According to X-ray diffraction, Y_{HH} gave 8.2 Å line and 7.6 Å line after 3 days. 8.2 Å line was intensified with age, then disappeared after 21 days. 7.6 Å line was not to be seen after 7 days. C_2ASH_n was not recognized before 21 days, but was recognized distinctly after 35 days. On the other hand, (001) spacing of hydrated halloysite became very weak after 3 days, and it disappeared almost completely after 35 days. (02) spacing, however, stayed unchanged. M_{HH} showed the same tendency as Y_{HH}, but C_2ASH_n formation started earlier, the existence of the new phase being recognized after 14 days. N_{HH} resulted C_2ASH_n further earlier.

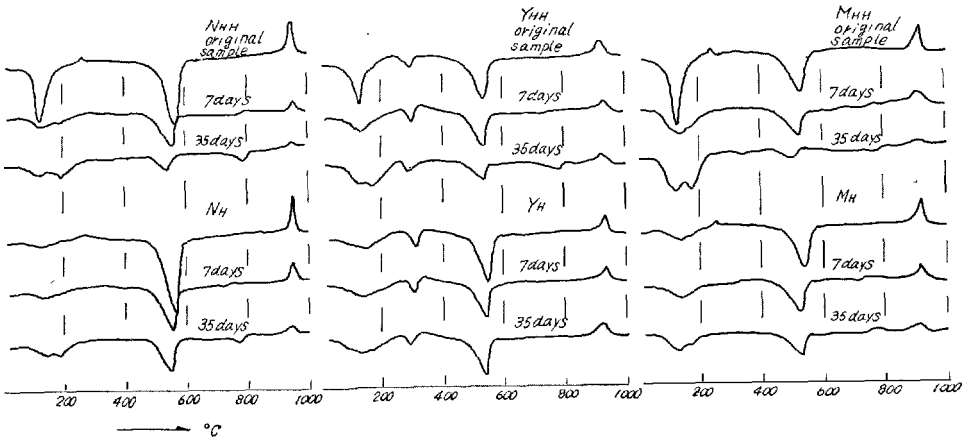

Fig. 4. *DTA diagrams of reaction products 0.100 g sample to 100 cc lime saturated solution, 20°C*

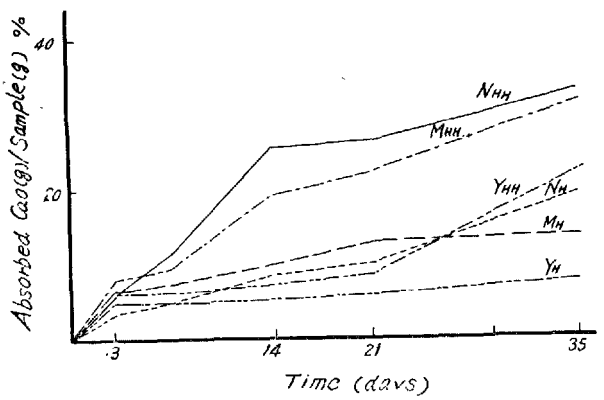

Fig. 5. *Lime absorption velocity at 20°C*

Y_H presented both of 8.2 Å line and 7.6 Å line for each reaction age, the pattern of X-ray diffraction remained almost unchanged, although the amount of absorbed lime was measurable. M_H showed greater reactivity than Y_H, (001) spacing became weak with age, a small amount of C_2ASH_n was observed after 35 days. N_H behaved similarly to M_H, but C_2ASH_n formation started earlier.

DTA curves of reacting specimens were found to have the following general tendency. The endothermic peak of 550°C shifted to lower temperature side, diffusing itself and becoming shallow. The exothermic peak of 970°C shifted to lower temperature side, the height of peak becoming lower and the profile rounded.

Gibbsite did not disappear, and loose endothermic peak of 750°C~800°C was observed. In correspondence to the structural perfectness of the specimens, the DTA curves were varied. The appearance of 200°C peak, which was based on C_2ASH_n, was in a good agreement with the results of X-ray analysis. The change of (001) spacing of hydrated halloysite, however, was in a poor agreement with the DTA analysis. The curves of N_H, M_H and Y_H presented a tendency similar to that of the hydrated specimens, although the profiles were not quite in evidence.

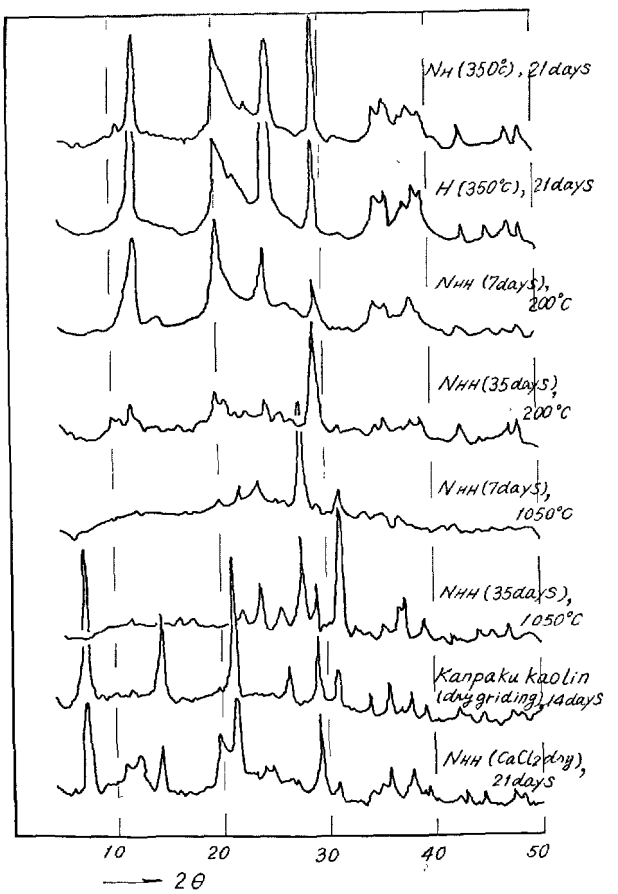

Fig. 6. *X-ray diffraction diagrams of reaction products with various treatment*

Fig. 6 shows X-ray diffraction patterns of resulted

material through the reaction between heated specimens and lime as well as of heat-treated resultants. Treatment conditions were the following.

a. N_{HH}, heated at 350°C for 2 hrs (7.35 Å), 21 days reaction
b. H_H, heated at 350°C for 2 hrs (7.25 Å), 21 days reaction
c. N_{HH}, 7 days reaction, then heat-treated at 200°C
d. N_{HH}, 35 days reaction, then heat-treated at 200°C
e. N_{HH}, 7 days reaction, then heat-treated at 1050°C
f. N_{HH}, 35 days reaction, then heat-treated at 1050°C
g. Kanpaku kaolin, ground, 14 days reaction
h. N_{HH}, kept in $CaCl_2$-desiccator for long time (7.5 Å), then 21-day reaction

As is observed in Fig. 6, the preheated specimens caused a decreased reactivity. When well-reacted specimen, which showed strong lines of C_2ASH_n and no (001) spacing of hydrated halloysite, was post-heated, then C_2ASH_n decomposed and halloysite appeared instead. On post-heating the reacted specimen at 1050°C, patterns of C_2AS and wollastonite were to be observed. Well-crystallized kaolinite, when dry-ground in agate mortar to give X-ray amorphous material, reacted easily with lime and resulted in C_2ASH_n. N_{HH} specimen, when dehydrated in $CaCl_2$ desiccator to give 7.5 Å line of halloysite, formed C_2ASH_n easily.

It was observed through electron microscope that clay specimen formed aggregate, then the aggregate changed into an edge-shaped form, crystal growth being started. This transformation is shown in Fig. 7.

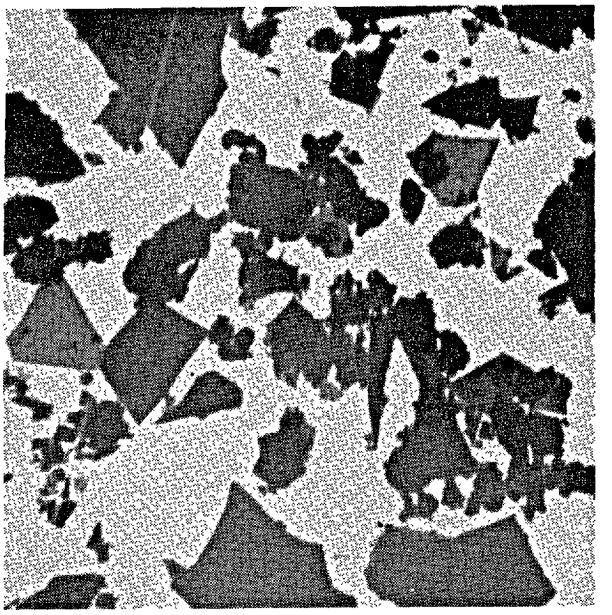

Fig. 7. *Electron micrograph of reaction product N_{HH}, 35 days, 20°C, Magnification ×5,000*

Discussion

Hydrated halloysite (N_{HH}, M_{HH}, Y_{HH}) absorbed lime when it was placed in lime solution, C_2ASH_n could be recognized by X-ray analysis after the amount of absorbed lime had attained a limited value. Even in the stage when the amount of absorbed lime was small and C_2ASH_n lines were not to be seen, (001) spacing of hydrated halloysite became weak, but the intensity of (02) spacing stayed unchanged. It can be assumed from this observation that the disorder along c-axis became greater with the reaction, lime being absorbed between layers. Further, the absorbed lime reacted with the adjacent layer, which resulted in forming C_2ASH_n. From the X-ray diffraction patterns of the heat-treated specimen causing decomposition of C_2ASH_n, it can be assumed that the clay remained retaining its crystallinity almost intact during the reaction process.

Eades and Grim (11) described about the mechanism of lime-clay reaction as such reaction with solution starting on the edge of crystals for three-layers minerals. According to the opinion of Diamond and Kinter (12), the reaction proceeds between absorbed lime and surface layers of clays. These observations are based on experiment with clay minerals of rather poor reactivity. From the present auther's experiment, in which such clay mineral of high reactivity and with interlayer water as hydrated halloysite was used, it is concluded that the reaction on surface layer could be more dominant than the one on layer's edge. It is also described that the resultant materials from clay minerals of poor reactivity are calcium aluminate hydrates and calcium silicates hydrate but not C_2ASH_n.

In the case of allophane, it was found that C_4AH_{13} and 7.6 Å hydrate appeared transiently and disappeared as C_2ASH_n began to be formed. This phenomenon, as was confirmed also by the case of hydrated halloysite, could be explained as that a part of Al_2O_3 dissolved into liquid phase when lime was absorbed. To satisfy the resulting condition of C_2ASH_n, the amount of absorbed lime should be more than 10% to the weight of air-dried hydrated halloysite. The value for allophane being about 20%, the deviation is caused by the difference of crystal structure of each clay mineral.

Generally speaking, the better-crystallized hydrated halloysite was found to possess the greater reactivity. This tendency was also confirmed with specimens, which were pre-heated at 150°C and showed 7.5 Å basal reflexion of halloysite. The pre-heat treatment, however, deteriorated the reactivity. It is assumed that high structural perfectness favored the invasion of lime between layers or the orientation of lime on layer surface. When specimens were heated at 350°C, interlayer water evaporate away and (001) reflexion shifted to about 7.3 Å, then the invasion of lime became difficult, the reactivity being decreased to a great extent.

Well-crystallized kaolinite, which is usually of poor reactivity, could be activated through dry-grinding to react easily with lime. The X-ray amorphous dry-ground kaolinite could recover its layer structure through the lime reaction, forming well-crystallized C_2ASH_n.

The final or metastable from materials resulting from the lime-clay reaction are, as is well known, dependent upon the reaction conditions such as paste form, slurry form or suspension form. Kudo, Tukiyama and Okabe (13) investigated the lime-clay (hydrated halloysite) reaction in paste form, in which C_4AH_{13} and C_2ASH_n were identified through X-ray analysis in early stage of reaction, tobermorite gel was identified through electron microscope in later stage, and the resulting crystal materials of early stage disappeared gradually as the reaction time elapsed. The reaction in paste form proceeds in the saturated lime solution, and the reaction speed is slow, thus giving different results compared with the present author's results.

Although no detailed examination was made to confirm the existence of calcium silicate hydrates, it is assumed that the endothermic peak of 750°C~800°C could be related to both of calcite and tobermorite gel. Davidson and Hilt (14) examined the 7.6 Å hydrate which was obtained by the lime-montmorillonite reaction, and concluded that a part of Al in C_4AH_{13} could be substituted isomorphously by Si, thus giving 7.6 Å line instead of 8.2 Å. This problem needs a further investigation.

Properties of Hydrated Gehlenite

On the properties of C_2ASH_n, which is obtainable by the lime-allophane reaction, some descriptions were already made (2) (3). The behavior of SiO_2 in allophane or of Fe_2O_3 as the contaminant is still unknown. The present author made detailed examinations on the properties of C_2ASH_n, which was prepared as purest as possible, comparing the newly obtained data with the published ones.

Specimens and Experimental Method

There was 20 g of coprecipitated gel(H_2O^- 17.5%, H_2O^+ 8.80%, Al_2O_3 46.45%, SiO_2 27.35%, Al_2O_3/SiO_2 = 1.00) was added to 20*l* of saturated lime solution, aged for 1 year at 20°C in a CO_2 free atmosphere. White crystal of C_2ASH_n was filtered out and kept in $CaCl_2$ desiccator. Chemical analysis, X-ray diffraction, DTA, TGA, infra-red analysis and electron microscope were applied to the obtained C_2ASH_n. Also the specific gravity and the heat of solution against 2N HNO_3 containing small amount of HF were measured.

Experimental Results

Chemical analysis (%) gave the following;

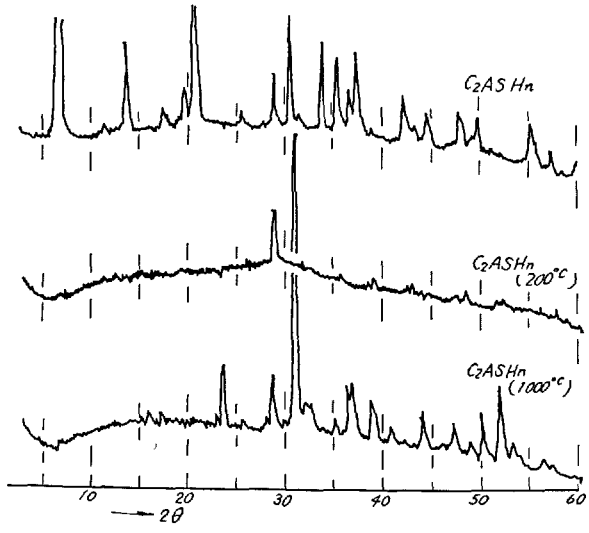

Fig. 8. *X-ray diffraction diagrams of* C_2ASH_8

H_2O^-: 7.60, H_2O^+: 25.25, CaO: 29.45,

(ig. loss 5.33%) and with 950°C heated sample respectively to be 336 cal/g, 577 cal/g, 672 cal/g. Specific gravity was measured to be 1.89.

Discussion

C_2ASH_n was firstly obtained by Strätling (1) who examined the resulting material of the reaction between meta-kaolin and lime solution. Turriziani and Schippa (15) confirmed this substance when they carried out the same experiment as the above, and investigated the nature of C_2ASH_n in detail. According to the study of Dörr, as is cited by Locher (16) and by zur Strassen (17), C_2ASH_n was formed through the reaction of C_2AS-glass and lime solution. C_2ASH_n could be obtainable from various starting materials through lime reaction such as quenched slag with high Al_2O_3 contents (18) (19) (20), dry ground amorphous kaolin (21) (9), allophane (2) (22), hydrated halloysite (9) (13), kaolinite (although reaction time elapsed very long) (23), coprecipitated SiO_2–Al_2O_3 gel (5) and metakaolin (1) (5) (24). C_2ASH_n was found also in the hydrates mixture of pozzolan cement of low alkali portland cement and burnt kaolin (25). Although the formation of C_2ASH_n has been reported by many authors, its properties are not yet clear because it is difficult to prepare C_2ASH_n in pure form.

Chemical composition can be calculated on the basis of the results of chemical analysis, being denoted by the formula $C_{2.33}AS_{1.08}H_{8.70}$. If CO_2 exists in the form of $CaCO_3$, and a small amount of lime is absorbed, the resulting material should be $C_2ASH_{8.45}$ together with a small amount of C_2SH to be assumed to exist. Thus the purity of the sample is about 90%. Dörr's sample, as was referred already, has the formula $C_{2.5}ASH_{9.3}$, which could be re-written as C_2ASH_8 when the existence of hydrogarnet is taken into consideration. Schmitt's sample (20), which was obtained through lime reaction of $C_2A_{(1-x)}F_xS$ glass, has the formula C_2ASH_8. The present author's sample, which was proved to be in relatively pure form through X-ray analysis as well as electron microscope, possesses the approximate composition of C_2ASH_8.

On the X-ray diffraction patterns, as shown in Fig. 8, calcite is found to be in existence, but no carboaluminate is to be seen. Calcium silicate hydrates were not recognized while weak lines of hydrogarnet are identified. Not regarding the lines, of which intensity is less than 10% to the intensity of (001) spacing, and eliminating the lines of above stated contaminants, C_2ASH_8 should possess the following spacing:

12.54(100)	6.24 (44)	4.92 (12)	4.17 (100)	2.868(60)
2.614(44)	2.495(27)	2.488(34)	2.405(20)	2.378(40)
2.118(16)	2.076(10)	2.014(12)	1.888(10)	1.824(16)
1.658(25)	1.645(14)	1.605(10)	1.542(10)	1.435(15)

Spacing values of C_2ASH_8 are already given by Strätling (1), Turriziani and Frantini (26), Schmitt

(20) and the present author (3). Now the above values are compared with the data of Schmitt. Lines of 4.28 Å and 3.52 Å, which are given by Schmitt, are not found by the present author. On the other hand, line of 2.01 Å is found here, lines of 2.50 Å and 2.38 Å showing doublet profile, and intensity of 2.87 Å line being greater than that of (002) spacing. When the above data are compared with the one already reported by the present author, all spacings possess a smaller value, and the intensity of lines is relatively strong as compared with the intensity of (001) spacing. From this observation it can be concluded that the sample is of high purity as well as of high degree of crystallinity, and isomorphous substitution by Fe is not assumable.

On DTA diagram a relatively sharp endothermic peak at 210°C and exothermic one at 940°C are to be seen. At 840°C calcite shows endothermic peak. Peaks based on gibbsite, hydrogarnet, tobermorite or hydrated lime are not recognized. Peak of 210°C results from the decomposition of hydrate water, 940°C peak results from the formation of C_2AS. According to the TGA diagram, dehydration starts at 50°C, it is intensified above 150°C. Up to 350°C, 90% of hydrate water decomposes. Weight loss above 750°C is attributable to calcite decomposition.

On infra-red absorption diagram, as shown in Fig. 10, absorption of calcite, Si–O, O–Al–OH, water and hydrogen bond are to be observed. Besides these, unidentified absorption bands are found as follows:

1500, 1380, 1160, 960, 865 (cm^{-1})

When heat treated at 200°C, 1160 band and 865 band disappeared, and a broad 800～1200 band, which allophane shows, comes out instead. These two bands are thought to be related to C_2ASH_8.

Electron microscope was applied to samples in which crystals of more than 5μ are removed through sedimentation method. As seen in Fig. 11, C_2ASH_8 possesses an irregular plate form, and hexagonal crystal is not observed. The edge of plates is not of straight line, but of curved line, and they tend to elongate. Degree of crystallinity is high. No gel substance is to be seen. Electron diffraction pattern which is taken along c-axis of crystal gives regular hexagonal figure. The results agree with the data of zur Strassen (17).

For this study, carried out in chemistry section of Public Works Research Institute, Ministry of Construction, the auther is much obliged to the co-workers, Mr. M. Ohba, Mr. T. Maki, Mr. K. Fujisaki and Mr. S. Wada as well as the assistant researchers, Mr. T. Kaibara and Mr. T. Nishijima.

Supplementary Paper II-67 Successful Prevention of Loss of Strength in Concrete Made with High-Alumina Cement

Povindar K. Mehta*

Synopsis

Utilization of High-Alumina cement for structural purposes is seriously limited due to the gradual loss of strength which High-Alumina cement concretes undergo especially under hot-wet environments. This phenomena is accompanied by conversion to C_3AH_6 of the hexagonal phase CAH_{10}, which is the initial product of hydration.

A calcium sulfoaluminate additive was added to a High-Alumina cement which was used for making 2″×4″ concrete cylinders at 40° to 50°F. The concrete was wet cured for 28 days at 40° to 50°F, and later exposed to warm water at 100°F. At regular intervals the cylinders were tested for strength up to a period of 168 days from the date of hydration. No loss of strength was observed. X-ray diffraction studies on the corresponding concrete samples showed that only an insignificant portion of CAH_{10} converted to C_3AH_6.

As compared with portland cements, High-Alumina cements (HA cements) are known to possess superior characteristics with regards to refractoriness, high early strength and resistance to chemical attack by acidic and sulfate-bearing waters. Development of high early strength is a valuable property for application of this cement both for emergency repair and construction jobs, and for production of prestressed concrete.

In spite of the advantages offered by HA cements, their use for structural purposes is handicapped due to partial loss of strength after long periods, particularly when the concretes are exposed to hot-wet environments. The loss of strength in certain cases is reported to have caused structural failures. Some countries have, therefore, forbidden the use of HA cement for structural applications.

Hypotheses on Loss of Strength

The main constituents in HA cements is generally the compound, CA. In his comprehensive review of aqueous cementitious systems containing lime and alumina, Steinour (1) states that, of the eight different hydrates reported by several investigators, only the following four are commonly present in the products of hydration of commercial calcium aluminate cements: C_4AH_{13}, CAH_{10}, C_2AH_8 and C_3AH_6. The former three hydrates are hexagonal and they crystallize as thin acicular needles which contribute to the binding strength of the hydrating cement. The hexagonal phases, however, are metastable and they transform eventually to the stable cubic C_3AH_6.

The data from the investigation of Lea (2), Neville (3) Lehmann and Leers (4), and several other investigators have proved beyond any doubt that the conversion of hexagonal calcium aluminate hydrates to the cubic phase is related to strength loss in HA cement concretes. Regarding the precise mechanism which is responsible for retrogression of strength, Lehmann and Leers (4) attributed this to the intrinsic properties of the hydrates involved. According to them, the cubic morphology of C_3AH_6 does not permit a high surface area to become necessary for development of strong binding forces. The data from the investigation of Gitzen and Hart (5), and Neville (3), however, shows that the loss strength may also be attributed to increased porosity in the concrete structure when CAH_{10} converted to C_3AH_6. Mehta (6) has made calculations to show that for every cubic centimetre of CAH_{10} which transform to C_3AH_6, the solids undergo a reduction in volume by about one—half of cubic centimetre. Such a reduction in the volume of solids after hardening of concrete would evidently lead to a porous structure, which not only is inherently weak with regards to load-bearing capacity, but is also more susceptible to corrosion by permeating acidic fluids, especially when calcium hydroxide is not present in the products of hydration of HA cements.

*The University of California, Berkeley, California, U.S.A.

Additives Already Investigated for Preventing Conversion

Robson (7) lists several chemical additives which have been tried by different investigators to prevent the conversion of CAH_{10} to C_3AH_6. The additives mentioned are preformed calcium aluminate hydrates, calcium sulfate, aluminum sulfate, ammonium chloride, sodium phosphate, polysaccharides and polyhydric alcohols, anionic, cationic and non-ionic surface active agents, etc. But, according to him, "No reliable and effective method has been discovered which will greatly retard or prevent the conversion process when the condition for the latter are especially favourable."

According to Young (8), presence of ligno-sulfonate yielded thermodynamically more stable hexagonal calcium aluminate hydrate phases, but the hydration reactions were considerably retarded. Obviously, therefore, such additives which do not interfere with the rate of hydration of CA (or rate of formation of CAH_{10}) but which counteract the conditions favouring conversion of CAH_{10} to C_3AH_6 seem to hold promise for solution of this problem.

Materials and Experimental Procedure

In carrying out this investigation a HA cement composed principally of mono-calcium aluminate was used. This cement was produced by heat treatment at 2600°F of stoichiometric quantities of reagent quality calcium carbonate and alumina hydrate. The chemical analysis of cement showed 35.5 percent CaO and 64.5 percent Al_2O_3. It was ground to 3130 cm^2/g Blaine. When this cement was hydrated at 40–70°F, the principal product of hydration, as determined by powder X-ray diffraction analysis, was CAH_{10}. For preventing conversion of CAH_{10} to C_3AH_6 under hot-wet conditions, a calcium sulfoaluminate additive was included in the HA cement. The additive consisted of a high-purity chemical compound having the molar composition $4CaO \cdot 3Al_2O_3 \cdot SO_3$. It was prepared by heat treatment at 2600°F of stoichiometric amounts of reagent quality calcium carbonate, calcium sulfate and alumina hydrate for a time sufficient to complete the reaction. It was also ground to 3130 cm^2/g Blaine. To chemical analysis of the additive showed 36.8 percent CaO, 50.1 percent Al_2O_3, and 13.1 percent SO_3. Using 0.6 water-cement ratio, graded Standard Ottawa sand (ASTM Standard No. C109) and 3/8″–1/2″ crushed quartz as coarse aggregate 2″ × 4″ cylinders were prepared from a six-sacks per cubic yard concrete, with and without the presence of the additive in the HA cement. Series A shown in Table 1 represents a concrete mix which had no additive in the cement, while series B represents the concrete mix which had 5 percent additive by weight of the total cementitious material.

In order to prevent the instantaneous formation of some C_3AH_6 due to high heat of hydration normally produced during the rapid hydration of High-Alumina cement at early ages, the concretes were made with cold water (40° to 50°F), cast in pre-chilled 2″ × 4″ C. I. molds, and the molds stored in a cold room maintained at 40° to 50°F. They were stripped after 24 hours, and finally cured in 40° to 50°F water for 27 days. This procedure of curing helped to hydrate most of the CA of the HA cement to CAH_{10} without producing any detectable C_3AH_6 in the specimens. On the 28th day three concrete cylinders from each series were tested, both for compressive strength and for changes in the compound composition of the cement. The other cylinders were moved to a water storage maintained at a constant temperature of 100°F. The purpose of curing in warm water was to test whether the presence of calcium sulfoaluminate additive helped to prevent conversion of CAH_{10} to C_3AH_6 and thereby checked the resultant loss in strength. At 35, 56, 84, 112, 140 and 168 days, tests were made to determine both the changes in compressive strength and the compound composition of cement. In addition, modulus of elasticity of both the concretes was also determined before exposure to hot-wet curing and after exposure to hot-wet curing for 140 days.

The cylinders were capped and tested for compressive strength in accordance with the Standard ASTM procedures (C192–62T and C39–64). Representative

$CaO \cdot Al_2O_3 10H_2O$	7.132	12.4
$3CaO \cdot Al_2O_3 \cdot 6H_2O$	5.121	17.3

samples of mortar were collected from the broken pieces of concrete. The mortar was crushed, sifted through a 100 mesh sieve in order to remove most of the sand, and tested by powder X-ray diffraction analysis for determining the compound composition of the cement paste. Phillips Norelco X-ray diffraction equipment with copper target, nickel filter and scintillation counter was used.

In Table 2 are shown the specific peaks of the X-ray diffraction (XRD) pattern which were selected for identification and for semi-quantitative evaluation of the respective compounds by comparison of their relative peak intensities (counts per second at 1/8 degrees 2θ scanning rate).

Results and Discussion

The results of these tests are shown in Table 3, and are also plotted in Fig. 1:

It is evident from the strength data that substitution of 5 percent $4CaO \cdot 3Al_2O_3 \cdot SO_3$ in HA cement did not alter the compressive strength characteristics of concrete specimens cured at 40° to 50°F for 28 days, the strength values (average of three specimens) being about 8.3 Ksi in both the additive-containing and the nonadditive-containing concretes. The X-ray diffraction analysis of the cement paste showed that in both cases the hydration product consisted mainly of the hexagonal phase, CAH_{10}. No cubic phase, C_3AH_6, was detected, while a substantial amount of anhydrous CA was still present in the samples. When the specimens were exposed to moist curing at 100°F, initially, the strengths rose to a value of about 11.0 Ksi in both cases (due to hydration of the remaining unhydrated CA as confirmed by X-ray diffraction data), but later on started to decline. It can be seen from the curves in Fig. 1 that while the strength of HA cement concrete having no additive declined from about 11.0 Ksi to about 2.1 Ksi during the hot-wet curing period of 56 days to 168 days, the strength loss under the same conditions during the corresponding period for HA cement concretes having 5 percent $4CaO \cdot 3Al_2O_3 \cdot SO_3$ as additive was insignificant (within the value of experimental error).

In fact, the average compressive strength of reference specimens of Concrete B stored continuously in cold water (40° to 50°F) for 168 days was found to be 10.47 Ksi as against 10.28 Ksi for the identical specimens of concrete which were initially cured with cold water (40° to 50°F for 28 days) and later exposed to a prolonged period of hot-wet conditions (stored continuously under water at 100°F until age 168 days). Furthermore, prolonged hot-wet curing (under water at 100°F from age 28–168 days) of cylinders of Concrete A showed a drop in the modulus of elasticity from 5.23×10^6 psi to 2.74×10^6 psi., whereas under the same conditions the values of modulus of elasticity for cylinders of Concrete B remained essentially unchanged (5.67×10^6 psi.,

Table 3. *Compressive strengths and XRD peak ratios of Concretes A and B at different ages*

Age	Concrete A (made with cement containing no additive)		Concrete B (made with cement containing additive)	
	Compressive strength Ksi.	XRD, ratio of peak intensities C_3AH_6/CAH_{10}	Compressive strength Ksi.	XRD, ratio of peak intensities C_3AH_6/CAH_{10}
28	8.24	0	8.29	0
35	10.69	0.145	11.38	0.06
56	11.55	0.25	10.85	0.08
84	7.98	0.39	10.98	0.14
112	5.50	2.50	10.10	0.14
140	2.48	9.70	10.03	0.19
168	2.17	11.00	10.28	0.19

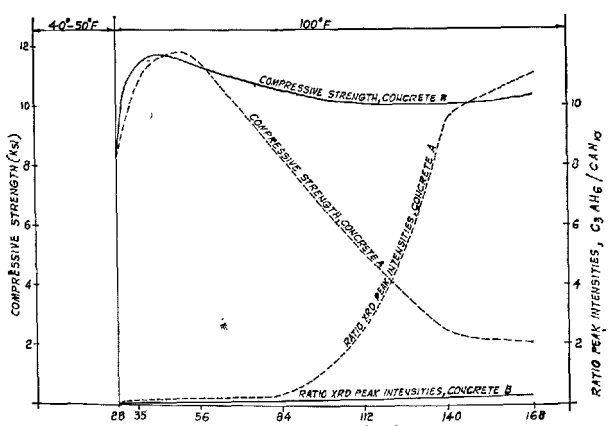

Fig. 1. *Compressive strength and XRD peak ratios of Concretes A and B at different ages of curing*

before exposure to hot-wet conditions, and 5.56×10^6 psi., after exposure to hot-wet conditions for 140 days).

The intensity ratios of diffraction peaks indicate that during the hot-wet curing period of 28 days to 168 days, the ratio of C_3AH_6 to CAH_{10} peaks increased from zero to about 11 for HA cement concrete having no additive, while it increased from zero to only 0.20 for HA cement concretes containing the calcium sulfoaluminate additive.

Conclusion

It can be concluded from the results of this investigation that, under the test conditions employed, the presence of $4CaO \cdot 3Al_2O_3 \cdot SO_3$ additive during hydration at high-alumina cement was capable of stabilizing the compound CAH_{10} under hot-wet conditions, thus ensuring that no loss in compressive strength of concretes resulted when such concretes were exposed to hot-wet conditions. It can also be concluded that the presence of this additive did not, in any derogatory way, interfere with the initial hydration rate of CA.

It is, however, realized that some further tests are necessary to show the details of behaviour under other conditions such as exposure to hot-wet conditions at different stages of hydration.

Oral Discussion

Shunro Ueda and Renichi Kondo

Dr. Mehta emphasized that CAH_{10} could be stabilized by the addition of calcium sulfoaluminate. We formerly tested the effect of calcium sulfoaluminate on the conversion of the aluminous cement in water at 50°C, because the aluminous cement manufactured in Japan by the sinter process using rotary kiln and heavy oil usually contains a certain amount of calcium sulfoaluminate in the clinker. In our test, not only CAH_{10} but also C_2AH_8 transformed to C_3AH_6 and gibbsite and the strength of the test pieces decreased. But the rate of the conversion was generally little retarded by the presence of additives such as

calcium sulfoaluminate.

You did not discuss the reason of the stability of CAH_{10}. However we think the prevention of the conversion cannot be explained by the consideration that the phase equilibrium of $CaO–Al_2O_3–H_2O$ system changes with the addition of SO_3 ion. We would like to ask you about those points.

Oral Discussion

Keiko Okada

It is of much interest that $C_4A_3\bar{S}$ added in alumina cement on hydration prevents the hydrate CAH_{10} from converting into C_3AH_6 during long age without losing any strength of the cement.

To stabilize CAH_{10}, however, we have found it necessary to keep the hydrate specimen at relatively low temperature during such a long time as 28 days even if any additives were present.

Practically, however, it seems to be difficult to keep the large specimen under those conditions.

We should like to ask the author's opinions what properties were expected when the concrete having $C_4A_3\bar{S}$ were placed and cured at room temperature.

Author's Closure

Povindar K. Mehta

Reply to S. Ueda and R. Kondo

The author used 5% addition of a laboratory-made specimen of $C_4A_3\bar{S}$ for stabilizing strengths of concretes made with high-purity calcium aluminate cement. No conversion of CAH_{10} to C_3AH_6, and correspondingly no strength loss was observed when the concrete specimens, initially cured for 28 days at 40–50°F, were finally exposed to hot-wet conditions at 40°C for 140 days. The discussers used different types of high alumina cements, differently made from calcium sulfoaluminate additive with perhaps unknown ratio of additive to cement, and different curing conditions (50°C). Since their materials and the experimental conditions differed significantly from those of the author, it is possible that the discussers also obtained different results. The author already acknowledged that more work is needed using a wider range of materials and curing conditions before complete success in solving the problem of retrogression of high-alumina cement concretes is attained.

Regarding the mechanism of CAH_{10} stabilization, no work has yet been done in this direction, and author's thoughts on the subject are still of a speculative nature.

Reply to K. Okada

Results of research on properties of calcium aluminate cement concretes containing $C_4A_3\bar{S}$ additive, and placed-cured at room temperature, are not yet available. The author appreciates the concern of the discusser that the results may not be the same under more practical conditions of placement and curing. Research work is being planned in this direction at the Structural Engineering and Structural Mechanics Laboratory of the University of California.

In the mean time, the findings reported in this paper clearly establish that an initial long period of low temperature curing is not adequate by itself to prevent CAH_{10} conversion of concretes exposed to hot-wet conditions at later ages. The presence or absence of the $C_4A_3\bar{S}$ additive did make all the difference between final strengths and CAH_{10}-stabilization characteristics of Concretes A($C_4A_3\bar{S}$ absent) and B($C_4A_3\bar{S}$ present), considering that both the concretes were subject to identical conditions of placement and curing, i.e. cured at 40–50°F for the first 28 days and thereafter at 100°F in water.

Supplementary Paper II-68 Amorphous Phase in the $CaO-Al_2O_3-CaCl_2-H_2O$ System

Ferenc Tamás*

Synopsis

The reaction between supersaturated aqueous monocalcium aluminate solution and diluted calcium chloride solution in the presence of calcium hydroxide was studied formerly by Turriziani and Schippa. The precipitate being formed in this process was always a crystalline solid solution of Friedel's salt ($3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$) and C_4AH_{13}. In this study the same reaction was re-examined, but extending the range to more saturated $CaCl_2$ solutions and the absence of calcium hydroxide as well. In the absence of calcium hydroxide, the precipitate is crystalline and completely amorphous if the $CaCl_2$ solution is diluted and concentrated, respectively. This change is not abrupt but gradual: $CaCl_2$ solutions of 0.5 molar or above cause amorphous, $CaCl_2$ solutions of 0.375 molar or less cause crystalline precipitates. The crystalline precipitates have an X-ray pattern very similar to that of Friedel's salt, but their chemical composition varies, aluminium content is always higher, calcium content always lower than indicated by the formula. The chloride contents are not volatilized by ignition: a common feature of crystalline and amorphous precipitates. Infrared spectra of the amorphous and crystalline phases differ quantitatively but are qualitatively similar. The two phases are entirely different under the electron microscope.

Introduction

The reaction between supersaturated aqueous monocalcium aluminate solution and aqueous calcium chloride solution yields precipitates. Composition and mineralogy of these solutions were cleared by the systematic study of Turriziani and Schippa (1): they consist of solid solutions of $C_3A \cdot CaCl_2 \cdot xH_2O$ and C_4AH_x. The $CaCl_2/Al_2O_3$ ratios of the products range from 0.1 to 1.0, this latter conforming to pure tricalcium aluminate-calcium chloride-dekahydrate (hereinafter called "Friedel's salt" for short).

However, the Italian authors have studied the reaction using rather diluted (56 g/l, i.e. roughly 0.5 mol/l as a maximum) calcium chloride solutions only; further this solutions were saturated in respect to $Ca(OH)_2$. It thus occurred promising to re-examine this reaction and extend the range towards more saturated $CaCl_2$ solutions, and without $Ca(OH)_2$-saturation too. As a further difference, pure monocalcium aluminate was used as a starting substance in this study as contrasted to the aluminous cement raw material of Turriziani and Schippa (1).

Experimental

Preparation of Samples

Supersaturated, metastable monocalcium aluminate solution was prepared by shaking synthetically produced, pure CA (containing no alkalies and free lime) for 30 mins with CO_2-free distilled water in polythene flasks. Shaking was done machinally at room temperature.

The clear, supernatant liquor was sucked down and added to an equal volume of $CaCl_2$-solution, of concentrations ranging from 0.125 M to 2.0 M. Precipitation occurred usually within a few seconds; the mixtures were allowed to stand for 1 hr, then filtered and washed with a little water.

All the mixing, shaking, filtering, and other operations were made in a controlled atmosphere cabinet (glove box) in pure nitrogen atmosphere. Distilled water was always used after a previous vigorous

*Central Research and Design Institute for Silicate Industry, Budapest, Hungary.

boiling for 10 mins; the hot water was cooled to room temperature in the glove box. These rigorous measures eliminated the danger of contamination of the products by airborne carbon dioxide against which they are extremely sensitive.

Sample preparation was made at laboratory temperature (about 22–25°C); some additional experiments were made at 0°C and 70°C too.

X-ray Investigation

Filtered precipitates were examined partly in moist state and partly after drying in a $NaOH + CaO$ filled desiccator. For the X-ray tests a Japanese diffractometer (Type Geigerflex, Rigaku-Denki) was used, with filtered Cukα radiation. The scanning speed was usually 1 deg/min; in some cases a lower speed was used to enable a better resolution.

Chemical Analysis

The precipitates were only partly soluble in nitric acid; thus they were analysed for CaO, Al_2O_3 and Cl^- after attacked with $KNaCO_3$. The melts were dissolved in diluted nitric acid and stock solutions made. CaO and Al_2O_3 were determined volumetrically by EDTA, Cl^- by adding an excess amount of 0.1N $AgNO_3$ and back-titrated with 0.1N NH_4SCN. All analytical results are given, on an anhydrous basis, in terms of mols taking the amount of Al_2O_3 as unit.

Results

The most striking result is that not all products are crystalline. The crystallinity of the product depends primarily on the concentration of the calcium chloride solution: dilute $CaCl_2$ solutions yield crystalline, concentrated ones amorphous precipitates. The limit is slightly below 0.5 M.

The crystalline products have a sharp pattern, diffraction peaks are intensive; positions and intensities are almost identical with those obtained by Turriziani and Schippa (1). Table 1 gives some characteristic crystalline patterns selected from more than 200 patterns of crystalline precipitates obtained during the last two years; additionally, two patterns published by the cited authors as well as that of standard Friedel's salt (card 2–0081 of the ASTM Powder Diffraction File). The similarity of the patterns is striking, though two peaks mentioned in the ASTM card are missing. But these two peaks have never been found in the präparat patterns neither during this study nor by the Italian authors, so they must be considered as incorrect data.

*These two lines have never occurred in our samples.

The amorphous precipitates showed no peaks at all, not even the slightest trace of them; only one broad ring was visible extending over 20–25 degrees in more than 150 amorphous samples investigated.

The change in preparation temperature has had no marked effect upon the crystallinity of the precipitates.

To elucidate phenomena in more detail, additional experiments were made with $CaCl_2$ solutions in the concentration range between 0.250 and 0.500 M, in steps of 0.05 M; in the range of 0.450 and 0.500 M in steps of 0.005 M. For the examination of these samples a scanning speed of 1 deg/4 min. was chosen and only a narrow range, $\theta = 4$–8 deg. was scanned for the main (0001) peak of Friedel's salt and its solid solutions appear in this range. The relative intensities of this peak as read off from the diffractometer tracing against the background are given in Table 2.

As well seen from these data, the changeover from crystalline to amorphous is not abrupt but gradual.

Table 2. *Intensity of the (0001) peak in X-ray patterns of precipitates made with 0.250 M—0.500 M* $CaCl_2$ *solutions*

Molarity of $CaCl_2$ soln.	Intensity
0.250	100
.300	100
.350	100
.400	100
.450	78
.455	71
.460	68
.465	62
.470	38
.475	25
.480	5
.485	2
.490	0

In any case, the samples made with $CaCl_2$ solutions being more concentrated than 0.5 M are undoubtedly amorphous, and those with $CaCl_2$ solutions less concentrated than 0.400 M crystalline.

The chemical composition of the precipitates showed very great variability; at present this will not be discussed in detail. The ignition of samples at 1000°C for three hours causes no loss of Cl^-. The examination of thermal behavior of crystalline and amorphous substances has not been finished yet.

Infrared spectra of the crystalline and amorphous preparates are similar, though the crystalline samples give more distinct bands. OH stretching vibrations do not occur; the source of the double band in the range of 2800–3000 cm^{-1} is the Al–O stretching vibration. The 1480 cm^{-1} band is presumably due to water molecules coordinated to calcium.

Crystalline and amorphous preparates are entirely different under the electron microscope.

Supplementary Paper II-81 Barium Aluminate and Barium Silicate and Their Hydraulic Properties

Hiroshi Uchikawa and Koichi Tsukiyama*

Synopsis

The crystal structure and hydraulic properties of principal hydraulic compounds of refractory barium aluminous cement ($BaAl_2O_4$) and rapid hardening barium silicate cement (Ba_2SiO_4) were investigated.

Crystal structure of $BaAl_2O_4$, Ba_2SiO_4 and their hydration products of $Ba(OH)_2 \cdot H_2O$, $BaAl_2O_4 \cdot 6.5H_2O$, $BaSiO_3 \cdot 6H_2O$ were precisely determined by electron diffraction of single crystal and powder X-ray diffraction using IBM 7040 and IBM 360 computer from the structure model and Patterson or Fourier synthesis.

Stoichiometry of the hydration of barium aluminate and barium orthosilicate was proposed by the identification of produced compounds based on the analysis of crystal structure, electronmicroscopic observation and liquid phase equilibrium.

Physical properties and structural change of barium aluminate and silicate hydrate under various atmosphere and at elevated temperature were discussed in relation to crystallographic consideration.

Introduction

It has been reported that there are two kinds of barium cement consisting mainly of barium aluminate ($BaAl_2O_4$) (1) and barium orthosilicate (Ba_2SiO_4) (2). The high refractoriness of barium aluminous cement and high early strength of barium silicate cement as well as the radioactive rays absorbing property have been interested in from the viewpoint of industrial utilization. But owing to the lack of the foundamental knowledge of the constituent compounds, produced hydrates and the mechanism of hydration, it has been very inconvenient for us to increase the production and utilization of these barium cements. In order to make clear these undissolved problems, the authors performed a series of crystal chemical studies on both of the hydrated and unhydrated barium aluminate and barium silicate as summerized later.

Method of the Precise Measurement of the Position and the Intensity of Diffracted X-ray Peak

X-ray diffraction was carried out using the powdered sample with X-ray diffractometer as it is too difficult to obtain the single crystal large enough to do single crystal X-ray diffractometry. Conditions of the X-ray diffraction are summerized in Table 1. The sample was finely ground to under five microns so as to avoid the preferred orientation of the crystal and the microabsorption effect of the X-ray. Silicon or magnesium oxide fine powder was used as an internal standard in order to determine the Bragg angle precisely and avoid the variation of the apparatus. Possible slow scanning speed and fine slit were selected to satisfy the relation of the time width. Five measurements were performed on each sample, and the error in this case was smaller than 0.01° in 2θ and 3% in intensity.

Table 1. *Conditions of X-ray diffraction*

X-ray	CuKα radiation (Ni filtered)
Distance from X-ray source to sample	180 mm
Distance from sample to receiving slit	180 mm
Width of receiving slit	0.2 mm
Horizontal divergence	1°
Vertical divergence	1°
Time constant	4 sec or 2sec
Scanning speed	1/4°/min
Ratemeter scale factor	8

*Central Research Laboratory, Onoda Cement Co., Ltd, Tokyo, Japan.

So we can conclude that the measurement has good reproducibility enough to use in the present work.

Method of the Determination of the Lattice Constants and the Atomic Coordinates

Reciprocal cell of a crystal is capable of being represented independently of its symmetry, as triclinic cell using six appropriate vectors. If we choose $E(\theta)$ as a function of systematic error, next equation is right in general case.

$$4\sin^2\theta = h^2a^{*2} + k^2b^{*2} + l^2c^{*2} + 2hka^*b^*\cos\gamma^* + 2hla^*c^*\cos\beta^* + 2klb^*c^*\cos\alpha^* + E(\theta)$$

Observed 2θ value and random sets of (hk$l$) are given to the computer as input in ascending order. The computer then solves the above-given equation by means of least square method as the observed 2θ values are numerous in comparison with variable reciprocal vectors. When calculated $1/d^2_{obs}$ is not fitted to observed $1/d^2_{cal}$, this set of (hk$l$) is eliminated as unsuitable. This procedure is repeated until all sets of (hk$l$) are satisfied by selected lattice parameter.

Atomic coordinates are first estimated roughly by means of Patterson synthesis and heavy atom method. Precise determination is performed by slight removal of the atoms considering the crystal symmetry and by the calculation of diffracted X-ray intensity to the corresponding positional parameter so as to minimize the

$$R(=\sum|(I_0)-(I_c)|/|I_0|) \text{ value.}$$

All calculation was carried out by the computers, types of which were IBM 7040 and IBM 360.

Barium Aluminate and Barium Orthosilicate

Crystal Structure of Barium Aluminate ($BaAl_2O_4$)

Precedent Works

In 1937, X-ray diffraction data on barium aluminate was first reported by S. Wallmark and A. Westgren (3). Structural survey for a series of K_2AlSiO_4, $BaAl_2O_4$, K_2LiSO_4 and Na_2AlSiO_4 has been performed by W. Nowachi (4) using the relationship to β-tridymite, but the precise determination of $BaAl_2O_4$ cell and atomic coordinates have not been clarified. Recently, precise determination of $BaAl_2O_4$ structure and certification of the formation of the iron-bearing solid solution were reported by the authors (5).

Precise Determination of the Lattice Constants and Atomic Coordinates.

$BaAl_2O_4$ was synthesized by heating the stoichiometric mixture of barium carbonate and α-Alumina in a electric furnace at 1500°C for four hours. The chemical compositions and specific gravity and powder X-ray diffraction patterns of synthesized $BaAl_2O_4$ are shown in Table 2 and Fig. 1. Indexing of the powder diffraction peaks was carried out by referring the S. Wallmark and A. Westgrens' crystal data (3)

Table 2. *Chemical composition, specific gravity and refractive index of* $BaAl_2O_4$.

Compound	Chemical composition				Free BaO	Specific gravity (g/cm³)	Refractive index (20°C)
	Ig. loss	Al_2O_3	BaO	Total			
$BaAl_2O_4$	0.28	39.54	60.07	99.89	0.01	4.004	1.682 ± 0.003

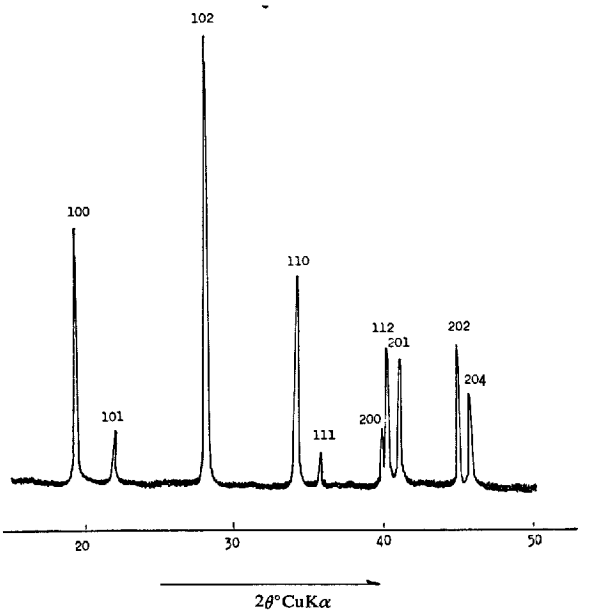

Fig. 1. *Powder X-ray diffraction pattern of* $BaAl_2O_4$

considering the close resemblance of the pattern. The unit cell dimensions determined by means of a least-squares treatment were $a = 5.224$ Å, $c = 8.777$ Å. Assuming that $Z = 2$, the density at room temperature was calculated as 4.087 g/cm³, which was good agreement with observed density (4.004 g/cm³).

(hk*l*) reflections are observed only when (00*l*) is even, which corresponds to the space group D_6^6–$P6_322$.

A two dimentional Fourier synthesis with reflection normal to *c*-axis and at intervals of 1/120 along *a*- and *c*-axis was computed by IBM 7040 computer using the atomic coordinates reported by W. Nowachi (4). From the calculated electron density distribution diagram of $BaAl_2O_4$, the interval of positional parameter of aluminum correspond to the same electron density along *z* direction was determined as ± 0.009 and oxygen along x direction as ± 0.08. Possible positional parameter of aluminum and six oxygen atom were selected from each of fifty values from -0.05 to 0.15 along *c*-axis and from 0.16 to 1.16 along *a*-axis, respectively. With these 2500 sets of positional parameters, structure of $BaAl_2O_4$ was refined by comparing the calculated intensities with observed one. When suitable atomic coordinates are selected, final *R* value for all observed reflections was 0.175, which is better than $R = 0.181$ obtained from our calculation to W. Nowachi's atomic coordinates. Final atomic coordinates of $BaAl_2O_4$ are given in Table 3. Observed diffracted X-ray intensities, calculated structure factors and intensities are shown in Table 4. The interatomic distances calculated from above-mentioned atomic coordinates are listed in Table 5.

Crystal Structure

The atomic arrangement projected along *c*- and *b*-axis is shown in Fig. 2. Two barium atoms in special position in the cell are situated at 1/4 and 3/4 level of *c*-axis and four AlO_4 in the unit cell form distorted tetrahedron with covalent bonding. Each of the oxygen situated at the apex of AlO_4 tetrahedra is shared with two inversed AlO_4 tetrahedra. Other three basal oxygens are situated at the same levels along *c*-axis. The average Al–O distance in AlO_4 tetrahedra is 1.79 Å, which shows good coincidence with 1.78 Å obtained by J. W. Smith (6). Another average value is reported in anorthite as 1.788 Å and 1.719 Å ac-

panying with the partial transformation of the coordination of Fe^{3+} from FeO_4 to FeO_6.

Crystal Structure of Barium Orthosilicate (Ba_2SiO_4)

Precedent Work

Crystal structure of Ba_2SiO_4 was proposed by H. O'Daniel and L. Tscheischwilli (9) that this compound belongs to orthorhombic system with $a = 5.77$ Å, $c = 7.56$ Å as a series of structural studies on the orthosilicates such as K_2BeF_4 and $SrSiO_4$. H. P. Rooksby (10) suggested that the structure of Ba_2SiO_4 has a close resemblance to β-K_2SO_4 and E. M. Levin and G. M. Ugrinic (11) measured the interplaner spacing and relative intensities of Ba_2SiO_4 by powder X-ray diffraction. The structure of Ba_2SiO_4 has been considered isostructural with β-K_2SO_4 from the close resemblance of both ionic radius of barium to potassium and silicon to sulfur as well as $(SiO_4)^{2-}$ to $(SO_4)^{2-}$.

Recently indexing of powder X-ray diffraction patterns and the precise determination of lattice constants and atomic coordinates of Ba_2SiO_4 using structure model of β-K_2SO_4 were reported by the authors (12).

Indexing of the Powder X-ray Diffraction Patterns and Precise Determination of Lattice Constants

Ba_2SiO_4 was synthesized stoichiometric mixture of guaranteed reagents of barium carbonate and silicic anhydride powder by heating in platinum crucible in electric furnace at 1500°C for seven hours. Chemical compositions, refractive indices and powder X-ray pattern are shown in Table 8 and Fig. 5.

Table 8. *Chemical compositions, specific gravity and refractive indices of synthesized* Ba_2SiO_4

Synthesized sample	Ig. loss	SiO_2	BaO	Total	Free BaO	Specific gravity (g/cm³)	Refractive index (20°C)
Ba_2SiO_4	0.29	17.25	82.19	99.73	0.05	5.427	n = 1.80 n = 1.80 n = 1.826

Powder X-ray diffraction peaks of barium orthosilicate were indexed by using the H. O'Daniel and L. Tscheischwilli's (9) approximate cell constants. Then precise cell constants were determined from previously obtained (hk*l*) and the precise peak position by the aid of least square method. The lattice constants obtained by these procedures were $a = 5.772$ Å, $b = 10.225$ Å, $c = 7.513$ Å. The extinctions of (0k*l*) with $k + l = 2n + l$, (hk0) with $h = 2n + l$ and (h00) (0k0) (00*l*) with h, k, $l = 2n + l$ lead to the determined space group D_{2h}^{16}–Pmcn.

Atomic Coordinate

From the above-mentioned space group, presumed structure was built up on the assumption that eight barium atoms were placed in position (4c), four silicon atoms and eight oxygen atoms in (4c) and the other eight oxygen atoms in (8d) to form the exact tetrahedron of SiO_4 keeping 1.61 Å of Si–O distance. Diffracted X-ray intensities were calculated for each of barium atom with systematically variable positional parameters of 81 cases for range of 6.37% of b value along b-axis and 6.06% of c value along c-axis. While x coordinate was fixed on the mirror plane. The atomic coordinates in the first approximation obtained in comparison with calculated and observed diffracted X-ray intensities are shown in

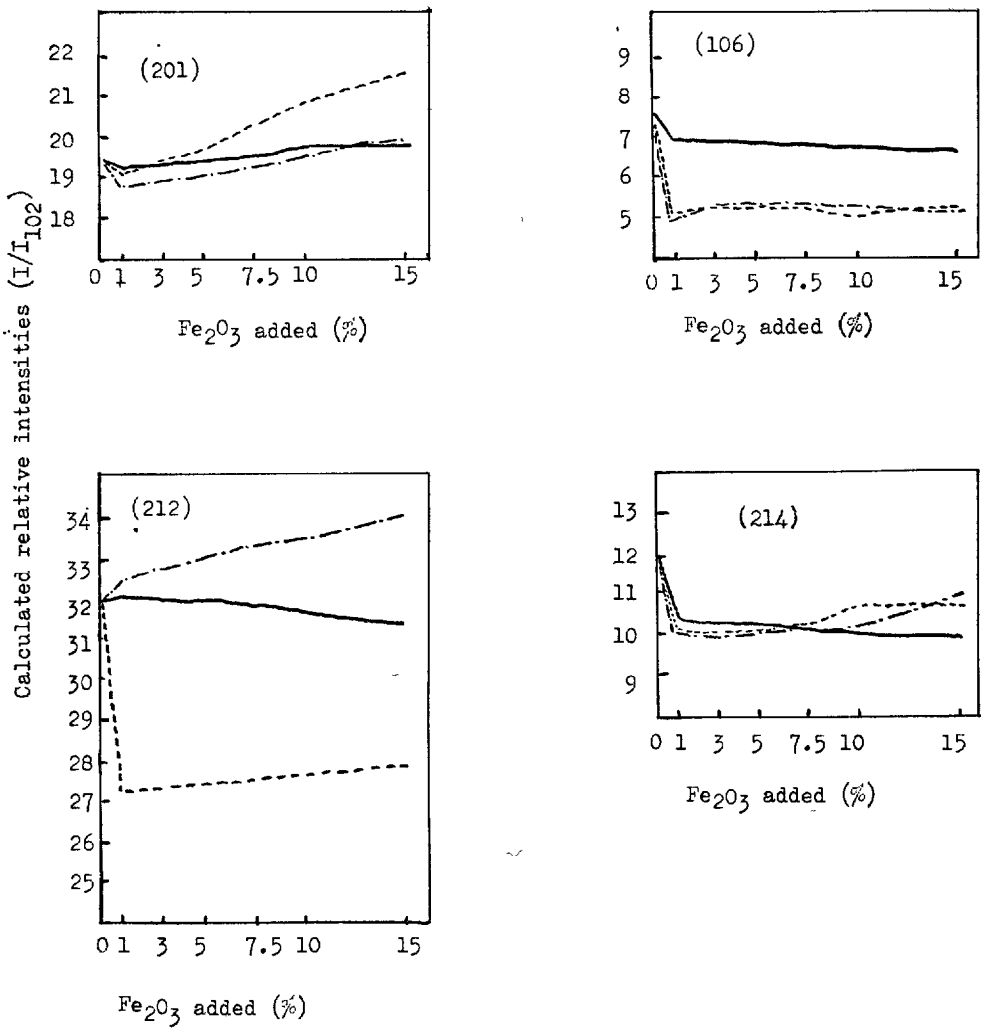

Fig. 4. *Relation between the calculated relative intensities and the quantity of added* Fe_2O_3

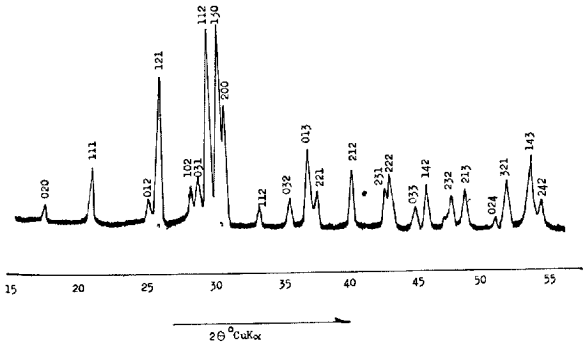

Fig. 5. *Powder X-ray diffraction pattern of synthesized* Ba_2SiO_4

Table 9. Obtained R value in this case was 0.249.

The same procedure was applied to the determination of silicon and oxygen atomic coordinates to attain

Table 9. *Atomic coordinates of* Ba_2SiO_4 *obtained by the first approximation*

	Atomic coordinate					
Parameter	Ba_1	Ba_2	Si	O_1	O_2	O_3
x	0.2500	0.2500	0.2500	0.2500	0.2500	0.0410
y	0.0761	0.7046	0.4155	0.4032	0.5579	0.3482
z	0.1768	−0.0123	0.2358	0.0315	0.2970	0.2997

the more accurate results. The range of variation of the positional parameter is ±2.90% of *b* value along *y* direction, ±2.66% of *c* value along *z* direction and *x* coordinate was fixed on mirror plane. For the oxygen atoms, range of the variation of positional parameter is the same as Si atom except for 1.64% of a value along *x* coordinate. From this, the final refined

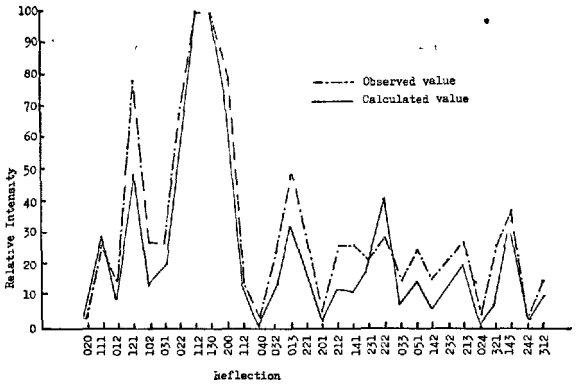

Fig. 6. *Comparison of the observed and the calculated intensities using the atomic coordinates shown in Table 10*

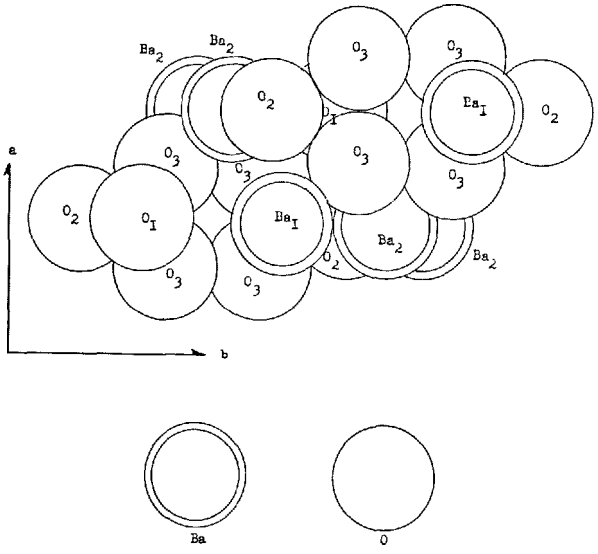

Fig. 7. *Packing of atoms in the* Ba_2SiO_4 *structure with their ionic sizes*

atomic coordinates for Ba_2SiO_4 are obtained as shown in Table 10. Calculated F value and the comparison with observed diffracted X-ray intensities are shown in Fig. 6.

Reliability calculated from thirty peaks was 0.171, which is better than the *R* value of 0.249 in first approximation. Interatomic distances in Ba_2SiO_4 structure are listed in Table 11.

Crystal Structure

Packing diagram of Ba_2SiO_4 illustrated by the sphere with their ionic radius is given in Fig. 7. In Fig. 8. are shown ab, bc projection of Ba_2SiO_4 structure about barium atom and SiO_4 group. Ba_1, Ba_2, Si, O_1 and O_2 atom are situated on the mirror plane perpendicular to *a*-axis and SiO_4 forms distorted tetrahedron having 1.60 Å, 1.67 Å and 1.61 Å intera-

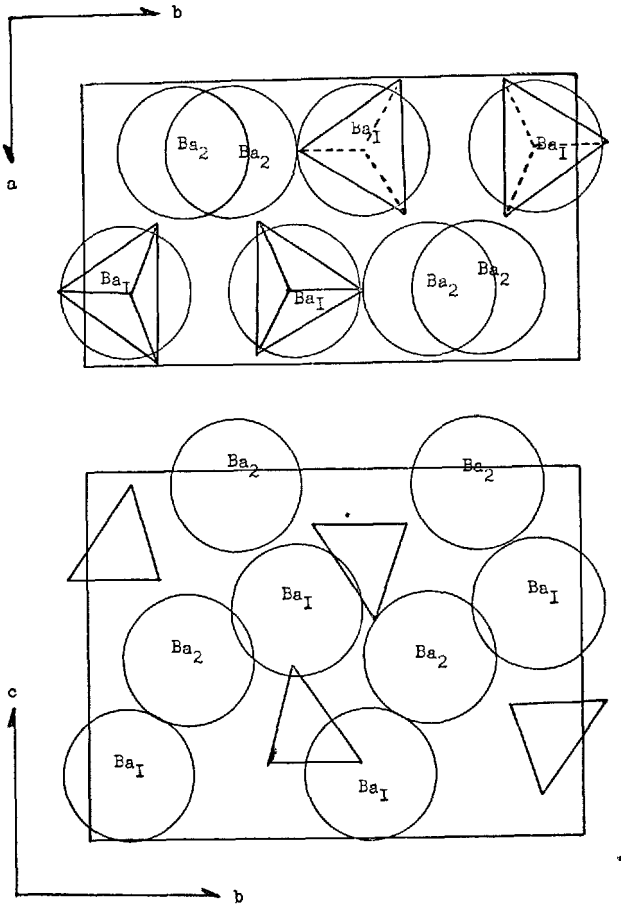

Fig. 8. ab, bc-*projection of the* Ba_2SiO_4 *structure*

Table 10. *Determined atomic coordinates of* Ba_2SiO_4

z	0.1768	−0.0123	0.2624	0.0488	0.3236	0.3523

Table 11. *Interatomic distances*

Atom	Distance (Å)
Ba_1—O_1	2.79
Ba_1—O_2	3.22
Ba_1—O_3	2.79
Ba_2—O_1	2.82
Ba_2—O_2	2.74
Ba_2—O_3	2.76
Si—O_1	1.61
Si—O_2	1.69
Si—O_3	1.60
O_1—O_2	2.70
O_1—O_3	2.67
O_2—O_3	2.68

tomic distances of Si–O_1, Si–O_2 and Si–O_3. As O_2 atom is influenced by the neighbouring Ba_2, Si–O_2 distance is somewhat larger than in the exact SiO_4 tetrahedron. Resonanced structure of double and single bond of Si–O is suggested from the value 1.77 Å observed in the single covalent bond. Average interatomic distance of Ba and O was 2.87 Å which indicate the ionic bonding of Ba–O in Ba_2SiO_4.

Hydration of Barium Aluminate and Barium Orthosilicate

Stoichiometry of the Hydration of Barium Aluminate and Barium Orthosilicate

Precedent Work

Al. Braniski (1) reported the equation on the hydration of $BaAl_2O_4$ and Ba_2SiO_4 but no detailed explanation for the derivation of the equation has yet been attempted.

Stoichiometry of the Hydration

One of the produced barium aluminate hydrate and barium orthosilicate are $BaAl_2O_4 \cdot 6.5H_2O$ and $BaSiO_3 \cdot 6H_2O$ mentioned later. In the hydration of $BaAl_2O_4$ initially liberated $Ba(OH)_2 \cdot H_2O$ was consumed in the process of hydration as shown in Fig. 9. On the contrary, $Ba(OH)_2 \cdot H_2O$ was recognized in the later stage of hydration in Ba_2SiO_4 by powder X-ray diffraction of hydrated specimen. Electronmicroscopic observation of the sample obtained from the early stage of hydration of $BaAl_2O_4$ indicates the gel hydrate of $Al(OH)_3$. In the early stage of hydration of Ba_2SiO_4, thin plate of $BaSiO_3 \cdot 6H_2O$ and spindle shaped $Ba_2SiO_4 \cdot nH_2O$ were observed, but the latter disappeared with the passage of time (Fig. 11, Photo 4 and 5). From these experimental results we supposed the stoichiometry of the hydration of $BaAl_2O_4$ and Ba_2SiO_4 as follows:

$BaAl_2O_4$

$$2BaAl_2O_4 + 11.5H_2O = BaAl_2O_4 \cdot 6.5H_2O + Ba(OH)_2 \cdot H_2O + 2Al(OH)_3 \quad \text{(initial reaction)}$$

$$BaAl_2O_4 + Ba(OH)_2 \cdot H_2O + 7H_2O = Ba_2Al_2O_5 \cdot 9H_2O \quad \text{(successive reaction)}$$

$$3BaAl_2O_4 + 18.5H_2O = BaAl_2O_4 \cdot 6.5H_2O + Ba_2Al_2O_5 \cdot 9H_2O + 2Al(OH)_3 \quad \text{(reaction as a whole)}$$

Ba_2SiO_4

$$Ba_2SiO_4 + nH_2O = Ba_2SiO_4 \cdot nH_2O \quad \text{(reaction at early stage)}$$

$$Ba_2SiO_4 \cdot nH_2O + (8-n)H_2O = BaSiO_3 \cdot 6H_2O + Ba(OH)_2 \cdot H_2O \quad \text{(reaction at later stage)}$$

$$2Ba_2SiO_4 + 8H_2O = BaSiO_3 \cdot 6H_2O + Ba(OH)_2 \cdot H_2O \quad \text{(reaction as a whole)}$$

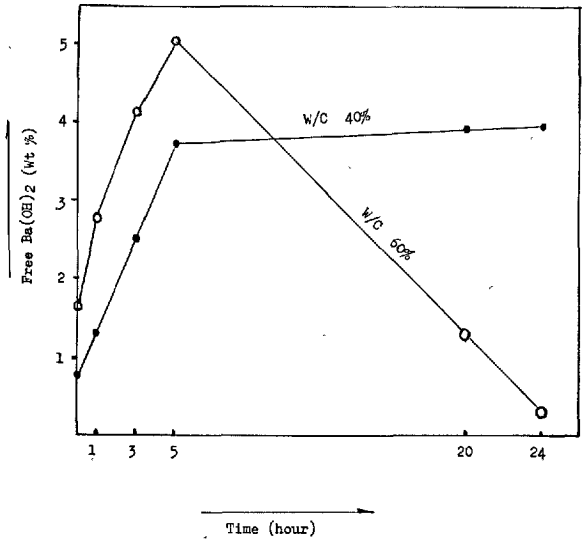

Fig. 9. *Change of produced barium hydroxide in the hydration of* $BaAl_2O_4$

Equilibrium Relationships of Liquid Phase in the Initial Stage of Hydration

The process of the dissolution of unhydrated compounds was followed by the chemical analysis of liquid phase separated from hydrated specimen. Relation between molar concentration of each ion in aqueous solution and time of hydration are summarized in Fig. 10 (13).

Composition of Liquid Phase in the Hydration of $BaAl_2O_4$

Stepwise change in the composition was recognized as in Fig. 10. Increase in concentration in the first step corresponds to initial hydration which contains the absorption of water to the surface of unhydrated particles, the diffusion of water into unhydrated particles, the formation of thin rectangular and gel-like hydrate.

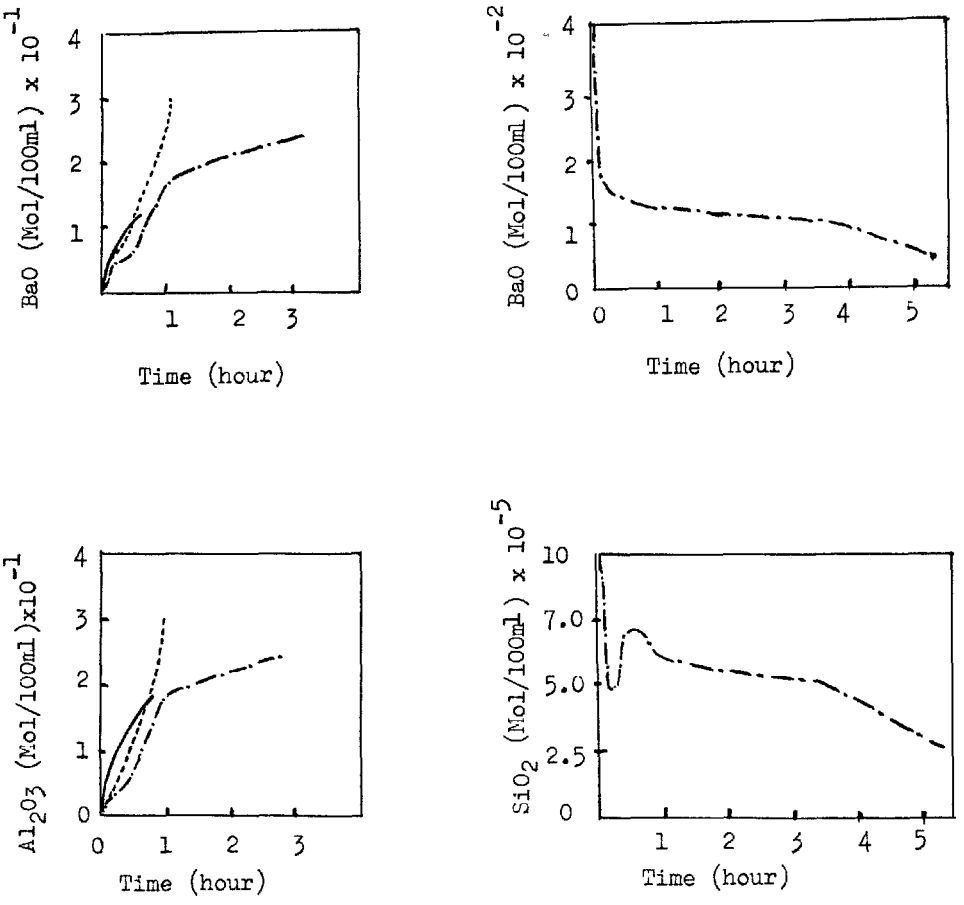

Fig. 10. *The compositions of liquid phase in the early stage of hydration of* $BaAl_2O_4$ *and* Ba_2SiO_4

In this period the vivid dissolution of unhydrate is predominant over the crystallization of hydrate, so the concentration of barium and aluminum ion increases until equilibrium is completed. The second step has to do with the successive reaction mentioned before. High ion concentration in low content of water is considered to be caused by the high super satulation concentration in equilibrium state. As little liberated $Ba(OH)_2 \cdot H_2O$ is recognized, when monoclinic hydrate is produced, from the equimolecular relation between BaO and Al_2O_3 in liquid phase, it comes to a conclusion that the rectangular barium aluminate hydrate is equimolecular compound.

Composition of Liquid Phase in the Hydration of Ba_2SiO_4

As the hardening of Ba_2SiO_4 is quick, the separation of liquid phase was very difficult without addition of large quantity of water. Barium ion concentration showed monotonous decreasing while silicon ion showed maximum value at thirty minutes after mixing with water, but its absolute value was very small in comparison with barium ion.

Hydraulic Properties of $BaAl_2O_4$

Electronmicroscopic Observation

Electronmicrographs of hydrated barium aluminate in W/C = 0.6 at room temperature are shown in Fig. 11 (14). At thirty minutes after mixing, thin plate like crystal of $BaAl_2O_4 \cdot 6.5H_2O$ and groups of minute granular substance of $Al(OH)_3$ were produced among the unhydrated particles. Besides these substances, spherical hydrates of $Ba(OH)_2 \cdot H_2O$ were recognized (Fig. 11, Photo 1). At one hour after mixing, plate like hydrates gradually widened into rectangular plate and spheric hydrate disappeared (Fig. 11, Photo 2). After five hours of hydration rectangular crystal increased the thickness and irregular polyhedral hydrate which was considered to be $Ba_2Al_2O_5 \cdot 9H_2O$ from the hexagonal pattern of electron diffraction was appeared (Fig. 11, Photo 3a, b).

Degree of Hydration

Degree of hydration of $BaAl_2O_4$ calculated from the ignition loss, free $Ba(OH)_2$ and unhydrated $BaAl_2O_4$ measured by quantitative X-ray diffraction analysis are shown in Fig. 12 (14). The larger the water content, the higher was the rate of hydration of $BaAl_2O_4$. One of the reason for this is supposed to be the higher

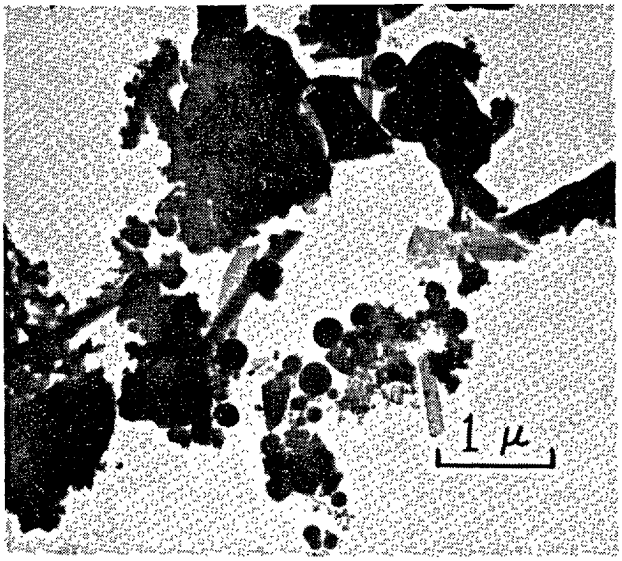

Photo 1. *W/C = 0.6, 30 minutes after mixing* ($BaAl_2O_4$)

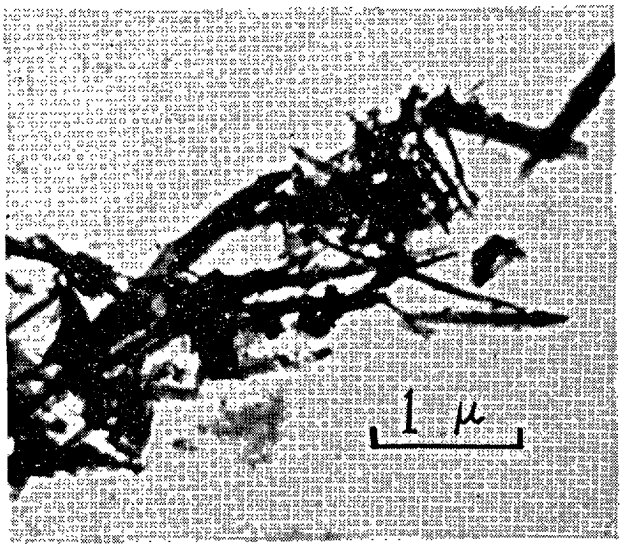

Photo 2. *W/C = 0.6, 1 hour after mixing* ($BaAl_2O_4$)

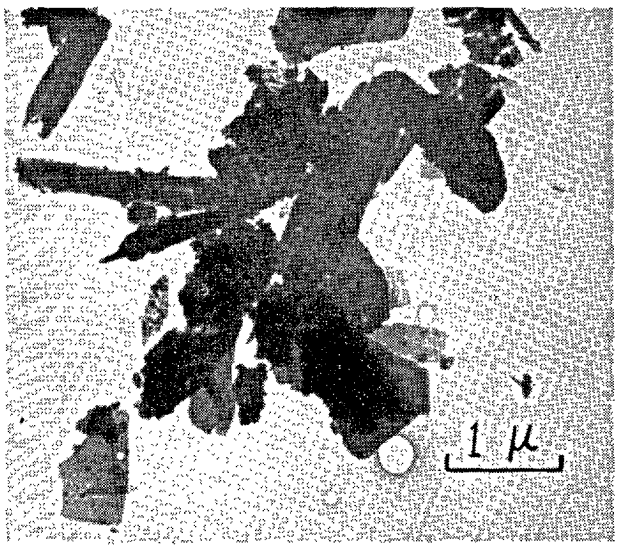

Photo 3a. *W/C = 0.6, 5 hours after mixing* ($BaAl_2O_4$)

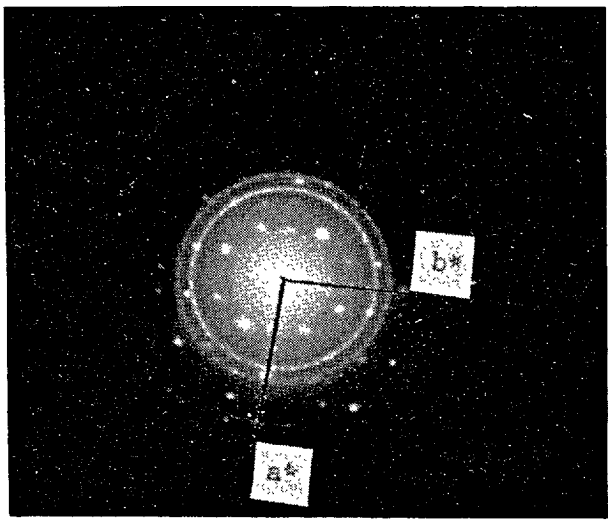

Photo 3b. *W/C = 0.6, 5 hours after mixing; Electron diffraction pattern* ($BaAl_2O_4$)

(Fig. 11.)

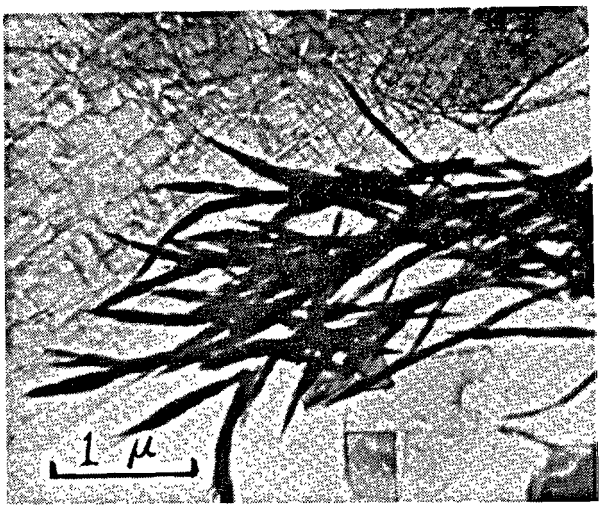

Photo 4. *W/C = 2.0, 15 minutes after mixing* (Ba_2SiO_4)

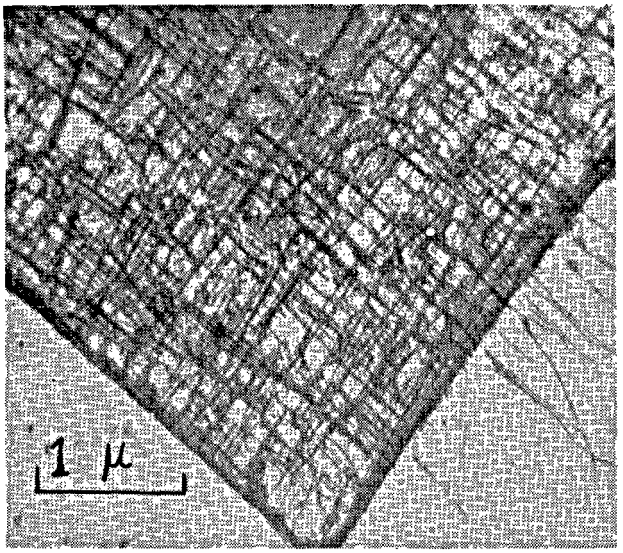

Photo 5. *W/C = 2.0, 1 hour after mixing* (Ba_2SiO_4)

Fig. 11. *Electronmicrographs of hydrated* $BaAl_2O_4$ *and* Ba_2SiO_4

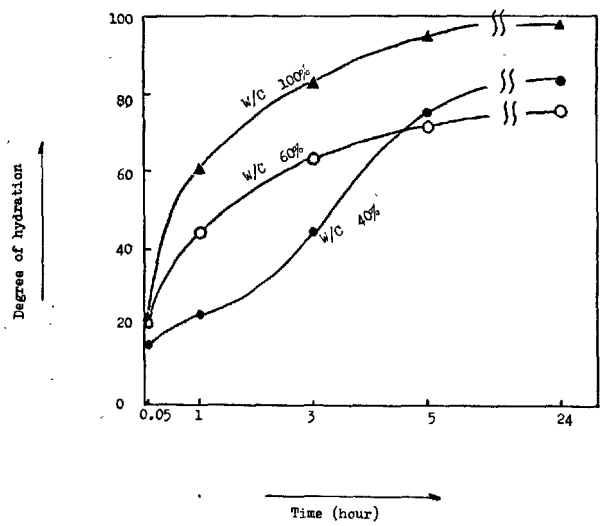

Fig. 12. *Degree of hydration of* $BaAl_2O_4$ *measured by means of X-ray diffraction*

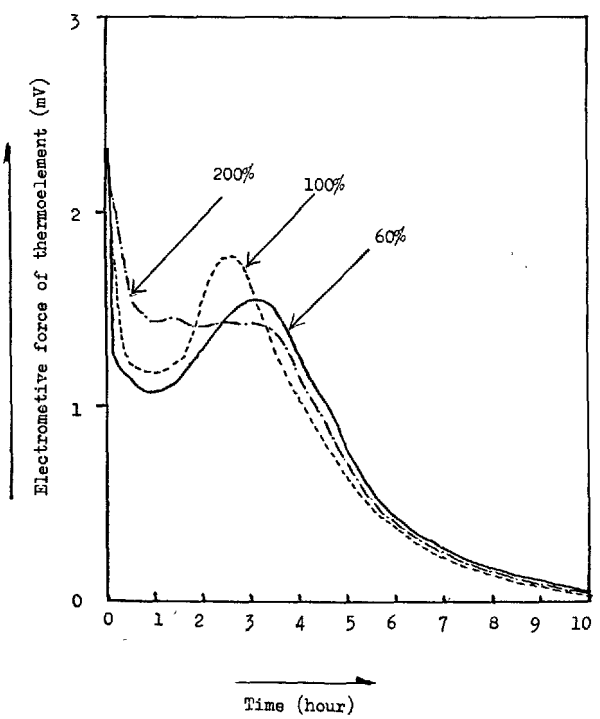

Fig. 13. *Liberated heat in the hydration of* $BaAl_2O_4$ *measured by conduction calorimeter*

rate of dissolution of $BaAl_2O_4$ caused by the large gradient of concentration between the liquid and the margin of $BaAl_2O_4$. The other is low rate of deposition of hydrate on account of the smaller degree of liquid saturation, which helps the development of crystal and deposition of hydrates apart from unhydrated $BaAl_2O_4$. The third is the formation of skeleton structure even if the hydrate deposits around the unhydrated particles. The period of the appearance of these hydrates is variable owing to the difference of the activity of synthesized $BaAl_2O_4$ and of other conditions such as fineness, water content, temperature.

Rate of Liberation of Heat in the Early Stage of Hydration

The rate of heat liberation in the early stage of hy-

dration of $BaAl_2O_4$ was measured by conduction calorimeter. Heat distribution curves consist of three divisions as shown in Fig. 13 (15). The first peak immediately after mixing with water is considered to be caused by the rapid hydration of directly contacted active $BaAl_2O_4$. The formation of porous film of hydrates on the surface of $BaAl_2O_4$ particles is responsible to the successive flat division appeared two hours after mixing, but this is different essentially from the dormant period recognized in the hydration of portland cement owing to higher electromotive force of some ten times than in the case of portland cement. The final peak at later than three hours is supposed to occur from the partial destruction of hydrates film caused by the formation of different hydrate such as $Ba_2Al_2O_5 \cdot 9H_2O$ by the consumption of $Ba(OH)_2 \cdot H_2O$. The sum of the liberated heat within one day was about 80–90% of the heat of hydration measured by the specimen cured for six months.

Table 12. *Heat of hydration calculated from heat of solution*

Water (%)	Heat of hydration (cal/g)			
	1 day	3 days	7 days	6 months
40	69.2	72.8	75.8	80.4
60	72.3	76.3	78.6	

Heat of Hydration

Heat of hydration of $BaAl_2O_4$ in various curing period calculated from the heat of solution to mixed strong acid of 4N–HNO_3 and hydrofluoric acid is listed in Table 12.

From Table 12 heat of complete hydration is considered to be about 80 cal/g. In some case of larger water content than 60%, reduction of the heat of hydration observed in longer period of curing. This may probably suggest the transformation to another stable phase.

Crystal Structure of Barium Hydroxide, Barium Aluminate Hydrate and Barium Silicate Hydrate

Crystal Structure of Barium Hydroxide Monohydrate ($Ba(OH)_2 \cdot H_2O$)

Precedent Work

The coordination polyhedra of hydrated barium compounds such as $Ba(OH)_2 \cdot 8H_2O$ and $Ba(ClO_4) \cdot 3H_2O$ were reported that barium atom is coordinated by eight water oxygens in the former, while in the latter coordinated by twelve oxygen (16). No investigation, however, was intended to analyse the crystal structure of barium hydroxide monohydrate.

Determination of Lattice Constants and Other Crystallographic Data

Sample to be analysed was obtained from the hydrated Ba_2SiO_4 specimen for six months which contained about 50% of $Ba(OH)_2 \cdot H_2O$. Considering the strong resemblance of powder X-ray diffraction pattern and the ionic radius of metallic ion to $Sr(OH)_2 \cdot H_2O$ and $Eu(OH)_2 \cdot H_2O$ (17), isostructure was presumed on the $Ba(OH)_2 \cdot H_2O$. Approximate lattice constants of a and b were obtained from (hk0) reflection taken by the electron diffraction of $Ba(OH)_2 \cdot H_2O$ single crystal. Precise lattice constants were determined as $a = 6.99$ Å, $b = 6.33$ Å and $c = 3.92$ Å from the dissolution of the least square equation using the (hk$l$) indexed on the $Sr(OH)_2 \cdot H_2O$. The systematic extinction in (h0l) and (h00) reflection with h odd indicates the same space group of $Sr(OH)_2 \cdot H_2O$ as C_{2v}^2–$P2_1am$. The number of molecule in the unit cell is four and the calculated density is 4.589 g/cm³.

Atomic Coordinates

The unit cell of $Ba(OH)_2 \cdot H_2O$ contains two barium atom, two water and four hydroxyl oxygen. All of them situated in special position from the space group symmetry. In the calculation of diffracted X-ray intensities positional parameter of barium atom was fixed in the same position of strontium as in $Sr(OH)_2 \cdot H_2O$, but the positional parameter of oxygen atoms was fixed only z direction and variable ± 0.349 Å (correspond to $\pm 5\%$ for x coordinate) for O_2 and O_3 along x direction and 0.317 Å (correspond to $\pm 5\%$ for y coordinate) for O_1 and O_3 along y direction. Suitable atomic coordinates were decided to the best R value obtained from abovementioned combinations of positional parameter as shown in Table 13. Calculated intensities in this case are shown

Table 13. *Determined atomic coordinates of* $Ba(OH)_2 \cdot H_2O$

	x	y	z

in Table 14 and interatomic distance are listed in Table 15.

Crystal Structure

The packing diagram of $Ba(OH)_2 \cdot H_2O$ structure projected on a plane perpendicular to *c*- and *b*-axis is shown in Fig. 14. The barium and oxygen atoms exist in the layer at zero level and hydroxyl oxygens are situated at about 1/2 level along *c*-axis. Barium atoms between hydroxyl oxygen layers are coordinated by six hydroxyl oxygens and form a distorted octahedron as shown in Ba–O distance from 2.61 Å to 2.94 Å. It is interesting to compare the barium atoms in barium hydroxide octahydrate coordinated by water oxygen molecules.

Crystal Structure of Barium Aluminate Hydrate ($BaAl_2O_4 \cdot 6.5H_2O$)

Precedent Work

Some kinds of barium aluminate precipitated from barium and aluminum hydroxide aqueous solution were first identified by E. T. Carlson and L. S. Wells (18) with X-ray and chemical analysis. Since then many studies have been reported on the optical, physical properties, X-ray diffraction data, but crystal structure of barium aluminate hydrates has not been determined.

Determination of Lattice Constants and Other Crystallographic Data

Sample was prepared by the hydration of $BaAl_2O_4$ at W/C = 0.6 at room temperature. The barium aluminate hydrates produced at the early stage of hydration of $BaAl_2O_4$ were a mixture of two kinds of hydrates and aluminum hydroxide, but latter hydration they changes into a kind of hydrate in the laterstage of hydration which has the composition of $BaO \cdot Al_2O_3 \cdot 6.5H_2O$ as shown in Table 16.

From the electron diffraction pattern of a single crystal of $BaO \cdot Al_2O_3 \cdot 6.5H_2O$, symmetry elements were deduced to be twofold or twofold screw axis parallel to *c*-axis and a mirror plane on the *a-b* face. Approximate lattice constants were $a = 8.5$ Å $b = 7.0$ Å and $\gamma = 92°55'$. Unit cell dimension along *c*-axis was determined as about 16.7 Å from the powder X-ray diffraction data and observed density (2.519 g/cm³). Space group of this hydrate is assumed to be C_{2h}^2–$P2_1/m$ since the (00*l*) reflections are systematically absent with *l* odd. More precise lattice constants were obtained from a least squares fit of 23 lines of powder X-ray diffraction. That is $a = 8.523$ Å $b = 6.939$ Å, $c = 16.667$ Å and $\gamma = 92°55'$. Numbers of the molecules contained in unit cell were determined as four from the lattice constants and observed density.

Atomic Coordinate

A detailed study of the crystal structure was difficult because of small numbers of reflections, so we calculate the electron density by means of one dimensional Patterson function along *c*-axis using (00*l*) reflection intensities. From this we assumed the approximate positional parameters of barium and oxygen along *z* direction. One dimensional Patterson synthesis was also performed in consideration of the coordinate of all atoms in this structure. As shown in Fig. 15, the electron density distribution represents a centrosymmetric structure and two barium atoms are situated at each levels of 0 and 0.5, five oxygen atoms at 0.125, 0.250, 0.375, 0.625, 0.750 and 0.875, respectively. Aluminum atoms are situated two by two at the neighbouring oxygen positions and are coordinated by oxygen atoms. The other oxygen atoms must be distributed according to space group C_{2h}^2–$P2_1/m$. The calculated (00*l*) reflection intensities using above-mentioned positional parameters showed comparatively good coincidence with observed one, so that above-mentioned parameters are able to be adopted as approximate atomic coordinates along *z* direction. The atomic arrangement along *b*-axis was introduced from comparative resemblance of *a*-direction in $Ba(OH)_2 \cdot H_2O$ and the packing of three oxygen atoms was thought to be positioned along *a*-axis.

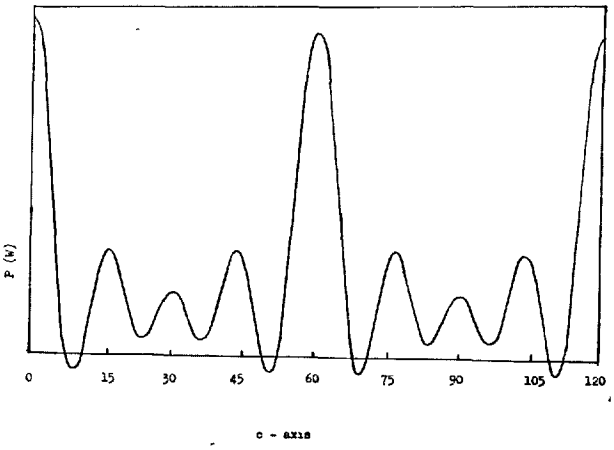

Fig. 15. *Electron density distribution curve of* $BaAl_2O_4 \cdot 6.5H_2O$ *along c-axis calculated from Patterson function*

Possible atomic positions derived from Fourier synthesis along *z* direction and previous mentioned structure on ab-plane was then refined by trial and error method considering much contribution of heavy barium atom on the diffracted X-ray intensities. In this calculation barium atom positional parameters are variable in the range of ± 0.04 considering the framework of $Ba(OH)_2 \cdot H_2O$ in the structure. The most suitable atomic coordinates in many calculation and interatomic distances are given in Table 17 and Table 18. *R* value obtained in this case was 0.147 as shown in Table 19.

Crystal Structure

Fig. 16 shows the projection of the assymmetric unit on (00*l*). Each barium atom is coordinated by six oxygen atoms which form a framework of barium hydroxide monohydrate, so average Ba–O distance of 2.84 Å is almost equal to the value in $Ba(OH)_2 \cdot H_2O$. Other two oxygen atoms neighbouring the barium atom on the zero level along *c*-axis may belong to water molecules because they exist apart from other six oxygen atoms. The apex oxygen atom of AlO_4 tetrahedron in special position is bounded to both of two AlO_4 tetrahedra like as in $BaAl_2O_4$. The basal three oxygens of these tetrahedra link to oxygen atom surrounding the barium atoms keeping the interatomic distance from 1.72 Å to 1.78 Å. Three kinds of another oxygen atom in general position are not contact with barium or aluminum

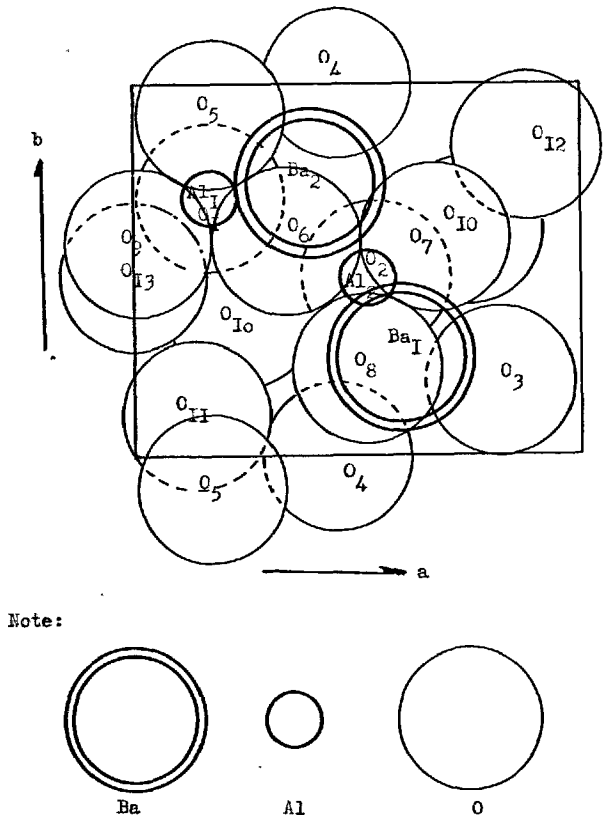

Fig. 16. *Packing diagram of* $BaAl_2O_4 \cdot 6.5H_2O$

atom but it occupies a possible situation in the vacancy of oxygen packing. $BaAl_2O_4 \cdot 6.5H_2O$ is built up from the framework of $Ba(OH)_2 \cdot H_2O$ and the linkage of two AlO_4 tetrahedra extending along *c*-axis. The existence of a set of AlO_4 tetrahedra sharing the apex oxygen atom is observed in unhydrated $BaAl_2O_4$ which is considered to be one of the reasons why $BaAl_2O_4$ paste has high refractoriness.

Crystal Structure of Barium Silicate Hydrate ($BaSiO_3 \cdot 6H_2O$)

Precedent Work

$BaSiO_3 \cdot 6H_2O$ was recently studied by E. Höhen and K. Dornbergen-Schift (19) who determined the crystal structure by means of two and three dimensional Patterson function synthesis. Barium silicate hydrate in the hydrated sample of Ba_2SiO_4, however, have not been identified clearly and their crystal structure have not been determined.

Determination of Lattice Constants and Other Crystallographic Data

Sample was prepared by the complete hydration of

Ba_2SiO_4 in 200% water suspension for a month at room temperature. The hydration products of Ba_2SiO_4 in later stage of hydration are $BaSiO_3 \cdot 6H_2O$ and $Ba(OH)_2 \cdot H_2O$ as mentioned before, so we can easily distinguish barium silicate hydrate from barium hydroxide monohydrate. The electron diffraction pattern of barium silicate hydrate single crystal showed the structural accordance with $BaSiO_3 \cdot 6H_2O$ reported by E. Höhen and K. Dornbergen-Schift (19), and approximate lattice constants were determined to be $a = 8.4$ Å and $b = 13.0$ Å. As the powder X-ray diffraction patterns is characterized by systematic decreasing in diffracted X-ray intensities keeping the constant intervals of the diffraction peaks toward high angle, these peaks are considered to correspond to (00l) reflection of the crystal. Cell dimension of c-axis was therefore decided to be about 15 Å. Using these approximate lattice constants, observed X-ray diffraction peaks were first indexed for all possible set of (hk$l$) as the lattice constants were large and less precise. Precise lattice constants were next determined by the least squares fit of twenty-six lines as $a = 8.44$ Å, $b = 13.00$ Å and $c = 15.06$ Å, space group was C_{2v}^9–$P2_1cn$ and the extinction was for (hk0) with $h + k = 2n$, for (hk0) with $h + k = 2h$ for (h0l) with $l = 2n$, for (h00), (0k0) and (00l) with $h = 2n$, $k = 2n$, $l = 2n$, respectively. The numbers of molecules in unit cell were eight and calculated density was 2.603 g/cm³.

Atomic Coordinate

The diffracted X-ray intensities were calculated for the range that the changes of the positional parameters of barium atom were ±0.337 Å (correspond to ±0.04 for x coordinate) along x direction and ±0.518 Å (correspond to ±0.05 for y coordinate) along y direction under the condition that barium atom is bound to oxygen atom by ionic bonds. In this calculation the positional parameters of SiO_4 tetrahedra were fixed in the Höhen and Dornbergen-Schifts (19) structure because of less contribution to the structure factor compared with barium atoms. From the condition that (002) reflection must be the strongest intenstiy, the positional parameters of Ba_1 and three Ba_2 to be variable were stricted to the combination of 0.250 and 0.210 along x direction and 0.109 and 0.049 along y direction. So that the selected combinations became $2 \times 2 \times 3 \times 3$. The strongest intensity was calculated in (022), (131), (113) and (021) reflection in combinations of another parameters, so that these were eliminated. From these calculation, it was concluded that suitable atomic coordinates of Ba_1 and Ba_2 along x direction must be in the range from 0.210 to 0.250 and from 0.710 to 0.790, respectively from the restriction for Ba–O ionic distances. After the calculation on eighty-one combinations of barium positional parameters on all the possible 101 reflections, atomic coordinates of all atoms in unit cell were determined as given in Table 20. Calculated intensities in this case showed good coincidence with observed one as represented by $R = 0.124 \sim 0.159$ in Table 21. Ba–O distances calculated from deter-

Crystal Structure

Projections of the structure of $BaSiO_3 \cdot 6H_2O$ to (010) is shown in Fig. 17. Barium atoms in general position make two types of polyhedra coordinated by eight and ten oxygen atoms. SiO_4 tetrahedra lie independently in general position contacting with the oxygen atoms which form barium octa—and deca—hydrates. Two water molecules in $Ba(H_2O)_{10}$ coordinate polyhedra are not shared two barium atom, that is, exist in free water. It is very interesting to note that $BaSiO_3 \cdot 6H_2O$ consists of positionally unstable barium atoms which can remove in the limited range without influence on the diffracted X-ray intensities. The differences in barium atomic coordinates and

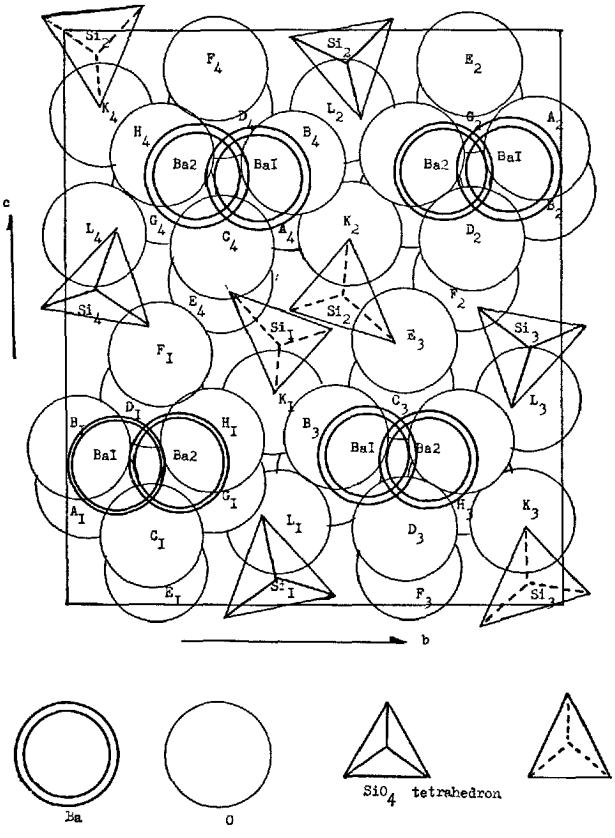

Fig. 17. *Packing diagram of* $BaSiO_3 \cdot 6H_2O$

interatomic distances in the authors and previous research (19) have probably been caused by the difference of the source of sample and consequently by the difference of condition and process of crystalization. The mean Ba–O distance in both of polyhedron coordinated by eight and ten oxygens, however, are 2.94 Å and 2.95 Å, which is good coincidence with precedent work (19).

Physical and Crystal Chemical Properties of the Produced Hydrates

Physical Properties of Barium Aluminate Hydrate

Specific Surface Area of Hydrated Barium Aluminate

The specific surface area of $BaAl_2O_4 \cdot 6.5H_2O$ and $BaAl_2O_4 \cdot 4H_2O$ produced in lower water sample ratio were measured with BET method by N_2 gas adsorption. Period of hydration of samples are both three months. Obtained values were 2 m^2/g for $BaAl_2O_4 \cdot 6.5H_2O$ and 6.0 m^2/g for $BaAl_2O_4 \cdot 4H_2O$ (14) which indicate the existence of these hydrates in complete crystalline state.

Mechanical Strength of Hydrated Barium Aluminate

The compressive and bending strength of hydrated barium aluminate by using the mortar specimen is shown in Fig. 18 (17). When the amount of hydration water is small, the mechanical strength of $BaAl_2O_4$ mortar is high. Therefore, it seems that the theory of the water cement ratio for portland cement may also be applied in this case, but the mechanism of the development of strength is quite different from the

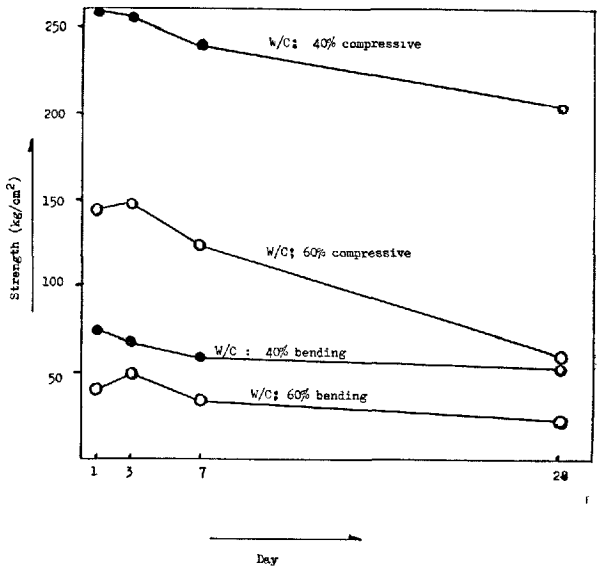

Fig. 18. *Compressive and bending strength of barium aluminate mortar* ($BaAl_2O_4$: Sand = 1 : 2)

mortar specimen cured in wet air for four weeks by the powder X-ray diffraction which may probably be one of the reason for the decrease in strength with age.

Properties of Hydrated Barium Aluminate at Elevated Temperature

Structural Change of Hydrate in Heating

Differential thermal analysis, thermogravimetry and powder X-ray diffraction at high temperature was done to pursue the dehydration and structural change of hydrate in heating (15). Results are represented in Fig. 19 and Fig. 20. A greater part of the combined water dehydrated under 350°C leaving one molecule of water, but the remarkable difference in dehydration process was observed between the sample hydrated with 40% of water and others. This was probably due to the difference of originally existed hydrate. Amorphous and illcrystalized phase was clearly observed at 100 to 300°C in the specimen

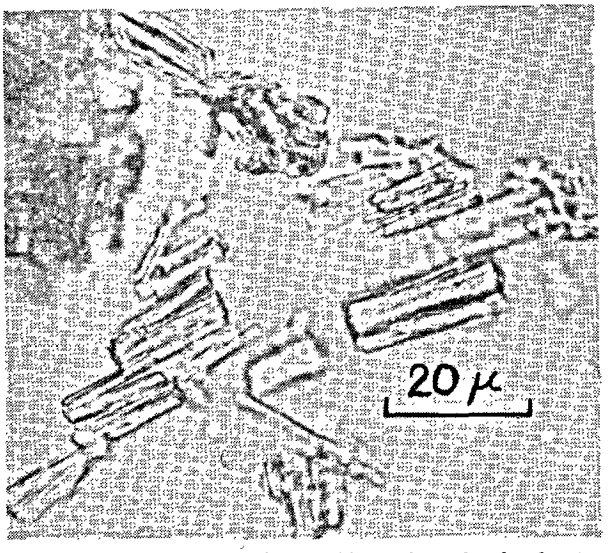

Fig. 21. *Opticalmicrograph of* $BaAl_2O_4 \cdot 6.5H_2O$ *after heating at 300°C*

hydrated over 60% of water which indicate the destruction of original crystal structure and the rearrangement of atoms. As the crystal correspond to the amorphous state keeps the external form of original hydrate as shown in Fig. 21, it is reconfirmed that the set of two AlO_4 tetrahedra shared the apex oxygen remained as they are through all period of heating. This may be one of the reason why limited decrease in the mechanical strength at elevated temperature.

Phase Relation in Heating

Phase relation of hydrated barium aluminate in heating is summerized in Fig. 22. Converted phase appeared above 200°C was agreed with the cubic hydrate of $BaAl_2O_4 \cdot H_2O$ reported by E. T. Carlson, T. J. Chaconas and L. S. Wells (18).

Mechanical Strength

Mechanical strength of mortar specimen at various elevated temperature is shown in Fig. 23. When the water cement ratio is low such as 0.4, unstable hydrate (probably be $BaAl_2O_4 \cdot 4H_2O$) is tend to be formed, which shows the favorable influence on the development of the mechanical strength. Compressive strength is first increase by the drying of the specimen and then decreased according to the temperature. The degree of decrease in strength, however, is fairly small compared with calcium aluminous cement as well as portland cement. Remarkable increase above about 700°C is caused by the formation of $BaAl_2O_4$, which contributes the favorable effects on the utilization of

barium aluminous cement.

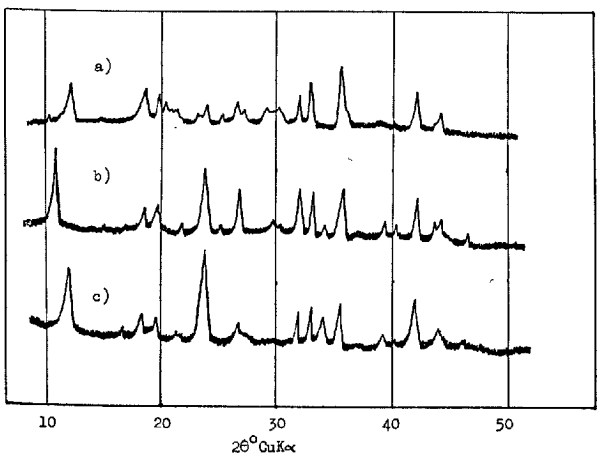
Effect of the Atomosphere on the Structure of Hydrates (20)

Method of Experiment

Completely hydrated sample prepared by the bottle hydration for twenty-eight days at room temperature with 500% of water is dried under 1 mmHg and then mounted on the sample holder of X-ray diffractometer which is specially designed for the control of humidity and atmosphere. The optical system of the diffractometer including the sample mount was filled with desired gas with selected humidity which was attained by the passage of the gas through aqueous solution of suitable salts. The powder X-ray diffraction patterns of samples under various conditions were recorded by this method.

Effect of Humidity

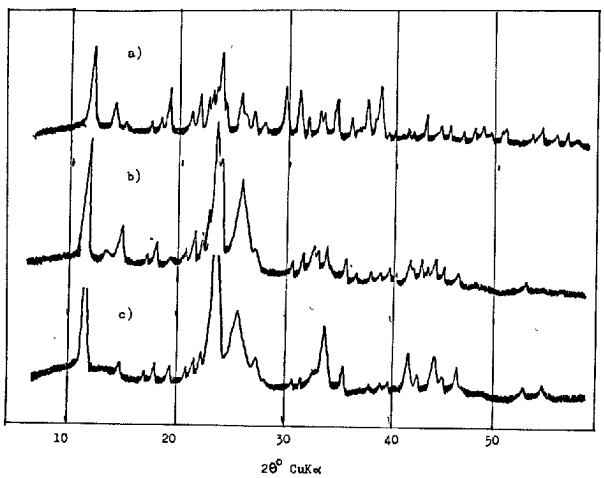
Fig. 24 shows the change of X-ray diffraction patterns of hydrated barium aluminate exposed in dry and wet nitrogen gas after being dried under 1 mmHg. The third chart of X-ray diffraction are that of the sample redried by the exposure of dried nitrogen gas. The interplaner spacing of the barium aluminate hydrate ($BaAl_2O_4 \cdot 6.5H_2O$) represented by the diffraction profiles in 2θ CuK$\alpha = 11 \sim 12°$ shows the reversible change in accordance with the variation of humidity. These experimental facts lead us to the conclusion that the structure of $BaAl_2O_4 \cdot 6.5H_2O$ contains barium hydroxide monohydrate layer and water molecules stacked along *c*-axis which is able to remove without destruction of crystal structure.



Note: a) Saturated with dry nitrogen gas
b) Saturated with wet nitrogen gas (R.H = 100%)
c) Resaturated with dry nitrogen gas

Fig. 24. *X-ray diffraction patterns of hydrated barium aluminate exposed in various humidity after dried under 1 mm Hg.*

Results on the hydrated barium silicate obtained under same experimental conditions are illustrated in Fig. 25. Crystal structure of $BaSiO_3 \cdot 6H_2O$ and $Ba(OH)_2 \cdot H_2O$ showed no essential change by the mere repetition of dry and wet cycle. This is easily deduced from the crystal structure of $BaSiO_3 \cdot 6H_2O$ that SiO_4 (probably $Si(OH)_4$) tetrahedra arranged along *a*-axis contacted fairly tight to water molecule neighbouring barium atom. But unfortunately small amount of carbon dioxide mixed into the sample space, carbonation of $Ba(OH)_2 \cdot H_2O$ occurred as shown in Fig. 25 (a) and (b).



Note: a) Saturated with dry nitrogen gas
b) Saturated with wet nitrogen gas (R.H. = 100%)
c) Resaturated with dry nitrogen gas

Fig. 25. *X-ray diffraction patterns of hydrated barium silicate exposed in various humidity after dried under 1 mm Hg.*

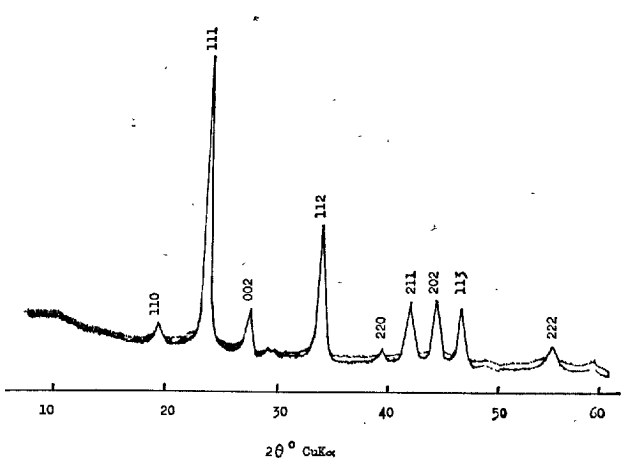


Fig. 26. *X-ray diffraction pattern of hydrated barium silicate exposed in wet carbon dioxide after dried under 1 mm Hg.*

Effect of Carbon Dioxide

Diffraction profiles of $d = 2.56$ Å, 2.62 Å and 3.72 Å gradually appeared when hydrated barium aluminate expose for long time to wet carbon dioxide gas. The above-mentioned diffraction peaks are considered to be carbonated barium hydroxide hydrate ($l BaCO_3 \cdot mBa(OH)_2 \cdot nH_2O$). The formation of this compound is slow and small.

Hydrated barium silicate was irreversibly changed immediately by the exposure of wet carbon dioxide gas into the carbonated barium hydroxide hydrate. X-ray diffraction pattern of the hydrate is resemble to that of witherite ($BaCO_3$) as shown in Fig. 26. As SiO_4 tetrahedra exist separately without formation of both chain and network, main structure of $BaSiO_3 \cdot H_2O$ resemble to barium octahydrate. This may be one of the reasons why hydrated barium silicate is easily carbonated under high humidity.

Summary and Conclusions

Crystal structure of barium aluminate, barium silicate and their hydrated products were determined as follows:

$BaAl_2O_4$:
D_6^6–$P6_322$, hexagonal, $z = 2$, $\rho_{obs} = 4.004$ g/cm³, $a = 5.224$ Å, $b = 8.777$ Å, atomic coordinate, see Table 3.

Ba_2SiO_4:
D_{2h}^6–Pmcn, orthorhombic, $z = 4$, $\rho_{obs} = 5.427$ g/cm³, $a = 5.772$ Å, $b = 10.225$ Å, $c = 7.513$ Å, atomic coordinate, see Table 10.

$Ba(OH)_2 \cdot H_2O$:
C_{2v}^2–$P2_1am$, orthorhombic, $z = 2$, $\rho_{cal} = 4.589$ g/cm³, $a = 6.99$ Å, $b = 6.33$ Å, $c = 3.92$ Å, atomic coordinate, see Table 13.

$BaAl_2O_4 \cdot 6.5H_2O$:
C_{2h}^2–$P2_1/m$, monoclinic, $z = 4$, $\rho_{obs} = 2.519$ g/cm³, $a = 8.523$ Å, $b = 6.939$ Å, $c = 16.667$ Å, $\gamma = 92°55'$, atomic coordinate, see Table 17.

$BaSiO_3 \cdot 6H_2O$:
C_{2v}^9–$P2_1cn$, orthorhombic, $z = 8$, $\rho_{cal} = 2.603$ g/cm³, $a = 8.44$ Å, $b = 13.00$ Å, $c = 15.06$ Å, atomic coordinate, see Table 20.

Stoichiometry of the hydration of barium aluminate and barium orthosilicate with enough water was proposed as follows:

$BaAl_2O_4$:

$$2BaAl_2O_4 + 11.5H_2O = BaAl_2O_4 \cdot 6.5H_2O + Ba(OH)_2 \cdot H_2O + 2Al(OH)_3 \quad \text{(initial reaction)}$$

$$BaAl_2O_4 + Ba(OH)_2 \cdot H_2O + 7H_2O = Ba_2Al_2O_5 \cdot 9H_2O \quad \text{(successive reaction)}$$

$$3BaAl_2O_4 + 18.5H_2O = BaAl_2O_4 \cdot 6.5H_2O + Ba_2Al_2O_5 \cdot 9H_2O + 2Al(OH)_3 \quad \text{(reaction as a whole)}$$

Ba_2SiO_4:

$$Ba_2SiO_4 + nH_2O = Ba_2SiO_4 \cdot nH_2O \quad \text{(reaction at early stage)}$$

$$Ba_2SiO_4 \cdot nH_2O + (8 - n)H_2O = BaSiO_3 \cdot 6H_2O + Ba(OH)_2 \cdot H_2O \quad \text{(reaction at later stage)}$$

$$2Ba_2SiO_4 + 8H_2O = BaSiO_3 \cdot 6H_2O + Ba(OH)_2 \cdot H_2O \quad \text{(reaction as a whole)}$$

Barium aluminate hydrate changes into $BaAl_2O_4$ at a considerable low temperature through intermediate phase (probably be $BaAl_2O_4 \cdot H_2O$) without destruction of external crystal form. Completely hydrated barium aluminate shows the reversible change of interplaner spacing along c-axis in accordance with the variation of humidity. These experimental facts are able to be explained by the arrangement of AlO_4 tetrahedra and the stacking of water molecules in the structure of $BaAl_2O_4 \cdot 6.5H_2O$.

Rapid hardening and high strength development of hydrated barium silicate in wet atmosphere are considered due to the network structure of hydrogen bonding among SiO_4 (probably be $Si(OH)_4$), $Ba(H_2O)_8$ and $Ba(H_2O)_{10}$ judging from the fairly long interatomic distance of Ba–O. The property of the hydrate being easily carbonated can also be illustrated from its crystal structure.

SESSION II-3 PHASE EQUILIBRIA OF CEMENT-WATER

Principal Paper Phase Equilibria of Cement-Water

Paul Seligmann and Nathan R. Greening*

Synopsis

The solid phases at complete hydration in the cement-water system are identified as a calcium silicate hydrate gel containing appreciable quantities of alumina, sulfate, and alkalies, the low sulfate form of calcium sulfoaluminoferrite hydrate, the lowest sulfate form of calcium sulfohydroxyaluminate hydrate, an alumina-silica hydrogarnet, and calcium hydroxide. Ettringite or its iron analogue is also present in cements low in C_3A, but more often forms as a result of carbonation.

Questions still remain on the thermodynamic stability of some of the phases at ultimate hydration. Evidence is presented that indicates that afwillite and calcium sulfohydroxyaluminate hydrate may be stable at ordinary temperatures of cement hydration.

The early hydration reactions can be considered to be an essentially continuous sequence of phase equilibrium situations. The contact between cement and water immediately produces a set of reactions determined by local solution concentrations at the cement-water interfaces to produce materials such as calcium sulfoaluminate hydrates and a hydrogarnet. These local reactions are followed by a period of slow hydration in which the solution composition is relatively constant as ettringite precipitates and lime supersaturation persists. When the calcium hydroxide nucleates, a calcium silicate hydrate gel containing sulfate and a little alumina forms. Ettringite continues to form until the gypsum is depleted; the solution sulfate concentration drops. Rapid solution of the ettringite and the remaining aluminate and ferrite phases causes formation of a gel, richer in alumina, the calcium sulfoaluminoferrite hydrate, and the low sulfate form of calcium sulfoaluminate hydrate. The formation of further aluminasilica hydrogarnet at this stage may be due to local depletions of sulfate in the liquid phase. After the ettringite is depleted, the lowest sulfate form of calcium sulfohydroxyaluminate is ultimately produced.

Introduction

The techniques of portland cement manufacture and of the production of strong, durable concrete were originally developed largely empirically, as has usually been the case in processes involving naturally occurring complex raw materials and equally complex products. These developments were accompanied by research that originated with observed correlations between variations in the processes and the performance of the products and ultimately produced a sophisticated applied science and technology. As the science of the cement and concrete field has developed, progress has been reflected in specifications, codifications, and quality control procedures. As a consequence, control of the properties of concrete and prevention of concrete deterioration has been facilitated. In addition, considerable fundamental understanding of the nature and mechanisms of cement hydration and concrete deterioration has been achieved.

By contrast, more fundamental scientific research on the chemistry of cement, or any other complex material or process, must necessarily begin with studies of vastly oversimplified situations. The real situation is approached as progress is made. Complications can then be added to the study. In fundamental

*Portland Cement Association, Research and Development Laboratories, Skokie, Illinois, U. S. A.

research on the chemistry of cement hydration, studies of phase equilibria of aqueous systems involving particular components found in cement have been a focal point for many years. The relationship between these studies and actual cement hydration have frequently been somewhat tenuous, because of the complexity of the cement-water system.

The purpose of the present paper is to apply current knowledge of the phase equilibria of pure cement constituents and water to improve understanding of the chemistry of the cement hydration process. This procedure implies certain limitations that must be set forth at the outset. Cement hydration in field concrete, on the one hand, can be influenced by various factors such as carbonation, aggregate reactivity, etc., that are not strictly part of the cement-water system. On the other hand, portland cement contains trace quantities of oxides for which systematic phase equilibrium studies are not available. Furthermore, the cement hydration process is known to be affected qualitatively by additional factors such as the amount of SO_3 in the cement and perhaps the water content of the hydrating system.

The process to be considered here is therefore the hydration of a cement at or near the optimum gypsum content (1) and showing a depletion of the solid calcium sulfate phase at 18–24 hours of hydration (2). This cement is assumed to be in a paste with a water-cement ratio in or slightly above the range normally found in concrete. The data available limit the presentation to the behavior of the major oxides in the cement and largely to a consideration of the nature of just the solid phases, since analyses of the liquid phase in the cement-water system are available only at early ages. The value and potential utility of a study with these limitations must be judged by its adequacy. It is shown that many features of the chemistry of cement hydration, from the time of first contact with water, can be qualitatively interpreted in terms of phase equilibria. The analysis made here naturally provides, often merely by implication, possible directions of future research in resolving those uncertainties, difficulties, and discrepancies that still remain.

The presentation in the present paper begins with evaluation of some aspects of the experimental identification of solid phases in the cement-water system. A discussion of the final products of cement hydration is followed by consideration of the thermodynamic stability of these products. Finally, the relation of the early hydration reactions to phase equilibria is presented.

Details of the phase equilibria involving pure compounds will be developed only where needed. Excellent reviews of these equilibria have been published quite recently (3) and will be referred to where appropriate. Other reference to work in this field will be largely confined to papers published since the appearance of these reviews.

Some of the conclusions drawn result from previously unpublished original work. For completeness, details of this work are given where appropriate. The emphasis of the study is perhaps slightly selective, since the authors have not had experience with all of the various aspects of the cement-water system.

The present paper is based largely on information on cement hydration developed since the Fourth Symposium. The expansion of knowledge during this period has been made possible by extensive use of relatively new instruments, especially the X-ray diffractometer. Results of considerable interest have also been obtained with the Mössbauer spectrometer, a very new instrument.

Studies of a condensed heterogeneous system must commence with the identification of the phases present and the determination of their composition. The following section deals with certain problems and techniques of identification that are important in studies of the cement-water system.

Identification of Solid Phases

An examination of recent literature reveals that present knowledge of the equilibrium state of the cement-water system has come a long way since that time, only twenty years ago (4), when it appeared that the only solid phases present at ultimate hydration were crystalline calcium hydroxide and an essentially undifferentiated, poorly crystallized solid consisting primarily of a calcium silicate hydrate. The progress that has been made has resulted largely from the improvement of techniques for identifying solid phases in hydrated portland cement.

It has been shown, for example, that the calcium silicate hydrate has an X-ray diffraction pattern that has at least a rudimentary crystallinity (5). Additional diffraction lines have been observed that can be associated with crystalline phases containing aluminum and iron, by comparison of the patterns with those of the corresponding pure compounds (6). Great pro-

gress has also been made in recent years in the preparation and characterization of both simple and complex calcium aluminates such as might occur in hardened cement paste (7).

The X-ray diffractometer has a great advantage over many other techniques for identifying solid phases in the cement-water system in that the state of the material under study can be rigorously controlled (8). The same can be said for the optical microscope and also for the Mössbauer spectrometer, to be discussed later. Many other techniques, such as differential thermal analysis, thermogravimetric analysis, and electron microscopy, require that the sample be subjected to treatments, such as preheating in a laboratory atmosphere or evacuation, that can demonstrably change its character prior to observation. Since the optical microscope is limited by its resolving power, results from X-ray diffraction studies are considered the primary source of data for identification of phases for present purposes. Results from other techniques are used as confirmatory evidence or for consideration of ambiguities not yet resolved or inherently not resolvable by X-ray diffraction studies.

The above paragraph is not meant to imply that all existing X-ray diffraction studies provide a complete and consistent picture. This is certainly not the case. Many uncertainties and even contradictions appear in the published literature. It is believed, however, that presently available information provides a basis for resolving many of the problems that have been encountered and for identifying most or even all of the solid phases that exist during the hydration of portland cement.

No attempt will be made here to analyze all of the various uncertainties that have appeared in the literature. The following sections deal primarily with those aspects of instrumentation that are essential for the present argument and that can aid in resolving many problems that have been encountered.

Effect of Carbonation

Published examinations of hydrated cement pastes or of calcium aluminate and ferrite hydrates have generally shown the presence of one or more carbonated phases. It has proved to be extremely difficult to prepare materials of this type that are truly free of carbon dioxide (9). In most instances where exclusion of carbon dioxide has been claimed, the claim has not been substantiated by a chemical determination of CO_2. It is of course recognized that the presence of a small proportion of a carbonated phase has little effect on the gross composition or properties of a bulk phase; even slight carbonation, however, can cause gross misinterpretation of diffraction patterns of materials because the bulk of the carbonation may occur precisely at the surface where the diffraction is taking place. As a result, a slight degree of carbonation, while only a small proportion of the bulk phase, can result in a diffraction pattern that has little relation to the material being studied. For example, Wells, Clarke, and McMurdie (10) gave a basal spacing of 8.2 Å as characteristic of their preparation of the tetracalcium aluminate hydrate. Even though this spacing is now known to belong to a carbonated phase (8), this fact does not in itself imply that the bulk material was unduly carbonated nor prove the rest of that phase equilibrium study invalid. In terms of the small quantities of materials used in the powder cameras of that time, carbonation could have occurred very early during handling of the sample, so that the material in the camera was simply no longer representative of the bulk of material under study. This illustration does, however, point up the need both for care in interpreting diffraction patterns and for recognition of the effects of carbonation on the phases present.

The above conclusion applies directly to the significance of an identification of the high sulfate form of calcium sulfoaluminate (hereinafter called *ettringite*) in hydrated cement pastes. It has been found that carbon dioxide reacts with the low sulfate form of calcium sulfoaluminate hydrate (hereinafter generally referred to as *monosulfate*) to produce the calcium hemicarboaluminate hydrate and ettringite:

$$3[Ca_3A \cdot CaSO_4 \cdot 12H_2O] + CO_2 + 20H_2O \rightarrow 2[C_3A \cdot \tfrac{1}{2}Ca(OH)_2 \cdot \tfrac{1}{2}CaCO_3 \cdot 12H_2O] + C_3A \cdot 3CaSO_4 \cdot 32H_2O$$

Further carbonation then converts the hemicarboaluminate to the carboaluminate and ultimately to some form of calcium carbonate. Fig. 1 illustrates the effect. Here carbonation was deliberately induced by blending calcium carbonate with Long-Time Study cement 18 in pastes at a water-cement ratio of 0.5. The cement composition is shown in Table 1. The top pattern shows the diffraction pattern of the carbonate-free

Table 1. *Compositions(48) of cements used in study of ettringite as an ultimate hydration product*

Cement	LTS 18	LTS 41
C_3S	44.5%	20.0%
C_2S	28.0	51.0
C_3A*	12.2	3.4
C_4AF	6.8	15.2
SO_3	1.83	1.98
Alkalies as Na_2O	0.22	0.84

*Corrected for minor oxides (49).

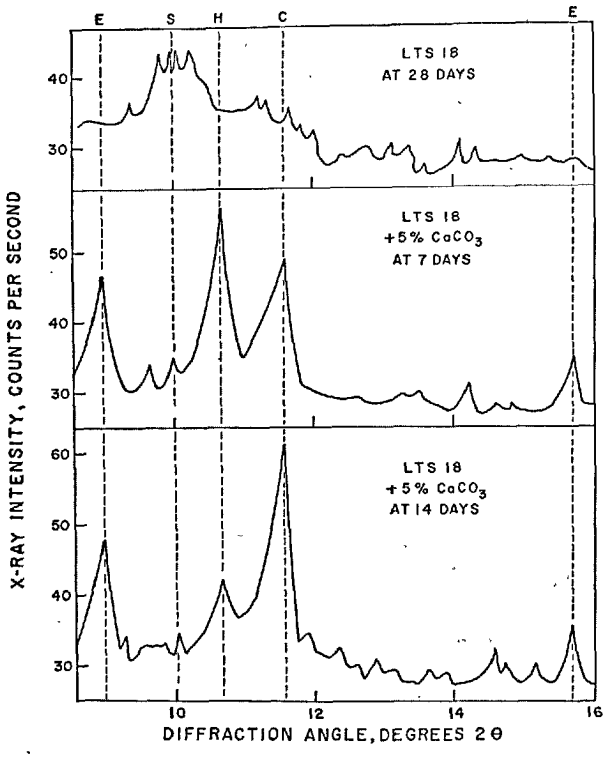

Fig. 1. *Carbonation of cement produces secondary ettringite. Legend: E = ettringite; S = calcium sulfohydroxyaluminate hydrate; H = calcium hemicarboaluminate hydrate; C = calcium carboaluminate hydrate.*

paste after 28 days of moist curing. The ettringite peaks are absent. In the presence of the carbonate, as shown in the other two patterns at 7 and 14 days, respectively, the peaks for ettringite and the carbonated phases are very prominent, whereas the monosulfate-hydroxide solid solution (11) (hereinafter referred to as *calcium sulfohydroxyaluminate hydrate*) pattern that is prominent in the top pattern is essentially absent in the others.

Thus, the presence of ettringite in a well hydrated paste or similar system containing lime, alumina, sulfate, and water does not in itself indicate this compound to be a primary equilibrium product, but may merely indicate that this material was formed as a secondary product from incidental carbonation. It is believed that this reaction explains many of the reported inconsistencies regarding the presence of ettringite in well-hydrated pastes. Since diffraction studies on hydration of simulated cement pastes (11) have shown that the sulfate ultimately forms monosulfate and the sulfohydroxyaluminate, it appears that the ultimate hydration products of the cement-water system in the absence of carbon dioxide may not always include ettringite.

In an extension of this study, samples of pastes made from longtime study cements 18 and 41, whose compositions may be found in Table 1, were examined after 14 years of continuous moist curing. The samples were sawed out of the centers of 2 × 6 inch paste cylinders made up at a water-cement ratio of 0.5. The diffraction pattern for cement 18 gave no indication of carbonation and also no indication of ettringite. That for cement 41, on the other hand, contained the ettringite peaks and yet displayed no evidence of carbonation. Occurrence of ettringite as an ultimate hydration product of the cement-water system, as discussed later, depends upon the cement composition.

Although the existence of the calcium hemicarboaluminate hydrate was reported some years ago (8), the evidence for its existence and composition was not published at that time. Since the reported composition has been viewed with considerable skepticism (12, 13), and since recognition of this material is of great importance in diffraction studies of the cement-water system, it is essential that the details of this identification be presented here. The following discussion also covers the preparation and the properties of the material and gives some indication of the reasons for the existing confusion.

In the present work, a suspicion that the material was not a form of C_4AH_{13} as had been generally supposed, arose when it was found that it could not be converted to a higher hydrate. Thus, when a solid exhibiting the diffraction pattern of this material and C_4AH_{13} was repeatedly wetted and dried, the C_4AH_{13} would transform reversibly to C_4AH_{19}, whereas the 8.2 Å line would remain unchanged. The material responsible for this line therefore had to be either some form of C_4AH_{13} that was metastable toward absorption of water or some other compound. Although no C_4AH_{13} preparation could be made that was free of this line, routine CO_2 determinations revealed that the intensity of the 8.2 Å line varied with the CO_2 content of the preparation.

A series of preparations was then made using slurries containing tricalcium aluminate, calcium carbonate, and calcium hydroxide, in which the mole ratio $CaCO_3/C_3A$ was varied from 0.1 to 1 in steps of 0.1, and the mole ratio $Ca(OH)_2/C_3A$ was held constant at 1. These slurries were agitated at 40°F, to avoid formation of the cubic C_3AH_6, for 70 days. After filtration of the slurries, diffraction patterns were made of the wet solids. The material with a mole ratio $CaCO_3/C_3A$ of 0.5 had a major diffraction intensity for a basal spacing at 8.2 Å whereas the preparation with lower $CaCO_3/C_3A$ ratios showed increasing intensities of the 10.7 Å spacing of C_4AH_{19},

and those with higher $CaCO_3/C_3A$ ratios showed increasing intensities of the 7.6 Å spacing of $C_3A \cdot CaCO_3 \cdot 12H_2O$. The intensity of the 8.2 Å peak varied with the carbonate-to-alumina ratio and attained its maximum at $CaCO_3/C_3A = 0.5$.

Subsequently, preparations of the hemicarboaluminate have been made to study its properties. For these preparations, 1 mole of C_3A, 0.45 mole of $CaCO_3$, and 0.55 mole of $Ca(OH)_2$ are mixed in a slurry and agitated until the C_3A is hydrated. It has been found that the preparation can be made at room temperature since the hemicarboaluminate, unlike C_4AH_{13}, is stable with respect to the cubic phase, C_3AH_6; in fact, the complex also forms, although slowly, from similar mixtures in which the C_3A is replaced by C_3AH_6. The slight deficiency in carbonate is deliberately introduced, since the mix absorbs enough atmospheric CO_2 during filtration and subsequent handling to produce the desired composition. Chemical analyses of these preparations are within 0.25 per cent of the composition demanded by the assigned formula. Successive drying over $CaCl_2 \cdot 2H_2O$ and then $CaCl_2$, followed by equilibration at 50 per cent relative humidity over dilute sulfuric acid, yields the desired compound with the 8.2 Å basal reflection and close to 12 moles of water per formula weight. A very weak pattern for C_3AH_6 also appears in the diffraction charts of these preparations.

Microscopic examination shows the material to crystallize in poorly defined hexagonal plates that are uniaxial negative with refractive indices: $N_O = 1.537 \pm 0.002$, $N_E = 1.510 \pm 0.002$.

The X-ray diffraction pattern obtained agrees essentially with that already published and indexed as "C_4AH_{13}" by Wells, Clarke, and McMurdie (10) on the basis of a hexagonal cell with $a = 8.89$ Å, $c = 8.20$ Å. The spacings and indices obtained by Wells et al are reproduced in Table 2 for reference.

Dehydration of the material produces successive structures with successive reduction of the longest spacing from 8.20 Å to 7.74 Å, 7.30 Å, 6.80 Å, and 6.09 Å. The last value was obtained by prolonged drying over phosphorus pentoxide and corresponded to a measured water content of 6.78 moles of water per mole of Al_2O_3. The first stage of dehydration was observed by Dosch and zur Strassen (12), who reported a spacing of 7.7 Å and a water content of $9H_2O$ per Al_2O_3.

Table 2. *Interplanar spacings and miller indices for calcium hemicarboaluminate hydrate(10)*

d(Å)	hkl	d(Å)	hkl
8.2	001	2.06	004
4.1	002	2.000	104
3.9	111	1.951	222
2.9	210	1.766	320
2.73	211	1.670	410
2.64	103	1.637	411
2.55	300	1.554	403
2.45	301	1.500	501
2.37	212	1.475	323
2.31	113	1.440	420
2.24	203		

The indexing given in Table 2 is confirmed by the observation that dehydration causes systematic shifts in all low-order lines except the one at 2.88 Å, which is the only low-order spacing of the form (hk0). Thus, the dehydration can be explained on the basis of changes in the c spacing only. This material is then quite different from the other materials of the type $C_3A \cdot CaX_2 \cdot yH_2O$, to which a spacing of the order of 5.7 Å has been attributed (14).

The major source of confusion in the identification of calcium hemicarboaluminate hydrate as a form of C_4AH_{13} arises from the fact that a very small degree of surface carbonation of a sample in an X-ray diffractometer can produce a high intensity 8.2 Å line. The existence of the dehydration states of the hemicarboaluminate helps further to explain the confusion regarding the number of calcium aluminate hydrates. When the phase changes in these materials occur on dehydration, the shifts in the X-ray diffraction pattern are accompanied by line broadening. As a result, the 7.9 Å line of the C_4AH_{13} overlaps the 7.7 Å peak of the first dehydration state of the carbonated phase, and the 7.4 Å line of the C_4AH_{11} overlaps the peak for the second dehydrated carbonate state at 7.3 Å. Thus, the hemicarboaluminate and the C_4AH_{13} have appeared to produce identical dehydration states.

Calcium Hemicarboferrite Hydrate

The results described above naturally lead to the question of whether the behavior of the calcium ferrite and aluminoferrite hydrates on carbonation is analogous to that of the calcium aluminate hydrates. Two sets of experiments have demonstrated that this analogous behavior actually does occur.

In one study, samples of tetracalcium aluminoferrite were hydrated at 40°F in the presence of systematically varied quantities of calcium carbonate, just as already described for tricalcium aluminate. Each slurry contained four moles of calcium hydroxide per mole of C_4AF to bring the $CaO/(Al_2O_3 + Fe_2O_3)$ mole ratio to 4. The original slurries were dark colored, but became white upon completion of the hydration. The diffraction patterns of the products were completely parallel to those of the C_3A series. The peak for the

highest spacing of the $C_4(A, F)H_{19}$ decreased with increasing carbonate contents and disappeared when the $CO_2/(Al_2O_3 + Fe_2O_3)$ mole ratio reached 0.5. At this point, the peak for the 8.2 Å spacing reached its maximum intensity, decreasing at higher CO_2 contents as the peak for the 7.6 Å spacing for the calcium monocarboaluminoferrite hydrate became stronger. The alumina-ferric oxide combination apparently forms a series of carbonated calcium salts completely analogous to those of the alumina alone.

The evidence for the formation of a hemicarboferrite comes from a test in which very finely ground C_2F was hydrated in a slurry at 40°F with two moles of $Ca(OH)_2$. After 8 days of agitation considerable reaction had occurred. X-ray diffraction showed major spacings of 10.7 Å and 8.20 Å, indicating that atmospheric CO_2 had produced the calcium hemicarboferrite hydrate in the absence of alumina. The *c* spacings for these carbonated phases containing alumina or ferric oxide appear to be identical.

Alumina Versus Ferric Oxide

Cement hydration is usually discussed in terms of the alumina in the cement despite the fact that ferric oxide forms a set of high limed hydrates completely analogous to the calcium aluminate hydrates and their complexes (15). Since those compounds based on ferric oxide are essentially indistinguishable from their alumina counterparts by X-ray diffraction, attempts to study the role of the ferric oxide in the cement-water system have encountered formidable experimental problems. Recently, a new instrument, the Mössbauer spectrometer, has become available for studies of the state of the iron. The presence of aluminum does not complicate such studies. The instrument has yielded results that provide considerable insight regarding the separate roles of the alumina and the ferric oxide in cement hydration.

The space available here does not permit a discussion of the principle and the operation of this instrument, other than to say that an X-ray spectrographic technique is used that is somewhat analogous to one used recently to determine the coordination number of aluminum in various compounds (16). The Mössbauer technique, however, measures total resonance absorption, by the sample, of radiation from a very different type of radiation source and is much more sensitive than the usual type of X-ray spectrograph. The interested reader can find a good and inexpensive elementary English language text readily available (17).

Reference patterns for the use of this instrument have been obtained from tests run for these laboratories by Dr. R. L. Collins of Austin Science Associates, Inc. Two fully hydrated mixtures prepared by long time agitation of slurries of tetracalcium aluminoferrite, gypsum and calcium hydroxide were submitted for examination. A light colored material made from a slurry having a $SO_3/(Al_2O_3 + Fe_2O_3)$ mole ratio equal to one and containing sufficient calcium hydroxide to produce a $CaO/(Fe_2O_3 + Al_2O_3)$ mole ratio of 4 gave an X-ray diffraction pattern characteristic of the monosulfate and a characteristic Mössbauer pattern shown in Fig. 2.

In this figure, the ordinate, reading downward, represents the absorption, in percent, of the incident beam by the sample. No calibration was made for this exploratory test, so that the energy units on the abscissa simply represent channel numbers of the memory in the recording analyzer. Under proper calibration, as shown later in the present paper, these channel numbers represent numerical values for velocities that are proportional to differences in beam energy from that represented by the mid-line that intersects the horizontal scale. Two parameters are used to characterize these spectra. One is the displacement of the center of gravity of the spectrum from the zero of the figure. This parameter is known as the *isomer shift*. The other parameter, known as the *quadrupole splitting* is the difference in energy (expressed as velocity) between the two absorption peaks that frequently appear for a single solid phase, particularly for crystals of low symmetry.

A much darker material prepared from a similar mixture, but with only half the quantity of gypsum per unit C_4AF, gave a diffraction pattern identical with that of the light colored material, so far as could be determined with copper Kα radiation without special monochromators. Special care might perhaps have detected a broad peak, but it is certain that no other well-crystallized phase was present. The dark material produced the Mössbauer pattern shown in Fig. 3. This figure can be interpreted as indicating the presence of at least two phases, one of which is probably the one responsible for the pattern shown in Fig. 2. It thus becomes quite clear that the instrument is responsive to changes in the state of the iron in the presence of lime, alumina, sulfate and water. The result indicates further that the color of the product provides an index to the purity of the phase. Since it had been found that mixtures of intermediate composition produced dark products, it could be conclude that the light colored single phase with the highest sulfate content was the low sulfate from of calcium sulfoaluminoferrite hydrate, $C_6AF \cdot 2CaSO_4 \cdot xH_2O$.

A further confirmation of the sensitivity of the instrument was obtained from a Mössbauer pattern of the aluminoferrite analog of ettringite as prepared from a slurry of aluminum and ferric sulfates and calcium hydroxide in the appropriate stoichiometric ratios. Again a pattern for a single compound was found. This pattern was, moreover, distinctly different from that of the monosulfate.

The above considerations have now paved the way for a discussion of the existing evidence regarding the nature of the ultimate hydration products of portland cement.

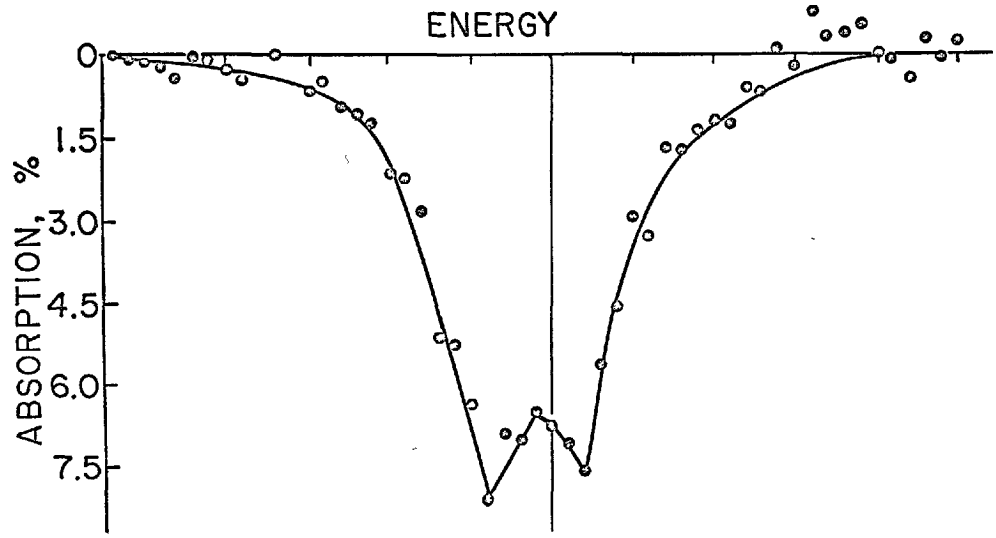

Fig. 2. *Mössbauer spectrum of the low sulfate form of calcium sulfoaluminoferrite hydrate.*

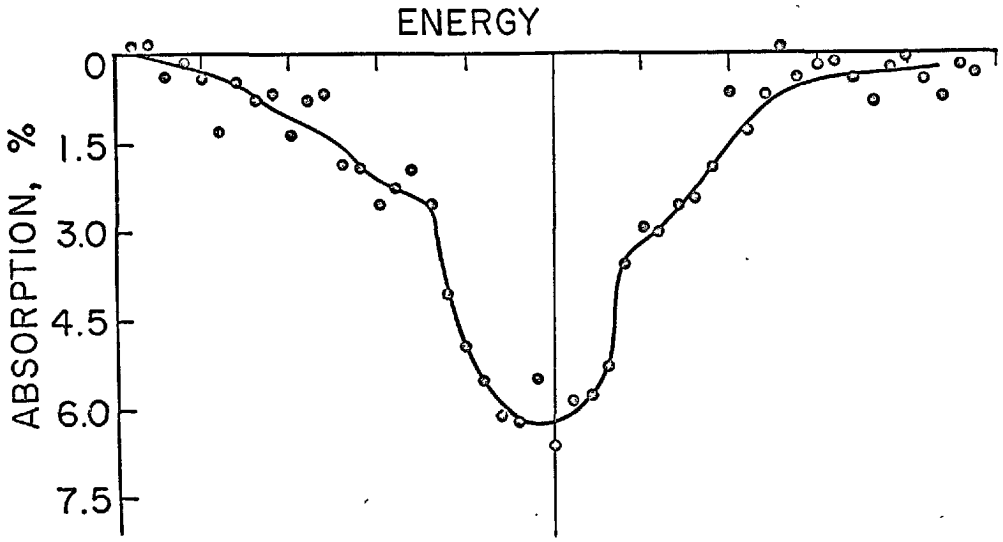

Fig. 3. *Mössbauer spectrum of a fully hydrated material with the molar composition:* $C_4AF + 3CaO + CaSO_4 \cdot 2H_2O$.

The Ultimate Hydration Products

The most comprehensive survey by X-ray diffraction of the phase composition of the ultimate hydration products in portland cement is the study of well aged pastes by Kantro, Copeland and Anderson (6).

After exclusion of the carbonated phases as not properly belonging in the cement-water system, and of ettringite in the presence of CO_2 as frequently secondary, the patterns obtained consistently show the presence of a calcium silicate hydrate gel, sulfated calcium aluminate and ferrite hydrates, a hydrogarnet phase, and calcium hydroxide.

Since no work has been reported on the composition of the liquid phase in equilibrium with all of these ultimate hydration products, present knowledge of the final state of the cement-water phase equilibrium is necessarily limited to the nature, composition, and thermodynamic stability of these materials. The calcium hydroxide is very well defined and crystallized, and is always present, in the normal range of cement compositions, in sufficient quantity to saturate the liquid phase in the cement-water system. The interest here therefore centers on the nature and composition of the remaining solid phases. The matter of thermodynamic stability is considered later.

The Calcium Silicate Hydrate Phase

The calcium silicate hydrate gel found in portland cement pastes is the primary cementitious material. It is a very poorly crystallized material, whose presence and general characteristics have been recognized for many years. It is only relatively recently, however, that X-ray diffraction techniques have demonstrated a fragmentary pattern of three lines (5), and electron microscopy has demonstrated a characteristic morphology for dried samples (18). Crystallographically, the material is a distorted version of the structure known as CSH (I) that is usually formed in room temperature equilibrium studies in the CaO–SiO_2–H_2O system (19). The most significant structural difference between the cement product and CSH (I) is the absence, in the former, of any lines involving a c spacing. The spacings that are observed in both materials are also found in the naturally occurring crystalline mineral tobermorite (19).

Paste hydration of tricalcium silicate or beta-dicalcium silicate at room temperature yields a gel with the same X-ray pattern as the cement hydration product. It thus appears that the structure of the product is little affected by the presence of the other constituents of portland cement. This conclusion is strengthened by the close agreement that has been found between the heats of hydration of the anhydrous silicates and the values for the corresponding phases in portland cement as calculated by least squares from the heats of hydration of cements of various compositions (20). The electron microscope, however, does show a difference in morphology (18).

It is not surprising that a material as poorly defined as this major cement hydration product should show minor variations in composition. Various studies have shown that small quantities of alumina, ferric oxide, sulfate, or alkalies can be incorporated in the material without causing a change in X-ray pattern. It thus appears that changes in composition of this phase could accompany changes in the equilibrium liquid phase. Such changes are of interest in relation to the early hydration reactions and are discussed in that context after consideration of the effects of other solid hydration products on the liquid phase composition. It is, however, pertinent to consider here the ranges of composition that have been found for individual substituents and combinations of them.

The work of Copeland, Bodor, Chang, and Weise (21) indicates that alumina, ferric oxide, or sulfate ion can be incorporated into the gel by substitution of the aluminum, iron, or sulfur atoms, respectively, for calcium or silicon atoms up to a maximum of one atom of substituent per six atoms of silicon in the hydrate. These preparations were made by wet ball milling of the anhydrous C_3S or alite with an appropriate anhydrous or hydrated calcium compound containing the constituent and appear to be good approaches to equilibrium. It was also found that exposure of an alumina substituted gel to a sulfate solution produced ettringite. This result provides a direct demonstration of the effect of the liquid phase on the gel composition, even though no quantitative analyses of the liquid phases were made.

It will be shown later that the calcium silicate hydrate phase finally formed in hydrated cement paste contains considerable alumina and little ferric oxide or sulfate ion.

Effect of Alkalies

The classical study of Kalousek (22) on the Na_2O–CaO–SiO_2–H_2O system determined equilibrium points for gels prepared by reaction of calcium hydroxide with sodium silicate solutions. Equilibrium as measured by constancy of solution composition, was attained in a few weeks. It was pointed out, however, that the equilibria depended strongly on the nature of the solid phase and that slow changes in crystallinity of that phase over a long period of time could produce very different equilibrium points. Little has been reported since the time of that study in relation to the effect of alkalies on calcium silicate hydrate gels.

Powers and Steinour (23), in their study of alkali-aggregate reaction, have reported alkali contents of

solutions and solid phases resulting from two year contact of water with five hydrating cements beginning with pastes one day old. It was found that the alkali contents of the gels were much lower than would be expected from the results obtained by Kalousek,

Recent studies at these laboratories have indicated the reason for the discrepancy and have provided a limited amount of additional information regarding the role of the alkalies in the gel of the cement-water system. In these studies, various cements, anhydrous calcium silicates, and synthetic calcium silicate hydrates with a range of lime-to-silica ratios up to 1.45 were treated as slurries with alkali solutions from 0.125 molar up to 2 molar in sodium or potassium hydroxide for a period of six months. X-ray diffraction patterns were made of the wet solid phases obtained by filtration of these slurries. In many cases, the filtrates were weighed and analyzed to determine the distribution of alkalies in the system. Inconsistencies in the analytical results indicated that equilibrium had probably not been attained in six months, particularly at the higher alkali contents. The present discussion of these results is limited to those essentially qualitative aspects believed significant in the cement-water system.

The alkali contents of the solid phases were in all instances of the magnitude found by Powers and Steinour and considerably less than those found by Kalousek. The tests of the effect of potash were limited to the synthetic calcium silicate hydrate gels; for these preparations, with a range of lime-to-silica ratios of 0.9 to 1.45, the potash and soda behaved very similarly.

After six months of exposure to alkali, all solid phases, including those of the cements, developed some degree of crystallinity, as revealed by the presence of a peak for the (002) spacing of tobermorite in the diffraction patterns. Some variation of the position of this peak was noted at low alkali contents for the tests on C_3S and β–C_2S, where spacings as low as 9.6 Å were observed. At the higher alkali contents the peak became sharper and in all cases attained a spacing of 12.3–12.4 Å, the constant spacing observed for the highest limed calcium silicate hydrate at all alkali contents. The results clearly confirm Kalousek's surmises regarding the dependence of the equilibria on the state of the gel and the presence of slow crystallization processes.

An additional feature of interest in the tests on the highest limed calcium silicate hydrate was the presence of the peaks for the (001) and (101) spacings for calcium hydroxide. These lines appeared at soda or potash concentrations above 0.25 molar and increased in intensity with increasing alkali contents.

A comparison of these results with Kalousek's data indicates that the limiting alkali concentration for appearance of solid calcium hydroxide was much lower for his gels. The equilibrium state for the present gel is characterized by a higher lime content as well as a lower alkali content.

It might be speculated that the increasing crystallinity of the gel with time of exposure might be accompanied by a decreased tolerance for alkalies in the structure. An indication of this effect was observed in another series of tests in which the soda content of the gel formed from the highest limed calcium silicate hydrate decreased during the time from 20 to 98 days of exposure. Unfortunately, this series of tests included sodium chloride in solution as an additional source of alkali, so that secondary effects may have occurred even though no appreciable change of the chloride ion concentration in solution was observed.

Since diffraction patterns of hydrated cements do not normally exhibit the d_{002} spacing found in the above study, it must be assumed that the significant quantities of alumina present in cement gel affect the structure. Evidence for this has been found in the electron microscope (21). A more complete study of the role of the alkalies in the cement-water system would therefore require the addition of alumina to the calcium silicate hydrates. The evidence already presented, however, indicates that the difference in capacity for alkali between a high limed calcium silicate hydrate gel and the gel in hydrated cement must be small. The primary conclusion to be drawn from the studies just described is that the alkali content of the gel in cement paste must be quite low and of the order of magnitude found by Powers and Steinour.

The Sulfated Aluminate and Ferrite Hydrates

A large number of studies have produced evidence for the existence of calcium sulfoaluminates at the various stages of cement hydration. The best evidence available for the ultimate hydration state is probably that of the X-ray diffraction study already cited (6). As already mentioned, caution must be used in the evaluation of such studies with respect to the presence of ettringite as a final hydration product in the cement-water system in the presence of carbonated phases.

The most interesting recent development in this area has been the use of the Mössbauer spectrometer in studies of cement paste. Wittmann, Pobell, and Wiedemann (24) have used the instrument to study the hydration of a single cement with a potential

compound composition of 33 percent C_3S, 38 percent C_2S, 14 percent C_3A, and 9 percent C_4AF, and with an SO_3 content of 3.1 percent (25). The spectrometer was used to monitor the state of the iron during the hydration of the cement in pastes at water-cement ratios of 0.4 and 1.0. Hydration was complete after two years.

The results are shown in Fig. 4. The spectrum of the original cement is shown at the top of the figure. The work of Pobell and Wittmann (26) on the ferrite solid solution series has shown this pattern to be characteristic of C_4AF. This pattern was also obtained from the pastes for the first two days after mixing. Thus, it appears that no hydration had taken place during this period. The middle spectrum was obtained for the paste with a water-cement ratio of 1.0 at 27 days. Here the C_4AF peaks have decreased in intensity and two peaks for a hydrated phase have appeared. Finally, at 200 days, the bottom spectrum was obtained. Here, only the pattern for the hydrate appears; it can be assumed that the material was completely hydrated. The phase appearing at ultimate hydration was the only hydrated phase that was found throughout the hydration process. This phase was not identified.

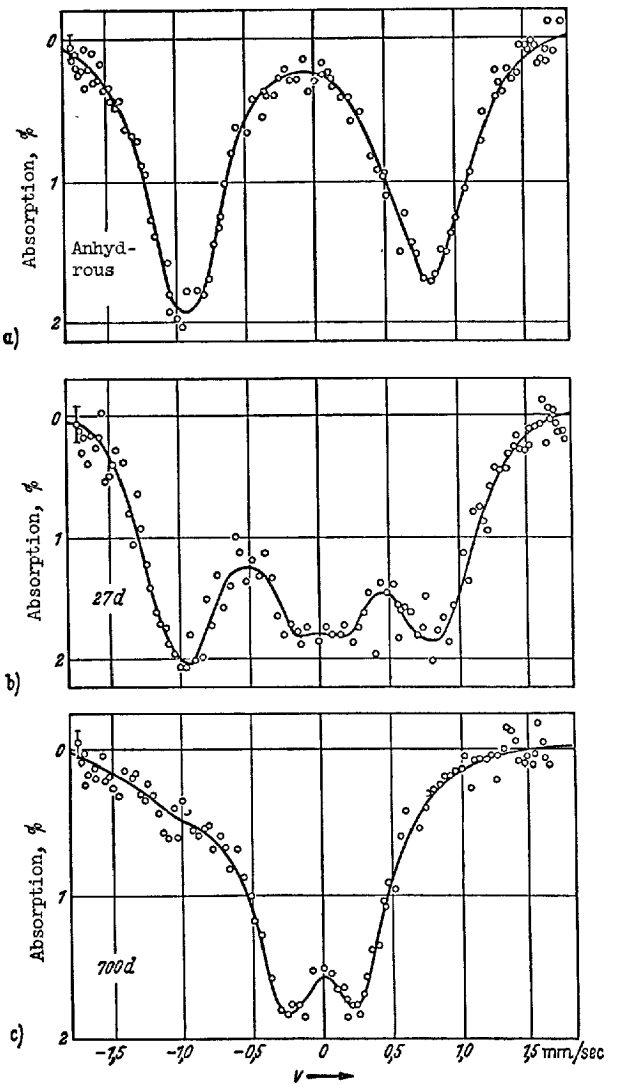

Fig. 4. *Mössbauer spectra of a cement at successive stages of hydration (from Reference 23).*

Comparison with the results obtained by Collins reveals that the final spectrum of Fig. 4 is identical with that shown in Fig. 2. This matching identifies the hydrated ferrite as the low sulfate form of calcium sulfoaluminoferrite hydrate. It must be recognized that this identification cannot be regarded as complete until Mössbauer patterns of all other possible alternatives are available; it is believed, however, that general experience with the sensitivity of the instrument indicates that other materials containing ferric oxide, such as the sulfate-free C_4FH_x or $C_4(A, F)H_x$, would give distinctly different patterns. This identification is also made with the qualification that the Mössbauer spectrometer is known to be insensitive to highly dispersed states of iron (26), i.e., a small quantity of ferrite hydrate dispersed in the gel would probably not be detectable by this means.

From the result obtained, definite conclusions can be drawn regarding the final distribution of the alumina and the ferric oxide in the cement tested by Wittmann. The mole ratio of Fe_2O_3 to SO_3 in this cement is 0.477. Thus, the Mössbauer results indicate that for each mole of sulfate present, $2 \times 0.477 = 0.954$ mole is ultimately transformed to a calcium sulfoaluminoferrite hydrate and 0.477 mole of alumina is consumed. The mole ratio of Al_2O_3 to SO_3 is 1.814. From the X-ray evidence, it is reasonable to assume that the lowest sulfate form of calcium sulfohydroxyaluminate hydrate is present. The experimental evidence, as shown later in the present paper and also in reference 11, indicates that this compound contains about 0.6 mole of SO_3 per mole of alumina. The 0.046 mole of sulfate not accounted for in the ferrite complex can thus combine with $0.046/0.6 = 0.077$ mole of alumina. This supposition still leaves $1.814 - 0.477 - 0.077 = 1.260$ mole of alumina per mole of sulfate unaccounted for. If this 69 percent of the alumina in the cement were to combine with the free calcium hydroxide that must be present in the hydration products, a tetracalcium aluminate hydrate would form and could be identified by diffraction. Since this hydrate has not been found in well hydrated pastes, it must be concluded that the remaining alumina is

ultimately distributed between the calcium silicate gel and the calcium aluminosilicate hydrogarnet phase discussed later. Without X-ray diffraction patterns of saturated, well-aged, uncarbonated pastes of the cement studied by Wittmann, however, it is not feasible to verify this analysis.

A Mössbauer spectrometer study of the pastes described in reference 6 is now underway in cooperation with the National Bureau of Standards. To at least a first approximation, all pastes tested have produced spectra similar to Fig. 2 for the hydrated ferrites. It thus appears that the above analysis should be quite generally applicable.

The above calculation of the distribution of cement components into the ultimate hydration products can always be performed provided that the mole ratio Al_2O_3/Fe_2O_3 is at least unity and the mole ratio SO_3/Fe_2O_3 is at least two. The first of these requirements is met by all portland cements except certain special cements designed to have a zero C_3A content. The second requirement is met by most present-day normal cements, such as ASTM Type I, especially with the continuing rise in specification limits for SO_3 content (27), but not by low heat or sulfate resistant cements or even by many older cements with relatively low SO_3 contents. In well hydrated pastes made from cements not meeting the second requirement, preliminary results from the present cooperative study reveal that only unhydrated C_4AF can be found as an additional iron-containing phase, even in pastes cured continuously moist for 10 years. Thus, it appears that hydration of the ferrite phase in cement essentially ceases when sulfate is no longer available for formation of the sulfoaluminoferrite complex. These cements with the unhydrated C_4AF residue are the very ones whose X-ray diffraction patterns indicate the presence of ettringite as an ultimate hydration product. It is therefore apparent that the hydration in these pastes is of a character more usually associated with the early hydration reactions and will be discussed further when these reactions are considered.

With respect to the phase equilibria in the cement-water system a problem remains in that some cements produce pastes containing an unhydrated residue at later ages that is certainly not an equilibrium phase, and yet one that hydrates so slowly that no hydration products are identifiable in a reasonable time.

Effect of Alkalies

With regard to the possible effect of alkalies on the sulfated aluminates and ferrites, it is necessary to consider the recent work of Dosch and zur Strassen (28) dealing with a solid calcium sulfoaluminate hydrate phase containing soda. After a great deal of effort, these workers were unable to establish either the precise composition of the phase or the boundaries of its region of stability. Both of these problems proved to be very complex. It was concluded that this phase, with the approximate composition:

$$4CaO \cdot 0.9Al_2O_3 \cdot 1.1SO_3 \cdot 0.5Na_2O \cdot 18H_2O,$$

was unlikely to occur in cement paste, except possibly in dried pastes at very early ages.

The results of a series of studies by the present authors on the effect of sodium hydroxide solutions on the concentrations of sulfate that are in equilibrium with calcium sulfoaluminate and sulfoferrite hydrates add a little more to the story. Examination by X-ray diffraction of the solid phases obtained in this study revealed the presence of calcium hydroxide and the solid phase with the 10.0 Å and 5.0 Å spacings studied by Dosch and zur Strassen. Those workers found it necessary to use relatively low lime and high alumina levels in order to determine the composition of the solid phase. The present work, on the other hand, with solid $Ca(OH)_2$ present and with very low Al_2O_3 in solution, represents a range of liquid phase compositions that is much closer to those occurring in cement pastes.

In one series of tests, mixtures of ettringite with a series of solutions of sodium hydroxide with concentrations from 0.4 to 8.6 percent NaOH were agitated in polyethylene bottles for 4 weeks. The new phase was detected in many of the tests. In only one case, however, did the reaction proceed to the point that ettringite was no longer detectable by diffraction. In this test, 5 grams of ettringite were treated with 40 ml of 2.55 N sodium hydroxide. On the assumption of the Dosch and zur Strassen composition for the alkali-containing solid, it was to be expected that the final solution would contain 6.69 percent Na_2O and 1.25 percent SO_3. The actual values found were 7.59 percent Na_2O and 1.30 percent SO_3. The result indicates that the new phase can form in highly alkaline media in the presence of excess lime and in the absence of excess alumina. There is, further, an indication here that the phase has a different composition under these conditions.

An analogous set of experiments with the high sulfate form of calcium sulfoferrite hydrate yielded similar results, with considerably greater sulfate solubility at low alkali concentrations and with similar reduction in Na_2O in the liquid phase. Here the basal spacing of the new phase was 10.3 Å, which is the same as that for the low sulfate form of calcium

sulfoferrite hydrate. It appears that, in principle, either the aluminate or the ferrite can form this type of solid phase.

A similar set of tests with the calcium sulfohydroxyaluminate hydrate showed slight but definite increases in SO_3 and decreases in Na_2O solution concentrations. However, excessive carbonation prevented careful diffraction studies of the solid phases.

In the course of the previously discussed tests on the effect of alkalies on the gel in hydrated cement, the 10.0 Å and 5.0 Å spacings were observed in the diffraction patterns of the solids from various reaction mixtures. It was found that when slurries made from one part of cement and as much as 8 parts of 8 percent sodium hydroxide solution were hydrated, these peaks represented the only identifiable sulfate-containing phase in the solid. It thus appears that the compound can form in cement in the presence of excess alkali, although it has not been detected under oridinary conditions of cement hydration.

The Hydrogarnet Phase

Kantro, Copeland and Anderson (6), in their X-ray studies, reported the presence of a set of diffraction peaks attributable to a cubic hydrogarnet phase. This pattern appeared quite early in the hydration process and did not increase appreciably in intensity during aging of pastes. The unit cell edge, 12.40 Å, was definitely different from the 12.58 Å of the tricalcium aluminate hydrate, C_3AH_6. Since substitutions, both of alumina by ferric oxide and of water by silica, are possible, the observed cell size could not be used for identification of the composition. The formation of this phase has been confirmed by electron microscope studies (29).

The persistence of the hydrogarnet phase during the remainder of the hydration process indicates a high degree of stability. On the other hand, the inability of the phase to nucleate C_3AH_6 is of considerable interest. Apparently the cell sizes and compositions are too different for this process to occur. Another alternative is that C_3AH_6 is not a stable phase in the $CaO–Al_2O_3–SO_3–H_2O$ system in the presence of excess lime, a possibility that is considered later.

The Mössbauer results provide a clue regarding the composition of the material. Cubic phases are known to give spectra different from those of hexagonal phases. All of the pastes that have been studied by this technique have produced spectra with appreciable intensities only for the patterns of unhydrated C_4AF and the calcium sulfoaluminoferrite hydrate. Strong evidence thus exists for the absence of ferric oxide in the hydrogarnet phase. Comparison of the observed cell edge of 12.4 Å with those found by Flint, McMurdie, and Wells (30) indicates that the hydrogarnet formed should have a composition on the order of $C_3AS_{0.5}H_5$.

Summary

The present knowledge of the cement-water system indicates that five hydrated solid phases are ultimately formed. These phases are a calcium silicate hydrate gel containing significant quantities of alumina, sulfate, and alkalies, the low sulfate form of calcium sulfoaluminoferrite hydrate, the lowest sulfate form of calcium sulfohydroxyaluminate hydrate, and aluminasilica hydrogarnet, and calcium hydroxide. In cements with relatively low C_3A contents, such as ASTM Type IV or Type V, ettringite and unhydrated C_4AF may also be present.

Thermodynamic Stability of the Ultimate Hydration Products

Although true thermodynamic equilibrium in a condensed heterogeneous system implies the presence of stable solid phases, the continued presence of a solid phase in a reaction mixture does not rule out a metastable situation. In fact, previous studies and reviews on the cement-water system and related phase equilibria have indicated considerable doubt regarding the stability of some of the solid phases that have been found.

The purpose of the present section is to review the available information insofar as it bears on the cement-water system. In particular, recent original studies have produced results of considerable interest.

The Calcium Silicate Hydrate Gel

Work on the lime-silica-water phase equilibrium has generally shown that, at ordinary temperatures and high lime contents, the silica in the system occurs as a calcium silicate hydrate gel (19). The lime concentration in solution varies with the lime to silica ratio of the gel. As already indicated, the gel phase in hydrated cement appears to be a high limed, poorly organized, and partially substituted version of the

calcium silicate hydrate gel found in the phase studies.

A variety of crystalline calcium silicate hydrates have been prepared by hydrothermal means and have usually been considered as stable only at elevated temperatures. A single exception is the room temperature preparation of afwillite, by $C_3S_2H_3$, Brunauer, Copeland, and Bragg (31), which was accomplished by ball milling of slurries of tricalcium silicate in water. In this exceptional instance, it could, however, be argued that the milling process introduced sufficient energy to produce a metastable phase.

Further work has confirmed the possibility that afwillite may well be the stable room temperature calcium silicate hydrate in the lime-silica-water system, but yet may not be the stable phase in the cement-water system. These studies centered around the discovery that the presence of small quantities of afwillite during hydration of tricalcium silicate in pastes caused formation of crystalline afwillite rather than the usual gel. The results obtained and the properties of the material formed are believed of sufficient interest for inclusion here.

Table 3 shows properties of a set of 1/2-inch cubes prepared from C_3S at the water-to-solids ratios shown. Nucleation was accomplished with 2 percent, by weight of the C_3S, of an afwillite formed spontaneously in hydration of a C_3S slurry and purified by leaching with water until no calcium hydroxide was detectable by X-ray diffraction. The cubes were stored in the molds for one day and then in water until the time of test. X-ray diffraction of the specimens indicated a more rapid hydration and the formation of afwillite rather than gel in the seeded cubes. The increase in hydration rate is reflected in the increase in non-evaporable water at 7 days, as measured by the method of Copeland and Hayes (32), and also in the relatively high compressive strengths at that age.

Table 3. *Effect of nucleation by afwillite on the properties of tricalcium silicate pastes*

One half inch cubes stored in the mold for one day and then cured under water until time of test.

Sample No.	Admixture	Water-to-solids ratio	Non-evaporable water		Compressive strength	
			7d.	28d.	7d.	28d.

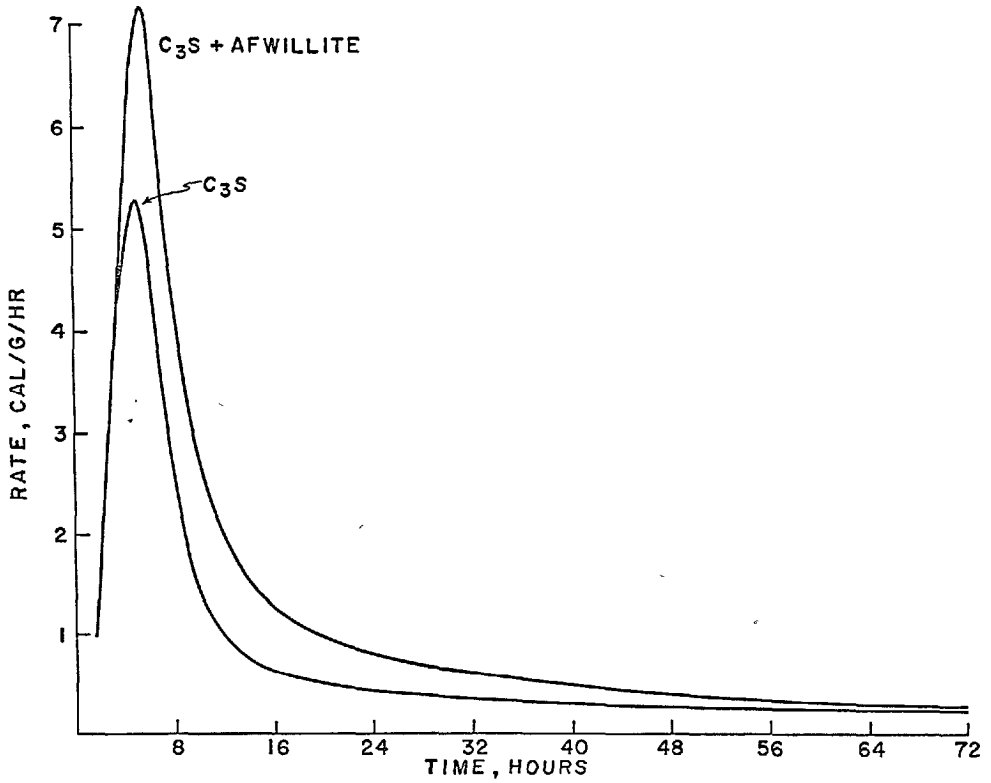

Fig. 5. *Nucleation by afwillite increases the rate of heat liberation during the hydration of tricalcium silicate.*

both seeded and unseeded C_3S pastes made from a sample ground to a specific surface of 4400 cm^2/g (Blaine). The results, from pastes at a water-to-solids ratio of 0.40, reveal a great difference in heat evolution at times as early as 8 hours. After 24 hours the total heat evolved for the nucleated sample was 57.4 cal/g as opposed to 38.6 cal/g for the paste without the afwillite.

The crystalline material also showed the expected reduction in shrinkage as compared with the behavior of an ordinary paste. Fig. 6 shows shrinkage as a function of water content for seeded and unseeded material for 1/4 × 1/4 × 6 inch bars with a gauge length of 5 inches cast from pastes with a water-to-solids ratio of 0.40. After a 28 day cure in water, the bars were stored successively in CO_2-free atmospheres at 85, 65, 55, 45, 25, 7 and 0 percent relative humidity for 24 days at each exposure. It can be seen that, below 85 percent, the shrinkage of the paste containing the crystalline silicate was consistently less than one-third of that of the paste containing the poorly crystalline material.

Further studies included attempts to induce afwillite crystallization in pastes of materials closer in composition to cement and in cement itself. Crystallization could, indeed, be induced in pastes of an alite that has a composition corresponding to the Jeffery formula $C_{54}S_{16}AM$ (33), and also in pastes of alites having alumina and magnesia contents 1/3 to 2/3 of those required by the Jeffery formula. However, crystallization could not be induced in pastes of beta-dicalcium silicate, a mixture of 90 percent C_3S and 10 percent C_3A, or cement.

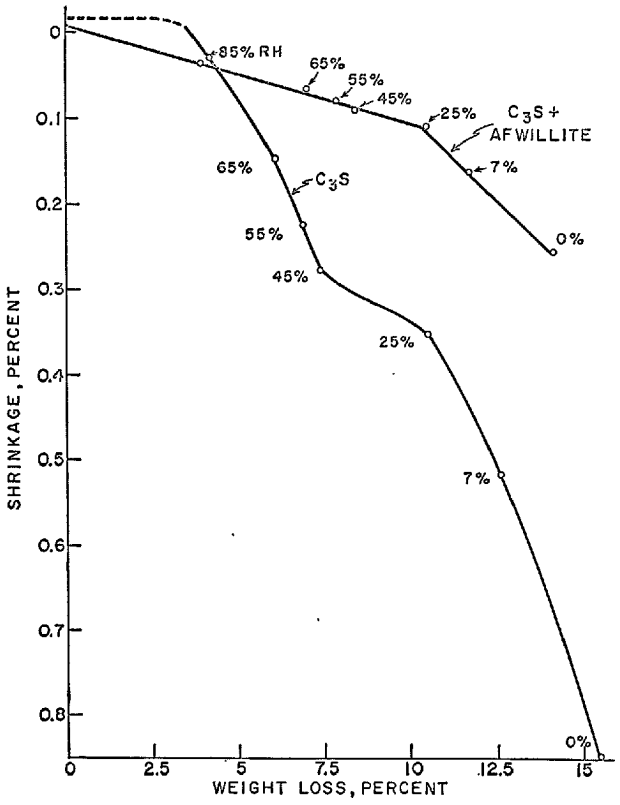

Fig. 6. *Nucleation by afwillite reduces the drying shrinkage of hardened tricalcium silicate pastes*

From the results obtained, it appears that the nature of the stable equilibrium state of the substituted calcium silicate hydrate in cement is still open to question. The difference in free energy between afwillite and the pure calcium silicate hydrate gel may be quite small. It is also possible that the introduction of appreciable quantities of sulfate or alumina into the gel to produce the material found in cement may reverse this free energy difference. Such an explanation would account for all results except the failure to nucleate crystalline afwillite from the dicalcium silicate paste. The presence of the stabilizer in that compound, however, may also have affected the free energy difference.

The Calcium Aluminate Hydrate Phase

Although the alumina and the ferric oxide can potentially form analogous hydrates in cement hydration, only the alumina is of interest in the present context; the cubic tricalcium aluminate hexahydrate, C_3AH_6, has long been recognized as a stable phase in the $CaO–Al_2O_3–H_2O$ system at room temperature, even though it is found to be unstable at temperatures just above the freezing point of water in the presence of excess lime (8). The ferrite analog, C_3FH_6, on the other hand, appears to be structurally unstable (7).

The stability of C_3AH_6 in the presence of sulfate and excess alumina has been clearly established. However, in the presence of sulfate and excess lime, the area of interest in cement chemistry, the picture is much less clear. Considerable controversy over this matter has appeared in the literature and has been summarized by Steinour (34). In relation to the cement-water system it must be noted that the presence of C_3AH_6 in hydrated cement pastes has not been observed by X-ray diffraction, even though a closely related cubic phase, the hydrogarnet, has been found, even at early ages. The latter phase may indeed be only metastable, since it is present only in small quantity throughout the hydration. This phase also appears incapable of nucleating the closely related C_3AH_6. Tests conducted at these laboratories indicate that sulfate inhibits the formation of C_3AH_6

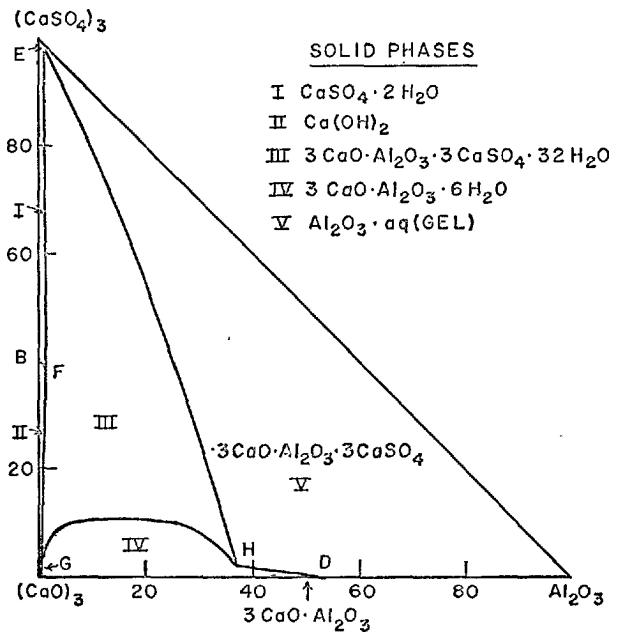

Fig. 7. *System* $CaO–Al_2O_3–CaSO_4–H_2O$ *(with alumina gel) at 25°C (Jones(46)). The diagram is distorted slightly at the left side to show the fields there more distinctly (from Reference 33)*

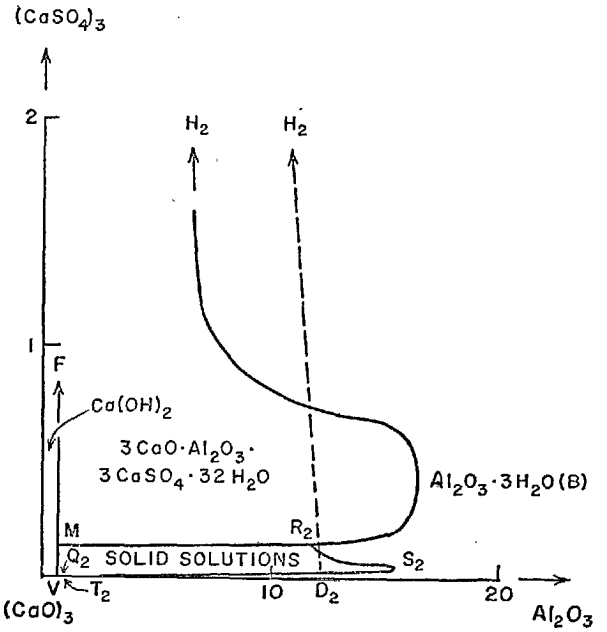

Fig. 8. *Portion of the system* $CaO–Al_2O_3–CaSO_4–H_2O$ *at 25°C showing the region of calcium sulfohydroxyaluminate hydrate (according to Jones(47), from Reference 33).*

in the cement-water system (11). In more recent studies of clinkers having high C_3A contents, C_3AH_6 was observed by diffraction to form in pastes, early and quite readily, in the absence of sulfate.

A previously unpublished study of the calcium sulfohydroxyaluminate hydrates is believed to throw additional light on the stability relations in the $CaO–Al_2O_3–SO_3–H_2O$ system. As background for the discussion of this study and for later reference, it is necessary at this point to review the principal features of that portion of the system where calcium hydroxide exists as a solid phase.

Figs. 7 and 8, from Steinour (34), show the features of interest. These figures are so-called Janecke projections and are particular representations of the four component system. An excellent discussion of this type of representation has been given by Purdon and Slater (35). In Fig. 7, the origin represents pure CaO. For convenience in considering the stoichiometry, the composition of an aqueous mixture, containing calcium, sulfate, and aluminate ions, is expressed in terms of moles of $(CaO)_3$, $(CaSO_4)_3$ and Al_2O_3. On this basis, the mole fraction of Al_2O_3 in the mixture is plotted along the abscissa and the mole fraction of $(CaSO_4)_3$ along the ordinate. Moles of water per mole of total solid can be visualized as being plotted along a third axis perpendicular to the paper. Solution compositions are then represented as surfaces in space. The lines in the figure are vertical projections of the boundaries of the fields of the various phases. The figure shows the liquid phase compositions for the "stable" equilibria at 25°C under the condition that free Al_2O_3, when present, occurs as a gel. The present paper is concerned only with the high lime portion of the system (along CaO–G–F–E in the figure), thus the form of the alumina is irrelevant.

Fig. 8 shows the situation of "metastable" equilibria at 20°C. Here the point G has been replaced by the segment MV. The point M represents the liquid phase composition in equilibrium with three solids: calcium hydroxide, ettringite, and monosulfate.

Studies of the effect of small percentages of alkalies on this system have revealed (34) that the boundaries of the fields shift only quantitatively in the high-lime region and that no new phases appear. Figs. 7 and 8 will therefore also be referred to in relation to appropriate systems containing alkalies.

In a major investigation of the calcium sulfohydroxyaluminate hydrates, three sets of slurries were made in which C_3A and $Ca(OH)_2$ in equimolar proportions were mixed in an excess of water with various quantities of gypsum necessary to introduce 0.1 to 1.1 mole of SO_3 per mole of alumina. These mixtures were agitated in polyethylene bottles for periods up to one year at temperatures of storage of 40°F, 73°F, and 100°F. Periodic examinations of the solid phases at

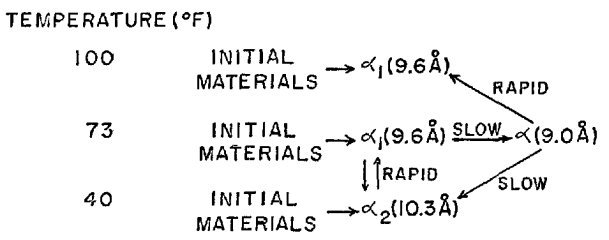

Fig. 9. *Stabilities and conversion rates of the crystalline forms of the low sulfate form of calcium sulfoaluminate hydrate.*

the storage temperatures were made by X-ray diffraction. After the final filtration, the wet solids were subjected to temperature changes while in the diffractometer.

The results shown in Fig. 9, for a mole ratio of $SO_3/C_3A = 1$, indicate that the structure of the monosulfate is highly dependent on temperature. The results shown duplicate in part those of Turriziani (36), whose notation is used here. The α_1 form is stable at 100°F; the α form, at 73°F; and the α_2 form, at 40°F. At 73°F, the α_1 form is produced first, either from the raw materials or by warming of the α_2 form. The α phase, once formed, is relatively stable toward cooling, but converts quite rapidly to the α_1 phase on heating.

The range of calcium sulfohydroxyaluminate hydrates found at SO_3/Al_2O_3 ratios from 0.7 to 1.0 indicated that the solid solutions are stable at 73° and 100° but not at 40°F, where they decompose into the α_2 form of the monosulfate and C_4AH_{19}. The range of d spacings for these calcium sulfohydroxyaluminate hydrates is 8.80–9.01 Å, with the higher spacings corresponding to higher sulfate contents. They are formed at both 73°F and 100°F, after initial formation of the α_1 form of the monosulfate. The rate of formation from the α_1 form was found to decrease rapidly with increase in sulfate content of the system, requiring years at sulfate contents near unity.

It is believed significant that in those mixtures with the very low SO_3 contents stored at 100°F, both C_3AH_6 and the lowest sulfate form of the calcium sulfohydroxyaluminate hydrate were formed, with no trace, in the diffraction patterns, of the ettringite that would be formed from decomposition of the solid solution into the phases usually considered stable. This result would tend to indicate stability for the solid solution at that temperature, and would establish the existence of a boundary in Fig. 8 between the fields of the hexagonal solid solution and the cubic calcium aluminate hydrate. At both 40°F and 73°F, the excess alumina in these low sulfate mixes appeared as C_4AH_{19}. It is to be expected that the C_4AH_{19} would eventually convert to C_3AH_6 and $Ca(OH)_2$ at 73°F.

It is therefore proposed that another invariant point occurs between M and V in Fig. 8 that represents the liquid phase composition in equilibrium with $Ca(OH)_2$, C_3AH_6, and the lowest sulfate form of calcium sulfohydroxyaluminate hydrate as the solid phases. The segment from that point to V would then be the boundary between a C_3AH_6 field and the $Ca(OH)_2$ field. The complete phase diagram would then include a new boundary extending from the low limit of the solid solution field on MV to some point on MR_2, to the left of the field of Al_2O_3.

An exploratory test, completed while the present paper was being written, provides somewhat more direct evidence for the stability of the lowest sulfate form of calcium sulfohydroxyaluminate hydrate. The test was based on various previous studies that indicated a high degree of stability of the α_1 form of the monosulfate in the presence of excess lime over the temperature range 100–190°F. In the present test a slurry containing this form of the monosulfate together with C_3AH_6 and excess lime was stored at 100°F. After 3 weeks, weak diffraction peaks appeared for the lowest sulfate form of the calcium sulfohydroxyaluminate hydrate. The estimated 3–4 percent of the reaction product are believed to constitute direct evidence for its thermodynamic stability at 100°F.

In another study, the details of which are beyond the scope of the present paper, it was found that slurries of appropriate proportions of C_3AH_6, $Ca(OH)_2$, and calcium carbonate formed the calcium hemicarboaluminate hydrate on prolonged agitation at room temperature. It was thus demonstrated that C_3AH_6 is not stable with respect to formation of the $C_3A \cdot \frac{1}{2}CaCO_3 \cdot \frac{1}{2}Ca(OH)_2 \cdot 12H_2O$ in the $CaO–Al_2O_3–CO_2–H_2O$ system.

Phase Equilibria and the Early Hydration Reactions

Although the early stages of portland cement hydration cannot represent equilibrium states, the studies that have been made of the equilibria among the phases involved have provided considerable insight into the nature of the reactions that are occurring. The reactions that occur in this heterogeneous system are relatively slow in comparison with those occurring, for example, among inorganic ions in aqueous

solution. The processes limiting the rates of reaction appear to be those of solution and of crystallization that occur at interfaces between solid and liquid phases. The nature of these processes will naturally depend upon the composition of the liquid phase at these interfaces. For very rapid reactions, this composition will be only locally uniform; for the slower reactions in pastes, on the other hand, the composition of the entire liquid phase can be considered uniform. Thus, in the absence of high activation energies, the reactions at these interfaces can be considered as heterogeneous equilibrium situations that involve shifts in composition as the hydration reactions continue. The existing evidence indicates that this description furnishes adequate mechanisms for many features of the early hydration reactions. It is in this sense that the stages of early hydration can be related to phase equilibria in the cement-water system.

The earlier writers on phase equilibria of those aqueous systems that include components of cement made predictions only reluctantly with regard to the course of the early hydration reactions. This reluctance had several based, namely, that slow reaction rates could prevent attainment of a predicted equilibrium situation, that the presence of other cement constituents would cause radical changes in the limited systems that they were studying, that there was no clear-cut experimental evidence to support their conclusions, and, finally, that there was considerable uncertainty regarding the nature and stability of the solid phases present in cement pastes, or even in some of the more limited systems studied. A major cause of the uncertainties was probably the presence of products from rapid local reactions and from carbonation. Present knowledge largely confirms the premise that many aspects of the early hydration are entirely predictable from the phase equilibrium studies.

The background for the present interpretation comes from the published studies on phase equilibria, from the more recent studies of the early hydration reactions and, finally, from the excellent recent studies of the composition of the liquid phase (37, 38, 39). The approach used here is to interpret the hydration process from the time of the first contact of the cement with water to the time of formation of the ultimate hydration products already described. Because of the nature of this approach, little attention will be given to the components of the original cement. It will generally be assumed that the various components diffuse into the solution until the sources of the components are exhausted. A major exception is the ferrite phase, for which the results from Mössbauer spectroscopy, as well as evidence from X-ray diffraction (40) indicate a considerable delay in initiation of hydration. It is therefore assumed that ferrite is initially "absent".

Of the various recent studies of the liquid phase at early ages, that of Lawrence (37) appears to be the most complete and to give the most detail. The results of this study are used in the following sections wherever references to a uniform liquid phase composition are appropriate.

Fig. 10 is a reproduction of one of Lawrence's plots of liquid phase composition, up to about 16 hours, for a cement paste having a water-cement ratio of 1.0. This figure displays most of the features relevant to the present discussion. After the initial contact with the cement, the liquid phase has high lime and sulfate concentrations. The alkalies of the cement are released gradually. The lime concentration passes through a maximum, which is accompanied by a drop in sulfate concentration. This sequence is accompanied by an increase in the alkalinity (basicity). The composition then remains relatively constant with slow increase in alkalies until rapid decreases in lime and sulfate concentration occur, accompanied by a rise in alkalinity. The cement composition was not given, but the plot indicates that the material is undersulfated, by the present criterion, since sulfate depletion occurs before 18 hours. Most of the features of the plot are included in the interpretation given below.

First Contact Between Cement and Water

The period of first contact between cement and water is a time of highly energetic reaction, as evi-

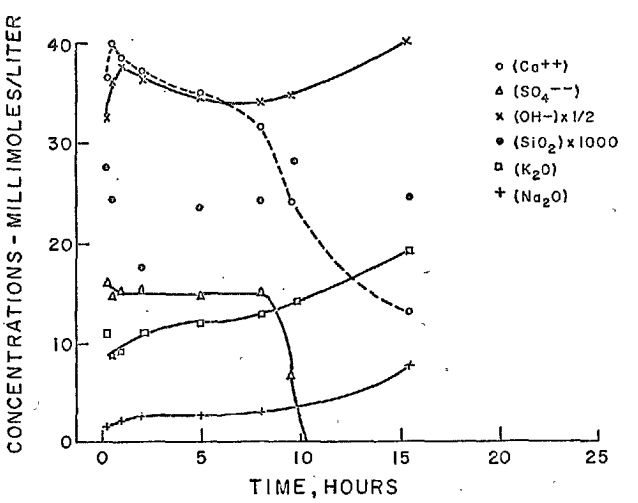

Fig. 10. *Composition of the liquid phase during early hydration reactions of a cement at 25°C (from Reference 37).*

denced by the rate of heat evolution. It is to be expected that solution compositions and temperatures vary widely over the entire body of liquid during this brief period and that the highest concentrations and temperatures occur in the liquid layer closest to the cement particles. It is therefore not surprising that considerable uncertainty has existed regarding the first alumina-containing phase to be precipitated.

Under an assumption of localized approaches to equilibrium, it is perfectly possible for a variety of immediate hydration products to form. The solid product would merely depend upon the local temperature and the local concentrations of lime, sulfate, silica, alumina, and alkali existing at the surface of the hydrating cement particle. This expected variety has in fact actually been observed in an electron microscope study of the products of brief periods of hydration (29). By means of a replica technique, various products formed after as brief a hydration period as 30 seconds have been observed. Rods of ettringite, plates of calcium aluminate hydrates probably containing various amounts of sulfate, and cubic crystals of hydrogarnet were observed against a background of gel, as might be expected from local variations in alumina and sulfate ion concentrations.

Dormant Phase

After the immediate reactions the liquid phase is supersaturated with calcium hydroxide and saturated with calcium sulfate. Alkalies are also present. Unfortunately, values for the alumina content of the liquid phase during that period are not available but are known to be very low. Relative to the components shown in Fig. 7, or its analogue at low alkali concentrations (41), the solution composition could be represented along a metastable extension of the boundary EF toward G. This point could not lie on the boundary FG, since this position would imply the presence of calcium hydroxide as a solid phase. Along the boundary EF, the solid phases are calcium sulfate and ettringite, as in the present case. During the period before the crystallization of calcium hydroxide, when the rate of heat evolution is very low, the alumina, which is already dissolving from the tricalcium aluminate, reacts with the calcium sulfate in solution to produce the solid ettringite. Thus, as shown for the first six hours in Fig. 10, the solution composition remains relatively constant except for changes in calcium hydroxide supersaturation as represented along the prolongation of the boundary EF in Fig. 7. The increase in supersaturation tends to decrease the sulfate concentration because of the common ion effect, as shown in Fig. 10 for the initial hour. The alkalinity remains quite constant during the period because the alkali released from the cement reacts with the calcium sulfate to form calcium hydroxide (42):

$$2KOH + CaSO_4 \rightarrow Ca(OH)_2 + K_2SO_4 \qquad (1)$$

Since the alumina concentration at F is very small, and is probably decreased by the increase in lime, the metastable extension of EF must be almost parallel to the $(CaO)_3$–$(CaSO_3)_3$ axis and probably turns slightly toward that axis. The effect of the release of alkalies on alumina concentration has not been measured directly, but can be estimated from the phase equilibrium studies, which indicate that the alumina concentration at point F in Fig. 7 is decreased in the presence of alkalies.

So far nothing has been said about the silicates. It has been indicated, however, that the liquid phase rapidly becomes supersaturated in lime. This calcium hydroxide must result primarily from the reaction of water with the alite phase. The crystallization of $Ca(OH)_2$ from this solution usually initiates the setting process.

Reactions at the Time of Set

The formation of crystalline calcium hydroxide is accompanied by a great increase in the rate of cement hydration. The alite phase hydrates rapidly with considerable heat evolution and deposition of calcium silicate hydrate gel. In view of the high sulfate and low alumina concentrations in solution at this time, it is to be expected that the gel formed contains appreciable sulfate. This composition has been verified for C_3S hydration by Celani and coworkers (38), who used their results to verify that the gel was the location of "missing" sulfate, as postulated by Kalousek (43) in a very careful study of the early hydration reactions by differential thermal analysis.

The phase equilibrium diagram of Fig. 7 indicates that the precipitation of the $Ca(OH)_2$ should produce a decrease in calcium ion concentration and a corresponding increase in sulfate ion in solution. Fig. 10 does not show this effect because the gypsum becomes depleted during this period. Other data of Lawrence do, however, show the anticipated result. The system moves from the metastable state to point F and remains there as long as the three solid phases, ettringite, calcium hydroxide, and gypsum are present in the system.

A discussion of the variation of the lime to silica ratio in the gel during early hydration can be found in

another paper in the present symposium (44).

Hydration of the Aluminate and Ferrite Phases

For a cement of the type being considered, the solid gypsum in the cement-water system becomes depleted between 18 and 24 hours after initial contact of the cement with water. This period is marked by a final rise in the rate of heat evolution. The reactions that occur at this time have again proved to correspond to expectations arising from phase equilibrium studies.

When the solid gypsum is no longer present, the requirements for point F in Fig. 7 are no longer satisfied. The sulfate ion concentration in solution drops as this ion continues to react with the tricalcium aluminate, which is still slowly dissolving to produce a further crystallization of ettringite. The loss of sulfate from solution is accompanied by the reverse reaction of Eq. (1) and a consequent rise in alkalinity, as shown in Fig. 10 for the period after 6 hours. The solution composition moves from point F toward point M in Fig. 8, the invariant point at which the three solids calcium hydroxide, ettringite, and the monosulfate can coexist. When the sulfate concentration at point M is reached, the monosulfate begins to precipitate.

X-ray diffraction and Mössbauer studies have produced evidence that the rapid hydration of C_3A is accompanied by rapid hydration of the ferrite phase at this point. Although the delay of the ferrite hydration in the cement studied by Wittmann appears lengthy, the result is understandable because the composition indicates that the cement may be "oversulfated". As already indicated, the reaction product of the ferrite appears to be the low sulfate form of calcium sulfoaluminoferrite hydrate. During this period, therefore, the ettringite reacts with C_3A and C_4AF to produce monosulfate and the complex ferrite hydrate. Lawrence (37) has observed that the sulfate concentration at this transition point is higher when there is a higher alkali concentration.

Although the precise mechanism for the high rate of reaction at point M in Fig. 8 is unknown, it appears possible that the decreased sulfate concentration causes a rapid solution of ettringite and a high reactivity of the C_4AF and the remaining C_3A phases. This explanation provides a mechanism that is completely analogous to the observed increase in rate of alite hydration as the lime supersaturation decreases at the time of setting. It is assumed here that the process involves a dissolution of the ettringite, and of the anhydrous aluminate and ferrite phases followed by a reaction in the liquid phase to produce the solid low-sulfated products. The rapid increase in reactivity of the anhydrous phases can be attributed to dissolution of an ettringite coating on the tricalcium aluminate. No explanation has yet been found for the absence of any very early hydration product for the ferrite phase of the cement studied by Wittmann.

The Wittmann results thus indicate that the sulfate is preferentially taken up by the aluminoferrite rather than by the aluminate. The absence of any iron-containing phase other than the sulfoaluminoferrite indicates that the equilibrium concentration of sulfate from this phase must be less than that for the corresponding aluminate phase at point M in Fig. 8. The rate of ferrite hydration must be controlled by some factor other than solution concentration, since the hydration is much slower than the rate of solution of the ettringite.

Electron microscope evidence indicates that some hydrogarnet phase forms during this period (45). No good explanation exists for this phenomenon, other than that widely varying local solution concentrations during the rapid reaction may be the cause.

Finally, after the ettringite is depleted, the sulfate ion concentration again decreases. The remaining C_3A and C_4AF react with the monosulfate to give the lowest sulfate form of calcium sulfohydroxyaluminate hydrate and the calcium sulfoaluminoferrite hydrate; part of the alumina also goes into the gel. The system moves along the line MV in Fig. 8 to the invariant point involving the lowest sulfate solid solution. This stage of the hydration is not attained by the cements with low C_3A contents. Thus, the final products from hydration of the C_3A and C_4AF phases in these cements are the calcium monosulfoaluminoferrite hydrate, the monosulfate, and ettringite; a portion of the C_4AF apparently remains unhydrated indefinitely.

The continued hydration of the remaining calcium silicates and the C_4AF result in the ultimate hydration products discussed earlier.

Gel Composition

Few direct measurements are available on the extent of substitution by other cement constituents in the calcium silicate hydrate gel formed during cement hydration at ordinary temperatures and at the water-cement ratios found in concrete. The type and degree of substitution must depend both on the composition of the liquid phase and on the rate of the process.

At equilibrium, a given gel composition must be in contact with a liquid phase of definite composition. From the known variations in the liquid phase and

from the information available regarding the stoichiometry of the hydration process during the early hydration reactions, as already described, it is possible to survey the type of variations in gel composition that can occur.

With respect to the alkalies, the results of Powers and Steinour (23) and the original work already described indicate the orders of magnitude to be expected. The liquid phase compositions obtained by Lawrence (37) indicate the variations in the alkali concentrations that occur during the hydration process. The actual alkali content of the gel depends primarily on the rate of substitution, which appears to be slow.

The available Mössbauer spectrometer results indicate the degree of iron substitution to be very small.

For a discussion of the degree of substitution by alumina and sulfate ion, it is convenient to consider the variations in solution composition shown in Figs. 7 and 8. These variations have been plotted schematically in Fig. 11. For the cement-water phase equilibria, the values obtained for the $CaO–Al_2O_3–SO_3–H_2O$ system must be modified by the presence of alkalies, ferric oxide, and silica. The numbers in Fig. 11 therefore represent only orders of magnitude and are based on exploratory tests below the level of saturation of calcium silicate hydrate gel by the substituents (45).

For each point on the curve of Fig. 11, there must correspond an equilibrium gel of definite composition in the presence of calcium hydroxide as an additional solid phase.

The points of interest are labeled to conform with the corresponding points in Figs. 7 and 8, which represent the corresponding silica-free system. Thus point B represents the concentration of SO_3 in the liquid phase in contact with calcium sulfate, calcium hydroxide, and gel saturated with SO_3, similar to that described in reference 21. Point F represents the alumina concentration necessary to initiate precipitation of ettringite. Point M represents an invariant point where the solid phases are $Ca(OH)_2$, the monosulfoaluminoferrite, ettringite, and the gel. This point has been approximated in original experiments with the iron-free system in which C_3S was hydrated in the presence of about 40 percent of its weight of calcium monosulfoaluminate hydrate. Ettringite was formed during the hydration; its proportion increased with the degree of C_3S hydration. Evidently, the gel

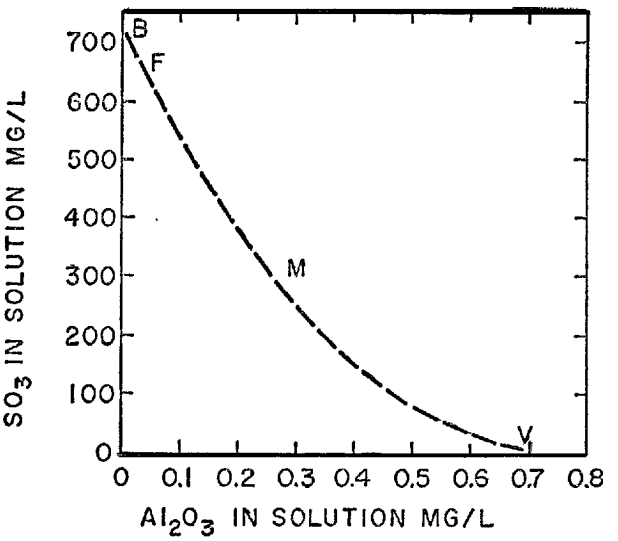

Fig. 11. *Schematic phase diagram of the variation in liquid phase composition during cement hydration.*

at this equilibrium point contains more Al_2O_3 than SO_3 on a molar basis. The portion of the curve to the right of M then represents those compositions higher in alumina where the solid phases are, successively, the monosulfate, the solid solution sulfohydroxyaluminate, and finally, C_4AH_{19}. Point V would then represent a sulfate-free system in which the solid phases are $Ca(OH)_2$, C_4AH_{19} or C_3AH_6, and an alumina-saturated gel similar to that described in reference 21.

Good experimental evidence exists to indicate that shifts in gel composition during cement hydration are sufficiently rapid to attain or at least closely approach equilibrium. The high sulfate content of the gel at point F has been observed (38, 43). No crystalline alumina-containing phase free of sulfate, such as C_3AH_6 or C_4AH_{19} has been observed as the hydration proceeds from F through M toward V. This fact, together with the high alumina content of the gel at ultimate hydration indicates that the alumina must be absorbed by the gel rapidly during the hydration of the C_3A and C_4AF remaining at point M after the gypsum has become depleted. Presumably, there is a simultaneous release of SO_3 from the gel during this period to participate in the formation of the calcium sulfoaluminoferrite hydrate.

Conclusion

No attempt will be made here to summarize the various equilibria that have been described. It is of

interest, however, that the major features of cement-water phase equilibria can be condensed into a diagram of the type shown in Fig. 11. A series of curves for various alkali contents on such a plot would represent the appropriate small portion of the seven-component system $CaO–SiO_2–Al_2O_3–Na_2O–K_2O–SO_3–H_2O$. The calcium silicate hydrate gel and calcium hydroxide are always present as solid phases. There must be definite equilibrium values for the lime and silica in solution at each point of the curves for alkali content. The gel composition should vary in accordance with the equilibrium liquid phase. Other solid phases are associated with the various ranges of solution composition. By the use of a third dimension, the effect of Fe_2O_3 content could be represented as well.

Oral Discussion

Shunro Ueda and Renichi Kondo

The effect of the addition of the seed crystals on the rate and mechanism of cement hydration was mentioned in your paper and also briefly in our principal paper. In your case, the reaction may be promoted and the physical properties of the paste are remarkably changed. It seems that not only the formation of the outer product but also that of the inner product are affected considerably. Especially when the composition of the seed crystal is similar to that of the hydrate, the transformation of the ordinary hydrate into the stable hydrate may occur easily because the migration of atoms is not needed during the transformation.

Whether the additive acts as a seed or as a catalizer may be determined by the identification of the product.

Oral Discussion

Heinrich zur Strassen

The authors as well as Dr. Roberts (1) confirm their former results that the low-carbonate phase with a basal spacing of 8.2 Å is only a semicarbonate. Some years ago, we were of the opinion that the low-carbonate phase would be a quarter carbonate (2), but now we have found, as explained in our Written Discussion (3) to the Principal Paper No. II-2 that there exists a solid-solution range between semicarbonate and quarter carbonate.

The solid solution is not easily to be detected because all compositions have the same basal distance of 8.2 Å. The most convincing experiment is reaction 4 in Table 2 of the Written Discussion: Quarter carbonate free from rests of tetracalcium aluminate hydrate is prepared and controlled by X-rays (Fig. 1).

This substance is shaken together with monocarbonate in the molar ratio 2 to 1 in aqueous suspension. After one week, the monocarbonate has disappeared completely whereas the remaining reflections which now must belong to the semicarbonate phase have not changed their position.

The disappearance of monocarbonate would be impossible if there would exist only a single phase of lower CO_2 content than the monocarbonate phase, either a quarter carbonate as we thought before, or a semicarbonate as the other authors believe.

Authors' Closure

Paul Seligamann and Nathan R. Greening

Dr. zur Strassen has not indicated the temperature at which his tests were made. It will be recalled that our tests were made at 40°F to avoid formation of the cubic phase, C_3AH_6. At room temperature, the cubic phase does indeed form, but its presence is manifested by only a very weak X-ray diffraction pattern in comparison with that of the calcium hemicarbonate hydrate. This pattern is very easily overlooked. The tetracalcium aluminate hydrate, on the other hand,

has a pattern with an intensity comparable with that of the carbonated phase.

We have made tests of the type described by Dr. zur Strassen both at room temperature (73°F) and at 40°F. The results confirm our original conclusion. Room temperature mixes with a molar CO_2/Al_2O_3 ratio between 0.25 and 0.5 show little beside the hemicarbonate pattern; cooling to 40°F, however, reveals the true situation as the cubic hydrate converts to the hexagonal and the intense lines of the latter phase appear. We have no reason to expect that the formation of the C_4AH_{19} pattern is accompanied by any shift in the binding of the carbonate in the mix, since there is no change in the intensity of the hemicarbonate pattern.

In response to the discussion by Mr. Ueda and Dr. Kondo, the paper perhaps did not make sufficiently clear that the pastes whose properties were reported in Figs. 5 and 6 and Table 3 were examined by diffraction and found to contain crystalline afwillite rather than the gel obtained without nucleation. The properties are thus attributable to the change in paste structure rather than to the changed reaction rate, which itself appears characteristic of the transformation to the afwillite rather than the gel.

SESSION II-4 KINETICS OF HYDRATION OF CEMENTS

Principal Paper Kinetics and Mechanisms of the Hydration of Cements

Renichi Kondo* and Shunro Ueda**

Synopsis

This paper deals with the results obtained by the authors as well as by reviewing related literatures which appeared mainly during 1960 to 1967 in order to provide the present, advanced knowledge on the kinetics and the mechanisms of hydration of cements.

The accuracy of conduction calorimetry and quantitative X-ray diffractometry among methods for the estimation of the degree of hydration have been greatly improved and they are being widely used. While the measurements on the surface electron diffraction and the pore size distribution are still under development, they are already providing useful information. Interesting results can also be expected by the application of electron microscope either with electron microprobe analyzer attached or of the scanning type.

Such chemical properties as hydraulic, latent hydraulic and pozzolanic of cement components as well as the reaction with additives are compared and discussed. An attempt was made to explain the concepts of the so-called topo-chemical and through solution. Important factors which are dealt with are the fineness of cement, the water cement ratio and the curing temperature.

Since the rate of hydration is closely related with the properties of the hydrates, it is necessary to study the concentration and constitution of the liquid phase, nucleation and crystal growth, the composition and morphology of hydrates, the pore structure, and permeability and diffusion.

As the rate and mechanism of hydration vary, in general, with the progress of reaction, it is divided into 5 stages and each of these are discussed in detail with reference to the hydration of tricalcium silicate as an example. Some comments are made on the rate equations of the solid state reaction which appeared previously and an equation which explains the rate of the whole hydration process is derived in consideration of the above mentioned complexity in the process.

Introduction

As most inorganic cements harden by the hydration reaction, investigations concerning the rate and mechanism of their reaction not only have scientific interest but also practical importance. In this paper chiefly the hydration of pure substances will be dealt with to elucidate fundamentally the rate and mechanism of their reactions. Problems such as the hydration of actual cement or the rate and mechanism of the development of strength are not described in this paper. These problems will be explained by the other authors in this Symposium.

Most researches up to 1960 have been presented at the Washington Symposium. Particularly the stoichiometry, kinetics and energetics of the hydration of portland cement have been described by Copeland, Kantro and Verbeck (1). Accordingly fundamental researches concerning subjects reported from 1960 to 1967 will be reviewed in this paper, together with some results obtained by authors. The contents of this paper are under the following headings:

* Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Tokyo, Japan.

**Research Laboratory, Nihon Cement Co. Ltd., Tokyo, Japan.

Determination of the degree of hydration
Reactivities of cement components and types of reaction
Several factors concerned with the rate of hydration
Properties of hydrates concerned with the rate of hydration
Relation between the rates and mechanisms of hydration

Determination of the Degree of Hydration

The degree of the hydration of cement components is measured by various methods. The degree of hydration is usually shown by the amount of residual reactant as the compositions and the crystallinities of hydrates change widely with the progress of the reaction. We can measure the amount by X-ray diffractometry and optical observation but there are still problems concerned with the accuracy. The former is more hopeful than the latter.

The determinations of the amount of non-evaporable water and free $Ca(OH)_2$, and also the measurements of the electric conductivity, the heat of hydration and the strength conveniently give the relative values for the degree of hydration with rather good reproducibility.

Differential thermal analysis, thermo-gravimetric analysis, differential thermo-gravimetry, infra-red absorption, electron microscopic observation, and selected-area electron diffraction are frequently used for studying the hydration mechanism.

Besides the phase-contrast microscope, the recently-developed electron microprobe analyzer and scanning electron microscope will find use in the near future. Ueda, Hashimoto and Kondo (2) applied the method of surface electron diffraction to the study on the hydration process.

The characteristics and the problems involved in the methods commonly used with respect to the rate and the mechanism of hydration are discussed.

X-ray Diffractometry

The measurement of quantities of unhydrated reactants using X-ray diffractometry have been attempted as a useful method for determining the degree of hydration since the development of X-ray diffractometer. The reliability of this analysis has been remarkably improved recently. The large error by this analysis is due to the difference in the distortion and the fineness of powder. When the unhydrated particle is enveloped by the hydrates, the reproducibility is especially reduced. The accuracy is improved by analysis with the digital computer.

The following two methods are generally used in quantitative X-ray analysis. Seligmann and Greening modified X-ray sample holder to provide control of the temperature of the sample and the humidity and composition of the ambient atmosphere surrounding the sample, and studied the reaction occurring in a mixture of tricalcium aluminate, calcium hydroxide, gypsum and water (3), and the dehydration reactions of calcium aluminate hydrates (4). Angstadt and Hurley observed that the hydration rate of the alite in portland cement paste reaches the maximum after 7 hours in the case of the internal standard method, whereas it is reached slightly faster in the hydration of neat paste on X-ray goniometer (5)(6). Tsumura and Kawachi (7) and Tsumura (8) determined the hydration rate of each clinker mineral in paste form by a similar method. The operation of this direct method is very easy but it has some defects such as the preferential deposition of hydrates on the surface of the film, the appearance of a large halo by film and hydrated layer, and the amount of unhydrated reactant is apt to be estimated lower than the real amount.

The most common quantitative X-ray diffraction analysis is the internal standard method. In this method, the effect of mass absorption coefficient can be neglected theoretically, however Smolczyk (9) pointed out that the correct application of mass absorption coefficient must be considered in actual experiments. The calibration curves of alite, $Ca(OH)_2$ and ettringite were obtained by Smolczyk (10) after the theoretical correction for loss on ignition of hydrates has been made since the presence of H_2O and CO_2 decreases the diffraction intensity. The curves of alite and $Ca(OH)_2$ are in accordance with the theory, but a large error still exists in that of ettringite. The results of the progress of hydration determined by X-ray diffractometry are shown in Fig. 1.

In the estimation of the degree of hydration using X-ray diffractometry, it is necessary to calibrate the presence of poor-crystalline hydrates particularly at the early stage and the formation of products on the surface of unhydrated grain in order to obtain better accuracy. The diffraction lines $2\theta = 41°$ and $43°$ CuKα were selected for C_3S (tricalcium silicate) and MgO as the internal standard respectively in the estimation of the degree of hydration of C_3S by the

authors. It is necessary to repeat measurements 12 times in order to obtain a mean value with an accuracy as high as $2\sigma = 4\%$.

Calorimetry

The heat-of-solution, the adiabatic and the conduction calorimeters are used for the measurement of the heat of hydration. In the measurement by the heat-of-solution continuous result of hydration heat cannot be obtained, but it is possible to accurately measure the heat of hydration of the sample curing for a long time. Continuous curve of temperature change can be obtained with the adiabatic calorimeter but it is not suitable for obtaining the heat change for long time and it has the defect of change in curing temperature due to heat liberation. The conduction calorimeter which was adopted by Lerch (11) is most suitable as heat can be obtained continuously at almost constant cured temperature and in addition, it is self-recording. This type of calorimeter has been made smaller by Danielson (12), Stein (13), and Monfore and Ost (14), and also it has made possible the measurement of several grams of synthesized sample.

The conduction calorimeter expresses differentially the relation between the heat liberation and the curing time.

$$q = \sigma \Delta T + H_{\text{eff}} \frac{d(\Delta T)}{dt}$$

where q is the heat flows into the container per unit time dt, σ is the coefficient of heat transfer, ΔT is the temperature difference between the container and an isothermal body with a large heat capacity, and H_{eff} is the effective heat capacity of the sample, container and heat conductor. The temperature change of the isothermal body shifts the base line, however,

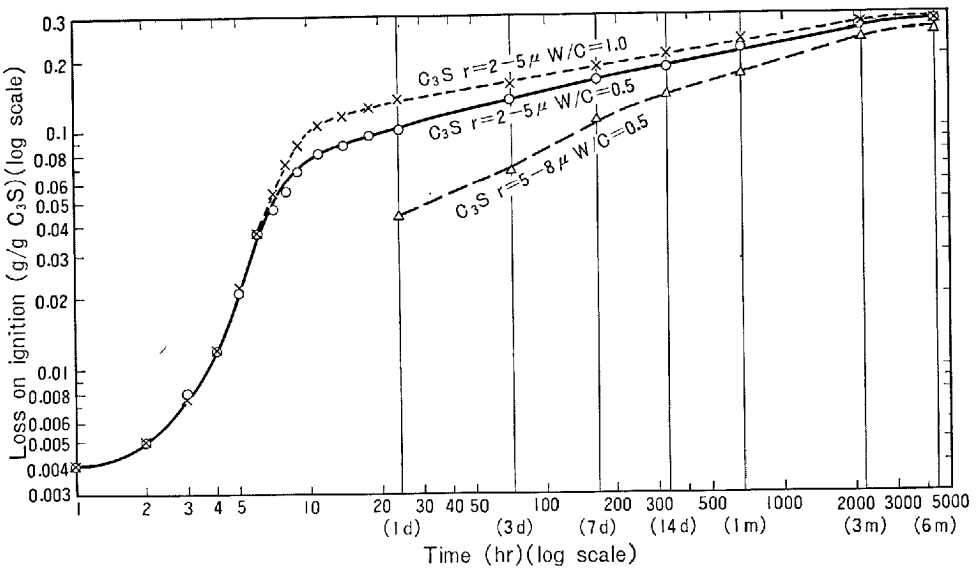

Fig. 2. *Change in content of non-evaporable water per original C_3S with progress of hydration*

the isothermal body and container are coupled by relatively good heat conductor in a conduction calorimeter. In order to remove this defect the twin-type conduction calorimeter has been developed and widely used, in which two of the same kind of calorimeter are differentially connected to offset the various heat changes. The hydration rate and mechanism by the results of heat liberation will be discussed later in detail.

The same reaction is not carried out from the early stage to the later stage in the hydration of cement, and particularly at the early stage unstable products are formed to liberate low heat of hydration compared with the degree of hydration. Accordingly, the absolute value of the degree of hydration reaction cannot be determined by the heat evolution as in the case of the amount of free $Ca(OH)_2$ and the thermo-gravimetric result. However, the results of calorimetry indicate a parallel tendency with the degree of hydration reaction obtained by X-ray diffractometry. It is convenient to study the effect of the factors on the rate of hydration as the relative value of the degree of hydration can be obtained with high sensitivity especially at early stage.

Chemical Analysis

The quantity of the non-evaporable water of hydrated sample depends on the drying conditions. Copeland and Hayes (15) revised the evacuated drying method at the temperature of dry ice (−79°C). They asserted that the time to reach an end point is usually shorter, and that the partial pressure of water vapor can be maintained constant in 0.5×10^{-3} mmHg with great ease, and that the obtained value is more nearly equal to the chemically combined water. However it must be considered that most of the combined water in some aluminate hydrates, ettringite and gypsum is lost under this condition.

The amount of the non-evaporable water in cement paste, as is shown in Fig. 2, increases with the curing time to give a similar result as the curve of the reduction of reactant. But the former result does not coincide exactly with the latter, as the stoichiometry of products is indefinite at the early stage of hydration. Kondo, Ueda and Kodama (16) showed that the molar H_2O/SiO_2 and CaO/SiO_2 ratios of calcium silicate hydrate changed very irregularly within 24 hours.

The amount of free $Ca(OH)_2$ is determined by the Lerch-Bogue method (17), Franke method (18), X-ray diffractometry and thermal measurement method. Yamaguchi, Takemoto, Uchikawa and Takagi (19) pointed out that in Lerch-Bogue method a small part of the lime was removed from the hydrate due to heating of the sample for a long time, whereas a single extraction by the Franke method did not come even close to removing all the free $Ca(OH)_2$. Brunauer and Greenberg (20) described that the free $Ca(OH)_2$ could be accurately determined by modified Franke method characterized by multiple extraction. In our

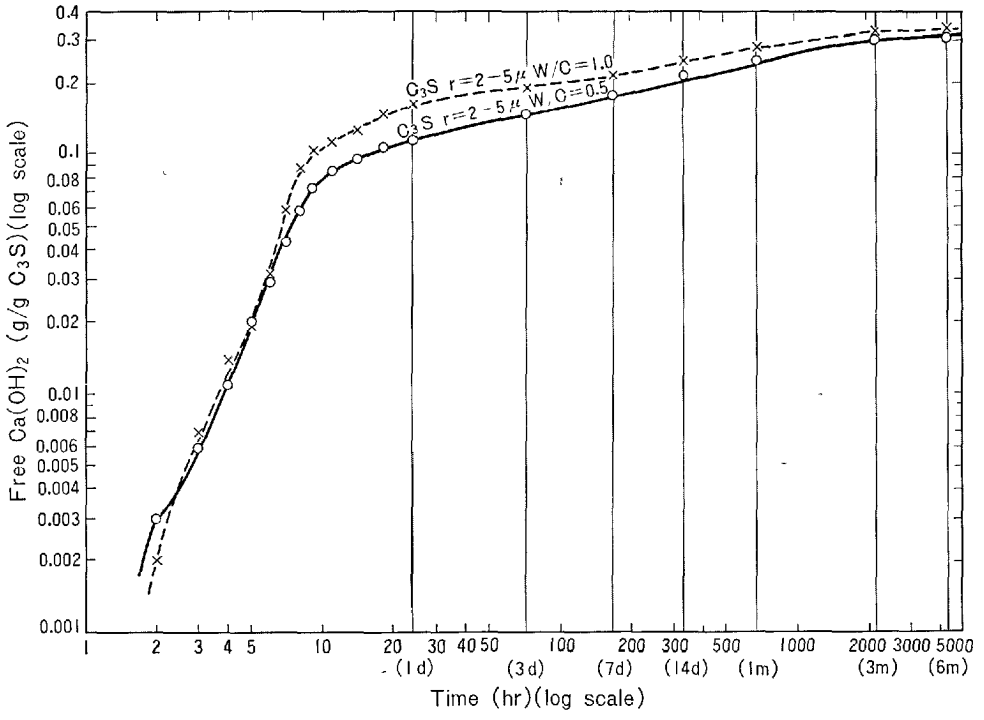

Fig. 3. *Change in content of free* $Ca(OH)_2$ *per original* C_3S *with progress of hydration*

laboratory we adopted the modified multiple extraction method and obtained the results of Fig. 3. One of the reasons for the different compositions of calcium silicate hydrate given by the different investigators may be attributed to the difference in the experimental condition.

