca(OH)_2$ + 80% pozzolana	18.24	96.30
15% $Ca(OH)_2$ + 85% pozzolana	12.93	96.80

material, in which the difference of constitution of the reaction products of lime with the two materials produces a more remarkable effect.

X-ray Analysis

For better investigation of the nature of the combination compounds between lime and slag, or pozzolana, some mixtures of pure calcium hydroxide with 50–65–75–80 and 85% of slag No. 2 and of pozzolana No. 1 were prepared. These mixtures were hydrated for 15 days under the same conditions as for the hydrolysis lime absorption test. On the solution the alkalinity and the lime concentration were determined, on the solid the free lime and the ignition loss.

In Table 6 there are given the lime amounts absorbed by the two materials in the different mixtures.

Finally the solids were analyzed by X-ray diffraction.

From the development of the X-ray diffraction diagrams the following observations can be made:

—The lines of $Ca(OH)_2$ at 4.90 and 2.63 Å are always present in the mixtures containing slag, even with high percentages of this material. Comparison of the diagrams of the same mixtures before their hydrating shows that the lime absorption is only of little extent, which let us suppose that this absorption is of mostly physical nature, even if high percentages of absorbed lime result from the analysis.

In the case of pozzolanas the lines of $Ca(OH)_2$, on the contrary, have been found to be already quite absent with mixtures containing 25% $Ca(OH)_2$ and 75% material. According to the results of the chemical analysis this confirms the quantitative absorption of the available lime which, moreover, results to be wholly combined with the material to give new compounds.

—For all mixtures with slag the lines of the tetracalcium aluminate hydrate, C_4AH_{13}, at 7.9 and 3.95 appear very clear together with the less strong lines at 2.86 Å. These lines are completely absent for the mixtures with pozzolana.

—In the diffraction diagrams of the hydrated mixtures of lime and slag the lines of the hydrated dicalcium aluminate silicates, C_2ASH_8 (gehlenite), appear as well, the line at 4.18 Å being more evident, while the one at 2.87 Å is hardly distinguishable on account of the near line of the C_4AH_{13}.

—In the case of mixtures with slag the lines of calcium hydrosilicate with high CaO/SiO_2 ratio, CSH(II), at 9.8, 3.07 and 2.80 Å are visible. They appear stronger for mixtures with higher material content and therefore it seems clear that this compound is derived directly from the hydration of the hydraulic compounds of the slag, whereas hardly probable is its formation from combining of lime with slag.

—All mixtures containing pozzolana show also the lines at 3.07 and 2.80 Å, while at 9.80 no line is present. Thereafter the calcium hydrosilicate formed must be supposed as belonging to the type CSH(I) with low CaO/SiO_2 ratio, even if in the various mixtures the line at 12.5 Å, proper to such compound, seems to be hardly distinguishable because of the low value of the diffraction angle θ.

Leaching with Dilute Lime Solution

With the tests previously described, the quantitative differences in the hydrolysis lime absorption as well as the diversity of the compounds formed by the action of the lime on slags and on pozzolanas were pointed out.

A very important aspect of such phenomenon, on which the attention must be recalled, is the different binding power with which the lime can be retained by the two examined materials.

To this aim, the samples derived from the lime absorption test at 28 days have been submitted to a treatment, which may be told to as leaching, with a dilute lime solution.

A prefixed quantity of sample was mixed with 100 ml

Table 7. *Leaching action of a* $Ca(OH)_2$ *0.002m solution on hydrated cements with slag or pozzolana*

Mixture	free CaO	fixed CaO	total CaO	leached CaO	ΔCaO fixed

of a 0.002 M $Ca(OH)_2$ solution in a polyethylene bottle and kept in a thermostat at 40°C under agitation. After 8 days the suspension was filtered in CO_2 free air. On the solution the alkalinity and the new lime concentration, while on the solid free lime and ignition loss were determined.

Of each mixture, the lime content being known from the previous tests, such an amount was weighed that, were all the free lime passed into the leaching solution, the latter should have a concentration of 0.010 M. In this way, if the final concentration resulted higher than this value, also a partial going into solution of the lime previously combined would be proved; in the contrary case a further lime absorption would be proved.

In order to take into account any possible ulterior hydration of cement during treatment with leaching solution, a first test was carried out with cement-$BaSO_4$ mixtures and for each of them was calculated the amount of hydrolysis lime passed into solution.

The results of the leaching test are reported in Table 7. All values are given as percent of the initial anhydrous mixture.

The first three columns show respectively the free and fixed lime concentration of the sample before the test, as well as their sum.

In the fourth column there is reported the difference between the total amount of lime passed into solution during leaching and the lime passed into solution owing to further hydration of cement, that is the true leached lime. A negative variation will then indicate a lime absorption from the solution.

In the fifth column the difference is given between the true leached lime and the free lime in the solid before testing. This value, if negative, will indicate the quantity of the previously combined lime drawn off during leaching; it will, on the contrary, indicate the quantity of lime further fixed by the material, if it is positive.

The difference in the behaviour of the two kinds of cement is evident. While for the cement containing slag all free lime and some of the lime previously combined is passed into solution, for the cements containing pozzolanas no leaching of the previously combined lime occurs, not only, but rather, for the mixtures with higher amount of such material, a further lime absorption from the solution was observed.

Discussion of Results

The experimental results, on the whole, may be so summarized:

—The pozzolanic activity test, carried out according to Italian Standards 1966, gives positive result only with cements containing more than 70% slag, whilst it is sufficient an addition of 20–30 per cent of pozzolana.

—During the hydration of cements containing additions of the two examined materials, both slags and pozzolanas may react with the lime developed by hydrolysis from portland cement.

However, the amount of lime absorbed by the slag is, at each age and for whatever cement/material ratio, by far inferior to that absorbed by poz-

zolana. Slag contents of 70% in the cement absorb, after 28 days hydration, at the most 60% of the lime available through hydrolysis, whilst at the same age the lime absorption is practically quantitative for cements containing 30–50% of pozzolana.

—The contact solution with the pozzolanic cements tends, with the hydration development, to assume a lime concentration inferior to 2 mmols/l, corresponding to an equilibrium concentration with the products of the lime-silica combination of tobermoritic type, CSH(I). In the case of cements containing slag there is, on the contrary, no evidence of the formation of well defined compounds, and the contact solution reaches a lime concentration equal or superior to the equilibrium value for the amount of alkalies developed by the material.

—The products of combination between lime of hydrolysis and pozzolana present high specific surface, whilst, at the same age and material/cement ratio the contribution of the corresponding products of the lime-slag combination is smaller.

