Preface

Though more than a half century ago meetings covering various materials including cements were held among researchers, it was not before 1918 in London where an international meeting was held to discuss the setting of cements under the sponsorship of the Faraday Society that the chemistry of cements was dealt with independently and systematically in such a magnitude worth a title of an international symposium. Hence, this international gathering became more and more accustomed to be called as the First International Symposium on the Chemistry of Cement, though not so called at the beginning.

Just as the famous ancient Olympics in Greece which in their earliest stage were celebrated for one day only, the First International Symposium on the Chemistry of Cement dawned on January 14, 1918 in London was closed on the same day, with the presentation of 10 papers followed by 12 discussions. The Proceedings consisting of 69 pages were published in the Transactions of the Faraday Society, Volume XIV, 1918–19, thus leaving the first footprints and pattern to the later Symposia.

The Second Symposium on the Chemistry of Cement took place from July 6 to 8, 1938, in Stockholm, sponsored by the Royal Swedish Institute for Engineering Research and the Swedish Cement Association. With the participation of 47 persons from 13 countries, 52 discussions were made on 13 papers presented thereto. The Proceedings consisting of 578 pages were published in Stockholm in 1939 by the Royal Swedish Institute for Engineering Research.

The devastation of World War II could not nip the Symposium in the bud. On the contrary, it called for a Post-War program of reconstruction everywhere on a scale never before attempted, in which the cement was destined to play an important role all around. With this background, the Third International Symposium on the Chemistry of Cement was held in London in September, 1952. It was a five-day meeting in which 260 persons took part and 23 papers were presented. The number of discussions amounted to 102. The Proceedings consisting of 870 pages were published in London in 1954 by the Cement and Concrete Association, who cosponsored this Symposium with Department of Scientific and Industrial Research of the United Kingdom.

The host country of the Fourth Symposium was the United States of America. Under the sponsorship of the National Bureau of Standard and the Portland Cement Association, the Fourth International Symposium on the Chemistry of Cement was held at Washington, D. C., October 2–7, 1960. Among 362 persons who accepted the invitations, 271 persons were in attendance from various countries including the host country. The number of papers presented thereto amounts to 66 of which 18 were Principal Papers and 48 were Supplementary Papers, and they were followed by 87 Discussions.

As the Post-Symposium event, a travel to Skokie (Illinois) was organized and many Symposium members took part in it. The participants visited the laboratories of the Portland Cement Association and attended a series of seminars. The Proceedings consisting of 1125 pages were published in Washington, D.C., in 1962 by the National Bureau of Standards.

It was during the Fourth Symposium in Washington that the Japanese cement circles were asked to assume a task of organizing the Fifth Symposium. Encouraged by elder authorities of many participating countries, the representatives of the Japanese cement circles finally accepted to hold in Japan the Fifth International Symposium on the Chemistry of Cement. In 1964, a provisional organizing committee was formed in the bureau of Japan Cement Engineering Association and preparation work started right away. In 1966, Japan Cement Engineering Association was merged in the organization of the Cement Association of Japan, and the proper Organizing Committee and Secretariat were settled in the office of the latter.

Since then, the Organizing Committee and the Secretariat coped with the colossal work for staging the Symposium in Tokyo, and preparation works went on smoothly thanks to the cooperations of the Symposium members in Japan and abroad. Thus, on October 6, 1968, the Fifth International Symposium on the Chemistry of Cement, sponsored by the Cement Association of Japan, dawned with a cocktail party celebrating the 50th anniversary of this Symposium, under the auspices of the Science and Technology Agency and the Ministry of International Trade and Industry, and supported by the Science Council of Japan, the Ceramic Association of Japan, Japan Society of Civil Engineers, the Architectural Institute of Japan and the Chemical Society of Japan.

All the sessions of the Symposium were held, from October 7 to 11, at the Tokyo Metropolitan Festival Hall, Ueno Park, Tokyo. The whole day of October 12 was devoted to technical visits to laboratories and cement works in and around Tokyo.

The Symposium members regularly registered amounted to 606 persons including 325 from Japan and 281 from 42 other countries. But number actually in attendance was 485 including 307 from Japan and 178 from 34 other countries. Accompanying persons from abroad amounted to 40 persons.

An opening ceremony was held on Monday morning, October 7, at the Tokyo Metropolitan Festival Hall before calling to order proper working sessions. The addresses of welcome were given by Mr. H. Inouye, President of the Organizing Committee and by Mr. N. Nabeshima, Minister of State and Director of Science and Technology Agency of Japan. Mr. J. H. Walker, Vice President of the Portland Cement Association, U.S.A., responded on behalf of the members of the Symposium.

The first formal speech entitled "On the Contribution of Chemical Studies to Japanese Cement Industry" was made by Dr. S. Nagai, Professor Emeritus of the University of Tokyo. In succession, Sir F. M. Lea, former Director of the Building Research Station of the United Kingdom, made a speech entitled "Cement Research —Some Views for the Future".

Succeeding working sessions are devoted to technical papers submitted to this Symposium, which amounted to 172 including 20 Principal Papers, 124 Supplementary Papers and 28 Written Discussions. In consideration of too short period of this Symposium to allow each author of Supplementary Papers to present paper in person, the Organizing Committee adopted General Report System where each group of Supplementary Papers under each specific topic was digested systematically by a General Reporter and presented in summarized version at each corresponding session. Thus, time for oral discussions getting available, 69 oral discussions were made throughout five day working sessions.

The themes of the Fifth Symposium consisted of four Parts, and each Part had a categorical topic of its own to which specific subjects treated by Principal and Supplementary Papers were attributed. Each working session covered a group of these specific subjects.

Preprints of Principal Papers in full text and Supplementary Papers in abstract were distributed to enrolled members before the Symposium. Preprints of Written Discussions and General Reports both in full text were distributed at the Symposium site to the attending members.

Technical visits to laboratories and cement plants on October 12 (Saturday) were carried out with the participation of many Symposium members, divided into three groups. The first group visited the cement plant in Saitama Pref. of Nihon Cement Co. Ltd., the second inspected the cement plant of Chichibu Cement Co. Ltd. in Kumagaya city and the Central Research Laboratory of Onoda Cement Co. Ltd. in Tokyo, and the third made a tour of inspection to Kajima Institute of Construction Technology, the Research Laboratory of Engineering Materials of Tokyo Institute of Technology and the Central Research Laboratory of Onoda Cement Co. Ltd, all the three in Tokyo metropolis.

The Proceedings of the Fifth International Symposium on the Chemistry of Cement contain all the written contributions in full text except General Reports, all the oral discussions made on Principal and Supplementary Papers together with their closing discussions and two inauguration speeches at the Opening Ceremony. Being English the official language of this symposium, the Proceedings have been published in English only.

A survey of this Symposium can be made by referring to the annexed table of general program.

General Program of the Fifth International Symposium on the Chemistry of Cement

Parts & Topics	Dates	Sessions and Subjects	Authors of P. P.	Chairmen & Co-Chairmen	Number of S. P.	General Reporters of S. P.
Part I Chemistry of Cement Clinker	Oct. 7 Afternoon	I-1 Structure of Portland Cement Minerals	A. Guinier M. Regourd (France)	I-1 & 2 F. M. Lea (U.K.) T. Yamauchi (Japan)	6	Th. Hahn (W. Germany)
		I-2 Phase Equilibria and Formation of Portland Cement Minerals	R. W. Nurse (U.K.)		9	Y. Suzukawa (Japan)
	Oct. 8 Morning	I-3 Analysis of Portland Cement Clinker	G. Yamaguchi S. Takagi (Japan)	I-3 & 4 R. W. Nurse (U.K.) G. Yamaguchi (Japan)	12	A. E. Moore (U.K.)
		I-4 Chemistry of Calcium Aluminates and their Relating Compounds	T. D. Robson (U.K.)		2	P. E. Halstead (U.K.)
Part II Hydration of Cements	Oct. 8 Afternoon	II-1 Crystal Structures and Properties of Cement Hydration Prodocuts (Calcium Silicate Hydrates)	H. F. W. Taylor (U.K.)	II-1, 2 & 3 H. F. W. Taylor (U.K.) R. Kondo (Japan)	0	
		II-2 Crystal Structures and Properties of Cement Hydration Products (Hydrated Calcium Aluminates and Ferrites)	H. E. Schwiete U. Ludwig (W. Germany)		7 (Structures) 5 (Properties)	W. Locher (W. Germany) M. H. Roberts (U.K.)
		II-3 Phase Equilibria of Cement-Water	P. Seligmann N. R. Greening (U.S.A.)		0	
	Oct. 9 Morning	II-4 Kinetics of Hydration of Cements	R. Kondo S. Ueda (Japan)	II-4 & 5 H. zur Strassen (W. Germany) S. Nagai (Japan)	6 (Mechanism) 8 (Kinetics)	H. Mori (Japan) H. N. Stein (Netherlands)
		II-5 Hydration of Portland Cement	L. E. Copeland D. L. Kantro (U.S.A.)		7	H. zur Strassen (W. Germany)
Part III Properties of Cement Paste and Concrete	Oct. 10 Morning	III-1 Structures and Physical Properties of Cement Paste	G. J. Verbeck R. A. Helmuth (U.S.A.)	III-1 & 2 G. J. Verbeck (U.S.A.) M. Kokubu (Japan)	8 (Fundamental) 7 (Application)	W. C. Hansen (U.S.A.) W. L. Dolch (U.S.A.)
		III-2 Durability of Concrete	O. Valenta (Czech)		10	Imre Biczok (Hungary)
		III-3 Carbonation of Concrete	M. Hamada (Japan)	III-3, 4 & 5 R. H. Mills (Canada) T. Nishi (Japan)	3	H. G. Smolczyk (W. Germany)
	Oct. 10 Afternoon	III-4-a Hydration of Portland Cement Paste at High-Temperature under Atmospheric Pressure	G. M. Idorn (Denmark)		3	P. J. Sereda (Canada)
		III-4-b High-Temperature Curing of Concrete under Atmospheric Pressure	Yu. M. Butt V. M. Kolbasov V. V. Timashev (U.S.S.R.)			
		III-5 High-Temperature Curing of Concrete under High Pressure	G. Kalousek (U.S.A.)		3	H. E. Vivian (Australia)
Part IV Admixtures and Special Cements	Oct. 11 Morning	IV-1 Use of Surface Active Agents in Concrete	R. Mielenz (U.S.A.)	IV-1 & 2 N. Stutterheim (S. Africa) M. Okushima (Japan)	5	K. Okada (Japan)
		IV-2 Fly Ash and Fly Ash Cement	M. Kokubu (Japan)		4	A. Joisel (France)
	Oct. 11 Afternoon	IV-3 Slags and Slag Cements	F. Schröder (W. Germany)	IV-3, 4 & 5 J. H. Walker (U.S.A.) K. Chujo (Japan)	9 (Slag) 3 (High-Sulphate Slag)	R. Sersale (Italy) S. K. Chopra (India)
		IV-4 Expansive Cement	P. P. Budnikov I. V. Kravchenko (U.S.S.R.)		7	G. J. Verbeck (U.S.A.)
		IV-5 By-product Gypsum from Various Chemical industries, as a Retarder for the Setting of Cement	K. Murakami (Japan)		0	
Total		20 sessions	20 papers	16 persons	124 papers	20 persons

List of the Symposium Regular Members

ABE, Hirotoshi
Central Research Institute of Electric Power Industry ..... Japan
AGO, Shunji
Onoda Cement Co., Ltd. ..... Japan
AHN, Kyu Young ..... Rep. of Korea
AKAIWA, Shigeo
Chichibu Cement Co., Ltd. ..... Japan

Inauguration Speeches at the Opening Ceremony of the Fifth International Symposium

Cement Research—Some Views for the Future

Frederick M. Lea*

It is just fifty years since the Faraday Society arranged an international meeting in London to discuss the setting of cements. Though not so-called at the time, we count this as the first international symposium on the chemistry of cements. It was, however, the symposium held in Stockholm in 1938 which first reviewed the main fields of cement chemistry and set the pattern for the later symposia in London in 1952, in Washington in 1960 and now here in Tokyo. These symposia have all been held in countries where research in cement chemistry has been vigorously pursued. In meeting here in Japan we continue that same tradition and pay tribute to the many contributions to the subject that have come from research workers in this country.

There can be only a few of us here today who were present at the Stockholm Symposium in 1938. At that time our knowledge of the phase equilibria between the various oxides present in cements was well advanced and the constitution of Portland cement had been established in terms of the four major clinker compounds. The properties of cements had been broadly linked with their constitution, though much still remained to be resolved on the influence of the minor constituents. The main features of the chemistry of the hydrated cement compounds and of the reactions of cements with water were clearer for the aluminate than the silicate compounds, for which the existing techniques of investigation were not sufficiently powerful to resolve some of the problems involved. We had only just started to probe into the crystal structure of the cement compounds, anhydrous or hydrated, and our knowledge of the physical structure of set cement was lacking in depth. We saw at Stockholm that wide fields still awaited investigation, but nevertheless we felt that the basic foundations of cement chemistry had been well laid. Indeed I remember my old friend, the late Dr. Lennart Forsén of Sweden, saying to me at the end of the Stockholm Symposium—'the main questions are now solved, what remains is detail.' That was I think a legitimate expression of gratification at the way in which the Stockholm Symposium had shown how existing knowledge fitted together, even if in hindsight one would add to the word 'detail' some such phrase as—'and new principles of which we are as yet unaware.' I recently came across a quotation from Goethe which said—'Every solution of a problem is a new problem.' It is characteristic of science that the introduction of new concepts and new techniques opens new fields for investigation and the ensuing years have shown that the chemistry—and physics—of cement is no exception to this rule.

I would like in passing to recall that it was to Lennart Forsén that we really owe the concept of these symposia. If one further recollection may be permitted, as a matter of history, I have never forgotten how the plans for the 1938 Stockholm Symposium were worked out during discussions between Dr. Forsén, Mr. Giertz-Hedström, also of Sweden, Dr. Robert Bogue and myself when we all met in the USA in 1936.

The symposia in 1952 and 1960 showed how much our subject had advanced, thanks to the introduction of new and improved techniques. The crystal structures of cement compounds, the physical structure and properties of set cement paste and the chemistry of cement hydration can be mentioned as examples. The London Symposium of 1952 was widened to include various special types of cements, the durability of concrete and some questions relevant to cement manufacture. If the Stockholm Symposium was devoted solely to science, the London Symposium introduced also technology. This process was continued in 1960 in Washington when we added to our discussions such problems as volume change in concrete, admixtures, cement-aggregate reaction and frost resistances of concrete.

The reports presented to the present symposium

*Former Director of Building Research Station, United Kingdom.

again introduce some new subjects and show how notable have been the advances in the older ones. I cannot attempt in the time available to survey these in detail. Rather would I use them as a starting point for some comments on fields which seem potentially fruitful for future research.

Let me start with cement constitution. We are accustomed to calculate the compound content of Portland cement from its composition, or to estimate it by X-ray and microscopic methods. Much effort has been devoted to reducing the imperfections of these methods. Phase equilibrium studies have yielded much information on the limits of solid solution of other oxides in the silicate, aluminate and ferrite compounds. We now have in the electron probe a powerful new method for analysis of the clinker minerals as present in Portland cement. Already reliable results are available on the silicate phases, but to obtain equal reliability with the interstitial material in clinker either the instrument must be improved or some selection and heat processing of the clinker may be necessary. From electron probe analysis on clinker compounds we may be able to reach agreement on certain average formulae for the composition of the clinker minerals and to use these in calculating the compound content of a cement from its chemical analysis. The results will still be approximate since some minor constituents will not be present in sufficient quantity to saturate the clinker compounds, but we should obtain a closer approximation to the true values than is given by the simple Bogue calculation. The general availability of computer services will facilitate such calculations. A complementary study lies in the effect of the composition of the clinker components on strength development. It is well established that the strength of dicalcium silicate can be controlled by solid solution and to some extent the early, if not the final, strength of tricalcium silicate. Electron probe analysis will tell us how a given minor constituent is partitioned between the main phases of the clinker and provide a basis for more systematic study on the influence of solid solution on strength development.

On the chemistry of hydrated cement we still need to know more about the properties of the calcium silicate hydrates. It is well known that other oxides can be taken up in the tobermorite lattice and we have an indication that this may influence both strength and shrinkage. Can we control this solid solution in a favourable way? Is it related solely to the composition of the anhydrous clinker components or is it determined by the particular equilibria, or lack of equilibria, associated with the hydration process? Electron probe analysis of the composition of the calcium silicate hydrates in set cements is likely to be more difficult than on cement clinker, but if it proves possible it may provide data to help us link physical properties with the composition of the hydrates. Perhaps we have looked too much at clinker composition as the determinant of strength and not enough at how it is influenced by the vagaries of the hydration process.

The last two decades have seen notable advances in our knowledge of the physical structure of set cement, but how wide are still the fields of ignorance. Can we remain satisfied while we still lack an adequate understanding of bonding and strength, of fracture, of shrinkage and creep, an understanding that might help us to do more to control these properties. We have various rival theories based on particular models and mechanisms. They give us only descriptions, often, it is true, capable of mathematical formulation, but not real understanding of phenomena. We shall not get that understanding until we can base the theories on a fundamental knowledge of the way in which hydrated cement particles bond to each other and to the aggregate particles. Attempts have been made to account for the mechanical properties of cement paste by reference to the morphology and crystal structure of the constituents, but we know little of the real nature of the bonds formed between them. The crucial experiments have still to be devised.

High surface area is a common characteristic of set cements of different kinds, but it is not essential for strength as is shown by the properties of autoclaved products. The strength of all materials is much lower than theory would indicate. In materials such as metal or glass we explain this by theories such as the Griffith's crack theory, but how far this is applicable to concrete is still open to question. We may speculate that the low strength of set cement, as compared with theoretical calculation based on the strength of the crystals, may reflect not so much a low strength of the individual bonds—physical or chemical—but to the bonds being too few in number. Most of our present data and theories come from studies on Portland cement. Many studies have been made on the specific surface, crystal size and physical properties of set Portland cement. These studies need to be extended to other cements and to crystalline hydrates to help to elcuidate the mechanism of bonding.

The strength tests we use are adequate for structural purposes but they are crude as measures of the parameters we need to investigate in developing theories of fracture mechanics. Most of the strength

data we have refer only to wet or dry concrete with little information over the intermediate range. We know little about the effect of other polar liquids on any of the physical properties of concrete. Such information could well increase our understanding of the role played by water in set cement.

The development of high voltage electron microscopy with 500 or 1000 kV electrons combined with the developments of skill in making very thin sections is making possible high resolution photography and diffractometry while at the same time reducing damage to the specimen while under observation. The scanning electron microscope provides stereographic images at lower resolution but giving a more global picture of the structure and in greater depth facilitating the study of fracture cracking and porosity in great detail. We might for instance resolve such an apparently simple problem as the part played by calcium hydroxide crystals in the strength of Portland cement and learn more of the nature of the cement-aggregate bond.

An increase in the strength of concrete would be valuable, but the outstanding problem is shrinkage and cracking. We see one attack on this problem in the development of expansive cements, but, though these may eliminate or reduce the initial drying shrinkage, the reversible wet-dry movement still remains. If we could find means of reducing the elastic modulus of concrete without reducing the tensile strength more deformation would be possible without cracking. This would be of major importance in many uses of concrete, but no practicable solution is in sight. I have mentioned earlier that solid solution of other oxides in the tobermorite lattice may influence shrinkage. The field for study of this phenomenon is wide. It is also surprising, in view of its importance, how few are the published papers on the nature of the bond between cement paste and aggregate.

There are many other problems which I can do no more than mention which have much practical significance in the use of cement and concrete. There is no reason to believe that we have yet found the optimum solutions in the use of admixtures and particularly in the development of water-reducing agents, and of plasticising agents less sensitive to the cement composition. We are beginning to understand the physical chemistry of the action of admixtures but there is still scope for basic studies. Acceleration of hardening both in precast concrete manufacture and for in-situ work has much economic significance. The effect of temperature on the physical structure of the set cement paste and the way in which it is built up needs clarification.

The durability of concrete has been much studied both by field surveys and trials and by laboratory tests and experiments. We cannot say, however, that we know enough about the basic mechanism of the various chemical and physical destructive processes that lead to deterioration of concrete, nor can we express durability sufficiently in quantitative terms. With the trend in structural engineering to limit state design, which depends on estimates of the probability that a structure will not become unfit for its intended purpose during its lifetime, it would be an added gain if one of the parameters considered was more directly related to durability. Deterioration, not collapse, is the normal determinant of the life of a structure.

The role of the minor components in a cement clinker and their influence on the properties of the resulting cement and the burning process should continue to occupy a place in research. The influence on burning appears to have particular significance with the more unusual processes or raw materials as in the cement-sulphuric acid process or when unusual amounts of components such as phosphorus pentoxide or fluorine are present in the raw materials. The chemical and physical problems of manufacture, and indeed those of the use of cement, have received less attention than they warrant in our symposia.

I do not wish to suggest that there are not still many outstanding problems in the chemistry of cements other than Portland, such as pozzolanic cement, slag-containing cements and high alumina cement, and it is evident that expansive cements are still a developing material with scope for further investigation. Nor would I imply that there is not a good deal of detail to work out on the hydration of cements generally. My purpose in this address, however, has been to stress what seem to me to be some major areas which call for new and imaginative approaches.

On the Contribution of Chemical Studies to Japanese Cement Industry

Shoichiro Nagai*

Mr. President, Ladies and Gentlemen;

It is a great pleasure and honor for me to present this lecture on this occasion.

The Third International Symposium was held in London in 1952 when many nations had gone through a period of reconstruction following World War II. Three delegates from Japan attended this Symposium. Eight years later, in 1960, the Fourth Symposium was held in Washington D.C. with the participation of fifteen delegates from Japan. It was on the occasion, that I, being the senior Japanese delegate, proposed that the Fifth Symposium be held in Tokyo. This proposal was unanimously accepted during the course of the grand banquet. Thus, the first symposium on the cement chemistry ever to be held in Asia became a reality.

With your permission I would like to confine my talk to chemical studies which have contributed to the development of the Japanese cement industry in the following three progressive stages.

The first stage began about 95 years ago with the establishment of the first cement industry in Japan in the form of a public enterprise. In 1883, after ten years later, the management was transferred from public to private. From 1881 to 1883, a few other factories were established. Together they contributed to the gradual development of the cement industry. After the Sino-Japanese War and the Russo-Japanese War, Japanese industries as a whole became prosperous and the cement industry was no exception. It made particularly remarkable progress up to 1913, just before the outbreak of World War I.

During this first stage of fourty years, research and experimentation on quality improvement in cement factories, as well as studies on mortar and concrete, in relation to the establishment and revisions of the Japanese Engineering Standards (JES) of cement, were extensively carried out. In this connection, exceptionally important contributions were made in the chemical field by Dr. S. Kasai, Mr. M. Fujii, Mr. T. Taniguchi, Mr. M. Okada, Prof. Dr. S. Kondo, Mr. S. Nagaya, Mr. K. Otomo, Mr. S. Kano, Mr. M. Komuro, Mr. S. Asaeda, and others.

The scale of the Annual General Meeting of the then Portland Cement Association grew larger each year. Those of us who were in the middle age group (now senior group) profited from the learning and were greatly influenced by the great scholars just mentioned, and we participated in joint research and experimentation.

The prosperity of the cement industry from 1913 to 1917 (just during World War I) owed much to the contribution made by chemical studies on cement, and its production. In those days, researches and tests on Portland cement, Portland blast-furnace slag cement, slag and the relevant pozzolan were carried out very frequently. The strength of cement and mortar, as specified in the Japanese Engineering Standards, was based on the standard sand-cement dry or so-called non-plastic mortar method. Efforts to perform comparative tests were made and several revisions of standards were sought concerning standard sand and testing apparatus. Consequently, the quality of cement rapidly improved.

During the early second stage which involved World War I period, the cement industry did not suffer from that war, and made great strides, together with other industries. During the ensuing 24 to 25 years, i.e., until World War II, annual cement production in Japan increased continuously to reach its highest peak of about 6.2 million tons in 1939.

In this second stage, those who studied under or collaborated with the forerunners of the first stage, became independent, and those who returned from studying in Europe became leading researchers. For example, Dr. K. Koyanagi, Mr. Y. Tokune, Prof. Dr. T. Yamauchi, Mr. T. Ando, Dr. T. Tanaka, Dr. Y. Sanada, Mr. J. Hosoi, Mr. T. Asano, Dr. T. Yoshii, Dr. M. Nakahara and many others (including ourselves) indefatigably conducted studies on cement. Results of detailed and fundamental chemical, microscopic and X-ray researches made on cement minerals were presented in both national and foreign scientific journals and are frequently referred to in technical documents.

*Professor Emeritus of the University of Tokyo
Vice-President of the Organizing Committee for the Fifth International Symposium.

At the same time, a number of younger researchers were developing, forming a solid cadre of cement chemical researchers who would become active in the present time.

The third stage commenced at the end of World War II and spans the last approximately 23 years to the present day. All Japanese industries were destroyed during World War II, including the cement industry. Thus cement production in 1946, the year following the end of the war, was at its lowest with only about 930,000 tons, dropping below 1 million tons. However, since cement, together with steel, was regarded as an indispensable building material in the national reconstruction program, production increased very rapidly. As a consequence, six years later, in 1951, annual production exceeded 6.7 million tons, and three years later, in 1954, it exceeded 11 million tons. Again, six years later, in 1960, annual production was over 22.7 million tons, while three years later, in 1963, it reached over 31.1 million tons. In 1967, production figures of over 42.6 million tons were obtained. The population also has steadily increased, to reach 100 million. Thus, annual production is 426 kg per capita, which is still inferior to the highest European level of 600–650kg per capita, but it is expected to reach over 500–550kg per capita before long.

Remarkable fact during this third stage is that research was conducted on the fifth and sixth components magnesia and alkali, in addition to research started in the second stage, that is, studies on clinker minerals by the four component system lime, silica, alumina and ferric oxide. The relation between magnesia and ferric oxide and the color of cement was also studied, as the tint of mortar and concrete is of much importance. In this connection, reports of studies on the five component system, lime, silica, alumina, ferric oxide, magnesia, and on the importance of alkali were also presented at the Third London Symposium.

The next fact worthy of special mention is the research on hydration products of cement—the synthetic research concerning calcium silicate hydrates and calcium aluminate hydrates which were found largely in natural form or in hardened cement. From 1930 to 1932, I made synthetic studies at the former Kaiser Wilhelm Institut für Silikat-forschung in Berlin, under Prof. Dr. W. Eitel and reports on calcium silicate hydrates and calcium aluminate hydrates obtained by a hydrothermal synthetic process in autoclaving of the ternary systems of lime-silica-water and lime-alumina-water. Those were presented in German, English and Japanese chemical journals. Furthermore, at the Fourth Symposium held in Washington D. C., in 1960, many reports on tobermorite as the principal product of cement hydration were presented. Moreover, concerning this hydrothermal reaction of lime-silica-water system, there are many reports on the hardening test for autoclaved lightweight concrete (ALC) in prefabricated building materials.

As to the types of cement, basic researches on high early strength Portland cement and low heat or moderate heat Portland cement were carried over from the second stage, and production and utilization of high quality products were supplied as essential building and construction materials. These research programs of the second and third stages were conducted by many young prominent researchers, such as the chairman of Program Committee of this Fifth International Symposium, Dr. K. Chujo, the chairman of Arrangements Committee, Dr. T. Yamaguchi, and the authors of the principal papers of this symposium, Prof. Dr. K. Murakami, Prof. Dr. G. Yamaguchi, Dr. R. Kondo and many other younger researchers who will present many supplementary papers. It is a great joy to see so many of these cement researchers here today.

Around 1948 or 1949, when the cement industry was about to arise from wartime destruction, the former JES became the JIS (Japan Industrial Standards). After that, new standards were set concerning blended cements in terms of A, B and C, according to the proportion of admixture in Portland blast-furnace slag cement, silica cement and fly ash cement. As to the strength test for mortar, after about ten years of research and tests, the wet or so-called plastic mortar method was introduced, to replace the conventional dry method. Thus, in Japan, mortar strength of high early strength Portland cement and that of normal Portland cement and of A grade blended cements of all three types are extremely good, being among the best quality in the world. It seems only natural that Japan should lead the world in cement exports.

In regard to special cement, that is, in 1937 high aluminous (53 to 55% alumina content) cement and alumina began to be produced simultaneously. This led to research and development of hydraulic refractory mortar, and now it is known as castable refractories. Research and utilization of low expansive or non-contractive cement, making use of the expansive nature of calcium sulpho-aluminate hydrate was also started in Japan. Three supplementary papers on this subject will be presented at this symposium.

Before concluding, I would like to touch upon the

following two points.

(a) The first is that annual production of natural gypsum in Japan is only 600,000~700,000 tons, and its quality is so poor that it can scarcely be used only for cement. On the other hand, with production of cement increasing yearly, reaching 46~47 million tons this year, about 3 percents, of that figure (about 1.5 million tons/year) of gypsum is necessary. We have to seek the source of supply of half the necessary amount in byproduct gypsum from various chemical industries. Production of phosphoric acid solution by reacting sulphuric acid to phosphate rock yields a particularly large amount (about 2 million tons this year) of phospho-gypsum as a byproduct, and half that amount goes successfully into cement production. One principal paper will be presented by Prof. Dr. K. Murakami's research group concerning this special point.

(b) The next point I wish to mention is the treatment of papers on the subject of concrete at this symposium. In Japan, more than half the papers presented at the Annual General Meeting on Cement Engineering, held every year by the Cement Association of Japan, were related to concrete. In view of these facts, both principal papers and supplementary papers on concrete based on the chemistry of cement are dealt with in Parts III and IV, ranking with Parts I and II where papers on the chemistry of cement will be presented. Supplementary papers being so numerous, they will be presented by general reporters in the form of summarized report. This system is something new in our international symposium, but I hope this solution proves to be highly successful.

I have spoken of the development of research and experimentation in cement chemistry in Japan, and I very much appreciate the kind attention you have paid me. Thank you.

Explanatory Notes

Abbreviations.

The following symbols, which have been universally recognized by cement chemists for formulating more complex compounds, are used interchangeably with the respective oxide formulas throughout this book:

$C = CaO$, $S = SiO_2$, $A = Al_2O_3$, $F = Fe_2O_3$,
$M = MgO$, $N = Na_2O$, $K = K_2O$, $H = H_2O$,

Less common abbreviations of this type are defined as they occur.

Commonly used abbreviations of more general nature are as follows:

DTA = differential thermal analysis
EPMA = electron probe micro analysis
IR = infrared
NMR = nuclear magnetic resonance
psi (or p s.i.) = pounds per square inch
rh (or RH) = relative humidity
w/c (or W/C) = water — cement ratio
XRD = X-ray diffraction

Identification Number of Supplementary Papers

Example: Supplementary Paper III—50, III is session III and 50 is the arrival number of contribution. This number coincides with the number used in the preprint of papers distributed in advance of the symposium.

Session I-3 Analysis of Portland Cement Clinker

SESSION I-1 STRUCTURE OF PORTLAND CEMENT MINERALS

Principal Paper Structure of Portland Cement Minerals

André Guinier and Micheline Regourd*

Synopsis

In portland cement clinker, the four principal constituents are found in the form of solid solutions. The polymorphic variations of these solid solutions being numerous and ill-defined, we have first dealt with the structure and polymorphism of the pure compounds.

Pure C_3S, passes through six allotropic forms between ambient temperature and 1100°C, all very close to the trigonal high-temperature form. A pseudo-structure which is a good approximation to the real structure has been proposed by Jeffery. Alites usually crystallize in the monoclinic and trigonal forms of C_3S.

On the other hand, the five forms of C_2S are different. Their crystal lattices are distinct and the stacking of silicate tetrahedra differs from one to another. Only the structures of β and γ have been determined. Belites usually crystallize in modified β forms, more rarely as the γ' form.

The cubic structure of C_3A has not been determined. Tricalcium aluminate forms solid solutions with the aluminoferrites of the interstitial phase. This can occur as a glassy phase when clinkering temperature is high, quenching rapid and the A/F ratio >1.

The hydraulic properties of the clinker constituents are linked to their crystal structure, particularly the irregular Ca co-ordination, and the presence of holes in the structure. All the forms of C_3S show comparable reactivity whereas the forms of C_2S differ in their hydraulic properties.

Introduction

This is a study of the four minerals which are the principal constituents of all portland cement clinkers and are designated, following the classical abbreviations, as C_3S, C_2S, C_3A and C_4AF.

In fact, each of these abbreviations represents a group comprising the pure phase and the solid solutions having a crystal lattice with identical or very similar lattice dimensions. The alites and belites which correspond respectively to C_3S and C_2S are the solid solutions formed by the addition of impurities which are present in all commercial cement clinkers and are principally the ions or oxides of Al, Mg, Fe, Na, K, Cr, Ti, Mn, P, et cetera. Even when no impurities are present, the aluminoferrite, "C_4AF", can have a variable composition $C_2(A_pF_{1-p})$ where p varies from 0 to 0.7.

On a polished clinker surface, the microscope clearly distinguishes the different phases. C_3S appears in the form of well-defined crystalline grains varying in size from 10μ to 40μ. C_2S occurs as rounded crystals or twinned polyhedra, with a smooth or striated surface.

Between these grains there lies an interstitial phase in which it is sometimes possible to identify well-formed crystals of C_3A but often the interstitial phase is so finely crystallized that the individual grains are not visible.

The object of this paper is to describe the crystal structure of each of the phases listed above and how the structure varies with temperature and with additions to the pure stoichiometric composition.

*Centre d'Etudes et de Recherches de l'Industrie des Liants Hydrauliques, Paris, France

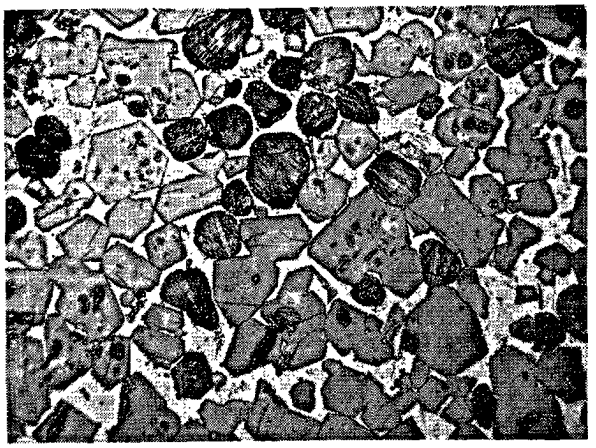

Fig. 1. *Photomicrograph of portland cement clinker: the alite crystals are pseudo-hexagonal, the belite grains rounded and striated. The interstitial phase lies between the C_3S and C_2S crystals. Terrier and Hormain (105).*

The whole system presents a difficult field of study because, with certain exceptions, one cannot obtain the clinker phases in the form of single crystals of sufficient size to permit a structure determination by classical methods. In general, one is reduced to characterising a phase solely by its lattice, deduced from powder diagrams. But even this technique is difficult to use in this field because of the low symmetry or large unit cell of certain phases and above all because the variations which one is trying to detect as a function of temperature or of additions are very small. Furthermore, it has only recently become possible to obtain high quality powder patterns at temperatures up to 1500°C. In his paper of 1960, F. Ordway (1) insisted upon the necessity for developing special high temperature techniques adapted to the study of clinker minerals.

The results obtained by X-ray diffraction must obviously be checked with those given by other techniques such as microscopy, infra-red absorption, spectroscopy, electron-probe microanalysis, etc., and especially differential thermal analysis.

Numerous papers have appeared on problems in this field. Not all of these are based upon the use of the most sophisticated techniques and contradictions exist between the results reported. However, on the whole, certain facts emerge which clarify the problem. A general review must naturally emphasize the points on which there is agreement but one must also mention other observations even where they are contradictory.

In order to resolve these two incompatible demands, we have chosen not to follow the chronological order in reporting successive papers. In each chapter of this article, dealing respectively with tricalcium silicate, dicalcium silicate and the interstitial phase (calcium aluminoferrite and tricalcium aluminate), we begin by giving what we ourselves regard as the most complete and satisfactory solution to the structural problem. Next, we group the studies which make a partial contribution to the preceding results, or contradict them. We try then, in the latter case, to discuss the possible origin of these differences with what we consider to be the most probable soultions.

In the conclusion, we discuss the general character of the polymorphism of the calcium silicates and hence the relations between the crystal structures and clinker properties.

Tricalcium Silicate

It is the tricalcium silicate phase which has the most numerous allotropic forms. We have shown that there are six between ambient temperature and 1100°C. One can find all the same forms in the solid solutions but all have lattices extremely close to trigonal, the simplest form.

The X-ray powder diffraction patterns are indistinguishable except for slight movements of certain lines or their separation into very close multiplets; but the relative intensities do not vary. This shows that the structure of the least symmetrical forms remains, to a very good approximation, that of the most symmetrical.

Jeffery's Structure (2)

The structure of C_3S has been determined by Jeffery on a single crystal of sufficient size, which was isolated from a blast-furnace slag. In this work, which dates from 1950, Jeffery, on the basis of the visually estimated intensities of the diffracted spots (without Lorentz-polarization correction), determined a trial structure which is a good approximation to the true structure. O' Daniel, Hahn and Müller (3, 4) have confirmed these results by a Patterson synthesis. No other structure has been proposed.

The pseudo-structure, proposed by Jeffery, is trigonal, with $a = 7$, $c = 25$ Å (hexagonal notation), space group R3m. It is composed of independent tetrahedra; three SiO_4 tetrahedra and three oxygen ions lie on the trigonal axes (5). The calcium ions link the tetrahedra and are octahedrally co-ordinated to the three oxygen ions which are not linked to Si^{4+} (see Fig. 2). Identical columns are found on each

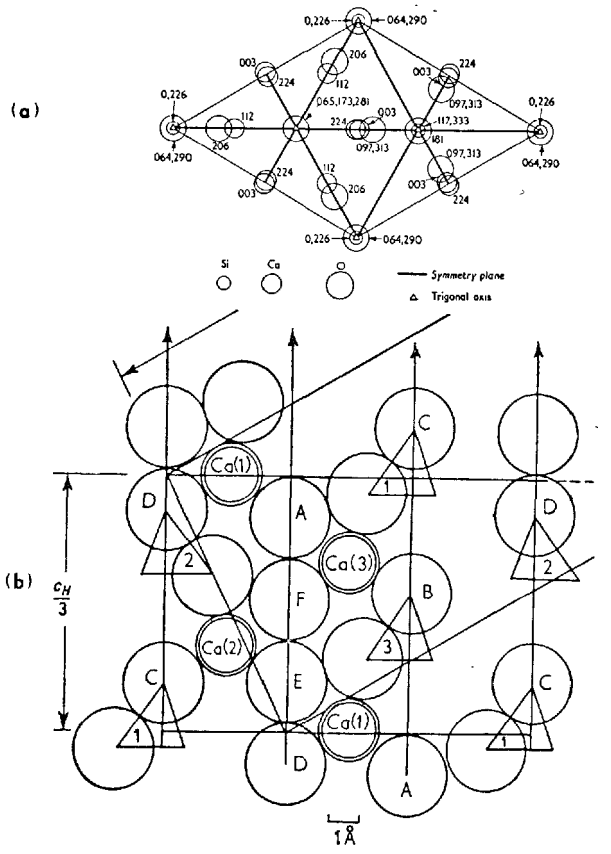

Fig. 2. *Tricalcium silicate: Jeffery's structure.*
a) basal plane
b) vertical section through the long diagonal of the hexagonal cell. The relationship of the monoclinic axes to the hexagonal cell is shown. (Taylor: Chemistry of Cements, pp. 149–150).

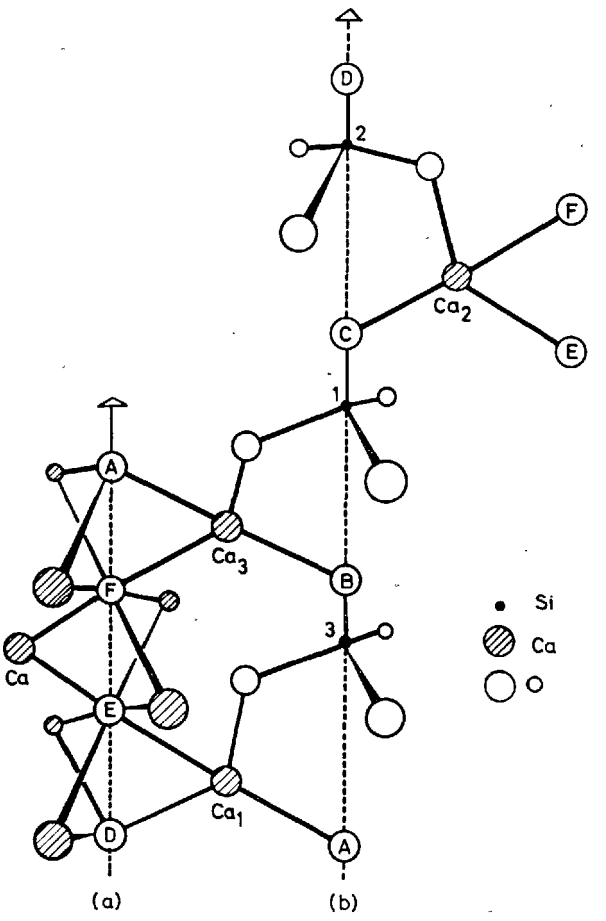

Fig. 3. *Tricalcium silicate Jeffery's structure.*
Two adjacent columns of tetrahedra and single 0 atoms, surrounded by Ca atoms. A complete column is obtained if (b) is placed on top of (a) and the labelling of the various atoms corresponds to that of Figure 2b). (Taylor: Chemistry of Cements, p. 148).

trigonal axis, but at different heights (see Fig. 3). These form irregular octahedra of atoms around the calcium ions and leave holes large enough to accommodate other atoms.

It is the irregular co-ordination of the Ca ions (the bonds vary from 2.54 to 3.24 Å) and the holes adjacent to these ions that give C_3S its hydraulicity.

Nevertheless, Jeffery's structure is certainly only approximate. The lattice of the lower temperature forms is not the simple trigonal. We have tried to grow crystals from molten $CaCl_2$ (6). From a number of crystals between 4 and 10μ, we chose a 7μ pseudo-hexagonal crystal. An oscillation photograph shows superlattice lines corresponding to a = 14 Å (7). Construction of the reciprocal lattice from a Weissenberg photograph gives approximate values for b and c of 14 and 25 Å. The parameters may be obtained more accurately by indexing powder photographs on a pseudo-hexagonal lattice.

Study of Polymorphic Transformations of C_3S by DTA

The results of differential thermal analysis are the most straightforward and a definitive list of the transition points can be established (see Table 1). Four reversible DTA peaks at 600°, 920°, 980° and 990°C characterize C_3S (see Fig. 4). Due to the powerful resolution of micro DTA (8), the peaks at 980°C and 990°C are well resolved. The thermal effects of these transitions are very weak, smaller than the $\alpha - \beta$ transformation of quartz (1.4 cal/g) (9). The transformation point at 990°C was discovered both by Boikova and Toropov (10) in pure C_3S, and by Woermann, Hahn and Eysel (11) in both C_3S and in the solid solutions.

Boikova and Toropov (10) cross-checked the

Table 1. *Characteristic properties of D.T.A. peaks of pure C_3S*

Temperature of transformation (beginning of the signal during heating, °C)	Shape of the peaks—hysteresis	Estimated thermal effect related to the transformation (cal/g)	
		D.T.A.*	direct ** calorimetry
585 ± 5	Broad peak up to 30° width depending on heating rate and strong hysteresis (20–40°C) upon cooling		0.6
917 ± 3	Sharp, strong peak, weak hysteresis (10°C)	1	1.3
975 ± 3	Sharp, strong peak without appreciable hysteresis	0.5	0.6
990 ± 2	Sharp, very small peak without appreciable hysteresis	0.05	

* From area of the peaks and comparison with the area of the peak obtained in high-low quartz transition. For this last thermal effect 1.4 cal/g was admitted as given by R. ROY(9).
**In this set of experiments(13) the thermal effect of the quartz transition was found to be 2 cal/g.

DTA results by a study of a small crystal on a high-temperature microscope. The transformations at 620°, 920° and 980°C could be observed and were found to be reversible, but the authors do not indicate whether the crystal transforms without change of habit.

Study of the Polymorphic Transformations of C_3S by X-ray Diffraction (XRD)

At high temperature, the lattice is trigonal. On cooling, the lowering of the symmetry causes splitting of the hexagonal reflexions into groups of lines whose number and spacing permit the determination of the true lattice (7).

At 1100°C the lattice is trigonal, with hexagonal parameters a = 7.15, c = 25.56 Å. The 30 lines of the powder pattern (up to 1.48 Å) show the extinctions corresponding to space-group R3m: $-h + k + l = 3n$.

Our results are in good agreement with Jeffery's predictions, deduced from the trial structure.

With decreasing temperature, the transformations are clearly visible on three hexagonal spacings $\bar{2}01$, $\bar{2}04$ and 220, which become successively doublets and triplets (see Fig. 5).

In the range of temperatures used, the 009 reflexion does not show any splitting at all and its relative intensity remains constant relative to the other reflexions. The stacking of planes perpendicular to c, about 8.4 Å apart, therefore remains the same. A sliding of these planes in the direction perpendicular to the c axis takes place.

The principal characteristics of the transformations are:

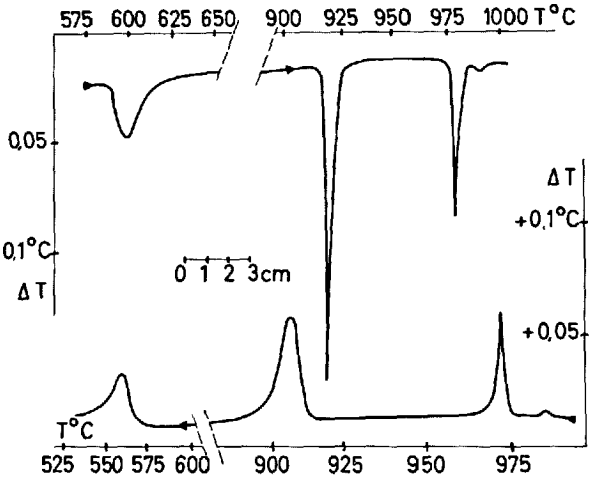

Fig. 4. *Tricalcium silicate. DTA diagram, heating rate 13°C/min. Mazières (8).*

1) *1050°C: change of symmetry from rhombohedral→ monoclinic* ($R \rightarrow M_{II}$). The transformation is continuous and only the hexagonal basal plane is deformed (see Fig. 6).

The pseudo-hexagonal cell deduced from the reduced cell chosen according to Donnay (14) is defined by the parameters a = b = 7.130 Å, c = 25.43 Å, $\alpha = \beta = 90°$, $\gamma = 119.88°$. This can be considered as an orthorhombic cell with parameters a = 12.342, b = 7.143, c = 25.434 Å (7).

Nevertheless, the structure cannot be anything but monoclinic: the small but continuous deformation of the trigonal lattice does not permit of the formation of an orthorhombic structure; there is no orthorhombic sub-group of the trigonal space group. The transformation is probably of the second order, the structure can only be monoclinic (M_{II}) (11).

2) *990°C: discontinuous transformation of the unit cell without change of symmetry:* $M_{II} \rightarrow M_I$. The components of the doublets $\bar{2}01$, $\bar{2}04$ and 220 are clearly separated (see Fig. 5).

As well as the deformation of the hexagonal basal plane, there is now added an inclination of the c axis to this plane ($\beta = 89.88°$) (see Fig. 6).

The stability region of the M_I phase is only 10°. We suspected the presence of this form from the small signal given by μDTA at 990°C. We therefore took a series of photographs between 970°C and 990°C and found a diagram characteristic of M_I. The components of the doublets are, indeed, less well defined than in the other forms but this variety has been confirmed in solid solutions of $C_3S + Al_2O_3$ by both Bigaré (12) and Woermann, Hahn and Eysel (15). These authors have all observed an increase in the zone of stability of M_I to 60° for the solid solution $C_3S + 1\%\ Al_2O_3$.

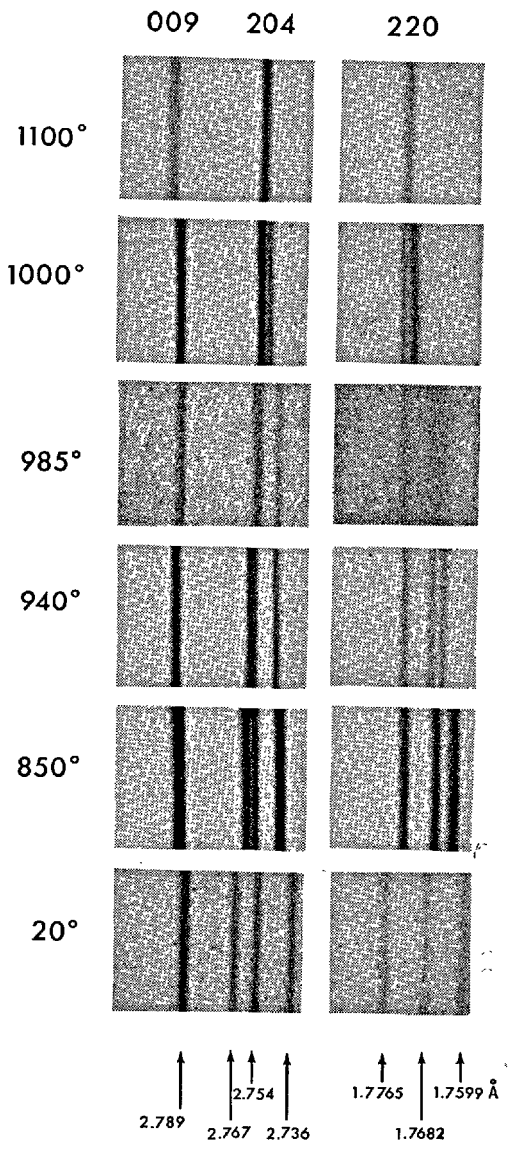

Fig. 5. *Tricaliium silicate. Evolution of the hexagonal reflexions 009, 204, 220 from 1100°C to ambient temperature. The powder patterns are obtained with a high temperature Guinier camera. At 1000°C the components of the 220 doublet are separated by* 3×10^{-3} *Å, 220 → 1.786, 1.783 Å, and 204 → 2.780, 2.776 Å Regourd (32).*

3) *980°C: change of symmetry* $M_I \rightarrow T_{III}$. The characteristic doublets become triplets and the lattice is now triclinic; in the hexagonal basal plane the three axis a, b and d are different. A diagram taken at 940°C shows about 100 lines which can not be indexed without doubling the pseudo-hexagonal parameters a and b to 14 Å. The superlattice in the basal plane only involves a change of orientation of the rhombohedron in which obverse becomes inverse. If one retains the orientation of the original unit cell, the extinction rule

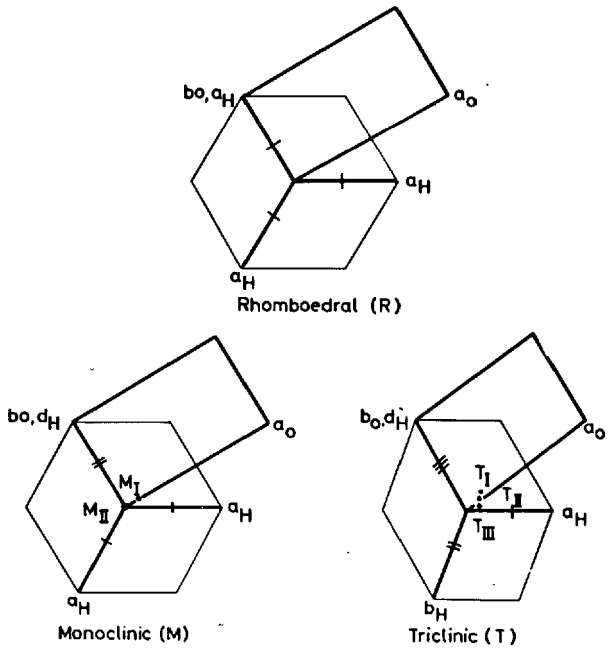

Fig. 6. *Tricalcium silicate: deformation of basal plane of the hexagonal cell. H = (pseudo-) hexagonal, O = (pseudo-) orthohexagonal. Dots indicate the projections of vectors [001] on the (001) plane. Regourd (11, 32).*

is not the same: it becomes $+ h - k + 1 = 3n$ (11). At 940C°, the pseudo-hexagonal cell has the parameters a = 14.229, b = 14.249, c = 25.412 Å, $\alpha = 90.10°$, $\beta = 89.85°$, $\gamma = 119.76°$.

4) *920°C.* Although DTA gives a strong signal, we observe *no change of symmetry , nor any change in volume of the unit cell.* The components of the triplets, arising from the hexagonal reflexions $\bar{2}01$, $\bar{2}04$ and 220 separate progressively from 980° until 620°.

5) *600°C. No change of symmetry* is observed but a slight discontinuity in the splitting of the characteristic triplets.

6) *20°C.* On a photograph exposed for 40 hours (6 mA, 30 KV, Cu Kα), we detected two very weak reflexions ($I/I_o < 1/100$) with long spacings 14 and 8.2 Å. These are hk0 reflexions and would imply the doubling of parameters a and b. The new unit cell would be defined thus:

a = 28.160	b = 28.294	c = 25.103 Å
$\alpha = 90.30°$	$\beta = 89.77°$	$\gamma = 119.53°$

The variations in the pseudo-hexagonal parameters from ambient temperature to 1100°C are shown in Table 2.

Nature of C_3S Transformations

The characteristic properties of the transformations

Table 2. *Lattice constants of the modifications of pure* C_3S (*Average errors: a, b, c;* $\pm 2 \times 10^{-3}$ Å; *α, β, γ:* $\pm 3 \times 10^{-2}$ *degree*) Pseudo-hexagonal lattice constants

Temperature °C	Allotropic form	$a_{(Å)}$	$b_{(Å)}$	$c_{(Å)}$	$\alpha_{(°)}$	$\beta_{(°)}$	$\gamma_{(°)}$
1100	Rhombohedral R	7.150	7.150	25.560	90	90	120
1000	Monoclinic M_{II}	7.130	7.130	25.434	90	90	119.88

20	Triclinic T_I	14.080	14.147	25.103	90.30	89.77	119.53

Table 3. *Characteristic properties of the transitions in pure* Ca_3SiO_5

Transition temperatures (°C)	Characteristic effects		Type of* transition	Allotropic form	Space group
	X-Ray	D.T.A.			
1050	Change of symmetry, continuous deformation of the cell	No peak	Type a continuous	Rhombohedral (R) Monoclinic II (M_{II})	R3m C1m1
990	No change of symmetry, change of cell volume	Very small reversible peak	Type a discontinuous	Monoclinic I (M_I)	C1m1
980	Change of symmetry, change of cell volume; superstructure: doubling of *a* and *b* to 14Å	Strong reversible peak	Type a + b discontinuous	Triclinic III (T_{III})	C1
920	No change of symmetry, no change of subcell volume; (possibly second superstructure)	Strong reversible peak	Type b discontinuous	Triclinic II (T_{II})	C1
600	No change of symmetry, small deformation of the cell; possibly second superstructure	Broad reversible peak	Type a discontinuous	Triclinic I (T_I)	C1

*Type a: with decreasing temperature the degrees of freedom of the thermal vibrations are reduced thus leading to discontinuous or continuous changes in cell volume. The structural groups are slightly deformed but their periodicity is unaffected.

Type b: upon cooling, in the arrangement of the groups, regular stacking faults perpendicular to the c axis are produced, leading to the formation of superstructures but not affecting appreciably the volume of the subcell.

of C_3S are collected in Table 3 (11).

DTA and X-ray have established 5 reversible transformations between six allotropic forms. Three of these transitions (990°, 980° and 600°C) have been observed by both DTA and X-ray methods.

The transformation $R - M_{II}$, found by X-ray, gives no DTA signal. The transition, which is continuous and weak, extends over 60°C, beginning at about 1050°C. Possibly it is a second order transition.

The transition $T_{III} - T_{II}$, at 920°C, undetectable by X-rays, is characterised by a strong DTA signal. The unit cell is triclinic up to 980°C and the Debye-Scherrer pattern maintains the same relative intensities. The strong thermal effect is perhaps due to a second superstructure which, while leaving the fundamental spacings unchanged, modifies the long spacings which are too weak to be detected under normal conditions. The superstructure found for T_I could exist equally in T_{II} (we have not verified this hypothesis because of the very long exposures which would be required at high temperature). A re-arrangement of the hexagonal groups in the lattice could vary the energy of the structure appreciably and this would explain the thermal effect.

To conclude, C_3S undergoes numerous small amplitude transformations around a constant atomic arrangement. All the transformations are of the "displacive" type (16). They are produced by small movements of the atoms from their positions in the original structure, without any alteration of the general arrangement of the chemical bonds.

We have shown evidence of two types of transition: change of symmetry and superstructure:

—the hexagonal structure, advanced by Jeffery (2), is constructed of independent SiO_4 tetrahedra. At high temperature, the atoms of the SiO_4 tetrahedra are vibrating freely; the hexagonal unit cell shows a corresponding symmetry. As the temperature decreases, the degrees of freedom diminish and the departures from symmetry appear. They reveal themselves by changes in the X-ray powder diagram, that is to say, by the splitting of characteristic reflexions;

—the structure of C_3S is a stacking of hexagonal groups. With decreasing temperature the stacking faults give rise to a superstructure which is revealed by weak reflexions at low angles.

Certain of our results (the superstructure in T_{II}), not being directly proved, may be open to discussion. The powder patterns which we have studied permit determination of lattice dimensions and symmetry but give no other information on the structure. We are unable to distinguish a pseudo-orthorhombic form from a true orthorhombic structure. The superstructure in T_I is only indicated by the presence of two very

weak Debye-Scherrer lines at long spacings. However, in an oscillating crystal photograph of alite (with the hexagonal axis parallel to the axis of rotation) Jeffery (2) has shown evidence for the existence of superlattice lines corresponding to a = 40 Å. Thus, in the T_I form of pure C_3S, it seems more likely that a = 42 Å than 28 Å.

The study of the polymorphism of C_3S demands experimental techniques with great powers of resolution. Only the combination of X-ray and DTA has given complete results. To elucidate the structural relations of the different polymorphs completely, it will be necessary to prepare single crystals of sufficient size.

Tricalcium silicate, being of type A_3BX_5, is isomorphous with tricalcium germanate, Ca_3GeO_5 (17, 18) and sodium fluoberyllate, Na_3BeF_5 (19).

Other Studies on Tricalcium Silicate

All the transitions which have been described in the preceding paragraphs have not been detected by the first workers in the field either because they did not use DTA or because they had no X-ray equipment of sufficient resolution. On the other hand, transitions which proved to be due to an impurity (such as a small amount of C_2S) have been attributed to C_3S.

Thus Nurse and Welch (20) found 6 transformation points, at 464°, 622°, 750°, 923°, 980°, 1465°C. An interpretation of this thermogram was proposed by Jeffery (21). The first transformation corresponds to the dehydration of free lime. The peaks at 622°, 750°, 1465°C are characteristic of the $\beta - \alpha'$, $\gamma - \alpha'$, and $\alpha' - \alpha$ transformations of C_2S. The only peaks, due to C_3S are those at 923°C and 980°C, characteristic of three forms following this scheme:

$$\text{Triclinic} \xrightarrow{923} \text{Monoclinic} \xrightarrow{980} \text{Trigonal}$$

Yamaguchi and Miyabe (22) repeated, in 1960, Jeffery's work, and defined the same polymorphic transformations. A triclinic, pseudo-orthorhombic unit cell, calculated by these authors, has the parameters

$a = 12.195$	$b = 7.104$	$c = 25.069$ Å
$\alpha = 90°$	$\beta = 89°44'$	$\gamma = 89°44'$

The transformation at 990°C was not detected in a recent study by Miyabe and Roy (23). These authors, on the other hand, attribute to C_3S a broad signal at 675°C, which is characteristic of the $\beta \rightarrow \alpha'$ transformation of C_2S. Boikova and Toropov (10) have shown evidence for the existence of this thermal effect when the tricalcium silicate synthesis is incomplete. We ourselves have verified that, in DTA, traces of βC_2S give a thermal effect at 675°C.

The polymorphism of C_3S has been studied, in 1964, with the help of powder patterns, by Miyabe and Roy (23), who used a high temperature diffractometer, as we ourselves were using a high temperature Guinier camera (24) (see Fig. 7).

Fig. 7 shows the diffractometer traces of Miyabe and Roy at 600°C and 650°C, together with one of our double-exposure Guinier photographs taken at 600°C and 625°C (1962) (24). Miyabe and Roy found a mixture of phases T_α and T_β; we observed only, in accordance with the phase rule, T_I at 600°C and T_{II} at 625°C.

The resolution of the focussing camera (25) is better because we are operating with rigorously monochromatised (Cu $K\alpha_1$) radiation and we eliminate variations of intensity and apparent displacements of certain lines due to crystal growth at transformation points. The sample temperature is more difficult to measure than in the diffractometer but it is sufficiently uniform and well-controlled to give lines at high temperature which are as sharp as those produced at ambient. We have established a temperature scale using known transition points. This calibration curve between the heating current and the temperature of the sample-holder is re-adjusted with the help of the temperatures of the DTA peaks of C_3S. We can thus obtain a set of high-resolution photographs at selected temperatures which show the progress of the transformations.

Our results are in disagreement with those of Miyabe and Roy. The differences are as follows:

1) Miyabe and Roy found only the rhombohedral form (R) above 970°C; we detected three modifications (R, M_{II}, M_I) above 980°C (Fig. 8).

2) According to Miyabe and Roy, the stable form between 980°C and 920°C is monoclinic. We have shown evidence, in the splitting of the 620 reflexion (620, $\bar{6}20$), for the presence of a triclinic form, T_{III}. The separation of the lines is 0.003 Å, which was not resolved by previous workers.

3) Miyabe and Roy obtained a considerable contraction of the unit cell of T_β between 600°C and 700°C (Fig. 9) suggesting a new transition, $T_\beta \rightarrow T\gamma$, at about 700°C. We consider that some of the lines for T_β, T_γ and M are incorrectly indexed. If the spacings in Miyabe and Roy's diagrams are correctly indexed and the parameters recalculated, the contraction disappears (see Fig. 10). The curve showing variation of pseudo-orthohexagonal parameters is then similar to ours (Fig. 11).

Solid Solutions of Tricalcium Silicate

The transformations of C_3S occur rapidly at well-defined temperatures, and without noticeable hysteresis. One cannot stabilize, by quenching, any of the high temperature forms.

On the other hand, if one introduces small amounts of foreign ions into the C_3S lattice, one obtains, at ambient temperature, phases which have the same lattice as one of the phases of pure C_3S. There is thus, by additions, stabilization at ambient temperature of forms which in the pure compound only exist in narrow ranges of temperature. One might say that the disorder introduced by foreign ions is playing a role analogous to the disorder of thermal vibration.

Table 4 (11) indicates the nature of the phases observed by different additions, as a function of their concentration. The different solid solutions have been prepared by synthesis from pure materials. In clinker, the solid solutions must be more complex. Table 4 shows how one addition will not, in general, stabilize all the forms. The highest symmetry phase is stabilized by ZnO but not by any other single oxide. Nevertheless, it is observed in certain clinkers which contain insufficient ZnO but a very large number of other impurities (Al_2O_3, Fe_2O_3, MgO, Cr_2O_3, TiO_2, Na_2O, K_2O etc.). These complex mixtures have not been reproduced by synthesis. The studies of the solid solutions as a function of temperature have been made only on the simplest synthetic products and we will begin with the addition of ZnO which stabilizes the most complete range of phases.

Solid solutions of C_3S + ZnO. Zinc oxide stabilizes, at ambient temperature, the forms T_I, T_{II}, M_I, M_{II}, R of C_3S (11); Zn^{2+} replaces Ca^{2+} in the C_3S lattice. The variations in the parameters as a function of percentage of ZnO show clearly the different varities stabilized (Fig. 12). The DTA results confirm the stability ranges. The transformation temperatures are decreased by the addition of ZnO. At 0.75% ZnO

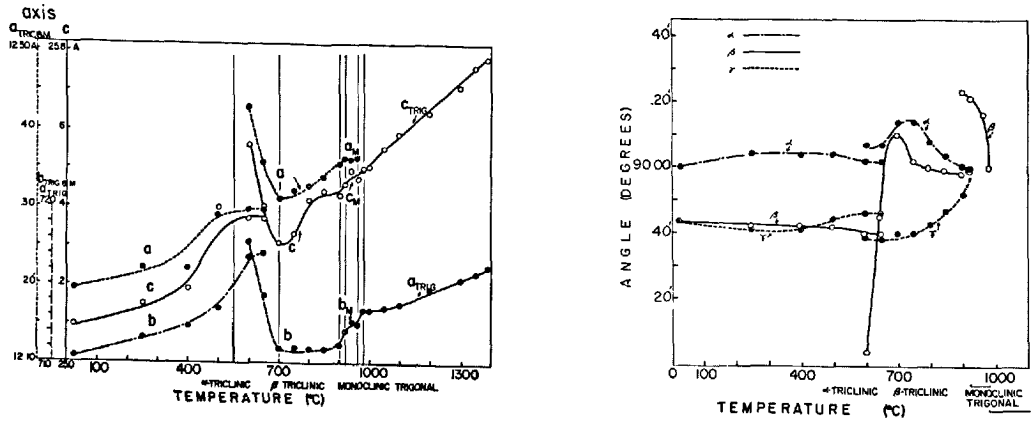

Fig. 9. *Tricalcium silicate: variation of pseudo-orthohexagonal lattice constants with temperature, Miyabe and Roy.*

the thermal effects at 920°C and 980°C marge into one with addition of their intensities. The stability zone of T_{III} disapears. Above 0.75% ZnO, M_I transforms directly to T_{II}. The fusion of the two DTA peaks implies a change of symmetry from monoclinic to triclinic, with the formation of two superstructures, simultaneously.

The temperature of the small signal at 990°C does not vary and the thermal effect persists above 2.25% ZnO, into the region where, according to X-rays, M_{II} and R appear to be stabilized. This is a new example of a phase-change detected by DTA but imperceptible by XRD. Above 2.25% ZnO, the solid solutions C_3S + ZnO would again be monoclinic but of a form approaching so closely to rhombohedral that XRD cannot resolve the symmetry.

There is one difference between the monoclinic

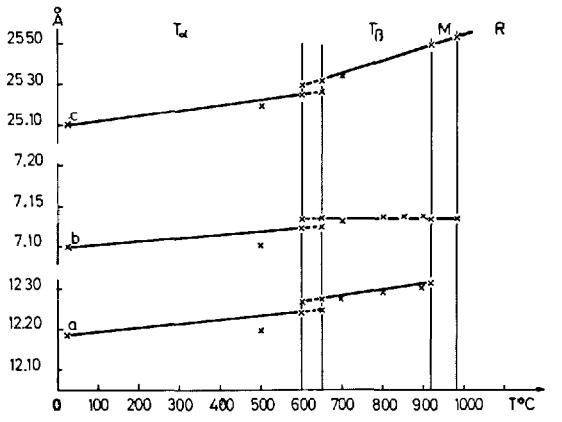

Fig. 10. *Tricalcium silicate. Variation of pseudo-orthohexagonal lattice constants with temperature, recalculated (11) from data of Miyabe and Roy.*

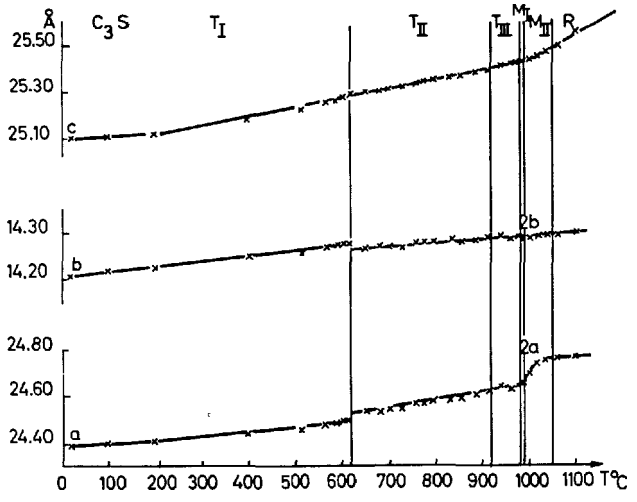

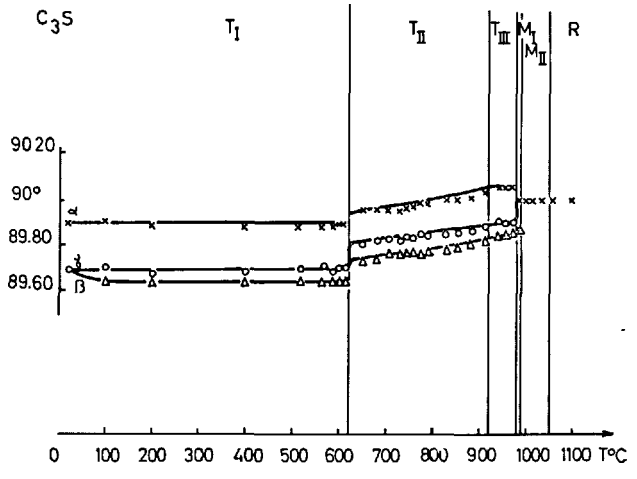

Fig. 11. *Tricalcium silicate. Variation of pseudo-orthohexagonal lattice constants with temperature. Regourd (11, 32).*

forms M_I and M_{II} of pure C_3S and the solid solutions $C_3S + ZnO$. The characteristic reflexions 224, $\bar{4}04$ and 620, 040 are reversed (Fig. 13).

This inversion has already been observed by Yamaguchi and Miyabe (22) and interpreted in a study of the solid solutions $3CaO\text{-}SiO_2\text{-}Al_2O_3\text{-}MgO$ by Yamaguchi and Kato (26). It corresponds to a different a/b ratio of the pseudo-orthohexagonal parameters and a different β angle. In the case of pure C_3S at 985°C: $a/b < \sqrt{3}$, $\beta \leq 90°$, in the solid solution $C_3S + 2\%$ ZnO: $a/b > \sqrt{3}$, $\beta > 90°$. The monoclinic forms of the solid solutions reverse at high temperature to the monoclinic forms of pure C_3S. The intermediate form with $a/b = \sqrt{3}$ and $\beta = 90°$ has an orthohexagonal unit cell even though the symmetry is not rhombohedral.

Ono, Uno and Kanai (27) have also stabilized the trigonal form of C_3S by the addition of 6.3% ZnO. Furthermore, a solid solution $C_3S + 15\%\ C_3A + 5\%\ CaF_2$, prepared by the same authors, is reported as rhombohedral with hexagonal parameters $a = 7.088$, $c = 25.115$ Å, but the optic axial angle 2V is not 0 as in the case of $C_3S + 6.3\%\ Zn_3SiO_5$; it is less than 15°(−). Presumably, this solid solution is not truly hexagonal.

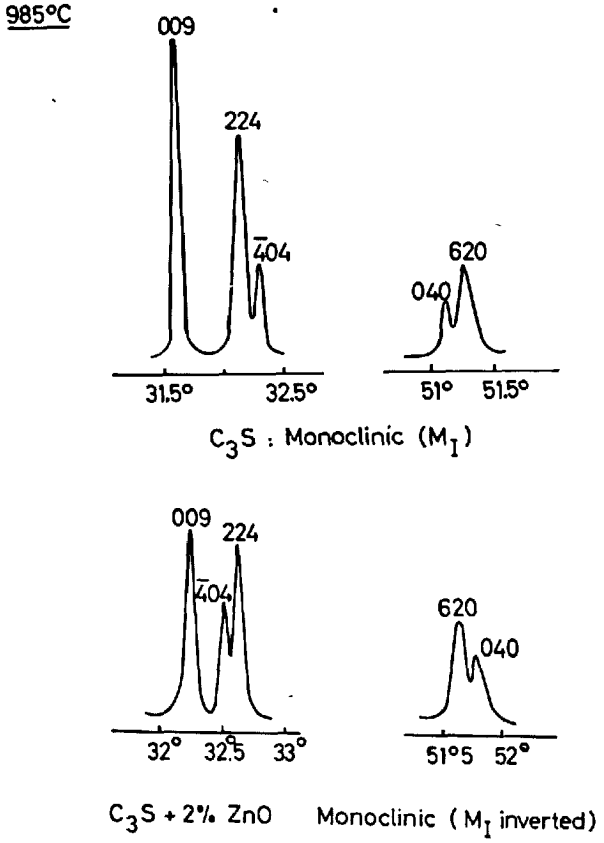

Fig. 13. *Comparison of densitometer records showing characteristic reflexions of monoclinic forms of pure C_3S at 985°C and $C_3S + 2\%\ ZnO$ at ambient temperature. In the solid solution ($C_3S + 2\%\ ZnO$) the 224, $\bar{4}04$ and 620, 040 reflexions are inverted.*

Solid solutions $C_3S + MgO$. Woermann, Hahn and Eysel (15) have proposed, for the solid solutions $C_3S + MgO$, the following formula: $(Ca_{1-x}Mg_x)_3SiO_5$, where $0 \leq x \leq 0.0125$ at 1550°C. The Mg^{2+} ions replace an equal number of Ca^{2+} ions in the C_3S lattice (28). The solubility limit is 2% MgO but this depends on the temperature (15, 26, 29). In addition, CaO dissolves small quantities of MgO (30). Thus crystals of the solid solutions Ca_3SiO_5 — "Mg_3SiO_5" and (Ca, Mg)O (31) can co-exist. The forms of C_3S which are stabilized are T_I (up to 0.55% MgO), T_{II} (0.55 to 1.45% MgO) and M_I (from 1.45 to 2.0% MgO). Above 2%, periclase appears, identified both optically and by the lines in the X-ray powder diagram. In the monoclinic form, the characteristic lines are again inverted: in the solid solution $C_3S + 2\%$ MgO, $a/b = 1.737$ and $\beta = 90.12°$ (32).

Solid solutions $C_3S + Al_2O_3$. The alumina incorporated in the lattice of C_3S can be either in the form of Al_2O_3 or C_3A. The solid solutions are characterized by a field in the system $CaO\text{-}Al_2O_3\text{-}SiO_2$. This implies that the solid solution is formed by CaO and Al_2O_3 (31). Woermann, Hahn and Eysel (15) have distinguished two types of solid solution:

a) *between 0 and 0.45% Al_2O_3*

Al^{3+} replaces Si^{4+} in the tetrahedra but occupies the free octahedral sites also, thus maintaining the electrostatic neutrality of the lattice. The formation of the solid solution, by both addition and substitution, is expressed by the formula:

$$Ca_3^{IV}Al_{x/4}^{VI'}(Si_{1-3x/4}Al_{3x/4})^{IV}O_5$$

where $0 \leq x \leq 0.02$, IV′ being a vacant octahedral site. The only form of C_3S stabilized is T_I (12, 15).

b) *between 0.45 and 1% Al_2O_3*

above 0.4% Al_2O_3, the incorporation of Al_2O_3 may be: —either the result of two linked substitutions: Si-Al (tetrahedral sites), Ca-Al (octahedral sites), following the formula:

$$(Ca_{3-x/2}Al_{x/2})^{VI}(Si_{1-x/2}Al_{x/2})^{IV}O_5$$

—or the continuous balanced replacement of Si by Al for the most part in the octahedral sites occupied by Ca(VI) and to a very small extent in the vacant octahedral sites (VI′).

These interpretations appear more probable than that of Locher (28) in which the loss of the oxygens which are not bonded to the tetrahedra permits the neutralization of the charge after substitution of Al for Si.

The form which is stabilized is T_{II} (10, 15, 29).

DTA shows the decrease in transformation temperatures of the forms stabilized by Al_2O_3, up to 1%, the limit of solubility. Above the solubility limit the lines of C_3A appear in X-ray powder patterns (12). The solubility limit is independent of temperature. Midgley and Fletcher (29) found the same results, but maintain that the substitution of Al in the lattice is not due to insertion of C_3A in C_3S but to a solid solution of the series C_3S — "$C_{4.5}A$".

The presence of Al does not change the type of substitution of Mg, but, on the other hand, Mg does affect the substitution scheme of Al (31).

Solid solutions $C_3S + Fe_2O_3$. The limit of solubility of Fe_2O_3 in C_3S is 1.1% (15). Only the triclinic forms T_I (from 0 to 0.8% Fe_2O_3) and T_{II} (from 0.8 to 1.1% Fe_2O_3) are stabilized. According to Fletcher (33), the solid solutions are of the type C_3S — "C_3F": $3Ca^{2+}$ are replaced by $3Fe^{3+}$, $6Si^{4+}$ by $6Fe^{3+}$, and the charge is compensated by one Fe^{3+} ion in an interstitial position.

Other solid solutions of C_3S. Tricalcium silicate also forms solid solutions with the following additions: $La_2O \cdot SiO_2$ (34), $Y_2O_3 \cdot SiO_2$ (35), SO_3 (36), Co_2O_3 (37) and Na_2O(38).

Na_2O substitutes for CaO in the C_3S lattice. Above 0.3% Na_2O, the structure is monoclinic with parameters $a = 12.262$, $b = 7.053$, $c = 25.086$ Å, $\beta = 90°07'$ (39).

CaF_2 (40) enters into solid solution in C_3S. At 0.74% CaF_2, the X-ray powder diagram is similar to that of alite in clinker. Above 0.74% there is a decomposition of C_3S into α' C_2S.

It seems equally probable that C_3S can take up to 1% P_2O_5 into solid solution (40), involving more a distortion of the lattice than true polymorphism.

Constitution and Structure of Alites in Clinker

In alites, one can find triclinic, monoclinic and trigonal forms (41, 42). In Fig. 14, we show the patterns of two clinkers in which the alite is in the forms M_{II} (inverse) and R.

The alite grains in portland cement clinker appear to have trigonal symmetry and to be practically uniaxial. However, each grain is an assembly of numerous crystallites of lower symmetry, twinned at 120°. As Jeffery (2) has suggested, these crystals are thus paramorphs of the high temperature form.

A recent study by Yamaguchi and Ono (43) shows evidence for two types of alite crystal: regular hexagons corresponding to the 0001 face and hexagonal sections elongated in the characteristic planes $1\bar{1}02$ and $10\bar{1}1$ (Fig. 15).

The transition form rhombohedral → monoclinic is a small energy change: the monoclinic a axis coincides effectively with the rhombohedral c axis and the monoclinic b axis with one of the rhombohedral

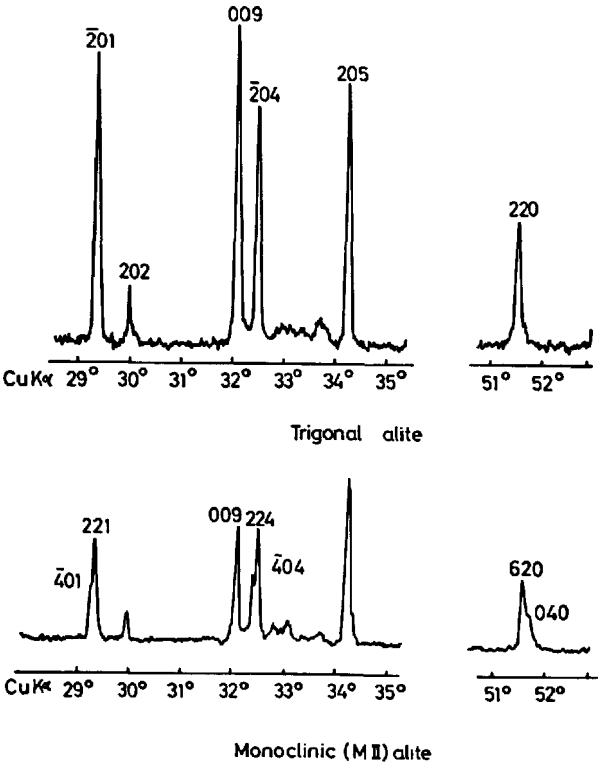

Fig. 14. *Densitometer records of powder patterns (Guinier camera) of two clinkers, in which the alite is respectively trigonal and inverse monoclinic.*

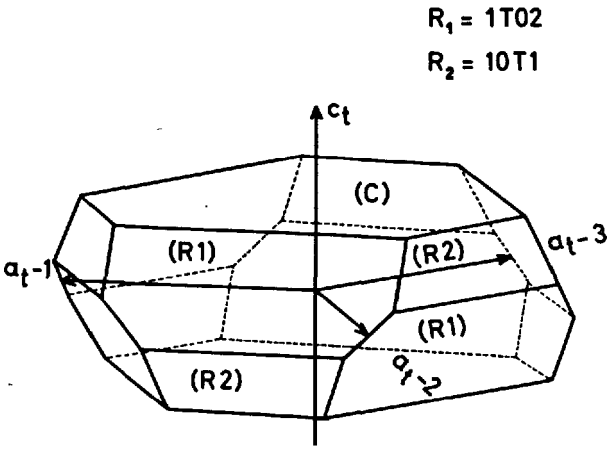

Fig. 15. *Relation between the trigonal axes $a_t - 1$, $a_t - 2$, $a_t - 3$, c_t and the crystal habit of a clinker alite. Yamaguchi and Ono (43).*

a_1, a_2, a_3 such that the twinning of the transformation is triple.

Jeffery (2) has considered alite as a definite composition with additional atoms in fixed lattice sites. In alite of formula $54CaO \cdot MgO \cdot Al_2O_3 \cdot 16SiO_2$ there is replacement of Ca by Mg, of 2Si by 2Al, and the addition of one Mg ion in a vacant hole, to maintain neutrality of the lattice.

The structure of this alite is monoclinic, with parameters a = 33.08, b = 7.07, c = 18.56 Å, $\beta = 94°10'$, space group Cm. One of the 3 true mirror planes of the trigonal structure is preseved in monoclinic structure, two become pseudo mirror planes (Fig. 2). The oscillation and Weissenberg photographs show a large number of satellite spots, which could be interpreted to give a "c" spacing of 150 Å.

The existence of different types of C_3S solid solutions shows that alite is a true solid solution. The introduction of foreign ions and balancing of charges are continuous and statistical. Alite is not a compound with a definite composition like the stoichiometric formula given by Jeffery. As early as 1958, Von Euw (44) showed that this composition contains C_3A as an impurity.

From powder diagrams, Yamaguchi and Miyabe (22) calculated the monoclinic unit cell of Jeffery's alite and found the parameters a = 12.246, b = 7.045, c = 24.975 Å, $\beta = 90°04'$. Ordway (1) re-calculated the unit cell to a = 12.248, b = 7.045, c = 24.972 Å, $\beta = 90°06'$, an elementary cell which allows the indexing of all the lines visible in the powder diagram. Only Jeffery studied a single crystal of alite and was able to find the true larger unit cell.

Toropov and Volkonskii (45) (1960) and Chromy (46) (1964) observed only two forms of C_3S in clinker: β and α, the α form being trigonal and the transformation $\beta \rightarrow \alpha$ taking place at 1375°C.

Stability of Tricalcium Silicate and Alites

Several methods of preparation of tricalcium silicate have been reported (47, 48, 49, 50, 51). Mineralizers such as NaF, Na_2SiF_6 (47), LiCl (52), CaF_2, CO_2 (53) accelerate the formation of C_3S. Complete synthesis of tricalcium silicate is difficult. Boikova and Toropov (10) detected, by DTA and by microscopy, C_2S in contact with C_3S. If this C_2S is saturated with CaO, the CaO/SiO_2 ratio becomes equal to 3.02 — 3.04 in tricalcium silicate.

On the other hand, a chemical and optical study by Woermann, Hahn and Eysel (31) has shown that tricalcium silicate is a definite compound, with the stoichiometric formula $3CaO \cdot SiO_2$ (CaO = 73.68%, SiO_2 = 26.32%). In samples with a lime content higher than 73.68%, C_3S co-exists with free CaO; there is no C_2S.

C_3S is stable between 1250°C and 2070°C, the temperature at which it melts incongruently to form CaO and a liquid phase (54). Below 1250°C, pure C_3S does not decompose (55, 22) or its decomposition is so slow that it can only be detected by the analysis of trace quantities of free lime (54).

Alite will decompose into belite and free lime in the presence of certain minor elements (K_2O, CaF_2). A considerable decomposition of alite occurs at 1180°C in metallurgical clinkers. The Fe^{2+} ions replace the Ca^{2+} in the C_3S lattice (56).

Dicalcium Silicate

It is necessary to note first of all the differences that exist between the polymorphisms of C_2S and C_3S. The lattices of the different C_2S form are known and their parameters are quite distinct. At the moment, only the structures of the β and γ forms have been determined; they are completely different. It seems equally certain that the α and α' structures show small but distinct differences. In addition, there is complete agreement between the transition points revealed by DTA and by XRD crystal analysis. In the case of C_2S we have the usual types of transformations, whereas in C_3S we have a very special case because all the forms can be derived from a single structure by slight variations.

Structure of the 5 Forms of C_2S

αC_2S. Of all the forms of C_2S, the α form, which exists only between 1425°C and its melting point, at 2130°C, has been least studied because of the difficulties of carrying out high temperature experiments.

The most recent work is that of Yamaguchi, Ono, Kawamura and Soda (57) who used diffractometry at 1500°C to determine the trigonal lattice (space group P $\bar{3}$m 1) with parameters a = 5.527, c = 7.311 Å (hexagonal notation). These results agree with those of Bredig (58) (a = 5.45, c = 7.19 Å) obtained from high temperature powder photographs taken by Van Valkenburg and McMurdie (59). The space group is

C $\bar{3}$m (P $\bar{3}$m 1) by analogy with glaserite, $NaK_3(SO_4)_2$.

The other determinations have been made on stabilized phases but with additions of such large proportions that one ought to consider whether the lattice has been substantially altered. Thus a α form "stabilized" by 2.5% Al_2O_3 + 2.5% Fe_2O_3 + 6% Na_2O has parameters a = 5.419, c = 7.022 Å (57).

A.M.B. Duglas (60) observed a small amount of a trigonal phase, with parameters a = 5.46, c = 6.76 Å, similar to α C_2S, in the 'single' crystals of bredigite extracted from vugs in blast furnace slag. These composite crystals, of composition $Ca_{1.59}Ba_{0.08}Mg_{0.31}Mn_{0.09}SiO_4$, always contained the trigonal and orthorhombic phases in fixed relative orientation.

The crystals of nagelschmidtite $2Ca_2SiO_4 \cdot Ca_3(PO_4)_2$, also extracted from a vug in slag (61), have a hexagonal lattice defined by unit cell parameters which are multiples of those given above: a = 21.80, c = 21.54 Å. Likewise, Yamaguchi, Miyabe, Amano and Komatsu (62) in 1957, have suggested that the lattice of glaserite cannot be applied to α C_2S unless a is multiplied by 4 (a = 21.8 Å) and c by 3 (21.50 Å). The unit cell of α C_2S would, in this case, be more complex, but these results were not retained by Yamaguchi, Ono, Kawamura and Soda (57) in 1963.

$\alpha'C_2S$. There exist two forms of $\alpha'C_2S$: α'_H and α'_L whose stability regions are respectively 1420° — 1160°C and 1160° — 675°C (63). The parameter variation curves calculated by Niesel and Thormann (63) from diffractometer traces of pure C_2S, show a reversible change of slope at 1160°C. We ourselves, with the help of high-temperature powder photographs, have confirmed the existence of two different forms of α' C_2S at 1145°C and 1200°C. Our results form the subject of a Supplementary paper to this Symposium.

Smith, Majumdar and Ordway (64) have already observed on diffractometer charts a variety $C_2S\alpha'_L$, obtained by heating γ C_2S, slightly different from $C_2S\alpha'_H$, obtained by cooling the α form. Similarly, Yamaguchi, Ono, Kawamura and Soda (57) have detected differences of intensity in the lines of α' prepared from α on the one hand and from γ on the other. This intensity difference disappears towards 1100°C. At 1300°C, the orthorhombic unit cell of α'_HC_2S, calculated by Yamaguchi, Ono, Kawamura and Soda (57) from powder patterns, has parameters a = 6.883, b = 5.600, c = 9.543 Å (space group Pnma).

Determinations have been made on stabilized α' forms. Thus, for a phase containing 10% $CaMgSiO_4$ and 4% K_2O, Yamaguchi, Ono, Kawamura and Soda (57) found the following parameters: a = 6.748, b = 5.494, c = 9.261 Å. The form stabilized corresponded to the form α'_HC_2S above, described by the same authors. In this case, the differences are not due solely to thermal expansion, but also to distortion of the lattice by the impurities.

Douglas (60), working on the natural mineral bredigite, usually considered identical with $\alpha'C_2S$, and on the composite crystals referred to above, calculated a cell which has the a and b parameters doubled: a = 10.91, b = 19.41, c = 6.76 Å (space group Pmnn) and she found a similar cell by indexing Trömel's powder data (65) taken at 750°C; certain weak lines necessitate the doubled cell. Ordway (1) points out that the powder patterns of pure $\alpha'C_2S$ and Douglas's material are significantly different though the structures are probably closely related.

The $\alpha'C_2S$ structure is unknown. Bredig (58) has proposed the hypothesis that it is analogous to that of βK_2SO_4. Majumdar, Smith and Ordway (66) give a model founded upon the analogy between βC_2S and βK_2SO_4 but without justification by intensity measurements.

βC_2S. The most precise determination of the parameters was obtained by Yannaquis (55) using a synthetic preparation of pure βC_2S. The lattice is monoclinic with parameters a = 5.507, b = 6.754, c = 9.317 Å, β = 94°38′ (A.S.T.M. card 9–351), space group $P2_1/n$.

From a powder diagram of βC_2S at 550°C ,Yamaguchi, Ono, Kawamura and Soda (57) have proposed a monoclinic unit cell with parameters a = 5.558, b = 6.823, c = 11.261 Å, β = 123°11′, space group $P2_1/c$, which is identical to the Yannaquis's lattice (see Fig. 16).

Lattice determinations have also been made on stabilized βC_2S phases: C_2S + 0.5% B_2O_3 is defined by the parameters a = 5.48, b = 6.76, c = 9.28 Å, β = 94°33′, (space group $P2_1/n$) (61) and βC_2S + 0.25% Cr_2O_3 by parameters a = 5.514, b = 6.757, c = 11.197 Å, β = 123°59′ (57). These results show that the distortions introduced by foreign ions, though not negligible, are very small.

The structure of monocrystals of βC_2S stabilized by 0.5% B_2O_3 is monoclinic (61), and is constructed from independent SiO_4 tetrahedra and two sorts of Ca atoms. Four of these 8 Ca atoms (Ca_I) are placed alternately above and below the SiO_4 tetrahedra in the direction of the b axis. The structure can be described as columns of alternating tetrahedra and Ca atoms, linked together by the other four Ca atoms (Ca_{II}) placed in the holes between the tetrahedra (21). The pseudo-trigonal arrangement of the SiO_4 tetrahedra around the Ca_{II} atoms is shown in Fig. 16.

The co-ordination of Ca_I is irregular: 6 neighbours

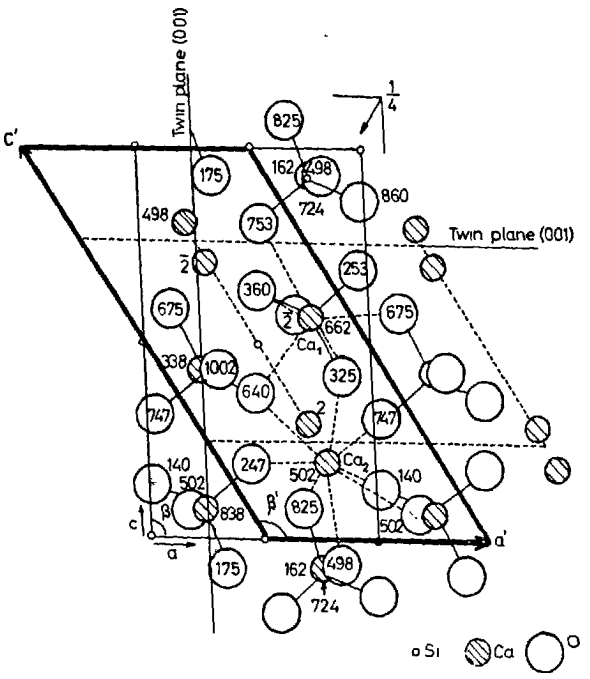

Fig. 16. *Dicalcium silicate. The projection of β C_2S structure on a plane perpendicular to the b-axis Midgley (61). The pseudo-hexagonal cell, axes a′ and b′, is shown Yamaguchi, Ono, Kawamura and Soda (57).*

lie at distances between 2.30 and 2.75 Å and six others between 2.98 and 3.56 Å. If the co-ordination is equal to 9, the contribution of each of the six nearest neighbours being 2/9 and that of the other six 1/9, Pauling's rule is approximately satisfied. The co-ordination of Ca_{II} is equally irregular. The eight neighbours belonging to six neighbouring tetrahedra lie at distances between 2.36 and 2.80 Å.

This structure, determined by Midgley (61) from 200 h01, 0k1 and hk0 reflexions, has a "reliability" factor of 19%, the R factor being reduced to 9% by McIver (67). McIver suggests that the space group $P2_1/n$ is incorrect, the true space group being one of: $P2_1$, Pn, $P\bar{1}$ or P1. Furthermore, Midgley notes that slight displacements of the atoms transform this sturcture to an orthorhombic structure of the βK_2SO_4 type, and somewhat larger changes give a trigonal structure (αC_2S). The polysynthetic twinning occurs on the (100) and (001) planes (Fig. 16) which become the planes of symmetry in the structure of $\alpha' C_2S$.

The unit cell of Yamaguchi, Ono, Kawamura and Soda (57) defined by the parameters a′, b′, c′ (Fig 16) is deduced from that of Midgley (a, b, c) by the following relations:

$$\vec{a'} = \vec{a}, \quad \vec{b'} = \vec{b}, \quad \vec{c'} = \vec{c} - \vec{a}$$

γC_2S. The unit cell has been determined from

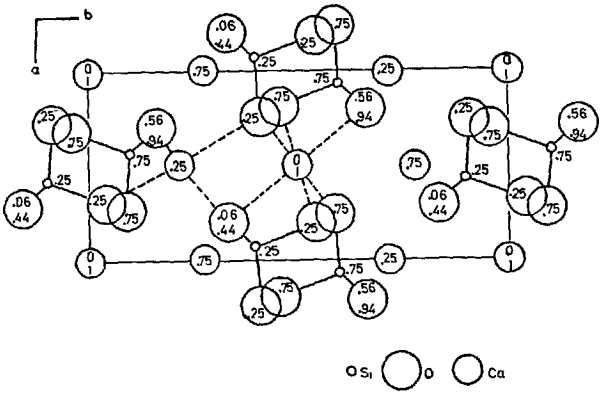

Fig. 17. *Dicalcium silicate. The projection of γC_2S structure on a plane perpendicular to the c-axis. Smith, Majumdar and Ordway (66).*

powder data by several authors. Their results are in agreement:

a = 5.076 b = 6.756 c = 11.230 Å (space group Pmcn) A.S.T.M. card 9-369 (55);

a = 11.232 b = 6.773 c = 5.083 Å (57) (space group Pnma);

a = 5.091 ± 0.010 b = 11.371 ± 0.020 c = 6.782 ± 0.010 Å (66) (space group Pbnm).

The volume expansion during the $\beta - \gamma$ transformation on cooling, shatters the crystals into fragments too small ($1 - 100\mu$) for single crystal study. Smith, Majumdar and Ordway (54) prepared C_2S from ethyl orthosilicate hydrolysed by a solution of $Ca(NO_3)_2$. The mixture was dried at 100°C, denitrated at 400°C, heated to 1500°C and quenched in air. Several single crystals were isolated and their complete structure was determined. This structure is of the olivine type Mg_2SiO_4 (55, 56). The Ca^{2+} ions replace the Mg^{2+} but, being larger, expand the unit cell of Mg_2SiO_4 but without altering the general regular arrangement (21). The SiO_4 tetrahedron is irregualr (Fig. 17). The Si-O distances vary from 1.589 to 1.725 Å. This irregularity is probably due to the distortions in the hexagonal arrangement of the oxygen ions. All the Ca ions are octahedrally co-ordinated; the low co-ordination of Ca explains the greater molar volume of the low temperature phase.

There is also a structural analogy between C_2S and Na_2BeF_4 (68, 69) on the one hand, and C_2S and Ca_2GeO_4 (70) on the other.

Other Studies on C_2S

Apart from these five phases which are universally agreed and well defined, some authors have claimed

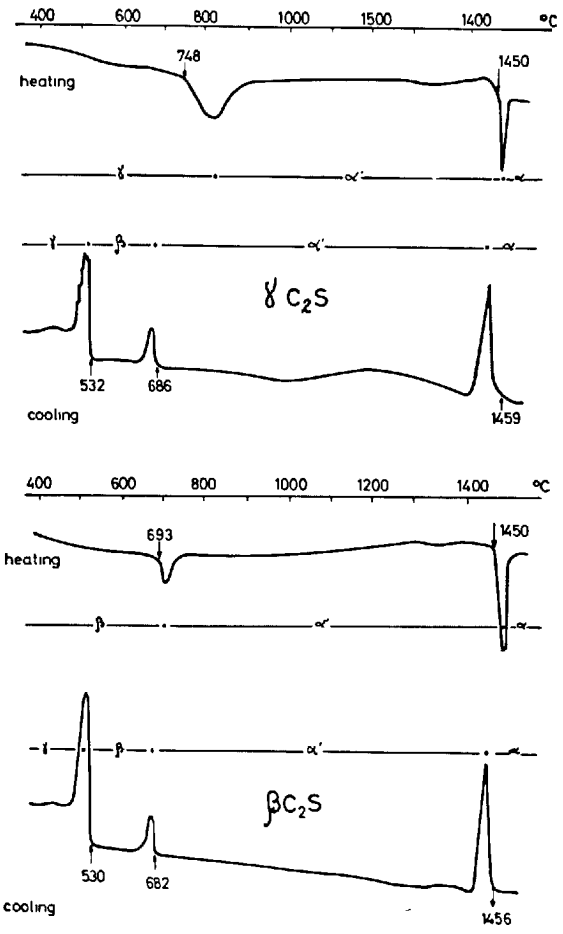

Fig. 18. *Dicalcium silicate. DTA diagram of γC_2S and βC_2S (Courtault) The temperatures of transformations seem higher than usual.*

the existence of other modifications.

1) A modification of β, called β', has been detected by Vasenin (71) in a DTA study. This phase, as described by Toropov, Volkonskii and Sadkov (72), has a pattern similar to that of α' ,and is stable from 900 to 1230°C. Its existence seems to be confirmed by a DTA signal at 1230°C, found by Schlaudt and Roy (73) in a study of the system Ca_2SiO_4–$CaMgSiO_4$. The β' phase has not been confirmed by Welch and Gutt (40) nor by ourselves.

2) Kurdowski (74) reported a new phase produced at 600°C from a β form stabilized by excess silica, which was very close to β'. This phase appears doubtful because excess silica does not stabilize βC_2S but favours the transformation $\beta \rightarrow \gamma$ (30).

3) A cubic form stable at 1600°C has been reported by Saalfeld (75). His high temperature patterns show an absence of 110 reflexion and enhanced intensity of 102. This behaviour, wihch is reversible, could be due either to a variation of the hexagonal axial ratio c/a resulting from the rotation of the anions or to the formation of a cubic phase (a = 5.8 Å). The trigonal 102 reflexion would become the cubic 200. Since 1953, this phase has not been reported by other research workers. However, a solid solution $C_2S + Na_2O$ reported by Ono (76) is perhaps a superstructure of Saalfeld's cubic form stabilized at room temperature. The mineral obtained in the CaO–SiO_2–Al_2O_3–Fe_2O_3 system by an equimolar substitution of Na_2O for CaO is isotropic with a = 17.769 Å $\fallingdotseq$ 3 × 5.8.

Study of the Transformations of C_2S

To describe the processes of change from one phase to another, we will consider the transformations observed first with decrease and then with increase in temperature.

1) *With decreasing temperature.* We start with the α phase, stable at high temperature (t > 1420°C):

$\alpha - \alpha'_H$: the transformation is reversible without hysteresis (Fig. 18). The structural changes of the $\alpha - \alpha'_H$ inversion cannot be characterized with certainty. Smith, Majumdar and Ordway (66) suggest that "half the SiO_4 tetrahedra rotate so that their apices point in opposite directions at the phase change. The rapidity of the transformation is certainly facilitated by the elevated temperature, even though the change may require a structural re-arrangement". Niesel and Thormann (63) have found at 1160°C, a DTA peak, corresponding to the $\alpha'_H - \alpha'_L$ transformation.

$\alpha' \rightarrow \beta$: 650°C. The transformation is reversible with a hysteresis of 25°C (Roy (77) found a hysteresis of 50°C); it occurs at a well-defined temperature. According to Smith, Majumdar and Ordway (66) the transformation involves a rotation of the SiO_4 tetrahedra and a change in the Ca ion co-ordination. From 8-fold in the α', the Ca co-ordination becomes variable, 8 or 9 fold, in the β form.

$\beta \rightarrow \gamma$: the β phase forms the γ by the process $\alpha' \rightleftarrows \beta \rightarrow \gamma$ This monotropic transition involves a considerable change in volume (dusting). From the structural point of view, the $\beta \rightarrow \gamma$ transition is a transformation of primary co-ordination (78). According to Smith, Majumdar and Ordway (66) the transition involves a rotation of the SiO_4 tetrahedron and should be considered as semi-reconstructive because of the large movements of some of the Ca atoms. The sluggish nature of the transformation is perhaps due to the complexity of the bond re-adjust-

ments.

The $\beta \rightarrow \gamma$ transformation has certain peculiar characteristics: in effect, it has been observed at different temperatures by different authors, 525°C (79), 450°C (71), 400°C (74), 375°C (80), 300°C (81, 82), and in addition it is incomplete. One usually obtains a mixture of β and γ but in variable proportions; one can obtain anything from nearly pure γ to nearly pure β. These phenomena will be the subject of a later paragraph.

2) *With increasing temperature.* At ambient temperature, one may start with either β or γ:

a) βC_2S: the transformation $\beta \rightarrow \alpha'_L$ takes place at 675°C then $\alpha'_L \rightarrow \alpha'_H$ at 1160°C (63) and $\alpha'_H \rightarrow \alpha$ at 1420°C. The transformations are visible on DTA and are confirmed by XRD.

b) γC_2S: starting with the γ phase, α'_L forms slowly between 725°C and 860°C. The DTA peak is elongated (spread out). Guinier camera photographs (see Fig. 19) taken at 750°C and 850°C show the co-existence of the two forms γ and α'_L.

One can explain the different characters of the $\beta \rightarrow \alpha'_L$ and $\gamma \rightarrow \alpha'_L$ transformations by structural considerations. If the α'_L structure is only slightly different from β, it is very different from γ. The $\gamma \rightarrow \alpha'_L$ transformation is semi-reconstructive. According to Smith, Majumdar and Ordway (66) this implies a rotation of the SiO_4 tetrahedra, a change in Ca coordination from 6 to 8, and an appreciable displacement of one type of Ca atom. Like the $\beta \rightarrow \gamma$ transformation, its sluggishness is perhaps due to the complexity of the bond changes.

The whole group of C_2S transformations is shown schematically by Niesel and Thormann (63) (see Fig. 20).

The energy diagram proposed by Bredig (58) now requires to be completed.

The different form of C_2S can also be identified by infra-red absorption spectra (83, 84).

Stabilization of Different Forms of C_2S

As indicated on Bredig's diagram, it is the γ phase which is most stable at ambient temperature. However, one can succeed instabilizing α and α', and one can obtain β at ambient temperature.

Certain oxides, such as MgO, Al_2O_3, Fe_2O_3, BaO, K_2O, P_2O_5 and Cr_2O_3, stabilize both α' and α forms (85, 86, 87, 88, 89, 90). A phase previously considered to be a definite compound of composition $K_2O \cdot 23CaO \cdot 12SiO_2$ was shown by Suzukawa (91) to be a solid solution of K_2O in the α' form of C_2S. However, Welch and Gutt (40) could not obtain this form at ambient temperature, finding that it trans-

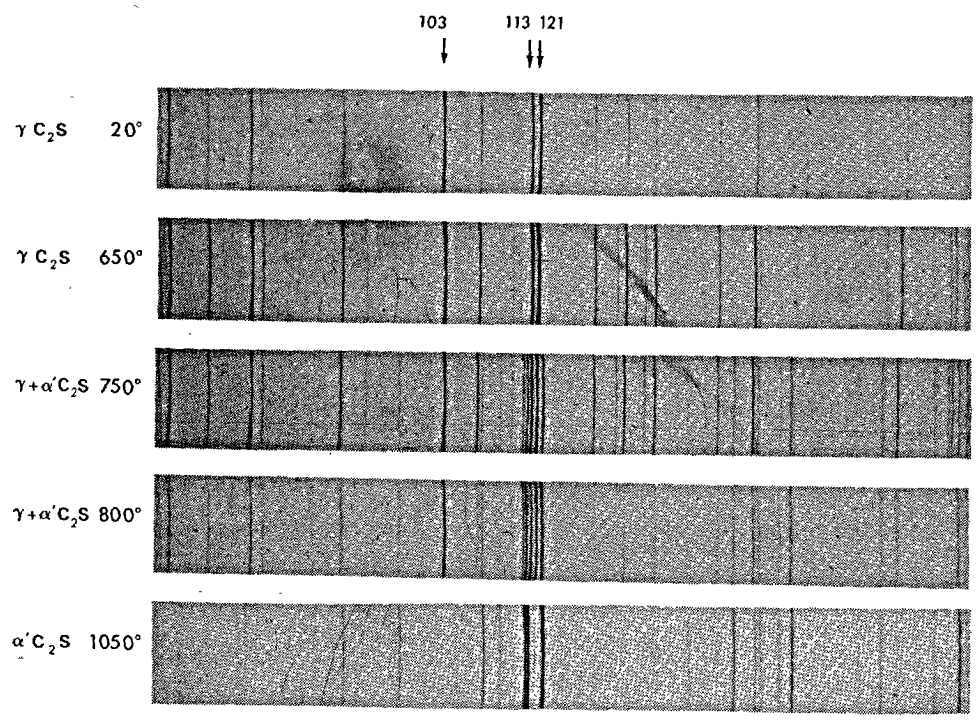

Fig. 19. *Dicalcium silicate. $\gamma \rightarrow \alpha'_L$ transformation investigated by high-temperature X-ray powder patterns. At 750° and 850°C, the γ and α'_L forms coexist.*

formed rapidly to β. On the other hand, merwinite does not seem to be solid solution of MgO in $\alpha'C_2S$ (5), as was proposed by Bredig (58). Yamaguchi and Suzuki (92) have prepared crystals of $3CaO \cdot MgO \cdot 2SiO_2$ of stoichiometric composition, and with a monoclinic structure ($a = 9.336$, $b = 5.301$, $c = 13.286$ Å, $\beta = 92°8'$, space group $P2_1/c$). Furthermore, Gutt (93) reports the existence of a still higher Ca compound, $CaO_{1.7}\ MgO_{0.3}SiO_2$, which is stated to co-exist with the C_2S polymorphs. The most interesting problems are those of the $\beta \rightarrow \gamma$ transformation and the conditions of stabilization of the β form.

a) *Influence of nucleation.* Even with pure synthetic products, considerable variation can be observed in the conditions for the $\beta \rightarrow \gamma$ transformation. Yannaquis and Guinier (78) have reported the influence which crystallite size has upon the stability of β: this phase is more stable the smaller the crystals. Microscope observations show that grains of β which are stable at ambient temperature are never larger than 5μ, although grains of γ which have been derived from β are in general 10 to 100μ in size. These observations are confirmed by XRD patterns. The reflexions from a stationary sample of γC_2S are spotty, while, under the same conditions, those of βC_2S are continuous, (Fig. 21).

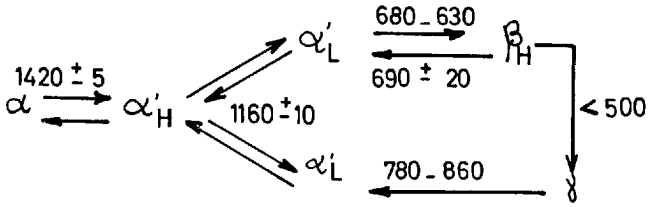

Fig. 20. *Dicalcium silicate. Schematic diagram of C_2S transformations. Niesel and Thormann (63).*

This behaviour may be explained by the mechanism of the $\beta \rightarrow \gamma$ transformation, which operates by nucleation and growth. Let us suppose that nucleation is difficult; in these circumstance a grain of β, whatever its size, will transform entirely if it contains at least one nucleus of γ. If after the $\alpha' \rightarrow \beta$ transformation the crystals of the latter are sufficiently large, the probability that each grain will contain a nucleus of γ is high, and one obtains, at ambient temperature, a high proportion of γ. If, on the other hand, the crystals of β are very small, many of them will not contain γ nuclei and cannot transform during cooling.

One can thus predict that if one can succeed in preparing α' in very small grains, stabilization of the β form may be achieved. This condition is realized if C_2S is prepared by solid state reaction between CaO and SiO_2 at 1200°C (94). In the stability range of the α' phase, the ratio rate of growth/rate of nucleation is low or nearly zero. In the same way, a smaple of C_2S heated to 1550°C, in the α zone, gives 90% of β on quenching because the passage through the $\alpha \rightarrow \alpha'$ transition is very rapid and the crystals remain small. On the other hand, the same smaple cooled slowly from 1550° to 1400°C and then quenched, gives 95% γ. The slow passage through the $\alpha \rightarrow \alpha$ transformation allows time for crystal growth and in spite of quenching the transition $\beta \rightarrow \gamma$ is practically complete. This explains also the role of the temperature of 1420°C in the stabilization of β or γ, which has been remarked by several authors (64, 95). According to Niesel and Thormann (63) it seems that 1160°C should be the optimum growth temperature for crystals of $\alpha'C_2S$; if C_2S is synthesized below 1160°C, one obtains β, while a sample prepared at a temprature above

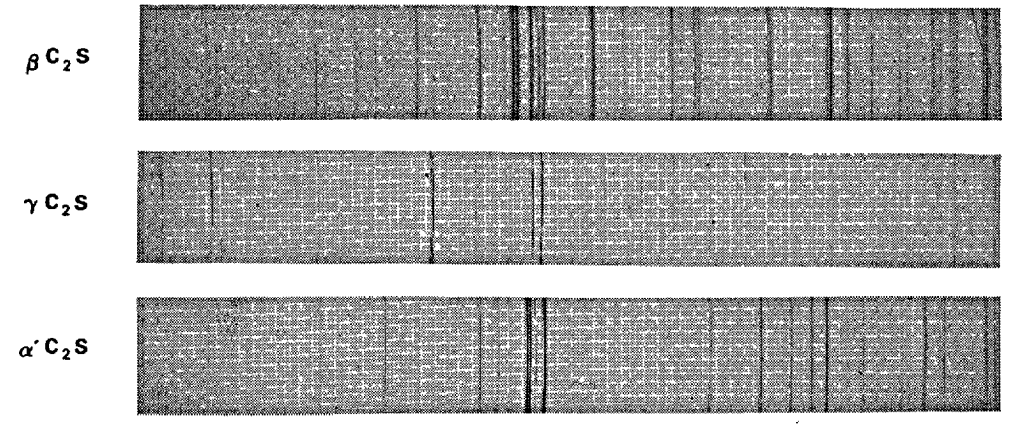

Fig. 21. *Dicalcium silicate. X-ray powder patterns of high-temperature Guinier camera with a stationary sample. The lines of γC_2S are spotty while, under the same conditions, those of βC_2S are continuous.*

1160°C gives a mixture of β and γ. One should point out that Chromy (96) has also shown, by optical methods, the effect of crystallite size of C_2S.

Again, the analogy between the structure of γC_2S and $NaBeF_4$ is to be found in the nature of their transformations. The process of nucleation (97) is the determining factor in the transition $\gamma \rightarrow \alpha'$ of Na_2BeF_4.

b) *Influence of pressure.* The nature of the phenomenon of apparent stability of βC_2S has been more precisely defined (98). It is possible to provoke a partial transformation from β to γ even at room temperature. Percussion of pellets of βC_2S will induce a transformation to γ of as much as 30%. Crushing between the platens of an hydraulic press may give up to 50% γ. The transformation is activated by the creation of nuclei of γ as the crystals are sheared under compression. On the other hand, if powdered β is submitted to hydrostatic pressure, even very high (9 tonnes/cm^2 $= 8.8 \times 10^5$ KN/M^2), no transformation occurs; the γ phase is less dense than the β phase, and increase of pressure does not favour the transformation (99). High pressures give β a stability region which does not exist at atmospheric pressure (77). Thus, the β phase is stable at ambient temperature under 2 atmospheres and it would be possible to transform γ to β under 17 bars (100).

c) *stabilization by additions of forign ions and by departures from stoichiometry.* The effect of grain size is, according to the theory presented above, merely statistical; but other factors are certainly involved in the stabilization of β, in particular the presence of impurities or of excess CaO or SiO_2 over the stoichiometric ratio:

Effect of excess CaO: it is possible to introduce an excess of CaO (1%) into C_2S. The form obtained at ambient temperature is β, yet the crystals are quite large (10μ). The specific effect of CaO is thus independent of that of size (78).

These results may be relevant to the work of Roy (77) who, having prepared large crystals of βC_2S from the hydrates, seemed to disagree with the theory of Yannaquis and Guinier. It is possible that these crystals were stabilized by an excess of CaO present in the hydrates (54).

Effect of an excess of SiO_2: the solubility of SiO_2 in C_2S lies between 1.5 and 2%, and the form obtained is γ. Crystals of C_2S–SiO_2 solid solutions range in size from 5 to 250μ. The addition of silica modifies the distribution of growth rates in the C_2S crystal and favours the transformation $\beta \rightarrow \gamma$ (78).

The effect of an excess of SiO_2 can be seen in the dusting of badly quenched clinkers or slags. Microscopic examination shows that the sources of the dusting lie round the grains of quartz; the crystals of belite which are to rich in silica transform to γ.

Effect of foreign ions: B_2O_3 is the classical stabilizer for β C_2S (61, 55). Using less than 0.5% B_2O_3, the lattice of βC_2S is not significantly altered (Fig. 22).

Yannaquis and Guinier (98) suggest that holes are formed by the elimination of Si^{4+} ions (probably in the form of silica) necessary to balance the charges of the higher valency $(BO_4)^{5-}$ groups. At 0.5% B_2O_3, there is one Si vacancy in 160 molecules of C_2S. Such holes seem a more likely site for additional Ca^{2+} ions than do interstitial positions in a lattice as compact as that of C_2S.

The solid solutions of $C_2S + B_2O_3$ are well crystallized. The lattice of C_2S + 2% B_2O_3 is monoclinic with parameters a = 5.475, b = 6.770, c = 9.290 Å, $\beta = 93°42'$. One can regard this solid solution as a limit structure and refer to it as a model.

Na_2O and K_2O also stabilize the β form (101) which is then formed as large crystals (78). Na_2O seems to diminish, even more than CaO, the probability of nucleation of γ C_2S. Very small numbers of Na atoms

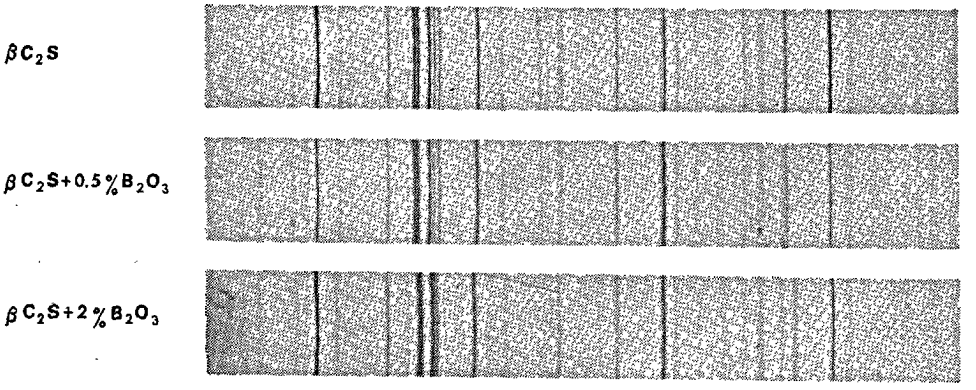

Fig. 22. *Dicalcium silicate and its solid solutions with B_2O_3. The lattice of $\beta C_2S + 0.5\% B_2O_3$ is not significantly altered.*

are sufficient to inhibit completely the $\beta \rightarrow \gamma$ inversion. The threshold of effectiveness seems to lie between 0.17 and 0.27% Na_2O but, contrary to Thilo and Funk's views, Yannaquis and Guinier (98), Niesel and Thormann (63) have shown that the alkalis are not essential for the stabilization of βC_2S.

Niesel and Thormann (63) have studied the solid solutions $C_2S + MoO_3$, $C_2S + C_3A$. Observations on the reaction products with the electron micro-probe have shown that there is formation of an envelope of $CaMoO_4$ or of an aluminous layer which hinders the $\beta \rightarrow \gamma$ transformation during rapid cooling (1000°C/minute) but which breaks up during slow cooling (10°C/minute) to permit the formation of grains of γC_2S.

Yannaquis and Guinier (98) have reported, during the Fourth Symposium, the influence of pressure on the stabilization of the β form of C_2S. The $\beta \rightarrow \gamma$ transformation occurs more readily when the C_2S lattice is not modified, as is the case with the solid solution $C_2S \cdot P_2O_5$ (1% $CaNaPO_4$). On the other hand, the silicates with a modified lattice, $C_2S + 0.5\%$ B_2O_3 or larnite (natural dicalcium silicate containing traces of Al_2O_3 or Fe_2O_3) give rise to no $\beta \rightarrow \gamma$ transformation under the influence of pressure. Either the crystals deform less or the formation of nuclei of γ is more difficult.

Belites in Clinker

In clinker, belite corresponds to a βC_2S with a lattice slightly modified by the addition of foreign ions. The XRD pattern of crystals of belite extracted from portland cement clinker (55) is in general that of βC_2S. It shows, however, some reflexions which are broader and certain others slightly displaced. Belite is thus a product of imperfect crystallization and apparently a non-equilibrium composition. In the lattice of C_2S, Ca^{2+} can be substituted by Mg^{2+}, K^+, Na^+, Ba^{2+}, Cr^{3+}, Mn^{2+} and the $(SiO_4)^{4-}$ group by $(PO_4)^{3-}$ or $(SO_4)^{2-}$ (79).

If β C_2S is stabilized by an ion substituting for Si, it is stable when fired in reducing conditions (102). On the other hand, under these conditions the $\beta \rightarrow \gamma$ inversion is easily produced in Ca-substituted pre parations (102, 73). In a reducing atmosphere, Fe^{2+} can replace Ca^{2+} or another stabilizing ion, to form a solid solution $FeO + C_2S$ and provoke dusting of the clinker.

The XRD pattern of belite is different from that of the solid solutions $C_2S + B_2O_3$. The theory of Mircea (103) that in clinker B_2O_3 reacts with C_3S to form CaO and a solid solution saturated with C_2S and C_5BS must be regarded as untenable.

Belite usually occurs as rounded, striated grains, with markedly laminated structure. The striations appear at the moment of the α—α' transformations (Type I: singly orientated)and the α'—β (type II: doubly orientated) (104). The usual form is β, and only occasionally does one find α' (105, 106) or α (107).

The composition of belite is unknown; syntheitc studies, by substitution for Ca (V, Ti, Na, K) or by addition of Al_2O_3, Fe_2O_3 to C_2S, have not given positive results.

Forest (108) has been able to prepare belites similar to those in clinker. These are oxygen-defective solid solutions with substituted Si of general formula $Ca_2M_xSi_{1-x}O_{4-x/2}$. The synthesis and crystallographic character of these belites form the subject of a communication to this Symposium.

Interstitial Phase

The interstitial phase, visible between the C_2S and C_3S in micrographs of clinker (Fig. 1) consists of two crystalline phases, generally referred to as C_3A and C_4AF. In reality, each of these phases can differ from the stoichiometric composition either by variation in the proportions of A and F or by the introduction of impurities in solid solution.

Tricalcium Aluminate

Structure of C_3A. Tricalcium aluminate is a definite composition which shows no polymorphic transformations (109). It melts incongruently at 1542°C to form CaO and a liquid phase. The crystal lattice is cubic with a = 15.262 Å (110) but the structure is still unknown.

Büssem (111) proposes a structure based on measurements of the strontium isomorph. The structure is a lattice of planar AlO_4 groups and octahedra of both AlO_6 and CaO_6; but as shown by Ordway (112) the oxygen atoms all lie at x, y, z = 0 or $\frac{1}{2}$, and the sub-cell ($\frac{1}{8}$ the true cell) contains 8 calcium *and no other* ions inside the faces. Ordway (112) succeeded in growing a C_3A crystal and determined, using Laue and Weissenberg photographs, the unit cell and

space-group ($T_h^6 - Pa_3$) which agree with Büssem's structure.

Schroeder and Lyons (113) have proposed a structure in which the AlO_6 groups are present as elongated octahedra, but Tarte (114) disagrees with this structure because it requires unusually large Al–O distances (2.6 Å). Further studies of C_3A by both infra-red absorption and X-ray fluorescence (115, 116) suggest that the aluminium/oxygen co-ordination is probably all tetrahedral.

A structure which is based on Al_6O_{18} rings of six tetrahedra has been proposed by Moore (117) with 64 Ca at the corners of the a/4 lattice and a further 16 positions to be occupied by 8 Ca or 16 Na. Using diffractometer powder intensities and some of Ordway's single crystal data, least squares refinement has not given values of R below 40%.

Solid solutions of C_3A: solid solutions $C_3(A_{1-x}F_x)$. Schlaudt and Roy (118), Tarte (119), Majumdar (120) and Moore (117) have reported the existence of solid solutions $C_3(A_{1-x}F_x)$. The limits of composition obtained for the solid solutions are different.

Fig. 23 represents the variations of cell parameter a as a function of the molar percentage $C_3F/C_3A + C_3F$.

These results show great differencies. Although the methods and temperatures of preparation were different, Majumdar and Moore found that the parameter continued to increase slowly with iron content beyond the limiting compositions. These compositions have thus not reached their equilibrium state. In Tarte's work, on the other hand, the parameter is constant when the ratio Fe/Al + Fe exceeds 10%. Furthermore, the isomorphous replacement Al–Fe is accompanied, in the IR absorption spectra, by a change of position of bands, a more or less profound alteration in band profiles and the appearance of a new band which suggests the presence of tetrahedral FeO_4 groups.

Other solid soultions. In the lattice of C_3A, CaO can be replaced by Na_2O. Brownmiller and Bogue (121) found the composition $Na_2O \cdot 8CaO \cdot 3Al_2O_3$ in the Na_2O–CaO–Al_2O_3 system. Conwicke and Day (122), Fletcher, Midgley and Moore (123) proposed a limiting composition 91% C_3A, 9% N_3A (mol) which is close to NC_8A_3. The parameter a decreases with addition of Na_2O. At 3% (mol) Na_2O there is a discontinuous change of symmetry from cubic to orthorhombic (123).

A composition $K_2O \cdot 8CaO \cdot 3Al_2O_3$ (91), isomorphous with $Na_2O \cdot 8CaO \cdot 3Al_2O_3$, exists in the presence of SiO_2; the K atom has a large ionic radius, 1.33 Å, (Na = 0.95 Å), and some Si ($\tau = 0.41$ Å) would replace the larger Al ions ($\tau = 0.50$ Å) (114).

The limit of solubility of MgO in C_3A is 2.5% (by weight) according to Muller-Hesse and Schwiete (124). MgO substitutes for CaO, and the parameter a decreases (117). Examination of portland cement clinker in the electron-probe suggests that MgO concentrates preferentially in the C_3A (125), at least when the C_3A is in the orthorhombic form.

In the solid solution $C_3A + SiO_2$, Si replaces Al. If one considers that the number of oxygen atoms remains constant, there atoms of Si replace four of Al, creating vacant sites (117). The parameter a decreases and the limit of solubility is 5–6% Si/Al + Si (atom %).

Alumino-Ferrite Phase

Hansen, Brownmiller and Bogue (126) showed that complete miscibility exists between C_2F and a hypothetical "C_2A "up to C_4AF.

(a)—*C_2F: structure.* Bertaut, Blum and Sagnières (127) have determined the structure of C_2F. The unit cell is orthorhombic with parameters a = 5.64, b = 14.68, c = 5.39 Å and space group Pcmn, and contains 4 molecules of C_2F.

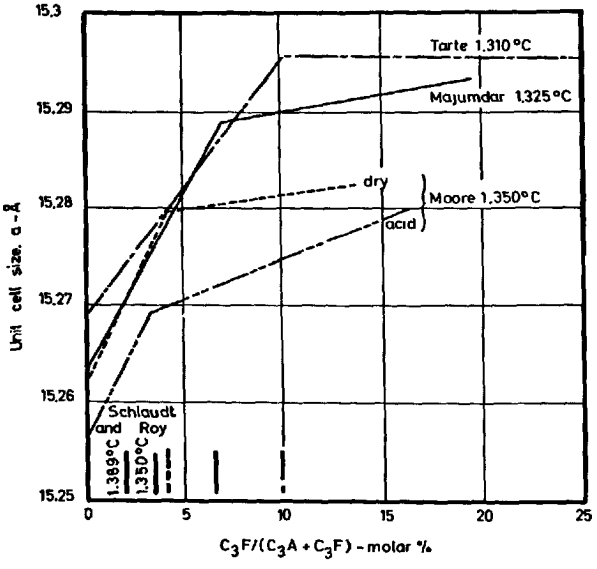

Fig. 23. *Tricalcium aluminate. Change in lattice parameter of C_3A with replacement of Al^{3+} by Fe^{3+}. Moore (117).*

The structure is pseudo-tetragonal. Projections along a and c are very similar (Fig. 24).

Along the b axis, a layer of FeO_6 octahedra alternates with a layer of FeO_4 tetrahedra; these tetrahedra and octahedra do not share oxygens. Ca is lodged in large cavities in the lattice of oxygen atoms and its co-ordination is very irregular; there are 9 neighbours, of which one is rather distant (3.3 Å), to share the bonding. Cirilli and Burdese (128) and Malquori and Cirilli (129) proposed the space group Imma for the whole series of alumino-ferrite solid solutions. Bertaut, Blum and Sagnières (127) found weak reflexions which could not be indexed except in the space group Pcmn; the layers of octahedra have the symmetry Imma but slight changes in the tetrahedral layers and in the Ca atom positions reduce the symmetry to Pnma (130), (≡ Pcmn in Bertaut's orientation).

—*Allotropic transformations of C_2F:* Differential thermograms of C_2F give two signals, at 430°C and 690°C, with a very flat region between the two peaks (131). The transformations are reversible with about 10° hysteresis.

We have attempted to determine the nature of these two allotropic transformations with the help of high-temperature X-ray diagrams. The transformation at 430°C is linked with a discontinuity in unit-cell volume. At 690°C, the curve of parameter variation shows a slight change of slope, the expansion being slower above 690°C. The number of reflexions does not change and there seems to be no change of lattice.

(b) *C_4AF.* C_4AF or brownmillerite has the same lattice as C_2F. The orthorhombic parameters are a = 5.428, b = 14.760, c = 5.596 Å (130) but the space group is Imma. The complete structure, especially the role of A and F, has not yet been determined. Brownmillerite is one member of the solid solution series C_2F + "C_2A" and seems the most stable. Hansen, Brownmiller and Bogue considered C_4AF to be a definite compound.

(c) *Aluminoferrite solid solutions.* Solid solutions $C_2F_{1-p}A_p$: In C_2F, some of the Fe ions can be replaced by Al ions; these solid solutions are of the form $C_2F_{1-p}A_p$.

A study of these solid solutions by X-ray powder disgrams has enabled Woermann, Hahn and Eysel (131) to detect two discontinuities in the variation of parameters as a function of p, the molar fraction of Al ions (see Fig. 25).

But these discontinuities correspond to very slight changes of slope. The limit of solubility is reached at p = 0.70. Examination of differential thermograms shows that the temperature of the first signal at 430°C decreases, as a function of alumina content, to 200°C and disappears at p = 0.30. The temperature of the signal at 690°C decreases similarly up to p = 0.2.

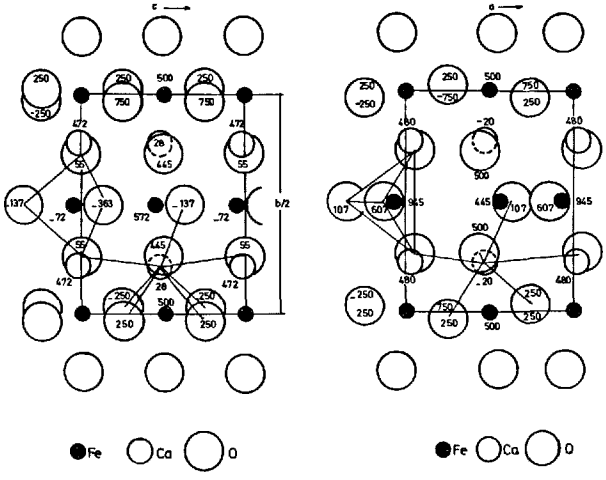

Fig. 24. *Dicalcium ferrite. Structure of C_2F. The projections along a and c axes are very similar. Bertaut, Blum and Sagnièrer (127).*

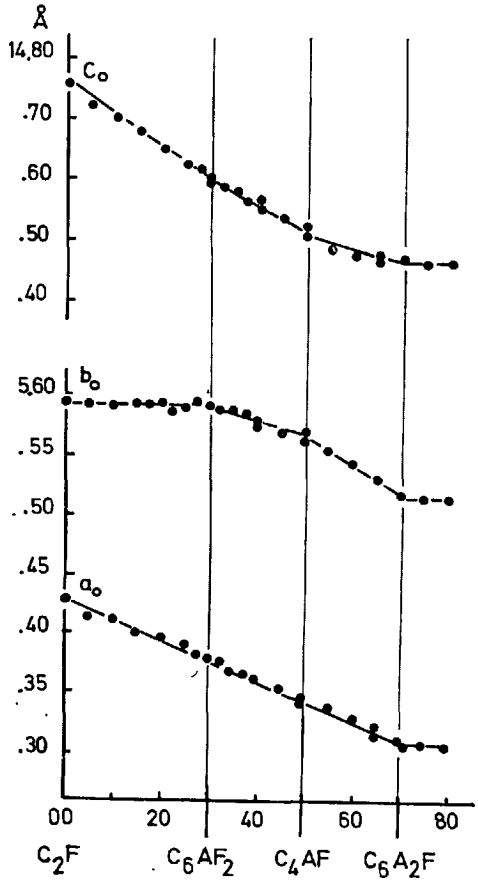

Fig. 25. *C_2F solid solutions: variation of C_2F lattice constants a_0, b_0, c_0 with composition in the C_2F—"C_2A" solid solutions series. Woermann, Hahn and Eysel (131).*

From $p = 0.2$ to $p = 0.5$, two peaks are observed which disappear at $p = 0.5$. It is difficult to draw precise conclsuions from this work; only the disappearance of the first signal at $p = 0.30$ seems to be linked with the change of symmetry from Pnma to Imma found by Smith (130) in his study of single crystals of composition $C_2F_{1-p}A_p$.

From the variations in intensity of characteristic h01 and 0k0 reflexions as a function of Al content, Smith (130) deduced that initially Al replaces tetrahedral Fe. When about half the tetrahedral sites are filled, Al enters both types of site equally. At about $p = 0.33$ the change of space group Pnma → Imma occurs. This change involves a contraction and rotation of the tetrahedra, and displacement of the Ca atoms. The Al atoms are distributed about equally in tetrahedral and octahedral sites. The variation of parameters a, b and c as a function of p is continuous. In brownmillerite, $C_2A_{0.5}F_{0.5}$, approximately 75% of the Al atoms are substituted for tetrahedral Fe and 25% for octahedral.

At the same time, Majumdar (120), in studying the phases in the pseudo-system $CaO–CaO\cdot Al_2O_3–2CaO\cdot Fe_2O_3$, found that the equidus temperatures for mixes on the hypothetical line C_2F–"C_2A" varied continuously as a function of the substitution Al^{3+}–Fe^{3+} in the ferrite lattice. C_3A and $C_{12}A_7$ appear when p is greater than 0.70.

In a study by infra-red spectra, of solid solutions $C_2A_pF_{1-p}$, Tarte (119) observed an increase in wave number and then, above $C_2A_{0.7}F_{0.3}$, no change, until at higher alumina contents, up to $C_2A_{0.85}F_{0.15}$, the position of certain lines changes again apparently due to the apperance of new phases such as C_3A and $C_{12}A_7$.

On the other hand, according to P. Longuet (132), the rate of reduction of C_4AF in a hydrogen atmosphere is regular as in the case of a definite composition. It seems that brownmillerite is the most stable member of the solid solution series $C_2A_pF_{1-p}$.

MgO-ferrite solid solutions: Magnesia enters into the ferrite lattice; normally red-brown, the latter becomes grey-black in the presence of MgO. It has been assumed for a long while that Mg substitutes for Ca but Woermann, Hahn and Eysel (131) have detected two types of solid solution. These authors used a precise analytical method to determine the free or uncombined CaO: the samples contained a small quantity of excess CaO; after the addition of a given percentage of MgO, the quantity of free CaO was determined and from the resultant curve, the type and the limit of solid solution were deduced.

The solid solution MgO-ferrite takes up more lime than the ferrite. According to the slope of the curve representing the change in free lime content as a function of added MgO, it appears that for 3 parts of MgO, 2 parts (molar equivalent) of CaO are combined; the limit of solid solution corresponds to the formation of periclase. The formula of the hypothetical end-member of the solid solution series is $Ca_2Mg_3O_5$ and the solid solution of Mg in C_2F is thus a substitution of Mg^{2+} for Fe^{3+}. Electroneutrality is maintained by the addition of an Mg ion in an interstitial position for every two Mg ions substituting for Fe. Hence, the type I solid solution:

$$Ca_2(Fe_{1-2x/3}Mg_x)_2O_5 \quad O < x < 0.023 \text{ at } 1400°C$$

At about $p = 0.50$, only one part of CaO is combined to 3 parts of MgO. Woermann, Hahn and Eysel proposed a superposition of a type I solid solution upon a normal Ca–Mg substitution. In type II, 1/5 of the Mg is substituing for Ca, while 4/5 is in type I solid solution (8/15 replacing the trivalent Fe_2, 4/15 in interstitial positions). Hence the formula:

$$(Ca_{1-x/5}Mg_{x/5})_2(R_{1-8x/15}Mg_{4x/5})_2O_5, \; x=0.049 (1300°C)$$

The change from type I to type II occurs at about $p = 0.49$. The discontinuity in the substitution of MgO can be established in the crystal structure, suggesting a discontinuity in the ferrite solid solution series. The aluminoferrites $C_2A_pF_{1-p}$ corresponding to $p > 0.5$ are unstable in the presence of free CaO. For this reason, Woermann, Hahn and Eysel did not extend their work to the whole solid solution series.

The MgO-ferrite solid solutions have also been studied by Kato (133), who finds that SiO_2 and MgO substitute for $(Al,Fe)_2O_3$ up to about 10% (molar). The substitution is of the melilite type.

SiO_2 alone can also enter into the ferrite lattice. The mechanism of SiO_2 solubility could be explained by the same type of substitution.

(d) *Interactions between the phases C_3A and $C_2(A,F)$.* C_3A and $C_2(A, F)$ constitute the interstitial phase of clinker. It is of interest to see whether, in synthetic preparations, these two phases can react to give solid solutions. This work, undertaken by Tarte (119) has shown the following results:

(1) Fe–Al exchange: in a mixture of $C_3A + C_4AF$, there is formed after heating to 1300°C a solid solution $C_3(A, F)$ resulting from the passage of a certain amount of iron from the C_4AF to the C_3A, this being compensated by the transfer of the equivalent Al from the C_3A to the C_4AF. The solid solution $C_3(A, F)$ has the limiting composition $C_3(A_{0.90}F_{0.10})$;

(2) Formation of poorly-crystalline phases: besides the displacements of characteristic XRD reflexions, Tarte (119) has observed in the solid solutions a simultaneous broadening of some of the high angle XR

reflexions and of the infra-red absorption bands, when comparing a mixture of the two phases before thermal treatment with the same mixture after treatment. This effect is more marked when the mixture already treated at 1300°C is taken to 1340°C.

Yet the same phases treated separately at the same temperature retain their IR spectra and XRD patterns perfectly sharp.

Tarte (119) has deduced that the state of crystallization of the phases obtained by mutual reaction is incomplete. This alteration of the crystallization is more marked at 1340°C, this being the temperature at which the majority of the mixture undergoes a partial fusion;

(3) Formation of a glassy phase: when the solid solutions have a high alumina content, a vitreous phase appears, the IR absorption spectrum of a sample of composition $C_2(A_{0.8}F_{0.2})$ taken to 1340°C is diffuse (Fig. 26) and shows no XRD lines whatever. On the other hand, the crystallization is complete when the Al/Fe ratio is colse to 1.

The Interstitial Phase in Clinker

In portland cement clinker, one finds tricalcium aluminate, the aluminoferrites and their respective solid solutions.

(1) *C_3A.* The tricalcium aluminate extracted from clinker has the lattice parameter a smaller than that

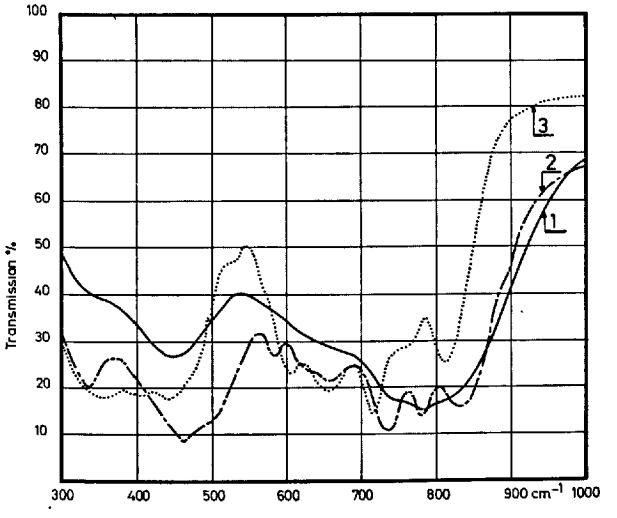

Fig. 26. *C_2F solid solutions. Infra-red absorption spectra Tarte (119):*
(1) of the vitreous phase formed from a composition $C_2(A_{0.80}F_{0.20})$;
(2) of the cryrtalline phases formed from the same composition as (1);
(3) of C_4AF.

of C_3A (117). It is thus in the form of solid solutions due to the addition of impurity oxides such as Na_2O, K_2O, MgO, Fe_2O_3, SiO_2 but the concentration limits of these different additions are not known.

(2) *Aluminoferrites.* The composition of the ferrite phase in commercial cements depends as much on the thermal treatment as on the A/F ratio, in all cases where equilibrium is not reached (134).

Midgley (135) has observed broad lines in the diffraction patterns of clinker ferrites and attributes this broadening to the fact that equilibrium could not be established in the course of cooling. Yamaguchi and Kato (136), Satou, Takashima and Kato (137) have both obtained less well-defined lines in patterns from clinker than in those from pure synthetic compositions.

The IR absorption bands of C_3A and $C_2(A, F)$ in clinker, easily observed in a smaple synthesized at 1200°C, become more and more diffuse as the sample is taken up to 1300–1400°C. In certain clinkers, there exists a very diffuse absorption band which seems to be linked with the alumina content, and hence with the existence of a glassy phase (119).

Hansen, Brownmiller and Bogue (126) have shown that complete miscibility exists between C_2F and "C_2A" up to C_4AF. Numerous studies (138 to 142) thereafter have established that the ferrite phase in clinker is not necessarily of the composition C_4AF but may extend to the solid solutions richer in alumina, in which the ratio Al_2O_3/Fe_2O_3 reaches 2.2 to 2.3 ($p \simeq 0.70$ in the series $C_2A_pF_{1-p}$).

Midgley (135) has studied the composition of the ferrite phase in fifteen English clinkers: 2 had the composition C_4AF, 2 had C_6AF_2, 4 an intermediate composition and the remainder an ill-defined composition (broadened XRD lines) but always lying between C_6AF_2 and C_6A_2F.

In American clinkers, Copeland, Brunauer, Kantro, Schultz and Weise (143) found that the compositions of the ferrites lay between $C_6A_{1.22}F_{1.78}$ and $C_6A_{1.77}F_{1.23}$. The mean value $C_6A_{1.47}F_{1.53}$ is very close to brownmillerite.

Gourdin (144) has analysed by XR diffraction the ferrite phase from 15 French cements; four clinkers contained the composition C_4AF, one contained C_6AF_2, and the other 8 an intermediate composition very close to C_4AF.

Schwartz (145) separated out the aluminoferrite phase from 66 French clinkers, by the salicylic acid in methanol method of Takashima (146). The aluminoferrite phases separated out had a chemical composition much more complex than the interstitial phase calculated by the Bogue method. The analyses,

by X-ray fluorescence spectrometry, revealed a stoichiometric defect in CaO which reached as much as 5%. This lime definiency increased if one included K_2O, Na_2O and MgO and diminished if one included SiO_2. The solubility limits of the minor elements in the interstitial phase were determined as 3% K_2O, 4% MgO, 7% SiO_2.

To conclude, C_3A and $C_2(A, F)$ cannot co-exist as such in clinker. Exchange of Al_2O_3 and Fe_2O_3 occur easily in the aluminates and aluminoferrites. Furthermore, at 1300°C, a small amount of iron will convert from the ferric to the ferrous state (120, 147). The presence of ferrous oxide noticeably modifies the stability regions of the solid solutions (148). The solid solutions $2CaO\,(Al, Fe)_2O_3$ decompose in the presence of CaF_2 and $CaCl_2$ (149).

Conclusion

Properties of the Clinker Minerals

We have considered the structures of the various polymorphs of the principal clinker components and there is a correlation between the crystalline structures of these components and the hydraulic properties of the clinker.

1) *C_3S.* Of all the phases in clinker, it is the tricalcium silicate which is the most significant and important from the point of view of the hardening of cements (150). The hydraulic cementing properties of C_3S are associated with the poor co-ordination of calcium ions and the presence of 'holes' in the crystal lattice (21). We have shown that the crystal structures of the different forms of C_3S and its solid solutions are very close to that of the trigonal form of pure C_3S stable at high temperatures. On the other hand, differences in the relative intensities of the diffracted rays are scarcely noticeable. The different crystalline forms are thus constructed from the same atomic groupings. These are only very slightly displaced or distorted. The polymorphic transformations are 'displacive', they bring into play only weak forces and do not appreciably alter the chemical combinations (151). This results in all the forms having a similar reactivity. Nurse, Midgley, Gutt and Fletcher (152) have found that the transformations $T_I \rightarrow T_{II} \rightarrow M$ of the synthetic solid solutions $C_{156-x}M_xS_{52}$ have no effect on the strengths developed when these materials hydrate. In the same manner, the strength of commercial cements containing trigonal alite does not differ significantly from that of cements in which the alite is in the monoclinic form. Yamaguchi, Shirasuka and Ota (153) have compared the properties of monoclinic and trigonal alite. Monoclinic alite (inverse) hydrates more rapidly. It is obtained by rapid cooling and seems to be thermodynamically unstable. If subjected to gentle heating it is converted into the triclinic form which by contrast gives greater early strength (154). Verbeck (155) has shown that the introduction of alumina and magnesia into tricalcium silicate brings about a significant increase in early strength but the effect does not persist beyond 70–80 days. The introduction of other foreign ions such as P_2O_5 (156), SO_3 (157), $CaSO_4 \cdot 2H_2O$ and $CaCl_2$ (158), Cr_2O_3 (159), can modify the properties of C_3S but the changes in reactivity do not seem to correlated with changes instructure (160). An increase in size of the alite crystals is generally observed.

2) *C_2S.* The five forms of C_2S have, on the other hand, quite different structures. The lattices are different and the ionic groupings change from one form to another. One can therefore reasonably presuppose that the five forms will have different hydraulic properties.

In the β form, the polyhedral co-ordination of the Ca ions is irregular and the extra-long Ca-O bonds facilitate the hydration reaction. Similarly, because of its predisposition to undergo a major structural rearrangement (64), metastable βC_2S is more readily hydratable. The γ form of C_2S is known to be inert (79) or feebly hydraulic (161). This poor reactivity is associated with the symmetrical co-ordination of the calcium ions (21) and the strong Ca–O bonds arising from the low co-ordination number of the Ca ions (64).

The α' forms should be only hydrated with difficulty and seem to possess no hydraulic cementive power (79).

The minor consistuents of clinker which stabilize the different forms of C_2S can affect the relationship between the hydraulic cementive characteristics of belite (40, 162, 163) and its other properties (164).

3) *Interstitial phase.* Tricalcium aluminate reacts rapidly with water. Calcium auminoferrite is only feebly hydraulic.

However, during the clinkering process, the burning temperature, the method of clinker cooling, the interaction of C_3A with the ferrite phase, the presence of foreign ions and the formation of a vitreous phase all alter the phase equilibrium conditions and so change the properties of the clinker in respect of the kinetics of its reactivity towards water (119).

Acknowledgments

We gratefully acknowledge the assistance of the many research-workers who have communicated their results to us, and especially those who have allowed us to read their papers before publication:

Written Discussion

Jean Forest

It is important to emphasize that alite is formed by pseudomorphosis (1) in what is at that time a tridimensionnal space (time, temperature, physical, chemical and mineralogical nature of the components of the raw meal).

Two cases can be envisaged:

The sintering reaction takes place in the solid state. Only the diffusion mechanisms must be considered, CaO in Al_2O_3, Fe_2O_3, SiO_2 (2) then in α C_2S.

The mineralogy and especially the granularity of the components of the raw meal, quartz in particular, affect the reaction fundamentally. Under certain conditions which we have studied, it is possible at 1300°C to combine completely the oxides present.

The sintering reaction continues with the liquidus. It becomes heterogeneous, once again, this is a diffusion process which permits the combining of CaO, although the physico-chemical properties of the liquidus—which may be impaired by minor elements either naturally present or added (3), influence the kinetics of the process.

However, as α C_2S has been transformed into belite, part of the latter produces alite, simultaneously liberating aluminates (4).

According to well established data it appears that the most symmetrical forms of alite are obtained at room temperature by replacing Ca by more polarizing atoms. If the substitution concerns Si, an atom with less polarizing power will have to be introduced, although its effect will not permit the symmetry T_{II} to be surpassed. Finally if the substitution concerns Ca and Si, the form M_{II} is obtained. The group Mg, Al stabilizes an inverse monoclinic alite. With the group Al, Ti one can obtain all forms from Ti to M_{II} as we verified by sintering at 1550°C, to a degree of accuracy of one supplementary molecule of CaO, a mixture corresponding to the composition of a belite saturated with alumina in which 0.02 moles of SiO_2 are replaced by TiO_2.

The insertion of Mg^{2+}, Al^{3+}, Ti^{4+}, produces the form R (5), whereas that of P^{5+} produces no modification at least in our experimental context.

It is also essential to recall that the symmetry deduced from the X-rays spectrum is sometimes superior to that which the interpretation of the DTA thermogram furnishes.

The sum of the data is assembled in Table I. It is conceivable therefore that the alite of industrial clinkers generally presents the forms M(inverse) and R. This situation, in the first case at least, can be modified as we shall see further on.

It is now opportune to generalize the notion of paragenesis into the chemistry of cement. It is possible to group under this heading intermediate substances which although not necessary to the fabrication of clinker. $CaSO_4$; $(C_2S)_2CaSO_4^*$; $2CaSO_4$, K_2SO_4; $(C_2S)_2$ $CaCO_3$, modify the normal course of reactions, often facilitating them and sometimes disturbing certain of their properties.

Table 1.

Composition	Burning: Time in hour	Burning: Temperature in °C	Symmetry of the alite	Free CaO %	Observations
$Ca_3Al_{0.06}Si_{0.92}Ti_{0.02}O_{4.97}$	6 +4 +16	1540 1500 1550	T forms M_I M_{II}	presence traces	presence of C_3A
Clinker α 100%	15	1300	inverse M_I	0.65	Blaine fineness of the quartz: 12000 cm^2g^{-1}
Clinker α 99.5% $Ca_3(PO_4)_2$ 0.5%	15 4	1300 1450	inverse M_I	0.18 —	
Clinker α 99.4% $CaSO_4$ 0.6%	15	1300	R	0.98	
Clinker α without MgO	15	1300	T_{II}	11.72	
Clinker α without MgO 99.5% $Ca_3(PO_4)_2$ 0.5%	15	1300	T_{II}	3.71	
Clinker α without MgO 99.4% $CaSO_4$ 0.6%	15	1300	T forms	5.82	

"Dusting" is observed with all these products and γC_2S is caracterized by X-rays. Heating rate 500°C h^{-1}. The time of 15 hours has been chosen for the sakes of convenience, but the reaction is finished a long time before.