Chemical analysis and the measurement of electric conductivity of the liquid phase with the progress of reaction are frequently carried out. The concentration and constitution of liquid phase has indispensable effect on the nucleation and crystal growth of the hydration product.

Surface Area and Pore Size Distribution

The multiple adsorption theory has been applied to the measurement of surface area as the BET method (21). Not only the surface area, but also the pore size distribution and the shape of the open pore of hardened cement paste can be determined by the measurement of adsorption and desorption isotherms. A greater part of the surface area of hardened sample is due to the poor crystalline C–S–H gel. There have been many discussions on the adsorbate used and the surface area of calcium silicate hydrate in water vapor is from 2 to 3 times that in nitrogen gas. Regarding this matter, Kalousek (22) pointed out that the smaller size of water molecule enabled it to penetrate into pore spaces which were inaccessible to the large nitrogen molecules. However the pore size distribution calculated from nitrogen adsorption by Eipeltauer, Schilcher and Czernin (23) indicates that there are no pores of less than $d = 16$ Å. This value is larger than the size of nitrogen molecule, so they proposed that nitrogen adsorption showed the true surface area, as persorption phenomena is caused by water vapor adsorption such as is seen in zeolite. On the other hand Brunauer, Kantro and Weise (24) pointed out that nitrogen adsorption did not measure the true surface area because of leading to negative surface energy value in C–S–H gel.

The differences of surface area due to the difference in water cement ratio, according to Hunt (25), are small at 1 day but become very large as hydration proceeds. Besides, Mikhail and Selim (26) showed that water vapor always gave larger areas than the other gases of larger molecule, and gases of moderate molecules, such as nitrogen and methanol, resulted in different values of surface area depending on the difference in water cement ratio as shown in Fig. 4.

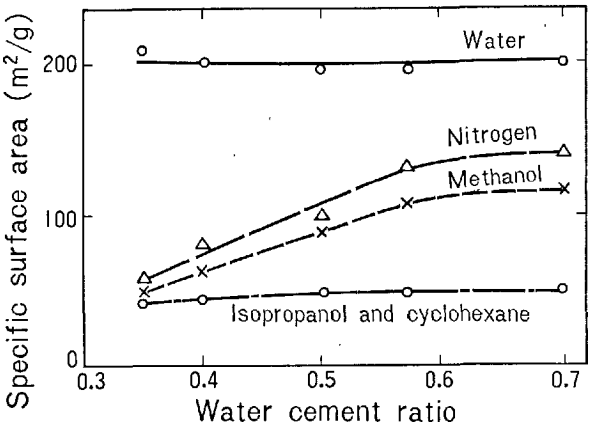

Fig. 4. *Variation with water cement ratio of surface area available to the different adsorbates. After Mikhail and Selim(26)*

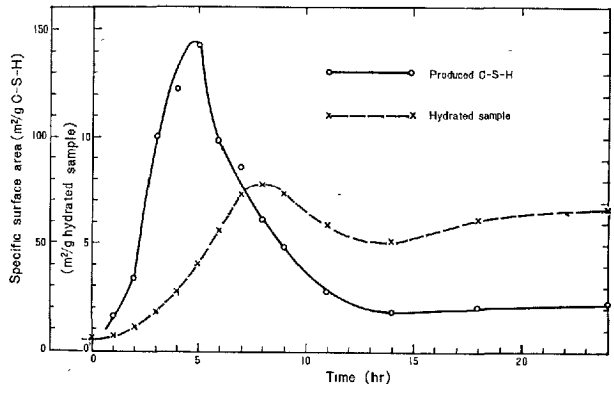

Fig. 5. *Change in specific surface area of hydrated* C_3S *($r = 2 \sim 5\mu$) with progress of hydration. ($W/C = 1.0$, at 25°C)*

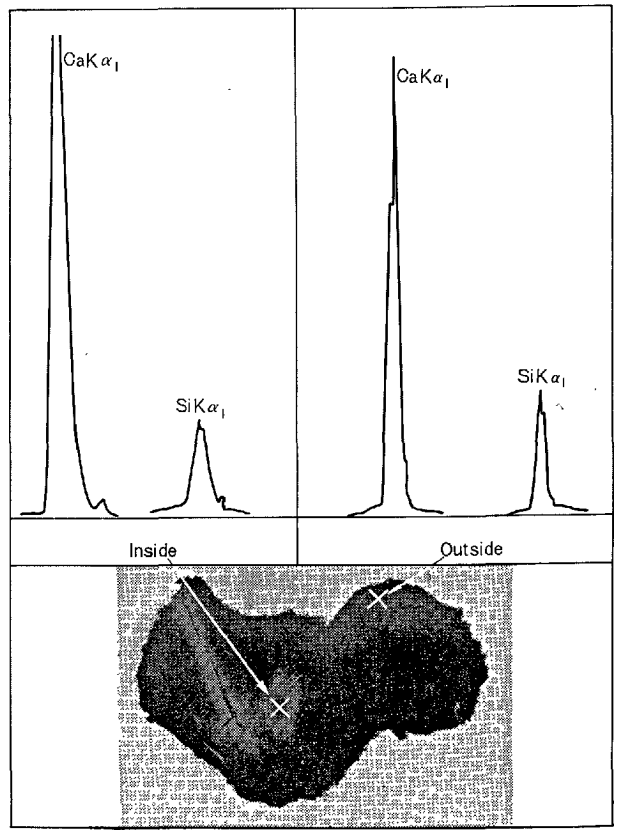

Fig. 6. *An example of chemical analysis by electron microprobe analyzer attached to an electron microscope*

The quantity of nitrogen adsorption, according to Kondo, Ueda and Kodama (16), has a maximum value at first and then reaches a minimum value at the early stage and thereafter increases gradually, as is shown in Fig. 5. That is, it is possible to discuss the crystallinities and the changes of the related properties of hydrated products from the result of adsorption. However, the degree of hydration is not so closely related with the surface area.

The pore size distribution of porous material such as hardened cement paste is measured by adsorption, mercury penetration, fluid permeation, back diffusion, electron microscope, selective adsorption and so on.

In the mercury penetration method the pore size distribution is calculated, on the assumption that the shape of the pore is cylindrical. However the pore radius measured by this method is smaller than the true value as the size of the neck of the capillary is measured. Particularly this error appears in case of sample in large lump form.

In the mercury pressure method all the pores in the gel cannot be measured owing to the difficulty of the high pressure technique and the minimum radius to be determined is 15 Å. On the contrary in the adsorption method the pores between several hundred Å and 10 Å in diameter can be measured. In calculation of the pore size distribution from adsorption data, the Cranston-Inkley method (27), which assumes the pore as a cylindrical capillary is widely used for instance, by Eipelatuer, Schilcher and Czernin (23). The Innes method (28) used by Hunt (25) assumes that the pores are in parallel plates.

Electron Microscope

A high resolution electron microscope is effective for the study of hydrate because of its low crystallinities. The morphologies of hydrates have been clarified considerably by Grudemo (29) (30) who published many results obtained with the electron microscope. As the electron beam has a much larger

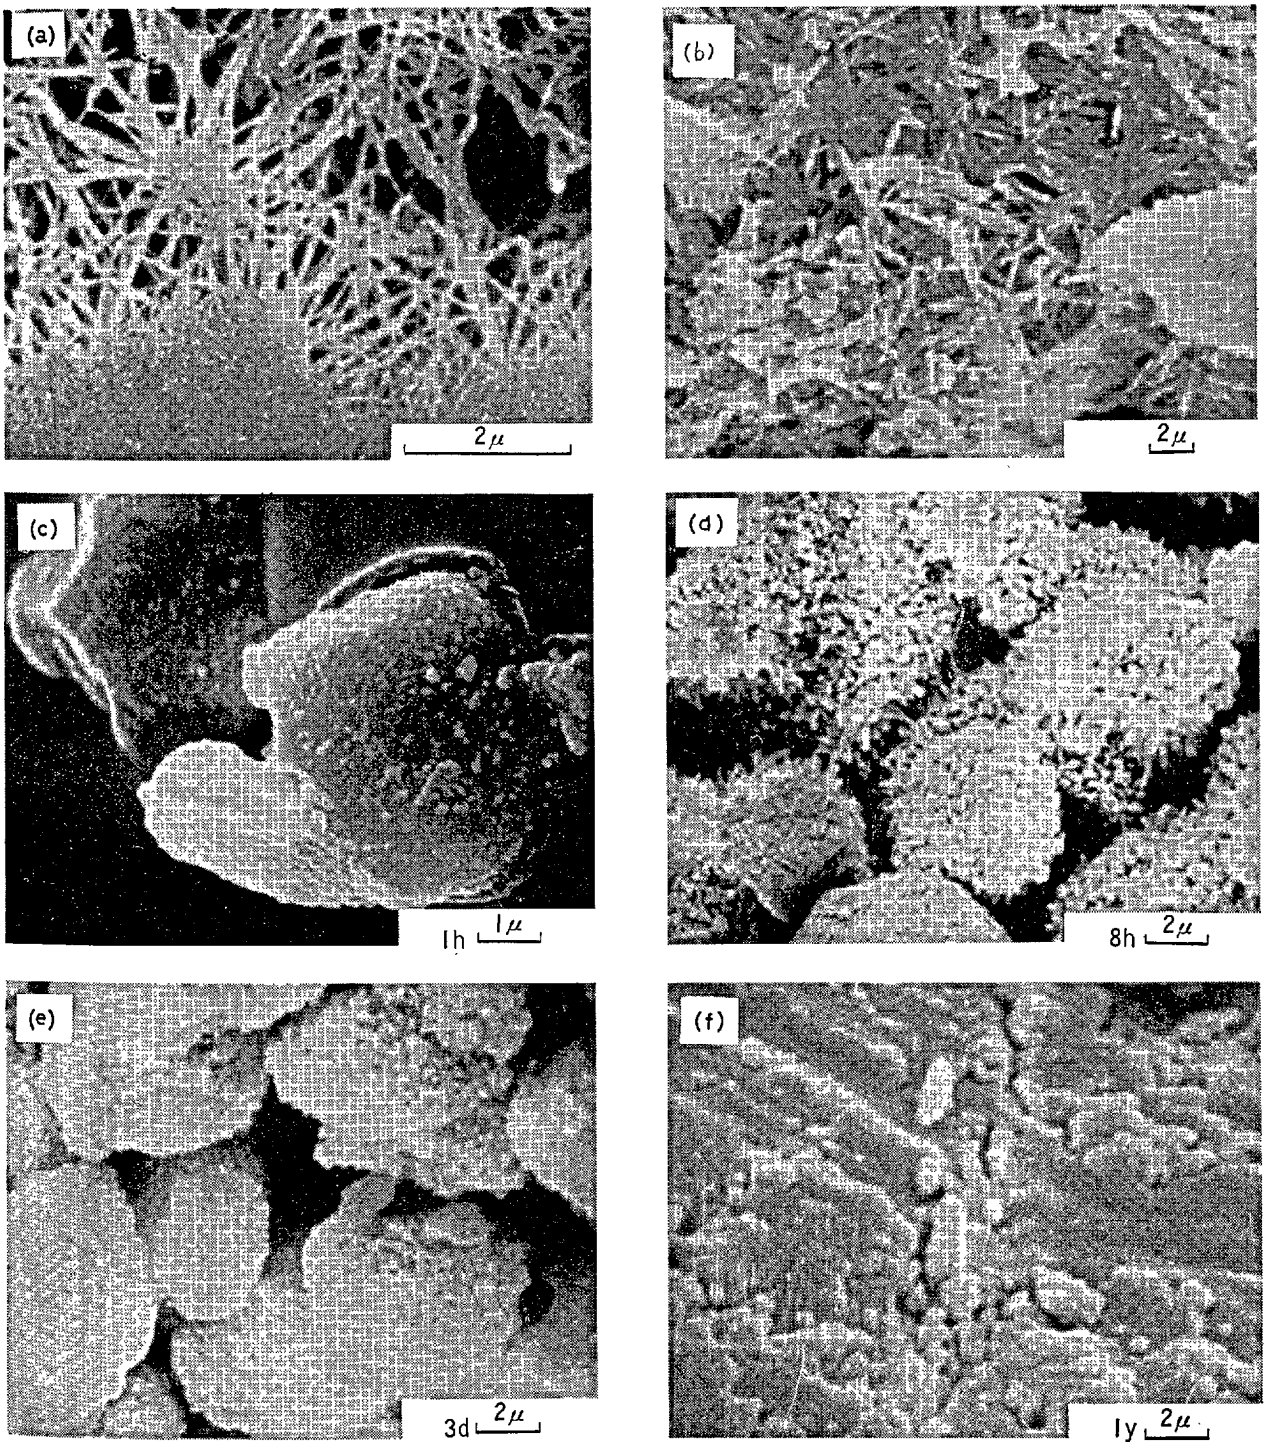

Fig. 7. *Textures at broken surface examined by a scanning electron microscope.* (a), (b): *sand-lime brick by G. Sudoh,* (c)~(f): *surface state of* C_3S *powder in hydration with* $W/C = 0.5$ *by Kondo, Daimon and Ueda(55)*

sectional area of adsorption and scattering amplitude than X-ray and neutron beams, it provides sufficiently strong diffraction pattern so that measurement even in thin crystal is possible while it can pass about 1000 Å of the thickness of crystal without disappearance of coherency.

Direct observation and diffraction of fine crystal are obtained by the suspension method but the observation of the surface of hydrated particle is also important for the study of the hydration of cement. However, there are many problems when observing the particle boundary and distinguishing the figure by two step replica method. The character of the evaporation film of carbon has been applied in the one step replica method and this is being studied (31). It is considered that this method is suitable for study to distinguish the reactivities of various crystal surfaces in hydration.

The microtome technique is useful instead of the single crystal experiment as it is difficult to obtain in hydration. The preparation of ruby or diamond knife and the embedding method are being studied (32). Application of high voltage electron microscope is also interesting.

The method of using surface electron diffraction was used by Ueda, Hashimoto and Kondo (2) for the study of the state of the cement particle at the induction period which was only assumed in the past.

The recently developed electron microscope with electron microprobe analyzer may also assist the study of hydration. It becomes possible by this to identify the chemical composition, with the exception of observation of the figure and the diffraction pattern. As an example, the result obtained on hydrated C_3S particle is shown in Fig. 6.

On the other hand the scanning electron microscope which was recently developed in England and Japan has a deep focal length and this is useful for direct observation of the surface of sample. The broken plane of the sand lime brick treated in an autoclave as well as the surface state of the C_3S particle in hydration are shown in Fig. 7.

Reactivites of Cement Components and Types of Reaction

The hydration reaction is first of all affected by the natures of the reactants which possess hydraulic, latent hydraulic or pozzolanic reactivities. So-called clinker minerals have unstable crystal structure and low bond energy. The conditions of heat treatment and cooling, and the presence of minor components affect their crystal structure and lattice defect. Admixtures such as retarder and accelerator control the hydration rate and the properties of hardened pastes owing to the changes in species, morphology and volume of the hydrated product. There are many discussions on the mechanism of hydration whether it progresses by through solution or topochemically.

Reactivities of Hydraulic Components

Calcium silicates, calcium aluminates, calcium alumino-ferrites and calcium sulfates are well known as components which react with water to harden. There are components in which strontium or barium replaces calcium, or germanium replaces silicon. Some kind of phosphates, for instance $Al(H_2PO_4)_2$ and $Zn(PO_4)_2$, have also hydraulic properties.

The free energy in a certain system must be decreased in order to carry out the hydration reaction. The values of ΔG_{298} per mole of CaO or MgO for the hydration of CaO, calcium silicates, calcium aluminates, calcium sulfates and lime-silica mixtures are given in Table 1. As can be seen in Table 1, the energy gains for the Ca–O bond for these reactions are near the values of ΔH_{298}. The low values of bond energy of the cement components are considered to be attributed to low coordination number of Ca^{++} and Al^{+++} ions by Brandenberger (33) and to the coordination with low symmetry by Bredig (34). According to Jeffery (35) Ca^{++} ion in C_3S is surrounded by six oxygens, and five of them are in one hemisphere, and only one is in the other hemisphere whereby a large hole. C_3S is therefore reactive. Kondo (36) studied the structure of $Ca_8Al_{12}O_{24}(SO_4)_2$ and found that Al^{+++} ion was in a fourfold coordination, and that Ca^{++} ion was surrounded asymmetrically by oxygen, and also found the presence of free SO_4^{--} ion. Accordingly this compound is reactive with water. Burdick and Day (37) mentioned that most of the aluminium ions in tricalcium aluminate were in fourfold coordination.

When the cement composing minerals are brought into contact with water, a decrease of bond energies is promoted and is dissolved by thermodynamic instability. According to Mchedlov-Petrosyan and Babushkin (38), calcium ion dissolves together with oxygen, whereas Si^{4+} ion hydrates in water and polymerizes in order to neutralize its charge and finally forms nuclei. The supersaturated solution permits crystal growth of the hydrated compound

Table 1. *Heat of formation and free energy change of various hydration reactions. After Mchedlov-Petrosyan and Babushkin (38) modified by Kondo.*

Hydration reactions	ΔH_{298} (kcal/mole CaO)	ΔG_{298} (kcal/mole CaO)

$CaSO_4 + 2H_2O \rightarrow CaSO_4 \cdot 2H_2O$	− 4.00	− 0.25

with higher Ca–O bond energy and low solubility.

Compared with many cement composing minerals, the reactivity of the reactant with high lime content is generally high because of the decrease in free energy or the increase in bond energy gain. The hydration rate of such a reactant is accelerated due to difference in concentration between the reactant interface and the surrounding liquid becoming larger. Compared with silicates, aluminates are generally high in reactivity and have rapid hydration rate due to high solubilities of both the unhydrate and hydrate, and also to the increase in the difference of concentration. However, when hydrates are formed on the surface of the particles of reactant to control the overall reaction by ion diffusion in pores, the hydration rate is significantly affected by the physico-chemical properties of hydrates. A comparison of the hydration rates of the principal compounds of cement is shown in Fig. 1.

Next we will consider the reactivities of hydraulic components with approximately the same chemical composition. It is well known that minor components and conditions of heat treatment and cooling produce several polymorphisms of C_3S and C_2S. Yamaguchi, Shirasuka and Ota (39) found that monoclinic alite hydrated slightly faster, but early strength of the triclinic one seemed to be a little higher, in comparison with polymorphisms of alite with the same composition. Lehmann, Traustel and Jacob (40) measured the heat of hydration of alites, which were prepared by various rates of cooling, and found that alite subjected to slow cooling had lower heat of hydration and strength than that subjected to rapid cooling. Ono and Soda (41) reported that crystal structure with high energy level caused acceleration of the hydration rate.

According to Kondo (42), the hydration rate of C_3S is accelerated if it contains SO_3 and the reactivity of C_3S with water is decreased if it contains P_2O_5. Kondo and Yoshida (43) confirmed that the alite which is defined as a solid solution containing Al_2O_3 and MgO has a higher hydration rate than pure C_3S, and when alite or C_3S contains TiO_2 the reaction within 1 day is retarded, but the subsequent reaction is remarkably accelerated. It is regarded that the reactivity is increased because of the substitution of Al and Ti for Si in the structure of C_3S but the retardation of the induction period in the C_3S and alite containing Ti may be attributed to the difficulty of the growth of nuclei of more stable hydrate formed in the impermeable coating.

When $KC_{23}S_{12}$ and NC_8A_3 are compared with β–C_2S and C_3A, according to Kryzhanovskaya, Mirak'yan, Shokotova and Horodnui (44) a significantly different hydration rate is not indicated.

Imperfections, such as lattice defects and dislocations, play important roles in the chemical reactivities of solids and a surface may be considered to be a giant lattice defect. When particles and water are brought into contact, ionic species dissolve apart from particles. Dislocation density contributes to the rate of the dissolution. The formation of dislocation etch pits is generally attributed to enhanced chemical reactivity resulting from the lattice strain in the vicinity of edge or screw dislocations. But Gatos (45) indicated that dislocations could also be revealed at low angle boundaries where they possessed no additional lattice energy, and that the lattice strain associated with dislocations was not of primary importance in determining their increased chemical reactivity. In certain instances surfaces with dislocation can become entirely inactive in the presence of adsorbed molecules in solution. If the surface reaction is the slow step the dissolution of the surface becomes activation-controlled, and differences in reactivity among surfaces with various indices (hkl) may be observed. However, differences in reactivity shall not be observed when the mass-transport is the slow

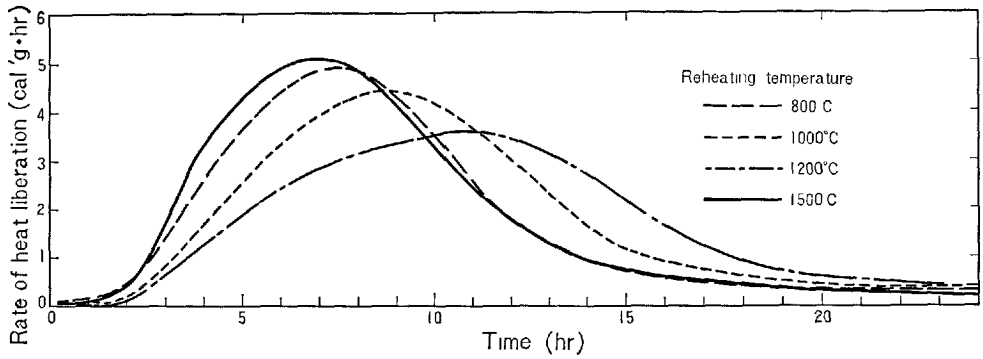

Fig. 8. *Variation with reheating temperature of heat liberation of* C_3S. *(W/C = 0.5, at 25°C)*

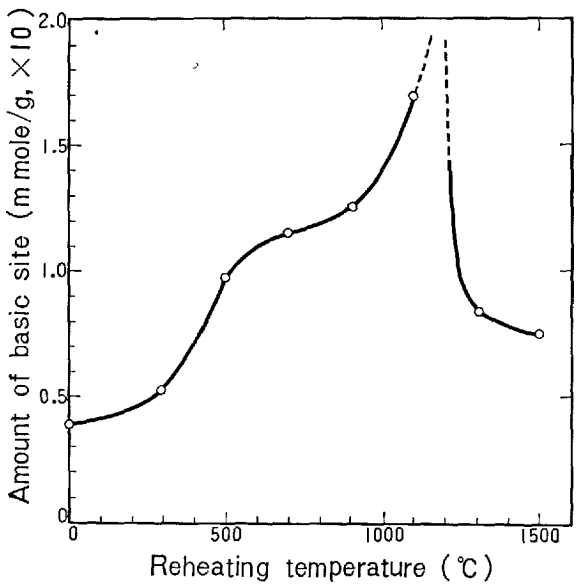

Fig. 9. *Amount of basic site of reheated* C_3S.

step.

Kondo, Daimon and Akiba (46) investigated the relationship between the amount of basic site and the hydration rate of C_3S. The change in the amount of basic site in reheated C_3S corresponds to that of the hydration rate as is seen in Figs. 8 and 9. With the increase in annealing temperature, C_3S powder loses adsorbed water at about 400°C and dissociates into CaO and C_2S at the surface and the amount of basic site increases rapidly at about 1100°C. If it is reheated above 1300°C, however, C_3S is stabilized at its surface and the amount of basic site decreases. The surface which easily accepts proton or donates the electron pair seems to lower the hydration rate.

Through Solution and Topochemical Reactions

There are two theories about the mechanism of cement hydration, particularly with respect to the location forming hydrates. It has long been discussed whether it takes place by through solution or topochemically.

Through Rolution Seaction

The through solution theory at present is close to the crystallization theory of LeChatelier (47). According to him, the dissolution of the cement composing mineral takes place at first and then the dissolved species are hydrated in the solution. During this period as the hydration compounds produced has lower solubility than the reactants, crystallization is commenced in solution.

Brunauer and Greenberg (20) proposed the following process, if the hydration reaction is advanced with the through solution mechanism.

1. the hydrated ions form at the surface.
2. they diffuse away from the surface.
3. they react with each other to form C–S–H molecules.
4. the molecules form nuclei.
5. the nuclei grow.
6. colloidal particles precipitate and flocculate.

They practically observed that $Ca(OH)_2$ separated out of the solution as relatively large particles and was overlaid by C–S–H gel or grew around and occluded C–S–H gel, and the gel appeared to form at considerable distances from the grains. According to Richartz and Locher (48), calcium silicate hydrates grow from the surface of the alite and belite particles into the surrounding water as large as the pore space allows.

Table 2. *Hydration mechanism of* C_3S.

		C_3S		t_i C_3S	C_3S		C_3S		

Topochemical Reaction

A type of hydration other than through solution is so called topochemical reaction. According to Michaelis (49), when the Ca-rich silicious clinker mineral is brought into contact with water, Ca^{++} ion is liberated into the solution and the Ca-poor skeleton of crystal remains. This skeleton is swollen by the action of the prepared lime solution to form gel. He assumed that inner suction took place towards the interior of the cement particles.

Hansen (50) concluded that the hydrolysis of C_3S to form hydrated silicate and $Ca(OH)_2$ took place topochemically, as he could not detect a significant amount of SiO_2 and Al_2O_3 in the filtrate. Funk (51) showed by X-ray diagrams and optical observations that β–C_2S crystals took up H_2O at 100°C and 100% relative humidity to form the intermediate products with low refractive indices, however it alters into the C–S–H phase with increasing water content.

Feldman, Ramachandran and Sereda (52) believed that the hydration of C_3A in the vapor phase at 50% relative humidity took place and the reaction would proceed by a direct mechanism, because only one or two molecular layers of adsorbed water are present on the surface under these conditions and a through solution mechanism does not have any meaning. Trojer (53), who observed the formation of the intermediate products of decreased refractive indices inside the original cement particle, considered that ionic species transported by lattice diffusion, i.e. Ca^{++} ion, migrated toward the outside and H^+ ion penetrated from the liquid in order to maintain the electrical neutrality of the lattice. Terrier and Moreau (54) affirmed by optical observations that the hydration of a silicate proceeded topochemically and calcium moved from the reactant interface which shifted inwards gradually, through the inner product layer to the outside of the grain as is seen in Table 2, which is partly modified by Kondo, Daimon and Ueda (55).

Hydration of plaster of Paris is generally regarded to take place with through solution mechanism, but Eipeltauer (56) observed the formation of inner product.

From the consideration of the specific volume and the pore space of hydrated gel, Taplin (57) and Powers (58) considered that the hydration reaction proceeded towards the interior of the cement particle to form the inner product, but simultaneously 1.2 times the volume of the reacted part was required by the outer product. Accordingly the formation of inner and outer products in the respective stages of the process must be examined with consideration given to counter diffusion through the product layer.

Kondo, Ueda and Kodama (16) examined the hydration of C_3S by calorimetry, quantitative X-ray analysis, chemical analysis of liquid phase and microscopic observation. In the extension of this study Kondo, Daimon and Ueda (55) pointed out that SiO_2 content of the suspension of only the outer products exceeded SiO_2 concentration of the extracted liquid phase and thus confirmed the existence of C–S–H gel other than $Ca(OH)_2$ as the outer products formed in solution.

However before the end of the induction period CaO concentration of the liquid rises rapidly to commence precipitation of $Ca(OH)_2$ crystal. The difference in CaO concentration between the C_3S interface and liquid increases due to the beginning of the precipitation of $Ca(OH)_2$ and liberation of Ca^{++} ion becomes easier. On the other hand SiO_2 concentration in the C_3S interface of the exceedingly high CaO concentration decreases and the liquid phase remains in the saturated state. Therefore it will become difficult for Si^{4+} ion to migrate due to the small SiO_2 concentration difference.

Kondo, Ueda and Kodama (16) have studied the hydration process of single particle of C_3S under the

microscope. After 8 hours the surface alters slightly, as can be seen in Fig. 10. The inner product which has a double refraction of almost zero extends toward the interior of the particle with the progress of hydration. The unhydrated part has been eliminated by 8 days in the case of fine particles. As shown in Fig. 10, the hydration seems to proceed without any remarkable changes in shape and size of the original C_3S grain. The outer products which are formed outsides the C_3S particle consist of $Ca(OH)_2$ crystals which are growing large and calcium silicate hydrate gel appears on the slide glass and the cover glass. With the exception of the early stage, the reaction proceeds topochemically, while liberating Ca^{++} ion and also keeping the original shape. Similar microscopic observation in the hydration of $C_4A_3\bar{S}$ were separately reported by Okushima, Kondo, Muguruma and Ono (59). $C_4A_3\bar{S}$ reacts with water to form inner products, while the particle expands by topochemical reaction when $C\bar{S}H_2$ and CH are existing.

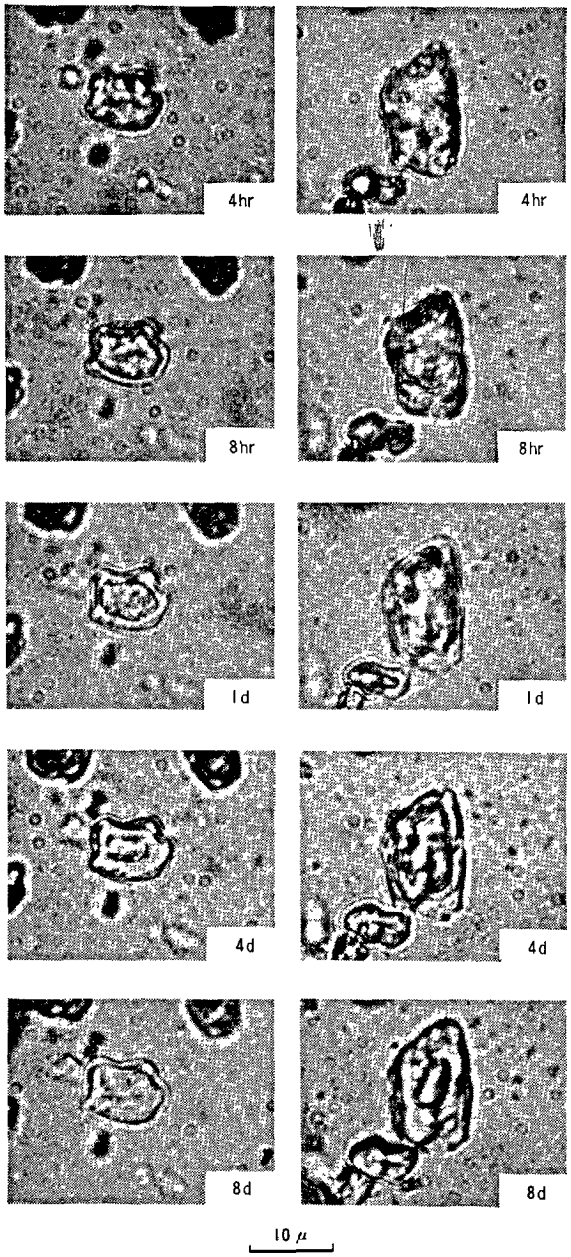

Fig. 10. *Hydration process of single particle of* $C_3S(r = 2 \sim 5\mu)$ *under microscope. After Kondo, Ueda and Kodama(16)*

It was also pointed out by Kondo, Ueda and Kodama (16) that the crystallization of the inner product was by no means chaotic, but proceeded epitaxially, from the observation of the Becke line around the particle whose reaction was considerably advanced. McConnell (60) has found similarly by a single-crystal X-ray technique that the *b*-direction of the hydrated phase is oriented parallel to the *c*-direction of the parent bredigite (natural α'–C_2S). Such epitaxial crystal growth as mentioned above may have taken place due to the similarity between the arrangements of SiO_4 tetrahedra in C_3S and that in tobermorite as pointed out by Kawada and Nemoto (61).

As mentioned above, C_3S is hydrated to form C–S–H with a definite direction without much change in the Si site of the original C_3S. The oxygen site is generally not changed in the so-called topotactic reaction. On the other hand, the SiO_4 tetrahedra migrates slightly to drop the energy level in the hydration of C_3S because the original SiO_4 tetrahedra is independent while that of the product is in chain.

A reactant which participates in mutual reaction and moreover has a large dissolution rate, for instance, gypsum in portland cement, reacts by the through solution mechanism. Cement components generally form the outer products by the through solution mechanism while they form the inner product topochemically. Topochemical reaction is characterized by taking place near the interface of reactant and includes not only a topotactic reaction but also a local through solution mechanism.

Latent Hydraulic and Pozzolanic Materials

Besides the hydraulic components, calcium aluminosilicate glass such as granulated blast-furnace slag produces hydrates and hardens in the presence of activators, and also reactive silica or silicates hydrates and hardens by the reaction with lime.

Latent Hydraulic Materials

There are calcium alumino-silicate glass and $CaSO_4$

Table 3. *pH of suspension with calcium alumino-silicate glass powders. After Kondo (62).*

as materials which react with water to form hydrated products and to which an activator is added in order to accelerate their very slow reaction rate. Ortho silico-ethyl ester $Si(OC_2H_5)_4$ is hydrolized and hardened at a present of exciter such as acid or organic base.

Kondo (62) studied the hydration of calcium alumino-silicate glass powders in excess water and obtained the pH values of liquid shown in Table 3. Glasses with composition of above 50% CaO and below 20% SiO_2 content have hydraulic properties and the pH values become more than 11～12. Glasses which indicate pH values lower than this due to their CaO contents have latent hydraulic properties.

Granulated blast-furnace slag is a glass whose main potential constituents are C_2AS–C_2MS_2 solid solution, CS and C_2S. Kondo (62) studied the mechanism of the hydration of latent hydraulic materials using C_2AS glass to simplify the complicated composition of slag. Compared with C_2MS_2 or CS, C_2AS is difficult to dissolve in water. Particularly the amount of SiO_2 and Al_2O_3 liberated is very low when compared with that of CaO (Fig. 11). The dissolution rate of these compound is in general slightly larger in the glassy state than in the crystalline state.

In the suspension hydration of C_2AS glass powders, a low permeable coating which is approximately ASH_6 in composition and 0.2μ in thickness is formed on their surfaces. D'Ans and Eick (63) similarly reported that the surface of the slag was covered with acid gel by reaction with water. Fig. 12 shows that the suspension hydration of C_2AS glass is accelerated by the addition of $Ca(OH)_2$ to form the hydrate with approximately C_3ASH_5 composition because SiO_2 and particularly Al_2O_3 are apt to be liberated and the solubility of hydrate also decreases under this condition. Nevertheless if C_2AS is in a crystalline state, the amount of dissolution does not increase even in the presence of $Ca(OH)_2$.

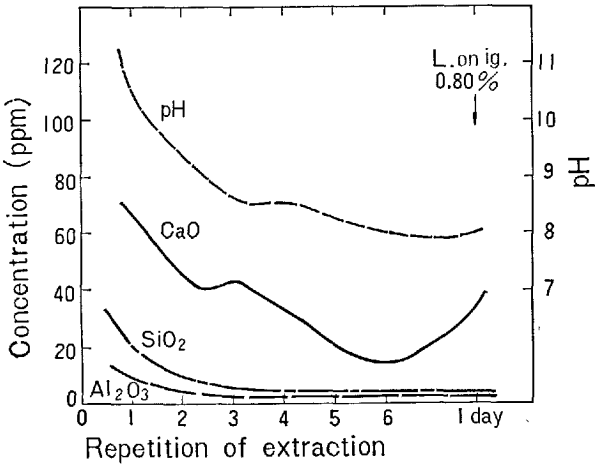

Fig. 11. *Repeated extraction of C_2AS glass. (5 grams of C_2AS per 100 c.c. of water) After Kondo(62)*

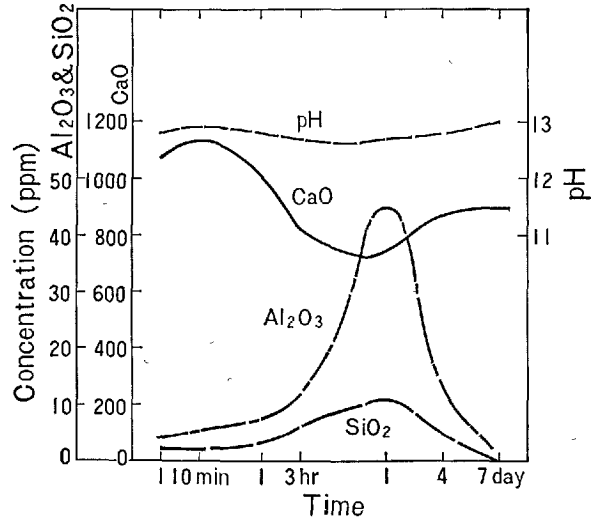

Fig. 12. *Solubility of C_2AS glass with 2 moles of $Ca(OH)_2$. (1 gram of solid per 100 c.c. of water) After Kondo(62)*

$CaSO_4$ is not an exciter in super-sulfate slag cement but an important reactant on account of its hydration. The reaction between both reactants, however, is not proceeded in the absence of an alkaline exciter.

While there is no example of investigation on the degree of hydration of slag in the portland blast-furnace cement and super-sulfate slag cement. The reason for this is that a suitable method for estimation of residual slag in hydrated cement paste has not been found. Kondo and Ohsawa (64) developed a method and determined the rate of hydration of slag in various slag cements.

Pozzolanic Materials.

The pozzolanic cement is a kind of blended cement and historically the oldest cement.

In the pozzolanic cement the reactive silicas and silicates, which are called pozzolanic materials, combine with lime at ordinary temperature in the presence of water to form hydrates similar to those found in the hydration of portland cement. There are natural and artificial pozzolanic materials and their mineral constituents and properties have been reviewed by Malquori (65). Colloidal silica, opal, diatomite, alumino-silicate glass, zeolites, allophane, halloysite and metakaolin have been found to be reactive components. The hydration of pozzolanic materials containing a reactive alumina is especially accelerated by the addition of gypsum, besides lime. Quartz which has low reactivity at ordinary temperature reacts with lime rapidly at a high curing temperature.

Halstead and Lawrence (66) and also Greenberg (67) examined the rate of reaction between colloidal silica and lime solution. It is shown that the surface of silica is covered with acidic silanol groups, SiOH, which react immediately with $Ca(OH)_2$ in an acid-base reaction. Concentration of C–S–H is expressed in the solubility products as $[Ca(OH)_2]^x [SiO_2] = k$, in which $x = 1.9$ and $k = 3.4$ (66) (68).

The pozzolanic reactivities of silica glass and quartz are compared at various temperatures and the results are mentioned later (69).

Mutual Reactions and the Effect of Admixtures

The addition of additives in cement or mixing water changes the rate of hydration. As additives sometimes a large amount of materials such as blast-furnace slag or pozzolan is added to the portland cement and occasionally a nearly inert powder of quartz or limestone is added. On the contrary, materials such as gypsum, calcium chloride and surfactants affect hydration reaction considerably even when a small amount is added. To avoid quick-setting of C_3A, which is contained to some extent in portland cement, gypsum is always added.

Interaction of Silicates

The concentration of the liquid phase in paste is varied by the addition of admixtures. Kondo, Daimon and Ueda (55) examined the hydration of C_3S with liquids supersaturated with respect to both $Ca(OH)_2$ and C–S–H. The fresh C_3S was hydrated with this liquid and then it was found that its hydration is extremely retarded as seen in Fig. 13 (70). Steinour (71) and de Jong, Stein and Stevels (72) reported similar results. When the surrounding liquid is in supersaturation, the dissolution of C_3S is retarded to extend the induction period.

According to Kawada and Nemoto (61), the hydration of C_3S is accelerated when gypsum is added as the supersolubility with respect to $Ca(OH)_2$ rises in the presence of gypsum. According to Kurczyk and Schwiete (73), a small amount of $CaCl_2$ accelerates the hydration of C_3S and the pH value of liquid

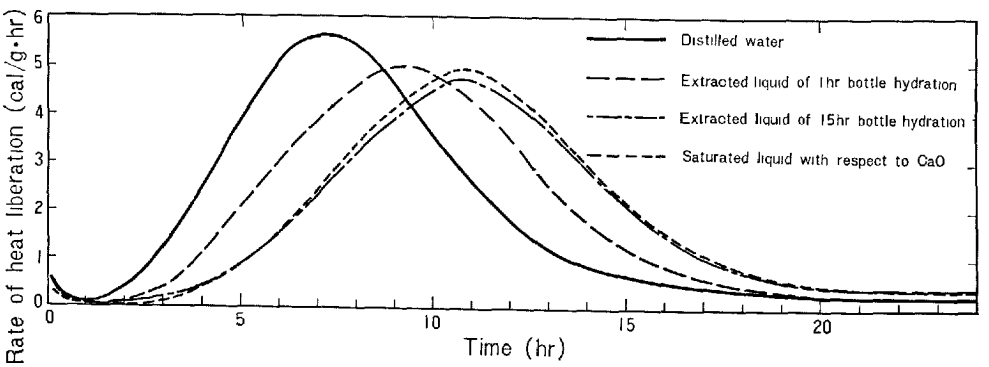

Fig. 13. *Variation with mixing liquid of heat liberation of* C_3S. *($r = 2 \sim 5\mu$, $W/C = 0.5$, at 25°C)*

decreases with the amount of addition. But when $CaCl_2$ above 2% is added the pH value drops to below 12 to hinder the formation of a C–S–H gel. Stein and Stevels (74) reported that the hydration of C_3S was accelerated by an autocatalytic type of reaction, as the addition of aerosol changed in calcium ion and silicate concentrations, and pH value.

Admixtures also change the composition, morphology and amount of hydrated products which are closely related to the rate of mass-transfer. According to Kurczyk and Schwiete (73), the addition of gypsum impedes the hydration of β–C_2S due to the low degree of crystallization of acicular product.

The rate of reaction of β–C_2S is retarded at the early stage in the presence of C_3S but it is accelerated after liquid is supersaturated by the dissolution of C_3S (75). The hydration of β–C_2S is retarded considerably in the presence of $C_{12}A_7$ (76).

Interaction of Aluminates

There are many studies on the mutual reactions of aluminates with admixtures such as gypsum because these reactions are concerned with retardation of the setting of portland cement and with the expansion of expansive cement.

According to Kondo (62), when C_3A powder is hydrated in excess water, it dissolves stoichiometrically and the concentration of liquid indicates high supersolubility with respect to hydrates, which precipitate rapidly as shown in Fig. 14. The surface of C_3A particle is covered with an ettringite coating from the beginning if gypsum is added to decrease the dissolution rate and the Al_2O_3 concentration of the liquid until gypsum is consumed as shown in Fig. 15. Similarly Fig. 16 shows that the hydration rate is kept low in the presence of $Ca(OH)_2$. Particularly when gypsum and lime are added simultaneously to the hydration of C_3A, the solubility of ettringite decreases further to form very small crystals and causes an increase in the compactness of coating. Therefore the hydration rate of C_3A is retarded ex-

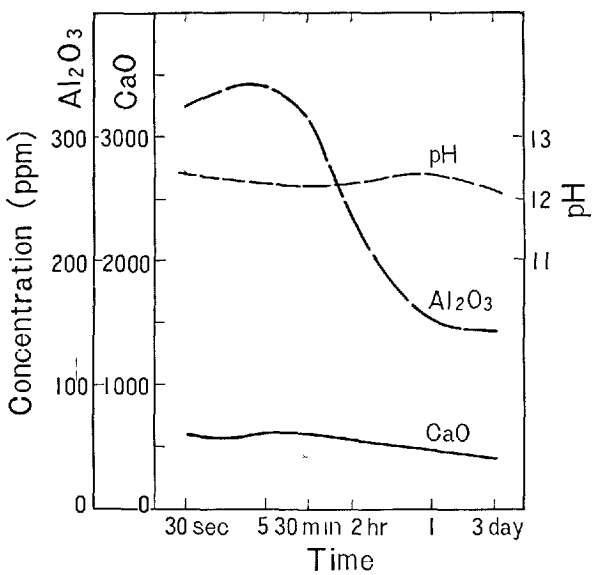

Fig. 14. *Solubility of* C_3A. *(2 grams of* C_3A *per 100 c.c. of water) After Kondo*(62)

tremely, and the Al_2O_3 concentration of liquid is kept very low as shown in Fig. 17.

The hydration rate of C_3A, according to Stein (77), is attributed to the degree of crystallization of calcium sulfoaluminate hydrate corresponding to the amount of additives. The formation of acicular crystal seems generally to have a tendency to accelerate hydration, however, less soluble products such as

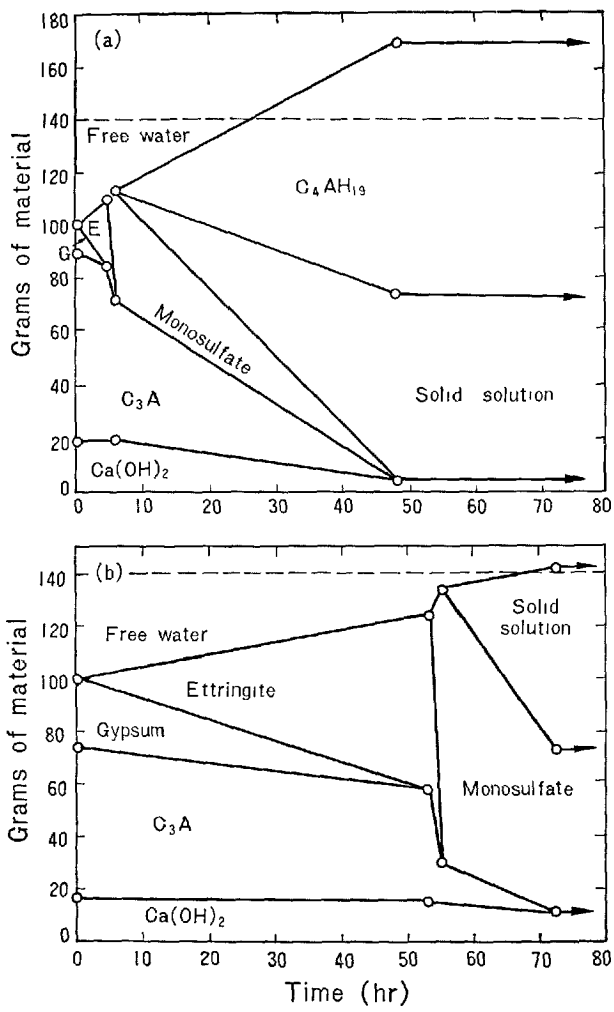

Fig. 18. *Effect of gypsum on aluminate hydration reaction with* $W/S = 0.4$. *Molar proportion of reactants* C_3A, $Ca(OH)_2$ *and* $CaSO_4 \cdot 2H_2O$; (a) $1:1:\frac{1}{4}$, (b) $1:1:\frac{3}{4}$. E = *Ettringite*, G = *Gypsum. After Verbeck(79)*

ettringite retards the reaction due to its lower permeability.

Schwiete, Ludwig and Jäger (78) found that a layer of ettringite was topochemically formed around the C_3A particles immediately after the addition of water, enveloping them in "hedge hog" fashion and owing to the formation of this layer the following reaction between C_3A and sulfate ions was considerably retarded. These ions are thought to diffuse to form additional ettringite at the C_3A interface. As long as the sulfate ion concentration is sufficient for an ettringite formation, the ettringite skin is sound or healed by new formation when it breaks in consequence of crystallization pressure. After the concentration of sulfate ion is lowered by the consumption of gypsum a rapid reaction of the remaining C_3A occurs.

According to Verbeck (79), after the consumption of gypsum the conversion of ettringite to monosulfate hydrate commences as seen in Fig. 18. Henning and Danowsky (80) discussed the mechanism of hydration with the measurement of high frequency conductivity. According to them, Ca^{++} ion and $[Al(OH)_6]^{---}$ group liberate from C_3A, and SO_4^{--} ion and Ca^{++} ion from gypsum. SO_4^{--} ion reacts with the C_3A surface to form monosulfate film on it and $[Al(OH)_6]^{---}$ ion with the gypsum surface to form acicular trisulfate on it.

Tenoutasse (81) observed that the time required for consumption of gypsum was in square proportion to the amount of added gypsum and was reduced with increasing temperature. The hydration of C_3A with gypsum is accelerated, if $CaCl_2$ is added, and after the consumption of gypsum the reaction between C_3A and the Cl^- ions commences. He applied the kinetic equations conventionally but the model of reaction was not given.

According to Okushima, Kondo, Muguruma and Ono (59), hydration of C_3A or $C_4A_3\bar{S}$ forms monosulfate at the interface of reactant locally even in such a case to form ettringite as an inner product. On the other hand it is difficult to form products at the surface of gypsum which has a large solubility and rate of dissolution. They also discussed the mechanism of hydration of expansive cement accompanying with an expansion which occurred in the consumption of mechanical energy.

Feldman and Ramachandran (82) proposed that the formation of ettringite did not have any direct role in the retardation and rather the presence of $CaSO_4$ in solution decreased the reaction rate of C_3A by sorption of SO_4^{--} which affected the operation of surface source of dislocation. Feldman and Ramachandran (82) also found a two step reaction in which C_3A and gypsum first formed the hexagonal hydro-aluminates immediately on contact with water, and then the gypsum reacted partly with the hexagonal hydro-aluminates to form the trisulfate hydrate.

The surfactants in general lower the water requirement and retard the setting, however, Young (83) reported that C_3A formed needle-like crystals at a presence of more than 3% of lignosulfonate. According to Kawada and Nishiyama (84), C_3A does not physically adsorb calcium lignosulfonate but reacts chemically to form a new hydration product. However, when the concentration of anionic calcium lignosulfonate is low, C_3S or C_2S adsorbs physically to satisfy the Langmuir's equation. Thus the hydration is retarded. The retardation mechanism was explained by Kasai (85) from the standpoint of the complex chemistry whereby the structure of hydrate had been explained by Forsén (86).

Stein (87) found that the hydration of C_3A became faster as more C_3AH_6 was added, so that the second peak in the hydration of C_3A is dependent upon the formation of C_3AH_6 from the intermediates. He also stated in a later report (88) that the precipitation of amorphous hydrous alumina inactivated the nuclei of C_3AH_6 to stop the reaction and this effect was lowered in the presence of quartz because the precipitation occurs partially on the quartz surface. According to Feldman, Ramachandran and Sereda (52), the effect of the addition of $CaCO_3$ does not seem to be significant. Stein (13) reported that the addition of sodium carbonate accelerated the hydration of C_3S, whereas it retarded the hydration of C_3A as the result of the formation of $3CaO \cdot Al_2O_3 \cdot CaCO_3 \cdot 11H_2O$.

Several Factors Concerned with the Rate of Hydration

Pulverizing of cement not only makes the surface area of sample large but also changes the energy state of its surface. These variances affect the reactivity with water. The water cement ratio and curing temperature are the most effective factors on the hydration reaction. Furthermore hydration may be affected by vibration and ultrasonic treatment in the casting of paste, and by the relative humidity and the existence of CO_2 gas during atmospheric curing.

Fineness of Cements

The particle size or the surface area of powder contributes to the rate of hydration and in general of solid state reaction and is inclusive in the kinetic constant. The hydration rate of the classified C_3S is accelerated further, the finer the C_3S grain, as shown in Fig. 1. From these data the thickness of the hydration layer can be calculated under an assumption in which the thickness of the hydration layer in C_3S particle increases in correlation with time, without any relation with particle size. It is presumed that the time required for the reaction to be completed is about 1 year in particles with 8μ radii and is about 10 years in particles with 20μ radii.

Sylvan (89) pointed out that the specific surface

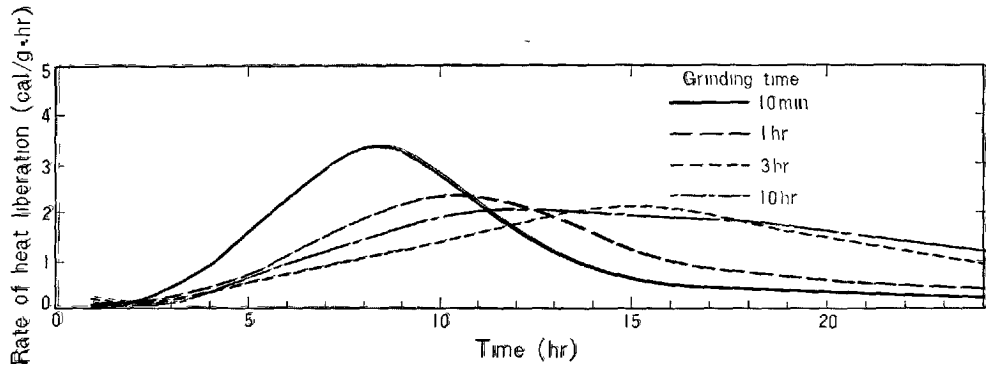

Fig. 19. *Variation with grinding time of heat liberation of* C_3S. *($r = 2 \sim 15\mu$, $W/C = 0.5$, at 25°C)*

was to a large extent dependent upon the measure of dispersion of the grading, whereas the hydrated quantity was not. The strength of the hardened cement paste is more closely bound up with the average value of the particle size and with the degree of hydration than with the specific surface.

From the measurement of the amount of non-evaporable water, Gronau (90) proposed an equation to determine the degree of hydration. It was derived from the assumptions that the thickness of reaction layer did not depend on the particle size and the particle size of cement was in a logarithmic regular distribution.

$$\alpha = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{1/\sigma \ln h/r_0} e^{-t^2/2}dt + \frac{3h}{r_0}e^{\sigma^2/2}\int_{t_1}^{\infty}\frac{1}{\sqrt{2\pi}}e^{-u^2/2}du - \frac{3h^2}{r_0^2}e^{2\sigma^2}\int_{t_2}^{\infty}\frac{1}{\sqrt{2\pi}}e^{-v^2/2}dv + \frac{h^3}{r_0^3}e^{9/2\cdot\sigma^2}\int_{t_3}^{\infty}\frac{1}{2}e^{-w^2/2}dw$$

where $t = 1/\sigma \cdot \ln \cdot r/r_0$, $u = 1/\sigma \cdot \ln \cdot r/r_{01}$, $v = 1/\sigma \cdot \ln \cdot r/r_{02}$, $w = 1/\sigma \cdot \ln \cdot r/r_{03}$, $h = f(t)$, r_0 is the median of volume distribution, σ is the variance and α is the degree of hydration. This equation can be solved by the help of the table of Gauss' error function as all the right side terms are this type of function. The relation between α and g H_2O/g cement is experimentally obtained.

Otherwise the surface energy of the particle changes with the degree of grinding. Beke and Opoczky (91) obtained a very fine powder by grinding of clinker minerals by addition of tri-ethanolamine as a grinding aid to avoid adhesion and aggregation. It was observed by X-ray diffraction that the intensity of the fine powder decreased with grinding time and the width of peak became broad and also that split peaks became a single peak. They explained that the fine grinding of clinker mineral assisted the formation of lattice distortion and lattice defect, and then the rearrangement of atom in the crystal structure. Ueda, Hashimoto and Kondo (2) studied the hydration rate on classified C_3S with different grinding time with results illustrated in Fig. 19. The surface structure was also investigated by surface electron diffraction and its results are shown in Fig. 20. X-ray diffraction intensity of a sample ground for 10 hours decreases but there are no changes in the peak width and the background. The surface electron diffraction pattern shows that the surface is to some extent amorphous and the thickness of this amorphous layer increases with the grinding time. The hydration rate is retarded with the grinding time and the volume of heat evolution immediately after the addition of water is not in linear correlation with the grinding time. Accordingly, it is clear that the lattice defect does not always promote the reactivity of C_3S particle at least in the early stage of reaction.

In order to accelerate the hydration such a study on the pulverizing method to obtain the reactant powder with limited particle size distribution must be important, however, we must simultaneously consider the rheological properties of cement paste.

Water Cement Ratio

The water cement ratio of the paste determines the space of the capillary void where the reaction progresses, and particularly controls the state of the outer products. The relationship between the water cement ratio and the concentration of the liquid extracted from the paste is shown in Fig. 21. This figure indicates that the degree of supersaturation becomes higher with decrease in the water cement ratio. The degree of supersaturation contributes significantly to the rate of nucleation. The reaction rate is accelerated with increase in the water cement ratio when the slow

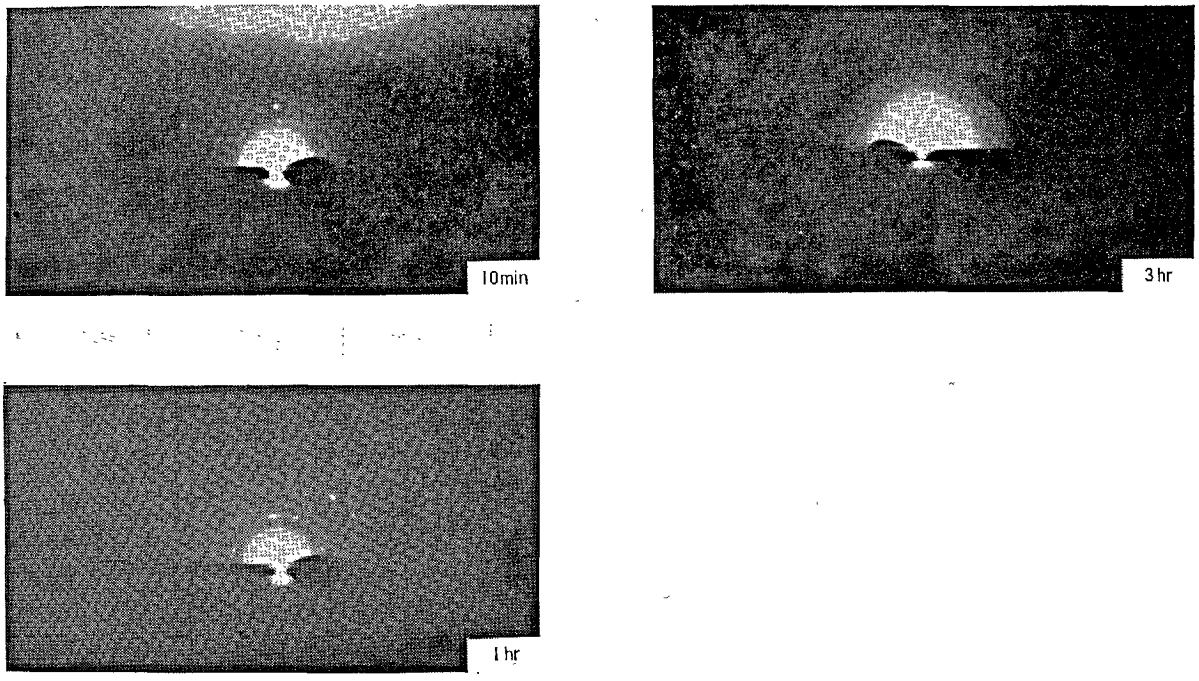

Fig. 20. *Surface electron diffraction patterns of* C_3S *with different grinding time*

step is dissolution but with decrease in the water cement ratio when the rate of hydration is controlled by nucleation.

Different results have been reported by numerous investigators on the dependence of the water cement ratio upon the rate of hydration. Sudoh and Mori (92), and Kantro, Weise and Brunauer (93) noted that at an early age the degree of hydration of C_3S and β–C_2S was nearly the same for W/C = 0.3 to 0.7, whereas at a later age it gave a higher value with increase in the water cement ratio. According to Kondo, Ueda and Kodama (16), the hydration rate of C_3S within 6 hours does not seem to depend upon the difference between W/C = 0.5 and 1.0, however, the following reaction is distinctly accelerated to a great extent in a large W/C ratio. As is shown in Fig. 1, the degree of hydration in W/C = 1.0 is about 2 times that in W/C = 0.5 within a short time but the difference between them decreases in case of a long time. This indicates that the hydration reaction is determined neither by solution control nor by nucleation control.

The amount of combined water of the product increases with increase in the water cement ratio at the early stage, while it is kept constant regardless of different water cement ratios at the later stage as is shown in Fig. 22.

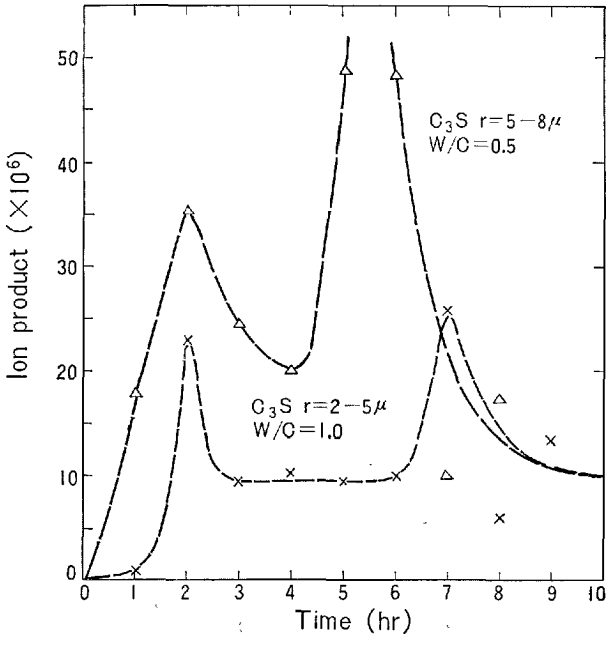

Fig. 21. *Concentration of extracted liquid from* C_3S *paste*

In contrast with the above results, Locher (94) recently reported that with increase in the amount of mixing water the degree of hydration decreases until the age of 7 days and reaches the minimum

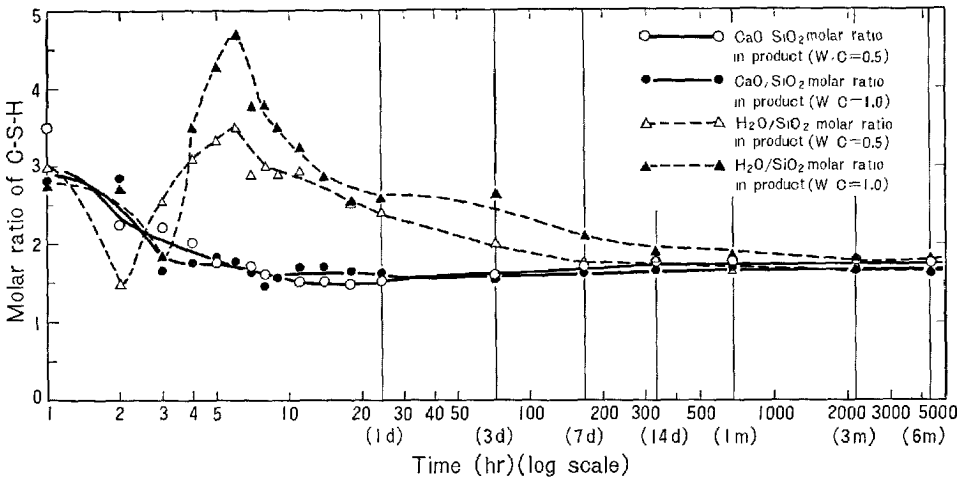

Fig. 22. *Change in molar ratio of produced calcium silicate hydrate in hydration of* C_3S. ($r = 2 \sim 5\mu$, *at 25°C*)

with W/C = 0.8. However he did not discuss the significance of this. According to Locher (94), C–S–H occurs with approximately equal CaO/SiO_2 ratio in the C_3S paste at above W/C = 0.6, but in samples with low water content CaO-rich C–S–H whose CaO/SiO_2 ratio rises with decreasing W/C value are formed.

Kantro, Brunauer and Weise (95) studied the hydration of C_3S in a steel ball mill at room temperature and found that $Ca(OH)_2$ and hydrate III were formed at the early stage but the latter was unstable and was converted gradually to well-crystallized afwillite.

According to Tsumura and Kawachi (7), the hydration rate of C_3A is accelerated with increase in the water cement ratio, while the early stage of C_4AF is accelerated by the decrease in the ratio. Seligmann and Greening (3) found that at the very early stage the hydration in C_3A-gypsum-water system was accelerated by the presence of excess water.

Curing Temperature

Curing temperature has a large effect on the hydration of cement and introduces the changes in the products and the reaction rate. The reaction is generally accelerated with rise in temperature. On the contrary, for instance, the hydration product of CA is transformed at about 20°C and consequently the rate of hydration is not accelerated with the curing temperature. When C_3S or C_2S is hydrated at temperatures higher than 70 to 80°C, hydrates are produced in high lime and low surface area and then the strength of the hardened paste decreases.

The rate of the hydration reaction of lime-quartz mixture is very slow at room temperature but is accelerated with rise in temperature. Accordingly such binding materials are subjected to curing at about 180°C in industry using an autoclave. For convenience's sake the effect of curing temperature is explained by separating it into that of lower than 100°C and that of higher than 100°C. However, the practical problems on temperature treatment will be described in detail at part III of this Symposium.

Reaction Occurs under Atmospheric Condition

Kantro, Brunauer and Weise (96) found that in the comparison of hydration of C_3S at 5°, 25° and 50°C, the reaction rate at the early stage was accelerated with the temperature. However, the temperature dependence after 1 day becomes ambiguous. Kondo and Daimon (70) studied the effect of curing temperature on the early hydration of C_3S. The difference in heat evolution is shown in Fig. 23, and the results will be discussed in the later section.

Mchedlov-Petrosyan and Chernyavskii (97) studied the effect of low temperature, even below the freezing point and reported that the reaction rate was retarded by increase in the specific volume of silicate gel.

According to Carlson (98) who studied the hydration of aluminates, the hexagonal hydrates are more stable than C_3AH_6 at low temperature. Compared with the hydration at ordinary temperature, the hydration mechanism itself is different at low temperature.

Hydrothermal Reaction

The reaction between lime and pozzolan proceeds

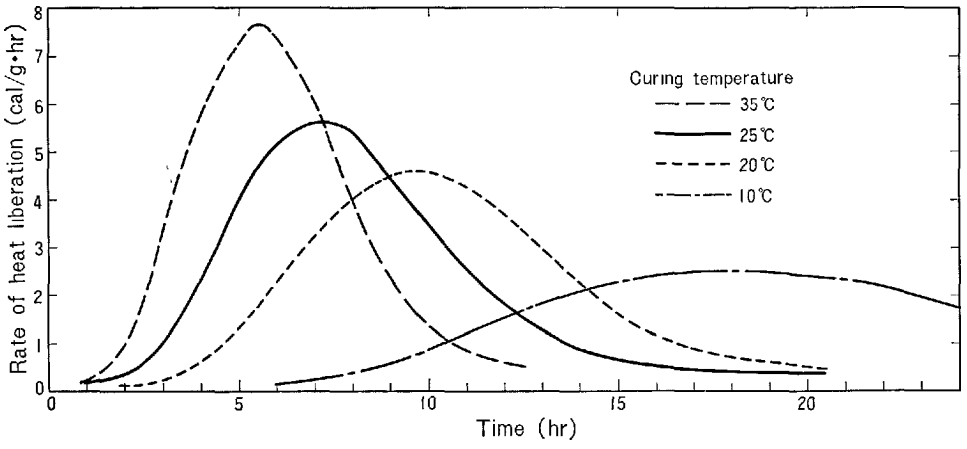

Fig. 23. *Variation with curing temperature of heat liberation of* C_3S. ($r = 2 \sim 5\mu$, $W/C = 0.5$)

considerably even at ordinary temperature but the reaction of lime-quartz mixture cannot appreciably take place, although this is accelerated by heat treatment. The autoclave is used for heat treatment at a temperature higher than 100°C in order to avoid loss of the liquid phase.

Mchedlov-Petrosyan and Babushkin (38) reported on the free energy change of the hydrothermal reaction in a CaO-quartz-H_2O system. The result of the free energy change when compared with that in CaO–SiO_2–H_2O system in which quartz is replaced by silica glass is shown in Fig. 24. The hydrothermal reaction in the CaO–SiO_2–H_2O system was summarized by Taylor (99), and the reaction rate was discussed by several authors.

Moorehead and McCartney (100) suspended a crystal quartz in saturated lime solution and treated it in an autoclave. It was shown that tobermorite was formed at 235°C and xonotlite at 335°C on the surface of crystal quartz. They proposed that the reaction was a diffusion-controlled process limited by the diffusion of $H_2SiO_4^{--}$ species through the product layer formed on the outside. The higher temperature of this experiment makes probably the silica concentration in the solution very high and the calcium concentration very low. It is therefore possible that the diffusing species and the precipitation sites of products may differ in the reaction at temperatures of 150° to 200°C which are used in industry.

Krzheminskii, Rashkovich, Sudina and Vorlamov (101) developed a method for quantitative X-ray diffraction analysis while carrying out autoclave treatment. They carried out treatment at 150°C and found that at the early stage the reaction rate was determined by the nucleation process and at the later

stage by the diffusion which is proportional to the root of the absolute temperature.

Sauman (102) studied the hydration of β-C_2S at 175°C and found that α-C_2S hydrate began to form after 4 hours and it was converted into β-C_2S hydrate after 7 days. He also described that the addition of quartz stopped the hydration of β-C_2S due to the formation of silica gel but the addition of a small amount of $Ca(OH)_2$ or C_3S accelerated the formation of CSH (I) and tobermorite.

Kondo (69) studied the kinetics of hydrothermal reaction between lime and silica. As representatives of the silica reactants, silica glass and quartz were chosen, the former being a species of pure silica, which possessed pozzolanic properties and the latter being the most stable form of silica, widely used for manufacturing autoclaved products. The particles of silica reactants between 5 and 10μ in radius were mixed with calcium oxide in a molar ratio of 1:1. The specimens were processed in an autoclave at various temperatures between 80 and 216°C, for various periods between 0.5 and 24 hours.

In the case of quartz, the reaction proceeds regularly without falling into any slump in a wide range of conditions, as shown in Fig. 25. The reaction of silica glass, on the other hand, is retarded excessively with the progress of reaction except when it is below 100°C or in the initial stage at higher temperature. As the reaction progresses, the lime-silica ratio of the product is converted from high to low in the case of quartz but a reverse trend is observed in case of a product obtained from silica glass as shown in Fig. 26. The rate of reaction seems to have a close relationship with the compactness of the product which varies with the process of formation. Such differences in composition or compactness of the product may be closely associated with the magnitude of solubilities of quartz and silica glass in the liquid phase.

It was found furthermore by Kondo, Ohsawa, Matsumaru, Kitamura and Kato (103) that the reaction rate was remarkably lowered by replacement of a part of the quartz with silicates, such as clay minerals, feldspar and fly ash, all of which contained alumina. Accelerating effect of alkali, on the contrary, is probably due to the increase in solubility of quartz. The results are shown in Fig. 27.

In connection with the composition of hydrous calcium silicate, they noticed that it was difficult for SO_3 to enter into the tobermorite lattice, in which, however, certain amounts of Na_2O, K_2O, Al_2O_3 and P_2O_5 seemed to be dissolved. Considerable amount of alumina was also found dissolved into α-dicalcium silicate hydrate as a sub-component.

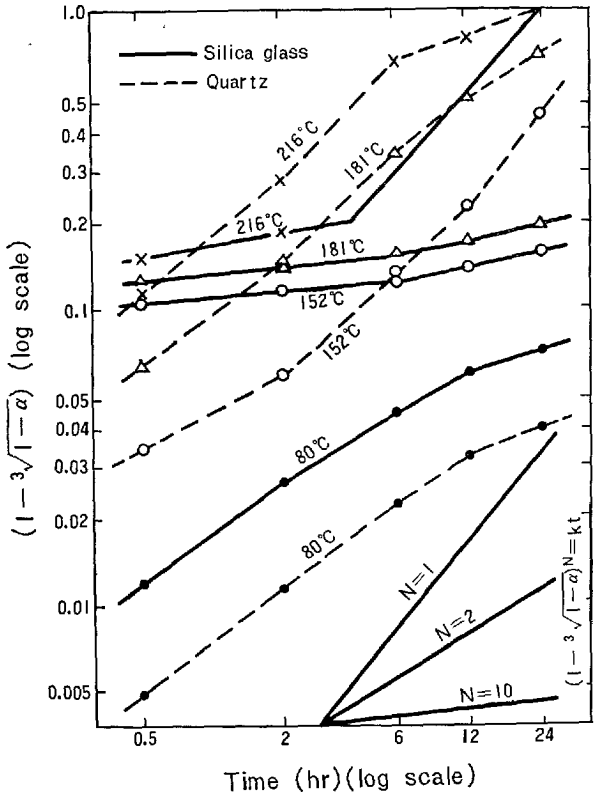

Fig. 25. *Rate of hydrothermal reaction between lime and quartz or silica glass. After Kondo(69)*

Next, they dealt similarly with the reactivity of diatomite. It tends to react easily with lime even at below 100°C to form a hydrate in bulky gel state, with considerable combined water and indefinite lime silica ratio which changes from low to high with the progress of reaction.

Temperature Dependence on the Rate of Hydration

Temperature dependence on the processes such as dissolution or hydration is frequently expressed perfunctorily as an activation energy. The activation energy is sometimes estimated as more than 10 kcal/mole even when the hydration of cement is controlled by diffusion. This seems to depend on the effect of the increase in pore size and pore volume due to the crystal growth of product with increase in curing temperature, however the chemical restriction may partly be concerned.

The temperature coefficients on the hydration rate of C_3S and C_2S are positive, according to Knoblauch (104), but on the other hand, van Bemst (105) shows negative values. According to Kantro, Brunauer and Weise (96), it is positive for hydration of C_2S and C_3S up to 70 and 30 percent degree of hydration,

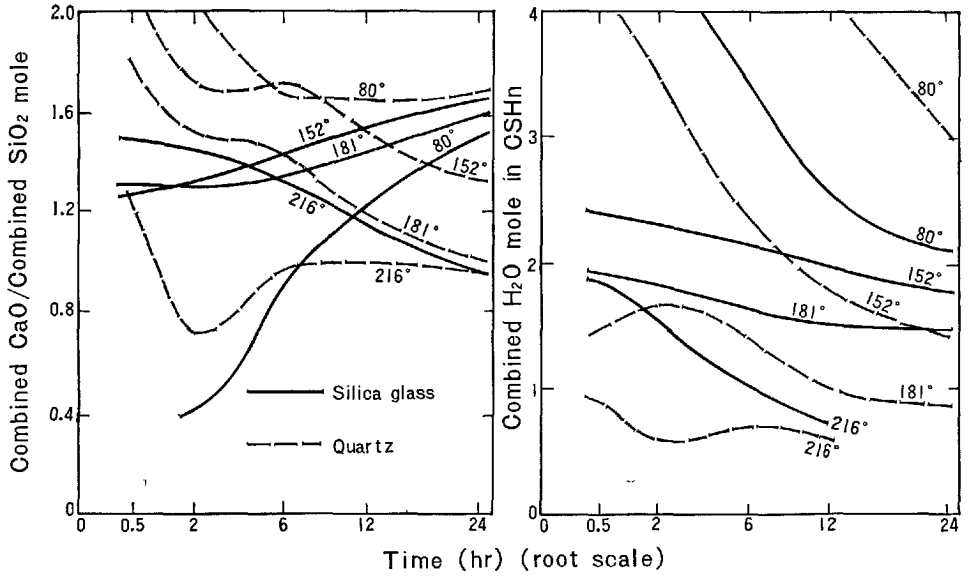

Fig. 26. *Changes in combined* CaO/SiO_2 *ratio (left) and combined* H_2O/SiO_2 *ratio (right) with processing time. After Kondo(69)*

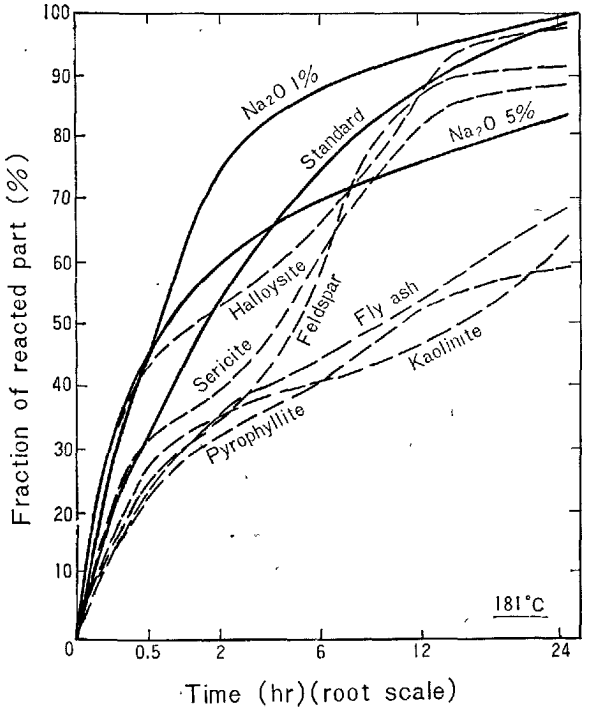

Fig. 27. *Effect on reaction rate of solubility alumina for 10% of silica by replacing part of quartz by other silicates, and of added alkali. After Kondo, Ohsawa, Matsumaru, Kitamura and Kato (103)*

respectively. Copeland and Kantro (106) examined the kinetics of overall reactions of portland cement from the heat of hydration, and found that the apparent activation energy was not a constant, but decreased from 8 to 2.3 kcal/mole with the degree of hydration.

The dissolution process of colloidal silica powder into lime solution is a reaction with an average activation energy of 16.7 kcal/mole by Halstead and Lawrence (66) and 9.4 to 18.4 kcal/mole by Greenberg (67). In the hydrothermal reaction between quartz and lime Kondo (69) indicated that an activation energy is 14.3 kcal/mole in the early reaction and 12.5 kcal/mole in the later. According to Moorehead and McCartney (107), the activation energy to produce xonotlite hydrothermally is 52.1 kcal/mole but this unusually high value probably depends on the change in pore volume.

The activation energy in the reaction of gypsum in a C_3A-gypsum system, according to Tenoutasse (81), is 12 kcal/mole. Tanaka, Murakami and Sato (108) reported that the activation energy in the early reaction of C_4AF to form hexagonal hydrates such as C_4AH_{13} and C_4FH_{13}, was 9.1 kcal/mole and that the subsequent reaction was retarded by the transformation of hexagonal hydrates to cubic ones. Layden and Brindley (109) obtained an activation energy of 16.1 kcal/mole in the hydration of magnesium oxide.

There are few data on the diffusion coefficients in hydration product of cement at various temperatures. For reference, the temperature dependence on the diffusion coefficient of the cation exchange in clay and

zeolite is given. According to Low (110) the activation energy for exchangeable ion movement in bentonite changed parallel with the specific volume of the adsorbed water, and the electrical interaction between ion and clay have little effect on the activation energy; that is, the activation energies for the migration of Li^+, Na^+ and K^+ ion in pure solution are 4.0, 3.9 and 3.4 kcal/mole respectively, and those in clay are only about 0.5 kcal/mole higher than in the former. The self-diffusion coefficients of Na^+ and SO_4^{--} ion in water and in bentonite are given by Lai and Mortland (111) as shown in Table 4. According to Rao and Rees (112), the diffusion coefficient in mordenite crystal at 60°C is expected as low as 1.0×10^{-12} in Na and 0.47×10^{-12} cm²/sec in K. The diffusion of Na which is controlled in the Na form by 2.8 Å windows has an activation energy of 8.74 kcal/g.ion.

Properties of Hydrates Concerned with the Rate of Hydration

The rate and mechanism of hydration are affected by the reactivity of the reactant and the various factors mentioned previously. However it is controlled more directly by the concentration and the constitution of the liquid phase at various sites, nucleation and crystal growth in the liquid or in hydrates, the composition and morphology of hydrates, the pore structure and the easiness of the mass transfer in the product.

Concentration and Constitution of Liquid Phase

The concentration of the liquid phase in cement paste and in suspension is equal to the solubilities of the hydrates when the reaction is completed. On the other hand, during the progress of hydration it is in the supersaturated state with respect to the outer hydration product. The liquid phase coexists with the outer product and is in the lower concentration with respect to the inner hydration product.

According to Mchedlov-Petrosyan and Babushkin (38), Ca^{++} ion dissolves accompanying with oxygen from reactant suface and Si^{4+} ion joins with existing OH^- group or forms double bonds with oxygen. $HSiO_3^-$ ion is stable at the range $pH = 8 \sim 13$. Whereas at $pH > 13$ SiO_3^{--} ion is the principal constitution unit. In the presence of Ca^{++} ion the latter polymerizes to form chains $(Si_6O_{17})^{10-}$, layers $(Si_{12}O_{31})^{14-}$ and networks $(Si_6O_{15})^{6-}$. Greenberg (67) reported that the silicate ion in the solution was monosilicic.

In the bottle hydration of C_3S with $W/C = 20$, according to Kondo, Daimon and Ueda (55) the concentration of the liquid after 1 hour is not saturated with respect to $Ca(OH)_2$, but is supersaturated with respect to C–S–H. After 3 hours it rises slightly with respect to $Ca(OH)_2$ and falls with respect to C–S–H than at 1 hour but both are in the supersaturated state. Thereafter the concentration of the liquid remains almost constant. Greenberg and Chang (113) also found similar results in the bottle hydration of C_3S.

The results of the chemical analysis of the liquids extracted from the C_3S paste were reported by Malinin, Lopathikova, Guseva and Klishanis (114), and Kawada and Nemoto (61) (75).

In addition, two maxima in the concentration are observed by Kondo, Ueda and Kodama (16) at the beginning and at the end of the acceleratory period as shown in Fig. 21. The coating layer produced or C_3S dissolves very slowly until the liquid reaches supersaturation with respect to $Ca(OH)_2$ during the induction period. After the supersaturation the outer products which consist mainly of $Ca(OH)_2$ are precipitated. The liquid concentration remains almost constant as the crystallization rate is larger than the rate of Ca^{++} ion supply from unhydrated C_3S. The crystal of $Ca(OH)_2$ grows rapidly but the rate of the growth decreases slightly after $7 \sim 9$ hours and thereby the liquid concentration becomes the second peak. At the same time C_3S particles begin to be enveloped by the growing crystals of $Ca(OH)_2$. Therefore the liquid concentration drops again because hydration reaction becomes retarded. It is difficult to estimate the very low SiO_2 concentration in the presence of CaO.

Greenberg and Chang (113) examined a C_3S paste with $W/C = 0.7$ and found that the saturation with respect to C–S–H was obtained within 2.75 min.

The liquid concentration in the suspension hydration of calcium aluminates or aluminous cement is independent of the composition difference of reactants as reported by Wells and Carlson (115).

Electric conductivity or resistance is sometimes

measured besides chemical analysis. It was reported by Greenberg and Chang (113) that the electric resistance in suspension hydration of C_3S showed a sudden drop within several minutes and a plateau appeared between 10 and 20 min. This fact seems to indicate very rapid dissolution of C_3S and the existence of time lag for nucleation.

The measurement of pH value is not difficult in excess water. Mchedlov-Petrosyan and Salop (116) developed tungsten and molybdenum electrodes which could act stably even in the hardening process.

In the above-mentioned studies only the liquid concentration outside the particle was measured. The method for measurement of the concentration and the constitution of the liquid in the interface of unreacted reactant has not been established, however it is very important to elucidate hydration reaction.

Nucleation and Crystal Growth

The free energy difference ΔG between the solute molecule and the solute crystallite in solution goes through a maximum when the radius of the crystallite increases to a certain value. The crystallite, which is larger in size than the critical nuclei of radius, commences to grow as a stable nucleus. When the liquid concentration becomes larger than supersolubility, the liquid becomes unstable to form a solute crystallite.

For nucleation from condensed phases Melia (117) proposed the rate equation

$$\log_{10} J = \log_{10} A - \frac{16\pi\sigma^3 V^2 N^3}{3(2.303\ RT)^3(\log_{10} S)^2}$$

where J is the nucleation rate, A is the kinetic constant, σ is the interfacial free energy per unit area between the forming phase and the metastable phase, V is the volume of a single molecule of the forming phase, R is the gas constant, and N is Avogadro's number. The nucleation rate, accordingly, is determined by the supersaturation ratio S, which is the ratio of the activities of the solute in the supersaturated solution and in the saturated solution.

Greenberg and Chang (113) measured the rates of formation of products from solutions of monosilicic acid and calcium ions by light-scattering measurements. They found that the rate of change of scattering increased with calcium concentration and pH in solution. They also observed that the dissymmetry values $Z = i_{45}/i_{135}$ decreased with reaction time, and proposed that the dissymmetry had to be attributed partially to the changes in size of the growing particles, to the anisotropy of hydrated calcium silicate particles, and to flocculation.

The precipitation of $Ca(OH)_2$ crystal commences at the end of the induction period. Kondo, Ueda and Kodama (16) observed C_3S hydration under a polarizing microscope and found that the outer product consisted of a few but yet well-crystallized $Ca(OH)_2$ and the C–S–H gel. The presence of the latter was confirmed by electron microscope, appearing very thin on the slide glass and the cover glass. The crystal growth rate of $Ca(OH)_2$ in the C_3S paste at W/C = 0.5 is shown in Fig. 28 (55). In view of this, they considered the formation of the metastable phase of the nuclei of $Ca(OH)_2$ and C–S–H gel based on Takiyama's consideration (118) with the relationship between supersolubility and solubility as shown in Fig. 29.

Ueda, Hashimoto and Kondo (2) reported from the result of surface electron diffraction that the depth of the intermediate product layer was 200–300 Å. According to Uhara (119) the size of the critical nuclei at which free energy becomes the maximum is in the order of 10^{-6} cm in case of solid nuclei. The C–S–H produced after 1 day grows to the extent a surface electron diffraction pattern is indicated (2).

Composition and Morphology

The rate of species migration through the hydrated product layer seems to be influenced mainly by the pore size distribution and morphology of the inner products. The particle size and morphology of the hydrate are closely related with its chemical composition. Furthermore the rate of hydration of C_3S in the later stage is related with the crystal size of $Ca(OH)_2$ produced.

The composition of hydration products illustrated in Fig. 22 shows that the reaction takes place with the same stoichiometry at the later stage. However, the hydration reaction of calcium silicate is not carried out with the same stoichiometry at least until the formation of stable hydrated product and becomes diffusion-controlled reaction. The compositions of hydrated products have been calculated from the results of several experiments. Particularly the different compositions at the very early stage have been reported by several investigators. Ueda, Hashimoto and Kondo (2) attempted to determine the composition and performed an experiment in which the hydrated particle was gradually dissolved with weak acid solution from its surface.

The difference in the morphology of C–S–H gel depending upon the difference of its composition has been discussed in detail by Richartz and Locher

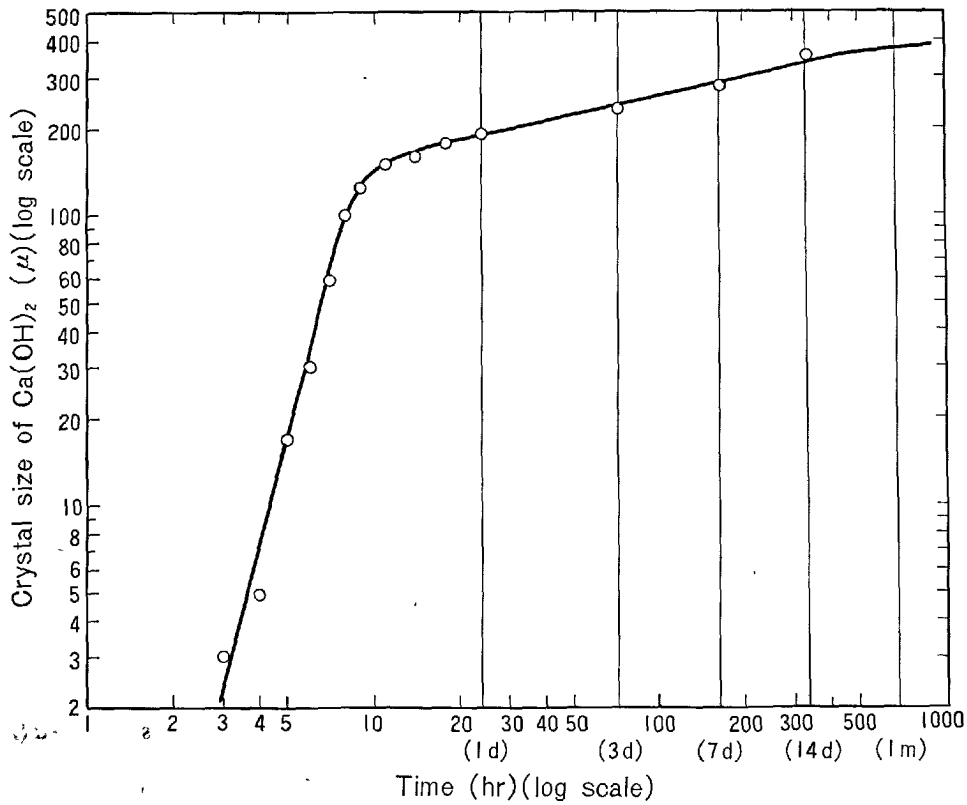

Fig. 28. *Crystal growth of* $Ca(OH)_2$ *in paste hydration of* C_3S. *($r = 2 \sim 5\mu$, $W/C = 0.5$, at 25°C)*

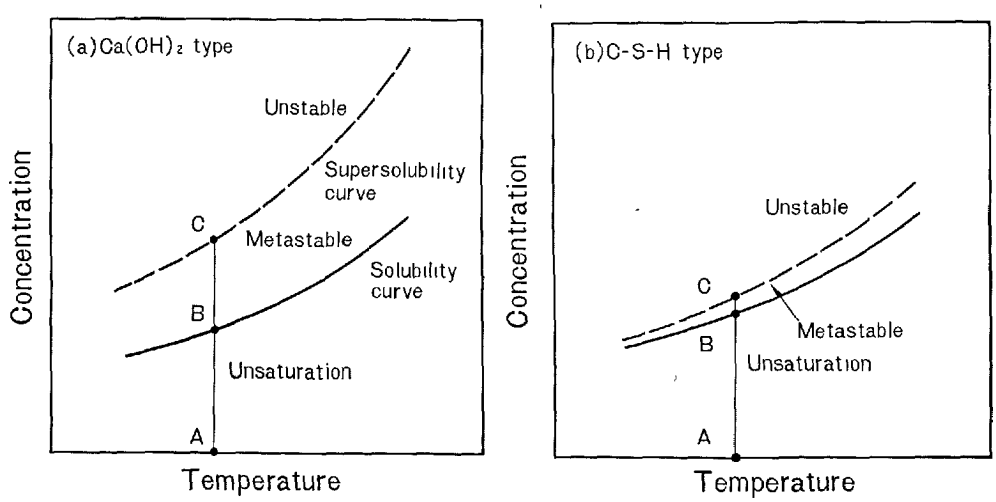

Fig. 29. *Relation between solubility and supersolubility.*

(48). Calcium silicate hydrates with a molar CaO/SiO_2 ratio of 1.0 crystallize in pseudorhombic foil and those of 1.3 in partly rolled-up foil, whereas those with a ratio above 1.4 form fibrous crystal. The electron diffraction of this fibre shows a diffuse pattern perpendicular to the fibrous direction. Thus, they confirmed that this fibre was of the rolled-up form. According to Sakurai, Ueda, Hashimoto and Fukunaga (120), CAH_{10} may also be of the rolled-up form.

Stein and Stevels (74) observed that the hydrate

habit converted from the crinkly foil (CSH(B)) to needle-like cigar-shaped agglomerates (C_2SH_2) before and after the induction period. But they thought that the acceleration of the hydration rate of C_3S depends upon the conversion of crinkly foil from closely fitting hydrate. The conversion begins in the induction period and then accelerates the main reaction. The kinetic equations were given by them as described later. Kondo, Daimon and Ueda (55) have further proved the changes of the surface state of C_3S powder in hydration by a scanning electron microscope as shown in Fig. 7. In 1 hour hydration, the particle surface is covered with scale-like products and the hydration itself does not make any progress, but 8 hours later the hydrate becomes active and the particle surface is highly progressed as can be seen in this figure. It can also be realized that in 3 days and 1 year the product gradually develops and as a result retarding the hydration.

Funk, Schreppel and Thilo (121) studied the hydration of β–C_2S and found that on the surface of crystal there was a zone of low refractive index and the thickness of this zone increased with increasing binding water to grow into the tobermorite-like phase. They called this product with low refractive index the intermediate product. McConnell (60) found the formation of gel pseudomorphs with relict lamellae twinning after natural β–C_2S (larnite). Such investigators, Trojer (53), Terrier and Moreau (54), Kondo, Ueda and Kodama (16), who studied the process of C_3S hydration with an optical microscope found that an intermediate product with low birefringence has formed surrounding the C_3S particle. According to Kondo, Ueda and Kodama (16), the inner product is formed epitaxially with a preferred orientation to the direction of the parent C_3S.

Until recently the calcium hydroxide in cement paste has not received much attention. According to Terrier and Moreau (54) (122), the $Ca(OH)_2$ crystal appears in the interstices of cement particles and crystallizes preferentially in larger pore to grow in 7 to 90 days to the extent the space permits. They also observed the second portlandite in the matrix between above cited first-crystallized portlandite and clinker particles. According to Kondo, Ueda and Kodama (16), a particle of $Ca(OH)_2$ grows not only in the pore space but also envelops the C_3S grains. This fact has a significant meaning as the acceleratory period of C_3S approximately coincides with the period of the largest crystal growth rate of $Ca(OH)_2$.

Aluminium substitutes silicon in hydrates and changes the properties of the products. Copeland, Boden, Chang and Weise (123) discussed in detail the relations among the molar CaO/SiO_2, H_2O/SiO_2 and Al_2O_3/SiO_2 ratios in a series of C–S–H gels containing different amounts of alumina. They also found that the aluminium substituted gel looked very much like the gel formed in the early stages of hydration of cement. Diamond (124) found also by X-ray fluorescence spectroscopy that Al^{+++} ion could substitute 15% of Si^{4+} ion in tobermorite produced by hydrothermal synthesis.

Pore Structure

The rate of hydration is occasionally discussed with the results of loss on ignition and free $Ca(OH)_2$ as the degree of hydration and even with strength. The pore volume is also closely related with the degree of hydration and strength, independently of the composition of cement. The pore structure of product in the radial direction to the reactant particle is most desirable to be elucidated in connection with the rate of hydration.

The pore system is divided into capillary pore and gel pore by Powers (125). Edel'man, Sominskii and Kopchikova (126) reported as a result of measurement with a mercury pressure porosimeter that the large capillary pores were the matrix between unhydrated clinker particles and new products, and the small pores correspond to the pore in the texture among the growing produced crystals. Mikhail, Copeland and Brunauer (127) reported that the nuclei of hydration products could not grow into crystals in small pores. Whereas Richartz and Locher (48) pointed out that there was a continuous size distribution for the entire pore space as the diameters of the calcium silicate hydrate tubes varied over a wide range. There may be no distinct difference between the small and large pore systems. The result of Kondo, Ueda and Kodama (16) indicates a continuous pore size distribution.

The relationship between pore size distribution and curing time is shown in Fig. 30. This figure shows that both the total pore volume and the size of pore decrease with the progress of hydration.

The fact that the pore shape in hardened cement paste is not always cylindrical was found by Schwiete and Ludwig (128) in observation of electron microscope. The shape of the pore can be determined to some extent by the hysteresis loop of adsorption and desorption isotherms. Mikhail, Copeland and Brunauer (127) pointed out that the shapes of hysteresis loops in hardened portland cement pastes came closest to those classified as type D loops by de Boer (129). Such type of capillaries is consisted of wide

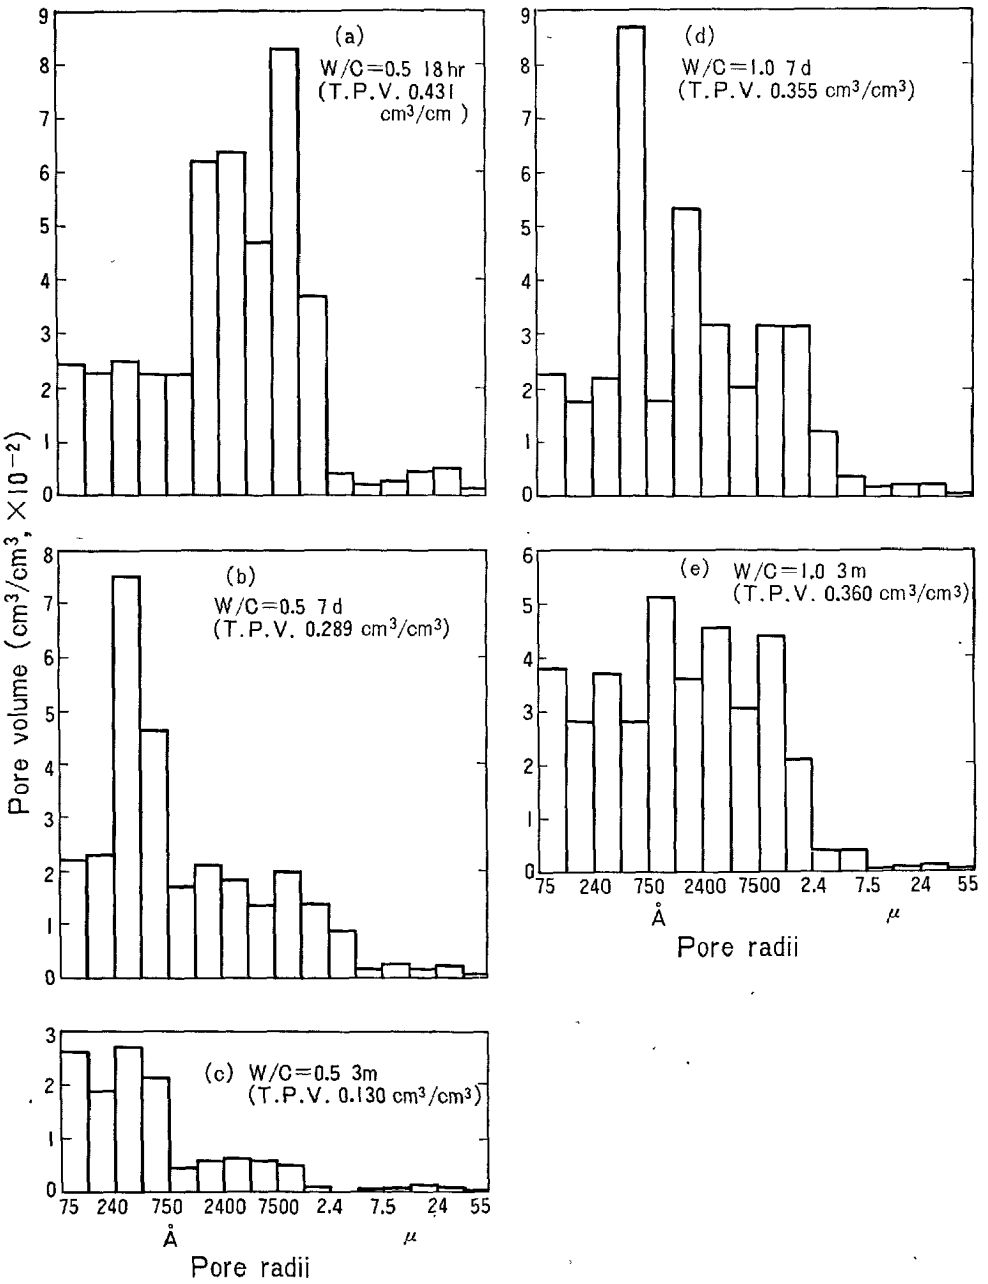

Fig. 30. *Pore size distribution of* C_3S *paste hydrated at 25°C. T.P.V. indicates total pore volume.*

bodies having a varying range of narrow short necks.

Besides open pore and sack-like pore, Powers, Copeland and Mann (130) pointed out the creation of capillary cavity. The necessary curing time for the creation of capillary cavity are affected by water cement ratio and temperature. For standard laboratory conditions, they were as follows: W/C = 0.7, 1 year; 0.6, 6 months; 0.5, 14 days; 0.45, 7 days; 0.40, 3 days. The fact suggests an increase in the hydration rate with water cement ratio. It has been confirmed that the surface area and the pore size distribution change due to the difference in water cement ratio by Hunt (25) and also by Kondo, Ueda and Kodama (16).

As a special experiments on the pore size distribution change with curing time, Feldman and Ramachandran (131) and Feldman and Sereda (132) studied on the hydration of C_3A compact. The effects of sand

cement ratio and CO_2 curing are studied by Kroone and Crook (133) (134). The effects of autoclaving are examined by Moorehead and McCartney (100) and also by Kondo, Ohsawa, Matsumaru, Kitamura and Kato (103).

Permeability and Diffusion

As hydration progresses, the interstices among cement particles are filled with the outer products to decrease the pore volume and particularly the pore size. As a result the permeability or the diffusivity in the hardened cement paste is lowered. This effect relates also with such as water permeation, rate of hydration, carbonation of hardened paste, sulfate attack and so on.

The rate of permeation and diffusion is expressed by the following equation,

$$Q = \frac{v}{t} = PA\frac{h}{\xi} = DA\frac{C}{\xi}$$

where v is the volume of permeation (cm^3), t is time (sec), P is the coefficient of permeability $P = \xi \cdot v/A \cdot h \cdot t$ (cm/sec) and A is sectional area (cm^2), h is the pressure difference (cm), ξ is the thickness (cm), D is the diffusion coefficient $D = \xi \cdot v/A \cdot C \cdot t$ (cm^2/sec) and C is the concentration difference (vol/vol).

The rate of permeation through a pore Q is expressed by the Poiseuille's equation as follows:

$$Q = \frac{\pi r^4}{8\eta} \cdot \frac{h}{l}$$

where r and l are the radius and length of single pore and η is the viscosity of the fluid.

In the case of gas, D decreases proportionally with r if r is less than about 1000 Å.

$$D = \frac{4r}{3}\sqrt{\frac{2RT}{\pi m}}$$

where m is the molecular weight of gas.

The molecules and ions in solution usually are hydrated with water molecules. The strongly hydrated species move less easily through the pore, whereas water molecule is most permeable because of its small size.

The membrane permeability coefficient P is equal to the value obtained by multiplying the diffusion coefficient in pore D by the pore volume ratio Ae/A and the tortuosity. D gives a lower value when compared with the diffusion coefficient in solution D because of the interaction of the adsorption sites along the pore. When the hydrated layer is electrically charged, the effect of the Coulomb's force appears. If it is negatively charged, it will be difficult for anion to migrate in the pore and it is the opposite in case of cation. Colloidal particles diffuse by Brownian motion and its diffusion coefficient D' is expressed as

$$D' = \frac{RT}{N} \cdot \frac{1}{3\pi\eta d}$$

where N is the Avogadro's number and d is the diameter of the particle.

In the hydration of cement, the outer reactants such as gypsum dissolve and diffuse inwards with water through the product layer around another reactant particle so that the latter reacts at the interface and a part of hydrate deposits to form inner products while the remainder diffuses outwards to form outer products. The pore size in the cement paste is exceedingly small and has a peak of pore volume at radii of 10 to 20 Å, and therefore interaction with diffusing ions cannot be neglected. Colloid particles formed as inner product hardly migrate outward. On the other hand, according to Moorehead and McCartney (100), the product treated in an autoclave at a very high temperature has big pores with radii of 2700 to 10800 Å. Thus, it appears that the migration is not affected by the interaction along the pore. They also determined the diffusion coefficient of Na^+ or Ca^{++} ion in these specimen (100).

In the hydration of hydraulic compound it is difficult to measure the concentration of the interface, and also it is almost impossible to study the diffusion coefficients of the produced layer after this layer is removed from the unhydrated particles.

Ionic diffusion in pores is comparatively well known in clay paste, zeolites and high-polymer film and some of these have already been mentioned. But it has not yet been examined the relationship between diffusion coefficient and the pore structure of hydrated cement.

Ratinov, Kurcheryaeva and Melentéva (135) measured the dissolution rate of pellets of C_3S, β–C_2S and hydrothermally synthesized C_3SH_2 and $C_2SH(A)$. The solubility of C_3S is 0.256, 0.338 and 0.387 g/l at 2°, 10° and 20°C, respectively. They also obtained the diffusion coefficients, which were 0.26×10^{-5} at 2°C, 0.30×10^{-5} at 10°C and 3.4×10^{-5} cm^2/sec at 20°C.

Spinks, Baldwin and Thorvaldson (136) determined the diffusion coefficient of hardened cement paste with a radioactive tracer. The diffusion coefficient D of 1:2 mortar in 4 weeks is 2.8×10^{-10} cm^2/sec for Ca^{++} and that of neat paste is smaller. They also found that anion generally indicated a diffusion coefficient higher than that of cation.

As the diffusion coefficient changes with the pore

structure, precise experiments to elucidate the relationship between the pore structure and the diffusion coefficient or the rate of hydration must be systematically carried out in the future.

The diffusion-controlled exchange between calcium in calcium silicate hydrate crystal and its surrounding solution was measured by Forrester and Lawrence (137). The self-diffusion coefficient for calcium in the hydrate crystal is very low, however it increases from 1.08×10^{-23} to 60.7×10^{-23} cm^2/sec as the molar CaO/SiO_2 ratio of hydrates change from 0.36 to 1.39. They considered that the low mobilities of calcium ion accounted for the slowness with which calcium silicate hydrate came to equilibrium with its aqueous solution and for the high durability of portland cement products.

Relation between the Rates and the Mechanisms of Hydration

The hydration mechanism of cement components changes with the progress of reaction even in the case of a certain single component. Therefore an equation which explains a single step cannot represent the actual rate which changes complexly. The kinetics of hydration should correspond to the mechanism but a strict model for the later stage especially is difficult to be given and an accurate measurement of the degree of reaction is also difficult particularly in the very early stage.

Variation in the Hydration Mechanisms with the Progress of Reaction

Periodical changes in the rate and the mechanism are generally observed in the hydration of plaster of Paris, portland cement, aluminous cement and so on. The variation with progress of hydration will be described in the case of C_3S as an example for it can represent the behavior of portland cement.

The result of measurement of heat evolution of C_3S with a conduction calorimeter gives the characteristic curve as shown in Fig. 31. Kondo, Ueda and Kodama (16) classified this characteristic curve into five stages to discuss the hydration process.

- S_I: The stage in which a short but rapid reaction takes place immediately on contact with water.
- S_{II}: The stage which corresponds to the so-called dormant period and the reaction rate is very low.
- S_{III}: The stage in which the reaction takes place very actively and is accelerated with time.
- S_{IV}: The stage in which the reaction rate is decreased after the most active reaction is over.
- S_V: The stage in which deceleration is more remarkable.

The whole process can also be differently divided into 3 periods. S_I and S_{II} correspond to the induction period, S_{III} is the acceleratory period and S_{IV} and S_V belong to the decay period. The variations in the properties of the liquid phase and the solid phase are summarized in Table 5.

The Induction Period

It had been considered that the exothermic reaction which took place immediately on contact of portland cement with water was due to the rapid hydration of C_3A, as already described but it was confirmed that

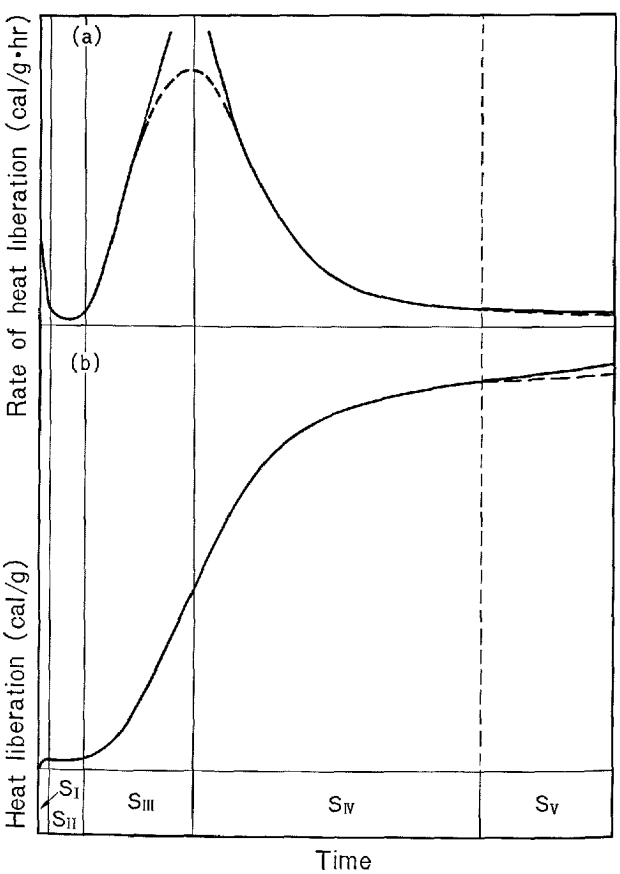

Fig. 31. *Classification of hydration stages of* C_3S

Table 5. *Characters of respective stages.*

	Stage	Induction period I	Induction period II (Dormant p.)	III (Acceleratory period) Start to reaction	III (Acceleratory period) Most active	Decay period IV	Decay period V
Liquid	CaO concentrn.	negligible	promptly up	down	a little up	down	
	(OH) concentrn.	negligible	promptly up	down	suddenly up	down	
	Ion product	negligible	promptly up	down	suddenly up	down	
Solid	Degree of hydrn. or combined H_2O	a little	dormant	start again	most actively up	gradually up	slowly up
	Amount of $Ca(OH)_2$	negligible		up	most actively up	gradually up	slowly up
	Amount of C–S–H	negligible		up	actively up	gradually up	slowly up
	C/S of C–S–H	about 3		suddenly down	constant	constant 1.6	1.6 → 1.7
	H/S of C–S–H	about 3		highest	down	down	2.5 → 1.7
	Surface area of total solid	small		up	highest	down	gradually up
	Surface area of C–S–H	small		highest	down	gradually down	

it appeared in the paste of C_3S.

According to Greenberg and Chang (113) the supersaturation with respect to C–S–H is reached within only 2.75 min. in a C_3S paste with W/C = 0.7. As the amount of C–S–H is large but of poor crystallinity, its metastable region is narrow as shown in Fig. 29 and it precipitates soon after the supersaturation. It may be formed on the surface of the C_3S particle, as Richartz and Locher (48) and Greenberg and Chang (113) pointed out.

The composition of the product which is formed immediately after C_3S is brought into contact with water, differes with investigators but it is believed to coincide with C_3S to which water has combined as shown in Table 5. This can be understood from the fact that the CaO concentration of the liquid is very low. Kondo, Ueda and Kodama (16) pointed out that the product layer is only less than 200 Å in thickness at 1 hour after the addition of water. The critical nucleus has the maximum difference of interfacial free energy at a product layer of the order of 10^2 Å by Uhara (119).

Kondo and Daimon (70) discussed the causes of formation of such a thin and compact layer in accordance with the following three hypotheses: (1) The formation of a protective layer of very low diffusion coefficient by the addition of water to the reactant. (2) The conversion of the amorphous layer around the reactant surface formed by grinding. (3) Minimizing the free energy by the strain energy of the surface product. In the third hypothesis the chemical free energy decreases with increase in the thickness of the layer but the total free energy reaches the minimum at a certain thickness due to the surface free energy of the thin layer. It reaches the maximum due to the compressive strain with increase in thickness. The strain energy which is stored at the surface of C_3S is

$$\Delta G_{\text{strain}} = \int_0^{k\sqrt{\delta}} \frac{4}{k^4}(k\sqrt{\delta} - y)^2 dy = \left[\frac{4}{3k^4}(k\sqrt{\delta} - y)^3\right]_0^{k\sqrt{\delta}} = c\delta^{3/2}$$

where δ is the thickness of the compressed layer, $k\sqrt{\delta}$ is the thickness of the stretched layer, y is a distance from the interface of C_3S and c is a constant. The ratio of the dependence of hypotheses (1)~(3) to the mechanism of actual hydration is not clear.

After the formation of metastable nuclei at the product layer, the inner products, which consist mainly of C–S–H with high CaO content, are topochemically formed and liberated excess Ca^{++} ion dissolves into the liquid. The outer product which is formed in solution may consist of much $Ca(OH)_2$ and lesser amount of C–S–H as the concentration of silica is lowered by increase in lime concentration of the liquid.

When a reaction does not begin immediately but has a time lag, this time is called the induction or incubation period. The term dormant period used in the hydration of cement is equivalent to this period.

Powers (138) assumed in the hydration of portland cement that during the dormant period the exposed surface of C_3A became coated by small amounts of their own products, and the physical characteristics of cement paste are not altered appreciably. But various kinds of chemical changes may take place during this period. The most characteristics in this period is the change in liquid concentration as shown in Table 5. The composition and the surface area of reaction product seems to be altering gradually. Namely the induction period is the stage in which the dissolution of Ca^{++} ion mainly takes place through the protective coating layer. This gradual dissolution continues until the liquid reaches to the unstable degree of supersaturation. According to Ueda, Hashimoto and Kondo (2), a 1 hour hydrated sample does not indicate a

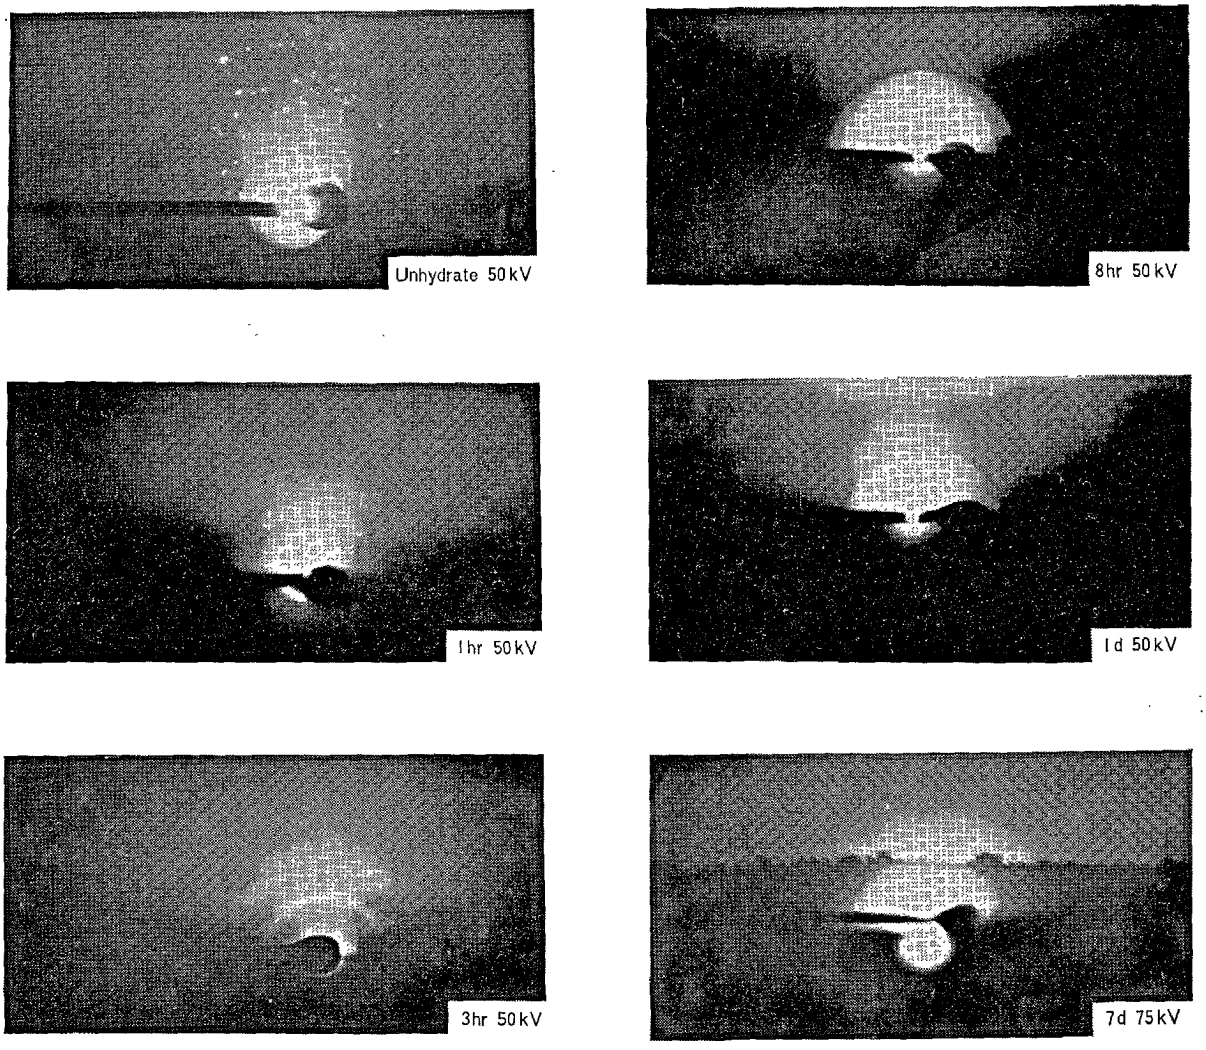

Fig. 32. *Surface electron diffraction patterns of hydrated* C_3S *particles.*

surface electron diffraction pattern but a 3 hour hydrated sample, which has already passed through the induction period, indicates a weak pattern. These results are shown in Fig. 32. It seems that the product layer liberates Ca^{++} ion during this period to give low mass absorption coefficient.

As is shown in Fig. 13, the hydration of C_3S with the saturated solution is to some extent retarded when compared with the case of pure water. According to Kondo and Daimon (70), the dissolution of Ca^{++} ion is decreased due to the small concentration difference by which the formation of topochemically produced nuclei is retarded.

Experiments on hydration by addition of seed crystal have been attempted. Funk (51) found that β-C_2S was practically transformed into dicalcium silicate α-hydrate at 100° to 200°C through the solution, if seed crystals of this compound were added. Stein (87) also found that the hydration of C_3A was accelerated by an addition of C_3AH_6. Kondo and Daimon (70) examined the hydration of C_3S paste by the addition of seed which was prepared by grinding 6 months hydrated paste, and found that the hydration became more retarded as more seed crystal was added as seen in Fig. 33. This suggests that the seed crystal plays the role of only increasing the liquid concentration due to the dissolution of $Ca(OH)_2$ in the seed. Accordingly the seed crystal seems to give only the same effect as the hydration with the saturated solution as has already been shown in Fig. 13. While de Jong, Stein and Stevels (72) found that the addition of CaO or $Ca(OH)_2$ to C_3S paste resulted in

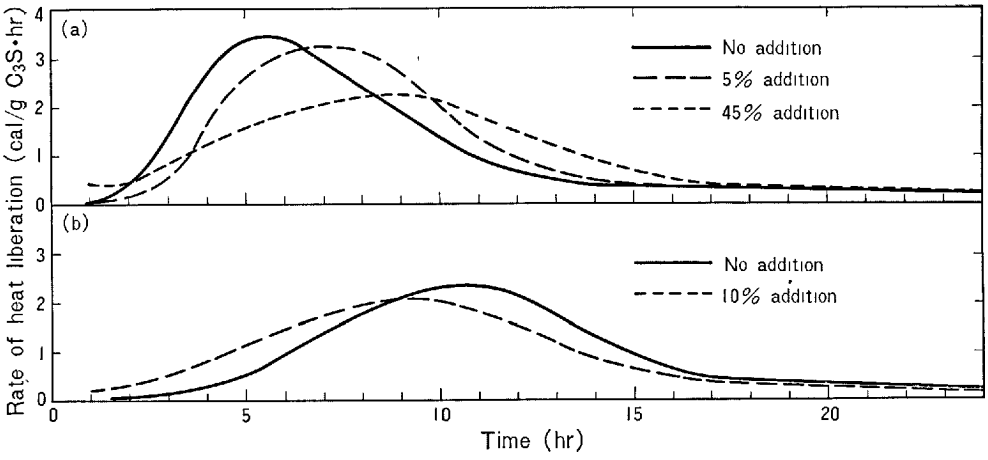

Fig. 33. *Effect of added seed on heat liberation of* C_3S. ($r = 2 \sim 5\mu$, $W/S = 0.5$, *at* 25°C) (*a*) *by pure water.* (*b*) *by saturated solution with respect to* $Ca(OH)_2$ *and* C–S–H

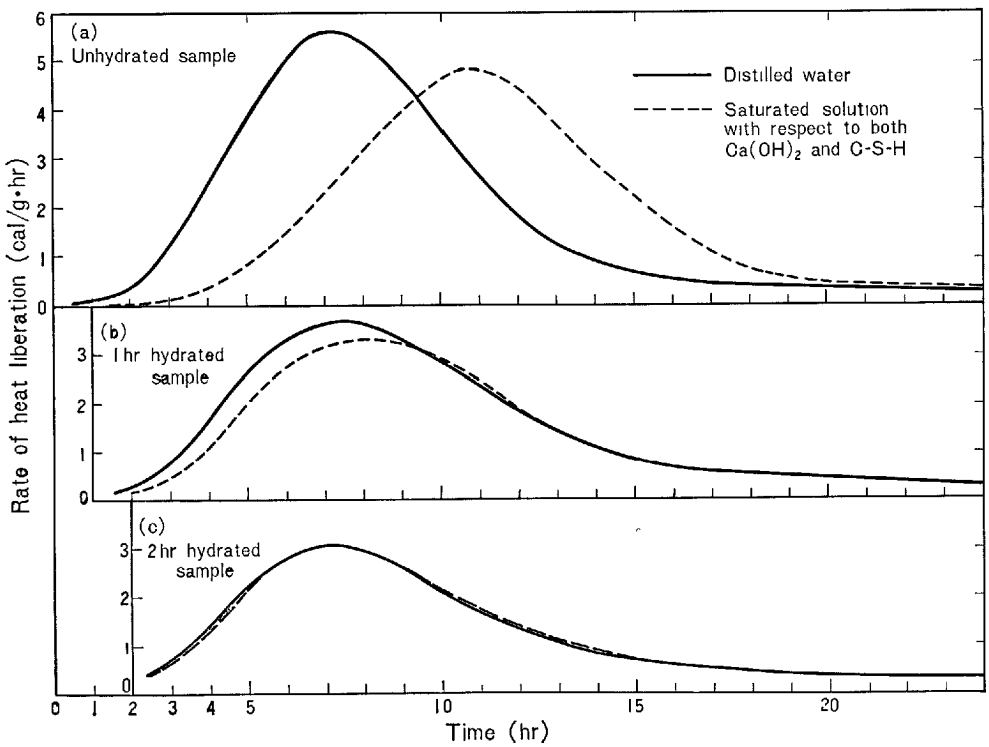

Fig. 34. *Heat liberation rate of rehydration of* C_3S.

the retardation, which was supposed to be due to suppressing the nucleation of meta-stable hydrate from unstable coating. On the other hand, Kondo and Daimon (70) pointed out that the hydration of C_3S with the saturated liquid with respect to both $Ca(OH)_2$ and C–S–H is accelerated if seed crystals are added as shown in Fig. 33. It seems desirable to testify the effect of seeds of various hydrates previously removed $Ca(OH)_2$ to avoid the complexity. The effect of seed consisting of C–S–H is considered to be the acceleration of the deposition of the outer product by increasing the growing sites and also to be the improvement of the crystallinity of the inner product which controls the rate of hydration.

On the other hand, despite of the cessation of hydration by drying the paste at a certain time of the induction period the hydration proceeds successively as usual as shown in Fig. 34 when dried sample is re-

wetted. This suggests that the metastable nuclei produced promotes the following reaction.

S_{II} is after all the stage in which the nuclei of C–S–H is being formed in the coating layer accompanying with increasing the liquid concentration. Thereafter not only the inner product but also the outer product are formed in S_{III} stage due to increase of the permeation of the protective layer.

The Acceleratory Period

There are various theories for the reason why a reaction begins to be accelerated after a certain period. Powers (138) considered that at the inside of a gel coating on a particle of cement osmotic pressure developed to split off pieces of the gel covering and the crystal surface was immediately accessible to water and thus permitted rapid reaction. Brunauer and Kantro (139) also considered that a protective skin on the unhydrated substrate had the same CaO/SiO_2 ratio as the substrate and such a high-lime gel coating might be unstable and decomposed with the liberation of calcium hydroxide, accompanied by the splitting off of thin layer of the second intermediate. Stein and Stevels (74) thought that the hydration of C_3S was accelerated by the conversion from a closely fitting hydrate to a crinkly foil hydrate with the change in liquid concentration. Kawada and Nemoto (75) considered that the seed crystal precipitated and at the same time the thickness of the intermediate product layer on the substrate decreased to make the diffusion of water easy and accelerated the hydration of C_3S. However, the theories mentioned above cannot explain satisfactorily the changes in the stoichiometry and morphology of hydrates and also the fact that the induction period is never appeared in the reaction of refreshed reactant surface.

Kondo, Ueda and Kodama (16) considered that the properties of the early produced protective layer with low permeability might be changed. Kondo, Daimon and Ueda (55) proposed further that the protective layer became porous. That is, when the nuclei of metastable C–S–H in the protective layer are grown to an extent of the thickness of the layer, the hydration of reactant begins again as the result of increase in permeability of the layer due to the liberation of lime. The rate of hydration reaction of C_3S in this period must be controlled by the degree of the sectional area of permeable part in the protective layer. The inner product composes of metastable C–S–H which has not become thick enough to control the rate of reaction in S_{III} stage.

When t_i is the time required for the induction period to be over, and k' is the slope of the differential for rate d^2q/dt^2, k' becomes smaller as t_i becomes longer as seen in Fig. 35. According to Kondo and Ueda (140), it was confirmed that d^2q/dt^2 was always positive, independent of the slope k', and the reaction proceeded with positive acceleration. When k' is positive, there is almost no resistance to retard the reaction effects and so the acceleration of hydration reaction increases with time. As is shown in Fig. 36, however, when the thickness of the inner product layer increases the material transfer is limited and k' becomes negative. As is shown in Fig. 36, when the degree of hydration is large and consequently the inner product is thick and $Ca(OH)_2$ crystals are large, the time required for k' to become negative shortens.

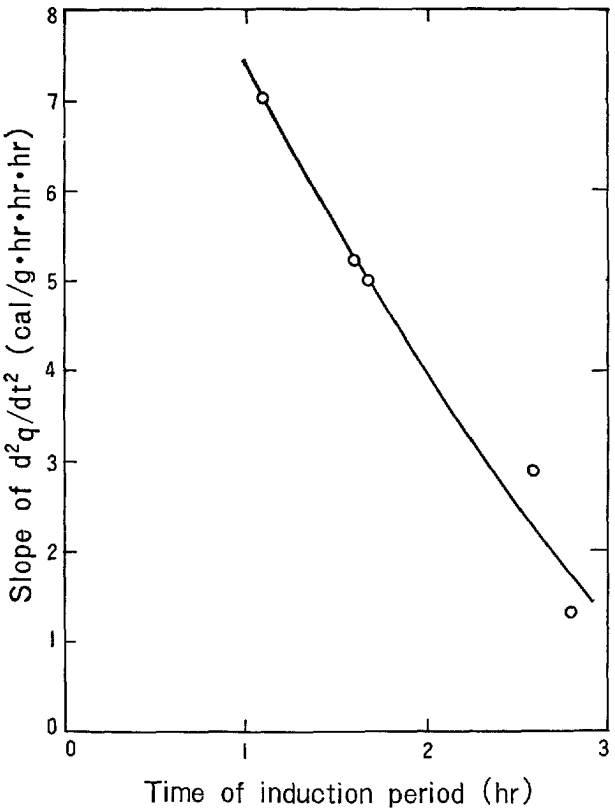

Fig. 35. *Change in velocity of acceleration of* C_3S *hydration with time of induction period*

The Decay Period

When the reaction proceeds further, it indicates negative $d^2\alpha/dt^2$ and the rate begins to decrease. At the beginning of this period the thickness of the inner product exceeds 2000 Å and the surface of the original C_3S particle seems to be changed as is seen in Fig. 10. The reaction in this period depends upon the rate $N = 2$ as seen in Fig. 1, and is controlled by the outer diffusion through the inner product layer. $Ca(OH)_2$

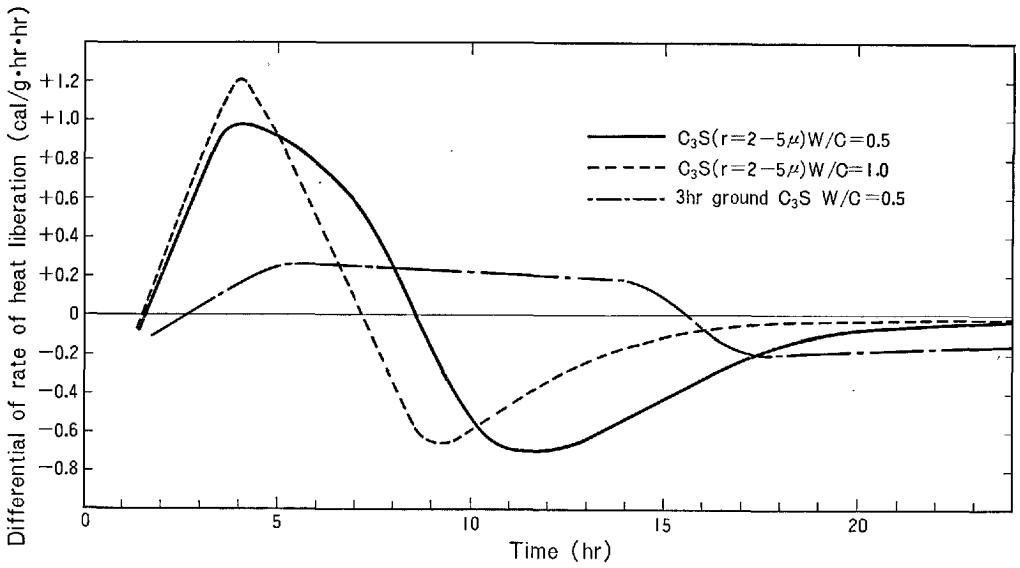

Fig. 36. *Curve of differential of heat liberation rate*

formed in the outer hydration space becomes larger than 100 μ and envelops many C_3S particles.

It is apparent from Fig. 32 that the S_{IV} stage shifts to S_V stage gradually. The inner product increases in compactness and is enveloped by $Ca(OH)_2$, and the reaction is controlled by a diffusion such as $N > 2$, namely the diffusion coefficient decreases with increase in time.

At the beginning of the S_V stage the size of the $Ca(OH)_2$ crystal reaches already 200 μ. Thereafter it grows gradually and envelops most of C_3S particles as is shown in Fig. 37. According to Kondo, Daimon and Ueda (55), it has been confirmed that the inner product consists of two zones in a perfectly hydrated sample. Compared with the outside part, the inside part indicates greater refractive index. Terrier and Moreau (54) observed two kinds of inner products and reported that the inside part had the higher CaO/SiO_2 ratio. The C_3S enveloped by $Ca(OH)_2$ cannot react with the outer water, but reacts with the gel water held in the product previously formed. Therefore the inside part may consist of a product of higher CaO/SiO_2 ratio and lower H_2O/SiO_2 ratio than the outside part which is formed before. The second portlandite is formed surrounding the C_3S particle as mentioned by Terrier and Moreau (54). According to Ueda, Hashimoto and Kondo (2), the inner product at 1 day grows to indicate the surface electron diffraction pattern, as shown in Fig. 32.

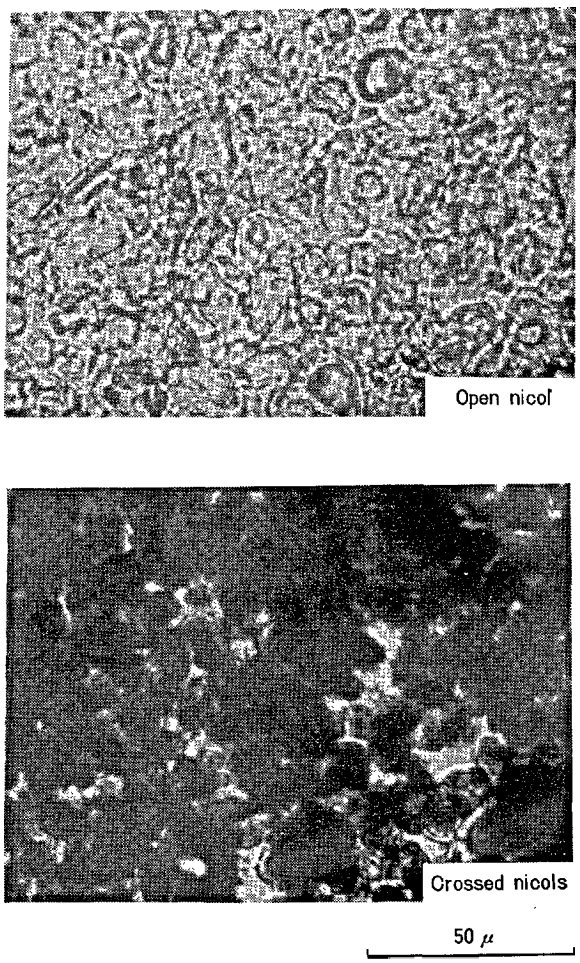

Fig. 37. *Inside and outside products in inner product*

Rate Equation of Hydration

The rate of hydration of cement components is

generally determined by the mass transfer through the product layer formed around the reactant particles, except at the early stage of paste hydration and ball-mill hydration. The rate equation for whole hydration process is shown, although the rate determining step changes with progress of reaction. As the rate has already been discussed for the case in which the particle size of the reactant is distributed, it will be discussed here by assuming a sphere of a single size.

Non-Diffusion Controlled Reaction

First, the rate equations other than the diffusion controlled step, for instance the boundary reaction being a slow step, will be reviewed. Furthermore, several reports have applied conventionally the rate equations for homogeneous reaction to discuss the order of reaction and empirical equations which do not correspond to an actual model.

As cited previously, Halstead and Lawrence (66) and also O'Connor and Greenberg (68) discussed the rate of reaction between colloid silica and lime solution and expressed the results by the following equation.

$$1 - x^{1/3} = kt$$

where x is the fraction of silica remaining in solid form after time t. In this reaction the dissolution of silica is the slow step and the rate is proportional to the surface area of reactant. The rate of solution is independent of the hydroxyl-ion concentration in the range of 15–40 milli-equivalents/ liter.

Greenberg and Chang (113) determined the rate of hydration of C_3S from the measurement of concentration and electric resistance of the solution, as C_3S dissolved congruently about 0.25 g per liter of water. The rate equation is as follows

$$-\frac{d(C_3S)}{dt} = k_1 S - k_2(C_3S)_a S$$

where (C_3S) is the concentration of unreacted C_3S, $(C_3S)_a$ is the concentration of dissolved C_3S, S is the surface area of unreacted C_3S, and k_1 and k_2 are the rate constants of dissolution and precipitation on the surface of particles, respectively. However, this does not always correspond to the experimental results.

According to Brunauer and Kantro (139), the reaction of C_3S in ball-mill hydration is always accelerated as the gel coating is removed. If it is assumed that the reducing rate of C_3S is equal to the disappearing rate of the gel coating, this can be expressed by the following equation.

$$-\frac{d(C_3S)}{dt} = k(C_3S)^{2/3} \qquad (1)$$

The rate is proportional to the surface area of C_3S. k is $0.095\,h^{-1}$ and then C_3S reacts completely at 31.5 h.

In the case of the hydration of calcum sulfate hemihydrate, a maximum in the rate was found by Taplin (141) near the mid-point of the reaction. The precipitation of gypsum controls the rate until the maximum, and thereafter the control passes to the dissolution of hemihydrate, which may be related with diffusion. An equation mentioned below is given

$$\frac{1}{\frac{d\alpha}{dt}} = \frac{1}{g} \cdot \alpha^{2/3} + \frac{1}{h} \cdot (1 - \alpha)^{2/3}$$

where g and h are the empirical rate constants for the precipitation and for the dissolution respectively. In practice the exponents become more than 2/3. The accelerators usually increase the rate of precipitation.

Knoblauch (104) examined the rate of hydration of C_3S and C_2S at several temperatures and reported that the former was the reaction of the third order and the latter was 1.5. Brunauer and Greenberg (20) suggested that these reactions were rather the diffusion controlled reaction. zur Strassen (142) interpreted from the result of Knoblauch (104) that the hydration of C_2S was obeyed by the surface controlled reaction from several days up to 120 days and it was controlled by diffusion thereafter, and that the hydration of C_3S was diffusion controlled until 30 days.

The rate of dissolution can be apparently expressed by an equation for the first order reaction which was derived by Nernst. As an example of such reaction there is the hydration of magnesia studied by Coleman and Ford (143). When the sample is exposed to an atmosphere saturated with water vapor, the hydration rate can be expressed by such type of equation as follows,

$$\ln(1 - \alpha) = -kt$$

The relationship between the rate and the mechanism is not clear, but they concluded that this hydration was the result of capillary condensation of water-vapor in the micro-pores of MgO and its rate was dependent, not on specific surface, but on the difference in the starting materials and calcination temperatures. On the other hand Layden and Brindley (109) found an incubation period in the hydration of magnesia and interpreted that an interface reaction controlled the progress of the overall reaction. The rate of hydration of magnesia in the vapor-phase can be expressed by similar equation as like (1).

Rate Equations of the Solid State Reaction

Rate equations of the solid state reaction controlled by diffusion are given by many investigators. Particularly the equation derived by Jander (144) is frequently used. The equation is as follows:

$$[1-(1-\alpha)^{1/3}]^2 = kt$$

where α is the reaction ratio and t is time. This equation was derived by assuming the sectional area of diffusion being the original surface but the area should be the geometric mean between the former and the interface of the reactant which reduced with progress of reaction. However it was reported by Kondo and Choi (145) that this equation conformed to another kind of the solid state reaction which took place in the presence of melt, for an example $C + C_2S \rightarrow C_3S$ in the portland cement formation.

Ginstling and Brounshtein (146) obtained a more accurate equation. Their equation can be modified to express by the function of the thickness of reaction layer in convenience of later discussion and to elucidate the meaning of the rate constant.

$$[1-(1-\alpha)^{1/3}]^2 - \frac{2}{3}[1-(1-\alpha)^{1/3}]^3 = 2DCt \cdot \frac{1}{ar_0^2} \quad (2)$$

where α is the reaction ratio, D is the diffusion coefficient, C is the concentration difference expressed as g reactant/1000 $cm^3 \cdot \rho$, where ρ is the density (g/cm^3) of the solid reactant and "a" is a constant described later and r_0 is the radius of the original reactant particle. As shown in the above equation, the first term of the left side dominates the reaction in the early stage to coincide with Jander's equation and on the other hand, the second term dominates the reaction in the later stage to complete faster.

The above two rate equations are given under a very simple assumption that the mass transfer depends only upon inward diffusion and the volume of the reacted reactant is equal to that of the formed product. Thereafter Carter (147) proposed an equation in which the volume ratio of the reacted part to the formed product was considered. But all of these equations are not natural because of the assumption that the product is formed only at the interface of reactant. If it is true each particle must be expanded and the rate constant cannot remain unchanged owing to the destruction of the texture of the formerly formed product.

Regarding this matter Taplin (57) considered that the outer product and inner product were formed simultaneously by counter diffusion in the hydration of C_2S and gave the equation (148) in which two diffusion coefficients on both products were taken into account. The following equation is a modification of Taplin's equation to make easy to compare with the equations mentioned above.

$$\frac{1}{D_i}\left[1-(1-\alpha)^{2/3}-\frac{2}{3}\alpha\right] + \frac{1}{D_o}(z-1)\left\{1+\frac{2}{3}(z-1)\alpha-[1+(z-1)\alpha]^{2/3}\right\} = \frac{2Ct}{ar_o^2}$$

where D_i and D_o are the diffusion coefficients on the inner and outer products, respectively, and z is the volume ratio of the product to reactant.

The above equation is reduced to Carter's equation if $D_i = D_o$, and coincides with the equation of Ginstling and Brounshtein if $z = 1$. The meaning of rate constant is here clarified, however it is not described by Ginstling and Brounshtein (146) and Carter (147). A factor "a" in the right side term must not be neglected, nevertheless it is not considered by Taplin (148) as all of the reacted reactant does not diffuse outward but only a part "a" of this diffuses. In addition, "a" is to be $(z-1)/z$ when the densities of inner and outer products are the same. It is obvious from the above equation that particularly the rate at the later stage decreases when the diffusion through the outer product is the slow step.

Mass Transfer Controlled by Diffusion

The rate equations mentioned above is applicable to the case of hydration if the diffusion is a slow step. Furthermore some rate equations mainly concerned with the hydration reaction will be reviewed.

Greenberg and Chang (113) considered that the rate of the hydration of C_3S was controlled by the rate of diffusion of the ions into the surrounding solution through the product layer and applied an equation given by Brunner and Tolloczko.

$$-\frac{d(C_3S)}{dt} = kS[(C_3S)_s - (C_3S)_d]$$

where k is a function of diffusion, S is the surface area of C_3S particle, (C_3S), $(C_3S)_s$ and $(C_3S)_d$ are the concentrations of unhydrated C_3S, dissolved C_3S on the interface of unhydrated C_3S and dissolved C_3S in the solution far from the unhydrated particle surface respectively. This equation, however, does not coincide with the experimental results. It seems that it is necessary to take into consideration the thickness of the product layer.

On the other hand, Ratinov and Lavut (149) discussed the early stage of suspension hydration of C_3S.

with the rate of solution. The solution rate of a disk is as follows.

$$\frac{dl}{dt} = \frac{D}{\rho\delta}(C - C')$$

where, l is the size of particles, D is diffusion coefficient, ρ is density, δ is the effective thickness of the diffusion layer and estimated from the study of Levich as $\delta = kD^{1/3}$ in which convection and diffusion are taken into consideration, C is saturated concentration and C′ is the concentration of the liquid. The dissolution rates of the pressed pellets of C_3S, C_2S or hydrothermally synthesized product such as C_3SH_2 or $C_2SH(A)$ are obtained (135). Both results were substituted in the above equation, by which the following equation was derived.

$$\frac{1}{k_1}(m_1^{\frac{1}{3}} - m_{1.0}^{\frac{1}{3}}) - \frac{1}{k_2}(m_2^{\frac{1}{3}} - m_{2.0}^{\frac{1}{3}}) = -D^{\frac{2}{3}}(C_1 - C_2)t$$

where, m_1 and m_2 are the weight of reactant and product, respectively, at time t, $m_{1.0}$ and $m_{2.0}$ are those at $t = 0$. As l_1 and l_2 are in the order of $10 \sim 50\ \mu$ and $100 \sim 500$Å respectively, $C_1' - C \gg C - C_2'$, and $k_1 D^{2/3}(C_1 - C_2)$ can be approximated as a constant, so that

$$m_1^{\frac{1}{3}} - m_{1.0}^{\frac{1}{3}} \simeq -kD^{\frac{2}{3}}(C_1 - C_2)t$$

In the case of cement, C_2 can be ignored as $C_1 \gg C_2$. The determined value of $-k \cdot 10^4$ is $1.0 \sim 1.1$ at $20° \sim 65°$C. The value $m_1^{1/3} - m_{1.0}^{1/3}$ is kept nearly zero for $2 \sim 3$ hr, thereafter it increases proportionally with lapse of time. The slope of the line obtained from this equation becomes steeper, which implies that the reaction is accelerated by the addition of a salt such as $NaNO_2$, KCl and K_2SO_4. This rate equation is dealt with carefully but this cannot be utilized for paste hydration in which the diffusion through the product layer becomes the slow step.

Stein (150) discussed the retardation of the reaction of C_3A by the formation of ettringite in the presence of gypsum and lime. If the amount of the ettringite produced is P, f is the fraction of ettringite formed around the interface of reactant to cause retardation, the following equation was obtained from Fick's first law of diffusion.

$$-\frac{d\ln f}{dt} + 2\frac{d\ln \mathrm{A}}{dt} = \frac{1}{\mathrm{P}} \cdot \frac{d\mathrm{P}}{dt} + \frac{\dfrac{d^2\mathrm{P}}{dt^2}}{\dfrac{d\mathrm{P}}{dt}}$$

The relation of P vs t is a straight line when the beginning of the second peak of the rate of heat liberation is taken as t. He substituted Blaine's surface of C_3A for A which is the area of the relevant surface concerned with diffusion as he intended only to apply to the early stage of reaction.

Rate Determining Steps in Hydration

In the case of the reaction of spherical particle the relation between the thickness of the reacted layer ξ and time t is expressed as $\xi = kt$ when the rate determining step is boundary reaction. On the other hand when the reaction is controlled by diffusion, the relation $\xi^2 - \frac{2}{3}\xi^3 = kt$ is given as shown by equation (2) but this equation becomes approximately $\xi^2 = kt$ in the very early stage.

It is hold for many reactions an empirical equation in which the N power of the function of the thickness of reaction layer $1 - (1 - \alpha)^{1/3}$ is regarded as being equal to kt. The value of N is 1 if the slow step is boundary reaction and approximately 2 if it is diffusion. This value sometimes becomes less than 1 or more than 2, however almost no discussion has been made on hydration reaction in the past.

When N is less than 1, an autocatalytic reaction is expected and the rate is accelerated with progress of reaction. This type of reaction occurs at the acceleratory period.

It can be considered that an impermeable product layer formed at the S_I stage decreases in thickness gradually to become permeable at the S_{III} stage. However, the consideration of the change of rate with time and of mechanism leads us to a conclusion that the formation and growth of nuclei start by the transformation from unstable to metastable phase during S_{II} stage already. When the size of transformed spots reaches the thickness of protective layer, this layer becomes permeable to change to S_{III} stage and further growth of these spots seems to increase the sectional area of permeable part. This process leads to a proportional increase in the rate of hydration.

Kondo and Daimon (70) proposed a following rate equation for transformation in the product layer. They considered that the reaction was boundary controlled, and that the transformed part grew linearly at a constant rate k.

$$\alpha_j = \frac{\pi}{2}k^2(t - t_g)^2$$

where α_j is the transformed volume and t_g is the time when the center of transformation is formed. If the rate of increase of the center is k', the following equation is obtained.

$$\alpha - \alpha_i = \sum_{t_g=t_i}^{t} k'\alpha_j = \frac{\pi}{2}k^2k' \int_{t_i}^{t} (t - t_g)^2 dt_g$$

$$\alpha - \alpha_i = \frac{\pi}{6}k^2k'(t - t_i)^3$$

The rate of increase in α_j is practically decreased by

the collision of the growing fronts and the roughness of the particle surface. k' is also saturated by the end of S_{III}.

If we next assume diffusion as being the slow step,

$$d\alpha = \frac{3DC\epsilon}{\xi r}dt = k\epsilon\, dt$$

where ϵ is the volume fraction of the permeable part. In case of the transformed part grows in length and width with time,

$$\epsilon(t) = k'(t - t_i)^2$$
$$d\alpha = kk'(t - t_i)^2\, dt$$
$$\alpha - \alpha_i = \frac{1}{2}kk'(t - t_i)^3$$

where ϵ is a fraction of the total transformed metastable phase ϵ'. Accordingly, ϵ' increases in the S_{II} stage but ϵ remains zero.

On the other hand, from the heat liberation data during the S_{III} stage, the following equation is given.

$$\frac{d^2q}{dt^2} = k(t - t_i)$$

where, k(cal/g·hr^3) indicates the rate of increase in the permeable area, and t_i is the time of the induction period. Since the temperature dependance of k is as large as 37 kcal/mole, the hydration of C_3S at the S_{III} stage is regarded as being controlled by the chemical reaction in which the protective layer is transformed into the metastable phase.

When N is a value larger than 2, the diffusion may be the slow step, however the diffusion coefficient decreases gradually. The reaction at the S_V stage mentioned above is an example of this type. The diffusion coefficient through the hydration product is generally smaller than in bulk liquid so that the ratio of sectional area of the total through pores to the relevant surface is smaller than 1, the tortuosity is higher than 1 and chemisorption of capillary is also effective. When the pore structure becomes more dense, it can be expressed by $\xi^N = kt$ where $N > 2$. In general $\xi^2 = vt$, where v is a variance, which is expressed as $v = k'/\xi^{N-2}$. Accordingly the diffusion coefficient D decreases in this case at a rate of $1/\xi^{N-2}$ with progress of reaction.

In the hydration of C_3S, the S_{IV} stage whose reaction is controlled by diffusion through only inner product is very short. In the S_V stage most particles are enveloped by the growing $Ca(OH)_2$ crystal and thereafter the subsequent hydration is very limited as the gel water in the inner product formed before is only available for hydration. Then the value of N of the overall reaction after 1 day becomes 2.5 to 2.8.

Kinetics of the Whole Hydration Process Having Various Stages.

The complicated change occurring in the hydration of cement with progress of reaction has already been explained. Kondo and Kodama (151) tried to formulate these complicated changes without over simplification. Here the whole hydration process containing the five stages from S_I to S_V will be described. The equations obtained are also applicable to somekind of solid state reactions having induction and acceleratory periods.

A dense protective layer seems to be formed on the reactant suface during the early part of the reaction and this follows the parabolic law as a kind of an erosion reaction.

$$\frac{d\xi}{dt} = \frac{k}{\xi} \qquad \text{or} \qquad \xi^2 = kt + k'$$

where, k' refers to the very early chemical reaction term which is not affected by diffusion. In this period, it can be considered that ξ will be proportional to α, so

$$\alpha^2 = k_\alpha t + k'_\alpha$$

The change of $d\alpha/dt$ or α with time is shown in Fig. 38, (a) and (b), respectively.

Next, the geometry of a single sphere of reactant whose original radius and the radius of the partly reacted reactant are r_o and r, respectively, is shown in Fig. 39. Among the overall transport processes of the chemical species, the slowest one is assumed to govern the rate of reaction.

Now, let us consider the situation where the reaction $d\alpha$ advances in the duration dt at time t. The flux of the material or ion in relation to the rate determining transport process F, is formed in proportion to $d\alpha$, so that the flux in a single spherical particle can be expressed by the following equation.

$$F = \frac{4}{3}\pi r_o^3\, a\frac{d\alpha}{dt}$$

where, "a" is the proportionality constant when the chemical species concerning the rate controlling diffusion are formed in proportion to the quantity of the hydrated reactant.

Hence, it is possible to derive the following equations.

$$C_1 - C_2 = \frac{4}{3}\pi r_o^3\, a\frac{d\alpha}{dt}\cdot\frac{\Delta r_a}{D_a\cdot S_a} \tag{3}$$

$$C_2 - C_3 = \frac{4}{3}\pi r_o^3\, a\frac{d\alpha}{dt}\cdot\frac{\Delta r_b}{D_b\cdot S_b} \tag{4}$$

$$C_3 - C_4 = \frac{4}{3}\pi r_o^3\, a\frac{d\alpha}{dt}\cdot\frac{1}{D_c\cdot S_c} \tag{5}$$

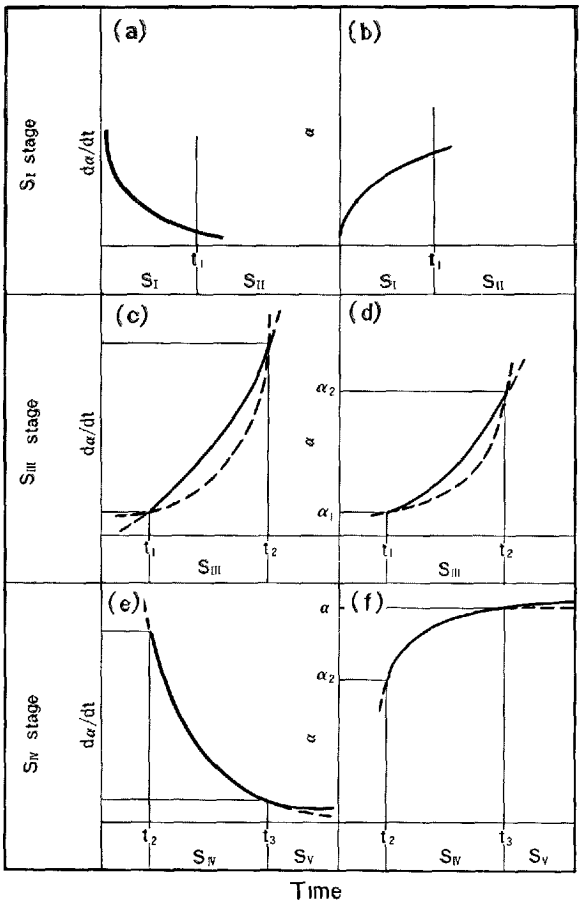

Fig. 38. *Relation between hydration rate or degree of hydration and time at each stage*

where, C_1, C_2, C_3 and C_4 are the concentrations of the rate determining chemical species in each position, D_a, D_b and D_c are the mass transfer coefficients of the rate determining chemical species in each position, and S_a or S_b is the geometric mean surface between S and S_o', or between S_o' and S_o, respectively. By combining (3), (4) and (5), we obtain,

$$\frac{4}{3}\pi r_o^3 a\frac{d\alpha}{dt} = \frac{C_1 - C_4}{\dfrac{\Delta r_a}{D_a \cdot S_a} + \dfrac{\Delta r_b}{D_b \cdot S_b} + \dfrac{1}{D_c \cdot S_o}} = \frac{C}{\sum_{i=1}^{3} R_i} \tag{6}$$

where, C is the overall concentration difference, and R refers to the resistance to the flux of the rate determining process, and is expressed by,

$$R_1 = \frac{\Delta r_a}{D_a \cdot S_a},\quad R_2 = \frac{\Delta r_b}{D_b \cdot S_b},\quad R_3 = \frac{1}{D_c \cdot S_o}$$

Now, the flux of the rate determining process is given from equation (6).

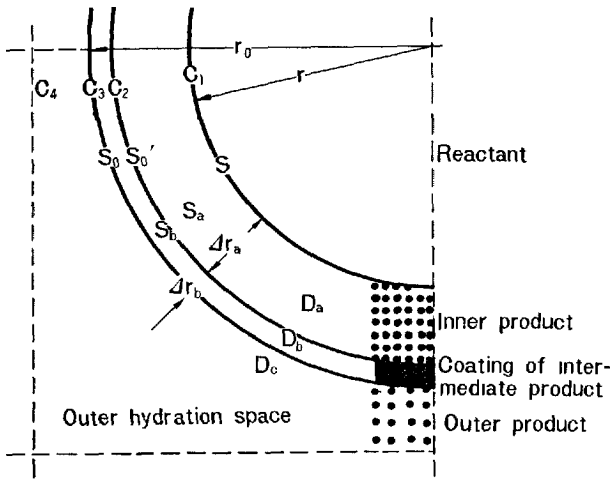

Fig. 39. *Schematic diagram of hydrated spherical particle*

$$\frac{4}{3}\pi r_o^3 a\frac{d\alpha}{dt} = \frac{S_o \cdot C}{\dfrac{\Delta r_a \cdot S_o}{D_a \cdot S_a} + \dfrac{\Delta r_b \cdot S_o}{D_b \cdot S_b} + \dfrac{1}{D_c}} \tag{7}$$

where S_o, S_a and S_b are

$$S_o = 4\pi r_o^2$$

$$S_a = (S_o' \cdot S)^{\frac{1}{2}} \fallingdotseq [4\pi r_o^2 \cdot 4\pi r_o^2(1-\alpha)^{\frac{2}{3}}]^{\frac{1}{2}} = 4\pi r_o^2(1-\alpha)^{\frac{1}{3}}$$

$$S_b = (S_o' \cdot S_o)^{\frac{1}{2}} \fallingdotseq 4\pi r_o^2$$

The protective layer is first simply assumed to become gradually thiner linearly with time by the dissolution process. Thence,

$$\Delta r_a = r_o[1 - (1-\alpha)^{\frac{1}{3}}] \tag{8}$$

$$\Delta r_b = \xi_o - k_s(t - t_1) \tag{9}$$

where, ξ_o is the layer thickness at time t_1.

Hence, from equations (7), (8) and (9), we obtain the following differential equation which should be solved.

$$\left\{\frac{r_o}{D_a}\cdot\frac{1-(1-\alpha)^{\frac{1}{3}}}{(1-\alpha)^{\frac{1}{3}}} + \frac{1}{D_b}[\xi_0 - k_s(t-t_1)] + \frac{1}{D_c}\right\}\frac{d\alpha}{dt} = \frac{3C}{ar_0} \tag{10}$$

If we assume that in the S_{III} stage the process which governs the overall rate is the mass transfer through the protective layer, $R_2 \gg R_1 + R_3$. When the R_1 term is ignored and the equation (10) is integrated from α_1 to α and from t_1 to t,

$$\int_{\alpha_1}^{\alpha} d\alpha = \frac{3C}{r_0 a}\int_{t_1}^{t}\frac{1}{\left(\dfrac{\xi_0}{D_b} + \dfrac{1}{D_c}\right) - \dfrac{k_s}{D_b}(t-t_1)}dt$$

The solution which gives the relationship between α and t in the S_{III} stage is

$$\alpha - \alpha_1 = A_3 \ln \frac{1}{1-(t-t_1)/B_3}$$

where,

$$A_3 = \frac{6.9C}{ar_0} \cdot \frac{D_b}{k_s} \quad \text{and} \quad B_3 = \frac{D_b}{k_s}\left(\frac{\xi_0}{D_b} + \frac{1}{D_c}\right)$$

The solid curves shown in Fig. 38 as (c) and (d) represent the relationship between t and $d\alpha/dt$ or α, respectively.

It was assumed after equation (9) that the coating layer became thin linearly but the rate of reaction for the acceleratory period increased in the proportion of nearly second power of time. This leads to the hypothetical mechanism that the area of permeable part in the coating layer increases in two dimensions with time.

Thus, the term, $1/D_b[\xi_0 - k_s(t-t_1)]$, in equation (10) must be changed to $\xi_0/k(t-t_1)^n$. The following equation is similarly obtained by ignoring the R_1 and R_3 terms,

$$\alpha - \alpha_1 = \frac{3kC}{(n+1)ar_0\xi_0}(t^{n+1} - t_1^{n+1}) = k'(t^{n+1} - t_1^{n+1})$$

The dotted curves (c) and (d) in Fig. 38 are from calculated value.

As for the S_{IV} stage, we assume that the process which governs the overall rate is the mass transfer through the inner products, so that $R_1 \gg R_2 + R_3$, by which equation (10) reduces to

$$\frac{r_0}{D_a} \cdot \frac{1-(1-\alpha)^{\frac{1}{3}}}{(1-\alpha)^{\frac{1}{3}}} d\alpha = \frac{3C}{ar_0} dt$$

When integrated from t_2 to t and from α_2 to α,

$$\frac{r_0}{D_a}\int_{\alpha_2}^{\alpha}[(1-\alpha)^{\frac{1}{3}} - 1]d\alpha = \frac{3C}{ar_0}\int_{t_2}^{t} dt$$

The solution which gives the relationship between α and t in the S_{IV} stage is

$$t = A_4[B_4 - \frac{3}{2}(1-\alpha)^{\frac{2}{3}} - \alpha] \qquad (11)$$

where $A_4 = \frac{ar_o^2}{3D_aC}$

and $B_4 = \frac{3}{2}(1-\alpha_2)^{\frac{2}{3}} + \alpha_2 + \frac{3D_aC}{ar_o^2}t_2$

Equation (11) corresponds to that derived by Ginstling and Brounshtein (146) if t_2 and α_2 are zero because the reaction has no induction and acceleratory periods. If we assume the value C is in the order of g/l, and "a" is about 0.5, although they have not been experimentally confirmed in cement hydration, the order of D may be evaluated from the data of the hydration rate as $10^{-11\sim12}$. In Fig. 38, (e) and (f) show the relationship between t and $d\alpha/dt$ or α in the S_{IV} stage.

Further, in the later period of hydration in which the unsteady diffusion process through the inner and outer products is the rate determining step, the diffusion equation is generally given by Fick's second law rewritten in spherical coordinates as follows.

$$\frac{\partial C(r,t)}{\partial t} = \frac{1}{r^2}\frac{\partial}{\partial r}\left(Dr^2\frac{\partial C}{\partial r}\right)$$

where $D(r, C, t)$ is not a constant. This equation represents the S_V stage and expresses a trend for retarding qualitatively more than the rate of reaction in the S_{IV} stage. We do not have sufficient information on the structures and concentrations of the system at this stage but the rate of the overall reaction can be expressed by an empirical equation, $[1-(1-\alpha)^{1/3}]^N = kt$, in which $N > 2$ generally and $N = 2.5\sim2.8$ in the case of paste hydration of C_3S, as previously described.

Finally, the whole hydration process consisting of various stages can be expressed as shown in Fig. 31, in which the solid curves are the sum of the results shown in Fig. 38 for every stage and the dotted curves are for the actual reaction course.

Written Discussion

Hans N. Stein

Dr. Kondo and Mr. Ueda are to be congratulated for having derived mathematical expressions that can be applied to the mechanism proposed for the hydration of C_3S by Kantro, Brunauer and Weise (1) and by Stein and Stevels (2) (3) (4).

These authors adduced experimental arguments indicating that during the accelerated phase of C_3S hydration, the reaction rate is determined by the transition of a closely fitting, strongly retarding first hydrate (=F. H., probably C_3SH_n) into a second one, less retarding one (=S. H., probably CSH-I). This transition was found to be determined by the amount of S. H. nuclei present. It appears from Kondo and Ueda's paper that this mechanism is corroborated by recent measurements of theirs.

The equations of Kondo and Ueda are, in principle at least, capable of dealing with this mechanism. However, in their derivation one very important factor, viz. the rate of formation of S. H. nuclei, has not yet been fully worked out. In Kondo and Ueda's paper, the rate of S. H. nucleus formation is thought to be independent of time, i.e. independent of the concentrations in the aqueous phase. This, however, is improbable and at variance with the experimental results that led to the mechanism mentioned (viz. the influence of amorphous silica on the suspension hydration of C_3S). The introduction of parameters (t_1 and n in Kondo and Ueda's final equation) may make the equation fit experimental data, but this procedure may conceal rather than solve the fundamental difficulties. It is clear that the theory must be supplemented on this point before it can be applied with confidence.

Written Discussion

John H. Taplin

Kondo and Ueda state that a kinetic equation of mine (1) defines two diffusion constants but omits a factor which is the fraction of material which eventually diffuses outwards. The equation was originally given as:

$$i[1 - (1 - F)^{2/3} - 2F/3] + (o/v)[1 + 2vF/3 - (1 + vF)^{2/3} = 2Ct/R^2 \quad (1)$$

The quantities i and o were stated to be specific resistances. If C is the concentration difference and if D_i is the diffusion coefficient of outward moving material, in the inner products, then a/D_i can be written for i. However "a" is not the fraction of material which diffuses out, it is the concentration in the cement mineral, of the material involved in the rate controlling diffusion.

In a Supplementary paper to this Symposium (2) it has been argued that equation (1) is more likely to apply to the inward diffusion of water than to the outward diffusion of soluble products. However equation (1) could still apply to outward diffusion if the cement mineral, or some thin impermeable coating or its surface, is able to come to equilibrium with the aqueous solution so as to maintain the constant concentration difference, C, which was assumed in deriving equation (1).

However, equation (1) applies to a particle of radius R. In order to take account of the particle size distribution possessed by most powders, it is convenient to approximate equation (1). It is more accurate (3) to use equation (2) rather than Jander's eqaution.

$$dF/d(t^z) = k_z(1 - F)^N/R \quad (2)$$

where $z = 2$ for parabolic kinetics and where N is always well below the 2/3 value given by Jander's approximation. For example:

N = 0.43 for quadratic kinetics (all diffusion resistance in the inner products)

N = 0.30 for $i = 0$, as in Valensi's equation (4), and $v = 1$

Of course, the exact effect of particle size distribution on the reaction kinetics of a powder depends on the nature of the particle size distribution. However, the effect can be illustrated for linear kinetics, as follows. Let $(f)_R$ be the frequency function on a weight basis so that the proportion of the powder consisting of particles with a radius greater than R is $\int_R^\infty (f)_R\, dR$. If the particles keep their shape as they react then:

$$(1 - F)_R = (1 - p/R)^3 \quad (3)$$

where p is the distance the reaction has penetrated a particle of size R. For simplicity, assume linear kinetics so that p is independent of R, $p = kt$. For the whole powder

$$\int_p^\infty (1 - F)_R\, (f)_R\, dR \quad (4)$$

By differentiating equation (4) four times with respect to p it follows that:

$$(1 - F) = 6\,(f)_p/p^3$$

or

$$(f)_p = p^3(1 - F)^{IV}/6 \quad (5)$$

Integrating equation (5) by parts, we obtain:

$$\int_0^P (f)_R\, dR = F - \sum_1^3 (-p)^n\, (1 - F)^n/n! \quad (6)$$

An important difference between a mono-sized powder and one with a range of sizes is that the surface area of the mono-sized powder decreases more slowly as it reacts. This fact suggests a modification of equation (2) where allowance is made for a range of sizes by increasing the value of N. Assume

$$dF/dt = Akp(1 - F)^M \quad (7)$$

for a powder reacting by linear kinetics where A is the specific surface area, ρ the density and $M > 2/3$. By using $p = kt$, making the necessary differentiations, and substituting in equation (6), the appropriate cumulative particle size distribution is found. For example for $M > 1$.

$$\int_0^x (f)_x\, dx = 1 - q^L[1 + x/q + Mx^2/2q^2 + M(2M - 1)x^3/6q^3] \quad (8)$$

where $L = 1/(1 - M)$ and $q = 1 - (1 - M)x$

Fig. 1 is a log probability plot of three distributions of size which, for linear kinetics, will obey equation (7) with M = 1, 1.5 and 2.0. It will be seen that at the lower values of M the distributions are approximately lognormal.

This effect of particle size distribution, means that plots of $\ln[1 - (1 - F)^{1/3}]$ versus $\ln(t)$, as used by Kondo and Ueda in their Fig. 1, are difficult to interpret except for closely sized materials such as their C_3S samples. Consider particle size distributions such as are found for commercial portland cements. The

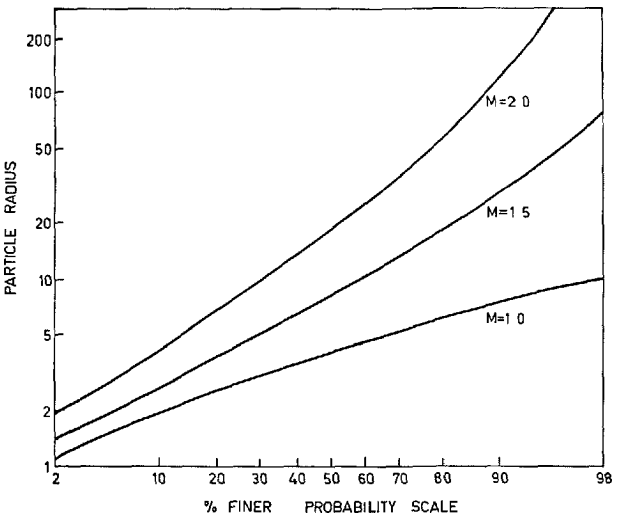

Fig. 1. *Log probability plots of particle size distributions of powders which, for linear kinetics, meet the following requirements: (i) the reaction rate is proportional to* $(1 - F)^M$ *(ii) the particles retain their shape as they react*

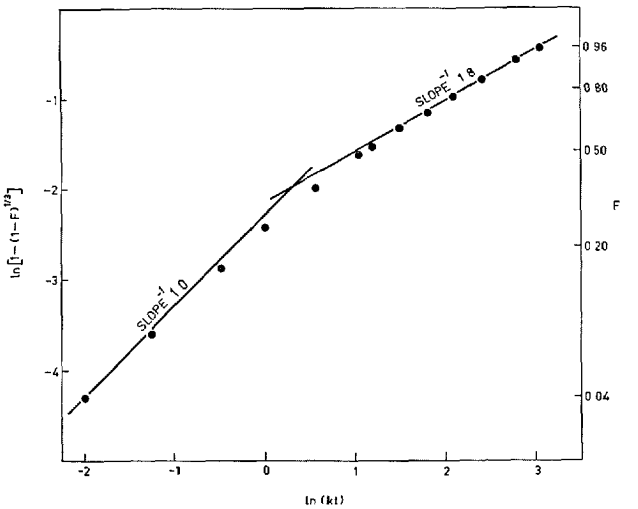

Fig. 2. *The failure of the relation,* $[1 - (1 - F)^{1/3}] \propto t$, *for the linear reaction of a hypothetical powder of spherical particles with a Furnas distribution of sizes approximating that found in commercial portland cements*

Furnas distribution usually fits cement data closely from a radius of 1.7 to about 25 microns (5), i.e. from about 8 to 90% passing. For $C \neq 0$, the Furnas distribution is

$$\int_0^x (f)_R \, dR = (R^C - R_0^C)/(R_1^C - R_0^C)$$

The linear and quadratic kinetics were computed for a size distribution typical of a cement, $C = 1/2$, $R_0 = 0.84$ microns and $R_1 = 31.5$ microns. Fig. 2 is a plot of $\ln [1 - (1 - F)^{1/3}]$ versus $\ln (kt)$ for linear kinetics. If interpreted as the kinetics of a mono-sized powder it would suggest a transition to diffusion kinetics at about a third of the way through the reaction. Fig. 3 is a similar plot for quadratic kinetics. Again the initial slope is that expected for a mono-sized powder and again it falls as the reaction proceeds. These plots would show even greater curvature if allowance was made for the usual deviation of cement from the Furnas distribution. There is usually 5–10% of material which is coarser than the fitted R_1.

Nucleation, crystal growth, dissolution and diffusion are some of the possible rate controlling processes in the hydration of cement. In trying to distinguish between them, the effect of particle size distribution can hardly be ignored. In the later stages

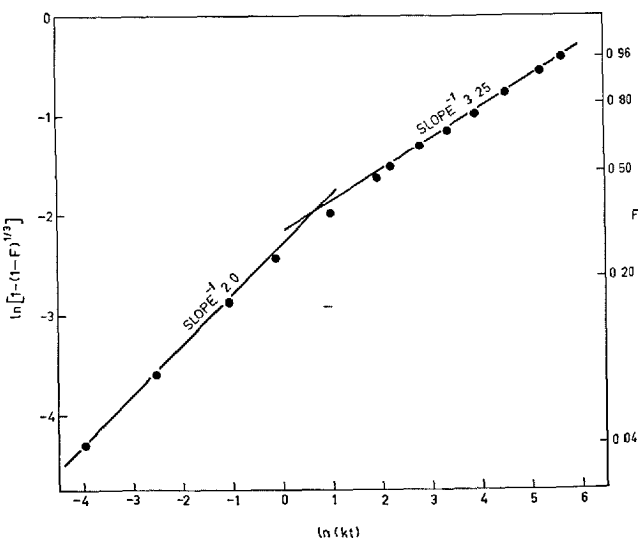

Fig. 3. *The failure of the relation,* $[1 - (1 - F)^{1/3}]^2 \propto t$, *for the parabolic reaction (diffusion resistance in inner products) of a hypothetical powder of spherical particles with a Furnas distribution of sizes approximating that found in commercial portland cements*

of the reaction, this size distribution effect is generally about as great in comparison with a mono-sized powder as is a change from a linear to a parabolic reaction mechanism.

Written Discussion

Rolf F. Feldman

In this very comprehensive review the authors have discussed the various parameters that control the rate of hydration of a solid. These can be categorized as follows:

(a) Reactivity of the solid,
(b) Nucleation and crystal growth,
(c) Mass transfer through the solid product.

The authors have also outlined how these parameters may be affected by the addition of foreign molecules or ions. It is the purpose here to discuss the effect of sulphate ions on the hydration of C_3A.

On the assumption that the rate-controlling process is the rate of decomposition of the solid, sorption of ions on surface sources of dislocation may decrease the reaction rate, effectively decreasing the reactivity of the solid. Foreign molecules can also affect the number of nuclei available for crystallization and modify the rate of growth and morphology of crystals. They may even alter the product of hydration more drastically: for example, the presence of sulphate ion prevents, for a time, the conversion of hexagonal hydro-aluminates to the cubic hexahydrate (1) in the hydration of C_3A. It is this conversion that accelerates the normal hydration of C_3A (2).

The additive might affect the rate of hydration through the third category by changing the nature of the solid product (as stated previously) that might accumulate around the reactant. This has been the most common explanation for the retardation of C_3A hydration in the presence of additions of gypsum. It has been concluded that ettringite forms a dense impermeable layer around unhydrated C_3A grains, thereby retarding the reaction.

The main purpose of this discussion is to show that the above conclusion may be premature. If it is accepted that the rate of diffusion through the solid product is the rate-controlling process, then one is faced with two possibilities:

(1) The product modified by the additive has a greater density and impermeability than the product formed without the additive. In the case of the hydration of C_3A in the presence of gypsum, it is generally concluded that ettringite, which forms around the unhydrated C_3A, has these properties of high density and impermeability relative to the properties of the hexagonal hydroaluminate. The latter product forms around the C_3A during its earlier periods of hydration in the absence of gypsum.

(2) The effect of the sulphate ion in small pores with its high electric-field intensity may significantly reduce the rate of mass transport through the solid product.

This mechanism for retardation will then remove the necessity of giving special properties to the ettringite layer.

The importance attached to the nature of the solid product requires an understanding of the formation of the structure of a body when the solid product forms during hydration. The nature of the stresses and strains produced during hydration should provide some information on whether the layer around the unhydrated grains will be dense and impermeable.

The final structure of an agglomeration of particles of a solid which may undergo a reaction with water depends upon many factors. The morphology of the product and the place where it is deposited must be considered as part of the over-all reaction mechanism; reaction conditions may affect all of these. The state of the structure and the volume change of the body reflect the morphology of the product and its place of deposition. Volume or length change may be large or small; a large length change does not necessarily lead to a weak and soft body. When the expansion leads to a weak and soft structure, it is considered disruptive.

Compaction of the solid reactant tends to emphasize some of the properties of the reaction by bringing particles in contact and, although compaction may alter the relative periods at the different stages of the reaction, it must be kept in mind that a body of low porosity is also the final product of normal paste hydration. Studies of length change of compacts of several materials during hydration have been made to aid in understanding the nature of the stresses and strains involved during formation of the solid product. It was assumed that the forces that cause expansion of the body would also operate in the formation of a layer around a grain of unhydrated material; results have led us to believe that this is so.

The fact that hydration reactions involve an increase in the volume of solid product over solid reactants

does not account for the various types of length change and structuring during reaction. At the beginning of hydration, expansion of the compact is caused by the thrust of the product at or close to the points of contact of the grains of the reactants. In some cases, this expansion is slight and a fairly dense impermeable product is built around each grain and penetrates into the pore spaces. The structure of the body would then consist of a dense impermeable product and should be and is of good strength and low porosity. The hydrate product is probably continuous but the unhydrate material is embedded in it, and the reaction is terminated or almost so by the lack of space or water. Examples of this type of reaction with the solid in compact form are C_3S and β-C_2S both with linear expansion of 0.10 to 0.15 per cent (3) and portland cement with 0.3 per cent (4).

The hydration of $CaSO_4 \cdot 1/2H_2O$ compacts (5) is accompanied by somewhat larger linear expansions (from 1 to 4 per cent,) depending upon the hydration conditions, but also produces a strong fairly dense body. The expansion in this case is not disruptive. Slurries of calcium sulphate hemi-hydrate may produce linear expansions of 0.5 per cent. CaO hydrates with a disruptive expansion in the presence of water vapour (6); there is a weakening of the structure during hydration, little or no reduction in reaction rate, and a complete disintegration of the body, leaving only a powder. Under these conditions, one cannot visualize the formation of a dense impermeable product around the CaO particles because this would mean that the unhydrated material was joined together and surrounded by the dense product (thereby forming a strong body) and that the reaction rate had been drastically reduced.

The reaction of CO_2 with compacts of $Ca(OH)_2$ in the presence of water vapour (7) is an example of another type of structuring. Although the reaction produces an increase in solid volume, densification of the body is accompanied by shrinkage up to 0.3 per cent linear measurement.

These examples show something of the complex nature and relationship of length change to structuring and reaction mechanism.

The expansive behaviour observed for the compacts of mixtures of C_3A with 10 and 20 per cent gypsum was disruptive; the body was in fact a "much". It is difficult to see how, in the light of the above discussion, this can be the result of a special dense and impermeable product of ettringite. The retardation of C_3A hydration by gypsum when the reaction is controlled by diffusion is thus considered to be due to the effect of the electric field intensity of sulphate ions upon mass transport through small pores.

In contrast to this, hydration of C_3A at 52°C (8) produced a firm strong product, and the expansion of the compact was only 0.7 per cent after 4 days, most of this taking place in less than one hour. The degree of hydration was only 17 per cent although plenty of pore space was available for hydrate product. It appeared clear that, under these conditions of hydration, there was a dense impermeable product of $C_3A \cdot H_6$ around the C_3A grains.

Oral Discussion

J. Albeck, Udo Ludwig and Hans E. Schwiete

Our investigations (1, 2) of the hydration of aluminate-ferrite phase (W/S = 1.0–1.2) of portland clinker and of technical clinkers (W/S = 0.5) together with $CaSO_4$ (as anhydrite or dihydrate) and increasing amounts of $CaCl_2$ in lime saturated pastes can be summarized as follows:

1. In accordance with Schwiete, Ludwig and Jäger (3) we found a decrease of reaction velocity of the following clinker minerals with dihydrate and anhydrite in lime saturated pastes:

$$C_3A \longrightarrow C_6A_2F \longrightarrow C_4AF \longrightarrow C_2F$$

Correspondingly the sulphate combination velocity of clinkers decreases with decreasing C_3A content of the clinker.

2. With anhydrite the sulphate fixation of the aluminate-ferrite phases and the clinkers itself is more rapid than with dihydrate. This is due to the lower dissolving velocity and the therefore minor tendency for initial formation of ettringite coatings.

3. The addition of $CaCl_2$ accelerates the sulphate fixation. Increasing amounts of $CaCl_2$ are effecting increasing accelerations. This effect is due to the reduction respectively prevention of the ettringite layer on the aluminate-ferrite phases of the clinker grains.

4. With 20% of Cl^- addition we found in the first minutes of hydration (up to 30 minutes) the simultaneous formation of $C_3(A, F)\cdot 3CaCl_2\cdot H_{30}$, $C_3(A, F)\cdot 3CaSO_4\cdot H_{32}$ and $C_3(A, F)\cdot CaCl_2\cdot H_{10}$, afterwards the formation of the two latter salts only. That means in disagreement with Tenoutasse (4)—that $CaCl_2$— and $CaSO_4$-fixation runs at higher $CaCl_2$-content simultaneous.

5. The reaction of $CaCl_2$ to Friedel salt stabilizes the initial formed ettringite for there are minor aluminate ions for the formation of $C_3(A, F)\cdot CaSO_4\cdot H_{12}$ or the solid solution series $C_3(A, F)\cdot(Ca(OH)_2, CaSO_4)H_{12}$.

6. On slurries (W/S = 10) with C_3A an increasing $CaCl_2$-content leads to an increasing Al_2O_3 and a decreasing SO_3 content and pH value in the filtered solution. By this we establish the minor formation of ettringite coatings.

Authors' Closure

Renichi Kondo and Shunro Ueda

Three written discussions were given to our paper. First of all, Dr. Stein pointed out the similarity of ideas on the explanation of acceleratory period between our's and of other investigators. But the reason why the reaction in the acceleratory period takes place can hardly be explained logically simply by insisting that the propective layer splits off as viewed by Messers Kantro, Brunauer and Weise. Their theory cannot explain satisfactorily the mechanism that the reaction of this period is accelerated as the splitting off makes expose the new unreacted surface. According to us, the sudden reaction in the acceleratory period can be explained mathematically by considering that the protective layer partially becomes porous. We made reference to this point in our principal paper.

Dr. Stein also pointed out that the kinetic equation of the nucleation as conceived by us didn't take the concentration of liquid into our consideration. To this comment we have described that the nucleation rate is functioned with the liquid concentration, in the section of "Nucleation and Crystal Growth". On the other hand, our own data shows that the liquid concentration remains for a while in comparatively same level during the course of the acceleratory period. By taking advantage of this phenomenon, we obtained the equation as shown in the section "Rate determining step in hydration" by going so far as setting the liquid concentration at constant.

In his discussion, an empirical equation which appeared in principal paper's last page was criticized as having escaped the difficulty in the fundamental solution. In response to this comment, we wish to point out that there is a fear of perfunctory handling even if a theoretical equation is forcively induced, as there are many doubtful points in later stages of the reaction. As a first-hand step to cope with the difficulties, we are going ahead with a plan to seek the diffusion coefficient by using the radioactive isotope and observing the hydrate's structure by the electron microscope either scanning type or using the microtome.

The equation in which N was referred to as parameter is an empirical one. However, we explained already the relationship between N and diffusion coefficient or the compactness of the product layer in the section mentioned above so far as the concentration difference is constant. This is the very reason why we gave a temporary conclusion by utilizing this equation.

Next, Mr. Taplin raised an objection to our opinion in his written discussion that the factor "a" in the rate constant must be regarded as a concentration in the cement mineral of the material involved in the rate controlling diffusion, instead of a fraction of material which diffuses out. Our view on the terms, C, "a" and D in the rate constant will be here described in detail, since the examination of the rate constant is important in order to evaluate the magnitude of diffusion coefficient, although it is not incorrect to combine the terms such as "a" and D in the so called resistance as treated by Mr. Taplin.

As described in our principal paper, Mr. Taplin's equation can be reduced to the Ginstling's equation when the diffusion in the inner product layer determines the rate of reaction, and Ginstling's equation was improved by Kondo as follows:

$$[1-(1-\alpha)^{1/3}]^2-\frac{2}{3}[1-(1-\alpha)^{1/3}]^3=2DCt\frac{1}{ar_0^2}$$

where C is the concentration difference of the species involved in the rate controlling diffusion between outside and inside interfaces of the inner product. C is expressed as follows in consideration of the material balance:

$$\frac{\text{wt. difference of dissolved reactant (g)}}{\text{unit volume (cm}^3\text{)}}\times\frac{1}{\text{density of reactant (g/cm}^3\text{)}}$$

And the factor "a" is taken as the weight fraction of the material diffused out to the reacted reactant.

An example will be shown to clarify the characters of C and "a", and also to examine the order of D in a hydration reaction.

At first let us assume that the amounts and compositions of inner and outer products are the same in the hydration of C_3S, and the difference of concentrations in the liquid phase is 1.63 gC_3S/l. When the concentration is expressed on the liquid phase, it must be multiplied by a ratio of pore volume to total volume of the inner product, and this ratio estimated is approximately 0.2. And the density of C_3S is 3.2 g/cm³. Then

$$a=\frac{1}{1+1}=0.5,\quad C=\frac{1}{3.2}\times 0.2\times\frac{1.63}{1000}=0.0001$$

If we use C_3S powder with $r_0=3.5\,\mu$, the thickness of the reacted layer reaches $1-(1-\alpha)^{1/3}=0.06$ in 5 hrs (18000 sec.) from 5th to 10th hr. in early hydration, and $1-(1-\alpha)^{1/3}=0.285$ in 27 days (2330000 sec.) from 1st to 28th day in later hydration.

Then the magnitude of D can be estimated as follows. In the case of early hydration,

$$0.06^2-\frac{2}{3}\cdot 0.06^3$$

$$= 2 \times D \times 0.0001 \times 18000 \times \frac{1}{0.5 \times 0.00035^2}$$

$$D = 5.8 \times 10^{-11} \text{ cm}^2/\text{sec}$$

In the case of later hydration,

$$0.285^2 - \frac{2}{3} \cdot 0.285^3$$

$$= 2 \times D \times 0.0001 \times 2330000 \times \frac{1}{0.5 \times 0.00035^2}$$

$$D = 8.5 \times 10^{-12} \text{ cm}^2/\text{sec}$$

Next we shall assume that 1 mole C_3S reacts topochemically with water to form $C_{1.5}SH_n$ as the inner product and 1.5 mole CaO diffuses outerward to form $1.5Ca(OH)_2$ as the outer product, and the concentration difference is 1.2 gCaO/l. Then

$$a = \frac{1.5 \times \text{m.w. of CaO}}{\text{m.w. of } C_3S} = 0.37$$

This value may be called as the concentration in C_3S, of the material involved in the rate controlling diffusion as Mr. Taplin stated.

$$C = \frac{1}{3.2} \times \frac{\text{m.w. of } C_3S}{3 \times \text{m.w. of CaO}} \times 0.2 \times \frac{1.2}{1000}$$
$$= 0.0001$$

The value D can similarly be evaluated as follows: In the case of early hydration,

$$D = 4.3 \times 10^{-11} \text{ cm}^2/\text{sec}$$

In the case of later hydration,

$$D = 6.2 \times 10^{-12} \text{ cm}^2/\text{sec}$$

The evaluated value of D in hydration, thus obtained is a little lower than in paste or mortar. This is expectable, as only radial through pores around the reactant particles are available for material transfer in hydration reaction. On the other hand the diffusion in bulk specimen of paste or mortar must be mainly taken place in the pores of outer product. Regardless of the considerable amount of pore volume, the order of diffusion coefficient in hydration product, even in the bulk specimen, is as low as that in zeolites with very fine pores of several Å. Chemical interaction between the surface of pores and the diffusing species seems to be responsible for lowering the diffusion coefficient and worth systematical study in future.

In addition, we have recently received a private communication from Mr. Taplin, whose opinion is not fully agreed with us, but he described that we had the density of the reactant as a factor C whereas he had it as a factor of "a". He granted us an "a" which was the fraction of material which diffused out if we wrote for the right hand side of the equation $2DCt/apr_0^2$, where ρ is the density of reactant.

On the other hand, Mr. Taplin in his written discussion emphasizes the importance of the particle size distribution on the rate of hydration and gives the equation, which are believed very useful. However we do not think that we have ignored the effect of particle size distribution, so that we have used elutriated samples and discussed about it not only in the paper but also especially in the paper refered as number (69) in the former.

Finally it is generally considered that the retardation mechanism of C_3A hydration by added gypsum is attributable to the formation of a dense ettringite coating. But Mr. Feldman and his colleague have put forward an idea to the effect that the sorption of SO_4^{--} ions over the dislocations of the particle surface is related thereto. This idea was already referred to in our principal paper.

Mr. Feldman supplemented afresh with a view that where diffusion is rate controlling, the transport rate of mass such as water molecules can be reduced by the high electric field of SO_4^{--} ion within the small pore.

In connection with the hydration rate of cement, we attach importance to the necessity of clarifying the hydrate's conditions on the surface of cement compounds, and are actually going ahead with researches by utilizing either the surface electron diffraction or scanning electron microscope. As a matter of fact, we already have obtained considerably clear results which cover silicate hydration just as we mentioned in our principal paper. We further expect to be able to solve the problem of aluminate hydration by the similar method.

While on the other hand, we cited an example in Table 4 of our principal paper with respect to the mobility of various ions in the porous body. However, it is difficult to recognize such special trend as SO_4^{--} ion serving to lower down the diffusion coefficient more than other ions. Thus it is desirable to verify by further experiments Mr. Feldman's idea that the electric field has an effect on the rate of hydration.

In any case, we believe that his idea will serve as useful working hypothesis in pushing forward more detailed fundamental researches in days to follow.

(A) Papers regarding Mechanism

Supplementary Paper II-26 The Influence of Sugars on the Hydration of Tricalcium Aluminate

James F. Young*

Synopsis

The influence of monosaccharides and polysaccharides on the paste hydration of tricalcium aluminate (C_3A) was studied for periods up to 90 days using X-ray diffraction, thermal analysis and electron microscopy. Each of the sugars used was found to retard the hydration of C_3A. Sucrose and raffinose were strongly retarding at all ages, and trehalose, xylose and ribose were the least retarding. The other sugars studied gave intermediate results, although lactose, xylose and fructose were strongly retarding at very early ages. It was shown that the presence of sugars prevents the rapid formation of C_3AH_6 which is observed in pastes without additives. The principal hydration product was C_4AH_{13} while C_2AH_8 was often present; the morphology of these hydrates was considerably modified.

Sugars also influenced the formation of sulphoaluminates in pastes of C_3A and gypsum. Apart from some early acceleration by xylose, fructose and glucose, all sugars retarded the rate of formation of ettringite and its subsequent conversion to the low-sulphate sulphoaluminate hydrate. An increase in the rate of formation of ettringite was apparent after 14 days in pastes containing lactose, raffinose and sucrose. The morphology of ettringite was also modified by sugars.

The experimental results are discussed with reference to the different mechanisms of retardation that have been postulated. It is suggested that the complexing of organic compounds with metals, such as calcium or aluminium, could be the main factor underlying their behaviour as retarders.

Introduction

Interest in the use of organic compounds as potential set-retarding additives for cement has prompted several recent investigations (1–4) on their effects on the setting characteristics and hydration of cement pastes. However, apart from lignosulphonates and related materials, and with the exception of work by Suzuki and Nishi (2), no detailed study of the physical and chemical effects of organic additives on the hydration of cements and cement compounds has been reported.

This paper presents results of preliminary studies on the influence of organic compounds on the chemistry of the hydration of cement compounds. The saccharides were chosen for this initial study because earlier reports indicated that these compounds generally behave as strong retarders. Interest in sugars was stimulated by previous work with lignosulphonates (5) which themselves contained appreciable amounts of sugars and other carbohydrates as impurities. It has been shown (6) that the performance of lignosulphonate additives is not impaired by a high carbohydrate content and that sucrose behaves satisfactorily (6, 7) as an additive to concrete at low dosages (0.05% by wt. of cement) giving some decrease in water requirements and slight gains in strength at 7 and 28 days. Nevertheless, it appears that sugars are still viewed with concern by the concrete industry.

With the exception of trehalose (4) it has generally been found that all saccharides strongly retard the set of cement even when used at moderately low dosages. An earlier report (1) that fructose and raffinose are not strong retarders has not been substantiated (2, 4). Although sucrose may be the strongest retarding sugar, all sugars show complete inhibition of set after several days at high concentrations (> 0.25%) (1, 2). Suzuki and Nishi (2) found that large additions of sugar (1% by wt.) tend to promote flash set when the water: cement ratio is low.

*Chemistry Division, Department of Scientific and Industrial Research, Wellington, New Zealand.

Experimental

Materials

C_3A was prepared by repeatedly firing at 1300°C and grinding pellets made from the appropriate mixture of the constituent oxides. The C_3A had a specific surface area of 3430 cm^2/g. (air-permeability method), an initial free lime content of 2.1% and an iron content of 0.5% (from ball-mill contamination). No other phase was detected by X-ray diffraction, but a differential thermal analysis showed that the free lime was partially hydrated or carbonated and that trace amounts of C_3A were hydrated.

C_3A-gypsum mixtures were prepared by blending 2 parts by weight of C_3A to 1 part of AR gypsum in a Pascall end-runner mill.

The sugars were of laboratory reagent grades and were used without further purification. The following were used in this study: ribose, xylose, glucose, mannose, fructose (monosaccharides); sucrose, lactose, $\alpha\alpha$-trehalose (disaccharides); and the trisaccharide raffinose.

Preparation of Pastes

The sugars were dissolved in CO_2-free distilled water and the solutions cooled to 0°C before being mixed with solid. The concentration of the solutions was such that 1% sugar by wt. of C_3A was added at a water: solid ratio of 0.6. This dosage gives a sugar: C_3A ratio similar to that when 0.05–0.10% sugar is added to a typical cement, and it is sufficiently high to ensure that any change occurring is readily detectable.

The pastes were mixed by hand for 1–2 minutes in the glass vials in which they were stored. The tightly stoppered vials were then stored at 21°C over CO_2-free distilled water in a desiccator containing soda-lime. This procedure ensures protection against CO_2 during the hydration period and the maintenance of 100% R. H. within the vials.

At the end of each hydration period a vial was opened, the contents crushed where necessary and washed with acetone to remove excess water and stop hydration. A sample was set aside for immediate X-ray diffraction analysis and the remainder dried to constant weight over $MgCl_2 \cdot 6H_2O$ at 21°C (33% R. H.) in the absence of air. As the pastes were not protected from CO_2 during crushing and washing, the carbonation later observed would have occurred at this stage. The reactivity of different pastes with CO_2 from the air during this brief exposure was found to vary. The dried pastes were subsequently subjected to thermal analysis and, in some cases, to quantitative X-ray diffraction analysis.

Apparatus

Differential thermal analysis (DTA) was carried out on a "Deltatherm" instrument (Technical Equipment Corp.) using chromel-alumel thermocouples in contact with the samples and a heating rate of 10°C/min. Thermogravimetric analyses (TGA) were run on a Chevenard thermobalance at 5°C/min. A specially designed "cylinder and piston" sample, similar to that described by Garn and Kessler (8), was used so that the samples decomposed in self-generated atmospheres.

A Phillips Norelco X-ray diffractometer was used for diffraction (XRD) work using CuKα radiation with nickel filters. The scanning speed was 1° 2θ/min., the scale factor 4 and the time constant 4. Commercial titanium dioxide (Rutiox CR, British Titan Products), having an average particle size of 0.25 μ, was used without further treatment as an internal standard in quantitative work.

Electron micrographs were taken on a Phillips EM200 microscope at 80 kV. Samples were prepared by dispersing a small portion of the paste in alcohol and evaporating a drop of the suspension on a copper grid backed with a carbon film supported on collodion. No shadowing was used.

Results

C_3A Pastes

All pastes, except those containing trehalose, were quite fluid on mixing. Using a fixed water: solids ratio, pastes containing trehalose remained as a thick slurry after the initial mixing; but there was no evidence of premature set. All the other sugars showed slight water-reducing properties in pastes as evidence by bleeding which was not observed in the control pastes without sugars.

Amount of Hydration

Fig. 1 shows the rate of hydration of C_3A in pastes as determined by quantitative XRD analysis. Very little hydration occurs within 3 hours in pastes containing xylose and lactose. This is confirmed by thermal analyses and by the lack of any strength development in these pastes. In the case of lactose this abnormal behaviour continues during the first 24 hours and appreciable hydration occurs only later. On the other hand pastes with xylose hydrate very rapidly between 3 and 24 hours, and from this point hydration is but weakly retarded as compared with that observed in pastes without additives. Pastes with fructose show a behaviour similar to that of xylose, but to a lesser degree. Both sucrose and raffinose are strongly retarding at all ages. The weakest retarders are trehalose, xylose and ribose.

Hydration Products

Table 1 lists the hydration products detected in C_3A pastes by DTA and XRD. In DTA thermograms, of which typical examples are given in Figs. 2–4 the hexagonal phases C_4AH_{13}* and C_2AH_8 are recognized by

*Throughout the text the formula C_4AH_{13} is taken to include the carbonation products of this hydrate. XRD shows the predominant phase to be generally α-C_4AH_{13} (10) but sometimes $C_3A \cdot CaCO_3 \cdot 12H_2O$ is present in appreciable quantities.

three endotherms peaking just above 100°, 200° and 300°C respectively. C_3AH_6 is characterized by a strong endotherm at 300–350°C, superimposed on an endotherm due to the hexagonal phases, and another at about 550°C which originates from the dehydration of calcium hydroxide formed in the first dehydration step (9). An exothermic hump at about 400°C (Figs. 3 and 4), usually only readily seen at early ages, is attributed to the combusiton of organic matter. These results agree with earlier observations (5). It is not easy to distinguish between C_4AH_{13} and C_2AH_8 by DTA because their thermograms are so similar, but in samples where C_2AH_8 is detected by XRD the initial 100°C endotherm is more intense than that at 200°C (Fig. 2) whereas these two endotherms are of comparable intensity (Figs. 3 and 4) when C_2AH_8 is absent. The endothermic effects of DTA correspond to successive weight-loss steps in the TGA curves with a correlation between the intensities of the endotherms and the magnitude of the weight losses. As expected, TGA shows that there is appreciable overlap of the first three dehydration steps under the experimental conditions used.

The hexagonal hydrates were estimated from the XRD patterns by the relative intensities of their basal reflections and C_3AH_6 from its reflections at 4.43 Å and 3.14 Å, which are free of interference from C_3A. Small quantities of C_3AH_6 were preferably estimated by DTA using the intensity of the endotherm at about 550°C. Several samples did not show this endotherm, although their XRD patterns apparently indicated that small amounts of C_3AH_6 were present. It is our experience that DTA is more sensitive in detecting trace amounts of hydrates. The 3-hour pastes with xylose and fructose, and the 23-hour paste with lactose showed very small quantities of the hexagonal hydrates to be present, although these were not detected by XRD.

The relative amounts of the hydrates listed in Table 1 have only been estimated qualitatively, and hence

the details must be treated with caution. However, the main trends are clear, and two main points should be noted: (1) the large amount of C_3AH_6 found in pastes without additives compared with the much smaller quantities found in all other pastes even after 90 days, and (2) the formation of C_2AH_8 in appreciable amounts in the majority of pastes hydrated with sugars. The pastes in which no C_2AH_8 (or only trace amounts) was detected, contain those sugars (mannose, lactose, sucrose and raffinose) which are the strongest retarders. C_2AH_8 was not detected in pastes without additives, although it has been reported by others (11, 12) and was detected in low temperature hydration (5).

TGA Data as a Measure of Hydration

It was not possible to obtain reliable quantitative data on the amounts of the different hydrates present in the pastes. Although attempts were made to calculate these quantities from TGA curves using empirical methods, consistent results could not be obtained. The main difficulty arises from the variability in the relative magnitudes of the weight loss steps of the curves. It should be possible to obtain reliable figures from TGA data by paying closer attention to the control of experimental conditions. Making TGA measurements in steam atmospheres may achieve a separation of the overlapping dehydration steps.

The quantitative XRD estimation of the hydrates is not considered to be practicable at present because of (a) the uncertainty of detecting small amounts of C_3AH_6, as discussed previously, and (b) the strong tendency to preferred orientation of the hexagonal hydrates and the difficulty in preparing suitable samples for calibration.

Nevertheless, a remarkably good linear relationship was found between the ignition loss at 1100°C, as measured by TGA, and the amount of C_3A hydrated as measured by XRD (Fig. 5). This is due to the fact that most of the pastes form mainly the hexagonal hydrates which have very similar percentage weight losses for total dehydration. The ignition losses for the pastes without additives lie on a separate straight line as a result of their high C_3AH_6 contents. The lower slope of this line indicates that the C_3AH_6: C_4AH_{13} ratio is always much higher than in other pastes.

Crystal Development and Morphology

The behaviour of the pastes hydrated without additives is distinctive in that large amounts of C_3AH_6 are formed at all ages. The TGA data in Table 2 indicates that after the first 24 hours the C_4AH_{13} content

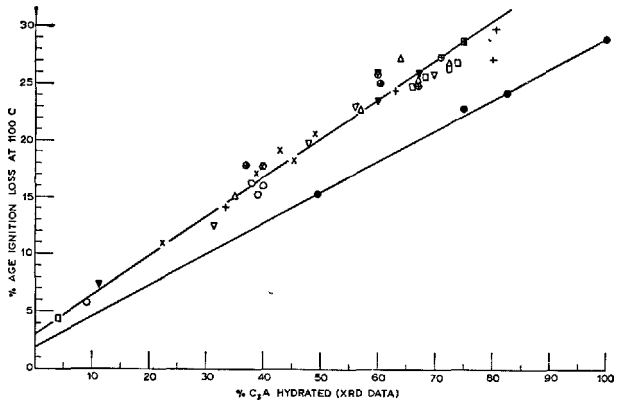

Fig. 5. *The relationship between ignition loss and the amount of* C_3A *hydrated. (Key as in Fig. 1)*

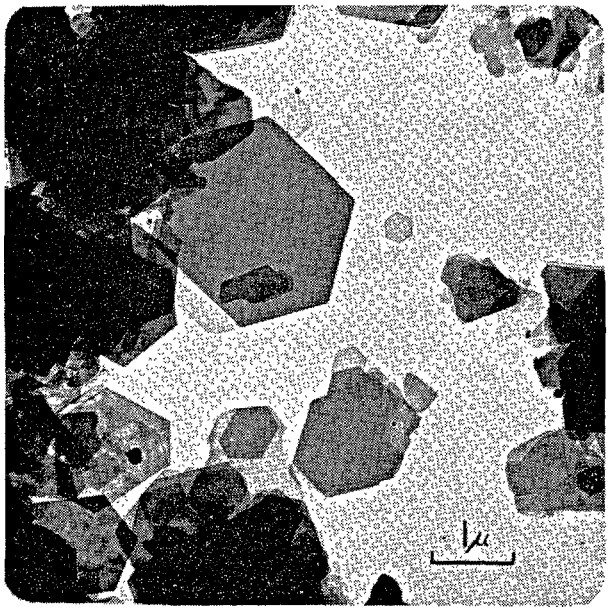
Table 2. *Percentage weight losses for* C_3A *pastes hydrated without additives*

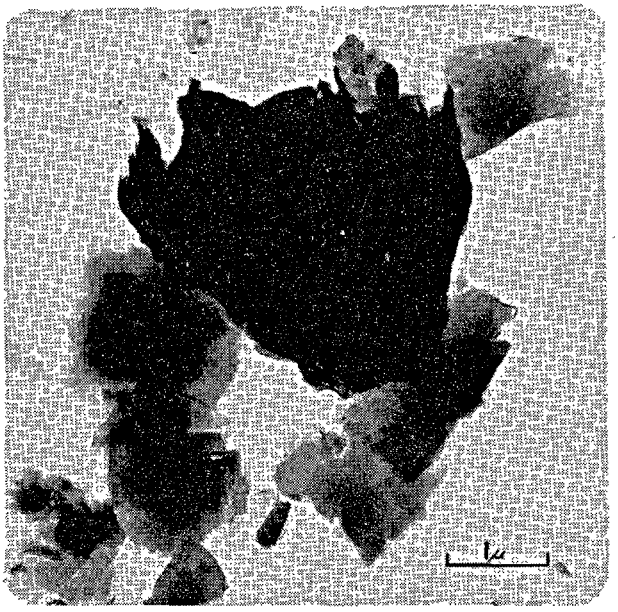
	Time of hydration			
Temp. interval	3 hrs	24 hrs	14 days	90 days
Up to 200°C	3.2	3.4	3.4	3.4
200—400°C	7 5	14.0	15.4	18.1

remains constant throughout the hydration period and only the C_3AH_6 content increases. The weight loss up to 200°C represents only C_4AH_{13} and the loss from 200–400°C represents both C_4AH_{13} and C_3AH_6. It is generally assumed that C_3AH_6 forms from the conversion of the metastable hexagonal hydrates which are the first products of reaction. Therefore it would seem that after the initial period of hydration a steady state is set up as the rate of conversion to C_3AH_6 equals the rate of formation of the intermediate hydrates. The question then arises as to why the hexagonal hydrates readily convert to C_3AH_6 in pastes which do not contain additives, but are stable in the presence of sugars. It is possible that, as a result of the initial rapid heat evolution that occurs when sugars are not present, the temperature in the control pastes may rise sufficiently high for the conversion to become quite rapid. However, the experimental procedures were designed to prevent this.

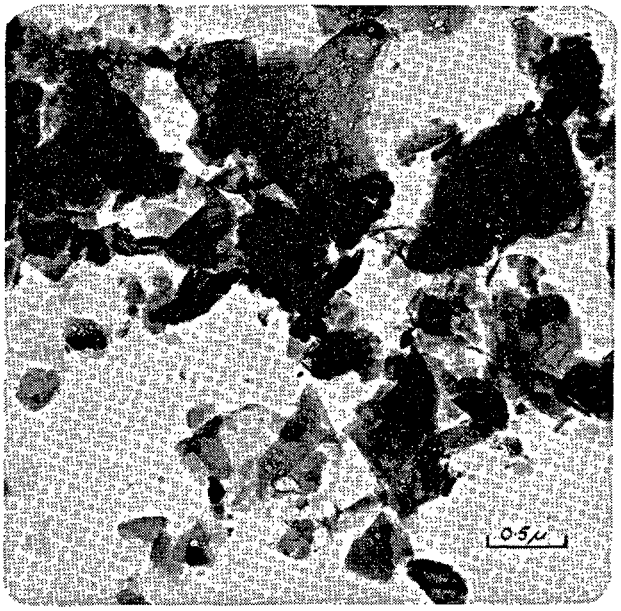
An examination of the hydration products by electron microscopy (Fig. 6) show changes in crystal morphology which may be the main cause of this difference in reactivity. Fig. 6a shows the well-developed hexagons of C_4AH_{13} normally found in C_3A pastes. These are up to 2 microns in diameter, but are very thin since the electron beam can penetrate through the stacks of crystals which are generally found. Nevertheless, the crystals are quite stable in the beam.



(a)



(b)



(c)

Fig. 6. *Electron micrographs of* C_3A *pastes after 24 hours.* (*a*) *No additive* (×*19,750*) (*b*) *with 1% mannose* (×*24,650*) (*c*) *with 1% trehalose* (×*37,500*).

The stippled material superimposed on some hexagons is most probably dehydrated aluminium hydroxide which must be formed with C_4AH_{13}. Figs. 6b and 6c show the typical material formed when sugars are present. There is no sign of hexagonal crystals, but instead there are extremely thin laminae which have no regular shape. They are usually piled up on each other in a large number of layers to give large aggregates of hydrated material 1–2 microns in diameter (Fig. 6b), but when the laminae are smaller, e.g. < 1 micron across, the material tends to be more scattered as in Fig. 6c. This latter micrograph clearly shows

the extreme thinness of the laminae and indicates that they are much less stable under the electron beam than the well-formed hexagonal crystals. The "bubbly" appearance probably results from free water released from the structure after having been trapped between laminae, and it occurs at relatively low beam intensities. Electron diffraction experiments show multicrystal patterns revealing hexagonal symmetry, and thus confirm the nature of the material. These patterns were much weaker than those of the hexagonal crystals and, although they were more distinct in the case of material hydrated for 3 or 4 days, hexagonal crystals were not seen.

XRD and DTA of pastes indicate that in pastes with sugars C_4AH_{13} is much more susceptible to attack by CO_2 than in pastes without additives, the latter showing very little carbonation. The extent of carbonation precludes any estimate of line broadening in XRD reflections which would result from poor crystallinity. Nevertheless, it is clear that the crystallinity of the hexagonal hydrates is less well developed in the presence of sugars. Lignosulphonate additives have also been found (5) to alter crystal morphologies and stabilize the hexagonal hydrates with respect to C_3AH_6. It is not yet certain how the changes in crystallinity affect the formation of C_3AH_6, but the observed decrease in the rate of this reaction could have an influence on the rate of hydration of C_3A. Stein (11) has suggested that the acceleration of C_3A hydration by the addition of C_3AH_6 is due to the C_3AH_6 particles acting as nuclei and thereby hastening its formation from the hexagonal hydrates.

C_3A-Gypsum Mixtures

C_3A pastes containing gypsum had a C_3A: gypsum ratio of 2 which is similar to that found in many cements. Sufficient C_3A is present to allow ettringite, which forms initially, to convert completely to the low-sulphate sulphoaluminate, but this change does not occur until later ages and was not studied in detail. Nevertheless, several interesting observations were made.

Hydration Products

In all pastes ettringite was the only product of hydration in the first 14 days. Qualitative estimations of ettringite by XRD generally give the same trends as calculated values (see Figs. 7 and 8), but in some cases preferred orientation gave misleading results. Although ettringite gives sharp reflections, it could not be detected at concentrations less than about 8%. Typical DTA thermograms are shown in Figs. 7 and 8.

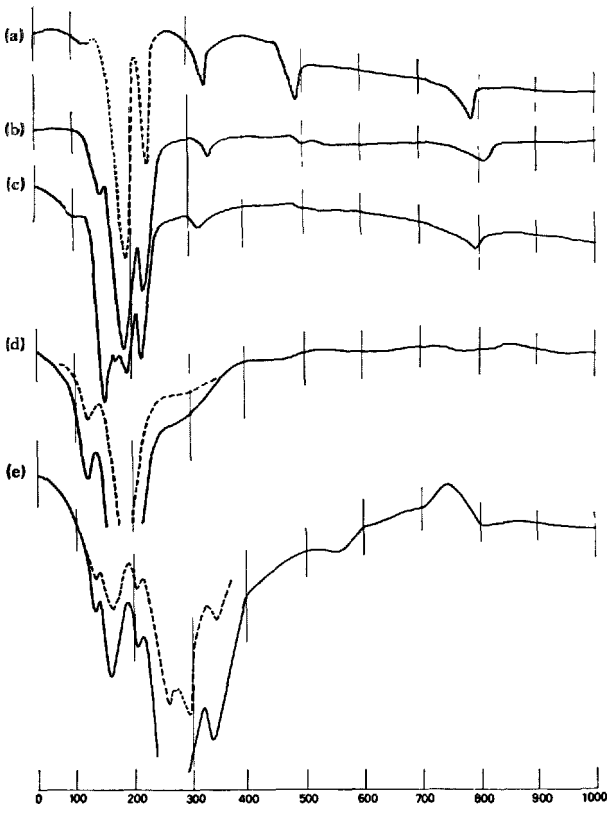


Fig. 7. *DTA thermograms of C_3A-gypsum pastes hydrates without additives. (a) No hydration (b) 3 hours hydration (c) 24 hours (d) 14 days (e) 90 days. Dashed curves were recorded at half sensitivity*

In the early stages of hydration four overlapping endotherms lie between 150°C and 250°C. The lowest endotherm is due to ettringite, and later it grows so intense that it obscures the whole region. The two highest endotherms are attributed to gypsum even though their relative intensities are different from that which is usually observed. The gypsum peaks are obscured eventually by the growing ettringite endotherm. The fourth endotherm at 150–200°C has not been positively identified, but is tentatively assigned to water adsorbed on the gypsum. Adsorbed water has been detected earlier in this laboratory (13a) as an endothermic shoulder on the lower gypsum peak. In pastes without additives a small endothermic shoulder appears on the low temperature side of the strong ettringite peak (Fig. 7d). This effect has been shown (13b) to be due to water adsorbed on ettringite. The peak was not observed with pastes containing sugars.

A broad exothermic effect at about 400°C (Fig. 8) is again attributed to the organic matter, but

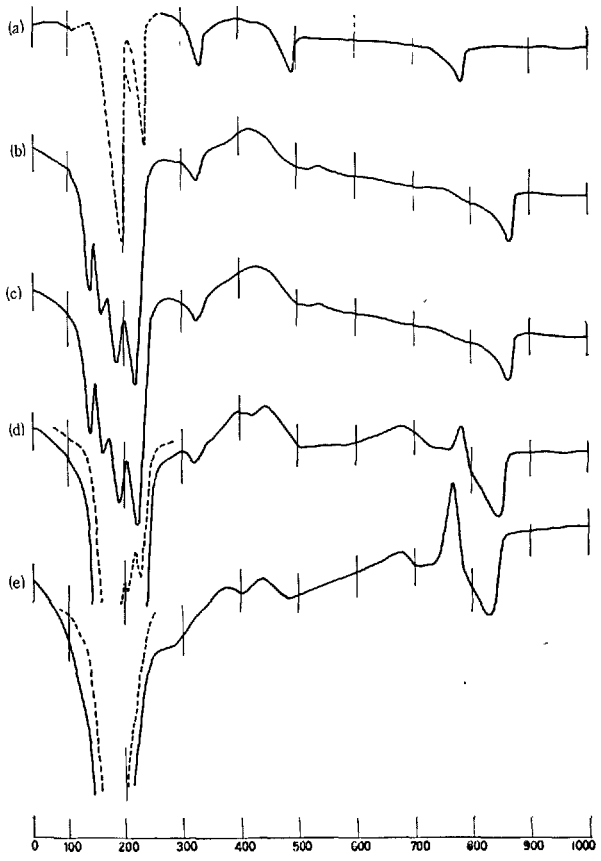

Fig. 8. *DTA thermograms of C_3A-gypsum pastes hydrated with 1% sucrose. (a) No hydration (b) 3 hours hydration (c) 24 hours (d) 14 days (e) 90 days. Dashed curves were recorded at half sensitivity*

probably also arises from the formation of insoluble anhydrite after the gypsum has dehydrated. A broad exotherm at about 650°C and the sharper one at about 750°C (Fig. 8) are dependent on the amount of ettringite that was initially in the pastes, but are not found either in the thermograms of pastes hydrated without additives (Fig. 7) or in the thermograms of synthetic ettringite. These effects have previously been observed (5) in C_3A-gypsum pastes, but their origin is still not clear.

The presence of the low-sulphate sulphoaluminate is readily detected by XRD and DTA. In DTA thermograms the endothermic region is shifted to 200–300°C (Fig. 7e) and the broad exotherm at 750°C has been shown (14) to be characteristic of the low-sulphate sulphoaluminate. Low-sulphate sulphoaluminate has only been detected at 28 days in pastes without additives and by 90 days in pastes containing lactose, trehalsoe and raffinose (Table 3). It can be seen (Table 3) that C_4AH_{13} appears before the conversion of the sulphoaluminates is complete.

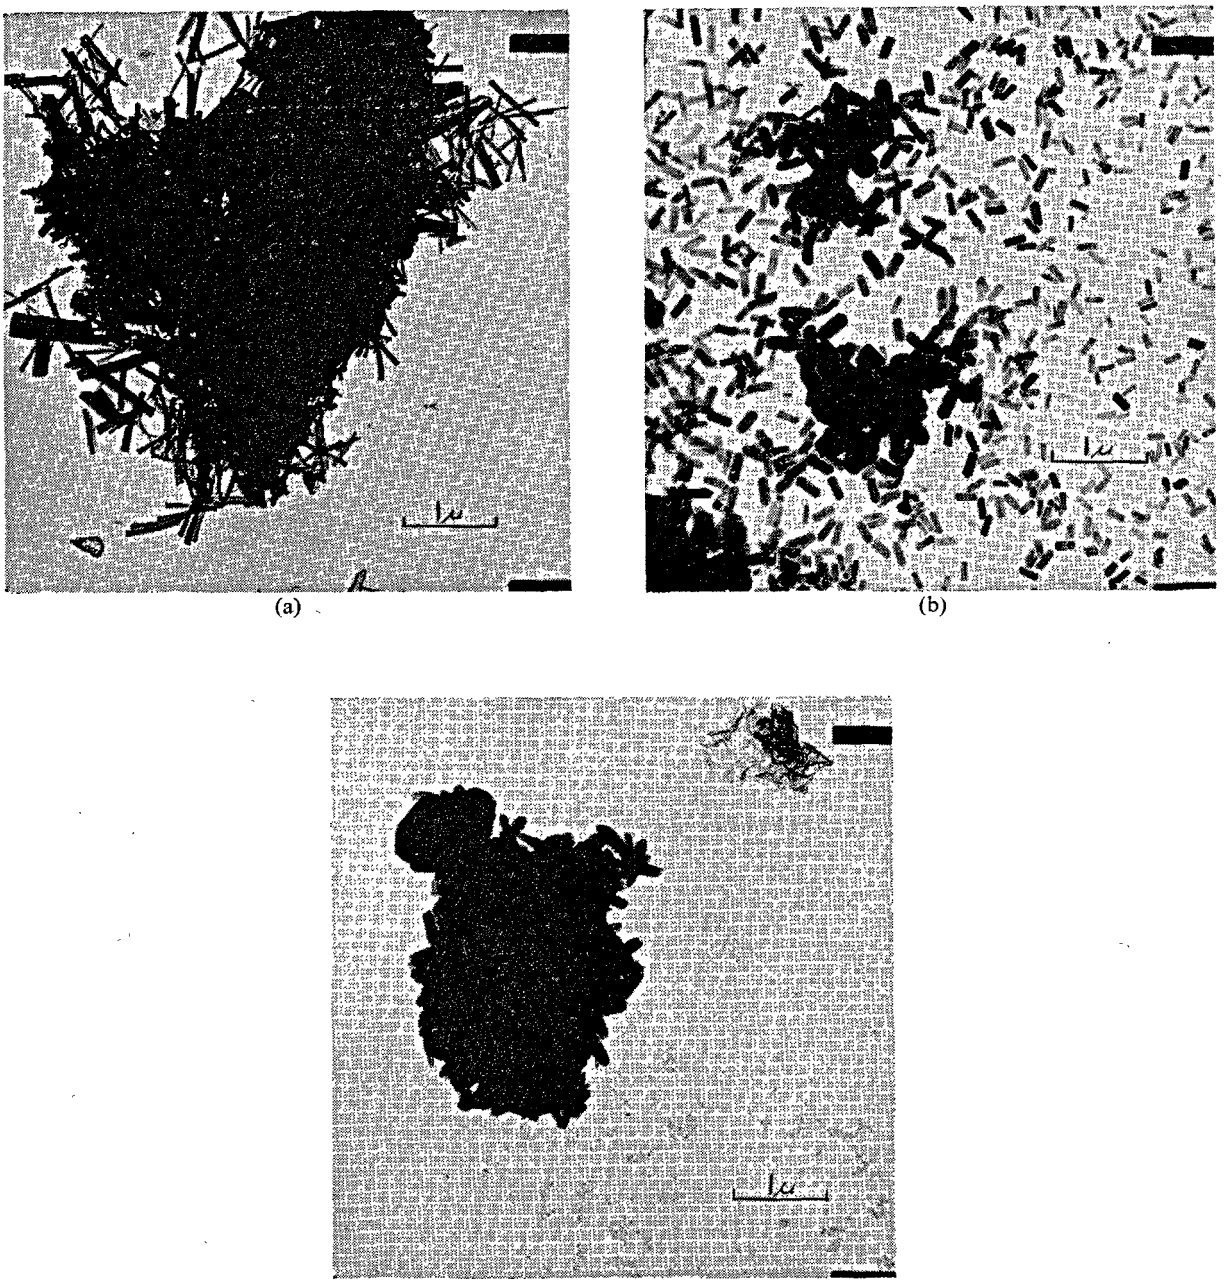
*Complete reaction of gypsum gives a maximum of 62.0% by weight of ettringite.
†Low-sulphate sulphoaluminate was present and the amount of ettringite could not be calculated.

Rate of Hydration

The amounts of ettringite formed in pastes, calculated, as described below, from TGA data, are presented in Table 4. The weight losses up to 400°C for gypsum and ettringite were determined on pure samples. If it is assumed that no reaction has occurred, then the theoretical weight loss due to gypsum is known and the extra loss observed in any sample is attributed solely to ettringite. Using the reaction

$$C_3A + 3CaSO_4 \cdot 2H_2O + 26H_2O \longrightarrow C_3A \cdot 3CaSO_4 \cdot 32H_2O$$

the amount of gypsum reacted to form ettringite can be calculated, and this leads to a new value for the amount of ettringite formed. By successive approximations the concentrations of gypsum and ettringite are eventually determined. The assumption that adsorbed water does not contribute to the TGA weight losses is probably not justified in view of DTA interpretations (see previous section). However, accurate corrections would be difficult to make, because adsorbed water was not distinguished in TGA data, and consequently they have been neglected. Although the calculated values of ettringite may consequently be too high (and this would explain the apparent insen-



(a) (b)

(c)

Fig. 9. *Electron micrographs of* C_3A*-gypsum pastes after 24 hours* (×*24,650*). (*a*) *No additive* (*b*) *with 1% xylose* (*c*) *with 1% glucose*

sitivity of XRD), the general trends will not be affected.

The formation of ettringite is retarded by the addition of sugars. However, there is a small, initial acceleration in pastes with xylose, fructose and glucose, although the rate of formation of ettringite appears to be less at later ages in these pastes. On the other hand pastes with raffinose, trehalose and lactose are initially strongly retarding and the appearance of low-sulphate sulphoaluminate by 90 days is the consequence of an increase in the rate of formation of ettringite at later ages. Sucrose also shows this later

acceleration in rate, but to a smaller extent.

This action of the sugars is rather different from their effects in C_3A pastes. Thus xylose and fructose accclerate hydration at early ages, but retard strongly later. Raffinose and lactose are initially strongly retarding, but only moderately retarding later; while sucrose is again strongly retarding at all ages. Trehalose, apart from an initial strong retardation, delays hydration less than the other sugars.

Crystal Morphology

A brief electron microscopic examination of C_3A-gypsum pastes show that sugars also modify the morphology of ettringite. The familiar needles of ettringite are well formed in pastes without additives by 24 hours (Fig. 9a), although good electron diffraction patterns could not be obtained. These needles are also present in pastes hydrated with trehalose, but are not generally as well developed. Usually they have been modified to small rectangular crystals (Fig. 9b) or to thick chunky crystals (Fig. 9c). The needles were not observed with other sugars and only the modified forms were present. However, no appreciable strength was developed in C_3A-gypsum pastes until the low-sulphate sulphoaluminate was formed, so that ettringite does not contribute to the strength of pastes whether modified or not.

Discussion

The Behaviour of Sugars in Pastes

Structures

At the beginning of this study it was hoped to be able to relate the effects of the different sugars to their structural differences; but no definite pattern has emerged. From this point of view the saccharides are not good compounds to study because they are complex structurally. Sugars are capable of existence in an open chain form and as 5-membered (furanose) or 6-membered (pyranose) ring forms and these are all rapidly interconvertible. Most saccharides exist predominantly in the pyranose form in neutral aqueous solutions, but fructose is mainly in its furanose form, and ribose has abnormally high amounts of the open-chain form. Thus the equilibria between the different structural forms may vary widely under the experimental conditions.