—The X-ray analysis of mixtures of $Ca(OH)_2$ with different quantities of both materials shows the different constitution of the combination products. In the case of pozzolana the $Ca(OH)_2$ is fixed almost qusntitatively and the obtained compounds are of tobermoritic type, CSH(I). In the case of slag, on the contrary, there is formation of tetracalcium aluminate hydrate, C_4AH_{13}, hydrated gehlenite, C_2ASH_8, and calcium hydrosilicates of the type CSH(II), which present higher CaO/SiO_2 ratio. All these compounds seem to be derived directly from the hydration of the hydraulic compounds in the slag, whereas the lime absorption seems to be mostly of physical nature and the formation of combination products of lime with slag is not evident.

—The products of the combination of lime with slag or with pozzolana which are formed during the hydration of the cements added with such materials show a different stability in regard to the leaching action of a very dilute lime solution. Whilst in the case of the cements containing slag, all free lime and some of the combined lime pass into contact solution, in the case of the cements containing pozzolana it occurs, on the contrary, that during the test, further lime combines.

The results, on the whole, demostrate that slags and pozzolanas are not equivalent in view of their action on the hydrolysis lime of portland cement. The amount of the lime fixed by pozzolanas is much higher than in the case of slags and by far stabler reaction products are obtained.

This is due to different nature of the lime hydrosilicates formed from the reaction of hydrolysis lime with pozzolanas or with slags. In the first case compounds of tobermoritic type, CSH(I), are formed, with a low CaO/SiO_2 ratio, therefore scarcely basic and chemically more stable compounds. In the case of slag, on the contrary, the formed products present a higher CaO/SiO_2 ratio and are then more basic and chemically less stable.

The different stability of the compounds from the combination of lime with pozzolanas or with slags, that is, the different power with which the lime is retained from both materials, is proved by the lower lime concentration of the solution in contact with the solid phase when a sufficient quantity of pozzolana is present, as well as from the different behaviour towards the leaching action of an aqueous solution.

Lime is only weakly retained by slag and a part of it is easily given to the contact solution, whilst the compounds from the combination with pozzolana appear absolutely stable to the action of the leaching solution.

SESSION IV-3 SLAGS AND SLAG CEMENTS

Principal Paper Blastfurnace Slags and Slag Cements

Fritz Schröder*

Synopsis

Blastfurnace slags continuously grow in importance for the manufacture of cements. Type and quantity of the blastfurnace slag produced are intimately connected with the trend and measures taken to economize the blastfurnace processes. One of these measures is to decrease the volume of slag referred to 1 ton of pig iron produced. The results of research work evaluated in this connection covered the chemical composition changed for this purpose, especially the increased MgO content and the dependence on temperature and viscosity of slag melts of optimum composition.

By appropriate granulation, the liquid condition of these melts is frozen in and settles the latent hydraulicity of the granulated glassy slags. Some studies dealt with the application of the ion theory of solutions on slag melts. The structure of the liquid slags and their behaviour in frozen-in condition can best be explained by a liquid structure which, in an ternary system with Frenkel type, Stewart type and Bernal type fluids as corners, is closer to the Frenkel type corner. The participation of the Frenkel type fluid indicates that the glassy state of granulated slags can be described neither by the glass structure model of Zachariasen nor by that of Porai-Koshits alone.

Further studies—e. g. on the separation of different slag phases and on fluorescence properties—substantiate the views on structure and hydraulicity of glassy slags.

The composition of both slag cements and their individual components—slag, clinker and sulphate components—largely influence the properties of cement, such as setting, volume stability, and evolution of mechanical strength.

The particular properties of slag cements can be attributed to the properties of granulated blastfurnace slag and are, therefore, most pronounced in slag cements having high contents of blastfurnace slag:

Good elasticity on account of a relatively high ratio of flexural strength/compressive strength.

Very low heat of hydration, high after-hardening and good suitability for heat or steam treatment.

High resistance to sulphate solutions and some other aggressive media. Especially the durability against sea water has been proved by several long-time studies.

The behaviour of slag cements during carbonation is, as a physical property, largely influenced by the type of precuring of the concrete. On sufficient moist after treatment, no difference from cements without slag can be found. In slag cements the strength increases considerably during carbonation, in supersulphated cements it decreases. As a protection of steel reinforcement, concrete made with slag cements has for decades proved satisfactory and, in cases of simultaneous chemical attack, even highly satisfactory.

For these reasons, slag cements rich in granulated blastfurnace slag have been used successfully in many important concrete structures, especially in massive structure elements or where action of chemically aggressive waters had to be expected.

*Forschungsinstitut für Hochofenschlacke, Rheinhausen, West Germany.

Introduction

The 100th anniversary of slag cements (slag in this context applying only to blastfurnace slag as yielded by modern coke furnaces) happens to have fallen in the period between the 4th and 5th International Symposium on the Chemistry of Cement (Washington 1960 and Tokyo 1968). It may be remembered that on March 12th, 1863, E. Langen, the chief director at the time of the Friedrich-Wilhelm Iron and Steelworks at Troisdorf near Bonn (Germany) first produced cements from granulated blastfurnace slag (1). These first slag cements were well homogenised mixtures of finely ground granulated slag and hydrate of lime. In quality standards they were the equal of the portland types made at the time.

Though the invention did not at the time give an impetus to the use of granulated blastfurnace slag in cement production in Germany itself—in contrast to its neighbours, such as Belgium, France, Austria and Switzerland—yet Langen had laid the foundation for intensive research into its latent hydraulic hardening properties. In addition to a number of engineers from the cement industry, leading cement chemists, such as W. Michaelis, L. Tetmeyer, E. Dietrich, later H. Passow and H. Kühl to name only a few, carried out research into the suitability of slag granulated by quick water quenching. It is on these early investigations that the development of present-day "portland blastfurnace slag cements" or "ciments metallurgiques" or "Hüttenzemente" and the "supersulfated" is based. Today these are made and used all over the world.

Output of slag cements activated with portland cement clinker—or calcium sulphate—has registered a further increase in countries with major cement and iron and steel industries in the years since the 4th International Symposium on the Chemistry of Cement (Washington 1960). A few statistical data will illustrate the point. According to the returns of the Cement Statistical and Technical Association "CEMBUREAU" in Malmö (2), the number of plants producing slag cements rose from 117 in 1961 to 179 in 1965.