α Clinker composition:

SiO_2	21.3%
Al_2O_3	7.0%
Fe_2O_3	2.5%
TiO_2	0.3%
MgO	1.8%
CaO	67.1%

*Experiment shows that $3C_2S \cdot 2CaSO_4$, in fact is a mixture of $(C_2S)_2CaSO_4$ and $CaSO_4$.

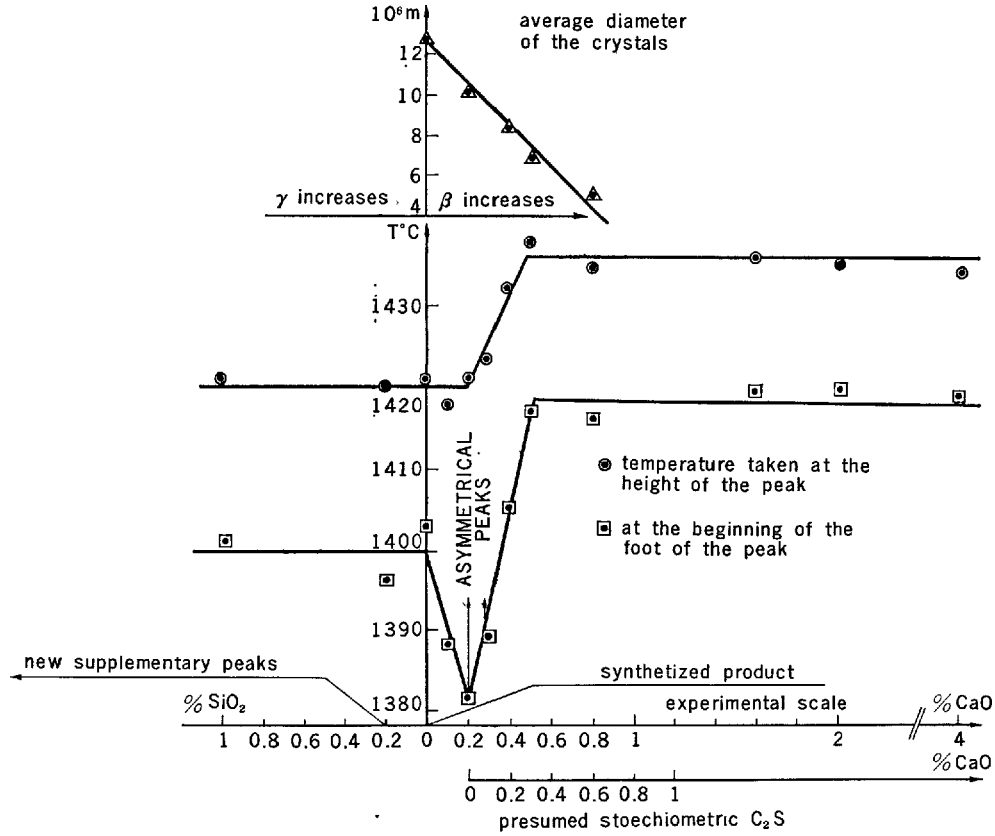

Fig. 1 *Synthesis made with 14.0176g of* SiO_2 *impurity 0.26% determined by chemical analysis 46.4895g of* $CaCO_3$, *rate of purity: more than 99% Prolabo RP. loss of weight at 100°C 0.094% 1000°C 43.89%*

That is why we consider that generally the dynamic process of sintering takes place in a quadridimensionnal space. In fact it is fitting to add to the preceding dimensions the sintering capacity of the substance during the sintering process which more or less disturbed leads to the fabrication of light even pulverulent clinkers without γ form of dicalcium silicate.

The technical literature is regularly enriched by new examples of paragenesis and the matter is treated in certain papers at this symposium.

The rotary cement kiln acts like a phase separator. Each phase may appear in a given temperature range and may be deposited on the inner surfaces inasmuch as it participates directly in the formation of a liquidus or that it is the final evolutionnary stage of the latter.

The use of the unitary scale and of Gygi's temperature curves constitutes an instrument which is useful for the comprehension of these phenomena (6).

Various thermic treatments were undertaken to determine the effect of CaO on C_2S for rates up to 6 per cent. It was found that the $\alpha'_H \rightleftharpoons \alpha$ inversion temperature is displaced from 1420°C to 1437°C for 100% C_2S to 99.7% C_2S–0.3% CaO.** Simultaneously the amo unt of βC_2S increases.

Between 0.6 and 1.4 per cent of CaO the X-rays spectrum obtained with Guinier de Wolff's camera equipped with a monochromator permits one to induce that there is a strong probability of the presence of C_3ST_I. With 6 per cent of the oxide, C_3S is particularly evident.

Finally the D.T.A. thermograms specify that the passage from $\alpha'_H \leftrightarrows \alpha$ takes place approximately at the same temperature as that of CaO–C_2S limit solid solution for the three independent series of trials undertaken. The entirety of the data which conflicts with that presented by V. I. Korneev and E. B. Bygalina (7) is grouped in Table 2.

This preliminary which needed developping is

**A more complete development about this problem will be published as soon as possible.

not in complete disagreement with the hypothesis of the compact structure of β C_2S and facilitates the considerations which follow.

The establishment of a closed cycle of SO_2 in the rotary kiln can lead to various disorders in the regular working order and provoke the blocking of a section by the thickening of a ring formed primarily by sulfatic spurrite and by β C_2S (8).

Generally, self-destructive deposits are formed. The mixture of their fragments with the raw-material more or less affects the sintering capacity. Finally, the clinker can contain variable rates of SO_3 according to the thermic rhythm. When the latter contains K_2SO_4, measurable by the thermogravimetric method of P. Longuet (9), the cement may lump rapidly in humid air as the result of the formation of a tangle

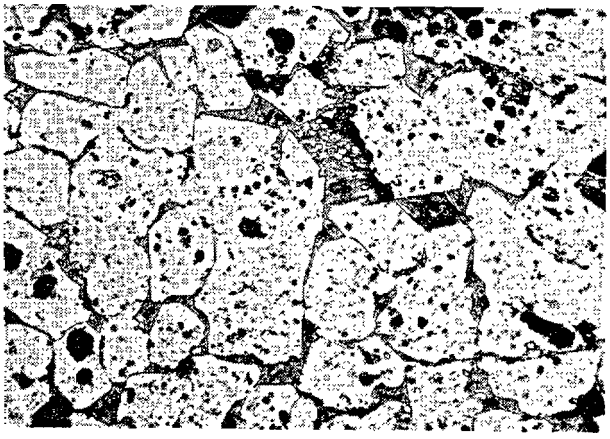

Fig. 2. $(Ca_2SiO_4)_2$ $CaSO_4$ *completed with* CaO *to give* C_3S (T_I *Alite*) × *62* — NO_3H *etching.*

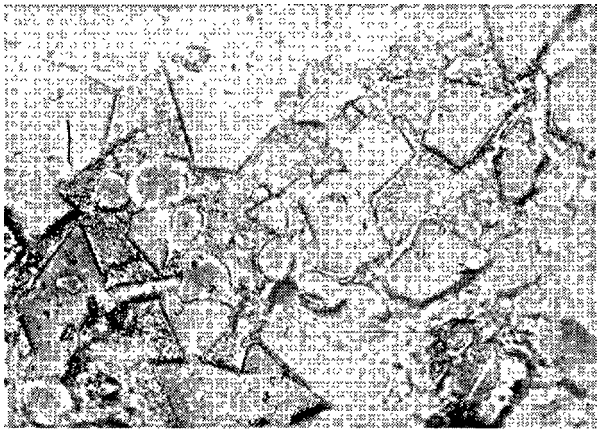

Fig. 3 *2* $(Ca_2Al_{0,065}Fe_{0,015}Si_{0,92}O_{3,96})$, $Ca_2K_2(SO_4)_3$ *completed with* CaO *to give* C_3S (*R. Alite*) × *180* — NO_3H *etching.*

of syngenite needles, $K_2Ca(SO_4)_2 \cdot H_2O$ (10).

In the presence of sulfates, silicates are capable of forming solid solutions.

An equimolecular mixture of sulfatic spurrite and of CaO burned for one hour at 1450°C gives alite crystals of the form T_I (D.T.A. gives peaks at 636°C, 882°C, 930°C, 978°C) attaining 300 μ on an average, by means of the well known mineralizing effect of SO_3 (Fig. 2).

Conversely, the global composition: $2(Ca_2Al_{0.065}$ $Fe_{0.015}$ $Si_{0.92}$ $O_{3.96})$, Ca_2 K_2 $(SO_4)_3$, 2 CaO forms R alite under the same thermic treatment as previously explained (Fig. 3).

Similarly the heating of the mixture corresponding to 99.4 per cent clinker and 0.6 per cent $CaSO_4$ (Table 1) gives an R alite. The same observation can be made in sintering, in a confined atmosphere with a model which permits heating at real time temperature, raw cement material enriched by $CaSO_4$ and Ca_2K_2 $(SO_4)_3$ as may be produced for example in the cyclones of the Humboldt kiln.

The percentage of SO_3 which produces the transition from the inverse form M to R seems to fall between 0.24 and 0.45 per cent for an amount of potential C_3S in the neighbourhood of 55 per cent. Inasmuch as all the SO_3 is combined with the alite, the result is in close accordance with that which H. Lafuma indicates (11).

Taking in account the hypothesis concerning the compacity of the β C_2S structure, one can easily predict that the formula for the constitution of the sulfate belites can be written:

$$Ca_{2-x}Si_{1-x}S_xO_4$$
$$Ca_{2-2x}K_{2x}Si_{1-x}S_xO_4$$

The solubility limits were determined by D.T.A. during the second heating cycle, from mixtures corresponding to various values of x, previously heated for two hours at 900°C then for 3 hours at 1180°C.***

In this way we verified that with $CaSO_4$, $x = 0.06$, and with K_2SO_4, $x = 0.02$ (Fig. 4 and 5).

Moreover it appears in the second case that the insertion takes place in the form α'_L, whereas it is necessary to go beyond the inversion temperature $\alpha'_L \rightleftarrows \alpha'_H$ in the presence of $CaSO_4$. The X-rays spectra reveal that a β_1 belite (12) corresponding to a weak variation of the constants of the lattice, is stabilized. K_2SO_4 is discernable from the point $x = 0.05$ onwards, and is detected by the peak of transition at 560°C for $x = 0.04$ in D.T.A.

$CaSO_4$ is partly combined in the form of sulfatic spurrite between 900°C and 1150°C, and at 1180°C $CaSO_4$, $Ca(OH)_2$ are additionally present along with β C_2S, the reaction not yet being complete. Heating for 10 minutes at 1450°C followed by quenching, produces mixtures where γ C_2S is found, with the exception of the $CaSO_4$ synthesis which on the contrary contain a form α' for high values of x.

Belites are of the β_1 type slightly modified. 2 hour plateau at the same temperature increases the modification of the crystalline cell when SO_3 is introduced as $CaSO_4$. Slow cooling accentuates the instability in a manner similar to that of the belites Ca_2 M_x Si_{1-x} $O_{4-x/2}$

The same is true for the K_2O belites all of which have the form β_1, and which seem to correspond to the composition formula $Ca_{2-x}K_xSiO_{4-x/2}$.

The solubility limit $x = 8 \cdot 10^{-2}$ was deduced from

***This temperature has been chosen in order to avoid the risks of volatilization.

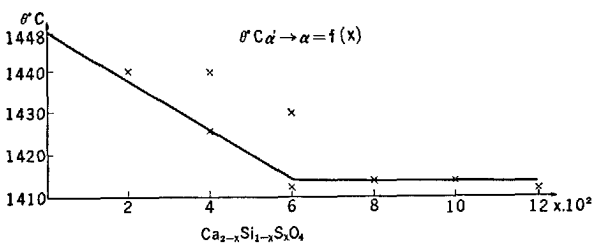

Fig. 4. *The two experimental points figuring on the graph for $x = 0.04$ and $x = 0.06$ results from the observation of a double peak.*

Note: *During the first heating cycle, an endothermic peak is noticed about 1360°C, which characterizes $(C_2S)_2CaSO_4$, increasing with x, and which disappears during the second heating.*

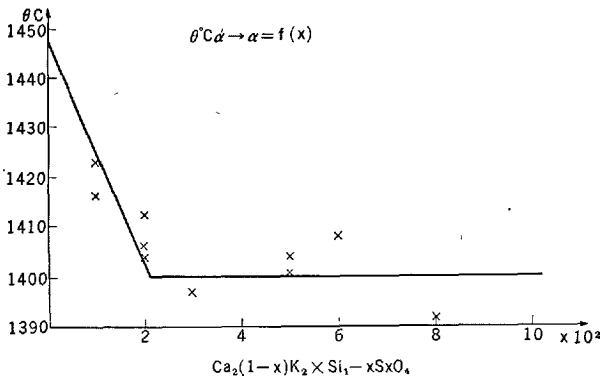

Fig. 5. *The different points which are represented for the same value of x have been obtained with several experiments and distinct synthesis.*

the D.T.A. (Fig. 6) during the second heating cycle as precedently on products heated for 3 hours at 1180°C,* although the peak $\alpha'_H \rightleftarrows \alpha$ was very flat. For $0.07 < x < 0.12$, a temporary phase—giving at approximately 1250°C endothermic peak which increases in size with x—appears during the course of the first heating.

Moreover, with $K_2CO_3 \cdot 23\ CaCO_3 \cdot 12\ SiO_2$ heated at 950°C this effect is observed:

The result of the heating at 950°C gives an X-rays spectrum which corresponds to an imperfectly crystallized α' configuration. After a 3 hour plateau at 1180°C the X-rays spectrum resembles that of $Ca_{1.88}\ K_{0.12}\ SiO_{3.94}$ where one perceives β C_2S and some supplementary equidistances in the neighbourhood of 2.705 Å and 1.99 Å.

The diverse synthesis expressible by the formula $Ca_{2-x}K_xSiO_{4-x/2}$ brought to a temperature of 1180°C for 3 hours contain percentages of γ C_2S which decrease when x increases. The reaction not yet being complete it is possible to detect CaO and cristobalite.

Heating at 1450°C for 10 minutes followed by

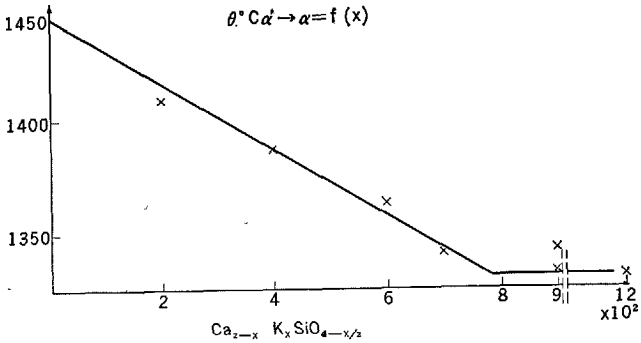

Fig. 6. *Two synthesis have been made for $x = 0.09$.*

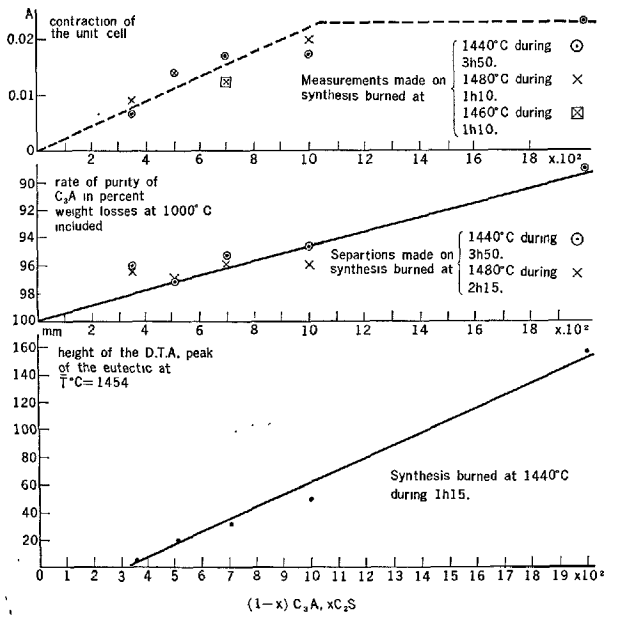

Fig. 7. *The spectra of powder containing silicium as an internal standard of reference were obtained with Guinier de Wolff's focalisation chamber equipped with a monochromator. The contraction of the crystalline unit cell was determined by applying the statistical method to approximately 35 reticular distances, which were calculated after being corrected by comparison with the silicium, and whoss bragg angles are located in the domain of achromatization $\alpha_1\alpha_2$ of Kα Cu. (C.V.% = 18)*

Note: *A broadening of the lines is observed when x rises. Blaine fineness of SiO_2 used for the synthesis: 12000 cm^2g^{-1} when $x = 0.1$, it seems that the intensity of the lines 440 and 008 is about 10%, lower than those observed with C_3A.*

intense quenching leads to β_1 belites and stabilizes an α' form for $x \geq 0.07$.

These observations, as N. F. Fedorov and E. R. Brodkina have already demonstrated, therefore seem to contradict the accepted fact that the formula $KC_{23}S_{12}$ represents K_2O belite (14).

Finally, the study of the process of inserting Si

into C_3A which we are continuing to study and which is included in the framework of the activities of C.E.T.I.C. (14) concerning the diffractometric measurement of this phase was based on the publication of A. E. Moore (15).

Considering the movement of the figurative point of the Rankin diagram along the C_3A–C_2S line, experience shows that the saturation corresponding to a contraction of the crystalline cell of 0.02 Å is obtained for 0.1 C_2S–0.9 C_3A with a purity rate of 95 per cent determined by the salicylic acid method of S. Takashima (16) (Fig. 7 groups all the observations).

Structures of α'-and α-Ca_2SiO_4

At this symposium, Regourd et al. (1) reported the existence of two α'–Ca_2SiO_4 forms: α'_H and α'_L (transformation temperature 1160°C). The high-form is *isotypic*, the low-form *homeotypic* to low-K_2SO_4. The structure of α'_L represents a small deformation of the α'_H structure, involving doubling of *a* and *b*. This is clearly evident from the structure determination of Suzuki and Yamaguchi (2). The space group of α'_H is Pmcn. For α'_L, however, it is not yet certain whether all the space groups listed in Table 1 actually occur (for instance in different solid solutions) but in all of these space groups structures homeotypic to low-K_2SO_4 may be attained.

For the high-temperature α-form only little data exist: On the basis of crystal-chemical considerations and by comparison of powder patterns. Bredig (5) suggested that this modification is trigonal and isotypic to high-K_2SO_4 (space group $P\bar{3}ml$). This result is supported by single crystal studies by Douglas (3).

Recent single crystal investigations, however, indicate that the symmetry of α-Ca_2SiO_4 and α-Ca_2GeO_4 is not trigonal but hexagonal (Table 2): For all three crystals the Laue symmetry 6/mm was clearly established. For two crystals a *c*-glide was found. Packing considerations exclude a mirror plane perpendicular to the six-fold axis. Therefore, of the three possible space groups, $P\bar{6}2c$, $P6_3/mmc$ and $P6_3mc$, the first two can be rejected and the last one appears to be the most probable space group

Table 1. *Lattice constants and space groups of* α'_L *and* α'_H-Ca_2SiO_4

Author	Type	a[Å]	b[Å]	c[Å]	Space group	Temperature of pattern	Material
Regourd et al. (1)	α'_L	11.184	18.952	6.837	Pmcn or Pbcn or Pmnn	1000°C	Powder, pure Ca_2SiO_4
Douglas (3)	α'_L	11.08	18.55	6.76	Pmnn (?)	750°C	Powder, pure Ca_2SiO_4
"	α'_L	10.91	18.41	6.76	Pmnn	20°C	Single crystals, bredigite
Suzuki and Yamaguchi (2)	α'_L	11.07	18.80	6.85	$Cmc2_1$	20°C	Single crystals, stabilized with BaO
" " "	α'_L	11.02	18.69	6.83	$Cmc2_1$	20°C	Single crystals, stabilized with SrO

Yamaguchi et al. (4)	α'_H	5.605	9.543	6.883	Pmcn	1300°C	Powder, pure Ca_2SiO_4

Table 2. *Crystallographic data of single crystals of* α-Ca_2SiO_4

Material (Stabilizer)	a[Å]	c[Å]	Extinctions	Probable space group
α-Ca_2SiO_4(6) (V_2O_5)	5.45	3 × 7.20	hhl with l odd	$P6_3mc$
α-Ca_2GeO_4(7) (Al_2O_3)	5.52	7.16	hhl with l odd	$P6_3mc$
α-Ca_2SiO_4(8) ($Na_4P_2O_7$)	5.47	7.23	None	(P6mm)

of hexagonal α-Ca_2SiO_4.*

If the new results are correct, the structures of α-Ca_2SiO_4 and α-Ca_2GeO_4 can not be isomorphous to high-K_2SO_4: In the hexagonal structure the apices of all tetrahedra are aligned in one direction (along the *c*-axis) while in the trigonal structure they are alternately oriented. Regardless whether the symmetry of α-Ca_2SiO_4 is hexagonal or trigonal, the transformation α'_H-α involves a structural rearrangement: Half of the tetrahedra must rotate but in each case different tetrahedra are involved.

Isotypism of Na_3BeF_5, Ca_3SiO_5 and Ca_3GeO_5

Structure and polymorphism of Ca_3SiO_5 and Ca_3GeO_5 are very similar (9). One of the present authors (10) showed that Na_3BeF_5 is the fluoride "model" of Ca_3SiO_5. Recent investigations revealed that at room temperature Na_3BeF_5 occurs in a triclinic modification, which is very similar to modification T_I of Ca_3SiO_5 and Ca_3GeO_5 (Table 3).

In this table the doubling of the *a*- and *b*-axes, as found for Ca_3SiO_5 (11), has been neglected. The close analogy of all three compounds is apparent. As expected, the fluoride has a smaller cell. We have indications that for Na_3BeF_5 also a monoclinic modification exists.

*Even if twinning is assumed, a hexagonal space group with a *c*-glide can not be derived from the trigonal space group $P\bar{3}ml$.

Table 3. *Lattice parameters of* Ca_3SiO_5, Ca_3GeO_5 *and* Na_3BeF_5 (*Modification* T_I)

	a[Å]	b[Å]	c[Å]	α[°]	β[°]	γ[°]

Modification M_I of Ca_3SiO_5

The monoclinic form M_I of Ca_3SiO_5 occurs in two types: Pure C_3S, between 980 and 990°C, has a mono-

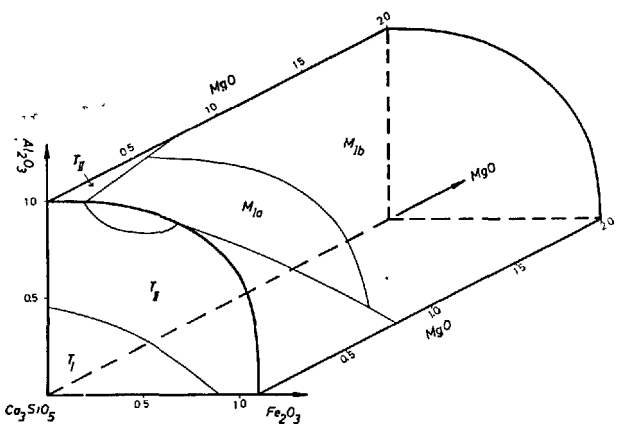

Fig. 2. *Body of solid solutions of* Ca_3SiO_5 *with* MgO, Al_2O_3 *and* Fe_2O_3 *(weight %). The domains of the stabilized modifications* T_I, T_{II}, M_{Ia} *and* M_{Ib} *on the surface of this body are indicated by thin lines.*

clinic cell with $a/b < \sqrt{3}$ and $\beta < 90°$ (11). For solid solutions at room temperature, however, only $a/b > \sqrt{3}$ and $\beta > 90°$ have been reported thus far. We have recently found that *both* types can be stabilized by incorporation of $MgO + Al_2O_3 + Fe_2O_3$. In Fig. 1 characteristic 2θ-values are plotted. The difference between both types is evident.

Previously (11), it was assumed that the two types represent different metrices of the unit cell of M_I. The *discontinuous* change with composition (Fig. 1), however, suggests the existence of two distinct forms: M_{Ia} with $a/b < \sqrt{3}$, $\beta < 90°$ and M_{Ib} with $a/b > \sqrt{3}$, $\beta > 90°$.

The composition region of the monoclinic Ca_3SiO_5 solid solutions with MgO, Al_2O_3 and Fe_2O_3 is subdivided into domains of M_{Ia} and M_{Ib} as shown in Fig. 2.

Further details will be reported in Zement-Kalk-Gips.

Oral Discussion

Kinzo Tomita

Guinier and Regourd show that α'-C_2S hardly reacts to water, that is, it may have no hydraulic property.

Ono, Kawamura and Soda (1), however, have reported on the α'-C_2S stabilization by MgO and K_2O, and Suzuki, Morita and Sugiyama (2) also have reported on the α'-C_2S stabilization by BaO, SrO and other additives. Both of these have shown that these α'-C_2S have a higher hydraulic strength than β-C_2S.

Oral Discussion

Yoshio Ono

In your study, M-II phase of alite is monoclinic after space group, but the three angles between the

orthohexagonal crystal axes are kept to be 90°, against variation of temperature and solid solution, and the inversion from R to M-II takes place continuously without detective heat change.

On our microscopic study, alite in portland cement clinker seems optically as if orthorhombic, e.g. $2V = 20° - 60°$ and X II c (3-fold axis of trigonal outer shape). The optical axial angle and birefringence are varied widely according as the variation of minute component and burning condition, but the parallelism between X and c is kept rigidly against the above variations.

I suppose that there is substantial relationship between your X-ray crystallographic result and my optical observation. Though these phenomena can not be explained by the symmetry of space group, these must not be accidental on view point of phenomenon.

I should be very much obliged if you would give me your opinion.

Oral Discussion

Hans E. Schmiete, W. Krönert and K. Deckert

According to our investigations the crystal chemical stabilization of C_2S is determined by three factors:

1. by the size of the stabilizing impurity ions or ion complexes
2. by the amount of stabilizer added
3. by the presence of a non-stabilizing substance, which may replace the stabilizer within certain limits

The Size of the Stabilizing Ion

According to the hypothesis of A. Dietzel and L. Tscheischwili (1), stability can be achieved in two different ways.

a) The Ca^{2+}-ions are replaced by a corresponding amount of larger cations, or
b) a part of $(SiO_4)^{4-}$-groups, is replaced by a smaller anion complex.

Our results for oxides of chrome and manganese can also be explained by this theory. We found in these experiments a relationship between the partial pressure of oxygen present and the stabilizing effect of C_2S, as follows:

At a pressure of ≥ 75 Torr O_2 for chrome and ≥ 150 Torr O_2 for manganese, the impurity ions will oxydize. Cr^{6+} with a radius of 0, 35 Å and M^{6+} with ~ 0.4 Å radius exist, so that the specified conditions for stability are fulfilled.

Quantity of Stabilizing Ion

With regard to the added stabilizers, H. Funk (2) found out, that the substances which stabilize α–C_2S as well as α'–C_2S, also supply β–C_2S when added in very small quantities. This is made clear in the case of Na_3BO_3, in which the quantities of 200, 100, and 1 mol per 1000 mol C_2S clearly showed the X-ray results: α-, α'-and β-forms respectively.

The Interchangeability of Stabilizing Ion

By our experiments we are able to show that stabilizers could be exchanged partly by iron, manganese and magnesium silicates. This is evident from X-ray diffraction diagrams of C_2S with a constant quantity of 3 mol% Ba_2SiO_4 and with variable admixture of Mg_2SiO_4, shown in Fig. 1.

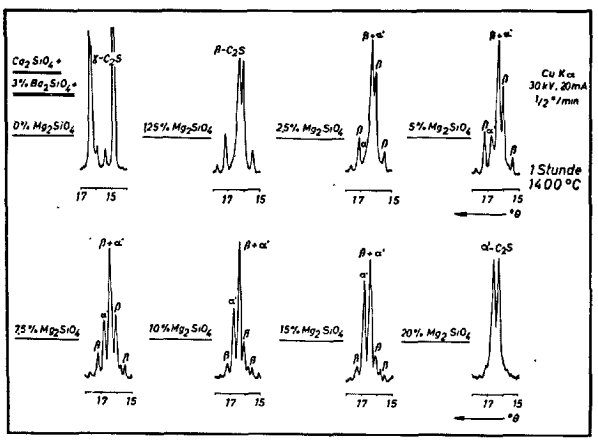

Fig. 1.

For the stability condition we propose the following hypothesis: According to the findings of M. Volmer (3), I. N. Stranski and co-workers (4, 5) on nucleation regarding the modifications of polymorphic transformation, there is below the transformation point for each temperature a critical nucleus size for the new phase. All the smaller nuclei return to the old phase, whilst all the larger nuclei grow and build up new modifications. As the rate of undercooling in-

creases the critical nucleus size decreases. The transformation of a sample into the new modification is more probable when cooled.

If one considers a substance stabilized by crystal chemical means, it can be deduced, that the nucleus growth will be interrupted by the stabilizing ions. But when these impurity ions are present in the sample in such quantities that no nucleus exceeds the critical size, than the old phase remains stable.

With this theory it is possible to explain the small amounts which are necessary for the stabilization in the case the change of phase is determined by spatial nuclei. Then by statistical division of the stabilizing ions, the substance is subdivided into small blocks whose corners are each occupied by an impurity ion. Because a stabilized ion belongs simultaneously to 8 adjoining blocks, it follows that one impurity ion is necessary for the stabilization of each block. But this would mean that at room temperature the amount of 0.1% for the prevention of β-γ-transformation of C_2S, would be required. So that a cube of C_2S of $10 \times 10 \times 10$ formula units could be stabilized by one stabilizing ion, and would correspond to a critical nucleus radius of ~ 15 Å.

According to the hypothesis of A. Dietzel and L. Tscheischwili (1), only those substances whose size allows them to fit well into the C_2S-lattice, act as stabilizers. Beside that certain substances, which because of their ion radii should not be structural effective, can replace the stabilizers within certain limits. This process may be explained by the higher degree of disorder, so that the incorporation of stabilizers into the C_2S-lattice is facilitated.

Because for α-C_2S as well as for α'-C_2S at room temperature the degree of supercooling correspondingly increases, a greater number of impurity ions is necessary for the stabilization of these modifications, compared with β-C_2S.

Authors' Closure

André Gunier and Micheline Regourd

Reply to J. Forest

Dr Forest's contribution establishes a link between the behaviour of the pure components and the reactions actually taking place during the clinkerisation of industrial products: synthesis of belites and alites have been carried out in presence of minor oxides MgO, Al_2O_3, TiO_2, K_2O and sulfates $CaSO_4$, K_2SO_4.

Another important and new result is the evaluation of the maximum content of CaO which can be introduced in βC_2S (0.5%): these additions of CaO cause an increase of the $\alpha'_H \rightarrow \alpha$ transition temperature. However one must note that the accuracy of the chemical analysis is of the order of 0.2%. Furthermore the state and location in the lattice of the excess Ca ions is not known. Perhaps CaO is simply dissolved in the lattice or its introduction is accompanied by imperfections like oxygen vacancies for instance.

Dr. Forest's reports that "the symmetry deduced from the X-ray spectrum is sometimes superior to that which the interpretation of the DTA thermogram furnishes". G. Yamaguchi, K. Shirasuka and T. Ota have shown that the monoclinic alite in the system C_3S–Al_2O_3–MgO is thermodynamically instable. During a slow heating, the monoclinic form inverts to the stable triclinic form. In agreement with these results, Th. Hahn, E. Woermann and W. Eysel have found that the M_I forms in the C_3S–MgO solid solutions, during heating, transforms first into T_{II} at about 700°C, the temperature being dependent on the amount of MgO. Further heating causes the usual endothermic transformation T_{II}–M_I at about 900°C.

Reply to Th. Hahn, W. Eysel. P. Brenner and E. Woermann

Phase transformation of $\alpha \rightarrow \alpha'$ Ca_2SiO_4

It seems difficult to characterize surely the nature of the $\alpha \rightarrow \alpha'_H$ C_2S transformation. Perhaps this transition is not purely displacive as indicated by the sharp and reversible DTA signal or the α C_2S structure is not trigonal as suggested by Bredig but hexagonal.

Stabilized crystals of α C_2S have an hexagonal structure, however the space groups are different. In the solid solutions, the nature and amount of the stabilizer, the burning and cooling of the sample can modify substantially the structure of α C_2S. Further

studies would be necessary.

Modification M_I of Ca_3SiO_5

The discontinuous change of the two C_3S monoclinic forms M_{Ia} and M_{Ib} in Al_2O_3, Fe_2O_3, MgO, C_3S solid solutions is very interesting.

We had also found two types of M_I modification in synthesized MgO-C_3S solid solutions: M_{Ia} for $C_3S + 1.25$ MgO and M_{Ib} for $C_3S + 2\%$MgO (we had called it inverted form). The last form is metastable: M_{Ia} is obtained, at room temperature, after 4 hours at 650°C.

Reply to K. Tomita

We thank Mr. K. Tomita for his contribution on hydrated $\alpha'C_2S$ strength.

In our paper, we had reported Dr. Nurse's results: $\alpha'C_2S$ stabilized by P_2O_5 hardly reacts to water. However, another stabilizers such as MgO, K_2O, BaO, SrO ... can modify the C_2S lattice and give better hydraulic properties.

Reply to Y. Ono

The M_{II} form of pure C_3S is monoclinic with $\beta = 90°$. The lattice parameters have been obtained accurately by indexing powder patterns on a pseudo-hexagonal lattice.

The shape of the crystal lattice is orthorhombic. Dr. Ono's microscopic observations show the parallelism between the optical axis X and the axis $\vec{c}$. However, the stacking of the structural groups does not permit the orthorhombic symmetry: there is no orthorhombic subgroup of the R 3 m trigonal space-group and the $R \rightarrow M_{II}$ transformation is small and continuous. However, we have not exactly proved this result. Only Laue and oscillation photographs of a single crystal would distinguish a pseudo-orthorhombic form from a true orthorhombic structure.

Another examples of monoclinic structures with $\beta = 90°$ exist. For instance, the W V_2O_7 crystals are monoclinic (1) with the parameters $a = 12.20$, $b = 3.72$, $c = 3.95$ Å, $\beta = 90°$.

Reply to H. E. Schwiete, W. Krönert and K. Decket

According to the working hypothesis of A. Dietzel and L. Tscheischwili on the size of the stabilizing ions, H. E. Schwiete, W. Krönert and K. Deckert have given two examples showing that, in the C_2S lattice, the Ca^{2+} ions (0.99 Å) may be replaced only by a respective amount of bigger cations or a part of $(SiO_4)^{4-}$ groups (Si = 0.39 Å) is replaced by a smaller anion complex.

But our own experiments do not verify this criteria. J. Forest (1) has been able to synthesize some belites $Ca_2\ M_x\ Si_{1-x}\ O_{4-x/2}$ in which. M = Al^{3+} (0.50 Å) and Fe^{3+} (0.64 Å) are out of the precedent limits, however the β form is obtained.

Closure

The Supplementary Papers and Discussions permit to clarify some problems and to propose further studies on the structures of portland cement minerals.

C_3S The results of C_3S studies are the most complete. The list of the transition points and the various phases is definitively established. The identification of any alite form is possible and sure with high resolution X-ray diffraction and DTA. However, the DTA diagrams must be interpreted with care in the case of inverted monoclinic forms M_{Ib} and M_{IIb} which are decomposed above 600°C. Some alites, similar to those found in clinkers have been synthesized: they are solid solutions with Al_2O_3, Fe_2O_3, MgO, Cr_2O_3, TiO_2, MnO_2. It shall be possible to classify all the alites of clinker with the combined use of electron probe microanalysis which identifies the foreign ions and X-ray diffraction which characterizes the crystalline structure.

The six forms of C_3S have very close crystal structures and present a similar reactivity. Only the early strength can be increased in presence of some foreign ions as Cr_2O_3 but these effect does not persist.

C_2S A new transformation $\alpha'_L \overset{1170°C}{\rightleftarrows} \alpha'_H$ C_2S has been detected by DTA and X-ray diffraction. The α'_L form is a superstructure of the orthorhombic α'_H structure (a and b doubled).

The structures of the α' and α forms are not well known. Stabilized crystals of these forms have different space groups. Further studies would be necessary about the following topics:

—the nature of the $\alpha \rightarrow \alpha'_H$ transition

—the space group of the α and α'_L forms

—the formation of α' and α belites

—the introduction of CaO in βC_2S

The five forms of C_2S have different structures and present different hydraulic properties. The minor oxides, present in the clinker, can modify the crystal lattice of C_2S and affect the cementive properties of belites.

C_3A The structure of C_3A is not known. In the cubic lattice, the aluminium/oxygen coordination is probably all tetrahedral. A new paper (1) on isomorphous replacement in tricalcium aluminate indicates that the aluminium ions are not in AlO_6 octahedra and the Ca^{2+} ions occupy two types of reticular sites.

In C_3A, it is possible to replace the group Ca–Al by Na–Si, K–Si. Orthorhombic C_3A solid solutions with alkalis would be more reactive at early ages than cubic forms.

C_4AF Solid solutions of $C_2(A_pF_{1-p})$ with MgO, Cr_2O_3, Mn_2O_3 have been synthesized. Microcrystalline ferrite phase has been observed in industrial clinkers by X-ray diffraction (broad powder lines); the Mössbauer spectra (2) of Fe^{57} of the ferrite present in portland cement can be understood assuming that the volumes of some of the ferrite particles are small enough to show superparamagnetism instead ferromagnetism.

Supplementary Paper I-10 Synthesis and Cyrstallographic Investigation of Some Belites

Micheline Regourd,* Michel Bigaré,* Jean Forest and André Guinier*****

Belites in clinker are solid solutions of dicalcium silicate. Their X-ray diagrams are, usually, similar to that of the βC_2S form, more rarely to that of the $\alpha' C_2S$ forms.

Dicalcium Silicate

The structure of the five C_2S forms is described in the Principal Paper entitled "Structure of Portland Cement Minerals" (1).

At high temperature ($t > 1420°C$) the αC_2S form is hexagonal. We have calculated the lattice constants from powder pattern: $a = 5.526$, $c = 7.307$ Å at 1500°C. These results agree with those of Yamaguchi, Ono, Kawamura and Soda (2): $a = 5.527$, $c = 7.311$ Å, space group $P\bar{3}m1$.

With decreasing temperature, the α variety gives the α' form. By X-rays and D.T.A., Niesel and Thormann (3) have proved the existence of two α' forms: α'_H and α'_L whose stability domains are respectively 1420–1165°C and 1165–650°C. We have confirmed the existence of these two $\alpha' C_2S$ forms.

At 1250°C the parameters of the orthorhombic $\alpha'_H C_2S$ unit cell are $a = 5.593$, $b = 9.535$, $c = 6.860$ Å, space group Pmcn (Table 1).

Yamaguchi, Ono, Kawamura and Soda (2) have found the same unit cell $a = 6.883$, $b = 5.606$, $c = 9.543$ Å, space group Pnma at 1300°C.

We have determined the lattice of the α'_L form, at 1000°C.

The orthorhombic parameters are $a = 11.184$, $b = 18.952$, $c = 6.837$ Å, space group Pmcn (Table 2).

Table 1. $\alpha'_H C_2S$ (1250°C)

hkl	I/I_1	$d_{observed}$	$d_{calculated}$

The doubling of a and b parameters is required by the presence of five weak lines which cannot be indexed with a cell similar to α'_H cell ($d_{231} = 3.565$ Å, $d_{122} = 3.088$ Å, $d_{341} = 2.699$ Å, $d_{350} = 2.658$ Å, $d_{123} = 2.176$ Å).

A.M.B. Douglas (4) using a natural mineral, bredigite $Ca_{1.59}$ $Ba_{0.08}$ $Mg_{0.31}$ $Mn_{0.09}$ SiO_4 usually considered identical with $\alpha'C_2S$ has found an analogous cell a = 10.91, b = 19.41, c = 6.76 Å space group Pmnn and on the other hand she indexed Trömel's (5) powder data taken at 750°C with an orthorhombic cell of parameters a = 11.08, b = 18.55, c = 6.76 Å.

The $\alpha'_H \rightarrow \alpha'_L$ transition corresponds therefore to a superstructure and beside to a small change of parameters.

The Fig. 1 shows the microdensitometer tracings of α'_H and α'_L focussing film patterns. At 1250°C, the calculated components of the doublet 220, 112 being only separated by 1×10^{-3} Å (Table 1) are not resolved on the powder pattern but it is obvious that the 200 line is broader than the single line 130.

The transition $\alpha'_L \rightarrow \beta$ takes place at 650°C. The β structure is monoclinic (6). The new parameters of pure β C_2S, calculated from powder Guinier camera pattern, at room temperature, are a = 5.506, b = 6.749, c = 9.304 Å, $\beta = 94.62°$, space group $P\,2_{1/n}$.

Yannaquis and Guinier (7) have suggested that the βC_2S, B_2O_3 solid solutions correspond to a partial substitution of $(SiO_4)^{4-}$ by $(BO_4)^{5-}$ groups and to the formation of tetrahedric vacancies in order to maintain electroneutrality in the lattice by the elimination of Si^{4+} ions (probably in the form of silica). The insertion of supplementary ions seems difficult in a lattice as compact as that of βC_2S. Sasaki (8), Schlaudt and Roy (9) have shown that β form is not stabilized in Ca substituted preparations.

Forest (10) has been able to prepare some belites similar to those found in clinker. These belites are oxygen-defective solid solutions with Si substituted, with general formula $Ca_2M_xSi_{1-x}O_{4-x/2}$. In the C_2S crystal lattice, the exchange reaction $2Si^{4+} + O^{2-} \rightarrow 2M^{3+}$ forms the solid solutions at temperatures higher than $\alpha'_H \rightarrow \alpha$ inversion.

The limits of solubility of Al, Fe, B in C_2S have been determined by D.T.A., through the decrease of the $\alpha'_H \rightarrow \alpha$ transition temperature (Fig. 2). The microscopic examination shows that the belite generally bistriated by the quenching contains a very small amount of interstitial phase located at the grain boundaries (Fig. 3 (a)).

Belite is apparently a non-equilibrium phase. In a belite containing alumina, synthesized at 1550°C, a very rapid quenching from 1550°C stabilizes a large part of α' type form, quenching from 1450° gives a mixture of α' and β forms and from 1000°C the β form with C_3A (Fig. 4). Furthermore, the microscopic examination of slowly cooled belites reveals the presence of solutes within the β grain which is spotty (Fig. 3 (b)).

Crystallographic investigation of some β Belites

Powder patterns of four β belites $Ca_2M_xSi_{1-x}O_{4-x/2}$ in which M = B, Al = Fe, and the C_2S–C_2F mixture are reproduced in Fig. 5. The comparison with the βC_2S diagram shows the displacement of some lines,

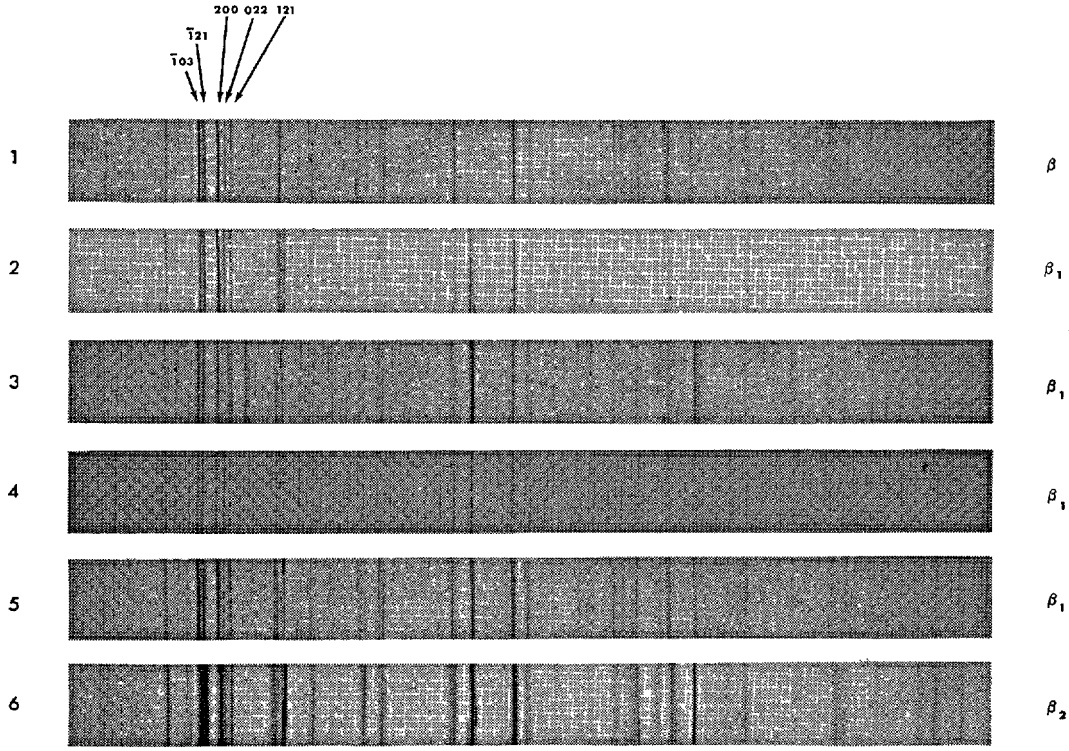

Fig. 5. *X-ray diagrams of some β belites (Guinier camera, Cu K* α_1 *radiation).*
1. βCa_2SiO_4
2. $Ca_2B_{0.01}Si_{0.99}O_{3.995}$
3. Ca_2SiO_4(70%) + Ca_2FeO_5(*30%*) (*presence of* C_2F)
4. $Ca_2Fe_{0.012}Al_{0.012}Si_{0.976}O_{3.988}$ (*prerence of* γC_2S)
5. $Ca_2Fe_{0.035}Al_{0.035}Si_{0.930}O_{3.965}$
6. $Ca_2Fe_{0.050}Al_{0.050}Si_{0.900}O_{3.950}$

in particular $\bar{1}03$, $\bar{1}21$ and 200, 022, 121.

Belite is a product of imperfect crystallisation. With increasing proportion of foreign ions, reflections are broader and broader (see in Fig. 5, M = Al, Fe, in 4, 5, 6).

The lattice constants of five β belites have been calculated, the results being collected in Table 3. The βC_2S lattice is slightly altered, the symmetry remaining monoclinic. We have called β_1 the type of belites in which the βC_2S lattice is not significantly modified and β_2 a belite such as $Ca_2Fe_{0.05}Al_{0.05}Si_{0.90}O_{3.95}$ in which the powder pattern presents broad lines and a modification more important of the triplet 200, 022, 121, corresponding to a larger variation of c and β parameters.

Table 3. *Lattice constants of some β belites*

Type of belite	Constitution Formula	$a_{(Å)}$	$b_{(Å)}$	$c_{(Å)}$	$\beta_{(°)}$
	$\beta\ Ca_2SiO_4$	5.506	6.749	9.304	94.62
β_1	$Ca_2Al_{0.10}Si_{0.90}O_{3.95}$ (quenched at 1000°C)	5.499	6.745	9.318	94.53
β_1	$Ca_2B_{0.01}Si_{0.99}O_{3.995}$	5.503	6.749	9.302	94.51
β_1	$Ca_2Fe_{0.035}Al_{0.035}Si_{0.930}O_{3.965}$	5.502	6.750	9.316	94.45
β_1	Ca_2SiO_4(70%) + Ca_2FeO_5(30%)	5.507	6.755	9.325	94.45
β_2	$Ca_2Fe_{0.050}Al_{0.050}Si_{0.900}O_{3.950}$	5.502	6.753	9.344	94.19

Synthetic belites of β_1 type with M = Al, Fe are similar to some belites extracted from industrial clinkers (10) but are different from solid solutions C_2S, B_2O_3 (11) wich approach β_2 belites.

Conclusion

The X-ray diagrams of belites are similar to those of β and $\alpha'C_2S$ forms.

The precise parameters of $\beta, \alpha'_L, \alpha'_H, \alpha C_2S$ have been calculated from powder Guinier camera patterns. Our observations on pure dicalcium silicate confirm the previous data obtained with bredigite, C_2S solid solution. The α'_H—α'_L transition, at 1170°C, corresponds to a superstructure (a and b doubled) and a very small change of lattice which remains orthorhombic.

In the C_2S crystal lattice, the reaction $2Si^{4+} + O^{2-} \rightarrow 2M^{3-}$ forms belites at temperatures higher than $\alpha'_H \rightarrow \alpha$ inversion. These solid solutions, oxygen-defective compositions $Ca_2M_xSi_{1-x}O_{4-x/2}$, synthesized at 1500°C, are metastable in the case of M = Al, Fe. Furthermore, a decrease of foreign ions solubility in C_2S is observed after a long heating at high temperature.

The crystal lattice of stabilized belites, similar to some belites extracted from industrial clinkers is monoclinic, corresponding to a slightly altered βC_2S lattice. However belites are products of imperfect crystallization.

It seems to exist one form of $\alpha'C_2S$ type, its lattice constants shall be calculated.

Other β belites may be synthesized in the presence of sulphates and alkalis. Their powder patterns are similar to those of precedent belites.

Supplementary Paper I-36 Cation and Anion Replacements in the Structure of Tricalcium Silicate

Nikita A. Toropov*

Synopsis

This article contains the results of experimental work by the author and his collaborators establishing numerous cases of formation of solid solution between different constituents of portland cement clinker. The authors have established the dissolution of rare-earth oxyorthosilicates in tricalcium silicate, the formation of continuous solid solution between Ba_2GeO_4–Ba_2SiO_4, between Ca_3SiO_5–Ca_3GeO_5 etc. These studies were accomplished with the aid of the polarizing microscope, X-rays, and thermal analysis.

Crystal Lattice of Tricalcium Silicate

The anionic part of the structure of tricalcium silicate is treated usually as constructed by silicon-oxygen tetrahedra SiO_4^{4-} and by additional oxygen ions which do not participate in the formation of tetrahedra. The cationic part of the structure is formed by calcium ions characterized by two kinds of oxygen coordination polyhedra.

The accurate determination of the crystal structure of tricalcium silicate using direct diffraction methods is rather complicated. The main difficulties are connected with large single cell parameters, existence of superstructure and with complexity of the mutual coordination of atoms composing this structure. And this is why other methods of crystal chemistry are of great importance. The study of compounds isostructural (or isomorphous) to tricalcium silicate is especially promising. Equally important are the investigations of solid solutions produced by tricalcium silicate and its structural components with some other radicals.

The most useful and effective is the studying of the crystals of chemical compounds isostructural to C_3S.

Solid Solutions of Tricalcium Silicate

Particular investigations of the solid solutions formed by C_3S or its separate structural radicals and various structural constituents are of special value. A waste number of isovalence or hetervalence type substitutions are possible as well as partial penetration of some atoms and ions in the lattice of tricalcium silicate.

These solid solutions may be confined by certain limits of possible replacements or may be quite continuous. However the second type of solid solutions formed by C_3S has not yet been described in literature.

Contrarily, all examples studied up to date have been characterized by small concentrations of replacements in the matrix lattice of C_3S (0.5 to 5.0 weight %).

Only recently in our laboratory the possibility of the full replacement of one of the structural units has been demonstrated in the system $3CaO \cdot SiO_2$–$3CaO \cdot GeO_2$ by Boikova, Toropov and Vavilonova (1). Nonlimited substitution of SiO_4^{4-} radicals by isomorphous radicals GeO_4^{4-} takes place in this system. It is worth mentioning that in the case of the system $2BaO \cdot SiO_2$–$2BaO \cdot GeO_2$ there occurs only a very narrow region of interruption according to

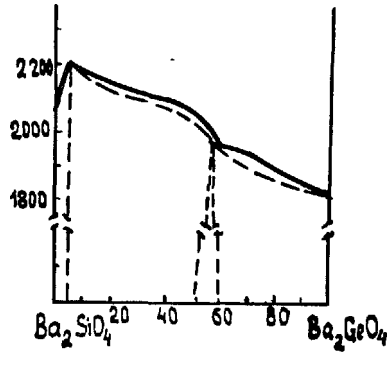

Fig. 1. *Phase diagram of the system* Ba_2SiO_4–Ba_2GeO_4

*The Academy of Science of the USSR, Institute of Silicate Chemistry, Leningrad, U.S.S.R.

Grebenschikov, Toropov (2).

The possibility of the synthesis of C_3S single-crystals where one of the structural components–SiO_4^{4-} is fully replaced by other component with larger atomic weight is of great importance for the further X-ray investigations of the initial crystal and its structural analog.

In our recent investigations special attention has been paid to the structural transitions between the states with different degree of ordering of the atomic arrangement in the structure of tricalcium silicate.

These transformations for the case of pure tricalcium silicate have been previously examined by X-ray and DTA methods by Regourd (3, 4). Only a few data are available concerning such transformations in solid solutions of this compound.

Nonstoichiometry of the Composition of Tricalcium Silicate

The synthesis of nonstoichiometric forms of C_3S and of solid solutions of C_3S with the excess of CaO is considered to be very important. The possibility of the penetration of some additional amounts of calcium oxide into the lattice of tricalcium silicate has been found in our laboratory in the course of the examination of the solid solutions between $Ca_3O \cdot SiO_4$ and $Y_2O \cdot SiO_4$.

The choice of yttrium silicate as a component of this new type of the solid solutions was made by various reasons. One of them is the closeness of the ionic radii $Ca^{2+} = 0.96$ Å and $Y^{3+} = 0.99$ Å (according to Pauling's data). The other one is concerned with the similarity in chemical structure of both silicates. The differencies between these compounds in optical properties, density and other characteristics provide the use of yttrium oxyorthosilicate and some other rare-earth silicates as a kind of crystal chemicals indicators. The determination of concentration limits for solid solutions, and the study of complex polymorphism of them are considerably simplified when using such indicators.

For example, only the use of this method enables us to succeed in the determination of the possible entering of some excess calcium atoms into the lattice of C_3S and its solid solutions.

Microscopical (in transmitted and in reflected light) and X-ray analyses of the samples with 6–7 weight % of yttrium oxyorthosilicate proved the homogeneity of this solid solution. At higher concentrations this silicate separates into a second crystalline phase.

From these data follows the formation of a limited series of solid solutions between $Ca_3O \cdot SiO_4$ and $Y_2O \cdot SiO_4$.

All samples of solid solutions contained some amounts of β–Ca_2SiO_4 and γ–Ca_2SiO_4 crystals.

The amounts of these crystals increased with increasing yttrium oxyorthosilicate contents and reached the value of 10-15%. The increase in the number of the vacant positions in the structure caused by the heterovalent replacement $3Ca^{2+} \rightleftarrows 2Y^{3+}$ is the cause of this phenomenon. The filling of these vacancies causes formation of the solid solutions of oxyorthosilicates with the excess CaO according to the stoichiometric ratio 3: 1.

The chemical analysis data given in Table 1 confirmed these predictions and showed that the excess of chemically bonded CaO increased from 0.5 weight % in pure $Ca_3O \cdot SiO_4$ to 2.5–3.0 weight % in the solid solution. The accuracy of the determinations amounted $\pm 0.3\%$ for CaO and $\pm 0.2\%$ for SiO_2 and Y_2O_3.

These results were checked up additionally using the C_3S samples obtained by sintering $CaCO_3$ precipitated from $Ca(NO_3)_2$ and $(NH_4)_2CO_3$ of high purity and by sintering rock crystal.

Our data concerning C_3S polymorphism are well correlated with polymorphism of its crystal chemistry analog—tricalcium germanate, and region of solid solutions in the phase diagram for the system $3CaO \cdot SiO_2$–$3CaO \cdot GeO_2$.

DTA data (Fig. 4) show that increasing germanate concentration in the solid solution primarily causes slight decrease in the temperatures of endothermic effects. Then these temperatures begin to increase and approach those for germanate. According to Regourd (4) phase transitions of C_3S are as follows:

$$\text{triclinic I} \overset{620^\circ C}{\rightleftarrows} \text{triclinic II} \overset{920^\circ C}{\rightleftarrows} \rightleftarrows \text{triclinic III} \overset{970^\circ C}{\rightleftarrows} \text{monoclinic} \overset{990^\circ C}{\rightleftarrows} \rightleftarrows \text{orthorhombic} \overset{1050^\circ C}{\rightleftarrows} \text{hexagonal.}$$

T_{II}— " " " (II)
T_{III}— " " " (III)

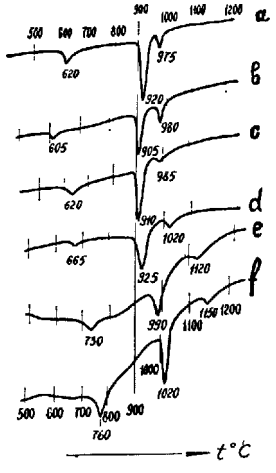

Fig. 4. *DTA-curves of solid solutions* Ca_3SiO_5-Ca_3GeO_5

These transitions of $3CaO \cdot GeO_2$ take place according to our data at 750°, 1020°, 1150°C and are as follows:

$$\text{triclinic I} \overset{750^\circ C}{\rightleftarrows} \text{triclinic II} \overset{1090^\circ C}{\rightleftarrows} \rightleftarrows \text{tricilinic III} \overset{1150^\circ C}{\rightleftarrows} \text{monoclinic}$$

It was previously shown by Toropov, Boikova (5)(6) that C_3S can contain some amount of the excess CaO according to the stoichiometric ratio 3: 1.

This content of nonstoichiometric CaO can be increased with increasing firing temperature. Deviations from stoichiometry were also observed in $3CaO \cdot GeO_2$.

Chemical analysis of $3CaO \cdot GeO_2$ carried out for the composition containing excess CaO proved that the excess CaO in germanate can achieve 1.5 weight %. The presence of free lime was not observed.

solutions recorded in the interval 700–1200 cm^{-1}. They are in agreement with other data indicating the formation of continuous solid solutions. Some shift of Si–O stretching bands to lower wave numbers corresponding to the increasing $3CaO \cdot GeO_2$ content is typical of orthosilicate-orthogermanate solid solutions. On the other hand, Ge–O stretching bands between 700 and 800 cm^{-1} move to slightly higher wave numbers when the content of the silicate increases. This concentration dependence is another straightforward indication of continuous series of solid solutions in this system.

The above-mentioned system $3CaO \cdot SiO_2$–$Y_2O_3 \cdot SiO_2$ is an example of C_3S solid solutions with limited solubility of another component. Phase diagram for its subsolidus region is shown in Fig. 2 according to Boikova and Toropov (7).

Electron Microscopic Investigations

Studies of solid solutions of C_3S with various oxides have been carried out in our laboratory with the aid of electron microscope. The main points of this investigation are:

1. Morphological study of crystals of solid solutions.
2. Observations of some defects of crystal surface with various minor components.
3. One of the first tasks of this investigation is connected with refinements in sample preparations and conditions of etching. Figs. 6 and 7 give the obtained photomicrographs which show different forms of etching figures, their interorientation and emergences of dislocations.

Supplementary Paper I-54 Polymorphism and Solid Solution of the Ferrite Phase

Eduard Woermann, Walter Eysel and Theodor Hahn*

Synopsis

In the ferrite solid solution $Ca_2(Fe_{1-p}Al_p)_2O_5$ with $0 \leq p \leq 0.70$ magnesium is incorporated according to two different substitution schemes. For $0 \leq p < 0.50$ the substitution ratio Ca/Mg = 2/3 is verified (limit of solid solution 1.6 mol. % MgO), while for $p \geq 0.50$ the ratio is Ca/Mg = 1/3 (solubility limit 3.0 mol.% MgO).

The curves of the lattice parameters as a function of p indicate two discontinuities at $p \approx 0.30$ and $p \approx 0.50$.

DTA-investigations of $Ca_2Fe_2O_5$ revealed two polymorphic transformations of very small enthalpies. High-temperature X-ray patterns showed that the three modifications are very similar.

DTA-results on samples with varying p support the discontinuities at $p \approx 0.30$ and at $p \approx 0.50$.

Introduction

Since the publication by Hansen, Brownmiller and Bogue (1) on the system $CaO–Al_2O_3–Fe_2O_3$ the ferrite solid solution series $Ca_2Fe_2O_5$–"$Ca_2Al_2O_5$" has been the subject of many detailed investigations. The present paper deals with the polymorphism of the ferrite series and its solid solution with MgO.

The ferrites are represented by the chemical formula $Ca_2(Fe_{1-p}\ Al_p)_2O_5$ where, (Majumdar (2)), $0 \leq p \leq 0.70$ (line C_2F–L in Fig. 1). According to Swayze (3), in equilibrium with free CaO the solid solution terminates slightly below $p = 0.50$, according to Newkirk and Thwaite (4) and Majumdar (2) slightly above this value. In agreement with the latter we found $p = 0.52$ for the limiting composition of ferrites in equilibrium with free CaO and aluminate at 1300°C (point B in Fig. 1).

Substitution of Magnesium in Ferrite

The fact that the ferrites take up MgO in solid solution is well known. Fujii and Asaoka (6) as well as Schwiete and zur Strassen (7) observed that a normally reddish-brown ferrite acquires a greenish-black colour in the presence of MgO. The latter authors found that upon incorporation of MgO into the ferrite structure no CaO is liberated. They concluded that Mg cannot substitute for Ca. On the other hand, Kato (8) as well as Sanada and Miyazawa (9, 10) assume replacement of Ca by Mg. The limits of solid solution are given by Sanada and Miyazawa to be < 1.0 wt.% MgO in $Ca_2Fe_2O_5$ ($p = 0$) and 1.5% in Ca_2FeAlO_5 ($p = 0.50$).

We have investigated the modes and limits of substitution of Mg by means of the "lime deviation method": The original ferrite sample was synthesized with a small excess of free CaO which was analytically determined using the method of Franke (11). Subsequently, a definite amount of MgO was added to the sample and after equilibration at 1300°C the free CaO was analyzed again. From the gain or loss of free CaO the type and limit of substitution of MgO in the structure can be derived. This procedure is of high accuracy (maximum error ±0.05% CaO). It should be noted, however, that it can only be applied to phase assemblages containing free CaO in equilibrium.

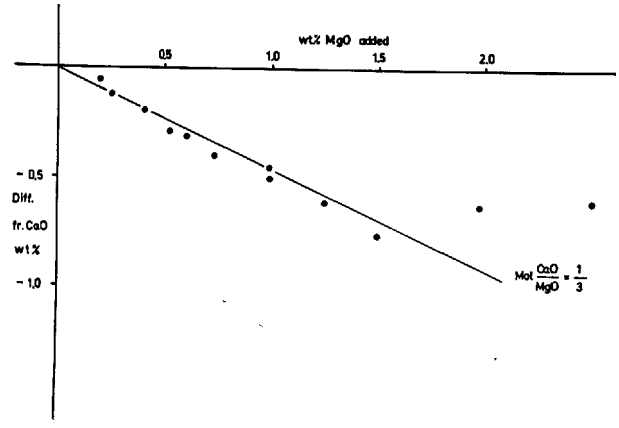

Fig. 3. *Decrease in free* CaO *as a function of incorporation of* MgO *in* Ca_2FeAlO_5 *(p = 0.50). Temperature of ignition 1300°C.*

Fig. 2 represents the results for $Ca_2Fe_2O_5$: Upon addition of MgO the amount of free CaO is reduced, i.e. additional CaO is combined by the ferrite. Beyond 0.7% MgO the amount of free CaO remains constant. Surplus MgO forms periclase without reacting with the ferrite phase. Thus the bend in the curve represents the limit of solid solution.

The slope of the curve corresponds to an atomic ratio Ca/Mg = 2/3. This indicates that incorporation of three Mg atoms causes two additional Ca-atoms to enter the structure, resulting in a solid solution of $Ca_2Fe_2O_5$ with the hypothetical end member "$Ca_2Mg_3O_5$". This implies that two out of three Mg^{2+} ions replace two Fe^{3+} ions, while the third Mg^{2+} ion occupies one of the interstitial sites, according to the formula:

$$Ca_2^{2+}Mg_{\frac{x}{3}}^{2+}[Fe_{1-\frac{1}{3}x}^{3+}Mg_{\frac{1}{3}x}^{2+}]_2O_5 \qquad (1)$$

with $0 \leq x \leq 0.045$ at 1300°C.

Similar investigations on Ca_2FeAlO_5 (p = 0.50) gave somewhat different results (Fig. 3): Again, additional CaO is combined by incorporation of MgO (solubility limit 1.5% MgO). The atomic substitution ratio, however, is changed to Ca/Mg = 1/3, i.e. with three Mg atoms one additional Ca atom is incorporated. This leads to another solid solution with the hypothetical end-member "$CaMg_3O_4$" = "$Ca_5Mg_{15}O_{20}$".

This end-member can be compared with the pure ferrite $Ca_2R_2O_5$:

$$[Ca_8] \qquad [R_8]O_{20}$$
$$[Ca_5Mg_3] \quad Mg_4 \quad [Mg_8]O_{20}$$

where $R = Fe^{3+}, Al^{3+}$

Thus, the solid solution involves simultaneous Mg-substitution in three different structural sites: Replacement of Ca, replacement of R and occupation of interstitial positions. This effect can be described as superposition of the two simple substitution types

$[Mg_8]$		$[R_8]O_{20}$	Ca/Mg = −1 (Ca/Mg-substitution)
$[Ca_8]$	Mg_4	$[Mg_8]O_{20}$	Ca/Mg = +2/3 (end-member of (1))

in the fixed ratio 1: 4, resulting in formula (2) for Mg-incorporation into a ferrite with p = 0.50.

$$[Ca_{1-\frac{x}{10}}Mg_{\frac{x}{10}}]_2Mg_{\frac{4}{15}x}[R_{1-\frac{4}{15}x}Mg_{\frac{4}{15}x}]_2O_5 \qquad (2)$$

with $0 \leq x \leq 0.100$.

Figs. 4 and 5 represent the solid solutions of the ferrites with p = 0 and p = 0.50 resp. in the respective "ternary" systems.

The question arises on whether the change from the

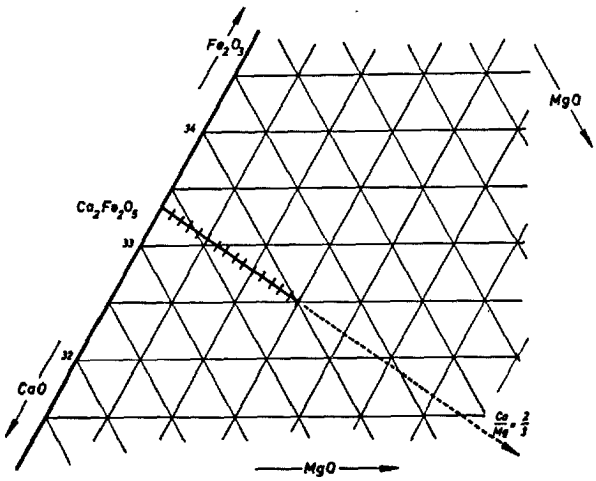

Fig. 4. *Solid solution of* $Ca_2Fe_2O_5$ *in the ternary system* CaO–MgO–Fe_2O_3 *at 1300°C; concentration lines in intervals of 0.5 mol. %.*

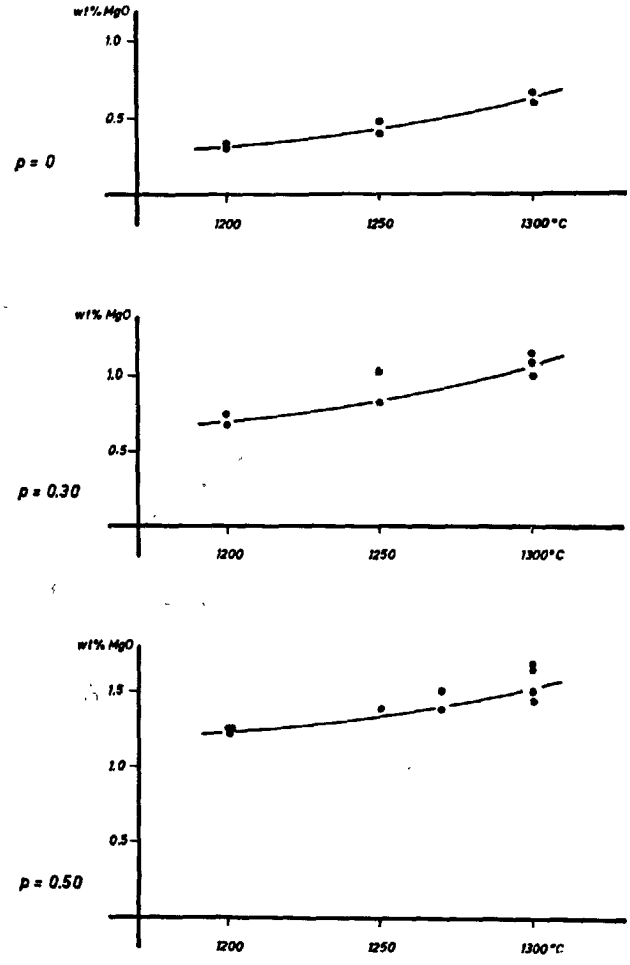

Fig. 6. *Solubility of MgO in several ferrites as a function of temperature.*

substitution ratio Ca/Mg = 2/3 to Ca/Mg = 1/3 is gradual or whether occurs as a discontinuous step. Experiments show that Mg is substituted according to formula (1) in ferrites with $0 \leq p \leq 0.48$, and according to formula (2) in ferrites with $0.50 \leq p \leq 0.52$. The composition p = 0.49 gave somewhat scattering results. Members with $p > 0.52$ cannot be investigated by the lime-deviation method since they are not stable in equilibrium with free CaO (see Fig. 1). Therefore, it could not be ascertained whether formula (2) is valid up to p = 0.70.

These results indicate an abrupt change in the mode of substitution of MgO near p = 0.49 to 0.50. Since all specimens were quenched rapidly, a transformation of one type into the other during cooling can be excluded, particularly in view of the structural rearrangements involved. The observed substitution type of Mg, therefore, corresponds to that of the temperature of synthesis (1300°C).

The solubility limit of MgO increases with the Al-concentration as well as with temperature (Fig. 6). At 1300°C, the limits are 0.7 wt.% MgO for $Ca_2Fe_2O_5$ and 1.5 wt.% MgO for Ca_2FeAlO_5, corresponding to 1.6 mol.% MgO and 3.0 mol.% MgO resp. These data are in good agreement with those of Sanada and Miyazawa (9, 10).

X-ray Investigations

X-ray investigations of the ferrite series have been carried out by various authors. Smith (12) has established a structural discontinuity around $p = 0.30$. For $p < 0.30$ the space group is Pnma, in agreement with the structure determination by Bertaut, Blum and Sagnieres (13). Above $p = 0.33$ the higher-symmetrical space group Imma exists. The change of the structure is gradual as indicated by the continuous decrease of the intensities of certain reflexions and their final disappearance at $p \approx 0.30$. In $Ca_2Fe_2O_5$ half of the Fe atoms occupy octahedral, the other half tetrahedral positions. Smith assumes that in the Pnma-phase the tetrahedral Fe are preferentially replaced by Al, while above $p = 0.33$ the rate of Al-substitution in both positions is nearly equal. This assumption has been confirmed by Tarte (14) with the aid of infrared absorption spectra and by Pobell and Wittmann (15) by means of the Mößbauer technique.

The discontinuity at $p \approx 0.30$ is reflected in Smith's curves of lattice constants: The *b*- and *c*-axes show changes of slope, while the *a*-axis remains straight. This confirms the results of Newkirk and Thwaite (2) who found slight bends in the curves of all three lattice constants at $p \approx 0.33$.

We have investigated the lattice parameters as a function of composition for two ferrite solid solution series, one without MgO and one saturated with MgO. The samples were prepared in the subsolidus region at 1300°C, and investigated by powder diffractometry using FeK_α-radiation and NaCl as internal standard.

The results for the MgO-free ferrites are given in

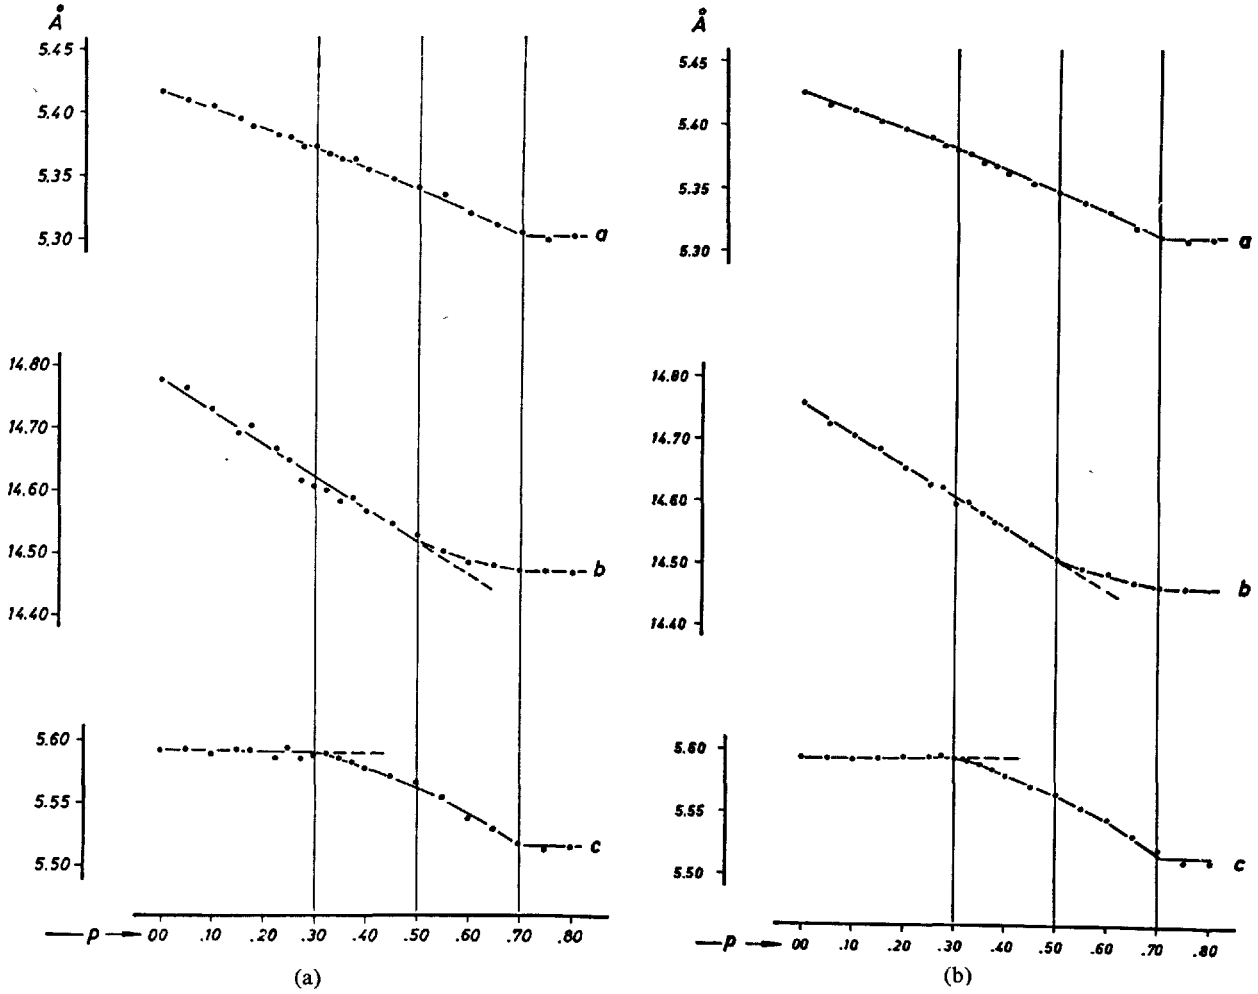

Fig. 7. *Variation of lattice parameters of ferrites as a function of the Al-content, a) MgO-free samples, b) samples saturated with MgO.*

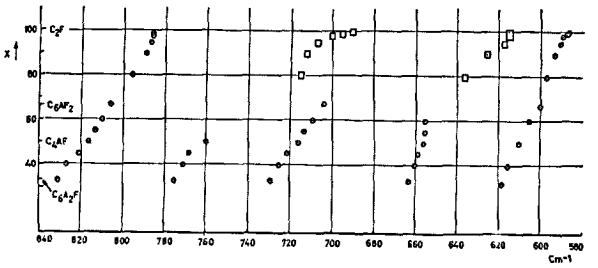

Fig. 8. *Position of infrared absorption bands in the ferrite series after Tarte (Fig. 6 in ref. 13); p = 1 − x/100.*

Fig. 7. The cell-dimensions decrease with increasing substitution of the smaller Al ion for the larger Fe ion. The plot of the *a*-axis is nearly a straight line without any discontinuity. The curves for the *b*- and the *c*-axes, however, exhibit one bend each. The *c*-axis plot shows a dinstinct inflection at $p \approx 0.30$, thus confirming the discontinuity discussed above. The *b*-axis curve is straight up to $p \approx 0.50$. At this value the slope changes distinctly.

Similar effects are observed in the samples saturated with MgO, thus confirming again the two discontinuities at $p \approx 0.30$ and $p \approx 0.50$ (Fig. 7b). A comparison of the lattice constants in Table 1 demonstrates that the incorporation of MgO causes the *a*-axis to increase and the *b*-axis to decrease while it has no effect on *c*.

Indications of a discontinuity at $p = 0.50$ have been described previously by two authors: Swayze (3) found that the composition $p = 0.50$ "acts as a definite compound so far as its influence on melting temperature along the C_3A–$C_6A_xF_y$ phase boundary line is concerned". Tarte's (14) diagram of infrared absorption spectra (Fig. 8) shows the occurrence of a new absorption band at 780–760 cm^{-1}. According to the author, no explanation of this effect can yet be given (16).

High-Temperature Investigations

Several members of the ferrite solid solution series were investigated by differential thermal analysis.

The end-member $Ca_2Fe_2O_5$ shows two weak (order of magnitude 0.1 cal./g) but distinct signals at 430°C and 690°C resp. (Fig. 9). Both are reversible without any measurable hysteresis. This implies that $Ca_2Fe_2O_5$ occurs in three different polymorphic forms. Yannaquis & Regourd (17) have kindly investigated the nature of these phase transformations by means of high-temperature X-ray measurements (Fig. 10): The transformation at 430°C is accompanied by a sudden shrinkage of the cell in all dimensions ($\Delta V = 0.7\%$), while the 690°C-transformation involves a slight decrease of thermal expansion. No systematic extinctions of X-ray diffraction lines occur up to 900°C, thus proving that the space group Pnma persists in the entire temperature range. All experiments indicate that the differences between the three polymorphic forms are very small and that the transformations are of the displacive type.

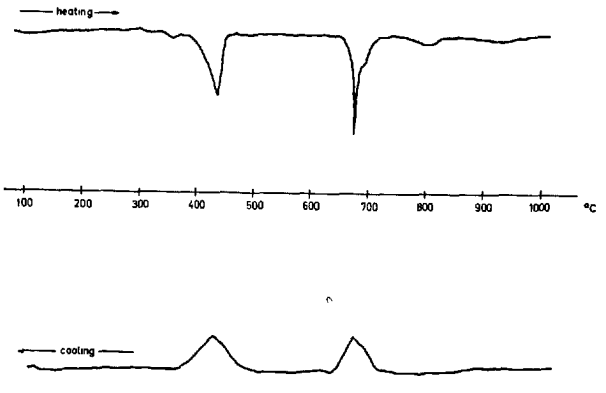

Fig. 9. *DTA-diagram of* $Ca_2Fe_2O_5$*(5°C/min).*

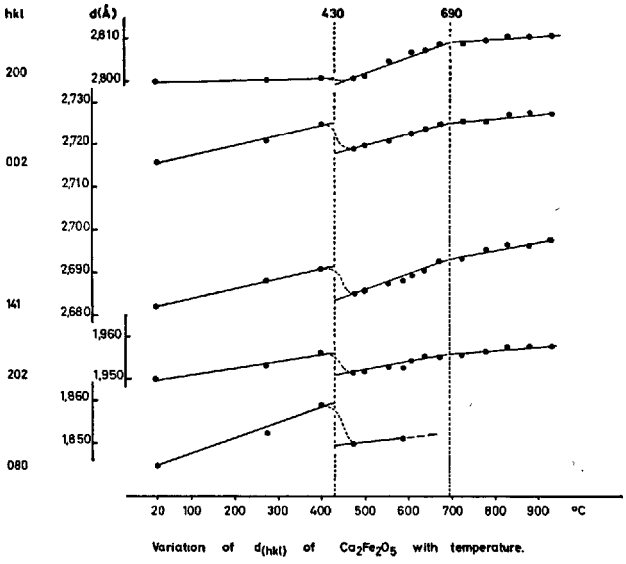

Fig. 10. *High-temperature X-ray results: Variation of spacings of several lines with temperature. (After Yannaquis & Regourd 17).*

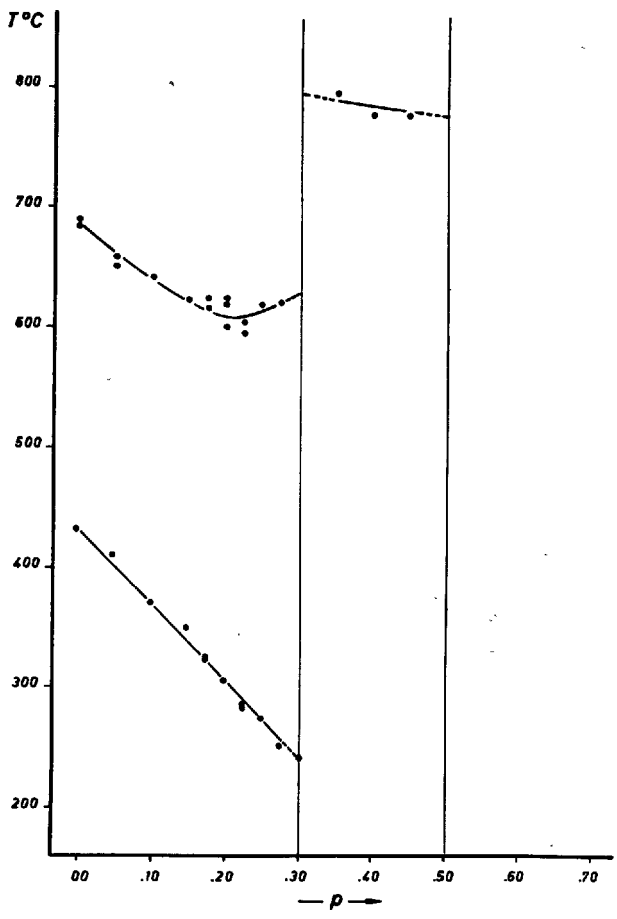

Fig. 11. *Variation of transition temperatures in the ferrite series as determined by DTA.*

According to Fig. 11 both DTA-peaks are shifted to lower temperatures with increasing amount of Al, at the same time decreasing in intensity and finally disappearing around $p = 0.30$ at temperatures of 220°C and 630°C resp. There is an indication that the latter peak is splitting into a doublet just before its disappearance (17). For compositions $0.30 < p < 0.50$ a very weak and indistinct thermal effect occurs in the region 780°–800°C. For solid solutions with $p > 0.50$ no DTA-signals have been observed.

The DTA signals of $Ca_2Fe_2O_5$ saturated with MgO occur at slightly lower temperatures (365°C and 670°C resp.). With increasing p the signals again shift to lower temperatures and finally disappear. Here, too, very weak thermal effects are observed around 800°C for samples with $p = 0.35$, 0.40 and 0.45. The thermal behaviour of magnesia-free and magnesia-saturated ferrites thus is quite similar.

Conclusion

The investigations offer evidence for two discontinuities in the ferrite solid solution series $Ca_2(Fe_{1-p}Al_p)_2O_5$ at $p \approx 0.30$ and $p \approx 0.50$. Of these only the first one has been described before.

The discontinuity at $p \approx 0.30$ is indicated by the following effects:

1. Change of space group from Pnma to Imma (Smith, 12)
2. Bend in the curve of the *c*-axis
3. Disappearance of the two DTA signals at 220°C and 630°C
4. Infrared-absorption spectra (Tarte, 14).

The new discontinuity at $p \approx 0.50$ is supported by the following evidence:

1. Bend in the plot of the *b*-axis
2. Disappearance of the weak DTA signal at 800°C
3. Appearance of an additional IR absorption band (Tarte, 14)
4. Change of the substitution type of MgO.

The discontinuity at $p \approx 0.50$ has been established for MgO-free samples. This suggests that the discontinuity is inherent in the ferrite series and thus is the reason for the change in the substitution type of MgO.

Smith (12) has explained the discontinuity at $p \approx 0.30$ as the transition from predominant Al-incorporation in tetrahedral sites to nearly equal rates of replacement in both tetrahedral and octahedral positions. It seems reasonable to interpret the effect at $p \approx 0.50$ as the beginning of preferential Al-substitution into octahedral sites.

Supplementary Paper 1-55 Crystal Chemisty of Tricalcium Silicate Solid Solutions

Theodor Hahn, Walter Eysel and Eduard Woermann*

Synopsis

The incorporation of various atoms into Ca_3SiO_5 has been investigated with respect to the types of substitution, the limits of solubility and the stabilization of high-temperature modifications. In particular, the effects of the following oxides have been studied: MgO, ZnO, GeO_2, Fe_2O_3, Al_2O_3.

The combined substitutions of MgO and Al_2O_3, MgO and Fe_2O_3, Al_2O_3 and Fe_2O_3 correspond to three-dimensional bodies in the appropriate quaternary systems. From these results conclusions about the alite phase in the quinary system CaO–MgO–Al_2O_3–Fe_2O_3–SiO_2 have been drawn.

Introduction

Solid solutions of Ca_3SiO_5, called alite, are the main constituents of cement clinker. Confusion existed about the nature of the alite phase until in 1933 Guttmann and Gille (1) were able to prove that alite is Ca_3SiO_5, modified by slight solid solution. In 1952 Jeffery (2) determined the structure of Ca_3SiO_5. Later work confirmed his results (3). The structure consists of Ca ions, isolated SiO_4 tetrahedra and additional oxygens, the latter being coordinated to Ca only. The oxygen coordination around calcium is very irregular and the structure contains voids. These features are considered to be the main reasons for the hydraulic properties of this substance (4).

Jeffery postulated three modifications for C_3S. Recent detailed investigations, however, revealed six polymorphs (5): three triclinic (T_I, T_{II}, T_{III}), two monoclinic (M_I, M_{II}) and the rhombohedral high-temperature form (R). The structures of all these modifications are extremely similar. The five transformations represent small distortions of the structural framework (displacive transformations) and their enthalpies are minute.

Of particular interest, both for the crystal chemistry and the technical role of Ca_3SiO_5, are the modes and limits of incorporation of foreign atoms into the structure and the stabilization of the different polymorphs.

Pure Ca_3SiO_5 is unstable with respect to Ca_2SiO_4 and CaO below ~1200°C. In solid solutions this temperature is shifted slightly; the principal situation, however, remains unchanged. This necessitates that Ca_3SiO_5 and its solid solutions can be prepared only above 1200°C, i.e. in the stability range of the rhombohedral modification (R).

Fortunately, the solid solutions can be quenched and investigated at room temperature. Depending on the composition of the solid solution, some of the transformations are suppressed, thus causing the stabilization of high-temperature modifications. In particular, ZnO is unique in stabilizing all polymorphs except T_{III} (5). It should be noted that all transformations occur in the temperature range in which Ca_3SiO_5 is metastable.

We have studied the incorporation of various oxides into Ca_3SiO_5 (6, 7, 8, 9, 10). In particular, the combined substitution of MgO, Al_2O_3 and Fe_2O_3 resembles very closely the alite phase in clinker; accordingly, the results reveal several aspects of the nature of this phase.

Our investigations established that pure tricalcium silicate possesses no compositional range, but represents a stoichiometric compound of composition $3CaO \cdot SiO_2$ (7). This disagrees with results by Boikova and Toropov (11), who found an excess of 0.5—1.0 wt.% CaO in pure tricalcium silicate, corresponding to ratios CaO: SiO_2 of 3.02—3.04.

Individual Substitution of Foreign Atoms

Replacement of Ca in 6-coordinated (VI) positions:

$$(Ca_{1-x}Me_x)_3^{VI}SiO_4 \quad (Ca/Me = 1.0) \qquad (1)$$

with Me = Zn, Mg

The limits of solid solution for MgO and ZnO are strongly dependent on temperature. At 1550°C up to 2.0 wt.% MgO and at 1400°C up to 5.0 wt.% ZnO can be incorporated into Ca_3SiO_5.

For MgO, very similar results have been obtained by Locher (12) and by Midgley and Fletcher (13).

Replacement of Si in tetrahedral (IV) sites by Ge:

$$Ca_3^{VI}(Si_{1-x}Ge_x)^{IV}O_5 \quad (Ca/Ge = 3.0) \qquad (2)$$

Our results (14) are in good agreement with those of Boikova et al. (15). Ca_3GeO_5 exhibits the same structures and polymorphism as Ca_3SiO_5; unlimited solid solution exists between both compounds. In analogy to Ca_3SiO_5, germanate-alites can be prepared and high-temperature modifications can be stabilized. Likewise, Ca_3GeO_5 is metastable at lower temperatures (below 1335°C) but the rate of decomposition into Ca_2GeO_4 and CaO is much higher than that of the silicate. Thus the investigations on Ca_3GeO_5 support the results obtained for the silicate.

The incorporation of the trivalent ions Fe and Al is more complicated:

Substitution of Fe^{3+} takes place in two structural sites. Half of the Fe-ions substitute for Si, the other half for Ca:

$$(Ca_{1-\frac{x}{6}}Fe_{\frac{x}{6}})_3^{VI}(Si_{1-\frac{x}{2}}Fe_{\frac{x}{2}})^{IV}O_5 \quad (Ca/Fe = 1.0) \qquad (3)$$

Accordingly, the solid solution is represented on the line Ca_3SiO_5–"$Ca_2Fe_2O_5$" in the system CaO–Fe_2O_3–SiO_2. Contrary to these results, Fletcher (16) found a solid solution along the line Ca_3SiO_5–"$Ca_3Fe_2O_6$". The limit of solid solution at 1550°C is 1.1 wt.% Fe_2O_3, in good agreement with Fletcher's value of 1.05% Fe_2O_3.

Substitution of Al: Aluminum atoms can enter into three different positions in the structure of Ca_3SiO_5: Substitution for Si (IV), substitution for Ca (VI) and occupation of 6-coordinated voids (VI'). The distribution of Al among these three sites is variable and controlled by the amount of Ca-atoms available.

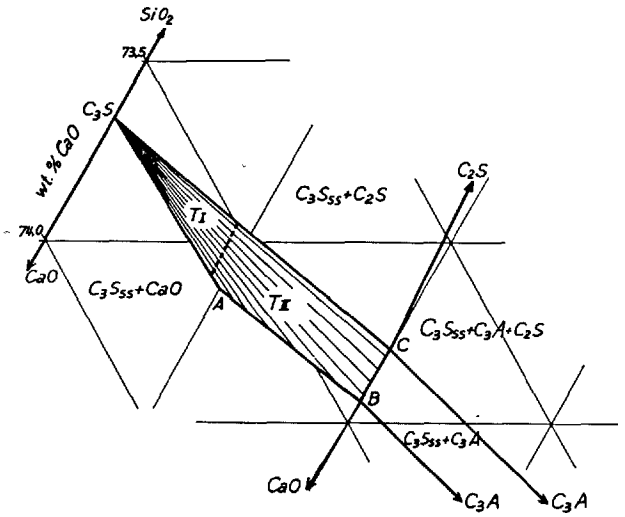

Fig. 1. *Field of* Ca_3SiO_5 *solid solution in the ternary system* CaO–Al_2O_3–SiO_2 *at 1550°C. The regions of the stabilized modifications* T_I *and* T_{II} *apply to room temperature.*

Thus, Al as well as Ca take part in the solid solution and the substitution must be described by two parameters, i.e. in the system CaO–Al_2O_3–SiO_2 the C_3S-phase is represented by an area and not by a line. This area has a small but well defined "CaO-width" (up to 0.14% CaO at B–C in Fig. 1).

All solid solutions can be described by superposition of the two formulae:

$$(Ca_{1-\frac{y}{6}}Al_{\frac{y}{6}})_3^{VI}(Si_{1-\frac{y}{2}}Al_{\frac{y}{2}})^{IV}O_5 \quad (Ca/Al = 1.0) \qquad (4)$$

$$Ca_3^{VI}Al_{\frac{z}{4}}^{VI'}(Si_{1-\frac{3}{4}z}Al_{\frac{3}{4}z}^{3})^{IV}O_5 \quad (Ca/Al = 2.25) \qquad (5)$$

These substitution types correspond to the hypothetical end-members "$Ca_2Al_2O_5$" and "$Ca_3Al_{4/3}O_5$" respectively. Midgley and Fletcher (13) found substitution type (5) only, while Locher (12) assumed replacement of Si by Al, the balance of charges being maintained by removal of oxygen atoms from the structure. Both models correspond to lines in the ternary diagram but not to areas. The limit of solubility of Al_2O_3 in Ca_3SiO_5 is independent of temperature and amounts to 1.0 wt.% Al_2O_3.

Combined Substitution of Mg and Al in Ca_3SiO_5

So far the solid solutions of Ca_3SiO_5 with individual oxides have been described. In the following chapters the results of the combined substitution of MgO, Al_2O_3 and Fe_2O_3 will be presented. The object of the investigations has been to establish the one-phase regions of the alites in the respective quaternary sys-

*The line A–A′ in Figure 2 represents a bend in this face which is of no significance for the phase relations.

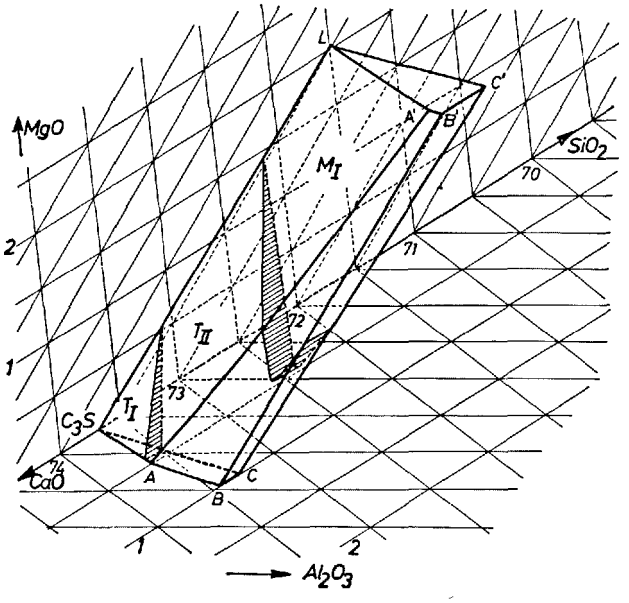

Fig. 2. *Body of* Ca_3SiO_5 *solid solution in the quaternary system* $CaO–MgO–Al_2O_3–SiO_2$ *at 1550°C.*

tems.

Fig. 2 shows that the solid solutions of Ca_3SiO_5 with MgO and Al_2O_3 in the quaternary system $CaO–MgO–Al_2O_3–SiO_2$ are represented by a nearly prismatic body. This implies that not only MgO and Al_2O_3 but also CaO participate in the solid solution. The basis C_3S–A–B–C corresponds to the Al-substitution in the system $CaO–Al_2O_3–SiO_2$ (Fig. 1). The edge C_3S–L corresponds to the Mg-substitution in the system $CaO–MgO–SiO_2$. The phases which coexist on the different faces of the body are given in Table 1.

The "CaO-width" B–C (0.14% CaO) is enlarged to B′–C′ (0.34% CaO) due to the influence of Mg. Upon combined substitution the individual limits of solid solution of MgO and Al_2O_3 remain unchanged and amount to 2.0% MgO and 1.0% Al_2O_3 at 1550°C. This is in good agreement with the results of Midgley and Fletcher (13). The limit for Al_2O_3 is independent of temperature, while the MgO-solubility decreases with falling temperature (e.g. 1.5% at 1420°C). No accurate data exists about the temperature-dependence of the CaO-width.

The solid solutions with Al_2O_3 are described above as superpositions of formulae (4) and (5), while the incorporation of MgO is represented by formula (1). Upon combined incorporation of MgO and Al_2O_3 the individual substitution types remain valid. Accordingly, the solid solution can be described by superposition of formulae (6) and (7):

$$(Ca_{1-x-\frac{y}{6}}Mg_xAl_{\frac{y}{6}})_3{}^{IV}(Si_{1-\frac{y}{2}}Al_{\frac{y}{2}})^{IV}O_5 \qquad (Ca/Al = 1.0) \qquad (6)$$

$$(Ca_{1-x}Mg_x)_3{}^{VI}Al_{\frac{z}{4}}{}^{VI'}(Si_{1-\frac{3}{4}z}Al_{\frac{3}{4}z})^{IV}O_5 \qquad (Ca/Al = 2.25) \qquad (7)$$

Independence of substitution types was already proposed by Midgley and Fletcher (13). Their model, however, corresponds to formula (7) only, i.e. to one of the limiting faces of the body in Fig. 2. Jeffery's alite (2, 4) $Ca_{54}MgAl_2Si_{16}O_{90}$ as well as the line connecting this composition with the point of pure Ca_3SiO_5 are entirely outside of this body.

Fig. 2 also shows the regions of the various modifications which can be quenched to room temperature. The stabilized forms depend upon the amount of MgO and Al_2O_3 but are independent of the CaO-concentration. The stabilization effects were also investigated by Yamaguchi and Kato (17) and by Midgley and Fletcher (13).

Combined Substitution of Mg and Fe in Ca_3SiO_5

The combined substitution of MgO and Fe_2O_3 in Ca_3SiO_5 is represented in the system $CaO–MgO–Fe_2O_3–SiO_2$ by the body of Fig. 3, which is less complicated than that of Fig. 2. While the individual solid solutions with MgO and with Fe_2O_3 (lines C_3S–L and C_3S–M resp.) exhibit no "CaO-width", combined

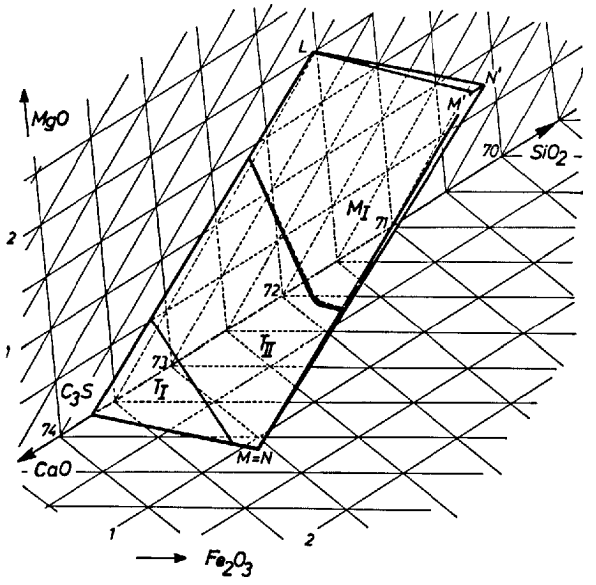

Fig. 3. *Body of* Ca_3SiO_5 *solid solution in the quaternary system* $CaO–MgO–Fe_2O_3–SiO_2$ *at 1550°C.*

substitution results in a very small width with a maximum value at M'–N'. The coexisting phases are compiled in Table 1.

From the shape of the body it can be deduced that the individual limits of solid solution of both oxides (2.0% MgO and 1.1% Fe_2O_3 at 1550°C) do not influence each other. The substitution types are analogous to those for combined Mg–and Al–substitution (formulae (6) and (7)).

The regions of the stabilized modifications T_I, T_{II} and M_I are also indicated in Fig. 3.

Combined Substitution of Al and Fe in Ca_3SiO_5

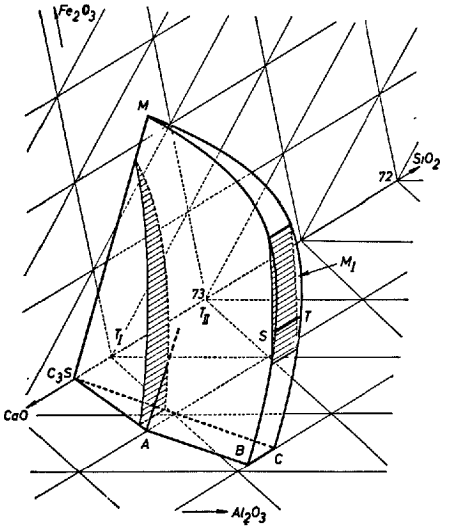

Fig. 4. *Body of* Ca_3SiO_5 *solid solution in the quaternary system* $CaO–Al_2O_3–Fe_2O_3–SiO_2$ *at 1550°C. The points S and T apply to subsolidus temperatures (< 1340°C).*

For the tricalcium silicate phase in the system $CaO–Al_2O_3–Fe_2O_3–SiO_2$ the body of Fig. 4 has been found. It is again characterized by a CaO–width, which in this case is predominantly a function of the Al_2O_3–concentration. The coexisting phases are given in Table 1.

In contrast to the two cases discussed above, the limits of solid solution of Al_2O_3 and Fe_2O_3 are not independent. The interaction causes the face B–C–M to be curved. This can be accounted for by the fact that Fe and Al atoms compete for the same positions in the structure. Fletcher (16), however, reports independent limits of solid solution.

In this system the modifications T_I and T_{II} occur at room temperature (Fig. 4). In addition, a small region of form M_I has been found.

Combined Substitution of Mg, Al and Fe in Ca_3SiO_5

On the basis of the results in the three quaternary systems and of additional experiments in the quinary system $CaO–MgO–Al_2O_3–Fe_2O_3–SiO_2$ the following conclusions on the tricalcium silicate phase in the latter system can be drawn (10):

1. Since the Ca_3SiO_5 phases in the various quater-

nary systems are represented by three-dimensional bodies, it follows that in the quinary system a four-dimensional "body" occurs. The bodies in Figs. 2 to 4 represent limiting "faces" of the latter.

2. The independence of the limits of solubility, for the atoms Mg and Al as well as Mg and Fe resp. and the interaction between Al and Fe, observed in the quaternary systems, have been found to persist in the quinary system. The CaO-concentration does not influence the solubility limits of the other atoms.

3. The "CaO-width" of the tricalcium silicate phase saturated with ($Al_2O_3 + Fe_2O_3$) is increased by addition of MgO.

4. No "higher" modification than M_I has been obtained in the quinary system at room temperature.

5. Tricalcium silicate in the quinary system CaO–MgO–Al_2O_3–Fe_2O_3–SiO_2 closely resembles the alite phase in technical clinker. Thus our results may safely be extended to technical alite (10).

Discussion

The investigations established that alites are true solid solutions of Ca_3SiO_5 which are represented by definite phase regions in the appropriate multi-component systems. The ranges of these solid solutions are very small, except for the unlimited substitution Si–Ge.

The different modes of incorporation of foreign ions are based on simple substitution types which are well known in crystal chemistry, for example the distribution of Al^{3+} or Fe^{3+} among tetrahedral and octahedral sites in silicates.

Mutual interactions of Mg, Al and Fe influence the stabilization of the high-temperature modifications T_I, T_{II} and M_I: Figs. 2 to 4 demonstrate that the amount of one oxide which is necessary to obtain a "higher" form is decreased with increasing amounts of the other oxide. These results as well as those of Ono, Uno and Kanai (18) indicate that by addition of further suitable atoms also the modifications M_{II} and R can be stabilized., thus explaining the occurrence of these forms in some clinkers.

Supplementary Paper 1-92 A Structural Study on α'-Ca_2SiO_4

Kazutaka Suzuki* and Goro Yamaguchi**

Synopsis

The α'-C_2S is synthesized by substituting Ba, Sr for Ca and substituting B for Si. The authors synthesized the single crystal of α' form and analyzed the structure of it by optical observation, Laue method, rotating crystal method and X-ray goniometry. The lattice parameters of the α' form with Ba, Sr and B were obtained about as follows; $a = 11.07$Å, $b = 18.80$Å, $c = 6.85$Å in Ba stabilized, $a = 11.02$Å, $b = 18.69$Å, $c = 6.83$Å in Sr stabilized and $a = 10.96$Å, $b = 18.43$Å, $c = 6.86$Å in B stabilized. Among them the lengths of a- and b-axes are 2 times as long as so far authorized ones ($a = 5.49$Å, $b = 9.26$Å, $c = 6.75$Å). The 152 diffraction which could be interpreted only by these large lattice was also observed in pure α'-C_2S by the high temperature X-ray diffraction. The crystal structure of α'-C_2S stabilized by Ba was analyzed and the atomic parameters were determined.

Introduction

As to the crystal structure of C_2S polymorphs, only that of β-C_2S is reliable because it has been analyzed by the single crystal method (1). The structures of other polymorphs have been estimated by Yamaguchi et al. (2), but they cannot but be said to be approximation. Suzuki (3) investigated the substitution amount and the sort of the ion which can stabilize each form and obtained α' form by Ba, Sr and B, α form by Ba, V, P and β form by a small quantity of each ion when the preparations were carried out by quenching from about 1500°C. According to the above mentioned experiments, the authors succeeded to obtain single crystals of α'–C_2S so that they attempted to analyze a true crystal structure.

Preparation of α'-C_2S Stabilized by Ba, Sr and its X-ray Analysis

The mixtures of raw materials of C_2S whose CaO is substituted by 0.15–0.30 mole of BaO or SrO were burned at 1500°C about 20 minutes and quenched, thus α'–C_2S was formed distinctly containing single crystals of fairly good size. In more substitution of BaO, about 0.7 mole, α type was formed by quenching, but by substitution of SrO none of α type was formed. The composition of single crystal was 56.12 per cent CaO, 11.21 per cent BaO and 32.67 per cent SiO_2 and that stabilized by Sr was 57.84 per cent CaO, 8.65 per cent SrO and 33.51 per cent SiO_2. Optical observation revealed the crystals have no twinning and the refraction indices are $n_g = 1.741$, $n_p = 1.726$ in Ba stabilized one and $n_g = 1.737$ and $n_p = 1.721$ in Sr stabilized one. Laue's photographs of these α'–C_2S are really same one another, namely, the symmetries along X, Y are that with perpendicularly crossed mirror planes, but along Z is pseudo 3 fold. The reciprocal lattice projections on $b^* - c^*$ plane and rotating crystal photographs about a-axis show that the length of a-, b-axis are about 2 times as long as those of Tromel's α'–C_2S (4); $a = 11.07$Å, $b = 18.80$Å, $c = 6.85$Å in Ba stabilized one and $a = 11.02$Å, $b = 18.69$Å, $c = 6.83$Å in Sr stabilized one. These Laue's photographs, rotating crystal photograph and reciprocal projections are shown in Fig. 1, Fig. 2 and Fig. 3. The systematic absence of this projections are as follows:

hkl	$h + k = 2n$	h00	$h = 2n$

Preparation of α′-C_2S Stabilized by B and its X-ray Analysis

The raw materials mixtures were prepared supposing the substitution of B for Si. The most proper composition to get α′ form was 67.88 per cent CaO, 31.17 per cent SiO_2, 0.95 per cent B_2O_3. This mixture was heated and quenched from the temperature of 1450–1500°C and the single crystal was picked up from the products whose composition was analyzed to have about the same composition as the raw materials mixture; 67.91 per cent, CaO, 31.18 per cent SiO_2, 0.91 per cent B_2O_3. Optical properties are the same as that of Ba stabilized one and the refraction indices were $n_g = 1.732$ and $n_p = 1.709$. The symmetry of Laue's photographs and the projection data by Weissenberg goniometry are nearly the same as those of

α′ form substituted by Ba and Sr. Thus, it was clarified that this crystal has the same structure as those synthesized by Ba, Sr. Laue's photographs and rotating crystal photograph are shown in Fig. 5 and Fig. 6, and X-ray powder diffraction data and figure are shown in Fig. 7 and Table 2. Lattice lengths of it are listed as $a = 10.96$Å, $b = 18.43$Å, $c = 6.86$Å.

Lattice Parameters of Pure α′-Ca_2SiO_4

The lattice parameters of α′ form stabilized by Ba, Sr and B have all the same periodicity along each axis, and this is based on the same stacking of Ca and SiO_4 packing. But these periodicity seems unlikely

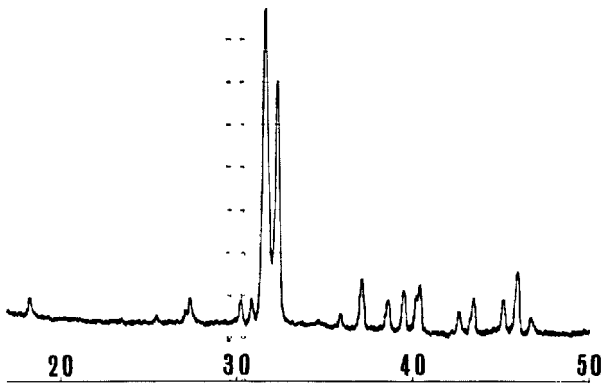

Fig. 8. *High temperature X-ray diffraction pattern of pure* α'-C_2S *(at 1000°C)*

due to the substutution of Ba, Sr or B ion at the symmetrical place such as to make these periodicity along each axis. For example, in the calculation of the structure factor of α' form stabilized by Ba, an assumption that Ba is substituted for the special position of Ca gives less agreement than an assumption that Ba enters to the position of Ca at random. In the former assumption, the atomic scattering factor of Ba and Ca were adopted for each atom respectively in calculation, but in the latter, mean values according to the composition ratio of Ba and Ca were adopted. The synthesis of a single crystal of pure α'-C_2S is unable, so that the high temperature X-ray diffraction method should be taken as the only method to confirm the periodicity. Pure γ-C_2S was employed for this experiment. It inverts into α' at about 890°C and to α at 1450°C. In the range of temperature where α' form is stable, the characteristic peak such as to suggest the lattice parameters appears in the diffraction pattern; this was confirmed by 152 diffraction. This diffraction pattern is shown in Fig. 8.

The Crystal Structure of α'-C_2S Stabilized by Ba

Determination of atomic parameters of α'-C_2S and their refining by Fourier synthesis were carried out. The α' form stabilized by Ba was used because its X-ray powder diffraction figure is most similar to that of pure α'-C_2S. Approximately cylindrical crystal having average radius of 0.2 mm, was used for collecting intensity data. The intensity data were recorded on equi-inclination Weissenberg photographs by the multiple-film technique with Cu Kα radiation. Five layers 0k*l*–4k*l* were collected about the *a*-axis. Absorption effect was so small that it was neglected and the extinction effect was also negligible. The structure factors were caluculated using the temperature factor 1.1, and the parameters that was made by piling the Yamaguchi's unit cell (2) gave a reliability index $R = 0.42$. This shows that Yamaguchi's data are fairly reliable. But about the structure of stabilized by Ba, the pile are not constructed by parallel moving of the Yamaguchi's cell but are constructed with small shift. This is explained by the fact that if the pile is made by parallel moving of the unit cell, the diffraction such as $h + k = 2n$ disappeared when h and k are both odd, but if the pile is constructed with small shift, the upper diffraction appears and its structure factors are not usually zero. Thus the slight moving of Ca, Si or O atom can make the structure factors to have more good agreement with observed structure factors. For this purpose two-dimensional or three-dimensional Fourier summations were carried out on the computer. Form the symmetry of the space group it is understood that the projection is sufficient to be limited in $a/2 \times b/2 \times c$. The former was carried out to obtain a projection on *b*-*c* plane deviding $b/2$ into 30 parts and *c* into 20 parts and calculating the summation of F(0k*l*) in a range of $k = 0 - 8$, $l = 0 - 4$. The latter was carried out to obtain bounded projections on *a*-*c* plane limited bound of *b*-axis 0.0–0.25, 0.25–0.50, deviding $a/2$ into 20 parts and *c* into 20 parts and calculating the summation of F(hk*l*) in a range of $h = 0 - 4$, $k = 0 - 8$, $l = 0 - 4$. Thus the atomic parameters in the step of the present time, the bond lengths and angles were obtained as shown in Table 4 and Table 5. The structure factor calculated showed fairly good agreement with those observed. Thus the R index was reduced to 0.11 for both 0k*l* and kh*l* reflexions. A list of observed and calculated

Conclusion

From the result of high temperature X-ray diffraction of pure C_2S, we acknowledged that 152 peak appears in many case in the temperature range where α' form is stable. This shows that the pure C_2S has perhaps the same periodicity as that of α' solid solution phase. But the intensity of this diffraction is not strong and it does not appear immediately after α' inversion. When the specimen is kept in its stable temperature more than 20 minutes, the peak appears perhaps according to the good rearrangement of atom packing The other diffractions which prove the doubling of *a*- and *b*-axes, lie overlapping upon another diffractions, so we cannot confirm the doubling of *a*-, *b*-axis by them. This 152 diffraction appears also in other α' forms stabilized by V and P. Four Si–O distances of the SiO_4 tetrahedra are significantly different. And this is caused by the combination of each O to two types of Ca ion. As to 32 Ca ions, 16 of them (Ca 1, 2, 3) are positioned alternately above and below SiO_4 tetrahedra in the *z* direction and the remaining 16 (Ca 4, 5, 6) are accommodated in the holes between the tetrahedra. The co-ordination number of Ca, 1, 2, 3 are eight and of Ca 4, 5, 6 are six. The positions of Ca 1, 2, 3 are perhaps easily substituted by other ions but in the structure of α' form the stabilizing ion does not enter into the special position of Ca or Si but enters at random.

Oral Discussion

Yoshio Ono

As I understand, you have determined the space-group of the low-temperature form of α'–C_2S being $Cmc2_1$. Could you tell me how you did it? What is the correlation between this and the high-temperature form?

Authors' Closure

K. Suzuki and G. Yamaguchi

The space group and the structure of α'_H was suggested by us.* Its space group is Pnma and in another setting Pmcn as shown in the figure. While the X-ray powder diffraction pattern of α'_L is very similar to that of α'_H, so that α'_L has a very similar atomic arrangement to α'_H. It was interpreted that the unit cell of α'_H is piled toward *a*- and *b*-directions by two times slightly changing symmetries as shown in the figure. Thus the space group of α'_L was determined as $Cmc2_1$.

Supplementary Paper 1-127 New Crystallographic Data of Some Calcium Silicate Phases

Friedrich K. F. Liebau*

Synopsis

Attempts to prepare material of Ca_2SiO_4 and Ca_3SiO_5 for hydration studies yielded besides others single crystals which by X-ray methods gave crystallographic data different from those given in the literature for calcium silicates.

1) Ca_2SiO_4: For one phase lattice constants similar but definitely $CaCl_2$ small amounts of slightly hygroscopic needle-like crystals were formed. X-ray single crystal studies and crystal optical studies revealed two different but structurally related phases. Lattice constants show no relation to other known calcium-silicates. Crystals of both phases show diffuse OD-structure diffraction effects. The chemical composition could not yet been determined but chloride ions were not detectable in them.

Lattice constants of all these phases will be given and other results of investigations in progress will be discussed.

Introduction

Experiments for the synthesis of material of Ca_2SiO_4 and Ca_3SiO_5 for hydration studies yielded a large number of crystals which were large enough for single crystal X-ray work. Many of these gave lattice constants in agreement with values given in the literature by various authors. A number of crystals, however, gave crystal data different from those given before. These new results only are described in this paper.

Ca_2SiO_4

A mixture of polycrystalline Ca_3SiO_5, Ca_2SiO_4 and a large excess of $CaCl_2$ was heated to 1500°C for 4 1/2 hours in a platinum vessel and slowly cooled in the furnace. After dissolution of the calcium chloride with methanol twinned crystals of γ-Ca_2SiO_4 ($\leq 400\ \mu$) and some platy crystals of up to 100 μ were found in the sample. One of the latter gave lattice constants which are compared with those given for α'-Ca_2SiO_4 by Bredig (1) and Douglas (2) and for merwinite $Ca_3Mg[SiO_4]_2$ by Nurse (3) in Table 1.

Although the cell dimensions of our crystal are similar to the values of Douglas' α'-Ca_2SiO_4 our crystal is certainly not identical with Douglas' α' because

$$^{a}\text{Liebau} < {}^{a}\text{Douglas}$$

while

$$^{b}\text{Liebau} > {}^{b}\text{Douglas}.$$

Only hk0 reflexions with $h + k = 2n$ and h00 reflexions with $h = 4n$ were observed in the Weissenberg diagram.

This and some other observations suggest that, depending on the amount and kind of impurities as well as the heating and cooling history of the Ca_2SiO_4 sample, the structure of the α' phase may be somewhat different. These structural differences are probably small at temperatures in the stability range of the α' phase and become more pronounced below this temperature range.

Pseudowollastonite α-$CaSiO_3$

The low-temperature form β–$CaSiO_3$ is known as wollastonite. It is an inosilicate in which the [SiO_4] tetrahedra are joined to long chains. Due to different stacking sequences, there are at least three polytypes of this phase:

1) ordered triclinic wollastonite (4)
2) ordered monoclinic wollastonite (5)
3) disordered wollastonite (6, 7)

The high-temperature modification α-$CaSiO_3$ is called pseudowollastonite. It is a cyclosilicate containing [Si_3O_9] rings. So far three stacking modifications of this phase have been reported.

A fourth one has been found in this investigation.

From polycrystalline Ca_3SiO_5 heated with small amounts of $Ca(OH)_2$ and CaF_2 in a sealed quartz tube to 1300°C for 18 hours, dendritic pseudowollastonite crystals were formed by transport reactions. On Weissenberg photographs these crystals gave diffuse streaks parallel c* with intensity maxima for which $\zeta = n1\frac{l}{2}$ (related to c = 9.72 Å). No deviations from hexagonal symmetry were observed for the intensities. This disordered form of α–$CaSiO_3$ is, therefore, analogous to the disordered forms of $Sr_3Si_3O_9$ and $Ba_3Si_3O_9$ described by Hilmer (11) and Dornberger-Schiff (12).

Phases of Unknown Chemical Compositions

An equimolar mixture of polycrystalline Ca_2SiO_4 and CaO was heated to 1500°C with an excess of $CaCl_2$ until the calcium chloride was almost evaporated. After treatment with methanol the resulting material was found containing a small amount of slightly hygroscopic needles. Microanalytically no chloride ions were detectable in them.

Single crystal diagrams revealed two different but structurally related phases with [010] as needle axes. The lattice constants of these two phases are given in Table 3.

They show no simple relations to the cell dimensions of any of the known calcium silicate phases.

For both phases reflexions with k = 2n + 1 are extremely weak and diffuse so that rotation photographs about [010] look similar to those of disordered β-wollastonite.

Due to the small amount and the failure to seperate these phases their chemical compositions could not yet be determined. Attempts to study these two phases in more detail are going on.

Table 3. *Cell dimensions of two new calcium silicate phases of unknown chemical composition*

SESSION I-2 PHASE EQUILIBRIA AND FORMATION OF PORTLAND CEMENT MINERALS

Principal Paper Phase Equilibria and Formation of Portland Cement Minerals

Ronald W. Nurse*

Synopsis

A review is made of new or revised phase diagrams or associated data published since the Washington Symposium. Crystalline solutions of the main clinker phase are considered; insufficient attention has been paid to the dependence of solubility on temperature and to the precise composition of the solute. Systems between CaO, SiO_2 or CaO, Al_2O_3 and volatile components such as SO_3 and water vapour are described and also systems with fluxing agents such as fluorides. Deviations from equilibrium and especially the question of glass content are discussed. Some reference is made to kinetics of reactions occurring during the formation of the clinker minerals.

The conclusion is drawn that phase studies are a valuable aid to understanding clinker constitution, but that it is not warranted to try to obtain very great accuracy in calculating constitution from the chemical analysis. If very precise estimates of constitution are required each clinker must be individually studied by chemical, microscopie, X-ray and electron beam microprobe methods.

Introduction

In the course of this paper the constitution of clinker will be considered solely from the point of view of phase studies. Questions of mineral structure and direct estimation of consititution will be dealt with by other authors. Papers earlier than the Washington (1960) Symposium will rarely be referred to, and in order to avoid a too lengthy list of references it will be assumed that detailed references to the Washington and earlier symposia are unnecessary.

Cement Quaternary System, with MgO

System $CaO–SiO_2$

The currently accepted melting point diagram and stability relations in the pure system are given as diagram 237 in reference (1) and incorporate the revised melting behaviour of C_3S described by Welch and Gutt (2). Gutt has since revised the temperature of incongruent melting of C_3S to 2150°C with concomitant rise in the liquidus temperature (Fig. 1). From the viewpoint of cement technology the effects of solid solutions in the system on the silicate phases are of major interest and these will be discussed next.

The Solid Solutions of $3CaO \cdot SiO_2$

As has been shown in the previous paper, the pure substance C_3S can exist in many polymorphic forms.

*Building Research Station, Ministry of Public Building and Works, Garston, Watford, Herts., United Kingdom.

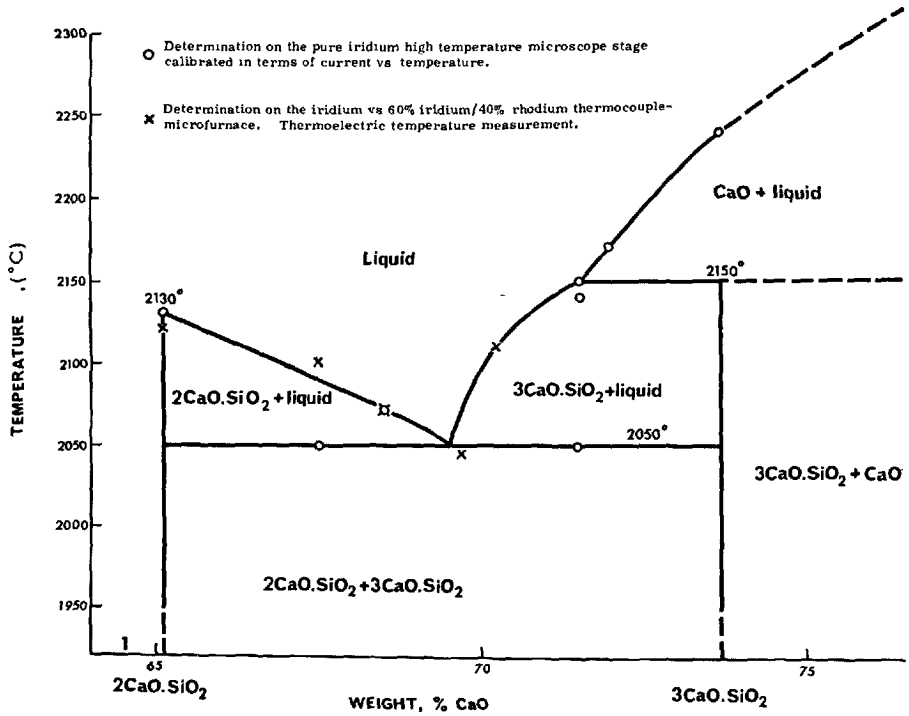

Fig. 1. *Revised phase diagram for lime-rich portion of system* $CaO–SiO_2$ *(Ref. 12)*

In theory, when C_3S is in equilibrium with other compounds and crystalline solutions are a possibility, the solubility/temperature curve for a given impurity will be different for each of the modifications, and the trend of this curve towards higher or lower temperatures will determine whether the presence of the impurity will stabilize the given polymorph or vice versa. In practice, the inversions all take place below 1050°C at a temperature where solution and exsolution will be very slow, and where they are metastable (because of the decomposition of C_3S at about 1275°C); therefore the matter of principal concern is the solid solubility of impurities in the trigonal form of C_3S stable at clinkering temperatures. This is the so-called alite of portland cement, although it may have inverted to a lower symmetry on cooling. The interval between first liquid formation and clinkering temperature is several hundred degrees, so that it is possible for a range of alite compositions to be found even in the same clinker, corresponding to the solubility levels of impurities at the different temperatures of formation.

We have to consider whether in these circumstances the phase diagram, being necessarily drawn for equilibrium conditions, is helpful.

An examination of recent investigations into alite shows that in many cases the results become clearer when the phase diagram is taken into account. Thus one frequently reads that the solubility of Al_2O_3 in C_3S has been determined. Such a crystalline solution must fall within the diagram C–A–S and since Al_2O_3 is not in equilibrium with C_3S in that system, it is extremely unlikely that a solid solution of these two components would form without side reactions involving the formation of C_2S in order to make extra calcium available for the solid solution. Midgley and Fletcher (3) have shown that this is the case and that 4.5 moles of CaO must accompany each mole of Al_2O_3 taken into solution in C_3S. An enlarged part of the phase diagram would appear as in Fig. 2. Below 1475°C, the temperature of the $C_3S–CaO–C_3A$ invariant point, the C_3S solid solution will be in equilibrium with C_3A and CaO; above, it will be in equilibrium with CaO and liquid. If now we consider the results of Woermann, Hahn and Eysel (4), we note that their preparations were made up with up to 4% excess CaO, and were processed at 1550°C. The inflections in their curves of CaO absorbed do not therefore indicate a change in the nature or composition of the solid solution but are to be expected as the composition of the starting material leaves the triangle $CaO–C_3S–C_3S$ (Solid Solution) and begins to form liquid at point "A". Considering only the compositions which do not melt, their results confirm exactly

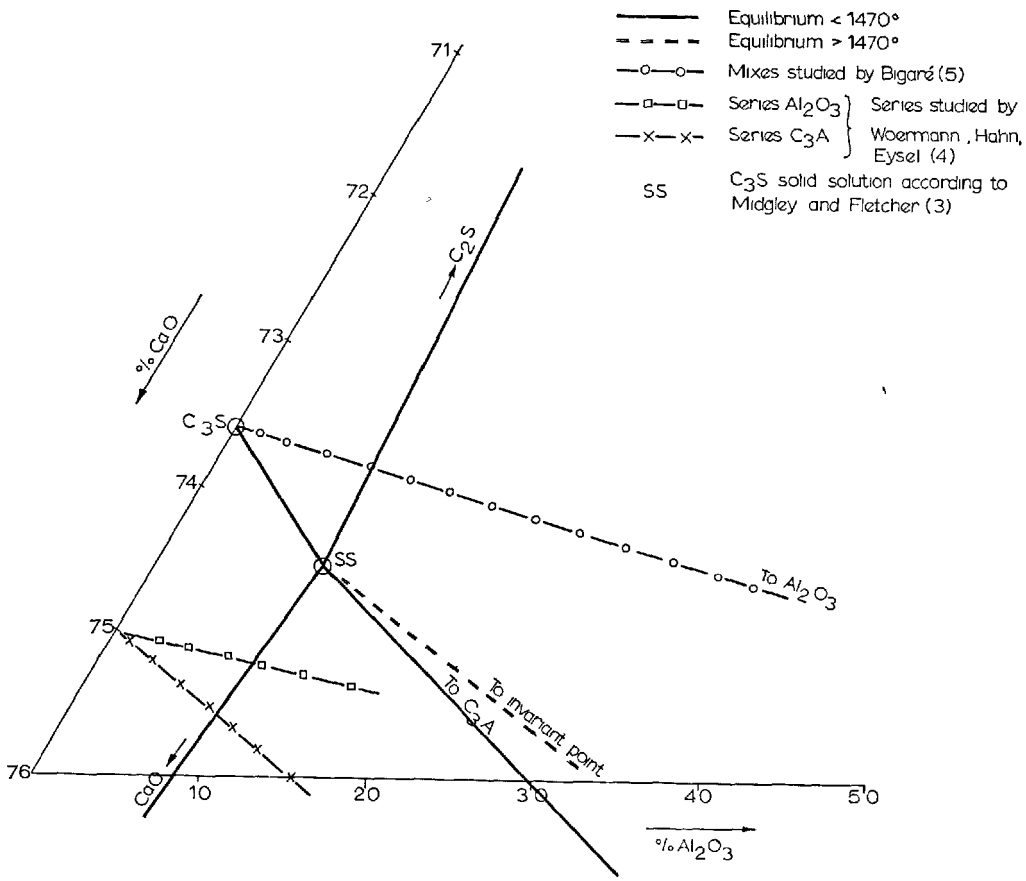

Fig. 2. *Part of system* $CaO–Al_2O_3–SiO_2$ *(Diagrammatic only)*

Midgley and Fletcher's ratio of 4.5 for the C/A in solid solution. Similarly Bigaré (5) calculates an "expected" C_3A content although his mixes were processed at 1650°C; the C_3A he found must have formed during the cooling of his specimens. Midgley and Fletcher also processed their mixes at a temperature where liquid formation is expected, but their solid solution composition was calculated after substraction of all other solid phases present including C_2S and C_3A and although the results are variable they should be free from consistent error. Locher (6) recognised that melting was occurring in those mixes between C_3S and C_3A containing more than 2% C_3A, but he assumed without proof that the solid solution lies on this join.

Midgley and Fletcher, and Woermann, Hahn and Eysel agree that each Al incorporated requires 2.25 Ca and a structural explanation can be found for this (3). Since the lines solid solution—CaO and solid solution—C_2S are essentially parallel to the $CaO–SiO_2$ side of the ternary system, the results of all authors can be compared as to the approximate percentage of Al_2O_3 taken up at the temperature of synthesis. About 1% by weight of Al_2O_3 is taken up at 1500°C, accompanied by enough CaO to maintain a C/A ratio of 4.5. There is some indication that the solubility falls off with increasing temperature but this tentative conclusion requires checking by further experiments. If it proved to be correct, it would explain why synthetic preparations based on Jeffery's (7) formula for alite are found to contain C_3A when processed at 1400–1450°C. Microprobe analyses of alite in clinker give Al_2O_3 contents from 0.2–1.1%.

By contrast, the solid solution of MgO in C_3S is a simple substitution of MgO for CaO. A phase diagram is suggested by Schlaudt and Roy (8) (Fig.3) and by Schlaudt (9). Woermann, Hahn and Eysel (4) show the increase in solubility with temperature (Fig. 4); their results are in fair agreement with others but probably underestimate the solubility somewhat, since they studied the join C_3S–MgO and not C_3S–"M_3S"; according to Fig. 3 their estimate represents the composition on the line from CaO towards the solid solution in equilibrium with CaO and MgO. Most

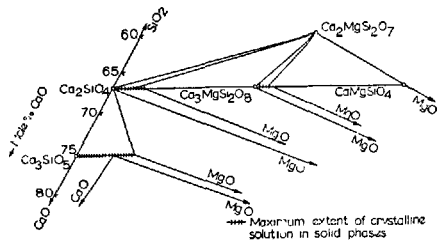

Fig. 3. *Revised solidus compatibility relations in part of system* $CaO–MgO–SiO_2$ *(Ref. 8)*

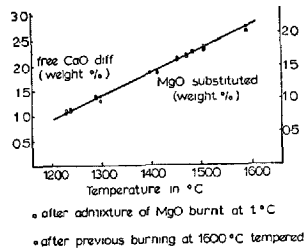

Fig. 4. *Increase in free* CaO *and consequent substitution of* MgO-*oversaturated* C_3S *samples (3% or 5%* MgO*) in relation to the reaction temperature (Ref. 4)*

authors agree that the solubility of MgO is little affected by Al_2O_3 and vice versa. Fletcher (10) found that Fe_2O_3 dissolved in C_3S to the extent of 1% by weight at 1400–1500°C in the form of a hypothetical $3CaO \cdot Fe_2O_3$. This conclusion was little changed by the simultaneous presence in solution of Al_2O_3 or MgO.

Solid Solutions of $2CaO \cdot SiO_2$

The position in this case is simpler, since the inversions in C_2S take place over a temperature range where the parent phase is stable. Most of the data reported by the present author at the 1952 Symposium remain valid, and most authors of new work have recognized the need to establish the nature of the new phase in equilibrium with the C_2S solid solution studied.

Yamaguchi, Ono and Kawamura state that in the presence of 2% MgO, C_2S is stable in content with C_3A and C_4AF when Al_2O_3 and Fe_2O_3 are added. The solubility of Al_2O_3 is between 2–3% by weight in the α-form (1400–1500°C) and less than 1% in the α′-form (1300°–1350°C); the solubility of Fe_2O_3 is 1.5% in the α-form at 1400°C, 2.5% in the α-form at 1500°C, and less than 1% in the α′-form at 1300–1350°C.

The solubility of MgO in C_2S according to Schlaudt and Roy is shown in Fig. 3. Gutt (12) also investigated the system $C_2S–C_3MS_2$; he noted some solubility of merwinite in α-C_2S but did not give a limit; Schlaudt and Roy give the equivalent of 1.5% MgO in α-C_2S at 1600°C. For α′C_2S at 1400°C Gutt gives 2% as against Schlaudt and Roy's 1.0% of MgO, but his diagram shows the solid solution in contact with phase $T(C_{1.7}M_{0.3}S)$, not merwinite.

System $CaO–Al_2O_3$

This system was revised (13) by Nurse, Welch and Majumdar, using high temperature microscopy and X-ray studies. That portion of special interest in portland cement was studied in more detail by the same

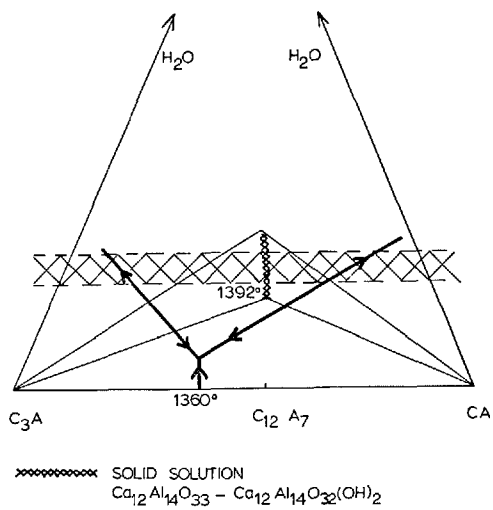

Fig. 5. *Hypothetical diagram* $CaO–Al_2O_3–H_2O$

authors (14), who showed the important effect of water in the furnace atmosphere on the equilibria observed. It appears probable that in a completely dry atmosphere a eutectic is formed between C_3A and CA, but at normal laboratory humidities a compound intermediate between $Ca_{12}Al_{14}O_{33}$ and $Ca_{12}Al_{14}O_{32}(OH)_2$ intervenes, melting into homogenous liquid at 1392°C with expulsion of water vapour. In the presence of products of combustion in rotary kilns, the formation of a '$C_{12}A_7$' phase in appropriate circumstances can be assumed.

No work appears to have been done to establish the effect of water vapour on the temperatures or positions of the invariant points involving $C_{12}A_7$ in such systems as C–A–S, C–A–S–F. Since the water vapour counts as an additional component, such invariant points will be one phase higher in rank and the additional phase will be in equilibrium.

Fig. 5 is a hypothetical representation of the phase equilibria in the system $CaO–Al_2O_3–H_2O$ at high temperatures. Preparations processed in moist laboratory air will fall within the shaded band, giving a '$C_{12}A_7$' phase which will expel water as the tempera-

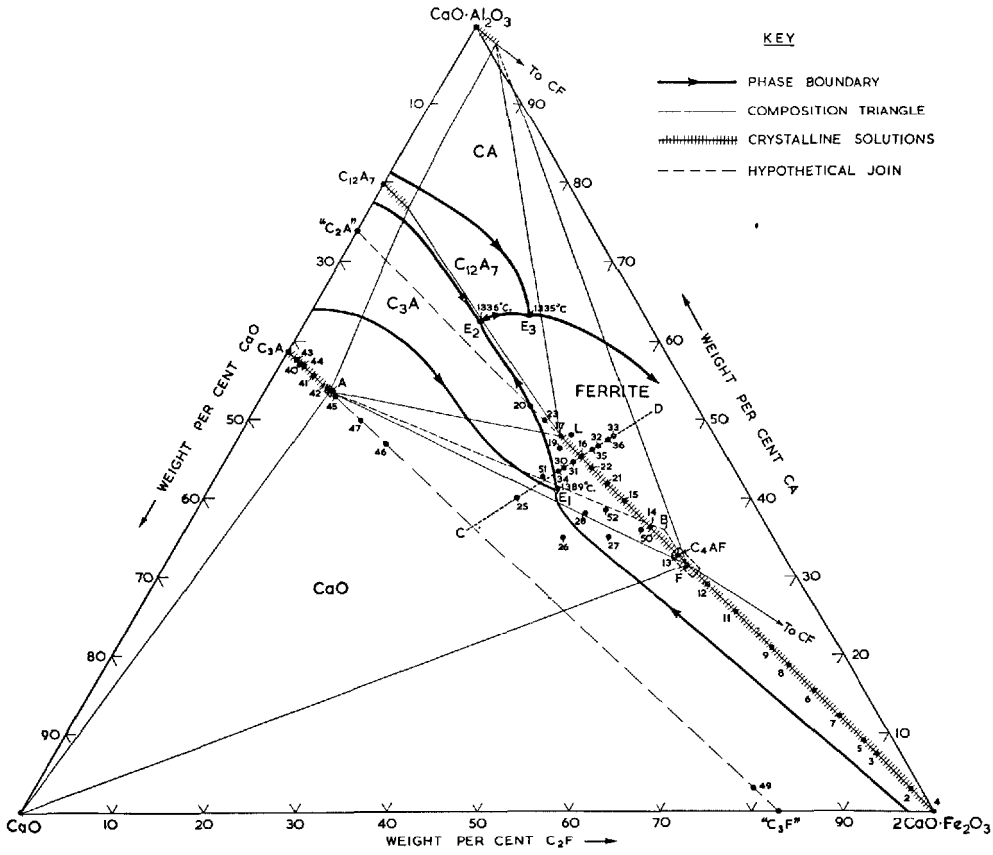

Fig. 6. *Amended phase-diagram for* $CaO–CaO \cdot Al_2O_3–2CaO \cdot Fe_2O_3$ *system.*

ture is raised so that '$C_{12}A_7$' disappears at the constant temperature 1392°C as reported in (14).

Solid Solutions of Calcium Aluminates

Miyazawa and Tomita (15) quote various determinations of the maximum solubility of MgO in C_3A but finally redetermine it as 0.4% MgO replacing CaO at 1410°C, Majumdar (16) found 4.5% of Fe_2O_3 present in C_3A as "C_3F" at 1325°C and Lister and Glasser (17) 4.2% Fe_2O_3 as "C_3F" at 1180°C. The latter authors find 4.9% Fe_2O_3 as C_2F in $C_{12}A_7$ at 1180°C.

System $CaO–Al_2O_3–Fe_2O_3$

This system has been re-investigated by Lister and Glasser (17) and the portion of interest to cement technology by Majumdar (16). The latter's diagram is reproduced as Fig. 6. The principal conclusions were that, although the solid solutions C_2F–'C_2A' are continuous from 70% mol% 'C_2A', the ferrite phase compatible with C_3A(SS) and CaO is 48 mol% C_2A, i.e. very close to C_4AF. The C_3A(SS)–C–Ferrite invariant point was judged to be peritectic. To obtain exact phase relations Majumdar carried out his preparations in pure oxygen atmosphere, in air some slight reduction occurred. Lister and Glasser worked at controlled partial pressures of oxygen in a specially constructed furnace. Schlaudt obtained very similar results (9).

System $CaO–MgO–SiO_2$

The high MgO region of this system has been further studied by Gutt (12) and Roy (8) (9). Both groups record the occurrence of a new compound "T" described by Gutt (18) with the composition $C_{1.7}M_{0.3}S$, stable in contact with C_2S at sub-solidus temperatures. Schlaudt and Roy thought that it decomposed at 1381°C and was therefore unstable with respect to α-C_2S, but Gutt shows α-C_2S and T in co-existence, T decomposing at 1460°C. This discrepancy could be of some importance since according to Gutt's diagram T might form in portland cement clinkers in contact with liquid. Schlaudt and Roy also show a lower

decomposition limit for T at 979°C, but Gutt considers it stable at room temperature.

System $CaO–Al_2O_3–MgO–SiO_2$

Two new compounds in the system C–M–A were described by Welch (19); $C_{25}A_{17}M_8$ exists at the liquidus and CAM is metastable. While not of direct importance to portland cement they could occur in high alumina cement and Majumdar (20) has pointed out their relationship to the quaternary phase of high alumina cement. Majumdar considers the stable ternary phase to be C_3A_2M, but he was unable to resolve the discrepancy between X-ray and phase equilibrium results on the quaternary compound; the composition must be close to the C_6A_4MS of Parker. Welch's view that it is a solid solution was not upheld.

The sections $C_2S–M_2S–A$ and $C_3MS_2–MA–C_2AS$ have been delineated by Gutt (21, 22) and Christie (23) has reviewed the melilite series as a whole. Schlaudt (9) records significant solid solution of CaO and SiO_2 in MgO at 1750°C; if such solution takes place at clinkering temperature it could be highly significant in cement technology.

The Alkali Systems

The latest work confirms that in the system C_2S–KCS solid solutions are formed, and not the compound $KC_{23}S_{12}$; at 1300°C. and air quenching β C_2S is stable up to 5% KCS, at 10% α'-C_2S is stabilized and at 25% α-C_2S (24). Yamaguchi and Ono give a diagram (Fig. 7) showing C_2S solid solutions of Na_2O together with Al_2O_3 and Fe_2O_3 (25). According to Yamaguchi and Uchikawa (26), Na substitutes for Ca and/or Mg in Jeffery's alite structure. The solubility in material processed at 1200–1400°C is 0.3 to 6.7% Na_2O.

Brownmiller and Bogue reported temperature maxima on the boundary curves "C_5A_3"–CA and 'C_3A_3'–C_3A which they interpreted as indicating solid solution in "C_5A_3" of one or more of the calcium sodium aluminates. The extent of this solid solution would be about 1% of Na_2O.

The relation between C_3A and C_8NA_3 has been re-investigated (27). Lattice changes were observed in C_3A up to 2% replacement of CaO by Na_2O. The results for greater amounts of Na_2O could be interpreted as mixtures of C_3A(SS) and C_8NA_3(SS) or as showing polymorphic behaviour in C_3A with extensive solid solution. The system $CaO–Na_2O–Al_2O_3$ close to the C–A boundary system should be re-investigated in a water-free atmosphere.

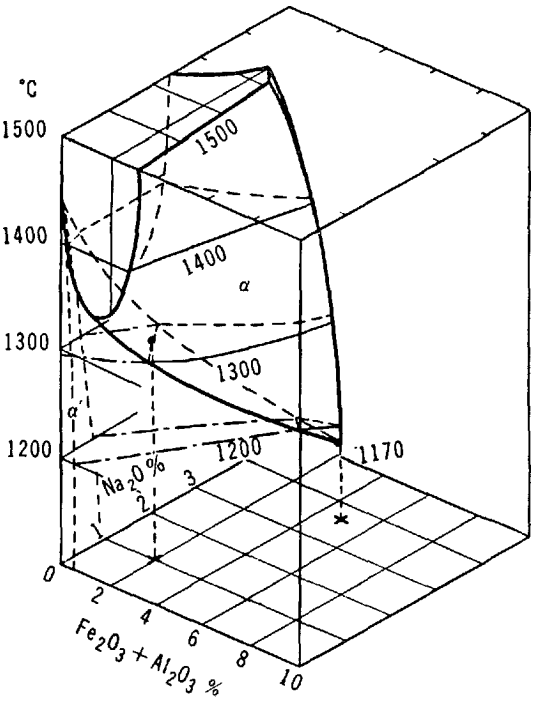

Fig. 7. *Solid solution region of* α-Ca_2SiO_4 *in the system* $2CaO \cdot SiO_2$–$(2CaO(Al_2O_3 \cdot Fe_2O_3))$–$Na_2O$–5% MgO; $Al_2O_3/Fe_2O_3 = 1$.

Sulphates, Fluorides, Phosphates

A technique of studying systems with volatile components using sealed capsules has been described (28), and used in studying part of the system $CaO–SiO_2–CaSO_4$ (29)(30). A new silico-sulphate, $2(2CaO \cdot SiO_2) \cdot CaSO_4$, was described, decomposing at 1298°C into α'-C_2S and $CaSO_4$. The maximum content of SO_3 in α'-C_2S at 1200°C is 0.4%.

Halstead and Moore confirm the composition of the expansive component of certain expanding cements as $3CaO \cdot 3Al_2O_3 \cdot CaSO_4$ and give a suggested structure (31). Budnikov, Kuznetsova and Savelev discuss the formation of this compound from the

aluminates in the presence of SO_3 (32).

A new version of the system $CaO–CaF_2–2CaO \cdot SiO_2$ has been produced by Mukerji (33). A much larger field of C_2S is shown compared with the earlier version of Eitel. No solid solution in the various forms of C_3S or C_2S was discovered. Similar results at the liquidus were reported by Gutt and Osborne (34) but they found an intermediate compound $2(2CaO \cdot SiO_2) \cdot CaF_2$, the fluoride analogue of calcio-chondrondite. The new compound decomposes at 1040°C into α'-C_2S and CaF_2. It seems likely that $2(2CaO \cdot SiO_2) \cdot CaF_2$ is 'phase B' described by Bereczky (35), who also found another compound in the system, 'phase A', related to C_3S. Akaiwa, Sudoh and Tanaka (36) identify this as $11CaO \cdot 4SiO_2 \cdot CaF_2$. The same authors also show changes in the X-ray spacings of β-C_2S up to 3% of added CaF_2.

In the system $CaO–Al_2O_3–CaF_2$, Leary (37) found $3CaO \cdot 3Al_2O_3 \cdot CaF_2$ and Jeevarathnam (38) $11CaO \cdot 7Al_2O_3 \cdot CaF_2$ ($Ca_{12}Al_{14}O_{32}F_2$, analogous with $Ca_{12}Al_{14}O_{32}(OH)_2$).

The system $CaO–P_2O_5–SiO_2$ in the high lime region has been described by Gutt (12), Fig 8. Schlaudt (9) also did some work on this system, and accepted Gutt's liquidus data. He interprets the solid solution equilibria rather differently, guided in part by an assumed structural interpretation. The conclusions for cement technology are not materially affected by the discussion.

Fig. 9 shows the section $3CaO \cdot SiO_2–3(3CaO \cdot P_2O_5)$ CaF_2 (fluorapatite) after Schlaudt (9), and Fig. 10 the system $CaO–C_2S$–fluorapatite. These systems were investigated in order to clarify the effect of fluorspar additions to phosphate-containing cement. Schlaudt concludes that since C_3S disappears from the system $CaO–C_3S–C_3P$ at 3 molecular percentage of C_3P and from the $CaO–C_3S$–fluorapatite system at 4 molecular percentage of fluorapatite, the "tolerance for combined fluoride and phosphate impurity in cement raw materials is seen not to be substantially different from the tolerance for phosphate alone." This does not however allow for the much higher molecular weight of apatite compared with tricalcium phosphate. In fact, the addition of fluorspar to the system according to Schlaudt's data increases the tolerance for phosphate in terms of the weight of P_2O_5 about $3\frac{1}{2}$ times. Fig. 10 also indicates that fluorapatite will not appear as a phase until all C_3S has been decomposed. This is in agreement with the mineralogical examination of cement clinkers containing these impurities.

Reducing Conditions

Several contributions at the Washington Symposium dealt with this question, and in particular the role of FeO. It was shown that formation of FeO in large quantities results in dusting of the clinker and an acceleration of the low-temperature decomposition of C_3S. Woermann determined the solubility of FeO in C_3S at 1500–1600°C as 2.6 per cent, substituting for CaO. Phillips, Somiya and Muan's (39) studies on MgO-iron oxide in air atmosphere indicate that extensive solid solution of FeO in MgO may occur at clinkering temperatures; earlier work (40) indicated solid solution of FeO in CaO (10 per cent maximum) which slowed down the rate of hydration.

The reduction of Cr_2O_3 and its effect on C_2S were studied by Glasser and Osborn (41), and Kondo and Goto have described a new compound $7CaO \cdot Cr_2O_5 \cdot 2SiO_2$ (42). In the system $2CaO \cdot SiO_2$–$2MnO \cdot SiO_2$ Glasser (43) measured maximum solid solubility of 19 and 31.5% Mn_2SiO_4 in α and α' C_2S, respectively.

Other Minor Components

The solid solutions of the orthosilicates of alkaline earth oxides were described by Toropov at the Washington Symposium, and a new study with Fedorov (44) concerns the system $2BaO \cdot SiO_2$–$2CaO \cdot SiO_2$. The same authors (45) find that 'complex' crystals as previously described by Douglas at the London 1952 Symposium occur in the system $2CaO \cdot SiO_2$–$2Nd_2O_3 \cdot 3SiO_2$ (neodymium orthosilicate). Four new compounds in the system $2BaO \cdot SiO_2$–$2CaO \cdot SiO_2$–$2MgO \cdot SiO_2$ were found by Nadchovski and Grylicki (46). Reference (4) quotes solubility (at 1550°C) of Cr_2O_3 (1.4%) and Ga_2O_3 (0.9%) in C_3S. Sychov and Korneev (47) state that Cr substitutes for Si in C_3S up to a weight percentage of 2% Cr_2O_3. Larger additions of oxide decompose the C_3S. See also (41). Part of the quaternary system CaO–ZnO–Al_2O_3–SiO_2 was investigated by Segnit (48). Willemite, $2Zno \cdot SiO_2$, does not co-exist with C_2S; the latter forms a join with ZnO and no solid solution was observed.