Reactivities

Sugars are also very labile in strongly alkaline solutions (15) such as occur in cement pastes. Initially isomerizations to other saccharides takes place and the hydrolysis of polysaccharides may also occur. Using gas chromatography it has been shown (16) that these reactions occur quite rapidly in saturated calcium hydroxide or in C_3A solutions (Table 5). Slower reactions also occur (15) which involve the formation of saccharinic acids and the breakdown of sugars into fragments which can then re-combine. These reactions cause the yellowing of alkaline sugar solutions and account for the yellow tints observed in the dried C_3A pastes from 24 hours onwards. The disappearance of the original sugars in alkaline solutions, as estimated from gas chromatography, cannot be wholly accounted for in the formation of other sugars, and the appreciable discrepancies are attributed to the formation of other undetected products. However, ribose and trehalose show no appreciable isomerization, hydrolysis or degradation and these sugars are moderately weak retarders. Therefore, it is possible that the degradation products may be more effective retarding compounds than the sugars themselves. Bruere (4) has earlier remarked on the stability of trehalose towards alkali.

Table 5. *The isomerization of sugars in saturated calcium hydroxide solution*

Initial sugar	New products detected by gas chromatography
Ribose	None
Xylose	Arabinose, Lyxose?
Mannose	No other hexoses, unidentified pentoses
Glucose	Galactose, mannose, fructose, xylose, arabinose
Fructose	Glucose, mannose
Sucrose	Glucose, fructose, traces of pentoses
Lactose	Galactose, glucose (only traces of both)
Trehalose	None
Raffinose	Galactose, glucose, fructose, traces of pentoses

Mechanisms of Retarding

Complexing

Taplin (3) has suggested that the HO–C–C=O grouping is an essential feature of any organic compound which is an effective retarder. This chemical grouping is one which can readily complex with metals by chelation. Taplin has pointed out that the two oxygen atoms must also be able to approach each other and this is also a necessary condition for chelation. The 5-membered chelate ring such as would be formed is the ring size of optimum stability. Those com-

pounds which are classed by Taplin as weak or negligible retarders are, in fact, generally poor complexing agents. However, the weak retarding action of some recognized strong complexing agents (e.g. acetylacetone, 8-hydroxyquinoline, salicylaldehyde, EDTA) suggests that the position of equilibria between complexed and uncomplexed forms may be important.

Although sugars are formally polyhydroxy aldehydes with the HO–C–C=O grouping, they exist predominantly in ring forms (as discussed above) in which the aldehyde group has become an ether linkage. Nevertheless, sugars complex with salts and hydroxides of the alkali metals (17), alkaline earth metals (17) and other metals (18), although the structures of these complexes are not definitely established. Sugars also complex with hydroxy complexes of metals (19, 20) such as borates, germanates, stannates, arsenites, and aluminates (21, 22). In these complexes it is considered (19, 20) that the sugar molecule chelates to the central metal atom by substituting for two metal hydroxyls to form two C–O–M bonds through adjacent hydroxy groups.

We consider, therefore, that complexing of metals, especially calcium, aluminium and iron, may be an important factor in the retarding action of organic compounds. The concentration of the metal in solution will increase on complexing, and this should influence the hydration reactions. Suzuki and Nishi (2) have observed increases in the total concentrations of aluminium, iron and silica in cement pastes containing sugars. It is anticipated that specific ion electrodes will be useful tools in the investigation of complexing in cement chemistry.

Adsorption

Hansen (23) has suggested that retarders adsorb on cement surfaces thereby preventing attack by water, and Taplin (3) has pointed out that adsorption on hydrate surfaces would also lead to retardation. Adsorption may be regarded as a special case of complexing in that the metal ions involved are located on solid surfaces and not in solution. Sugars have been found to have water-reducing properties, and this is usually explained by the repulsion of solid particles through adsorption.

The behaviour of trehalose is puzzling in that the particles appear to be attracted rather than repelled. Trehalose is a non-reducing sugar not readily attacked by alkali so that it will exist as two pyranose rings even in cement pastes. This contrasts with the isomerization or hydrolysis observed for other saccharides which indicates that the open-chain forms are readily formed under these conditions. Therefore, it is plausible to suggest that the structure of trehalose allows it to adsorb on solid surfaces in such a way that it can adsorb to a second surface simultaneously, as has been suggested (24) for additives which increase the flocculation of cement pastes.

Solubility

Suzuki and Nishi (2) have suggested that additives act through the precipitation of insoluble complexes which are assumed to prevent further reaction by coating the cement grains. They have suggested that a relationship exists between the solubilities of the calcium salts of carboxylic acids and their retarding properties. However, contrary to their statement, complexes of sucrose and other sugars with calcium hydroxide are very soluble in aqueous solutions (17). The solubility product of metal complexes on salts will play a part since this also affects the concentration of the metal in solution.

Concluding Remarks

At the present time it is not possible to do more than generalize about the theories of retarders, but it is likely that the three approaches discussed above are merely different aspects of the one phenomenon and can all be involved in influencing the hydration of cement. However, until more data is available to the cement chemist the details of mechanisms cannot be clarified, and more work is therefore required on the chemical aspects of retardation such as the rate of formation of hydration products and changes in their reactivity, the rate of release of components into the liquid phase, the extent and nature of adsorption and the chemical behaviour of additives in the alkaline environment of a cement paste. Our results have, therefore, been presented at this stage, although several points require further investigation. This work is being developed further with special attention being given to the possibilities of complexing.

Acknowledgements

I wish to thank the Director of Physics and Engineering Laboratory, D. S. I. R. for the use of the

Phillips Electron Microscope, and Mr. N. B. Milestone and Mr. G. T. Mentzer for assistance with the experimental work. I am indebted to Mr. R. A. Kennerley for his critical reading of the manuscript and his continued interest in this work. This paper is published with the permission of the Director of Chemistry Division.

Sapplementary Paper II-41 Some Principles in Cement Hydration

Albert Joisel*

Synopsis

During the hydration of cements their constituents, C, S, A, F, N, K, M, etc., regain a certain individuality.

1) *Calcium silicates* have an incongruent dissolution: lime passes into solution much faster than silica, the richer the silicate is in lime and the higher the concentration of strong anions in the interstitial water; it alone can result in a crystallization of portlandite.

Hydrated calcium silicates are not stoichiometrically defined.

2) *Calcium aluminates* pass into solution in their stoichiometric ratio faster, the richer they are in lime, the poorer in iron oxide, the higher the concentration of strong cations and the lower the concentration of strong anions in the interstitial water.

The crystallization of hydrated aluminates starts with a coacervation: the network of hydrates includes all the constituents present in the interstitial liquid: hydroxides, sulphates, chlorides, carbonates, etc. The most stable hydrated aluminate is C_3AH_6.

3) *Anions or cations in the interstitial solution* can precipitate on the calcic cement grains in an anhydrous form: they coat their surface and thus retard their hydration. Above the concentration corresponding to a monomolecular layer on the surface of the grains, they precipitate into the solution and contribute to the gelation of the aqueous interstices.

Anions in the interstitial solution can also precipitate with the calcium ion of the solution in a hydrated form and contribute to gelation without coating the cement grains.

4) *Calcium sulphate*, which is relatively soluble, is amphoteric. It behaves as a strong anion for silicates and highly calcic aluminates and as a strong cation for aluminates low in calcium.

It can also contribute to the gelation of aqueous interstices when partially dehydrated.

Introduction

The study of cement hydration which originated at the end of the last century, has only made strides in the course of the last scores of years. It has considerably developed during the last twenty years. A mere careful scrutiny of the book-reviews of the last symposiums on the chemistry of cements, mainly those of 1952 and of 1960 suffices to convince one of this development.

The science of hydration has still to improve a great deal and above all let's say that the existing data are often lacking in accuracy. It is due to the fact that the hydrated cement constitutes an *artificial rock*, and one knows there exists and infinite variety of rocks in nature . . .

Hence one can understand why hydrated cement is highly heterogeneous. One must not expect to find in it only perfectly defined bodies, from the stoichiometric point of view, and, a fortiori, from the crystallographic point of veiw, except in some particular cases affecting special cements only.

Yet, hydration is of the highest interest as it exerts an influence of primary importance on all the various properties of concretes: rapidity of setting; mechanical strength; stability of volume; impermeability; resistance to agressive agents, to freezing, to flames; protection of the reinforcement; and so on.

Conversely all that can be known concerning these different properties should be fully taken to account in the study of hydration, and provide indispensable precisions, complement to the mineralogical studies of hydrated products (chemical composition, water fixation, crystallography, etc.).

Two general methods may be envisaged for this study: the first one consists in examining separately the evolution of certain compounds, in presence of water, under certain conditions, as best as possibly can be defined, as for instance the evolution of calcium silicates, that of calcium aluminates, the influence exerted by minor components and by admix-

*Centre d'Etudes et de Recherches de l'Industrie des Liants Hydrauliques, Paris, France.

tures (i.e. by sulphates, chlorides, carboxolates, etc.), the influence of temperature, the consequence of the water/cement ratio, etc. The second method consists in taking advantage of the total results accumulated during the laboratory researches, and also in the practical experience of the utilization of cements. The first method is mainly *deductive*, it bears on the scale from the simple to the complex. The second method is more *inductive*, it tends to extract certain simple principles out of a complex entity. Most of the works published for the last scores of years, dealing with hydration, have generally adopted the first method. But one must not neglect the possibilities of intellectual induction, working from scientific observations, either technical or practical, on the greatest possible variety of cements (portlands, slags, pozzolanas) used under the most varied conditions (fineness, dilution, temperature, admixtures, etc.). On all cases it is imperative that *the basic principles of the science of hydration should be verified by all checked inferences, without any exception.*

The principles we wish to set out concern the studies which are carried out at the CERILH in France, after a very important confrontation of the works having been published in different countries in the world. We will mostly refer to data universally known and admitted by experts such as for instance the acceleration of the hydration of portland clinker by means of calcium chloride, or the retardment provoked by sodium fluoride. We will therefore not indicate the origins.

General Points

As from its initial mixing, concrete is heterogeneous, since it is a three-phased element: it has a solid phase (the aggregate grains and the cement grains), a liquid phase (water, or rather interstitial solution) and a gaseous phase, intended or not (the voids, and the air or hydrogen bubbles). The aggregates and the gases remain almost inert, at least at ambient temperatures, during a certain time. Hydration therefore occurs essentially in the paste constituted by the cement grains and the water.

The hydraulic components of the cement grains enter into solution in water, where they precipitate in a hydrated form, but this dissolution is accompanied by a *hydrolysis*, that is to say, that the acids (particularly silica and alumina) and the bases (mainly lime), which constitute the cement, regain *a certain individuality* at the time of dissolution.

This is particularly characteristic with silicates: for instance the lime of the clinker alite may escape alone from the cement grains in order to crystallize in the aqueous interstices in hydroxide form (which has been termed portlandite that may be easily observed under the microscope and with a microprobe on polished sections, and on thin plates) or even to form stalactites out of the rims of certain cracked reservoirs. This is true, too, for aluminates, though alumina passes into solution more easily than silica; the effects are the polystoichiometry of hydrated aluminates, the proportion of "fixed" water, the rising of the pH to a rate of about: from 11 to 13, etc . . . Cements are always basic, for lime is a strong base, whereas cement acids (silica, alumina) are weak, not much soluble, and not very much dissociated. Moreover, the dissolution of alkaline components present on occasion, is easy and rapid. So it may be noted that the main *stable* cement hydrates may be written as follows:

$$s\mathrm{SiO_2},\ a\mathrm{Al(OH)_3},\ f\mathrm{Fe(OH)_3},\ c\mathrm{Ca(OH)_2},\ n\mathrm{H_2O}$$

(This formulae is a generalization of that which had been formerly proposed by Brandenberger).

s, a, f, c, n are whole numbers. The OH have not the infrared absorption bands of water, and do not obey its laws of evaporation. For example, the curves of thermogravimetric analysis always present a level corresponding either to a $\mathrm{C_cS_sH_c}$ or to a $\mathrm{C_cA_aH_{3a+c}}$ formulae as $\mathrm{C_3S_2H_3}$, $\mathrm{C_3AH_6}$, $\mathrm{C_3FH_6}$ etc. Conversely, the $n\mathrm{H_2O}$ are *more or less "free"*, and they evaporate therefore more or less easily, and especially in keeping with the conditions of temperature and of steam pressure, and *their elimination is more or less reversible* in normal temperature.

The formulae shows that aluminates fix more water than silicates.

Hydration of Silicates

One may be tempted to argue in the following way: we know, according to the original theory of Le Chatelier, that the anhydrous silicates dissolve and crystallize in an hydrated form (that may be appre-

ciated by X-rays); then, whatever the initial fineness of the cement may be, the hydrated paste obtained in course of time depends only on the initial (water/cement) ratio. This would be proved by the fact that the mechanical strength is effectively almost the same in course of time, whatever the initial fineness. But it is to be noticed that the water taken out of the solution, at the start of mixing, contains lime, but contains almost no silica. Besides, the permeability of the hydrated paste varies in relation to the initial fineness and the hydraulic drying shrinkage is almost in proportion to the initial Blaine fineness, for usual portland cements, whatever the duration of hydration before they are exposed to the air. In other words the cement does not so soon forget its specific surface, and consequently it keeps intact the surface of its grains.

Hence, one is to think that hydration occurs as is described, in schematizing, on Fig. 1, for instance for tricalcium silicate and this is not annuled by microscopic observations and by microanalysis with the Castaing probe. *The initial surface of the cement grains remains a solution of continuity in the hydrated paste during the hydration. The topochemical "gel" formed inside a silicate grain and the gel created in the interstices initially filled with water, are quite distinct gels.*

Since the silicate grains keep the same surface during the hydration and thus keep their contact points between one another and with the aggregates, one understands why in wet medium and in constant temperature the apparent volume of the cement paste, and a fortiori, that of concrete are not modified: *there is no mould shrinkage for the portland cements which are rich in silicates.*

The interestices between the grains have, in fact, a lime concentration independent from the fineness of the cement, provided that the (water/cement) ratio remains the same; and one can think that the mechanical strength depends mainly on this concentration. But the network of interestices has ramifications depending on the fineness of cement, and one knows, too, that permeability, capillarity, hydraulic shrinkage depend on this texture: the permeability-meters used for the measuring of the fineness of cement originate in these principles, and the clay pastes shrinkage is consonant to them.

During the hydration the bonds which are formed in the interstices of the grains are in increasing number: they are represented on Fig. 1, in schematizing, by the $\boxed{CH}$.

The penetration of a fluid into a porous solid almost occurs in conformity to the usual law:

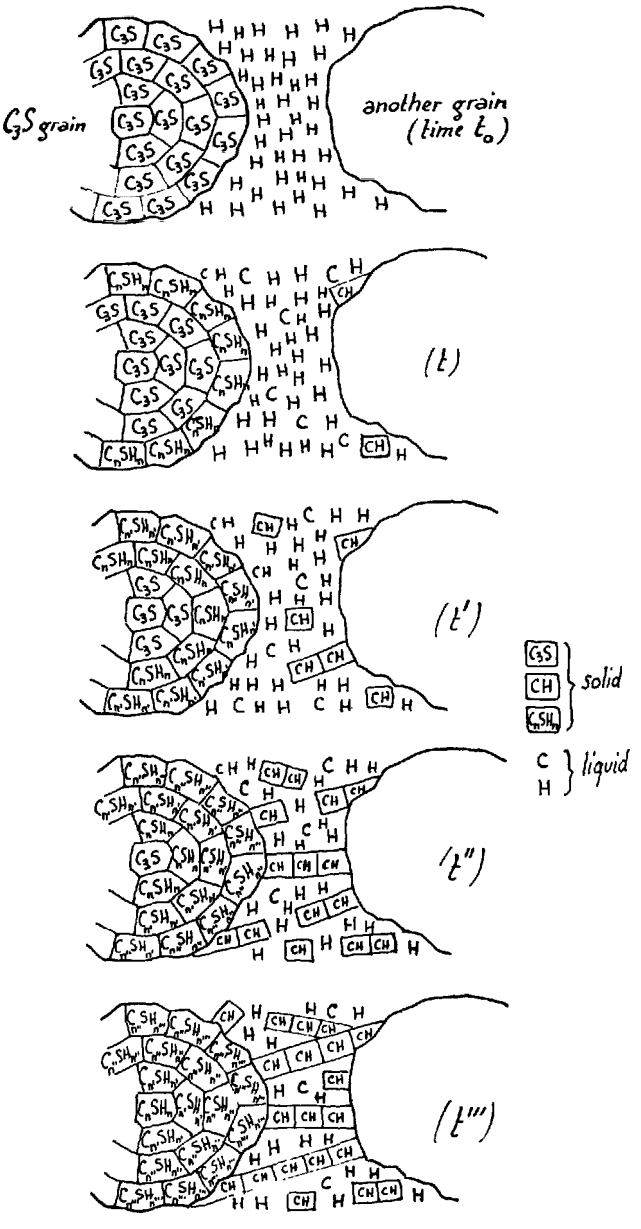

Fig. 1.

$$\text{depth } \boxed{x = k_s\sqrt{\text{time } t}}$$

For the silicate grains which are hydrolyzed by water, the expression of the penetration is, no doubt, a little more complex; but anyway this penetration of water into the grains occurs more and more slowly since the thickness of silicate that water must get through is increasing during the hydration: *one conceives that the setting of highly silicated portland cements is slow and that their mechanical strength is progressively and regularly increasing.*

A part of the lime in the calcic silicate passes into the interstitial water, leaving a free space for the penetration of water, for the molecules of water are smaller than those of lime. Besides, those among the molecules of lime which become hydrated, while staying at the same place in silicate grains, may undergo some changes in position. But if two lime molecules of a silicate are taken out, instead of one, the penetration of water is not two times more rapid. To understand the preceding statement it is enough to remember that the flow of a liquid in a pipe is in proportion to the square of its section. One then deduces that *tricalcium silicate hydrates more rapidly than dicalcium silicate*; and monocalcium silicate is not easily hydrated.

For one given (water/cement) ratio of the paste, the amount of portlandite in of the interstices is all the higher, the stronger the lime content of the silicates is, that is to say the alite content is higher.

During the hydration of an alite grain, the core of the grain may have remained anhydrous and one conceives that the hydrated part of the grain which is very near this core remains relatively rich in lime. But silica has little affinity with lime (one knows, for instance, that calcium silicates are relatively seldom found in nature, and that the burning of cement needs considerable energy). So, when recovering a certain individuality, during the hydration, *the lime has a propensity to make its concentration roughly uniform in the whole paste* containing the initial grains and the aqueous interstitial phase. As, in concrete, cement takes up a volume which is about 1/3 to 1/2 of the volume of the paste (cement + water), the hydrated silicate, which has a propensity to replace alite C_3S in wet medium, has a total composition roughly situated between CSH and $C_{1.5}SH_{1.5}$, but *there is no stoichiometrically defined hydrated calcium silicate*, and as a consequence, during the hydration, intermediate compositions may exist locally, compositions which can reach C_2SH_2, or even CH (as we saw previously).

As it is diffused in all the interstitial solution, the lime originating in the silicate grains, reinforces all the bonds. A vibration being effected on concrete, after the first precipitations are made, and even after the first bonds are established, i.e. a little moment after the initial set, no an ill effect on the final strength.

The penetration of water into the grains, and the concomitant migration of their lime into the interstices, depends on the viscosity of this water which lowers when temperature increases. It results that *the speed of hydration of the silicates increases with temperature*. One knows that the solubility of the lime diminishes when temperature increases; but it is the speed of dissolution which must be taken into account much more than solubility.

Silica is much less mobile than lime, during the hydration, but it is not strictly insoluble, in a water the pH of which is high. So, around the grains, *in course of time*, there are, undoubtedly, some movements of molecules or of siliceous anions in the silicates (alite or belite), in presence of lime in solution, and above all in presence of alkalies (see par. Accelerators and Retarders).

Hydration of Aluminates

It is to be noticed that *the water which is extracted from the paste of calcium aluminate, at the initial mixing, contains alumina and lime in the same C/A ratio, as the anhydrous aluminate: the hydrolysis of calcium aluminates is therefore quite different from that of the silicates*. Their hydration occurs as is indicated (in schematizing) in Fig. 2 for instance for the tricalcium aluminate.

The surface of the grains in contact with the solution is progressively dissolved by water. It disappears in so far as it is a discontinuity of the hydrated paste. It, therefore, establishes no solid bond with the aggregate grains (or the other cement grains) which are around it. A surface that is dissolving even prevents the bonds from being strongly established in the area in which it is found. It is only when the dissolution is complete in an area that strong bonds may be established. It results that the hardening occurs immediately after the moment in which the first bonds are established, that is, after the initial set. *Thus this hardening is always rapid:* after one day the average compressive strength of normal mortar ISO is of 600 kg/cm² for an aluminous cement, whereas it is ten times weaker for a portland cement having the same setting time.

It results also that a mixing or a vibration of concrete after the moment when the first bonds are established, i.e., after the initial set, breakes these bonds and considerably reduces the final strength. It is what happens with the aluminous cement, as with plaster, for the same reasons.

One could assert, in schematizing, that the bonds between silicate grains are produced one beside the other, in parallel; they are more and more numerous,

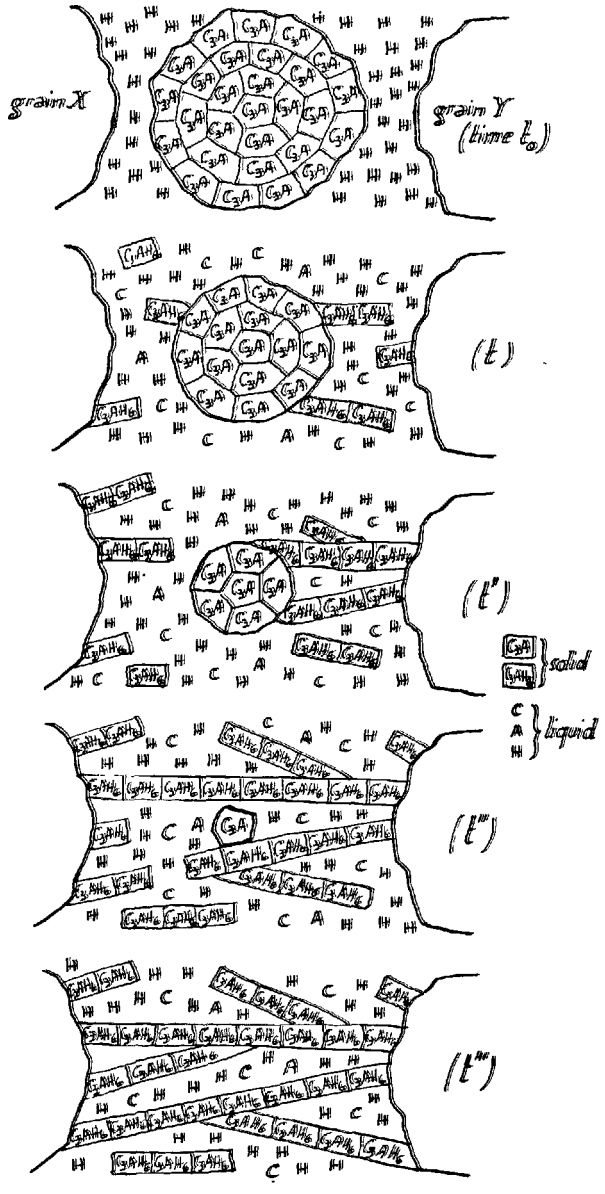

Fig. 2.

stronger and stronger, *they give one another more strength*, whereas the bonds between aluminate grains are produced, at least partly, one at the end of the other, in series. Every re-mixing breaks the bonds and if the latter afterwards go on extending, they are weakened once for all. This weakening, moreover, may be stressed by the fact that aluminates absorb more water than silicates, and the workability is more affected by the initial hydration.

The hydration of aluminates occuring with a shrinkage of the whole (solid + water), *the cement concrete rich in aluminate shows a mould shrinkage*, conversely to what happens with the cements which are rich in silicates. It is all the same, a fortiori, with neat cement paste, and specially with aluminous cement.

Whatever the initial fineness of the aluminate grains may be, the hydrated paste has about the same texture if the (water/cement) ratio is the same. It results that *the drying shrinkage does not much depend on the initial fineness of the aluminate*. Actually it is known that it is so, for the aluminous cement: the increase of the cement shrinkage due to the increase of fineness is small. It originates, to a great extent, in the small proportion of silicate that it contains. One conceives, too, that the permeability, the capillarity, and the freezing strength of concretes of aluminous cement little depend on the fineness of cement, contrary to what happens with the portland cements.

As the surface of the grains dissolves when it comes into contact with the interstitial water, the penetration of this water into the grains keeps more or less the $\boxed{x = k_a \cdot t}$ law, whereas for silicates we saw that it was rather $x = k_s\sqrt{t}$. It is one of the reasons why *the hydration of aluminates is more rapid than that of the silicates* for the same molar proportions of lime in relation either to the alumina or to the silica.

During the hydration of calcium aluminate, the alumina and the lime pass into solution, but alumina is much less soluble and much less mobile than lime. *Hydration therefore is the more rapid, the richer in lime the alminate is*: aluminate which is highly calcic grants the quick-setting cement a quick set. The same holds true in respect of the tricalcium aluminate of the portland, provided it is not retarded by the gypsum (see par. Accelerators and Retarders). Conversely, the aluminate of the aluminous cement, which is not very calcic, and the composition of which corresponds more or less to CA, is a slow-setting one.

Ferric oxide is still less soluble and less mobile than alumina, at least for the simple reason that the iron atom is more voluminous than the aluminium atom. Thus *the smaller their A/F ratio is, the less rapidly the aluminoferrites hydrate*.

Crystallization of hydrated aluminates in the interstitial solution has some common points with a coacervation: the aluminates which have passed into solution and have precipitated, behave like colloids in certain respects, and *they enclose in their networks the components contained in the interstitial liquid, i.e. hydroxides, sulphates, chlorides, carbonates, etc.* It results in a formation either of aluminates enriched with lime or of complex aluminates: sulphoaluminates, chloroaluminates, carboaluminates, etc. It is not the same thing with silicates.

Since the alumina of the aluminate passes into

solution at the same time as the lime, the changes in structure of the hydrated aluminate may possibly occur, and this explained why *the more stable hydrated aluminate eventually tends to be effected.* It is known that usually, it is C_3AH_6, above all if temperature rises above 30°C.

Accelerators and Retarders

The products which accelerate or retard the dissolution of the hydraulic components of cement, especially, lime, silica, and alumina, are accelerators or retarders. These admixtures, thus, must be *soluble* in the mixing water. If they are hydrolized, they behave like a mixture of the ionized acid and base which constitute them. In order to understand their activity one must consider that *the medium has always a high pH.*

1) The *accelerators* are essentially:

—the "*acid*" *anions* which accelerate the dissolution of the lime: hydrochloric, nitric, and sulphuric anions. These are *the acids of which the calcium salts are comparatively soluble*, and particularly the chloride whose anion is the smallest one, and thus the most mobile one.

—the "*basic*" *cations* which accelerate the dissolution of alumina and of silica: alkaline cations (sodium, potassium, ammonium, etc.) for all the aluminates and silicates; calcic cation for the aluminates which are poor in lime.

These are the bases of which the silicic or aluminic salts are comparatively soluble.

But *the alkaline cations remain "dissolvent" and hence weakening* for the final strengths, mainly if the cements are very much calcic (portlands).

The portland cement acts upon the aluminous cement as if it were a basic accelerator. The two cements, therefore, are incompatible.

One deduces from the above that the best accelerator salt of the portland cements is the *calcium chloride;* nitrate is more expensive than chloride, and moreover it is more dangerous for the reinforcement. For less calcic cements, containing high proportions of blast-furnace slag or of natural pozzolana or of artificial pozzolana (fly ash), an alkaline chloride may be preferred.

Alkaline hydroxides are accelerators for all the cements made of calcium silicates and aluminates. The alkaline salts of weak acids behave like the corresponding bases: silicates, aluminates, carbonates, etc. They are therefore accelerators. In strong dose, besides, they are "gelificators", too (see par. Setting and False-Setting).

The accelerating action varies regularly and more or less *in proportion to the concentration* of the accelerating admixture in the mixing water. But one understands that the slower the crystallization of the hydrated bonds is the more easily it is effected. The best final strengths, thus, are usually all the higher the more slowly the setting is.

2) *Retarders* can behave in two different ways. They are:

a) "*Reducers of solubility*": their presence in solution in the mixing water lowers the rate of solubility of the anhydrous cement components. For instance, calcium hydroxide retards the portland since it hinders the dissolution of the lime of the silicates; calcium chloride retards the "slag cement with lime" made mainly of slag (vitreous silico-aluminate of a potential composition which is very near $C_6S_3A_6$) and of $Ca(OH)_2$, since the Cl^- anion, like all the anions, retards the dissolution of silica and of alumina, and the Ca^{++} cation is already existing in the lime.

The activity of these reducers of solubility regularly varies with their concentration.

b) "*Coaters*": They form with a cement constituent, *on the surface of its grains in contact with the mixing water, an anhydrous compound almost insoluble*, and thus impermeable. It is the case of alkaline tetraborates, fluorides, phosphates and carboxilates, and of certain organic substances, such as the sugars, which form, with the calcium, compounds which are much less soluble than lime and which, therefore, fix the calcic cement ions and inhibit the dissolution of the silicates and aluminates. The latter are retarders for all cements (schema in Fig. 3).

It is the same case, too, for the cations which correspond to almost insoluble bases. These bases precipitate, by means of an exchange with $Ca(OH)_2$, on the surface of the cement grains, that is to say, where the OH^- anions are more concentrated (schema in Fig. 4). These hydroxides contain OH hydroxiles, but they are anhydrous, like all coaters.

These cations can originate in oxides insoluble in pure water and brought into solution in presence of cement alkalies. This is why, for instance, zinc oxide, which has no effect on cements without soluble alkalies (since it is insoluble), is a retarder for usual portlands which contain small amount of alkalies.

The coaters are retarders for a low proportion, since it is enough for them to form *a monomolecular layer* on the surface of the grain to be effective. Beyond

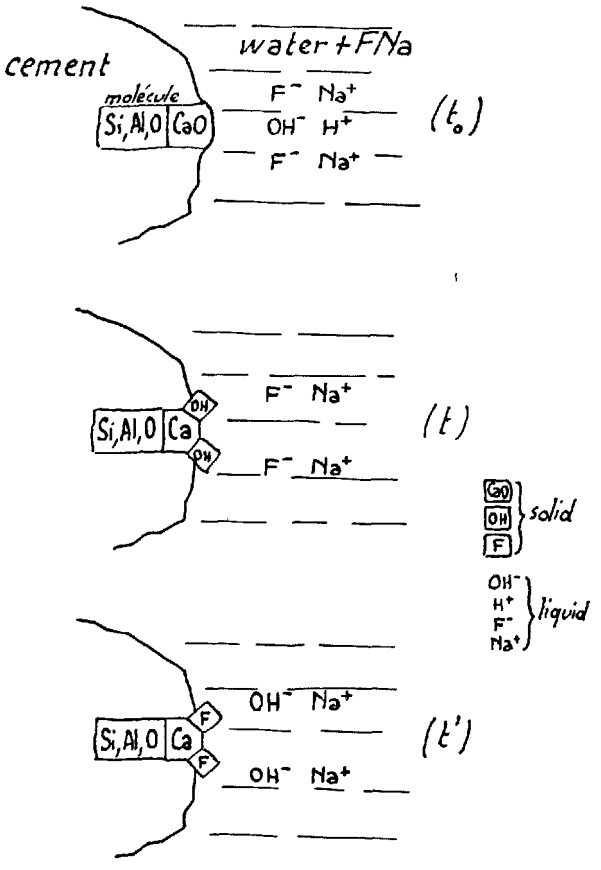

Fig. 3.

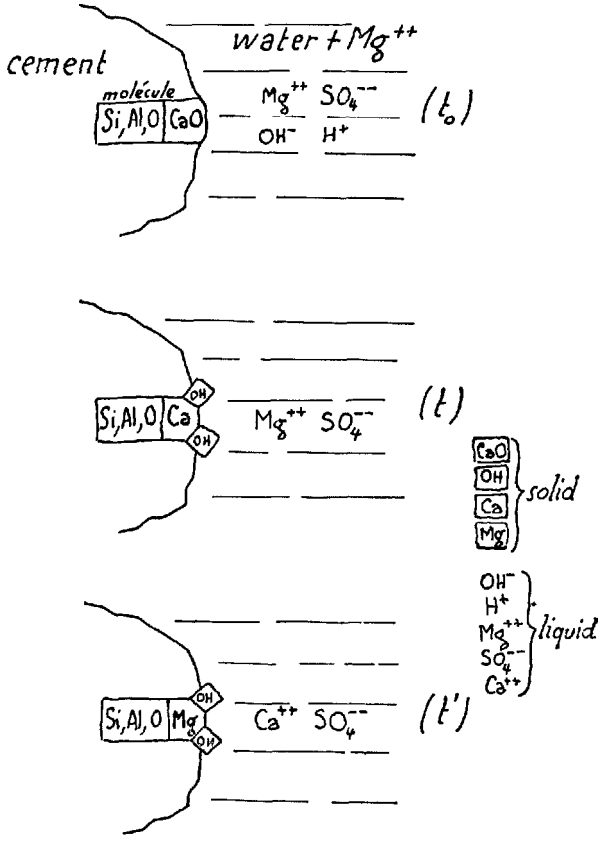

Fig. 4.

this proportion the retard does not become more marked in proportion to the addition. The coating coat is not rigorously impermeable. Hydration is just retarded and the final resistances may be excellent.

3) Certain compounds are *amphoterous*: They are either accelerators or retarders according to their effect on one or the other of the cement components. Or else these compounds include two ions the effects of which may act against each other. Generally speaking, to understand their effects, one must study the cement components the dissolution of which is absolutely necessary:

—To accelerate a silicate, one has better act upon its lime,

—To accelerate an aluminate, one must act upon its alumina,

—To retard something, one has better act upon the lime.

So, *calcium sulphate* is:

—By the *sulphate anion*, comparatively strong,

—An accelerator for calcium silicates (in which it accelerates the dissolution of the lime),

—A retarder for highly calcic aluminates, in which it retards the dissolution of the alumina (it is a "reducer of solubility").

It is, therefore, a regulator of setting and of hardening for the portlands. Its best proportion is all the stronger, the more rapid the initial hydration of the clinker is, and thus:

—the finer,
—the richer in alkalies (see below: 4)
—the richer in C_3A

} the clinker is.

—By the *calcium cation*, relatively strong, the sulphate is an accelerator for the aluminates and for the alumino-silicates, little calcic, and particularly for slags and pozzolanas.

If the action of the calcium sulphate must be extended so that it should not be wholly fixed from the initial hydration by hydrated aluminates, it must be little soluble. This is why the supersulphated cement (mainly composed of slag and of calcium sulphate) is made of anhydrite burnt in some special conditions. But if the supersulphated cement concrete, conceived to give good strengths in ordinary conditions of tem-

perature, is steam cured, the sulphate passes too rapidly into solution and the final strengths chance to be mediocre, as though gypsum instead of anhydrite had been used in normal conditions of temperature.

Amphoterous admixtures tend sometimes to behave differently according to the ambient temperature.

When two ions of a salt have opposing effects, *it is generally the retarding ion that prevails.* For example, calcium chloride is a retarder for aluminous cement although Ca^{++} tends to accelerate the dissolution of the alumina, because the Cl^- ion is a retarder for the same dissolution.

In particular, when an ion of the admixture is a coater, it is always its action which prevails.

Certain anionic tensio-active admixtures are:
—accelerators for the aluminates by means of the Na^+ cation,
—retarders for the silicates by means of R^- anion.

4) *Certain cement components*, which rapidly pass into solution in the mixing water, can, in certain respects, be considered as admixtures. This is the case of calcium sulphates added to most cements, of a part of the portland cement clinker alkalies, and even of the calcium hydroxide produced by the silicates of the clinkers, particularly by the alite (see par. Setting and False-Setting).

Setting and False-Setting

We have seen (par. General Points) that hydration of cements is produced by the dissolution of certain components of the grains in the interstitial water and crystallization in these interstices in a hydrated form. This dissolution takes place progressively as regards the aluminates (par. Hydration of Aluminates) and principally as regards the silicates (cf. par. Hydration of Silicates) since the penetration of water into the grains is itself progressive.

The concentration (in the initial aqueous phase) of hydrated solid products, therefore, progresses regularly, and this results in a higher shearing strength, which was initially null: by definition a fluid has no shearing strength. The Vicat needle measures, in fact, a shearing strength of the paste and allows one to appreciate what is termed the "*initial*" *and* "*the final setting time*".

The addition of a retarder-coater admixture such as sodium fluoride delays the "setting". For this a dose corresponding to a monomolecular coating of calcium fluoride on the cement grains suffices. That is:
—surface of grains × thickness of the coating × volumic mass of fluoride,
for instance, for one gram of cement of the specific surface of 3,000 cm^2/g:

$$3{,}000\ cm^2 \times 3.5 \cdot 10^{-8}\ cm \times 3.2\ g/cm^3 = 0.00034\ g$$

It follows that the dose of sodium fluoride of *0.4 per 1000* (in respect to the weight of the cement) sufficies to retard considerably the setting. For the coating admixtures having more important molecules than those of sodium fluoride, more important doses would be necessary. This is the case of for example, certain sodium lignosulfites which are retarders-coaters when they are used at high doses.

Yet the sodium fluoride is used as an "accelerator" for certain uses but at a rather high does. In fact, it is true that the fluoride is a *retarder for the cement hydration*, but if it is added in sufficient quantity to the mixing water saturated with lime by the initial hydration of the cement, it precipitates also with the Ca^{++} ions, *within the aqueous interstices*. So it is a "*gelificator*" or "*thickener*" for these interstices; it is rather a "pseudo-accelerator".

Water saturated with lime contains about 1 gram of calcium per litre. One can calculate that its precipitation under the CaF_2 form, requires about 2.1 gram of NaF per litre, that is to say about *one thousandth* of the cement for usual concretes. One obtains so, to get the gelification, a minimum dose of calcium fluoride of $0.4 + 1 = 1.4$ per 1.000. But the Ca^{++} ions which are precipitated by F^- ions are renewed by Ca^{++} ions originating in the cement and the stronger the dose of fluoride is, the more marked is the gelification. In fact doses of about 1 % or even more are used.

Thanks to this example one can distinguish "setting" from "false-setting":
—*The setting originates in the hydration of cement grains* which pass into solution and crystallize in the aqueous interstices.
—*The false-setting originates in the precipitation of admixtures* initially soluble, in the aqueous interstices.

One must take as admixtures, in this respect (as we saw it in par, Accelerators and Retarders), not admixtures specially added to the cement, but also the hydration products which pass into solution *during the mixing*: alkalies, lime originating in portland cement clinkers, calcium sulphate.

The setting and the false-setting have, of course, common points, in particular, both of them need the presence of the cement components which precipitate in the aqeuous interstices. But they show noteworthy differences which are deduced from the principles we have enacted:

—1) The false-setting is always quick (a few minutes, at most);

—2) It is almost not retarded by cold;

—3) *It does concern but a trifling proportion of the cement components* (a few per cent, and even sometimes less than 1 %);

—4) It only results in trifling strengths (a few kg/cm² at most);

—5) It only occurs with a trifling liberation of heat;

—6) It is "broken" by a re-mixing.

Even though the fringe between the setting and the false-setting is not quite defined, it is absolutely necessary to characterize clearly their respective process. The understanding of the latter may allow one to avoid them, to obviate their inconveniences or to use them rationally. We will give some examples of what is above:

1) We saw previously that the alkaline fluorides are either strong retarders or pseudo-accelerators (it means accelerators of setting, but retarders of hardening). They can so be used in order to get a false-setting, for instance, in the case of *projected concrete* or of rapid withdrawing from the mould. It is all the same with other admixtures which precipitate in presence of Ca^{++}: tetraborates, phosphates, carboxilates. This is why tensio-active admixtures (air entraining agents, plasticizers, fluidifiers) sometimes increase the viscosity of concrete, at a high dose, whereas they are retarders at a weak dose.

2) One can create a false-setting by means of the admixtures which precipitate in basic medium as, for instance, the ferric sulphate which involves the gelification of the aqueous interstices by the precipitation of $Fe(OH)_3$ and eventually of the hydrated calcium sulphate.

3) The *chlorideless accelerators* may be alkaline bases; but on one hand they are caustic for the workers, and, on the other hand they weaken the final strengths. They are generally replaced by salts of weak acids: silicates, aluminates, carbonates which behave like the corresponding alkaline ions (for the same molarity), and of which the anions participate in the gelification of the aqueous interstices by means of the precipitation with the lime originating in the portland cement, under the hydrated forms of calcium silicates, aluminates and carbonates. The final strengths can this way be not too much lowered.

4) This gelification is used too for the *waterproofing agents*, but in order to avoid a disturbing false-setting one must sometimes reduce the proportion of the lime of the cement which passes into solution, and must add for this effects a small dose of coater (a phosphate for instance).

5) A part of the *alkalies of portland cement* rapidly passes into solution in the course of the mixing. It can be said that the clinker alkalies are auto-accelerators. Their action is somewhat moderate for the reason that their dissolution is progressive; and so, a portland cement containing, for instance, 1 % of K_2O is not so rapid as when the corresponding proportion of caustic potash is added to a similar cement without alkalies. But it does happen that the aeration of certain cements relatively rich of soluble alkalies confers them a false-setting, although the aeration generally retards the setting. The *carbonation of the alkalies* entails at the time of mixing, in the aqueous interstices, the precipitation of the alkaline carbonates, in presence of the lime in solution, in the form of calcium carbonate.

6) The common false-setting is that of *dehydrated gypsum at the time of grinding* when the temperature of the cement is above 100°C. The setting of the plaster thus formed provokes the false-setting of the cement. This is really a false-setting in the proper sense that must be given to this term.

7) A sulphate false-setting is also provoked by the addition of barium chloride to cements which contain gypsum.

8) The acceleration of aluminous cement by means of lime or of portland (which rapidly liberates lime) proceeds partly from what we have termed a false-setting: in the aqueous interstices this lime passed into solution is precipitated in presence of calcium aluminate coming out of the aluminous cement.

Mechanical Strengths and Homogeneity

It results from the principles of hydration which we have exposed, that the strengths of the hydraulic binders are obtained with the normal fineness and at the normal temperature:

—*During the first minutes*, thanks to the very calcic aluminates (quick-setting cement, aluminous cement mixed with lime);
—*During the first hours*, to the little calcic aluminates (aluminous cement) or to the very calcic aluminates retarded by gypsum (portlands rich in C_3A);
—*On the first days*, to the very calcic silicates (portlands);
—*At a longer period*, to silicates and to silico-aluminates little calcic (slag cements, pozzolanic cements, portland cements relatively poor in lime and alkalies).

The obtainment of these strengths can be accelerated by favouring the dissolution of hydratable compounds:

—higher grade of fineness,
—addition of accelerating admixtures,
—heating,

Heating is more favourable to silicates than to aluminates: the portland cements rich in C_3A (from 12% to 15% of C_3A) have lower strengths when warm than when cold. Aluminous cements also.

The cement paste which confers strength to concrete has a *high heterogeneity* for different reasons:

1) Immediately after the mixing and the working stage the relatively soluble components which diffuse from the grains in the liquid, particularly alkalies, calcium sulphate, lime, are uniformly distributed to the aqueous interstices as they have only a few dozens of microns to travel for that purpose *in a liquid;* but as crystallization of the hydrates goes on, this phase acquires a shearing strength and the concrete acquires *ipso facto* a mechanical strength. The diffusion of the different components is progressively slowed down, so much their ions and molecules are bigger and less mobile, that is to say, less soluble. Thus the lower the (water/cement) ratio is, the less rapid the hydration.

The electrons themselves become less mobile from one atom to the other in the course of hydration and the *electrical conductibility* diminishes at the "end of the setting".

2) The cement grains have various dimensions: the grains inferior to a micron (the number of which is of the same importance as that of the grains superior to a micron) are rapidly hydrated (often in less than 24 hours) whereas the hydration of bigger grains sometimes lasts several years.

3) Cement grains are heterogeneous: they contain different silicates, aluminates, ferrites, sulphates, etc.. They can contain clinker, slag, pozzolana, gypsum. The diffusion of their components and their hydrations can be more or less rapid. The interior surfaces of the aqueous interstices have their origin from cement grains or from aggregates or from reinforcement, or from moulds.

4) Concrete is not always homogeneous for multiple reasons (mixing, segregation etc.).

5) The medium of conservation of concrete can create heterogeneities: evaporation of water, carbonation by the atmosphere, percolation of aggressive waters (either pure, acid, or sulphated).

One must, therefore, not be surprised at the diversity of hydrates occasioned during hydration.

Conclusion

The problem of hydration of cements is not simple; but one can already grasp at least qualitatively most of the phenomenons which are inherent: setting, hardening, hydraulic shrinkage, etc. No method should be neglected in order to progress in this respect, and further knowledge cannot be considered as acquired, unless all observations and all possible measures are corroborated. It is conspicuous to realize for instance that the first values of the dimension of the minute interstices which subsist between the solid hydrated surfaces were determined, thirty years ago, by measuring hydraulic shrinkage, and their order of importance has never been canceled since.

One can hope that ulterior researches will allow one to precise the present knowledge concerning hydration, particularly on the point of view of the quantitative data. One cannot, however, dissimulate that the way will be long, since cement hydrates are evidently more complex than water, and many particularities of this simple substance are not yet enlightened.

Supplementary Paper II-43 Contribution of Analysis by Means of an Electron Microprobe to the Cement Chemistry

Pierre Terrier*

Synopsis

The study of minerals and anhydrous glasses in cement and their change during hydration is carried out in CERILH using analysis with an electron microprobe. This enables the qualitative and quantitative analysis to be made by X-ray emission of the elements present in a volume of some cubic microns under the polished surface of the sample examined with a microscope.

Anhydrous silicates and aluminates in portland cement contain precipitated inclusions and impurities in solution. Microanalysis characterizes them in industrial clinkers.

The chemical composition of fly ashes used in cements is relatively constant; however, in the same ash some heterogeneity can occur between the grains as a consequence of the rapid passage of unburnt coal through the flame. The glass produced belongs to the silica-mullite-anorthite system and contains different proportions of iron, alkalies and magnesia.

In cement pastes, the hydration of aluminates with fixation of the sulphate ion leads to the formation of acicular crystals grouped in separate positions in the intergranular interstices. The hydration of tricalcium silicate is effected by the penetration of water which converts the anhydrous silicate into hydrated silicate in place while part of the lime diffuses outside the grain and crystallized in the form of hydroxide.

The reaction of ash grains in cement or lime pastes is effected by a superficial change of the vitreous grains with the formation of an hydrated envelope with a mainly low silica content which diffuses into the interstices and combines with lime.

Introduction

In 1949, A. Guinier and R. Castaing proposed a physical method of elements microanalysis at the congress in Delft. In 1951, R. Castaing described in his thesis the electron microprobe (1). Since then, the equipment has been perfected and the analysis has as much developed in metallurgy as in mineralogy and in biology.

We give, here, some examples of the use of this method in regard to cement chemistry. They deal with the composition of the minerals of cement clinker, the composition of fly ashes, the hydration of portland cement and the "pozzolanicity" of the ashes.

Electron Microprobe Analysis

A solid target bombarded under vacuum, with an electron beam, emits an X-ray radiation. The latter contains a continuous background, and lines representative of the constituent elements of the target, and there exists a relationship between the intensity of a line and the concentration of the element emitting it. The different lines are analysed, that is to say, separated by means of spectrometers.

A variable self-bias triode-type gun produces an electron beam which is focussed on the section to be studied, by means of two electro-magnetic lenses. An adjustment of electronic intensity eliminates the influence of possible variations in the emission of the electron gun.

The specimen contains a diamond-polished section; its surface is made conductive by a film of nickel deposited under vacuum. The observation of the impact of the electrons on the target is obtained by means of a microscope having a mirror objective which permits the coaxial focus of the electron and light beams. Two chambers, placed on each side of the

*Centre d'Etudes et de Recherches de l'Industrie des Liants Hydrauliques, Paris, France.

column, contain the curved crystals spectrometers and the gas-flow proportional counters, which are combined to them. These spectrometers allow the revelation of the radiations of the elements classified by Mendeleev, except for the first four elements.

The displacement of the analyzing crystal and of the detector on a focussing circle crossing the point of impact permits the qualitative analysis of the target. The quantitative analysis is achieved by clamping the spectrometer in an appropriate position, and by comparing the intensities of the radiation when emitted by the sample under consideration, and by a standard.

One may also possibly shape the image of the distribution of an element, by means of an oscilloscope: a small area of the specimen is scanned by the electron beam, in synchronism with the spot of the oscilloscope, the latter being modulated in intensity by the signal of the counter.

By modulating the intensity of the oscilloscope beam by a signal proportional to the number of electrons absorbed by the specimen, one forms the electron image, i.e. a data comparable to an optic view, but in which the fluctuation of the average atomic number from one phase to another comes into account for the differentiation.

The Clinker Minerals

The study of the influence of the various elements on the formation and the stability of the minerals depends on the solution of the problem of the composition of the minerals contained in industrial clinkers.

Images of the distribution of the elements in the crystals have been obtained by means of the microprobe by Philibert and Weinryb for an aluminous clinker (2). Taylor (3), later Moore (4), and more recently Terrier, Hornain and Socroun (8) have expounded those relative to portland clinkers.

Wright (3) has determined the calcium in alite and belite. Determinations in alite have been effected by Moore for MgO, by Terrier and Capitant (5) for Al_2O_3 and Fe_2O_3 and by Peterson (7) for MgO, Al_2O_3 and Fe_2O_3. In belite, Moore has determined MgO and Peterson K_2O. These authors have also effected determination in the interstitial phase.

The CERILH has undertaken the complete analysis of the clinker minerals. The values shown in Table 1 have been extracted from the "Revue des Matériaux" (8) in which our first results have been published.

It appears that the alite contains about 3% of minor oxides, the contents of which change from one clinker to another. Belite contains as far as 5% minor oxides; it is richer than alite in Al_2O_3, Fe_2O_3 and alkaline oxides.

Table 1. *Compositions of the crystals of alite and belite expressed in percentages*

Alite				Belite		
Clinker 1	Clinker 2	Clinker 3		Clinker 1	Clinker 2	Clinker 3
71.0	70.9	73.1	CaO	63.2	63.6	63.7
24.9	24.9	25.3	SiO_2	31.5	31.5	33.7
1.1	1.3	0.7	Al_2O_3	1.8	1.8	1.3
0.6	0.6	0.8	Fe_2O_3	0.9	0.8	1.1
0.9	0.3	0.4	MgO	0.5	0.3	0.3
0.2	0.2	—	K_2O	0.8	0.7	0.4
0.1	0.1	0.1	Na_2O	0.2	0.2	0.4
0.2	0.4	0.2	TiO_2	0.3	0.1	0.3
trace	0.1	0.1	P_2O_5	0.3	0.3	0.1
99.0	98.8	100.7	Total	99.5	99.3	101.3

The determinations relative to the C_3A and C_4AF aluminates are delicate if one takes into consideration the fact that the modern kilns deliver quenched products in which the components of the interstitial phase are often closely entangled. From the measures we have gathered, one can infer that the C_3A phase contains about 3% SiO_2, 5% Fe_2O_3, 0.6% MgO, 0.9%

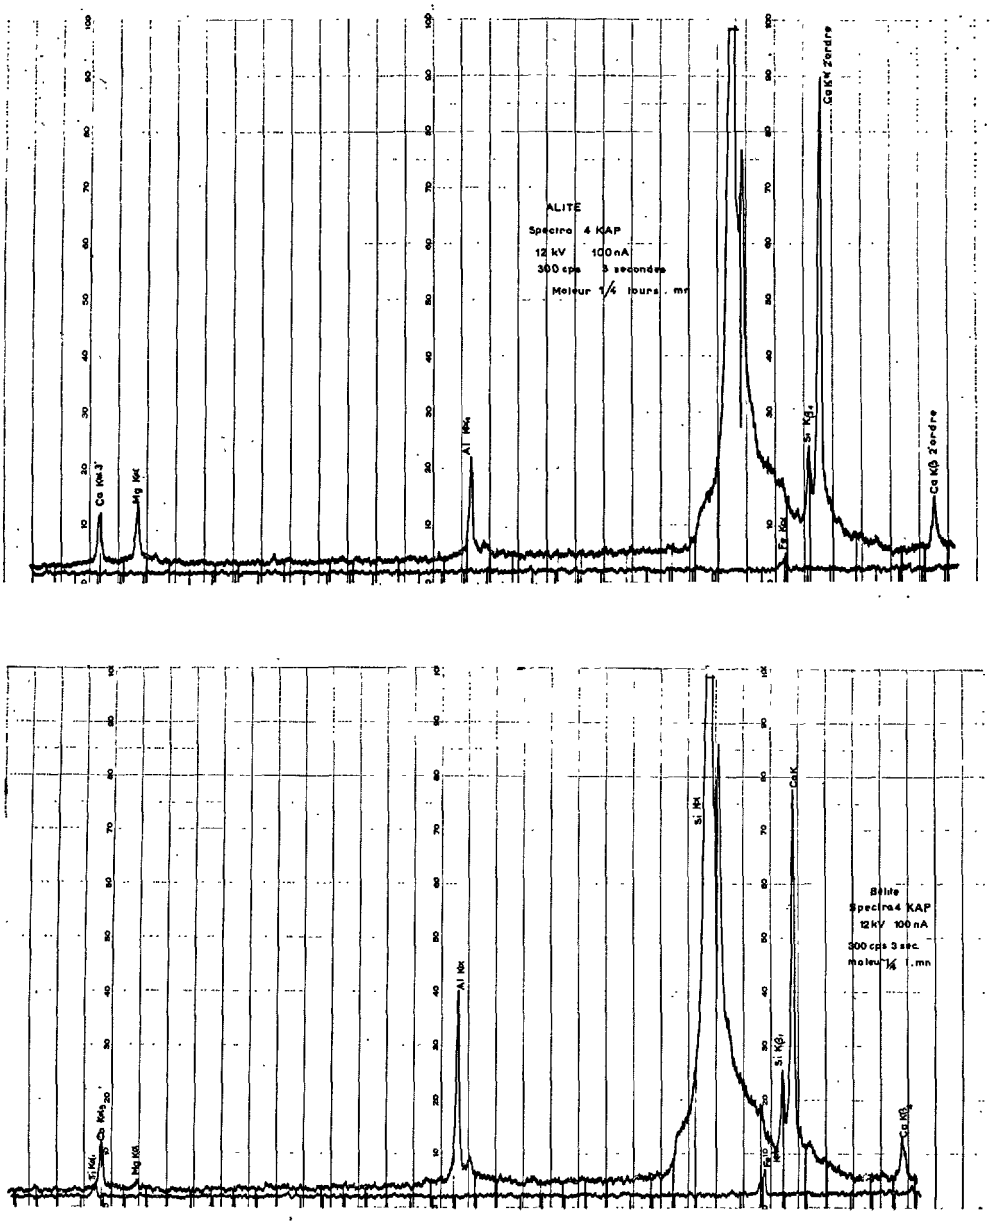

Fig. 2. *Qualitative composition of Alite and Belite crystals in clinker; lines records*

K_2O, 0.4% Na_2O and 0.3% TiO_2; whilst the percentages in the C_4AF phase are of about 2% SiO_2, 2% MgO and 1.8% TiO_2.

These determinations are still carried on at the CERILH, in collaboration with the crystallographic research team, by the study of the correlations which exist between the composition and the allotropic form in which the silicates occur in the clinkers.

Fly-Ashes

The fly-ashes issued by the flame of the generating plant result from the melting of coal leavings: clay, quartz, pyrites, calcite, gypsum, dolomite, etc.

Among the uses of ashes which profit of the spheric form of the grains, their lightness, their composition, or their pozzolanicity, the incorporation into cement particularly engage our attention, in France, an attention which is based at the same time on a long industrial experience and on laboratory studies in which the CERILH was very early involved.

The ashes are constituted by vitreous spheres, either solid or hollow, by spongy fragments, by mineral grains, and by unburnt fragments. The fineness of the ashes is related to that of the coal and to the type of the collector; the unburnt substance is related to the nature of the coal and the type of generating plant. The proportion of vitreous phase is due to the nature of the leavings, to the fineness of grinding, and to

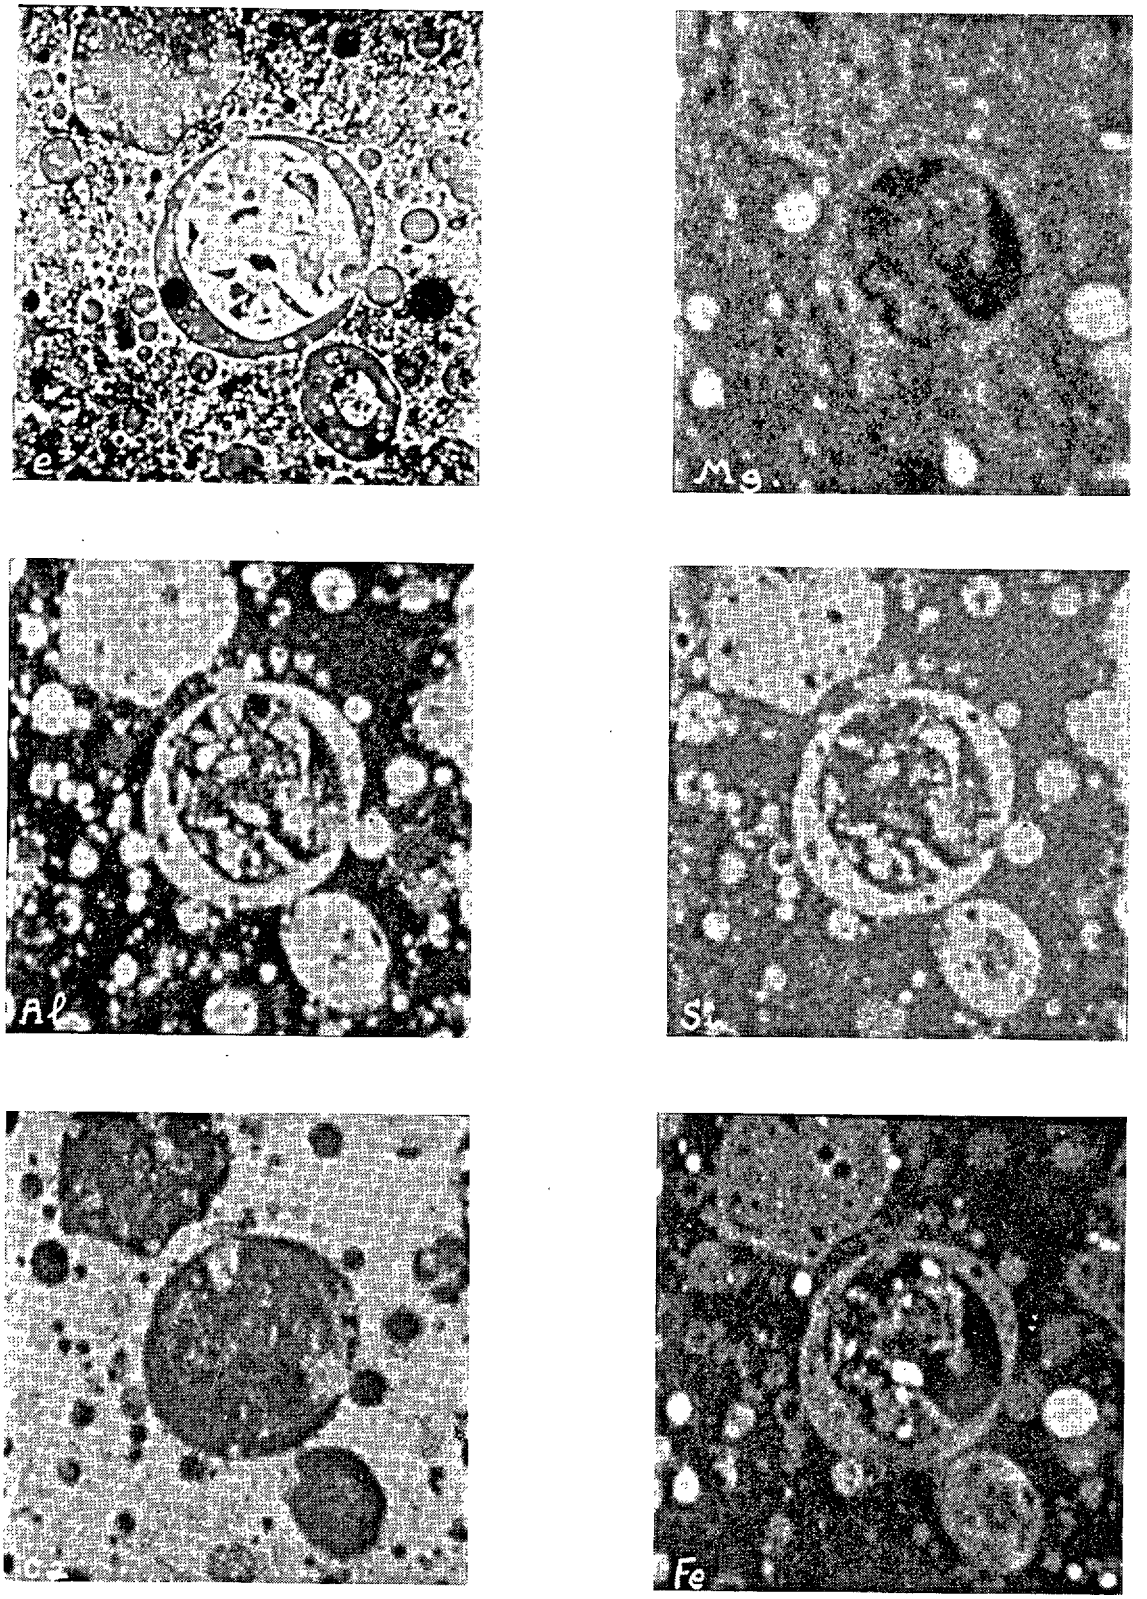

Fig. 4. *Electron image* (e^+) *and X-ray images for* Mg, Al, Si, Ca *and* Fe. *Polished section of lime and fly ash mixture; 100 microns side.*

TiO_2	1	1.6

*Special granulometric fraction 7 to 80μ

the thermal treatment.

The study of the representative samples taken in the generating plant shows a constant variation of all the properties of the ashes from the furnace to the end of the dust collector. The first precipitated fragments are the most important in size. They are porous and heterogeneous, whilst the finest ones, recovered at the end, are compact.

Table 3. *Elementary compositions obtained by probe for grains of a same ash*

SiO_2	Al_2O_3	Fe_2O_3	CaO
58	36.1	3.0	2
53.1	33.1	6.3	—
51.1	42.9	5.1	—
43.5	24.2	9.6	18.4
42.5	30.2	12.9	7
42.1	29.3	17.9	4.6
42.1	24.2	26.8	—
42	29.5	20.8	—

To the constancy of the macroscopic composition of coal ashes (Table 2) is opposed a microscopic heterogeneity, the consequence of the rapid passage of the coal leavings through the flame which does not allow a diffusion of the bodies in presence and a complete reaction.

Eight characteristic analyses of vitreous grains of the same ash are shown on Table 3. The glasses potentially contain mullite, quartz, anorthite and ferrites. They contain, moreover, 0 to 7% K_2O and variable contents of MgO. The unmelted quartz and the mullite of devitrification are associated to them.

Hydration of Portland Cement

The study of the hydration of portland cement has been undertaken on pastes of particular granulometric graduation (7 to 80μ) and pastes of complete granulometric gradation.

The hydration of aluminates takes place with fixation of the sulphate ion, and produces acicular crystals which are grouped in discrete sites in the intergranular interstices. Three determinations of this phase shown on Table 4 demonstrate that it has an intermediary composition between an aluminate and a sulphoaluminate of calcium.

Table 4. *Composition of the acicular crystal groups in portland pastes**

After	2 years	2 years	3 years
CaO	44.5	45.1	41.2
Al_2O_3	21.9	23.2	24.0
SO_3	9.8	9.0	9.2

*of 7–80μ granulometry.

The hydration of tricalcium silicate is obtained by a penetration of water which transforms anhydrous silicate into hydrated silicate whilst a part of the lime diffuses outside the grain and crystallizes in the hydroxide form: portlandite. The measurements obtained by the electron microprobe have shown that the hydrated silicate had a mean molecular ratio CaO/SiO_2 of 1.65 for a duration up to 90 days for the 7 — 80μ fraction tested (6). This ratio varies from one crystal to another. We have discussed the mechanism of the hydration of alite which probably begins by a topochemical reaction.

In the portland paste, the portlandite contains in course of time, small quantities of SiO_2, Al_2O_3 and K_2O. At the end of three years, the portlandite crystals have the following composition: CaO = 74.2, SiO_2 = 2.5, Al_2O_3 = 1.7, K_2O = 0.7.

Pozzolanicity of the Ashes

The reaction of the ash grains in cement or lime pastes takes place with a superficial transformation of the vitreous grains with formation of a "corroded" envelope, poor principally in silica.

Twenty compositions of active grains are shown in Table 5. It does seem that the vitreous phase is reac-

Table 5. *Compositions of active grains of the same ash*

tive in a large area of composition.

The study of the diffusion of the elements of the ash in the interstices of the pastes is undertaken for pastes of fly-ash cement and for lime-ashes mixtures. In the latter the progression of the diffusion of the silica and of the alumina terminates in concentrations of 14% SiO_2 and 2% Al_2O_3 in the interstices which also contain after 600 days of conservation at 60°C small quantities of MgO and K_2O.

The preparation of synthetic glasses having analogy of compositions with the fly-ashes was effected by means of the Verneuil blowpipe and allows one to carry on the study of the mechanism of the pozzolanic activity by the study of systems having a more limited number of variables.

Conclusion

It is often difficult to make the best of the microscopic observations that can be effected on anhydrous or hydrated products, because of the heterogeneity of the substance. The electron probe, which permits to analyze, point by point, what can be seen with a microscope, is thus a precious tool for the interpretation of the observations. Its high resolution ability is adapted to a great number of problems which concern the grains of the hydraulic binders as they are for the greater part visible with the microscope.

The method is applied whenever localized variations of the composition which cannot be appreciated by the global methods of analysis, impose the necessity of a punctual technique and direct investigation.

The electron probe is a basic research instrument which is unique for the punctual analysis by comparison with standards placed in the same geometry and detected by the same radiation.

Although corrections are necessary, they can be greatly reduced by the choice of standards neighbouring the phases to be analyzed.

Up to the present, the electron probe microanalysis only shows the quantitative distribution of the elements but not their bonding.

These studies which are developed at the CERILH thanks to the intensification of technical research in the French cement profession are effected with the participation of the Centre d'Etudes et de Recherches des Charbonnages de France and the financial help of the Communauté Européenne du Charbon et de l'Acier.

Oral Discussion

Renichi Kondo and Shunro Ueda

As the thickness of the hydration layer of C_3S particle is very thin, Dr. Roy and Mr. Grutzeck could not recognize the reaction rim by X-ray microanalyzer. Kondo and Ohsawa pointed out that the thickness of the hydration layer of slag was thinner. Accordingly the spot analysis of the hydrate by using X-ray microanalyzer with usual technique seems to be difficult. Therefore we used an electron microscope attached with X-ray microanalyzer and studied semiquantitatively the difference of the compositions between the inside part and the outside part of hydrated C_3S particle as was shown in Fig. 6 of the principal paper II-4.

It must be useful for us if Mr. Terrier shows his experimental conditions as his experiment seems to have good accuracy. Furthermore, if he has some experimental results on various hydrates of cements and additives which are not shown in his supplementary paper, it might be very interesting to show these results.

Oral Discussion

Della M. Roy

Dr. Terrier reports analyses of C_3S hydration products indicating that the phase has a 1.65 $CaO:SiO_2$ ratio. Was this observation made only after relatively long periods of hydration, or was it found to be true also of shorter reaction periods? Indication was also given that analyses varied from grain to grain. What were the limits of variation observed?

Author's Closure

Pierre Terrier

First ages observation of cement hydration products, by means of the EPMA, is difficult. The first condition for the analysis is the following one: the phase to be analysed must be optically defined, which is, generally, not the case. On the other way, the electron probe enters into the target and risks to get through the phase to be analysed. In the way to avoid it, we use an accelerating voltage of the 12 KV, limiting the penetration (while the current limitation limits the heating). The choice of a particular grading (7–80 microns) enables, in some way, to dilate the timescale, and to obtain the optically defined hydrates for which, between 28 and 90 days, the paste strength becomes 950 kg/cm² from 500 kg/cm². Our tests are related to this period and beyond it.

The knowing of the CaO/SiO_2 ratio, which is between 1.35 and 2.00, with a mean value of 1.65, for 28 to 90 days, is a first approach. We must table in account the alumina, the magnesia and the SO_3, and this has been yet well studied by EPMA, for anhydrous products only.

It is showed by Kondo and Ohsawa (1) that the thickness of the reacted layer on C_3S in C_3S-slag mixture is about 0.5 μ at 28 days and the thickness of the reacted layer on the slag particles is about 0.4 μ at the same time.

About C_3S we (2) observed that the thickness is higher on alite in cement, about 3 μ at 28 days, (and not the same from one to another crystal). This agrees with the fact that in the investigation you made (1) more than 70% of C_3S react in portland cement at 28 days and only 30% of C_3S in C_3S-slag mixture.

It is possible to observe the reacted layer on alite by EPMA after 28 days and to examine the ratio Ca/Si with V = 12 kV and I = 30 mA for example. Quantitative measurements are made point by point with a stationary beam on the specimen and on the standard (wollastonite). This conditions and those of Roy and Grutzek (4) are similar but these authors studied synthetic compounds.

Relating to cement aluminates hydration, your experiments (3) show that the simultaneous presence of $Ca(OH)_2$ and of semihydrated calcium sulfate makes the alumina practically insoluble, which undergoes little replacement. The hydrated aluminates are forming from the anhydrous aluminates and are developing in the interspace with fixation of the sulfate-ion, which is evidenced by the joint figures obtained with the microprobe for the cement granulometry of 7–80 μ, after three years curing.

On the other hand, the hydration mechanism with internal hydrates and external hydrates formation applies not only to portland cement, but also to high furnace slag. A 5–80 μ slag hydrated with 10% soda, with a W/C ratio = 0.46, has a compressive strength of nearly 500 kg/cm².

That was studied with the microprobe. The evolution is recapitulated in Table 1 for molar ratios and

$\frac{SiO_2}{Al_2O_3}$	3.46	4.65	2.16

by the diagram, Fig. 2.

You indicate (3), in good place, that the hydration rate of alite is modified by the minor elements. In some way, cement contains an impressive amount of additives whose action and ending are not already known. EPMA is useful to study this and we have done recently a new approach of the composition of alite (5).

Supplementary Paper II-62 The Behavior of Aluminate-Ferrite Phase during Hydration

Paul Jäger, Udo Ludwig and Hans E. Schwiete*

Introduction

In continuation of our earlier work (1, 2) the mechanism which occurs when the aluminate-ferrite clinker minerals C_3A, C_6A_2F, C_4AF and C_2F react with calcium hydroxide and gypsum or anhydrite in aqueous solution have been investigated by chemical means, by infra-red spectroscopy, by X-ray diffraction and with the aid of the electron microscope. The chosen fractions of C_3A or calcium aluminate ferrite and calcium sulphate correspond approximately to commercial portland cement. The amount of calcium hydroxide added was sufficient to form ettringite and convert the remaining C_3A and calcium aluminate ferrite into tetracalcium aluminate ferrite and into tetracalcium aluminate ferrite hydrate respectively in the presence of a saturated lime solution.

As an indicator for the rate of hydration the absorption of water and free sulphate were measured.

Reactions in the System C_3A–$CaSO_4$–CaO–H_2O

The investigation of C_3A was carried out with 0, 30, 60 and 90% gypsum relative to the C_3A content.

In the pure C_3A system the principal product in the first hours was hydrogarnet (C_3AH_6) and later tetracalcium aluminate hydrate (C_4AH_{19}). The proportion of tetracalcium aluminate hydrate remained the same during a three-year observation period, and this means that for a long while no appreciable recrystallization of the unstable C_4AH_{19} to the stable C_3AH_6 took place.

With 30% gypsum ettringite was first formed but disappeared again after 8 hours. In its place the sulphate-bearing phases monosulphate hydrate or the mixed crystals of this with tetracalcium aluminate hydrate were observed. The occurence of C_3AH_6 as well as C_4AH_{19} was clearly recognizable.

With 60% gypsum ettringite was stable over a greater range. Monosulphate hydrate and its mixed crystals with tetracalcium aluminate hydrate only appeared after a full day's hydration.

After 60 days ettringite reappeared and was still present after 300-day hydration together with monosulphate hydrate, the mixed crystals with tetracalcium aluminate hydrate and pure tetracalcium aluminate hydrate.

With 90% gypsum it was only after 2 days that a marked decrease in the content of the initially-formed ettringite was observed. Simultaneously monosulphate hydrate appeared in the reaction mixture. However, in contrast to the other mixtures, no solid solution between monosulphate hydrate and tetracalcium aluminate hydrate was observed.

The results of these experiments can be summarised in the following table:

These results show that with rising content of gypsum the amount and stability of ettringite increases in the period before monosulphate hydrate or the mixed crystals with tetracalcium aluminate hydrate are formed. The formation of monosulphate hydrate and tetracalcium aluminate hydrate or the mixed crystals of the two begins only when all the sulphate ions have been used to form ettringite or when the concentration of sulphate ions is no longer sufficient to allow this mineral to crystallize. Concomitant with the formation of monosulphate hydrate the initially-formed ettringite is decomposed and the remaining C_3A is hydrated. The amount of gypsum added determines the speed of hydration of C_3A.

Reactions in the System (C_2F–C_6A_2F)–$CaSO_4$–CaO–H_2O

In the experiments with the calcium aluminate ferrites C_2F, C_4AF and C_6A_2F a constant amount of sulphate containing 27.9% SO_3 was added; this corresponds to 60% dihydrate or 47.4% anhydrite. The amount of calcium hydroxide added was such that, allowing for the formation of the most lime-rich phases, a saturated solution of lime was still present.

Bonding of Sulphate

The combination of sulphate with calcium aluminate ferrite was determined, making allowance for the free sulphate in the solution and as a residue. Fig. 1 shows the amount of sulphate combining with C_6A_2F in the presence of lime in aqueous solution. It can be seen that the reaction is much faster in the case of anhydrite than if dihydrate is used. After only 6 hours 70% of the anhydrite has reacted but only 43% of the dihydrate. After 12 days both compounds are completely fixed.

C_4AF, also, is hydrated much faster in the presence of anhydrite than with dihydrate, as is obvious from Fig. 2. The combination of sulphate is only complete after 90 days in the case of anhydrite and in the case of the dihydrate it is almost complete after 180 days.

As may be expected, the slowest reaction is shown by C_2F, although for this compound also the reaction proceeds much faster in the presence of anhydrite than with dihydrate (Fig. 3). In this case the combination of sulphate is only complete after 180 — 270 days.

The reaction of calcium aluminate ferrite with gypsum or anhydrite shows the influence of the different sulphates on the concentration of sulphate ions in the solution. It was observed that the sulphate concentration increases with increasing ferrite con-

C_6A_2F	+	+	weak
C_4AF	+	+	"
C_2F	+	–	"

tent of the calcium aluminate ferrite, but decreases with rising aluminate content.

These reactions show in particular that C_6A_2F reacts so fast that at no time is the solution saturated with respect to anhydrite, or even with the dihydrate, under normal conditions of temperature and grain size of the reagents.

Formation of the Hydrates

The formation of hydrates in the residue was determined by X-rays over a period of 2 years. To begin with ettringite, phases ($C_3(A,F)\ Cs_3H_{32}$) with varying ratios of Al^{3+} to Fe^{3+} were formed almost exclusively. With increasing aluminate content of the calcium aluminate ferrites, the trisulphate hydrates are altered faster into the monosulphate hydrates and the mixed crystals of this with tetracalcium aluminate hydrate by using up the remaining ferrite. The solid solutions do not occur with C_2F. For the remaining ferrites C_4AF and C_6A_2F these mixed crystals prove increasingly unstable with time, i.e., their amount decreases, the longer the hydration continues, with the formation of monosulphate hydrate. As in the case of C_3A the appearance of the mixed crystals is less likely as the amount of sulphate is increased. In the case of the calcium aluminate ferrites, the formation of the mixed crystals decreases with increasing iron content of the ferrite, and is less pronounced in the presence of anhydrite than in the presence of dihydrate.

Hydrogarnets were observed in all the reaction mixtures. Their amount increases with a rising aluminate content of the ferrites.

The following table show the sulphate bearing hydration products formed by the reaction of calcium aluminate ferrite with anhydrite and lime in aqueous solution after a hydration period of two years.

Discussion and Summary

On the basis of previous and present work on the hydration of the aluminate ferrite phases in aqueous solutions of calcium hydroxide and calcium sulphate, we have been able to confirm our opinion that, directly after the addition of water, the calcium aluminates and calcium aluminate ferrites become protected from further rapid hydration by a layer of ettringite-like phases.

In the presence of solutions rich in sulphate and lime ettringite forms as soon as water is added, together with negligible amounts of monosulphate hydrate and its mixed crystals with tetracalcium aluminate hydrate. Only when the sulphate ion concentration is too low to allow ettringite to crystallize are monosulphate hydrate and the corresponding mixed crystals formed to any extent. The ettringite initially precipitated is then altered to monosulphate hydrate or the mixed crystals with tetracalcium aluminate hydrate by reaction with the remaining C_3A. The point at which all the remaining C_3A is used up and the ettringite decomposes is dependent upon the amount of sulphate present and the grain size of the C_3A. Similar results were found for the calcium aluminate ferrites.

Determination of the amounts of water and sulphate combined, and examination by X-rays and in the electron microscope have shown that the rate of hydration of the calcium aluminate ferrites increases with increasing alumina content in the system $C_2(A, F)$–$CaSO_4$–CaO–H_2O. This is seen in Fig. 4. If one refers the amounts of calcium aluminate ferrite to a common specific surface area, the increase in weight of the residue shows that, after one day the quantity of C_2F that has reacted is only 50% of the amount in the case of C_4AF, 30% in the case of C_6A_2F and 15% in the case of C_3A.

The schematic presentation in Fig. 5, which includes ideas of Manabe (3), shows that, during hydration in the presence of solutions rich in sulphate and lime, the principal hydration products of the aluminate ferrite phases in portland cement clinkers are trisulphate hydrate together with small amounts of monosulphate hydrate and its mixed crystals with tetracalcium aluminate hydrate. This occurs directly after the addition of water. Only when the sulphate ion concentration is insufficient to form ettringite do monosulphate hydrate and the mixed crystals begin to appear in increasing amounts. The trisulphate first formed is more or less completely altered to monosulphate hydrate after a few hours depending upon the amount of sulphate present.

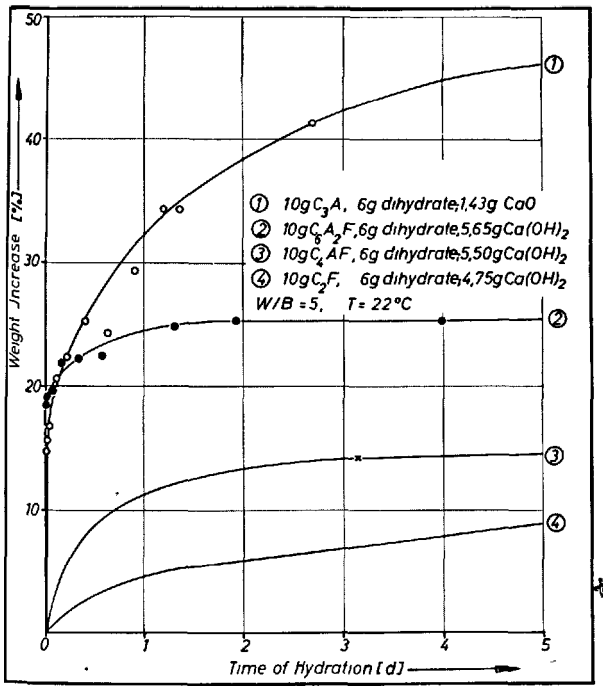

Fig. 4. *Weight increase of the precipitation during hydration of aluminate—ferrite phase based on the specific surphace of 1000 cm²/g (Blaine)*

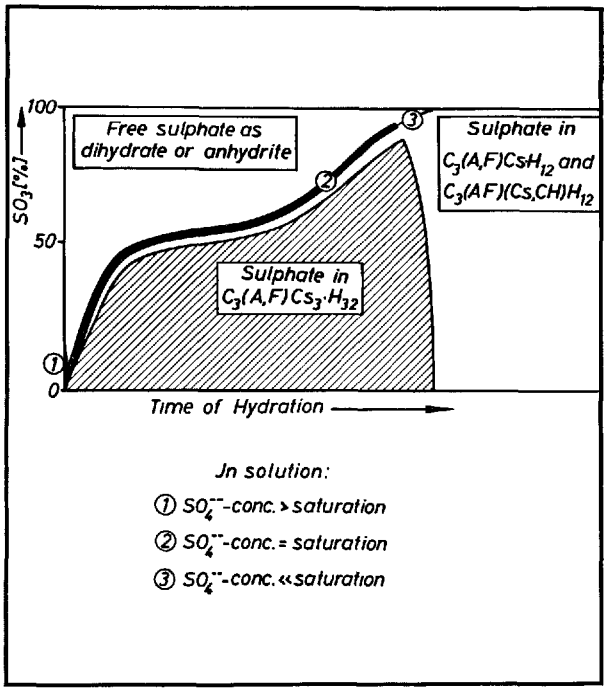

Fig. 5. *Reaction of sulphate during hydration of* C_3A *and* $C_2(A,F)$

The experimental results show that the amount and kind of the calcium sulphate added is of prime importance for the rate of hydration of the C_3A and the calcium aluminate ferrites.

Furthermore the formation of tri- and monosulphate hydrate from the calcium aluminate ferrites is only possible by combining 1 molecule of calcium hydroxide. This contrasts with the reaction for C_3A. When the formation of tri- and monosulphate hydrate is complete, hydration of the aluminate or aluminate ferrites to tetracalcium aluminate ferrite hydrate occurs by combination with calcium hydroxide which is split off the calcium silicates. Thus the hydrolysis and hydration of the calcium silicates is influenced and controlled by the course and speed of the hydration of the tricalcium aluminate and calcium aluminate ferrites and their combination with lime.

Also important is the fact that more or less rapid hydration of C_3A and the calcium aluminate ferrites has an effect on the area of reactive surface of the calcium silicates in the clinker.

It follows from the above results that the amount and kind of the calcium sulphate added has a complex influence on the rate of the initial hydration of the aluminate-ferrite phases of the clinker:

1. by retarding and controlling the hydration of C_3A and the calcium aluminate ferrites,
2. by fixing the free calcium hydroxide released by hydrolysis of the calcium silicates in the clinker, which is then combined with the crystallizing trisulphate hydrate, monosulphate hydrate and tetracalcium aluminate ferrite hydrate. This causes an acceleration in the hydrolysis of the calcium silicates and
3. by creating a greater reactive surface area in the calcium silicates of the clinker.

In practice the accelerative effect of anhydrite as compared to the dihydrate is of great importance, in particular in the production of portland cements low in, or free of C_3A.

We are grateful to the Association of German Cement Producers, Düsseldorf, for their financial support.

Supplementary Paper II-96 Synthesis of the Analogues of Portland Cement and Other Binding Materials on the Basis of Acidic-Basic Reactions

Nikolai F. Fedorov*

Synopsis

The analysis shows that the hardening of portland cement and other most widely distributed binding materials of normal and autoclave hardening (lime, phosphate and oxychloride cements) is the result of chemical reactions in which acid radicals and metal cations take part together with the protons and hydroxyl groups and which, therefore, are the reactions of acid-base interaction.

The results of investigation of binding properties of a great number of combinations are considered in the paper, the components of which were selected so that the process of acid-base interaction would take place.

Four groups of materials have been investigated on the basis of the following type systems:

1. Mineral-water systems, where minerals are the analogoues of calcium silicates or aluminates, viz. plumbates, stannates, titanates and zirconates of alkali earths.
2. Metal oxide-acid systems, where acids are HCl, H_3PO_4, H_2SO_4, $H_2C_2O_4$, etc.
3. (The binding materials of autoclave hardening). MeO–MeO_2–H_2O systems, where MeO are the oxides of alkali earths and MeO_2 are TiO_2, SnO_2, PbO_2 and ZrO_2.
4. Metal oxide-polyatomic alcohol systems (glycernie, glycol).

In each group, for a great number of investigated combinations the formation of stone-like materials has been established, physico-mechanical properties of the latter having been investigated and for separate, most typical ones, the phase composition of new formation has been investigated by means of X-ray, infrared and chemical analysis.

Introduction

At present it is difficult to find such an industry where artificial stone would not be used. Artificial stone is used both in the most ancient industries such as construction and the most modern ones, such as radioelectronics (1).

Among the methods of technical stone synthesis, the methods and ways of silicate technology are the most popular ones, including several varieties. Their common feature is the transition from the solid powder material of natural or artificial origin to the monolith—an artificial stone having a certain complex of properties. Schematically, separate varieties of silicate technology may be represented in the following way:

1. Ceramic technology:
   powder→moulding→burning→artificial stone
2. Technology of glass-crystalline materials:
   powder→melting→moulding→heat treatment →artificial stone.
3. Technology of cements:
   powder→mixing with fluid→artificial stone.
4. Technology of autoclave materials:
   powder→moulding→hydrothermal treatment →artificial stone.

The comparison of separate methods shows that, from the technological point of view, the most convenient one is the method of producing artificial stone by the technology of binding materials. However, in spite of this rather important fact, the technology of ceramics and glass have achieved the greatest progress in their development lately. So, during only one or two decades man has learned to produce and organized the industrial production of materials having unique electrical and magnetic characteristics, the ones having good mechanical properties in conditions under the influence of high temperatures, etc. by the ceramic technology, i.e. by the technology which was once developed for producing red brick, porcelain, and pottery.

The transition from traditional ceramic materials and glass to the new ones was stipulated in most cases not by any special changes in the technology of their production, but mainly by the expansion of the

*Chemical Technology of Cement, Leningrad Lensoviet Institut of Technology, Leningrad, U.S.S.R.

"geography" of the chemical elements used, by the substitution of the widely used in nature and readily available elements such as O, Si, Al, Fe, Ca, Na, K, Mg, H, etc. by less distributed and even rare ones, such as Ti, Sn, Pb, Zr, Nb, W, Mo, Sr, Ba, Ni, Co, F, etc.

The range of materials produced by the technology of binding materials may also be widened, and, if one takes into account the simplicity of the production and the fact that the development of technology is often hindered by the lack of suitable materials giving possibility, for instance, to cement together metals, ceramics, glass, plastics, particularly under ordinary conditions, the range of such materials has to be enlarged.

According to the experience of ceramic technology, when developing the new kinds of binding materials, it seems necessary to reject the idea of using only inexpensive, readily available raw materials. The search should be carried out very widely, enveloping possibly greater number of elements, including even the rare ones. In order that the search of the new kinds of binding materials would be more specific and economical it is necessary to proceed, first of all, from the ideas developed by V.F. Zhuravlev (2) and from his main conclusion in particular: "Binding properties are not something permanent and inherent only to a limited number of mineral compounds. The display of binding properties is a common link of the chain of phenomena subject to definite regularities; there are numerous other combination and chemical reactions, the binding properties of which should be expressed stronger or weaker than the known ones".

From numerous family of chemical reactions it is necessary first to consider the ones that are the main reactions for the preparation and application of the widely distributed binding materials.

The analysis shows that the hardening of portland cement, alumina cement and other most widely distributed binding materials (gypsum, lime, phosphate, and oxy-chloride cements) is the result of the crystallization of the products resulting from the chemical reactions in which acid radicals and cations of metals along with protons and hydroxyl groups interact. Chemical reactions of such kind are called acid—base reactions. So, one of the directions when searching for new binding materials which are the analogues of the traditional binding materials, should be the detailed consideration of all possible acid-base reactions; the range of the objects to be investigated should be limited by the reactions in the solid-liquid systems and solid-H_2O (vapour) ones, although acid-base reactions may be realized:

a) through a solution, b) in the saturated water vapour medium, c) through the melt, d) in the solid phase, and e) in the gaseous phase.

As it was stated above, in the present paper the range of the objects studied was limited by considering only such systems and such chemical reactions as have long been used for preparing binding materials, viz. 1) mineral (salt)—water, 2) oxide (hydroxide) —acid (salt), 3) base oxide-acid oxide (in the saturated vapour medium), 4) oxide (hydroxide)—organic compounds having acidic properties.

Binding Materials on the Basis of Mineral-Water System

The principal chemical reaction resulting in the hardening of the binding materials of this type is the exchange reaction with water when the hardly soluble compounds are formed. This reaction takes place when portland and alumina cements harden, to be more exact, when calcium silicates and aluminates react with water. It has long been noticed that calcium silicates and aluminates are not the only representatives of chemical compounds which are capable of being hydrolyzed. Zhuravlev and the collaborators of the Chair of Chemical Technology of Cement, Leningrad Lensoviet Technological Institute showed experimentally that there exist the analogues of calcium silicates, aluminates and ferrites, strontium and barium silicates and aluminates, in particular, as well as titanates, manganates, chromates and stannates of calcium, strontium and barium (2–6).

According to the periodic system of D.I. Mendeleev, one should expect the plumbates of the alkali earths to be hydraulically active ones. So, the comparative investigation of the binding properties of plumbates and other silicate analogues—stannates, titanates and zirconates of the alkali earths has been done in the given section, the latter having been investigated from the point of view of hardening in the hydrothermal conditions, since it has not been done before.

All the minerals in $MeO–MeO_2$ systems about which there is certain information have been synthesized. Due to the fact, that a number of systems formed by the dioxides of group IV and by the alkali earth oxides have not been investigated, the compositions corresponding to the investigated systems have been

chosen for the synthesis. The oxides of Mg, Cd, Zn, Ba, as well as the calcium and strontium carbonates and the Ti, Sn, Pb, Zr dioxides have been taken as the original materials. The synthesis has been done in the following way: the original materials were weighed in the amount corresponding to the stoichiometry of the mineral to be synthesized and then ground in the laboratory ball mill. The duration of the grinding was such that all the ground powder would pass through the sieve No. 0063. From the raw mixture prepared in this way the samples have been made, the tiles, having dimensions of 5 × 5 × 4 cm under the pressure of 500 kgs. per sq. cm., which have been burned. The burning has been done either in the muffle furnace or in the laboratory furnace with carborundum heaters. The temperature of burning was chosen according to the melting temperature of the minerals, and it amounted to 0.8–0.9 of the melting temperature. The readiness of the synthesised minerals was checked by chemical determination of the content of unreacted base oxide (excluding zinc and cadmium minerals) as well as by the X-ray or infrared analysis. The data of the condition of sample synthesis are given in Table 1. The samples which are not monomineral ones are marked with the sign "*".

All the products obtained were ground till they passed through the sieve 0063 mesh, and were mixed with water until the paste of ordinary consistense was prepared. The samples to be tested for mechanical strength were made of the paste in the shape of cubes having the edge of 1.41 cm long.

The results of investigating the strength properties of the materials obtained are given in Table 2. It should be noted that the hardening of all samples took place both in the normal and hydrothermal conditions of hardening, the autoclaving being done under the pressure of 8 and 16 atmospheres during 4 or 8 hrs. respectively, at a maximum pressure.

Consideration of the data given in Table 2 allows one to draw the following conclusions: When reacting with water minerals—calcium silicate analogues show pronounced binding properties, in contrast to minerals —silicates the binding properties of calcium plumbates and stannates, strontium and barium distinguishing themselves when the basicity of the mineral is

equal to 1. Autoclaving intensifies the process of hardening of the greater majority of the minerals investigated and it results in displaying the hydraulic activity for a number of them, e.g., monobasic calcium titanates, strontium and barium, which shows that monobasic strontium, calcium, and barium titanates are not hydraulically inert compounds as it was thought before. Since, as it was found in the laboratory of the chair, the same refers to the low basic silicates of the alkali earths. Therefore, speaking about some substance exhibiting binding properties or not doing so it is necessary to state the conditions under which it does so.

The fact that cadmium zirconates display binding properties contradicts to the point of view of V. F. Zhuravlev and a number of other investigators, according to whom minerals—silicates of zinc, cadmium and magnesium and their analogues are not able to display binding properties. The hydraulic activity of cadmium zirconates which is rather pronounced requires further attentive investigation. To find out the character of the hydration process of the minerals —calcium silicate analogues, the investigation of the hardening products formed during their reaction with water has been carried out when calcium stannates were hardening in particular.

For investigation the methods of thermography, X-ray and infrared analysis have been used. The comparison of thermograms, X-ray patterns, and the spectra of the original minerals and the hardening products showed their substantial differences. The respective curves for calcium ortho and metastannates also differ from each other. There are no effects on the thermograms of the original stannates while on the thermograms of the hardening products of dicalcium stannate are four endothermic effects at the temperature of 140–160°, 310–350°, 470–520° and 770–800°C and an exothermic one at the temperature of 700–730°C. The thermogram of the hardening products of calcium metastannate differs from that of the orthostannate by the absence of endothermal effect at the temperature of 470–520°C and by less intensive other effects. According to the available information in literature (5), the endoeffects at the temperature of 310–350° and 770–780°C appear to be due to the dehydratation of the calcium hydrostannate, and the one at the temperature of 470–520° is due to the decomposition of calcium hydroxide. As to the exothermal effect at the temperature of 700–730°, it is likely to be connected with the recrystallization of the amorphous calcium metastannate. Therfore, it may be suggested from the thermographic data that during the hardening process calcium orthostannate is hydrolyzed giving off calcium hydroxide and forming hydrostannate, while metastannate is hydrated.

The results of X-ray and infrared analysis confirm the fact that the original materials are converted into new hydrated compunds which is demonstrated by the appearance of new diffraction maxima in the X-ray patterns and new lines of absorption in the spectra. When calcium orthostannate hardens hydrolysis also takes place since on the X-ray patterns of the hardening products of calcium orthostannate along with the new diffraction maxima $d/n = 4.66$; 4.04; 2.32; 2.14; 2.08; 1.64; 1.38; 1.34 which are likely to be inherent to the calcium hydrostannates, the strongest lines of calcium hydroxide being distinguished when $d/n = 4.83$; 2.62; 2.40; 1.80. The latter are completely absent in the X-ray patterns of the hardening products of calcium metastannates.

The information given above allows to draw the conclusion that minerals—stannates and possibly, minerals analogues of calcium silicates, in general, when mixed with water are either hydrated or hydrolyzed forming hydrated compounds which are difficult to dissolve and the crystallization of which leads to the formation of cement stone. Exchange reactions with water are known to envelop an extensive class of chemical compounds—salts. So, the minerals considered in the given paper are a small part of chemical compounds which may be employed to obtain new binding materials. Thus, there are prospects for new materials search especially if one takes into account that hydrolysis should be looked upon as a particular case of solvolysis, i.e., an exchange reaction of a solute and a solvent in general. The facts that have been considered in the present paper in combination with the information received by other authors are a sound foundation for obtaining a great number of binding materials of the following type: $MeO–MeO_2–Me_2O_3$, where MeO_2 and Me_2O_3 may be represented both by separate compunds such as PbO_2 and Al_2O_3 and by numerous combinations of the oxides of the same type with each other.

Binding Materials on the Basis of Metal Oxide—Acid (Salt) Systems

Among various binding materials which have been widely used along with cement, gypsum and lime there are two more groups of binding materials—magnesium oxychloride and phosphate or dental cements. The

former are obtained by mixing powder magnesium oxide and its chloride solutions, the latter by mixing certain oxides or the compositions prepared on their basis and phosphoric acid. Until now those groups of binding materials have been considered separately, but the chemical basis of their hardening is nevertheless the same: acid-base reaction. The kinds of cements mentioned above seem to be particular representatives of a large family of binding materials prepared on the basis of solid—liquid systems, when solutions of acids and salts are taken as liquids and the solids are represented by the oxides and compositions formed on their basis.

The given section of the paper has been devoted to checking up the possibility of synthesis of artificial stone on the basis of oxides of different groups of D.I. Mendeleev's Periodic Table and a number of acids: HNO_3, diluted H_2SO_4, HCl, HI and $H_2C_2O_4$ as well as the solutions of sodium acid phosphates which may be used for obtaining the binders (7).

To determine the availability of binding properties the original oxides were ground in the agate mortar and the powder made was mixed with such amount of an acid or salt which was necessary to prepare the paste of normal consistency. Balls or pellets were formed from the paste which were kept under normal conditions during 1–3 days after which they were crushed. The availability of binding properties has been determined, as it was stated above, in the systems MeO–HNO_3, where MeO–ZnO, Bi_2O_3, CdO, ZnO, ZrO_2. If sulphuric acid was used, the hardening compositions were prepared on the basis of the following oxides: Fe_2O_3, Bi_2O_3, PbO, CdO, MgO. When mixing the compounds with HCl solution, the compositions hardened on the following basis: CaO, I_2O_3, La_2O_3 and other rare earths, ZrO_2, TiO_2, Nb_2O_5, Sn_2O, NiO, and all the alkali earth oxides and, when HI was used, the ones on the basis of V_2O_5, BaO, Co_2O_3, ZrO_2. In case the oxides were mixed with oxalic acid, the following oxides gave the cement stone: Sb_2O_5, Co_2O_3, MgO, ZrO, TiO_2 and others.

In the experiments where the oxides were mixed with solutions of acid phosphates of sodium the compositions containing P_2O_5 in the amount of 35% by weight were used. The binding properties were found in the following oxides: Co_2O_3, Fe_2O_3, FeO, CuO, CdO, HgO, PbO_2, SnO_2 when mixed with monosubstituted sodium phosphate in normal conditions of solidification, and in SiO_2, TiO_2, Cr_2O_3, V_2O_5 when heated at 200—300°C. The use of disubstituted sodium phosphate as a mixing agent allows one to obtain the binding properties on the basis of SiO_2, TiO_2, Al_2O_3, ZrO_2, MgO, CaO, SrO, Co_2O_3, Fe_2O_3, FeO, SnO_2, ZnO, CdO. The strength characteristics of some binding materials obtained were determined. The samples from the paste 1:0 having the shape of cubes the size of which was 1 × 1 × 1 cm were tested for compressive strength. The samples were stored in air during 3, 7 and 28 days. The results obtained are given in Table 3. For comparison, the results of testing the samples of portland cement are also given, the latter having been prepared and stored in a similar way.

The data obtained confirm the fact that on the basis of metal oxide—acid systems a whole number of cements may be synthesized, the strength characteristics of the latter being similar to those of portland cement and sometimes even much greater.

More detailed investigation of the binding substances of this kind will result in such new binding materials which will surpass the already well—known magnesia, oxychloride and dental cements. The investigation of the binding substances in the MeO—HCl systems, in particular, showed that the cements obtained by mixing CuO with solutions of cupric chloride or hydrochloric acid in contrast to magnesia cement appear to be not air but hydraulic binding materials since they can harden not only in air but also under water.

As to the cements formed on the basis of metal oxide—phosphoric acid systems, they are used, at present, not only in the dental technique. There are numerous kinds of phosphate cements which are used as heat resistant binders, vacuum lutes for cementing various materials. In the near future the scope of employing such binding materials is likely to become still wider as there are all necessary requisites for this:

Table 3. *Compressive strength (kg/cm²) of cements on the basis of metal oxide—acid (salt) systems*

No	System	Strength (kg/cm²) in 3 days	7 days	28 days

first, both the composition of the powder constituent and the mixing fluids for such cements may be varied greatly, second, the reacting capacity of the powder and the chemical activity of a mixing fluid may be changed, i.e. one may influence the processes of chemical interaction of solid and liquid components of the binder and the processes of structural formation of artificial stone and, as a result of this, to direct the synthesis of the artificial stone with predetermined properties.

Binding Materials of Autoclave Hardening on the Basis of $MeO-MeO_2-H_2O$ Systems

At present there is no such a definition as binding materials of autoclave hardening in spite of the fact that such materials have long been used in construction. The author suggests an idea of calling by this name solid powder materials of different chemical and mineralogical composition which change into strong stone-like body after moulding and hydrothermal treatment. The typical representatives of this group of materials known from the time of Michaelis are the silicate articles made of finely divided silica and lime, i.e., the articles that result from the reaction of acid and base oxides in the medium of saturated water vapour.

The author considers it probable to expect the existence of numerous analogues of such lime silicate materials.

The investigations carried out by D.I. Tchemodanov and his collaborators (8) as well as by the investigators from the Chair of Chemical Technology of Cement, Leningrad Lensoviet Institute of Technology, confirm the existence of such analogues. The results given below demonstrate this statement.

The following systems have been considered as the objects to be investigated: $MeO-H_3BO_3$, where MeO are the oxides of Mg, Ca, Sr, Ba, Zn and Cd; MeO_2 were taken as acid oxides, i.e. TiO_2, ZnO_2, PbO_2 and SnO_2.

The original samples were prepared from the raw mixture of variable composition from base and acid oxides or an acid. The raw mixture composition varied from 0 to 100% of each component every other 10% by weight. The raw mixtures were ground by means of wet grinding in a ball mill until the fineness of 0063 mesh. The samples were pressed from the mixture, under the pressure of 100 kgs. per sq. cm., their dimensions being $1.41 \times 1.41 \times 1.41$ cm. They were placed into an autoclave. The autoclaving was carried under the pressure of 8 and 16 atm. according to the scheme of raising the pressure—keeping at the same pressure—lowering the pressure during 2–8–2 hrs and 2–4–2 hrs respectively. On the day following the autoclaving the testing of the samples has been made. The testing results are given in Table 4.

The analysis of the data obtained from the quantitative point of view appears to be difficult since the materials of different granulometric composition were used in various combinations in the experiments and the conditions of the hydrothermal treatment were not strictly identical. Nevertheless, it is quite evident that the original statement about the possibility of the artificial stone synthesis by the technology of autoclave materials on the basis of the mixtures of the oxides of groups II and IV of the D.I. Mendeleev's Periodic Table or for the mixtures of H_3BO_3 and MeO is fully justified. The strength of the samples depends upon the nature of acid and base oxides, upon their concentration and as the special experiments proved, both upon the parameters of the hydrothermal treatment and upon the pressure of pressing the samples. One should note that all the systems of $MgO-MeO_2$ investigated are a good foundation for producing the artificial stone the strength of which

does not yield to that of the samples obtained with other alkali earths. The formation of magnesia compounds of calcium hydrosilicate type is likely to occur much easier from the oxides than in case the anhydrous magnesium titanates, stannates, plumbates and other analogues are used since the artificial stone does not form the latter even in the hydrothermal conditions as it is stated in the first section of the paper.

An interesting phenomenon also takes place in the systems containing zink and cadmium oxides. The combination of those oxides and zirconium dioxide allows one to synthesize the stone having rather high strength.

If the results of mechanical testing of the stone produced on the basis of the same systems of $MeO–MeO_2–H_2O$ by the technology of binding materials and using autoclaving as a hardening intensifier, i.e. with the preliminary synthesis of the anhydrous minerals—calcium silicate analogues were compared with the ones for the stone obtained by the technology of autoclave materials, the preference should be given to the latter ones since, in this case, the expensive operation of burning specially prepared raw material to obtain anhydrous materials has been eliminated.

In conclusion, it may be stated that the hydrothermal treatment of the samples, the components of which were chosen so that the acid—base reaction would take place among them, is an effective means of artificial stone synthesis.

Binding Materials on the Basis of Metal Oxide–Polyatomic Alcohol Systems

A whole number of organic compounds are known to display acid properties when reacting with metals and their oxides. Polyatomic alcohols refer to such kind of compounds in particular, the interaction of a representative of polyatomic alcohol—glycerine and lead oxide being used to obtain a special lute.

In the light of ideas developed by the author, this kind of binding materials may be expected to have analogues, too.

The interaction of the oxides of the elements of groups II, III, IV of the Periodic Table and glycerine or glycol have been investigated from the point of view of obtaining binding materials. The method of making an experiment was the same as the one in the second section of the paper. The results of testing are given in Table 5. They indicate the fact that calcium, strontium, barium, lead and minimum oxides when mixed with glycerine or glycol form quick hardening, high-strength binding materials, the strength of which (e.g., strontium oxide—glycerine system) amounts to 1000 kg. per sq. cm. exceeding that of cement having trade mark 500 and tested under similar conditions approximately fivefold. It should be noted that a number of combinations on the basis of the mixture of the oxides investigated and glycerine produce high—strength binding materials differing from other kind of cement in greater adhesion in relation to glass and metals.

Table 5. *Compressive strength (kg/cm²) of binding materials on the basis of* MeO*—polyatomic alcohol systems (air—kept)*

Oxide	Glycerine			Glycol		
	1 day	3 days	7 days	1 day	3 days	7 days
PbO	185	315	390	150	175	240
CaO	125	600	570	35	640	550
SrO	400	970	1050	—	—	—
70% PbO + 30% CaO	920	850	870	500	340	380
70% PbO + 30% SrO	200	780	—	—	—	—

As it was stated above, among organic compounds there are ones having both acid and basic properties. On account of this fact the author believes that the combination of a solid inorganic powder component and organic liquids will give possibility to synthesize a lot of new binding materials and, possibly, a new separte chapter of the chemistry of binding materials will develop on this basis.

Conclusion

While fulfilling the present investigation, the author set the task to investigate the possibility of synthesis of the new kinds of binding materials having taken the main thesis of V.F. Zhuravlev about binding properties of substances being chemical properties as a foundation. The author assumes that, when developing new binding substances, one should be guided by those chemical reactions which are the main ones in obtaining already well-known, widely distributed binding materials. Large experimental

material gathered indicate the correctness of the above idea, and shows the rich possibilities of the chemistry of binding materials in the synthesis of artificial stone the strength properties of which surpass those of portland cement and which has or, at least, may have specific properties that are the distinctive features of a solid powder component. The ideas of Prof. V.N. Young (9) who considered cement stone to be "microconcrete" containing unreacted grains of original minerals and compounds may be taken for the basis of such a conclusion. If one takes into account the statement mentioned above and the results of the experiments, it is theortically possible to obtain binding materials with most varied properties, such as electrophysical and others as well as binding materials having greater adhesion to metals, glass and ceramics than the cements known to-day.

Supplementary Paper II-122 Electron Microprobe Studies of Cement Phases

Della M. Roy and Michael W. Grutzeck*

Synopsis

The electron microprobe has been applied to the study of cement phases and their hydration products. The instrument used was an ARL-EMX modified microprobe equipped with three spectrometers. Visual cathode-ray tube displays of characteristic Ca–K_α, Al–K_α and Si–K_α emission, and electron back scatter (EBS) displays have been used to follow the progress of hydration of cement phases. In addition, counting techniques were employed to obtain quantitative analytical data. The C_3A hydration process was studied in detail as a function of time as it proceeds from C_3A through the early stage hydration products to C_3AH_6. The C_3S hydration was studied similarly, and finally mixtures of a simplified cement containing C_3A, C_3S and C_2S were examined. It is believed that techniques have been demonstrated which will apply more generally to the study of cement hydration problems.

Introduction

Portland cement offers the researcher a complex multicomponent system, replete with temperature and composition sensitive hydration reactions, poorly crystalline hydrates and extremely small grain size. In order to solve the complex problems involved in the hydration of portland cement researchers have been continually searching for new insights and new methods. An analytical tool which does not depend on crystallinity and which is well suited for non-destructive, in situ analysis of small grains is the electron microprobe. This investigation was begun with the intention of exploring the feasibility of applying the microprobe to various unsolved problems involving portland cement hydration.

While the microprobe was initially applied to the study of metals and sections of large single crystals, White (1, 2) in our laboratories has adapted the microprobe technique to the analysis of crystalline powders. More recently, Moore (3) and Yamaguchi (4) have conducted exploratory work with the microprobe on the identification and distribution of material in cement clinker phases. The microprobe has been recognized as an extremely powerful tool; however, it has not as yet been used to investigate portland cement hydration products. The specific purpose of this research was to adapt electron microprobe methods for examination of hydration products of cement compounds individually and in mixtures, to collect sufficient data to evaluate the method, to compare the results with data obtained by other means and, if possible to establish techniques that could be applied generally.

Experimental Method

General

Standard anhydrous compounds** and hydrates were prepared, identified and examined for purity by optical and X-ray diffraction methods. These were mounted in plastic and were used as microprobe standard samples. Repeated counts were made on different grains of the same material and the resulting data were treated statistically. Several of these materials were also used for preparation of hydrated pastes. Wherever possible, the results of microprobe analyses were compared with X-ray diffraction and optical data. In some cases these data were supplemented by thermogravimetric analysis data.

*Materials Research Laboratory and Department of Geochemistry and Mineralogy, The Pennsylvania State University, Pennsylvania, U.S.A.

** Throughout the paper standard cement nomenclature abbreviations are used as follows:
$C = CaO$, $A = Al_2O_3$, $S = SiO_2$, $H = H_2O$, $F = Fe_2O_3$

Equipment

Electron Microprobe

The electron microprobe used in this investigation was an ARL-EMX electron microprobe* modified with an automatic print out of three spectrometers, a preset time mode of collecting data and a step scanner which moved the sample one micron under the beam between each counting period.

Two types of data were collected: the first entailed the use of a rastering electron beam operating in unison with an oscilloscope. The output, in the form of electron back scatter (EBS) and elemental displays was photographed from the cathode ray tube. The second type of data involved the use of a stationary beam to perform quantitative analyses, registering the counts of characteristic X-rays emitted from the sample. The microprobe was operated at 30 kev with a one-to-two micron diameter spot size. For the rastering beam analysis the current used was 0.03 microamperes on the 3×10^{-8} A scale, while the current used for stationary beam analysis was 0.01 microamperes on the 10×10^{-9} A scale.

Microscopes

A standard Zeiss petrographic microscope and a Leitz reflecting light microscope were used to identify the materials and to follow the course of hydration in pastes.

X-ray Diffractometer

A GEXRD-5 wide range diffractometer equipped with a copper tube was used throughout the study. In addition to standard powder techniques, the diffractometer was used for some constant monitor experiments. In the latter case, the hydrating sample was placed in a square shallow depression in a glass or plexiglass slide and was covered with a 0.001 inch thick Mylar sheet. Repeated scans were then taken until the desired stage of hydration had been reached.

Sample Preparation

Preparation of Standards

Analyzed reagent-grade chemicals used as starting materials have as their highest levels of impurity, $CaCO_3$ (0.08% Na); Al_2O_3 (0.005% Cl); SiO_2 (0.005% heavy metals). The anhydrous compounds CA, C_3A, CA_2, pseudowollastonite (α-CS), β-C_2S and C_3S were prepared by reaction in the dry state at 1400°C. Calcium aluminoferrites were eliminated for simplicity because of the difficulty in analysis of Fe-containing compounds. 1% Al_2O_3 was added to the C_3S before firing to promote crystal growth, and β-C_2S contained 1% B_2O_3 as stabilizer. C_5S_2H (calciochodrodite) was prepared hydrothermally at 650° and 4000 psi (5, 6). For electron microprobe standards it was necessary to select crystals distinguished by their optical properties and X-ray diffraction pattern. It was found that sieved grains in the 44 to 74 μ size range made the best standards and starting materials for hydration studies. These sieved grains entirely contained the electron beam, and at the same time assured us that the observed hydration rims were due only to the outward growth of individual grains. Analysis of such materials and their use as standards of reference made it possible to correct for many of the sources of error in microprobe analysis.

Hydration of Sample for Microprobe Studies

Hydrated pastes of compounds and "synthetic cements" were prepared by mixing the above-mentioned size fraction with water, having a 0.5 water: solids ratio for C_3A, and 0.4 water: solids ratio for C_3S and the synthetic cement. The paste was mixed in a mortar, compacted into a 5 mm. I.D. glass tube, transferred to a rubber-stoppered shell vial and sealed with wax. The temperature of reaction ranged from 28 to 30°C. After the allocated reaction time the sample was immersed in liquid nitrogen (7) and the glass tube was broken away. In the usual case the hydration product was crushed gently in a mortar to enable examination of individual grains with their rims. The samples were then washed in very cold absolute alcohol and vacuum desiccated for five hours.

Sample Preparation for Microprobe

Initial experiments using a "cold-setting" resin, Quickmount revealed an undesirable temperature rise. The final material selected was a mixture of Selectron RS-5003 polyester (98.5 wt.%)**, Nuodex Cobalt Naphthenate (1.0 wt.%)*** here acting as a retarder and the catalyst t-butyl hydroperoxide (0.5 wt.%)****. A dough-like paste was made by adding a few drops of this material to about 250 mg of sample. This paste was placed in the center of a greased microscope

slide, surrounded by a greased section of 3/4" I.D. combustion tubing which was filled with additional plastic material, and covered with a greased 7/8" thinness zero cover glass square. Approximately four days was required for the set. A preliminary polish with 6, 3 and 1 μ Geonite diamond paste* and Metadi oil** was followed by buffing on pads of optical quality SnO_2. Absolute alcohol was used to clean the surfaces between each step. The final sample surface was coated with a few hundred Å layer of carbon and then mounted in brass sample holders.

Experimental Results

EBS Photographs and Elemental Displays

An electron back scatter (EBS) photograph conveys information as to the mean atomic weight of the material under the beam, and is very useful in detecting rims of hydrate formed around a crystal or grain. Such displays, as well as the cathode ray tube displays of the characteristic radiation for the major elements, CaK_α, AlK_α, and SiK_α were obtained for the various samples. Fig. 1 gives an example of EBS, Ca and Al displays for anhydrous C_3A and a sample of C_3A hydrated for one day. While the crystal boundaries are shown to be sharp, and the element distribution homogeneous in the anhydrous compound (1a), the hydrated sample (1b) reveals a distinct grain boundary observable between the hydrate and central core C_3A. Such rims were not clearly observable with C_3S samples, presumably because of the slower rate of hydration. However, occasional $Ca(OH)_2$ crystals were observed in C_3S hydrates as confirmed by the elemental displays.

Quantitative Analysis

Calibration-Standardization

In order to eliminate the effect of many non-random sources of error in obtaining quantitative analyses (such as described by McKinley (8); Birks (9) and Keil (10)) empirical correction was made by use of calibration standards. Calibration curves were constructed for calcium aluminates and silicates derived from measurement of Ca, Al and Si intensities for the compounds C_3A, CA, CA_2, C_3S, β-C_2S, α-CS and C_5S_2H. Measurements were made on five to ten grains of each compound. Values for grains showing high variation were discarded, and the remaining values used. The usual coefficient of variation ranged from 0.80 to 1.75%. The data are summarized in Fig. 2 and 3, which include the experimentally determined data, as well as interpolated and extrapolated values for calcium aluminates and calcium silicates, respectively. These curves were employed to analyze the data obtained for hydration products at various stages.

Effect of Dehydration

In order to correct for the effect of dehydration in the electron beam two lines of experiment were performed. In the first, the weight loss of a hydrate was determined as a function of temperature under a vacuum comparable to microprobe conditions. A thermobalance curve of C_3AH_6 run at a 10^{-5} torr vacuum is shown in Fig. 4a. It is seen that the weight loss is insignificant below 200°C.

To examine the effect of actual operating conditions in the microprobe, grains of C_3AH_6 having a 20 micron diameter were prepared in the usual manner and exposed to a 0.01 microampere sample current at 30 kev accelerating voltage with a one micron spot for ten minutes during which Ca and Al intensities were recorded simultaneously. Under these conditions Ca and Al intensities should have changed proportionately to the amount of water lost.

Fig. 4b shows the change in intensity of characteristic radiation as function of time, also plotted as a percent of the total water lost. It is seen that, within the relatively short time for quantitative analysis (10 seconds on a spot) the water loss would be negligible. When working with hydrates whose thermal properties are unknown, however, it is best to take precautions against dehydration by keeping the beam power as low as possible, selecting a short counting period, and spreading the beam spot over as wide an area as possible.

Problems of Sample Geometry

In addition to the calibration curves obtained above, it was occasionally necessary to correct for the effect of crossing a grain boundary. This was particularly necessary in examining the course of hydration when pursuing a traverse from the center of an unhydrated crystal through a hydration rim to the grain-plastic

tion rim is sufficiently large, a shoulder levels off and enables accurate measurement of the X-ray intensity. If not, the only measurement possible is the position of the first break in slope of the curve. Under the experimental conditions employed, it was necessary to have a minimum rim width of approximately 9 μ in order to record directly accurate X-ray intensities of the material in the hydration rim. Fig. 5b gives actual intensities of Ca and Al emission measured as a function of thickness of the rim. Using this latter fig. it was possible to calculate a correction factor when the rim width was below 9 μ.

Analytical Data Obtained from C_3A-Hydrate Traverses

X-ray intensities were measured with the microprobe for anhydrous C_3A and C_3A which had been hydrated for one, seven and twnety-one days, respectively. In each Case EBS displays were also recorded. Examples of the actual data obtained are shown in Figs. 6, 7, and 8 which give the measured X-ray intensities at 1 micron intervals, along with the EBS photograph showing the position of the traverse. The results for a typical unhydrated sample (Fig. 6) are unambiguous, and the interpretation of Fig. 7 is based on the information contained in Fig. 5 and 6 where it is seen that the point of first break in slope is significant and measurable. For the one-day hydration product this point represents a $CaO:Al_2O_3$ ratio of approxi-

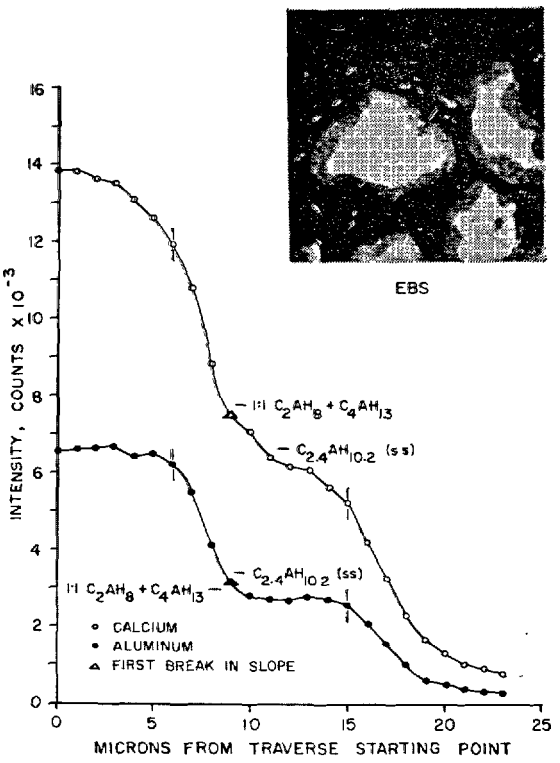

Fig. 7. *Measured X-ray intensities in traverse across a grain of* C_3A *hydrated for one day. Vertical lines show position of central core/hydrate and hydrate/plastic boundaries. Small grid division in EBS photo is 5μ*

mately 2.8. The hydration product at one day had been tentatively identified by X-ray diffraction as C_4AH_{13}. However, it is probable, in view of the microprobe analysis data, that the hydrate is either a crystalline solution of C_4AH_{13} with C_2AH_8 in its lattice, or a 1:1 mixture of crystalline C_4AH_{13} and amorphous C_2AH_8, which would provide the measured stoichiometry. Refractive indices of the plate-like crystals were different ($\omega = 1.552$, $\epsilon = 1.539$) from the reported values for C_4AH_{13} ($\omega = 1.534$–1.539, $\varepsilon = 1.514$–1.524), (II) suggesting probable crystalline solution. In any event, a total $CaO : Al_2O_3$ ratio of approximately 3:1 seems reasonable in view of conservation of matter from the original C_3A.

Data obtained after seven days of hydration (Fig. 8) show an initial break in slope on the Ca and Al intensity curves at a $CaO: Al_2O_3$ ratio of approximately 3.0. This agreed with the observed X-ray diffraction and optical data which indicated that the hydrate present was C_3AH_6.

After twenty-one days of hydration, the first break in slope was also observed at a $CaO: Al_2O_3$ ratio near 3.0; however, it was usually more difficult to determine this position precisely because of grain

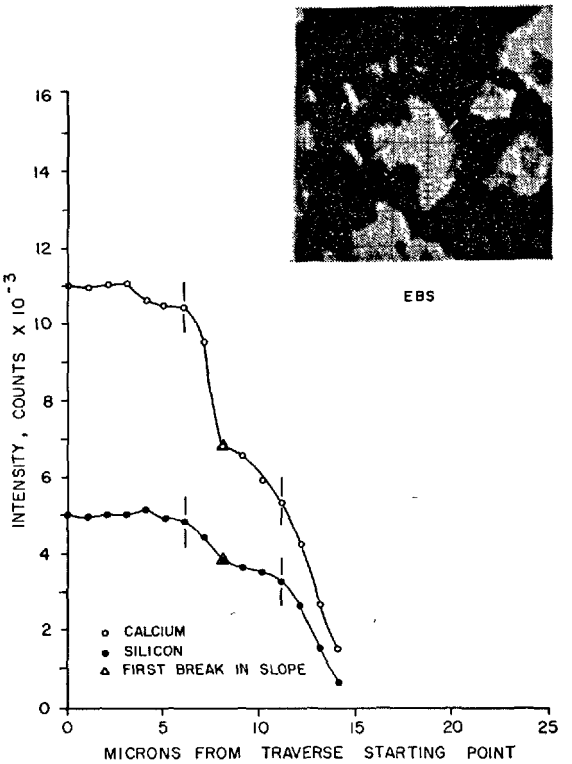

Fig. 9. *Traverse for* C_3S *hydrated twenty-one days. Small grid division in EBS photo is 5μ*

deterioration. The results are in general agreement with X-ray diffraction and optical data, which showed the presence of C_3AH_6.

Analytical Data Obtained from C_3S Traverses

X-ray intensity data were collected on anhydrous C_3S, and C_3S hydrated for three, twenty-one and forty-two days. No substantial rim build-ups were observed even after forty-two days had elapsed.

Data from a typical traverse after twenty-one days, hydration are given in Fig. 9, where an initial break in slope occurs at a $CaO: SiO_2$ ratio of about 2.4. The position of the traverse is shown in the EBS photograph. The first break in slope suggests the presence of a hydrate having a composition of the type $C_5S_2H_x$. Insufficient data were available to provide a valid correction factor due to small rim size, and hence no further inferences have been made. A somewhat lower $CaO: SiO_2$ ratio in the hydrate is reasonable in view of the existence of $Ca(OH)_2$ as identified both in the X-ray diffraction pattern and in the microprobe display. It appears that the relatively slow rate of hydration of C_3S prevents sufficient build-up of the hydration rim for accurate analysis to be possible at this stage.

Data on a Synthetic "Cement"

Preliminary studies were made on a synthetic "cement" composed of a mixture of the C_3A and C_3S

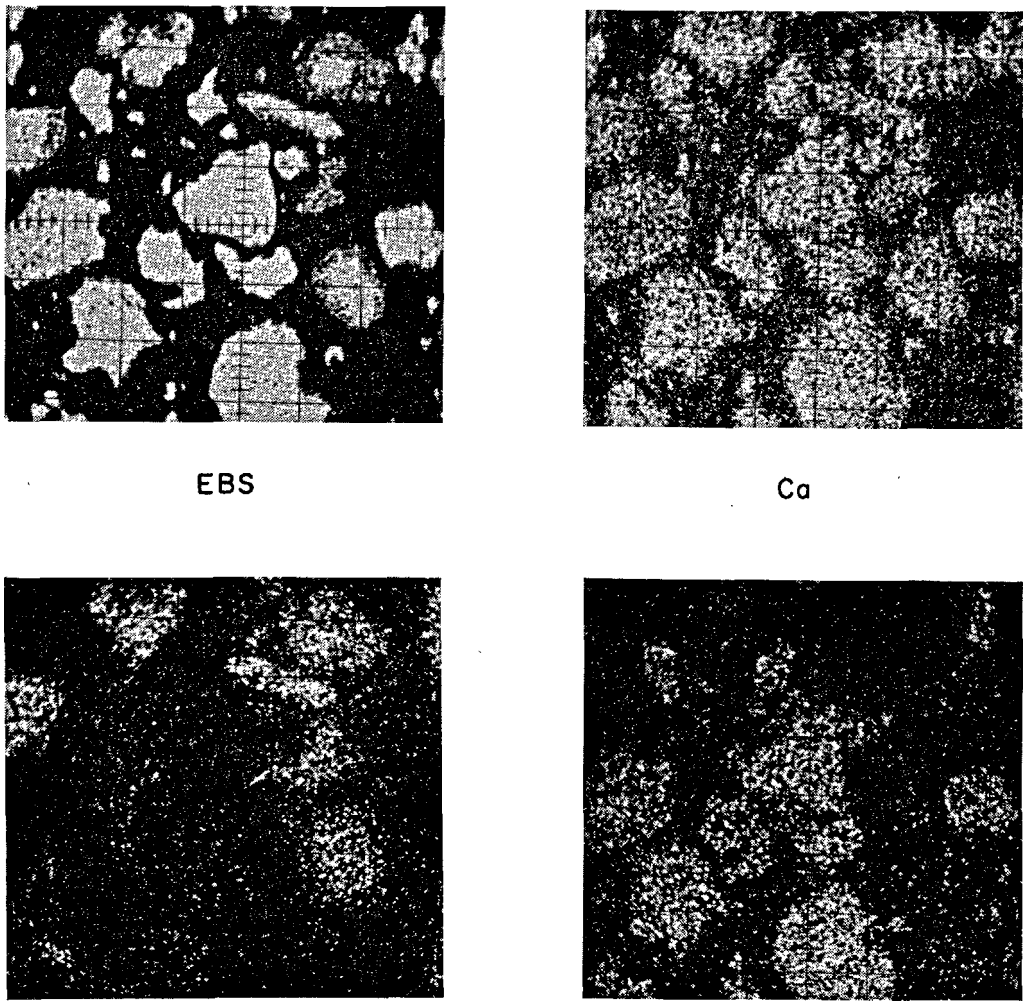

Fig. 10. *EBS and elemental displays for* C_3S–C_2S–C_3A *"cement" hydrated seven days. Small grid division is* 5μ

used in earlier experiments, along with β-C_2S*. Data were obtained on samples hydrated for seven and twnety-one days. Visual displays of the Ca, Al and Si emission, as well as the EBS for a typical sample hydrated for seven days are shown in Fig. 10. The EBS shows that some grains have substantial hydration rims while others do not. Elemental data indicate that the rimmed grains are C_3A, while the others are silicates, consistent with the data on the individual compounds. Insufficient time was available to carry these studies as far as desirable. However, the results showed comparatively little inter-reaction between the silicate and aluminate phases in this relatively early stage of reaction. It would appear that the aluminate hydrates early, and only after an extended period makes water available for silicate hydration.

Summary and Conclusions

Existing electron microprobe techniques have been successfully modified to cope with the specialized problems inherent in portland cement hydration studies. Limits of error in quantitative measurements have been established by applying standardization techniques and studying geometrical factors and effects of dehydration.

Two principal techniques have been employed: the use of electron back scatter (EBS) and elemental display data; and the analysis with a stationary beam at successive one micron intervals across a hydration rim. The first offered a physical description of the grain-hydrate relationships during the progress of the hydration and the possibility of observing the relative rate of hydration of aluminate and silicate phases both individually and combined in a synthetic cement. The second, the elemental analysis data taken along traverses, made it possible to follow the progress of the hydration in a quantitative manner Agreement between published and observed data and similar data gathered with the microprobe was good, and discrepancies could be explained.

The advantages of the method are: the direct analysis available on a micron scale; the visual nature of display data clearly showing inter-relationships; and rapid identification of individual grains. The disadvantages are concerned with the difficulty in sample preparation for quantitative analysis and the time consumed in obtaining significant quantitative data. It is believed that the advantages outweigh the disadvantages, and that the use of the microprobe should be extended to help solve many of the problems relating to portland cement and its hydration.

Acknowledgment

The authors are indebted to Dr. Eugene White and his staff for cooperation and helpful suggestions with the electron microprobe, and to Dr. Joseph Greig for help with experimental microscopic techniques and sample preparation. Financial assistance through NSF grants GP-2291 and GK-1154 made this study possible.

Oral Discussion

Giichi Sudoh

In the C_3S paste, it is difficult to observe the hydration rim even after 42 days' curing.
Dr. Roy and Mr. Grutzeck assume that this is because of the slow rate of hydration of C_3S, we also assume that there may be some other reasons causing difficulty in observing the C_3S hydration rim.

Among the above are as follows: and we should like to ask Dr. Roy on these points.

(1). The effect of the polishing conditions on the hydration rim of C_3S may be more sensitive than on that of the C_3A hydrates.
(2). The dehydration phenomena during observation may disturb the electron back scattering display.

Furthermore, in Dr. Roy's and Mr. Grutzeck's paper, it is reported that their C_3S hydrate has high molecular ratio of lime to silica, about 2.4.
This high ratio is considered to come from the dehydration of C_3S hydrates, isn't it?

Authors' Closure

Della M. Roy and M. Grutzeck

It is true that the rims observed on C_3S were smaller than those observed for C_3A. We do not believe that C_3S hydration rims were broken off during polishing. Great care was taken during mounting and polishing to prevent this happening. In addition, optical examination under high power indicated that the final polished surfaces are flat for both the C_3A and C_3S sample plaques.

Some dehydration undoubtedly does take place under the electron beam. While we investigated this for CA hydrates, we were not able to establish quantitatively the limits for "CSH gel", since it is difficult to produce a standard material for analysis. The absolute measured intensities of Ca and Si increase with loss of H_2O, but the Ca: Si ratio changes much less. Recent data obtained on C_3S samples hydrated for longer periods of time yield data which speak to both questions. Larger hydration rims were visible on these samples, and the size appears to be a function of time. In addition we obtained lower Ca: Si ratios in the latter analyses, close to those predicted by many for C-S-H gel. The dehydration effect does not appear in these instances to cause a substantial increase in Ca: Si ratio.

These supplementary data are reported elsewhere.

Supplementary Paper II-35 Mutual Interaction of C_3A and C_3S during Hydration

J. G. M. de Jong, Hans N. Stein and J. M. Stevels*

Synopsis

The following mechanism can be proposed for the mutual interaction of C_3A and C_3S during hydration: the compounds start to react individually, C_3A forming hexagonal aluminate hydrates, C_3S forming "first hydrate" (F.H.). Soon, however, the presence of silicate ions in the water phase influences C_3A hydration and the presence of calcium and aluminate ions in the water phase influences C_3S hydration.

A. The former can be understood by two opposing effects:
   1. an acceleration of the formation of C_3AH_6 nuclei
      a. by silicate ions incorporated into the C_3AH_6 nuclei
      b. because C_3S can be used in this case as precipitation place for amorphous $Al(OH)_3$ by which the C_3A hydration can carry through.
   2. a retardation of C_3AH_6 nucleus formation by a lowering of aluminate ion concentration in the water phase. The aluminate ions are taken away from the water phase and incorporated into the calcium hydrosilicates formed.
   If a small amount of C_3S is present, the former influence (A1) predominates, in the presence of larger amounts of C_3S the latter (A2) predominates.

B. C_3A retards the appearance of the C_3S heat evolution peak, since
   1. aluminate ions can be incorporated into F.H. This is more stable with respect to recrystallisation than aluminium-free calcium silicate hydrate.
   2. the calcium- and hydroxyl concentration in the water phase originating from the hydration of C_3A, retard the transition F.H. → S.H. too.

Introduction

Until now only limited research has been devoted to the mutual interaction of C_3A and C_3S during hydration.

Earlier work includes that by Chatterji and Jeffery (1) investigating mixtures of alite, C_3A, C_4AF and water by electron microscopy, electron diffraction and X-ray diffraction. As hydration products hexagonal crystals of $Ca(OH)_2$, $C_3A \cdot CaCO_3 \cdot H_{12}$ and C_4AH_x were found. After longer hydration times the hexagonal C_4AH_x changed into the cubic C_3AH_6 (hydrogarnet). Calcium silicate hydrates were observed too.

Strätling and zur Strassen (2, 3) investigated $C_3S - C_3A$ mixtures (molar ratio 2:1) in dilute suspensions, following CaO and Al_2O_3 concentrations in the water phase. They concluded that the "Al_2O_3" was probably incorporated into the calcium hydrosilicate, forming a quaternary compound.

Iwai (4) ground mixtures of C_3A and C_3S for 1 week in a ball mill (w/s = 5/1), left the resulting systems for 1 week, dried the mixture and investigated the hydration products by X-ray diffractometer. If only C_3A was present, the cubic C_3AH_6 was formed exclusively. The intensities of the X-ray peaks of this hydrate were smaller with increasing C_3S/C_3A ratio. In contrast with experiments with mixtures of C_4AF and C_3S, no silicate ions were build into the lattice of the cubic crystal. By hydration of C_3S afwillite ($C_3S_2H_3$) came into existence.

Richartz (5) found in mixtures of C_3S and C_3A, which were shaken in water (w/s = 5/1) for 28 days, that the quantity of hydrogarnet increased at small quantities of C_3S. At larger concentrations of C_3S the quantity of hydrogarnet decreased whereas more C_4AH_{13} was present which was ascribed to the influence of $Ca(OH)_2$ liberated. Because SiO_2 had been

*Laboratory of Inorganic Chemistry, Technological University, Eindhoven, Netherlands.

built into the lattice, the hydrogarnet had the composition $C_3AH_{5.6}S_{0.2}$.

According to Copeland et al. (6) aluminate ions can be incorporated in tobermorite gel which comes into existence by the hydration of C_3S. On account of the introduction of aluminium ions the morphology of tobermorite gel changes. Afwillite is the product formed by the hydration of pure C_3S in the ball mill (7) but simultaneous hydration of C_3S and C_3A (C_3S/C_3A ratio = 10/1) gives $Ca(OH)_2$ and tobermorite gel only. A hydrogarnet was detected when the proportion of C_3A was increased by 10 percent.

Bobrov et al (8) found by shrinkage measurements that the hydration of a mixture of C_3A and C_3S was more sluggish than would be expected from a summation of the hydration reactions of the separate compounds.

In this study the mutual interaction of C_3A and C_3S during hydration has been investigated both in pastes and in suspensions.

In pastes heat evolution rate was measured, supplemented by X-ray and DTA analyses of hydration products after predetermined hydration times.

In suspensions the electrical conductivity and the pH have been determined, and the calcium, aluminate and silicate ion concentrations were determined analytically. The solid phases were characterized by their X-ray diffraction patterns.

Experimental

Materials

C_3S

Calcium carbonate (reagent grade "Merck") and quartz (reagent grade "Merck"), ground separately in an agate ball mill, were ground together in an excess of benzene. There was a very slight excess of quartz over the stoichiometric amount in order to minimize contamination by free calcium oxide. The mixture was heated overnight in a vacuum oven (40°C) in order to remove the benzene and then heated for 40 hours at 1600°C. Every 8 hours the product was taken out of the furnace and ground in dry first, and then with water; after the last firing, the product was ground in dry only.

X-ray analysis showed that the product contained a very slight quantity of free CaO only, but that it was also contaminated with a small amount of γC_2S. From examination by microscope it was concluded that no other C_2S modification was present. The amount of γC_2S was estimated to be 3 to 4%. The percentage of free CaO was determined according to the method of Pressler et al. (9) and was found to be less than 0.3% by weight. The specific surface of this C_3S preparation was found by air permeability (10) to be 1.76×10^3 cm^2g^{-1}.

C_3A

This compound was prepared by heating a stoichiometric mixture of $CaCO_3$ (reagent grade "Merck") and Al_2O_3 (reagent grade "U.C.B."; loss on ignition 4.5%), ground previously in an agate ball mill, during four hours at 1375°C. Thereafter the mixture was heated two times for four hours at 1500°C. Between all firings, the product was ground in dry first, then with water. After the last firing, the product was only ground in dry in agate ball mills. The X-ray diffractogram of the product agrees completely with the data, mentioned by Taylor (11).

The percentage of free CaO, determined according to the method of Pressler et al. (9), was less than 0.8% by weight.

The specific surface, determined by air permeability (10) was 1.0×10^3 cm^2g^{-1}.

Water

The water used was twice distilled. All water had been boiled and cooled shortly before use so as to minimize contamination of the pastes or suspensions by CO_2.

Nitrogen

The nitrogen, used in the suspension measurements, was purified by passage successively through an adsorption tube filled with 13 — 20 mesh carbosorb, a washing bottle filled with 20% NaOH solution and a washing bottle filled with water.

Method

Paste Experiments

Preparation of the Pastes

The water/solid ratio in the pastes was 1 : 1 (2.00 g of solid with varying C_3A/C_3S ratio and 2.00 ml of water). The C_3A and C_3S mixed in dry; the mixture was transferred to a porcelain dish, after which the water was added. This paste was ground for 1 min.

with a porcelain pestle and transferred into the isothermal calorimeter.

At predetermined times, samples were taken and dispersed by being ground in a porcelain dish for 1½ to 2 min. in an excess of absolute ethanol (10 ml.). The ethanol was added in order not only to arrest the hydration reaction at a fixed moment but also to provide protection against CO_2 (12). It is generally held that the ethanol affects neither the nature of the hydrated phase nor that of the unhydrated phase (13; 14). The sample was dried in a vacuum oven (25 – 35°C) overnight.

Isothermal Calorimeter

The isothermal calorimeter which has been described earlier (15; 16) was placed in a thermostat (25 ± 0.1°C), situated in a constant temperature room (25 ± 0.25°C).

X-ray Analysis

Qualitative X-ray analysis was carried out with a Philips diffractometer (PW 1051) using CuK α_1 rays with a Ni filter.

Differential Thermal Analysis

As a reference Al_2O_3 (reagent grade "Merck"), heated previously to 1200°C was used. The equipment used (Licence CNRS; model M1) required only a few mg of sample. The rate of temperature increase was about 10°C per min.

Suspension experiments

Preparation of the Suspensions

Water (60 ml), brought previously to temperature, was pipetted into a glass beaker provided with a thermostating jacket. Stirring was started and the solid phase was added through a small hole in the cover that was closed immediately afterward by a rubber stopper. During the hydration the suspension was magnetically stirred and purified nitrogen was passed over the suspension. The nitrogen exit tube was protected against back flow of air by a carbosorb-filled tube. The speed of the magnetic stirrer was kept constant during any series of experiments. Care was taken that the magnetic stirrer swept the whole bottom of the thermostatic beaker (with the exception of a rim of about 1 mm. width) so as to avoid "dead spots" in stirring and to prevent settling of the suspended solids.

Determination of the Electrical Conductivity

Electrical conductivity in the suspensions during hydration was followed by means of a Philips PR 9501 direct reading conductometer in combination with a Philips PR 9510 immersion conductivity cell and a Philips PR 4069 M/00 recorder.

Determination of pH

Determination of pH was performed using conventional high alkali glass and calomel electrodes. The glass electrode was placed directly in the suspension, the calomel electrode in a 1 N KCl solution. The boundary between suspension and 1 N KCl solution was formed through a capillary as described by MacInnes and Belcher (17) and renewed once every 5 minutes in the earliest reaction stages, after one hour once every 10 min. After 7 hours' hydration, boundary renewal was omitted and only started again after 22 hours' hydration. Precipitation of hydrates near the boundary tended, if these precautions were not taken, to influence the pH measurements.

The pH was recorded by an Electrofact Laboratorium pH meter type 53 A and a Philips type PR 4069 M/00 recorder.

Chemical Analysis of the Water Phase

Separation of Liquid and Solid Phases

The suspension was filtrated with suction directly from the thermostatic beaker by way of a siphon through a Schott 1 G 4 sintered glass funnel. During filtration, purified nitrogen was passed still over the suspension by which the suspension was protected against contact with air. The filtration time varied from some seconds to sometimes fifteen minutes. Samples of the filtrate were pipetted for chemical analysis immediately after filtration; the solid phases were washed with absolute ethanol and dried in a vacuum oven overnight.

Determination of the Calcium Concentration

Calcium was titrated with EDTA after acidification, addition of 5 ml of a triethanolamine-water mixture, dilution to about 200 ml and addition of 10 ml 4 N KOH solution with murexide as indicator.

Determination of the Aluminate Concentration

Aluminium was determined gravimetrically with 8-hydroxyquinoline (18).

Determination of the Silicate Concentration

The silicate concentration was determined spectrophotometrically by the Mullin and Riley method (19) as modified by van Lier (20).

Experimental Results

The Results of the Paste Experiments

The results of the measurements in the isothermal calorimeter have been reproduced in Fig. 1, in which the heat evolution rate has been expressed as a function of the time. Some experiments have been stopped after predetermined times and the hydration products have been investigated by X-ray analysis. These results, forming the basis for the interpretation of the calorimetric data have been reproduced in Table 1.

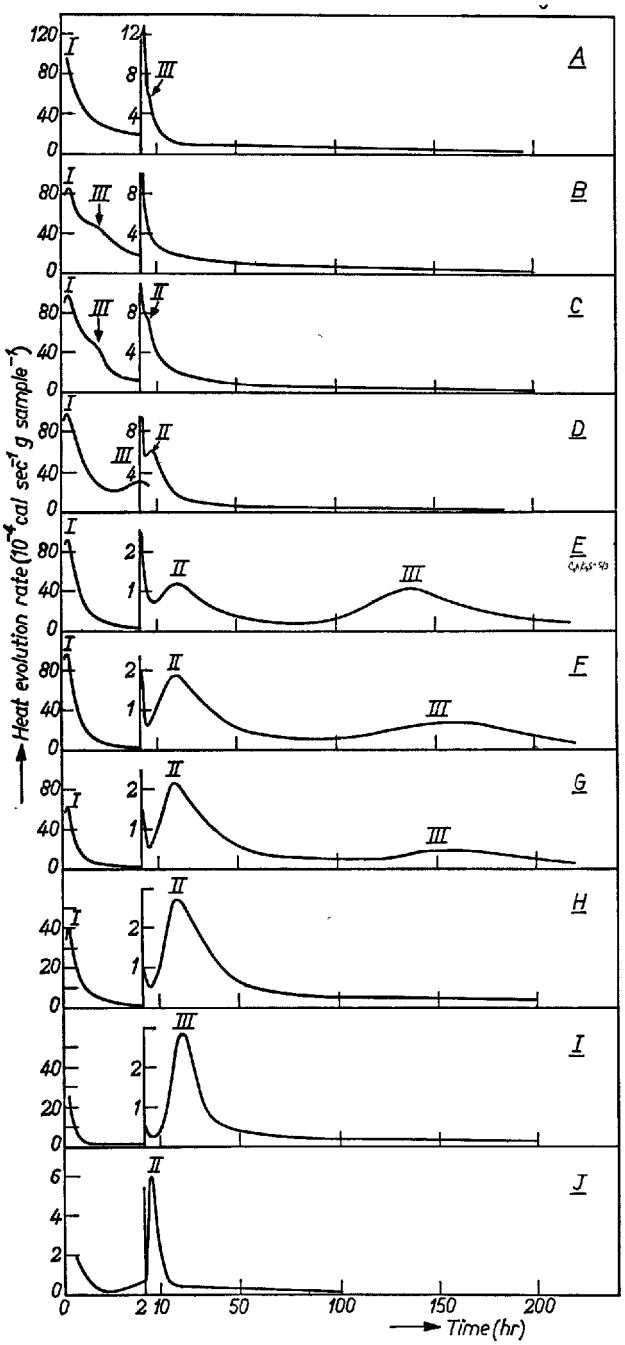

Fig. 1. *Heat liberation curves for pastes, containing* C_3A, C_3S *and water. Letters indicate the reactions as in Table 1*

The heat evolution per unit of time during the hydration of C_3S increased after an induction period, during which practically no reaction took place as described earlier (21, 22). It shows with the C_3S used a maximum after 5 hours and then decreases gradually (Fig. 1. J). By the addition of a small quantity of C_3A this C_3S heat peak (peak II) shifts from 5 to 20 h, it becomes lower but more spread out (Fig.

1.I). At still smaller C_3S/C_3A ratios this peak becomes lower always but more spread out too. This peak II shifts again to about $5\frac{1}{2}$ hours if peak III comes into existence after smaller hydration times (Fig. 1.C and 1.D).

In pastes of C_3A two heat evolution peaks are found (23; 24): the first one directly after the beginning of the hydration (peak I), the second one, for the sample used in the present investigation a very small effect (peak III) after about $6\frac{1}{2}$ hours (Fig. 1.A.). This peak III has been connected with the conversion of intermediate hexagonal hydrates into the cubic C_3AH_6 (24). By the addition of a small quantity of C_3S to C_3A this peak shifts to earlier reaction times and is more intensified (Fig. 1.B, 1.C, 1.D). If the C_3S/C_3A ratio $\geqslant 3/5$ the C_3A hydration and the C_3AH_6 formation is retarded strongly (Fig. 1.E, 1.F etc.).

This interpretation of the heat evolution peaks based on X-ray data (Table 1) is confirmed by DTA measurements (Fig. 2.): After 5 hours' reaction in pastes 1 g C_3A + 1 g C_3S + 2 ml H_2O (F) exclusively endothermal peaks of the hexagonal aluminate hydrates can be observed; after 70 hours the strong peak of $Ca(OH)_2$ at 475°C has appeared. After 200 hours the peaks of the hexagonal hydrates have disappeared almost but the strong peak of C_3AH_6 at about 330°C has appeared. The second, more weak peak of C_3AH_6 can not be distinguished from the peak of $Ca(OH)_2$.

The Results of the Suspension Experiments

The specific conductivity for suspensions with different C_3S/C_3A ratios has been reproduced as a function of the time in Fig. 3., the pH in Fig. 4. This pH has, in general, a similar course as the specific conductivity. The decrease of the conductivity which is found after 4 hours in the absence of C_3S, took place after earlier hydration times when a small quantity of C_3S had been added to the C_3A. The crystallisation of C_3AH_6 which causes this decrease in the specific conductivity (32), took place therefore earlier as is also evident from Table 2 where the X-ray diffractograms of the solid phases have been reproduced for some reactions. The conductivity increase, caused by the C_3S hydration (see later), shifts to earlier reaction times with increasing C_3S content of the paste and converges ultimately with the first part of the curve, caused by the C_3A hydration. The C_3S quantity decreases very gradually. After 16 hours hydration time (during experiment V) practically no C_3A is present but still a distinct amount of C_3S.

The X-ray patterns of the products of all these reactions after 24 hours hydration time have been reproduced in Table 3. It is seen that the sudden decrease of the specific conductivity in some experiments (V, VI, VII) after about 17 hours hydration time is caused by crystallisation of $Ca(OH)_2$. Usually no quaternary compound was formed, but in some cases traces of gehlenite hydrate were found.

By the addition of a small quantity of C_3A to C_3S the specific conductivity is distinctly lowered (Fig. 3. VIII).

The results of the analyses for calcium and aluminate ion concentrations in the water phase during the reactions I, II and V have been reproduced with the Jones and Roberts phase diagram for the ternary system, $CaO–Al_2O_3–H_2O$ (26) as a background (Fig. 5). The results of the ion concentrations during the reactions V and IX have been reproduced in Table 4, respectively Table 5. The results of Strätling and zur Strassen (2, 3) are in accordance with these results.

The addition of C_3S to C_3A does not change the concentration course in the beginning up to the time of establishment of a solution saturated towards both C_4AH_{19} and C_2AH_8. In the presence of small quantities of C_3S the crystallisation of C_3AH_6 takes place more

SiO_2 + H_2O (33) but equilibrium conditions (concentrations corresponding to solutions saturated towards C_3AH_6) are reached more quickly. In the presence of larger quantities of C_3S the concentration line leaves the point of metastable coexistence of solution with C_4AH_{19} and C_2AH_8 no longer in the same way as in suspensions of pure C_3A but along the C_4AH_{19} saturation line. It follows that the rising part of the conductivity curve is caused by the C_3S hydration; this is evident from the silicate determinations, too.

Discussion of the Experimental Results

C_3S Hydration

The following mechanism, proposed by Stein and Stevels (22; 26) based partly on results of Kantro et al. (27; 28), agrees with all data available concerning the hydration of C_3S:

$3CaO \cdot SiO_2 + H_2O$

$\downarrow$

$3CaO \cdot SiO_2 \cdot mH_2O$(F. H. = first hydrate)

$\downarrow$

$Ca(OH)_2 + (0.8 - 1.5)CaO \cdot SiO_2 \cdot nH_2O$
(C–S–H(I); S. H. = second hydrate)

$\downarrow$

$(1.5–2)CaO \cdot SiO_2 \cdot pH_2O$(C–S–H(II) or tobermorite gel; T. H. = third hydrate).

The influence of small quantities of C_3A added to C_3S is understood if it is supposed that the transition F. H. $\rightarrow$ S. H. is retarded. This is evident both in suspensions (see Fig. 3) and in pastes (see Fig. 1). There may be two reasons for this as for as the authors can see:

1. Aluminium ions are incorporated into the calcium silicate hydrate formed. This aluminium-containing calcium hydrosilicate is thought to be more stable with respect to recrystallisation than aluminium-free calcium hydrosilicate, in analogy to Kalousek's results on Al-containing tobermorite (29). This is the reason why addition of bayerite, or still more clearly, the addition of amorphous $Al(OH)_3$ retards the hydration of C_3S (28).

2. The calcium and hydroxyl ions in the water phase, resulting from the hydration of C_3A, retard the transition F. H. $\rightarrow$ S. H. too. It is already known that CaO or $Ca(OH)_2$, added to C_3S, retards the C_3S hydration (30).

Of these two possible mechanisms, the first-mentioned appears to be much more probable than the last-mentioned, though the latter may not be excluded. Although in C_3S + water systems $[Ca^{2+}]$ and $[OH^-]$ are generally higher than in C_3A + water systems, during the very first stages rapid reaction of C_3A may provide still higher $[Ca^{2+}]$ and $[OH^-]$ in mixed $C_3A + C_3S$ + water systems than are found in C_3S + water systems. It is known from the work of Stein and Stevels (22) that the calcium and hydroxyl ion concentrations during the first hydration stages have a far-reaching effect on C_3S hydration.

Larger quantities of C_3A are found not to exert this strong retarding action on C_3S hydration. The transition between both mechanisms lies at a C_3S/C_3A ratio less than 3/5 in pastes. The reasons for this changed mechanism are at present far from clear; it should be remembered, however, that in suspensions a rather striking difference in concentration course is found between suspensions with low C_3S/C_3A ratio and suspensions with high C_3S/C_3A ratio: the point of metastable coexistence of C_4AH_{19}, C_2AH_8 and solution is left in the former case more or less along the C_2AH_8 saturation line, in the latter case along the C_4AH_{19} saturation line (see Fig. 5). This suggests the following explanation: In the presence of large amounts of C_3A, C_3AH_6 precipitation occurs in such a way as to lower the aluminate ion concentration to a value represented by the C_3AH_6 saturation line in the $CaO–Al_2O_3–H_2O$ phase diagram. In this case only a slight amount of aluminium ions is incorporated into the calcium silicate hydrates:

C_3S hydration is not noticeably retarded. On the other hand, in the presence of small amounts of C_3A, C_3AH_6 precipitation is suppressed. The aluminate ion concentration in the water phase remains high (corresponding to a value represented by the C_4AH_{19} metastable saturation line in the $CaO–Al_2O_3–H_2O$ phase diagram), more aluminium ions are incorporated into the calcium silicate hydrates: C_3S hydration is considerably retarded. From the suspension measurements one would expect that this mechanism can be operative at later hydration times only; but it should be remembered that the suspension measurements are not to be taken too strictly as indications for the time scale of the paste mechanism; especially for the formation of C_3AH_6 nuclei an acceleration with decreasing water solids ratio has been reported (32).

The explanation offered is consistent with data by Copeland et al. (6) who report that a minimum amount of 20% C_3A should be present in order to make possible C_3AH_6 formation. It is confirmed by the calorimetric and X-ray data on paste experiment I (Table 1) obtained in the present investigation. If a small quantity of C_3A is added to C_3S the specific conductivity is lower. This is in accordance with the hypothesis that aluminate ions are incorporated into the calcium hydrosilicate formed by which the hydration of C_3S is retarded. For this reason less calcium and hydroxyl ions, which determine the conductivity, come into the solution.

C_3A Hydration

The following mechanism can explain the hydration of C_3A (32): in the first reaction stage, hexagonal metastable hydrates are present on the C_3A surface. After conversion of this layer, C_3AH_6 and hydrous alumina are precipitated, the latter also on the C_3A surface so that the C_3A hydration is retarded again. It has been found earlier that the addition of an inert material, like quartz, on which the amorphous $Al(OH)_3$, can precipitate, accelerates the reaction (32). If amorphous silica is added to C_3A, peak III in the heat evolution rate curve, connected with the conversion of intermediate hexagonal hydrates into the cubic one, shifts to earlier reaction times and is

intensified more clearly (33).

De Jong et al. (33) have demonstrated quantitatively, Richartz (5) and Chernykh et al. (34) qualitatively that at comparable times the quantity of hydrogarnets in the presence of amorphous silica is larger. Especially, the formation of C_3AH_6 nuclei appears to be accelerated by the presence of silicate ions. If a small quantity of C_3S is added to C_3A, the effect of this C_3S is analogous to that of amorphous silica, viz, and acceleration of the formation of C_3AH_6 nuclei by silicate ions. Peak III shifts, therefore, to earlier hydration times and is intensified. In accordance with this explanation Richartz (5) found, in the presence of small quantities of C_3S, a larger quantity of hydrogarnets. Since in this case no aluminium ions are incorporated into the F. H., the C_3S hydration is not perceptibly retarded.

For C_3S/C_3A ratio $\geqslant 3/5$ the retardation of the formation of C_3AH_6 nuclei by a lowering of aluminate ion concentration plays the most important part. The aluminium ions are incorporated in an early reaction stage into the F. H., in a later reaction stage into the tobermorite gel. By the absence of large quantities of aluminate ions, the formation of C_3AH_6 nuclei is retarded and therefore the C_3A hydration, too, because the hexagonal aluminate hydrates remain as a protecting layer around the C_3A grains. It is typical of the extreme case of high C_3S/C_3A ratio that in suspensions the invariant point of coexistence of solution with C_4AH_{19} and C_2AH_8 is left following the C_4AH_{19} saturation line (Fig. 5.), and that C_3AH_6 is observed late if at all by X-rays both in suspension and in pastes.

Acknowledgment

The authors express their gratitude to Miss Y. Leeuwenburgh for chemical analysis and for assistance in the X-ray diffraction work.

Supplementary Paper II-44 The Mathematical Simulation of Chemical, Physical and Mechanical Changes Accompanying the Hydration of Cement

Geoffrey J. C. Frohnsdorff, William G. Fryer and Paul D. Johnson*

Synopsis

In order to aid the understanding of the factors affecting cement performance, a quite general mathematical model has been developed to show the interrelationships between several important experimentally measurable variables.

The central and most complex part of the model is the representation of the kinetics of hydration. Once the kinetics are satisfactorily represented, many important properties of the system at any given point in time can be calculated from the quantity and composition of the liquid phase, the quantities and particle size distributions of the solid phases and the known properties of the phases.

The model is described and its use is illustrated by calculations depicting the chemical changes, heat liberation, volume changes, and changes in flow and mechanical properties accompanying the hydration of tricalcium silicate.

Introduction

When an inorganic cement is mixed with water, chemical and physical changes begin to take place which, in some cases, can continue for many years. These changes are, in large part, responsible for the engineering performance of the cement. While some qualitative relationships between the physics and chemistry of cement hydration and specific aspects of cement performance have been recognized, there is a need for improved insight into the physical and chemical factors affecting performance. A method for contributing to the insight which has recently become practicable is mathematical simulation using electronic computers. This paper illustrates the method and discusses its advantages and limitations.

Simulation has already been applied successfully to complex problems in many scientific, engineering and business applications and it appears to be equally applicable to the problem of cement hydration. In this case, the most general simulation could be described as a physical-chemical-mechanical model since it would have to relate physical, chemical and mechanical effects.

The desirability of being able to relate the engineering performance of cements to chemical and physical changes was apparent to Le Chatelier (1) in the late 19th century, and this recognition appears to have stimulated his important contributions to the field. In subsequent years, many persons have tried to relate specific aspects of cement performance to recognizable chemical and physical characteristics, and they have generally contributed in an important way to understanding. Examples of contributions of this sort for the case of portland cement have been those of Powers (2), Helmuth (3) and Volkov (4) and their collaborators, while the work of Ridge (5) and Schiller (6) has been concerned with gypsum plaster, and the work of Koishi (7) with dicalcium plumbate. The contributions of Volkov, Ridge, Schiller, and Koishi are particularly relevant to the present work since each developed mathematical expressions for the kinetics of the hydration reactions in which they were interested and, in some cases, attempted to relate experimentally determined performance characteristics (e.g. heat liberation, setting, etc.) to chemical changes. The present work illustrates how more comprehensive and more generally useful mathematical models for use with computers can be developed.

The application of computers to complex problems in chemical kinetics has recently been demonstrated by DeTar (8) and others (9, 10). Though their work has been oriented towards reactions in homogeneous systems, similar methods can be applied to reactions in heterogeneous systems, such as cement paste, in which reactions at the solid-liquid interface have to

*American Cement Corporation, Riverside, California, U.S.A.

be taken into account. In the physical-chemical-mechanical model to be described below, a quite general approach has been taken which may be applied to any solid-liquid system in which solution, nucleation and precipitation are taking place. Because of the complexity of the cement hydration process, it is not to be expected that the model as described will be entirely realistic but it does have features which can account for a number of aspects of cement behavior and it may be modified to deal with its shortcomings as they become apparent.

Outline of the Incremental Solution-Precipitation Model

The model which is to be described can be used with a computer of moderate capacity such as the IBM 360, Model 30. It is an incremental model which proceeds in steps covering more or less short time intervals. Starting from an input defining the state of the cement-water system at the start of mixing, calculations are made which allow the prediction of physical, chemical and mechanical changes which take place in successive time intervals. The predicted values are the output of the program. In this section, the input to and the output from the calculations and the calculations themselves will be outlined prior to the fuller discussion to be given in Section 3. The way in which the input, the output, and the calculations are related is indicated in the flow chart of Fig. 1.

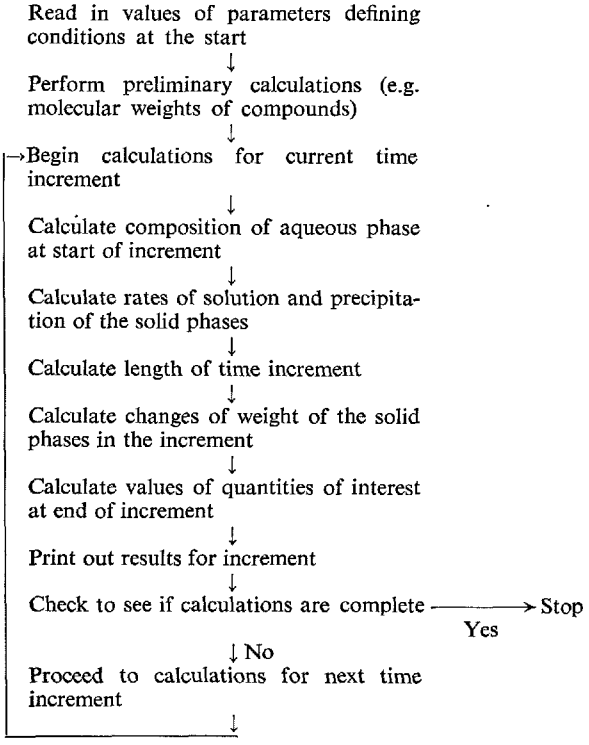

Fig. 1. *Flow chart depicting major subdivisions of the model calculations*

Input—The State of the System at the Start of Mixing

The characteristics used to describe the system at the start of mixing and which form the input to the calculations are (i) the quantities, compositions, and particle size distributions of the solid phases present in the cement, and (ii) the quantity and composition of the mixing water. In addition, it is necessary to know or assume the compositions of the possible reaction products and the values of the relevant chemical and physical properties of both products, and reactants. These properties include solubilities rate constants for solution, nucleation and precipitation, heat contents, and specific gravities together with other constants needed for calculation of mechanical properties.

Output—The Calculated Characteristics of the System at Various Points in Time

The output of the calculations consists of the quantities and particle size distributions of the solid phases present, the quantity and composition of the aqueous phase, the heat liberated, the volume, density, porosity, viscosity, and modulus of elasticity of the system. It must be emphasized that the quality of the output depends upon the quality of the input and upon the correctness of the many assumptions incorporated in the model.

Calculations

For simplicity, calculations are based on the assumption that each solid phase in the system consists of spherical particles which, depending on the composition of the aqueous phase, will either dissolve or precipitate when in contact with the aqueous solution. The rate of solution or precipitation of a compound at any point in time is governed by the degree of saturation of the solution with respect to that compound. Calculations of the rates of solution of dissolving phases and of the rates of nucleation and

growth of particles of precipitating phases make possible the further calculations of the changes which take place in the system over a suitably short time interval. Then, proceeding in steps over successive time intervals, the incremental calculations can be extended to cover the whole course of the reactions. In addition to the state of the system in terms of the quantities and particle size distributions of the phases present at a point in time, the calculations are extended to cover the porosity of the system, the rate of heat liberation, viscosity, and modulus of elasticity.

Details of the Model as Applied to Cement Hydration

The calculations associated with the chemical and physical changes taking place in the system are of three main types. These are calculations of the composition of the aqueous phase, calculations of rates of solution of dissolving phases, and calculations of rates of nucleation and growth of precipitating phases. The other major calculations are those of mechanical properties. These aspects of the calculations will now be discussed individually.

Calculation of Rates of Solution of Dissolving Phases

In the simplest case, the rate of solution (R_s) of a dissolving phase can be expressed in terms of the surface area (S) of the phase and the degree of unsaturation of the aqueous phase with respect to the dissolving compound (11). This is expressed by the equation:

$$R_s = k_s \cdot S \cdot (I_{sat} - I) \qquad (1)$$

where k_s is a constant, I is related to the ionic product for the compound in solution at a given point in time, and I_{sat} is the value of I for a saturated solution of the compound. For the compound $A_1B_mC_n \ldots$, I is given by:

$$I = \left[[A]^1 \cdot [B]^m \cdot [C]^n \cdot \ldots\right]^{\frac{1}{1+m+n\cdots}} \qquad (2)$$

where [A], [B], [C], ... are the concentrations of the ions in solution.

Calculation of the Rates of Nucleation and Growth of Precipitating Phases

Just as the rate of solution of a compound can be expressed by equation (1), so can the rate of growth of existing particles of the compound. However, calculations of precipitation are more complex than those of solution since the possibility of the nucleation of new particles must be taken into account (11). The rate of nucleation (R_n) may be expressed by the equation:

$$R_n = k_n \cdot (I - I_{sat})^p \qquad (3)$$

where p is an exponent characteristic of the particular compound and k_n is a constant. The value of p usually lies between about 4 and 20. In the calculations, it is assumed that all nuclei of a given compound are of the same size.

Calculation of the Composition of the Aqueous Phase

The most difficult part of the calculations for any given point in time involves the determination of the composition of the aqueous phase. In the terms used by DeTar, the aqueous phase is "a steady state intermediate" whose composition changes at a rate which is very low compared with the rates of change of the quantities of the solid phases in the system. This makes it difficult to use a material balance based on solution and precipitation calculations to calculate the composition of the aqueous phase. A more satisfactory method is to calculate the composition of the solution from the knowledge that its rate of change with time is close to zero. In this procedure, the rates of solution and precipitation of the solid phases at the point in time are calculated as functions of solution composition using the previously calculated surface area values, and then selecting the solution composition which minimizes the sum of squares of the relative rates of change of the concentrations of the ions in solution. Although the concept is straightforward, the calculations required are lengthy and account for the greater part of the computations.

Calculation of Physical and Mechanical Properties

Examples of the physical and mechanical properties which the model may be used to interpret are heat liberation, porosity, viscosity, and modulus of elasticity.

The calculation of the heat liberation as a function of time requires a knowledge of the molar heat contents of the individual phases in the system. Then the total heat content of the system at a point in time is given by the equation:

$$H = \sum_{1}^{n} N_i \cdot \tilde{H}_i \qquad (4)$$

where N_i is the number of moles of phase i in the system and $\tilde{H}_i$ is its molar heat content. The rate of heat liberation is calculated as the rate of change of the heat content of the system with time.

The viscosity n at moderate rates of shear can be related to the volume concentration of solids in the system using one of the well-known equations for the viscosity of concentrated suspensions. The volume concentration ϕ is calculated from the previously calculated weights of solid and water in the system at the particular point in time. While it is not yet known which viscosity equation is best suited to the case of cement paste, the one used in the present form of the model is the Mooney equation (12):

$$\eta = \eta_0 \exp\left(\frac{2.5\phi}{1 - k\phi}\right) \qquad (5)$$

In this equation, η_0 is the viscosity of the liquid phase and k is a constant.

Whereas the volume concentration of solid in the liquid governs the viscosity and other flow properties, the porosity of the system plays a major part in governing mechanical properties such as elastic moduli and compressive strength. The proosity is the fraction of the volume within the outer bounds of the mass which is not occupied by solid. Thus, the pores may be filled with water or air. Since the overall volume of a cement paste seldom changes more than a small fraction of 1 percent during hydration, the proosity ε at a point in time may be calculated from the expression:

$$\varepsilon = \frac{\text{volume of solid in system at the given time}}{\text{initial volume of system (solid + liquid)}} \qquad (6)$$

The porosity calculated in this way is used to calculate changes in the modulus of elasticity E using the equation:

$$E = E_0 \cdot (1 - \varepsilon)^3 \qquad (7)$$

where E_0 is a constant which may be interpreted as the modulus for zero porosity (3).

Application of the Model to the Case of C_3S Hydration

Calculations using the model have been made for a few hypothetical cases in which the hydration of C_3S* was considered to be represented by the equation:

$$2Ca_3SiO_5 + 5H_2O \longrightarrow Ca_3Si_2O_7 \cdot 2H_2O + 3Ca(OH)_2 \qquad (8)$$

The calculations differed in the values chosen for parameters such as the rate constants for solution, nucleation and growth, and I_{sat} for the solid phases. This approach, which was dictated by the lack of information about the actual values of the parameters, gave an insight into the sensitivity of the calculations to the choice of values.

An example of the results obtained is illustrated in Figs. 2 and 3. Only one set of calculations is represented since the work has not progressed sufficiently far for any critical evaluation to have been made. The values of the parameters used are given in Table 1. The axes of the curves in Figs. 2 and 3 have linear scales, but they are not marked in absolute units since, in view of the arbitrary choice of parameters for the calculations, these would not be meaningful. However, the curves do share a common time scale and may be compared with each other.

Table 1. *Values of parameters used in the illustrative calculations*

	C_3S	$C_3S_2H_2$	$Ca(OH)_2$

Discussion

Because the calculations represented in Figs. 2 and 3 merely represents an early attempts to simulate the hydration of a cementing material using a computer, the forms of the curves shown should not be considered to have great significance. What is significant is that the curves illustrate how physical, chemical and mechanical changes taking place in an hydrating cement can be interrelated. The capability of being able to relate so many different aspects gives hope of obtaining improved insights into the interrelationships between them.

Referring to Fig. 2, the changes in the weights of the solid phases with time shows several expected features such as an initial "dormant" period followed by a period of increasing rate of reaction. A wide range of control over the length of the dormant period and over the steepness of slope of the curve can be exercised through modification of the input parameters. However, in its present form, the model does not appear to have the capability of accounting for experimental data for the hydration of C_3S such as that obtained by de Jong, Stein and Stevels (13). de Jong's data showed the induction or dormant period to be followed by a period of fast reaction and a still later period of prolonged slow reaction. These findings were interpreted in terms of a sequence of reactions in which hydrated calcium silicates with different C/S ratios were formed and de Jong *et al* postulated that these products have different retarding effects on the hydration of C_3S. While the present model does not take into account effects such as those postulated by de Jong, such effects could easily be included in future versions of the model.

The relationships between the changes in weights of the solid phases and other variables such as the number of particles of the products, heat liberation and the porosity and volume concentration of solids in the system is apparent from Figs. 2 and 3, but the curves showing concentrations of ions in solution have a shape which is unexpected in the light of Lawrence's experimental data (14) for hydrating cements. However, the forms of these curves are particularly sensitive to the values of the input parameters and should not be considered as necessarily being representative.

The calculated values lead to an initially high rate of nucleation of the product compounds which is followed by a continuing period of growth without significant nucleation.

It is clear that no precipitation of reaction products can take place without the formation of particles of the compounds by nucleation, and this is consistent with results shown in the third frame of Fig. 2.

The first set of curves in Fig. 3 are closely related to the changes in weights of the compounds, and show no unexpected features. The curves for the volume of solids and the volume concentration of solids are closely similar, but they would diverge more if the calculations had been for a lower water/cement ratio than 0.6. From the calculated volume concentration of solids and the porosity, the calculations of viscosity and modulus of elasticity shown in the lower portions of the figure were made. The results indicate that the viscosity of the system increases markedly with time as a result of the volume concentration of solids increasing. This effect would be related, at least in part, to the setting of cement systems. Little can be said about the calculated curve of the modulus of elasticity except that the calculations are only likely to be useful for rigid systems. Thus, calculations of the modulus for early ages are unlikely to be of value, just as calculations of viscosity at late ages when the system is rigid are also of little value. The modulus increases with time because of the decreasing porosity. The changes in the modulus would be much more marked if the calculations had been made for a lower water-cement ratio. This draws attention to the fact that one of the uses of this and similar models is to attempt to predict the effects of changes of water/cement ratio, compound composition, particle size distribution and other variables on the performance of cement-containing systems and it will also be useful in aiding the design of experiments to test the predictions. In addition, the predictions will raise questions about the chemistry and physics of cement hydration which may stimulate research to answer them. An example of such a question concerns the nature of nuclei and the role of nucleation in affecting cement performance.

In conclusion, the advantages which a mathematical model offers to the individual researcher or cement technologist are

(a) A self-consistent, easily modified, representation of the state of knowledge concerning cement performance.
(b) An ability to test the implications of new concepts concerning cement performance.
(c) An aid to the planning and interpretation of research work.
(d) An educational tool for the teaching of concepts relevant to the understanding of cement behavior.

While it must be emphasized that the success which any general model will have in the prediction of cement performance from fundamental physical and chemical properties may be limited, there can be no doubt that such a model is an important aid to understanding. This is particularly true when the model is used as an evolving representation of the state of knowledge and is improved whenever its shortcomings are identified.

Summary

In this paper, we have shown how a general mathematical model for the hydration of cement and other materials can be developed. The model has been outlined and its use illustrated by calculations depicting the hydration of C_3S. The calculations were based on a single set of somewhat arbitrarily chosen parameters and are not expected to approximate closely to the real system. While the application of the model to the interpretation of real data has not been attempted, the results of the calculations have been discussed with reference to data in the literature and to known features of cement performance.

Supplementary Paper II-53 Study on Hydration of Alumina Cement by Ultrasonic Method

Shigeaki Koide and Keiko Okada*

Synopsis

Change in the mechanical property of alumina cement during hydration process was searched continuously by tracing the velocity of ultrasonic wave propagated through neat paste of the cement.

For the hydration of the cement paste a paraffine-made vessel was prepared which was a long parallelepiped and had a couple of transducers made of $BaTiO_3$ facing each other on both ends of the vessel. They were electrically connected with an electric oscillator as well as an amplifier followed by an oscilloscope. Generated power from the oscillator vibrated the specimen to propagate sonic wave between both the transducers, and finally a sinusoidal mode appeared on a screen of the oscilloscope. When the oscillator was directly connected with the oscilloscope, however, a similar mode was obtained having a phase different from the former. From the phase difference relating to the time necessary for the propagation of sound, sound velocity (v) could be obtained as follows:

$$v = l/(n\mathrm{T}_0 + \Delta\mathrm{T}),$$

where l is distance between both transducers, n is number of waves standing within both ends of the specimen, T_0 is period of vibration, and ΔT is phase difference, respectively.

At first the velocity in the paste was mostly constant for several hours, the value being near to that in water. After gradual increase in the next period, the velocity increased steeply and reached the constant value, both the period length and the final velocity depending on hydration temperature.

Mechanical strength was predicted on the basis of Young's modulus calculated from sound velocity of the hardened specimen. Between the above obtained result and that of crushing test carried out on corresponding specimen, a fairly good agreement was found out. Thus the progressive change in sound velocity in hydrating cement shows the hardening process. A time when the sound velocity has reached a saturated value, i.e., the hardening time, is more important to estimate the strength development of alumina cement than so-called setting time.

Introduction

There have been many studies dealing with hydration of alumina cement, and some proper phenomena appearing in early stage, e.g., remarkable heat evolution, sudden decrease of electric conductivity, etc., have often been discussed in comparison with rapid hardening of the cement (1). A number of studies on various crystalline and amorphous hydration products have made clear their structures as well as their crystallization processes depending on conditions, e.g. temperature, water-to-cement ratio, that were much influential on early strength development (2). Recently the early developed strength was discussed in quite a few studies, referring not only to hydrates produced in early stage of hydration, but also to their conversion in each other (3). Although the early strength was considered to be due to chemical reaction accompanied with heat evolution, very few has been reported on correlation between mechanical and chemical properties at the very early stage of hydration of the cement (4). In the present investigation a set of direct measurements of mechanical properties changing in the hydration process were carried out by means of ultrasonic method. The change in mechanical properties was continuously searched by tracing the velocity of ultrasonic wave propagated through the neat paste of the cement.

Although ultrasonic wave has well been used in many studies on cement and concrete (5), e.g., non-

*College of Technology, Seikei University, Tokyo, Japan.

destructive test on strength, non of the results reported hitherto has concerned such a slurry or muddy state that had been found in very early stage of hydration. The reason is considered to come from the fact that it was difficult to measure sound velocity in a muddy substance continuously which change entirely into solid. In the present work it was the most important subject to establish a method to transduce the sonic wave into the specimen and to pick it up out of the specimen as well as to keep off any trouble preventing a stable propagation during the hydration.

The sound velocity in the neat paste of the cement increased to the saturated values depending on conditions of hydration, the elastic modulus derived from the velocity showing the correspondence to mechanical strength of the hardened cement paste. And this happened coincidentally with the characteristic heat evolution as well as the sharp drop of electric conductivity.

Specimen, Apparatus and Procedures

Specimen

Through the whole experiment one of the commercial alumina cements produced by electro-fusion was used as specimen, the chemical composition being illustrated in Table 1. In preliminary experiment, however, some pure calcium aluminates prepared from chemical reagents, $CaCO_3$ and Al_2O_3, were also used in addition to the cement above mentioned. The specimen was confirmed to consist of $CaAl_2O_4$ in great majority and of $12CaO7Al_2O_3$ and $4CaOAl_2O_3Fe_2O_3$ as minor portions, although glassy or amorphous parts could not be inspected since the mineralogical inspection was carried out only by X-ray diffraction on the cement powder.

Physical properties of the specimen were shown in Table 2 and 3 which were obtained by the test based upon JIS-R-5201. Hydraulic strength and setting time of neat paste specimen were measured at several levels of curing temperatures and water-to-cement ratios to compare them with data on mechanical properties which would be obtained in later.

15>	32.24				

Apparatus and Procedures

Behavior of sound propagation in a substance is generally different depending either on its physical state, or on mechanical properties. There was obtained on the other hand, a set of close relations between mechanical strengths and elastic moduli of hardened alumina cement (6). Since the experiment searching early strength development was desired to be carried out by means of continuous and non-destructive measurement, the velocity of sound propagation through neat paste of the cement was being traced throughout the hydration process.

A couple of tansducing elements made of $BaTiO_3$ crystal were used both to propagate sonic wave into the specimen and to pick it up out of the specimen. Both the elements had high directional characteristics that was necessary for efficient transducing and good prevention of sonic wave from dispersion in the specimen.

For the hydration of the cement paste a parallelepiped vessel was prepared which was 15 cm × 2 cm × 2 cm on the inside and had a couple of $BaTiO_3$ elements facing each other on both ends of the vessel.

28 〃	75.4	671

Flow value 210 (mm) w/c (%) 60

The vessel was made of paraffine in which the sound velocity was lower than that in the cement paste. Thermally molten paraffine was poured into a steel mold and cooled to make the vessel into the long parallelepiped. Ratio of length to cross section of the vessel was so large that sonic wave was propagated through the specimen in longitudinal mode.

The transducers were electrically connected with an electric oscillator and an amplifier followed by an oscilloscope respectively. The arrangement was shown in Fig. 1. Thus, generated electric power from the oscillator vibrated the specimen with frequency ranging from 30 to 40 kc to propagate the sonic wave between both the transducers, and finally a sinusoidal mode appeared on a screen of the oscilloscope. Electric signal generated in a pick-up (one of $BaTiO_3$ elements) had the mode somewhat different from the perfect sine-wave because of unavoidable dispersion and reflection of sound in the specimen. So, such an amplifying circuit as a cathod-follower type was used to amplify the signal with high S-to-N ratio. The main amplifying circuit was shown in Fig. 2.

When the oscillator was directly connected with the oscilloscope, however, a similar mode was obtained having a phase different from the former. The phase

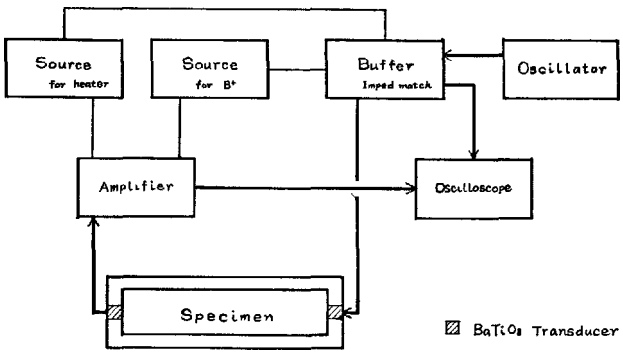

Fig. 1. *Arrangement of circuits on measurement of sonic wave*

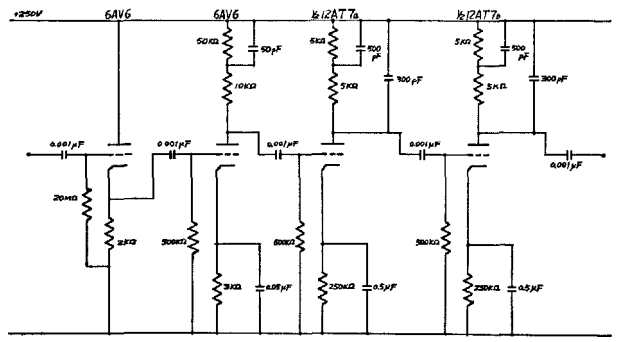

Fig. 2. *Amplifying circuit*

difference (ΔT) was obviously to correspond to the time necessary for the propagation of sound through the specimen. So, the sound velocity (v) in the cement paste could be obtained as follows:

$$v = l/(nT_0 + \Delta T),$$

where l is distance between both transducers,
T_0 is period of vibration, and
n is number of waves standing within both ends of the specimen.

The relation among v, l, T_0 and ΔT was shown in Fig. 3 schematically. ΔT was exactly measured on the oscilloscope and n was determined in preliminary experiment in which the relations of n to l had been obtained at the various distances.

After the transducers were molded in both ends of the vessel, it was put into a case in which temperature was controlled within 20 ~ 35°C with an accuracy of $\pm$0.05°C and relative humidity was kept over 85%. The control was carried out by means of both the electric heater and the coolant set in water stored at the bottom of the case. Alumina cement powder and water previously stored in a thermostat at the same temperature as that in the case were mixed with each other by a series of water-to-cement ratios ranging from 0.24 to 0.30. The mixture was kneaded for about 3 min., and poured into the vessel with a slight tapping. The progressive change in phase of mode of ultrasonic wave propagated through the specimen was recorded in photographs that were taken at regular intervals until the specimen hardened completely. The whole apparatus was shown in Fig. 4.

A couple of electrodes, on the other hand, made of copper plate with area of 2 cm × 3 cm was inserted in the specimen along the side walls of the vessel so as to face each other in parallel to the path of sonic wave as shown in Fig. 5. Applying alternative current between both the electrodes, electric conductivity of the specimen was continuously kept in an electronic recorder. The progressive change of the conductivity

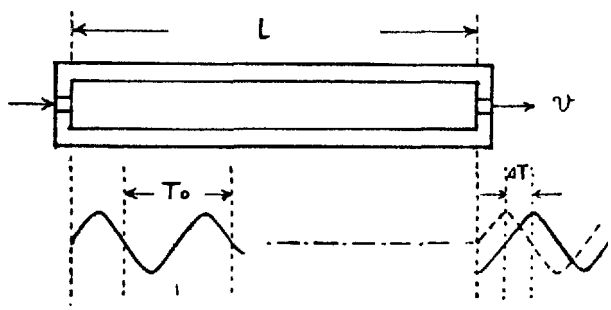

Fig. 3. *Phase difference of sonic wave induced by propagation through specimen*

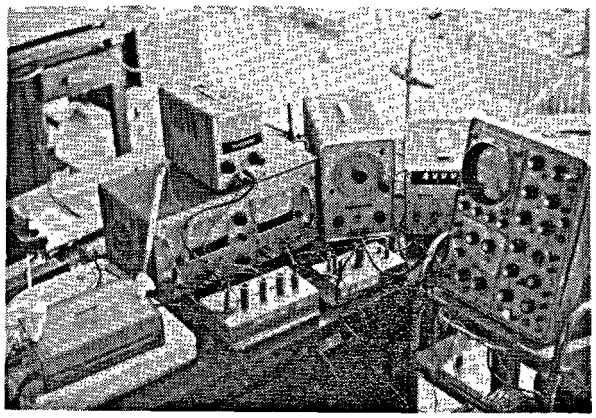

Fig. 4. *Bird's-eye-view of apparatus*

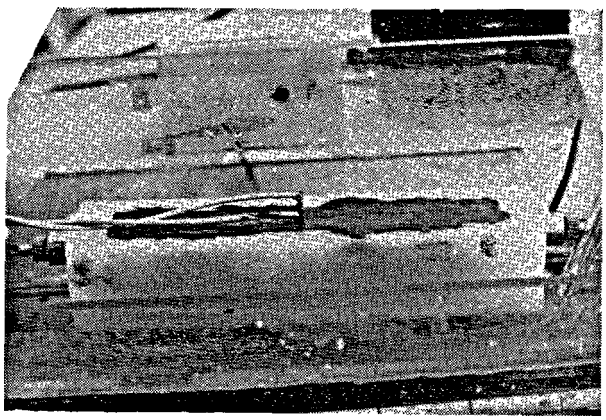

Fig. 5. *Electrodes inserted in vessel*

was measured simultaneously with that of sound velocity during hydration. Since it was avoided in the experiment to electrolyse the specimen, data were not obtained on D. C.—conductivity, but on admittance accompanied with capacitance. Keeping track of characteristic change in electric impedance of the specimen was of good use in this work even if the capacitance could not be measured separately. Therefore, voltage drop generated by alternative current flowing through the specimen was traced during hydration.

Results and Discussion

Sound Velocity

Characteristic patterns of progressive changes in sound velocities propagated through the specimens were obtained throughout the hydration. Fig. 6 showed both the modes of propagated (lower) and standard (upper) sonic waves on a dual beamed screen. The phase difference scarcely changed during the first 2 hours. Through a gradual increase the difference became rapidly greater. The velocity was mostly constant for the first period, the length of which was different depending on hydration temperature and water-to-cement ratio; the value of the velocity was near to that in water, about 1,400 m/sec. After a gradual increase in the second period, the velocity rose up suddenly, then reached again a constant value. Both the length of the second period and the final velocity were also dependent on hydration conditions, the values of them falling into $2 \sim 10$ hours and $2{,}400 \sim 4{,}600$ m/sec respectively.

Effect of Water-to-Cement Ratio

When specimen were prepared with water-to-cement ratio lower than 0.28, it was difficult to obtain sharp modes of sonic wave on the oscilloscope because the specimens were not sufficiently plastic to be molded homogeneously enough for stable propagation of sound. As for the specimens with water-to-cement ratios ranging from 0.28 to 0.30, measurements of the velocities were easily carried out and their progressive changes similarly appeared with a little differences depending on the ratio. The dependence of the pattern of progressive change in sound velocity on water-to-cement ratio was not so remarkable compared with that on hydration temperature. Therefore, the further experiments were carried out on the specimens with constant viscosity (or workability) irrespective of water-to-cement ratio.

Temperature Dependence of Progressive Change in Sound Velocity

Change in sound velocity during hydration was so much influenced by temperature as were periods of heat evolution and of setting as well as of strength development. The temperature dependence was obviously much more remarkable than that on water-to-cement ratio. In Fig. 7 each pattern of progressive change in sound velocity was shown as a function of hydration time with hydration temperature as a parameter. The characteristic increase of the velocity retarded with the increase of hydration temperature up to 30°C, at which the retardation reached the maximum. Over this temperature, on the other hand, the period of velocity-increase became earlier again. At

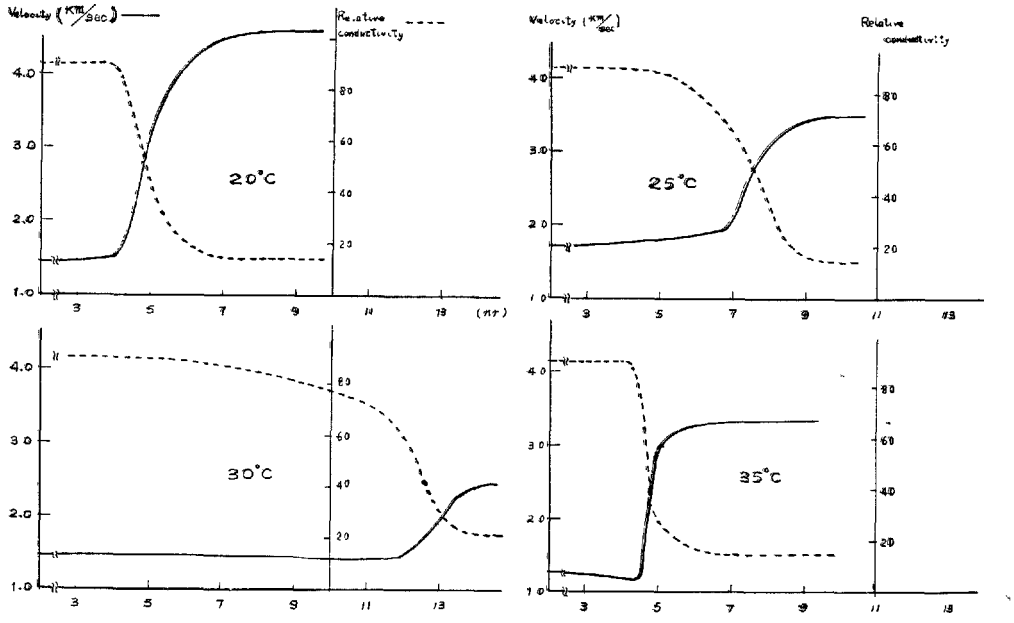

Fig. 7. *Sound velocity and electric conductivity in specimen as functions of time*

30°C, the slope of the velocity-increase became the smallest. Comparing these results with those previously reported (8), it was found out that correlation between the progressive change in sound velocity and hydration temperature closely resembled that between heat evolution and the temperature.

Electric Conductivity

During hydration of the specimen, electric conductivity decreased in characteristic manner depending on hydration temperature. The patterns of change in the conductivity were exactly same as those obtained previously (1). At 20°C, like the sound velocity, electric conductivity decreased scarcely for the first several hours, then sudden drop appeared after which the conductivity reached very low constant value. It is of interest that the time when the sudden drop appeared was exactly coincident with the sudden increase in the sound velocity.

When hydration proceeded at temperatures merely below 30°C., electric conductivity began to decrease gradually after the first period in which no change in the conductivity was found. Decrease in the conductivity continued thereafter with the slope becoming progressively steep, and finally the low constant value was reached. At 30°C, change in the conductivity was the most gradual without such a sharp drop as found at 20°C, although the steepest slope was recognized at a time about 12.5 hours after the beginning of hydration.

Since the electric conductivity was measured using alternative current, obtained data showed somewhat lower value of impedance than pure resistance against D. C.—current. The latter was usually 2~7 times as large as the former. It should be noted that the hardened specimen showed capacitance ranging from 100 pF to 0.01 μF, which was remarkably large compared with those reported on ordinary concrete (7).

At every hydration temperature, the coincidence of characteristic drop in electric conductivity with proper rising in the sound velocity was preserved as shown in Fig. 7. This fact suggests that characteristic change in mechanical properties of alumina cement during hydration exactly corresponds to chemical change.

Young's Modulus and Mechanical Strength

In the present work, sonic wave propagated through the specimen could be considered to be longitudinal wave, since the vessel used for measurement was a long parallelepiped. Therefore, the elastic constant regarded as the function of the obtained sound velocity is "volume modulus" until the specimen hardens, and is "Young's modulus" after hardening. For the sake of simplicity, we used Young's modulus to discuss the mechanical properties of the cement paste through-

Table 4. *Sound velocity and Young's modulus in neat paste of alumina cement during hydration*

Temperature (C°)	Time (hr)	3	4	5	6	7	8	9	10	11	12	13	14

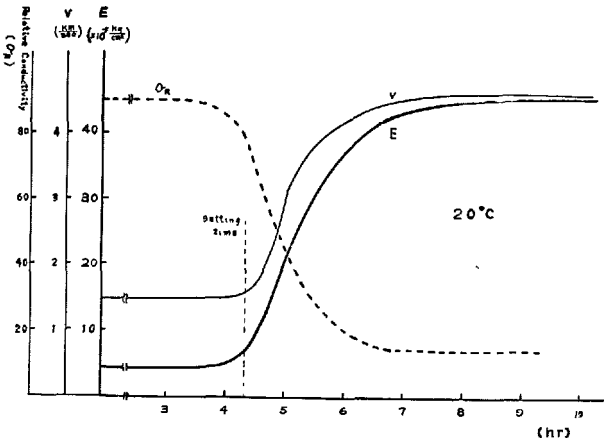

Fig. 8. *Correlation between Young's modulus and hydration time*

out the hydration process, since the latter could approximately take the place of volume modulus. Young's modulus of the specimen was derived from

$$E = \rho v^2,$$

where E is Young's modulus,
ρ is bulk density of specimen, and
v is velocity of longitudinal sonic wave in specimen.

Using the bulk density of specimen known to be 2.0 g/cm^3 at the beginning of hydration and finally to become 2.1 g/cm^3, Young's modulus of the cement paste was calculated at the various hydration temperatures as shown in Table 4. Young's modulus calculated from sound velocity and electric conductivity were shown in Fig. 8 as functions of time during hydration at 20°C. The modulus reached the final value of ca. 4.28×10^5 kg/cm^2 corresponding to the final velocity of sound. The coincidence of the characteristic period of change in Young's modulus with that in electric conductivity was, of course, preserved.

In our previous study (6), it has been found out that there were fairly good correlations between crushing

Table 5. *Correlation between predicted and measured strength*

Hydration temperature (°C)	Predicted strength (kg/cm^2)	Measured strength (kg/cm^2)	Hardening time (h-m)
20	800≦	675	7–20
25	450～500	420	9–15
30	150～200	141	13–40
35	390～440	378	6–40

strengths of hydrated alumina cement and their Young's moduli irrespective of hydration conditions. On the basis of the results mechanical strengths of the specimens were predicted from their Young's moduli. After the experiments, on the other hand, the hardened specimen were subjected to crushing test. Both the predicted and the measured strengths of the specimens hydrated at various temperatures were shown in Table 5. There were a fairly good agreement between them so that the estimation of the strength by ultrasonic method seemed to be possible even in early stage of hydration of alumina cement. Thus, it is clear that sound velocity propagated through the neat paste of alumina cement corresponds to its mechanical strength that is being developed during hydration, and that the progressive change in the velocity shows the hardening process of the cement.

The setting time was also different with hydration temperatures as shown in Table 2, the temperature dependence being similar to that of the saturation time of sound velocity. Comparing the final setting time with the saturating time of the velocity at each temperature in Fig. 7, however, it was difficult to find out quantitative relations between both the times. Therefore, a time when the sound velocity has reached a saturated value is considered to be more essential to the strength development of alumina cement than the setting time.

It was shown that alumina cement hardened within a short period accompanied by rapid increase in sound velocity as well as sharp drop of electric con-

ductivity which had been reported to coincide with a remarkable heat evolving time in the hydration process of the cement (8). This leads to the fact that all the characteristic properties change coincidentally with each other during hydration. On the basis of the experimental results, we propose that the hardening time be defined as a time when sound velocity in the cement paste has reached a saturated value. The hardening time is considered to be of more useful as a measure of strength development in alumina cement than the setting time.

Conclusion

To investigate the process of early strength development in alumina cement, a set of experiments were carried out measuring sound velocity in neat paste of the cement during hydration. For the measurement a method was established to transduce the sonic wave into and out of the muddy specimen that changed into solidus state during hydration, as well as to keep a stable propagation.

The progressive change in the sound velocity was obtained at each hydration temperature of 20°, 25°, 30° and 35°C. The velocity changed scarcely at first, gradually in the next period and then suddenly rose up to the saturated value, the manner of change and the final value depending on hydration temperature. The change proceeded more slowly with rising hydration temperature below 30°C, above that the change became faster again. The pattern of change in the velocity closely resembled that of electric conductivity and the final period in both patterns were exactly coincident.

Mechanical strength was predicted on the basis of Young's modulus calculated from sound velocity of the hardened specimen. The results was compared with that of crushing test carried out for corresponding specimen, and a fairly good agreement was found between them. Thus, the progressive change in sound velocity in hydrating cement is considered to show the hardening process. A time when the sound velocity has reached a saturated value, i.e., the hardening time, is more important to discuss the early strength development of alumina cement than the setting time.

Oral Discussion

Renichi Kondo

We are much interested in the use of ultrasonics in cement chemistry, which seems to give some influences on the rate and mechanism of hydration and to be of much interest for practical purposes. The authors showed the relation between the sound velocity and the electric conductivity of each specimens at each curing temperature in Fig. 7. It is considered that the sound velocity is concerned with the structure of hydrated specimens, while electric conductivity show the liquid phase concentration. I would like to know how to understand the relation between these physical and chemical properties and hydration mechanism of alumina cement. Especially, the relative conductivity in early stages is almost constant in many cases. How do you think about the hydration mechanism in relation to this fact?

Authors' Closure

Shigeaki Koide and Keiko Okada

Sound velocity and electric conductivity of alumina cement paste progressively change showing the characteristic pattern as a function of hydration time. On the basis of the pattern the mechanism of hardening process of the cement is considered to be as follows:

When the cement powders contact with water, CA immediately decomposes into calcium- and aluminum-ions on its surface, and some amount of the ions migrate out of the powder with the steep concentration gradient at a vicinity of the surface of the cement powder. While the rest of ions precipitate mostly on the surface of the powder turning into nuclei of CAH_{10} the new ions are produced by the reaction of CA with water diffusing through the surface layer.

The migrating ions seem to be kept in almost constant amount, so that the electric conductivity is also constant in this period, although it is not the case in which water to cement ratio becomes higher or some additives are present in the water. The length of the period (so-called induction period) falls into several hours depending on hydration temperature, water to cement ratio, amount of additives, etc. At the end of the period acicular CAH_{10} crystals are produced which bridge the aggregate with anhydrous cement powders. Then, the paste hardens into the solid with rigid texture, and the remained free water vaporizes due to the heat liberated coincidentally. So, the increase of elastic modulus and drop of electric conductivity occur simultaneously at a time which may be called the hardening time. The time is considered to be more effective aim of strength development of the cement than the setting time.

Supplementary Paper II-70 On the hydration Kinetics of Hydraulic Cements

John H. Taplin*

Synopsis

The hydration kinetics of seven hydraulic cements are explored. They are magnesia in 1.5–0.05 molar magnesium chloride or sulphate solution, anhydrite in potassium alum solution, one β–C_2S preparation without boric oxide and one with it, two preparations of monoclinic C_3S with excess alumina and a triclinic C_3S without excess alumina. From the particle size distributions of six of these cements, hypothetical linear and quadratic kinetics are calculated and used as a guide as to whether the rate of hydration depends on the reacting surface area or on the rate of diffusion of material to or from the surface.

The cements were stirred in some experiments and hardened in others. In all stirred experiments the kinetics are either approximately linear or approximately quadratic. Hardening specimens of magnesia, anhydrite and in final stages C_3S show a rate decay which is even more rapid than quadratic kinetics and which is taken to be controlled by resistance to diffusion through merging and perhaps thickening outer products.

Some aspects of the possible basis for a linear-diffusion kinetics model are treated. For a single discrete particle, for example, it is shown that a diffusion process is unlikely to control the rate either at the very beginning or at the very end of the reaction.

A possible mechanism by which the outward diffusion of a substance could control the rate is postulated and found to lead to joint linear-diffusion control. No direct evidence could be found in the stirred experiments for such a joint kinetics although the possibility exists when the rate is controlled by merging outer products.

Linear rate constants and apparent activation energies are quoted for several of these hydraulic cement systems. The ageing of C_3S preparations was found to slow the diffusion process and refiring to speed it up.

Introduction

The hydration of a hydraulic cement involves the reaction of discrete particles of the cement with an aqueous solution, and the formation of a coherent network of solid hydration products. It has been argued previously (1) that at least the outer products must be formed from material which has been transported by diffusion. Here we will consider the simple alternatives of a rate (i) proportioned to the surface area of cores of unreacted cement and (ii) invesely proportional to the resistance to diffusion provided by a coherent coating of reaction products.

The kinetics of (i) above will be referred to as "linear." The term "diffusion kinetics" will be used for a reaction rate controlled by any diffusion process, "parabolic kinetics" for control by diffusion through one or more layers of products each assumed to have a constant specific permeability and, "quadratic kinetics" for parabolic kinetics with the resistance of the outer products negligible compared to that of the inner products. Linear and quadratic kinetics have been discussed previously in relation to the hydration of β–C_2S (2).

The hydraulic cements to be described here are: magnesia in magnesium chloride and sulphate solution at concentrations below those needed for basic salt formation, anhydrite in potassium alum solution, two preparations of β–C_2S and three of C_3S. To test for linear or diffusion kinetics, the experimental hydration data are compared with hypothetical linear and quadratic curves computed from the measured particle size distribution (p.s.d.) assuming spherical shape and uniform reactivity. Quadratic kinetics was chosen as a test for diffusion kinetics because the inner products might be expected to provide most of the diffusion resistance for isolated particles with coherent coatings. It is also a useful choice in that the effect of a more complex parabolic reaction or other diffusion modifications such as for example a decreasing product porosity can be expected to show up as

*Commonwealth Scientific & Industrial Research Organization, Department of Civil Engineering, Sydney University, Sydney, Australia.

a deviation from quadratic kinetics in the direction of an even more rapidly falling rate, i.e., in the direction away from linear kinetics. Such deviations are to be expected under conditions of high strength since both phenomena are due to the outer products filling most of the space between the original cement particles.

Experimental

The hydration of the calcium silicates was followed by the method of Taplin (1), i.e., the reaction was stopped by vacuum drying, the specimens further dried at 125°C in an atmosphere of steam and the "chemically combined" water determined as the loss on heating to 540°C. For magnesia the procedure was modified by omitting the steam atmosphere in the oven and, for stirred magnesia, by first washing out most of the chloride or sulphate before vacuum drying. The weight loss between vacuum dry and 540°C was the hydration measure for anhydrite. The hydration values assumed for complete reaction are: 0.45 for magnesia, 0.26 for anhydrite, 0.21 for C_2S and 0.25 for C_3S.

Two types of specimen were made. The "stirred" specimens consisted of an aqueous suspension of cement in a glass bottle or tube sealed with a rubber gasket or stopper and attached to a wooden frame rotating about four times a minute. The curing temperature was 21°C and the suspension had a water cement ratio of 5, 8 or 10 depending on the tendency of the cement to stiffen.

The "hardening" specimens were paste specimens unless referred to as mortars. The water-cement ratio (W/C) is quoted by weight. The early specimens were $\frac{1}{2} \times \frac{1}{2} \times 4$ inch bars tested in compression as modified cubes. The anhydrite specimens were $\frac{1}{2}$ inch cubes and the 1967 C_3S specimens were cylinders, $\frac{1}{2}$ inch diameter, $1\frac{1}{4}$ inches high. Only the β-C_2S (5106) specimens at W/C = 0.35 were produced by mechanical compaction in a tamping machine. A vibrating table was used to help remove air bubbles from the more fluid mixes. The earlier specimens were kept saturated by the addition from time to time of a few drops of water to the tube in which they were cured. The cylinders were cured under water. Only the hydration results of these specimens will be discussed here.

The experimental p.s.d. of the cements are plotted on logarithmic probability paper in Fig. 1. For the purpose of computing linear and quadratic kinetics, these data were approximated by double composite lognormal distributions obtained by fitting two lines which meet at the median size and pass through the upper and lower parts of the distribution respectively. This p.s.d. was then treated as a histogram with each step containing one per cent of the powder at a size which was the median in the range. At various hypothetical reaction times, the fraction reacted was computed for each step of the histograms, by interpolating in tables of F versus t/R and F versus t/R^2 construc-

ted from equations (1) and (2) for linear and quadratic kinetics respectively.

$$1 - (1 - F)^{1/3} = k_1 t/R \qquad (1)$$

$$1 - (1 - F)^{2/3} - 2F/3 = k_2 t/R^2 \qquad (2)$$

where k_1 and k_2 were put equal to unity for the computation and then adjusted in attempts to fit the experimental hydration data. The distributions used in the computations can be described by the diameters in microns at the 15, 50 and 84% levels, they are: "fused" MgO 3.45/13.2/51, sintered anhydrite 7/20/44, β-C_2S (5106) 2.8/5.2/24, β-C_2S (5108) 4.8/8.6/34, alite (608) 7.1/23/77, C_3S (620) 5/10.3/29, C_3S (620) re-fired 5/9/22.

Magnesium Oxide

This material is a commercial "fused" magnesia with a chemical analysis of MgO 96%, SiO_2 3.0% and Fe_2O_3 0.4%. It had been ground in a ball mill. One sample of this material was separated into closely sized fractions by use of a cyclosizer (3).

Another sample "B", was analysed for size distribution by use of the cyclosizer, and the Andreasen pipette, the result in Fig. 1 (a) show good agreement.

Powdered magnesia mixed with concentrated solutions of magnesium chloride or magnesium sulphate forms basic magnesium salts which are the basis of sorel cement. However, at concentrations below about 2 molar, the X-ray diffraction patterns of the basic salts disappear and are replaced by that of a colloidal brucite. Although giving less strength than with the basic salts, the system still acts as a hydraulic cement.

The stirred experiments with the various size fractions in 1.25 molar magnesium sulphate show approximately linear kinetics as shown in Fig. 2 which is a plot of curing period versus $1 - (1 - F)^{1/3}$ where F, the fraction reacted, is the ratio of hydration value to 0.44. A logarithmic plot of the slopes of the lines in Fig. 2 versus the mean particle size in Fig. 3 has a slope approaching unity and tends to confirm the linear kinetics. Note that the non-spherical shape of the particles tends to compensate for the non-uniform particle size. Examination of reacted particles from this experiment showed a coherent coating of brucite about the unreacted cores. See Photo 1.

As the concentration is reduced the brucite becomes

more crystalline and at concentrations below about 0.05 molar the rate decays more rapidly than it does for linear kinetics. This phenomena is illustrated by Fig. 4 for both chloride and sulphate. In the region where linear kinetics apply the rate constants are 5.3×10^{-3} and 9.5×10^{-3} microns per hour for sulphate and chloride respectively.

The rate also decays more rapidly than for linear kinetics in hardened specimens. Data for a W/C ratio of 0.40 and 1.25 molar magnesium sulphate are plotted in Fig. 5. The continuous lines are drawn for the purpose of estimating an activation energy of 18 kcal in Fig. 8. They show a rate decay greater than that for quadratic kinetics. The broken line indicates the course of the reaction at a W/C ratio of 0.17 and 42°C. This rapid decay of the rate at low W/C ratios is not due to the specimens drying out because they were kept saturated by the addition from time to time of a drop of water to the tubes in which they were cured.

The way in which the reaction is choked off at low W/C ratios suggests the same explanation that was given for the similar behaviour of portland cement (1), i.e., the reaction rate becomes limited by the rate of diffusion of material to, and of nucleation of products in, water filled voids of above a certain critical size.

The difficulty with this explanation is to provide a mechanism, by which the lack of space in which to precipitate products, can slow down the decomposition of unstable oxide minerals to their thermodynamically more stable hydrated products. This difficulty will be taken up later.

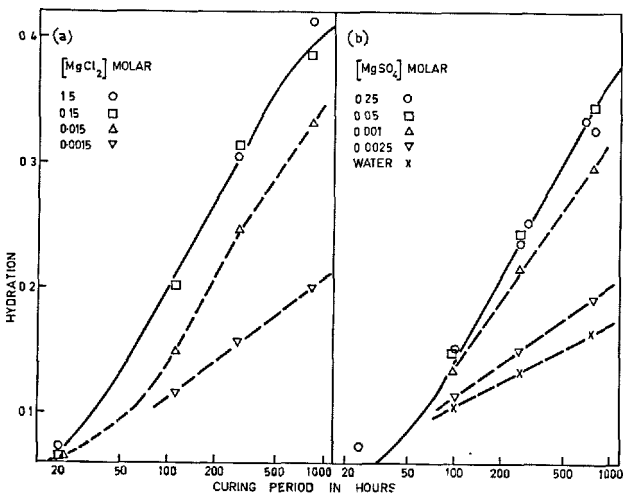

Fig. 4. *The hydration of a magnesia powder in a stirred slurry. The continuous lines represent linear kinetics as calculated for the p.s.d. in Fig. 1(A). The broken lines indicate the more rapidly falling rate at lower concentrations of (a) magnesium chloride, (b) magnesium sulphate*

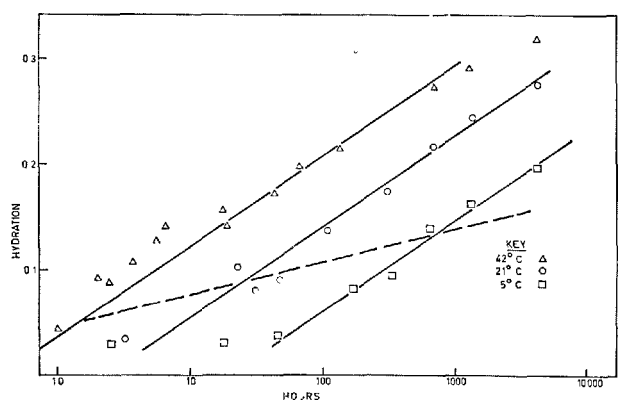

Fig. 5. *Hydration rate of hardening specimens of magnesia with 1.25 molar magnesium sulphate at a W/C ratio of 0.40. The broken line indicates the course of the reaction at a W/C ratio of 0.17 and at 42°C*

Anhydrite

Prepared from A. R. gypsum by adding one per cent of sodium chloride, kneading with water and sintering at 860°C. The chemical analysis is CaO, 40.61; SO_3, 58.60; NaCl, 1.59; SiO_2, 0.08; Al_2O_3, 0.04; MgO, 0.03; Fe_2O_3, 0.02. The material was ground with pestle and mortar and a particle-size analysis was carried out with the cyclosizer. The p.s.d. shown in Fig. 1(b) is probably in error in appearing too disperse at the fine end due to dissolution in the cyclosizer.

A 3% solution of potassium alum was the electro-

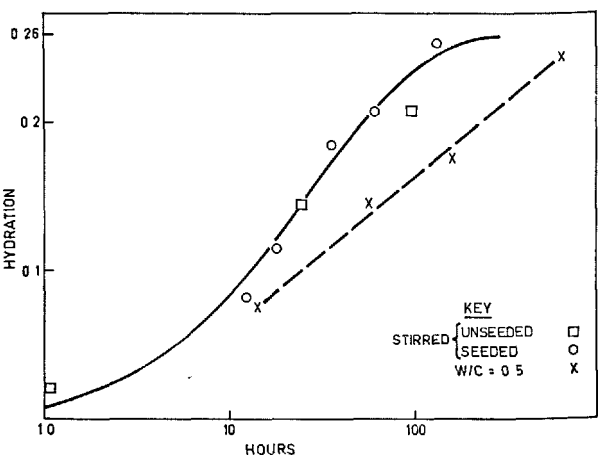

Fig. 6. *Hydration of anhydrite in 3% potassium alum solution. By assuming an induction period of ten and forty hours for seeded and unseeded experiments, stirred hydration approximates to linear kinetics represented here by the continuous line*

lyte used to promote hydraulic activity. The result of two stirred runs are shown in Fig. 6. In the run marked "seeded" 0.25 grams of A. R. calcium chloride were rapidly stirred into 80 mls of 3% alum solution and the resulting suspension of small gypsum crystals used as electrolyte. In order to approximate to the linear kinetics as calculated from the p.s.d. an induction period of ten and forty hours was assumed for the seeded and unseeded experiments respectively. The estimated linear rate constant is 8.5×10^{-2} microns per hour. An error in the fine end of the p.s.d. will not explain away more than an hour or so of the apparent induction period of the stirred experiment. However, it could be due to non-spherical shape and to different rates of dissolution along different axes of the anhydrite crystals.

For hardening specimens the rate decays more rapidly as is shown by the (1:1:0.5 sand, anhydrite, water) mortar specimens in Fig. 6 or by the specimens with a W/C ratio of 0.30 in Fig. 7. The approximation of these 0.3 W/C ratio runs to quadratic kinetics is probably no more than an indication of a diffusion process controlling the rate. Certainly the coarse network of gypsum crystals appears very different from the coherent coating of inner-products which are assumed in calculating quadratic kinetics.

Beta C_2S (5106)

This material was prepared from precipitated silica and A. R. calcium carbonate by a repeated procedure of grinding with pestle and mortar, mixing to a stiff paste with ethanol or water, pressing into small pellets and firing to 950°C. After five cycles the material contained no free lime by White's reagent. The crystal size is very small, but it was estimated that at least 80% of the material had a refractive index above 1.695. The X-ray diffraction pattern is that of β-C_2S. The p.s.d. obtained from the Andreasen pipette is shown in Fig. 1(c).

The kinetics of stirred specimens is considered with aid of Fig. 9. It will be seen that the rate appears to decay too slowly for linear kinetics and this suggests the remedy previously invoked for anhydrite, of

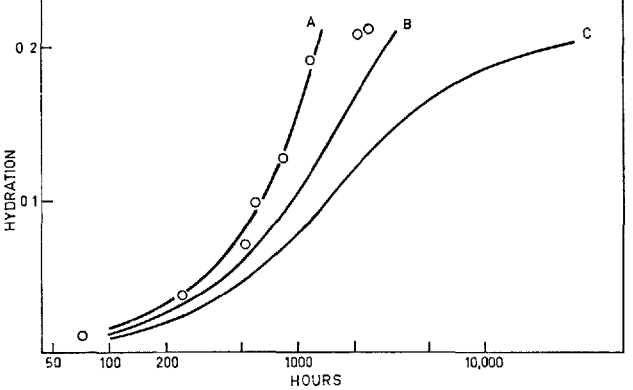

Fig. 9. *Hydration of β-C_2S (5106) in a stirred slurry compared to: (a) constant rate, (b) linear kinetics, (c) quadratic kinetics*

supposing an induction period. However when this is done, the data still give a better fit to constant rate kinetics as in Fig. 10.

The hydration rates of hardening specimens also approximate to constant rate kinetics as is shown in Fig. 11. Without taking this induction period plus constant rate model more seriously than is warranted by the data, it is of interest to note that, by treating the induction period as the completion time of a rate process, we obtain an apparent activation energy of 15 kcal from Fig. 8(b) compared to 9.6 kcal from Fig. 8(c) for the constant rates themselves.

Beta C_2S (5108)

This material was prepared from the same materials as (5106) but with the addition of 0.5% boric oxide which was assumed to replace silica. It was fired four times to 1400°C until White's reagent showed negligible free lime. It was much better crystallized than 5106, but had a very similar X-ray diffraction pattern. The p.s.d. obtained by Andreasen pipette is indicated in Fig. 1(d).

Fig. 12 suggests that linear kinetics fit the hydration of stirred specimens better than either constant rate or quadratic kinetics.

At a W/C ratio of 0.525 and curing temperatures of 42, 21 and 5°C the kinetics are again approximately linear as shown in Fig. 13. The linear rate constants are 41×10^{-4}, 8.5×10^{-4} and 2.8×10^{-4} microns per hour with an apparent activation energy of 13 kcal compared to our previous (2) estimates of 6×10^{-4} microns per hour at 25°C and 16 kcal for a previous β-C_2S which was also stabilized by boric oxide. If allowance is made for the discrepancy for irregular particles between Stoke's law and Feret diameters and for the difference in curing temperatures, the earlier preparation is seen to be reacting at only a third the rate of 5108.

Alite 286

This material was prepared in 1956 from a 99% pure calcium carbonate and 96% pure silica sand. Extra alumina and magnesia were added in an attempt to approach $C_{54}S_{16}AM$. The materials were interground overnight in a ball-mill and fired to 910°C. The powder was pressed into 2 inch diameter pellets, fired to 1500°C, cooled and reground. After three cycles of this treatment there was little free lime. Many particles had small inclusions which are thought to be C_2S. A chemical analysis gave the overall composition $C_{53}S_{16}A_{1.06}M_{0.53}F_{0.05}$. Both the X-ray diffraction pattern and a single endotherm at 835°C in the first D.T.A. heating cycle indicate (4), (5) a monoclinic crystal structure.

Two hydration experiments at a W/C of 0.525 were made with this material. The runs of 1956–7 are shown in Fig. 14. Simplifying the figure by means of the reference lines does not hide the complicated movement of the temperature coefficient of the rate which is first positive, then negative and finally approaches zero. The experiments of 1959 were undertaken to see if ageing slowed the reaction and if reheating would restore the rate. Fig. 15 shows that, although reheating to 540°C increased the rate by about a quarter, both experiments have similar kinetics. It seems that only at very early ages and low temperatures can the reaction be linear. For the test of the reaction the rate falls rapidly suggesting a diffusion or precipitation controlled reaction. Lack of a measured p.s.d. precludes a more detailed analysis of these experiments.

Alite 608

Prepared in 1959 by methods similar to those described for Alite 286 from precipitated silica and A. R. calcium carbonate, alumina and magnesia. The chemical analysis of this material can be written $C_{54}S_{16}A_{1.0}M_{0.8}F_{0\ 02}$. D.T.A. runs were made in 1960 and on untreated material in 1967 with the same result. Endotherms at 770 and 840°C were found in the first heating cycle but only the second endotherm occurred in later cycles. The first endotherm and a weight loss of 5% above 540°C are ascribed to carbonation of the aged material. The X-ray diffraction pattern indicated a monoclinic structure. A small region of this pattern is shown in Fig. 16. The p.s.d. is shown in Fig. 1.

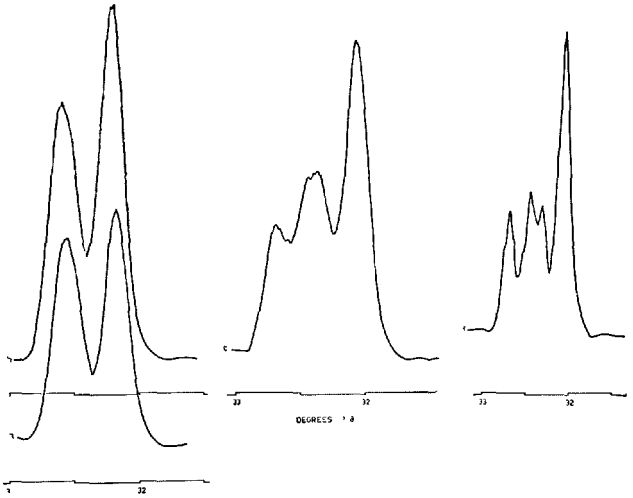

Fig. 16. *A small but characteristic portion of the X-ray diffraction pattern of the tricalcium silicate phase*
(a) alite (608) untreated, 1967; (b) alite (608) refired 1400°C, 1967; (c) C_3S (620) untreated, 1967; (d) C_3S (620) refired 1400°C, 1967

There are three sets of experiments: (a) those of 1960, (b) those with untreated material in 1967, (c) those with material re-fired to 1500°C in 1967. No change in X-ray diffraction pattern was detected except that re-firing had reduced the intensity of the very weak calcite pattern. Patterns (b) and (c) were prepared much more carefully than was pattern (a). There was insufficient of (c) for a full particle size analysis but it is probably very similar to (b) since the percentages passing a 30 micron sieve are 52 and 50 respectively.

From Fig. 17 it will be seen that the kinetics of (a) and (c) are linear but those of (b) are quadratic. The linear rate constant of (a) is 1.25×10^{-2} microns per hour.

Fig. 18 shows that hardening specimens react as they did when stirred except that now, as the water voids fill with outer products, a diffusion or precipitation process controls the rate for the last 30 or 40% of reaction. The apparent activation energies of the linear portions of (a) and (c) are found from the plots of Fig. 8(e) and (f) to be 8.5 and 9.7 kcal respectively.

C_3S (620)

This material was prepared from precipitated silica and A. R. calcium carbonate by repeated pressing to pellets, firing to 1500°C and grinding with pestle and mortar. The chemical analysis can be written $C_{3.06}SA_{0.005}M_{0.003}F_{0.0006}$. A D.T.A. run in 1960 gave sharp endotherms at about 920 and 970°C on heating and exotherms about 30° lower on cooling. Another run on untreated material in 1967 gave the same behaviour plus an additional endotherm at 780°C for the first heating cycle only. A Tα pattern was obtained by X-ray diffraction in 1960 and for untreated material in 1967.

The experiments fall into the same three groups as did those of alite (608): (a) 1960, original material; (b) 1967, untreated material; (c) 1967, material re-fired to 1400°C. The original and re-fired material have similar p.s.d. as can be seen from Fig. 1(f) and (g). However, re-firing has produced a Tβ X-ray diffraction pattern. Fig. 16 compares alite and C_3S patterns at 32° 2θ for CuKα.

The stirred hydrations all approximate to quadratic kinetics as shown by Fig. 19. The rate constants of (b) and (c) are only 27 and 36% of (a) and this represents a substantial change in rate without a change in kinetics.

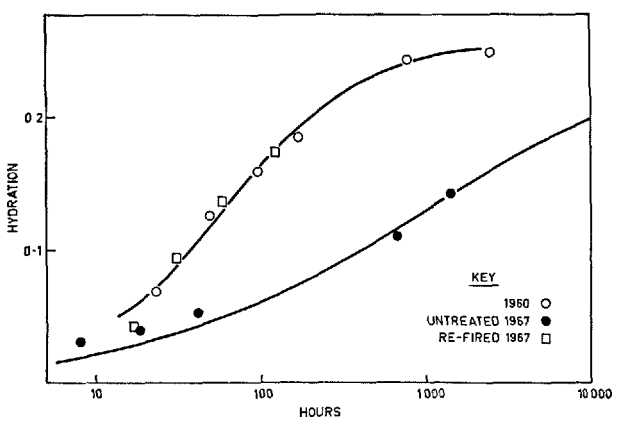

Fig. 17. *Stirred hydration of alite (608). The lines (A) and (B) are linear and quadratic kinetics respectively, they are calculated from the p.s.d. of the untreated material*

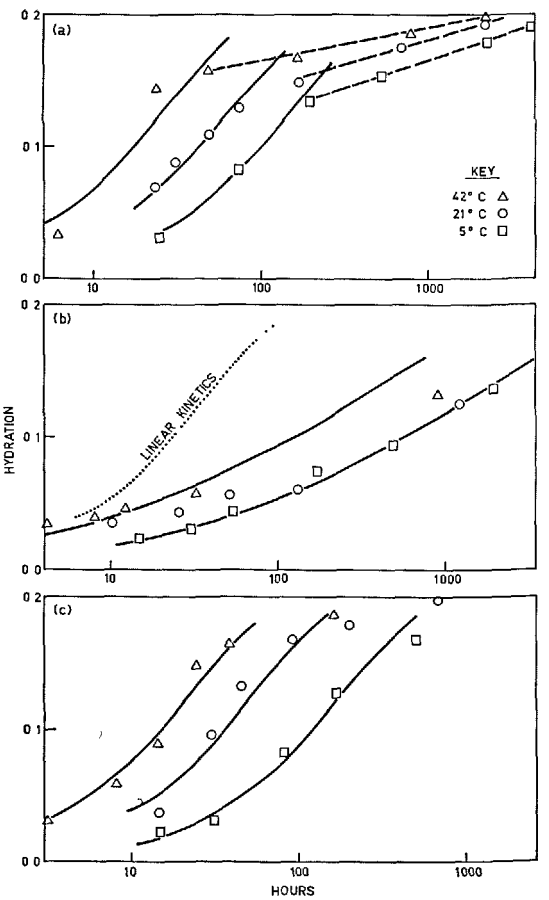

Fig. 18. *Hardening specimens of alite (608)*

(a) the 1960 runs at W/C ratio of 0.35. The continuous lines represent linear kinetics for this p.s.d.