Since the figures are based on answers to a questionnaire, they may not be wholly accurate. But if we consider that in West Germany alone the number of portland cement factories producing slag cements rose during the period from 41 to 48, we realise that they cannot be far wrong.

The proportion of slag cements in the overall production of some leading industrial nations in 1966 was as follows: USSR over 35 percent, Federal Republic of Germany over 28 percent, Belgium over 25 percent, Italy over 16 percent, France over 14 percent, Japan over 6 percent.

The growing use of granulated blastfurnace slag is also evident from the fact that various countries, such as the USSR, France etc., have meanwhile permitted the addition of up to 15 percent ground slag to portland cements.

In France, for instance, portland cements (class 160/250 and class 210/325) accounted for 71.1 of total production in 1962 and 71.2 percent in 1965 (3). This proportion was made up as follows, taking the figure of 71.2 percent (resp. 71.1) as 100:

		1962	1965
CPA	Portland cement without addition	25.3%	20.4%
CPAL	Portland cement with < 15% granulated slag	44.1%	45.1%
CPACL	Portland cement with < 15% granulated slag + fly ash	18.3%	19.2%
CPAC	Portland cement with < 15% fly ash	12.2%	15.4%

The growing use of blastfurnace slags in cement production is merely indicated by these few figures. Side by side we have seen the introduction of modern, highly perfected research methods and test instruments and the effects of the far-reaching modernisation and greater efficiency of blastfurnaces on the properties of furnace slag in general, granulated slags in particular and hence on slag cements, a drive which has continued unabated in industrialised countries since 1960. All these considerations prompted cement chemists to examine and deepen the knowledge gained so far and to tackle the remaining problems.

At the 4th International Symposium on the Chemistry of Cement (Washington 1960), W. Kramer (4) reported on "Blastfurnace slags and slag cements", and I. I. Kholin and S. M. Royak (5) on "Blastfurnace cement in the USSR".

For a discussion on the results of research published since 1960, we will find useful points of departure in several major publications issued after the Symposium. I cite first the second edition of the well known monograph "Hochofenschlacke" by F. Keil in 1963 (6), second the chapter "Slag cements" by R. W. Nurse in H. F. W. Taylor's "Chemistry of Cement", 1964, (7) and third the extensive survey contained in the paper "Caracteristiques et emplois des laitiers de hauts fourneaux" by P. Javelle and P. Ponteville (8). Other instructive accounts of the same theme are given by

R. H. Bogue (9), H. Kühl (10) and F. M. Lea and C. H. Desch (11).

Slags in Modern Blastfurnace Processes

World steel production, like that of cement, continues to expand steadily. Steel is today made mainly by the open-hearth (SM) and the converter method (Thomas, LD, LDAC processes). The open-hearth method today uses 50 to 70 percent of basic pig iron won from ore, the modern converter process 70 to 90 percent. This high proportion of basic pig has become necessary because the supply of scrap has not kept pace with the rise in steel output.

Moreover, in the last ten years the more modern LD and LDAC processes have increasingly superseded the open-hearth method, so that pig iron production must rise in step with steel output. In 1966, a world output of over 400×10^6 tons of steel consume 340×10^6 tons of crude pig and 60×10^6 tons of scrap. Failing other and equally economic methods, these huge quantities will continue to come mainly from blastfurnaces for the foreseeable future. The rise of 160% registered between 1950 and 1966, accompanied by a marked shift of emphasis from Thomas to stahleisen production, called for new modern blastfurnace plants as well as new developments in process technology to obtain substantially higher output from existing installations.

The present high level of capacity was achieved by the following means:

In new plants by units of greater size with throughputs up to 3,000 tons per day;

By feeding 100% classified burden (ore + fluxes + coke) or pellets of virtually limited grain size spread (6 — 30 mm) and the wide use of ore concentrates;

By using high blast temperatures (1,000 to 1,300 centigrade), with partial enrichment of the wind with oxygen and higher top pressures;

By injecting oil, coal breeze, methane, partly in water vapour, into the tuyeres;

By reducing the quantity of slag per ton of pig.

These measures and their success in improving blastfurnace technology and economy are due to the growing volume of theoretical and practical work carried out since 1950, and particularly as from 1960, in the major industrial nations, sometimes by international cooperation (12), (13), (14), (15), (16) and (17). Their results, with special emphasis on the properties of molten slags, may be summed up as follows:

In modern blastfurnace processes a reduction of the slag volume is of decisive importance. The heat exchange of a blastfurnace proceeds on the counterflow principle. To obtain ideal heat exchange conditions, the interaction of the ascending current of gases and the descending iron and slag melts in the stack should be kept to the minimum. Due to its lower density, a quantity of slag equal by weight to that of the iron melt has about three times its volume. Consequently, the larger the slag component—more or less irrespective of its viscosity—the slower will be the rise of the gas current, and the reduction process it produces, as well as the rate of melt descent (14).

For this reason the reduction of the slag volume per ton of pig is a decisive factor in the efficient operation of large furnaces. Less slag means a larger gas flow per unit of time, permitting a more efficient utilisation of fuels at higher blast temperatures. Whatever the furnace run and fluxes may be, a low volume of slag puts less strain on heat efficiency than a large one and so permits considerable reductions in the required coke charges.

Yet even a low volume of slag does not do away with the need for a suitable chemical slag composition to keep the furnace run trouble-free and obtain pig iron of uniform composition at a steady output rate.

According to W. Oelsen and H. G. Schubert (18) low quantities of slag react more fully, i. e. they foster the transfer of Fe and Mn into the pig melt. With a reduced slag volume, a small increase in its basicity will already improve the degree of sulphur and nitrogen extraction. There are few steel plants in the world today where, due to their dependence on poorer ore deposits, the volume of slag amounts to 400 to 1,000 kilogrammes per ton of pig iron. In most mills employing modern techniques in the mass production of pig, particularly in the USA, USSR, Japan and Western Europe, the average ratio today is 280 to 340 kilogrammes per ton of pig.

Increasing basicity by an addition of limestone alone can under otherwise identical conditions not be carried out at will over the customary furnace temperature range of 1,350 to 1,550 centigrade. A higher limestone content alone quickly makes the slag highly viscous and would give rise to operating troubles which could only be eliminated by substantial increase in temperature. In the past, no irregularity in the furnace run were observed where large quantities of slag were used and their basicity raised by the addition of dolomitic limestone. This led to the conclusion that a rise in the MgO content at the same time as that of CaO, or an

exchange of CaO against MgO improves the flow properties of basic slags within certain limits. The favourable metallurgical effect of increasing slag basicity in this way is limited by a low Al_2O_3 content. Raising the alumina content of low-lime slags does not improve their efficiency. Slags rich in lime, on the other hand, are given better flow properties by raising the Al_2O_3 component to between 15 and 18 percent. This will also facilitate desulphurisation of the bath. Viscosity can be further lowered by increasing furnace temperature or MgO content.