Glass Formation

Since the development of improved methods of X-ray analysis, in particular quantitative diffractometry, doubts have been expressed as to the possibility of a glassy phase existing in portland cement clinker. For instance it has been considered that such differences as do exist between clinkers cooled at different rates are "textural" rather than qualitative. Nevertheless, quicker cooling of clinker is accepted in practice as improving strength and particularly soundness with regard to MgO and resistance to sulphate attack.

All the observations on which opinions regarding the absence of glass are based have been made on commercial clinkers as received from the kiln and rely on the fact that the totals of C_3S, C_2S, C_3A and ferrite phases are reasonably close to that expected on the assumption of complete crystallinity, having regard to the known fairly high errors in diffractometry of clinker. It could be asked whether the method is accurate enough to detect the small quantities of glass which might be expected in commercially prepared clinkers. Jeffery and Chatterji (49) prepared quenched and annealed clinkers from plant clinkers, but although some changes in X-ray pattern were noted did not detect glass either by difference or by a diffuse X-ray reflection. It was therefore decided at the Building Research Station to look for glass in laboratory clinkers, cooled under controlled conditions. The clinkers chosen were repetitions of some of the compositions studied by Parker (50). The compositions chosen are given in Table 1 and the results obtained in Table 2. Methods of preparation and cooling were as described by Parker.

The quantities of glass calculated from the diffraction results are almost certainly significant and varied from 10–20% as compared with calculated values of 31–32% assuming perfect quenching. Looking at the results from a different angle, the reduction in C_3A brought about by quenching is from 15 to 5% for composition 15; 17–13 for composition 17 and 17–5 for composition 18. This correlates well with Parker's observations that the alkali– and magnesia-free clinker 17 was difficult to quench, and that this clinker differed little in sulphate resistance whether

quenched or crystallized. Clinkers 15 and 18 increased markedly in sulphate resistance when quenched.

It is worth while noting some other indications brought out in this study. In general the C_3S/C_2S ratio found by diffractometry or microscopy is higher than calculated from Bogue's formula. It is higher also than the raised values obtained by the modified Lea and Parker's formulae. Nurse and Parker reporting on the microscopy of Parker's clinkers found fair agreement with Bogue's formula for annealed clinkers but raised C_3S/C_2S ratios in better agreement with Lea and Parker's formulae for quenched clinkers. Lea in his book gives a table of factors all tending to raise the C_3S/C_2S ratio above that given by the simple Bogue formula.

Clinkers 15 and 18 when quenched gave a trigonal form of C_3S. It might be queried whether this could have affected the properties of the quenched series as compared with the crystalline. Parker's original tables indicate that such an effect if present is overshadowed by the effect of cooling rate.

It appears that glass cannot be ignored as a possible phase in cement. Present accuracy in diffractometry means that it cannot be detected unless present in large amounts. The effect of cooling rate on clinker warrants further study, both in regard to the factors affecting the glass stability and the effect of cooling rate on the C_3S/C_2S ratio (51).

Other recent studies of the liquid phase have not attempted to estimate changes in constitution with heating rate (49) (52).

Kinetics

The departures from equilibrium which have so far been considered are those arising from the range of the clinkering temperature and the rate of cooling. A very important deviation is caused by lack of homogeneity in the clinker, either by insufficient grinding, poor mixing, segregation or absorption of foreign material such as ash or volatile matter in the kiln; phase studies can be of only minor help in solving these problems. Studies with synthetic systems can be useful when carefully blended raw materials are processed according to a known temperature schedule and the progress towards equilibrium is measured. Alternatively the interface between reactants may be studied.

The author pointed out at the Washington Symposium the importance of free CaO as a clinker constituent, and the possible effect it may have on the composition of the liquid at the clinkering temperature. It is not unusual for British cements to have free CaO as high as 4%. Free CaO may be present as relict, unreacted matter; may have formed at equilibrium either in the absence of C_2S or in contact with C_3S and C_2S solid solutions; may have been formed by high temperature decomposition reactions, or may result from low temperature decomposition of C_3S. The composition of the clinker liquid at various stages of time and temperature and its viscosity are highly important factors in the kinetics of clinker formation. During the preheating and cooling stages solid/solid reactions are important.

A review of the contribution of the Brussels group to the subject of solid state reactions was published in 1956 (53). Andouze (54) showed that CA is the primary compound formed at 900°C in the system CaO–Al_2O_3, the rate-controlling process of formation of other aluminates being diffusion; on the other hand Uchikawa, Tsumagari and Koike found a preferential formation of C_3A in the early stages (55). In the system CaO–SiO_2 Schrämli and Becher (56) demonstrated the importance of the physical condition of the silica phase, the low rate of reaction of pure crystalline quartz is a severe problem in cement burning. The extension of DTA. methods to high temperatures has opened up new possibilities of studying the process of clinker formation (57).

It has always been recognized that the low temperature decomposition of C_3S represents a hazard in processes, such as shaft kiln burning, which involve slow cooling. Formation of FeO or presence of other oxides which lower the decomposition temperature increases these difficulties. On the other hand, in the presence of these substances there is a longer temperature range for the formation of C_3S in the heating cycle. Butt and Timashev show that C_3S forms already at 900–1000°C in the presence of $CaSO_4$ or CaF_2 (58). Under atmospheric conditions favouring the formation of spurrite $2(2CaO \cdot SiO_2)CaCO_3$, C_3S is formed at 1050°C (57) (59). The discovery of new silicofluorides, silicosulphates and the recognition of the possibility of transient formations of silicocarbonates throws new light on the possible use of mineralisers in cement burning. By further studying the kinetics and phase equilibria in these systems it might be possible to invent new methods of cement burning using a large excess of volatile flux at intermediate temperatures which could be driven off at a higher temperature, recovered and returned to the kiln. It seems important in each case to establish the phase equilibria precisely. This information is also required to follow processes using impure raw materials such as by-product gypsum.

Mineralizers affect not only the silicate phases but the aluminates, and it is important to study them in combination (60) (61). Also many minor components have a disproportionate effect on the composition of the ferrite phase.

Discussion and Conclusions

With the greater precision now attempted, the accuracy of chemical analysis needs to be questioned; e.g. recent changes in specifications have introduced a more direct estimation of Al_2O_3, of practical importance in defining sulphate-resistant cements.

The merits of phase studies as a means of elucidating clinker constitution are (1) the number of independent variables is reduced and trends emerge much more clearly (2) there is the possibility of calculating clinker constitution from the bulk analysis.

It is now becoming apparent that too close a limitation of the number of constituents will lead to errors of two kinds; an incorrect estimation of the nature and quantity of the phases present and the obscuring of variability that may exist among the physical and chemical properties of these phases. For instance, while the addition of MgO to the C–A–S–F system is fairly simply dealt with as in Swayze's classical work, when the C_3S and C_2S contain minor oxides in solid solution, the addition of MgO to the system often

materially changes the solid solubility. Even larger disturbances are created by some of the 'fluxing' substances such as fluorides, sulphates, carbonates and FeO. In each case it is necessary to work out the phase diagrams accurately. Some classification may then be possible e.g. between those minor components that form extensive C_2S solid solutions in equilibrium with C_3S and CaO, and those which either themselves enter into equilibrium with CaO and C_3S or form definite compounds which do so. The sub-solidus reactions of C_3S must be investigated in each case.

Attempts are made to introduce more accurate computations of phase constitution than the Bogue formula. For instance Schlaudt (9) has set up a computer programme which aims to take into account a number of minor constituents. Miyazawa (15) suggests allowing for MgO present in liquid and in solid solution in C_3S: Free MgO = Total MgO − (0.77 + $0.12C_3S$). It is doubtful if these formulae will be of much practical use until a more accurate allowance can be made for the composition of the ferrite phase. For most purposes the Bogue calculation is sufficient; otherwise the composition of the ferrite may be determined by X-rays and the "modified Bogue" composition calculated. For any more detailed estimation of clinker constitution a combination of optical microscopy, X-ray analysis, phase calculation, microprobe analysis and DTA. is desirable. Nevertheless proper and rigorous phase studies among clinker components remain a fruitful and necessary region of study.

Written Discussion

J. A. Hedvall

I have the impression that reactions in the solid state, taking place at temperatures as low as 500–600 degr. centigrade have not, as yet, been sufficiently investigated. Such reactions, whether the formation of more or less complex compounds or solid solutions, influence the reactions and sintering processes or the formation of molten phases at the higher temperatures in the kiln.

Many industries, especially cement factories, start with very heterogeneous raw materials. Many years ago it was established that calcium silicate (first C_2S) and aluminates are formed already at about 500 degr. and that the compositions of limestone and clay do not exactly correspond to the ideal formulae of calcium carbonate or kaolin. We have to take into consideration the influence of many factors, admixtures of other substances, lattice distortions in the form of guest particles and the formation of a number of unstable reactive phases formed during thermal decomposition processes. At our institute we have studied such reactivity effects. I am leaving out the great but very little investigated influence of dissolved inert gases on the properties of surfaces.

In order to complete our knowledge many problems are still left more or less unanswered about the properties of single substances, binary or more complex systems and the behaviour of such systems at different temperatures, especially the processes at relatively low temperatures.

Oral Discussion

E. Woermann and D. Knoefel

Non-Equilibrium Crystallization of Free Lime

In the ternary system CaO–Al_2O_3–SiO_2 the "lime limit" (1) of white portland cement clinker—i.e. the maximum amont of CaO which can be combined without the formation of free lime—is given by the straight line through the points C_3S and invariant point D ($CaO + C_3S + C_3A$ + liq; 1470°C). The equation of this line is: $CaO = 2.80\ SiO_2 + 1.18\ Al_2O_3$.

It has been found, however, that free lime can also appear upon quick cooling of certain mixtures in which equilibrium crystallization of free lime is

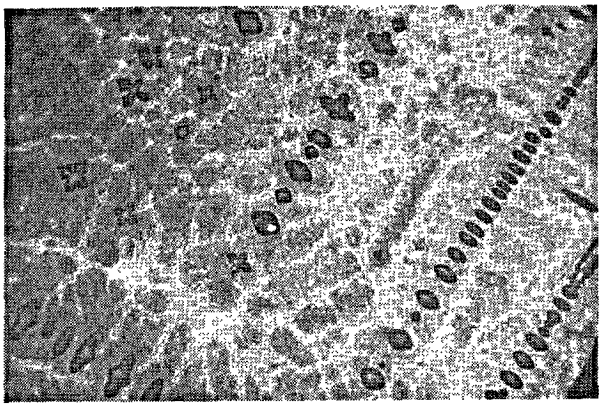

Fig. 1. *Quench growth of free lime (dark grey) in a sample corresponding to the composition of the invatriant point D (2), after rapid cooling (5°C/sec.) from above the liquidus temperature. Enlarged: 500x; etched with dist. water.*

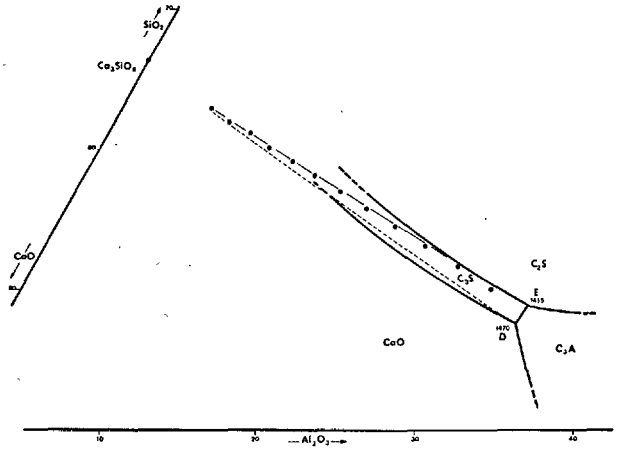

Fig. 2. CaO-*rich corner of the ternary system* CaO–Al_2O_3–SiO_2. *Experimental data on the "lime-limit" of samples cooled at a rate of 10°C/sec. The dashed line corresponds to the theoretical lime limit assuming quenched high-temperature equilibrium.*

excluded (Fig. 1). Thus the practical lime limit is shifted to lower CaO-concentrations (Fig. 2).

The possibility that the position of the invariant point D with: $CaO = 58.2\%$, $Al_2O_3 = 33.1\%$ and $SiO_2 = 8.7\%$ (2) is incorrect, can be excluded. Therefore the surprising appearance of free lime beyond the line C_3S–D must be due to non-equilibrium crystallization or quench growth, effected by the high viscosity of the liquid phase and the sluggish crystallization of the aluminate.

The amount of free lime is dependent on composition and cooling rate of the sample: Fig. 3 shows that for the sample-composition of the invariant point D a maximum value of about 4.5% free CaO is attained for a cooling rate of about 1°C/sec.

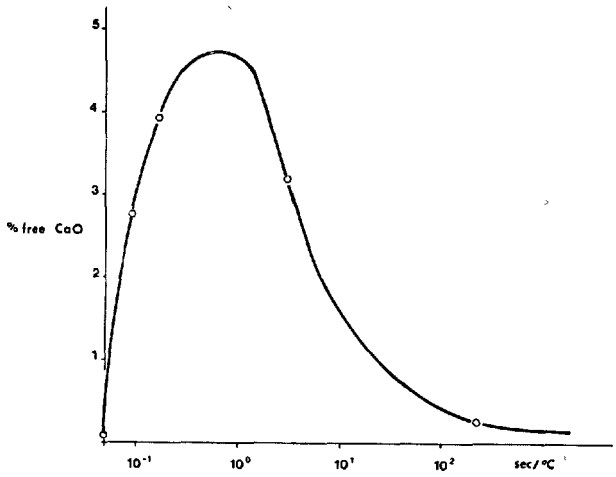

Fig. 3. *Formation of non-equilibrium free lime in a sample corresponding to composition D as a function of cooling rate. (The abscissa represents the reciprocal value of the cooling rate in an arbitrary spacing.)*

This effect may be important to manufacturers of white cement. In iron-containing systems, however, the viscosity of the liquid phase is lower and the ferrite phase crystallizes quite rapidly. Accordingly, non-equilibrium crystallization of free lime is not observed in normal portland cement clinker.

Oral Discussion

Della M. Roy

Dr. Nurse has emphasized the point that one must consider the effect of temperature when describing the limits of crystalline solution of a particular component in a given phase. A good example of this was found in our studies of C_3S–"M_3S" crystalline solutions, where we have found that up to 9 mole percent "M_3S" may be incorporated in C_3S at high temperatures in equilibrium with liquid. These crystalline solutions are, however, metastable at lower temperatures. Slow cooling, or re-cycling, such as under the conditions present in DTA experiments results in exsolution to produce a phase containing relatively little Mg. Such changes in the character of the crystalline solutions are reflected in the temperature of the DTA peaks of the resultant phase.

Author's Closure

Ronald W. Nurse

Since the preparation of the Principal Paper, Woerman, Hahn and Eysel have published two more papers (1) (2) on the question of MgO and Al_2O_3 in C_3S. Their first paper described a chemical investigation by the free lime method and used starting mixtures stated to contain 2–4% free CaO. The final limit of solution of Al_2O_3 at 1% was said to be determined microscopically. The second and third papers started in addition with mixes originating with C_3S or its solid solution, without excess free CaO, and relied also on microscopic determinations by reflected light. These investigations are therefore more rigorous than the original one and suggest that a range of solid solutions is possible, giving rise to a solid volume in the quaternary system CaO–MgO–Al_2O_3–SiO_2. The high CaO limit of this volume is in agreement with Midgley and Fletcher (loc.cit) in respect of CaO/Al_2O_3 ratio, but not in the Al_2O_3 value, which shows an inflexion at 0.5%, terminating at 1%. Both Woermann, Hahn and Eysel and Midgley and Fletcher chose to process their mixes above the eutectic temperature rather than wait long periods for equilibrium to be attained by solid state sintering. This may well account for the discrepancy between their results, for the appearance of C_3A on subsequent heat treatment will depend very markedly on time and temperature. It has been noted by all the early workers on the quaternary system that it is almost impossible to re-absorb free CaO formed by decomposition of C_3A. Nevertheless, if only those points in Woermann, Hahn and Eysel's diagram showing a homogenous crystalline solution of C_3S are noted, the evidence for solutions of varying C/A ratio is strong, and the authors have given a crystallographic interpretation of what happens.

Foster (3) has pointed out an error in the presentation of phase diagrams for pure C_2S. Regourd, Bigaré, Forest and Guinier (this Symposium) confirm the existence of the α'_H and α'_L forms. The difference in structure appears to be small and there may not therefore be much difference in the solubility of other

ions in the two α' forms. This could be checked by determining the variation of the $\alpha'_H \rightleftharpoons \alpha'_L$ inversion temperature in the presence of added ions. The same authors determined the effect of added ions on the $\alpha \rightleftharpoons \alpha'_H$ inversion and from this deduced the solubility in the α phase. Since the lowered inversion points are lower than the usual clinkering temperature of cement, this is the appropriate solubility to be considered. Inversion to β on cooling may produce exsolution, according to the cooling rate and the nature of the dissolved ions.

The various vlaues suggested for the solubility of MgO, Al_2O_3, Fe_2O_3 in alite and belite are in good agreement and approximate to what has been found in microprobe analysis. The "partition" of foreign ions between alite and belite will depend on the direction of the tie lines in the appropriate ternary system, or on the intersection of bounding planes in higher systems. For Mg, Al and Fe solutions these are almost parallel to the CaO–SiO_2 axis and so only a small range of the "partition coefficient" is found (Midgley, this Symposium). The relative proportions of K_2O and Na_2O in the silicate phase as found by microprobe analysis and by chemical separation (Pollitt and Brown, this Symposium) are not in good agreement. Some further work on this is required.

In the ferrite system Woermann, Eysel and Hahn (this Symposium) have again used their very accurate free CaO determinations to investigate the solid solutions with MgO for those ferrites in equilibrium with CaO. They propose polymorphic inversions in the ferrite phase.

The very interesting work by Pollitt and Brown reinforces the need to study further the phase relations of the orthorhombic calcium aluminate, especially in respect to K_2O. The new paper by Gutt and Smith (4) summarises data on the effect of Mg and SO_4 ions on the system CaO–Al_2O_3–SiO_2, but without alkalies. As Brown and Pollitt show, alkalies must always be considered together with SO_3 in clinker constitution. Compounds richer in SO_3 may form transiently during the burning process.

The new compound described as $Ca_{12}Si_4O_{19}F_2$ by Tanaka, Sudoh and Akaiwa (this Symposium) is identical with the $3(3CaO \cdot SiO_2) \cdot CaF_2$ of Gutt and Osborne (5), and phase II appears to be the $2(2CaO \cdot SiO_2) \cdot CaF_2$ of Gutt and Osborne. Tanaka et al. found a primary phase field for the incongruently melting $Ca_{12}Si_4O_{19}F_2$. Further study is required to settle the exact composition of this compound.

The possibility of glass formation has become of increased interest because of the renewed study of high-magnesia cements. Rapid cooling reduces the amount of free periclase, but whether this is due to glass formation or to retention of magnesia in crystalline solutions is not clear. Some Stereoscan photographs of clinker, appear to show glassy envelopes on silicate grains.

I am grateful to Prof. Hedvall for emphasising the importance of kinetics of reaction in the solid state, which was dealt with interestingly by a number of supplementary papers. Mrs. D.M. Roy underlines the importance of controlling the temperature when studying solid solubility.

The new reason advanced by E. Woermann for formation of free CaO in clinker mixes emphasizes the need for continuing study of the liquid formed at clinkering temperatures, and its crystallization independently of the silicate phases. At temperatures below 1250° the lime will form under equilibrium conditions.

I thank all those who have contributed to the discussion which emphasises the need to use a combination of crystallographic, synthetic and analytical methods in studying clinker.

Supplementary Paper I-9 Manufacture of Portland Cement from Phosphatic Raw Materials

Witold Gutt*

Synopsis

The importance of the minor constituents in modifying the major phases of portland cement clinker was emphasized by Welch and Gutt at the 4th International Symposium on the chemistry of cement. The present paper deals with the manufacture of portland cement from materials containing one such impurity, phosphate.

After discussing the possible mode of action of the minor constituents an account is given of studies by Nurse which led to the utilization of phosphatic limestone deposits at Totoro, Uganda, for cement manufacture. This work was followed by detailed studies at the Building Research Station of phase equilibria in the system $CaO–SiO_2–P_2O_5$, their objective being to provide a fundamental basis for the understanding of the effect of phosphate. Phase diagrams of the systems $2CaO \cdot SiO_2–3CaO \cdot P_2O_5$ and $2CaO \cdot SiO_2–3CaO \cdot P_2O_5–CaO$ have resulted from this work. The practical significance of these phase equilibria in relation to manufacture of portland cement from phosphatic limestone and other phosphatic raw materials is explained in the present paper.

Since fluorspar is in practice sometimes added to phosphatic cement raw meal to facilitate manufacture, the role of fluorine in the process is also considered. In the course of periodic examination of plant produced phosphatic cements it has been found that fluorine and sulphate may in some circumstances have a combined controlling influence on the hydration and therefore early strength of phosphatic portland cements. Examples of this are given.

The influence of sulphate and of fluorine is being studied systematically by examining the systems $CaO–SiO_2–CaF_2$ and $CaO–SiO_2–SO_3$. Some data is given in the present paper on the strength of tricalcium silicate containing sulphate and fluorine.

Introduction

The importance of the minor components in modifying the major clinker phases, a role in which their influence is far greater than their quantitative representation in the clinker might suggest, was emphasized by Welch and Gutt (1) at the 4th Symposium. The presence of these minor components may influence the formation of the principal cement compounds, their proportion in the clinker and their quality as cementing compounds. Generally, minor components can affect the properties of the cement in three main ways:

a) They can lead to different phase relations and therefore to different reaction products at the temperature at which cement clinker is made in the kiln. This effect may include the stabilization of high temperature polymorphs of the cement compounds. They may differ in their reactivity towards water.
b) They may alter the reactivity of the main cementing compounds towards water by forming solid solutions of different properties.
c) Minor components could produce compounds soluble in water which influence the process of setting and hardening.

Phosphate combined in the clinker has influence under categories (a) and (b). The nature of its influence, and the measures taken in the manufacture of portland cement from phosphatic raw materials to take account of this influence, and the side effects of these measures, are the subject of the present paper.

The Effect of Phosphate on the Constitution and Hardening of Portland Cement

Work Leading to the Establishment of the Uganda Cement Industry

While in most portland cements the phosphate level is of the order of 0.2% expressed as P_2O_5, phosphate occurs in significant amounts in various limestone deposits. In Uganda, for instance, the only limestone available for cement manufacture, until recently, was a carbonatite containing up to 6% P_2O_5. Phosphate in such amounts was known from experience to be deleterious in the cement making process but the nature of its action was not understood until Nurse (2) began to investigate it in 1950 in connection with the possible utilization of the Uganda phosphatic limestone for cement manufacture. This had been considered before, in 1940, and was rejected because of the phosphate, (3) but the intention to build the Owen Falls dam which controls the outflow of the river Nile from Lake Victoria lent special importance to the investigations in 1950.

Nurse (2) made experimental portland cement clinkers containing known amounts of CaO, SiO_2, Al_2O_3, Fe_2O_3 and P_2O_5 and studied their mineralogical content. He found that their tricalcium silicate content decreased as their P_2O_5 content grew and became nil at 7% P_2O_5 by weight. It was established that phosphate was present in the clinker in solid solution with dicalcium silicate and that the maximum solid solution had the approximate composition 66.5% CaO, 26.5% SiO_2, 7% P_2O_5. The practical recommendations made by Nurse (2) were that to obtain a satisfactory portland cement, phosphate should be kept below 2.25% P_2O_5 and a process was devised for reducing the phosphate content of the limestone by a three stage process consisting of ignition, hydration of the resulting CaO and elutriation of the lime hydrate. By elutriation the coarse fraction containing phosphatic material could be removed and the phosphate in the lime hydrate diluted.

On the basis of his findings Nurse (2) provided proportioning formulae for the manufacture of cement from phosphatic limestone. These formulae were based on the assumption that in a portland cement containing phosphate, all the phosphate would be combined as the previously mentioned solid solution, or if the cement is not lime-saturated, a solid solution lying between $2CaO \cdot SiO_2$ and the composition given above. He showed that for each 1% P_2O_5 added the content of $3CaO \cdot SiO_2$ is lowered by 9.9% and that of the dicalcium silicate phase is raised by 10.9%. Nurse (2) tested the validity of these equations by making experimental cements and comparing their compound content based on these equations with that obtained by microscopic point counts of crystals seen in polished and etched sections of clinker viewed in reflected light. These were found to be in agreement. Nurse stressed two other points, firstly the need to maintain the saturation of lime, and secondly, the lower water requirements in mixing phosphatic cement. In a dry mix (0.5% water) phosphatic cements gave better results than ordinary portland cements.

Nurse's work provided the basis for the establishment of the Uganda Cement Industry who commenced manufacture at Tororo in 1953. Over 17,000 tons of the cement was used in the building of the Owen Falls dam maintaining supply when it would have been impossible to obtain sufficient cement via the port of Mombasa.

Phase Equilibria in the System $CaO–SiO_2–P_2O_5$

Phase studies of the system dicalcium silicate—tricalcium phosphate by Nurse, Welch and Gutt (4) and of the system $2CaO \cdot SiO_2–3CaO \cdot P_2O_5–CaO$ by Gutt (5–6) have consolidated and extended the interpretations which followed from the earlier work. The system $2CaO \cdot SiO_2–3CaO \cdot P_2O_5$ presents at high temperature a continuous series of solid solutions with a liquidus maximum at 2240°C. A new high temperature form of $3CaO \cdot P_2O_5$ designated $\bar{\alpha}$ was discovered (4–7) which does not survive quenching to room temperature but is completely miscible with the α form of $2CaO \cdot SiO_2$. Since the discovery of the superalpha form ($\bar{\alpha}$) of tricalcium phosphate by Nurse, Welch and Gutt (4) Trömel and Fix (8) and Berak (9–10) repeated some of their earlier studies and published confirmations of the new polymorph. It is of practical importance that β, α' and α dicalcium silicates can in turn be stabilized by increasing phosphate additions. At lower temperatures two compounds are formed by solid state reactions, the long-known silicocarnotite stable below 1450°C and a new phase denoted 'A' stable below 1125°C of the approximate composition $7CaO \cdot P_2O_5 \cdot 2SiO_2$. The latter compound will not therefore be a compatibility product relevant to the clinkering temperature of portland cement. The phase diagram of the system $2CaO \cdot SiO_2–3CaO \cdot P_2O_5$ is reproduced in Fig. 1.

Gutt (5–6) studied the system $2CaO \cdot SiO_2–3CaO \cdot P_2O_5–CaO$ and delineated the liquidus surface. Four

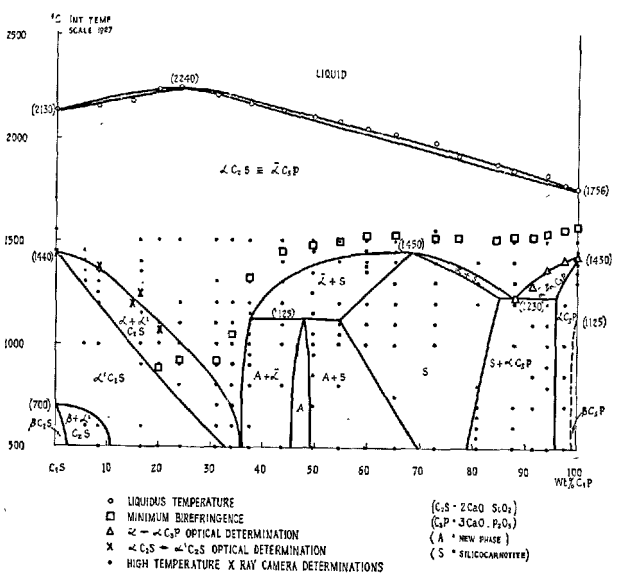

Fig. 1. *The system* $C_2S \cdot C_3P$

solid phases were individually recognisable at the liquidus, tricalcium silicate, lime. tetracalcium phosphate and dicalcium silicate/tricalcium phosphate solid solution.

The primary crystallisation fields of these phases were delineated by the examination of 68 compositions by high temperature microscopy. For these compositions the liquidus temperature and the primary phase were established and, where possible, the crystallisation path was followed and the second phase and its dissolution temperature were also determined. Some compositions selected for examination lay on two-phase boundaries and the composition of the reaction point where the three phases C_2S/C_3P_{SS}, CaO and C_4P coexist with liquid where also located experimentally. All the individual compositions studied and the observations relating to each of them together with an account of the melting behaviour and characteristics of crystal growth of the solid phases encountered in this system were given by Gutt (6) In accordance with the study of $3CaO \cdot SiO_2$ by Welch and Gutt (11) which established that this compound melts incongruently, $3CaO \cdot SiO_2$ has a primary crystallisation field in the system $2CaO \cdot SiO_2$–$3CaO \cdot P_2O_5$–CaO which extends to the binary system CaO–SiO_2. In the system $2CaO \cdot SiO_2$–$3CaO \cdot P_2O_5$–CaO this field extends to 13% P_2O_5.

There are two reaction points. The first of these R_1 between lime, C_4P and C_2S/C_3P_{SS} occurs at the composition 34.5 P_2O_5, 60.75 CaO, 4.75 SiO_2 (weight %) and has a liquidus temperature of 1636°C. The simultaneous presence of the three phases at the liquidus temperature in this composition was established by high temperature microscopy. R_1 is a ternary eutectic point. The boundary between the primary crystallisation fields of C_4P and the C_2S/C_3P_{SS} passes through a liquidus temperature maximum M_2 before reaching R_1. The maximum M_2 occurs at the point where the C_4P–C_2S/C_3P_{SS} boundary is intersected by the Alkemade line C_4P'–C_3P. The formula C_4P' represents a solid solution of C_4P with calcium and silicate ions.

The second reaction point between C_3S, CaO and C_2S/C_3P_{SS} occurs at the composition 67.2 CaO, 19.8 SiO_2, 13 P_2O_5 (wt %) and its liquidus temperature is 1970°C. The liquidus temperature maximum M_1 on the C_3S–C_2S/C_3P_{SS} field boundary is at the point where the Alkemade line C_2S–PSS' intersects this boundary although some displacement of PSS' towards C_3P is expected as the temperature rises.

The liquidus temperatures along the C_3S/CaO primary field boundary rise from the reaction point R_2 and reach 2150°C as this boundary approaches the CaO–SiO_2 system. This seemed to be in conflict with the liquidus temperature of 2070°C reported by Welch and Gutt (11) for the composition 71.5% CaO, 28.5% SiO_2 (wt %) where the incongruent boundary with lime occurs. In view of this the lime rich region of the system CaO–SiO_2 was re-examined leading to the revised diagram (5–6) in Fig. 2. It will be seen that the work of Welch and Gutt (11) is confirmed in every respect with the exception of the liquidus temperatures between the eutectic, between C_2S and C_3S and lime.

The phase diagram of the system C_2S–C_3P–CaO is reproduced (5–6) in Fig. 3. In comparing it with earlier phase diagrams proposed by Barret and McCaughey (12) and of Trömel, Harkort and Hotop (13) it should be remembered that their work preceded successful delineation of the equilibria in the binary system $2CaO \cdot SiO_2$–$3CaO \cdot P_2O_5$ (4), the detection of $\bar{\alpha}$ tricalcium phosphate (7) and the demonstration that $3CaO \cdot SiO_2$ melts incongruently (11). These earlier studies failed to detect the primary crystallisation field of $3CaO \cdot SiO_2$ in the system $2CaO \cdot SiO_2$–$3CaO \cdot P_2O_5$. Barret and McCaughey included in their proposed diagram a primary crystallisation field for silicocarnotite a phase which does not exist at liquidus temperatures as it inverts above 1450°C without decomposition into a $\bar{\alpha}$ tricalcium phosphate solid solution (see Fig. 1).

Compatibility relations were examined for the system C_2S–C_3P–CaO that apply at 1500°C since this is the temperature of particular importance in portland cement manufacture. While considering the division of the system into compatibility triangles a hypothe-

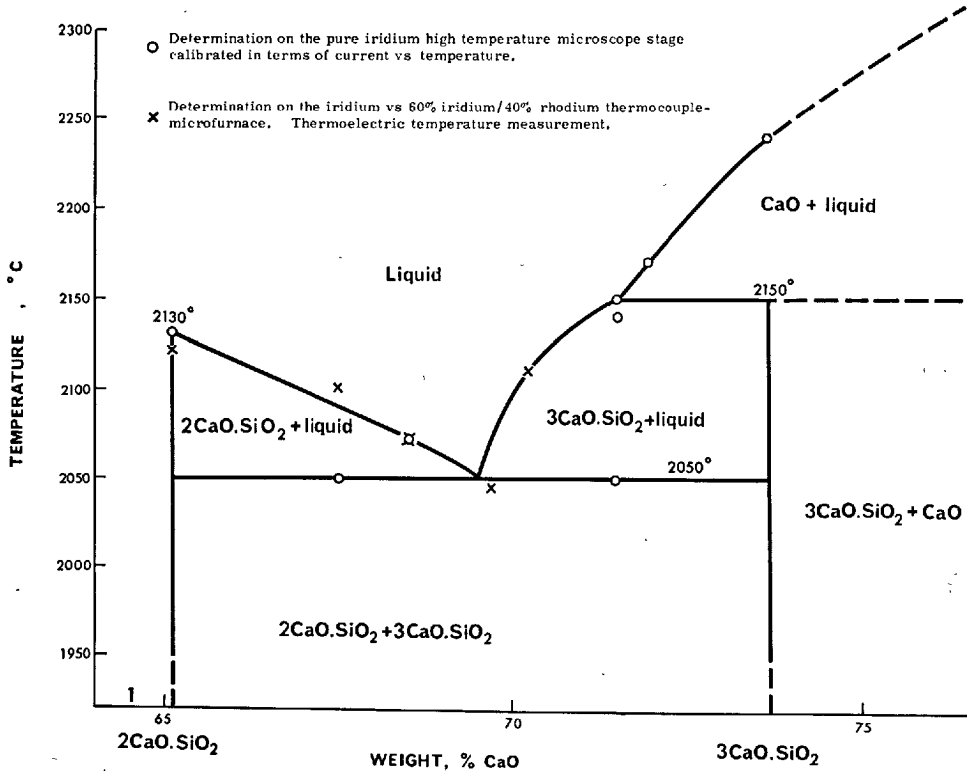

Fig. 2. *Revised phase diagram for lime rich portion of system* $CaO–SiO_2$

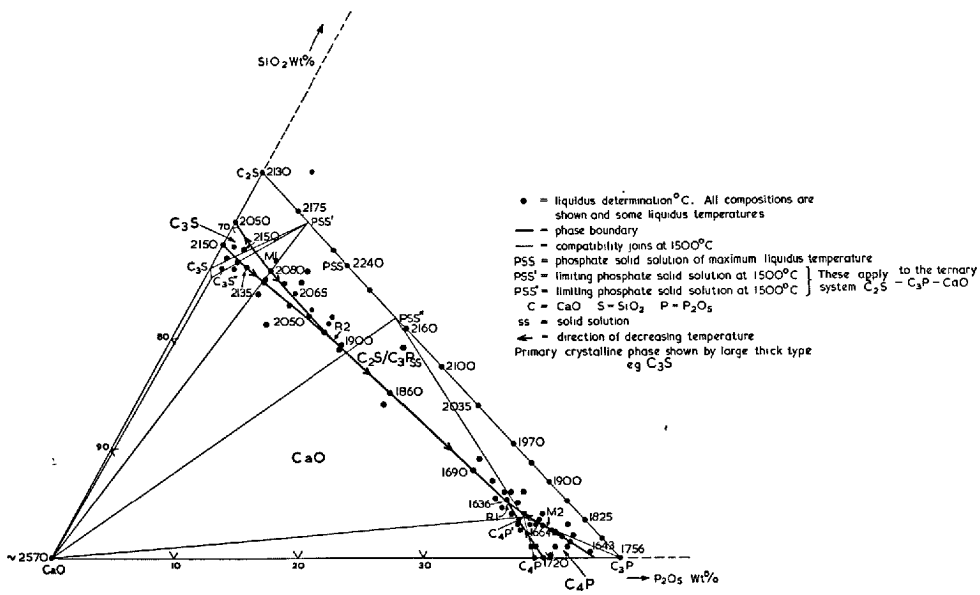

Fig. 3. *Phase diagram of the system* $C_2S–C_3P–CaO$

tical join was studied between C_3S and PSS the composition of maximum liquidus temperature on the C_2S–C_3P join (PSS = 75.9% C_2S, 24.1% C_3P wt). Examination of fully reacted compositions showed, however, that lime was present in compositions on the side of this join nearer to the system CaO–SiO_2 indicating that the true join led to a point on the C_2S–C_3P join poorer in C_3P than PSS. The method then adopted for the location of the true joins consisted of free lime analysis of selected compositions in the system in which CaO is one of the three stable phases at 1500°C. Subtraction of free lime gave the corresponding two phase compositions on the join.

The joins

	PSS′	—	C_3S''
	C_3S	—	C_3S''
	C_4P	—	C_4P'
and	C_4P	—	PSS″

where thus established.

The whole scheme was tested by examining by X-ray analysis the phases present in 40 selected compositions, which are plotted in Fig. 4, and further, by examining equilibria at 1650°C. The full details were given by Gutt (5–6), but the compatibility diagram is reproduced in Fig. 4.

Schlaudt (14) studied the system CaO–SiO_2–P_2O_5 with reference to C_3S crystalline solutions and examined experimentally 19 compositions on the joins $Ca_{19}Si_5O_{29}$–C_4P and C_3S–C_4P. For other parts of the system Schlaudt (14) accepted the liquidus data published by Gutt (5) and he also accepted the validity of the phase diagram of the system C_3S–C_3P provided by Nurse, Welch and Gutt (4). Since all the compositions studied experimentally by Schlaudt lie inside the primary crystallization field of lime and provide no data on phase boundaries, Schlaudt, in effect, assumed the validity of the whole of the liquidus surface of the system C_2S–C_3P–CaO due to Gutt (5) and reproduced here in Fig. 3. Schlaudt's work therefore produced no modification of the phase diagram at liquidus temperatures. Schlaudt further stated that "he disregarded subsolidus reactions in phase identification and that higher temperature assemblages were determined by observation of textures". He stated also however, that "crystal growth during the quenching process was so rapid throughout the system that the appearance of several quench phases often masked the true high-temperature equilibrium assemblages". In these circumstances, the interpretation of Schlaudt's observations by the methods he adopted must indeed have been difficult and the advantages of high temperature microscopy and X-ray analysis used by Gutt (5–6) are manifest.

While accepting Gutt's liquidus surface for the system C_2S–C_3P–CaO, Schlaudt suggested minor modifications to the compatibility diagram for the subsolidus. These included, firstly, a preferred composition for the tricalcium silicate solid solution with calcium and phosphate ions, i.e. 98.2 C_3S, 1.8 C_5P mole% = 73.4 CaO, 25.5 SiO_2, 1.1 P_2O_5 wt% for

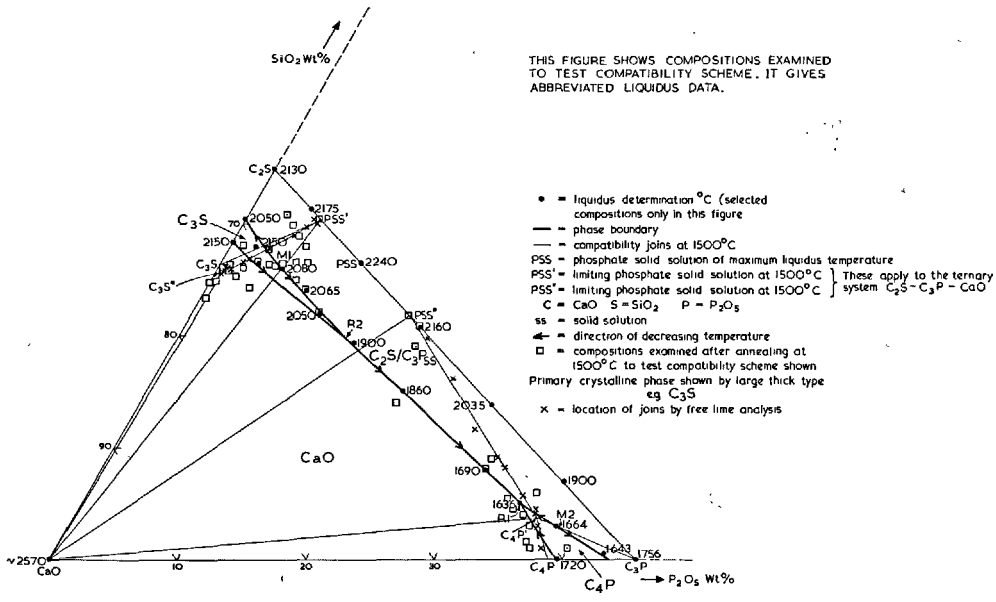

Fig. 4. *Phase diagram of the system* C_2S–C_3P–CaO

$C_{3.11}SP_{0.01}$ = 74 CaO, 25.5 SiO_2, 0.5 P_2O_5, wt%, on the grounds that it is theoretically more fitting. Secondly, Schlaudt arrived at the composition 58 mole% C_2S, 42 mole% C_3P as preferable to PSS'' which is equivalent to 75 mole% C_2S, 25 mole% C_3P. This preference does not appear to be borne out by Schlaudt's experimental results. Thirdly, Schlaudt would prefer the composition 94.8 C_2S, 5.2 C_3P mole% = 91 C_2S, 9 C_3P wt% = 64.1 CaO, 31.8 SiO_2, 4.1 P_2O_5, wt% to Gutt's point PSS' given at the composition 92.65 C_2S, 7.35 C_3P mole% = 87.5 C_2S, 12.5 C_3P wt%.

It should furthermore be noted that Schlaudt's compatibility triangles apply to unspecified solidus temperatures and cannot be directly compared with Gutt's (5–6) compatibility scheme for the system C_2S–C_3P–CaO applicable at 1500°C and checked at 1650°C. Further theoretical speculations were also made by Schlaudt (14) on compatibility in the region of C_4P but these were not based on any experimental data.

On p. 58 of his thesis Schlaudt (14) attributes to Welch and Gutt the assertion that αC_2S cannot be stabilized to room temperature by 'phosphorus' alone. These authors have, in fact, earlier shown (4) that αC_2S can be stabilized by calcium phosphate in the region of 34 C_3P (wt%) in the system C_2S–C_3P as shown in Fig. 1, reproduced here. Welch and Gutt (1) have also used the same composition to assess the hydraulicity of αC_2S stabilized as phosphate. The modifications suggested by Schlaudt to the system C_2S–C_3P–CaO do not affect significantly the practical considerations which follow in which Gutt's (5–6) original phase diagram for the system C_2S–C_3P–CaO is used and all subsolidus reactions (4) are taken into account.

Practical Significance of the Phase Data in Relation to the Cement Making Process

Before the publication of Nurse's paper in 1952 (2) it was believed that tricalcium silicate, the most important compound in portland cement clinker did not occur in the system CaO–SiO_2–P_2O_5 and that the phases formed in phosphate containing cement would be CaO, $2CaO \cdot SiO_2$ and Nagelschmidtite ($7CaO \cdot P_2O_5 \cdot 2SiO_2$) or $2CaO \cdot SiO_2$, $3CaO \cdot 2SiO_2$ and Nagelschmidtite. If this had been true it would have been impossible to make portland cement from phosphatic raw materials. Nurse showed by making cements containing tricalcium silicate with raw material having up to 7% P_2O_5 that the earlier phase diagrams of the system CaO–SiO_2–P_2O_5 could not be correct in relation at least to tricalcium silicate. The present work has shown directly that $3CaO \cdot SiO_2$ has a primary crystallization field extending to 13% P_2O_5 and that at 1500°C $3CaO \cdot SiO_2$ or $(3CaO \cdot SiO_2)''$ (see Figs. 3–4) would be present as compatibility products in compositions of low P_2O_5 concentration.

The second point in order of importance is that in addition to limiting the quantity of $3CaO \cdot SiO_2$ due to preferential formation of a phosphatic dicalcium silicate solid solution, the presence of phosphate may lead to stabilization of dicalcium silicate in the non-hydraulic α or the weakly hydraulic α' form. This adverse effect of phosphate is counter-balanced by the fact that β dicalcium silicate stabilized by phosphate may be of high cementing quality (15). The cementing quality of the four polymorphs of dicalcium silicate stabilized with calcium phosphate was assessed by Welch and Gutt (1).

The maximum solid solution of phosphate with $2CaO \cdot SiO_2$ at 1500°C would be in weight per cent PSS' (87.5% $2CaO \cdot SiO_2$, 12.5% $3CaO \cdot P_2O_5$) or PSS'' (62.4% $2CaO \cdot SiO_2$, 37.6% $3CaO \cdot P_2O_5$) not the composition suggested by Nurse (66.5% CaO, 26.5% SiO_2, 7% P_2O_5). This, however, applied to the ternary system. Nurse's (2) composition for this solid solution originates from studies of five component mixtures containing also Fe_2O_3 and Al_2O_3 and this difference must represent the effect of Fe and Al on the phase relations.

The tricalcium silicate solid solution with Ca^{++} and PO_4^{---} ions (C_3S'') has been tested for strength. The cementing quality of the composition (C_3S'') is not much different from that of pure $3CaO \cdot SiO_2$ apart from slightly lower one day strength.

The polymorphism of $3CaO \cdot SiO_2$ has been studied by Nurse and Welch (16) who found transformations at 923°C and 980°C respectively. These transformations have been confirmed and further studied by Yamaguchi and Miyabe (17). More recently further complexities of the polymorphism of this compound have been studied and (18–19) the question whether the cementing quality of the different structural modifications differs has received attention (20). The existing evidence indicates that the influence of polymorphism on hydraulicity of tricalcium silicate is small but in this connection it should be stated that both the phases $3CaO \cdot SiO_2$ and $(3CaO \cdot SiO_2)''$ identified in the system CaO–$2CaO \cdot SiO_2$–$3CaO \cdot P_2O_5$ were in the triclinic form.

The Role of Fluorine in Portland Cement Manufacture

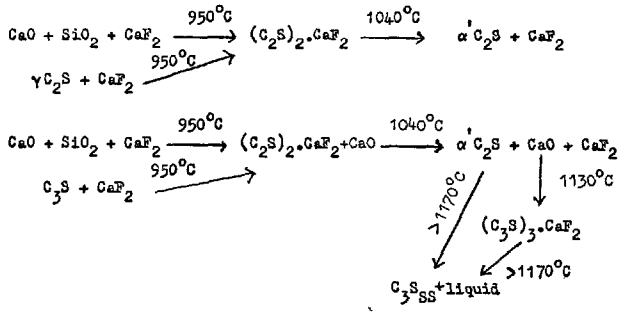
It is necessary to consider next the effect of fluorine on the reactions occurring in the formation of portland cement clinker since CaF_2 may be added to the raw meal to improve the quality of phosphatic cement. The phosphatic cement made at Tororo, Uganda, contains approximately 1% fluorine.

Welch and Gutt (1) reported at the previous symposium that fluorine ions enter the crystal lattice of tricalcium silicate changing the structure from triclinic in the direction of the monoclinic form. The addition of fluorine increased the rate of formation of $3CaO \cdot SiO_2$ but its cementing quality was reduced. Fluorine did not stabilize high temperature forms of C_2S. Nurse, Midgley, Gutt and Fletcher (20) explored the effect of polymorphism of C_3S on the reactivity of this compound towards water. They used preparations in the series $C_{156-x}M_xS_{52}$ in which x took the values 0, 1, 2, 5, 6. A second series of preparations of the same composition was made with addition of CaF_2 and subtraction of CaO so that 0.5% fluorine remained in the mix. In this way various polymorphs of C_3S were stabilized. It was concluded that the T_{II}–T_I–Mono structural changes do not have a strong influence on reactivity towards water as meausred by strength of mortars. The effect of the change to the trigonal structure remained in doubt since Gutt (21) had found that a trigonal (or possibly orthorhombic M_{II}) preparation of C_3S containing 2.9% MnO and 0.7% F give very low strength. Fluorine had a predominant effect independent of structural form leading to lowered strength for T_{II} structures.

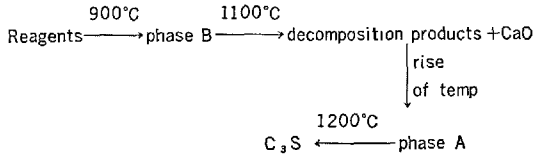
Since then the practical importance of the role of fluorine enhanced by world interest in fluorophosphatic materials had warranted renewed study of the system CaO–SiO_2–CaF_2. Gutt and Osborne (22) established the phase diagram of the system C_2S–CaF_2 showing that C_2S polymorphs do not form solid solutions with fluorine ions alone (1,22). These authors (22) characterized two calcium silico fluorides $(C_2S)_2 \cdot CaF_2$ and $(C_3S)_3 \cdot CaF_2$ which are believed to be intermediates in the formation of C_2S and C_3S when fluorine is present in the cement raw materials. The following reaction sequences have been identified:

This sequence of reactions was observable in compositions in the ternary system containing 2% fluorine. The formation of C_3S in the presence of fluorine occurs at 1170°C in agreement with previous work (1).

Evidence is available from two sources that the proposed mechanisms based on studies of the system



CaO–SiO_2–CaF_2 are applicable to cement clinker. Firstly, Bereczky (23) reported two calcium silicofluoride phases, which he named A and B, as present in ignited mixtures of C_3S and calcium fluoride. He did not assign compositions to these phases but they are identical with the compounds $(C_3S)_3 \cdot CaF_2$ and $(C_2S)_2 \cdot CaF_2$ respectively, both of which were characterized by Gutt and Osborne (22). Bereczky also identified phases A and B in cement compositions during ignition of cement raw meal containing fluorine and he proposed that C_3S was formed by the following mechanism:



Secondly, Akaiwa, Sudoh and Tanaka (24) have reported a calciumsilico-fluoride of the composition $11CaO \cdot 4SiO_2 \cdot CaF_2$. Comparison of their X-ray diffraction pattern for this compound shows that it is identical with the compound $(C_3S)_3 \cdot CaF_2$ reported by Gutt and Osborne (22a) and with phase A reported by Bereczky (23). Akaiwa et al.* found that the compound $11CaO \cdot 4SiO_2 \cdot CaF_2$ formed by decomposition of C_3S_{SS} and was especially prominent in slow cooled clinkers. They also stated that at 2% CaF_2, C_3A lines were no longer detectable and preferential formation of $11CaO \cdot 4SiO_2 \cdot CaF_2$ occurred in the clinker. Ignition of $11CaO \cdot 4SiO_2 \cdot CaF_2$ above 1190°C gave monoclinic C_3S.

The formation of the compounds $(C_2S)_2 \cdot CaF_2$ and $(C_3S)_3 \cdot CaF_2$ in the quaternary system CaO–SiO_2–P_2O_5–CaF_2 is being studied but there is no reason to suppose that the reaction sequences proposed above do not apply similarly to phosphatic cement.

The System $CaO–SiO_2–P_2O_5–CaF_2$

In considering the effect of fluorine in the specific case of phosphatic cement the system $CaO–SiO_2–P_2O_5–CaF_2$ is especially relevant.

The compositions which have been examined are given in Table 1 below. They were all ignited at 1450°C for $1\frac{1}{4}$ hr and air-quenched. The fluorine figures are derived from chemical analysis after heat treatment.

X-ray analysis of compositions 1 to 6 in Table 1 showed as the main phase, tricalcium silicate modified towards the monoclinic form in the same way as reported by Welch and Gutt (1) for C_3S containing fluorine alone.

The 7th preparation was the solid solution designated PSS′ (see Figs 3–4)with 1% added fluorine and ignited to nil free time. In this $\alpha'C_2S$ was the phase identified. The compressive strength of 1 : 3 half inch mortar cubes made from this preparation and 4% gypsum was 20 psi at 1 day and nil at later ages indicating that $\alpha'C_2S$ stabilized with phosphate in the presence of fluorine was even less hydraulic than phosphatic α' in the absence of fluorine (1).

Schlaudt (14) studied the system $CaO–C_2S–Ca_{10}P_6O_{24}F_2$ (fluorapatite) and proposed a phase diagram for the system $C_3S–Ca_{10}P_6O_{24}F_2$. α dicalcium silicate was stabilized to room temperature. A tricalcium silicate solid solution with fluorapatite was found on the join $C_3S–Ca_{10}P_6O_{24}F_2$ up to slightly more than 2 mole% at 1905°C, the invariant temperature for coexistence of liquid, C_3S, CaO and C_2S. On the basis of his work on this join a phase diagram was also proposed for the system $CaO–C_2S–Ca_{10}P_6O_{24}F_2$.

In this diagram a very small primary field is shown for C_3S extending to 3 mole% of $Ca_{10}P_6O_{24}F_2$ which is equivalent to 5.08% P_2O_5 whereas Gutt (5–6) has shown that in the system $C_2S–C_3P–CaO$ the C_3S field extends to 13% (wt) P_2O_5. It is considered that the existing data on the extent of the C_3S primary field in the system $CaO–SiO_2–CaF_2$ is still imprecise. Eitel (25) reported that this field in the system $CaO–C_2S–CaF_2$ ended at 43% CaF_2 and Mukerji (26–27) that it extends to 44% CaF_2 but the diagrams proposed by these authors differ substancially in the proposed stable phase assemblages in this region and include different phase grouping at invariant points. The discovery of the compound $(C_3S)_3 \cdot CaF_2$ means that the primary field of this compound may intrude in the ternary system. An important feature in Schlaudt's results for the join $C_3S–Ca_{10}P_6O_{24}F_2$ is that fluorapatite does not appear in mixtures containing less than 10% (mole%) of this compound.

This is equivalent to 1.2% fluorine (wt%) and this compound need not be expected therefore in detectable amounts in phosphatic-fluorinated portland cements which normally contain no more than 1.4% fluorine. Schlaudt stated that 3 mole% of C_3P or 4 mole% of fluorapatite would be needed to eliminate C_3S from the compatibility products. He argued that "the tolerance for combined fluoride and phosphate impurity in cement raw materials is not substantially different from the tolerance for phosphate alone (11). This interpretation must be questioned since 3 mole% of C_3P in the composition $97C_3S$, $3C_3P$ (mole%) is equivalent to 4.03 wt% C_3P or 1.84 wt% P_2O_5, whereas 4 mole% of $3C_3P \cdot CaF_2$ in the composition $96C_3S$, $4C_3P \cdot CaF_2$ (mole%) is equivalent to 15.75 wt% $3C_3P \cdot CaF_2$ or to 6.55 wt% P_2O_5. It follows that the tolerance for phosphate is substantially greater in the presence of fluoride and this is compatible with practical experience in cement manufacture.

The Role of Sulphate in the Manufacture of Phosphatic Portland Cement

Practical evidence exists from studies of Uganda cements that the amount of SO_3 in the clinker influences the quality of phosphatic portland cements. For this reason the systems $CaO–SiO_2–SO_3$ and $CaO–SiO_2–SO_3–F$ are being studied and a logical extension of this work would include the systems $CaO–SiO_2–P_2O_5–SO_3$ and $CaO–SiO_2–F–SO_3$.

The System $CaO–SiO_2–SO_3$

The volatility of sulphate causes considerable experimental difficulty in the study of this system being examined by Gutt and Smith. These authors have delineated the stable phase assemblages in the subsystem $CaO–CS–CaSO_4$ at 1000°C and 1200°C

(28). They also detected a new compound $(C_2S)_2 \cdot CaSO_4$ which takes part in stable assemblages at these temperatures. This compound is analogous to silicocarnotite C_5PS in the system C_2S–C_3P (4). The only solid solution detected in the 1000°–1200°C temperature range was between $\alpha' C_2S$ and Ca^{2+} and SO_4^{2-} ions giving 98.9 C_2S, 1.1 $CaSO_4$ mole% as the maximum solid solution at 1200°C and 98.3 C_2S, 1.7 $CaSO_4$ mole% at 1000°C. The C_3S primary crystallization field has not been delineated as yet. The compound $(C_2S)_2 \cdot CaSO_4$ appears to be incompatible with C_3S and the decomposition temperature for $(C_2S)_2 \cdot CaSO_4$ on the join C_2S–$CaSO_4$ is 1300°C. To study the behaviour of C_3S it is necessary to treat at above 1300°C where liquid is also present in the system CaO–CS–$CaSO_4$ as a stable phase. The presence of liquid complicates the diagram of the isothermal section at 1310°C which has been studied.

If it is assumed that the $CaSO_4$ present in preparations annealed at 1310°C and water quenched has crystallized from the glass and has not been exsolved from the C_3S_{ss} then compatibility triangles can be drawn for the system at 1310°C. The results based on this procedure give the maximum solid solution of C_3S and Ca^{2+} and SO_4^{2-} ions as 92% C_3S, 8% $2CaSO_4 \cdot SiO_2$ mole%, which is equivalent to 2.9 wt% SO_3. The substitution assumed was 1 sulphur ion for $2Ca^{2+} + 0.5Si^{4+}$. Tricalcium silicate was detected after this heat treatment at 1310°C, in the presence of 38 wt% SO_3, a much higher figure then the equivalent for phosphate.

Many workers (28, 30) have reported stabilization of the β form of C_2S by very small amounts of $CaSO_4$ and Okorokov, Golynko-Wolfson and Korneyev (30) claimed high strength for βC_2S so stabilized. It has also been claimed (31) that $CaSO_4$ accelerates formation of C_3S in the temperature range 1300°C–1450°C and improves its crystalline form. Sychev and Korneyev (32) reported that at 1500°C formation of C_3S was hindered by the presence of SO_3. The questions whether $(C_2S)_2 \cdot CaSO_4$ has a primary field in the ternary system and whether this compound is an intermediate in the formation of C_2S and C_3S solid solutions in cement clinker if the SO_3 content is substantial remain unanswered. It has been shown, however, that $(C_2S)_2 \cdot CaSO_4$ is compatible with $3CA \cdot CaSO_4$ at 1200°C. The effect of iron on the stability of $(C_2S)_2 \cdot CaSO_4$ was tested by prolonged heating of a mixture of reagents of the composition 33.3% $(C_2S)_2 \cdot CaSO_4$, 33.3% $3CA \cdot CaSO_4$, 33.3% C_4AF at 1200°C and air-quenching. The compound $(C_2S)_2 \cdot CaSO_4$ was also stable after this heat treatment.

Strength Test of Preparations on the Join C_3S–SO_3

Preparations of compositions on the join C_3S–SO_3 were ignited at 1400°C in covered platinum boats until free lime was less than 1%. Some of these preparations contained glass and they were annealed at 1300–1350°C to crystallize the glass phase. In Fig. 5 the time taken to obtain combination less than 1% free lime is plotted against % SO_3 added, showing a rapid fall in the time needed between 1 and 3% SO_3, a region in which SO_3 clearly aids the formation of C_3S; the effect of fluorine is as expected from earlier work. The heat treatment and phase composition of the preparations are shown in Table 2. These preparations were ground to 3700–4000 sq.cm/g mixed with 4% gypsum and tested for compressive strength on half inch 1 : 3 mortar cubes. The strength results are given in Fig. 6.

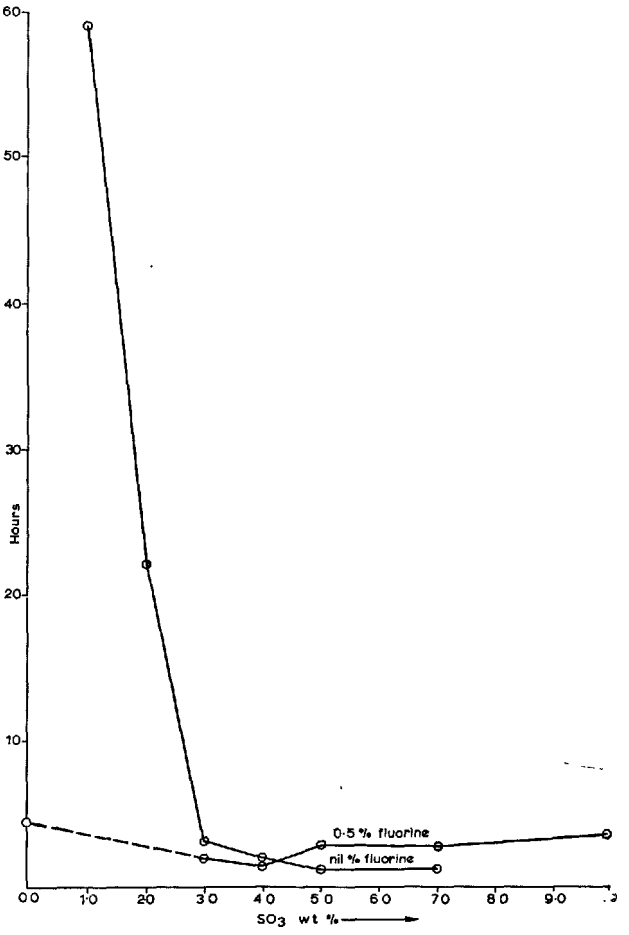

Fig. 5. *Time to obtain free lime ≤ 1.0% against added* SO_3 %

Results and Discussion

The phases identified in the preparations tested for strength are listed in Table 2. Tricalcium silicate was present in the triclinic form and there were no detectable changes towards the monoclinic structures such as reported by Welch and Gutt (1) for C_3S with added fluorine. The only marked change, probably connected with SO_4^{2-} solid solution, was that the intensity of the reflection at 32.1° 2θ increased relatively to that of the reflection at 34.4° 2θ. Dicalcium silicate was present in the β form.

The strength results (Fig. 6) show that up to 3% SO_3 there is a decline in strength followed by a very sudden drop just above 3% SO_3 as shown by the strengths of the preparation with analysed SO_3 figure of 3.035%. This SO_3 level is almost identical with the maximum solid solution limit for SO_3 in C_3S at 1310°C beyond which $CaSO_4$ appears.

The effect of sulphate ions is similar to that of phosphate ions (see Fig. 2 of ref. 1) in producing at low SO_3 concentrations a C_3S_{ss} of low strength but the analogy ends here since continued addition of sulphate, unlike that of phosphate, does not lead to enhanced hydraulicity of the C_3S_{ss}. Between 3 and 6.5% SO_3 the strength rises and this can be attributed to the entry of βC_2S_{ss} of high cementing quality (30). The slow decline in strength beyond 6.5% SO_3 is connected with the increased quantity and possibly also specific action of $CaSO_4$.

The System $CaO–SiO_2–SO_3–CaF_2$

Compositions on the join $C_3S–SO_3$ with 0.5% added fluorine were also studied. The details of the preparations used are shown in Table 3. The entry of βC_2S and of $CaSO_4$ occurs at a lower SO_3 content in the presence of fluorine indicating a C_3S_{ss} of lower SO_4^{2-} content. The strength results in Fig. 7 show that the features found in the presence of SO_3 without fluorine are reproduced, but largely at lower strengths. The strength minimum occurs again in the region of 3% SO_3. The most significant feature is presented by the 1 day strength curve. This has become isolated from the curves for later ages and it lies at very low strength with a minimum at 300 psi at 3.2(4)% SO_3 and 0.45% fluorine. Furthermore, the strength recovery seen in the 1 day strength curve for preparations containing SO_3 but not fluorine is not reproduced. It will be seen from a discussion of phosphatic cements

Note: The C_3S found in these mixes was triclinic modified towards monoclinic as described for C_3S with fluorine alone[1]

in the final section of this paper that the strength behaviour of C_3S with SO_3 and fluorine offers vital evidence for the theory that the combined influence of SO_3 and fluorine superimposed on the effects of phosphate can in certain circumstances decide the early strength of phosphatic cements especially at 1 day. In the region of nil to 2% SO_3 the effect of 0.5% fluorine is not great but it is expected that the position of the strength minimum on the SO_3 ordinate varies with the fluorine content and that it may occur at a lower SO_3 figure than 3.2(4)%.

Examination of Cements

In the preceding sections of this paper the various systems relevant to the manufacture of portland cement from phosphatic materials were considered in turn and the links between them and the manufacturing process have been indicated. The final section of this paper will be devoted to observations on phosphatic cements which may add to the information previously published (1, 2, 6).

The cements made by the Uganda Cement Industry have continued to be made at the rate of approximately 100,000 tons per annum and to pass B.S.12 Portland Cement in every respect. The P_2O_5 level has generally been near 2%. An important special feature of the process in Uganda is the addition of fluorspar to the raw meal in a quantity leading to approximately 0.9% fluorine in the clinker. The lime saturation factor calculated by the modified equations put forward by Nurse (2) is kept very near one. The alite present in Uganda cements is very often present in the trigonal form (20) whereas monoclinic alite is the predominant form in other portland cements. No correlation was found, however, between the strengths of Uganda cements and the polymorphic form of the alite present. Welch and Gutt (1) found $\alpha'C_2S$ in Uganda clinkers and the presence of this polymorphic has continued to be a feature of these cements. The C_3A content of Uganda cements is low and their low heat of hydration makes them suitable for use in massive concrete constructions as low heat cement. For the same reason their sulphate resistance is expected to be good.

Whereas the blended Uganda cement is satisfactory in every respect 'spot' samples of clinkers taken from the plant and examined individually have at times given low early strength at one day. Groups of such samples have been examined and examples are given below in Table 4 of their minor component content and other properties.

Welch and Gutt (1) argued at the previous symposium that strength measurements must be made in conjunction with microscopic estimates of phase present to assess cementing quality of clinkers and that the latter alone may mislead. The figures in Table 4 give further evidence of this. Cements containing alite

	72	9	19
B121	53	35	12

in quantities from 53 to 72% can be seen to give nil strength at 1 day.

The early hydration of cement B 121 was studied by X-ray diffractometry (33). Cement B 119 which gave 1505 psi at 1 day was used as a control. The low strength cement showed a much lower rate of production of calcium hydroxide and a lower rate of disappearance of alite than the high strength cement.

The rate of hydration of clinker B102 was followed by the method described by Lea and Jones (34) in which the development of strength is taken as proportional to the rate of hydration. The clinker was ground and a paste with 32% of water was sealed and stored at 64°F for varying periods of time. At 1, 3 and 7 days samples were removed, ground, dried at 110°C and heated to 900°C. Lea and Jones found that the corrected weight loss between 110°C and 550°C was a useful criterion of the degree of hydration and they obtained a smooth curve of compressive strength versus this weight loss. The loss for clinker B102 was at 5.5% low and corresponded to a strength of 300 psi for 1 : 2 : 4 concrete.

It is believed that these slow hydrating clinkers contain low strength alite of the type encountered in the studies of fluorinated C_3S and of phosphatic clinkers reported by Welch and Gutt (1), and in the present work especially in the case of C_3S containing fluorine and sulphate at certain levels. It is not argued that the fluorine and sulphate figures in Table 4 give the precise numerical position of the minimum strength region in all clinkers since it is known that other minor components such as K_2O, Na_2O and MgO exert additional influence. It is argued that the results derived from the examination of C_3S containing SO_3 and F together with the observations on the cements having nil one day strength show that a controlling influence by SO_3 and fluorine is at times probable and indicates how a pessimum in the cement strength may arise due to low strength alites or C_3S solid solutions.

The possibility that phosphate may produce compounds soluble in water which influence the process of setting and hardening of portland cement was explored. Two cements were selected from plant production of markedly different early strength but the same chemical and phase composition. A paste of high water cement ratio was made up with the weaker cement and after two hours the liquid was separated by centrifuging. This solution was then used as mixing water for the high strength cement. The strength of the latter was unaffected indicating absence of influence through the solution phase.

Supplementary Paper I-18 Burnability of Raw Mixes

Jerzy P. Sulikowski*

Synopsis

The work constitutes an attempt to elaborate a laboratory method to enable the quantitative, if only relative, definition of the burnability of a raw mix.

The suggested test consists in determining the changes in the content of uncombined CaO in the mix within the temperature range from 900°C to 1400°C and in measuring the temperatures at which the cylindrical specimens prepared from calcined mix undergo a definite deformation under a constant load.

The results of the above mentioned parallel tests serve for the calculation of three values which may serve as the basis for a comparative estimation of the behaviour of the raw mix during its burning in a rotary kiln.

Four industrial raw mixes of various origins were tested by means of the suggested method.

Observations were carried out during a long period on the behaviour of the mix during burning, its effect upon the refractory lining, and the length of the burning zone. These observations were carried out in the rotary kilns of the cement plants from which the four mixes tested originated.

The observations proved the possibility of applying the three suggested values for a comparative evaluation of the burnability of the raw mixes.

The results of the investigations also confirmed the known fact that the burnability of raw mixes cannot be assessed on the basis of their chemical composition.

Introduction

Observations of the material in the burning zone of industrial rotary kilns testify that raw mixes of various origin behave in a different way during burning.

In practice it is said that the mixes prepared for the production of portland clinker, but blended of components of different geologic origin, have a different burnability.

Some of these mixes sinter at a lower temperature and in a shorter time, others require higher temperature and a longer time for the synthesis of alite and thus a longer sintering zone in the rotary kiln.

The differences in burnability mentioned above may be estimated by observation of the differences in consistency of the whole mass of grains in motion in the hot zone of the rotating kiln. It should be mentioned here that a raw material mix of a given cement plant, i.e. a mix always blended with the same raw materials components also shows variations in burnability. This is caused by the natural chemical variation of the raw material deposit, that is, by the fluctuations in the content of such components as for example SiO_2 and Fe_2O_3.

Moreover, intentional changes in the degree of saturation with lime, which is sometimes applied for technical reasons, clearly influence the burnability of the mix.

It should be stressed that the burnability of mixes has also an evident influence on the refractory lining of the kiln and very often decrease in the burnability of the mix is decisive in the shortening of the lining life.

Thus the problem of burnability is of great importance in industrial practice. A correct, and if possible, quantitative determination of burnability will enable a more exact technological characterization of the raw material deposit and facilitate the selection of the suitable type of rotary kiln and kind of refractory material.

*Academy of Mining and Metallurgy, Kraków, Poland.

Discussion of the Problem

As mentioned in the previous chapter, the specific consistency of the whole mass of clinker grains in the burning zone of the rotary kiln is characterized by the fact that this material as a whole cannot be defined as bulk materials.

The separate grains of this material are lifted in consequence of the kiln rotations, but reaching their highest position they do not roll freely and individually on the slope of the material. The rotating kiln carries up the whole mass of material, which, though an agglomeration of separate granules, when considered as a whole, displays a certain compactness. This material has a dictinct adhesiveness occurring on the interferences of the individual granules.

This phenomenon is explained by the fact that each clinker grain while remaining in the high temperature zone is imbibed with a liquid phase.

In these circumstances it may be concluded that in the temperature range in which the said phase is liquid each clinker grain is not only sticky on the outside, but also deformable under the influence of mechanical static load.

Both the above mentioned adhesiveness and deformability of the clinker grains while in the high temperature zone depend on the amount of the liquid phase and its viscosity and both these features change in turn with temperature.

There exist, moreover, justified grounds for stating that the deformability of hot clinker granules depends also on the amount, size and habit of the crystals glued with the above mentioned liquid phase. This calls to mind an analogy with the macrostructure of fireclay bricks.

It should be also mentioned that in the case of portland clinker the dimensions and the crystal habit of the calcium silicate crystals and their distribution in a clinker granule depend to a great extent on the natural structure of the raw materials. Such a statement is the more justified as it is shown in practice, that the burnability of cement raw materials does not depend merely on their chemical composition.

The total result of the co-operation of all the above presented factors and phenomena is conclusive as regards the burnability of raw materials for cement plants. The burnability can be quantitatively and comparatively assessed visually by observing the differences in the consistency of the material in the burning zone of the rotary kiln.

The Idea of the Present Investigation

The present investigation is an attempt to elaborate a laboratory method which would enable a quantitative, though only a relative, determination of the burnability of the raw material mix.

The idea of the suggested method lies in the quantitative determination of the changes of one of the chemical features of a sample heated in given conditions and in the measurement of temperature at which appropriately shaped specimens of raw mix undergo defined physical changes.

Thus each raw material mix is tested in parallel in two different ways, two series of tests being carried out.

The first series is the determination of the changes in the content of uncombined calcium oxide in the mix in the temperature range from 900°C to 400°C.

The second series of investigation consists in the measurement of temperature at which the specimen formed of the tested mix undergoes further defined deformations during heating under the influence of a constant static load.

Investigated Materials

The idea of investigating the raw mix in the two different ways presented in the previous chapter was applied to several raw mixes of industrial origin.

The mixes originated from four cement plants working with the wet method. Each of these plants has its own deposit of raw materials and the deposits differ from each other as to geologic and petrographic characteristics.

The A cement plant exploits the raw material from cretaceous deposits. Soft chalk of great natural dispersion, easily forming slurries with water is the carbonate component of this raw material. In general the argillaceous component is distributed uniformly thoughout the whole mass of the deposit.

The B cement plant exploits Jurassic limestones, having a high $CaCO_3$ content and the mix has to be

prepared with additional component, i.e. bituminous shales.

The C cement plant also bases its production on its own deposit of raw material of Jurassic origin built of rather hard limestone interbedded with marls of various $CaCO_3$ content.

The D cement plant blends its mix for the production of portland clinker from marls with relatively low $CaCO_3$ content and from very hard crystal Devon limestones of high purity.

It should be added that in the four cement plants from which mixes were sampled, bituminous coal with a rather high ash content is burned in their rotary kilns. For this reason the mixes are adjusted to a rather high CaO content.

The portions of the mixes designed for the tests were not submitted to preliminary grinding to powder and they remained in the state in which they were supplied from the plants. The omission of the preliminary grinding of these samples is justified by the fact that the burnability of the raw mix is not only influenced by numerous factors such as chemical composition and textures of the raw material components, but also by the degree of grinding of the mix which is characteristic in each of the given plants.

The chemical composition of the raw mixes used is given in Table 1.

Methods of Investigation

Determination of Uncombined Lime

A sample of raw material mix was pressed by hand so as to give it the shape of a cylinder of the dimensions $\phi 20 \times 20$ mm.

The specimen thus shaped was placed in a cold electric furnace on a platinum plate and heated to a definite temperature. The measurement of temperature was carried out by means of a Pt-PtRh thermocouple.

Heating up to 1000°C was carried out at the rate of 10°C/min and above 1000°C at the rate of 5°C/min.

After the desired temperature has been reached, the specimen was removed from the furnace and after cooling in dessicator it was ground and the content of uncombined CaO was determined by the glycol method.

Deformation of the Samples During Heating under a Static Load

Cylindrical specimens of sizes $\phi 20 \times 20$ mm were pressed from the mixes and placed in a vertical electric furnace under a constant load of 0.02 kg/cm². The heating rate was the same as in the test described previously.

The readings of the value of the deformations of a cylindrical specimen squeezed during heating under a static load given above were taken by means of a gauge as accurate to within 0.01 mm. Changes in the sample height were transmitted directly to the gauge by means of a refractory bar. The terminal elongation of the bar during heating the furnace was predetermined experimentally, which made it possible to introduce a suitable correction to the measurements of the deformation of the specimen.

Results

Detailed numerical data are not presented in tables and only a graphic presentation of the results is given in Fig. 1 and Fig. 2.

D	425

Fig. 1. *Changes of free* CaO

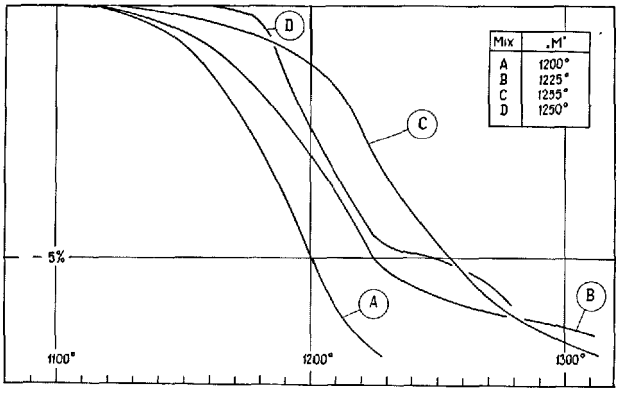

Fig. 2. *Deformations under load*

Discussion of the Results

All the four raw mixes tested were blended for the production of normal standard portland clinker and differed only relative slightly as regards their chemical composition.

Even a superficial comparison of the results obtained allows to state that the four mixes tested behave in a markedly different way during burning.

There are different temperature intervals in which, during burning of these mixes, a considerable amount of uncombined CaO exists.

Maximum amounts of free CaO which appear during the heating of each mix differ greatly.

The deformation of the specimens prepared from different mixes has a different course during burning.

The differences described above and observed during the tests confirm the comparative observations made during a long period in the cement plants from which the four raw mixes tested are supplied. As might be expected the attempt to establish a relationship between the chemical composition of the mixes and the numerical results of the tests did not indicate any regularity which would make it possible to assess the burnability of the mixes on the basis of their chemical composition.

The known fact that the burnability of a mix depends on many factors acting simultaneously which are difficult to formulate quantitatively, was confirmed by this.

The Suggested Quantitative Characterization of Burnability

On the basis of the results of the tests presented above the author suggests the characterization of the

burnability of raw mixes by means of the following three values: "K"—The ratio of the CaO content in the calcined raw mix to the maximum free lime content which occurs during the burning of the mix,
"L"—The temperature range in which the burned mix contains the free lime content in amounts exceeding 10%,
"M"—The temperature at which the cylindrical specimen of the pressed mix is sqeezed in its height by 5% under a static load of 0.02 kg/cm².

Table 2 illustrates the values of K, L and M calculated and measured for all the four mixes tested.

Table 2. *Characteristics of burnability*

	Mix			
	A	B	C	D
"K"	2.74	2.03	1.59	2.40
"L"	290°	440°	410°	425°
"M"	1200°	1225°	1255°	1250°

Conclusions

During a long period observations were carried out on the behaviour of the raw mixes in the burning zone of the rotary kilns of four cement plants from which the tested mixes were sampled. It was proved that in each of these cement plants the observed mix behaved differently. In other words, it was proved that each cement plant has at its disposal a raw material with a specific burnability for the given deposit.

The differences in burnability were considerable and it was impossible to explain them univocally by comparative analyses of the chemical composition of the mixes. It was impossible to establish neither any correlation nor any functional relationship between the chemical composition of the material and its burnability.

However the three values characterizing the burnability introduced in the present work make it possible to assess comparatively the raw mixes as regards their behaviour during burning.

Value "K" indicates the reactivity of the mix components and the degree of the chemical aggressiveness of the mix toward the refractory lining of the rotary kiln.

Value "L" enables to a certain degree a comparative estimation of the length of the burning zone and the time the burned material remains in the calcining and clinkering zones.

Value "M" may constitute an intermediate measure of viscosity of the liquid phase of the clinker and this value makes it possible to assess comparatively the tendency of the clinker granules to adhere to one another.

Supplementary Paper I-38 On Kinetics of Formation of Portland Cement Clinker

P. F. Rumyantsev*

Synopsis

Investigation of portland cement clinker burning as a single process and derivation of a general kinetic equation are connected with inconceivable difficulties. Therefore, it is worth while to study the mechanism and the rates of separate stages of clinker formation.

Formation of cement clinker is accomplished by physico-chemical processes in the liquid phase appearing as a result of partial melting of cement raw mix on heating.

Kinetics of these processes has been studied at the Institute of Silicate Chemistry for several years.

Data on kinetics of dissolution of CaO, $3CaO \cdot SiO_2$, $2CaO \cdot SiO_2$ clinker minerals and SiO_2 (quartz) in the clinker liquid phase have been obtained. These data confirm the determining role of the dissolution rates of CaO and $2CaO \cdot SiO_2$ in formation of $3CaO \cdot SiO_2$. Kinetic equation which adequately describes the dissolution functions got experimentally, may be used in the converted form as a kinetic equation of clinker formation.

Crystallization of the clinker liquid phase in the temperature range 850–1450°C proceeds very quickly disregarding the fact whether one phase or a eutectic is crystallizing.

In the case of the crystallization of one phase the process is mainly determined by the linear velocity of the crystal growth, while on the simultaneous crystallization of two and more phases the process is to a greater extent determined by the rate of the crystal nuclei formation.

Glasses obtained from the clinker liquid phase are stable up to 800°C. Above this temperature intense crystallization of the glasses is observed.

Introduction

Kinetics of the portland cement clinker formation is a very important and difficult problem.

The importance of its decision is determined by the necessity of further development of scientific views on the processes occurring in clinker formation. Evolution of these ideas is necessary for automatization and intensification of the existing cement technology and its progress.

The difficulties in the decision of this problem consist of a series of physico-chemical processes occurring on clinker formation, for it appears impossible to express the rates of these processes by common parameters. In addition, in studying the kinetics of some processes there arise difficulties due to the lack of the reliable methods and the impossibility of experimental modeling of the separate processes apart from the other processes.

The rate of CaO interactions with other constituents of cement raw mixture may serve as a general and most significant parameter for a series of physico-chemical processes occurring on cement burning. Usually a figured and graphical expression of the free CaO content is used for characterization of the given parameter. This parameter is common for the limestone decomposition, the majority of the solid state reactions, and the sintering process.

Using the available experimental material on the changes of free CaO in the burning process, it appears possible even at present to derive a kinetic equation for the given parameter. Such equation will be very complicated and formal because the constants will be deprived of physical sense, and the functional characteristics on different stages of burning will not reveal the mechanism of the processes taking place during the burning.

But it seems more difficult to derive a kinetic equation revealing the intrinsic nature and the character of the interaction between the elementary particles on burning. For derivation of such equation it is necessary to study the kinetics of separate processes, and on the base of the joining of kinetic equations for these

*Institute of Silicate Chemistry of the Academy of Science, Leningrad, U.S.S.R.

separate processes, to get more general kinetic characteristics and equations of clinker formation.

On Kinetics of Cement Clinker Sintering

Basing on the considerations given in introduction, kinetics of the processes occurring on cement clinker sintering (namely the final and less studied stage of sintering) has been under study at the Institute of Silicate Chemistry of the Academy of Science of the USSR for several years.

Sintering of clinker is considered to be a complex of three interdependent physico-chemical processes:

1. Dissolution of the minerals of raw mixture and the products of solid state reactions in the liquid phase of clinker.
2. Diffusion of Ca^{2+} and SiO_4^{4-} ions from the sites of their migration into the melt to the crystallization regions of new phases.
3. Crystallization of new phases.

The mutual connection and the chain character of the above processes stipulate the determining role of that process in the sintering which proceeds at the minimum rate.

Analysis of many literature data permitted us to assume that the dissolution process has the minimum rate.

The works by Toropov, Rumyantsev and Filipovich (1) and those by Toropov and Rumyantsev (2) give the results of the studies on dissolution kinetics of clinker minerals CaO, $3CaO \cdot SiO_2$, $2CaO \cdot SiO_2$ and SiO_2 (quartz) in the liquid phase of cement clinker.

Two equations have been derived to describe the dependence of the dissolution time (τ) on temperature (T) and diameter of the dissolving particles (D):

Experimentally

$$\tau = \frac{D}{A} \cdot e^{E/RT} \qquad (1)$$

and theoretically

$$\tau = \frac{N\bar{D}}{2\delta\nu_0} \cdot e^{(E+\Delta E)/RT} \qquad (2)$$

where E = activation energy of dissolution, R = gas constant, A = constant value, $\bar{D} < D$ = certain effective size of the grain, ΔE = activation energy of the block separated from the grain (for example, the activation energy of the crack emergence in crystals), N = multiplication factor considering that $10^9 - 10^{10}$ particles separated as a whole block fit for one molecularly separated particle, δ = diameter of the elementary particle, ν_0 = frequency of elastic vibrations of the elementary particle in the solid state.

Analogous appearance of two equations describing one and the same process but obtained in different ways confirms, to a certain extent, their accuracy.

Moreover, it can be imagined that $A = N/2\delta\nu_0$, and E of equation (1) is equal to $E + \Delta E$ of equation (2).

Thus both equations turn into one.

Establishment of the molecular-dispersion character of the dissolution is considered to be an important result of the presented works. This means that the dissolution of clinker minerals in the liquid phase doesn't proceed through migration of the elementary particles (atoms, ions, molecules) into melt, but it proceeds by means of separation of individual blocks with sizes to 1 micron from dissolving crystals and polycrystals.

Derived functions are analogous to temperature dependence of the rate of tricalcium silicate formation obtained by Kondo (3), but the activation energies of CaO and $2CaO \cdot SiO_2$ dissolution (150 kcal/mol) approach to the activation energy of the $3CaO \cdot SiO_2$ formation (200 kcal/mol).

The determining role of the dissolution and not that of the diffusion in silicate melts was shown by Cooper and Kingery (4).

The established time for the grain dissolution of CaO and $2CaO \cdot SiO_2$ about 0.1–0.01 mm in size is of the same order as the time for the assimilation of free CaO obtained by Toropov and Luginina (5).

The indicated conformities as well as the experimental confirmation of the determining role of dissolution given by Rumyantsev and Kozlov (6) permit us to convert equations (1) and (2) into kinetic equations for clinker formation of the following type:

$$V_k = \frac{A}{D} \cdot e^{-E/RT} \qquad (3)$$

$$V_k = \frac{2\delta\nu_0}{ND} \cdot e^{-(E+\Delta E)/RT} \qquad (4)$$

Where it is taken into consideration that $Vp = 1/\tau$ and $Vp = V_k$, V_k = rate of clinker formation, Vp = rate of dissolution of CaO or $2CaO \cdot SiO_2$ in the liquid phase of clinker; the values of the other letters are the same as in formulas (1) and (2).

On Kinetics of Crystallization of Clinker Liquid Phase

The final stage of clinker sintering—the liquid phase crystallization—is of interest from the view-point of clinker formation kinetics because it appears possible to obtain from here data on the mechanism and the rate of crystallization under conditions where participate diffusion and crystallization without overlap of the dissolution process.

Data on kinetics of crystallization of the liquid phase is also useful for the progress of crystallization theory in complex silicate systems. For our investigation a liquid clinker phase with alumina modulus $p = 1$ was synthesized at 1450°C. Its composition (in wt%) was as follows:

6.7 SiO_2; 18.5 Al_2O_3; 18.5 Fe_2O_3; 56.3 CaO.

The observation on the crystallization was accomplished with the aid of the high-temperature microscope.

On cooling the melt pre-heated up to 1500°C at the rate of 20° per second, there was observed the growth of one (sometimes two) crystal of tetra-calcium aluminoferrite, and the rate of its growth almost doesn't fall behind the rate of decreasing temperature.

Fig. 1a, represents photomicrographs of the melt at 1400°C where one can see such crystal.

Fig. 1b, shows an increase in the crystal size with decreasing temperature up to 1360°C.

The same photomicrograph also shows that crystallization of other phases is taking place at 1360°C. At the same time their crystallization is of different character, that is, it doesn't proceed through the linear crystal growth but it is due to the formation of a great amount of fine crystals.

With further decrease in temperature up to 1330°C the growth of tetra-calcium aluminoferrite crystal ceases and the formation of fine crystals continues down to the full crystallization of the sample shown in Fig. 1c.

Small samples of glass were obtained by rapid cooling of a fully fused liquid phase. At slow heating of these samples of glass quick crystallization was observed as soon as temperature exceeds 820°C, whereupon for this period of time crystals grew up to 20–30 microns. Photomicrographs of such crystals are given in Fig. 1d.

With fast heating and stoppings at higher temperatures (850–1250°C), still quicker crystallization was observed.

During seconds and parts of seconds crystallization from the melt on its fast cooling till 850–1250°C is also taking place.

In Fig. 1e, are shown crystals of 60–80 microns in size grown for 1 second at 1200°C.

The quenching method appears to be ineffective for determining crystallization rates, because a considerable crystal growth inhibiting to record the sample state at the temperature of the experiment occurs on cooling. In Fig. 1f, is given a photomicrograph of the sample quenched from 1390°C.

A crystal of $4CaO \cdot Al_2O_3 \cdot Fe_2O_3$ is seen here. It consists of two parts. The central part is a crystal which exists at temperature 1390°C, and the outer part is that formed during quenching.

The presented actual data indicate that crystallization processes in the clinker liquid phase proceed very intensively if they are not connected with the dissolution process. The latter is one more proof for the determining role of the dissolution of raw mixture minerals and products of solid state reactions on burning of cement clinker.

Quick crystallization, the rate of which is impossible to calculate because of the overlap of the crystal growth on determining the experimental temperature, doesn't permit to approximate with acceptable precision kinetic rules of the liquid phase crystallization with the aid of the existing methods of investigation.

Conclusions

Burning of cement at the stage connected with the process of CaO and $2CaO \cdot SiO_2$ dissolution in the liquid phase is depends upon by the rate of the dissolution. Therefore the formulas describing the dissolution process may be used as kinetic equations of clinker formation.

The principal conclusions on kinetics of crystallization of clinker liquid phase at the given stage of investigation may result in the following:

Crystallization of clinker liquid phase in the temperature range 820–1450°C proceeds very quickly.

In the case when one phase is crystallizing, the rate of crystal growth is predominant, while in the case of crystallization of two and more phases the rate of crystal nuclei formation appears to be prevailing.

There is also observed quick crystallization of glasses obtained from the liquid phase at temperatures above 800°C.

Supplementary Paper I-49 Clinker Burning in Fluidized Bed

Yuichi Suzukawa, Hisashi Kono, Haruhiko Miyazaki and Sigeyuki Nakai*

Synopsis

The burning of cement clinker in a fluidized bed has already been known as the Pyzel process. (1–4)

The purpose of this paper consists in establishing the basic chemical process designs on this process through the operation of a pilot plant, particularly on the combustion of fuel oil in the fluidized bed, control of the size distribution of solid particles in the bed, and heat-recovery installations of the exit gas and of the red hot clinker from the bed.

Through these studies, it has been found that this process makes it easy to control the burning temperature and makes it possible to manufacture clinker containing low alkalis and free lime of uniform and superior quality.

Introduction

The chemical process designs of clinker burning by the fluidized-bed process were studied by using the pilot plant.

The basic chemical process design of the combustion of fuel oil in the bed was established, and the particle size distribution of solid particles in the bed was controlled by charging a suitable amount of the seed pellets into the bed and simultaneously by selective discharge of coarse clinker particles from the bed.

The agglomeration of solid particles with each other and the adhesion of solid particles to the inside wall or the bottom of the bed were prevented by the injection of gas jet stream which is used for selective discharge of coarse clinker particles and does not pass the gas distributor of the bed. This gas jet stream was not only effective for the improvement of the flow and motion of solid particles in the bed, but also for the dispersion of fuel oil throughout the bed, thus the complete combustion of fuel oil being attained.

The heat-recovery systems for the exit gas at the high temperature and for the red hot clinker from the bed were also established.

Tests of the resulting clinker showed that the quality is good and is comparable with that of the clinker of rotary kiln.

Experimental

The schematic diagram of the fluidized-bed parts and the flow sheet of the pilot plant are shown in Figs. 1 and 2, respectively.

Powdered cement raw mix and seed pellets were fed into fluidized-bed reactor (1) together with preheated air through the injection opening of solid materials (10).

On the other hand, the fuel oil injected through injection nozzle of fuel oil (6) was burnt by the aid of the gas jet streams injected through the injection opening of gas jet stream (8) and the selective discharge pipe opening (12) so as to maintain the bed at the temperature required for burning cement clinker.

Into fluidized-bed reactor (1) was also introduced the fluidizing air through gas distributor (4) so as to maintain solid particles in the bed in a good fluidizing state.

Solid particles in the bed at a temperature of approximately 1450°C reacted with powdered raw mix and grew in size, simultaneously cement clinkering reaction being promoted.

The sintered coarse clinker particles which has grown in size larger than a definite diameter, e.g., approximately 2 mmϕ, were selectively discharged from the bed through the selective discharge pipe (11)

*Central Research Laboratory, Ube Industries, Ltd., Ube, Japan.

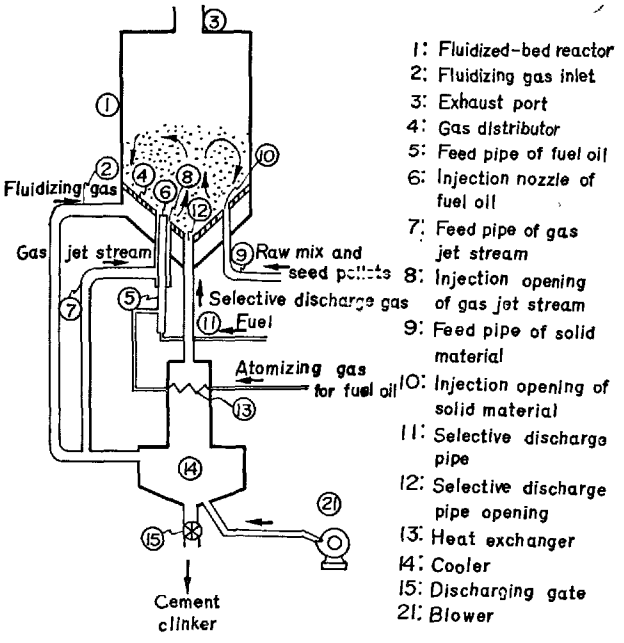

Fig. 1. *Schematic diagram of the fluidized-bed parts of the pilot plant.*

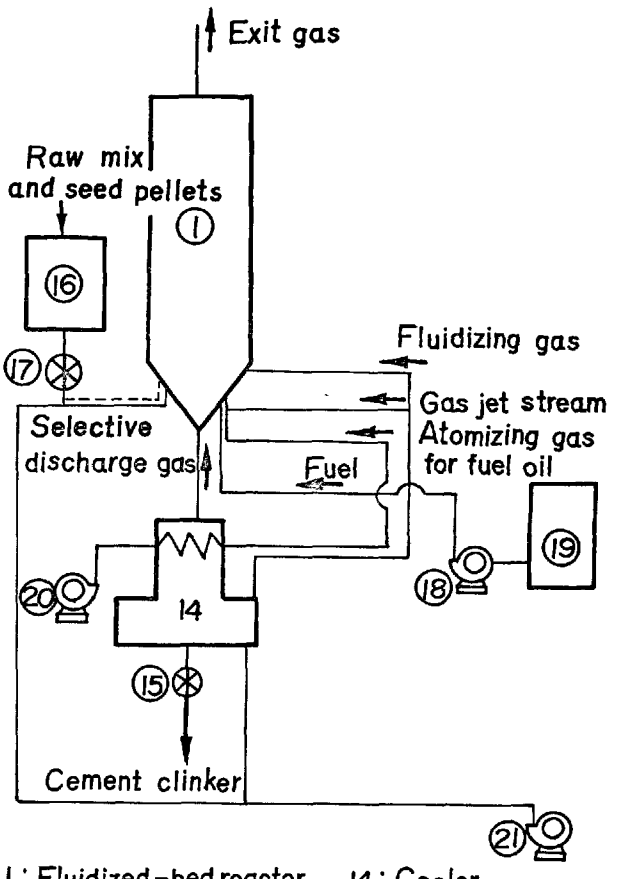

Fig. 2. *Flow sheet of the pilot plant.*

by means of the preheated air through heat exchanger (13), transferred to the clinker cooler (14) and then discharged as the final product by means of discharge gate (15). The gas velocity at selective discharge pipe opening (12) was adjusted at approximately 20 m/sec.

Further, in the present fluidized-bed reactor of cement clinker, funnel-shaped portion of gas distributor (4) is indispensable.

The solid particles in the bed which liquid fuel was blown on their surface, were dispersed from the vicinity of the injection nozzle of fuel oil (4) by gas jet stream injected through the injection opening of gas jet stream (8) around injection nozzle of fuel oil (6) and further dispersed throughout the bed by a forced circulation flow caused by the gas jet stream for use to discharge selectively the coarse clinker particles. Consequently the dispersion of fuel oil in the bed is very good, and the complete combustion of fuel oil in the bed is accomplished.

In order to cool the clinker discharged from the reactor, the cooler (14) shown in Fig. 1 was installed. The red hot clinker discharged from the bed and the air contact countercurrently with each other, and the resulting preheated gas was introduced into the bed through three pipes (2), (7) and (11) respectively. Thus the enthalpy of the hot clinker can be recovered efficiently, and the discharged clinker is cooled as low as 200°C.

To recover the enthalpy of the exit gas from the fluidized-bed reactor, a new hot cyclone system was developed. In the ordinary hot cyclone system used for cement kiln such as Humboldt system (5), the hot exit gas at higher than 1000°C could not be used directly for calcining and preheating cement raw mix, because the adhesion of raw mix to the inside wall of the cyclone is liable to occur. This adhesion phenomenon was prevented by contacting the hot gas at 1400–1450°C with lime and clay mix components separately as shown in Fig. 3.

The example of the chemical analysis of cement raw mix was shown in Table 1.

As a controlling factor of the size distribution of solid particles in the fluidized bed, seed pellets of 1.0–1.6 mm ϕ made with cement raw mix were used. The chemical composition was also shown in Table 1. These seed pellets were prepared with the fluidized-bed pelletizer developed in this laboratory (6).

approximately 1450°C., heavy oil (JIS C-heavy oil corresponding to ASTM D396–48T No. 6) was used.

Results and Discussion

Operating Condition of the Pilot Plant and Quality of the Cement Clinker

The pilot plant was operated under the condition shown in Table 2.

The quality of the clinker is shown in Table 3.

As shown in Table 3, the quality of the clinker is as good as that of the clinker of rotary kiln. It is characteristic of the clinker that it has low alkalis and free lime.

Combustion of Fuel Oil in the Fluidized Bed

It is very difficult to realize a complete combustion of fuel oil with a high load in the ordinary fluidized bed. In the pilot plant, however, the fuel oil could effectively be burnt with a combustion load as high as 6,000,000 Kcal./m.^{3} hr. so as to maintain the bed at a temperature required for burning cement clinker, and the temperature of the bed was controlled within a range of 10°C. Such a precise temperature control could have never been attained in the other burning processes of cement clinker.

Control of the Size Distribution of Solid Particles

To operate the pilot plant continuously for a long

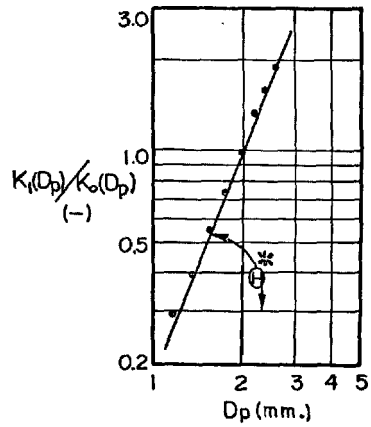
time, it is indispensable to control the size distribution of solid particles in the bed. For this purpose, the gas velocity for the selective discharge of clinker was adjusted, and also the size and amount of the seed pellets were controlled. The selective discharge efficiency of the clinker η_s was defined as shown in Fig. 4.

In Fig. 5, the relation between mean diameter of solid particles D_p mean and η_s is given.

In Fig. 6, the relation is shown between η_s, gas velocity of selective discharge U_s, and mean retention time of solid particles in the bed $\bar{\theta}$.

In Fig. 7, the relation between mass velocity of the discharged clinker F_c and gas velocity of selective discharge U_s is given, in which the amount of seed pellets F_s is used as a parameter.



Dp: Diameter of solid particle (mm.)

Fig. 7. *Relation between mass velocity of the discharged clinker and gas velocity of selective discharge.*

Conclusion

The burning of cement clinker in the fluidized-bed reactor was studied by using the pilot plant, and the basic chemical process designs were established. The characteristic points are summarized as follows;
(a) The fluidized bed in which solid particles were circulated forcedly by the gas jet streams, fuel oil such as heavy oil can efficiently be burnt with a combustion load as high as 6,000,000 Kcal./m.^{3}hr.
(b) The temperature of the bed can be controlled within a range of 10°C.
(c) The size distribution of solid particles in the bed can be controlled by the gas velocity of selective discharge and also the size and amount of the seed pellets. These seed pellets are efficiently prepared in the fluidized-bed pelletizer developed in this laboratory.
(d) The heat-recovery systems for the exit gas and the red hot clinker discharged from the bed were studied.
(e) The resulting clinker has low alkalis and free lime and shows a uniform and superior quality.

Oral Discussion

Hitoaki Mori

I am much interested in the burning of cement clinker in a fluidized bed. In your paper, the gas jet streams are injected into the fluidized bed in addition to the fluidizing gas which passes through the gas distributor.

Could the authors explain the effects of these gas jet streams on the burning process in the fluidized bed? Why the fuel oil could effectively be burnt with a high combustion load?

Author's Closure

Hisashi Kono

I should like to answer for the question presented by Mr. Mori.

As is shown in our paper, in addition to the fluidizing gas, which passes through the gas distributor, the gas jet streams are injected into the reactor in order to realize the forced circulation flow of solid particles in the bed.

The forced circulation flow of solid particles in the bed can be controlled by the gas velocity and volume flow rates of said gas jet streams. Through these circulation flows, the dispersion of atomized fuel oil in the bed can easily be controlled.

In this way, the complete combustion of fuel oil with a high combustion load in the bed can be attained, which have never been realized by the conventional fluidized bed.

Supplementary Paper I-75 New Compound $Ca_{12}Si_4O_{19}F_2$ in the System CaO–SiO_2–CaF_2 and the Role of CaF_2 in the Burning of Cement Clinker

Mitsuo Tanaka, Giichi Sudoh and Shigeo Akaiwa*

Synopsis

By finding the presence of a new ternary compound of the system CaO–SiO_2–CaF_2 and explicating its properties, a new interpretation was given to the mineralizing mechanism of CaF_2 in the burning of cement clinker.

The chemical formula of this phase was determined to be $Ca_{12}Si_4O_{19}F_2$ and it was considered that this phase takes up, when formed in the clinker, small amounts of Na_2O and Al_2O_3 in solid solution. The form of pure $Ca_{12}Si_4O_{19}F_2$ was orthorhombic (pseudo-hexagonal) with $a = 12.29$, $b = 7.09$, $c = 5.69$Å. Its observed density was 3.13 g/cm³ and the number of formula unit was 1. Under the microscope, it looked granular and colorless in thin section, being biaxial ($2V \simeq 0$) negative with the refractive indices $\alpha = 1.676 \pm 0.002$, $\gamma = 1.684 \pm 0.002$. The heat of hydration was low, approximately 7, 39, and 51 cal/g at the age of 7, 28, and 56 days, showing little hydraulic activity. The synthetic phase was stable in a temperature range of about 1110° to 1185°C if held in a closed state, and over 1185 ± 2°C it melted incongruently into trigonal C_3S, α'-C_2S, and a liquid phase. The primary crystallization field of $Ca_{12}Si_4O_{19}F_2$ in the phase diagram CaF_2–SiO_2–$2CaO \cdot SiO_2$ was determined.

In the burning of a raw mix with addition of CaF_2, formation of this phase was conspicuous at about 1050°C and it transformed into an alite phase and probably a belite phase, too, between 1100° and 1150°C. Namely, one of the important role of CaF_2 as a mineralizer is thought to be intermediate formation of the new phase $Ca_{12}Si_4O_{19}F_2$ solid solution, which mainly transforms into an alite phase at a low temperature level. Even in the cooling process after burning, $Ca_{12}Si_4O_{19}F_2$ solid solution was formed again while covering the alite phase when fluorine remained in the liquid phase. This peritectic structure was considered to be one cause of decline in the mechanical strength of cement.

In fluorine-containing clinker generally, the amounts of alite and belite phases tended to decrease, and formation of the aluminate phase was obstructed while the ferrite phase grew Al_2O_3—rich in composition as the fluorine content increased. Surplus fluorine became concentrated mainly in the liquid phase.

Introduction

Many investigations have been made concerning various effects of fluorite, a mineralizer actually in use for production of portland cement. In order to explicate the effects of fluorine component on the formation and structure of clinker minerals, we have also tried detailed studies on clinker burned with addition of CaF_2.

The studies revealed the presence of a new compound based on the system CaO–SiO_2–CaF_2 in the clinker (1) (2). The properties of this compound were investigated precisely, and at the same time the mineralizing mechanism of CaF_2 as well as the cement-chemical significance of this compound was discussed.

Moreover, the fine structure of clinker containing fluorine is explained in the present paper.

*Chichibu Cement Co., Ltd., Tokyo, Japan.

Experimental

Burning Conditions of CaF_2—Containing Raw Mix

Table 1 shows the chemical composition of the raw mix used in the present experiment. To this raw mix was added reagent-grade CaF_2 in varying amounts 0.0–5.0 wt-% and the burning temperature was varied from 800° to 1400°C. The variation of the raw mix moduli due to the addition of CaF_2 was corrected by simultaneous admixing of calculated amounts of powder reagents SiO_2, Al_2O_3, and Fe_2O_3 so that they might be equalized to the initial raw mix moduli. All burnings were carried out in an electric furnace. The clinker was immediately taken out of the furnace after burning and quenched in air or mercury.

Selective Dissolution and X-ray Diffraction Analysis of Clinker Minerals

In order to identify the new compound phase or determine its content in the clinker, a solution of salicylic acid in methanol (3) was used for selective dissolution and removal of silicate phases and free CaO. Namely, 7g of clinker powder was dispersed in 300 cc of the 10% salicylic acid methanol solution, and agitated for 2 hours with a magnetic stirrer. After separation of the liquid and solid by filtrating, the insoluble residue left on the filter paper was sufficiently washed with methanol and dried at 105°C. These conditions permitted an almost complete removal of the alite phase, belite phase, and free CaO.

The insoluble residue consisted mainly of the ferrite phase, new phase, and glass phase, and contained also an aluminate phase and CaF_2 depending upon the burning conditions. Meanwhile, the synthetic new compound that will be discussed later was hard to dissolve in the salicylic acid methanol solution, and 5 g in fine powder of the compound as put in 100 cc of the same solution dissolved no more than about 2 wt-% under the condition mentioned above. Therefore this method of selective dissolution was considered to satisfy the intended purposes. X-ray investigation and chemical analysis were carried out on the insoluble residue of clinker.

Synthesis of New Compound

Based on the results of X-ray powder diffraction and chemical analyses on findings of the clinker residue from selective dissolution, the various mixtures of pure chemicals were burned for X-ray diffraction and chemical analyses. The fluorine component of the synthetic compound was repeatedly analyzed by means of quantitative colorimetric determination with Neo Thorine. (4)

Studies on Crystallographic Property

The oscillating-crystal and powder X-ray diffraction methods were employed to determine the crystal system and lattice constants of the synthetic compound. The single crystals tested, measuring about 0.1–0.2 mm in size, were prepared from pre-synthesized fine crystals by heating them in a closed platinum capsule for 150 hours at 1140 $\pm$ 20°C.

Studies on Thermal Property

The thermal properties were studied by DTA, high-temperature X-ray diffraction analysis, and electron probe microanalysis methods. The starting materials used for DTA were the synthetic new compound and also the compositions which, in the phase equilibrium diagram CaF_2–SiO_2–$2CaO \cdot SiO_2$ of J. Mukerji (5), were included mainly in the primary crystallization field of C_3S, and moreover have a liquidus temperature range of 1200–1450°C. In order to minimize the loss of fluorine, the starting materials were sealed in platinum capsules. The DTA heating and cooling rates were 10°C/min, the synthetic new compounds and mixtures being held for 30 minutes at 1250°C and at a higher temperature than the expected liquidus before they were cooled. The heating rate of high-temperature X-ray analysis applied to the synthetic new compound was 0.94°C/min.

As the samples for electron probe microanalysis, pellets made of the pre-synthetized new compound of about 0.1 mm size were heated again at specified temperatures and then quenched in air. For selection

Table 1. *Chemical composition and fineness of starting raw mix.*

Chemical composition (%)										Fineness

of the field to be examined, slight etching was provided with a solution of 1% HNO_3 in alcohol. The etched surface was carbon spattered for conductive coating. The conditions for microanalysis were: acc. voltage, 15kV; sample current, 0.1 μA; X-rays, CaKα, SiKα, FKα; crystals, LiF, ADP, KAP; detectors, Kr-Exatron, Ne-Exatron, FPC; X-ray spot size, 1.5 $\mu\phi$; sample scan. speed, 8 μ/min; chart speed, 20 mm/min.

Studies on Solubility of Al_2O_3 and Na_2O in Pure $Ca_{12}Si_4O_{19}F_2$

The new compound phase formed in the clinker differed somewhat in lattice constants from pure synthetic compound. To explain this, studies were made. To the pure compound were added specified amounts of reagent-grade α-Al_2O_3 and Na_2CO_3 as Al_2O_3 and Na_2O, sufficiently mixed and finely ground in an agate mortar, and molded under pressure into pellets. After drying, the pellets were sealed in a platinum capsule and held at specified temperatures. With Al_2O_3 added, the pellets were heated at 1130°C for 3 hours, and with Na_2O added, they were heated for 2 hours with the temperature lowered from 1130°C at the rate of 30°C with every 1% increase in the dosage up to 8% because the temperature of transformation into C_3S declined depending on the Na_2O dosage. After being heated, they were quenched in air. The lattice constants were measured by X-ray powder diffraction analysis using silicon (99.99% purity) as an internal standard and compared with those of the phase existing in the clinker.

Results and Discussion

Identification of New Compound Phase in Clinker and Determination of Chemical Composition by Pure Synthesis

Table 2 shows the result of X-ray diffraction analysis for the cement clinker completely freed of silicate phases and free CaO by the solution of salicylic acid in methanol. In the clinker with addition of over 2% CaF_2, a total of 9 unknown peaks were identified over an angle range 10° to 70° 2θ CuKα. Especially, the 2.70Å peak (33.1° 2θ CuKα) in the diffraction pattern agreed well with the peaks of C_3A (the 440), α'-C_2S (the 130), and α-C_2S (the 110) (6) in position, but the presences of those compounds were denied because no other characteristic peaks of them were detected.

Notation of mineral: F = Calcium aluminoferrite; NC = New compound phase.

Checks by the synthesis on pure chemicals showed the unknown phase to be a ternary compound based on the system CaO–SiO_2–CaF_2, and experiments with open burning in a platinum boat disclosed that the synthetic which was composed of (8.0–8.1) CaO, $3SiO_2$, and (1.0–9.0) CaF_2 and burned 2 times at 1130°C for 3 hours, most easily gave only the unknown peaks detected in the insoluble residue of clinker. X-ray data of this compound did not correspond to those of various CaO–SiO_2 compounds or of cuspidine $Ca_4Si_2O_7F_2$ (7) (8) previously described in the system CaO–SiO_2–CaF_2.

The result of chemical analysis on the synthetic compound which was regarded as a single phase in X-ray diffraction and microscopic observation is given in Table 3, which tentatively shows the unknown

Table 3. *Chemical analysis of new compound*

	CaO	F	SiO_2	Chemical formula
Found (%)	71.2	3.99	(26.5)	11.1 CaO·4.2 SiO_2·CaF_2
Theoretical (%)	71.95	4.07	26.70	11 CaO·4 SiO_2·CaF_2 –

compound to be $Ca_{12}Si_4O_{19}F_2$. Because an accurately determined value can not be expected of silicon which easily combines with fluorine and volatilizes during chemical analysis, the percentage of SiO_2 given in Table 3 indicates the value obtained by subtracting the contents of CaO and F from the entire amount. Table 2 also shows the X-ray powder data of the synthetic $Ca_{12}Si_4O_{19}F_2$ compared with those of the phase detected in clinker.

Crystallographic and Optical Properties

Fig. 1 shows an oscillating-crystal photograph of the synthetic $Ca_{12}Si_4O_{19}F_2$. Analyses of the photographs and the X-ray powder data revealed its unit cell to be orthorhombic (pseudo-hexagonal) with $a = 12.28_6$, $b = 7.09_2$ $c = 5.68_9$Å. Its density was observed to be 3.13 g/cm³ and its number of formula unit Z was determined to be 1. Although the axial ratio a/b was equal to $\sqrt{3}$, the diffraction spots on the photograph showed no hexagonal symmetry. Thus, the indexing of the X-ray powder data given in Table 2 is based on the orthorhombic cell. Meanwhile oscillating-crystal photographs disclosed the presence of vertical oblique pairs of weak diffraction spots being centered on strong diffraction spots and forming weak layer lines above and below the strong layer lines. No definite interpretation is still available as to this pattern as well as to the weak peaks which could not be indexed in Table 2.

Under the microscope, the new compound when well developed usually looks granular, being colorless in thin section. Cleavage also is observed but few show twins. It is biaxial negative ($2V \simeq 0$) with refractive indices $\alpha = 1.676 \pm 0.002$, $\gamma = 1.684 \pm 0.002$, and its birefringence is weak. In the clinker, it could be identified as a phase of indeterminate form surrounding an alite phase.

Thermal Property and Determination of Primary Crystallization Field in Phase Equilibrium Diagram CaF_2–SiO_2–$2CaO \cdot SiO_2$

Fig. 2 shows the results of DTA and high-temperature X-ray diffraction analysis on the synthetic $Ca_{12}Si_4O_{19}F_2$. This compound was stable in a temperature range of about 1110° to 1185°C and metastable at room temperature. When cooled slowly or when held in an open state for many hours even in the stable temperature range, it had a tendency to dusting.

When being heated, it showed no particular decomposition temperature, began to decompose gradually at 500–600°C, and while liberating CaO and small amounts of C_2S, changed into a different unknown compound phase containing fluorine. In the present paper, this unknown phase is referred to tentatively as Phase II. The endothermic peak, at 825°C in the DTA curve shows an inversion of formed C_2S. Phase II decomposed at about 1040°C into C_2S, CaF_2, and probably CaO, too. The two phases A and B reported by E. Bereczky (9) seem, from their thermal proper-

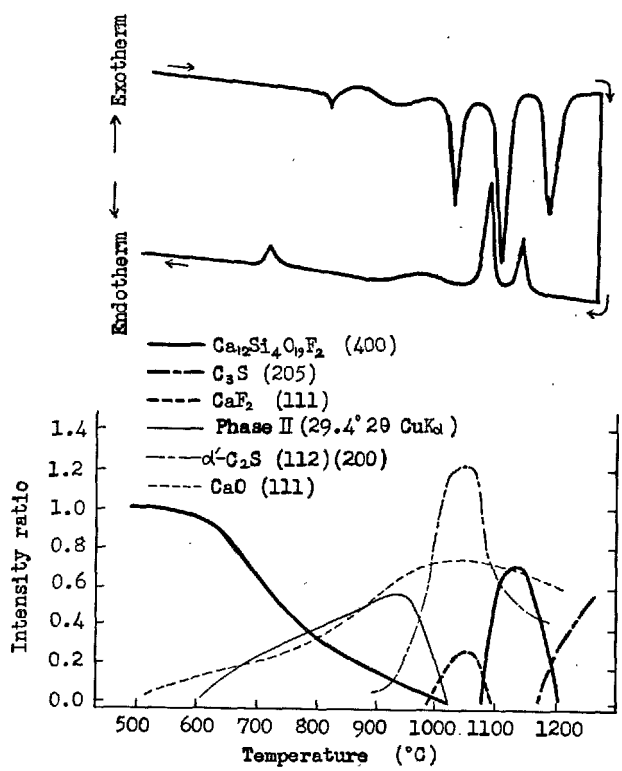

Fig. 2. *DTA and high-temperature X-ray diffraction analysis on* $Ca_{12}Si_4O_{19}F_2$.

ties, to correspond respectively with our $Ca_{12}Si_4O_{19}F_2$ and with Phase II. If Phase II is a single phase, it is a compound with considerably less CaO content than $Ca_{12}Si_4O_{19}F_2$ and showing 3.80, 3.31, 3.04, 2.95, 2.89 Å and so forth as its main interplanar spacings.

The prominent endothermic peak beginning at 1113°C indicates an initial formation of liquid or a solidus. At this temperature, an intial thin liquid layer was expected to form between CaF_2 and the grains aorund it, facilitating movement of atoms and allowing $Ca_{12}Si_4O_{19}F_2$ to crystallize rapidly here. The formed $Ca_{12}Si_4O_{19}F_2$ melted incongruently to crystallize C_3S and C_2S, together with a liquid phase when it reached 1185 ± 2°C by heating. In the burning of the raw mix, formation of such a liquid phase will accelerate diffusion of atoms and the alite phase crystallized by incongruent melting will also serve as a germ promoting the subsequent growth of alite crystals.

A large part of the C_3S crystallized by incongruent melting showed parallel growths. Alite phase of clinker burned with a relatively high CaF_2 dosage was also observed to present this elongated form. The C_3S crystallized here belonged to the trigonal system, its lattice constants a and c being 7.06 and 25.05 Å, respectively. When quenched in air, it showed a tendency to inversion into a monoclinic form. The lattice constants of this monoclinic C_3S were determined as $a = 12.26$, $b = 7.05$, $c = 25.09$ Å, and $\beta = 90°07'$. Both the trigonal and monoclinic forms of C_3S took lower values than their lattice constants previously reported (10), and this was thought to be due to containing some fluorine being contained in solid solution.

$$Ca_{12}Si_4O_{19}F_2 \xrightarrow[(1185\pm2°C)]{} \text{trigonal } C_3S + \alpha'\text{-}C_2S + \text{liquid}$$

Fig. 3–1 shows a representative form of synthetic $Ca_{12}Si_4O_{19}F_2$, and Figs. 3–2 to 3–5 illustrate the processes of incongruent melting indicated in the order of the numbers given. Namely, Fig. 3–2 represents the earliest stage of incongruent melting where $Ca_{12}Si_4O_{19}F_2$ began to transform. Fig. 3–3 shows C_3S beginning to develop in strip form with the progress of incongruent melting where the formation of a liquid phase and globular C_2S grains can be identified. Figs. 3–4 and 3–5 show completion of the melting with disappearance of $Ca_{12}Si_4O_{19}F_2$ and C_3S beginning to develop. The amount of liquid phase increases and C_3S grows in prismatic or rectangular form. Fig. 3–6 shows a characteristic structure due to the development of much grown trigonal C_3S and α'-C_2S.

In the cooling process, an exothermic peak was observed at 1145°C in addition to a major exothermic peak for the solidus. Quenching experiments showed this exothermic peak to mean an energy change due to peritectic reaction and not an exothermic peak for the liquidus. Namely, it indicated the presence of a ternary peritectic point where peritectic reaction took place on the surface of contact between C_3S and the liquid phase containing great amounts of fluorine, decomposing C_3S and at the same time absorbing C_2S to crystallize $Ca_{12}Si_4O_{19}F_2$. Microscopic observation revealed that the peritectic reaction did not proceed completely at the relatively rapid cooling from the above peritectic temperature, and the peritectic structure covering the periphery of C_3S with $Ca_{12}Si_4O_{19}F_2$ was formed as shown in Fig. 4. The cause for the peritectic temperature given by DTA being considerably lower than the decomposition temperature of $Ca_{12}Si_4O_{19}F_2$, 1185°C, is probably thermal hysteresis.

There are phase diagrams proposed by W. Eitel (11) and J. Mukerji (5) as typical of the system CaF_2–SiO_2–$2CaO \cdot SiO_2$. Despite the well-known presence of cuspidine $Ca_4Si_2O_7F_2$ as a compound of this system, none of the diagrams carries a ternary compound as the primary crystal phase. Because preparation of a phase equilibrium diagram for this system involves the difficulty of fluorine being easily volatilized in high temperature range, no complete diagram has yet been established. C. Brisi (7) stated that cupsidine was a eutectic stable compound melting congruently above 1400°C, if heated in welded containers. Our $Ca_{12}Si_4O_{19}F_2$ is a stable compound melting incongruently. DTA investigation of the cooling process down to 1090°C for the compositions contained in the various primary crystallization fields of C_3S, C_2S, CaO, and CaF_2 on the diagram of J. Mukerji disclosed mainly the compositions in the C_3S primary crystallization field to produce an exothermic peak at around 1145°C in addition to peaks for the liquidus and the solidus. Based on the results obtained, the primary crystallization field for $Ca_{12}Si_4O_{19}F_2$ has been established on the phase equilibrium diagram. It is shown in Fig. 5.

Result of Examination by Electron Probe X-ray Microanalyzer

The results of electron probe microanalysis are indicated in Fig. 6. These reveal the density distribution of elements and also phases present in the incongruent melting process of $Ca_{12}Si_4O_{19}F_2$ and the process of peritectic reaction that occurs during cooling.

Fig. 6–1 indicates the texture of coarse C_3S crystals, fine C_2S crystals, and liquid phase formed with the progress of incongruent melting as well as of the still remaining $Ca_{12}Si_4O_{19}F_2$. Fig. 6–2 indicates the incongruent melting completed, $Ca_{12}Si_4O_{19}F_2$ extinct, and all transformed into C_3S, C_2S, and liquid phase. Fig. 6–3 shows the structure of $Ca_{12}Si_4O_{19}F_2$ formed by peritectic reaction to cover C_3S in the process of cooling from above the peritectic temperature. The presence of $Ca_{12}Si_4O_{19}F_2$ enclosing C_3S was proved by the stepped curve of fluorine distribution on the periphery of C_3S as seen in the line analysis of Fig. 6–3. Figs. 6–1 to 6–3 disclose surplus fluorine concentrated mainly in the liquid phase, and in the cooling process, very fine CaF_2 crystals are easily crystallized secondarily from this liquid phase. Little silicon was

identified in the liquid phase.

The electron micrograph carried in Fig. 7 shows very fine stripes of CaF_2 grain crystallized from the liquid phase and also some $Ca_{12}Si_4O_{19}F_2$ formed on the surface of C_3S crystal even in the case of immediate quenching from above the peritectic temperature.

Heat of Hydration and Hydraulicity of $Ca_{12}Si_4O_{19}F_2$

As Table 4 shows, the heat of hydration measured for synthetic $Ca_{12}Si_4O_{19}F_2$ was only somewhat higher than that of β-C_2S. A twin-type conduction calorimeter was used for measurement at the age of one hour. With the progress of hydration, $Ca_{12}Si_4O_{19}F_2$ transformed gradually into fibrous tobermorite phase with liberating $Ca(OH)_2$ and showed some cementation at the age of 28 days, but this compound after all proved to be poor in hydraulicity.

R.W. Nurse et al (12) reported a low hardening property of C_3S holding fluorine in solid solution. But attention must be paid to the effect of $Ca_{12}Si_4O_{19}F_2$ which is frequently present together with C_3S solid solution containing fluorine. Our measurement on the insoluble residue from a salicylic acid methanol solution treatment of C_3S synthesized by adding fluorine in the form of CaF_2 gave the value of the residue as 18.7% with 1.64% fluorine, as 0.31% with 0.82% fluorine, and as 0.03% with 0.55% fluorine. On the other hand, the pure C_3S without addition of fluorine dissolved completely. This suggested these insoluble residues to be $Ca_{12}Si_4O_{19}F_2$.

Solubility of Al_2O_3 and Na_2O in Pure $Ca_{12}Si_4O_{19}F_2$

As already shown in Table 2, there is some difference in interplanar spacing and peak intensity in X-ray diffraction patterns between synthetic $Ca_{12}Si_4O_{19}F_2$ and the phase existing in the clinker. Further investigation in this respect revealed the difference to be due mainly to the solubility of Al_2O_3 and Na_2O in $Ca_{12}Si_4O_{19}F_2$. Fig. 8 shows the lattice constants of the

phase actually identified in the clinker and the variation of lattice constants with take-up of Al_2O_3 and Na_2O in $Ca_{12}Si_4O_{19}F_2$.

In the case of Al_2O_3, the interplanar spacings changed successively up to 3.0–3.5% addition, and above that level, $C_{12}A_7$ ($\bar{F}$) formed. When heated with addition of Na_2O, the synthetic compound encouraged liberation of CaO, and in a dosage range of 6–7%, developed a structural change to become an unknown phase having hexagonal lattice constants $a = 14.34$ and $c = 5.39$ Å which appeared to be a ternary compound based on the system CaO–SiO_2–NaF. CaO was liberated at the rate of 2 moles for 1 mole of Na_2O added—a unique phenomenon—and the content of free CaO became constant (12.7%) over 7% addition.

The dosages of Al_2O_3 and Na_2O with which the compound became most similar to the phase present in the clinker were 3.5 wt-% and 3.0–4.0 wt-%, respectively. The amount of C_2S liberated by heating with addition of Al_2O_3 and the amount of CaO liberated by heating with addition of Na_2O were quantitatively determined and calculated to be equivalent to about 4.0–5.0 wt-% of Al_2O_3 and about 3.5–4.5 wt-% of Na_2O held in solid solution. In this case, Al_2O_3 was assumed not to be contained in C_2S with heating at about 1100°C.

Formation Condition and Amount of New Compound Formed in Burning of Raw Mix

Fig. 9 shows the relationship between burning temperature and amount of mineral present in the clinker, and Fig. 10 shows the relationship between CaF_2 dosage and amount of mineral present in the clinker. At 800°C, $CaCO_3$ still remained in a considerable amount so that there also was much insoluble residue resulting from the treatment with the solution of salicylic acid in methanol, but at 850°C, decomposition of $CaCO_3$ was almost over and a $Ca_{12}Si_4O_{19}F_2$ solid solution began to form. The maximum amount of $Ca_{12}Si_4O_{19}F_2$ solid solution occurred at around 1050°C, and in this region free CaF_2 was absent. If this phase is of pure $Ca_{12}Si_4O_{19}F_2$ even when formed in the clinker, and moreover, if added CaF_2 entirely takes part in the formation of this phase, then:

$$\%\ Ca_{12}Si_4O_{19}F_2 = \%\ CaF_2\ \text{Added} \times (Ca_{12}Si_4O_{19}F_2\ \text{mol. weight})/(CaF_2\ \text{mol. weight})$$

Since the content of ignition loss of raw mix is 34.4% in the present experiment, the maximum amount of $Ca_{12}Si_4O_{19}F_2$ to be formed is calculated at 54.8 wt-% with addition of 3 wt-% CaF_2 (dry base) if the above-mentioned assumption is followed. Actually, however, the amount of it lessens because the fluorine is contained in other compounds, and also because it inevitably volatilizes out of the system. As Fig. 10 shows, with less than 1% CaF_2, $Ca_{12}Si_4O_{19}F_2$ solid solution could not be identified by X-ray investigation even at 1050°C where it was most stable.

In the raw mix system, $Ca_{12}Si_4O_{19}F_2$ soild solution transformed into an alite phase and probably a belite phase, too, at 1100–1150°C. Therefore, formation of the alite phase was started at a temperature 150–200°C lower than in the case of a raw mix not containing CaF_2. With an initial CaF_2 addition of over 2%, meanwhile, the presence of a $Ca_{12}Si_4O_{19}F_2$ solid solution was recognized even in the clinker burned over 1150°C. This was a product of secondary crystallization in the cooling process. Formation of a $Ca_{12}Si_4O_{19}F_2$ solid solution is considered as one cause of decline in the mechanical strength of cement, and it is practically supported by a sharp decline in

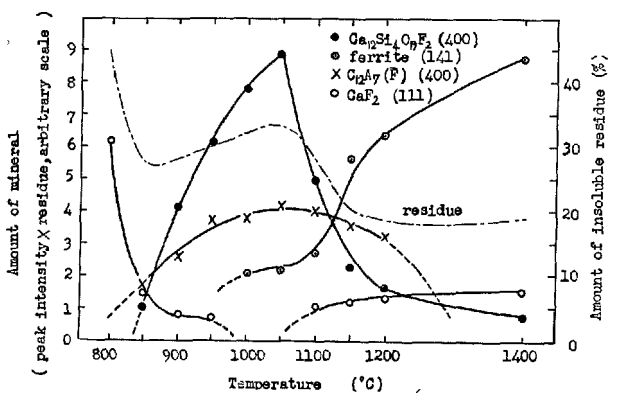

Fig. 9. *Burning temperature and amount of mineral existing in clinker (with 3.0% CaF_2 addition)*

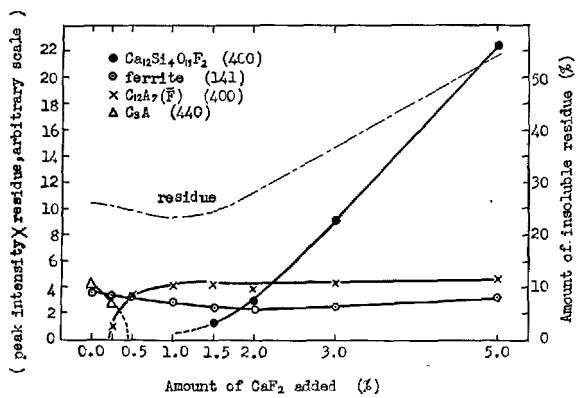

Fig. 10. *Amount of CaF_2 added and amount of mineral existing in clinker (burning temperature: 1050°C)*

the mechanical strength of cement burned with over 2% CaF_2 (2).

Influence of Burning with CaF_2 on Other Clinker Minerals

Among the alite, belite, aluminate, and ferrite phases that constitute portland cement clinker, most affected by the addition of CaF_2 is the aluminate phase. In the clinker burned at 1400°C with over 2% CaF_2, no aluminate phase whatever could be identified by X-ray examination. Instability of C_3A arising from fluorine has already been reported by W. Eitel (13), and it has been disclosed by J. Jeevaratnam et al (14) that the $C_{12}A_7(\bar{F})$ made stable instead of C_3A is a solid solution $Ca_{24}Al_{28}O_{64}F_4$ which has substituted 4 fluorine atoms for 2 oxygen atoms not definitely located but statistically distributed in the unit cell and whose lattice constant a is 11.964 Å, about 0.02 Å less than that of pure $C_{12}A_7$. In the present experiment, too, $C_{12}A_7(\bar{F})$ could be definitely identified in the clinker burned below 1250°C, but its formation could not be recognized in the clinker burned above 1300°C. It will remain to be studied why $C_{12}A_7(\bar{F})$ is absent in clinkers burned at high tempertures.

In contrast to the sharp decrease in the aluminate phase caused by fluorine, a quantitative increase and a shrinkage of interplanar spacing (the 141) were observed in the ferrite phase. Measurements on the 141 reflection revealed its intensity to be maximum with 3% CaF_2 addition, about 1.4 times its value in the case of burning without CaF_2. Likewise, with 3% CaF_2, the interplanar spacing (the 141) was minimum. Fig. 11 shows the variation of molar Al_2O_3/Fe_2O_3 ratio of the ferrite phase as calculated by the methods of L.E. Copeland et al, D.K. Smith, or H.G. Midgley (15).

The variations of interplanar spacings of alite phase at 30.1°, and belite phase at 31.0° 2θ CuKα are also indicated in Fig. 11. In the clinker burned without CaF_2, the composition of ferrite phase was approximate to that of $C_{10}A_2F_3$ in the present experiment. With an increased dosage of CaF_2, however, it became Al_2O_3-rich and almost equal to the composition of C_4AF with 3.0% addition. This phenomenon is interpreted to mean that part of the alumina content to form aluminate entered into the ferrite phase to make this Al_2O_3-rich and at the same time to increase its amount. With over 3.0% CaF_2, however, the alumina content in the ferrite phase began to decrease again because of formation of a great deal of the $Ca_{12}Si_4O_{19}F_2$ solid solution holding Al_2O_3 in it.

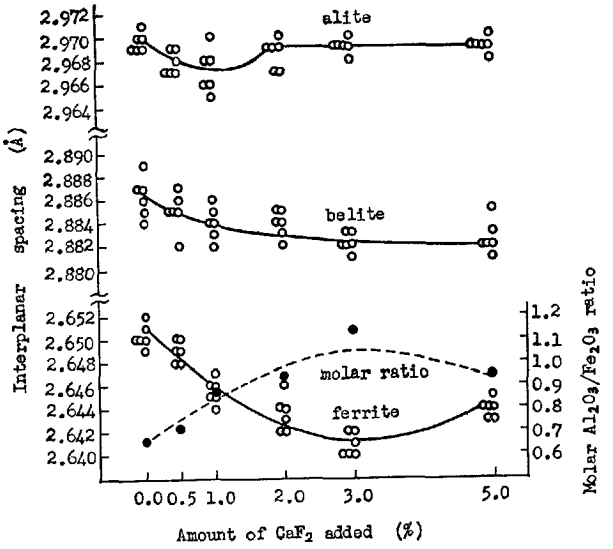

Fig. 11. *Amount of* CaF_2 *added and interplanar spacing of clinker mineral.*

The intensity of alite reflection at 30.1° 2θ CuKα began to decline appreciably and decrease in amount with addition of 2% CaF_2, and that of belite reflection at 31.0° 2θ CuKα, with 3% addition. With 5% CaF_2, they were 0.65 and 0.88 times respectively the intensities of them in the clinker burned without CaF_2. These decreases in amount both came probably from peritectic crystallization of $Ca_{12}Si_4O_{19}F_2$ solid solution in the cooling process of clinker. The interplanar spacing of alite phase at 30.1° 2θ CuKα shrank up to 1.0% CaF_2 addition, but beyond that, it again expanded. The interplanar spacing of belite phase at 31.0° 2θ CuKα contracted unilaterally with an increased addition of CaF_2. Generally, surplus fluorine occurred mainly in the glass phase, and fine free CaF_2 produced secondarily was frequently identified in the clinker burned with over 2% CaF_2.

Acknowledgements

We sincerely thank Professor S. Iwai of Tokyo Institute of Technology for his invaluable advice, and one of us (G.S.) wishes to express his profound gratitude to Professor G. Yamaguchi of Tokyo University for his continuing guidance. Thanks are also due to President T. Ohtomo and Vice-president M. Horiguchi of the Chichibu Cement Co., Ltd., for their interest and encouragement.

Notation

Chemical compositions were expressed by abbreviation symbols based on the usage of cement chemistry, but fluorine contained in solid solution was distinguished as $\bar{F}$ and parenthesized at the end of chemical formula.

Supplementary Paper I-82 Formation of Double Salt in Cement Burning

Morio Amafuji and Akira Tsumagari*

Synopsis

We have undertaken an investigation concerning the mineral composition of ring in cement kiln in order to expose the cause of the formation of ring.

Through this investigation we found in the texture of ring a few kinds of double salt minerals, $2Ca_2SiO_4 \cdot CaCO_3$, $3Ca_2SiO_4 \cdot 2CaSO_4$** and $2CaSO_4 \cdot K_2SO_4$ etc., besides single salt minerals, $CaCO_3$, $CaSO_4$ and $(K, Na)_2SO_4$.

Two double salt minerals, except $2Ca_2SiO_4 \cdot CaCO_3$, have not been produced yet in natural world, they were synthetized in laboratory.

$2Ca_2SiO_4 \cdot CaCO_3$, named spurrite in mineralogy, is rarely found in geological metamorphic calcite rock zone.

We assumed that these salt minerals in cement kiln were formed by gas-solid reaction between CO_2 or SO_2 of fuel gas and raw material or clinker in cement burning. Thereupon, we made an experiment for verifying this gas-solid reaction under current of CO_2 or SO_2 gas by electric furnace in laboratory.

The results of this burning experiment determined clearly the forming condition of these double salt minerals in the burning of raw material or clinker under current of CO_2 or SO_2 gas.

We were able to conclude that even a small quantity of SO_2 gas by far predominates a large quantity of CO_2 gas at the reaction with raw material and clinker at high temperature.

Moreover, we found by the original experiment that the burned pieces bearing a large quantity of double salt minerals have great coagulative strength.

The results obtained from these experiments are expected to give some important suggestions to the research both about the cause of the generation of ring and about the temperature condition at each inner part of kiln where ring adheres.

Introduction

Since long ago, many reports of the research about ring adhered in cement kiln have been published (1, 2, 3, 4, 5, 6, 7, 8, 9, 10). Almost all of them have not dealt with the texture of the ring body, but generally with the various operating conditions of kiln or the chemical properties of clinker which were supposed to have an principal effect upon the generation of the ring.

It is natural that the burning condition of cement kiln is strongly influenced by the ring adhered to the inner wall. The ring is always an obstacle in the burning operation of kiln. It is especially affected in case of excess charge of raw material or in case of long period operation. Naturally, generation of the ring has attracted attentions of many investigators.

Fortunately, we had many chances to observe directly the state of formation of the ring in kiln and pick pieces of sample for test purposes from each part of the body of ring from surface to bottom.

Each sample picked up systematically from the each part of ring as shown Fig. 1 was tested for making

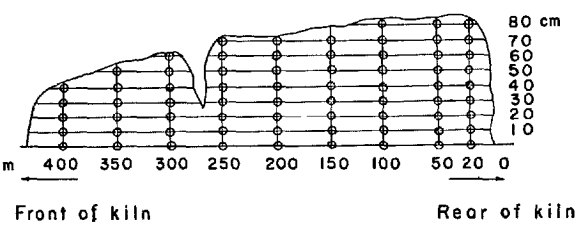

Fig. 1. *The position in ring where the samples were picked.*

* Central Research Laboratory, Onoda Cement Co., Ltd., Tokyo, Japan.

** The chemical formula of this silicosulphate is postulated from the chemical analysis of this mineral occuring in ring. The theoretical formula should be detected by crystalographic study.

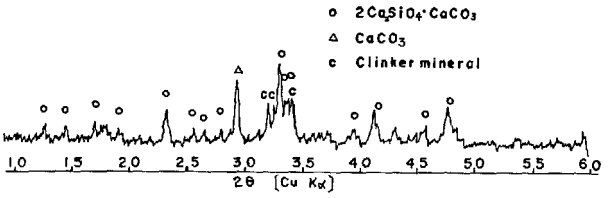

Fig. 2. *The X-ray diffraction pattern of a ring material principally composed of* $2Ca_2SiO_4 \cdot CaCO_3$.

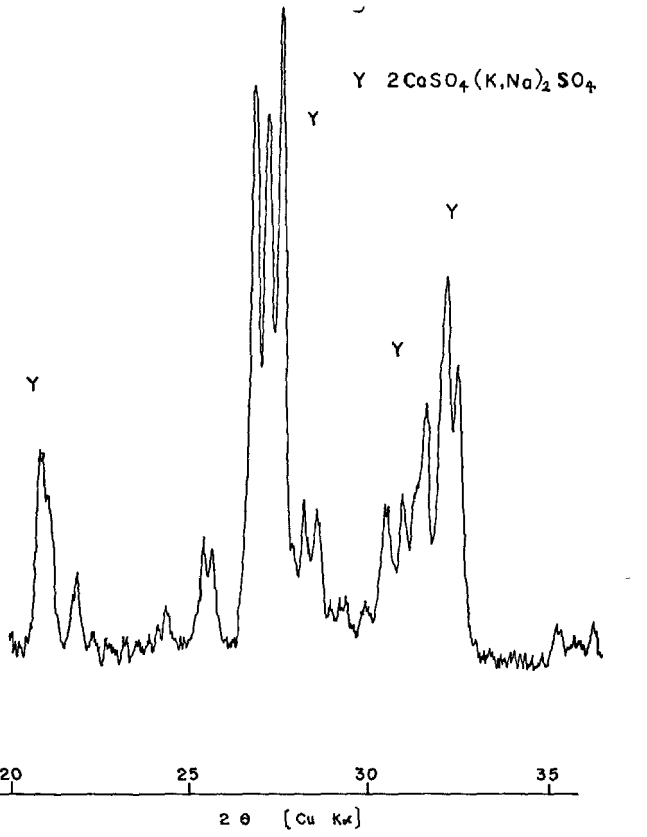

Fig. 4. *The X-ray diffraction pattern of a ring material principally composed of* $2CaSO_4 \cdot (K, Na)_2SO_4$.

clear mineralogical composition by simple chemical treatment, chemical analysis, microscopic observation, X-ray diffraction, and differential thermal analysis etc.

We found a few kinds of mineral which were not expected to be formed in cement kiln. They are double salt minerals composed of Ca_2SiO_4 or $CaSO_4$.

$2Ca_2SiO_4 \cdot CaCO_3$ was frequently found in the ring adhered to the wall not far from burning zone (11). On the other hand, $3Ca_2SiO_4 \cdot 2CaSO_4$ (12, 13) and $2CaSO_4 \cdot (K, Na)_2SO_4$ were found in the ring adhered to the wall of calcing zone or the one near the upper end of kiln.

When we used grate chamber or disused gas utilized boiler directly connecting to the upper end of kiln, the pile that adhered to the wall or to water tubes was principally composed of $3Ca_2SiO_4 \cdot 2CaSO_4$ or $2CaSO_4 \cdot (K, Na)_2SO_4$. We regard the piles as ring in this paper.

These double salt minerals are generally formed accompanied by Ca_2SiO_4, $CaSO_4$, $CaCO_3$ or $(K, Na)_2SO_4$ respectively.

Fig. 2, Fig. 3 and Fig. 4 which show the results of X-ray diffraction of the ring are principally composed of $2Ca_2SiO_4 \cdot CaCO_3$, $3Ca_2SiO_4 \cdot 2CaSO_4$ or $2CaSO_4 \cdot (K, Na)_2SO_4$ respectively. Table 1 shows the difference in chemical and mineralogical characters between the double salt minerals and the already known clinker minerals.

$2Ca_2SiO_4 \cdot CaCO_3$ is rarely formed in geological metamorphic calcite rock region in natural world (14, 15). It is supposed that CO_2 gas at a certain temperature range plays an important part in forming $2Ca_2SiO_4 \cdot CaCO_3$. $3Ca_2SiO_4 \cdot 2CaSO_4$ and $2CaSO_4 \cdot (K, Na)_2SO_4$ were synthesized by J. J. Rowe, G. W. Morey and C. C. Silber through solid-solid reaction using of reagents of sulphates (16).

We supposed that these double salt minerals in the ring were formed by gas-solid reaction between CO_2 or SO_2 of fuel gas and raw material or clinker in cement burning.

Thereupon, we made an experiment for verifying the above mentioned gas-solid reaction under current of CO_2 or SO_2 gas by electric furnace in laboratory.

The Manner of an Experiment of the Gas-Solid Reaction

For the experiments of the gas-solid reaction we used a horizontally laid electric furnace, made of about 5cm in diameter mullite tube surrounded with six heat elements of SiC. Two end sides of the tube are tightly closed by plugs which have openings for passages of both gas and thermocouple.

The material was laid in the center of the tube and the top of the thermocouple was laid very closely to the material in order to measure the accurate temperature of it. The temperature controller was employed.

The gas drawn from the gas bomb was led to passing through the bin for regulation of gas pressure filled with conc H_2SO_4, and then through the flow-meter. The bin of conc H_2SO_4 was used for the purpose of dehydration of gas. The disused gas that passed through the furnace was led into the bin of conc NH_4OH for the purpose of absorption of wasted SO_2 gas and then was sucked out by aspirater. In the experiment by the mixed gas we used the bin for mixing of gases.

The whole apparatus of experiment is shown in Fig. 5.

The actual disused gas of the upper end of cement kiln contains about 0.05 percent SO_2 gas and about 20 percent CO_2 gas. Even very small quantity of SO_3 was supposed to have strong reactivity.

We made an experiment with saturated CO_2 or SO_2 gas in the first step. Next we used the mixed gas component which is similar to the actual disused gas located at the upper end of kiln. The gas was let flow at room temperature with a constant quantity of 150 cc per minute, except in special cases.

As the material cement clinker we used ordinary one. As the material cement raw material we used the one in which calcined calcite was mixed as CaO component. Their chemical analysis are shown in Table 2.

After the material was burned in rising temperature with constant speed of 15°C per minute it was kept for an hour at a certain aimed temperature. Then the mineral constituent of the burning pieces was investigated mainly by means of X-ray diffraction.

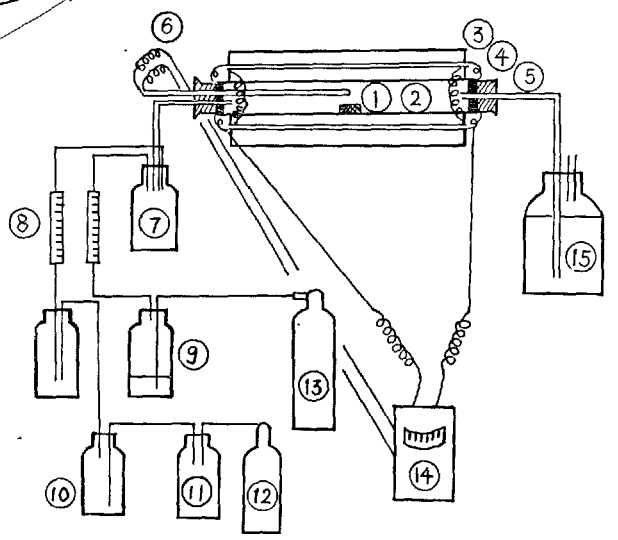

Fig. 5. *Outline of the apparatus for experiment of the gas-solid reaction.*

The Reaction between CO_2 Gas and Raw Material or Clinker

By the pre-experiment we ascertained the phenomenon that $2Ca_2SiO_4 \cdot CaCO_3$ could be synthesized by the gas-solid reaction between CO_2 gas and β-Ca_2SiO_4, γ-Ca_2SiO_4 or β-$CaSiO_3$ with $CaCO_3$ in the range of temperature from 800°C to 900°C.

In this experiment, by the improved apparatus, we studied details in regard to the formation of $2Ca_2SiO_4 \cdot CaCO_3$ by the gas-solid reaction. The result of X-ray diffraction of the burned pieces of raw material under the current of CO_2 gas is omitted here as it does not show special phenomenon.

Fig. 6 and Table 3 show the result of X-ray diffraction of the burned pieces of clinker under the current of CO_2 gas. By these results we came to the conclusion described below.

Re-crystalized $CaCO_3$ was formed and no $2Ca_2SiO_4 \cdot CaCO_3$ was formed in the reaction between CO_2 gas and raw material. On the other hand, $2Ca_2SiO_4 \cdot CaCO_3$ was remarkably formed in the reaction between CO_2 gas and clinker.

In case of the former, $CaCO_3$ was remarkably formed at temperature above 600°C and de-carbonized mostly in the range of temperatures between 900°C and 1,000°C, then $2Ca_2SiO_4$ was formed at 1,100°C.

Table 3. *The mineral composition of the burned pieces of clinker under current of CO_2 gas.*

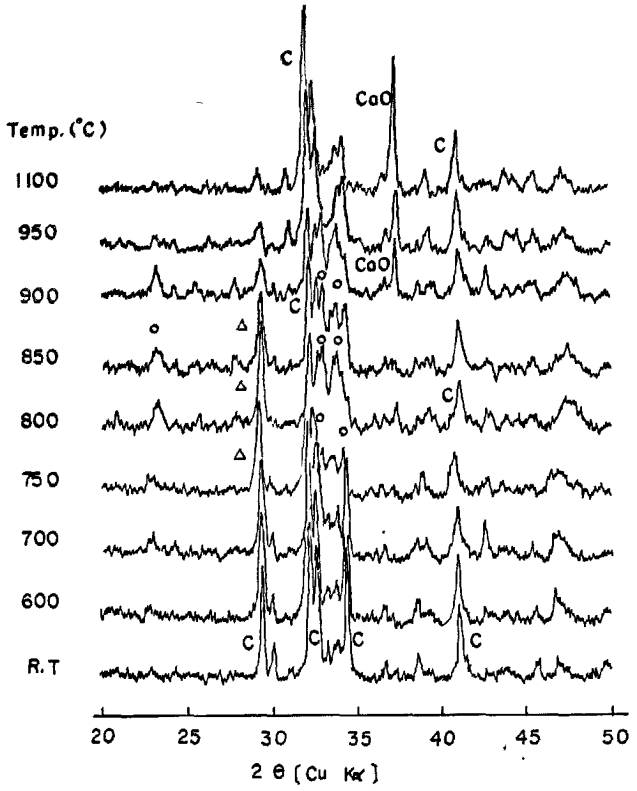

Fig. 6. *The X-ray diffraction patterns of the burned pieces of clinker under current of CO_2 gas.*

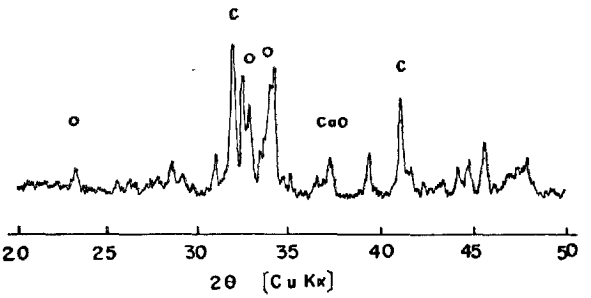

Fig. 7. *The X-ray diffraction pattern of the burned piece mixing β-Ca_2SiO_4 and $CaCO_3$ under current of CO_2 gas. (Keeping temperature at 850°C)*

In case of the latter, we found a decrease in intensity of X-ray diffraction peak of alite, Ca_3SiO_5, as increase in $2Ca_2SiO_4 \cdot CaCO_3$. The diffraction peak of $2Ca_2SiO_4 \cdot CaCO_3$ showed the strongest intensity in the range of temperatures between 800°C and 900°C and mostly disappeared at 950°C, while the diffraction peak of β-Ca_2SiO_4 and CaO showed the strongest intensity at temperature above 950°C.