(b) the 1967 runs for untreated material at W/C ratio of 0.436. The lines are for the quadratic kinetics of this p.s.d.

(c) the 1967 runs with re-fired material at W/C of 0.367. The lines are for linear kinetics of the p.s.d. of the untreated material.

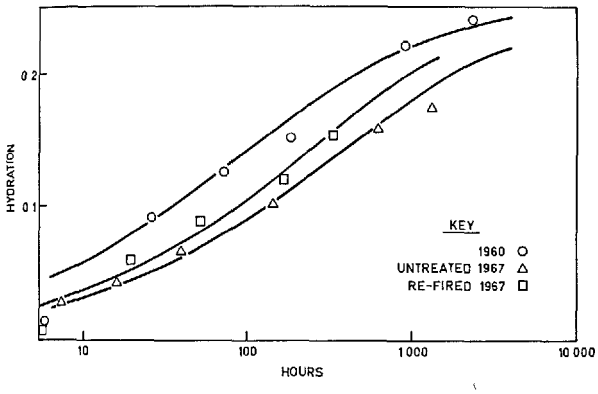

Fig. 19. *Stirred hydration of* C_3S *(620) compared with quadratic kinetics as calculated from the relevant p.s.d.*

Fig. 20 shows that the hydration kinetics of hardening specimens is again approximately quadratic, with the rate falling even more rapidly as the reaction approaches completion. The kinetics of (a) and (c) are similar to those of alite (286) in that the curves are initially separated but merge later. There is also the same suggestion of linear reaction at early ages and lower temperatures. The kinetics of (b) are different because there is no suggestion of an early linear reaction and yet the temperature coefficient remains fairly large. The apparent activation energy from Fig. 8(g) is 7.4 kcal. This aged material like that of alite (608) has a weight loss of 5% above 540°C which is ascribed to carbonation, although the calcite pattern is barely detectable.

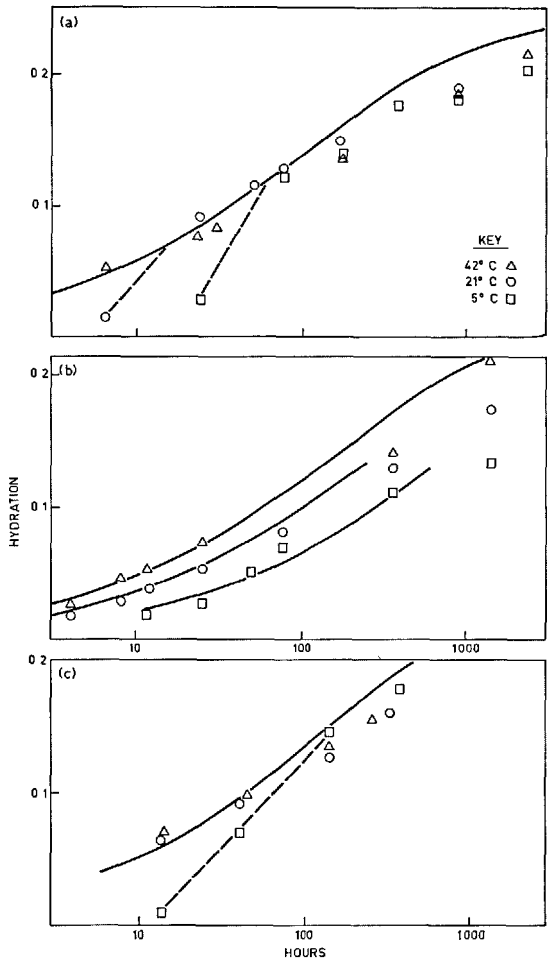

Fig. 20. *Hardening specimens of* C_3S *(620). The continuous lines represent quadratic kinetics as calculated from the relevant p.s.d. The different experiments are shown as follows:*
(a) 1960, W/C = 0.40.
(b) 1967 untreated material, W/C = 0.50.
(c) 1967 material re-fired to 1400°C, W/C = 0.50.

Discussion

For stirred experiments where the particles can be considered as reacting without interference from their neighbours, the data are consistent with either linear or quadratic kinetics except for β–C_2S (5106) where the rate decays too slowly for even linear kinetics. The lack of an effect for W/C ratio suggests that the constant rate process is not a homogeneous reaction in solution. However the presence of an induction period for this material indicates a process which accelerated the rate. If such an effect were to continue throughout the reaction, it would tend to counteract the effect of the decreasing reaction surface and produce an approximately constant rate from what might be essentially linear kinetics.

When the cements are allowed to harden, the rate tends to decay more rapidly than for the same material stirred. This effect depends on the W/C ratio and at the values used here is most pronounced for magnesia and anhydrite, it affects the C_3S phases only at later ages and has little effect on β–C_2S.

Generally, then, the data is not inconsistent with the attractively simple model of a reaction which starts linear but which may become diffusion controlled if the resistance of the diffusion process exceeds that of the surface decomposition. Where diffusion kinetics hold for isolated particles, the rate approximates to

quadratic kinetics. However, when the reaction becomes diffusion controlled due to merging outer products, then the kinetics vary with W/C ratio and possibly depend on the relative specific permeabilities of inner and outer products.

Even a good fit to a kinetic equation does not establish it as a mechanism, but merely fails to eliminate it. The present data is not precise and it is plotted against the integrated form of the rate equation which is a notoriously insensitive test (6) for a kinetic model. Consequently, the possible basis for this simple linear diffusion kinetics will be treated next.

The Linear-Diffusion Kinetic Model

Consider the general model, put forward by this author (1) in 1959, to account for the phenomenon of hydraulic hardening. It is suggested that at least the outer-products must form a coherent network; and, to minimize the generation of disruptive stress, that these products must be precipitated from material which has diffused away from the cement grains. For portland cement, the limited growth of the crystals of hydration product and their supposed inability to nucleate in pores below a critical size, are phenomena invoked to further limit the generation of stress and to explain the very great reduction in hydration rate which occurs at low W/C ratios as the outer-products fill the space available to them. Under these conditions it is probable that diffusion or precipitation control the rate. However, neither in this (1) account of the argument nor in the later versions of Powers (7), Verbeck (8) or Brunauer and Greenberg (9) is any mechanism offered to explain the difficulty to which we alluded in describing the limited hydration of magnesia at low W/C ratios.

The difficulty is this. In order to prevent the accumulation of products at the cement mineral surface and the consequent generation of disruptive stress, the outward diffusion process must always keep pace with the rate of mineral decomposition. If we suppose that the hydration rate is controlled by the inward diffusion of water, then this implies that the outward diffusion of hydrated material occurs more readily. This is difficult to accept in view of the higher concentration and greater mobility of water compared to say divalent cations in aqueous solution. On the other hand, if we suppose that outward diffusion or precipitation controls the rate, then we need a mechanism to prevent the cement decomposition from exceeding this rate.

Such a mechanism is not hard to find when the free energy change and hence solubility difference between cement mineral and hydration product is small. Anhydrite is an instance of this and at low W/C ratios when the precipitation of gypsum is hindered the concentration rises towards the solubility of anhydrite, slowing the rate of its dissolution. However, for more thermodynamically unstable materials such as C_3S, such a mechanism is not possible.

A possible mechanism for such unstable materials is that a stable surface is produced by the adsorption of an outward diffusing chemical species which in this way poisons the reaction if its concentration rises. From such a mechanism we have derived (10) the following rate equation:

$$r^2 k\eta_A + rKX_i\eta_W + rk([A]_o + K) = X_i[W]_o K \quad (3)$$

where r is the reaction rate, k is the resistance to a linear reaction, η_A and η_W are the respective resistances of the intermediate product A and water to diffusion across the product coating, (1/K) is the Langmuir adsorption coefficient for A on the cement, X_i is the surface area of the unreacted cement cores and $[A]_o$ and $[W]_o$ are the concentration of A and water at the outer surface of the reaction coating.

If the third term of the left hand side dominates, we get linear kinetics. For example, equation (1) is obtained by expressing X_i in terms of the fraction reacted of a sphere.

If the second term of the L. H. S. dominates we get parabolic kinetics for the inward flow of water. Substituting an expression for the resistance due to the inner products of a spherical particle gives the equation (2) for quadratic kinetics. Introducing the resistance of the outer products of an isolated sphere gives equation (4) of reference (2).

If the first term dominates, we get joint control by the surface decomposition and by the outward diffusion of the poisoning species. For a plane surface $F^{3/2} = a + bt$, compared to $F = bt'$ for linear and $F^2 = a + bt$ for parabolic kinetics. For joint kinetics the empirical rate constant b is compound (11) and the activation energy is half the sum of the enthalpy charge for adsorption and the activation energies for diffusion and linear reaction. The rate equation for the joint kinetics of a sphere is complicated.

The condition for joint kinetics is

$$\eta_A k[W]_o K\eta_W \gg X_i\eta_A \gg k([A]_o + K)^2/k[W]_o \quad (4)$$

If $X_i\eta_A$ lies below these limits the reaction is linear, if above, it is parabolic. Notice that $X_i\eta_A$ tends to zero at both the beignning and at the end of the reaction so that it must start and finish linear. If inequality (4) does not hold, the reaction is either completely linear; or starts linear, becomes parabolic and then ends linear. The necessity for a linear finish is not

explicit in earlier treatments (2), (12), (13). Such an effect is unlikely to be of experimental importance as the particles will generally reach this final stage at different times depending on their size and the proximity of their neighbours.

Alternatively, we could provide a mechanism for outward diffusion to control the rate by postulating a direct coupling between this process and the inflow of water.

Evidence from the Experiments

These experiments produce no direct evidence for joint kinetics. Hydration curves on log time for the joint kinetics of isolated particles will have slopes which lie between those of our calculated linear and quadratic kinetics. Examination of the figures for stirred hydration show no such evidence. We must conclude that, if joint kinetics exists in our experiments, it can be only in those regions where the kinetics are affected by merging outer products. Unfortunately it is just here that the geometry of the diminishing water spaces makes calculation of the kinetics most difficult.

Two of these cements, β–C_2S (5106) and anhydrite show a definite induction period. That of β–C_2S has an apparent activation energy of 15 kcal, whereas that of anhydrite appears only in stirred experiments and is greatly reduced if the solution is already seeded with gypsum.

It should be mentioned that, if the magnesia is fired to 910°C and then stirred in 1.25 molar magnesium sulphate, as in Fig. 4, then it gives the usual linear kinetics after an induction period of 170 hours. There is no evidence in these experiments from which one can draw conclusions about factors which might affect the linear reaction constants of these cements.

There is evidence in Figs. 17–20 to show that the diffusion process for C_3S is affected by the ageing or re-firing of the cement. This result is somewhat surprising and requires further investigation. It seems to imply a difference in either the structure of the gel of hydration products or in the concentration difference driving the process or both. It may be due to the presence of carbonate.

Conclusions

For the seven hydraulic cements described here and with only a few additional hypotheses it is possible to describe the hydration kinetics at least approximately by an attractively simple model in which the rate after allowance for particle shape, particle size distribution and the merging of outer products, is controlled by either linear or parabolic kinetics. The additional hypotheses are the induction period for β–C_2S (5106) and anhydrite, and an extra accelerating process for β–C_2S (5106) which counteracts the effect on the rate of the diminishing reaction surface on linear kinetics.

Consideration of the possible basis of such a model leads to the dilemma that it is difficult to see how the rate of diffusion of water in through a coherent coating of products should be slower than the outward diffusion of products, yet, if the outward diffusion is slowest, then a mechanism must be provided to prevent the rate of cement decomposition exceeding the rate of outward diffusion. A solution to this dilemma is to suppose that an outward diffusing substance can adsorb on, and poison, the cement surface. This hypothesis raises the possibility of joint linear-diffusion control. It is shown that, regardless of the nature of the linear-diffusion transistion, the rate must obey linear kinetics at the very end of the reaction of a discrete particle. No evidence is found in these experiments for joint kinetics, but it is not possible to rule out this possibility in the region where the merging of outer products controls the rate.

Evidence for the effect of ageing and re-firing of C_3S suggests that these effects are due to a change in the rate of a diffusion process.

Supplementary Paper II-73 Effect of the Temperature on the Early Hydration of the System $3CaO \cdot Al_2O_3$–$CaSO_4 \cdot 2H_2O$–$Ca(OH)_2$–H_2O

Hitoaki Mori and Keiichi Minegishi*

Synopsis

The hydration course of $3CaO \cdot Al_2O_3$ with $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ at 5°C to 70°C has been investigated mainly by using twin-type conduction calorimeters. The hydration reaction of the present system can be classified into four stages: 1) the first rapid reaction (the first heat evolution peak), 2) the dormant period after the first peak, 3) the rapid reaction of the remaining $3CaO \cdot Al_2O_3$ (the second heat evolution peak), and 4) the suppressed reaction after the second peak. These stages appear successively.

The reaction rate in the first stage is not greatly affected by the hydration temperature. In the second stage, however, a considerable increase in the rate of hydration is observed when the temperature is raised, because the physical properties of the ettringite coating vary with temperature. The reaction of forming a coating on the surface of the $3CaO \cdot Al_2O_3$ grains proceeds below 40°C, while the reaction proceeds on the surface of $3CaO \cdot Al_2O_3$ at 70°C without forming a protective layer. The change in the properties of the ettringite coating has a greater effect on the reaction rate. The presence of sufficient $Ca(OH)_2$ restrains the dissolution of $3CaO \cdot Al_2O_3$ and ettringite, and makes the ettringite layer more dense. The addition of $Ca(OH)_2$ has a similar effect to the lowering of the temperature.

The reaction in the third stage appears when the $CaSO_4$ content in the solution becomes insufficient to form ettringite, and calcium monosulfate precipitates from the liquid phase near the $3CaO \cdot Al_2O_3$ grains and simultaneously the ettringite coating is removed by being dissolved. The reaction of $3CaO \cdot Al_2O_3$ with ettringite is fairly rapid and is accelerated by raising temperature.

In the fourth stage, the hydrates which are produced in the second rapid reaction enclose the unhydrated $3CaO \cdot Al_2O_3$ grains and suppress the subsequent hydration.

Introduction

The early hydration of $3CaO \cdot Al_2O_3$ has been known to be retarded by the presence of $CaSO_4 \cdot 2H_2O$. Recently the kinetics and the mechanisms of the reaction of $3CaO \cdot Al_2O_3$ (C_3A) with $CaSO_4 \cdot 2H_2O$ have been discussed in many papers (1–7). In general, it has been found that $CaSO_4 \cdot 2H_2O$ can retard the hydration of C_3A by the forming of the ettringite ($C_3A \cdot 3CaSO_4 \cdot 32H_2O$) coating on the surface of the C_3A grain, and that the reaction proceeds with the diffusion of sulfate ions through the coating in the earlier stage and with the occurrence of cracking in the coating in consequence of the formation of more ettringite in the later hydration (2, 3). On the other hand, there are papers in which the formation of monosulfate on the C_3A grains in the very early hydration (5) and the retardation of calcium aluminate hydrates on the hydration of C_3A, not of ettringite (6) have been reported. It follows that there is some doubt about the hydration course of the present system.

Calorimetric methods are often used successfully to trace continuously the hydration process, and calorimeters which were constructed in laboratories have been used to study the hydration of C_3A (1, 2). The heat of hydration in the present system at a temperature ranging from 5°C to 40°C was studied in the previous paper (7). This experiment is concerned with the early hydration of the system at 5°C to 70°C. The hydration course of C_3A with $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ has been studied by analyzing quantitatively the effects of the hydration temperature and the reactant composition on the heat evolution rate, and by determining the hydration product and the degree of hydration by X-ray diffraction analysis.

Materials and Methods

Materials

C_3A was prepared from reagent grade $CaCO_3$ and Al_2O_3. These reagents were weighed in the fixed molar ratio and, after mixing, they were heated three times in an electric furnace at 1450°C. Free CaO determined by the alcohol-glycerol method was 0.2%, and loss on ignition was 0.2%. SiO_2 and Fe_2O_3 determined by the chemical analysis as other impurities were 0.1 and 0.1% respectively. The synthetic product had a CaO/Al_2O_3 molar ratio of 2.96 and was free of other calcium aluminates. The product was pulverized in a porcelain potmill to 2980 cm^2/g of Blaine value in this experiment. Reagent grade $CaSO_4 \cdot 2H_2O$ was dried at 40°C after washing sufficiently with pure water. $Ca(OH)_2$ was prepared by mixing CaO with CO_2-free water and by desiccating the hydrate. CaO was made by heating reagent grade $CaCO_3$ at 900°C. Prepared $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ contained few impurities.

These preparations were mixed with each other so as to get mixtures containing the molar ratio as shown in Table 1. All of the samples were dry-mixed throughly until they became homogeneous. The effects of the $CaSO_4 \cdot 2H_2O$ content and the hydration temperature on the early hydration of C_3A were determined from the results of calorimetric measurements on samples No. 1 to 6, and the effect of the CaO concentration was determined by measuring the heat evolution of samples No. 7 to 11 at 20°C.

Ettringite, which was used to examine its reactivity with C_3A, was prepared by suspending 1 mole of C_3A and 3 moles of $CaSO_4 \cdot 2H_2O$ in excess pure water in a tightly closed 300-ml Erlenmeyer flask. The flask was shaken sufficiently for six months at 20°C. The result of the X-ray powder diffraction in Table 2 showed that no reactant was present and most of the lines were found to be due to ettringite. The differential thermal analysis curve of the product was also identical with the ettringite one. Loss on ignition of the synthetic ettringite was 44.6% of its weight.

Methods

The measurements of heat evolution, which was observed in the hydration of the mixed samples at a temperature ranging from 5°C to 70°C, were performed at an interval of 5°C or 10°C. This temperature range was decided on because the hydration reaction at 5°C is similar to the reaction which occurs in concrete casted in winter, and because the conditions at 70°C are near to those in the steam curing of concrete. The reaction processes of samples were traced by using twin-type conduction calorimeters which were designed by Amaya (8). Block diagrams of the two conduction calorimeters improved to be installed with temperature controlled baths are shown in Fig. 1. The one for lower temperature was used at a temperature from 5°C to 40°C, and the calorimeter for higher temperature was used at 50°C to 70°C. The temperature in the baths was controlled by the thermister temperature regulator and the temperature of the reaction vessel was kept within ± 0.1°C and ± 0.03°C of the desired temperature for the former and for the latter respectively. For measurement at higher temperature, the reaction vessel was kept as tight as possible so as to prevent the water-solid ratio from varying during the hydration of the paste.

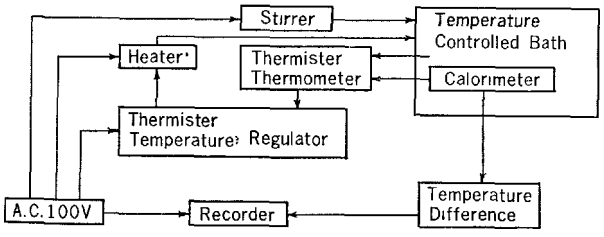
(1) Calorimeter for lower temperature



(2) Calorimeter for higher temperature

Fig. 1. *Block diagram of twin-type conduction calorimeter*

These calorimeters have installations for stirring and are suitable for continuous measuring of heat evolution after the addition of water when the hydration was made with the mixed sample in paste form. Sensitivity of the heat conductor used is 6.5 mv/°C at 20°C.

Pastes for calorimetric investigation were prepared by mixing 4 g of sample with 2 ml of distilled pure water for 5 minutes at a speed of 60 r.p.m. In these experiments the hydration reaction up to a period of 3 days was traced and discussed.

Heat of hydration of the sample was calculated from the ratio of the area within the curve of heat evolution rate of the sample to the area within the curve of heat evolution rate of a manganin coil (100 cal/hr) over a fixed time. And the rate of heat evolution was determined by the ratio of thermo-electromotive force measured during the hydration of the sample at a fixed time to that of the standard coil.

The increase in temperature of the paste during hydration was about 4°C at its maximum when either gypsum and $Ca(OH)_2$ were absent or the hydration temperature was raised. To determine the reproducibility of a measurement, the heat evolution of CaO and C_3A, which are known to be very active for water, were measured three times at 20°C. These results showed that the heat of hydration of CaO after 1 hour was 252 ± 3.5 cal/g and the heat of 1 hour hydration of C_3A was 103 ± 1.8 cal/g, and that heat evolution rates of C_3A at the first peak after the addition of water agreed within $\pm 3.6\%$. When measurements were taken with an amount of C_3A ranging from 3 g to 5 g, results obtained were within the same range as above. The reproducibility of measurements was satisfactory enough.

The hydration products were identified by X-ray diffraction analysis and differential thermal analysis. The hydration degree of C_3A against time was determined by means of the calorimeter when the reaction rate was greater, considering it to be proportional to the heat of hydration, and by the X-ray internal standard method when the reaction became steady. The hydration was stopped by suspending the product in acetone, and the product was dried over soda lime and/or $CaCl_2$ in a desiccator at room temperature.

Results and Discussion

Effect of the Hydration Temperature and Gypsum Content on the Heat Evolution

Table 3 and Figs. 2 to 5 show the heat of hydration which were liberated during the hydration of samples No. 1 to 6 containing different amounts of gypsum at 5°, 20°, 40° and 70°C. From Fig. 2 it is evident that the immediate hydration of samples No. 1 and 2 with no gypsum occurs at a slower rate at 5°C than at a higher temperature, and that the heat of hydration after 1 hour is found to be less. The heat evolution rate after that, however, decreases so slowly in both cases that considerable increases in the heat of hydration after 1 day are observed in Table 3. C_2AH_8 and C_4AH_{13} were detected during the hydration of sample No. 1, and C_4AH_{13} was the only product in the hydration of No. 2. These products seem to have had no great retarding effect on the hydration of C_3A.

The presence of gypsum decreased the rate of heat evolution when the C_3A grains came in contact with water and also the rate after the first peak. Accordingly, heat of hydration of only 16.7 to 22.3 cal/g. C_3A were measured after 1 day. The difference in the gypsum contents hardly affected the hydration reaction for 3 days. The second peak of heat evolution, which was accompanied by the conversion of ettringite to monosulfate, did not appear in this time. It is apparent that by the formation of an impermeable

and dense coating around the C_3A grains ettringite retards the hydration of C_3A more effectively at 5°C.

At 20°C the rates of hydration at the first peak of samples No. 1 and 2 were two times as great as that at 5°C, subsequent rates, however, tended to decrease markedly. The products fromed during 1 hour's hydration were some C_3AH_6 and a little C_4AH_{13}. It is found that C_3AH_6 is able to form a more impermeable coating than C_2AH_8 and C_4AH_{13}. A small peak of heat evolution, which can not be shown in Fig. 3, appeared after about 2 hours during the hydration course of No. 2. This peak was observed at 15°C, but was not recognized for 3 days either at a temperature below 10°C or above 25°C. The small peak corresponds to a heat effect which is due to crystallization of C_3AH_6 from the intermediate C_4AH_{13}, as

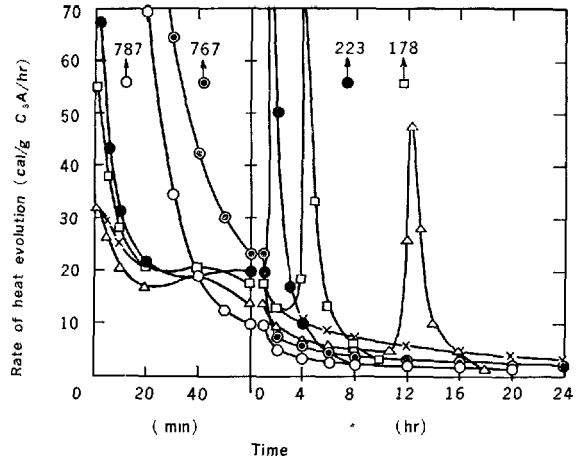

Fig. 4. *Effect of* $CaSO_4 \cdot 2H_2O$ *content on the early hydration of* C_3A *at 40°C (symbols as in Fig. 2)*

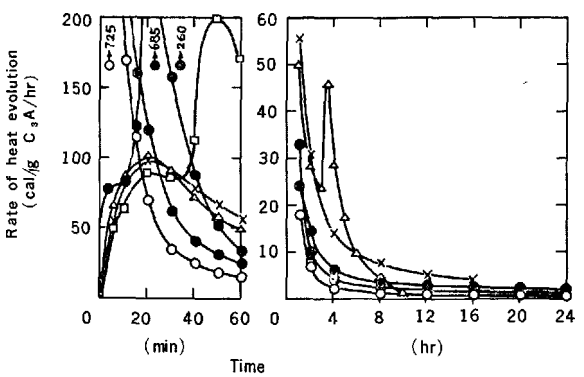

Fig. 5. *Effect of* $CaSO_4 \cdot 2H_2O$ *content on the early hydration of* C_3A *at 70°C (symbols as in Fig. 2)*

observed previously by Stein (9), because an apparent increase in the amount of C_3AH_6 was observed after this peak.

During the hydration courses of samples No. 3 to 6 which contained gypsum, gypsum effectively retarded the hydration of C_3A at 20°C. As shown in Fig. 3, the second peak of heat evolution occurred after 12 and 44 hours for samples No. 3 and 4, respectively. The second peak of No. 4 was divided in two parts. This phenomenon will be discussed later. The second peak took place when most of the added gypsum had reacted with the C_3A. It is assumed that ettringite forms a coating on the surfaces of the C_3A grains and the retarding effect of the coating on the hydration of C_3A increases as the reaction proceeds.

After 3 days only ettringite was detected in the products of samples No. 5 and 6 in which the molar ratios of $CaSO_4 \cdot 2H_2O/C_3A$ were 1.0 and 3.0, respectively. The second peak was not observed during 3 days hydration.

At 40°C No. 1 and 2 formed C_3AH_6 just after the addition of water, and then the immediate hydration was promoted more markedly than at 20°C. After 1 hour, however, the reaction rate decreased sharply as stated by Tanaka, Murakami and Sato (10). The heat of 1 day's hydration of No. 1 at 40°C was 41 cal/g C_3A less than at 20°C.

In the cases of samples No. 3 to 6, the heat evolution rates of the first peak were lower at 40°C than at 20°C. But the decrease in the rates was gradual afterwards, and the reaction was so markedly accelerated that the heat evolution rate at the onset of the second peak was fourteen or fifteen times that at 20°C. And the reaction of the second peak was also accelerated and, therefore, the heat of 1 day's hydration increased. It might be said that at 40°C gypsum acted as an accelerator for the hydration of C_3A. In Fig. 4 small heat effects are recognized after about 40 minutes in No. 3 to 6. These effects were already observed at 35°C. After the peak no change could be recognized in the hydration product except a noticeable increase in the amount of ettringite.

At 70°C gypsum hardly retarded the hydration of C_3A. Fig. 5 shows that in the hydration of lower gypsum content the second peaks occur after 10 and 35 minutes for No. 3 and 4 respectively without an apparent decrease in the rate following the broad first peak. The onset of the second peak of No. 5 with higher gypsum content was 6 hours earlier than at 40°C, though a considerable decrease in the rate is observed after the first peak. After the second peak, however, the heat evolution rate declined rapidly. Since sample No. 6 had stoichiometric amounts of C_3A and gypsum for ettringite, it formed only ettringite even at 70°C and the ettringite did not convert to monosulfate. For 1 day's hydration of No. 6, 6.6% of C_3A hydrated at 5°C, 13.5% at 20°C, 49.8% at 40°C, and 63.0% at 70°C. These results show that the retarding effect of gypsum decreases with increasing temperature.

The same tendency was shown by the calorimetric measurements at other temperatures which were not included in Table 3 and Figs. 2 to 5. In Fig. 6, it is evident that the hydration of C_3A is continuously promoted by temperature increase. At a lower temperature, a fast heat evolution after the addition of water is followed after about 2 hours by a slow increase in the heat of hydration. In this dormant period added gypsum reacts with C_3A and retards the hydration of C_3A by forming ettringite. Marked differences among the inclines of heat evolution against time are observed

5	3.73	—	5.6	3.9

a: Data were calculated from the following equation.

$$C_3A + 3CaSO_4 \cdot 2H_2O + 26H_2O \rightarrow C_3A \cdot 3CaSO_4 \cdot 32H_2O \quad \ldots\ldots(-53.9\ cm^3)$$

in the dormant period, showing that the retarding effect of gypsum became apparently smaller above 35°C.

The relations between the heat of hydration before the start of the second peak and the hydration temperature, and between the onset of the second peak and the temperature are illustrated in Fig. 7. Linear decreases in the heat of hydration by raising temperature are observed. Using the heat of formation of ettringite, 347 cal/g C_3A, the heats of hydration before the second peak were calculated to be 29.4, 58.8, and 117 cal/g C_3A for No. 3, 4 and 5 respectively from added gypsum contents. On comparing the calculated values with the measured values, the latter were greater than the former at a lower temperature, but at a higher temperature were inversely smaller. The same trend is recognized in Table 4, where the volume shrinkages of pastes from 30 minutes after the addition of water are shown. These shrinkages are responsible for the formation of ettringite. The formation of such a product as C_3AH_6, for which both the heat of formation and the volume shrinkage accompanied by the formation are smaller than for ettringite, might be expected. But its presence in the products was not observed by X-ray

analysis and differential thermal analysis (DTA). The amount of unhydrated C_3A determined by X-ray quantitative analysis at the onset of the second peak undoubtedly decreased when the temperature was raised. As stated by Lieber (11), the reaction between C_3A and $CaSO_4 \cdot 2H_2O$ is not quantitative especially with a lower gypsum content and at a higher temperature.

The onset of the second peak is shortened with temperature rise as shown in Fig. 7. Though this trend is affected to some extent by temperature and the gypsum content, it may be said that below 40°C the time for the complete reaction of gypsum with C_3A decreases to one fourth or one third when the temperature is raised by 10°C, and above 50°C decreases to about one half when the temperature is raised by 10°C. The effect of gypsum on the reaction time is recognized more distinctly below 30°C, and the time measured for the hydration of No. 4 is three times that for No. 3 and that for No. 5 is about three times that for No. 4. Added gypsum retards the hydration of C_3A more strikingly as the amount of it is increased at a temperature below 30°C. As already mentioned, it is thought to be caused by a structural change of the ettringite coating, e.g., an increase of its thickness or a decrease in the void space.

It may be concluded from the calorimetric measurements that gypsum retards the early hydration of C_3A and its action becomes more effective by increasing the amount, but the effect of gypsum is weakened above 35°C.

Hydration Products and Reaction Sequence

So as to compare the changes in the hydration products with results by the calorimeters, X-ray analysis and DTA were carried out on the products which were prepared under the same procedure as employed for the calorimetric measurement. The hydration products which were detected after 1 hour and 1 day are listed in Table 3. Figs. 8 to 10 show the X-ray diffraction patterns of the products during the hydration of sample No. 4. In Fig. 8 the pattern after 5 minutes indicates the presence of a slight peak of ettringite at 9°. In addition, a small endotherm at 155°C, which was responsible for ettringite, was observed in the DTA curve of the same product. However, both analyses showed the formation of no other product, such as monosulfate, C_4AH_{13}, or C_3AH_6. Up to the onset of the second heat evolution peak, continuous decreases in the amounts of unhydrated C_3A and gypsum and a continuing increase of ettringite are observed. No change was observed in the amount of $Ca(OH)_2$ which was determined by the loss in weight between 500°C and 600°C on the thermogravimetric curve. Therefore, no significant reaction between $Ca(OH)_2$ and C_3A occurred. Immediately after the second peak starts, a peak at 31° appears indicating the formation of monosulfate and, on the other hand, the interference of gypsum is noticeable. As the hydration proceeds the interferences of C_3A, gypsum, and ettringite decrease. The interference of ettringite can not be recognized any

longer after 1 hour from the top of the second peak, and that of gypsum disappears entirely at the end of the peak. At the same time a considerable increase in the intensities of monosulfate interferences at 9.8° and 31.0° appears. A line of monosulfate was observed at 9.2° in the wet specimen, but it shifted to 9.8° when washed with acetone and further to 10.4° upon drying over $CaCl_2$. Accordingly, after the onset of the second peak the samples were preserved on soda lime in a desiccator. After 1 hour from the top of the heat evolution peak, $Ca(OH)_2$ decreases considerably and an interference of monosulfate at 9.8° is found to be extending to about 11°. These observations show that a solid solution of monosulfate with C_4AH_{13} had already formed. It can be seen from Fig. 8 that monosulfate is formed at first, followed by the formation of the solid solution, and that the doubled peak of sample No. 4, as already shown in Fig. 3, are explained in the following way; the first half shows the formation of monosulfate and the second the solid solution.

The reactions at 40°C and 70°C produced the same products as at 20°C. But a great increase in peak intensity at 9.8° was observed, and little solid solution was formed. At 40°C after 1 day C_3AH_6 was present in the product instead of the solid solution. At 70°C the formation of C_3AH_6 was so accelerated as to be recognized after 6 hours. In the hydration of No. 3 with lower gypsum content, C_3AH_6 was formed in greater quantities above 30°C. In No. 5 with higher gypsum content, however, after the second peak the formation of monosulfate was only observed over the entire temperature range.

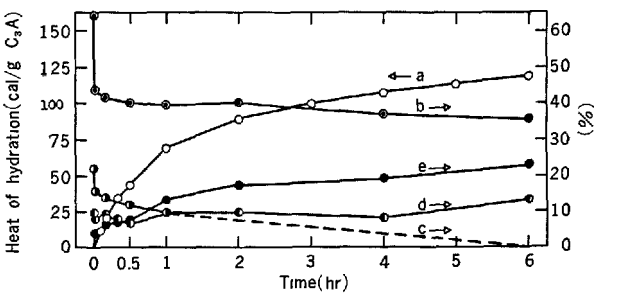
On comparison of the thermal processes to the change in the hydration products with time, it is found that the first peak of heat evolution and following slow evolution are responsible for the heat of formation of ettringite. The second intense reaction occurs with the conversion of ettringite to monosulfate, and with the formation of monosulfate and the solid solution of monosulfate and C_4AH_{13}, or with the formation of monosulfate and C_3AH_6.

Stein (12) pointed out that from the fact that the presence of unhydrated C_3A and ettringite can be demonstrated when the second peak must have been passed, this second peak corresponds to the scaling-off of a protective layer of ettringite and its replacement by a layer of C_4AH_{19}, monosulfate or a mixed phase of these two compounds. The results of present investigation indicate the presence of ettringite even after the onset of the second peak, but the amount of ettringite decreases considerably because it reacts with the remaining C_3A forming monosulfate or the solid solution.

To determine the reactivity of C_3A with ettringite, the hydration reactions of the mixtures, which had the same compositions that samples No. 3, 4, and 5 had at the beginning of the second peak, were traced by the conduction calorimeters, X-ray diffraction analysis, DTA and thermogravimetic analysis (TGA). Fig. 11 shows the development of heat of hydration, and changes in the amounts of the reactants and the products of the mixture, $11C_3A + C_3A \cdot 3CaSO_4 \cdot 32H_2O$ (ettringite) $+ 6Ca(OH)_2$, which corresponds to the composition of No. 3 after a complete consumption of the gypsum. The amounts of unhydrated C_3A, and both ettringite and $Ca(OH)_2$ were determined by X-ray internal standard method and by TGA respectively. DTA endotherms between 200° and 300°C are thought to contribute to the dehydration of monosulfate and/or the solid solution of that with C_4AH_{13}. In Fig. 11 an immediate hydration with great velocity is followed by a rapid decrease in the reaction rate. Free C_3A, ettringite, and $Ca(OH)_2$ decrease rapidly at first, but after 10 minutes decrease slowly. After 6 hours the presence of ettringite is not observed at all. No calcium aluminate hydrate other than monosulfate and its solid solution with C_4AH_{13} can not be observed in the X-ray diffraction patterns. It can be concluded from the results in Fig. 11 that the reactivity of ettringite with C_3A in water is very high. And it is thought that the second peak takes place when ettringite begins to react with the remaining C_3A, and that a great increase in the heat of hydration is responsible for the reaction of C_3A with ettringite, and further reaction of the system C_3A–$Ca(OH)_2$–H_2O.

Kinetics of the Hydration Reaction

From the results by the conduction calorimeters, it seems that the ettringite coating, which was fomred



a: heat of hydration b: hydration degree of C_3A
c: ettringite d: $Ca(OH)_2$
e: loss in weight during 200° to 300°C endotherm

Fig. 11. *Heat of hydration and hydration degree of the system* C_3A–$C_3A \cdot 3CaSO_4 \cdot 32H_2O$–$Ca(OH)_2$–$H_2O$

on the C_3A grains in the hydration of C_3A with gypsum and $Ca(OH)_2$, acts as a diffusion layer. However, the rate of heat evolution varied noticeably with varying temperature and the dependence of the rate upon the temperature was considerable.

In general, the hydration reaction of the present system can be classified into four stages; 1) the rapid reaction after the addition of water (the first peak of the heat evolution), 2) the dormant period after the first peak, 3) the second rapid reaction (the second peak of the heat evolution) and 4) the suppressed reaction after the second peak. The equation of the reaction rate which was introduced by Kondo (13), $(1-\sqrt[3]{1-\alpha})^N = kt$, was applied to interpret these processes; where α is the degree of hydration, k is the rate constant, t is the hydration time and N is the value which is variable according to the reaction type. The logarithms of $(1-\sqrt[3]{1-\alpha})$, which were calculated from the degree of hydration as a function of time, were plotted against the logarithms of the hydration durations. In Fig. 12 there are linear relationships between them over the whole temperature range, and except at 5°C three straight lines are observed. The values of N in the equation were determined from the slopes of the first lines in the second stage when the reaction became steady. The estimations are listed in Table 5. The reaction of C_3A is retarded at a temperature below 40°C because the ettringite, which is formed in the very early hydration, forms a coating on the C_3A grains and the solution probably containing Ca^{2+} and SO_4^{2-} ions have to diffuse through the coating. At 70°C, however, the type of the reaction differs considerably from that at a lower temperature.

The reaction processes for sample No. 4 as shown in Fig. 12 are discussed in detail as follows: At 5°C the slope becomes fairly gradual after the first 20 minutes of the reaction. Then N is about 4. This means that ettringite has formed dense coating around the C_3A grains, and that the coating has become more compact in structure and simultaneously the resistance of the coating to the diffusion increases as the reaction proceeds. Accordingly the reaction is retarded markedly after the first peak of heat evolution and is followed by a decrease in rate. Namely at 5°C, the saturated concentration of CaO in the liquid phase is higher, and the solubility of ettringite is lower, so the dissolution of C_3A into the solution is suppressed and the oversaturation of ettringite is attained more easily, and then a large number of nuclei will be formed. It is assumed that fairly fine crystals of ettringite, which are formed near the surface of the C_3A grains, form an impermeable layer by filling up capillary pores in the layer with more ettringite.

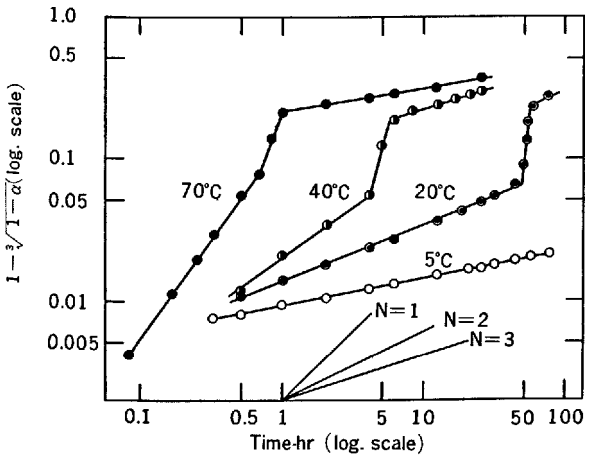


Fig. 12. *Determination of the value of N in the equation,* $(1-\sqrt[3]{1-\alpha})^N = kt$, *on the hydration of sample No. 4*

At 20°C, the value of N was about 3 at a duration from 30 minutes to 44 hours. The value of N shows the formation of a fairly compact coating. But the concentration of CaO becomes lower and the solubility of ettringite is greater than at 5°C; therefore, the ettringite crystals must grow larger. It is evident from the above that the reaction has been promoted by a decrease in the resistance of the ettringite coating to the diffusion of the solution.

At 40°C this trend is encouraged more and more. The value of N is about 2 from 30 minutes to 4 hours, and the equation is near to Jander's equation. It is assumed from the value of N that an increase in the amount of ettringite during the progress of the reaction increases the thickness of the coating, but brings no change in the structure. Furthermore, the diffusion constant increases with rising temperature. These cause apparent increases in the reaction rates so that considerable differences in the heat evolution rates are observed in Figs. 2 to 7.

The reaction at 70°C is not divided into four stages because of overlapping of the first stage with the second one. The first linear relationship is observed after only 5 minutes in Fig. 12. The slope of this line

Table 5. *Determination of the value of N on the hydration of* C_3A *with* $CaSO_4 \cdot 2H_2O$

Sample No.	Temperature (°C)			
	5	20	40	70
3	3.5	2.5	1.5	1
4	4	3	2	1
5	3.5	2.5	1.5	1(1.5)
6	3.5	2.5	1.5	1(1.5)

is about 1 unitl 40 minutes' hydration. This value of 1 shows that ettringite does not interfere with the progress of the reaction of C_3A, and the reaction proceeds on the surface of the C_3A grains. However, for samples No. 5 and 6, higher in gypsum content, the first lines were broken into two parts on their way to the third stage. Namely, for No. 5 N was about 1 for the next 25 minutes, but about 1.5 for the following 2.5 hours, and for No. 6 the value of N was about 1 for the next 45 minutes and after that N was approximately 1.5. In the hydration at 70°C ettringite crystals grew large enough to be visible under the optical microscope, and did not form what is called a protective layer. An increase in the quantity of ettringite, which was formed near the C_3A grains, would decrease the reaction rate after some duration in the hydration of the sample high in gypsum content.

The nitrogen adsorption measurement of the surface area (BET method) was carried out on the hydration products of sample No. 6, at 5°, 20°, 40°, and 70°C, after sufficient washing with acetone. An outgassing of the products, which were dried over soda lime and $CaCl_2$, was performed at −20°C and under 10^{-5} mmHg for 2 hours to prevent the ettringite from decomposing. Under these conditions no decomposition of ettringite was apparent according to X-ray diffraction analysis and DTA. Table 6 shows increase of the surface area after 1 day. As above described sample No. 6 had always formed only ettringite. A loss on ignition in Table 6 is caused only by ettringite, and the quantity of ettringite can be calculated from the ignition loss. An increase in the surface area of the product means the difference between the surface area of the product and that of the reactant. It has been corrected by the decreases in the areas of C_3A and gypsum which are calculated from the degree of hydration. Hence, the increase is approximately equivalent to the surface area of ettringite, because most of the ettringite is separated from the C_3A grains by suspension in acetone with enough mixing to break up the product. In Table 6 the increase in the area markedly varies with the hydration temperature as the degree of hydration increases with rising temperature. The surface area per gram of ettringite is at a maximum at 5°C and decreases with temperature increase. It is evident from these results that the manner in which ettringite is formed is variable according to the hydration temperature. In this discussion a growth of ettringite crystal as the result of recrystallization can be neglected because of the low watersolid ratio of 0.5.

Table 6. *Increase in surface area of hydrated product of sample No. 6 after 1 day by nitrogen adsorption method*

Temperature (°C)	Increase in loss on ignition (%)	Ettringite formed[a] (g/g product)	Increase in surface area[b] (m^2/g)	b/a (m^2/g ettringite)
5	2.30	0.062	3.30	53.2
20	5.11	0.137	5.62	41.0
40	14.17	0.380	12.44	32.7
70	20.94	0.561	12.71	22.7

It can be concluded from the above results that, the type of the reaction differs with the temperature because, at a temperature below 20°C, the fine crystals of ettringite form a dense coating around the C_3A grains and, at a higher temperature, the crystals grow larger and cannot form such a compact layer and finally ettringite forms no protective layer at 70°C. In these experiments, the gypsum content did not affect the N value distinctly. But the effect of temperature on the hydration rate of the sample higher in gypsum content tended to decrease at a temperature above 40°C.

The heat evolution of samples No. 7 to 11, in Table 1, were measured at 20°C by the conduction calorimeter to examine the dependence of the retarding effect of gypsum upon the physical properties of the ettringite layer. In Fig. 13 the reaction rate of C_3A with gypsum is significantly influenced by the presence of $Ca(OH)_2$, especially, in the early stage. The extent of the effect of $Ca(OH)_2$ reaches a maximum

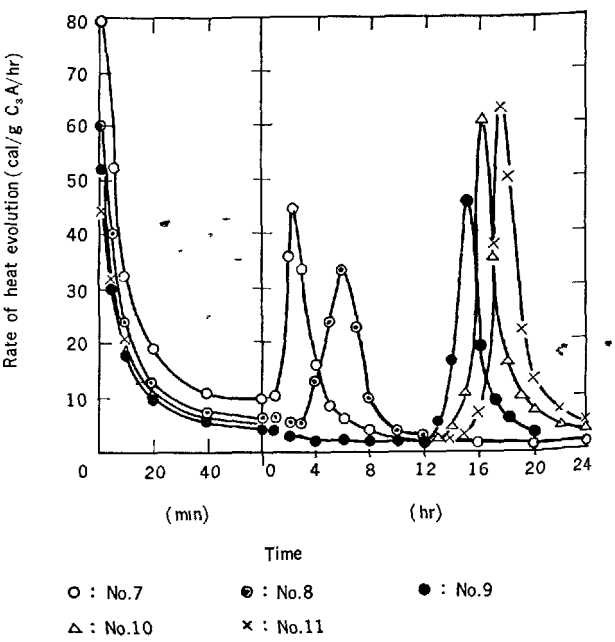

Fig. 13. *Effect of* $Ca(OH)_2$ *concentration on the hydration of* C_3A *with* $CaSO_4 \cdot 2H_2O$

at a higher $Ca(OH)_2/C_3A$ molar ratio than 0.1. The addition of $Ca(OH)_2$ is similar to the lowering of the temperature and the reaction rate of sample No. 7 without $Ca(OH)_2$ at 20°C is equivalent to that of No. 3 with 0.5 $Ca(OH)_2/C_3A$ molar ratio at about 35°C. During the continuous observations of the hydration reaction at water-solid ratio of 5.0 by the optical microscope, needle-like crystals were observed after only 10 minutes, if $Ca(OH)_2$ was not present, and grew to a few score μm in length after several hours. Then the crystals covered the C_3A grains radial like. The increase of $Ca(OH)_2$ concentration shortened the crystal and, in the case of saturated solution, the ettringite crystals became invisible under the microscope. Thus, $Ca(OH)_2$ suppresses the dissolution of C_3A and ettringite, and disturbs the growth of the ettringite crystals. In the calorimetric measurements at low water-solid ratio of 0.5, the relation between them may be expected to differ from that described above. But even at low water-solid ratio $Ca(OH)_2$ may retard the hydration of C_3A with gypsum in the same manner as at water-solid ratio of 5.0, because the surface area of the product increased after raising the $Ca(OH)_2$ content.

It seems from the above results that the effect of the $Ca(OH)_2$ concentration on the hydration rate of C_3A with gypsum can be explained in terms of the size of the ettringite crystal and the manner in which the crystal covers the C_3A grains.

The values of N, as shown in Table 5, were substituted for N in the equation, $(1-\sqrt[3]{1-\alpha})^N = kt$. The mean value of k was determined from the calculations at various hydration times during the reaction in the second stage, using the equation of $\ln k = N \times \ln(1-\sqrt[3]{1-\alpha}) - \ln t$. For the hydration of sample No. 4 at 5°, 20°, 40° and 70°C, mean value of k was calculated to be 5.7×10^{-8}, 3.9×10^{-6}, 9.1×10^{-4}, and 2.5×10^{-1} (hr^{-1}) respectively. Similar values to these were given for other samples. The considerable differences in the values of the rate constant, k, is thought to be caused chiefly by the changes in the physical properties of the ettringite coating, because the dependence of the diffusion constant upon temperature must be too small to account for the variation of k. The reaction rate is determined by the changes in the properties of the ettringite coating.

The discussion of the sequence of the second rapid reaction, as already described, leads to the investigation of the possible cause of the reaction. In Fig. 12, the value of N is always smaller than 1 for the rapid reaction, and it shows that the reaction proceeds with increasing velocity. Fig. 14 shows free CaO and free

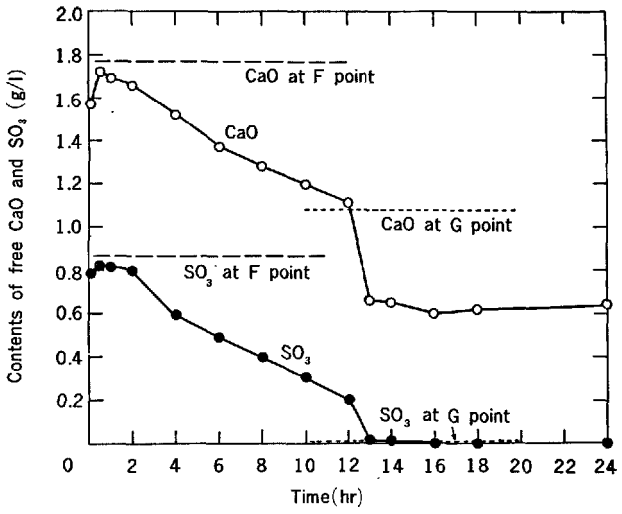

Fig. 14. *Free CaO and SO_3 contents in the liquid phase during suspension hydration of sample No. 3 at 20°C*

SO_3 contents in the solution during the suspension hydration of sample No. 3 in 20 water-solid ratio at 20°C. Free CaO was determined by the EDTA titration method and free SO_3 was by gravimetric analysis. Since no important change was observed in the characteristic pattern of heat evolution by increasing water-solid ratio to 20, it was chosen so as to get the conditions as similar as possible to those at the onset of the second peak when little gypsum was present in the solid phase. In Fig. 14 free CaO and free SO_3 concentrations exist in the region near to Jones' F point (14) for 2 hours after the addition of water and decrease gradually to the composition at G point. After 12 hours considerable decreases in their concentrations, during which the contents of free CaO and SO_3 dropped below those at G point, were observed. These rapid decreases correspond to the start of the second peak in the heat evolution curve.

From these results, it may be concluded that monosulfate crystallizes thereby withdrawing free CaO and free SO_3 from the liquid phase when CaO and SO_3 contents in the solution become insufficient to form ettringite, and that simultaneously the ettringite coating is removed by being partially dissolved. Then the second rapid reaction, that is, the third stage occurs with increasing velocity because more ettringite must be removed in proportion to time.

After the second peak the hydrates around the C_3A grains formed a new barrier and the value of N in the equation of the reaction rate was greater than 2. Thus the reaction rate decreased again, so that a slow decrease in the amount of unhydrated C_3A was observed.

Conclusion

The following conclusions may be drawn from this investigation:

1. For the sake of the convenience the reaction can be classified into four stages; 1) the rapid reaction after the addition of water (the first peak of the heat evolution), 2) the dormant period after the first peak, 3) the second rapid reaction (the second peak of the heat evolution), and 4) the suppressed period after the second peak.

2. The reaction in the first stage is not greatly influenced by the temperature and reveals its maximum rate at a temperature ranging from 15°C to 25°C. But the rate is markedly decreased by the presence of both gypsum and $Ca(OH)_2$.

3. On the other hand, the hydration in the second stage is considerably affected by the hydration temperature and the $Ca(OH)_2$ concentration. The degree of these effects is closely related to the properties of the ettringite layer. At a temperature below 40°C, and further by the presence of sufficient $Ca(OH)_2$, the reaction of forming a coating on the surface of the C_3A grains proceeds with decreasing velocity in proportion to the lowering of the temperature. This is because, the lower the hydration temperature, the finer the crystals of ettringite which are formed and the more compact the ettringite coating. At 70°C, even if sufficient $Ca(OH)_2$ is present, the ettringite crystals grow larger and do not form a protective layer. Then the reaction takes place with little decrease in rate. From considerable increases in the rate constant with rising temperature, it is considered that the changes in the properties of the ettringite layer rather than the diffusion through the layer or the occurrence of the cracking in the layer determine the reaction rate at a temperature between 5° to 70°C.

4. The second rapid reaction in the third stage occurs when the gypsum content in the solution is insufficient to form ettringite. This reaction also accelerated by a rise in temperature. Great increases in the heat of hydration during the second peak are responsible for the reaction of the remaining C_3A with dissolved ettringite and, when more C_3A is present, are responsible for the further hydration of the system C_3A–$Ca(OH)_2$–H_2O.

5. In the last stage, the reaction seems to proceed with the diffusion of the solution through the clusters of the hydrates which have formed around the C_3A grains.

Supplementary Paper II-93 Hydration of Tricalcium Silicate in a Very Early Stage

Kinjiro Fujii and Wakichi Kondo*

Synopsis

Hydration of tricalcium silicate which occurred immediately after mixing with water (C_3S/water 1:0.7) was studied by following the evolution of heat, the increase in combined water, and the dissolution of calcium and silicate ions. The heat evolution was followed by using a twin type conduction calorimeter and the combined water was measured by micro-electrometric titration using Karl—Fischer's reagent with the hydrate sample as wetted with petroleum ether, which was obtained first by mixing the sample of paste with alcohol to interrupt the progress of hydration, and then by replacing the alcohol with petroleum ether centrifugally. To determine the concentrations of calcium and silicate ions in the aqueous phase, the solutions were squeezed out of the paste by hand loading through a plunger and absorbed into the filter papers, which were then subjected to chemical analysis.

As a result, there were obtained curves of combined water versus period of hydration, in which a rapid increase of combined water was observed during the first five minutes, followed by a dormant period which continued for half an hour at 20°C. At this immediate stage combined water amounted to 0.05 wt. % of tricalcium silicate used, irrespective of the temperature for hydration, while the concentration of Ca^{++} ions in the aqueous phase was 9 millimoles/l and tricalcium silicate was found to dissolve instantaneously as it was mixed with water in a ratio of $CaO/SiO_2 = 3$, that is, congruently, it being suggested that the dissolution of one mole layer of C_3S on the surface of the grain would result in adsorption of 3 or 4 mole layers water on it.

Once the immediate hydration has ceased, it begins the sluggish stage durable for about three hours, in which the heat evolution and the increase in combined water are mild and sluggish. During this stage are observed the supersaturation of Ca^{++} ion in the aqueous phase, the maximum concentration being about twice as high as the solubility of $Ca(OH)_2$ in water, and the exceedingly large mean heat of hydration per mole combined water. From these data available together with electron micrographs, it was considered that until the end of the sluggish stage, about four mole layers of C_3S (equivalent to a depth of 20 Å) on the surface of original grains should be hydrated, and the outmost of the four mole layers does emigrate elsewhere through a solution-precipitation process (in the immediate stage), however the remaining three mole layers will be hydrolyzed in situ under the participation of the adsorbed water to form an intermediate substance prior to tobermorite—formation (in the sluggish stage).

Introduction

When tricalcium silicate ($3CaO \cdot SiO_2$ or C_3S for brevity) comes into contact with water, a rapid hydration reaction occurs with evolution of some detectable heat. This early hydration has been followed by several means containing electron microscope (1) (2), calorimetry (3), measurement of specific surface area (4), and analysis of solution (5). Much elaborate work has been reported, nevertheless the detailed mechanism of the hydration of C_3S in a very early stage is likely to remain ambiguously. The present study, therefore, was undertaken with the hope of obtaining some information necessary for a quantitative approach.

Experimental

Materials

Tricalcium silicate

Tricalcium silicates used in this study had such characteristics as are shown in Table 1. And the preparative method for them was as follows:

A slight excess of tetraethyl silicate over the stoichiometric amount was added into an aqueous suspension of $Ca(OH)_2$ at room temperature and the whole mixture was shaken for a while to cause ethyl silicate to hydrolyze into the formation of calcium hydrosilicate gel. After drying, the mixture was so ground as to pass through 80 mesh sieve, subjected to chemical analysis and then corrected by adding a necessary amount of $CaCO_3$ for the stoichiometric ratio of CaO to SiO_2 3:1. The calcium carbonate used was a reagent suitable for flame photometry. The mixture was then moistened with ethyl alcohol, hand-pressed to form cylindrical shapes, prefired at 1400°C for two hours, ground, shaped again by hand-pressing, fired for two hours at 1500°C, then ground, shaped repeatedly under a pressure of 1250 kg/cm², fired for five hours at 1550°C and so ground as to pass through 200 mesh sieve (for sample No. 1). For sample No. 2, the second heating and a relating process was omitted. It is indispensable for the reproducibility of kinetic data on the hydration in an early stage to use an almost completely moisture-free tricalcium silicate, so that before used, it was reheated at 1300°–1350°C, followed by distintegration of lumps in a porcelain mortar while hot (300°–400°C) and preservation in a P_2O_5 desiccator.

Isothermal Calorimetry

The isothermal calorimetry was performed in a constant temperature room (20°C ± 0.3°C) by use of the twin type conduction calorimeter which has been described earlier (6). Ten grams of tricalcium silicate was fallen down into the reaction vessel and mixed with ten milliliters of decarbonated water, resulting in liberation of heat, which was detected by a recorder through the circuit of wire connecting two thermoelement in twin form and having a sensitivity of 3 millivolt/1°C.

The curves to be traced in a chart are the ones representing the rates of heat evolution, and from these data the integral curves can be made to show an overall amounts of the heat evolved during any predetermined reaction time, if account is taken of the heat conserved in the reaction vessel at the end of that time. This conserved heat will be measured from the area under the attenuation curve which for any heat evolution rate would be traced from the moment at which the evolution of heat will be suddenly stopped. In practice, the relations between the areas under the attenuation curves and the heat evolution rates were made previously by use of a standard heater having a known resistivity, and were utilized as calibration curves.

Analysis of Aqueous Solution in the Paste

To determine the concentrations of calcium and silicate ions in the aqueous phases, the solutions were squeezed out of the paste by hand loading through a plunger and absorbed into the filter papers as shown in Fig. 1.

That is, 5 g of C_3S was mixed with decarbonated water in a cylindrical vessel (stainless steel, inner diameter 45 mm, depth 15 mm), the ratio of water to C_3S being 0.7, and the mixture was enclosed therein tightly with a lid, submerged in a thermostat. At predetermined time it was taken, and then closely upon the mixture were placed five sheets of 100% nylon cloths, on which further ten sheets of filter papers No. 7 supplied by Toyo Roshi Kaisha, Ltd. were successively placed. The nylon clothes, which were nonchemically treated as woven and had a fine texture suitable for the purpose of making umbrella, were used after precoating with a thin slurry of low soda alumina

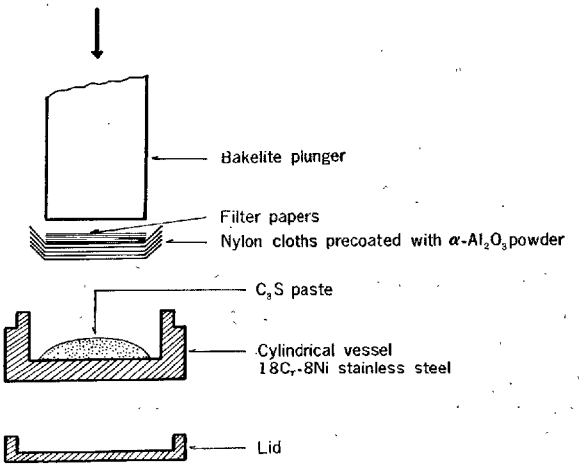

Fig. 1. *Assembly for sequeezing the aqueous solution from the paste*

(α–Al_2O_3, mean grain size of 3μ) and then drying, to secure the liquid absorbed in filter papers from the contamination with C_3S particles. Care should be paid here not to substitute filter papers for nylon clothes, because the filter papers commercially available do adsorb substantial amount of Ca^{++} ion from the basic aqueous solution to be analyzed. After hand-loading through a plunger, the whole filter papers were separated from, weighed, mixed with 30 ml of 0.03 N HCl, filtered and washed. The solutes in the filtrate thus obtained were analyzed as follows: After adding about 2 ml of 0.1 mol Mg-EDTA solution to the half filtrate, the content of calcium ion was determined by titration with 0.001 mol EDTA under the indicator of BT (7). To determine the SiO_2 content in the other half filtrate, molybdenum blue photometric method (8) was carried out, a Hitachi Spectro-photometer Model EPU-2 being utilized for the purpose.

Combined Water

After hand pressing, the residue left under the nylon sheets was taken and the combined water therein was measured as follows: The residue (about 5 g in dry basis) was diluted with about 70 ml of absolute iso-propyl alcohol to interrupt the progressive hydration of C_3S and was centrifugalized. The sediment was mixed with another 70 ml of absolute alcohol and re-centrifugalized, this treatment being repeated successively four times, followed by replacements with each 70 ml of petroleum ether three times. The sediment thus obtained was then placed, as wetted with petroleum ether, on a combustion boat made of silica glass and the combined water therein was released by heating in a tube furnace, absorbed in a methanol—glycol solution and titrated with Karl Fischer's reagent (3 mg H_2O /ml) as described in the recent paper (9). To obtain a correct value, it was necessary to run through blank test with almost the same amount of α-alumina —petroleum ether paste and to make a corresponding reduction (i.e. equivalent to 0.2–0.3 ml of the reagent) from the result of analysis. Thus, the combined water described in this paper should be defined as the one combined to the solid phase tightly enough not to be released by the dissolving effect of absolute iso-propyl alcohol.

Electron Micrograph

The electron micrographs were made by means of a Nippon Denshi K. K., Model JEM-7A. Samples treated with organic solvent at predetermined times were air-dried and sprinkled over a collodion film supported by a grid in the usual manner.

Results

Immediate Heat Liberation of C_3S as Mixed with Water

In Fig. 2 the heat evolution rate during the hydration of C_3S is plotted versus time. A peak of heat evolution rate appears immediately after mixing C_3S with water, but soon declines to a minimum, the minimum being at around 30 min.—in this paper the period until the minimum appears is refered to as immediate stage,— and then the heat evolution rate increases gradually but almost linearly with time (sluggish stage), followed by an abrupt raising (hardening stage).

From the peak area in Fig. 2, the heat liberated in the immediate stage was calculated to be 0.096 cal/g C_3S or 0.25 cal/m² C_3S for the sample C_3S (I) and 0.14 cal/g C_3S or 0.33 cal/m² C_3S for the sample C_3S (II). The discrepancy between both calorimetric values would be in a close relation to the difference in the specific gravity, as shown in Table 1. It is further noticeable that these calorimetric values were so small in comparison with those of portland cements, the values being around 4 cal/g cement in general (6). Passing through a minimum heat evolution rate, there came the sluggish stage, which was durable for about

three hours and showed a mean heat evolution rate of one cal. sec^{-1}. 10^{-4}/g C_3S.

Increase in Combined Water

Based upon the application of the devised analytical method mentioned above, it was made possible to follow clearly the increase in combined water during the early stage of hydration.

From the titers of Karl Fischer's reagent, the percentage of water by weight released from the solid samples were plotted against temperaturs as shown in Fig. 3 a. b., where the continuous dehydration curves were seen over the temperature range up to 700°C, but slight sharp slopes were observed at around 100°C and between 400°C–500°C. Such dehydration curves were obtained for the series of samples which had been hydrated at various temperatures of 10°C, 20°C and 40°C, and the total amounts of water released by heating up to 850°C were determined and refered to as a combined water in the hydrated sample, the results being shown in Fig. 4.

The curves in Fig. 4 indicate that after mixing C_3S with water a combined water is formed almost instantaneously and the amount thereof soon reaches to a constant value of about 0.05 ± 0.005 wt.% irrespective of the temperatures for hydration. This constant value holds for a while (i. e. for a dormant period) but the durations thereof are considered as depending upon the temperatures for hydration. Passing through

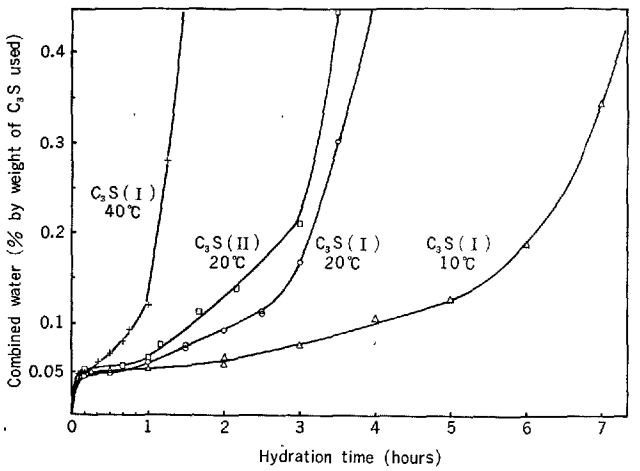

Fig. 4. *The amounts of combined water (wt.% by weight of C_3S used) versus hydration time*

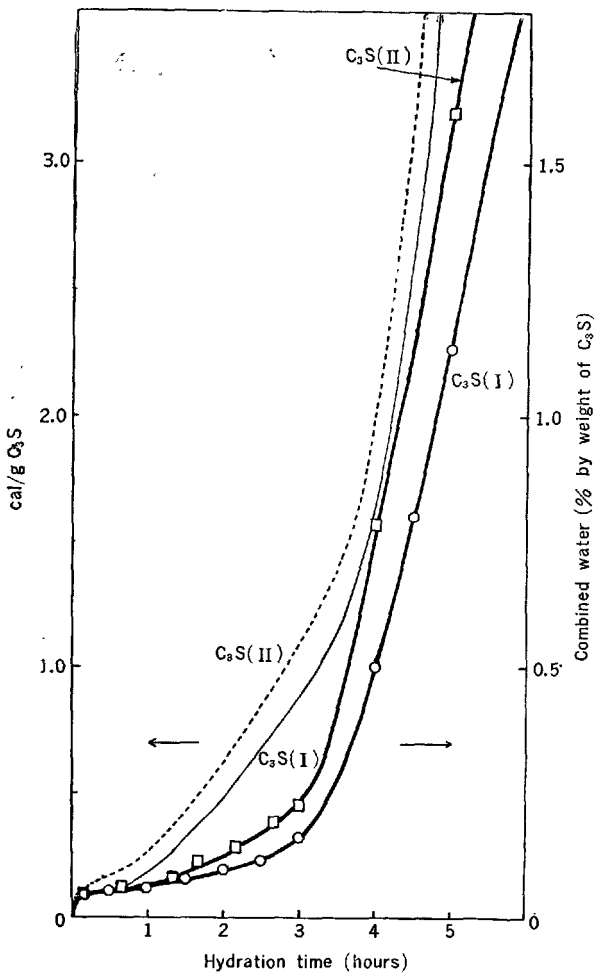

Fig. 5. *Cumulative curves of the amounts of heat evolved and combined water versus hydration time, at 20°C*

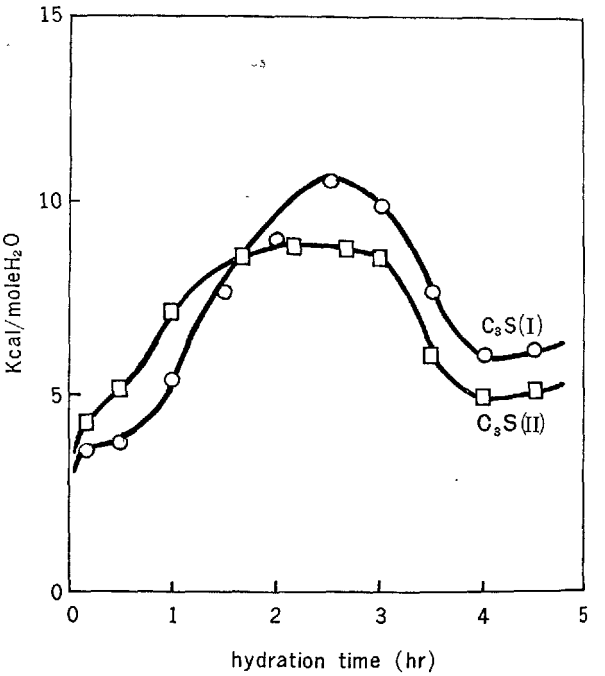

Fig. 6. *Mean heat of hydration per mole of combined water versus hydration time, at 20°C*

the dormant period, the curves are rising with a nearly linear slope up to the point indicating about 0.12 wt.% of combined water, this period being corresponding to the sluggish stage in Fig. 2.

To make clear the relationship between the liberation of heat and the formation of combined water, it is necessary to transform the curves shown as heat evolution rate versus time in Fig. 2 into the one in the form of integral amount of heat evolved versus time. The results obtained are shown in Fig. 5, wherin are seen the cumulative curves of the amounts of heat evolved (in this case however, the heat of solution or crystallization of Ca $(OH)_2$ is excluded) and combined water versus time during hydration (at 20°C), indicating that a remarkable difference in the slopes of curves occurs at the time range from 1 hour to 3.5 hours. When the mean heat of hydration per one mole of combined water may be presented as (cumulative amount of heat evolved)/(cumulative amount [moles] of water combined), so the values can readily be calculated as shown in Fig. 6.

From Fig. 6, it was revealed that at the immediate stage the mean heat of hydration was as small as about 3.5 Kcal/mole H_2O, but gradually became larger until a maximum of 10 Kcal/mole H_2O was reached in a later sluggish stage, followed by a sudden decrease at the beginning of the hardening stage.

Analytical Results of Aqueous Phases

The aqueous phase in a paste with a 0.7:1 water—tricalcium silicate ratio by weight was squeezed out in the immediate stage and subjected to chemical analysis.

As shown in Fig. 7 a, b, c, the dissolutions of both calcium ion and silicic acid did occur immediately as tricalcium silicate was mixed with water and the amount of silicic acid was recorded to be about one millimole/l soln. at a reaction time of 0.5 min. The concentration of silicic acid, however, reduced rapidly in contrast with gradual increase in that of calcium ion along with time. Such trends were observed not only for C_3S(I) at 20°C but also for the same at 10°C and for C_3S(II) at 20°C, and when these data were represented so as to illustrate the variation in CaO/SiO_2 ratio with time, then were obtained the curves shown in Fig. 8.

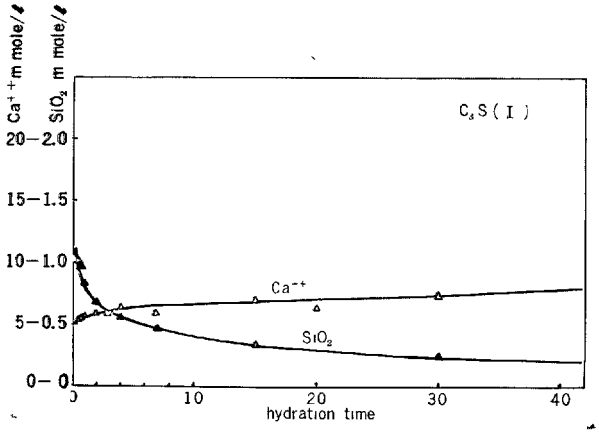

Fig. 7a. *Dissolutions of calcium ion and silicic acid from* C_3S(I), *at 20°C*

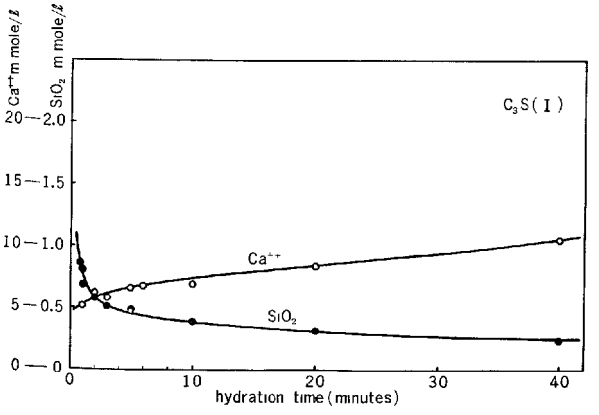

Fig. 7b. *Dissolutions of calcium ion and silicic acid from* C_3S(I), *at 10°C*

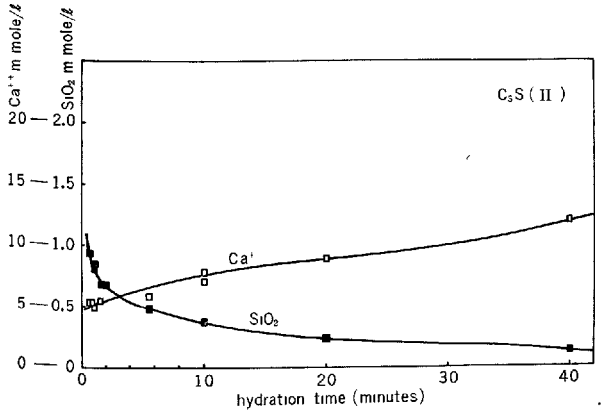

Fig. 7c. *Disolutions of calcium ion and silicic acid from* C_3S(II), *at 20°C*

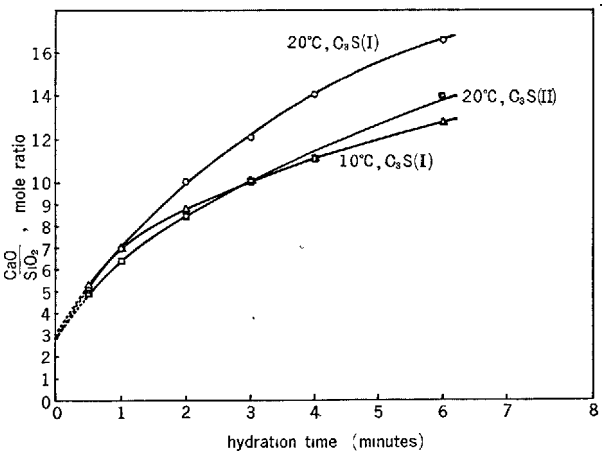

Fig. 8. *Variations in* CaO/SiO_2 *mole ratio in the aqueous phases of pastes with hydration time*

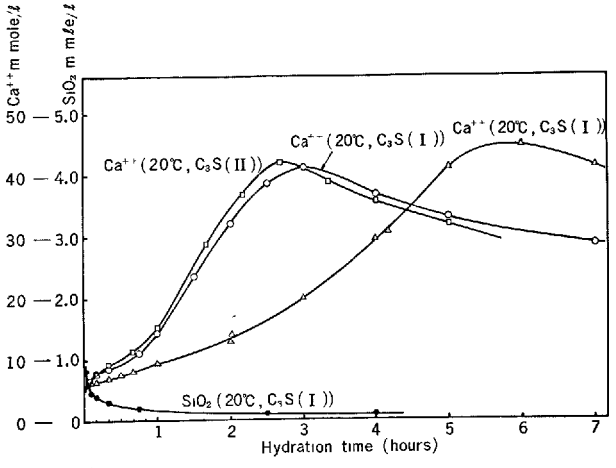

Fig. 9. *Concentrations of Calcium ion and silicic acid in aqueous phase versus hydration time (view over the long period)*

Extrapolating the curves to a reaction time of zero in Fig. 8, so the CaO/SiO_2 ratio of 3 was probably attained, it being suggested that at the moment of their mixing with water, some surface layers of tricalcium silicate were likely to dissolve instantaneously in water at a stoichiometric ratio or congruently, and that the silicic acid once dissolved would soon precipitate from aqueous solution presumably as a calcium hydrosilicate.

The concentration of calcium ion in the aqueous phase varied with reaction time, and the feature could be viewed until after seven hours as shown in Fig. 9.

In the immediate stage, the concentration of calcium ion as CaO was far below the level of saturation, and remained unsaturated until a hydration time of 1.3 hours (at 20°C) and 3.2 hours (at 10°C) has elapsed. After reaching the saturation, however, a further increase in concentration took place continuously up to the maximum concentration which was about twice as high as the solubility of calcium hydroxide. It is worthwhile to note that the time at which the maximum concentration was attained was in a later sluggish stage, that is, a start on the crystallization of $Ca(OH)_2$ from the supersaturated solution would likely be in a close relation to the beginning of the hardening stage.

Discussion

Based on the data described above, some interpretations may be put on the hydration processes of tricalcium silicate in an early stage.

An Immediate Stage

On mixture with water, tricalcium silicate was found to dissolve instantaneously in a ratio of $CaO/SiO_2 = 3$, that is congruently (See Fig. 8). If such dissolution should occur from the surface of the grain, the amount of dissolution of one mole layer on the outer shell of C_3S can be calculated to be (specific surface area of C_3S)/(mean area occupied by one molecule of C_3S) × (Avogaro's number), where the mean area occupied by one molecule of C_3S may be 25.2 Å², the value being obtained as

$$(\text{abc. sin } \beta . \sin\gamma/Z)^{2/3}$$

unit cell constants (10): $a = 12.915$ Å $\quad \alpha = 90° \quad Z = 18$; $b = 7.104$ Å $\quad \beta = 89.8°$; $c = 25.096$ Å $\quad \gamma = 89.8°$

Therefore, the amount of dissolution of one mole layer on the outer shell of C_3S can be expected to be 2.54×10^{-3} millimoles/g C_3S(I) or 2.86×10^{-3} millimoles/g C_3S(II), namely the concentration of C_3S dissolved in the aqueous phase of the paste ($C_3S : H_2O = 1:0.7$ in weight ratio) will amount to 2.54/0.7 millimoles/1 = 3.63 millimoles/1 for C_3S(I) or 2.86/0.7 millimoles/1 = 4.08 millimoles/1 for C_3S(II). These values are fairly comparable with the concentrations of calcium ion in the aqueous phases 8.5 millimoles/1 for C_3S(I) and 9.0 millimoles/1 for C_3S(II), measured at a hydration time of twenty minutes, the time being at a later immediate stage, (see Fig. 7 a, b, and Fig. 2), because the hydrolysis of one mole of tricalcium silicate dissolved should split off more than one mole of $Ca(OH)_2$ in accordance with the following formula.

$$3CaO \cdot SiO_2 + (3 + m - n)H_2O = nCaO \cdot SiO_2 \cdot mH_2O + (3-n)Ca(OH)_2 \quad (1)$$

for calcium silicate hydrate (I), $n = 1$–1.5

Providing n to be 1, so the calculated concentrations of calcium ion in the aqueous phases would become $2 \times 3.63 = 7.26$ millimoles/1 for C_3S(I) and $2 \times 4.08 = 8.16$ millimoles/1 for C_3S (II).

The amount of the combined water formed at the end of the immediate stage was found to be about 0.05% by weight of C_3S used, as seen in Fig. 4a, and the nature of this combined water will be mentioned in the following.

The combined water described in this work will be hydrated water to form calcium hydroxide and calcium hydrosilicate, the remainder presumably being an adsorbed water. An approximate estimation of each combined water would be possible, provided that the calcium hydrosilicate crystallized out of the solution during the immediate stage has a mole ratio H_2O/SiO_2 of 2.0 in based on the value given by Taylor (11), that was obtained for calcium silicate hydrate (I) dried with alcohol and ether, in the present work also the same drying procedure with organic solvent being employed. If m in the equation (1) is thus supposed to be 2, so the equation (1) becomes as follows:

$$3CaO \cdot SiO_2 + (5 - n)H_2O = nCaO \cdot SiO_2 \cdot 2H_2O + (3 - n)Ca(OH)_2 \quad (2)$$

The amount of one mole layer of C_3S on the outmost surface dissolved into aqueous phase could be estimated to be 2.54×10^{-3} millimoles/g C_3S (I) or 2.86×10^{-3} millimoles/g C_3S (II) as mentioned

above, and should the C_3S thus dissolved hydrolyze to precipitate nCaO·SiO_2·2H_2O with remaining $Ca(OH)_2$ formed in an aqueous phase, the amount of three species of combined water could be calculated and the result is shown in Table 2.

From Table 2, an adsorbed water can be considered as a principal constituent of the combined water. It will be reasonable to suppose that the adsorbed water should be formed on the surface of C_3S grains as compensation for the dissolution of one mole layer of C_3S situated on the outmost surface. Then, the number of layers of water molecules adsorbed on the C_3S grains can be calculated using the cross sectional area of 11.4 Å^2 for one water molecule (12) and the

Total comb. water	0.050	0.050	0.050	0.050
Number of layers of H_2O molecules adsorbed on the C_3S grain	3.6	3.4	3.3	3.1

*About 40% by weight of total amount of solution in the paste tested was squeezed out for analysis of the solution. Therefore, the amount of the combined water for $Ca(OH)_2$ in the solution must be $0.6 \times 0.009 = 0.005$ for $n = 1.0$, C_3S(I) and so on.

results are also shown in Table 2. The mean values are seen to be 3.5 for $n = 1$ and 3.2 for $n = 1.5$, but, the most probable number of layers of adsorbed water molecules will be 4, because that the alcohol added to the paste to interrupt the progressive hydration of C_3S does dissolve a very few but, influential amount of $Ca(OH)_2$ and if account is taken of the low concentration of Ca^{++} ions in the aqueous phase at the immediate stage, the value of n will probably be 1.2–1.3.

The Sluggish Stage

Once the immediate reaction of C_3S with water has ceased, it begins the durable sluggish stage in which the heat evolution is mild and the increase in the amount of combined water is sluggish. Of the data obtained in this work, the followings seem to be important for understanding the characteristic reaction that has occured in the sluggish stage.

1. The concentration of calcium ion reached to about 40 millimoles/l soln. in a later sluggish stage, this maximum concentration being about twice as high as the solubility of $Ca(OH)_2$ in water (Fig. 9).

2. From Fig. 6, the mean heat of hydration per one mole of combined water in the sluggish stage is found to be exceedingly large in comparison with those in the immediate stage and the hardening stage.

3. From the electron microscope data (Fig. 10), no distinct changes could be observed in the sluggish stage and the fibrous or crinkly foil-type hydrate lying stragglingly on the C_3S grains will most likely be a precipitate of calcium hydrosilicate from the solution during the immediate stage.

Based on these facts, it will be possible to put some interpretations on the characteristic reactions at the sluggish stage. In the first place, it may reasonably be deduced that at the later sluggish stage, about four mole layers of C_3S (equivalent to a depth of about 20 Å) on the surface of original grains should be hydrated with splitting off Ca ion into solution in accordance with the formula 1, because that the concentration of $Ca(OH)_2$ thus splitted off into the solution at the later sluggish stage (40 millimoles/l) is four times as high as that at the end of the immediate stage, the latter being approximately equivalent to one mole layer of C_3S as mentioned above. The outmost of the four mole layers does emigrate elsewhere through a solution—precipitation process. However the remaining three mole layers will be hydrolyzed in situ to form an intermediate substance as was anticipated from the concentration of silicic acid shown in Fig. 7 and 9, the intermediate compound being presumably a non-crystalline hydrate prior to tobermorite—formation.

In the second place, about four mole layers of the adsorbed water which have been made presumably loosely on the surface of grains during the immediate stage, must rearrange themselves to form hydrates and contribute to heat evolution during the sluggish stage. This effect will be one of the causes for the exceedingly high mean heat of hydration observed during the sluggish stage (Fig. 6).

Lastly, it will be interesting to note the fact that the beginning of crystallizing calcium hydroxide out of the solution with a maximum supersaturation did timely correspond with the entrance into the hardening stage. However, further investigation will be necessary to solve the problem as to whether both are in a causal relation or not.

Oral Discussion

Shunro Ueda

You stated that the combined water was only 0.05% of C_3S immediately after the mixing with water. Our tests have shown that powered C_3S usually contains about 0.1% moisture and combines with 0.3 to 0.4% water immediately after the mixing. You considered that the thickness of the reaction layer was about 20 Å at the end of the sluggish stage. Terrier and Moreau presumed the thickness to be several Å while we presumed it to be 200 to 300 Å in agreement with the thickness of a nucleus, based on our tests by surface electron diffraction.

I would like to ask your opinion on these points.

Arthor's Closure

Kinjiro Fujii

It would be due to the hydration condition of C_3S varying with each other that our results remarkably differ from those obtained by Mr. Ueda and Dr. Kondo, that is, in our test C_3S was hydrated at a water/C_3S ratio of 0.7, while Mr. Ueda and Dr. Kondo studied on the hydration of C_3S in a suspension state, the water/C_3S ratio being 20. Our determination of calcium ions concentration in the solution one hour after mixing with water showed that the amount of Ca^{++} dissolved was only 0.01 m. mole/g. C_3S at a water/C_3S ratio of 0.7, while in case of water/C_3S ratio of 200, under which Greenberg and Chang (1) studied on the kinetics of the hydration of C_3S, it was about 1.7 m. moles/g.C_3S, that is 170 times of the former. From this, different conclusions may be conducted on the hydration layer thickness.

With regard to the determination of combined water content of C_3S hydrated in a short period, a satisfactory result may be obtained by the analytical procedure written in the present paper within a error of $\pm$0.005 wt/% of C_3S used. From our blank test by Kirl-Fischer's method, it was estimated that the absorbed moisture content of original sample which was heated in advance and allowed to cool in desiccator was 0.01 wt% or less. D-dry method stated by Copeland and Hayes is said to require two days in drying, and so there remains some different questions in its application for the study on hydration process of C_3S in a very early stage.

Supplementary Paper II-118 The Hydration Mechanism of C_3A and C_3S in the Presence of Calcium Chloride and Calcium Sulphate

Nemat Tenoutasse*

Synopsis

We have studied the paste hydration of C_3A and C_3S in the presence of gypsum and/or $CaCl_2$.

The methods of investigation used in this work are: isothermal microcalorimetry, X-rays, chemical analysis, measurements of specific surface area (B.E.T. method), etc.

During this investigation we have developed a simple method for determining free $CaCl_2$ in the system C_3A–$CaCl_2$–H_2O; this method is based on the high solubility of $CaCl_2$ in ethyl alcohol.

The influence of the temperature on the hydration of $C_3A + CaCl_2$ and $C_3A + CaSO_4 \cdot 2H_2O$ is determined by microcalorimetry.

The activation energy for hydration is also determined.

The hydration of the system C_3A–$CaCl_2$–$CaSO_4 \cdot 2H_2O$ has shown that $CaCl_2$ accelerates the reaction between C_3A and gypsum.

In the hydration of C_3A in the presence of SO_4^{--} and Cl^-, the SO_4^{--} ions react first, and the C_3A reacts with the Cl^- ions only after the gypsum has been used up.

The trisulphoaluminate remains stable as long as the aqueous phase contains calcium chloride.

Our results on the system C_3S–$CaCl_2$–H_2O show that the $CaCl_2$ which can be extracted by alcohol decreases during hydration.

Using all of our results as a basis, we discuss the mechanism by which $CaCl_2$ and $CaSO_4 \cdot 2H_2O$ influence the hydration of tricalcium aluminate and silicate.

Introduction

Calcium sulphate and chloride are two substances frequently used to control the setting and hardening of portland cement.

The action of gypsum ($CaSO_4 \cdot 2H_2O$) on the hydration of cement and its constituents has been the subject of numerous investigations.

Jones (1) has carried out a detailed investigation of the system CaO–Al_2O_3–$CaSO_4$–H_2O. The chemical nature and the stability domains of the various hydrates have been determined. D'Ans and Eick (2) have also studied the calcium sulphoaluminates.

Schwiete, Ludwig and Jäger (3) have recently studied the system C_3A–$CaSO_4$–$Ca(OH)_2$–H_2O; amongst the various hydrates of the system CaO–Al_2O_3–$CaSO_4 \cdot H_2O$, there are two of particular interest in cement chemistry:

1. Calcium trisulphoaluminate, $C_3A \cdot 3CaSO_4 \cdot 32H_2O$ (Candlot's salt); this is found in nature as ettringite.

2. Calcium monosulphoaluminate or $C_3A \cdot CaSO_4 \cdot 12H_2O$; this hydrate is isomorphous with C_4AH_{13}; calcium monosulphoaluminate crystallises as thin hexagonal platelets.

As far as research on the role of $CaCl_2$ in the setting and hardening of cements is concerned, a literature review by Vollmer (4) should be mentioned. The latter summarizes almost 200 publications on the role of $CaCl_2$ in the hydration of cements.

Most of the research on the behaviour of cement in the presence of $CaCl_2$ is concerned with the technological aspect and with mechanical characteristics; the exact mechanism by which $CaCl_2$ exerts its effect is not well understood.

Calcium chloride modifies the hydration kinetics of all the constituents of cement; it accelerates the hydration of silicates and slows down that of aluminates and aluminoferrites.

Certain investigators believe that the acceleration of the hydration of silicates by $CaCl_2$ is due to a lowering of the pH of the aqueous phase by the calcium chloride.

*Centre National de Recherches Scientifiques et Techniques pour l'Industrie Cimentière, Bruxelles, Belgium.

Amongst the chlorine-containing hydrates of interest in cement chemistry, the following ones should be mentioned:

monochloroaluminate: $C_3A \cdot CaCl_2 \cdot 10H_2O$ (Friedel's salt)

trichloroaluminate: $C_3A \cdot 3CaCl_2 \cdot 32H_2O$

calcium oxychloride: $3CaO \cdot CaCl_2 \cdot 15H_2O$.

Calcium monochloroaluminate is the only hydrate formed in the usual conditions of cement use.

It is known that aluminates and aluminoferrites containing $CaCl_2$ do not influence positively the mechanical performance of cements. The favorable results obtained by the addition of $CaCl_2$ are due essentially to its role in the hydration of C_3S.

We shall discuss briefly below our work on the hydration of C_3A and C_3S in the presence of $CaSO_4 \cdot 2H_2O$ and/or $CaCl_2$.

Materials and Methods

C_3S and C_3A are prepared by heat treatment from stoichiometric mixtures of the oxides.

The purity of the final products is checked by X-rays and by a determination of free lime using a method developed by the author (5).

The products thus obtained are crushed until they pass through an A.S.T.M. 325 sieve.

In order to obtain fractions of definite grain sizes, we fractionated C_3A and C_3S using a BAHCO elutor-centrifuge.

The gypsum and $CaCl_2$ used are Merck "pro analisi" reagents.

The determination of gypsum and $CaCl_2$ was carried out as described previously (6 and 7).

The thermal phenomena accompanying the hydration of our samples are followed using an isothermal microcalorimeter.

The technical characteristics of this apparatus have been described by Stein (8) and the author (9).

In order to determine the structure of the hydrates we used X-rays. The apparatus employed is the Philips P. W. 1010 diffractometer, fitted with a P. W. 1050/30 wide-angle goniometer.

Results and Discussion

$C_3A + CaSO_4 \cdot 2H_2O$

Literature data on the hydration of C_3A in the presence of gypsum indicates that ettringite (the trisulphoaluminate) is formed at the beginning of hydration: it persists until the SO_4^{--} ions are used up; afterwards it is converted into monosulphoaluminate which, in turn, forms mixed crystals with C_4AH_{13}.

It is well-known that gypsum influences the hydration kinetics of C_3A; isothermal microcalorimetry is a useful method for confirming the role of $CaSO_4 \cdot 2H_2O$ in the hydration rate of tricalcium aluminate.

The thermograms in Fig. 1 show the influence of various gypsum concentrations on the thermal phenomena accompanying hydration.

An examination of the curves shows that a variation in the percentage of $CaSO_4 \cdot 2H_2O$ greatly modifies the profile of the thermograms; in fact, the gypsum concentration of the samples influences not only the time necessary for the appearance of thermal phenomena, but the amplitude of the peaks (hydration rate) is also changed.

An analysis of the sample by X-rays, and also by chemical analysis, shows that at the top of the second thermal phenomenon, the gypsum has been entirely used up. It is, therefore, possible to measure the time necessary for the consumption of a definite quantity of gypsum by microcalorimetry; in fact, it is sufficient to measure the time which has passed in order to

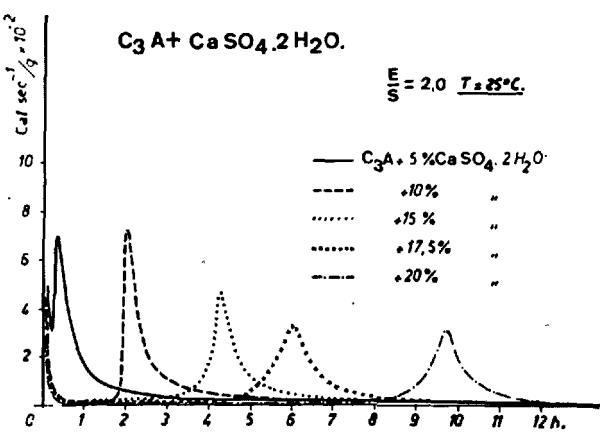

Fig. 1.

obtain the maximum of the second thermal phenomenon.

This time has been calculated from the thermograms of Fig. 1 for several gypsum concentrations. It is seen that the gypsum consumption time varies linearly with the square of the gypsum percentage (Fig. 2). In other words the delay caused by gypsum in the appearance of the second thermal phenomenon is proportional to the square of the $CaSO_4 \cdot 2H_2O$ concentration.

The fact that the gypsum consumption time depend linearly on the square of its concentration suggests that the gypsum reacts by a diffusion mechanism.

The effect of temperature on the hydration kinetics is demonstrated by microcalorimetric tests at various temperatures.

If rate constants are calculated from peak heights, the Arrhenius equation is shown to be valid.

Using the thermograms carried out at different temperatures, we have determined the activation energy for hydration for the system $C_3A + CaSO_4 \cdot 2H_2O + H_2O$. This energy is of the order of 12 $Kcal \cdot mole^{-1}$.

$C_3A + CaCl_2$

The hydration kinetics of C_3A in the presence of $CaCl_2$ has been studied under the same conditions as $C_3A + CaSO_4 \cdot 2H_2O$. The role of $CaCl_2$ in influencing the thermal phenomena is analogous to that of $CaSO_4 \cdot 2H_2O$. Fig. 3 shows the thermograms obtained for the hydration of C_3A in the presence of various quantities of $CaCl_2$; the ratio E/S = 1.2; calcium chloride is dissolved in the water before tempering.

It can be seen from Fig. 3 that an increase in the concentration of $CaCl_2$ in the aqueous phase retards the appearance of the second thermal phenomenon.

We have followed the $CaCl_2$ consumption during hydration. We shall denote by α the degree of transformation (percentage of $CaCl_2$ which has reacted).

By studying the function $F(\alpha) = A(t)$ where t is the hydration time, it is observed that the hydration kinetics is controlled by diffusion processes.

Amongst the different relations proposed by various investigators, the equation for diffusion in a sphere is in best agreement with our experimental results:

$$[1 - (1 - \alpha)^{1/3}]^2 = Kt$$

The straight lines in Fig. 4 show satisfactory agreement between this expression and the experimental data.

$C_3A + CaSO_4 \cdot 2H_2O + CaCl_2$

The paste hydration of C_3A in the presence of Cl^- and SO_4^{--} ions is of an obvious practical interest; when $CaCl_2$ is added to portland cement, the tricalcium aluminate of the cement is hydrated under the simultaneous influence of calcium chloride and calcium sulphate. Roberts (10) has investigated this problem, but his experimental methods do not enable a determination of the chloride which has reacted to be carried out. Our method, on the other hand, ena-

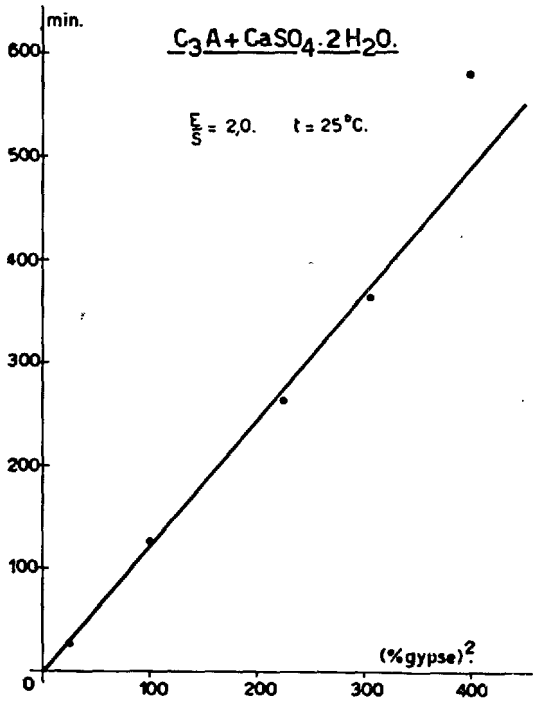

Fig. 2.

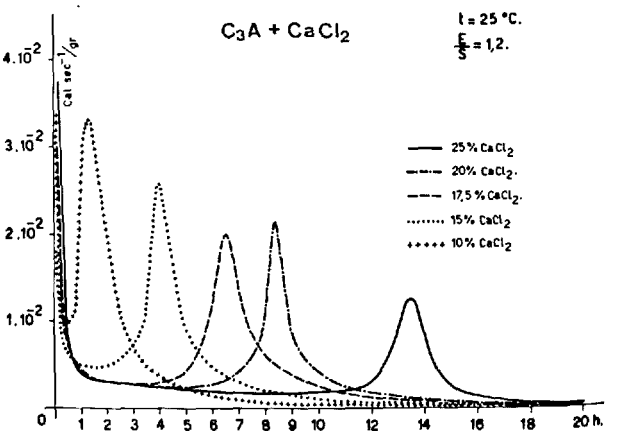

Fig. 3.

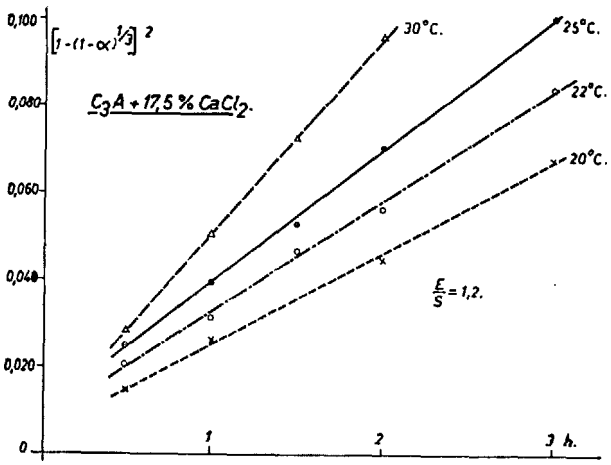

Fig. 4.

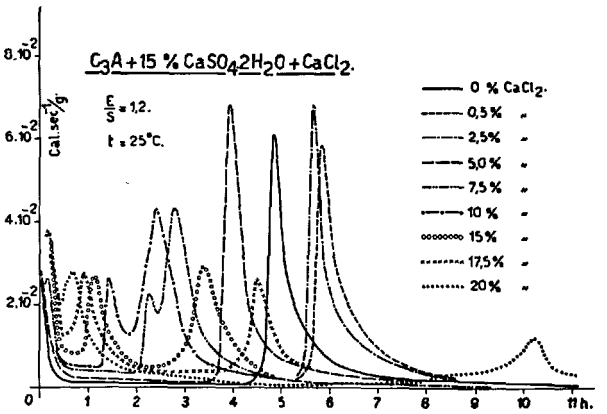

Fig. 5.

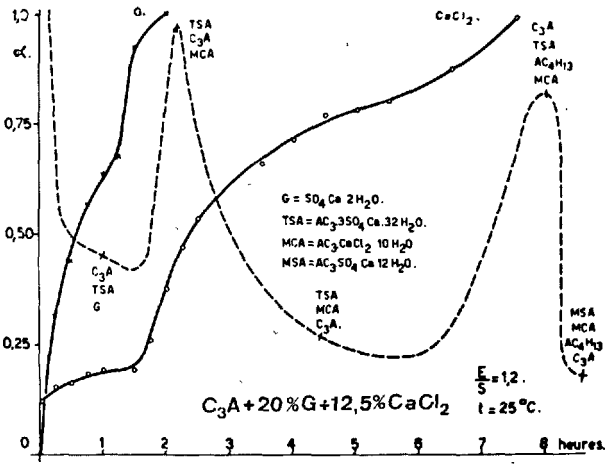

Fig. 6.

bles one to determine precisely how much $CaCl_2$ has been consumed at a given time; the presence of $CaSO_4 \cdot 2H_2O$ has no effect on the estimation of $CaCl_2$.

Microcalorimetry has provided us with valuable information on the action of $CaCl_2$ in the hydration of $C_3A + CaSO_4 \cdot 2H_2O$.

The curves in Fig. 5 show the influence of various percentages of $CaCl_2$ on the hydration of a mixture of $C_3A + 15\%\ CaSO_4 \cdot 2H_2O$.

An examination of these thermograms shows that percentages of $CaCl_2$ greater than 5% accelerate the appearance of the thermal phenomena; above 7.5% $CaCl_2$ the main thermal phenomenon is doubled; $CaCl_2$ concentrations less than 5% slow down the appearance of the thermal phenomena; it seems that the addition of small amounts of $CaCl_2$ (less than 5%) increases the effect of gypsum.

To arrive at a better understanding of the hydration process, we shall consider in particular the hydration of a sample having the following composition:

$$C_3A + 20\%CaSO_4 \cdot 2H_2O + 12.5\%CaCl_2$$

The choice of the composition of this sample is based on microcalorimetric data, since with these percentages of sulphate and chloride, the thermal phenomena are considerably separated and one can easily stop the hydration between two microcalorimetric peaks.

The hydration of this sample is followed by the methods listed below:

1. The thermal phenomena are recorded using an isothermal microcalorimeter.

2. The $CaCl_2$ consumption is followed by estimation of the $CaCl_2$ which has not reacted (free chloride).

3. The reaction between C_3A and $CaSO_4 \cdot 2H_2O$ is studied by determining the gypsum percentage by radiocrystallography.

4. The hydration products are identified throughout hydration by X-rays.

Our results are shown schematically in Fig. 6.

At the beginning of hydration, a small amount of $CaCl_2$ reacts to give chloroaluminate; but it is observed in particular that SO_4^{--} ions react at first to give calcium trisulphoaluminate.

Consumption of Cl^- ions begins only after the SO_4^{--} ions have been completely used up; the complete consumption of $CaCl_2$ coincides with the maximum of the third peak.

In the light of these results, one can represent the hydration process of C_3A in the presence of Cl^- and SO_4^{--} by the following reaction steps;

A. first microcalorimetric peak "liquid-solid contact"

$$C_3A + 3CaSO_4 + 32H_2O \rightarrow C_3A \cdot 3CaSO_4 \cdot 32H_2O$$
$$C_3A + CaCl_2 + 10H_2O \rightarrow C_3A \cdot CaCl_2 \cdot 10H_2O$$

B. between the first and second peaks

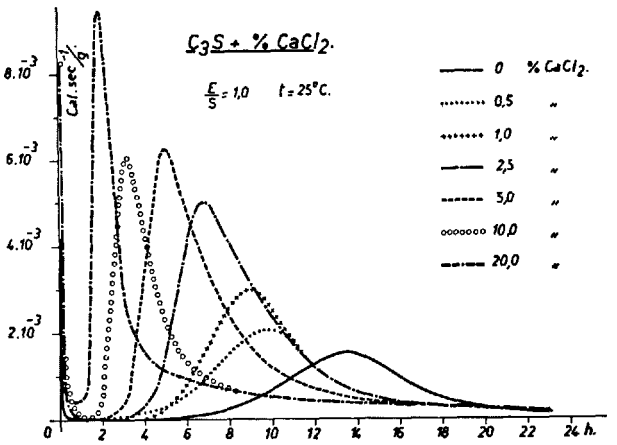

Fig. 7.

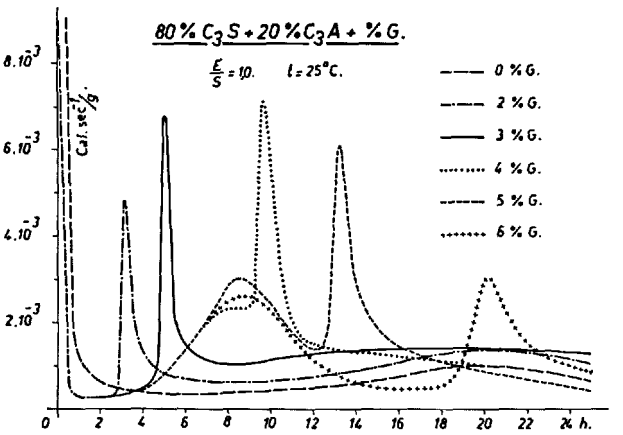

Fig. 8.

$$C_3A + 3CaSO_4 + 3H_2O \rightarrow C_3A \cdot 3CaSO_4 \cdot 32H_2O$$

This reaction proceeds until the gypsum has been completely used up; during this period the $CaCl_2$ does not react.

C. between the second and third thermal phenomena

$$CaCl_2 + C_3A + 10H_2O \rightarrow C_3A \cdot CaCl_2 \cdot 10H_2O$$

D. after the third thermal phenomenon

The remaining C_3A is hydrated to give $C_3A \cdot Ca(OH)_2 \cdot 12H_2O$; this hydrate converts the trisulphoaluminate into monosulphoaluminate (after the Cl^- ions have been used up):

$$C_3A \cdot 3CaSO_4 \cdot 32H_2O + 2C_3A \cdot Ca(OH)_2 \cdot 12H_2O \rightarrow 3C_3A \cdot CaSO_4 \cdot 12H_2O + 20H_2O + 2CH_2$$

After conversion of the ettringite (the trisulphoaluminate) the hydrates having a hexagonal structure; $C_3A \cdot Ca(OH)_2 \cdot 12H_2O$, $C_3A \cdot CaCl_2 \cdot 10H_2O$ and $C_3A \cdot CaSO_4 \cdot 12H_2O$ form solid solutions.

The Hydration of C_3S

The hydration of C_3S has been studied in particular by isothermal microcalorimetry.

Fig. 7 shows the effect of $CaCl_2$ on the hydration kinetics of C_3S. It can be seen that $CaCl_2$ accelerates the appearance of the second thermal phenomenon.

It should also be noted that an increase in the concentration of $CaCl_2$ in the aqueous phase causes the height of the peak to increase.

X-ray examination of samples of C_3S hydrated in the presence of $CaCl_2$ did not enable us to detect any compound containing $CaCl_2$, except in the sample containing 20% $CaCl_2$; in fact, X-rays show that this sample contains calcium oxychloride ($3CaO \cdot CaCl_2 \cdot 15H_2O$).

We have also studied the hydration of mixtures of C_3S and C_3A; our first results show that the presence of C_3A considerably modifies the thermal phenomena accompanying the hydration of C_3S. Tricalcium aluminate slows down the hydration of C_3S.

In Fig. 8 are shown thermograms for a mixture of C_3S and C_3A, containing increasing percentages of gypsum.

An examination of the curves in Fig. 8 shows that; when the microcalorimetric peak due to the complete consumption of the gypsum lies before the peak due to the hydration of C_3S, the latter peak is greatly retarded.

On the other hand, when the thermal phenomenon attributed to the hydration of $C_3A + CaSO_4 \cdot 2H_2O$ lies after the thermal phenomena due to the hydration of C_3S, the latter peak is practically unchanged.

General Conclusions

In the present investigation, we have studied the hydration of C_3S and C_3A in the presence of $CaCl_2$ and/or $CaSO_4 \cdot 2H_2O$.

Great importance is attached to the kinetic aspect of hydration.

In order to study the hydration kinetics, adequate methods of investigation are above all necessary to follow the transformation.

By using simple methods, we have followed with precision the concentration of Cl^- and SO_4^{--} in the liquid phase.

In this way we have been able to show the determining role of diffusion processes in the hydration of C_3A in the presence of calcium chloride or calcium sulphate.

We have proposed equations to describe the hydration kinetics.

Our microcalorimetric investigations have led us to devise a simple method for determining the activation energy for hydration.

The values obtained by microcalorimetry for the activation energy are in agreement with those measured by chemical methods.

As regards the nature of the hydration products, it should be remembered that the hydration of pure C_3A gives unstable hydrates with a hexagonal structure (C_4AH_{13}, C_2AH_8) which are converted into the cubic hydrate C_3AH_6, which is the only stable hydrated calcium aluminate in the system CaO–Al_2O_3–H_2O; but according to our X-ray crystallographic data, the hydration of C_3A in the presence of $CaSO_4 \cdot 2H_2O$ and $CaCl_2$ gives rise to sulpho- and chloroaluminates which have the hexagonal structure. These complex hydrates containing Cl^- and SO_4^{--} form solid solutions with C_4AH_{13}. The formation of a solid solution stabilises C_4AH_{13} and greatly slows down its conversion into C_3AH_6.

A study of the nature of the hydrates in the hydration of the system C_3A–$CaSO_4 \cdot 2H_2O$–$CaCl_2$ enables us to define certain aspects of the hydration of C_3A in the presence of Cl^- and SO_4^{--}:

I. $CaCl_2$ accelerates the reaction between gypsum and C_3A.

II. When C_3A is hydrated in the presence of $CaCl_2$ and $CaSO_4 \cdot 2H_2O$, the SO_4^{--} ions react first to give the trisulphoaluminate; formation of monochloroaluminate begins only after the SO_4^{--} ions have been used up.

III. The trisulphoaluminate formed in the presence of $CaCl_2$ is converted into monosulphoaluminate only after all the $CaCl_2$ has been used up.

IV. $CaCl_2$ accelerates the reaction between C_3A and $CaSO_4 \cdot 2H_2O$.

V. Calcium hydroxide does not alter the hydration mechanism of C_3A in the presence of Cl^- and SO_4^{--} ions.

Our work on the kinetic aspect of the hydration of $C_3A + CaCl_2$ and/or $CaSO_4 \cdot 2H_2O$ has shown that for a complex kinetic study, it is useful to use several methods of investigation such as; isothermal microcalorimetry, X-ray crystallography, chemical analysis, etc.

As regards the hydration of the binary system $C_3S + C_3A$ in the presence of $CaCl_2$ and $CaSO_4 \cdot 2H_2O$, our first results are encouraging, but further research is necessary to understand the hydration mechanism of $C_3S + C_3A$.

Supplementary Paper II-120 The Hydration of the Ferrite Phase of Cements

Walter L. De Keyser and Nemat Tenoutasse*

Synopsis

It is generally accepted that the ferrite phase of cements is a solid solution having the formula $C_6A_xF_y$.

During the investigation of the hydration of cements, we have studied some aspects of the solid solution of the ferrite phase under different conditions for pastes having a low water to solid ratio.

The action of iron during hydration was established by chemical analysis of the hydrated phase separated from the mixture by heavy liquids.

We have also studied the hydration of alumino-ferrites in the presence of gypsum and the latter was found to influence strongly the kinetics of hydration. The nature and stability of different hydrates was determined by X-ray studies and by electron microscopy.

The part dealing with the kinetics is entirely devoted to studies of the effect of the following parameters, which influence the rate of reaction:

I. time of contact of the specimens with gypsum,
II. water to solid ratio,
III. specific surface area,
IV. temperature, and
V. chemical composition of the specimens.

Introduction

The system Al_2O_3–CaO–H_2O has been studied in many investigations, and we now have a good understanding of it; this is neither the case for the system Fe_2O_3–CaO–H_2O, nor that of the system Al_2O_3–Fe_2O_3–CaO–H_2O, obtained by hydration of the ferrite phase, symbolically represented by $C_6A_xF_y$, where $x + y = 3$.

It should be remembered that a study of the system Fe_2O_3–CaO–H_2O presents difficulties owing to the instability of hydrates containing iron: for example FC_3H_6 is a hydrate which is difficult to synthesize in the pure state, while the synthesis of AC_3H_6 presents no difficulty.

In this investigation we have looked into the hydration of certain components of the solid solution of the ferrite phase in a pure paste or in the presence of $Ca(OH)_2$. The hydration of the ferrite phase is also studied in the presence of certain setting regulators such as $CaSO_4 \cdot 2H_2O$ and $CaCl_2$.

The hydration of tricalcium aluminate in the presence of gypsum and/or $CaCl_2$ is the subject of a paper presented at this symposium (1).

This paper is a condensed summary of work carried out over the last few years.

Materials and Methods

Nine components of the solid solution of $C_6A_xF_y$ were synthesized from "pro analisi" reagents. Mixtures of $CaCO_3$, Fe_2O_3 and $Al(OH)_3$ having a definite stoichiometry (lying between C_2F and C_6A_2F) are subjected to three heat treatments at 1340°C.

After the heat treatments the product is crushed until it passes through an ASTM 325 sieve (16,900 mesh/cm²).

In order to obtain fractions of definite granulometries, we carried out a fractionation of the products after sieving, using a BAHCO elutriator-centrifuge.

The gypsum used is U.C.B. "pro analisi" $CaSO_4 \cdot 2H_2O$ (No. 1234); it is passed through an ASTM 325

*Centre National de Recherches Scientifiques et Techniques pour l'Industrie Cimentière, Bruxelles, Belgium.

sieve (limiting mesh diameter 44 microns).

The gypsum is also elutriated to obtain fractions with different specific surface areas. In all the experiments we used Merck "pro analisi" $CaCl_2 \cdot 2H_2O$ (2832). The $CaCl_2$ content is always expressed as a percentage of anhydrous $CaCl_2$ respect to anhydrous aluminoferrite.

The calcium chloride is always dissolved in the water before tempering.

In order to follow the $CaCl_2$ concentration during hydration, we extracted the $CaCl_2$ which had not reacted by means of ethyl alcohol. After the alcohol extraction the chloride is determined by the silver nitrate method in a non-aqueous medium.

The thermal phenomena accompanying the hydration of our samples are followed using an isothermal microcalorimeter, described previously (2).

In order to determine the nature of the hydrates, we employed thermogravimetric analysis: the differential thermobalance was developed in 1953 by W. L. De Keyser (3).

Since then this method has been used frequently in studying the hydration of cement and its constituents.

The applications of differential thermogravimetry to cement chemistry are dealt with in a publication by De Keyser, Derie and Van Bemst (4).

In order to identify the structure of the hydrates, we used X-ray diffraction and electron microscopy.

We should like to point out that we have studied only the paste hydration of aluminoferrites.

The synthesized products were mixed with freshly boiled distilled water to obtain a plastic paste; the amount of water necessary to obtain such a paste varies from 25 to 40% depending on the nature of the aluminoferrite.

The hydration of the aluminoferrites was carried out at 25°C; the samples were stored in an atmosphere saturated with water and free from CO_2.

Results and Discussion

The Hydration of the Ferrite Phase in the Pure State and in the Presence of $Ca(OH)_2$

The rate of hydration of C_2F is very small. At the beginning of hydration the X-ray diagram of the sample of $C_2F + H_2O$ resembles that of the anhydrous substance.

As the iron is progressively replaced by aluminium in C_2F, the rate of hydration increases. For instance, C_6AF_2 is hydrated more rapidly than C_2F.

As regards the nature of the hydrates obtained by the hydration of C_6AF_2, it should be remembered that these hydrates are similar to those obtained by hydration of C_4AF and C_6A_2F.

The hydration of C_4AF is more rapid than that of C_2F and C_6AF_2. After five minute hydration, electron microscopy enables one to identify hydrates of hexagonal structure (Fig. 1).

24 hours later, the platelets are thicker, but the hexagonal platelets disappear gradually and hydrates of the cubic system are observed to appear. Fig. 2 shows an electron micrograph of a C_4AF sample hydrated for 4 months.

Fig. 3 shows differential thermogravimetric analysis

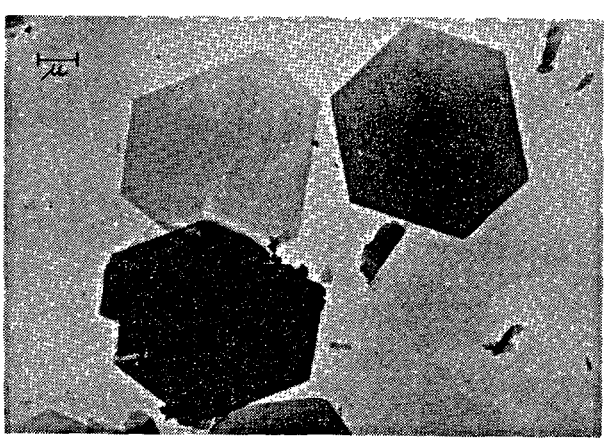

Fig. 1.

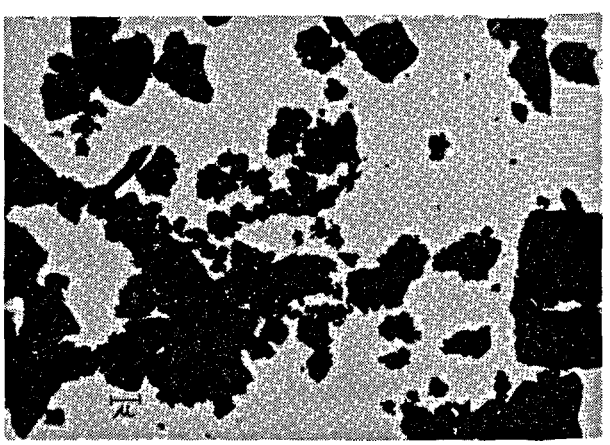

Fig. 2.

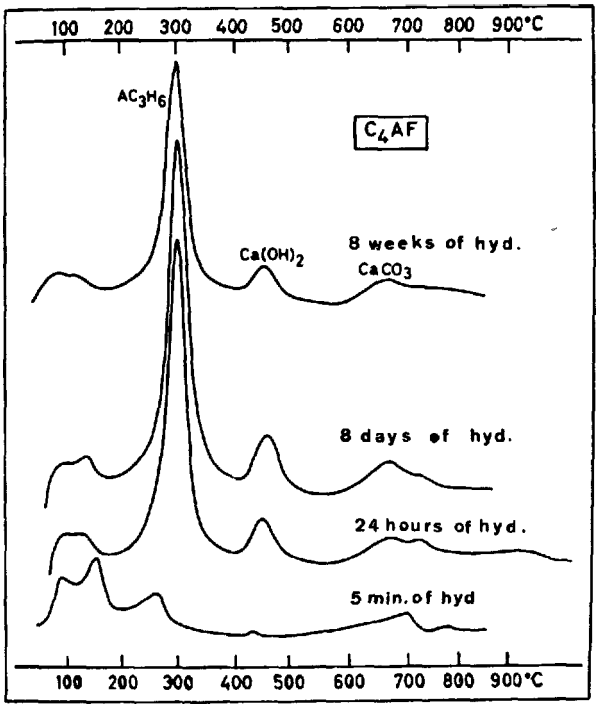

Fig. 3.

curves obtained after various hydration times. An examination of the curves in Fig. 3 shows clearly that after 5 minute hydration there are various peaks situated in the region lying between 100°C and 250°C, the peak at 150°C being characteristic of the hexagonal compounds.

But after 24 hour hydration it is seen that these peaks disappear gradually and an important peak appears at 300°C corresponding to the dehydration of the cubic compounds (A, F)C_3H_6. The appearance of this peak at 300°C is accompanied by that of another peak at 450°C, which corresponds to the dehydration of the $Ca(OH)_2$ liberated by the dehydration of the cubic hydrate.

It can, therefore, be seen that during this hydration hexagonal compounds are formed at first; these then turn into cubic compounds.

The process by which C_6A_2F is hydrated is very similar to that of C_4AF; however, the hydration of C_6A_2F is even faster than that of C_4AF.

When aluminoferrites are hydrated in the presence of $Ca(OH)_2$, the hydration process changes considerably.

This investigation was undertaken on account of its practical importance. This is due to the fact that portland cements liberate $Ca(OH)_2$ during hydration.

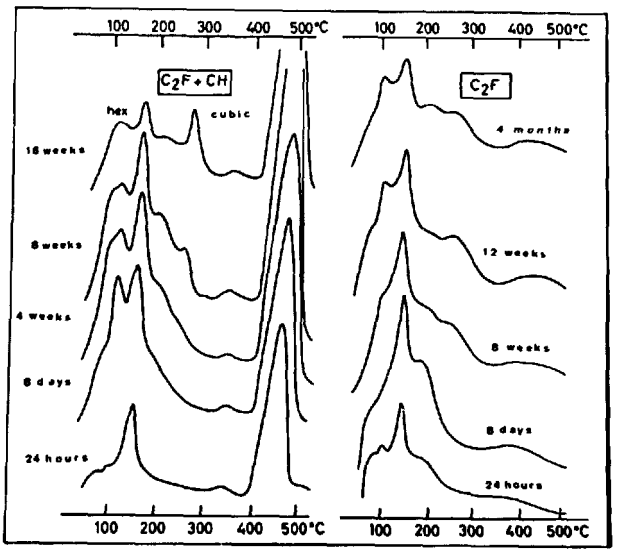

Fig. 4.

The role of $Ca(OH)_2$ in the hydration of C_2F is illustrated in Fig. 4; this figure shows the differential thermogravimetric analysis curves for C_2F hydrated in the presence and in the absence of lime.

It can be seen that in the system $C_2F + Ca(OH)_2$, hexagonal compounds are formed at first; but after 16 weeks hydration a peak characteristic of cubic compounds appears.

It seems that in this case the hydration process is greatly accelerated by lime and that hexagons are first formed, followed by cubes, which are not observed in the case of C_2F free from lime, even after 4 months hydration.

When C_4AF is hydrated in the presence of $Ca(OH)_2$, the formation of hexagonal hydrates can be demonstrated using an electron microscope.

An examination carried out after 8 weeks shows the persistence of hexagonal platelets, while for C_4AF free from lime these platelets had then completely disappeared.

It follows that $Ca(OH)_2$ considerably slows down the conversion of hydrates having the hexagonal structure.

The evolution of the hydration of C_6A_2F in the presence of $Ca(OH)_2$ is similar to that of C_4AF. Here too, lime slows down the conversion of hexagonal hydrates.

The slower conversion of hexagonal crystals into cubic ones enables one to obtain cubic crystals having better shapes, which is moreover explained by the general rules of crystallochemistry.

The Hydration of the Ferrite Phase in the Presence of Gypsum and/or $CaCl_2$

The Hydration of $C_6A_xF_y$ in the Presence of $CaSO_4 \cdot 2H_2O$

We shall describe here our results on the hydration of C_4AF in the presence of $CaSO_4 \cdot 2H_2O$. Fig. 5 shows the effect of various gypsum concentrations on the thermal phenomena accompanying hydration.

To arrive at a better understanding of the hydration mechanism, we shall consider the hydration of the mixture $C_4AF + 10\%$ $CaSO_4 \cdot 2H_2O$ (Fig. 6). The hydration of this sample is stopped at the points M, N, O and P marked on the curve. After each interruption of hydration, the hydrated phase is identified by X-rays. Fig. 6 summarizes clearly the hydration process of $C_4AF + CaSO_4 \cdot 2H_2O$.

Using the microcalorimetric method we have studied the influence of several parameters on the hydration kinetics. The thermograms in Fig. 7 illustrate the influence of the specific surface area of C_4AF on the appearance time of the thermal phenomena. It can be seen that an increase in the specific surface area reduces the time required for the appearance of the second thermal phenomenon.

The thermograms in Fig. 8 show the influence of the water/solid ratio on the hydration kinetics.

The Hydration of the Ferrite Phase in the Presence of $CaCl_2$ and $CaSO_4 \cdot 2H_2O$

Our work on the hydration of C_3A in the presence of $CaCl_2$ shows that $CaCl_2$ considerably retards the hydration of tricalcium aluminate; the thermal phenomena accompanying the hydration of $C_3A + CaCl_2$ can easily be recorded using the isothermal microcalorimeter (1).

Microcalorimetric experiments show that $CaCl_2$ reacts so fast with aluminoferrites that it is very difficult to analyse the effect of $CaCl_2$ on the hydration kinetics of C_4AF by this method. It should be remembered here that it is the second thermal phenomenon which reveals the retarding effect of $CaCl_2$ or $CaSO_4 \cdot$

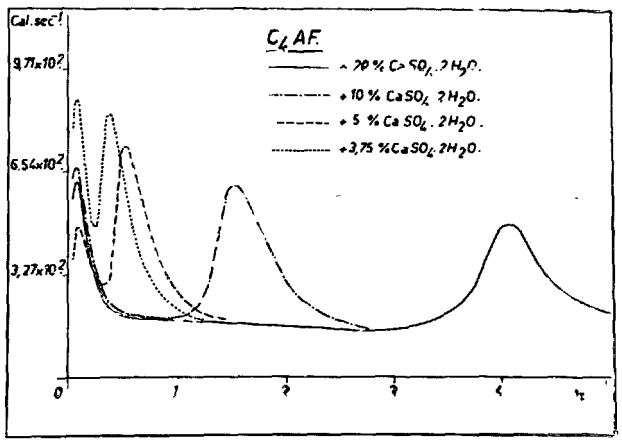

Fig. 5.

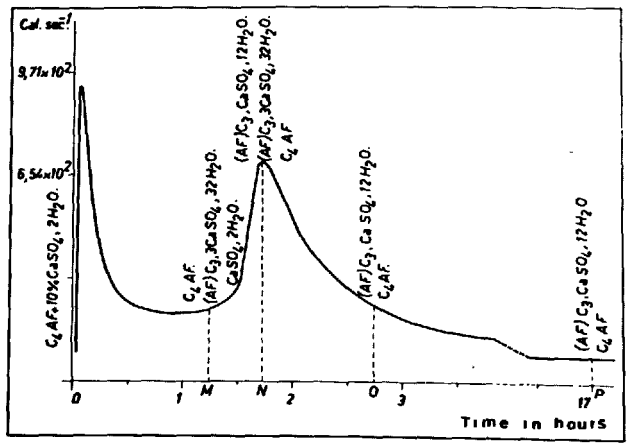

Fig. 6.

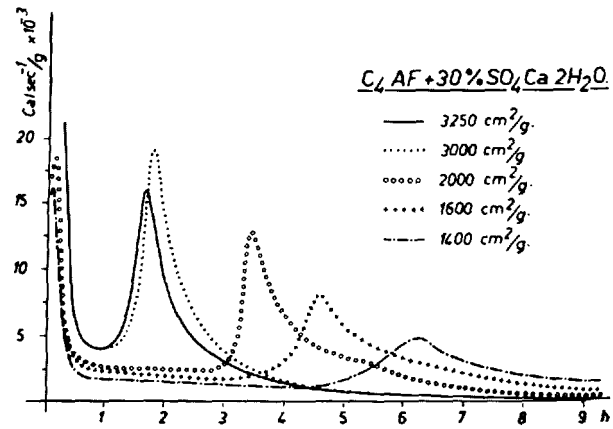

Fig. 7.

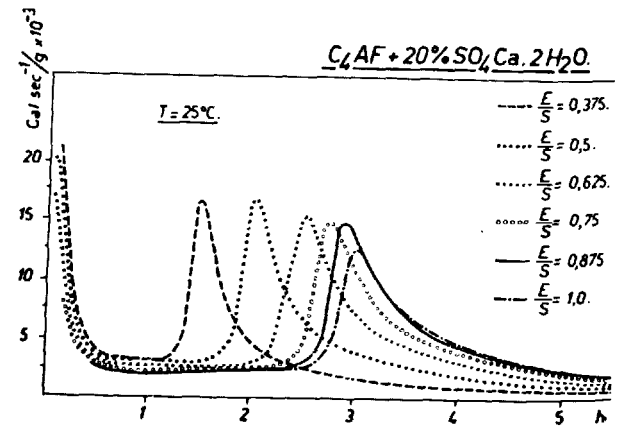

Fig. 8.

$2H_2O$. In the system $C_4AF + CaCl_2$, the $CaCl_2$ consumption is so rapid that practically only one thermal phenomenon is recorded.

A study of the system $C_4AF + CaCl_2$ has shown us that under certain conditions, the hydrate $C_3(AF) \cdot 3CaCl_2 \cdot 30H_2O$, rich in chlorine, is formed. But the trichloroaluminoferrite is easily converted into monochloroaluminoferrite. Fig. 9 shows a micrograph of $C_4AF + 20\%$ $CaCl_2$ after five minute hydration. Fig. 10 shows a micrograph of the same sample after one hour hydration.

In Fig. 9, needles of $C_3(AF) \cdot 3CaCl_2 \cdot 30H_2O$ are easily distinguished; $C_3(AF) \cdot 3CaCl_2 \cdot 30H_2O$ closely resembles ettringite, $C_3A \cdot 3CaSO_4 \cdot 32H_2O$. When the variation of $CaCl_2$ concentration is followed during the hydration of $C_4AF + 30\%$ $CaCl_2$, a rapid consumption of $CaCl_2$ with formation of trichloroaluminoferrites is observed (Fig. 11); afterwards the $CaCl_2$ consumption decreases.

This phenomenon is observed better when the hydration is carried out with D_2O; in fact, the replacement of H_2O by D_2O greatly reduces the rate of hydration and a plateau can easily be distinguished on the $CaCl_2$ consumption curve (Fig. 11).

When $CaCl_2$ is added to portland cement, the hydration of the ferrite phase of the cement is influenced by the simultaneous presence of calcium sulphate and calcium chloride; this is why the paste hydration of the ferrite phase in the presence of Cl^- and SO_4^{--} ions presents an obvious practical interest.

The thermograms in Fig. 12 illustrate the effect of various percentages of $CaCl_2$ on the hydration of a mixture of $C_4AF + 25\%$ $CaSO_4 \cdot 2H_2O$. It can be seen that $CaCl_2$ accelerates the appearance of the thermal phenomenon. When the $CaCl_2$ concentration reaches 5%, the second thermal phenomenon is doubled.

We have studied the progress of the hydration of the mixture $C_4AF + 25\%$ $CaSO_4 \cdot 2H_2O + 7.5\%$ $CaCl_2$ by stopping the hydration after the various times indicated on the thermogram of the sample. After

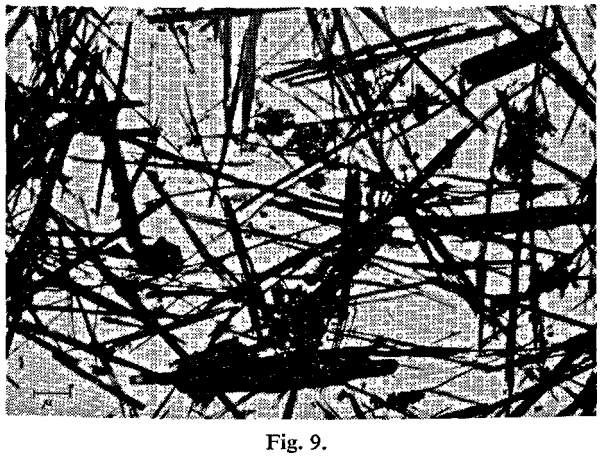

Fig. 9.

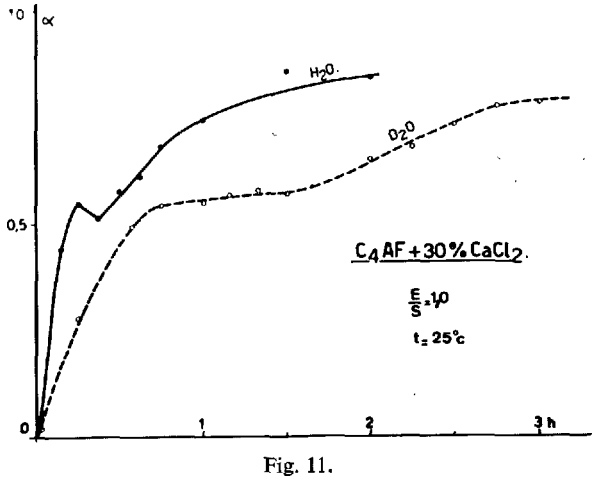

Fig. 11.

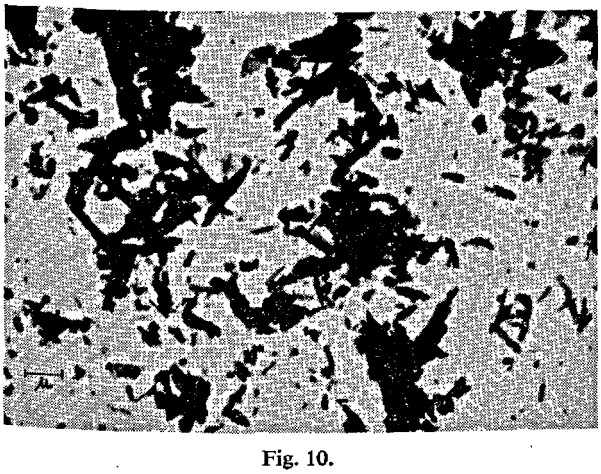

Fig. 10.

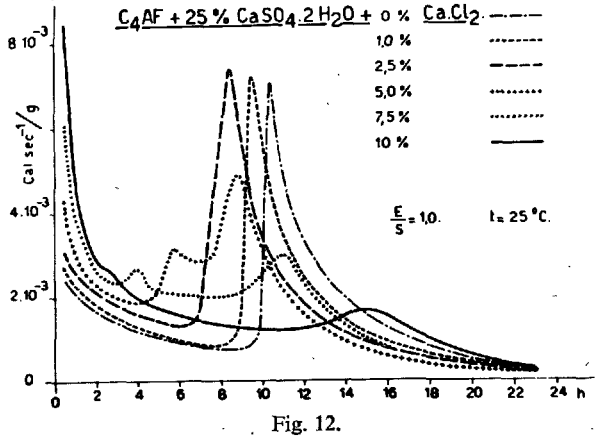

Fig. 12.

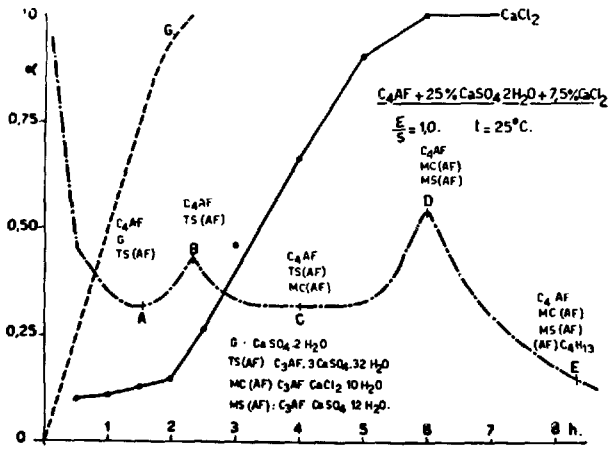

Fig. 13.

the hydration has been stopped, the sample undergoes chemical analysis and X-ray crystallography.

Fig. 13 shows all of our results. Using the results illustrated schematically in Fig. 13 as a basis, we can summarize the hydration process of C_4AF in the presence of Cl^- and SO_4^{--} ions as follows:

A. Between the first and second peaks: the gypsum reacts to give calcium trisulphoaluminoferrite. On the X-ray diagram of the sample at point A, the principal line of $C_3(AF)\cdot 3CaSO_4\cdot 32H_2O$ can be detected at 9.75 Å: the presence of $CaSO_4\cdot 2H_2O$ and anhydrous C_4AF is also confirmed by X-ray crystallography.

B. The gypsum consumption continues up to point B: the X-ray diagram of the sample at point B shows that all the gypsum has been consumed; between points A and B, there is an increase in intensity of the trisulphoaluminoferrite line which we shall designate by TS(AF). At the top of the second thermal phenomenon (point B), the gypsum has been completely used up. After the complete consumption of $CaSO_4\cdot 2H_2O$, the Cl^- ions begin to react to form calcium monochloroaluminoferrite.

C. In the system $C_3A + CaSO_4\cdot 2H_2O$ and $C_4AF + CaSO_4\cdot 2H_2O$, at the top of the second calorimetric peak (point B), when the gypsum has been used up, the hydrates rich in sulphate are converted into hydrates poor in sulphate; in other words, the trisulphated phases are converted into monosulphated phases. In the presence of Cl^- ions this transformation does not occur.

X-ray crystallography shows that at point C (between the second and third thermal phenomena) TS(AF) and MC(AF) are present. This observation supports our conclusions on the system $C_3A + CaCl_2 + CaSO_4\cdot 2H_2O + H_2O$ (1).

D. Between the second and third thermal phenomena (points B and D), $CaCl_2$ reacts to give monochloroaluminoferrite. At point D all the $CaCl_2$ has reacted and the TS(AF) begins to be converted into monosulphoaluminoferrite MS(AF).

E. When the $CaCl_2$ has reacted completely (point D), the hydration continues on account of the presence of anhydrous C_4AF; after point D the hydration of C_4AF gives hexagonal hydrates $(AF)C_4H_{13}$. This hydrate forms solid solutions with $C_3(AF)\cdot CaCl_2\cdot 10H_2O$ and $C_3(AF)CaSO_4\cdot 12H_2O$.

General Conclusions

Literature data tell us that aluminoferrites behave in a similar manner to calcium aluminates.

According to the work of Malquori and Caruso (5), there is a great similarity between $FC_3\cdot CaSO_4\cdot 12H_2O$ and $C_3A\cdot CaSO_4\cdot 12H_2O$.

In our work we have dealt with the hydration kinetics, using various means of investigation.

Our results on the hydration of the ferrite phase in the pure state show that the hydration rate increases from C_2F up to C_6A_2F.

As regards the nature of the hydrates, it is observed that, in the initial period of hydration, the hydrates are of hexagonal structure, but that under our experimental conditions the hexagonal hydrates (AC_2H_8, AC_4H_3) are unstable; they are converted into cubic hydrates (AC_3H_6); calcium hydroxide considerably slows down this transformation.

In the presence of $CaSO_4\cdot 2H_2O$, calcium trisulphoaluminoferrite $C_3(AF)\cdot 3CaSO_4\cdot 32H_2O$ is formed at the beginning of the hydration. After the gypsum has been used up, the trisulphate phase is converted into calcium monosulphoaluminoferrite $C_3(AF)\cdot CaSO_4\cdot 12H_2O$.

An inspection of our results on the hydration of the system $C_6A_xF_y + CaSO_4\cdot 2H_2O$ shows that there is a great similarity between the effect of gypsum on the ferrite phase and its role in the hydration of C_3A.

Our conclusions on the hydration of the ferrite phase are in agreement with the results of Chatterji and Jeffery (6, 7).

A study of the hydration mechanism of the system $C_4AF + CaSO_4\cdot 2H_2O + CaCl_2$ shows that the hydration process of this system is similar to that of C_3A in the presence of Cl^- and SO_4^{--} ions (1).

$CaCl_2$ accelerates the reaction between gypsum and C_4AF.

When C_4AF is hydrated in the presence of $CaCl_2$ and $CaSO_4 . 2H_2O$, the SO_4^{--} ions react first to give trisulphoaluminoferrite; during the consumption of SO_4^{--} ions the Cl^- ions do not react. The formation of monochloroaluminoferrite begins only after the complete consumption of SO_4^{--} ions.

The trisulphate phase (calcium trisulphoaluminoferrite) formed in the system $C_4AF + CaSO_4 \cdot 2H_2O + H_2O$ is converted into a monosulphate phase after the complete consumption of $CaSO_4 \cdot 2H_2O$. In the presence of $CaCl_2$ the trisulphate phase persists after the complete consumption of the gypsum, in other words the presence of $CaCl_2$ prevents the conversion of TS(AF) into MS(AF).

This phenomenon can be explained by the fact that it is above all the hydrated calcium aluminoferrites, $(AF)C_4H_{13}$ and $(AF)C_2H_8$, which react with the trisulphate phase to convert it into the monosulphate phase. When the aqueous phase contains Cl^- ions, the calcium aluminoferrites react with $CaCl_2$ to give hydrated chloroaluminoferrites, and as long as there are Cl^- ions in the liquid phase, the trisulphoaluminoferrite is not converted into monosulphoaluminoferrite.

In this work we have separated off the hydrated phase by using heavy liquids: the A/F ratio of the hydrates is different from the A/F ratio of the anhydrous aluminoferrite.

In the hydration of C_4AF, the phases hydrated under different conditions have an A/F ratio greater than 1. It, therefore, seems that only part of the iron is to be found in the hydrates; the rest may be in the form of ferric hydroxide.

We have investigated the influence of certain parameters on the hydration kinetics. Differential microcalorimetry has proved to be a useful method for determining the influence of various factors such as the E/S ratio, the grain size, etc, on the hydration of the ferrite phase.

We have seen above that C_4AF forms hexagonal hydrates after five minutes hydration.

Recently we have shown directly that these hexagonal platelets contain iron.

It is by means of an electron microprobe that one can demonstrate the presence of iron in the hexagonal platelets (8).

As a sample mount for the microprobe examination we used a single crystal of MgO.

It should be remembered that a study of the role of iron in the hydration of cements is of an obvious practical interest; indeed it is well known that cements rich in Fe_2O_3 are very resistant to agressive media (sea-water, water containing sulphates, etc.).

SESSION II-5 HYDRATION OF PORTLAND CEMENT

Principal Paper Hydration of Porltand Cement

L. E. Copeland and D. L. Kantro*

Synopsis

Various factors influence the reactions of alite and belite in cement; temperature, water-cement ratio and composition are among these. Their effects on cement are comparable with their effects on the corresponding "pure" compounds.

The temperature data lead to activation energy results consistent with early age solution reaction processes and later age diffusion processes. The hydration factors are of two types, one involving the composition of the alite or belite phase itself and the nature of the polymorphic form and the other concerning the presence of other substances, i.e., C_3A, $CaSO_4 \cdot 2H_2O$ and $CaCl_2$.

These various factors also influence the composition of the hydration products of the "pure" phases. For example, the C/S ratio of C–S–H gel has been found to increase significantly with decreasing w_0/c ratio.

The presence of other substances such as sulfate ion in the hydrating system leads to the formation of substituted C–S–H gels.

The hydration of C_3A starts immediately upon contact with water. The products that form depend upon the composition of the solution phase. If sulfate ion and $Ca(OH)_2$ are present the first product is hexacalcium aluminate trisulfate. When the sulfate ion is depleted further hydration of C_3A produces tetracalcium aluminate sulfate. Thereafter the solid solution of monosulfate and tetracalcium aluminate is formed. The presence of the ferrite solid solution phases leads to substitution of F for A in all hydration products.

Sufficient sulfate ion is present in properly retarded cements to assure that the conversion of hexacalcium aluminate trisulfate to tetracalcium aluminate sulfate does not occur until after the paste has hardened.

Introduction

The hydration of portland cement consists of sets of simultaneous and consecutive chemical reactions that are practically impossible to investigate in detail if study is limited to the cement-water system. However much progress has been made by studying this complex cement-water system. One method of study has been to make the tacit assumption that cement is one component of a two component system and use an estimate of the "chemically bound" water (such as the non-evaporable water) or the heat of hydration as a measure of the amount of cement that has hydrated. Many characteristics of hardened neat cement pastes are closely related to the extent of hydration of the cement so deduced. It is also possible to identify most of the hydration products of cement without any knowledge of the hydration characteristics of the individual compounds that comprise cement, and most of the hydration products that normally occur had been so identified at the time of the Fourth International Symposium on the Chemistry of Cement.

The attempt to obtain more detailed information on hydration characteristics of the individual cement compounds was started long ago with studies of the hydration of each of the pure compounds individually. More recently the hydration of pure compounds under conditions like those that exist in the cement-water system have proven to be fruitful. The primary

*Portland Cement Association, Research and Development Laboratories, Skokie, Illinois, U.S.A.

purpose of this paper is to review pertinent information on the hydration of "pure" cement compounds, individually and in mixtures; to compare this information with information obtained from hydration of portland cement; and finally to describe a sequence of events in the early hydration reactions of cement that seems to be consistent with the experimental results and the interpretations of most researchers.

The Hydration of Silicate Phases of Portland Cement

The Consumption of Alite and Belite

Dependence on w_0/c

The disappearance of alite and belite in cement is conveniently observed by means of X-rays. Examples of the type of results obtained are given in the 1960 Symposium (1, 2). Since that time, other investigators (3, 4) have also employed the X-ray method.

Some of these authors (1, 4) have indicated the difficulty in obtaining good precision in the belite results because of the small amount of material in the cement. The difficulty is compounded if the belite line at 2.88 Å is used, as was pointed out by von Euw (5) a decade ago.

The X-ray analysis procedure for the silicate phases in cements and clinkers reported a few years ago (6) may be used with only minor modifications (7) for alite and more reliable belite analyses than is obtained from use of the 2.88 Å line of partly hydrated cement pastes.

Alite and belite data have recently been obtained for cement pastes hydrated under various conditions (7). The curves in Fig. 1 represent data obtained from an ordinary (ASTM Type I) cement hydrated at two different water-cement ratios. The curves show that the percentages of alite that had hydrated by 1 day are about the same at both water-cement ratios. The curves diverge from 1 day on, more alite hydrating at the higher water-cement ratio in a given time.

As can be seen from the data points on the figure, somewhat greater scatter occurs in the case of the belite. Nevertheless, the belite results have characteristics somewhat similar to those of alite. At 1 day the amount of belite hydrated is almost independent of water-cement ratio. The curves diverge thereafter, although, in contrast to the alite curves, they reconverge to some extent at later ages.

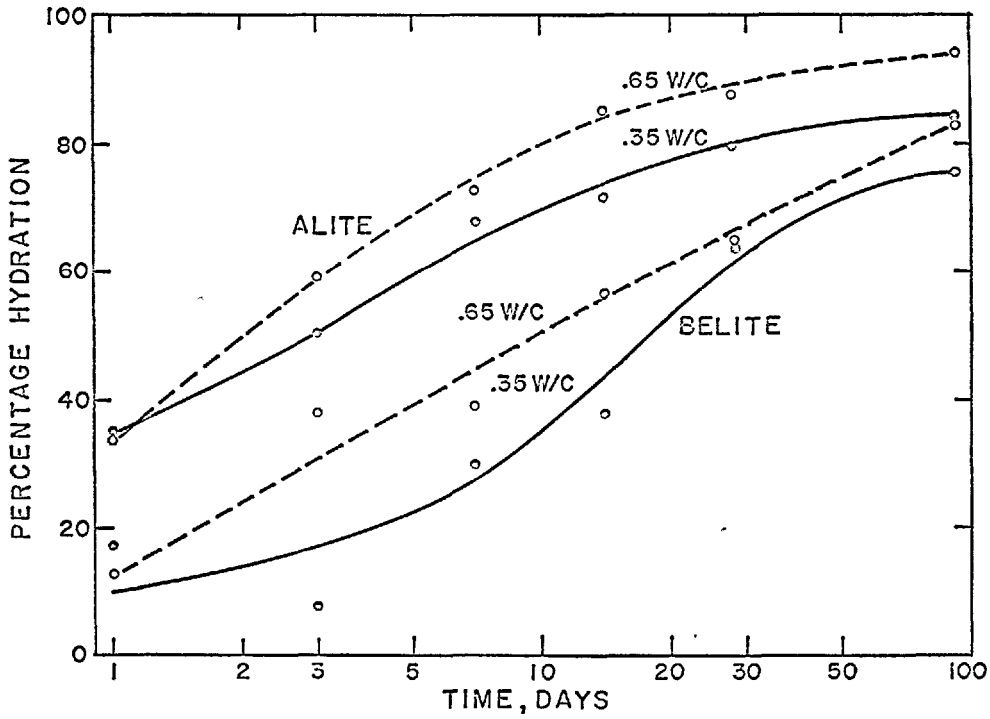

Fig. 1. *Alite and Belite hydration in an ordinary portland cement. (Initial alite, 57.8 percent; initial belite, 19.6 percent).*

The X-ray results in Fig. 1 indicate the same type of effect of water-cement ratio on cement hydration as do the fixed water data given previously (8).

The investigation of the hydration of C_3S and C_2S as a function of w_0/c-ratio has led to similar results (9, 10, 11). Thus, in general, it is found that more C_3S and C_2S hydrate in a given time, the higher the w_0/c ratio. However for ages up to 7 days, Locher finds that the degree of hydration of C_3S decreases with increasing w_0/c, above a value of .35 w_0/c, reaching a minimum at .80 w_0/c. We have found this same type of effect at shorter times but only in a lower w_0/c range, .20 to .35. Various factors, such as mixing conditions, fineness of C_3S, and sample size and shape may influence these earlier age results.

Alite and belite data were obtained for another oridinary portland cement hydrated at 3 different temperatures, 5, 25 and 50°C (7). The alite results are shown in Fig. 2. A very significant temperature influence can be seen, especially during the early stages of hydration, since the widest divergence in results occurs at the earliest age investigated, 12 hours. Nevertheless, the curves begin to converge significantly only after about 1 day. The rate of alite hydration at 50°C becomes very low after about 14 days of hydration.

These alite results may be compared with the results obtained for the hydration of pure C_3S at the same 3 temperatures (12). As can be seen in Fig. 3, the 5° results at early ages are lower than the results at 25 and 50°C; these latter two do not differ significantly. Furthermore, the percentage hydration from about 1 day on is independent of temperature over the entire range examined, the data for all pastes falling on the same curve within experimental error. Hence the rate of hydration is independent of temperature. Earlier results, by others, have indicated small regular temperature dependence (13) and small inverse temperature dependence (14).

The small or zero temperature dependence indicates a diffusion controlled hydration process (15). As is well known, diffusion controlled processes have low temperature coefficients of rate (16), and hence low activation energies.

Rates of hydration of alites in cement at different temperatures have been obtained from the data in Fig. 2. The apparent activation energies at 60 and 70 percent hydration were calculated from the ln R vs. 1/T plots shown in Fig. 4.

The value obtained at 60 percent hydration, 9.8

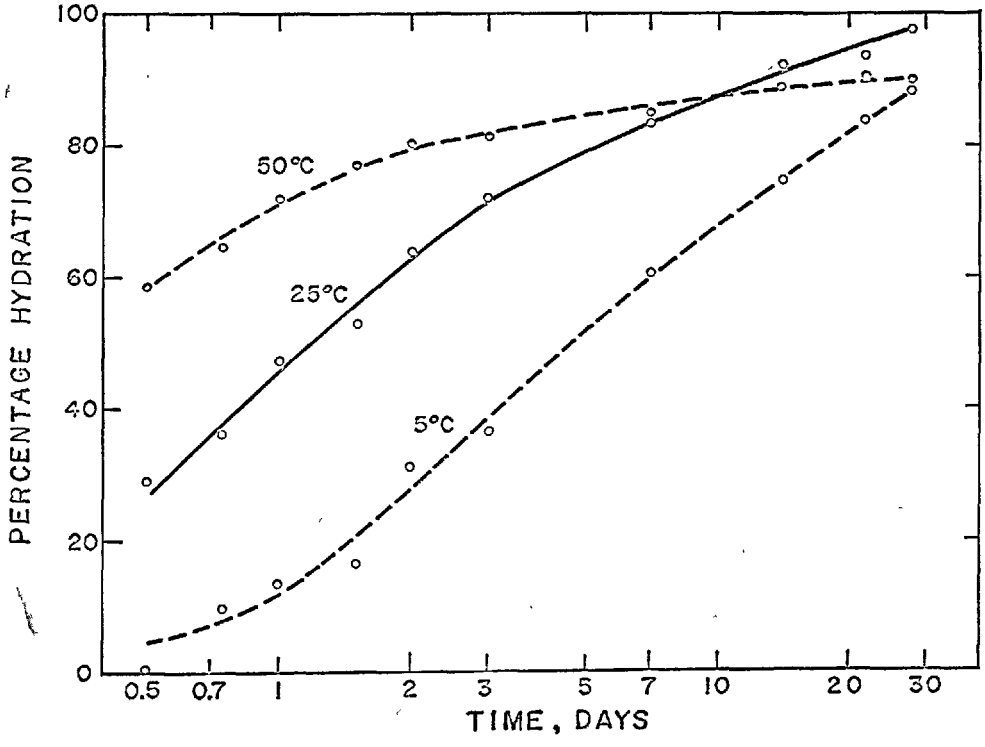

Fig. 2. *Alite hydration in an ordinary portland cement at different temperatures. (Initial alite, 50.0 percent, initial belite, 31.1 percent; $w_0/c = 0.57$.)*

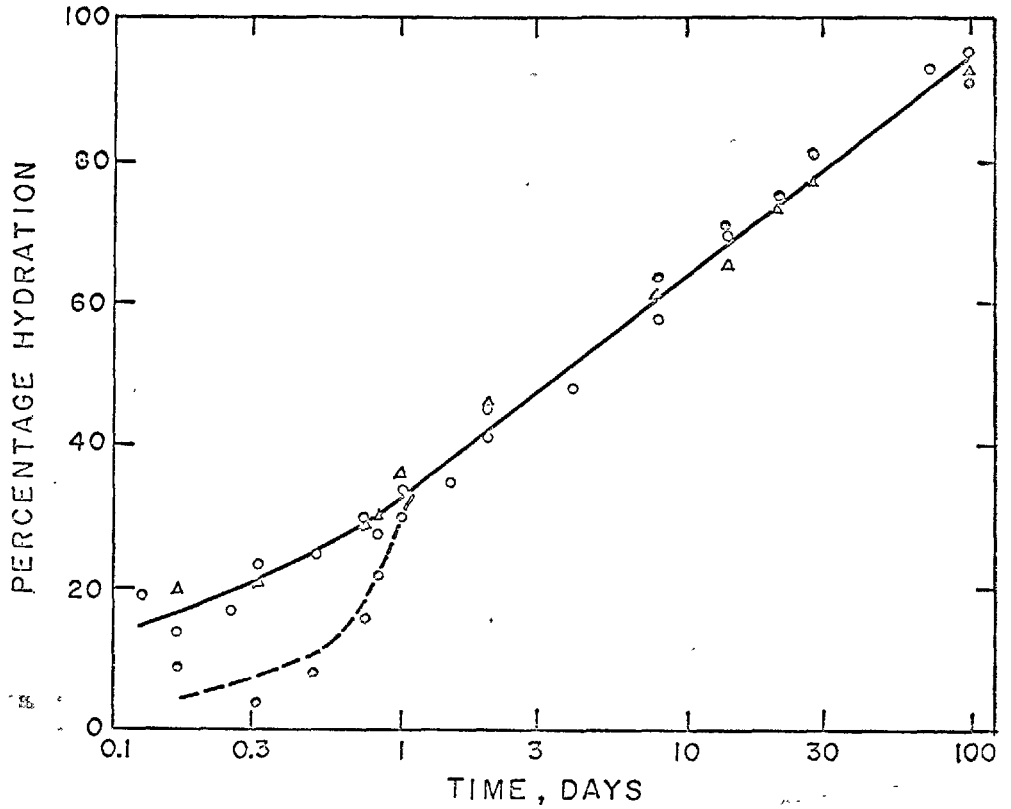

Fig. 3. *Hydration of* C_3S *at different temperatures* ($w_0/c = 0.70$; ●5°C; ○25°C; △50°C)

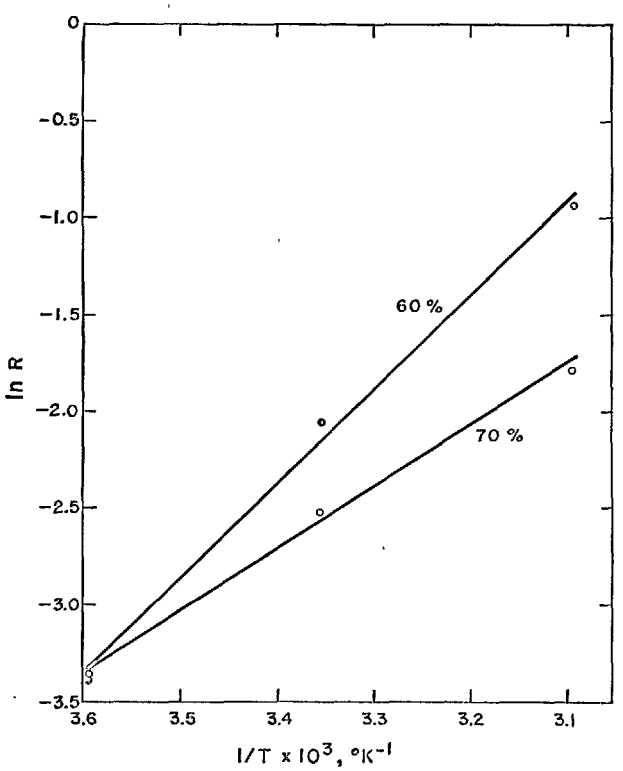

Fig. 4. *ln R vs 1/T plots, cement alite at 60 and 70 percent hydration.*

kcal/mol, is considerably higher than values attributed to diffusion processes (17), but is in the range of values given by Iler (18) for the acid and base catalyzed polymerization of silicic acid. The hydration of alite and belite to a calcium silicate hydrate gel also include silicate polymerization steps. As has been recently shown by Lentz (19) and by Funk and Frydrych (20) C_3S and C_2S both consist of orthosilicate ions; these same authors have shown that the calcium silicate hydrate consists of condensed silicate chains of various lengths, in agreement with Taylor's hypothesis (21).

The apparent activation energy of the cement alite at 70 percent hydration is 6.30 kcal/mol. The significant decrease in the apparent activation energy from 60 to 70 percent hydration indicates that the hydration process is becoming more and more diffusion-controlled.

Taplin (22) reports a value of 10 kcal/mol for portland cement paste. An apparent activation energy of about 9.3 kcal/mol was obtained for C_3S during its early stages of hydration from conduction calorimeter data (10). Taplin reports a value of 10 kcal/mol for one C_3S preparation.

A comparison of the C_3S results (Fig. 3) with those of alite (Fig. 2) suggests that the hydration of C_3S is probably diffusion-controlled by the time 25 percent hydration has occurred; while for alite, even at 60 percent hydration, the reaction may still be controlled primarily by the rate of polymerization of orthosilicate ions and diffusion has not yet become the rate determining step.

The belite results corresponding to the alite data of Fig. 2 are shown in Fig. 5. These results may be compared with similar data obtained for β–C_2S (B_2O_3-stabilized) (12), shown in Fig. 6. The two sets of curves do show some similarities, as contrasted to the alite and C_3S results. However a greater fraction of the belite in cement hydrates in a given time than of β–C_2S by itself, possibly simply because of the smaller amount of belite in cement, as compared to the relatively pure material. The cement belite hydration has a greater temperature dependence than the β–C_2S hydration. The apparent activation energies calculated at 40 percent hydration are 13.5 and 7.4 kcal/mol respectively for belite and β–C_2S. These values indicate that diffusion control occurs at lower extents of hydration in C_2S as compared to the belite in cement, just as it does in the case of C_3S as compared with cement alite.

Apparent activation energy values for different β–C_2S preparations examined by Taplin (22) were stated to be 18 kcal/mol and greater than 10 kcal/mol. These values were based on moisture loss data.

Dependence of Alite Hydration on Composition

The reactions of C_3S and alite are also influenced by the composition of the hydrating mixture. Three different types of composition variation may be considered: the presence of small amounts of other constituents in C_3S, making it an alite, the presence of other cement compounds, and the presence of other substances, such as gypsum or calcium chloride. Although the behavior of alite in cement is the principal concern of this section, C_3S is considered in some detail, because it serves as a convenient reference material with which to compare cement alite.

Tricalcium silicate has a number of polymorphic forms, stable in various temperature ranges (23). The presence of small amounts of foreign ions in the C_3S structure will stabilize one or another of these polymorphic forms at room temperature, as has been done by Woermann, Hahn and Eysel (24). Different polymorphic forms of alite in different portland cements were observed by Midgley, Fletcher and

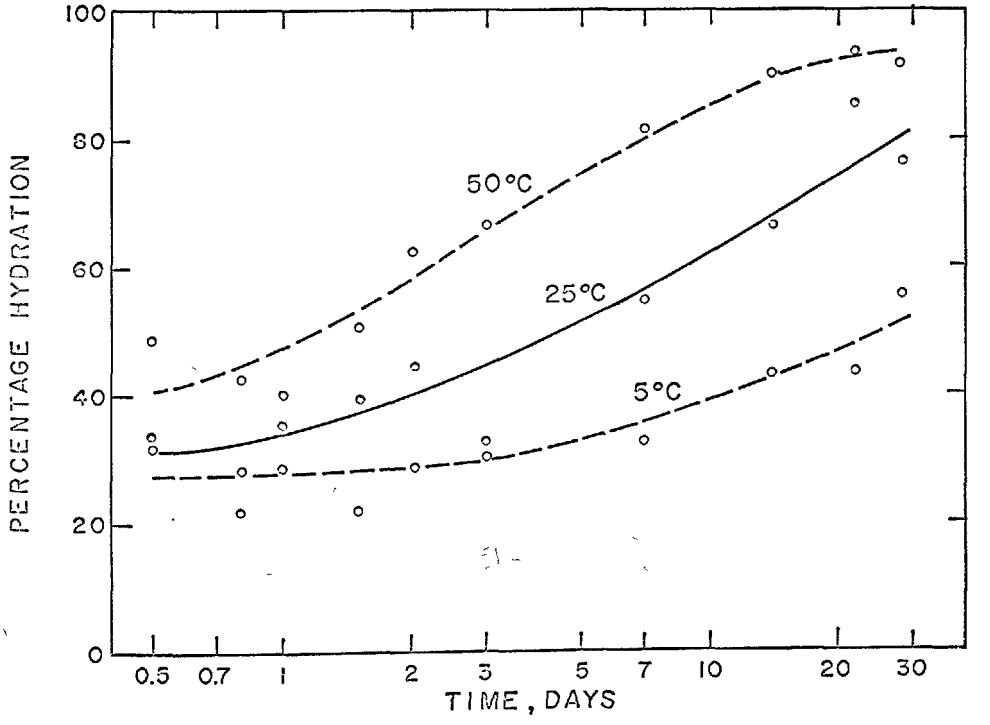

Fig. 5. *Belite hydration in an ordinary portland cement at different temperatures. (Initial alite, 50.0 percent; initial belite 31.1 percent; $w_0/c = 0.57$)*

Cooper (25) and by Ono, Uno and Kanai (26). With the knowledge that different alites can occur in different cements, the question immediately arises as to how the hydration characteristics of these alites differ. Differences can occur because of differences in crystal structure, differences in composition, or both. Yamaguchi, Shirasuka and Ota (27) have succeeded in obtaining alite of one composition, $C_{29.5}M_6S_{99}A$, in two polymorphic forms, triclinic and monoclinic. Pastes of each of these alite modifications were hydrated, and the alite residues at various ages were determined by X-rays. The results are given in Fig. 7. The results show that the monoclinic form hydrates slightly more rapidly between 5 hours and one day; thereafter, the two curves run approximately parallel. Nurse, Midgley, Gutt and Fletcher (28) used compressive strength as a measure of reactivity in an investigation of the various polymorphic forms of C_3S. These forms were obtained by inclusion of MgO, F, MnO, and a combination of MnO + F in various amounts in the alite. The results for preparations including only magnesia are in general agreement with those of Yamaguchi and his coworkers, showing a slight increase in strength from the lowest symmetry form

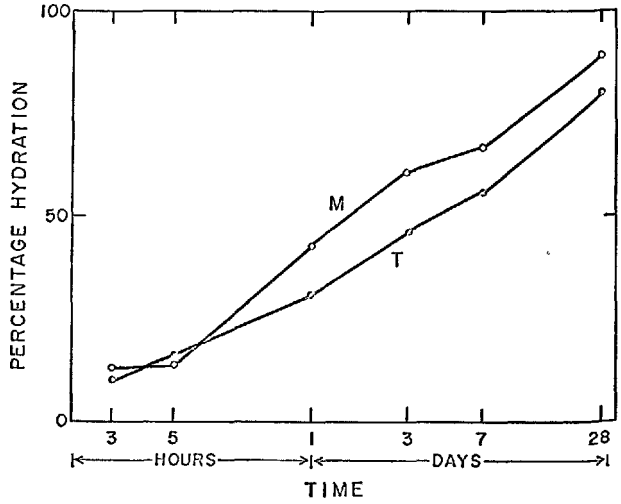

Fig. 7. *Hydration of different alite polymorphs.* (*M = Monoclinic, T = Triclinic*) (*ref. 27*)

(triclinic) to the highest (monoclinic). The alites containing fluorine did not show any clear-cut relationship.

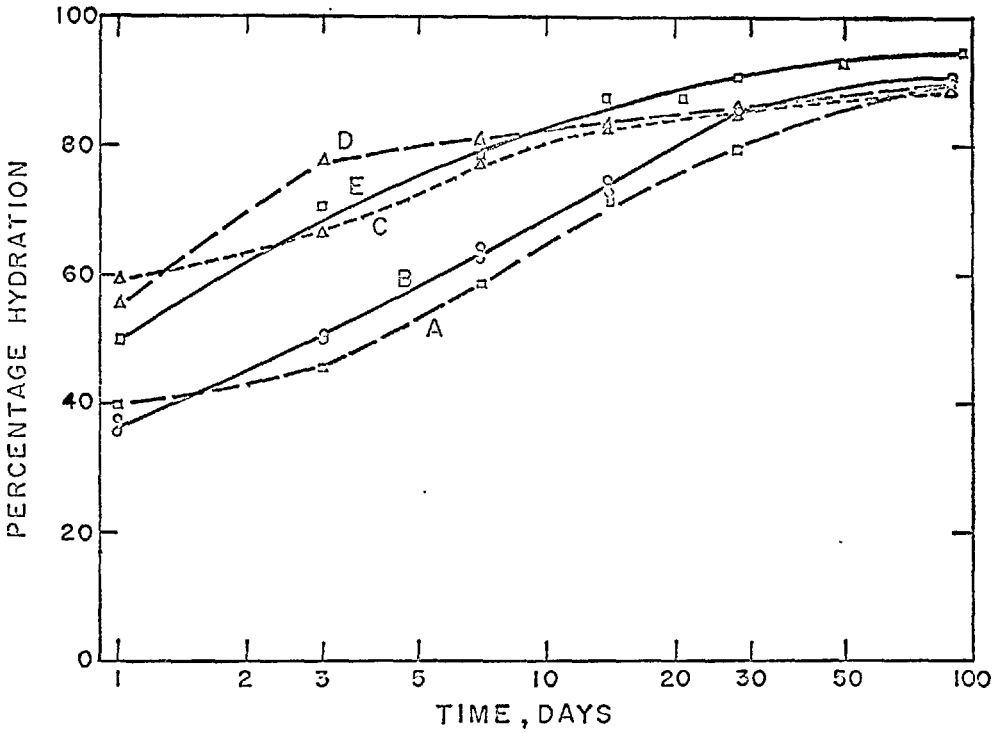

Fig. 8. *Hydration of alite and* C_3S. ($w_0/c = 0.45$; *high-speed blender mixing;* A ■ C_3S; B, ○ *triclinic alite and* ● *monoclinic alite;* C, △ *alite* +*2.3 percent* C_3A; D, ▲ *alite* +*4.5 percent* C_3A; E, □ *cement LTS-11 [57.1 percent alite and 8.3 percent* C_3A])

The presence of other compounds along with alite in pastes can have a significant effect on the hydration characteristics. Alites containing small amounts of free C_3A have been hydrated and the alite residues at various times determined by X-rays (29). The results are shown in Fig. 8. Also included in this figure are results for C_3S, a triclinic alite (9), a monoclinic alite, all of which are C_3A-free, and a normal portland cement. The triclinic alite contains 1 percent Al_2O_3 and 0.3 percent MgO; the monoclinic alite contains 1 percent Al_2O_3 and 1 percent MgO.

The curves A and B in Fig. 8 indicate the same kind of differences Nurse, Midgley, Gutt and Fletcher found.

Curve A represents the case of a pure C_3S, which is triclinic, T_I in the nomenclature of Woermann, Hahn and Eysel (24). Curve B is the composite of data from a triclinic alite, T_{II}, and a monoclinic alite which was prepared from the triclinic alite by reburning with additional MgO. These two alites behave alike. Effects that may have been caused by differences in their structures must therefore be compensated for by effects due to differences in their composition. It seems probable that the difference between curves A and B is caused by the difference in alumina of the corresponding materials, 0.1 percent in C_3S and 0.9 percent in each of the alites. The higher reactivity of the monoclinic alite reported by Yamaguchi, Shirasuka and Ota (27) may be attributed to the fact that the companion triclinic form was the stable phase at the hydration temperature.

The two alites represented by curves C and D both contain 1 percent Al_2O_3. One (curve C) contains 0.7 percent MgO and the other (curve D) 1 percent MgO. This latter alite is almost identical in composition to the monoclinic alite of curve B. The alite in cement LTS-11 is also monoclinic. In all cases in which free C_3A is present, as can be seen from the curves, a significant increase in the rate of hydration occurs during the first day of hydration, the rate then remaining higher even beyond the second day for the two highest C_3A cases (curves D and E).

The accelerating action of gypsum on alite hydration has been deduced from heat liberation data (8) and from DTA data such as has been reported by Raccanelli (30). The latter finds alite hydration in

cement is accelerated by either gypsum or alkali sulfate, but the acceleration is independent of sulfate concentration. He does find, however, that the duration of the acceleration is proportional to the alkali sulfate concentration.

A normal portland cement clinker hydrated with various gypsum additions was subjected to X-ray analysis (7). Some of the results are shown in Fig. 9. There is an indication from these data that there is an "optimum" gypsum level for maximum rate of hydration of alite in cement. This effect is particularly noticeable in the 1 and 3 day hydration curves. By 7 days the "optimum" value, if one exists, is below 1 percent SO_3. It appears from these results that the "optimum" value decreases with time of hydration. The accelerating effect of the gypsum is rather small however, and in fact, with larger gypsum additions, a significant retarding action occurs.

A number of investigators have examined the influence of gypsum on C_3S hydration. Kurczyk and Schwiete (31) conclude on the basis of free lime results that gypsum admixtures up to 4 percent by weight have no effect on the hydration kinetics of C_3S. Celani, Collepardi and Rio (32) conclude, also from free lime data, that gypsum does accelerate C_3S hydration, but only during the first day.

Pastes of C_3S with different amounts of admixed gypsum were analyzed by X-rays for unhydrated C_3S residues after various hydration times (10). A significant acceleration occurred even with the lowest amount of gypsum added, 0.7 percent as SO_3, as can be seen in Fig. 10. There was some evidence for an "optimum" effect, but the variation was rather small over the entire range of amounts added, 0.7 to 3.0 percent as SO_3. The C_3S with added SO_3 hydrates at about the same rate as the alite in a properly retarded cement.

The accelerating action of $CaCl_2$ on cement hydration is well known. Kurczyk and Schwiete (31) found, by an X-ray method, that at a time when 68 percent of C_3S in a paste had hydrated, 96 percent had hydrated in a paste also containing 2 percent $CaCl_2$. Results of a similar nature were obtained by Celani, Collepardi and Rio (32).

Alite analyses have been made on hydrated pastes of 3 widely differing cements, one a normal cement, one a white cement, and one a nominal zero-C_3A cement (33). The results are shown in Fig. 11. The curves for the alites of these cements all follow approximately the same paths. However, the shape of curve

C, for the zero C_3A-cement is slightly different from those of A and B.

Dependence of Belite Hydration on Composition

Dicalcium silicate is a polymorphic material; four different forms are known (34, 35). Of these four forms, α, α', β and γ the first and last are considered to be nonhydraulic (36, 37) although Yamaguchi, Ono, Kawamura and Soda (38) have reported strength development of mortars made with α–C_2S.

The normal belite phase in portland cement consists of the β–modification. The α'–modification has been reported to occur also, but this could be the alkali silicate $KC_{23}S_{12}$. Both Nurse and Midgley indicate that $KC_{23}S_{12}$ is a potassium stabilized α'–C_2S.

It has not been possible to compare hydration characteristics of different polymorphs of C_2S having the same composition. However, some investigations of the effect of belite composition including more than one polymorph have been carried out (38, 39).

Yamaguchi, Ono, Kawamura and Soda (38) investigating mortars made with the α, α' and β-forms, observed that there was little difference in strengths between mortars of α' and β forms, but found that mortars of the α-form gave much more strength. Strength results, however, do not give a good indication of the hydration characteristics of the anhydrous materials because of the influence of other factors, such as the composition and morphology of the hydration product.

Kryzhanovskaya, Mirak'yan, Shokotova and Kholodnyi (39) investigating the bound water content as a function of time for pastes of $KC_{23}S_{12}$ and β–C_2S found little difference in the hydration characteristics of these two materials.

The results reported with regard to similarity in hydration characteristics of $KC_{23}S_{12}$ and β–C_2S are rather surprising in view of the significant influence that the composition of β–C_2S has on its hydration properties (28, 34). Results of X-ray analyses have been obtained for paste series of β–C_2S preparations stabilized in different ways (29). Among these preparations were a β–C_2S stabilized with 0.8 percent SO_3, added as $CaSO_4$, as described by Funk (40), a β–C_2S stabilized with 1.9 percent Al_2O_3 and 0.9 percent MgO (41), and two stabilized in the conventional way with B_2O_3, one containing 0.5 percent and the other 0.8 percent. The results of the X-ray analyses are shown in Fig. 12. These results show that all the C_2S

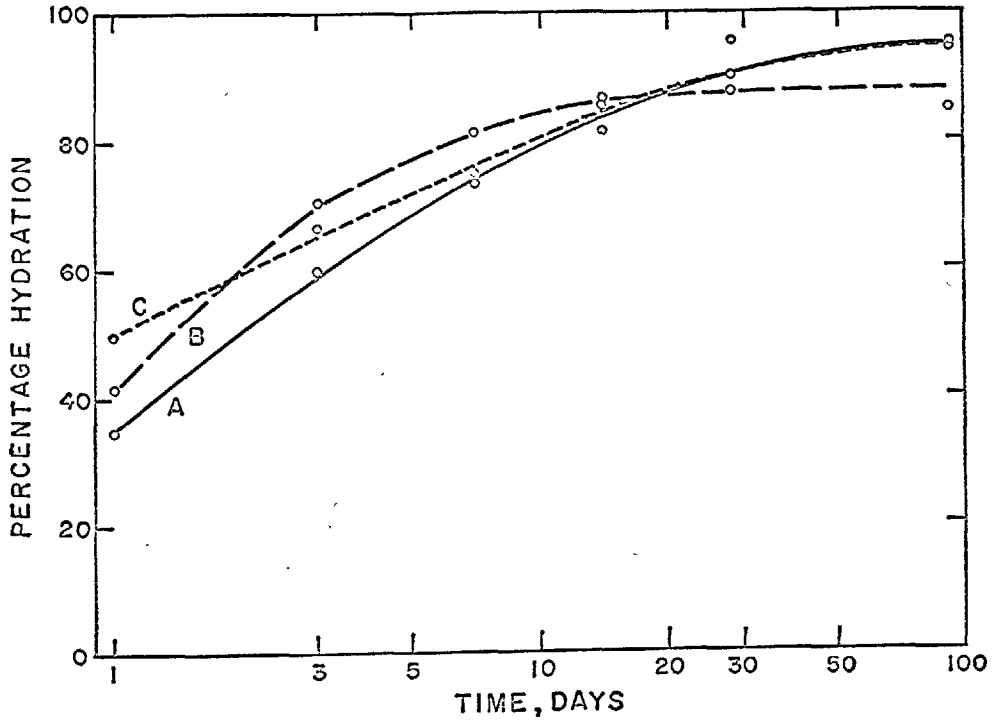

Fig. 11. *Hydration of alites in different cements.* ($w_0/c = 0.65$; A, *normal cement, 57.8 percent alite;* B, *white cement, 50.8 percent alite;* C, *zero-C_3A cement, 67.2 percent alite*)

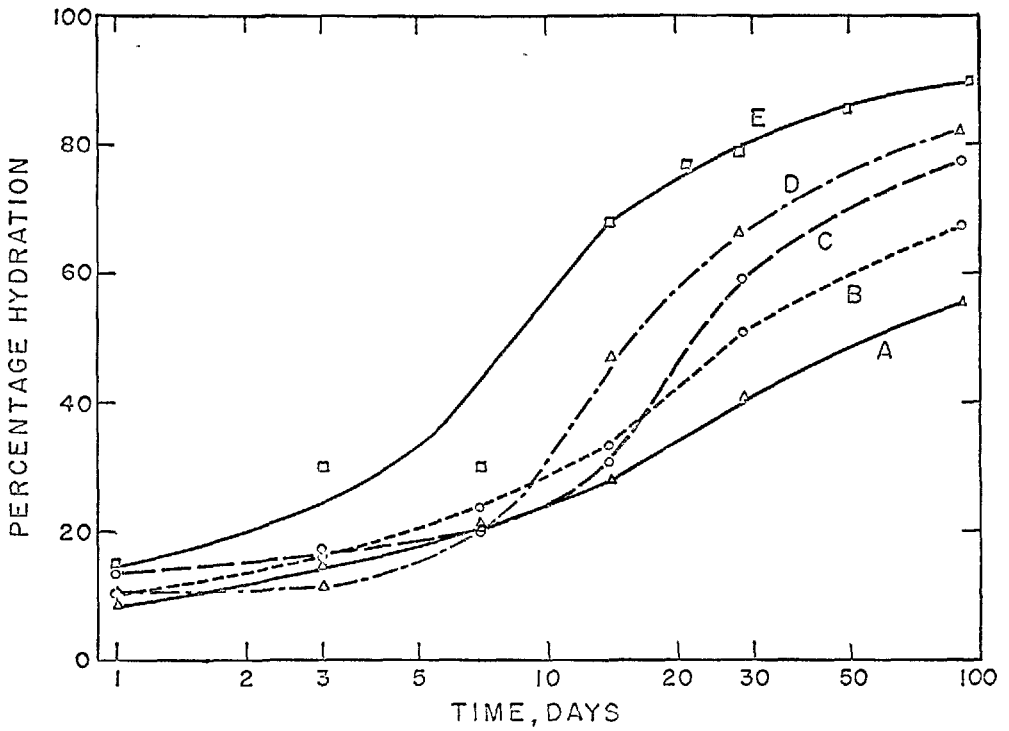

Fig. 12. *Hydration of different* β-C_2S *preparations and of cement belite.* ($w_0/c = 0.45$; A, △ *0.8 percent* B_2O_3; B, ● *0.5 percent* B_2O_3; C, ○ *1.9 percent* Al_2O_3 + *0.9 percent* MgO; D, ▲ *0.8 percent* SO_3; E, □ *cement belite, LTS-11*)

preparations hydrate to about the same extent during the first week of hydration. Thereafter, the influence of the stabilizer becomes apparent. The B_2O_3–stabilized preparations (curves A and B) hydrate to a lesser extent at later ages, the highest B_2O_3 content material (curve A) hydrating the least. The Al_2O_3–MgO and SO_3–containing materials (curves C and D) react to a greater extent than do the B_2O_3–containing materials, but still do not demonstrate the reactivity of belite in an ordinary portland cement (curve E). Although the Al_2O_3–MgO stabilized C_2S was made in an attempt to reproduce a cement belite, it is likely that either there is still some difference in the compositions of these two, or the cement belite is influenced by the presence of some other substance, such as sulfate of C_3A. As an example of a composition variation, the cement belite may have a somewhat higher Al_2O_3 content, and possibly some iron as well (34).

Belite results in cement were obtained which are analogous to the alite results in Fig. 9 (7). A slight "optimum" effect was observed at all ages for the paste series with 1.5 percent SO_3 added. The curves for 3 and 4 percent SO_3 additions were almost alike and higher additions resulted in a marked decrease in belite hydration.

Belite hydration is also accelerated by $CaCl_2$. Kurczyk and Schwiete report 48 percent hydration of β–C_2S as compared with 82 percent hydration when 2 percent $CaCl_2$ was present. Funk (42) had previously reported complete hydration of β–C_2S in 30–40 days in the presence of 15 percent $CaCl_2$. This result may be compared with hydration times for pure β–C_2S greater than 1 year, even in an excess of water (43).

Belite results analogous to the alite results in Fig. 11 have also been obtained (33) and are shown in Fig. 13. The belite in the white cement appears to be less reactive than the belites in the other two cements. Because of the absence of iron in the white cement, the composition of the belite may be slightly different from its compositions in the other two cements. It is also possible that the amount of belite present has some relationship to the behavior. Not enough data is available at the present time to allow any definite conclusions to be made.

The Alite and Belite Hydration Products

The Calcium Silicate Hydrate Phase

The hydration products of portland cement consist

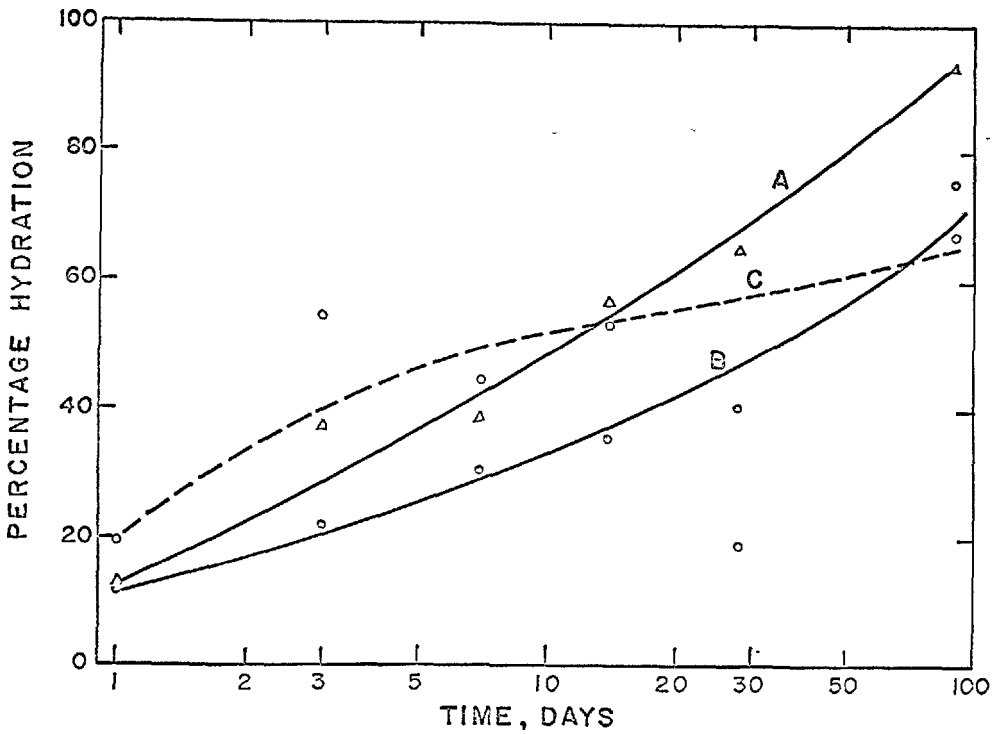

Fig. 13. *Hydration of Belites in different cements.* ($w_0/c = 0.65$; A, △ *normal cement, 19.5 percent belite;* B, ● *white cement 40.0 percent belite,* C, ○ *zero-*C_3A *cement, 13.7 percent belite*)

of two types of materials—substances that are relatively well-crystallized, such as calcium hydroxide and ettringite, and a substance that is poorly crystallized, namely a calcium silicate hydrate gel. For some years, this calcium silicate hydrate has been called variously tobermorite, tobermorite (G) and tobermorite gel. The tobermorite designation was applied because of some similarity of this material to the well-crystallized natural mineral of the same name. The primary similarity is in the X-ray diffraction diagram. Three broad peaks are obtained for the calcium silicate hydration product, these peaks corresponding approximately in d-spacing to three strong natural mineral tobermorite X-ray peaks. In this respect the calcium silicate hydrate resembles tobermorite more than it does any other calcium silicate hydrate.

On the other hand, the composition of the calcium silicate hydrate gel is quite different from that of natural mineral tobermorite, or even of hydrothermally prepared tobermorite (21). In order to distinguish between the product of paste hydration of tricalcium, dicalcium silicate, alite, or belite on the one hand, and any other calcium silicate hydrate on the other, the poorly crystallized calcium silicate hydrate gel which is the product of the paste hydration is here designated C–S–H gel.

Of primary importance in the present discussion is the composition of the C–S–H gel that is produced by the hydration of portland cement. Unfortunately, because of the complexities of the system little is known about this composition, except by analogy with the products of hydration of C_3S and β–C_2S.

The Determination of the Composition of C–S–H Gel

Various investigations have been carried out in recent years on the composition of C–S–H gel. Even in the case of the hydration of the "pure" calcium silicates, the determination of the composition of the calcium silicate hydrate gel presents certain difficulties. No method has yet been devised that will permit direct determination of the C/S and H/S ratios of this gel. It is therefore necessary to determine all of the other constituents in the system, and obtain the composition and amount of the calcium silicate hydrate gel by difference (44). To obtain the difference requires determination of the unhydrated residue and the calcium hydroxide content of the material. Several methods have been used to determine the calcium hydroxide content (15, 43). Three such methods may be considered. These are chemical extraction using ethyl

acetoacetate, X-ray analysis, and thermogravimetric analysis. The chemical extraction method gives higher results than the other two, both of which give about the same result (43).

Two different points of view have been expressed in explanation of this phenomenon (15, 21, 43, 45). One is that the lime not detected by X-rays is lime which is chemically extracted from lime-rich regions of the C–S–H gel. The other is that some amorphous lime is present, which cannot be detected by X-rays and which consequently would not give a sharp step in the thermal weight loss curves. One explanation for the formation of amorphous lime was given by Grudemo (46). More recently Locher (11) reported results obtained on free lime contents of hydrated C_3S pastes by both chemical and thermogravimetric methods. His observed difference in $Ca(OH)_2$ values, in terms of moles $Ca(OH)_2$ per mole SiO_2, appeared to be nearly independent of the C/S ratio of the C–S–H gel. If both the firmly bound lime and the labile lime were associated with the silica in a given C–S–H gel, one might expect from spatial considerations that if an increase in firmly bound lime occurred, a corresponding decrease in labile lime could occur. If, however, the lime were amorphous and not associated with the gel, no relationship would need to exist between its amount and the C/S ratio of the gel.

In further discussion of gel compositions, values based on chemical lime determination will be considered.

Influence of Time, Temperature and w_0/c on Composition of the C–S–H Gel

Investigations in recent years have shown that various paste hydration conditions, such as time, temperature, water-solids ratio and presence of other substances can affect the composition of the C–S–H gel hydration product.

The effect of time on the hydration of C_3S and C_2S has been examined for pastes hydrated at .70 w_0/c at three different temperatures (12, 44) for periods from 1/2 hour to 400 days. The results indicated that both C_3S and β–C_2S formed initial hydration products with C/S-ratios near those of the original anhydrous compounds. These C/S-ratios decreased during the early stages of hydration. In the case of C_3S, the initial decrease was rapid, and was followed by a slow decrease during the remainder of the hydration reaction. In the case of C_2S, the early age decrease was also rapid; however it was followed by a slower rise during the remainder of the hydration (9).

The influence of temperature on the C/S-ratio of the C–S–H gel formed by hydration of C_3S appears to be negligible over the temperature range examined. The lowest C/S-ratios were obtained for pastes hydrated at 25°C; pastes hydrated at either 5 or 50°C gave slightly higher values.

In the case of C_2S pastes, there appeared to be a correlation of C/S-ratio with hydration temperature, the value of the C/S-ratio increasing with increasing temperature, as had been observed previously (40) (43).

The influence of w_0/c on the composition of the hydration product is significant. Investigations by Locher (11, 45), Sudoh and Mori (47) and by the present authors and their coworkers (9, 10) have yielded results in quite good agreement. It is found that as the w_0/c-ratio is decreased the C/S-ratio increases. Over the entire range of w_0/c-ratios covered by these various investigators, 2.00 to 0.20, the C/S-ratio was found to vary from about 1.3 to 2.3. It was also found that C_3S pastes below a certain w_0/c value, about 0.45, showed a slight increase in C/S-ratio with time at later ages. One set of results is shown in the upper curve in Fig. 14 (10). The data points represent average values obtained from pastes hydrated 6 months or more. All of these pastes were hydrated more than 60 percent, a time beyond which any further increase in C/S at a given w_0/c is negligible.

The H/S values associated with the C–S–H gel are

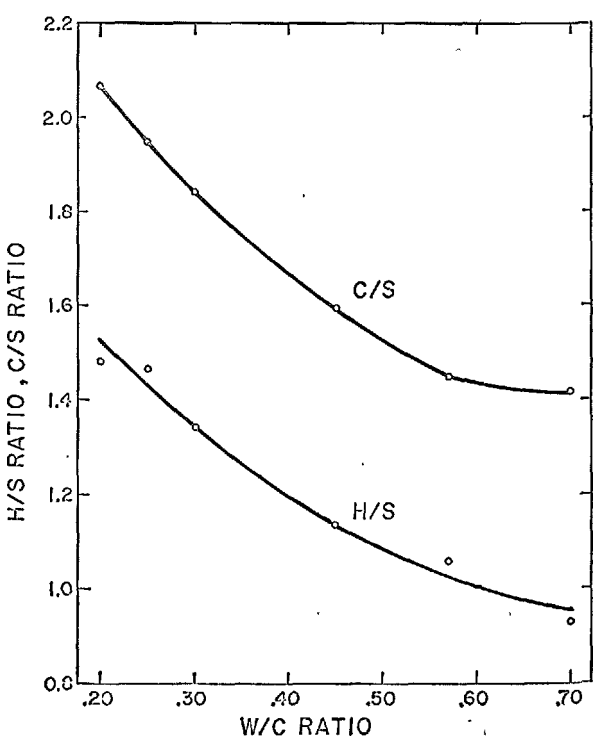

Fig. 14. *Influence of* w_0/c *on* C–S–H *gel composition*

first of all related to the extent to which moisture has been removed from the paste at the end of the hydration period. Various methods of drying have been used. In the investigation of C_3S and C_2S pastes, one method has been to remove water with the aid of organic agents such as cyclohexanol followed by drying in CO_2-free air (11). Another has been vacuum drying, the so-called "D-drying" (9, 15). These two methods lead to results not too different from one another, as is indicated by the fact that the amounts of water retained, after drying, by fully hydrated C_3S pastes were found to be about the same by both methods.

The H/S ratios calculated for a given paste are obtained from loss on ignition data (1000–1050°C) corrected for the water in the free $Ca(OH)_2$ and for the CO_2 present. For well-hydrated systems, it has been found that the H/S ratio is about 0.5 mole/mole SiO_2 less than the C/S ratio, as is shown in Fig. 14. This indicates that the composition of C–S–H gel varies as calcium hydroxide enters or leaves it. The general composition of C–S–H gel in well-hydrated systems may, as a first approximation, be represented by the expression.

$$C_xSH_{x-0.5}$$

where x is the C/S ratio. However, another type of H/S variation has also been observed, which depends on time. The above expression may therefore be modified to

$$C_xSH_{x-0.5+y}$$

where y is the difference in H/S-ratio between the experimental value and that estimated from the C/S-ratio. Results on the hydration of C_3S (11, 44) and C_2S (44) have shown that values of y are negative during the early stages of hydration. In the case of C_2S at 5°C, the value of y at the earliest stages of hydration was almost $-(x - 0.5)$, that is, the net H/S ratio was nearly zero. A similar observation was reported by Kawada and Nemoto (48). As hydration progresses, the value of y increases, finally becoming slightly positive, of the order of 0.1 moles H_2O/mole SiO_2. Upon reaching this value, y remains approximately constant.

Substituted C–S–H Gels

The above discussion has dealt with "pure" C_3S and C_2S. Some analogy may be drawn to the behavior of alite and belite in cement. Turriziani, Rio and Collepardi (49) found some similarities regarding free-lime formation in clinker and C_3S. It is well-known that a C–S–H gel also forms by hydration of cement, this gel having properties similar in many respects to those of the gel formed by C_3S or C_2S hydration. The gel formation in cement is probably controlled to a significant extent by the same factors operating in C_3S and C_2S pastes. However, other variables exist in the cement system, these being related to the presence of other substances—gypsum, other cement compounds, alkali. Furthermore, the alite and belite phases contain small amounts of other substances—Al_2O_3, Fe_2O_3, MgO, K_2O, in solid solution, which may have an important bearing on their behavior.

The composition and properties of the hydration products are more important in the following discussions than are the influences of these various "impurities" upon the hydration characteristics of C_3S and C_2S. In the past few years, work by a number of investigators has shown that substances such as alumina or calcium sulfate could enter the calcium silicate hydrate structure chemically without destroying the identity of the gel. Kalousek (50) prepared samples of tobermorite hydrothermally containing as much as 6.5 percent Al_2O_3. His results indicated that the alumina substituted for silica in the structure. In addition Kalousek suggested that this type of substitution is possible in the products of hydration of cement at ordinary temperatures. A similar hydrothermal investigation was also carried out by Diamond, White and Dolch (51), in which such products containing iron or magnesium were also prepared. Kurczyk and Schwiete (31) and Celani, Collepardi and Rio (32) found that when C_3S was hydrated with added gypsum, a morphologically altered hydration product resulted. The latter investigators also observed that the sulfate in the paste present as gypsum was less after a period of hydration than the amount added initially. They concluded that some of the sulfate had entered the C–S–H gel lattice.

Recently a study was made of the reaction products of hydrated C_3S pastes with C_3A, C_2F and $CaSO_4 \cdot 2H_2O$ (52). Substituted C–S–H gels were produced in all cases, as was indicated from X-ray analysis and electron microscopic examination.

The substitution of other species for silica or for lime in the C–S–H gel lattice is not, strictly speaking, an isomorphous substitution, inasmuch as slight structural changes must occur because of valence differences between the substituent species and the normally present species. Furthermore, these reactions may easily be considered as addition reactions, since, for example, silica is not released in the reaction between C–S–H gel and calcium sulfate; the entry of the sulfate into the lattice is essentially a structural

Fig. 15. C_3S *paste after agitation in water 3 months.*

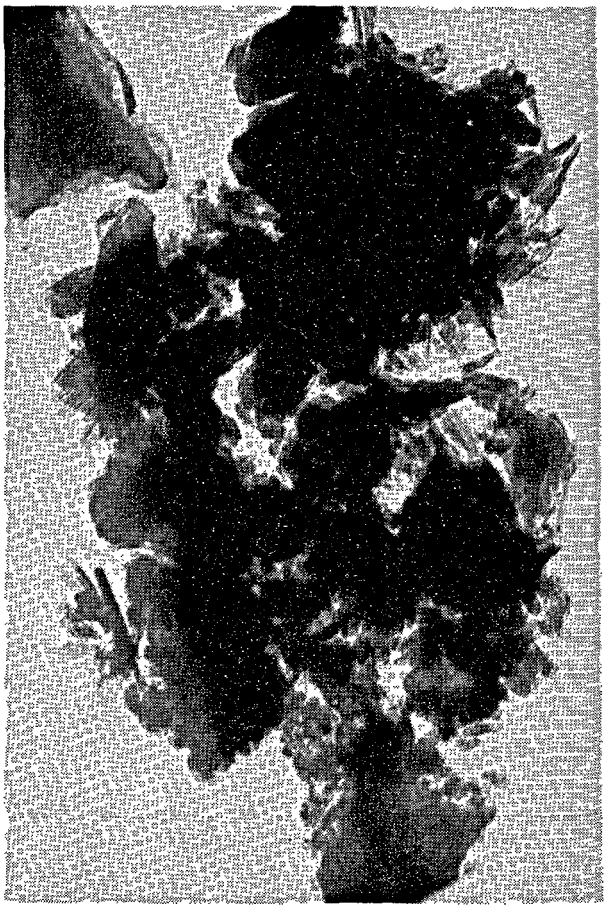

Fig. 16. C_3S *paste containing added* C_4AH_{13} *after agitation in water 3 months*

extension in which more gel is produced.

The maximum ratio of substituent ion to silica was found to be 1/6, for sulfate, aluminum, or iron. The substitution reaction occurs either during formation of the gel or between the gel and the substituting species. Substitution for both calcium and silica by the same species can occur. Thus it was found that, at maximum substitution of alumina, 74 percent of the total alumina had replaced silica; the remainder substituted for calcium. In the case of iron, 50 percent substitutes for silica, and all sulfate substitutes for silica. Electron microscopic examinations indicate that significant morphological changes occur along with the substitution reactions. Examples of the changes observed are shown in Figs. 15–17. Fig. 15 shows a field of a hardened C_3S paste after agitation in water for 3 months; Fig. 16 shows a field of this same material with added C_4AH_{13} after agitation in water for 3 months; Fig. 17 shows a field of the C_3S paste with 20 percent added gypsum after agitation in water for 3 months. The rolled sheet type of structure evident in Fig. 15 and characteristic of C_3S pastes is absent in Figs. 16 and 17. In Fig. 16, the gel more nearly resembles that formed during the early stages of cement hydration, and in Fig. 17, a less fibrous product (than in Fig. 15) occurs with an indication of numerous small platelets.

The examination of the substitution reactions has been extended to the hydrating paste system (10). Pastes of C_3S have been hydrated in the presence of various quantities of gypsum up to 3 percent as SO_3 on the C_3S basis. The net effect of the sulfate in the case of reaction in a hydrating system was much the same as in the case of reaction with a previously formed C–S–H gel. The results obtained by the two methods are shown in Fig. 18, in which the linear relationships between C/S-ratio of the gel, and the extent of sulfate substitution in the gel, expressed as the molar SO_3/SiO_2 ratio, are illustrated. The lower line was obtained by the reaction in an agitated slurry, and the upper curve by the direct reaction in a hydrating paste. The intercepts of the lines represent the

Fig. 17. C_3S *paste containing added gypsum after agitation in water 3 months*

C/S ratios of unsubstituted gels obtained with the respective reaction conditions, and the slopes represent the uptake of lime accompanying the SO_3 substitution. If the only lime to enter with the sulfate were that required to extend the structure, the slope would be equal to the intercept, that is, the C/SO_3 ratio would equal the initial C/S ratio. However, the slopes of both lines exceed the intercept values by 1.5 moles of lime per mole of SO_3. One mole of this amount may be considered to enter the structure so as to maintain charge balance.

The H/S results are consistent with the C/S results. The value of the slope of the H/S line is 0.5 moles/mole SiO_2 less than the value of the slope of the C/S line, maintaining the difference in the initial H/S and C/S ratios. The difference between the slope and the intercept of the H/S line is 1.5 moles/mole SiO_2, indicating that the additional lime, over that required for structure extension and charge balance, entering in with the SO_3, enters in as $Ca(OH)_2$.

The morphological changes which accompany entry of sulfate into the structure are similar regardless of when during the history of the C–S–H gel this entry occurs. This is illustrated by the stereo pairs of electron micrographs of surface replicas shown in Fig. 19. Pair (a) represents a field obtained from a C_3S paste hydrated for 5 years at 0.7 w_0/c; pair (b) represents a field of this same paste after immersion in 0.15 M K_2SO_4 for 30 days. The sulfate-treated paste shows only vague suggestions of the structure that appeared in the untreated paste. The rosettes of cone-shaped particles have completely disappeared.

Fig. 20. *Alite paste after agitation in water 3 months*

Pairs (c) and (d) represent fields of C_3S paste hydrated at .45 w_0/c in the absence and in the presence of 3 percent SO_3 as gypsum. The pastes are 28 days old. Pair (c) shows particles similar to those in pair (a), except that they are much more elongated. They, too, seem to grow out of the substrate in clusters, or rosettes. Pair (d) shows broader, thicker and much shorter cones. The change in morphology from (c) to (d) is not at all as severe as in the case of (a) and (b). Pairs (a) and (b) represent the case of attack on an already existing C–S–H gel, while (c) and (d) represent formation without or with gypsum present.

The investigation of the composition of the hydration products of alite pastes brings one a step closer to the cement-water system. In past years, one alite, containing approximately 0.9 percent Al_2O_3 has been investigated (9, 12, 44). Recently, the hydrations of two other alite preparations containing excess alumina, as C_3A, have been examined (29). Alumina was found to enter the C–S–H gel as a substituent. An electron micrograph of an alite paste is shown in Fig. 20. Fewer rolled sheets of the type shown in Fig. 15 are found in alite pastes; there is a similarity in the appearance of the field in Fig. 20 to that of a C_4AH_{13} treated C_3S paste shown in Fig. 16.

The C/S ratios obtained for pastes with various alumina contents, hydrated at .45 w_0/c for 28 days or more are shown in Fig. 21, along with the results obtained from the slurry reaction products of hydrated C_3S paste and C_4AH_{13}. Linear relationships were obtained for the two series, the lines having about the same slope, corresponding to an uptake of 1 mole

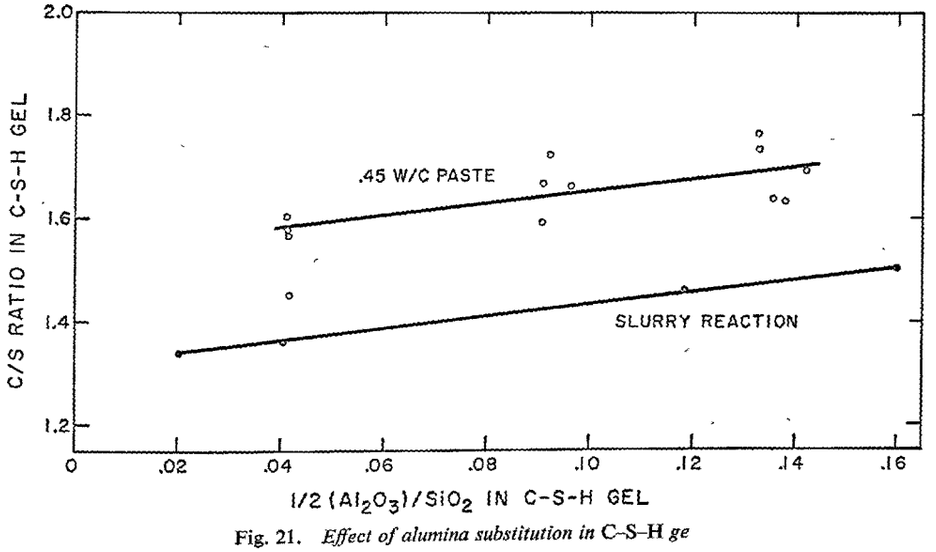

Fig. 21. *Effect of alumina substitution in* C–S–H *ge*

CaO per equivalent of Al_2O_3.

Two investigations have been carried out that suggest that substitution in C–S–H gel occurs during hydration of cement. In one of these Kalousek (53) found, using a quantitative DTA technique, that not all the sulfate in cement paste was accounted for by the amounts of gypsum and sulfoaluminate phases present. Some sulfate was "missing"; Kalousek suggests that this "missing" SO_3 is a "lattice substituent" in the gel. As much as 2.83 percent SO_3 of this type was determined. If all the SiO_2 in the cement used was in the silicate phases, this would correspond to a SO_3/SiO_2 ratio of 0.10, which is below the maximum ratio of 1/6, given above. Since the pastes used by Kalousek were not completely hydrated, the ratio 0.1 should be somewhat higher, probably by about 25 percent. In the other Smolczyk (54) observed that the calcium aluminate hydrates could not account for all the alumina present in blast furnace slag cement paste. He pointed out that the concentration of Ca^{2+} and OH^- was too high to permit the presence of amorphous alumina and concluded that the C–S–H phase retained the "missing" alumina.

It has been demonstrated that a significant morphological change in C–S–H gel produced by cement hydration occurs when sulfate enters the gel (55). This is demonstrated by electron micrograph stereo pairs of replicas of the gel produced by hydration of a clinker and by hydration of the cement (containing 4 percent SO_3 as gypsum) shown in Figs. 22a and 22b, respectively.

Some consideration has been given to the simultaneous substitution of both alumina and sulfate in C–S–H gel. Kalousek suggests that the amounts of these materials that can enter the gel are interdependent to the extent that less of each can enter when both are present.

More recently, it was found that ettringite reacted

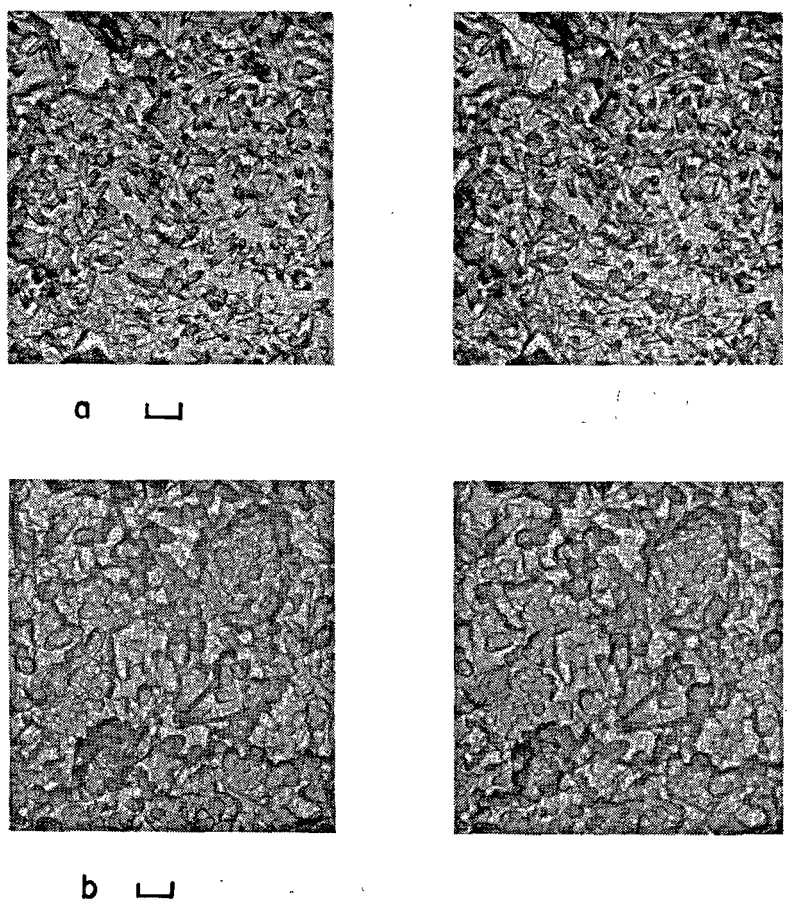

Fig. 22. *Stereo pairs of electron micrographs of hardened cement pastes.* a, *clinker paste made with* $w_0/c = 0.45$, *cured 14 days.* b, *paste of same clinker plus 4 percent* SO_3 *as gypsum,* $w_0/c = 0.45$, *cured 14 days. Mark represents 1* μ.

only slightly with C_3S paste, but that the sulfoferrite analog reacted more extensively (52). Furthermore, it was observed that ettringite was a product of the reaction of calcium sulfate with the alumina-substituted gel formed by hydration of alite, and also a product of the reactions of C_3A and tetracalcium aluminate hydrate with sulfate substituted C–S–H gel. However, the conversions to ettringite were apparently not complete; the evidence indicated that some alumina and sulfate could coexist as substituents in C–S–H gel.

The structural changes occurring because of substitution result in changes in other physical characteristics besides particle morphology. Of great significance with regard to cement technology is the influence of these various reactions on the strength properties of the paste. The compressive strengths of C_3S pastes (.45 w_0/c) as a function of extent of sulfate substitution are shown in Fig. 23. The strength drops significantly with increasing sulfate content. The strength at the highest sulfate content (3 percent on the C_3S basis) is 56 percent of that of the corresponding sulfate free paste, for both percentage hydrations illustrated, 75 and 90 percent. Possibly the lack of resistance of many cements to sulfate attack is at least in part related to these changes caused by replacement of Si^{4+} by S^{6+} in the gel.

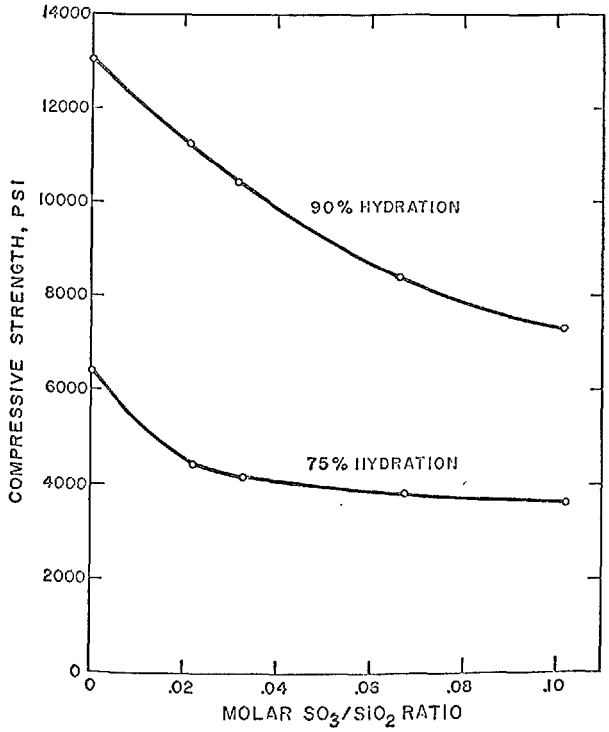

Fig. 23. *Variation of compressive strength with extent of sulfate substitution at constant amount of* C_3S *hydration*

The data obtained regarding the influence of alumina substitution on compressive strength indicate that a slight improvement may result.

Early Hydration Reaction of C_3S

The results of most researches on the hydration of C_3S are generally compatible; the minor differences in interpretation that do exist are probably caused by the fact that most groups of workers do not have the time or facilities to make a complete study. Nevertheless by comparing the work of all it is possible to propose a sequence of reactions during the first few hours that is fairly consistent with all results.

Kawada and Nemoto (48) studied most of the aspects of the early stages of C_3S hydration. They showed that when C_3S was mixed with water there was an immediate liberation of heat for a few minutes, after which the rate of heat liberation fell to a low level. Later the rate of heat liberation increased, passed through a maximum and decreased to a low level again in about eighteen hours. The essential features of this heat liberation curve have been duplicated in our own laboratories. They, Turriziani, Rio and Collepardi (49), as well as Celani, Collepardi and Rio (32) measured the increase in lime content in solution as well as in the solid phases during the early reactions. The solution phase becomes saturated with lime in less than an hour after mixing; concentration of lime continues to increase until maximum supersaturation is reached at 2–6 hours. At about 6 hours crystalline calcium hydroxide can be detected by X-ray diffraction. Turriziani, Rio and Collepardi report free lime in the solid phases is found at about 4 hours by chemical extraction but not by X-ray diffraction. They consider this lime to be amorphous, as have Brunauer, Kantro and Copeland (56). The lime concentration in solution remains high until crystalline $Ca(OH)_2$ begins to be formed; after that it drops slowly to the saturation value.

Greenberg and Chang (57) report that in suspensions of C_3S in water the concentration of silicate ion in solution decreased rapidly as the concentration of $Ca(OH)_2$ in solution increased, and that the silicate ion in the solution phase of C_3S pastes reached a concentration of 6.7×10^{-5} moles per liter within 2 minutes after first contact with water. The Ca^{2+} concentration was .032 moles with a pH = 12.8; comparison of these values with values they obtained (58) by analysis of the solution formed by prolonged stirring of aqueous suspensions of well hydrated C_3S

pastes (wherein the silica concentration was less than 10^{-5} molar in solutions containing .0193 M Ca^{2+} at a pH = 12.46) shows that within 2 minutes the solution became supersaturated with respect to calcium hydroxide and also with respect to the C–S–H gel in C_3S paste.

The results of determining C/S ratio in the hydration (or hydrolysis) product that have been obtained by different research teams differ to some extent. Kawada and Nemoto (48) find the C/S ratio is about 1.5 initially; it rises to 2.5 at about 6 hours, after which it falls and remains essentially constant at 1.5. On the other hand Kantro, Brunauer and Weise (12), and Locher (11) find that the first product formed has a C/S ratio nearly 3. This high ratio decreases rapidly to an approximately constant value, depending upon the water/C_3S ratio of the paste. In pastes, mixed with w_0/C_3S equal to 0.7 and 0.57, the reaction product at 30 minutes had a C/S ratio of 2.9; after 4 hours (14% hydration) the C/S ratio had fallen to about 1.7; it then decreased slowly to about 1.5 at complete hydration in 1 year. Kawada and Nemoto report that the calcium silicate formed initially has practically no bound water. Kantro, Brunauer and Weise as well as Locher also have reported that the water content of the hydration products of C_3S pastes at early ages is essentially the water bound in calcium hydroxide.

These results indicate that the first reaction upon contact of C_3S with water is hydrolysis of C_3S. The solid product of the hydrolysis is a reaction intermediate left as a coating remaining on C_3S surfaces, which retards the reaction. The intermediate product has a C/S ratio somewhat below 3 (but perhaps not far below 3) and has little, if any, bound water. The hydrolysis proceeds to form a solution that is supersaturated with respect to calcium hydroxide and also with respect to the C–S–H gel finally formed. The increase in rate of heat liberation at about 2 hours indicates that cleaning of surfaces by dissolution of the intermediate product to form C–S–H gel has started. Maximum lime concentration in solution is reached at about this time. The increase in rate of hydration is accompanied by a decrease in C/S ratios of the reaction product and the first appearance of extractable lime (between 2 and 4 hours). At 4 hours the C/S ratio of the C–S–H gel has fallen to about 1.6. The lime concentration has decreased somewhat. Crystalline $Ca(OH)_2$ is nucleated in the period between 4 and 6 hours at which time the rate of hydration reaches its maximum. The rate of hydration then decreases as surfaces become covered and space becomes filled with C–S–H gel.

As hydration proceeds, more and more available space becomes filled with hydration products. Calcium hydroxide precipitates with increasing difficulty and the hydration products leave the anhydrous silicate only with greater difficulty. The net result is an increase in the C/S-ratio of the gel with formation of proportionately less free lime, and an increase in the distance which ions must diffuse through hydration product in order to arrive at the solution boundary. The effect of limited available volume becomes more significant, the lower the w_0/c-ratio, and accounts for the marked increase in the C/S ratio of the C–S–H gel that occurs as the w_0/c-ratio of the paste is decreased.

The Hydration of Alumina-Bearing Phases

Tricalcium Aluminate Phase

Hydration in Pure Water

The study of the hydration of pure C_3A in water has been shown to have little similarity to the hydration of C_3A in cement because in cement or clinker pastes the solution formed quickly attains relatively high concentrations of $Ca(OH)_2$, alkalies, and sulfates. These solutes influence the rate and also the products that are formed in the hydration of C_3A. Nevertheless, a brief review of the simple system will serve to illustrate the sensitivity of this component of cement to the conditions of hydration.

Steinour (59) reports that Candlot and LeChatelier believed that C_3A hydrated to form C_3AH_{12}. Klein and Phillips (60) later reported that hexagonal plates, needles, and spherulites, all with the same optical properties were formed by hydration of C_3A at room temperature. The chemical analysis showed the hydrate to have a C/A ratio of 3. In 1929 Thorvaldson and Grace (61) prepared pure cubic crystals of C_3AH_6 by hydration of C_3A at 150°C and also at room temperature. Nacken and Mosebach (62), among others, showed that hydration of C_3A does not always produce a hydrate with a C/A ratio of 3. They found that the solution formed in the first few days was not congruent, and became so only when the "hexagonal" phase transformed to the cubic C_3AH_6. Wells, Clarke, and McMurdie (63) were able to show that the "hexagonal" hydrates formed by hydration of C_3A

in water consisted of two compounds: $C_2A \cdot Aq$ and $C_4A \cdot Aq$.

Recently H. N. Stein (64, 65) examined the hydration reaction of C_3A using calorimetric, conductometric, and X-ray diffraction techniques. Two heat evolution maxima were found in pastes of C_3A, $w_0/C_3A = 1.0$. The first started immediately upon mixing the paste with water, the second, appearing 2 to 3 hours later, was connected with the conversion of the intermediate hexagonal hydrates, C_2AH_8 and C_4AH_{19}, into C_3AH_6 and hydrous alumina. Addition of C_3AH_6 to the C_3A-water paste shifted the second peak to earlier time without affecting its intensity appreciably. Addition of finely ground quartz to the C_3A-water pastes had little effect upon the time of appearance of the second maximum, but did increase its intensity, Fig. 24. Decreasing the water to C_3A ratio shifted the second peak to shorter times. These results are consistent with a mechanism in which the hexagonal hydrates begin to form immediately upon contact of the C_3A with water, and later convert to the more stable C_3AH_6. The results show that C_2AH_8 disappears more rapidly than does C_4AH_{19}. The decreased rate of conversion was attributed to deposition of hydrous alumina upon the C_3AH_6 crystal faces. The action of added C_3AH_6 was to provide seed so that the conversion of hexagonal to cubic phase could start sooner. Addition of quartz to the pastes apparently did not provide nucleation sites for C_3AH_6, but did provide surfaces for precipitation of hydrous alumina, and thus gave some protection to the surface of the C_3AH_6 crystals.

This mechanism seems consistent with the results of Feldman and Ramachandran (66) who studied the

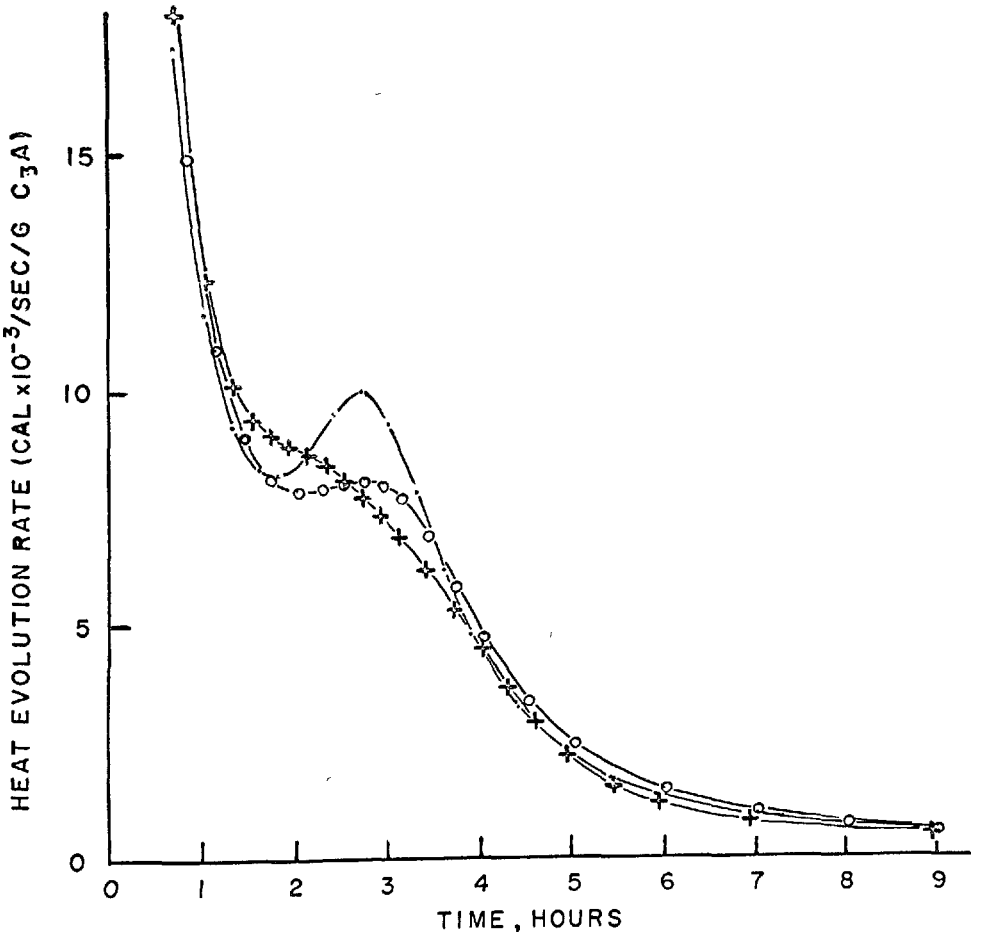

Fig. 24. *Influence of quartz on heat evolution characteristics of* C_3A + *water pastes.* C_3A: *batch B, surface area 16.3* × $10^2/g$
+ —*0.9991 g* C_3A + *1000 g water.*
○—*1.0004 g* C_3A + *0.1228 g quartz* + *1000 g water.*

hydration of compacts of C_3A in water at different temperatures and examined the products by DTA and expansion measurements. They found that hexagonal phases formed first at all temperatures, although only small amounts were formed above 50°C. At temperatures above 52°C conversion to C_3AH_6 occurred rapidly and hydration of C_3A virtually ceased at that time. These authors suggest that at the higher temperatures the C_3AH_6 formed directly on the C_3A surfaces and blocked the entrance of water. At room temperature, and below, the hexagonal phases formed on the surface of the C_3A grains; their conversion to C_3AH_6 cleaned the surface and accelerated hydration for a time.

Effect of Gypsum

Feldman and Ramachandran also studied the influence of gypsum upon the hydration of C_3A (67) using identical techniques. C_3A contained 2 percent free lime; this amount is not sufficient to supply all the lime needed to prevent the hydrolysis of C_3A. The amount of gypsum, which was mixed with the C_3A before making the compact, was varied from 0.25 percent to 20 percent. Consequently even the highest gypsum content contained a smaller proportion of gypsum relative to C_3A than would normally be found in portland cement even if its C_3A content were high. Nevertheless they did find that the rate of hydration was retarded even at the lowest gypsum level (0.25 percent) although they could not identify hexacalcium aluminate trisulfate hydrate (ettringite) as a product of hydration. They reported that at all other gypsum levels except the highest (20 percent) the hydration products comprised a mixture of C_2AH_8 C_4AH_{13}, and $C_6A\bar{S}_3H_{32}$. Conversion of the hexagonal hydrates to C_3AH_6 was delayed but not prevented by the presence of SO_4^{2-}. With 20 percent gypsum at 52°C the rate of expansion of the compact was very much higher than observed in the corresponding compact without gypsum. Apparently the hexacalcium aluminate trisulfate formed with gypsum present retards the hydration of C_3A less than does the C_3AH_6 that forms at high temperatures in the absence of gypsum. Feldman and Ramachandran concluded that although the formation of the mixed hexagonal aluminates on the surface of the C_3A retarded the reaction to some extent, the adsorption of SO_4^{2-} ion on the surface of C_3A was still the major factor. Other workers seem not to agree with this conclusion.