The connections between the chemical composition of slags and optimal working conditions, temperature, viscosity and desulphurisation capacity had already been largely established (4) before the 4th International Symposium on the Chemistry of Cement was held at Washington 1960. The change-over to low slag volumes during the last 10 years has given rise to fresh investigations in laboratories and full-scale production plants of the sequence and speed in the reaction between Fe bath and slag (19), (20), (21), (22), (23), (24), (25) and (26). A number of investigations was devoted in particular to the influence of higher MgO content on viscosity and desulphurisation capacity in the temperature range between 1,350 and 1,600 centigrade and in general on the control of slag run and uniformity of the pig iron produced (27), (28), (29), (30), (31), (32), (33), (34), (35), (36), (37) and (38).

Within the scope of this paper it is impossible to deal in detail with the many conclusions reached. Evaluation of the results obtained shows that the conclusions reached differ, as yet, regarding an optimum content of MgO for the lowest viscosity and the highest degree of desulphurisation. However, the discrepancy still existing is understandable if one considers that both different testing conditions and working hypotheses and slags of different pig iron melts have served as starting points for the relevant research work.

However, as a common result of the various investigations, it can be confirmed that the most favourable slag compositions for the production of different pig iron grades are not solely governed by the amount of the MgO content. One must rather consider all, but at least the four most important components CaO—MgO—Al_2O_3—SiO_2 that make up 93 to 95 weight percent of the composition (33), (37).

Tables 1a and 1b give a survey of the chemical composition of blastfurnace slags from different countries. A comparison of the MgO figures in the two tables shows the general tendency to apply higher MgO contents (38), (39), (40), (41), (42), (43), (44), and (45).

With regard to slag composition, blast furnace operators, especially in countries where,—in the absence of national ore bases—the burden consists of various ores, follow the suggestions of E. F. Osborne, R. C. deVries, K. H. Gee and H. N. Kraner (46). Table 2a shows optimum slag compositions; the values are taken from cit. lits. (46) and (47). Also the indications on composition, temperatures and viscosities in Table 2b are taken from these sources (46) and (47).

Slags of this composition require only low melting temperatures. Already below 1,500 centigrade their viscosity is very low and their sulphur absorption

capacity at optimum level.

A comparison of these most effective slag compositions clearly shows that smaller fluctuations in CaO and MgO content or a moderate raising or lowering of the Al_2O_3/SiO_2 ratio will have a limited bearing on the properties listed. In other words, suitably formulated slag compositions will not produce sudden increases in viscosity and thus no trouble in the furnace run, even if their composition alters a little in line with the unavoidable fluctuations in the burden.

The influence of Al_2O_3 and especially MgO content on viscosity (and desulphurisation capacity) becomes apparent from the space diagram (Fig. 1) of O. Farkas (33). This author infers from it that, for all slags of any Al_2O_3 percentage, an MgO content of 10 to 12 percent may be considered an optimum. If the points of optimum slag compositions, based on $CaO + MgO + Al_2O_3 + SiO_2 = 100$ weight percent, are plotted at the 10-percent-MgO-level of the quaternary system silica-alumina-calcium oxide—magnesium oxide (Fig. 2), these points, according to O. Farkas (33), lie in the area shown in the phase fields of Merwinite and Melilithe.

However if, for plotting optimum slags in this quaternary system, one for instance selects the levels of equal Al_2O_3 contents (10, 15, 20 weight percent), the points come also into the phase fields of merwinite aud melilithe.

Fig. 3 shows the range of compositions of optimum slags for equal contents of 15 weight percent of Al_2O_3.

With a view to taking into account possible losses of temperature when filling the ladles, it is indispensable to know the liquidus temperature of the slag melts selected for being fed to the granulation plant for cement slag production. Due to their functions in the blastfurnace, blastfurnace slags are among those materials which are most often chemically analysed. For their chemical composition which is thus always well known the relevant liquidus temperature can be calculated from the figures given by (46). The liquidus temperature can be ascertained direct on small samples by means of the high-temperature microscope according to J. H. Welch (48), (49). In this connection the high-temperature microscope

indicates also the kind of the primary mineral phases and admits estimations of the viscosity.

S. Klemantaski (17) describes the method of E. T. Turkdogan and P. M. Bills (32) to determine the viscosity after computation of the mole fractions of the silicic acid (N_{SiO_2}) and that of the silicic acid equivalent alumina (N_a) from a diagram that indicates the $\log \eta$ of viscosity in function of the sum $N_{SiO_2} + N_a$. (The silicic acid equivalent of alumina is the difference silicic acid-mole fractions in the composition of melts of identical viscosity of the systems $CaO - SiO_2$ and $CaO - Al_2O_3 - SiO_2$.

The relations between chemical compositions, the temperature and the viscosity shows the graph published by P. Kozakevitch (54) on Fig. 4. The supplementary scheme on this graphe by F. Schröder may serve as an illustration of detections in the next chapter.

The Problems of the Liquid Slags and their Glassy State

The Ion Theory and the Structure of the Liquid Slags

The results of earlier comparative investigations (50) (51) and (37) showed that the latent hydraulic properties of granulated slags depend on virtually the same conditions which make for optimum slag runs in blastfurnaces. They are temperature, viscosity and the chemical composition of the silicate melts. In the past chemical analysis was mainly employed to elucidate the factors which governed the selection of slag composition for the type of pig iron to be obtained, on the one hand, and the further use of the solid slag on the other. Meanwhile, the application of modern physical and electro-chemical methods to research into the melting processes producing slag has modified our views on the structure of liquid slags as well. Since this change also effects the explanation of the hydraulic properties of vitreous slag, we have included in our bibliography the publications of the following authors, representative of the large volume of work done: P. Herasymenko and G. E. Speight (52), H. Flood and K. Grjotheim (53), P. Kozakevitch (54), R. Kammel and H. Winterhager (55), M. Frohberg (56), H. P. Schulz (24), and R. E. Boni and G. Derge (57).

Earlier ideas of metallurgists on the "constitution" of slags which considered the melts as result of mutual solutions of melt-resistant oxide molecules were originally formulated by H. Schenck (58). On them are based the deliberations by F. Keil (6) on the transition of liquid slags into the vitreous state, and H. E. Schwiete and F. C. Dölbor (59) still mention molecules as components of vitreous slags.