The following chemical reaction was noted with the increase in the temperature.

$$\underset{\text{Alite}}{Ca_3SiO_5} + \underset{\text{Belite}}{Ca_2SiO_4} + CO_2 \xrightarrow{750°C \sim 900°C}$$

$$2Ca_2SiO_4 \cdot CaCO_3 \xrightarrow{\text{above } 900°C} 2Ca_2SiO_4 + CaO$$

Fig. 7 shows the result of X-ray diffraction of the burning piece which was made by the reaction of pure β-Ca_2SiO_4, $CaCO_3$ and CO_2 gas. We also found clearly the formation of $2Ca_2SiO_4 \cdot CaCO_3$ in this case.

At any rate, the evidence thus obtained supports the suggestion that the formation of $2Ca_2SiO_4 \cdot CaCO_3$ is influenced by the control of density of CO_2 gas, the quantity of clinker mineral and the temperature of reaction. Therefore we can know why $2Ca_2SiO_4 \cdot CaCO_3$ was not formed from raw material which does not change to clinker mineral at temperature under 900°C. The existence of Ca_3SiO_5 is presumed to accelerate the production of $2Ca_2SiO_4 \cdot CaCO_3$.

In both cases of the gas-solid reaction with raw material and the one with clinker, $CaCO_3$ was clearly re-crystalized as shown in Fig. 6 and Table 3.

The Reaction between SO_2 Gas and Raw Materal or Clinker

We made an experiment of the gas-solid reaction between SO_2 gas and raw material or clinker at a

fixed condition, 15°C per minute speed of rising temperature, keeping the aimed temperature constant for an hour and a 150 cc per minute speed of SO_2 flow.

Fig. 8 and Table 4 show the result of X-ray diffraction of the burned pieces by the reaction between SO_2 gas and raw material. Fig. 9 and Table 5 show the burned pieces of clinker under current of SO_2 gas. We can notice by these that there is a remarkable formation of $CaSO_4$ or $3Ca_2SiO_4 \cdot 2CaSO_4$ in both cases by the reaction of raw material and the one by clinker.

In case of the former, $CaSO_4$ is first formed at 600°C and $3Ca_2SiO_4 \cdot 2CaSO_4$ is formed when β-Ca_2SiO_4 begins to appear at 1,050°C. This double salt mineral grows and increases at 1,100°C. In case of the latter, the condition of the formation of $CaSO_4$ and $3Ca_2SiO_4 \cdot 2CaSO_4$ is similar to the former one. $CaSO_4$ is first formed at 550°C and $3Ca_2SiO_4 \cdot 2CaSO_4$ is formed at 1,050°C and this double salt mineral grows and increases at 1,100°C.

No doubt the formation of $CaSO_4$ is due to the decomposition of clinker minerals with the attack of SO_2 gas and the formation of $3Ca_2SiO_4 \cdot 2CaSO_4$ is due to the reaction between formed $CaSO_4$ and Ca_2SiO_4 in clinker. The SO_2 gas itself plays a very important part in the reaction as a catalyzer. Furthermore the existance of H_2O vapour may remarkably affect the reaction.

In reference to the result of the gas-solid reaction we show the result of the solid-solid reaction in Fig. 10. This shows the result of X-ray diffraction of the burned pieces which are products of the experiment of the reaction between the powder of synthesized belite ($2Ca_2SiO_4$) and the reagent of anhydrite ($CaSO_4$), in a proportion of 3: 2 at temperature over 1,100°C. It was found that $3Ca_2SiO_4 \cdot 2CaSO_4$ is rarely formed at 1,100°C and a little quantity of $3Ca_2SiO_4 \cdot 2CaSO_4$ is formed at 1,150°C.

Fig. 11 shows the relation between SO_3 content and burning temperature concerning the burned pieces formed by the reaction between SO_2 gas and raw material or clinker.

E. Vogel performed a similar experiment as ours (17). Fig. 12 shows the result of the experiment by him. The results of Vogel's experiment the condition of which are probably different from ours in the equipment, the quantity of gas-flow and the way of keeping of temperature etc., is almost similar to ours in case of raw material. However, there is a remarkable difference in the results between his experiment and our one in case of clinker.

In both experiments, Vogel's and ours, the quantity of absorbed SO_3 increases slowly as the temperature increases to 1,000°C. It decreases slowly as the temperature increases over 1,000°C in Vogel's experiment. In our experiment it increases rapidly as the temperature increases to 1,100°C and reaches to the maximum quantity at 1,100°C.

The increase of absorbed SO_3 between 500°C and 1,000°C means the formation of $CaSO_4$, while the rapid increase of absorbed SO_3 between 1,070°C and

1,100°C means the formation of $3Ca_2SiO_4 \cdot 2CaSO_4$. The earlier investigator did not find the phenomenon of the extraordinary absorption of SO_2 gas by clinker caused by the formation of $3Ca_2SiO_4 \cdot 2CaSO_4$.

The Reaction under Current of Mixed Gas

By the results of the above mentioned experiment we know that cement clinker is very easily decomposed by CO_2 gas or SO_2 gas.

It is presumed that general fuel gas consists of about 80 percent N_2 gas, less than 20 percent CO_2 gas and less than 1 percent SO_2 gas. Naturally, if we want to study about the gas-solid reaction in cement kiln, we must consider the effect of the mixed gas consisting mainly of N_2, CO_2 and SO_2, especially the effect of SO_2 as change of density of it.

We made the same experiment of gas-solid reaction as mentioned above using the mixed gas the composition of which is shown in Table 6. The apparatus for this experiment is the same as that used in the foregoing experiment.

The value of chemical analysis of raw material and clinker used here is shown in Table 7. No. 1 raw material is chosen as one of a little more alkali component, but No. 2 raw material as one of a little less alkali component. The clinker is the same as used in the foregoing experiment.

Each gas was passed into the burning tube of the furnace through the bin for mixing gas after it was dehydrated by conc H_2SO_4 solution and was measured by flow meter.

The conditions of experiment, speed in rising temperature, timing of the aimed temperature and the speed of gas flow etc., were the same as the above.

Tables 8, 9, 10 and 11 show the result of this experiment. The tables show the mineral composition of burned pieces after the reaction at each temperature. Data is derived from the result of X-ray diffraction. In these tables two signs are shown in each mineral component. The upper sign shows the quantity of the mineral component of the upper part of the pieces, from the surface down to the 3 cm, while the lower sign shows the lower part of the pieces, from the 3 cm to the bottom.

It was unavoidable that there was a few difference of the mineral component between the upper part and the lower one of the burned pieces, because the length of time of the aimed temperature was not enough for uniform reaction through the body in case of mixed gas. These tables, however, undoubtedly show the general tendency of the reaction in case of the mixed gas.

Table 8 and Table 9 show the results of the examinations of two kinds of raw material. The former shows the result for No. 1 raw material and the latter for No. 2 raw material. This experiment indicates that we can not find the double salt minerals derived from the gas-solid reaction between CO_2 or SO_2 gas and raw material, but find the single salt minerals, $CaCO_3$ and $CaSO_4$.

In contrast to this result, we found evidently the double salt minerals, $2Ca_2SiO_4 \cdot CaCO_3$ and $3Ca_2SiO_4 \cdot 2CaSO_4$ in the reaction by clinker as shown in Table 10 and Table 11. Table 10 shows the result of the reaction keeping the aimed temperature for one hour and Table 11 when the temperature is keeped for two hours.

The range of the producing temperature of each double salt minerals is clearly distinguishable: $2Ca_2SiO_4 \cdot CaCO_3$ is produced in range of temperatures from 800°C to 850°C, and $3Ca_2SiO_4 \cdot 2CaSO_4$ is from 900°C to 1,100°C. At 850°C $2Ca_2SiO_4 \cdot CaCO_3$ is decomposed to Ca_2SiO_4, CaO and CO_2.

In the reaction with the raw material the formation of $CaCO_3$ is dominant at temperature below 800°C and $CaSO_4$ above 700°C. In the reaction with the clinker the formation of $CaCO_3$ is barely seen in range of whole temperature and that of $CaSO_4$ is dominant at temperature above 700°C. By these results it seems reasonable to assume that even a small quantity of SO_2 gas by far predominates a large quantity of CO_2 gas at the reaction with raw material and clinker at high temperature.

Effect by Alkali Component upon the Gas-Solid Reaction

In the foregoing experiment of the gas-solid reaction we used both raw material and clinker of a small quantity of alkali component, not more than 1 percent of R_2O.

It is widely known that the flying dust at the end side of the kiln contains a large quantity of alkali sulphate. As it is apt to condense at the end part of the kiln, alkali sulphates are presumed to be one of the cause of the generation of the ring (18, 19, 20, 21).

Therefore, we made an experiment of the gas-solid reaction using the raw material and the clinker consisting of a great deal of alkali components.

The manner of the experiment is the same as above. We selected K_2CO_3 as alkali component as its vapor pressure is moderate, and added it to the raw material or the clinker, which were used in the foregoing experiment under current of saturated gas, so as to K_2O is calculated 3, 6 and 9 weight percent for the

raw material or the clinker. The values of chemical analysis of the raw material and clinker are much the same as in the foregoing experiment.

The mineral components of the burned pieces after the gas-solid reaction were made clear by X-ray diffraction. Table 12, Table 13 and Table 14 show the mineral components of the burned pieces of raw material with K_2O added. Table 15, Table 16 and Table 17 show mineral components of the burned pieces of clinker with K_2O added. Fig. 13, Fig. 14 and Fig. 15 show parts of the results of X-ray diffraction of the burned pieces.

We found both single salt mineral and double salt mineral $CaCO_3$, $CaSO_4$ and $2Ca_2SiO_4 \cdot CaCO_3$ in the foregoing experiments, at the proper temperature, and also found K_2SO_4 which had not been found in the foregoing experiments. We found an unknown mineral Y also.

This unknown mineral could be found remarkably well in the samples picked up from the pile that adhered to the surface of the water tube of the wasted gas boiler. Fig. 4 shows the result of X-ray diffraction of the sample obtained from one place in the gas boiler.

We presumed that this unknown mineral Y must be a double salt mineral consisting of $CaSO_4$ and $(K, Na)_2SO_4$. In order to ascertain this assumption we made the experiment of gas-solid reaction among K_2CO_3, $CaCO_3$ and SO_2 gas. The manner of the experiment for the reaction is the same as the one in the foregoing experiment. Two kinds of solid material, K_2CO_3 and $CaCO_3$ were inserted into the center of the tube of the furnace.

Fig. 16 shows the result of X-ray diffraction of the burned sample in range of temperatures from 600°C to 900°C. $CaCO_3$ and K_2CO_3 were mixed in the pro-

portion of 2: 1. We could detect three characteristic diffraction peak in a row from 27° to 28° in 2θ as shown in Fig. 16. These three characteristic diffraction peaks coincide with the characteristic peaks of the unknown mineral Y.

Other experiment for the solid-solid reaction between $CaSO_4$ and K_2SO_4 in proportion 2: 1, 1: 1 and 3: 1 at each temperature proved that the three characteristic diffraction peaks stood in a row from 27° to 28° in 2θ must be of $2CaSO_4 \cdot K_2SO_4$.

The burned pieces mixed in 2: 1 proportion have neither diffraction peaks of $CaSO_4$ nor ones of K_2SO_4, but have only several characteristic lines that is attributed to the synthesized double salt mineral. The burned pieces mixed in 1: 1 proportion have the refractive lines of unreacted K_2SO_4 in addition to the ones of the synthesized double salt mineral, and the burned pieces mixed in 3: 1 proportion have the refractive lines of unreacted $CaSO_4$ in addition to the synthesized double salt mineral. It seems most reasonable to conclude that this synthesized double salt mineral is $2CaSO_4 \cdot K_2SO_4$. Fig. 17 shows one part of the result of X-ray analysis of the burned pieces in this experiment of solid-solid reaction.

Recently we chanced to read the paper "The Ternary System K_2SO_4–$MgSO_4$–$CaSO_4$" by J. J. Rowe, G. W. Morey and C. C. Silber. We got the information of the binary system K_2SO_4 from it and knew that $2CaSO_4 \cdot K_2SO_4$ was already named "calcium langbeinite" (16).

The index of optic refraction of our synthesized double salt mineral shows about 1.550, while the double salt mineral show about 1.553 which is a component of the sample picked from the pile in the gas boiler. This little difference is supposed to be caused by other chemical elements which are soluble in very small quantity.

In view of the above facts it was made clear that a great quantity of alkali component condensed at the end part of the kiln easily reacts with SO_2 gas forming the double salt mineral, $2CaSO_4 \cdot K_2SO_4$, in addition to the single salt mineral, K_2SO_4, and both salt minerals are contained in abundance in the pile or the ring.

One of Physical Properties of Double Salt Minerals

We could find a few double salt minerals, $2Ca_2SiO_4 \cdot CaCO_3$, $3Ca_2SiO_4 \cdot 2CaSO_4$ and $2CaSO_4 \cdot K_2SO_4$ in addition to re-crystallized single salt minerals, $CaCO_3$, $CaSO_4$ and K_2SO_4 both in the ring and in the pile at end part of the kiln.

On the other hand we could succeed in synthesizing those double salt minerals by means of the gas-solid reaction between raw material or clinker and CO_2 or SO_2 gas.

Furthermore we found the character of strong coagulation of those double salt minerals in the course of the gas-solid reaction.

We show the result of the experiment of coagulation by the following data. We are sure that this data gives important suggestion to the elucidation of the cause of generation of the ring.

Hitherto various kinds of means have been devised concerning measurement of the strength of adhesion or coagulation of solid grains at lower or room temperature, but it has been hard to apply a higher temperature for industrial purposes.

We devised an original apparatus for the measurement of the strength of coagulation of the burned pieces in the gas-solid reaction. Outline of the apparatus is shown in Fig. 18. It was changed from the Vicker's cement-setting test apparatus.

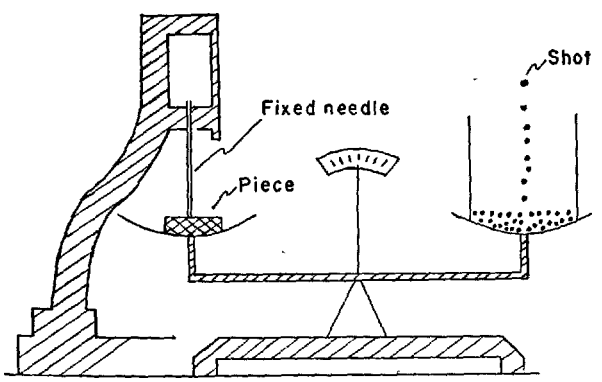

Fig. 18. *Outline of the apparatus for the measurement of the strength of coagulation.*

We regarded the penetrative degree of the fixed needle as the strength of coagulation of the burned pieces on the one side of dish of the balance. The penetrative degree was measured by the weight of shot on the other side of the dish just when the fixed needle penetrated into the bottom of the piece. The figure of the penetrative degree of the fixed needle is written down in each foregoing table which show the mineral composition of the burned pieces at the gas-solid reaction, Tables 3, 4, 5, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17.

Figs. 19, 20, 21, 22 show graphs of the temperature and the penetrative degree of the needle obtained from the result of the experiment of each foregoing

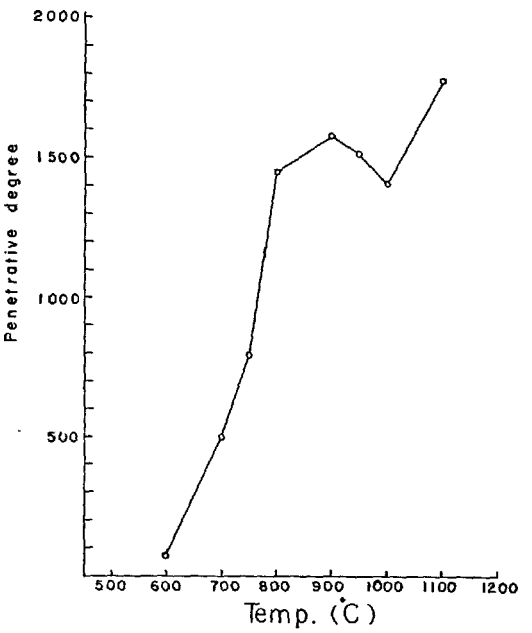

Fig. 19. *The relation between the burning temperature and the penetrative degree of the burned pieces of clinker under current of saturated* CO_2 *gas.*

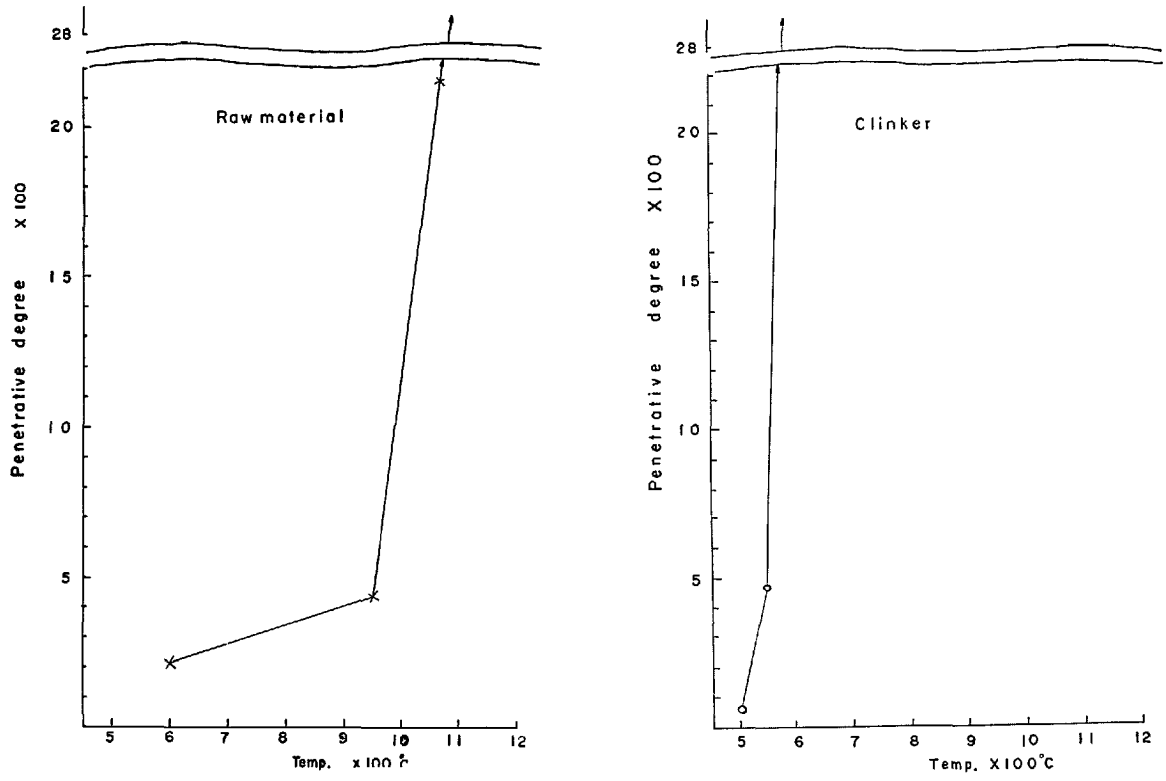

Fig. 20. *The relation between the burning temperature and the penetrative degree of the burned pieces of raw material and clinker under current of saturated* SO_2 *gas.*

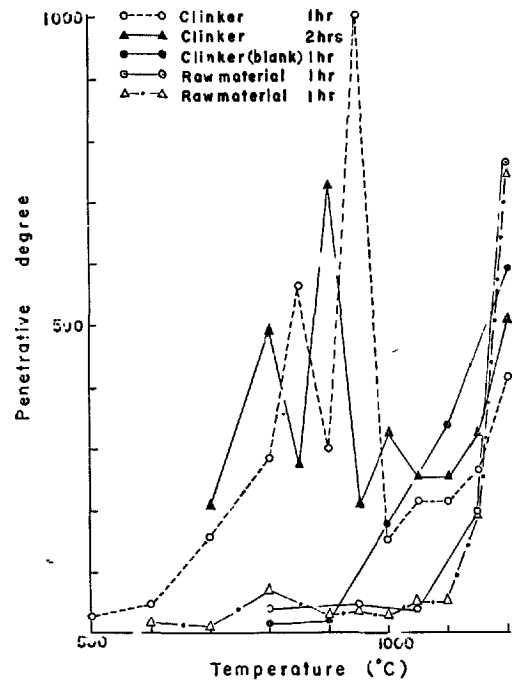

Fig. 21. *The relation between the burning temperature and the penetrative degree of the burned pieces of raw material or clinker under current of the mixed gas.*

gas-solid reaction.

Fig. 19 shows graph of the burning temperature and the penetrative degree of the burned pieces in the gas-solid reaction between saturated CO_2 gas and raw material or clinker. Fig. 20 shows the one in the reaction between saturated SO_2 gas and raw material or clinker. Fig. 21 shows the one in the reaction between the mixed gas and raw material or clinker. Fig. 22 shows the one in the reaction between the mixed gas and the clinker to which a little quantity of K_2O are added.

From Fig. 19 we know that the penetrative degree of burned pieces in the reaction with clinker increases remarkably at 800°C as the quantity of $2Ca_2SiO_4 \cdot CaCO_3$ increases. On the other hand, there shows very small quantity of the penetrative degree of pieces at each burning temperature in the reaction with raw material, because $2Ca_2SiO_4 \cdot CaCO_3$ is barely formed from raw material unable to produce $2Ca_2SiO_4$ easily.

From Fig. 20 we know that a very rapid increase of the penetrative degree is shown at 1,050°C as $3Ca_2SiO_4 \cdot 2CaSO_4$ is formed in the reaction with raw material. In the reaction with clinker, however,

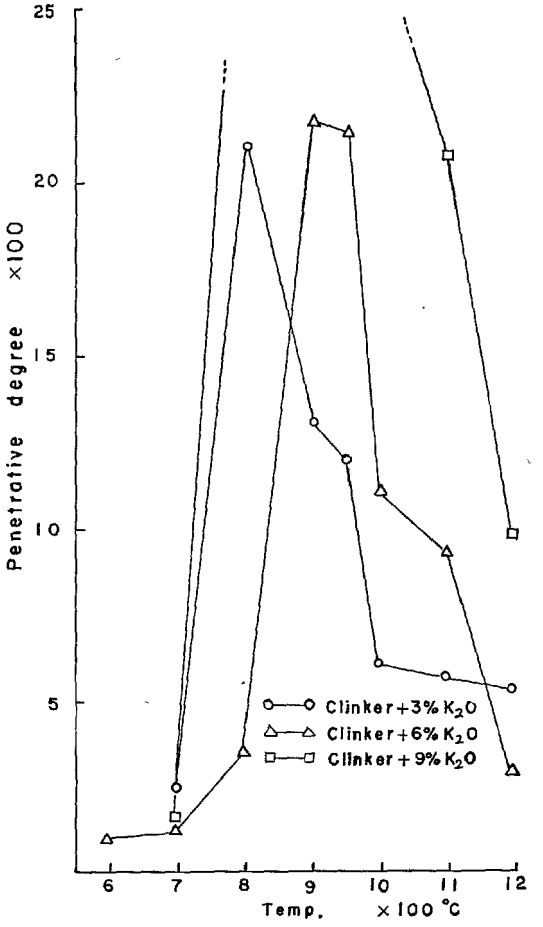

Fig. 22. *The relation between the burning temperature and the penetrative degree of the burned pieces of clinker* K_2O *added under current of the mixed gas.*

very rapid increase of the penetrative degree is shown at 600°C as $CaSO_4$ is formed. The piece burned at 1,070°C forming $3Ca_2SiO_4 \cdot 2CaSO_4$ shows very strong coagulation in appearance. Its penetrative degree is far over the limit of measurement.

From Fig. 21 we know that extraordinary increase of the penetrative degree is shown at the range of temperatures from 800°C to 1,000°C in the reaction between the mixed gas and clinker. On the contrary no increase of the penetrative degree is shown in the reaction with raw material and sintering appears at 1,200°C. It is surprising that even a very small quantity of SO_2 gas gives considerable effect on the penetrative degree of burned pieces producing $3Ca_2SiO_4 \cdot 2CaSO_4$.

From Fig. 22 we know that an extraordinary increase of the penetrative degree is shown at the range of the temperatures from 800°C to 1,000°C in the reaction between the mixed gas and clinker with addition of K_2O. It is probably caused by the formation of $2K_2SO_4 \cdot CaSO_4$. The increase of the penetrative degree in the reaction with raw material with addition of K_2O is far less than the one in the reaction with clinker by addition of K_2O.

Conclusion

From the investigation for the detail of mineral composition of ring we found ordinarily some kind of double salt minerals, $2Ca_2SiO_4 \cdot CaCO_3$, $3Ca_2SiO_4 \cdot 2CaSO_4$ and $2CaSO_4 \cdot K_2SO_4$ besides single salt minerals, $CaCO_3$, $CaSO_4$ and $(K, Na)_2SO_4$, in the texture of ring.

As we assumed that these salt minerals found in cement kiln were formed by gas-solid reaction between CO_2 or SO_2 of fuel gas and raw material or clinker in cement burning, we tried to make an experiment to verify the existence of this reaction.

The experiment was made by burning raw material or clinker in the electric furnace at each temperature under the current of CO_2 or SO_2 gas.

The results of this experiment led to determine exactly the forming condition of these salt minerals in burning of raw material or clinker under current of CO_2 or SO_2 gas.

In the reaction between saturated CO_2 gas and clinker, $CaCO_3$ was newly formed at the range of temperatures from 700°C to 900°C and $2Ca_2SiO_4 \cdot CaCO_3$ was formed remarkably well from 750°C to 900°C, but in the reaction between CO_2 gas and raw material $2Ca_2SiO_4 \cdot CaCO_3$ was not observed. It is supposed that gas density, temperature condition and volume of clinker minerals, especially volume of Ca_3SiO_5 play an important role in the formation of $2Ca_2SiO_4 \cdot CaCO_3$.

In the reaction between saturated SO_2 gas and raw material or clinker, $CaSO_4$ was newly formed well in the range of temperatures from 550°C to 1,150°C and $3Ca_2SiO_4 \cdot 2CaSO_4$ was formed well from 1,050°C to 1,150°C. It is probable that SO_2 gas has the action of catalyzer for acceleration of the formation of $3Ca_2SiO_4 \cdot 2CaSO_4$.

On the other hand, in the reaction between the

mixed gas, N_2 of 79.5 vol. percent, CO_2 of 19.9 vol. percent and SO_2 of 0.6 vol. percent, and clinker $CaCO_3$ was not newly formed in the range of temperatures used, but $CaSO_4$ was dominant above 700°C. In this case $2Ca_2SiO_4 \cdot CaCO_3$ was formed in the range of temperatures from 800°C to 850°C and $3Ca_2SiO_4 \cdot 2CaSO_4$ was formed from 900°C to 1,100°C. We could conclude that even a small quantity of SO_2 gas by far predominates than a large quantity of CO_2 gas in the reaction with raw material and clinker at high temperature. In the reaction between the mixed gas and raw material we could synthesize $CaCO_3$ and $CaSO_4$, however could not do the double salt minerals at each temperature.

In the reaction between the mixed gas and raw material and clinker to which K_2O of 3, 6 and 9 wt. percent was added, $2CaSO_4 \cdot K_2SO_4$ was formed at 600°C and remarkably well in the range of temperatures from 600°C to 900°C. From this fact we assumed that after clinker minerals, especially alite (Ca_3SiO_5), was dissociated to belite (Ca_2SiO_4) and CaO, $CaSO_4$ was formed by the reaction between CaO and SO_2 gas and K_2SO_4 was formed from K_2O, then the double salt mineral ($2CaSO_4 \cdot K_2SO_4$) was formed by the reaction between $CaSO_4$ and K_2SO_4.

Furthermore we found that the double salt minerals show greater strength of coagulation than clinker minerals. We verified this fact by the original experiment.

The results obtained from these experiments should give important suggestions to the research about the cause of the generation of the ring and also about the temperature condition of each inner part of kiln where the ring adheres.

Supplementary Paper I-94 Problem of Admixtures

Maxim M. Sichov*

Synopsis

The influence of raw material admixtures and alloying additions on the properties of the liquid are considered in the paper, (viscosity, electrical conductivity, surface tension) as well as the peculiarities of clinker sintering and the microstructure in the presence of admixtures. The influence of admixtures and alloying additions on the properties of cement is also discussed. The role of BaO, SrO, Cr_2O_3, R_2O, P_2O_5, B_2O_3, SO_3, TiO_2, Mn_2O_3 in the formation of tricalcium silicate has been found. It has been shown that in the presence of P_2O_5 and B_2O_3 the passivation of SiO_2 and CaO takes place, which results in the difficulties of the reaction of CaO + SiO_2. It has been found that the formation of C_3S in the presence of certain admixtures goes not only according to the scheme of C_2S + CaO but also by means of the interaction of C_2S supersaturated with CaO and C_3S. It is shown that the hydraulic activity of C_3S increases when the concentration of P_2O_5 and Cr_2O_3 are low. It occurs if the concentration of P_2O_5 and Cr_2O_3 in the solid solution does not exceed the solubility limit.

The modifying action of P_2O_5 and Cr_2O_3 is the reason of increasing the hydraulic activity of cement in the presence of P_2O_5 and Cr_2O_3 which appeared to be surface active substances and they affect the conditions of the crystallization of the minerals from the liquid. The action of the raw material admixtures is seen not only on the surface tension but also on the viscosity. So, there is a miximum on the viscosity curves for concentration of the liquid containing MgO. In contrast to the generally recognized ideas, alkalies increase the viscosity of the liquid which is the result of increasing the basicity of the melt and the fact that aluminium and iron ions show more expressed acidic properties. The connection has been found between the physicochemical properties of the liquid in the presence of admixtures and the peculiarities of clinker sintering in the case of contamination of the raw material by MgO and R_2O. It has been shown that the raw material admixtures and the alloying additions may be mineralizers and the mineralizers may become alloying components. It has been suggested, therefore, to single out the problem of admixtures and additions into a special section of the chemistry of cement.

Introduction

The minor components of portland-cement clinker have been investigated mainly with concentrations of 1–3 per cent. (1, 2, 3, 4). When the works of L.D. Ershov appeared (5) who introduced the idea of alloying action of admixtures, it became necessary to pay greater attention to admixtures when their concentration is less than 1–0.5 per cent.

From the author's point of view the role of minor components of raw materials in clinker sintering has not been considered quite fully.

The present work carried out by V. I. Korneev, P. V. Zozulia and G. I. Kopina under the guidance of the author, at the chair of chemical technology of cement, Leningrad Lensoviet Institute of Technology, USSR, is dedicated to the role of admixtures in sintering and to the influence of low concentration of admixtures and additions on the properties of cement.

*Leningrad Lensoviet Institute of Technology, Leningrad, U.S.S.R.

Influence of Admixtures on Hydraulic Activity of C_3S and Cements

To find out the influence of admixture components upon the formation and the properties of C_3S it was necessary to elaborate the method of obtaining pure monomineral C_3S during one burning since the existing methods require repeated sintering which leads to the passivation of the mineral. For this it was necessary to secure great fineness of the raw materilas ($CaCO_3$ and SiO_2) while retaining the purity of the latter.

It was realized by grinding the raw materials in a jet mill (particle size 0.5–3 micron, specific surface 11,500 sq.cm per g.) After a single burning at the temperature of 1500°C (during 6 or 7 hrs) there was no free CaO in the product. The preparation, however, contained several per cent of C_2S, it being the result of supersaturating of C_3S with excess CaO.

Thus, to obtain monomineral C_3S the raw mixture should be prepared with the greater molar ratio than 3. As a result, a sufficiently pure preparation containing 99 per cent of C_3S can be obtained.

Further, on the basis of physico-chemical and petrographic analysis the influence of admixtures (K_2O, Na_2O, P_2O_5, SO_3, TiO_2, Mn_2O_3) on the formation and composition of tricalcium silicate has been found. Beside the admixtures of raw materials, BaO, SrO, B_2O_3, Cr_2O_3 have been considered which are analogous to the raw materials components. A number of interesting peculiarties of C_3S formation in the presence of admixtures have been discovered. Below is given the information about the admixtures for which the new data were received.

In the presence of P_2O_5 the preparation contained free CaO the amount of which required approximately 13 per cent of C_3S; However, with regard to the presence of about 40–45 per cent of low-basic compounds in the sintered material, the author explains from the fact that CaO forms solid solutions with $2CaO \cdot SiO_2$ and $3CaO \cdot SiO_2$. Quartz was also present in the sinter material in the shape of grains which were like those of the original raw silicic acid. Thus, if concentration P_2O_5 exceeds its solubility limit in C_3S, it leads not only to the dissociation of C_3S but also brings about the passivation of CaO and SiO_2. The same picture may be noticed in the presence of B_2O_3. The reason for such a course of synthesis can be explained by the difficulty of the reaction of $CaO + SiO_2$ in the presence of B_2O_3 and P_2O_5 rather than of the reaction of $2CaO \cdot SiO_2 + CaO$ as it is usually thought.

Therefore, the formation of C_3S in the presence of admixtures goes not only according to the scheme of $C_2S + CaO$, but also by means of the interaction of C_2S (supersaturated with CaO) and tricalcium silicate. This fact indicates to the importance of studying the phase relations in the system of C_2S–C_3S in greater detail than the author and his collaborators are now doing.

Further, it was necessary to find out the influence of additions on the technical properties of C_3S. For this purpose the physico-mechanical properties of sintered materials of C_3S have been determined with regard to compressive strength and grindability as well as its hydraulic activity, the latter containing 0.25, 0.5 and 1.0 per cent of additives. It was found that TiO_2, Mn_2O_3 and Cr_2O_3 decrease the strength of sintered materials and improves the grindability. P_2O_5, SrO, Cr_2O_3, TiO_2, Mn_2O_3, La_2O_3, CeO_2, and Na_2O_3 increase the hydraulic activity of C_3S, the latter changing in the presence of admixtures more often during the first three days of hardening. Thus, the admixture effect depends both upon its nature and upon the concentration.

As a result of this, it became clear that most of the raw material admixtures affect the composition and the formation of the alit crystals that points to the alloying role of certain admixtures (natural alloying) and also to the possibility of employing a number of materials for the artificial alloying of the clinker. As it was mentioned above, the action of admixtures is determined not only by their nature but also by their concentration. Therefore, a number of oxides, the presence of which in the raw material is generally considered to be harmful, may be thought of as prospective alloying components if proper concentration, lower than the solubility limit in C_3S is provided. Taking this into consideration, P_2O_5, Cr_2O_3, TiO_2 and SrO present greatest interest as alloying components. To confirm this statement it was necessary to study the formation of solid solutions of the alloying oxides in C_3S and their properties in greater detail. From the systems C_3S–alloying oxide, it was decided to consider C_3S–Cr_2O_3 system, as far as the solid solutions of P_2O_5 and SrO have been already studied (1, 6, 7).

The physico-chemical investigations give reason to think that chrome plays the same role in chromalite as aluminium in alite, i.e. it substitutes a silicon atom. The maximum solubility of Cr_2O_3 in C_3S may be estimated at 2 per cent and it corresponds to the data of A. I. Boikova (8). When the concentration of Cr_2O_3 is more than 2 per cent, solid solution dissociates as a result of chemical interaction with Cr_2O_3. In the presence of TiO_2 alite is formed in the shape of short

prismatic crystals, their refractive indices being higher than those of C_3S. This indicates the formation of the solid solution of TiO_2 in $3CaO \cdot SiO_2$.

The hydraulic activity of solid solutions of TiO_2 in C_3S appeared to be higher than that of the pure C_3S. Therefore, one should consider titanium-containing clays as a raw material which is suitable for obtaining natural alloying clinkers.

Further, it was important to define more exactly the allowable content of P_2O_5, TiO_2, Cr_2O_3 in the clinker and to find the materials suitable for use as alloying additions. It appeared that, at a certain concentration of Cr_2O_3, free CaO is found in the clinker, the amount of which is connected with the CS value (CS-coefficient of saturation). The permitted Cr_2O_3 amount in the clinker depends upon the CS value. It is 2.6% when CS = 0.85; 1.6% when CS = 0.90; 1.4% if CS = 0.95.

The concentration of Cr_2O_3 resulting in the improvement of cement properties (approximately 0.25 per cent) is five or six times lower than the permitted Cr_2O_3 content in the clinker that allows proportioning of chrome—containing materials in a usual way. The permitted P_2O_5 content in the clinker is equal to 0.10–0.20%. For this purpose it is advisable to deal with materials having low content of P_2O_5, and in certain cases it is necessary to dilute the phosphorus—containing material with limestone. The utmost permissible TiO_2 content is estimated at 2–2.5 per cent to obtain high alite cements.

The Reasons for Increasing the Hydraulic Activity of Cements in the Presence of Raw Material Admixtures or Alloying Additions

It was stated above that the formation of the solid solutions of admixtures in C_3S increases the hydraulic activity if the concentration of the admixture is lower than the solubility limit in C_3S. If the concentration of an admixture or an alloying addition is lower than it is necessary for the depolymerization of the structure, its presence leads to the formation of defects and vacancies in the lattice of $3CaO \cdot SiO_2$ which explains the higher hydraulic activity of solid solutions in comparison to pure C_3S. If the concentration of admixtures or additions is sufficient to form the overstructure, the increase of the hydraulic activity is explained by increasing the energy of the lattice, by breaking the bonds and by lowering the density of the high—temperature form. It should be taken into account that the hydraulic activity of C_3S containing admixtures depends upon the nature of an ion which is a part of the structure of $3CaO \cdot SiO_2$. (basic or acidic character, valency, ion radius).

In 1955—56 the works of E. Grzhimek and V. N. Young (9, 10) appeared in which it was stated that the increase of the hydraulic activity of cement may be realized by the modification of the microstructure.

E. Grzhimek showed, in particular, that the modification may be realized by introducing certain admixtures into the alite lattice and in this way may be obtained the alite having the ratio of axes up to 1 : 7. Later, U. M. Butt and V. V. Timashov (11) developed those works and at present modification showed to be a recognized method of improving cement quality.

The raw material admixtures affect the physico-chemical properties of the liquid. As far as the greatest amount of C_3S is crystallized from the clinker liquid (liquid phase) and aluminates and aluminoferrites are crystallized when the melt solidifies, the presence of admixtures or alloying and mineralizing additions cannot but affect the crystallization conditions and therefore the clinker microstructure. There appeared the idea whether the increase of the hydraulic activity of cement in the presence of admixtures and alloying additions is connected not only with the formation of solid solutions but also with the modification of the clinker microstructure at the expense of surface—active action of admixtures.

From the point of view of adsorption theory, the modification should lead to the change of shape, since when adsorbing a surface-active substance the relation of the crystallization speed is changed on different faces. Thermo-dynamic description of the phenomena taking place during modification was given by P. A. Rebinder and M. S. Lipman (12). According to P. A. Rebinder, if the surface activity of $d\sigma/dc$ is less than zero (the gradient of surface tension in concentration) i.e. if the surface tension decreases when the concentration increases, the positive adsorption takes place and the dissolved substance should be considered a surface-active one. And, on the contrary, if the surface tension increases when the concentration is raised ($d\sigma/dc$ is greater than 0) a negative adsorption takes place and the dissolved substance should be considered as a surface-inactive one. Therefore, the surface activity of substances is determined by changing the surface tension of the melt and the estimation of the modifier may be based on the information about the influence of additions upon the surface tension of the melt. That is why P. V. Zozulia and G. I. Kopina studied the influence

Table 1.

alumina modulus P	Composition in per cent			
	CaO	SiO_2	Al_2O_3	Fe_2O_3
1.0	55.2	7.1	18.85	18.85
2.5	57.0	8.0	25.0	10.0

of Cr_2O_3, P_2O_5 and TiO_2 on the surface tension of the liquid.

To measure the surface tension the method of determining the shape of drops of fluid was used. The measurement was done at the temperature of 1400°C. The measurement of the parameters of the melted drops on the negative was made by means of a microscope. The surface tension was calculated with the help of the tables of Bashfort and Adams (13) according to the formula:

$$\sigma = a^2 \rho g$$

where

a—is a capillary constant
ρ—the density of the melt
g—the acceleration of the gravitational force.

There have been two melts chosen the composition of which was determined according to Lea and Parker (14), the former corresponding to the composition of the melt at 1450°C formed from the readily sintered raw mixture having alumina modulus p = 1.0, the latter corresponding to the melt at 1450°C formed from hard sintered raw mixture having alumina modulus p = 2.5. The chosen compositions are given in Table 1.

The additions were introduced into the original mixtures in the amount providing in the melt 0.25, 0.5, 2.05, and 4.0 per cent. The results of determination of the surface tension are given in Table 2.

The analysis of the data given in Table 2 shows that when Cr_2O_3 and P_2O_5 are introduced a considerable decrease of the surface tension of the liquid is observed. The isotherms of dependability of surface tension on the concentration of the addition have the appearance of the curve convex to the X-axis which is characteristic, according to V. K. Semchenko, for the surface active substances. Cr_2O_3 has the greatest surface activity: when the content of Cr_2O_3 is four per cent in the melt, $\Delta\sigma = \sigma_0 - \sigma$ reaches 70–100 erg per sq.cm.

One should note the similarity of the values of surface tension of the melts having different alumina modulus and containing either Cr_2O_3 or P_2O_5. Therefore, Cr_2O_3 and P_2O_5 are typical modifiers, the introduction of which favours the microstructure of the clinker, particularly when burning hard-sintered raw material.

And indeed, when alloying additions are introduced into the raw mixture in amounts providing the maximum increase of hydraulic activity of cement (0.25% of Cr_2O_3, 0.15% of P_2O_5 in the clinker), the size of the crystals and the habit of alite and belite are changed (the elongated alite and split belite appear) i.e. the modification of the clinker with the compounds of chrome in particular takes place which is one of the reasons for increasing the hydraulic activity of cements.

Table 2.

The Role of Admixtures in the Process of Sintering

It was shown by the author above that the peculiarities of sintering raw mixtures of different compositions are determined by the properties of the liquid during the final period that allows the use of physico-chemical analysis as the basis of optimization of raw mixtures composition. The presence of admixtures in the raw materials, however, cannot but affect the properties of the liquid and their viscosity in the first instance. That is why P.V. Zozulia made an experimental determination of viscosity of the clinker liquid containing

MgO and R_2O in the laboratory of the chair.

According to the data of Kholin and Entin (15) and Mgjdic and Schwiete (16) the greater the decrease of the viscosity and of the eutectic melt, the greater the content of MgO in the raw material. According to the determinations made by P. V. Zozulia, the viscosity decrease in the presence of MgO is particularly noticable at the temperatures approaching the eutectic one. Such viscosity decrease is connected with the destruction of the prenucleous groups in the preliquid area (group P according to Augustinik (17)) and by lowering the eutectic temperature at the expence of making the melt composition more complex. If MgO concentration in the melt is brought to 5–6 per cent (1.5–2.0% in the clinker) the viscosity of the liquid is again raised. At first the introduction of Mg^{2+} cations having greater field of force than Ca^{2+} (greater electronegativity and smaller radius) promotes the transformation of Al^{3+} and Fe^{3+} from tetrahedral coordination to the octahedral one is accompanied by the viscosity decrease. With greater Mg^{2+} concentration the ion bridge can be formed between the tetrahedrons of SiO_4 which is possible only when MgO content in the melt becomes comparable to the silica amount that takes place when the MgO concentration in the melt is increased up to 5 or 6 per cent.

In contrast to the generally recognized views it appeared that the introduction of alkalies into the clinker liquid leads to the viscosity increase. Such a mechanism of alkalies action is connected with the basicity increase of the melt the result of which is that aluminium and iron ions acquire acidic properties that leads to the tetrahedral coordination of aluminium and iron in relation to oxygen. The complexes $[AlO_4]$ are able to replace tetrahedrons isomorphously, $[SiO_4]$ forming alumino—silicon—oxygen frame that increases the viscosity. In the light of the data obtained the generally accepted explanation of the peculiarities of sintering in the presence of R_2O needs to be corrected.

In the system C–S–A–F–R–M the viscosity is lower than that of the clinker liquid of the like composition without MgO. Therefore, it is assumed that in the raw material containing alkalies, the presence of a small amount of MgO (up to 1 per cent in the clinker) or the intensional introduction of such amounts of magnesia additions may be favourable for the clinker formation, that is confirmed by the investigators (18). When there are alkalies and a great amount of MgO (more than 1.5% in the clinker) in the raw material the raw mixtures will sinter with greater difficulties.

Since the eutectic melts in the system C_3S–C_2S–C_3A–C_4AF refer to the associated liquids, the Frenkel equation cannot be used for the description of the temperature dependence of their viscosity. The temperature dependence of viscosity may be well described by means of the Evstropiev equation (19). MgO effect on the viscosity of the clinker melt brings to the changes in the crystallization character as well. So, for clinkers containing one per cent of MgO the more distinct crystallization of silicates is typical, the crystal sections have more regular shapes, greater uniformity of size, it referring particularly to alite, the uniformity of the distribution of all phases and negligible content of joints and aggregates of alite and belite. When MgO content is increased up to two per cent in the clinker the deterioration of crystallization takes place. For clinkers containing alkalies (1% of R_2O) zonal structure of the grains is typical—in a thin layer on the surface of a grain greater crystals of alite are formed—up to 300 micron and in the centre their size is up to 50–70 microns. When introducing magnesium oxide into alkali-containing raw mixtures the weakening of alkalies influence upon the character of silicates crystallization takes place.

The cited information shows that most raw material admixtures affect the composition and formation of alite crystals that indicates the alloying role of certain admixtures (natural alloying) as well as the possibility of using a number of materials for the artificial alloying of the clinker. It is the alloying action of natural admixtures that explains the differences in the activity of cements produced at the mills having the same kind of equipment and similar clinker composition.

The action of admixtures and additions is seen also during the solid phase stage of clinker minerals formation, the admixtures and alloying additions producing mineralizing and inhibiting effect. Thus, there is a direct connection between admixtures and alloying and mineralizing additions. Mineralizing additions should not be considered only from the point of view of catalytic effect. The influence of mineralizers upon the properties of the liquid phase of sintering clinker may bring about the modification of clinker minerals. Besides, mineralizers may affect the peculiarities of structure of clinker minerals. Therfore, mineralizers often have alloying effect. Meaning by alloying the artificially introduced additions, one should not forget that many admixture additions may be considered as natural alloying materials, rendering proper effect if their concentration is low enough. The raw material admixtures having high concentration produce harmful effect on technology and properties of cement.

Taking into account the facts stated above, the author suggests to single out the problem of admix-

tures and additives including admixtures, as well as alloying and mineralizing components into a separate section of the chemistry of cements.

Supplementary Paper I-98 Mechanisms and Kinetics of Portland Cement Clinker Formation for an Example of the Solid State Reaction in the Presence of a Liquid Phase

Renichi Kondo* and San-Heul Choi**

Synopsis

The mechanism and kinetics of the solid state reaction between CaO and C_2S to form C_3S, in the presence of a melt, was investigated.

In order to make clear the mechanism of reaction the sandwich method was employed, powdered glassy phase is sandwiched between the compact disk of CaO and β-C_2S. After where heating, studies were carried out with the aid of X-ray diffraction, microscopic observation, and electron probe micro analysis. The results show dissolution and diffusion of CaO and C_2S into the melt. The melt is supersaturated on these components, and C_3S crystallizes out from the melt.

The viscosities were measured by the ball pulling-up device for the melt containing various amounts of CaO, γ-C_2S, and C_3S. The relationship between η vs. 1/T could not be acccpted as linear in a wide temperature range.

Furthermore the kinetics of the solid state reaction in the presence of a liquid phase has been developed. The reaction is thought to be controlled mainly by the diffusion in the liquid phase. On the same assumption, a Jander's type of equation is derived where dissolution is considered in spite of the inward diffusion being assumed by Jander. This equation is found to express the experimental data most appropriately.

Finally, diffusion coefficient was calculated from the results on the rate of reaction and the concentration difference estimated in the phase diagram. Calculated value was lower than those obtained by viscosity and tracer experiments. As these discrepancies are in such a magnitude to be compensated by the effects of a limited amount of melt and the tortuosity of diffusion path, the assumptions on the kinetics in this study seem to be reasonable.

Introduction

On the solid state reaction a number of studies which dealt with the mechanisms and kinetics have appeared since the early works of Tamman and Jander. So far as a melt is concerned, however, it has not been investigated owing to the difficulties experienced.

There are also a few studies on the mechanisms and kinetics of the formation of portland cement clinker. One of the present authors, Kondo (1) in his studies on the kinetics of this reaction found it necessary to simplify the experimental conditions in order to obtain accurate results. Yamaguchi, Uchikawa, and Kawamura (2), on the other hand, observed by microscope that the formation of alite took place in the liquid phase. Further, the rate of dissolution of CaO, C_2S, C_3S, and silica in a melt was studied by Toropov, Rumyantsev, and Filipovich (3) using a high-temperature microscope.

In this paper, the solid state reaction in the presence of a liquid phase in the formation of portland cement clinker is dealt with.

Experimental Methods and Results

Starting Materials

Starting materials except silica used for synthesis were special grade reagents. As the source of silica, quartz with high purity was selected and ground. It was then purified by acid washing and elutriated to cut off coarser particles of more than 10 μ in radius. Synthesis of γ-C_2S, C_3S and the glassy phase were made. The composition of the glassy phase was chosen the invariant point (4) in which C_3S, C_2S, C_3A, and C_4AF are coexisted at 1338°C. Its chemical composition corresponds to 54.8 CaO 22.7 Al_2O_3 6.0 SiO_2 and 16.5 Fe_2O_3. The particles of synthetics of limited size were then isolated by the Bahco type classifier.

The Reaction on the Boundary Layer

In order to investigate the mechanism of reactions on the boundaries of CaO–melt and C_2S–melt, a sandwich method was designed. A powdered glassy phase is sandwiched between the specimens which consists of two compact disks of CaO and β-C_2S each. After heating in an electric furnace, the specimen was air quenched, and then examined by X-ray diffraction, microscopic observation and electron probe micro analysis.

X-ray Diffraction

The heat-treated specimen was cut at the position of interfaces of CaO and C_2S each in parallel with the boundary of the two disks and investigated by X-ray diffraction on each surface. In consequence, the formation of C_3S was clarified in the melt of the boundary surface. Fig. 1 shows the diffraction patterns of each part before heating (A) and after heating for 120 min. at 1450°C (B).

Microscopic Observation

The heat-treated specimen was cut vertically at the boundary of disks and the thin sections were utilized, so that it can be observed through the reflection and transparent polarizing microscopes. The formation of C_3S crystals was confirmed in the melt of the boundary surface. Fig. 2 shows the appearances forming C_3S by heat treatment of for 120 min. at 1450°C. The crystals of C_3S tended to elongate to the parallel with the boundary.

Concentration Distribution of Components in the Boundary Layer

Since the analysis of the chemical composition of micro area of solid surface became possible by electron probe micro analysis, it has been applicable to the analysis of cement clinker. The concentration distribution of Ca, Si, Al, and Fe on the boundary layer was investigated by electron probe micro analysis

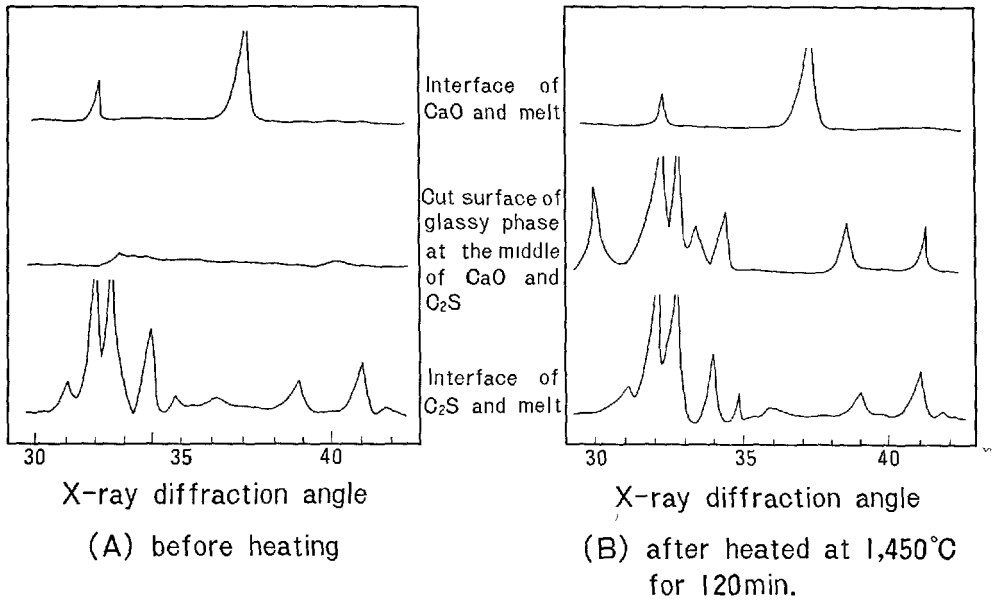

Fig. 1. *X-ray diffraction patterns of sandwich specimen.*

with the results as shown in Fig. 3.

The concentrations of various chemical components on the boundary layer were corresponding to the theoretical value of mineral components. Nearly the same amount of Al and Fe seems to be incorporated in both C_2S and C_3S, more in the former, to form solid solutions. The reason for the higher concentration of Si at the holes, is attributed to carborundum intermixed at polishing (5).

From the experimental results it is considered that, when the sandwiched specimen is heat-treated, the glassy phase melts above 1338°C, and dissolves CaO and C_2S, and then after the melt is supersaturated on these components, C_3S crystallizes out from the melt.

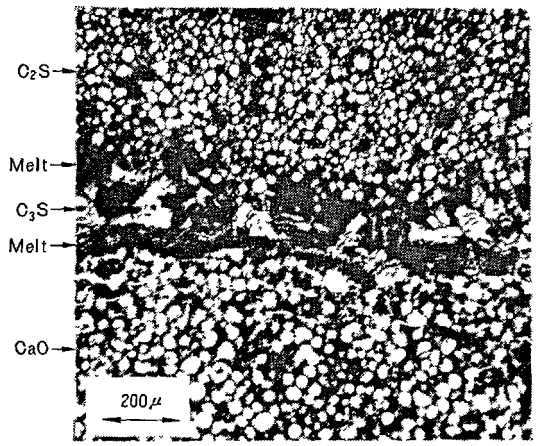

Fig. 2. C_3S *formed in the melt heated at 1450°C for 120 min. (Open nicol)*

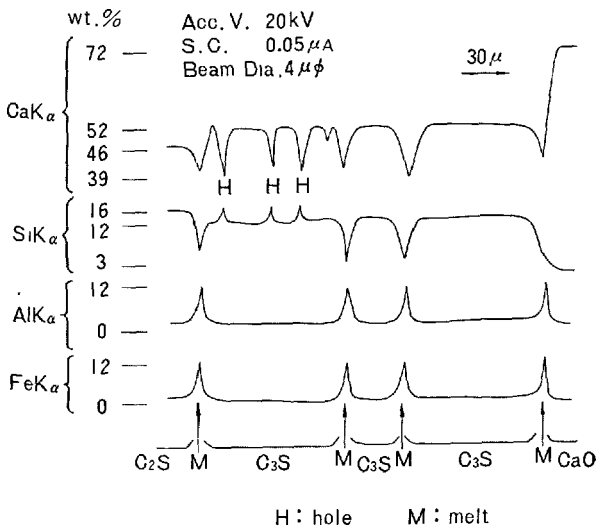

Fig. 3. *Concentration distribution in sandwich specimen by line analysis of EPMA.*

Viscosity of the Melt

On the viscosity of the melt assumed to exist at the time of portland cement clinker formation, Vysotskii, Butt and Timashev (6) studied the effect of temperature and chemical composition, and Sychev, Zozulya, Shtefan, and Ivantsova (7) studied the influence of raw admixture and additional agents such as Cr_2O_3, TiO_2, MgO, P_2O_5, and $K_2O + Na_2O$.

In this study, the viscosities were measured with the ball pulling-up device (8) for the melt containing various amount of CaO, γ-C_2S and C_3S in the temperature range from 1360°C to 1550°C. Fig. 4 shows the relationship between the viscosity (η) and reciprocal absolute temperature ($1/T$). The relationship could not be accepted as linear, in a wide temperature range. The values of activation energy for the viscous flow were calculated from the following equation, on the assumption that the linear relationship holds within a narrow temperature range.

$$\log \eta = \log A + 0.4343 \frac{E\eta}{RT} \qquad (1)$$

A marked decrease in the activation energy is observed with increasing temperature which may result from the structural change.

Fig. 5 shows the influence of the addition of CaO, γ-C_2S, and C_3S respectively on the viscosity of the melt. The viscosity increases with the amount of C_3S or C_2S and decreases with the amount of CaO, but the effect of composition on the activation energy of viscosity affects reversely.

Determination of the Reaction Rate

The raw mixtures consisting of the particles of CaO,

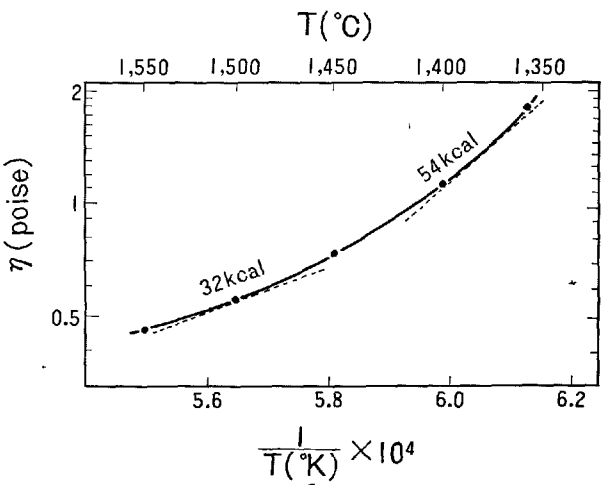

Fig. 4. *Temperature dependence of the viscosity of the melt.*

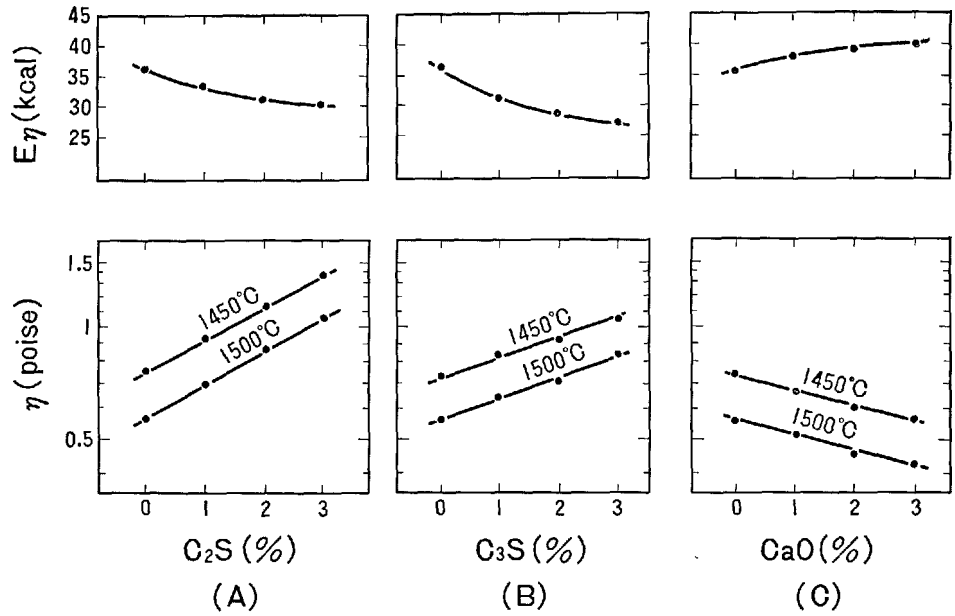

Fig. 5. *Viscosity isotherms and energy of activation for viscous flow.*

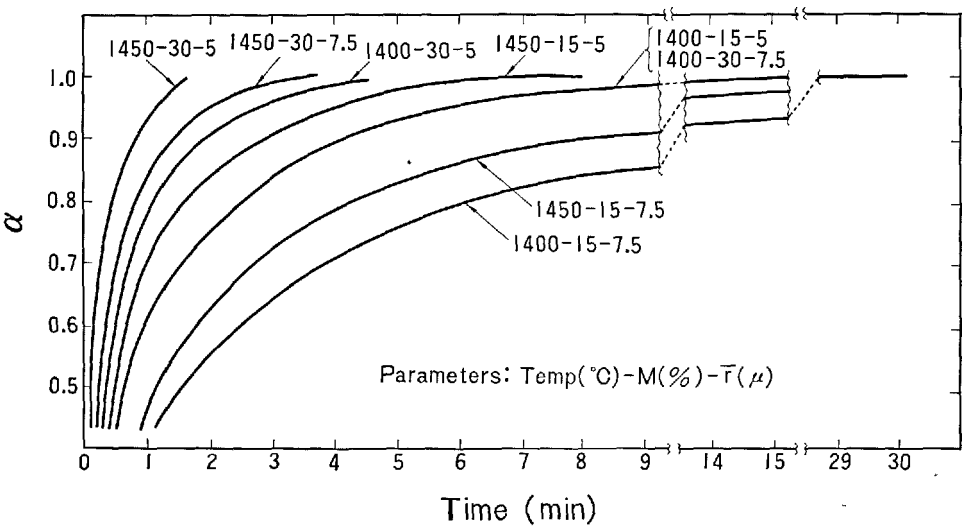

Fig. 6. *Fraction of reacted part vs. reaction time.*

γ-C_2S and the glassy phases were pressed at a pressure of 100 kg/cm² to form disk of an area of 1 cm² and weight of 1 gr. Determinations of the free CaO were made on these disks after they were heat-treated and air quenched. For the simplification in the theoretical treatment, uniform size of particles were used. The chemical composition and fineness of the raw mixtures and the burning conditions in this experiment are as follows:

CaO: γ-C_2S = 1: 1 (molar ratio)

amount of the glassy phase = 15%, 30% (in wt% of CaO and C_2S)

particle size $\bar{r} = 5\mu, 7.5\mu$

heating temperature = 1400°C, 1450°C

heating time = 2, 4, 8, 15, 30, 60 min.

The heating was done in a vertical electric furnace with an automatic temperature controller. The specimen was put into a small container made of platinum foil and suspended with platinum wire for the convenience of rapid heating and quenching.

The free CaO content of the heat-treated specimen was determined by modified Franke's method, using a mixture of isoprophyl alcohol and ethyl aceto acetate as the extraction solvent.

The reaction ratio are calculated from the value of free CaO as shown in Fig. 6. The rate of C_3S formation increases with the content of the glassy phase, fineness of the particle of reactants, and temperature. And the degree of these effect is approximately in this order.

Discussion

Mechanism of the Reaction

On the reaction of CaO and C_2S in the presence of the melt, the composition change accompanied with dissolution is considered. The phase diagram of the system CaO–C_2S–C_4AF (4) is selected for simplification and used for consideration. Fig. 7 is a part of the diagram of above system. The course and composition of dissolutions of CaO and C_2S in the melt indicated by point T will be examined. In the process of dissolution, if the boundary reaction is sufficiently rapid compared with transport, the interface composition has the value of the liquid composition and if the boundary reaction is sufficiently slow, the interface composition is identical with that of the bulk. We shall now consider the mechanism of the formation of C_3S in making use of Fig. 7. It is expected that the concentration path would be along the straight lines T–CaO and T–C_2S when CaO and C_2S are separately dissolved in the melt marked as T. In the concentration path, however, the interface compositions are not always located on the straight line but shifts as indicated by the dotted line, because of the difference in the relative rates of diffusions of the components. This effect has been described by Cooper and Kingery; Samaddar, Kingery, and Cooper; Oishi, Cooper, and Kingery (9) in their studies on the dissolution mechanisms in a ceramic system.

If we suppose the temperature is 1450°C, the composition of melts at the interfaces of CaO and C_2S should be C_1 and D_1 respectively. According to the counter diffusion between the melts C_1 and D_1, the compositions of melts move with the isotherms towards M beyond C_2 and D_2 which indicate the solubility of C_3S in coexistence with CaO or C_2S respectively. For the supersaturated solution with compositions beyond C_2 and D_2, C_3S is crystallized out. After a steady state is reached, the concentration of the interface of CaO and C_2S are indicated as C_3 and D_3, the melt is in this range, as a result of counter diffusion between the interfaces. Accompanied with increasing temperature, the rate of formation of C_3S is accelerated because of increasing the amount of melt, decreasing of the viscosity and increasing of the diffusion coefficient.

Kinetics of the Reaction

Since Jander the kinetics of the solid state reaction have been studied by many investigators. The effect of a melt coexist with reactants has never been considered in the solid state reactions, especially when they are in powder. In the presence of a melt,

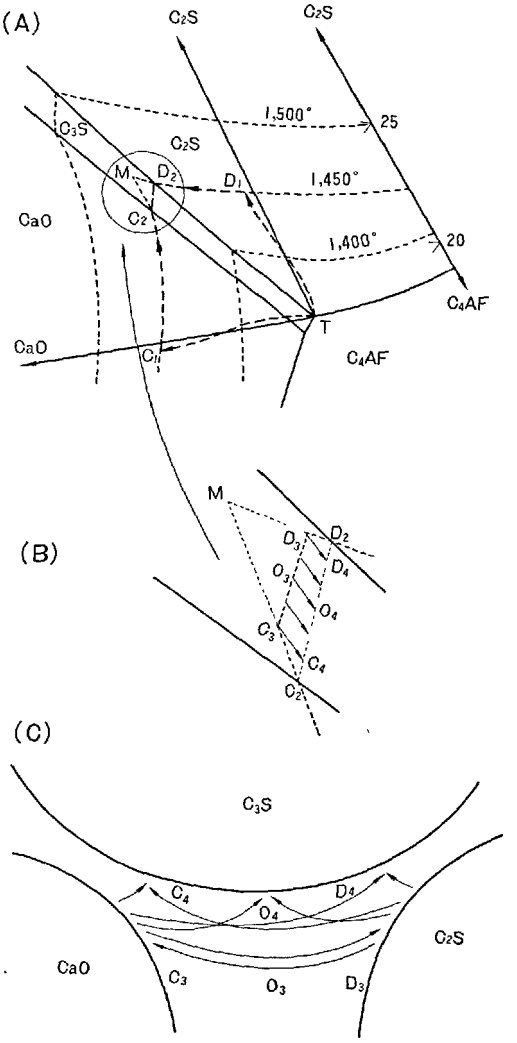

Fig. 7. *Detail of the high* C_4AF *portion of the system* CaO–C_2S–C_4AF [4] *(A) (B) and schematic illustration of the concentration difference and diffusion paths in the melt (C).*

the starting material are dissolved and diffuse each other in a melt from which a product is formed.

Depth of Dissolved Layer

On the assumption that the dissolution begins from the surface of a spherical particle of radius r_0, the volume of the substance unreacted after the time t is

$$V = \frac{4}{3}\pi(r_0 - \xi)^3 \tag{2}$$

or

$$V = \frac{4}{3}\pi r_0^3(1 - \alpha) \tag{3}$$

from Eq. (2) and Eq. (3), Eq. (4) is obtained

$$\xi = r_0(1 - \sqrt[3]{1 - \alpha}) \tag{4}$$

where ξ is the depth of the dissolved layer and α is the reaction ratio.

Fig. 8 shows the relationship between the depth of dissolution and heating time obtained by author in comparison with the results obtained by Cooper and Kingery (9), and Toropov, Rumyantsev, and Filipovich (3). Within the limits of experimental error, the depth of the dissolved layer does not depend upon the particle size. The plots of the depth of dissolution ξ versus the root time treated $t^{1/2}$ can be taken as linear in a certain range. It is observed some shift from the straight line at the later stage of reaction, and this seems to be due to the effect of distribution of the particle size, however the powder of reactants was elutriated. Above mentioned facts suggest that the particle dissolution is diffusion-controlled.

Similar results were obtained by Cooper and Kingery (9). However, they employed an alumina rod dipped in molten slag. On the other hand, Toropov, Rumyantsev, and Filipovich (3) presents somewhat different results from those above mentioned, and this discrepancy seems to have a relation with their experimental conditions in which they used different sizes of reactant particles. As the big particle may not be a single crystal, it disperses before dissolution so that it may be eliminated in a shorter time than expected.

Rate of Reaction

The rate of solid state reaction is accelerated by the presence of a melt, in which the solid reactants are dissolved and counter diffused. The composition of the melt is supersaturated with the product which crystallizes out from the melt. Assuming that the rate is proportional to the concentration gradient across the diffusion layer formed around the dissolving particle, as the amount of the melt is limited, the

	T°C	glassy phase%	r̄μ		T°C
(1)	1,450	30	7.5	(9)	1,480
(2)	1,450	30	5	(10)	1,410
(3)	1,400	30	7 5	(11)	1,350
(4)	1,400	30	5		
(5)	1,450	15	7 5	(12)	1,450
(6)	1,450	15	5	(13)	1,400
(7)	1,400	15	7.5	(14)	1,350
(8)	1,400	15	5		

Fig. 8. *Thickness of dissolved layer vs. time of heat-treatment.*

area of diffusion is regarded as corresponding to the surface of dissolving particle. The following equations are derived from Fick's first law.

$$\frac{d\alpha}{dt} = -AD\frac{\Delta C}{\Delta X} \tag{5}$$

or

$$\frac{dr}{dt} = -D\frac{\Delta C}{\xi} \tag{6}$$

where $A = 4\pi r^2$, $\xi = r_0 - r$, and

$$d\xi = -dr \tag{7}$$

and hence

$$\frac{\xi^2}{2} + c = D \cdot \Delta C \cdot t \tag{8}$$

and $c = 0$ which the initial condition $\xi = 0$ when $t = 0$ therefore

$$\xi^2 = 2D \cdot \Delta C \cdot t \tag{9}$$

from Eq. (4) and Eq. (9)

$$(1 - \sqrt[3]{1 - \alpha})^2 = \frac{2D \cdot \Delta C}{r_0^2}t = Kt = F(\alpha) \tag{10}$$

Thus a Jander's type of equation is derived with a clear physical meaning where dissolution is considered in this paper in spite of the inward diffusion being assumed by Jander. This equation is found to express the experimental results with better accordance than

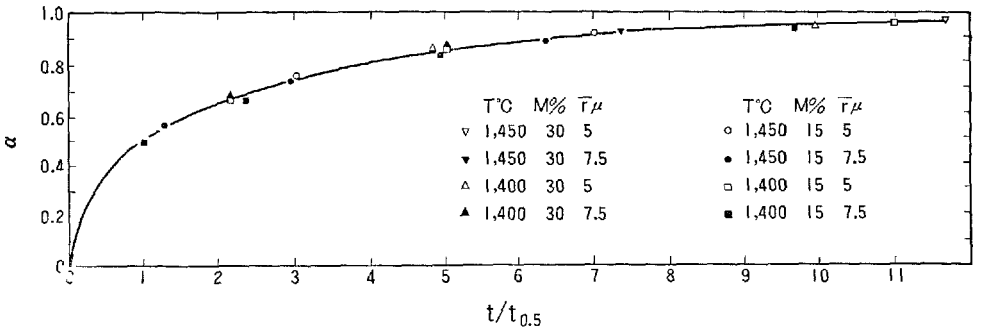

Fig. 9. *Fraction of reacted part vs. reduced time.*

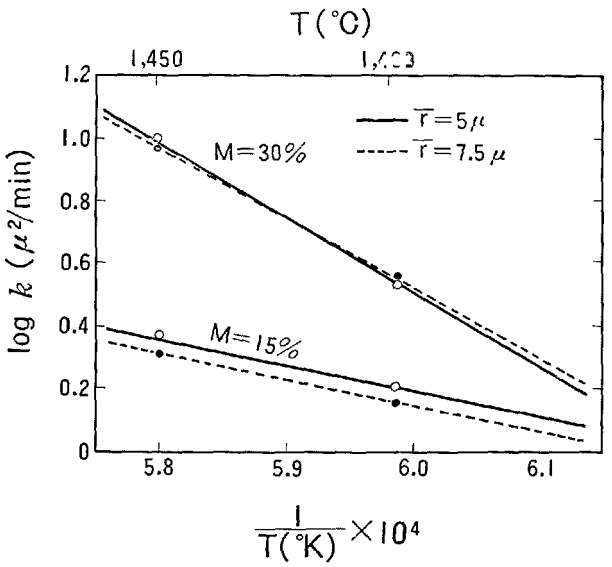

Fig. 10. *Temperature dependence of the reaction constant.*

the other kinetic formulas such as the one reported by Ginstling.

It is convenient in comparing experimental data with Eq. (10) to use a reduced time scale, such as $t/t_{0.5}$ where $t_{0.5}$ corresponds to $\alpha = 0.5$. Then

$$F(0.5) = 0.0426 = Kt_{0.5} \tag{11}$$

combining Eq. (10) and Eq. (11) gives

$$F(\alpha) = 0.0426\left(\frac{t}{t_{0.5}}\right) \tag{12}$$

From Eq. (12), a single curve can be drawn on α versus $t/t_{0.5}$. This single curve represents all the data obtained in various conditions including temperature, particle size, and content of the melt as shown in Fig. 9.

The apparent activation energy E can be obtained by Arrhenius' equation;

$$\log K = \log A - \frac{E}{4.574T} \tag{13}$$

Table 1. *Apperent activation energy*

Glassy phase M (%)	Particle size $\bar{r}(\mu)$	E (kcal/mol)	A
30	5	123	$10^{16.5}$
30	7.5	121	$10^{15.5}$
15	5	42	$10^{6.7}$
15	7.5	42	$10^{5.8}$

As shown in Table 1 the activation energy depends upon the content of the melt, so that, the activation energy increases with amount of the melt.

Further research will be carried out to examine the relation between the rate of reaction and the relevant surface area or the tortuosity or the situation of the phases.

Activiation Energy

The temperature dependence of the reaction constant K on each experimental condition was calculated from Eq. (10) and plotted in Fig. 10. The slopes of $\log k$ ($k = \bar{r}^2K$) versus $1/T$ show different tendencies according to the content of melt, that is, the temperature dependence becomes greater with the content of the melt, and point of intersection of the lines coincide with the melting point of the melt.

The value of activation energy in a low amount of the melt coincides with the one from viscosity measurement. On the other hand, the value obtained with a large amount of the melt is in the same order with the value reported by Toropov, Rumyantsev, and Filipovich (3). The similarity in order obtained by the dissolution of various oxides in a melt imply that the counter diffusion in the melt is directly related with activation energy. There are unexpectedly greater values which doesn't seem to be a real activation energy on the material transfer in the melt but contains other effects such as dispersion or a change of tortuosity of the path for diffusion.

Diffusion Coefficient

The diffusion coefficient of each species could be calculated from Eq. (10) in which α is given experimentally, r_0 and t are known, and ΔC is approximated to one half of the concentration difference between C_2 and D_2 in Fig. 7(B).

As the diffusion of silicon in the melt is regarded as the slow step in the reaction, calculated results on silicon are shown in Fig. 10 as M-line.

Next, the diffusion coefficient is also calculated from the following equation,

$$D = \frac{RT}{6\pi\eta\delta N} \tag{14}$$

where η is experimentally obtained in this study and δ is the radius of diffusing species and assumed to be Si^{4+} ion with 0.4 Å. Result is shown in Fig. 11 as V-line, however, the values must be somewhat lowered if the silicate ions are the diffusing species.

On the other hand, tracer diffusion coefficient for Si^{31} in a molten slag has been measured by Towers and Chipman (10). In consideration of the melt, however, diffusion coefficient must be corrected on the basis of the effect of viscosity. Following relation must hold good, when T and δ are the same.

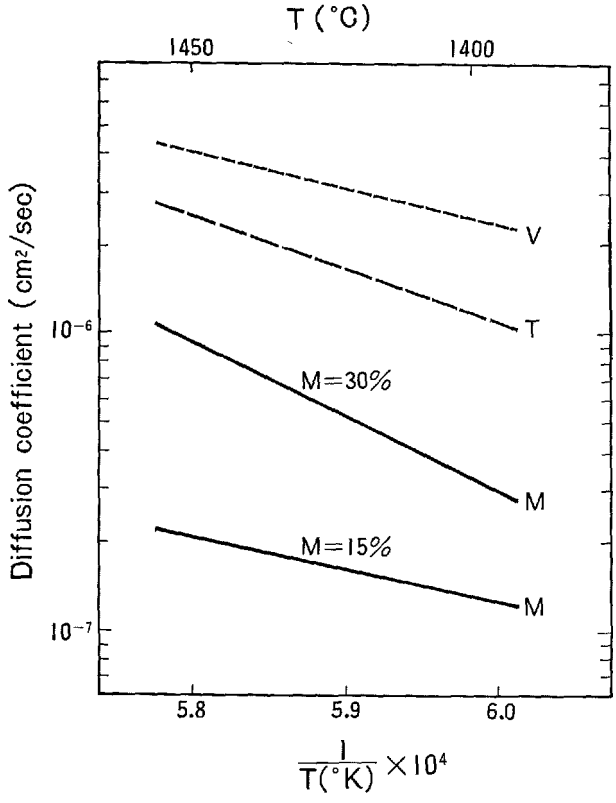

Fig. 11. *Diffusion coefficients of silicon in the melt.*

$$D\eta = D'\eta' \tag{15}$$

where D and D' are diffusion coefficients of the melt and the slag. η and η' are viscosities of the melt and the slag (11). The corrected result is shown in Fig. 10 as T-line.

In comparison between various results, V and T are in good accordance, however M is lower than the formers. This discrepancy is considered to be due to the effects of the amount of melt and tortuosity of the diffusion paths.

Thus, the assumption on the kinetics in this study seem to be reasonable as such result on diffusion coefficient was obtained from the rate of reaction.

The authors are indebted to Mr. M. Kobayashi and his co-workers for electron probe micro analysis.

One of the present authors, S. Choi is studying abroad from Korea at the Japanese Governments expense. Thanks are due to the authorities concerned of both countries.

Supplementary Paper I-133 A Refinement of the Lime Standard Formula

Eberhard Spohn,* Eduard Woermann, and Dietbert Knoefel**

Synopsis

The lime standard formula I was postulated by Kühl on the basis of investigations by Spohn. Its modification by Lea and Parker has served for more than 30 years as a valuable tool in calculating the raw mix composition. Together with the

$$\text{Silica Ratio (Silikatmodul)} \frac{SiO_2}{Al_2O_3 + Fe_2O_3} \text{ and the}$$

$$\text{Alumina Ratio (Tonerdemodul)} \frac{Al_2O_3}{Fe_2O_3}$$

cement properties can be well judged. The following refined Lime Standard Formula is now proposed.

$$\text{LSt III} = \frac{100(CaO + 0.75\ MgO)}{2.80\ SiO_2 + 1.18\ Al_2O_3 + 0.65\ Fe_2O_3}$$

where the values for MgO shall not exceed 2.0.

The complete analysis data of a cement clinker expressed in the oxides CaO, SiO_2, Al_2O_3 etc. are not very convenient for the purpose of recognizing the phase composition from which the cement properties can be deduced. The cement manufacturer cannot judge directly, whether the mixture has an optimum lime content, or whether some lime deficiency will lead to poor strength, or excess of lime to expansion of the cement product.

A number of manufacturers use Spohn's lime deviation method (1) to measure directly the deviation from the optimum lime content. The result can be obtained in approximately one hour. Today, however, a complete analysis can be made by X-ray fluorescence-method within a few minutes. Here again, we look for a method to transform the analysis data to some figures which meet our purpose.

For many years, two such methods have been in use: One is connected with the name of Bogue, the other one with the name of Kühl. Since the time of their origin, our knowledge of the chemistry of cement clinker has been enlarged. Let us have a look at these two methods from the point of view we have today.

The classical research of Bogue and the other scientists is still the foundation of our cement industry. From the investigation of phase relationships in the ternary system $CaO–Al_2O_3–SiO_2$ and the quaternary system $CaO–Al_2O_3–Fe_2O_3–SiO_2$ Bogue devised a method to calculate the theoretical amounts of the cement minerals C_3S, C_2S, C_3A and C_4AF. This calculation seems to be ideal for the classification of cement, if we suppose that the cement properties can be deduced from the mineral composition. This helped to spread the Bogue-formula (2) all over the world.

Some disadvantages, however, have to be taken account of:

1. The formula does not indicate the optimum amount of lime in a technical clinker and
2. some errors are introduced by neglecting the mutual solid solutions of the clinker minerals as well as the fact that the calculated amount of C_2S partially is not present as a mineral itself at sintering temperature but makes up part of

* Portlandzementwerke Heidelberg A.-G., Heidelberg, West Germany.

** Institut für Kristallographie der Technischen Hochschule Aachen, West Germany.

the liquid phase. Upon cooling the high-temperature equilibrium will be quenched.

The mineral composition calculated according to Bogue, has been called "potential composition" in the English language. The word "potential" is easily forgotten, especially when translating into languages which have no corresponding expression. After the "potential composition" has been incorporated into the standards of some countries, this expression has been shifted from the use of the chemists to the use of salesmen and cement consumers. They readily ignore the word "potential" and even take the calculated phase composition for actual or approximately so. By the time this formula was borne, one could not probably think of the actual size of descrepancies which were faintly suggested by that word "potential". Meanwhile, it became evident that in a clinker not the pure compounds C_3S, C_2S etc. are present but quite complex solid solutions, and the old names of alite, belite and ferritic phase were taken up again.

In order to obtain a comparison between the "real" phase composition and the calculated "potential" composition according to Bogue's formula 52 technical clinkers from 9 cement plants were analyzed by standard wet-chemical methods for the oxides as well as by microscopic point-counting methods for their respective phase compositions. The data obtained by point-counting methods were transformed to weight-percent data by multiplication with the corresponding density factors:

alite	$d = 3.22$ g/cm³
belite	$d = 3.28$ "
aluminate	$d = 3.04$ "
ferrite	$d = 3.76$ "

The data obtained by these methods are compared graphically in Fig. 1.

It appears that the alite content is higher than the calculated amount of C_3S throughout, in some cases by as much as 20%. Conversely, the belite content is lower than the potential C_2S-content. The differences between calculated and measured values for the aluminate and the ferrite phases are sometimes positive, sometimes negative, but generally small by comparison. It can be expected that the latter deviations will be more serious in the range of a smaller C_3A-content than in our samples. Analogous effects have been observed by other authors, and they are discussed in detail by Lea (3). According to Krämer and zur Strassen (4), the MgO-content is a predominant factor in controlling the deviation of the alite content from the potential C_3S-value. The presumptive advantage that cement properties can be estimated with sufficient accuracy from the potential composition proves to be an illusion.

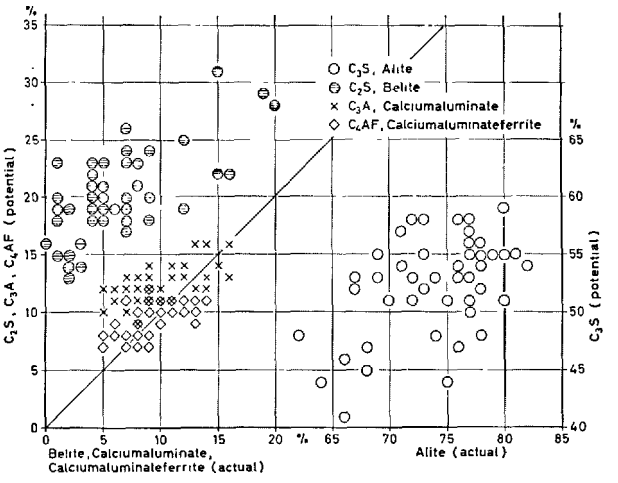

Fig. 1. *Comparison of the potential composition of technical portland cement clinker and their actual phase composition determined by microscopical point counting method.*

Another method to transform the analysis data has been given by Kühl (5). His consideration is based on the comparison of the actual lime content of a clinker with the maximum amount of lime to be combined under technical conditions, the "Standard Lime" (Standardkalk). Taking the Standard Lime as 100, the ratio of the lime content of a technical clinker to its Standard Lime will be the "Lime Standard" (Kalkstandard). Together with the Silica Ratio (Silikatmodul) $S/(A+F)$ and the Alumina Ratio (Tonerdemodul) A/F an expert has a clear concept of the composition of a cement and its properties. For the layman the figures are not as temptingly demonstrative as the "potential composition"—we would say fortunately they are not.

Kühl's lime standard formula was based on a paper by Spohn (6) who found that the "*lime limit*" of a clinker is controlled by equilibrium conditions at sintering temperature. Upon cooling this equilibrium is quenched. The formula suggested by Kühl (5) was

$$\text{LSt I} = \frac{100\text{CaO}}{2.8\text{SiO}_2 + 1.1\text{Al}_2\text{O}_3 + 0.7\text{Fe}_2\text{O}_3}$$

Basing on the work of Lea and Parker (7) the formula was later modified to

$$\text{LSt II} = \frac{100\text{CaO}}{2.80\text{SiO}_2 + 1.18\text{Al}_2\text{O}_3 + 0.65\text{Fe}_2\text{O}_3}$$

In the British Standards (8) the so-called Lime Saturation-Factor of a cement is defined as

$$\text{LSF} = \frac{\text{CaO} - 0.7\text{SO}_3}{2.8\text{SiO}_2 + 1.2\text{Al}_2\text{O}_3 + 0.65\text{Fe}_2\text{O}_3}$$

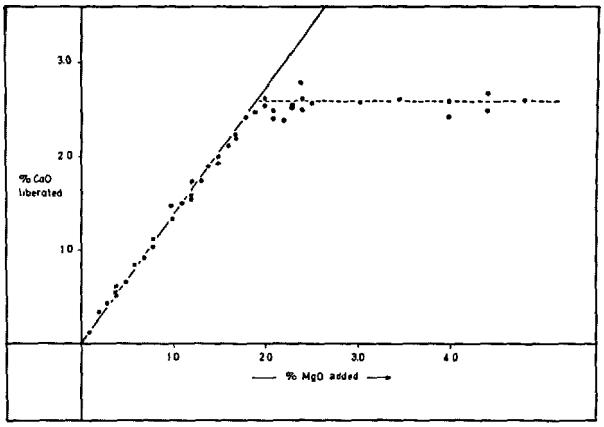

Fig. 2. CaO *liberated from* C_3S *as a function of additions of* MgO. (*11*)

(thus taking consideration of the gypsum content of cement by the SO_3-factor.)

Kühl's as well as Lea and Parker's formulas, however, are functions of CaO, SiO_2, Al_2O_3 and Fe_2O_3 only. Minor components, such as MgO, Na_2O, K_2O, SO_3, P_2O_5, TiO_2 and others are not being considered although some of them may be present in measurable amounts and accordingly exert influences on the lime-limit of a clinker. Both formulas, therefore, do contain a certain error. It is known for a long time, indeed, that with some raw materials lime standard values of approximately 100 can be attained, while with some other materials the practical limit is lower, sometimes, even as low as 96.

In this paper it is attempted to refine the lime standard formula by including a factor for MgO. Investigations of the solid solution of Ca_3SiO_5 with MgO (9, 10, 11) (Fig. 2) proved that MgO is replacing CaO up to a limit which, being temperature dependent, is 1.6% MgO at 1450°C the normal firing temperature of portland cement clinker.

Since in lime-saturated clinker C_3S is a major compound and, at sintering temperature, the only solid phase in equilibrium with liquid, it is evident that the liberation of lime by incorporation of MgO in C_3S must be a measurable quantity in clinker, too.

In the ternary system $CaO–Al_2O_3–SiO_2$ the formula

$$CaO = 2.80SiO_2 + 1.18Al_2O_3$$

is the analytical expression for the straight line connecting the point of C_3S and the invariant point $C_3S + C_3A + CaO +$ liquid. It must be kept in mind, however, that the C_3S-phase contains some Al_2O_3 in solid solution, and the point representing the composition of the alite-phase is shifted accordingly.

Any MgO added to this phase assemblage is distributed among the coexisting phases alite + liquid according to a defined distribution scheme. A set of tielines exists, until finally both the C_3S-phase and the liquid are saturated with MgO and periclase appears. Accordingly the lime-limit is to be defined as surface between the points:

1. Alite (saturated with respect to CaO and Al_2O_3)
2. Invariant point $C_3S + CaO + C_3A +$ liquid
3. Invariant point $C_3S + CaO + C_3A + MgO +$ liquid
4. Alite (saturated with respect to CaO, Al_2O_3 and MgO)

The line through the latter two points at the same time is the magnesia-limit.

These four points do not lie in one plane, however, and the surface connecting these points is slightly contorted. Its analytical expression is complicated and not suitable for quick calculations on clinker analyses.

It is more convenient to select a certain sector of this surface around "normal" clinker compositions, treating the latter as a plane by approximation.

Analogous problems arise on defining the lime-limit in the quinary system $CaO–MgO–Al_2O_3–Fe_2O_3–SiO_2$, requiring the same limitations to "normal" compositional ranges.

Preliminary experiments were conducted to prove the assumption, that CaO is liberated by addition of MgO to clinkers.

A laboratory clinker with composition:

CaO	69.69%
Al_2O_3	5.46%
Fe_2O_3	3.64%
SiO_2	21.21%
Alumina Ratio	1.50
Silica Ratio	2.33

—thus representing a "normal" portland cement clinker-composition—was carefully mixed from r.g. reagents and heated to a temperature of 1500°C, rapidly cooled and analysed for free CaO after the method of Franke (12)*. Subsequently this finely ground homogeneous clinker was subdivided into equal portions of 3 grams each, and different, well defined amounts of MgO were added to each sample which was finally heated for a second time for two hours at 1500°C to accomplish equilibrium. After cooling the free lime was determined. The sample's increase in free lime above that of the magnesia-free charge was entered into a graph (Fig. 3) against the corresponding addition of MgO.

*In preliminary experiments, the method after Schlaepfer-Bukowski (13) was applied. This method, however, introduces analytical errors by attacking the C_3S-phase.

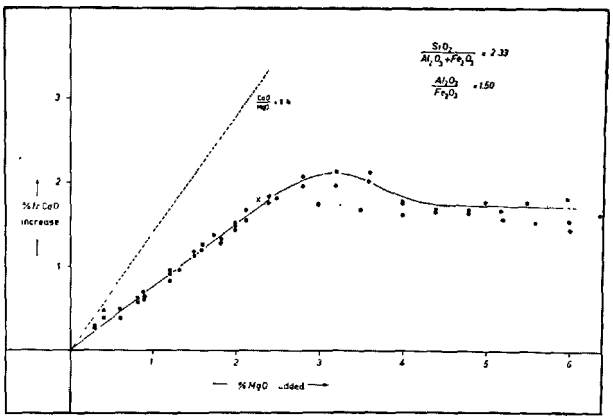

Fig. 3. *Increase in free* CaO *by additions of* MgO *to a laboratory clinker with "normal" clinker composition.*

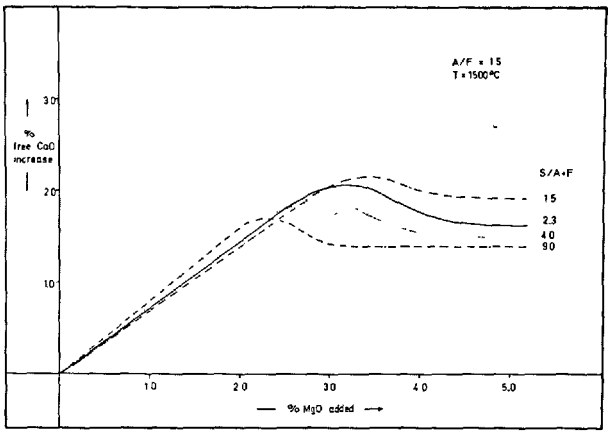

Fig. 4. *Influence of variable silica-ratio on the combination of* MgO *and liberation of* CaO *in laboratory clinkers.*

The curve in Fig. 3 may be subdivided into three sections:

In section I (low magnesia-contents) a steady increase in free lime, proportional—but not equivalent—to the MgO-additions is observed. This is due partly to the solid solution of MgO in alite, thus causing a liberation of free lime as demonstrated in Fig. 2 and partly to the solution of MgO in the liquid phase at sintering temperature, thus causing a change of its composition to lower CaO–contents. No periclase has been observed during microscopical investigation of these samples. Thus all MgO is present in the combined form.

In section II the free lime content with a smooth curve passes through a maximum and then decreases with higher MgO–contents to lower free CaO–values. No satisfactory explanation so far is given for the maximum of the curve. It may be due to supersaturation of the sample with respect to MgO. The first periclase is observed on the descending part of the curve.

In section III (high magnesia-contents) the curve is straight again and practically parallel to the abscissa. Further additions of MgO do not exert any influence on the lime-limit of the clinker. They result in formation of periclase which can be observed microscopically.

The following information is gained from the curve:

1. The relationship between liberated CaO and combined MgO–the "C/M–ratio"—is given by the slope of the curve in section I.
2. For the limiting amount of MgO to be combined, the maximum of the curve should be representative. Since, however, the data in section II of the curve were less reliable and were, moreover, influenced by the cooling rate, the intersection of the two straight portions of the curve—sections I and III (point "X" in Fig. 3)—was preferred to define the magnesia-limit. In addition, this point makes it possible to determine the amount of CaO liberated by MgO, regardless of higher MgO–concentrations.

The above model clinker was selected to have a normal clinker-composition. It is necessary, however, to investigate whether

1. the C/M–ratio and
2. the magnesia-limit

are influenced by a change of composition or of temperature. For the purpose a series of laboratory clinkers was investigated by analogous methods.

Fig. 4 presents graphically the results of these experiments on some clinker with constant alumina-ratios A/F but changing silica ratio $S/(A + F)$. With increasing silica ratio there is a shift towards higher C/M–ratios of the first section of the curve, but a decrease of combined MgO. In the range of normal clinker compositions, however, this shift is small.

Fig. 5 shows the results of experiments on clinker with constant silica ratio but varying alumina-ratios: The C/M–ratio remains essentially unchanged, but the total amount of combined MgO increases with increasing Al_2O_3–content and decreases with increasing Fe_2O_3–content.

Fig. 6 shows the influence of the firing temperature on the solution of MgO in the solid and liquid clinker-phases: Again the C/M–ratio remains unchanged while the total amount of MgO combined is temperature dependent.

From the above data the following deductions are made:

1. The C/M–ratio is independent of temperature

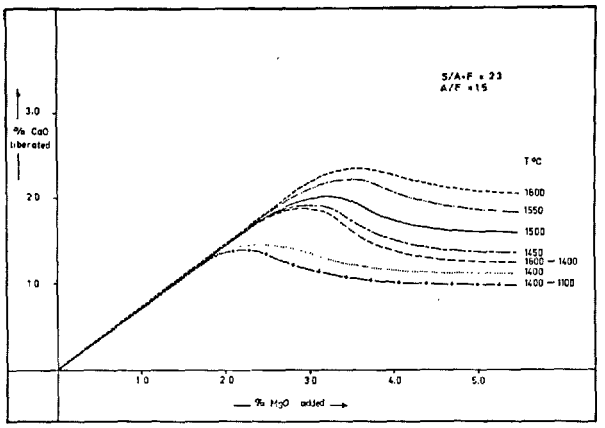

Fig. 5. *Influence of variable alumina ratio on the combination of* MgO *and liberation of* CaO.

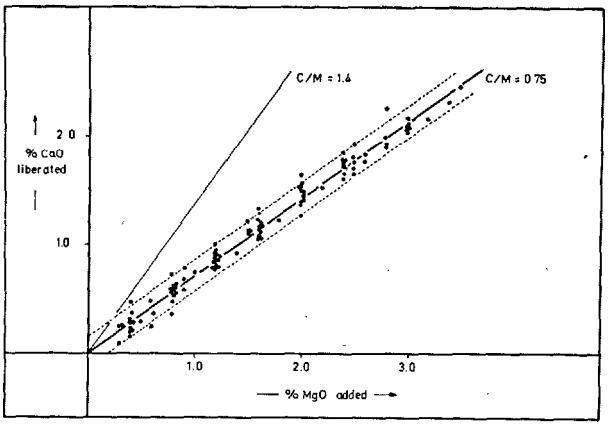

Fig. 7. *Experimental data on the C/M-ratio of all clinker samples investigated in the range of silica ratio 1.5–4.0*

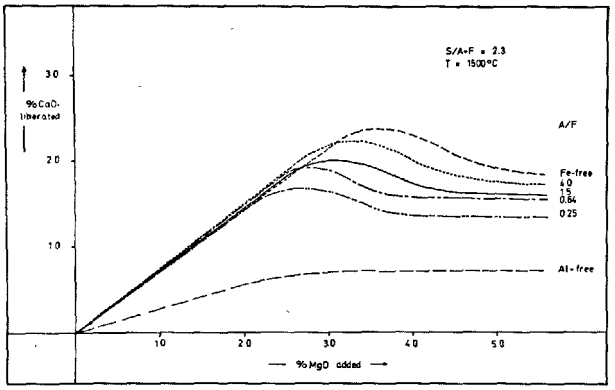

Fig. 6. *Influence of temperature on the combination of* MgO *and liberation of* CaO *from a laboratory clinker. The curves marked 1600°–1400° and 1400°–1100°C show the corresponding results on clinker samples heated to the higher temperature indicated and cooled slowly—within 1 hour—to the lower temperature.*

and of the alumina-ratio of the clinker, but it is slightly shifted with the silica ratio. This shift, however, is small, being hardly greater than the experimental error if only normal cement compositions with silica ratio = 1.5 — 4.0 are considered. Fig. 7 contains all experimental data within this range. The weighted average of these points lies on a line representing a C/M–ratio of 0.75. Accordingly, it may be concluded that MgO is distributed among the solid and liquid clinker phases in such a way that as a resultant effect for each weight unit of MgO dissolved 0.75 units of CaO are liberated. This distribution factor is independent of temperature in the investigated temperature range.

2. The total amount of MgO combined is influenced by a greater variety of factors:

Table 1. *The magnesia-limit at various clinker compositions*

$\frac{S}{A+F}$	1.50	1.86	2.33	3.0	4.0
$\frac{A}{F}$					
0.64	(2.5)*	(2.3)	2.1	(2.0)	(1.9)
1.50	2.6	(2.4)	2.2	(2.1)	2.0
4.0	(2.7)	(2.5)	2.3	(2.2)	(2.1)

*numbers in brackets are interpolations

The increase of the MgO–limit with temperature (±0.6%/100°C according to Fig. 6) is in agreement with the higher solubility of magnesia in the liquid phase at higher temperatures, and at the same time with the temperature dependence of the solid solution of MgO in C_3S.

Since the concentration of MgO in alite (1.8% MgO at 1500°C) is considerably lower than the magnesia content of the Mg–saturated liquid (5.5% MgO at the invariant point $C_3S + CaO + C_3A + MgO +$ liq. (14) and ±5.0% MgO at the invariant point $C_3S + CaO + C_3A +$ ferrite $+ MgO +$ liquid (15)) an increase in the liquid content will result in a corresponding increase of the magnesia-limit. Since the concentration of the silicates (i.e. of C_3S at the lime limit) and of liquid are controlled by the silica-ratio, and since, moreover, with constant silica-ratio a clinker with higher alumina-ratio contains a higher amount of liquid, the influence of these factors on the total amount of combined MgO is explained.

The following data for the magnesia-limit in clinker in equilibrium at 1500°C are taken from Figs. 4 and 5.

Thus for compositions of technical portland cement clinker (inside the frame in the table) about 2.1–2.5%

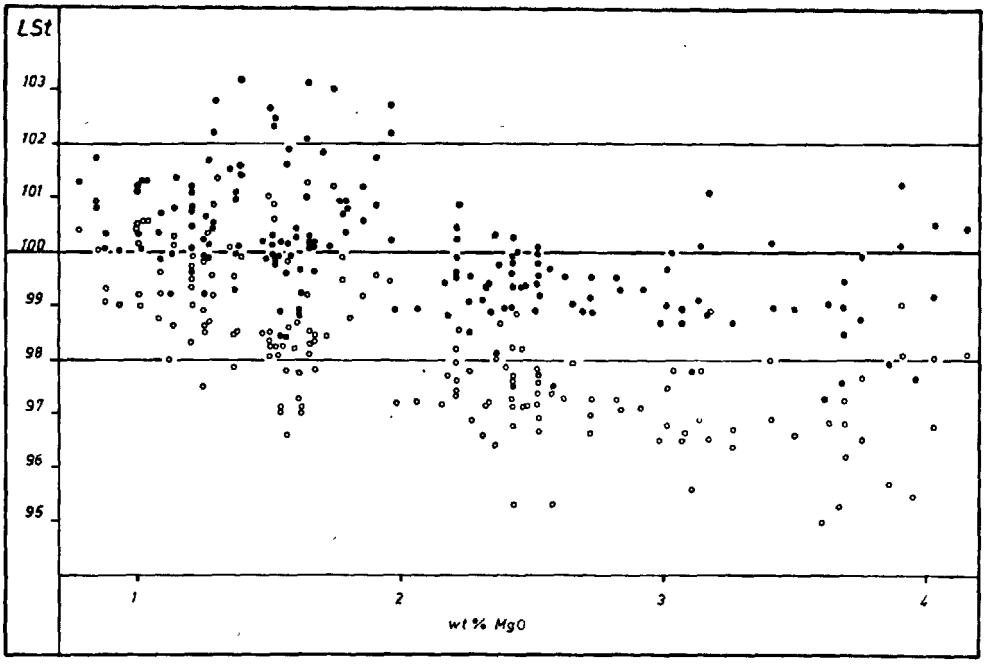

Fig. 8. *Comparison of the formulas LSt II (open circles) and LSt III (black dots) as applied to technical clinker from nine different cement plants. The lime limit of these clinkers has been determined by the lime deviation method. The straight lines at LSt = 98 and 102 define the total error tolerated in wet-chemical routine-analyses.*

MgO are combined by alite and the liquid phase at 1500°C. Assuming a temperature dependance of 0.6% MgO/100°C (see Fig. 6), this range will be shifted to 1.8–2.2% MgO at 1450°C, or, in the average, to 2.0% MgO.

The magnesia-limit at 2.0% MgO is supported by microscopical investigation of technical clinker: With considerable regularity periclase is observed in clinker with more than about 2.0% MgO. There are exceptions, however. In some cases clinker with MgO–contents of up to 2.5% did not show periclase, or, on the other hand, clinker with lower MgO–concentration contained periclase. Mostly the latter case, however, may be due to inhomogenities of the raw mix.

In order to apply these results successfully to technical conditions they may be simplified as follows:

A maximum of 2.0% MgO can be combined in clinker at a CaO/MgO–ratio of 0.75.

Based on these data a factor for MgO may be included into the formula LSt II. Since MgO is equivalent to CaO, this factor must be added to the amount of CaO.

The modified formula will be:

$$\text{LSt III} = \frac{100(\text{CaO} + 0.75\text{MgO})}{2.80\text{SiO}_2 + 1.18\text{Al}_2\text{O}_3 + 0.65\text{Fe}_2\text{O}_3}$$

for all compositions with $\text{MgO} \leqq 2.0\%$ and

$$\text{LSt III} = \frac{100(\text{CaO} + 1.50)}{2.80\text{SiO}_2 + 1.18\text{Al}_2\text{O}_3 + 0.65\text{Fe}_2\text{O}_3}$$

for clinker compositions with $\text{MgO} > 2.0\%$.

In order to check whether the new formula is an improvement for the calculation of the lime limit under technical conditions, carefully analysed clinkers from nine different cement plants were tested: They were finely ground and according to Spohn's lime deviation method mixed with a well defined addition of $CaCO_3$, then subsequently heated for 30 minutes to 1450°C. Free lime was determined and subtracted from the bulk composition. The results were calculated according to LSt II and LSt III. Under ideal conditions now the lime standard should be equal to 100. The experimental results are compared graphically in Fig. 8. Here the open circles represent the calculations after LSt II while the black dots show corresponding data for LSt III.

From Fig. 8 it follows that the points calculated after LSt II are, in the average, distinctly too low.

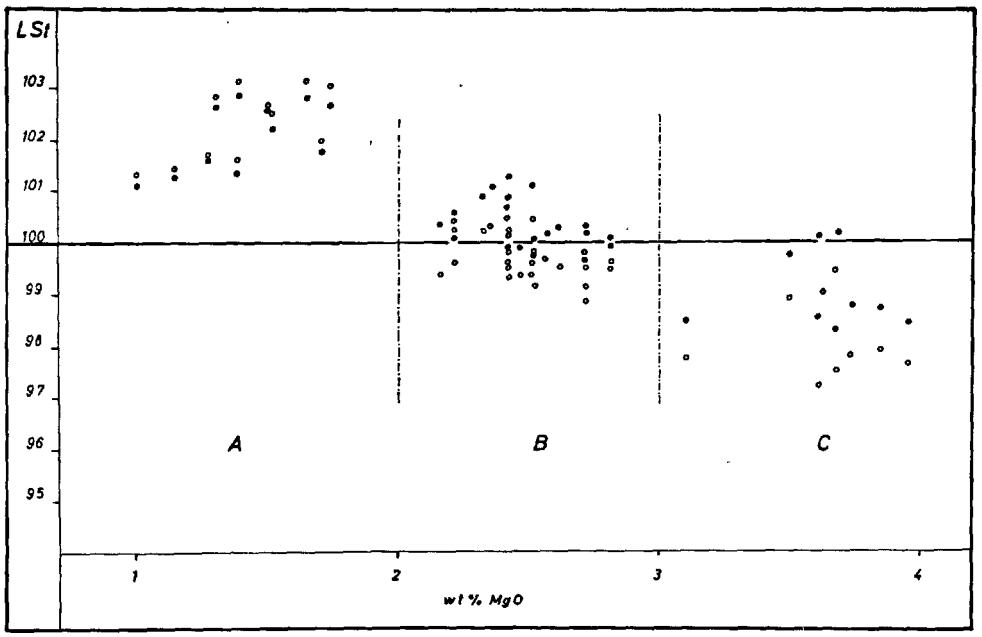

Fig. 9. *Standard Lime for clinker of three different cement works (A, B and C)*
Open circles: heated for 30 minutes at 1450°C
Black dots: heated for 15 hours at 1500°C

Calculated after LSt III the points are shifted to higher values. For the greater part of the investigated clinkers they now fall within a range between LSt = 98 — 102, which is set by tolerance limits of wet-chemical analyses in plant laboratories.

It may be noted that still some of the points are too low, but some distinctly too high. On comparing the clinkers of single plants seperately, it is demonstrated that a certain high or low deviation is typical for each cement plant. These deviations are due to the influence of further minor components in clinker. Some clinkers, containing more alkalies than their equivalent of SO_3 will have the tendency to shift the points to lower LSt values, while others containing more SO_3 will shift the points to higher LSt values. Expelling these components by heating the sample for a few hours at 1500°C helped to shift these points closer to the line of LSt = 100 (Fig. 9). Here we find an indication that the formula LSt III still can be improved by further investigations.

In consideration, however, of the fact that our values are within the range of analytical error, the formula LSt III seems to be accurate enough for most practical purposes.

SESSION I-3 ANALYSIS OF PORTLAND CEMENT CLINKER

Principal Paper I-3 The Analysis of Portland Cement Clinker

Goro Yamaguchi and Shigehide Takagi*

Synopsis

The identification study in the cement chemistry by the X-ray powder diffraction method has been developed immensely since diffraction patterns of the cement minerals became able to be interpreted precisely. Circumstances of the development are described.

As to the separation of the cement minerals from clinker, physical separation and chemical separation were employed. Any separation method was not perfect alone but combination of treatments was useful for clarifying the nature of the minerals.

Analysis of the chemical composition of the minerals and the mineral composition of clinker was attempted using a combination method of separations and chemical analysis.

Transmitted light and reflected light microscopy are both useful for analyzing the texture of clinker, especially the former is indispensable for clarifying it completely. Using these methods the inversion texture was interpreted.

Using an electron microscope fine textures of inverted belite were analyzed and photographs are presented.

Application of an electron probe microanalyzer to the clinker analysis is explained. Photographs of reflected light microscopy and electron probe microanalysis in the same field of clinker are presented and explained in order to clarify alite, belite, ferrite and aluminate textures.

The chemical composition of the minerals and the mineral composition of clinker obtained by several methods are discussed.

Introduction

It is so long since portland cement has been invented and it seems that the improvement has been already at a top level. In spite of the scientific researches performed by many investigators, the analysis from the standpoint of the modern materials science is not enough and delicate properties of cement are still left not clear.

The first problem is about the nature of the clinker minerals. What are true chemical compositions of alite phase, belite phase, ferrite phase and aluminate phase? What are their crystal structures? What relationship is there between properties of cement such as hydration, hardening etc. and the natures of mineral phases? About those problems there exist many questions.

The second problem is how do those minerals exist and make textures in clinker. Although the development of measuring and observing equipments made some successful answers possible, many questions are yet left as future problems.

The third problem is how their textures are produced in sintering and cooling processes of manufacturing. The process and the result of solid state reaction, crystal growth and modification transition have many insolvable points.

At this circumstance a project of this thesis is to attempt to systematize an analytical method of cement clinker. In order to approach to the project many analytical procedures conducted by former investiga-

*Faculty of Engineering, The University of Tokyo, Tokyo, Japan.

tors were practiced, considered and improved and new procedures were developed using several Japanese clinkers as testing samples.

Mineral phases mainly objected in this experiment are four major components of clinker, that is, alite phase, belite phase, ferrite phase and aluminate phase, and minor components are treated in a necessary case. Clinkers employed in the experiment are ten kinds from Japanese factories denoted N_1, N_2, N_3, N_4, N_5, R, M_1, M_2, W_1 and W_2. N means normal cement, R rapidly hardening cement, M moderate heat cement and W white cement.

Identification by the X-ray Diffraction

The identification of the cement minerals by the X-ray powder diffraction method has been carried out since so long time. However, the correct interpretation of diffraction patterns has not been done before the development of a recording X-ray diffractometer. The same subject was dealt with in the last symposium but this time it will be described on the standpoint of clarifying circumstances.

The X-ray powder diffraction data before the development of a recording X-ray diffractometer were less reliable, because many diffraction lines were not indexed and some times wrongly indexed. The development of the apparatus resulted in correct measurement to separate and index multiplets and to revise wrong indexings. Those studies were conducted by many investigators by means of synthesizing and examining clinker and its component minerals in pure state and solid solution state.

A recording X-ray diffractometer caused splendid progress in a field of the identification of the cement minerals. However, its weak point is that it cannot resolve an extremely close multiplet because of adjoining of α_1 and α_2 diffractions although it has a higher resolution power than an ordinary diffraction camera. For this purpose an application of a focusing diffraction camera caused the wonderful results.

The following is description about respective minerals. Through this experiment a diffraction angle is expressed in 2θ by Cu Kα radiation.

Alite and Relating Minerals

R. Naito, Y. Ono and T. Iiyama (1957) (1) described examining characteristic powder diffraction patterns of pure C_3S and C_3S solid solution that a diffraction pattern of pure C_3S mentioned as triclinic seemed more complex and lower symmetric than that of C_3S solid solution mentioned as monoclinic and that indexing of the powder diffraction patterns seemed nearly impossible.

However, G. Yamaguchi, H. Miyabe and K. Tanaka (1959) (2) successfully attempted to index the main diffractions of pure C_3S and C_3S solid solution using a pseudo-orthorhombic provisional lattice based upon the result of the structure analysis done by J. W. Jeffery (1952) (3). Moreover, G. Yamaguchi, H. Miyabe (1960) (4) measured precisely and indexed the diffraction patterns of the triclinic and the monoclinic lattices, and succeeded in an interpretation of the diffraction patterns and a calculation of the lattice parameters, and presented useful data for the identification of the minerals.

The characteristics of the diffraction pattern of C_3S minerals are diffractions of 221, 401, 222 and 402 at 29°–30°, 009, 224, $\bar{4}04$, $\bar{2}25$ and 405 at 31°–34°, $\bar{2}28$ and 319 at 41°, and 620 and 040 at 51°–52°. These indexes are after the provisional pseudo-orthorhombic lattice of Yamaguchi et al. Among these diffractions 620 and 040 diffractions are most important because they are independent from other minerals and remarkably changeable according to lattice deformation.

N. Yannaquis, M. Regourd, Ch. Mazieres and A. Guinier (1962) (5) mentioned there exist six kinds of polymorphs in pure C_3S, and they denoted T_I, T_{II} and T_{III} in triclinic, M_I and M_{II} in monoclinic and R in trigonal according to an experiment using a focusing camera. They did not agree with the indexing of Yamaguchi et al. but it seems misunderstanding as well as a description in "The Chemistry of Cement" by J. W. Jeffery (1964) (6). M. Regourd (1964) (7), however, adopted the principle of Yamaguchi et al. and connected her result with that principle using a pseudo-hexagonal lattice based on the trigonal lattice instead of the pseudo-orthorhombic lattice of Yamaguchi et al. She suggested T_I and T_{II} have large lattices because of some extra diffractions of long spacings and M_{II} might be orthorhombic. According to the author's opinion, it is more convenient to use the pseudo-orthorhombic lattice as a provisional lattice, anyway it is no more than a convenient one.

H. Miyabe and D. M. Roy (1964) (8) studied that problem using a recording X-ray diffractometer and recognized polymorphs corresponding to T_I and T_{II} but not T_{III} and M_{II}. This disagreement seems due to the lower resolution power of a recording diffractometer than a focusing camera.

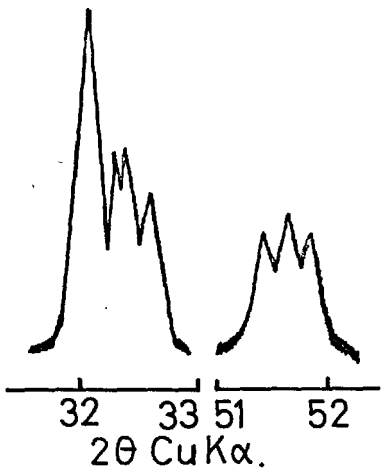

Fig. 1. *Characteristic diffraction pattern of triclinic* C_3S

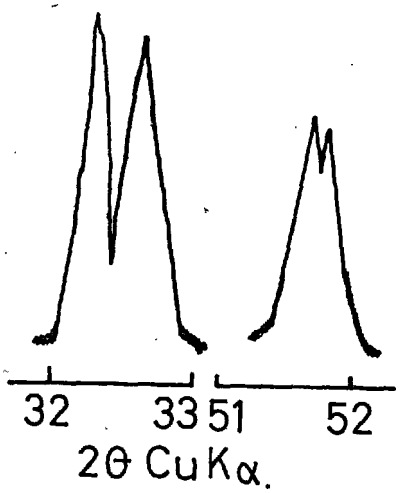

Fig. 2. *Characteristic diffraction pattern of monoclinic* C_3S

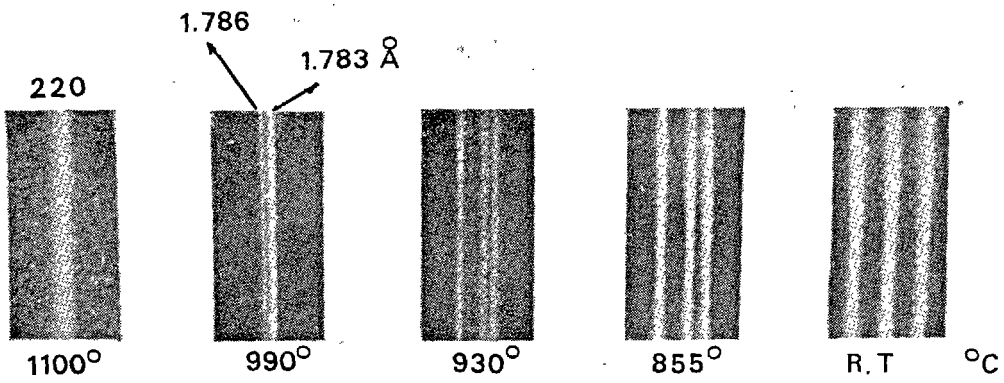

Fig. 3. *Fine structure of diffraction pattern of* C_3S *polymorphs* (7)

Besides thermal polymorphism of C_3S, studies of lattice deformation caused by impurity solid solution were carried out. G. Yamaguchi and H. Uchikawa (1960–1) (9), (1961–2) (10) described that a triplet diffraction at 51°–52° of triclinic C_3S solid solution with Na_2O gets closer in proportion to an amount of Na_2O and inverts into monoclinic having a doublet diffraction with 040 shifted to high angle side.

G. Yamaguchi, H. Uchikawa, S. Takagi and H. Koike (1962) (11) and G. Yamaguchi, H. Uchikawa and S. Kawamura (1961) (12), (1962) (13) recognized the same phenomena in C_3S solid solution system with Al_2O_3, Fe_2O_3 and Na_2O. G. Yamaguchi and H. Uchikawa (1962) (14) traced that lattice deformation concerning to alite in commercial clinkers. G. Yamaguchi and K. Kato (1962) (15) studied a lattice deformation in the solid solution system with MgO and Al_2O_3. E. Woermann, Th. Hahn and W. Eysel (1963) (16) and H. G. Midgley and K. E. Fletcher (1963) (17) performed the same investigation more minutely. Especially Woermann et al. found out a discontinuity of spacing shift among triclinic forms with gradiently different amount of impurities and denoted them T_{I} and T_{II} corresponding to pure C_3S polymorphs.

Y. Ono, T. Uno and Y. Kanai (1965) (18) synthesized triclinic C_3S solid solutions with various impurities having different features of diffractions. These phases seem to be discontinuous one another, but it remains as a problem to define them as different polymorphs until the certification of the phase discontinuity or another certification would be done.

G. Yamaguchi and K. Kato (1964) (19) and G. Yamaguchi, K. Shirasuka and T. Ohta (1966) (20) examined that monoclinic C_3S solid solution inverts into triclinic by reheating.

Recently M. Bigaré, A. Guinier, M. Regourd, N. Yannaquis, W. Eysel, Th. Hahn and E. Woermann (1967) (21) summarized this C_3S polymorphs problem

202	222	220	222
	204	024	024

and confirmed the correspondency of T_I, T_{II} and T_{III} in the pure system to those of the solid solution system from the standpoint of the spacing discontinuity and the differential thermal analysis.

The classification and the identification of polymorphs among those which have only such very small gaps of physico-chemical continuity as seen in the C_3S system are delicate problem and it needs much more experiments to systematize the problem. Any way, since Yamaguchi et al. have succeeded in interpretation of the X-ray powder diffraction through Bigaré et al. have summarized the problems, a splendid progress has been brought in this field.

As to relating minerals, S. Akaiwa, G. Sudoh and M. Tanaka (1966) (22) found and analyzed a new mineral $11CaO \cdot 4SiO_2 \cdot CaF_2$ which resembles C_3S structurally.

Belite and Relating Minerals

G. Yamaguchi, H. Miyabe, K. Amano and S. Komatsu (1957) (23) and G. Yamaguchi, Y. Ono, S. Kawamura and Y. Sohda (1963–1) (24), (1963–2) (25) interpreted and indexed X-ray powder diffraction patterns of C_2S polymorphs at high temperature and stabilized by several impurities, using a provisional lattice based on the monoclinic lattice obtained by C. M. Midgley (1952) (26) and presented useful data for identification. The lattice of β–C_2S should be P2 1/c after International Table for X-ray Crystallography (27) but P2 1/n is more convenient to compare with the α'–C_2S lattice (Pnma). The indexes will be shown in P2 1/n followed by those in P2 1/n as hkl (h'k'l').

Characteristic diffractions of β–C_2S are 10$\bar{4}$(10$\bar{3}$), 12$\bar{2}$(12$\bar{1}$), 20$\bar{2}$(200), 022(022) and 120(121) at 32°–33°, 102(103) at 34° and 014(014) and 031(031) at 41°. However, all these diffractions overlap to those of C_3S, so that these diffractions are not convenient for identification. For that purpose 12$\bar{1}$(120) diffraction at 31° is independent and convenient though it has somewhat weak intensity.

As to α–C_2S, 110 diffraction at 33° is the strongest and characteristic one though it situates rather near by diffractions of others.

The strongest diffraction of α'–C_2S, 020, 211, 202 at 32°–33° overlaps to others then 013 diffraction near by 110 of α–C_2S is characteristic. Suggestions of a slight inversion in α'–C_2S, $\alpha'_L \rightleftarrows \alpha'_H$, were presented by D. K. Smith, A. J. Majumdar and F. Ordway (1961) (28) and K. Niesel and P. Thormann (1967) (29), although confirmation by the X-ray diffraction was not carried out.

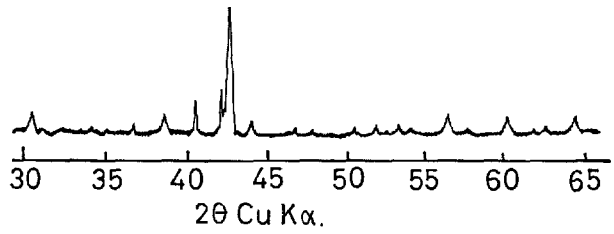

Fig. 9. *Diffraction pattern of* C_4AF

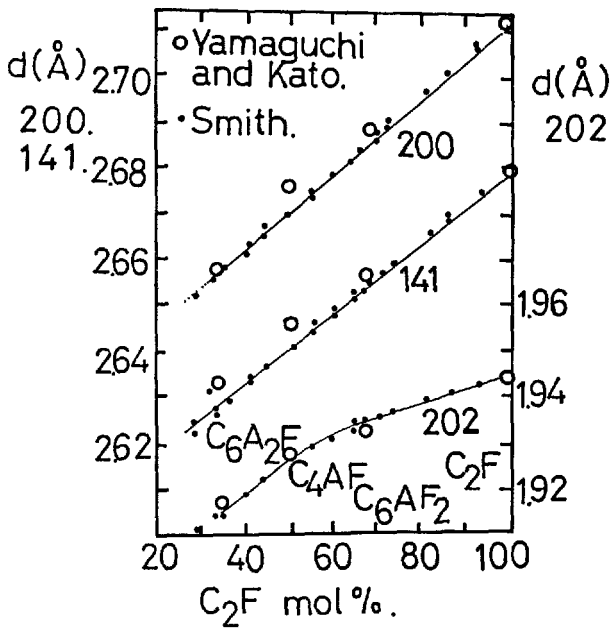

Fig. 10. *D-spacing of* C_4AF *solid solution of* C_2F–C_2A *system*

The lattice parameters and the situations of diffractions of polymorphs of pure C_2S can not be obtained because pure C_2S inverts into γ–C_2S at room temperature. The shift of the lattice parameters and diffractions of polymorphs of C_2S solid solutions according to impurity amount cannot also be determined because each polymorph is not able to be stabilized by any kind and any amount of impurities. However, the fact that a shift of diffractions of C_2S is caused by impurity is shown in data of G. Yamaguchi, Y. Ono, S. Kawamura and Y. Sohda (1962) (30).

As to relating minerals, a precise interpretation of X-ray powder diffraction of $KC_{23}S_{12}$ was done by Y. Ono (1963) (31), a diffraction of merwinite, C_3MS_2, was correctly determined from powder diffractions and single crystal data by G. Yamaguchi and K. Suzuki (1967) (32) although questionable data of M. A. Bredig (1945) (33) (34) had been so far quoted, and a intermediate mineral, $(C_2S)_{5.6}(C_3MS_2)_{4.4}$, between C_2S and C_3MS_2 was reported by W. Gutt (1961) (35).

Ferrite and Relating Minerals

The lattice parameters of C_4AF solid solution had been determined by the single crystal analysis but the analysis of powder diffraction patterns for identification had been incorrect, for instance, diffractions of 141 and 200 had been misindexed. G. Yamaguchi and A. Kato (1957) (36) correctly analyzed it followed by E. F. Bertaut, P. Blum and A. Sagieres (1959) (37) who determined the atomic parameters also. Relation between compositions of solid solutions and d-spacings has been measured somewhat differently according to investigators. Fig. 10 shows data of G. Yamaguchi et al. and D. K. Smith (1962) (38).

A. Kato (1958) (39), (1959) (40) studied the solid

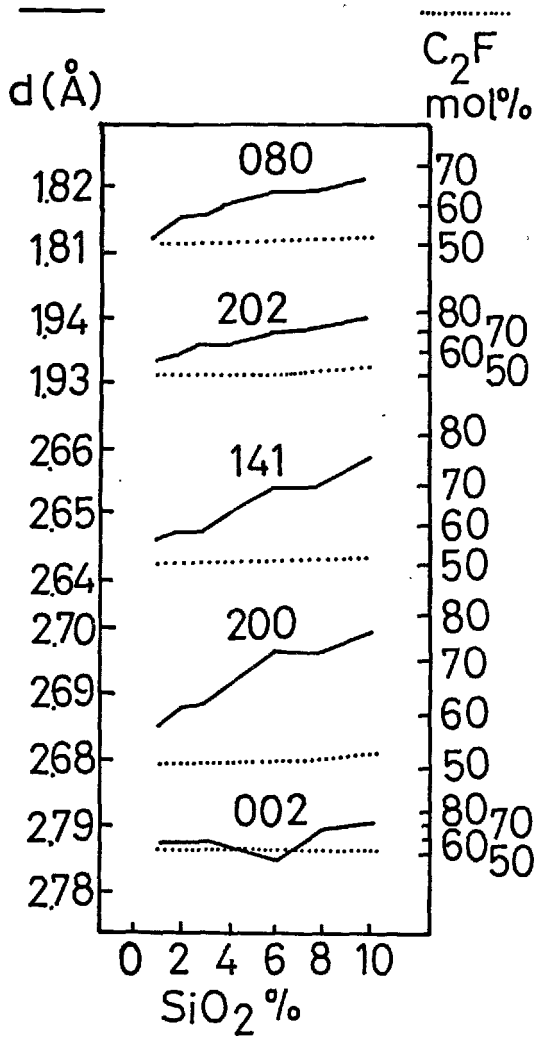

Fig. 11. *D-spacing of* C_4AF *solid solution with* SiO_2, *right scale side corresponds to* C_2F *mol %*

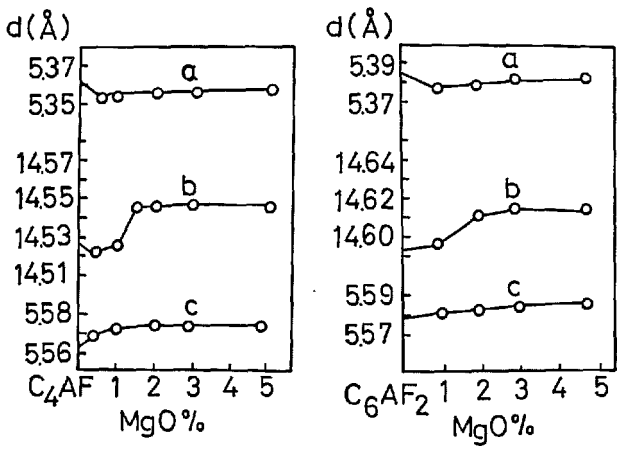

Fig. 12. *Lattice parameters of* C_4AF *solid solution with* MgO

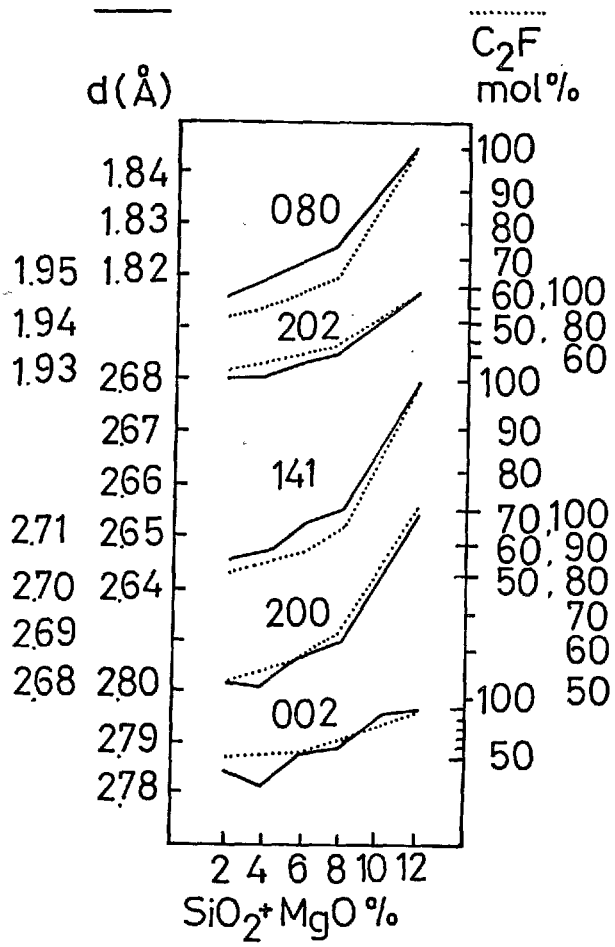

Fig. 13. *D-spacing of* C_4AF *solid solution with* MgO *and* SiO_2, *right side scale corresponds to* C_2F *mol %*

solution system of C_4AF with MgO and SiO_2 and found out the fact that some spacings and crystal axes expand according to the dissolution of MgO and SiO_2.

Aluminate and Relating Minerals

Pure C_3A and its solid solution with small amount of impurities are cubic having diffractions analyzed already but the splitting of cubic diffractions has been recognized by many investigators in the case of solid solution with some amount of Na_2O, especially NC_8A_3. A. E. Moore (1963) (41) interpreted the splitting as a formation of an orthorhombic lattice. J. A. Conwicke and D. E. Day (1964) (42) dealt with the same problem and K. E. Fletcher, H. G. Midgley and A. E. Moore (1965) (43) summarized well this problem.

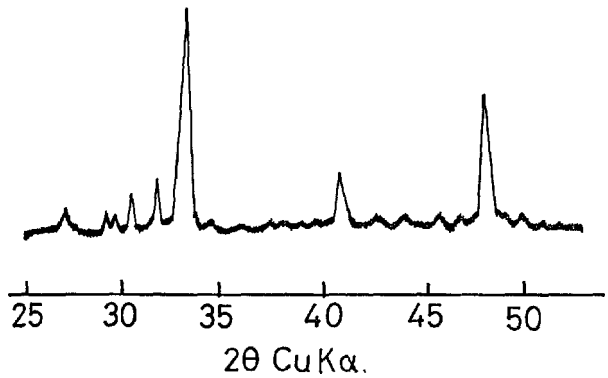

Fig. 14. *Diffraction pattern of cubic* C_3A

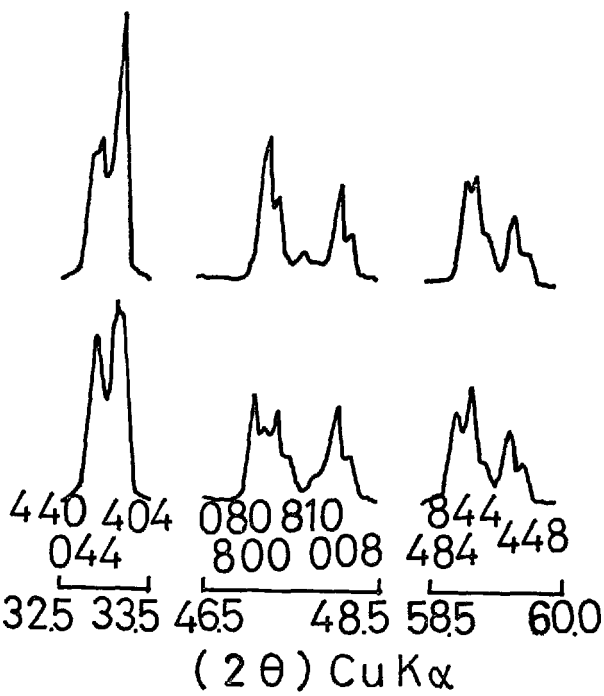

Fig. 15. *Diffraction pattern of orthorhombic* C_3A

A shift of diffractions caused in cubic C_3A by small amount of impurities such as Na_2O, MgO, SiO_2 and Fe_2O_3 was investigated by C. M. Schlaut, D. M. Roy (1965) (44), A. J. Majumdar (1965) (45), P. Tarte (1965) (46) and A. E. Moore (1966) (47) and it was clarified that Na_2O, MgO and SiO_2 cause shrinking of a lattice while Fe_2O_3 causes expanding.

Commercial Clinker

Fig. 17 is a typical X-ray powder diffraction pattern of a commercial clinker. In general the pattern of alite is dominant because of its large amount and high

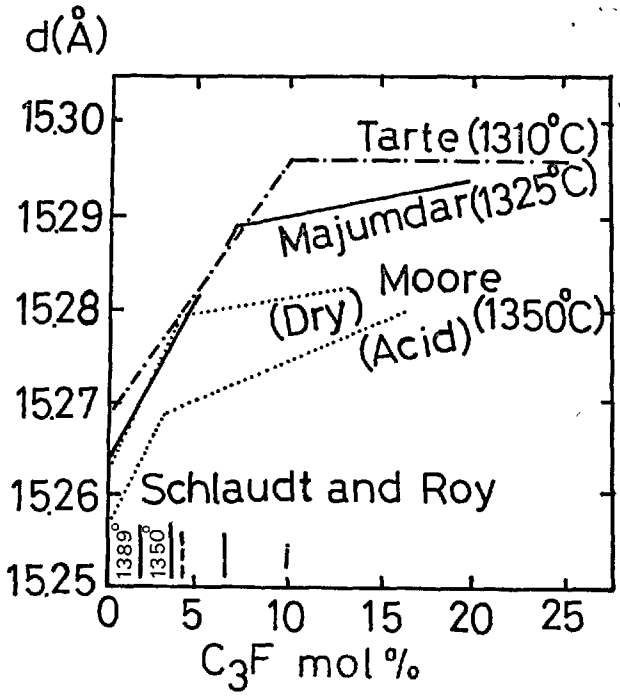

Fig. 16. *Lattice parameter of* C_3A-C_3F *solid solution*

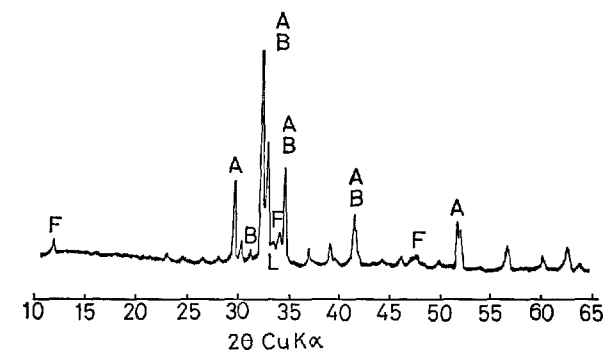

Fig. 17. *Typical diffraction pattern of commercial clinker*

crystallinity.

At 51°–52°, 610 and 040 diffractions of alite (A) appear as a doublet in the case of monoclinic but a triplet in the case of tricilnic, so that a question which is dominant whether monoclinic or triclinic is detectable. At 41°–42°, $\bar{2}28$ and 319 diffractions of alite and 014(014) and 031(031) diffractions of belite (B) as β-C_2S are overlapping. At high angle side of 34°, $\bar{2}25$ and 405 diffractions of alite are dominant but 102(103) diffraction of belite is overlapping. At low angle side of 34°, 141 diffraction of ferrite (F) solid solution appears. Its 200 diffraction appears at about 1/2° lower from 141 in the case of pure C_4AF but in the case of commercial clinker it usually overlaps to a low angle side of 141 diffraction with clearance about

1/4°. Other diffractions of ferrite solid solution appear at 47° overlapping to high angle side of $\bar{4}0,10$ and $2\bar{2},10$ diffractions of alite and at 12° independently. The former diffraction is 202 and the latter 020.

A diffraction at 33.3° is 440 of aluminate (L) but this is somehow overlapping to 220 of C_4AF in the case of pure minerals. However, in the case of commercial clinker the overlapping does not realize. If a part of belite is the form of α–C_2S or α'–C_2S, 110 diffraction of the former or 013 diffraction of the latter appears near 33°. At 32°–33°, 009, 224 and $\bar{4}04$ diffractions of alite and $10\bar{4}(10\bar{3})$, $12\bar{2}(12\bar{1})$, $20\bar{2}(200)$, 022(022) and 120(121) diffractions of belite as β–C_2S appear overlapping and forming two peaks. A diffraction at 31° is $12\bar{1}(120)$ of belite as β–C_2S and diffractions at 29°–30° are 221, 401, 222 and 402 of alite. Figs. 18 a–j are diffraction patterns of Japanese commercial clinkers.

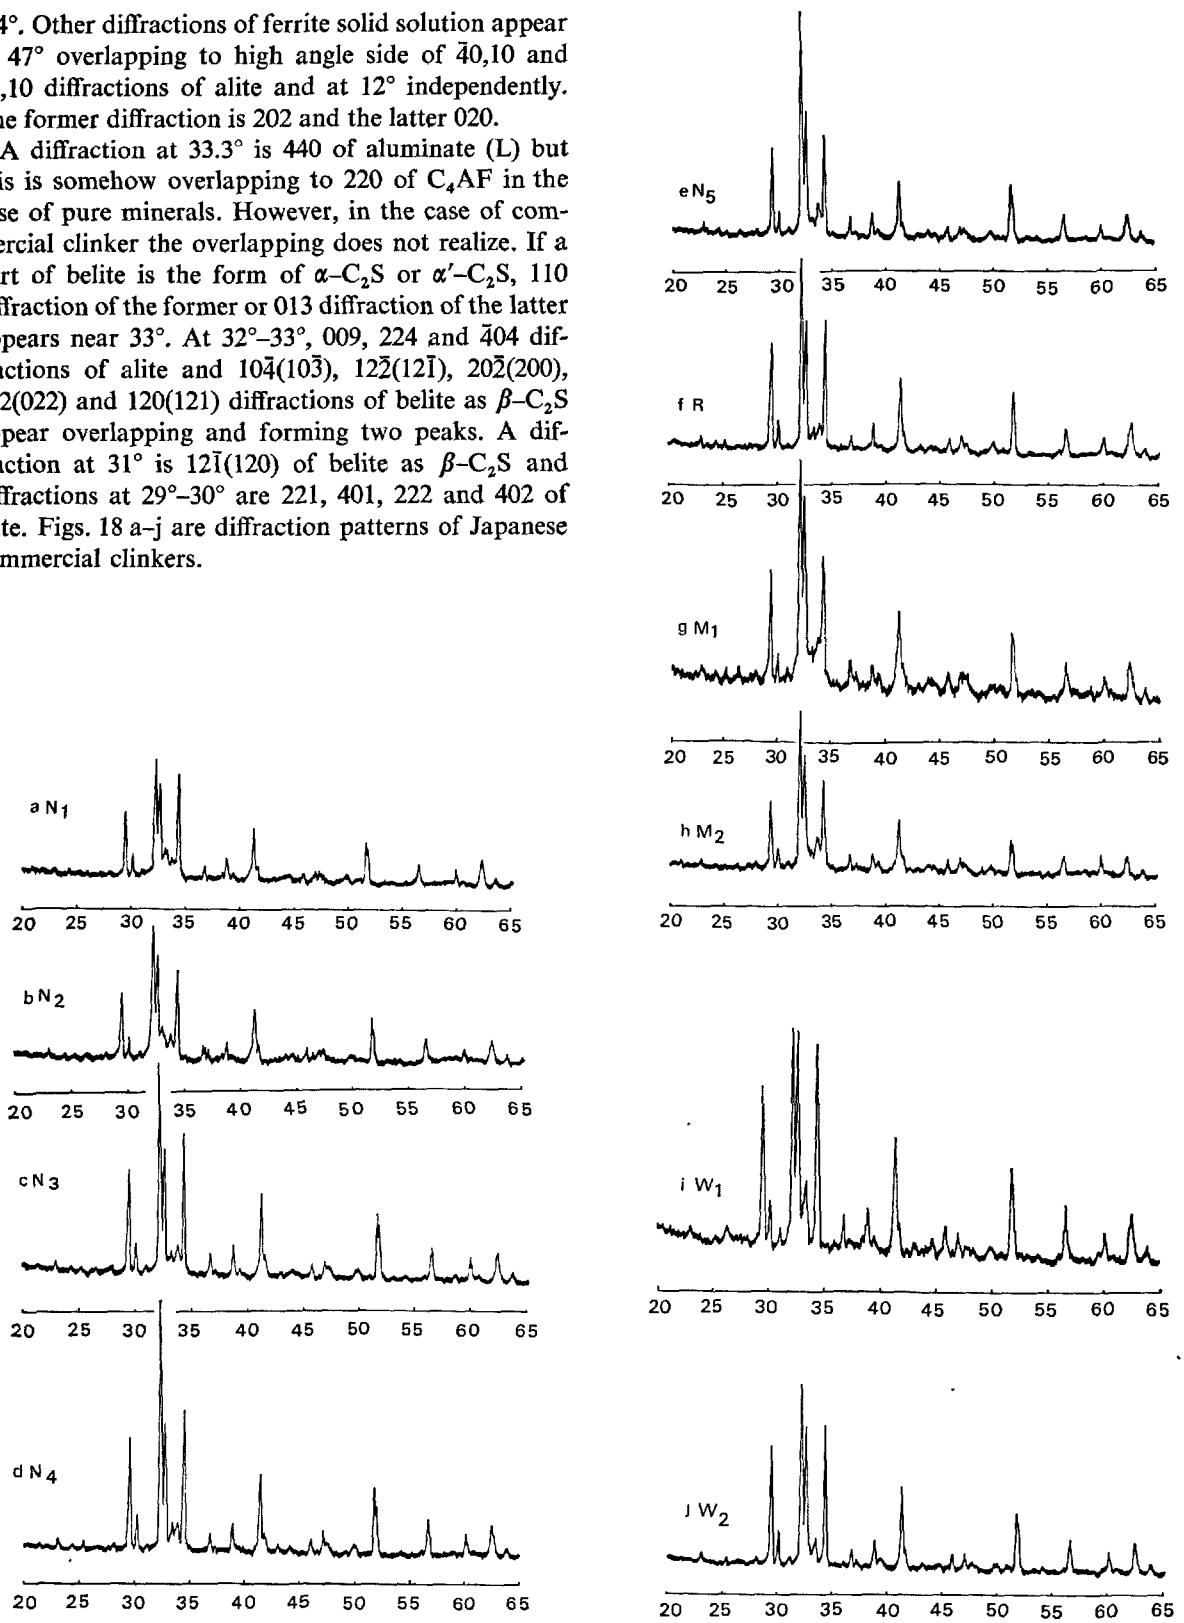

Fig. 18. *Diffraction pattern of commercial clinker*

Monoclinic alite is dominant in all clinkers and belite is β–C_2S except diffractions at 33° in N_1 and N_2 seem belonging to α–C_2S. In W_1 and W_2 there exists little amount of ferrite but a large amount of aluminate.

Heavy Liquid Separation

The heavy liquid separation study of the cement minerals has been carried out since long time but perfect separation is very difficult. On the other hand a separation yield is so small that there is a fear whether or not a gathered sample may represent a whole lot. The method of separation employed in this experiment to gather average samples as far as possible was as follows:

Clinker were pulverized into particles all passable through a 4900 mesh (88μ) sieve. Then 10 kg of them were suspended in absolute alcohol and particles smaller than 20μ were removed by sedimentation. Next, 3 kg of them were treated with a magnetic separator repeatedly until 300 g of sample with low ferrite content remained. At last, the centrifugal separation by heavy liquid of a definite specific gravity was employed to gather alite part and belite part. The liquid was made from methylene iodide-benzene mixture. Proper ranges of specific gravity were 3.13–3.17 for alite and 3.18–3.26 for belite. Figs. 19a–j are X-ray diffraction patterns of separated alite parts and Figs. 20a–j are those of belite parts.

Difficulty of the separation is differrent according to kind of clinkers. In general, alite is separated easily but belite is not and has a tendency of being accompanied with ferrite and alite.

The belite parts of N_1 and N_2 show strong diffractions at 33° and they seem to be 110 diffractions of

α–C_2S. However, 013 diffraction of α'–C_2S is expected to appear near by, so that a careful checking is needed to confirm that the diffraction is whether α or α'. Table 2 shows the checking data of them.

These data show α–C_2S is probable. If the diffraction were 013 of α'–C_2S the strongest diffraction of 020 and 211 would appear together at 33.5° and a shape of diffraction peak would change immensely. As a further evidence for α–C_2S, nearly pure α–C_2S was gathered by careful separation of N_1 clinker as shown in Fig. 21. This problem will be reported separately (48).

It was not until the precise interpretation of X-ray powder diffraction patterns of cement minerals could be established that a discussion of this kind became possible.

A principle of the separation method mentioned above is an equal weight sampling from all parts of clinker, so that it does not contain such a pretreatment that ferrite-less parts in clinker are selected. Therefore, the interstitital phase is apt to adhere to alite and belite, and a perfect separation is nearly impossible.

Another experiment of separation including a pretreatment of selecting ferrite-less parts was performed, although it might be a problem in an equal weight sampling. X-ray diffraction patterns of those samples are shown in Figs. 22 and 23. Both of these samples seem fairly pure and it is interesting that diffractions of belite are broader than those of alite.

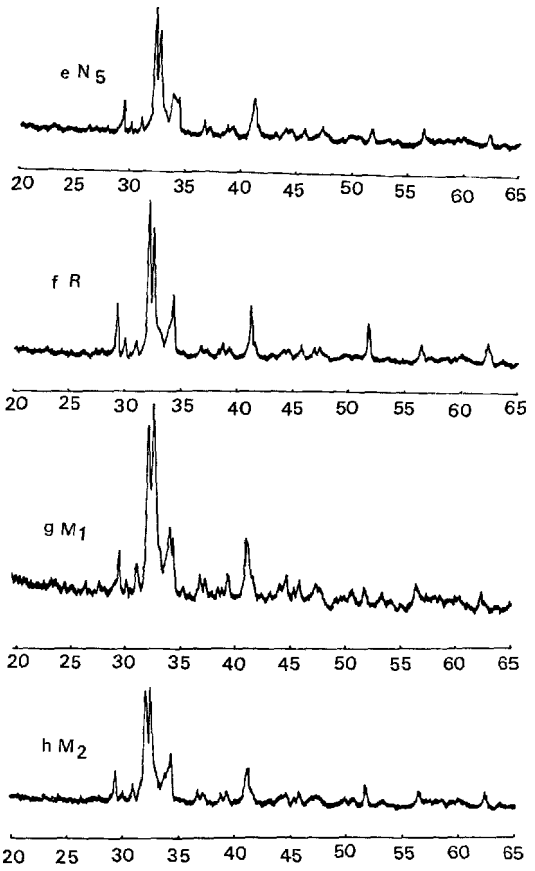

Fig. 20-2.

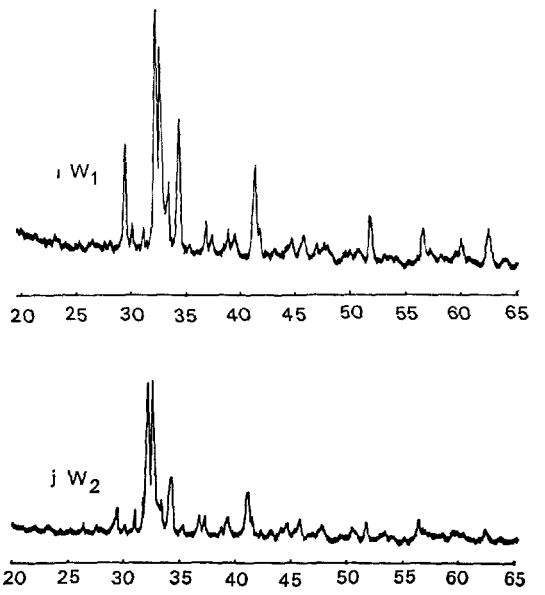

Fig. 20-3.

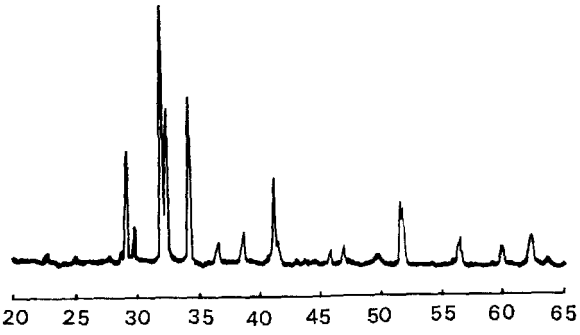

Fig. 22. *Diffraction pattern of well separated alite*

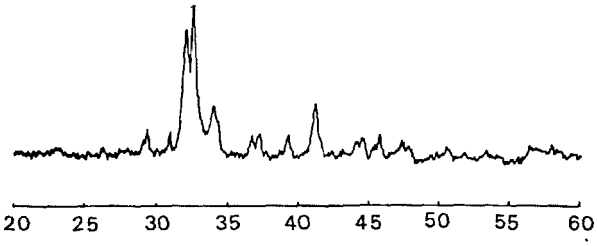

Fig. 23. *Diffraction pattern of well separated belite*

Chemical Separation

A separation between alite and belite is nearly impossible because they have very close chemical property. Various methods of separating the interstitial phase were tested and it was found that salicylic acid methanol solution method studied by S. Takashima (1958) (49) is the best and quantitative method.