Effect of Gypsum Plus Calcium Hydroxide

Seligmann and Greening (68) monitored, by X-ray diffraction examinations of wet pastes, the hydration reaction of C_3A in pastes containing gypsum and equimolar quantities of C_3A and $Ca(OH)_2$. The water: solids ratio was 0.4. Fig. 25 shows a series of X-ray patterns obtained from a paste containing 1/4 mole SO_3 per mole of alumina, which is a lower gypsum content than corresponds to most portland cements.

The results are semiquantitative and show that the sequence of hydration reactions can be divided into three stages: In the first stage the hydration reaction produces hexacalcium aluminate trisulfate hydrate $C_6A\bar{S}_3H_{32}$. The second stage starts when the SO_4^{2-} is depleted; the hexacalcium aluminate trisulfate $C_6A\bar{S}_3H_{32}$ reacts with C_3A to produce tetracalcium aluminate monosulfate hydrate, $C_4A\bar{S}H_{14}$. In the third stage the hydration of tricalcium aluminate produces the tetracalcium aluminate hydrate—tetracalcium aluminate monosulfate hydrate solid solution, and tetracalcium aluminate hydrate.

In Fig. 25 the pattern at 15 minutes shows peaks of gypsum (G) and tricalcium aluminate (A); weak lines for hexacalcium aluminate trisulfate hydrate (E) are present. By 2 hours the gypsum peaks are considerably reduced and the peaks for hexacalcium aluminate trisulfate hydrate are stronger. The first stage of hydration ends by 5 hours when the gypsum has completely reacted. By six hours the second stage of hydration is completed; the hexacalcium aluminate trisulfate hydrate has converted completely to tetracalcium aluminate monosulfate hydrate. This reaction produces the heat evolution peak marking rapid reaction of C_3A shown by Lerch (69). The final stage is completed at 48 hours when the C_3A has completely reacted. In this stage the monosulfate peak at 9.2° (2θ) increases in intensity and shifts to higher angles as the monosulfate reacts with tricalcium aluminate and calcium hydroxide to form a solid solution. The monosulfate peak at 31.0° (2θ) eventually disappears. By 12 hours the peak of tetracalcium aluminate hydrate at 8.3° (2θ) appears and continues to increase in intensity with continued hydration of C_3A. The fact that tetracalcium aluminate hydrate coexists with the solid solution suggests that there is an upper limit to the amount of $Ca(OH)_2$ that can be taken up in formation of the solid solution phase. Hydration of pastes with higher gypsum contents showed essentially the same effects except that when enough gypsum was present the monosulfate persisted as the final calcium aluminate hydrate phase.

Stein (70) showed the sequence of the reactions involving hydration of tricalcium aluminate in the presence of gypsum and enough calcium hydroxide to insure formation of tetracalcium aluminate hydrate by use of calorimetric measurements and X-ray dif-

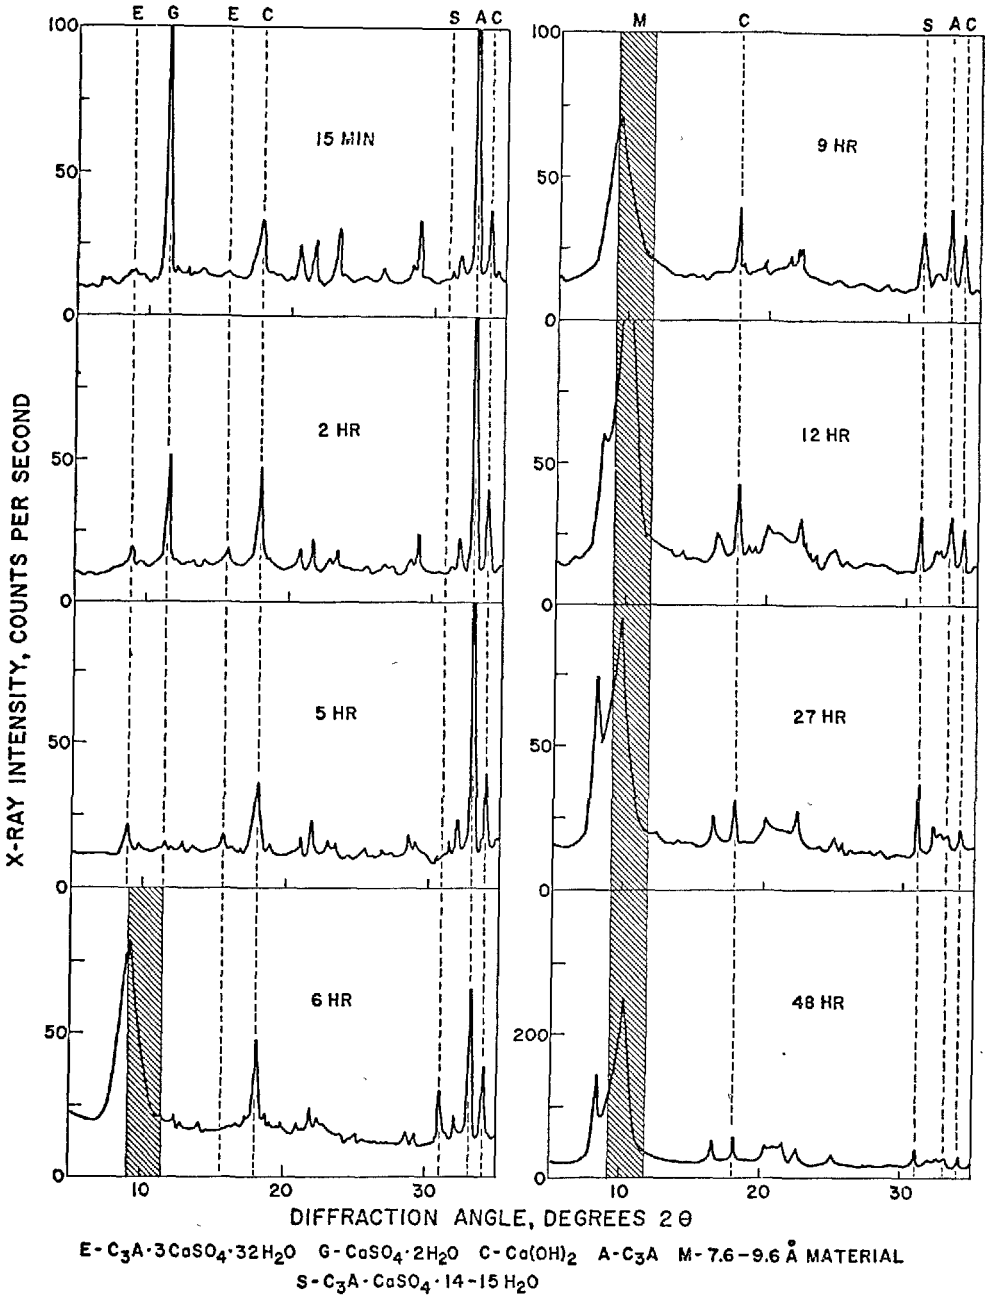

Fig. 25. *Diffraction patterns of base mixture with 3/4 mole* SO_3 *per mole alumina*

fraction examinations. His heat curve is shown in Fig. 26. As with cement there is at first a large heat liberation peak followed by a "dormant" period, in which the rate of heat liberation is low until the gypsum has completely reacted. Immediately following there is a second large peak during which the hexacalcium aluminate trisulfate hydrate formed in the "dormant" period reacts with tricalcium aluminate to form tetracalcium aluminate monosulfate hydrate. Stein concluded: (1) that the trisulfate is formed first on the surfaces of the tricalcium aluminate grains, and (2) that the layer of trisulfate must eventually peel off because the volume of the trisulfate is so much larger than the volume of the tricalcium aluminate from which it was formed. Schwiete, Ludwig and Jäger (71) concur with Stein's proposed mechanism on the basis of their

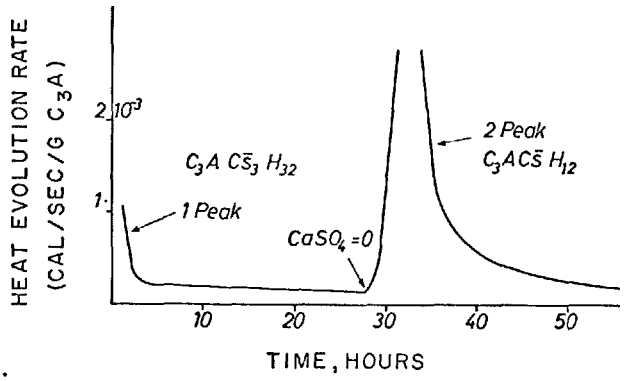

Fig. 26. *Isothermal heat liberation of* C_3A–$CaSO_4 \cdot 2H_2O$–$Ca(OH)_2$–H_2O; *mixture—3 g.* C_3A, *0.4 g.* $CaSO_4 \cdot 2H_2O$ *2 cc 0.0196 m* $Ca(OH)_2$ *solution. (Ref. 71)*

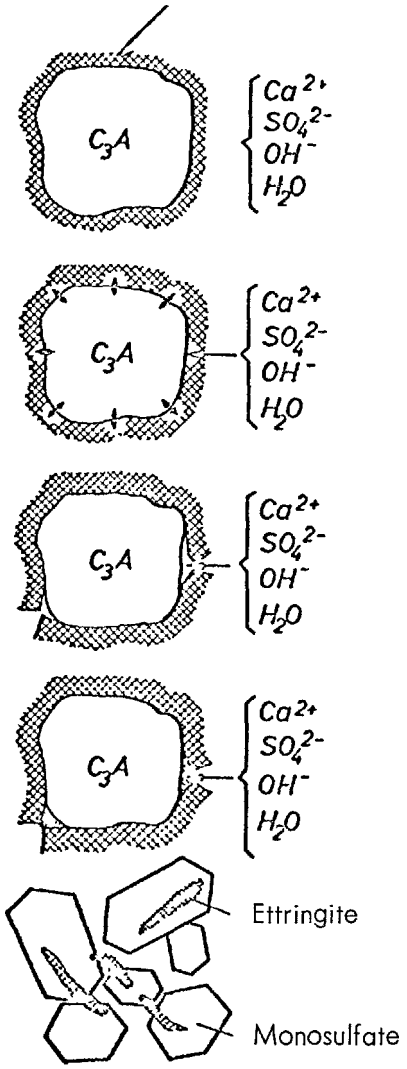
own experimental results. They followed the rate of disappearance of SO_3 and CaO from solution in slurries of tricalcium aluminate, CaO, and gypsum in distilled water. X-ray examination of the reaction products showed the same sequence of reactions reported by Stein, and Seligmann and Greening. Their conception of Stein's proposed mechanism is illustrated by their diagram reproduced in Fig. 27. Schwiete and his coworkers were able to show by electron microscopy, Fig. 28, that hexacalcium aluminate trisulfate hydrate formed upon the surface of C_3A grains within thirty second after the introduction of water.



First stage: Formation of a thin cover of $C_6A\bar{S}_3H_{32}$ on the C_3A surface.

Second stage: A thicker layer of $C_6A\bar{S}_3H_{32}$ formed on the C_3A surface produces crystallization pressure.

Third stage: Bursting of $C_6A\bar{S}_3H_{32}$ layer caused by pressure of crystallization.

Fourth stage: Burst section sealed by newly formed $C_6A\bar{S}_3H_{32}$.

Fifth stage: Insufficient $\bar{S}$ for formation of $C_6A\bar{S}_3H_{32}$; complete hydration of C_6A with consumption of $C_6A\bar{S}_3H_{32}$ to form $C_4A\bar{S}H_{12}$ and $C_4A(\bar{S}, OH)H_{12}$.

Fig. 27. *Schematic description of retarded setting caused by sulfates (after Stein, as modified by Schweite). (Ref. 71)*

Hydration of the Calcium Aluminate Ferrites

The reactions of the calcium aluminate ferrite solid solution phases are more complicated than those of tricalcium aluminate although there are many similarities between the two sets of reactions. In the discussion of these solid solutions we shall for brevity use the symbol, F_{ss}, in place of the name "calcium aluminate ferrite" solid solution. Whenever it is necessary to designate a particular composition of the solid solution the symbol will be written $F_{ss}(p)$, where p is the mole ratio, $A/(A + F)$; thus tetracalcium aluminate ferrite will be written either $F_{ss}(1/2)$ or $F_{ss}(0.5)$. The range of p is thus $0 \leq p \leq 2/3$; the solid solution phase found in portland cement usually lies in the range $1/3 \leq p \leq 2/3$.

F_{ss} Reaction with Pure Water

Carlson (72) investigated the action of pure water on six different F_{ss} phases in leaching experiments, and found it possible to remove all of the alumina and most of the lime from the solid solutions and leave most of the iron as oxide with a little lime adsorbed upon it. If F_{ss} is shaken with water the solution becomes sufficiently concentrated to precipitate C_2AH_8 at room temperature. At 70°C the precipitate that forms is hydrogarnet with about ten percent of A replaced by F. The rate of the reaction increases with temperature and decreases with increasing iron content in the F_{ss}. The presence of $Ca(OH)_2$ in solution will retard the dissolution reaction but will not prevent it even at lime saturation.

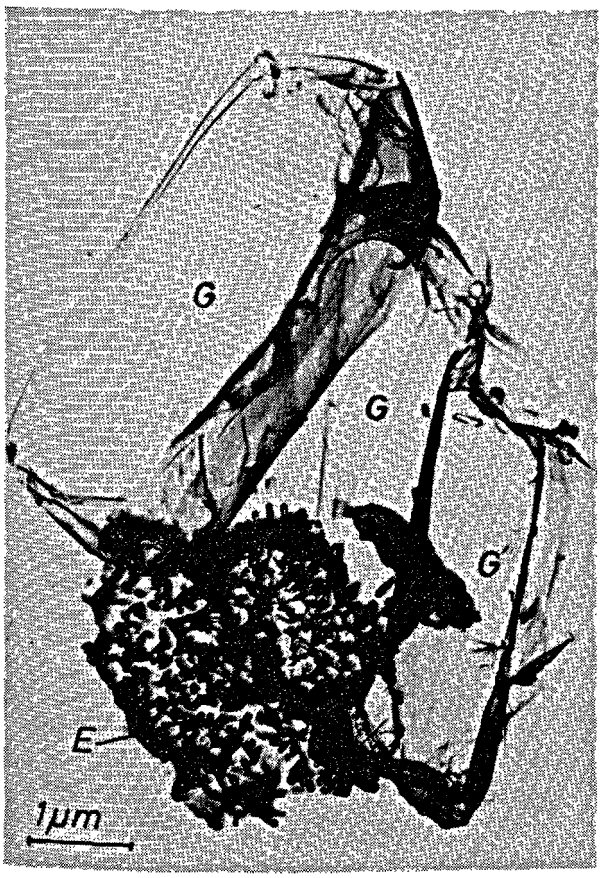


Fig. 28. *Electron micrograph of replica of field in* C_3A–$C\bar{S}$–C–H *system.* $E = C_6A\bar{S}H_{32}$, $C_2 = C\bar{S}H_2$

The reactions in pastes with water are similar in most respects. The composition of the hydrogarnet varied with the composition of the F_{ss}, but the iron to alumina ratio of the hydrogarnet was always lower than that of the F_{ss} phase. When p of the F_{ss} phase is small (high iron content) the hydration product is $C_4(A, F)H_x$, especially at low temperature. If p is high and the temperature is low, C_2AH_8 is formed. The reactivity of F_{ss} decreases with increasing iron content. Chatterji and Jeffery (73) reported that pastes of $F_{ss}(1/2)$ with water/solids ratio of 0.6 were a deep brick red and remained soft up to three months. Hexagonal plates forming early in the hydration (4 min.) were identified as C_2AH_x. Calcium carboaluminate and a small quantity of C_4AH_x were also found. The predominant hydrate was hydrogarnet. No calcium hydroxide, iron oxide, nor any other iron compound was identified by either electron or X-ray diffraction. The lack of iron compounds and calcium hydroxide along with the occurrence of some shift in the magnitude of a_H for the hexagonal phases lead to the suggestion that iron may substitute for aluminium in the hydration products. Carlson's work shows that such substitution does occur; substitution also occurs in C_4AH_x, trisulfate, and monosulfate phases but the diffraction patterns are almost identical to the unsubstituted hydrates (74) so it is generally difficult to detect substitution from the diffraction pattern alone.

Pastes of F_{ss} + $Ca(OH)_2$

Chatterji and Jeffery (73) found that pastes of F_{ss} (1/2) mixed with a suspension of lime-water did not harden in three months. The color of the paste changed from a brick red to a light yellow during this time. Hexagonal hydrates began to form within 4 minutes after mixing. At 24 hours small cubic crystals were also seen. The diffraction patterns showed presence of $C_4(A, F)H_x$, carboaluminate, $C_3(A, F)H_6$, $Ca(OH)_2$ and C_4AF. During the 3 month period, the $Ca(OH)_2$ disappeared while the proportions of $C_4(A, F)H_x$ and $C_3(A, F)H_6$ increased. The fading of the red color of the paste to yellow indicated that the proportion of iron in the hydration products increased during the

hydration period. At 3 months the unit cell of the cubic phase was 0.5 percent larger than that of the cubic phase formed in the C_4AF-water pastes at the same age. During the same period the a parameter of the hexagonal phase in the pure water increased from 5.7 to 5.8 Å. (Chatterji and Jeffery report a for the pure iron compound to be 5.8 Å) They concluded that the iron remained in the hexagonal phase and did not substitute for aluminium in the cubic phase unless excess lime was present.

Schwiete and Iwai (75) studied the hydration of C_4AF mixed with the stoichiometric quantity of CaO needed to form the hexagonal hydrate. The mixture was ground with water, water/solid ~ 5, in an agate mill for 24 hours, then one portion was stored at 5°C, and a second portion was stored at 25°C for a month. At 5°C the C_4AF hydrated to $C_4(A, F)H_{13}$ and $C_3(A, F)H_6$. At 25°C the cubic hydrate was formed with only a meager quantity of the hexagonal hydrate. They also hydrated F_{ss} phases with various iron contents with the stoichiometric quantity of CaO necessary to produce the corresponding cubic hydrate. For F_{ss} phases with iron contents below $p \sim 0.2$ the diffraction lines of the cubic hydrates were sharp and shifted to lower angles with increasing iron content. At higher iron contents the diffraction peaks were not clearly defined because of the low reactivity of the iron-rich F_{ss} phases. The lattice constant a for the cubic hydrates varied with p of the F_{ss} phases in good agreement with the values found by Flint, McMurdie, and Wells (76) for the hydrogarnets.

Work of Carlson (77) has corroborated the findings of Schwiete and Iwai to a large extent. Carlson hydrated a series of F_{ss} solid solutions with the necessary quantity of lime to produce either the hexagonal phase or the cubic phase. He was able to achieve colorless, or light yellow hydrates with p of the hydrate the same as for the F_{ss} phase. He was not successful in preparing C_3FH_6, and found that hydration became more sluggish as the iron content of the F_{ss} phase was increased.

Pastes of F_{ss} + Gypsum

In their study of pastes of C_4AF and gypsum Chatterji and Jeffery (73) found that the first hydration product formed as needles on C_4AF surfaces. The needles did not give an electron diffraction pattern, but had the morphology of ettringite, and their X-ray diffraction patterns showed them to be that. At 14 days the hydration product was a mixture of two types of hexagonal plates. One type had $a = 6.14$ Å; the other had a pseudo cell with $a = 5.66$ Å but also showed joint intermediate spots indicating a doubled a axis. The hexagonal phase with $a = 6.14$ Å was not identified. The other is tetracalcium aluminate monosulfate or its solid solution phase. Some C_4AH_x was also present. Gypsum and ettringite had disappeared. At 3 months the sample was a mixture of the cubic phase, C_4AH_x and the monosulfate. The paste was brick red in color so only a part, if any, of the iron was in the hydration products. Tenoutasse (78) studied the behavior of C_2F, C_6AF_2, C_4AF, and C_6A_2F with gypsum in pastes. C_2F hydrated slowly to give hexagonal plates identified as $C_4F\bar{S}H_x$. With C_6AF_2 the trisulfate was the first hydration product. Hexagonal plates, identified as $C_4(A, F)\bar{S}H_{12}$ and $C_4(A, F)H_{13}$, appeared in a week, and at the end of a month the trisulfate phase had practically disappeared. No cubic phases appeared. The hydration reactions of C_4AF and C_6A_2F were examined in more detail and proved to be similar to each other. Calorimetric measurements showed that when water was added to the F_{ss} phase and gypsum there was an immediate heat evolution which subsided after a short time. Some time later there was a second peak in the heat curve. The time of appearance of the second peak depended upon the quantity of gypsum that had been added. The trisulfate hydrate was formed immediately on adding water. After the gypsum had completely reacted, the second heat peak developed with the further reaction of F_{ss} and trisulfate to produce the monosulfate phase. The A/F ratios of the hydration products were found to be higher than those of the F_{ss} phases from which they were formed. This reaction sequence is like that of C_3A + gypsum.

Pastes of F_{ss} + $Ca(OH)_2$ + Gypsum

Chatterji and Jeffery (73) found that the trisulfate phase was formed immediately when a paste containing C_4AF: $Ca(OH)_2$: gypsum = 10:1:1, was mixed, but that the rate of formation was very low in comparison to the rate of formation in the absence of lime. The X-ray diffraction peaks of the trisulfate were somewhat diffuse so it could not be determined whether or not there was substitution of F for A in the trisulfate phase. After 3 months the paste contained mostly the monosulfate phase with some $C_3(A, F)H_6$ and $C_4(A, F)H_x$. The color of the paste changed from grey at the time of mixing to light red at 3 months. The color indicates that amorphous ferric oxide was liberated slowly; some substitution of F for A must have taken place. These results agree with those of Seligmann and Greening (68) who examined the F_{ss} solutions with $p = 0$, 1/3, 1/2 and 2/3. In all instances the rates of hydration were low, even at low SO_3 levels; C_2F gave no hydration products

even after 13 days. They did find that the hydration sequence of the other F_{ss} phases was like that of C_3A; that is three stages occur: the trisulfate phase formed first in Stage I, Stage II started when SO_3 was depleted and further hydration produced the monosulfate phase, but Stage III differed in that absorption of $Ca(OH)_2$ was not accompanied by the changes in the X-ray pattern in the 7.6–9.6 Å range. Their pastes were also red and they were unable to determine the extent of substitution of F for A. Seligmann and Greening also found that not only were the rates of hydration of the ferrite phases low, but also that C_3A hydrated slowly in pastes containing $C_3A:C_4AF = 2:1$ with lime and gypsum at a constant ratio of SO_3/total Al_2O_3, i.e., the presence of C_4AF under these conditions retarded the hydration of C_3A.

Effect of Tricalcium Silicate Phase on Hydration of $C_3A + F_{ss}$

Aside from the comparative reactivity of tricalcium aluminate and the F_{ss} phases their hydration characteristics are similar, and their hydration products are so similar that it is difficult to differentiate between them under the most favorable conditions. The presence of calcium hydroxide has a pronounced effect upon both the rate and the products formed in the hydration reactions. Since the silicates are sources of calcium hydroxide in cement it is important to know how the hydrations of the aluminates and ferrites in the presence of gypsum are affected when the calcium hydroxide in the system must be obtained by the hydrolysis of the silicate phases. Some work has been reported on hydration of simple (relative to cement) mixtures of gypsum, C_3S, or alite, with C_3A and/or F_{ss}.

Pastes of C_3S, C_3A with Gypsum

Seligmann and Greening (68) found that the Stage I hydration of C_3A was accelerated when the $Ca(OH)_2$ in their mixture was replaced by 3 moles of C_3S. This effect is probably caused by the initial absence of calcium hydroxide in solution. The later hydration though was markedly retarded, and the hydration products were poorly crystallized relative to those obtained in the mixture containing calcium hydroxide. Finally, no C_4AH_{19} was formed.

The retardation of Stage II and III reactions probably results from the decreased rate of imbibition of water caused by hardening of the paste. The effects of C_3S are shown in Fig. 29 where diffraction patterns of pastes with increasing C_3S contents are compared

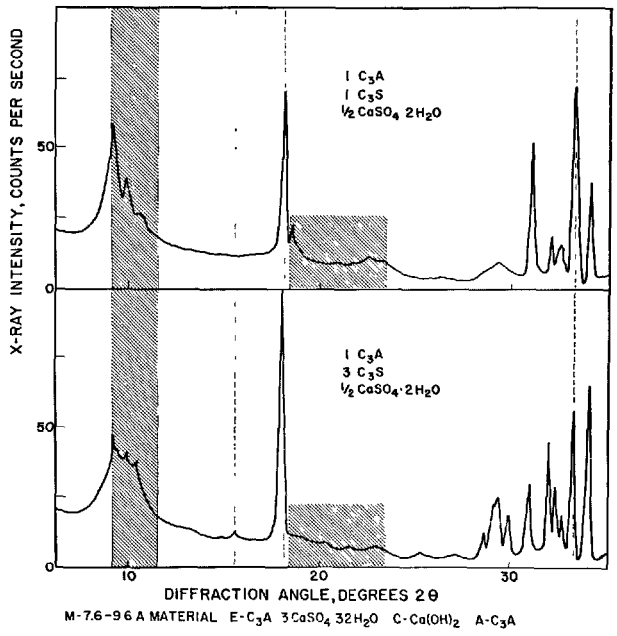

Fig. 29. C_3S *retards hydration of base mixture and causes formation of poorly crystallized products*

after 24 hours of hydration. One must consider, of course, that the C_3A content of the pastes is reduced as the C_3S content increases. In the paste containing 3 moles of C_3S per mole of C_3A a faint line for ettringite is still visible indicating that Stage II hydration has not been completed, yet the tetracalcium aluminate sulfate is already converting to the mixed hydrate M shown by the broad peaks in the 7.6–9.6 Å region. The peaks in the 4 Å region are hardly discernible. Pastes containing 1 mole of C_3S per mole of C_3A show no tetracalcium aluminate trisulfate, but do show the 9.6 Å monosulfate peak. Nevertheless, except for the monosulfate peak, the peaks in the 4 Å region are not resolved. The results suggest that Stages II and III are not clearly separated in the presence of C_3S.

The fact that no C_4AH_{19} is found in the hydration products of pastes containing C_3S may be related to the ability of the calcium silicate gel to absorb alumina, which is discussed in the section "Substituted C–S–H Gels".

Pastes of C_4AF, C_3S and Lime

Schwiete and Iwai (75) prepared hydrogarnets by hydration of C_4AF with different preparations of C_3S chosen to achieve different degrees of substitution of silica for water. They found a linear decrease in the value of the lattice constant of the hydrogarnet with increasing mole ratio of C_3S/C_4AF of the starting

material up to a ratio of 2. Above 2 the lattice parameter was constant. The values of the unit cell parameters agree very well with the values reported by Flint, McMurdie and Wells (76) if it is assumed that the cubic phase produced by C_4AF in excess lime was $C_3(A_{0.5}F_{0.5})H_6$ and S substituted for 2H until the composition became $C_3(A_{0.5}F_{0.5})SH_4$, i.e., below the mole ratio of 2 the iron, alumina, and silica were present in the hydrogarnet in the same proportion as in the starting materials. The final value of the unit cell parameter was 12.419 Å; a value that agrees closely with value usually found in cement pastes (8).

Paste Hydration of Mixtures of Alite, C_3S and C_4AF, with and without Gypsum

The hydration of mixtures of alite, C_3A and C_4AF should be as good a model for cement hydration as it is possible to get by mixing pure phases. It is encouraging that a study of this model by Chatterji and Jeffery (79) produced results that are consistent with the results on simpler systems. In the absence of gypsum thin foils and small hexagonal plates formed on particles in the mixture. Neither gave electron diffraction patterns. After 3 hours the hexagonal plates gave hexagonal electron diffraction patterns with $a_H =$ 5.7 Å showing that they were calcium aluminate hydrates. At 24 hours the paste had set. The foils appeared to have transformed to splines that look very much like the splines of C–S–H gel observed in hydrated cement at 4–6 hours (80) and observed in C–S–H gel after exposure to C_4AH_{13} in a slurry, see Fig. 16. It may be that substitution of alumina for silica in C–S–H gel causes the change in morphology.

Weak X-ray lines at 8.1 Å and 7.6 Å showed the presence of calcium carboaluminate hydrate and α–C_4AH_{13}, which contains essential CO_2 (81). At 14 days the cubic aluminate phase had formed; the X-ray pattern showed a smaller unit cell size, which indicates that silica had replaced some water in the crystallites. At 3 months the alite had reacted completely, but C_3A and C_4AF were still present. There was essentially no change in the hydration product. In another set of experiments 0.1 N NaOH was used to mix the pastes. The only difference noted was a slight delay in the formation of hexagonal phases.

Pastes made with gypsum were more fluid when mixed and setting occurred during the first day. Ettringite and foils of C–S–H gel were present after 4 minutes. Splines of C–S–H gel appeared at 3 hours. At 14 days the monosulfate and tetracalcium aluminate hydrate with a little ettringite were present as well as another unidentified hexagonal phase with $a_H =$ 6.3 Å. At 3 months the ettringite had disappeared; only a trace of alite was present along with C_3A and C_4AF. The presence of 0.1 N NaOH had little effect on the hydration characteristics except that the splines of C–S–H gel appeared within 4 minutes.

Early Reactions in Portland Cement Pastes

Reaction Sequence

In a normally regulated cement the SO_4^{2-} ion will be depleted in about 24 hours; this then is the length of the Stage I period for hydration of the aluminates, and the early cement reactions are completed during this time. The hydration characteristics of pure C_3S, C_3A, and F_{ss} phases provide a basis for understanding the early hydration reactions of cement. These reactions start immediately upon contact of the cement and water. Schwiete, Ludwig and Niel (82, 83) showed that hydration products formed on the surface of cement particles within 30 seconds after contact of the cement with water. Bar-shaped crystals, hexagonal plates, and gel could be delineated in electron micrographs. After 20 minutes ettringite was identified; larger hexagonal plates and hydrogarnets were also observed. The hexagonal plates could be either the monosulfate phase or the dispropor tionation products of C_3A, i.e., C_2AH_8 and C_4AH_{19}. The fact that hydrogarnet was also found implies that the SO_4^{2-} concentration was low and that consequently the hexagonal plates were the disproportionation products. It is possible that some of the gel first observed was amorphous Fe_2O_3 from hydrolysis of F_{ss}. Chatterji and Jeffery (84) identified ettringite as a product of hydration of cement after 4 minutes. They followed the hydration reactions through 3 months time, and found trisulfate, monosulfate, and carboaluminate in all samples after 24 hours. Carbonation at concentrations as low as is provided by calcite will react with the monosulfate phase to form the trisulfate phase and the hemicarboaluminate (α–C_4AH_{13}), or carboaluminate, depending upon the amount of available monosulfate phase (85).

The free lime in the clinker and the hydrolysis of alite furnish the lime to retard the hydrolysis of the calcium aluminate and F_{ss} phases. Because the hydration of the calcium silicates in cement also starts immediately upon contact with water (82, 84) so

shortly after the introduction of water both calcium hydroxide and sulfate ion are available to retard the hydration of the alumina-bearing phases and to accelerate the hydration of alite if the proper amount of SO_4^{2-} is present. Several investigators (see for example (32, 48, 49, 86, 87)) have shown that the solution phase in contact with clinker, portland cement, or C_3S quickly becomes supersaturated with respect to $Ca(OH)_2$. Among these workers, Lawrence found that the silica concentration in the solution phase quickly exceeded the saturation value with respect to the system C–S–$\bar{S}$–A, then remained practically constant during the early hydration period. Kawada and Nemoto found that the solution in contact with C_3S and gypsum never became supersaturated with gypsum, but remained saturated for about nine hours. Rio, Celani and Collepardi observed that the first crystalline calcium hydroxide began to precipitate at about 4 hours; this is about the same time as the rate of heat liberation from the hydration of alite begins to increase. The Ca^{2+} ion concentration of the solution phase continued to increase after the first appearance of crystalline $Ca(OH)_2$, and passed through a maximum during the time interval in which rapid hydration of alite is normally observed.

These observations and the interpretations offered by the various research teams suggest a mechanism for setting of cement pastes. In a freshly mixed paste hydrolysis of all phases starts immediately. Before the SO_4^{2-} concentration can be built up the alumina bearing phases should produce C_2AH_8, C_4AH_{19}, hydrous Fe_2O_3, and sometimes hydrogarnet. The hydrolysis of alite soon supersaturates the liquid phase with respect to calcium hydroxide and produces a high concentration of silicate ions, simultaneously leaving the surfaces of alite coated with a metastable product, probably with high C/S and low H/S ratios (12, 48).

The gypsum dissolves rapidly to produce a saturated solution (in some instances the solution must become supersaturated with respect to gypsum, depending upon the form of $CaSO_4$ in the cement). The high concentrations of $Ca(OH)_2$ and $CaSO_4$ soon transform the aluminate hydrates to $C_6(A, F)\bar{S}_3H_{32}$. Evidence from X-ray diffraction, DTA, and electron microscopy indicates that all this happens within 30 seconds to 4 minutes. The hydration of the alumina bearing phases to produce the trisulfate proceeds slowly simultaneously with the hydrolysis of alite which increases the concentration of $Ca(OH)_2$ in solution and produces a thicker layer of the metastable product. Eventually nuclei for crystallization of $Ca(OH)_2$ appear throughout the system, and crystalline $Ca(OH)_2$ appears. At about the same time nucleation of the stable C–S–H gel starts. When this nucleation occurs the unstable gel that coats alite surfaces dissolves to precipitate on nuclei, some of which may appear within the coating itself; as the alite surface becomes cleaner the hydration of alite accelerates and the supersaturation of Ca^{2+} increases. As the alite surfaces again become coated (with the stable gel this time) the rate of hydration increases less rapidly and passes through a maximum. The concentration of Ca^{2+} ion also passes through a maximum at about the same time. During the period of rapid hydration of alite the stable C–S–H gel forms in laths protruding from the clinker grains and starts to precipitate upon calcium hydroxide surfaces as well. The gel soon forms a continuous network throughout the paste and setting occurs.

The intergrowth of gel and $Ca(OH)_2$ has been observed microscopically using time-lapse photography by Erlin and Greening (88). Evidence of it is sometimes found in surface replicas of hardened pastes. One method of preparing these is to slice the paste with a fine-grit diamond saw using water as a lubricant (52). Calcium hydroxide crystals in the cut surface are dissolved away during this process. The voids remaining frequently show that C–S–H gel had intergrown with the $Ca(OH)_2$ in a preferred orientation, see Fig. 30. H. F. W. Taylor (89, 90) has pointed out that the octahedral arrangement of OH^- around each Ca^{2+} in the $Ca(OH)_2$ crystal has a spacing such that an SiO_4^{4-} tetrahedron can share an edge of the octahedron with only a little distortion. This ability of the tetrahedra to share edges of octahedra could well lead to epitaxial growth of gel on crystal surfaces. It also suggests that the nuclei for formation of crystalline $Ca(OH)_2$ may be similar to those that form stable C–S–H gel; that the two kinds of nuclei form under similar conditions.

Stages II and III of the aluminate reactions may be prolonged in hardened portland cement pastes. An example of the transformation of the trisulfate phase to the monosulfate phase in a portland cement paste is shown in Fig. 31. The portland cement had a potential C_3A content of 14.3 percent with 3 percent SO_3 added as gypsum. The paste, $w_0/c = 0.45$, had been stored continuously moist for 14 days. Rods of the trisulfate phase and hexagonal plates of the monosulfate phase are both present. Some of the rods seem to pierce the plates of the monosulfate phase.

Optimum Gypsum

Lerch's work (69) on the influence of gypsum upon

hydration of cement was undertaken to examine the basis for specifications on SO_3 content of cements. As a result of the work he found that there was a quantity of gypsum for each cement that would produce a maximum strength and a minimum drying shrinkage in mortars. In only a few instances did cements with optimum gypsum show larger expansions than were found with the maximum permissible SO_3 content (ASTM Specifications). This quantity of gypsum he called the optimum gypsum content. Its magnitude depends upon the composition and fineness of the cement. In addition to the properties of the cement, the conditions of use of the cement must be also considered, for example, the optimum gypsum content for cement used for making concrete at 4°C is lower than for cement ground from the same clinker and used for making concrete at 20°C. Lerch found that the optimum gypsum content was that quantity that would be completely reacted in 18 to 24 hours. From the preceding discussion it is clear that optimum physical properties of hardened pastes and concretes will be attained when Stage I of the hydration of the alumina containing phases is extended through the period of setting and into the period of hardening of the paste.

The sequence of early hydration reactions provides some insight into why an optimum gypsum content exists. Too much gypsum extends the Stage I hydration for too long a time; SO_4^{2-} ion will be present to produce the trisulfate phase long after setting, causing

a continuous expansion of the paste structure that inhibits the development of strength. If too little gypsum is used Stage I hydration ends before the hardening of the paste is well enough advanced; the reaction transforming the trisulfate to the monosulfate proceeds very rapidly; and this reaction is followed by the formation of the solid solution between the monosulfate and $C_4(A, F)H_{19}$, which reduces the high concentration of $Ca(OH)_2$. The decreased $Ca(OH)_2$ concentration permits further hydrolysis of C_3S to the metastable product, delays the nucleation of the stable gel, and consequently retards the development of the C–S–H gel structure, as described in the previous section.

Written Discussion

J. G. M. de Jong, Hans N. Stein and J. M. Stevels

In the survey on the early hydration of C_3S, given by Dr. Copeland and Dr. Kantro, one point is only shortly mentioned that may be of some other than trivial nature: the accelerated, "autocatalytic" character of the hydration of C_3S during the first day.

The phenomenon has been known from calorimetric measurements as early as 1940 (1). It has been confirmed by later calorimetric experiments (2, 3), and its interpretation of indicating accelerated conversion of C_3S has been corroborated by X-ray measurements (4, 5).

The accelerated character of the hydration of C_3S has been ascribed (2, 6, 7) to the conversion of a first, strongly retarding hydrate (F. H.) into a second, less retarding one (S. H.) under the action of nuclei of the second hydrate. F. H. was assumed, following Kantro, Brunauer and Weise (8), to have the composition C_3SH_n; S. H. resembles C–S–H–I samples as regards electron microscope habit, and may therefore be supposed to have a much lower CaO/SiO_2 molar ratio.

The following facts are consistent with this mechanism:

a. The hydration of C_3S can be accelerated by artificially lowering the Ca^{2+} and OH^- concentrations during the first minutes by the addition of amorphous silica. Indeed, the formation rate of S. H. nuclei from F. H. is expected to be accelerated by the lowering of calcium and hydroxyl ion concentrations.
b. The hydration of C_3S can be retarded by the addition of CaO or $Ca(OH)_2$ (9). This equally can be explained by the mechanism mentioned: the formation of S. H. nuclei from F. H. is expected to be retarded by an initial excess of calcium and hydroxyl ions in the water phase.
c. The hydration of C_3S is retarded by the addition of aluminate ions, either as $Al(OH)_3$ (10) or as C_3A (11), when the aluminate ion concentration surpasses a certain limit. This is explianed through incorporation of aluminium ions into F. H., retarding its conversion, as found by Kalousek (12) for the case of the conversion of tobermorite into xonotlite.

Some results reported by Copeland and Kantro (Fig. 8 of their paper) appear to indicate an increase rather than a decrease of the hydration rate of C_3S by the presence of aluminium ions. However, their first data were obtained after 1 day's hydration. Indeed we found calorimetrically that the *total* heat evolved during the C_3S hydration peak is increased by aluminate ions; by means of quantitative X-ray analysis, it was found that after 96 hours more C_3S had been converted in the presence of $Al(OH)_3$ than in its absence (10).

As regards C_3A hydration in the presence of $CaSO_4 \cdot 2H_2O$, Copeland and Kantro remark that the ettringite layer first formed on the C_3A surface is supposed to be removed by a "scaling off" mechanism. This indeed was the view supported in 1962 by one of the present authors (13). However, later (14) some results were obtained indicating a chemical rather than a mechanical destruction of this layer. This interpretation had been, as appears now, anticipated by Seligmann and Greening (15), and has been confirmed recently by Mori and Minegishi (16). There rests the difficulty of explaining the persistent coexistence of ettringite and monosulfate or C_4AH_{19} crystals in hardening cement pastes, as mentioned by Copeland and Kantro (Fig. 31). Most probably a rapid conversion of ettringite demands high values of calcium and aluminate ion concentrations as are found in a hardening cement paste locally only, in the direct vicinity of a C_3A surface.

Oral Discussion

John H. Taplin

In a Written Discussion of paper II-4 by Kondo and Ueda I have made a plea that where researchers do not have closely sized materials, they should measure the particle size distribution.

This request is perhaps even more relevant here. Copeland and Kantro have quoted a great deal of kinetic data but much of the kinetic significance has been lost because of a lack of particle size information about the anhydrous cement materials.

Authors' Closure

L. E. Copeland and D. L. Kantro

Mr. Taplin is correct in the sense that little of the data presented in our paper gives information about the effects of particle size upon the kinetics of hydration. Nevertheless, something has been learned about the effects of factors other than fineness (or particle size), and there is much more to be learned. The effects of temperature, water/cement ratio, and chemical composition can be studied individually by working with cements ground by the same procedures to a constant fineness. The conclusions reached in this type of study may have to be modified if there is a strong interaction between fineness and one or more of the other factors.

The results of hydration studies by independent teams of workers are fairly consistent with each other and suggests that interactions between fineness and other factors are probably not strong over the range of finenesses usually encountered in cements.

Supplementary Paper II-2 Contribution of Calcium Thiosulphate to the Acceleration of the Hydration of Portland Cement and Comparison with Other Soluble Inorganic Salts

Keiichi Murakami and Hirobumi Tanaka*

Synopsis

In this paper, the accelerating ability of calcium thiosulphate which was newly discovered by the authors is investigated by means of various methods, in comparison with other soluble inorganic salts, such as calcium chloride, calcium nitrate etc.

The accelerating action of calcium thiosulphate on the setting of portland cement is approximately similar to that of calcium chloride. The early development of strength of portland cement gradually increases as the quantity of calcium thiosulphate in portland cement increases. Especially, the early strength of mortar of portland blast furnace slag cements (consisting of granulated blast furnace slag 65 and portland cement 35), when calcium thiosulphate is used at concentration of 3% to the cement, is developed near that of ordinary portland cement.

The result of corrosion test showed that the test pieces of mild steel buried in mortar containing respectively 3% and 6% calcium thiosulphate weres carcely corroded after the mortar was exposed under the atmosphere for 6 months. Under the same condition, the test piece of mild steel buried in the mortar containing 2% calcium chloride was markedly corroded after only one month.

The acceleration of hydration of portland cement by inorganic salts results from the acceleration of hydration of alite phase. The order of effectiveness of anions and cations as the accelerators of hydration of portland cement is $Cl^- > S_2O_3^{--} > SO_4^{--} > NO_3^-$, $Cl^- > Br^- > I^-$ and $Ca^{--} > Mg^{--} > Na^-$. The anion in salt is closely related to the tangent of the ascending portion in the heat liberation curve of the hydration of alite. The cation is closely related to the beginning time of the second peak in the heat liberation curves of the hydration of portland cement.

The hydration products of C_3S at later stage of hydration are generally CSH(II) when calcium chloride was used, are CSH(I) when no additives was used and can not be evidently detected when calcium thiosulphate is present.

At early stage of the hydration without gypsum, the hydration products of C_3A which are obtained in the presence of calcium chloride and calcium thiosulphate are gel-like substance, however, when calcium nitrate is present, the hydration products are polygonal crystalline particles and hexagonal plate-like crystals.

Introduction

Calcium chloride is now well known as an excellent accelerator of the hydration of portland cement. However, the chloride attack to the steel in reinforced concrete is hardly ignored from the viewpoint of the maintenance of concrete constructions. Furthermore, a troublesome problem connected with the chloride attack is being brought about by the use of beach-sand that resulted from the lack of fine aggregates in making concrete in large cities in Japan. Therefore, it is very favorable if the chloride ion remaining in concrete can be turned into the very difficult soluble compound and so be inactivated. But it may be now very difficult.

In the present study, the accelerating action of calcium thiosulphate discovered by the authors is investigated and is compared with other soluble inorganic salts, such as calcium chloride, calcium nitrate, calcium sulphate etc. Because, it is suggested that calcium thiosulphate does not probably give any corrosion to the steel in concrete.

A number of studies have been undertaken to clarify the accelerating actions of various salts and, especially, the effect is brought about by the addition of calcium chloride to portland cement.

*Faculty of Engineering, Tohoku University, Sendai, Japan.

Shinohara and Naritomi (1), Nagai (2), Narahashi, Amamiya and Nakajima (3) examined the influences of various salts on the setting and hardening of portland cement. Their results showed that calcium chloride and barium chloride have a most effective accelerating action among various salts used. The heat liberation process of the hydration of portland cement containing the accelerators was studied by Bogue (4), Stein (5), Edwards and Angstadt (6), Angstadt and Hurley (7), Zimonyi and Balazs (8), etc. by the use of conduction calorimeter. They obtained an identical conclusion, in which the accelerators do not promote the hydration of C_3A, but predominantly accelerate the hydration of C_3S phase of portland cement. Edwards and Angstadt (6) reported that both cations and anions are ranked according to their general effectiveness as accelerators of the hydration of the C_3S phase: $Ca^{++} > Mg^{++} > Li^{+} > Na^{+} > H_2O > Zn^{++}$ and $OH^{-} > Cl^{-} > Br^{-} > NO_3^{-} > SO_4^{--} > H_2O > CH_3COO^{-}$. It was reported by Bogue (9) and Jones (10) that, although calcium chloride does not accelerate the hydration of C_3A, such complex salts as $C_3A \cdot CaCl_2 \cdot 10H_2O$ and $C_3A \cdot 3CaCl_2 \cdot 30H_2O$ are produced by the reaction between calcium chloride and C_3A. The reaction with C_3A and $CaSO_4 \cdot 2H_2O$ was found by Rosenberg (11) to occur rapidly than the reaction with C_3A and $CaCl_2$, when C_3A was added to the aq.solution containing $CaCl_2$ and $CaSO_4 \cdot 2H_2O$. Calcium chloraluminate complex salts are produced after gypsum was depleted. Andreeva and Segalova (12) reported that the concentration of Cl^- in the liquid phase of C_3S paste containing $CaCl_2$ does not vary with time. Therefore, it was suggested that the accelerating action of calcium chloride on the hydration of C_3S may be catalytic. Moreover, Johnston (13) confirmed that the concentration of Ca^{++} in the liquid phase of portland cement paste is increased by the addition of calcium chloride. It was shown by Libermann and Kireev (14) that some calcium salts, as $CaCl_2$, $MgCl_2$, etc., however, may so reduce the OH^- concentration of aq. solution, even though saturated with lime. Recently, Kawada and Nemoto (15) have reported that the addition of calcium chloride at a optimum concentration on the acceleration brings about an increase of the quantity of lime and silicate which are saturated in liquid phase and therefore, that the early strength development of portland cement is given by the great precipitation of resultant hydration products. Another study suggested that the coagulation of CSH may be strengthened by the ionic strength which was increased by the addition of calcium chloride. The morphologie of CSH produced in the presence of calcium chloride were studied by Richartz and Locher (16) by electron microscopic observation. They stated that the high strength obtained by the addition of calcium chloride may resulted from the cross-linking of the long fibrous crystals of CSH.

Experimental

Materials

In this study, each of commercial portland cement, commercial portland blast furnace slag cement and commercial early strength portland cement was employed. Tricalcium aluminate, tricalcium silicate and alite as clinker mineral of portland cement were synthesized and were also employed.

Crystals of calcium thiosulphate can be prepared (17) by making a 3/4 saturated solution of $CaCl_2 \cdot 6H_2O$, adjusting the pH of 8–9 with CaO, and adding pure $Na_2S_2O_3 \cdot 5H_2O$ excluding air and CO_2 with a stream of N_2. After 4 hours, at 40°C, the solution is freed of precipitated salt by filtration, and two corps of calcium thiosulphate are obtained, one at 0°C and a second at −20°C. In order that the crystals are completely freed from Cl^-, subsequently, a series of such operations as dissolution, crystallization and washing with water is twice repeated. The resultant crystals were very pure.

Calcium thiosulphate has a molecular equation as $CaS_2O_3 \cdot 6H_2O$ and a large solubility in water. Since the vapor tension of crystal water is very high, some portions of crystal water are easily lost and simultaneously sulphur and calcium sulphite is produced as decomposed compounds, when the crystal is kept standing in dry atmosphere. Therefore, calcium thiosulphate must be stored in a vessel with saturated humidity, however, it is stable for long period in the aqueous solution.

Fig. 1 shows the DTA curve of calcium thiosulphate crystal and its thermal balance curve. The curves indicate the loss of crystal water (50°C), the dehydration of the calcium sulphite crystal (100°C), the combustion of the sulphur (300°C) and the oxidation of the calcium sulphite (600°C).

Procedures

In order to investigate the accelerating action of

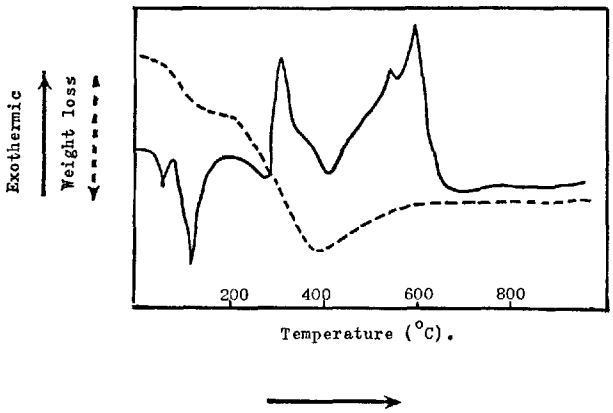

Fig. 1. *DTA of calcium thiosulphate crystal. Heating rate: 5°C/min., Standard substance: α-Al_2O_3., Sample holder: Pt, Thermocouple: Pt-PtRh 13%. Solid curve: DTA, Broken curve: Thermal balance.*

calcium thiosulphate and other soluble inorganic salts, various methods are used, namely, setting and strength development test, measurement of the heat liberation on the hydration of portland cement, quantitative and qualitative X-ray analysis, differential thermal analysis, thermal balance, electron microscopic observation, measurement of free lime, corrosion test and measurement of specific surface area.

Results and Discussion

The time of set of paste made from portland cement containing $CaCl_2$, CaS_2O_3 and $Ca(NO_3)_2$ is shown in Table 1. When 1% of calcium chloride was added to the portland cement, the setting time is reduced to half that of portland cement with only gypsum. Calcium nitrate accelerates the set at concentration of 0.5% to the cement, but it acts as a retarder beyond its concentration. Calcium thiosulphate is very effective as an accelerator to the setting of ordinary portland cement, portland blast furnace slag cement and early strength portland cement. The results are shown in Tables 2 and 3. The strength development of mortar made from portland cement containing $CaCl_2$, CaS_2O_3 and $Ca(NO_3)_2$ is shown in Table 4. The accelerating effect of calcium chloride on the strength development at early stage of the hydration of portland cement is largest among them. However, there is a tendency that the strength development of the 28 day of portland cement with calcium chloride is relatively less than that of portland cement without calcium chloride. From this result, it is suggested that an optimum amount of calcium chloride for the acceleration of portland cement hydration may be 2%. Calcium nitrate does not reveal the accelerating action on the strength development of portland cement mortar.

B: Bending strength, C: Compressive strength, unit of strength: kg/cm².

The accelerating action of calcium thiosulphate, which is relatively less than that of calcium chloride, however, is gradually strengthened in proportion to the amount of calcium thiosulphate added to the cement. Consequently, a high strength is obtained at the one and three days, but the strength development at the 28 days is less, as in the case of calcium chloride, than that of portland cement with only gypsum.

An interesting example in the acceleration of strength development by the addition of calcium thiosulphate is shown in Table 5. The early strength development of portland blast furnace slag cement containing a large quantity of granulated blast furnace slag is generally poor, according to the delayed hydration of blast furnace slag, on the other hand, the strength development at later stage of the hydration is very high. When calcium thiosulphate was added at concentration of 3% to the blast furnace slag cement, not only the early strength development can be approached to the value near that of ordinary portland cement, but also a higher value can be kept at later stage without such adverse reduction that is frequently observed when the accelerators were used, because the quantity of portland cement clinker is only 35% of the blast furnace slag cement, in which the influence of portland cement on the strength development of the blast furnace slag cement will be small at later stage. Therefore, it can be suggested that the hydration mechanism of granulated blast furnace slag is markedly different from that of portland cement and the accelerating action of calcium thiosulphate is scarcely related to the hydration of slag.

It is evident that calcium thiosulphate is effective as an accelerator on the 15 hour strength development of early strength portland cement, however, it

has not an available action on the one and three day strength development (Table 6). On the manufacture of ready-made concrete products, if the high early strength can be developed by the addition of calcium thiosulphate, consequently, the rate of production will be accelerated and the economical production will be accomplished. As an example of this attempt, Table 7 shows the strength development of portland cement mortar containing calcium thiosulphate after 5 and 8 hour curing in air at 20°C and, in addition, subsequently after 6 hour hot curing in hot water. From this result, it may be suggested that the removing of concrete products from frame can be accelerated by the use of calcium thiosulphate.

Corrosion Test

In order to compare with the corrosive character of $CaCl_2$, CaS_2O_3 and $Ca(NO_3)_2$, the test pieces made of mild steel were buried in portland cement mortar containing a definite quantity of each salt. Then, the mortars was kept standing for a definite period in outdoors. The occurrence of corrosion was observed on the surface of all the test pieces buried in the mor-

tar with 2% and 5% additions of $CaCl_2$ after only one month. On the contrary, the corrosion on the surface of test pieces buried in the mortar containing calcium thiosulphate and calcium nitrate was scarcely observed after 6 months, even when both salts were respectively used at concentration of 5%. Consequently, calcium thiosulphate has been confirmed to be an accelerator without the corrosive action.

Effect of Accelerators on the Heat Liberation Process of the Hydration of Portland Cement and Clinker Minerals

An adiabatic calorimeter, of which the detailed operating procedure and construction were described in the previous paper (18), was used. The compositions of cement samples charged in the calorimeter are shown in each figure. From Fig. 2 to 9, the heat liberation caused by the hydration of sample in the calorimeter is plotted as "Temperature rising" (Thermal electromotive force μV by thermocouple) versus hydration time. This device uses such paste that contains a large water- content and is not entirely

tion of portland cement containing accelerators is measured by conduction calorimeter, generally, there is a tendency that the analysis of accelerating action becomes very difficult by overlapping of both the first and second cycle in the heat liberation curve, because the hydration of alite phase corresponding to the second cycle is considerably accelerated by the agitation. The separation between the both cycles is approximately possible in the heat liberation curve given by the use of this device.

Fig. 2 shows the accelerating actions of acidic salt $CaCl_2$ and neutral salt NaCl. They accelerate the set and hardening of portland cement by accelerating the hydration of alite phase, namely, by accelerating the occurrence of the second cycle. Besides, it is suggested that the anion of salts is closely related to the tangent of ascending portion of the second cycle, and that the cation, to the beginning time of second cycle. When the both salts are used at the same concentration, the beginning time is more shortened by calcium chloride than by sodium chloride. When sodium chloride is used at a concentration of 6%, the beginning time is slightly shortened than that in the case of 3% sodium chloride, however, it is still longer than that in the case of 3% calcium chloride.

The effects of some salts consisted of a common cation Ca^{++} and different anions of halogens Cl^-, Br^- and I^- on the hydration of portland cement are shown in Fig. 3. From this result, it is found that the stronger the non-metallic character of anions, the larger the tangent of ascending portion of the second peak. The addition of salt containing anion with a strong metallic character causes the second peak to be less intense.

Fig. 4 shows the accelerating action of some chlorides with different cation and calcium nitrate on the hydration of portland cement. $CaCl_2$ and $MgCl_2$ have a similar accelerating effect on the hydration of alite. On the other hand, the heat liberation curves of the hydration of portland cement with $AlCl_3$ 3% and $Ca(NO_3)_2$ 3% are anomalous. In the case of the former, especially, there is a considerable increase, which can be caused by the flash set of alumina-gel which is most likely produced by the reaction with an acidic salt $AlCl_3$ and lime in liquid phase or aluminate phase, in the initial heat evolution. The produced gel will coat the cement grains and will hinder the hydration of cement, therefore, the second peak may not be consequently developed in spite of the presence of chloride ion. Calcium nitrate shows an abnormal curve as if it not only indicates the absence of accelerating action, but also may obstructs the hydration of alite phase. From this fact, it will be considered that the hydration behaviors of calcium aluminate in the presence of accelerators must be also studied for understanding the acceleration of hydration of portland cement.

The second peak of the hydration of portland cement accelerated by 3% $CaCl_2$ has an intensity which is twice larger than that accelerated by calcium thiosulphate at the same concentration as shown in Fig. 5. Namely, the tangent of ascending portion of the second peak with 3% $CaCl_2$ is also twice that of the case of 3% CaS_2O_3. When the concentration of CaS_2O_3 was increased from 3% to 6%, the second peak in the heat liberation curve is slightly accelerated and also is leveled up with the original profile. Although calcium thiosulphate accelerates the occurrence of the second peak in the heat liberation of portland cement hydration, it does not relate to the increase in tangent of ascending portion of the second peak. A considerable increase in the initial heat evolution, in the case of 6% CaS_2O_3, is supposed apparently to be caused by the interaction between CaS_2O_3 and C_3A or calcium aluminoferrites.

In order to confirm the accelerating action on the hydration of only alite, the effect of calcium chloride

on the hydration of synthetic alite was studied at both temperatures of 35°C and 55°C. The result is shown in Fig. 6. The accelerating action of calcium chloride is apparent by the facts that the beginning time of heat liberation is gradually shortened and the intensity of heat liberation is rapidly strengthened in proportion to the increasing amount of calcium chloride. However, the effect of temperature is so great that the hydration at 55°C corresponds to that with the addition of 10% $CaCl_2$.

Fig. 7 shows the accelerating action of calcium thiosulphate on the hydration of synthetic alite. The principal effect is a shifting of the peak of maximum heat liberation to an earlier age. Of course, an increase in the heat liberation during the first ten hours is larger than that of the case without calcium thiosulphate, however, the liberated heat is not increased as the addition of calcium thiosulphate increases. It seems a tendency in the accelerating action of calcium thiosulphate.

Although the accelerating action of calcium nitrate has not been observed in Fig. 4 and Tables 1 and 4, the hydration of alite is slightly accelerated as shown in Fig. 8. But, a shifting of the peak is less than that with $CaCl_2$ or CaS_2O_3, in spite of the increasing additions. Fig. 9 shows the effect of representative accelerators used in this experiment on the hydration of synthetic tricalcium silicate. The general order of effectiveness as accelerator is $Cl^- > S_2O_3^{--} > SO_4^{--} > NO_3^-$. But, only the order of the last two obtained in this experiment is contrary to that shown by Edwards and Angstadt (6).

pH of Liquid Phase of Paste Containing Accelerators

Libermann and Kireev (14) already stated that pH of liquid phase of portland cement is lowered when the accelerator was added. Table 8 shows the pH in liquid phase of portland cement paste immediately after the paste was prepared. Although the lowering of pH by the addition of possible accelerators is evidently observed, it is not always true that all the salts which lower the pH of liquid phase are accelerators.

Hydration Products of C_3S Paste Containing $CaCl_2$ CaS_2O_3 and $Ca(NO_3)_2$

Various phenomena in the hydration process are affected not only by the addition of accelerators, but also by the different morphologie and different physicochemical properties of the hydration products which were formed in the hydration process. Fig. 10 shows the DTA curves of the 7 hour hydration products of C_3S pastes containing such $CaCl_2$, $CaSO_4 \cdot 2H_2O$, CaS_2O_3 and $Ca(NO_3)_2$. The intensity of endothermic peaks near 100°C and 500°C shows approximately the rate of hydration. A shoulder of peak at 500°C indicates the presence of amorphous calcium hydroxide. The two endothermic peaks at temperature of over 900°C show the two inversions of C_3S, namely, triclinic $\xrightarrow{923°C}$ monoclinic $\xrightarrow{980°C}$ trigonal. The defference between $CaCl_2$ and CaS_2O_3 is apparently demonstrated by the continued two exothermic peaks occurred at a temperature range from 600°C to 700°C. The DTA and thermal balance curves of the 24 hour hydration products, which are shown in Fig. 11, indicate evidently the differences mentioned above. In the case of $CaCl_2$, since the exothermic peak at 650°C does not brings about any changes in weight,

it is seen as the heat evolution due to the crystallization of CSH. In the case of CaS_2O_3, the first heat evolution without the change in weight and the second heat evolution with some increments in weight are observed. Therefore, it is suggested that the second heat evolution shows the oxidation reaction of calcium sulphite as the decomposed compound of calcium thiosulphate. Assuming that the first heat evolution is due to the combustion of sulphur as the decomposed product of calcium thiosulphate, the weight loss in thermal balance curve should be observed naturally. But, it is not observed in Fig. 11. This reason is not yet clarified.

In general, it has been well known that the hydration products of C_3S or portland cement at room temperature are mainly CSH(I) and CSH(II), of which the occurrence is controlled by the lime concentrations of liquid phase. These CSH are poor in crystallinity at early stage of the hydration of C_3S or portland cement, therefore, it can be scarcely detected by X-ray diffraction. The X-ray diffraction patterns of the 100 day hydration products of C_3S paste showed CSH(II) when calcium chloride was added, did not evidently indicate either CSH(I) or (II) when calcium thiosulphate was added and showed CSH(I) when any additives were not added.

According to the fact that CSH(II) is converted by heating, the production of CSH(II) in the hydration of C_3S in the presence of calcium chloride has been confirmed by the formation of β–C_2S in the 24 hour hydration products by heating at 650°C. Kalousek (19) reported, using DTA, that synthetic CSH(II) is converted into β–C_2S by heating at temperature of over 900°C. The principal cause may be that, in the hydration products of C_3S, the large amounts of fine grain calcium hydroxide which are present near CSH(II) will promote the inversion to β–C_2S, however, in the case of synthetic CSH(II), any calcium hydroxide is not present near it.

One of the main characteristics of CSH is a large specific surface area. It has been suggested that the measurement of specific surface area of CSH will be an available method for detecting the effect of accelerators on the properties of CSH. Therefore, the specific surface area of CSH in the hydration products of C_3S produced in the presence of $CaCl_2$, CaS_2O_3 and $Ca(NO_3)_2$ were measured by following various methods; the measurement of specific surface area of the hydration products of C_3S by BET with water-vapor, the X-ray quantitative analysis of the remaining unhydrated C_3S in hydration products and the quantitative analysis of the produced calcium hydroxide by new Franke method (20).

Fig. 12–1 shows the change of specific surface area of CSH in the hydration products of C_3S. The CSH in the hydration products of C_3S hydrated in the presence of $CaCl_2$ has a considerable large surface area at earlier age, however, this high value of surface area reduces gradually in proportion to curing age and, consequently, it approaches to the value of CSH in the hydration products without any accelerators at later age. In the case of the addition of calcium thiosulphate, on the contrary, the surface area of CSH is small, but it increases with curing age as if it approaches to the value of CSH in the hydration products without any accelerators.

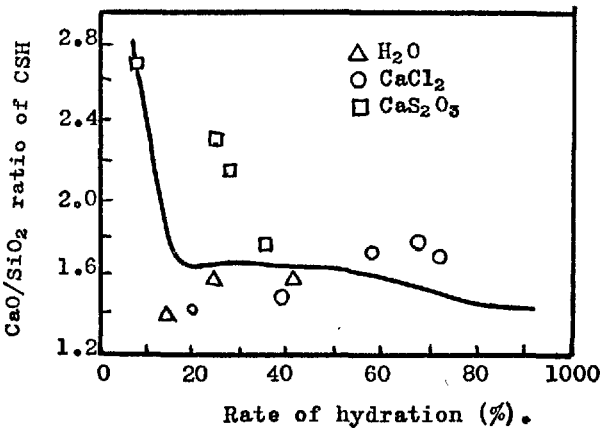

Fig. 12-2. CaO/SiO_2 *molar ratio of* CSH *in the 100 day hydration products of* C_3S *in the presence of various salts* Hydration temperature: 20°C, Solid curve: Kantro's result.

Fig. 12–2 shows CaO/SiO_2 ratio of CSH in the hydration products. Comparing with Kantro and others results (21), the CaO/SiO_2 ratio of CSH in low rate period of hydration is near 1.60 when any accelerators are not used, is 1.70 when calcium chloride is used and is 2.72 at 8% hydration when calcium thiosulphate is used. These values gradually approach to that of the case without any accelerators as the degree of hydration increases. The principal cause of the irregularity of CaO/SiO_2 ratio of CSH at early stage of the hydration may be explained by the hypothesis that CSH is produced from aq. solution in the state of non-equilibrium, in which the formation of CSH is initiated before the aq.solution is saturated with lime and silicate ions.

In another experiment, the CSH with CaO/SiO_2 ratio 0.8 was prepared, using CaO and SiO_2 gel, at 50°C for 7 hours in the presence of such various salts as calcium chloride, calcium thiosulphate and calcium nitrate. These specific surface areas showed an identical value; 328 m^2/g when any accelerators were not used, 339 m^2/g when calcium chloride was added and 323 m^2/g when calcium thiosulphate was added. From this result, it can be considered that the presence of accelerators in the hydration process of C_3S markedly affects the hydration process and the physicochemical properties of produced CSH, however, that the presence in the synthetic process of CSH is not closely related to the properties of resulted CSH.

Electron Microscopic Observation of the Hydration Products of C_3S

CSH, having a large specific surface area, is generally regarded as a gel-like substance, therefore, it can not be confirmed evidently by X-ray diffraction. The application of electron microscope is very significant to observe the morphologie of CSH.

Photo 1 shows the hydration products of C_3S pastes with H_2O/C_3S 0.5 at 35°C. In the C_3S–$CaSO_4 \cdot 2H_2O$ system, the fibrous hydration products are produced, but it does not markedly grow. In the C_3S–$CaCl_2$ system, the hydration products, regarding as calcium hydroxide from Grudemo's study (22), grow as if it likely forms the cross-linked net work. When gypsum was added to the system, the net work structure is progressively developed and, simultaneously, the cigarette type CSH which has been known as CSH(II) is produced.

The presence of CSH(II) in the hydration products of C_3S paste with calcium chloride not only was already confirmed by X-ray diffraction, but also is found by electron microscope. The considerable development of strength of portland cement by the

addition of calcium chloride may be caused by the co-operative effect of both the progress of hydration and the three dimensional development of net-work structure mentioned above. When calcium nitrate was added, the thin plate-like products are predominantly produced after 3 hours hydration. When calcium thiosulphate was used, the large amounts of the fibrous and hexagonal-plate like products are produced. Especially, only the latter is identified with calcium hydroxide. The relationship between the morphologie of these products and the strength development is not yet sufficiently studied.

Effect of Accelerators on the Hydration of C_3A

Figs. 13 and 14 show the X-ray diffraction patterns and the DTA curves of the hydration products of C_3A which hydrated in the presence of $CaCl_2$, CaS_2O_3 and $Ca(NO_3)_2$ Photo 2. is the electron micrographs of the hydration products. These results, which were obtained from the C_3A-Accelerator-H_2O system without gypsum, may not be appropriate for understanding the effects of accelerators on the hydration of portland cement. However, it will be useful as one of possible feature in the hydration of portland cement in the presence of accelerators.

A large and broad diffraction pattern in the range of from 5° of 2θ to 10°, when calcium chloride and calcium thiosulphate were added, is observed in the hydration products after 10 minutes hydration. This diffraction pattern probably demonstrates that many kinds of hydration products, which are small in quan-

tity and poor in crystallinity, with the lattice constants corresponding to the above diffracted range are produced. On the other hand, when calcium nitrate was added, the two relatively sharp diffractions at 8°–9° and 10° of 2θ are observed. Such diffractions are not observed evidently in the hydration products with calcium chloride and calcium thiosulphate. In the DTA curves, a few of endothermic peak are observed near 100°C, 200°C and 300°C. Above all, the endothermic peak at 300°C is most sharp when calcium nitrate was added. Furthermore, Photo 2 shows that the gel-like hydrates are product in plenty when calcium chloride and calcium thiosulphate were added, on the contrary, that the polygonal small particles and plate-like hydrates are markedly produced when calcium nitrate was added.

All the X-ray diffraction lines of the hydration products after 2 hour hydration are considerably developed. Both the diffraction lines with calcium nitrate at 8°–9° and 10° of 2θ are most sharply strengthened. Also, all the endothermic peaks in DTA curves are remarkably developed. The two endothermic peaks near 100°C and 200°C which likely belongs to an identical hydration product are more strengthened together in the hydration products after 2 hour hydration than that after 10 minute hydration.

The electron micrographs of the hydration products show an unchangeable feature also at 2 hour hydration as well as at 10 minute hydration, when calcium chloride and calcium thiosulphate were added. Only in the case of calcium nitrate, the different products from the two formers are observed.

It has been already reported, by Heller and Ben—Yair (23), that a synthetic $C_3A \cdot CaCl_2 \cdot XH_2O$ as the complex salt between C_3A and $CaCl_2$ shows the basal spacing at 7.9 Å of d and has a sharp endothermic peak at 215°C and four kinds of weak endothermic peaks at 110°C, 256°C, 330°C and 550°C. The X-ray diffraction patterns of the hydration products at the two curing ages show the diffraction lines indicating that the product corresponded to calcium chloroaluminate by Heller and Ben-Yair(23). Simultaneously, the formation of $C_3A \cdot Ca(OH)_2 \cdot 18H_2O$ and $C_2A \cdot 8H_2O$ is also observed, therefore, it is suggested that the formation of solid solution between $C_3A \cdot CaCl_2 \cdot XH_2O$ and $C_3A \cdot Ca(OH)_2 \cdot XH_2O$ are likely possible. In the cases of calcium thiosulphate and calcium nitrate, although the detailed information about the complex salts containing $S_2O_3^{--}$ and NO_3^- has not been reported, the products substituting these anions for some portions of OH^- in the structure of $C_3A \cdot Ca(OH)_2 \cdot XH_2O$ may be produced.

In the cases of calcium chloride and calcium thiosulphate, it is thought that the endothermic peaks at 100°C and 280°C in DTA curves show the dehydration of $C_2A \cdot 8H_2O$ and that the endothermic peaks at 200°C and 300°C show the dehydration either of $C_3A \cdot Ca(OH)_2 \cdot XH_2O$ or of products substituting Cl^- or $S_2O_3^{--}$ for OH^- in the structure. The formation of $C_3A \cdot 6H_2O$ is not detected by X-ray diffraction. The polygonal small particles in the hydration products of C_3A which hydrated in the presence of calcium nitrate are confirmed as $C_3A \cdot 6H_2O$ by X-ray diffraction, therefore, the endothermic peak at 300°C in DTA curve shows the dehydration of $C_3A \cdot 6H_2O$.

When the weak accelerating action of calcium nitrate is connected with the fact that the hydration reaction of C_3A with calcium nitrate is very different from that with calcium chloride or calcium thiosulphate, it should be naturally considered that, for understanding the accelerating action on the hydration of portland cement, the effect of accelerators on the hydration of C_3A must be studied together with that on the hydration of C_3S.

Conclusion

Although calcium chloride is being used as an excellent accelerator on the hydration of portland cement, the corrosive action of Cl^-, remaining in concrete, to steel is considerable and can be scarcely avoided. It will be most favorable if an appropriate accelerator without corrosive character is found and used.

The accelerating action of calcium thiosulphate studied in the present paper is slightly lower than that of calcium chloride. However, it seems that calcium thiosulphate is available as an accelerator without the corrosive character to the steel in reinforced concrete.

The accelerating action of calcium thiosulphate increases in proportion to the amount of addition to cement. However, the effect on the strength development of mortar is not available beyond the three day age. The use of a large amount of accelerator will cost one dear.

When calcium thiosulphate is added to portland blast furnace slag cement which consists of, for example, the granulated blast furnace slag 65 % and portland cement 35 %, the accelerating action is predominantly given for the hydration of portland cement. Therefore, if the same quantity of calcium thiosulphate is

respectively added to the two cements, the hydration of portland cement in the blast furnace slag cement will be doubly affected by the calcium thiosulphate. The initial strength development, comparing with that of the blast furnace slag cement without calcium thiosulphate, is considerably promoted.

Besides, since the slag hydrates independently of whether the accelerators are present or not, namely, the hydration mechanism of the slag greatly differs from that of portland cement, the high strength development at later stage can be kept, without any fall in the strength development, by the hydration of slag.

Supplementary Paper II-4 Significance of Total and Water Soluble Alkali Contents of Cement

Walter J. McCoy and Ottomar L. Eshenour*

Synopsis

The portion of the alkalis in the clinker that are water soluble depends on the form the alkalis are in, which in turn depends on the chemical composition of the raw mix and the conditions during the burning operation. It was found that the amount of the alkalis that are water soluble can vary from less than 10% to over 60% of the total alkali content. In some cases a better correlation was obtained between the soluble alkali content and the amount of alkali-aggregate expansion than between the total alkali content and the amount of expansion. Soluble alkalis were found to have a significant effect on the rate of hydration but not on the pH of the aqueous extract from cement pastes. Even after hydration at room temperature for 1 year a considerable portion of the alkalis in cement may not be water soluble.

Introduction

The subject of alkalis, namely, sodium oxide (Na_2O) and potassium oxide (K_2O) in cement and the various aspects of the alkali-aggregate reaction has been the subject of numerous papers and symposia during the past 25 years. The interest in alkalis and the concern with the alkali-aggregate problem has steadily increased since 1940 when P. H. Bates, Chief, Clay & Silicate Production, National Bureau of Standards (and Chairman ASTM Committee C-1 on Cement), invited cement company representatives to attend a conference at the Bureau where they were advised of the findings of T. E. Stanton (1**) that excessive expansion of concrete could be caused by chemical actions between cements of relatively high alkali content and certain aggregates. Since that time most of the investigations concerning alkalis in cement have been in connection with the alkali-aggregate reaction. Practically all of these studies refer to the total alkali content, and this is especially true of the many investigations of the relationship between alkali content and the amount of expansion. Alkali specifications for cement are based on total alkali content calculated as Na_2O equivalent. Test data have been obtained which indicate that in some cases there is a better correlation between the soluble alkali content and the amount of expansion than between the total alkali content and the amount of expansion. To complicate the situation, tests on a large number of various cements have shown that the amount of alkalis that are water soluble within the first hour of hydration can vary from 10 to 60% of the total alkali content.

Since the findings of our study includes other important aspects of the alkali content of cement besides that associated with the alkaliaggregate reaction, it seems appropriate to review some background information regarding the alkali component of cement.

Background

Alkalis, namely, Na_2O and K_2O occur in varying amounts in cement raw materials, and coal ash with the natural silicate or clay mineral components of the raw mix usually being the principal sources. In the burning of the clinker a portion of the alkali is volatilized when the natural alkali containing silicates react with the lime in or near the clinkering zone in the kiln. The amount of the alkalis volatilized can depend on a number of factors such as:

(a) Whether alkalis are present principally as potassium or sodium compounds since a survey of 73 cement plants showed that on the average

*Lehigh Portland Cement Co., Allentown, Pennsylvania, U.S.A.

**The numbers in brackets refer to list of references appended to this paper.

no Na_2O is volatilized until about 30% of the K_2O is volatilized, and above the 30% mark the additional volatilization of the K_2O will be 50% greater than the amount of Na_2O that is volatilized (2).

(b) Temperature of burning zone in the kiln which in turn is somewhat limited by the composition of the raw mix.

(c) The amount of sulfur compounds in the raw mix or fuel since sulfate in the clinker and SO_3 in the combustion gases tend to retain the alkalis.

(d) With other conditions being similar, higher alkali volatilization is obtained with gas and with oil than with coal as a fuel (3).

(e) Chloride, if added to the kiln feed, is effective in volatilizing K_2O.

If we had to pick a figure for the average amount of alkali volatilized during the burning operation, it would be of the order of 40–50% of that present in the kiln feed. If stack dust is collected and returned to the kiln, the amount volatilized could be significantly less.

Alkali Compounds in Portland Cement Clinker

The alkalis in portland cement clinker occur in many different forms depending upon the composition of the kiln feed, conditions of burning and rate of cooling (4). In most cases the alkalis combine with the available SO_3 during the burning operation to form an alkali phase that contains both K_2O and Na_2O with the K_2O predominating. The amount of sulfate present is usually sufficient to combine with only part of the alkalis and the remaining portion is combined with the aluminates and silicates with Na_2O principally in the aluminates and the K_2O in the silicates. According to Kryzhanovskaya and Mirakyan (5), the principal compounds formed in this case are NC_8A_3 which is a solid solution of Na_2O in C_3A and $KC_{23}S_{12}$ which represents a solid solution of K_2O in C_2S. $KC_{23}S_{12}$ which is formed by this reaction of K_2O and C_2S is a stable compound, and is not converted to C_3S during the burning operation even in the presence of excessive free lime. It is possible for a clinker with less than 1% K_2O to have all the potential C_2S in the form of $KC_{23}S_{12}$. If there is more than enough K_2O to convert all the C_2S to $KC_{23}S_{12}$, then some of the C_3S in the clinker may be decomposed by the K_2O to form additional amounts of $KC_{23}S_{12}$ and free lime. Burnability test data in a paper by Yu M. Butt, V. V. Myshlyaeva and T. A. Osokina (6) clearly show that the presence of alkalis in the raw mix slows down the clinkering reactions.

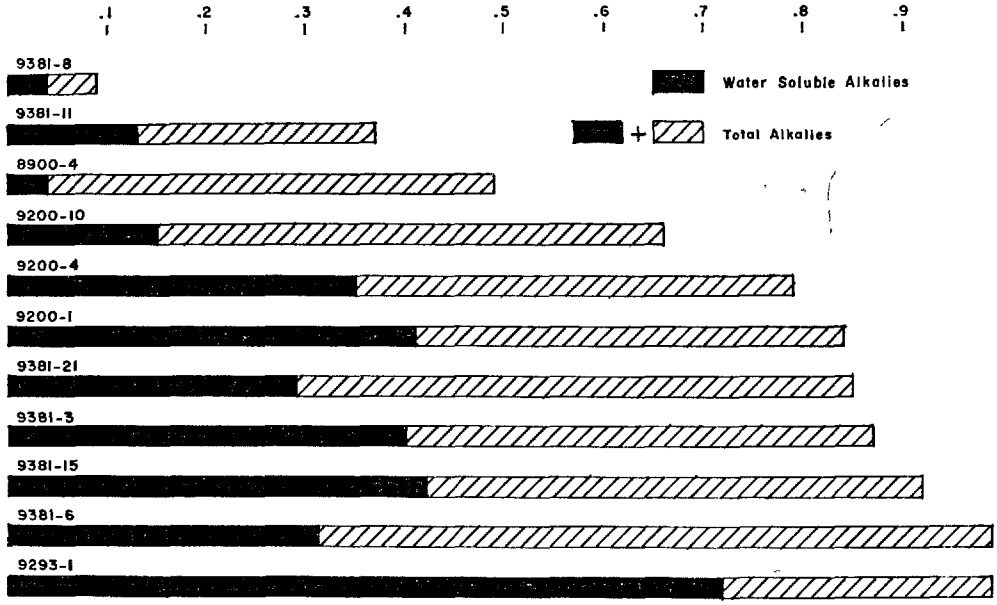

Fig. 1. *% total alkalies vs. % water soluble alkalies—Type I cements*

When cement is mixed with water, the alkali sulfates dissolve immediately, and the concentration of K_2O in solution is usually greater than Na_2O at very early ages. The Na_2O phases tend to dissolve more rapidly than the other K_2O phases since the aluminates hydrate more rapidly than the silicates. In view of the foregoing, the portion of the alkalis that are water soluble after any given period of hydration can vary considerably depending on the clinker. This variation in the portion of the alkalis that are water soluble is illustrated by Figs. 1, 2 and 3 which show both the total and water soluble alkali contents for a number of Type I, II and III cements respectively. The total and water soluble alkalis were determined by

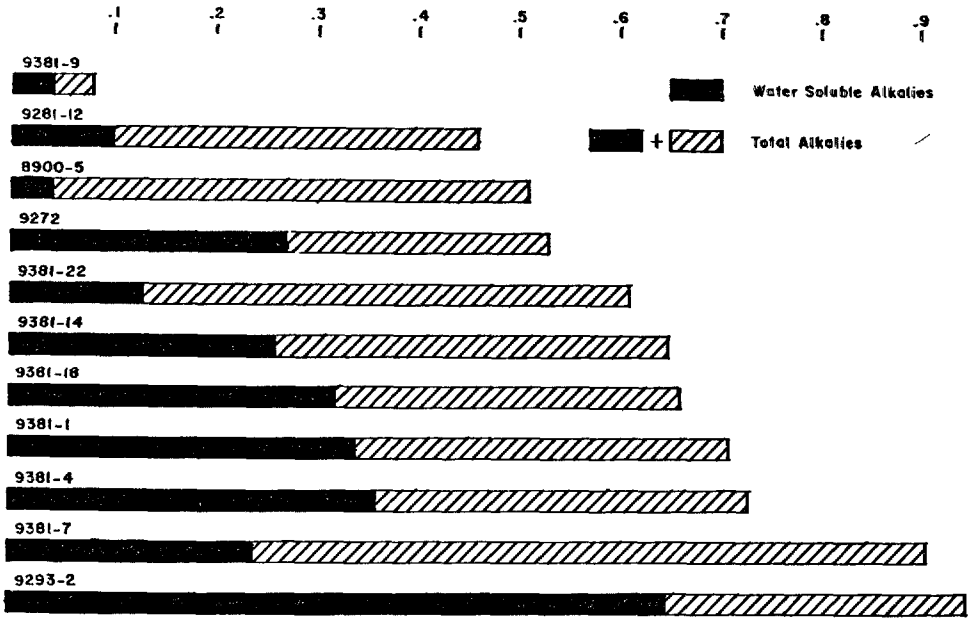

Fig. 2. *% total alkalies vs. % water soluble alkalies— Type II cements*

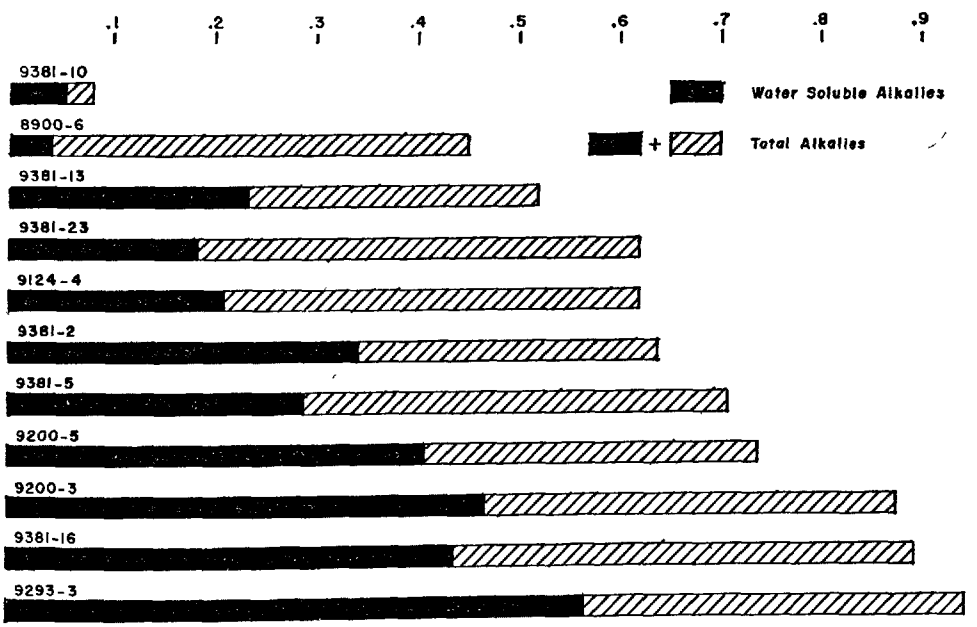

Fig. 3. *% total alkalies vs. water soluble alkalies— Type III cements*

ASTM Method C 114–65. Figs. 1–3 illustrate that the amount of alkali in a cement that is water soluble varies from less than 10% to over 60% of the total alkali present.

A high water soluble K_2O content as determined by ASTM Method C 114–65 will frequently indicate that the cement clinker contained appreciable quantities of K_2SO_4 in which case it would not be unusual for the cement to have satisfactory or high strengths at 1 and 3 days but a relatively poor strength gain between 3 and 28 days. This is illustrated by the ASTM Method C 109 mortar cube strengths given in Table 1 which were obtained for the cement with the highest and lowest soluble K_2O as illustrated in Fig. 1. These two Type I cements had similar potential C_3S, C_3A and fineness characteristics.

Alkalis in cement are usually thought of as serving no useful purpose, and the lower the amount of alkali the better. To obtain information on this subject, we prepared some portland cement clinker in the laboratory that contained no alkalis, and compared the strength characteristic of portland cement from that clinker with a cement prepared from similar clinker except for a nominal amount of alkalis. These two clinkers were prepared from a lot of commercially burned Type I clinker which was divided into two portions. One lot was reburned in a laboratory kiln with no additions, and had an alkali content of .57% Na_2O equivalent most of which was potassium. The other portion was similarly reburned except for a quantity of ammonium chloride (NH_4Cl) which was added to effect a volatilization of the alkali during the reburning, and this reburned clinker had no alkali. NH_4Cl was used to remove the alkali since all this material would be volatilized, along with the alkali, so that the only change in the chemical composition of the clinker was the loss of the alkali.

Both clinkers were ground with gypsum to the same fineness and ASTM C 109 mortar cubes were fabricated from each of the two cements, and the compressive strength determined at 1, 3, 7 and 28 days. A similar set of mortar cubes was also made with the zero alkali cement to which potassium hydroxide (KOH) was added equivalent to .4% Na_2O on the basis of the cement content. These data as given in Table 2 indicate that the alkali component has an appreciable beneficial effect on the early strength development. Further tests showed that small additional quantities of alkali in excess of the .4% had no significant effect on early strength development unless they were added in another form such as carbonate, sulfate or chloride which is an entirely different situation because of the effect of the anion.

A series of tests was made to determine what effect the quantity of alkali in a cement would have on the pH of an aqueous extract from a cement paste after 1/2 hr. hydration with water-cement ratios of 0.5 and 2.0 and after 24 hr. with a water-cement ratio of 2.0. In the 24 hr. test series the samples were continuously agitated. The data obtained are given in Table 3, and show that the quantity of alkali has very little effect on the pH of the aqueous phase. The extracts of the cements which had alkali contents ranging from .03% to 1.19% Na_2O equivalent all had a pH in the range of 12.3 to 12.7 even after the 24 hr. extraction period.

Studies of the significance of total and water soluble alkali with regard to the amount of expansion obtained with reactive aggregates in ASTM C 227 mortar bar tests have not shown a uniform relationship. In some cases such as with Bishop and Saticoy sands from

California, the amount of expansion correlated better with the total alkali content than with the amount of soluble alkali. However, this was not true in the tests with reactive dolomite obtained by H. H. Newlon and W. C. Sherwood (7) who have pointed out that certain types of carbonate rock are alkali reactive, and that the reaction differs from the well known alkali-silica type. Mortar bar tests with a reactive sand from Watertown, South Dakota described in U. S. Army Engineer Waterways Experiment Station Paper No. 6-530 (8) shows better correlation between the amount of expansion and the soluble alkali content than with the total alkali content. Both the reactive dolomite and the Watertown sand were tested for expansion characteristics by ASTM C 227 mortar bar procedure with three portland cements which had the same total alkali content and soluble alkali contents of .48%, .32% and .14% respectively. The expansion data are given in Table 4.

Some additional C 227 expansion tests were made with the reactive dolomite and three portland cements which had the same approximate soluble alkali content but different total alkali contents. A similar series of tests were made on a sample of Republican River aggregate. The results obtained on this series of tests which are given in Table 5 also show a better correlation between the amount of expansion and the soluble alkali content than with the total alkali content.

J. L. Gilliland and T. R. Bartley (9) have pointed out that "water-soluble alkali" in portland cement is a relative quantity, which depends upon the length of time that the cement has hydrated as well as the testing technique. He reported that for cements hydrating at 100°F substantially all of the alkalis are rendered water-soluble within 90 days, sodium becoming soluble somewhat faster than potassium does. Apparently Gilliland used a high water cement ratio in making up the specimens used in his tests since he explains the procedure as follows: "Ten grams of cement are placed in a small vial. The vial is filled with distilled water and the mixture thoroughly stirred. The vial is then sealed and stored in an over at 100°F."

Tests were made on a series of neat cement bars similar to those used in ASTM Method C 151 to determine what effect hydration of cement with a "normal consistency" water-cement ratio at 23°C (73.4°F) would have on increasing the relative amount of alkalis in a cement that are water soluble. The specimens were stored in a moist closet with a relative humidity in excess of 90 percent. After storage, the hydrated bars were crushed, dried and ground to the same approximate fineness as the cement was originally. The soluble alkalis were determined on the finely ground hydrated samples with appropriate corrections being made for the water of hydration. The results are given in Table 6 and clearly show that, even after hydration for one year under the condition described, a considerable portion of the alkalis are still insoluble in water.

Table 4. *Expansion of ASTM C 227 mortar bars; Water soluble Vs. total alkali*

% of alkali, water soluble	64	46	60

Conclusions

1. The presence of alkalis in the raw mix can slow down the clinkering reactions.

2. The amount of alkali in a cement that is water soluble can vary from less than 10% to over 60% of the total alkali present.

3. A relatively high water soluble K_2O content frequently indicates the cement clinker contained appreciable quantities of K_2SO_4 in which case a relatively poor strength gain is sometimes obtained between 3 and 28 days.

4. If a cement has no alkali the early strength can be abnormally low.

5. The amount of total or water soluble alkali in a cement has very little effect on the pH of the aqueous extract from cement pastes.

6. With some reactive aggregates a better correlation was obtained between the amount of expansion and the soluble alkali content than with the total alkali content.

7. Even after hydration at room temperature for 1 year, a considerable portion of the alkalis in cement may not be water soluble.

Oral Discussion

Arthur W. Brown

I would comment that with respect to soluble alkali sulphates, the results in Table 6 would plot well on Fig. 3 of our paper on "The distribution of alkalis in portland cement clinker". However our work shows that the idea of the soda not as sulphate migrating to C_3A and the potash not as sulphate going preferentially to C_2S is an oversimplification. It also suggests that the restriction of combination by the stabilisation of belite with potash is not generally as serious a risk as the paper appears to suggest, although that it does occur as a real problem is illustrated by photo 5 from our paper which shows alkali stabilized belite coexisting in contact with free lime and demonstrating this restriction of combination. Finally I would like to take this opportunity of congratulating the authors, more especially for illustrating the importance of the nature of the alkalis as distinct from their quantity in the context of alkali-aggregate reactions.

Oral Discussion

Heinz G. Smolczyk

Concerning the very interesting paper II-4 of W. J. McCoy and O. L. Eshenour, I want to make a contribution to a widely interesting problem:

The authors found that in most of the cases not the amount of total alkali but the amount of water

soluble alkali shows the better relation to the expansion through alkali-aggregate reaction. This better relation is confirmed even more clearly if not only portland cements but also other types of cement e.g. pozzolanic cements and blastfurnace slag cements are included in this kind of studies. These cements often have a higher content of total alkali but only a very small amount of water soluble alkali.

This is one reason for the wellknown favourable effect of blastfurnace slag or pozzolanas on the elimination of alkali reaction which is also mentioned once again by O. Valenta in his Principal Paper III-2 "*Durability of Concrete*". And this is a very serious point for all countries with a greater amount of mixed cements because the wellknown American recommendation of 0.6% total alkali is based on tests with portland cements only.

As we have been asked about this problem, sometimes even in Germany, we were forced to develop an approximate but safe formula which takes into consideration the amount of granulated slag. On the basis of leaching experiments with well-hydrated and afterwards finely ground cement mortars we got the following safe alkali limit for slag cements:

$$\text{Alkali } \% \cong 0.60 + 0.075 \text{ slag } \%$$

Soon after we had found this (April 1967) we received the results of the very precise studies of P. Klieger and A. W. Isberner (PCA) on this same problem. A graphical comparison of their expansion-test values with our approximate formula proved a nearly complete accordance (*see Fig. 1*).

On account of all the wellknown experiences and the new facts I think it would be a good idea to extend the American recommendation of 0.6% total alkali to a more characteristic limit, which should take into consideration the far more characteristic amount of water soluble alkali or the special composition of the cement, and which then would possibly be valid for all the other types of cements, too.

We are working hard on this problem and we will be grateful for any help or advice of the colleagues with special experience in this difficult field.

Supplementary Paper II-22 The Influence of Lead and Zinc Compounds on the Hydration of Portland Cement

Werner Lieber*

Synopsis

Small amounts of lead oxide PbO and zinc oxide ZnO of less than 0.1 % cause a retardation of the setting time of portland cement. Equivalent other simple lead and zinc compounds show the same influence. The retardation effect of definite amounts of the retarding agents depends on the specific surface area and on the C_3S content of a cement. PbO and ZnO have an influence on the C_3S only, which will be retarded. The strengths of cements will be increased after 28 days by these admixtures.

X-ray diffraction studies revealed that the portland cements do not hydrate and that no $Ca(OH)_2$ is formed during the retardation period, while the initial reaction of the aluminate and ferrite phases with the gypsum takes place as usual.

During the retardation period another zinc compound, calcium-trihydroxo-aquozincate, $Ca[Zn(OH)_3H_2O]_2$, is formed.

Adding the complex zincate instead of simple zinc compounds to a cement, the retardation period will be very short, but even the early strengths after one day will be increased up to 20% and more. The formation of the silicate hydrates tends into the range of fibrous phases.

Introduction

Thirty years ago L. Forsén (1) reported on the effect of admixtures on ground portland cement clinker. A certain group of admixtures was defined by him as "cement destroying", as they may considerably reduce the strength of the cement clinker and even prevent its hardening.

To this group belong, for instance, lead and zinc compounds. Even small quantities of less than 0.1% of lead oxide or zinc oxide retard the setting time by many hours. Other authors (2, 3), too, reported on the retarding effect of lead and zinc compounds.

This paper describes the influence of lead and zinc compounds on the setting and hardening of portland cement.

The Effect of Lead Compounds

Among the oxides PbO, PbO_2, Pb_3O_4 and the hydroxide $Pb(OH)_2$, the PbO_2 is practically inert, while the Pb_3O_4 has a rather insignificant retarding effect. The lead (II)oxide and the lead hydroxide retard the setting and hardening of portland cements very much. Equivalent quantities show approximately the same effect. Water soluble lead salts, for instance, lead nitrate, have practically the same strong retarding effect, because in the cement paste the formation of lead hydroxide takes place immediately.

The experiments described here, therefore, deal exclusively with the action of PbO.

Setting Time

The determination of the setting time, according to Vicat, leads to less exact results particularly when the setting is very much retarded. A more exact method is the measurement of the temperature evolution of cement pastes in relation to time. For that purpose resistance thermometers are imbedded into pastes of 500 grams of cement and 175 grams of water. The temperature is registered continuously. The initial

*Portland-Zementwerke Heidelberg A. G., Heidelberg, West Germany.

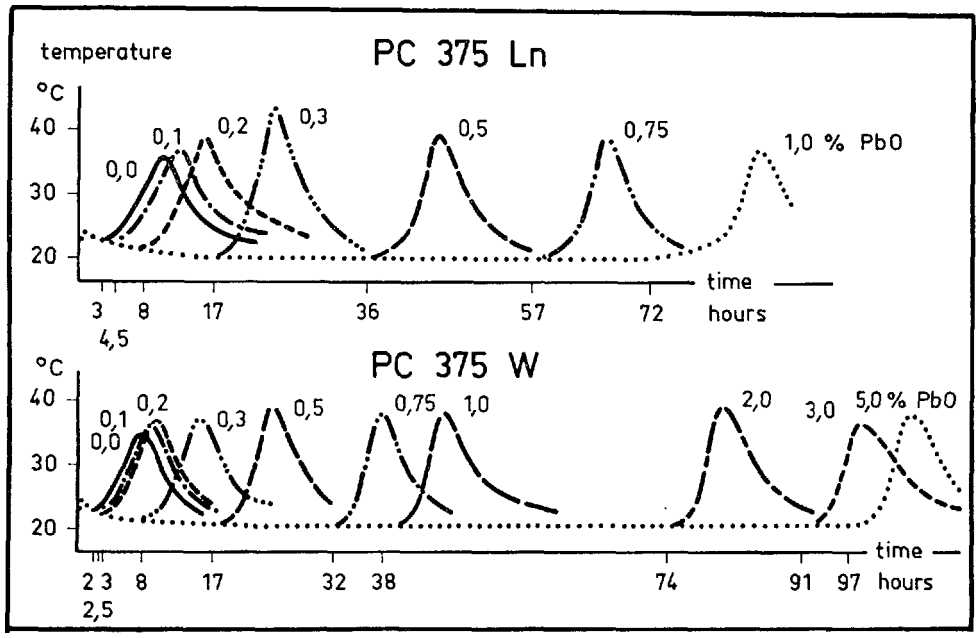

Fig. 1. *Set-retarding effect of lead oxide, represented by the temperature evolution of pure cement pastes (w/c = 0.35)*

set starts at approximately the same time as the marked rise in temperature.

Fig. 1 shows the time-temperature curves of cement pastes with lead oxide. It can be seen that equal quantities of PbO cause, in different cements, different retardations. It can also be observed, however, that the retarded cements–even after an interval of 100 hours–continue to show completely normal reactions as soon as the retardation period has been finished. There was no loss of quality. In many cases it can even be observed that the maximum temperature rises with PbO, which indicates a more intensive reaction as compared with the blank test. Fig. 2 shows the initial setting time as a function of the lead oxide content.

When cements of different degrees of fineness are ground from the same kind of clinker and the action of lead oxide on them is studied, it results that the retardation period is inversely proportional to the specific surface area of the cements (Fig. 3).

Strength

The path of the time-temperature curves permitted the conclusion that the cements are in no way damaged by means of lead oxide, but when the retardation period has been finished, they harden as well as cements not containing lead oxide and attain even better final strengths.

Specific Influence

W. Koenne (3) has reported that gypsum slag cement is not retarded by PbO. As a result of experiments carried out in our laboratories, it has been found that all types of portland cement and all slag containing cements are retarded by PbO, and that, however, the specific surface is not the exclusive criterion for the intensity of the retardation. From systematic research with pure phases of clinker prepared in the laboratory it resulted that the PbO has exclusively an influence on C_3S. The other phases of clinker, C_2S, C_3A and C_4AF are not retarded.

By means of X-ray diffraction studies with pastes consisting of C_3S with and without PbO, it could be demonstrated that no formation of calcium hydroxide takes place during the retardation period which may last for many hours or even several days, depending on the quantity of PbO. Thermogravimetric studies

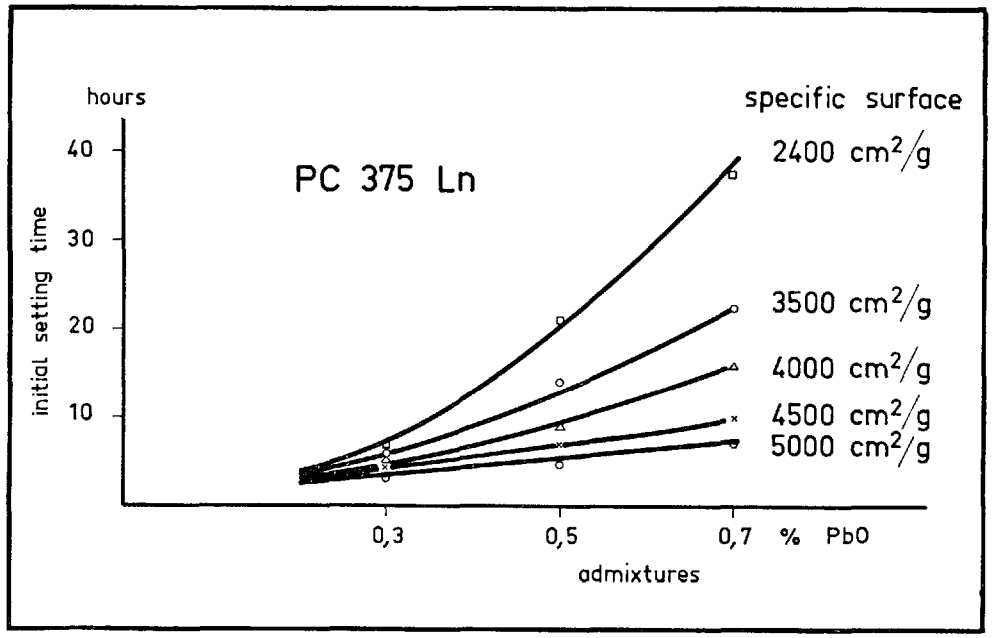

Fig. 3. *Relation between initial setting time, lead oxide admixture and specific surface*

showed that practically no water is bound. Immediately after the termination of the retardation period, however, a very rapid hydration and hydrolysis of C_3S takes place.

It seems that a cement retarded by lead oxide shows no reaction at all during the retardation period. It is true, however, that the typical reaction between gypsum and aluminates and ferrites in the first minutes after mixing a cement with water is not delayed.

The amount of water-soluble sulfate, still unbound

and consequently extractible, which is present in an unretarded cement normally decreases, within the first hour, from approximately 3% to about 1.5%. The sulfate is then bound rather slowly and decreases continuously and, after a period of 24 hours, water-soluble sulfate is no longer detectable. The first period of rapid sulfate binding to form the ettringite is not delayed by lead oxide, respective retardation concerns exclusively the subsequent binding process. As soon as the retardation period has been finished, the concentration of the water-soluble sulfate decreases rapidly (Fig. 13).

At present no satisfactory explanation of the surprising effect of PbO exists. There will be no doubt as to a blocking up of the surface of C_3S. The relation between retardation time end specific surface area is rather apparent. It is still unclear, however, which factor causes the hydration to start. The initial period of the hydration is accompanied by a simultaneous marked decrease in intensity of the X-ray interferences of the PbO which finally disappear completely. On the other hand, no new peaks from any lead compound can be detected.

The Effect of Zinc Compounds

Several authors, including H. Kühl (2, 4), W. Koenne (3), F. Keil (5) and F. Spalovsky (6) reported on the retarding effect of simple zinc compounds, particularly of zinc oxide. Some of these authors stated that zinc compounds would "destroy" the cement.

Several experiments have shown (7) that the effects of zinc oxide are practically the same as those of lead oxide. Equivalent quantities of other simple zinc compounds as, for instance, $Zn(OH)_2$, $Zn(NO_3)_2$, $ZnSO_4$ etc. have the same effect as ZnO itself.

The Effect of ZnO

It can be seen from Fig. 4 that small quantities of ZnO have a marked retarding effect on the setting process, without causing any damage to the cement. Equal quantities of ZnO cause retardation periods of different duration in different cements (Fig. 5).

Experiments carried out with pure clinker phases which have been prepared in the laboratory showed that ZnO has a specific retarding influence only on the C_3S. The retarding action of a defined quantity of ZnO is inversely proportional to the fineness and the C_3S content of the cements. The early strengths of the cements are, of course, in many cases, reduced by the retarding action of the ZnO; however, equal strengths can be observed after seven days, and after 28 days great strengths are principally attained as compared with cements which do not contain ZnO.

Reactions during the Retarding Period

Numerous experiments with pure C_3S and different portland cements show that practically no hydration and hydrolysis of the C_3S takes place during the retarding period. The characteristic reaction of the sulfate with the aluminates and ferrites which takes place during the first minutes after mixing the cement with water is, however, not delayed by zinc oxide which acts only on the subsequent binding of the sulfate (Fig. 13).

X-ray diffraction studies have shown that during the retardation period practically no formation of calcium hydroxide takes place. The intensity of the ZnO reflexes decreased continuously, whereas the characteristic lines (Fig. 7) of a calcium-hydroxo-zincate appeared which will be described later. The ZnO was completely transformed into the complex zincate, and then a very rapid hydrolysis of the C_3S and the formation of $Ca(OH)_2$ could be observed. Simultaneously the zincate also disappeared.

Formation of Calcium-Hydroxo-Zincate

It is known that, due to their amphoteric character, zinc oxide and zinc hydroxide have the tendency to form alkali zincates. Also a calcium-hydroxo-zincate has long since been known (8, 9, 10), but it became known as such only some 30 years ago. Its formula is $Ca[Zn(OH)_3H_2O]_2$. The zincate contains 18.1% CaO, 52.7% ZnO and 29.2% H_2O.

Notwithstanding its low solubility, the formation of this compound takes place within a few hours, for instance, by precipitation of zinc salts with a solution of calcium hydroxide or by a reaction of an alkali zincate solution with calcium hydroxide. Fig. 6 shows some crystals of calcium zincate. Fig. 7 shows the X-ray diffraction diagram of the compound.

By means of X-ray diffraction studies it has been possible to demonstrate that the synthetically pro-

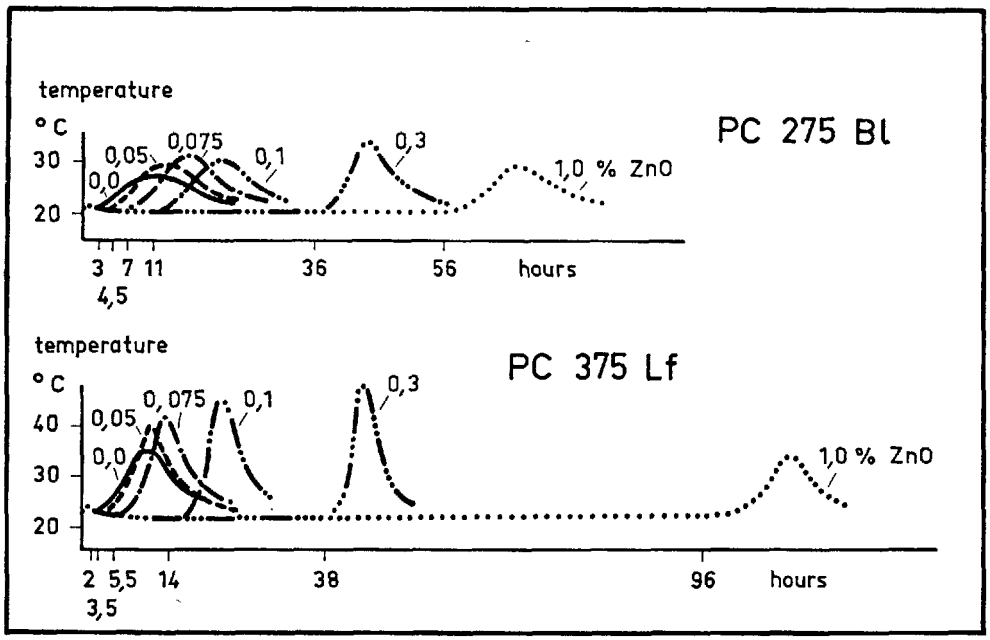

Fig. 4. *Set-retarding effect of zinc oxide, represented by the temperature evolution of pure cement pastes*

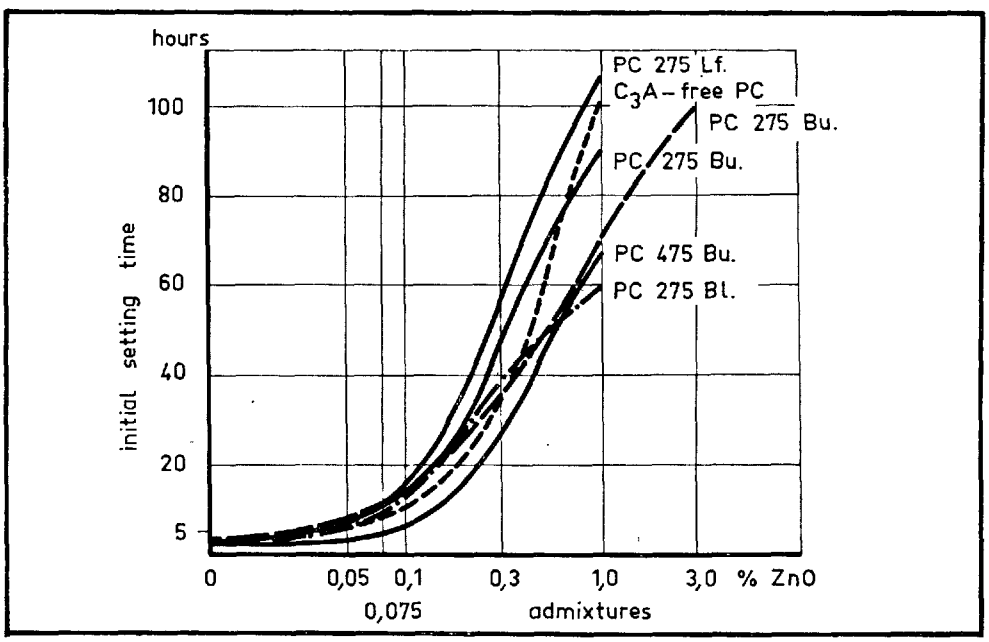

Fig. 5. *Initial setting time of pure cement pastes with zinc oxide* ($w/c = 0.35$)

duced calcium-hydroxo-zincate is identical with the zincate which is formed in pastes of C_3S or portland cement with ZnO. Consequently, the formation takes place without difficulty according to the equation:

$$2ZnO + Ca(OH)_2 + 4H_2O \rightarrow Ca[Zn(OH)_3H_2O]_2$$

Reactions of C_3S Pastes Containing Calcium Zincate

Tests carried out with zinc oxide showed that the formation of calcium-hydroxo-zincate takes place

during the very long retardation period, and that the hydration starts at about the same time when the zincate begins to disappear. Due to this fact, experiments were made in order to study the reactions taking place when calcium zincate instead of ZnO is mixed to the C_3S. For that purpose pastes were prepared of pure C_3S with and without 2% calcium zincate and tightly closed up in glass tubes. The heat of hydration, the loss on ignition and the formation of $Ca(OH)_2$ has been determined at different time intervals.

Figs. 8 and 9 show that 2% zincate (which are equivalent to 1% ZnO) cause only a very slight retardation of the hydration and the hydrolysis of the C_3S.

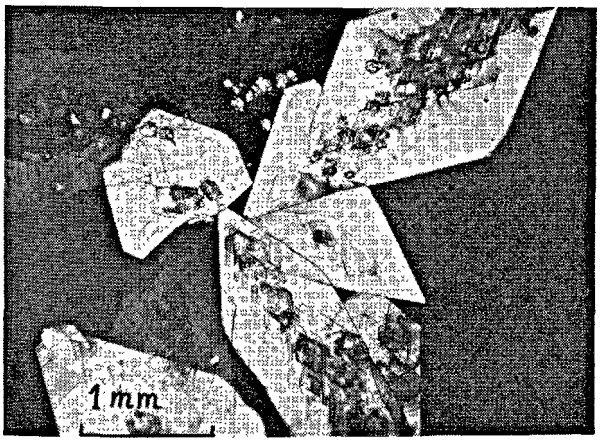

Fig. 6. *Calciumtrihydroxo-aquo-zincate crystals. Crossed nicols*

X-ray diffraction studies in several test series with different contents of zincate showed that during the short retardation period the intensity of the calcium zincate is reduced by leaps and bounds. Only then the hydrolysis of C_3S and the formation of $Ca(OH)_2$ begins. The zincate is no longer detectable by X-ray diffraction.

When C_3S reacts in an aqueous suspension with a small quantity of calcium zincate, intensive corrosion (see Fig. 10) can be observed as soon as 24 hours later on the originally sharp developed zincate crystals. Most of the small crystals disappeared after 3 days, while the big crystals showed corrosion phenomena particularly on sharp-developed corners and edges. In spite of its remarkable low solubility, the zincate does react. It is supposed that during this process an even more stable compound is formed. But, as there is no new zinc compound detectable, the zinc must have been entered the crystal lattice of the calcium silicate hydrates.

Influence of Calcium Zincate on Portland Cement

According to the described results, it was to be supposed that also mortars made from portland cements will be only slightly retarded by calcium zincate, and that, however, the strength could be in-

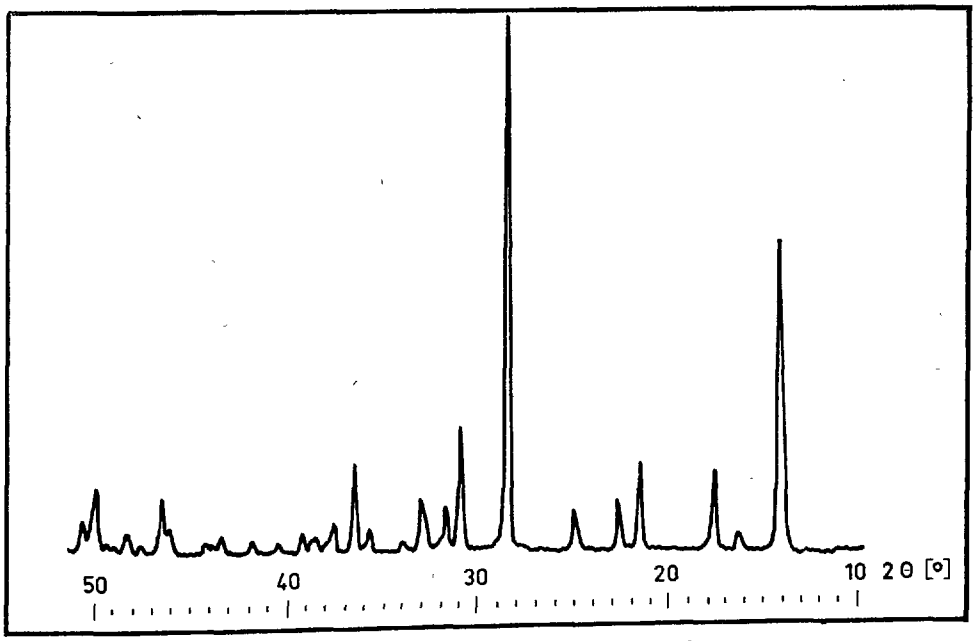

Fig. 7. *X-ray diffraction pattern of calciumtrihydroxo-aquo-zincate* Cu k_α

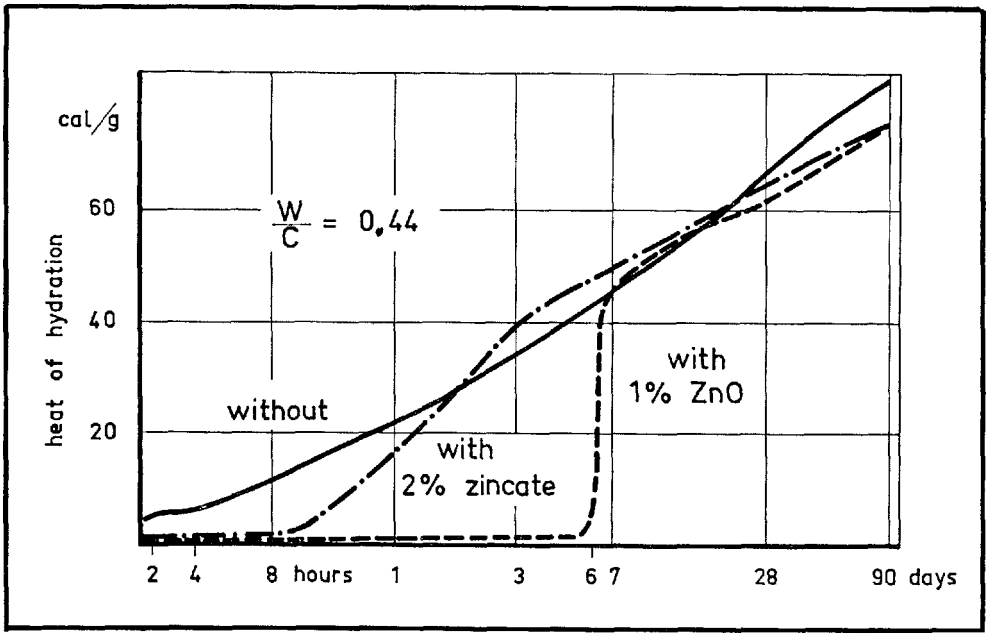

Fig. 9. *Heat of hydration of* C_3S, *containing zinc compounds*

creased. Fig. 11 shows some time-temperature curves of hydrating pure cement pastes with and without calcium zincate.

It results that the retardation period in the presence of calcium zincate is extremely shorter than with an equivalent quantity of ZnO.

Fig. 12 shows that for any cement a definite optimal quantity of calcium zincate admixture can be determined. This optimal quantity depends substantially on the specific surface area and the C_3S content. For obtaining optimal strengths a very fine cement containing much C_3S can be mixed with a larger quantity

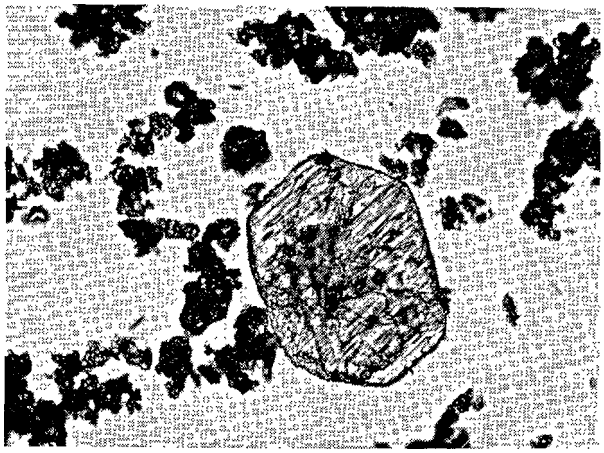

Fig. 10. *Corroded calcium zincate crystal in a* C_3S*-suspension*

of zincate than a coarse cement with a low C_3S content. Even larger quantities added cause no harm.

The chemical reaction between sulphate (of the gypsum contained in the cement) and the aluminates and ferrites is represented in Fig. 13. The cement containing no admixture shows the well-known decrease of the water-soluble SO_3. With 1 % of $CaCl_2$ somewhat less sulphate is bound during the first hour. After a period of 8 hours the quantity of sulphate bound in the cement which contains no admixtures is somewhat larger than the quantity of sulphate bound in the cement containing calcium zincate. The total quantity of sulphate is bound after a period of 24 to 48 hours. Lead and zinc oxide, however, cause marked retardations so that all of the sulphate is bound after 4 days only.

Although the setting time of the cements is slightly retarded by the admixture of calcium zincates, a remarkable increase in the strengths was demonstrated after only 24 hours, as is shown in Tables 2 and 3. This increase was observed over the entire hardening period. In many cases it was even higher.

It was also of particular interest to know whether the zinc which did evidently enter the crystal lattice of the calcium silicate hydrates, influences their chemistry and their morphology as compared with the silicate hydrates containing no admixtures. In some experiments hydrates have been found exhibiting a

ratio $CaO:SiO_2$ of approximately 2.0, whereas this ratio was approximately 1.5 without calcium zincate.

Electron micrographs carried out by W. Richartz (11) showed that the C_3S with 2% calcium zincate and 1% ZnO (Figs. 8 and 9) preferably forms long-fibered silicate hydrates, while the other one containing no admixture preferably exhibits foil-shaped hydrates. Fig. 14 shows hydrated C_3S with 2% calcium zincate after seven days of hydration. It can be seen that long fibres cover the pore.

Calcium hydroxozincate is an admixture which, in spite of its slight retarding effect, influences the hydrating process in a very favorable way by forming long-fibered silicate hydrates, thus increasing remarkably even the strengths in early stages and the long time strengths, too.

Oral Discussion

Giichi Sudoh

I have listened with profound interest to Dr. Lieber's presentation of his research findings, and I want to ask a few questions.

He has stated that the remarkable retardation effect of ZnO on the setting time is due to a blocking-up of the surface of C_3S particles, and may I consider here that the blocking-up compound is zincate? If this compound be zincate, what is the reason the sharp hydrolysis of C_3S starts at the same time that all of the ZnO has been transformed into the zincate?

Also he has stated that Zn is dissolved into calcium

silicate hydrate, and interesting is the phenomenon of the C/S mol ratio of calcium silicate hydrate rising as a result of the dissolution. In this case, what is the form of dissolution? Also what is approximately the maximum amount of dissolution?

Oral Discussion

John H. Taplin

Dr. Lieber is to be congratulated on his research. He may like to comment on the following idea which has occured to me since I discussed the action of retarders in the 1960 Symposium. In the early stages alite reacts slowly due to the formation of an impermeable coating of products or because of the presence of a stable surface. With the nucleation of a stable C–S–H phase the reaction accelerates. Because many organic and inorganic retarders have such similar effects, I suggest that all retarders may act by delaying the nucleation of a stable C–S–H phase and thereby extending the normal dormant period. Retarding action may therefore be independent of any adsorption on anhydrous minerals.

Author's Closure

Werner Lieber

The retardation effect of both PbO and ZnO as well is due to a blocking-up of the surface of C_3S. The ZnO is transformed into the calcium zincate, while a related lead compound could not be detected yet. In the case of retardation by zinc oxide, the rapid hydrolysis of C_3S starts at about the same time, at which all of the ZnO has been transformed into the zincate. Although a similar transformation of lead oxide into a plumbate is not to be observed, the retardation with PbO is about as long as that with ZnO. So I don't think that the rapid hydrolysis of C_3S is the result of a rapid dissolution of the zincate.

It can be seen from the Figs. 8 and 13 that the zincate has only a small influence on the speed of the hydration, the more it has an influence on the morphology of the CSH-phase (Fig. 14). With help of electron microscopy we were able to show that only a very small amount of C_3S reacts with water and forms extremely long-fibered hydrates. This process goes on during the dormant period. I agree with Mr. Taplin that many retarders act by delaying the nucleation of the CSH-phase. The hydration and hydrolysis of the C_3S is significant for the setting and hardening of the portland cements, at least those of usual composition. The aluminate and ferrite phases do not play such an important role as usually mentioned in the literature.

Mr. Sudoh's question is an interesting one. We have examined many samples of hydrates C_3S-pastes by electron microprobe and found that about 3% zinc oxide enter the CSH-phase, when we hydrated mixtures of 90% C_3S and 10% calcium zincate. But, 3% seem not to be the maximum amount. The amount of entering zinc is variable and depends on the quantity of calcium zincate mixed to the C_3S before starting the hydration. I suppose the zinc will enter the lattice of the CSH-phases as $Zn(OH)_2$ interlayer material.

Supplementary Paper II-47 Some Observations upon the Determination of Heat of Hydration of Slag and Portland Cements by the Method of Differential Heat of Solution

Georges A. Toubeau*

Synopsis

The determination of heat of hydration of cements by the method of differential heat of solution is at present studied in many countries in order to establish a classification according to this very important property. So, the C.E.T.I.C. Chemical Commission and a Cembureau Sub-Committee have for many years been working upon this problem. On the other hand, the R.I.L.E.M. has recently proposed a classification of cements based on the value of heat of hydration after conservation during three days at +5°C.

With a view to promotion of concerting in winter, a complete study of the Belgian cements was done in collaboration by several laboratories. This study involved specially the measure of heat of hydration by the solution method.

The base procedure was this one proposed by Santarelli and Goggi, inspired from the old A.S.T.M. method. However, several modifications were made at this original procedure: standard dimensions for the tubes for the conservation of the hydrated cement pastes, conservation in a thermostatic water-bath, mechanical grinding of the hydrated cement under alcohol in a special mill, introduction of the loss on ignition's value in the calculations for the slag and supersulphated cements.

From the numerous determinations that were carried out, it appears clearly that it is absolutely necessary to normalise the following conditions in order to obtain good, comparable and reproducible results: preparation of hydrated cement samples (temperature, tubes), conservation, grinding of the hydrated cement (time, fineness, liquid), drying of the ground sample (time, temperature), determination of heat capacity (preparation, quality and quantity of the ZnO), loss on ignition determination. Of these conditions the drying process seems to be the most important.

Numerous examples give an idea of the errors that can be made in case of variation of the above-mentioned conditions.

Introduction

The determination of the heat of hydration of cements has long formed the subject of many researches. As it is not possible to mention them all, we shall quote here three types of methods put forward, that is adiabatic (1), (2), (3), thermometric or semi-adiabatic (4), (5), (6), (7), (8), and solution (9), (10), (11), (12), (13), (14).

Notwithstanding the existence of these three methods, however, the choice of such and such a cement was based more on the chemical composition than on the direct determination of the heat of hydration and its development speed in terms of time, and mortar and concrete preservation conditions. The standards issued by the different countries did not, as a matter of fact, make any express provision as regards this cement property.

Now, an evolution of the tendencies in this field has been observed in the last few years. Some research work in order to promote cold weather concreting depends on the determination of the heat of hydration; making rapid progress, the R.I.L.E.M. proposed, besides, to classify cements in terms of their heat of hydration at 3 days and ±5°C determined by the solution method.

Some countries intend, moreover, to introduce in their standards characteristics other than mechanical strengths and, more particularly, the value of the heat of hydration. This is, for example, the case with the new German standards issued in 1967 (15).

Such an evolution obviously calls forth an important problem of methodology. It must be added that many international organizations are anxious to co-

*S. A. Ciments d'Obourg, Obourg, Belgium.

ordinate their efforts and investigations in order to attain a method valid both from a national and an international point of view. In this regard we will, more particularly, quote the work achieved by the Chemical Commission of the C.E.T.I.C. (8), (16), (17) and by the Cembureau Sub-committee "Testing of cement and concreté".

Within the limits of this problem of methodology we think it advisable to inform you about the results and observations achieved by our laboratory during a lot of series of tests made by the solution method. In order to promote winter concreting in Belgium an extensive programme of research work is being carried on. This programme consists, more particularly, of an attempt to classify all Belgian cement types in terms of the above mentioned R.I.L.E.M. criterion.

A first attempt of classification using the *original A.S.T.M. method* failed; this was due to possible cement class overlappings (see Table 1, 1st column). The problem was then studied on new bases using the *modified solution method* by Santarelli and Goggi (13), (18) with, however, a few adjustments.

The results achieved by various laboratories showed an excellent concordance (see Table 1, 2nd column) and allowed a classification of Belgian cements into 6 classes spaced from 5 to 10 calories (see Table 1, third column).

During a second series of tests intended for the selection of 6 cements for concrete testing, however, important differences, some of them amounting to 15 and even 20 calories per gram appeared between these laboratories. This led to a revision of the initial cement classification and, what is more, of the validity of the solution method as a calculation method.

Now, a checking of these differences showed that some laboratories had modified the mode of procedure initially put forward. This ascertainment led the laboratory of the S. A. Ciments d'Obourg to start a series of additional researches in order to determine the possible causes of error and to emphasize the problems set with a view to subsequent standardization.

Table 1bis. *Influence of the value of the heat capacity determined with different quantities of* ZnO *on the value of the heat of hydration*

Basic data $\begin{cases} \theta_c \text{ for anhydrous cement: } 4.2383 \\ \theta_c \text{ for hydrated cement: } 4.104 \\ R = \dfrac{100 - PFi}{100 - PFa} = 0.8865 \end{cases}$

Quantity of ZnO used for the stamping	Heat capacity M	Dispersion constant K	Heat of solution of the anhydrous cement in cal/g	Heat of solution of the hydrated cement in cal/g	Heat of hydration in cal/g

Description of the Equipment Used

—The calorimeter used here is described in the publication by Santarelli, Piselli and Covarelli (13), (16)

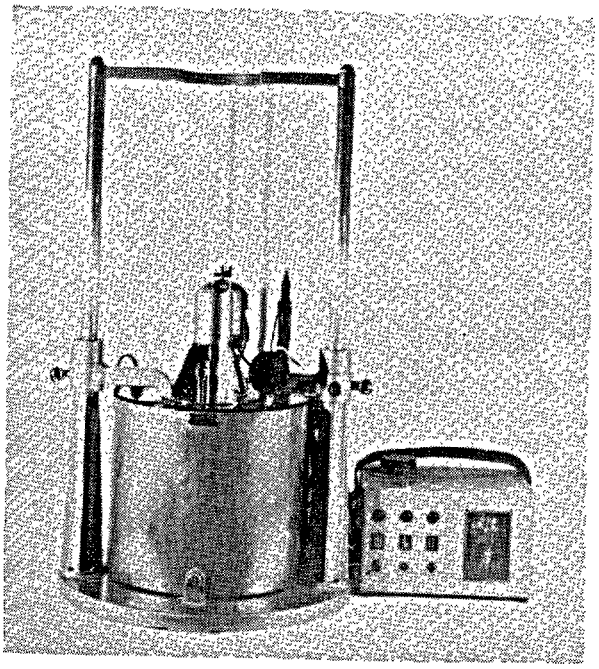

Photo 1. *Calorimeter*

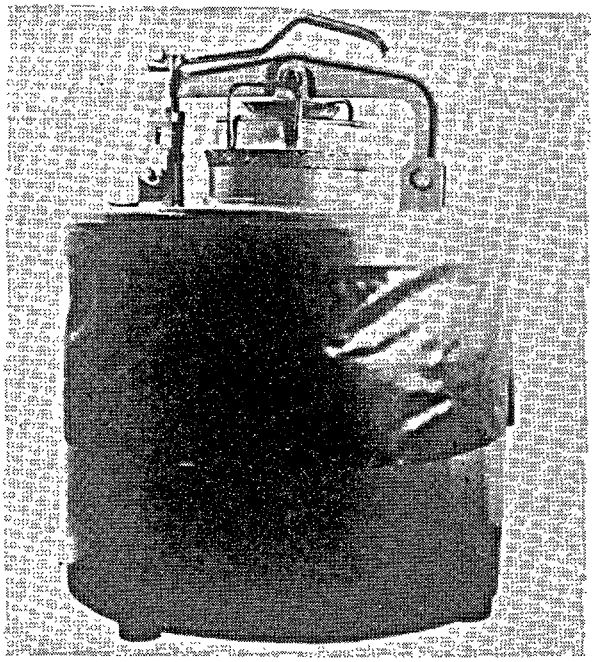

Photo 3. *Laboratory swinging disk grinder*

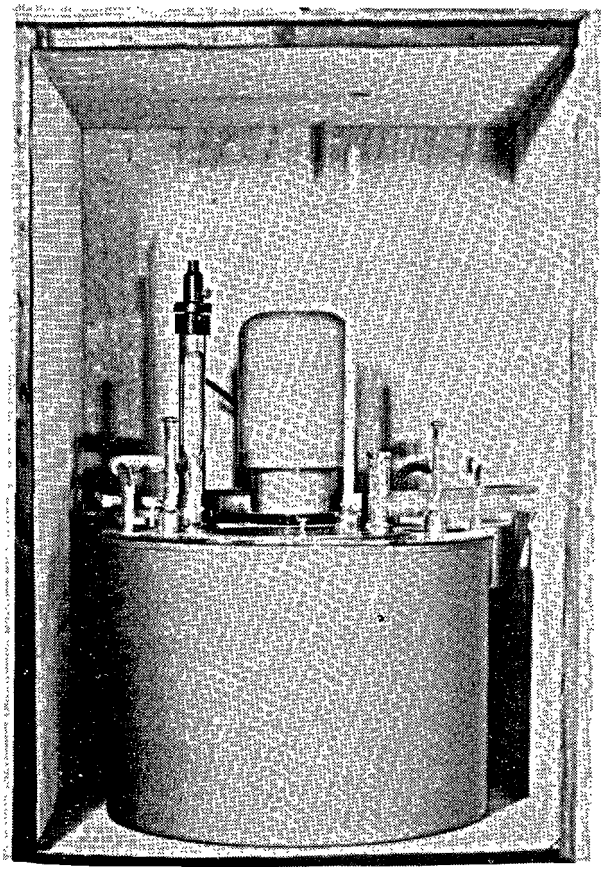

Photo 2. *Ultrathermostat*

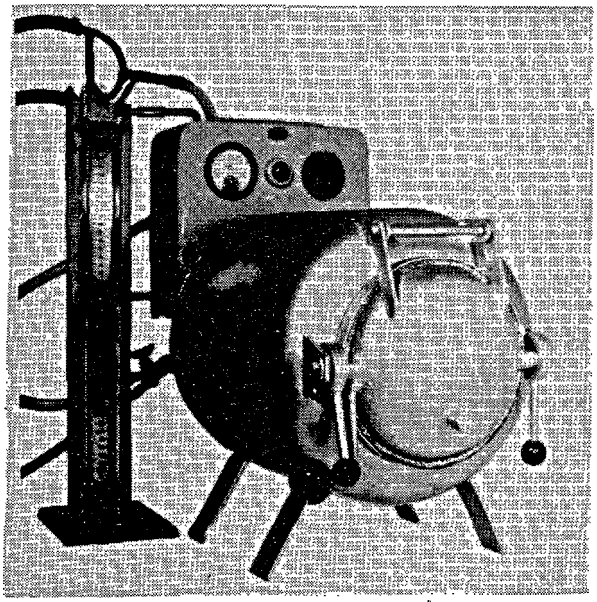

Photo 4. *Nitrogen forced circulation laboratory kiln*

(19) (see photo 1.)

Although other calorimeters of the same design can yield excellent results, we recommend the use of a funnel for introducing samples into the acid bath. The use of this funnel, as a matter of fact, allows an uniform and rapid introduction. Besides, any risk of carbonation of the sample is avoided and the temperature of the substance to be solved

can be risen to the same temperature as the acid solution before starting the measurements. The use of this funnel also make it possible to work in a room with a steady and regular temperature.

—An ultrathermostat allowing the preservation of the cement pastes with an accuracy of $\pm 0.01°C$ (photo 2).

—Small laboratory swinging disk grinder to grind hydrated cement samples (photo 3),

—Nitrogen forced circulation laboratory kiln for measuring the loss on ignition in a nitrogen atmosphere of metallurgic cements (photo 4).

—Vacuum pump.

Method for the Determination of the Heat of Hydration

The method used here has been described in a lot of publications issued by Dr. Goggi (16), (19). Nevertheless, three important modifications were introduced:

Sample Preservation

The preservation in the air of cement pastes could not be guaranteed with accuracy for a temperature of $5°C \pm 0.1°C$. We chosed, therefore, a preservation in water, the temperature of the bath being kept at $\pm 0.01°C$ by means of an ultrathermostat.

The cement pastes are preserved in polyethylene tubes of standardized dimensions (height 68 mm, diameter 26 mm). They are sealed with paraffin and horizontally set in the body of the ultrathermostat to avoid any segregation in the hydrated cement paste.

No matter how high the preservation temperature may be, we propose that the sample preservation in water be generalized.

Grinding of Hydrated Cement Samples

When cement pastes are preserved for three days at $+5°C$, the hardened pastes to be ground are still relatively humid. A dry grinding as prescribed by the original A.S.T.M. method is thus impossible. Besides, it is important to avoid any further reaction of the water still free with the particles of anhydrous cement.

The grinding by hand in alcohol and a nitrogenic atmosphere, which is long, difficult and not free from carbonation hazard, has been replaced by a grinding in alcohol in a swinging disk grinder. This allows a reduction of the grinding time which is now comprised between 1 and 4 minutes, a more even fineness of grinding and the cancellation of any contamination hazard by air CO_2, the cap of the grinder being hermetically closed.

Determination of the Heat of Solution of Hydrated Cement

The formula put forward for the determination of the heat of solution for metallurgic cements read as follows (16):

$$Q_x = \frac{\theta_c \times M}{P \times \frac{CaOi}{CaOa}} + 0.4(T_{30} - T_0) + 0.3(T_{30} - 20°) \quad (1)$$

It thus appeals to the CaO content value of anhydrous and hydrated cement samples. Now, a quick determination of CaO by complexometry is accurate at $\pm 0.5\%$ only. This corresponds to a possible error of 7 cal/g on the heat of solution of hydrated cement and, consequently, on the heat of hydration.

A CaO quantity determination could be devised using wet chemical analysis. In the case of metallurgic cements, however, the quantity of MnO and Mn_2O_3 which are always to be found in slags should be determined, too, and the necessary corrections be made as regards the CaO value. This, consequently, would seriously lengthen and complicate the solution method.

That is the reason why we replaced the quantity determination of CaO by the determination of the loss on ignition in nitrogen with an accuracy of $\pm 0.1\%$. In this case the heat of solution of hydrated cement is determined, as for portlands, by means of the following formula:

$$Q_x = \frac{\theta_c \times M}{P \times \frac{100 - PFi}{100 - PFa}} + 0.4(T_{30} - T_0) + 0.3(T_{30} - T_{20}) \quad (2)$$

After having described the equipment and the method of determination used here, we can now examine such parameters as may influence the measures studied in the course of our additional tests.

Description and Results of Additional Tests

Calibration of the Calorimeter with ZnO

In the course of collective tests it is important that the zinc oxide used for the calibration of the calorimeter should have an even quality. To avoid gross impurities, we recommend the use of ZnO p.a.

In addition, the ZnO preparation has to be standardized as regards the *calcination temperature* and the *fineness of grinding*.

Our experience led us to put forward the following preparation: ± 100 g. ZnO p.a. are calcined for an hour in a ALO_2 alloy dish at a temperature of 950°C. It is then slowly cooled down in a dessicator at 100–110°C, then ground in a china mortar till the whole mass can pass a 295 micron sieve. *A finer grinding should be avoided.* Some laboratories stipulate a fineness lower than 160 μ and even 148 μ. In this case, the ZnO powder tends to form clots by the imperfect dissolution, which in the acid mixture can make the calibration erroneous. The ground ZnO is carefully preserved in a hermetically closed flask.

As regards the quantity of ZnO to be used for calibration, it should be such that the thermal jump be of the same range as the one attained when proceeding with either 6 g. anhydrous cement or 7 g. hydrated cement. The ideal quantity of ZnO is thus 14 grams.

As a rule the ratio acid/ZnO is thus equal to 60. Should a greater ratio be adopted, for ex. 68, viz. a calibration with 12.5 g. ZnO, one can see from Table 1 bis that in spite of the variation of the calorific capacity M, the values of the heat of hydration remain unchanged.

However, to avoid greater errors, we think that the quantity of ZnO should not show a difference greater than 14 grams.

When it is not possible to perform a calibration with help of an electric method, it is then of great interest to accurately standardize the calibration by a thermochemical proceeding in order to attain, at least, anhydrous cement measures which can be compared between different laboratories.

Acid Mixture Composition

Our experiments compared with those of other laboratories showed that the composition of the acid mixture does not practically influence the heat of solution either of ZnO or of anhydrous or hydrated cements.

In order, however, to avoid the introduction of a cause of additional error, a standard mixture consisting of HNO_3 $2N \pm 0.05N$ and of HF 38 to 40% shall be used, preferably, in such a proportion that one has 10 ml HF per 425 grams acid mixture.

Mixing Conditions for Tests on Hydrated Cement

When measuring the heat of hydration after a 7 days preservation at $+20$°C, it should be noted that a mixing of the paste at the laboratory ambient temperature does not lead to any error.

On the contrary, when the mixing is followed by a preservation at $+5$°C, the question may be whether it may not be necessary or not that water and mixing temperature should amount to $+5$°C too.

To answer this question, we performed tests on two very different types of cement. The results are shown on Table 2.

This table shows that the mixing conditions do not influence—or very slightly influence—the results attained for metallurgic cements. In the case of rapid-hardening portland cements (i.e. the most unfavourable case), on the contrary, differences amounting to 2 calories per gram are possible.

With a view to attain an increased accuracy, it is

Table 2. *Influence of the mixing conditions of the cement paste on the heat of hydration after conservation during 3 days at +5°C*

Cement type	Heat of solution and of hydration after mixing of the cement paste at +20°C			Heat of solution and of hydration after mixing of the cement paste at +5°C		
	Heat of solution of the anhydrous cement	Heat of solution of the hydrated cement	Heat of hydration in cal/g	Heat of solution of the anhydrous cement	Heat of solution of the hydrated cement	Heat of hydration in cal/g
PDR (Rapid hardening portland cement)	596.0 595.7 } 595.9	527.7 527.6 528.1 } 527.8	68.1	595.9	529.8 529.6 } 529.7	66.2
HFHR (Slag cement)	582.9 582.7 } 582.8	549.0 549.0 } 549.0	33.7	582.8	548.9 549.5 } 549.2	33.5

therefore recommended to rise the temperature of mixing water to that of the subsequent paste preservation.

Influence of the Determination of the Loss on Ignition for Metallurgic Cements

As said above, the determination of the heat of hydration of metallurgic cements should be made by substituting the loss on ignition in nitrogen to the CaO calibration. This, however, supposes the determination of this loss on ignition at $\pm 0.1\%$ under accurately settled operating conditions.

We undertook some experiments with a view to attain accurate values for these. The results thereof are shown on Tables 3 to 5. These tables show every test series corresponding to 5 measures made from 5 crucibles introduced simultaneously in the nitrogen laboratory kiln and thus submitted to similar operating conditions. Owing to the large dimensions of the laboratory kiln, however, there are slight differences between the temperature recorded by the sheathed pyrometer and that of each sample. With a view to discussing our results we shall, therefore, consider the means attained, not taking extreme values into account.

The loss on ignition of the cement used for the tests amounts to 5.37% under the optimal testing conditions defined hereafter. Quoting this value, an examination of Tables 3 to 5 allows the following conclusions:

1. *the calcination temperature* of the sample should amount to at least 1,000°C. At lower temperatures an incomplete decarbonation leads to errors on the low side comprised between 0.5 and 2.5% (see Table 4).
2. *the calcination time* will be of *60 minutes*. Less time will yield errors on the low side of $\pm 0.3\%$ and more time does not give any important variation provided on proceeds with at least 1,000°C (see Table 5).
3. the samples should not be taken out of the nitrogen laboratory kiln at a temperature higher than 300°C. This is particularly important in calcinating the hydrated cements (see Table 3).

When these three conditions are fulfilled, our experiments show that an excellent accuracy and a very good reproducibility can be attained.

In order to better emphasize the importance of an accurate determination of the loss on ignition in nitrogen, Table 6 shows two examples with measures

Table 3. *Loss on ignition unter nitrogen—Influence of the exit temperature of the sample from the laboratory kiln*
Trial conditions: samples ignited 1/2 h. at 1,000°C

60	5.32	5.42	5.56	5.58	5.63	5.50	5.32

Table 6. *Influence of the value of the loss on ignition for a slag cement on the calculated head of solution of the same cement hydrated during 3 days at +5°C*

	Corrected θ_c in cal/g	Head capacity in cal/g	Loss on ignition of the anhydrous cement in %	Loss on ignition of the hydrated cement in %	Heat of solution of the hydrated cement in cal/g
Example 1: Slag cement HFHR					
Laboratory A	3.6425	813.06	4.47	21.78	516.71
Laboratory B	—	—	2.17	19.82	516.27
Example 2: Slag cement HFN					
Laboratory A	4.020	813.06	5.33	14.88	519.30
Laboratory B	—	—	1.57	9.97	510.50

performed in two different laboratories. These examples show that differences in the values of the loss on ignition used for the determination can lead either to differences which can bc overlooked (example 1) or to differences amounting to *10 calories per gram* for the heats of solution of hydrated cements (example 2).

An accurate standardization of the operating procedure is therefore quite justified.

Conditions for the Preparation of Hydrated Cement Samples

Mixing and drying hydrated cement samples are, in our opinion, the two delicates operations of the solution method. Owing to the numerous fests made in Belgium it appeared absolutely necessary to lay down with accuracy the conditions under which both operations should be carried out.

Samples are being preserved for a very short time (3 days at +5°C). Besides, it is important to take care to avoid any action of the atmosphere CO_2 which might alter subsequent measures. The grinding of hydrated cement is thus carried out in a liquid in order to avoid any contamination and prevent from hydration. As far as grinding is concerned, different finenesses of grinding can be attained.

Then the last traces of the liquid used must be removed by means of an ether rinsing and a more or less prolonged drying.

Carrying out all these operations showed some differences between Belgian laboratories, some of them amounting to 15 cal/g for the heat of hydration of the same cement type.

This prompted us to carry out a serie of tests to study the influence of the following parameters on the value measured for the heat of hydration:

1. *Nature of the liquid used for grinding.* Two types of liquid—which are the most commonly used—were used here; they are: ethyl alcohol and acetone.

2. *Fineness of grinding of hydrated cements.* Two finenesses of grinding were adopted: less than 147 microns and less than 297 microns.

3. *Drying time and drying temperature of the ground sample.* Four types of drying were considered:

—a vacuum drying for 45 minutes under ambient temperature conditions as initially put forward by Dr. Goggi (16). Conventionally, we will agree to consider the respective heats of hydration as *values of reference.*

—a vacuum drying for 1 hour at 35°C.

—a vacuum drying for 40 minutes at 30°C.

—a vacuum drying for $1\frac{1}{2}$ hour at 30°C.

Two cement types were used for these tests: a rapid hardening portland cement (PDR) and a rapid hardening blast-furnace cement (HFDR).

After mixing the cement pastes were preserved for three days at +5°C under above-defined conditions. At the time of settlment for testing the hydrated cements were ground and dried under various conditions. Then we measured their heat of solution. The heats

Table 7. *Determination of heat of hydration of PDR hydrated cement samples, crushed and dried in various conditions*

of hydration were determined after some additional measures of the heat of solution of anhydrous cement and of the losses on ignition of anhydrous and hydrated cements had been made.

Table 7 is a summary of the results attained for a PDR cement and Table 8 shows those attained for a HFDR cement, both to them being ground with a fineness lower than 147 microns, while Table 9 shows the results attained for cement pastes with a fineness lower than 297 microns.

In order to further investigate an eventual drying action of the grinding liquid and of the drying process on the mineralogic structure of hydrated cement, a certain number of ground and dried samples underwent some physical examination: X-ray diffraction, thermogravimetry and differential thermal analysis

Table 8. *Determination of heat of hydration of HFDR hydrated cement samples, crushed and dried in various conditions*
Basic data:—heat capacity M: 836.17 cal/g—heat of solution of the anhydrous cement HFDR: 573.66 cal/g—loss on ignition, unter nitrogen, of the anhydrous cement: 5.62%—grinding fineness $< 147\,\mu$

to 24. Logically, a coarser sample grinding should eliminate alcohol-ether more easily. Now it is just the opposite with a PDR cement, as in this case, the losses on ignition of samples ground more coarsely are always higher by 1 to 2%. This is a systematic fact which is always recorded, *whatever the drying process adopted after grinding may be.*

The occurrence of some residual ethyl alcohol cannot, in our opinion, explain the recorded differences, some of which amount to 8 or 9 calories (see Tables 7 and 9). As it is not possible to find a logical explanation, we think that this parameter should be studied once again using portland cements of a lower fineness.

Influence of the Liquid used for Grinding

For a given drying process, the differences between the values of series 13 to 16 and 17 to 20 are comprised between 1 and 4 cal/g. Compared with ethyl alcohol, the differences attained when using acetone are sometimes on the higher, sometimes on the lower side.

It seems that the type of liquid does not play a fundamental part as far as portland cements are concerned. The differences recorded seem to be explainable through the occurrence of a certain quantity of residual alcohol or acetone.

Influence of the Drying Temperature and of the Drying Time

After treating samples 13 to 16 with *ethyl alcohol,* the following statements can be made:

—for a limited drying period, the values attained for the heat of hydration are almost identical, whether the drying be carried out at the ambient temperature or at 30°C.

—should the drying time be prolonged or the temperature risen to 35°C, important differences should be recorded, more particularly, when drying is being carried out for 1 hour at 35°C.

A reading on the thermograms does not allow to state that there is a loss of combination labile water of the hydration constituents.

The difference recorded in comparison with the value of reference 13, however, cannot be explained through a more complete alcohol elimination. And the 3% loss on ignition shows that a hydration water loss is probable.

It should thus be remembered that when using ethyl alcohol one should have a maximum temperature of 30°C and a drying time not exceeding 40 minutes.

The differences, when these two conditions are not complied with, are more important when proceeding with a high fineness of grinding.

When using acetone, it should be noted that:

—the effects of a drying period exceeding 1 hour are less important when using ethyl alcohol.

—the combination of a prolonged drying with a temperature of 35°C leads once more to a very important drop of the heat of hydration.

Conclusions

Owing to this series of tests, it can be stated that the values attained for the heat of hydration are comprised between 51 and 58 cal/g., i.e. a dispersion of 7 cal/g. This dispersion can sometimes be explained by an incomplete elimination of the grinding liquid, and also by a reduced elimination of combination labile water when the period of drying exceeds 40 minutes. This conclusion is valid whatever the liquid used and the adopted fineness of grinding may be.

On the contrary, it is clear that a drying at 35°C automatically leads to a more or less important destruction of the hydrated structure with a loss of labile water which is not to be overlooked. The dif-

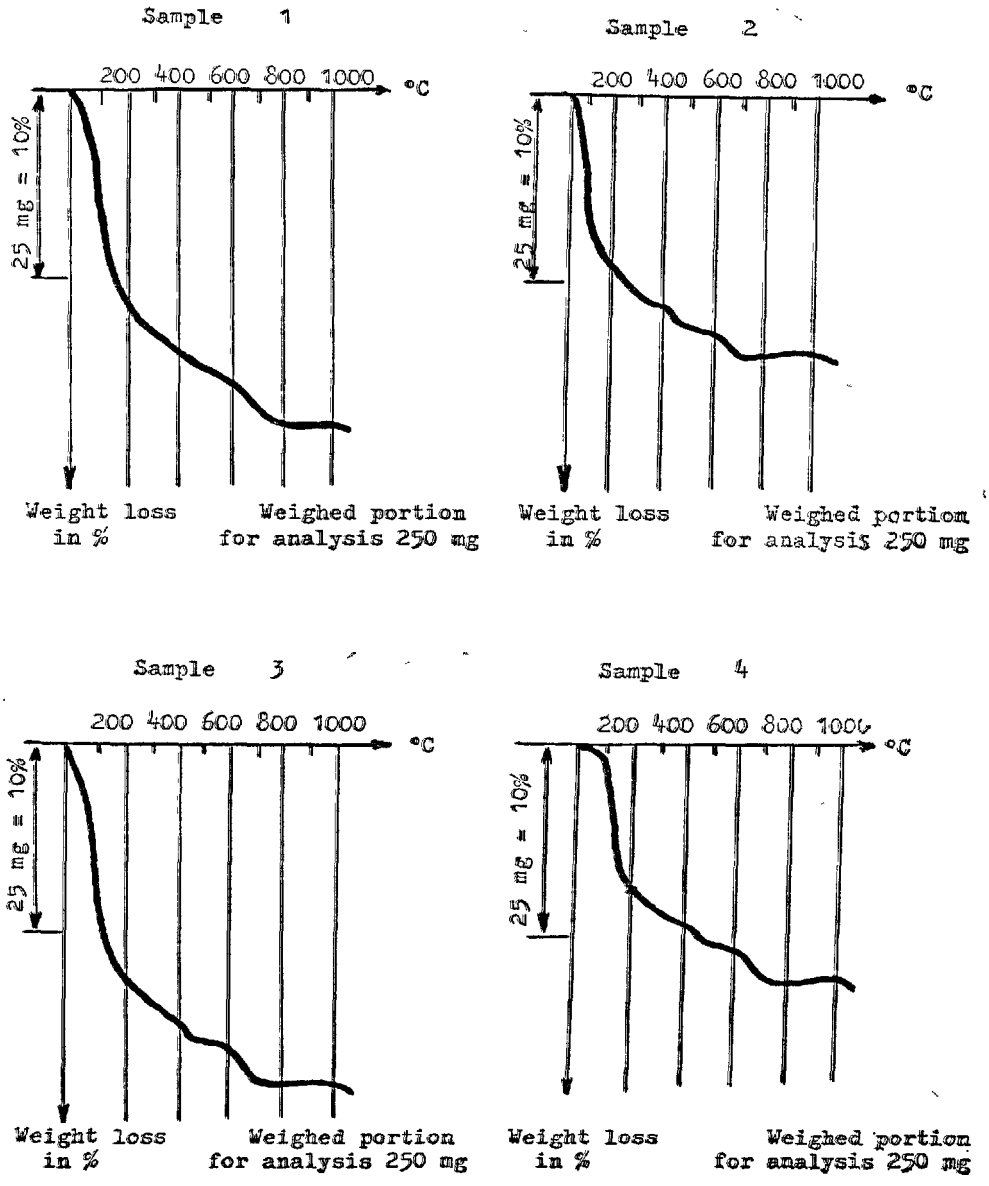

Fig. 4. *TGA graphs of hydrated cement samples*

ferences versus the value of reference may then amount to at least 8 and 9 cal/g.

HFDR Cement (samples 1 to 12)

Influence of the Fineness of Grinding

Lets us now compare measure series 1 to 4 and 9 to 12. It is found that samples ground more coarsely give less important values for the heat of hydration. As their loss on ignition is much lower, it appears that the ethyl alcohol elimination was more complete than for finely ground pastes. It is evident that in this case we are isolating the fineness parameter and that only two samples which underwent the same drying process can be compared with one another.

Influence of the Liquid used for Grinding

When comparing two by two the values of series 1 to 4 and 5 to 8, it clearly appears that the values 5 to 8 are very well grouped together within a mean

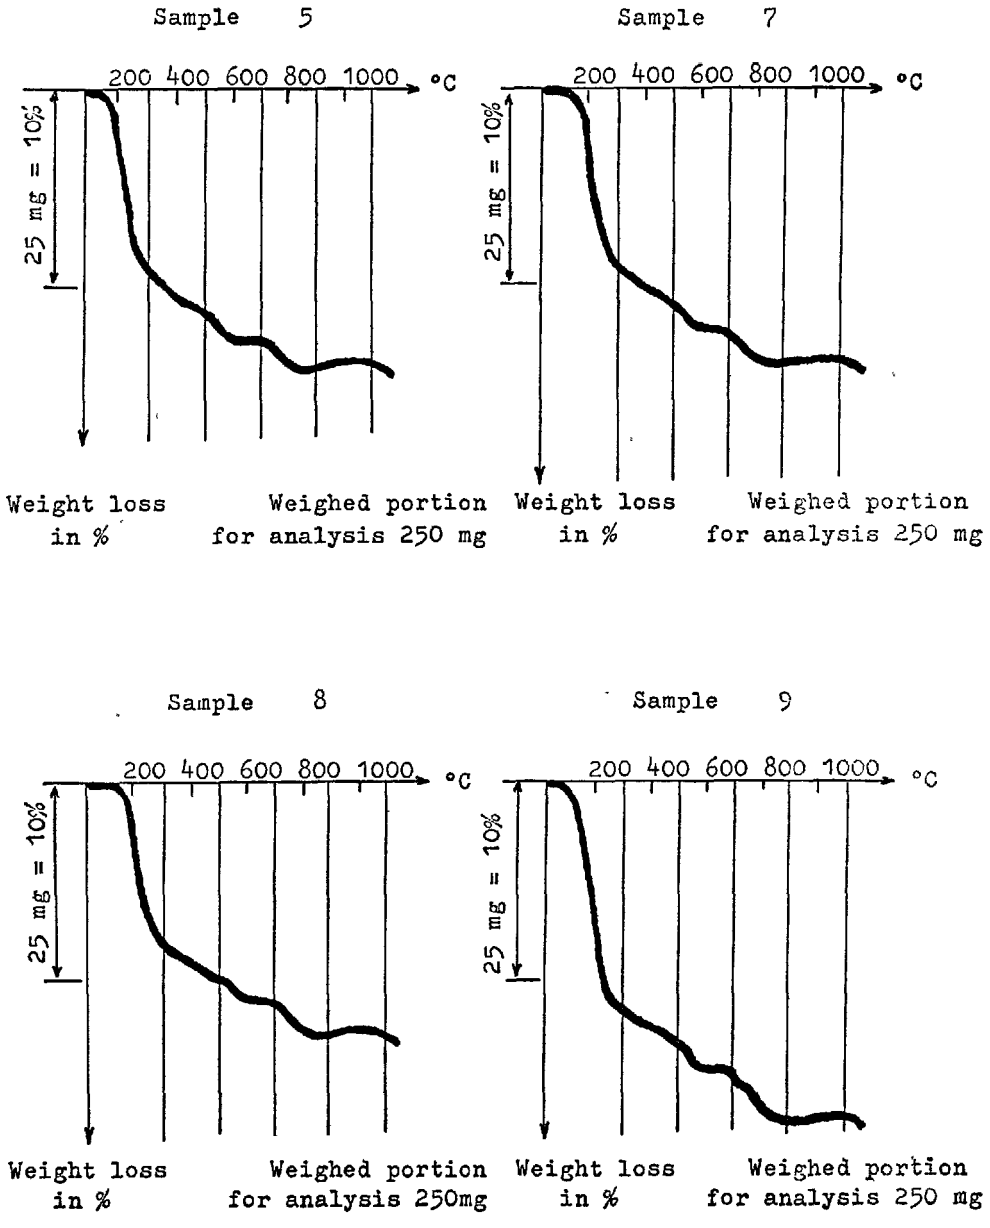

Fig. 5. *TGA graphs of hydrated cement samples*

range of 39 cal/g. Drying conditions seem, therefore, to have very little influence in the value of the heat of hydration when using *acetone*.

This clearly shows that the use of acetone under drying conditions similar to those used with ethyl alcohol leads to an exaggerated desiccation of the ground paste with an important labile water loss of the hydrated constituents. This loss is more particularly characterized by the thermogram features and the differences recorded as regards weight losses between 80°C and 150°C.

Influence of the Drying Temperature and of the Drying Time

For samples 1 to 4 which underwent an *ethyl alcohol treatment*, it appears that a non-prolonged drying period (with a maximum of 40 minutes) at a lower temperature than or equal to 30°C leaves very similar values for the heats of hydration measured.

Too long a drying or a temperature of 35°C only

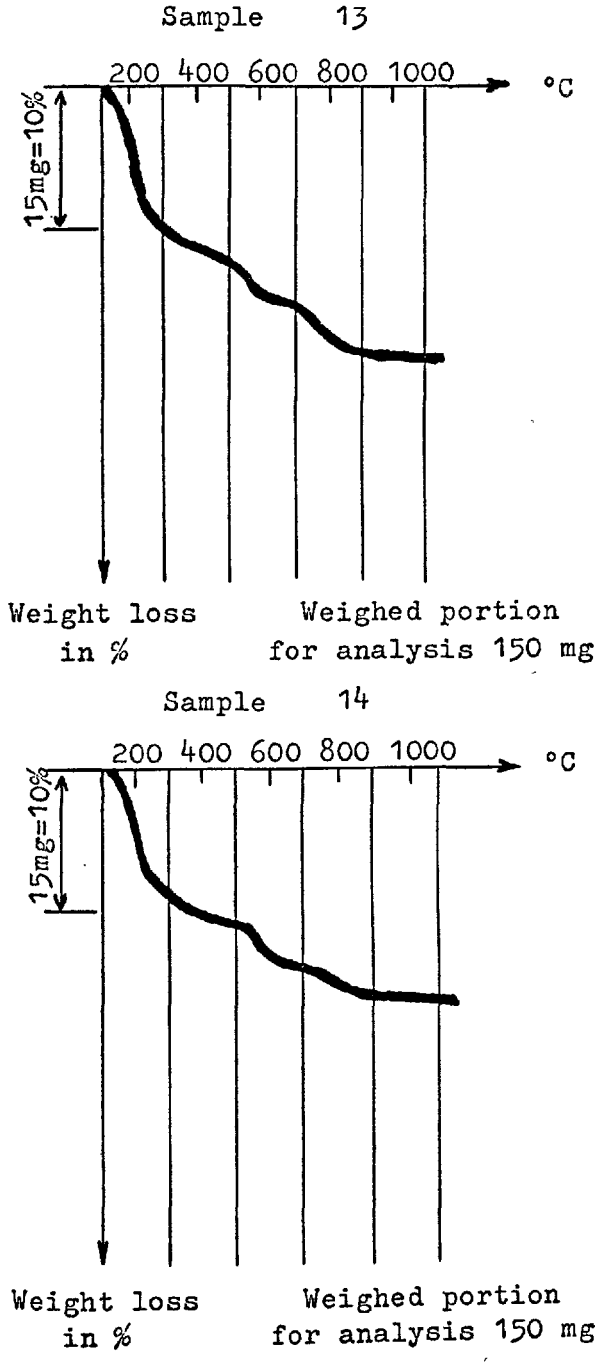

Fig. 6. *TGA graphs of hydrated cement samples*

leads to an indisputable degradation of the hydrated constituents of the paste.

When acetone is used there is always a degradation of the hydrated structure whatever the drying conditions may be.

Conclusions

When ethyl alcohol is used a coarser grinding allows a more complete elimination of this liquid. For a given fineness the value dispersion is of 2 to 3 cal/g. provided that moderate drying conditions be adopted.

When drying takes place under drastic conditions, however, there is an important degradation of the hydrated constituents of the paste and the values measured mean nothing any more.

The same thing occurs when using acetone whatever the adopted method of drying may be. The use of this liquid should thus be prohibited.

Conclusions

Above-mentioned tests dealt with two cement types only. The conclusions drawn, therefore, should not be considered as definitive ones, but rather as indications allowing a limitation of the problems set and an orientation with a view to subsequent researches. They may be summarized as follows:

a. The fineness of grinding of hydrated cement pastes should not be too high and a fineness lower than 300 microns should represent an adequate minimum. The elimination of the grinding liquid and of the rinsing ether will consequently be more complete. This conclusion, however, should be confirmed by subsequent testing on anhydrous cements of a lower fineness.

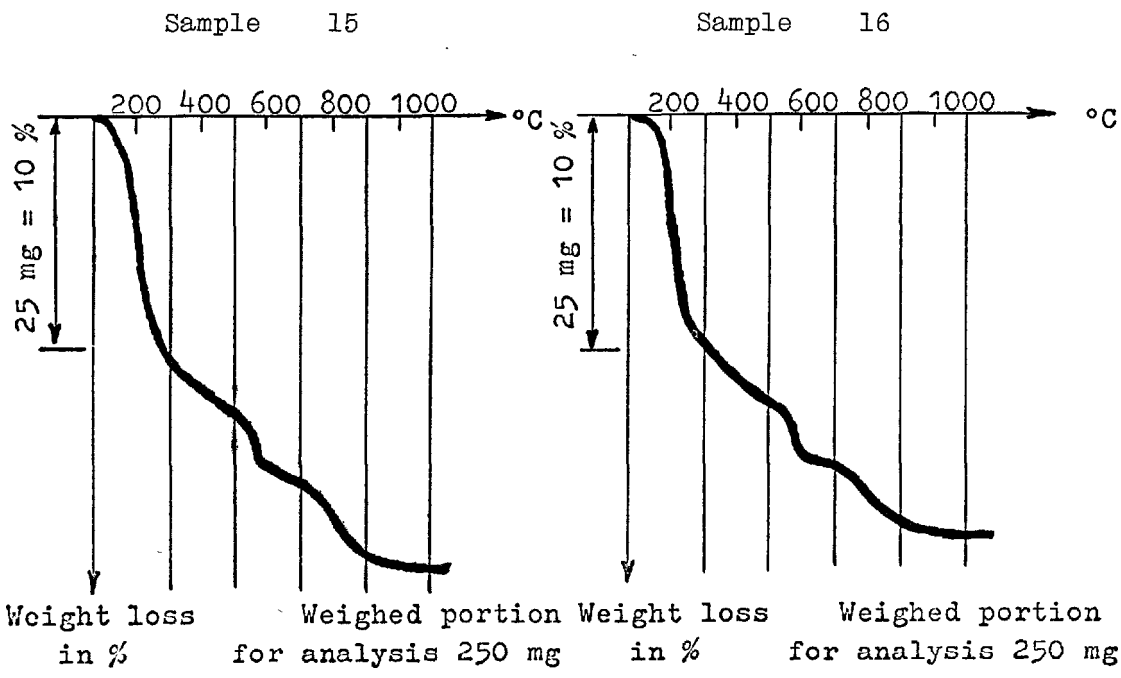
b. The use of acetone as a grinding liquid leads to the destruction of the structure of the cement paste whatever the subsequent drying conditions may be. Used of this liquid should thus be strictly prohibited.

c. When using ethyl alcohol drastic drying conditions should be avoided as these cause a more or less important loss of the combination labile water of hydrated components. The effect of an exaggerate drying is particularly bad in the case of blast-furnace cements.

In the present state of our research work we recommend a high vacuum drying for a maximum of 40 minutes, at a temperature not exceeding 30°C.

Subsequent research work should allow an increased accuracy of the limits thus determined.

It may also be questioned whether the combined action of alcohol and rinsing ether does not cause a substantial etching of residual hydrated and anhydrous constituents of the cement paste, this etching being characterized by the flowing of a certain quantity of soluble matter into the filtrate.



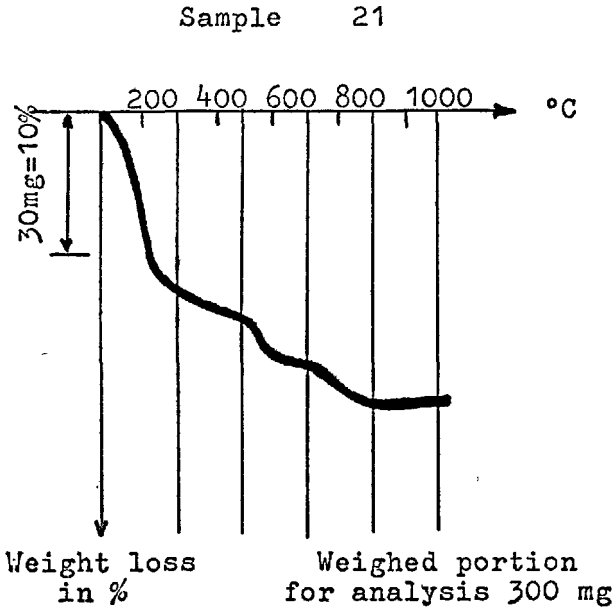


Fig. 7. *TGA graphs of hydrated cement samples*

To answer this question two types to tests were performed:

a) Chemical analysis of filtrates derived from the washing of hydrated cement samples with alcohol-ether.

The following results expressed in % of the quantity

of dry cement initially mixed were attained:

	Sample 1	Sample 2
SiO_2	% 0.0016	% 0.0009
R_2O_3	0.0022	0.0005
CaO	0.0008	0.0006
$Ca(OH)_2$ solved	0.0008	0.0009

b) Compared analysis of anhydrous, hydrated but not washed with alcohol-ether, hydrated then washed with alcohol-ether cement.

The following table shows analysis results determined with a null loss on ignition.

	PDR anhydrous cement	PDR hydrated cement, unwashed			PDR hydrated cement then washed with alcohol-ether
		1st test	2nd test	Mean	
	%	%	%	%	%
SiO_2	20.60	20.79	20.22	20.50	20.45
Al_2O_3	7.34	6.83	6.73	6.78	6.98
Fe_2O_3	3.27	3.26	3.26	3.26	3.26
CaO	65.96	65.33	65.05	65.19	65.14
MgO	0.82	—	0.74	0.74	0.74

The above-mentioned results clearly show that an usual grinding in ethyl alcohol followed by an ether rinsing will not modify in the least the chemical composition of the hydrated cement by matter flowing into the filtrate. The cause of the differences recorded should thus be searched elsewhere.

Conclusions

Very important differences, some of them amounting to 15 calories per gram were recorded between different laboratories when measuring the heat of hydration of the same cement type using the solution method.

A certain number of factors capable of explaining these differences have been studied in this record.

The calibration of the calorimeter will be carried out with 14 grams zinc oxide with an even but not too high fineness of grinding. The heat capacity M will be the mean of at least 6 determinations. If all these conditions are complied with, any cause of error due to a faulty calibration is eliminated.

Though it does not seem to have any influence on the values of the heats of solution measured, the composition of the acid mixture will be standardized, too.

The mixing of the cement will be carried out, if possible, with water having the subsequent paste preserving temperature. Errors of ± 2 calories per gram are possible when water is at the laboratory temperature whereas heating is being carried on at a low temperature.

The loss on ignition of anhydrous and hydrated cements interferes in the determination of the heat of solution of hydrated cement and has, consequently, an influence on the value of the heat of hydration. These losses on ignition will be determined by calcinating samples for an hour at $1{,}050°C \pm 50°C$. For blast-furnace cements this determination will be carried out in a laboratory kiln with a neutral atmosphere (nitrogen, argon). The procedure should be accurately described and strictly complied with. Should this not be done, differences of 10 calories per gram could be recorded between some laboratories.

It should be noted, however, that the standardization of above-mentioned operations allows the cancellation of practically any cause of systematic error. Such ideal operating conditions are, in our opinion, very well settled now and an agreement between laboratories on these various points is susceptible of being reached within a short time.

The delicate point of the solution method remains, therefore, the determination of the conditions for the preparation of hydrated cement samples. The tests which were carried out in our laboratories dealt with a limited number of cements and it is not possible, as a matter of fact, to draw now definite conclusions in this regard. In our opinion, however, these tests allowed a recording of some interesting facts which could be the base of new tests dealing with a greater number of cements having a different fineness and a different nature.

The following points should eseentially be recorded:

1. When heating of cement pastes occurs at a low temperature and for a very short time, it is absolutely necessary to use a liquid for grinding hydrated cement. Otherwise the carrying on of hydration and carbonation would cause errors which could only be estimated with much difficulty.
   Nevertheless for heatings of a longer period at a temperature of $+20°C$, the question remains whether it is advisable to use a liquid of which the subsequent elimination cannot be easily performed.
2. The liquid used should not modify the composition of the hydrated cement sample by matter flowing into solution. With ethyl alcohol this possibility does not practically exist.
3. The liquid used should be totally eliminated; if

not, the values of the losses on ignition and that of the heat of hydration determined could be altered. The fineness of grinding of hydrated cement should not be too high. We propose to limit it to a size non-remaining on a 297–micron sieve.

Besides, the elimination of this liquid by ether rinsing and vacuum drying should be performed under such conditions that the structure of some hydrated constituents should not be modified. More particularly, a loss of combination labile water of some hydrates should be avoided at all costs.

Owing to our experiments, we think that, provided a high vacuum drying (till 1 Torr) be performed, a drying period of a maximum 40 minutes at a temperature not exceeding 30°C is quite enough to eliminate totally a liquid like ethyl alcohol. On the contrary, the adoption of the same drying conditions in acetone leads most of the time to a high degradation of the hydrated paste structure. The use of such a liquid should, therefore, be prohibited.

Besides, we would like to emphasize that the above-recommended drying conditions were determined after a testing on rapid-hardening cements of which the Blaine specific surface is of about 5,000 sq. cm/g. It is thus quite clear that these conditions may be slightly modified for cements with a lower fineness, and that the period of drying may be further shortened. The temperature, however, should in no case exceed 30°C and it is, in our opinion, even preferable to proceed at the ambient laboratory temperature that is about 20°C.

It appears therefore absolutely necessary to carry out for the shortest possible time numerous tests enabling us to make a definite determination of the conditions for the preparation of hydrated cement samples allowing thus the accuracy and reproducibility of the measures performed.

As long as these optimal conditions remain indeterminate any attempt of a cement classification in which the differences between classes would not exceed 5 calories per gram appears to us as illusory and premature.

An important work of methodology remains to be done, as far as the solution method is concerned. Besides, it will be extremely interesting to compare the results attained with those concerned with other methods such as the predetermined dispersion method (6) and the isothermal calorimeter method (22).

We wish the work described here could contribute to some progress of this problem of methodology.

Supplementary Paper II-117 The Influence of Alkali-Carbonate on the Hydration of Cement

Egide M. M. G. Niël*

Synopsis

The setting and the strength-development of mortars of portland cements and blast furnace slag cements is affected by the presence of alkali-carbonate.

It has been noticed for all these cements that the setting time is retarded at first in proportion to the alkali-carbonate content (at about 0.2% K_2CO_3), and gets gradually shorter so that at about 2% K_2CO_3 a flash setting occurs.

At a further increase of the alkali-carbonate content this flash setting effect continues to occur, until at about 15% K_2CO_3 setting times of about 20 minutes show up again.

Also the strength-development of prisms of mortar shows clearly that alkali-carbonates exert an influence.

By following the hydration closely, an insight is gained in the reactions, to which the above mentioned phenomenons can be related.

For this examination chiefly use has been made of chemical analyses and semi-quantitative measurements with the help of X-ray diffraction and infrared measurements.

Introduction

Literature (1, 2, 3) chiefly mentions two cases in which the hydration process is influenced by alkali-carbonate, viz. when alkali-carbonate is added to cement in mortars, and in case of false set which occurs after long-stored cements are used.

The addition of alkali-carbonate in cement mortars either serves to accelerate set at a normal temperature or enables to use mortar at temperatures below 0°C.

However, the presence of alkali-carbonate in mortar causes several properties of this mortar to change during the stiffening an hardening process. This hardened mortar reacts differently from the usual mortar.

The investigations and tests have established that by addition of alkali-carbonate the following irregularities occur by the use of portland cement and blast furnace cement:

1) deviations in setting and workability
2) increase compressive strength and flexural strength
3) rise of the temperature of mortar

When moist air can penetrate the storage yard where cement is kept, hydration-reactions will occur on the cement particles. In these reactions the alkalies bound in the clinker can be liberated which react with carbon-dioxide from the air to form alkali-carbonate.

By some authors (1) this alkali-carbonate is held responsible for above mentioned irregularities.

In this contribution we have tried to find an explanation for these irregularities by investigating the hydration process as well as we could with the means available and by applying the results of this investigation to the above mentioned deviations.

Physical Tests

Paste Tests

The respective rheological behaviour and the hardening characteristics of the mortar to which alkali-carbonate has been added, result from the hydration-reactions in the cement paste.

To get an insight about the effect of the different alkali-carbonate proportions, tests have been carried out with cement pastes. After it appeared from orientation tests that sodium-carbonate had a similar activ-

*Eerste Nederlandse Cement Industrie, Maastricht, Netherlands.

ity as K_2CO_3, only potassium-carbonate was used for the rest of the series to be tested.

To start with a series of determinations of the setting time was carried out at five portland- and blast furnace slag cements with addition of K_2CO_3. They were carried out, according to the German specification DIN 1164, presuming that the temperature at preparing and preserving amounted to 4°C for one series and 20°C for the other series.

Potassium-carbonate was dissolved in the gauging water. The proportioning of this salt was calculated in the percentage of weight of the cement. The results of these series have been reproduced by means of examples on the Figs. 1 and 2.

The curve representing the relation between initial, final setting and the percentage of potassium-carbonate at a fixed temperature is practically the same for all cements, which means:

—at very small proportionings (0.2%) a considerable delay of the setting (especially at low temperatures)

—at proportionings of 2 to 10% a considerable shortening of the setting time, so that the cement paste can hardly be worked

—at large proportionings over 10% potassium-carbonate a less considerable shortening of the setting time.

Although sufficient data about the reduction of the setting time can be found in literature (3), the indications about the retarding effect are lacking. This effect however is such that it is worth while to pay attention. At 20°C the retardation amounts to 1 hour and 25 minutes; at 4°C to 22 hours (slag-cement).

The tests have been carried out with the laboratory portland cement "M".

With this, cement pastes have been made with gauging water containing potassium-carbonate. The above-mentioned characteristics changes in the setting time at 23°C proved to be most striking for the following K_2CO_3-proportionings: 0, 0.25, 2.5 and 20% (see Fig. 3).

In all the following tests and in the hydration examination, these mixing ratios were used.

The second part of the paste-tests aimed at obta-

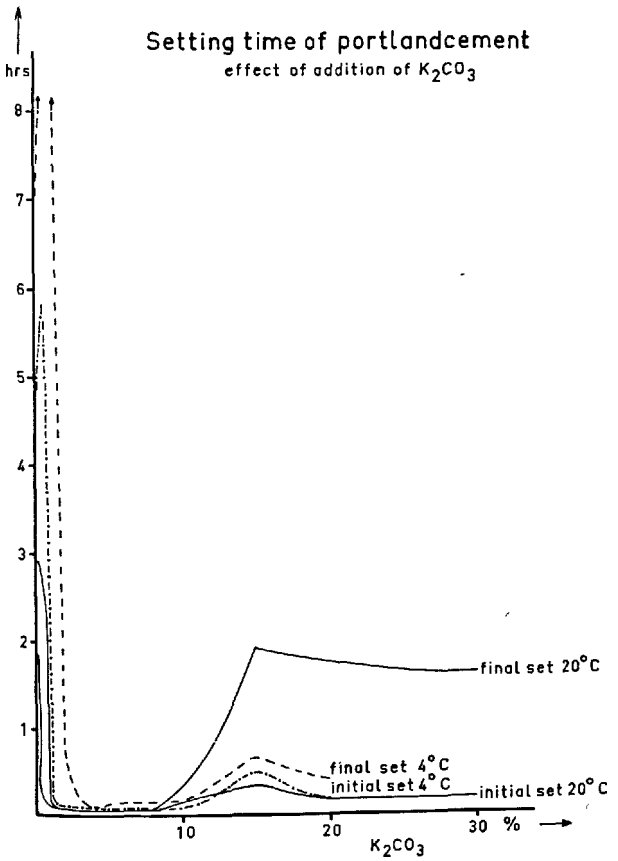

Fig. 1. *The initial and final setting time of portland cement at various additions of* K_2CO_3

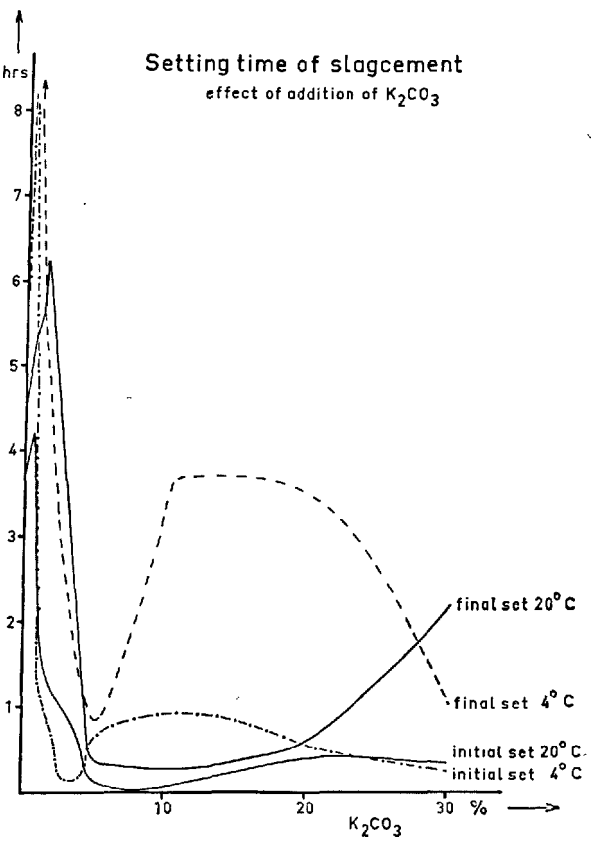

Fig. 2. *The initial and final setting time of slag cement at various additions of* K_2CO_3

ining more data about the behaviour of the pastes after the mixture was completed.

To that end determinations were carried out with the penetrometer according to Francardi (4, 5), with which the setting of the pastes can be watched continuously. Simultaneously, temperature measurements in the pastes were carried out. With the penetrometer, according to Francardi, a so-called consistency curve may be drawn up, which reproduces the course of setting.

In Fig. 4a the consistency curves of the 4 pastes have been reproduced. From these it can be read how the setting is accelerated when potassium-carbonate is present.

Moreover, it is clearly to be seen that, at a proportioning of 0.25% K_2CO_3, in the initial setting after slightly more than half an hour, K_2CO_3 changes into a retarder. This initial setting may be regarded as a flash setting. The degree of flash set is larger in proportion as more K_2CO_3 is added. The temperature measurements were carried out by inserting a thermocouple in the paste, with which a paste-container of the penetrometer had been filled.

The results of these measurements are shown in Fig. 4b. They were carried out simultaneously with the consistency-measurements with the penetrometer, and they show the change of temperature at the inside of the paste.

The retarding in the setting at 0.25% K_2CO_3 is accompanied by a retarded start of the temperature rise whereas the increase in temperature is less than in the reference sample. In the initial period after preparing the paste containing 0.25% K_2CO_3, a temperature rise occurs which however decreases after about half an hour. Linked with this is the early setting, which after this half an hour does not continue in a setting-course.

In the larger amounts, the steep change in consistency is in accordance with the violent increase of temperature shortly after preparation. About 2 hours after preparation the temperature rises to a second maximum.

Mortar Tests

The examination made of setting phenomena showed that when potassium-carbonate is added flash setting may occur. This may influence the workability of fresh concrete. Workability was measured by the slump method. With fresh concrete containing aggregates, graduated according to the Fuller-curve, and with 350 kg/m³ normal portland cement, at a water/cement ratio of 0.5 a slump of 10 cm was obtained. In Table 1 the changes caused by the addition of potassium-carbonate (calculated on cement) are shown. At small percentages the workability is lessened; in proportionings of over 5% the slump is again increased.

To get an idea of the influence of the potassium-carbonate on the strength development of mortars (according to Cembureau specifications) compres-

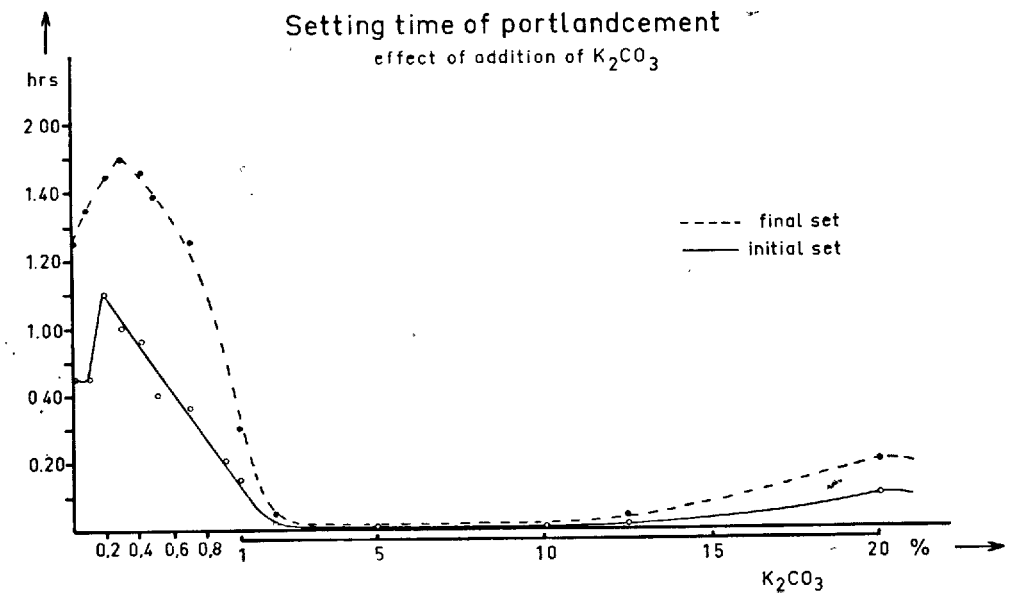

Fig. 3. *The initial and final setting time of portland cement "M" at various additions of* K_2CO_3 (20°C)

4b. *Development of temperature in the portland cement paste*

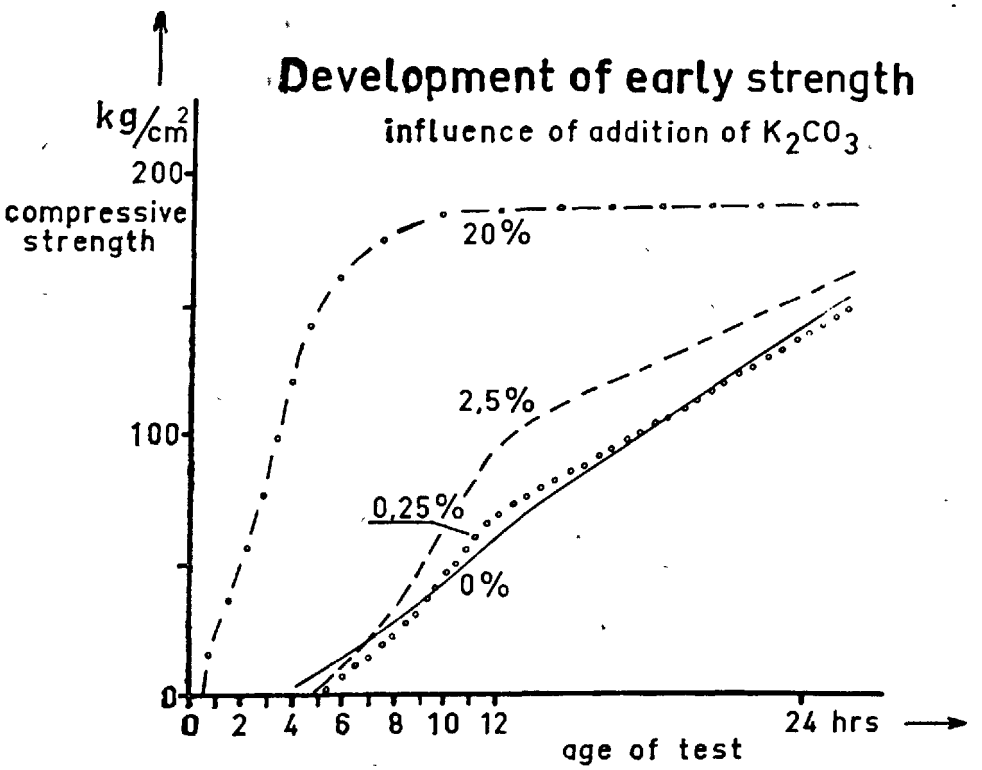

Fig. 5. *The development of early strength on mortar prisms of portland cement*

sive and bending/tensile strengths have been determined about hardened mortars, which originally were composed of sand, cement "M" and gauging water, in which 0–2.5 and 20% potassium-carbonate was dissolved. The results of these tests after 12 hours, 1–3–7 and 28 days of hardening, are shown in Table 2.

It may be concluded that at 12 hours after prepara tion, with a high proportioning of K_2CO_3 (20%) the strengths are already considerable. The increase of strength after these 12 hours is however relatively slight.

The lower proportionings showed this in a lesser degree, whereas 0.25% K_2CO_3 caused a decrease of the strengths after 12 hours in comparison with the reference sample.

In view of the considerable differences in strength after 12 hours of the various mortars a series of mortar prisms was prepared. Every hour after preparation prisms were tested; until the moment of testing they were left in the mould. In this way the development of strength in the initial period of the hydration could be observed.

Unfortunately, we had to use a clinker of a slightly different quality, owing to which the curves in Fig. 4 cannot be simply compared with the results in Table 2.

However, the same tendency may be observed, viz., the pastes with 20–2.5–0 and 0.25% start the hardening in this sequence and also reach in this sequence the highest strengths in the initial 12 hours.

Hydration-Reactions of Portland Cement with K_2CO_3

As pointed out in the foregoing 4th Symposium on Chemistry of Cement, the reactions which occur in the hydration of a portland cement are known for the greater part. The progress of the hydration of each of the clinker components has been examined by analysing pastes and suspensions of C_3S, C_2S, C_3A and the "ferrite phase".

In the last few years this examination has been extended to the more complex course of hydration in cement pastes (6, 7).

In this study the hydration-reactions which occur when K_2CO_3 is added to portland cement "M", have been observed.

Procedure

To get an idea of the reactions, which occur during the hydration process, the following procedure was adopted:

A paste is made from cement "M" with water (W/C 0.3), in which potassium-carbonate in the required percentages has been dissolved; this paste is put into a plastic bottle and stored in a water-bath of 23°C (±1°).

At definite times a small sample of paste was taken and the hydration was stopped immediately with isopropyl-alcohol. For the hardened paste it was necessary to pulverize the small sample prior to vibrating ultrasonic with excess of water-free isopropyl-alcohol. After that the samples were ground in an agate grinder to achieve a constant fineness. This constant fineness is necessary to achieve comparable measurements. This technique to put a stop to the hydration-reactions has been applied successfully in earlier studies (8, 9).

By suspending in excess of water-free isopropyl-alcohol the components, are precipitated practically completely and the so-called free water is eliminated from the particles, which has been confirmed ab origine by the infrared spectra. Practically no increase in the water peak at wave number 1650 cm^{-1} is perceptible.

Finally the alcoholic suspensions were filtered off by millipore filters (ϕ max. $= 0.45\ \mu$) and then the remaining residues of alcohol were removed in a drying-oven at 40°C and 60 mm Hg.

Then the small samples were examined, viz.:

a) by determining the loss on ignition
b) by X-ray diffraction
c) by infrared spectrography

Before discussing the results of the determinations, an elucidation to the methods of the examination is given.

a) loss on ignition

The loss on ignition was determined by heating at 1060°C for 10 minutes of the water-free sample.

b) X-ray diffraction

The X-ray diffraction recordings were carried out with the Philips diffractometer 1010/1050/1051/4082/. The further details are:

X-ray tube:	Cu-anode + Ni-filter (96 KV + 26 mA)
divergence slit:	1°
receiving slit:	0.2 mm
scatter slit:	1°
counter:	proportional counter (1700 V)
goniometer-speed:	1°/min.
paper-speed:	800 mm/h

Amplitude 25.5 V; channel width 20 V; discriminator: attenuation 4.

The sample was rotated during the measurement.

The following interferences were measured from the various components:

component	value
$C_3S + C_2S$	2.18 Å
C_3S	1.765 Å
C_3A	2.69 Å
"C_4AF"	2.64 Å
$Ca(OH)_2$ or CH	4.92 Å
$C_3A \cdot Ca(OH)_2 \cdot 12H_2O$ or C_4AH_{13}	8.2 Å
$C_3A \cdot CaCO_3 \cdot 11H_2O$ or $C_4A\bar{C}H_{11}$	7.56 Å
$C_3A \cdot 3CaSO_4 \cdot 31H_2O$ or $C_6A\bar{S}_3H_{31}$	9.7 Å
$C_3A \cdot CaSO_4 \cdot 12H_2O$ or $C_4A\bar{S}H_{12}$	8.9 Å
$3K_2CO_3 \cdot 2CaCO_3 \cdot 6H_2O$	2.07 Å
$CaCO_3$	2.49 Å
$CaSO_4 \cdot 2H_2O$	7.56 Å
K_2SO_4	4.17 Å

c) infrared spectrography

For the infrared measurements the Perkin-Elmer infrared spectrophotometer 337, speed 94 cm/min.-slit 3 was used. Sample: KBr-tablet.

Quantitative measurements were carried out. The contents could not be given in percentages, because not all the calibration lines are available; therefore, extinction values have been mentioned in the graphs.

The following components were measured quantitatively at the specific wave numbers mentioned behind:

$Ca(OH)_2$	at	3650 cm^{-1}
K_2SO_4	at	623 cm^{-1}
$CaSO_4 \cdot 2H_2O$	at	670 cm^{-1}
$K_2SO_4 \cdot CaSO_4 \cdot H_2O$	at	660 cm^{-1}
OH (total)	at	3400–3600 cm^{-1}

Data about Cement "M"

The cement was obtained by grinding 95 parts by weight of clinker with 5 parts of gypsum in a laboratory ball mill.

During this process of grinding gypsum did not decompose into semihydrate. The specific surface amounts to 5600 cm^2/g, according to Blaine. Under the microscope the mineralogical composition has been studied. The clinker minerals proved to be practically completely crystallized, with the exception of the ferrite phase, which is mainly glassy. The potential mineral composition of clinker calculated according to Bogue and the complementary data have been collected in Table 3.

Table 3. *Chemical composition and potential mineral composition of portland cement "M" according to Bogue*

Chemical composition of the cement		
loss on ignition	1.48%	
SO_3	2.34%	
K_2O	0.30%	
insoluble	0.35%	
Potential mineral composition according to Bogue		
C_3S —65.2%	lime saturation formula	94.1
C_2S —15.5%		
C_3A — 8.6%	free lime	0.64
C_4AF— 7.6%		

For the tests distilled water was used.
The added potassium-carbonate was a mixture of equal parts K_2CO_3 and $K_2CO_3 \cdot 1\frac{1}{2}H_2O$.

Interpretation of Measurements

Before proceeding to the discussion of the hydration-reactions, it may be observed that these measurements cannot give a complete picture of the hydration-reactions. The X-ray diffraction only allows to detect sufficiently crystallized compounds, which give sufficiently strong intensities, and the peaks of which do not coincide with those of other components. For these reasons it was not possible to measure C_2S at a separate peak but only as total $C_2S + C_3S$, and the fer-

rite phase was only partly perceptible. The important hydration products of the tobermorite phase were not or hardly measurable, whereas it is only possible to measure sufficiently clearly the monosulphate ($C_4A\bar{S}H_{12}$) after longer periods (>1 month) of hydration.

Also K_2CO_3 in hydrated cement is also hard to measure. With infrared the carbonates have strongly developed peaks, but from these the K_2CO_3-peak could be selected with difficulty. Due to such effects it may be possible that, when certain reaction products appear, they can only be observed at a somewhat later time. For the measurements for infrared as well as for X-ray diffraction, care has been taken so that they are carried out 3 times at least. The averages can be found back in the graph 6 as measuring-points.

In all the following graphs these measuring-points have been omitted to make the presentation more clearly.

The measurements are shown as intensities or as extinctions (infrared), because the X-ray diffraction and, to some extent, also the infrared measuring technique are not yet apt to carry out quantitative mineralogical analysis in weight percentages.

Since the measuring circumstances do not vary from measuring-point to measuring-point and each sample undergoes a similar particle-preparation, the variables which hamper a quantitative interpretation of measuring results are minimized. Since the measurements of the decrease of the intensities of the clinker minerals are least affected by crystal effect, they are reproduced separately in the graphs. Due to the hydration-reactions the weight of "solid material" increases. The values of the clinker minerals are only corrected with the losses on ignition. Some of these measurements have been repeated with an internal standard. After addition of 10% CdS to the probe, the mixture is homogenized by gently milling a suspension in cryclohexane. The clinker interference was measured at 2.18 Å ($C_3S + C_2S$). Also the degree of hydration of the calcium silicates was esti-

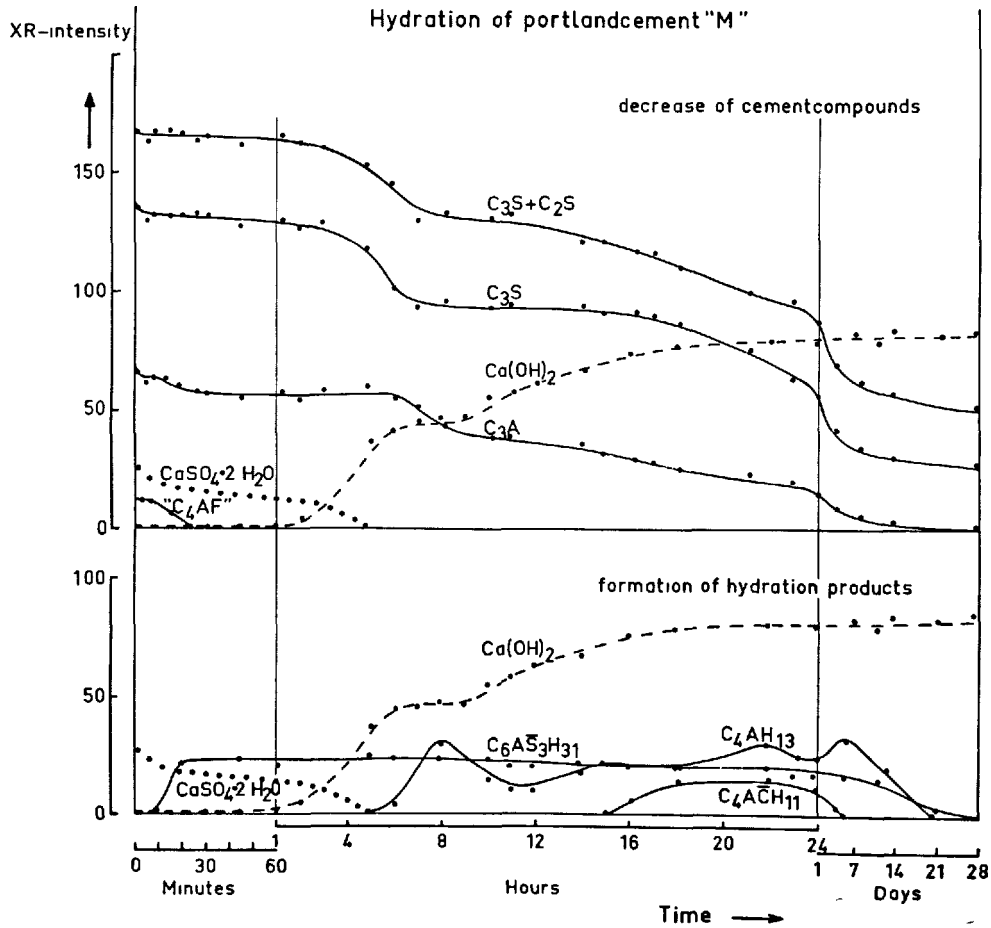

Fig. 6. *Hydration of portland cement "M"; W/C-ratio 0.3 X-ray measurements; indication of the average measuring-points*

mated at 60 minutes, and 7 days, being 3.5% and 63%. These results are in accordance with the degree of hydration which can be derived from the data in graph 6 by comparing the XR-intensities at these times with those of the unhydrated portland cement "M".

Discussion of the Results

The results of the measurements are shown in the graphs 6–13. Because a relation should be established between the reactions in the paste on the one hand, and the workability of the paste, the development of strength initially and after longer periods on the other hand, a classification in 3 periods with 3 different time scales has been made, viz., 1 hour, 1 day and 28 days. The first graph shows the averages of the measurements, the divergence and the times of the measurements.

In Table 4 the data regarding the measurements after 2 and 3 months have been recorded.

Reactions in the Initial Period and Setting

The reactions of the portland cement "M" (see Figs. 6 and 7) correspond with the observations in the literature (10). G. Yamaguchi, K. Takemoto, H. Uchikawa and S. Takagi (7) ascertained that in the first 3 minutes slight hydration-reactions of the calcium-silicates and violent reactions of the aluminate-containing phases are to be expected. H. Schwiete and E. Niël (8) could follow by infrared measurements the reactions in which the sulphates are involved in the first minutes of the hydration. They came to the conclusion that in particular C_3A reacts in the first minutes, and that the reactions of the ferrite phase are of some importance only after about 15 minutes.

The calcium-hydroxide which is liberated during hydration can be measured by both analysing methods. Contrary to the X-ray measurements the hydrate could be established already in the first hour with infrared. The greater part of this calcium-hydroxide, however, was already present in the portland cement as free lime. Generally the amount of free calcium-hydroxide during hydration can be measured in a more sensible way with infrared. The little amount of syngenite, which has been formed in the first minutes of hydration reacts together with gypsum and the aluminate-containing phases. In Fig. 7 the measuring of the infrared absorption at 3400–3600 cm^{-1} is shown. In this absorption-band, many hydration products are represented. As there are uncertainties in the interpretations their diagram will not be further discussed.

Although not all the reaction products among which the important tobermorite phase could be measured, it is evident that the hydration-reactions of portland cement "M" are influenced by the presence of K_2CO_3. The larger is the amount of K_2CO_3. the larger is the share of the clinker phases and of gypsum in the reactions in the initial minutes. These reactions are promoted by the conversion of K_2CO_3 and gypsum, owing to which the regulating influence of the gypsum on the hydration-reactions decreases. This explains the effect of flash setting in the cement paste (high temperatures and early stiffening).

As a result of these conversions, the following salts appear at the various amounts of addition:

0.25% K_2CO_3—syngenite ($CaSO_4 \cdot K_2SO_4 \cdot H_2O$), little K_2SO_4 and $CaCO_3$

2.5% K_2CO_3—K_2SO_4 and $CaCO_3$

20% K_2SO_4–K_2SO_4 + $3K_2CO_3 \cdot 2CaCO_3 \cdot 6H_2O$ (in addition to non-converted K_2CO_3)

The aluminate phase and the ferrite phase react within a few minutes with the above-mentioned calcium salts. This is shown by the detection by means of X-ray diffraction of ettringite after 3 minutes (at 0% K_2CO_3), of ettringite immediately after gauging (at 0.25% K_2CO_3), of ettringite followed immediately by carbo-aluminate (at 2.5% K_2CO_3) and of only carbo-aluminate (at 20% K_2CO_3).

The formation of carbo-aluminate confirms the observations of K. T. Greene (10), who found peaks in the D. T. A.-curve of alkali carbonate-containing cement after 24 hours of hydration (W/C ratio 0.35) at room-temperature. These peaks bore a marked resemblance to the curve for the mono-carbo-aluminate given by Turriziani and Schippa. R. F. Feldmann, V. S. Ramachandran and P. J. Sereda (11) found that the hydration-reaction of C_3A is suppressed by $CaCO_3$-additions.

This is due primarily to the formation of the low form of calcium carbo-aluminate on the surface of the C_3A. The important addition of 20% K_2CO_3 does raise the temperature of the cement paste. Å. Grudemo (12) mentioned that the carboaluminate is not stable at a higher temperature. This is also visible in the course of the $C_4A\overline{C}H_{11}$-curve given in Fig. 12. The initial formed carboaluminate is not stable after a few minutes of hydration. Mono-sulphate and other aluminate-hydrates could not be proved on account of difficulties at the measurements.

In the initial period reactions causing the stiffening occur in the cement paste. In the cements containing potassium-carbonate, this stiffening is a direct result of the hydration-reactions, not controlled enough by Ca^{++}-ions. Obviously the stiffening starts by reactions of the aluminate-containing phases, as is established at the cement "M". At an addition of 0.25% K_2CO_3 the stiffening starts, under the influence of reactions of the ferrite phase. The stiffening will no doubt be supported by the formation of poor soluble calcium salts such as $CaCO_3$, $3K_2CO_3 \cdot 2CaCO_3 \cdot 6H_2O$ and $CaSO_4 \cdot K_2SO_4 \cdot H_2O$ (1).

After the rather important conversions in the initial minutes, C_3S and C_2S hardly react in the first hour of the hydration process. In this period the loss on ignition also hardly changes. Although rather important reactions occur, in which the aluminate-containing compounds are involved, the amount of fixed water hardly increases during the first hour. This may be an indication that the hydration products react mutually with the aluminate, ferrite phase or with one of the salts.

Period of Strength Development

In the first hours of this period the reactions, which

initiate the increase in the strength, start. The development of strength, such as measured at the mortar prisms, follows for portland cement practically a straight line, from the moment of the strength of 10 kg/cm² was measured till the strength at 24 hours of hydration. Also for portland cement "M" with an addition of 0.25 % K_2CO_3, the development of strength follows practically a straight line. The consumption of clinker components during the reactions in this period is in accordance with this representation. In the period that the hardening is initiated, rather important reactions take place, which are accompanied with the decrease of the amount of clinker components and a considerable increase of water, fixed during the hydration, as may be concluded from the determinations of the loss on ignition.

As far as the increase of the hydration products at portland cement "M" can be observed, C_3A reacts first with gypsum or with $CaSO_4$ from syngenite, probably to form mono-sulphate to react then with $Ca(OH)_2$, which is released at the hydration of lime and calcium silicates, under the formation of C_4AH_{13}. Although this product disappears partly within 2 hours of hydration, from 10 to 24 hours of hydration, a steady decrease of C_3A and an increase of calcium aluminate may be observed. This is accompanied with a slight decrease in ettringite. The K_2SO_4 which shows up after 8 hours of hydration may be formed as a result.

During the hydration of portland cement "M" with 0.25 % K_2CO_3 approximately the same pattern is shown. Again an increase of the loss on ignition, which is stronger till 9 hours of hydration than afterwards. C_3A reacts at about 6 hours of hydration less strongly than in the cement free from carbonate. After 16 hours C_3A reacts, however, while forming C_4AH_{13}. For the cements containing alkali-carbonate (2.5 and 20 %) the course of hardening differs from the portland cement "M". After obtaining measurable mortar strength this increase is at about 11 respectively 6 hours proportional, to change then into a less steep increase of strength. With 2.5 % K_2CO_3 the reactions develop most intensely in the first hours after hydration. The steep decrease of calcium silicates and C_3A is in accordance with the great development of heat. H. N. Stein (13) already mentioned that the heat development in this period of hydration is increased by the addition of alkali-carbonate to the portland cement. This heat development increases the paste temperature (see Fig. 4b). This will be the reason for the rather strange behaviour of the $Ca(OH)_2$-curve in the first hours of hydration.

In this period ettringite is fully disintegrated, the amount of carbo-aluminate increases, as well as the amount of free lime, of this increase something is retracted by reactions, in which besides $Ca(OH)_2$, also K_2SO_4 is involved (probably formation of mono-sulphate). The increase of the loss on ignition and free lime after 12 hours of hydration is very slight. Also the decrease of the clinker components is slight; only a temporary, weak revival of C_3A at about 14 hours simultaneously with an increase of carbo-aluminate may be ascertained. At an addition of 20 % K_2CO_3 the initial strength can be measured already after well over half an hour. In this period the temperature in the paste has also highly increased. The very strong development of strength, which follows hereupon, stops at about 5 hours. The basis for this course is already formed by the reactions during gauging. For any paste the decrease of the aluminate-containing phases and of calcium silicates is very important. The lime which is formed by the hydration-reactions of C_3S and C_2S in the environment rich in potassium-carbonate, is absorbed by the aluminate-containing phases in the form of carbo-aluminate. Lime is still formed, but for a few minutes no longer absorbed by C_3A. The decrease of C_3A, which is measured, shows that it still takes part in the hydration-reactions after the initial period. This is weak till 4 hours of hydration, but it is strong between 4 and 6 hours. The first hour after the initial reactions, the carbo-aluminate decreases, because it is not resistant to the high temperature, which has developed in the meantime, as well as the $Ca(OH)_2$ and increases then strongly between 4 and 6 hours in content, also again in the same order as in the initial phases. At the end of the first day, after 16 hours of hydration, C_3A is again remarkable active. The double-salt $3K_2CO_3 \cdot 2CaCO_3 \cdot 6H_2O$ is then disinte grated, $CaCO_3$ is formed, which partly combines with C_3A to carbo-aluminate.

Conclusion

The hydration of portland cement "M" was clearly influenced by the presence of potassium-carbonate. After correction on the loss on ignition, the consumption of clinker components during the hydration of portland cement "M" could be followed clearly by X-ray measurements.

These reactions are in accordance with the observations at the tests on stiffening and strength develop-

ment of the same cement. Less complete is the representation of the hydration products. Partly they are not apparent in this mixture of components or only measurable after they are either present in larger amounts or crystallized sufficiently. A particular case is the $Ca(OH)_2$-measurement with infrared spectrography or with X-ray diffraction. Although the large changes are observed with both methods, the infrared measurement is somewhat more sensitive, especially in the first hour and the last phase of the hydration. The following reactions and phenomena have been observed more in detail.

Setting

The gypsum present in cement, is converted during the period of gauging fully or partly by the potassium-carbonate into K_2SO_4, $CaCO_3$ or in the double-salts $3K_2CO_3 \cdot 2CaCO_3 \cdot 6H_2O$ and $K_2SO_4 \cdot CaSO_4 \cdot H_2O$. Owing to this gypsum and even a part of the calcium-ions ($Ca^{++} \rightarrow CaCO_3$) can no longer act as setting regulators. In this environment in which the concentration of the K^+-ions has been increased, the aluminate-containing phases react violently.

Dependent on the added amount of K_2CO_3 other reactions occur. Although not all the hydration products can be detected, the impression exists that, when 0.25% K_2CO_3 is added, the initial reactions are activated. Since sufficient gypsum is available for the formation of ettringite, the aluminate phase reacts faster and to a larger extent, while forming more ettringite than in samples without addition from alkali-carbonate. Owing to this, a better retarding envelopment is formed on the clinker particles, resulting in the absence of reactions of C_3A for a relatively long period. At the consistency measurements in the paste, this is reflected in a retardation period in the stiffening process. At a higher K_2CO_3-percentage (2.5%) all the gypsum starts reactions already during the gauging period. An amount of gypsum equivalent to the K_2CO_3-content converts into K_2SO_4 and $CaCO_3$, whereas the rest of gypsum and a part of the calcium-carbonate reacts spontaneously with C_3A.

Since the heat development starts initially and the stiffening in the cement-paste still goes on for a while, it may be concluded that the protective activity of the combination of carbo-aluminate and ettringite is inferior. Due to this C_3A continues to react still very strongly in the first hour, and incites the C_3S and C_2S to a rather violent activity.

When gauging the mixture consisting of cement with 20% K_2CO_3, the C_3A as well as "C_4AF" react violently. These violent reactions are controlled for a few minutes by the initially formed carbo-aluminate. This is, however, at the temporary high temperature of the paste not stable enough so that under breakdown of this hydrate, the stiffening process may go on.

The consequence of the temporary retardation of the hydration is that the setting times of cement with 20% K_2CO_3 are somewhat longer (about 10 minutes) than at the lower percentages (about 3 minutes).

Also the calcium-silicates in the clinker reacts differently due to the presence of potash. However, the initial reactions in portland cement "M" are small, the amount of C_3S which reacts in the cement-pastes rich in K_2CO_3 is considerable. Especially the splitting off of calcium-hydroxide, which is due to this reaction, will be sufficient for formation of $CaCO_3$. The crystallization of poor soluble calcium salts like $CaCO_3$, $3K_2CO_3 \cdot 3CaCO_3 \cdot 6H_2O$ and $CaSO_4 \cdot K_2SO_4 \cdot H_2O$ will support the early stiffening of the alkali-carbonate-containing cement-pastes.

Strength

After 5 hours of hydration an initial strength in mortars has been measured, this strength increases gradually till 24 hours. Mortars containing much potassium-carbonate do not react in the same way. The increase of strength till 12 hours after gauging is greater than from 12 to 24 hours. The hydration mechanism will be responsible for this. In the paste containing hardly any alkali-carbonate the course of hydration-reactions during the first day is such that a continuous decrease of the clinker phases can be recorded. At higher percentages of alkali-carbonate these reactions are rather important during the first few hours, after which at 8–11 hours a period of relative rest sets in, which goes on till the end of the first day. This decrease in strength development is explicable with the reactions of the fresh C_3A to carbo-aluminate, owing to which the clinker particles are well enclosed again.

The writer wishes to express his appreciation to the co-workers of the ENCI-Research Department for their assistance in the preparation of this paper. He is indebted to Mr. S. Brouns for his assistance in carrying out the X-ray measurements and to Mr. V. Vaessens for the infrared measurements.

Supplementary Paper II-129 Aqueous Phase in Portland Cement Pastes Containing Soluble Chloride Ion

Kenneth T. Greene and Kenneth E. Palmer*

Synopsis

Data which can be used as a basis for determining whether the aqeuous phase in a cement paste at any particular early age is undersaturated, saturated, or supersaturated with respect to gypsum and calcium hydroxide are useful in studies of cement hydration, and are pertinent to various theories which have been proposed to explain early stiffening phenomena. This paper presents such data for pastes containing calcium chloride in concentrations equivalent to those commonly used in concrete.

Concentrations of Ca^{++}, OH^-, and SO_4^{--} are reported for solutions in equilibrium with both $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ at 25°C, and which contain potassium from 0 to 0.20 mole per liter expressed as $(K^+)_2$ and chloride from 0 to 0.27 mole per liter expressed as $(Cl^-)_2$.

Extracts from actual cement pastes containing calcium chloride were analyzed and concentrations of the various ions compared with the determined equilibrium values. The data indicated that marked supersaturation with either $Ca(OH)_2$ or $CaSO_4 \cdot 2H_2O$ or both may exist in such pastes during the first few minutes after mixing.

Introduction

Freshly mixed portland cement pastes or slurries are not in equilibrium with respect to the ions in solution, and a knowledge of conditions of unsaturation, saturation, or supersaturation is useful in studies of early hydration reactions and early stiffening phenomena. The aqueous phase in a paste without admixture is predominantly a solution of the following ions: Na^+ and K^+, Ca^{++}, OH^- and SO_4^{--}. Some CO_3^{--} ions are invariably present as a result of carbonates in the cement or from atmospheric carbonation of the solution after mixing. CO_3^{--} ions often can be neglected, but an estimation of CO_3^{--} concentration is desirable to insure that carbonation has not been excessive.

Silica, alumina, iron and minor elements are also present in some form in the solution, but their concentrations are very much lower than those of the ions mentioned above. They may affect the properties of fresh cement pastes to a greater extent than now realized, but they can scarcely have any major effect on the solubility relationships of gypsum and calcium hydroxide, which many cement chemists regard as highly pertinent to early stiffening problems.

Hansen and Pressler (1) determined the composition of solutions containing varying concentrations of alkalies which were saturated with both gypsum and calcium hydroxide at 25°C and 30°C. Their data demonstrated that at a given temperature, the equilibrium or saturation concentrations of Ca^{++}, SO_4^{--} and OH^- ions, as determined by analysis, are fixed by the total concentrations of Na^+ and K^+. They provided a basis for determining whether the aqueous phase in a cement paste at any particular early age is unsaturated, saturated, or supersaturated with gypsum and calcium hydroxide.

Calcium chloride, a common admixture, is added to concrete to accelerate setting and hardening, particularly in cold weather. The presence of chloride ions in the aqueous phase of the cement paste alters the equilibrium concentrations of Ca^{++}, SO_4^{--} and OH^- ions in contact with gypsum and calcium hydroxide so that the Hansen and Pressler data cannot be used. The work reported in this paper was done to provide information similar to that of Hansen and Pressler for the aqueous phase of concrete containing chloride ion, since such data could not be found in the literature.

Hansen and Pressler showed that the effects of sodium and potassium were essentially equivalent and that mixtures of the alkalies gave very nearly the same

*Ideal Cement Co., Colorado, U.S.A.

results as the individual elements when converted to a molar basis. For this reason, potassium was used in the present study, except for two experiments using sodium. The following table shows the results obtained with two solutions of NaCl compared to two solutions of KCl of equal molarity.

	(Moles per liter)			
Alkalies	Ca^{++}	SO_4^{--}	$(OH^-)_2$	CO_3^{--}
$0.100(NaCl)_2$	0.0454	0.0208	0.0226	0.0013
$.100(KCl)_2$	.0462	.0216	.215	.0018
$.200(NaCl)_2$	.0501	.0263	.236	.0016
$.200(KCl)_2$	.0536	.0292	.0248	—

We report here the concentrations of Ca^{++}, SO_4^{--} and OH^- in equilibrium with gypsum and calcium hydroxide at 25°C for solutions containing potassium from 0 to 0.20 mole per liter expressed as $(K^+)_2$ and chloride from 0 to 0.27 mole per liter expressed as $(Cl^-)_2$. This latter level of chloride is approximately equivalent to the initial concentration in the aqueous phase of concrete of W/C = 0.50 to which 2 percent of $CaCl_2 \cdot 2H_2O$ by weight of cement has been added. This is usually the recommended upper limit of calcium chloride addition.

In the absence of chloride, the aqueous phase is a four-component system (considering mixed alkalies as one component) with three compositional degrees of freedom. If we stipulate that the two solid phases, gypsum and calcium hydroxide, must both be present in excess, we reduce the compositional degrees of freedom to one. If in addition we fix the level of alkali concentration and perform the experiment at a constant temperature and at one atmosphere pressure, the system becomes invariant, which means that the concentrations of Ca^{++}, SO_4^{--} and OH^- are also fixed. With chloride present, the compositional degrees of freedom increase by one and we must fix the chloride concentration as well as the alkali concentration in order to have an invariant system.

From the above relationship it follows that, if we know the total concentrations of alkalies and of chloride in any given cement extract, we can then determine the concentrations of Ca^{++}, SO_4^{--} and OH^- which represent the saturation conditions for $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ in that particular extract at the temperature in question.

When the solution is saturated with $CaSO_4 \cdot 2H_2O$, the ion product $(Ca^{++})(SO_4^{--})$ will be equal to a fixed value determined by the concentrations of alkalies and chloride. Likewise, at saturation with $Ca(OH)_2$ the ion product $(Ca^{++})(OH^-)^2$ will be fixed. These equilibrium or saturation products can be estimated from the data reported in this paper. By calculating the ion products in actual analyzed cement extracts and comparing them with the equilibrium or saturation products, we can determine whether the solutions are saturated, undersaturated, or supersaturated with respect to these phases and the approximate degree of supersaturation or undersaturation. An analytically determined product greater than the equilibrium product indicates supersaturation, while an analytical product smaller than the equilibrium product indicates undersaturation.

Materials and Methods

The solutions were made up from analytical reagent chemicals and distilled water which had been freshly boiled and cooled to room temperature to remove dissolved carbon dioxide. Starting solutions whose K:Cl molar ratio was less than 1 were prepared with mixtures of KCl and a standard solution of $CaCl_2$. Solutions with a K:Cl ratio greater than 1 were made with mixtures of KCl and K_2SO_4. One hundred ml. of each solution was prepared in a volumetric flask, then transferred to a 250-ml. conical flask. Sufficient solid $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ were added to saturate the solutions and leave a definite excess. The flasks were stoppered, and stored (with occasional shaking) for several days at approximately 25°C. Preliminary tests indicated that equilibrium was reached rather rapidly and that one week was more than sufficient.

Before filtering, the flasks were placed in a water bath at 25° ± 1°C for several hours. The solutions were filtered rapidly and aliquots taken for analysis.

We analyzed for Ca^{++}, SO_4^{--} and Cl^- by standard gravimetric or volumetric procedures. Hydroxide was determined by titration with dilute HCl or HNO_3. Carbonate was estimated in several of the solutions by titration to a pH of 8.5 to indicate the OH^- plus approximately one-half of the CO_3^{--}, followed by further titration to a pH of 3.9, which gave the OH^- plus essentially all the CO_3^{--}.

Concentrations were calculated with the aid of the following formulas:

For hydroxide: 2P − M
For carbonate: 2(M − P)
Where P = volume of standard acid to reach pH 8.5
M = volume of standard acid to reach pH 3.9

Potassium (K^+) concentrations were not determined analytically in the equilibrium experiments, but were taken to be those of the original solutions. We disregarded the very small change in K^+ and Cl^- concentrations caused by the solution of the $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$. In experiments to be described later, in which actual cement extracts were analyzed, alkalies were determined by the flame photometer method.

Results

Solubility Studies

The compositions of the various solutions in equilibrium with solid $CaSO_4 \cdot 2H_2O$ and $Ca(OH)_2$ at 25°C are presented in Table 1. Since concentrations are expressed as moles per liter of $(K^+)_2$, $(Cl^-)_2$, Ca^{++}, SO_4^{--}, $(OH^-)_2$ and CO_3^{--}, all ions are on an equivalent basis and can be compared to one another without regard to valence. Four groups of data from Hansen and Pressler (1) for chloride-free mixes are included in the table.

It will be noted that about half of the $(Cl^-)_2$ values were determined by analysis, whereas the others were calculated by difference, i.e. the difference between the sum of the cations and the sum of the other anions. This is justified by the principle of electrical neutrality and the absence of appreciable quantities of other ions. In all cases where all the ions were determined analytically, the sums of the cations were in satisfactory agreement with the sums of the anions.

The data in Table 1 are shown graphically in Figs. 1, 2 and 3, in which the concentrations of Ca^{++}, SO_4^{--} and $(OH^-)_2$ are plotted against $(Cl^-)_2$ content at five levels of $(K^+)_2$ concentration.

Cement Extracts

To illustrate the application of the data, we studied several commercial cements by analyzing solutions extracted a few minutes after mixing. The water-cement ratio was 0.50 by weight in all cases, and calcium chloride was added to the mix water at the rate of either 1% or 2% $CaCl_2 \cdot 2H_2O$ by weight of cement. The data are presented in Table 2.

The equilibrium concentrations of Ca^{++}, SO_4^{--} and $(OH^-)_2$ in the cement extracts at the determined total alkali and chloride concentrations were estimated by interpolation from Figs. 1, 2 and 3. We then calculated the equilibrium ion products and compared them to the products calculated from the analytically determined concentrations of the ions so that saturation conditions could be determined. Table 3 shows these comparisons and the conclusions which were drawn.

Discussion

The data in Table 3 suggests that in cement pastes containing calcium chloride, some supersaturation with gypsum commonly exists up to approximately 15 minutes after mixing. Supersaturation with calcium hydroxide also appears to be common during this period and may sometimes be quite strong, giving ion products over twice the equilibrium value. The study of extracts as it applies to the hydration reactions and physical behavior of fresh cement pastes containing calcium chloride admixture would appear to be a fruitful area of research.

Supplementary Paper II-134 The Effect of Tricalcium Aluminate on the Hydration of Tricalcium Silicate and Portland Cement

Adriano Celani, Pietro A. Moggi and Arturo Rio*

Synopsis

The effect of tricalcium aluminate, present in portland cement in variable percentages, on the hydration kinetics of tricalcium silicate and development of mechanical strengths at early and later ages has been investigated.

To this aim, by means of physical-chemical measurements, the hydration of cements containing various percentages of tricalcium aluminate, with or without gypsum and with or without calcium chloride additions has been followed in the time.

The experimental results altoghther show the positive effect of tricalcium aluminate contents increasing up to an optimum value on the hydraulic properties of portland cement, and permit us to formulate some interesting hypothesis on the nature of hydration processes.

Introduction

In recent years several investigators have devoted themselves to study the reactions of hydration of cement and its compounds, with or without additions. These researches not only aimed at explaining the complex chemical-physical processes occurring by cement hydration, but tended often to state the best conditions to be realized for controlling setting and hardening processes in order to meet the latest requirements of the modern building technology. The problem of the first rank is how to obtain a sharp increase of mechanical strengths, especially at the early ages. Gypsum and calcium chloride have resulted to be the most affective additions in this regard, acting the former principally as a regulator of the setting phenomena and the latter by accelerating the hydration process of the most hydraulic compounds of cement (1, 2, 3).