Research into the electrolytic properties and surface tensions at high temperatures have increasingly displaced this molecular theory.

It is now widely held that the oxide components of

slag melts are disproportionately bound into complex ion compounds of smaller or larger size. According to the ion-theory on the structure of silicates in solid and liquid form, the more or less regular arrangement of the ions in coordination lattices is attributed to electrovalent and covalent binding forces. Si^{4+} as the central ion of a tetrahedron, surrounded by four oxygen ions, can actuate valencies to neighbouring Si^{4+} ions via oxygen bridge links. In this way, an open lattice of unlimited space form into which the metallic cations are built by virtue of their coordination trend and following the laws of electro-neutrality.

The tetrahedral SiO_4^{4-}-complex anion is produced during the melting from the silicic acid of the gangue, fluxes and coke ash. It also forms during dissociation, e.g. of the orthosilicates (Fe_2SiO_4, $CaSiO_4$) produced before the meltdown of the burden, as per $R_2SiO_4 = 2R^{2-} + SiO_4^{4-}$.

The decreasing viscosity (growing liquefication) of silicates with increasing temperatures is attributed, on the one hand, to a rising number of thermal linkage fractures. On the other hand, the addition of metallic oxides (alkaline, alkaline earth and other metal oxides) which foster the coordination trend of the SiO_4^{4-} anion also promotes chemical linkage fractures.

The division of a spatially unlimited SiO_4^{4-} tetrahedra-lattice or network into complex silicate anions of smaller size as the basic oxide component rises is assumed to be governed by the equations shown in Table 3.

Since blastfurnace slag melts never consist exclusively of neso-silicates (O/Si = 4), so that a situation similar to the formation of orthosilicates (Ca_2SiO_4, Mg_2SiO_4) cannot occur, the more complex-anion structures form in line with the O/Si ratio obtaining at any time, such as $(Si_8O_{20})^{8-}$ or $(Si_3O_9)^{6-}$. The ratio O/Si governs their dimensions which have an important influence on slag flow properties.

J. O. M. Bockris and J. D. Kitchener (60) are of the opinion that in melts with metal oxide content of 10 — 60 mol-%, $(Si_3O_9)^{6-}$-rings form the basic unit, while complexes of formula $(Si_nO_{2n+1})^{6-}$ determine the viscosity.

Table 3. *Reactions for the disproportionation of a spatially unlimited SiO_2-lattice According to R. Kammel and H. Winterhager (55)*

Basicity		Silicate Structure	Relationship O/Si	Viscosity η
acid	SiO_2	Tekto-Silicates	2.0	diminishing
	$2SiO_2 + O^{2-} = Si_2O_5^{2-}$	Phyllo-Silicates	2.5	
	$Si_2O_5^{2-} + O^{2-} = 2SiO_3^{2-}$	Ino-Silicates	3.0	
	$2SiO_3^{2-} + O^{2-} = Si_2O_7^{6-}$	Soro-Silicates	3.5	
basic	$Si_2O_7^{6-} + O^{2-} = 2SiO_4^{4-}$	Neso-Silicates (Single-Tetrahedra)	4.0	

According to O. Farkas (33), a base oxide content of 25 mol-% leads to the formation of larger complex anions, such as $(Si_9O_{21})^{6-}$ or $(Si_{12}O_{28})^{8-}$, at 33 mol-% those of $(Si_6O_{15})^{6-}$ or $(Si_8O_{20})^{8-}$. Only at a base oxide content of 50 mol-% are complex anions with structures such as $(Si_3O_9)^{6-}$ or $(Si_4O_{12})^{8-}$ said to form. The concentration limit of orthosilicate lies within the range of 66 to 70 mol-% base oxide. In this case, the slags would contain practically only freely moving $(SiO_4)^{4-}$-anions surrounded with the metal cations.

In the most effective blastfurnace slags the CaO + MgO content generally lies above 50 mol-%, mainly between 54 and 57. In this base concentration range, according to (60), small complex anions of the general composition $(Si_nO_{3n+1})^{2n+2-}$ (example: $(Si_2O_7)^{6-}$) are formed. The cations present in the liquid slag surround the complex anions and saturate their free negative charges. In this way, 2 Ca^+ and 1 Mg^{2+} will be found in the hollow spaces of the $(Si_2O_7)^{6-}$ anion in the structure of the akermanite ($Ca_2MgSi_2O_7$) which is of great importance in blastfurnace slags.

In the even more important structure of the merwinite ($Ca_3MgSi_2O_8$) the Ca^{2+} and Mg^{2+} cations are said to hold together the single tetrahedrons of $(SiO_4)^{4-}$ anions present in it.

In the gehlenite structure ($Ca_2Al_2SiO_7$), where a $(SiO_4)^{4-}$ tetrahedron of the $(Si_2O_7)^{6-}$ anion can be replaced by an $(AlO_4)^{4-}$ tetrahedron as a lattice component, the free valencies of complex anion $(SiAlO_7)^{7-}$ are assumed to be saturated by the two Ca^{2-} cations and the one Al^{3+} ion.

In the transition of slag melts into the vitreous state, we must consider the important fact that the binding link fractures produced by the thermal agitation are reversible. This means that during the cooling down fissures in the lattice close again. Bearing this in mind, the production of glassy blastfurnace slags with optimum hydraulic properties would call for a faster rate than the speed at which the lattice fragments recombine.

In melts at temperatures of 1,500 to 1,600 centigrade, the binding forces acting between cations and anions are weakened by the thermal agitation, and the disproportionate development of smaller and larger complex silicate structures (e.g. as neso-silicates and soro-silicates) is fostered.

It may be assumed that in these processes Ca^{2+} and Mg^{2+} cations behave in different ways. For the same valency, the ion radius of Mg^{2+} is smaller than that of Ca^{2+}. The Mg^{2+} consequently has a higher ion

potential and stronger covalency forces. Possibly, the Mg^{2+} cation promotes the enrichment (cluster formation) of small, more mobile structural units between larger coherent silicate complexes or lattice fragments and so contributes to the lowering of viscosity.

Research into structure models for molten liquids has made contributions to this subject which raise the probability of the conclusions drawn from the ion theory as applied to slag melts.