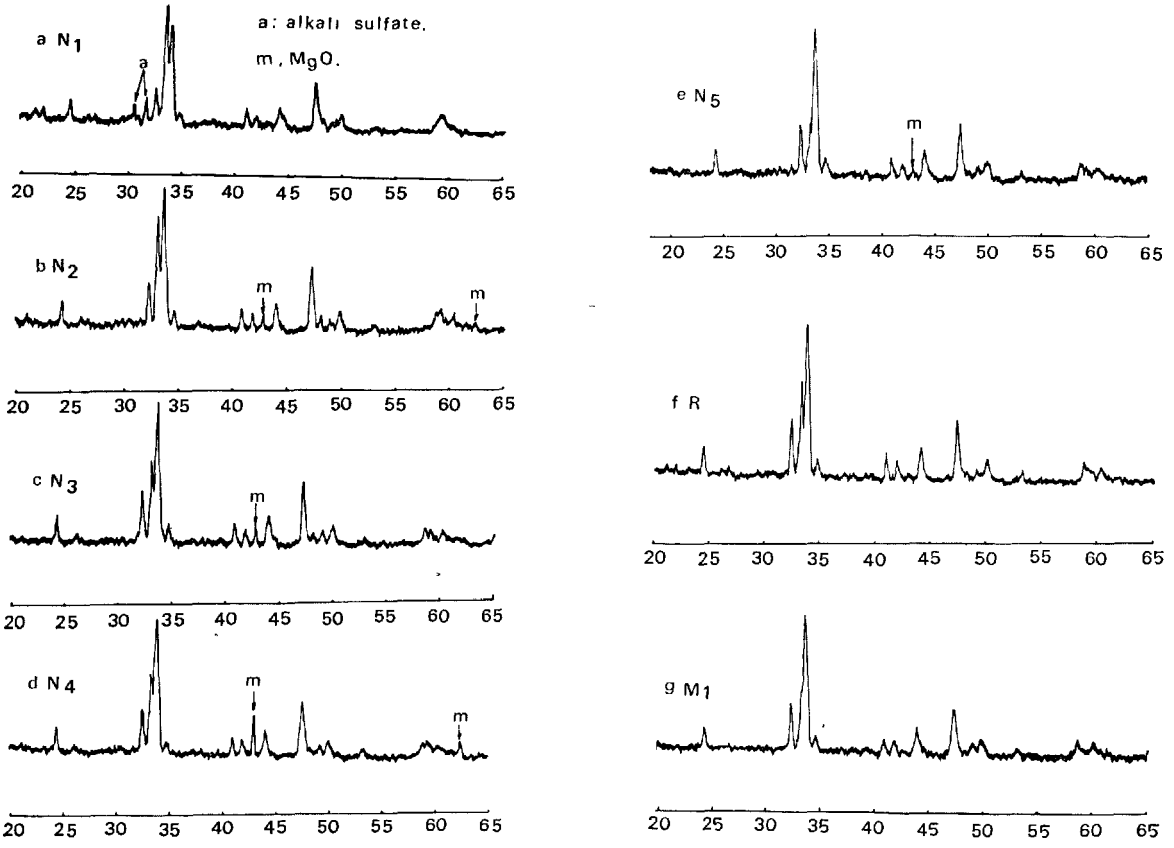

Fig. 24. *Diffraction pattern of separated interstitial phase*

The residue of this treatment was again treated with 1 N acetic acid aqueous solution and after this treatment all of aluminate and a part of ferrite were dissolved into solution and the major part of ferrite was left as a residue. The glass phase is also hardly dissolved. Figs. 24a–j are X-ray diffraction patterns of the interstitial phases and Fig. 25 is characteristic patterns of the interstitial and the ferrite phase of N_3 clinker. Amounts of the interstitial phase determined by this method are shown in Table 10 (line C).

The interstitial phase of N_1 contains fairly large amount of alkali sulphate and the aluminate phase. Those of N_2, N_3 and N_4 contain free MgO. Those of M_1 and M_2 consist almost only of ferrite. Those of W_1 and W_2 contain no ferrite. The 440 diffraction of all aluminate show splitting, so that all aluminates consist of or contain orthorhombic one.

The diffraction of 141 and 200 of ferrite appear very closely. The former lies at about 33.8° and the latter at about 1/4° low angle side. In the case of pure C_4AF, 141 is at almost the same situation but 200 is at about 1/2° low angle side.

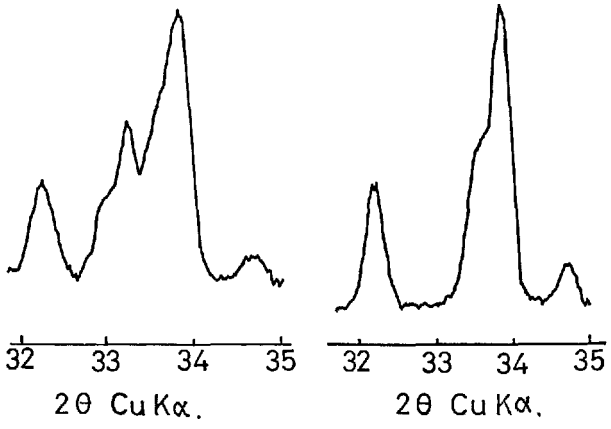

Fig. 25. *Characteristic diffraction patterns of separated interstitial and ferrite phase from* N_3 *clinker*

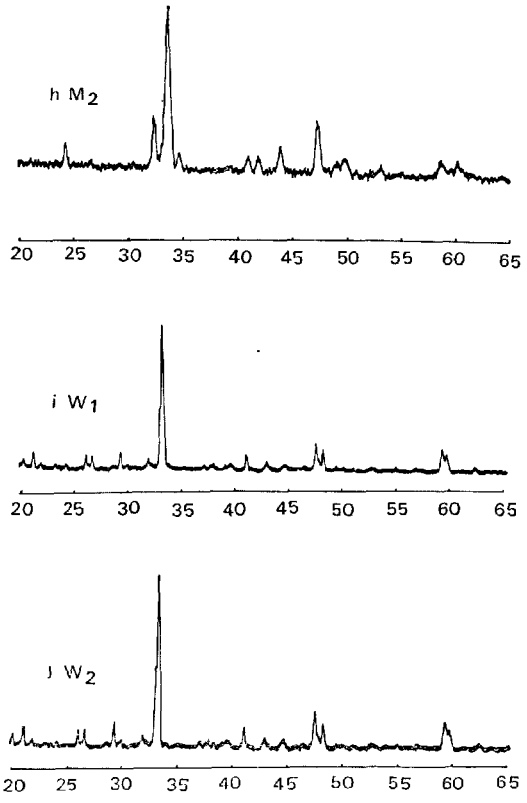

Fig. 24. *continued*

Chemical Analysis

As to wet chemical analysis there are many studies and regulations in every country. The chemical analysis was conducted applying Japanese Industrial Standard, JIS R 5202. Table 3 shows results of wet chemical analysis.

Chemical analysis of the separated alite part (A), the belite part (B), the residue of the salicylic acid treatment (R) and the residue of the acetic acid treatment (F) were conducted.

If the glass phase does not exist in (F), its chemical composition is that of the ferrite phase. Mixed ratio of ferrite and aluminate in (R) was determined by the X-ray quantitative analysis. Then chemical composition of the aluminate phase was determined considering free MgO and free alkali sulphate.

(A) and (B) were treated with salicylic acid methanol solution, and chemical compositions of alite-belite mixtures in (A) and (B) were obtained. Contents of alite and belite in (A) and (B), α_A, β_A, α_B and β_B, were determined by the X-ray quantitative

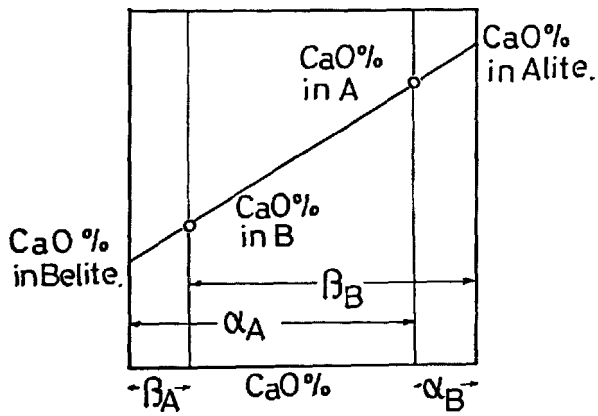

Fig. 26. *Calculation chart of chemical composition of component from mixture.*

analysis. From these values, chemical compositions of alite and belite were determined. This calculation was performed following Fig. 26, an example of CaO.

Chemical compositions of the salicylic acid dissolved parts of the clinkers are values of alite and belite mixtures in clinkers. Then using these values and CaO contents in alite and belite, which were most reliable and had sufficient gradient, contents of alite and belite in the original clinkers could be calculated. Details will be reported separately (50).

Transmitted Light Microscopic Observation

Transmitted light microscopic observation has been established as the mineralogical optics. Nevertheless, the application of this method to the cement minerals is not so frequently conducted because its technique is more difficult than that of reflected light microscopic observation. This technique, however, is indispensable in order to investigate the nature of minerals and should be applied more frequently. The measurement of optical properties and the observation of stereographic structure cannot be done by a reflected light microscopy. The systematization of both microscopy of cement clinker was almost established by H. Insley and V. D. Frechette (1955) (51).

Almost no study using the transmitted light microscopic technique has been carried out since the last symposium with some exception. G. Yamaguchi and Y. Ono (1966) (52) studied the alite phase. They measured precisely angles of two characteristic shapes of alite and correctly interpreted that these shapes are trigonal own shapes formed at high temperature. Moreover, they recognized two kinds of twins whose twinning planes are a basal plane and an R_1 plane, characteristic optical properties such as wavy extinction caused by trigonal-monoclinic inversion twinning and a polysynthetic twinning parallel to c axis caused by monoclinic-triclinic inversion.

As to the type I and type II structure of belite, it had been interpreted that the type I structure is a polysynthetic twinning of α-α' inversion and the type II structure is that of α'-β inversion. But no more detail of twinning structure had not been clarified.

G. Yamaguchi and Y. Ono (1962) (53) mentioned that the type I and type II structures can be seen without nicol and in almost all cases neighboring parallel lamellas have the same extinction position, and therefore lamella structures are not always polysynthetic twinnings but dominantly simple flake structures. Their further results are as follows:

Parallel lamella structure of the type I is a simple flake structure and not parallel polysynthetic twinning structure, but as it will be mentioned later, sometimes α–C_2S phase is being sandwiched between main lamellas which have already inverted into β–C_2S but remain as α'–C_2S skeletons. However, the intersecting parts of lamellas show usually complex wavy extinction and seem probably having twinning structure whose twinning plane should be $\alpha'\{013\}$ as will be shown later.

Yamaguchi et al. measured the orientation of lamellas using microscope with universal stage and found out that there exist six directions of lamellas in one grain at maximum and that angles between lamellas and the X-Y plane $33 \pm 5°$. The angle between {102} and c plane in α–C_2S is theoretically 36°, so that the type I lamellas seem to be $\alpha'\{101\}$ planes which are equistructural to the $\alpha\{102\}$ plane and developed topotaxitically on that plane. Fig. 27 shows the orientation of the type I lamellas of belite corresponding to {102} of α–C_2S.

In Fig. 28 the type II lamellas of belite can be observed also without nicol. They lie nearly parallel to the Y-Z plane (b-c plane in P2 1/n) and can be observed distinctly from Y direction but imperfectly from Z direction. When the lamellas are observed with crossed nicols from Y direction extinction position of every parallel lamella is same, but from Z direction polysynthetic twinning structure parallel to lamellas can be seen. Therefore lamellas observed without

nicol are flake structure of {101} in P2 1/n or {100} in P2 1/n which topotaxially developed on {010} plane of α'–C_2S(Pnma) and polysynthetic structures of the same direction can be observed only from Z direction with crossed nicols.

The orientation of lamellas and twinning planes can be clearly explained in the following interpretation in which the structure of α'–C_2S is treated as α'_H and Pnma same as the above description.

In α–C_2S($P\bar{3}cl$), {110}, {$\bar{1}$20} and {2$\bar{1}$0} are mirror planes, so that when it inverts topotaxially into α'–C_2S (Pnma), these mirror planes change into twinning planes or remain as a mirror plane of α'. In Fig. 29, if α'{101} lamella grows topotaxitically on α{102}, in this α' lamella crystal α{110} and {2$\bar{1}$0} change into twinning planes as α'{013} and {0$\bar{1}$3} respectively and α{1$\bar{2}$0} remains as a mirror plane α'{010}.

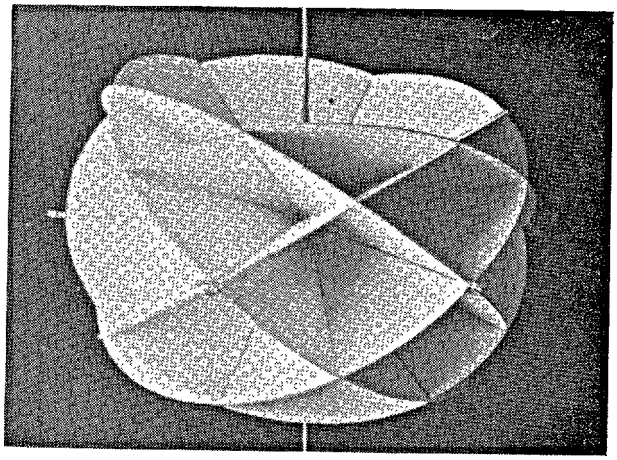

Fig. 27. *Orientation of type I lamellas*

Then, when α'–C_2S inverts topotaxitically into β–C_2S(P2 1/n), mirror plane {010} of α'–C_2S changes into a twinning plane {100} of β–C_2S.

The type I lamella in belite and the type III belite which have already inverted into β–C_2S should have a structure like type II. However, that structure can not be observed so easily. They might have extremely fine flake structure and polysynthetic structure.

A. Metzger (1953) (54) mentioned that α'–C_2S was found by the optical observation at a drop like inclusion in C_3S. In the present experiment α'–C_2S was never found in any of Japanese clinkers but in N_1 and N_2 clinker many grains containing α–C_2S could be found.

Fig. 30 shows a belite grain of N_1 clinker having the type I structure in which lamellas of two directions can be seen. A reason why only lamellas of two directions are distinct is that only those lamellas are nearly perpendicular to a stage. In a space between lamellas

a matter of low refractive index and low birefringence is sandwiched. This structure is liable to be misunderstood as a polysynthetic twinning structure. If α–C_2S had inverted into α'–C_2S to make polysynthetic twinning structure and α'–C_2S had remained as it was or reinverted into β–C_2S, it would be possible that extinction positions are different one another, but it would be impossible that lamellas have so dif-

ferent birefringence from the stand point of topotaxitic inversion. Moreover, the sandwiched matter has low refractive index, considering all those facts it is nearly unquestionable that the matter should be α–C_2S.

In Fig. 31 a reflected light microscopic photograph of an etched surface and transmitted light microscopic photographs of the thin sectioned same field are shown. A large belite grain has two parallel lamella groups A and B. Both groups can be recognized even in parallel nicols. Each group has almost the same extinction position and the difference of angle between extinction position of A and B groups is only about 4°. Although, the α'–β inversion structure cannot be seen in this figure.

Reflected Light Microscopic Obeservation

Reflected light microscopic observation has been systematized also by Insley et al. Investigations applying this method are being conducted as a daily work, especially a point counting quantitative analysis of the mineral composition. The essential point of this method is a polishing and etching technique. Table 4 shows usual etching techniques.

The interpretation about informations observed from a polished and etched surface of clinker is established. Recently F. Trojer (1966) (55) described this problem clearly. Figs. 32–36 are typical photographs of clinkers of the present experiment.

Electron Microscopic Observation

A few investigations into cement clinker using an electron microscope have been reported since the last symposium. G. Yamaguchi and Y. Ono (1962) (53) observed very fine type II structure in the type III belite and lamella of the type I belite. P. Brunner (1965) (56) explained electron microscopic photographs of clinker comparing to reflected light microscopic photographs. F. Trojer (1966) (55) presented a photograph taken by the ion etching technique. The photograph shows the very fine type II structure in

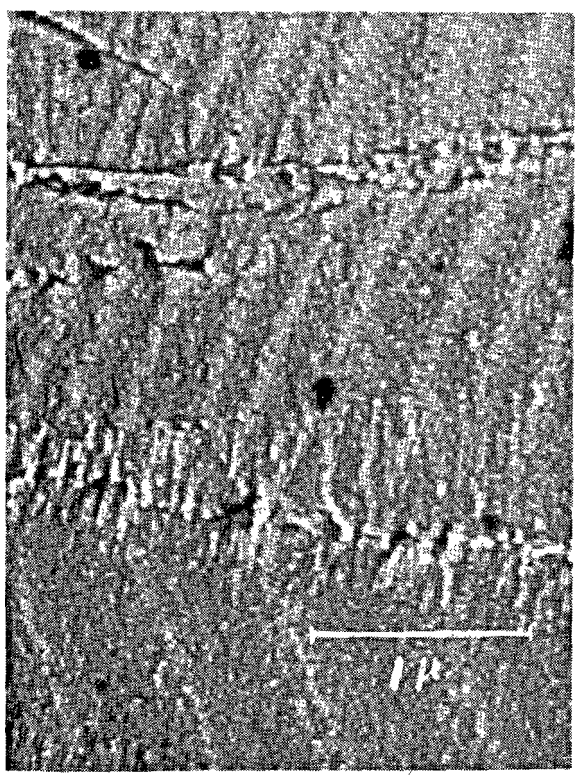

Fig. 37. *Electron microscopic photograph of type II structure in type III belite.*

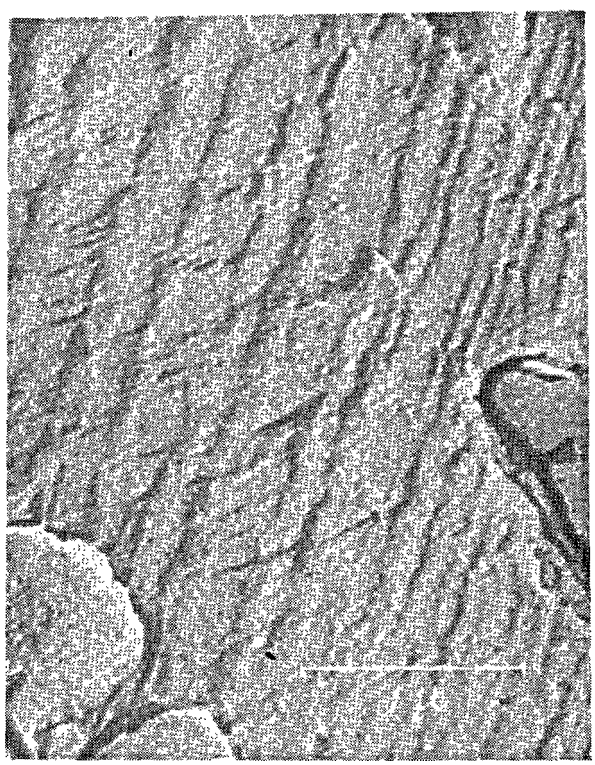

Fig. 38. *Electron microscopic photograph of type II structure in type I lamella of belite.*

lamellas of the type I belite.

It is necessary to use the electron microscopic technique in order to clarify fine textures which cannot generally be observed with an ordinary optical microscope. The $\alpha'-\beta$ inversion in belite is not always observed even with an electron microscope, so that improved observation techniques are needed to confirm this structure. Some photographs taken with an electron microscope in this experiment are presented in Figs. 40–42 in which whether or not a fine structure in belite is due to the $\alpha'-\beta$ inversion is not clear.

The scanning type electron microscopic observation will become useful in future. Some photographs are shown in Figs. 43 and 44.

Differential Thermal Analysis

The differential thermal analysis (DTA) has been applied as a testing technique of experimentally synthesized clinker. Especially it is useful for a supplementary method to identify a polymorph of minerals. For instance, it is not reasonable to maintain that some C_3S solid solution should be classified into the same polymorph of pure C_3S such as T_{II} from only a reason of resemblance of 620 and 040 diffractions. But if there is resemblance of DTA feature, the reliability of the classification increases.

The fact that two phases belong to the same polymorph means thermodynamical parameters (atomic parameter, lattice parameter, lattice enthalpy, lattice entropy etc.) of those phases are varying with no gap according to conditions such as temperature, chemical composition etc. In other words, the fact that two phases belong to different polymorphs means there exists a gap between two continuous series of parameters of those phases. That gap is sometimes so small that its detection is not so easy and even impossible as in the case of some polymorph of C_3S.

In an experiment of comparing polymorphs of pure C_3S and C_3S solid solution, the continuity between T_I of pure C_3S and that of C_3S solid solution can be proved by an experiment, but the continuity between T_{II} of pure C_3S and that of C_3S solid solution cannot be proved. Therefore there is nothing useful but DTA experiment to increase the reliability to maintain those classification, so far as today's experimental technique.

A problem of clarifying a relation among polymorphs of minerals in clinker, those of pure minerals at several temperatures and those of solid solution phases is very important. For this project DTA method will act an important role as well as the X-ray method etc. Moreover, a study of thermal change in the cooling process of the manufacturing should be an essential problem.

Electron Probe Micro Analysis

An application of the electron probe micro analysis (EPMA) to an investigation of cement clinker developed after the last symposium. Some results have been reported. H. G. Midgley (1964) (57) presented EPMA

photographs of clinker in "The Chemistry of Cement". K. E. Fletcher, H. G. Midgley and A. E. Moore (1965) (58) applied this technique to determine the chemical composition of a phase of Na_2O–Al_2O_3–CaO system. G. Yamaguchi, H. Uchikawa and S. Takagi (1965) (59) discussed the method of the application, took photographs and performed the quantitative analysis of Al and Fe in alite and belite. G. Yamaguchi, S. Takagi, M. Yoshizumi and T. Ohta (1966) (60) analyzed the ferrite phase and obtained such a result that its composition is in a range between C_4AF and C_6A_2F containing special elements such as Zn, Cu, Co etc. At the same time they reported that a back scattered electron image (BSEI) has very good resolution power. G. Yamaguchi, S. Takagi and M. Yoshizumi (1967) (61) analyzed MgO, Na_2O and K_2O quantitatively in alite and belite. S. Akaiwa, G. Sudoh and M. Tanaka (1966) (22), (1967) (62) reported a new mineral $11CaO \cdot 4SiO_2 \cdot CaF_2$ analyzing with EPMA. I. Peterson (1967) (63) analyzed Al_2O_3, K_2O and MgO in clinker.

An application of EPMA to cement clinker has some difficulties comparing to that to metals because it consists of light metal oxides and has very fine textures. Details will be reported separately (64) but essential points are as follows; they are preparation methods of specimens such as grinding and coating, and setting of experimental conditions such as voltage, current, beam diameter, diffraction crystal, counter and pulse hight analyzer system.

Specimen Preparation

Grade of grinding should be the same as microscopy specimens but more flat surface is needed so that it is desirable to use fine diamond powder paste whose diameter is less than 0.2μ at finishing. Carbon coating and beryllium coating are both useful for giving electric conductivity but the latter is better.

Resolution Power

The texture of clinker is so fine that the resolution power is important to decide a limit of the application. An ability expected to EPMA is to analyze the composition of every texture quantitatively, therefore, not only in that analysis but also in measuring a qualitative distribution of elements the check of resolution power is essential. Because clinker consists of light metal oxides, there exist such several causes which decrease the resolution power as an electron penetration effect and a secondary X-ray effect. Among several setting conditions which cause to decrease the resolution power are too high voltage, unsuitableness of coating and too large diameter of electron beam. However, decreasing the exitation voltage causes decrease of signal intensity and results badly in a signal noise ratio, so that it has naturally a limit to decrease the voltage. In general, a proper range of the exitation voltage is 15–35 KV. Even when the exitation voltage is 15 KV the resolution power of the X-ray image is about 5μ. Therefore, a matter having a diameter or thickness less than 5μ can not be reliably detected. On the contrary BSEI has a good resolution power which can be expected less than 1μ.

X-ray Image

The X-ray image has a demerit of lower resolution power but a merit of conveniency to look over the distribution of elements. Its essential points are to set a proper voltage, to cut a noise well enough by pulse hight analyzer and to give a long exposure in order to gain an enough density of light points, but so small beam size is not necessary. The X-ray image of any element can make the contrast between a low content part and a high content part, but can not make so good contrast between parts in which difference of contents is not so large.

Back Scattered Electron Image

The BSEI has high resolution power and it can resolve less than 1μ. That image has the contrast caused by difference of the electron scattering power, so that difference of composition can be detected.

Figs. 45–49 are photographs taken in this experiment. Photographs (a) are reflected light microscopic figures in which the alite phase, the belite phase, the dark interstitital phase and the light interstitial phase are clear. These photographs were taken by such a procedure that after EPMA test specimens were repolished and etched. Photographs (b) are BSEI which can detect all phases distinctly with high resolution. Photographs (c) are Fe X-ray image (XRI), photographs (d) are Al XRI, photographs (e) are Si XRI, photographs (f) are Ca XRI and photographs (g) are Mg XRI. Those EPMA photographs have non linear deformations which result in shortening of longitudinal size.

In Fig. 49 correspondency of (b) to (a) is very good because careful polishing has been conducted, but in other figures images are somewhat changed. Photographs (c) and (d) reveal that Fe_2O_3 and Al_2O_3 distribute nearly uniformly in the interstitial phase but only at some parts which are ferrite phases of large size

high concentration of Fe can be vaguely seen. This fact is due to low resolution power of the XRI.

Photographs (f) show nearly uniform intensities of Ca in the alite phase, the blite phase and the interstitial phase, but according to an experimental condition some difference can be given. Photographs (e) show Si is rich in alite and belite and also show existence of some Si in the interstitial phase.

The order of whiteness in photographs (b) is as follows; light interstitial, alite, dark interstitial, then belite. This phenomenon corresponds to the fact that light interstitial is the ferrite phase and dark interstitial is the aluminate phase.

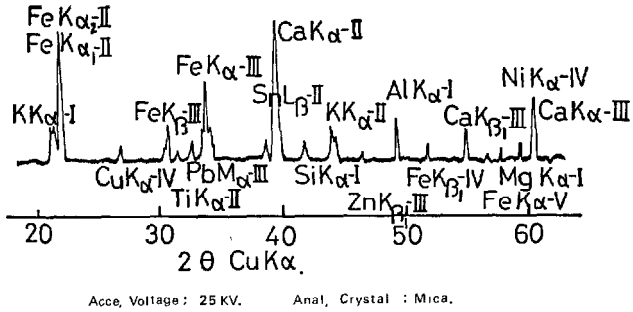

Fig. 50. *EPMA qualitative analysis of interstitial phase.*

Table 5. *Result of EPMA quantitative analysis*

	Al_2O_3	Fe_2O_3	MgO	Na_2O	K_2O
N_1 alite	0.88–1.40	0.40–1.20	0.11–0.98	0.01–0.12	0.01–0.10
N_1 belite	0.80–3.10	0.63–1.55	0.21–1.05	0.01–0.20	0.10–0.42
M_1 alite	0.45–2.50	0.51–1.31	0.32–0.65	0.01–0.02	0.03–0.09
M_1 belite	0.60–3.51	0.40–1.51	0.36–1.11	0.01–0.06	0.11–0.33

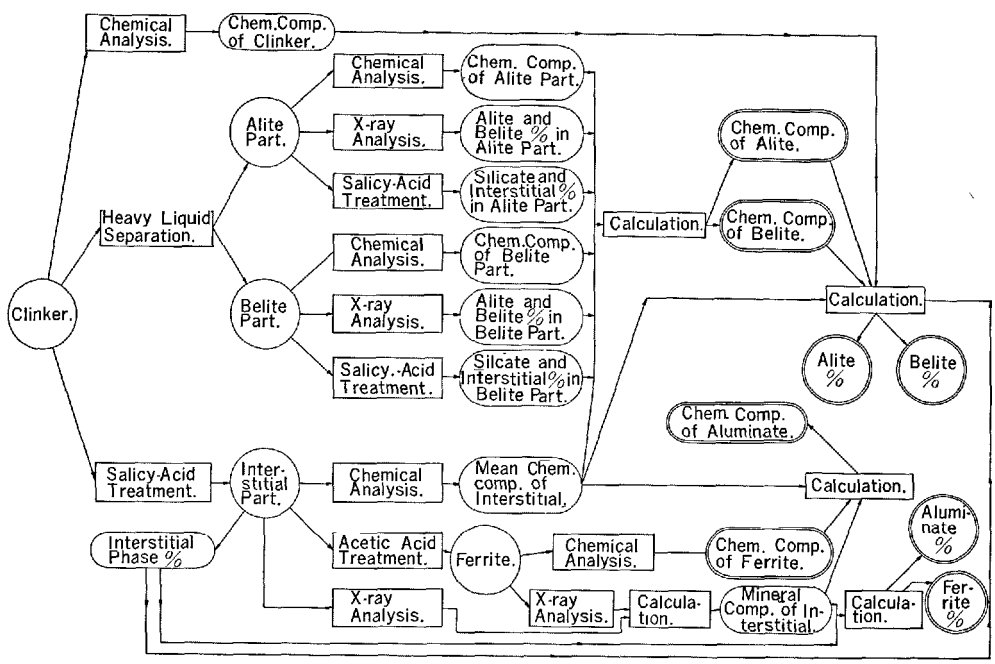
Point Analysis

The resolution power of the point analysis is also not so high. The information seems to come from a range of several microns diameter from the center of a beam though signal intensity is weighted average about the center. The point qualitative analysis is conducted simply by rotating a diffraction crystal. Fig. 50 is a result of the qualitative analysis of the interstitial phase showing the existence of many heavy metals.

As to the quantitative analysis, the first problem is also the resolution power. In the case of a small crystal, a thin crystal or an inclusion containing crystal, the determination of the true chemical composition is difficult. Therefore, it is impossible by this method to obtain the reliable chemical composition of minerals in cement clinker except it contains fairly large crystals.

The second problem is a procedure of the quantitative treatment. In the case of metals it is well known that the calculation is not so hard to conduct, but in the case of light metal oxides such as cement clinker, the quantitative calculation is nearly impossible. So that a method using standard samples is the only way of conducting the quantitative analysis. The

Table 6. *Flow chart of clinker analysis*



best standard samples are experimentally synthesized alite, belite, ferrite and aluminate crystals which contain definite amount of impurities and have large sizes, but to make those samples is impossible. Therefore, instead of true base crystals, lithium borate glasses containing 50 weight % of constituents of each base crystal were employed as standard bases. Definite amounts of several impurities were dissolved into base glasses to make standard samples. These standard samples were tested by the point analysis and calibration curves were drawn in intensity ratio to Ca and Si. Values of EPMA analysis were so variable according to conditions that calibration curves had to be drawn by a test conducted together with unknown samples at the same time and on the same sample holder.

Results of quantitative analysis are shown in Table 5.

Chemical Composition of Minerals

Chemical composition of the cement minerals has not yet been determined precisely because of experimental difficulties, nevertheless it is one of the most important problems in the chemistry of cement. Therefore, this problem was considered from all directions as a main project.

X-ray Diffraction Method

The chemical composition of a solid solution can be determined by measuring the d-spacing if the solid solution system is simple.

L. E. Copeland, S. Brunauer, D. L. Kantro, E. D. Schulz and C. H. Weise (1959) (65) and M. G. Midgley, D. Rosaman and K. E. Fletcher (1960) (66) reported results of employing this method to the ferrite phase. S. Sato, S. Takashima and M. Kato (1962) (67) reported the same kind of result. This method is effective when a shift of some diffraction caused by solid solution formation is remarkable but if a complex solid solution is formed this method is unapplicable.

In the case of the ferrite phase, 141 diffraction shifts to low angle side according to the substitution of Al by Fe while it shifts to high angle side according to the substitution of Fe by Al. However, A. Kato (1958) (39), (1959) (40) clarified that the ferrite solid solution with Si and Mg have a shift of 141 diffraction to low angle side as shown in Figs. 11–13.

The former three reports mentioned above show that the ferrite phase in clinker is generally C_4AF composition and sometimes shifts to Fe_2O_3 rich side. However, this conclusion has disregarded the effect of Si and Mg, so that the true composition should be at C_6A_2F side. In this experiment, 141 diffraction of the ferrite phase appears at about 33.8° as shown in Figs. 23 and 24 and this situation is that of pure C_4AF. Therefore, if the system were pure C_2F–C_2A, the composition would be C_4AF, but in fact the ferrite phase contains some amount of Si and Mg, so that the true composition seems surely to be at C_6A_2F side.

This method cannot be employed in the polycomponent system. But, in this experiment, it was applied successfully to the determination of alkali sulphate composition in the interstitial phase. According to Fig. 51, the composition of alkali sulphate in N_1 clinker was determined to be at slightly K rich side of $3K_2SO_4 \cdot Na_2SO_4$.

EPMA Method

A result of EPMA method is not reliable unless a

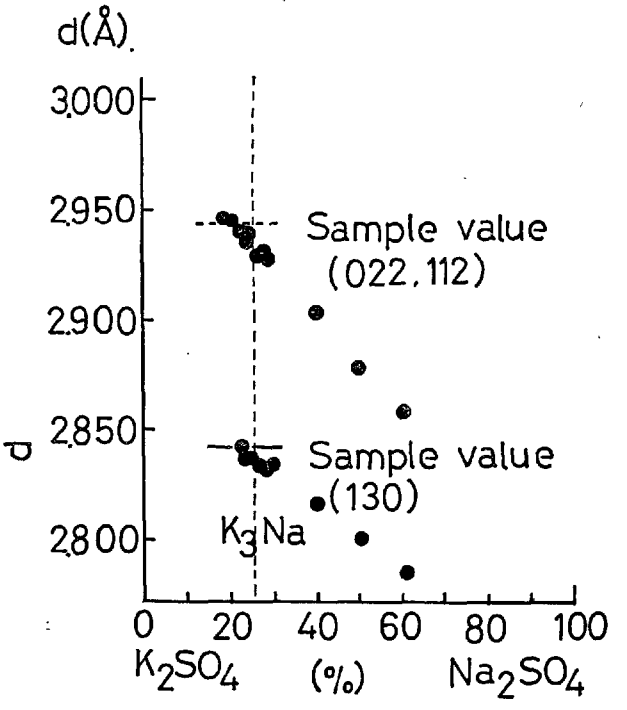


Fig. 51. *X-ray quantitative analysis of composition of alkali sulphate.*

tested point is more than 10μ far from another phase from the standpoint of the resolution power. On the other hand, from the standpoint of the technique, a reliable analysis seems not to be easily realized. In this experiment, it was successful result that the solid solution composition of alite and belite was roughly estimated and the composition of the ferrite phase was obtained to be at rather C_6A_2F side.

Chemical Analysis

A method combining the chemical treating separation, the heavy liquid separation, the X-ray analysis and the chemical analysis was already mentioned above. A combination flow chart is shown as Table 6. Results of that calculation are shown in Table 7. The chemical formulas of them are expressed as a standardized form having 90 oxygen atoms as shown in Table 8. Moreover, the standard chemical formulas having 180 oxygen atoms and the theoretical chemical compositions of cement minerals contained in Japanese clinkers are obtained and shown in Table 9. Details will be reported separately (68).

Texture of Interstitial Phase

It seems a reasonable interpretation that the light interstitial corresponds to the ferrite phase and the dark interstitial to the aluminate phase in the etched figure of the interstitial phase. However, a perfect

certification of the fact from many experimental standpoints has never been carried out. In the figure of the interstitial in Fig. 49, correspondency of the reflected light microscopic figure to the back scattered electron image is very good, while the X-ray images are not so clear because of the low resolution for too small crystals. One of the best methods to identify the ferrite phase and the aluminate phase is to combine the transmitted light microscopic observation in a thin section. This combined technique was attempted and the result is shown in Fig. 52. In this figure, correspondency among two reflecting (reflected light and back scattered electron) images and two transmitting (open nicols and crossed nicols) images is fairly good about silicate crystals but not so good, though somehow detactable, about ferrite crystals which show yellow-colored high birefringence. The reason is that the section is not so thin that crystals lie one upon another in the vertical direction especially in the case of small crystals.

Therefore, a synthesis of the interstitial phase of large crystals were attempted with experimental composition from the residue of the salicylic acid methanol treatment. The texture of thus synthesized interstitial phase resembled that of commercial clinker but consisted in more than ten times larger crystals, and the specimen could be polished into a thin section easily. Ferrite crystals are sectioned longitudinally in Fig. 53, and transversely in Fig. 54. In both figures, correspondency among light and dark

Fig. 52 Silicate part is alite. Interstitial seems dark because of its complex structure rich in Fe_2O_3. Ferrite seems strongly anisotropic with yellow polarization color in crossed nicols.

Fig. 53 Ferrite seems strongly anisotropic with yellow polarization color while aluminate seems weakly anisotropic with dark bluish color in crossed nicols.

Fig. 54 Ferrite seems anisotropic with yellow polarization color and dark brown own color. Aluminate seems weakly anisotropic. (This photo-plate was contributed by the authors).

interstitials, electron scattering power, Fe and Al distribution and optical properties of crystals is reasonable.

Especially it is characteristically stressed that Al distribution is nearly uniform, ferrite has strong birefringence and aluminte is somewhat anisotropic. The anisotropy of aluminate agrees with the X-ray diffraction data showing orthorhombic. This analysis will be reported separately (68).

Mineral Composition of Clinker

Bogue's Method

Mineral compositions were calculated by the conventional Bogue's method. It is well known that Bogue's calculation is fairly practical in spite of neglecting the solid solution phenomena. This fact is explained as follows: The composition of the ferrite phase has lower Fe_2O_3 than C_4AF but Bogue's calculation is conducted applying the composition C_4AF, so that the fact that Fe_2O_3 content is lower is compensated by its distribution other phases. The composition of the aluminate phase has also lower Al_2O_3 than C_3A, but this fact is compensated by substitution with Fe_2O_3 etc., and the calculation value becomes rather reasonable. In the silicate phases, CaO contents are lower than the simple theoretical value but the same phenomenon takes place and rather reasonable values are obtained. Results are shown in Table 10.

Point by Point Counting Method

The counting method has been already established. The reliability depends technically on the etching method and theoretically on the distribution character. The relation among content, accuracy, reliability and count number is informed from values of the binominal distribution shown in Table 11.

However, the distribution uniformity should be taken into account for measurement. If the distribution is uniform enough, the distance between one counted point and a next point must not be so long, on the contrary if the uniformity is not enough, for instance, when there exist nests of some phase, the distance must be long. Therefore employing the same counting system independently to the uniformity is not reasonable, and a measuring method of the uniformity and a proper counting distance suitable to that should be established. Counted results are shown in Table 10.

Calculation from Chemical Composition

According to the method of calculation of the

mineral composition from chemical analysis, the mineral compositions were calculated as shown in Table 10 (line C). Moreover, if the standard chemical compositions of the minerals shown in Tables 8 and 9 are reliable, the mineral compositions can be obtained by solving the following equations applying the least square method. Solutions of this method obtained using an automatic computor are shown in Table 10 (line N).

Equation	Main notation	Suffix

$x + y + z + u = 100$		c cement

X-ray Quantitative Analysis

The X-ray quantitative analysis has been studied by many investigators. This method concerning to the cement chemistry employed first to the analysis of $Ca(OH)_2$. G. Yamaguchi and A. Kato (1956) (69) and L. E. Copeland and R. H. Bragg (1958) (70) conducted such an analysis. The analysis of clinker in the early stage was studied by G. Yamaguchi, H. Miyabe and K. Tanaka (1958) (71), M. Euw (1958) (72), G. Yamaguchi, K. Tanaka and M. Kajii (1959) (73), L. E. Copeland, S. Brunauer, D. L. Kantro, E. G. Schulz and C. H. Weise (1959) (74), G. Yamaguchi, K. Takemoto, H. Uchikawa and S. Takagi (1959) (75), H. G. Midgley, D. Rosaman, K. E. Fletcher (1960) (76), G. Yamaguchi, K. Takemoto, H. Uchikawa and S. Takagi (1960–1) (77), (1960–2) (78) and H. G. Smolzyk (1961) (79). As the latest one, R. L. Berger, G.J.C. Erohnsdorff, P. H. Harris and P. D. Johnson (1966) (80) reported a routine method using an automatic computor. Principles of these methods are almost the same and there would be no trouble if the diffraction patterns of minerals were always constant. But the fact is not so simple and there are habits of patterns according to clinkers. Some problems are shown as follows:

a. What are the best for standard samples?
b. A pattern of alite always appears dominantly. Therefore, what is the best way to determine belite? To use the diffraction at 31° or what?
c. At the valley between 33° and 34°, there appear diffractions of ferrite, aluminate and α–C_2S. How are they treated?

After some considerations in this experiment the following conclusion was obtained. Details will be reported separately (68).

a. The separated minerals are the best for standards.
b. The intensity of diffraction is measured as total counts through a proper angular range.
c. The determination of alite can be conducted by counting only two doublet diffractions, 620 and 040 at 51°–52°, and 221 and 401 at 29° more reliably than by counting other diffractions together.
d. The determination of belite can be conducted by counting only two diffractions, 014 and 031 at 41°, and $12\bar{1}$ at 31° more reliably than by counting other diffractions together.
e. The primary approximate contents of ferrite, aluminate and α–C_2S are calculated from those peak-point intensities, and each overlapping total count is estimated and used as correction value to others.

Discussion of Compositions

As to the chemical compositions of alite and belite, if the formulas keep the structural stoichiometry, they may be described as follows respectively referring to the experimental ones:

$$Ca_{104}Mg_2Al(Na_{1/4}K_{1/4}Fe_{1/2})O_{36}(AlSi_{35}O_{144})$$

and

$$Ca_{85}MgAl_2Fe(Na_{1/2}K_{1/2})(Al_2Si_{43}O_{180}).$$

However, these formulas result in lower CaO and higher SiO_2 values than experimental ones in both minerals. On the contrary the following experimental formulas,

$$C_{106}Mg_2(Na_{1/4}K_{1/4}Fe_{1/2})O_{36}(Al_2Si_{34}O_{144})$$

and

$$Ca_{87}MgAlFe(Na_{1/2}K_{1/2})(Al_3Si_{42}O_{180}),$$

are slightly out of the structural stoichiometry and have cations occupied excess lattice points.

Alite has little impurity except MgO and Al_2O_3, so that the simplified typical formula is described as $Ca_{105}Mg_2AlO_{36}(AlSi_{35}O_{144})$. This corresponds to Jeffery's alite formula which may be described as $Ca_{108}Mg_2O_{36}(Al_4Si_{32}O_{144})$ but has a half of Al_2O_3. Less Al_2O_3 content in alite has been recognized and mentioned by many investigators.

The formulas of ferrite and aluminate may have some errors because the existence of glass phase was neglected, but in general they show the tendency of the chemical compositions of those minerals, so that several crystallochemical phenomena can be interpreted from these compositions. The mineral compositions of clinkers calculated from the simultaneous equation are fairly reasonable, this fact shows a reliability of these chemical compositions of the minerals. However, about these problems it needs further investigation to obtain the perfect solution.

As to the quantitive analysis of the mineral composition of clinker, of course the X-ray analysis is a direct and desirable method, but still it has many problems and establishment of that system is expected.

This experiment was carried out by the following members besides the authors:
Motohiko Yoshizumi, Takeshi Ohta, Shunji Takeda, Eiichi Miyao and Akio Kawashima.

Written Discussion

Pierre Terrier

When different methods lead independently to the same result, they strengthen this result. It is the case for the Fe_2O_3 content of alite crystals of clinker.

Our results, obtained from the electron microprobe indicate that the Fe_2O_3 content of the alite crystals is variable, it depends on the Fe_2O_3 content of the clinker (Table 1). Your results (Table 3 and Table 6 of the principal paper: The analysis of portland cement clinker) obtained from a different manner agree with this observation. We can group these data on Fig. 1, showing as an average

$$Fe_2O_{3\ \text{ALITE}} = 0.2Fe_2O_{3\ \text{CLINKER}}$$

Our operating conditions are as follows:
—MS 46 CAMERA electron microprobe
—diamond polishing of embedded clinker
—nickel metallization of the polished face
—Fe K_α radiation analysis
—crystal analyzer quartz 10^{-}II
—accelerating tension of the electrons 20 kV
—standard = S_2Fe pyrite
—corrected concentration from TONG formula

Table 1. Fe_2O_3 *in alite crystals (by EPMA) and* Fe_2O_3 *content of clinkers (chemical analysis)*

Fe_2O_3 Alite	Fe_2O_3 Clinker
0.35	0.51
0.47	2.25
0.48	2.61
0.53	2.55
0.63	3.02
0.66	3.42
0.73	2.81
1.04	5.09
1.36	5.42

Table 2. MgO *in alite crystals (by EPMA) T or M, and* MgO *content of clinkers (chemical analysis)*

Form	MgO Alite	MgO Clinker
trigonal	0.23	0.41
trigonal	0.30	0.91
trigonal	0.33	0.30
trigonal	0.37	1.02
monoclinic	0.55	1.81
trigonal	0.58	1.44
monoclinic	1.00	1.61
monoclinic	1.04	2.11
monoclinic	1.10	2.32

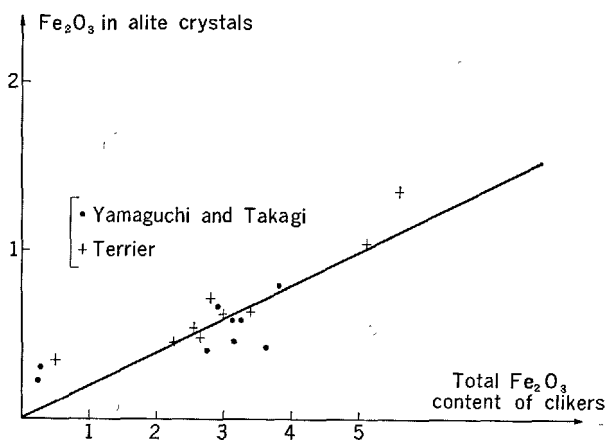

Fig. 1. *Relation between* Fe_2O_3 *in Alite crystals and total* Fe_2O_3 *content of clinkers*

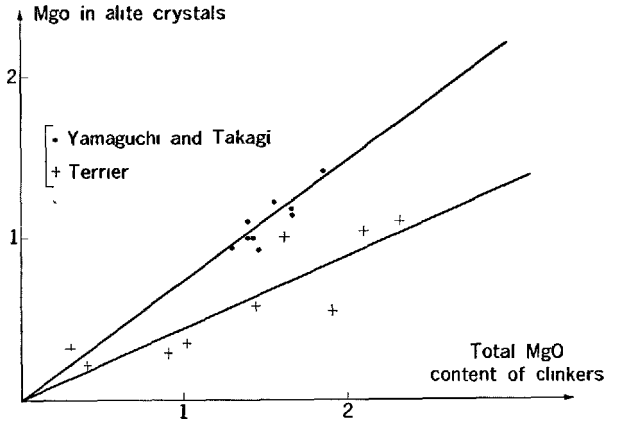

Fig. 2. *Relation between* MgO *in Alite crystals and total* MgO *content of clinkers*

On the other hand, your results (Table 3 and Table 6 of principal paper: The analysis of portland cement clinker) and ours (Table 2) indicate that the MgO content of alite crystals is variable, depending on the MgO content of the clinker.

But, whilst your results organize about the right line with a 0.74 slope, ours do about 0.45 slope line (Fig. 2).

Here is a problem, the importance of which will not escape to us, so much the more that the X-ray diffratometers have shown that the low MgO content alites were trigonals and the high content ones were monoclinic.

Our operating conditions are as follows:
—Mg K_α radiation analysis
—crystal analyser KAP
—accelerating tension of the electrons 12 kV
—standard: MgO, periclase

Written Discussion

Kenneth E. Palmer and Kenneth T. Greene

The authors have indicated the applicability of the electron probe microanalyzer in the analysis of portland cement clinker and have described several of the techniques which may be used with this instrument. Another method which they did not mention is the line scan, which gives an X-ray intensity profile for an element of interest along a preselected line on the surface of the specimen. Such scans, while not highly quantitative, provide data for a qualitative and semiquantitative correlation of the various elements present in the phases occurring along the line of scan.

Line scan analyses of several portland cement clinkers were performed for us by the Applications Laboratory of Applied Research Laboratories, Dearborn, Michigan, U.S.A. The instrument used was an AMX microprobe, and scanning was done by the electron beam scanning method. This instrument has a take-off angle of 52½°. Operating parameters were: 15 kV excitation potential and 0.1 μA sample current. The beam diameter was 1 μm or less.

Data on two clinkers are presented in Figs. 1–4. These specimens received a final polish with 1 μm diamond paste and were coated with an evaporated carbon film. Clinker A was a failry normal U.S.A. Type II clinker. Clinker B was of U.S.A. Type I composition but was laboratory prepared from relatively pure natural raw materials and contained 0.21 percent chlorine by chemical analysis as a result of interburning with a small addition of $CaCl_2$. In these figures the zero positions of the traces for some of the elements have been adjusted in a vertical direction to avoid confusing overlap.

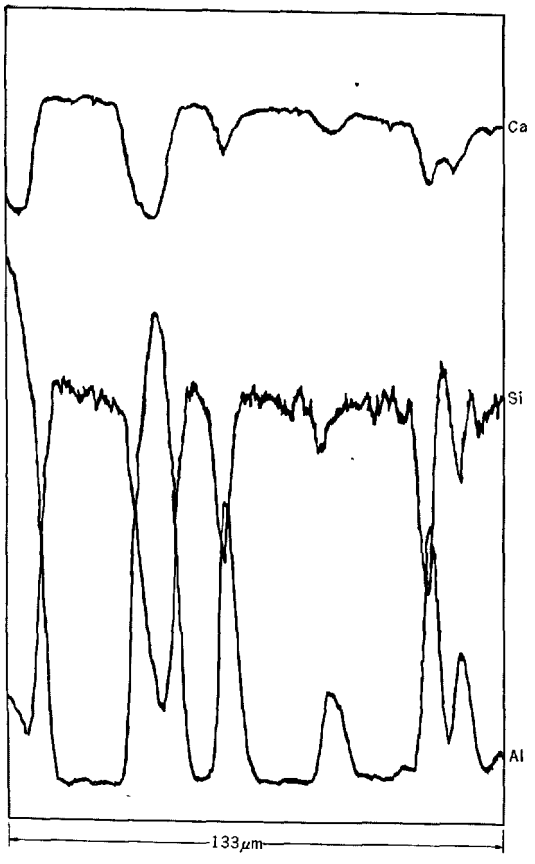

Fig. 1. *X-ray line scans across clinker A. Counts per second full scale;* Ca 30,000; Si 3000; Al 10,000.

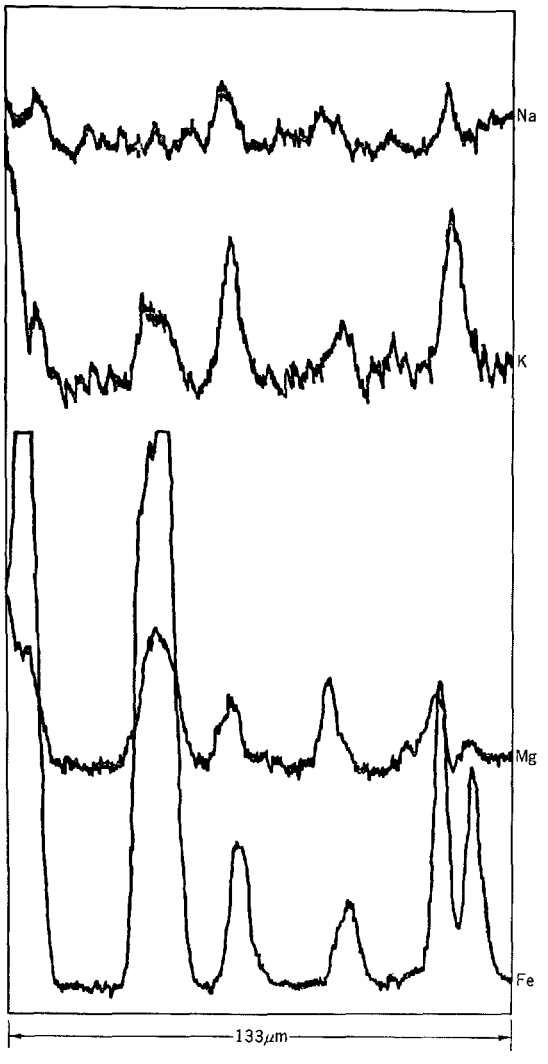

Fig. 2. *X-ray scans along same line on clinker A as in Fig. 1. Counts per second full scale:* Na 300; K 1000; Mg 3000; Fe 3000.

Figs. 1 and 2 show line scans taken along the same line on Clinker A. Of particular interest is the strong direct correlation of Mg with Fe and Al (ferrite phase) and the partial direct correlation of Na and K. There is some indication that part of the Na and K is concentrated in the belite phase (direct correlation with Si), whereas part—particularly K—may be in the ferrite phase. It appears from Fig. 1 that the silicate grains along this traverse line on Clinker A are essentially all alite, except for a small belite grain near the right side of the figure.

Of primary interest in Figs. 3 and 4 is the distribution of Cl relative to the other elements. It appears that Cl generally correlates directly with Al when Fe and Mg are low but not when they are high. This suggests that Cl is present in an aluminate phase such as $C_{11}A_7 \cdot CaCl_2$ or possibly an impure C_3A, but is absent or of much lower concentration in the ferrite phase. One exception may be noted where, about midway across Fig. 4, a Cl peak appears to correlate directly with moderate-sized Al and Fe peaks and a small Mg peak. The silicate grains along this line on Clinker B are also mainly alite. However, the higher Si and somewhat lower Ca concentrations located at about 30 μm from the left side of Fig. 3 indicate the presence of a small belite grain.

In these experiments we observed that the instrument was able to reproduce an X-ray scan rather accurately on repeated traverses along the same line. Small peaks no more than 1 or 2 μm broad were reproduced quite faithfully.

Obviously, these observations are of a preliminary nature, but they serve to illustrate further the potentialities of the electron probe microanalyzer in cement research.

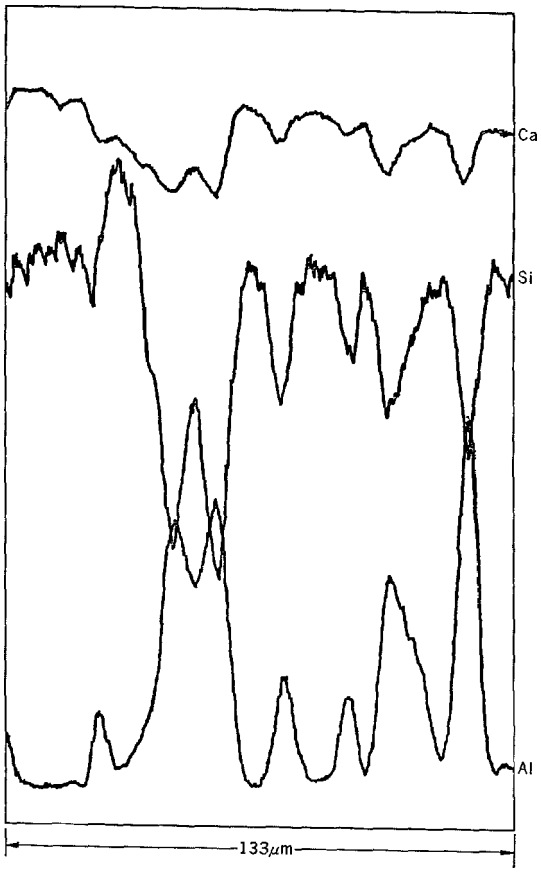

Fig. 3. *X-ray line scans across clinker B. Counts per second full scale:* Ca 30,000; Si 3000; Al 10,000.

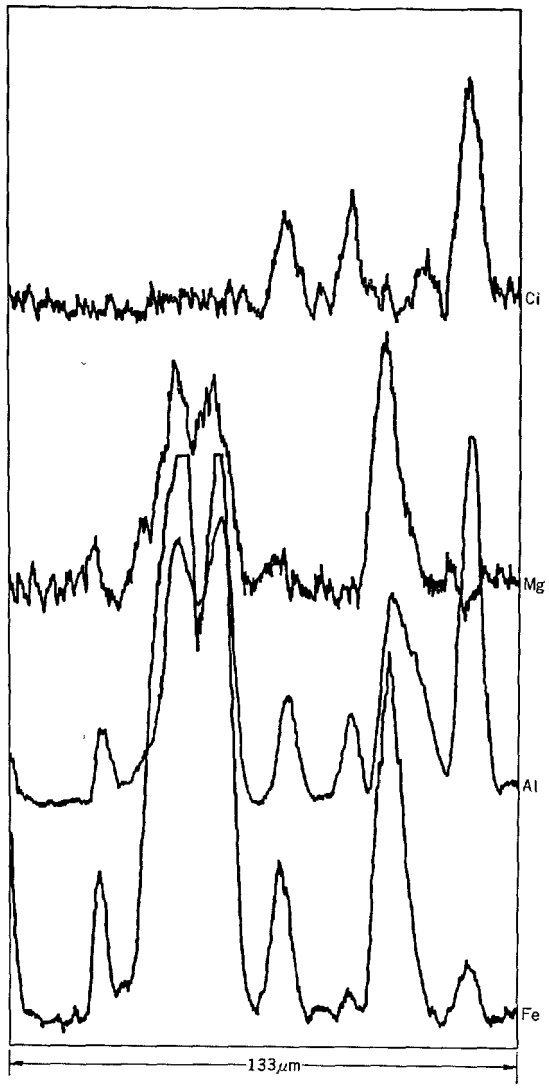

Fig. 4. *X-ray scans along same line on clinker B as in Fig. 3. Counts per second full scale:* Cl 1000; Mg 1000; Al 10,000; Fe 3000.

Written Discussion

Toshio Sakurai and Takeshi Sato

Introduction

The purpose of this discussion is to report the results of some studies on an application of X-ray fluorescent spectrometry to a solid state analysis of minor components, such as chromium oxide, in portland cement minerals.

Although an analysis of solid state of minor components is very important in order to explain the physical and chemical properties of clinker minerals, it is, nevertheless, very difficult to separate the solid state of minor components from that of their mothers.

From this viewpoint the authors think that an application of X-ray fluorescent spectrometry on an solid state analysis of chromium oxide in clinker minerals is very effective.

Experimental

The Philips' vacuum spectrometer was used in

this work with a special receiving slit of 10 cm long. Excitation condition was fixed at voltage of 50 KV, used with 36 mA. Topaz crystal was used for chromium lines $K\beta_{1,3}$. The step scanning method was adopted at the fixed time of 20 seconds in every 0.01 degree (2θ) step. And this method was repeated 10 times on each sample.

In order to detect the direct relation between 2 and valency of chromium in the crystal field, chromium $K\beta_{1,3}$ line of Cr_2O_3, CrO_2, Cr_3O_8 and CrO_3 was measured.

Each spectral curve was analyzed as follows; as this spectral curve can be regarded as Gaussian distribution function:

$$S = \frac{A}{\sqrt{2\pi}\,\sigma} \quad e \times p\left[\frac{-(x-\mu)^2}{2\sigma^2}\right]$$

where S is intensity, σ the standard deviation of each curve, μ the average value, x the degree (2θ) and A the coefficient determined by the chromium concentration in each sample. At the region of $x \approx \mu$, this function can be written as:

$$S = -\frac{A}{2\sqrt{2\pi}\,\sigma^3}x^2 + \frac{A\mu}{\sqrt{2\pi}\,\sigma^3}x + \frac{A}{2\sqrt{2\pi}\,\sigma^3}(2\sigma^2 - \mu^2)$$

In this equation, each coefficient σ, μ and A can be calculated from the measured data by the simultaneous equations using the least mean square method. simultaneous equations.

Experimental Results

Listed in Table 1 are the terms σ, μ and A calculated from the coefficients of each spectral curve equation. Fig. 1 shows three examples of the spectral curves. Fig. 2 shows a calibration curve correlating each 2θ with the valency of each standard chromium.

Although each point has some deviation from the calibration curve, this linear relation is very significant.

The average valencies gained by interpolating the measured values in this linear relation are listed in Table 2. In this table the average valencies of dissolved chromium obtained by chemical analysis (1) are also listed in contrast with the former.

For tri-calcium silicate solid solutions, these pairs of values agree fairly well with each other. For di-

C_3S solid solution ($Ca_{300}Si_{94}Al_6Fe_2Cr_5O_x$)	4.7	4.8

calcium ferrite solid solutions and for tetra-calcium alumino ferrite solid solutions, however, the values by chemical analysis are considerably smaller than those by X-ray spectrometry. This may be because, in chemical analysis, chromium in these solid solutions reduces to the more stable valence state, Cr^{3+}, during dissolving of these solid solution into H_2SO_4 solvent. Therefore, these values obtained by X-ray spectrometry show the truer valence state in solid solutions.

In Fig. 2, chromium in these ferrites takes the average valencies of 3.7~3.8 which are corresponding to the valency of chromium in CrO_2.

CrO_2 has the structure of rutile TiO_2 of 6 : 3 coordination. Every chromium atom is surrounded by six oxygen atoms approximately at the corners of a regular octahedron, and every oxygen atom by three chromium atoms approximately at the corners of an equilateral triangle.

The structure of $2CaO \cdot Fe_2O_3$ determined by Bertaut et al. is composed of one layer of octahedral groups of oxygen atoms around iron atom connected with another layer of tetrahedral groups of oxygen atoms around iron atom.

On the other hand, chromium trioxide, CrO_3, has an arrangement composed of CrO_3 chains held together only by van der Waals forces within which each chromium atom has four oxygen neighbors. Every two of these four oxygens is combined with only one chromium atom and every other two is surrounded by two chromium atoms.

Considering these structures, the structure of CrO_2 octahedra is far similar to the iron octahedra in $2CaO \cdot Fe_2O_3$ than the structure of CrO_3 tetrahedra is.

Therefore, it may be sure that chromium in the ferrites substitutes for octahedral iron or aluminum ion. The similarity of the standard deviation σ of the chromium spectral curves of the ferrites to those of the standard samples also proves that chromium in ferrite substitutes only for octahedral iron or aluminum ion.

Fig. 2 also shows that chromium in tri-calcium silicate solid solutions take the average valencies of 4.6~4.9.

In this case, these average valencies are situated about in the middle between those of CrO_2 and CrO_3.

In Table 1, the standard deviation σ from the chromuim spectral curves of tri-calcium silicate solid solutions is obviously a little larger than the standard deviation from the chromium spectral curves of the ferrites and of the standard chromium oxides.

This result means that these spectral curves of tricalcium silicate solid solutions are composed of two or more curves.

In other words it may be sure that chromium in tri-calcium silicate solid solutions has two or more kinds of valence states and coordination numbers.

In order to clarify the details of these considerations, however, the study of X-ray absorption-edge spectrometry for chromium in these tricalcium silicate solid solutions must be performed.

Conclusion

As mentioned above, solid state of minor compo-

nent, chromium oxide, dissolved in portland cement clinker minerals can be clarified failry well by X-ray spectrometry using the proper standard samples.

This method can be, of course, applied to the other transition elements dissolved as minor components.

The key to a significant resolution of the problem is to find the most profitable standard samples for a coming minor element and to improve the analytical accuracy of X-ray spectrometer.

Oral Discussion

Hiroshi Uchikawa

I should like to ask you about the calculation of the mineral compositions.

Although you did not refer to it today, in your principal paper you have put forward a method for it, that is, solutions of simultaneous equations by the least square method. May I ask, to what extent we can count on the accuracy of this method?

Author's Closure

Goro Yamaguchi

Reply to Terrier

It seems reasonable that the contents of minor constituents in clinker minerals depend to their total contents in clinker. In our study, however, we could not confirm this phenomenon because there is little dispersion of contents of minor constituents in Japanese clikers.

Mr. Terrier's and our results about Fe_2O_3 content in alite are coincident, so that the values seem highly reliable. As to MgO content in alite our result and his are somewhat different. It is not clear whether or not the contents are essentially different between Japanese clinkers and others.

I would like to check the reliability of our results. We also attempted to determine minor constituents in clinker minerals by the electron probe microanalysis. However, we could not obtain a reliable result because of the low resolution of the microanalysis. I would like to know many details and error problem of his experiment such as resolution, standard specimen and calculation.

Reply to Palmer and others

We also carried out the line scanning analysis of the electron probe microanalyzer but did not describe it in our principal paper. I think that analysis is valuable to find some special elements at some points. In their results a behavior of chroline is especially interesting. If whole data had been presented together with reflected light microscopic images they would be more valuable.

I think spectrum of line scanning analysis should show nearly rectangular shape. In their case, however, as well as our experiment a fact that the spectrum does not show rectangular shape seems due to low resolution of the microanalysis. I can not estimate sizes of ferrite and aluminate of their clinker. In our clinkers texture of ferrite and aluminate is very fine and complex as shown in our principal paper. Therefore, I can not exectly discuss the descrimination between ferrite and aluminate in the interstitial phase of their clinker and the descrimination seems not so clear as well as in our clinkers.

Reply to Sakurai and others

I also think that X-ray florescent study is useful to investigate states of elements in solid phase if uniform samples can be provided as in the case of synthesized samples.

We applied an electron probe microanalyzer to obtain such an information from fine minerals in clinker, especially an information of iron. We have recognized that the diffraction of Fe Kα radiation from ferrite in clinker shifts to slightly higher angle side than that from a metalic iron. As to Fe radiation from other mineral phases in clinker, such an observation has not been accomplished because of very low intensity.

Reply to Uchikawa

The simultaneous equations consist of four varia-

bles and five equations. If analytical data of chemical composition of minerals were exact it would be able to solve the mineral composition from upper four equations. However, because some errors are inevitable, the fifth equation become necessary in order to apply the least square method. The calculation was carried out using an automatic computer giving some proper weight to equations.

The calculation did not become possible until fairly exact chemical compositions of minerals could be obtained. However, a little deviation of the chemical composition of minerals affects a value of the mineral composition, so that as much as possibly exact chemical compositions are needed. Especially, ratios of $CaO: SiO_2$ in alite and belite affect the results. Moreover, exactly saying, chemical compositions of minerals are slightly different according to a kind of clinkers, especially in white cement, so that we can not obtain exact mineral composition unless using special data according to a kind of clinkers.

At the todays' step, errors have not become so small but I think it is valuable to use this analyzing system in each factory according to its own clinker.

Supplementary Paper I-12 The Minor Elements in Alite (Tricalcium Silicate) and Belite (Dicalcium Silicate) from Some Portland Cement Clinkers as Determined by Electron Probe X-ray Microanalysis

Henry G. Midgley*

Synopsis

The minor elements present in tricalcium silicate (alite) and dicalcium silicate (belite) from four portland cement clinkers have been determined quantitatively by electron probe X-ray micro analysis.

The following elements were detected in alite: calcium, silicon, iron, aluminium, potassium, magnesium with traces of cobalt and sulphur; and in belite, calcium, silicon, iron, aluminium, potassium, phosphorous, chromium, titanium and traces of cobalt, sulphur and magnesium.

It has been found that magnesium, aluminium and iron are present as important additions in alite, and that alkalies, iron and aluminium are important constituents of belite, and these have been determined quantitatively. The ranges of each substituting element have been investigated for the clinkers and compared.

Introduction

Midgley (1) referred to the use of electron probe X-ray micro analysis, gave an analysis for alite and published a series of elemental distribution photographs of portland cement clinker in 1964, but the first serious work on the subject published seems to be that by A.E. Moore (2) in 1965. Peterson (3) has presented some values for Al_2O_3, K_2O, Na_2O and SO_3 in alite and belite crystals in portland cement clinkers. Midgley (4) has investigated the composition of alite in one portland cement clinker and Fletcher (5) has investigated the composition of belite in two portland cement clinkers.

Experimental

The technique of electron probe X-ray micro analysis has been dealt with extensively in the literature; for a recent compendium of the methods and a review of mineralogical applications Adler (6) should be consulted.

In the present work a "Geoscan" microprobe manufactured by the Cambridge Instrument Co. Ltd. of Cambridge, United Kingdom was used. This instrument is capable of resolving an electron "spot" of 1μ m. in size. The take-off angle is 75° for X-rays and the spectrometer is of the fully focussing type. A flow proportional counter using argon-carbon dioxide gas mixture is used as the X-ray sensing device and the output is capable of pulse height analysis. The high take-off angle has a major advantage in that it minimizes the effect of surface relief and at the same time reduces the need for large adsorption corrections. One of the few disadvantages of the geometry is that the instrument is thus capable of receiving X-rays generated at a comparatively great depth below the surface. The presence of shallowly lying artefacts beneath the surface can thus give rise to erroneous results. Such results can usually be checked by moving the sample in relation to the static probe. In the event of an artefact giving rise to a signal the count rate would significantly change in the vicinity, the exception being where the boundary of the

*Ministry of Public Building and Works, Building Research Station, Garston, Herts, United Kingdom.

two phases lies parallel to the surface of the sample. The likelihood of this occurring is statistically small when compared with the probability of the phase boundary making a significant angle to the specimen surface.

An accelerating voltage of 20 kV was used for all elements and a specimen current of about 100 mμ amps was found to give the best compromise between stability and counter rates. The diffracting crystals used were mica for sodium, magnesium and aluminium K alpha X-radiation; quartz for potassium K alpha X-radiation and lithium fluoride for titanium, manganese, and iron K alpha X-radiation.

The specimens were prepared by standard methods used for optical microscopy of polished sections, Midgley and Taylor (7). The clinkers were embedded in a resin (araldite) and the specimen surface ground flat using a rotating steel lap with 120 grade silicon carbide powder. The specimen surface was then polished by using successively 6μ, 1μ, and $\frac{1}{4}\mu$ diamond paste on nylon bolting cloths. Following polishing the specimens were given a conducting coating with about 200 Å layer of graphite deposited in a vacuum shadow casting unit.

Since the electron probe had co-axial visual and electron optics the specimen could be examined microscopically with the same instrument.

The method of analysis depended upon the nature and size of the mineral grains. Where the minerals were sufficiently large (alite and belite) at least two local spot analyses were made on each grain. Where the minerals were present as complex intergrowths in the ground mass recourse was made to a scanning method by which the sample was moved very slowly, 3μm per min., under a stationary probe, the ratemeter readings being used to activate the pen of a chart recorder. Ratemeter readings had a much lower precision than those obtained by counting but interference of phases could be readily assessed and therefore the overall accuracy was better for this type of specimen.

For quantitative analysis standards were prepared by synthesizing minerals with bulk compositions near those to be analysed and spanning the range of elemental content encountered in the unknowns.

The composition of C_3S and the introduction of elements into its lattice has been studied in detail by various workers and preparations based on these studies were made with magnesium, aluminium, potassium, titanium, sodium and iron in C_3S. These preparations were also used as standards for C_2S with appropriate corrections for absorption and enhancement. One of the major advantages of using C_3S or other mineral of similar matrix as a standard for C_2S instead of the pure metals is that the corrections due to matrix differences are very small and this minimizes the errors introduced by uncertainty of values for mass absorption coefficients. The homogeneity of all standards was checked by X-ray diffractometry and by optical microscopy. The standards used are listed in Table 1.

A melt corresponding to the invariant point in the system $CaO—Al_2O_3—Fe_2O_3—SiO_2$, Lea and Parker (8) was also made; this was useful in estimating small quantities of aluminium and iron.

Absorption corrections were made following the general formula given by Philibert (9) and fluorescence enhancement corrections were made by the formula given by Castaing (10).

The sensitivities of the method for various elements are given in Table 2.

A considerable amount of information can be obtained by deflecting the electron beam to describe a raster over the surface of the clinker. The outputs of the counterrecording the reflected electrons and the countermeasuring the X-ray output can then be used to modulate a cathode ray tube. Typical "pictures" for certain elements are shown in Fig. 1 which illustrates element distribution in a part of a cement clinker, (P.1012/3), showing alite, belite and interstitial minerals.

Table 1. *Standards used for electron probe micro analysis*

Sodium	C_3A containing 3%Na_2O
Magnesium	C_3S containing 1.02% 0.67% and 0.32%MgO
Aluminium	C_3A, C_4AF, and C_3S containing 0.80%Al_2O_3

It is quite evident from these pictures that the aluminium is concentrated in the interstitial, which is also deficient in silicon.*

Cement Clinkers Examined

Four samples of portland cement clinker, P 1012/3, P 1017/2, P 1018/1 and P 1020/1 of the collection of the Mineralogy Laboratory, Building Research Station, were examined. Table 3 is a summary of the chemical and mineralogical compositions. The mineralogical composition was determined by the quantitative X-ray diffraction analysis (Q.X.R.D.) method proposed by Midgley, Fletcher and Cooper (11). Clinkers No. P 1012/3 and P 1017/2 are of the sulphate resisting type, having a C_3A content of less than 3.5 per cent (S.R.P.C.). The other two are ordinary portland cements (O.P.C.).

*All the alites were monoclinic by X-ray diffraction (X.R.D.)

Composition of Alite

The following elements were detected by the probe in alite crystals in various clinkers: calcium, silicon, iron, aluminium, potassium, manganese, magnesium, with traces of cobalt and sulphur. It was found that sodium, magnesium, aluminium, potassium, titanium, manganese and iron were the more important and so these were determined quantitatively. The resulting alite compositions are given in Table 4 where the elements have been calculated as being present as the oxides. It is clear from the coefficients of variation 'c' that the difference in composition between individual alite grains with some clinker is real since the 'c' values for most elements present should be much lower, in the range of 0.5 per cent to 10.0 per cent. Fletcher (5) using the same instrument as the present author has given the standard deviations (Table 5) for determination of the same elements in similar cements. The coefficient of variation 'c' has also been calculated assuming average oxide contents for alite. It must be noted here that the large values for the coefficient of variation for sodium determinations (Table 4) may be due to the inaccuracies of the estimation.

Examination of the results for the minor elements

†The coefficient of variation has been calculated using approximate values for the contents of the oxides in alite.

present in alites from the four clinkers show that for sodium, magnesium, potassium, titanium, and manganese, the difference between clinkers is less than the differences expected between individual crystals in a single clinker. The greatest difference between clinkers occurs with aluminium and iron, the ratio of Fe_2O_3–Al_2O_3 in the alite being governed by the ratio in the whole clinker. Table 3 gives the analyses of the clinkers used; Table 6 gives the Fe_2O_3–Al_2O_3 ratios for alite and for clinker. It must be noted here that it is the iron content of the alite which varies most; Al_2O_3 varies from 0.92 to 1.68 per cent, difference 0.76 per cent while the Fe_2O_3 varies from 0.43 to 1.62 per cent, difference 1.19 per cent. If the molar contents of the alites are calculated for the three clinkers P 1012/3, P 1017/2 and P 1020/1 the sums for Fe_2O_3 and Al_2O_3 are very similar, respectively 0.020, 0.022 and 0.021. Clinker P 1018/1 is different, having a molar percentage of Al_2O_3 plus Fe_2O_3 of 0.015. It is not clear why this should be so, except that the original material is exceptionally low in iron, 2.55 per cent Fe_2O_3, as compared with 3.09, 6.33 and 6.99 per cent for the other clinkers.

Table 6. Fe_2O_3–Al_2O_3 *ratios in alite and in cement clinker*

Sample number	P1012/3	P1017/2	P1018/1	P1020/1
Alite	1.17	1.76	0.34	0.43
Clinker	1.50	1.72	0.53	0.51

The analyses of the alites expressed as molar contents are Na_2O : 0.004; K_2O: 0.002; MgO: 0.020; TiO_2: 0.002; $Al_2O_3 + Fe_2O_3$: 0.020.

These results may be compared with one alite crystal thoroughly analyzed by Midgley (4); with Na_2O: 0.005; K_2O: 0.001; MgO: 0.020; TiO_2: 0.001; Al_2O_3: 0.010; Fe_2O_3: 0.009; $Al_2O_3 + Fe_2O_3$: 0.019.

One the basis of a cell content of 180 oxygens the composition is $Ca_{165.54}Fe_{1.43}Al_{1.92}Na_{0.80}K_{0.18}Mn_{0.02}Ti_{0.11}Si_{34.48}O_{180}$.

In one special clinker, B.R.S. sample No. B102, the following elements were also detected in the alite; phosphorus and strontium, equivalent to P_2O_5: 2.0; SrO: 0.5 per cent by weight. This result shows that the average composition for alite only applies to raw materials that contain similar elemental compositions.

Composition of Belite

n = }
s = } See key at end of Table 4
c = }
$\bar{x}$ = Average wt % of oxide present in belite in clinker.

The following elements were detected by the probe in belite crystals in the clinker samples: calcium, silicon, iron, aluminium, potassium, magnesium, phosphorus, chromium, titanium, and traces of cobalt and sulphur. The same elements were determined quantitatively for belite as for alite. Results are given in Table 7, calculated as oxides. It is noticeable that the coefficient of variation, c, is of the same order as for alite, but that Na_2O, Al_2O_3, K_2O and Fe_2O_3 contents are higher in belite than in alite, MgO is less and TiO_2 about the same. Again the greatest difference between belite in different clinkers is in the Fe_2O_3 and Al_2O_3 contents, the ratio being governed by the Fe_2O_3–Al_2O_3 ratio of the original clinker. The results are given in Table 8.

The average molar compositions of the belites can be represented by Na_2O: 0.008; K_2O: 0.008; MgO: 0.010; TiO_2: 0.002; $Al_2O_3 + Fe_2O_3$: 0.026. The ranges in compositions are given in Table 7.

Distribution of Elements between Co-Existing Alite and Belite Crystals

The partition of minor elements between alite and belite crystals has been determined by experimentally estimating the elements in adjacent grains of alite and belite; the results are given in Tables 9 and 10.

The factors influencing partitioning of the trace elements between co-existing mineral phases in portland cement clinker are many and complex. There is some evidence to indicate that there is a considerable lack of homogeneity in the sample populations. Tables 9 and 10 show that the values of minor elements in the host minerals may differ by a factor of 4 within the same sample.

Generally speaking, however, the partition coefficients, here defined as the ratio of element concentration in belite to alite, do not depart from each other to the same degree. This, of course, may only reflect gross inhomogeneities within the initial raw material, and that the mainly solid state reactions have not been sufficiently energetic or have not continued for a sufficiently long time to average out these differences. It is thus likely that areas initially high in potassium, for example, would favour the nucleation and growth of belite. Belite is often concentrated around vesicles in the clinker, which may have contained gaseous potassium ions, flue gases are often rich in this constituent. However, owing to the difficulty of obtaining reliable analyses for the interstitial clinker phases it

is not possible to give a quantitative expression for this inhomogeneity. No data is available for the temperature of formation and the differences in partition coefficients, although generally small, are nevertheless significantly greater than would be expected, were the clinkers all brought to equilibrium at the same temperature. In many cases, however, the distributions are distinctly different between clinkers and the minor differences within the clinkers could be attributed to differences in the temperatures at which parts of the clinker achieved equilibrium.

Supplementary Paper I-37 The Effect of Chromium Oxide on the Structural Transformations in Tricalcium Silicate

A. I. Boikova*

Synopsis

Solid solutions between $3CaO \cdot SiO_2$ and Cr_2O_3, and $3CaO \cdot SiO_2$, Cr_2O_3 and MgO have been investigated. It has been shown that at Cr_2O_3 concentration higher than 1.5 wt % decomposition of solid solutions with formation of new phases takes place. MgO as a component of solid solutions prevents this decomposition.

The effect of oxidation-reduction conditions on the oxidation degree of Cr_2O_3 in solid solutions has been studied. Solid solutions of yellow, green and blue color have been obtained under various conditions. Chromium valence has been determined in the samples by chemical analysis.

Spectroscopic investigation has shown that solid solutions of yellow, green and blue color have different spectra characteristic for each of them. Theoretical interpretation of the absorption spectra has been considered.

Assumptions on Cr^{3+} and Cr^{6+} positions in the structure of the solid solutions have been proposed.

X-ray method was used to show disordering of the solid solutions. Solid solutions can be triclinic and monoclinic depending on chemical nature of addition, its amount and heat-treatment conditions.

Introduction

The main cementing mineral of commercial clinkers-$3CaO \cdot SiO_2$-always contains some amount of additions occurring in the lattice in the form of solid solution. Chemical nature of the addition, its amount and heat-treatment conditions considerably change the structure of the silicate and consequently, its chemical and technical properties.

Among the studied solid solutions of $3CaO \cdot SiO_2$ with other components, chromium solid solutions are of special interest because of the presence of a cation of variable valence in the lattice.

Experiment

The tested samples were obtained by annealing in air in a Pt–Rh furnace at temperatures 600–1500°C and in argon at 1600–1800°C using a tungsten vacuum microfurnace.

The synthesis of the samples was realized according to the method described by Boikova and Toropov (1). Solid solutions of the yellow (at 600°C in air), green (at 1500°C in air), and blue (at 1600–1800°C in argon) color were obtained.

Most of the tests were carried out at temperatures 1450–1500°C in air under conditions near to practical ones.

Methods of Investigation and Results

The preference was given to the study of the solid solutions of the green color. The blue and the yellow solid solutions were examined in connection with the question of the influence of oxidation-reduction conditions on the chromium valence.

By means of optical, X-ray, DTA and chemical (determination of free CaO) methods it was found that

*Grebenshchikov Institute of Silicate Chemistry of the Academy of Science, Leningrad, U.S.S.R.

the limiting solid solution contained only 1.5 wt % Cr_2O_3, had light green color and refractive indices higher than those of pure $3CaO \cdot SiO_2$:

$Ng_{Na} = 1.726 \pm 0.003$ and $Np_{Na} = 1.722 \pm 0.003$

Characteristic property of the solid solutions with Cr_2O_3 is their instability. If Cr_2O_3 content in the mixture exceeds 2 wt %, there occurs the decomposition of the solid solutions with formation of free CaO and crystals of the green color brighter than the solid solution itself and representing one of the high-temperature forms of dicalcium silicate stabilized by Cr_2O_3. Their refractive indices are as follows:

$Ng_{Na} = 1.767 \pm 0.003$ and $Np_{Na} = 1.754 \pm 0.003$.

With increasing Cr_2O_3 content in the mixture the amount of the solid solution $3CaO \cdot SiO_2$ with Cr_2O_3 decreases, and at more than 5 wt % Cr_2O_3 no formation of the solid solution is observed.

Differential Thermal Analysis

DTA curves in Figs 1 and 2 show polymorphous transformations most characteristic of pure $3CaO \cdot SiO_2$, where two brightly expressed effects are observed at 920° and 980°C (Fig. 2, a).

One of the interesting phenomena detected in the DTA curves is the splitting effect of the curves for solid solutions with 1.5 and 2 wt % Cr_2O_3 (Fig. 1, c, d).

The DTA curves also show that with increasing Cr_2O_3 content in the samples, the amount of $3CaO \cdot SiO_2$ solid solution with Cr_2O_3 decreases while in the samples with 5 %Cr_2O_3 and 95% $3CaO \cdot SiO_2$ the solid solution does not form. Endothermic effects in the temperature regions 700–800°C, 1000–1100°C and 1200–1300°C characterize the phases developed as a result of the decomposition (Fig. 1, e, f, g). The splitting of endothermic effects is characteristic of the state preceding the decomposition.

In the study of the solid solutions between $3CaO \cdot SiO_2$, Cr_2O_3 and MgO, the presence of magnesium in the lattice was found to prevent the decomposition. DTA curves for the solid solutions with MgO (Fig. 2) allow to observe the phenomenon opposite to that characteristic of the curves for the solid solutions without MgO. With increasing MgO content in the solid solution two endothermic effects converge, and in the sample curves two endothermic effects fuse into a single effect (Fig. 2, d, e, f).

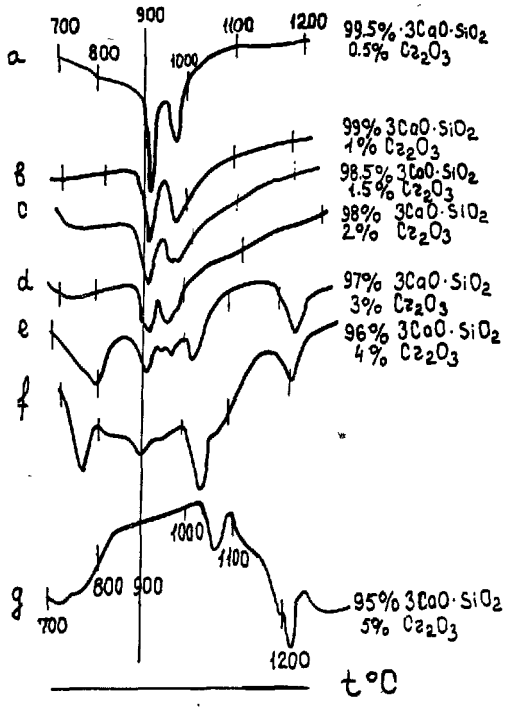

Fig. 1. *DTA curves of the solid solutions with* Cr_2O_3.

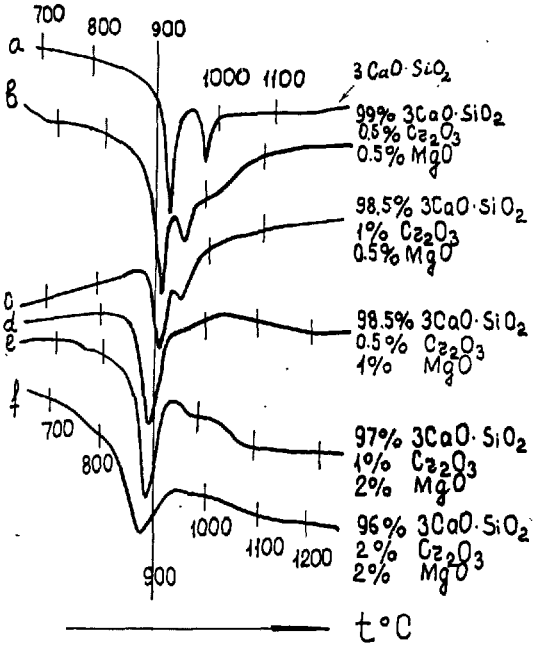

Fig. 2. *DTA curves of the solid solutions with* Cr_2O_3 *and* MgO.

X-ray Analysis

X-ray diffraction patterns of pure $3CaO \cdot SiO_2$ represent complicated lines changing their shape and intensity in relation to certain factors: chemical nature of the addition, its amount and heat-treatment conditions. In Figs. 3 and 4 are given most characteristic areas of X-ray diffraction pattern for the solid solutions at the angles 2θ 32–34° and 51–53°.

Analysis of the diffraction effects show that depending on the nature of the addition (Fig. 3, b, c) and heat-treatment conditions (Fig. 4, b, c, d), distances between the effects change, splitting or fusing of some of them and redistribution of the intensities are observed. These factors indicate the disordering of the solid solution lattice. Solid solutions may be both triclinic and monoclinic depending on the nature of the addition, its amount and heat-treatment conditions.

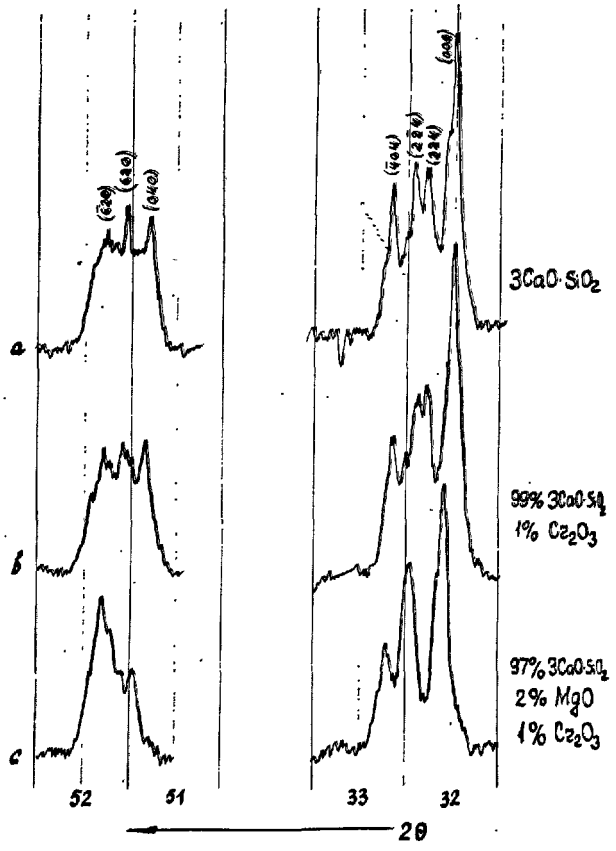

Fig. 3. *X-ray diffraction patterns of the solid solutions with* Cr_2O_3 *and with* Cr_2O_3 *and* MgO.

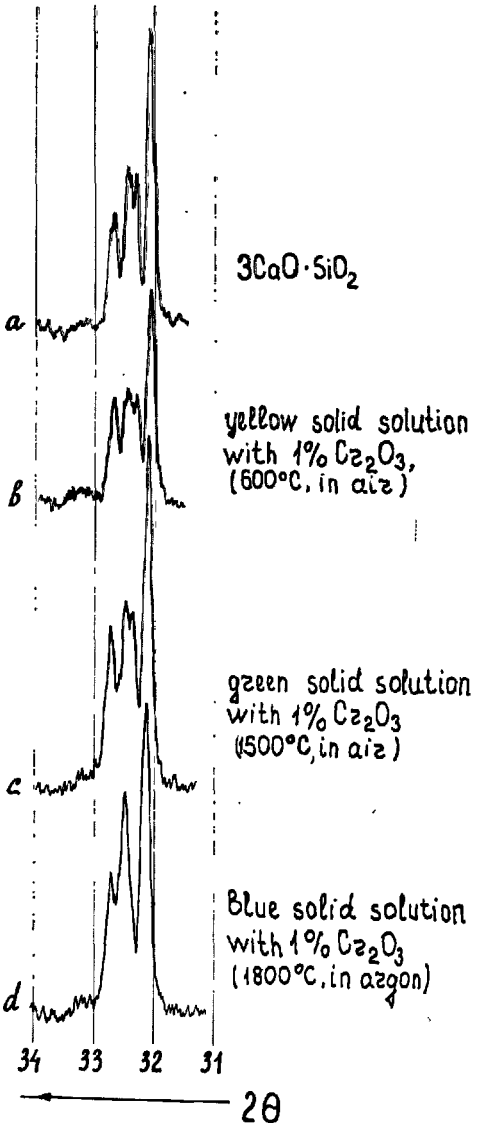

Fig. 4. *X-ray diffraction patterns of the yellow (b), green (c), and blue (d) solid solutions.*

Chemical Analysis

Depending on the change in the oxidation-reduction conditions of the experiment, the oxidation degree of chromium altered, too. Thus, it was found by chemical analysis that solid solutions of the yellow color obtained in air at 600°C contained mainly Cr^{6+}. Solid solutions heated in air at 1500°C got green color and

showed the presence of both Cr^{6+} and Cr^{3+}. Heating in vacuum in argon under gas pressure of about 7–8 psi at 1600–1800°C produced solid solutions of blue color. According to the chemical analysis data, these samples contained mainly Cr^{6+}.

Table 1 represents results of the chemical analysis of the solid solutions with Cr_2O_3.

Optical Investigations

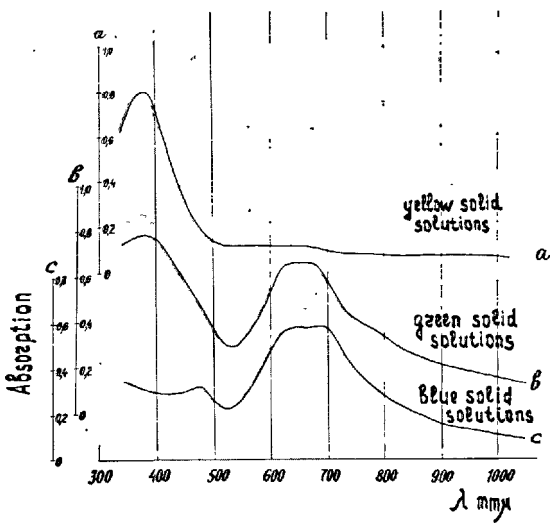

Fig. 5. *Absorption spectra curves of the yellow (a), green (b), and blue (c) solid solutions.*

Fig. 5 shows the absorption spectra curves obtained on a spectrograph SF-4 for polycrystalline samples in the region 340–1100mmμ under reflected light. The absorption spectrum curve for the yellow sample represents one band in the shortwave range with a maximum at 380 mmμ. The absorption spectrum of the green solid solution exhibits two bands (Fig. 5, b): one corresponding to the intense band of the yellow sample with a maximum at 380 mmμ and the other-to the broad band of the blue sample with a flat maximum in the wavelength range 640–700 mmμ. The blue crystal spectrum displays two absorption bands: an intense broad band with a flat maximum in the wavelength range 640–700 mmμ and a considerably more narrow weak band with a maximum at 470 mmμ (Fig. 5, c).

Discussion

According to the chemical analysis data for the yellow solid solutions and to the conditions of the synthesis providing the maximum degree of Cr oxidation, the absorption band at 380 mmμ characterizes Cr^{6+}. The blue solid solutions contain mainly Cr^{3+}. Two absorption bands—a broad one with a maximum at the wavelength region 640–700 mmμ and a narrow weak band with a maximum at 470 mmμ-characterize Cr^{3+}. Though in the samples heated in vacuum there was chiefly found Cr^{3+}, nevertheless conditions of vacuum could provide formation of chromium with lower valence, namely Cr^{2+}, as a result of partial reduction or possible disproportionation of Cr^{3+}. But according to the method of chemical analysis

used by Boikova, Toropov, Grum-Grzimailo and Piryutko (2), it was impossible to determine Cr^{2+} in the presence of Cr with valence higher than three. Theoretical interpretation of the absorption spectra given by Sviridov and Boikova (3) permits to suppose the occurrence of Cr^{2+} in the blue solid solutions, too.

The absorption spectrum of the green solid solutions seems to represent a summary curve of two spectra: one—for the yellow sample (with Cr^{6+}) and the other —for the blue one (with Cr^{3+}). Chemical analysis data for the green solid solutions show that crystals really contain both Cr^{6+} and Cr^{3+}.

In the lattice of $3CaO \cdot SiO_2$ additions may occupy three positions: to substitute isomorphously Ca^{2+} and Si^{4+} and to be placed in the holes whose occurrence was stated by Jeffery (4) in studying the fine structure. Cr^{6+} ($\tau_k = 0.35$Å) probably substitutes Si^{4+} ($\tau_k = 0.39$Å) in tetrahedral coordination. The substitution proceeds with formation of vacancies according to the scheme $3Si^{4+} \rightleftarrows 2Cr^{6+} + \square$.

In case of Cr^{3+} ions, the octahedral coordination is most advantageous, and in our opinion, isomorphous substitution of Ca^{2+}($\tau_k = 1.04$Å) by Cr^{3+} in octahedral coordination takes places in the structure of the solid solutions: $3Ca^{2+} \rightleftarrows 2Cr^{3+} + \square$.

Supplementary Paper I-42 The Use of Thermogravimetric Measurements in Cement Chemistry

Paul Longuet*

Synopsis

In this paper the contribution of the thermogravimetry to the chemistry of cements is reported with a particular mention of the works carried out at the CERILH (Centre d'Etudes et de Recherches de l'Industrie des Liants Hydrauliques).

After a short map of generalities the characteristics of the thermogravimetric measure are specified and the essential contribution of the quantitative ponderable balance to the interpretation of thermograms is shown.

Next it is suggested to present the bibliographical analysis of the works starting from the principal thermoponderable reactions met in the chemistry of cements, particularly the heterogeneous equilibria solid-gas, in presence or no of the equilibrium gas, of the type hydration-dehydration, carbonation-decarbonation, oxidation-reduction, adsorption-desorption.

In this summary, two examples will only be quoted:

1. In the scope of the general reaction hydration-dehydration the use of the equilibrium:

$$\underset{\text{(solid)}}{Ca(OH)_2} \qquad \underset{\text{(solid) (gas)}}{CaO + H_2O}$$

for the investigation and the determination of "free" CaO and $Ca(OH)_2$, for the reactivity of $Ca(OH)_2$ in complex systems and for the hydration in the vapor phase of the system $C_3S + C$.

2. In the scope of the general reaction carbonation-decarbonation, the use of the equilibrium:

$$\underset{\text{(solid)}}{CO_3Ca} \qquad \underset{\text{(solid) (gas)}}{CaO + CO_2}$$

for the measurements of reactivity in the systems calling into action CO_3Ca (synthetic mixes, raw mixes), for the study of C_3S behaviour in CO_2 and its determination in the complex powdered mixtures and for the evolution of the system CO_3Ca–SiO_2–CO_2 under atmospheric pressure in presence of mineralizers with the showing and the synthesis of spurrite $Ca_5(SiO_4)_2CO_3$.

The conclusion shows the research possibilities given by the thermoponderable analysis and the continuous weighing applied to the chemistry of cements.

Thermogravimetry allows one to measure in a constant way the changes in weight, as a function, either of temperature or of time, of a sample undergoing a given thermic treatment in a definite atmosphere.

The conception of continuous weighing goes back to the beginning of the century. The first reference to it seems to be that of Nernst and Riesenfeld (1) and the thermobalance was invented by Honda (2). Reference can be made to an excellent historical summary of the question in the book of Clement Duval (3).

*Centre d'Etudes et de Recherches de l'Industrie des Liants Hydrauliques, Paris, France.

Apparatus

Thermogravimetry may be used, as a rule, to study all the physico-chemical systems the evolution of which occurs with a ponderable change. This highly general use of the method is the source of an impressive number of laboratory devices and various commercial applications. In the present work, only the general principles will be quickly commented on, in referring to notes 3 and 5 for the essential descriptions and the drawing up of a fairly complete list of the different models we put forward.

A thermobalance has 3 essential components: the balance, the thermal and the recording components.

The Balance Component

This component may be divided into two large sections according as the change in weight is measured either by a deviation (deflection balances) or by the value of the restoring force to return to the original null-point (compensation or null-point balances).

In both cases the same weighing arrangements are used in the laboratory apparatus: conventional analytical balance, more or less modified, wire suspension balance, torsion balance, helical springs in silica glass or in invar, strain gauges... These instruments can weight from one milligram to one hundred grams, the sensitivity being of about 10^{-6} times the weight.

In the deflection balances, the deviation generally in proportion to the change in weight, can be measured with an optical collector (a turning mirror), electric collector (feeler with mechanical deviation), a magnetic, photo-electric, ionizing collector.

In case the collector should exert no stain on the deviation, the initial properties of the balance which is used remain entirely the same. One may reproach this type of instrument with having an area of measures relatively narrow bound to the sensitivity. Moreover, the deviation may binder direct actions on the sample (simultaneous measures, magneto chemistry...)

In the null-point, any change in balance is at once counterbalanced. This compensation entails, first, the detection of the lack of balance (electric, electrostatic, magnetic, photo-electric and ionizing collectors). This detection must have a sensitivity higher than that of the weighing arrangements which are used. The feed-back force may either have a mechanical origin (deviation of a chain bound to the beam, torque, electro deposit, hydrostatic pull on a diver), or be of an electric nature (action of a magnetic field on a permanent magnet, an iron core, or a mobile coil). Sometimes, the same arrangement provides for both the detector and the compensation. With the null-point the sample keeps a fixed position, which increases the number of possible measurements (connector without feed-back torque permitting electric connections or direct gas admission, sedimentometric analysis....).

The Thermal Component

As a rule, it is the thermal resistance of the sample holder which limits the temperature of thermogravimetric measurements which can be effected either in constant temperature, or according to a definite thermal cycle.

For low temperatures, one uses liquefied gases or refrigerating machines (from about −80° C), around the room temperature the thermostats or conventional drying ovens, and, at last, electric ovens for higher temperatures (nichrome resistor up to 1,200°C, platinum, alloy of platinum or rhodium, from 1,200 to 1,700°C, graphite or tungsten (under vacuum up to 3,000°C (16),). One must secure, first, a homogeneous thermal area around the sample, then in the case of the thermal cycle, carry out a continuous temperature change vs time in a determined programme, (generally linear). These requirements set delicate problems in the designing of ovens, problems of regulation and of planning which have been rightly resolved, in several different ways mainly up to 1,600°C.

The Recording Component

This component must ensure the recording of changes in weight and that of temperature. The recording of these two variables vs time on a same diagram is preferred to the recording in X—Y in order to allow the immediate examination of the incidence of a casual thermal anomaly on the weighing curve.

The type of balance and the method of regulation of temperature make one decide on the type(s) of recorders to be used.

Additional Devices

Most of the apparatus, to-day, permit one to work either under vacuum or in a controlled atmosphere by atmospheric pressure, whilst higher pressures need very special apparatus.

The gases evolved during the reaction may often be collected quantitatively. Many thermobalances

permit one to associate differential thermal analysis (DTA) to thermogravimetry (TGA) so as to complete understanding of the thermal effects occuring in the studied system, although it often happens that the ideal thermal conditions for each technique are not simultaneously fulfilled. Many commercial thermobalances now put on the market offer this possibility which often leads to make easier the comparison between the curves, to draw also, on the same diagram, the derivated thermogravimetric curve (DTGA) achieved by electric or electronic treatment of the direct TGA information. Densitometric (gas and liquids), tensiometric, magnetochemical, sedimentometric, chromatographic measurements... can as well be effected with the thermogravimetric apparatus (8).

Thermogravimetric Measurement

The use and interpretation of the experimental values achieved with a thermogravimetric apparatus must take into account the conditions which are peculiar to the measurement. The problems having been raised lead to a lot of published works we referred to in the general articles already quoted (3) to (15). In this study we will only give the essential points of the problems.

The Thermogramme

The changes in weight plotted against temperature, as showed in Fig. 1, represent the most commonly faced aspects. A plateau shows that there is no weighing change. An isolated weighing change—A—shows a continuous loss of weigh $\Delta\omega$ characterized by an initial temperature t_i and a final temperature t_f (the value of $\frac{d\omega}{dt}$ which starts from zero, goes up to a maximum and goes down to zero, generally allows a strict definition of t_i, t_f and also t_m corresponding to a maximum). In the case of simultaneous weighing changes (chosen with opposed signs in B part) $\frac{d\omega}{dt}$ is not reduced to zero. These reflections show the advantage of the simultaneous recording of the TGA and DTGA values.

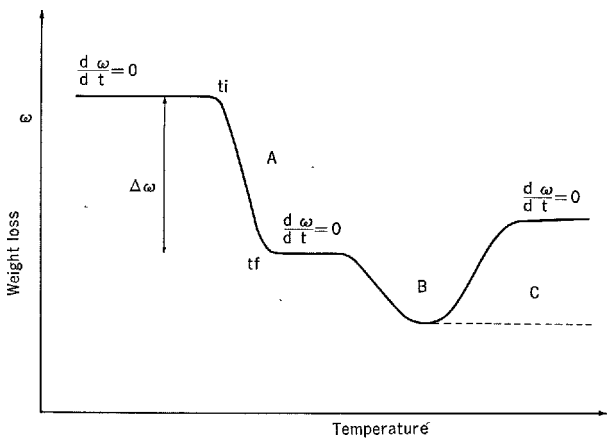

Fig. 1. *Schematic thermogramme.*

Measurement of Temperatures

Any influence preventing the instantaneous homogeneous distribution of temperature alters the real value.

Influence of the Collector

The measurement of temperature depends on the position of the collector (usually a thermo-electric torque). The optimum position enabling one to obtain the real value is the center of the sample. This condition is now often fulfilled, in the apparatus specially in those achieving simultaneously TGA and DTA.

Influence of the Studied System

Weight, volume, calorific capacity, thermal conductivity, reaction heat, state of subdivision, compactness, sintering, apparition of a liquid phase and any other cause which can be the start of a temperature gradient disturbs the measurement.

Influence of the Crucible or Sample Container

In addition to its own thermal inertia, this fitting determines the importance of the interface system-wall and marks the limits of the free area of the sample (catalytic effects—gaseous exchanges).

Influence of the Thermal Cycle

All the other conditions remaining the same, a more rapid heating rate strengthens the heterogeneity of the temperatures due to the previous influences. The deviation can reach tens of centigrade degrees for a sample of about one milligram, under requested conditions of temperature, with a speed varying from one to three.

Influence of the Gaseous Environment

This influence has an effect on the conditions of the

balance gas-solid and must be considered as an influencial factor, and not as a disturbing factor.

Measurement of Weights

Any influence liable to exert an action on the balance of the weighing devices apart from the changes in weight of the system must be either taken into account, or suppressed.

Influence of the Gaseous Buoyancy

The gaseous atmosphere surrounding the sample container, the crucible and its content, exerts on the whole a pressure function of temperature, nature of the gas and gas flow too, in the case of a renewed atmosphere. In spite of the different trials of a priori calculation, the rectification is most often effected by achieving a blank test in the expected conditions. This rectification is almost always indispensable.

A lowering of pressure permits the buoyancy to be reduced but phenomena of molecular pressure occur when the average molecular courses reach the value of the chamber dimensions.

A dependent shell reduces this effect but hinders the gaseous exchanges. Devices also exist allowing to act in presence of corrosive gases.

Influence of Convection

The crucible must be at best protected by shields against the turbulence resulting from the overheating of the gaseous atmosphere.

Various Influences

The distortions obtained by expansion of the weighing system must be avoided by keeping isotherm the balance housing.

In microthermogravimetry (weighing at a 10^{-9} g.) radiometric and electrostatic effects are to be taken into consideration.

Standardization of the Thermogramme

The buoyancy rectification being most often enough to achieve correct variations in weight, the exact values of the reaction temperatures are the most difficult to reach, and a certain number of thermogravimetric standards allowing interesting comparisons, have been proposed (18).

Anyway, it is advisable, when issuing a thermogramme, to state precisely as much as possible the experimental conditions and especially to indicate clearly which thermal cycle is used.

Interpretation of the Thermogravimetric Data

Thermogravimetry presents the fundamental advantage to obtain the weight balance of the studied reactions. This sound quantitative element has lead numerous authors to attempt the reckoning, from the thermogrammes, of a certain number of kinetic constants: the speed of polymerization, the order of the reactions, the activating energy (4), (5), (8). The evaluations are often long and delicate, but the expansion of the calculations, using an electronic computer, will certainly make this kind of application easier.

Present Tendencies in Thermogravimetry

The critical study of the disturbing causes in thermogravimetric measurement shows the advantage of working with very small quantities of substance.

The evolution will certainly go that way up to a compromise taking into account the easiness of measurements and the limits of representativity of the studied sample. Moreover, the simultaneous TGA, DTGA and DTA measurements on the same apparatus will be generalized.

Fundamental Reactions

The heterogeneous solid-gas systems, or, more rarely, liquid-gas systems, under the general decarbonation-carbonation, dehydration-hydration, oxidation-reduction and desorption-adsorption forms, are at the origin of the main thermogravimetric studies concerning he cement chemistry. It is thus necessary to start with the study of basic reactions before dealing with the applications often involving several simple reactions (19).

Decarbonation-Carbonation

The CO_2 combinations take an important part, as well in the production as in its use and they deserve a detailed study.

Equilibrium $CO_3Ca \rightleftharpoons CaO + CO_2$

It has been the subject of numerous theoretical studies apart from the programme of the present work;

the Fig. 2 gathers the essential thermogravimetirc conclusions:

—In a current of gas, inert towards the system (air without H_2O and CO_2, nitrogen, argon, etc. . .) the plot of the curve (in dotted lines) is fixed by the variation of dissociation pressures, vs temperature, the evolved CO_2 being continuously withdrawn.

—In a current of CO_2 equilibrated with the atmospheric pressure there is no reaction up to the dissociation temperature at this pressure. Over that stage, the decomposition is quite rapid. During the cooling cycle, a rapid recarbonation, always incomplete and variable, is noticed. No compound of the $CO_3Ca \cdot CaO$ type, pointed out by Raoult (20) could be revealed.

Equilibrium $CO_3Mg \rightleftarrows MgO + CO_2$

Under the same conditions as those achieved for CO_3Ca the pure giobertite (CO_3Mg) gives the same curves as in Fig. 3.

CO_2 at the atmospheric pressure fairly changes the dissociation temperature of CO_3Mg and the resulting MgO does not fix CO_2 during the cooling. The reaction is practically irreversible.

Dehydration-Hydration

The process of the thermal elimination of water depends on its type of binding in the studied compound. The association of water with solids assumes very different forms and the numerous types of classification which are offered (21) do nothing else but stress the complexity of the problem. Bader's proposition (22) concerning the fixed water in a continuous way, and the water fixed in a discontinuous way fits perfectly with the thermogravimetric studies of the hydrated compounds of the cement chemistry for which a superposition of the different types of binding of water are often noticed. The thermogrammes must be achieved in well-controlled experimental conditions (well-defined law of the heating rate and definite water-vapor pressure) in order to allow an interpretation. The water-vapor adds a further difficulty during the treatment of the atmosphere by condensing on every "cool-point" for which it becomes saturing. To avoid this trouble, many devices have been proposed (23) (24). We will quote as the main basic reactions, those referring to the well-defined crystalline structured hydrates. For the hydrated phases imperfectly crystallized and sometimes unstable requiring the setting of a network of isobaric and isothermal curves, so as to state precisely the different equilibria of hydration, the excellent study by Lavanant on hydrated calcium aluminates will be referred to (24).

Equilibrium $Ca(OH)_2 \rightleftarrows CaO + H_2O$

The loss of water is bound to the disparition of the OH^- groups. The thermogravimetric study (23) is summarized in Fig. 4.

—In a current of gas, inert towards the system (air without H_2O and CO_2, nitrogen and argon. . .) the plot of the curve is the dotted one. The weight balance often shows an incomplete hydration and a light carbonation. The pressures of dissociation varying rapidly with temperature, the slope changes are quite clearly marked.

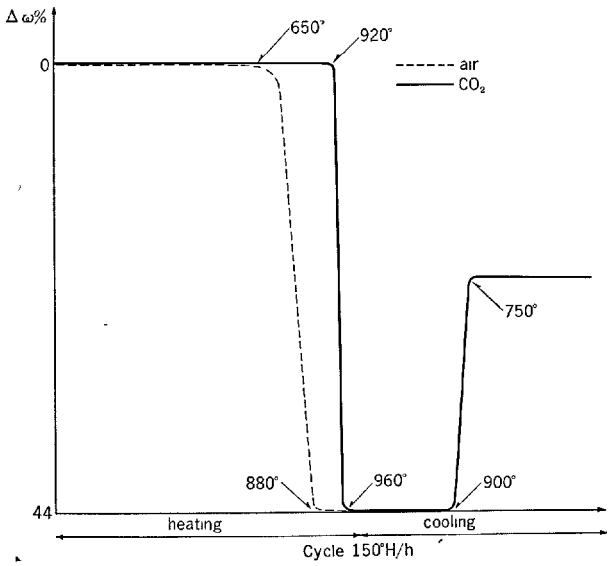

Fig. 2. $CO_3Ca \rightleftarrows CaO + CO_2$

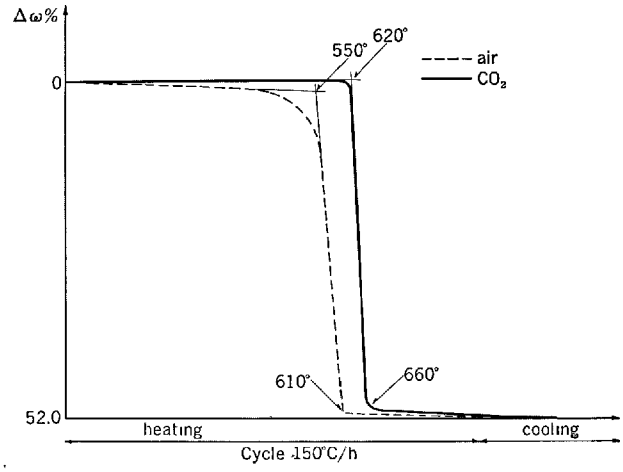

Fig. 3. $CO_3Mg \rightleftarrows MgO + CO_2$

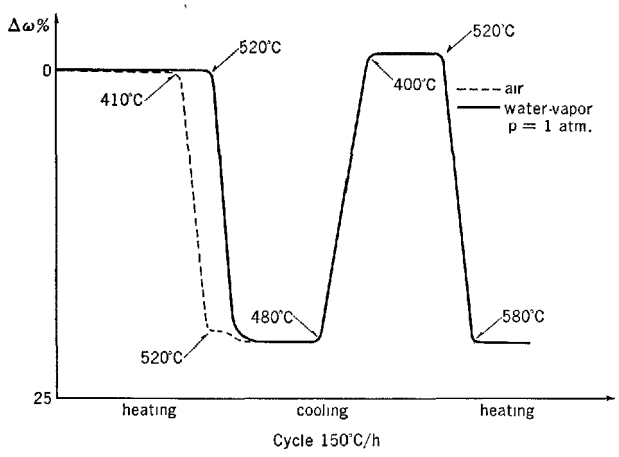

Fig. 4. $Ca(OH)_2 \rightleftarrows CaO + H_2O$

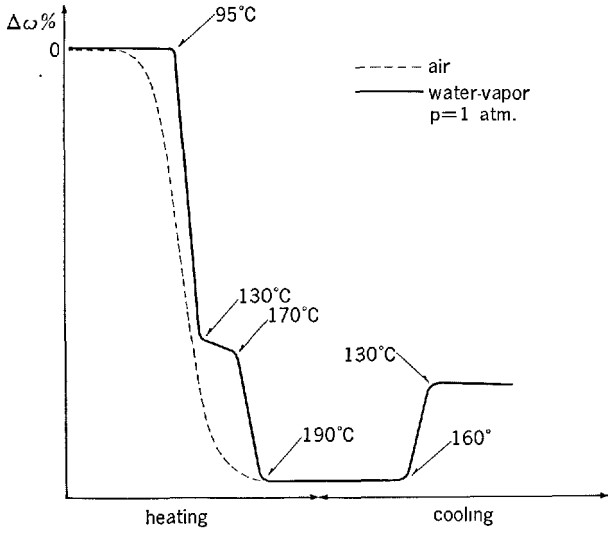

Fig. 5. $SO_4Ca \cdot 2H_2O \rightleftarrows SO_4Ca + 2H_2O$

—In a water-vapor saturated atmosphere, at the ambient pressure, (curve drawn in thick line), the dissociation temperature is clearly stressed. A series of hydration-dehydration cycles points out the previous remark about the weight balance by achieving a total rehydration after the loss of CO_2 and shows the perfect reversibility of the system.

Equilibrium $SO_4Ca \cdot 2H_2O \rightleftarrows SO_4Ca + 2H_2O$ (23)

In conditions similar to those achieved for $Ca(OH)_2$, SO_4Ca, $2H_2O$ provides the curves shown in Fig. 5.

The water-vapor saturated atmosphere makes clear the formation of hemihydrate. At this moment the rehydration is incomplete and variable according to the nature of the sample.

Oxidation-Reduction

Carbon, iron and sulphur elements or their compounds are mainly at the origin of the auto-reducing phenomena met in cement chemistry. The nature of the gaseous environment encompassing the sample gives rise to the different simple reactions liable to occur (19, 25).

Oxidizing Atmosphere

It is the most frequent case, the reactions occurring, most often, in presence of air. The action can be strengthened by the use of pure oxygen.

$C + O_2 \longrightarrow CO_2$

$SCa + 2O_2 \longrightarrow SO_4Ca$

$4Fe + 3O_2 \longrightarrow 2Fe_2O_3$ This reaction may occur from 400°C in CO_2 atmosphere with the oxygen resulting from the dissociation: $2CO_2 \rightleftarrows 2CO + O_2$

Neutral or Inert Atmosphere

Oxidation is hindered. Nitrogen, argon, helium and vacuum too, are used. However, the present reducers may then react with other components of the system during the increase of temperature. The reduction of sulphates by the carbon is a frequent example (19):

$SO_4Ca + 2C \longrightarrow 2CO_2 + SCa$

$SO_4K_2 + 2C \longrightarrow 2CO_2 + SK_2$ (the resulting alkali sulphide is volatile above 800°C and can be eliminated).

The relative initial concentrations of the reactants fix the reaction balance.

Reducing Atmosphere

Hydrogen is often used. The three reactions:

$SO_4Ca + 4H_2 \longrightarrow SCa + 4H_2O$

$SO_4K_2 + 4H_2 \longrightarrow SK_2 + 4H_2O$

(same reaction with $SO_3\ Na_2$)

$Fe_2O_3 + 3H_2 \longrightarrow 2Fe + 3H_2O$

are very important in cement industry. The reductant being in excess, the reactions are complete. The disadvantage comes from the secondary reaction of the possible interaction between the watervapor and the resulting sulphides (25).

Adsorption-Desorption

These phenomena are mainly used in the specific surface area measurements by gaseous adsorption for which the sluggish balancing and the very small changes in weight require special techniques (from 9 to 14). In the conventional measurements, disturbing effects are bound to changes of gaseous environment

(passage from H_2 to CO_2, for instance) during the same determination. They specially appear with systems of noticeable surface (from m^2/g.)

Real Systems

A real system is most often the site of several simple reactions. The following general cases may occur.

Distinct Reactions

It is the most simple case. Each reaction is marked by its characteristic temperatures and its importance measured by the corresponding change in weight.

Simultaneous Reactions

The curves are more or less mingled together and directly uninterpretable. One tries thus to make the balance factors varying in order to diversify the two reactions. A conventional example is given by the dolomite $(CO_3)_2Ca$, Mg which forms in the air, a continuous carbonation curve parting in two stages in a CO_2 atmosphere (see Figs. 2 and 3).

Competitive Reactions

There are simultaneous reactions with interaction.

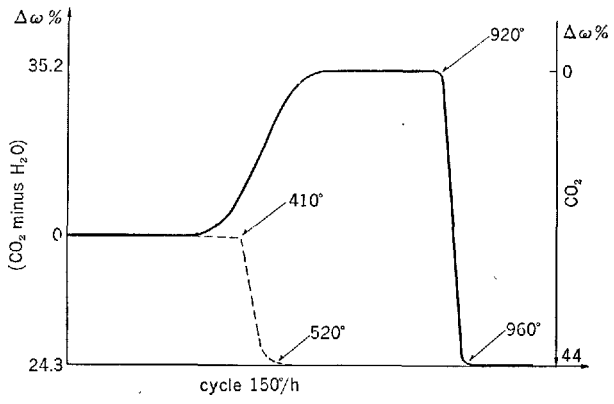

Fig. 6. —$Ca(OH)_2$ *in* CO_2 *atmosphere*
----$Ca(OH)_2 \rightarrow CaO + H_2O$ *in air*

The interpretation is delicate and additional measurements are often necessary (X-rays, diffraction, analysis of the gaseous compounds eventually evolving). Fig. 6 relative to the dehydration of $Ca(OH)_2$ in CO_2 atmosphere at the atmospheric pressure (19) illustrates a case of carbonation-dehydration competition. The weight balance and the thermogramme in inert atmosphere allow the complete understanding.

Applications

The applications will be introduced by following the conventional order of the different chapters of cement chemistry; the most characteristic researches will be stated if necessary for each of them.

Raw Materials

Clays

In cement chemistry the "clay-phase" is often wrongly defined and raises delicate problems of characterization (26). This is the reason why basic studies dealing with the thermogravimetric behaviour of definite mineral species (from 27 to 35), the influence of the particle sizes in same particular cases (36, 37), the grinding effects (38) or the formation of clay organometallic complex (39, 40) will certainly allow one to make the problem clearer.

Limestones

The determination of the CO_3Ca content does not generally present difficulties. The case of the simultaneous presence of CO_3Ca and CO_3Mg has been examined (19). Calcareous substances are often thermogravimetrically studied (41, 42, 43).

Raw Mixtures—Formation and Synthesis of the Spurrite

In this area, the problem of reactivity is raised. The principle of the thermogravimetric measurement utilizes the $CO_3Ca \rightleftarrows CaO + CO_2$ balance under a CO_2 pressure of one atmosphere. In such conditions a system containing CO_3Ca, does not show any loss of weight before the dissociation temperature (about 900°C) is reached, except if stable combinations with the present CO_3Ca occur. In the latter case the loss of weight before 900°C permits to estimate the "reactivity" of the system at this temperature (Fig. 7). On this basis, numerous studies have been carried out at the CERILH either on the technological level for calcareous pastes (45), raw mixes with or without mineralizers (46, 47) or in the fundamental research level, where the study of the CO_2–CaO–SiO_2 system in presence of small quantities of F_2Ca, has proved that the stable phase was the spurrite $(SiO_2 \cdot 2CaO)_2$ CO_3Ca which offers the thermogravimetric peculiarity of decomposing at about 980°C under CO_2 at

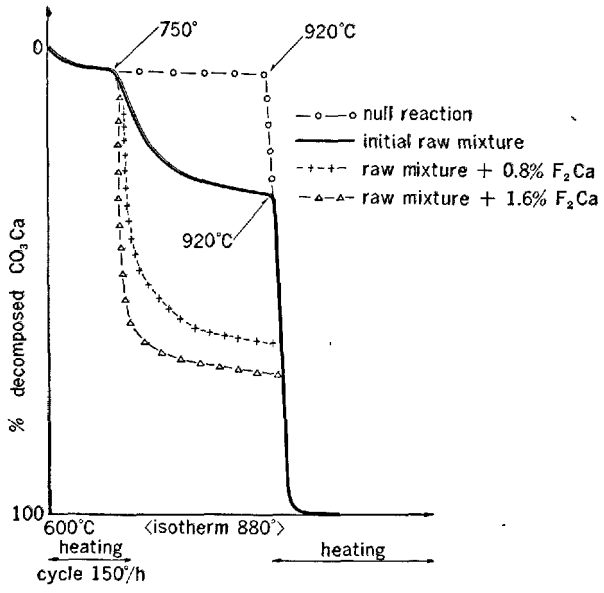

Fig. 7. *Reactivity of raw mixtures.*

the atmospheric pressure (48, 49). The compound synthesis has been described, with its main properties (50). The CO_2–CaO–Al_2O_3 system has been also partly studied in the same conditions and a compound of empirical formula $7\,Al_2O_3 \cdot 12\,CaO \cdot 2.5\,CO_3Ca$ pointed out (48).

Fuels

The fact of working either in an inert atmosphere (argon, nitrogen...) or in an oxidizing atmosphere permits and easy study and determination of the humidity, of the volatile substances and of the coal ashes (19 and 51).

Clinkers

The basic studies refer more specially to the pure clinker components (C_3S, C_2S, C_3A, C_4AF...).

Determination of C_3S

The systematic study of the behaviour of these components in CO_2 atmosphere allows to state that C_3S only (after the possible elimination of free lime) binds CO_2 according to the theoretical equation $SC_3 + CO_2 \rightarrow CO_3Ca + SC_2$. The importance of the binding allows one to estimate the SC_3 content. In reality, the reaction is more complex (19) and it really results in a mixture of spurrite and CO_3Ca. An addition of F_2Ca leads more rapidly to the compelte equilibrium (48, 53). This determination offers the advantage of being liable to be achieved on ground cement

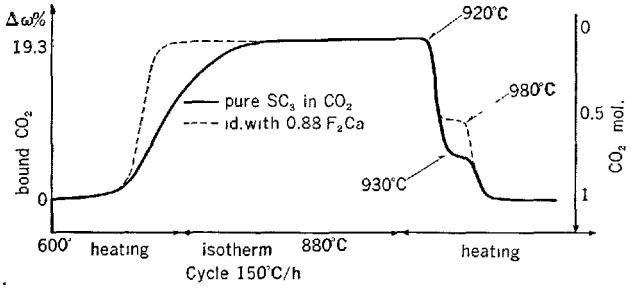

Fig. 8. *Reactions between* CO_2 *and* SC_3
—Pure SC_3 fixes one mole CO_2 per mole SC_3. A mixture of variable composition is formed. This binding allows the determination of SC_3 in clinkers.
----With fluoride, the reaction is faster and reproducible. Spurrite $Ca_5(SiO_4)_2CO_3$ is quantitatively formed as per equation $2SC_3 + 2CO_2 \rightarrow CO_3Ca + (SC_2)_2CO_3Ca$ (spurrite).

D. Oxidation of SCa 1,000°C by O_2 atm.

and of being of a precision comparable with the methods of determination by X-ray diffraction. (Fig. 8).

Oxidoreduction Reactions

The behaviour of the alumino ferrite phase and sulphated combination in hydrogen atmosphere, already mentioned (25) allows one to indicate the quantity of iron having reacted and the nature of sulphated phases existing by the action at 1,000°C, after reduction and elimination by volatilization of alkali sulphide, of CO_2 first oxidizing of reduced iron) then O_2 (oxidizing of SCa into SO_4Ca) (Fig. 9).

Preparation of Pure Compounds

The checking of the reactivity of the initial mixtures intended to the preparation of calcium silicates or aluminates has led to recommend the general method of coprecipitation from homogeneous solutions of the components (calcium nitrate, aluminium nitrate, colloidal silica gel. . . .) in order to obtain the close contact of the reagents (19). The fact that the weight balance is known enables one to verify the compound formula from the changes in weight: thus the $4\,CaO_3 \cdot Al_2O_3 \cdot SO_3$ compound has been made clear in the CaO, Al_2O_3, SO_3 system (54), the reactions of CO_3Ca with SO_2 in oxidizing environment have been stated (55) and the simple or composite ferrite stoichiometry has been better defined (56).

Addition Products

Calcium Sulphates

Before addition to the clinker, the nature of the sulphate ($SO_4Ca \cdot 2H_2O$, generally) and its purity are of easy determination. After grinding, the more delicate problem of the state of hydration is raised. Solutions have been offered for the mixtures of pure components, as plasters, for instance (57, 58) but the low relative sulphate content of cement makes the determination more complex.

Blast-Furnace Slags

The slags contain reductant substances and show a gain in weight after the roasting above 700°C in air environment. In inert atmosphere takes place the real loss (19). To the roasting, a devitrification is joined, and so the thermal analysis of a slag cement often uses both the two techniques DTA and TGA (48, 59, 60).

Thermic Power Station Ashes

No marked characterization for these products except the determination of the unburnt substances, made easier, if necessary, by a pure oxygen environment.

Cements

The Problem of Free Lime

The free calcium oxide of the clinker hydrates more or less completely during the making of cement and may, if noticeable quantities are left, cause prejudicial swellings after use. The usual chemical methods give the sum: $CaO + Ca(OH)_2$, the thermogramme measures $Ca(OH)_2$ and free CaO is deducted by difference. In order to avoid the uncertainties of the chemical titration, it is possible, by starting from Bied's observations (61) to achieve a preferential hydration of free CaO at 250°C in the water-vapor, at the atmospheric pressure. The comparison between the thermogramme, after the hydration and the thermogramme of the initial sample, allows an easy estimation of free CaO which may be corrected of a casual carbonation (Fig. 10). This method (62, 19) has been compared with the chemical or physical methods (63 and 64).

Aeration of Cements (19)

The hydraulic properties of a cement are altered when left for a long time in air environment. Thermogravimetry contributes to the study of this phenomenon (Fig. 11). The small variation of $Ca(OH)_2$ content seems to prove a superficial attack of the anhydrous components by atmospheric water and CO_2 with a cumulative formation of CO_3Ca and rather loose bindings of water which are shown by the dotted curve obtained after alcohol treatment according to Hayden (65). Besides the determination of C_3S which has already been described (19) shows the decrease of the content of this phase. Let us remark, too, a formation of syngenite $(SO_4)_2\ K_2Ca \cdot H_2O$ in a study on the clodding during aeration (66).

Loss on Ignition of Cements

When oxidizable compounds are lacking, the thermogramme differenciates the loss on ignition into three areas (Fig. 11). The first one corresponds to water fixed on SO_4Ca and eventually aeration water, the

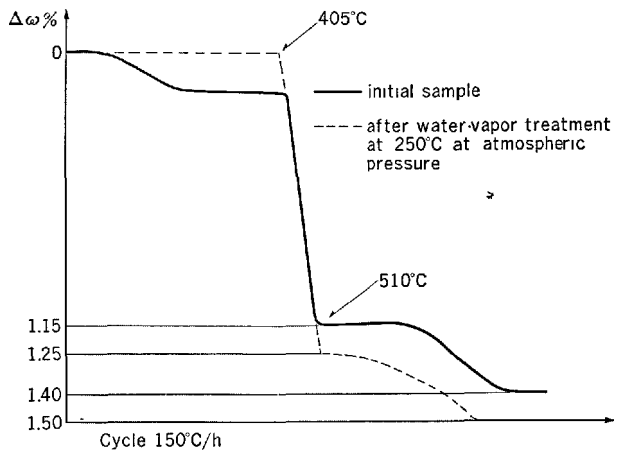

Fig. 10. *Determination of free* CaO *and* $Ca(OH)_2$. *Water loss due to the free* CaO *hydration:* $1.25 - 1.05 = 0.15\%$ *or in* CaO *content:* $\frac{0.15 \times 56}{18} = 0.46$

C. aerated cement treated by Hayden method.

second one to water fixed on $Ca(OH)_2$ and the third on to CO_2 fixed on CO_3Ca. In presence of reductors (slags, unburnt substances) an inert environment enables one to avoid the oxidizing but secondary reactions may be observed (62,19).

Hydrated Products

Hydration forms an important fundamental part of cement chemistry liable to have numerous thermogravimetric applications

Pure Compounds

The first study on the hydrates of cement chemistry appears to be Lefol's thesis (67). Since then the method has been often used to measure the stage of progress of the hydration reaction by evaluating the quantity of released $Ca(OH)_2$, (68, 69). As this quantity does not perhaps represent all the released lime (70) the DTGA brings some precisions (71, 72). The beginning of a thermogramme of an hydrated product depends on the evolution of the different existing hydrated phases; according to the heating rate and the water vapor pressure which are in the shell. Numerous checkings are necessary to definite the system, we have already referred to the study on the calcium aluminates (24). The zeolithic water may also be indicated in certain cases (73).

Cement Pastes, Mortars, Concretes

The technological studies are numerous. They use almost exclusively the changes of the $Ca(OH)_2$ content to follow the different studied phenomena: setting and hardening (74, 75), influence of thermal treatments (76, 77, 78, 79), resistance to corrosion (80) action of accelerators and retarders (81). The action of CO_2 under pressure on $Ca(OH)_2$ and the concretes have been subject to a particular examination (82). The pozzolanic activity of an addition can be evaluated by comparing the quantities of released $Ca(OH)_2$ during the hydration, in comparable conditions, for the same binder, either with an addition of pozzolane, or of an equal quantity of inert substance (19).

Various Considerations

We shall only mention, in this chapter, a certain number of references regarding articles issued from the previous headings but which have a general interest for cement chemistry. Application of thermogravimetric analysis to building materials, to the study of soils (83, 84), to refractory rocks (from 85 to 88), to different minerals: asbestos (89, 90), brucite (91), siderite (92), oxidized compounds (93), zeolites (94), phosphate cements (95) and at last to fundamental problems: action of fluoride on kaolin (96), dehydroxilation of kaolinite (97), study of Fe-Mg spinel (98), evaporation and dehydration (99) and on adsorbed water (100).

Supplementary Paper I-64 On the Color Change of Portland Cement

Kiyoshi Miyazawa and Kinzo Tomita*

Synopsis

The cause of the color change of portland cement in presence of a small amount of MgO is studied by measuring the electrical specific resistance of synthesized C_4AF–MgO solid solution. The result obtained shows that lightness L and specific resistance tend to decrease with increasing of MgO content in analogous inclination.

The experiment may suggest that C_4AF–MgO solid solution contains, in its structure, somewhat free electrons or positive holes, which would increase the conductivity and as well respond to any wave length of the visible spectrum; thus leading to color change in black.

In addition, the color change of portland cement with the increase of rate of cooling is studied by measuring the color, strength, and heat of hydration of the prepared cements. These clinkers are cooled from 1450°C in following methods: that is, slow cooling, quenching in air, and quenching in water. When the clinker is quenched in air, the color of cement is more darkened than that of the clinker cooled slowly. If the clinker is quenched in water, the color of cement becomes yellow with the highest lightness. Strength test shows maximum strength can be obtained when the clinker is cooled slowly from 1450°C to 1250°C or above and then quenched in air.

X-ray diffraction of the interstitial materials of these clinkers shows that the change of d-spacings with the increase of rate of cooling gives different inclination from that with the increase of C_2F content in system C_2A–C_2F.

When quenched in nitrogen, the color of the clinker becomes as yellow as that of the clinker quenched in water. X-ray diffraction patterns of the interstitial material of the clinker quenched in nitrogen agree with those of the clinker quenched in air. This fact may suggest that light color of the clinker quenched in water is not due to freezing the iron-containing liquid to glass, but to the absence of oxygen.

Introduction

Color of portland cement is changeable with innumerable factors. In this report, effect of MgO contained in clinker, and that of cooling rate were studied.

Effect of MgO on the Color of Portland Cement

The Color of the Prepared Cement (1)

It is well-known that portland cement is darkened by small amounts of MgO. K. Fujii and K. Asaoka (2) have took the lead in this subject. Practically, MgO is useful not only for obtaining a slate-gray color, but also for promoting a strength of the cement. However, the reason of the above color change has not been clarified yet.

Three kinds of original raw mixes of portland cement, i.e. normal type (type N), high early strength type (type H), and moderate heat type (type M) were made from pure chemical reagents to which magnesium carbonate were added so as to contain MgO 0 to 3% on nonvolatile basis. The chemical compositions of the clinkers resulting from original raw mixes are shown in Table 1. These raw mixes were burnt at 1450°C for half an hour. Produced clinkers were

*Sumitomo Cement Co., Ltd, Tokyo, Japan.

ground with adequate amounts of natural gypsum as shown in Table 2.

The color of the prepared cement was measured by means of the photo-electric color difference meter. The prepared cement was packed into a capsule made by transparent glass. The light beam was reflected at the capsule and the reflected light was converted to electric current by the photo-cells which were fitted in three windows with color filter. The color was measured reading the current and indicated L, a, and b color scale values (3). L indicates lightness, and $+a$, $-a$, $+b$ and $-b$ indicates degree of red, green, yellow and blue respectively (Fig. 1).

The color of the prepared portland cement was given in Fig. 2 as function of MgO content.

As to value L, all types of the cement have a minimum point in the range of 1 to 2% in weight of MgO.

The Color of Ferrite Phase (1)

The color of ferrite phase, which may principally dominate the color of cement, was examined. Raw mixes composed of the formula $4\{(1-x)\mathrm{CaO}\cdot$

Table 2. *Properties of the prepared cement*

	SO_3(%)	Specific surface (cm²/g)	F. CaO(%)
Type N	1.6	3200 ± 100	< 0.2
Type H	2.3	4300 ± 100	< 0.6
Type M	1.6	3200 ± 100	< 0.3

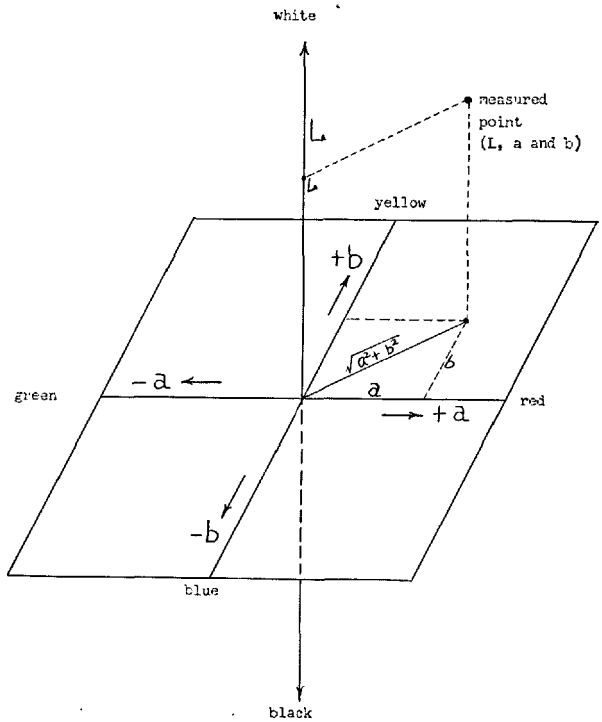

Fig. 1. *Color diagram of L, a and b color scale system.*

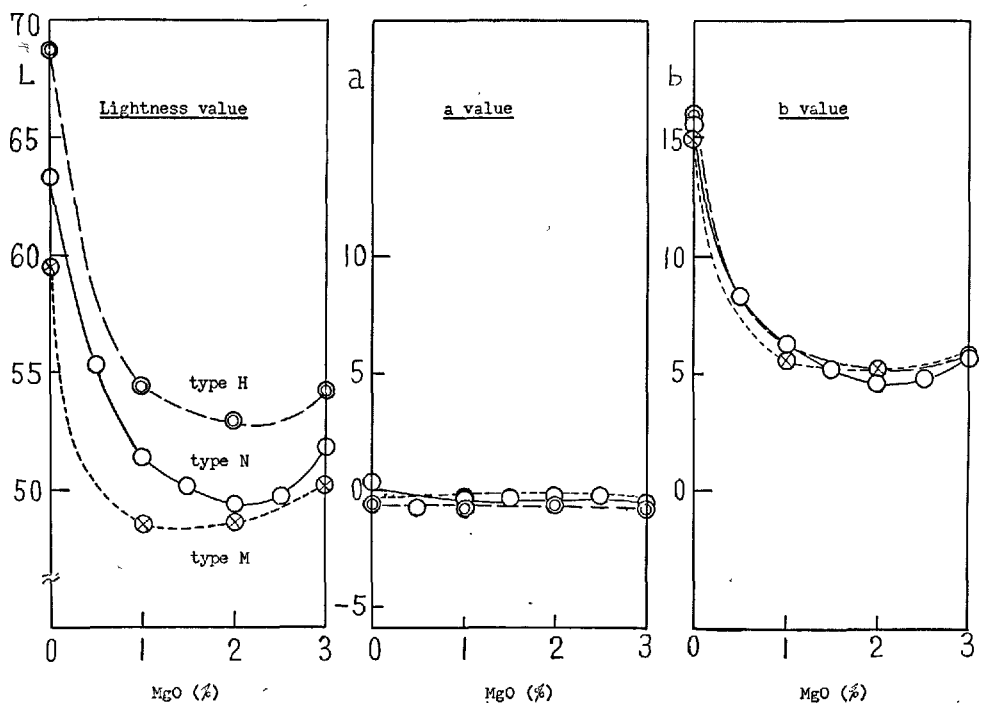

Fig. 2. *The color of the prepared cement.*

$xMgO\}Al_2O_3 \cdot Fe_2O_3$ were made from pure chemical reagents and burnt somewhat below their melting point and cooled quickly. The chemical compositions of the ground clinkers are shown in Table 3 and the lightness values of them are shown in Fig. 5.

Lightness L of the ferrite decreases with the increase of MgO content and has the minimum at 4.5 to 6 moles % of MgO, in agreement with the solubility limit of MgO in C_4AF, as clarified in our previous report (4).

Electrical Specific Resistance of Ferrite Phase

The ferrite shown in Table 3 were examined by X-ray diffractometer. In this study, it is found that d-spacing for (141) expands with the increase of MgO content and becomes unchangeable at 4.5 to 6 moles % of MgO; however, intensity of the reflection lines of X-ray diffraction is almost unchangeable. Therefore, cause of the color change cannot be explained by the slight change of crystal structure of ferrite phase directly.

In this report, the cause of above color change was studied by measuring the electrical specific resistance of synthesized C_4AF–MgO solid solution.

The specimens were made by compressing the synthesized ferrites in a steel mold under a pressure of 300 kg/cm², to form disks of 40 mm in diameter, about 5 mm in thickness and by reheating at 1200, 1250 and 1300°C respectively. The specimens were coated by the conductive silver coating material as shown in Fig. 3 and put between electrode as shown in Fig. 4.

Each of the specific resistance values of the specimens, as shown in Fig. 5, was measured by the microamperemeter at 50 volts and calculated from following formulas.

ρ: specific resistance (Ω-cm) $= A \cdot R/d$
A: available area of specimen (cm²) $= \pi \cdot r_0^2$, $r_0 = (r_1 + r_2)/2$
d: thickness of specimen (cm)
R: Resistance (Ω) = voltage/current

The bulk specific gravities of the specimens depended on the reheating temperature as shown by following results: — about 2.3 g/cm³, 2.5 g/cm³ and 3.2 g/cm³ at 1200°C, 1250°C, and 1300°C respectively; however, they did not depend on the MgO content. The result obtained showed that lightness L and specific resistance tended to decrease with the increase of MgO content in analogous inclination (Fig. 5).

Somewhat higher resistance of the specimens reheated at 1200°C may be affected with the insufficiency of

sintering. The curve of the specimens burnt at 1250°C almost agreed with that of the specimens burnt at 1300°C in spite of considerable difference of bulk specific gravities.

Discussion on the Color Change of Ferrite Phase by Small Amount of MgO

Because the color of C_4AF–MgO becomes darkest when MgO ranges from 4.5 to 6 mol. % (1.5 to 2% by weight), in agreement with the solubility limit of MgO in C_4AF, the above color change may be due to incorporation of MgO into ferrite phase. However, it is considered that the color change cannot be explained by a slight change of some spacings of C_4AF–MgO solid solution.

As mobility of ions increases at high temperature, specific resistance at high temperature may be affected by ionic conduction; however, above measuring being carried out at room temperature, the increase in the electrical conductivity was considered to be caused by the increase in electrons playing as carrier.

The experiment may suggest that C_4AF solid solution with MgO contains, in its structure, somewhat free electrons or positive holes, which would increase the conductivity and as well respond to any wave length of the visible spectrum; thus leading to color change in black (5). As an example, it is possible that positive holes are brought about by substitution of Mg^{2+} ions for Fe^{3+} ions.

Effect of Rate of Cooling on the Color of Portland Cement

Effect of Cooling Rate on the Properties of Portland Cement

In cement clinker burning, effect of cooling rate is more important for strength and heat of hydration of cement than the matter of color. On the color, it is said that the color of clinker quenched in air is darkened than that of the clinker cooled slowly. Light color of the clinker quenched in water takes advantageous to white cement production.

Two kinds of industrial raw mixes used in A or B works, were put into a electric furnace and heated at a rate of 180°C/hour and held at 1450°C for half an hour. After burning, they were cooled by five following methods:—

a) cooled slowly: the clinkers were cooled at a rate of 100°C/hour up to 1000°C; and then cooled with the furnace to room temperature.
b) quenched in air (1250): the clinkers were cooled at a rate of 200°C/hour up to 1250°C; and then taken out from the furnace to air.
c) quenched in air: immediately, the clinkers were taken out from the furnace to air.
d) quenched in water (1250): the clinkers were cooled at a rate of 200°C/hour up to 1250°C; and then the clinkers taken out from the furnace were put into water and dried.
e) quenched in water: immediately, the clinkers taken out from the furnace were put into water and dried.

The chemical compositions of the clinkers quenched in air are shown in Table 4.

Produced clinkers were ground with adequate amounts of natural gypsum containing 44.6% of SO_3 as shown in Table 5. The color of the prepared cement was shown in Table 6.

When the clinker is quenched in air, the color of cement is more darkened than that of the clinker cooled slowly. If the clinker is quenched in water, the color of cement becomes yellow with the highest lightness as shown in Table 6. The difference of color between A and B is small because the specific surface, and Fe_2O_3 or MgO content of the cement A are almost equal to the cement B.

In addition, the color of the cement almost depends on the color of its ground clinker containing no gypsum. At same finesnes, the color of the cement is almost equal to its ground clinker.

The strength of these cement mortars was measured by means of JIS R 5201 and heat of hydration was tested also by means of JIS R 5203. The result obtained is shown in Table 7 and Table 8.

Industrial cement*	48.1	±0.0	+7.3	50.4	−0.3	+7.3

*These industrial cements are produced by A or B works. Chemical composition and fineness are somewhat different from the prepared cement.

It is well-known that the higher strength of cement is obtained when a clinker is cooled slowly from the sintering temperature to about 1250°C, and then quenched in air. As shown in Table 7, this result agrees with this experience. Moreover, maximum strength is obtained when clinker is quenched from higher temperature above 1250°C. The cement prepared from clinker of water quenching shows retardation of setting and lower strength at 3 days; but the strength of 28–91 days approaches to that of air quenching.

Heat of hydration may tend to increase correspondingly with their strength; however, the difference of heat of hydration with the increase of cooling rate is so small that the ratio of heat of hydration to strength for higher strength cement is smaller than that for lower strength cement.

The color of hydrated cement paste was measured also. The color of hydrated cement may be considerably changeable depending upon its hydrating conditions.

In this test, the cement prepared above was mixed with water (W/C = 0.30), spread on glass plate and then cured in damp closet for 24 hours, and then the specimens were put into boiling water for 90 minutes, and dried in air.

The surface color of the prepared specimens was measured and the results were shown in Table 9.

In roughly speaking, the color of hydrated cement paste depends on the color of dry cement; however, the difference in the lightness values of hydrated cement is smaller than that of dry cement and the lightness values of cement cooled slowly are rather lower than that of cement quenched in air. The lightness values of the hydrated cement B containing high calcium are higher than those of the hydrated cement A containing low calcium.

X-ray Diffraction of the Residue after Salicylic Acid Treatment of the Clinkers

The color change of portland cement with the increase of cooling rate was studied by means of X-ray diffraction of the residue after salicylic acid treatment of the clinkers shown in Table 6. Since X-ray diffraction of clinker is not enough to provide information of ferrite or interstitial materials, which may principally dominate the color of clinker, ferrite enriched residue was prepared by means of treatment with salicylic acid proposed by Satō, Takashima and Katō (6).

The residue was prepared as follows:—5 g of clinker was treated with 35 g of salicylic acid and 200 ml of methanol, stirred for 30 minutes, filtered and dried. The typical chemical composition of the residues is shown in Table 10. No appreciable difference of composition between A and B or among cooling rate was observed.

FeO was determined by titrimetric method with dichromate as titrant proposed by Ishii, Einaga and Watanuki (7). Loss of ignition and FeO content of water quenching specimens are somewhat greater than others.

X-ray diffraction patterns of the residue resulting from the clinker A are shown in Fig. 6. As internal standard, α-Al_2O_3 was used. Both the residues resulting from A and B clinkers showed almost the same X-ray patterns and d-spacings, except for difference of relative intensity of C_3A and ferrite.

The patterns of ferrite phase become broader and smaller with the increase of rate of cooling. It may show an increase of vitrified part. The d-spacings also change with the increase of the rate of cooling as shown in Fig. 7.

As the cooling rate is increased, d-spacing for (141) reflection expands, but d-spacings for (002) and (202) reflections shrink. This shrinking phenomena gives contrary inclination comparing with that the spacings for (002) and (202) reflections expand with the increase of C_2F content in system C_2A–C_2F.

The result of Fig. 7 suggests that crystalline ferrite

Table 10. *The typical chemical composition of the residues after salicyclic acid treatment of clinker—(%)*

Loss	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	FeO	
1.0	10.4	23.0	13.9	45.8	4.0	Cooled slowly:	0.12—0.19
						Quenched in air:	0.15—0.19
						Quenched in water:	0.26—0.30
						Industrial clinker:	0.10—0.20

in the clinker deforms by rapid cooling as well as its partial vitrification. When the lattice parameters are calculated from d-spacings for (141), (002) and (202), *a* is almost unchangeable, *b* expands and *c* shrinks with the increase of rate of cooling; however, somewhat different *a*, *b* and *c* values are given, when they are calculated from other d-spacings values. The cause of the crystal deformation cannot be clarified yet. Perhaps the change of co-ordination of some atoms may occur.

Above experiments indicate that the expansion of d-spacing for (141) does not always mean the increase of iron content in ferrite.

X-ray diffraction patterns and d-spacings for the residue resulting from the industrial clinkers (A and B works) almost coincide with those of the clinker quenched in air.

However, above experiments do not make clear the reason for the color change with the increase of the cooling rate.

Study of Clinker Quenched in Nitrogen

A raw mix from the same cement works as shown in Table 4-A was burnt at same process (1450°C–30 minutes) and quenched in a cylindrical vessel which had been filled with nitrogen. Comparative test was carried out, quenching this clinker in the above vessel which had been filled with air instead of nitrogen. The color of the ground cl nkers (specific surface: 3200 cm^2/g) is shown in Table 11.

The color of the clinker quenched in nitrogen agrees with that of the clinker quenched in water as shown in Table 6. Of course, the color of the clinker

Table 11. *The color of the ground clinkers quenched in nitrogen or in air*

	L	a	b
Clinker quenched in nitrogen	65.9	+0.1	+15.6
Clinker quenched in air	50.1	−0.5	+7.3

quenched in the vessel which is filled with air instead of nitrogen agrees with that of the clinker quenched in air as already shown in Table 6.

The residue after salicylic acid treatment of both clinkers gives similar X-ray diffraction patterns and d-spacings, which are almost equal to those of the clinker quenched in air (Fig. 8).

FeO content of the residue resulting from the clinker quenched in nitrogen and in air was 0.39 and 0.15 % respectively.