Whilst it was studied hard for the hydration of the single cement compounds, C_3S, beta-C_2S, aluminates and ferrite phase, as well for the effects of addition compounds, such as gypsum and calcium chloride, little or nothing was done, on the other hand, to know how the compounds themselves influence each other, during hydration, when that structure develops which all they contribute to form.

In the group of cement compounds, C_3A is often regarded as useless, or deleterious because of the troubles it brings about by its rapid setting; its hydraulic properties are questioned and its action seems to be limited to make possible the clinker burning at no very high temperature (4). Actually, when pure tricalcium aluminate undergoes hydration the product obtained after quick set, under an intensive heat evolution, shows very low strengths, which scarcely increase with the time.

Nevertheless, some decades ago, many investigators (5, 6) noted, from their sometimes also contradictory results, that mixtures prepared by adding even appreciable C_3A amounts (19 and 15 per cent) to the other more sharply hydraulic compounds of cement, like C_3S and beta-C_2S, show strengths higher than those expected from additivity, or even higher than the strengths of pure C_3S, beta-C_2S or their mixtures at the same ages. The phenomenon occurs, sometimes emphasized, also when gypsum is added to the mixture.

It is evident that the significance of such results must have been undervaluated; indeed, since then on, the literature does not report any research thereon.

This feeling of a possitive effect of C_3A on the strength development may be indirectly confirmed by some data, deducible from W. Lerch's work (7), which refer to the influence of gypsum on portland cement hydration. Comparison between the mechanical strengths of cements containing different C_3A and equal alkalies shows that such strengths generally increase with the C_3A content, this effect being more remarkable at the early ages.

We have often noted this phenomenon by con-

*Soc. Calci e Cementi di Segni, Laboratorio Centrale, Rome, Italy.

trolling the strength development of cements, with different C_3A amounts, produced in several factories.

A systematic research was, therefore, undertaken to investigate the influence of the tricalcium aluminate present in various proportions in portland cement on the hydration of cement compounds, specifically C_3S, as well on the strength development at the early and later ages.

The hitherto obtained results and the possible deductions are the subject of the present paper.

Experimental

According to the considerations and purposes previously spoken of, a series of preliminary tests was carried out for determining the influence of C_3A on the hydration and strengths of portland cement. The tests were done on mixtures of C_3S and C_3A, prepared with pure compounds. The percentage of C_3S was kept constant, whereas that of the C_3A was variable. The mixture was completed with $CaCO_3$. Each mixture was added with 5 per cent of gypsum and the compressive strength at 1, 7 and 28 days was determined on 4 cm cubes of I.S.O. mortar 1:3, *w/c* ratio 0.50. The results are given in Table 1.

These results indicated that the highest strength is found with C_3A content ranging from 2 to 5 per cent, and that there was a very remarkable difference of behaviour between the addition of C_3A and that of the only carbonate of equal fineness.

Other preliminary tests for compressive strengths at 1, 3, 7 and 28 days were performed on specimens similar to the above, but made up with clinkers of different industrial source. These were corrected with an addition of pure compounds for obtaining an equal percentage of C_3S, thereafter they were reburnt and ground with 5 per cent of gypsum to the same fineness.

Table 1. *Compressive strengths of mixtures of pure compounds*

Compounds %	C_3S	80	80	80	80
	C_3A	—	2	5	10
	$CaCO_3$	15	13	10	5
	$CaSO_4 \cdot 2H_2O$	5	5	5	5
Compressive strengths kg/cm²	1 day	70	90	82	60
	7 days	144	208	184	178
	28 days	250	345	325	288

The results are given in Table 2 wherein all strength values are the average of two determinations.

Table 2. *Compressive strengths of industrial cements with the same C_3S percent*

Mineralogical composition %	C_3S	58.14	61.02	58.79
	C_2S	22.24	15.65	20.22
	C_3A	3.41	5.10	8.77
	C_4AF	12.29	13.81	9.12
Compressive strengths kg/cm²	1 day	138	194	142
	3 days	330	452	374
	7 days	391	502	459
	28 days	560	680	618

The positive effect of C_3A on the strengths appears clearly also from this series of measurements which besides confirms the presence of an optimum amount of C_3A ranging, in this series, from 5 to 8 per cent.

At this point, four clinkers were prepared by burning mixtures of pure $CaCO_3$, SiO_2, Al_2O_3 and Fe_2O_3 for 4 hours at 1450°C in order to prosecute the tests on materials of homogeneous chemical and physical properties. The mixtures were so proportioned to give burned products with constant C_3S and C_2S content (nearly 50 and 25 per cent respectively) and variable C_3A content (nearly 3, 5, 10, 15 per cent), the remaining being the ferrite phase.

After burning, the clinkers were cooled in air, ground in porcelain mills, analyzed by chemical analysis and submitted to successive burnings with the same procedure as before, till the complete disappearance of free lime. The final analysis of the four clinkers and the mineralogical compositions, calculated according to Bogue, are reported in Table 3.

The mineralogical composition of the four clinkers was also examined experimentally by reflected light microscope. The micrographs obtained are given in Fig. 1. The examination resulted to be in good aggreement with the mineralogical compositions calculated as above.

The clinkers were ground to an equal fineness corresponding to a residue of 15 per cent on the 40 micron sieve and to a Blaine specific surface of 3500 cm²/g. They were then utilized partly so as they were, partly with gypsum added.

The gypsum addition had been calculated in order

to obtain a constant $C_3A/CaSO_4$ ratio for all four cements. It was roughly corresponding to the optimum gypsum content, as derived from W. Lerch's data (7) and a control was once more made on it by the chemical method of extraction with water and determination of SO_3 soluble, as proposed by the same author (A.S.T.M. C265–58T).

By this way it was tried that each cement had the best SO_3 concentration for developing strengths and an equal ratio during hydration between the C_3A combined as sulphoaluminate and the C_3A available, in order that the effect of the latter may be better isolated. The mineralogical compositions of the cements after addition of gypsum are reported in Table 4.

In connection with previous studies (3) of the influence of gypsum on the hydration process, tests were carried out by adding a constant amount of $CaCl_2$, corresponding to 2 per cent by weight of cement, dissolved in the mixing water.

With the cements prepared as described, a number of researches was made for studying the influence of different amounts of C_3A on the course of hydration of the tested cements using the following parameters:

—Mechanical strengths
—Hydration rate and extent of hydrolysis
—Development of the specific surface of hydrated pastes.

Table 4. *Mineralogical composition of cements with gypsum added*

Mechanical Strengths

The various cements were used to prepare 4 cm cubes of I. S. O. mortar 1 : 3, mixed with a constant water amount, corresponding to a *w/c* ratio of 0.5, although the consistency, measured according to the A.S.T.M. C 230–61 method, resulted clearly tending to increase with higher C_3A contents.

The compressive strengths were determined at 1, 3, 7, 28 days. The obtained values are given in Table 5.

The development of the strengths in the time may be seen on the graphs in Fig. 2.

From the results, the following considerations can be made:

—The compressive strengths at various ages show a maximum in correspondance of one of the four cements, or better, of a determined percentage of C_3A.

—For the same cement, the strengths are sharply higher for addition of gypsum and moreover of calcium chloride. The overall course is yet the same in the three series, therefore the addition of gypsum and calcium chloride does not alterate the effect of the different proportion of C_3A.

—The position of the maximum strength shifts from high C_3A contents at the early ages to low C_3A contents at the subsequent ages. Indeed, while at 3 days the maximum of strengths is found between cement III and IV, it has passed at 28 days between cement I and II.

To have also a quantitative indication on the development of the phenomenon, the strengths at a given age have been assumed as varying with the C_3A content according to a function of parabolic type and the maximum of such a function was calculated thereafter analytically. The obtained values for the C_3A content in correspondance to the maxima are gathered in Table 6.

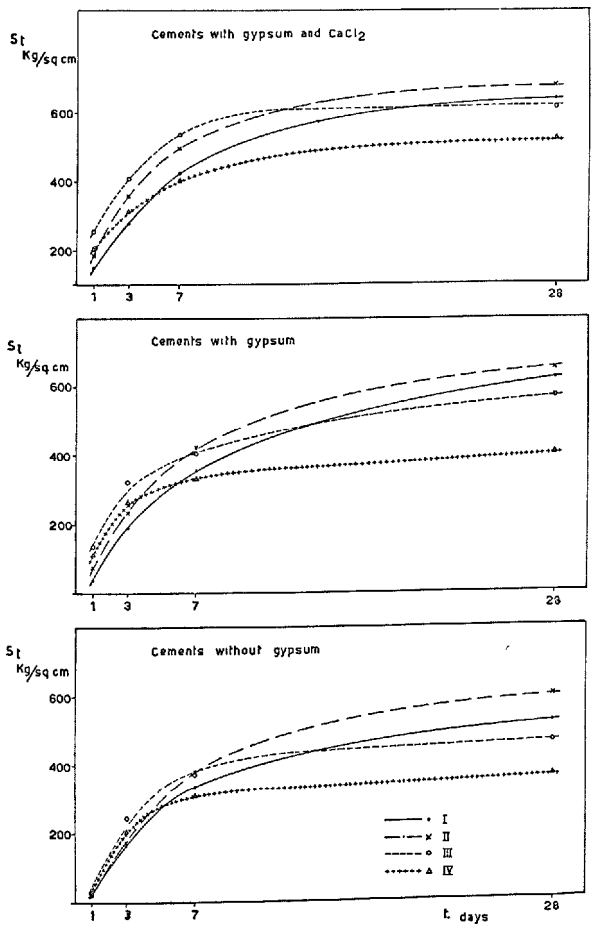

Fig. 2. *Compressive strengths vs. time*

Rate of Hydration and Extent of Hydrolysis

As we have done in earlier studies of hydration processes (1, 2, 3), we based our investigation on determination of hydrolysis lime and on analysis of the contact solution with cement paste.

Furthermore, for studying the rate of hydration of cements, we used the determination of the non-evaporable water content. Finally we have carried out

measurements of the specific surface to investigate the variations of this parameter with time, relating it to the course of hydration and to the development of strengths.

The determination of the free lime content in cement pastes was also used by other investigators (8) as an indirect method for studying the rate of hydration of the C_3S and C_2S in cement.

Furthermore, we found it useful to take into account also the measurement of the lime supersaturation of the contact solution. Indeed, it is known that the contact solution with portland cement pastes presents supersaturation phenomena at the early ages since the rate of passing into solution of the hydrolysis lime is greater than that of precipitation of the lime itself from the solution, according to the equilibrium

$$Ca(OH)_2 \text{ Solution} \rightleftarrows Ca(OH)_2 \text{ Solid}$$

This brings about a progressive accumulating of lime in the contact solution beyond the supersaturation value, which continues till the rate of precipitation of the lime becomes higher than the rate of its going into solution. At this moment, a maximum of the supersaturation is reached, and subsequently this decreases more or less rapidly.

Since the rate of hydrolysis of C_2S is negligible, the supersaturation of the contact solution may be considered as resulting from an equilibrium between the rate of hydration of the C_3S alone and the rate of precipitation of the lime, whereas the variation with the time of the free lime content of the solid phase will be influenced also by the hydrolysis of C_2S.

The content of non-evaporable water at the various ages, determined under equal conditions for all samples was assumed by a number of investigators (9) as index of the fixed water amount in the hydration products and therefore as a criterion for the measurement of the extent and rate of the cement hydration.

Finally, in many studies (10) the development of the specific surface of hydrated pastes in the time has been related to the extent and the rate of hydration of cement and its components. Furthermore, it is evident that there is a correlation between specific surface and mechanical strengths of a cement during hydration.

In the first series of test for studying the rate of hydration of C_3S at the early ages, all samples were hydrated with a w/c ratio $= 5$, in order to have a sufficient quantity of solution to analyze, and kept in a thermostat at 40°C till ages of 1, 2, 4, 8, 16, 24, 28, 72, 120 hours. At the end of the curing, the suspension was filtered rapidly in a CO_2 free atmosphere, while the solid phase was ground in a mortar with alcohol to interrupt the hydration, filtered again in the same a CO_2 free conditions, washed with ether and oven-dried for 2 hours at 105°C, in stream of CO_2 free air.

On the dried solid the free lime was determined, according to the T. V. M. method (11), by extraction in boiling by the solvent mixture isobutyl alcohol (87%)—acetoacetic ester (13%) and subsequent titration of the extract with isobutylic perchloric acid, thymol blue as indicator.

On the dried solid the ignition loss at 950°C was also determined. The alkalinity of the filtered solution was determined by titration with HCl, using methyl orange as indicator, and the CaO concentration was determined by complessometric titration with EDTA, using calconcarbonic acid as indicator.

The SO_3 concentration of the contact solutions with the cement samples with gypsum was determined by nephelometry. Finally, for the series to which also calcium chloride was added, the Cl^- ion concentration was determined by titration with $AgNO_3$ according to the method of Fayans, with fluorescein as indicator.

For cements without gypsum addition, the CaO concentrations at the equilibrium were calculated by means of the lime-alkali isotherm at 40°C (12). In the case of cements with gypsum addition it was necessary to examinate the more complex equilibrium CaO–SO_3-alkali (13, 1). Finally, for the series with calcium chloride also the CaO amount corresponding to the Cl^- ion concentration was considered.

The extent of the lime supersaturation of each solution is derived from the difference between the value of the CaO concentration found and the CaO concentration at the equilibrium.

The course of the CaO supersaturation of the three series of samples is reported as function of the time on the graphs in Figs. 3–4–5. On the side of each figure appears, enlarged, the evolution of free lime at the early stages of hydration.

The following observations can be done:

—The rate of hydrolysis of the C_3S increases with the C_3A content without a maximum being evident, at least in the field of the compositions examined. On the other side, it may be noted that the differences between the maximum supersaturations are not proportional to the differences between the C_3A contents, therefore a maximum should be nevertheless present for the rate of hydration of C_3S at the early ages, in correspondence to a given C_3A content.

—The accelerating effect of gypsum and calcium

B) *Cements with gypsum*

chloride on the hydration is also evident; indeed the maxima of supersaturation of the three series are about in a ratio of 1 : 1, 4 : 3.

In the series with calcium chloride the maxima of supersaturation are very close to each other because the marked accelerating action of this salt conceals the differences due to the different C_3A content.

Within the earliest hours the free lime amount increases with increasing C_3A, without maxima being present, but already within the twelfth and the sixteenth hour a maximum free lime amount appears in correspondence of cement III. This observation agrees both with the results from the supersaturation and with the progressive shifting of the maximum of

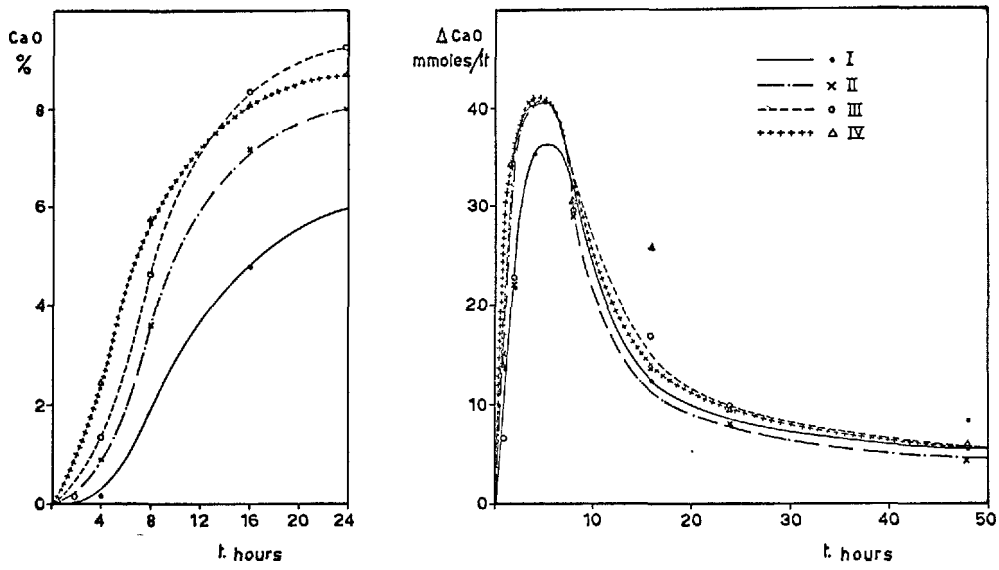

Fig. 5. *Development of* CaO *of hydrolysis at early ages and supersaturation of contact solution with cement pastes*
C) *Cements with gypsum and* $CaCl_2$

strengths towards lower C_3A contents which was observed during the course of hydration.

It is important to remark that the free lime amount in the solid phase, after the earliest hours, is clearly free from contributions due to the C_3A hydration which, by means of a mechanism "through solution" (14), could affect the supersaturation degree of contact solution. Therefore, from the differences found for the free lime amounts, the influence of C_3A on the rate of hydration of silicates appears evident.

In a second series of tests, all samples have been submitted to hydration as a paste with *w/c* ratio = 0.5. The pastes were kept in thermostat at 25°C till fixed ages of 1, 3, 5, 7, 14, 28, 60, 90 days. At the end of the curing the hydrated paste was treated with the same procedures as used for determinating the supersaturation. On the dried solid the free lime content and the loss on ignition at 950°C were determined.

From the free lime amount, the extent of hydrolysis was calculated, defined as the ratio between the amount of lime developed by hydrolysis at a given age and the amount of lime developed at the end of the hydration. To calculate the latter value, it was assumed that the stoichiometry of the hydration of the C_3S and beta-C_2S in the paste form be represented by the equations [1] and [2] (15).

$$2C_3S + 6H_2O = C_3S_2 \cdot 3H_2O + 3Ca(OH)_2 \quad [1]$$

$$2C_2S + 4H_2O = C_3S_2 \cdot 3H_2O + Ca(OH)_2 \quad [2]$$

From the loss on ignition at 950°C the content of the non-evaporable water was derived.

The results obtained for free lime and hydrolysis extent of the three series of samples; cement without gypsum, cements with gypsum, cements with gypsum and calcium chloride, are reported in Table 7. All values are referred to as percentage of the original anhydrous material.

—The course in the time of the hydrolysis extent of silicates (Fig. 6) agrees essentially with the development of the strengths. The presence of a maximum shifting for all series with the time, from high to low C_3A contents, appears clearly at each age.

To confirm the results from the strength tests, the proportions of C_3S corresponding to the maximum extent of hydrolysis of silicates at the ages of 1, 3, 7, 28 days were calculated, also in this case, analytically. The results are given in Table 8.

As may be seen, the accordance is very satisfactory.

—On comparing the results of the three series of tests with each other, the favourable effect of gypsum and also of calcium chloride on the rate of hydration of silicates is as yet remarkable.

It may be controlled that for the same cement, at the early ages, the addition of gypsum brings about an increment of nearly 150 per cent, and a further addition of calcium chloride brings about an increment of nearly 250 per cent for the extent of hydrolysis. Nevertheless, the action of these additions ends at the early ages. In fact the hydration rate becomes almost identical for all samples already after 5 days, and the initial difference of the extent of hydrolysis tend to disappear.

In Table 9 there are reported the content of non-evaporable water of the hydrated pastes at various ages and the amount of the fixed water in the hydration products. This is calculated by subtracting the amount of the combined water in $Ca(OH)_2$ from the amount of the non-evaporable water.

The course of the non-evaporable water is affected both by the rate of hydrolysis of the silicates according to the above considered course and by the variable amount of the aluminates present. Generally it is noted that the amount of combined water increases within the same series with the tricalcium aluminate content. On passing from a series to another, the reactions of hydration to take into consideration become too much complex for an easy comparison.

Development of the Specific Surface of the Hydrated Pastes

The hydrated pastes of the cements with gypsum added, at ages of 1, 7, 28 days were tested for specific surface. The measurement was carried out by adsor-

ption of nitrogen from mixtures nitrogen-helium after the B.E.T. method (16) by means of a Perkin-Elmer Sorpmeter mod. 212-D. Before being tested, the sample were degased for two hours at 150°C in helium stream.

The results are reported in Table 10, whereas the development of specific surface of the various samples is plotted in Fig. 7 as a function of the time.

On comparing this development with those of strengths and hydrolysis extent obtained for the same series (Figs. 2b and 6b), a good agreement is observed. This is also confirmed by the values, given in Table 11, which refer to the calculation of the percentage of C_3A corresponding to the maximum specific surface at the various ages (see Tables 7 and 9).

Discussion of the Results

The experimental results may be summarized, on the whole, as follows:

The presence of increasing C_3A contents in a portland cement has a sharply positive action on the devel-

opment of the strengths, particularly at the early ages. Such influence tends to become less appreciable, or even deleterious, if C_3A is present in too high amounts, at the most advanced ages. This is at least the results at the conditions of at our test.

The presence of increasing C_3A contents affects catalytically the hydration of C_3S; the rate of the lime supersaturation of the contact solution with the cement pastes increases and earlier appear appreciable amounts of free lime in the solid phase.

The hydrolysis extent of silicates rises with the C_3A content, especially at the early ages. Afterwards, the influence of C_3A becomes less appreciable, or even if high amounts of C_3A are present, its effect is negative for the progressing of the hydration.

In the first stage of hydration, the specific surface of the hydrated pastes rises sharply with the C_3A content. At the subsequent hydration stages the cements of high C_3A present a very slow development of their specific surface.

The results from the measurements of compressive strengths, hydrolysis extent of silicates, and specific surface of the hydrated pastes are concordant in indicating the presence of an optimum C_3A amount for these quantities, which ranges from 10–11 per cent at the early ages to 6–7 per cent at more advanced ages.

We intend to extend our investigation to other cement series by varying the C_3S content for the various series, but keeping it constant, as we have already done, for each series.

Furthermore, gypsum and calcium chloride produce an accelerating effect on the cement hydration, acting particularly on the C_3S. However they do not appreciably alterate the influence of the C_3A and the optimum values of this constituent at the different ages.

Most of our experimental results seem to agree with the theories of W. Foster (14) and P. Rehbinder (17), as well with the recent views of A. Joisel (18) on the hydration mechanism of tricalcium aluminate in portland cement.

In the presence of water, tricalcium aluminate goes into solution and dissociates into its constituents to give, among other things, calcium ions. Lime and alumina in solution then recombine as tricalcium aluminate hydrate, or, if gypsum is present too, as calcium sulpho-aluminate. These compounds precipitate from the supersaturated interstitial solution in the colloidal form at first giving hydrophil products of high specific surface which adsorb other ions and large amounts of water. The contribution of such compounds to strengths is negligible. Later the colloidal hydrates crystallize as local agglomerates which assemble and grow to give greater crystals of well defined structure and chemical composition.

It seems to us that the interpretation of the influence of the aluminates on the calcium silicates during hydration, as given by Bogue and Lerch (6), be inacceptable. According to these authors, the increase of strengths at early ages would be due to a lowering of water amount available to silicates, that is, a kind of local reduction of the *w/c* ratio caused by the rapid hydration of aluminates.

It is known that cement pastes, after a rapid surface reaction, prosecute to hydrate very slowly because of the difficulty met by the water in penetrating into the internal structure.

Therefore, the effect of C_3A could be that of promoting, with the rapid hydration and the originary formation of highly hydrophil colloidal products the penetration of water to the interior, so that greater amounts of this become available for the hydration of silicates which is anticipated and its rate is increased.

For this reason, higher C_3A contents at the early ages would not only give products of high specific surface, but also produce an accelerating effect on the hydration of silicates and consequently on the passing into solution of hydrolysis lime as well on the strength development.

Successively, however, the aluminate crystallize with formation of crystalline products which by themselves give a negligible contribution to the specific surface of hydrated pastes and to the strengths. Moreover, they would hinder the progress of hydration of silicates with their occupying the intergranular space, and would bring about a solution of continuity in the gels of hydrated silicates. In the presence of high C_3A amounts that would negatively effect the development of specific surface, hydrolysis lime and strengths at later ages. It would, thereafter, establish a balance between a sharply positive initial action of the increasing C_3A content and a subsequent negligible or even deleterious one. That would result in the appearance of an optimum amount of this compound ranging from high contents, at the early ages, to lower values, at the more advanced ages.

The value of such an optimum per cent of C_3A will be, of course, dependent on the amount of the more sharply hydraulic products, such as C_3S, in the cement. A systematic study of the C_3A action in cement also at other levels of C_3S amounts shall be therefore interesting.

Gypsum and calcium chloride accelerate the hydrating of C_3S appreciably (3). Their effect on the hydration of tricalcium aluminate has not yet been investi-

gated thoroughly (18, 19). It seems us, however, it is lower than that on C_3S and the mechanism of hydration is not essentially modified by it. Indeed, the phenomena due to different C_3A contents keep their particular course in the presence of gypsum and calcium as well. The accelerating effect of these salts on the C_3S hydration has the only result of making the hydration of C_3A less noticeable at the early ages, which gives account for the slightly lower optimum values of C_3A for the extent of hydrolysis of silicates and for the mechanical strengths at different ages.

Conclusions

The results of our investigation demonstrate that tricalcium aluminate influences positively the rate of hydration of the other constituents of cement, particularly the tricalcium silicate, and the development of mechanical strengths, principally at the early ages.

This is of great practical importance for the production of rapid hardening cements without having to resort to the addition of substances, which, as calcium chloride, may bave secondary negative effects under certain conditions.

The significance of the obtained results shows clearly the need of prosecuting a thoroughly study on the mutual influence of the cement compounds during hydration.

Oral Discussion

Shigeru Yamane

I will make a brief discussion of the interesting paper of Dr. Celani and coworkers.

1. The authors stated that C_3A acts catalytically on C_3S. What is the mechanism of this catalytic action?

2. In order to clarify the effect of C_3A, I think it is necessary and important that not only the alkalinity and C_2O, SO_3, Cl^- but also Al_2O_3 and SiO_2 in the liquid phase have to be investigated. What is your opinion on this point?

3. The addition of calcium chloride certainly promotes the hydration of C_3A and C_3S. According to my experimental results, the addition of $CaCl_2$ increases rapidly the amounts of Al_2O_3 and SiO_2 in the liquid phase in early stage of hydration of cement. With much Al_2O_3 in the liquid phase, the concentration of SO_3 decreases rapidly due to the formation of ettringite type hydration product. Namely, there is the interrelation between the concentrations of SO_3 and Al_2O_3 in the liquid phase. These facts can be useful keys for the clarification of the above problem.

Oral Discussion

Hans N. Stein

There is an apparent contrast between the results obtained by Celani, Moggi and Rio (especially as regards data on CaO of hydrolysis at very early ages) and those reported by de Jong, Stein and Stevels (see Supplementary Paper II-35): whereas Celani c.s. report an acceleration of C_3S hydration by small amounts of C_3A, de Jong c.s. find a retardation.

However, it should be kept in mind that Celani c.s. investigated systems at 40°C, at which temperature the recrystallization of hexagonal hydrates to C_3AH_6 is quite different from that at 25°C. A second complicating factor may be that Celani c.s. investigated systems of a much more complex character than de Jong c.s.

Authors' Closure

Adriano Celani, Pietro A. Moggi and Arturo Rio

Reply to S. Yamane

1) The positive influence of C_3A on the hydration of C_3S at early stages and of alite in portland cement has been shown by the authors, according to L. E. Copeland and D. L. Kantro, Principal Paper "Hydration of Portland Cement" Part II—Session 5.

About the reaction's mechanism, the authors tried to give in their paper a reasonable explanation. The subject is still a matter of investigation and the authors will give to Mr. Yamane all the eventual information.

2) In order to explain 1) the authors emphasize the opportunity to determine the Al_2O_3 and SiO_2 in the liquid phase.

3) Authors think there is no correlation between the accelerating action of $CaCl_2$ on C_3S and on alite in portalnd cement and the possible increase of the interaction between Al_2O_3 and SO_3 as reported by Mr. Yamane.

Reply to H. N. Stein

1) The positive influence of C_3A on the hydration of C_3S at early stages and of alite in portland cement has been shown by the authors, according to L. E. Copeland and D. L. Kantro, Principal Paper "Hydration of Portland Cement" Part II—Session 5.

About the reaction's mechanism, the authors tried to give in their paper a reasonable explanation. The subject is still a matter of investigation and the authors will give to Mr. Stein all the eventual information.

2) Authors agree that the investigated systems have a much more complex character than de Jong c.s. They, however, think the recrystallization of hexagonal hydrates to C_3AH_6 cannot explain the apparent contrast between the results.

Explanatory Notes

Abbreviations.

The following symbols, which have been universally recognized by cement chemists for formulating more complex compounds, are used interchangeably with the respective oxide formulas throughout this book:

$C = CaO$, $S = SiO_2$, $A = Al_2O_3$, $F = Fe_2O_3$,
$M = MgO$, $N = Na_2O$, $K = K_2O$, $H = H_2O$,

Less common abbreviations of this type are defined as they occur.

Commonly used abbreviations of more general nature are as follows:

DTA = differential thermal analysis
EPMA = electron probe micro analysis
IR = infrared
NMR = nuclear magnetic resonace
psi (or p.s.i.) = pounds per square inch
rh (or RH) = relative humidity
w/c (or W/C) = water — cement ratio
XRD = X-ray diffraction

Identification Number of Supplementary Papers

Example: Supplementary Paper III—50, III is session III and 50 is the arrival number of contribution. This number coincides with the number used in the preprint of papers distributed in advance of the symposium.

Synopsis

Pseudomorphs of the original cement grains in hardened pastes result from differences in hydration products deposited within and between the original grain boundaries. Structures of the various hydration products, as seen in the electron microscope are described. Pore size distributions for cement pastes obtained by a variety of methods are consistent. Surface area values measured by nitrogen adsorption decrease with the water-cement ratio. The distinctions between capillary, gel, and non-evaporable water are reviewed. The gel water resembles interlayer water in clays.

Strength depends primarily on the capillary porosity. The uniformity of distribution of the hydration products explains the effects of gypsum content and temperature.

Initial drying shrinkage is relatively independent of clinker composition at "optimum" gypsum content. The dependence of this shrinkage on water loss suggests independent effects from different classes of water in the paste. The dependence of this shrinkage on water-cement ratio and duration both of curing and of subsequent drying is discussed. Carbonation shrinkage varies with the ambient relative humidity. Releases of equal amounts of water by carbonation or drying result in equal shrinkages. Cycles of wetting and drying reveal that volume changes have reversible and irreversible components.

Thermal expansivity depends on moisture content, rate of temperature change, and the nature of the solid phases. Thermal conductivity changes little with water-cement ratio or temperature.

The elastic properties are primarily related to capillary porosity. Inelastic properties are discussed. The relationship between permeability and capillary porosity applies even to bleeding fresh pastes. Available data on moisture diffusion are sufficiently consistent to permit determination of the activation energy. The importance of osmotic and electrokinetic effects in studies of liquid flow is discussed.

Introduction

This paper is a selected review of the state of knowledge of the structure and physical properties of cement pastes. We have not attempted to repeat detailed review of each of the topics treated in the corresponding paper of the Fourth Symposium (1). Apart from space limitations this is because little information can be added to some of the topics treated in the 1960 review. On the other hand, we have included much new material, particularly on strength and shrinkage, and have included some properties not previously included.

In addition, some differences from previous points of view are presented. We have tended more to include primary data concerning the actual behavior of the pastes under different conditions, and less theoretical interpretation. We have, however, presented new interpretations of physical properties in terms of features of the structure wherever desirable.

*Portland Cement Association, Research and Development Laboratories, Illinois, U.S.A.

A second difference in point of view concerns the state of the water in hardened pastes. This has developed because it has become increasingly clear that much of the evaporable water is in a more highly organized state than previously supposed. Although it is not yet possible to make quantitative classifications different from those based on the concepts of gel water and capillary water, there is considerable evidence that some of the evaporable water in hardened pastes exists in distinct states similar either to the interlayer water in swelling clays or water of crystallization. Such water is therefore a component of the structure of the paste. Changes in water content therefore have important effects on the physical properties and dimensional stability of the structure.

The morphology of the hydration products as revealed by electron microscopy was covered in detail in the Fourth Symposium (2). We have therefore given only a brief summary of such work, and combined such results with newer methods of investigation of the paste structure, as given in the next section.

Structures of Hardened Pastes

In regard to the structure of hardened paste we will first consider the morphology or microstructure of the solid components of the hardened paste, then the microstructure of the pore system of the paste, and finally discuss the nature of the state of the water component of paste.

Microstructure of Hardened Paste

The microstructure of hardened paste has been studied by direct optical methods and by the electron microscope observing both the fragmented dispersed hydrated particles and replicas of sawed or fractured surfaces.

Optical Studies

Although optical examination of portland cement paste reveals little about its detailed structure, by such examination it can be directly observed that the space between clinker grains, initially water filled, soon becomes filled with hydration products formed by dissolution of portions of the clinker grains. Portions of the larger clinker grains hydrate and form hydration products in the space within the original grain boundary created by the prior solution process. These hydration products have optical properties which are somewhat different from those of the products precipitated in the water-filled space (3, 4) and thus remain visible as pseudomorphs of the original clinker particles. Under such conditions the original clinker structure appears to be preserved in the pseudomorph; outlines of the silicate phases are preserved. Portions of the larger clinker grains may remain unhydrated within the paste depending upon clinker grain size, the original water-cement ratio (w/c), of the paste, and the duration of exposure to water.

Crystals of calcium hydroxide can be seen to form in the waterfilled space between clinker grains about 4 hours after mixing. These crystals grow around any impediment, e.g., there is a continuous intergrowth of calcium hydroxide and gel; in mortars, grains of sand frequently appear to be engulfed in calcium hydroxide.

The hydration products other than calcium hydroxide are so finely divided that they cannot be resolved with an optical microscope, but the electron microscope has revealed information about the morphology of the hydration products as well as structure of the hardened paste. Information about morphology of hydration products is obtained by direct study of powdered and dispersed pastes; information about paste structure is obtained by electron microscopic examination of surface replicas of hardened pastes.

Electron Microscopic Studies

Direct electron microscopic examination of the individual products of hydration of cement pastes requires dispersion of the paste particles. Studies in which dispersion has been used have followed the course of hydration of cement, and also of the pure silicates, from the time of mixing of the paste through several days of hydration after which time the paste can no longer be properly dispersed. These studies have shown that hydration starts immediately upon contact of the cement with water. Ettringite is one of the first products that can be identified in cement pastes. It forms primarily as stubby hexagonal prisms on C_3A faces, but can also form as long hexagonal prisms away from cement particles in water-filled space. After about 2 hours thin acicular particles of calcium silicate hydrate are observed protruding from the surfaces of unhydrated grains of cement. These particles grow longer and broader to form thin laths which are striated along their length. At the time of final set they appear to be long enough and numerous enough to form an interlooking network through-

out the paste. By 24 hours the paste is somewhat difficult to disperse, but thin, striated sheets of calcium silicate hydrate are observed. The edges of the undispersed masses also show sufficient detail to confirm that these masses are aggregations of the thin sheets which sometimes occlude crystallites of calcium hydroxide (5, 6, 7).

The calcium silicate "gel" formed by hydration of pure calcium silicate is poorly crystalline. However a significant fraction of the gel comprises particles, which appear to be rolled sheets, that are sufficiently well crystallized to give single-crystal electron diffraction patterns. Occasionally the X-ray diffraction patterns of a wet, hardened paste of C_3S will show a layer spacing (8).

In comparison with the gel formed by hydration of pure calcium silicates the gel formed by hydration of cement is not nearly so well crystallized. Indeed, single-crystal electron diffraction patterns of gel particles have not been obtained. Since isomorphous substitution of aluminum and sulfur for silicon is possible in the calcium silicate hydrate "gel" (9), and since these substitutions are accompanied by changes in the morphology of the gel, it is likely that such substitution is the cause of the more nearly amorphous character of the gel formed from cement as compared to that formed from pure calcium silicate. Cement pastes stored under water for up to 10 years do not show any marked increase in crystallinity of its hydration products.

Electron microscopic examination of carbon replicas gives information about the arrangement of hydration products within hardened paste. Different techniques of preparing surfaces for replication emphasize different aspects of the structure of pastes. Two types of surfaces have been examined: (1) surfaces prepared by cutting a slice of paste with a diamond saw on a sectioning machine, using water as the saw lubricant, and (2) surfaces prepared by fracturing pastes.

Flushing the paste surface with water during the cutting dissolves calcium hydroxide crystallites in the surface region but reveals aggregations of calcium silicate hydrate "gel" and the crystallites of the hydration products of the alumina bearing phases. Details of the techniques used and several examples of replicas prepared from *sawed* surfaces can be seen in paper II-5 (Figs. 19, 22, 30, and 31) of this symposium. Comparison of the form of the calcium silicate hydrate seen in these replicas with that found by direct electron microscopic examination suggests that the particles seen in replicas are indeed aggregations of thin sheets. Pores both within and between these aggregations are too small to be revolved by the replica.

The aggregations of calcium silicate hydrate "gel" are not so prominent in replicas of *fractured* surfaces. Apparently the fracture passes through the aggregations instead of along boundaries between them. However cavities that may be several microns across are frequently seen; these contain acicular particles which implies that they grew in initially water-filled free space. Most frequently the particles in the cavities appear to be fibrous—these are calcium silicate hydrate—but sometimes crystallites of ettringite can be recognized protruding from the walls.

Fig. 1 is an example of a fractured surface of moist-cured hardened portland cement paste. The lower part of the field shows fractures approximately perpendicular to the cleavage plane of calcium hydroxide. It is likely that the striations in the crystal result from the manner in which gel and calcium hydroxide grow together which is illustrated at left in the field. In the upper part of the field, to the right of center, there is a cavity, approximately 6μ long, partially filled with a network of gel laths and a few prisms of ettringite (10).

Pore Size Distributions

General Considerations

The water-filled spaces between the cement particles in the fresh cement paste may be regarded as an interconnected capillary system. As hydration pro-

Fig. 1. *Photomicrograph of a carbon replica of a fractured hardened cement paste surface*

ceeds these spaces become partly filled with gel and microcrystalline hydrate particles. However, the manner of filling of the original water-filled spaces with hydration products depends upon the particle size distribution of the cement, upon the water-cement ratio, and upon the availability of water during hydration. If partial drying occurs during hydration, large pores empty and precipitation from solution cannot then occur in such spaces. We may thus expect differences in the pore size distributions depending upon whether the paste was kept saturated, kept sealed and hence allowed to self-desiccate, or allowed dry by direct loss of water.

Pore size distributions can be calculated from either of two different kinds of experimental results: 1, porosimetry, in which the volume of mercury that is forced into a porous system is measured as a function of the applied pressure, and 2, capillary condensation of vapors from either the adsorption or desorption isotherm of the porous system. In both techniques the Kelvin equation is used with an assumption that must be made about the shapes of pores. The assumption of a pore shape influences the calculated pore size distribution because the pressure at which a pore fills depends upon the curvature of a meniscus and therefore upon the shape of a pore. Most commonly the pores sizes are calculated as if they were either a system of cylindrical capillaries, or a system of parallel plates. Recently a method of calculating the pore size distribution without a model for the shapes of the pores has been proposed and it utilizes the "hydraulic radius" (pore volume/pore wall area), as a measure of pore size (11).

Mercury Porosimetry

Fig. 2 shows results of pore size distributions

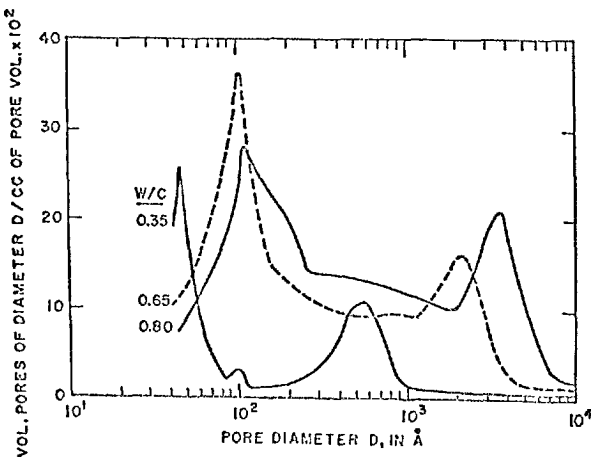

Fig. 2. *Pore size distributions of cement pastes, moist cured for 11 years, obtained with a high pressure mercury porosimeter.*

obtained with a high pressure (50,000 psi) mercury porosimeter (12). Results for 11 year moist-cured cement pastes at three water-cement ratios, 0.35, 0.65 and 0.80, are shown. The results span more than three orders of magnitude, from about 9×10^4 to about 40 Å. A logarithmic abscissa is used. The curves has been normalized. Each curve shows two clearly defined maxima. For the 0.35 paste maxima occur at pore diameters of 45 and 550 Å; for the 0.65 paste maxima occur at 105 and 2100 Å; for the 0.80 paste maxima occur at 110 and 3500 Å.

The large diameter maxima are in substantial agreement with those of another study (13) showing that they represented a class of pores that depended upon water-cement ratio, cement fineness, and curing. These are usually denoted by the term "capillary" pore (14). The small diameter maxima occurred at somewhat larger diameters than in Fig. 2, possibly because of differences in curing times. In addition to these maxima each distribution includes measureable pore volumes of intermediate sizes as well as very large pores with diameters exceeding 10^4 Å.

The main features of these pore size distributions are supported by two other kinds of experimental evidence: 1, as discussed above, large cavities or pores, are observed by electron microscopic examination of surface replicas of hardened pastes, and 2, the studies of ice propagation in freezing experiments (15) gave evidence of a bimodal distribution of pores that are completely compatible with the mercury porosimeter results. This agreement is of special importance because the freezing experiments were performed with pastes that had never been dried and the porosimetry and adsorption measurements are made on dried pastes. Since drying is known to product irreversible changes of structure it is possible that the indicated pore structures would be different. These results, however, do not indicate any great changes in the pore structure during drying.

The sizes of pores given by both the mercury porosimetry and the freezing propagation studies are not necessarily the sizes of the pores filled, but only the sizes of the entry ways.

Pore Structure from Adsorption Isotherms

Pore size distributions have been calculated from measurements of nitrogen adsorptions, Fig. 3 (16), and cyclohexane adsorption, Fig. 4, on a series of hardened pastes made with water-cement ratios in the range from 0.35 to 0.70 (17). The distribution curves calculated from the cyclohexane isotherms are not strictly comparable to those calculated from nitrogen

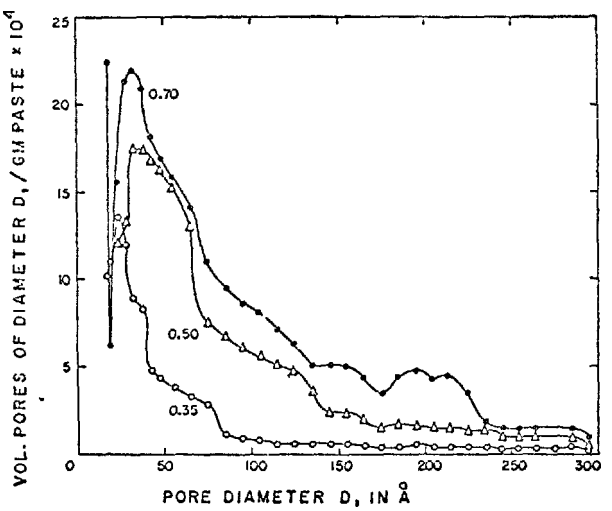

Fig. 3. *Pore size distributions of mature cement pastes obtained from nitrogen absorption*

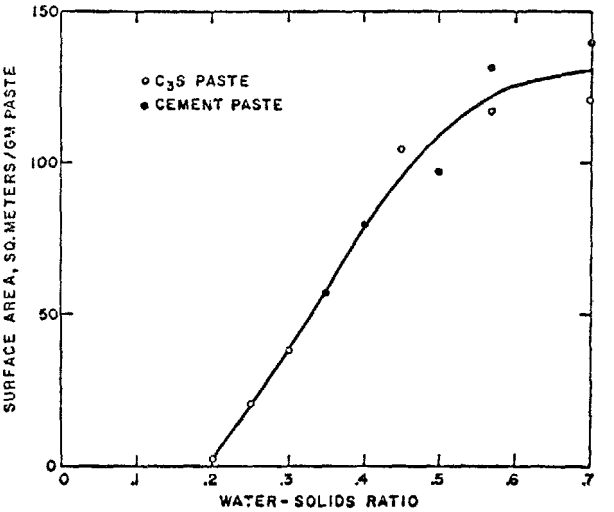

Fig. 5. *Nitrogen adsorption on cement pastes decreases with water-cement ratio*

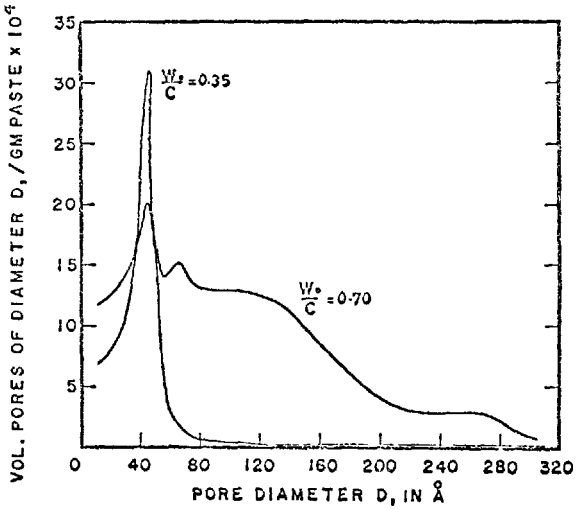

Fig. 4. *Pore size distributions of mature cement paste obtained from cyclohexane adsorption*

isotherms because the desorption branch was used for cyclohexane while the adsorption branch was used for nitrogen. All these distributions have a well defined mode; with cyclohexane the mode is at 45 Å for two pastes, one with $w_0/c = 0.35$, the other with $w_0/c = 0.70$; with nitrogen, the modes for these same two pastes were at 22 Å and 32 Å respectively. One cannot be certain whether the smaller diameters obtained from nitrogen resulted from its smaller molecular size or from using the adsorption branch of the isotherm. The effect of difference in size of the molecules is shown by the fact that the surface area and total pore volume calculated from cyclohexane isotherms were smaller than those calculated from nitrogen isotherms.

The largest pore diameters that can be calculated from sorption isotherm is limited to about 300 Å, consequently none of the these distributions reached a pore size large enough for the second mode shown in the porosimeter distribution curve.

The two methods agree in one respect; neither account for all the space occupied by evaporable water in hardened paste. About 70 percent of the pore volume is accounted for by the porosimeter and nitrogen in the more porous paste, cyclohexane fills less than 50 per cent of the space. A part of the effect is the result of molecular sizes. The inability of the porosimeter to fill all the space may be caused by the limited pressure than can be attained, but may also be caused by the inability of the non-polar molecule to enter some spaces that water can occupy.

It is well known that the "specific surface", (surface area per gram of cement gel), calculated from water-sorption data is a constant, approximately 200 square meters per gram, that is independent of w/c of the paste and its degree of hydration. Such is not the case for the specific surface as determined by nitrogen. The "nitrogen surface" is always smaller than the "water surface" and decreases with decreasing water/cement ratio of pastes (18). Recently a study of nitrogen surface areas of hardened pastes of tricalcium silicate with water-cement ratios as low as 0.2 was made (19). The results of this investigation agreed very well with results of other investigations using portland cement pastes. The lowest nitrogen area attained was 3.5 square meters per gram of gel on pastes with $w_0/C_3S = 0.2$ cured 14 months. The trend of the results, shown in Fig. 5, suggests that the

nitrogen area will become zero at a water-cement ratio slightly below 0.2.

The State of the Water in Hardened Paste

The state of the water in the pore system is important because any difference between the state of the water in the pores from that of liquid water implies the existence of forces on the water and reaction forces on the solid. This has important implications with respect to volume change and structural change phenomena.

Water in cement pastes may be arbitrarily classified into "evaporable water" and "non-evaporable water" (water not removed under a standard drying condition). The best defined drying condition for this purpose is drying in vacuum over ice at the dry-ice (solid CO_2) temperature, −79°C, sometimes called "D-drying" (20). The non-evaporable water determination is intended to remove nearly all of the "physically adsorbed" water and leave only "chemically bound" water. It is believed that this is accomplished, but there is uncertainty concerning the degree to which loss of the evaporable water represents loss of water of hydration.

The evaporable water in cement pastes may also be arbitrarily classified into "gel" water and "capillary" water (14). This is based upon the conception that the cement gel has a certain minimum porosity, which may be arbitrarily defined from measurements of water contents of saturated, well hydrated, low water-cement ratio pastes. In such pastes it is found that cement hydration virtually ceases before all the cement is hydrated. Such pastes are assumed to contain only gel water. Capillary water is defined as the difference between the total evaporable water of a paste and its gel water content.

The distinction between "capillary" water and "gel" water is useful in the discussion of the porosity of the paste for the following reason. By variation of water-cement ratio and curing time the capillary water content can be varied from zero to nearly the entire volume of the hydrated part of the paste. Hence it was possible to shown (21) by standard thermodynamic methods that the partial specific volume of the capillary water was constant at about 1.0. That is, capillary water in saturated pastes has near normal density. The gel water content, however, cannot be arbitrarily varied. Hence the partial specific volume of the gel water cannot be similarly determined, and various attempts have been made to estimate its volume by other methods (1).

The main problem then centers on the state of the gel water. This has two aspects: how much of the gel water is hydrate water, and what is the nature of that part of gel and capillary water not combined as hydrate water.

Evidence concerning the state of the water in pastes has been obtained from NMR (nuclear magnetic resonance) studies of some calcium silicate hydrates. The results have been summarized and compared with results obtained with ettringite, silica gel, and montmorillonite clays of different water contents (22). In NMR techniques one of the parameters measured is the transverse or spin-spin relaxation time, T_2. This quantity is a measure of the magnitude of local fields surrounding the protons. In strong local fields T_2 is very short because the resonating protons react quickly (spins flip over) to the local forces. In weak local fields T_2 is long. T_2 is thus a measure of how "tightly" the proton is bound. More correctly, T_2 is a measure of mobility of the magnetic moment of the proton rather than a thermodynamic property, such as bond energy. In liquid water T_2 is about 2.5 sec. In ice it is only 7 microseconds, indicating that the water molecules in ice have a strongly fixed "orientation".

Results of pulsed NMR measurements on some calcium silicate hydrates and other materials are given in Table 1. In an alite paste at 16 per cent RH values of T_2 ranged from 300–500 microseconds, in agreement with values for montmorillonite clay, 250 microseconds, and various other calcium silicate hydrate preparations at relative humidities ranging from 3×10^{-3} to 70 per cent. These results indicate that the water molecules in these systems were under the influence of local forces which caused relatively rapid reorientation after the pulsed radiation was cut off. A further indication of the strength of the local fields was given by the absence of spin echoes. Spin echoes are detected when the protons are in liquid water and water adsorbed on silica gel, but not in the calcium silicate hydrates, except at high water con-

Table 1. *Results of pulsed NMR measurements*

tents.

The first five samples shown in Table 1 are samples in which no capillary water was present. The first two were synthesized from calcium hydroxide and silica gel; neither had capillary pores. The third was an alite paste that had been dried sufficiently to empty the capillaries. The fourth and fifth samples had only non-evaporable water. The T_2 values obtained for these materials are of the same order of magnitude as those calculated from wide-line NMR measurements on hardened cement pastes (23). Thus the evaporable water present in the first three samples can be assumed to be in the same state as gel water in hardened cement pastes; the results show that gel water is probably interlayer water and suggest that NMR may provide a good measure of capillary porosity in saturated samples.

Similarity of the calcium silicate hydrates to swelling clays is not limited to the spin-spin relaxation times. In addition, we may note that: 1) The montmorillonites and zeolites lose water continuously as do cement pastes even though the lattice spacing changes in discreet (1, 2, etc.) monomolecular layer steps. 2) The swelling of pastes is limited, as in the zeolites, rather than unlimited, as in the montmorillonites. 3) The irreversible loss of water and shrinkage during D-drying is very like the irreversible collapse of structure of the swelling clays observed during strong drying. 4) Much of the evaporable water in cement pastes seems to be part of the solid structure because of the decrease of the elastic moduli caused by drying.

Physical Properties of Hardened Pastes

Strength

The strength of hydrated portland cement paste, as with other porous materials, depends primarily upon its capillary porosity or its degree of space filling. In addition, the strength of hydrated paste depends upon the uniformity of distribution of the hydration product within the microstructure of the paste.

The "classical" concept of the relationship between the strength of hydrated cement paste and "gel-space ratio" is shown in Fig. 6. This concept has proven most useful in connection with many interpretations regarding the strength properties of hydrated cement paste but perhaps has been somewhat misleading regarding the strength producting qualities of "tobermorite gel" per se. In addition, it has not been satisfactory in providing an understanding of certain other factors that can significantly affect the strength of cement paste, such as the SO_3 content of the cement or the hydration temperature. The information present in Fig. 6 regarding the relationship between the compressive strength and gel-space ratio (24, 14) can be used to provide the corresponding relationship between the strength and the "capillary porosity" of these pastes. Such information is shown in Fig. 7. Here we see that within the limits of the concept of "capillary porosity" or "calillary water", as previously discussed, there is a close relationship between the amount of this relatively less strongly bound water and strength. In this particular comparison the relationship appears almost linear but must be curvilinear because there is obviously no strength at "100 per cent capillary porosity".

Fig. 7 contains three datum points that are specifically identified and which represent the compressive strengths and capillary porosities measured of fully autoclaved cement pastes made at the indicated water-cement ratios. These pastes contained essentially no "gel" as measured by the normal water vapor adsorption techniques. It can be seen that when the strengths of these autoclaved pastes containing no gel are compared with those of pastes containing

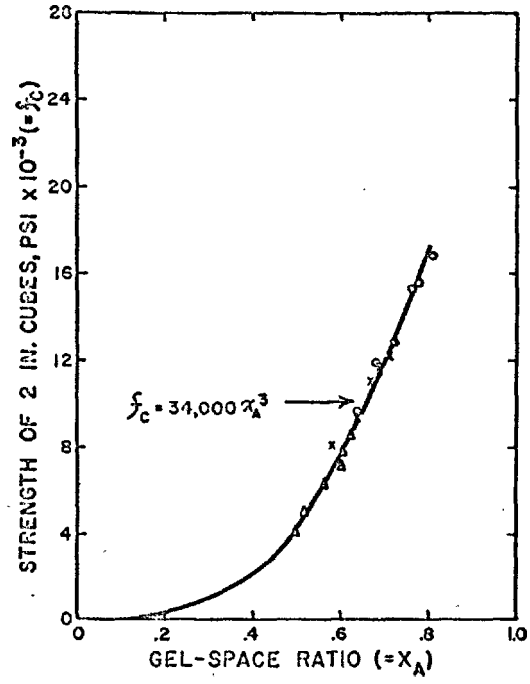

Fig. 6. *Cement paste strength depends on "gel-space ratio"*

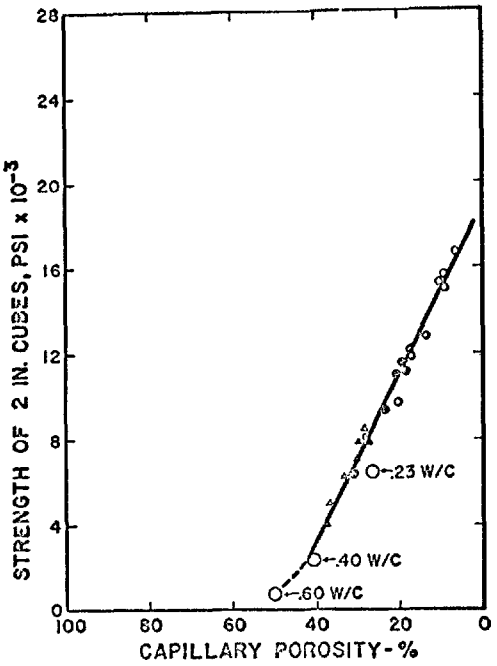

Fig. 7. *Cement paste strength depends on capillary porosity*

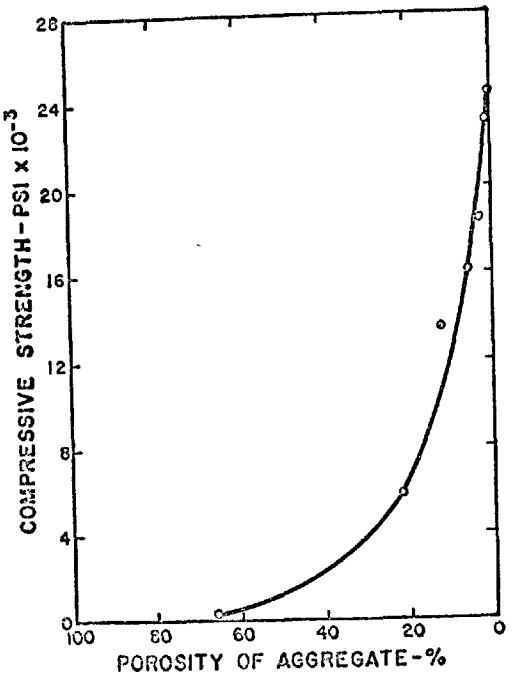

Fig. 8. *Aggregates strength depends on capillary porosity*

"gel" they demonstrated essentially the strength that would be anticipated on a capillary porosity basis. The point intended to be made here is that the low strength shown by autoclaved pastes (without added silica), which is quite low at water-cement ratios substantially above those of "normal consistency", is simply a result of the relatively low volume contributions of the hydration product produced under autoclaving conditions. Under normal curing conditions a product is obtained that has a volume approximately 2-fold that of the volume of the original cement. This is in large part due to the fact that the volume of this product is increased because the amount of water that it contained (interlayer water such as in a clay, zeolitic water, or water of crystallization) increases the volume of the hydration product and hence decreases the capillary porosity of the system. In essence it is more a matter of the degree of filling of the space rather than what the space is filled with.

Similar information can be obtained for other types of materials.

Fig. 8 shows the general relationship between the average compressive strengths and the average porosities of approximately 100 aggregates (25), the individual points representing the averages of groups of aggregates, ground on the basis of porosity range. It can be noted that the same general type of relationship is obtained.

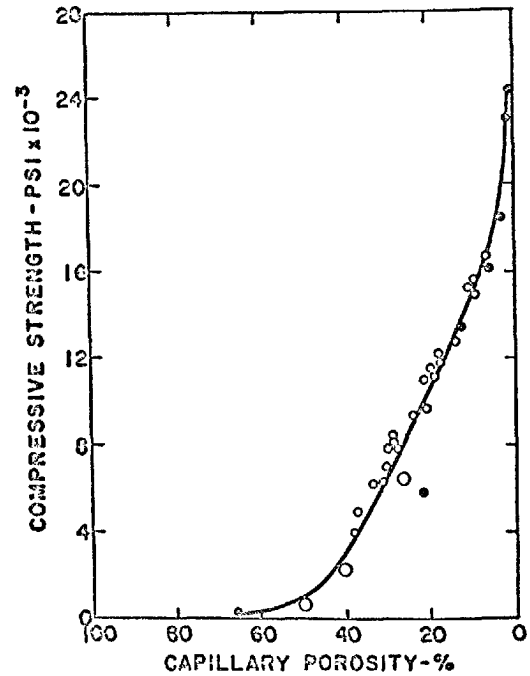

Fig. 9. *General relationship between capillary porosity and average strength of the various materials*

Fig. 9 compares all the data contained in Figs. 7 and 8. This represents data for normally cured paste containing "tobermorite gel" of normal curing, for

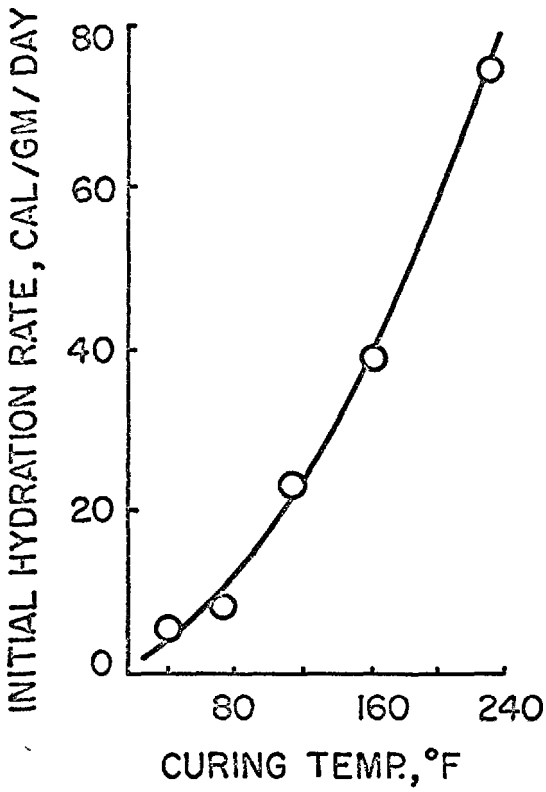

Fig. 10. *The initial rate of cement hydration increases with temperature*

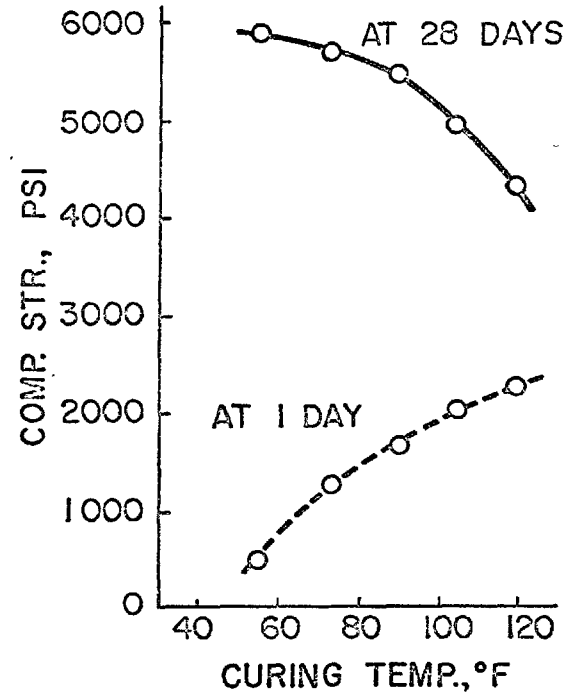

Fig. 11. *One day strength increases with increasing curing temperature but 28 day strength decreases with increasing curing temperature*

the crystalline non-gel-like material obtained by autoclaving, and for a wide variety of aggregates. This figure is taken to indicate that there is nothing greatly unusual about the strength properties of hydrated cement paste or of "tobermorite gel", but rather that in the case of any of these materials the primary factor influencing strength is the degree of space filling or, conversely, the capillary porosity of the system.

However, almost needless to say, it is well recognized that there are other factors that influence the strength of the various materials. There was considerable variation among the strengths of the aggregates within each group that were averaged to produce the relationship shown in Fig. 8. This variation certainly involves factors such as the size and distribution of the individual mineral constituents, the orientation of the bedding place during test and the elasticity of the material. Likewise, for normally hydrated cement paste, it is known that the strength that is developed by a hydrated paste is influenced by many factors other than its capillary porosity; these factors include the effect of "optimum" gypsum content and an apparently somewhat anomalous effect of hydration temperature, both effects will be shown below to be interpretable in terms of the early rate of cement hydration. However, it is also known that the SO_3 in a hydrating portland cement participates in the formation of the calcium silicate hydration product and thus may to some degree affect the inherent physical strength properties of the silicates.

The reaction between cement and water is like other chemical reactions in that the rate at which the reaction occurs increase with increasing temperature. Fig. 10 shows the relationship between the initial rate of hydration of cement, as measured by the rate at which heat is evolved by the chemical hydration reactions, and the temperature of the hydrating cement paste. The data cover the range from 40 to 230°F. The rapid increase of the initial rate of hydration of cement with hydration temperature would lead one to expect that at a given early age the strength of the concrete also would be higher, at a higher hydration temperature. That this expectation is true is shown in the lower curve of Fig. 11 which compares the compressive strengths of concretes after one day of moist curing at temperatures within the range 55 to 120°F. Thus, at 1 day, in the temperature range shown, the higher the curing temperature, the higher the compressive strength. One might expect that the same effect

would be true at later ages. However, the temperature variation of the strengths of these same concrete for a curing period of 28 days at these same temperatures is exactly opposite to that of the 1 day curve, as is shown in the upper curve of Fig. 11.

In the search for an explanation for these apparently anomalous results, the inherent nature of the hydration products obtained at different temperatures has been studied to see if it significantly changes with hydration temperature. The *chemical* nature of the hydration product can be evaluated to some degree from the relationship between the amount of water chemically combined and the heat evolved during the process of hydration. Fig. 12 shows immediately that the *chemical* nature of the hydration product, as measured by the ratio of the non-evaporable water to the heat evolved, does not vary with cement hydration temperature in the range from 40 to 230°F.

The *Physical* nature of the hydration product—that is, the degree to which the product is "colloidal"—can be evaluated from the amount of water vapor adsorbed by the product—its "surface area"—in relation to the amount of product formed, as measured by the heat evolved during hydration. Fig. 13 which contains such information, shows a measure of "surface area" per unit of hydration product (percent water vapor adsorbed at 36 per cent relative humidity per calorie of heat evolved) in relation to hydration temperature. Obviously the *physical* nature of the product of hydration is independent of the temperatures of hydration. Therefore the explanation of the variation of strength with temperature at later ages cannot involve either chemical or physical differences in the nature of the hydration product.

The explanation of the beneficial effect of high hydration temperatures on early strength and their detrimental effect on later age strength is believed, primarily, to involve two opposing factors. One factor is that an increased hydration temperature increases the initial rate of hydration and hence is beneficial to early hydration and to early strength. The opposing factor is that this same initial reaction, because of its rapidity, is detrimental to ultimate strength because it both retards subsequent hydration, as is indicated below, and because it produces a non-uniform distribution of hydration product within the paste microstructure. The non-uniformity of distribution within the microstructure of hydrated paste cannot be easily revealed by the classical methods for characterizing the hydration product, such as adsorption techniques.

One line of evidence for such an argument comes from the early hydration reactions of cement, as revealed by the conduction calorimeter. The heat evolution peak that occurs at about 6 to 8 hours at normal temperatures appears to have particular significance. During this period the cement is undergoing very rapid reaction at normal temperatures; perhaps 20 per cent of the cement hydrates a period of 2 or 3 hours. At elevated curing temperatures, these reactions are accelerated; at 105°F as much as 30 to 40 per cent of the cement may hydrate in a 2-hour period. At steam curing temperatures, perhaps 50 per cent or more of the cement hydrates in an hour or less. The rate in any instance depends upon cement composition and fineness, hydration and temperature. These very high rates of reaction can have a significant physical effect. The low solubility and low diffusibility of the cement hydration products make it appear doubtful that these products could diffuse to any significant distance from the surface of the hydrating cement grains within the time of the observed rapid hydration. In other words, when the cement hydrates at a low temperature, and therefore hydrates slowly, there is ample time for the hydration product to dif-

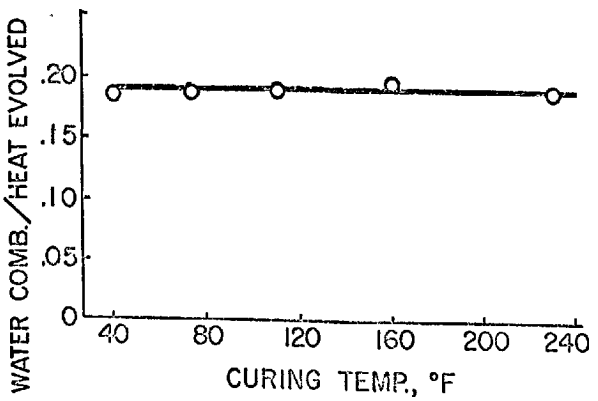

Fig. 12. *Evidence for temperature independence of the* chemical *nature of cement hydration products*

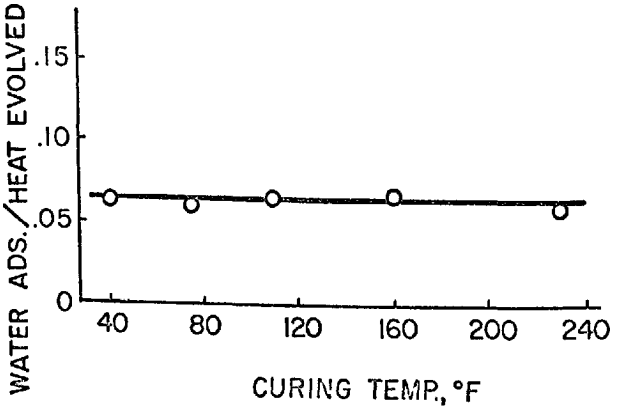

Fig. 13. *Thermal evidence for temperature independence of the* physical *nature of cement hydration products*

fuse and precipitate relatively uniformly throughout the interstitial space among the cement grains. However if the hydration is accelerated, as by increased curing temperature, the high rate of reaction does not allow time for such diffusion and therefore a high concentration of hydration product must be built up in the zone immediately surrounding the hydrating cement grain. If, in fact, this highly concentrated, dense and encapsulating layer does develop as postulated, then its presence should influence at least two properties of the paste. First, this relatively impermeable rim around the cement grain should retard subsequent hydration. That the rate of hydration of cement is significantly affected by the gel-space ratio of the paste has been demonstrated from such heat of hydration studies (26) as shown in Fig. 14. In addition, entirely independent studies have shown that the ultimate degree of hydration of C_3S (and also C_2S), as measured by X-ray diffraction techniques, is actually retarded by increased temperature during the early stages of hydration (27). This is demonstrated in Fig. 15 for C_3S pastes. This figure shows the degrees of hydration of C_3S at ages varying from 1 day to 5 years for C_3S pastes hydrated at different initial temperatures. It is seen that at 1 day the degree of hydration increases with the hydration temperature, as would be expected. However, at later ages a reversal is observed. It is believed that the dense zone of hydration product around the hydrating grain created by the rapid early hydration significantly reduces the ultimate degree of hydration of these silicate phases, even after 5 years of moist curing. Therefore, a high initial hydration temperature is detrimental to later age strength development because it, per se, reduces the degree of hydration of the cement at later ages.

The formation of the densified layer encapsulating the hydrating cement grain should cause a reduction in strength even if the same overall degree of cement hydration were attained. In Fig. 16 is shown the usually observed relationship between strength of mortars cured at "normal" temperature (solid line) and the concentration of the hydration product (measured as the "gel-space" ratio). As already discussed, this concentration is a function of original water-cement ratio and degree of cement hydration. The more concentrated the hydration product, the greater the observed strength. A paste having an overall gel-space ratio of, for example, 0.7 and a uniformly distributed hydration product would attain then a strength of about 12,000 psi as shown. However, at this same average gel-space ratio a non-uniform distribution of the hydration product could significantly influence the observed strength. For example, if one assumes a high concentration of 0.8 around the cement grain residues and 0.6 in the interstitial space, then a minimum strength of less than 8,000 psi would be antici-

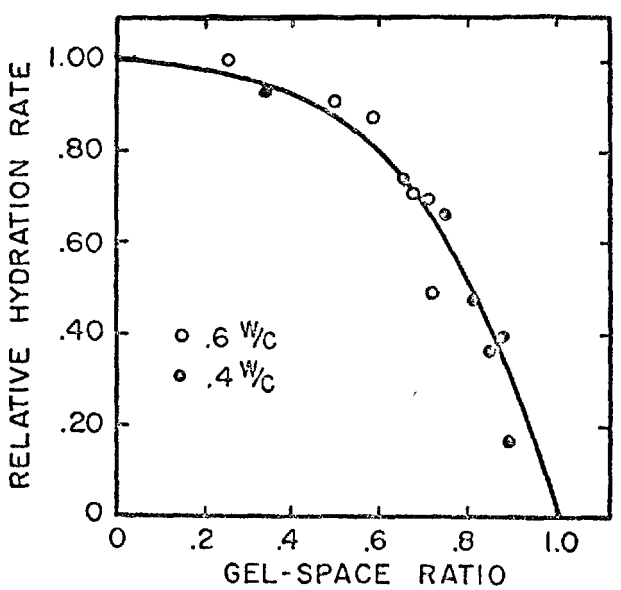

Fig. 14. *The denser the coating of hydration product the lower the rate of cement hydration*

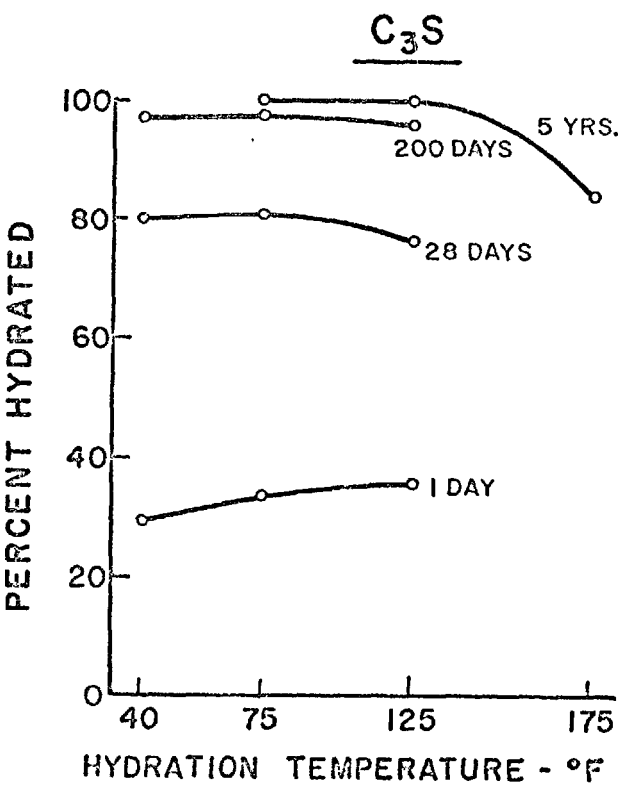

Fig. 15. *At later ages, degree of C_3S hydration was less for pastes initially cured at higher temperature*

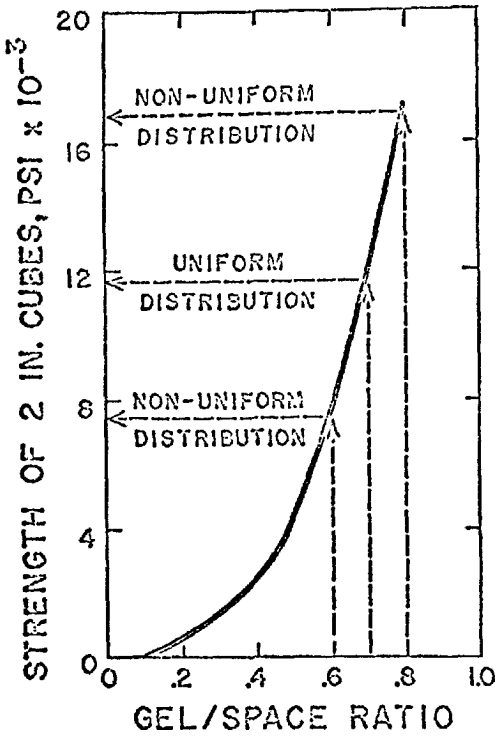

Fig. 16. *Uniform distribution of gel provides optimum strength. For the same average gel-space ratio but with non-uniform distribution the strength is reduced to that corresponding to the lower gel-space ratio*

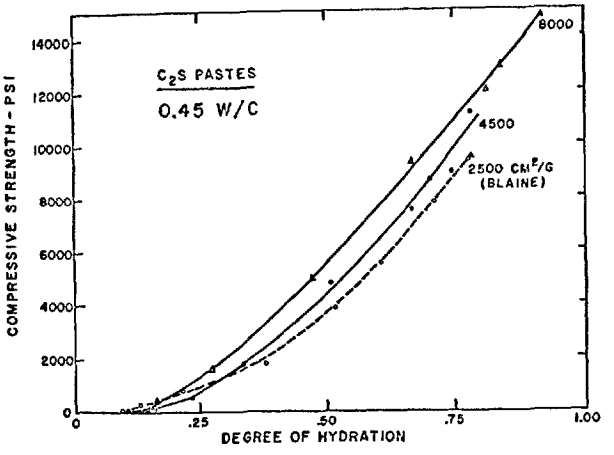

Fig. 17. *Finer grinding of C_3S produces increased strength at same degree of hydration because of greater uniformity of distribution of hydration product*

pated since the weaker portion of the paste must limit the strength attained (dashed lines). Both the retarded subsequent hydration and primarily the nonuniform distribution of the hydration product are presently considered to be the major causes of the detrimental effect of elevated curing temperatures. The role of gypsum at "optimum" gypsum content could be largely due to an optimization of the rate of early reactions in the sense of minimizing the development of such an encapsulating, retarding layer, thus permitting formation of a hydration product of more uniform density distribution and hence of higher inherent strength. This concept is also borne out by recent studies concerning of strength development (28) in pastes made with C_2S of different finenesses at various degrees of hydration, as is shown in Fig. 17. Here it may be noted that at comparable degrees of hydration, higher strengths were attained as the fineness of the C_2S increased. It can reasonably be expected that a more uniform, less disproportionated, hydration product should be obtained for a cement of higher fineness and hence that a greater strength therefore should be attained. Chemical studies of the hydration product obtained in these latter studies show the products at any particular degree of hydration to be essentially identical, since the CaO/SiO_2 ratio was observed to be independent of the fineness of the C_2S. It is anticipated that, using recently developed techniques, future studies of the pore size distribution in pastes of different SO_3 contents, cured at various temperatures, will be of considerable value in further elucidating the role of these factors in strength development.

Drying and Carbonation Shrinkage

The shrinkage of hydrated cement paste is influenced by many factors. These include the composition and fineness of the cement, the water-cement ratio, the degree of hydration, the degree of drying, and the conditions and degree of carbonation. The shrinkage of paste on first drying may or may not be reversible during subsequent rewetting and redrying cycles, depending upon details of the process of drying. We will consider first those factors that affect the shrinkage of paste on initial drying, a process that causes the largest shrinkage, except for effects associated with continued hydration or carbonation.

Cement

In regard to the effects of cement characteristics on shrinkage some previous investigators have concluded that the tricalcium aluminate and alkali contents of cement and its fineness, have large effects on shrinkage. At the time such observations were made they appeared correct from the data then available, but actually they have been found to be somewhat misleading. Most of these investigations were conducted

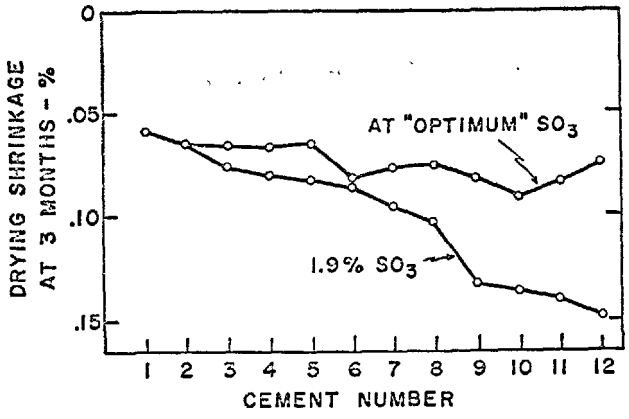

Fig. 18. *Drying shrinkage of mortars is relatively independent of clinker composition at "optimum" gypsum content*

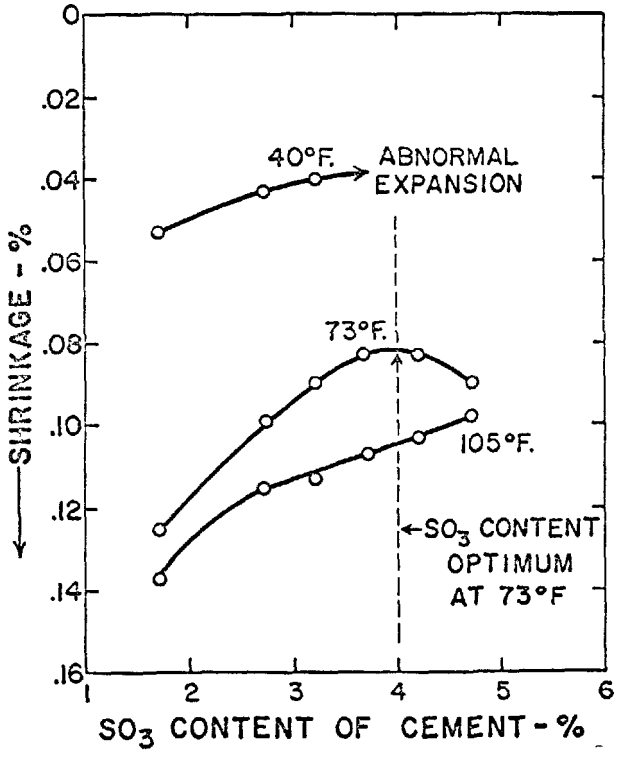

Fig. 19. *The "optimum" gypsum for minimum drying shrinkage changes with temperature of early hydration*

years ago during the period when it was thought that the primary effect of gypsum addition was to control the setting time of cement. The general practice throughout the cement industry was to use a relatively small and uniform amount of gypsum with little regard for the chemical composition of the clinker or the fineness of grinding. Subsequently it has been learned that if the gypsum content of cement is properly adjusted to an "optimum" level dependent upon the cement, the presumed detrimental effects of C_3A, alkalies, and fineness can be largely avoided and the differences among cements significantly reduced (29). This is demonstrated in Fig. 18 which compared the drying shrinkages of comparable mortars made with a group of cements varying in C_3A content from 2.4 to 14.3 per cent and in alkali content, expressed as Na_2O equivalent, ranging from 0.17 to 1.48 per cent. As shown in the lower curve, the cements have been arranged in order of increasing shrinkage as observed when a constant SO_3 content of 1.9 per cent was used with each clinker composition. From the least to the greatest shrinkage, there is approximately a 2-1/2 fold difference. From the upper curve it can be seen that the range of drying shrinkages of these mortars is considerably reduced when the SO_3 contents of the various cements were adjusted to "optimum". An increase in the C_3A content or the alkali content of a clinker increases the "optimum" SO_3 content requirements of the cement. Similar effects are found when the fineness of the cement is increased; with increasing fineness the amount of SO_3 required to minimize shrinkage and to maximize strength, under normal conditions of test, is also increased.

The "optimum" SO_3 content of a cement is not clearly definable even when tested under standard laboratory conditions. This "optimum" depends upon whether maximum strength or minimum shrinkage is required, and upon the age such qualities are required. In addition, it depends significantly upon the early hydration temperature of the cement. This effect is shown in Fig. 19. The effect of temperature on strength previously discussed, indicates that the SO_3 content that is optimum for minimum shrinkage increases as the early hydration temperature of the cement is increased. From Fig. 19, an SO_3 content of 4.0 per cent, which appears optimum for shrinkage when tested at 73°F, is almost 1 per cent low for minimum shrinkage if the early hydration reactions are at 105°F, and 1 per cent too high to prevent abnormal expansion during early moist curing at 40°F.

In addition to these influences on shrinkage, it has been shown that some chemical admixtures can increase the shrinkage characteristics of cement, perhaps by altering the SO_3 content required for "optimum" which had already been adjusted during manufacture of the cement. It is also possible that the size of the concrete section in which the cement is used (a temperature effect), and the duration of concrete mixing or agitation, might have important effects on the "optimum" SO_3 content of cement.

Water Content

At present the relationship between the water loss of a cement paste to its shrinkage can be expressed only in semi-quantitative terms. Certainly, in most of the investigations of this matter during the past several decades, pertinent details regarding either the nature of the materials used, or the environment to which the specimens were actually exposed, have been omitted from the published reports. Therefore, the present authors will draw largely upon their own studies that are believed to have taken into consideration at least most of the important factors. Of course, data from other sources will be incorporated where appropriate.

Realization of the complexity of this matter has increased in recent decades. Whereas the purpose of early investigators was to find means to reduce the shrinkage of field-placed concrete, current interest has broadened so that a major purpose of more recent investigators has been to develop an understanding of the phenomena of shrinkage itself, with the ultimate hope of minimizing or eliminating volume change property of the paste component itself.

As indicated in the discussion relative to the role of cement properties, there are many traditional concepts that may not have adequate technical support. The information to be presented here is believed to satisfactorily reveal at least the semi-quantitative influence of the various factors involved in the shrinkage of neat cement paste.

The over-all relationship between loss of water of a neat cement paste and the resulting change in length or volume, in an atmosphere free of even the low concentration of CO_2 present in normal air, is shown in Fig. 20. The data in this figure, as in the case of all data shown in Fig. 20 through Fig. 28, represent the shrinkages obtained during the first drying of individual neat cement paste or mortar specimens, each to a single "equilibrium" humidity (as contrasted to progressive step-by-step drying to "equilibrium" of single specimens, which produces irreversible structural effects within the pastes). The paste specimens now to be discussed were 1/4 × 1/4-inch in cross section, and the mortar specimens were 1/4 × 1/2-inch in cross section.

The data in Fig. 20 shows the relationship between shrinkage and water loss on "drying", in a CO_2-free atmosphere, from 100 per cent relative humidity RH, to 0 per cent RH (defined as "D-drying") and then with further dehydration accomplished by progressive heating to temperatures as high as 525°C.

There are several features of Fig. 20 that are of considerable significance. Six separate specimens are

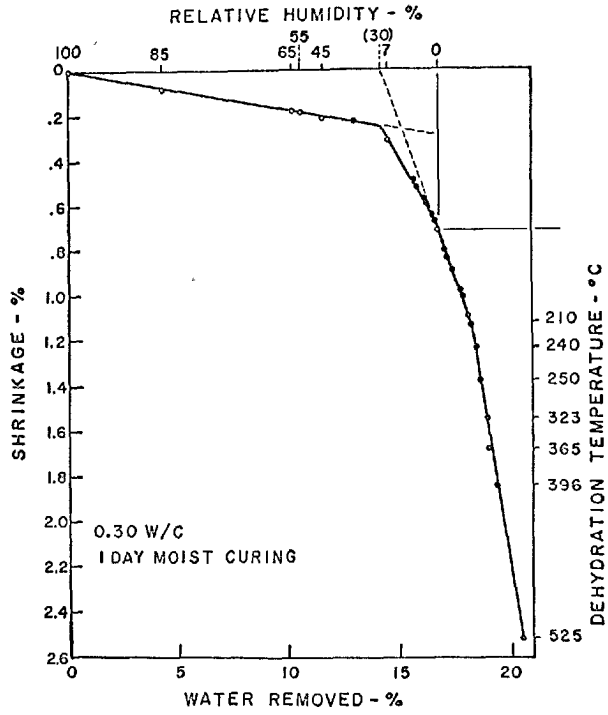

Fig. 20. *The variation of the first shrinkage of moist cured cement paste with water removed by drying in air and dehydration at elevated temperatures*

represented, each of which was dried to apparent length and weight "equilibrium" at a single relative humidity. The open circles represent these specimens equilibrated at the relative humidities shown. The closed dots represent non-equilibrium transient measurements made during drying of the specimen being equilibrated at 0 per cent RH. It can be noted that these non-equilibrium measurements fall consistently on the straight line segment representing data for equilibria from 100 to approximately 30 per cent RH, and similarly on the straight line segment extending from about 30 to about 1 per cent RH. A further change in relationship begins at about 1 per cent RH and extends to 0 per cent RH and beyond. In this experiment further increments of water were removed by heating the specimen to progressively higher temperatures; after each heating, the specimen was cooled to 23°C and its length and weight determined. It may be noted that this third segment extends to water removals attained by heating to about 210°C. The fourth segment extends from 210°C to approximately 525°C, a temperature at which the specimen showed physical disruption. In other experiments that involved various water-cement ratios and various degrees of hydration there has frequently been observed an initial horizontal segment representing satura-

ted pastes from which substantial water losses, perhaps approaching 10 per cent, could be sustained before there was any evidence of shrinkage.

The observed linearity of the segments and the abruptness of change between them suggests that the transitions mark stages of drying where the water is being removed from the different types of hydrated compounds or from sites within the calcium silicate hydrate and other hydrated phases. A belief that shrinkage is not due to loss of "adsorbed" water of the type found on a finely divided material such as silica gel is fully supported by recent studies using nuclear magnetic resonance techniques (22). These studies clearly show that all the water held below 80 per cent RH by paste or by hydrated calcium silicates is not "adsorbed" in that sense but rather in a state similar to that of interlayer water (such as in clays), zeolitic water, or hydrate water of crystallization (such as in ettringite, $C_3A \cdot 3CaSO_4 \cdot 32H_2O$).

Quantitative data on the shrinkage-weight loss relationships of the different linear segments, shown in Table 2, provides several interesting features. The 1:1 concordance between over-all loss of volume of the paste and loss of volume of water in the high temperature range, segment 4, would appear most unusual. This effect would appear to have considerable significance regarding the structure of the paste and the distribution of the residual water in the paste, and will be the subject of further study.

The relations among the $\Delta V_p/\Delta V_w$ of segments 1, 2 and 3 are particularly interesting and suggestive of the nature of the mechanism of shrinkage. These three segments can be interpreted to represent the loss of only two types of water, that represented by the relationship of segment 1 and that of segment 3. Indeed, as can be seen in Fig. 20 an extrapolation of segment 3 intercepts the axis of zero shrinkgae at almost exactly the weight loss and relative humidity at which the junction between segments 1 and 2 occurred. In addition, the $\Delta V_p/\Delta V_w$ factor of segment 2 is almost exactly the average of those for segments 1 and 3. This strongly suggests that segment 2 is simply a combined relation of simultaneous loss of water by the phenomena represented by segments 1 and 3. Upon drying of a saturated specimen, the segment 1 mechanism is joined by the segment 3 mechanism to produce segment 2, with the segment 1 mechanism participating from 100 per cent RH to about 1–3 per cent RH and the segment 3 mechanism participating from about 30 per cent RH to an extended drying condition represented by heating to approximately 210°C. The observation that the $\Delta V_p/\Delta V_w$ for segment 2 is the mean of those for segments 1 and 3 may be coincidental, or may indicate that in the range of 30 to 1–3 per cent RH equal numbers of water molecules are simultaneously released by both the segment 1 and 3 mechanisms, and hence the observed $\Delta V_p/\Delta V_w$ has the mean value of segments 1 and 3, or that in this range the loss of a water molecule results in two different shrinkage mechanisms. Special tests using a SO_3-free cement show a similarly abrupt change in relationship at about 30 per cent RH, thus establishing that the segment 2 or 3 mechanisms do not involve dehydration of the highly hydrated calcium sulfoaluminates.

Table 2. *Ratio of volume change of paste, ΔV_p, to volume of water removed, ΔV_w, during drying in air*

Segement	Range	$\Delta V_p/\Delta V_w$ (cc/cc)
1	100% RH—30% RH	0.025
2	30% RH—1% RH	0.22
3	1% RH—200°C	0.40
4	200°C—525°C	1.00

Subsequent discussion of shrinkage and dehydration phenomena will be limited to those that occur in the more usual range of 100 to 0 per cent RH.

Water-Cement Ratio and Duration of Curing

The relationships obtained between shrinkage and water loss for pastes of 0.3, 0.5 and 0.7 water-cement ratio, when dried in a CO_2-free atmosphere after periods of prior moist curing of 1, 7, 28, 90 and 365 days, are shown in Fig. 21. The points shown are "equilibrium" data obtained with duplicate paste specimens after drying to 85, 65, 55, 45, 7, or 0 percent RH. First it should be noted that the segmented type of shrinkage-water loss relationship previously shown in Fig. 20 is invariably obtained in this type of experimental procedure. The minor deviations from strict consistency of the data are attributable to small differences in the initial weights of the individual specimens. For the segment 1 portion of the relationships, from 10 to approximately 30 per cent RH, the shrinkage to water loss becomes greater the greater the duration of prior curing. It should also be noted that the water loss corresponding to the junction of the segment 1 and the segment 2 relationships decreases with duration of prior curing as might be expected. In general the slopes of the segment 2 relationship, at least for that data representing a single water-cement ratio, appears relatively independent of duration of hydration. For each of these general observations it may be noted that the greatest shift occurs between those specimens cured 1 day and those cured

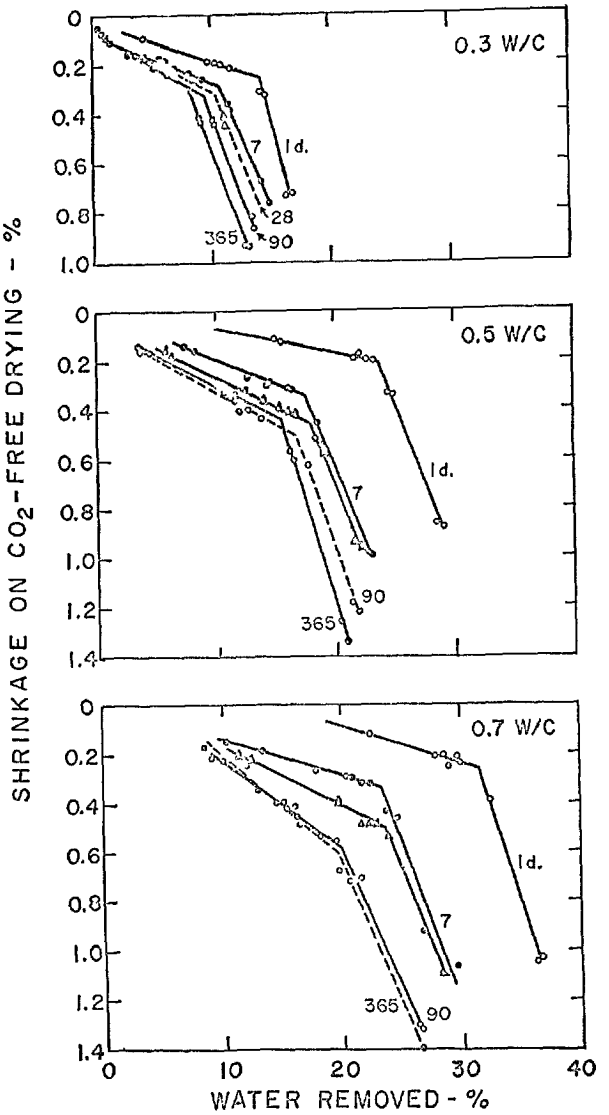

Fig. 21. *Drying shrinkage of cement pastes at various ages and water-cement ratios*

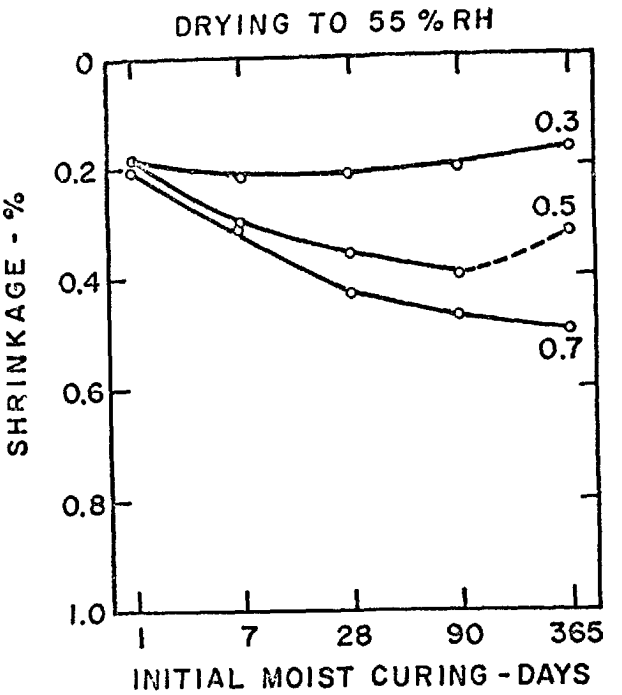

Fig. 22. *Dependence of first drying shrinkage on duration of moist curing and water-cement ratio*

for 7 days, as also might be expected since this period probably reflectes the greatest change in degree of hydration of the cement. A clearer understanding of the effect of duration of initial moist curing (degree of hydration of the paste) prior to CO_2-free drying is shown in Fig. 22. These data are again equilibrium data attained on exposure of the specimens, after the indicated periods of moist curing, to drying at 55 percent RH. As will be discussed later, some differences occurred in the total drying time of these individual specimens before "equilibrium" was attained, but it may be noted that at 0.30 water-cement ratio the shrinkage observed on drying to 55 per cent RH was little affected by curing for periods ranging from 1 to 365 days, and, if anything, the shrinkage at 365 days was slightly less than that at 1 or 7 days. However, at 0.7 water-cement ratio the longer the period of moist curing before drying the greater the subsequent shrinkage due to drying. This would be the normal expectation from "theoretical" considerations: the longer the period of hydration the greater the amount of the "shrinking gel" produced and the less the amount of "restraining" unhydrated clinker particles. The relationships obtained, particularly that at 0.5 water-cement ratio, suggest that for any initial water-cement ratio there may be a duration of initial moist curing that produces within the paste a concentration of hydration product that has maximum shrinkage potential. It should be noted that the shrinkages of the paste of 0.3, 0.5 and 0.7 water-cement ratio were essentially identical when the pastes were initially moist cured only 1 day.

Effect of Duration of Drying

In the previous discussion of shrinkage, the shrinkage values that have been reported were considered to be "equilibrium" values. However it has been observed in the conduct of these various tests that, whereas "equilibrium" was established relatively rapidly at intermediate humidities, decreases in length and weight of the specimens occurred very slowly at

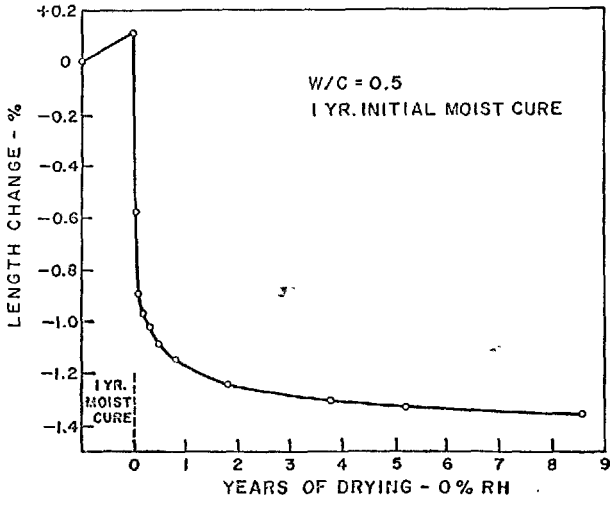

Fig. 23. *Drying shrinkage at 0 percent RH of a cement paste cured moist for 1 year*

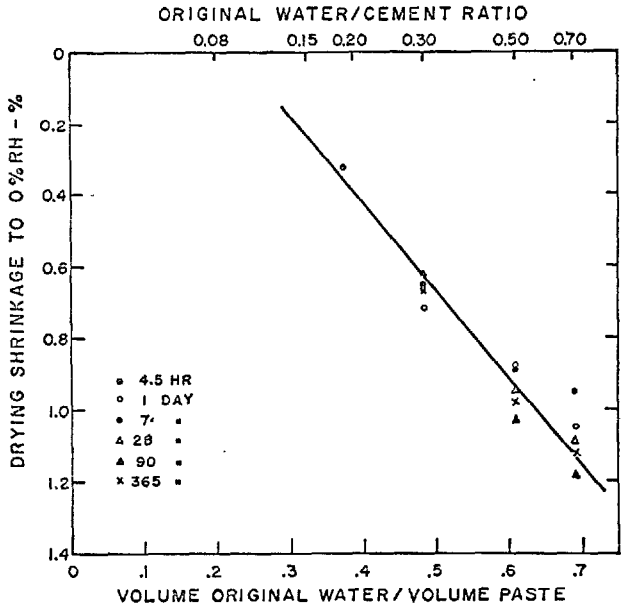

Fig. 24. *Drying shrinkages of cement pastes at 0 percent RH is a function of porosity of the original pastes. Pastes dried approximately 2 months*

very low humidities. Data for a neat cement paste of 0.5 water-cement ratio and initially cured 365 days prior to drying is shown in Fig. 23. Here it may be noted that an expansion of approximately 0.1 per cent occurred during the first 365 days of initial curing. Subsequent exposure of this specimen to "D-drying" condition (0.5μ water vapor pressure in a vacuum, CO_2-free, atmosphere) gave rise to a progressive shrinkage of the specimen during a period of 8–1/2 years of drying in this condition. This prolonged period for approach to equilibrium is not caused by drift of the measuring instrument because these changes in length were accompanied throughout this whole period by a corresponding, and constant, shrinkage-weight loss relationship. Furthermore, the times of drying are far too great to permit interpretation in terms of water release without corresponding changes in the solid phases. Thus, these data indicate that, under certain drying conditions at least, structural changes can occur within the cement paste over very extended periods of time.

This observation is of particular importance in connection with the interpretation of Fig. 21. In the tests shown in Fig. 21, it was found that those specimens receiving a preliminary curing of 90 or 365 days before drying at 0 per cent humidity required or were allowed significantly longer times to reach "equilibrium" than those cured 1, 7, or 28 days. It is of interest to examine the "terminal" shrinkages of the specimens at 0 per cent RH at a time that all of the specimens had been subjected to essentially equal durations of drying. Such information is shown in Fig. 24. Fig. 24 compares the average shrinkages to 0 per cent RH of those specimens initially cured 1, 7, 28, 90 or 365 days and having an original water-cement ratio of 0.3. 0.5 and 0.7. In Fig. 24 the data are presented both on an original water-cement ratio basis and an initial volume of water per volume of paste basis. In addition to the aforementioned data there is also shown a point representing the shrinkage of a similar paste of 0.18 water-cement ratio cured only 4.5 hours (set time). It may be seen that there is no consistent effect of duration of moist curing among the data and that the over-all shrinkage of a paste from 100 per cent to 0 per cent RH is essentially a linear function of original water porosity of the paste rather than its degree of hydration.

The observation that the total shrinkage of paste between 100 and 0 per cent RH is essentially independent of degree of hydration, at least for the type of specimen and drying used in this study, is paralleled by similar observations of the heat of adsorption of hydrated pastes (26). Fig. 25 shows that the total heat of adsorption from 0 per cent RH to saturation is essentially identical for two pastes hydrated to different degrees as reflected by their different non-evaporable water contents (0.156 and 0.204 g/g ign. wt.). The heat of adsorption-water content relationships are observed to consist of two essentially linear segments similar to the previously observed shrinkage-water content relationships. However, it is difficult to believe that the observed segments theore-

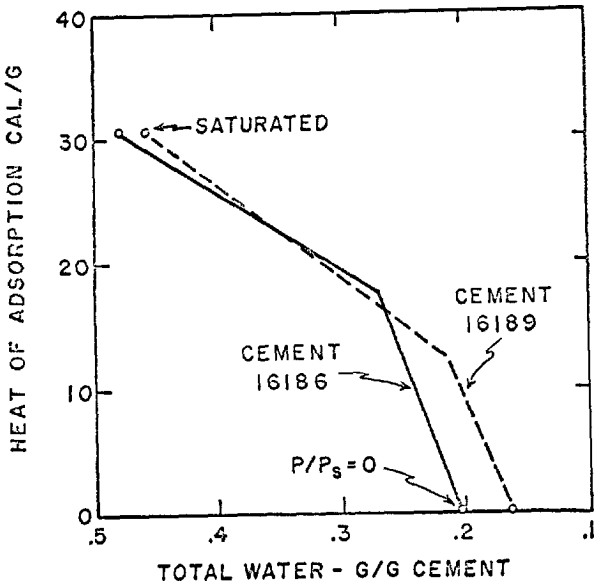

Fig. 25. *Variation of heat of water adsorption of paste follows a pattern similar to that of drying shrinkage with water content*

tically can be absolutely linear and that each increment of water between 100 per cent and 30 per cent RH has an equal energy of binding because the adsorption isotherm is continuous and not a step function. It would therefore appear that the energy increments that result in the different amounts of water that are adsorbed over this range in relative humidity are relatively small.

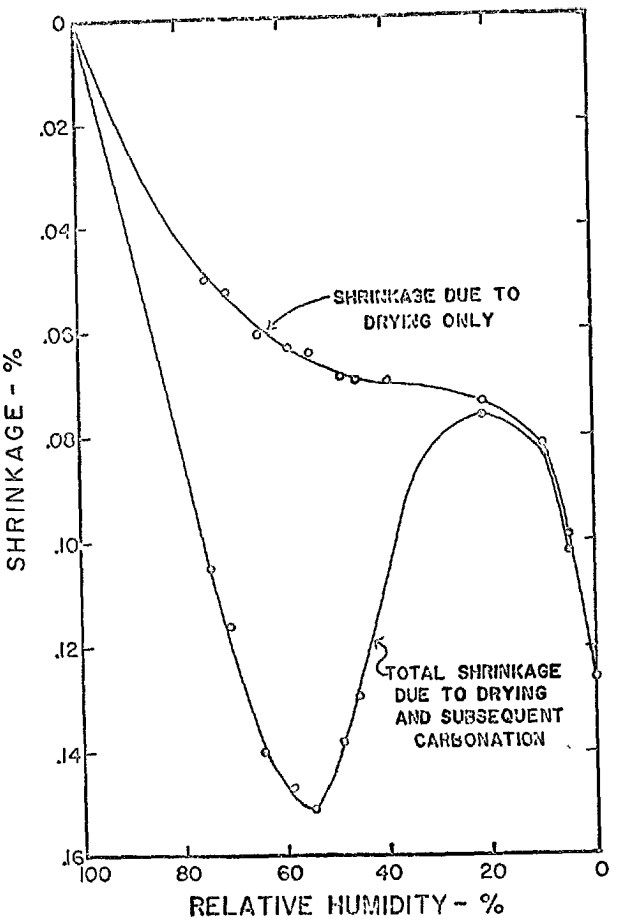

Fig. 26. *Contributions of drying and carbonation to total mortar shrinkages at various relative humidities*

Carbonation Shrinkage

It has been long established that cement paste, mortar, or concrete is also susceptible to that shrinkage caused by reaction with the CO_2, even at the low concentration present in normal air. That this reaction is very dependent upon the relative humidity of the environment in which the exposure to carbon dioxide occurs, is shown in Fig. 26. This figure shows the shrinkages of mortar bars exposed first to CO_2-free drying at relative humidities varying from 100 to 0 per cent and subsequently to atmospheres maintained at these same relative humidities but containing carbon dioxide. The shrinkage due to carbon dioxide is seen to be strongly dependent on humidity; although some carbonation did occur at 100 per cent RH, no shrinkage was found and at humidities below about 25 per cent no reaction or shrinkage resulted from exposure to CO_2. A maximum shrinkage due to chemical reaction with CO_2 was observed at approximately 55 per cent RH. It can be observed that the shrinkage at 55 per cent RH due to carbonation was greater than that due to drying alone at this same humidity. Carbonation in cement paste, mortar, or concrete extends to a much greater depth than is ordinarily assumed on the basis of the phenolphthalein indicator color test, which essentially indicates the depth to which the degree of carbonation is almost complete. It has been shown that the carbon dioxide can carbonate not only the calcium hydroxide liberated by the hydration reactions of the cement but can react with 85 per cent or perhaps more of all the solid components within the cement paste—the calcium hydroxide, the hydrated calcium silicates, the hydrated calcium aluminates, and the magnesium hydroxide. There has been some conjecture as to the mechanism of carbonation shrinkage, and it is believed that this matter can be now somewhat clarified.

In Fig. 27 is shown another typical drying shrinkage versus water loss relationship. The points represented are all "equilibrium" values. After reaching equilibrium in air at the indicated relative humidities

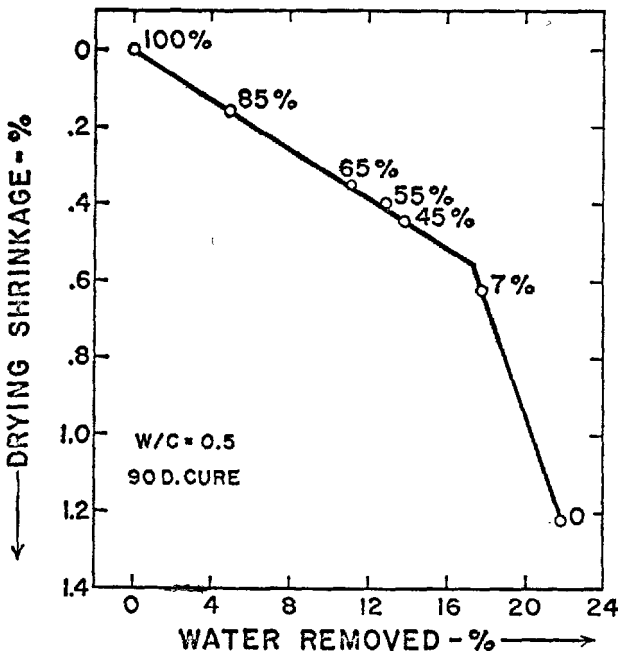

Fig. 27. *Drying shrinkages vs water removed relationship for paste specimens*

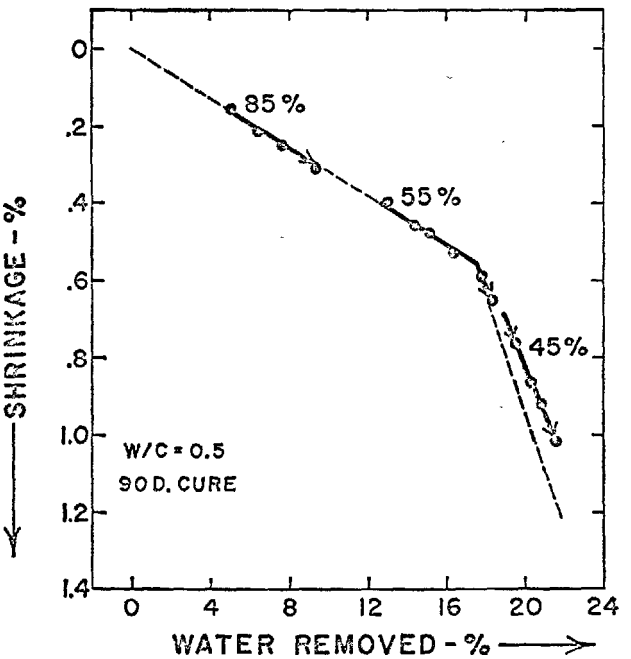

Fig. 28. *Effect of subsequent carbonation on the specimens used for the data in Fig. 27 on shrinkage as water removed relationship*

the specimens then were exposed to air, at the same indicated humidity, but containing relatively low concentrations of CO_2. Under these conditions, one mole of H_2O is released for each mole of CO_2 that reacts and from the gain in weight of a specimen, the loss in water that the specimen has sustained can be calculated. A typical shrinkage water loss due to carbonation relationship sustained by the same specimens of Fig. 27 is shown in Fig. 28 along with a dashed line representing the relationship for water loss due to drying alone, previously shown in Fig. 27. In Fig. 28 it may be noted that the specimen maintained at 85 per cent RH lost water due to reaction with CO_2 but that its shrinkage water loss relationship was identical with the relationship that had been previously established in Fig. 27 where the water loss resulted from the reduction in relative humidity alone. Similar concordance was observed for the specimen maintained at 55 per cent RH which lost water due to carbonation and it can be seen in Fig. 28 that the specimen underwent the transition from segment 1 to segment 2 in a manner strikingly similar to that which would have been expected had the specimen been subjected to reductions in relative humidity in the absence of CO_2. A portion of the relationship attained at 45 per cent RH is also indicated. The data shown in Fig. 28 are typical of those obtained during the carbonation of other specimens of this group at different water-cement ratios and subjected to different prior curing periods. This information can only indicate that the shrinkage-water loss relationship of a cement paste is similar whether the water loss results from evaporation due to a reduction in relative humidity of the specimen or from displacement during reaction with CO_2. It must be admitted at this state of our knowledge that the exact structural significance of these observations is not clearly interpretable. It is intended that these matters will be dealt with in much more quantitative detail in a subsequent paper dealing specifically with this subject.

As had been previously noted the discussion to this point has been limited essentially to the shrinkage properties of cement paste on first drying. The reaction of the cement paste on rewetting and the degree to which the length changes of the paste are reversible will now be considered.

Irreversibility and Stabilization by Drying

The experimental information presented in the following discussion of shrinkage of paste was obtained using thin paste slabs approximately 15 by 80 millimeters and varying in thickness from 0.5 to 3.0 millimeters in thickness (30). As previously discussed the shrinkage of a moist-cured cement paste during its first drying is always greater than the swelling that occurs upon rewetting. However, if the ce-

ment is completely hydrated and protected from carbonation during drying at a relative humidity not below 11 per cent then the swelling and shrinkage cycles that occur on subsequent rewetting and drying are reversible. Typical results are shown in Fig. 29. This particular paste specimen that had received 8 months of initial moist curing was subjected to 3 cycles of drying and rewetting at relative humidities between 11 and 100 per cent. The specimen was held at each of the humidity exposures for periods of about 5 to 8 weeks during which time the thin specimens closely approached equilibrium. The 3 cycles of rewetting and redrying following the first drying of the specimen differed somewhat in detail, as can be ascertained from the data points, which are numbered in chronological order. After the first drying to 11 per cent RH the data show good reproducibility within the range of 11 to 100 per cent RH and it is considered that the paste was essentially stabilized by the first drying. The difference between the length of a saturated specimen prior to first drying and the length attained at 100% RH on subsequent cycles of drying and wetting is the irreversible shrinkage component, and is accompanied by a corresponding irreversible loss of water content.

The first drying shrinkage of a cement paste to equilibrium at intermediate humidity has been shown in Fig. 21 to depend upon the water-cement ratio of the paste and the degree of hydration of the cement. Not all investigators have observed the linear and segmented relationships such as are shown in Fig. 21. The data in Fig. 21 was obtained in this instance by subjecting companion initially-saturated specimens directly to drying at the final humidity desired. In other studies a single specimen has been equilibrated at progressively lower relative humidities and it is believed that the irreversible changes that develop in a paste at each of the equilibrium levels could be the cause for the non-linearity of the relationships obtained. In other words, as the paste was moved progressively from "equilibrium" at a higher humidity to a lower humidity the inherent nature of the paste had been altered by its prior drying and hence the individual data points do not represent equivalent paste structures.

For paste dried to intermediate relative humidities, it has been observed that the irreversible component is strongly dependent upon the porosity of the paste whereas the reversible swelling-shrinking component that arises on subsequent cycling is independent of porosity. As an example, the results for portland cement paste moist-cured for approximately 6 to 7 months prior to drying at 46 per cent RH are shown in Fig. 30 (30). The lower line shows the first shrinkage of these pastes, which had initial water-cement ratios between 0.40 and 0.60. It may be seen that this first shrinkage varied linearly with the "total porosity" of the paste. The swelling of the paste upon rewetting to 100 per cent RH is practically independent of porosity, as indicated by the fact that the irreversible shrinkage line is essentially parallel to that for the first shrinkage. Drying to humidities lower than 47 per cent increases both the reversible shrinkage component and the irreversible shrinkage component of the paste. The first shrinkage of a saturated paste to 47 per cent

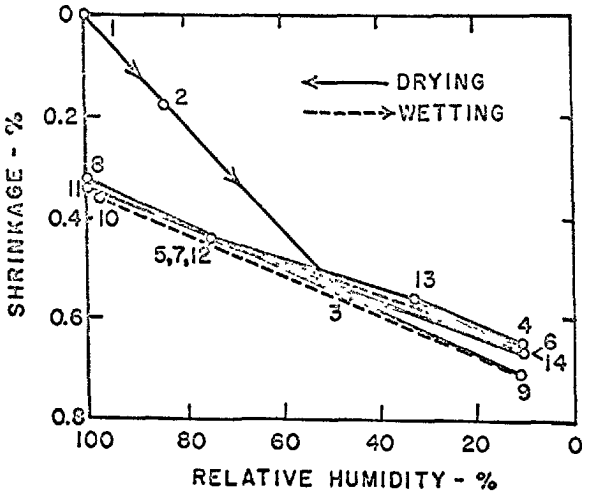

Fig. 29. *Reversibility of volume changes of pastes with relative humidity after first drying*

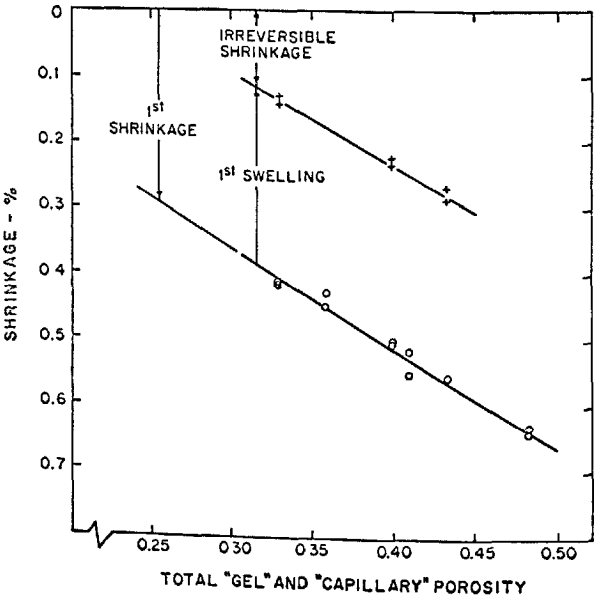

Fig. 30. *Dependence of reversible and irreversible components of drying shrinkage on paste porosity*

RH is found to depend somewhat upon the length of time that the specimen was held at the intermediate relative humidities. If the thin slabs were dried at 84 per cent RH for 5 weeks before drying at 47 per cent RH the effect was slight. However, if the pastes were dried in smaller steps at 92, 84, 75, 67 and 58 per cent RH, during a total of 31 weeks, before drying at 47 per cent RH, the first shrinkage was reduced by about 20 per cent below that by drying directly to 47 per cent RH.

The preceding results show that there can be a pronounced difference between the first drying shrinkage and the subsequent swelling and shrinkage behavior of a hydrated paste. The shrinkage-water content relationship during first drying and redrying appeared to depend significantly upon the length of time the specimen was held in the "dried" condition. Such information is shown in Fig. 31. These particular paste specimens were cured for 19 months, hence were essentially completely hydrated. Each of the 4 specimens was held at 47 per cent RH for different periods of time during first drying as indicated in Fig. 31. Very little irreversible shrinkage or irreversible water loss resulted from drying for only 0.1 days; the redrying curve agreed well with the first drying curve. Paste dried for 1 day or more showed considerable irreversible shrinkage and water loss. Although the loss of water during each redrying cycle is nearly as great as that during the first drying cycle, the swelling and redrying shrinkages are progressively reduced.

Progressive Changes and "Equilibrium" Values

In studies of the mechanism of shrinkage of paste it has often been presumed that the system itself does not undergo changes in structural properties between one "equilibrium" state and another. However, the above results clearly show that hardened cement pastes are subject to progressive irreversible changes during drying.

From the foregoing it seems obvious that there are numerous factors influencing and obscuring any direct quantitative or thermodynamic analysis of shrinkage phenomena. However, it is believed that studies of the nature herein described, supplemented by studies of a much more exploratory nature, may develop concepts and techniques capable either of the reduction in the inherent shrinkage potential of cement paste, or an understanding of those factors that create irreversibility during the first drying shrinkage of paste, so that a stabilizing mechanism can be brought about during the normal hydration process of cement paste.

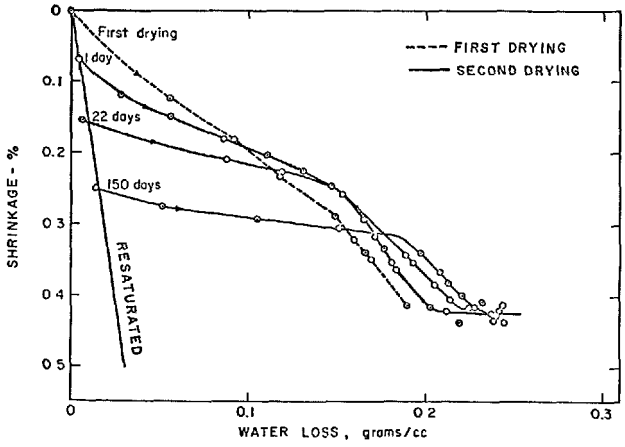

Fig. 31. *Effect of drying at 47 percent RH for periods indicated on length recovery on resaturation and on shrinkage vs water loss relationship of second drying*

Thermal Properties

The thermal properties of hardened cement paste have considerable practical importance. Since concrete structures are subjected to temperature changes and gradients a knowledge of their potential behavior under such conditions may be needed.

It is necessary to consider the relationship of each of these properties to cement paste porosity (initial water-cement ratio and degree of hydration), to moisture content, and to temperature.

Temperature: Effect on Paste Volume

Of the various thermal properties to be discussed here, the dimensional changes accompanying variations in temperature are the most complex.

Wet pastes. For an understanding of the effects of temperature on cement pastes hydrated under normal conditions and containing evaporable water, it is necessary to consider the effect of temperature on degree of saturation. The capacity of a paste for water, at a given vapor pressure, increases as the paste is cooled. This means that a paste not having access to water is effectively "dried" during cooling, and therefore should shrink simply because of this desiccation.

In addition to such a change in overall degree of saturation, distribution of moisture within the paste may occur. This effect, found with nearly saturated pastes (31), is illustrated in Fig. 32. It can be seen here that during rapid cooling (under conditions where there is a negligible temperature lag) the initial contraction coefficient is quite large, 29×10^{-6}/degree C. When cooling was stopped, the specimen began expanding (called "thermal swelling"). The expansion

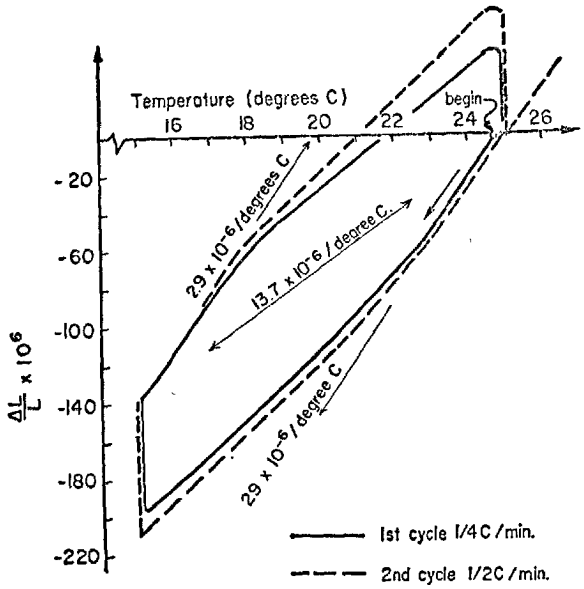

Fig. 32. *Effect of redistribution of moisture on paste volume after rapid temperature changes*

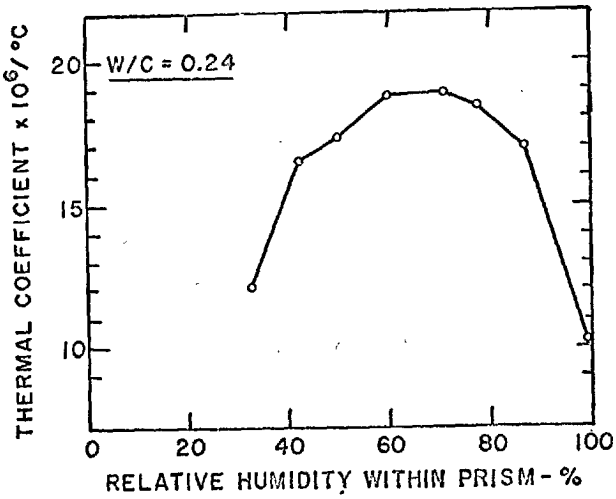

Fig. 33. *The thermal coefficient of expansion varies with the relative humidity within the paste*

followed an exponential decay curve until finally attaininig constant length. Warming caused the process to be reversed, and faster rates of cooling or warming caused greater lags of the length changes. Obviously a contraction (or an expansion) thus depends upon rate of temperature variation, being much lower at slower rates or when calculated from the end points obtained at "equilibrium". Note in Fig. 32 that the "equilibrium" thermal coefficient for this paste was 13.7×10^{-6}/degree C. If the specimen is immersed in water during the experiment, the moisture movement should be affected, and indeed additional swelling can occur after cooling (that is, less overall contraction results).

Dry pastes. Hardened cement pastes that have been completely dried show no time-dependent cooling or heating effects (32). The volume changes that do accompany temperature variations are reversible, except, in certain instances, for the first heating. Thermal coefficients ranging from $10.5–12.4 \times 10^{-6}$/degree C have been obtained (32, 33). The higher value represents a more highly hydrated paste; i.e., less restraining unhydrated cement particles.

Autoclaved pastes. The thermal behavior of an autoclaved paste appears independent of moisture content and the thermal expansion coefficient is about that of a dry paste (34).

Temperature: Discussion of "Coefficient of Thermal Expansion"

"Coefficient of thermal expansion" cannot be uniquely defined for a cement paste. The coefficient depends upon the moisture content of the paste and upon the rate of change of temperature. Three types of thermal coefficient have been usefully employed.

One coefficient, α_i, can be termed the "instantaneous" coefficient. It is used to measure a process too rapid to permit an appreciable redistribution of moisture within the specimen.

A different coefficient, α_w, measures a process that is slow enough for continuous redistribution of moisture to occur but without change in total moisture content.

For a process in which equilibrium is maintained in a paste that is saturated and has access to water, a coefficient, α_{sat}, is used. Several measurements of this coefficient are shown in Table 3. The last item in Table 3 may represent data for the only fully hydrated paste that has been studied.

Since a value of 6.1×10^{-6}/°C has been obtained (36) for a specimen that can be assumed to be clinker alone, the coefficient for the hydrated product appears to be about double that for unhydrated material.

Values of α_w depend greatly upon humidity. They are much highest at intermediate relative humidities than at either water-saturation or at extreme dryness (32, 33, 34, 35). Typical results are shown in Fig. 33. Similar results were obtained with pastes of higher water-cement ratio, but these experiments showed that as hydration proceeds the maximum coefficient decreases while at the same time the values at the extremes remain unchanged (34, 35).

Partial drying of hardened cement pastes can cause the recovery effect (that is, the swelling and contrac-

Table 3. *Thermal expansion coefficients, water-saturated hardened cement pastes*

34	0.277	0.408
43	0.303	0.455
54	0.340	0.505
65	0.400	0.580

tions at constant temperature) to disappear completely. This results in a large increase in α_w, a value as high as 25×10^{-6}/°C has been obtained (31). This is nearly as high as the initial rates for rapid cooling shown in Fig. 32, and considerably higher than those of Fig. 33. Approximately similar results have been reported elsewhere (35).

Thermal Conductivity

Measurements under carefully controlled conditions (37) suggest that paste porosity and temperature have little effect on the thermal conductivity of saturated pastes. The values obtained, 7.3–9.3 BTU/(hr) (sq ft) (°F/in), are, however, about twice that calculated for oven-dried pastes.

Specific Heat

The specific heat of hardened cement paste has apparently not been measured under conditions where all the variables were known or controlled. For example, data (38) published for a single cement at two water-cement ratios and at a number of temperatures, although the pastes were described as well hydrated, no information was given on the degree of saturation The values, shown in Table 4, indicate strong dependence upon porosity and temperature.

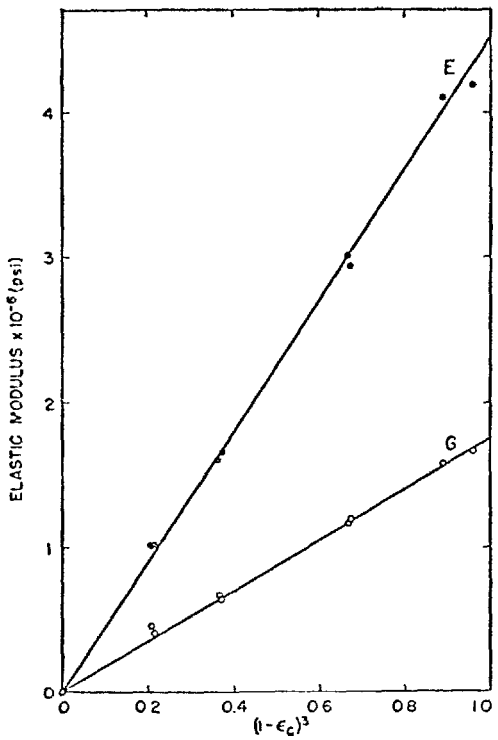

Fig. 34. *Dependence of elastic moduli of paste on "capillary" porosity*

Elastic Properties of Hardened Paste

We will now consider the elastic properties of hardened paste: Young's modulus, shear modulus, and Poisson's ratio, and the effects of porosity, temperature and drying on these properties.

Effect of Porosity

Elastic moduli have been determined for nearly fully hydrated portland cement pastes and tricalcium silicate pastes of various porosities (39). The Young's modulus, E, was found to depend upon the capillary porosity, ε_c, according to:

$$E = E_g(1 - \varepsilon_c)^3 \qquad (1)$$

where E_g is Young's modulus of the gel at "zero capillary porosity". A similar equation was found to hold for the shear modulus, G. Data for water-saturated portland cement pastes are shown in Fig. 34. It was also found that good conformance to Eq. (1) is obtained if the "total porosity" ("gel" and "capillary" porosity) is used as shown in Fig. 35 for the same set of results. The value of E when the "total porosity"

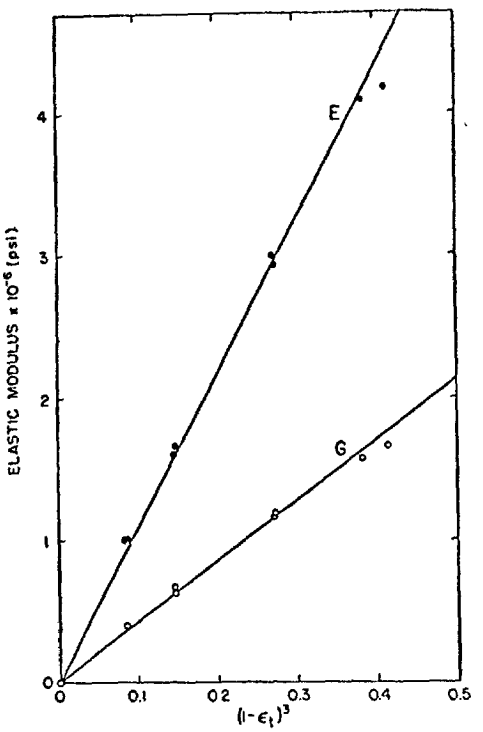

Fig. 35. *Dependence of elastic moduli of paste on "total" porosity*

Table 5. *Elastic moduli for hardened pastes of zero porosity (by extrapolation)*

	Gel phases				Solid phases			
Material	E_g × 10⁻⁶ (psi)	G_g × 10⁻⁶ (psi)	K_g × 10⁻⁶ (psi)	ν_g	E_s × 10⁻⁶ (psi)	G_s × 10⁻⁶ (psi)	K_s × 10⁻⁶ (psi)	ν_s
Tricalcium silicate	6.8	2.7	4.4	0.25	13.8	5.6	8.8	0.23
Portland cement	4.5	1.75	3.4	0.28	10.8	4.3	7.9	0.27

is zero, E_g, represents the average Young's modulus of the solid phases within the gel and the unhydrated cement particles. The bulk modulus, K, and Poisson's ratio, ν, were also calculated from the Young's and shear moduli. The limiting values on both the zero "capillary" and "total porosity" basis of all of these quantities are given in Table 5 for pastes made from pure tricalcium silicate and a portland cement, cured, saturated, and measured at 25°C. The data for E_g, G_g, etc. are of greater accuracy than the corresponding values for E_s, G_s, etc. because of the minimal extrapolation involved.

Effect of Curing

During curing, the originally water-filled spaces in the fresh paste fill with hydration products and the cement grains are progressively transformed into hydrated pseudomorphs. The moduli of all fresh pastes are zero, but during curing increase to values corresponding to the straight lines shown in Figs. 34 and 35 for mature pastes. Pastes at an early age or incompletely hydrated pastes may be regarded as a two phase system consisting of unhydrated cement particles embedded in a matrix of hydration products; the moduli in these instances may be approximated from equations for the elastic moduli of heterogenesis systems (40).

Effect of Temperature

The elastic moduli of concrete decrease with increasing temperature (41) but the information available is not sufficient for quantitative detailed analysis. With mortars of 0.35 water-cement ratio, with a 50 per cent volume of cement paste, that were cured 2 months in water at 20°C, it was found the dynamic Young's moduli varied according to (42):

$$E(10^6 \text{ psi}) = 5.11 - 0.016\ T°C \qquad (2)$$

The effect of temperature on the Young's moduli of neat pastes (0.35 water-cement ratio, cured at 97°C) has been determined over the range 0–100°C (43). For one such paste the temperature coefficient was only 0.0045×10^6 psi/°C, about one-fourth that for the room temperature cured mortar specimens of Eq. (2). Perhaps the difference is related to the effect of curing temperature on the nature of the hydration products, such as the degree of hydration and uniformity of hydration product as previously discussed in connection with the effect of temperature on strength.

Effect of Drying

Fig. 36 shows the effect of drying on the bulk moduli calculated from the resonance frequencies of thin slabs of hardened cement pastes. The wet (water-saturated) pastes have higher moduli than those dried to 47 to 7 per cent relative humidity. Also, rewetting causes a partial, but not complete, recovery. This result is taken to indicate that an irreversible change occurs in the structure of the paste during drying, in agreement with shrinkage and surface area measurements (30, 44).

Fig. 36 shows one other difference between water-saturated pastes and dried pastes. The data for the dried pastes fall on a straight line through the origin, just as found for the Young's and shear moduli data. The line for the rewet specimens and the line for the

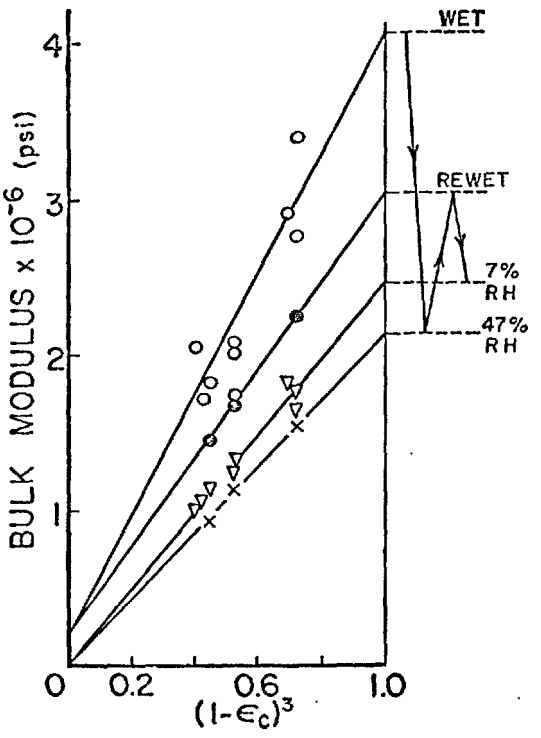

Fig. 36. *Dependence of the bulk modulus of paste on capillary porosity at different moisture conditions*

Table 6. *Changes of poisson's ratio with drying and rewetting*

Moisture condition	Poisson's ratio
Saturated	0.31
Dried to 47% RH	0.18
Rewetted	0.26
Dried to 7% RH	0.18

saturated pastes, however, show a finite intercept of about 0.2×10^6 psi, in approximate agreement with the bulk modulus of water, 0.3×10^6 psi.

Poisson's Ratio

Drying of nearly fully hydrated paste decreases Poisson's ratio (39) and the magnitude of the changes in the ratio appears to be independent of porosity of the paste within the precision of these measurements. Table 6 compares the average Poisson's ratio of saturated pastes, and the effects of drying to 47 per cent RH, rewetting (vacuum saturation), and redrying to 7 per cent RH. The pastes ranged in capillary porosity from about 0.1 to 0.3. The results are similar to those for the bulk moduli in indicating that irreversible changes are caused by drying.

Compressibility of the Hydrates

The compressibilities of an unhydrated portland cement and of "D-dried" solids in hydrated cement pastes have been measured at pressures up to 10,000 atmospheres (45). The compressibility of the unhydrated cement was found to vary with pressure range, being (0.21 ± 0.01) and $(0.12 \pm 0.01) \times 10^{-6}$/psi in pressure ranges of 0 to 4000 and 4000 to 10,000 atmospheres respectively. Compressibilities of the dried solids in hardened pastes cured for periods ranging from 1 to 32 weeks varied considerably but no correlation with curing time or initial water-cement ratio (0.3 to 0.7) could be developed. The mean value for ten such pastes was $(0.22 \pm 0.03) \times 10^{-6}$/psi. The mean value for compressibilities of the hydrates in these pastes (the paste compressibility corrected for the compression of the volume fraction of unhydrated cement) is calculated as $(0.24 \pm 0.08) \times 10^{-6}$/psi. Since the compressibility of dried calcium hydroxide (46), $(0.25 \times 10^{-6}$/psi) is very close to the value for dried pastes, the compressibilities of calcium hydroxide and "tobermorite" gel in the hardened paste cannot be very different.

The compressibilities of dried hydrates that were determined by application of hydraulic pressure (a light petroleum distillate) to the sample are about twice as great as the compressibilities determined by direct physical compression, or conversely, the bulk modulus of elasticity obtained by direct compression is only about half as great as that obtained by the hydraulic pressure technique. This discrepancy may indicate that the petroleum distillate did not penetrate all of the "gel" pores in the hardened paste even at 10,000 atmospheres pressure. Use of the $(1 - \varepsilon_c)^3$ relationship of Eq. (1) indicates that the lower bulk modulus corresponds to a porosity of about 24 per cent for the dried hydrates which agrees closely with the 26 per cent porosity generally assigned to the "gel" substance itself, Hence the discrepancies in compressibilities and bulk moduli can be explained if very little if any of the "gel" porosity was penetrated by the fluid during the compression measurements.

Inelastic Properties of Hardened Paste

Somewhat analogous to our knowledge concerning the shrinkage of pastes, the information available on the inelastic properties of pastes, mortars or concretes appears insufficient for quantitative description. The large number of papers on creep of concrete are somewhat conflicting and in many instances either the necessary details as to the exact nature of the material studied or an adequate description of the methods employed and precautions taken are lacking. However,

the discussion to follow is believed to represent, at least semi-quantitatively, some of the factors involved.

Creep

When hardened cement pastes are subjected to externally applied loads both instantaneous and time-dependent deformations occur. The instantaneous portion may include both a truly elastic deformation and a "permanent set". The time-dependent portions resulting from the applied stress is called "creep". The creep of cement, mortar, and concrete is generally regarded to result mainly from the creep of the cement paste fraction. At moderate stress level (below 30 to 40 per cent of the ultimate strength of the material) the creep deformation is proportional to the applied stress at equal times after loading (47, 48). The total creep deformation may be divided into two parts, one of which is reversible, and the other irreversible (49). Creep which occurs under constant humidity has been called "basic creep" (50). During drying while under load the total deformation is larger than can be accounted for by the drying shrinkage. The increase in the deformation may be called the "drying creep" (47).

A typical creep curve is shown in Fig. 37 (51). This curve shows compressive strain per unit stress (at 3500 psi) of a cement paste cylinder of 0.30 water-cement ratio. The specimen, a thin-walled (2.5 mm) hollow cylinder, was tested in water to insure water-saturation throughout the test. Three separate creep zones were identified as shown in the figure. The test was continued for 1300 hours, and although constant length had not yet been reached, the total strain was more than twice the instantaneous strain.

Flexural deflections of small, sealed, hardened cement paste beams of 0.32 water-cement ratio have been found to continue for about 500 days, attaining apparently constant values about four times as great as the instantaneous deflections (48).

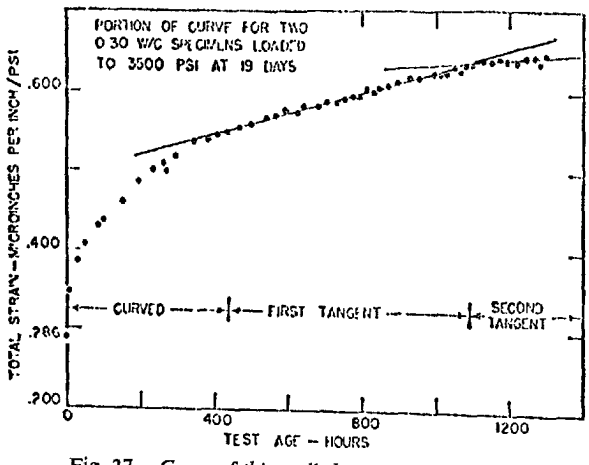

Fig. 37. *Creep of thin-walled cement paste cylinder*

Effect of Water-Cement Ratio and Curing on Creep

Although the creep of mortar and concrete can be approximately calculated from the volume fractions of cement gel and unhydrated cement in the cement paste fraction (41) (47) few detailed studies of this kind have been reported for cement pastes. The creep is known to increase with water-cement ratio and to decrease with curing time before loading. The effect of water-cement ratio on the creep is shown in Table 7 for water-saturated portland cement pastes cured for 29 days before loading (51).

Effect of Drying on Creep

If concrete or mortar is loaded at the same time that it is dried for the first time the total deformation can be several times as great as the sum of the shrinkage and the creep measured separately (52) (53). The effect is observed in shear as well as in compression and flexure (54). The effect was not observed during subsequent drying after rewetting (55). This fact indicates that the effect may be associated with an irreversible change of structure of the paste during first drying. To what extent this effect may depend upon reaction with atmospheric carbon dioxide is not known. However, as already discussed, it is known that irreversible changes of the shrinkage behavior occur during the first drying in the absence of carbon dioxide (30). It therefore seems likely that the irreversibility seen in the creep during first drying is not totally dependent upon carbonation. The phenomenological similarities and certain theoretical considerations indicate that drying shrinkage and creep may have a common origin (56).

Creep is practically eliminated if the paste is oven dried at 110°C before loading and kept dry while under load. Upon rewetting the paste may again creep under stress, but at a lower rate than before drying (51).

Table 7. *Effect of water-cement ratio on creep of water-saturated pastes*

w/c	Load* (psi)	Duration of load (hours)	Specific instantaneous strain	Specific creep strain
0.45	3370	800	0.47 × 10⁻⁶/psi	0.68 × 10⁻⁶/psi
0.40	4300	875	0.41 × 10⁻⁶/psi	0.56 × 10⁻⁶/psi
0.33	5825	875	0.30 × 10⁻⁶/psi	0.45 × 10⁻⁶/psi
0.30	6000	800	0.26 × 10⁻⁶/psi	0.35 × 10⁻⁶/psi

*Approximately 33 to 40 percent of compressive strength of specimens.

Effect of Temperature on Creep

Creep of moist mortars and concretes increases with temperature above 10°C, but shows irregular variations with temperature near 0°C. Results (55) reported for measurements on sealed, moist cured mortars of 59 per cent cement paste, 0.35 water-cement ratio, cured 6 months at 35°C before loading in flexure are given in Fig. 38. Also shown are results obtained by in similar tests (57) of for moist concretes moist cured 41 days before loading to compression. The relative creep, the ratio of the creep at each temperature to that at 20°C is given as a function of the temperature. The creep values were those determined after 24 days under load at about 30 per cent of the ultimate load. The agreement between the two sets of data is excellent. The relative creep for sealed, but not water-saturated, specimens of hardened portland cement paste beams of 0.32 water-cement ratio did not increase with temperature as much as indicated by the data of Fig. 38 (58). The higher creep at temperatures near 0°C is considered to be an artifact attributable to cyclic freeze-thaw action associated with the temperature control. Much larger deflections are observed when the specimen is subjected to temperature variations while loaded than when loaded at any constant temperature within the range (57, 42).

Internal Friction

The mechanical processes of creep under static loads have relatively long relaxation times. In addition, there are mechanical relaxation processes of much shorter duration which produce internal friction and damping when cement pastes are dynamically loaded. The "vibration damping" at very low frequencies may be a result of some of the same relaxation processes that control creep. Measurements of the logarithmic decrement, δ, at low frequencies show a marked increase in internal friction at frequencies below 2.5 cycles per sec., Hz (59). Portland cement pastes of 0.33 water-cement ratio, cured at 95 per cent RH for at least 2 weeks and dried in air until 2 months old showed a value of δ of 0.026 above 2.5 Hz, but δ increased to 0.036 at 0.5 Hz, the lowest frequency employed. The results suggest even greater damping at lower frequencies.

At higher frequencies it is sometimes more convenient to measure "tan δ" by measuring the width of a resonance peak, rather than the logarithmic decrement directly.

In a preliminary study of the temperature dependence of tan δ of cement pastes results were reported (43) for values of tan δ ranging from 0.005 for a partially dried cement paste cured at 27°C to peak values as high as 0.04 for water-saturated pastes that had been cured at 97°C (0.35 water-cement ratio). Five internal friction peaks were identified in the water-saturated pastes in the frequency range 500 to 3000 Hz between −30 and 100°C. The temperature dependence pattern indicated one peak to be a relaxation process associated with the flow of water of nearly normal viscosity. In the one partly dried paste no internal friction peaks were observed, but the value of tan δ was high enough to indicate the existence of relaxation processes differing widely in their relaxation times.

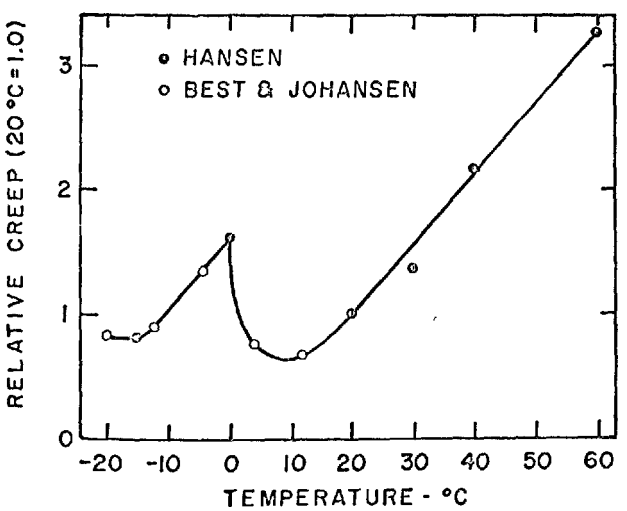

Fig. 38. *Variation of creep of sealed mortars with temperature*

Permeability to Water

Saturated Flow

The rate of flow of water through hardened cement pastes under the action of a hydraulic gradient, as given by D'Arcy's law, depends upon the paste structure and the viscosity of the fluid. The viscosity of the liquid phase may depend upon dissolved impurities, such as the alkalies present in most portland cements. Gradients in the concentration of dissolved alkalies may also cause "osmotic pressure" effects that cause apparent deviations from D'Arcy's law. When such "osmotic" effects occur a plot of the observed flow rate versus the applied hydraulic pressure is linear, but an intercept on the pressure axis is observed. The intercept on the pressure axis may be taken as the "osmotic" pressure, and the slope of the relationship used to calculate the permeability coefficient (60).

The relationships between permeability and other properties, such as porosity and "specific surface

area" are not simple. In a freshly mixed cement paste "bleeding" or "settlement" is observed. From bleeding measurements the permeability coefficient of fresh pastes can be calculated (1, 61). The total water content of the paste can be considered to be "capillary" space. Even after the paste has set, in the early stages of hydration, the originally water-filled spaces between the cement grains form a continuous system of capillaries; thus, the resistance afforded by the cement particles and hydration product is not great and the permeability remains high. As hydration proceeds these capillaries are partially filled by the hydration products, the permeability decreases, and, for well hydrated paste of intermediate water-cement ratio, becomes very low.

For sufficiently hydrated pastes the relationship between permeability and "total" porosity (gel and capillary porosity) was found to satisfy the following equation (62):

$$K_1 = \frac{1.36 \times 10^{-10}}{\eta(T)} \frac{\varepsilon^2}{1-\varepsilon} \exp\left[-\left(\frac{1242}{T} + 0.7\right)\frac{1-\varepsilon}{\varepsilon}\right] \quad (3)$$

in which K_1 is the permeability coefficient, $\eta(T)$ is the viscosity of water in poises at temperature T(°K), and ε is the "total porosity".

This equation has been previously applied to flow through both the "gel" and "capillary" pores, or the "total porosity", of the paste. However, in keeping with the prior discussions, if the "gel" water is considered to be part of the "solid" phase of the hydrated paste, and if the "total" porosity, ε, is replaced by only the "capillary" porosity, ε_c, then the equation applies over the whole range, from fresh, bleeding and plastic pastes, to mature pastes as is shown in Fig. 39.

This figure obtained for pastes of C_3S show acceptable conformance with Eq. (3) for fresh, bleeding pastes (61) and for hardened pastes after 4 to 242 days of hydration without any suggestion of major change in the permeated system, i.e., such as "continuous" versus "discontinuous" capillaries. It has been noted that pastes made of cements of normal fineness but at high water-cement ratio, 0.70 by wt., do not quantitatively conform to Eq. (3) until relatively well hydrated. Specimens prepared without special precautions at such water-cement ratios may contain "bleeding channels" that can produce misleadingly high experimental results.

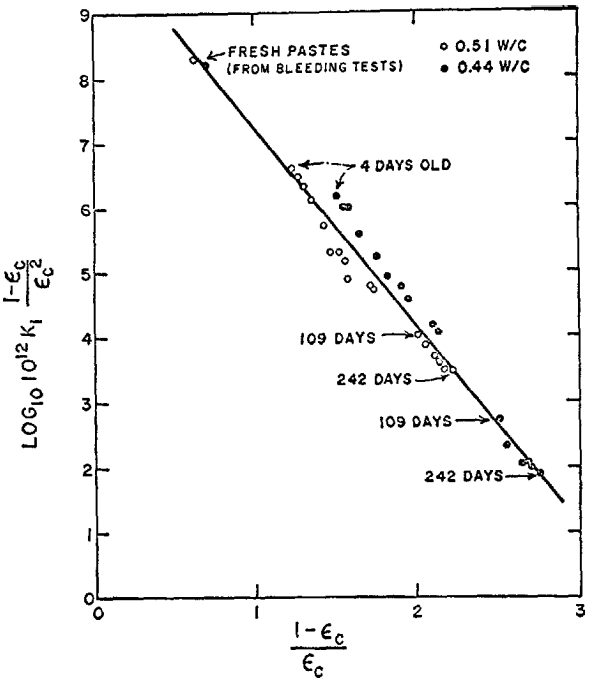

Fig. 39. *The functional relationship between permeability and capillary porosity is linear over the porosity range from fresh pastes (bleeding) to essentially fully hydrated pastes (242 days moist cured)*

Diffusion of Moisture in Unsaturated Pastes

Moisture may diffuse through an unsaturated paste because of concentration of dissolved material, humidity and temperature gradients. A general treatment for capillary porous systems, including both mass and heat transport, has been given (63). For isothermal, uniaxial flow, mass transport is proportional to the concentration gradient. In hardened cement pastes the diffusion coefficient is found to increase with paste porosity, moisture content and temperature, and to decrease with curing time (64, 65, 66, 67).

Most determinations of the water diffusion coefficients are based on transient measurements of water contents during drying rather than steady state conditions. In many instances, the drying rate then is not controlled by diffusion through the material, because of retardation by slow drying at the surface of the specimen. Unless a particular effort is taken to maintain humidity and temperature control at the specimen's surface the initial rate of drying will not be the diffusion controlled rate. When, in later stages of drying the rate becomes diffusion controlled, there is a marked change in the rate. Values of the "diffusion coefficient" may then be calculated from the drying curves.

Data on diffusion coefficients shown in Fig. 40 pertain to determinations on moist cured hardened cement pastes (67).

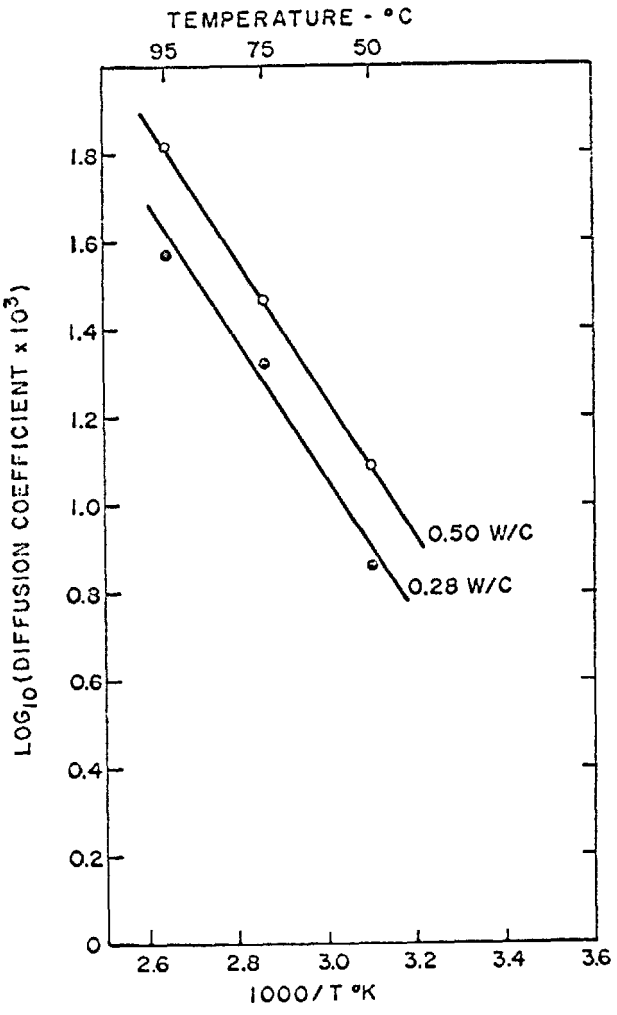

Fig. 40. *Moisture diffusion in paste varies with temperature*

The results agree with values obtained by other investigations (66) at the higher temperatures.

The temperature dependence of the diffusion coefficients may be used to calculate the activation energy for moisture diffusion through the paste; 6.5 ± 3 kcal/mole for 0.5 *w/c* and 7.5 ± 3 kcal/mole for 0.28 *w/c*. These values were derived from pastes from which more than half the evaporable water had been removed. Lower values would be expected at higher water contents.

Ionic Mobility and Electrokinetic Effects

The effects of "ionic mobility" and of "electrokinetic phenomena" in cement paste, although discussed only briefly in this paper, are believed to be of considerable importance in connection with various aspects of paste, mortar, and concrete properties. Because of their complexity these matters will be dealt with in necessary detail in a subsequent paper.

Ionic Mobility

The inherent mobility of the particular ionic species influences the relative ease with which they can be leached from paste and hence also presumably the relative ease with which they can penetrate the paste. For example, the hydrated lithium ion because of its relatively low ionic mobility (conductance) is leached less rapidly than the hydrated sodium ion which has an intermediate ionic mobility. The hydrated potassium ion, which has a mobility higher than sodium ion, is leached more rapidly.

There is also evidence that the relative ionic mobilities influence not only the distribution among ionic species during simultaneous leaching but also the overall rate of leaching of all ions. The addition of a lithium salt to cement containing soda and potash reduces the rate of leaching of all alkalies. Apparently the ion of lowest mobility present has a significant effect on the total leaching rate of all alkalies.

In addition to their influence on movement of ions within the paste, the mobilities of the ions can have considerable effect upon certain chemical reactions. For example, it has been shown (68) that at essentially equal thermodynamic activities, the rate of attack of the alkali hydroxides on siliceous aggregates is directly related to ionic mobility, i.e., lithium hydroxide is least aggressive, sodium hydroxide is moderately aggressive, and potassium hydroxide is the most aggressive. In other tests it has been shown that tetramethyl ammonium hydroxide is less aggressive than lithium hydroxide and that the tetramethyl ammonium ion has a correspondingly lower mobility than lithium ion.

We have found that consideration of ionic mobilities also successfully explains the effects of various chemical inhibitors of the alkali aggregate reaction (69).

Electrokinetic Effects

Cement paste behaves as a reasonably efficient semi-permeable membrane as indicated by observations of osmotic flow when differences exist in the thermodynamic activities of the water component of contact aqueous solutions.

In addition, cement paste appears to be a permselective, electronegative membrane and show phenomena associated with this type of membrane. Streaming potentials or electroosmosis results when

an electrolyte is forced through the paste or an electrical potential gradient applied. Also, since the paste membrane shows greater transference for cations, "anamalous osmosis" develops if gradients in activity of cations exist. A suitable description of the phenomena and the experimental results obtained are beyond the scope of this paper.

Written Discussion

Sidney Diamond

Synopsis

New data on mercury intrusion into portland cement pastes are presented, and are interpreted as indicating a continuous distribution of pore sizes from an upper limit of the order of 0.1 to 1 microns, depending on water-cement ratio and maturity. Attention is drawn to the potential utility of the scanning electron microscope in elucidating the details of portland cement paste microstructure.

The microstructure of so complex a material as portland cement paste is far from perfectly understood, despite the very extensive assemblage of evidence of various kinds presented by Verbeck and Helmuth. The present discussion is aimed at adding several additional items of evidence in the specific areas of pore size distribution and of electron optical observation of microstructure.

Mercury Porosimetry of Cement Pastes

The pore size distributions of a number of cement pastes of various water-cement ratios and degrees of maturity have been examined by D. N. Winslow in the writer's laboratory, using slightly-modified commercial mercury intrusion equipment capable of intruding cylindrical pores down to an effective

diameter of slightly greater than 100 Å. These pastes were mixed under vacuum and hydrated in sealed containers for 24 hours, stripped and hydrated under lime-water for their remaining hydration period, then oven-dried. Representative pore size distribution curves are shown in Fig. 1 for young (3-day) and mature (320-day) pastes of 0.4 and 0.6 initial water-cement ratios. A wetting angle of 130° has been assumed.

In contrast to the curves discussed by Verbeck and Helmuth, these results are presented as cumulative distribution curves rather than as differential distribution curves. In point of fact the mercury intrusion data are obtained in precisely this fashion, that is, in terms of cumulative intrusion following stepwise increments of increasing pressure. For many interpretive purposes, especially those involving estimation of relative volumes of pore space existing between arbitrary size bounds, this form of presentation was found to be much more satisfactory than the differential functions.

Examination of the data suggests the following:

1. Cement pastes prepared in this manner show only a negligible content of "large" pores that is, those larger than one micron in diameter.
2. In each of the curves there is a pronounced inflection point at a pressure corresponding to that required to intrude pores of a size range somewhere between 1 micron and 0.1 micron, depending on water-cement ratio and degree of maturity.
3. For pressures higher than that corresponding to the inflection point, an increase in pressure always brings about a significant increase in mercury intrusion; i.e. from this point down the cumulative pore size distribution curve shows a continuous distribution of sizes down to pores (or interstices) corresponding to the limit of pressuring capacity of the instrument. There are no gaps corresponding to size regions where pores capable of being penetrated by mercury are lacking.

The curves obtained generally resemble those of Edelman, Sominskii and Kopchikova (1), for comparable water cement ratios and ages, but differ from them in that the latter show significant contents of pores larger than 1 micron. The difference is apparently due to the mode of hydration, the samples of Edelman et al. being hydrated at atmospheric humidity rather than under water. Presumably water was lost from some large capillary spaces early in the hydration process and these pores remained incompletely filled with hydration product even after prolonged periods.

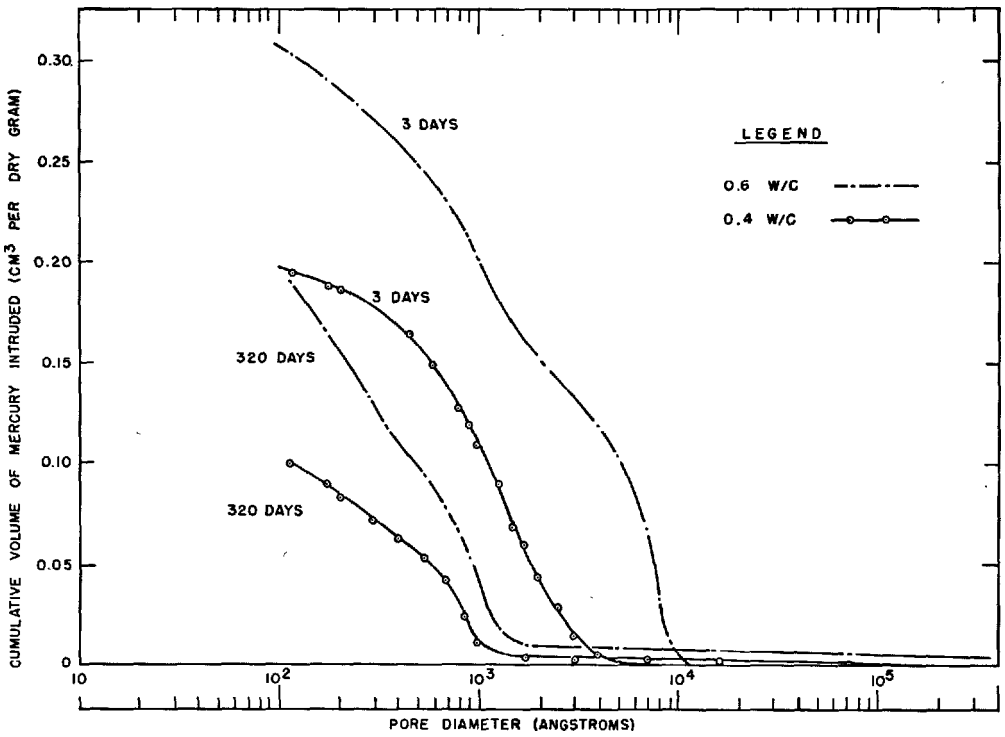

Fig. 1. *Pore size distribution curves for cement pastes*

It is entirely possible to plot such data in differential form and draw inferences about the number and extent of "modes" of pore sizes that seem to be present. It seems more to the point to the writer to emphasize the fact for sizes below the order of a significant fraction of a micron and above about 100 Å. a continuous distribution of pore sizes is indicated by mercury intrusion.

In all cases the volume of "space" potentially available in the paste (in terms of volume formerly occupied by water lost on drying) is substantially greater than the volume of mercury intruded. Thus the evidence cited here does not preclude the possibility of a significant gap in the pore size distribution between the roughly 100 Å lower limit explored and some hypothetical upper limit of a special category of "gel" pores, with the remaining volume of porosity concentrated in some narrow "gel" size range. However, the evidence of the nitrogen pore size distribution curves cited by Verbeck and Helmuth suggest that this is not the case; rather, that the continuous distribution of pore sizes also seems to exist between 100 Å (or more) and the lower limit of pore sizes. The significance of the apparent continuity in the cumulative pore size distribution curve is debatable. The writer, however, is led to the supposition that the distinction between "gel" pores and ordinary pores in cement paste may be largely conventional.

Application of Scanning Electron Microscopy

Another aspect of the microstructure of cement paste that is of current concern in a number of laboratories involves the application of the scanning electron microscope to the problem of delineating the significant details of the morphology and topographic arrangement of the particles and of the pore spaces between them. This instrument has several significant advantages over transmission electron microscopy for this purpose. In particular, one can examine a fracture surface directly, without the necessity of preparing replicas. Not only is the possibility of replication artifacts or imperfect reproduction of the surface avoided, but the entire surface of a relatively large sample may be scanned systematically and quickly; hence, much greater assurance is forthcoming that the small areas photographed are representative of the entire sample. The depth of field is extremely great, and the curved path taken by the secondary electrons which form the image permit visualization of details of microstructure within cavities and interstices between particles.

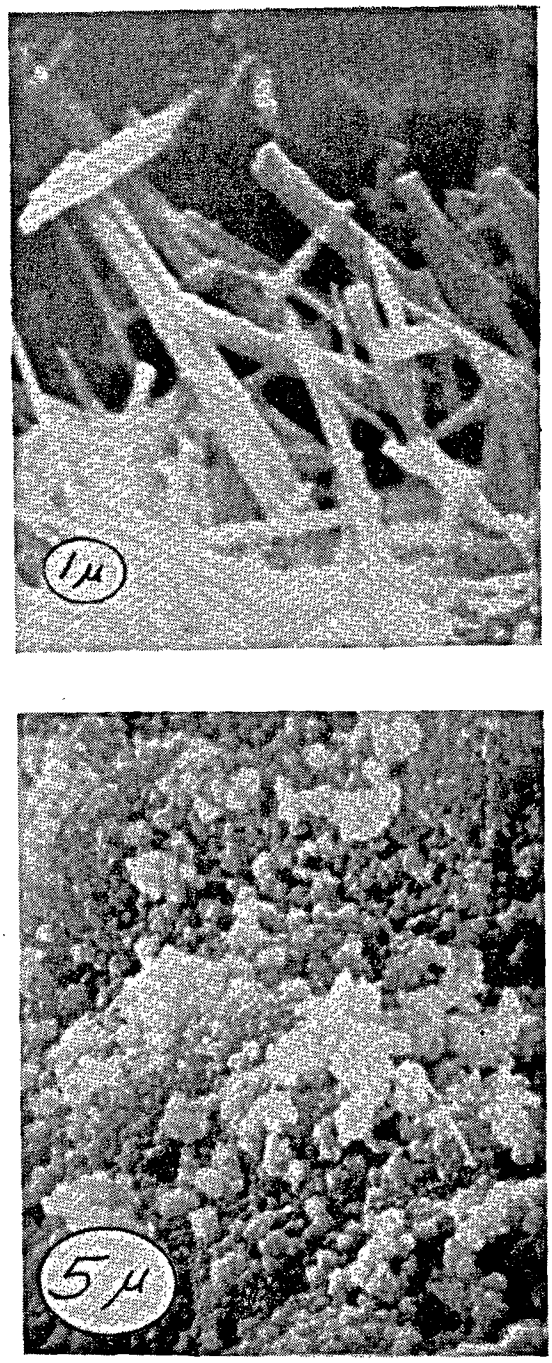

Fig. 2. *Scanning electron micrographs of cement pastes showing extremes of variation in locally-dominant particle morphology*

Details of the theory and practical aspects of image formation and interpretation have been authoritatively reviewed (2) and the proceedings of a recent conference (3) illustrated the wide range of applications possible. A direct comparison of the utility of scanning electron microscopy relative to that of examination of replicas of fracture surfaces

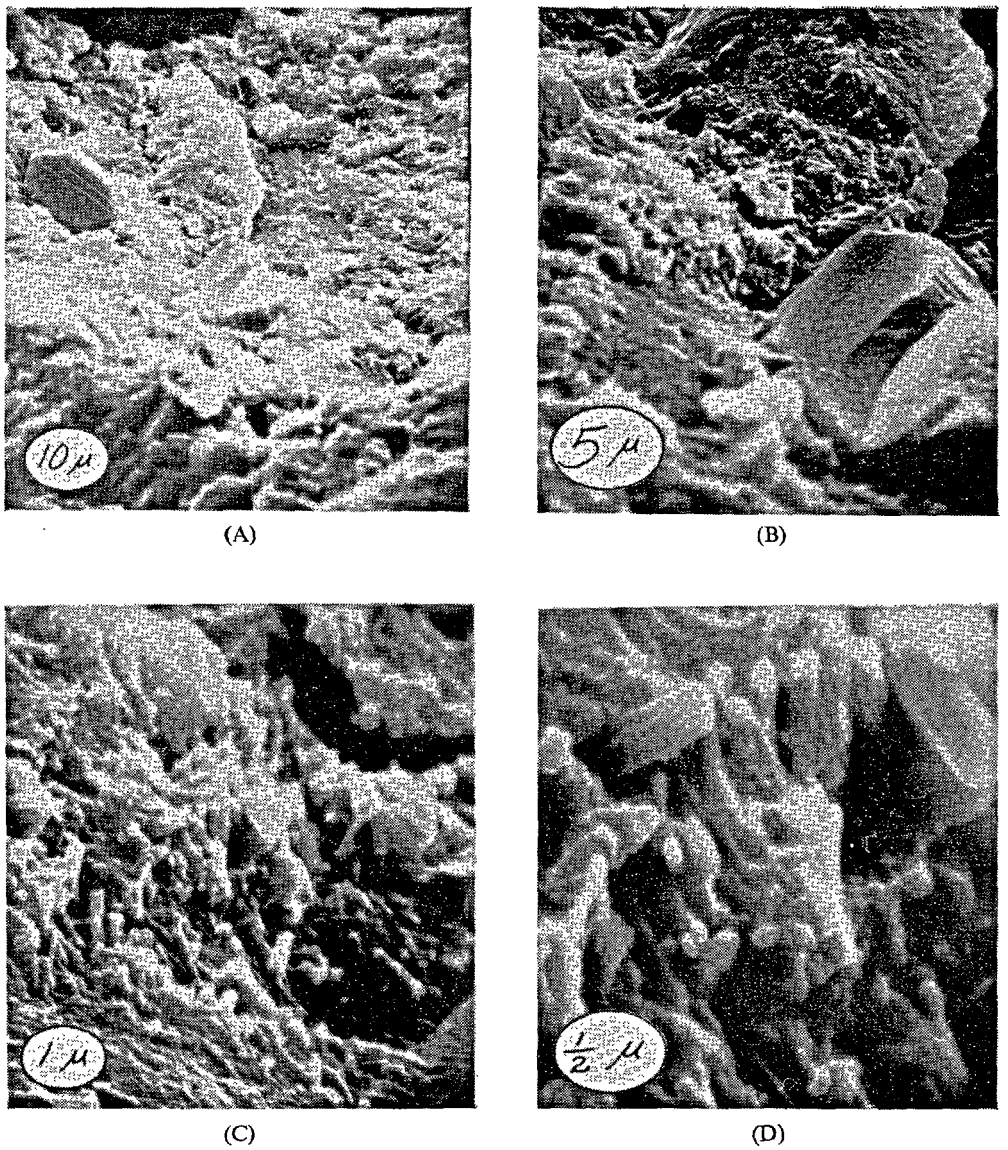

Fig. 3. *Scanning electron micrographs of a portion of the fracture surface of dried cement paste taken at progressively increasing magnification*

by transmission electron microscopy has recently been carried out (4) and examinations of the surface topography of ceramics and other materials related to cement paste have been published (5,6).

A preliminary examination of the three-dimensional arrangement of hydration products in set cement paste was reported by Chatterji and Jeffery (7) and in a subsequent paper (8) the same authors proposed a hypothesis of strength development based in part on their scanning electron microscope observations. In interpreting their observations of portland cement paste, these authors place major emphasis on their observation that the large elongated particles of ettringite and in particular the smaller needle-shaped particles of calcium silicate hydrate form an entangled mass in three dimensions.

Some very preliminary observations by the present writer illustrate that the cement paste morphology problem is much more intricate than this. In addition to areas where only entangled elongated particles are visible (Fig. 2A) we have observed areas comprising only more or less equant "gel bodies" (Fig.

2B) and areas where both particle morphologies occur in locally uniform mixtures.

Some indication of the potential of this instrument in delineating topographic relationships in cement pastes may be seen in Fig. 3 which represents several steps in a series of plates taken at the same spot on a fracture surface of a dried cement paste at progressively increasing magnifications. The sizes indicated are approximate; the ellipse indicates that the magnification indicated for the vertical direction is less than that indicated for the "horizontal" direction because of the tilt of the sample holder. The relation of Fig. 3B to Fig. 3A is obvious. Fig. 3C may be related to Fig. 3B by reference to the curved crack in the upper left hand portion which in Fig. 3B is found near the center of the figure. The advantage of the very large depth of field of the scanning microscope is apparent. Further, the complexity of the topographical features would seem to make successful replication of areas like this exceedingly difficult. Fig. 3D resolves individual particles sticking out of the ground mass. This figure illustrates one of the difficulties of scanning microscopy for viewing very small particles emerging from a base elevation; the excessive brightness observed in such cases is one of the characteristics of secondary emission and tends to obscure fine details of structure. This feature, and the limited present resolution of the scanning electron microscope (150-200 Å) makes it somewhat less satisfactory than the transmission microscope for viewing details of the finest ultimate particles of cement pastes, but its potential utility in elucidating details of microstructure on higher levels of organization appears to be very promising.

Acknowledgements

The courtesy of the Engis Equipment Company in making available their "Stereoscan" scanning electron microscope and that of Mr. Frank Rossi, who operated the instrument, are acknowledged with thanks. The data for Fig. 1 were obtained in connection with a research project sponsored jointly by the Indiana State Highway Commission and the Bureau of Public Roads, U.S. Department of Transportation. The opinions expressed, however, are entirely those of the writer.

Written Discussion

Rolf F. Feldman and Peter J. Sereda

It is appreciated that the authors faced a formidable task in writing on the broad subject of the structure and physical properties of cement pastes, and in this regard they are to be complimented. It must be noted, however, that the authors omitted an appreciable body of published information (1, 6, 8, 9, 10, 11, 16) and, having accepted a new concept for the "state" of the water in cement gel, did not attempt to reas-

sess the significance of this on much of the previously published information.

It is readily accepted and the authors adequately support the idea that in hydrated cement paste the physical and mechanical properties are intimately dependent and profoundly affected by the "adsorbed" water. This being the case, it has long been recognized that one of the key questions in the understanding of this system was the "state" of the water. In this regard two schools of thought have existed: one proposing that the "gel" water was physically adsorbed, and the other that at least part of this water was interlayer. The existence of these two divergent ideas in this field of science has not been documented by the authors.

The importance of these concepts pertaining to the state of the water cannot be overemphasized because they served as the basis for a model to explain the physical and mechanical properties. Most of the literature deals with these properties of hydrated cement on the basis that the "gel" water was physically adsorbed. The proposal that part of the "gel" water was interlayer water was first made by Kalousek and substantiated by extensive research at the Division of Building Research of the National Research Council of Canada.

It is gratifying to note that the authors of the principal paper under discussion are now supporting the idea that much of the "gel" water is interlayer based on the results from nuclear magnetic resonance (N. M. R.) measurements by Seligmann. The authors, however, have not discussed the profound implication of this fact on the understanding of the whole nature of hydrated portland cement and its properties. A reassessment of much previous work is certainly necessary. The work at the Division of Building Research of the National Research Council of Canada, dating from 1963, makes available a body of information and discussion on this vital question, culminating in a proposal of a new model for hydrated portland cement. The publications containing the results of these studies have not been cited as references by the authors of this principal paper, although we realize that they may not have had access to our most recent papers (12, 14, 17). This discussion, therefore, attempts to summarize the information that has been omitted from the paper under review.

We fully recognized the complex nature of cement paste and the simplified model proposed is merely another step in the development of the understanding of this system. Much has yet to be done to provide full understanding.

The development of the present model of hydrated portland cement has been largely based on surface chemical considerations; this involved the establishment of criteria to distinguish between chemically-combined and physically adsorbed water. The determination of the stoichiometry of the tobermorite gel, its water surface area, and its porosity were based on the above criteria.

Water adsorption experiments have been used to measure the porosity and surface area of hydrated portland cement; results of the latter have yielded values in excess of 200 m^2/g. This value was of great importance and was used to estimate the number of layers in the tobermorite gel "crystallites"; it also provided the basis for calculating other physical parameters.

Kalousek (1) observed that the surface area using N_2 as adsorbate yielded very low values compared with those of water; the N_2 value was shown by Mikhail et al (2) to decrease with the water-to-cement ratio to values below 30 m^2/g, and, as reported by the authors, by Kantro to values below 1 m^2/g. Similar results were obtained when organic vapours such as $CH_3 \cdot OH$ were used as adsorbates (3).

The determination of surface area by adsorption of N_2, together with a calculation based on the B. E. T. equation, has become a standard method in the realm of surface chemistry. Carbons with very high surface areas and very small pores have yielded nitrogen surface areas that approach 1000 m^2/g. Yet in the case of hydrated portland cement, the "water area" has been the one generally held "true and valid." It was considered that the N_2 molecule could not enter small pores and be adsorbed on the whole surface because of its large size (2). The diameters of the water, nitrogen, and methanol molecules are approximately 3.25, 4.05 and 4.4 Å respectively; it seems difficult to accept the situation where over 90 per cent of the area is excluded to N_2 because of the small difference in diameters. If the holes were part of the cyrstal structure as in certain "molecular sieves" that are cage-like molecules with small entrances, it would be realistic, but hydrated cement is not of this nature.

Several years ago, in the laboratories of the Division of Building Research of the National Research Council of Canada, it was decided to undertake a careful study of the water-hydrated portland cement sorption system. This study included measurement of both length change and weight change with changing relative humidity. The measurements were done simultaneously in carefully controlled conditions and in a high-vacuum apparatus. We believe, therefore, that we are correct in stating that the Division of Building Research of the NRC of Canada was the first laboratory to carry out this type of study on hydrated

portland cement.

In light of this, it is indeed surprising that the authors of this principal paper state, "... in most of the investigations of this matter during the past several decades, pertinent details regarding either the nature of the materials used, or the environment to which the specimens were actually exposed, have been omitted from the published reports, Therefore, the present authors will draw largely upon their own studies that are believed to have taken into consideration at least most of the important factors." This would seem to confine unduly the scope of the discussion presented in this principal paper.

Before these experiments could be started, it was necessary to understand the adsorption and length-change process. The project began, therefore, with studies of the adsorption of water on materials less complicated than hydrated portland cement, but related to it in some way. These materials included an alumino-silicate (molecular sieves), calcium sulphate hemihydrate, precipitated calcium carbonate, finely divided silica, porous glass and calcium hydroxide. A series of papers were published on this work (4 to 8).

The results of the early experiments on bottle-hydrated cement showed that it was possible to detect characteristic differences in the type of water that was being removed on drying (9). These characteristics provided the base for a hypothesis on the expansion and contraction of hydrated portland cement on sorption and desorption of water (10, 11). It must be emphasized that this hypothesis did not relate to the phenomena that operate during first drying. The hypothesis emphasized the role of the Gibbs and Bangham equations in the intermediate pressure regions and it was concluded that the expansion on sorption was initiated by the decrease in surface energy of the solid. It was not necessary to introduce the concept that individual crystallites could move back and forth with respect to each other. As will be shown later, other evidence also disproves this concept.

From the length change and weight change characteristics and the sorption isotherm (10, 11) it was recognized that the exit and entry of the interlayer water between the sheets of the tobermorite gel played an important role in expansion and contraction. At this stage no real quantitative estimate could be made as we have now been able to do.

The effect of interlayer water rehydration on water sorption properties may be easily illustrated. First, however, a brief discussion of some cases of sorption hysteresis will clarify the point.

Fig. 1 illustrates three forms of hysteresis that have been observed on various materials. A loop of type I is formed over a limited range of pressures and is generally considered to be associated with the formation of a meniscus. Scanning of the loop may be performed by desorbing after reaching X on the ascending boundary curve; thus, one reaches Y on the descending curve and may return to X by readsorption. Type II hysteresis, where the loop extends over the whole pressure range, has been observed for water on cellulose or protein fibres and also for polar adsorbates on montmorillonite. In type III, which combines the characteristics of the other types, the ascending and descending branches only join at very low or zero pressure. The dotted lines show the pattern followed if adsorption recommences at X. Type III loops are found with some graphites, clay minerals and, as has

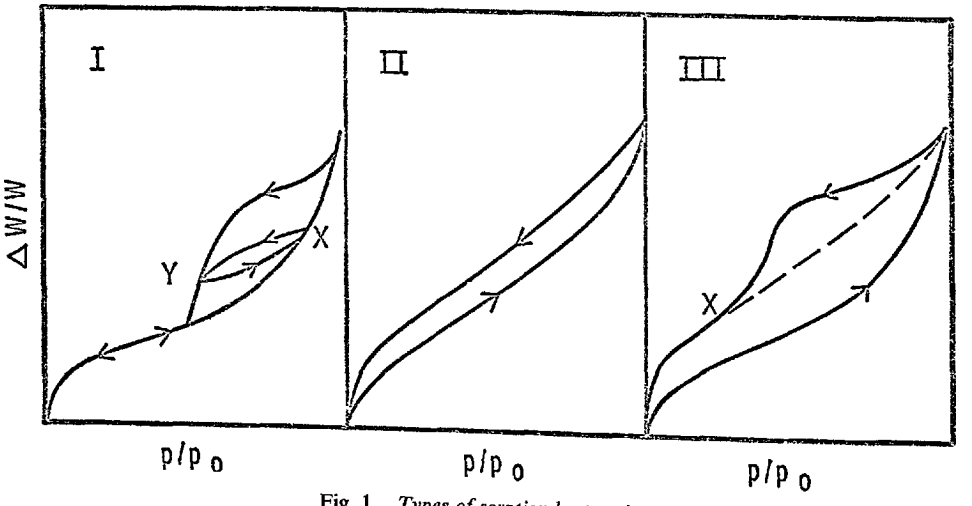

Fig. 1. *Types of sorption hysteresis*

been shown (10), with hydrated portland cement.

This low-pressure hysteresis phenomenon is usually attributed to irreversible intercalation of adsorbate within the structure of the solid. Quite often the solids have a layer structure and a change in the spacing of these layers has been observed. Unfortunately, because of the nature of the tobermorite gel with regard to the *c* axis, it has not been possible to confirm the interlamellar penetration by X-ray methods. It is clear, however, that somewhere along the ascending branch of the isotherm water is sorbed irreversibly. This would affect the over-all mechanism for the sorption-expansion phenomena, and the use of the ascending curve for B. E. T. calculations if interlayer water re-enters in the 0 to 35 per cent relative humidity range.

The importance of these results was realized at an early stage in our laboratories. Both the classification and role of the various forms of water became a prime objective of our activities; it was suspected that the entry of interlayer water might affect many mechanical properties. The effect of physically-adsorbed water on the bond between crystallites (and the nature of this bond) was also considered to be of critical importance. As a result, further work in our laboratories was planned to re-examine some areas in greater detail and to extend it in other areas.

Experiments at DBR/NRC can be divided into two categories:

i) measurement of the variation of adsorbed water, length, Young's modulus, flexural strength, and microhardness with relative humidity;

ii) measurement of the variation of Young's modulus, flexural strength, microhardness at constant conditions of relative humidity as a function of porosity, and method of fabrication.

The methods of fabrication involved were as follows:

(a) compaction of hydrated portland cement powder at different pressures to form rigid bodies of different porosity;
(b) cast samples at different water-cement ratios;
(c) recompacted cast samples to lower effective porosites than (b) above.

All these samples were made with small dimensions (= 30 mm diameter and 1 mm thick) to avoid stresses due to moisture gradients and to facilitate equilibrium.

These experiments were also performed on porous glass and some other materials of which more is known with regard to their properties and behaviour. The results from these were used to aid interpretation.

A discussion follows of the results of the various experiments.

Length and Sorption Isotherms and Scanning Loops

Some of this work has been presented in paper No. III-23 (12) of this Symposium and only those conclusions that contribute to this discussion will be restated. We would like to draw attention to Fig. 1 to 4 of the above paper. It was concluded that interlayer water was entering simultaneously as adsorption occurs up the isotherm.

From the scanning loops and from some assumptions that later provided to be justified, we were able to separate quantitatively the interlayer and physically adsorbed water and construct isotherms for both [Fig. 5 and 6 of paper No. III-23 (12)]. From these calculations we were able to make the following conclusions that completely supported this approach.

1. Surface areas from N_2 and H_2O adsorption are very similar.

2. The total interlayer water found by calculation from the scanning isotherms was equal to the difference between the total water sorbed and the total nitrogen or methanol sorbed for many samples. This had previously been ascribed to small pores that prevented nitrogen but not water from entering.

3. A plot of length change versus weight change for the reversible isotherms produced a linear plot up to a relative humidity of about 45 per cent. This type of linear plot has been observed for water adsorption on many relatively inert materials.

4. A plot of length change versus the surface-free energy change was constructed, using the Gibbs and Bangham equations:

$$\Delta L/L \propto \Delta F = RT/\sigma \int_0^p ndp/p$$

where $\Delta L/L$ is the length change, ΔF is the surface-free energy change, σ is the surface area (cm^2/g), n is the number of moles adsorbed per unit weight of material. This plot produced a straight line through zero, and thus the equations were obeyed (see Fig. 5, paper No. III-23).

5. From these calculations, Young's modulus for the solid material was calculated to be 4.35×10^6 lb/in^2. Helmuth and Turk (13) extrapolated from porosity E plots to get E of "gel phase" as 4.5 and of the "solid phase" as 10.8 lb/in^2. This latter value was similar to the extrapolation of Soroka and Sereda (14) (paper No. III-34 of this Symposium). Both these values suffer from including as porosity the interlayer water removed during "*d*-drying". Considering the assumptions, the value found for the modulus of the solid phases is very good and is considered as further evidence of the validity of this approach.

6. Further calculations from the scanning isotherms showed that less than 20 per cent of the total expansion along the isotherm was due to physically adsorbed water. On the desorption branch of the curve at 29 per cent R. H. only 15 per cent of the evaporable water is physically adsorbed.

This is consistent qualitatively with recent N. M. R. work (15) which suggests that no physically adsorbed water is present at 70 per cent R. H. and that the water is similar to the interlayer water in montmorillonite. It is difficult to agree with the authors' statement however, that no physically adsorbed water is present since nitrogen adsorption measurements do show a fairly significant surface area even at a water-to-cement ratio of 0.25.

Sorption and the Variation of Young's Modulus

In measuring Young's modulus as a function of relative humidity two types of responses have been observed for surface active materials:

(a) no change for rigid porous bodies (this has been observed with porous glass);

(b) a continuous decrease (this has been observed largely with cellulosic materials (see Fig. 2).

Hydrated portland cement gave results which partly conformed with the first type but in addition presented certain features which at first we could not explain. These results were published in 1966 (16) and at that time were explained generally by interlayer dehydration and rehydration. Fig. 3 is a representative sketch of some of the results.

As is shown, there was very little change in Young's modulus from 100 per cent R. H. to low humidites on drying and then on "*d*-drying" a large decrease in E. On sorption an increase in E took place just above 50 per cent R. H.

In the irreversible isotherms presented as Fig. 6 of paper No. III-23, for $\Delta L/L$ and $\Delta W/W$ versus relative humidity, it will be noted that there is a similarity between them and the E versus relative humidity plot. The hysteresis and effects beyond 50 per cent R. H. are the same, and the $\Delta L/L$ versus $\Delta W/W$ plot shows a sharp break just above 50 per cent R. H.

We were able to incorporate these results in a simple model which can explain most of the properties described. This model has already been described (17) and is referred to briefly in paper No. III-23.

The main points are that interlayer water re-enters between the layers from the outer edges, causing expansion by some opening of the layers (see Fig. 7 in paper No. III-23); the water acts as webs or cross-links; there will be no real increase in E until the middle starts to fill, similar to sandwich-type construction; when this filling takes place, E goes up markedly. The length-to-weight change results indicate a rapid increase of interlayer water with a not so great length change beyond 50 per cent R. H. The model shows that most of the expansion has already taken place from the edges. Emptying now starts from the edges but only at low pressures; this explains the hysteresis shown in these plots. "E" does not decrease until the water has left the middle of the layers, and this occurs only at

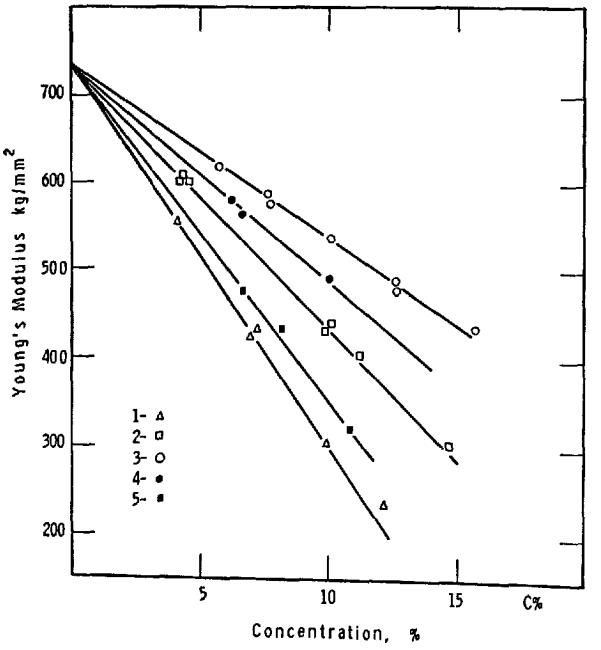

Fig. 2. *Effect of various gases on Young's modulus of acetate silk; 1-methyl alcohol, 2-ethyl alcohol, 3-butyl alcohol, 4-acetone, 5-water*

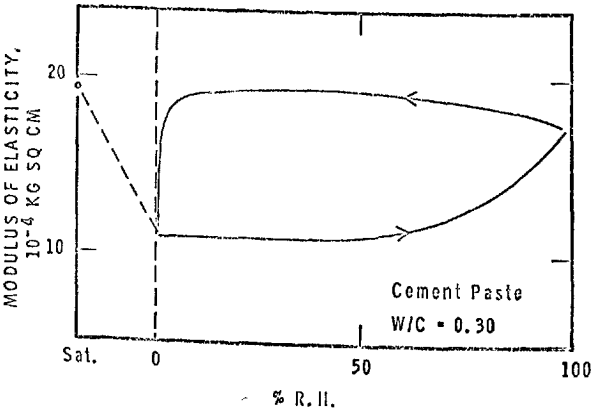

Fig. 3. *Modulus of elasticity as a function of relative humidity*

very low vapour pressures. In addition, since desorption starts from the edges when the middle is still full, the $\Delta L/L$ versus $\Delta W/W$ characteristics will be changed and a hysteresis must be expected in this plot also.

We must emphasize that this model is simplified and much work remains to be done to confirm it. The role of the hydrate water from the aluminates and sulphoaluminates will have to be taken into account.

Flexural Strength and Microhardness as a Function of Relative Humidity

On Fig. 4 is shown, relative to 0 relative humidity, the variation of strength or microhardness of porous silica glass, hydrated portland cement paste, and fused quartz. It will be noted that there is a great similarity. The results for hydrated portland cement were published in 1966 (16). In contrast, results for cellulosic products show a linear decrease with the amount sorbed, similar to Fig. 2 which shows results for the variation of E with amount sorbed.

These results are important; the decrease in flexural strength of cellulosic materials has been shown (8) to be due to the attenuation of hydrogen bonds between fibres by adsorbed water. These hydrogen bonds hold individual fibres together. A previous model for swelling of hydrated portland cement which visualizes a separation of individual crystallite units (18) is similar to the model for cellulosic materials and would require similar "E" and flexural strength variations with change in R. H. As this is not borne out, because of this and other evidence the old model for swelling and shrinking must be discarded.

The similarity in behaviour of hydrated cement and glass can be fully explained (8). Strained $-\overset{|}{\underset{|}{Si}}-O-\overset{|}{\underset{|}{Si}}-$ bonds at the apex of cracks yield at lower stresses in the presence of water vapour; this results in the formation of (–OH) groups. This process is regarded as a form of stress corrosion. Thus the change in flexural strength is due to the change in environment rather than a change in structure of the material.

The experiments under category ii) variation of mechanical properties as a function of porosity and method of fabrication, will now be discussed.

Interrelation of Hardness, Modulus of Elasticity and Porosity in Various Gypsum Systems

Generally, for otherwise identical conditions, mechanical properties such as strength and modulus of elasticity are related to porosity. The relation usually takes the form of an exponential expression

$$S = S_0 e^{-b_1 p} \qquad \text{or} \qquad E = E_0 e^{-b_2 p}$$

where S and E are the strength and modulus of elasticity of the specimen respectively, S_0 and E_0 are these parameters at zero porosity; and p is the porosity (8). This type of equation was found to hold for various gypsum systems (19).

Study of the gypsum systems which are distinctly crystalline and in which intergrowth of crystals during hydration is a possibility was considered useful for comparison with the cement systems.

Results may be summarized by Figs. 5 and 6 where "E" and hardness versus porosity are plotted for the several systems.

1. Hardness and modulus of elasticity are related to porosity. This relation can be described by the

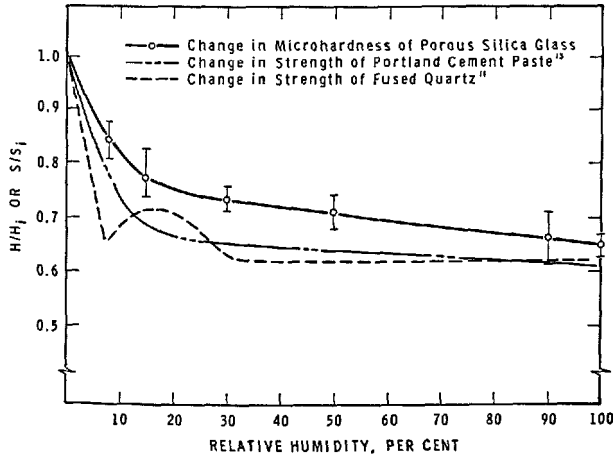

Fig. 4. *Effect of humidity on microhardness and strength*

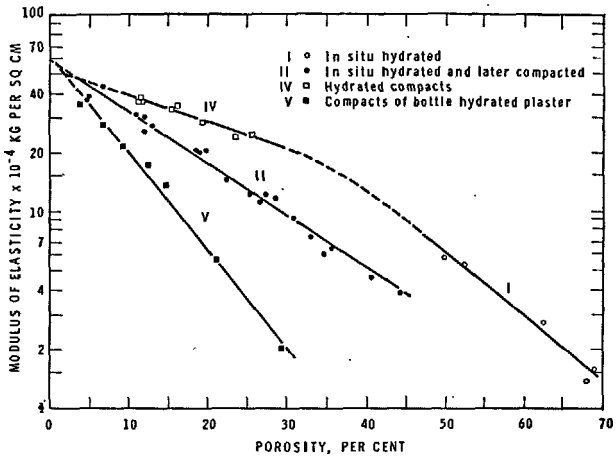

Fig. 5. *Modulus of elasticity vs porosity for the gypsum systems*

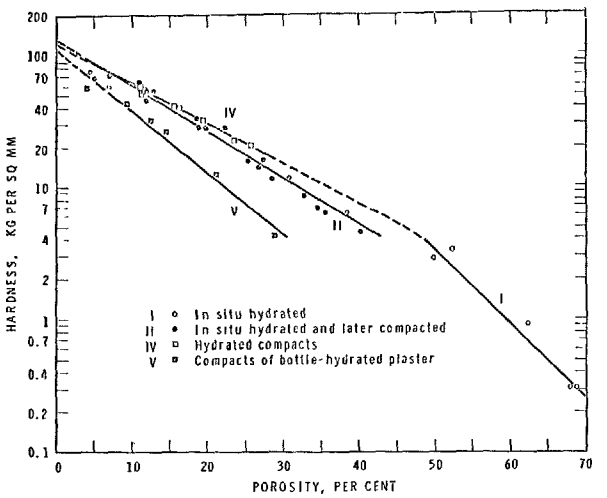

Fig. 6. *Hardness vs porosity for the gypsum systems*

exponential expression already discussed.

2. Intergrowth and interlocking of crystals formed during hydration significantly affect mechanical properties. Depending on the porosity, hardness values were as much as four times higher and modulus of elasticity up to ten times higher than corresponding values in otherwise identical systems in which crystal intergrowth is not very likely to occur. These latter systems were type V (Figs. 5 and 6), which had been prepared by compaction of bottle-hydrated plaster, and type II, which was in situ hydrated and recompacted.

Variation of Microhardness, Strength and Modulus of Elasticity of Hydrated Portland Cement

A detailed study of the above is presented to this Symposium (paper No. III-34); this study was instigated, however, by results obtained some time ago and published in 1966 (16). These results showed the then surprising fact that bottle-hydrated cement compacts showed almost identical porosity vs flexural strength and porosity vs E characteristics.

The results presented in paper No. III-34 to this Symposium have expanded this work and the following conclusions could be made:

1. The results for both hardness and modulus of elasticity could be plotted according to the following equations:

$$E = E_0 e^{-b_2 p}$$

$$H = H_0 e^{-b_3 p}$$

2. The values for the modulus of the compacts of bottle-hydrated cement fit very closely to those of the paste and compacted paste when plotted against porosity (Fig. 2, paper No. III-34).

3. The results of micro-hardness versus porosity lead to the same conclusions as the result for modulus (Fig. 3, paper No. III-34).

These results enabled the conclusion to be made that pressure produced either by compaction or hydration would yield the same type of solid-solid bonds between crystallites. This is, of course, in sharp contrast to the effect observed from the gypsum systems studied. In the gypsum system, the intergrowth of crystals seems to occur during hydration and forms "chemical" bonds which produce greater strength than do the bonds formed during compaction. Similarly, some recent work involving compacts of $Ca(OH)_2$ during ageing (20) and during carbonation (21) shows how these interparticle bonds can be increased because of recrystallization of the material or because of new products formed as the result of the reaction.

The further contrasting results between the gypsum systems and the hydrated cement system produces convincing evidence for the nature of the interparticle bond in hydrated cement. The experiments where hydrated cement paste was compacted to lower porosities involving a reduction of porosity varying from as little as 5 per cent to as much as 45 per cent showed that in all cases the modulus values fitted the same relation as for the hydrated paste samples. If a "chemical" bond were to be formed during hydration, such a bond would be broken during subsequent compaction and would not be remade, resulting in a lower modulus for compacted paste. This was not the case, which is evidence of the absence of "chemical" bonds and leads to the conclusion (mentioned previously) that the interparticle bonds are solid-to-solid which are responsible for the stable structure of cement paste after first drying. These bonds appear to be of such a nature that they can be broken and remade without suffering permanent decrease in modulus.

Before discussing some of the features of the interparticle bonds in hydrated cement, perhaps a more general discussion of interparticle bonds may be made by way of definition.

It is recognized that the terms "chemical" or "primary" and "secondary" bonds have been used in describing the structure of hydrated cement systems without a strict definition of their meaning. This has led to considerable midunderstanding. It is believed that what was meant by the "chemical" bond between the particles was a solid-to-solid contact similar to that of a grain boundary in a polycrystalline material where some atoms approach the spacing and arrange-

ment in the crystal. Such "chemical" bonds could be formed during a crystallization process accompanying a chemical reaction where the mobility of atoms allows for a regular arrangement resulting in an intergrowth of crystals. It follows that these bonds would be stong and when broken would not be remade in normal circumstances.

It is believed that the term "secondary" bonds as applied to the hydrated cement system arose from the assumption that physically adsorbed water was a constituent part of the interparticle bond; thus, the general term of van der Waals forces was considered appropriate. It is suggested, therefore, that a different interparticle bond be postulated which would involve a solid-to-solid contact resulting from the bringing together of surfaces (by pressure externally or internally generated by the hydration reaction) forming a particle boundary having little or no regular atomic arrangement or spacing. Atoms at such a boundary would engage a varying proportion of the long-range and short-range forces depending on the degree of disorder and the average spacing. It can be visualized that this interparticle bond can be broken and subsequently remade under appropriate loading conditions. This type of bond differs from the "chemical" bond just defined, which has a more regular atomic arrangement and the spacing of more of the atoms may approach that of the lattice spacing in the crystal. If water is involved in such a bond (it will be either chemisorbed, hydrated or interlayer), it is considered a constituent part of the crystal.

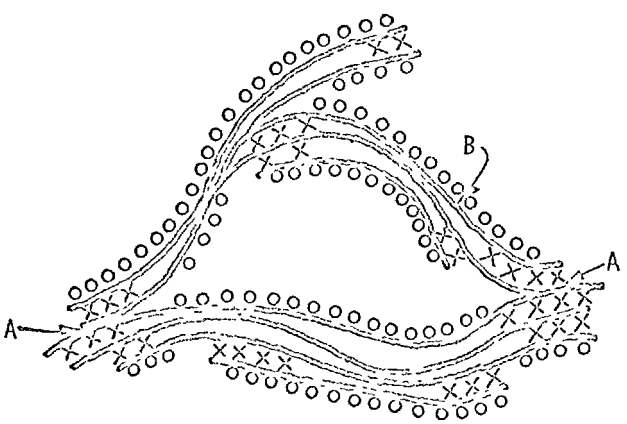

Fig. 7. *Simplified model for hydrated portland cement*

Of all the various experiments leading to the understanding of hydrated portland cement, and the bonding system involved in the structure, perhaps the most conclusive in support of the idea that interparticle bonds do not have adsorbed water at the boundary comes from the measurements of elastic modulus and strength at different conditions of relative humidity (16). If the adsorbed water were entering the interparticle bond area, the net result should be a decrease in modulus or strength as occurs in the case of cellulosic materials (8).

A very simplified and tentative model for the structure of hydrated portland cement is presented as Fig. 7 which shows the layerd structure of hydrated portland cement. The role of the types of water and possible bonding between sheets is shown. *The irreversible shrinkage* during first drying might involve formation of more solid-to-solid bonds or further aggregation of layers. First drying would involve great energy changes, and the structure may be subject to forces which demand new positions of stability.

Creep Phenomena

The establishment of a new model for hydrated cement enables a fresh approach in understanding some of its properties. A discussion of some possibilities with regard to creep follows:

1. The importance of interlayer water in hydrated portland cement is now recognized, and this interlayer water may be removed at low relative humidities. Under higher stress levels creep may be associated with a slow decomposition of the interlayer hydrates. This effect is influenced by relative humidity and may result in both reversible and irreversible creep.
2. The nature of the interparticle bonds which show the capacity for breaking and remaking may be involved in irreversible creep.
3. A large part of creep, when measured before first drying, might be related to the irreversible shrinkage phenomena.

Concluding Statement

It is hoped that the interpretation of experimental work described in this discussion, and the model evolved, may lead to further understanding and subsequently a more advanced model for hydrated portland cement.

(A) Papers regarding Fundamental

Supplementary Paper III-8 Changing of the Specific Surface of Cement Stone in Different Conditions of Hardening

Otar. P. Mchedlov-Petrosyan and Dmitrijs A. Uginčius*

Synopsis

The work on the determination of specific surface of cement stone is a part of the investigation in the field of hydration and structure formation and it attracts attention of many researchers. We can cite works of Brunauer, Greenberg, Kantro, Weise (4, 7), Copeland, Hayes (5) Khodakov, Edel'man, Kornienko (9) Hunt, Tomes, Blaine (6, 24), Krasil'nikov (10, 11), Mikhail, Selim (16, 17), Powers, Brownyard (18, 19), Stupachenko (22) and many others.

Naturally, the list does not cover all works, because such a review is not the task of the authors.

Two main reasons may explain the interest to this problem. Firstly, a developed enough surface of hydrosilicate component of cement stone determines to a great extent its strength, deformative properties and durability. Secondly, the data on paste surface development kinetics may essentially supply available information on hydration and structure formation kinetics, and the value of specific surface of cement stone is connected with the rate of cement hydration.

Among the methods of investigation mentioned, particularly, in reviews of Reitlinger, Chekhovski (20) and in ours (15), the BET method is employed. It is based on wellknown works of Brunauer, Emmett and Teller (1, 3). The BET method calls for preliminary sample preparation and for a long time experiment. That is why we were looking for a suitable method to study the kinetics surface development.

The following points are examined in this paper as a continuation of our previously published work (25):

1. The development of cement stone specific surface at room temperature.
2. The change of silicate gel specific surface.
3. The influence of water-cement ratio on the value of specific surface.
4. The influence of high temperature on the specific surface.
5. The influence of low temperature on specific surface.
6. The effect of chemical additives on the development and value of specific surface of cement stone.

Method

The experimental investigations have been carried out by means of the thermographic method elaborated by Kazanski (8). While choosing the method, we considered the peculiarity of hardening cement stone as an object of the investigation. The rate and character of the reactions taking place in cement stone are defined to a great extent by hydrothermal conditions of the medium.

The method is based on regularity of water desorption from a thin (1–2 mm) layer of dispersive body at the constant medium temperature.

While experimenting the sample temperature changing in coordinates "time-temperature difference of the sample and medium" (the desorption thermogram) and the kinetic curve of sample weight changing were registered (Fig. 1).

The singular points are defined on the thermogram which correspond according to Kazanski (8), to the following forms of bond of water:

1. Free water on the surface of the cement stone granules and between them.
2. Capillary water of macropores $r > 10^{-5}$ cm.
3. Capillary water of micropores $r < 10^{-5}$ cm.

Such a classification of macro- and micropores, suggested by Rehbinder, is given in Lykov's book (12).

4. Water of polymolecular adsorption.
5. Water of monomolecular adsorption (Vm).

*Railway Engineering Institute, Kharkov, U.S.S.R.

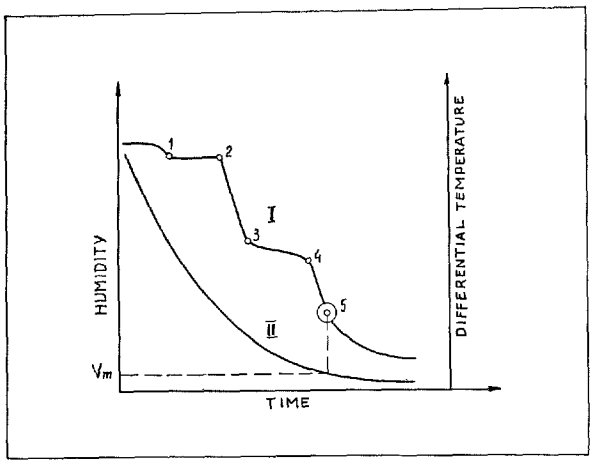

Fig. 1. *The desorption thermogram (I) and gravimetric curve (II). Monomolecular layer water amount determination by singular point 5*

We are now interested only in decoding of the value of singular point 5. By projecting point 5 on the gravimetric curve, we get the value Vm (Fig. 1). Counting begins from weight of the sample obtained by D-drying. In our point of view it is very important for maximum water content corresponding to point 5 to be defined under conditions close to normal (at temperatures less then 60°C and at air rarefaction up to residual pressure of 5 mm Hg.).

The sample soaked with water is placed into a vacuum thermostat in a cell suspended from the automatic photoelectric balance.

The sensitivity of weight recording is up to 0.4 mg for 1 mm of the scale of the self-recording potentiometer. The thermogram is recorded by a copper resistance thermometer.

The approximate temperature of the medium is maintained by thermistor relay and accurate control within ± 0.01°C is achieved with the help of proportional regulator.

The size of sample granules was made as 0.25–0.50 mm to prevent from appearing high temperature gradients in a single granule which makes thermogram recording difficult.

The value of specific surface of cement stone has been calculated by Vm in conformity with the BET theory (1), ωH_2O was assumed to be equal to 11.4 Å^2 according to Brunauer, Kantro and Copeland (2).

Object of Investigation

3 types of portland cement, with different phase composition and specific surfaces were investigated (Table 1).

The samples prepared of type 2 cement were kindly presented for the investigation during our joint work by Dr.-Eng. Werner Reichel from the Leipzig Building Institute.

Table 1.

Type	Specific surface, cm²/g	Phase composition, %				
		C_3S	C_2S	C_3A	$C_xA_yF_z$	$CaSO_4$
1	2870	51.2	26.9	6.6	10.5	1.6
2	3100	41.0	25.6	6.1	15.4	3.1
3	4912	67.6	8.7	7.6	12.5	2.5

Experimental

Normal Temperature

The samples were prepared of types 1 and 2 cement with water-cement ratio-0.24 in metal forms of $2 \times 2 \times 2$ cm and being vibrated with vibration frequency of 3000 ± 200 per minute and average amplitude of 0.35 mm for 30 seconds. Samples were kept at 20 ± 2°C and at 100% relative air humidity. The demoulding of the samples from the forms were made in a day after their preparation.

The type 1 cement stone underwent investigations each day for 28 days, the type 2 at 1, 3, 7, 14 and 28 days of hardening. About 2 g of cement stone were taken for one experiment. The results are given in Fig. 2.

The intensive increasing of specific surface is observed for both types of cements (and also for type 3, Fig. 5) up to 7–10 days, and then the perceptible stabilization takes place. Unfortunately, our method does not make it possible to investigate changing of the specific surface of cement paste at the beginning of hardening (for the first day) as the testing time becomes commeasurable with the sample age.

The data on absolute values of specific surface are in good conformity with the data of the authors listed by us in the synopsis. If we take into consideration

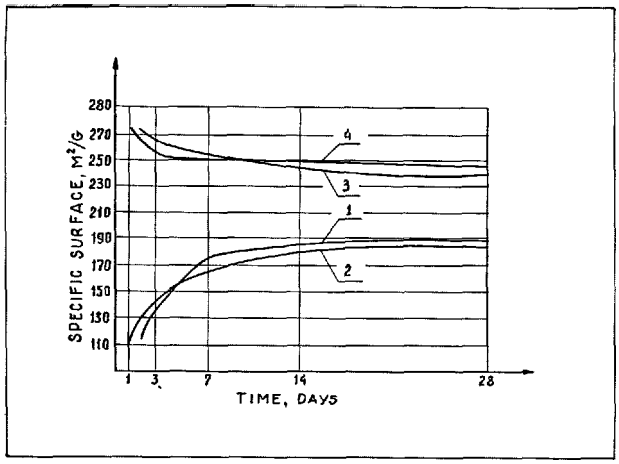

Fig. 2. *Hardening cement stone specific surface changing (1-type 1 cement, 2-type 2) and gel specific surface changing (3-type 1, 4-type 2)*

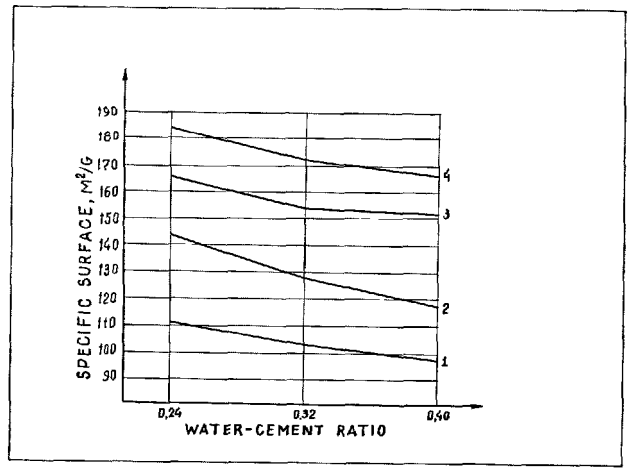

Fig. 3. *Specific surface of cement stone at the different water-cement ratios (type 2 cement) 1–1st, 2–3rd, 3–7th, 4–28th day of hardening*

that the main volume of hydrated cement, approximately 80% according to Brunauer and Greenberg's data (4), consists of tobermorite-like calcium hydrosilicates, then Fig. 2 will reflect the kinetics of silicate hardening.

Specific Surface of Gel

According to our data, the specific surface of gel of both types of cement are in the range of 275–240 m^2/g in different time of hardening, the gel having a clear tendency to "aging" due to recrystallization of hydrosilicates and formation of structure with more rough dispersity. Volzhenski (26) pays much attention to this phenomenon as the strength of cement stone along with the rate of hydration is determined by dispersity of gel particles.

The additional investigations made by us have shown that with increasing water cement ratio this gel tendency to "aging" increases to some extent.

Water-Cement Ratio

The samples of 2 type-cement were prepared for water-cement ratios of 0.24; 0.32; 0.40. To prevent from bleeding at large *w/c* for first two hours, the forms were turned over each 5 minutes.

The specific surface was determined at the 1, 3, 7, 28 days of hardening. The results of the experiments are given in Fig. 3.

The diminishing of the specific surface of cement stone with rising of *w/c* is observed during all investigated stages of hardening. This is explained, in general, by lower specific volume of silicate gel at larger *w/c* and, only to some extent, by more intensive "aging" of gel during later stages of hardening.

High Temperature

The samples prepared of type 1 cement with water-cement ratio of 0.24 in accordance with above-mentioned technique had been kept for 1 hour at $20 \pm 2°C$ and at 100% relative humidity, and then they were undergone steam curing with the following parameters:

the rate of rising temperature—40°C per hour;
the temperatures of isothermal heating—40, 60 and 90°C;
the time of isothermal heating—1–9 hours.

The samples were heated in closed forms. During steam curing after each hour of isothermal heating the samples were taken out of the chamber and placed into the exsiccators (desiccators) at $20 \pm 2°C$ and 100% relative air humidity, and they were kept there for 28 days and then investigated. In this way we tried to gain a certain comparison of the data obtained at normal and high temperatures of hardening.

The results obtained (Fig. 4) enable us to make the following conclusions:

The specific surface of the steam-cured cement stone is much less than the paste hardening under normal conditions.

The increasing of the temperature of isothermal heating leads to the decreasing of the specific surface.

It should be noted that the sample heated at 40°C

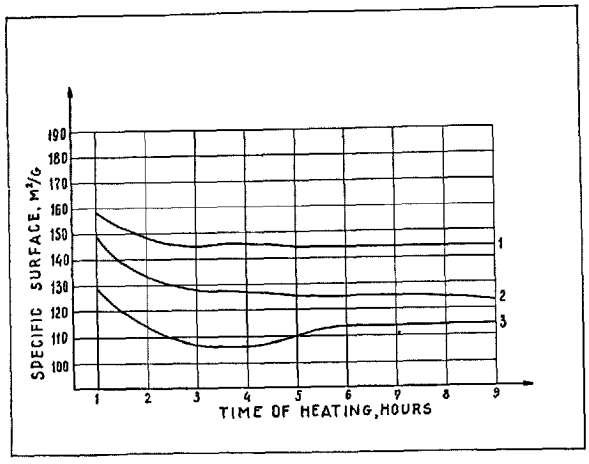

Fig. 4. *Specific surface of steam curing cement stone (on 28th day of hardening, type 1 cement) 1-at 40°C, 2-at 60°C, 3-at 90°C*

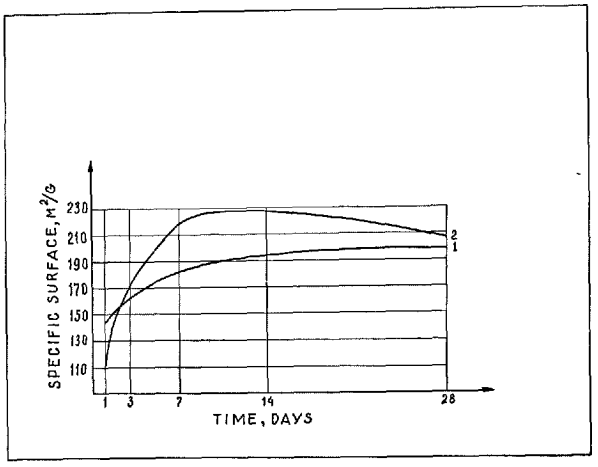

Fig. 5. *Changing of specific surface of control samples (1) and of cooled paste (2). Type 3 cement*

for more than 3 hours, at 60°C for more than 5 hours and at 90°C for more than 6 hours did not appear to cause any perceptible changes in the specific surface. In general, the specific surface decreases until this time.

The influence of temperature on cement hardening processes is connected with the regularities of proceeding the process in the diffusion area, described by Einstein. With temperature increase by 1°C, the hydration rate at the liquid/solid phases boundary is increased by 3–10 times.

Thus the rate ratio of heterogeneous processes is equal to 1, 2 and depends on the process duration as the thickness and density of diffusion layer changes from instant to instant.

However, in practice, the hydration processes at higher temperatures do not proceed quite satisfactorily Firstly, from the point of view of thermodynamics the heating contributes to proceeding the endothermal processes of hydrolysis and solution, but the hydration processes going with the decreasing of free energy proceed under unfavorable conditions.

Secondly, steam curing causes the formation of dense hydrate films on cement particles, thus retarding diffusion process of water and new formations.

All these results in formation of more rough dispersive structure of gel and in decrease of its specific volume in cement stone. Volzhenski (26) reports that the samples of cement paste with $w/c = 0.30$ after 8 hours of steam-curing at 90°C have specific surface of gel equal to 133 m^2/g, and at hardening at normal temperature on the 28th day-186 m^2/g. Thus, more rough gel dispersity was obtained. However, it is difficult to explain whether rough dispersity of gel or smaller rate of hydration cause the decrease of specific surface.

Low Temperature

The cement paste prepared from type 3 cement according to above-mentioned technique ($w/c = 0.29$) was immediately placed into a freezing chamber at -20 ± 1°C for one day. The further hardening took place up to the 28th day at +20°C and 100% relative humidity.

The specific surface was measured at 1, 3, 7, 14 and 28 days of hardening (Fig. 5).

The specific surface development of cement paste cooled in such a way proceeds more intensively than that of controlled samples.

This discrepancy decreases considerably with time, but it is still large enough at the 28th day.

From the thermodynamic and kinetic points of view, more favourable conditions for crystal structure formation are observed in this case. The temperature decreasing retards clinker mineral hydration, but the probability of high basic calcium hydrosilicate formation rises.

There is no doubt that at low temperatures the degree of solution of silicate clinker phase decreases and the probability of the appearing of a new phase reduces to a greater extent.

The decreasing of growth of hydrate crystal in comparison with the rate of initial phase solution causes the increasing of solution concentration (according to CaO). It creates favourable conditions for high basic tobermorite formation. The favourable conditions created at the primary cooling influence

greatly on further cement paste hardening at normal temperature.

Chemical Additives

Mchedlov-Petrosyan and Filatov (14) have suggested a compounded additive elaborated in conformity with so called "principle of compensated expansion". The additive consists of reaction accelerators (calcium chloride, aluminium sulphate), expander (aluminium powder) and retarder (sulphite-cellulose liquor).

The porous structure of such a cement stone was studied by Uginčius, Mchedlov-Petrosyan, Lutsyk and Kazanski (25). The combined introduction of these additives proved to provide higher density, strength of cement stone and to reduce its permeability.

The results of studying the influence of both the compounded additive and its components on the development of specific surface of cement stone (type 1 cement) are given in this paper; *w/c* was 0.24. The amount of components (in % to cement weight) was taken in accordance with the suggestion of the authors (14):

Aluminium powder (specific surface is 15000 cm^2/g)—0.01%
Aluminium sulphate (pure)—2%
Calcium chloride (pure)—2%
Sulphite-cellulose liquor (commercial)—0.15%

According to technological requirements aluminium sulphate solution and suspension of aluminium powder, calcum chloride and sulphite-cellulose liquor were poured together in the moment of paste mixing.

In the rest the technique of preparation, curing and testing of samples was the same.

Aluminium powder and aluminium sulphate did not greatly effect the value and changing of the specific surface.

The controlled samples and samples with compounded additive were tested at 1, 2, 3, 4, 5, 7, 9, 13, 14, 21 and 28 days of hardening, the samples with additives of calcium chloride and of sulphite-sellulose liquor at 1, 2, 3, 7, 14 and 28 days. The compounded additive appeared to increase greatly the specific surface, the process of its development taking place up to the 13th or the 14th day of hardening (control sample—up to the 7th or 8th day) (Fig. 6).

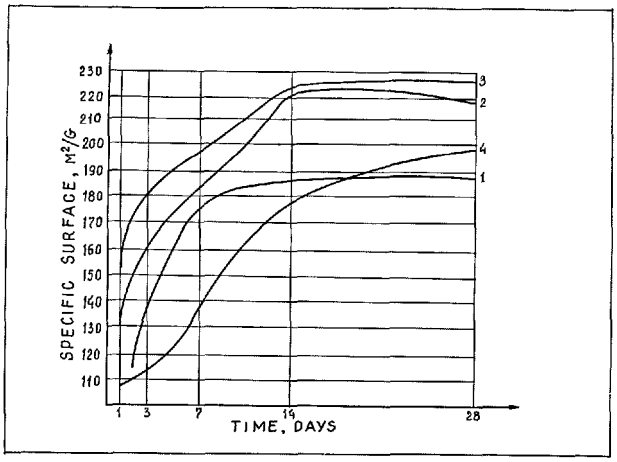

Fig. 6. *Influence of chemical additives on cement stone specific surface changing.; 1-control samples (type 1 cement),* 2-2% $CaCl_2 + 2\% Al_2(SO_4)_3 + 0.15\%$ *sulphite-cellulose liquor* +0.01% *aluminium powder,* 3-2% $CaCl_2$, 4-0.15% *sulphite-cellulose liquor*

We assumed that this compounded additive had a component causing a great effect on calcium silicate hydration processes. In fact, only silicate hardening products may affect the value of cement stone specific surface.

Calcium chloride proved to be such a component. It accelerates processes of silicate hardening and provides their plenitude for a long time (Fig. 6). The problem of mechanism that calcium chloride effect on silicate hardening processes is elaborated by Tamas (23). We think that results of great interest are obtained while investigating samples with sulphite-cellulose liquor known as plasticizer (21). The major component of this additive is calcium lignosulphonate, while adsorbing on cement particles retards silicate hardening processes.

However, the retarding of calcium hydrosilicate crystal growth under the influence of adsorption layers causes their dispergation (modification phenomenon). This phenomenon leads to some increasing of specific surface of cement stone.

Conclusion

The investigations have shown that various technological factors (water-cement ratio, temperature changing, chemical additives) influence on the value of specific surface of cement stone and on its changing.

It should be taken into account that the value of

specific surface is connected with such an important factor as strength of cement stone. Indeed, Powers and Brownyard (19) have found direct correlation between amount of water of monomolecular layer (Vm) and amount of "non-evaporable" water (Wn).

The value of Wn may serve as basis of new formation concentration calculation.

The strength of cement stone is in parabolic relationship to the concentration of new formations (18).

The increasing of cement stone specific surface is, first of all, the increasing of hydrosilicate gel specific volume which, in its term, increases material strength and density.

The creation of proper conditions for hardening, which change the value of gel specific volume, is one of the problems of so called "directed structure formation" (13).

The basis of this trend in cement materials technology should be kinetics control and intensification of silicate hardening processes.