According to the atomistic interpretations of the structure of liquids by W. A. Weyl (61) such silicate melts can be described by using a ternary diagram whose corners represent the extreme models of liquids, outlined by J. D. Bernal (62), J. Frenkel (63), and G. W. Stewart (64). The exact location therein of slag melts cannot yet be stated. A number of electron-microscope investigations on melt phase separation seem to indicate that slag melts in particular have a relatively high proportion of the "Frenkel"-model, as compared with the other two liquid models.

Frenkel's liquid no longer has any structural relation to the configuration of the corresponding crystal phases. Rising temperatures result in faulty arrangements (empty sites, displacements) which form centers of assymetry exerting an influence on the binding forces in their vicinity. The cristalline substances melt at a disproportionate binding energy rate. Stronger forces may be lead to temporary clusters and weaker forces to fluctuating fissures. Therefore the structure of such a melt alters continuously.

Already a few centigrade above their thermodynamically and kinetically well defined melting point the liquid has a very low viscosity. The temperature coefficient of the viscosity is small. Such a melt may at any point of time be described by the presence of variable clusters separated by fluctuating fissures. Liquids of the Frenkel-type cannot be supercooled sufficiently to form a glass.

The Bernal liquid has a structure free of faulty arrangements and similar to the crystal from which it has originated during the rise in temperature. Mostly such crystals can be strongly overheated. The melting process takes place progressively. The liquid remains still stable above the melting point. Such melts are of very high viscosity and have also a high temperature coefficient of viscosity. Melts having "Bernal structure" can just as well as "Stewart liquids" be easily undercooled to form glass.

An essential characteristic of the Stewart liquid is its ability to be drawn out into long fibres, i.e. that contrary to the clusters of the Frenkel liquid the structural elements are arranged into groups capable of orientation, e.g. to chainlike or ringlike shape. For this type of substances exists no relation between the average bond energy and the lattice energy, nor between the melting point and the viscosity.

The slag melts rich in basic oxides (mainly CaO + MgO) cannot straight away be blown into fibres. This is only possible by increasing their proportion of Stewart liquid after being melted together with fine quartz sand. Lime basic blastfurnace slags will only become very highly fluid a few degrees above melting point by adding other oxides, viz magnesia.

The MgO thus influences increasing of their portion in Frenkel liquid. There is also another fact which points to the proportion of Frenkel liquid, viz optimal effective slag melts with 10 ± 4 wt% of magnesia and 16 ± 4 wt% of alumina. They cannot normally be undercooled, but have to be very rapid quenched during the granulation process. Other indications for the participation of the "Frenkel type" in liquid slags are the extraordinary crystallization capacity below liquidus and the often found heterogeneity of the slag glasses in micro range by separation of liquid phases (see photos No. 7–11).

Last not least also the intensive violet, blue and red fluorescence radiations (65) may be signs for the participation of the Frenkel liquid, it will be considered that this liquid type melts are favoured by formation of assymetry centers. The last will be surely multiplied by the O^{2-} of variable polymerisation degree, introduced by CaO and MgO.

The employ of the ion-theory (52) (55) (56) and of the atomistic conception of the phase relations due to the complex structure of liquids (61) on the hot slag melts may lead us to the opinion that: the amount of the oxygen content depending on the increasing sum of CaO + MgO up to ~56 wt%, the great number of the silicate anions with a low polymerisation degree, and the participation of liquid of the Frenkel type capable of a fluctuating formation of clusters and fissures, determine the very low viscosity a few centigrades above liquidus and the desulphurization rate of slag melts.

The Glassy State

Most of what has been said so far also applies to granulated vitreous blastfurnace slags, because the melt structure has been frozen into them by very rapid quenching.

The degree of latent hydraulic hardening properties of granulated slags is governed by the extent to which this quick quenching freezes in the disproportionate structure of the melt.

In addition to the tapping temperature the viscosity

and the chemical composition of the melts, the granulation temperature and the granulation speed determine thereby mainly the glass-structure and glass content, resp. the latent hydraulicity, resp. the quality of the cement slags.

The above statements are also apt to facilitate the answer to the question of the structure of the slag glasses and their properties. In 1964 R. W. Nurse (7) in his explanations on the crystal-chemical structure has compared the glass structure models elaborated by W. H. Zachariasen (66) and E. A. Porai-Koshits (67).

Based on the interpretations of a number of deductions from glass properties and referring to further results of investigations R. W. Nurse reaches the conclusion that the differences between the network theory and the crystallite theory in its modern form will vanish.

According to the present state of our knowledge, it can be assumed from the still "hypothetical" position of the slag melts in the ternary diagram (Frenkel—Bernal—Stewart) that the structure of the slag glasses forms a solid solution in a chain whose final links may be the two mentioned structure models.

Whether the glassy state of slags corresponds more to the one or to the other of the two glass-structure types will probably depend on the proportion of Frenkel-liquid which was able to be transformed into the solid glass state. According to R. W. Nurse, he and his coll. F. W. Parker, T. Tanaka, T. Sakai and J. Yamane as well as R. Kondo assume that the network theory is more convenient (7), whilst de Langavant (7) and S. Solacolu (7) prefer the crystallite theory. F. Keil (6) and H. E. Schwiete and F. C. Dölbor (59) plead also for the network theory.

The Granulation

Slag melts as they are nowadays preponderant in blastfurnace processes are liquids that easily crystallize by normal cooling down. The liquidus temperatures of these slags are situated—dependent on their composition—between 1320 and 1450°C (56). From heating-up tests carried out on slags (45) (68) we know that nucleation and growth of crystallites starts with temperatures > 840°C. When freezing in the structure of the slag melts it is, therefore, necessary to very quickly undercool the range of the liquidus temperature and the range up to below 800°C in order to avoid formation of undesirable heterogeneities, e.g. the separation of melilite crystals.

Granulation of slag melts, i.e. their transformation into a granular solid sand which can be easily evacuated from the blastfurnace zone is about ten years older than the discovery of the hydraulic properties of this product. The various processes developed to this purpose have simultaneously a double function: splitting the slag to the size of sand grains, and cooling it quickly down to 100°C. In nearly all cases water is used as a cooling means. In view of good cement properties it is convenient, according to P. Großstück (69) to granulate currently with fresh water instead of using circulatory water system. In the latter case the water will heat up so as to favour devitrification. Often the use of abundant water already results in the required splitting. With a view to reducing the amount of water required, compressed air, pressure water, or specific mechanical devices are used to intensify the splitting process. F. Keil (6) has recently described the different granulation processes.