Thermal Gravimetrical Analysis and Differential Thermal Analysis

Both of the residues resulting from the clinkers shown in Fig. 6 and from the clinker quenched in nitrogen were tested by means of thermal gravimetrical analysis and differential thermal analysis. During operating temperature up to 1000°C, the color of the residues resulting from both the clinkers quenched in water and in nitrogen changed from yellow to black;

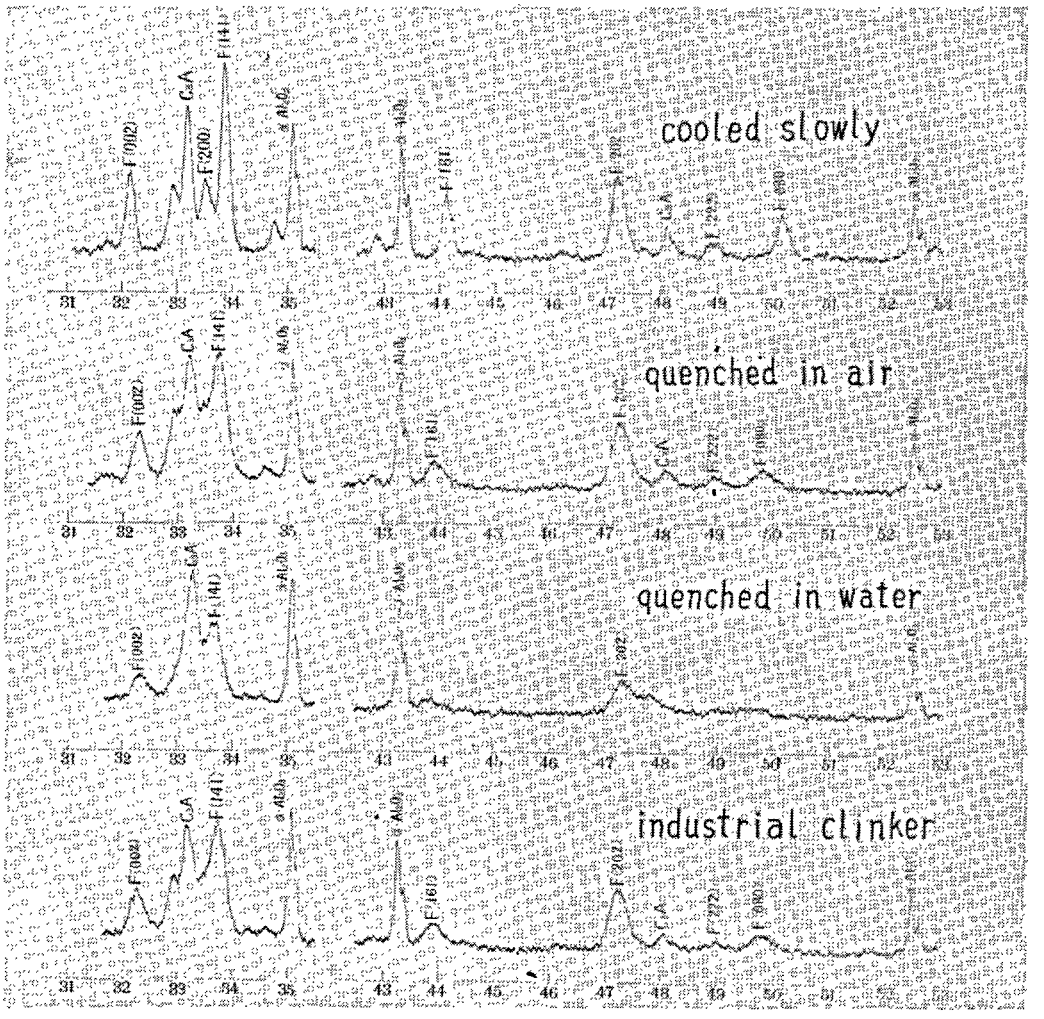

Fig. 6. *X-ray diffraction patterns of the residue after salicylic acid treatment of the clinkers.*
Target: Cu, Filter: Ni, Voltage: 40 KVP, Current: 16 mA, Time constant: 4 sec., Scanning speed: 0.25°/min., Divergence slit: 1°, Receiving slit: 0.15 mm, Internal standard: α-Alumina.

however, no appreciable thermal change was observed.

Operating condition of X-ray diffractometer is the same as Fig. 6.

Discussion on the Color Change of Portland Cement with the Increase of the Cooling Rate

There is a concept that the color change of portland cement with the increase of rate of cooling is due to the decrease of the amount of crystalline iron compound present and its replacement by glass (8). Generally, it may be considered that, in rapid cooling, MgO comprised in ferrite solid solution is released and dissolves in the liquid phase, and as a result the absence of MgO in crystalline ferrite leads to the light color of clinker.

However, the color of the clinker quenched in nitrogen became as yellow as that of the clinker quenched in water. This result suggests that the color change of the clinker quenched in water may not depend on freezing the iron-containing liquid to glass, but on the absence of oxygen in cooling process. Both in the water quenching and nitrogen quenching, the clinkers did not contact with oxygen in cooling process.

Though the color of the clinker quenched in nitrogen is considerably different from that of the clinker quenched in air, the X-ray diffraction patterns of their residues are almost equal as shown in Fig. 8. This fact suggests that the reason for the color change of the clinker with the increase of the cooling rate does not largely depend on the crystal structure of ferrite, but on the distribution of electrons which surround the ions constituting the crystal, as in the case of the C_4AF–MgO as shown in above. These information may rather be determined by electrical or magnetic methods.

The effect of oxygen to ferrite could not be clarified. Both by the fact that little FeO is present in the residues and by the results of thermal gravimetrical analysis and differential thermal analysis, it is suggested that no simple oxydation occurs.

It is doubtful that oxygen can diffuse into clinker grain within a few seconds. Peculiar mechanism of oxygen to ferrite phase may be concerned.

It could not also be clarified why the color of the clinker quenched in air is darkened than that of the clinker cooled slowly. Although a part of this may be due to the properties of C_2S, it may be chiefly due to the slight color change of the ferrite itself.

Moreover, microscopic or electron microscopic examination also should be carried out besides above testing methods.

The authors wish to express their gratitude for guidance and encouragement received from Dr. Eiji Anbo, Professor of Gumma University. We would like to thank Mr. Etuzō Kato, Chief of first section of ceramics department, Government Industrial Research Institute, Nagoya, for valuable information. Acknowledgement is also due to Mr. Hiroshi Narahashi, director of Sumitomo Cement Co., Ltd. for permission to publish this paper.

Oral Discussion

Kinjiro Fujii

I should like to make two questions. First, did you measure the photoconductivity of your material? Secondly, what is the temperature coefficient of the electrical conductivity? As I understand, these measurements will help you to interpret the mechanism of the electrical conduction of the material.

Authors' Closure

Kiyoshi Miyazawa and Kinzo Tomita

Neither of these properties you mentioned has been determined yet. I agree with you in that such measurements are necessary for understanding the mechanism of the electric conductivity more accurately. Since these are the iron-containing compounds, the partial pressure of oxygen should be taken into consideration in order to clarify the relationship between the temperature and the electric conductivity.

Supplementary Paper I-76 Miscibilities of Special Elements in Tricalcium Silicate and Alite and the Hydration Properties of C_3S Solid Solutions

Renichi Kondo* and Kozaburo Yoshida**

Synopsis

The purposes of this study are, firstly, to determine the miscibilities of special elements such as Ti and Mn in C_3S and alite and, secondly, to elucidate the hydraulic properties of these solid solutions.

The compositions lay in the hypothetical systems, C_3S–$3CaO \cdot TiO_2$, C_3S–$3CaO \cdot MnO_2$, alite-$3CaO \cdot TiO_2$ and alite-$3CaO \cdot MnO_2$. To synthesize the sample, each mixture was heated at 1500°C or 1600°C and air-quenched.

The limit of miscibility and the modification of the synthesized solid solution were examined by means of chemical analysis, X-ray diffraction, microscopic observation and electron probe X-ray microanalysis.

It was found that Ti can substitute for 0.13 mole Si both in C_3S and alite and that their crystal lattice expands and their modifications change into the high-temperature forms through its substitution. In the case of dissolution of Mn, it was also found that Mn dissolves up to 0.06 mole in C_3S and up to 0.08 mole in alite. Their crystal lattice contracts very slightly and the modification of C_3S changes into the high-temperature form and that of alite changes into the low-temperature form through its dissolution.

Moreover, the effects of Ti and Mn on the hydraulic properties of C_3S and alite were studied. The samples used were C_3S, alite, and their solid solutions containing 0.07 mole Ti or 0.05 mole Mn. As shown formerly, these samples were prepared by heating at 1500°C.

The hydration on paste was investigated by means of calorimetry, X-ray diffraction and chemical analysis, and the mortar strength was also tested. It was found that the hydration characteristics of C_3S and alite are affected by the dissolution of Ti or Mn. In the Ti bearing solid solutions, the degree of hydration is lowest at early stage, but, after 3 days' curing, it becomes highest and the mortar strength also becomes highest. In the Mn bearing solid solutions, the degree of hydration and the mortar strength become higher at later stage. These results seem to be due to the chemical composition rather than to the change in the modification of C_3S or alite.

Introduction

An investigation on the behavior of additional special elements in cement compounds is considered not only interesting scientifically but also as enabling us to expect therefrom some technological advancement.

Above all, as alite is the most important hydraulic mineral in portland cement, many reports have been found on the miscibilities of Al and Mg, both and individual, and on the polymorphism of alite by Woermann, Hahn and Eysel (1–2), Yamaguchi and Kato (3), Locher (4) and Midgley and Fletcher (5).

Yamaguchi, Shirasuka and Ota (6), Nurse, Midgley, Gutt and Fletcher (7) and Ono, Uno and Soda (8) recently reported on the effects of the polymorphism on the hydration and mechanical strength of C_3S. However, no clear conclusion has yet been obtained, partly because this is due to the greater effects of some foreign elements added.

The miscibilities of minor or special elements such as Ti, Mn, P, S and Cr in C_3S or alite were studied by Kondo (9). The effects of these elements on the properties of cement had been studied in order to improve the hardening ability or utilize special raw materials for cement manufacture (10–12). Moreover, studies

* Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Tokyo, Japan.
**Central Research Laboratory, Ube Industries Ltd., Ube, Japan.

were made on the effect of F and P by Welch and Gutt (13), on Ti by Ershov (12) and on Mn by Sakurai (14). However, systematical studies on the limit of miscibility, type of dissolution, rate of hydration and mechanical strength have been scarcely made. The effects of additional special elements on the properties of alite containing Al and Mg, have not yet been reported.

The purpose of this study is to elucidate the miscibilities of Ti or Mn in C_3S and alite as well as their effects on the hydraulic properties such as the rate of hydration and the mortar strength.

The Miscibility of Ti or Mn in C_3S and Alite

Experimental Procedure

In order to clarify the limits of miscibily of Ti or Mn in C_3S and alite, the hypothetical systems, C_3S–$3CaO \cdot TiO_2$, C_3S–$3CaO \cdot MnO_2$, alite-$3CaO \cdot TiO_2$ and alite-$3CaO \cdot MnO_2$ were examined, on the assumption that Ti^{4+} or Mn^{4+} substitutes for the Si^{4+} in C_3S or alite up to a certain amount and that when the special element added exceeds this limit, the other low-lime compound will be formed, accompanying with the liberation of free CaO. According to the report by Woermann, Hahn and Eysel (1), the chemical composition of alite used in this experiment was CaO 71.08, MgO 2.14, Al_2O_3 1.01 and SiO_2 25.77%.

All these preparations were made by using guarantee grade reagents in Japanese industrial standards and quartz powder of high purity and smaller than 10μ in radius. Each mixture was ground, mixed thoroughly and then formed into granules of 3 mm in radius with water and dried at 110°C. The granules were placed in a platinum crucible and heated at 1500°C for 5 hours in an automatically controlled electric furnace and then air-quenched. This process was repeated three times to approach to the equilibrium state. The heating was made also at 1600°C on samples in hypothetical systems, C_3S–$3CaO \cdot TiO_2$ and C_3S–$3CaO \cdot MnO_2$.

The samples obtained were then examined by means of chemical analysis, X-ray diffraction, microscopic observation and electron probe X-ray microanalysis. Free CaO was determined by a modified Franke's method, the solution consisting of 80 parts isopropanol and 12 parts acetoacetic ethylester being used as the extraction solvent. X-ray diffraction was made in the region of 15–55° (2θ, CuKα). In order to identify the modification of solid solutions of C_3S and alite containing Ti or Mn, accurate determination was made by using quartz as an internal standard. Selected peaks are those of (009), (224), ($2\bar{2}4$), ($\bar{4}04$), (040), ($\bar{6}20$) and (620). The identification was made with reference to the shape of these peaks which had been studied by Bigaré, Guinier, Mázières, Regourd, Yannaquis, Eysel, Hahn and Woermann (15). Especially in the case of Mn, an electron probe X-ray microanalyzer was also used to determine the limit of miscibility in C_3S or alite.

Experimental Results

The results of free CaO determination on the samples in the systems, C_3S–$3CaO \cdot TiO_2$ and C_3S–$3CaO \cdot MnO_2$ heated at 1500°C or 1600°C are shown in Fig. 1. Fig. 2 shows free CaO on the samples in the systems alite-$3CaO \cdot TiO_2$ and alite-$3CaO \cdot MnO_2$ at 1500°C.

The changes in the d-values of (040), (620) and ($\bar{6}20$) on the samples in the system C_3S–$3CaO \cdot TiO_2$ are shown in Fig. 3; those in the system C_3S–$3CaO \cdot MnO_2$ in Fig. 4; and those in systems alite-$3CaO \cdot TiO_2$ and alite-$3CaO \cdot MnO_2$ in Fig. 5, respectively.

The X-ray diffraction patterns of the samples in which the miscibility is approximately above or below its maximum value are shown in Figs. 6–7.

The characteristic X-ray images by CaKα, by SiKα and by MnKα on the sample containing 3CaO.

MnO_2 0.08 mole in the system C_3S–$3CaO \cdot MnO_2$ and these images on the sample containing $3CaO \cdot MnO_2$ 0.10 mole in the system alite-$3CaO \cdot MnO_2$ are shown in Figs. 8 and 9, respectively,

Discussion

It is convenient to discuss the miscibilities case by case on the combinations of components.

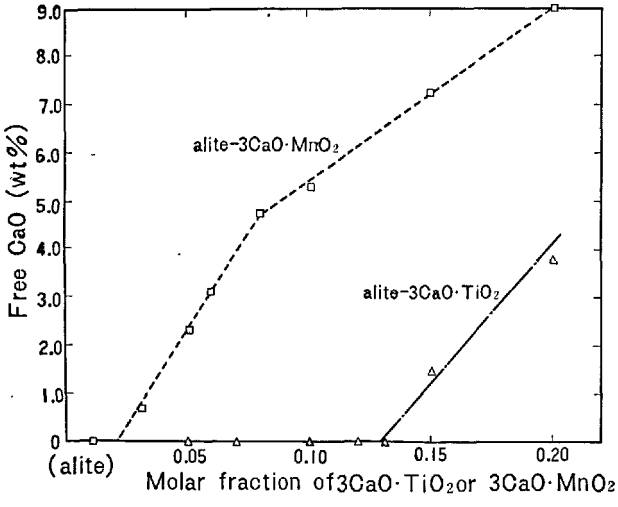

Fig. 2. *Free* CaO *content on sample in the systems, alite–*$3CaO \cdot TiO_2$ *and* C_3S–$3CaO \cdot MnO_2$ *heated at 1500°C and quenched.*

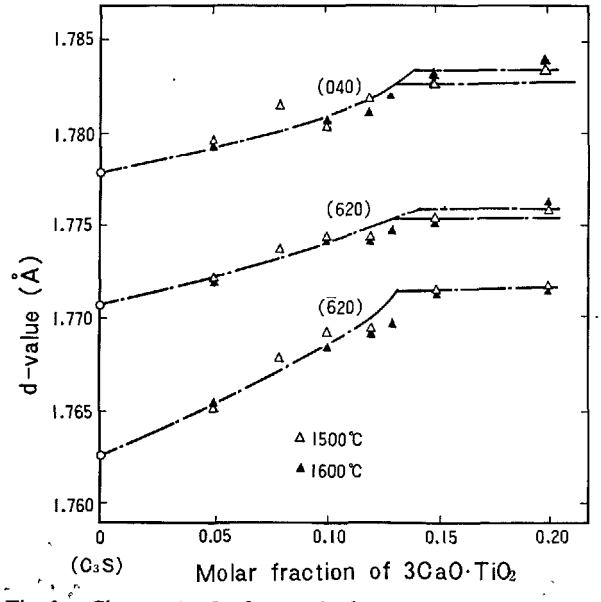

Fig. 3. *Changes in d-values with the content of* $3CaO \cdot TiO_2$ *in* C_3S.

Miscibility of Ti in C_3S

It is concluded from the facts described below, that the Si^{4+} in C_3S is substituted by Ti^{4+} up to 0.13 mole at 1500°C and up to 0.14 mole at 1600°C, and that the triclinic lattice of C_3S expands slightly with increasing amount of dissolved Ti^{4+}.

First of all, free CaO is hardly found in the samples

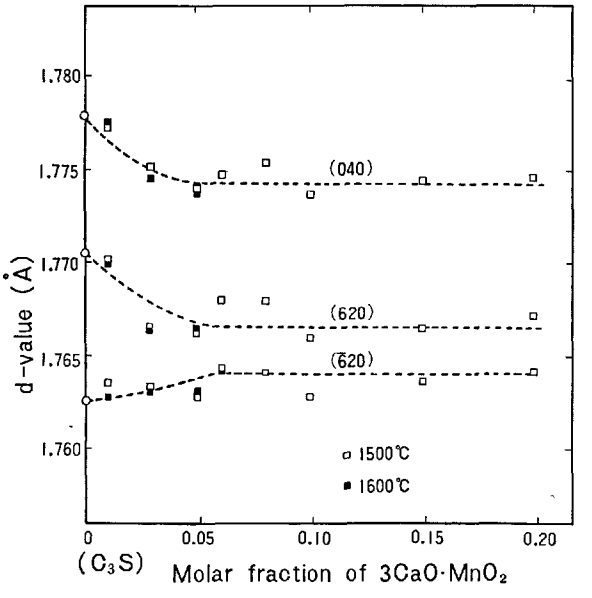

Fig. 4. *Changes in d-values with the content of* $3CaO \cdot MnO_2$ *in* C_3S.

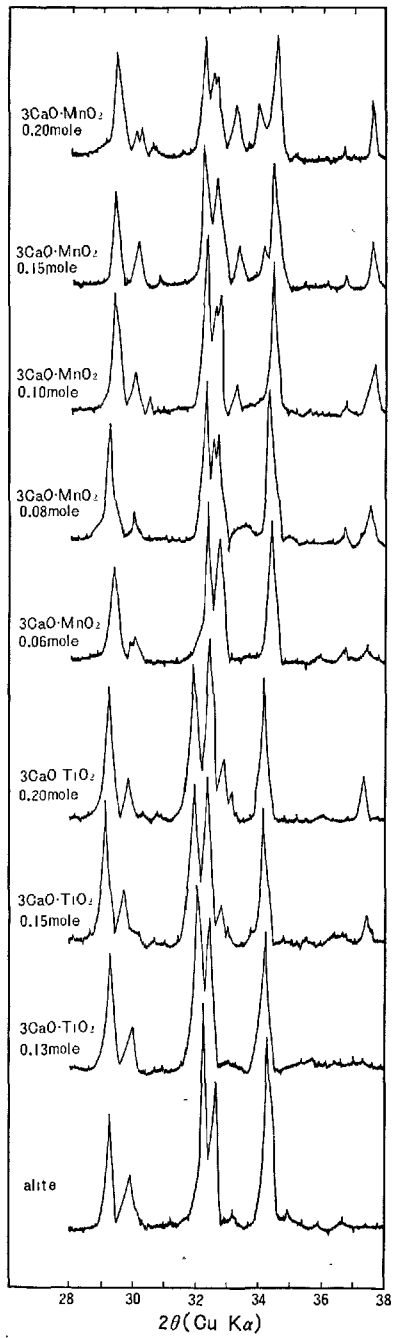

Fig. 7. *X-ray diffraction diagram of alite, alite*–$3CaO \cdot TiO_2$ *and alite*–$3CaO \cdot MnO_2$

containing up to 0.13 mole $3CaO \cdot TiO_2$ and heated at 1500°C and up to 0.14 mole and heated at 1600°C. The d-values of (040), (620), ($\bar{6}20$) expand slightly with increasing amount of replaced $3CaO \cdot TiO_2$ up to 0.13 mole at 1500°C and up to 0.14 mole at 1600°C. However, in the case exceeding these value, they become constant. Moreover, the X-ray diagram of each sample containing 0.15 or 0.20 mole $3CaO \cdot TiO_2$ indicates the existence of $3CaO \cdot 2TiO_2$ or $CaO \cdot TiO_2$. As an evidence, a peak is found at approximately $2\theta =$

33° (CuKα). The sample containing 0.20 mole $3CaO \cdot TiO_2$ was treated with a salithylic acid-methanol solution to remove CaO and C_3S phases (16), and then the residue was examined by X-ray diffraction. And the result showed that the residue is most likely $CaO \cdot TiO_2$. Attention must be paid, however, to the fact that $CaO \cdot TiO_2$ precipitated also from the Ti dissolved solution with lapse of time by this method.

The modification of C_3S solid solution changes from triclinic T_I to triclinic T_{II} through the dissolution

of Ti under 0.05 mole.

The lattice expansion due to the dissolution of Ti in C_3S seems to be related with the difference of ionic radii between Si^{4+} and Ti^{4+}, Ionic radii are reported as 0.40Å for Si^{4+} and 0.68Å for Ti^{4+}, and a little smaller value is expected for the 4-fold co-ordinated ion, Ti^{4+}.

Miscibility of Mn in C_3S

On the miscibility of Mn in C_3S, it is found that the hypothetical compound, $3CaO \cdot MnO_2$, dissolves at 1500°C congruently in C_3S up to 0.01 mole and incongruently from 0.01 to 0.06 mole with the liberation of free CaO. When the amount of Mn extends over 0.06 mole, free CaO and $2CaO \cdot MnO_2$ are formed.

As for the evidence, free CaO was not liberated up to 0.01 mole $3CaO \cdot MnO_2$ in the system C_3S–$3CaO \cdot MnO_2$ at 1500 or 1600°C, and the liberation of free CaO occurs, when the amount of $3CaO \cdot MnO_2$ extends over 0.01 mole. The amount of free CaO in sample increases sharply in propertion to the amount of $3CaO \cdot MnO_2$ in the range from 0.01 to 0.06 mole and less sharply in the range exceeding 0.06 mole. The molar ratio of free CaO to Mn can be calculated from the curve in Fig. 1. This ratio is 0 for the amount of Mn up to 0.01 mole, approximately 3 for its amount from 0.01 to 0.06 mole and approximately 1 for its amount over 0.06 mole.

The d-values of (040) and (620) of C_3S decrease very slightly with increasing amount of mixed $3CaO \cdot MnO_2$ up to 0.06 mole, and become almost constant over this value. The d-value of $(\bar{6}20)$, however, increases very slightly, and both values of (620) and $(\bar{6}20)$ approach each other, with increasing amount of mixed $3CaO \cdot MnO_2$ up to approximately 0.06 mole.

The peaks at $2\theta(CuK\alpha) = 32 - 33°$ in Fig. 6 are found on the samples containing not less than 0.10 mole $3CaO \cdot MnO_2$, and these peaks seem to be due to the existence of $2CaO \cdot MnO_2$. Under a polarization microscope, this phase was an opaque crystal, identified as $2CaO \cdot MnO_2$ and also detected in the sample containing 0.08 mole $3CaO \cdot MnO_2$. Moreover, the electron probe microanalysis revealed that Mn is distributed uniformly in C_3S on the sample containing $3CaO \cdot MnO_2$ not more than 0.06 mole. On the other hand, the mass concentration of Mn occurs on the sample containing $3CaO \cdot MnO_2$ at 0.08 mole, as shown in Fig. 8.

It may be considered from the results described above that the Si^{4+} in C_3S is substituted by Mn^{4+} up to 0.01 mole, and that when the amount of Mn extends over 0.01 mole, the simultaneous substitution of Ca^{2+} and Si^{4+} with Mn^{2+} and Mn^{4+} occurs in the ratio of 3:1, or all Mn, regardless of valencies, is introduced in the interstitial positions of C_3S, up to 0.06 mole. The ionic radii of Ca^{2+} and Si^{4+} are 0.99 and 0.40Å, respectively and those of Mn^{2+} and Mn^{4+} are 0.80 and 0.60Å respectively. The last value is that for the 6-fold co-ordinated ion, and a little samller value is expected for the 4-fold co-ordinated ion. The lattice of C_3S will expand slightly, if Si^{4+} is substituted by Mn^{4+}, and the lattice will contract slightly, if Ca^{2+} is substituted by Mn^{2+}. As the lattice are found to be contracted in this experiment, the substitution for Si^{4+} is probably superseded by the substitution for Ca^{2+}. The modification of C_3S solid solution changes from triclinic T_I to triclinic T_{II} through the dissolution of Mn under 0.01 mole and changes from triclinic T_{II} to triclinic T_{III} through its dissolution above approximately 0.06 mole. According to Yamaguchi and Uchikawa (17), the modification of C_3S has a tendency to change from triclinic to monoclinic through the substitution of Ca^{2+} with other ion.

Miscibility of Ti in Alite

It is obvious from the data in Figs. 2, 5 and 7 that the Si^{4+} in alite is also substituted by Ti^{4+} to the extent of 0.13 mole at 1500°C in accordance with the case of C_3S, nevertheless alite is already saturated with Al^{3+} and Mg^{2+}. The modification of alite changes from monoclinic M_{II} to rhombohedral R through the dissolution of Ti above approximately 0.07 mole. The d-values of alite expand slightly with increasing amount of replaced $3CaO \cdot TiO_2$ up to 0.13 mole. But, when the amount of $3CaO \cdot TiO_2$ is beyond this value, free CaO and calcium titanate are formed. The composition of this titanate is suggested to be $CaO \cdot TiO_2$ by the X-ray diagram in Fig. 7 and also by the chemical analysis, in which the molar ratio of combined CaO to excessive TiO_2 is approximately 1, as shown in Fig. 2. An additional evidence of the formation of $CaO \cdot TiO_2$ is the result of X-ray analysis of the residue from which CaO and C_3S or alite phases were separated by the treatment of the sample containing 0.20 mole $3CaO \cdot TiO_2$ with the salithylic acid-methanol solution.

Miscibility of Mn in Alite

It is estimated from Figs. 2 and 7, that the hypothetical compound $3CaO \cdot MnO_2$ dissolves congruently in alite up to 0.02 mole at 1500°C and incongruently from 0.02 to 0.08 mole with the liberation of free CaO. The molar ratio of free CaO to Mn reaches to 3, when $3CaO \cdot MnO_2$ from 0.02 to 0.08 mole is contained (Fig. 2). $2CaO \cdot MnO_2$ was detected in the sample containing $3CaO \cdot MnO_2$ not less than 0.10 mole by

X-ray diffraction (Fig. 7) and also by microscopic observation. Moreover, the characteristic X-ray images on the samples containing $3CaO \cdot MnO_2$ not more than 0.08 mole showed that Mn is distributed uniformly in alite. Meanwhile, the mass concentration of Mn occurs on the sample containing $3CaO \cdot MnO_2$ at 0.10 mole, as shown in Fig. 9.

These results probably indicate that the Si^{4+} in alite is substituted by Mn^{4+} up to 0.02 mole, and that the simultaneous substitution of Ca^{2+} and Si^{4+} with Mn^{2+} and Mn^{4+} occurs in the ratio 3:1 up to 0.08 mole, when the amount of Mn extends over 0.02 mole. It may also be concluded that the excessive amount of $3CaO \cdot MnO_2$ forms free CaO and calcium manganate. From the fact that the molar ratio of combined CaO to excessive Mn is not 2 but 1.5, it seems that the composition of the manganate is $2CaO \cdot MnO_2$, and C_2S is not formed appreciably.

The d-values of (040) and (620) decrease very slightly with increasing amount of dissolved Mn. The modification of alite changes from monoclinic M_{II} to monoclinic M_I through the dissolution of Mn above approximately 0.03 mole.

The Hydraulic Properties of C_3S, Alite and Their Solid Solutions Containing Ti or Mn

Experimental Procedure

Preparation of Samples

The samples used for hydration experiment were C_3S, 0.07 mole Ti bearing C_3S (hereafter abbreviated as C_3S (Ti 0.07)), C_3S (Mn 0.05), alite, alite (Ti 0.07) and alite (Mn 0.05), all of which were synthesized by heating three times at 1500°C for 5 hours as described previously. It was confirmed that the samples thus obtained contain no free CaO and other foreign phases. The chemical compositions of them are shown in Table 1. The modifications were identified as triclinic T_I for C_3S, triclinic T_{II} for C_3S (Ti) and C_3S (Mn), monoclinic M_{II} for alite and alite (Mn) and rhombohedral R for alite (Ti).

The sintered products were crushed to pass through a sieve with 2 mm openings and pulverized in a pot mill of sintered corundum. The particle size distributions of the final samples were determined with Bahco particle classifier.

As shown in Fig. 10, the particle size distributions showed no difference in the samples of C_3S series and those in alite series, respectively. Blaine surface area of C_3S series was $3{,}220 \pm 20$ cm²/g and that of alite series was $3{,}420 \pm 20$ cm²/g, respectively.

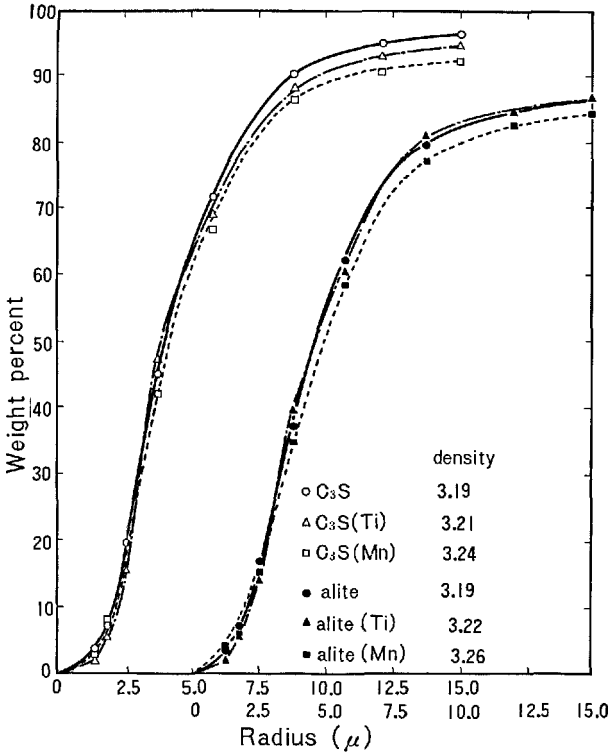

Fig. 10. *Particle size distribution of sample for hydration experiment.*

ratio of 0.50 was prepared and, after sealing in a plastics bottle, cured at 20 ± 1°C. After reaching a certain period, hardened paste was crushed, stopped the hydration, and subjected to "D-drying" reported by Copeland and Hayes (18). The free $Ca(OH)_2$ and loss on ignition of each dried sample were determined, and the unhydrated part was determined quantitatively by X-ray diffraction.

Free $Ca(OH)_2$ was determined by a modified Franke's method and loss on ignition was determined by heating at 1000°C and its amount was regarded as the amount of combined water. In the quantitative determination by X-ray diffraction, periclase powder from 2 to 5μ in radius was used as the internal standard. On the same sample, five new compacted specimens were used and its determination was repeated twice. The intensities of peaks, $2\theta(CuK\alpha) = 42.9°$ (200) of periclase and $2\theta(CuK\alpha) = 41$–$42°$(319 etc.) of C_3S or alite, were used for this determination.

The hydration at early stage was also examined with a conduction calorimeter at 20°C on paste with a water-cement ratio of 0.50.

Mortar Test

Mortar strength was determined according to the RILEM method on each sample without gypsum. The sand-cement-water ratio was 3–1–0.5. The test pieces of 2 × 2 × 8 cm were cured in water at 20 ± 1°C.

Experimental Results and Discussion

Hydration Characteristics

The degree of hydration determined by X-ray dif fraction, the content of combined water and free $Ca(OH)_2$ are shown in Figs. 11–13, respectively. All of the data were determined on D-dried paste and represented on ignited base.

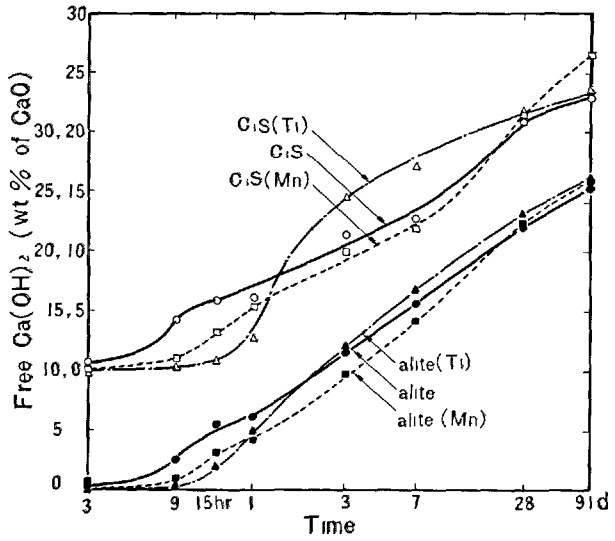

Fig. 13. *Free* $Ca(OH)_2$ *in D-dried paste with* C_3S, *alite and their solid solutions represented on ignited base* ($w/c = 0.5$, *at 20°C).*

alite (Mn)	4.2	2.4	3.3	3.3	2.3	2.3	2.5

As Figs. 11–13 show the similar tendency, the data in Fig. 11 are used as the representing ones to discuss the degree of hydration. But the data are accompanied inevitably with experimental errors in the intensity of X-ray diffraction. In addition, the chemical composition of calcium silicate hydrate seems to change during the progress of reaction as shown in Table 2.

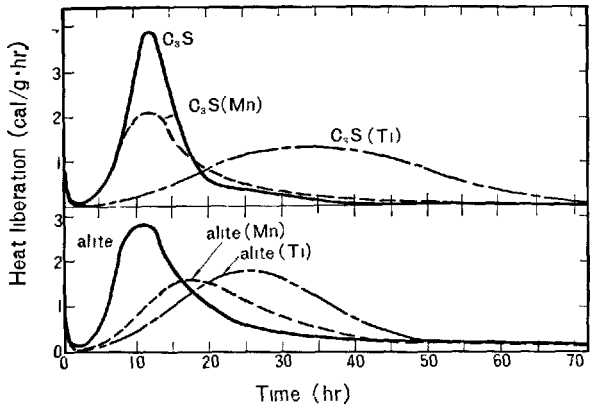

Fig. 14. *Heat of liberation on paste with* C_3S, *alite and their solid solutions* ($w/c = 0.5$, *at 20°C).*

The rate of heat liberation was determined with the conduction calorimeter, and the results are shown in Fig. 14.

As shown in Figs. 11–14 except from a very rapid hydration immediately after contact with water, the progress of hydration can be divided into the following three stages:

(1) At the induction period the rate of hydration is extremely low;
(2) At the acceleratory period the rate of hydration increases and then reaches to a maximum value;
(3) At the decay period the rate of hydration decreases.

The induction period of C_3S and alite is over within 2 hours and the maximum rate is observed at 11 hours. The maximum rate of C_3S and alite is higher than those of their solid solutions, (Fig. 14). In the case of C_3S (Mn) and alite (Mn), the induction period is a little longer and the acceleratory period is a little shorter than those of C_3S and alite, respectively. The hydration behaviors of C_3S (Ti) and alite (Ti) differ extremely from those of the other samples.

Rate of Hydration

To compare the rate of hydration, the thickness of reacted layer was calculated from the data of the particle size distribution (Fig. 10) and of the degree of hydration (Fig. 11). In this calculation, it was assumed that the individual reactant particles were spherical and the thickness of the reacted layer is always uniform. Although the thickness of the reacted layer is not the same with that of the layer of hydration product, it can be regarded equal to the thickness

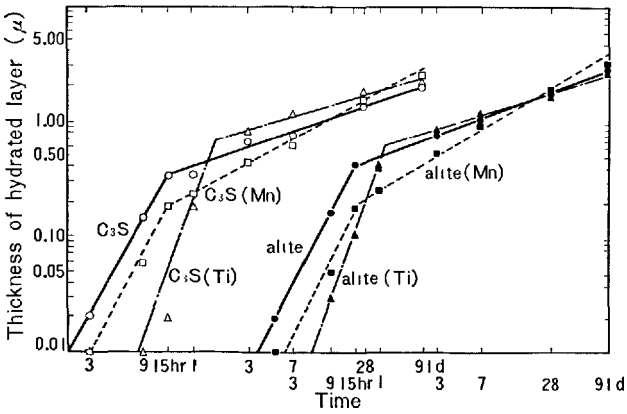

Fig. 15. *Thickness of hydrated layer calculated from degree of hydration and particle size distribution (w/c = 0.5, at 20°C)*

of the layer of inner product. In Fig. 15, the relationship between thickness of reacted layer (y) and the curing time (t) is expressed on logarithmic scale.

In the figure, the degree of hydration is expressed by two-straight lines with a crook point, and the rate corresponds to the slope of these lines. The reaction time required for reaching the crook point corresponds to that required for reaching the maximum rate of hydration on each sample (Fig. 14). The inclinations of the lines before the crook points are approximately 1.7, 1.9, 1.9, and 2.0 for C_3S, C_3S (Mn), alite and alite (Mn), respectively. As these are all approximately 2, the following equation is derived,

$$\frac{d\log y}{d\log t} = 2. \tag{1}$$

Therefore,

$$\log y = 2\log t + \log k_1 \text{ or } y = k_1 t^2 \tag{2}$$

The differentiation with respect to t, one obtains

$$\frac{dy}{dt} = 2K_1 t = K_1' t \tag{3}$$

In this equation, K_1' is the rate constant which is calculated from the thickness of hydrated layer at a certain unit of time.

Thus, in the acceleratory period, the rates of hydration of C_3S, alite and their solid solutions of Mn increase with time. The hydration during this stage may be considered to be a kind of autocatalytic reaction. In connection with this process, further discussion will be presented by one of the authors in the other paper at this symposium (19).

On the other hand, the inclinations of the lines before the crook points are approximately 2.7 for C_3S (Ti) and approximately 2.8 for alite (Ti). When these values approach to 3, the rate of this reaction can be expressed as follows;

$$\frac{dy}{dt} = K_2' t^2. \tag{4}$$

In this equation, K'_2 is the rate constant which can be calculated from the thickness of reacted layer at a certain unit of time. Thus, this type of hydration may also be considered to be a kind of autocatalytic reaction. This type of reaction will also be discussed by one of the authors in the other paper at this symposium.

The inclinations of lines after the crook points are 0.39 for C_3S, 0.32 for C_3S s.s. (Ti), 0.57 for C_3S. (Mn), 0.40 for alite, 0.37 for alite (Ti), 0.62 for alite (Mn). If they are approximated as 0.5, the following equation is derived,

$$\frac{d\log y}{d\log t} = 0.5. \tag{5}$$

Therefore,

$$\log y = 0.5\log t + \log k_3 \text{ or } y = k_3 t^{0.5} \tag{6}$$

Differentiation with respect to t, one obtains

$$\frac{dy}{dt} = 0.5k_3^2\frac{1}{y} = K_3'\frac{1}{y}, \tag{7}$$

where K_3' is the rate constant which can be calculated from the apparent thickness of the reacted layer obtained by extrapolating the lines straightly to a certain unit of time.

Thus, the rate of hydration at this stage changes in inverse proportion to the thickness of the hydrated layer. It can be considered that the thickness of the hydration product layer is in proportion to that of the hydrated layer, so that the rate of hydration during this decay period is controlled by diffusion through the layer of hydration product formed around the particle of reactant. As described previously, all the inclinations obtained on C_3S, alite and their solid solutions of Ti are smaller than 0.5, so their hydration products may become denser with the progress of reaction.

Finally, the hydration process of the samples used in this experiment is outlined as follows:

In the hydration of C_3S and alite, the induction period is shorter, so that the acceleratory hydration begins earlier. After the thickness of hydrated layer reaches to 0.3μ, the rate of hydration is affected mainly by the diffusion through the layer of hydration product and the value is decreased gradually. In the cases of Ti bearing C_3S and alite, on the contrary, the induction period is exceedingly prolonged, but the degree of hydration at 1–3 days is high, because the rapid autocatalytic hydration continues until the hydration product layer reaches to 0.6μ. In the hydration of the Mn bearing C_3S and alite, the induction period is prolonged a little at early stage. After the

thickness of the hydrated layer reaches to 0.2μ, the rate of hydration is affected mainly by the diffusion phenomenon through the layer of the hydration product and the value is decreased gradually. After 28 days, however, the degree of hydration is highest in comparison with that of the other samples, because the layer of hydration product is not so dense compared with the other samples.

Mortar Test

It was observed that the setting of mortar made with C_3S and alite occurs within a few hours after mixing. The setting of C_3S (Mn) and alite (Mn) were a little slower and that of C_3S (Ti) and alite (Ti) occurred after approximately 10 hours.

Mortar strength is shown in Fig. 16. On 1 day strength, the highest value is obtained by C_3S and alite, followed by C_3S (Mn) and alite (Mn) and the lowest by C_3S (Ti) and alite (Ti). However, the strength of the samples containing Ti was increased, extremely between 1 day and 7 days, C_3S (Ti) showing the highest strength at 3, 7, 28 and 91 days among the samples of C_3S series. Alite (Ti) showed also the highest strength at 3, 7, and 28 days among the samples of alite series. The increases in the strength development of C_3S and alite are a little greater at early stage and a little smaller at later stage than those of C_3S (Mn) and alite (Mn). The strength development of alite is a little greater than that of C_3S and the strength development of alite (Mn) is also a little greater than that of C_3S (Mn).

The significant effects of Ti, Mn or Mg and Al on mortar strength of C_3S may be mainly due to the chemical effects of the elements rather than to the changes of the modification.

Relations between the Degree of Hydration and the Mortar Strength

The relationship between the degree of hydration and the mortar strength is shown in Fig. 17.

The effects of the degree of hydration on the strength, both compressive and bending, are similar in the series C_3S solid solution and alite series. The effects of Ti or Mn are also observed similarly in both series.

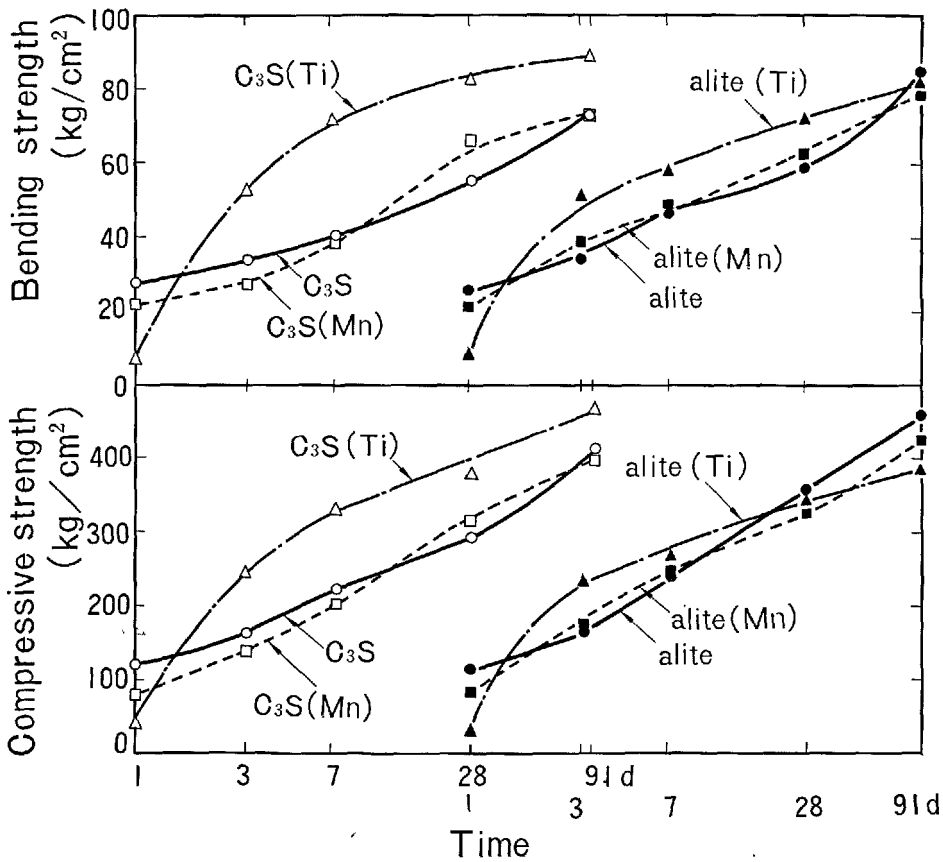

Fig. 16. *Mortar strength on C_3S, alite and their solid solutions (c: s: w = 1: 3: 0.5, at 20°C)*

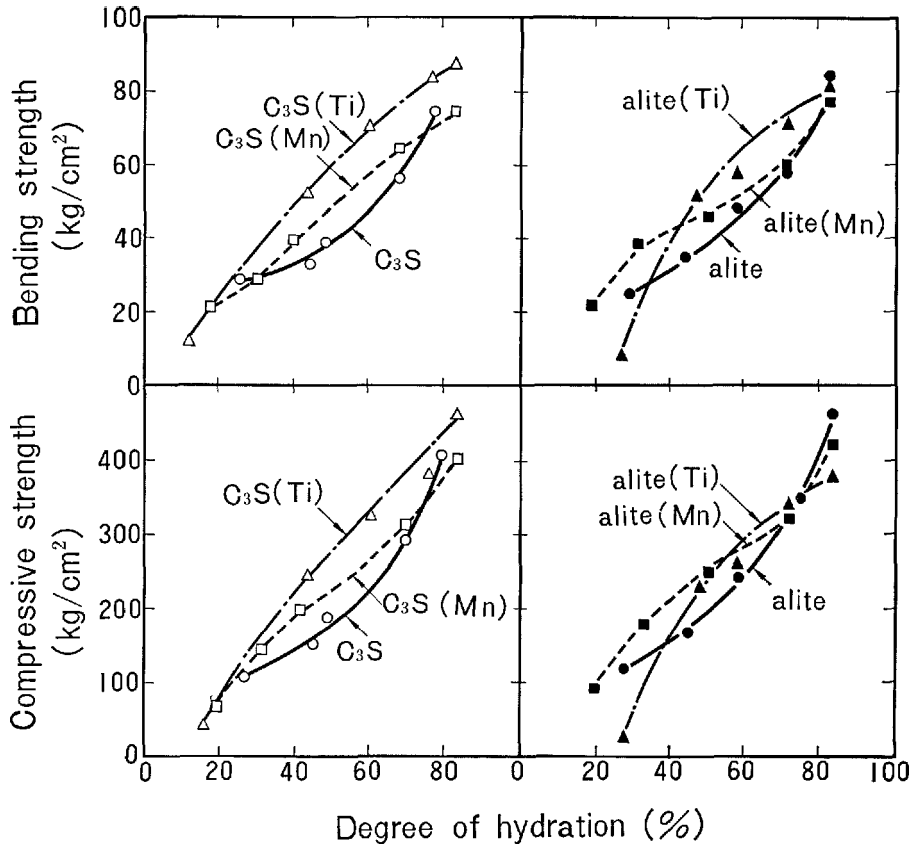

Fig. 17. *Relationship between degree of hydration and mortar strength.*

The ratio of the strength to the degree of hydration is higher for the Mn bearing solid solutions at early age of hydration, but the ratio decreases at later ages. The strength of the Ti bearing solid solutions shows highest value at later above middle ages of hydration. These facts suggest that mortar strength is affected greatly by the change in property of hydration product which occurs by the addition of the special elements.

The authors wish to thank Dr. Y. Suzukawa of the Central Research Laboratory of Ube Industries, Ltd. for his encouragement. Thanks are also due to Mr. M. Kobayashi in charge of Tokyo Institute of Technology for his assistance in using the electron probe X-ray microanalyzer.

Supplementary Paper I-79 Microscopic Observations of Alite and Belite and Hydraulic Strength of Cement

Yoshio Ono, Shigeo Kawamura and Yoshiaki Soda*

Synopsis

The external forms and the inner texture of alite and belite occurring in clinker are studied, referring to the crystal structures and inversion of the temperature modifications. And the facial indexes and the orientation of optical axes are determined.

Relationships between the microscopic figure of alite and belite, the conditions of cement burning and the hydraulic strength are given.

The microscopic exermination is effective to the daily control of clinker burning in manufacture. For this purpose, observation of the crystallization and the inversion textures of alite and belite, birefringence of alite, color of belite and content of α-phase in belite, is light and effective.

Introduction

For a long time, many microscopic investigations were made on the clinker minerals, and were in detail. But the analysis and the interpretations on the crystal form and the inner texture remained incomplete, since the microscopic measurement of the minute and complex textures is very difficult.

A. E. Törnebohm (1) showed by poralizing microscopic examination that clinker was composed of "Alit", "Belit", "Celit", "Felit" and "isotrop Substanz", "Alite" was psendo-hexagonal orthorhombic. E. S. Shepherd and G. A. Rankin (2) and N. Sundius (3) found more complex and minute textures in clinker minerals. B. Tavasci (4), H. Insley (5) and W. C. Taylor (6) presented precise reflecting microphotographs of the clinker minerals, and explained the minute texture of belite in relation to the burning condition. C. E. Tilley (7) (8) examined on larnite (β-C_2S) and bredigite (α'-C_2S) occurring in natural rock and slag, and it was concluded that the former was monoclinic and the latter was pseudo-hexagonal orthorhombic. In recent year, the former microscopic studies on clinker minerals were compiled by F. Trojer, (9) P. Terrier and H. Hornain (10).

Through the advance of X-ray crystallographic studies on synthetic single crystals of clinker minerals, the crystal structure and polymorphism of Alite were made clear by A. Guttmann and F. Gille (11) and J. W. Jeffery (12) and those of belite by M. A. Bredig (13), C. M. Midgley (14), D. K. Smith et al.

In this paper, the microscopic figure, texture and optical property of alite and belite are examined (16), (17), (18) by polarizing microscope and explained from the crystal structure and the polymorphism, and the relationships between burning condition, crystallographic property and hydraulic strength are given.

Microscopy on Clinker Minerals

In this study, polarizing microscope, X400, with universal stage was used. For precise observation, the thin section must be polished perfectly, to be free from irregular dispersion of light, and the thickness of thin section must be fit for each purposes, e.g. for the optics of alite: 25μ, for the fine texture of belite: 10μ.

*Central Research Laboratory, Onoda Cement Co., Ltd, Tokyo, Japan.

The direction of the acute bisectrix, X, of alite can be determined most accurately, and is suitable for the basis of goniometry of the crystal faces and the textures.

The horizontal section, X being perpendicular to the section, shows a regular hexagonal shape with 3-fold symmetry, and the side planes bounding the hexagon are inclined against X. The birefringence of this section is very weak.

The vertical section, X being parallel to the section, shows a elongate hexagonal shape. The elongate sides are normal to X, and the faces are perpendicular to the section. Rotating the section about X, the another four faces can be brought to vertical position. At this position, the all six faces are parallel to view line, and the elongate hexagonal outline shows 2-fold symmetry.

Above observation shows that the external form of alite is bounded by a set of basal planes (c), and two sets of rohmbohedrons, (r1) and (r2), and may belong to D_{3d}. The angles between the rohmbohedrons and X are measured as (r1) $\wedge$ X = 26.2°, (r2) $\wedge$ X = 13.5°, therefor

$$\{c\}:\{0001\},\ \{r1\}:\{01\bar{1}2\},\ \{r2\}:\{10\bar{1}1\}.$$

These observations are in good agreement with the results obtained by Guttmann, who could measure accurately the facial angles of alite, grown in a large crystal in basic slag, using reflective goniometer.

Guttmann showed the facial indises as $\{r1\}:\{10\bar{1}2\}$ and $\{r2\}:\{1\bar{1}01\}$. The difference in the notation of facial indices comes from differing in setting of crystallographic axes, and is not substantial.

In this paper the crystal axes are set as, $-h + k + 1 = 3n$, after International Table for X-ray Crystallography, for the benefit of comparison with the X-ray diffraction data.

Jeffery concluded from the X-ray crystallographic study that the high temperature modification of alite belonged to C_{3v}. D_{3d} is made by adding point of symmetry to C_{3v}. From the careful observation on the difference in growth of crystal faces, no indication is found which shows lack of point of symmetry.

The form of alite changes extremely by the paragenetic twin due to the trigonal symmetry. These twin crystals are abundant in clinker. The twin planes are (c) and (r1).

In twin crystal, twin plane being (c), the difference in extinction position of each twins cannot be detected by polarizing microscope, and the twin crystal seems as if single crystal having horizontal symmetry and being D_{3h}. When alite inverts to triclinic form, inversion polysynthetic twin of triclinic system occurs and the textures are discontinuous at the twin plane, and it becomes evident that the crystal is not single crystal but twin crystal.

The twin crystal of which twin plane is (r1), shows frequently hexagonal outline in thin section, and the diagonal of the hexagon is coincident with the twin plane (r1). In these sections, the twin method was frequently mistaken for $(10\bar{1}0)$ of pseude-hexagonal system. When a twin plane (r1) inclines to the section, remarkable wavy extinction appears on the contact zone.

No other paragenetic twin of the symmetry in trigonal system, except (c) and (r1), occurs in alite in commercial cement.

The external form of alite occurring in cement clinkers shows the trigonal symmetry of its high temperature polymorph, but almost all of the diffractometer traces of alite are monoclinic and those of trigonal and triclinic are very rare.

Alite of which diffractometer traces are trigonal of the high temperature polymorph is uniaxial negative or its optic angle is very small:

$$2V = 0 - 20°\mathrm{X}\|\mathrm{c(trigonal)}$$

Alite of which diffractmeter traces are monoclinic of the medium temperature polymorph (metastable) is biaxial negative, 2V = 20 — 60°, X||c (trigonal): This relation is accurately established. Y||a (trigonal), Z$\perp$a (trigonal): The accuracy in the determination is less than in that of the direction of the X axis.

In the horizontal section, the extinction position differs locally, and irregular patches of triple cryclic twin can be observed. On the contrary, in the vertical section, the crystal extincts at the same time exactly, and the twin structure can not be detected. This cyclic twin is paragenetric twin through R $\rightarrow$ M inversion, so the twins must be orientated geometrically with 3-fold symmetry of R. Therefore, it is concluded that X of monoclinic form exactly coincides with 3-fold axis, c, of trigonal form. Through R $\rightarrow$ M inversion, 3-fold axis changes to oblique axis of monoclinic form. It is unnatural that an optical elastic axis coincides with an oblique axis of monoclinic form. These properties are those of pseudo-hexagonal orthorhombic crystal, and may be caused by the remarkable likeness of crystal structure between the trigonal form and the monoclinic form or existence of submicroscopic twin.

Alite of which diffractometric traces are triclinic of low temperature polymorph is biaxial negative,

$2V = 20 - 60°$. X axis inclines to c (trigonal) :X $\wedge$ c (trigonal) $= 0 - 15°$.

In the horizontal section of the crystal the extinction is very obscure. In the vertical section, indistinct stripes parallel to c axis like the polysynthetic twins are observed.

The presence of (0001) twin is clear from the discontinuous stripes in two crystals.

Fudamentals on Belite

H. Insley classified belite into the types of I, Iα, II and III from the observations of clinkers by the reflecting microscope.

Belite of type I and Iα is obtained by heating up to the stability temperature region of α-form.

Belite of these types has the complex inversion textures due to the transitions of $\alpha \rightarrow \alpha'$ and $\alpha' \rightarrow \beta$. Belite of type I$\alpha$ separates its impurities along the inversion texture of $\alpha \rightarrow \alpha'$ inversion and has the textures as well as type I.

Belite of type II crystallizes at the α' phase region of temperature and is cooled to room temperature having the inversion textures due to $\alpha' \rightarrow \beta$ inversion.

Belite of type III belongs to type I or type II having the indistinct inversion textures which are so minute as not to be determined by the optical microscope or not to be observed in some sections.

Thus belite is then classified into type I and II from its inversion textures. Törnebohm called the former "Belit" and the latter "Felit".

Belite of Type 1

Type I crystallizes in a rounded grain having indistinct crystal faces. It has a complicatedly crossed lamellar structure and a set of lamellae, in two directions crossing in about 60° each other, is usually observed distinctly. The acute bisectrixes, Z, of all lamellae in a grain are parallel each other, and can be accurately determined.

In horizontal section, Z being perpendicular to the section, the birefringence is very weak and the extinction are indistinct. The section is divided into minute patches by the difference of the extinction positions.

In the vertical section, Z being parallel to the section, the birefringence is highest and it extincts at the same time. Rotating the vertical section around Z, a set of lamellae, in two directions crossing about 60° each other, can be brought to vertical position, the crystal faces of the lamellae being parallel to view line. At this position, the set of lamellae makes a symmetry extinction, and the obtuse bisectrix of angle of the lamellae is coincident with Z. The angle between the lamellae and X–Y plane is about 33°. Then the section is further rotated 60° form the vertical position around Z, a new set of lamellae becomes prominent and the crystal faces of the lamellae become parallel to view line.

Above observation shows that belite is composed of 3 sets of lamellae and the sets are orientated with 3-fold symmetry around Z.

Usually, the lamellae do not rigidly connect each other, but there are some spaces between the lamellae. The spaces are filled with glassy phase. The refractive index and birefringence of the lamellae with high birefringence are shown as follows: $N = 1.720$, $B = 0.015 - 0.018$.

Those of the glassy phase with low birefringence are shown as follows:

$$N = 1.700 - 1.710 \quad B = 0.000 - 0.003$$

The very minute polysynthetic twins are often observed in the lamellae with high birefringence and its twin planes are parallel to Z.

Above shows that the high birefringence phase is β and the low birefringence phase is α.

The complex lamellar structure with 3-fold symmetry must be skeleton structure through $\alpha \rightarrow \alpha'$ inversion with remainder of α-phase, The minute polysynthetic twin structure of lamella must be inversion twin structure through $\alpha' \rightarrow \beta$ inversion.

Because of the resemblance of crystal structure between α, α' and β-forms, the crystal axes of each modifications keep in same direction through the inversions, and 3-fold axis, c, of α form is transformed to unique axis, b, of β-form.

The facial indexes of the lamellae of the skeleton structure are calculated, from the facial angle obtained by microscopic measurement and the lattice constants obtained by X-ray diffraction. The facial indexes are as follows:

α-form $(10\bar{1}2) \rightarrow \alpha'$-form (112),

$(022) \rightarrow \beta$-form $(1\bar{1}2)(112)(022)$

For the convenience of comparison, the crystal axes of α'- and β-form are set after the ortho-hexagonal axes of α-form.

Belite of Type II

This type of Belite crystallizes in a irregular grain with the distinct parallel striations whose directions are in Z'.

In the horizontal section, Z being perpendicular to the section, the striations are incomplete and observed as cleavage or parting parallel to X and Z. The minute polysynthetic twins, i.e. (100) and (010) approximately parallel to X and Y, are clearly observed and the difference of their extinction positions is from 10° to 20°.

In the vertical section, Z being parallel to the section, striations are observed as complete cleavage or parting parallel to Z. The section extincts at the same time, and the polysynthetic twin structure cannot be observed. Though never abundant, the lamellae parallel to Z and inclined to the optic plane in 60°, i.e. to (110), and those of nearly parallel to X and inclined X-Y plane in 35°, i.e. (011), are observed. These are important to determine the directions of the crystal axes.

Following may be concluded from the aboves. X ||a (approx.), Y||b (approx.), Z||c and X $\wedge$ a = 10°. (In this case, the monoclinic acute bisectrix is c.)

It is evident that the polysynthetic twin structure of (100) and (010) can not occur in orthorhombic system (α') but in $\alpha' \rightarrow \beta$ inversion. The polysynthetic twins observed in the lamellae in belite of type I may be the same ones in belite of type II.

Effects of the Burning Condition of Clinker on the Microscopic Textures of Clinker Minerals

The minerals in clinkers and cements being examined in detail by the microscope, the clear differences will be found in their microscopic textures. This comes from the differences in the conditions of producing: For examples, in kinds, fineness and minor components of raw mixtures or in heat treatments. Thus the conditions of producing may be analyzed from the microscopic textures of minerals.

Many factors exist in the conditions of cement producing. They can be simplified in terms of the crystallization velocity and the recrystallization of minerals, their solution and exsolution of impurities and polymorphic transformation.

Textures of Alite

Effects of the Crystallization Velocity

Since alite crystallizes as precipitation from the liquid phase in which Ca^{2+} and SiO_4^{4-} diffuse and mix and supersaturate for C_3S, the crystallization velocity will be effective on the shape and size of crystals.

When the crystallization is rapid, the crystals will be in small and thin grains of developing in (0001). The slow crystallization will result in the formation of large and thick crystals of well developing in rohmbohedrons of $(01\bar{1}2)$ and $(10\bar{1}1)$.

In the early state of formation of alite, at the temperature of 1250–1300°C, CaO and C_2S are very minute, as 1–2μ, and in contact with each other. The reaction between CaO and C_2S proceeds rapidly and alite is crystallized in minute and thin crystal. As the coming reaction brings about the consumption and the crystal growth of CaO and C_2S, the resulting long distance between them in the reaction and the down of the crystallization velocity result in the formation of the moderate size of alite (15–30μ).

Since it is considerable of decreasing in amount of CaO, as less than 5%, in the late period of reaction, the further long distance between CaO and C_2S and

the delay in the reaction velocity result in the formation of thick and large size of alite (30–60μ).

The crystallization reaction of alite going on through the liquid in which Ca^{2+} and SiO_4^{4-} diffuse, and the diffusing velocity of Ca^{2+} is regarded higher than SiO_4^{4-}, alite crystallizes in a large crystal near the nest of belite, because of the reaction occurring near the nest of belite.

Alite occurring near the nest of belite has often a periodic zonal structure. The width of the zones coming broad near belite. The zoning structure of alite shows that alite grews toward belite.

It may be concluded that the minute alite flocking in a region, in which often small grains of CaO are dispersed, crystallizes in the early state.

Even in a piece of clinker alite distributes differing is shape and grain size, according to the varying period of reaction.

When clinkers are burnt quickly to a high temperature, the amount of the small alite increases and that of large one decreases.

When clinkers are burnt slowly at a medium low temperature, amount of the small alite decreases and amount of the thick and moderate size alite increases with accompanying considerable amount of large alite.

When the raw mixture is fine, the small alite occurs. The raw mixture being coarse, large alite increases. These all come from the difference in the crystallization velocity of alite.

The components of Na_2O, K_2O and SO_3 restrain the crystallization of alite. When these components are contained considerablely in clinkers, alite becomes extremely thick and large, as up to 100–200μ.

Effects of Recrystallization

Alite being treated at a high temperature for a long time, it recrystallizes and grows, but the rate of recrystallization is very slow: It requires 20 hours at 1450°C for 10μ alite to grow to 20μ. Therefore, effects of the recrystallization of alite are practically negligible in a clinker burnt by rotary kiln and its shape and size are considered to be kept as it is at the state of crystallizing.

Alite of moderate size is generally abundant in the well-burnt clinkers, and alite in the half-burnt clinkers is small. These phenomena are not caused by the length of time in treatment at a high temperature, but by the following: In the former case, a raw mixture comes into the burning zone after limestone has already been decomposed and silica has been spent to form C_2S and CaO and C_2S grow to some crystal size in decarbonating zone. In the latter, since a raw mixture containing the half decomposed limestone and free silica comes into the igniting zone, the decarbonation of limestone, C_2S formation and one of C_3S all occurs at the same time to crystallize C_3S explosively.

Effects of the Solid Solution

Birefringence of pure C_3S is in 0.002–0.003. That of alite in clinkers is generally in 0.004–0.007, but comes up to 0.010 in clinkers rich in Na_2O, SO_3 and MgO and burnt at a high temperature.

In general, birefringence of alite is low in clinkers burnt at a low temperature, and that is high when clinkers are burnt sufficiently at a high temperature. These may be caused by the high solubility of impurities in alite at a high temperature and the poor one at a low temperature.

A zoning alite whose birefringence is lower in the inner part of the crystal than in its outer zone is often found in clinkers burnt slowly to a high temperature. This may shows the process that alite with low birefringence crystallized at a low temperature absorbs the impurities from the liquid in the course of its heating up to a high temperature.

Effects of Polymorphic Transformation

Alite is usually monoclinic and rarely trigonal and triclinic in clinkers. Trigonal C_3S, containing some stabilizer, shows a high birefringence and triclinic C_3S, being pure, shows a low birefringence. It is difficult to determine whether the above tendency exists on the three forms of alite with the same chemical composition in the same quantity or trigonal alite is cooled absorbing a large quantity of impurities and triclinic alite is in the comparatively high purity.

When alite is cooled slowly in the temperature range of 1250–1300°C, its birefringence often comes to be remarkably low in spite of the absence of the decomposition of $C_3S(C_3S \rightarrow CaO + C_2S)$ and its being monoclinic optically and in the diffractometric traces. In this case, the texture of alite always departs into many small parts with the different extinction positions and the extinction in whole is indistinct. It may be reasonable that the indetectable decomposition of alite at 1250–1300°C makes the crystal structure into disorder, and this disorder acts as a nucleus in the trigonal → monoclinic inversion.

Textures of Belite

Effects of Crystallization Velocity

Belite crystallizes mostly in the very minute crystals of 1–4μ below 1300°C through the dry solid-solid reaction. The crystals of 20–40μ found in clinkers is formed by recrystallization in the course of the heat treatment at a high temperature. The direct relation cannot be found between the size of belite and its formation velocity.

Effects of Recrystallization

The liquid being formed in the course of the rising of temperature, belite begins to recrystallize quickly to a large crystal. The growth of belite in clinkers is due to the recrystallization. The grain size of belite is related to the period of the heat treatment at a high temperature after the liquid formation.

Since the large grains of feldspar or clay and CaO always react to form the liquid with a low melting point, belite contacting to the liquid crystallizes quickly to form a crust of belite crystals around the liquid. Thus these crystals are then larger than those usual.

Effects of the Solution and Separation of Impurities

Belite crystallizes at first in α'-form which is almost pure. In the previous investigation (20) the solubility of Al_2O_3, Fe_2O_3 and Na_2O are less than 1% in total. After $\alpha' \rightarrow \alpha$ inversion belite begins to absorb the impurities.

Belite separate the impurities according to the difference in their solubility during $\alpha \rightarrow \alpha'$ inversion on cooling. When belite is cooled quickly, the separation of impurities cannot be observed optically and crystals are colorless. Being cooled in a medium velocity, crystals are pale yellow. A slow cooling makes belite muddy yellow. In a extremely slow cooling, it can be observed the minute dots of impurities separated to be despersing.

Yellow or muddy of belite is more remarkable in outer zone of the crystal than in its inner part. This may be attributed to the fact that the inner part of the crystal has scarcely absorbed impurities in $\alpha' \rightarrow \alpha$ inversion and its outer part has overgrown on the former absorbing plenty of impurities by the recrystallization in $\alpha' \rightarrow \alpha$ inversion.

The half-burnt clinker burnt at a remarkably low temperature easily brings about "dusting", because belite is cooled in a pure α'-form.

Effects of Polymorphic Transformation

When clinkers are burnt below the temperature of the stable α–C_2S and cooled from the stability temperature of α'–C_2S, belite is cooled in type II with the monoclinic polysynthetic twins due to $\alpha' \rightarrow \beta$ inversion. But belite of type II is scarcely found in the commercial cements.

When clinkers are burnt at the stability temperature of α–C_2S, belite is cooled in type I with both of the skeletal structure due to $\alpha \rightarrow \alpha'$ inversion and the monoclinic polysynthetic twins due to $\alpha' \rightarrow \beta$ inversion.

The quantity of α phase of belite being contained among skeletons varys in the range of 0–30% with differing clinkers.

For α phase of belite being cooled to room temperature, it is necessary to be rich in Al_2O_3, Fe_2O_3 and Na_2O in clinkers and to cool clinkers quickly.

When clinkers are kept for a sufficiently long time at a high temperature and cooled quickly from near the lower limit of stability temperature of α–C_2S, the quantity of α phase of belit increases. This shows that the crystallinity of α–C_2S rises to restrain $\alpha \rightarrow \alpha'$ inversion under the above condition.

When clinkers are cooled very slowly, α–C_2S inverts completely to α'–C_2S. The skeletal structure occurred in three directions disappears entirely to alter into a single crystal of α'–C_2S taking a texture recrystallized in one direction, which inverts immediately to β–C_2S taking a texture of type II.

It can be easily determined whether belite of type II is one formed by the burning at a low temperature or one by the very slow cooling, because the former is taking a small round shape and the latter is a large irregular shaped grain.

Strength of Cement and Burning Condition

Hydraulic modulus, free lime and fineness of cement are known as important factors for the strength of

cement, and these are always controled by cement makers to be optimum values. But the considerable difference of the strength of cement, such as the compressive strength at the age of 28 days is 300–450 kg/cm², is usually examined. These must be due to the difference of properties of clinker minerals, such as polymorphism, crystallinity and solid solution.

Alite in commercial clinkers is almost monoclinic form, and exsolution of solutes from solid solution through cooling period cannot be detected. The difference of crystallinity can be deduced from the difference of the birefringence and of the intensity of X-ray diffraction.

Belite in commercial clinker consists of α and β-phase, and the difference of solid solution and of crystallinity also can be detected.

The compressive strength of each modifications of belite stabilized by usual components of commercial cement is examined, and the compressive strength of α-form is found to be about 3 times, that of β-form.

The chemical composition of each modifications is as follows:

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	K_2O	Na_2O
α-form	30.4	2.4	2.5	59.1	—	—	5.8
α'-form	33.8	—	—	60.0	2.3	3.8	—
β-form	31.4	2.5	2.5	63.1	—	—	0.5

(%)

The compressive strength of each modifications is as follows:

	7 days	28 days	91 days
α-form	47	80	169
α'-form	11	41	86
β-form	11	38	51

(kg/cm²)

In commercial cement, α'-form cannot be detected. Even if α'-form is contained in cement, the crystallinity may be exceedingly imperfect, and may be practically regarded as warped β-form, the compressive strength of both modifications is about the same.

The content of α-form in belite is varied according to the cooling condition. Belite quickly cooled from a high temperature contains α-form abundantly, and gives high strength. Belite slowly cooled to a low temperature scarcely contains α-form, and gives very low strength.

The relationship between the content of α-form and the strength of belite, saturated with Al_2O_3, Fe_2O_3 and Na_2O, is examined.

The chemical composition of belite is as follows:–

SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O
32.3	1.5	1.5	62.3	0.5	2.0

(%)

The samples of belite are burnt at 1450°C for 0.5, 1.0, 2.0 and 3.0 hours, and cooled under several conditions. The content of α-form is determined by X-ray diffraction method, and the strength of the cement is examined.

The results are shown as follows:

The relationship between the content of α-form and the compressive strength of belite, burnt under several burning conditions.

Burning period at 1450°C (hr)	Quickly cooled from the temp. (°C)	α-form (%)	Compressive strength* (kg/cm²) 7d.	28d.	91d.
0.5	1400	20	42	102	183
	1300	24	57	132	231
	1200	29	42	126	251

	1300	26	53	138	262
	1200	20	45	101	204
	1100	0	26	53	142
3.0	1400	4	46	116	253
	1300	22	47	132	265
	1200	17	32	89	206
	1100	0	19	53	172

*Test pieces of 1 × 1 × 7cm—1/2 Mortar (W/C = 0.65)

The effect of colling condition on the strength of cements prepared from raw materials used in plant is examined.

The chemical composition and the mineral composition of the clinker are as follows:

	SiO_2	Al_2O_3	Fe_2O_3	CaI	MgO	Na_2O	K_2O (%)
MC	24.5	4.2	4.3	65.7	1.7	0.33	0.41
NC	22.7	5.1	3.3	66.2	1.6	0.30	0.54
HC	21.9	5.1	3.0	67.3	1.7	0.28	0.45

Free CaO	C_3S	C_2S	C_3A	C_4AF	Alite	Belite	Matrix (%)
0.0	46.3	35.5	3.9	13.1	46	36	18
0.5	56.2	22.9	8.0	10.0	64	16	20
1.4	63.7	14.9	8.4	9.0	76	2	22

Note: MC; Moderate heat cement, NC; Normal cement
HC; High early strength cement
C_3S—C_4AF; Calculated by Bogue's equation
Alite—matrix; Measured by microscopic method.

The moderate heat cements and the normal cements were burnt at 1450°C for 30 minutes, and the high early strength cements were burnt at 1500°C for 45 minutes, and each cements were cooled under four conditions, shown as (Q), (M), (S) and (VS).

(Q): Quickly cooled from burning temperature.
(M): → 1200°C for 15 mins., → 500°C for 10 mins.
(S): → 1000°C for 25 mins., → 500°C for 15 mins.
(VS): → 1000°C for 25 mins., → 500°C for 35 mins.
The compressive strength of cements are as follows:

Cement	Cooling condition	3d	7d	(kg/cm²) 28d
MC	Q	57	93	215
	M	60	83	172
	S	62	94	157
	VS	59	89	158
NC	Q	99	153	259
	M	97	210	273
	S	97	193	239
	VS	87	187	230
HC	Q	102	188	293
	M	142	267	333
	S	102	210	292
	VS	91	181	279

The strength of moderate heat cement at the ages of 3 days and 7days is scarcely varied by cooling condition. At the age of 28 days, the slower is the cooling, the lower is the strength.

The strength of high early strength cement, at all ages, moderately cooled is strongest.

The situation of normal cement is medium for the above two types cements. From these facts, the following is induced.

1) When clinker is cooled quickly, belite contains α-form abundantly, and the compressive strength becomes stronger.
2) When clinker is cooled moderately, the crystallinity of R-form of alite may rise at the lower part in the stable temperature reagion of the R-form, and inversion of modifications may be disturbed, and alite is cooled in active state.
3) The compressive strength of cement is additive for that of alite and belite.

The burning condition and strength of cement are now inferable from the optical and X-ray diffraction test, and the faults in burning can be pointed out to reform the quality of clinker.

Normal portland cements sold in Japan in 1962 and 1963 were examined. Some of them are omitted, having the obvious faults on chemical composition, free lime, fineness and storage.

The properties of the 45 cements used in this examination were as follows:
Specific gravity: 3.12–3.18 specific surface (Blaine) 3010–3430 cm²/g., ig. loss: 0.5–1.5%, SM: 2.5–3.0, HM: 2.02–2.11, free lime: 0.2–1.1%.

Among the several properties obtained by microscopic observation and X-ray diffraction, content of α-form in belite, color of belite and birefringence of alite were most characteristic.

Compressive strength at 28 days (kg/cm²)	Number of cement	α-form(%) Max.–Min.(Mean)	Color of belite (No. of cement) Color-less	Yellow	Amber
(455)— 410	14	36—13(22.4)	14	0	0
410 — 360	19	30— 8(18.2)	0	18	1
300 —(298)	12	24— 0(9.7)	0	3	9

birefringence of alite (number of cement)	
$B \geqq 0.007$	$B < 0.007$
13	1
3	16
0	12

Occurrance of alite with high birefringence and belite containing α-form abundantly and being colorless in high strength cement shows that the cement was burnt at a high temperature and quickly cooled. Low temperature burning and slow cooling almost go together in cement burning, and take the greater parts of faults in cement burning.

Conclusion

The authors studied the microscopic figures and inner textures of the minerals occurring in clinkers, referring to the fundamental knowledges about the crystal structures and the polymorphisms. And the meaning of the figures and the textures were ascertained.

The conclusions are as follows:

a–1 The external figure of alite is that of trigonal form with the symmetry of D3d.

a–2 The crystal faces are indexed, setting the crystal axes as $-h + k + 1 = 3n$, as tabular basal planes {c}:{0001}, rhombohedral planes {r1}: $\{01\bar{1}2\}$ and rhombohedral planes {r2}:$\{10\bar{1}1\}$.

a–3 Acute bisectrix, X, is exactly parallel to the 3-fold axis, c, of trigonal form and perpendicular to basal plane, (c), except triclinic form. X is used as most sure datum line.

a–4 The external figure of alite is deformed by paragenetic twin. The twin planes, (c) and (r1), are common.

a–5 The optical property of alite is disordered by metagenetic twin. Triple cyclic twin occurres by trigonal → monoclinic inversion, polysynthetic twin occurres by monoclinic → triclinic inversion.

b–1 Belite in clinker is crystallized in irregular rounded grain.

b–2 Belite is classified into two types, named "Type I" and "Type II"

b–3 Type I has a skeleton structure and a polysynthetic structure. Type II has only a polysynthetic twin structure. The skeleton structure is observed as complexed lamellae structure. The polysynthetic twin structure of Type I is very minute. The polysynthetic twin structure of Type II, substantially same as that of Type I, is observed as parallel striations.

b–4 The skeleton structure occurres by $\alpha \rightarrow \alpha'$ inversion. Through this process, α'-phase grows into skeleton crystal, following the crystal structure and symmetry of α-form, and a part of α-form remains between the lamellae of skeleton crystal.

The crystal faces of the lamellae of skeleton crystal are indexed as follows:

α-form $\{10\bar{1}2\} \rightarrow \alpha'$-form $\{112\}$,

$\{022\} \rightarrow \beta$-form $\{1\bar{1}2\}$, $\{112\}$, $\{022\}$

b–5 The polysynthetic twin structure occurres by $\alpha' \rightarrow \beta$ inversion. The conjugate planes of the twin structure are as follows: (100) and (010) are dominant, (110) and (011) are rare.

b–6 The acute bisectiox, Z, of β-form is exactly parallel to the 3-fold axis, c, of α-form, and is used as most sure datum line.

Burning condition of cement clinker and hydraulic strength of cement can be deduced from the microscopic observations of clinker minerals. In this examination, immersed powder preparation of clinker or cement may be used for thin section. This technique is effective to the daily control of clinker burning in manufacture.

Distinct features of clinker minerals varied with burning conditions are as follows:

c–1 When raw mixture is heated slowly, at low temperature C_2S and CaO grow to coarse grains, and velocity of C_3S formation at high temperature decreases, and alite in clinker crystallizes in large and thick form.

c–2 When clinker is burnt up to a high temperature, birefringence of alite becomes higher. This phenomenon may depend on the crystallinity of alite and the content of impurities in alite.

c–3 When clinker is burnt for a long period, alite and belite recrystallize into large crystals.

c–4 When clinker is cooled slowly, value of birefringence of alite decreases and that of belite increases, and α–C_2S content of belite decreases and belite exsolutes the solid solute and the color of belite grains turns from colorless to yellow or amber. These phenomena are related to transformation of temperature modifications of alite and belite.

The quality of alite and belite is a dominant factor affecting the compressive strength of cement. Generally, high temperature modification of crystals is more active than low temperature modification.

In order to obtain a high strength cement, (1) clinker must be burnt at a high temperature for a sufficiently long period to raise crystallinity of high temperature modification and (2) cooled quickly from moderately high temperature to stop the inversion.

Supplementary Paper I-95 Thermal Stabilization of β-2CaO, SiO_2

Valentin I. Korneev and Elysaveta B. Bygalina*

Synopsis

The conditions of transformation of γ–2CaO·SiO_2 into the β-form due to heat treatment without introducing the additions—stabilizers have been studied. The degree of transformation of γ–β–C_2S depends upon the temperature and upon the duration of heat treatment (reheating in the range of 900–1500°C). Thermally stabilized β–C_2S has the refractive indices, X-ray data and differential thermal analysis corresponding to the β-form, and it preserves the shape of the grains, the cleavage, the extinction and the elongation which is typical of the original γ–C_2S. The formation of solid solutions of CaO in dicalcium silicate promotes the stabilization of the β-form. β–2CaO·SiO_2 has been obtained which contains up to 6 per cent of excess CaO in a solid solution. The availability of binding properties of γ–C_2S containing CaO in a solid solution has been determined. The dependence of the hydraulic activity of the β-form of dicalcium silicate upon the concentration of CaO in a solid solution has been found.

Introduction

It is considered that dicalcium silicate which is one of the main minerals of portland-cement clinker may exist in four polymorphous modifications: γ, β, α' and α, from which only γ–C_2S is stable at room temperature (1, 2). The existence of high temperature modifications of Ca_2SiO_4 in industrial products is connected with crystallochemical stabilization (the presence of additions-stabilizers). The attempts to obtain β, α' or α–C_2S without introducing stabilizers were not successful.

In the works of the chair of chemical technology of cement, Leningrad Lensoviet Institute of Technology, the Soviet Union, the possibility to obtain β–C_2S without stabilizers by means of thermal stabilization (by annealing) has been considered. The problems of thermal stabilization of β–C_2S depending upon the formation and the concentration of solid solutions of calcium oxide in dicalcium silicate (with the ratio of $\frac{CaO}{SiO_2} \leqslant 2$) are discussed in the present paper.

Experimental Part

The raw mixture of $\frac{CaCO_3}{SiO_2} = \frac{2}{1}$ was prepared from the calcium carbonate of high purity and anhydrous spectrally pure silicic acid. The raw mixture was ground in a jet mill until the fineness of 1–3 microns was reached, in conditions excluding contamination. On the basis of such a raw mixture, after its having been mixed according to the chemical analysis, the mixtures of the following compositions have been prepared: $\frac{CaO}{SiO_2} = 2.00$, 2.10, 2.20, 2.22 and 2.24. The burning of the samples was carried out in the laboratory kiln with carborundum heaters at the temperature of 1500°C and rapidly cooled in air.

The petrographic analysis of sinter materials (not containing CaO) did not show the presence of any other phases but dicalcium silicate up to the ratio of $\frac{CaO}{SiO_2} = 2.20$. Only with greater CaO content the phases different from those of C_2S appear in the sinter material.

As far as the authors were interested in the stage where dicalcium silicate appeared, the work was further carried on with the following compositions of $\frac{CaO}{SiO_2} = 2.00$, 2.10, and 2.20, which contained 0.3 and 6 per cent of excess CaO respectively in comparison

*Leningrad Lensoviet Technological Institute, U.S.S.R.

with the stoichiometric dicalcium silicate. The immersion analysis has shown that the sinter material of $\frac{CaO}{SiO_2} = 2.0$ composition, which crumbled on cooling, consists completely of γ-C_2S, where $Ng' = 1.656$ and $Np' = 1.642$ ($Ng' - Np' = 0.014$). The crystals of γ-C_2S are prismatically elongated in shape, have perfect cleavage and great 2V, positive optical sign and negative elongation; they are also biaxial. The extinction is parallel to the prism.

The sinter materials which $\frac{CaO}{SiO_2}$ is higher than 2.0, except γ-form, have a certain amount of β-C_2S ($Ng' = 1.739$, $Np' = 1.718$); it amounts to 10–15 per cent for $\frac{CaO}{SiO_2} = 2.10$ and 15–20 per cent for $\frac{CaO}{SiO_2} = 2.20$. γ-$2CaO \cdot SiO_2$ in those sinter materials has $Ng' = 1.662$; $Np' = 1.642$; $Ng' - Np' = 0.020$. The shape of the grains is prismatically elongated, with perfect cleavage. The elongation is negative, 2V is great, the optical sign is negative, the grains are biaxial. The extinction is parallel to the cleavage.

The durable burning at the temperature of synthesis did not change the phase relationships (the relation between γ-β forms), only the dimensions of the grains of $2CaO \cdot SiO_2$ were altered. Thus, the difference of sinter materials having $\frac{CaO}{SiO_2}$ more than 2.0 from stoichometric composition is in the appearance of β-form, which is connected with the excess lime stabilization. The stabilization, however, takes place only partially (up to 20 per cent). γ-$2CaO \cdot SiO_2$ in sinter materials which $\frac{CaO}{SiO_2}$ is more than 2.0 has higher refractive index than the normal ones, greater birefringence and it changes the optical sign of the crystals from positive to the negative one, which indicates the formation of solid solution of CaO in γ-dicalcium silicate. This conclusion is confirmed by the X-ray analysis and the infra-red spectroscopy.

The compositions burned at 1500°C and having molar ratio of $\frac{CaO}{SiO_2} = 2.00$; 2.10; 2.20 were annealed (reheated) within the temperature range of 800–1400°C during the time from 5 to 240 min. The degree of thermal stabilization (the content of β-$2CaO \cdot SiO_2$) was determined by the immersion method for all samples (See Table 1).

It follows from the table that 90–95 per cent β-C_2S can be obtained as a result of thermal stabilization, by means of annealing γ-C_2S. The degree of γ-β transformation during thermal stabilization (annealing) depends upon the composition of the original γ-$2CaO \cdot SiO_2$. The most favourable conditions for stabilizing β-C_2S are obtained at a maximum level of supersaturation γ-dicalcium silicate with $CaO\left(\frac{CaO}{SiO_2} = 2.20\right)$.

For C_2S having $\frac{CaO}{SiO_2} = 2.00$ and 2.10, β-C_2S is thermally stabilized only at the temperature of 1000°C. For the composition having $\frac{CaO}{SiO_2} = 2.20$, β-form is stabilized within the temperature range of 1000–1400°C. For each annealing temperature there is a most favourable time period, giving the maximum yield of β-$2CaO \cdot SiO_2$.

To avoid possible stabilization of β-C_2S by the materials sublimed out of refractories, coatings, and heaters of the furnace, the control experiments were made with annealing of γ-C_2S in a closed platinum crusible sealed in quartz tube. Under those conditions the stabilization of β-$2CaO \cdot SiO_2$ also took place, that gives reason to consider the process of stabilization from the point of view of annealing exclusively.

Petrographically, in β-C_2S, stabilized by the annealing of the γ-form and having the ratio of $\frac{CaO}{SiO_2} = 2.00$, the shape of the grains, the cleavage, the extinction, the elongation, which are characteristic for the γ-dicalcium silicate are retained. At the same time the optical sign of the crystals is changed and the refractive indices are found, which are characteristic for β-$2CaO \cdot SiO_2$ $Ng' = 1.734$, $Np' = 1.716$ ($Ng' - Np' = 0.018$). The crystals of β-C_2S, obtained from

Table 1. *Thermal stabilization of* β-$2\,CaO \cdot SiO_2$

The ratio of $\frac{CaO}{SiO_2}$ in dicalcium silicate	The degree of thermal stabilization (content of β-C_2S in %)														
	800°C			1000°C			1100°C			1200°C			1400°C		
	Time of annealing in minutes														
	5	30	90	5	30	90	5	30	90	5	30	90	5	30	90
2.00	0	0	0	75	85	70	0	0	0	0	0	0	0	0	0
2.10	0	0	0	55	80	80	0	0	0	0	0	0	0	0	0
2.20	0	0	0	70	80	95	75	85	95	80	90	95	90	95	95

γ–$2CaO \cdot SiO_2$, which contains in the lattice 3 and 6 per cent of excess lime respectively are characterised by the prismatically elongated shape, perfect cleavage, greater 2V value, negative optical sign and $Ng' = 1.739$; $Np' = 1.716$. $(Ng' - Np' = 0.023)$

The X-ray patterns of the annealed products with variable ratio of $\frac{CaO}{SiO_2}$ show the difraction maximums of the β-form of C_2S (in the samples, where $\frac{CaO}{SiO_2} = 2.00$ and 2.10, γ-C_2S is also present). Particularly clearly the thermal stabilization of β–$2CaO \cdot SiO_2$ is determined by the method of differential thermal analysis (Fig. 1). Thus, for the curves 5, 3 and 1 corresponding to γ–C_2S, having the ratio of $\frac{CaO}{SiO_2} = 2.00$; 2.10 and 2.20 respectively, the transformation of γ-α' is typical at the temperatures 750–760°C. The curves 6, 4, 2 correspond to the same products in the annealed state. In the curves 6 and 4 the endothermal effects are shown which are characteristic of the β to α' (at 660°C) and γ to α' (at 745°C) transformations.

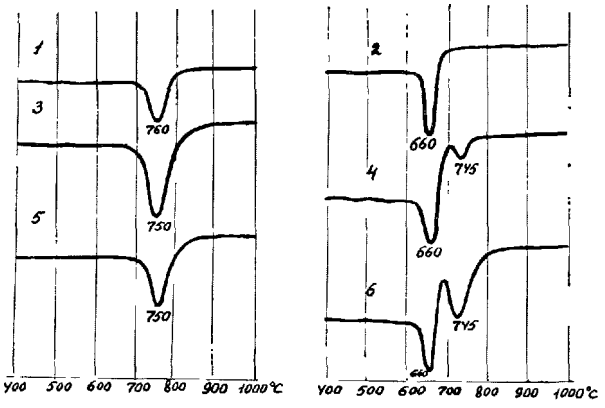

Fig. 1. *Differential thermal analysis of* $2CaO \cdot SiO_2$.
1, 3, 5 are the curves of heat treatment of γ-C_2S obtained from the raw material and having $CaO/SiO_2 = 2.20$, 2.10 and 2.00 respectively.
2, 4, 6 are the curves of heat treatment of the annealed materials of γ–C_2S having the same ratio of CaO/SiO_2 (respectively).

β-from thermally stabilized from γ–C_2S, where $\frac{CaO}{SiO_2} = 2.20$ (curve 2) does not contain γ–C_2S and so it gives only one endothermal effect (at 660°C) which is characteristic for the β to α' transformation.

As far as non-stoichiometric γ–C_2S or β–C_2S which did not contain the additions-stabilizers were not known, it was interesting to study the properties of these phases and especially their hydraulic activity. The compressive strength of samples (1 : 3 mortar) kept under humid condition is determined after 7,28 days and three months curing. Moreover, the compressive strength of specimens autoclaved under the pressure of 8 atm. is determined (See Table 2). The binding properties of the compounds received by the authors have been compared with those of γ–C_2S and β-form stabilized by boric anhydride (Table 2). Two points should be considered (Table 2):

1. The appearance of binding properties of γ–C_2S containing CaO in solid solution.
2. The influence of CaO concentration in solid solution $\left(\text{the ratio of } \frac{CaO}{SiO_2}\right)$ on the hydraulic activity of β–$2CaO \cdot SiO_2$.

The hydraulic activity of γ–C_2S (having $\frac{CaO}{SiO_2} = 2.20$) is of the same order as that of the β-form stabilized by B_2O_3 and on the same level as β–C_2S thermally stabilized and having $\frac{CaO}{SiO_2} = 2.00$.

While increasing the ratio of $\frac{CaO}{SiO_2}$ up to 2.20 (6 per cent of CaO in solid solution) the hydraulic activity of C_2S increases twice during 28 days, and four times when autoclaving. γ–$2CaO \cdot SiO_2$ with the molar ratio of $\frac{CaO}{SiO_2} = 2.00$ has no binding properties. One should think that when excess CaO is dissolved in dicalcium silicate, the regular olivine structure of γ–C_2S is changed into the one having irregular coordination of calcium with oxygen that is supposed to be the reason of the appearance of binding properties.

Table 2. *Binding properties of synthesized forms of dicalcium silicate*

Composition of the product	Molar relation of $\frac{CaO}{SiO_2}$	Compressive strength in kgs. per sq. cm			
		after 7 days	after 28 days	after 3 months	after autoclaving under 8 atm.
γ–C_2S	2.00	0	0	0	not determined
γ–C_2S	2.20	10	15	not determined	40
β–C_2S stabilized by B_2O_3	2.00	15	15	not determined	15
β–C_2S	2.00	10	15	not determined	10
β–C_2S	2.10	10	20	40	55
β–C_2S	2.20	10	15	140	250

Summary

1. The authors have the conditions of stabilizing β–$2CaO \cdot SiO_2$ not containing additions-stabilizers, due to annealing γ–C_2S. The formation of solid solutions CaO in C_2S propmotes the stabilization of the β-form of dicalcium.

2. γ and β–$2CaO \cdot SiO_2$ have been synthesized which contain up to six per cent of excess calcium oxide in a solid solution.

3. The binding properties of γ–C_2S has been given when it contained CaO in a solid solution.

The dependence of the hydraulic activity of β–C_2S upon concentration in a solid solution of calcium oxide has been shown.

Supplementary Paper I-101 Properties of Substituted Dicalcium Silicate and Alumino-Ferrite

M. K. Gharpurey and V. N. Pai*

Synopsis

It is known that ionic substitutions can occur in portland cement clinker minerals, and that such substitutions can materially alter their properties including the rate of hydration.

In this study β–C_2S was prepared in which some of the Si^{4+} ions were substituted with tetrahedral Al^{3+}, by using lime-soda felspar (bytownite) and potash soda felspar (microcline), in which all the Al^{3+} ions are tetrahedrally coordinated as the main siliceous material.

The bytownite-based products required boric acid for stabilization of the β–C_2S phase, while the microcline-based preparations did not require boric acid. The products contained some C_3A, those with larger attempted substitution containing more C_3A.

The larger was the attempted substitution of Si^{4+} by Al^{3+}, the faster was the rate of hydration. The bytownite-based products released much more $Ca(OH)_2$ during hydration.

In the $C_6A_xF_{3-x}$ series, in C_4AF with Fe partly or wholly substituted with Mn and/or Ca partly substituted with Mg and in C_6AF_2 with half of Fe substituted by Mn, the rates and the products of hydration were studied, and differences observed.

On admixing with water, some of these started hydrating immediately while the others exhibited induction periods of at least 1 1/2–2 hours before the start of hydration.

Introduction

The main phases of portalnd cement clinker, viz. the two calcium silicates, and calcium aluminate and alumino-ferrite are not pure in that other ions such as aluminium and magnesium are known to enter e.g. the silicate lattice. The presence of such foreign ions may modify the structure and stabilize certain phases, or make the compound more or less hydraulic.

Thus e.g. a number of oxides besides B_2O_3 stabilize the β–C_2S structure by substitution for SiO_4^{4-} other groups such as BO_4^{5-}, PO_4^{3-} where B^{3+}, P^{5+} are smaller than Si^{4+} ions, or by replacing some of the Ca^{2+} ions with larger cations Ba^{2+}, K^+ etc. (1). Stabilization due to larger size ions such as of chromium and manganese substituting for Si^{4+} has also been reported (2). Incorporation of P_2O_5, V_2O_5, BaO makes β–C_2S chemically more active to the hydration reactions (3), and it is thought that in the extreme case β–C_2S can be made to approach C_3S in the development of early strength (4). Therefore, a study of the formation of such substituted compounds and their hydration behaviour should prove to be of interest.

One of the possible significant modifications of β–C_2S is the substitution of some of the Si^{4+} ions with tetrahedrally coordinated Al^{3+} ions with the charge neutralization being obtained with interstitial cations or in some other way. Towards this end members of the felspar series were chosen as the main siliceous material since in these all the Al^{3+} ions are tetrahedrally coordinated with the oxygens and form part of the silicate network, the charge balance being effected by cations such as Na^+, K^+, Ca^{2+} in intermediate lattice positions (5). The felspar together with lime and silica to give varying degrees of substitution of Si^{4+} by Al^{3+} was heated to high temperatures to give the β–C_2S.

The calcium alumino-ferrite in portland cement is a member of the solid solution series from C_2F to alumina-rich $C_6A_{2.1}F_{0.9}$. The rate of hydration as well as the nature of hydrated products in this series are known to depend on the A/F ratio of the material (6). Further changes in the properties of these compounds on replacing the Fe_2O_3 partly or wholly by Mn_2O_3 as also on replacing CaO partly by MgO should prove of interest. The manganite analogue of C_4AF, viz. C_4AM' ($M' = Mn_2O_3$) is known, and a complete solid solution range between C_4AF and

*The Associated Cement Cos'. Central Research Station, Thana, India.

C_4AM' has been observed (7). However, the hydration behaviour of the manganese-containing compounds does not appear to have been reported.

Experimental

The finely powdered −90 microns materials were blended, pelletized at 30 tons/sq. inch pressure, and heated for 2–4 hours at temperatures around 1250°–1450°C at which the pellets showed slight softening. After powdering the pellets the free lime of the product was determined, and in case it was above 1.0 per cent, the pelletizing and the heat treatment were repeated. The pellets were now pulverized to −44 microns and used for further hydration studies. The powdered material as such or after admixing 4.3% $CaSO_4 \cdot 2H_2O$ (2.0% SO_3) was used for further hydration studies.

1. The specific gravity of the samples was determined. The different substituted β–C_2S preparations were assumed to have the same monoclinic symmetry as β–C_2S, and the various ferrites and manganites to have the same orthorhombic symmetry as brownmillerite. From the X-ray spacings of four and three lines respectively the unit cell dimensions were calculated and, in the case of ferrite-manganite series, the density as determined in this manner from the X-ray data was compared with the above value. Cu KαX-radiation was used for the diffraction studies.
2. The different powders (with and without $CaSO_4 \cdot 2H_2O$) were mixed with water to have a W/C ratio of 0.4–0.5 for the β–C_2S preparations and 0.5 for the ferrite-manganites (0.75 was required for C_6A_2F in order to avoid undue stiffening during mixing) and left hydrating in sealed test tubes. At the end of 1- (for ferrite-manganites only), 3-, 7-, 14-, 28- and 56- (for β–C_2S preparations only) day hydration the material was powdered to −592 microns, washed twice with acetone and ether, filtered, further powdered to −75 microns, and taken up for D.T.A. and X-ray diffraction examination as well as for fixed water (loss on ignition). It was found that the loss due to any uncombined water, acetone and ether still remaining in the sample was less than 1 per cent so that prior drying of the sample before ignition was not resorted to. For D.T.A. 125 mg of the sample was mixed with equal mass of finely powdered calcined alumina and the whole material was packed in the sample holder. For X-ray examination 0.5 g of the unhydrated material or 0.45 g of the hydrated material was packed in the standard size diffractometer specimen holder.
3. In some case 100 ml of water were added to 0.4 g of the sample along with 0.15 g of $CaSO_4 \cdot 2H_2O$, and the flask was shaken continuously. The pH of the suspension was periodically determined. At the end of 1 and 3 days the suspension were filtered and the residue examined by D.T.A.
4. In the case of the ferrites-manganites the sample was mixed with water (W/C = 0.5), packed in the X-ray diffractometer specimen holder, covered with a thin polythene film, the diffractometer adjusted to the top of the most intense ferrite peak, and the X-ray count taken periodically to determine the initial rate of hydration according to the method described by Tsumura (8).

The results for the β–C_2S and the alumino-ferrites are discussed separately in the following.

Substituted β-C_2S

Materials

There were two felspars used for the following experiments, a lime-soda felspar and a potash-soda felspar called bytownite and microline respectively in the following:

In calculating the compositions of the felspars the following assumptions were made:

i) Al^{3+} went into tetrahedral positions along with Si^{4+} to the extent that other charge neutralizing cations were available;

ii) In the case of bytownite, where there was an excess of the charge neutralizing cations, these were present in the felspar lattice in proportion to their molar concentration in the sample.

On these assumptions, these samples were supposed to be composed of the following:

Bytownite $Na_{0.51}K_{0.05}Ca_{0.96}Mg_{0.19}Al_{2.85}Si_{5.15}O_{16}$		94.46%
	Excess Fe_2O_3	4.20
	CaO	0.16
	MgO	0.02
	Na_2O	0.19
	K_2O	0.03
	Loss	0.50
	Total	99.56
Microcline $K_{1.34}Na_{0.47}Al_{1.81}Si_{6.19}O_{16}$		94.94%
	Excess Al_2O_3	3.67
	Loss	0.63
	Total	99.24

Thus, in bytownite, the Al^{3+} had substituted for Si^{4+} in 5.70 positions out of 16 and, in microcline, the substitution was in 3.62 positions in 16.

This tetrahedrally coordinated aluminium was regarded as equivalent to silicon and the felspar was regarded as equivalent to SiO_2 with some charge neutralizing interstitial cations. Silica and lime were added to the felspar so that in the β–C_2S finally produced the Al^{3+} should substitute for Si^{4+} in 4, 2,1 positions in 16. (The microcline did not require any silica addition for approximate 4 in 16 substitution).

Silica gel (B.D.H) and dehydrated amorphous silicic acid were used for silica additions. The lime used was obtained by calcining $CaCO_3$ of better than 99.5% purity.

The following observations were made:

i) The microcline-based preparations required heating at 1460°–1480°C, while the bytownite-based preparations reacted at 1380°–1400°C only.

ii) The two preparations with 4 in 16 Al substitution required two heating cycles, while the remaining four required a single heating cycle only for bringing down the free lime.

iii) The bytownite-based preparations required 0.5 % B_2O_3 added to the raw mix to prevent conversion of the product to γ–C_2S and consequent dusting. On the other hand, the microcline-based preparations did not require a stabilizer for the β–C_2S phase. The 4 in 16 substitution product did not dust at all. The 2 in 16 product showed slight dusting tendency and the 1 in 16 product dusted to the extent of 10% only, and was examined free of dust.

The bytownite-based 4 in 16 product was analyzed for ferrous iron since Fe^{2+} has been reported to promote the conversion of β–C_2S to γ–C_2S (2). However, all the iron in it was found to be in the ferric state.

For comparison, synthetic C_3S and boric acid stabilized β–C_2S were also used.

Results

The six products were chemically analyzed. The design and the actual values of the alkalis are given in the following:

Bytownite-based preparations

Desired replacement of Si *by* Al:	*4 in 16*		*2 in 16*		*1 in 16*	
	Actual	*Design*	*Actual*	*Design*	*Actual*	*Design*
Na_2O	0.81%	0.77%	0.49%	0.39%	0.32%	0.20%
K_2O	Nil	0.10	Nil	0.05	Nil	0.03

Microcline-based preparations:

Desired replacement of Si *by* Al:	*4 in 16*		*2 in 16*		*1 in 16*	
	Actual	*Design*	*Actual*	*Design*	*Actual*	*Design*
Na_2O	0.54%	0.96%	0.32%	0.57%	0.26%	0.28%
K_2O	0.19	4.18	0.19	2.43	0.58	1.24

The analyses show that from the microcline-based preparations a large proportion of the potash as well as some soda also had evaporated during the heat treatment. From the bytownite-based preparations also the minor quantities of potash volatilized completely.

The X-ray diffraction analysis also showed these samples to be composed of β–C_2S as the main phase along with some C_3A, the proportion of C_3A increasing in the higher substituted compounds. Obviously some of the aluminium ions had come out of the β–C_2S lattice so that the actual substitution of Si^{4+} by Al^{3+} was less than the attempted 4, 2 and 1 in 16. For convenience, however, these samples will be referred to as 4, 2 and 1 in 16 substitution products.

In addition to the above, the two 4 in 16 products contained some C_3S. (In the microcline-based sample a little more lime than needed was already present in the raw mix).

The 4 in 16 bytownite-based product showed, in addition, the presence of some α–C_2S from the 32.4° 2θ line between the 32.1° and 32.6° β–C_2S lines as well as from the fact that the 33.2° 2θ line (due to C_3A) did not disappear completely at 3-day hydration, but rather went down to a small peak at 33.0° 2θ, which corresponds to α–C_2S and which had earlier merged in the strong C_3A line.

Unit Cell Dimensions

The X-ray diffractometer records of these six products were taken with silicon metal as internal standard, and the positions of the (020), (210), (031) and (202) peaks of β–C_2S accurately determined. Assuming these products to have the same monoclinic

symmetry as boric acid stabilized β–C_2S, the lattice constants of these modified β–C_2S products were determined.

Attempted substitution	β–C_2S *Bytownite-based*	*Microcline-based*
4 in 16	$a = 5.50$Å	$a = 5.51$Å
	$b = 6.79$	$b = 6.78$
	$c = 11.06$	$c = 11.00$
	$\beta = 123°28'$	$\beta = 123°47'$
2 in 16	$a = 5.50$Å	$a = 5.50$Å
	$b = 6.77$	$b = 6.76$
	$c = 11.22$	$c = 11.18$
	$\beta = 123°40'$	$\beta = 123°45'$
1 in 16	$a = 5.50$Å	$a = 5.51$Å
	$b = 6.77$	$b = 6.77$
	$c = 10.98$	$c = 11.04$
	$\beta = 123°39'$	$\beta = 123°46'$

These values may be compared with the literature values for β–C_2S (9)

$a = 5.514$Å
$b = 6.757$
$c = 11.197$
$\beta = 123°59'$

The differences are thus not very significant.

Specific Gravity

The specific gravity of these products was found to be:

Design substitution	*Bytownite-based*	*Microcline-based*
4 in 16	3.19	3.23
2 in 16	3.24	3.25
1 in 16	3.24	3.29

The literature values of the specific gravity of a few of the substances concerned are as follows (9):

β–C_2S	3.28
γ–C_2S	2.97
α–C_2S	3.04
α'–C_2S	3.40
C_3S	3.12–3.25
CaO	3.345
C_3A	3.03

The 4 in 16 products contained the largest C_3A, besides some C_3S. In addition, the bytownite-based product showed some α–C_2S also. Thus, these products showed lowest specific gravity.

One may add that, if there is 4 in 16 substitution of Si^{4+} by Al^{3+} with lime alone as the charge neutralizing cation, the formula for C_2S would be:

Table 1. *Fixed water of samples hydrated for varying periods/days (Unhydrated basis)* (%)

	Hydrated as such					Hydrated with 2.0%SO_3*				
Preparation	3	8	14	28	56	3	8	14	28	56
Bytownite-based

2 in 16	8.7	13.8	18.1	25.5	28.7	10.2	15.2	18.3	24.5	25.8
1 in 16	4.2	7.4	12.2	19.0	28.9	7.1	9.2	12.6	17.0	23.8
Microcline-based										
4 in 16	19.8	23.3	24.2	25.3	30.6	18.1	23.5	24.4	25.5	30.4
2 in 16	6.2	7.9	8.0	10.9	18.5	8.3	18.9	10.5	12.0	13.8
1 in 16	4.7	5.9	5.9	10.7	19.0	7.5	7.8	10.4	14.7	21.2
β-C_2S (Boric acid stabilized)	3.7	9.5	13.9	18.8	—					
C_3S	16.0	19.3	24.1	29.0	—					

*The fixed water of unhydrated material will be 0.9% due to 4.3% gypsum.

$16CaO \cdot CaAl_2Si_6O_{16}$ instead of $16CaO \cdot Si_8O_{16}$. Assuming no change in the lattice dimensions, the specific gravity would increase from 3.28 to 3.37 only.

Fixed water

The water fixed at 3 days is, to non-inconsiderable extent, due to the hydration of C_3A. Since the higher substitution products contained more C_3A, their higher fixed water contents are partly due to the C_3A hydration.

The difference in the water fixed at 3 days and at 8 days can be, for a given series of products, a measure of the rate of hydration of the β–C_2S. The higher substitution products thus appear to hydrate faster.

The water fixed by the bytownite-based products is higher than that by the microcline-based products. This is, to some extent, due to more $Ca(OH)_2$ being released by the former during hydration, as will be presently seen.

Hydration Studies with X-ray Diffraction and D.T.A.

Bytownite-Based Products:
4 in 16:

Almost all the C_3A had hydrated at 3 days giving C_4AH_{13} when hydrated as such, and monosulphate with a trace of ettringite when hydrated with gypsum. The ettringite disappeared at later ages while the C_4AH_{13} and monosulphate respectively remained at the same level as examined both by X-rays as well as by D.T.A.

The small quantity of C_3S had of course hydrated at 3 days.

The amount of $Ca(OH)_2$ formed was large com-

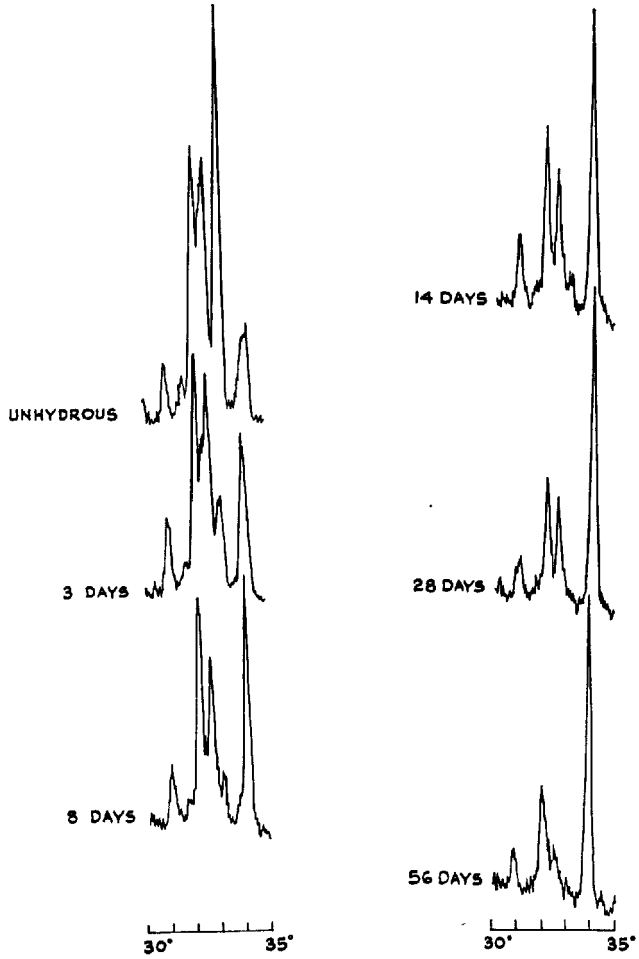

Fig. 1. *X-ray diffractometer trace between 30° and 35° 2θ of bytownite-based "4 in 16" substituted β-C_2S hydrated for different periods.*

pared to that formed by pure β–C_2S at 3 days, and this increased with age along with the endothermic dip due to tobermorite gel, while at the same time the X-ray lines due to the unhydrated β–C_2S went down in intensity (Fig. 1). The lime was obviously coming out of the β–C_2S lattice.

A small tobermorite peak at 50.0° 2θ appeared at 14-day hydration only as with C_3S, and a further low angle 8.1° peak appeared at 28 days.

On hydrating with SO_3, α–C_2S also appeared to hydrate by 2 months.

The X-ray lines due to the β–C_2S went down in intensity considerably by 56 days.

2 in 16 and 1 in 16:

These products contained, besides β–C_2S, lower and lower amounts of C_3A as compared with 4 in 16, the C_3A formed decreasing with the attempted substitution of Si by Al. As a result, on hydrating without SO_3 less and less of C_4AH_{13} was formed, the low angle X-ray peak of which became much diffused and smaller at 28 days.

On hydrating with SO_3, the 2 in 16 gave monosulphate and ettringite, while the 1 in 16 gave ettringite only. These sulpho-aluminates remained constant at later ages except that in 1 in 16 the ettringite peak at 8.9° split up into two (9.0°, 9.2°) at 28 days.

The lower the attempted substitution, the less was the $Ca(OH)_2$ formed, and the tobermorite D.T.A. endothermic peak was less strong at a given age with lower substitution products. Under X-rays the 50.0° 2θ peak also appeared later at 28 days with the 2 in 16 product hydrated with SO_3, and with the 1 in 16 products.

The higher substitution products thus appeared to hydrate faster.

Microcline-Based Products:

4 in 16:

At 3 days the small quantity of C_3S and the C_3A hydrated completely, the latter yielding C_4AH_{13} on hydration without SO_3, and monosulphate and C_4AH_{13} when hydrated with SO_3. These compounds remained at a constant level throughout further period of hydration.

There was only a trace of $Ca(OH)_2$ at 3 days. Of course some of the lime released must have been taken up to form C_4AH_{13} from C_3A. The $Ca(OH)_2$ increased with age.

A prominent endotherm due to tobermorite was seen at 3 days, comparable to that due to C_3S (Figs. 2 & 3). However, the 50.0° 2θ X-ray peak due to tobermorite was noticeable at 28–56 days only.

If the tobermorite gel formed by the substituted β–C_2S contained some Al^{3+} ions, the associated endothermic effect could be a little higher since the heat of hydration of aluminates (e.g. C_3A) is higher.

2 in 16 and 1 in 16:

These gave C_4AH_{13} at 3 days on hydrating without SO_3, the quantity of C_4AH_{13} being less the lower the substitution. In fact the 1 in 16 substitution products gave only a trace of C_3A.

On hydrating with SO_3 the 2 in 16 gave monosulphate with a trace of ettringite. The latter disappeared at 8 days while the monosulphate increased, and then remained constant at later ages, showing a sharp low angle peak.

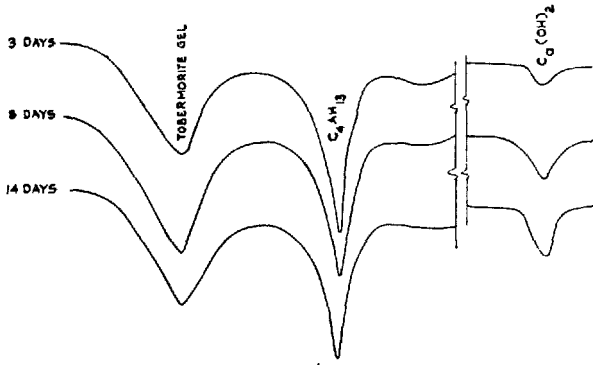

Fig. 2. *D.T.A. curves of microcline-based "4 in 16" substituted β-C_2S hydrated for different periods.*

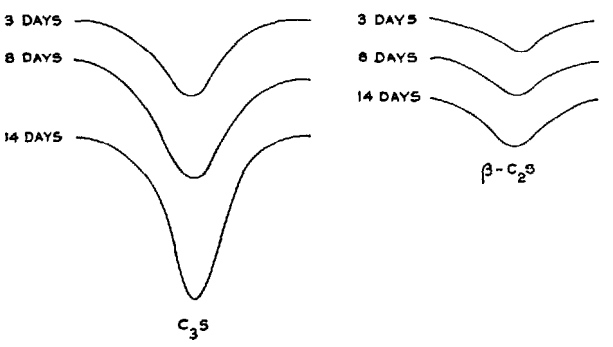

Fig. 3. *D.T.A. endotherms due to tobermorite gel formed by C_3S and boric acid stabilized β-C_2S hydrated for different periods.*

The 1 in 16, surprisingly enough, gave ettringite and C_4AH_{13} at 3 days. Both remained constant till 14 days. At 28 days, the 9.05° 2θ ettringite peak split up into two (8.95° and 9.25°) and the C_4AH_{13} went down.

The lower the substitution products, lesser $Ca(OH)_2$ was formed, which nevertheless increased with duration of hydration.

The tobermorite endotherm also developed slower with lower substitution products, and the 50.0° 2θ X-ray peak also appeared at 28–56 days.

From the fall in the unhydrate β–C_2S peak intensities it was estimated that the 2 in 16 microcline-based product hydrated less in 2 months than the 1 in 16 bytownite-based product.

It was, however, felt that the microcline-based products started hydrating earlier. In order to check this 0.5 g of C_3S, and the products were kept shaking in 100 ml water for 3 days, filtered and the residue examined by D.T.A. The microcline-based 4 in 16 product showed a much stronger endotherm of tobermorite than even C_3S, while the corresponding 2 in 16 exhibited only a trace of the same. The bytownite-based 4 in 16 and 2 in 16 products also showed only a trace of tobermorite endotherm. Nevertheless at later ages, the bytownite-based products appeared to have hydrated to a greater extent (as seen from the X-ray intensities) as compared with the corresponding microcline-based preparations.

Discussion

In the above, attempts were made to prepare β–C_2S with varying degrees of substitution of Si^{4+} with Al^{3+} tetrahedrally coordinated. However, the substitution was not complete as seen from the formation of C_3A in all cases, the quantity of C_3A being larger, the larger the attempted substitution. Even then, the products with larger attempted substitution appeared to hydrate faster.

The usual stabilizers of β–C_2S such as B_2O_3 act by forming BO_4^{5-} groups replacing SiO_4^{4-}, where the B^{3+} ions are smaller in size than Si^{4+} and where these ions are small enough so that the size of the RO_4 group is almost entirely determined by the O–O distances, the substitution not involving a significant change in lattice dimensions (1). It is further believed that the substitution of Si^{4+} by Al^{3+} or Fe^{3+} would increase the size of the tetrahedral group and would favour the α or γ forms. The self-stabilization of the microcline-based products is contrary to the above.

As regards charge balancing, it has been suggested that when BO_4^{5-} groups are inserted, extra Ca^{2+} ions must be introduced in the holes in C_2S since a sample of β–C_2S containing 0.3% B_2O_3 had a $CaO:SiO_2$ molar ratio of 2.1:1(1). As an alternative, since β–C_2S is a compact structure the stabilization by B_2O_3 is again explained as due to BO_4^{5-} replacing SiO_4^{4-}, the charge being balanced by missing Si^{4+} ions, probably in the form of silica (10)—although for charge neutralization it has to be missing SiO_4^{4-}.

The stabilization of β–C_2S by excess lime has also been suggested as due to the excess Ca^{2+} and O^{2-} ions occupying interstitial positions (1). Again, however, doubts have been expressed if there would be room for the large O^{2-} ions in the β–C_2S structure and, as an alternative, it has been proposed that the Ca^{2+} occupy normal lattice positions and that some of the Si^{4+} sites are vacant for charge balancing (11).

In the case of the bytownite-based products, with Al^{3+} substituting for some of the Si^{4+}, one may explain the charge balancing in one of the two alternate ways: (i) with the charge balancing Ca^{2+} ions occupying interstitial positions as in the bytownite itself; or (ii) with some of the SiO_4^{4-} groups missing from the lattice. If the latter were the case, then these SiO_4^{4+} groups which are released and the Ca^{2+} ions

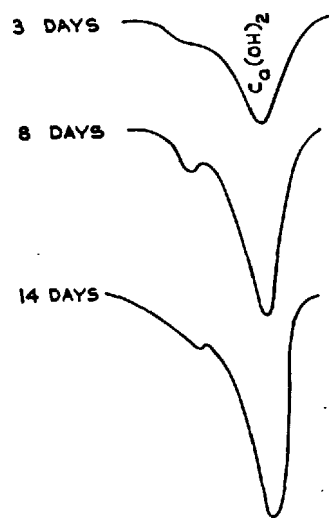

Fig. 4. *D.T.A. endotherms due to* $Ca(OH)_2$ *formed during the hydration of bytownite-based " 4 in 16" substituted* β-C_2S *hydrated for different periods.*

which acted as charge neutralizers in the bytownite and which also are released now would from some more β–C_2S. In this case, the lime released as $Ca(OH)_2$ during hydration would be the same as that released during the hydration of boric acid stabilized β–C_2S.

However, since during the course of hydration, while the unhydrated material went down, both the tobermorite and the $Ca(OH)_2$ were on the increase, and since this $Ca(OH)_2$ was definitely more than in the case of boric acid stabilized β–C_2S, or the microcline-based β–C_2S (Figs. 2 and 4), this lime may well have come from interstitial Ca^{2+}. Again, the more $Ca(OH)_2$ was released, the larger was the attempted substitution confirming this hypothesis.

In the case of microcline-based products, since most of the potash and half of soda, which are the charge neutralizers in this felspar network, evaporated off, either the lime added during the preparation of β–C_2S may have served the purpose of charge neutralizing cations by replacing K^+ or the charge balance may have been effected say by missing SiO_4^{4-}. In this case, if Ca^{2+} had replaced the alkalis as charge neutralizing cations, then these products would have had properties similar to the bytownite-based products. However, these two products are different in at least three ways:

i) Boric acid had to be added to the bytownite-based raw mixes in order to stabilize the β–C_2S, while the microcline-based products were self-stabilized.

ii) A Larger amount of lime was released from the bytownite-based products.

iii) The bytownite-based products hydrated to a larger extents during the course of, say, 28 days. However, the microcline-based products started hydrating early and started showing tobermorite endotherms at earlier ages.

It is thus possible that in the microcline-based products the charge compensation may be effected in a way different from that in the bytownite-based products.

Substituted Alumino-Frerrite

Materials

Finely powdered oxides Al_2O_3, Fe_2O_3, MgO, CaO (calcined $CaCO_3$), and MnO_2 were taken. MnO_2 reduces to Mn_2O_3 at 535°C, which further reduces to Mn_3O_4 at 933°C (12). However, the second stage reduction was inhibited since the compounds containing manganese also had their X-ray diffraction patterns resembling C_4AF. In some cases, e.g., in an attempt to prepare $2CaO \cdot Mn_2O_3$, the compound actually formed was $2CaO \cdot 2MnO_2$ ($CaMnO_3$) showing that in this case MnO_2 had not reduced at all.

The temperatures of heat treatment for synthesis of the different compounds are given in the following:

1220–1240°C: C_6AF_2, $C_{3.7}M_{0.3}AF$, $C_{3.7}M_{0.3}AF_{0.85}M'_{0.15}$;

1280–1300°C: $C_4AF_{0.85}M'_{0.15}$, C_6AFM';

1310–1330°C: C_6A_2F, C_4AF, $C_4AF_{0.5}M'_{0.5}$, C_4AM';

1370–1390°C: C_2F.

($M = MgO$, $M' = Mn_2O_3$)

Results

X-ray diffractometer records of the different samples were taken with silicon metal as internal standard. From the positions of three lines the unit cell dimensions and the density were calculated. All these data are given in Table 2, from which the X-ray calculated density values may be compared with those obtained directly.

Fixed Water

The values of the fixed water given in Table 3 give

Table 2.

Compound	Molecular wt.	Unit cell dimensions				Density g/cc	
		$a_{Å}$	$b_{Å}$	$c_{Å}$	$v = abc_{Å^3}$	From X-ray data	Measured

an idea of the rate at which the different compounds hydrated. These results are discussed at the relevant places along with the D.T.A. and X-ray diffraction results.

Hydration Studies with X-ray Diffraction and D.T.A.

The results are discussed separately for the different series of compounds.

C_6A_2F–C_4AF–C_6AF_2–C_2F

A number of workers have studied the hydration behaviour of these compounds. On hydrating C_4AF at 25°C (W/C = 0.7) Kalousek and Adams (15) found cubic hydrogarnets with some hexagonal C_4AF_{13} type phase at 7 days. The hydrogarnets decreased with age, while the hexagonal phase increased, and the product was the hexagonal hydrate at 180 days. On hydrating with gypsum, ettringite was formed at 7 days which slowly changed over to the solid solution $3C(A, F)\cdot CaSO_4\cdot 12H_2O$–$3C(A, F)\cdot Ca(OH)_2\cdot 12H_2O$. Jones (16), summarizing the earlier work, concluded that $C_4A\cdot aq$–$C_4F\cdot aq$ was formed as a first step towards $C_3A\cdot aq$–$C_3F\cdot aq$. Dekeyser (6) reported that among these, C_6A_2F hydrated fastest, and that the rate of hydration decreased with the decreasing alumina content. He also reported, in agreement with Jones, that all these formed the hexagonal phase which changed over to the cubic hydrogarnets in due course, except with C_2F in which case this transformation did not occur unless C_2F was hydrated with lime.

In the present work, in conformity with the loss on ignition data, both C_6A_2F and C_6AF_2 hydrated rather fast, as was seen by X-ray diffraction and D.T.A., and substantial amounts of these were hydrated at 24 hours. C_4AF did not hydrate as fast, and C_2F even slower. Thus, at 28 days, quite some C_4AF and a larger quantity of C_2F were still unhydrated.

C_6A_2F, C_4AF and C_6AF_2 all gave the cubic hydrogarnets at 1 day along with some hexagonal hydrate. While C_6A_2F showed the C_2AH_8 type in some small quantity, the other two gave only trace of C_4AH_{13} type. The cubic hydrate increased with age. The hexagonal hydrate disappeared at 3 days in the case of C_4AF, but the latter two gave the hexagonal

hydrates at later ages also, although to lesser extent. C_4AF gave, in addition, some $Ca(OH)_2$.

C_2F gave only the hexagonal hydrate C_4FH_{13} at all ages.

On hydrating with SO_3, C_4AF did not react fast enough so that some gypsum was still left at 24-hour hydration, and a 740°C exotherm was present presumably due to a gel. Both the gypsum and this endotherm disappeared at 3 days. The small ettringite and monosulphate peaks at 8.9° and 9.7° 2θ disappeared at 3 days into broad diffuse area. The monosulphate-$C_4(A, F)H_{13}$ solid solution was shown up at later ages. The hydrogarnets appeared at 7 days and later.

Most of the C_6A_2F had hydrated at 3 days giving C_2AH_8 type hexagonal phase, ettringite and monosulphate. The ettringite disappeared at 28 days giving monosulphate-$C_4(A, F)_{13}$ solid solution along with the C_2AH_8 type hexagonal phase. The hydrogarnets were absent.

A large part of C_6AF_2 hydrated at 7 days after which the hydration was relatively slow as judged from the X-ray line intensities and from the fixed water (Table 3). It showed ettringite at 1 day, and monosulphate and solid solution at later ages.

C_2F did not hydrate to an appreciable extent in 28 days, and showed a trace of ettringite. The fixed water data (in Table 3) confirmed this observation as also that C_6AF_2 hydrated faster than C_4AF.

In order to see if the relatively high rate of hydration of C_6AF_2 was due to the finer pulverization of this compound, the specific surface of undermentioned compounds was measured with the Blaine apparatus.

Compound	*Specific surface* (cm^2/g)
C_6A_2F	1700
C_4AF	2050
C_6AF_2	2590
C_2F	1640

Thus the C_6AF_2 was finer ground. However, as will be seen later, the initial rate of hydration also of C_6AF_2 was found to be higher.

C_4AF–$C_4AF_{0.85}M'_{0.15}$–$C_4AF_{0.5}M'_{0.5}$–C_4AM' ($M' = Mn_2O_3$)

This series was studied with a view to studying the effect of progressive replacement of iron by manganese on the hydration behaviour.

The main products on hydrating without SO_3 were the hydrogarnets besides some hexagonal hydrates shown at early ages (especially at 1 day) by all except $C_4AF_{0.5}M'_{0.5}$. Unlike C_4AF, the other two gave C_2AH_8 type, C_4AM' giving the same in larger quantity.

At 28 days $C_4AF_{0.85}M'_{0.15}$ had substantially hydrated while $C_4AF_{0.5}M'_{0.5}$ showed probably the largest unhydrated material. The fixed water data (Table 3) confirmed that on replacing a small part of Fe by Mn the compound hydrated faster than C_4AF, while with 50:50 replacement the hydration was slowed down, C_4AM' again hydrating faster.

The 720–740°C endotherm present in the products of the two compounds containing both Fe and Mn may be ascribed to Fe-Mn hydroxide gel.

On hydrating with SO_3, $C_4AF_{0.5}M'_{0.5}$ hydrated rather slowly, showing only ettringite and the presence of gypsum even at 28 days. (Please see Table 3 also). The others (except C_4AF) had consumed gypsum at 1 day.

Both $C_4AF_{0.85}M'_{0.15}$ and C_4AM' showed broad prominent ettringite-monosulphate low angle X-ray peak. The peak decreased till 7 days after which the monosulphate rose up and other monosulphate peaks also showed up. These monosulphate peaks were sharper in the case of C_4AM', and diffuse in the case of $C_4AF_{0.85}M'_{0.15}$. This was in marked contrast with C_4AF. All these three gave the cubic hydrate at later ages.

The pH studies of $C_4AF_{0.85}M'_{0.15}$ hydrated with SO_3 showed erratic pH changes at early ages.

C_4AF–$C_{3.7}M_{0.3}AF$–$C_4AF_{0.85}M'_{0.15}$–$C_{3.7}M_{0.3}AF_{0.85}M'_{0.15}$ ($M = MgO$, $M' = Mn_2O_3$)

This series was studied with a view to seeing the effect of partial replacement of CaO with MgO and/or of Fe_2O_3 with Mn_2O_3.

On hydrating without SO_3, C_4AF, $C_4AF_{0.85}M'_{0.15}$ and $C_{3.7}M_{0.3}AF_{0.85}M'_{0.15}$ all gave the cubic hydrate at one day with a little hexagonal hydrate. The latter two, unlike C_4AF, gave the lime-poor C_2AH_8 type hexagonal hydrate, the last one giving it in a slightly larger quantity. Again at later ages only the cubic hydrate was found and in larger quantities.

$C_{3.7}M_{0.3}AF$ formed C_2AH_8 type hydrate in large quantity by 1 day. This came down only slowly up to 28 days. The cubic hydrate was noticed at 7 days only and it increased with age. A trace of $Mg(OH)_2$ was detected from 3 days onwards.

Manganese thus accelerated the formation of the cubic hydrate while magnesia gave rise to the lime-poor C_2AH_8 type hydrate and delayed the formation of the cubic hydrate phase.

On hydrating with gypsum, the products formed by C_4AF and $C_4AF_{0.85}M'_{0.15}$ are already discussed in the

earlier sections.

$C_{3.7}M_{0.3}AF_{0.85}M'_{0.15}$ also gave ettringite and monosulphate at early ages and a fairly strong monosulphate peak which had grown up at 28 days.

$C_{3.7}M_{0.3}AF$ gave strong low angle ettringite and monosulphate peaks at early ages, which went down, and showed a broad solid solution area at 28 days resembling the behaviour of C_4AF. These peaks, however, appeared to be displaced somewhat in this case.

C_6AF_2–C_6AFM' ($M' = Mn_2O_3$)

Unlike C_6AF_2 which had substantially hydrated in 3 days, C_6AFM' remained partly unhydrated even at 28 days. Thus, in this case also, replacement of half of Fe_2O_3 by Mn_2O_3 gave a slower hydrating compound. (See Table 3 also).

C_6AFM' gave the cubic hydrate only and showed a 740°C exothermic peak ascribed to Fe-Mn hydroxide gel.

On hydrating with SO_3, less of C_6AFM' had hydrated even by 28 days. Although C_6AF_2 had substantially hydrated by 7 days.

As mentioned earlier, C_6AF_2 gave ettringite at 1 day, monosulphate-solid solution at later ages.

C_6AFM' gave ettringite at 1 day which decreased and disappeared at 7 days. Strong monosulphate and some C_4AH_{13} type phase appeared at 3 days. The latter went down later, while the monosulphate remained very strong even at 28 days, thus showing lesser tendency of Mn containing compounds to form monosulphate-$C_4(A, F, M')H_{13}$ type solid solutions. The cubic hydrate appeared at 7 days and increased with age.

Initial Rate of Hydration

From a knowledge of the specific surface of the compound, and from the rate at which the height of a prominent X-ray peak falls down, the initial rate of hydration (as depth of hydration, microns/hour) can be calculated according to Tsumura's method (8). The values found for hydration without SO_3 are:

Compound	*Depth of hydration (microns/hr)*
C_6A_2F	2.4
C_4AF	2.1
C_6AF_2	3.2
C_2F	1.0
$C_4AF_{0.85}M_{0.15}$	1.6

The remaining compounds, even though they did hydrate appreciably at 24 hours, had not hydrated at all in the first two hours and thus exhibited initial induction period of at least 2 hours, and did not start appreciable hydration in this time.

C_6AF_2 again showed the largest initial rate of hydration, contrary to the earlier finding that its rate of hydration is intermediate to that of C_4AF and C_2F.

Again $C_4AF_{0.85}M'_{0.15}$ hydrated to a larger extent at 28 days than C_4AF. However, its initial rate of hydration was less than that of C_4AF.

It may be mentioned that these initial rates of hydration fell off to much lower values within a matter of 10–15 minutes probably as the thickness of the hydrated layer increased so that further hydration was governed by the rate of diffusion through the hydrated layer.

The value of the rate of hydration for C_4AF may be compared with the value obtained by Tsumura of 1.65 microns/hr who took the density of C_4AF as 3.89 g/cc.

Conclusions

1) The rate of hydration of the C_2F–$C_6A_{2.1}F_{0.9}$ series is thus found to depend on the A/F ratio in agreement with the previous workers. However, C_6AF_2 appeared to hydrate faster than C_4AF.
2) If in C_4AF a small part of the Ca was replaced by Mg and/or a small part of Fe was replaced by Mn, then the resulting product hydrated faster.
3) Replacing half of the Fe in C_4AF and in C_6AF_2 by Mn gave compounds which hydrated considerably slower. With complete substitution in C_4AF of Fe by Mn, the resulting product viz. C_4AM' hydrated faster than $C_4AF_{0.5}M'_{0.5}$.
4) On hydration with water, all the compounds tended to give the hexagonal phase at early ages (along with the cubic hydrate) which changed over to the cubic phase. C_2F gave only the hexagonal phase.
5) C_4AF and the two compounds C_6AF_2 and C_2F gave the $C_4(A, F)H_{13}$ type hydrate. The iron oxide poorer C_6A_2F gave the lime-poor C_2AH_8 type hydrate phase.
6) Replacing the iron oxide in C_4AF either partly or wholly by Mn_2O_3 or the lime partly by magnesia gave compounds which on hydration again

gave the lime-poor hexagonal hydrate of the C_2AH_8 type.

7) On hydration with SO_3 compounds containing Mn generally gave a large monosulphate peak at 28 days indicating that these did not form the monosulphate-$C_4(A, F, M')H_{13}$ solid solution readily.

8) Some of these compounds started hydrating immediately on admixture with water, while others exhibited induction periods, before the start of hydration, of 1 1/2–2 hours.

Supplementary Paper I-105 The Effect of Minor Components on the Early Hydraulic Activity of the Major Phases of Portland Cement Clinker

Toshio Sakurai, Takeshi Sato and Atushi Yoshinaga*

Synopsis

Solid state physics is well applicable to the effect of minor components on the early hydraulic activity of C_3S and calcium aluminoferrite.

C_3S can take 1.7 wt. % Cr_2O_3. With addition of 0–1.4% Cr_2O_3, modification T_I is obtained and T_{II} with addition of 1.4–1.7%.

C_2F and C_4AF can dissolve 4.8% and 5.4% Cr_2O_3 respectively in ordinary atmosphere. These introductions of Cr_2O_3 increase enormously the early hydraulic activity of both C_3S and calcium aluminoferrite.

C_3S with Cr_2O_3 is a P-type semiconductor, of which the electric conductivity and the dielectric constant increase with Cr_2O_3.

Dislocations are found on the C_3S crystal surfaces electronmicroscopically.

The density of dislocation etch pits increases with introduction of Cr_2O_3 and it attains to the maximum $10^8/cm^2$.

These dislocations have been thought to be a key to the hydraulic activity of clinker minerals. For this case, however, not all dislocations are sensitive to hydration. It is the screw dislocation at the centre of growth spiral that is vigorously active at hydration.

The early hydration reaction starts both at the point of emergence of screw dislocations and at the grain boundaries. The reaction then progresses along the step and deepens the crystal surface step by step until the depth of one thousand several hundred angstrom of the surface layer is dissolved out.

The early hydration reaction is explainable as the dissolution of Ca^{++} ions on the surface of a P-type semiconductor. The case of calcium alumino ferrite is similarly explainable.

Introduction

The minor components, their incorporated state and the clinkering condition affect the hydraulic activity and the strength of the major phases of portland cement clinker. Jander (1) suggested that the strength produced by the alite in a cement might depend not only on the presence of ions in solid solution but also on the occurrence of structural defect and of cracks and irregularities of colloidal dimensions. These three factors are nevertheless not to be independent individually but related closely to one another.

In this report, the authors will try from the viewpoint of both crystal chemistry and solid state physics to explain systematically how minor components affect crystal structure and structural imperfections of C_3S, calcium alumino-ferrite, and also how minor components affect their hydraulic activity.

The minor components used are Cr_2O_3 (Cr ions as a cationic minor component), CaF_2 (F ions as an anionic minor component) and P_2O_5.

The role which Cr_2O_3 plays in the early strength of portland cement clinkers has been discussed by various researchers. Of such studies, notable were those by K. Akiyama (2), M.M. Sychov and V. I. Korneev (3).

The influence of fluorine on C_3S hydration was reported by J. H. Welch and W. Gutt (4) and P_2O_5 by W. Gutt (4) and M.M. Sychov and V. I. Korneev (3).

Many reports have supposed the effect of minor components at the early hydration and the early strength of clinker minerals, connecting with the formation of crystal imperfections or defects (5), but no details of these mechanisms have been clarified.

The Effect of Cr_2O_3 on C_3S

Solid Solution of C_3S with Cr_2O_3

In this series the solid solubility of Cr_2O_3 is investigated by using guaranteed chemical reagents, $CaCO_3$, SiO_2 and Cr_2O_3 as starting materials. Synthesis is performed at 1550°C for 3 hours in air for each cycle, with the SiC furnance, and five cycles of burning are repeated for each sample to obtain desired solid solutions.

C_3S can take up to 1.7 wt. % Cr_2O_3 instead of 1.4 wt. % reported by E. Woermann et al (6). With addition of 0–1.4% Cr_2O_3, modification T_I is obtained at room temperature and T_{II} are obtained with addition of 1.4–1.7%.

The lattice parameters are plotted by using Yamaguchi's indices (7) in Fig. 1.

The discontinuity at 1.4% is the opposite nature to that of the transition T_I–T_{II} in C_3S with Al_2O_3 reported by M. Bigaré et al (8). The lattice parameters shrink continuously during 0–1.4%, 1.4%–1.7% Cr_2O_3, while the discontinuity at 1.4% is far larger than that at Al_2O_3 0.45%.

The X-ray powder patterns near this transition region are shown in Fig. 2.

The average valencies of Cr ion in this series are measured by chemical analysis and +4.6 is gained which is constant in all this series. This fact shows Cr ion can dissolve in the same way in all this series.

With addition of more than 1.8% Cr_2O_3, C_3S decomposes into C_2S and CaO.

Solid Solution of C_3S with Cr_2O_3, Al_2O_3 and Fe_2O_3

In this series, solid solubility of a mixture of Cr_2O_3, Al_2O_3 and Fe_2O_3 in C_3S is studied.

In Table 1 each chemical composition of the clinkers of C_3S–C_3A–C_4AF–Cr_2O_3 system is shown.

Table 1. *Clinker composition in the* C_3S–C_3A–C_4AF–Cr_2O_3 *system*

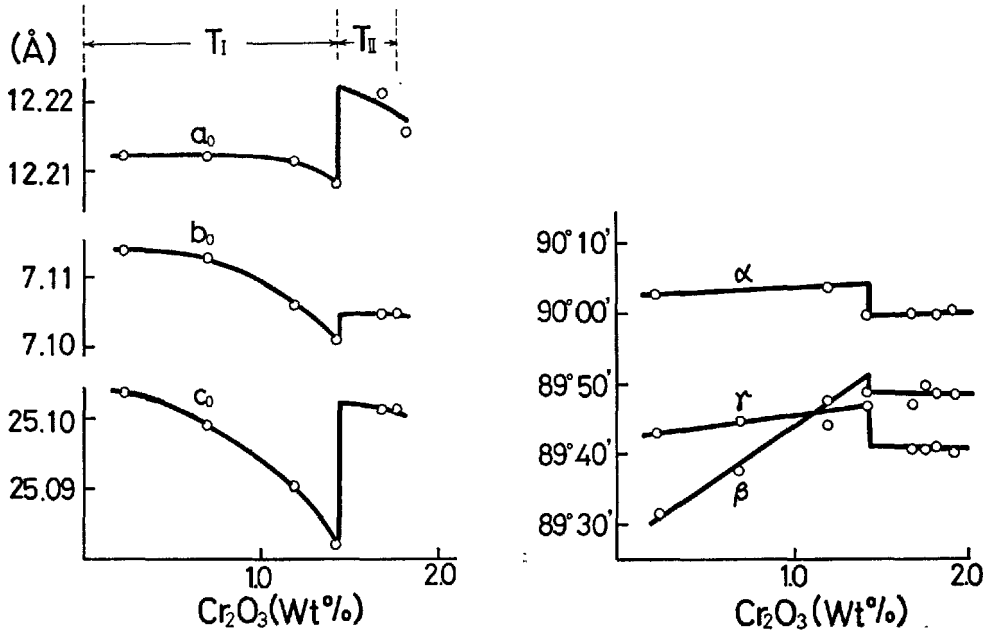

Fig. 1. *Variation of pseudo-orthorhombic lattice constants at room temperature in the* C_3S–Cr_2O_3 *solid solution series.*

Solid solubility of Cr_2O_3, Al_2O_3 and Fe_2O_3 in C_3S is determined by the fractional dissolution method with salicylic acid in methyl alcohol (9). In order to confirm these compositions obtained, the C_3S solid solutions are synthesized based on the chemical compositions obtained.

In Fig. 3, the chemical composition of each C_3S_{ss} is illustrated in comparison with the early hydraulic activity of C_3S_{ss} which will be discussed in the subsequent section.

C_3S can introduce 1.7% Cr_2O_3, 1.3% Al_2O_3 and 0.7% Fe_2O_3 altogether. With no Cr_2O_3, C_3S can take up to 1.1% Al_2O_3 and 0.9% Fe_2O_3. With dissolution of Cr_2O_3, solid solubility of Al_2O_3 increases, while that of Fe_2O_3 decreases. The limit of solid solubility of Cr_2O_3 1.7% in this series is quite the same with the limit of solubility of Cr_2O_3 alone in C_3S studied in the above section. This fact means that Cr_2O_3 can be taken in C_3S independently of Al_2O_3 and Fe_2O_3 in a mixture.

The average charge of Cr ion of each C_3S in this series is constantly +4.6 which is also the same value with the case of Cr_2O_3 alone in C_3S.

In this case C_3S takes the modification of T_{II} at room temperature. In Table 2 the ionic mole ratio of C_3S_{ss} in this series is shown standardizing Ca^{++} ionic mole number as 3000.

With addition of Cr_2O_3, Al^{3+} increases while Si^{4+} and iron ion decrease instead.

These changes suggest that Cr ions and Al ions are substituting for Si ions in tetrahedra. The increased mole number of $Cr^{4.7+}$ is much more than two times of the decreased mole number of Si^{4+}. Moreover, it is impossible for Cr ions to neutralize the charge +4.7 only by ordinary substitution for Si^{4+} or for Ca^{++}.

The D.C. Conductivity of C_3S with Cr_2O_3

As mentioned in the preceding section there will be electron holes or vacancies in C_3S crystal, if Cr ions of positive charge 4.6 are substituting for cations in the lattices. In order to study the property of such the lattices doped with transition element, Cr, it may be available to measure the d.c. conductivity of the crystal.

There have been few studies about the electroconductivity of cement clinker minerals (10).

Samples for measurement are prepared from the synthesized C_3S with Cr_2O_3 and some other minor components. Some examples of composition of the samples are listed in Table 2.

Samples are pressed to 50 mm ϕ × 20 mm disks at the pressure of 1 ton/cm², and then sintered at 1550°C until the desired density is obtained.

These sintered samples are then cut to the disks of 45 mm ϕ × 3 mm, coated with the silver paste as electrodes. The insulation resistor is used to measure the d.c. conductivity of samples.

Some of the results are shown in Fig. 4.

As the d.c. conductivity of these specimens is in the region of 10^{-11}–10^{-12} [Ω-cm] at room temperature, these C_3S with Cr_2O_3 are in the region of semiconductor. As the conductivity increases with additon of Cr ions, this conductivity is caused by the migration of electrons and/or holes between Cr ions in the different charges.

Considering that Cr ions can exist as Cr^{2+}, Cr^{3+}, Cr^{4+}, Cr^{5+} and Cr^{6+} among which Cr^{2+} and Cr^{6+} are unstable in this experimental condition (11), (12) and that the average charge of Cr ions in C_3S_{ss} is +4.6, Cr^{3+}, Cr^{4+} and Cr^{5+} must play part in this conduction.

The d.c. conductivity of $Cr^{3+} - O^{2-} - Cr^{4+}$ has been studied by many researchers. G.H. Jonker (13) proved $Cr^{3+} \rightarrow Cr^{4+}$ is prior to $Fe^{3+} \rightarrow Fe^{4+}$. F. Kanamaru and R. Kiriyama (14) measured the activation energy of Cr^{3+}–O^{2-}–Cr^{4+} conduction in solid

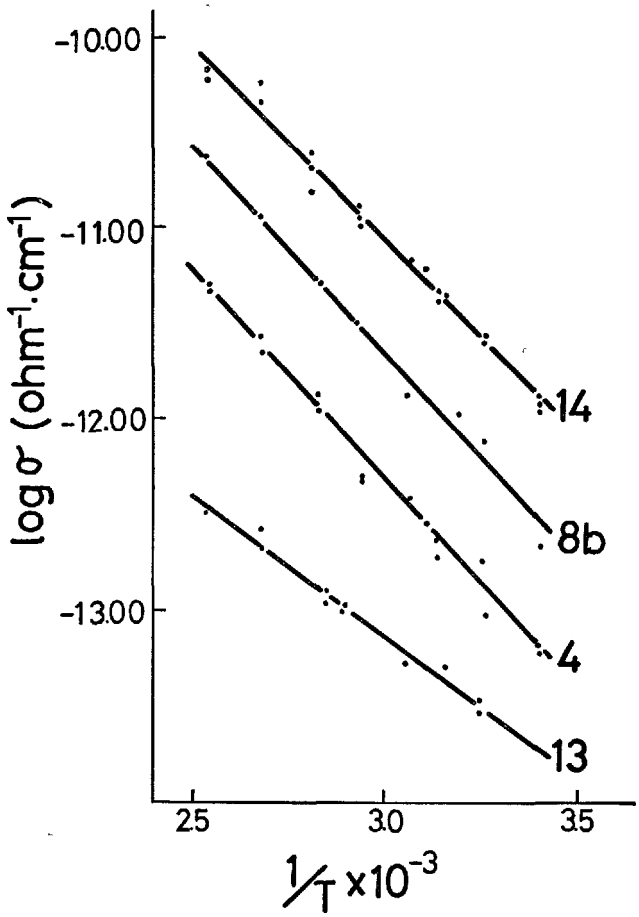

Fig. 4. *D. C. conductivity of* C_3S_{ss} *in the* C_3S–Cr_2O_3–Al_2O_3–Fe_2O_3 *solid solution series, sintered at 1550°C in air.*

solution of $CaFeO_4$ with Cr_2O_3. This activation energy is 0.16–0.27 eV.

The activation energy of the d.c. conductivity calculated from the incline of $\log \sigma - \frac{1}{T}$ curves is between 0.25 eV and 0.38 eV, which is a little larger than the activation energy of Cr^{3+}–Cr^{4+}, Fe^{2+}–Fe^{3+}, Fe^{3+}–Fe^{4+} and Mn^{3+}–Mn^{4+} measured by many researchers. Therefore, the mechanism of this d.c. conduction in these solid solutions may surely consist of Cr^{3+}–O^{2-}–Cr^{4+} and/or Cr^{4+}–O^{2-}–Cr^{5+} and/or Cr^{3+}–O^{2-}–Cr^{5+}. From these results, Cr ions in C_3S solid solution may be in charges of Cr^{3+}, Cr^{4+} and Cr^{5+}.

Dielectric Property of C_3S with Cr_2O_3

In order to study more about the situation of Cr ions in C_3S solid solution, the dielectric constant of C_3S_{ss} is used. The C_3S_{ss} disks used are the same specimens used in the measurement of the d.c. conductivity.

In an electric field, dielectric polarization of an insulator may be generated in the following mechanisms; (a) shift of electron distribution of atoms or molecules in an electric field; (b) relative migration of foreign atoms or ions; (c) orientation of molecules which have the permanent dipole moment along with the direction of an electric field.

To a dielectric substance in an electric field, the Calusius—Mosotti equation is applicable;

$$\frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{M}{d} = \frac{4\pi}{3} N\bar{\alpha} \qquad (1)$$

where ϵ is the dielectric constant of the substance, d is the density, M is the molecular weight, N is the Avogadro's number and $\bar{\alpha}$ is the polarizability of a substance. For a polar substance, which has a permanent dipole moment, the term $\mathrm{Po} = \frac{4}{3}\pi N \cdot \frac{\mu^2}{3\kappa T}$ must be inserted to the equation (1), that is;

$$P_G = \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{M}{d} = \frac{4}{3}\pi N\bar{\alpha} + \frac{4}{3}\pi N \cdot \frac{\mu^2}{3\kappa T} \qquad (2)$$

where P_G is the total polarization, μ is the permanent dipole moment and κ is the Boltzmann constant. From the equation (2), there comes a linear relationship between P_G and $\frac{1}{T}$, so that μ can be calculated from the incline of the $P_G - \frac{1}{T}$ curves obtained experimentally.

Though this equation is well applicable to gas phases, there are some problems in applying this to solid phases. However, the approximate tendencies may be able to be obtained.

The dielectric constant of each specimen is measured with the Q-metre at 20°C, 60°C, 70°C and 90°C in a thermostat. The frequency used is 100 KC.

In Table 3 the results are listed.

In this Table, $(\epsilon - 1)/(\epsilon + 2)$ is a fraction of the molar polarization in the equation (1). Because M/d in this equation may be nearly constant in this series of solid solution and within this temperature condition, it is used instead of the molar polarization P_G. The relation between a fraction of the molar polarization $(\epsilon - 1)/(\epsilon + 2)$ and $1/T$ is shown in Fig. 5.

The curves rise with temperature from 20°C to 70°C. From the equation (2), P_G falls at the higher temperature, while these curves in Fig. 5 rise at the higher temperature. It is very difficult to explain this inclination, but it may be considered that C_3S with Cr_2O_3 have no permanent dipole moment.