Oral Discussion

Rolf F. Feldman

A great deal of research has been directed over a period of many years towards establishing criteria to distinguish quantitatively between adsorbed and hydrate water in hydrated cement paste.

These efforts were largely unsuccessful because of the slight differences in energy of attachment between the hydrate and adsorbed water.

In the field of surface chemistry it has been impossible, more often than not, to make a clear distinction between mono-molecular and multi-molecular adsorption even by accurate adiabatic calorimetry; clear distinctions between free water, capillary water in macropores, and capillary water in micropores, etc. as made by the authors (categories 1 to 4) are considered as unlikely occurrences. With these considerations in mind, it is difficult to explain the irregular curve obtained by the authors and surprising to see that the T.G.A. curve shows no change in slope at the positions corresponding to positions 1 to 5.

Another and perhaps more important area of discussion in this work is the fact that the authors have not included the decomposition of interlayer or other hydrates in their listing of the various types of water given off and it is suggested here that part of the water assessed as water of mono-molecular adsorption is hydrate water; surface areas calculated from water sorption and B.E.T. calculations are not valid for this reason, and it is unlikely that this thermal method is free of the above criticism.

Authors' Closure

O. P. Mchedlov-Petrosyan and D. A. Uginčius

Mr. Feldman in his paper and oral discussion of our paper spoke about a number of interesting problems concerning the sorption investigations of the structure of silicate materials; in this connection we take an advantage of giving our point of view as to this problem.

We think there is no reason to oppose water vapour and nitrogen adsorption methods while investigating the silicate structure.

We simply define different things: by nitrogen adsorption one can determine only external surface of hydrates because nitrogen molecules can not penetrate into the interlayer structure spaces, especially if we take into consideration that these spaces decrease as the result of dehydration up to 1 Å.

The water is adsorbed in interlayer spaces. This water is not a part of crystal lattice and its molecules have a mobility close to that of free water (7). Thus it is not necessary to take this "interlayer hydrate water" as a separate class.

This was clearly shown by K. G. Krasil'nikov while working with tobermorite (5, 6, 7,) It is he who in 1962 showed that characteristic vertical section caused by withdrawing water which is sorbed by swelling structure was seen on the adsorption isotherm of tobermorite when $P_0/P = 0.35$ (5).

That is why we may speak about a total surface S_{H_2O} and an external surface S_{N_2}.

The loss of some quantity of crystal water by high-basic hydrates can not greatly affect the results obtained. We can rather be afraid of compression effect of surface forces which was in particular pointed out by J. H. de Boer (1). Nevertheless, the results obtained by means of water vapour adsorption are in good accordance with samll angle X-rays method data (L. E. Copeland), which is precise enough and quite different.

We consider that at present there is no reason to reject the BET-method and to be satisfied with an approximate pattern of the cement stone porous structure.

The problem of fixing positions 1 to 5 on the desorption thermogram (given schematically in our paper)

was only mentioned at this Symposium. Therefore we should like only to refer to our previous paper (8) and particularly to a number of works by M. F. Kazansky (2, 3, 4) who suggested this method.

In conclusion we want to thank the V-ISCC Organizing Committee for giving us an opportunity to take part in this interesting discussion.

Supplementary Paper III-23 Sorption and Length-Change Scanning Isotherms of Methanol and Water on Hydrated Portland Cement

Rolf F. Feldman*

Synopsis

The purpose of this work was to investigate the nature and the reversibility of the CH_3OH and H_2O isotherms, and to compare their length-change and sorption characteristics. These characteristics for water on hydrated portland cement have caused some controversy, due to several complicating features in the isotherm, with regard to the surface properties and stoichiometry of the compounds, and the length change and creep mechanisms.

Introduction

The development of the present model of hydrated portland cement has been largely based on surface chemical considerations; this involved establishing criteria for distinguishing between chemical and physio-sorbed water. The determination of the stoichiometry of the tobermorite gel, its water surface area, and its porosity was based on these criteria, and these parameters are among the most important factors related to the phenomena of expansion-contraction and creep, and the mechanical properties, strength and elasticity.

The most important experiments performed using the surface chemical approach have been the sorption and length change isotherms but, as no detailed investigation of the isotherms has been made, their validity and results obtained from them have been assumed to be correct. Results of surface area investigations, however, differ markedly from those obtained from nitrogen adsorption, and this has led to some suspicion of the results.

In a series of papers by the author and co-workers, (1, 2) a more detailed examination of the isotherms was started, involving both length change and weight change as function of the vapour-pressure of water; measurements of Young's modulus and relative breaking stress were also made as functions of vapour pressure. The results led the authors to conclude that the surface area of hydrated portland cement was considerably lower than the accepted value ($\simeq$200 m^2/gm), and that inter-layer hydrate water was playing a role in both the length change and sorption isotherms, and in the variation of Young's modulus with relative humidity.

The present work is a further stage in these investigations. Detailed cycling and scanning loops were obtained for samples dried at three different conditions during the determination of precise length change and weight change isotherms based on numerous data for water and methanol on bottle and paste-hydrated cement.

Results qualitatively confirmed the earlier work, although some assumptions made previously were proved to be not completely correct. The work enabled a revised model for portland cement paste to be made, however, and allowed further evolution of the theory of volume change and suggestions with regard to the creep phenomena.

Experimental

Meterials

The cement used in this work was a type I; its composition was reported in a previous paper (1). The cement was hydrated in two ways; paste hydrated for 1 year at a water cement ratio (w/c) of 0.5 and bottle hydrated for a period of 4 months at a w/c ratio of 5.0. The degree of hydration and other properties are shown in Table 1. The bottle-hydrated cement was stored and conditioned in desiccators to 10 to 15 per cent relative humidity (R. H.) using a concentrated NaOH solution. The cast paste cylinders were sliced to 0.05 in. (1.27 mm) thickness and were approximately 1.25 in. in diameter and then stored as above. Compacts were formed at a load of 10,000 lb in a mould 1.25 in. (3.175 cm) diameter from the bottle-hydrated cement. The procedure for making the compacts and the samples has been described previously (2).

The methanol used in this work was purified by making a magnesium iodine Grignard complex by refluxing magnesium turnings and iodine in a large excess of 99 per cent pure methanol. After several distillations, the methanol was distilled directly into the high-vacuum apparatus.

Apparatus

The high-vacuum apparatus used for this work was designed to expose 12 samples simultaneously for long periods to the same vapour pressure conditions, with air excluded. Six of these samples were mounted in individual tubes on quartz spirals of the McBain-Bakr type and gave values of the weight changes to a sensitivity of 3.0×10^{-5} gm. The remaining six samples were mounted on modified Tuckerman optical extensometers and placed in individual cells equipped with optical windows (3). This determined the dimensional changes to a sensitivity of 4×10^{-6} in./in. A quartz Bourdon-type spiral gauge was used to measure the vapour pressure to a sensitivity of 1 micron and an absolute accuracy of 10 microns at low pressures.

A three-stage oil diffusion pump backed by a rotary vacuum pump was used to obtain pressures of 10^{-6} mm of mercury. The adsorbate was introduced into the system from a bulb immersed in a bath that could be controlled at temperatures down to −45°C within 0.05°C, although most of the pressure readings were taken with the Bourdon gauge. The samples were maintained at 21.3°C within 0.05°C by immersing the lower ends of the tubes and cells containing the samples to a depth of 12 in. in a controlled bath. Room temperature was controlled at 23°C ± 0.5.

Procedure

Two samples measuring 3 by 1 by 0.127 cm were cut from the discs and mounted, one section on the extensometer and the other on the quartz spiral. Samples were degassed by evacuating simultaneously through a manifold. The samples were heated during the evacuation. Three samples of bottle hydrated cement were used and one each was heated at: 80°C for 3 hours, 85°C for 3 hours, and 95°C for 3 hours plus 1 hour at 96°C. Two samples of hydrated paste were used and one each was heated at: 85°C for 3 hours, and 95°C for 3 hours plus 1 hour at 96°C. Preliminary work using a vacuum electro-balance and thermal balance techniques had established that vacuum degassing at 85°C for 3 hours with these samples produced the same result for the non-evaporable water as the conventional 'd-drying' procedure. For

the methanol isotherm, 1 day was generally allowed for equilibrium between points; for the water isotherm from 1 day to as much as 33 days was allowed. Generally 1 to 3 days was found adequate. It took over 10 months to determine the whole isotherm. Adsorption was effected by allowing the manifold and samples to attain the desired vapour pressure by control of the temperature of the bath in which the adsorbate source was immersed, or by introducing or withdrawing adsorbate from the manifold and system and measuring the vapour pressure. It was found that equilibrium was attained more rapidly with the latter method.

Theory

Adsorption

The isotherm for a given solid gas system should be reversible if there is no irreversible change in the nature of the solid and/or gas, since there thus can be only one equilibrium state at a given vapour pressure. This is usually the case at low pressures but at high pressures the problem of primary hysteresis arises. This is usually related to the pore structure of the solid and a change in nature of the adsorbate.

The well-known B. E. T. equation, valid for the low pressure region, implicitly assumes reversibility and a constant surface area. There is an isotherm, however, referred to as Type C, which has the characteristic that the ascending and descending branches only join at very low or zero pressure(4). Type C loops are found with some graphites, clay minerals, and hydrated portland cement (1). This low-pressure hysteresis phenomenon is usually attributed to irreversible intercalation of adsorbate within the structure of the solid, which usually has a layer structure. Changes in the spacing of some of these layers has been observed (5) by X-ray methods, but unfortunately, due to the disordered nature of the layers of the hydrated silicates in hydrated portland cement, this has not been possible for this material.

Length Change due to Adsorption

The Gibbs' adsorption equation is extremely important in length-change adsorption theory (6), but it has been applied in different ways by various workers and sometimes not justifiably. The equation

$$\Delta F = -RT \int_0^P n \frac{dP}{P} \qquad (1)$$

represents the change in free energy of pure adsorbent from its initial state under its own vapour pressure to its combining state, provided that this integral represents a path of thermodynamic reversibility. n is the number of moles of adsorbate on a fixed mass of absorbent. If it is supposed that the constant solid surface area, σ m^2/g, has undergone a change in surface tension, $\Delta\gamma$, one can write

$$\Delta F = \sigma \Delta\gamma \qquad (2)$$

thus

$$\Delta\gamma = \frac{RT}{\sigma} \int_0^P n \frac{dP}{P} \qquad (3)$$

$\Delta\gamma$ in fact indicates changes in the state of stress of the solid brought about by the interaction of the adsorbed molecule with forces on the solid surface; these forces have placed the solid in a state of compressive stress.

The Bangham equation (7) provides a basis for testing Gibbs' equation on solids

$$\frac{\Delta L}{L} = k_1 \Delta\gamma \qquad (4)$$

where $\Delta L/L$ is the length change of an adsorbent during the reversible adsorption process. From another relation derived by Bangham and co-workers (7), the Young's modulus of the solid material may be calculated:

$$E = \rho \frac{\sigma}{k_1} \qquad (5)$$

where E is Young's modulus of the material, and, ρ, in g/cc, is the density. The equation is derived for plates, or infinitely long cylinders, where the only surface is that of the curved surface of the cylinder or the major surface of a thin plate. The latter model might approximate hydrated cement paste. As Gibb's equation requires thermodynamic reversibility it can only be used at low pressures where normal hysteresis does not occur. If low pressure hysteresis does occur, then this region of the isotherm may be also irreversible. As will be shown later, this is true for hydrated portland cement, but a way has been found to overcome it.

Some authors (8, 9, 10) have used an equation of the osmotic pressure type and applied it to the low pressure region:

$$\Delta P = \frac{RT}{\rho M} ln \frac{P_2}{P_1} \quad \text{or} \quad \frac{\Delta L}{L} = k_2 \frac{RT}{\rho M} ln \frac{P_2}{P_1} \qquad (6)$$

where ΔP is suggested as being the pressure of the adsorbed film. This equation can only be valid if the water-hydrated cement system is considered to be a dilute solution, i.e., a change in concentration of water with respect to the adsorbent is not taking place during adsorption or desorption, and if the adsorbed water is not adsorbed water but bulk water. Both of these assumptions are completely untenable in this region.

In the reversible high-pressure region of the isotherm where capillary condensation has occurred and menisci exist, one might assume that a change in concentration is not taking place, if one defines capillary water as being remote from the surface forces; thus the capillary water in this assumption will also be 'bulk'. The capillary water maintains equilibrium with different vapour pressures by changing the radius of its meniscus. The water within the range of surface forces, however, will still effect a change in surface free energy with a change in vapour pressure of the system even if one defines it as being constant at two molecular layers. This must be taken into account as in the equations for the capillary region:

$$\Delta\gamma = \frac{RT}{\sigma} \cdot n \int_{P_1}^{P_2} \frac{dP}{P} \quad \text{and} \quad \frac{\Delta L}{L} = \left(k_1 \frac{RT}{\sigma} \cdot n + k_2 \frac{RT}{\rho M}\right) ln \frac{P_2}{P_1} \tag{7}$$

Results and Discussion

Water Adsorption

The sorption and Length Change Isotherms

The sorption and length change isotherms for the bottle-hydrated cement degassed at 80°C and 96°C are shown in Figs. 1 and 2 respectively. Results for a degassing temperature of 85°C were also obtained, but are not presented here. They were of a similar nature, but gave a slightly different 'conventional water surface area, as is shown in Table 1. In addition, it was observed that the weight of water present (in per cent) on the descending boundary curves of the isotherm at P/P_0 of 0.14, for the three temperatures 96°, 85° and 80°C, was 8.51, 8.19 and 7.91 per cent respectively. These values were less than 0.5 per cent different from the weight lost on degassing. As the starting condition was only known approximately

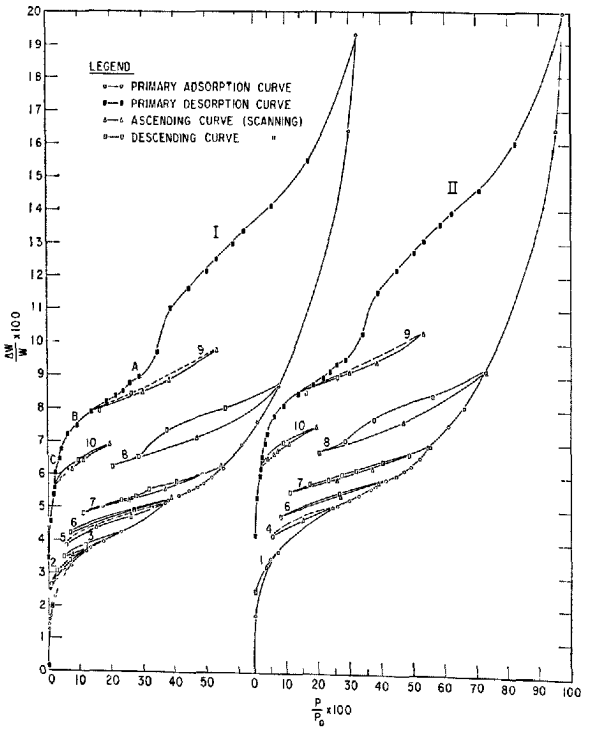

Fig. 1. *Weight change isotherms for bottle-hydrated portland cement compacts: I—degassed at 80°C; II—degassed at 96°C (scanning loops marked 1 to 10).*

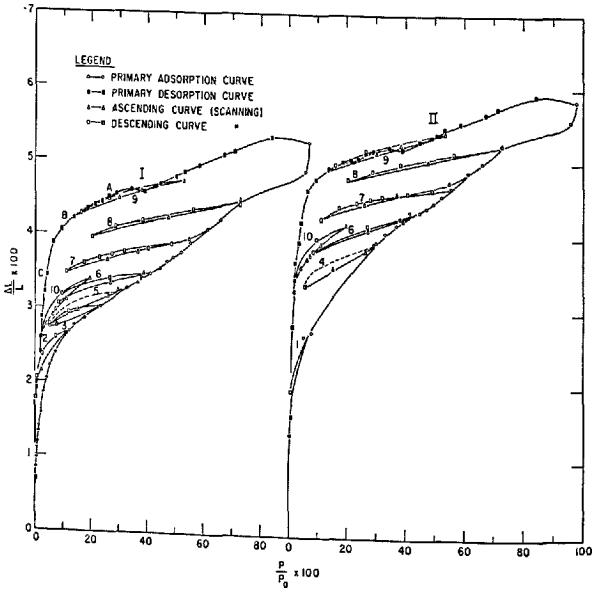

Fig. 2. *Length change isotherms for bottle-hydrated portland cement compacts: I—degassed at 80°C; II—degassed at 96°C (scanning loops marked 1 to 10).*

(P/P_0 of 0.10 to 0.15), it must be assumed that practically all the water lost on degassing was regained after the sample had been returned to the starting condition through the P/P_0 of 0.97. The degassing procedure, however, produced an irreversible shrinkage.

A general examination of both length and weight change in the two isotherms shows a large low pressure hysteresis formed by what will be called the adsorption (ascending) and desorption (descending) boundary or primary curves. Off the boundary curves are scanning loops, which contain descending and ascending portions. These loops are numbered on Figs. 1 and 2 from 1 to 10, and will be referred to as loop 1, 2, etc. It will be observed that the point where the scanning loop left the primary curve was always very close to, if not exactly at, the point where it rejoined the primary curve. This is considered as evidence for good equilibrium. The scanning loops determined for the two isotherms in Figs. 1 and 2 were not the same in all cases; detailed analysis of only the sample degassed at 80°C will be made here, however, and passing reference to the others included.

All the experimental points obtained for this sample are shown in Table 2, in the order in which they were obtained. The points with asterisks are those which have left the primary curves and are of scanning loops, both descending and ascending.

Length and sorption isotherms for one of the paste-hydrated samples, the one that was degassed at 85°C, are shown on Fig. 3. Again the similarity with the other samples is striking, although the extent of the low pressure hysteresis is not as great as for the paste samples. The general form of the primary curves for the paste- and bottle-hydrated samples agrees with that obtained from somewhat fewer data obtained by the authors and co-workers in a previous study (11), but the low-pressure hysteresis here is much larger than was obtained in an earlier investigation (1). It will be shown that this is due to the more severe drying used in the present study. No detailed analysis will be made here of the paste samples (Fig. 3), but it was again found that all the water lost on degassing was regained after the sample had been returned to the starting condition through the P/P_0 of 0.97; the surface areas for water and nitrogen are given in Table I. The areas, corrected for incomplete hydration, vary from 151 to 174 m^2/g for the water determination, and are only a bit lower than usually obtained, but,

*Points on scanning curve

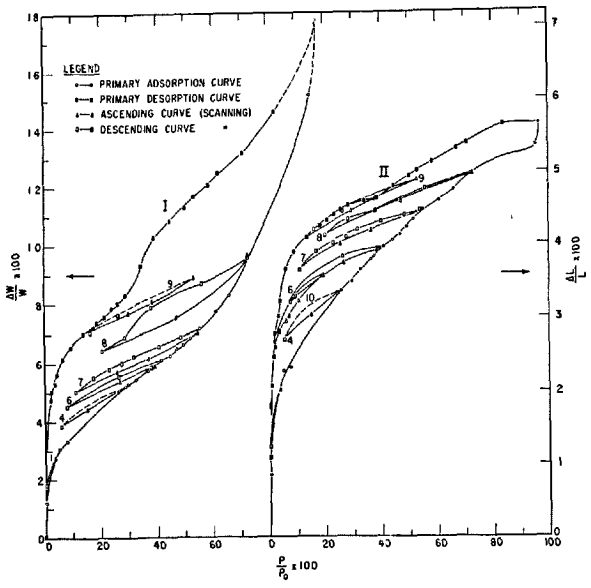

Fig. 3. *Weight change (I) and length change (II) isotherms of hydrated portland cement paste (water/cement ratio = 0.5). Scanning loops marked.*

as will be shown, a water area determination cannot be considered as a valid procedure. The nitrogen areas are, for these samples, 1/3 to 1/5 of the water areas, as has been observed by other workers (12).

Detailed examination of the isotherms, and especially the loops (Figs. 1 and 2), reveal the following:

(a) The isotherm is irreversible even at as low a P/P_0 value as 0.05 as is shown by loop 1; much of the irreversibly sorbed water, contributing to the low-pressure hysteresis, is sorbed below a P/P_0 of 0.35. (This irreversibly sorbed water, as will be shown, is interlayer hydrate water and will also be referred to as 'irreversible water.')

(b) All descending portions of loops 3 to 9 are essentially parallel and are much less steep than the primary curve. Thus means of course that a large part of the water sorbed on the primary adsorption curve is irreversible.

(c) In loops 7 and 8, where the descending curve has not gone below a P/P_0 of 0.11, the loops, although very close to, are not quite reversible.

(d) Both loops 7 and 8 exhibit a small primary hysteresis. This is to be expected since these loops leave the primary curve at P/P_0 values of 0.56 and 0.73 respectively. The desorption of the capillary water takes place between P/P_0 values of 0.38 and 0.29. This is lower than has been reported (8), but is confirmation of what was found previously (1).

(e) The primary desorption curve shows a large primary hysteresis. This primary hysteresis disappears between P/P_0 values of 0.39 and 0.29. The length change isotherm shows a small expansion in this region.

(f) The primary desorption curve below a P/P_0 of 0.29 shows that the low pressure hysteresis has increased markedly since the last loop, 8; the length change isotherm shows large changes between earlier loops, but does not show a further change in this region in the same relation to the irreverible water added.

(g) Fig. 3 shows the $\Delta L/L$ vs. $\Delta W/W$ plots for the sample degassed at 80°C; loops are numbered. Curve I contains most of the loops, curve II is a magnified version of I, and curve III shows only the primary ascending and descending curves. The $\Delta L/L$ vs. $\Delta W/W$ characteristics for the primary curve and the loops are completely different; the slope of the primary curve is much steeper and only if the loop goes below a P/P_0 value of 0.10 or thereabout does it become steep. This implies that the mean location of the water sorbed on the primary loop is different from that desorbed. The water sorbed on the primary curve is composed of a reversible and irreversible component and the $\Delta L/L$ vs. $\Delta W/W$ slope of this water is much greater in the low pressure range than the reversible component, most of which comes off separately if the loop is not carried to too low a pressure. It now seems clear that this 'irreversible water' is interlayer hydrate water. Sorption and length change theory (13) (see also earlier part of this paper) allows for length change due to physical adsorption by a decrease in surface energy of the solid. If a "crystal" is anisotropic, this may lead to the development of shear forces. In the case of hydrated cement, the hydrated silicate which has lost most of its intelayer hydrate water will accept physically adsorbed water (sometimes referred to as "reversible water") on its external surface, most of which is perpendicular to the *c*-axis. The resulting expansion on top of the layer should cause some warp at the edges, allowing some interlayer hydrate water to enter. This process will continue up the isotherm. (More will be said later about how this interlayer water enters and leaves and how it affects $\Delta L/L$ and Young's modulus.)

(h) The primary desorption curve below P/P_0 of 0.29, (Figs. 1 and 2) is surprisingly much steeper than all the desorption curves of the scanning loops. Loop 9 shows that 'irreversible water' was being desorbed in this region; the $\Delta L/L$ vs. $\Delta W/W$ slope (Fig. 4) for the primary desorption loop is much lower than in the primary adsorption region. Loop 9, however, is still steeper than loop 7, and it appears that some

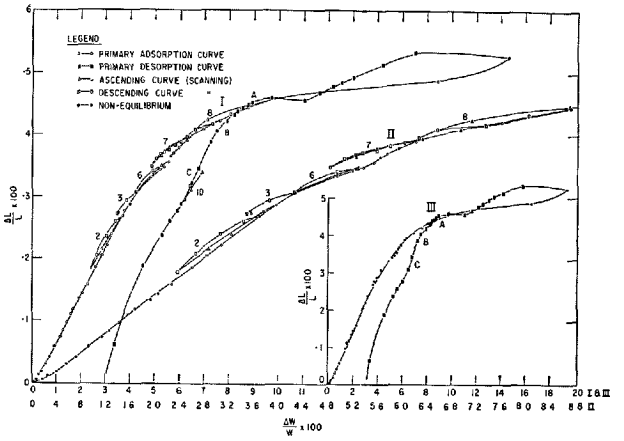

Fig. 4. ΔL/L vs. ΔW/W *plot for water sorbed on bottle-hydrated sample degassed at 80°C: I—containing all loops; II—enlarged portion of I; III—only showing primary sorption and desorption curves (scanning loops marked 1 to 10).*

interlayer hydration may be taking place along the adsorption curve of loop 9.

(i) ABC on Figs. 1, 2 and 4 mark the area where two regions of distinctly different slope of the ΔL/L vs. ΔW/W curve occurs on the primary desorption curve (2). As will be seen later, this probably represents a change in the response of length change due to unit weight loss of interlayer water. The assumption made previously (2) that this characteristic is constant now appears to be incorrect.

(j) The line BC marks the region where a considerable hysteresis in the ΔL/L vs. ΔW/W plot is formed (Fig. 4). (How this may illustrate the difference between entry and exit of interlayer water will be discussed later.) Below BC, the curve first gradually returns towards the zero point but then turns away, resulting in a large contraction below the zero point at zero ΔW/W.

(k) Loop 10 illustrates how a smaller low pressure hysteresis may be obtained in the isotherm when the sample has not been degassed as much as the initial degassing. Along the adsorption curve of the loop, a change in slope again occurs at about a P/P_0 of 0.10.

(l) Sorption and desorption measurements were taken at very low pressures (Table 2). On sorption the lowest P/P_0 value was 0.0027 and 0.0044 gave a ΔW/W × 100 value of 1.42. On desorption, the value was 3.45 at a P/P_0 value of 0.0042. This shows that there is large hysteresis in the sorption isotherm even at the lowest pressures. The length change isotherm shows a hysteresis in the other direction. At P/P_0 below 0.0093, a very large shrinkage occurs (0.420 per cent below the original zero). The pressure at zero was less than 1 micron of Hg (10^{-3} torr).

Construction of a Reversible Isotherm

The following conclusions can be derived from the previous discussion.

(a) The water isotherm for the several degrees of drying investigated is irreversible at all primary regions and, as such, cannot be used for B. E. T. calculations.

(b) As a large but unknown portion of the 'sorbed' water in the low pressure region is interlayer hydration, the surface area must be considerably lower than the original value calculated for water. The surface area obtained from N_2 will be considered here as the more reliable figure.

It still seems possible to separate, to some extent, the interlayer and physically adsorbed water from the isotherm. This can be done with the help of the scanning loops. If the desorption part of each loop up to the point where it overlaps with the inception of the previous loop (at a lower pressure)is regarded as reversible and involving only physically held water, one would be able to calculate for the pressure region over which the loop extended, the amounts of 'irreversible' and 'reversible' water sorbed along the primary adsorption curve. Since loops 7 and 8 exhibited primary hysteresis, the adsorption curve was used in these instances. For the estimate between P/P_0 of 0.727 and 0.97, it was assumed that no 'irreversible water' was desorbed between P/P_0 of 0.97 and 0.289; then the separation between this point on the primary desorption curve and loop 8, represented the water irreversibly sorbed between P/P_0 of 0.727 and 0.97. This procedure was also performed for the length change isotherm.

Fig. 5 shows the reversible length change and sorption isotherms. The desorption curve between P/P_0 of 0.97 and 0.289 was fitted on this curve. From the length change isotherm it is clear that too much contraction took place in this region to fit properly onto the adsorption curve. It is suspected that some 'irreversible water' was lost between at least P/P_0 of 0.345 and 0.289. Calculation of the reversible desorption between P/P_0 of 0.289 and 0.139 using loop 9 was not satisfactory since the validity of the assumption that the adsorption curve of the loop only involves physical water is suspect.

A plot of ΔL/L vs. ΔW/W (Fig. 5), shows a sharp deviation from the linear part of the curve at a P/P_0 of 0.10. This linear plot has been observed for the adsorption of water on porous glass, finely divided silica, precipitated calcium carbonate, calcium sulphate hemihydrate and $Ca(OH)_2$ and goes through

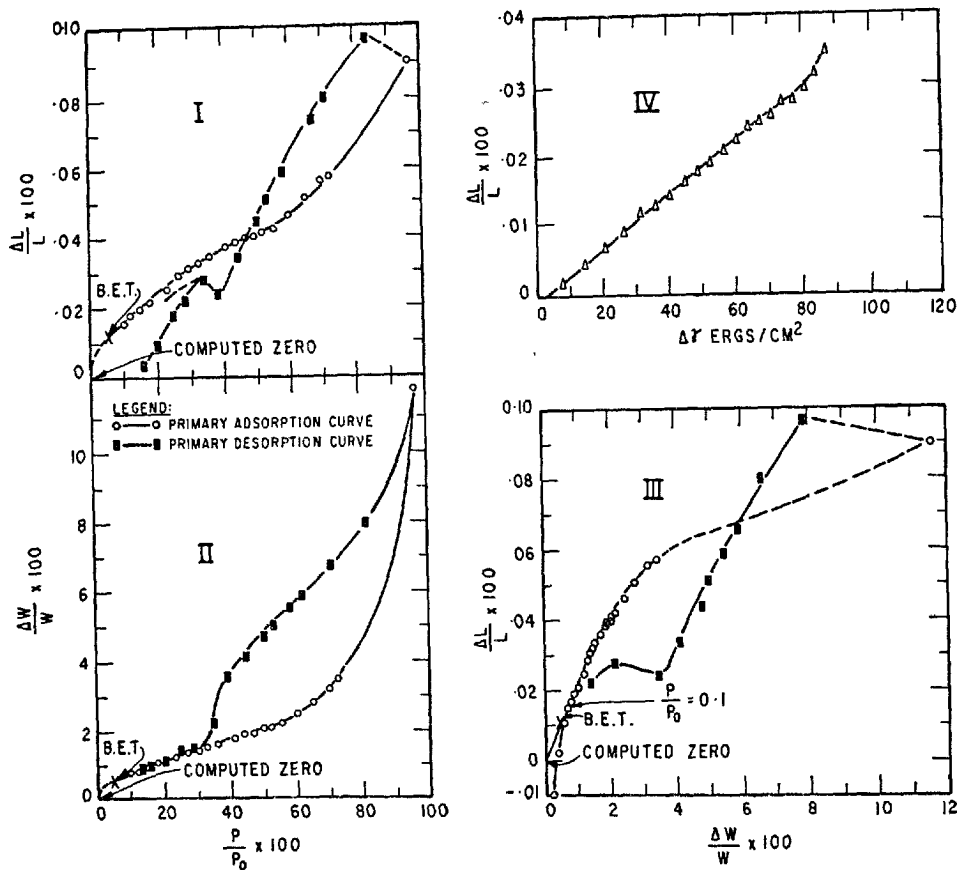

Fig. 5. *Constructed reversible water isotherm and computations: I*—$\Delta L/L \times 100$ vs. $P/P_0 \times 100$; *II*—$\Delta W/W \times 100$ vs. $P/P_0 \times 100$; *III*—$\Delta L/L \times 100$ vs. $\Delta W/W \times 100$; *IV*—$\Delta L/L$ vs. $\Delta\gamma$.

zero (14–17). Thus it is concluded that a larger amount of 'irreversible water' is removed below P/P_0 of 0.10, and so the physically held water cannot be estimated in this region using loops 1 or 2. An alternative procedure was used to achieve this. The N_2 surface area of 30 m^2/g (Table 1) was assumed to be approximately correct. Then, using the B.E.T. equation and adding different amounts of reversible water to represent that adsorbed below a P/P_0 of 0.10, calculations were made allowing the assumed surface area to vary slightly, until the monolayer capacity fell on a P/P_0 of 0.15 to 0.20. Using the area of the water molecule as 10.8 m^2/g, the water area obtained was 40.8 m^2/g; 0.70 per cent for $\Delta W/W \times 100$ was used for the 'reversible water' between P/P_0 of 0 to 0.10. From the B. E. T., a $\Delta W/W$ value for P/P_0 of 0.05 was obtained, and all other points below this were made by extrapolation of the curve. No significance was attributed to values below P/P_0 of 0.05 for 'reversible water.' Similar values for $\Delta L/L$ could be obtained by extrapolation of the $\Delta L/L$ vs. $\Delta W/W$ plot to the zero obtained for $\Delta W/W$.

All these results are included in Table 3 together with the results for the 'irreversible water,' which will be discussed together in more detail later.

Application of Gibbs' Equation and the Estimation of Young's Modulus from the Reversible Isotherm

An integration over the adsorption branch of the reversible isotherm was made between P/P_0 values of 0.05 (to avoid the extrapolated area and errors in integration as the pressure approaches zero) and 0.60, according to Gibbs' equation (Eqs. (1) and (3)). The change in state of stress of the solid $\Delta\gamma$, is plotted against $\Delta L/L$ according to Eq. (4). As shown on Fig. 5, this plot yields a very good straight line, and it appears that the whole procedure in constructing the reversible isotherm is justified. The slope of this line, k_1, from Eq. (4) is 3.90×10^{-6} cm/dyne.

* Total irreversible sorbed
**Total reversibly desorbed

Using a value of 2.86 g/cc for $Ca_3Si_2O_7 \cdot 2H_2O$ (18) since at a P/P_0 of 0.30 only about 40 per cent of the irreversible water has re-entered and since most of the adsorption is taking place on this "crystal" which constitutes most of the area, and using 40.8 m^2/g for the surface area, the value of 'E' from Eq. (5) is 2.99×10^{11} dyne/cm^2 or 4.35×10^6 lb/in.^{2}. This value is about 8 times as large as that measured for the equivalent compact (19), or of the equivalent water to cement ratio paste (20). This calculated value, however, represents 'E' for the solid material, not the porous body. Helmuth and Turk (20) extrapolated from porosity-E plots to get 'E' of 'gel phase' as 4.5, and of 'solid phase' 10.8 (lb/in.^{2}). This latter value was similar to the extrapolation of Soroka and Sereda (19). Both these values suffer from the difficulty of measuring the correct porosity; however, since a large part of the water removed during 'd-drying' is interlayer water which returns on sorption. Thus, the water porosity (determined by water) would be much lower than anticipated, making the extrapolated value much too high. Considering these assumptions, the value found for the modulus of the solid phases is very good and is considered as further evidence of the validity of this approach.

The Irreversible Isotherm

The method outlined in the previous section (construction of a reversible isotherm) also enables one to obtain the irreversible isotherm (Fig. 6 and Table 3). The large hysteresis in both length and weight change isotherms is evident. As already described, this hysteresis exists even to vapour pressures of only a few microns. The 'irreversible water' is sorbed at all pressures along the primary adsorption isotherm, and this explains why the time to attain equilibrium was always longer on this curve. Values below P/P_0

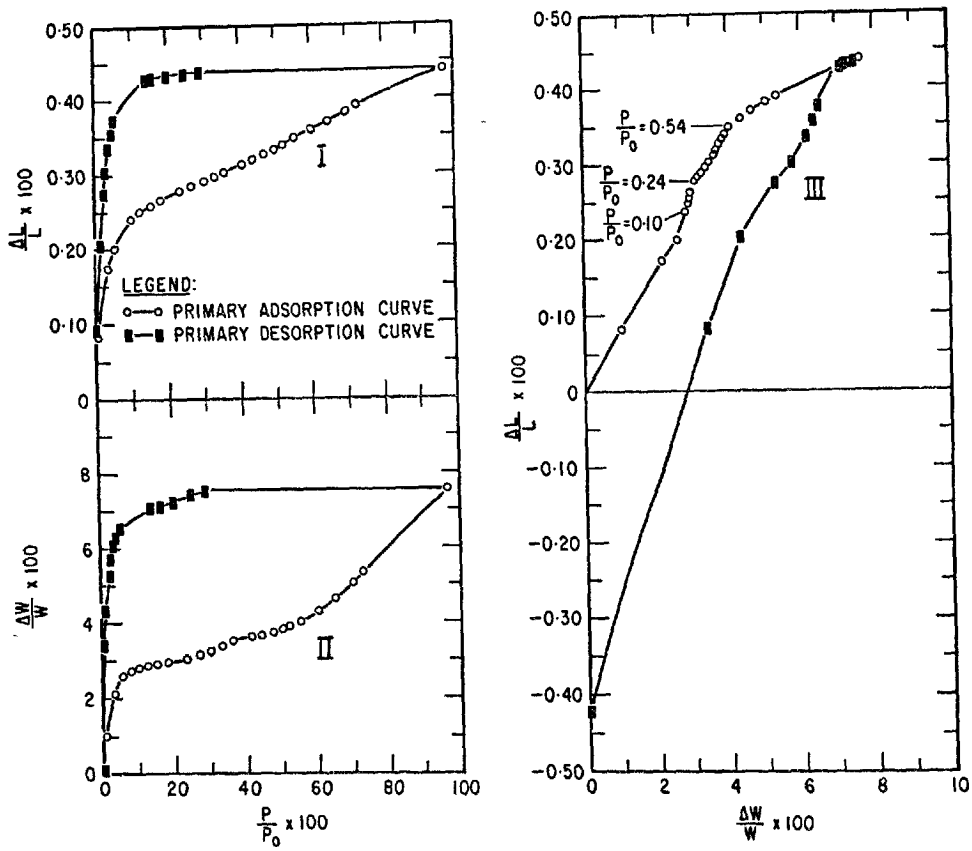

Fig. 6. *Constructed irreversible water isotherm: I*—$\Delta L/L \times 100$ vs. $P/P_0 \times 100$; *II*—$\Delta W/W \times 100$ vs. $P/P_0 \times 100$; *III*—$\Delta L/L \times 100$ vs. $\Delta W/W \times 100$.

of 0.05 were extrapolated for 'reversible water', but since this became small compared with the 'irreversible water', any error would be negligible.

The plot of the $\Delta L/L$ vs. $\Delta W/W$ shows the important change in slope on the sorption curve at P/P_0 of 0.54. This is precisely the point where the value of the modulus of elasticity (11) starts to increase, when measured as a function of relative pressure. In addition, the hysteresis of this curve shows that the withdrawal of interlayer water follows a completely different path from its entry. Again this might be implied from the results of the modulus measurements (11). As the desorption continued, it appeared as if the loop might gradually close, but below P/P_0 of 0.009 it diverged yielding a large irreversible shrinkage below the original zero by 0.420 per cent, although the zero for $\Delta W/W$ was the same.

This irreversible effect also occurred on the first degassing, but did not occur when degassing took place after a methanol cycle. Thus it must be associated with the effect of water. Solution effects of water on calcium hydroxide (14) are ruled out because the effect is considered too large; the explanation favoured is that when the final interlayer water is expelled, a reorientation of the layers occurs, resulting in an irreversible contraction. More work is needed in this area. Nevertheless, a plausible model can be suggested to explain most of the general behaviour of the entrance and exit of interlayer water and the variation of $\Delta L/L$ and modulus of elasticity with P/P_0.

Fig. 7 illustrates in model form the process of exit and entry of interlayer water: initially drying will take place from the edges with little contraction ((a) to (b)); drying to state (c) will provide some collapse and large contraction; drying at the edges probably occurs below P/P_0 of 0.30 and stronger drying (state (c)), below P/P_0 of 0.07; the final removal of the water in the middle will not take place above P/P_0 of 0.009. It is considered that this water in the centre provides the main bracing for a higher rigidity and, when it is removed, the modulus decreases as experiments show. This state of drying (d) also involves possible reorientation of the plates to produce an irreversible contraction. Resorption now occurs

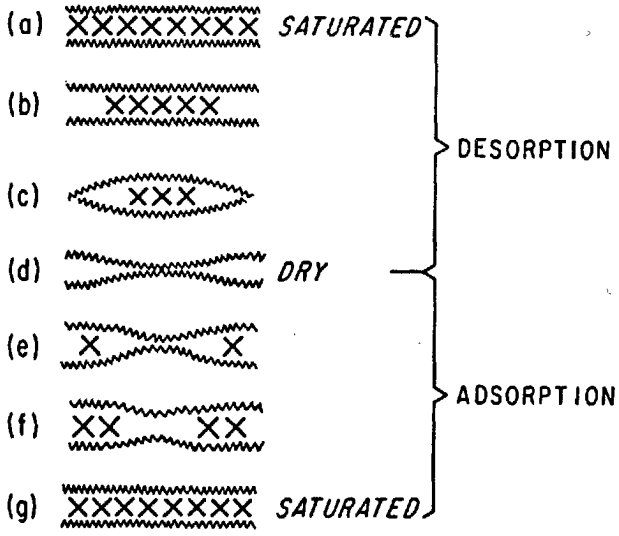

Fig. 7. *Simplified model for exit and entry of water between layers of tobermorite gel*

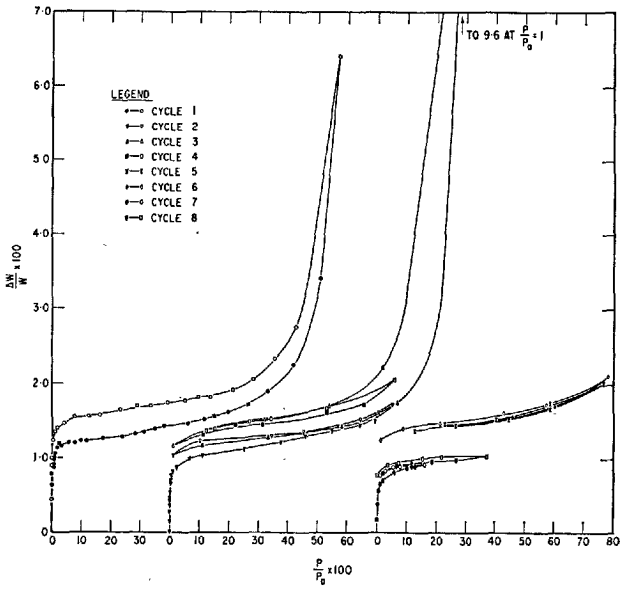

Fig. 9. *Length change isotherms of methanol on bottle-hydrated portland cement compacts degassed at 80°C.*

at the edges (states (e) and (f)), being initiated by physical adsorption and resultant surface free energy change on the external surfaces. Here, the pressure vs. $\Delta L/L$ or $\Delta W/W$ hysteresis is apparent, since interlayer water cannot enter until some external movement occurs. Further sorption will continue inward from the edges, causing large expansions. As the layers are filled towards the middle (states (f) to (g)), it is apparent that the modulus will start to increase due to "bracing" of the layers by the water molecules; the resultant $\Delta L/L$ will not be as large because most of the expansion occurred from the edges.

Further implications of the interlayer water can be observed from Table 3:

(a) Total interlayer water for this sample is 7.54 per cent, although it may be somewhat higher, as discussed above. This means that the difference between pore volumes obtained by water, on the one hand, and nitrogen and methanol, on the other, would be in the order of 0.08 ml/g. This explains the discrepancies in pore volume obtained by Mikhail and Selim (21) for pastes with a *w/c* of 0.35 to 0.57. It is postulated here that, since the interlayer penetration by nitrogen is very small, this gas would give the best pore volume for mechanical property extrapolations.

(b) Less than 20 per cent of the total expansion along the isotherm is due to physically adsorbed water. The percentages of physical and 'irreversible' water, and their concomitant length changes for the different pressure ranges are shown in Table 3.

The only remaining evidence to support the previous model of hydrated portland cement is the density measurements of Brunauer, Kantro, and Copeland (18). It is clear, however, that when the density is measured with a water solution, the interlayer water has already re-entered. The slow decrease in density obtained by these authors for some less severely dried samples is probably associated with some slow recovery of the irreversible shrinkage observed by Helmuth and Turk (22), or as observed here below P/P_0 of 0.009. Density measurements should be perhaps obtained with nitrogen.

Methanol Adsorption

Methanol sorption was measured on the same compacted sample degassed at 80°C.

The sorption results (Fig. 8) are very similar to those obtained by Mikhail (21) inasmuch as a surface area of similar magnitude was obtained (area of molecule taken as 18.1 Å², see Table 1), and the low pressure hysteresis is of the same magnitude (intermediate between water and nitrogen). Several cycles were performed, however, and length change measurements, (Fig. 9) were made during these cycles. Significant features of these results are the following:

(a) After significant sorption at very low pressures, the isotherm is very flat; for cycle 2 to P/P_0 of 0.75 the desorption is even flatter. This may be explained by the concept of autophobicity of alcohol adsorption (23), where the isotherms exhibit strong monolayer

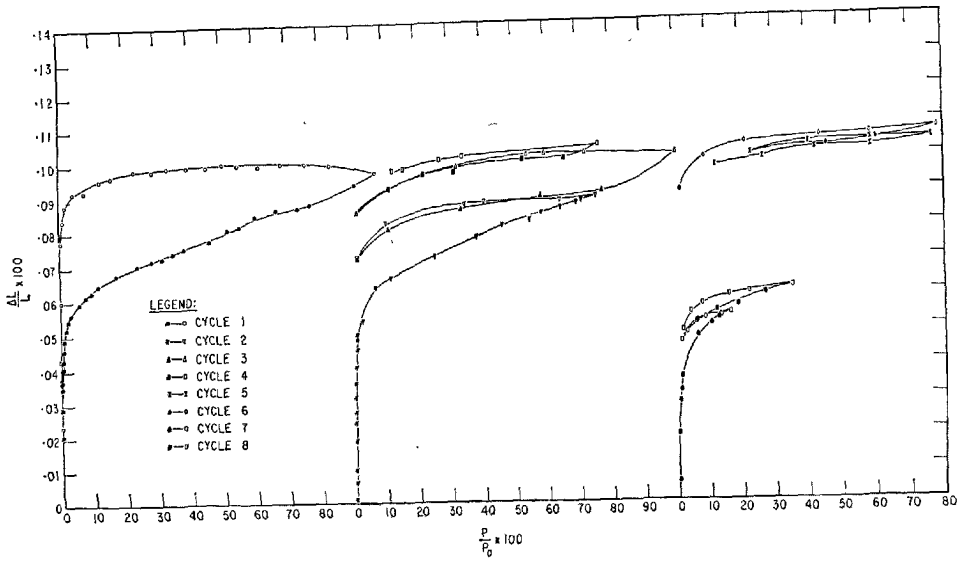

Fig. 8. *Sorption isotherms of methanol on bottle-hydrated portland cement compacts degassed at 80°C.*

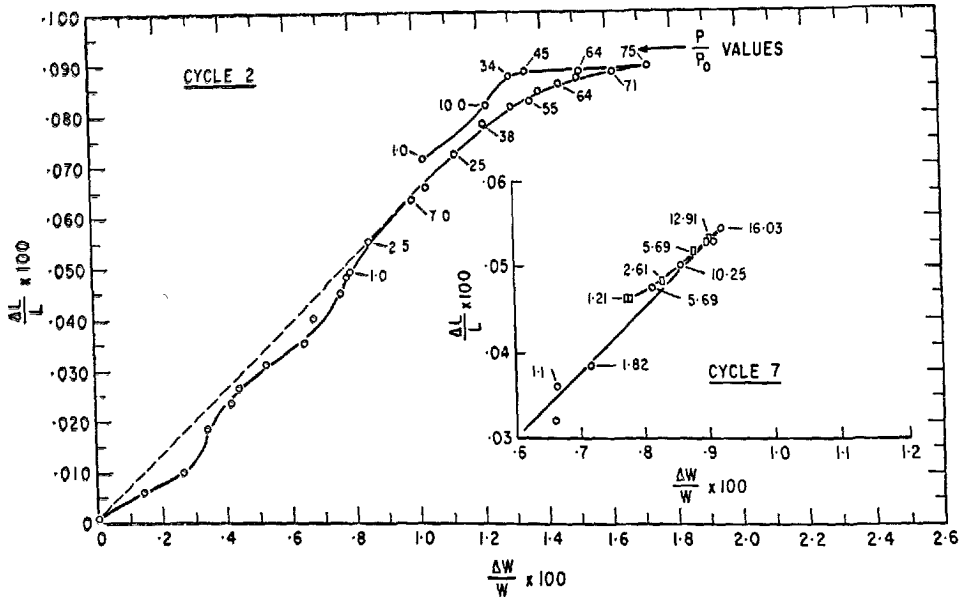

Fig. 10. ΔL/L vs. ΔW/W *plots for methanol sorbed on bottle-hydrated portland cement compact degassed at 80°C* (P/P_0 *values are* × *100*)

binding with little tendency toward multilayer formation; multilayer formation occurred almost asymptotically at high vapour pressures. The autophobicity is due to strongly oriented adsorption in the first adsorbate layer which would permit multilayer formation at a distance remote from the initial interface so that its influence is lost. The result would approximate to a Langmuir isotherm, but for methanol, whose hydrocarbon chain is not so long, this approximation is not completely attained.

(b) Cycles 2, 7 and 8 show that the hysteresis, like that for water, is cumulative, significant low pressure hysteresis occurring even after sorption to only P/P_0 of 0.17. Cycle 3 rejoins precisely where cycle 2 stopped on the adsorption curve, but for cycles 7 and 8, the rejoining is not so exact. Cycle 4 shows that some of the irreversibly sorbed methanol may be withdrawn at about P/P_0 of 0.01; cycle 5 shows that the isotherm

is close to reversible between P/P_0 of 0.12 and 0.77 on the descending branch, and cycle 6, that some irreversible sorbed methanol is added when this cycle goes to a higher pressure than did cycles 4 and 5.

(c) The length results show the same result as far as irreversibility is concerned. The ascending 'sorption' curves, however, cycles 1, 2, 3, show a significant length change at the beginning and all the way up the isotherm, contrary to the assumption of Mikhail and Selim (21). Despite the large desorption, there is very little contraction on the desorption curve. This length change plot looks very similar to the constructed irreversible plot for water. The explanation is clear: along the sorption curve, both physical adsorption (of a strong nature at low P/P_0), and interlayer penetration are taking place. The penetration is less than that of water because of the respective sizes of the molecules; on the desorption curve only weakly held methanol is coming off. At P/P_0 of 0.10, the slope $(\Delta L/L)/(\Delta W/W)$ for the hysteresis is taken to represent that for interlayer methanol (see Table 1); the value 0.0955 is more than that for water (0.0860) which is reasonable since the methanol molecule is bigger than water. Curve I in Fig. 10 shows the $\Delta L/L$ vs. $\Delta W/W$ plot. The points below P/P_0 of 0.01 show signs of specific interaction, but the adsorbed methanol cannot be separated from the interlayer methanol. If the average slope is taken and the surface area is assumed to be 30 m^2/g (nitrogen value), the physically adsorbed methanol will have a $(\Delta L/L)/(\Delta W/W)$ of 0.0525, over twice that for water. This is consistent with Gibbs' equation if, as assumed, a larger proportion of the methanol is adsorbed at low pressures. There would be reason to expect that the specific adsorption for methanol would be different from the one for water if the surface contains many hydroxyl groups (13). Details of this will not be included here, but it is apparent that the methanol isotherm is more complicated than previous interpretations (21), and that it is consistent in every way with the results obtained from water sorption.

Conclusions

1. Exposure of dried (below approximately 10 per cent R. H.) hydrated portland cement paste to water vapour at any pressure results in the entry of interlayer hydrate water simultaneously with physically adsorbed water.

2. Surface areas are much lower than was believed, the nitrogen area probably being the most reliable figure.

3. Less than 18 per cent of the expansion along the isotherm is due to physically adsorbed water.

4. Porosity values obtained from water sorption are too high. Nitrogen would give more reliable figures.

5. Gibbs' equation is obeyed for the constructed reversible isotherm, and a calculation of the modulus of elasticity of the solid material gives a reasonable value.

6. A model for the entry and exit of interlayer water is given which explains the effect of vapour pressure on the modulus of elasticity. This model suggests that the entry and exit of interlayer hydrate water plays an important part in creep phenomena.

7. Results from methanol sorption, which also involves interlayer penetration, are consistent with those of water.

Supplementary Paper III-34 The Structure of Cement-Stone and the Use of Compacts as Structural Models

I. Soroka* and Peter J. Sereda**

Synopsis

The relation between hardness, modulus of elasticity and porosity was investigated in three different systems prepared from normal Type I portland cement. This study was undertaken to obtain some data on the structure of cement-stone, particularly with regard to the nature of the interparticle bonds and their effect on mechanical properties. The study also enabled the evaluation of the possible use of compacts in cement research.

The three cement systems, designated as I, II, and III, cement pastes (I) in which porosity varied from 40% to 70% and the degree of hydration from 73% to 98% (w/c ratio 0.40 to 1.20), compacted cement pastes (II) in which porosity varied within the range of 25% to 60%, and compacts of bottle hydrated cement (III) in which the porosity varied from 20% to 55% and the degree of hydration from 0% to 90% (i.e., unhydrated cement compacts were included).

Test results generally supported the concept that the strength of the cement-stone is mainly derived from a particular type of interparticle bond. It is concluded that this bond is a solid to solid contact resulting from the bringing together of surfaces, and that it is essentially the same in compacts as in cement paste.

The close agreement between values for mechanical properties of compacts as compared to paste suggests that compacts, used as a model of the cement-stone, are a promising and a reliable tool in cement research.

Introduction

It is generally accepted that the structure of cement-stone*** is rather complex, and there are still quite a few aspects concerning its nature awaiting clarification. Although extensive data exist to indicate that the hydration products are essentially comprised of colloidal-sized particles having a great variety of microstructure, as shown by Grudemo (1), little is known about the nature of the bonds between these colloidal particles to account for the strength of the cement-stone. Philleo in his review (2) discussed the various types of bonds and pointed out that limited swelling of the cement-stone in water has been considered as evidence for the existence of some chemical (primary) bonds between the gel particles but that the secondary bonds accounted for most of the strength of the cement paste. This conclusion was made on the grounds that adsorbed water was a constituent part of the bond, in order to account for some of the unusual physical and mechanical behaviour. Recent work at DBR (3–6), however, contradicts the above hypothesis.

It is recognized that the terms "chemical" and "secondary" bonds have been used in describing the structure of hydrated cement system without a strict definition of their meaning. This has led to considerable misunderstanding. It is believed that what was meant by the "chemical" bond between the particles was a solid to solid contact similar to that of a grain boundary in a polycrystalline material where some atoms approach the spacing and arrangement in the crystal. Such "chemical" bonds could be formed during a crystallization process accompanying a chemical reaction where the mobility of atoms allows for a regular arrangement resulting in an intergrowth of crystals. It follows that these bonds would be strong and, when broken, would not be remade in normal circumstances.

It is believed that the term "secondary" bonds as applied to the hydrated cement system arose out of the assumption that adsorbed water was a constitu-

***Cement-stone refers to the system of cement gel and the associated capillary space, and is an alternate name for the hardened cement paste.

ent part of the interparticle bond; hence the general term of van der Waals forces was considered appropriate.

Previous work in this laboratory has indicated that neither of these definitions would fit adequately the interparticle bonds in the hydrated cement system. It is suggested, therefore, that a different interparticle bond be postulated which would involve a solid to solid contact resulting from the bringing together of surfaces (by pressure or accommodation) forming a particle boundary having no regular atomic arrangement or spacing. Atoms at such a boundary would engage a varying proportion of the long range and the short range forces depending on the degree of disorder and the average spacing. It can be visualized that this interparticle bond can be broken and subsequently remade under appropriate loading conditions. This type of bond differs from the "chemical" bond defined above, which has a more regular atomic arrangement, and in which the spacing of the atoms may approach that of the lattice spacing in the crystal.

The vital question of the structural model for hydrated cement, therefore, has yet to be resolved, especially in regard to the nature of the particular interparticle bonds for which there is considerable evidence from the work at DBR involving compacts of hydrated cement. The present work was designed to shed some further light on the above questions of the structure of portland cement-stone.

In the first stage of the study, some mechanical properties of compacts and pastes were compared in a gypsum system, which is distinctly crystalline and where intergrowing of crystals is a distinct possibility. The results of this stage of the work were reported elsewhere (7), but the essential part is reproduced here to enable direct comparison of the gypsum system with the cement system.

In the second series of experiments reported here, essentially the same tests were carried out with Type I normal portland cement instead of gypsum. It was hoped that the comparison of results for the two systems (distinctly different in the degree of crystallinity) would reveal information about the nature of the bonds.

Experimental

In the tests described, the hardness and modulus of elasticity of portland cement pastes and of compacts with a wide range of porosities were compared. All specimens involved were flat, round plates 1.25 in. (approximately 32 mm) in diameter and 0.050 in. (approximately 1.25 mm) thick. Specimens of three different systems were prepared, all from the same brand of Type I normal portland cement.

Preparation of Specimens

System I—Cement Paste

The cement was mixed in vacuum with boiled distilled water to give cylinders measuring 1.25 in. in diameter and approximately 5 in. high. (For the chemical composition of the cement see reference (3), and for further details of mixing procedure see reference (8)). The water/cement ratio in the specimens varied from 0.40 to 1.20 resulting in pastes of seven different porosities ranging from approximately 40% to 70% (Table 1).

Specimens were demoulded after 48 hours and, to avoid carbonation, were wet-cured in tightly closed rubber bags. At the age of approximately 3 months the cylinders were taken out and sliced to give specimens having the required thickness of 0.050 in. Conditioning of specimens involved two stages; they were first allowed to dry at 30% R. H. and 22°C (saturated solution of $CaCl_2$), and then placed over a NaOH solution to reach equilibrium at 50% R. H. and 22°C both in a CO_2-free atmosphere.

The porosity of the samples was calculated from the weight, volume, and degree of hydration, taking the density of the unhydrated cement to be 3.15 g/cc and that of the hydration products to be 2.60 g/cc.

System II—Compacted Cement Paste

Some of the cement paste specimens (system I),

after being cured and sliced, were subjected to a compacting pressure in a closely fitting mould (0.003 in. nominal clearance). In each case the thickness of the sliced specimens was adjusted to yield the nominal thickness of 0.050 in. after compaction. Porosity was controlled by the amount of the applied pressure and ranged from approximately 25% to 60% (Table 2). When the initial porosity was known, porosity after compaction was determined simply from the change in the dimension of the specimens involved.

Compaction was affected when the paste specimens reached equilibrium at 30% R. H.; however, testing was carried out after they were conditioned at 50% R. H.

System III—Compacts of Bottle Hydrated Portland Cement

The hydrated cement was prepared by mixing 1:5 mixtures of cement and water in tightly closed bottles which were mounted on a rotating disc. The mixing period varied between 24 hours and 28 months, resulting in products of different degrees of hydration within the range of approximately 35% to 90% (Table 3).

When mixing was completed, the hydrated cement was filtered, dried at 30% R. H. over $CaCl_2$, and then screened through a 100-mesh sieve. The remaining fraction (mostly $Ca(OH)_2$ crystals) was ground and recombined with the sieved material. At this stage the powdered hydrated cement was used to produce the compacts by the method described elsewhere (3–5). Altogether, compacts of 5 different degrees of hydration were prepared within the porosity range of approximately 20% to 55% (Table 3). To complete the picture and to provide data for "zero" degree of hydration, compacts of unhydrated cement were also prepared in the porosity range of 18% to 31% (system IIIa-Table 4). As in system I (cement pastes) porosity was determined from the weight, volume and degree of hydration and using the density values mentioned previously. To conform with the

other systems, testing was carried out after specimens reached equilibrium at 50% R. H. and 22°C.

Testing Methods

All tests were carried out in a gloved box which was conditioned at 50% by means of a NaOH solution (Fig. 1). The following tests were conducted.

Hardness

Vickers hardness was determined with a Leitz Miniload hardness tester; the load was adjusted in each case to give indentation to a depth of 35 to 50μ. For each specimen tested, the hardness was taken as the average of 10 tests carried out along an arbitrary diameter at 0.1-in. spacing.

Young's modulus of elasticity was determined with an apparatus described elsewhere (5). Essentially the procedure involves the measuring of the deflection of a specimen when it is loaded at its centre and supported at three points located at the circumference of a circle 1 in. in diameter. Under such conditions, Young's modulus is related to centre-deflection as follows (9):

$$\text{Def} = \beta \frac{\text{P}a^2}{\text{E}h^3}$$

where P = the applied load
a = radius of circle of support
E = Young's modulus of elasticity
h = specimen thickness
β = parameter related to Poisson's ratio (μ), number of supports (m) and the ratio (t) between the radius of circle of supports (a) and radius of specimen (c).

To determine the value of β in the above formula, it was assumed that the modulus of elasticity in compression is equal to the value determined from the deflection test. In turn, the modulus of elasticity in compression was determined on cylinders 1.25 in. $\times$ 2 in. which were, in fact, the companion specimens of the cylinders used for preparing systems I and II.

The average of five tests was considered as Young's modulus for any given set of conditions.

Degree of hydration was determined by means of a thermo-balance test (TGA). The weight of the sample in a "dry state" was taken as the value recorded when no weight loss was observed (readings to the nearest milligram) with the oven temperature kept constant at 120°C. The amount of water required for complete hydration was considered to be 25.4% of the unhydrated cement weight. For each set of conditions, the degree of hydration was taken as the average of three or four such tests.

It is realized that the accuracy and reproducibility of the results of the above procedure are questionable to some extent. This, in fact, is somewhat indicated in the results reported in Tables 1 and 3. It can be seen that, contrary to what could have been expected, the degree of hydration in the paste with a w/c ratio of 1.20 was found to be higher than that observed in the cement which was bottle-hydrated for 28 months. It should be kept in mind, however, that for the purpose in hand, where the degree of hydration is used to calculate porosity, the use of a better established value is less critical than it perhaps would be under different conditions. Using, for instance, the formula suggested by Powers (10) it can be shown that a difference of 10% in the degree of hydration is associated only with approximately 3% variation in the porosity of denser pastes (w/c = 0.40) and 1% variation in high-porosity pastes (w/c = 1.20). It is, therefore, considered that possible errors of such order are not liable to affect materially the results and the use of the above procedure in no way limits the following conclusions.

Results and Discussion

In Figs. 2 and 3 respectively, hardness and modulus of elasticity are plotted against porosity, together

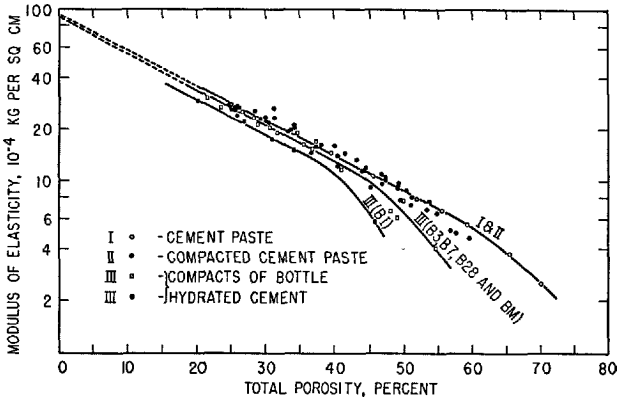

Fig. 2. *Modulus of elasticity vs. porosity for the cement systems*

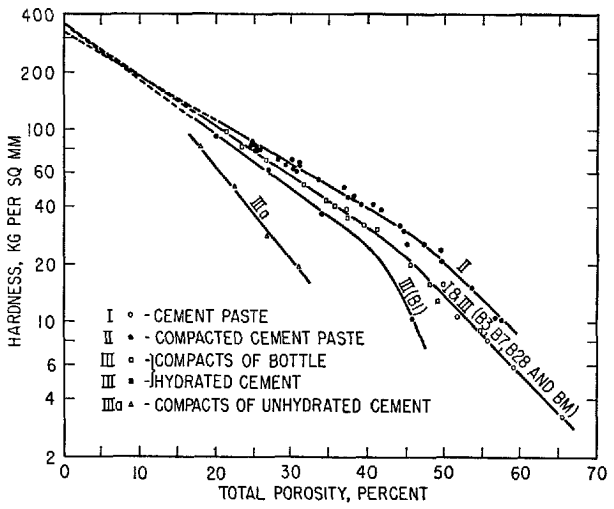

Fig. 3. *Hardness vs. porosity for the cement systems*

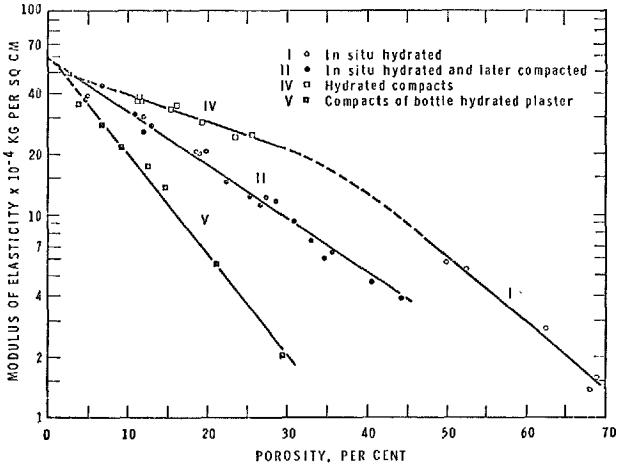

Fig. 4. *Modulus of elasticity vs. porosity for the gypsum systems*

with the corresponding regression line. These lines were calculated to fit test data employing the least squares method and assuming a semi-logarithmic relation between the factors involved. It can be seen that for each of the systems prepared, (excluding the higher end of the porosity range), such an assumption resulted in fairly good agreement with the experimental data. It should be realized, however, that the exponential expression used here, although suggested and used by others (11, 12), is purely empirical and therefore does not necessarily represent the "true" relation between the factors involved. Moreover, it is possible to devise other expressions to fit the very same data. In the present study, however, where the main object is the comparative evaluation of the different cement systems, this aspect becomes of secondary importance. In fact, for the present purpose, any other expression which can be shown to represent the experimental data may be used with more or less the same degree of success.

The most significant result, as shown in Fig. 2, is that the modulus versus porosity relation was the same for the compacted cement paste as for the cement paste despite the fact that paste samples, having an original porosity in the range of 40 to 70% were compacted to porosities in the range of 25 to 60%. This is strong evidence for the absence of "chemical" bonds because it is unlikely that these would not be broken (if they were present) when the pore volume is reduced by one half during compaction. The fact that the values for the modulus of the compacts of bottle hydrated cement fit so closely to that of the paste and compacted paste lends further support to the idea that this system has none or very few "chemical" bonds.

The above results are in striking contrast with the results for the gypsum systems presented in Fig. 4 (reproduced from reference (7)) where "chemical" bonds can be identified. In this case the modulus for the in-situ hydrated gypsum was an order of magnitude greater than for the compacts at the same porosity.

The results of microhardness versus porosity presented in Fig. 3 lead to the same conclusions as the results for modulus; the "chemical" bonds, if present in the paste, play an insignificant role because paste and compacts give the same relation with porosity. It is surprising, however, that the compacted paste samples give higher values for hardness. This may be related to a surface effect in the case of these samples.

It is also evident from the data in Figs. 2 and 3 that the degree of hydration is a significant factor only when its value is below 50% as represented by system III (B1). All series of cement compacts (system III) made from material in which the degree of hydration exceeded 50% (B3, B7, B28 and BM-Table 3) are

represented by a single line. This point is further demonstrated from the data related to systems I and II (Fig. 2). Here, although the degree of hydration varied in the various series (Tables 1 and 2), in all cases it exceeded 50% and the results from both systems are represented by a single line. A similar result was obtained by Sereda et al. (5) for cement pastes in which the degree of hydration exceeded 58%.

The above result suggests that, when cement is hydrated in excess of 50%, it is possible to obtain bonds between the hydrated and the unhydrated particles in the paste and in the compacts that are as strong as between hydrated particles themselves.

A case has been made for the absence in cement paste of "chemical" bonds which would fit the strict definition given and which seem to be present in other crystalline hydrates such as gypsum. This conclusion directs attention to the type of interparticle bonds in all the systems of hydrated cement prepared for this study. The nature of these bonds can now be deduced.

Any analysis of experimental results to be used in the deduction of the nature of the interparticle bond in cement must take into account the high total porosity of the system and, correspondingly, the fact that the bond area is small relative to the apparent cross-sectional area. This means that the bond area must always experience high stress concentrations relative to what the particle itself experiences. It is reasonable to postulate, therefore, that some of these bonds can be broken and remade for any loading condition because the system of particles is poorly organized and non-isotropic.

The interparticle bonds are undoubtedly solid to solid contacts which are responsible for the limited swelling. These bonds are obviously made by bringing the surfaces together with the appropriate pressure resulting from the chemical reaction or from the externally applied load. This being the case, increasing the pressure as in compaction increased strength or modulus in proportion to the reduction of the void volume. The increased modulus reflects either an increased area of contact or increased bond strength due to closer and more regular spacing of the atoms, but is probably due to both.

This concept of the nature of the interparticle bonds in cement paste allows for the possibility of one particle breaking its bond with one neighbouring particle and remaking a similar bond with another neighbour. The result would be permanent deformation but no net loss of strength, when the system is subjected to sustained load. These concepts of the structural model are further discussed by Feldman and Sereda (13).

These bonds may approach the character of the "chemical" bonds when the porosity approaches zero. In fact, the extrapolated regression lines for modulus of gypsum systems in Fig. 4 virtually intersect at zero porosity. This result from the study with the gypsum systems suggests that the extrapolated values of modulus for the cement systems have a definite meaning. It follows, therefore, that the modulus of elasticity of the systems at zero porosity is actually the modulus of elasticity of the solid phase of the cement gel. Under test conditions this extrapolated value was found to be 88×10^4 and 92×10^4 kg per sq cm, for systems I and II, and system III, respectively. It is of interest to note that the above values agree surprisingly well with the data reported by Helmuth and Turk (14). Although quite a different method was employed (resonance frequency), the reported values for the two cements tested were 76×10^4 and 81×10^4 kg per sq cm.

The above conclusions, regarding the bonds in the structure of hydrated portland cement paste, are applicable to the interparticle connections and not necessarily to the bond system operating within the postulated layered structure of the tobermorite gel particle. A suitable model for the particle itself, proposed by Feldman and Sereda (13) to explain its physical and mechanical behaviour, has been based on detailed analyses of sorption isotherms. In the proposed model for the gel particle, water molecules do act as structural components, but this water has not the characteristics of adsorbed water, in contrast to what was suggested by Powers (15).

It is hoped that the proposed structural model for hydrated cement paste will assist in resolving the physical and mechanical behaviour of this material.

The implication that compacts of bottle hydrated cement can serve as models of the cement-stone has been demonstrated by the present data, by data reported elsewhere (3–5), and by the experience gained at DBR. It is believed, therefore, that the compact is a reliable tool in cement research.

Supplementary Paper III-46 Molecular Sieve Effect in Concrete

Ronald H. Mills*

Synopsis

Certain polar and non-polar fluids and gases including nitrogen are incapable of penetrating the finest pores in hydrated cement. Water is capable of greater, though incomplete penetration. The difference between the volumes of water and large-molecular fluid which can be accommodated in hydrated cement paste is a measure of cohesive forces which give concrete its strength and also of the extent to which such forces and dimensions of the gross structure may be modified by swelling or disjoining pressure.

Taking the volume of pore space occupied by water = V_w and that occupied by a fluid with large molecules = V_f, then the ratio: $k = (V_w - V_f)/V_w$ is shown to be a function of the rate and extent of hydration and of the $CaO:SiO_2$ ratio C/S. For a particular value of this ratio, strength σ is a linear function of k and the slope $d\sigma/dk$ increases with increase in C/S. On the other hand the relationship between strength σ and the volume concentration of hydrate C does not appear subject to variations in C/S.

Volume changes due to creep and shrinkage appeared to increase with increase in k but values of kV_w after shrinkage and creep had taken place were less than at the start of the test. This suggested a *collapse of structure* in the cement hydrate. The volume kV_w was found to represent between 1 and 3 monolayers capacity of water and corresponded to the water held at relative humidities of between 0 and 28 per cent. Shrinkage varied linearly with weight of water gained or lost within this range of relative humidities.

Introduction

Since publication of the classic studies of Powers and Brownyard in which it was apparent that gases such as nitrogen, hydrogen and helium and fluids with large molecules such as acetone, carbon tetrachloride and toluene (1) were excluded from sites accessible to water, other evidence (e.g. 2, 3, 4, 5) supported the view that cement hydrate acted as a molecular sieve.

More recently Copeland, Mikhail et al were able to make deductions regarding the pore structure of cement paste through study of sorption characteristics of various organic fluids. Of particular significance was their conclusion that large-molecular fluids such as cyclohexane could be accommodated only in capillary pores (6, 7).

Comparatively little attention seems to have been paid to the correlation of these phenomena with engineering properties such as strength and dimensional stability until Hrennikoff noted the almost total absence of swelling which accompanied saturation with kerosene, methyl alcohol and mineral oil (8). A year later Mills discussed the "wedging" action of water in relation to diminution of strength accompanying adsorption and postulated that absence of this effect when concrete was saturated with kerosene and carbon tetrachloride could be attributed to lack of penetration of these fluids into the gel structure (9).

A geometrical model based simply on exclusion of large molecules from narrow spaces admittedly neglects factors such as hydrogen-bonding and packing of molecules (10); but it is probably accurate enough for the present purpose. Contemporary models of the structure and behaviour of hardened cement paste assign great importance to the interaction of water and solid in zones of restricted adsorption (11, 12) and the molecular sieve effect provides a ready means of establishing the volume proportion of this class of pore water.

*Department of Civil Engineering, The University of Calgary, Alberta, Canada.

The Model

When cement reacts with water the products of hydration grow outward from the unhydrated nucleus into space originally occupied by the mixing water. This is illustrated in the electron micrographs of Figs. 1 and 2 which show calcium silicate hydrate *flowers* growing on a cement grain. The absolute volume of the hydrate is greater than that of the original cement but less than the sum of the volumes of the reacting components. In order to maintain saturation of pores an increment of water has to be supplied from an external source. This increment of water, Δw, is proportional to the non-evaporable water which has become part of the solid. For reasons discussed elsewhere (13) the characteristic ratio of w_n:Δw must be determined in a separate experiment by hydrating cement with water:cement ratio w_0 of 6 or more in a pycnometer bottle. Equations for the volume proportions of solid and water in cement paste may be set forth as follows:

volume concentration of unhydrated cement

$$V_{uhc} = \frac{1 - \alpha}{gw_0 + 1} \qquad (1);$$

volume concentration of hydrated cement,

$$V_{hc} = \frac{\alpha\left\{1 + gw_n^0\left(1 - \frac{\Delta w}{w_n^0}\right)\right\}}{gw_0 + 1} \qquad (2);$$

volume concentration of evaporable water,

$$V_w = \frac{w_0 g - \alpha g w_n^0\left(1 - \frac{\Delta w}{w_n^0}\right)}{gw_0 + 1} \qquad (3);$$

the volume concentration of hydrate in space available to accommodate it,

$$C = \frac{V_{hc}}{1 - V_{uhc}} \qquad (4);$$

where $1/g$ = the specific volume of the unhydrated cement cc/gm; w_0 = the original water: cement ratio; w_n^0 = the non evaporable water gm/gm of fully hydrated cement; Δw is the reduction in specific volume resulting from the complete reaction of w_n^0 and 1 gram of cement and α is the degree of hydration.

If the concrete is dried to equilibrium weight at 110°C and then vacuum saturated with a fluid having large molecules, the ratio:

$$k = \frac{V_w - V_f}{V_w} \qquad (5);$$

represents the fraction of water which has access to space which excludes the fluid. To a first approximation, kV_w is a measure of pore water strongly adsorbed in the micro-cellular structure of the cement hydrate.

The kV_w fraction is, in terms of the model, that portion of the pore water which is active in the sense

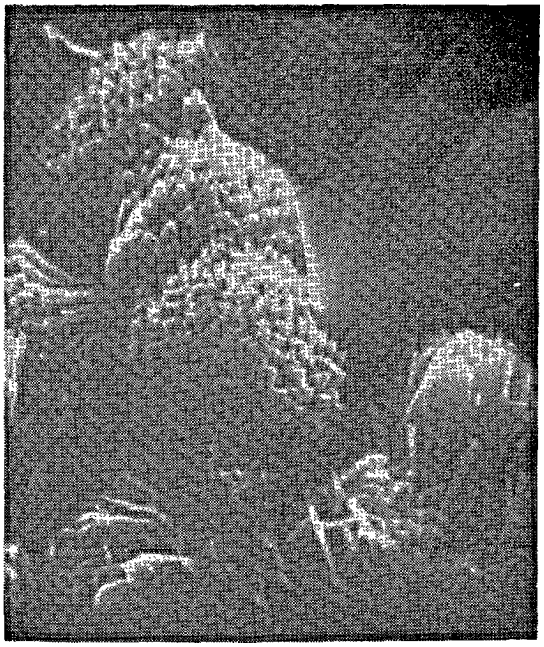

Fig. 1. *Growth of calcium silicate hydrate from the surface of a cement grain* (×6,500)

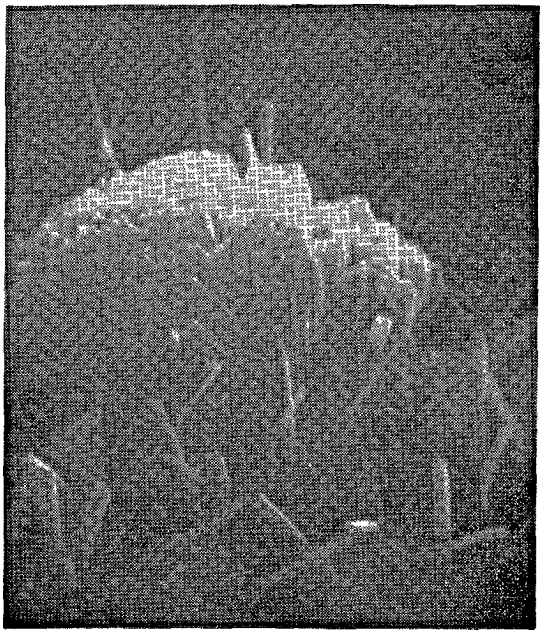

Fig. 2. *Cluster of calcium silicate hydrate fibres* (×13,500)

of applying swelling or disjoining pressure tending to separate primary particles of cement hydrate. It is under pressure at the time hydration products are laid down and this pressure is equilibrated in part by surface forces which tend to draw primary particles of solid together. As concrete drys, and meniscus forces become active, pressure is reduced and partial closure of spaces between primary particles results. At the same time, meniscus forces react on assemblies of primary particles (such as *petals*) and produce volume contraction of the gross structure. Both these effects would result in isotropic contraction of the paste.

The spaces separating primary particles are unlikely to have parallel sides and judging from Figs. 1 and 2 may be described as *wedge-shaped* with the sharp end of the *wedge* pointing in random directions. In terms of this model water is excluded from the apex of the *wedge* where inter-particle cohesion is provided by primary bonds. In drying concrete, increase in the magnitude of meniscus forces, or decrease in relative humidity in the pores would result in migration of water towards the wide part of the *wedge*. Retreat of water from sites on the surface would result in increase of surface energy residing in the solid surface and, in addition, closure of the gap between surfaces. As before this would give rise to isotropic strain in an unloaded specimen. In a specimen subjected to uniaxial load this effect would be supplemented by migration of water molecules out of spaces tending to be closed by the load and into spaces tending to be opened by the load. Thus creep may be viewed as one component of adjustment following variation of other components contributing to equilibrium of kV_w water whether or not drying occurs at the same time.

If the model is realistic, both creep and shrinkage should be accompanied by permanent exclusion of water from zones near the apex of the *wedge* in a process analogous to *sintering*. At first sight it is not easy to judge whether this would result in increase or decrease of the k factor: increase in k would imply that the walls of wedges had rotated about a point near the sharp end; and reduction of k would imply rotation in the opposite sense. In reality the platey structures of primary particles would probably buckle in a rather complicated fashion. In general the variation of k would not be the same for both loaded and unloaded specimens since both rotations and buckling would be of opposite sense parallel to and transverse to the load while drying shrinkage would have the same effect in all directions. This model is consistent with results appearing in recent reports (14, 15, 16) and the characteristics of models recently proposed by Powers (11, 12) and Ishai (17). Perhaps the only significant difference lies in the present emphasis on initial stress in pore water and the possibility of internal *seepage* even in saturated pastes.

Experimental

The data described herein was obtained during the course of other investigations in which the observation of k factors was not the primary objective. Although a considerable quantity of data has been accumulated over the past 10 years or so it is only recently that there has been sufficient incentive to process the observations. The data presented herein is typical but incomplete, particularly insofar as creep tests are concerned. More work is being prepared for publication.

Five series of experiments are described:

Series I

Two groups of mixes containing cement having $C/S = 2.82$ and 1.70 respectively were made with water: cement ratios of approximately 0.25, 0.50 and 0.80. Specimens were exposed to drying atmospheres after water curing for 7, 28 and 56 days. Linear shrinkage and moisture loss were determined for various values of the relative humidity p/p_s on both desorption and asorption cycles. Specimens were ovendried then vacuum saturated with methyl alcohol, ethyl alcohol, propyl alcohol, benzol and kerosene and then re-saturated with water. Values of k, mean V_w and V_f were observed.

Series II

Four mixes having C/S ratio 2.82 and water: cement ratios 0.25, 0.45, 0.65 and 0.85 were ovendried at 28 days; shrinkage, ε_s, moisture loss, V_w and k were observed as outlined in Series II above. Fluids used were methyl alcohol, ethyl alcohol, propyl alcohol, benzol, carbon tetrachloride and cyclo-hexane.

Series III

Various combinations of normal, and rapid hardening portland cement and blastfurnace slag were used to give variation of the C/S ratio in 12 mixes having $w_0 = 0.50$. Cubes were tested at various ages up to 112 days and observations of cube strength σ, w_n, Δw, and k from kerosene absorption were made at each age.

Series IV

k values using kerosene were observed before and after creep and shrinkage were recorded for mixes having $w_0 = 0.6$ and aggregate: cement ratio = 6, the period of testing being approximately 1200 days. A preliminary report of these tests appeared in 1958 (18) and the final report is due to be published in the same journal.

Series V

Concrete and mortar prisms were oven-dried and re-saturated in water and kerosene, methyl alcohol and benzol. The mean coefficient of expansion over the temperature range 10 to 45°C and the static and dynamic moduli determined at room temperature.

In all these tests it was found necessary to isolate specimens and fluids from contamination by atmospheric moisture. The specimens were, except for very brief periods, isolated in evacuated drums. The end-point of weighings was taken as that corresponding to disappearance of the surface sheen on saturated specimens. Irregularly shaped specimens were avoided as far as possible in k tests by using unbroken cubes. In Series IV, however, all the specimens subjected to k tests were end *pyramids* chosen from the debris of equivalent cube tests.

Chemical compositions of cements are recorded in Table 1 and constants obtained from bottle-hydrated cements in Table 2. Other details of mixes are given in Table 3.

Results and Discussion

Volume occupied by Various Fluids

The results of these tests are recorded in Tables 4 and 5. Typical curves are shown in Fig. 4 together with results taken from Mikhail and Selim (7). Although the ratio of molecular weight to density represents only a first approximation to molecular volume, the curves show a progressive reduction in V_f/V_w with increase in M/ρ except for saturation with cyclohexane. Discussion of packing density of molecules

and the possible effects of hydrogen bonding is beyond the scope of this paper. It is sufficient for the present to note that substantial and apparently systematic differences exist between the volume occupied by water and other fluids. It may be noted from Table 4 that the shape of gel spaces varies with C/S. As C/S is reduced, the taper of the wedge apparently becomes more acute. Further, the acutance of the *angle* would seem to depend upon the water: cement ratio. This is, to some extent, verified by comparison of the size of *flowers* shown in Fig. 3 taken from a specimen having $w_0 = 0.4$ and Figs. 1 and 2 in which the water: cement ratio was effectively 1.0 (19).

Relationship between k Obtained by Kerosene Absorption and Various Parameters

Table 6 records the relationship between hydration factor α, volume of unhydrated cement V_{uhc}, volume of hydrated cement V_{hc}, V_w the volume of free water, C the volume concentration of hydrate in space avail-

Fig. 3. *Calcium silicate hydrate cluster in cement paste having water: cement ratio = 0.4 (×104,000)*

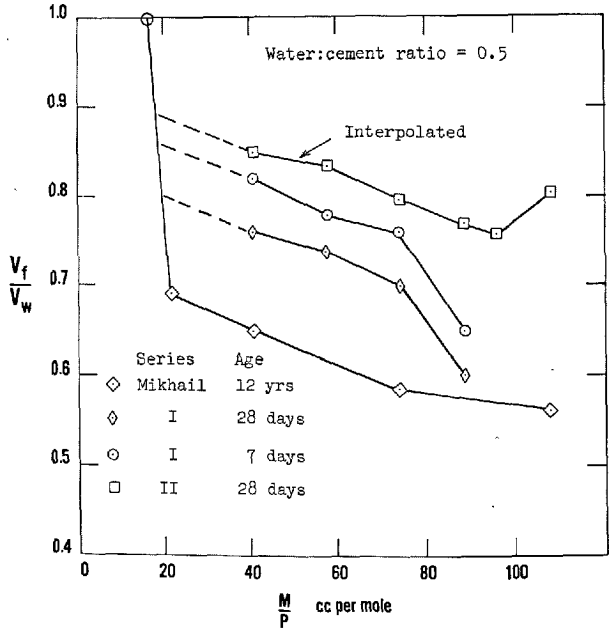

Fig. 4. *Volume occupied by various fluids*

able to accommodate it and kV_w the volume of water in zones of restricted adsorption. It is seen that increase in kV_w is associated with decrease in V_{uhc} and V_w and increase in α, strength σ, V_{hc} and C. In other words kV_w increases with increase in the volume of new solids produced by hydration. Not shown but reported elsewhere (20) is the systematic increase of V_w with α implicit in equations 2, 3 and 4.

Fig. 5 shows that the relationship between strength σ and C in this series is substantially independent of C/S. Fig. 6 on the other hand shows that the

relationship between kV_w and σ varies according to the C/S ratio. The slope of these curves $d\sigma/dk$ appears to vary systematically with C/S as shown in Fig. 7. The ratio kV_w/V_{hc}, the volume of water in zones of restricted adsorption to the absolute volume of hydrate is seen from results plotted in Fig. 8 to increase with decrease in C/S.

It has been shown (21) that decrease in C/S favours the formation of 2 rather than 3 layer tobermorite. Thus, although the variation of strength with volume proportion of solids may indeed be independent of C/S, the surface area and morphology of hydration products are, on the other hand, profoundly influen-

ced by this ratio. This deduction is in agreement with observed behaviour of portland-blastfurnace cement pastes which are know to creep and shrink more than comparable portland cement pastes (13, 16).

Relationship between k and Monolayer Capacity

The ratio of kV_w to monolayer capacity, V_{ml}, as determined from kerosene absorption and B. E. T. surface area determinations are recorded in Table 7. It is seen that kV_w/V_{ml} increases with w_0 and C/S. This is interpreted as meaning that products of hydration form in a different way according to the space available to accommodate cement hydrate. Low C/S and high values of w_0 produce long narrow *petals* and hence long narrow *wedges*.

kV_w in Relation to Water Adsorbed at Various Relative Humidities

Table 8 shows the relation between kV_w expressed as a quantity of water taken up from *bare surface* condition and the corresponding value of p/p_s as determined by an isopiestic method (15).

kV_w is seen to correspond with the quantity of water held at values of p/p_s lying between 20% and 28%, p/p_s increasing both with w_0 and C/S.

Shrinkage and the Value of k

As discussed in previous paragraphs kV_w as measure by kerosene absorption corresponds to the volume of water held by cement pastes at low relative humidities. Figs. 9 and 10 show the location of kV_w on curves of swelling of dried pastes and mortars of Series I versus gain in moisture and variation of p/p_s. Evidently sorption of water from the surface dry condition to kV_w results in expansion varying linearly with weight gain in moisture. Reverse curvature of the expansion-moisture gain plots probably results from the effect of surface tension following formation of menisci in about this region. This is to be expected from corresponding values of kV_w/V_{ml} and p/p_s which mark a transition zone between molecular adsorption in gel pores and condensation of liquid water in capil-

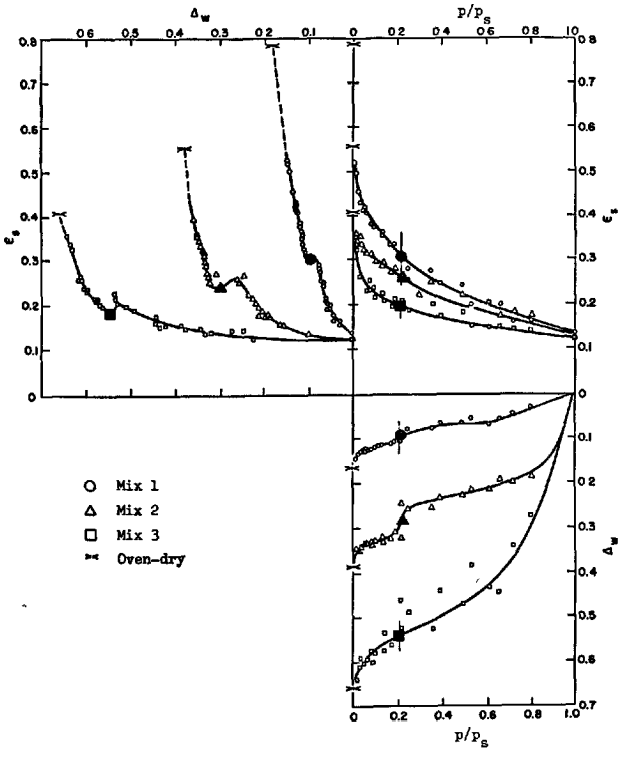

Fig. 9. *Relationship between* kV_w, Δw, p/p_s *and* ε_s *for Series I. Large black symbols represent pore volume which can accommodate water but which excludes kerosene*

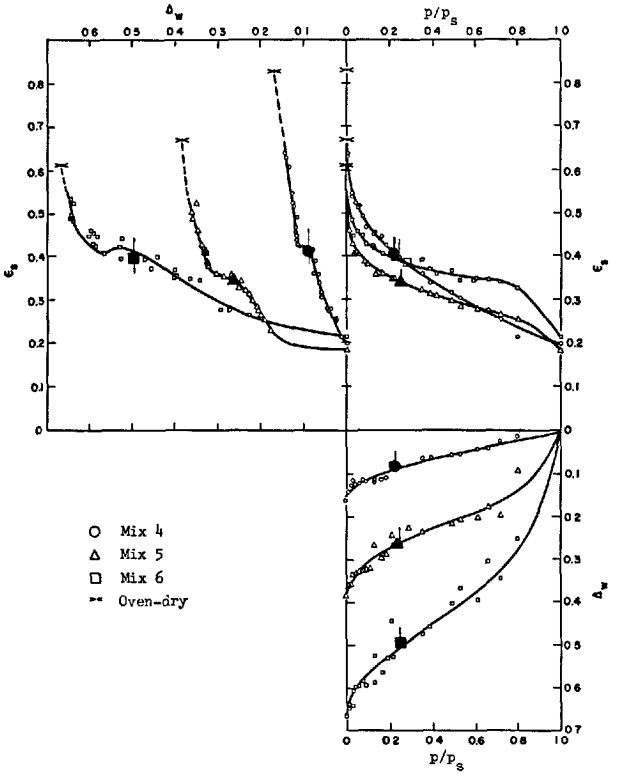

Fig. 10. *Relationship between* kV_w, Δw, p/p_s *and* ε_s *for Series I. Large black symbols represent pore volume which can accommodate water but which excludes kerosene*

laries.

Since kV_w increases with the hydration factor α and, consequently the surface area, it is to be expected that shrinkage would increase with kV_w or decrease with V_f/V_w. This was found to be the case with oven-dried shrinkages of Series II as shown in Fig. 11.

Collapse of Structure in Creep Experiments

In the case of creep and shrinkage experiments of Series IV as reported elsewhere (16), kV_w values obtained at the start of the tests and after 1200 days sustained loading were observed, with the results shown in Fig. 12. It appeared that kV_w reduced with both kinds of volumetric strain but that changes in kV_w over the test period were not the same for shrinkage and creep specimens. Generally, strains associated with change in kV_w were greater for creep and shrinkage than for shrinkage alone.

This would be consistent with opening of *wedge* shaped spaces having their axes parallel, and closure of those transverse, to the load.

Load-Bearing Water

The results of static elastic modulus, measured in uniaxial compression, and dynamic modulus as measured in Series V are recorded in Table 9. In many static modulus tests performed by the author there has been no convincing evidence of change in elastic modulus with moisture content. This was probably because drying was never taken far enough to remove water from areas of restricted adsorption. In the present tests the concrete was first oven-dried and then allowed to take up moisture and various liquids. It is clear from these tests that water capable of penetrating to sites of restricted adsorption in the gel is capable of bearing load and contributing to stiffness of the concrete. Other fluids which do not penetrate these areas do not make this contribution. It would be reasonable to assume therefore that strongly adsorbed water is capable of resisting shear stress while that

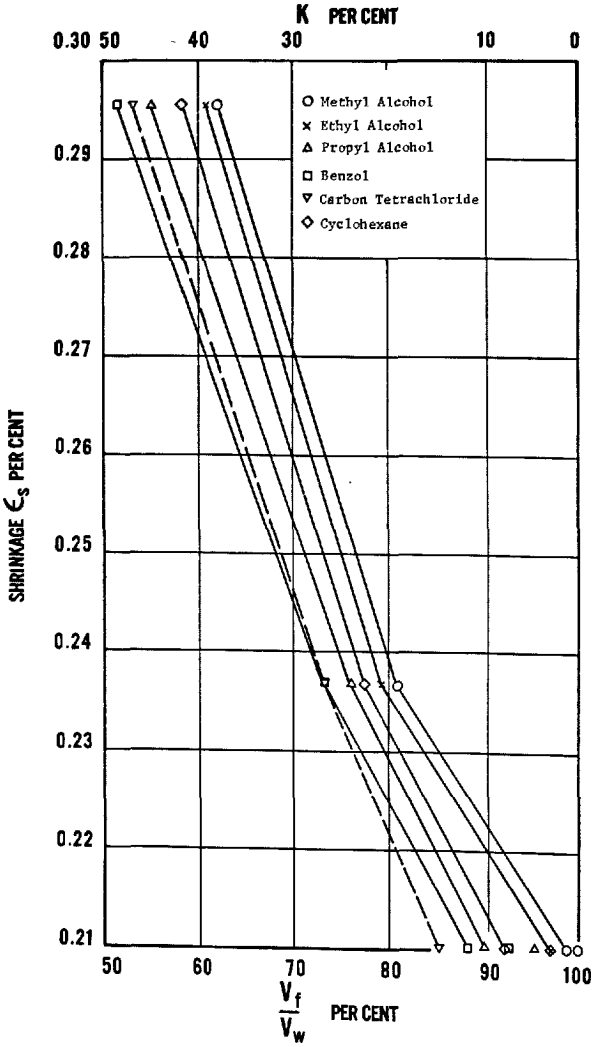

Fig. 11. *Variation of oven-dry shrinkage with fraction of pore volume filled by large-molecular fluids*

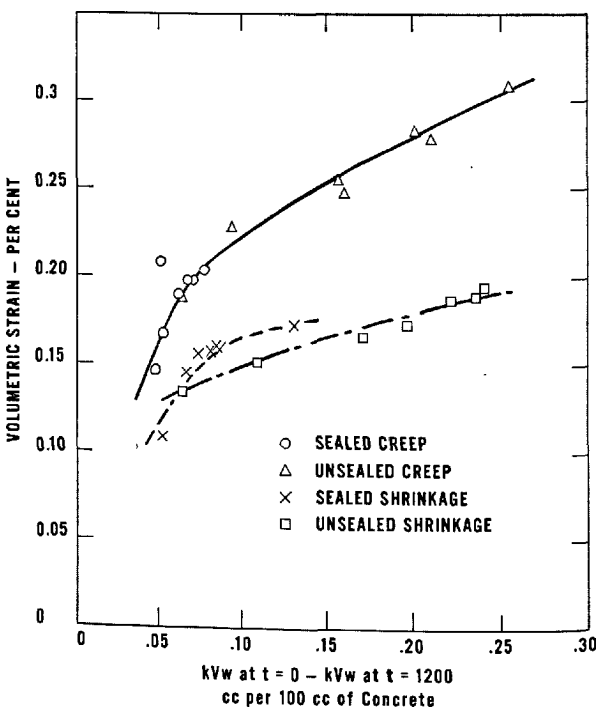

Fig. 12. *Relationship between plastic strain and reduction in volume of water in zones of restricted adsorption*

condensed in comparatively coarse capillaries is incapable of making this contribution.

Table 9. *Elastic moduli of concrete and mortar saturated with various fluids*

Series V Mix	Static and dynamic elastic moduli 10^6 p.s.i. when saturated with			
	Water	Kerosene	Methyl alcohol	Benzol
	Static modulus			
1	5.35	4.25	3.45	3.75
2	4.93	3.45	3.25	3.60
3	4.90	4.10	4.10	4.25
	Dynamic modulus			
1	4.66	3.96	4.21	3.62
2	4.30	3.65	3.58	3.52
3	4.15	3.47	3.52	3.36

Temperature Coefficient of Expansion

The temperature coefficients of expansion recorded in Table 10 clearly indicate that concrete containing even small quantities of water is subject to greater volume changes than dry concrete or concrete saturated in large molecular fluids which do not penetrate the gel structure. It would appear, though, that even large molecular fluids may contribute to the overall volume changes accompanying rise or fall of temperature. The lowest coefficients of expansion were recorded for concrete in the oven-dry condition.

By far the predominating influence, however, appeared to be due to thermal agitation of small quantities of water in areas of restricted adsorption.

Table 10. *Thermal coefficient of expansion of concrete and mortar containing various quantities of water and saturated with various liquids*

Liquid in pores	Thermal coefficient 10^{-6} per °C Series V mix number		
	1	2	3
H_2O saturated	11.20	11.45	11.95
1% by weight	15.60	15.40	15.75
2% by weight	15.50	15.79	15.55
4% by weight	13.50	13.21	13.98
Kerosene	9.61	9.78	10.01
Methyl alcohol	12.70	11.50	11.00
Benzol	10.00	11.49	11.90
Oven-dry	9.40	9.60	9.90

Conclusions

1. The detection of differences in the volumes of water and large molecular fluids taken up by dry concrete affords a convenient method of estimating the volume of pore water held in zones of restricted adsorption. Ordinary kerosene is a convenient fluid to use for comparison with water. The parameter $k = (V_w - V_l)/V_w$ is related to degree of hydration, surface area and strength. Further research may show close dependance of creep and shrinkage characteristics on this parameter.

2. Strongly adsorped water is capable of supporting mechanical load in short term tests. Any agency such as depression of external relative humidity or mechanical loading which disturbs the equilibrium state of water in areas of restricted adsorption will result in the time-dependant volume changes known as creep and shrinkage.

3. The shape of spaces separating the surfaces of colloidal particles in cement gel varies with water: cement ratio and the weight ratio $CaO:SiO_2$. This property may well depend upon the distance between nucleation sites from which calcium silicate hydrate *flowers* grow. The distance of separation would increase with increase in water: cement ratio and with decrease in $CaO:SiO_2$ ratio: this would tend to form attenuated *petals* and longer, narrower gel spaces.

Oral Discussion

Rolf F. Feldman

It has been known for some time that hydrated portland cement that has been "d-dried" can "sorb" a greater volume of water than nitrogen, methanol, cyclo-hexane and several other sorbates (1, 2); it was clear that with large molecules such as cyclohexane, isopropanol, etc, some pores might exist that are too small to allow their entrance. For nitrogen, helium and methanol, however, this reasoning is not as clear; the determination of surface area by adsorption of N_2, together with a calculation based on the B.E.T. equation, has become a standard method in surface chemistry. Carbons with very high surface areas and very small pores have yielded nitrogen surface areas that approach 1000 m^2/gm. Yet, in the case of hydrated portland cement, the "water area" has been the one generally held "true and valid", and it was considered that the N_2 molecule could not enter pores and adsorb on the whole surface. The diameters of the water, nitrogen and methanol molecules are such as 3.25,

4.05 and 4.4 Å respectively; it seems difficult to allow for the situation where in some cases more than 99 per cent of the area is excluded to N_2.

Results have now shown clearly that the differences between surface areas, porosities and densities obtained by water on the one hand and nitrogen on the other, can be quantitatively accounted for when it is recognized that d-dried hydrated cement rehydrates as it is exposed to increasing humidities.

The importance of the hydrate of interlayer water must be emphasized; it is part of the crystal structure contributing to the mechanical properties of the solid. The removal of the water which may have specific sites for bonding, results in a collapse of the layers and causes a reduction in the modulus of elasticity of the material. It is clear that the role of interlayer water and the spaces between the layers are quite different from adsorbed water and pores, and the entrance or exit of interlayer water involves different forces and energy terms which should be included in accounting for total free energy changes during sorption.

A relation between the parameter $V_W - V_F$ of the author and the cohesive forces of hydrated cement is difficult to conceive; certainly the more hydrated silicate present in the porous body, the stronger the body will become because there will be a decrease in the porosity of this body and with this, a greater area of contact between crystallites; likewise, as the quantity of hydrated silicate increases, the amount of interlayer water will increase, i.e., $V_W - V_F$. This same reasoning also applies to the expansion observed on sorption of water; more than 80 per cent of the expansion observed on exposing "d-dried" hydrated cement to 100 per cent R.H. is due to interlayer rehydration. Thus, as the degree of hydration increases, more interlayer hydration sites exist and the expansion on rehydration will be greater.

Supplementary Paper III-50 A Statistical Study of the Effects of Trace Elements on the Properties of Portland Cement

Raymond L. Blaine*

Synopsis

A digital computer was used to find and evaluate significant relationships between the properties of a large number of portland cements and various independent variables which included chemical compounds, minor constituents, and trace elements. This article presents a review of the probable effects of minor constituents and trace elements on various properties including heat hydration, sulfate expansion, compressive strength with different curing conditions, shrinkage, and durability. On the basis of the statistical study, Na_2O or K_2O were associated with most of the properties measured but not always to the same degree. Very few of the individual trace elements had a highly significant relationship to the various properties measured, but when used in equations in addition to other commonly determined variables, there was usually a highly significant reduction in variance. The coefficients for Ba, Cu, SrO, P and Li were significant at the 0.01 probability level in some tests and at the 0.05 probability level in other tests. The coefficients for Cr, Ni, Rb, Ti, V, and Zr were significant at the 0.05 probability level in equations for some of the tests. The effects of the alkalies and trace elements were generally small compared to the effects of major constituents and other independent variables.

Introduction

During the past 50 years there have been four,—now five, international symposia on the chemistry of cement. Information on the many aspects of the nature of hydraulic cements and the hydration products which are formed have been published in the proceedings of these symposia. We have, as a result, a much better understanding of these complex materials, and the major compounds and reactions which are involved. There still appear to be some unsolved questions with respect to possible or probable modifications of the properties of cements by minor constituents and trace elements. Exploratory work was conducted at the National Bureau of Standards to determine the quantities of trace elements that occur in commercial portland cements, as well as their probable effects on properties of neat cements, mortars, and concretes. Most of this information has been published or is in process of analysis and publication (1, 2, 3, 4). These publications have dealt with the effects on various properties of both the major and minor constituents. The present article will summarize and review some of the results of these studies of the contributions of minor constituents and trace elements in non-air-entraining cements to the various properties that were determined.

Materials

The tests were made on 199 commercial portland cements, most of which were obtained from different manufacturing plants within the U.S.A., but a few were obtained from other countries. Of these cements, 185 were, according to our tests, non-air-entraining cements. These included 82 type I, 68 type II, 20 type III, 3 type IV, and 12 type V cements as classified on the basis of chemical and physical properties. There was, in most instances, a fairly broad but normal distribution of values for the chemical and physical properties.

*National Bureau of Standards, Washington, D.C., U.S.A.

Tests

The tests made on the cements included fineness, and the usual chemical analyses, plus flame photometric determinations of Na_2O, K_2O and SrO. Semiquantitative spectrochemical determinations were made on most of the cements for all the other trace elements which could be detected.

Other tests included heat of hydration at 7 days, 28 days, and 1 year, autoclave expansion, potential sulfate expansion, compressive strength of 1:2.75 (cement to sand) mortars at 1, 3, 7, 28 days, 1, 5 and 10 years, as well as compressive strength of mortars cured with steam at atmospheric pressure, and at 10 atmospheres steam pressure. Nonrestrained and restrained shrinkage tests were made on neat cements which had been cured in moist air for 24 hours.

Two series of concretes were made with each cement,—the one with a water/cement ratio of 0.635, and the other with the water adjusted to give a concrete with a 5 ± 1 inch slump. The cement content was 5 1/2 bags per cubic yard or about 300 kg/m³. Tests made on the concretes included shrinkage in air after 14 days moist curing and subsequent expansion when air-dried specimens were placed in water for 28 days. The weight loss and weight gain was determined as well as the dynamic Young's modulus of elasticity after the various curing conditions. Freeze-thaw durability tests were made on air-dried specimens; studies were made of the regain of strength of specimens after the freeze-thaw tests.

The details of the test methods and the results of the tests have previously been reported and, except for the range of values for the minor constituents and trace elements, will not be repeated in this article.

The semiquantitative spectrochemical values for the trace elements ranged from zero up to 1.0 per cent for Ti and Mn, to 0.5 per cent for P and Zr, to 0.2 per cent for Ba and Zn, to 0.1 per cent for V, to 0.05 per cent for Cu, Mo, and Pb, to 0.02 per cent for Cr, Li and Ni, and to 0.01 per cent for Co and Rb. The flame photometric values for Na_2O ranged from zero up to 0.75 per cent, for K_2O to 1.1 per cent, and for SrO to 0.4 per cent.

Statistical Treatment of Data

A digital computer was used to find and evaluate significant relationships between the results of tests (the dependent variables) and various independent variables which included chemical composition, minor constituents, and trace elements. Multivariable regression equations were calculated by a least-squares method using only commonly determined variables (including Na_2O and K_2O) and these variables together with trace elements. Numerous trial equations were required to determine which of the independent variables were significantly related to the dependent variable, and the combination of variables which resulted in the lowest estimated standard deviation for the equation.

Up to 13 independent variables could be accommodated in an equation with the computer program used. The output of the computer included the estimated coefficient of each of the independent variables used in the multivariable equation, as well as the estimates of the standard deviation of each of the coefficients. An independent variable was retained in an equation if the ratio of the estimated coefficient to its estimated standard deviation (coef./s.d.) was greater than 1.0. Although this represents a very low probability of significance, such independent variables were retained in an equation primarily because these studies were exploratory. Values between 1.0 and 2.0 for the coef./s.d., ratio may also be considered of doubtful significance, and further studies of the effects of such independent variables would be desirable. Values of 2.0 or greater for the coef./s.d. ratio would occur by chance with a probability of 0.05, and therefore independent variables having values of the coef./s.d. ratio between 2 and 3 will be referred to as probably having a significant relationship to the dependent variable. A coef./s.d. ratio of 3 or greater would occur by chance with a probability of less than 0.01, and therefore it can be assumed that the independent variable has a significant effect on the dependent variable. The probable significance of contributions of Na_2O and K_2O (when used in multivariable equations) to the independent variables were evaluated solely on the basis of the coef./s.d. ratios.

Various techniques were used to determine which of the trace elements were associated with the dependent variables when used in equations with commonly determined variables having coef./s.d. ratios greater than 1. The magnitude of the coef./s.d. ratio was also used in evaluating the significance of the individual trace elements. With the additional use of the trace

elements in an equation with commonly determined variables, there was usually a further reduction of variance,—that is, the mean square of differences between the observed values and the values computed from the equation. This offered another statistical means for evaluating the significance of contributions of the trace elements as critical values for significance at the 0.01 and 0.05 probability levels of Fisher's ratio of variances for different degrees of freedom are given in most mathematical textbooks.

Results of the Statistical Evaluation

The Effects of Na_2O and K_2O

When used as independent variables in multivariable equations, the coefficients for Na_2O and K_2O were, in some tests, highly significant and in other tests, variations in one or both of the alkalies had no apparent effect on the property measured. A summary of some of the results is presented in Table 1. In this table the sign of the coefficient (+ or −) is presented together with an index of significance in parentheses. The coef./s.d. ratio is here labeled "index of significance" for convenience, but this is not standard statistical terminology. A (0) indicates that when tried in an equation, the coef./s.d. ratio was less than 1.0; a (1) indicates that the coef./s.d. ratio was between 1.0 and 2.0; a (2) indicates the ratio was between 2.0 and 3.0; a (3) that the coef./s.d. ratio was 3.0 or greater. The first three lines of the table may be interpreted as follows:—an increase in the K_2O content was significantly associated (0.01 probability level) with an increase in the heat of hydration at 7 days but not at 28 days or 1 year. Also, an increase in the Na_2O content was probably associated (0.05 probability level) with a decrease in the heat of hydration at 1 year but not at 7 or 28 days. It may be noted also, that at 28 days, variations in the quantities of neither of the alkalies had a significant effect on the heat of hydration values.

As indicated in Table 1, higher K_2O contents were associated, or probably associated with higher 7 day heat of hydration, with higher sulfate expansion, with higher compressive strength of mortars at early ages, and with higher compressive strength of low-pressure-steam-cured mortars. Higher K_2O contents were also associated with higher shrinkage of neat cement pastes, with higher dynamic modulus of elasticity of concretes moist cured for 14 days, but with lower weight loss and gain of concretes in drying and wetting tests, with lower freeze-thaw durability. Higher Na_2O contents were associated, or probably associated, with lower heat of hydration at one year, with lower compressive strengths of mortars at 1 to 10 years, with higher shrinkage of neat cements at 7 days to 7 months and with higher dynamic modulus of elasticity of concrete at 14 days. Higher Na_2O contents were also associated with lower compressive

strength of high-pressure-steam-cured mortars, with lower shrinkage of air-dried concretes, lower weight gain on rewetting, but with higher expansion when the air-dried specimens were resoaked.

Although there were many instances in these equations where the coefficients for Na_2O and K_2O were significant at the 0.01 probability level, the probable effects on the various properties were generally small compared with the effect of some of the major constituents or some of the other variables. Reference should be made to the complete equations in the published articles (1).

The Effect of Other Trace Elements

In Table 2 are presented the trace elements (and SrO) which were found to have coef./s.d. ratios greater than one when used in multivariable regression equations containing the commonly determined independent variables. The sign of each coefficient (+ or −) is presented as well as the coef./s.d. ratio. The significance of the numbers in parentheses are the same as for Na_2O and K_2O of the previous table. Also presented is the level of significance of the reduction in variance as a result of including the added independent variables,—the trace elements.

It may be noted that although the coefficients of most of the individual trace elements were not highly significant, the use in an equation of all having a coef./s.d. ratio greater than one resulted in a reduction of variance, significant at the 0.01 probability level in the equations for most of the properties measured. The reduction in variance was significant at the 0.05 probability level in a few equations and was less than that in equations for two of the properties.

SrO and the elements Ba, Cu, Rb and Zr appeared most often in Table 2. Zn, V, P and Cr were next in frequency, and Co, Ni, Mn, Li, Pb and Ti, appeared

least frequently. Mo, one of the trace elements detected in a few cements did not appear in any of the equations.

Of the four trace elements that appeared most frequently in the equations, higher Ba contents were probably associated with lower heat of hydration at one year, with lower compressive strength of both low- and high-pressure steam cured mortars, lower dynamic modulus of concrete, and higher shrinkage of neat cements,—especially at the later ages. Higher Cu contents were probably associated with lower heat of hydration, lower sulfate expansion, lower compressive strengths of steam cured and autoclaved mortars, and lower dynamic modulus of concrete after rewetting. Higher Rb contents were probably associated with lower compressive strength of mortars at 1 and 5 years, and lower compressive strength of high-pressure-steam-cured mortars when steam curing was started at 24 hours, and also with higher shrinkage of neat cements, and higher expansion of concretes when rewetted. Higher Zr contents were probably associated with higher heat of hydration at 7 days, higher compressive strengths at 1 and 10 years, and with higher dynamic modulus of elasticity of concretes after rewetting.

Of the other trace elements only Li, P and SrO had coefficients significant at the 0.01 probability level in any of the equations for the various properties. Increased SrO was associated with increased autoclave expansion, and probably with lower heat of hydration at 28 days, lower compressive strength of mortars at 1 and 3 days, lower compressive strength of mortars autoclaved at 24 hours. Higher SrO contents were probably associated with higher sulfate expansion and higher shrinkage of concrete when air dried. Increased Li was associated with higher compressive strength of autocalved mortars when curing was started at 5 hours.

As was found with the alkalies, Na_2O and K_2O, the probable effects of the other trace elements were generally small compared with the effects of some of the major constituents or some of the other variables. The combined effect was in most instances highly significant.

Discussion

In any statistical studies of this nature, the empirical equations derived are dependent on the adequacy of sampling of all possible portland cements. Somewhat different coefficients would be obtained with a different group of cements, with different methods of making the physical tests, and with different treatment of the data.

These tests were made with commercial portland cements and no information was available of the temperature at which the clinker was burned nor the rate of cooling. These factors may have contributed to an increased variance of the equations. Another contributing factor, especially with some tests, is the normal variation of the testing procedures and test-results. Relatively small quantities of cement are used in concrete, and the effect of the cement may be masked because of variations of the aggregates. The trace elements other than Na_2O, K_2O and SrO were reported to the closest value of a series such as 1, 2, 5, 10, 20 etc. More accurate means of analyses and values for the trace elements would be desirable.

Cements with a trace element value less than the minimum reported value, were assigned a value of zero for the element. All of these factors may have masked not only the actual effect of the trace elements which were indicated as probably having a significant relationship but may possibly have eliminated other elements as not having a significant relationship. The results of these statistical studies explain in part, however, some of the reasons why different cements may have somewhat different properties. Further work is necessary to determine the role that the trace elements may have in the hydration and hydration products of portland cements.

Summary and Conclusions

On the basis of the statistical evaluation, Na_2O and K_2O were associated with most of the properties of portland cement pastes, mortars, and concretes. The two alkalies sometimes have the same effect in some tests, but with other tests one may have a significant effect and the other not. Of the other trace elements, very few had a highly significant relationship to the various properties measured. However, by use of the trace elements in equations in addition to commonly determined variables, there was usually

a highly significant reduction in variance. Ba, Cu, Rb, SrO and Zr appeared most often in the equations for the various properties.

The probable effects of variations of Na_2O, K_2O as well as those of the other trace elements on the properties measured were small compared with the effects of variations of some of the major constitutents or some of the other independent variables. However, the contributions of the minor constituents and trace elements, although small, were in many instances, significant, and help to explain some of the differences in properties of portland cements.

Supplementary Paper III-71 Cement Paste Shrinkage-Relationships to Hydration, Young's Modulus and Concrete Shrinkage

Harold Roper*

Synopsis

The paper presents paste shrinkage, hydration and Young's modulus data for sixteen cements with various chemical compositions. These cements fall into two categories, based on high or low shrinkage characteristics. Of the eight cements in the high shrinkage group, three showed definite evidence of the diagnostic triple peak heat of hydration phenomenon described by Lerch. The effects of chemical composition and fineness of the unhydrated cement are considered, and the paper stresses the relationships between shrinkage characteristics and other physical properties of the paste; namely the degree of hydration and the Young's modulus.

For individual cements, data over a wide range of water: cement ratios fit an equation of the form:

$$\frac{1}{\Delta L} = a - b(W_n)$$

where ΔL is the paste shrinkage, W_n is the non-evaporable water and a and b are constants.

When shrinkage data for the various cements are compared, the effect of the paste modulus and its interaction with the hydration must be considered. For all the data, highly significant correlations are observed between the shrinkage and hydration and Young's modulus. It is concluded that different pastes, with the same hydration and Young's modulus values, will undergo equal shrinkage irrespective of the chemical composition or fineness of the cement.

The paper compares briefly the paste shrinkage with concrete shrinkage at an equivalent water:cement ratio. Concrete shrinkage up to drying periods of at least one year can be satisfactorily predicted using paste shrinkage data. The importance of early shrinkage rates of the various concretes is noted.

Introduction

The stringent demands made by engineers who aim to decrease or eliminate cracking associated with the restraint of forces induced by concrete shrinkage, have stimulated research into the factors which influence paste shrinkage. The work of Lerch (1) and Pickett (2) demonstrated the role of C_3A and proved the importance of optimum gypsum contents in reducing shrinkage. More recent developments have been the presentation, by Fulton (3) and Hansen and Nielsen (4), of formulae which relate the shrinkage of concrete to the volume changes and elastic constants of paste and aggregate. Such formulae are fully applicable only if it is assumed that tests on neat paste reflect shrinkages in larger concrete specimens; this assumption has been criticized by Swayze (5, 6), but defended by Tremper (7).

The work described in this paper is a study of the relative magnitude of shrinkages of pastes under controlled conditions, and the comparison of these values with those of concrete shrinkages. Factors which influence the paste shrinkage and the conditions under which paste shrinkage becomes particularly important are considered.

*C.S.I.R.O., Department of Civil Engineering, Sydney University, Sydney, Australia.

Materials and Techniques

The investigation was limited to sixteen cements, which represented a random sample of Type A ordinary portland cements (in accord with the relevant Australian Standard (8)) produced in thirteen different plants during November 1965. Compositional and fineness data are given in Table 1 for these cements, which are arranged in increasing C_3A content.

Cement specimens $3 \times \frac{1}{4} \times \frac{1}{4}$ inch were cast at water: cement ratios ranging from 0.2 to 0.6, stripped at 24 hours and cured at 21°C under water for various periods of time. The cured length was taken as datum and the specimens were dried in desiccators at 20° ± 2°C and 50% relative humidity over a saturated salt solution and at a pressure of 460 mm of mercury. After 7 days drying the length was recorded to 0.0001 inch and the shrinkage calculated as a percentage decrease. This period of time allowed the cement pastes to closely approach equilibrium conditions. After completion of the shrinkage measurements the paste specimens were crushed and their non-evaporable water was determined by the method of Copeland and Hayes (9).

For Young's modulus determinations 2 inch diameter by 4 inch cylinders were case at different water: cement ratios, stripped at 24 hours and cured under water for 28 days. The specimens were brought to equilibrium in a 50% RH atmosphere before being loaded to their ultimate compressive strength. Strain measurements were recorded using resistance wire strain gauges attached on opposite sides of the specimens. The chord modulus was measured between the values of 1,500 and 3,500 lb/sq.in.; this value closely approximated the tangent modulus of the paste.

The coarse aggregate generally used in the concrete investigations was a river gravel. This aggregate yields concretes of relatively low shrinkage. In comparing concretes made with aggregates which affect the shrinkage characteristics, this river gravel was contrasted with a basic igneous rock known to produce higher shrinkage in concrete. The same quartz sand was used in both series of mixes.

Concrete shrinkages were measured to 0.0001 inch on $8 \times 3 \times 3$ inch specimens having anvils set vertically to provide a 6 inch gause length. Specimens were demoulded at the age of 24 hours during which period they were cured at 100% relative humidity. For the subsequent 6 days they were cured under water at 23° ± 2°C, after which time the zero reading was recorded. Drying occurred in laboratory air at 23° ± 2°C and a relative humidity of 50 ± 4%.

Cement Paste Shrinkage

Paste Shrinkage Data

Data for two typical cements using the paste shrinkage test procedure described, and a range of curing periods from 3 to 90 days are shown in Figs. 1 and 2. For the longer curing periods the shrinkages for the high water: cement ratio pastes in Fig. 1 are approximately twice those of pastes in Fig. 2; however, at low water: cement ratios and short curing periods differences betweeen the cements are small.

Similar data were obtained for the same curing periods for the sixteen cements having compositions as given in Table 1. However, since cracking was suspected to occur during the drying of some specimens having short curing periods, all paste data presented in this paper will henceforth refer to underwater curing for 28 days. Paste shrinkage data for this curing period, using the 16 cements, are given in Table 2.

Concrete Shrinkage

Relationships between Cement Composition and Paste Shrinkage

Linear regression analyses using various forms of equations relating paste shrinkage at constant water: cement ratio to cement composition, were calculated from the relevant data in Tables 1 and 2. Using an equation of the form:

$$\Delta L = a(C_3S) + b(C_2S) + c(C_3A) + d(C_4AF) + e(SO_3),$$

the only regression coefficient which was consistently significant was that of C_3A.

Comparisons of results of various equations indicated that the most significant one for the prediction of shrinkage is of the form:

$$\frac{1}{\Delta L} = f - g(C_3A).$$

The statistical data obtained using this equation for various water: cement ratios are given in Table 3. The constant term remains the same for all water: cement ratios, whereas the coefficient g changes systematically. All the correlation coefficients in the table are significant at the 0.1% significance level for 14 degrees of freedom; up to 80% of the variance of the paste shrinkage is explicable by the variation in C_3A. The addition of terms relating to the other components of the cement and to the fineness improved the fit insignificantly.

It was concluded from the results of all these analyses that the role of C_3A was dominant in explaining the variance in shrinkage of the cements, provided that the water: cement ratios equalled or exceeded 0.325. Increases in shrinkage which relate to C_3A may be affected in three ways, *viz.* greater shrinkage of the C_3A hydration products *per se*; depletion of SO_3, resulting in modified hydration rates and products; and increase in the hydration rates of the silicates by the presence of C_3A in solid solution or as discrete inclusions within the silicate clinker grains. It is probable that all three factors play a part in the outcome.

A noteworthy fact is that the cements used in this investigation show a negative linear association, significant at the 5% level, between C_3A and SO_3. This relationship is the opposite to what would be expected, however, the practical problems associated with establishing and maintaining an optimum gypsum content are complex and certain clinkers produced throughout the world have gypsum demands which exceed the SO_3 limits in cement specifications. The relatively high alkali contents of the tested cements tend to increase their gypsum demands. A further complicating factor is that some SO_3 derived from kiln fuels may be present in the clinker; up to 0.75% has been detected in the clinker of cement E. Such SO_3 in clinker minerals is not necessarily available for reaction in the same way as that derived from added gypsum, yet it is not considered as a different entity when SO_3 limits are imposed. High sulfate contents which satisfy the optimum requirements may lead to false set, thus solving one problem but creating another.

Table 3. *Statistical data for least squares fit for C_3A and shrinkage*

Water: Cement ratio	Constant (f)	Standard error	Coefficient of C_3A (g)	Standard error	Correlation coefficient (r*)
0.325	4.928	0.222	−0.149	0.028	0.816
0.350	4.782	0.284	−0.166	0.036	0.775
0.400	4.905	0.291	−0.234	0.037	0.861
0.450	5.001	0.319	−0.276	0.041	0.878
0.500	5.019	0.330	−0.299	0.042	0.888
0.600	5.082	0.335	−0.325	0.043	0.901

r = Correlation coefficient for 14 degree of freedom. An r value greater than 0.742 indicates a significant relationship at the 0.001 level.

An unpublished investigation undertaken by the author and J. H. Taplin indicated that three of the cements *viz.* K, L and O showed the typical diagnostic triple peak heat of hydration phenomena described by Lerch (1), indicating gypsum deficiency. Cement M showed a slight plateau on its second peak, but it was not sufficiently pronounced to demonstrate conclusively that the gypsum content was less than optimum. For the other cements no indications of more than two peaks were observed.

Despite the heat of hydration data it is noted that the shrinkage characteristics of cements A to H differ significantly from those of cements I to P providing the water: cement ratio exceeds 0.325. Those of the first group give shrinkage curves of the same type as those in Fig. 2, where Fig. 1 is typical of the higher shrinkage cements. In order to confirm the fact that a cement may have no sulphate deficiency by its hydration curve yet give relatively high shrinkage, cement P was selected for further study.

Clinker was ground to the fineness of the comparable cement, and gypsum, again of comparable fineness, was added to give a range from 0 to 5% SO_3. Paste bars with a water: cement ratio of 0.5 were cast from these blends and tested in the usual manner. The curve for paste shrinkage versus SO_3 % is given in Fig. 3. Two commercial cements, from the same plant but with different SO_3 levels were tested for shrinkage, and the data were plotted on the figure. It appears that, for the shrinkage measured by this technique, even at 5% SO_3, optimum gypsum content had not been reached. The results of gypsum addition in the laboratory closely approximate those obtained for the commercially ground products.

As further confirmation that the sulphate levels were low for certain of the cements, the effects of replacing small amounts of cement by a 1:1 mixture by weight of ground limestone and anhydrite were studied. Pastes having water: cement ratios of 0.45

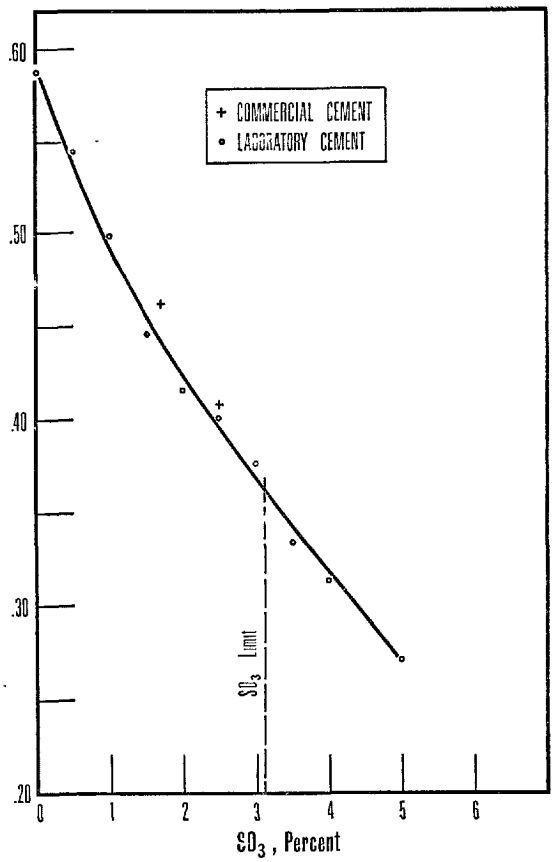

Fig. 3. *Paste shrinkage as a function of* SO_3 *content.*

were cast, using cements as received. Similar pastes were cast with 2, 3, 4 and 5% replacement by weight of the ground limestone and anhydrite. The specimens were cured, measured and dried in the usual manner. It was found that, although there was virtually no observable effect in the case of the low shrinkage cements, all the cements of the higher shrinkage group showed decreases in shrinkage of up to 35%. As expected, only some of these cements displayed an optimum SO_3 content within the replacement range. Although the use of such additions in concrete could overcome the rigid sulphate limits imposed by the cement specifications, the long term effects could be as detrimental to the concrete as the presence of SO_3 in the usual form.

Relationships between Non-Evaporable Water, Young's Modulus and Shrinkage of Cement Paste

It was considered that the effects of differences in hydration rates of the various cements were influencing the shrinkage results significantly and the non-evaporable water contents of the various pastes were measured as described. As was expected, the cements with high C_3A contents generally gave higher non-evaporable water contents at equal ages and at water: cement ratios within the range considered important for this investigation. The hydration rate of some of the high C_3A cements was very rapid, and for these very little change was noted between values measured at-28 days and 3 months. Such cements gave excellent 28 day concrete strengths. However, they cannot be considered ideal materials when design criteria depend on continued strength gain long after the first month of the life of a structure and when shrinkage cracking may be promoted by both the hygric dimensional change of the concrete and thermal dimensional changes accentuated by high heats of hydration at early ages.

In order to study relationships between paste shrinkage and hydration an empirical approach to the problem was adopted. Using the data given in Table 2 for the paste shrinkage and non-evaporable water, the following equation was found to apply for each individual cement:

$$\frac{1}{\Delta L} = a - b(W_n)$$

where ΔL is the paste shrinkage expressed as a percentage, W_n is the non-evaporable water and a and b are constants.

The interpretation of "a" in physical terms is that it represents the reciprocal of the percentage shrinkage which an unhydrated cement compact would undergo from a saturated state to the experimental drying conditions, always provided that the lines may be extrapolated. From the values of "a" it appears that such a compact could exhibit between 0.05 and 0.14% shrinkage under these conditions.

Plots of this equation for results on cements M and G for 28 days curing are given in Fig. 4. The conclusion, always allowing for the fact that direct causal relation may be through a third factor, is that, for a particular cement cured for the same period of time, the reciprocal of the paste shrinkage is a linear function of the hydration at the time of test.

When the 144 results of the cements are treated as a series of independent values, the following equation results:

$$\frac{1}{\Delta L} = 10.844 - 37.035W_n$$

with a correlation coefficient of 0.835 for 142 degrees of freedom and with standard errors of 0.397 and

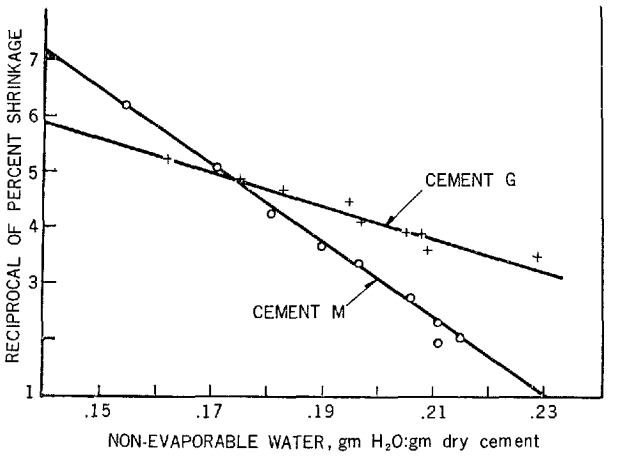

Fig. 4. *Relationship between the reciprocal of paste shrinkage and non-evaporable water.*

2.048 for the constant term and the coefficient of the variable respectively. Using this equation 70% of the variance in shrinkage of all cements is explicable by the nonevaporable water contents of the hydrated pastes.

In order to improve the fit of the equation, the inclusion of a term representing the compressibility of the paste was desirable. The Young's modulus of the material was selected rather than the compressibility since the measurement of the Poisson's ratio is tedious and relatively inaccurate. The technique of the modulus measurement has been described, and the results for the various cements are given in Table 2. Only eighty observations were available for computation. The resulting equation was:

$$\frac{1}{\Delta L} = 7.620 - 27.301W_n + 0.485E$$

with a multiple correlation coefficient of 0.890 for 77 degrees of freedom and with standard errors of 0.689, 2.808 and 0.076 for the three terms in that order. Statistical tests indicate that the inclusion of the Young's modulus term is advantageous and now 80% of the variance is explicable by these two variables. The only other attempt to improve the fit of the equation was to substitute the relative hydration, i.e., the ratio of non-evaporable water content to the non-evaporable water content at complete hydration, for the W_n term. This led to no improvement in the results.

It appears from the above results that different pastes with the same non-evaporable water content and equal Young's modulus values will undergo similar shrinkages, irrespective of the chemical composition or fineness of the cement. In practice, however, compositions which increase early strength generally lead to higher measured paste shrinkage due to the higher rate of hydration. Similarly, finer cements of identical chemical composition show an increase in shrinkage when tested after equal periods of curing simply due to the hydration effect.

In contrast, some low heat cements tend to give high shrinkage values when tested by the procedure used for the present series of cements. Since the hydration of these cements is relatively low at 28 days, a possible conclusion is that the effect of increased compressibility becomes dominant. Such a conclusion should be made with care since it is based on an empirical rather than a physical model.

Relationships between Cement Paste Shrinkage and Concrete Shrinkage

The study of this relationship has a two fold purepose, firstly, for the empirical prediction of concrete shrinkage from paste shrinkage data, and secondly, for the assessment of the accuracy of theoretical formulae which relate vairous physical properties of aggregate and paste to concrete shrinkage.

In order to establish whether a significant relationship exists between paste and concrete shrinkages, regression analyses were conducted on data from 15 of the Australian type A cements referred to in Tables 1 and 2. Paste shrinkage data for 28 days curing and a water: cement ratio of 0.50 were used. The comparative shrinkage data for concretes having maximum 3/8 inch aggregate and mix proportions of 3.0:2.4:1.0:0.5, gravel aggregate: quartz sand: cement: water, were provided by 8 × 3 × 3 inch specimens which were cured, measured and dried as previously described. The results are summarized in Table 4.

The concrete shrinkages after 7, 28, 90 and 365 days drying are recorded together with the correlation coefficient from linear regression analyses which relate paste shrinkage after 7 days drying to the concrete shrinkage at the various ages. It is concluded that highly significant correlation exists between the paste and concrete shrinkages even for drying periods up to 1 year.

Following the method used by Ross (10), final shrinkage values were calculated for each concrete from the test data by assuming that the shrinkage-time curves can be represented by a hyperbolic equation of the form:

$$\Delta L = \frac{\Delta L\infty \cdot t}{N + t}$$

where ΔL is the concrete shrinkage at time t,

Table 4. *Paste and concrete shrinkage data*
Water: Cement ratio = 0.5

Cement	Paste shrinkage per cent	Concrete shrinkage per cent					Prriod to reach half final shrinkage day
		7 day drying	28 day dyring	90 day dyring	1 year drying	Calculated final shrinkage

N	.716	.032	.065	.080	.093	.099	14.9
	r*	.962	.966	.886	.841	.755	

r* = Correlation coefficient for 13 degrees of freedom. An r* value greater than 0.760 indicates a significant relationship at the 0.001 level.

$\Delta L\infty$ is the final shrinkage and
N is a constant equal to the time at which the shrinkage strain becomes half the final value.

By calculating $t/\Delta L$ as a linear function of t and fitting straight lines by least squares, $\Delta L\infty$ and N are easily obtained. Fig. 5 illustrates the type of data obtained from the concrete shrinkage measurements, and the linear form of this data for cement O. It should be noted that the relationship between the paste shrinkages and calculated final shrinkages no longer holds at the 0.1% significance level but does so at the 1% level.

Dependence of Concrete Shrinkage Rates on Cement

A result considered to be of more practical importance than the determination of the final shrinkage value, is that the shrinkage rates, particularly early in the shrinkage period, are significantly different for concretes cast with different cements.

In Table 4, values of N, the period in days required to reach half the ultimate shrinkage, are given for the concretes. Although the final concrete shrinkages differ at maximum by only 30% of the mean value, the period required to attain half of this final shrinkage varies by about 100% of the mean. At this laboratory, crack tendency tests, using embedded reinforcing rods to produce restraint to concrete shrinkage, have indicated that early shrinkage rates have a major influence on crack development. The longer the

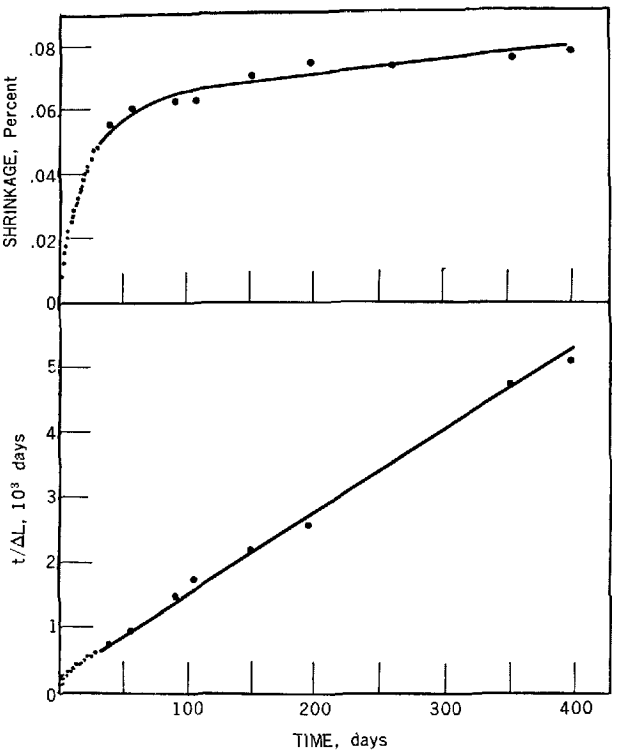

Fig. 5. *Observed and linearized relationships between shrinkage.*

elapsed period of drying without the formation of a crack, the less the possibility that cracking will occur. This fact is due to creep, which reduces the rate of tensile stress increment, and to the continued increase in tensile strength.

Three important warnings should be noted. Firstly, the size effect and drying conditions of concretes in the field will naturally modify the laboratory findings, but so far the crack tendency tests appear to correlate well with field observations. Secondaly, this rate effect is most important only when unsightly cracking occurs; indeed, from some other viewpoints, the more rapidly shrinkage reaches an asymptotic value, the better. Thirdly, under normal concreting conditions all the cements so far studied may give equally satisfactory results; however, in adverse circumstances, either in combination with other materials or due to extreme drying conditions, the likelihood of cracking is increased by cements with high early shrinkage rates.

Interaction Effects between Cement and Aggregate Shrinkages

The use of high shrinkage cements is of greatest

consequence when combined with aggregates which themselves exhibit dimensional changes due to adsorption and desorption of water. The interaction effects of various factors on the relative shrinkage value have been described (11); however, the effects on rate of shrinkage are again considered to be of prime importance in crack development.

Fig. 6 shows the shrinkage-drying time curves for three commercial concrete mixes which were designed to give equivalent strengths at 28 days using constant water contents. The difference in shrinkage behaviour using cement O and the two different aggregates is large, and the early shrinkage rates should be compared. When cement H was used with the dimensionally unstable aggregate, both the amount of shrinkage after 90 days drying and the rate of shrinkage was reduced relative to the companion specimen using cement O. For the first 18 days drying, a critical period for the development of strength and crack propagation, shrinkage rates of the concretes made with cements O and H and with the two aggregate materials were quite similar. This result suggests that when aggregates of doubtful quality must be used due to economic necessity, particuar attention should be paid to the cement-aggregate interactions and effects on both rates and absolute values of shrinkage.

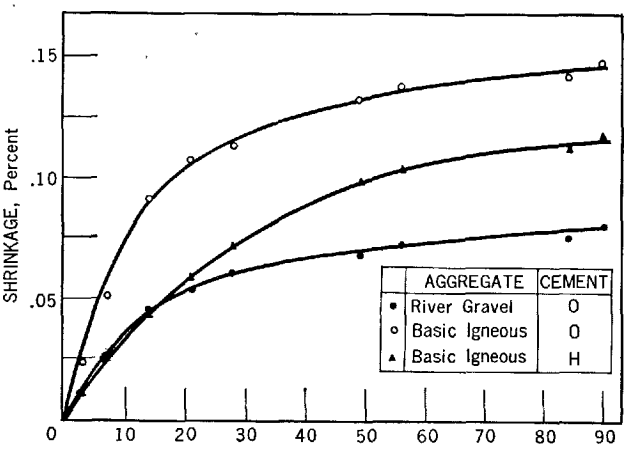

Fig. 6. *Shrinkage as a function of time for different cement and aggregate combinations.*

Conclusion

From the results presented in this paper it is concluded that, when satisfactory procedures are adopted, shrinkage tests on neat paste can be related to concrete shrinkage and chemical properties of the cement. Shrinkage should be considered as a rate process rather than in absolute terms when its effect on concrete cracking is studied. Future research should be oriented towards combinations of materials which effect early shrinkage rates, thereby influencing cracking tendency.

Supplementary Paper III-115 On Some Main Aspects of Theory of Solidification and Strength Formation of Cement Stone and Concrete

Ivan Petrowitsch Vyrodov*

Synopsis

The present work deals mainly with a few aspects of the theory of hardening of mineral binding materials. It includes, for example such problems as the applicability of the main principles of molecular physics and thermodynamics to the study of the character and trends of conversion (Chapter 1). In this Chapter the most important principles were determined, that is, the connection between thermodynamic parameters and kinetic parameters of the system: between energy and thermodynamic potential of the process of activation.

In Chapter 2 some works are analyzed, which support the view that the process of hardening of binding materials takes place in a kinetic range. As a result of the analysis of some theoretical and experimental works it is considered that the hardening of binders is a complex process and it takes place (macroscopically) in the diffusional range. Further, it is confirmed that it is impossible to judge from the form of the principal kinetic equation whether the main process takes place in the diffusional, or in the kinetic range. The hardening process is much more complicated, than it could be imagined, judging by these two mutually eliminating conceptions.

In Chapter 3 the existing conceptions on the main aspects of the structure formation theory are critically analysed, and equations for strength of cement stone and concrete are introduced. They are more versatile in comparison with the ones in common use. The conception of ripeness of concrete is specified in connection with changes in strength properties of cement stone and concrete.

Concluding, the present work deals with the prospects of development of general problems of structure formation, that is, with the coagulation processes and with coalescence-cohesion processes. The author works out a cohesion-coalescence mechanism of structure formation resulting in a quantitative theory of hardening of mineral binding substances.

Introduction

The hardening of mineral binders is a very complex process. It takes place in a heterogeneous interaction of original substances and products of interaction. So in working out the quantitative theory of hardening of mineral binders, the use of laws formulated for homogeneous systems results in inadequate quantitative ratios.

Owing to limited space in this work, only a few principles of molecular physics and thermodynamics the most often used by scientists in their studies of heterogeneous systems are pointed out.

There is one peculiarity more, which we should like to point out and to which much attention is paid in this work because of its importance.

As distinct from the theory of coagulation structure formation, the mechanism of which is qualitatively investigated by P. A. Rehbinder and E. E. Segalova, a cohesion-coalescence mechanism of structure formation is presented in this work.

The main motivation for elaboration of this mechanism was as follows:

First, during the crystallisation of the resulting products from the oversaturated solution two processes are quite inevitable: the "distillation" process (coalescence), and the process of direct fluctuative formation of particles of the final product on the bases and inside the volume of solution.

Second, during the crystallising growth of the particles, the cohesive linkage of crystals is also inevitable. In highly oversaturated solutions cohesion results in a formation of so called true contacts, the strength of which, if we do not consider the marginal effects resulting in defective contacts, is similar to the strength of crystals in general.

Third, in highly oversaturated solutions the coagulation as a process of agglutination of particles in

*Krasnodar Polytechnical Institute, Krasnodar, U.S.S.R.

dispersion systems, taking place under the effect of molecular (van-der-Waals) forces, is quite out of question. The coagulation process may occur in systems which allow a very low solubility, where the process of coalescence, of "distillation" of the substrate through the solution does not take place. In the here investigated systems, characterized by a cohesive-coalescent mechanism of hardening, the coagulation as an ante-crystallisation period, is not necessary. It may be supposed that after the disappearance of the coalescent mechanism of crystallisation the coagulation of non-agglutinative crystals will begin to take place. Such supposition is hardly probable as in the formed cage the mobility of these crystals is hardly sufficient for the coagulation mechanism of increase of these particles to take place. But if these effects were present in the final step of the process, their role would be quite negligible in comparison with the principal process of crystallisation, with coalescence.

Taking into consideration the cohesive-coalescent mechanism of hardening of mineral binders, the author elaborates the quantitative theory of appearance of tixotropically irreversible properties of hardening cement pastes, which, unfortunately, is not reflected in the present work.

The present work deals with the actual problems of the theory of hardening and strength formation of cement stone (brick) and concrete, and the groundlessness of some conceptions is proved, which deny the limiting role of diffusion processes in hardening of mineral binders. It is proved, that to elaborate a valuable theory of strength of cement stone and concrete, it is necessary to operate with asymptotic functions of distribution of particles according to their size.

The modern theory of hardening of mineral binders according to the physical-chemical standpoint of P. A. Rehbinder and his co-workers is briefly reviewed and critically analysed in the present work.

Presenting of new formulas of strength of cement stone and concrete, the introduction of the conception of concrete ripeness qualitatively, and of a cohesive-coalescent scheme of hardening of mineral binders, all the above mentioned is to contribute to the development of the modern quantitative physical-chemical theory of hardening of mineral binders.

Chapter 1
On the Possibility of Applying the Main Principles of Molecular Physics and Thermodynamics to the Study of Character of Changes of Mineral Binders

Limitations for Applying the Common Phenomenological Thermodynamics to the Theory of Hardening of Mineral Binders

As it is known, in the fifties of the last century Berthelau formulated the principle, in accordance to which only exothermic reactions take place spontaneously, that is, the reactions which are followed with a decrease of the enthalpy value (thermal content) of the system H. In general case this principle is not adequete. For example some reactions are known where a negative thermal effect takes place (dissolving of salts, etc.). Later it was stated that the thermodynamic potential may be measure of chemical affinity, more exactly, it change. As the thermodynamic (isobaric-isothermic) potential is connected with the enthalpy and entropy S by a known equation (having P and T constant).

$$\Delta Z = \Delta H - T\Delta S, \qquad (1.1)$$

at low temperatures and low values of ΔS it follows from $\Delta Z \approx \Delta H$ and the Berthelau principle takes place. At high temperatures and high values of ΔS this approximated equation is not adequate.

Mathematical calculations of changes of the thermodynamic potential of the system for different types of reactions very often result in negative values of ΔZ. From the standpoint of chemical thermodynamics all these reactions are possible and it appears to some degree that it is possible to consider the reactions having a more negative value ΔZ to be more preferable. However, from the point of view of common thermodynamics it is impossible to predict in this case what variant will be realised. Intuitive assumptions on preferability of reactions with a more pronounced negative value of ΔZ, as it is shown later on, have the same basis as the Berthelau's principle.

The change of the thermodynamic potential for a standard state looks as follows:

$$\Delta Z^{\circ} = -RT \ln K_p, \qquad (1.2)$$

where $K_p = k_1/k_2$, k_i are constants of velocities of chemical (direct and inverse) reactions, $k_i - A_i \exp [-E_i/RT]$ we have:

$$E_1 = E_2 + RT \ln (A_1/A_2), \qquad (1.3)$$

where E_1 and E_2 are energies of activation of endothemic processes respectively. In the works of Polyani, Evans and Semenov it is shown that for many exothermic reactions (radical ones) the following expression is true: $E_2 = A - BQ$, where A and B are some constants, and Q is a thermal effect of the chemical reaction. Generally the values are: $B \approx 0.25$ $A = 11.5$. Substituting for E_2 in the above mentioned equation for E_1 and neglecting the entropic item $RT \ln(A_1/A_2)$, we will have $E_1 \sim C + \Delta Z^\circ$, where C is some new constant which changes within negligible limits. In these cases it is quite true, the reaction with a more negative value of ΔZ° is more preferable. In other words, preferable reactions take place more rapidly in comparison with other reactions.

Let us make one very short, but strict and consistent conclusion, which links the thermodynamic potential of activation with the change of the thermodynamic potential of the system. For this purpose we shall put down in accordance with the theory of transient state, the interaction between the constant of the chemical equilibrium K_p and the constant of equilibrium of the complex K_k:

$$K_p = K_k \frac{(2\pi m_k kT)^{1/2}}{h} \qquad (1.4)$$

Then, taking into consideration, that the constants of the equilibrium of the complex are valid for this equation, we shall put down the similar equation for the constant of the chemical equilibrium:

$$\Delta Z_A = -RT\left[\ln K_k - \ln \frac{\prod\limits_{(i)} a_{ik}}{\prod\limits_{(j)} a_{jk}}\right], \qquad (1.5)$$

and we shall get following formula, which links the thermodynamic potential of the activation system ΔZ_A with the change of the thermodynamic potential of the system ΔZ:

$$\Delta Z_A = \Delta Z - RT\left[\ln \frac{\prod\limits_{(i)} a_i}{\prod\limits_{(j)} a_j} - \ln \frac{\prod\limits_{(i)} a_{ik}}{\prod\limits_{(j)} a_{jk}}\right] + RT \ln \left[\frac{(2\pi m_k kT)^{1/2}}{h}\right] \qquad (1.6)$$

From the equation (1.6) for the standard change of the thermodynamic potential of the activation system we shall obtain the following equation:

$$\Delta Z_A^0 = \Delta Z^0 + RT \ln \left[\frac{(2\pi m_k kT)^{1/2}}{h}\right] \qquad (1.7)$$

The thermodynamic potential of the activation system represents a kinetic character of the system: the more is ΔZ_A^0 the less intensively does the reaction take place, as the constant of the velocity of the chemical reaction is determined by a known equation:

$$K = x \frac{kT}{h} e^{-\Delta Z_A/RT}, \qquad (1.8)$$

which follows from the theory of the transient state. It follows from the equation (1.7) that ΔZ_A^0 is fully determined by the change of the standard value of the thermodynamic potential of the system if the second, or, if the first item is much more than the second item. In this case we consider much more preferable those reactions which have the change of the thermodynamic potential the most negative from possible values of ΔZ^0. Thus the range of application of the principle of preferability of reactions is settled.

To illustrate the formula (1.7) we shall give below some calculations with ΔZ_A^0 for some hydration reactions and the total data are given in a table:

Original compound	ΔZ_1^0 298 ccal/M	Final compound	ΔZ_2^0 298 ccal/M	ΔZ_A^0 298 ccal/M
CaO	144.40	$Ca(OH)_2$	214.33	14.86
MgO	136.13	$Mg(OH)_2$	199.27	21.84
$CaSO_4 0.5H_2O$	342.78	$CaSO_4 \cdot 2H_2O$	429.19	27.12
H_2O	56.69	—	56.69	—
C_2S		$C_2SH_{1.17}$		25.86
C_2S		$C_2SH_{1.17}$		9.60
C_3A		$\frac{1}{2}(C_4AH_{19}) + \frac{1}{2}(AH_3)$		20.04

The given data are confirmed experimentally. It must be noted that the formation of C_4AH_{19} takes place without the energy of activation. In this case we do not take into consideration some peculiarities connected with the presence of the chemical potential gradient, which are favourable for the topochemical process. We must mention among these peculiarities, for example, the surface of the chemical reaction, which leads to the reduction of the surface tention according to the formula

$$\Delta\sigma = M\Delta\mu \qquad (1.9)$$

where $\Delta\sigma$ is a change of the surface tention, $\Delta\mu$ is the change of the chemical potential and M is the value of the surface transfer of the component.

Thus, the symbol ΔZ shows the possibility for the process to take place, and the numerical value of it gives the possibility to state the preferability of reactions (3).

On Applying the Basic Laws of Thermodynamics of Non-Equilibrium Processes To the Theory of Hardening of Mineral Binders.

From the above written it follows that the character of the change of the thermodynamic potential cannot serve as satisfying measure of chemical affinity. For a full description of the process we had a consideration of parameters determining the kinetics of the process. Such parameter which determines the chemical activity of the given transformation is the energy of activation, or, more exactly, the thermodynamic potential of activation: ΔZ_A. The calculation of these values in quantum mechanics is followed with considerable mathematical difficulties and the obtained data are not of high accuracy. Generally, the error of determination of energy of activation is about 20–25%. Consequently, it is quite natural from the part of the scientists in physics and in physical chemistry to try to obtain the correlaton between the energy of activation and the thermodynamic parameters, which reflect the change of state of the systems, what is calculated with much more accuracy than is indicated above.

Before pointing out this correlation it would be necessary to note the time scantiness of methods of phenomenological non-equilibrium thermodynamics, which follows from its linear phenomenological laws.

Its main disadvantage is that it describes the processes only in the neighborhood of their equilibrium state. However, despite of this very strict limitation in some cases we can obtain very valuable information on the process rate "in toto". These are the cases when linear approximations appear to be true with slight errors during the whole process of transformation, that is, when the law of acting masses is taken into consideration.

It may be supposed that the elaboration of methods of non-linear thermodynamics of irreversible processes will considerably enlarge the possibilities of thermodynamics in solving the most important problems of the chemical kinetics. First of all we must verbalize the conditions necessary to solve our problem and then we shall analyze the obtained results.

Let us consider the most simple case of the chemical transformation $I \rightarrow II$, which takes place in a diffusional region and draw a relation for the activation energy process E_A (an experimental value), and also for the thermodynamic potential of the activation process ΔZ_A. As further on for transfer processes we shall use linear phenomenological laws of thermodynamics of irreversible processes, so for the difference of thermodynamic potentials of different states of the system ΔZ in the given case we have an inequality: $\Delta Z \ll RT$, so we shall use the equality $\Delta Z \approx 0$. For sake of simplicity we shall consider only such systems which have the difference of the standard values of thermodynamic potentials of the original and final products $\Delta Z^0 \gg RT$, and the flow of substance ζ_n is stationary in relation to some internal coordinate of the system y.

Taking into consideration all the above mentioned we may take as an example the case of transformation of highly dispersed substance, which leads for E_A to the relation, similar to the known rule of Polyani-Semenov.

Let us present the chemical potential for a mass unit of the system $\mu(y)$ as follows:

$$\mu(y) = \frac{kT}{m} \ln \lambda(y) + \mu^\circ, \tag{1.10}$$

where m is the mass of the particle, y is some internal parmeter of the system, $\lambda(y)$ is the activity of the substance, μ^0 is a standard (true or hypothetic) value of the chemical potential of the substance. The true value of the chemical potential μ^0 is necessary to take for substances which allow a non-limited solubility, and hypothetic values of μ must be taken for such substances which allow only a limited solubility in some ambience where the chemical reaction occurs (transformation).

For the chemical reaction rate $j(y)$ which is proportional to the value of the flow $j_n(y)$ we shall write a phenomenological equation

$$j(y) = -L\frac{\partial \mu(y)}{\partial y} \tag{1.11}$$

Then we shall get from (1.10)and (1.11):

$$j(y) = -\frac{LkT}{m\lambda(y)} \frac{\partial \lambda(y)}{\partial y} \tag{1.12}$$

Introducing the "mobility" $u = L/\lambda$ and the "diffusion" coefficient $D = kTu/m$ according to some internal coordinate y we shall obtain:

$$j(y) = -D\frac{\partial \lambda(y)}{y} \tag{1.13}$$

writing it beforehand (3) in the following form:

$$j(y) = -\frac{LD}{u} \frac{\partial}{\partial y}[e^{\ln \lambda(y)}]\, 1^{-\ln \lambda(y)} \tag{1.14}$$

and multiplying the result by $u/LD \cdot 1^{\ln \lambda(y)}$, after integration by y, we shall get:

$$j = \alpha[1 - e^{-(A-A^0)/RT}] \tag{1.15}$$

where chemical affinities A and A^0 are equal to a difference of thermodynamic potentials: $A = Z_1 - Z_2 = -\Delta Z$, $A^0 = Z_1^0 - Z_2^0 = -\Delta Z^0$

and $$\alpha = \frac{e^{(Z_1 - Z_1^0)/RT}}{\int_1^2 D^{-1}(y)dy}$$

Now we shall draw out the relation for the chemical reaction rate. This reaction occurs in the diffusional region, judging by kinetic considerations.

Let us consider the interaction of the spherical part of the radius S_i, having the mass $m_i = \frac{4}{3}\pi S_i^3 d_0$ where d_0 is the density of the substance of the particle, with a gas·ous or liquid medium. The quantity of the substance dm_i which diffused into solusion during the time dt is so formulated after the first law of Fick:
From that

$$\frac{d\rho_i}{dt} = \frac{D}{d_0}\frac{\partial C}{\partial r}\bigg|_{r=\rho_i} \qquad (1.17)$$

The concentration change rate in the near-to-surface layer is

$$\frac{dC}{dt} = \varphi(K_i, C_\Pi) + D\frac{\partial^2 C}{\partial r^2}\bigg|_{r=\rho_i} \qquad (1.18)$$

After some time the concentration C reached some ultimate value C_Π in the near-to-surface layer. Let the process occur at $C(r = \rho_i) = C_\Pi$. Then from (1.18) we get:

$$D\frac{\partial^2 C}{\partial r^2}\bigg|_{r=\rho_i} = -\varphi(K_i, C_\Pi) \qquad (1.19)$$

From this by integration we get:

$$D\frac{\partial C}{\partial \rho_i} = \varphi(K_i, C_\Pi)\rho_i, \qquad (1.20)$$

as at $\rho_i = 0$ also $\frac{\partial C}{\partial \rho_i} = 0$
Substituting (1.20) into (1.17) we shall obtain:

$$\frac{d\rho_i}{dt} = -\frac{\varphi(K_i, C_\Pi)}{d_0}\rho_i \qquad (1.21)$$

From the evident equation

$$\frac{dm_i}{m_i} = 3\frac{d}{\rho_i} = -3\frac{\varphi(K_i, C_\Pi)}{d_0}dt \qquad (1.22)$$

we shall get:

$$\frac{dm_i}{dt} = -km \qquad (1.23)$$

Introducing some approximated value of the reaction rate constant

$$k = \frac{\sum k_i m_i}{m}, \text{ we shall get:} \qquad (1.24)$$

$$\frac{dm}{dt} = -km,$$

where m is the mass of the substance for a unit of the volume of the system.

Thus the reactions controlled by the diffusion are the reactions of the first order. According to this scheme the oxychloride gypsum and other mineral binders are hardening.

For these systems the time necessary to reach the critical concentration on the surface of hard bodies is about a few seconds.

To describe the character of the system it is necessary to choose the inner coordinate of the system. For this we must choose such a parameter which will reflect rather fully the state of the system and will lead to a single value of the chemical potential $\mu(y)$. If the surface of the particle was determined by a single value of the mass of the reacting substance, we could choose as an inner coordinate a value proportional to the mass of the reagent m or to the surfaces of its particles S_Π. However, it is necessary to take into consideration that during the process of chemical interaction as a result of an invasion of the adsorption active medium into the micropores of the particles, the process of chemical dispersion of the substance occurs too. As a result of two parallel processes we cannot indicate a single value correspondance between m and S_Π. Moreover, opening of new surfaces of the reaction leads to an occurence of an excessive free surface energy, which contributes in addition to the chemical (or thermodynamic) potential of the system. Further, when we have a known m we can determine the quantity of the substance in the solution. Thus, the parameters m and S_Π rather fully describe the state of the system but on the other hand they somewhat synonymously determine the chemical potential of the system. Considering the measure of y, $y = S_\Pi/\Delta m$ should be taken. This choice of the inner coordinate, as it will be shown below, does not contrdaict the conditions in which the laws of linear phenomenological thermodynamics of irreversible processes are valid.

Let us choose some mean value of D and thus suppose that D = const(y). Then

$$j = D\Delta m l^{(Z_1 - Z_1^0)/RT}\left[\frac{1 - e^{-(A - A^0)/RT}}{S}\right] \qquad (1.25)$$

In accordance with (1.24) we get:

$$k = \frac{j}{m} = -\frac{D}{\Delta S_\Pi}e^{(Z_1 - Z_1^0)/RT}(1 - e^{(\Delta Z - \Delta Z^0)/RT}) \qquad (1.26)$$

In accordance with data of the theory of transient state we write the constant of the reaction rate in the following form:

$$K = x\frac{kT}{h}e^{-Z_{\Delta\Pi}/RT} = x\frac{kTe}{h}e^{\Delta S_A/R}e^{-E_A/RT} = Be^{-E_A/RT}, \quad (1.27)$$

where x is the transmission coefficient, $x = 1$. K is the Boltsman's constant, S is the entropy of activation. Considering (1.27) we get the following:

$$-\frac{ekT\Delta S_\Pi}{Dh}e^{-(E_A+Z_1-Z_1^0-TS_A)/RT} = 1 - e^{(\Delta Z-\Delta Z^0)/RT} \quad (1.28)$$

or, as $Z_A = E_A - T\Delta S_A$:

$$e^{(\Delta Z-AZ^0)/RT}\left[1 - \frac{ekT\Delta S_\Pi}{Dh}e^{-(\Delta Z_A-\Delta Z-\Delta Z^0-Z_1-Z_1^0)/RT}\right] = 1 \quad (1.29)$$

Introducing the identifications:

$$Z_2^0 - Z_2 = \Delta Z_2 \qquad Z_1^0 - Z_1 = \Delta Z_1, \quad (1.30)$$

$$\Delta Z - \Delta Z^0 = \Delta Z_{12}, \quad (1.31)$$

instead of (1.29) we obtain:

$$e^{\Delta Z_{12}/RT}\left(1 - \frac{ekT\Delta S_\Pi}{Dh}e^{-(\Delta Z_A-\Delta Z_2)/RT}\right) = 1. \quad (1.32)$$

For a state near to a balanced Z the last equation must be re-written as

$$\Delta Z_A = RT\ln\left[-\frac{ekT\Delta S_\Pi}{Dh}\cdot\frac{e^{\Delta Z_2/RT}}{1 - e^{-\Delta Z_0/RT}}\right] \quad (1.33)$$

Taking into consideration the second equation formulated by us $|\Delta Z^0| \gg RT$, we get the following:

$$E_A = \Delta Z^0 + RT\ln\left[\frac{B\Delta S_\Pi}{Dh}e^{\Delta Z_2/RT}\right] \quad (1.34)$$

Taking for the reactions of the same type the expression $\Delta Z_2 + T\Delta S_A = \alpha\Delta Z^\circ$, where α is some factor, a constant item for the reactions of the same type, and supposing that $\gamma = 1 + \alpha$ we may write the following:

$$E_A = \gamma\Delta Z^0 + RT\ln\frac{-2\Delta D_i nekT}{DhD_i^{-3}}, \quad (1.35)$$

which is valid for the end of the process, when $\Delta Z_2 \approx 0$. In the above equation $S_\Pi = nd^2$, n is the number of reacting particles, d is their mean size, and $D_i = 1/d$ is the dispersion of the substance. This equation links the energy of the activation of the process with the heat of the phase conversion, and with the change of the standard values of thermodynamic potentials. This may be easily seen from the following example. The conditions for the reacting substance are: $|\ln \Delta S_\Pi T/D| \ll |\ln ek/h|$ and the reaction proceeds at temperature of T = 300°K. Then from (1.35) we get:

$$E_A = \gamma\Delta Z^0 + 13.8 \quad (1.36)$$

In the case of limited solubility of at least one of substances of the system instead of the Z^0 it is necessary to take $Z = Z^0 + G$ where G is some constant. Then $\Delta Z_2 + T\Delta S_A = \Delta Z_2^0 - Z_2 + T\Delta S_A = \alpha\Delta Z^0 - G$ and from the equation (1.34) we again get (1. 35 and 1. 36). Lastly it is necessary to note that for systems in which proceed the chemical reactions, linear phenomenological interrelations are carried out near to balanced states. or in conditions where the molecules of reacting substances during the reaction do not alter the Maxwell's distribution by velocities*. (* = It is evident, that as in the theory of transient state, this condition is not necessary). Thus, the obtained values of ΔZ_A characterize the rate of the system approximation to the final equilibrium state or to a state, characterised by an induction period.

On a Directed Change of Properties of Hardening Mineral Binders under the Effect of Surfactants

The directed change of properties of hardening mineral binders with the help of surfactants is one of the main and most difficult tasks of the chemical technology of building materials and concretes. Theoretical investigations here are far behind the actual requirements and successes of the practical branch of this science. Some attempts for creating the prerequisites explaining (but not predicting) the mode of action of surfactants were made by Academician P.A. Rehbinder (see, for example, the last work 4). As in the above mentioned work (4), in the preceding works the central item of the theory is the use of e-theorem of Boltzman for surfactants distributed by volume of liquid and on the surface of the solid.

But, as it was shown in the work (5), the utilization of Boltzman's e-theorem is rather limited. Particularly, it is not applied to heterogenous systems. Aside from the mathematical proof of its inapplicability to these systems which may be found in the thesis, it should be noted that the said inapplicability follows from the physical sense of Boltzman's e-theorem, obtained for gaseous states. The following conditions are necessary. First of all, the equation of state of ideal *gas* is utilised in deduction of the theorem. Uniformity and stability of temperature for the system are supposed, and uniformity of vector field in which the particles of the ideal system are. If at least one of these conditions is not present we do not obtain e-theorem. Thus it may be seen how complex is the problem for real heterogenous systems where vector fields act being

different in the whole volume of the system and not being a single value function of space coordinates.

Even in the most simple case, in the system "solid-liquid" the vector field on the surface of the solid differs from the vector field inside the liquid. Particularly this phenomenon is one of the main objections to the utilisation of e-theorem.

Under the effect of the internal field of isolated liquid and of the external field of gravity the Boltzman's distribution of particles by height really takes place. However, as the solution comes into contact with the adsorption-active medium this distribution is changed as a result of non-equilibrium process leading to the adsorption of the substance from the solution containing a surfactant. Similarly, as the trasformation of mineral binders takes place, the continued alteration of sequence of settling (but not settled) distributions not only inside the volume of the solution but near the surface of the transformated sbustance takes place. The character of the distribution of surfactants determines the rate of substance conversion. On the other hand the surfactants influence the rate of increase of particles of the new phase. The correlation between the dispersion of particles D_i and the rate of change of surface tension σ_i and of particle size l_i is established in the work (5):

$$\frac{\partial \sigma_i}{\partial t} : \frac{\partial l_i}{\partial t} = -\sigma_i D_i \qquad (1.37)$$

A very important conclusion thus follows. The surfactant action itself is not single-valued. When evaluating the action of surfactant it is necessary to consider kinetic particularities of converting substances and the temperature of the system too.

The study of influence of surfactants on dispersibility of forming particles leads to very interesting conclusions.

The relative concentration of additive surfactant C_g to achieve extreme dispercibility value D_i in the field of small D_{i3}, depends upon chemical potential of the additive surfactant:

$$C_g \text{ relative} = \frac{\gamma_0}{\mu_g}, \qquad (1.38)$$

where $\gamma_0 = \text{constant}$. It follows that the greater is the chemical potential of the substance of the additive, the less is portion necessary to obtain the same effect.

In the field of high values D_{i3} we have:

$$C_g = \frac{\gamma_{j0}}{k_j^1}, \qquad (1.39)$$

where

$$\gamma_{j0} = \sum \frac{1_q C_{qj}}{\gamma_j} \frac{\partial \tau_q}{\partial 1_q}; \quad k_j^1 = \rho(T) \qquad (1.40)$$

Thus, in the field of high values of D_{i3} the role of individual properties of surfactants is limited to a character of change of edge tensions determining the effectiveness of surfactant action and it is not dependant on the chemical potential of the additive. Here is the limit of utilisation of main thermodynamic parameters in high-dispersibility phases. The same is for Gibbs-Curie-Wolf principle stating the dependance of the process of crystals growth upon the surface tension of edges. By these parameters, that is, by rates of changes of edge tension and by particle bond energy the extreme strength of hardened binders is determined.

Chapter 2
Role of Diffusion Kinetics of Reactions in the Process of Hardening of Mineral Binders

Some Critique on Studies Denying the Diffusion Mechanism in the Process of Hardening of Mineral Binders

Some works based on the study (6), state that the diffusion kinetics does not limit the process of hardening of the mineral binders.

The conclusions of Shiller (6) are based on comparing two approximately evaluated items: the length of diffusion D path, and the coefficient of diffusion *l*. They are values of one order of smallness. The approximations are made with the exactitude of smallness order equal to 1. Consequently, the comparison of values of the same order of smallness, which are estimated with the same exactitude—one order of smallness—is absolutely senseless.

Moreover, it should be noted that K. Shiller uses the equation which reflects the effect of free diffusion, that is, the self-diffusion of Brown particles, as in reality in this system we see just another diffusion, of another origin, which takes place in the presence of concentration gradient. K. Shiller does not notice this, he substitutes diffusion by the selfdiffusion.

It should also be noted that Einstein's formula is

valid only for some mean value $l - \bar{l}$ (that would be sufficient for non-applicability of the said formula in solving the present problem) and for rather great values of time t. Having these conditions let us consider $t = \Delta t$ and $l = \Delta x$. Then the relation $\Delta t = \Delta x^2/2D$ is a criterion (a condition) of stability in solving the equation of diffusion in final-differential approximation. In this case particularly the Einstein's equation gets a definite interpretation with a diffusion conditioned by a presence of concentration gradients.

The above mentioned is sufficient to prove the K. Shiller's conclusions to be highly unconvincing.

Let us consider another study, which has something common with the conclusion of K. Shiller. This is the work of A. F. Polak (7), where the evaluation of character of the process is based on the Bertrand's formula (2. 75):

$$\xi = \frac{k_1 D}{k_1 \delta + D}(C_\infty - C), \qquad (2.1)$$

which is valid in "mixed" kinetics and is obtained by excluding the concentration of the substance C_x near the surface of the binder from two relations. One of them describes the kinetic field, the other the diffusion field of "dissolving".

Then, this relation is used for recording the Peckle's value:

$$Pe = \frac{k_1}{D/\delta} = \frac{\xi\delta}{D(C_\infty - C) - \xi\delta}, \qquad (2.2)$$

from which supposedly follows that with $Pe \gg 1$ the process is a diffusion one, and with $Pe \ll 1$ the process takes place in the kinetic field. Presenting the evaluation data for this formula A. F. Polak comes to the conclusion that at small oversaturations the process proceeds according to the "mixed" kinetics, and at high oversaturations it goes in the kinetic field. We consider these conclusions to be highly doubtful for following reasons.

Polak's intention to use Peckle's value to solve the above mentioned problem is reasonable. However, in the formula (2.2) the value of rate of loss of the molecule of the binder into the boundary layer:

$$\xi_k = k_1(C_\infty - C_x) \qquad (2.3)$$

and the value of rate of diffusion transport of particles from the boundary layer into the volume of solution:

$$\xi_D = \frac{D}{\delta}(C_x - C). \qquad (2.4)$$

should be used.

Then the Peckle's value would have the form:

$$Pe = \frac{\xi k}{\xi D} = \frac{k_1}{D/\delta}\frac{(C_\infty - C_x)}{(C_x - C)} \qquad (2.5)$$

Particularly this correct formula should be used for estimations rather than the formula (2.2). Using the formula (2.2) the author essentially can not overstep the limits of mixed kinetics as there is one condition in it: $\xi_D = \xi_K$.

On the other hand, excluding the $(C_\infty - C_x)/(C_x - C)$ (2.5) see formula (2.2), Polak records the wrong value for Peckle's number from the very beginning. By force of this second reason it is possible to get very controversing conclusion from the formula (2.2), what is actually characteristic for the work (7).

It is rather important to note the difference between the work (6) and (7). In considering the whole process the work (6) deals only with the stage of crystallisation of new formations, while the work (7) deals with the meachanism of "dissolving" of the binder. It is evident that these one-sided investigations can not be used as criteria in considering what is the scheme of the process.

Substantiation of Diffusion Mechanism of Solidification of Mineral Binders

A rather full substantiation of the diffusion mechanism of solidification of binders is the subject of the works of Ratinov V. B. and his co-workers. Diffusion coefficients and diffusion flows were experimentally obtained in these works. The comparison of diffusion flows with rates of solidification of binders is the first proof for a diffusion mechanism of solidification of binders. My thesis was confirmed with the works of V. B. Ratinov using experiments establishing the dependance of rates of solidification on intensity of blending cement dough and by solving corresponding equations of diffusion as well.

It should be specially noted that the works on diffusion from a mobile boundary gave as a result of using the computers URALS-1 the functions of change of size of particles depending on time. The obtained functions are near to linear. These results are very valuable as they show the limit of utilization of a highly utilized formula:

$$S = (Dt)^{1/2} \qquad (2.6)$$

to determine the coordinate ρ of the moving boundary of the phase conversion limited by diffusion. In our solved marginal problem the exponent at t is near to 1.

On Criterium of Applicability of Molecular Diffusion Equations to Solve More Complicated Problems of Turbulent Diffusion

Let the molecular diffusion coefficient be $D_m \sim v_m l_m$, where v_m is the diffusing particle velocity, l_m is the length of free path of molecule. A similar relation may be written for turbulent diffusion coefficient $D_T \sim v_T l_T$ having in mind that proportional coefficients D_m and D_T are taken into consideration between diffusion flows j and gradients of concentration of substances. v_T is here the mean value of turbulent fluctuation of velocity, being the measur of intensity of turbulence, l_T is the turbulence scale, a value similar to the length of free path, or after Prantle—the path of blending. Molecules moving along the distances $l \leq l_T$ are statistically bound with each other. If the turbulence scale l_T is very small in comparison with the region inside which the diffusion takes place, this turbulent diffusion is called a small scale diffusion, or a gradient diffusion, and its description is similar to that of the molecular diffusion, as in this case it is possible to carry out the condition of proportionality between the flows and concentration gradients of substances, and the processes of diffusion are described apparantly similar differential equations. When there is no continued blending of solidifying cement dough, a molecular diffusion proceeds, in the presence of distributed temperature gradients a turbulent small scale diffusion proceeds too.

But also in the case large scale turbulent diffusion, that is, in the presence of large turbulences the form of differential equations will not change. Only the interpretation of desired functions a parameter of equations will change in this case.

On the Main Kinetic Equation of Solidification of Mineral Binders

As it was already noted, there are two tendencies in our and foreign literature representing the basements for a quantitative theory of solidification of mineral binders.

The first tendency establishes the diffusion mechanism of solidification of mineral binders. According to the second tendency the process of solidification of binders proceeds in the kinetic region. Although the principle difference between the said tendencies is quite evident, it is quite stated in the work (8) that both tendencies are just and valid, as "... the process rate undergoes the general laws of chemical reactions kinetics ...". Naturally, if the process of solidification of binders proceeded in the diffusion region, the consideration of kinetics of chemical reactions from the general positions of physical chemistry would necessarily lead to the differential equation of diffusion. In this sense only it is possible to consider any process whether it proceeds in kinetic or in diffusion region, from general positions of chemical reactions. However, the experimental basements of any mechanism make easy drawing the conclusion of the main kinetic equation of the process of solidification of binders.

Some works may be found sometimes which confirm the second tendency basing on a check of "apriori" kinetic equation of the first order. But it is not difficult to demonstrate that the processes occuring in diffusion region are also described by equations of the first order. Thus and because of this the good confirmation between the theoretical formula and the experiment can not serve as a confirmation of any scheme of solidification of binders.

It is also necessary to note that the works (7) are characterised by numerous constants of the process. It should be borne in mind that the more constants we have the more arbitrariness in the choice of kinetic law, and the more incorrect is the conclusion about the mechanism of solidification of binders.

The process of solidification of binders is a very complicated one. Although in general the process of solidification of binders proceeds in diffusion region (5), some local processes are possible. They proceed in kinetic region. In these cases in some limits the local processes can be descirbed by the law of acting masses.

Before establishing the main kinetic equation according to this law we will consider the change of different forms of water which is present in solidifying binders.

According to our point of view all waters in solidifying concrete may by divided into three categories.

To the first category belongs the chemically bound water, B_{xc}. This is the water of the product of reaction. It includes zeolitic, structural and non-structural water.

The second category includes the sorption-bound water. This is the water adsorbed by the surface of the aggregate B_3 (physical sorption), by the surface of

cement grains $B_{u\partial}$ (chemisorbed water corresponding to pre-reactional period), and also water contained in the capillaries and micropores of product of hardening and of aggregate $B_{K\Pi}$.

The third category includes the free water into which come the dissociation products of new formations: B_c.

Such distribution is based on the principle of consideration of binding forces of water with solids contained in concrete mixtures, as the rate of activity of water to trasformations occuring in concrete depends on these bonds.

To put down the relation for the chemical reaction rate it is necessary to consider that in accordance with the law of acting masses the rate of change of the reaction product depends on the quantity of collisions of active molecules having the possibility to interact. Such molecules are the molecules of water $B_ц$ and the cement grain molecules on the surface of the grains, that is the active moecules of cement $Ц_a$. It may be seen that the reaction rate will not depend on B_c, even though how large this value would have been changed. Although B_c is not included into the law of acting masses it should be borne in mind that during the transport of reäction products inside the free water the rate of transport will depend on volume of this water. If the process is purely topochemical and the reaction products are left on the surface of the grains the water B_c does not affect the transformation rate. The principal mistake of the author of the work (8) is that while establishing the main kinetic equation is included in the active water.

Thus in accordance with the law of acting masses we have:

$$v = \frac{\partial m}{\partial t} = k B_ц^m Ц_A^n \qquad (2.7)$$

where m is the mass of reaction product.

$$m = B_x + \alpha B_x = (1 + \alpha) B_x \qquad (2.8)$$

Here α is stechiometric coefficient equal to the relation of mass of waterless part of reaction product to the mass of in it contained chemically bound water.

From equations (2.7) and (2.8) we have:

$$\frac{\partial B_x}{\partial t} = \frac{k}{1 + \alpha} B_ц^m Ц_A^n \qquad (2.9)$$

This equation essentially differs from that obtained in the work(8), representing the main equation in the theory of heat emission of concrete.

The values $B_ц$ and $Ц_A$ are proportional to the specific surface of the binder S, so we have:

$$B_ц^m Ц_A^n = \beta S^{m+n} \qquad (2.10)$$

Carrying out the integration in (2.9) with a consideration of (2.10) we get:

$$B_x = \frac{\beta}{1 + \alpha} \int_\partial^t k(t) S^{m+n}(t) dt \qquad (2.11)$$

It is possible to make the final integration of (2.11) only if we know the position in time of "constant" of chemical reaction rate $k(t)$ and $S(t)$. The introduction of system model is necessary at this stage.

In the work (5) is shown, that if the process is limited by diffusion, then having a rather large quantity of particles in a unit of volume their size will decrease linearly with the time. In this case

$$S = \sum S_i = \sum 4\pi R_i^2 = 4\pi(\bar{R}_0 - \gamma_1 t)^2 \qquad (2.12)$$

When the quantity of particles in the unit of volume is not high:

$$S = 4\pi(R_0 - \gamma_2 t) \qquad (2.13)$$

For a general case we may write:

$$S = S_0(1 - \gamma t)^\mu \qquad (2.14)$$

where μ may be any number.

Substituting (2.14) into (2.11) and taking into consideration that the process is almost isothermic we will get:

$$B_x = \frac{B k S_0}{1 + \alpha} \int_0^t (1 - \gamma t)^{\mu(m+n)} dt = \frac{C}{r}[1 - (1 - \gamma t)^r], \qquad (2.15)$$

where

$$C = \frac{B k S_0}{\gamma(1 + \gamma)}, \qquad (2.16)$$

$$r = \mu(m + n) + 1 \qquad (2.17)$$

As at the end of the process

$$B_{xk} = B - B_3 - B_{k\Pi} = \frac{C}{r}, \qquad (2.18)$$

instead of (2.15) we get

$$B_x = B_{xk}[1 - (1 - \gamma t)^r] \qquad (2.19)$$

As $B_x \sim m$, this equation represent not only the equation of hydration but also the main kinetic equation reflecting the transformation rate in general.

If we took, that the process took place not in the diffusion region, we would get another equation for specific surface of substance, and, consequently, another kinetic equation.

Let us suppose now, that in the process of transformation of original substance some part of its surface is permanently screened by products of reaction. If the constant of screening is not changed with time the kinetic equation will not change either. If the constant of screening changes with time the kinetic equation will change too.

It is necessary to note, that the form of kinetic equation is influenced not only by time dependance of specific surface of original binder, but also by time dependance of "constant" of reaction rate. In case of limiting role of diffusion this constant includes directly the diffusion coefficient and the degree of influence of volume of solving water B_c. As in case of diffusion mechanism the consideration of screening is quite necessary in the kinetic region. In both cases the consideration of sc eening does not influence the character of transformation, that is, the process being in diffusion region does transfer into kinetic region with the change of screening constant. On the other hand, the introduction of different constants(8) representing the physical sense of the character of the process does not give the possibility to reveal the nature of any of the processes. (This must be more detailed. The formation of solid surface films surely prevents the transportation and later on the chemical interaction of reagents. From this point of view the process macroscopically must be transferred from kinetic into the diffusion region. So, if the films representing the products of new formations are semi-permeable, the process can take place macroscopically in diffusion region or in the region of mixed kinetics. The character of interaction of original substances "in pure state" /"in nascent state"/is not changed.)

We may finish here the evaluation of the main kinetic equation. Finally, the most natural is the supposition that the "acting" surface (that is, not screened part of the surface) is proportional to whole surface. Thus it should be considered that the form of the principal kinetic equation (2.19) is not changed even if considering the screening effect. (We mean the case of practically impermeable films).

Let us now consider the case when the solidification of concrete is limited within the kinetic region. In this case $S = l(B_x)$. In fact:

$$\frac{4}{3}\pi(R_{0i}^3 - R_i^3) = kB_x \tag{2.20}$$

It is not difficult to obtain the following equation from the above equation for sherical particles:

$$S_i = S_{0i}\left(1 - \frac{B_{xi}}{B_{kxi}}\right)^{\frac{2}{3}} \tag{2.21}$$

For a poly-disperse substance and for a particle of random shape we get:

$$S = S_0\left(1 - \frac{B_x}{B_{kx}}\right)^{\nu}, \tag{2.22}$$

where ν is so far an uncertain number.

Considering (2.9) (2.10) we get:

$$\frac{\partial B_x}{\partial t} = \frac{K_\beta S_0}{1+\alpha}\left(1 - \frac{B_x}{B_{kx}}\right)^{N}, \tag{2.23}$$

where $N = (1 + n)\nu$. After integration of this equation with a constant K we get:

$$\left(1 - \frac{B_x}{B_{kx}}\right)^{-N+1} = 1 + \frac{K_\beta S_0}{1+\alpha}(N-1)B_{kx}t \tag{2.24}$$

or

$$B_x = B_{kx}[1 - (1 + \gamma_3 t)^{1/(N-1)}] \tag{2.25}$$

Using the denominations $B_{kx}(N-1)\gamma_2 = \gamma_3$ and $N - 1 = q$ we get the principal kinetic equation in the following form:

$$B_x = B_{kx}[1 - (1 + \gamma_3 t)^{-q^{-1}}] \tag{2.26}$$

The form of this equation is similar to the one of (2.19). Moreover at $N < 1$ and $r > 0$ these equations are analogous in the sense of their application to the description of the given process. We got this at first glance paradox conclusion because at the diffusion and "kinetic" mechanism of solidification of concrete the hydration rate is directly proportional to the specific surface S^N of the binding substance. In the first case the diffusion meehanism influences the character of dependance $S(t)$, and the value of N. Just the same we have in the case of the process occuring in the kinetic region.

The equations (2.19) and (2.26) can be used to study heat emission regularities. Taking into consideration that heat emission of concrete is ruled by the hydration process (not bearing in mind other transformations) we get:

$$Q = \alpha_0 B_x, \tag{2.27}$$

where α_0 is a coefficient.

The equations (2.19) and (2.26) can be used to determine the hydration degree K_r after the formula

$$K_r = \frac{B_x}{B_{kx}}. \tag{2.28}$$

The constants (parameters) of equations (2.19) and (2.26) are determined after the kinetic curves.

Chapter 3
On Some Principal Aspects of the Theory of Solidification and Strength Formation of Cement Stone And Concrete

Establishing of the Formula of Strength of Solidifying Pastes

In accordance with the data obtained in (21), the strength of the solidifying paste may be expressed in the following way:

$$R = \frac{9}{4d^2}\sum n_{ik}f_{ik} \tag{3.1}$$

where f_{ik} are forces of bonds between i-and k-ions of two different particles, n_{ik} is the density of saturating valence bonds determined by the structure of the substance, d is the mean size of the particles. With a rather good accuracy we may write:

$$\sum n_{ik}f_{ik} = f_{цц}(n_{цц} + \alpha_{цц}), \tag{3.2}$$

where $f_{цц}$ are forces generated by atoms of cement and $f_{\sigma ц}$ are forces of bonds appearing as the result of interaction of molecules of water with the atoms of cement.

As $n_{цц}$ and $n_{\sigma ц}$ are proportional to the mass of reacted substance m:

$$m = m_k(1 - e^{-kt}) \tag{3.3}$$

where k is the constant of rate of transformation, m_k is the mass of solidified product. Then the quantity of contacts and the quantity of bonds are proportional to the following item:

$$n_{цц} \sim m Ц^2; \qquad n_{\sigma ц} \sim m B Ц. \tag{3.4}$$

where B and Ц correspond to the total quantities of masses of water and cement respectively. Taking also into consideration the interval of concentrations, for which $d \sim B$, we get:

$$R \sim \frac{9}{4R^2}m_k(1 - e^{-kt})(Ц^2 + \alpha B Ц), \tag{3.5}$$

$$R = A(1 - e^{-kt})\left(\frac{Ц}{B}\right)\left(\alpha + \frac{Ц}{B}\right) \tag{3.6}$$

Thus we got a very important formula, which connects the strength of solidifying cement paste with the water-cement ratio, constant of transformation rate and the time of solidification. In the limit of a rather large time (for examble, after the Standard, for 28 days) the exponential member appears to be very small and we obtain the formula 31 in the work (21).

The obtained formula gives some perspectives to consider the dependance of strength of solidifying pastes on reduction effects, (shrinkage effects).

On Some Factors Influencing the Strength of Cement Stone and Concrete

On the preceding pages we considered the dependance of strength of solidifying cement stone and concrete R on time and water-cement ratio. This dependance is obtained by us in the form (3.6) where

$$A = R_k\left\{\left(\frac{Ц}{B}\right)_k\left[\alpha + \left(\frac{Ц}{B}\right)_k\right]\right\}^{-1} \tag{3.7}$$

Here the item "k" at B and Ц/B corresponds to the final values.

If in the process of concrete solidification (or cement) the ratio Ц/B is constant, that is, if $Ц/B = (Ц/B)_k$, the strength of concrete is expressed by a simple equation:

$$R = R_k(1 - e^{-kt}) \tag{3.8}$$

From here for difference $R_k - R = \Delta R$ we get:

$$\Delta R = R_k e^{-kt} \tag{3.9}$$

In accordance with existing standards $R_k = R_{28}$ If in the process of solidification the warer-cement ratio changes, then for ΔR a simple exponential dependance of type (3.9) will not be obtained.

In fact, if we denominate $Ц/B = x$, we shall get utilising (3.6) and (3.7) the following equation:

$$R = R_k\frac{x(\alpha + x)}{x_k(\alpha + x_k)}(1 - e^{-kt}) \tag{3.10}$$

From here

$$\Delta R = R_k\left[1 - \frac{x(\alpha + x)}{X_k(\alpha + x_k)}(1 - e^{-kt})\right] \tag{3.11}$$

From this relation we can establish the connection between x_0 and t_0 corresponding to relative extremes: on the strength curve $R(t)$. The knowledge of this connection is very important as with its help we can determine beforehand the moment in time during which it is necessary to introduce the corresponding intensification of the process (vibration, ultrasonic processing of concrete mixtures and so on) to eliminate the time loss of strength of concrete. We shall analyse the presence of the said connection only for a simpliest case.

Let us take the variation $\delta R = 0$ for variables x and t. Utilising (3.10) we get:

$$(\alpha + 2x_0)(1 - e^{-kt})\delta x + kx_0(\alpha + x_0)e^{-kt}\delta t = 0 \qquad (3.12)$$

From here

$$\frac{\delta x}{\delta t} = \frac{kx_0(\alpha + x_0)}{\alpha + 2x_0}\left(\frac{1}{1 - e^{kt_0}}\right) \qquad (3.13)$$

As by time the surface of the binder for a range of concrete mixtures increases linearly, so supposing we get:

$$\mu = \frac{kx_0(\alpha + x_0)}{\alpha + 2x_0}\left(\frac{1}{1 - e^{kt_0}}\right) \qquad (3.14)$$

From here

$$t_0 = \frac{1}{k}\ln\left[1 - \frac{kx_0(\alpha + x_0)}{\mu(\alpha + 2x_0)}\right] \qquad (3.15)$$

Considering that $\mu = \frac{x}{t} = \frac{x_0}{t_0} = \frac{x_k}{t_k}$ we re-write this expression in the form:

$$t_0 = \frac{1}{k}\ln\left[1 - \frac{kt_k\left[\alpha\frac{t_0}{t_k} + xk\left(\frac{t_0}{t_k}\right)^2\right]}{\alpha + 2x_k\frac{t_0}{t_k}}\right] \qquad (3.16)$$

Thus we have got a transcendent equation to determine t_0. If the curve of increase of strength is monotonous, that is, does not include relative extremes, then $t_0 = t_k$ and the expression (3.16) can be utilised to determine the constant α:

$$\alpha = x_k\left[1 + \frac{e^{kt_k} - 1}{e^{kt_k} - 1 + tk_k}\right] \qquad (3.17)$$

At $t_k \to \infty$ from (3.16) we obtain the following expression to determine t_0:

$$kt_0 = \ln(1 - kt_0) \qquad (3.18)$$

The solution of this equation (besides the above given) is the only one: $t_0 = 0$. From here follows, that at a linear change x the curve $R(t)$ increases monotonously. The change on monotonous character is thus determined by a change of x from linear interrelation $x = \mu t$, or from the interrelation $x = x_k$.

To find t_0 in a case of more complicated dependance $x(t)$ it is necessary to analyse the original products in the process of solidification of concrete.

This analysis can be done with the help of X-ray study of the solidifying dough.

The Concrete Age

With the help of the formula (3.8) it is possible to introduce the necessary notion of concrete age in the theory and practice of binders technology. In accordance with (30, 31) the concrete age is determined by a number equal to product of age by the temperature of solidification. If we consider the concrete age from the point of view of its approaching to a certain utmost state, then the most convenient property to determine the concrete age is the value ΔR. Let ΔR_{tn} and ΔR_t correspond some standard deviation and current deviation of strength. Generally $\Delta R \to 0$ at $t \to \infty$. However the state of $\Delta R = 0$ as a result of inevitable errors of measuring and smallness of ΔR will appear far more early. So we can consider the end of the process as some moment of time t_n, and the value corresponding to ΔR_{tn} we may consider as a standard value for the given type of binder and concrete. Then taking the concrete age in the form:

$$\mathscr{Z} = \frac{\Delta R_{tn}}{\Delta R_t} = e^{k(t_n - t)} \qquad (3.19)$$

we see, that the age of concrete is evaluated in parts of 1 and can not exceed it: $0 \leq \mathscr{Z} \leq 1$. From the last expression it is possible to calculate beforehand the time left to concrete to reach the full ripeness, if we have beforehand the admissible value of age $\mathscr{Z}_g$:

$$\Delta t_g = -\frac{1}{k}\ln \mathscr{Z}_g. \qquad (3.20)$$

In case if the solidification of concrete occurs at different temperature conditions the value k will be variable and to determine the concrete age (ripeness) it is necessary to use statistical methods.

Let $\bar{k}$ be the mean value of the "constant" of the process of solidification of concrete. Then the age may be introduced for each period of time within the limits of which k_i is constant according to the formula:

$$\mathscr{Z}_i = \frac{\Delta R_{tn}}{\Delta R_{ti}} = e^{-kt_n + (kt)_i} \qquad (3.21)$$

From here we may get the age of concrete as an arithmetic mean from the values of ripeness for each period:

$$\mathscr{Z} \approx \bar{\mathscr{Z}} = \frac{1}{n}\sum_{i=1}^{n}\mathscr{Z}_i = \frac{e^{-kt_n}}{n}\sum_{i=1}^{n}l^{(kt)_i} \qquad (3.22)$$

Using this expression it is possible to obtain the expression for some mean value of time left to reach the total ripeness at some mean value of ripeness given beforehand:

$$\bar{\mathscr{Z}}_g \approx \mathscr{Z}_g;\ \Delta\bar{t}_g = -\frac{1}{k}\ln \bar{\mathscr{Z}}_g$$

In comparison with in (30, 31) introduced term of age (ripeness), the term age, given by us, is somewhat absolute (28) and includes a certain physical sense. Using (3.2) it is possible to write the following generalised expression for concrete age:

$$\bar{\mathscr{Z}} = l^{-kt_n} \sum_{i=1}^{n} \frac{1}{1 - \frac{x_i(\alpha + x_i)}{x_n(\alpha + x_n)}(1 - e^{-(\bar{k}t)_i})} \quad (3.23)$$

where $x_i(t)$ is known function for the given type of concrete. Finally, it should be said that we have calculated the approximated value of $\alpha \approx 2x_k$ in the given work, and have noted the uncertainties for the expression (3.9), and also the reasons for temporary loss of strength of concrete. We have proposed universal expressions for determination of concrete age.

Diffusion Mechanism to Determine the Functions of Distribution of Particles by Size and the Solution of the Main Problem of the Theory of Strength.

As it is known the statistical theories of strength of Veibull, Kontorova and Frenkel give the possibility to explain the difference between the theoretical strengths of crystal grids of substances and their technical strengths.

However these theories have some important disadvantages, namely that they use some original formulae without serious physical basements.

Thus, in accordance with the most strictly phyisical-based physically theory of Kontorova and Frenkel (32) the mean value of strength F_{xp} is calculated from the expression:

$$\frac{\partial P(F_{xp})}{\partial F_{xp}} = \frac{\bar{n}V[P(F_{xp})]^2}{\int_{F_{xp}}^{\infty} P(F)dF}, \quad (7)$$

where $\bar{n}$ is the mean number of defects in the unit of the volume of the sample, V is the acting volume of the sample, P(F) is the function of distribution of defects by their danger in the sense of strength. In their works Kontorova and Frenkel used the normal law of distribution for the function of danger. This leads to some false conclusions from the theory in general. Chechulin (33) used the function of distribution of Pearson of the third type as the function of danger, although there is no physical basement for such utilization either. It is evident that the function of distribution of the defects by their danger for strength must correlate with the function of pores distribution or of cracks by sizes. In fact if some samples are made which have certain definite sizes of pores (or cracks), it is quite evident that the sample having more defects will be less strong.

The utilization of asymptotic functions of distribution of particles (or pores) by size, formed as a result of a continued diffusion breakdown of oversaturated solutions gives the possibility to base the choice of function of danger. Besides, the utilisation of asymptotic distributions of particles by sizes gives the possibility to elaborate a theory of strength having a sufficient basing its main positions.

The problem of considering the functions of distribution of particles by size must be a central item of scientific technology of cements and concretes.

There are only a few works on this subject so far, as the finding of functions of distribution is connected with considerable mathematical difficulties (34).

It was proposed in the work (35) to establish the functions of distribution of particles by size with the help of data of X-ray small angle method. This is more detailed in work (2).

Conclusions

The analysis of modern physical and chemical views on the theory of solidification of mineral binders, showed that the attempts to ignore the main physical and chemical properties of binders and the attempts to elaborate a modern theory of solidification of mineral binders only on the basement of qualitative non-single interpretations of some experimental curves having a very limited information lead to false impression about the modernisation of actual views in the theory of solidification of mineral binders, and in the theory of obtaining the strength of cement concrete.

Directed changes of the processes of solidification of concretes unfortunately have not so far scientifically basement. However, they can be explained (not solely, or hypothetically) only after some experimental statements.

It would be unreasonable to wish more on a present state of knowledge of these very complex phenomena. However, according to modern state of sciences, of physics, chemistry, mathematics and engineering

there are some possibilities to elaborate such theory. After all, there is a possibility to review the information contained in text books on some monomineral binders, for example, as manganese binders, the solidification processes of which are studied rather thoroughly (36).

It is also necessary that specialists of different branches of science collaborate for sake of establishment of this theory.

The critical analysis of main positions of modern physical and chemical theory of solidification of mineral binders of P. A. Rehbinder and his co-workers was necessary not because we consider their view not correct and new scientific and more adequate views must be confronted with theirs, but also because of following considerations.

Although the author published some critical remarks on main positions of the said modern physical and chemical theory of solidification of mineral binders, some foreign authors (37–39) consider these main positions to be theoretical basements of the "Russian scientific school", disregarding the fact that they are supported mainly by P. A. Rehbinder and his co-workers, (see work 38 at page 289). Proceeding with the critical analysis of the main experimental works of P. A. Rehbinder and his co-workers which are the basements of their theoretical views the said foreign authors (9, 38) give as examples contradictory experimental results, not those given and obtained by P. A. Rehbinder and his co-workers. For example, such is the position with experimental data on the change of the specific surface of the original mineral binder in the process of its solidification, and so on.

Thus the second task with which the author is confronted is to clear up the situation, which characterises the false views abroad concerning the achievements of the Soviet science and which lower the Russian scientific thought to the views of P. A. Rehbinder and his co-workers.

Some foreign and Soviet scientists share the false impression that P. A. Rehbinder and his co-workers continue the main hypothesis of Baikov (37) in their theory of solidification of mineral binders. It is a false impression and it could be easily clarified only with a single sentence from the second column of the main theoretical work of E. E. Segalova and P. A. Rehbinder (10), directed against the topochemical scheme of A. A. Baikov. This could be understood, as theoretical positions of P. A. Rehbinder and his co-workers are based on the "through-solution" mechanism of solidification of mineral binders.

In accordance with the through-solution mechanism of Le Chatellier the crystallisation of new formations occurs only from the solution.

A. A. Baikov divided the process into three periods:

1. Dissolving of the original mineral binder with the formation of an oversaturated solution as a result of that.

2. Colloidation, that is the formation by the chemical reaction on the surface of the binder of smallest particles of the final product sponsoring the formation of high oversaturations;

3. Crystallisation of amorphous gels.

These conceptions are seemed to be established in Soviet and foreign scientists. Very often the arguments for any of the conceptions are purely qualitative, while the main positions of the theory of solidification of mineral binders after A. A. Baikov (39), which are not very well known among foreign scientists, are falsely interpretated. Evidently, this happened because of publications where the Baikov's theory was denominated as a result of synthesis based on main positions of Le Chatellier and Michaelis. Such denomination is not correct, because the most valuable in the theory of A. A. Baikov is that view, in which it differs from the views of Le Chatellier and Michaelis on the scheme of solidification of mineral binders. The Baikov's theory continues the idea of Baikov about the permanent topochemical process occuring in solidification of mineral binders. This point differs it from the point of view of Le Chatellier and Michaelis.

The supporters of Le Chatellier's conception include D. Bernal (40) and other foreign scientists. In the work (40) it is stated that "the mechanism of solidification of silicates . . . confirms with the present knowledge on gypsum solutions . ." which are obtained ". . by dissolving a highly more soluble semi-hydrate $CaSO_4 \cdot 0.5H_2O$ . .". If this really occurs in this way, the author would like to see the experimental and theoretical basements of these conceptions made by D. Bernal and his colleagues.

We consider that the reference to the mechanism of solidification of gypsum is not valid, as the works of the author showed (17) that the crystals of dihydrate gypsum are formed in the system in the period before the maximum of oversaturation of the solution. In such cases, when the original substance chemically interacts with the liquid medium it is quite senseless to speak about the solubility of the substance.

Brunauer and Grinberg (9) point out that the mechanism of dissolving of the original mineral binder is not the single possible, but the topochemical process is possible too. As it was shown in the works (9, 41), the reactions on the surface are possible in the absence of the liquid phase, they occur as a result of interaction of the binder with the vapour of this phase.

Describing the "through-solution" mechanism, the authors (9) use some rather primitive standpoints. For example, at page 153 of the Russian translation of the works of the 4th International Congress on the chemistry of cement they write that the invaded into the liquid medium ions form the molecules, "the molecules form embryos, which grow up to colloidal sizes, the colloidal particles are sedimented from the solution and coagulate".

Here are the main objections to the above mentioned.

1. All the authors do not worry about the proofs of the mechanism of dissolving of original binder from the positions of thermodynamics and kinetics.

2. In the presence of oversaturated solutions do not all embryos grow. Part of them breaks down as a result of the mechanism of coalescence (after-critical particles "eat out" the pre-critical particles) during the permanently changing critical size of the particles. Thus the selection of regions of the fast formation of embryos and of crystals growth is rather artificial. The growth of crystals from dispersions occurs in the whole interval of concentrations over that one of saturation. Establishing the quantitative theory of the processes of solidification of cements without this character of the mechanism of solidification is quite impossible.

3. The coagulation process of particles is not typical at crystallisation from oversaturated solutions. Crystallisation at the presence of coalescence process leads to cohesion. This cohesive process of formation of the network of solidifying dough is well pronounced, and the more it is pronounced when the oversaturation of the solution and the time of oversaturation state of the system are larger. The mechanism of coagulation structure formation is possible only in the cases when the substances are low soluble and do not create visible oversaturations. In that case the rate of growth of crystals is very little and the diffusion collision of colloidal particles may lead to a formation of coagulation-van-der-Waals' bonds.

An illustration of the effect of van der Waals' bonds were the experiments of Chernin (43), who proved that the mixture of 100 g of well ground quartz sand (up to the specific surface 2 sq. meters) and of 20 g of water can withstand a load (when formed) up to 10 kg. This case is typical for low soluble substances.

If in slightly oversaturated solutions van der Waals' bonds are formed, then later, due to introduction of ions into the near-contact region in the oversaturated solution, there happens a lack of contacts originally possessing the van der Waals' bonds. Our electron-microscopic studies (44) proved that the character of this lack of contacts is determined by properties of the surfactant additives intoduced into the system. The more intensive this process of lack of contacts is, the more is the oversaturated solution. The typical binder for these conditions is the semi-hydrate gypsum.

The described mechanism of occurence of cohesion (chemical) bonds shows the methods for considering van der Waals and cohesion bonds from the quantitative point of view. These considerations are rather important. They admit the possibility of counter opposition of two different conceptions on the nature of bonds and about their role in the process of solidification of the binder at different steps of solidification of binders.

From the standpoint of cohesion-coalescence scheme of which the present author is a supporter, the effects of tixotropy are explained by a small quantity of cohesion bonds in the systems admitting the high solubility of reaction products and semi-products.

There is one consideration more in the work (38). "It is possible that the earliest reactions occur by means of dissolving and sedimentation, while the later hydration is controlled by diffusion and is near to the processes of solid phase type" (p. 290).

This statement contradicts the elegant experiments conducted in the work (45). They show that the products of the topochemical reaction on the grain surface of elyte cement were formed in the first minutes of interaction of the binder with water ($t = 5$ min).

As topochemical processes are thermodynamically more profitable in comparison with the processes of dissolving (as from the data of the work 46), we may consider that the local processes of dissolving in the systems may occur only in the presence of activating effect of heat emitted at topochemical reactions. This effect is the main process, the acting force of the mechanism of interaction of the binder with the liquid medium. Particularly by these by-effects and by dissolving of the products and semi-products it is possible to explain the crystallisation of new formed products beyond the limits of particles of the original binder. The alternative solution of the problem—what is the mechanism of solidification of binders—is possible only from the positions of adequate quantitative theory.

In accordance with our views based on experimental and theoretical data of the scheme of A. A. Baikov, the main, principal item is correct and it represents the motivating force of the process—that is the presence of topochemical reactions. And concerning the content of the stages, the periods of solidification, they are radically reviewed in our scheme.

Taking into consideration the material presented in

the D. Ch.'s Thesis (5) and in the paragraph I of the chapter III of the present communication it is possible to divide the mechanism of solidification of binders into three main processes:

1. Dissolving of hydrates of the products and semi-products of chemical interaction of binder with the liquid active medium.

2. Formation of crystalline products and semi-products on the surface of the binder in the period after settling of the concentration of the system, and of the utmost level of saturation, corresponding to the mean sizes of particles of new formations.

3. Process of crystallisation of new formations.

All the three above mentioned process may occur at the same periods of time.

We must detail the 3rd item of our scheme. It should be borne in mind that the process of crystallisation occurs at the expence of coalescence (distillation). The crystallisation occurs at the expence of direct intergrowth of formed crystals of new formations on the surface of original binder and the inner volume of solution. These both processes are interconnected. Mainly, at the crystallisation there happens the *selection* (thermodynamically) of more resistant, stable in the given conditions crystals of the final product as a result of dissolving of less stable particles of semi-products. As a result of this some surfaces are freed and serve as suppliers of new particles capable to intergrow to a distillation depending on defect degree and on the size. Crystallisation occurs due to a fluctuation formation of new particles on the surface of old particles containing the centers of embryo-formation. The rate of appearance of these particles is determined by the oversaturation rate of the solution and surface state of embryo-forming centers.

A. A. Baikov considered that the third period occuring in the solid phase represents the re-crystallisation of the amorphous jelly. Our X-rays graphic studies of the products of solidification of Cl-and sulphate-manganese cement, gypsum and other binders showed that the crystalline products are formed from the very beginning of interaction of the binder with the liquid medium. We stated also that at certain conditions which are not common to the processes of solidification in the products of solidification of some binders some amorphous phases can appear.

In accordance with the above presented scheme of solidification of mineral binders the main points of theory are determined. They include the compiling and solving of the equations which describe the kinetics of interaction between the liquid medium and the binder, and of equations which describe the presented mechanisms of crystallisation: coalescence, cohesion and fluctuation. The detailed study of the coalescence process makes possible to establish the distribution of particles of new formations by size at the moment of loss of flowing capacity of the mass, that is, by the moment of appearance of tixotrophically irreversible structures. While deducing the functions of distribution it is necessary to introduce corresponding corrections for fluctuation and cohesion mechanisms of particles growth. It is quite clear, that from the practical point of view very important moment of loss of tixotrophic reversible properties will be determined as by means of the total quantity of particles, as by the form of function of distribution of particles by sizes. The more shifted the maximum of this function is towards the smaller particles, the more uniformly will the particles be distributed for cohesion interaction and consequently, the more percentage of cohesion bonds will form in the unit of the volume of mass at the given moment of time.

The process of interaction of mineral binders leads to the formation of lyophilic dispersoidal systems, where the coagulation properties are pronouncedly weak, and we cannot use the rule of Schultz-Hardy in connection with them. Having such a low specific weight, we see that coagulation is governed by processes which correspond to the third item of our scheme of solidification of mineral binders. The study of these problems will contribute to the possibility of controlling the processes of solidification of mineral binders to obtain the desired properties of the products of their solidification. To these questions, to the main points of the theory of solidification of mineral binders predicting some prospective discoveries in the future is dedicated the D. Ch.'s thesis of the author (5).

In the present paper some details are considered. They include the cohesion-coalescence mechanism of solidification of mineral binders proposed by the author (5). Thus we see that our approach to the development of the theory of strength of concrete, being substantially semi-phenomenological, leads us to theoretical basement of well known empirical equations, which connect the strength of concrete with the water-cement ratio. As a result of our theoretical studies it became possible to clear up the physical sense of the parameters, which are part of these equations, and to establish the limits of utilization of the said equations. We consider that the establishment of the theory of solidification and of strength is an infinite process. But we show the way and we consider it right as it conforms to the experiment and has no controversies in itself.

Supplementary Paper III-125 Electron Microscopic Investigations about the Relations between Structure and Strength of Hardened Cement

Wermer Richartz*

Synopsis

Electron microscopic investigations show that the hardening of cement may be classified in three stages.

Calcium hydroxide and ettringite are formed a short time after the addition of water. The first stage of hydration is finished after nearly one hour, as to that moment it is firstly possible to indicate that the calcium silicate hydrates are decisive to the development of strength.

The second stage of hydration takes about 24 hours. During this time the calcium silicate hydrates and the ettringite formed to relative long fibres or needles, may grow into the big pores of the labile basic structure. In the second stage of hydration it is established a structure which is decisive to the further development of the strength.

In the third stage of hydration the pores, still existing, will be filled up by the arising products of hydration and the structure will be consequently more compact. If the cement hardens at low temperature or under the influence of a retarder, in the second stage of hydration the calcium silicate hydrates may grow to longer fibres. Consequently the final strength can increase for 20%.

If the hydration is accelerated, less long fibrous calcium silicate hydrates are formed. In this case the final strength is lower than at normal hardening.

Calcium silicate hydrates have a small characteristic strength because of their high structural disorder. But still, they are the principal strength forming phases of the hardened cement. Foreign fibres of inorganic or organic materials may only increase the strength of the hardened cement, if the adherence to the hydration products is ensured.

Introduction

The structure of the hardened cement formed by hydration consists mainly of 4 crystalline phases. The calcium silicate hydrates are the most important constituents. They are formed by hydration of alite and β–C_2S and mainly consist of fibrous crystals which have a very small degree of structural order. The length of the fibrous crystals is about 1 μm, the diameter of the fibre varies between 50 Å and 1000 Å (0.005 and 0.1 μm).

The ettringite crystallizes in long acicular crystals as a product of the reaction of C_3A and C_4AF with gypsum. Ettringite and calcium hydroxide are the first hydration products which are formed immediately after the addition of the mixing water. Later on the ettringite can convert into monosulfate and calcium sulfate during the advanced hardening process. It is doubtful whether this phase with its low stability can give a significant contribution to a stable structure of the hardened cement.

Calcium hydroxide and calcium aluminate hydrate both crystallize in hexagonal-tabular form. Their contribution to the total strength of the hardened cement is quite small; therefore, they are no longer discussed.

The pores are also a quite important fact in the structure of hardened cement. The structural composition and the process of hardening can also be understood as an alteration of the pore space. The strength mainly depends on how the pores are bridged; according to this the investigations about the structure of the hardened cement has to be concentrated on the pores.

For the electron microscopic investigation the cement paste was filled into a glass- or plastic-tube. The water cement ratio was in the range between 0.40 and 0.45. The tube then was hermetically sealed. After a hydration time of at least 1 day, the tube was broken. From the very plain boudary surface of the hardened cement, carbon replicas were taken

*Forschungsinstitut der Zementindustrie, Düsseldorf, West Germany.

which reproduce fine details of the structure in the pores. Here the hydration took place undisturbed, and hence the walls of the pores reproduce the real structure of the hardened paste.

Most of the investigations were made with pastes of C_3S to facilitate the identification of the constituents of the structure.

Structure Development of Hardened Paste

Fig. 1 shows a pore of hydrated C_3S-paste, into which fibrous crystals of calcium silicate hydrate grow from all directions. Several parts of the pore are already bridged by long firbous calcium silicate hydrates. Inside the pore most of the calcium silicate hydrates can grow unhindered, because there is still enough space. The upper and the lower edge of the pore are connected by a few calcium silicate hydrate fibres only. That means, inside the pore the development of the structure is in an early stage. But in the lower part of the figure the structure consists of closely packed calcium silicate hydrates and has already reached the final stage of hydration.

Fig. 2 shows an originally larger pore in a 3-days-hydrated C_3S-paste. The pore is filled with interlocking fibrous crystals of calcium silicate hydrate. Several long fibres bridge the whole pore space, in the remaining very small pores grow short crystals only. Hence it follows that hydration starts with the crystallization of long fibres, which bridge the big pores originally filled out by mixing water. Consequently the big pores become subdivided into several smaller pores and the total pore volume has decreased. The smaller the pores, the shorter the calcium silicate hydrate fibres crystallizing during the further steps of hydration. This results in a condensing of the paste structure.

Fig. 3 shows the stage of C_3S-hydration after 90 days. It reveals a highly condensed structure, which consists of fine pores and short-fibrous calcium silicate hydrates only. The long fibres were covered during the hardening by the fine granular hydration products, and thus they cannot be detected.

The electron micrographs (Figs. 1–3) show the

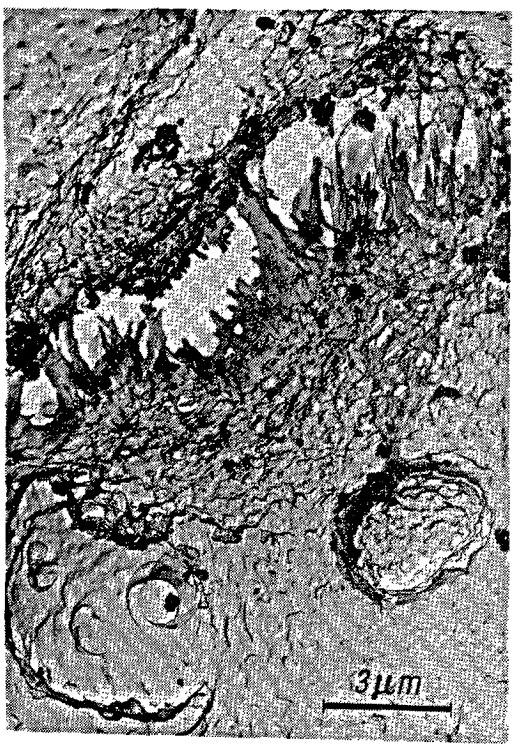

Fig. 1. *Electron micrograph of a* C_3S*-paste hardened 3 days* w/c = *0.44 (carbon replica)*

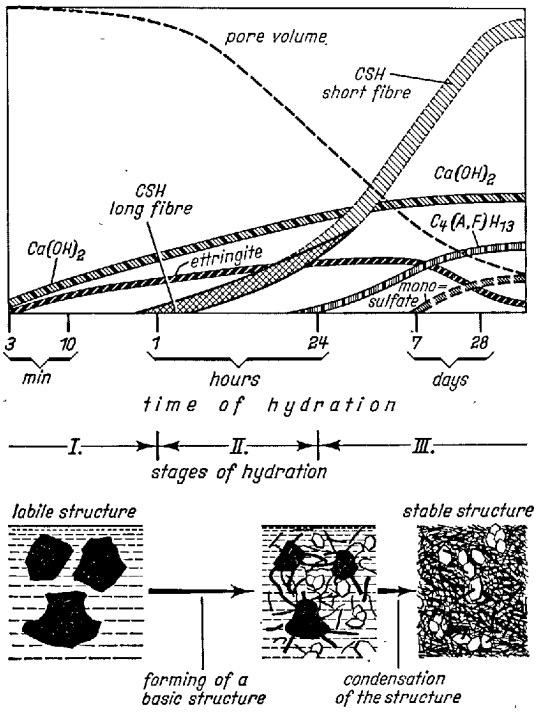

Fig. 4. *Formation of the hydrate phases and constitution of the structure during the hardening of the cement*

relations between the development of structure and strength of hardened cement. Simplifying this, they reveal the structural composition of a paste which consists of calcium silicate hydrates only. During hydration of cement, however, other hydration products,i.e., ettringite, monosulfate and tetracalcium aluminate hydrate are formed, not simultaneously but successively. Consequently, the whole process of hydration can be classified in 3 stages (Fig. 4). The first stage of hydration is designated by the formation of $Ca(OH)_2$ and ettringite, which can already be detected by electron microscope after 3 to 5 minutes. Ettringite grows on the surface of the cement grains, and calcium hydroxide crystallizes from the solution as thin plates. The second stage of hydration starts after about 1 hour. At this time the first formation of calcium silicate hydrates in at first very fine crystals can be identified. By this moment the volumes of the cement particles have not distinctly decreased, because only a thin surface layer has reacted. The interspace between the cement grains has still nearly the same size as at the beginning of the hydration. Consequently the calcium silicate hydrates grow to be long interlocking fibres. After the complete hydration such long fibres will act as a microreinforcement of the structure of hardened cement and will increase the ultimate strength. At the end of the second stage of hydration after about 24 hours, the formation of ettringite is finished as all gypsum has reacted. At this moment the structure mainly consists of long interlocked fibrous calcium silicate hydrates which bridge a condiderable part of the originally water filled space.

During the third stage of hydration from about 24 hours up to the end of the reaction the still remaining pores are filled out by new hydration products as described above. During this stage of hydration tetracalcium aluminate ferrite hydrate $C_4(A, F)H_{13}$ is formed instead of ettringite, and the ettringite can be converted into monosulfate. Therefore, its contribution to the total strength is doubtful but, in any case, it influences the setting of cement and the early strength.

Influences on the Structure of Hardened Paste

Retarded Hardening

K. Walz and J. Bonzel (1) report that the process of hardening is distinctly retarded at low temperatures of hydration, and that nearly always a higher ulitmate strength is reached. This can be explained in the following way:

Because of the reduced rate of reaction the different stages of hydration, especially, the second stage are extended. Consequently, in the second stage of hydration, more long-fibrous calcium silicate hydrates are formed. This influence of the temperature on the morphology of the calcium silicate hydrates was already reported in an earlier publication (2).

The hydration being retarded by chemical additions the structual constitution is influenced in the same way as afore mentioned. Fig. 5 shows an electron micrograph of C_3S-paste, which hardened 7 days efficaciously retarded. Fibres of calcium silicate hydrate are formed 10 μm long, several fibres have lengths up to 30 μm.

According to this distinctly changed structual constitution which is developed by the influence of a retarder, the final strengths were up to 20% higher than those of normally hardened cement paste. These investigations confirm and explain the results of measurements of K. Walz and H. Mathieu (3) who found that by addition of retarders always significantly higher final strengths result although the early strength is decreased.

The reaction inhibiting effect of retarders remains still today incompletely settled. A logical assumption is that the surface of the cement grains are blocked up by the retarding additions and so the cement reacts slower.

Accelerated Hardening

An accelerating of the reaction can be caused either by a higher fineness, higher temperature or addition of an accelerator. If an accelerator is added, the surface of the cement grains obviously is activated, so that the solution in the pores is always supersaturated. Hence the conditions for spontaneous nucleus formation and increased crystal growth are given. So

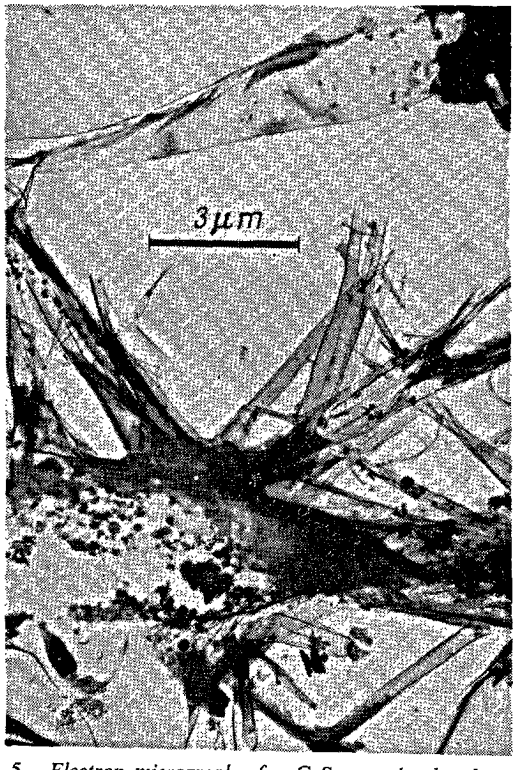

Fig. 5. *Electron micrograph of a C_3S-paste hardened 7 days with addition of a retarder* w/c = *0.44 (carbon replica)*

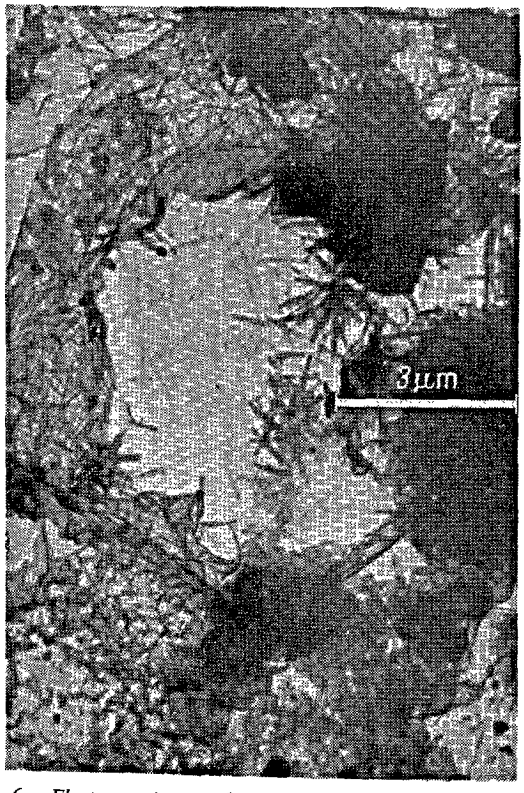

Fig. 6. *Electron micrograph of a C_3S-paste hardened 7 days with addition of an accelerator* w/c = *0.44 (carbon replica)*

only a few crystals can grow to be long fibres also in the second stage of hydration, although at this time there were space enough for the formation of long fibrous crystals. So, by the influence of an accelerator a structure with more short fibrous crystals is formed than by hydration under normal or retarding conditions as shown in Fig. 6.

The strength of the hardened paste after one day is distinctly higher as compared with a paste without accelerator because a higher degree of hydration is reached. Also, after a 7-days-hardening only a few calcium silicate hydrate crystals with a fibre length of more than 1 μm are formed.

The strength development of a cement without addition, with an accelerator and with a retarder is given in Fig. 7. The accelerated cement yields the highest initial strength because of the higher degree of hydration. After about 28 days the final strength is reached. The normally hardened cement shows a significant lower initial strength, but after 28 days it reaches approximately the strength of the accelerated cement and exceeds it during the further hardening.

The retarded cement gets a low initial strength. But after 28 days it reaches and after 90 days it exceeds the strengths of normal and accelerated cements.

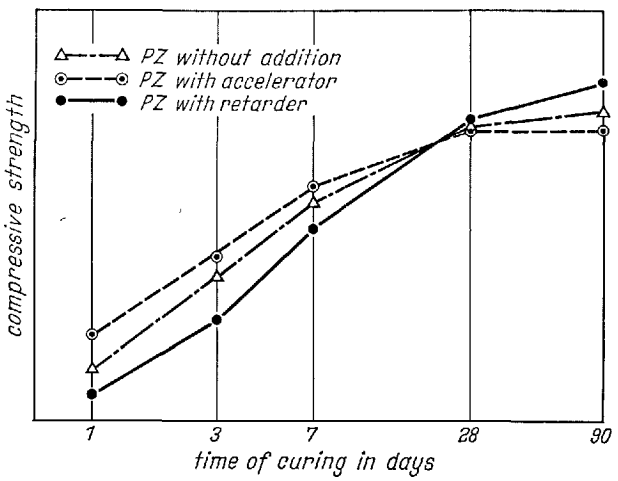

Fig. 7. *Development of strength of a normal, a retarded and an accelerated hardening*

These results show that a strict relationship exists between the development of the structure and of the strength. High initial strength is caused by a high degree of reaction, high final strength by a close packing and a significant part of fairly long calcium silicate hydrate fibres.

High Initial and Final Strength

If it is possible to get quickly a larger quantity of long fibrous crystals in the early stages of hydration, even a cement with a usual fineness can reach as well high initial as final strengths. A mixture of 75% C_3S and 25% tricalcium germanate (C_3G) is a model cement according to this condition. After one day the C_3G portion has nearly completely reacted. This is characteristic for an accelerated hardening. In spite of the high rate of reaction, the hydration products are long-fibrous interlocking crystals of calcium germanate hydrate (2). So, the conditions for a high final strength are satisfied. The subsequent hydration of C_3S supplies the mass of short-fibrous calcium silicate hydrates which fills out the space between the calcium germanate hydrate crystals forming the basic structure. Fig. 8 concerning a micrograph of the hardened paste of this germanate cement shows the long-fibrous crystals after one day of hydration.