Running slags have the highest possible temperatures. Therefore running slag granulation always provides very reactive cement slags. With this process the melt after leaving the slag mold flows over a short fire-proof runner or spout and then drops ~ 20 cm down into a pressure water jet. This causes splitting and quick cooling and conveys the more or less porous-foamy granulated product into provided Talbot-cars. From these the excess water can run off at once.

Due to the flowing-off of the running slags, the height of the slag layer is reduced above the bath raising between two tappings. According to A. Send (26) this phenomenon handicaps the desulphurization. For this reason, recently with very large furnace units the slags are drawn off together with the pig iron.

It depends on local space conditions whether the large volume of tapping slags will be granulated directly at the furnace or at a more distant centralised plant. If granulation takes place at the furnace, the melt flows on to a runner at the track-free head of the furnace platform. At the runner end it drops into a sufficiently long water runner positioned below, where it is seized, separated, quenched and flushed on into a concrete basin. The quality of the granulated slag with regard to splitting off and glass content depends on the length of the water runner. On the bottom of the basin there is an 80—100 cm thick sand-gravel filter layer (70) which in turn is covered by a framing of steel rails. The granulated slag drains into the sand-gravel layer and can be lifted up by the grab excavator without thereby destroying the filter layer. By means of tubes perforated at the base of the filter layer, it is possible to flush the latter so as to remove any accumulated slag fines.

Also in central granulation plants grain separation

and quenching is accomplished in the runner with or without pressurised water. Here granulation may be improved by fitting spraying heads through which the pressurised water for granulation and the cooling and convoying water arrive in two super-imposed levels. According to I. I. Kholin and S. Royak (5) the U.S.S.R. formerly preferred granulation with and without runners into basins. But already before 1960 they gradually changed over side by side with this wet granulation to the "semi-dry" granulation. The terms "wet" and "semi-dry" referring to the water content of the granulated slag. In the latter process, granulation proceeds in a drum in two stages: at first quenching and foaming with little water under pressure. At second the still hot and highly porous slag is mechanically splitted off, and expelled out of the drum. The advantage of this method consists in: decomposing less sulphide, and forming less hydrogen sulphide. This reduces corrosion of concrete and steel of the granular plants.

In 1963 V. F. Krylov (71) stated in a comparative report on these two granulation processes that wet granulation in the runner is the most efficient; except for very hot slag melts it is suitable for any acid and basic slag.

In the United States S. P. Kinney and F. Osborne (72) have introduced a splitting and quenching process. This is characterized by the slag jet being torn by means of steam-air jets in a fixed wide steel tube and blown at high pressure through an atomized water curtain. The steam, air and water nozzles are arranged in a semi-circle at the rear of the tube. This process is capable of producing granulated slag and foamed slag.

According to W. Altpeter (73) granulated slag can be safely conveyed hydraulically if the slag- (15% in volume) water- (85% in volume) mixture is carried in rubber conduits. A report by W. Hahn and S. Geron (74) inform both on the wear of tubes made of other materials and of the pumps, as well as on the minimum transportation speed.

Granulated Slag for Cements

(by F. Schröder and K. Grade)

Condition and Characteristics

By a suitable granulation process the slag melts are converted into a vitreous granular sand 0—5 mm, which is more or less porous. In connection with the systematic study of the qualities of granulated slags, the Forschungsinstitut für Hochofenschlacke, Rheinhausen (Research Institute for Blastfurnace Slags) has also currently made grain size analyses. As during these investigations (76) also air-granulated slags and slags quenched in granulation mills were screened, the results are summarily represented by the attached diagram (Fig. 5). The scattered range of variations of the wet granulated slags of the diagram corresponds with the results obtained by E. Prandi (75), testing 54 slag samples.

Photos No. 1—6 demonstrate the petrographic condition of cement slag grains of good hydraulicity. A high percentage of porous grains (Photos 1 and 2) is an advantage for the production of blastfurnace slag cements with relatively high initial strength. Dense vitreous grain portions (Photos 3, 4 and 5) stimulate the development of high final strengths and favour above all the post-hardening. Photo No. 6 shows a vitreous grain with interspersed melilite crystals. Those crystals and skeleton crystals, e.g.

C_2S-C_3MS_2- and CS-like, grow below the liquidus by too slowly cooling rate.

Foamy-porous granulated slags form during granulation of running slags or hot tapping slags resulting from the production of stahleisen, foundry and hematite and hot operated basic pig iron.

Dense-vitreous grain mixtures are generally obtained from cold-blast stahleisen slags and normal Thomas pig iron slags. Blastfurnace cement works connected to blastfurnace plants with two or more blastfurnaces have thus the possibility, by cutting different granulated slags, of producing cements with high initial and final strength.

P. Aitcin (68) and S. L. Kolhatkar and T. V. Cherian (77) report on the influence of high tapping or granulating temperatures on the color.

While the first (68) elucidates the change of the color, in function of the tapping temperature, from dark grey-brown to brownish-white, the last (77) related the brightening to the increasing liquidus temperature of synthetic, modified, high-alumina slag glasses. These vitreous slags have simultaneously been investigated in respect of temperature influences on other physical properties, such as bulk density, porosity and water retention potential. The results attained are similar to the findings of H. E. Schwiete and F. C. Dölbor (59) testing the relations between granulation conditions and properties of granulated hematite slags on numerous technical specimens.

The results obtained from the investigations of the dependence of the bulk density, the water and vitreous content on the slag temperature and in particular on the granulating conditions confirm the previous findings: the bulk density decreases and the amount of retained water increases as the temperature becomes higher.

Quality of granulation is characterized by the amount of vitreous grains. H. E. Schwiete and F. C. Dölbor (59) modified the quenching conditions by using molds with varied calibers so as to obtain between 6 and 98% glass contents. The strength development of test cements selected from 30 technical slags specifically granulated for this purpose showed a dominant dependence on the glass content measured by microscope.

According to a generally accepted view increasing contents of crystalline components in vitreous slags considerably reduce the quality of their hydraulicity but not to such an extent that slags with only 30—40% vitreous constituents can no more be used for the production of cements with low strength specifications. I. I. Kholin and S. M. Royak (5) make the same statements, however, with the difference that they regard part of the mineral formations as hydraulically active. According to the findings of F. Keil and F. Gille (78) that akermanites react hydraulically without activator, this opinion is justified, and, no doubt, certain orthosilicate formations in vitreous slag will behave analogously.—

P. P. Budnikov and V. S. Gorskov (79) are of the same opinion. It has incited them to carry out investigations with a view to increasing the hydraulicity by a controlled crystallization. The results obtained show that by repeated re-melting at different temperatures and cooling to 1,000 centigrades via unstable crystallizations the ratio merwinite/gehlenite can be so varied that the more reactive component is preponderant.