Mechanism of Dissolution of Cr Ions in C_3S_{ss}

As mentioned in the preceding section, the number of Cr ions dissolved in C_3S is much more than the number of Si^{4+} which is replaced by Cr ions. Therefore, it is natural to assume that Cr ions may substitute not only for Si^{4+} but also for Ca^{++}. Measuring the activation energy of the d.c. conductivity, Cr ions in C_3S are confirmed to stay as Cr^{3+}, Cr^{4+} and Cr^{5+}. And the average charge of Cr ions in C_3S is constantly +4.6. Therefore, 80% of the total Cr ions would be Cr^{5+} and the rest Cr^{3+}, if these Cr ions could be classified into Cr^{5+} and Cr^{3+}.

Considering all the information obtained, the following formulas for substitution of Cr ions could be suggested;

$$Si^{4+} + Ca^{2+} \rightarrow Cr^{5+} + Ca\square^{--} + Cr^{3+} \quad (1)$$

$$2Si^{4+} + (Ca^{2+} + Ca\square^{--}) \rightarrow 2Cr^{5+} + Ca\square^{--} \quad (2)$$

$$Si^{4+} \rightarrow Cr^{4+} \quad (3), \qquad 2Si^{4+} \rightarrow Cr^{5+} + Cr^{3+} \quad (4)$$

where $Ca\square^{--}$ is a Ca ion vacancy with minus two charge.

In these formulas the equation (4) would seldom occur. Referring the model of Na dissolution in C_3S proposed by G. Yamaguchi and H. Uchikawa (15) a Ca ion vacancy or $Ca\square^{--}$ in the formula (1), may generate at the site between the Cr^{5+} tetrahedra and Cr^{3+} in the Ca^{++} site. Oxygen ions surrounding the $Ca\square^{--}$ site may be then attracted toward the adjacent Cr^{5+} and Cr^{3+}, and their charges may be neutralized. In the formula (2), a Ca ion vacancy may generate at the Ca^{++} site where is adjacent to two Cr^{5+} tetrahedra. Oxygen ions surrounding $Ca\square^{--}$ may be neutralized by these two Cr^{5+}.

Considering these substitution and vacancies, the lattice shrinkage of C_3S with Cr_2O_3 may be well explained.

In this model the increase of the molar plarization of C_3S_{ss} in the electric field may be also explained as follows; Cr^{3+} of which ionic radius is 0.67 angstrom by Goldschmidt may have room for self-polarization in the electric field, when it substitutes for Ca^{++} of which ionic radius is 1.05 angstrom.

Otherwise, oxygen ions surrounding $Ca\square^{--}$ may cause the polarization in the electric field.

These dissolved Cr^{5+} and Cr^{3+} may exert the strong polarizing power on the adjacent oxygens and may polarize the surrounding oxygens. Therefore Ca ions in the vicinity of polarized field may not be screened enough by oxygen ions and may stay rather unstable.

C_3S_{ss} with Cr_2O_3 is, therefore, a P-type semiconductor.

Lattice Imperfections on Crystals of C_3S with Cr_2O_3

It has long been deducted by many cement researchers that lattice imperfections in cement clinker minerals may probably have a great influence on their hydraulic activity (5). This deduction, however, has not yet been realized, because no actual examination or observation of lattice imperfections has been successful.

The authors have tried the various methods of examination to verify lattice imperfections on C_3S crystals. Among them are the measurement of the lattice strain from the powder diffraction patterns, the X-ray topographical observation of lattice imperfections and the observation of dislocations with the electronmicroscope. The authors, however, have not

succeeded in obtaining the satisfactory results except in the observation of dislocation by E. M. method on C_3S crystals in an aggregate.

In the following study these observations will be described. Lattice imperfections are generally classified into

(a) point defects (Frenkel type and Schottky type)
(b) line imperfections (edge and screw dislocation)
(c) boundary dislocations and stacking faults
(d) lattice distortion.

The details of these classifications were summarized in the preceding Symposium by F. Ordway (16).

Among these imperfections the existence of point defects are mentioned in the above section by defining C_3S with Cr_2O_3 to be a P-type semiconductor.

There are two keys in the observation of dislocation etch pits on C_3S_{ss} aggregate with the electronmicroscope.

The one is how to make up the most smooth fracture surfaces, and the other is to find the most suitable etchant.

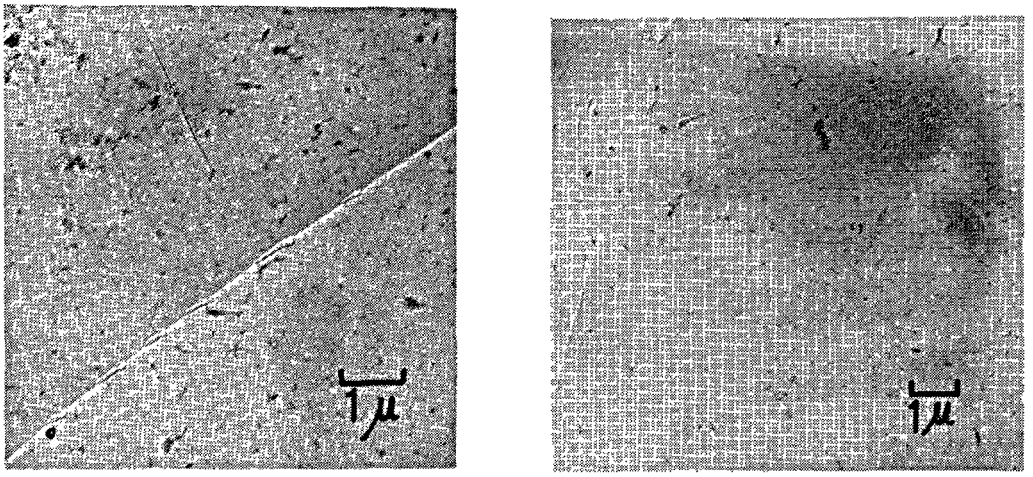

Fig. 6. *Unetched fracture surfaces of* C_3S_{ss} *crystals in the* C_3S–Cr_2O_3–Al_2O_3–Fe_2O_3 *solid solution series.*

Etchant : 0.4% HF with 0.6% HNO_3 in ethyl alcohol
Etching time: 1 minute

As for the etching specimens, the C_3S_{ss} in Fig. 3 are used. These are pressed at 1 ton/cm², and sintered enough at 1550°C until the desired density is obtained. The specimens are then gradually cooled down and quenched at 1200°C in open air. Thereby the smooth fracture surfaces of single crystals are created in these dense aggregate by the rapid volume change and the cracking. In Fig. 6 the nonetched fracture surfaces are shown.

As for the etchant, 0.4% HF with 0.6% HNO_3 in C_2H_5OH solution, and 0.4% HF with 0.3% HNO_3 in H_2O are successfully used.

In the following figures the dislocation etch pits are shown comparing the etch pit density with Cr_2O_3 content of C_3S_{ss}.

Etch pits observed are trigons, hexagons and their pseudo-morphs which may reflect their crystal symmetry.

There have been few studies about the morphology or the crystal habits of C_3S in which the study of Grzymek (17) is evident.

These etch pit shapes in this observation are, however, very difficult to connect with morphology, because the crystal axis cannot be determined.

In Fig. 7, the general shapes of dislocation etch pits are exhibited.
Some surfaces have dense etch pits, while some others have rare ones. Grain boundary dislocations are also observed.

Figs. 8, 9, and 10 show that the etch pit density increases depending upon the addition of Cr_2O_3 in C_3S_{ss}. These relation will be discussed in the subsequent section.

Figs. 11–18 show the changes of the surface behavior of C_3S_{ss} at the initial stage of hydration. In this case, the etchant used is distilled water containing 0.4% HF with 0.3% HNO_3. The etchant-C_3S_{ss} ratio is about 200 %. Fig. 11 shows the spiral etch pits formed at the points of emergence of the screw dislocations. These spiral etch pits are enlarged concentrically along the steps. This corrosion proceeds further and, then, eliminates the corrosion front from the surface and no more corrosion occurs at the point of screw dislocation. However, the vicinity of the screw dislocation becomes selectively rough. These changes are shown in Fig. 12.

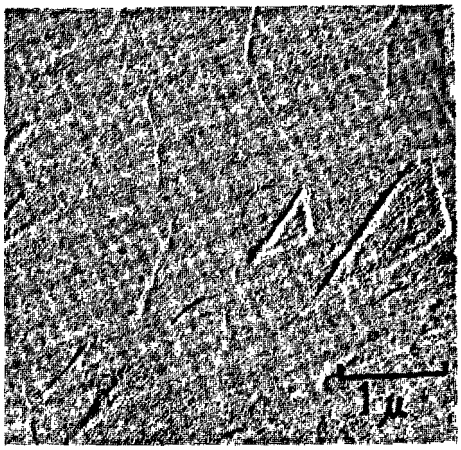

Fig. 9. *Variation of etch pit density with* Cr_2O_3 *content of* C_3S_{ss}. *Etch pit density about* $10^7/cm^2$ *in* C_3S_{ss} *with 0.50 wt. %* Cr_2O_3.
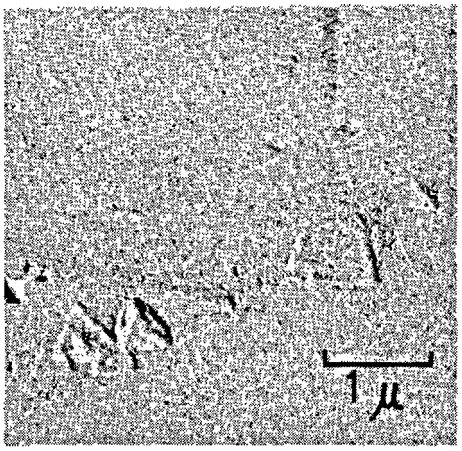
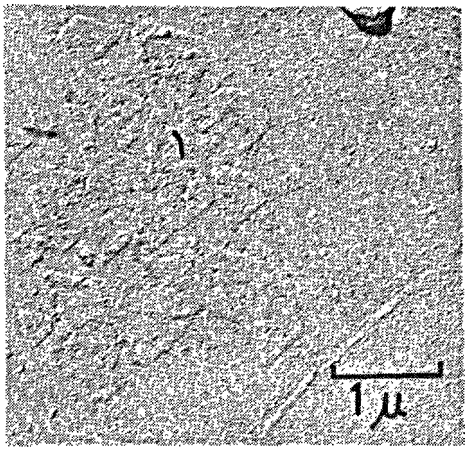
Etchant : 0.4% HF with 0.6% HNO_3 in ethyl alcohol.
Etching time: 1 minute





In Figs. 13–16 the changes of the surfaces at the later stage of hydration are shown. In Fig. 17, exhibited is corrosion at the surface contacted with the interstitial phases which have already been eliminated.

Fig. 18 shows the surface behavior after continuous contact with the etchant for one hour. The surfaces have been covered with the gel like skin, so that morphology of the surfaces becomes obscure.

These hydration reactions on C_3S surfaces at the initial stage of hydration can be schematically drawn in Fig. 19.

This dissolution mechanism would be in reverse to that of the crystal growth.

In summary, the violent dissolution reaction on C_3S surfaces at the initial stage of hydration occurs (a) at the point of emergence of screw dislocations, (b) at the grain boundaries and the edges of a crystal, (c) at the surfaces contacting with the interstitial phases. Through this initial dissolution reaction, the surfaces of a C_3S_{ss} crystal are dissolved to the depth of about one thousand several hundred angstrom.

The Early Hydraulic Activity of C_3S with Cr_2O_3, Al_2O_3 and Fe_2O_3 altogether

In this section, the effect of minor components, Cr_2O_3, Al_2O_3 and Fe_2O_3 on the early hydraulic activity of C_3S is studied. This early hydraulic activity of C_3S_{ss} is discussed based on the heat liberation curve obtained with a twin type micro conduction calorimetre (18).

Specimens used are those which are listed in Table 1, in the section of solid solution of C_3S with Cr_2O_3, Al_2O_3 and Fe_2O_3 altogether.

The early hydration reaction of C_3S_{ss} is defined on

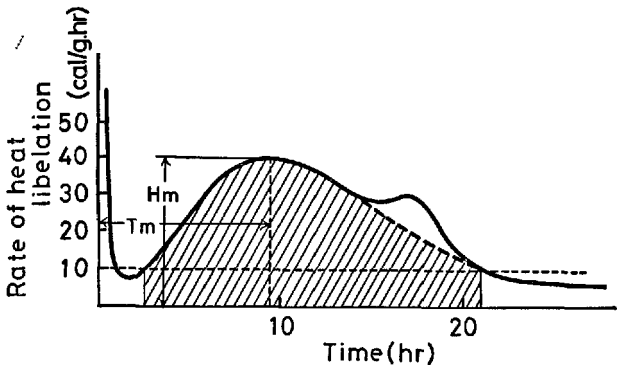

Fig. 21. *The definition of early hydraulic activity of* C_3S_{ss} *on a heat liberation curve of a clinker.*
The shaded portion: The early heat liberation of C_3S_{ss} *(cal/g)*
Hm: The maximum rate of heat liberation (cal/g. hr)
Tm: The time interval from just after contact with water to the maximum rate of heat liberation. (hour)

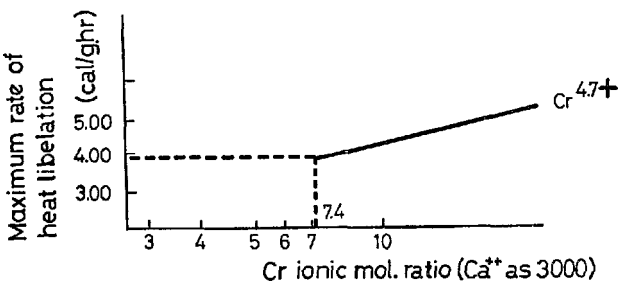

Fig. 22. *Relation between* Cr_2O_3 *content and the maximum rate of heat liberation of* C_3S_{ss}.

the heat liberation curve divided between at the point of 1 cal/g.hr. of heat liberation on the rising curve and at the point of 1 cal/g.hr. of heat liberation on the falling curve. If a third peak which corresponds to hydration reaction of the unhydrated C_3A appears on the heat liberation curve, it is eliminated as shown in Fig. 21.

The early hydraulic activity is defined by the following terms; the early heat liberation which corresponds to the total heat liberation in the above region; the maximum rate of heat liberation; and the time interval of from just after contact with water to the maximum rate of heat liberation. But the direct definition of the early hydraulic activity is represented by the latter two terms.

All the specimens are powdered to 4000 cm^2/g exactly, and 4.0 % SO_3 is added as gypsum to each specimen. The water cement ratio is 50 per cent.

In Fig. 3, illustrated are the heat liberation, the maximum rate of heat liberation and the time just after contact with water to the maximum rate of heat liberation comparing to the C_3S content of clinker, Cr_2O_3, Al_2O_3 and Fe_2O_3 in C_3S_{ss}. The heat liberation of each specimen is about 50 cal/g and is nearly constant independently of minor components. On the other hand both the maximum rate of heat liberation and the time interval have a direct relation with Cr_2O_3 content of C_3S_{ss}. The former increases and the latter is shortened with addition of Cr_2O_3. Between the maximum rate of heat liberation and Cr_2O_3 content, there exists a formula; $Hm = A \log(Cr^{+4.7}) + B$, where Hm is the maximum rate of heat liberation, A and B are the positive constans and $(Cr^{+4.7})$ means the ionic mole ratio of $Cr^{+4.7}$ comparing to the Ca^{++} mole number in C_3S_{ss} standardized as 3000 in Table 2.

Al_2O_3 and Fe_2O_3 seem to have no serious effect on the early hydraulic activity of C_3S_{ss}.

Solid Solution of C_3S with Fluorine and P_2O_5

In order to confirm the effect of Cr_2O_3 in a mixture of Cr_2O_3, Fe_2O_3, Al_2O_3, and also to confirm the effect of fluorine and phosphate on C_3S_{ss} with Al_2O_3, Fe_2O_3, fluorine and P_2O_5, solid solutions of C_3S with Al_2O_3, Fe_2O_3, fluorine and phosphate altogether are studied.

This experiment is performed in the same way as described in the study of C_3S_{ss} with Cr_2O_3, Al_2O_3 and Fe_2O_3. Fluorine is added as CaF_2 and phosphate is added as $3CaO \cdot P_2O_5$. In Table 4 each chemical composition of the clinkers of the C_3S–C_3A–C_4AF–CaF_2–$3CaO \cdot P_2O_5$ system is shown. Solid solubility of flourine, Al_2O_3, Fe_2O_3 and P_2O_5 in C_3S_{ss} is determined by the fractional dissolution method with salicyclic acid in methyl alcohol (14)(15). In order to confirm these compositions obtained, the C_3S solid solutions are synthesized based on the above results obtained.

The solid solubility of each in a mixture of Al_2O_3, Fe_2O_3, fluorine and P_2O_5 in C_3S_{ss} is shown in Fig. 23. The ionic mole ratios of cations, fluorine and phosphor in C_3S_{ss} in this series are listed in Table 5, where the Ca^{++} ionic mole ratio is defined as 3000.

Al^{3+} ionic mole ratio increases proportionately to fluorine in C_3S_{ss}, while Fe^{3+} decreases instead. As Al^{3+} increases, Si^{4+} decreases in a reciprocal proportion.

Therefore, it may be assumed that Al^{3+} will substitute for the Si^{4+} tetrahedra $(SiO_4)^{4-}$ in the form of $(AlO_3F)^{4-}$ accompanying with fluorine.

The Effect of Fluorine on the Early Heat Liberation of C_3S_{ss}

In Fig. 23 shown are the early heat liberation, the maximum rate of heat liberation, the time interval comparing with fluorine, Al_2O_3, Fe_2O_3 and P_2O_5 dissolved in C_3S solid solution. In these series, the maximum rate of heat liberation and the time interval are invariable with addition of Al_2O_3, fluorine, Fe_2O_3 and P_2O_5. On the other hand, the early heat liberation increases with addition of Al_2O_3 and fluorine. In Figs.

24–27 the relations between heat liberation of C_3S_{ss} and minor components are illustrated. These results mean that the dissolution of Al_2O_3 and fluorine in C_3S_{ss} increases the early heat liberation, but does not accelerate the early hydration reaction.

This is a remarkable feature of Al_2O_3 and fluorine in C_3S compared with Cr_2O_3 in C_3S.

Effect of Cr_2O_3 on the Ferrite Phase

In portland cement, the calcium alumino ferrite phases are always present with several major constituents. It is, therefore, of importance to examine the effect of Cr_2O_3 on the ferrite phase as well as the above examination of Cr_2O_3 on C_3S_{ss}.

Solid Solution of Ferrite (C_2F, C_4AF) with Cr_2O_3

In this study, the C_4AF-hypothetical "C_2Cr" system as well as the C_2F–"C_2Cr" system has been examined in air and in O_2. Mixes (in Table 6) were prepared in a horizontal externally heated tube furnace by solid state sintering at 1300°C. Mixes were then cooled at the rate of 50 degree per hour. The limit of Cr substitution in C_2F and C_4AF at 1300°C in air were determined by means of X-ray, optical and chemical techniques. The variation of the lattice constants with Cr_2O_3 are shown in Figs. 28 and 29.

The limits of Cr substitution are 4.8 wt. % of C_2F_{ss} and 5.3 wt. % of C_4AF_{ss}, which correspond to 9.1 mole % "C_2Cr" and 8.4 mole % "C_2Cr" respectively.

The average charges of Cr ions in the ferrite phases are +3.2 which were obtained by chemical analysis. The excess Cr ions, if present, coexist with the ferrite phases in the form of calcium chromate, $3CaO \cdot Cr_2O_5$.

The shrinkage of the C_2F_{ss} lattice constants is in good proportion to the difference of Cr^{3+} (0.64Å) from Fe^{3+} (0.67Å). Now, it is the variation of the C_4AF_{ss} lattices with Cr_2O_3 that deviates from the

calculated values; the *b* axis shrinks beyond the calculated values, while the *a,c* axes expand unexpectedly.

These kinds of unexplainable variations of the ferrite lattices have been, however, reported by several researchers; among them, Sakurai (19) has observed in the C_4AF–C_4AM solid solution series, the *b* axis expands with addition of Mn_2O_3, while the *a,c* axes shrink instead; Kato (20) has found the similar irregular changes in the C_2F–MgO system, the C_4AF–MgO system and the C_2F–CaO system. Furthermore, Kato's cases are accompanied by the unusual increase in the intensity of the 020 reflection. If the ferrite structure proposed by Bertaut et al (21) and Smith (22) is correct, these lattice variation must be considered to result from the special characters of the doped transition metal ion Cr^{3+} in the ferrite ligand field.

These lattice variations, however, is recovered to some extent, by re-sintering these ferrite phases in O_2. This is partly because Cr^{3+} ions in the lattices are oxidized into the higher charges and eliminated from the lattices.

The early hydraulic activity of C_2F_{ss} with Cr_2O_3 was determined in the same way as in C_3S_{ss}. As a result, it was proved that Cr_2O_3 can activate the early hydraulic activity of C_2F, although the total heat liberation is invariable. Addition of Cr_2O_3 beyond the limit of substitution, however, decreases the early hydraulic activity of C_2F.

Abnormal Properties of the Ferrite Phase with Cr_2O_3

It was observed that the ferrite with Cr_2O_3 causes an abnormal increase in the diffraction intensity of 0k0 reflection. As some instances shown in Fig. 30, the diffraction intensities of 080, 040 and 020 plane in the ferrite phases prepared in air increase by more than 30 times in C_2F_{ss} and 15 times in C_4AF_{ss}, whereas no intensity change occurs in the other planes. In C_2F_{ss}, however, this intensity decreases if the C_2F_{ss} is sintered in O_2, whereas the intensity in C_4AF_{ss} shows no changes.

To analyse these phenomena, the infrared absorption spectra of these ferrites were studied.

The absorption curves obtained are shown in Figs. 31, 32 and 33.

In the infrared absorption spectra of the ferrite in the C_2F–"C_2Cr" system, the absorption peaks at 1160 cm^{-1}, 950 cm^{-1} and 710 cm^{-1} become stronger

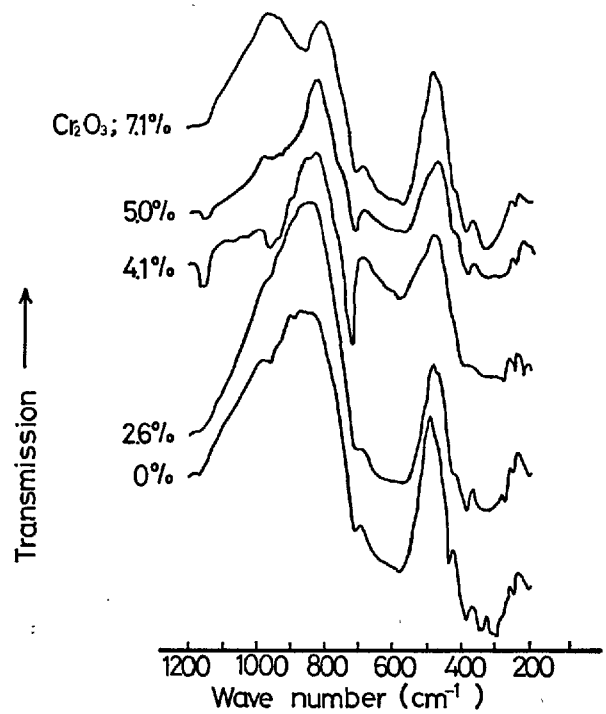

Fig. 31. *Infrared absorption spectra of samples of composition* $2CaO \cdot xFe_2O_3 \cdot (1-x) \cdot Cr_2O_3$.

with increasing substitutions of Cr_2O_3, but the absorption bands in the 640 cm^{-1}–580 cm^{-1} region become weaker instead.

In the infrared absorption spectra of the ferrite in the C_4AF–"C_2Cr" system, the absorption peaks at 1160 cm^{-1} and 720 cm^{-1}, which are also observed in the C_2F–"C_2Cr" system, become stronger, too, with increasing substitution of Cr_2O_3, whereas the strong absorption spectra at 780 cm^{-1} and 430 cm^{-1} become weaker.

After Koresova (23), the frequency of the band in the 720 cm^{-1}–780 cm^{-1} region in the silicate crystals whose lattices contain Al atoms is determined by the fraction of its covalency. An increase in the ionic character of the band, i.e. transfer of Al atoms from anion shell into cation state, eliminates the 720 cm^{-1}–780 cm^{-1} band from the spectrum.

As these spectra at 780 cm^{-1} and 430 cm^{-1}, which are observed in the C_4AF–"C_2Cr" system and in the C_2F–"C_2A" system, cannot be observed in the C_2F–"C_2Cr" system, they may be caused by AlO_4 tetrahedra, and then the spectra in the lower frequency region 660 cm^{-1}–610 cm^{-1} may be caused by the FeO_4 tetrahedra.

In these cases, the above spectra are weakened by increasing substitution of Cr_2O_3. As described above, this decrease of absorption may correspond to an increase in the ionic character of the bonding. Therefore, the substituted Cr_2O_3 seems to increase the ionic character of AlO_4 and FeO_4 tetrahedra.

The strong absorption band in the 710–730 region which is observed in these three phases is subject to no effect by substitution of Cr_2O_3. This absorption peak may belong to a bond of the high symmetry, but is difficult to be indexed.

The above unusual diffraction intensity can be influenced by an adsorption and a desorption of H_2O on the ferrite surfaces.

This is a reversible variation which accompanies no structural change. Therefore this phenomenon may be caused by an electrostatic effect of H_2O.

This reduction of intensity is also caused by mechanical crushing of the ferrite crystals.

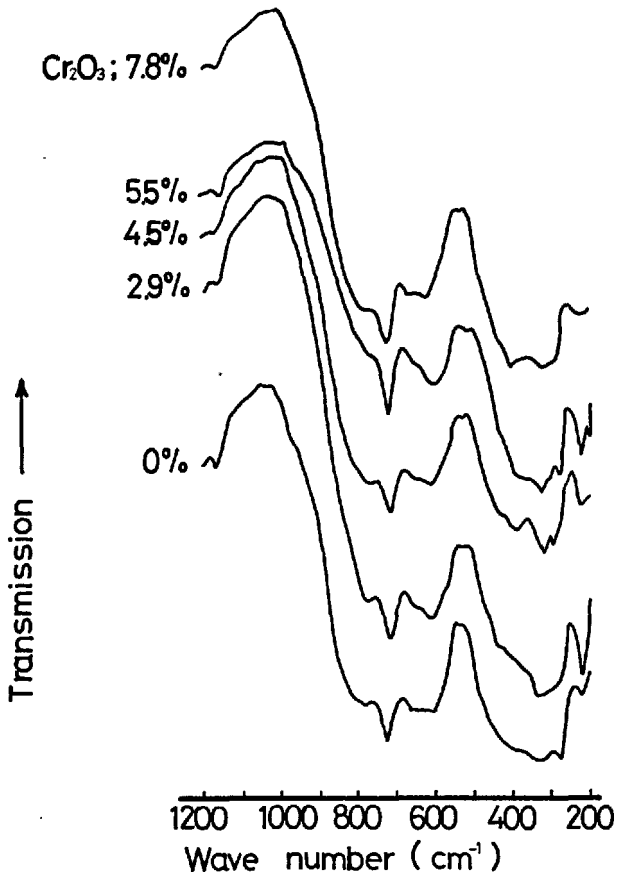

Fig. 32. *Infrared absorption spectra of samples of composition* $4CaO \cdot xFe_2O_3 \cdot xAl_2O_3 \cdot (1 - 2x)Cr_2O_3$.

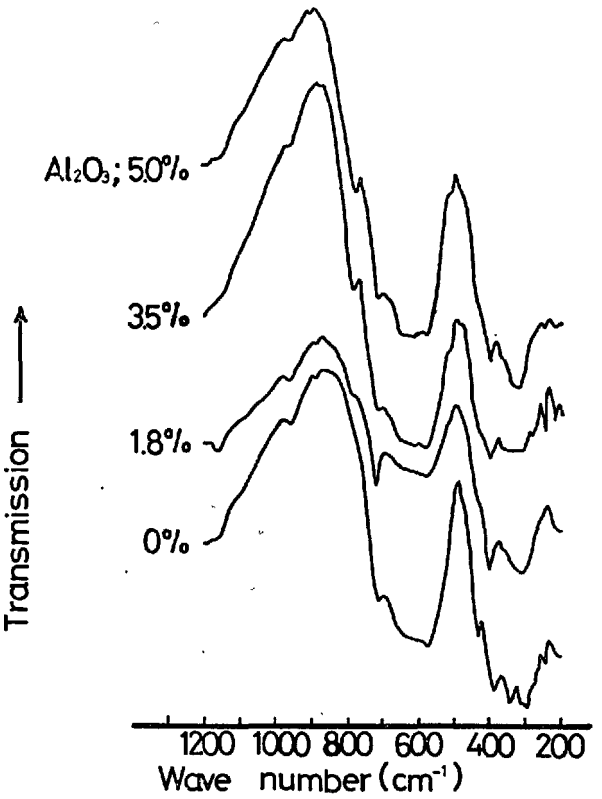

Fig. 33 *Infrared absorption spectra of samples of composition* $2CaO \cdot xFe_2O_3 \cdot (1 - x)Al_2O_3$.

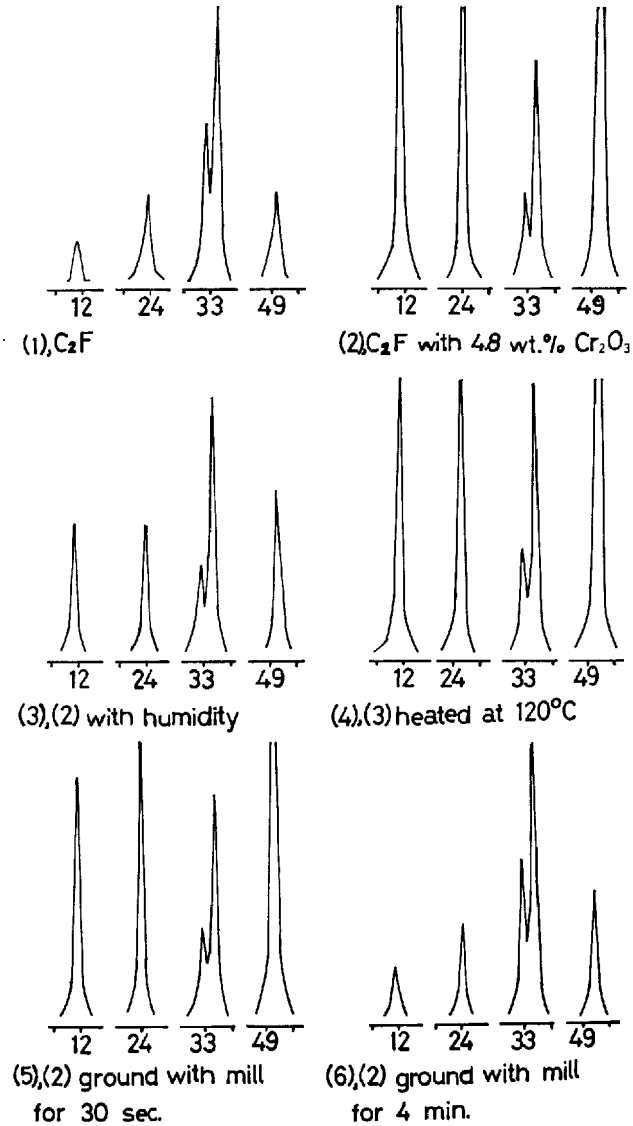

Fig. 34. *Abnormal variation of intensity for* 0k0 *reflections of ferrite solid solutions with* Cr_2O_3.
Sample 1; C_2F sintered at 1300°C in O_2.
Sample 2; C_2F with 4.8 wt% Cr_2O_3 sintered at 1300°C in O_2.

This change is irreversible and cannot be recovered even if the crushed ferrite be heated at 1000°C or at the higher temperature.

The phenomenon caused by an adsorption of H_2O is directly relative to the effect of Cr_2O_3 on the early hydraulic activity of ferrite.

The Mechanism of the Early Hydraulic Action of C_3S with Cr_2O_3

It may be clear from the results in the preceding sections that C_3S with Cr_2O_3 promotes its early hydraluic activity, whereas C_3S with fluorine and Al_2O_3 in the form of $(AlO_3F)^{4-}$ does not, though it increases the early heat liberation.

This difference may be based on semiconductivity of C_3S with Cr_2O_3.

Chatterji and Phatak (10) studied the semiconductivity of normal portland cement. They reported that the clinker material was behaving as a P-type semiconductor, and that the hydraulic action of portland cement clinker was N-type reaction on P-type semiconductor. Hansen (22) reported that the reaction between lime and water might be a N-type reaction on P-type semiconductor. As mentioned above, C_3S with Cr_2O_3 is a P-type extrinsic semiconductor.

Though the hydration reaction of C_3S with Cr_2O_3 starts at the point of emergence of screw dislocation, the later process of hydration may be affected rather by semiconductivity of C_3S solid solution than by

dislocations of C_3S solid solution.

In another words, in the early hydration, the hydration velocity on the surface of C_3S solid solution is accelerated multiplicatively both by the density of screw dislocations and by semiconductivity of C_3S solid solution.

When a P-type semiconductor, C_3S solid solution is in contact with water, the contact surface may be surrounded by a diffuse double layer of water. By screening theory, Si^{4+} is screened enough by the oxygen tetrahedra even on the surface of C_3S_{ss}. Ca^{++} on the surface, however, may not be screened enough by oxygen so that H_2O molecules may be able to attain Ca^{++}, and combine with Ca^{++} as follows;

$$Ca_{lattice} + 2H_2O = Ca(OH)_2 + 2H^+ + Ca\square^{--}$$

In this case, the corrosion theory of semiconductor of germanium (23) may be applicable.

During this combination action, $2e^-$ from $Ca\square^{--}$ may be carried out to the other places by electron holes, where they may recombine with H^+. This reaction may be, however, considerably slow, because of the relaxation effect of the C_3S surface.

That is to say, for the hydraulic action on the C_3S surface, it postulates the operation of two half-cell reactions, the oxidation of Ca and the reduction of H^+. These reactions may be assumed to proceed independently, as if they were the two half-reactions of a short circuited battery.

This oxidation-reduction reaction may be remarkable in the weathering of natural rocks. Therefore the hydraulic action of C_3S may be able to regard as a violent weathering action.

Conclusion

The early hydraulic activity of C_3S is remarkably promoted by addition of Cr_2O_3. This unique effect of Cr_2O_3 must be based on semiconductivity of C_3S with Cr_2O_3. Among imperfections in C_3S solid solution, electron holes and vacancies may help Ca ions being released from the lattice sites. Screw dislocations observed are the starting points of dissolution reaction on C_3S surfaces, while the other dislocations seem to give no obvious effect on the hydration reaction of C_3S_{ss}. These effect of promotion of the early hydraulic activity of C_3S may be also found in some other transition elements which have the similar properties with Cr.

Calcium aluminoferrite also has its hydraulic activity promoted by Cr_2O_3. This case may be also explained by semiconductivity of ferrite with Cr_2O_3.

As everybody know, there remain so many problems of clinkers unsolved. These are the effect of rapid cooling or quenching, the effect of overburning, the effect of minor components on cement clinker minerals and so on. If studies of clinkers are developed from the two viewpoints both of solid state physics and of crystal chemistry, these problems may be easily solved and the properties of clinkers may be improved further.

In order to proceed with a study of the hydration reaction of cement clinker minerals, it may be also very useful to know the weathering mechanism of the natural rocks.

Supplementary Paper I-126 The Distribution of Alkalis in Portland Cement Clinker

Harry W. W. Pollitt and Arthur W. Brown*

Synopsis

The distribution of alkalis in portland cement clinker has been studied using X-ray diffraction and selective solvent extraction and hydrolysis of clinkers.

Alkalis occur in clinker in the form of sulphates outside the four main crystalline components, and as substitution compounds within these crystalline components.

If sufficient SO_3 is available the alkalis occur as sulphates rather than as substitution compounds. Increasing quantities of SO_3 produce more calcium sulphate. Potassium sulphate is the preferred form of alkali sulphate; the molar ratio of potash/soda in sulphate form can be twice that in the alkalis as a whole. There is evidence of a series of double alkali sulphates and of a specific compound $2CaSO_4 \cdot K_2SO_4$ frequently found in clinker. Potassium sulphate is shown to have an important bearing on cement storage properties.

At least half the alkalis not accounted for as sulphate occur in the C_3A and ferrite in quantities determined by the alumina contents of those two compounds. The crystal form of C_3A is modified by potash as well as by soda.

In the silicates the quantitative distribution of alkalis is as yet less clear. Certainly soda as well as potash is capable of modifying belite. It is considered probable that both potash and soda exist in alite in small quantities, probably associated with alumina in solid solution. The association of alkalis with alumina may relate to that proved in the C_3A and ferrite phases.

Introduction

The Research Department of the Associated Portland Cement Manufacturers, Ltd. took a special interest in the distribution of alkalis in clinker following an investigation of the storage properties of ordinary portland cement. This investigation showed that potassium sulphate in cement could influence air-setting or pack-setting through its capacity to react with the gypsum component to form syngenite, $K_2SO_4 \cdot CaSO_4 \cdot H_2O$, during storage. Forest (1) reached a different conclusion in respect of blastfurnace cements.

X-ray diffraction studies of cement composition had also produced evidence that the "split-peak" orthorhombic form of C_3A reported by Moore (2) was not exclusively confined to cements with significant soda contents.

The present paper describes work that has been done by the Department to throw more light on the location of the alkalis in portland cement clinker. Whilst the more advanced techniques have proved invaluable, much has been learned by differential solvent extraction and by microscopic studies.

Separation of Alkali Sulphates in Clinker

In the course of the study of storage properties of cement already referred to, micro-electron probe techniques revealed a close association between the elements potassium and sulphur in what appeared to be deposits sited in the celite (C_3A + ferrite). Improved microscopic techniques permitted the identification of alkali sulphate (Photo 1) and attempts were made to estimate them quantitatively by wet chemical methods.

It was found that alkali sulphates as such could be extracted by hot ethylene glycol using the normal technique for free lime determination. Analysis of the extract and the residual clinker showed that alkali and sulphate in some form remained in the clinker. Further controlled extraction by water was shown to

Photo 1. *This shows alkali sulphate, arrowed A, infilling irregular pores in the clinker and is thus clearly one of the last phases to crystallise. It occurs here as small oriented crystals, etched a dark colour with hydrofluoric acid vapour. Interpenetration of the embedding plastic resin, arrowed B, used during specimen preparation, indicates volume changes during cooling.*
Characteristically the alkali sulphate is surrounded by a halo of unetched clinker.

remove from the clinker further alkali and calcium sulphate, the quantity of the latter suggesting that it was in a highly soluble form. The remaining sulphate in the clinker was later shown to be β-calcium sulphate.

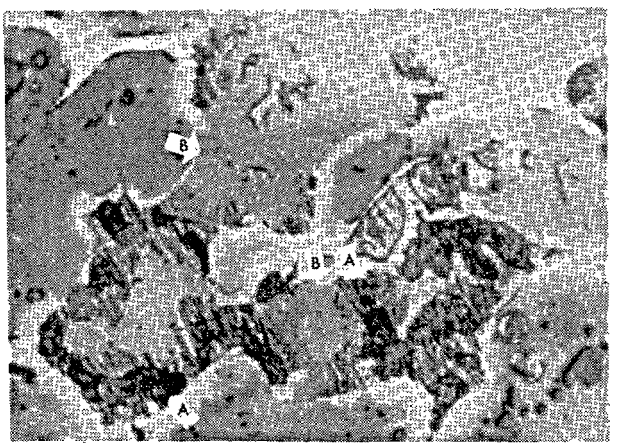
Thus differential extraction separated simple alkali sulphates on the one hand from some other form of alkali and calcium sulphates on the other leaving relatively insoluble β-calcium sulphate in the clinker. The whole of the sulphate could be accounted for in this way. It was also found that no significant quantity of alkali remaining in forms other than as sulphate (or in two cases as free alkali) was removed by the extraction process.

A water extraction alone of course removes the simple alkali sulphates as well as the other water-soluble form of alkali and calcium sulphate. The totals of alkalis and sulphates so extracted are referred to as the water-soluble alkalis and sulphates respectively.

Forms of Calcium Sulphate

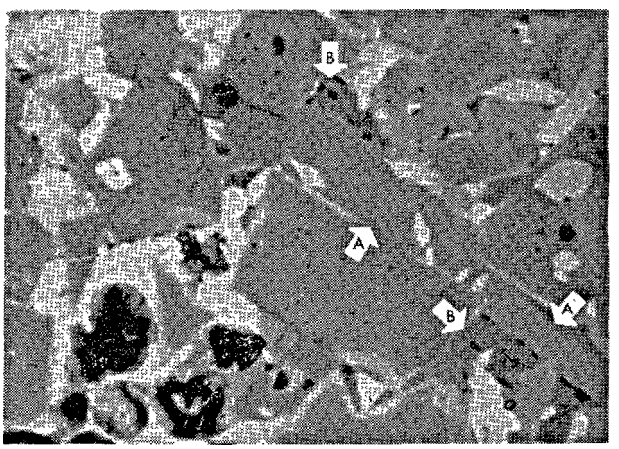
As mentioned above, calcium sulphate was shown to occur in a very water-soluble form.

Initial examination by X-ray diffraction of clinkers containing this form of calcium sulphate did not



⊢⊣ 10 μ ×800

Photo 2. *The coexistence of alkali sulphate, arrowed A, and* $2CaSO_4 \cdot K_2SO_4$, *arrowed B, in clinker is shown here.*
Clearly the original composition of the alkali and calcium sulphate melt lay to the potassium sulphate side of the eutectic composition and crystallisation of the small needles of alkali sulphate took place as the temperature fell. The composition of the liquidus moved towards $2CaSO_4 \cdot K_2SO_4$, *which finally crystallised encasing the earlier formed alkali sulphate. The characteristic halo appears on both the sulphates although it is narrower around the* $2CaSO_4 \cdot K_2SO_4$.



⊢⊣ 10 μ ×800

Photo 3. *In this photomicrograph the coexistence of calcium sulphate, arrowed A, with* $2CaSO_4 \cdot K_2SO_4$, *arrowed B, is illustrated. In this case the alkali sulphate is not present and it is apparent that the composition of the melt lay towards the calcium sulphate side of the eutectic composition. The initial crystallisation of calcium sulphate was followed by that of the* $2CaSO_4 \cdot K_2SO_4$.

reveal anything identifiable against the background radiation, but further examination of fine fractions of ground clinker, separated in a Bahco air-separator, in which the sulphate content was considerably concentrated resulted in the appearance of a triple peak between 26.5 and 28° 2θ CuKα. This, see Fig. 1, was identified as being due to the double sulphate $2CaSO_4 \cdot K_2SO_4$, which was found to be produced by heating together any form of calcium sulphate with potassium sulphate. Subsequent work showed that this compound can form with an excess of either alkali sulphate or calcium sulphate indicating that it is a preferred mode of occurrence in this system. The presence of sodium sulphate can, however, modify this conclusion.

In some clinkers with high sulphate alkali ratios, β-calcium sulphate remained after water extraction and has been identified by its main diffraction peak at 25.4° 2θ CuKα. Clinkers containing a relatively large amount of soda were also found to contain β-calcium sulphate, and this will be referred to again. These forms have been observed microscopically, and Photo 2 and 3 illustrate their co-existence in clinker.

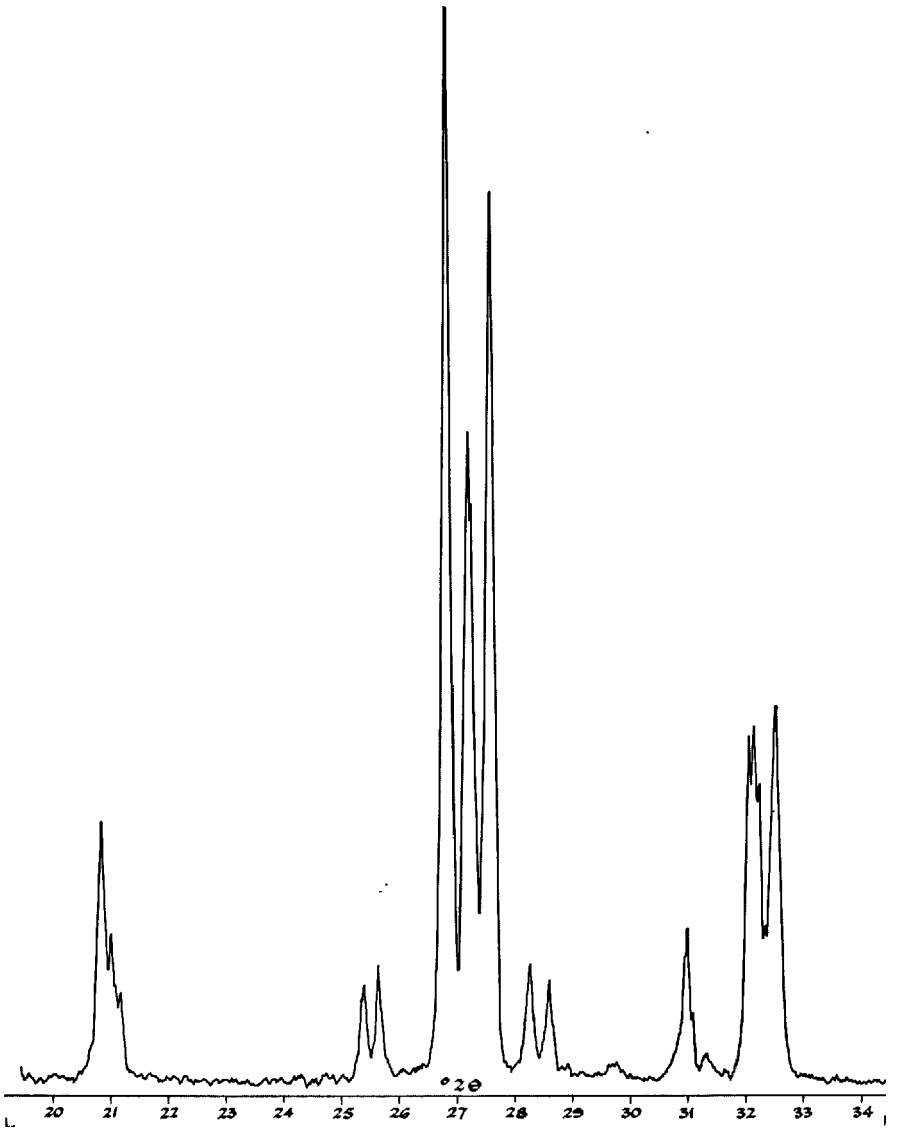


Fig. 1. *X-ray diffraction pattern for the double sulphate.* $2CaSO_4 \cdot K_2SO_4$

In order to examine whether any systematic relationship exists between the clinker sulphate and alkali content, and the proportion of the sulphate which is present as alkali sulphate, works clinkers were examined together with a series of laboratory-prepared clinkers for which the relative amounts of alkali and sulphate in the raw materials were varied over a wide range. On these clinkers the total alkalis and sulphates were determined together with the corresponding water-soluble alkalis and sulphates.

Table 1 shows the results for 11 laboratory prepared clinkers, and Table 2 the corresponding results for 30 works clinkers representing clinker produced in 20 different works by a variety of processes.

In these tables the relative quantities of sulphate and alkalis are expressed by the ratios $\bar{S}_{Tot}/\equiv K$, in which $\bar{S}_{Tot}$ is the total sulphate, and $\equiv K$ is the total alkali content expressed as equivalent potash. (Potash is the predominant alkali in most of the clinkers studies). The proportion of the total sulphate which is present as alkali sulphate is expressed by the ratio $\bar{S}_{Alk}/\bar{S}_{Tot}$, where $\bar{S}_{Alk}$ is the sulphate equivalent to the soluble alkalis. In Fig. 2 values of $\bar{S}_{Alk}/\bar{S}_{Tot}$ are plotted against the corresponding values of $\bar{S}_{Tot}/\equiv K$. The points for the laboratory-prepared clinkers show a good relationship. The works clinkers follow a similar trend but are in general below the drawn curve. This is considered to reflect the fact that as regards CaO, K_2O and SO_3, equilibrium conditions are not fully attained or uniformly approached in a kiln, so that works clinkers tend to contain more calcium sulphate than do laboratory clinkers.

Study of the relationship between total potash and soda and that present as sulphate indicates that there

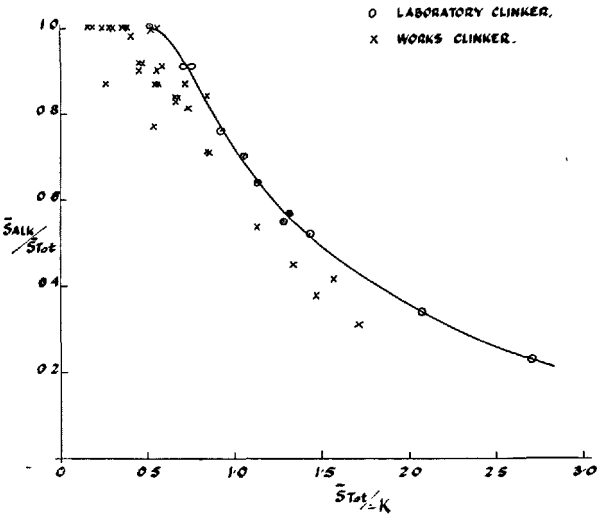

Fig. 2. *Proportion of total sulphate combined with alkalis* ($\bar{S}_{Alk}/\bar{S}_{Tot}$) *as a function of the ratio total sulphate to total alkali as equivalent potash* ($\bar{S}_{Tot}/\equiv K$)

is a marked preference for potash to form sulphate. Table 3 and Fig. 3 show the comparison of corresponding molar ratios for 43 works clinkers. In general the molar ratio of potash to soda as sulphate is about twice the molar ratio of potash to soda in the clinker as a whole.

X-ray diffraction studies of heated mixtures of potassium and sodium sulphates showed that they form a continuous series of double sulphates between molar ratios of 3:1 and 1:3 K_2SO_4/Na_2SO_4 giving characteristic diffraction patterns differing essentially only in changing peak positions with changing molar ratio. The X-ray diffraction patterns of the extremes and centre of this system are shown in Fig. 4. While at the level of occurrence this double sulphate has not yet been directly detected in cement clinkers, it has been found in flue dusts and kiln deposits with a sufficiently high alkali sulphate content. It, therefore, seems probable that within the above molar range any sodium sulphate present in clinker with potassium sulphate will be as a double alkali sulphate.

Where potash, soda and lime are all available it is possible, as has previously been remarked, that the double alkali sulphate may affect the production of $2CaSO_4 \cdot K_2SO_4$. In some clinkers, of which 15A in Table 4 is one, the considerable quantity of calcium sulphate present is in the β-form only. In these clinkers there is sufficient Na_2SO_4 to form the double alkali sulphate with the whole of the K_2SO_4 present, and it would appear likely that the stability or order of crystallisation of the double alkali sulphate is such as to preclude the formation of $2CaSO_4 \cdot K_2SO_4$. This suggestion remains to be confirmed by further study.

Summing up, it appears that K_2SO_4 is likely to occur either alone or in one of two double sulphate forms according to the available quantities of Na_2SO_4 and $CaSO_4$, the preference probably being for the double alkali sulphate. Na_2SO_4 may occur alone but in the clinkers examined is more probably as the double alkali sulphate. It does not form a double sulphate with calcium sulphate. Calcium sulphate occurs alone or as $2CaSO_4 \cdot K_2SO_4$ subject to the prior formation of double alkali sulphate. Overall, potash is twice as likely to produce soluble sulphate as soda.

Determination of Alkali in the Main Phases

The distribution of the alkalis within the four crystalline phases; tricalcium aluminate, calcium aluminoferrite and the two calcium silicates has been studied by a process of progressive solution to remove the phases stepwise and determine the alkalis in the undissolved residues. Following the removal of the

alkali sulphates and double sulphates by aqueous extraction as described above, the remaining alkalis were determined. The silicates were next removed by selective hydrolysis using a solution of salicylic acid in methanol and the residual alkalis in the celite were determined. Finally, the ferrite was isolated using

aqueous acetic acid as the solvent for the other phases with a final pH of 3.5–3.8, and the alkali content of the ferrite residue was determined.

At each stage it was confirmed by chemical analysis and X-ray diffraction examination that the residues used for alkali determinations were in the one case a mixture of C_3A and ferrite uncontaminated with alite or belite and in the second case ferrite containing neither silicates nor C_3A.

From these results the alkali content of the combined silicates, of the C_3A and of the ferrite were obtained and in Table 4 these results are shown for 16 clinkers together with their chemical analyses and compound compositions as determined by X-ray diffraction.

Alkali in Tricalcium Aluminate and Ferrite

Examination of the results shown in Table 4 for the alkali content of the C_3A and ferrite, related to the quantity of each of these phases in the clinkers suggests that the distribution of alkalis between C_3A and ferrite is dependent on the quantities of alumina in these compounds. In Table 5 the alkali content of both C_3A and ferrite is shown expressed as a percentage of the alumina present in those phases. The same results are plotted in Fig. 5. The fit of the points to the line is considered good in relation to possible experimental error and provides evidence that the alkalis are associated with alumina equally in the two phases.

Also in Table 5 the alkali content of the C_3A expressed as a percentage of the C_3A present is shown relative to the crystal form of the C_3A, whether as the normal cubic form or as the alkali-modified orthorhombic form (Photo 4) showing the peak splitting at about 33° 2θCuKα and in the regions 46.5 to 48.5° 2θ and 59.5 to 60° 2θCuKα. The highest level of alkali consistent with the cubic form is just below 2.7% equivalent potash, whereas the lowest level of alkali consistent with the orthorhombic form is at 2.9% equivalent potash, suggesting a critical level at about 2.8% equivalent potash or 1.8% of soda. This is lower than the level (2.25% soda) reported by Conwicke and Day (3) in their investigation of the system C_3A–NC_8A_3, or indeed that (2.1% soda) suggested by Fletcher, Midgley and Moore (4), which strengthens their suggestion that the production of orthorhombic C_3A in clinker need not be due solely to soda.

That this modification can be caused by potash as well as by soda is also indicated by these results, and is particularly well illustrated by clinker 4A in which the total soda content of the clinker only represents

0.7% of the C_3A present and where less than 10% of the alkali determined in the C_3A is soda, but which nevertheless shows the characteristic change in X-ray pattern and characteristic appearance under microscopic examination as illustrated by the photomicrograph of this clinker (Photo 4).

Clinkers 7A and 9A also show these same features, the soda in the C_3A being 0.5% and 0.4% respectively. In these cases the potash is mainly responsible for the orthorhombic C_3A.

We have been unable so far to synthesise C_3A in the orthorhombic form using potash as the sole alkali present. It is believed that when potash is the sole or predominant alkali involved, the inclusion of silica and additional lime in the structure may be necessary to produce the orthorhombic crystal form of C_3A. In this connection lime and silica are known to occur in C_3A in works clinkers.

Alkalis in the Silicates

The distribution of alkalis in the silicates is still being studied. We have not yet succeeded in isolating the two silicates separately to permit direct analysis, nor have we obtained firm evidence using the micro-electron probe technique.

Nevertheless, Table 4 shows the potash and soda contained in the silicates in the 16 clinkers on which Table 5 was based. Newkirk (5) suggested that potash, other than as sulphate, appeared in belite as $KC_{23}S_{12}$. In Fig. 6 the equivalent potash in the silicates is plotted against belite content for the 16 clinkers. Also plotted is a line indicating Newkirk's alkaline belite composition.

It will be seen that four points lie reasonably close to the Newkirk line, but that the remainder lie well below that line. An immediate interpretation is that in only 4 cases are the quantities of alkali and belite both consistent with Newkirk's composition, whereas in the other 12 cases there is insufficient alkali to convert more than a part of the available belite.

Photo 5 illustrates the coexistence of normal belite and alkali stabilised belite, while Photo 6 shows unstable belite inverting to the γ-form in a clinker in which the alkali content of the silicates was known to be extremely low.

The above interpretation may well be the only one necessary in many cases, but it has occurred to us that some of the alkali may also be found in the alite. Alite is known to contain alumina in solid solution to an extent influenced by the magnesia present. Furthermore, it was shown earlier that the distribution of alkali between C_3A and ferrite is well related to their alumina contents.

Following this line of thought the clinker (11A) closest to the Newkirk composition in Fig. 6 was

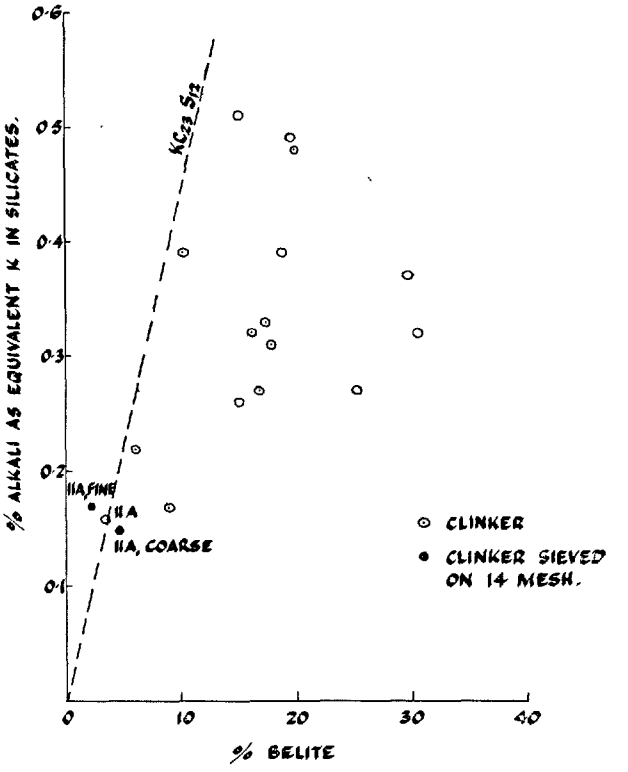

Fig. 6. *Alkali (equivalent potash) in silicates as function of belite quantity in works clinkers*

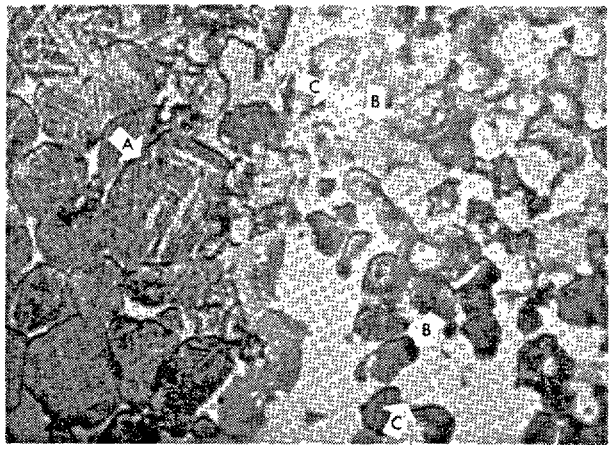
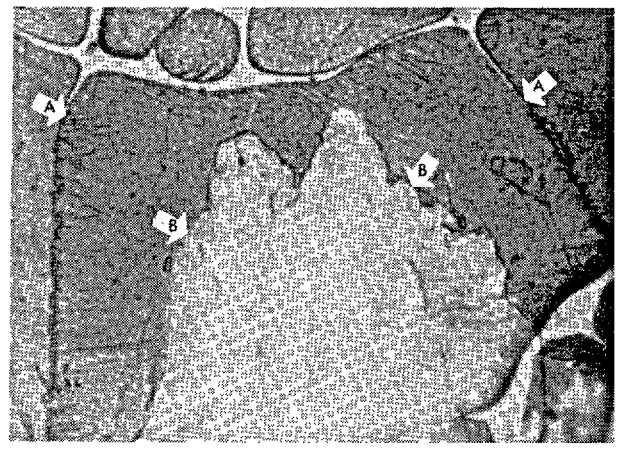


⊢⊣ 10 μ ×800

Photo 5. *Both the normal belite, arrowed A, and the alkali stabilised belite, arrowed B, are illustrated here. The coexistence of alkali modified belite in contact with free lime crystals, arrowed C, indicates the considerable stability of the alkaline belite inhibiting its assimilation of further lime to form alite.*



⊢⊣ 10 μ ×800

Photo 6. *In clinker of very low alkali content the β-C_2S may exhibit considerable instability and tend to invert to its more stable γ-phase. This is illustrated here where a single crystal of β-C_2S, arrowed A, is undergoing inversion to the γ form, arrowed B. This inversion is accompanied by a 10% volume increase and the resulting microcracking can be seen radiating away from the inverted area.*

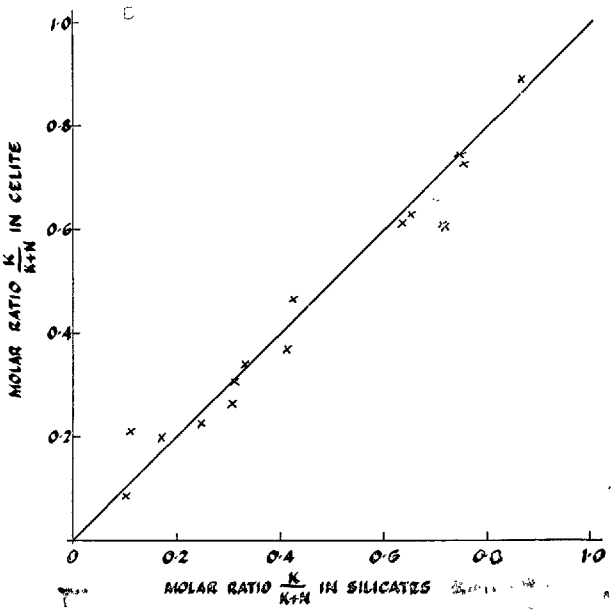


Fig. 7. *Proportion of potash in alkalis in celite as a function of that in silicates.*

fractionated by sieving on a 14 mesh sieve, in order to vary the alite/belite proportions, and the coarse and fine components analysed. The resulting data are plotted adjacent to the point for the clinker as a whole. Clearly the fine fraction contains more alkali in the silicates than can be explained by Newkirk's alkaline belite. This, in itself, does not prove that the alkali is not in the belite, but since between the three relevant points an increase in belite appears to be associated with, if anything, a decrease in alkali, there is a good case for suggesting that there is alkali in the alite. The estimated alkali/alumina ratio in the silicates in clin-

ker 11A is 11%. This figure compares with approximately 7% for the C_3A and ferrite in that clinker. This could suggest that part of the alkali is in the alite, associated with alumina, the remainder being in the belite and not associated with alumina.

It is worth adding that, while the remaining points in Fig. 5 are consistent with partial conversion of the belite to Newkirk's form, this does not mean that all the alkali available to the silicates is in fact in the belite.

It was shown above that the molar ratio of potash to soda as sulphate was about twice that for total potash and soda. Fig. 7 shows the molar proportion of potash in the alkalis in the celite plotted against that in the silicates. Fig. 8 is a similar graph for the C_3A and ferrite separately. These Figs. indicate no tendency for potash to prefer the silicates and soda the aluminates, but rather that in works clinkers potash and soda are equally likely to be found in the phases in proportion to their residual concentrations in the clinker after sulphate formation.

Free Alkali

In two clinkers out of 43 the water-soluble alkalis exceeded the water soluble sulphates equivalent to alkali. The excess of alkali represents so-called free alkali, probably in the form of carbonate. The presence of free alkali is associated with low $\bar{S}_{Tot}/\equiv K$ ratios and high alkali content, but in the two clinkers concerned the crystal phases contain less alkali than is possible. It is considered that the explanation must lie in the mechanisms of dissociation and formation of alkali compounds in the clinkering process.

Conclusions and Discussion

The main points which emerge from the work are:

1. Alkalis occur in clinker as sulphates and double sulphates and as substitution components of the crystal phases. In a few cases free alkali may also be found.
2. The evidence suggests that the sulphate content of the clinker makes the prior demand on the alkalis. The resulting quantity of alkali sulphate is determined by the ratio of total clinker sulphate to total alkali. The remaining sulphate is calcium sulphate either as a soluble double sulphate or as β-calcium sulphate. At this stage potash has twice the affinity of soda for sulphate.
3. After allocating alkali to sulphate as in 2, the remainder appears to be distributed between the silicates, the C_3A and the ferrite, with no evidence of a preference of the silicates for potash or of the aluminates for soda.
4. The quantity of alkalis in the C_3A and ferrite respectively is well related to the alumina contents of those phases.
5. The orthorhombic form of C_3A is formed with a minimum alkali content of 2.8% equivalent potash or 1.8% equivalent soda.
6. The proportion of potash in the alkali is broadly the same in the silicates, C_3A and ferrite respectively.
7. The basis for the quantitative division of alkalis between silicates on the one hand and C_3A and ferrite on the other is not yet clear, although the latter generally take about half or more of the available alkali. There is evidence that alite may contain alkali.
8. Overall, potash and soda appear to be interchangeable in the crystal phases, but potash is distinguished in that it has a much greater affinity than soda for sulphate and a capacity, which soda has not, to form two double sulphates with lime: $2CaSO_4 \cdot K_2SO_4$ in clinker and $K_2SO_4 \cdot CaSO_4 \cdot H_2O$ in cement.

Further work will be done to elucidate the distribution of alkali in silicates. In the meantime the vairous forms of alkali shown to occur in clinker may well behave differently during hydration. In practice, therefore, it may be important to distinguish the alkalis more precisely. The specific influence of potassium sulphate on cement storage properties has been referred to.

Perhaps the most important practical interest in alkalis arises from the limitation imposed by certain standards on total alkali as equivalent dosa where alkali-aggregate reaction is feared. The literature in this field contains enough anomalous or controversial information to suggest that a closer definition of the forms in which the alkalis occur in a clinker may lead to a more precise understanding of its capacity to promote alkali-aggregate reaction.

The same closer definition may also be important

in the wider field of the setting, workability and strength characteristics of cements.

Supplementary Paper I-131 Cement Surface Area Determination by Gas Adsorption near Room Temperature

Ali A. Tabikh*

Synopsis

An apparatus to determine the specific surface areas of hydrated and unhydrous cements has been developed employing gas flow techniques and thermistor detectors. The specific surface area of a sample is determined by measuring the desorbed organic molecules. The adsorption equilibrium is maintained at 30°C. and the desorption temperature used is 200°C. The adsorbate used is either benzene, acetone, or methyl alchohol. Helium is used as a carrier, but also serves as a diluent to obtain the desired relative pressure (P/P_0).

The determination is rapid since a single point measurement, at a given P/P_0, is required. However, if one wishes to make measurements at several P/P_0 points, the BET equation may be applied to calculate the surface area.

The results of adsorption studies using this method on two hydrated and several unhydrated cements are discussed.

Introduction

The measurements of surface area of cement are usually made by air permeability methods or calculated from turbidimeter data. Both procedures are inadequate for providing detailed information about surface properties, particularly with regard to internal surfaces and porosity.

Continuous flow methods have been developed which greatly simplify nitrogen adsorption measurements (1, 2). Other more recent papers have been published which describe flow methods using various organic vapors as adsorbates (3, 4).

The present study was undertaken to develop the equipment and methods for a simple and rapid procedure of surface area measurement. Therefore, emphasis was placed on adsorption near ambient temperature, minimum handling of the sample, and the ability to measure a wide range of surface areas (.01 m^2 and up) accurately. The instrument which has been developed appears to fulfill the objectives of the project.

The data presented here have been derived from a current investigation being conducted on hydrated as well as unhydrated cements using various vapor pressures in order to evaluate the surface properties. These data are intended to illustrate the capabilities of the apparatus and the methods of studying these surface properties. In addition, some of the properties related to the specific surface of a cement particle are pointed out.

Apparatus

The schematic diagram of Fig. 1 illustrates the apparatus which has been developed. The carrier gas used is helium. A sensitive pressure regulating system is necessary to obtain uniform and accurate flow rates. All tubing in the flow system is one-eighth inch diameter nylon or copper tubing.

The carrier gas flows through two calibrated flowmeters H and V, where the portion going through H supplies the diluent, and that going through V becomes the vapor-saturated gas. The two streams are mixed in a mixing tube M where the desired partial vapor pressure P/P_0 of the adsorbate is obtained. The tube M feeds the two identical flow channels from this point on to the vent. In regard to the forward flow, tube M acts as a back-pressure damper, thus there is no cross channel interference during the sudden heating of desorption. The vapor saturating arrangement, in-

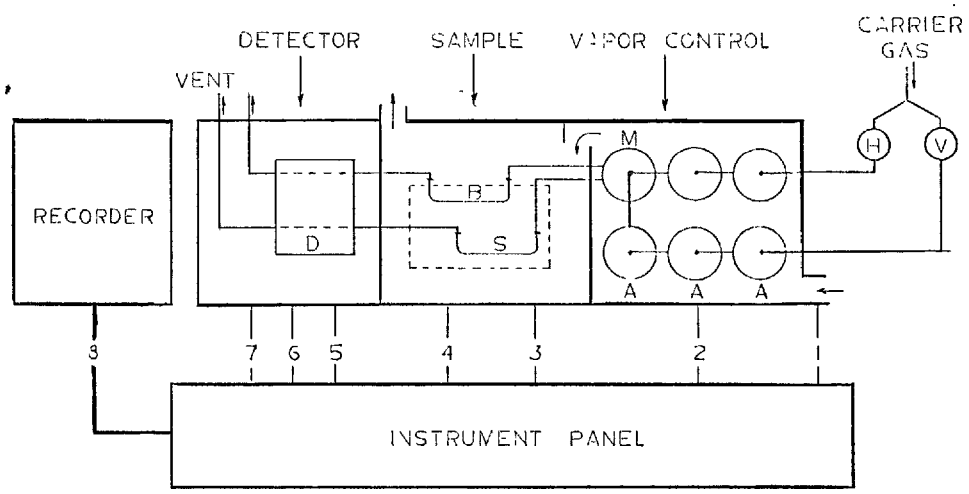

Fig. 1. *Diagram illustrating the surface area apparatus. H and V are flowmeters. The cells A contain the liquid adsorbate. M is the mixing tube and back pressure damper. S and B are the sample tubes; B is the blank in the reference channel. The dotted area is the high temperature enclosure. D is the thermal conductivity cell. The instrument panel provides the following controls: (1) air heater, (2) temperature sensing and control, (3) high temperature power supply, (4) high temperature regulator, (5) constant temperature source, (6) power supply to detector, (7) signal output balance, and (8) signal output to recorder.*

cluding tube *M*, is made up of a series of vacuum trap-type tubes. The tubes A containing liquid adsorbate are connected in series and are lined inside with filter paper to assure a vapor saturated atmosphere. The vapor control chamber is held at 30°C ± .01 using a thermister controlled circuit. The temperature setting, however, is variable from a potentiometer.

In the test chamber one of the gas streams flows through a blank sample tube *B*. The other stream flows through the sample tube *S* which contains the specimen. These sample tubes are constructed from glass tubing 0.6 cm I.D. They form a broad U, 10 cm long, and are equipped with tapered glass joints for quick connecting.

The sample tubes are mounted into an aluminum rack which is equipped with a heating unit capable of bringing the temperature of the sample up to 200°C in 2 minutes. With this arrangement it is possible to degas the sample prior to making the adsorption measurements in the apparatus itself. This rapid, controlled heating also provides the means to measure the desorption peaks for determinations of the surface area.

The adsorption temperature is nomrally the same as the temperature in the vapor control chamber (30°C ± .01).

The thermal conductivity cell *D* was developed in this research laboratory. It employs two matched thermisters which are mounted in the paths of the two gas streams. They are powered by a well regulated D.C. voltage source (normal operating voltage is about 17 volts). The output signals, 0–125 millivolts, from the two thermistors are balanced by a bridge circuit and sent to a recorder.

In addition to operating the apparatus near room temperature, its design allows studies to be made at either extremely low or higher than ambient temperatures. Both are achieved with minor modifications and/or auxiliary equipment.

Procedure

All samples are oven-dried at 105°C before weighing. The required sample weight varies from .01 to .5 g depending on the surface area of the sample. In the case of unhydrated cement, 0.0500 g is used.

The *U*-tube containing the sample is connected to the apparatus, and the flowmeter *H* is adjusted to deliver 30 cc per minute. Then, the high heat is turned on and the sample is purged at the preset temperature

(200°C is used in this study) until a steady output signal is received. The high heat is turned off at this time and the sample is allowed to cool down to the adsorption temperature, usually 30°C. At the same time the flowmeters are adjusted to give the desired vapor pressure.

The partial vapor pressure calculations are made in normal manner with corrections for slight volume changes when the carrier gas is saturated with the organic vapor. The necessary saturation vapor pressure data are taken from Jordan (5).

The total flow rates are kept constant for all the points of the very isotherm. These are, in cc per minute, 32 for benzene, 70 for acetone, 37.5 for alcohol, and 30 cc for nitrogen. Half of each quantity flows through the sample, the other half through the blank channel. When a steady signal is received from the detector, indicating a steady state between the sample surface and the vapor phase of the gas stream, it is time to desorb and mesure the desorption peak. This is accomplished by turning the high heat on. The time required to degas a cement sample is 15 to 20 minutes, and an adsorption-desorption cycle takes about 15 minutes.

The organic liquids used are all Mallinkrodt spectrophotometric grade reagents. The carrier gas is atomic grade helium. The nitrogen is a Matheson prepurified grade.

The recorder used in this study is a Sargent model SR equipped with a Disc integrator and an output range of 0–125 millivolts. The desorption peaks are usually sharply defined and are sometimes over 100 millivolts high with tails of 1 to 4 minutes duration depending on the nature of the sample being tested.

The detector response is linear within the normal surface area range of cements, when the single point method of determination is used, i.e., at any single vapor pressure setting. However, its sensitivity decreases as the vapor pressure of the adsorbate is raised. So, it becomes necessary to establish a correction curve in order to convert all peak areas to a common reference point, as illustrated in Fig. 2. The descending curve in this figure shows the decrease in sensitivity when 0.2 ul increments of benzene are injected into the sample gas stream at increasing partial vapor pressures. The ascending curve gives the correction factors at similar vapor pressure levels which would convert the counts to values comparable to those taken at $P' = 0.1$. For example, at $P' = 0.6$ (point A in Fig. 2) the peak counts are 492 and the correction factor is 1.768 (point B), and their product is 870 which is what the counts would be if no decrease in sensitivity would take place.

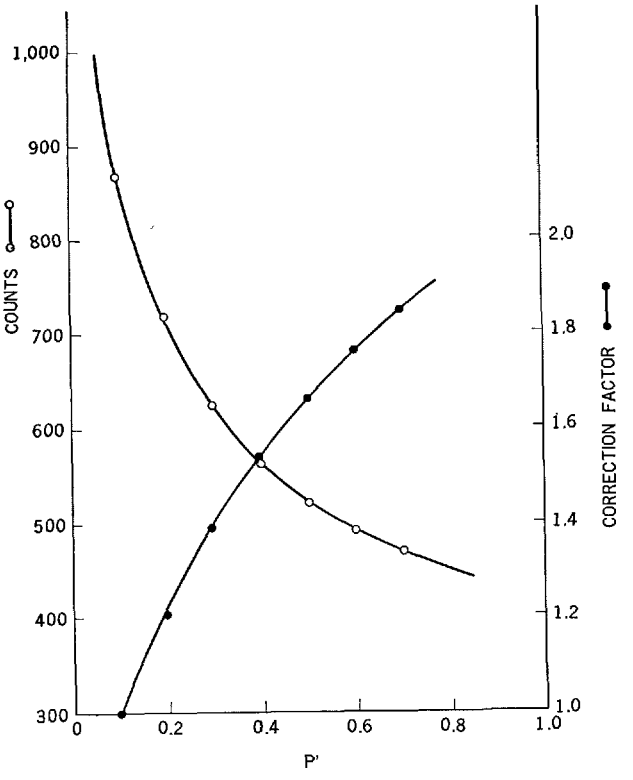

Fig. 2. *Change of detector response to benzene increments as the vapor pressure of benzene in the gas stream approached saturation, and the correction curve to change the output counts to $P = 0.10$ basis.*

The desorption peak areas are expressed in integrator counts at one millivolt in all calculations and plotting. The final values which represent the monolayer are converted to Cm^2 or m^2 by using the equation $A = fc$ where f is a calibration factor and c is counts at one millivolt per gram. The factor f is obtained by comparing the peaks from nitrogen adsorption versus, say, benzene for a given cement sample.

In the case of nitrogen adsorption, 0.5 cc increments of the gas are injected into the sample stream and the resulting counts are taken. From the known weight of nitrogen injected these are expressed as counts per unit area by use of the equation:

$$S = \frac{G}{M} N \cdot A_{mx}\, 10^{-20}$$

where S is the specific surface in $m^2/g.$, G is the nitrogen used in grams, M is the molecular weight of nitrogen, N is Avogadro's number, and A_m is the molecular cross-sectional area of nitrogen. The value 16.2 Å^2 is used for A_m in the calculations. Since the desorption peaks of organic vapors have been calibrated with samples whose nitrogen adsorption values are known, there is no need to know the mole-

cular cross-sectional surface areas of the organic adsorbate. This is a safe approach since these areas vary widely (7) because the packing arrangement of the adsorbed molecules is influenced by the energetic properties of the solid surface.

When a complete adsorption isotherm is made the calculations are based on the BET equation (6), written in the following form:

$$\frac{P''}{X} = \frac{1}{X_m C} + \frac{C-1}{X_m C} P'$$

where P' is the partial pressure P/P_0, P'' is the term $\frac{P}{P_0 - P}$, X is the quantity of vapor adsorbed, X_m the portion of vapor equivalent to the monolayer coverage, and C is a constant related to the net heat of adsorption. From the slope and intercept of the BET curve X_m can be expressed as follows:

$$X_m = \frac{1}{s+i}$$

where s = the slope, and i = the intercept.

The hydrated cements tested have been treated in the following manner: Oven dried samples weighing 0.25 g are placed in 3 cc size polyethylene tubes. The tubes are stoppered after adding 2 cc of CO_2 free distilled water and shaken in a rotary mixer for the desired interval of time. The slurry is centrifuged and the supernatant liquid is replaced by methyl alchohol. The solids are dispersed and shaken in the alcohol for one minute. Following centrifugation the alcohol wash is repeated once more. The solids are transferred into a tared polyethylene weighing dish. After oven drying the final weight of the hydrated cement is determined. Carefully weighed samples equivalent to .0125 g of the original unhydrated cement are weighed and used for the surface area determination.

The unhydrated cements tested are all Type II. At the time of testing cements 1 and 4 were several weeks old, cement 2 was one day old, cement 3 was fresh from the mill, and cement 5 was from the same clinker as cement 3 but ground coarser. All of these, except cement 4, are the products of one cement plant.

The samples of C_2S and C_3S were furnished by the Engineering Materials Laboratory of the University of California in Berkeley.

Discussion

Three methods have thus far been used to measure surface area with the apparatus described here. Nitrogen adsorption at liquid nitrogen temperature is made by pouring liquid nitrogen into a modified sample tube holder and recording the adsorption peaks. By repeating this at several vapor pressure levels sufficient data are obtained to draw the adsorption isotherm curve and calculate the monolayer area by the BET equation. This is done to establish a basis for comparison between organic vapor and nitrogen adsorption on various materials. The other two methods of measurement employ benzene, methyl alcohol, or acetone. They are the single point method and the complete adsorption isotherm determination. The latter is especially necessary for a completely unknown sample, while the former approach is satisfactory for samples of similar surface properties. A recent abstract of a paper (in Russian) by Gavrilova and Kiselev (8) indicates they are using a similar approach, measuring near P/P_0 of 0.05.

Preliminary results indicate dry cements are similar in their overall surface adsorption behavior. Fig. 3 shows the BET curve for cements from two different plants to be practically identical. Calculations from these and several other cements show the monolayer coverage to fall between vapor pressure values of 0.07 and 0.1.

The values of the specific surface determined for unhydrated samples are given in Table 1. In comparison to the Blaine surfaces which fall between 3100 and 4100 cm² per gram, the higher values, by a factor approximately of 10, have been verified by nitrogen

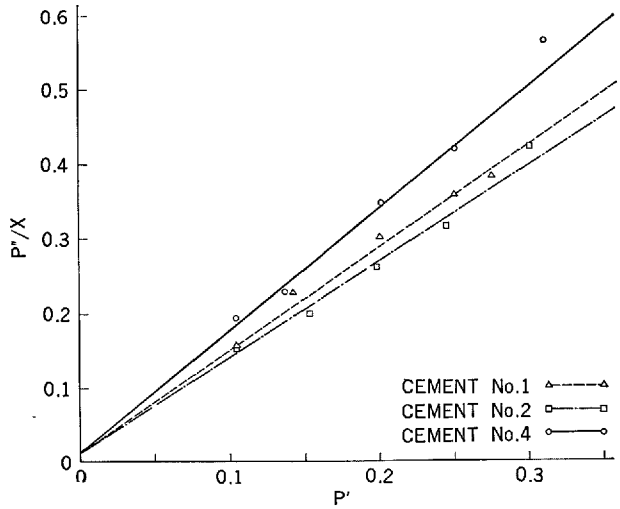

Fig. 3. *B.E.T. curves for three cements to illustrate the similarity between their surface adsorption properties.*

adsorption and are accepted as the true total solid surfaces. The explanation which has been offered (9) attributing such differences between air permeability and gas adsorption results to hydration during the normal handling of a sample, does not appear valid at least in the samples examined here. Age differences of these dry cements do not seem to have a measurable influence on their specific surface areas. As indicated in Table 1, a fresh-from-the mill cement (No. 3) has the largest area. We know with certainty that it has had no air hydration of any extent. Therefore, it looks like the larger adsorption areas reported here being indicative of the extent of crevaces and micropores on the particles.

Sample No. 5 lends support to the foregoing argument. It is made from the same clinker as No. 3; it was produced only three days later in the same mill, but ground coarser. Its Blaine area is 3100 cm^2 per gram against 4070 cm^2 per gram for No. 3. Therefore, by grinding finer the air permeability area increases about 30 percent, whereas the adsorption area increases by about 200 percent. Since the air permeability results are primarily influenced by the external surface properties it becomes evident that as the particles are broken up into smaller fragments they must be exposing many new pores and cracks in order to cause the internal surface area to increase at such a faster rate. This suggests, at least in this instance, that the cement particles possess a microcellular structure.

The older cements (No. 1 and 4) were stored in metal containers under optimum atmospheric conditions, however, some hydration was anticipated. If this does occur, evidently it produces no significant change in the adsorption surface area. Of course, exposure to an atmosphere of high relative humidity will ultimately cause sufficient hydration to impart a measurable increase of the cement surface.

Cements 1 and 4 were hydrated as described earlier for intervals of time from 5 minutes to 7 days. The surface development is presented in Fig. 4. A few

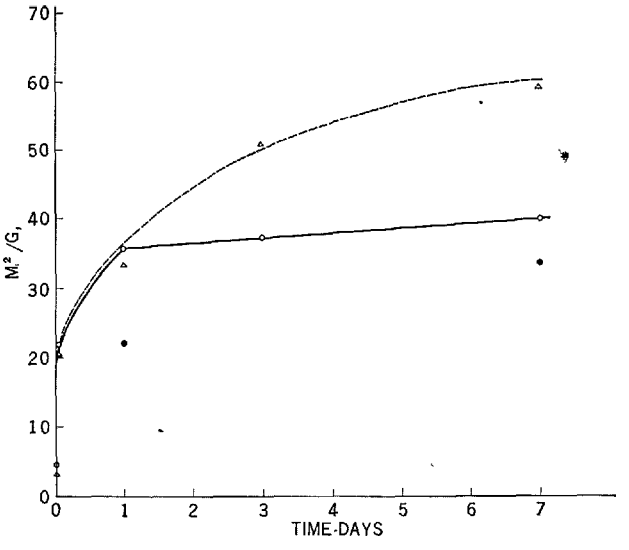

Fig. 4. *The surface area development of two different cements hydrated up to 7 days.*

other hydrated specimens give values between 50–70 m^2 which are comparable to some of the results given by Hunt, Tomes, and Blaine (10) and somewhat lower than those presented by Powers and Brownyard (9). As pointed out by Powers (11), the nitrogen adsorption values are usually 20 to 50 percent of the specific surfaces measured with water. Furthermore, the hydration procedure used here and the degassing at 200°C are likely to cause a contraction of the crystal lattice structure. This might render a considerable portion of the surface area inaccessible to the nitrogen or benzene molecules; whereas, the penetration of the highly polar and smaller water molecules might be affected to a lesser extent.

The points below the curve in Fig. 4 are hydrated samples of cement 1 which are not centrifuged but taken to dryness at 105°C. The lower surface areas shown are probably caused by higher lime content than in the centrifuged samples. This seems to be consistent with the discussion of Kantro, Brunauer, and Weise (12) that the higher the lime content is in tobermorite, the lower the surface area, which could be attributed to the cementing effect of lime on the crystals of tobermorite.

The foregoing discussion illustrates some of the results which can be obtained by this new technique. It would be feasible to study the surface properties of cement pastes by water adsorption without change or addition to the apparatus. In addition, it would be possible to study the porosity by measuring adsorption at high vapor pressures ($P' = 0.8$ to 1.0). At thse higher vapor pressures the desorption peaks of unhy-

drous cements start splitting and forming patterns characteristics of the sample, and may represent fractions of the adsorbate which have been adsorbed at different energy levels.

Supplementary Paper I-136 The Crystallization of Compounds in the Presence of Cr_2O_3, P_2O_5 or SO_3 and the Properties of the Resultant Cement

Yuri M. Butt, Vladimir V. Timashev and Ludmila I. Malozohn*

Synopsis

The influences of Cr_2O_3, P_2O_5 or SO_3 on the crystallic lattice of clinkers having high (1) and low (0.67) saturation factors at various technological conditions were studied. Also were studied the properties of cements made on these clinkers. The amounts of the said oxides introduced amounted to 0.5, 1.0, 1.5, 2.0 and 3 per cent respectively.

The presence of 0.5 per cent of an oxide in the raw mix rather increases the clearness of the clinker crystallic lattice. The amount of an admixture over 1.0 per cent brings about the formation of imperfect forms of crystals. The crystals of belite had strong hatching, had splitted edges or disintegrated into separate "blocks"; the number of inclusion into alite crystals increased. In the presence of SO_3 some alite crystals assumed an indefinite form.

The occlusion of the modifying agents into the lattice was accompanied, in case of Cr_2O_3—with an increase, and in case of SO_3 or P_2O_5—with a decrease of alite and belite refringence data.

The time of grinding in the presence of Cr_2O_3, P_2O_5 or SO_3 decreases–especially in clinkers of high saturation factor.

The presence of Cr_2O_3 or SO_3 in cement having SF = 1 contributes to rapid gain of strength during the initial period of the cement paste hardening. In the presence of P_2O_5 the rate of cement hardening decreases.

Introduction

Crystallization of alite and belite in clinkers was studied—depending on the amount of Cr_2O_3, P_2O_5 or SO_3. Features of resultant cements were studied.

The composition of raw mixes was so designed as to obtain clinkers with saturation factors (SF) 1 and 0.67. The flux content amounted to 20 per cent (14 per cent of C_4AF and 6 per cent of C_3A). The admixture investigated were added in the form of Cr_2O_3, P_2O_5 and $CaSO_4 \cdot 2H_2O$ in amounts of 0.5, 1.0, 1.5, 2.0 and 3.0 per cent—expressed as SO_3 content. Specimens pressed with 400 kg/cm² force were burnt in silit furnace at 1450°C. The retention time at this temperature was 1 and 4 hours for clinkers having SF values 0.67 and 1 respectively (excluding alite clinkers with 3 per cent admixture—these being burnt for 1 hour). The clinkers resulted were air quenched and slowly cooled in the furnace at the rate of 5° approximately per minute. In addition, the clinkers with 3 per cent admixture suffered three-times burning—in order to obtain more complete assimilation of the lime.

The presence of 0.5–3.0 per cent of Cr_2O_5, P_2O_5 or SO_3 in the raw mix having saturation factor of 0.67, does not adversely influence the forming of clinker: the amount of free CaO in clinker did not exceed some

*The Moscow Mendeleev's Institute of Chemical Technology, Moscow, U.S.S.R.

tenth of per cent (2, 4, 5). In clinkers having saturation factor 1 and with 0.5–2.0 per cent of SO_3 or P_2O_5 the content of free CaO does not exceed 1 per cent while in those with the addition of Cr_2O_3 the free CaO content is 2 per cent.

During the burning partial and rather uneven volatilization of oxide admixtures was observed (Table 1).

Table 1. *The amount of* P_2O_5, SO_3 *or* Cr_2O_3 *in clinkers, per cent, as to the chemical analysis data*

The designed amount of an oxide into the raw mix, per cent	P_2O_5		SO_3		Cr_2O_3	
	SF = 0.67	SF = 1	SF = 0.67	SF = 1	SF = 0.67	SF = 1
0.5	0.44	0.47	no	0.17	0.35	0.63
1.0	1.37	0.98	no	0.33	0.51	0.57
1.5	1.34	0.92	no	0.12	0.82	0.82
2.0	1.62	1.32	0.84	0.14	1.14	1.45

Crystallic Structure of Clinkers

The presence of 0.5 per cent of P_2O_5, Cr_2O_3 or SO_3 in a raw mix having saturation factor of—0.67 (Belite clinker) brings about some more distinct crystallization of the clinkering minerals and to more distinct forming of crystals as to compare with the clinkers without admixtures—though the microscopic figures of both these clinkers are very similar. The crystals of belite in these clinkers are of rounded or almost polygonal form with even edges and with smooth or weakly hatched surface. The clinker forming compounds (except alite and belite) are heterogenous with a disordered location of light and dark crystals of shapeless form.

In a raw mix the increasing of the concentrations of: P_2O_5 up to 2–3 per cent, Cr_2O_3 up to 1.5–3.0 per cent or SO_3 over 1.0 per cent brought about the appearing of not properly formed crystals, when seen under the microscope. The defects of these crystals reveal in the form of appearing of the sharp hatching of the crystals of belite (Fig. 1), full or partial splitting of the crystals for separate "blocks" in the marginal zone and in the form of stains of various colours during the etching of crystals. To add, that in the presence of SO_3 there occur belite crystals of an indefinite form; these crystals are of an increased microporic structure.

The refractive index of belite in the presence of P_2O_5 and SO_3 lowers (Table 2), when 0.5–2.0 per cent of SO_3 is introduced into the raw mix, belite in clinker stabilizes into the form of β–C_2S, when 3.0

*Clinkers having SF = 1 were cured at the temperature 1450°C during 4 hours.

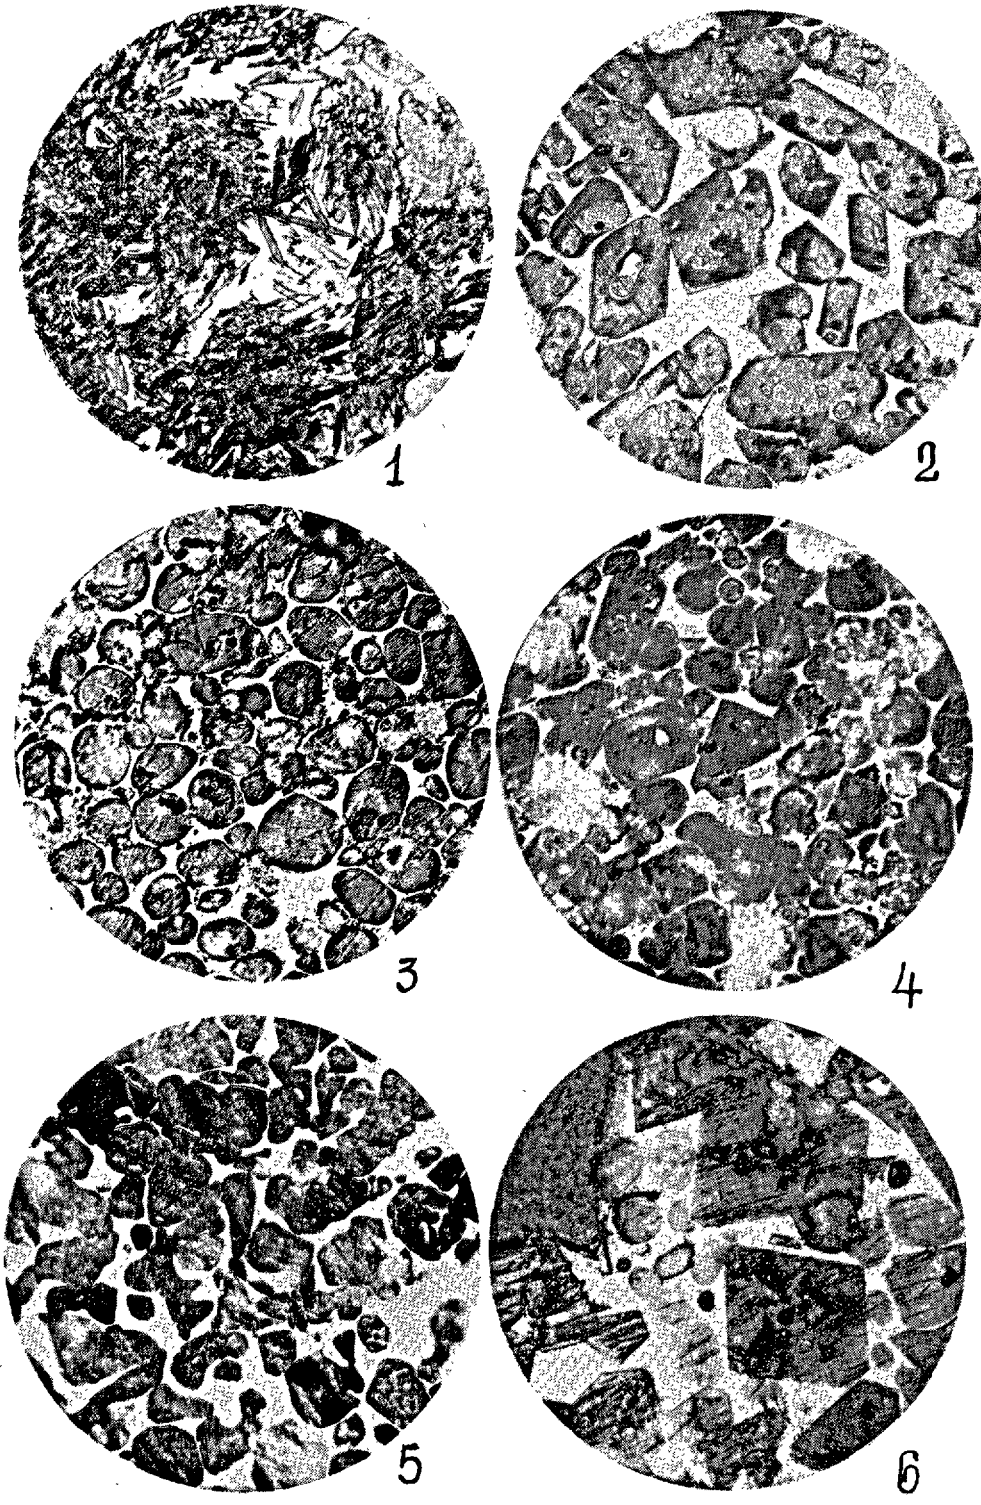

Fig. 1. *Microscopic structures of clinkers containing* Cr_2O_3, P_2O_5 *or* SO_3. *Specific macrodefects. Reflected light* $\times 400$.

1—belite clinker, 3 per cent of Cr_2O_3
2—alite clinker, 0.5 per cent of Cr_2O_3
3—belite clinker, 3 per cent of P_2O_5
4—alite clinker, 2 per cent of P_2O_5
5—belite clinker, 1.5 per cent of SO_3
6—alite clinker, 2 per cent of SO_3

per cent of SO_3 is introduced, the refractive index correspond to that of α'–C_2S. In the presence of 0.5 per cent of P_2O_5, the refractive index becomes near to β–C_2S; when increasing the content of phosphorus pentoxide up to 1.0–2.0 per cent, the refractive index becomes lower up to the data, specified to α'–C_2S, while 3.0 per cent of this pentoxide lowers the refractive index even a little bit more. The refractive index of belite crystals in the presence of Cr_2O_3 increases—and the more of this oxide is introduced into the raw mix, the higher these data are. The change of the refractive index of the crystals proves the occlusion of ions into the crystallic lattice of C_2S. However, this occlusion did not bring about a pronounced influence on the character of analytic lines of belite on the X-ray patterns of respective clinkers. Clinkers having 5 per cent admixture of either Cr_2O_3 or SO_3 reveal some amount of γ–C_2S, which disappeared with the increase of the admixture content.

The composition of aluminoferrous phase in clinker having 0.5 and 1.0 per cent of SO_3 and 0.5, 1.5 and 2.0 per cent of Cr_2O_3 is near to C_4AF, while in clinkers having 0.5–2.0 per cent of P_2O_5, 1.0 per cent of Cr_2O_3 or 1.5–2.0 per cent of SO_3 the composition of this phase approaches to C_6A_2F. Slow cooling of clinkers, containing 3 per cent of P_2O_5, SO_3 or Cr_2O_3 contributed both to the increasing of dimensions of belite crystals and to the formation of crystals of an indefinite form, these crystals being partly coalescent.

Refractive index of belite in a slowly cooled clinkers in the presence of P_2O_5 and SO_3 lowered down compared with quenched clinkers; The presence of Cr_2O_3 did not bring about the change of refractive index with the alteration of the cooling process. The three-times burning of clinkers having 3 per cent admixture contributed to the splitting of crystals for separate "blocks" and to the increase of the refractive idex compare with the single burning.

The introduction in the raw mix having SF = 1 (alite clinker) of 0.5 per cent P_2O_5, Cr_2O_3 or SO_3 as well, as in clinkers having low saturation factor, does not bring to any considerable change into the way of the crystallization of the clinkering minerals, but it makes the crystal structure more distinct. The crystals of alite have the form of elongated (1:1.5; 1:2) hexagonal plates. The inclusions of belite grains and of the phase, containing clinker forming compounds (except alite and belite) into the crystals of alite are not numerous and the edges of the crystals are quite distinct and smooth. The increase of Cr_2O_3, P_2O_5 and SO_3 over 0.5 per cent contributes to enlargement of the dimensions of alite crystals in the mass, to the alteration of a long-prismatic form of crystals for a shortprismatic, polyhedral one and to the increasing of the number of crystals coalescences (Fig. 1). The amount of inclusions of the intermediate phase and especially of belite into the crystals of alite increases as well. Very sharp alterations are observed in the clinkers resulted from raw mix with 2 and 3 per cent of oxide introduced. The crystals of alite in clinker having 2 per cent of SO_3 are of high microporous structure. The dimensions of some alite crystals amount to 500 microns, i.e. 10–15 times greater of a middle dimension of alite crystals in a clinker having 0.5 per cent of SO_3.

In the presence of 2–3 per cent of the admixture in clinkers, the amount of belite in alite clinkers and of CaO increases. The crystals of belite in alite clinkers, as to be judged by both X-ray and refractive index have the form of β–C_2S. In the presence of 3 per cent of the admixture in the raw mix, the synthesis of alite, for obtaining of which the raw mix had been designed, performed, as to be judged by the amount of free CaO, just as much as 20–30 per cent.

In polished microsections of this clinker the crystals of alite were not identified—but in the clinker with the addition of SO_3, where separate alite crystals of 450–500 microns size were seen. Therefore, the synthesis of high alite crystals is hard to perform in the presence of P_2O_5, Cr_2O_3 and SO_3.

The refractive index of the crystals of alite in the presence of Cr_2O_3 increase, while in the presence of P_2O_5 or SO_3 the refractive index decreases. However, the variation of the refractive index of the said crystals, depending on the amount of the admixture is a little or somewhat lesser than the variation of these data for the crystals of belite (Table 2). In the presence of 3 per cent of each admixture in clinkers having SF = 1, a crystallic phase was observed, this might be referred to as α-quartz; its amount does not exceed 3 per cent. The change of the rapid cooling for a slow cooling did not bring the pattern of crystallization of minerals in clinkers having SF = 1 and with 3 per cent of the addition. As a result of the three-times burning of the clinker with SF = 1 and with 3 per cent of SO_3, resulted in the full assimilation of lime. The crystallic pattern of the clinker with 3 per cent of P_2O_5 or Cr_2O_3, as a result of a three-times burning, was, in comparison with a single burning, negligible.

As seen from the X-ray structural analysis, the introduction of 0.5, 1.0, 1.5 and 2.0 per cent of Cr_2O_3 does not influence the pattern of analytical lines of alite, while the introduction of the similar amounts of P_2O_5 and SO_3 rather decreases the half width of the said lines of alite, without changing their position.

In addition, in the presence of 0.5 per cent of P_2O_5 some asymmetry of the profile of C_3S line is observed (620 + 040); this asymmetry in the case of 2 per cent addition of P_2O_5, turns into a poorly resulting twin reflection.

Aluminoferrous phase in clinkers having SF = 1 and with admixtures of Cr_2O_3, P_2O_5 and SO_3 up to 2 per cent, is of C_4AF compound composition. In microscopic observation, the intermediate phase in clinkers with the admixture of Cr_2O_3 and P_2O_5 is seemed as light and dark crystals having an indefinite form, while in the presence of SO_3 the dark crystals are distinct ones in the form of short prisms.

The Properties of Cements

The cements studied were made by grinding clinkers having 5.1 per cent of $CaSO_4 \cdot 2H_2O$ to specific area of 3,000 cm^2/g. From the cements obtained were made specimens of 1.41 × 1.41 × 1.41 cm. size (paste = 1:0), which were tested for compression strength after 0.5, 1, 3 and 28 days and 3, 6, 12 and 36 months of air-humid curing. Every age was represented by 12 twin-samples.

The time necessary to grind clinkers with SF = 1 and containing either P_2O_5, Cr_2O_3 or SO_3, decreases by 35–60 per cent as compared with that required for grinding (up to the same specific area) a clinker without these admixtures.

However, the introduction of but P_2O_5 considerably increases the grindability of the clinker and the maximum effect is attained when 0.5 per cent of this oxide is introduced, while the least effect is attained when 2.0 per cent is introduced (Fig. 2).

The grindability of clinkers with low saturation factor (0.67), which contain either P_2O_5 or SO_3, is near to that without the admixtures. The grindability of clinkers containing 0.5 and 1.0 per cent of chromium oxide is by 40–50 per cent higher while that of clinkers containing 1.5 and 2.0 per cent is 30–10 per cent lower compared with clinkers without admixtures.

Normal consistency of the cement paste containing P_2O_5, Cr_2O_3 and SO_3 increases by 1–6 per cent (absolutely). Initial and final setting times of the cement paste of clinkers having P_2O_5, Cr_2O_3 and SO_3 increase, except for the paste of clinker with SO_3 and having SF = 1; initial setting time of this clinker is about the half of that of the clinker without this admixture.

The setting time of the cement paste also increases, except in the case of cement paste resulted from the clinker having 0.5 per cent of P_2O_5 and SF = 0.67; for this paste the setting time is a minimum one–6 min.

According to the X-ray data (Table 3) the biggest influence on the rate of hydration process is shown by Cr_2O_3, P_2O_5 and SO_3 during the initial period of the cement paste hardening, i.e. during 12 hours after the cement has been mixed with water.

0.5, 1.0, 1.5 and 2.0 per cent of SO_3 and 0.5, 1.0 and 1.5 per cent of Cr_2O_3 increase the hydration rate of alite by 1.5–2 times compared with the cements without admixtures. Phosphorus pentoxide shows a delaying effect on the hydration process of alite during the initial period, but at 3 days the hydration rate of alite both in cement without admixtures and in cements containing one of the oxide, assumes common rate and, in 28 days of hardening in air-humid conditions, it amounts nearly 80 per cent in all the specimens studied.

The hydration process of the aluminoferrite phase is accelerated by minor traces of the admixtures considered: 0.5 per cent of Cr_2O_3 and of SO_3 and 0.5–1.0 per cent of P_2O_5. These oxides in more quantities retard the hydration process of the aluminoferrite phase.

Chromium oxide does not show significant influ-

ence on the hydration process of calcium aluminates, while phosporus pentoxide and sulphur trioxide retard their hydration process.

It is impossible to trace the influence of the admixtures on the hydration process of belite in an early age (up to 3 days) due to the low rate of the process of this age. At the age of 28 days the tendency of an accelerated hydration process of C_2S appears by the addition of SO_3 and rather a retarded one by the addition of P_2O_5 and Cr_2O_3.

According to the X-ray data, the products of hydration of calcuim silicates are $Ca(OH)_2$ and tobermorite-like silicate hydrate of C_2SH_2 type while the products of hydration of alumina-bearing compounds is a high-sulphate form of calcium sulphoaluminate hydrate (ettringite) ($d = 9.8$; 5.6Å)—this probably containing some ferric oxide. Gradually ettringite transforms into a low sulphate form of sulphoaluminate hydrate ($d = 9$Å), which, at the age of 28 days, becomes a prevailing form. In samples of hardened cement paste on resulted from cement containing either phosphor or sulphur and having SF = 0.67, and at 28-day hydration of cement pastes resulted from cement containing either phosphor or sulphur and having SF = 0.57, C_4AH_{13} and α-C_4AH_{13} are also observed and they form mixed crystals in a phospho-containing cement paste with the low sulphate form of calcium aluminate sulphate.

There is a definite dependence between the rate of hydration of tricalcium silicate hydrate and of aluminoferrous phase contained in the hardened cement paste, and the strength of the said paste.

The presence of Cr_2O_3 in cements having high saturation factor contributes to a quick gain of strength, in an initial period of hardening, this strength increasing with the increase of the amount of Cr_2O_3 (Fig. 3). However, at the age of over 28 days, the com-

b) SF = 0.67 (as designed)
1–0.5 day; 2–1 day; 3–3 days; 4–28 days; 5–3 months; 6–6 months

pressive strength of the chrome containing hardened cement paste is lower than that of the paste without the admixture. And there is an inverse dependence between the compressive strength of a clinker and the amount of the admixture.

The presence of Cr_2O_3 in cement with SF = 0.67 brings to the strength increase during neither initial nor subsequent periods of hardening.

The presence of SO_3 in cement with SF = 1 also contributes to the quick strength gain of the cement paste during its initial period of the hardening. And, up to 3-day age of the hardening cement paste no definite relation is observed between the strength of the paste and the amount of the admixture. During the period of 28 days–3 months, the maximum strength is obtained in the samples of the hardening cement paste made on clinker resulting from the raw mix with 1 per cent of SO_3 introduced (Fig. 4). 0.5 per cent of SO_3 is an optimum one for the cement having SF = 0.67. The compressive strength of 28 days samples was higher than that of the cement without the admixture approximately by 100 and 500 kg/cm² in cements having saturation factor 1 and 0.67 respectively.

The compressive strength of the hardening cement paste made with phosphor-containing clinker samples is—up to 28-day age and irrespective of P_2O_5 content —considerably lower compared with the samples made from cements without the admixture (Fig. 5). Only in later age the strength values of various cements level off.

Conclusion

Minor amounts of Cr_2O_3, SO_3 and P_2O_5 (0.–0.5 per cent) do not delay the formation of clinkering compounds during the manufacture of clinker, though, with an increasing of the solid oxides in the range 0.5–

2.0 per cent, the reaction of C_3S formation greatly retards and completely performs for a 4-hour burning at 1450°C. The crystallic structure of clinker having 0.5 per cent of the said oxides is near to that of common clinkers. However, when the concentration of the oxides is raised up to 1.5–2.0 per cent, the crystals of alite and belite show the defects, specific to the presence of a modifying element. The occlusion of modifying elements into the lattice is accompanied with the increase (Cr_2O_3) or the decrease (P_2O_5, SO_3) of the refractive index of the compound. The microhardness of crystals increases in the presence of Cr_2O_3 and SO_3 and decreases in the presence of P_2O_5.

The grindability of alite clinkers having 0.5–2.0 per cent of the said oxides increases.

The presence of SO_3 accelerates the setting of cement, while the presence of Cr_2O_3 and P_2O_5 retards it. Both SO_3 and Cr_2O_3 contribute to a quicker hardening of cements up to 28 days, while P_2O_5 retards the strength gain.

SESSION I-4 CHEMISTRY OF CALCIUM ALMINATES AND THEIR RELATING COMPOUNDS

Principal Paper The Chemistry of Calcium Aluminates and Their Relating Compounds

Thomas D. Robson*

Synopsis

A survey is made of the compounds present in the $CaO–Al_2O_3$ system, including their historical background, properties and cell structure. Confirmation of the existence and stoichiometry of CA_6, the incongruent melting of CA and CA_2, and doubts about the stability of $C_{12}A_7$ when entirely free from hydroxyl ion, represent the main developments in this system in recent years. Certain changes at the high-alumina end of the $CaO–Al_2O_3–SiO_2$ phase diagram are also reported. These changes result mainly from a re-allocation of the anorthite—CA_6—corundum invariant point thus increasing the area of the corundum field at the expense of the CA_6 field.

Aluminous cements are classified here into four types on the basis of analysis and method of manufacture and a short account is given of the various processes by which the clinkers are obtained industrially. The calcium aluminates, as they appear in aluminous cement clinker are then further discussed, and details are reported of two related compounds ($3CA \cdot CaF_2$ and $C_{11}A_7 \cdot CaF_2$) both of which have probably been identified in clinkers made by one particular process. Very considerable progress has recently been made in elucidating the constitution of the pleochroic compound found in some clinkers and the latest ideas on its structure are described. It is now clear that this material is definitely a quaternary compound (but with a formula different from that previously allocated) and a cell structure has been proposed. The calcium alumino-ferrite solid solutions which form an important part of certain types of clinker have also received attention and a report is given of work (as yet unpublished) which indicates a clear correlation between reflectivity values and the degree of substitution of ferric oxide by titania.

The ternary compound $4CaO \cdot 3Al_2O_3 \cdot SO_3$ (or $3CA \cdot CaSO_4$), which has been discovered in the $CaO–Al_2O_3–SO_3$ system is now important in the manufacture of expansive cements. It is treated in this survey as a compound related to the calcium aluminates and its history, properties and structure are dealt with.

In conclusion a brief summary is made of proposed uses for calcium aluminates in fields outside those of hydraulic cements.

Introduction

Practical interest in calcium aluminates (other than C_3A) results mainly from the presence of certain members of this series in aluminous or high-alumina cements (calcium aluminate cements). The following survey of the anhydrous calcium aluminates, and of some related compounds, has therefore been written with this particular interest predominantly in mind, although other possible applications are mentioned where appropriate. Tricalcium aluminate, which is not thought to be a normal constituent of aluminous cement, receives no detailed treatment since the importance of this compound to the portland cement chemist guarantees further discussion elsewhere.

The relative activities of the compounds during

*The Lafarge Organization Ltd, London, United Kingdom.

hydration and the resulting cementitious properties will be compared but the scope of this account is otherwise limited to the anhydrous compounds and the hydration products are not discussed.

The Pure Calcium Aluminates

The compounds occurring in the binary CaO–Al_2O_3 phase system are normally given as C_3A, $C_{12}A_7$, CA, CA_2 and CA_6. The formulae of $C_{12}A_7$ and CA_2 have been agreed only after much investigation, and even the existence of CA_6 has been questioned until relatively recently. It will be seen later that the inclusion of $C_{12}A_7$ in this system is subject to an interesting controversy but, apart from this, and perhaps a small residual doubt concerning the exact stoichiometry of CA_6, all the above calcium aluminate formula are now widely accepted. The existence of the metastable orthorhombic C_5A_3 phase has also been confirmed.

The lattice structure of CA is known in fair detail but many of the structures proposed for the other aluminates are only partially resolved, and all require various degrees of refinement.

Tricalcium Aluminate, $3CaO \cdot Al_2O_3$

This compound is cubic and often forms rounded or spherical grains although rectangular, hexagonal or octagonal tablet forms are also reported. It has a hardness of about 6, a density of 3.03 g/cc. and a refractive index $n = 1.710$.

At 1539° ± 5°C it melts incongruently to CaO and a liquid of composition 57.2% CaO, 42.8% Al_2O_3 by weight (1), the liquidus temperature being about 1700°C.

There is only one form of C_3A but, in spite of numerous investigations, the structure has not yet been acceptably defined. The stronger lines of the powder pattern originally indicated a cubic unit cell having $a = 7.6$Å but the true cell edge is approximately double this length and has been given as $a = 15.262$Å (2). The unit cell (with space-group T_h^6–Pa3) is therefore composed of eight similar pseudocells. The aluminium ions appear to have 4-fold (tetrahedral) co-ordination with the oxygens and according to Burdick and Day (3) there is no evidence of 6-fold co-ordination.

C_3A hydrates more rapidly than any other calcium aluminate but, by itself, produces little or no hydraulic strength in mortars.

The $12CaO \cdot 7Al_2O_3$ Phase

The stable cubic "C_5A_3" compound of Rankin and Wright (4) was shown to have the formula $C_{12}A_7$ by Büssem and Eitel (5) who originally gave the following data:

$a = 11.95$Å. $Z = 2$.

Probable space-group T_d^6 Density 2.69.

The lattice was envisaged as a framework of distorted AlO_4 tetrahedra, partially linked by oxygen atoms, but leaving two of the 64 oxygen atoms to be distributed statistically. The calcium ions were in 6-fold co-ordination with oxygen and the lattice contained large structural "holes" which might account for the rapid hydration observed in practice. Analogies with the structures of C_3AH_6 and lime-alumina garnet were noted (6). The space-group is now thought to be $I\bar{4}3d$.

Although other C/A ratios were subsequently proposed for this compound, several workers have since confirmed the $C_{12}A_7$ formula and this ratio is now accepted generally. Nevertheless difficulty has long been experienced in delineating that portion of the binary C–A phase diagram which is adjacent to the $C_{12}A_7$ composition, and indeed this region appeared to have ternary characteristics (7). The refractive index of $C_{12}A_7$ had previously been found to be lower than that of quenched glass of the same composition and other peculiarities in density and in melting behaviour were evident.

Welch (8) noted that the compound absorbed atmospheric moisture at high temperatures and that the presence of water in the crystal was responsible for variations in cell volume, density and refractive index. Similar observations were made by Roy and Roy (9) who concluded that, in atmospheric air, $C_{12}A_7$ was not an anhydrous phase but a hydrate near in composition to $C_{12}A_7H$. Because of the reversible absorption of water over a wide temperature range (without major change of structure) $C_{12}A_7$ could be termed a zeolitic phase.

Jeevaratnam, Glasser and Dent Glasser (10) also noted that water was retained at about 1100°C, but crystals prepared from compositions by heating at 1200°C then at 1390°C for several days, were con-

sidered anhydrous, and would subsequently take up water only when heated to 400°–500°C. As a result of later work (11) they again judged that $C_{12}A_7$ could definitely exist in essentially anhydrous form and that the water was present in the crystal as OH^-. However, Nurse, Welch and Majumdar (12) found that when a $C_{12}A_7$ composition was melted at 1500°C, annealed at 1000°C, and cooled in a dry oxygen-free nitrogen atmosphere, traces of hydroxyl ion could still be detected by infra-red spectroscopy and a small weight loss was observed when a sample was re-heated to 950°C–1375°C in the nitrogen atmosphere. Although agreeing that the constitutional formula for the fully saturated compound is best represented as $Ca_{12}Al_{14}O_{32}(OH)_2$, they were therefore not convinced that completely anhydrous $C_{12}A_7$ could be prepared.

The $12CaO \cdot 7Al_2O_3$ compound is customarily given a small stable field between those of C_3A and CA. As shown in Fig. 1, it has a congruent melting-point at about 1392°C and the binary eutectics $C_{12}A_7$–C_3A and $C_{12}A_7$–CA are both at about 1360°C (13).

However, the congruent melting of $C_{12}A_7$ has been questioned for several reasons, including the fact that two endotherms at about 1370°C and 1395°C have been observed in D.T.A. work (12). Nurse, Welch and Majumdar found that the liquidus temperature of $C_{12}A_7$ in moist air was certainly at 1392°C ± 3°C but this remained substantially constant for compositions with a range of C/A ratios on either side of that of $C_{12}A_7$, and, in dry argon, $C_{12}A_7$ melted incongruently to CA and liquid at 1374°C.

If hydroxyl ions remain in the lattice of $C_{12}A_7$ the compound cannot strictly be included in the binary C–A diagram and a possible representation of this part of the system under anhydrous conditions has been given by Nurse, Welch and Majumdar (Fig. 2).

The stable field of $C_{12}A_7$ disappears and is replaced by a eutectic between C_3A and CA at 50.7% Al_2O_3 (wt.) and 1360°C ± 5°C. Thermodynamic calculations (although not yet conclusive) indicate that the C_3A + CA assemblage may indeed be more stable than $C_{12}A_7$ at the latter composition (12).

The reversible equilibrium between $C_{12}A_7$ and water vapour at high temperatures can be briefly summarised as follows: Between 950°–1350°C, weight is lost on the heating cycle and gained on the cooling cycle, but this process becomes irreversible if the crystals are allowed to melt or, of course, if the cooling cycle takes place under anhydrous conditions. The maximum uptake of water occurs at 950°–100°C corresponding to an increase in weight (over that of the "anhydrous" compound) of about 1.3% (12). In this condition the compound corresponds to $C_{12}A_7H$ and, with hydroxyl ions present in the lattice, the constitutional formula is believed to be $Ca_{12}Al_{14}O_{32}(OH)_2$.

When the compound is prepared by fusion and cooling to room temperature (always under anhydrous conditions) the formula $C_{12}A_7$ is correct or nearly correct but it is not certain that a completely anhydrous material has yet been prepared.

	$C_{12}A_7H$	11.977	11.9747 ±0.0002	11.982

The effect of water in the lattice on density, refractive index, and cell dimensions is shown in Table 1 where A, B and C are the results respectively of Jeevaratnam, Glasser and Dent Glasser, (11) Nurse, Welch and Majumdar (1) and D. M. Roy and R. Roy (9).

On passing from $C_{12}A_7$ to $C_{12}A_7H$ there is an increase in density and two of the above teams indicate an increase in refractive index and a decrease in cell volume. Roy and Roy reported a reduction in refractive index and a slight increase in cell volume. The values shown for cell dimension under C in Table 1 are those calculated by Jeevaratnam, Glasser and Dent Glasser from the original data of Roy and Roy who gave results for the d_{642} spacing.

$C_{12}A_7$ can form halogenated derivatives and it has been proposed that this occurs by the complete or partial replacement of two oxygen atoms per cell by up to four univalent ions (11). In this work Jeevaratnam, Glasser and Dent Glasser noted the attraction of equating the replaceable oxygens with those which (according to the Büssem and Eitel structure) require to be distributed statistically. Reaction between calcium fluoride or chloride and $C_{12}A_7$ at 900°–1000°C gave isotropic products identified as $C_{11}A_7 \cdot CaF_2$ and $C_{11}A_7 \cdot CaCl_2$. On the other hand calcium bromide did not react. The new compounds appear to be based on the $C_{12}A_7$ structure with cell contents $C_{24}Al_{28}O_{64}X_4$ where X is F or Cl (the cell contents of $C_{12}A_7H$ by analogy are consequently $C_{24}A_{28}O_{64}(OH)_4$). Substitution of oxygen by halogen in the $C_{12}A_7$ lattice caused progressive increase in cell volume until the equivalent of two oxygen atoms per cell had been replaced. Further investigation of $C_{11}A_7 \cdot CaCl_2$ and $C_{12}A_7$ led these workers to doubt the Büssem and Eitel structure for the latter compound, serious discrepancies arising during the preparation of Patterson maps of both compounds.

It is certainly clear that $C_{12}A_7$ is an unusually interesting compound in which the lattice may be under considerable strain. Birefringent inclusions found in crystals of $C_{12}A_7$ (particularly when prepared under anhydrous conditions) may possible be visual evidence of this (12). The 6-oxygen co-ordination shell of the calcium atoms is evidently extremely irregular and the large structural holes together with the presence of several vacant sites in the lattice (which can be filled by suitable univalent ions) may be responsible for the rapid hydration characteristics and for the uptake of hydroxyl ion at high temperatures.

Pentacalcium Trialuminate, $5CaO \cdot 3Al_2O_3$

Rankin and Wright (4) reported two polymorphs of C_5A_3 in the $CaO–Al_2O_3$ system. The stable cubic form has since been assigned the formula $C_{12}A_7$ but the other "unstable" form, originally described as possibly orthorhombic, has later been the subject of much confusion.

It is now reasonably certain that a metastable C_5A_3 compound with the properties described by Rankin and Wright does exist; it is not the pleochroic material which appears as fibres or laths in certain aluminous cements, and it is not a high-temperature polymorph of $C_{12}A_7$ (14).

An examination by Aruja (15) of single crystals prepared on a hot-wire microscope confirmed the C_5A_3 formula (18) and the orthorhombic symmetry. The until cell contained four molecules and had the following parameters.

$a = 10.975$, $b = 11.250$, $c = 10.284$ (±0.005Å)

Probable space-group $C\,222_1$ Density 3.06–3.03 g/cc.

The structure was not further determined but Aruja noted points of similarity to gehlenite, C_2AS. The latter compound has $Si_2O_7^{6-}$ groups in the lattice while orthorbombic C_5A_3 may be based on $Al_2O_7^{8-}$ groups.

Majumdar (16), in work on ternary $CaO–Al_2O_3–MgO$ compounds, noted that the *a* dimensions of the cells were all simple multiples of about 5.5Å. Since the *b* and *c* dimensions were almost identical, the unit cell of the relevant compounds appeared to be built up of blocks having the approximate volume $5.5 \times 10.75 \times 5.13$Å.

A possible similarity in basic structure can be noted in the case of orthorhombic C_5A_3 and Midgley (17) has suggested that this compound is best represented by the constitutional formula $Ca_5Al_2(Al_2O_7)_2$ with the cell containing two layers viz:

A A ⟶ *a* (doubled)
A A *b*

The structure could therefore be represented by

$$\begin{array}{cccc} A & Y & Z & A \\ A & Y & Z & A \end{array} \begin{array}{l} \longrightarrow a \\ \downarrow b \end{array}$$

where A = Al_2O_7, Y = Ca and Z = vacant site. Three calcium atoms lie between the Al_2O_7 groups and four calcium atoms between the layers.

Majumdar and Smith (14) were not able to form C_5A_3 from melts having compositions between C_5A_3 and $C_{12}A_7$, by cooling slowly to 1000°C and then quenching, but they were able to grow C_5A_3 crystals by the hot-wire technique of Welch as described by Aruja. They never obtained orthorhomic C_5A_3 alone, or from melts of C_5A_3 composition, although it could be grown from a $C_{12}A_7$ melt. Melts with compositions bordering the $C_{12}A_7$ composition may yield orthorhombic C_5A_3 essentially, when cooling takes place in an anhydrous atmosphere (12).

C_5A_3 melts incongruently in air at 1361°C and at 1352°C in dry argon. The corresponding melting-points of $C_{12}A_7$ are 1392°C and 1374°C and it would seem that orthorhombic C_5A_3 must be metastable to $C_{12}A_7$ near its melting-point. It crystallises from melts in tabular form and the refractive indices are

$$\alpha = 1.680,\ \beta = 1.682,\ \gamma = 1.685 \text{ (17)}$$

Monocalcium Aluminate, $CaO \cdot Al_2O_3$

The structure of CA was investigated by Heller (19) but, as she had to work with a twinned crystal, the resolution of crystal structure was only partial. Further examination by Dougill (20) of fragments cut from large single-crystals gave initial data reasonably similar to those reported by Heller.

The cell dimensions were $a = 8.69$, $b = 8.09$, $c = 15.21 \pm 0.02$Å, $\beta = 90°8'$. Space-group $P2_1/n$. Slightly amended dimensions have since appeared (21). The observed density was 2.96 g/cc. against a calculated density of 2.94 g/cc. indicating Z = 12.

CA is structurally related to β-tridymite by substituting all the silicon atoms of the latter with aluminium atoms. This produces an unusual three-dimensional arrangement of linked tetrahedra which was illustrated in this work by the pseudo-hexagonal b-axis projection. The general β-tridymite framework is strongly distorted by the large calcium ions which are accommodated in cavities. While two of the three types of calcium ions are co-ordinated by six oxygens in an octahedron (Ca–O distances 2.31–2.72Å) the third calcium is surrounded by nine oxygens (Ca–O distances 2.36–3.17Å). The earlier structure of Heller had proposed 6-co-ordination for two of the calciums but 7-co-ordination for the third type. Of the nine oxygens just mentioned, six (each shared by two calciums) from an elongated octahedron giving a continuous chain in the b-direction. The remaining three oxygens lie in the plane at right-angles to the chain at greater Ca–O distances, and Al–O–Al angles in the pseudo-hexagonal direction have an average value of 132°, others being about 120°. The atomic co-ordinates for CA have been reported by Jeffery (21).

Pure CA forms prismatic or irregular grains which, although monoclinic are frequently pseudo-hexagonal. It is biaxial negative, 2V = 36°, the refractive indices being

$$\alpha = 1.643,\quad \beta = 1.655,\quad \gamma = 1.663$$

Uniaxial interference figures previously reported have not been fully confirmed and such anomalous figures may possibly be due to spherulitic quench growths (1). Twinning is very frequent, indeed characteristic, and an example of multiple twinning is shown in Fig. 3 (22).

The melting-point of Ca was thought to be congruent but high-temperature microscopy by Welch and by Auriol, Hauser and Wurm has revealed that it melts just incongruently at 1602° ± 5°C to CA_2 and liquid (1).

Pure, well crystallised, CA hydrates more slowly than the more basic calcium aluminates and produces high mortar or concrete strengths. Taylor (23) has noted that in CA there are no "free" oxide ions linked only to calcium, since every oxygen is bonded to two aluminium ions as well as to calcium. The reactivity to water cannot therefore be so explained but, as with all the other more basic calcium aluminates CA appears to exhibit irregular cation co-ordination, leading no doubt to high lattice energy.

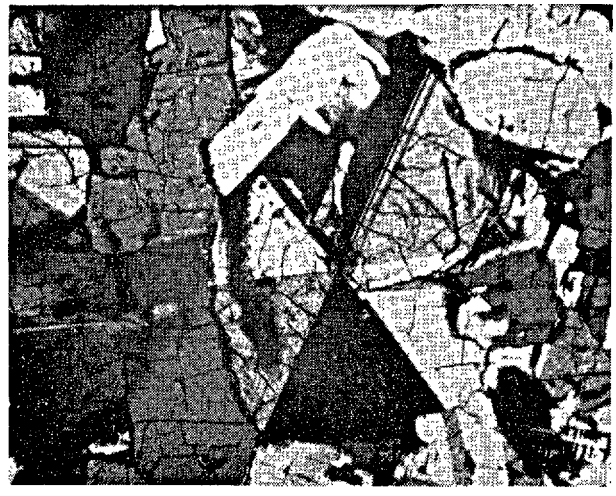

Fig. 3. *Monocalcium aluminate hexa-twin (22) (crossed nicols. ×60)*

Calcium Dialuminate, $CaO \cdot 2Al_2O_3$

Of the two polymorphs of C_3A_5 described by Rankin and Wright (4) the unstable form has never since been confirmed. The stable form of C_3A_5 was given the formula CA_2 in 1935 by Tavasci (24) who found the same optical properties as Rankin and Wright. This C/A ratio was confirmed by Lagerqvist, Wallmark and Westgren, and by several workers in Russia, Japan, Italy, U.S.A. and England.

Lagerqvist, Wallmark and Westgren (25) determined that the compound was monoclinic with $a = 12.82$ Å, $b = 8.84$ Å, $c = 5.42$ Å and similar values for the cell dimensions were found by Goria and Burdese (26) who placed CA_2 in the space-group C_2^6H.

Up to this time most investigators had to report that CA_2 was uniaxial positive but, after a detailed study of CA_2 and the isomorphous SrO_2, Boyko and Wisnyi (27) found that it was biaxial positive with $\alpha = 1.6178$, $\beta = 1.6184$, $\gamma = 1.6516$, $2V = 12°$. The negligible difference between α and β explained why this had not been previously resolved. For the unit cell, Boyko and Wisnyi gave $a = 12.897$ Å, $b = 8.879$ Å, $c = 5.454$ Å, $\beta = 107°3'$. The density of 2.86 g/cc. was rather lower than that of earlier studies. The space-group is $C2/c$, $Z = 4$.

In CA_2 the Al atoms are again tetrahedrally co-ordinated by oxygen. Three tetrahedra share one oxygen at the common corner and the Ca atoms are asymmetrically co-ordinated with five Ca–O bonds much shorter than the other four.

CA_2 grows from melts as strongly birefringent needles or laths but can also appear as rounded grains. There has been little agreement in the past over melting-point, the values having varied from 1720°–1790°C, and opinion has been equally divided on whether the melting-point was congruent or incongruent. The most recent work indicates that it is definitely incongruent giving CA_6 and liquid. Welch (28), Rolin and Pham Huu Thanh (29), Auriol, Hauser and Wurm (30) and Nurse, Welch and Majumdar (1) have reported values of 1789°, 1780°, 1770° and 1762° ± 5°C respectively, and in Fig. 4 CA_2 is shown to melt incongruently at about 1765°C.

CA_2 hydrates very slowly and it was considered that it might be hydraulically inert at ordinary temperatures if completely pure. Buttler and Taylor (31) showed that CA_2 did react slowly with water even at 5°C and the reaction is faster at higher temperatures and at higher pH values. At ordinary temperatures the reaction, once started, may therefore become self-accelerating.

The presence of very small amounts of alkali metal ion in this compound could obviously have a very marked effect on the rate of reaction with water at atmospheric temperatures and it remains doubtful whether CA_2 has yet been prepared in a form sufficiently free from Na^+ to allow one to be certain about the behaviour of the "pure" compound.

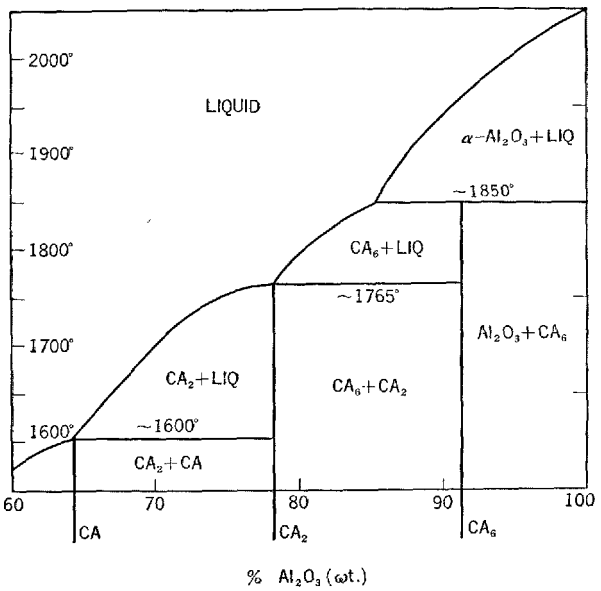

Fig. 4. *High alumina part of* $CaO–Al_2O_3$ *system*

Calcium Hexa-Aluminate $CaO \cdot 6Al_2O_3$

Lagerqvist, Wallmark and Westgren (25) first reported a new compound at the higher alumina end of the $CaO–Al_2O_3$ system and assigned the formula C_3A_{16}. The compound was hexagonal and appeared isomorphous with β-alumina (NA_{11}).

Adelskold (32) supported by Toropov and Stukalova (33) confirmed the cell dimensions given by the above workers ($a = 5.536$, $c = 21.825$ Å) but considered that the compound was CA_6 and that it was isomorphous with magneto-plumbite ($PbO \cdot 6Fe_2O_3$). In 1949 Filonenko confirmed the existence of CA_6 in the $CaO–Al_2O_3$ system and, in further work with Lavrov the same year (34), amended the $CaO–Al_2O_3–SiO_2$ phase-diagram to include a stable field for this compound.

However, as late as 1963, Gentile and Foster (35) pointed out that acceptance of Filonenko's work was by no means general on the part of American investigators—some of whom regarded CA_6 as a metastable phase and failed to allot any stable field. Mohanty (36) and others (30) had also reverted to the original formula C_3A_{16}, claiming that free alumina could be

found in melts having the composition CA_6. Nevertheless, the work of Gentile and Foster confirmed the existence of a stable compound CA_6 and, in general, confirmed the findings of Filonenko and Lavrov.

The compound has hexagonal symmetry with the cell parameters as given above. There are two molecules in the unit cell, the space-group being $P6_3/mmc$. The structure has strong similarities to that of β-alumina (NA_{11}) and magnetoplumbite but details remain to be agreed.

The optical properties are sufficiently close to those of corundum to cause confusion since it crystallises as perfect hexagonal plates, uniaxial negative, $\omega = 1.759$, $\epsilon = 1.667$ (34) Buist (37) has recently given $\omega = 1.755$, $\epsilon = 1.763$ (in white light) for pure CA_6 prepared by sintering for an hour in argon at 1850°C.

The melting-point of CA_6 has been found incongruent by all investigators, but considerable differences exist between the actual values which range from 1833° ± 15°C (1) to 1870° ± 10°C (37). In Fig. 4, CA_6 is shown to melt incongruently at about 1850°C, but although the general form of this diagram is probably correct in showing incongruent melting of CA, CA_2 and CA_6, further re-examination of the exact melting points of CA_2 and CA_6 is called for. The melting-point of α-alumina has been placed at 2050°C but again there remains much controversy about the exact value, which may be as high as 2070°C or as low as 2040°C.

CA_6 is harder than any other calcium aluminate and does not appear to hydrate in water.

Aluminous Cement Clinker

Before proceeding to an examination of the aluminates and related compounds which may be present in a clinker, it is necessary to give some account of the various manufacturing processes, and of the different raw materials used, since these can have a very marked effect on the constitution of the product.

The major cementitious component in clinker is always the monocalcium aluminate, CA, but the commercial cements from various countries show a remarkably wide range of chemical composition. In certain cases additions to the clinker (during or after grinding) may contribute to this diversity but, even without this, the clinker analyses still cover a much broader range than is usual in the portland cement field.

Types of Cement and Their Manufacture

Nearly all the cements in commercial manufacture today can be included in one or other of the four categories given in Tabe 2, where the classification is based on chemical analyses and methods of manufacture. The variable appearance and chemical composition of these types are due either to the nature of the raw materials (in particular the source of the alumina required for the formation of CA) or to the method of clinker manufacture. In general, the final composition of the clinker is always arranged to produce the maximum amount of CA.

Type 1. By far the largest proportion of world production consists of this type, the raw materials being limestone and red ferruginous bauxite, which is the most widely distributed economic source of alumina. A fusion process is almost invariably used to manufacture Type 1 clinkers and they contain all the non-volatile constituents of the raw materials. The variable Al_2O_3/Fe_2O_3 and Al_2O_3/SiO_2 ratios in diverse, but suitable, red bauxites is therefore responsible for the range of total iron oxide and silica contents found in the clinkers.

During fusion, part of the Fe_2O_3 present is reduced to FeO and the ferrous compounds impart to Type 1 clinkers their characteristic dark colour. The precise colour shade depends on the total iron oxide content and the Fe_2O_3/FeO ratio and, to some extent, the lime content. The small amount of Type 1 cement which is made by sintering these raw materials remains more highly oxidised and therefore may have a brown-rust colour.

Table 2. *Main types of high-alumina cement*

Type	Colour	Al_2O_3 %	Iron oxides as % Fe_2O_3	SiO_2 %	CaO %	Source of alumina	Process of manufacture
1	Grey to black	37–40	11–17	3–8	36–40	Red bauxite	Fusion
2	Light-grey	48–51	1–1.5	5–8	39–42	Red bauxite	Reductive fusion with removal of Fe metal
3	Cream or light-grey	51–60	1–2.5	3–6	30–40	'White' bauxite	Sintering clinkering fusion
4	White	72–80	0–0.5	0–0.5	17–27	Alumina	Sintering clinkering

Type 2. Such cements are made from essentially the same raw materials as Type 1 but during fusion the iron oxide in the bauxite is reduced to metallic iron which is then separated. The residual iron oxide (FeO) content of the clinker is low, although a small amount of residual iron metal is also found. Clinkers in this category may be produced in a blast furnace (38) or in a cupola (39) using coke as the reducing agent.

Type 3. The natural distribution of "white" bauxite is much more restricted than that of red bauxite but its much lower Fe_2O_3 content allows the production of low-iron Type 3 clinker by direct fusion, sintering or clinkering with a pure limestone. The sintering or clinkering process (40) is more common when, as in this case, the clinker contains less than about 5% Fe_2O_3, but completely fused cements of this type are also produced.

Type 4. Analysis of these cements reveals little apart from lime and alumina. The raw materials are pure limestone and alumina of (at least) Bayer-process purity. The high melting-point of the clinker usually imposes a sintering or clinkering method of manufacture but fusion in an electric furnace may be justified in certain countries. The virtual absence of titania from the analysis distinguishes this type from all the others—which employ some kind of bauxite as a raw material. The clinkers produced in this group differ mainly in the proportion of CA_2 which may be present with the CA.

Manufacture from Other Raw Materials or by Other Processes

A full appraisal of methods of manufacture and of possible raw materials has been given elsewhere (41) but some continuing interest has been shown in the simultaneous manufacture of calcium aluminate clinker and yellow phosphorus.

In the electric-furnace reduction process for phosphorus, a mixture of aluminium phosphate, calcium phosphate or lime, and coke has been substituted for the normal furnace charge (42) and this resulted in the production of an aluminous cement slag. Ablichenkov and Postnikov (43) similarly investigated an electric-furnace reduction method employing phosphate rock, or apatite concentrate, together with bauxite or titania-alumina slags (derived from the production of ferro-titanium). The use of apatite concentrate and a titania-alumina slag appeared to give greater productivity and saving in electricity.

Other claims have recently been made for the reductive fusion of bauxite and phosphates (44) and

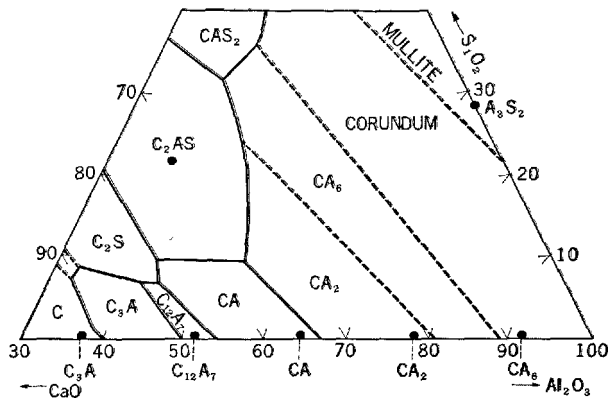

Fig. 5. *Part of* $CaO–Al_2O_3–SiO_2$ *phase diagram*

for the use of a rotary kiln in treating a mixture of calcareous and aluminous materials containing phosphates (45). However, it seems that there has been little or no commercial manufacture by any of the above processes.

In the U.S.S.R. aluminous cement compositions have also been made by adding more alumina to the molten lime-alumina slag used in steel-refining (46). The aluminous materials added to the converter for this purpose are bauxite or the titania-alumina slag mentioned above (47). The latter material has also been directly fused with limestone (instead of steel slag) in order to yield an aluminous cement clinker (48).

Clinker produced by many of the above processes would contain constituents not present to any significant extent in those made by usual methods (e.g. chromium, vanadium, manganese, fluorine etc.). In other cases greatly increased percentages of titania and alkali might result and therefore the properties of such cements need not be similar in all respects to those of the customary types. However, advantages have been claimed (48) for cements containing substantial proportions of certain metal ions such as Cr^{3+}, Mn^{3+} and Ti^{3+}.

Calcium Aluminates in Clinker

The $CaO–Al_2O_3–SiO_2$ phase diagram, which is relevant for aluminous cements containing little or no iron oxide, has undergone some change in recent years. The general outlines of the necessary part of this diagram are as shown in Fig. 5 which represents the position after the inclusion of a stable field for CA_6 but before it was accepted that CA and CA_2 melted incongruently.

Further work by Gentile and Foster (35) on CA_6

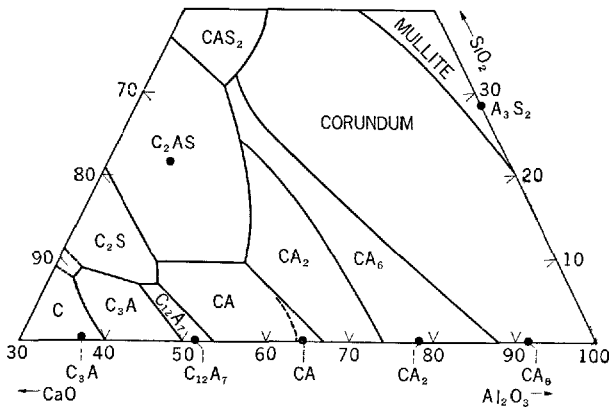

Fig. 6. *Part of* $CaO–Al_2O_3–SiO_2$ *phase diagram (as amended by Gentile and Foster)*

in this system led to a considerable reduction in the area of the CA_6 field since they placed the anorthite—CA_6—corundum invariant point at 28% CaO, 39.7% Al_2O_3, 32.3% SiO_2 and at a temperature of 1405° ± 5°C. Filonenko and Lavrov (34) (to whom Fig. 5 is largely due) had previously located this point at 23% CaO, 41% Al_2O_3, 36% SiO_2 and at 1495° ± 5°C.

The altered character of the diagram produced by Gentile and Foster is shown in Fig. 6 and this requires a small further change (indicated by the dotted line amendment of the CA field) to allow for the incongruent melting of CA.

It will be seen that the field of $C_{12}A_7$ has been retained in the ternary diagram although Fig. 2 omits it from the $CaO–Al_2O_3$ system. In the furnaces used for clinker manufacture the atmosphere is always humid and the anhydrous conditions represented by Fig. 2 do not apply. Accordingly the phase assemblages found in practice agree more closely with those indicated by the ternary diagram or by Fig. 1. An additional reason for this is the great rapidity of crystal growth of $C_{12}A_7$. The maximum linear rate of growth found by Scholze and Kumm (49) was 8700 μ per minute and, although 1% additions of CaO, Al_2O_3, K_2O, SiO_2 or Fe_2O_3 decreased this rate by varying extents, it is clear that crystal growth is much faster with $C_{12}A_7$ than with any other calcium aluminate in comparable conditions. When nucleation occurs it is therefore probable that $C_{12}A_7$ will precipitate rapidly and may exclude the formation of other phases which might be more stable.

Consequently, C_3A is not a normal constituent of aluminous cements—especially those which have been completely fused and whose raw materials have been correctly compounded. However, in sintering or clinkering processes of manufacture, it is conceivable that some C_3A might be produced locally in the clinker or sinter, for example in any unusually large particle of lime. Particles of lime or alumina which are too large to reach chemical equilibrium under the specific kiln conditions may have a zoned structure after passage through the kiln and may contain aluminates other than those desired. Because of the number of different calcium aluminates, careful control of the maximum particle size of raw materials is a particularly vital factor in maintaining the correct mineralogical composition of sinters or of clinkers not wholly fused.

The solid-state reaction between lime and alumina has been studied by numerous investigators without final agreement on its mechanism. Adouze (50) and de Keyser (51) included unstable C_5A_3 among the reaction products and this renders their work difficult to interpret since it is no longer thought that this compound is formed in these conditions. Adouze found that CA was first formed at 900°C and $C_{12}A_7$ at 950°C, while de Keyser also concluded that CA had a tendency to form as first product. Mchedlov-Petrosyan and Babushkin (52) predicted that $C_{12}A_7$ will form preferentially at temperatures below 1000°C, but that it ceases to be an important non-equilibrium product above 1100°C. They also believed that C_3A will not form directly from lime and alumina but only by reaction of $C_{12}A_7$ with lime, while CA will form only by reaction of $C_{12}A_7$ with alumina. These conclusions were not confirmed to any substantial extent by Williamson and Glasser (53) who investigated compositions corresponding to all the calcium aluminates and who showed the critical effect of particle size upon the time taken to reach equilibrium. The most recent work on this reaction seems to lend support to the findings of Uchikawa, Tsumagari and Koike (54) who found that C_3A was formed preferentially at 800°–1000°C, whatever the initial proportions of lime and alumina. However, until there is more standardisation of the particle size of raw materials, differences in interpretation of results will continue. Somewhat different conclusions may also be reached according to whether the materials are heated in a static condition or in motion (as in a rotary kiln).

The proportion of $C_{12}A_7$ in a normal aluminous cement clinker is usually kept low since more than about 10% may cause unduly fast setting-times, and this effect is accentuated if, for any reason, the clinker contains more alkali ions than is customary. Like all other calcium aluminates, $C_{12}A_7$ can take Fe^{3+} ions into the lattice and therefore it is rarely found in a substantially pure form in the clinker. On the other hand Ti^{4+} enters the lattice in insignificant amounts.

Fig. 7. $C_{12}A_7$ (*probably* $C_{11}A_7 \cdot CaF_2$) *in calcium aluminate slag* (22) (*Plane polarised light.* ×22)

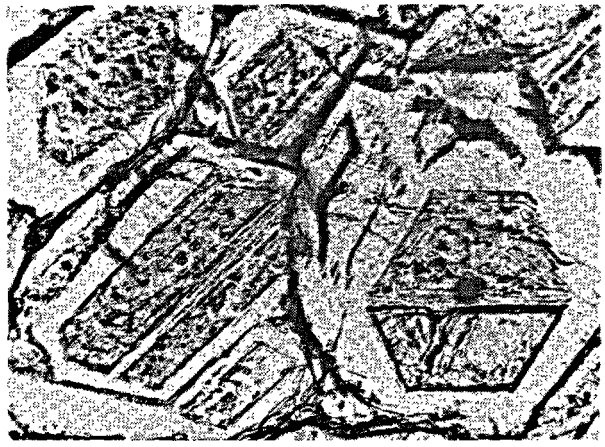

Fig. 8. *The compound* $3CaO \cdot 3Al_2O_3 \cdot CaF_2$ (22) (*Plane polarised light.* ×100)

When made by the process which simultaneously yields phosphorus, aluminous cement clinkers normally contain an appreciable proportion of fluorine, and refractive index determinations suggest that any "$C_{12}A_7$" in such clinkers may in fact be present as the $C_{11}A_7 \cdot CaF_2$ compound described by Jeevaratnam, Glasser and Dent Glasser (11). The refractive index of $C_{11}A_7 \cdot CaF_2$, as found by the latter, was $n = 1.601$ which must be compared with $n = 1.611$ for $C_{12}A_7$ and $n = 1.620$ for $C_{12}A_7H$. An investigation by Leary (22) of "$C_{12}A_7$" in aluminous slag from the phosphorus process showed that its refractive index was 1.602 ± 0.002 (see Fig. 7).

CA crystallises readily from the fused clinker composition and, even when the cooling process is relatively rapid, the compound appears as quite large prismatic crystals, often in a dendritic arrangement and inter-grown. Twinned crystals with opposite extinctions are very frequent and, when a comparison is made with the pure compound, an increase in refractive index and a reduction in axial angle are usual. If the clinker contains any appreciable amount of iron oxide, some is always taken up by the CA. In any given clinker the amount taken up by CA is remarkably constant throughout, but in different clinkers the degree of substitution by iron varies directly with the ferric oxide content (55), lending support to the belief that it is primarily Fe^{3+} which is involved. In many Type 1 clinkers (which have high iron oxide contents) the substitution in CA approaches the limit concentration of 4.5% Fe found by Dayal (56) in work on the CaO–Al_2O_3–FeO–Fe_2O_3 system. It is therefore clear that CA may take up a considerable part of the total ferric oxide present in Type 1 clinkers. In addition, an examination of CA crystals in commercial clinker by the scanning micro-probe has revealed the presence of many small inclusions of the ironbearing interstitial material (55). Micro-probe images of the clinker itself have been shown by Crussard (57) and these reveal the general distribution of Al, Si, Ca, Ti and Fe across the surface of a clinker fragment.

An interesting new compound (believed to be $3CaO \cdot 3Al_2O_3 \cdot CaF_2$) has been identified by Leary (58) in calcium aluminate slag produced in the phosphorus process. The compound has hexagonal symmetry with

$$a = b = 17.29, \quad c = 7.01 \text{ Å}$$

Experimental density 2.96 g/cc. Theoretical 3.03 g/cc.

The X-ray diffraction data were also determined by Leary. The crystals, uniaxial negative with refractive indices $\omega = 1.628$, $\epsilon = 1.618$, are shown in Fig. 8.

The fluorine in this compound is quite labile at high temperatures and subsequent attempts to repeat the synthesis by heating CaO, Al_2O_3 and CaF_2 at 1340°C for four hours were not successful, the product being $C_{12}A_7$, CA and some CA_2 (59). However other workers found that $3CA \cdot CaF_2$ (together with some $C_{12}A_7$) could be produced by heating the appropriate composition for a much shorter time (30 mins.–1 hour) at 1400°C. Longer heating at higher temperatures released fluorine; for example after heating for 6 hours at 1450°C the composition retained only 2% fluorine whereas $3CA \cdot CaF_2$ should contain 6.38% (60). After adapting a high-temperature D.T.A. technique to deal with systems containing a volatile constituent, Gutt (61) found that the compound appears to melt congruently at $1505° \pm 2°C$ which confirms the original value of $1507° \pm 2°C$ given by Leary. When $3CA \cdot CaF_2$ was ground to cement fineness, Leary found that it set and hardened giving

excellent mortar strengths at one day. The setting-time was greatly affected by water-cement ratio and there was always a very long delay between initial and final sets. This behaviour is possibly what would be expected if the compound progressively dissociates into CA and CaF_2 during hydration.