The strength development of this mixture and of pure C_3S is given in Fig. 9. Special attention is called to the fact that strength of the mixture C_3S–C_3G after 1 day of hardening is about the same as the strength of pure C_3S after 28 days. After 28 days the strength of the mixture is still 20% higher than the corresponding strength of pure C_3S.

The example shows that the formation of long fibrous crystals during the second stage of hydration significantly raises the final strength, and that a high hydration activity increases the initial strength.

Fig. 8. *Electron micrograph of a* C_3S–C_3G*-paste hardened 1 day* w/c = *0.50 (carbon replica)* C_3G = *tricalcium germanate* = $3CaO \cdot GeO_2$

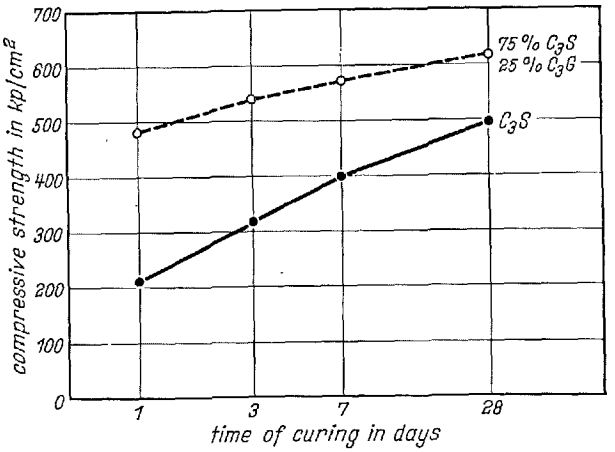

Fig. 9. *Development of strength of* C_3S *and of a mixture of* C_3S–C_3G, C_3G = *tricalcium germanate* = $3CaO \cdot GeO_2$

Reinforcing of Paste by Fibres

The favorable effect of long fibres on the strength suggests to examine the effect of fibres added to the cement as a micro reinforcement. Nylon threads with a diameter of 0.25 mm and 0.6 mm and a length between 5 and 10 mm were used as fibres. They were mixed with a portland cement in a quantity of 1% 3% and 5% by weight. The measured strengths are given in Fig. 10. It reveals that additions from 1 to 3% results in a higher strength at all ages. Additions of 5% on the other hand diminish the strength probably because of the difficulty to get a homogenous mixture with higher contents of fibres. The increase of the strength by addition of 1 and 3% of nylon threads was fairly small and did not fulfil the expectations.

The small effect of reinforcement of the paste by nylon threads is attributed to the poor adherence to the paste. But also with alkali resistant borosilicate glass fibres no better adherence was obtained.

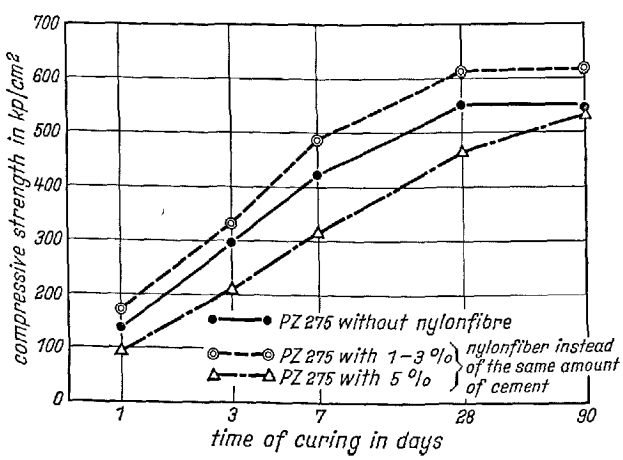

Fig. 10. *Compressive strength of cement mortar with various additions of nylon threads*

Adherence of Hydration Products in the Hardened Paste

Calcium silicate hydrates formed by cement hydration have a high degree of structural disorder. So, a single calcium silicate hydrate crystal has a comparatively low characteristic strength. On the other hand, the adherence of the calcium silicate hydrates with each other and with other hydrate phases is very strong. This is demonstrated by the electron micrographs of Fig. 11–13. They show replicas of C_3S and cement pastes, prepared with retarders and hardened 7 or 28 days. Fig. 11 shows a network-like arrangement of calcium silicate hydrates. All the fibres bridging the pore are connected with each other. The shadow of all fibres in the background indicates that the represented object is not a defect of the foil. Similarly the micrographs of Fig. 12 and 13 show the bridging effect and the adherence of the calcium silicate hydrate fibres. The fibres are strongly branched and form new cross connections between the bigger fibres and the walls of the pores. Besides it is probable that the joint between the fibres is improved by bristly calcium silicate hydrate crystals which are grown in similar orientation on the surfaces of the bigger crystals.

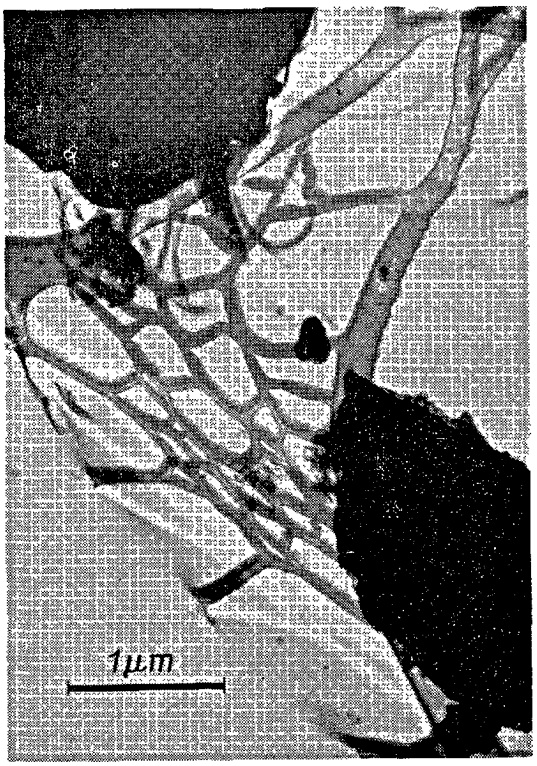

Fig. 13. *Electron micrograph of a blastfurnace slag cement paste hardened 28 days* w/c = *0.45 (carbon replica)*

Flexibility of Calcium Silicate Hydrate Fibres

Calcium silicate hydrates do not crystallize in form of rigid needles, they rather show the character of threads and a high flexibility. Fig. 14 shows calcium silicate hydrates formed by hydration of C_3S in presence of excessive water. The fibres are highly flexible. But during the microscopic investigation the calcium silicate hydrate fibres are exposed in this case to the alternating effect of the electron beam in contrast to the investigation mentioned before. For that reason it is not sure whether a more or less destruction of the structure has effected a deformation of the calcium silicate hydrates and simulates a flexibility. But the electron micrographs taken with the replica method indicate the same flexibility (Figs. 15–17).

When the hardened paste is broken, the calcium silicate hydrate fibres tear up. In the zone near the fracture the fibres orient themselves into the direction of the breaking stress owing to their flexibility. This is shown by the Figs. 18 and 19 which represent micrographs of the fracture surfaces of hardened cement paste. It is to be recognized that the ends of the torn calcium silicate hydrate fibres protrude out of the surface of the paste and have about the same orientation.

(B) Papers regarding Application

Supplementary Paper III-1 Comparison of Various Measurements Concerning the Kinetics of Hydration of Portland Cements

Sandor Popovics*

Synopsis

The use of a simple cement model for the description of the kinetics of hydration of portland cement is the subject of this paper.

Following the general description of the proposed model, its application for the strength development is shown. Then, the kinetics of the developments of non-evaporable water content and vapor sorption of the hardening portland cement paste are investigated by using the cement model again. Calculated values are compared to pertinent experimental data. The similarities and dissimilarities of the kinetics of various hydration characteristics are also discussed. Finally, the model is applied to demonstrate the effect of temperature on the strength development of portland cement concretes.

Introduction

A simple model was recommended recently for the descritption of the hardening of portland cement paste, mortar, or concrete in terms of the compound composition of the cement and the age of the strength specimen (1). Strength values provided by that model were shown to be in a reasonable agreement with experimental data. In this paper, an attempt is made to develop similar models for two other characteristics of the hydration process, namely, the vapor sorption and non-evaporable water content of the hardened cement pastes. These models can be used conveniently for the comparison of strength, sorption, and other measurements connected with the kinetics of hydration of portland cements. It will also be shown that the model is suitable for the description of the effect of temperature on the hardening process.

A pertinent speculation of Philleo will conclude this introduction. He says, it can be shown from purely geometric considerations that for a given degree of hydration the standard deviation of hydration rate at various points is approximately proportional to the hydration rate (2).

General Description of the Model

The mathematical form of the model developed for strength is [1]:

$$f_{rel} = 100\frac{1 - pe^{-a_1 t} - (1-p)e^{-a_2 t}}{1 - pe^{-28a_1} - (1-p)e^{-28a_2}} \qquad [1]$$

where

f_{rel} = relative strength of portland cement paste, mortar or concrete, that is, the ratio of the strength at a certain t age and the 28-day strength, percent,

t = age of the strength specimen, day,

p = computed C_3S content of the portland cement, percent/100, and

a_1 and a_2 = parameters which are independent of the strength and age, but may be a function of the fineness and composition of the cement, curing and testing methods, etc.

This cement model satisfies the following conditions:

1. It consists of only two hardening components. The first component is the C_3S, the second component is a mixture of the other cement ingredients.

*Department of Civil Engineering, Auburn University, Alabama, U.S.A.

2. These two components hydrate simultaneously with differing rates but without any interaction. Thus, their resulting strengths can be superimposed.

3. The final strength of C_3S is the same as the final strength of the second component.

4. The decelerations of the hardening of both the C_3S and the second component are proportional at a given age to the remaining strength development at that time, but the two proportionality factors are different.

5. The proportionality factors may be functions of the C_3A content.

Thus, it is apparent that this model is a simplification of an actual portland cement; that is, in accordance with the technical meaning of the term "model" (3), it resembles a portland cement in several but not in all respects. The a parameters in Equation [1] represent the specific rates of hardening, that is, (rate of hardening)/(remaining strength at a given age). The squares of these parameters represent the specific decelerations of hardening. The a_1 parameter characterizes the early strength development, while the a_2 parameter characterizes the strength development at later ages. More specifically, the greater the value of a_1, the higher the early strengths will be as compared to the 28-day strength; and the smaller is the value of a_2 up to a certain limit, the longer and larger will be the relative strength increase after 28 days. Thus, these parameters can be used for the description of the kinetics of hardening of various portland cements.

Equation [1] is not the first attempt to establish a quantitative relationship between compound composition of cement and strength development. The previous attempts are based on the assumption that each cement compound contributes strength at a given age in proportion to the percentage of that compound present [(4) through (9)]. The mathematical form of this assumption for the four main compounds is as follows:

$$\text{Strength} = a(C_3S) + b(C_2S) + c(C_3A) + d(C_4AF) \quad [2]$$

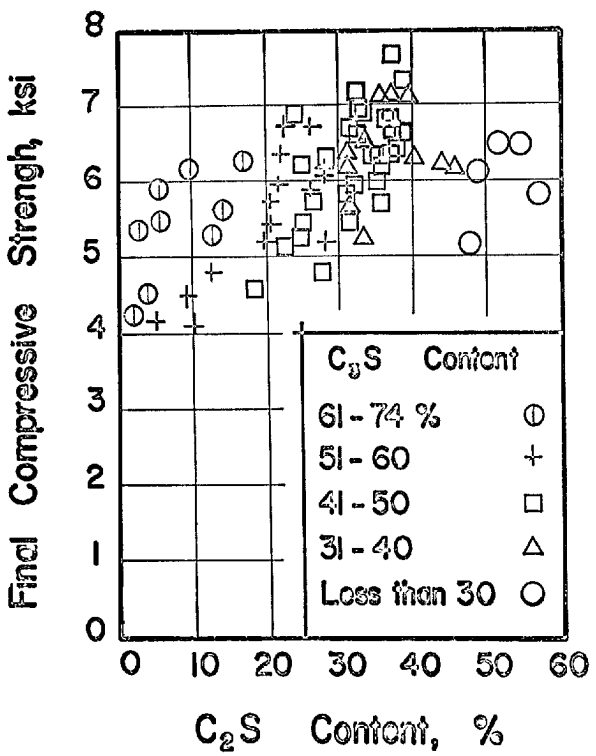

Fig. 1. *Final compressive strengths of 1: 2.75 mortars made with various portland cements as a function of the compound composition. The values are based on data published by Gonnerman (9). I*

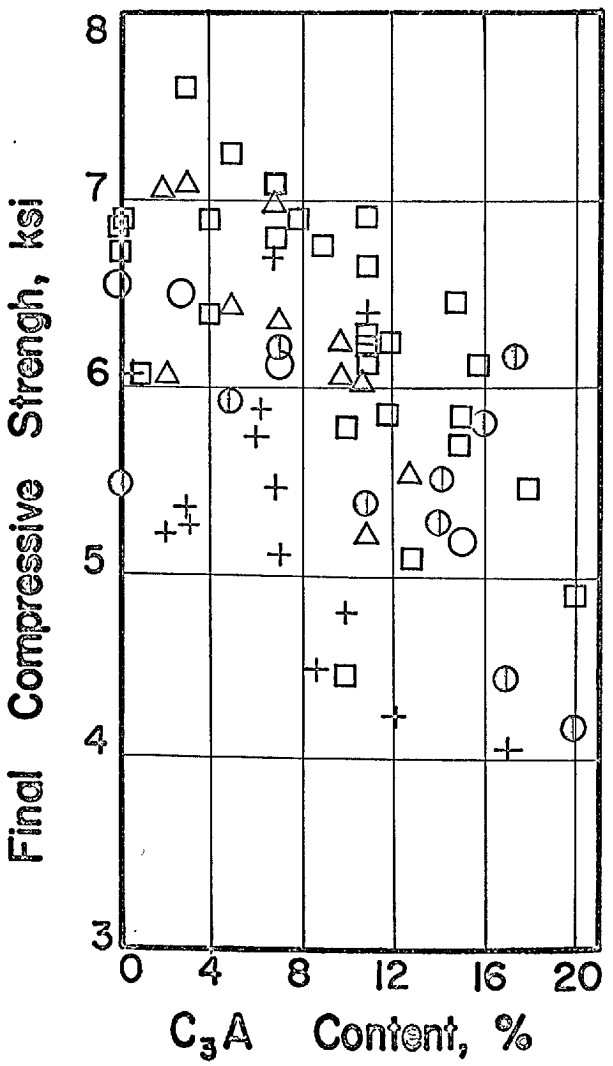

Fig. 2. *Final compressive strengths of 1: 2.75 mortars made with various portland cements as a function of the compound composition. The values are based on data published by Gonnerman (9). II. The symbols are the same as in Fig. 1*

where the symbols in parentheses represent the percentage by weight of the compound, and a, b, c, and d are empirical parameters representing the contribution of one percent of the corresponding compound to the strength of the hardened mixture at a given age.

Experimental data obtained by Gonnerman with Ottawa-sand mortars (9) showed reasonably satisfactory agreement with Equation [2]. Nevertheless, the linear model is objectionable for several reasons. First, the number of the empirical parameters is high, four for each age group. Another reason is that variations in burning and cooling condition, as well as differences in the mineralogical composition of the raw materials used in cement making, may affect the hardening process of cement (10). Therefore, without the consideration of these factors, one cannot expect a good correlation between the compound composition and strength of cement (Figs. 1 and 2). Finally, experimental evidence indicates that the hydration process of various clinker minerals, especially the calcium silicates and aluminum silicate, may interact with each other (8, 11, 12, 13). Thus, the simple superposition of the compound strengths is objectionable in principle. The cement model represented by Equation [1] eliminates some of these objections.

Application of the Model for the Strength Development

It has been demonstrated (1) that experimental results obtained by various investigators support fairly well the applicability of Equation [1]. By computing an average deviation between the calculated and experimental values (14), it was found to be less than 10 per cent.

It has also been shown that the values of a_1 and a_2 may be functions of the potential C_3A content of the portland cement (1). For instance, Table 1 presents a_1 and a_2 values for various cases that were obtained from pertinent experimental results (15) by the method of least squares. Fig. 3 illustrates how the model reproduces the effect of the C_3A content on the rela-

Table 1. *Specific rates of hardening for mortars and concretes tested by Klieger*

Type of test	w/c by weight (approx.)	a_1, 1/day	a_2, 1/day
Tensile strength of mortar (ASTM C 190-49)		0.80	$0.02C_3A$
Compressive strength of mortar (ASTM C 109-49)		0.20	$0.005C_3A$
Flexural strength of mortar		0.45	$0.01C_3A$
Compressive strength of concrete, 6 bags/cu yd	0.43	0.40	$0.002C_3A + 0.02$
Flexural strength of concrete, 6 bags/cu yd	0.43	0.55	$0.001C_3A + 0.02$
Compressive strength of concrete, 4½ bags/cu yd	0.54	0.30	$0.005C_3A$
Flexural strength of concrete, 4½ bags/cu yd	0.54	0.5	$0.005C_3A$
Compressive strength of concrete, 3 bags/cu yd	0.80	0.15	$0.003C_3A$
Flexural strength of concrete, 3 bags/cu yd	0.80	0.25	$0.004C_3A$

Note: C_3A designates the percent of the potential tricalcium silicate content of the portland cement computed according to the Bogue method. (16)

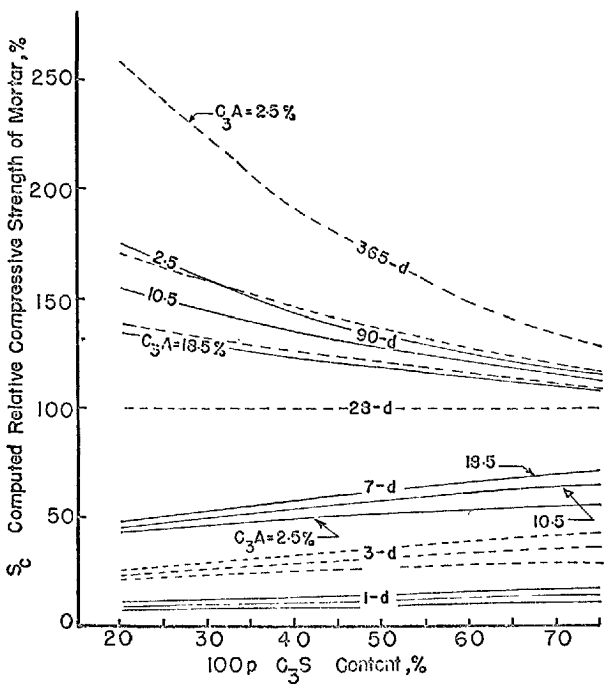

Fig. 3. *Effect of the* C_3A *content on the relative compressive strength of 1: 2.75 mortars at various ages. (1)*

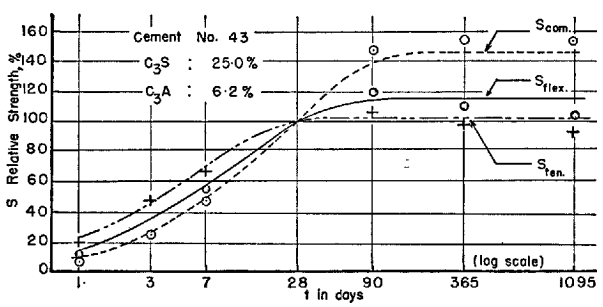

Fig. 4. *Comparison of experimental and computed values to illustrate the effect of test method on the kinetics of the hardening of portland cement in mortars. Experimental values are represented by points, computed values by lines. (1)*

tive compressive strength of 1:2.75 mortars tested by Gonnerman (9) at various ages.

A group of calculated values and experimental results is presented in Fig. 4. Here the relative values of tensile strength, compressive strength, and flexural strength of mortars made with the same cement are plotted as a function of age. Points represent the experimental values, and lines designate the values calculated by Equation [1] with the appropriate values of a_1 and a_2 of Table 1 (1). It can be seen that the rate of increase in the relative tensile strength of a portland cement is much higher than the rate of increase in the relative compressive strength, but the deceleration of the development of tensile strength is also stronger.

A comparison of the a values for concretes of two different cement contents reveals that the development of relative strength is quicker and the deceleration is stronger for higher cement contents and for lower water-cement ratios, other factors being equal.

Application of the Model for Non-Evaporable Water Content and Vapor Sorption

The applicability of this model concept to other characteristics of the hydration of portland cement may be questioned. Two such characteristics will be discussed here (as indicated in the title above). Investigations concerning a third characteristic, the heat of hydration, are in progress.

To answer the question raised above, experimental results of such portland cements should be analyzed where the compound composition is the sole variable; that is, where the fineness and gypsum content of the cements, curing and testing methods, etc. are practically identical. Such a test series was performed by Verbeck and Foster where the non-evaporable water contents and vapor sorptions of various Types I, II, IV, and V portland cements were measured up to the age of $6\frac{1}{2}$ years (17). Their results obtained with Type III cements are not applicable here because of the differing fineness of these cements.

Several attempts revealed that a better goodness of fit can be obtained for the experimental values of non-evaporable water content when the third condition of the model is modified. It seems suitable to apply the modification that the C_3S is capable of withholding three times as much non-evaporable water as the second component. The mathematical form of this modified cement model is the following:

$$w^0_{rel} = 100\frac{1 + 2p - 3pe^{-a_1 t} - (1-p)e^{-a_2 t}}{1 + 2p - 3pe^{-28a_1} - (1-p)e^{-28a_2}} \quad [3]$$

where

w^0_{rel} = relative non-evaporable water content of portland cement paste, percent of the 28-day non-evaporable water content.

The other symbols of Equation [3] are the same as the symbols of Equation [1].

A stepwise approximation provides the following a values for Equation (3) and the experimental values by Verbeck and Foster (17):

$$a_1 = 0.01C_3A + 0.25, \text{ 1/day} \quad [4]$$

$$a_2 = 0.0005C_3A + 0.010, \text{ 1/day} \quad [5]$$

where C_3A is again the percent of the potential tricalcium aluminate content of the portland cement computed according to the Bogue method (16).

The thus calculated and measured values are summarized in Table 2. The first digit of the cement numbers used indicates the standard type of the cement. For instance, cement No. 14 is a Type I portland cement. It can be seen that the calculated values of the non-evaporable water contents for Type I and Type II portland cements generally approximate the experimental values quite well within the time limits of 7 days and $6\frac{1}{2}$ years. The approximation for Types IV and V is not as good.

The reasonable goodness of fit shown in Table 2 appears to indicate that the kinetics of the increase of non-evaporable water content differs from the kinetics of hardening. The main difference is that the C_3S, at least in the model, binds more non-evaporable water for a given strength than the second component. Kantro and Copeland have presented a similar tendency (18). That is, in the case of an identical amount of non-evaporable water, a portland cement with a low C_3S content is expected to provide a greater f_{rel} relative strength at early ages than a comparable cement with a high C_3S content. It should be realized, however, that regardless of the validity of this mechanism of hydration, the model represented by Equation [3] seems applicable for the estimation of the amount of non-evaporable water at various ages for a large group of portland cements.

It may be mentioned that Powers and Brownyard (19), and later Kantro and Copeland (18) have published a linear empirical formula for the non-evaporable water content versus compound composition relationship in the form of Equation [2]. Essentially the same criticism is valid for this linear model that

was previously presented concerning the linear strength model of Gonnerman.

Less successful is the attempt to apply the presented model concept to the kinetics of vapor sorption, that is, to the kinetics of the development of specific surface of hardening cement pastes. The following a

values appeared to be relatively the best with Equation [1]:

$$a_1 = 0.7 \text{ 1/day}, \quad \text{and} \quad a_2 = 0.033 \text{ 1/day} \qquad [6]$$

The values calculated with these parameters along with the corresponding values measured by Verbeck and Foster (17) are summarized in Table 3. The cements tested were the same as those presented in Table 2. It can be seen that the goodness of fit between the calculated and measured values is fairly poor. It should be pointed out, however, that at least a part of the discrepancies result from the uncertainty of the sorption measurements. For instance, cement No. 14 shows an unaccountably high vapor sorption at the age of 7 days as compared to cement No. 15, considering that both the C_3S and C_3A contents of the latter are much higher.

Despite this uncertainty, the difference between Equation [3] and Equation [1] appears to show that perhaps there is no single linear relationship between the non-evaporable water content and the corresponding vapor sorption (or strength) which is generally valid for every portland cement and every age. Certain experimental results also support this view (18, 20). Therefore, when one talks about the kinetics of hydration of portland cement, the characteristic of the hydration used (compressive strength, non-evaporable water content, etc.) should always be specified.

It should be reemphasized here that the influence of the water-cement ratio on the kinetics of hydration may be significant. This is demonstrated for strength in Table 1, and in (21). Pertinent data can also be found in the technical literautre concerning the non-evaporable water content (22), and the specific surface of the hardening cement paste (20).

It is also important that Equations [1] and [3] indicate the effect of C_3A on the kinetids of hydration in the model. Namely, they reveal that the specific rate of the hydration process is, in numerous cases, a linear function, and consequently, the specific deceleration is a quadratic function of the C_3A content with a reasonable degree of approximation. This relation is not restricted to the C_3A. It seems also applicable to many other factors that influence the hydration of portland cement, such as the fineness of cement, the curing temperature, etc. If a change in any of these factors increases the early strength by increasing the specific rate of hydration, then, simultaneously the same factor increases the deceleration of the hydration to a higher degree; thus the final strength, or at least the final relative strength, will be less. This principle is further illustrated in the next paragraph by the effect of temperature on strength.

Effect of Temperature on the Hardening

It will be shown now that the presented model concept is suitable for the demonstration of the effect of temperature on the hydration. A natural point of departure is the so-called Arrhenius equation:

$$a = A_0 e^{-Q/RT_a} \qquad [7]$$

where

a = specific rate of reaction,
Q = activation energy,
R = gas constant,
T_a = temperature, °K, and
A_0 = empirical constant.

One can obtain the following simplified form by expanding Equation [7] into a series:

$$a = A\left[B - \frac{Q}{R(273 + T)}\right] \qquad [8]$$

where

T = temperature of the mixture, °C, and
A and B = empirical constants.

The other symbols are identical with the symbols of Equation [7].

It may be assumed for this demonstration that the value of Q is independent of the temperature and is about 16,000 cal/g mol. If the usual assumption (that the hydration of portland cement ceases when the temperature is −10°C or lower) is also used, then the value of 30.4 can be computed for the B constant. The value of A is dependent on numerous factors, such as the measured characteristic of hydration, the hydrating cement component, the composition and fineness of the cement, the water-cement ratio, etc. As is shown in Table 1, the cements tested by Klieger (15), with 0.43 water-cement ratio and 23°C curing temperature, provided $a_1 = 0.40$ 1/day, and $a_2 = 0.002C_3A + 0.02$ 1/day values for the compressive strength of concrete. Thus, for this case

$$A_1 = \frac{0.40}{30.4 - 8000/296} = 0.12 \qquad [9]$$

Similarly,

$$A_2 = 0.0006C_3A + 0.006 \qquad [10]$$

Therefore, the a parameters of Equation [1] can be expressed as a function of temperature for this case

and for 10 percent C_3A content as follows:

$$a_1 = 0.12\left(30.4 - \frac{8000}{273 + T}\right) \quad [11]$$

and

$$a_2 = 0.012\left(30.4 - \frac{8000}{273 + T}\right) \quad [12]$$

A convenient way to check the extent of support given these speculations by experimental results is to apply the "maturity rule" to the formulas above. As is well known, the maturity rule states that within certain limits the effects of curing temperature and age on the strength of concrete can be expressed in terms of a single parameter given by the product of age and temperature where the temperature is reckoned from −10 °C (23, 24, 25). That is,

$$M = (T + 10)t \quad [13]$$

where

M = maturity, °C × day,
T = curing temperature of concrete, °C, and
t = age of the specimen at testing, days.

If one expresses the a_1t and a_2t parameters defined by Equations [11] and [12] in terms of maturity, the following is the result:

$$a_1t = \frac{3.6}{273 + T}M \quad [14]$$

and

$$a_2t = \frac{0.36}{273 + T}M \quad [15]$$

It can be seen that the strengths calculated by the presented cement model are dependent not only on the maturity but also on the curing temperature. However, within certain limits (e.g., 0 and 25°C), the temperature has little effect on Equations [14] and [15]. To help illustrate the temperature sensitivity of these equations, one can use the following expression for the strength development from Equation [1]:

$$f = f_0[1 - pe^{-a_1t} - (1 - p)e^{-a_2t}] \quad [16]$$

where

f_0 = compressive strength of concrete after infinitely long wet curing, and
f = compressive strength of the same concrete at the age of t.

The other symbols are identical with the symbols of Equation [1].

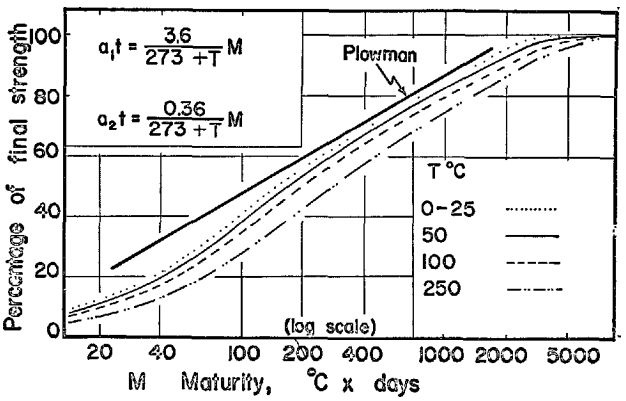

Fig. 5. *Compressive strength of concretes cured at differing temperatures as a function of maturity.*

By substituting Equations [14] and [15] into Equation [16], and introducing the $f^0_{rel} = 100f/f_0$ relative strength, the following relationship is obtained between the f^0_{rel} compressive strength of the concrete discussed and the M maturity:

$$f^0_{rel} = 100[1 - pe^{-3.6M/(273+T)} - (1 - p)e^{-0.36M/(273+T)}] \quad [17]$$

where the symbols are identical with the symbols of Equations [1] and [13].

Values of strength calculated by Equation [17] and with 50 percent C_3S content are shown in Fig. 5 for various temperatures. It can be seen that strengths related to a given maturity are lower when the curing temperature is higher. Experimental results by various authors show similar tendency (26, 27). The presented discussion of the temperature sensitivity of strength is also in accordance with a conclusion of Klieger (27), namely, that the relationship between strength and maturity is affected by the type of the cement and the composition of the concrete as well.

Fig. 5 also shows, with thick line, an empirical relationship for the effect of maturity on the relative compressive strength of concrete. This relationship was estimated from experimental data published by Plowman (28). This line also appears to support the applicability of the presented cement model for the estimation of the effect of temperature on the strength development of concrete.

Topics for Further Research

1. The approximation of the model for the hydration of Type IV and Type V portland cements at later ages is not entirely satisfactory. It is conceivable that a modification of the model would improve the ap-

proximation. For instance, the assumption of a composition for the C_3S different from the one used by Bogue, might be such a modification. Thus, further research in this direction is desirable.

2. A fundamental topic is the derivation of the form of the *a* parameters as a function of C_3A content from theoretical considerations.

3. An experimental topic is to determine the effects of fineness, temperature, mix proportion, admixtures, etc. on the numerical values of the *a* parameters.

4. An investigation is desirable concerning the cause of the differences between the kinetics of the various hydration characteristics.

5. It would be interesting to check the applicability of the model for high alumina cements.

Conclusions

1. The presented simple model concept seems applicable for the kinetics of various characteristics of hydration for a large group of portland cements.

2. The kinetics of the various hydration characteristics of a paste, (or mortar or concrete) may differ considerably. For instance, the rate and the deceleration of the development of tensile strength are much more intensive than those of the compressive strength of the same mixture. The kinetics of the non-evaporable water content, or that of the specific surface of a hardening cement paste seem also different.

3. Therefore, it is not expected that there exists a single linear relationship between any two of the discussed hydration characteristics which is valid for every age and every portland cement.

4. The presented cement model seems also suitable for the demonstration of the effect of temperature on the hydration process.

5. The goodness of fit between experimental data and values calculated by the model is reasonable enough to encourage further research for the refinement and further application of the presented model concept.

Supplementary Paper III-3 Mechanical Properties of Precompressed Cement-Mortar Specimens

Ori Ishai*

Synopsis

Mortar specimens, cured by different procedures, were subjected to creep and shrinkage tests, and their instantaneous mechanical properties were determined.

Experimental results indicate the superiority of specimens precompressed during the setting period (2–4 hours after mixing), to their counterparts subjected to ordinary moisture curing. Precompressed specimens were characterized by higher compressive strength, rigidity and density, lower creep, shrinkage and smaller thermal expansion. Oven-dried specimens showed negligible compressive creep.

The above characteristics are attributable to the reduction in both the voids ratio and the evaporable-water content, obtainable by the precompression and drying processes.

Introduction

Cement paste, mortar and concrete are highly-porous materials whose mechanical properties are strongly influenced by their porosity characteristics.

The porous phase covers a wide range of pore sizes, from 20–30 Å for gel pores to 10,000 Å for capillaries.

At the initial stage of hardening, almost the entire pore volume is filled with absorbed and adsorbed evaporable water. The role of the pores and the pore water on the mechanical properties of cementitious products was investigated and discussed extensively. It was found that while the voids ratio mainly influences time-independent properties such as elastic modulus and strength (1, 2, 3), content and distribution of the evaporable water within the microstructure are the predominant factors in the time-dependent behavior manifested by shrinkage (1, 4, 5, 6) and creep (7, 8, 9, 10).

It was concluded that while a higher voids ratio results in low strength and rigidity, a high evaporable-water content favors high time-deformation.

The object of the present work was:

a) An appropriate method of reducing both the voids ratio and the water content.

b) A study of the mechanical behaviour of the more compact and dry cementitious product obtained by such methods.

Experimental Prodecure

According to the main object, two extreme methods of treatment were chosen:

1) Almost total drying of hardened ordinary moist-cured mortar specimens, in order to expel the evaporable water.
2) Compaction of the fresh mortar mix, in order to reduce the voids ratio before hardening.

Compacted dry tubular (Fig. 1) (o.d. 7.5, i.d. 4, height 15 cm), compared to orinary moist-cured ones. Four mechanical parameters were studied: strength, rigidity, shrinkage and creep.

*Technion, Israel Institute of Technology, Haifa, Israel.

Preparation of Specimens

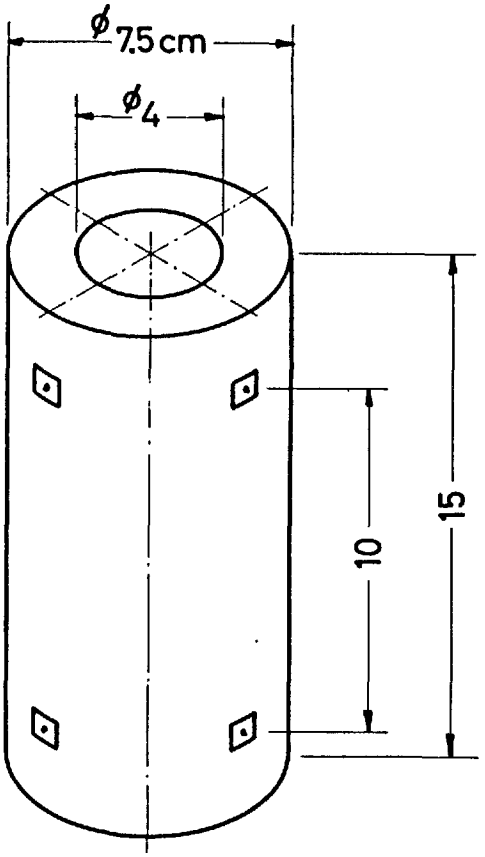

Fig. 1. *Mortar specimens used for testing the compressive deformational behavior*

Mix proportions were 1.1: 1 Leighton-Buzzard sand to portland cement by weight; initial water/cement ratio — w/c = 0.33.

Two main groups of specimens were prepared according to mode of curing and treatment as follows:

Group A: Ordinary Moist-Cured Specimens

Specimens were stored at 90% R.H. and water-cured for 6 more days after demolding.

Group B: Precompressed Specimens

The fresh mix was precompressed in the mold by a central axial force*, exerting an axial pressure of about 160 kg/cm² on the material. This pressure, transmitted by a prestressing device and counterbalanced laterally by the mold walls, was maintained for 3 days in a moist environment.

At 3 days, after release of the axial compression and demolding, the hardened specimens were moist-cured for 4 more days.

Procedure

Four series of test were conducted as follows:

Series I: Compressive Strength

The influence of precompression time (1, 2, 3 and 4 hours) on strength at 7 days, measured on a standard testing apparatus.

Series II: Young's Modulus in Compression

Longitudinal deformations under axial load applied at 7 days, measured by means of Steiger-type extensometers along the generatrices (Accuracy — 10^{-5} micro strains).

Series III: Shrinkage

Dry-wetting cycles applied at 7 days:
11 days at 90% R. H., 22°C
11 days at 50% R. H., 22°C
4 days oven-drying, 105°C
150 days at 90% R. H., 22°C
30 days under water, 22°C

Axial deformation measurements were taken daily (hourly during the oven-drying period).

Series IV: Creep

Wet specimens of both groups, moist-cured for 35 days, and insulated** specimens of group A oven-dried at 105°C to almost constant weight were kept under axial load in a climate room at 50% R. H. and 22°C.

Axial deformations were measured daily up to 130 days after loading.

*This compaction process resulted in immediate squeezing-out of water and an average volume contraction of about 10%.

**Dried specimens were immersed several times in liquid epoxy resin, which hardened and provided good insulation for at least 10 weeks.

Results and Discussion

The influence of precompression was evident in all cases. The resulting disruption of the setting process seemed to have no adverse effect on strength and other properties of the hardened mortar—rather to improve them. Expulsion of the evaporable water from the hardened mortar reduced appreciably all time-dependent deformations and almost eliminated creep.

Series I

Precompression 1 hour after mixing does not affect compressive strength, but when applied 3–4 hours after mixing a strength increase up to 100% is obtained.

Series II

Precompressed specimens showed modulus values higher by about 10%. The same trend is reflected in the higher density and lower coefficient of thermal expansion characterizing the specimens of group B.

Series III

Both groups exhibit the same general trend: increase of shrinkage during exposure to dry environment (higher rate at 50% R. H. compared to 90% R. H.), and a steeper increase, terminated by stabilization, during the oven-drying period. Shrinkage recovery during wetting follows the usual course of swelling, which becomes pronounced under immersion.

In all stages, precompressed specimens exhibit lower shrinkage and swelling characteristics and seem to tend to long-term total recovery (Fig. 3).

Series IV

Creep strain vs. time curves show, as expected, a high time-rate of deformation after loading, and a decreasing rate later on (Fig. 4). Precompressed

Table 1. *Effect of precompression on mechanical properties*

Group	Density gr/cm³	Young's modulus in compression kg/cm²	Compressive strength at 7 days kg/cm²	Coefficient of thermal expansion	Shrinkage (10 days) at 50% R.H.	Creep at 10 weeks under 160 kg/cm²
A Ordinary moist-cured	2.28	4.0×10^5	280	11.5×10^{-6}	43×10^{-5}	55×10^{-5}
B Precompressed 2 hours after mixing	2.42	4.5×10^5	420	10.8×10^{-6}	26×10^{-5}	30×10^{-5}

(average of at least two specimens, 4 deformation measurements on each).

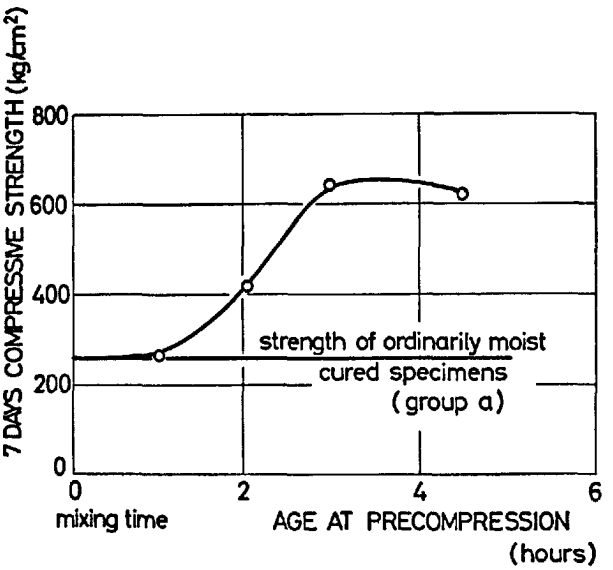

Fig. 2. *Influence of time at precompression on compressive strength of specimens*

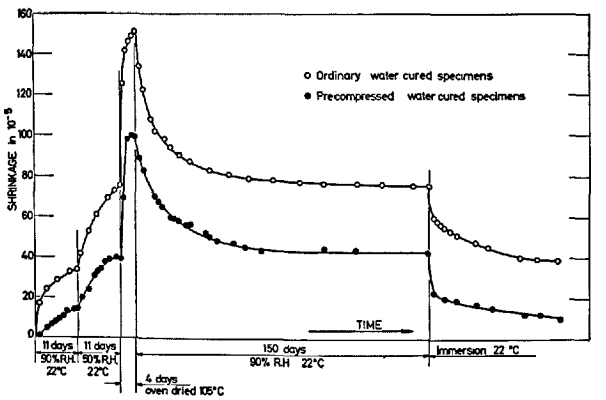

Fig. 3. *Shrinkage and swelling characteristics of wet specimens exposed to drying-wetting cycle*

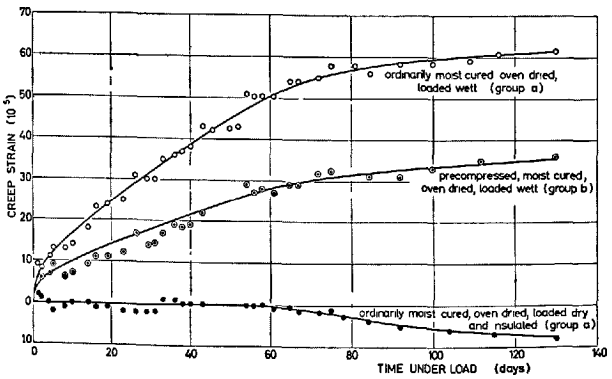

Fig. 4. *Compresive creep of specimens with different curing and treatment histories*

specimens show appreciably lower creep (up to almost 50%), but long-term slopes seem to be identical for both curves.

Dried specimens of group A showed no noticeable deformational change during the first 10 weeks after loading. Later a slight swelling was recorded (attributable to water diffusion through the insulating coating) followed by recovery.

In view of their higher voids ratio compared with group B, it is concluded that the evaporable-water content is the main factor governing the above creep behaviour.

Conclusions

1) Precompression of the mix during setting influenced appreciably the mechanical properties of the hardened product.

2) Precompression 3–4 hours after mixing seems to yield optimal results with regard to compressive strength.

3) Precompressed specimens are characterized by higher compressive strength and rigidity, higher density and lower coefficient of thermal expansion compared with their ordinary counterparts.

4) Precompressed specimens exhibit markedly lower shrinkage and creep characteristics compared with their ordinary counterparts.

5) Insulated oven-dried specimens show negligible creep under compressive load.

6) The superior quality of the precompressed and dried specimens is attributable to their low porosity and low evaporable-water content, believed to be the main factors determining the mechanical behavior of the hardened cement paste.

Acknowledgments

The project was sponsored in part by the Fohs Foundation. The author is indebted to J. Jerushalmi for assistance in conducting the experiments, and to P. Schechter for the drawings.

Supplementary Paper III-33 Determination of Plain Concrete

Floyd O. Slate* and Bernard L. Meyers**

Synopsis

This paper describes and explains, in general terms, various aspects of deformations of the concrete system. The subject is introduced by a description of the composite material, followed by a breakdown into components, including aggregate, aggregate-paste interface, crystals, crystallites, gel, holes of various sizes, water, and air. The various individual components that are deformed (called Deformees), are discussed one-by-one, as related to deformation of the over-all system. Then the stimuli causing deformation (called Deformers) are listed and discussed. This is followed by a general discussion of the interactions between the Deformees and the Deformers, that result in significant engineering deformations. Finally, the paper attempts to show that local, internal deformations and their cumulative effects limit the usefulness of concrete, and are directly related to short-term deflection, long-term deflection, cracking, and failure.

The paper breaks down the various components of the system, and the various stimuli and actions, into individual variables, discusses them item-by-item, then combines them into the composite system concrete. Thus, the first portion of the paper is written from the point of view of structure of matter and materials science; as the paper proceeds, the emphasis is shifted toward the point of view of engineering applications.

Local, internal deformations, and their cumulative effects, are considered to be of overwhelming importance in determining the stiffness, deflections, and strength of concrete. These local deformations initiate cracking and creep; the progress of cracking and creep follows the progressive development of local deformations; and fracture or excessive deformation is the cumulative effect of local deformations. The proper isolation and study of the variables associated with local deformations should be fruitful in leading to a better understanding of the performance of concrete, and to its improvement.

Introduction

The purpose of this paper is to describe and explain, in general terms, various aspects of the deformation of concrete system. Several types of deformation as well as how and why they occur, are discussed. The paper is not intended to be a review of the literature, but rather to be the authors' analysis of concrete deformations, based on general principles, on existing knowledge, and on research carried out by the authors over a period of years. Consideration is limited to deformations caused by such things as loading and unloading, hydration, and changes in moisture content; deformations associated with such things as thermal changes and freeze-thaw action are not considered.

The general subject is introduced by a description of the concrete system, including aggregate, aggregate-paste interface, crystals, gel, holes of various sizes, water, and air. Deformations, prior to, during, and after the time under load, are explained and discussed in terms of the reaction of the concrete system and its elements to such stimuli as: load, moisture migration, hydration, and recrystallization. The general approach is based on consideration of a heterogeneous internal structure, and on the internal forces that hold matter together and govern its differential displacement and recovery. The first part of the paper is written from the point of view of materials science; as the paper proceeds, the emphasis is shifted toward the point of view of engineering application.

Many papers (only a few of which are referenced

*Cornell University, New York.
**The University of Iowa, Iowa, U.S.A.

here) have been written on the internal structure of concrete (1, 2, 3)*, on the general elastic and inelastic behavior of concrete under the action of loads of short duration (4, 5), on the shrinkage behavior of concrete (6), and on the time-dependent deformation of concrete caused by sustained load (7, 8, 9, 10, 11, 12). But very few authors (13) have tried to present a coordinated overall picture of the deformation of concrete.

Internal Structure of Concrete

A brief statement will be made here of those aspects of internal structure which have major effects on deformations. A later section of the paper, "Deformees—Things that are Deformed," will discuss one-by-one some of the individual components of the structure.

Concrete is a multiphase heterogeneous material. Its individual components and their interfaces act differently from each other, resulting in a very complex variation in local deformations throughout the material, including both differing magnitudes of deformations and differing time-deformation responses, in different parts of the same concrete specimen. In the opinion of the authors, local deformation is the item that is directly related to failure (or to local separation, fracture, or flow), and stress is thus only indirectly related to failure. For a proper understanding and explanation of failure of concrete, it is likely that approaches based on stress, or based on the assumption that "strain" is constant throughout the specimen, are doomed to limited sucess at best, and that an approach based on varying local deformations is both correct and necessary.

Interactions at the aggregate-past interface play an important role in the overall behavior and deformation of concrete (7, 14, 15). A considerable portion of the total deformation of concrete is probably usually concentrated at these interfaces.

The paste itself is also a multiphase material. It can be assumed that paste is made up of crystals, and of needles, plates, filaments, and crumpled sheets (2) of very small size (crystallites) arranged mostly at random in a three-dimensional system to form a gel (a colloidal, spongy structure). These crystallites that form the gel have surfaces that are multipolar, attract each other by secondary electrostatic forces, and are strongly hydrophillic. Thus, water is strongly attracted to the surfaces of the gel and into spaces between closely-spaced gel particles, tending to separate them. The thickness of these layers of adsorbed water varies from about one to ten molecules. There are also water-filled holes (pores, capillaries, and voids) of widely varying size in the concrete system. In addition, many of the larger holes (voids) hold only air.

Deformees—Things That are Deformed

An attempt will be made to list, as separate variables, the various parts of the concrete system that are deformed—that is, generally changed in position or shape. The basic consideration is any *relative* movement in space of atoms, ions, or molecules; the movement must be relative to other matter in the same concrete system.

Concrete as a Whole

It is customary to measure gross deformation in concrete, by use of deformators, compressometers, and strain gages. Then, on the assumption that the deformations are distributed equally throughout the specimen (or the gage length), "strains" are calculated to represent the concrete as a whole. Actually, the gross deformation measured is the sum total of, or the result of, very many small, varying, discreet deformations occurring in the various constituents and parts of the concrete. Thus highly localized deformations or "strains" may be greatly different from the average for the concrete as a whole. For example, the "strain" across an aggregate-paste interface where a crack opens up will probably be an order of magnitude greater than for the average of the specimen as a whole.

*Numbers in parenthesis refer to entries in the References at the end of this paper.

Aggregate

The mineral aggregates used in concrete are brittle under short-time loading. That is, deformations are small up to brittle fracture, and are largely elastic. Under long-time loading, inelastic deformation may take place; although it may be appreciable, especially for some aggregates such as some limestones, it is generally very small as compared to deformations of other parts of the concrete system. Formation of cracks in the aggregate is usually small until the moment of catastrophic failure of the concrete; for higher water-cement ratios, for younger ages, and with rounded aggregate, the total amount of ultimate cracking in the aggregate is usually very small-it generally increases with lower water-cement ratios, with greater ages, and with more angular aggregate. The mineral composition and lithologic structure influence all deformation and fracture properties. Since the deformations of aggregate are small as compared to those of paste, their primary significance is that of *differential* deformation at the interfaces, often leading to a greater *net* deformation across the interface.

Aggregate-Paste Interface

Ideally, the interface might be considered to be an infinitely thin surface, not subject to deformation across its surface. However, in this paper the interface will be considered to be the region extending slihtly into both aggregate and paste, and will still be called an aggregate-paste interface (cracked) even after a crack has been formed, consisting of a void of air or water, and in reality creating two new interfaces, aggregate-air (or water) and paste-air (or water).

The aggregate-paste interface (or aggregate-mortar interface, as it is sometimes called), has been shown to be the site of a very large amount of cracking, and thus of deformation, under many different conditions of loading, hydration, and drying (7, 14, 15, 16). The separation may be "clean," between aggregate and paste, or may occur partly within one or the other material. For example, soft, porous limestones may fail partially within the limestone, leaving some thin layers of limestone still adhering to the paste on the paste side of the separation. More often, the other case, of some failure through paste very close to the aggregate surface, is noted. The latter case seems to occur more often when the aggregate surface is rough, even on a microscopic scale, thus providing a greater area of bonding and sometimes forcing "brittle shear" to occur through one of the materials.

The interfacial bond should be primarily brittle in nature, and primarily elastic in action until actual separation. The separation can be more or less perpendicular to the interface, forming an opened crack-in this case a brittle tensile failure seems to be the predominating action. The local displacement can also occur as sliding along a compression-shear-loaded interface (presumably after an initial brittle failure of the bond), in which case friction could resist further sliding deformation (17). An interfacial crack may partially close upon removal of load, giving an effect of partial "elastic action."

In many cases, a crack-like "semi-void," or apparently a thin layer of paste of high water-cement ratio, can be seen adjacent to the interface. This weak region is presumably caused at the time of placement by gravity segregation (particularly at interfaces at the bottom surfaces of aggregate particles), and on all surfaces by vibration of aggregate particles, thus displacing all material away from the surfaces, followed by faster and greater return to the depleted region by water as compared to cement.

The deformations occurring at the interfaces have been shown to be directly related to, and to be a major influence controlling, the shape of the stress-strain curve (14) and to involve a portion of the average strain in long-time deformation (7). It is probable that a majority of the total short-time, uniaxial compressive deformation in concrete, from about 50% to 70% of ultimate load, (and almost all the inelastic deformation below 50% of ultimate), is contributed by the cumulative effect of interfacial deformations, particularly interfacial cracking. Of course, the paste phase, which is the continuous phase, must be deformed to allow deformation of the concrete as a whole, but in many or most concretes its local deformation is probably appreciably controlled and "forced" by deformations at interfaces, at least up to about 70 percent of the short-time ultimate strength.

Paste

An attempt will be made to divide paste into its basic material components, and to discuss each (crystals, crystallites, air, free water, capillary water, adsorbed water, water of hydration, and miscellaneous structures and effects such as holes, solution, deffusion, reprecipitation, and crystal-to-crystal contact) as a separate variable. It must be recognized that one

component may have a profound effect on another, and that the actual behavior is caused by interrelated properties of the system, rather than by additive effects of each part in turn. However, it will be fruitful to examine each part, as it exists within the system.

Crystals

This section refers primarily to those crystals large enough to be seen with the optical microscope. They are brittle in nature, both in short-time loading and long-time loading-long-time as understood for concrete (a few years). Their deformations, short of fracture, are small and primarily elastic. Rod, needle, plate, and sheet crystals should be able to withstand, without fracturing, much more deformation in certain directions than in others (such as bending of a beam as compared to direct compression). Deformations associated with fracture are non-recoverable. The sum total of deformations contributed by these "large" crystals is probably very small, at least until the moment of catastrophic fracture of the specimen, and perhaps even then. Thus, these deformations are relatively unimportant in concrete.

Crystallites

This refers to crystals (often highly imperfect) beyond the resolution of the optical microscope. Another useful definition (allowing a larger size) would be to place them within the colloidal range, with at least one dimension less than one-tenth micron. These tiny crystals (often needles, plates, filaments, and crumpled sheets), arranged more or less at random, separated more or less by thin layers of water, and containing various-sized spaces filled with water and air, constitute cement paste, and compose what is often called cement "gel," particularly when the larger spaces or holes are not considered. The crystallites can be expected to act much as do the larger crystals, but their total mass is so much greater that their cumulative deformation must be much greater. Their less-perfect crystal structures might allow more plastic crystal deformation, but the amount should still be small as compared to other deformations in concrete.

Air

Air is very easily deformed and easily compressed. Its solubility in water and aqueous solutions is appreciably increased by pressure, leading to reduced volume. It will readily flow from regions of high to lower pressure. Its flow may be inhibited by water saturation of all spaces that otherwise could afford routes of flow.

Free Water

This refers generally to water at distances greater than about 1 mm. from crystal or crystallite surfaces. It is present in the larger spaces, holes, and voids. Its compressibility is so small that it can be ignored. It is very easily deformed, and will tend to flow easily and quickly from regions of high to low pressure, if unrestricted. Its flow may be restricted by the smallness of the holes through which it must flow, leading to significant time effects. Free water is relatively easily removed from the system by evaporation.

Capillary Water

This refers generally to water at distances between about 1 mm. and 30 Å from crystal or crystallite surfaces. It is attracted with appreciable, but not great, force to those surfaces, which are highly hydrophillic. The attraction to the surfaces (primarily polar, secondary forces) will oppose and delay, but not prevent, movement of the water away from the surfaces. Thus an additional time effect is present for deformation (or movement) of this water; it will be removed from a surface, or evaporated, slower and with more difficulty than free water. Otherwise, its characteristics are the same as those listed above for free water, with one vitally important exception: upon removal of a load (or effect causing evaporation) which has removed capillary water from an attractive surface, the water will tend to return. Since removal of the water caused crystal surfaces to move closer together (or vice versa), return of the water will cause the crystal surfaces to move apart. Thus deformations from load or drying, and involving capillary water, can be recovered with time. For example, water between two crystals could be squeezed out into a relatively large air void; upon removal of the load, the water would tend to return and spread the space between the two crystals to its original distance.

Adsorbed Water

This refers generally to water at distances between 0 and about 30 Å from crystal and crystallite surfaces, and represents a layer of water from one to ten molecules thick. The attraction of the surface varies greatly across this distance, and there is no sharp dividing line between adsorbed water and capillary water. The adsorbed water is held very tightly by the strongly hydrophillic surfaces of the crystals

and crystallites. It can be moved by load or evaporation, but only with great difficulty (large pressure) and only slowly. It generally acts very much in the manner described above for capillary water, except it moves from a surface with more difficulty and more slowly. Its removal from a region will result in deformation, and it will *strongly* tend to return in time after load (or other driving force) is removed, causing a delayed recovery of deformation. The first three molecular layers of water are probably not much affected through most of the concrete system, even at catastrophic failure of the system (although they may be, at isolated points of great pressure), and the innermost molecular layer is probably deformed or removed little if at all.

Water of Hydration

This term is often used somewhat loosely. It should refer to water of crystallization held directly in a crystal lattice, in a definite combining ratio with the other building blocks of the crystal. It often refers to water held tightly in variable hydrates, and sometimes apparently even to very tightly bound surface water on a crystal. Thus the binding forces vary from primary chemical bonds to secondary chemical bonds (such as hydrogen bonds) and even to very strong secondary physico-chemical bonds in adsorbed layers. In all cases, the water is held very tightly, and most tightly of all water in the system. Some of this water can be moved by elevated temperatures, still within expected experience for some concrete, by very low external relative humidities, and by high local pressures caused by external load. This latter point may be of appreciable importance, although deformations involving water of hydration should be expected (except possibly in cases of extreme temperature leading to disintegration) to be relatively small as compared to those involving other forms of water.

Holes

Holes are not properly component materials of the paste, but perhaps a brief consideration of them may be helpful. In general, by holes is meant any space not occupied by a solid. Thus holes may be filled with air, with water (solutions), or with some of each. They vary in size from "huge" spaces in honeycombed concrete to tiny spaces between crystallites in the gel system, measured in a few angstrom units. In general, whenever the fluid (air or water) is removed from the hole by some force, the hole becomes smaller, and the solid surfaces bounding the hole come closer together—both local and gross deformations can then be observed. The effect is greater for smaller holes. Upon removal of the force which caused removal of the fluid, the system will attempt to reach a new equilibrium. If the hole is small enough that its attraction for water is appreciably large, and if water is available to move into the hole, water will flow back into the hole, the hole will become larger, and both local and gross deformations (of recovery) can be observed. Such recovery will be time dependent.

There will be a tendency for all similar solid surfaces to be covered by an equal thickness of water film, at true equilibrium. This condition will not exist for concrete at any time, including before loading. As loading re-distributes the water films, the new position of some of the water will be expected to be nearer true equilibrium conditions, even for non-loaded concrete. Thus some of the water will never return to its original position after unloading of the concrete, and some of the deformation will be non-recoverable.

Crystal-to-Crystal Contact

There may be points of crystal-to-crystal contact, without any intervening layers of water, although this point is not at all certain. Such contact should vary from an intimate relationship in which one crystal is part of the system of the other (as in twinning) where primary chemical bonds (electrovalent for these mineral systems) are involved, down to a touching of neighboring adjacent, but independent, crystals, which would attract each other by multipolar, secondary chemical forces. In either case, the bond should be brittle, and should be relatively strong, even for the weaker case of independent crystals with multipolar forces of attraction. If these bonds from crystal-to-crystal contact exist, they may be one of the last points of failure or deformation to occur just before or at the moment of catastrophic failure of the concrete specimen, and may appreciably influence the ultimate strength of concrete, in both short- and long-time loading.

Solution, Diffusion, and Reprecipitation

The solubility of crystals and crystallites increases under pressure. The load through concrete must be transmitted unevenly through the mass, at least on a micro scale. Therefore, at concentrated load-bearing points, some material dissolves, diffuses to a region of lower pressure (or where a newly-precipitated crystal would be under less pressure),

and precipitates out (as in a void). This represents a permanent deformation, is a time-dependent process, and is non-recoverable creep. The effect under short-time load should be much smaller than under long-time load, but might still result in a small amount of non-recoverable deformation even for the short-time load. This process *must* occur, qualitatively. It probably is of considerable importance in autogenous healing of concrete under load.

Deformers—Things That Cause Deformation

We have seen that each part of the concrete system, from the largest piece of aggregate to the smallest gel crystallite and on to individual water molecules, contributes to the overall deformation. Deformation is induced in each of the components by various influences. The most important of these influences are those which alter pressure in, and hygral equilibrium of, the system; other influences are such things as hydration and carbonation.

Hydration and Carbonation

An autogenous shrinkage of the paste is caused by hydration of cement (in the absence of available external free water) because the products of hydration occupy a smaller volume than do the reactants. If external free water is available and allowed to enter the system, a net expansion of the paste occurs, as expansion from ingress of water to adhere to and spread newly-formed hydrophillic hydrate surfaces, more than overcomes shrinkage from hydration. Carbonation (an acid-base reaction involving carbonic acid and the basic paste components) apparently involves solution of basic crystals such as calcium hydroxide, perhaps under pressure from drying shrinkage, and precipitation of resulting carbonates in open void spaces.

Change of Average Load or Pressure

The application and the removal of load affects the overall pressure causing deformation in various parts of the system. Change of load also induces localized pressure peaks and troughs because of the heterogenity of the system. Change of load, in addition, affects hygral equilibrium because of load-induced moisture migration.

Change of Local Pressure

The pressure at various local internal places can be expected to change greatly as the external load is changed; as the volume changes from wetting, drying, hydration, and carbonation; and as internal redistribution of individual portions of the structure forces changes of load-bearing points and areas. These localized regions of pressure differential must strongly influence diffusion of water, solution of solids, diffusion of dissloved material, and positions of crystal reprecipitation.

Wetting and Drying

These actions increase or decrease the thickness of water films separating the hydrophillic hydrate surfaces, forcing them apart upon wetting, or forcing them together upon drying as internal pressure falls below that of the external environment. These effects occur for both adsorbed water and capillary water. There is little effect from change in "free" water content in the larger voids and honeycomb spaces.

Physical Processes Caused by the Deformers

There is generally an intermediate step between application of a Deformer and the physical occurrance of deformation. This intermediate step consists of physical processes that are caused by the Deformers, and which in turn cause, control, or result in deformations. These physical processes that are caused by the Deformers include such things as the following: Direct deformation and breakage of crystals and crystallites, Separation of interfaces, Flow, Diffusion, Solution, and Reprecipitation. Any process involving diffusion can be expected to be strongly time-dependent; therefore, all deformations—either primary or of recovery—involving diffusion should be strongly time-dependent, and all such deformations from load and from drying should be partly recoverable and partly non-recoverable, depending on the relative stability or energy levels before and after diffusion, and the possibility of irreversible processes following diffusion.

Deformation Behavior

In this section the deformation of concrete as an engineering material is discussed in detail. The discussion is divided into the following sections: Deformation without Load, Deformation due to Short-Time Load, and Deformation due to Long-Time Load. This rather arbitrary separation is not intended to imply that the various types of deformation are independent. It is recognized that all components of deformation can occur ar the same time and are highly dependent on each other.

Deformation without Load

Volume changes caused by the hydration process and by carbonation are time-dependent and may be considered small compared to the deformations caused by load.

The deformation caused by the migration of water into and out of a specimen is of sufficient magnitude to affect the structural performance. In most practical cases, the relative humidity of a concrete specimen is higher than that of its surroundings. Thus, the matrix will lose water in an effort to establish hygral equilibrium with its environment. Moisture is evaporated first from the larger pores and capillaries, introducing small volume changes, and later from the smaller capillary spaces and from the layers of water adsorbed to the gel surfaces, introducing relatively large volume changes. The resulting deformation is defined as drying shrinkage (normal range = 0.0001 to 0.001 in/in). If water is returned to the matrix a corresponding swelling will take place.

Since drying shrinkage and swelling take place in the paste, tensile stresses are introduced at the interface between the paste and the relatively rigid aggregate particles (15). When the tensile strength of the interface is exceeded, microcracks are developed, resulting in non-recoverable deformation. Microcracks are also developed, to a lesser degree, by the volume changes caused by the hydration process and by carbonation.

Deformation Due to Short-Time Load

When loads of short duration (10 to 10^3psi/sec) are applied to a concrete specimen, elastic and inelastic deformations take place. The stress-strain curve of concrete can be divided into three ranges. From 0 to about 30% of the ultimate strength, the deformation is elastic and linear. Between 30 and 70% of the ultimate strength, both elastic and inelastic deformations take place, the majority being inelastic. Above 70% of the ultimate strength, most of the deformation is inelastic. The inelastic and elastic deformation caused by loads of short duration are not affected by strain rate and, therefore, are not time-dependent.

The general behavior of concrete subjected to short-time loads, described above, will now be analyzed in detail by discussing the deformation of each component of the matrix.

Aggregate

The deformation of the aggregate particles is small compared to the total deformation and may be assumed to be linear and elastic.

Paste

The deformation of the paste is also, for the most part, linear and elastic. As load is applied, atoms (ions) and molecules move. For each crystal and crystallite, if this local motion is less than 1/2 of the ionic or molecular diameter, the resulting deformation is completely recoverable and linear. The gel crystals bend, deform, and return to their original configurations upon removal of the load. If the load is of sufficient magnitude, some of the weaker cyrstals will break, introducing non-recoverable deformation.

Aggregate-Paste Interface

Most of the inelastic, nonrecoverable strain exhibited by the short-time stress-strain curve of concrete is a result of cracking at the aggregate-paste interface and through the paste (14). As the load is applied, existing cracks do not propagate and new ones do not form until the load reaches about 30% of the ultimate strength. Above this load, bond cracks start to increase in width, length and number. As the load is further increased, some cracked interfaces continue to carry, by friction, about the same load that caused the initial failure. All additional load is carried by the uncracked interfaces and the surrounding paste. Local cracks begin to form in the paste, at the tip of existing bond cracks, allowing the aggregate particles to slide relative to the paste, causing the initial inelasticity of the short-time stress-strain curve. As the load is increased above about 70% of the ultimate strength, the local cracks start to bridge between adjacent aggregate particles causing additional inelasticity and internal disruption that ultimately

leads to failure of the specimen (17).

Water

The water in the system will also move under the influence of short-time load introducing a relatively small amount of deformation. In contrast, the time-dependent migration of moisture within and to the surface of the system has a much more pronounced effect on the creep of concrete, and will be discussed more fully later in the paper.

Deformation Due to Long-Time Load

If a load is applied, and maintained at a constant stress level, or applied at a rate slower than about 1 psi/sec, a concrete specimen continues to deform without any increase in applied stress. This time-dependent deformation is usually 1 to 4 times greater than the initial strain from the applied load, for specimens on which a load within the working stress range is maintained for more than about a month. Upon release of the sustained load, part of the total strain is immediately recovered, part is slowly recovered, and part is never recovered.

Stress is developed throughout the matrix when it is subjected to a sustained load: in the aggregate, in the hydrated cement gel, at the aggregate-paste interface, and in the various types of water. The long-time, load-induced deformation of concrete consists of the response of all of the above to stress: progressive internal microcracking at the aggregate-paste interface, elastic and inelastic deformation of the aggregate and of the paste, migration of load-bearing water within and to the surface of the specimen, solution and recrystallization of gel particles, and other stress-induced changes in the gel structure.

Moisture Movement

When load is applied, the pressure and the hygral equilibrium within the specimen are altered. In order to re-establish equilibrium the water contained in the larger holes (pores, capillaries and voids) is forced out of its original position, through capillaries and between gel surfaces to air voids and to the surface. The resulting volume change, which takes place rather quickly (probably in a few weeks or less), may be considered increased or accelerated shrinkage caused by the sustained load. It is non-recoverable, unless water is returned to the specimen after the sustained load is removed (3).

The water strongly adsorbed to the gel surface diffuses from its original position very slowly. As this water diffuses from between the gel surfaces to larger holes, and eventually to the surface of the specimen, the gel particles are forced closer together by the load. The resulting deformation (creep) takes place very slowly and probably never completely reduces the thickness of the adsorbed water layers to zero (9).

If there is no change in the internal structure of the gel and the amount of water in the specimen remains constant, creep should be completey recoverable. When load is removed, the hydrophillic gel attracts water which deffuses from the larger holes back to the closely spaced gel surfaces, tending to force them apart. The resulting deformation is creep recovery.

The magnitude of the deformation caused by internal moisture migration (creep and creep recovery) depends on the properties (such as surface area) of the cement gel, on the water content, and on the storage conditions at the time of load application and during the time under load.

Effect of Adsorbed Water

In most practical mixes the hydration of the cement continues for six months or more. During this time the surface area of the gel increases and available water is attracted to the surfaces between the new gel particles, increasing the number of and the total thickness of the adsorbed water layers. At some stage of hydration the adsorbed layers may begin to decrease in average thickness, as the area of the gel increases and the amount of available free water is decreased through combination with cement and by evaporation. Therefore, a specimen sealed prior to and during the time under load will exhibit more creep than a companion specimen that is allowed to dry prior to and during the time under load. The total deformation of the unsealed specimen, including increased shrinkage, may or may not be greater than that of the sealed specimen, depending on the age and drying at the time of loading (9).

Effect of Recrystallization and Changes in Internal Structure

The solubility of the gel (of all the solids) is increased by load. Gel and crystals dissolve, in water, at regions of high load intensity, diffuse to new locations, and reprecipitate as new crystals or on existing crystals in areas of lower load intensity. As a result of this diffusion, undissolved particles will move closer together as material is dissolved away from between them. The magnitude of this deformation depends on the maturity and stability of the gel at the time of load application. If the specimen is loaded early in the hydration process, a large amount of recrystalli-

zation will be introduced by the load. On the other hand, if the specimen is loaded when hydration is near completion, the gel will be more stable and additional deformation due to recrystallization will be small. Since the deformation described above is a result of a permanent change in the structure of the gel, it is non-recoverable (9).

Non-recoverable deformation is also introduced if the sustained load is of sufficient magnitude to break some of the gel crystallites and crystals.

Since the deformation resulting from internal changes in gel structure is non-recoverable, creep cannot, in fact, be completely recoverable. If the load is applied and maintained on a young specimen for a long period of time, recovery will be small compared to creep. On the other hand, if an older specimen is loaded for a shorter period of time, recovery will be large compared to creep (9).

Microcracking

Sustained load causes the propagation of more microcracking than an equal short-time load. If the sustained load is below about 70% of the ultimate strength, the same amount of bond cracking is introduced by time-dependent strain as would be by a short-time strain of equal magnitude. However, there is no increase in mortar (paste) cracking. For loads above 70% of the ultimate strength, mortar cracks are introduced by creep strain, and the specimen will probably fail after some time under a constant load. Deformation due to time-dependent microcracking is non-recoverable (7).

Relationships between Deformations and Failure or Deflection (19, 20, 21)

Local, internal deformations and their cumulative effects limit the usefulness of concrete, and are directly related to short-term deflection, long-term deflection, cracking, and failure. The distance between individual building blocks of matter, such as atoms, ions, and molecules, governs the attraction and repulsion between them, and thus controls the resistance to initial or further deformation, strain, or separation at any given load or stress. Attraction or repulsion is a geometric function of distance.

There should be a limiting deformation at each point (really two adjacent points) within concrete, that will result in brittle separation, excessive flow, or excessive deformation or deflection. It must be emphasized that the limiting deformation will vary greatly among the various Deformees in the system, and that it will be changed by conditions (such as rate of deformation) for any given Deformee. Therefore, *failure should be a deformation-dependent phenomenon*, with the critical deformation a function of various things, such as composition, rate of deformation, and environment.

There should be a limiting over-all deformation for a concrete specimen, that will result in failure. The amount of this limiting deformation should be about the same for all specimens of a given concrete, under a given set of conditions. However, a different concrete, or a different rate of deformation (for example), should cause a change in the limiting deformation. It seems reasonable that many or most concretes, under a variety of general conditions, but with a few critical conditions stated or controlled, should exhibit limiting deformations within a usable reproducible range. The range or general level of limiting deformations might then change with such things as age, moisture content, and rate of deformation, and even with the testing set-up for laboratory specimens.

Attempts to relate a maximum strain with failure, for complex heterogenous systems such as concrete, have generally not been successful, because only gross or over-all strain or deformation has been considered; consideration must also be given to local deformations or to control of those variables influencing local deformations and thus ultimately influencing gross deformations. If it is true that local deformations ultimately control deflection and failure of concrete, then it follows that the weaknesses and deficiencies of concrete related to deflection and load limit, can perhaps profitably be isolated, investigated, and alleviated by study of local deformations and their interactions.

For example, a concrete showing a large gross deformation or strain under a short-time uniaxial compressive load will probably contain more internal microcracks than a concrete showing a smaller gross deformation; in this case, any change (such as increase of aggregate-paste interfacial strength) that reduces the amount of microcracking at a given load will reduce the gross strain and deflection of the concrete at that load. Such sorting and isolation of variables moves studies for understanding and improvement of materials away from empiricism.

Supplementary Paper III-72 Correlation of Strength and Hydration with Composition of Portland Cement

Kenneth M. Alexander, John H. Taplin and John Wardlaw*

Synopsis

The paper presents the results obtained by multiple regression analysis of strength and hydration data from recent surveys of normal portland cement in Australia. Differences between the cements are largely attributed to C_3A. The effect is thought to be mainly an acceleration of the hydration of the cement as a whole. C_3A dominates at water/cement ratios from 0.35 to 0.80, curing temperatures from 5 to 75°C, and throughout most of the period from 1 day to 6 months. Strength is most sensitive to C_3A content under conditions which are frequently encountered in laboratory test work, namely, water/cement ratio 0.5, age 28 days, curing temperature 21°C.

With the present cements there is a smaller, but significant effect, for median particle size, whereas the effect of quite appreciable differences in C_3S content is of minor importance. The influence of other cement characteristics such as minor oxide compositions, surface areas, etc., is either non-significent, or can be accounted for as another aspect of the C_3A and size effects. Possible exceptions are the positive correlations of strength with Mn_2O_3 at early ages, and the negative correlations of strength with free lime at high water/cement ratio and later ages.

Introduction

As a result of recent investigations in these laboratories, a considerable volume of data on cement strength and hydration has been accumulated, both as a byproduct and as the main objective of several in dependent lines of enquiry. Spanning the full range of normal portland cements in Australia, these studies cover performance at early and later ages, from near freezing to steam curing conditions, and from the upper to the lower limits of water/cement ratio encountered in practice. In this paper, six thousand measurements from these studies are assembled and analysed for relationships between performance and mineral composition, fineness, minor element content, and other characteristics of cement.

Previous studies, for example, by Gonnerman and Lerch (1), support the widely held belief that the rate of hardening depends on the fineness and the C_3S content of cement. Gonnerman (2) found the contribution of C_3A to strength was important until 28 days, but with further curing it declined, to become zero or negative after a year or more. The accelerating effect of C_3A has been supported by authors such as Powers (3) and Budnikov and Erschler (4).

Experimental

The various series of experiments which are assembled in this paper fall naturally into two groups that will be analysed separately. The results in Experimental I are by Alexander and Wardlaw, those in Experimental II are by Taplin, and the analyses are by Alexander and Taplin respectively. Only the one statement of conclusions is presented, and this is based on the findings of both analyses.

Experimental I

The 15 cements used in this section of the investigation were commercial products from 15 different plants. All materials complied with the Australian Standard Specification A2 for Type A Ordinary

Portland Cement. The chemical and physical characteristics of these cements are given in Table 1, and their potential mineral compositions, calculated by the method of ASTM Standard C150–64, and corrected for free lime, are in Table 2. Surface areas were determined by air permeability, in accordance with ASTM Standard C204–55.

In the main series of tests, compressive strengths were determined on $\frac{1}{2}$-inch cubes of machine mixed paste which had been cured continuously under water at 21°C. Strength measurements were made at 1, 3, 7, 28, 56, 90 and 180 days on pastes with water/cement ratios 0.35, 0.50 and 0.80 by weight. The pastes with water/cement ratios of 0.80 were stabilized with 3%, by weight, of pre-gelled bentonite. A subsidiary group of tests was run at water/cement ratio 0.45, ages 16 to 56 days, and under water curing at 5, 21 and 43°C.

The results for the main series (Table 3) are means of at least 10 replications per point. Data for this table originated in the Organization's laboratories in Sydney and Melbourne. Co-ordination between the two laboratories was checked in a series of 600 tests at 1 to 180 days, using half the present range of cements. A coefficient of correlation of 0.993 was obtained.

Data for the subsidiary tests are in Table 8.

The compound compositions of cements 1 to 15 range from 44.5 to 61.7% for C_3S, 11.1 to 33.2% for C_2S, 1.1 to 11.2% for C_3A, and 7.6 to 15.8% for C_4AF. Surface areas are from 3130 to 4380 cm^2/g. At highest water/ cement ratios and earliest ages the highest paste strengths are about 3 times the lowest, whilst at the opposite extreme of late age and low water/cement ratio, this strength ratio is about 1.5 to 1.

Attention is drawn to the point that in the accompanying discussion, significance at the 5, 1 and 0.1% levels of probability will be termed significant, highly significant, and very highly significant respectively.

Table 2. *Potential mineral compositions for cements 1 to 15*

Experimental II

The fifteen cements, numbers 16 to 30, used in these experiments came from the same cement works as those quoted in the previous section but were, with one exception, completely different samples. The potential mineral composition was calculated by the method of ASTM C150 after correcting for free lime. Table 10 lists the relevant data on chemical composition and median particle size. The minor oxides TiO_2, P_2O_5 and Mn_2O_3 were also included in some statistical analyses their mean % values are 0.26, 0.07 and 0.09 respectively.

The cements, and those quoted in the previous section were sized by the method of Andreasen using

1 portland cement
2 ignition loss
3 free lime

ethanol with 0.01% calcium chloride. The measurements were made at 30, 20, 10, 5 and 3.4 μ and gave reasonably straight lines when plotted on log probability paper. The median size was obtained by interpolation. The cements were also sieved with uncalibrated 30 and 20 μ electro-formed sieves and this method indicated a median size 3 μ smaller than quoted. The correlation between the methods is 0.88.

Stirred Specimens

Tubes about two thirds filled by ten grams of cement and forty mls of water are attached to a slowly rotating frame so that they revolve end-over-end about four times a minute. At the appropriate time the specimen is filtered, dried under vacuum and the hydration determined by the method of Taplin (5). Hydration, in this paper, means the weight loss defined by this method. The curing periods are 5, 9, 16, 24, 30, 48, 96, 168, 240, 672, 2000 and 4000 hours.

Hardened Specimens

These specimens were $\frac{1}{2}$ inch diameter, 1.3 inches high, paste cylinders and were cured entirely under water. The ends were ground parallel, prior to testing in compression. These tests were made in duplicate and the remains of the cylinders were dried and used in hydration determinations. For those specimens which were cured entirely at 21°C the curing periods were 9, 16, 24, 72, 168, 240, 672, 2000, and 4000 hours. The specimens were made at W/C ratios of 0.35 and 0.60 by weight.

Complete sets of strength determinations at

W/C = 0.35 are available only to ten days. Additional specimens were given simulated steam curing after standing for 1, 4 and 7 hours at 21°C. The standard size glass jar containing the specimens under water was then placed in an oven at 75°C for twenty hours, the specimens were then cooled under running water for half an hour, and tested. The temperature of the specimens rose 30°C in the first hour in the oven. Only for one cement did the specimens show a significant increase in strength with the length of standing time at 21°C. The results were averaged over standing period giving nine replications to each measurement.

The pastes at W/C = 0.60 were stabilized against bleeding by the addition of one per cent, by weight of the cement, of bentonite. The bentonite was gelled by standing overnight in the mixing water. The 4000 hour results are not yet complete at the time of writing. The simulated steam curing procedure was also repeated at this W/C ratio but this time at 65°C, and an extra set of steamed specimens was given an additional 27 days curing at 21°C.

Discussion I

The Regression of Strength on Composition at Ages 7 to 180 Days

In this section, relationships between strength and potential mineral content for cements 1 to 15 (Tables 2 and 3) are studied by the techniques of multiple linear regression analysis. Attention is concentrated on curing periods from 7 to 180 days, and the discussion begins by considering the situation where all four major compounds, C_3S, C_2S, C_3A and C_4AF are included in the analysis.

Table 3 contains 13 sets of strengths for ages 7 to 180 days and water/cement ratios 0.35 to 0.80. All coefficients of multiple correlation for the regressions of these strengths on compound composition are found to be significant whereas, among the 13 sets of 4 regression coefficients, only 2 of the 52 individual values are significant. At this, the 5% level of significance, the observed proportion of significant regression coefficients could readily have occurred by chance.

The fact that the regressions as a whole are significant, whereas the influence of each individual variable is not, can be explained by the observation that the mineral contents of the cements do not vary independently. In this instance, the simple correlation coefficients for C_3S on C_2S and C_4AF on C_3A are both highly significant. A better description of observed strength is thus likely to be obtained by a regression in which the silicates and aluminates are each represented by only one independent variable. The analogous situation for heats of hydration has been analysed by Hald (6).

The point is illustrated by Fig. 1, where the coefficient of multiple correlation (R) is plotted for suc-

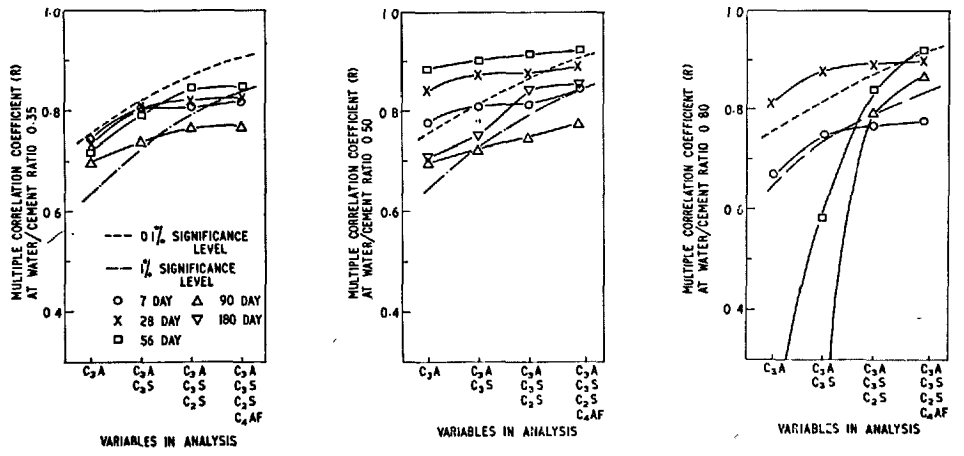

Fig. 1. *The regression of strength on potential mineral content: multiple correlation coefficients and significance levels for successive regression analyses, starting with a constant and one independent variable.*

cessive analyses in which the independent variables are added in the order C_3A, C_3S, C_2S, C_4AF, suggested by the simple correlations. It will be seen that at water/ cement ratios 0.35 and 0.50, the elimination of C_4AF and C_2S from the analysis has only a slight adverse effect on the significance of the association of strength with mineral composition. At water/cement ratio 0.80 these same conclusions apply up to 28 days, beyond which time the regression of strength on C_3A becomes non-significant, and the present order of analysis is no longer recommended.

Further details of the analysis show that the only occasion when the regression on C_3A, C_3S and C_2S is significantly better than on C_3A, C_3S, is at 180 days, where the data are, unfortunately, restricted to the single water/cement ratio 0.50. This limited evidence does however, serve as advance warning that C_2S should not be excluded at ages of 6 months and greater.

Within the range of cement compositions studied here, it is profitable to continue the process of elimination beyond the stage where silicates and aluminates are each represented by a single variable. It can be shown, by intermediate solution of the analyses, that with the exception of one borderline case at 7 days (water/cement ratio 0.80), C_3S itself can be omitted. In Fig. 1 the general effect of this omission is seen as a slight decrease in the coefficient of multiple correlation, coupled with an increase in the significance of the regression.

It is, therefore, concluded that for the present cements, the most significant association between strength and compound composition lies in the regression involving C_3A alone, and not in the more complex analyses involving two or more cement minerals. Over a wide range of water/cement ratios and ages, the significance of the regression on C_3A never falls below the 1% level and, in a high proportion of cases, exceeds the requirements for significance at the 0.01% level of probability.

In view of the key role indicated for C_3A, a further set of regressions on strength was calculated, using the proportion of C_3A determined by X-ray. The correlation between X-ray and potential C_3A was highly significant, but the correlation coefficients for the regressions of strength on the X-ray values averaged 15% lower than those for potential C_3A.

A more detailed examination will now be made of the regression of strength on C_3A. Consider, for example, the information in Table 4, where coefficients for the regression of strength on C_3A are given for curing periods from 7 to 90 days, and water/cement ratios 0.35 to 0.80. To facilitate comparisons within and between experiments the regression coefficients in this table are also given as proportions of the mean strength for the 15 cements tested under each combination of age and water/cement ratio. On first inspection it is perhaps tempting to identify patterns of behaviour among these transformed relationships. However, it can be shown by analysis of variance (Table 5) that the differences between the intercepts and between the slopes* of the regression lines are not significant (7). Thus, between the ages of 7 and 90 days, and for most water/cement ratios encountered in practice, the behaviour of these cements can be

Table 4. *The regression of paste compressive strength on* C_3A

*Although non-significant at the 5% level, the variance ratio testing the differences between coefficients is sufficiently high to warrant further investigation.

represented by a single regression:

$$Y = 0.75 + 0.037x \quad (1)$$

where

Y is the strength relative to the mean for all cements tested at that age and water/cement ratio,

and

x is the percentage of C_3A.

Since the sum of the silicates in the present cements is virtually constant (mean of 73%, standard deviation 2.6), one interpretation of the constant term in equation (1) is that, within the limits of the experiment, there is a specific strength for silicates.

Although equation (1) seems to imply that the strength of a particular cement is the sum of the strengths for silicates and C_3A, it is likely that some or most of the C_3A effect could be attributed to this component modifying the silicates, or accelerating their contribution to strength. One further point is that from 7 to 90 days, the relative importance of the silicate and C_3A effects is independent of age and water/cement ratio. Evidence presented later shows that this conclusion is unlikely to apply at early ages for, at 1 and 3 days, there is no significant relationship between strength and C_3A. The validity beyond 90 days too is doubtful, for, in this region, increasing age brings increasing departures from linearity in the relationships between strength and composition.

Although thus far, C_3S and C_2S have been treated collectively, under the heading of silicates, the present data can provide some indication of the relative contribution that each of these compounds makes to strength. With this object in mind, the analyses were repeated, but with the assumption that the regression should pass through the origin. Such a model has been used by Gonnerman (2), who retained all four major cement minerals in the analysis. However, for reasons analogous to those stated in developing the standard form of the analysis, a regression involving only C_3S, C_2S and C_3A is preferred here. Additional justification for omitting C_4AF comes from tests on cements containing constant amounts of C_3S, C_2S and C_3A, but variable amounts of C_4AF, which indicate that the latter compound has little or no effect on strength (2).

The results, given in Fig. 2, show a number of interesting features. For example, in accordance with the known properties of the pure compound, C_2S exhibits only a slow rate of strength development. At medium and high water/cement ratios (Figs. 1 (b) and (c)) it is about 90 days before the contribution made by each 1% of C_2S matches that of a corresponding amount of C_3S. Lowering the water/cement ratio to 0.35 (Fig. 2a) prevents the more slowly reacting constituent, C_2S, from attaining equality with C_3S, even at the latest age covered by these experiments.

Regarding C_3A ,the influence that this component exerts, relative to that of the silicates, rises to a maximum at water/cement ratio 0.50 and between the ages of 2 to 10 weeks (Fig. 2b). Under these conditions, each 1% increase in C_3A is accompanied by a 400 p.s.i. increase in compressive strength, thus equalling the maximum absolute contribution associated with this constituent in the stronger pastes at water/cement ratio 0.35. The influence of C_3A becomes negligible at late ages in the pastes of highest water/cement ratio (Fig. 2c). Finally, attention is drawn to the close agreement between the regression coefficients for C_3A in Fig. 2, and those calculated by the alternative form of analysis (Table 4).

Owing to a combination of uncertainties involved when the regression is forced through the origin (8), and when there are strong associations between the independent variables, the implications of the type of analysis in Fig. 2 should be viewed with considerable

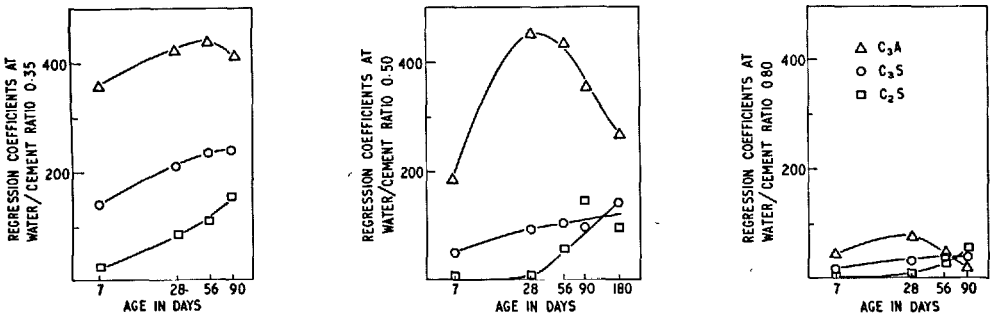

Fig. 2. *Regression coefficients (b_n), in p.s.i., for the regression:* $Y = b_1(\%C_3S) + b_2(\%C_2S) + b_3(\%C_3A)$

reservation. However, despite these limitations, it can be seen that there is an appreciable measure of agreement between the behaviour illustrated by this diagram, and some of the known properties of the cement minerals.

The Effect of Particle Size, Free Lime, Potassium, Phosphorous and other Factors, on the Strength of Cement

It has been shown that for the cements in Table 1, the addition of any major compound, or any combination of major compounds, almost invariably reduces the significance of the regression of strength on composition. However, the regression on C_3A never accounts for more than 80% of the total sum of squares. This raises the question of whether any of the other properties measured in this investigation could explain a useful proportion of the residual variation.

In order to check this possibility, the simple correlations between strength, and the following variables, were calculated for all ages and water/cement ratios: surface area, median particle size, MgO, SO_3, Na_2O, K_2O, Mn_2O_3, P_2O_5, TiO_2, free lime, ignition loss. The more promising leads were then followed by means of multiple regression analyses in which selected variables were added to C_3A singly, and in groups. Only particle size, free lime and potassium were significantly correlated with strength, although there were occasional borderline cases of significance for phosphorous.

In the case of phosphorous, the evidence suggests that the relationship with strength is not causal. There is significant positive correlation between the P_2O_5 and Fe_2O_3 levels in the oxide analyses of the cements and, in addition, the pattern of water/cement ratios at which significant negative correlations occur between strength and phosphorous, conforms to a stronger pattern of highly and very highly significant negative correlations between strength and iron.

With the alkalis, significant strength correlations are found only for potassium, and even then, only at the intermediate water/cement ratio of 0.50. These correlations are positive, and approach or attain significance at all ages from 7 to 90 days. Apart from one isolated exception there is no suggestion of significance at other water/cement ratios.

Turning finally to particle size and free lime, analysis shows that compared with phosphorous and potassium, the significance levels are higher and, in addition, the ages and water/cement ratios at which significance occurs, form a wider and more consistent pattern of behaviour. The influence of particle size and free lime is shown in Figs. 3 and 4, in which values of

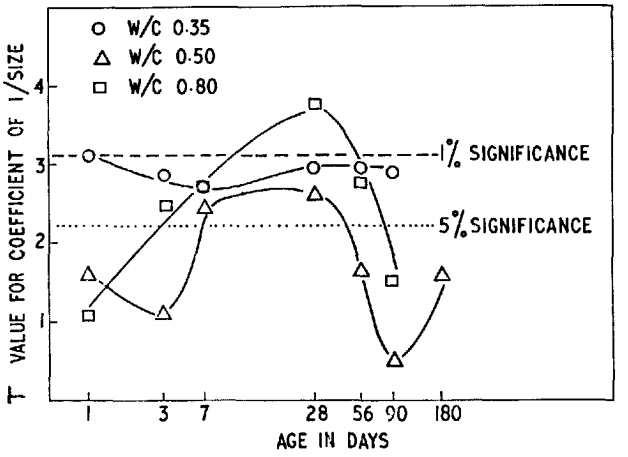

Fig. 3. *Significance of the coefficient (b_5) for particle size in the regression:*
$Y = b_0 + b_1(\%C_3A) + b_5((1/D_m) \times 10^3) + b_6(\%$ free lime$)$
where D_m is median particle diameter in microns

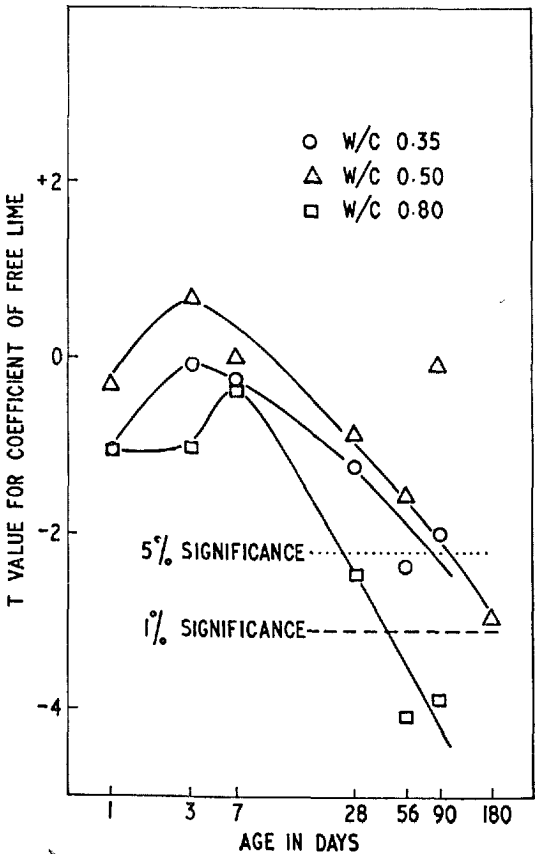

Fig. 4. *Significance of the coefficient (b_6) for free lime in the regression:*
$Y = b_0 + b_1(\%C_3A) + b_5((1/D_m) \times 10^3) + b_6(\%$ free lime$)$
where D_m *is median particle diameter in microns*

Student's T for the coefficients b_2 and b_3 in equation (2) are plotted against log time:

$$Y = b_0 + b_1x_1 + b_2x_2 + b_3x_3 \qquad (2)$$

where

Y = compressive strength of cement paste, in p.s.i.
$b_0 \ldots 3$ = regression coefficients
x_1 = percentage of C_3A
x_2 = reciprocal of median particle diameter in mm
x_3 = percentage of free lime

In these relationships, the reciprocal of particle diameter is preferred to the diameter itself, for reasons outlined later. Fig. 3 shows that at the water/cement ratios 0.35, 0.50 and 0.80, particle size is significant at 1 to 90 ,7 to 28, and 3 to 90 days respectively. Fig. 4 shows that the negative effect of free lime on strength begins to appear at about 7 days, reaching significance at about 90 days in pastes of low and medium water/cement ratio, and at 28 days in pastes of high water/cement ratio. At this latter water/cement ratio, free lime exerts a highly significant effect after about 6 weeks.

Coefficients for the regression of strength on C_3A and other significant factors are given in Table 6.

The Regression of Strength on Composition and other Variables at Ages less than 7 Days

The regression of strength on composition at 1 and 3 days differs markedly from that at 7 days onwards. Little will be said on this aspect, however, for there are too few results available at the earliest ages, the pattern of behaviour is more variable than at later ages, and significance is found in only a small proportion of cases.

Table 7 gives data for major components and other variables that are significantly correlated with strength at earliest ages. The best combination of two variables is also listed, whereas combinations of more than two are omitted since they are less significant.

The analysis is particularly unrewarding at water/cement ratio of 0.50 for, with the exception of C_3A at 3 days, neither major nor minor components, nor particle size, nor any combination of these variables gives a significant regression on strength.

At the extreme water/cement ratios C_2S is the major compound most significantly correlated with strength. The slight advantage over C_3S probably indicates that, at early ages, the proportion of this component, rather than the proportion of C_3S, is the more effective index of silicate quality. Particle size, as would be expected, is significantly correlated with strength on several occasions. However, greater interest lies in the very highly significant correlation between strength and the manganese content of cement at high water/cement ratio, and the analogous, though less striking, effect at low water/cement ratio.

Regression of Strength and Hydration on Compound Composition at Temperatures other than 21 Degrees

In a preliminary survey of the effect of temperature on the relationships between strength and composition, compressive strengths were measured for 0.45 water/cement ratio pastes which had been cured for 56, 28 and 16 days at 5, 21 and 43°C respectively. According to the empirical formula used by Saul (9), such pastes should be of equivalent maturity. The

maturity was also assessed by measuring the degree of hydration.

Only the regressions on C_3A are examined here. The results (Table 8) indicate that of the two groups of regressions, strength on C_3A, and hydration on C_3A, the latter is the more highly significant at all curing temperatures. Both groups attain highest significance at 21°C. The relative coefficients in Table 8 show that the greatest effect of temperature occurs with strength, and between 21 and 43°C, where there is a considerable reduction in the influence of C_3A.

Regressions in Terms of Transformed Variables

During this examination of the regression of strength on composition a search was made for improvements which could be achieved by the transformation of variables. Dependent and independent variables alike were subjected to transformations. The following two types of transformations were employed:

(a) Transformations by grouping and processing the raw variables into forms which have straightforward chemical or physical significance in the present context. Examples are the formation of variables to represent the quality of the silicate and aluminate phases, and the calculation of regressions for strength in terms of oxide analyses rather than compound compositions.

(b) Mathematical transformations with no immediately obvious physical interpretation.

Neither type of transformation produced consistent improvement throughout the range of ages and water/cement ratios used here, although some marginal gains could be made for the regression of 180 day strength on composition by correcting for departures from linearity. On the question of conducting regression analyses for strength directly on the oxide values, the procedure showed no general advantage in so far as levels of significance were concerned. However, in view of the convenience of working with oxide results rather than potential mineral contents, a summary of results is given in Table 9.

Table 9 shows that the level of significance for the regression of strength on alumina is similar to that for the regression on C_3A, and that the same conclusion applies to the comparison between multiple regressions on the four major compounds, and those on the four major oxides. It is of interest to note that in building up the regressions from the 1 to 4 oxide level, the best order for introducing the variables is Al_2O_3, CaO, Fe_2O_3, SiO_2.

An example of analysis on one of the more useful combinations of transformed variables is shown in the last column of Table 9, where multiple correlation coefficients are given for regressions on the calcium/silica and alumina/iron ratios. This set of transformations gives improved significance at early ages at the expense of some marginal loss of significance at later age.

Discussion II

It is to be expected that the rate at which a cement hydrates and hardens will depend on its particle size distribution as well as on its composition. The initial rate may depend on the specific surface area but, since the coarsest half of a cement may contribute as little as ten per cent of the surface area and, since the after the first day or so, reaction is mainly of these coarser particles, it follows that the specific area may be a poor indicator of the reaction rate in the later stages. A similar objection for the opposite reason can be made to the use of a sieve residue involving only a few per cent of the cement. In this paper, as a simple compromise, the median diameter by weight (Dm) is used as a measure of cement fineness.

The rate of hydration and hardening of cements 16 to 30 is indicated in Figs. 6 and 7; the vertical lines at each curing period represent a range of one standard deviation (S. D.) about the mean. The actual range is greater, but not distributed symmetrically about the mean. The experimental design is described in "Experimental II."

The almost traditional method (2) (10) (11) of analysing effects in terms of potential mineral composition is to fit an equation of the form

$$y = b_1(C_3S) + b_2(C_2S) + b_3(C_3A) + b_4(C_4AF)$$

This equation seems to assume that the effect of each mineral is linear and independent of the cement composition. These assumptions may be difficult enough to justify near complete hydration but seem quite inappropriate at early ages. Fig. 7 shows the result of such an analysis of the present data. It will be seen that, in each experiment, and for both hydration and strength, the initial coefficients for both of the silicates are negative. Even in the more mature pastes where the silicate coefficients are positive, the analysis ascribes the effect disproportionately to the aluminates, especially to C_3A. Of course C_3A does react more rapidly and combines more water than do the silicates, but this alone can not account for an effect as large as shown in Fig. 7. In particular, the high

coefficient for C_3A in the strength regressions is surprising because of the suggestion of Powers and Brownyard (12) that C_3A, in excess of that which forms sulpho-aluminate, weakens cement paste.

The likely explanation of the results in Fig. 7 is that the silicate minerals are hydrating more rapidly in the cements with the higher aluminate contents. The same explanation accounts for inflated aluminate coefficients, especially of C_3A, in the equations of Gonnerman (2), Powers and Brownyard (10) and Verbeck (11). The acceleration of cements with higher aluminate contents could be due to (i) direct interaction between aluminate and silicate phases, (ii) changes in the aluminium and iron substitutions in the silicates, (iii) finer grinding of cements with higher aluminate content, or (iv) a higher C_3S content in cements with a higher aluminate content.

The Hydration of Stirred Specimens

Tables 11 and 12 show that the cements with a higher aluminate ($C_3A + C_4AF$) content tend to have both a smaller median size and a higher C_3S/C_2S ratio. However, before drawing any conclusions from this, we will look at correlation coefficients (r) between hydration and various cement characteristics and between these characteristics themselves. Fig. 8 shows *r* between hydration of stirred specimens and various quantities associated with the cements, plotted against

the curing periods for this experiment as listed in "Experimental II." The curve for ($C_3A + C_4AF$) shows an r which is significant for almost the whole period from 5 hours to 6 months. The r for Dm is less significant. Correlations for 1/Dm were also evaluated because one might expect the hydration rate to depend on some power of this reciprocal but the significance level is little changed by this transformation. The negative r for C_2S is less significant than that of Dm, although more significant than the generally positive r of C_3S (not shown). Because both Dm and C_3S are highly correlated with C_2S, it seems that the correlation between hydration and ($C_3A + C_4AF$) is not explained by particle size or C_3S content.

Referring again to Fig. 9, the correlation of ($C_3A + C_4AF$) with hydration can be compared with those of C_3A and Al_2O_3, and it will be seen that, although less significant at early ages, these two curves are more significant than that of C_3A beyond 10 and 7 days respectively. The r for C_4AF on the other hand becomes significantly negative for these later curing periods. It should be noted that total aluminate content has a positive correlation with both C_3A and alumina but a slightly negatively correlation with C_4AF. Arguing then from the strength of the correlations with hydration and from the inter-correlations of the various cement characteristics, it seems possible that the correlation between hydration and total aluminates is due mainly to an effect of C_3A or alumina, helped to some extent by the effects of median size and C_4AF. The C_3S/C_2S ratio is also in a position to help, but since the silicates are correlated with Dm but give a poor correlation with hydration, this possibility must be somewhat discounted. It is risky to argue from simple correlations alone, but extensive multiple linear regression analysis did not reveal any hidden interactions. The multiple regression of hydration on C_3A and Dm is significant from 16 hours onwards and is more significant over-all than the simple regression on total aluminates alone. The

correlation curves in Fig. 8 for total silicates and for K_2O are at least partly explained by their dependence on Dm and C_3A respectively.

Hardened Specimens

The correlation coefficients between both hydration and strength and various cement characteristics are plotted for W/C = 0.35 in Fig. 9 and for W/C = 0.6 in Fig. 10. It will be seen that the curves of *r* versus curing period are of the same general shape as the corresponding curves of Fig. 9 but the correlation of C_3A with strength is not as significant as it is for hydration. Generally the steam cured specimens show the same behaviour as specimens cured entirely at 21°C to the same hydration value. Although the correlations are not shown, it must be stated that the correlation curve of C_2S is less significant than that of Dm but more significant than that of C_3S. A curve for the positive correlation of manganese is shown in Fig. 9. It reaches higher levels for strength than it does for hydration. It is less significant at the higher W/C ratio. The correlation between strength and both K_2O and Na_2O is shown in Fig. 11. It has already been suggested that the positive *r* for hydration on K_2O is partly a reflection of the C_3A effect but the possibility of a real alkali effect, as suggested by Fig. 11 can not be ruled out. However, such an effect is likely to be associated with the composition of the clinker minerals rather than the effect of alkali in solution because no difference was found by Alexander and Davis (13) who added both alkalies to the mix water.

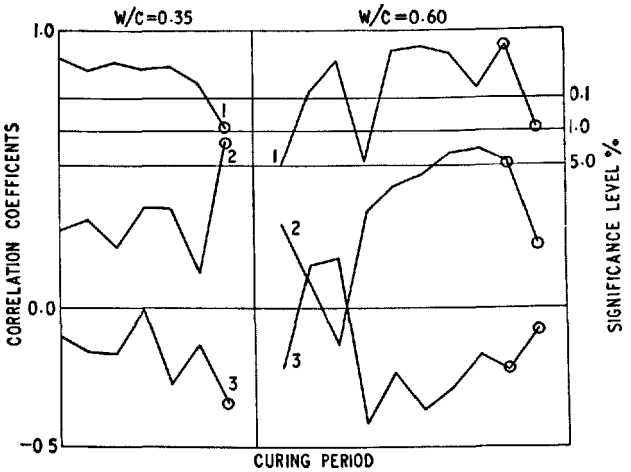

Fig. 11. *Coefficients for correlation between paste strength and* (1) *Hydration* (2) K_2O (3) Na_2O. *Curing periods at 21°C in sequence, then steam-cured specimens shown by circles*

The correlations of strength with hydration are also shown in Fig. 11. It will be seen that this correlation holds through all curing periods and is generally more significant than correlations shown here previously. Multiple regression analysis for strength on hydration and various cement characteristics gave no consistent pattern and an improvement in significance was found only occasionally for the addition of Dm, C_2S and TiO_2. In the multiple regression of strength on hydration and C_3A the coefficients for C_3A are not significantly different from zero. This means that, for these cements and at least

until six months, C_3A has little effect on the strength except that of accelerating the hydration reaction. The same conclusion can be stated in terms of Al_2O_3. From this study it is not possible to distinguish between the effect of C_3A itself and the effect of additional alumina on the properties of the other phases.

Conclusions

In this survey of commercial portland cements, differences between the strengths and between the hydrations are mainly attributed to differences in C_3A content. This factor dominates at water/cement ratios from 0.35 to 0.80, curing temperatures from 5 to 75°C, and throughout most of the 1-day to 6-month range of curing periods investigated. Strength is most sensitive to C_3A content under conditions which are frequently encountered in laboratory test work, namely, water/cement ratio 0.5, age 28 days, curing temperature 21°C.

With the present cements there is a smaller, but significant effect, for median particle size, whereas the effect of quite appreciable differences in C_3S content is of minor importance. Earlier work (1), which attributes differences in strength between older and more recent cements largely to differences in C_3S and in fineness, is not inconsistent with the present study, since the cements in the former investigation had a nearly constant level of C_3A.

The influence of other cement characteristics such as minor oxide composition, surface area, etc., is either non-significant, or can be accounted for as another aspect of the C_3A and size effects. Possible exceptions are the positive correlations of strength with Mn_2O_3 at early ages, and the negative correlations of strength with free lime at high water/cement ratio and later ages.

The C_3A effect is thought to be mainly an acceleration of the hydration of the cement as a whole. However, in assessing the influence of C_3A on the quality of cement, it should be borne in mind that the rate of strength gain is but one aspect. The possibility that, at late ages, C_3A may have a negative effect on strength must be considered (2), and allowance must also be made for any effects on drying shrinkage (2) (14), sulphate resistance, and heat of hydration.

Acknowledgments

The authors are indebted to Mr. C. H. Gray, of the Division of Computing Research, for Table 5, and to Dr. R. T. Leslie and Staff, of the Division of Mathematical Statistics, for helpful discussions. The oxide analyses of the cements are by Miss B. Terrell, and the X-ray determination of C_3A are by Mr. A. Wilson, both of the Division of Applied Mineralogy. Messrs. C. Larrewyn, B. Murphy and B. Press, of the same Division, participated in the conduct of the tests. The above are all members of the C.S.I.R.O., Australia.

Supplementary Paper III-88 Relation between the Hydration of Alumina Cement Mortars and Their Strength in the Early Stages

Kiyotaka Mishima*

Synopsis

Mineralogical changes involved in the early stages of the hydration of alumina cement mortar have been investigated under various conditions (w/c = 0.4 ~ 0.7, curing temperature 10 ~ 40°C) in comparison with changes in compressive strength. And setting time of neat alumina cement paste has also been measured in different temperatures.

When the mortar specimens were cured at temperatures lower than 30°C, CAH_{10} and C_2AH_8 were observed and their strengths were higher than those of specimens cured above 30°C. But above 30°C., the first hydration product was only C_2AH_8, which was converted to C_3AH_6 in later stages. In this temperature region CAH_{10} was not observed at any stage. The compressive strength had increased only for the first 1 to 3 days before lowering and their maximum strengths were lower than those cured below 30°C. At approximately 30°C, no hydrated product was observed until 12 hrs. of curing, then C_2AH_8 and CAH_{10} were produced and the strength developed very slowly. But no deterioration of strength was found until 7 days of curing. These results corresponded to the fact that setting time was extremely long at around 30°C.

There is no obvious relationship between the quantities of hydrates and the strength of mortars because the strength seems to be rather greatly influenced by their structure and behaviour of amorphous parts. However, distinct relationship is observed between the species of hydrates and strength of mortar specimens. That is, it may be said that the strengths of mortar specimens containing CAH_{10} is greater than those containing $C_2AH_8 + AH_3$ or $C_3AH_8 + AH_3$.

As to the reduction of hydration reaction at temperatures around 30°C, it is likely to be considered that two reactions take place at the same time, as follows:

$$CA + H \longrightarrow CAH_{10} \longrightarrow C_2AH_8 + AH_3$$
$$CA + H \longrightarrow C_2AH_8 + AH_3$$

Both hydrates, CAH_{10} and C_2AH_8, have their optimum temperatures for crystal growth below and above 30°C, respectively. Consequently, the rate of crystal growth seems to reach the minimum value about 30°C. which leads to the extremely long setting time.

Introduction

The main phases in anhydrous alumina cement are mostly CA, CA_2, $C_{12}A_7$, C_2AS, C_2S, C_2F and C_4AF. The rapid hardening qualities are attributed to the calcium aluminates, especially CA. The several hydrates are produced on the hydration of alumina cement and the most prominent hydrates are CAH_{10}, C_2AH_8, C_3AH_6 and AH_3 (gibbsite). It is said, however, that the only stable hydrates, at ordinary temperature, are gibbsite and cubic C_3AH_6. The metastable hexagonal calcium aluminate hydrates, CAH_{10} and C_2AH_8, are only formed at low temperatures.

It was thought that the main hydrate produced from alumina cement was C_2AH_8, but it is now believed that the most important phase of normal hydration is CAH_{10}. Recent work by Percival Buttler and Taylor (1) has shown that CAH_{10} is a persistent metastable phase at temperature lower than 21°C. However, Wells and Carlson have indicated that it was still main hydrate at 24°C., in paste hydration studies. Johns and Roberts (2) concluded that there was a transition temperature at 22°C above which C_2AH_8 was stable towards CAH_{10} in the aqueous phase.

It is thought that the metastable hexagonal CAH_{10} converts first to C_2AH_8 and then finally to stable

*Research Laboratory, Asahi Glass Co., Ltd., Yokohama, Japan.

C_3AH_6. And the rate of conversion is known to be very slow below about 25°C, but it increases with rising temperature. It has also been known that there is the loss in strength of alumina cement for a long time ageing or at high temperature curing. To explain the cause of strength reduction many investigations have been done. Wells and Carlson suggested that the loss in strength was due to crystallization of AH_3 from alumina gel. More recent work by Midgley (3) showed that the strength reduction was due to change of porosity associated with conversion and was affected by the rate of conversion. In the opinion of Robson (4) change of strength by conversion was mostly influenced by initial water cement ratio. But the exact causes have not been completely ascertained.

The effect of temperature on the setting time of alumina cement has been investigated by many workers. It is known that in the temperature range $1 \sim 30$°C the setting time becomes progressively longer as the temperature rises and over 30°C, the setting time rapidly becomes shorter again.

This phenomenon corresponds to the fact that the development of initial strength is retarded the most at 30°C, and the rate of hydration passes through a minimum value at around the same temperature.

The causes of the anomalies at around 30°C have not also been known exactly.

In this investigation mineralogical changes involved in the early stages of hydration of alumina cement mortar have been investigated under various curing temperature in comparison with changes in compressive strength.

On the basis of this experimental results, the relation between the mineralogical state of hydrates produced in mortar and compressive strength of mortar has been discussed. And some observation on the hydration reaction has also been carried out, then anomalies of hydration has been discussed at about 30°C.

Experimental Procedures

Preparation of Specimens

The specimens used in strength measurement and mineralogical analysis were made from 1:2 alumina cement: sand mortars to bring the test condition close to that of concrete. They were made in the form of prisms $4 \times 4 \times 16$ cm. The mixed materials for prisms were kneaded by hand and tamped into a steel mould. The specimens were usually cured in the mould up to 6 hrs., then were removed from the mould and cured in moist-air until they were subjected to test. All these operations were done in the curing room which was kept at testing temperature and at a relative humidity above 85%.

The neat alumina cement paste was employed in the measurement of setting time which were also carried out in that curing room.

The alumina cement used in this investigation was a commercial high alumina cement. The chemical analysis of the cement is given in Table 1. X-ray examination of the cement showed the following minerals to be present: CA, C_4AF and $C_{12}A_7$.

Table 1. *Chemical compositions of alumina cement*

	Weight (%)
Al_2O_3	40.34
CaO	37.15
SiO_2	2.90
FeO	3.95
Fe_2O_3	13.28
MgO	0.32

Condition of Hydration and Curing

For the strength measurements and the mineralogical analyses, the specimens were made from the mortars with four different water cement ratios: 40, 50, 60 and 70%. To find the effect of temperature of hydration and curing on the strength and the mineralogy, mortar specimens were examined in temperatures ranging from 10°C to 40°C with interval of 5°C. At each testing temperature the specimens were stored at a relative humidity above 85%.

Strength Measurements

The measurements of compressive strength were carried out for the specimens cured at various temperatures for the following periods: 6 hrs., 12hrs., 24hrs., 3days and 7 days.

Mineralogical Examinations

The mineralogical analyses were carried out by X-ray powder diffraction just after the strength measurements were done. The broken pieces of

specimens obtained in the test of compressive strength were used in the mineralogical analyses. The material from the specimens was roughly ground, then it was screened by 170-mesh sieve for separating the cement from the sand.

The specimens which did not perfectly harden were treated with absolute methanol in order to remove the water and separated from the sand by 170 mesh sieve in methanol.

The hydrated cements got by the such way were subjected to X-ray examination.

The quantitative determinations of unhydrated CA and hydrated crystals were tried by X-ray powder diffraction method. But the exact determination of minerals was not made, because the cement was not completely separated from sand, so the quantitative analysis by using the internal standard was not carried out. Therefore, the quantity of crystals was determined in comparison of the intensity of each peak of X-ray diffraction patterns.

As the method by means of integral intensities of each peak was generally better than by comparison of height in each peak, the measurements of area of each peak were carried out by fixed-time-method for some specimens. However, since the result showed a good agreement with that of height measurement, the determination by comparison of height in each peak was adopted in this investigation.

Measurement of Setting Time

The setting time of the neat alumina cement was determined at temperatures ranging from 5°C to 40°C with interval of 2°C by Vicat needle method. The water cement ratios of the specimens were determined by the normal consistency at each testing temperature.

Experimental Results

Compressive Strength

Table 2 shows the compressive strengths of mortar prisms which were made with different water cement ratios and cured at various temperatures and for various periods. For example, the strength of specimens made with a W/C = 40% and cured at various conditions is given in Fig. 1.

Table 2. *Compressive strength of mortar prisms cured at various temperatures for various periods*

The strength of specimens cured at a temperature below 30°C increased steadily with age until 7 days

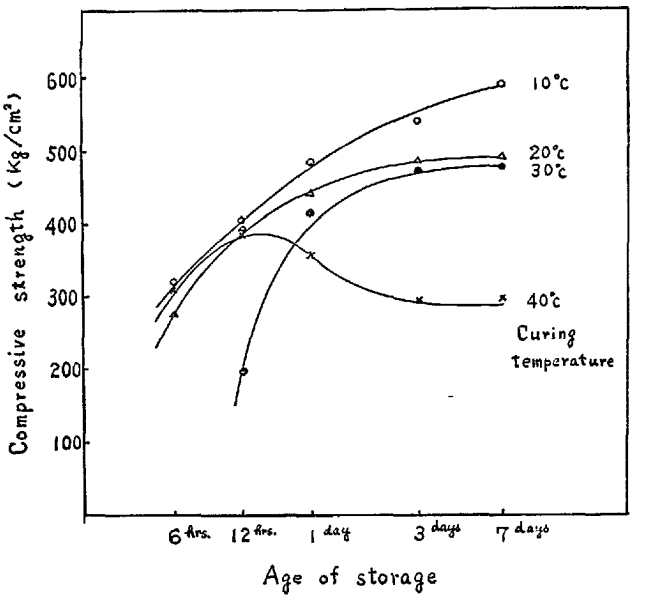

Fig. 1. *Strength of prisms made with alumina cement mortar of W/C = 0.4, cured at various temperatures*

and, the lower the curing temperature, the strength became the higher. At 30°C, the strength did not increase in the first 12 hrs., and then increased rapidly, the strength at 7days was lower than those found in specimens cured for the 7 days at below 30°C. Above 30°C, the strength increased during 1 to 3 days, then decreased gradually and the maximum strength was lower than those cured below 30°C.

As for the water cement ratio (Fig. 2, Fig. 3), at curing temperature up to 25°C, there was not clear correlation between the compressive strength and the water cement ratio, but above 25°C, the strength decreased with the ratio.

Mineralogical Examination

The results of semi-quantitative analyses by X-ray diffraction are given in Fig. 4. In this figure only CA of unhydrates is shown for simplification.

The hydrated crystals found in the mortar specimens were CAH_{10}, C_2AH_8, C_3AH_8, C_3AH_6 and gibbsite (AH_3). At low hydration temperatures the main phase produced on hydration was CAH_{10}, followed by C_2AH_8. At high temperatures, the primary hydration product was only C_2AH_8 which was converted to C_3AH_6 in later stages. The higher the temperature, the more rapidly this conversion proceeded.

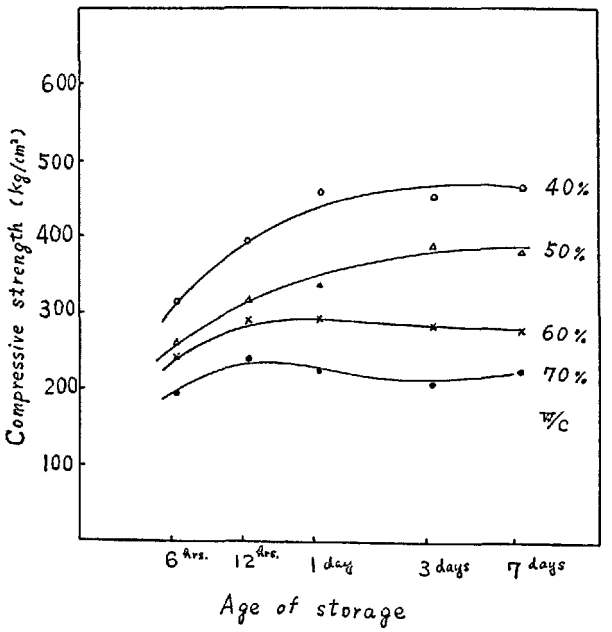

Fig. 3. *Strength of mortar prisms cured at 35°C for various periods*

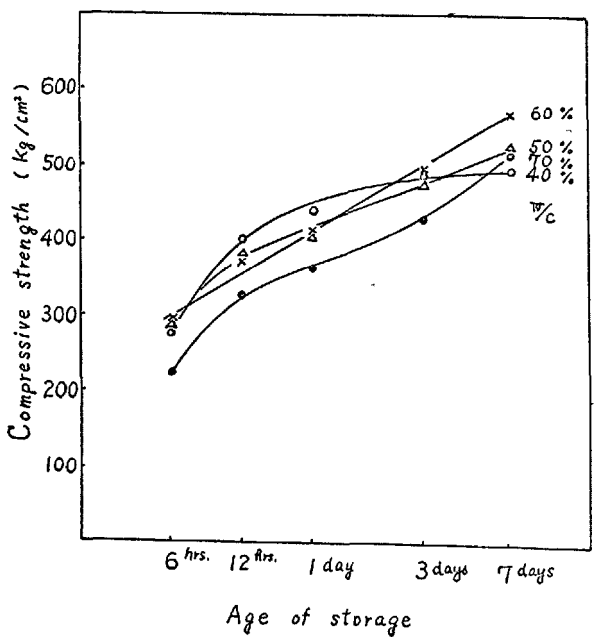

Fig. 2. *Strength of mortar prisms cured at 20°C for various periods*

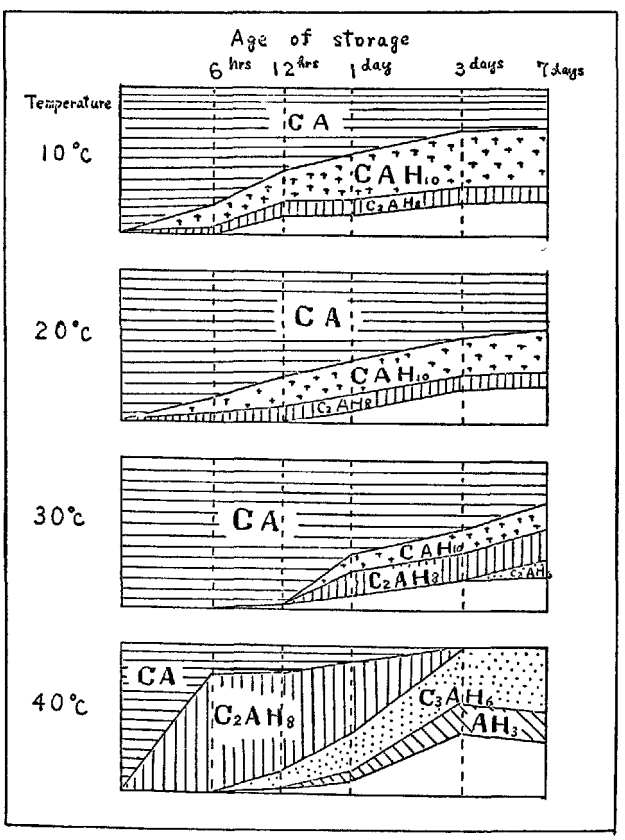

Fig. 4. *Results of X-ray examination. Quantity of crystals observed in specimens made with alumina cement mortar of W/C = 0.4, cured at various temperatures for various periods*

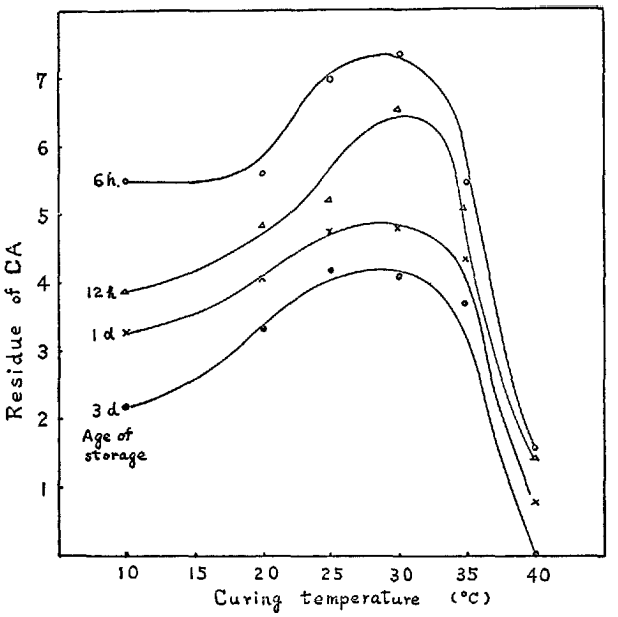

Fig. 5. *Residue of CA in the mortars cured at various temperatures for various periods*

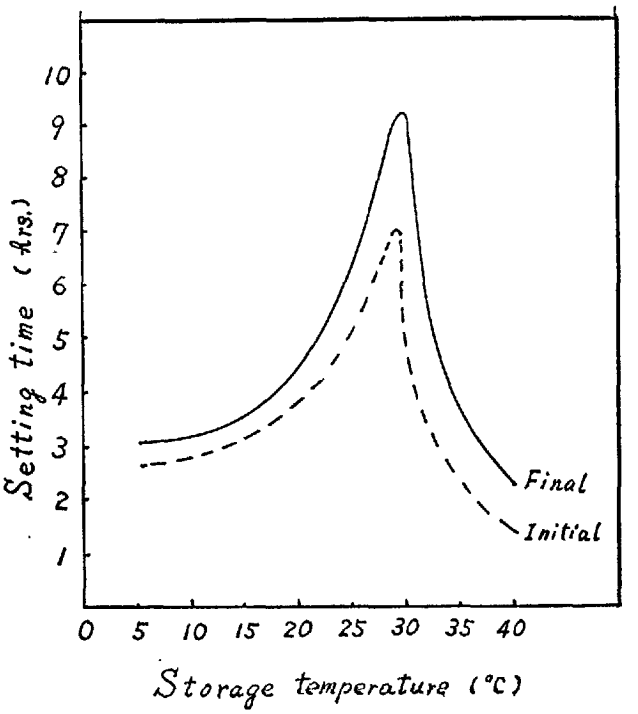

Fig. 6. *Setting time of neat cement pastes at various temperatures*

The changes of the amounts of CA are given in Fig. 5. The results showed that there was no obvious relationship between the reaction rate of CA and the temperature. There was an increase in remaining amounts of CA as the temperature was raised from 10°C to 30°C, but there was a decrease again at 40°C. Consequently, the quantities of hydrates produced in the reaction were very little at 30°C, in the early stage.

CAH_{10} was produced at temperatures below 30°C, above which it had never been observed. The amounts of CAH_{10} increased with the fall of temperature and the increase of the curing period.

C_2AH_8 observed always whenever the hydrated crystals were formed, and there was an increase in quantities as the temperature and curing age increased. However, when the hydration temperature was raised to 40°C, the amounts of C_2AH_8 increased up to 12 hrs. and then decreased and conversely the quantities of C_3AH_6 increased.

C_3AH_6 was not observed up to 7 days at temperatures below 25°C, but at higher temperature it was produced in the early stages. It was formed at the time more than 7 days at 30°C, and at 24 hrs. at 40°C respectively. The amounts of C_3AH_6 increased monotonically with curing periods.

Gibbsite was usually crystallized at the time of a little later than production of C_3AH_6.

As for the effect of water cement ratio on mineralogy, it was observed that the rate of hydration increased with a rise of water cement ratio.

Setting Time

The results of setting time measurements are given in Fig. 6. In the range from 5°C to 30°C the setting time of alumina cement paste became progressively longer as the temperature rose and above 30°C rapidly shortened again.

The results agree with the results of many workers.

Discussion

Relation between the Hydrates and the Strength

There is no obvious relationship between the quantities of crystalline hydrates produced in mortar specimen and the strength of mortar, because the strength seems to be rather greatly influenced by the structure of the whole body containing amorphous parts. However, supposing that the specimens made with

same water/cement ratio have the same structure, there are following relationships between the hydrates and the strength of the specimens with same water/cement ratio;

1. The strength increases with the amounts of CAH_{10}.
2. When the both crystals, CAH_{10} and C_2AH_8, are present simultaneously, the strength increases as the ratio of CAH_{10} to all produced hydrated crystals increases.
3. When the hexagonal C_2AH_8 and cubic C_3AH_6 exist together, that is, the conversion reaction proceeds, the strength decreases with the increase of C_3AH_6.
4. Whenever cubic C_3AH_6 is produced, the strength falls.

On the basis of these results, the following relation may be considered as existing among the three hydrates as to the strength

$$CAH_{10} > C_2AH_8 \gg C_3AH_6$$

This relation has not always shown that the binding strength of C_3AH_6 is less than that of CAH_{10} or C_2AH_8. Rather it has concerned the strength of whole body of mortar containing each hydrate, irrespectively of whether it is produced by conversion or not, that is, the strength of the mortar specimen containing CAH_{10} crystals is greater than that of the specimen containing C_2AH_8 or C_3AH_6.

The causes of strength reduction at higher temperature are thought as follows;

1. The binding strength of CAH_{10} is greater than C_3AH_6.
2. The change of structure by conversion of hexagonal hydrates to cubic hydrate.
3. The change of behavior of amorphous parts like a alumina gel by rising the temperature.

However, in this investigation, it could not be confirmed which reason is the most effective.

Setting Time and Hydrates

At temperatures around 30°C, the setting time is most delayed and final set is about 9 hrs., when no hydrated crystal is observed. CA decreases little until 12 hrs. of curing at this temperature. These results correspond to the fact that the strength develops very slowly. However, after 12 hrs. the reaction proceeded rapidly, so C_2AH_8 and CAH_{10} were produced and the strength increased rapidly, too.

There is a critical temperature at about 30°C above which crystal of CAH_{10} is not observed by X-ray diffraction. And at 30°C., sometimes C_2AH_8 is observed in earlier stage than formation of CAH_{10}.

Generally setting time agrees with the time when the hydrates begin to form the hydrate and crystals of hydrates grow enough to be found by X-ray diffraction in 2 or 3 hrs. after the final set.

Hydration Reaction at Each Curing Temperature

Generally the hydration reaction of CA is considered to proceed as follows;

$$CA + H \longrightarrow CAH_{10} \longrightarrow C_2AH_8 + AH_3 \longrightarrow C_3AH_6 + AH_3$$

At the first stage on hydration of CA metastable hexagonal compound CAH_{10} is produced, then it is subsequently converted to hexagonal C_2AH_8, and at ultimate stage C_2AH_8 is converted to stable cubic C_3AH_6. The rate of conversion of the metastable hydrates to the stable cubic hydrate is heavily dependent on the temperature. Therefore, at higher temperature, it seems apparently that the direct reaction from CA to C_2AH_8 will proceed and CAH_{10} is not observed.

But on the basis of these experimental results, it seems reasonable to consider that the following two reactions take place at the same time

$$CA + H \longrightarrow CAH_{10} \longrightarrow C_2AH_8 + AH_3 \longrightarrow C_3AH_6 + AH_3 \quad (1)$$

$$CA + H \longrightarrow C_2AH_8 + AH_3 \longrightarrow C_3AH_6 + AH_3 \quad (2)$$

that is, the reaction (1) is an ordinary way and the reaction (2) is direct reaction of CA to C_2AH_8.

Fig. 4 shows the quantities of CAH_{10} and C_2AH_8 produced at various temperature respectively. These figures show that the rate of hydration decreases gradually towards 30°C, at which it falls to its lowest, and then above 30°C, rapidly increases with the rise of temperature. To explain this fact it is favourable to consider that two reactions proceed simultaneously. And it is also explained smoothly that C_2AH_8 is produced at earlier stage than CAH_{10} at 30°C, and is observed always when the other hydrates are formed at any temperatures. However, at temperatures above 30°C, it may be considered that the reaction (1) does not occur practically.

To explain the reduction of hydration at 30°C, it is necessary to confirm the hydration mechanism of CA. Although the exact mechanism of the CA-water reaction is very difficult to prove conclusively, it seems reasonable for the explanation of above results to

consider as follows. When the CA grain gets in contact with water, at the first stage thin hydrated amorphous layer is formed on the surface of the grain (It may be considered that the layer is made from the saturated solution of the CA). This product probably retards the reaction by restraining the water supply to the CA (or by controlling the dissolution of the CA). As the layer becomes some thick to some extent, it appears that the reaction is not proceeding. At later stage in the reaction the crystallization of hexagonal hydrates occur in the layer and poorly crystalline hexagonal CAH_{10} and C_2AH_8 are formed. But in this stage they are not yet observed by X-ray diffraction. As the crystals of hexagonal hydrates become bigger, the water permeability of the layer may increase and the reaction progresses again. While from the Fig. 6, it may be considered that there is an optimum temperature of growth of hexagonal CAH_{10} crystal in lower temperatures, and C_2AH_8 crystal has an optimum temperature to grow in high temperature regions. These optimum temperatures are presumed to be below and above 30°C, respectively. Therefore in low temperature region crystals of CAH_{10} grow up in the early stage (C_2AH_8 grow little) and the layer becomes porous, the reaction proceeds rapidly. At high temperatures, too, the reaction accelerates by growth of C_2AH_8 crystals. But at approximately 30°C, the rate of hydration reaction decreases extremely because it is difficult for the crystal of two hexagonal hydrates to grow. Consequently, it is observed at temperatures around 30°C that the setting time is very delayed and the strength develops very slowly.

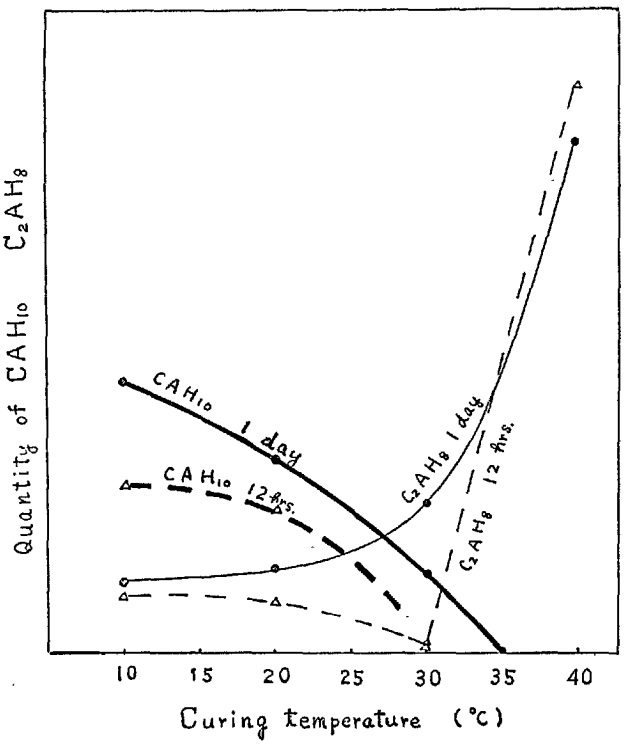

Fig. 7. *Quantity of* CAH_{10} *and* C_2AH_8 *produced at various temperatures for 6 hrs. and 1 day*

Summary

Mineralogical changes involved in the early stages of the hydration of alumina cement mortar have been investigated under various curing temperature (10 ~ 40°C) with different water cement ratios (40 ~ 70%), and associated changes in compressive strength have been determined. The setting time of neat alumina cement paste has also been measured in various temperatures (5 ~ 40°C).

On the basis of these experimental results the relation between the mineralogical state of produced hydrates and the compressive strength has been discussed. Some observation on the hydration reaction has also been carried out.

There was no obvious relationship between the quantities of hydrates produced on the hydration and the compressive strength of mortar because the strength seemed to be rather greatly influenced by its structure and behavior of amorphous parts produced in mortar specimens. However, distinct relationship was observed between species of hydrates produced in mortar specimens and mortar strength, as follows;

$$CAH_{10} > C_2AH_8 + AH \gg C_3AH_6 + AH_3$$

This relation shows that the strength of mortar containing CAH_{10} is greater than that containing $C_2AH_8 + AH_3$ or $C_3AH_6 + AH_3$.

To explain the reduction of hydration reaction at temperatures around 30°C, it seems reasonable to consider that two reactions take place at the same time, as follows;

$$CA + H \longrightarrow CAH_{10} \longrightarrow C_2AH_8 \longrightarrow C_3AH_6$$

$$CA + H \longrightarrow C_2AH_8 \longrightarrow C_3AH_6$$

At very early stage of hydration hydrated amorphous layer is formed around the CA grain. This product probably retards the reaction by restraining the water supply to the CA. At the next stage the hexagonal hydrates (CAH_{10}, C_2AH_8) crystallize in the

layer. As the crystals of hydrates grow, the water permeability of the layer increases and the reaction progresses again. There is an optimum temperature of growth of CAH_{10} crystal in lower temperature, on the other hand, C_2AH_8 crystal has an optimum temperature to grow in high temperature regions. Therefore, in low temperature regions crystals of CAH_{10} grow up at early stage and reaction proceeds rapidly. At high temperature the reaction also accelerates by growth of C_2AH_8 crystal. But at approximately 30°C the rate of hydration reaction decreases extremely because it is difficult for the crystals of two hexagonal hydrates to grow. Consequently, it is observed at temperatures about 30°C that the setting time is very delayed and the strength develops very slowly.

Supplementary Paper III-97 Effects of Hydration of Cement on Compressive Strength, Modulus of Elasticity and Creep of Concrete

Singo Seki, Kiyoshi Kasahara, Takeo Kuriyama and Makoto Kawasumi*

Synopsis

Relation between rate of hydration of cement and compressive strength, modulus of elasticity, and creep of concrete was examined from data of bound water of cement paste and wave velocity in it, and compressive strength and creep tests of concrete.

Introduction

It is natural to consider that the strength, modulus of elasticity, creep and many other properties of concrete are closely related to the hydration of cement.

We showed in the previous paper that the compressive strength of concrete is linearly related, regardless of its age to the weight ratio of hydrated cement to the mixing water, and derived an empirical formula to be used practically. In this paper, are summarized only important results of the above study. And descriptions are given on the result of some attempts to estimate modulus of elasticity of concrete at any age when the properties of aggregate are known. And the result on the relation between creep and progress of hydration of cement will also be stated.

The original mix proportion of the concrete of the specimens studied are shown in Table 1. And this is the one which was used to construct the Kurobe No. 4 Dam, one of the representative large dams in Japan. The concrete specimens, however, were made with the concrete wet screened through a sieve with 40 mm openings.

Table 1. *Mix proportion of full mix concrete*

Maximum size of aggregate (mm)	Cement (kg/m³)	Water (kg/m³)	Fine aggregate (kg/m³)	Coarse aggregate (kg/m³)	Water-cement ratio w/c (%)
180	180	85	434	1722	47.0

And the type of cement was moderate heat portland cement.

Measurement of the Amount of Bound Water in Cement Paste

In order to get the relation between the amount of bound water in cement paste and the strength of concrete, the amount of bound water in the cement paste with water-cement ratios (W/C) of 25, 35, 40 and 55%, at the ages of 7, 28, 91, 365 days were measured.

Type of Cement

The type of cement used in experiments was moderate heat portland cement and its mineral composition is shown in Table 2.

Table 2. *Mineral composition of cement*, (%)

C_3S	C_2S	C_3A	C_4AF	$CaSO_4$	Total
46.9	30.9	3.4	13.0	2.0	96.2

Manufacture of Specimens and Testing Procedures

Specimens for the measurement of the amount of bound water were prepared using the mold of 4 × 4 × 16 cm, cured in a constant temperature and

*Technical Laboratory, Central Research Institute of Electric Power Industry, Tokyo, Japan.

humidity chamber at 24°C and 80% RH for twenty hours after casting. Their respective water-cement ratios were 25, 35, 40 and 55%. After the mold was removed, they were cured in the waterpool with 21 ±1°C respectively for 7, 28, 91, 365 days.

Measurement of the weight of bound water was made with specimens cured in closed glass tubes, but as the purpose of the present experiments was to investigate the compressive strength of concrete cured in water, we particularly examined the amount of bound water found in cement cured in water. The method we used in testing was as follows:

After the specimens were ground in a steel mortar, they were passed through a sieve with 0.15 mm openings. About 5 grams of passed sample were dried in vacuum-type desiccator under a pressure of 5 mm mercury and stored in a silica gel dryer for three days to remove free water. Then after being put into a platinum melting pot, they were ignited in an electric furnace with the temperature of 900–950°C for about three hours. In the case of cement-paste with water-cement ratio 60–65%, the testing was given up as the materials were so badly segregated that the preparation of specimens became impossible.

The Result of the Measurement

The result of the measurement of the amount of bound water of cement-paste with different water-cement ratios is shown in Fig. 1.

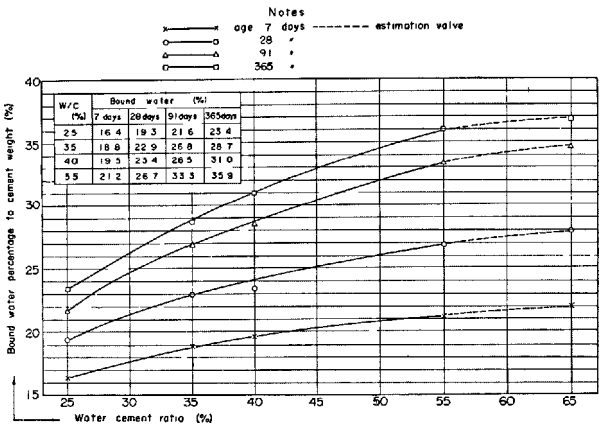

Fig. 1. *Bound water of moderate heat cement paste with different water cement ratios at each age (cured in water at 20°C)*

According to Kondo (1), the amount of bound water measured by weight when the cement is perfectly hydrated is said to account for 35–37%, of the weight of whole cement while Kinji Shinohara (2) regarded it as 32–37%. In consideration of these two experimental values, the amount of perfectly bound water will be estimated to be 37%. Or estimating from the results of experiments of concrete made by the authors, it is proper to consider its value as 37% in the case of moderate heat portland cement.

Rate of Hydration of Cement (R_H)

Experimental results on the relation between the amount of bound water and water-cement ratio with different ages are shown in Fig. 1, and according to it, the rate of hydration of cement increases with the water-cement ratio and the age. If the percentage of bound water to original cement by weight is 37% as described above, when the whole cement is hydrated in our experiment, the rate of hydration of moderate heat portland cement is calculated as shown in Table 3. When cement is cured in water for one year with its water-cement ratio of 55%, the rate of hydration is 35.9/37 = 0.97, that is, 97% of the cement is supposedly hydrated. The ratio of amount of bound water in hydrated cement at a specified age to that of bound water in its perfectly hydrated cement shows the rate of progress of hydration.

$$\text{Rate of hydration } (R_H) = \frac{\text{bound water at the specified age}}{\text{bound water in perfectly hydrated cement}} \quad (1)$$

This rate of hydration changes with the water-cement ratio and the age of cement paste. The relation between them is shown in Fig. 2. From this chart, the rate of hydration of cement at any water-cement ratio and age, can be obtained.

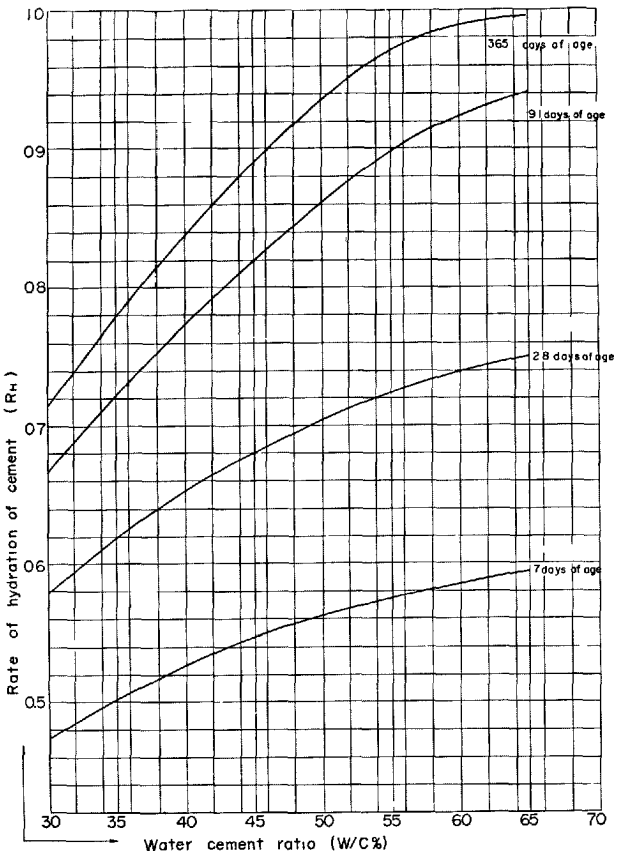

Fig. 2. *Relation between water-cement ratios and rates of hydration at early age (type of cement: moderate heat cement, 37% of perfect bound water)*

Table 3. *Rate of hydration* (R_H) *calculated from the amount of bound water*

W/C (%)	Amount of bound water (%)				Rate of hydration of cement (R_H) (%)				Remarks
	7 days	28 days	91 days	1 year	7 days	28 days	91 days	1 year

Note: (1) The amount of perfectly bound water of cement is 37% of the total weight of the cement.
(2) Sign ○ expresses experimental values, and sign □ values read from figures.

Effective Cement-Water Ratio and the Compressive Strength of Concrete

Compressive strength of concrete is supposedly related to the effective cement-water ratio expressed in the following formula:
Effective water-cement ratio (C_H/W)

$$= \frac{\text{cement weight per 1 m}^3\text{ concrete (kg/m}^3) \times \text{rate of hydration of cement } (R_H)}{\text{weight of water per 1 m}^3\text{ concrete (W) (kg/m}^3)}$$

$$= \frac{\text{weight of original cement that has become hydrated per 1 m}^3 \times \text{concrete } (C_H)\text{ (kg/m}^3)}{\text{weight of water per 1 m}^3\text{ concrete (W) (kg/m}^3)} \quad (2)$$

It became clear that the relation between the effective cement-water ratio calculated from the rate of hydration of cement and the compressive strength of concrete are showed almost on the same line at any age. Fig. 3 shows especially the relation between compressive strength of concrete used for the Kurobe No. 4 Dam and its effective cement water ratio at each age.

The mineral composition of this cement is almost the same as the one used for the measurement of bound water. Fig. 4 shows the plot of 36 values obtained from experiments in our laboratory and 28 experimental values of other dams.

From the data shown in Fig. 4, the following linear regression line was derived by the method of least squares,

$$\sigma_c = -281.2 + 413.97\,(C_H/W)\ \text{kg/cm}^2 \quad (3)$$

where σ_c is the compressive strength of concrete. A95% confidence prediction interval for future observation about the compressive strength of con-

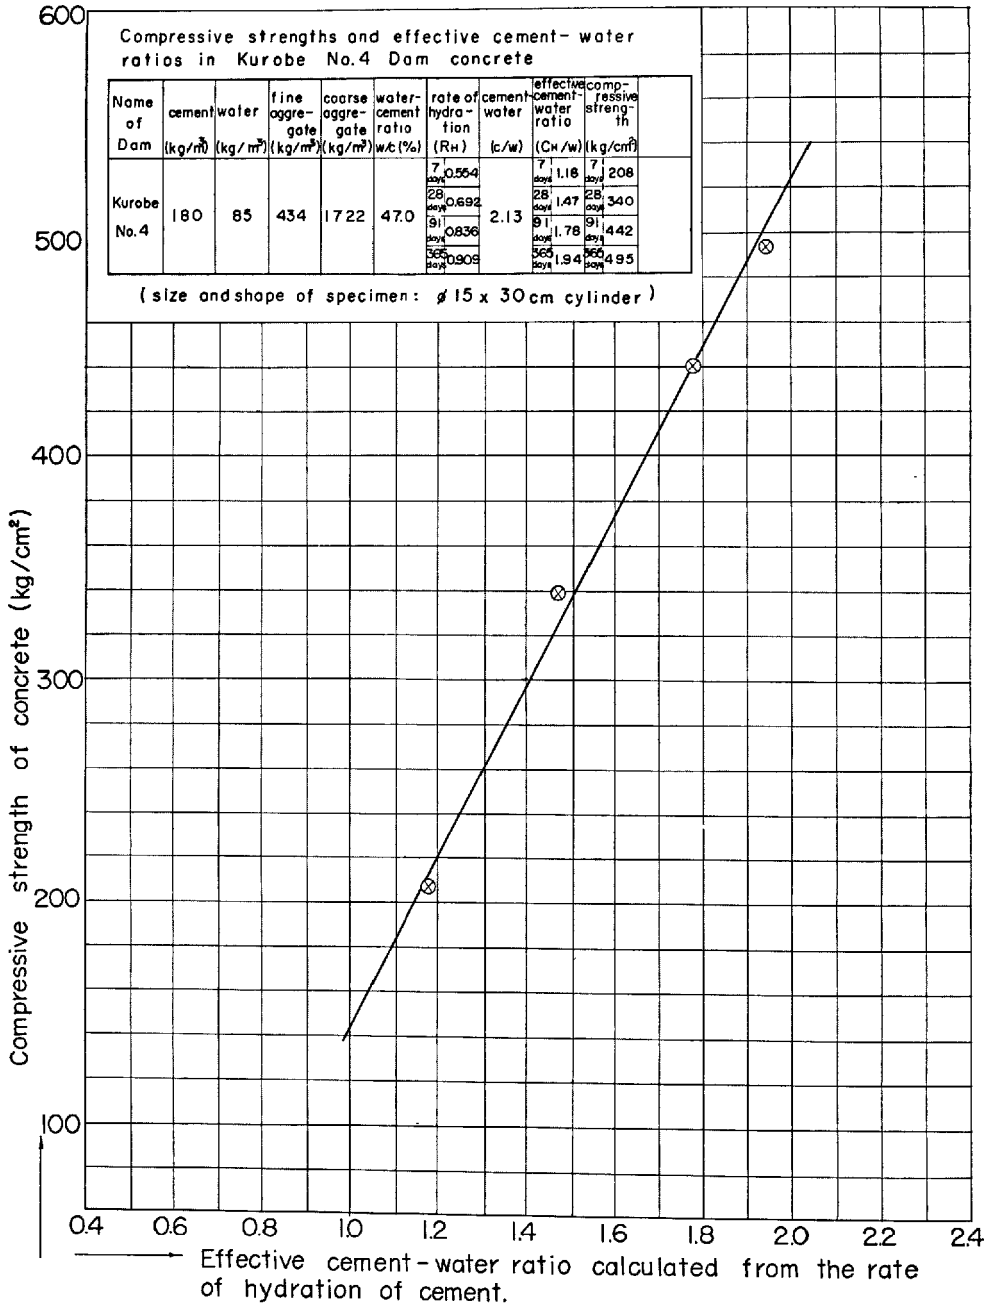

Fig. 3. *Relation between compressive strength of concrete and effective cement-water ratio calculated from the rate of hydration of cement in the Kurobe No. 4 Dam concrete. (type of cement: moderate heat cement, ages 7, 28, 91, 365 days)*

crete is also shown in Fig. 4.

We must recall that T. C. Powers and T. L. Brownyard stated in 1947 that the strength of cement-paste and mortar is expressed as a linear function of the ratio of the volume of hydrate of cement and void contained therein to the amount of water initially used (gel-space ratio) (3). Later developments are concisely summerized in Powers' report (4). Here, we derived a

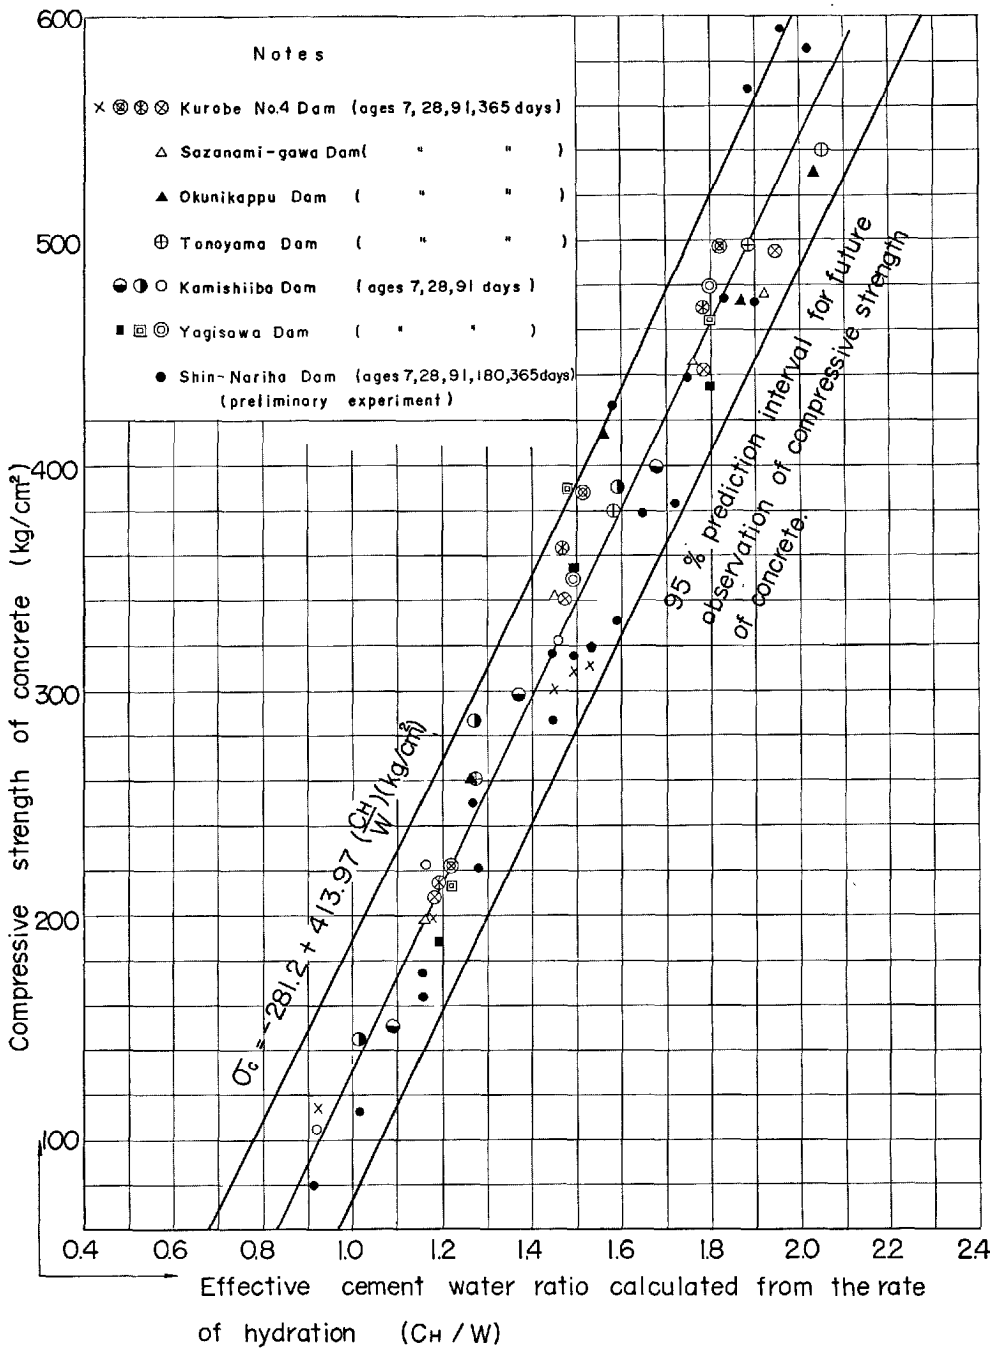

Fig. 4. *Relation between compressive strength of concrete and the effective cement-water ratio calculated from the rate of hydration (with perfect bound water ratio 37%)*

practical formula of broader application on the strength of concrete in terms of C_H/W.

The value C_H/W shows the hydrated cement-water ratio, and seems to be more suitable in the chemical terminology. But it shows the effective amount of cement-water ratio contributing to the enhancement of compressive strength of concrete, so this value was named effective cement-water ratio.

Measurement of Longitudinal Wave Velocity in Cement Paste

Longitudinal wave velocities in cement pastes with w/c, 26, 36, 44.5, 52% at the time of demoulding were measured at the ages of 7, 28, 91, 365 days, by ordinary direct pulse method using of an oscilloscope.

Size of specimens was $\phi 5 \times 10$ cm, and four specimens were used for each measurement. The results are shown in Table 4.

The densities of specimens at the times of measurement are shown, in Table 5.

Table 4. *Longitudinal wave velocities in cement pastes with different w/c and ages*

W/C (%)	Longitudinal wave velocity (m/sec)			
	Age (days)			
	7	28	91	365

Longitudinal Wave Velocity and Volume of Unhydrated Water in Cement Paste

The problem of longitudinal wave in cement paste will be treated from the two stand points,—the one is that of the elastic wave propagating through granular media and the other that of the wave through porous media. And with the former, there are theories described Takahashi—Y. Sato (5), S. Nagumo (6) and T. Momoi (7) and with the latter, by Y. Sato (8) (9).

But here, we try to find the effect of progress of hydration of cement on wave velocity experimentally.

In Fig. 5, is shown relation between volume of unhydrated water in cement paste and longitudinal wave velocity in it.

The volume of unhydrated water in cement paste were caluculated by the following formula:

$$V_{W-WH} = V_W - \frac{0.37C_H}{\rho_W} = V_W - \frac{0.37R_HC}{\rho_W} \quad (4)$$

where V_{W-WH}: volume of unhydrated water in 1 m³ cement paste [m³/m³]

V_W: volume of water in cement paste at the beginning [m³/m³]

C: cement mass in 1 m³ cement paste [kg/m³]

C_H: hydrated cement mass in 1 m³ cement paste [kg/m³]

R_H: rate of hydration of cement

ρ_W: density of water = 1000 kg/m³

From this figure, it was shown as a first approximation that the velocity is linearly dependent on the volume of unhydrated water as shown by the least squares solution,

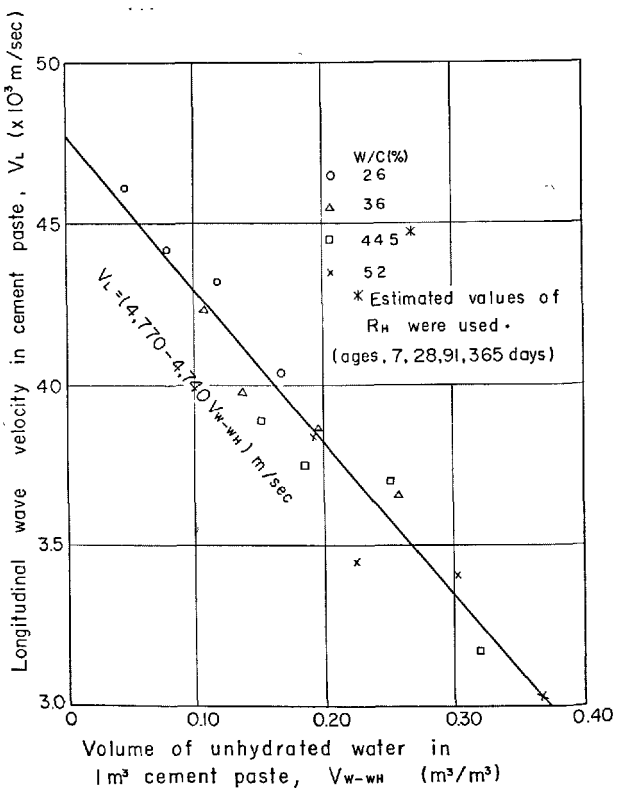

Fig. 5. *Relation between volume of unhydrated water in cement paste and longitudinal wave velocity*

$$V_L = 4{,}770 - 4{,}740 V_{W-WH} \quad \text{m/sec} \qquad (5)$$

where V_L: longitudinal wave velocity [m/sec]

In this calculation the data for those with w/c = 44.5% were excluded because only estimated values of R_H were available for those specimens.

Estimation of Young's Modulus of Cement Paste

The dynamic Young's modulus of cement paste by pulse method was calculated by the formula,

$$E_p = \rho \frac{(1+\sigma)(1-2\sigma)}{1-\sigma} V_L^2$$

$$= \rho \frac{(1+\sigma)(1-2\sigma)}{1-\sigma} (477{,}000 - 474{,}000\, V_{W-WH})^2$$

$$\text{dyne/cm}^2 \qquad (6)$$

where E_P: dynamic Young's modulus of elasticity of cement paste by pulse method

V_L: longitudinal wave velocity [cm/sec]

σ: Poisson's ratio of cement paste

ρ: density of cement paste [kg/cm³]

As the dynamic Poisson's ratio could not be measured, $\sigma = 0.2$ was assumed. Then the above formula with engineering units becomes,

$$E_P = 9.184 \rho_S (4{,}770 - 4{,}740\, V_{W-WH})^2 \times 10^{-3}$$

$$= 9.184 \rho_S \left\{ 4{,}770 - 4{,}740 \left(V_W - 0.37 \frac{R_H C}{\rho_W} \right) \right\}^2$$

$$\times 10^{-3} \text{ kg/cm}^2 \qquad (7)$$

where ρ_S: specific gravity of cement paste.

In Fig. 6, E_P/ρ_S vs. volume of unhydrated water in cement paste is shown.

To estimate static Young's modulus of cement paste from dynamic modulus, the relation we have obtained between static Young's modulus and dynamic modulus of dam concrete by resonance method was used, namely,

$$E_D = 1.369 E_S \qquad (8)$$

where E_D: dynamic Young's modulus by resonance method

E_S: static Young's modulus

And also $E_D = E_P$ was assumed. Experimental results between E_S and E_D are shown in Fig. 7.

These results are neither about cement paste nor by pulse method. But so far as the authors' other

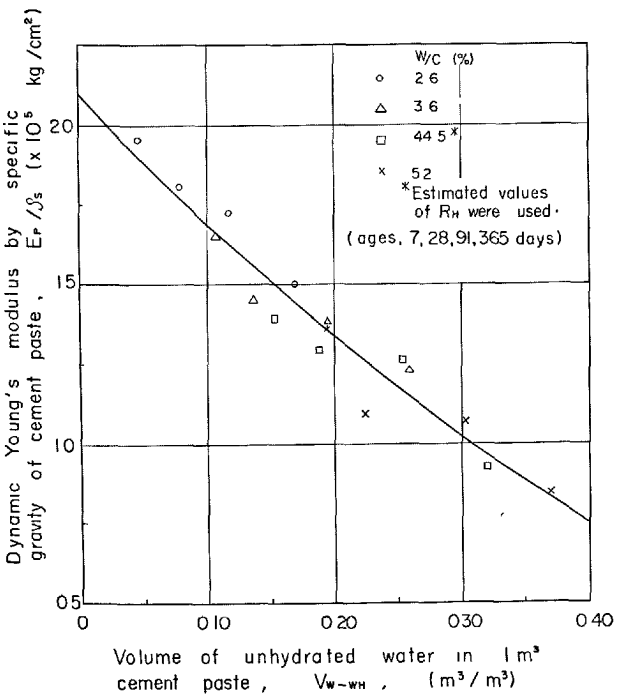

Fig. 6. *Relation between dynamic Young's modulus by specific gravity and volume of unhydrated water in cement paste*

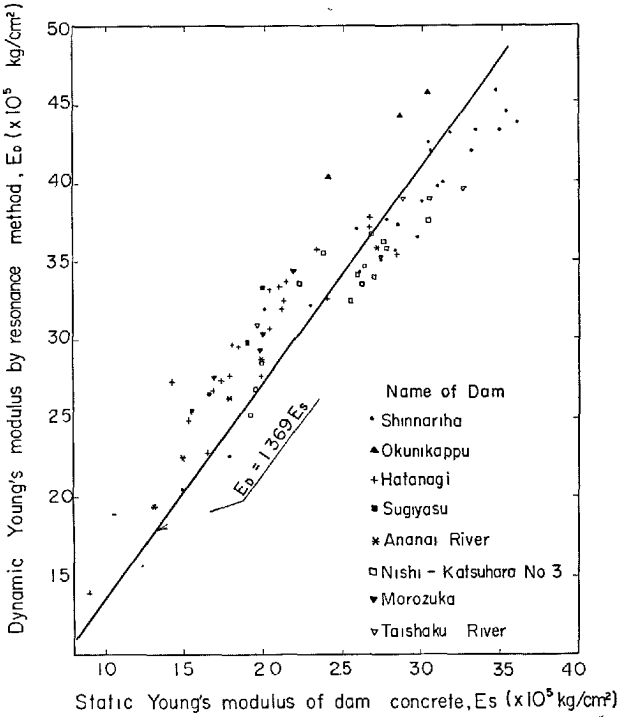

Fig. 7. *Relation between static Young's modulus and dynamic Young's modulus by resonance method in dam concrete* (ages, 4–365 days)

experiments are concerned, cement paste seems to obey the nearly equal rule. Though the ratio E_p/E_s may change with age, this effect was neglected.

The estimated dynamic and static moduli of cement paste with w/c = 47% by means of the above mentioned method are shown in Table 6.

Table 6. *Estimated dynamic and static elastic moduli of cement paste with w/c = 47%*

Age (days)	Dynamic Young's modulus (kg/cm²)	Static Young's modulus (kg/cm²)
7	177,200	129,400
28	213,400	155,900
91	254,900	186,200
365	277,600	202,800

Estimation of Modulus of Elasticity of Concrete

The elastic moduli of the Kurobe No. 4 Dam concrete cured in water were calculated at each age and compared with the experimental results shown in Table 7.

The aggregate used is granite, and its properties are shown in Table 8.

The static Young's modulus of the actual aggregate which was used for concrete specimens was not measured. But the values of the granite taken from the quarry were measured by H. Ishigai, K. Kasuya and K. Saito in wet condition by means of an Okhuizen compressometer (10).

The results are shown in Table 9.

Thus the mean value of static Young's moduli was as follows:

$$E_a = 284{,}000 \text{ kg/cm}^2 \tag{9}$$

This value will be used in the following calculations.

The present aspects of researches on the theory of elasticity of random media has been reviewed by Z. Hashin (11).

Here, several formulas which have been used by other authors for concrete research will be used to compute elastic modulus of concrete at each age.

From now on, the following symbols will be adopted,

E_c: static Young's modulus of concrete [kg/cm²]
E_a: static Young's modulus of aggregate [kg/cm²]
E_m: static Young's modulus of cement paste matrix [kg/cm²]
V_a: volume of aggregate in 1 m³ concrete [m³/m³]
V_m: volume of cement paste in 1 m³ concrete [m³/m³]

In case of wet screened the Kurobe Dam concrete,

$V_a = 0.7623$, $V_m = 0.2377$, and
$E_a = 284{,}000$ kg/cm²

Em at each age is taken from Table 6.

The formulas are,

$$E_c = V_a E_a + V_m E_m \tag{10}$$

$$\frac{1}{E_c} = \frac{V_a}{E_a} + \frac{V_m}{E_m} \tag{11}$$

by Dantu, Kaplan, and T. C. Hansen (12)

$$E_c = \left[\frac{(1 - V_a)E_m + (1 + V_a)E_a}{(1 + V_a)E_m + (1 - V_a)E_a}\right]E_m \tag{12}$$

Table 7. *Unit weight, modulus of elasticity, compressive strength of the Kurobe No. 4 Dam concrete*

Age (days)	Unit weight (kg/m³)	Static Young's modulus, Es (kg/cm²)	Compressive strength (kg/cm²)
7	2,335	174,000	208
28	2,331	224,000	340
91	2,352	258,000	442
366	2,356	303,000	495

*Five times tests were repeated with sodium sulfate solution.

Table 9. *Properties of granite taken from the quarry for the Kurobe No. 4 Dam concrete*

Place	Specific gravity	Water absorption (%)	Compressive strength (kg/cm²)		Static Young's modulus in wet condition (kg/cm²)
			dry	wet	
Quarry A	2.61	0.45	2,290	2,360	264,000
Quarry A	2.69	0.47	2,800	1,970	335,000
Quarry B	2.63	0.66	2,230	1,520	254,000
Mean	2.64	0.53	2,440	1,950	284,000

which Hansen (12) simplified the results due to Hashin (13), assuming Poisson's ratio of both aggregate and cement paste is 0.2,

$$\text{and,}\quad \frac{1}{E_c} = \frac{1-\sqrt{V_a}}{E_m} + \frac{1}{\left(\frac{1-\sqrt{V_a}}{\sqrt{V_a}}\right)E_m + E_a} \qquad (13)$$

by Counto (14).

Relation between the calculated static Young's moduli of concrete by the above formulas and the estimated static Young's moduli of cement paste are shown in Fig. 8.

Experimental results are also illustrated in the same figure.

Judging from these results, the difference % between them reaches about 30% at the maximum, although the trend of the calculated values coincide with the experimental.

These errors are attributable to the inaccuracies of elastic moduli of cement paste and aggregates, and the lack of sufficient accuracy in the above formulas. But it is not clear whether factor is most predominant or not.

To solve this problem, further efforts will be needed. As an additional remark, it may be worthy of mention that the results by Hashin-Hansen and by Counto almost coincide with those and other results obtained by rather gross assumptions are not so far from the results by a theoretical formula.

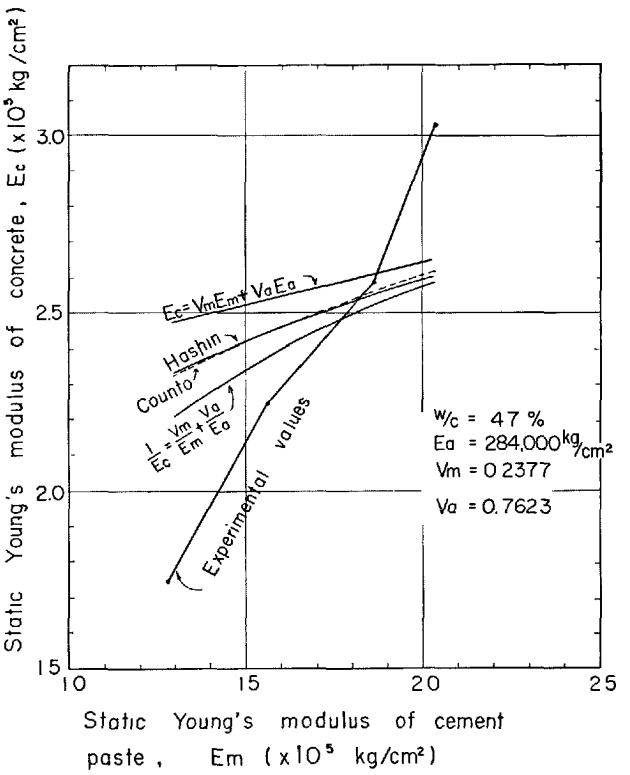

Fig. 8. *Static Young's modulus of cement paste vs. static Young's modulus of concrete*

Hydration of Cement and Creep of Concrete

The following fact has been well recognized that, in a creep test about a same kind of concrete, the later is the loading age, the smaller is the creep strain. This may be due to hardening of cement paste. But the definite relation between creep and hydration of cement has not been known to the authors.

As the first step of approaching this problem, relation between creep factor and volume of unhydrated water at the age of loading in our creep test is investigated and is shown in Fig. 9.

The term creep factor adopted here is defined in the following expression used for the analysis of creep curves per unit stress, and the factors are proportional to creep strains when the age is fixed.

$$\varepsilon_{(t)} = \frac{1}{E_i} + F(k)1_n(t+1) \qquad (14)$$

$\varepsilon_{(t)}$: elastic and creep strain per unit stress [1/kg/cm²]

E_i: instantaneous elastic modulus [kg/cm²]

k: age of loading [day]

$F(k)$: creep factor [1/kg/cm²]

t: days after loading [day]

This expression has been used by U.S. Bureau of Reclamation to analyse creep of dam concrete.

However, for analysis of the data obtained from 7 days loading, the fittness at the early ages was not good, so the following expression was introduced:

$$\varepsilon_{(t)} = \frac{1}{E_i(2)} + \left(\frac{1}{E(\infty)} - \frac{1}{E_i(2)}\right) \tanh\left\{\left(\frac{F^{(2)}_{(k)}}{\frac{1}{E(\infty)} - \frac{1}{E_i(2)}}\right)1_n(t+1)\right\}$$

$$= \varepsilon^{(2)}_{(0)} + (\varepsilon(\infty) - \varepsilon^{(2)}_{(0)})\left(1 - \frac{2}{1+(t+1)^{2\alpha}}\right) \qquad (15)$$

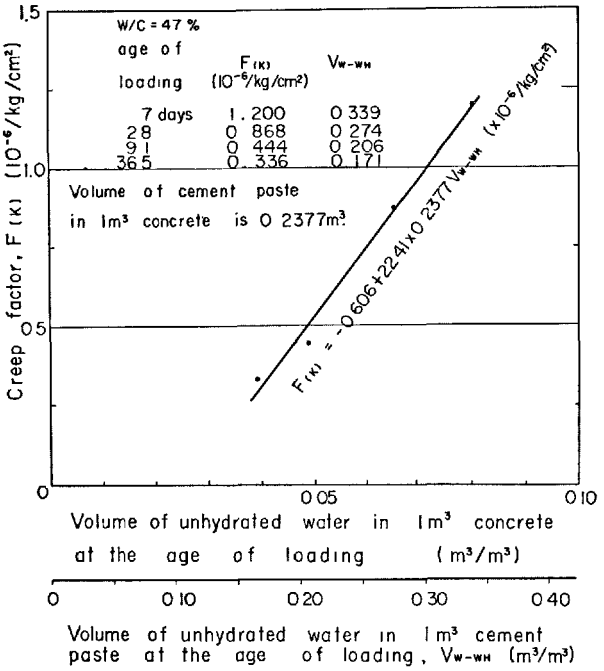

Fig. 9. *Relation between volume of unhydrated water in concrete or cement paste at the age of loading and creep factor*

where

$$\alpha = \frac{F^{(2)}_{(K)}}{\frac{1}{E(\infty)} - \frac{1}{E_i(2)}}$$

When $\ln(t+1)$ is sufficiently small the above expression tends to

$$\varepsilon^{(2)}_{(t)} \cong \varepsilon^{(2)}_{(0)} + F^{(2)}_{(K)} \ln(t+1) \qquad (16)$$

And when t is sufficiently large,

$$\varepsilon_{(t)} \to \frac{1}{E(\infty)} \qquad (17)$$

The creep curves obtained from a experiment is shown in Fig. 10.

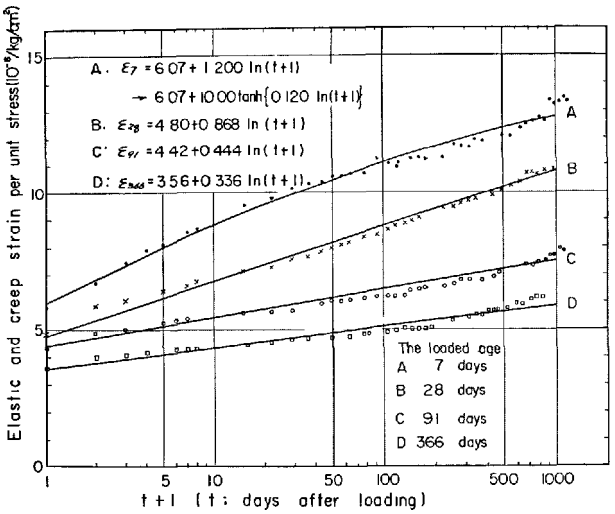

Fig. 10. *Creep curves of the Kurobe No. 4 Dam concrete*

The strains were measured by embedded Carlson type strain meters.

The mix of concrete was the same above, and the size of specimen was ϕ 15 × 60 cm. The specimens were sealed with rubber just after demoulding. The curing condition of these specimens therefore differs from water curing. The data on hydration of cement, however, were substituted by the value of hydration of the water cured cement paste obtained in the experiment previously referred to.

According to Fig. 9, creep factors are linearly related to the volumes of unhydrated water in the range for practical applications.

But the creep factor of 7 days loading was based on the data of strains observed at the relatively early ages. Then this linearlity including the result of 7 days loading, will hold true for limited ages.

This may be a natural consequence, because creep strain will be affected not only by the degree of hydration at the age of loading, but also by the progress of hydration thereafter.

Conclusion

A very close relation was observed between rate of hydration of cement and compressive strength of concrete. And a formula was presented expressing compressive strength of concrete at any age by a linear function of effective cement-water ratio.

This effective cement-water ratio introduced in our report means the ratio of hydrated cement weight to the weight of mixing water.

Linear relation between volume of unhydrated water in cement paste and velocity of longitudinal wave in it was observed. And a formula was derived to express dynamic modulus of elasticity of cement paste in terms of rate of hydration of cement and w/c.

Several formulas expressing elastic modulus of concrete in terms of the moduli of cement paste and aggregate and their relative volumes were examined.

A result showing the linear dependence of creep factor on the volume of unhydrated water at the age of loading was presented.

More advanced microscopic physico-chemical studies are recognized as necessary to make clear problems concerning compressive strength, elasticity, creep and other fundamental properties of concrete.

Supplementary Paper III-119 Some Recent Advances in the Study of Cement and Concrete

Harold E. Vivian*

Introduction

During the past 20 years a considerable amount of basic research has been carried out on the crystal lattice structures of clinker compounds and on their hydrated products. In addition many kinetic studies on cement in pastes and suspensions as well as in concrete have been made in order to describe the basic performance of hydrating cement. While all this work is necessary for an understanding of the nature and behaviour of the compounds that make up clinker and cement, it does not always allow the performance of clinker and cement to be predicted or controlled.

Much of the work done on cement performance in paste and concrete has also failed to demonstrate clearly and unequivocally how and for what reasons the observed physical phenomena occur. The immediate reasons for these failures arise from the complexity of clinker and the problems encountered in studying and understanding the hydration reactions and compound interactions in cement. However, behind all these difficulties lie some important and intractable problems. Commercially-produced clinker is not controlled sufficiently closely in any characteristic other than its gross chemical composition. Consequently cement used in experimental work is inadequately described especially in relation to certain physical characteristics that can exert a profound effect on paste and concrete performance. Thus it will be seen that arguments based on the performance of an inadequately described cement are liable to prove unsound and confusing if applied to the performance of cement paste and concrete in general. Additional difficulties associated with sampling and test methods have greatly confused the overall understanding of cement performance.

In recognition of these problems, studies are being made into the performance of clinker compounds in mixtures of identical chemical composition but different and closely-controlled physical characteristics. The purpose of this paper, therefore, is to indicate how some of the results of these studies may help in clarifying the performance of cement and concrete.

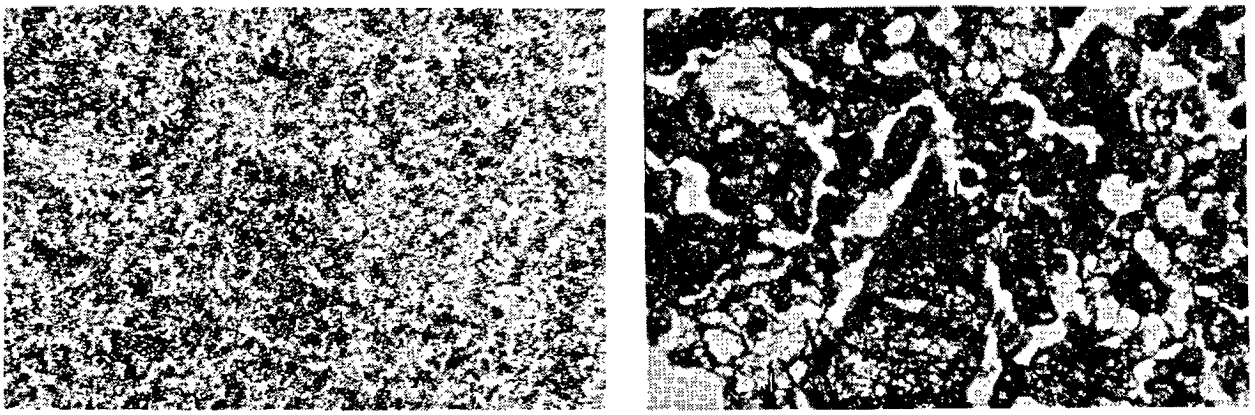
Clinker

It is well known that argillaceous limestones usually clinker readily even when coarsely ground. The fineness of grinding and the intimacy of mixing of the raw material components are major factors in controlling clinkering when mixtures of pure limestone and clay or shale are used. In large manufacturing plants chemical control testing is adequate but control of the particle size of the raw meal constituents may be so meagre that the desired levels of uniformity in burning and in the properties of clinker are not always maintained.

Coarse limestone and shale or silica particles, which do not undergo complete reaction during the time that they are resident in the buring zone in the kiln, modify the clinker composition both in their immediate vicinity and in more remote zones. Such particles, therefore, cause the clinker composition to be changed from that calculated, increasing the uncombined lime and residual silica. To minimize such defects a long burning time is required with consequent reduction in kiln output and a general deterioration in kiln performance. Clinker produced under these conditions is generally coarsely crystallized and inhomogeneous in composition. Fine grinding on the other hand produces finely-crystallized clinker with a high degree of uniformity and reduces the burning time required to give a low free lime content.

Two contrasting microphotographs shown in Fig. 1 illustrate the differences in crystal size and uniformity of clinker produced from raw meals of different particle size but identical chemical composition. These microphotographs show (1) a uniform, finely-crystallized clinker produced from raw meal particles that were all in the 12–24μ range and (2) a non-uniform, coarsely-crystallized clinker produced from

*C.S.I.R.O., Chemical Research Laboratories Melbourne, Australia.



A. Produced from raw meal particles 12-24μ

B. Produced from raw meal particles $+36\mu$ and up to 150μ

Fig. 1. *Photomicrographs of sections of clinker having the same calculated chemical composition*—C_3S 71.0%, C_2S 12.0% C_3A 5.0%, C_4AF 12.0%, *and burnt at 1400°C for 15 minutes. Magnification* ×40. (*Microphotographs by J. H. Weymouth*)

raw meal of the same chemical composition and made up of particles that were $+36\mu$ and up to 150μ. Commercial clinker is generally intermediate between these two extremes but tends to approach the more variable, coarser crystalline type. In the finely-crystalline clinker the crystals are generally-12μ whereas in the coarsely-crystalline clinker C_2S and C_3S crystals may be up to 300μ. C_3A and C_4AF are present in much smaller amounts and occur in finer crystals than those of C_2S and C_3S. The subsequent performance of these clinkers, when ground, appears on present indications to be different in many respects.

Control over the size of raw meal particles in commercial plants requires (1) a large scale separator that is capable of achieving a clean separation of the particles below 70μ from the ground raw meal and further studies may indicate that it is desirable for the maximum particle size to be smaller and (2) rapid and accurate test procedures to ensure that the required separation is being obtained consistently.

Cement Grinding

Although the principles of ball milling appear to be relatively simple certain factors in mill operation can adversely affect the uniformity and performance of cement. Two of these factors will be discussed. It has long been known that the gypsum content of the -12μ fraction of cement is generally much greater than that of the coarser fractions. Gypsum and clinker when ground together in a mill break down into different particle size distributions. Surface area measurements used for mill control do not distinguish between these two distributions and variations between the relative grindability of clinker and gypsum cannot be detected. Any circumstances leading to a coarser gypsum particle size distribution can result in the cement behaving as though it contained inadequate sulphate. Conversely excessive proportions of gypsum in the -12μ fraction can give the impression that the gypsum content of the cement is adequate or even excessively large at least in the behaviour of cement at early ages while the later behaviour of the cement may indicate some deficiency in sulphate. This type of variation can only be detected and minimized by using a control procedure based on a combination of particle size separation and determination of the gypsum content of each fraction.

Closed circuit grinding in air-swept mills accentuates problems arising from contact of cement particles with large volumes of air containing moisture and carbon dioxide. Such systems promote the surface hydration and carbonation of active clinker components, especially C_3A. These surface reactions modify the changes that occur in paste during the mixing period and cause premature stiffening and early loss of workability. Methods of minimizing this problem include a reduction in the amount and temperature of the circulating air-stream, closed circuitry of the air system as far as possible and reducing the residence time of the fine cement particles in the circuit by

increasing separator efficiency.

Consistency and Workability

The water requirement for normal consistency of cement paste is a function partly of the particle size distribution and partly of the effects produced by the early chemical reactions which change the solid-water relationship and produce stiffening. Finely-ground cement, which has been over-heated during grinding, and especially if it has also been aerated in a humid atmosphere, rapidly develops stiffening tendencies which may be caused by a wide range of factors.

A different stiffening phenomenon can occur generally at a time longer than ten minutes after mixing ceases. There are indications that this stiffening is influenced by a reduction in the availability of dissolved sulphate due to the rapid occlusion of gypsum particles by films of reaction products. Clinker particles deprived of sulphate then tend to hydrate as though unretarded and the paste stiffens rapidly. Although this unstable system of occluded gypsum may persist for a long time under static wet conditions, the sulphoaluminate reaction proceeds very slowly in the hardened paste and may ultimately cause expansion and cracking. One way of avoiding stiffening, which results from sulphate occlusion, is to provide a greater quantity of gypsum in the fine particle size range than would normally be necessary.

The actual amount of clinker hydrated, when stiffening occurs, is usually quite small. Finely-ground clinker without added gypsum undergoes a hard set very rapidly and when it is less than 5 per cent hydrated. Free water, however, can be readily removed under pressure from such hardened paste.

Since clinker hydration and chemical interactions begin as soon as cement and water are mixed together, the stiffening of paste may develop rapidly and can be modified in some instances by vigorous mixing especially in pastes containing low water contents. The stiffening reactions affect the consequent properties such as strength development, shrinkage, cracking tendencies and durability of hardened paste and concrete. Paste consistency and concrete workability can be improved by various procedures which involve modifications in clinker composition, coarser grinding, reduced aeration and reduction in grinding temperature.

Dimensional Stability of Paste

Experiments have shown that gypsum can react with C_3A and then become occluded by the reaction products. When gypsum is occluded by reaction products in hydrating cement paste, a certain proportion of the undissolved gypsum is either prevented from going into solution or is able to dissolve at only a very slow rate. This arrested solution condition can persist under static wet conditions for very long periods of time, at least for several years. Under continuously dry conditions the paste will remain permanently in its contracted state without undergoing any further changes. When pastes are subject to dry-wet cycling conditions, and especially when given heat-cool cycles as well, a certain amount of gypsum is intermittently released into solution during each wet cycle and this gypsum, on reacting with C_3A, can cause local and progressive expansion and eventual disruption of the paste. This appears to be the cause of a type of surface crazing that is apparent in concrete exposed to wet-dry and heat-cool cycles. Some heating in conjunction with drying is necessary to induce the maximum amount of change in the layers of reaction product surrounding the gypsum particles in order to ensure that further amounts of undissolved gypsum become available for reaction with C_3A.

The presence of gypsum in cement paste tends to reduce the magnitude of drying shrinkage because it reacts with C_3A to produce calcium sulphoaluminate. This latter compound has two effects in paste. It retrains shrinkage movements and, as a result of its continued formation, it causes an expansion that counteracts some of the drying shrinkage movement.

The internal restraint reduced in paste by sulphatoaluminate is roughly comparable with the more macroscopic restraining action of aggregate particles in mortar and concrete. The restraint imposed by the aggregate particles reduces the overall measured shrinkage but induces very considerable numbers of internal cracks. The development of crack patterns

in paste, mortar and concrete constitutes an important phenomenon which is indicative of the condition of the material and the types of actions that are proceeding in it.

The particle size distribution of the cement and particularly that of the clinker fraction exerts a major influence on the magnitude of shrinkage. In addition the dependent variable, the water/cement ratio, tends to accentuate shrinkage as it increases. Both of these factors increase the interparticle spacings in the cement paste and these distances in turn determine the shrinkage potential of the paste. When the interparticle distances in the paste are large, the effect on shrinkage of the particle size distribution will exceed that of any other factor.

The physical condition of the hydrated compounds and the conditions of their development in paste largely determine their shrinkage tendencies. Hydrated compounds produced at atmospheric temperature have colloidal properties and, therefore, undergo a marked volume decrease that is approximately proportional to their water content and to the initial interparticle spacing in the paste. When pastes are made from (a)-12μ clinker particles and (b) 24 – 36μ clinker particles and at identical water/solid ratios, the drying shrinkages of the fine particle pastes are always larger than those of the coarse particle pastes. Shrinkages of these pastes are shown in Fig. 2.

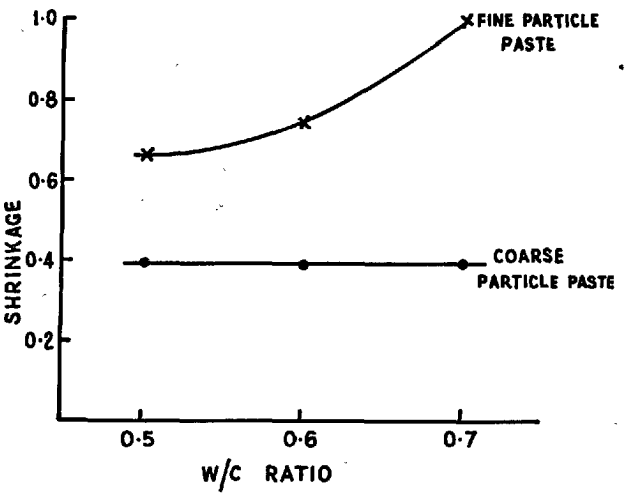


Fig. 2. *The drying shrinkages of clinker pastes made from* (a) -12μ *and* (b) *24–36*μ *particles at the same water/solid ratios*

The fine particle pastes contain more colloidal hydrated material and possess less internal restraint than the coarse particle pastes.

Strength

Movements of hydrated products from single particles and in paste have been observed to occur over finite distances. On mixing with water, hydration and interaction products deposit rapidly as a skin on the surface of the clinker particles. This surface layer then tends to retard but does not inhibit further hydration. As hydration and reaction proceed inwards, the internal pressure on the surface skin increases, the surface skin becomes distended and is eventually disrupted. This allows some of the internal hydrated product to escape and deposit in the freshly opened space in the surface skin or in the surrounding water-filled space. These hydrated products make contact with similar hydrated products derived from adjacent clinker particles or with aggregate particles.

These observations have indicated that fine and coarse clinker particles behave in somewhat different ways in pastes. The hydrated material derived from a fine particle is not present in sufficient quantity to move through such a large distance as that derived from a coarse particle of clinker. Moreover, as a result of particle contacts, pastes consisting only of coarse particles tend to expand as hydration occurs while pastes consisting only of fine particles never undergo serious expansion during hydration. This behaviour is consistent with the local disruptive forces being greater in large hydrating particles than in very small hydrating particles. In addition, in an equivalent volume of paste composed of fine particles, the ratio of hydrating material to available space is less than that in pastes composed of coarse particles. The hydrated product is, therefore, accommodated in the former without generating severe local stress concentrations. The water-filled space in fine particle pastes is approximately 30 per cent by volume while that in coarse particle pastes of approximately equivalent consistency is 15 –20 percent by volume.

In mixtures of fine and coarse particles, which produce pastes that are approximately equivalent to pastes produced from commercially-ground cements, the fine particles hydrate in contact with the coarse particles and contribute a large volume of hydrated product to form the skin on the surface of the coarse particles. The hydration of the coarse particles is thereby retarded to such an extent that they do not cause undue paste expansion.

The clinker compounds show marked difference in their rates of hydration. C_3A in water hydrates very rapidly and to such a great depth that even + 36μ particles are completely hydrated within a few days. C_3A particles, therefore, swell to a marked extent as they hydrate and, even though the hydrated develop some adherence and strength, the continued hydration and swelling of the particle disrupts and displaces the externally developed surface layers. In compacted pastes, the swelling particles produce large inter-particle forces that disrupt the mass. C_3S which is also a relatively rapid hydrating compound causes very minor expansion and disruption in pastes composed only of coarse particles. Pastes composed of fine C_3S particles are quite stable in volume. C_2S and C_4AF generally undergo slow or limited hydration reactions which do not proceed sufficiently deeply into the particles to cause paste expansion and disruption. Pastes made from these compounds appear to be stable and strong.

The presence of small amounts of gypsum and other compounds in the mixing water changes the physical condition of the hydration products that form the surface skin on the clinker particles and modifies the bonding characteristics of these products. Some admixtures form voluminous surface skins on clinker particles whereas others appear to suppress the hydration rate of clinker particles. Gypsum has been observed to promote the disruptive action in paste by reacting slowly with C_3A to form calcium sulphoaluminate. Thus, even though gypsum initially retards clinker hydration, the continued slow reaction of C_3A and gypsum increases the total amount of clinker hydrated over a long period of time. The continuing reaction of gypsum and clinker increases the rate of strength development and the ultimate strength attained by the paste.

Environmental Conditions and Durability

Environmental conditions affect the performance of hardened cement pastes and concrete. Observations have indicated that the drying shrinkage and re-wetting expansion of clinker pastes, as opposed to comparable movements of cement pastes, are quite dissimilar. Clinker pastes undergo a large initial drying shrinkage and on re-wetting expand to approximately 60 per cent of their initial length. Thereafter dry-wet cycling produces shrinkage and expansion movements that remain approximately constant. Cement pastes on the other hand differ from this type of behaviour in having an initial shrinkage that is only about 70 per cent of that given by a clinker paste and, on re-wetting, the cement paste expands almost to its initial dimensions. The initial dry-wet cycling movements of cement paste are therefore somewhat greater than those of clinker pastes. Subsequent cycles of drying and wetting can cause finely-ground cement pastes to undergo a positive expansion on each wetting cycle. Coarsely-ground cement pastes do not show a comparable tendency to undergo expansion when cycled. Clinker pastes composed of either fine or coarse particles do not undergo expansion when given cycles of drying and wetting. These differences are indicated in Fig. 3 which shows the length changes after each drying and wetting cycle of finely-ground clinker and cement pastes made up at the same water content. The slow expansion of the cement paste is caused by the reaction of C_3A and gypsum.

On account of its very many useful functions in paste, gypsum plays an important role in modifying behaviour and promoting desirable properties. How-

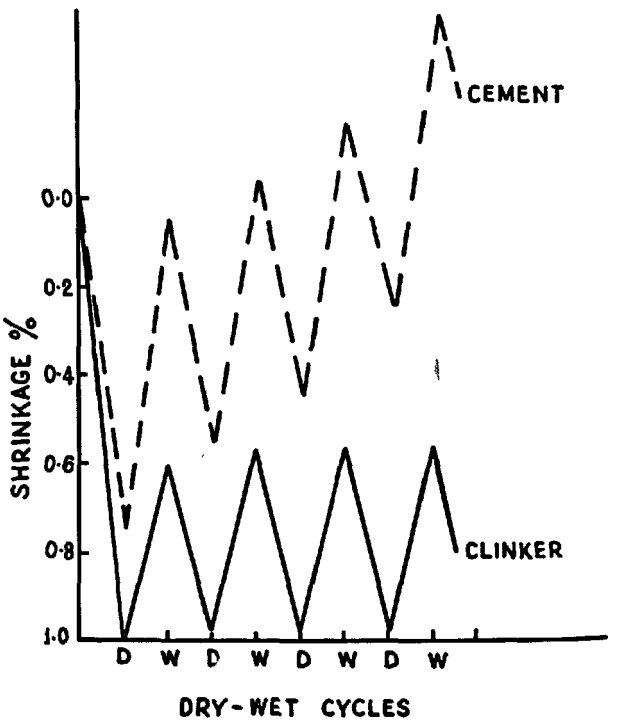

Fig. 3. *The dry-wet cycling movements of finely-ground (—12μ) clinker and cement pastes made at 0.7 water/solid ratio*

ever, since it can become occluded, undissolved gypsum and unreacted C_3A can co-exist in a paste under static wet conditions for long periods of time, at least several years. When the pastes are subjected to dry-wet cycling, and especially if given heat-cool cycles as well, some gypsum is intermittently released during each wetting cycle. When this soluble gypsum reacts with C_3A, expansion and disruption of the paste occurs. The expanding paste develops a closely-spaced crack pattern and undergoes a progressively increasing expansion.

These comments indicate the importance of C_3A and its interactions with gypsum on the durability of hardened cement paste and suggest that there is an increasing need to understand and control the mode of occurrence of C_3A in clinker. Deleterious changes in concrete usually occur slowly, and become obvious only after the concrete has been in service for a long time. At this late stage the basic causes of deterioration are often difficult to determine. To ensure durability of hardened paste ways should be found to minimize movements which are caused by cycling environmental conditions, and to reduce the undesirable expansive reactions that occur when gypsum continues to react slowly with C_3A.

Concluding Remarks

Some of the developments discussed briefly in this paper should be investigated further for possible future use in the cement manufacturing industry. The performance and uniformity of cement depend largely on the burning and grinding processes and grinding processes and improvements can be effected by a variety of modifications.

1. Increased control over clinkering and the uniformity of clinker can be achieved by a more stringent control over the particle size distribution of raw meal.

2. Control over the particle size distributions of both clinker and gypsum in cement is necessary to ensure satisfactory and uniform cement performance in paste and concrete. Reduction in grinding temperature, and in aeration and carbonation of cement will also assist in improving the performance of cement.

3. It would be advantageous to develop some new equipment including sampling devices and an effective large scale partial size separator.

4. Additional tests should be made to increase cement uniformity in performance and to indicate its potential behaviour in concrete. Determination of particle size distribution should become a normal test procedure in order to correct defects in grinding and determination of sulphate in the separated fraction would ensure the maintenance of a satisfactory gypsum grind.

5. Concrete performance tests under dry-wet and heat-cool cycling conditions would indicate the stability of hardened paste and its tendency to crack and undergo abnormal changes.

6. More attention should be given to studying the volume stability and durability of concrete especially as affected by the slow reaction of gypsum in hardened paste and concrete.

SESSION III-2 DURABILITY OF CONCRETE

Principal Paper Durability of Concrete

Oldřich Valenta*

Synopsis

Concrete durability is the most important factor of the durability and long time safety of concrete structures. Homogenity of concrete is more important for its durability than for its strength. Protection, systematic maintenance with timely repairs are other factors that significantly bear on concrete durability. The properties of the cement-aggregate joint are of utmost importance, too.

The various processes of concrete deterioration can be divided into three groups. Generally, concrete durability importantly depends on a number of physical and mechanical properties of the material: porosity, permeability, absorptivity, capillarity, tensile strength and bond of the components. The essential point is to express the extent and the properties of the pore system. Air entrained concrete is an example of a suitable system of pores.

Cement and hardened cement paste play a decisive role in the durability of concrete. The degree of hydration at the time concrete is attacked by aggressive agents is a very important factor in this respect. Many other factors—cement composition, fineness in grinding, etc.—have a lot to do with it too. Very important is the part played by admixtures, air entraining agents in particular. Formation and extent of cracks also significantly affect concrete durability as regards ingress of water and of other agents in concrete, and the tensile strength. Cracks have a number of causes: shrinkage, heat of hydration, load, pathologic phenomena, and aggressive agents.

Tests of concrete durability and their relation to actual concrete deterioration are of utmost importance for the control and design of concrete with specified durability, There are many requirements made on suitable tests while the existing ones have a number of shortcomings. Long-term observations and studies should be considered as an indispensable part of an appropriate system of durability tests leading to determination of the rate of concrete deterioration. Thence we should deduce the rate of deterioration and loss of safety of concrete structures. Cooperation in introducing suitable test methods is very important.

The fundamental requirements on further research work and the need of international cooperation are discussed in the conclusion.

General Observations on the Durability of Concrete Structures

Introduction

Considering the total volume and in particular, the diversity of applications ranging from light foam concrete of insulating walls to heavy concrete for shielding nuclear reactors, from pavement slabs to tall, slender masts, bridges and dams, cement concrete is without dispute the most important structural material the world over. The broad field of concrete uses indicative on the one hand of its outstanding possibilities, puts in on the other hand in greatly varying conditions of stress, mainly so far as it concerns the secondary effects of external media—no matter whether of natural (climatic phenomena and different waters) or industrial (mostly chemical) origin. The unfavourable action of those conditions, especially on the mechanical properties of concrete—a yardstick of its quality in most cases—has opened up

*Building Research Institute, Technical University, Prague, Czechoslovakia.

the question of the durability of concrete and concrete structures, the importance of which continues to grow proportional to the scope of applications and the volume of concrete used.

The durability of concrete cannot be separated from the durability of concrete structures—an important factor of their economy at present. The durability of concrete structures must be ensured on a complex basis—starting from the choice of the building site and suitable system of construction, and ending with the design proper and its task to take into consideration the nature of the surrounding medium, and the technology of concrete with its all important choice of suitable materials, composition, manufacture, placing and curing. As to the durability of concrete structures: it is imperative that proper care be accorded to finished structure, too; this can be done by the application of regular checks, timely maintenance or possibly repair.

Protection of concrete and concrete structures against excessive effects of aggressive media (underground waters, industrial effluents in particular) forms an inseparable part of measures designed to ensure durability. Such measures include: weakening or neutralization of aggressive substances before they come in contact with concrete, draining of such substances and reducing their contact with concrete to a minimum, immediate protection of concrete surface against direct contact with aggressive substances.

The significance of the durability and homogeneity of concrete becomes obvious once we start to consider the high demands that are imposed on the quality of any surface protection of concrete for the reason that it is the weakest spot that decides.

The durability of concrete structures is a very complex problem with two principal aspects: *physical* and *economical.*

The physical durability of concrete and concrete structures is expressed in terms of the loss of the decisive mechanical and physical properties of concrete to a value that ensures the minimum required safety of the structure no longer.

The economical durability of concrete and concrete structures follows from the minimum of total cost expended in its building and maintenance. This cost can be expressed by the relation

$$N = N_i + N_u + p_r S + N_1 \qquad (1)$$

where

N_i—the primary investment cost of the structure
N_u—the total maintenance cost for time T_r during which the structure is in use
p_r—the probability that the structure will collapse in time T_r
S—material damages caused by structure collapse
N_1—the cost of tearing down and removing the structure.

The economical durability of a structure is then given by the condition that is $\delta N/\delta T = 0$.

Considering that the last term of eq. 1 is virtually invariable, the main factors involved here are the ratios A, B of the investment cost, repair and maintenance costs, and the risk of failure of the structure (Fig. 1).

Savings in the investment cost usually lead to higher total cost of the structure during the time of its use.

Gradual deterioration of concrete texture caused by the most diverse external agents depends on the properties of concrete components and their relationships. Unlike under static action, it is the weakest spot of the structure (thin-wall members, concrete texture weakened by pores or cracks, aggregate grains-hardened cement paste joint) that are subjected to the most intensive attack of aggressive agents. This is the reason why such high demands are imposed by the durability on the quality of concrete and its ingredients with respect to homogeneity.

Professional literature all over the world has accorded considerable attention to the durability of concrete all along. The large amount of research studies published in the last 30 years notwithstanding, there are still not enough data or information avilable today to enable us to deal with the durability of concrete as we do with its strength. Yet an adequate understanding of the problem is just the thing that could help us in making concrete structures more economical by the application of refined methods of design.

As we have already pointed out, the relationships involved—be they ever of mechanical, physical or chemical character—are highly complicated and closely related to the nature of the components and the properties of concrete. Their elucidation is not

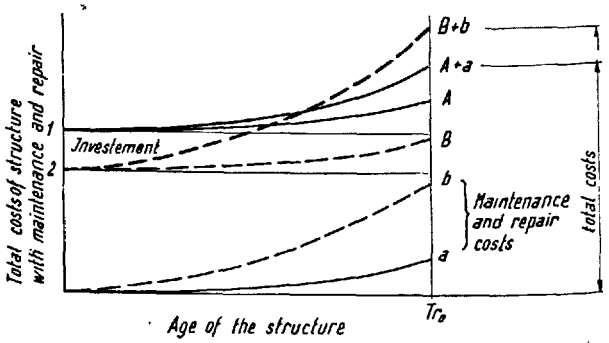

Fig. 1. *Effect of investment costs and maintenance on total costs of structure*

possible unless one resorts to the most modern techniques of research into the texture of concrete and its changes.

Even though it is necessary when ensuring the durability of concrete structures to consider those relations in all the stages of their realization (choice of building site, system of construction, materials and technology, protection) and their use (overloading, maintenance, repair), the crucial point of the whole problem lies in concrete technology, i.e. in making concrete of materials chosen so as to correspond to the specific conditions imposed.

Even if we disregard the complexity of the actual conditions, we are faced when studying the principal deteriorating factors (alternate frost, aggressive waters, alternate moisture, reinforcement corrosion, etc.) with a number of incompletely clarified relations, despite the fact that in some cases we know of suitable measures (air entrainment, appropriate composition of cement, choice of aggregates, etc.) that could reduce the unfavourable effects to an allowable minimum. Taken individually, the matter in question involves whole complexes of problems and relations that had been solved and reported in literature the world over.

I do not, therefore, deem it necessary to dwell here on either an analysis or a survey of the existing findings of world research not even for the selected most important cases of concrete deterioration.

As to the relation between research and practice: at the present time we are confronted with a very exacting but responsible question of intentionally, systematically ensuring concrete durability adequate to the given conditions, by the selection of suitable materials, composition and technology of concrete. This task bring us face to face with the necessity of determining the durability by accelerated tests relative to the important initial physical and mechanical properties of concrete. Simple tests of the fundamental properties of concrete and their changes based on scientific analyses of the deteriorating processes should afford us—jointly with the elucidation of the relations that exist between graudal deterioration and the loss of ultimate strength—the necessary data for forecasting and designing concrete of the required durability.

Safety and Durability of Concrete Structures

The safety of concrete structures is primarily given by the ratio of concrete strength to stress caused by loading. The design of concrete structures is usually based on the 28-day strength. As both concrete strength and load are functions of time, the safety of concrete structures, too, is a very complicated function of time (31, 117).

Although it is generally the compressive strength that is used for a measure of concrete strength, the tensile and shear strengths, the bond with reinforcement as well as deformation leading to unstable equilibrium between external and internal forces or attaining an inadmissible value, can also decide about structure failure. This considerably complicates the question of safety, and a distinction is, therefore, made, in the design of concrete structures, between three kinds of safety expressed by: reaching the concrete strength, state of dangerous cracks (particularly from the point of reinforcement corrosion and thus actually of the structure durability), and finally, limit deformation.

So long as a concrete structure or its components are acted on by no deteriorating factors, its safety without decreasing, increases due to gradual hydration of concrete after 28 days. Such is the case of a concrete structure exposed to no harmful effects of its environment, for instance a protected concrete structure of an above-ground building (Fig. 2).

As soon as a concrete structure begins to be acted upon by deteriorating factors in arbitrary time (age of concrete) T_x, a gradual loss of its strength and in turn, of its safety starts to take place so that after a time within the range T_{min} and $T_{r\,max}$, its strength is likely to drop below the value of the load and the structure might collapse (Fig. 3).

Such a drop in strength cannot be permitted under actual conditions. The degree of safety given by the strength-load ratio must not fall below a certain minimum value corresponding to the minimum strength æ.

The simplest though not the most economical solution to the given real case would consist in using concrete capable of long time resistance to aggressive agents in a way that the required minimum safety of

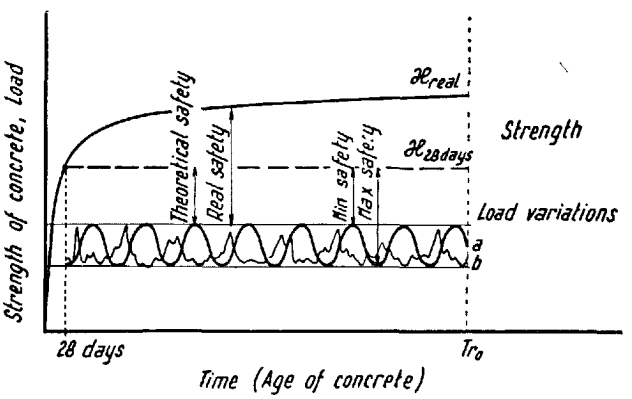

Fig. 2. *Long-time development of safety in favourable conditions*

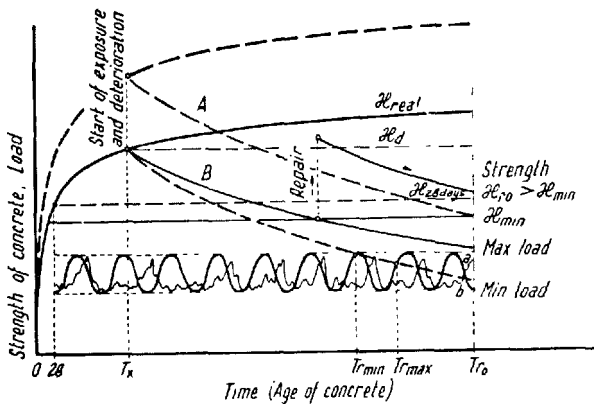

Fig. 3. *Long-time development of safety in adverse conditions*

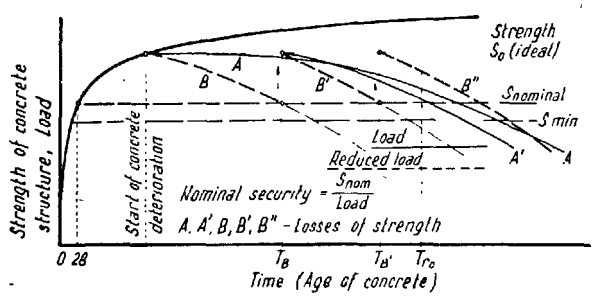

Fig. 4. *Securing the necessary concrete strength for the durability of the structure*

the structure—the concrete strength-to-stress ratio—would be ensured even after losses occurring in the structure during the time of economical durability of concrete T_{r_0}, have taken place (Fig. 4). This can generally be achieved by overdrawing the sections and the whole structure as well. While in the case of concrete deterioration following curve A, the requisite safety would be ensured during the whole of time T_{r_0}, it would be necessary in case B to:

either repair the structure in times T_B, $T_{B'}$, so that at the subsequent stages concrete weakening would proceed according to curve B' (or other B'') until the reduced strength would be higher in time T_{r_0} than $S_{nominal}$. Several such repairs might be required,

or reduce the load, for instance in time $T_{B'}$ so that the nominal safety would again be ensured in time T_{r_0},

or after the repair in time T_B has been made, protect the structure (e.g. on its surface) in a way that makes concrete lose its strength at a slower rate (e.g. according to curve A'), and thus again ensure that $S_{T_r} > S_{nominal}$ in time T_{r_0},

or finally, allow (e.g. after the structure was restored for the first time—curve B') a reduced safety with a higher risk of failure p_r under the same load for the time period $T_{B'}$ to T_{r_0}.

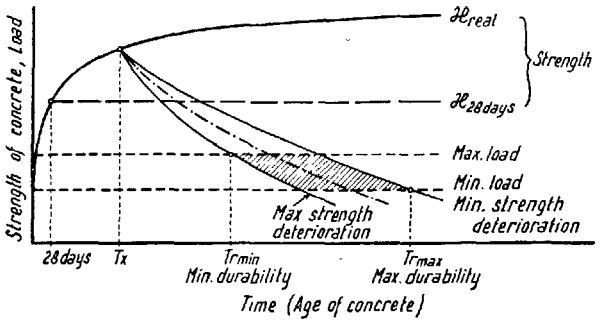

Fig. 5. *Probability factor in the durability of concrete structures*

Although each of the alternatives is likely to lead to the same engineering effect, it is clear at first sight that this is not so in the way of cost.

From the engineering point the relation shown in Fig. 4 in terms of curves A, A', B, B', B'' represents the time effect of a set of external aggressive agents, on strength or other important mechancical or physical properties of concrete. The difficulty we have to cope with is that such curves should be known in advance, before we start to build the structure, or or mastered to a degree that would allow us to create them by technological means and thus satisfy the design requirements similarly as we do in the case of for instance the 28-day strength of concrete.

This rational approach offers new criteria for an economic analysis of concrete structures, and places the initial investment cost in correct relation with the set of total costs.

Taking account of the complicated relations between concrete strength and the external factors and their combinations, the dependence of strength can be expressed in terms of a certain (say 90%) reliability or probability. This necessarily leads to a certain probable durability of the structure delimited by the minimum and the maximum probable durability (Fig. 5).

As this brief analysis clearly suggests, the relationships figuring in the solution of the durability of concrete (and other) structures are very complicated. They must, however, be borne in mind whenever a solution of the durability of concrete proper is attempted.

Significance of the Homogenity of Concrete for its Durability

Generally speaking the action of aggressive agents exert on concrete and its components depends on the following:

a) properties of the aggressive agent, its intensity or

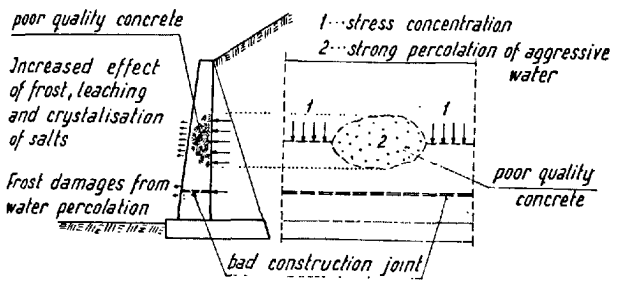

Fig. 6. *Adverse effect of concrete heterogeneity on the action of aggressive agents and the durability*

concentration,

b) properties of concrete and its components from the point of the relation between the aggressive agents and the mechanical properties of concrete and its ingredients, which are undergoing gradual deterioration,

c) the intensity of contact between the aggressive agent and concrete given by: the specific surface of the body, nature, quantity and accessibility of pores, removal of deteriorated parts of concrete from the surface, and supply of fresh aggressive agent.

So far as concrete proper is concerned, the adverse effect is given by: permeability, porosity, moisture absorption, reduced bond between ingredients, and strength—mainly the tensile one—of concrete.

While with respect to forces and stresses, the non-homogeneity of concrete leads to stress concentration in sections of high-quality (more compact, high-modulus-of elasticity and deformability) concrete, deteriorating processes usually concentrate in the weakest, most inferior parts of concrete. From this stems the *great significance of concrete homogeneity for its durability.*

In some cases the effect of concrete non-homogeneity can manifest itself in several ways, as indicated for instance by the sketch of an abutment wall in Fig. 6. Unfavourable seepage of water also intensively wets the adjacent high-quality concrete which is thus exposed to stronger action of aggressive water and frost on the wall face.

The homogeneity of concrete is a resultant of the homogeneities of its materials (cement, aggregates, admixtures), their proportioning, and of manufacture and placing of concrete. Even though the compressive strength of concrete is not a safe index of its durability, an evaluation of the various factors and their effects may well start out from the variability of this property of normal concretes (105). With respect to their effects on the variability of concrete strength, those factors are assigned the following rating:

Cement quality	50%
Aggregate grading	25%
Sand bulking	10–25%
Proportioning—by weight	8%
—by volume	16–100%
Compaction (poor)	50%

As to cement: its quantity relative to voids and surface of aggregates plays a more important role in concrete durability than does its strength. In sufficient filling of voids and covering of aggregate grains lead on the one hand to porosity and permeability, on the other to imperfect joining of aggregate grains (inferior bond). For these reasons the grading and variability of aggregates are of major importance in case of durable concrete. To ensure a dense concrete texture, proportioning of cement must start out from the most unfavourable grading of aggregates, and it is just in this that the high variability of aggregates manifests itself to disadvantage. It is, therefore, necessary, *to accord due attention to the grading of aggregates, variability of their fractions as well as to the proportioning of the fractions and cement.* This holds equally true for the placing (compacting in particular) of concrete. The relations between concrete workability, compacting means and compacting proper are eventually the decisive factors for the homogeneity of concrete in a structure.

In very close connection with concrete homogeneity is the quality of joints, mainly that of construction joints. Even when concreting is done very carfully, construction joints are usually a typical source of deterioration of concrete structures due to external agents. Poor quality of joints between old and fresh concrete is a regular source of deterioration by the action of waters and weather (Fig. 7). The importance of such joints increases still further in the case of reinforced concrete because of higher danger of reinforcement corrosion.

From the point of permeability, the non-homogeneity of concrete also asserts itself adversely by creating conditions conductive to electrolytic and chemical corrosion of the reinforcement.

The foregoing discussion was concerned with the statistical homogeneity of concrete expressing uniform distribution of heterogeneous concrete components in its mass or in each section.

Concrete is essentially a heterogeneous material in which consideration must be given to the important relations that exist between hardened cement paste, aggregates and reinforcement.

In regard to the durability of concrete, cement,

hardened cement paste and their properties play a decisive role also in the relation to the aggregates whose durability is usually higher than that of concrete or of hardened cement paste (Fig. 8). Accordingly it is the following three components that come into play whenever concrete is undergoing deterioration by diverse agents: aggregates, hardened cement paste and their bond ensuring mutual connection and collaboration. The relations shown in Fig. 8 convince us that the bond is actually the weakest link in that system. This circumstance in combination with other facts proving that the bond is the weakest link of concrete structure even from the point of tensile strength and permeability, suggests the way to be followed by basic research in an endeavour to improve the properties of concrete not only from the aspects of the durability but on all counts as well.

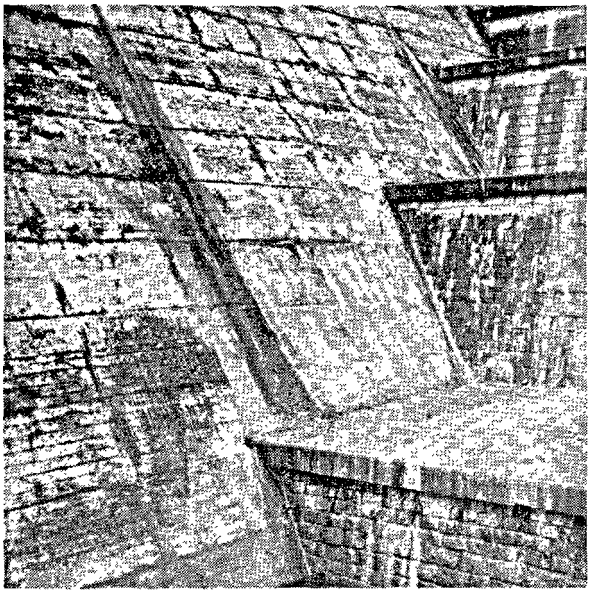

Fig. 7. *Construction joints in a dam as weak points of concrete structure*

Role of Protection in the Durability of Concrete Structures

The durability of concrete, particularly in a strongly aggressive environment, must also be ensured by protecting the material against intensive contact with aggressive agents. Protection of concrete must be considered an inseparable part of the solution to the problem of durability of heavily endangered concrete structures and their parts.

The object of protecting concrete structures is to restrict or completely eliminate the effect of adverse and aggressive external factors either by preventive or by supplemental measures. Timely preventive measures are the most effective and cheapest solution of all. All protective measures can be classified in two groups:

1 *Adjustment of the environment of the structure*, such as: drainage of the foundation soil, ventilation and withdrawal of aggressive vapours and gases, conveying of aggressive agents, weakening or neutralization of aggressive substances within the manufacturing process, neutralization of underground aggressive waters, etc.

As to *conveying of aggressive substances*: special emphasis should be put on the use of the various measures and on ensuring their correct functioning by

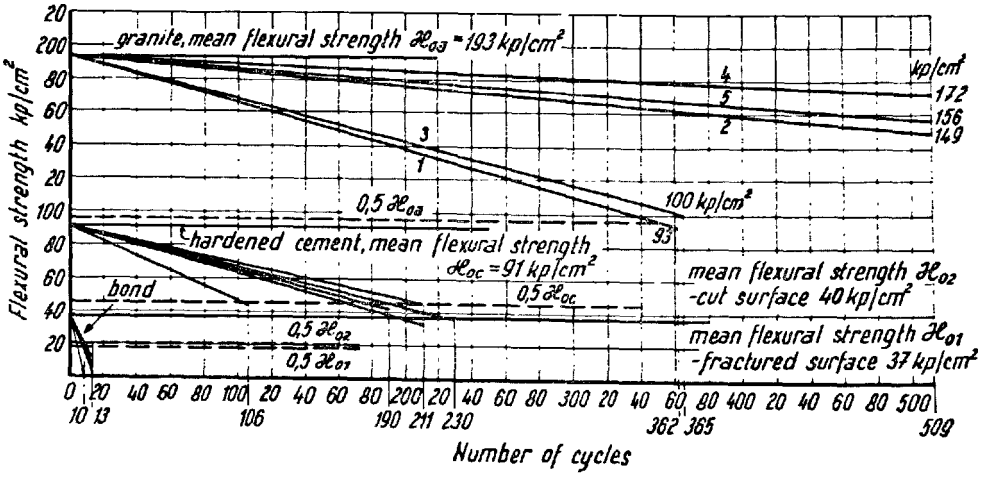

Fig. 8. *Frost resistance of granite, hardened cement paste and their bond (113)*

regular checks and maintenance. These measures include: ventilation and air conditioning, particularly of manufacturing spaces, prevention of steam condensation on concrete structures (ceilings, roofs), efficient drainage of roofs and perfectly functioning—especially in winter time—water withdrawal systems, perfect drainage of pavement, particularly when using de-icing salts, prevention of water flow on facades, a year-round reliable operation of drainage systems of bridge structures, protection of the structure against stray currents, etc.

2 *Treatment and protection of concrete surfaces* such as impregnation and chemical treatment of concrete surfaces (fluoro-silicates, ocratization), impermeable and resistent coatings and membranes (films), impermeable and resistant layers and plasters, impermeable and resistant linings and walling (protection of piles in sea water, of pavement, etc.).

The indispensable condition for a surface insulation to be effective is absolute impermeability.

The effectiveness of surface protection is contingent to: impermeability to gases and liquids, chemical resistance against agents present in the given medium, deformability as relating to the protected structure under all conditions of operation (temperature, humidity), high homogeneity of mechanical, physical and chemical properties, mechanical resistance against impacts and other effects of normal operation, static security, particularly from the point of limiting deformations and eliminating buckling (stability).

While in *conventional insulating materials* (clay, rocks, aggregates, etc.) it is the thickness that matters with regard to the coefficient of permeability, in modern insulating materials (impermeable films), the crucial point is the *absence of defects*. The necessary safety of the latter insulations as regard impermeability is usually obtained through the use of multiple films and of perfect, impermeable joints.

The decisive condition for an effective function of any insulation is high homogeneity and impermeability. This immediately implies high demands on the quality and control of the respective materials, of their technology and of the completed insulation. This leads to increased importance of prefabrication in this field.