In the Research Institute for Blastfurnace Slags, Rheinhausen, the glass content and the content of crystalline portions in granulated slags are determined as follows: the specimen reduced to a particle size of 40—60 μ is bedded into a plastic material and a polished section is made. The latter is etched with 1% alcoholic HNO_3 and HF-vapour, and subsequently the amount of vitreous and crystalline components (the latter possibly separated according to minerals) are counted by means of an integration ocular.—When checking the vitreous content of granulated slags in blastfurnace slag cements, a cement dispersion specimen (grain size 30—40 μ) is bedded into Canadabalsam and with the aid of the polarizers one ascertains the proportion of purely vitreous grains, of grains differing in respect of their crystal content and of entirely crystalline grains.

In a previous section of this report we have pointed out that the structure of vitreous slag cannot be described solely by the crystallite-theory of Porai-Koshits (67) nor by the network theory of Zachariasen (66). By means of electronic-optical investigations, by analysis of the X-ray small-angle scattering as well as on the basis of the diffuse light dispersion, a drop-shapped separation of melting phases could be demonstrated in many slag glasses, viz. a micro-heterogeneity not caused by crystal growth.

It is known, however, that often certain blastfurnace slags with a low liquidus temperature after cooling present an enamel-type condition. By microscopic examinations of such slags the writer could find droplet-like separation areas more than 1,000 Å in diameter. In the meantime, F. Schröder and K. Grade (80) examined many specimens of vitreous slags by light-microscopic and fluorescent-microscopic methods in respect of such separations and other petrographic textures which are indicative of phase separations in the melt.

Photo No. 7 shows a vitreous slag grain with a "schlieren-" or streak-chaped separation of different glass-phases. Fluorescence has shown in a glass-matrix (pink fluorescing; greyish white on the photo) streaks of orthosilicatic glass (blue fluorescing; grey on the photo;—the grey color is produced by etching with HF-vapour).

Photo No. 8: In a melilite glass matrix (red fluorescing) there are embedded drop-shaped roundish separation areas of orthosilicatic glass (intense bright blue fluorescing, thus mainly C_2S)—between polarizers showing only tensio birefringence; further a crystallite with myrmekitic eutectic texture consisting of melilite (crystalline, fluorescing violet, white on the photo) and of merwinite-glass-like particles(irregular rounded, partly crooked in the melilite, bright blue fluorescing; grey on the photo by etching with HF-vapour) and some needle-shaped wollastonite crystallites (fluorescing red, very weak; white on the photo).

Photo No. 9: Myrmekitic eutectic textures there are embedded in the melilite glass matrix (fluorescence color: salmon; dark grey on the photo). These textures consist of merwinite (fluorescence color: blue; on the photo lighter grey) and melilite (violet fluorescing; on the photo white). These textures can only be explained by separated melting phases in the beginning crystallization.

Photo No. 10: The vicor—glasslike matrix (rend-

ered visible by etching with HF-vapour; pink fluorescing; on the photo light grey) consists of statistically distributed mervinite droplets (blue fluorescing) and melilite glass (red fluorescing). A mixture of red and blue radiation results in pink fluorescence. In this matrix moreover occur: partly still roundish droplets, partly with needle-like crystallites, of orthosilicatic separations (bright blue fluorescing, black on the photo). These were confirmed also by W. Gutt (81).

On the occasion of paper read in Leipzig on "the hydraulic properties of vitreous blastfurnace slags" H. Busch (82) has pointed out, based on electron—optical representations of smallest vitreous slag splinters, that in a silicate glass matrix are embedded separated droplets of another vitreous silicate phase. As the relevant examination report is not available as yet, we are attaching hereto Photo No. 11 which is reproduced from a publication by H. Peyches (83) and which exactly shows what H. Busch (82) indicates in his electron—optical figures on the structure of the slags examined.

In air-cooled blastfurnace slags the melilites, members of the solide solution series akermanite (C_2MS_2)-gehlenite (C_2AS) are the predominant minerals. From optimum slag melts with an akermanite/gehlenite-ratio 1.2 up to 0.8. In addition to a very high nucleation capacity they have an extremely high speed of growth.

Melilite crystals fluoresce deep violet. If, therefore, in the above mentioned vitreous slag matrix a formation of melilite nuclei starts already at or a few centigrades below the liquidus temperature, such start of nucleation, however, not being detectable either by X-ray-diffraction or by microscopic examination,

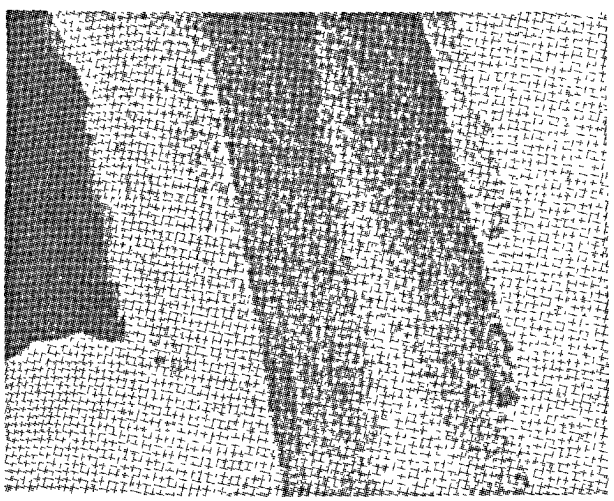

Photo 11. *Thin splinters of glass (electron micrographs by Peyches, 82). Demonstration o j dark droplets within a lighter glass-matrix*

yet the modification of the fluorescence with all the transitions between red and violet point to this submicroscopic heterogeneity of vitreous slags. It takes place essentially in lime—alumina—silica slags lower in MgO.

Microscopic examinations of vitreous slags give little information on where the sulphur of the molten slag remains. The fact is known that part of the sulphides is leached by granulation water. In thin sections of less basic vitreous grains, small skeleton crystals of CaS are seen very rarely. Glass grains obtained by quenching of cold operated slags have yellow-brown to dark-brown colors and remaind of the brown color of technical glasses containing sulphide-sulphur. CaS having a low content of MnS fluoresces orange. A mixture of the red fluorescence radiation with the orange fluorescence the writer calls "salmon". Such a fluorescence is radiated from $CaO—Al_2O_3—SiO_2$ slag glasses with only a few % (< 5) of MgO and $\sim 1.0\%$ S^{2-}.