The presence of CA_2 in Type 1 and Type 2 clinkers is not general and is usually due to non-equilibrium conditions existing locally in the melt, for example in the vicinity of a bauxite-lump residue. On the other hand, CA_2 may be a common constituent of some Type 3 and Type 4 clinkers. Dayal (56) found that CA_2 could take up iron oxide to a limit of 5.7% Fe, but this limit is apparently not closely approached in the CA_2 occurring in commercial clinkers. The hydration of CA_2 is accelerated when it takes place in company with that of CA but, even then, it is not sufficiently rapid to make any appreciable contribution to 1-day mortar or concrete strengths at atmospheric temperatures. It has been claimed that the inclusion in the lattice of certain trivalent ions (such as Cr^{3+}, Mn^{3+}, Ti^{3+}, and Fe^{3+}) increases the rate of hydration to the extent that CA_2 no longer behaves essentially as inert material during the earlier stages of concrete hardening (48). It would certainly appear that the hydration of CA containing Fe^{3+} is rather faster than that of the pure compound, and the same may apply to CA_2. The effect of "alien" ions in the lattice on hydration rate, and on the concrete strength produced by calcium aluminates, is a subject requiring much further investigation. The possibilities include not only some increase in the activity of compounds such as CA_2 but also (possibly by retardation of hydration) an increase in the hydraulic strength given by compounds such as $C_{12}A_7$.

Complete hydration of CA_2 can be achieved quite rapidly in the autoclave and investigators, chiefly in the U.S.S.R., have found that under such conditions it yields higher strengths than CA (62). It has been suggested that the superior properties of hydrated CA_2 are due to the relief of internal stresses through the agency of the boehmite which is produced during hydration (63). However, Robson (64) has given a different explanation, based on the relative void-filling capacities of the products of hydration of CA and CA_2, and has predicted that refractory castables, made with a CA_2 cement and then autoclaved, will retain a particularly high strength after firing to furnace temperatures.

Calcium hexa-aluminate (CA_6) is not found as a constituent of aluminous cement. The solid-state reaction of lime and alumina to form this compound is slow to reach equilibrium, particularly if much Na^+ ion is present in the raw materials. The synthesis of CA_6 in this way may therefore require more than one firing with intermediate re-grinding. It can be formed *in situ* when refractory castables, compounded of Type 4 cements and alumina aggregate, are heated to high temperatures in service, and Buist (37) has detected it in the immediate hot-face zone of high-alumina bricks serving in electric-arc furnace roofs. In this case a 12–13% atomic replacement of Al^{3+} by Fe^{3+} had occurred in the CA_6, giving an increased refractive index, reflectivity, and hardness. Dayal and Glasser (65), in a study of the CaO–Al_2O_3–Fe_2O_3 system, have shown that up to 40% replacement of Al^{3+} by Fe^{3+} can occur in CA_6.

The compound does not hydrate in water at ordinary temperature and is probably still inert at higher temperatures, although the behaviour of impure forms in the autoclave does not appear to have been fully investigated.

Some Other Clinker Phases

The Quaternary Compound

In cements such as those of Type 1, which contain substantial quantities of ferrous as well as ferric oxide, a strongly pleochroic material in the form of fibres or long laths is frequently observed. Although the amount present in a normal clinker should be small, special conditions of composition and furnace atmosphere may produce clinkers in which this material occurs to the exclusion of nearly all the CA.

As early as 1924 Dyckerhoff (66) noted its appearance in clinker and believed that it might be the unstable C_5A_3 compound reported by Rankin and Wright (4). At the Stockholm Symposium (1938), Sundius gave the results of work on crystals which had been carefully separated from a suitable clinker and analysis showed that oxides other than lime and alumina still remained in, or on, the crystals (67). Sundius treated such oxides as impurities in a calcium aluminate, but Parker (1952) stated that the pleochroic phase was definitely not the "unstable C_5A_3" and that it probably was a compound containing CaO, Al_2O_3, FeO and SiO_2 (68) Parker and Ryder had found a quaternary compound, of probable composition C_6A_4MS, with a primary phase field in the CaO–Al_2O_3–MgO–SiO_2 system and, by analogy, the pleochroic material in aluminous cement clinker might be C_6A_4fS (where f = FeO).

The magnesian compound and its ferrous "analogue" were crystallographically very similar but later work by Midgley and Gross (1952) (17) showed that

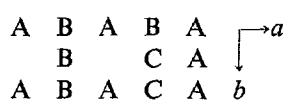
it was impossible to reconcile the C_6A_4MS formula with the unit cell volume and experimental density of a powder of that composition. High-temperature microscopy by Welch of C_6A_4MS compositions also failed to confirm that they yielded a single phase but he did discover two new ternary compounds (which had optical properties similar to C_6A_4MS) in the CaO–Al_2O_3–MgO system (69), and deduced that C_6A_4MS might really be a solid solution of one of these ternary compounds and gehlenite. However, later work by members of the same group including Nurse, Welch, and Majumdar indicated that "C_6A_4MS" was indeed a separate compound but again proved that it could not have that particular formula.

Majumdar (16), as was noted when previously discussing orthorhombic C_5A_3, found that the quaternary magnesian compound, the two ternary magnesian compounds, orthorhombic C_5A_3, and gehlenite all had cells which appeared to be composed of subcells of approximate volume $5.5 \times 10.75 \times 5.13$ Å, although he stressed that no evidence of such subcells was revealed by single-crystal X-ray photography. Although the orthorhombic C_5A_3 contained $Al_2O_7^{-8}$ groups the ternary and quaternary magnesian compounds were expected to have mixed groupings i.e., not exclusively X_2O_7 groups.

The most recent work by Midgley (17), who has examined the pleochroic compound from clinker (as well as the magnesian compounds) with the X-ray electron microprobe analyser, has given much further understanding of the nature of these compounds and has led to a proposed structure for the quaternary compound in clinker.

The sample of the latter material used in this work consisted of needles with straight extinction, negative elongation, refractive indices $\alpha = 1.676$, $\gamma = 1.680$, $2V = 40°$ positive, strong dispersion $v > r$. Experimental density $= 3.14$ g/cc. $a = 33.1$, $b = 11.0$, $c = 5.14$ Å.

Midgley determined a constitutional formula of $Ca_{22}Al_{35}Fe_3^{+}Si_2O_8$ (Molecular weight = 3302.41) with one formula unit to the cell. This formula can be written $Ca_{22}Fe_3^{+}Al_{14}(Al_2O_7)_8(AlO_4)_4(SiO_4)_2$ and the structure can be visualised as four layers of $2(Al_2O_7)$ groups and two layers of $3(XO_4)$ groups (where X is either Al or Si). The resulting six layers bring the a axis to $6 \times 5.5 = 33.0$ Å which is very close to the observed 33.1 Å. The packing arrangement is represented as follows:



where $A = Al_2O_7$, $B = AlO_4$ and $C = SiO_4$.

Rows of three calcium atoms fit between each layer of Al_2O_7 and XO_4 groups while rows of aluminium atoms occur between the Al_2O_7 and XO_4 groups. Four calcium atoms and three iron atoms fill alternate spaces between the Al_2O_7 groups leaving one vacant site.

All the magnesian compounds were also found to be mixed layers of $2(Al_2O_7)$ groups and $3(XO_4)$ groups, and the formula of the quaternary "C_6A_4MS" compound could be given as $CA_{35}Mg_4Al_{24}(Al_2O_7)_8(AlO_4)_{13}(SiO_4)_5$.

It is clearly not a magnesian analogue of "pleochroite"—the quaternary compound occurring in aluminous cement clinker.

The Iron-Bearing Phases

The mineralogical constitution of the clinker of aluminous cements which contain little iron oxide can often be deduced with satisfactory accuracy from the Al_2O_3–CaO–Fe_2O_3 phase diagram. In such cases the manufacturing process employed evidently allows a

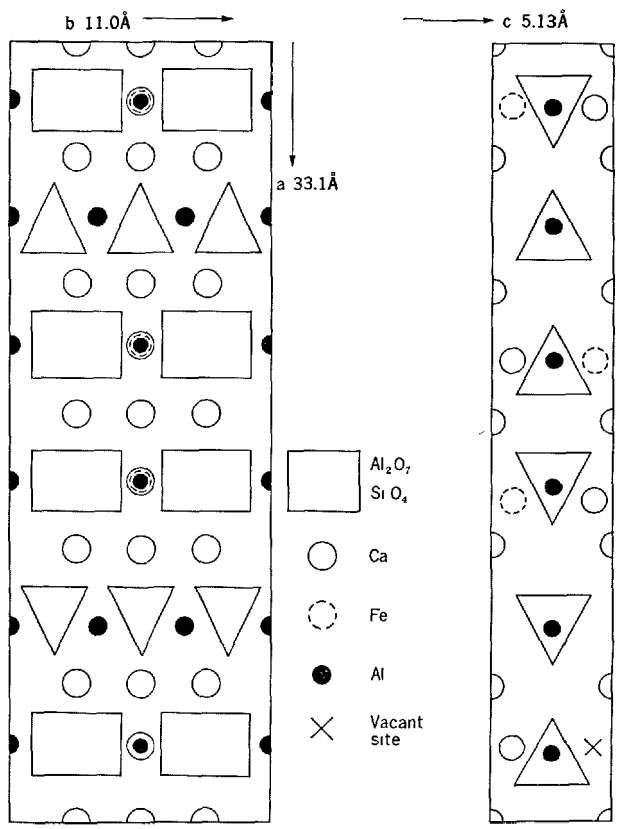


Fig. 9. *Possible structure of "Pleochroite" (after H. G. Midgley (17))*

close approach to equilibrium conditions. However, in the more general Type 1 cements, the nature and distribution of the iron-bearing phases (which are an important part of the whole) have not been known with reasonable certainty. Accordingly, calculation of the compounds present (from the chemical analysis) has never been consistently successful.

Parker (68) pointed out that FeO (wüstite) can be a final crystallization product in such cements and that the ratio Fe_2O_3/FeO cannot be predicted accurately. He suggested an analytical procedure followed by a method of calculation intended to allow for the presence of FeO as a separate phase and also for the presence of the pleochroic quaternary compound (at that time considered to be C_6A_4fS). It has been found with many clinkers that this method gives greatly exaggerated values of the amount of quaternary compound (70) and the search for a suitable method, applicable to a fairly wide variety of clinker types, still continues.

In the manufacture of Type 1 clinkers by fusion of limestone and red bauxite, process control is directed towards achieving a "standard" clinker and it is of interest to examine the constitution of such a clinker resulting from the successful application of certain manufacturing principles. Microscopic examination would show a "standard" clinker to consist of well-defined crystals of CA, a small amount of β-C_2S (usually as small rounded granules) and an appreciable quantity of iron-bearing interstitial material. $C_{12}A_7$ is not detectable or is present in small amount. Pleochroic needles or laths are similarly absent or exist in minimal quantities since their formation is avoided as far as possible during manufacture. Limits placed on the silica content of the melt prevent the formation of much C_2AS and CA_2 is normally absent. When the clinker is cooled fairly slowly there is very little true glass present.

Thus the constitution of the "standard" clinker is superficially simple and the interstitial matter can be broadly sub-divided into three types according to reflectivity capacity. The least abundant type, with the greatest reflectivity, is essentially wüstite but variable amounts of Fe_2O_3 may be present and it may be quite strongly magnetic. Areas of least reflectivity occur in the greatest abundance and the other areas are of intermediate reflectivity and abundance. The two latter types of material are classified as calcium aluminoferrite solid solutions with compositions on the join between C_2F and "C_2A", and X-ray diffraction studies indicate that, in this clinker, both have the general composition $C_{10}A_4F$ (55). This implies a higher concentration of C_2F in the solid solutions than had previously been accorded, but confirms the postulation of Cirilli and Abbatista (71).

A study of the two calcium aluminoferrite solid solutions in clinker has recently been made with the scanning electron micro-probe and several interesting observations resulted (55). It was found that, although the two phases contained substantially the same content of Al, Si and Ca, the difference in reflectivity was paralleled by a difference in Ti content.

In effect one molecule of Fe_2O_3 could be substituted by two molecules of TiO_2 and the solid solutions could be represented as (1) iron-rich $C_{10}A(0.9F \cdot 0.2T)_4$ and (2) titania-rich $C_{10}A(0.4F \cdot 1.2T)_4$. Substantially all the titania in this clinker was present in the calcium aluminoferrite solid solution and no perovskite was detected. It will be remembered that Sundius (67) found perovskite only in high-silica low-iron aluminous cements. An appreciable part of the SiO_2 also enters the aluminoferrite solid solution thus reducing the visible C_2S content of the clinker.

A comparison of an iron-free aluminous cement with one which contains a relatively high iron content demonstrates that the iron-containing clinker phases can make a substantial contribution to mortar and concrete strengths. Butt, Timashev and Paramonova (72), in an examination of several calcium aluminoferrite compositions, found that those possessing the greatest hydraulic activity were $C_{7.4}AF_{2.3}$, and $C_{4.9}AF_{1.3}$, which does not strongly support the idea that the hydraulic activity of the solid solution series increases with alumina content. These workers investigated the effect on various calcium aluminoferrite compositions of reduction in a hydrogen atmosphere and found that complete decomposition into CaO $3C_3A$, FeO and Fe occurred at high temperatures (1400°–1500°C). On the other hand incomplete reduction at 400°C, with much substitution of Fe^{2+} for Fe^{3+}, gave increased hydraulic activity which, it was suggested, might be due to the appearance of lattice defects and vacant sites.

Many manufacturing processes for aluminous cement allow reduction of Fe^{3+} to Fe^{2+} but it is not known whether this could occur at the time of formation of the calcium aluminoferrite phases. However it is interesting to speculate whether this action could be responsible for creating a more active solid-solution in the clinker.

The System CaO–Al_2O_3–SO_3

Zinsen (73) in 1943 suggested that the break-down of boiler-slag was due to the hydration of a compound

$C_3A \cdot 3CaSO_4$. However the existence of a ternary anhydrous compound in the system $CaO–Al_2O_3–SO_3$ was not generally accepted until very much later, e.g. in 1952 it was reported (74) that no ternary compound had been found in the clinker prepared as the expansive component for the cements developed by Lossier (75).

Ragozina (1957) claimed to have isolated a ternary compound in this system and, as a result of later work with Ahmedov (1962) finally assigned to it a formula corresponding to $3CA \cdot CaSO_4$ (76). In the interim period Klein and Troxell (77) examined clinkers prepared by firing aluminous and calcareous materials with gypsum and deduced from the X-ray diffraction pattern that an anhydrous calcium sulpho-aluminate was present. They estimated, from the oxide compositions, that the new compound might be $C_4A_2 \cdot CaSO_4$ or $C_8A_4 \cdot CaSO_4$, but Fukuda (78) in 1961 gave the formula $3CA \cdot CaSO_4$ to a ternary anhydrous compound which was found as the major constituent in clinkers obtained by firing mixtures of lime, bauxite and gypsum at 1350°C.

The work of Halstead and Moore (79) confirmed that the compound was $3CA \cdot CaSO_4 (4CaO \cdot 3Al_2O_3 \cdot SO_3)$ and that it seemed to be the only ternary compound in the system $CaO–Al_2O_3–SO_3$ below 1350°C. Crystallographic data indicated that it was identical with the compound detected by Kelin and Troxell, and by Fukuda. It could be synthesised by heating the appropriate chemical composition in air for several hours at 1350°–1400°C.

The compound was isotropic with refractive index 1.57 and the cell was cubic, body-centred ($a = 18.39$ Å). The calculated density for cell contents of $16(Ca_4Al_6O_{12}SO_4)$ agreed with the experimental density of 2.61 g/cc. All the strong reflections could be indexed on a cubic cell with $a = 9.195$ Å which therefore indicated that the structure contained a prominent pseudo-cell with contents $2(Ca_4Al_6O_{12}SO_4)$. This pseudo-cell is comparable in size to the cells of sodalite and haüynite and it seems that the ternary compound could be regarded as an end-member of the sodalite-noselite-haüynite series in which all Si is replaced by Al and all Na by Ca atoms. Its constitutional formula would thus be $Ca_4(Al_6O_{12})(SO_4)$, and the space-group $I\bar{4}3m$ is compatible with the structure of the pseudo-cell.

The structure is made up of a three-dimensional continuous framework of polyhedra whose vertices are all occupied by Al replacing the Si present in the sodalite series. Oxygen atoms lie at about the centres of edges and those projecting from the vertices form part of adjacent units. The SO_4 tetrahedra are situated at the centre of each unit, possibly stabilising the $CaO–Al_2O_3$ lattice, and the calcium atoms lie at the centres of the hexagonal faces.

The melting-point of the compound in an open system was in the region of 1590°–1600°C and the stability of the structure at elevated temperatures is quite high since Halstead and Moore found that the loss of SO_3 from $CaSO_4$ at 1350°C was about thirty times that of SO_3 from $Ca_4(Al_6O_{12})(SO_4)$ at the same temperature. This suggested that it might be formed and retained in portland cement or aluminous cement clinkers when a high-sulphur fuel is used during manufacture, but the presence of the anhydrous ternary compound has not yet been reported in aluminous cement clinkers even when made by a sintering or clinkering process.

The compound reacts with water readily to give mainly calcium aluminate hydrates and the expansive component required for addition to portland cement clinker (to produce expansive cements) must contain additional lime and calcium sulphate (80). Mehta and Klein (81) for example showed that the molar composition which hydrates completely to give only ettringite is $6CaO \cdot Al_2O_3 \cdot 3SO_3$ and this would consist of 30% ternary compound, 53.5% $CaSO_4$ and 16.5% CaO. Clinkers containing $Ca_4(Al_6O_{12})(SO_4)$ together with additional lime and sulphate are ground with portland cement clinker (low C_3A content) to form the shrinkage-compensated cements which have been commercially manufactured for some time (82).

An interesting possible application for the ternary compound follows from the claim by Mehta (83) that its presence in a calcium aluminate cement will prevent the conversion of the hydrate CAH_{10} into the cubic C_3AH_6, under hot-wet conditions. Mehta found that monocalcium aluminate, mixed with 5% (wt.) of $Ca_4(Al_6O_{12})(SO_4)$ and initially hydrated at low temperature, contained only a small amount of C_3AH_6 even after prolonged storage under water at 38°C.

Possible Uses of Calcium Aluminates other than in Cements

For cements, monocalcium aluminate is made in considerable tonnages; in most cases the product is very impure but in others the clinker consists of relatively pure material. However very few industrial uses outside the cement field have yet been developed for any of the calcium aluminates.

Some interest has been shown in the properties of calcium aluminate glasses (84) which have been found to have a high refractive index and high infra-red transmittance. Such glasses can be stabilized against devitrification by the incorporation of alkali and iron ions and the transmittance value is further increased in such material by the addition of other elements such as manganese or copper (85). The resistance to moisture remains lower than that of normal optical glass but some protection can be gained by "blooming" the glass with MgF_2. Optical and physical properties have been reported (86) and several patents have been granted. A crystalline ceramic material has also been made by melting a composition containing 65–100 mol. % of $CA_{1.5}$, cooling below the liquidus temperature to form a glass, and then reheating above the annealing temperature to allow crystallization (87). A powdered calcium aluminate glass may be useful in preventing atmospheric hydration of shapes pressed from pure calcium oxide. The glass and granular lime were mixed and hot-pressed in a graphite mould at 1250°–1450°C (88).

Cookayne (89) has described a technique for the preparation of very large optically transparent single crystals of $C_{12}A_7$ and CA_2 and such crystals may be useful as host lattices for laser ions, particularly those of CA_2 (90).

It would appear that CA_6 is of interest for microwave applications. A small proportion of CA_6 in alumina increases the ambient temperature microwave permittivity and loss tangent (91). The use of CA_6 as an aggregate for refractory castables has also been proposed. The aggregate is prepared by firing a 6:1 molar ratio of lime and alumina at 1150°–1815°C and crushing the product to form a grog (92).

Oral Discussion

Kiyotaka Mishima

Among various alumina cements, there are some in which plenty of gehlenite crystals is formed. How does this crystal influence upon cement hydration?

The new applications of calcium aluminates other than cement were very interesting. Are there any other applications in the modern technical fields such as space technology, atomic energy and so forth?

Author's Closure

Thomas D. Robson

An increasing proportion of gehlenite usually appears in high-alumina cement clinkers as the silica content rises (particularly above 5% SiO_2). Since the gehlenite is practically non-hydraulic at ordinary temperatures (and since it utilises alumina which otherwise could be present as calcium aluminate) the effect is to reduce the cement strength—especially the early strength. It is also usual for the setting-time of the cement to be delayed when the clinker contains higher percentages of silica.

Among the applications (actual or proposed) for calcium aluminate cements in modern technologies the following can be mentioned:

Castable refractories for forming the pads on which vertical-take-off aircraft are tested, for constructing flame-deflectors in tests on large rocket engines, and for constructing the inner wall of concrete pressure-vessels serving as the whole (or part) of the radiation shield of nuclear reactors. A mix of calcium aluminate and fused silica aggregate has been patented for casting rocket nozzles and a similar mix has been tested for infilling a stainless-steel honeycomb acting as protection to missiles during atmospheric re-entry.

Supplementary Paper I-78 The Crystal Structure of $11CaO, 7Al_2O_3, CaF_2$

Perter P. Williams*

Synopsis

The crystal structure of the material obtained by replacing two O^{2-} ions in the unit cell of $C_{12}A_7$ by four F^- ions has been determined. The structure previously deduced by Büssem and Eitel for $C_{12}A_7$ has been shown to be substantially correct, and the fluoride ions have been found to be randomly distributed on 12-fold positions. The calcium atoms have been found to be coordinated either to six oxygens in a very asymmetric manner, or to six oxygens and one fluorine, in an arrangement similar to octahedral coordination. The single position parameter of the calcium atoms may assume one of two values, depending upon whether an adjacent site is occupied by a fluoride ion. It is suggested that the affinity that $C_{12}A_7$ shows for water at high temperatures can be ascribed to the requirement that the coordination sphere about the calcium atoms be more or less regular.

Introduction

The observations by Roy and Roy (1) and by Nurse (2) that the compound $C_{12}A_7$ absorbs one mole of water from air of normal humidity at temperatures up to 1100°C reawakened interest in the crystal structure of this material. Büssem and Eitel (3) had previously deduced an approximate structure, but later work by Jeevaratnam, Glasser and Glasser (4, 5) failed to give definite confirmation of the structure. Jeevaratnam, Glasser and Glasser (5) also showed that by heating anhydrous $C_{12}A_7$ or $C_{12}A_7H$ with calcium fluoride or chloride, compounds of the type $C_{11}A_7 \cdot CaX_2$ could be formed, with structures closely related to those of $C_{12}A_7$ and $C_{12}A_7H$. These observations suggested that the hydrate contains replaceable OH^- groups, and can be formulated $C_{11}A_7 \cdot Ca(OH)_2$. The cubic unit cell contains two formula weights of the compound, i.e. $Ca_{24}Al_{28}O_{66}$ for the anhydrous material, and for the hydrate, or the halides, $Ca_{24}Al_{28}O_{64}X_4$. The space group chosen by Büssem and Eitel (3) for the anhydrous material, $I\bar{4}3d$, cannot accommodate 66 oxygen atoms in the normal equipoint sets, and the suggested structure accounted only for the cell contents $C_{24}Al_{28}O_{64}$, leaving two oxygen atoms per unit cell to be accounted for. It has been suggested (5) that it is these oxygen atoms that are used in forming hydroxyl groups in the hydrate.

It was clearly of interest to determine accurately the crystal structure of this material in order to locate the extra oxygen atoms, and, if possible, to find a reason for the unusual hydration behaviour of $C_{12}A_7$. Since, if Büssem and Eitel's (3) structure is correct, the unlocated oxygen atoms must be disordered, it was felt that there was a better chance of locating the extra atoms in the hydrate, or a halide analogue, in which there are four extra atoms per unit cell, than in the anhydrous material, which has only two, The very great similarity in the X-ray patterns of all the compounds make it seem likely that the extra atoms occupy the same types of position in the anhydrous material, the hydrate and the halides. However, it was realised that results obtained from the hydrate or a halide may not be applicable to the anhydrous material. Nevertheless, when crystals of the fluoride became available through the courtesy of Dr J. K. O'Leary, of Albright and Wilson Ltd, the structure determination was commenced.

*Chemistry Division, Department of Scientific and Industrial Research, Petone, New Zealand.

Experimental

Three-dimensional diffraction data from a small equant single crystal were collected on a Hilger Linear automatic diffractometer within a sphere of radius approximately 1.2 r.l.u., using Mo radiation and balanced fitters. Data were collected over four quadrants, so that general reflections hkl were observed up to 24 times. All reflections were reduced to structure amplitudes independently, and the root mean square averages of sets of equivalent structure amplitudes obtained. A total of 213 independent structure amplitudes were used in the structure analysis.

A critical examination was made of the diffractometer output, and of Weissenberg and precession photographs to verify the systematic absences previously reported, and to check for the absence of superlattice reflections. No reflections apart from those expected for a cubic structure, space group $I\bar{4}3d$ were observed, the reflections expected to be absent gave integrated intensities not greater than the standard deviation of the measurements, and equivalent reflections gave intensities agreeing to within two standard deviations. Thus, no experimental evidence could be found to contradict the conclusions formed by previous workers.

The cell dimension was measured from a powder diffractometer pattern calibrated with silicon powder. The value obtained, $a = 11.970$Å is in fair agreement with the published (5) value of 11.964Å.

An unsharpened Patterson synthesis computed from the full set of data appeared to indicate a structure in which the atoms occupy positions strictly analogous to those occupied in the similar compound C_3AH_6, i.e., calcium atoms in positions 24d (of $I\bar{4}3d$) with $x = 1/8$, and aluminium atoms in positions 16c with $x = 0$. Twelve other aluminium atoms were placed on the fixed positions 12a, and 64 oxygen atoms on 16c with $x = .07$ and on 48e, with $x = .19$, $y = .29$, $z = .10$. Structure factors computed with these parameters gave an R-factor of about 0.35. When refinement was attempted, the atoms moved towards the positions deduced by Büssem and Eitel. Consequently, Büssem and Eitel's parameters were used as a starting point for refinement. The R-factor, initially about 0.2 dropped to 0.12 after two cycles of block diagonal least squares refinement. A difference synthesis at this point indicated that the calcium atoms were very anisotropic, being elongated along the 2-fold axes on which they lie. Peaks occurred in the synthesis in the positions 12b, each peak corresponding approximately to one-third of a fluorine atom. Two more cycles of block diagonal least squares refinement in which an anisotropic temperature factor was refined for the calcium atoms indicated that the anisotropy of the calciums was much greater than could be expected for ordinary thermal vibrations. Two cycles of full matrix least squares refinement were carried out, in which occupancy factors, and position parameters of two fractional calcium atoms, and the occupancy factor of the fluorine atom were allowed to vary. This refinement resulted in an R-factor of .097. Since the essential features of the structure were clear at this stage, no further refinement was performed.

Discussion of the Structure

The final atomic parameters are given in Table 1.

The general features of the structure are as described by Büssem and Eitel (3). It is composed of a three dimensional network of linked AlO_4 tetrahedra, each oxygen (O(2)) in the general 48-fold position being bonded to an aluminium on a 16-fold position (Al(2), symmetry 3) and to an aluminium on a 12-fold position (Al(1), symmetry $\bar{4}$). The other 16 oxygens (O(1)) are bonded only to the neighbouring Al(2) atoms. The AlO_4 tetrahedra are slightly distorted, those for the Al(1) atoms being extended slightly in the direction of the 2-fold axis, and those for the Al(2) atoms being extended in the direction of the 3-fold axis. Bond lengths are shown in Table 2.

All Al–O bond lengths are within the normal range, except for the Al(2)–O(1) bond, which is longer than normal. However, the O(1) atom had not clearly reached its optimum position when refinement was stopped, and further refinement would probably reduce this bond length.

The calcium and Al(1) atoms lie in rows on the 2-fold axes, as shown in Fig. 1.

The arrangement of the atoms lying on the 2-fold axis is:

—Ca Al Ca hole Ca Al Ca hole—

In the crystals studied, roughly 24% of the holes are occupied by fluoride ions, and a corresponding frac-

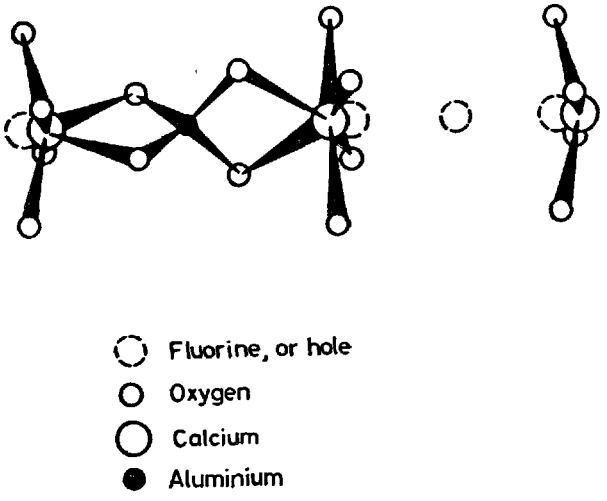

Fig. 1. *The coordination of the calcium atoms.*

tion of the calcium atoms, 25%, lie closer to the holes than the remaining 75%. It seems fairly certain, therefore, that if a hole is occupied by a fluoride ion, both the adjacent calcium atoms are displaced towards the fluoride ion by about 0.5Å from the positions they normally occupy.

In Fig. 1, it can be seen that the coordination of oxygens to the calcium is rather unusual if the adjacent hole is not occupied by fluorine. Six oxygens lie within 2.54Å of the calcium, four of them lying at the corners of a distorted square centred approximately on the calcium atom, and oriented at right angles to the 2-fold axis. This square planar coordination group has Ca–O distances of about 2.34Å. The two remaining oxygen atoms lie on the same side of the square planar group, at a distance of about 2.54Å from the calcium. If the neighbouring hole is occupied by a fluorine atom, the calcium atom occupies a different position, still near the centre of the square planar arrangement, but about 2.96Å away from the other two oxygen atoms. The calcium-fluorine distance is about 2.30Å. In this situation, therefore, the coordination of the calcium is 7-fold, and the arrangement approximately octahedral, there being two weak Ca–O interactions trans to the Ca–F bond.

If the results of this analysis are applied directly to anhydrous $C_{12}A_7$ and to the hydrate, it would appear that the unusual hydration characteristics of $C_{12}A_7$, can be explained in terms of the unsatisfactory coordination of five-sixths of the calcium atom in the anhydrous phase. Hydration or reaction with calcium fluoride or chloride allows one-third of the calcium to adopt an approximately octahedral coordination, leading to a more satisfactory structure. However, it may be noted that in the hydrate and the halides, two-thirds of the calcium atoms remain poorly coordinated, and it may be possible to introduce neutral ligands into the remaining holes in the structure, and so satisfy the coordination requirements of all the calcium atoms.

The results of this analysis suggest that in the particular sample studied, fewer than one-third of the holes are occupied by fluoride ions, and that if charge balance is to be preserved, the formula of the material must be approximately $11.56CaO \cdot 7Al_2O_3 \cdot 0.44CaF_2$. The good agreement between the fractional occupancy parameters for the Ca(2) and the fluorine atoms indicates that this is a real effect, and has not been introduced by the adoption of an unsatisfactory scattering curve for fluorine. The length of the cell edge for the material studied is slightly greater than that reported (5) for the fluoride, as would be expected for the composition given above.

Jeevaratnam, Glasser and Glasser (5) reported the lengths of the cell edges for the anhydrous phase, the hydrate, and the halides. The cell edges, according to their figures, increase in the order fluoride < hydrate (hydroxide) < anhydrous phase < chloride. These authors note that the results of Roy and Roy (1) indicate that the cell volume increases with hydration, whereas their own figures show a decrease. Since the calcium-aluminium—hole (or anion) chains indicated in Fig. 1 lie parallel to the cell edge, it is reasonable to

suppose that the length of the cell edge can be correlated with the extent of occupation of holes by anions, and by the calcium-anion distance. If values are adopted of 2.30Å for the Ca–F bond (as measured in this work), of 2.43Å for a typical Ca–OH bond, and of 2.73Å for a Ca–Cl bond, and these are plotted against the cell dimensions for the appropriate compounds, a straight line results, as shown in Fig. 2.

This result suggests, firstly, that the assumption that the anions occupy the same sites in these three compounds is justified, and secondly, that the reduction in cell size upon hydration observed by Jeevaratnam, Glasser and Glasser (5) is real, since the average size of the holes in the chains becomes smaller upon hydration.

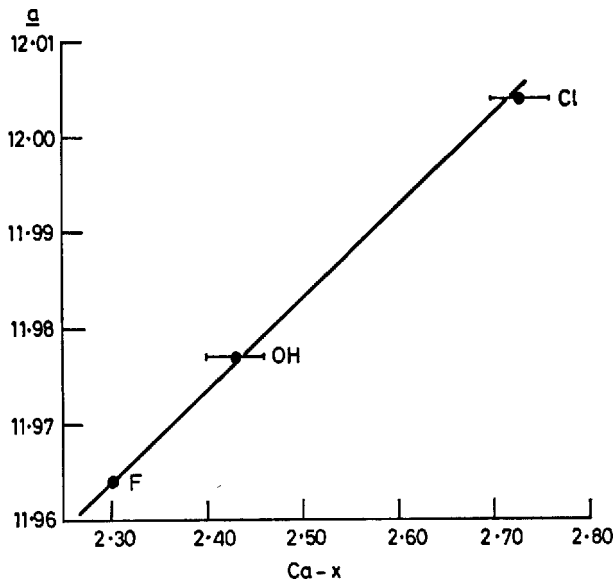

Fig. 2. *Variation of the unit cell parameter with expected calcium—anion distances.*

Conclusions

The structure reported by Büssem and Eitel (3) for $C_{12}A_7$ is substantially correct. However, in this phase, and in the hydrate, and the halide analogues, the anions which cannot be accommodated in a fully ordered structure are randomly distributed on a 12-fold equipoint of point symmetry $\bar{4}$. These anions contribute to a modified octahedral coordination of up to one-third of the calcium atoms. Large holes occur in the structure where sites in this equipoint remain unfilled, and adjacent calcium atoms have an unbalanced coordination shell. The cell dimensions of the hydrate and halide analogues can be correlated with the calcium-anion distances to be expected in the structures.

Supplementary Paper I-90 The Solid Solution in the System C_2AS (Gehlenite) —CA_2 and a New Ternary Phase

Kozo Sugiura and Takashi Yoshioka*

Synopsis

Studies were made on the crystal phase obtained by heating, at different temperatures, the glasses of the system C_2AS–CA_2, having several different chemical compositions.

As a result, it was found that the melilite crystallizing on the C_2AS side of the said system could form a metastable solid solution. This solid solution is in most cases metastable, but it may possibly be stable as for the glass having the composition quite near to C_2AS end member. The amount of the CA_2 taken up in solid solution, as far as determined by this experiment, is 16.6% by weight at the maximum, and when this solid solution is heated under a certain condition it separates CA_2 crystal. This solid solution has its lattice constant changed not only by the amount of its CA_2 but also by the heating condition.

When the glass of the said system having a certain composition was heated at 1000°C, a new crystal phase which has not been known heretofore was crystallized. This crystal phase, by heating glass granules having C_2AS, CA_2 equi-mole composition (C_3A_3S composition) at 1000°C for 4 – 48 hours, can be obtained as a monophase. By further studies it was disclosed that this phase has a relatively wide field of solid solubility. That is, under the heating condition of 1000°C for 48 hours, this phase can crystallize as a monophase inside the triangle having anorthite, CA and CA_2 as the vertices, and also in a composition range of SiO_2 extending from approximately 11–27%. Under differential thermal analysis, this phase shows an exothermic reaction at about 1100°C and decomposes into stable minerals. Therefore, this crystal phase can be considered as metastable.

The Melilite Solid Solution in the System C_2AS–CA_2

H. G. Midgley (1) analyzed the melilite, separated from marketed high alumina cement, and noted that its Al_2O_3 content is unusually greater than the ordinary gehlenite, and indicated that the solid solution must be generated between C_2AS and CA_2. J. R. Goldsmith (2) made a study on the system $CaAl_2Si_2O_8$–$Ca_2Al_2SiO_7$–$NaAlSiO_4$ and noted that the refractive indices of the melilite originating within this system are substantially lower than those of the pure gehlenite, and this, he thought, may have been caused by the gehlenite's solid solutioning of CA_2. H. J. Christie (3) studied the ionic substitutions of melilite by the synthetic method and stated that it may be possible to make Al completely replace the Si positions of gehlenite. The authors, while studying the high alumina cement clinker minerals, discovered that the melilite crystallizing from the glass of the system C_2AS–CA_2 could take up a certain amount of CA_2 to form a solid solution.

Homogeneous glasses having various compositions of the system C_2AS–CA_2 were obtained from pure quartz powder, pure reagent of $CaCO_3$ and Al_2O_3, by flame fusioning with oxygen-acetylene burner. However, when the CA_2 component is more than 70% by weight (hereinafter all % is by weight), even with the rapid quenching process perfect glass could not be obtained, the formation of C_2A crystal being inevitable. The glass granules (1–3 mm. ϕ) thus obtained were kept for 6 hours in an electric furnace at the temperatures of 900–1450°C. The phases were identified mainly by the X-ray powder method together with the microscopy. The lattice constant a_0 of the melilite thus formed was obtained from the d-values of 400, 330 and 420 for an measurement metallic germanium powder being used as the standard. The diffraction condition was as follows:

Target Cu, Filter Ni, Voltage 40 KV, Current 20 mA, Count Full Scale 200 C/S,
Time Constant 4 sec., Scanning Speed 1/8°/min., Receiving Slit 0.1 mm.

The refractive indices of this melilite were also measured by the oil immersion method.

The results of the identification of the formed phases

*Research Laboratory, Nihon Cement Co., Ltd. Tokyo, Japan.

are shown in Table 1. This melilite is monophase up to 5.7% CA_2 content at 1450°C, and monophase up to 16.6% CA_2 content at 1100°C. At the temperature below 1000°C, an unknown crystal, which will be described in the next section, was found to occur within the ranges of 16.6% to 63.0% CA_2 content. The glass phase remains at 900°C.

The lattice constant a_0 of the crystallized melilite is shown in Fig. 1. The richer was the CA_2 component in the glass composition, the greater was the a_0 of melilite crystallizing therefrom. The lower the heating temperature, the more eminent was this tendency. In spite of the fact that the melilite is monophase up to 16.6% CA_2 at 1100°C, the change of a_0 value is small in comparison with the component change. At 1200°C and at 1300°C, the melilite is monophase up to 11.2% CA_2 content in both cases, but the a_0 change is still smaller.

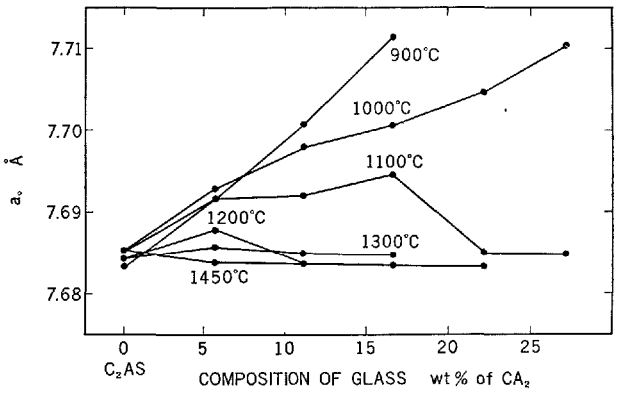

Fig. 1. *Lattice constant* a_0 *of melilites crystallized from the glasses of* C_2AS–CA_2 *composition at several temperatures.*

Taking the mixtures with 16.6% CA_2 content as an example, melilite crystallized and glass phase remained at 900°C; unknown crystal was also found to be formed at 1000°C; and, it became melitlie monophase only at 1100°C. The melilites crystallizing at the temperatures of 900–1100°C may probably have CA_2 in solid solution, and the size of the lattice dimensions became smaller with the rise of the temperature. Even at the low temperature, the lattice dimension shrinked when kept for long hours (Fig. 2). At 1200°C, CA_2 was found to be formed and the lattice dimension of the melilite became equal to that of the ordinary gehlenite. In the melilite having CA_2 in solid solution, it is assumed that a part of Si in the ordinary gehlenite is replaced by Al, and a part of Ca is also replaced by Al as follows: $(Ca_{2-x}Al_x)Al$ $Al(Si_{1-x}Al_x)O_7$. In the case of 16.6% CA_2 content, $X = 0.174$. These substitutions may probably take place, resulting in the formation of rather unstable substance, and if a sufficient thermal energy is given

the solid solution will be decomposed into C_2A and gehlenite. The fact, that the melilite having CA_2 in solid solution shows the change of lattice dimension subjected to temperatures must have some bearing on the instability of the structure. Such fact is not recognized in C_2AS end member. The D.T.A. curve of the glass with 16.6% CA_2 content is shown in Fig. 3. Exothermic peaks were seen at 995°C, 1020°C and 1120°C. It was confirmed by the use of X-ray analysis that the first peak (lower temperature side) is caused by the melilite crystallization and the second peak by the formation of unknown crystal. The third peak must be caused by the reaction of the decomposition of unknown crystal and the formation of melilite monophase as a whole. Because the specimen obtained by rapidly quenching from 1200°C is mostly composed of the melilite, a minute quantity of the unknown crystal remains, but CA_2 does not exist.

As to the glasses with 11.2% and 5.7% CA_2 contents, a_0 of the melilite decreases with the rise of the temperature, but when shrinked to the size exactly equal to a_0 of ordinary gehlenite, the melilite still contains CA_2 component in solid solution. Even when the specimen glass is used in powder form CA_2 does not segregate by 6 hours heating at 1300°C, up to 11.2% CA_2 content. The glass with 5.7% CA_2 content still does not segregate CA_2 by 6 hours heating at 1450°C, but it segregated CA_2 when heated at 1530°C for 6 hours.

It seems that the change of the lattice dimension of melilite has little effect upon the refractive indices. (Fig. 4 A, B.)

From the above facts, melilite having CA_2 in solid solution and also having large a_0 can be considered as metastable phase. The formation of the melilite containing CA_2 up to 11.2% at 1200°C and at 1300°C, and up to 5.7% at 1450°C and having lattice constant a_0 nearly equal to that of ordinary gehlenite shows a strong possibility of the existence of a range of solid solubility on the gehlenite side of this system, even under an equilibrium state. However, this is not confirmed yet.

New Ternary Phase in the System CaO–Al_2O_3–SiO_2

As shown in Table 1, when the glass granules of the system C_2AS–CA_2 were heated at the temperature below 1000°C, an unknown crystal was obtained in 15–60% CA_2 components ranges. By heating drop-

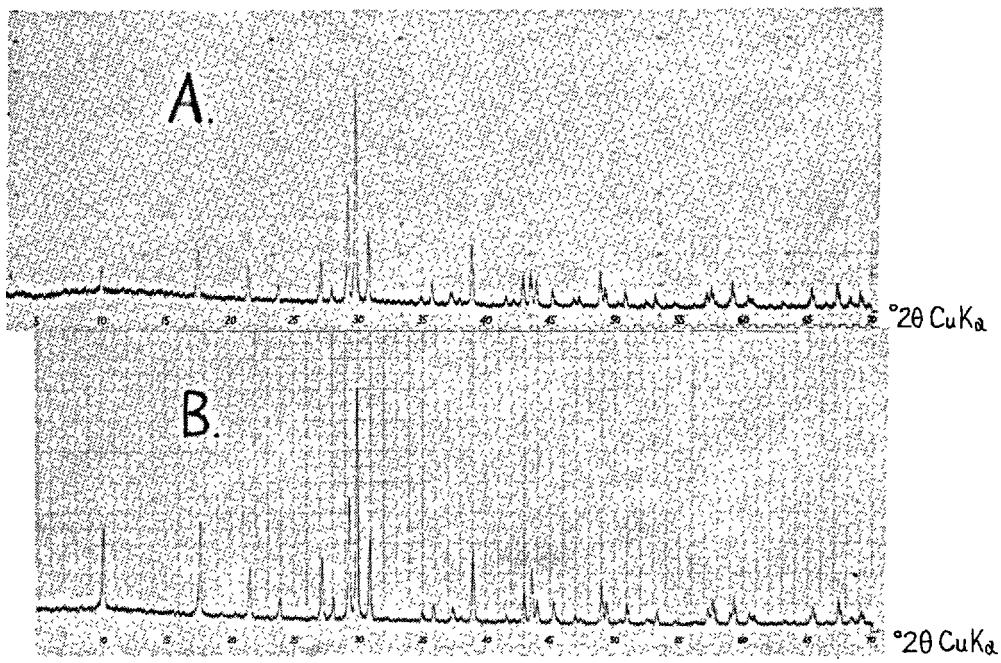

Fig. 5. *X-ray diffraction diagrams of the new ternary phase*

B. $C_3A_3S_2$ composition

lets (3–8 mm. ϕ) of the glass with C_2AS, CA_2 equimole, that is C_3A_3S composition, for 4 – 48 hours at 1000°C it was obtained in a monophase form. These droplets were prepared by flame fusioning as already mentioned.

Under microscopic observation this crystal shows straight extinction, it is uniaxial positive, has negative elongation, $n \fallingdotseq 1.626$ and its special property is that it has an extraordinary weak birefringence. Specific gravity = 2.86. X-ray powder diffraction diagram is shown in Fig. 5–A and Table 2. As shown in Table 2, indexing it as hexagonal system is possible. The D.T.A. curve of this crystal is given in Fig. 6–A. At about 1200°C it shows an exothermic reaction, decomposes and forms a stable mineral assemblage, which is composed of C_2AS and CA_2.

Result of the study of this phase, conducted on still wider range of chemical composition, is shown in Fig. 7. This shows the phase or the combination of the phases obtained when granules of glasses having various components were heated for 48 hours at 1000°C. Inside the triangle having anorthite, CA, CA_2 as vertices, only the new crystal phase alone forms in a relatively broad range, approximately 11–27%, of SiO_2.

All of the X-ray power diffraction diagrams of the new crystal phase formed are exceedingly similar but by compositions the peak positions were found shifted slightly. Taking the example of the new crystal phase forming on the connecting line of CA–anorthite, d values change linearly with the compositions, but the lines break at the point $C_3A_3S_2$, as shown in Fig. 8, which gives the result of the values measured, using quartz as standard. Studies were made on the new crystal phase formed on other composition lines and the same inflections were seen when crossing over the connecting line $C_3A_3S_2$–$C_2A_3S_2$. The above-mentioned crystal of C_3A_3S composition has a weak birefringence, but it becomes stronger as it nears the anorthite. A microscopic photo of the crystal with $C_3A_3S_2$ composition is presented in the Photo 1.

Although the new crystal phase is a solid solution belonging to the ternary system CaO–Al_2O_3–SiO_2, strictly it might be classified into two different phases somewhere in a vicinity of the connecting line $C_3A_3S_2$–$C_5A_6S_4$–$C_2A_3S_2$.

According to the differential thermal analysis, the new crystal phase when heated above a set temperature will decompose with an exothermic reaction into a stable mineral assemblage. The peak temperatures and the minerals formed by decomposition of course will differ with compositions. The D.T.A. curve of the new crystal phase with $C_3A_3S_2$ composition is given

Oral Discussion

Yoshio Ono and Kinjiro Fujii

I would like to ask about the new compound C_3A_3S. The optical properties as well as the specific gravity of C_3A_3S resemble those of melilite. The lattice constants a and *c*, however, are very close to those of feldspars.

Is it not possible that C_3A_3S has similar structure to anorthite, the composition of anorthite $CaAl_2Si_2O_8$ being partially replaced by monocalcium aluminate $Ca_2Al_4O_8$?

Author's Closure

Kozo Sugiura and Takashi Yoshioka

We have not attached much importance to the facts that the refractive indices and the specific gravity of the new crystal resemble those of gehlenite and that the lattice constants are close to those of anorthite. It seemed to us however that these facts have no any special meaning, because the new crystal phase seems to be one of the stuffed derivatives of silica structures (1). We give on reasoning as follows:

Further studies were made by T. Yoshioka on the

systems $3CaO \cdot 3Al_2O_3 \cdot 2SiO_2$–$NaAlSiO_4$ and $3CaO \cdot 3Al_2O_3 \cdot 2SiO_2$–$KAlSiO_4$ by the same method as described in the main paper. In the former system the new crystal single phase was obtained up to 3% $NaAlSiO_4$ composition. In 3~10% $NaAlSiO_4$ compositions the specimens were composed of two phases; one was the new crystal and the other the nepheline solid solution which resembles that of $NaAlSiO_4$–$CaO \cdot Al_2O_3$ system described by J. R. Goldsmith (1949) (2). In the compositions of more than 12% $NaAlSiO_4$ the nepheline solid solution was obtained as a single phase. The solid solution was optically positive up to 70% $NaAlSiO_4$ composition but at about 80% $NaAlSiO_4$ composition it was isotropic and above 80% it was negative, accompanying small amount of carnegieite. In the latter system the new crystal was obtained as a single phase up to 5% $KAlSiO_4$ composition. In the composition of more than 5% $KAlSiO_4$ the new crystal was found existing with the other crystal phase which was obtained as a single phase in the compositions of 13~50% $KAlSiO_4$. It was optically uniaxial positive and its X-ray powder pattern was almost identical with that of the nepheline solid solution above mentioned. It can be considered as K, Ca-nepheline solid solution.

It was observed that the new crystal resembled the nepheline solid solutions in its X-ray powder pattern. Therefore the powder data of the new crystals were re-examined to certify that they had hexagonal symmetry. In this case, a more acceptable match was obtained between Q-values observed and calculated and most of the reflections of the new crystal had the same indices with those of the nepheline solid solutions. On the assumption that the new crystal had a similar lattice with that of nepheline, a_0 of $3CaO \cdot 3Al_2O_3 \cdot 2SiO_2$ crystal was indentical with that extrapolated from the nepheline solid solutions, but rather different as to c_0. For example,*

nepheline s. s. of 88 $C_3A_3S_2$12$NaAlSiO_4$
composition . . . a_0 10.002 Å, c_0 8.410 Å
nepheline s. s. of 86.8 $C_3A_3S_2$13.2$KalSiO_4$
composition . . . a_0 10.036 Å, c_0 8.432 Å
new crystal of $100C_3A_3S_2$
composition . . . a_0 10.008 Å, c_0 8.224 Å

In this way we believe that the structure of the new crystal has a close relation to that of nepheline, a stuffed derivative of high temperature-tridymite.

It is also expected that some interesting relations can be found between the structures of the new crystal and that of $CaO \cdot Al_2O_3$ which is also a stuffed derivative of high temperature-tridymite.

*These were calculated from the d-values of 21.0, 21.1, 20.2, 30.0 of the nepheline and nepheline-type solid solutions observed by using Si as a standard.

On Preprint of Principal Papers and Other Information

Dear Sirs:

Please find enclosed herewith Preprint of Principal Papers (Full texts) covering 16 Principal Papers, which is distributed to each enrolled member of the Symposium as announced in Preliminary Program. Other 4 Principal Papers will be distributed in the same way as soon as we receive them.

Preprints in full text is prepared for Principal Papers only, so Written Discussions will be made only in connection with Principal Papers. (Please refer to Page 13 of "Circular No. 2"). Those who want to present Written Discussions will send their Paper in conformity with the instructions of "Guide for Authors of Supplementary Papers and Written Discussions" to the Organizing Secretariat so that they may arrive thereto not later than the end of June 1968.

After the example of Supplementary Papers, application of Written Discussions will be allowed at the rate of one Discussion per person, and for regular member only. Abstracts in 1000 Words of Written Discussions will be distributed at the Symposium site.

CONTENTS

SYNOPSIS

In Portland cement clinker, the four principal constituents are found in the form of solid solutions. The polymorphic variations of these solid solutions being numerous and ill-defined, we have first dealt with the structure and polymorphism of the pure compounds.

Pure C_3S, passes through six allotropic forms between ambient temperature and 1100°C, all very close to the trigonal high-temperature form. A pseudo-structure which is a good approximation to the real structure has been proposed by Jeffery. Alites usually crystallise in the monoclinic and trigonal forms of C_3S.

On the other hand, the five forms of C_2S are different. Their crystal lattices are distinct and the stacking of silicate tetrahedra differs from one to another. Only the structures of β and γ have been determined. Belites usually crystallize in modified β forms, more rarely as the γ' form.

The cubic structure of C_3A has not been determined. Tricalcium aluminate forms solid solutions with the aluminoferrites of the interstitial phase. This can occur as a glassy phase when clinkering temperature is high, quenching rapid and the A/F ratio > 1.

The hydraulic properties of the clinker constituents are linked to their crystal structure, particularly the irregular Ca co-ordination, and the presence of holes in the structure. All the forms of C_3S show comparable reactivity whereas the forms of C_2S differ in their hydraulic properties.

INTRODUCTION

This is a study of the four minerals which are the principal constituents of all portland cement clinkers and are designated, following the classical abbreviations, as C_3S, C_2S, C_3A and C_4AF.

In fact, each of these abbreviations represents a group comprising the pure phase and the solid solutions having a crystal lattice with identical or very similar lattice dimensions. The alites and belites which correspond respectively to C_3S and C_2S are the solid solutions formed by the addition of impurities which are present in all commercial cement clinkers and are principally the ions or oxides of Al, Mg, Fe, Na, K, Cr, Ti, Mn, P, et cetera. Even when no impurities are present, the aluminoferrite, "C_4AF", can have a variable composition $C_2(A_pF_{1-p})$ where p varies from 0 to 0·7.

On a polished clinker surface, the microscope clearly distinguishes the different phases. C_3S appears in the form of well-defined crystalline grains varying in size from 10μ to 40μ. C_2S occurs as rounded crystals or twinned polyhedra, with a smooth or striated surface.

Figure 1

Between these grains there lies an interstitial phase in which it is sometimes possible to identify well-formed crystals of C_3A but often the interstitial phase is so finely crystallised that the individual grains are not visible.

The object of this paper is to describe the crystal structure of each of the phases listed above and how the structure varies with temperature and with additions to the pure stoichiometric composition.

The whole system presents a difficult field of study because, with certain exceptions, one cannot obtain the clinker phases in the form of single crystals of sufficient size to permit a structure determination by classical methods. In general, one is reduced to characterising a phase solely by its lattice, deduced from powder diagrams. But even this technique is difficult to use in this field because of the low symmetry or large unit cell of certain phases and above all because the variations which one is trying to detect as a function of temperature or of additions are very small. Furthermore, it has only recently become possible to obtain high quality powder patterns at temperatures up to 1500°C. In his paper of 1960, F. Ordway[1] insisted upon the necessity for developing special high temperature techniques adapted to the study of clinker minerals.

The results obtained by X-ray diffraction must obviously be checked with those given by other techniques such as microscopy, infra-red absorption, spectroscopy, electron-probe microanalysis, etc., and especially differential thermal analysis.

Numerous papers have appeared on problems in this field. Not all of these are based upon the use of the most sophisticated techniques and contradictions exist between the results reported. However, on the whole, certain facts emerge which clarify the

problem. A general review must naturally emphasise the points on which there is agreement but one must also mention other observations even where they are contradictory.

In order to resolve these two incompatible demands, we have chosen not to follow the chronological order in reporting successive papers. In each chapter of this article, dealing respectively with tricalcium silicate, dicalcium silicate and the interstitial phase (calcium aluminoferrite and tricalcium aluminate), we begin by giving what we ourselves regard as the most complete and satisfactory solution to the structural problem. Next, we group the studies which make a partial contribution to the preceding results, or contradict them. We try then, in the latter case, to discuss the possible origin of these differences with what we consider to be the most probable solutions.

In the conclusion, we discuss the general character of the polymorphism of the calcium silicates and hence the relations between the crystal structures and clinker properties.

TRICALCIUM SILICATE

It is the tricalcium silicate phase which has the most numerous allotropic forms. We have shown that there are six between ambient temperature and 1100°C. One can find all the same forms in the solid solutions but all have lattices extremely close to trigonal, the simplest form.

The X-ray powder diffraction patterns are indistinguishable except for slight movements of certain lines or their separation into very close multiplets; but the relative intensities do not vary. This shows that the structure of the least symmetrical forms remains, to a very good approximation, that of the most symmetrical.

Jeffery's Structure[2]

The structure of C_3S has been determined by Jeffery on a single crystal of sufficient size, which was isolated from a blast-furnace slag. In this work, which dates from 1950, Jeffery, on the basis of the visually estimated intensities of the diffracted spots (without Lorentz-polarization correction), determined a trial structure which is a good approximation to the true structure. O'Daniel, Hahn and Müller[3,4] have confirmed these results by a Patterson synthesis. No other structure has been proposed.

The pseudo-structure, proposed by Jeffery, is trigonal, with a = 7, c = 25 Å (hexagonal notation), space group R3m. It is composed of independent tetrahedra; three SiO_4 tetrahedra and three oxygen ions lie on the trigonal axes.[5] The calcium ions link the tetrahedra and are octahedrally co-ordinated to

the three oxygen ions which are not linked to Si^{4+} (see Figure 2).

Figure 2

Identical columns are found on each trigonal axis, but at different heights (see Figure 3). These form irregular octahedra

Figure 3

of atoms around the calcium ions and leave holes large enough to accommodate other atoms.

It is the irregular co-ordination of the Ca ions (the bonds vary from 2·54 to 3·24 Å) and the holes adjacent to these ions that give C_3S its hydraulicity.

Nevertheless, Jeffery's structure is certainly only approximate. The lattice of the lower temperature forms is not the simple trigonal. We have tried to grow crystals from molten $CaCl_2$[6]. From a number of crystals between 4 and 10 μ, we chose a 7 μ pseudo-hexagonal crystal. An oscillation photograph shows superlattice lines corresponding to a = 14 Å [7]. Construction of the reciprocal lattice from a Weissenberg photograph gives approximate values for b and c of 14 and 25 Å. The parameters may be obtained more accurately by indexing powder photographs on a pseudo-hexagonal lattice.

Study of Polymorphic Transformations of C_3S by DTA

The results of differential thermal analysis are the most straightforward and a definitive list of the transition points can be established (see Table 1). Four reversible DTA peaks at

Table 1

600°, 920°, 980° and 990°C characterise C_3S (see Figure 4).

Figure 4

Due to the powerful resolution of micro DTA[8], the peaks at 980° and 990° are well resolved. The thermal effects of these transitions are very weak, smaller than the α - β transformation of quartz (1·4 cal/g)[9]. The transformation point at 990° was discovered both by Boikova and Toropov[10] in pure C_3S, and by Woermann, Hahn and Eysel[11] in both C_3S and in the solid solutions.

Boikova and Toropov[10] cross-checked the DTA results by a study of a small crystal on a high-temperature microscope. The transformations at 620°, 920° and 980° could be observed and were found to be reversible, but the authors do not indicate whether the crystal transforms without change of habit.

Study of the Polymorphic Transformations of C_3S by X-ray Diffraction (XRD)

At high temperature, the lattice is trigonal. On cooling, the lowering of the symmetry causes splitting of the hexagonal reflexions into groups of lines whose number and spacing permit the determination of the true lattice[7].

At 1100°C the lattice is trigonal, with hexagonal parameters a = 7·15, c = 25·56 Å. The 30 lines of the powder pattern (up to 1.48 Å) show the extinctions corresponding to space-group R3m: $-h + k + l = 3n$.

Our results are in good agreement with Jeffery's predictions, deduced from the trial structure.

With decreasing temperature, the transformations are clearly visible on three hexagonal spacings $\bar{2}01$, $\bar{2}04$ and 220, which become successively doublets and triplets (see Figure 5).

Figure 5

In the range of temperatures used, the 009 reflexion does not show any splitting at all and its relative intensity remains constant relative to the other reflexions. The stacking of planes perpendicular to c, about 8·4 Å apart, therefore remains the same. A sliding of these planes in the direction perpendicular to the c axis takes place.

The principal characteristics of the transformations are:

1) 1050°C: change of symmetry from rhombohedral → monoclinic ($R \rightarrow M_{II}$). The transformation is continuous and only the hexagonal basal plane is deformed (see Figure 6).

Figure 6

The pseudo-hexagonal cell deduced from the reduced cell chosen according to Donnay[14] is defined by the parameters a = b = 7·130 Å, c = 25·43 Å, $\alpha = \beta = 90°$, $\gamma = 119.88°$. This can be considered as an orthorhombic cell with parameters a = 12·342, b = 7·143, c = 25·434 Å [7].

Nevertheless, the structure cannot be anything but monoclinic: the small but continuous deformation of the trigonal lattice does not permit of the formation of an orthorhombic structure; there is no orthorhombic sub-group of the trigonal space group. The transformation is probably of the second order, the structure can only be monoclinic (M_{II})[15].

2) 990° C: discontinuous transformation of the unit cell without change of symmetry: $M_{II} \rightarrow M_I$. The components of the doublets $\bar{2}01$, $\bar{2}04$ and 220 are clearly separated (see Figure 5).

As well as the deformation of the hexagonal basal plane, there is now added an inclination of the c axis to this plane ($\beta = 89.88°$) (see Figure 6).

The stability region of the M_I phase is only 10°. We suspected the presence of this form from the small signal given by μ-DTA at 990°C. We therefore took a series of photographs between 970° and 990°C and found a diagram characteristic of M_I. The components of the doublets are, indeed, less well defined than in the other forms but this variety has been confirmed in solid solutions of $C_3S + Al_2O_3$ by both Bigaré[12] and Woermann, Hahn and Eysel[11]. These authors have all observed an increase in the zone of stability of M_I to 60° for the solid solution C_3S + 1% Al_2O_3.

3) 980°C: change of symmetry $M_I \rightarrow T_{III}$. The characteristic doublets become triplets and the lattice is now triclinic; in the hexagonal basal plane the three axes a, b and d are different. A diagram taken at 940° shows about 100 lines which cannot be indexed without doubling the pseudo-hexagonal parameters a and b to 14 Å. The superlattice in the basal plane only involves a change of orientation of the rhombohedron in which obverse becomes inverse. If one retains the orientation of the original unit cell, the extinction rule is not the same: it becomes $+ h - k + l = 3n$[15]. At 940°, the pseudo-hexagonal cell has the parameters a = 14·229, b = 14·249, c = 25·412 Å, α = 90.10°, β = 89.85°, γ = 119.76°.

4) 920°C. Although DTA gives a strong signal, we observe no change of symmetry, nor any change in volume of the unit cell. The components of the triplets, arising from the hexagonal reflexions $\bar{2}01$, $\bar{2}04$ and 220 separate progressively from 980° until 620°.

5) 600°C. No change of symmetry is observed but a slight discontinuity in the splitting of the characteristic triplets.

6) 20°C. On a photograph exposed for 40 hours (6 mA, 30 Kv, Cu K α), we detected two very weak reflexions ($I/I_o < \frac{1}{100}$) with long spacings 14 and 8·2 Å. These are hk0 reflexions and would imply the doubling of parameters a and b. The new unit cell would be defined thus:

$$a = 28{\cdot}160 \qquad b = 28{\cdot}294 \qquad c = 25{\cdot}103 \text{ Å}$$

$$\alpha = 90.30^\circ \qquad \beta = 89.77^\circ \qquad \gamma = 119.53^\circ$$

The variations in the pseudo-hexagonal parameters from ambient temperature to 1100° are shown in Table 2.

Table 2

Nature of C_3S Transformations

The characteristic properties of the transformations of C_3S are collected in Table 3[15].

Table 3

DTA and X-ray have established 5 reversible transformations between six allotropic forms. Three of these transitions (990°, 980° and 600°) have been observed by both DTA and X-ray methods.

The transformation R - M_{II}, found by X-ray, gives no DTA signal. The transition, which is continuous and weak, extends over 60°, beginning at about 1050°. Possibly it is a second order transition.

The transition T_{III} - T_{II}, at 920°, undetectable by X-rays, is characterised by a strong DTA signal. The unit cell is triclinic up to 980° and the Debye-Scherrer pattern maintains the same relative intensities. The strong thermal effect is perhaps due to a second superstructure which, while leaving the

fundamental spacings unchanged, modifies the long spacings which are too weak to be detected under normal conditions. The superstructure found for T_I could exist equally in T_{II} (we have not verified this hypothesis because of the very long exposures which would be required at high temperature). A re-arrangement of the hexagonal groups in the lattice could vary the energy of the structure appreciably and this would explain the thermal effect.

To conclude, C_3S undergoes numerous small amplitude transformations around a constant atomic arrangement. All the transformations are of the "displacive" type[16]. They are produced by small movements of the atoms from their positions in the original structure, without any alteration of the general arrangement of the chemical bonds.

We have shown evidence of two types of transition: change of symmetry and superstructure:

- the hexagonal structure, advanced by Jeffery[2], is constructed of independent SiO_4 tetrahedra. At high temperature, the atoms of the SiO_4 tetrahedra are vibrating freely; the hexagonal unit cell shows a corresponding symmetry. As the temperature decreases, the degrees of freedom diminish and the departures from symmetry appear. They reveal themselves by changes in the X-ray powder diagram, that is to say, by the splitting of characteristic reflexions;

- the structure of C_3S is a stacking of hexagonal groups. With decreasing temperature the stacking faults give rise to a superstructure which is revealed by weak reflexions at low angles.

Certain of our results (the superstructure in T_{II}), not being directly proved, may be open to discussion. The powder patterns which we have studied permit determination of lattice dimensions and symmetry but give no other information on the structure. We are unable to distinguish a pseudo-orthorhombic form from a true orthorhombic structure. The superstructure in T_I is only indicated by the presence of two very weak Debye-Scherrer lines at long spacings. However, in an oscillating crystal photograph of alite (with the hexagonal axis parallel to the axis of rotation) Jeffery[2] has shown evidence for the existence of superlattice lines corresponding to a = 40 Å. Thus, in the T_I form of pure C_3S, it seems more likely that a = 42 Å than 28 Å.

The study of the polymorphism of C_3S demands experimental techniques with great powers of resolution. Only the combination of X-ray and DTA has given complete results. To elucidate the structural relations of the different polymorphs completely, it will be necessary to prepare single crystals of sufficient size.

Tricalcium silicate, being of type A_3BX_5, is isomorphous with tricalcium germanate, Ca_3GeO_5[17,18] and sodium fluoberyllate, Na_3BeF_5[19].

Other Studies on Tricalcium Silicate

All the transitions which have been described in the preceding paragraphs have not been detected by the first workers in the field either because they did not use DTA or because they had no X-ray equipment of sufficient resolution. On the other hand, transitions which proved to be due to an impurity (such as a small amount of C_2S) have been attributed to C_3S.

Thus Nurse and Welch[20] found 6 transformation points, at 464°, 622°, 750°, 923°, 980°, 1465°. An interpretation of this thermogram was proposed by Jeffery[21]. The first transformation corresponds to the dehydration of free lime. The peaks at 622°, 750°, 1465° are characteristic of the β - α', γ - α', and α' - α transformations of C_2S. The only peaks due to C_3S are those at 923° and 980°, characteristic of three forms following this scheme:

$$\text{Triclinic} \xrightarrow{923} \text{Monoclinic} \xrightarrow{980} \text{Trigonal}$$

Yamaguchi and Miyabe[22] repeated, in 1960, Jeffery's work, and defined the same polymorphic transformations. A triclinic, pseudo-orthorhombic unit cell, calculated by these authors, has the parameters

$$a = 12{\cdot}195 \qquad b = 7{\cdot}104 \qquad c = 25{\cdot}096 \text{ Å}$$

$$\alpha = 90 \qquad \beta = 89°44' \qquad \gamma = 89°44'$$

The transformation at 990° was not detected in a recent study by Miyabe and Roy[23]. These authors, on the other hand, attribute to C_3S a broad signal at 675°, which is characteristic of the $\beta \rightarrow \alpha'$ transformation of C_2S. Boikova and Toropov[10] have shown evidence for the existence of this thermal effect when the tricalcium silicate synthesis is incomplete. We ourselves have verified that, in DTA, traces of β C_2S give a thermal effect at 675°.

The polymorphism of C_3S has been studied, in 1964, with the help of powder patterns, by Miyabe and Roy[23], who used a high temperature diffractometer, as we ourselves were using a high temperature Guinier camera[24] (see Figure 7).

Figure 7

Figure 7 shows the diffractometer traces of Miyabe and Roy at 600° and 650°C, together with one of our double-exposure Guinier photographs taken at 600° and 625°C (1962)[24]. Miyabe and Roy found a mixture of phases T α and T β; we observed only, in accordance with the phase rule, T_I at 600° and T_{II} at 625°.

The resolution of the focussing camera[25] is better because we are operating with rigorously monochromatised ($Cu\ K\alpha_1$) radiation and we eliminate variations of intensity and apparent displacements of certain lines due to crystal growth at transformation points. The sample temperature is more difficult to measure than in the diffractometer but it is sufficiently uniform and well-controlled to give lines at high temperature which are as sharp as those produced at ambient. We have established a temperature scale using known transition points. This calibration curve between the heating current and the temperature of the sample-holder is re-adjusted with the help of the temperatures of the DTA peaks of C_3S. We can thus obtain a set of high-resolution photographs at selected temperatures which show the progress of the transformations.

Our results are in disagreement with those of Miyabe and Roy. The differences are as follows:

1) Miyabe and Roy found only the rhombohedral form (R) above 970°; we detected three modifications (R, M_{II}, M_I) above 980° (Figure 8).

Figure 8

2) According to Miyabe and Roy, the stable form between 980° and 920° is monoclinic. We have shown evidence, in the splitting of the 620 reflexion (620, $\bar{6}20$), for the presence of a triclinic form, T_{III}. The separation of the lines is 0·003 Å, which was not resolved by previous workers.

3) Miyabe and Roy obtained a considerable contraction of the unit cell of T_β between 600 and 700° Figure 9) suggesting a new transition, $T_\beta \rightarrow T_\gamma$, at about 700°. We consider that

Figure 9

some of the lines for T_β, T_γ and M are incorrectly indexed. If the spacings in Miyabe and Roy's diagrams are correctly indexed and the parameters recalculated, the contraction disappears (see Figure 10). The curve showing variation of pseudo-orthohexagonal

Figure 10

parameters is then similar to ours (Figure 11).

Figure 11

Solid Solutions of Tricalcium Silicate

The transformations of C_3S occur rapidly at well-defined temperatures, and without noticeable hysteresis. One cannot stabilize, by quenching, any of the high temperature forms.

On the other hand, if one introduces small amounts of foreign ions into the C_3S lattice, one obtains, at ambient temperature, phases which have the same lattice as one of the phases of pure C_3S. There is thus, by additions, stabilisation at ambient temperature of forms which in the pure compound only exist in narrow ranges of temperature. One might say that the disorder introduced by foreign ions is playing a role analogous to the disorder of thermal vibration.

Table 4

Table 4[15] indicates the nature of the phases observed by different additions, as a function of their concentration. The different solid solutions have been prepared by synthesis from pure materials. In clinker, the solid solutions must be more complex. Table 4 shows how one addition will not, in general, stabilize all the forms. The highest symmetry phase is stabilized by ZnO but not by any other single oxide. Nevertheless, it is observed in certain clinkers which contain insufficient ZnO but a very large number of other impurities (Al_2O_3, Fe_2O_3, MgO, Cr_2O_3, TiO_2, Na_2O, K_2O etc.). These complex mixtures have not been reproduced by synthesis. The studies of the solid solutions as a function of temperature have been made only on the simplest synthetic products and we will begin with the addition of ZnO which stabilizes the most complete range of phases[19].

Solid solutions of C_3S + ZnO. Zinc oxide stabilizes, at ambient temperature, the forms T_I T_{II}, M_I, M_{II}, R of C_3S[15]; Zn^{2+} replaces Ca^{2+} in the C_3S lattice. The variations in the parameters as a function of percentage of ZnO show clearly the different varities stabilized (Figure 12). The DTA results confirm the stability

Figure 12

ranges. The transformation temperatures are decreased by the addition of ZnO. At 0·75% ZnO the thermal effects at 920 and 980° merge into one with addition of their intensities. The stability zone of T_{III} disappears. Above 0·75% ZnO, M_I transforms directly to T_{II}. The fusion of the two DTA peaks implies a change of symmetry from monoclinic to triclinic, with the formation of two superstructures, simultaneously.

The temperature of the small signal at 990° does not vary and the thermal effect persists above 2·25% ZnO, into the region where, according to X-rays, M_{II} and R appear to be stabilized. This is a new example of a phase-change detected by DTA but imperceptible by XRD. Above 2·25% ZnO, the solid solutions C_3S + ZnO would again be monoclinic but of a form approaching so closely to rhombohedral that XRD cannot resolve the symmetry.

There is one difference between the monoclinic forms M_I and M_{II} of pure C_3S and the solid solutions C_3S + ZnO. The characteristic reflexions 224, $\bar{4}04$ and 620, 040 are reversed (Figure 13).

Figure 13

This inversion has already been observed by Yamaguchi and Miyabe[22] and interpreted in a study of the solid solutions $3CaO\text{-}SiO_2\text{-}Al_2O_3\text{-}MgO$ by Yamaguchi and Kato[26]. It corresponds to a different a/b ratio of the pseudo-orthohexagonal parameters and a different β angle. In the case of pure C_3S at 985°: $a/b < \sqrt{3}$, $\beta \leq 90°$, in the solid solution C_3S + 2% ZnO: $a/b > \sqrt{3}$, $\beta > 90°$. The monoclinic forms of the solid solutions reverse at high temperature to the monoclinic forms of pure C_3S. The intermediate form with $a/b = \sqrt{3}$ and $\beta = 90°$ has an orthohexagonal unit cell even though the symmetry is not rhombohedral.

Ono, Uno and Kanai[27] have also stabilized the trigonal form of C_3S by the addition of 6·3% ZnO. Furthermore, a solid solution C_3S + 15% C_3A + 5% CaF_2, prepared by the same authors, is reported as rhombohedral with hexagonal parameters a = 7·088, c = 25·115 Å, but the optic axial angle 2V is not 0 as in the case

of C_3S + 6·3% Zn_3SiO_5; it is less than 15°(-). Presumably, this solid solution is not truly hexagonal.

Solid solutions C_3S + MgO. Woermann, Hahn and Eysel[11] have proposed, for the solid solutions C_3S + MgO, the following formula: $(Ca_{1-x}Mg_x)_3SiO_5$, where $0 \leq x \leq 0{\cdot}0125$ at 1550°C. The Mg^{2+} ions replace an equal number of Ca^{2+} ions in the C_3S lattice[28]. The solubility limit is 2% MgO but this depends on the temperature[26,29]. In addition, CaO dissolves small quantities of MgO[30]. Thus crystals of the solid solutions Ca_3SiO_5 - "Mg_3SiO_5" and (Ca, Mg)O[31] can co-exist. The forms of C_3S which are stabilized are T_I (up to 0·55% MgO), T_{II} (0·55 to 1·45% MgO) and M_I (from 1·45 to 2·0% MgO). Above 2%, periclase appears, identified both optically and by the lines in the X-ray powder diagram. In the monoclinic form, the characteristic lines are again inverted: in the solid solution C_3S + 2% MgO, $a/b = 1{\cdot}737$ and $\beta = 90.12°$[32].

Solid solutions C_3S + Al_2O_3. The alumina incorporated in the lattice of C_3S can be either in the form of Al_2O_3 or C_3A. Woermann, Hahn and Eysel[11] have distinguished two types of solid solution:

a) between 0 and 0·45% Al_2O_3

Al^{3+} replaces Si^{4+} in the tetrahedra but occupies the free octahedral sites also, thus maintaining the electrostatic neutrality of the lattice. The formation of the solid solution, by both addition and substitution, is expressed by the formula:

$$Ca_3^{IV}\ Al_{\frac{x}{4}}^{VI'}\left(Si_I - \frac{3x}{4}\ Al_{\frac{3x}{4}}\right)^{IV}\ O_5$$

where $0 \leq x \leq 0{\cdot}02$, VI' being a vacant octahedral site. The only form of C_3S stabilized is T_I[11,12].

b) <u>between 0·45 and 1% Al_2O_3</u>

above 0·4% Al_2O_3, the incorporation of Al_2O_3 may be:

- either the result of two linked substitutions: Si-Al (tetrahedral sites), Ca-Al (octahedral sites), following the formula:

$$\left(Ca_3 - \frac{x}{2}\ Al_{\frac{x}{2}}\right)^{VI}\quad\left(Si_I - \frac{x}{2}\ Al_{\frac{x}{2}}\right)^{IV}\ O_5$$

- or the continuous balanced replacement of Si by Al for the most part in the octahedral sites occupied by $Ca^{(VI)}$ and to a very small extent in the vacant octahedral sites (VI').

These interpretations appear more probable than that of Locher[28] in which the loss of the oxygens which are not bonded to the tetrahedra permits the neutralisation of the charge after substitution of Al for Si.

The form which is stabilized is T_{II}[10,11,29].

DTA shows the decrease in transformation temperatures of the forms stabilized by Al_2O_3, up to 1%, the limit of solubility. Above the solubility limit the lines of C_3A appear in X-ray powder patterns[12]. The solubility limit is independent of temperature. Midgley and Fletcher[29] found the same results, but maintain that the substitution of Al in the lattice is not due to insertion of C_3A in C_3S but to a solid solution of the series C_3S - "$C_{4\cdot5}A$".

The presence of Al does not change the type of substitution of Mg, but, on the other hand, Mg does affect the substitution scheme of Al[31].

Solid solutions $C_3S + Fe_2O_3$. The limit of solubility of Fe_2O_3 in C_3S is 1·05%[11]. Only the triclinic forms T_I (from 0 to 0·8% Fe_2O_3) and T_{II} (from 0·8 to 1·05% Fe_2O_3) are stabilized. According to Fletcher[33], the solid solutions are of the type C_3S - "C_3F": $3Ca^{2+}$ are replaced by $3Fe^{3+}$, $6Si^{4+}$ by $6Fe^{3+}$, and the charge is compensated by one Fe^{3+} ion in an interstitial position.

Other solid solutions of C_3S. Tricalcium silicate also forms solid solutions with the following additions: $La_2O.SiO_2$[34], $Y_2O_3.SiO_2$[35], SO_3[36], Co_2O_3[37] and Na_2O[38].

Na_2O substitutes for CaO in the C_3S lattice. Above 0·3% Na_2O, the structure is monoclinic with parameters a = 12·262, b = 7·053, c = 25·086 Å, $\beta = 90°07'$[39].

CaF_2[40] enters into solid solution in C_3S. At 0·74% CaF_2, the X-ray powder diagram is similar to that of alite in clinker. Above 0·74% there is a decomposition of C_3S into α' C_2S.

It seems equally probable that C_3S can take up to 1% P_2O_5 into solid solution[40], involving more a distortion of the lattice than true polymorphism.

Constitution and Structure of Alites in Clinker

In alites, one can find triclinic, monoclinic and trigonal forms[41,42]. In Figure 14, we show the patterns of two clinkers in which the alite is in the forms M_{II} (inverse) and R.

Figure 14

The alite grains in portland cement clinker appear to have trigonal symmetry and to be practically uniaxial. However, each grain is an assembly of numerous crystallites of lower symmetry,

twinned at 120°. As Jeffery[2] has suggested, these crystals are thus paramorphs of the high temperature form.

A recent study by Yamaguchi and Ono[43] shows evidence for two types of alite crystal: regular hexagons corresponding to the 0001 face and hexagonal sections elongated in the characteristic planes $1\bar{1}02$ and $10\bar{1}1$ (Figure 15).

Figure 15

The transition from rhombohedral → monoclinic is a small energy change: the monoclinic a axis coincides effectively with the rhombohedral c axis and the monoclinic b axis with one of the rhombohedral a_1, a_2, a_3 such that the twinning of the transformation is triple.

Jeffery[2] has considered alite as a definite composition with additional atoms in fixed lattice sites. In alite of formula $54CaO.MgO.Al_2O_3.16SiO_2$ there is replacement of Ca by Mg, of 2Si by 2Al, and the addition of one Mg ion in a vacant hole, to maintain neutrality of the lattice.

The structure of this alite is monoclinic, with parameters a = 33·08, b = 7·07, c = 18·56 Å, $\beta = 94°10'$, space group Cm. One of the pseudo mirror planes of the trigonal structure becomes a true mirror plane (Figure 2). The oscillation and Weissenberg photograph show a large number of satellite spots, which could be interpreted to give a "c" spacing of 150 Å.

The existence of different types of C_3S solid solutions shows that alite is a true solid solution. The introduction of foreign ions and balancing of charges are continuous and statistical. Alite is not a compound with a definite composition like the stoichiometric formula given by Jeffery. As early as 1958, Von Euw[44] showed that this composition contains C_3A as an impurity.

From powder diagrams, Yamaguchi and Miyabe[22] calculated the monoclinic unit cell of Jeffery's alite and found the parameters a = 12·246, b = 7·045, c = 24·975 Å, β = 90°04'. Ordway[1] re-calculated the unit cell to a = 12·248, b = 7·045, c = 24·972 Å, β = 90°06', an elementary cell which allows the indexing of all the lines visible in the powder diagram. Only Jeffery studied a single crystal of alite and was able to find the true larger unit cell.

Toropov and Volkonskii[45] (1960) and Chromy[46] (1964) observed only two forms of C_3S in clinker: β and α, the α' form being trigonal and the transformation $\beta \rightarrow \alpha'$ taking place at 1375°C.

Stability of Tricalcium Silicate and Alites

Several methods of preparation of tricalcium silicate have been reported[47,48,49,50,51]. Mineralisers such as NaF, Na_2SiF_6[47], LiCl[52], CaF_2, Co_2[53] accelerate the formation of C_3S. Complete synthesis of tricalcium silicate is difficult. Boikova and Toropov[10] detected, by DTA and by microscopy, C_2S in contact with C_3S. If this C_2S is saturated with CaO, the CaO/SiO_2 ratio becomes equal to 3·02 - 3·04 in tricalcium silicate.

On the other hand, a chemical and optical study by Woermann, Hahn and Eysel[31] has shown that tricalcium silicate is a definite compound, with the stoichiometric formula $3CaO.SiO_2$ (CaO = 73·68%, SiO_2 = 26·32%). In samples with a lime content lower than 73·68%, C_3S co-exists with free CaO; there is no C_2S.

C_3S is stable between 1250° and 2070°, the temperature at which it melts incongruently to form CaO and a liquid phase[54]. Below 1250°, pure C_3S does not decompose[55,22] or its decomposition is so

slow that it can only be detected by the analysis of trace quantities of free lime[54].

Alite will decompose into belite and free lime in the presence of certain minor elements (K_2O, CaF_2). A considerable decomposition of alite occurs at 1180° in metallurgical clinkers. The Fe^{2+} ions replace the Ca^{2+} in the C_3S lattice[56].

DICALCIUM SILICATE

It is necessary to note first of all the differences that exist between the polymorphisms of C_2S and C_3S. The lattices of the different C_2S forms are known and their parameters are quite distinct. At the moment, only the structures of the β and γ forms have been determined; they are completely different. It seems equally certain that the α and α' structures show small but distinct differences. In addition, there is complete agreement between the transition points revealed by DTA and by XRD crystal analysis. In the case of C_2S we have the usual types of transformations, whereas in C_3S we have a very special case because all the forms can be derived from a single structure by slight variations.

Structure of the 5 Forms of C_2S

α C_2S. Of all the forms of C_2S, the α form, which exists only between 1425° and its melting point, at 2130°C, has been least studied because of the difficulties of carrying out high temperature experiments.

The most recent work is that of Yamaguchi, Ono, Kawamura and Soda[57] who used diffractometry at 1500° to determine the trigonal lattice (space group P $\bar{3}$m 1) with parameters a = 5·527, c = 7·311 Å (hexagonal notation). These results agree with those of Bredig[58] (a = 5·45, c = 7·19 Å) obtained from high temperature powder photographs taken by Van Valkenburg and McMurdie[59]. The space group is C $\bar{3}$m (P $\bar{3}$m 1) by analogy with glaserite, $NaK_3(SO_4)_2$.

The other determinations have been made on stabilized phases but with additions of such large proportions that one ought to consider whether the lattice has been substantially altered. Thus a α form "stabilized" by 2·5% Al_2O_3 + 2·5% Fe_2O_3 + 6% Na_2O has parameters a = 5·419, c = 7·022 Å[57].

A.M.B. Douglas[60] observed a small amount of a trigonal phase, with parameters a = 5·46, c = 6·76 Å, similar to α' C_2S, in the 'single' crystals of bredigite extracted from vugs in blast furnace slag. These composite crystals, of composition $Ca_{1·59}Ba_{0·08}Mg_{0·31}Mn_{0·09}SiO_4$, always contained the trigonal and orthorhombic phases in fixed relative orientation.

The crystals of nagelschmidtite $2Ca_2SiO_4.Ca_3(PO_4)_2$, also extracted from a vug in slag[61], have a hexagonal lattice defined by unit cell parameters which are multiples of those given above: a = 21·80, c = 21·54 Å. Likewise, Yamaguchi, Miyabe, Amano and Komatsu[62] in 1957, have suggested that the lattice of glaserite cannot be applied to α C_2S unless a is multiplied by 4 (a = 21·8) and c by 3 (21·50). The unit cell of α C_2S would, in this case, be more complex, but these results were not retained by Yamaguchi, Ono, Kawamura and Soda[57] in 1963.

α' C_2S. There exist two forms of α' C_2S: α'_H and α'_L whose stability regions are respectively 1420° - 1160°C and 1160° - 675°C[63]. The parameter variation curves calculated by Niesel and Thormann[63] from diffractometer traces of pure C_2S, show a reversible change of slope at 1160°C. We ourselves, with the help of high-temperature powder photographs, have

confirmed the existence of two different forms of α' C_2S at 1145° and 1200°C. Our results form the subject of a Supplementary paper to this Symposium.

Smith, Majumdar and Ordway[64] have already observed on diffractometer charts a variety $C_2S\,\alpha'_L$, obtained by heating γ C_2S, slightly different from $C_2S\,\alpha'_H$, obtained by cooling the α form. Similarly, Yamaguchi, Ono, Kawamura and Soda[57] have detected differences of intensity in the lines of α' prepared from α on the one hand and from γ on the other. This intensity difference disappears towards 1100°C. At 1300°C, the orthorhombic unit cell of $\alpha'_H C_2S$, calculated by Yamaguchi, Ono, Kawamura and Soda[57] from powder patterns, has parameters a = 6·883, b = 5·600, c = 9·543 Å (space group Pnma).

Determinations have been made on stabilized α' forms. Thus, for a phase containing 10% $CaMgSiO_4$ and 4% K_2O, Yamaguchi, Ono, Kawamura and Soda[57] found the following parameters: a = 6·748, b = 5·494, c = 9·261 Å. The form stabilized corresponded to the form $\alpha'_H C_2S$ above, described by the same authors. In this case, the differences are not due solely to thermal expansion, but also to distortion of the lattice by the impurities.

Douglas[60], working on the natural mineral bredigite, usually considered identical with α' C_2S, and on the composite crystals referred to above, calculated a cell which has the a and b parameters doubled: a = 10·91, b = 19·41, c = 6·76 Å (space group Pmnn) and she found a similar cell by indexing Trömel's powder

data[65] taken at 750°C; certain weak lines necessitate the doubled cell. Ordway[1] points out that the powder patterns of pure α' C_2S and Douglas's material are significantly different though the structures are probably closely related.

The α' C_2S structure is unknown. Bredig[58] has proposed the hypothesis that it is analogous to that of β K_2SO_4. Majumdar, Smith and Ordway[66] give a model founded upon the analogy between β C_2S and β K_2SO_4 but without justification by intensity measurements.

_β C_2S. The most precise determination of the parameters was obtained by Yannaquis[55] using a synthetic preparation of pure β C_2S. The lattice is monoclinic with parameters a = 5·507, b = 6·754, c = 9·317 Å, β = 94°38' (A.S.T.M. card 9-351), space group $P2_{1/n}$

From a powder diagram of β C_2S at 550°C, Yamaguchi, Ono, Kawamura and Soda[57] have proposed a monoclinic unit cell with parameters a = 5·558, b = 6·823, c = 11·261 Å, β = 123°11', space group $P2_{1/c}$, which is identical to the Yannaquis's lattice (see figure 16)

Lattice determinations have also been made on stabilized β C_2S phases: C_2S + 0·5% B_2O_3 is defined by the parameters a = 5·48, b = 6·76, c = 9·28 Å, β = 94°33', (space group $P2_{1/n}$)[61] and β C_2S + 0·25% Cr_2O_3 by parameters a = 5·514, b = 6·757, c = 11·197 Å, β = 123°59'[57]. These results show that the distortions introduced by foreign ions, though not negligible, are very small.

The structure of monocrystals of β C_2S stabilized by 0·5% B_2O_3 is monoclinic[61], and is constructed from independent SiO_4 tetrahedra and two sorts of Ca atoms. Four of these 8 Ca atoms (Ca_I) are placed alternately above and below the SiO_4 tetrahedra in the direction of the b axis. The structure can be described as columns of alternating tetrahedra and Ca atoms, linked together by the other four Ca atoms (Ca_{II}) placed in the holes between the tetrahedra[21]. The pseudo-trigonal arrangement of the SiO_4 tetrahedra around the Ca_{II} atoms is shown in Figure 16.

Figure 16

The co-ordination of Ca_I is irregular: 6 neighbours lie at distances between 2·30 and 2·75 Å and six others between 2·98 and 3·56 Å. If the co-ordination is equal to 9, the contribution of each of the six nearest neighbours being $^2/_9$ and that of the other six $^1/_9$, Pauling's rule is approximately satisfied. The co-ordination of Ca_{II} is equally irregular. The eight neighbours belonging to six neighbouring tetrahedra lie at distances between 2·36 and 2·80 Å.

This structure, determined by Midgley[61] from 200 h0l, 0kl and hk0 reflexions, has a "reliability" factor of 19%, the R factor being reduced to 9% by McIver[67]. McIver suggests that the space group $P2_1/n$ is incorrect, the true space group being one of: $P2_1$, Pn, $P\bar{1}$ or P1. Furthermore, Midgley notes that slight displacements of the atoms transform this structure to an orthorhombic structure of the β K_2SO_4 type, and somewhat

larger changes give a trigonal structure (α C_2S). The polysynthetic twinning occurs on the (100) and (001) planes (Figure 16) which become the planes of symmetry in the structure of α' C_2S.

The unit cell of Yamaguchi, Ono, Kawamura and Soda[57] defined by the parameters a', b', c' (Figure 16) is deduced from that of Midgley (a, b, c) by the following relations:

$$\vec{a'} = \vec{a}, \quad \vec{b'} = \vec{b} \quad \vec{c'} = \vec{c} - \vec{a}$$

γ C_2S. The unit cell has been determined from powder data by several authors. Their results are in agreement:

a = 5·076 b = 6·756 c = 11·230 Å (space group Pmcn) A.S.T.M. card 9-369[55];

a = 11·232 b = 6·773 c = 5·083 Å[57] (space group Pnma);

a = 5·091 ± 0·010 b = 11·371 ± 0·020 c = 6·782 ± 0·010[66] (space group Pbnm).

The volume expansion during the β - γ transformation on cooling, shatters the crystals into fragments too small (1 - 100 μ) for single crystal study. Smith, Majumdar and Ordway[54] prepared C_2S from ethyl orthosilicate hydrolysed by a solution of $Ca(NO_3)_2$. The mixture was dried at 100°, denitrated at 400°, heated to 1500° and quenched in air. Several single crystals were isolated and their complete structure was determined. This structure is of the olivine type Mg_2SiO_4[55,56]. The Ca^{2+} ions replace the Mg^{2+} but, being larger, expand the unit cell of Mg_2SiO_4 but without altering the general regular arrangement[21]. The SiO_4 tetrahedron is irregular (Figure 17). The Si-O distances

Figure 17

vary from 1·589 to 1·725 Å. This irregularity is probably due to the distortions in the hexagonal arrangement of the oxygen ions. All the Ca ions are octahedrally co-ordinated; the low co-ordination of Ca explains the greater molar volume of the low temperature phase.

There is also a structural analogy between C_2S and Na_2BeF_4[68,69] on the one hand, and C_2S and Ca_2GeO_4[70] on the other.

Other Studies on C_2S

Apart from these five phases which are universally agreed and well defined, some authors have claimed the existence of other modifications.

1) A modification of β, called β', has been detected by Vasenin[71] in a DTA study. This phase, as described by Toropov, Volkonskii and Sadkov[72], has a pattern similar to that of α', and is stable from 900 to 1230°C. Its existence seems to be confirmed by a DTA signal at 1230°, found by Schlaudt and Roy[73] in a study of the system Ca_2SiO_4 - $CaMgSiO_4$. The β' phase has not been confirmed by Welch and Gutt[40] nor by ourselves.

2) Kurdowski[74] reported a new phase produced at 600° from a β form stabilized by excess silica, which was very close to β. This phase appears doubtful because excess silica does not stabilize β C_2S but favours the transformation $\beta \rightarrow \gamma$ [30].

3) A cubic form stable at 1600° has been reported by Saalfeld[75]. His high temperature patterns show an absence of 110 reflexion and enhanced intensity of 102. This behaviour, which is reversible, could be due either to a variation of the hexagonal axial ratio c/a resulting from the rotation of the anions or to the formation of a cubic phase (a = 5·8 Å). The trigonal 102 reflexion would become the cubic 200. Since 1953, this phase has not been reported by other research workers. However, a solid solution $C_2S + Na_2O$ reported by Ono[76] is perhaps a superstructure of Saalfeld's cubic form stabilized at room temperature. The mineral obtained in the $CaO - SiO_2 - Al_2O_3 - Fe_2O_3$ system by an equimolar substitution of Na_2O for CaO is isotropic with a = 17·769 Å ≠ 3 x 5.8.

Study of the Transformations of C_2S

To describe the processes of change from one phase to another, we will consider the transformations observed first with decrease and then with increase in temperature.

1) With decreasing temperature. We start with the α phase, stable at high temperature (t > 1420°):

$\alpha - \alpha'_H$: the transformation is reversible without hysteresis (Figure 18). The structural changes of the $\alpha - \alpha'_H$ inversion

Figure 18

cannot be characterized with certainty. Smith, Majumdar and Ordway[66] suggest that "half the SiO_4 tetrahedra rotate so that their apices point in opposite directions at the phase change. The rapidity of the transformation is certainly facilitated by the elevated temperature, even though the change may require a structural

re-arrangement". Niesel and Thormann [63] have found at 1160°, a DTA peak, corresponding to the α'_H —— α'_L transformation.

$\alpha' \rightarrow \beta$: 650°. The transformation is reversible with a hysteresis of 25° (Roy[77] found a hysteresis of 50°); it occurs at a well-defined temperature. According to Smith, Majumdar and Ordway[66] the transformation involves a rotation of the SiO_4 tetrahedra and a change in the Ca ion co-ordination. From 8-fold in the α', the Ca co-ordination becomes variable, 8 or 9 fold, in the β form.

$\beta \rightarrow \gamma$: the β phase forms the γ by the process $\alpha' \rightleftarrows \beta \rightarrow \gamma$ This monotropic transition involves a considerable change in volume (dusting). From the structural point of view, the $\beta \rightarrow \gamma$ transition is a transformation of primary co-ordination[78]. According to Smith, Majumdar and Ordway[66] the transition involves a rotation of the SiO_4 tetrahedron and should be considered as semi-reconstructive because of the large movements of some of the Ca atoms. The sluggish nature of the transformation is perhaps due to the complexity of the bond re-adjustments.

The $\beta \rightarrow \gamma$ transformation has certain peculiar characteristics: in effect, it has been observed at different temperatures by different authors, 525°[79], 450°[71], 400°[74], 375°[80], 300°[81,82], and in addition it is incomplete. One usually obtains a mixture of β and γ but in variable proportions; one can obtain anything from nearly pure γ to nearly pure β. These phenomena will be the subject of a later paragraph.

2) <u>With increasing temperature</u>. At ambient temperature, one may start with either β or γ :

a) βC_2S: the transformation $\beta \rightarrow \alpha'_L$ takes place at 675° then $\alpha'_L \rightarrow \alpha'_H$ at 1160°[63] and $\alpha'_H \rightarrow \alpha$ at 1420°C.

The transformations are visible on DTA and are confirmed by XRD.

b) γ C_2S: starting with the γ phase, α'_L forms slowly between 725° and 860°C. The DTA peak is elongated (spread out). Guinier camera photographs (see Figure 19) taken at 750° and 850°

Figure 19

show the co-existence of the two forms γ and α'_L.

One can explain the different characters of the $\beta \rightarrow \alpha'_L$ and $\gamma \rightarrow \alpha'_L$ transformations by structural considerations. If the α'_L structure is only slightly different from β, it is very different from γ. The $\gamma \rightarrow \alpha'_L$ transformation is semi-reconstructive. According to Smith, Majumdar and Ordway[66] this implies a rotation of the SiO_4 tetrahedra, a change in Ca co-ordination from 6 to 8, and an appreciable displacement of one type of Ca atom. Like the $\beta \rightarrow \gamma$ transformation, its sluggishness is perhaps due to the complexity of the bond changes.

The whole group of C_2S transformations is shown schematically by Niesel and Thormann[63] (see Figure 20).

Figure 20

The energy diagram proposed by Bredig[58] now requires to be completed.

The different forms of C_2S can also be identified by infra-red absorption spectra[83,84].

Stabilization of Different Forms of C_2S

As indicated on Bredig's diagram, it is the γ phase which is most stable at ambient temperature. However, one can succeed in stabilizing α and α', and one can obtain β at ambient temperature.

Certain oxides, such as MgO, Al_2O_3, Fe_2O_3, BaO, K_2O, P_2O_5 and Cr_2O_3, stabilize both α' and α forms[85,86,87,88,89,90]. A phase previously considered to be a definite compound of composition $K_2O.23CaO.12SiO_2$ was shown by Suzukawa[91] to be a solid solution of K_2O in the α' form of C_2S. However, Welch and Gutt[40] could not obtain this form at ambient temperature, finding that it transformed rapidly to β. On the other hand, merwinite does not seem to be a solid solution of MgO in $\alpha' C_2S$[5], as was proposed by Bredig[58]. Yamaguchi and Suzuki[92] have prepared crystals of $3CaO.MgO.SiO_2$ of stoichiometric composition, and with a monoclinic structure (a = 9·336, b = 5·301, c = 13·286 Å, β = 92°8', space group $P2_1/c$). Furthermore, Gutt[93] reports the existence of a still higher Ca compound, $CaO_{1.7}MgO_{0.3}SiO_2$, which is stated to co-exist with the C_2S polymorphs. The most interesting problems are those of the $\beta \rightarrow \gamma$ transformation and the conditions of stabilization of the β form.

a) Influence of nucleation. Even with pure synthetic products, considerable variation can be observed in the conditions for the $\beta \rightarrow \gamma$ transformation. Yannaquis and Guinier[78] have reported the influence which crystallite size has upon the stability of β: this phase is more stable the smaller the crystals. Microscope observations show that grains of β which are stable at ambient temperature are never larger than 5 μ, although grains of γ which have been derived from β are in general 10 to 100 μ in size. These observations are confirmed by XRD patterns. The reflexions from a stationary sample of γ C_2S are spotty, while, under the same conditions, those of β C_2S are continuous.

Figure 21

(Figure 21).

This behaviour may be explained by the mechanism of the $\beta \rightarrow \gamma$ transformation, which operates by nucleation and growth. Let us suppose that nucleation is difficult; in these circumstances a grain of β, whatever its size, will transform entirely if it contains at least one nucleus of γ. If after the $\alpha' \rightarrow \beta$ transformation the crystals of the latter are sufficiently large, the probability that each grain will contain a nucleus of γ is high, and one obtains, at ambient temperature, a high proportion of γ. If, on the other hand, the crystals of β are very small, many of them will not contain γ nuclei and cannot transform during cooling.

One can thus predict that if one can succeed in preparing α' in very small grains, stabilization of the β form may be achieved. This condition is realised if C_2S is prepared by solid state reaction between CaO and SiO_2 at 1200°(94). In the stability range of the α' phase, the ratio rate of growth/rate of nucleation is low or nearly zero. In the same way, a sample of C_2S heated to 1550°C, in the α zone, gives 90% of β on quenching because the passage through the $\alpha \rightarrow \alpha'$ transition is very rapid and the crystals remain small. On the other hand, the same sample cooled slowly from 1550° to 1400° and then quenched, gives 95% γ. The slow passage through the $\alpha \rightarrow \alpha$ transformation allows time for crystal growth and in spite of quenching the transition $\beta \rightarrow \gamma$ is practically complete. This explains also the role of the temperature of 1420° in the stabilization of β or γ, which has been remarked by

several authors[64,95]. According to Niesel and Thormann[63] it seems that 1160° should be the optimum growth temperature for crystals of α' C_2S; if C_2S is synthesized below 1160°C, one obtains β, while a sample prepared at a temperature above 1160° gives a mixture of β and γ. One should point out that Chromy[96] has also shown, by optical methods, the effect of crystallite size of C_2S.

Again, the analogy between the structure of γ C_2S and $NaBeF_4$ is to be found in the nature of their transformations. The process of nucleation[97] is the determining factor in the transition $\gamma \rightarrow \alpha'$ of Na_2BeF_4.

b) Influence of pressure. The nature of the phenomenon of apparent stability of β C_2S has been more precisely defined[98]. It is possible to provoke a partial transformation from β to γ even at room temperature. Percussion of pellets of β C_2S will induce a transformation to γ of as much as 30%. Crushing between the platens of an hydraulic press may give up to 50% γ. The transformation is activated by the creation of nuclei of γ as the crystals are sheared under compression. On the other hand, if powdered β is submitted to hydrostatic pressure, even very high (9 tonnes/cm^2 = 8.8×10^5 KN/M^2), no transformation occurs; the γ phase is less dense than the β phase, and increase of pressure does not favour the transformation[99]. High pressures give β a stability region which does not exist at atmospheric pressure[77]. Thus, the β phase is stable at ambient temperature under 2 atmospheres and it would be possible to transform γ to β under 17 bars (100).

c) Stabilization by additions of foreign ions and by departures from stoichiometry. The effect of grain size is, according to the theory presented above, merely statistical; but other factors are certainly involved in the stabilization of β, in particular the presence of impurities or of excess CaO or SiO_2 over the stoichiometric ratio:

Effect of excess CaO: it is possible to introduce an excess of CaO (1%) into C_2S. The form obtained at ambient temperature is β, yet the crystals are quite large (10 μ). The specific effect of CaO is thus independent of that of size[78].

These results may be relevant to the work of Roy[77] who, having prepared large crystals of β C_2S from the hydrates, seemed to disagree with the theory of Yannaquis and Guinier. It is possible that these crystals were stabilized by an excess of CaO present in the hydrates[54].

Effect of an excess of SiO_2: the solubility of SiO_2 in C_2S lies between 1·5 and 2%, and the form obtained is γ. Crystals of C_2S - SiO_2 solid solutions range in size from 5 to 250 μ. The addition of silica modifies the distribution of growth rates in the C_2S crystal and favours the transformation $\beta \rightarrow \gamma$ [78].

The effect of an excess of SiO_2 can be seen in the dusting of badly quenched clinkers or slags. Microscopic examination shows that the sources of the dusting lie round the grains of quartz; the crystals of belite which are too rich in silica transform to γ.

Effect of foreign ions: B_2O_3 is the classical stabilizer for β C_2S[61,55]. Using less than 0·5% B_2O_3, the lattice of

β C_2S is not significantly altered (Figure 22).

Figure 22

Yannaquis and Guinier[98] suggest that holes are formed by the elimination of Si^{4+} ions (probably in the form of silica) necessary to balance the charges of the higher valency $(BO_4)^{5-}$ groups. At 0·5% B_2O_3, there is one Si vacancy in 160 molecules of C_2S. Such holes seem a more likely site for additional Ca^{2+} ions than do interstitial positions in a lattice as compact as that of C_2S.

The solid solutions of C_2S + B_2O_3 are well crystallized. The lattice of C_2S + 2% B_2O_3 is monoclinic with parameters a = 5·475, b = 6·770, c = 9·290 Å, $\beta = 93^{\circ}42'$. One can regard this solid solution as a limit structure and refer to it as a model.

Na_2O and K_2O also stabilize the β form[101] which is then formed as large crystals[78]. Na_2O seems to diminish, even more than CaO, the probability of nucleation of γ C_2S. Very small numbers of Na atoms are sufficient to inhibit completely the $\beta \rightarrow \gamma$ inversion. The threshold of effectiveness seems to lie between 0·17 and 0·27% Na_2O but, contrary to Thilo and Funk's views, Yannaquis and Guinier[98], Niesel and Thormann[63] have shown that the alkalis are not essential for the stabilization of β C_2S.

Niesel and Thormann[63] have studied the solid solutions C_2S + MoO_3, C_2S + C_3A . Observations on the reaction products with the electron micro-probe have shown that there is formation of an envelope of $CaMoO_4$ or of an aluminous layer which hinders the $\beta \rightarrow \gamma$ transformation during rapid cooling (1000°C/minute)

but which breaks up during slow cooling ($10^{\circ}C$/minute) to permit the formation of grains of γ C_2S.

Yannaquis and Guinier[98] have reported, during the Fourth Symposium, the influence of pressure on the stabilization of the β form of C_2S. The $\beta \rightarrow \gamma$ transformation occurs more readily when the C_2S lattice is not modified, as is the case with the solid solution $C_2S.P_2O_5$ (1% $CaNaPO_4$). On the other hand, the silicates with a modified lattice, C_2S + 0·5% B_2O_3 or larnite (natural dicalcium silicate containing traces of Al_2O_3 or Fe_2O_3) give rise to no $\beta \rightarrow \gamma$ transformation under the influence of pressure. Either the crystals deform less or the formation of nuclei of γ is more difficult.

Belites in Clinker

In clinker, belite corresponds to a β C_2S with a lattice slightly modified by the addition of foreign ions. The XRD pattern of crystals of belite extracted from Portland cement clinker[55] is in general that of β C_2S. It shows, however, some reflexions which are broader and certain others slightly displaced. Belite is thus a product of imperfect crystallization and apparently a non-equilibrium composition. In the lattice of C_2S, Ca^{2+} can be substituted by Mg^{2+}, K^{+}, Na^{+}, Ba^{2+}, Cr^{3+}, Mn^{2+} and the $(SiO_4)^{4-}$ group by $(SO_4)^{3-}$ or $(SO_3)^{2-}$ [79].

If β C_2S is stabilized by an ion substituting for Si, it is stable when fired in reducing conditions[102]. On the other hand, under these conditions the $\beta \rightarrow \gamma$ inversion is easily produced in Ca-substituted preparations[102,73]. In a reducing atmosphere, Fe^{2+} can replace Ca^{2+} or another stabilizing ion, to form a solid solution FeO + C_2S and provoke dusting of the clinker.

The XRD pattern of belite is different from that of the solid solutions $C_2S + B_2O_3$. The theory of Mircea[103] that in clinker B_2O_3 reacts with C_3S to form CaO and a solid solution saturated with C_2S and C_5BS must be regarded as untenable.

Belite usually occurs as rounded, striated grains, with markedly laminated structure. The striations appear at the moment of the $\alpha - \alpha'$ transformations (Type I: singly orientated) and the $\alpha' - \beta$ (type II: doubly orientated)[104]. The usual form is β, and only occasionally does one find α'[105,106] or α[107].

The composition of belite is unknown; synthetic studies, by substitution for Ca (V, Ti, Na, K) or by addition of Al_2O_3, Fe_2O_3 to C_2S, have not given positive results.

Forest[108] has been able to prepare belites similar to those in clinker. These are oxygen-defective solid solutions with substituted Si of general formula $Ca_2M_xSi_{1-x}O_{4-x/2}$. The synthesis and crystallographic character of these belites form the subject of a communication to this Symposium.

INTERSTITIAL PHASE

The interstitial phase, visible between the C_2S and C_3S in micrographs of clinker (Figure 1) consists of two crystalline phases, generally referred to as C_3A and C_4AF. In reality, each of these phases can differ from the stoichiometric composition either by variation in the proportions of A and F or by the introduction of impurities in solid solution.

Tricalcium Aluminate

Structure of C_3A. Tricalcium aluminate is a definite composition which shows no polymorphic transformations[109]. It melts incongruently at 1542°C to form CaO and a liquid phase. The crystal lattice is cubic with a = 15·262 Å[110] but the structure is still unknown.

Büssem[111] proposes a structure based on measurements of the strontium isomorph. The structure is a lattice of planar AlO_4 groups and octahedra of both AlO_6 and CaO_6; but as shown by Ordway[112] the oxygen atoms all lie at x, y, z = 0 or $\frac{1}{2}$, and the sub-cell ($\frac{1}{8}$ the true cell) contains 8 calcium and no other ions inside the faces. Ordway[112] succeeded in growing a C_3A crystal and determined, using Laue and Weissenberg photographs, the unit cell and space-group (T_h^6 - Pa_3) which agree with Büssem's structure.

Schroeder and Lyons[113] have proposed a structure in which the AlO_6 groups are present as elongated octahedra, but Tarte[114] disagrees with this structure because it requires unusually large Al - O distances (2·6 Å). Further studies of C_3A by both

infra-red absorption and X-ray fluorescence[115,116] suggest that the aluminium/oxygen co-ordination is probably all tetrahedral.

A structure which is based on Al_6O_{18} rings of six tetrahedra has been proposed by Moore[117] with 64 Ca at the corners of the $a/_4$ lattice and a further 16 positions to be occupied by 8 Ca or 16 Na. Using diffractometer powder intensities and some of Ordway's single crystal data, least squares refinment has not given values of R below 40 %.

Solid solutions of C_3A: solid solutions $C_3(A_{1-x}F_x)$. Schlaudt and Roy[118], Tarte[119], Majumdar[120] and Moore[117] have reported the existence of solid solutions $C_3(A_{1-x}F_x)$. The limits of composition obtained for the solid solutions are different.

TABLE 5

Author	Experimental method	Temp. °C	x
Schlaudt and Roy	Optical examination of	1389	0·035

Tarte	Exact measurements of	1310	0·10
Majumdar	dimensions of lattice of	1325	0·07
Moore	the solid solution by	1350	0·04
	X-ray diffraction		

Figure 23

Figure 23 represents the variations of cell parameter a as a function of the molar percentage $\frac{C_3F}{C_3A + C_3F}$

These results show great differencies.

Although the methods and temperatures of preparation were different, Majumdar and Moore found that the parameter continued to increase slowly with iron content beyond the limiting compositions. These compositions have thus not reached their equilibrium state. In Tarte's work, on the other hand, the parameter is constant when the ratio $\frac{Fe}{Al + Fe}$ exceeds 10%.

Furthermore, the isomorphous replacement Al-Fe is accompanied, in the IR absorption spectra, by a change of position of bands, a more or less profound alteration in band profiles and the appearance of a new band which suggests the presence of tetrahedral FeO_4 groups.

Other solid solutions. In the lattice of C_3A, CaO can be replaced by Na_2O. Brownmiller and Bogue[121] found the composition $Na_2O.8CaO.3Al_2O_3$ in the Na_2O-CaO-Al_2O_3 system. Conwicke and Day[122], Fletcher, Midgley and Moore[123] proposed a limiting composition 91% C_3A, 9% N_3A (mol) which is close to NC_8A_3. The parameter a decreases with addition of Na_2O. At 3% (mol) Na_2O there is a discontinuous change of symmetry from cubic to orthorhombic[123].

A composition $K_2O.8CaO.3Al_2O_3$[91], isomorphous with $Na_2O.8CaO.3Al_2O_3$, exists in the presence of SiO_2; the K atom has a large ionic radius, 1·33 Å, (Na = 0·95 Å), and some Si (τ = 0·41 Å) would replace the larger Al ions (τ = 0·50 Å)[114].

The limit of solubility of MgO in C_3A is 2·5% (by weight) according to Muller-Hesse and Schwiete[124]. MgO substitutes for CaO, and the parameter a decreases[117]. Examination of Portland cement clinker in the electron-probe suggests that MgO

concentrates preferentially in the C_3A[125], at least when the C_3A is in the orthorhombic form.

In the solid solution $C_3A + SiO_2$, Si replaces Al. If one considers that the number of oxygen atoms remains constant, three atoms of Si replace four of Al, creating vacant sites[117]. The parameter a decreases and the limit of solubility is 5-6% $\frac{Si}{Al + Si}$ (atom %).

Alumino-Ferrite Phase

Hansen, Brownmiller and Bogue[126] showed that complete miscibility exists between C_2F and a hypothetical "C_2A" up to C_4AF.

(a) - C_2F : structure Bertaut, Blum and Sagnières[127] have determined the structure of C_2F. The unit cell is orthorhombic with parameters a = 5·64, b = 14·68, c = 5·39 and space group Pcmn, and contains 4 molecules of C_2F.

The structure is pseudo-tetragonal. Projections along a and c are very similar (Figure 24).

Figure 24

Along the b axis, a layer of FeO_6 octahedra alternates with a layer of FeO_4 tetrahedra; these tetrahedra and octahedra do not share oxygens. Ca is lodged in large cavities in the lattice of oxygen atoms and its co-ordination is very irregular; there are 9 neighbours, of which one is rather distant (3·3 Å), to share the

bonding. Cirilli and Burdese[128] and Malquori and Cirilli[129] proposed the space group Imma for the whole series of alumino-ferrite solid solutions. Bertaut, Blum and Sagnières[127] found weak reflexions which could not be indexed except in the space group Pcmn; the layers of octahedra have the symmetry Imma but slight changes in the tetrahedral layers and in the Ca atom positions reduce the symmetry to Pnma[130], (≡ Pcmn in Bertaut's orientation).

– Allotropic transformations of C_2F: Differential thermograms of C_2F give two signals, at 430°C and 690°C, with a very flat region between the two peaks[131]. The transformations are reversible with about 10° hysteresis.

We have attempted to determine the nature of these two allotropic transformations with the help of high-temperature X-ray diagrams. The transformation at 430° is linked with a discontinuity in unit-cell volume. At 690°, the curve of parameter variation shows a slight change of slope, the expansion being slower above 690°. The number of reflexions does not change and there seems to be no change of lattice.

(b) C_4AF. C_4AF or brownmillerite has the same lattice as C_2F. The orthorhombic parameters are a = 5·428, b = 14·760, c = 5·596 Å[130] but the space group is Imma. The complete structure, especially the role of A and F, has not yet been determined. Brownmillerite is one member of the solid solution series C_2F + "C_2A" and seems the most stable. Hansen, Brownmiller and Bogue considered C_4AF to be a definite compound.

(c) Aluminoferrite solid solutions. Solid solutions $C_2F_{1-p}A_p$: In C_2F, some of the Fe ions can be replaced by Al ions; these solid solutions are of the form $C_2F_{1-p}A_p$.

A study of these solid solutions by X-ray powder diagrams has enabled Woermann, Hahn and Eysel[131] to detect two discontinuities in the variation of parameters as a function of p, the molar fraction of Al Ions (see Figure 25).

Figure 25

But these discontinuities correspond to very slight changes of slope. The limit of solubility is reached at p = 0·70. Examination of differential thermograms shows that the temperature of the first signal at 430° decreases, as a function of alumina content, to 200° and disappears at p = 0·30. The temperature of the signal at 690° decreases similarly up to p = 0·2. From p = 0·2 to p = 0·5, two peaks are observed which disappear at p = 0·5. It is difficult to draw precise conclusions from this work; only the disappearance of the first signal at p = 0·30 seems to be linked with the change of symmetry from Pnma to Imma found by Smith[130] in his study of single crystals of composition $C_2F_{1-p}A_p$.

From the variations in intensity of characteristic h0l and 0k0 reflexions as a function of Al content, Smith[130] deduced that initially Al replaces tetrahedral Fe. When about half the tetrahedral sites are filled, Al enters both types of site equally. At about p = 0·33 the change of space group Pnma $\longrightarrow$ Imma occurs. This change involves a contraction and rotation of the tetrahedra, and displacement of the Ca atoms. The Al atoms are distributed about equally in tetrahedral and octahedral sites. The variation of parameters a, b and c as a function of p is continuous. In brownmillerite, $C_2A_{0·5}F_{0·5}$, approximately 75% of the Al atoms are substituted for

tetrahedral Fe and 25% for octahedral.

At the same time, Majumdar, in studying the phases in the pseudo-system CaO - $CaO.Al_2O_3$ - $2CaO.Fe_2O_3$, found that the liquidus temperatures for mixes on the hypothetical line C_2F - "C_2A" varied continuously as a function of the substitution Al^{3+} - Fe^{3+} in the ferrite lattice. C_3A and $C_{12}A_7$ appear when p is greater than 0·70.

In a study by infra-red spectra, of solid solutions $C_2A_pF_{1-p}$, Tarte[119] observed an increase in wave number and then, above $C_2A_{0.7}F_{0.3}$, no change, until at higher alumina contents, up to $C_2A_{0.85}F_{0.15}$, the position of certain lines changes again apparently due to the appearance of new phases such as C_3A and $C_{12}A_7$.

On the other hand, according to P. Longuet[132], the rate of reduction of C_4AF in a hydrogen atmosphere is regular as in the case of a definite composition. It seems that brownmillerite is the most stable member of the solid solution series $C_2A_pF_{1-p}$.

MgO-ferrite solid solutions: Magnesia enters into the ferrite lattice; normally red-brown, the latter becomes grey-black in the presence of MgO. It has been assumed for a long while that Mg substitutes for Ca but Woermann, Hahn and Eysel[131] have detected two types of solid solution. These authors used a precise analytical method to determine the free or uncombined CaO: the samples contained a small quantity of excess CaO; after the addition of a given percentage of MgO, the quantity of free CaO was determined and from the resultant curve, the type and the limit of solid solution were deduced.

The solid solution MgO-ferrite takes up more lime than the ferrite. According to the slope of the curve representing the change in free lime content as a function of added MgO, it appears that for 3 parts of MgO, 2 parts (molar equivalent) of CaO are combined; the limit of solid solution corresponds to the formation of periclase. The formula of the hypothetical end-member of the solid solution series is $Ca_2Mg_3O_5$ and the solid solution of Mg in C_2F is thus a substitution of Mg^{2+} for Fe^{3+}. Electroneutrality is maintained by the addition of an Mg ion in an interstitial position for every two Mg ions substituting for Fe. Hence, the type I solid solution:

$$Ca_2(Fe_{1-\frac{2}{3}x}Mg_x)_2O_5 \qquad o < x < 0{\cdot}023 \text{ at } 1400^{\circ}C$$

At about p = 0·50, only one part of CaO is combined to 3 parts of MgO. Woermann, Hahn and Eysel proposed a superposition of a type I solid solution upon a normal Ca - Mg substitution. In type II, $^1/_5$ of the Mg is substituting for Ca, while $^4/_5$ is in type I solid solution ($^8/_{15}$ replacing the trivalent Fe_2, $^4/_{15}$ in interstitial positions). Hence the formula:

$$(Ca_{1-\frac{x}{5}}Mg_{\frac{x}{5}})_2\,(R_{1-\frac{8x}{15}}Mg_{\frac{4x}{5}})_2\,O_5$$

The change from type I to type II occurs at about p = 0·49. The discontinuity in the substitution of MgO can be established in the crystal structure, suggesting a discontinuity in the ferrite solid solution series. The aluminoferrites $C_2A_pF_{1-p}$ corresponding to $p > 0{\cdot}5$ are unstable in the presence of free CaO. For this reason, Woermann, Hahn and Eysel did not extend their work to the whole solid solution series.

The MgO-ferrite solid solutions have also been studied by Kato[133], who finds that SiO_2 and MgO substitute for $(Al, Fe)_2O_3$ up to about 10% (molar). The substitution is of the melilite type.

SiO_2 alone can also enter into the ferrite lattice. The mechanism of SiO_2 solubility could be explained by the same type of substitution

(d) Interactions between the phases C_3A and $C_2(A,F)$.

C_3A and $C_2(A, F)$ constitute the interstitial phase of clinker. It is of interest to see whether, in synthetic preparations, these two phases can react to give solid solutions. This work, undertaken by Tarte[119] has shown the following results:

(1) Fe-Al exchange: in a mixture of $C_3A + C_4AF$, there is formed after heating to 1300°C a solid solution $C_3(A, F)$ resulting from the passage of a certain amount of iron from the C_4AF to the C_3A, this being compensated by the transfer of the equivalent Al from the C_3A to the C_4AF. The solid solution $C_3(A, F)$ has the limiting composition $C_3(A_{0.90}F_{0.10})$;

(2) Formation of poorly-crystalline phases: besides the displacements of characteristic XRD reflexions, Tarte[119] has observed in the solid solutions a simultaneous broadening of some of the high angle XR reflexions and of the infra-red absorption bands, when comparing a mixture of the two phases before thermal treatment with the same mixture after treatment. This effect is more marked when the mixture already treated at 1300° is taken to 1340°C.

Yet the same phases treated separately at the same temperature retain their IR spectra and XRD patterns perfectly sharp.

Tarte[119] has deduced that the state of crystallization of the phases obtained by mutual reaction is incomplete. This alteration of the crystallization is more marked at 1340°C, this being the temperature at which the majority of the mixture undergoes a partial fusion;

(3) Formation of a glassy phase: when the solid solutions have a high alumina content, a vitreous phase appears, the IR absorption spectrum of a sample of composition $C_2(A_{0.8}F_{0.2})$ taken to 1340°C is diffuse (Figure 26) and shows no XRD lines whatever. On the other hand, the crystallization

Figure 26

is complete when the Al/Fe ratio is close to 1.

The Interstitial Phase in Clinker

In Portland cement clinker, one finds tricalcium aluminate, the aluminoferrites and their respective solid solutions.

(1) C_3A. The tricalcium aluminate extracted from clinker has the lattice parameter a smaller than that of C_3A[117]. It is thus in the form of solid solutions due to the addition of impurity oxides such as Na_2O, K_2O, MgO, Fe_2O_3, SiO_2 but the concentration limits of these different additions are not known.

(2) Aluminoferrites. The composition of the ferrite phase in commercial cements depends as much on the thermal treatment as on the A/F ratio, in all cases where equilibrium is not reached[134].

Midgley[135] has observed broad lines in the diffraction patterns of clinker ferrites and attributes this broadening to the

fact that equilibrium could not be established in the course of cooling. Yamaguchi and Kato[136], Satou, Takashima and Kato[137] have both obtained less well-defined lines in patterns from clinker than in those from pure synthetic compositions.

The IR absorption bands of C_3A and $C_2(A, F)$ in clinker, easily observed in a sample synthesized at 1200°C, become more and more diffuse as the sample is taken up to 1300-1400°C. In certain clinkers, there exists a very diffuse absorption band which seems to be linked with the alumina content, and hence with the existence of a glassy phase[119].

Hansen, Brownmiller and Bogue[126] have shown that complete miscibility exists between C_2F and "C_2A" up to C_4AF. Numerous studies[138 to 142] thereafter have established that the ferrite phase in clinker is not necessarily of the composition C_4AF but may extend to the solid solutions richer in alumina, in which the ratio Al_2O_3/Fe_2O_3 reaches 2·2 to 2·3 ($p \simeq 0{\cdot}70$ in the series $C_2A_pF_{1-p}$).

Midgley[135] has studied the composition of the ferrite phase in fifteen English clinkers: 2 had the composition C_4AF, 2 had C_6AF_2, 4 an intermediate composition and the remainder an ill-defined composition (broadened XRD lines) but always lying between C_6AF_2 and C_6A_2F.

In American clinkers, Copeland, Brunauer, Kantro, Schultz and Weise[143] found that the compositions of the ferrites lay

between $C_6A_{1.22}F_{1.78}$ and $C_6A_{1.77}F_{1.23}$. The mean value $C_6A_{1.47}F_{1.53}$ is very close to brownmillerite.

Gourdin[144] has analysed by XR diffraction the ferrite phase from 15 French cements; four clinkers contained the composition C_4AF, one contained C_6AF_2, and the other 8 an intermediate composition very close to C_4AF.

Schwartz[145] separated out the aluminoferrite phase from 66 French clinkers, by the salicylic acid in methanol method of Takashima[146]. The aluminoferrite phases separated out had a chemical composition much more complex than the interstitial phase calculated by the Bogue method. The analyses, by X-ray fluorescence spectrometry, revealed a stoichiometric defect in CaO which reached as much as 5%. This lime deficiency increased if one included K_2O, Na_2O and MgO and diminished if one included SiO_2. The solubility limits of the minor elements in the interstitial phase were determined as 3% K_2O, 4% MgO, 7% SiO_2.

To conclude, C_3A and $C_2(A, F)$ cannot co-exist as such in clinker. Exchange of Al_2O_3 and Fe_2O_3 occur easily in the aluminates and aluminoferrites. Furthermore, at 1300°, a small amount of iron will convert from the ferric to the ferrous state[120,147]. The presence of ferrous oxide noticeably modifies the stability regions of the solid solutions[148]. The solid solutions $2CaO\ (Al,Fe)_2O_3$ decompose in the presence of CaF_2 and $CaCl_2$[149].

CONCLUSION

Properties of the Clinker Minerals

We have considered the structures of the various polymorphs of the principal clinker components and there is a correlation between the crystalline structures of these components and the hydraulic properties of the clinker.

1) C_3S. Of all the phases in clinker, it is the tricalcium silicate which is the most significant and important from the point of view of the hardening of cements[150]. The hydraulic cementing properties of C_3S are associated with the poor co-ordination of calcium ions and the presence of 'holes' in the crystal lattice[21]. We have shown that the crystal structures of the different forms of C_3S and its solid solutions are very close to that of the trigonal form of pure C_3S stable at high temperatures. On the other hand, differences in the relative intensities of the diffracted rays are scarcely noticeable. The different crystalline forms are thus constructed from the same atomic groupings. These are only very slightly displaced or distorted. The polymorphic transformations are 'displacive', they bring into play only weak forces and do not appreciably alter the chemical combinations[151]. This results in all the forms having a similar reactivity. Nurse, Midgley, Gutt and Fletcher[152] have found that the transformations $T_I \rightarrow T_{II} \longrightarrow M$ of the synthetic solid solutions $C_{156-x}M_xS_{52}$ have no effect on the strengths developed when these materials hydrate. In the same manner, the strength of commercial cements

containing trigonal alite does not differ significantly from that of cements in which the alite is in the monoclinic form. Yamaguchi, Shirasuka and Ota[153] have compared the properties of monoclinic and trigonal alite. Monoclinic alite (inverse) hydrates more rapidly. It is obtained by rapid cooling and seems to be thermodynamically unstable. If subjected to gentle heating it is converted into the triclinic form which by contrast gives greater early strength[154]. Verbeck[155] has shown that the introduction of alumina and magnesia into tricalcium silicate brings about a significant increase in early strength but the effect does not persist beyond 70 - 80 days. The introduction of other foreign ions such as P_2O_5[156], SO_3[157], $CaSO_4.2H_2O$ and $CaCl_2$[158], Cr_2O_3[159], can modify the properties of C_3S but the changes in reactivity do not seem to correlated with changes in structure[160]. An increase in size of the alite crystals is generally observed.

2) $\underline{C_2S}$. The four forms of C_2S have, on the other hand, quite different structures. The lattices are different and the ionic groupings change from one form to another. One can therefore reasonably presuppose that the four forms will have different hydraulic properties.

In the β form, the polyhedral co-ordination of the Ca ions is irregular and the extra-long Ca-O bonds facilitate the hydration reaction. Similarly, because of its predisposition to undergo a major structural re-arrangement[64], metastable β C_2S is more readily hydratable. The γ form of C_2S is known to be inert[79] or feebly hydraulic[161]. This poor reactivity is

associated with the symmetrical co-ordination of the calcium ions[21] and the strong Ca-O bonds arising from the low co-ordination number of the Ca ions[64].

The α' form of C_2S is only hydrated with difficulty and seems to possess no hydraulic cementive power[79].

The minor constituents of clinker which stabilize the different forms of C_2S can affect the relationship between the hydraulic cementive characteristics of belite[40,162,163] and its other properties[164].

3) Interstitial phase. Tricalcium aluminate reacts rapidly with water. Calcium aluminoferrite is only feebly hydraulic.

However, during the clinkering process, the burning temperature, the method of clinker cooling, the interaction of C_3A with the ferrite phase, the presence of foreign ions and the formation of a vitreous phase all alter the phase equilibrium conditions and so change the properties of the clinker in respect of the kinetics of its reactivity towards water[119].

Acknowledgments

We gratefully acknowledge the assistance of the many research-workers who have communicated their results to us, and especially those who have allowed us to read their papers before publication :

			Possibly doubling of a and b				
20	Triclinic T_I	14.080	14.147	25.103	90.30	89.77	119.53

Table 3

Characteristic properties of the transitions in pure $Ca_3Si_2O_5$

Transition temperatures (°C)	Characteristic effects		Type of transition *	Allotropic form	Space group
	X-Ray	D.T.A.			
1050	Change of symmetry, continuous deformation of the cell	No peak	Type a continuous	Rhombohedral (R)	R3m
				Monoclinic II (M_{II})	C1m1
990	No change of symmetry, change of cell volume	Very small reversible peak	Type a discontinuous	Monoclinic I (M_I)	C1m1
980	Change of symmetry, change of cell volume; superstructure : doubling of a and b to 14 Å	Strong reversible peak	Type a + b discontinuous	Triclinic III (T_{III})	C1
920	No change of symmetry, no change of subcell volume; (possibly second superstructure)	Strong reversible peak	Type b discontinuous	Triclinic II (T_{II})	C1
600	No change of symmetry, small deformation of the cell; possibly second superstructure	Broad reversible peak	Type a discontinuous	Triclinic I (T_I)	C1

* Type a : with decreasing temperature the degrees of freedom of the thermal vibrations are reduced thus leading to discontinuous or continuous changes in cell volume. The structural groups are slightly deformed but their periodicity is unaffected.

Type b : upon cooling, in the arrangement of the groups, regular stacking faults perpendicular to the c axis are produced, leading to the formation of superstructures but not affecting appreciably the volume of the subcell.

Explanatory Notes

Abbreviations.

The following symbols, which have been universally recognized by cement chemists for formulating more complex compounds, are used interchangeably with the respective oxide formulas throughout this book:

$C = CaO$, $S = SiO_2$, $A = Al_2O_3$, $F = Fe_2O_3$, $M = MgO$, $N = Na_2O$, $K = K_2O$, $H = H_2O$,

Less common abbreviations of this type are defined as they occur.

Commonly used abbreviations of more general nature are as follows:

DTA = differential thermal analysis
EPMA = electron probe micro analysis
IR = infrared
NMR = nuclear magnetic resonace
psi (or p.s.i.) = pounds per square inch
rh (or RH) = relative humidity
w/c (or W/C) = water – cement ratio
XRD = X-ray diffraction

Identification Number of Supplementary Papers

Example: Supplementary Paper III—50, III is session III and 50 is the arrival number of contribution. This number coincides with the number used in the preprint of papers distributed in advance of the symposium.

Principal Paper The Calcium Silicate Hydrates

H. F. W. Taylor*

Synopsis

This paper reviews progress on structural and phase equilibrium aspects of the calcium silicate hydrates and some related substances, under the following headings:

Introduction
New experimental techniques
Crystal structures: general points
Crystalline calcium silicate hydrates: new data
Crystalline calcium silicate hydrates: equilibria and conditions of formation
Crystalline calcium silicate hydrates with additional ions
Poorly crystalline calcium silicate hydrates
Paste hydration of C_3S and β–C_2S
Isomorphous substitution

The paper deals only with progress made since the Washington Symposium, and familiarity with the state of knowledge as summarized in the proceedings of the latter is assumed.

It is suggested that the evidence relating the hydration products formed in calcium silicate or cement pastes to tobermorite is weak and that the term "tobermorite gel" should not be used.

Introduction

In this paper, we shall review work on the structures, properties, and phase equilibria relating to the calcium silicate hydrates and some related compounds since the time of the Washington Symposium. It will be assumed that the reader is familiar with the state of knowledge at that time, as summarized in the proceedings (1). We shall deal only incidentally, if at all, with the kinetics, energetics and mechanisms of reactions yielding calcium silicate hydrates, and with the microstructures of calcium silicate or cement pastes and their relation to physical and mechanical properties.

Table 1 gives the names and compositions (in some cases, approximate) of the better established crystalline calcium silicate hydrates, and of some other related, crystalline phases that will be mentioned in this review. Not included in Table 1 is an indefinite range of semicrystalline and near-amorphous calcium silicate hydrates, which are nevertheless of great importance to cement chemistry. Their C/S ratios probably range from 0.5 to 3.0, and their H/S ratios from zero to about 2.0.

New Experimental Techniques

The Electron Microprobe

Since the time of the Washington Symposium, the electron microprobe has become a tool of major importance in the study of anhydrous systems. Its applications in the field of hydrated compounds are probably more limited, but it has been used to establish the compositions of some newly discovered calcium silicate hydrate minerals (2), and also in synthetic investigations (3).

X-ray Spectroscopy

The wavelengths of the characteristic X-rays emitted by an atom are influenced by the configuration of its valence electrons and its surroundings, and can therefore provide information on such matters as oxidation state, coordination number, bond lengths, and order-disorder effects. Unlike X-ray diffraction, the method is not affected by the degree of long-range order, and can therefore be used for amorphous as well as crystalline substances. X-ray spectra of silicates are conveniently studied either by fluorescence techniques, or by electron-excited emission using the electron microprobe.

The first applications of X-ray spectroscopy to silicate structures were concerned with aluminium coordination, White, McKinstry and Bates (4), Brindley and McKinstry (5) and Day (6) showing that four and six coordination could be distinguished in this way. Applications to Al-substituted calcium silicate hydrates are mentioned later in this review. Another application of X-ray spectroscopy, also mentioned later, concerns the environment of sulphate groups substituted in a silicate structure. Lastly, White and Gibbs (7) have shown that the method can be used to provide information on mean Si–O bond lengths and thereby on the degree of condensation of silicate anions. This has not yet been applied to calcium silicate hydrates, but should afford a valuable check on the chemical methods discussed below.

Chemical Methods for Studying Degrees of Anion Condensation in Silicates

Murata (8) showed that the behaviour of silicate minerals with acids was related to the degree of condensation of the anion. If the anion was of low molecular weight, as with ortho- and pyrosilicates and framework structures containing much tetrahedral aluminium, gelatinuous silica was formed; silicates with highly condensed anions, in contrast, yielded silica pseudomorphs. Subsequently, various attempts have been made to identify the anions in silicates more precisely by attacking the solids with acids under conditions that would break the bonds between metal cations and oxygen, while leaving the silicon-oxygen bonds intact, followed by identification of the resulting silicic acids. Such conditions are difficult to achieve with certainty, and the problem is further complicated by the fact that the silicic acids tend to condense to form larger units. Three methods have been developed recently in attempts to overcome these difficulties, and each has been applied to calcium silicate hydrates.

(i) Lentz (9, 10, 10a) decomposed the silicate in a solution containing HCl, hexamethyldisiloxane ($Me_3SiOSiMe_3$), isopropyl alcohol, and water. The hexamethyldisiloxane decomposed to give Me_3SiOH and Me_3SiCl, which in turn reacted with the silicic acids to yield esters. These were identified by gas chromatography; it was assumed that esterification occurred rapidly enough to forestall changes in the silicic acids, and that the esters were themselves stable. In practice, condensation of the silicic acids was not entirely avoided, orthosilicates such as olivine or C_3S yielding appreciable proportions of the pyrosilicate ester as well as that of the orthosilicate. On the other hand, it is possibly more widely applicable than either of the other methods.

(ii) Funk and Frydrych (11) and Funk (12) decomposed the silicate in methanolic HCl. This reagent was preferred to aqueous HCl because the silicic acids were more soluble and had a much lower condensing rate. The solution was then mixed with an aqueous molybdic acid solution and the rate of formation of the molybdosilicic acid followed by a volumetric methods. Previous investigators had shown that the molybdic acid reacts only with orthosilicic acid; the rate-determining step if condensed silicic acids are present is their hydrolysis to orthosilicic acid. The method was shown to give satisfactory results for a number of silicates containing alkali or alkali earth cations, including Ca^{2+}, but to be less satisfactory in the presence of Mg^{2+} or Al^{3+}.

(iii) Thilo, Wieker and Stade (13) and Wieker and Stade (14) added the finely powdered silicate directly to an acidified, aqueous solution of ammonium molybdate and followed the rate of formation of the molybdosilicic acid spectrophotometrically. The method can be applied only if dissolution of the silicate is sufficiently rapid. It was shown to give satisfactory results for a number of alkali and alkali earth silicates.

It would be premature to attempt to assess further the relative merits of these three methods, applications of which to calcium silicate hydrates are metnioned later in this review.

Crystal Structures: General Points

The main principles governing calcium silicate structures were established by the time of the Washington Symposium, and will only be briefly summarized here. The metal cations play an essential part in controlling the manner in which SiO_4 tetrahedra condense; anions similar to those found in the pyroxenes, amphiboles, and micas do not occur in calcium silicates, because they do not fit onto the bands or sheets of linked CaO_6 octahedra. In contrast, anions of the types found in wollastonite or xonotlite occur, because they fit onto these bands or sheets.

Belov (15) has since emphasized the important role in many calcium silicate structures of the pyrosilicate group, which is of the correct size to bridge two corners of a CaO_6 octahedron. The essential feature of such structures is therefore the occurrence of lines of Si_2O_7 groups (Fig. 1a), and the linkage of these in some cases into wollastonite-type chains by the interpolation of additional tetrahedra (Fig. 1b) is almost incidental. Below drew attention to the frequent occurrence of structures based on lines of Si_2O_7 groups condensed with puckered sheet or three-dimensional nets of linked CaO_6 octahedra, as in tilleyite ($Ca_5(Si_2O_7)(CO_3)_2$) and cuspidine ($Ca_4(Si_2O_7)F_2$).

These structures are interesting, not only because they illustrate structural principles that apply to other crystalline calcium silicates, but also because they suggest a possible way in which deterioration of crystallinity and variation in composition could occur. It would appear possible for some of the silicon atoms in a wollastonite chain (up to one in three in extreme

cases) to be omitted, thus decreasing the chain length and increasing the C/S ratio, without basically destroying the structure. This accords with the hypothesis advanced by Taylor and Howison (16) and developed in a modified form by Brunauer and Greenberg (17) to explain the variable C/S ratio in the poorly crystalline calcium silicate hydrates. As is discussed later in this review, even relatively highly crystalline tobermorites, of both synthetic and natural origin, appear frequently to be deficient in silicon, and the same explanation may well apply.

Mamedov and Belov (18) have noted that close similarities exist between certain borate and silicate structures; thus warwickite ($Mg_3Ti(BO_3)_2O_2$) is structurally very similar to cuspidine. Two BO_3^{3-} groups in warwickite occupy a position analogous to that of an $Si_2O_7^{6-}$ group in cuspidine (Fig. 1a and c). Mamedov (19) has pointed out that the similarity extends to some carbonates, such as malachite ($Cu_2(CO_3)(OH)_2$). These relationships are interesting because they suggest a way in which small amounts of CO_3^{2-} or BO_3^{3-} could enter the structures of silicates containing chains of the wollastonite or similar types. Such substitution appears to occur in several cases, such as xonotlite, scawtite and tobermorite. If it occurs in the way suggested here, it would be at the expense of silicon and would thus cause a break in the silicon-oxygen chain.

It is inherent in the ideas developed above that the anions in many long-chain calcium silicate hydrates are in reality probably often far from infinite in length, as the idealized crystal structures would indicate. A distribution of chain lengths presumably exists. The new experimental techniques mentioned in the previous section should permit this hypothesis to be tested.

The essential role of metal cations in controlling the condensation of SiO_4 tetrahedra leads to a prediction as to the mechanism whereby calcium silicate hydrates precipitate from solution. It is surely not correct to regard the condensation of the SiO_4 tetrahedra as the primary process, with the metal cations only becoming involved later, for if this was so, anions entirely inappropriate to the structure might well be formed. It is much more likely, either that condensation of SiO_4 tetrahedra and of metal cation—oxygen polyhedra occur simultaneously, each process influencing the other, or alternatively, that the metal hydroxide sheets are formed first and act as a matrix for subsequent condensation of the SiO_4 tetrahedra. This latter view has been argued in the analogous case of the clay minerals (20). If the language of polymer chemistry is adopted, it is misleading to regard the formation of a complex silicate primarily as a case of condensation polymerization of the silicate anions. It is at least as important, perhaps more important, to regard the process as one of coordination polymerization in which the metal cations play an essential part.

Crystalline Calcium Silicate Hydrates: New Data

Nekoite, Okenite, Xonotlite, Foshagite and Hillebrandite

These compounds, in common with wollastonite, the crystalline tobermorites, and some calcium silicate hydrates containing additional ions, have 7.3 Å repeat distances in one direction and are known or believed to have structures containing wollastonite-type chains. Little new information of significance has emerged about any of them since the Washington Symposium, and foshagite (21) and xonotlite are still the only two of which the crystal structures have been determined. A new analysis of nekoite (22) shows the composition to be $C_3S_6H_8$ and not $C_3S_6H_6$ as previously reported. Nekoite and okenite remain unsynthesized. Polytypism (occurence of stacking modifications of the same, basic structure) in xonotlite and foshagite has been studied using selected area electron diffraction, and a system of nomenclature devised to designate the polytypes in these and similar cases (23, 24). The formula of xonotlite is still generally written as C_6S_6H, although, as was pointed out at Washington (25), published analyses and weight-loss curves of both natural and synthetic specimens suggest a slightly higher water content. The formula is perhaps better written as C_5S_5H, or $Ca_6Si_6O_{17}(OH)_2 \cdot O \cdot 2H_2O$. Thilo, Wieker and Stade (13) and Wieker and Stade (14) have applied the chemical method previously mentioned to determine the degree of anion condensation in hillebrandite. They concluded (14) that single metasilicate chains were present; this does not support the structure postulated on unit-cell evidence by Mamedov and Belov (26).

Crystalline Tobermorites

14 Å tobermorite, previously known to occur in

nature only as a constituent of intergrowths with other minerals, has now been found pure at Crestmore, California (27). An X-ray, infrared, and thermal decomposition study of this specimen has been reported (28). The composition approximates to $C_5S_6H_9$, with small amounts of B_2O_3 and CO_2; the borate probably occurs as planar BO_3^{3-} ions, which, along with the CO_3^{2-}, probably replace parts of the metasilicate chains as suggested earlier in this review. At 55 ± 5°C there is a sharp loss of water, and an 11.3 Å tobermorite, of approximate composition $C_5S_6H_5$, is formed. This gradually loses water at 55–220°C; the X-ray pattern remains sharp up to about 120°C, but thereafter becomes progressively more weak and diffuse, and at 200–220°C both 11.3 and 9.35 Å tobermorites are present. The 11.3 Å tobermorite can probably lose part of its water before collapse to the 9.35 Å form occurs, and this is reflected by slight changes in X-ray pattern and infrared absorption spectrum. The weight-loss curve shows a step corresponding to the approximate composition C_5S_6H at 250–450°C and it was concluded that the 9.35 Å tobermorite has this definite composition; the higher water contents indicated by some earlier studies appear to be in error, at least for the product obtained from the Crestmore mineral. At 450–650°C, the remaining water and the CO_2 are lost, and the basal spacing gradually *increases* again, to 9.7 Å. This can perhaps be attributed to the condensation of SiOH groups in chains of adjacent layers to form new SiOSi links, which might be expected to cause some change in packing. The 9.7 Å phase thus has the approximate composition C_5S_6. At 730–770°C, it changes topotactically (*i.e.*, with partial preservation of crystalline order) to an imperfectly crystalline wollastonite. Crystallization of wollastonite is completed at 850–900°C.

The C/S ratio of 11.3 Å tobermorite can range from the idealized value of 5:6 to about 1.0 (29) or possibly somewhat higher. It is suggested that C/S ratios above 5:6 arise through omission of Si rather than incorporation of extra Ca. If this is so, one would expect increase in C/S ratio to be accompanied by decrease in chain length and probably also by decrease in layer thickness. Funk (12) reported some results that suggest that increase in C/S ratio is in fact accompanied by decrease in chain length. He made three autoclaved preparations at 150°C with C/S ratios of 0.81, 1.01 and 1.1, all of which he showed to consist of 11 Å tobermorite mixed with xonotlite, and determined the proportion of the total silica extracted by methanolic HCl in each case. The proportions increased from zero for the 0.81 C/S preparation, to 6% for the 1.1 C/S preparation. He obtained similar but more detailed results for preparations of C–S–H (I), which can probably be considered a structurally degenerate tobermorite; these are described later. The layer thicknesses of natural and synthetic tobermorites range from about 11.0 to about 11.5 Å, but it is difficult to distinguish the contributions to this variation from variations in C/S ratio, H/S ratio, and Al substitution; research into this would be of value. With C–S–H (I), the layer thickness seems definitely to decrease with increasing C/S ratio (30).

Lentz (10a) used his extraction method to study a mixed 14 Å–11.3 Å tobermrite from Crestmore. He found that about one-half of the total SiO_2 occurred in anions containing a mean of 28 terahedra, and that, of the rest, most was insoluble in acid and thus presumably more highly condensed.

No new information of significance seems to have been reported for the crystalline 10 Å and 12.6 Å tobermorites that occur in nature in intergrowths at Crestmore (31, 32). The 10 Å form occurs intergrown with 14 Å tobermorite, and on heating yields 9.3 Å tobermorite (32); it is therefore most unlikely to be identical with the anhydrous 9.7 Å form mentioned previously. It is possibly a lime-rich variety with substantial deficiency of silicon. The anomalous characteristics of certain 11.3 Å tobermorites, such as that from Loch Eynort, Scotland, also remain unexplained.

Tacharanite

A new mineral, named tacharanite, was reported as a natural mineral from Skye, Scotland, by Sweet (33) and may belong to the tobermorite group. It is particular interest because its composition and X-ray powder pattern are nearer to those to C–S–H (I) than are those of any other *crystalline* calcium silicate hydrate (the natural mineral, plombierite, which is semi-crystalline, is virtually identical with C–S–H (I) (34)). Tacharanite was found only in milligram amounts, in amygdules in dolerite in association with tobermorite, gyrolite, saponite, calcite and various zeolites. Chemical analysis indicated the approximate composition $0.86CaO \cdot SiO_2 \cdot 1.21H_2O$ with some Al_2O_3 and MgO. The mineral was cryptocrystalline and had a mean refractive index of 1.537 and a density of about 2.36 g cm^{-3}. X-ray powder data and a weight loss curve were also given; the water was lost gradually over the range 100–1000°C though the curve showed slight arrests at 350° and 650°C. Sweet reported that, on exposure to air, the mineral changed

to give tobermorite and gyrolite, and suggested that it might be the parent mineral from which these had been formed.

A few mg of the mineral were kindly made available to the author for study. Part of this sample was heated successively at 50° (6 hr.), 110° (15 hr.), 160° (15 hr.), 260° (5 hr.), 400° (5 hr.), 580° (4 hr.), 700° (15 hr.), 800° (2 hr.) and 1000°C (2 hr.); after each period of heating, the material was cooled to room temperature and an X-ray powder pattern obtained. The X-ray pattern of the original mineral agreed well with that reported by Sweet. No significant changes were observed up to 700°C. The 800°C sample gave a modified pattern, still recognizably similar to that of the original mineral; the 1000°C sample gave a pattern of wollastonite.

These results are not easily reconciled with Sweet's observation that the mineral changes spontaneously in air to gyrolite and tobermorite; the total time occupied by the series of heating periods and X-ray exposures was about one week. Further study of tacharanite would be of much interest but is restricted by the extreme scarcity of material. Attempts by the writer and others to find more material at the original locality have been unsuccessful.

Suolunite

This name was given to a new hydrated calcium silicate mineral which was reported from Inner Mongolia by Huang (35). As the original note describing the mineral is in Chinese, and the composition of the latter is in a range of great importance to cement chemistry, the main observations will be reported here in some detail. The mineral was found as a narrow vein cutting into a diabase vein in the centre of an ultrabasic rock body; the name was derived from the locality. Chemical analysis gave SiO_2 43.38, CaO 42.95, H_2O^+ 13.17 (total 99.50), corresponding to the formula $CaO \cdot SiO_2 \cdot H_2O$. The X-ray powder pattern was not given in full, but was reported to have strong peaks at 4.03, 3.11 and 2.80 Å. The mineral was reported to form transparent, colourless, rod-like or granular crystals, with no definite cleavage; optical properties were $\alpha = 1.610$, $\beta = 1.620$, $\gamma = 1.623$, $-2V = 30$–$50°$ (a later paper gives 30–35° (36)). DTA curves showed a strong endotherm at 440°C. The unit cell was orthorhombic, with a 11.15, b 19.67, c 6.08 Å, space group F dd2; specific gravity 2.683, $Z = 16$. The subsequent paper (in English) by Tseng, Hsüeh and Peng (36) reports a crystal structure determination. The structure contains Ca^{2+} and $(Si_2O_7)^{6-}$ ions and oxygen atoms not directly bonded to silicon; it was suggested that the ionic constitution might be $Ca_2H_2(Si_2O_7) \cdot H_2O$ or $Ca_2H_4(Si_2O_7)O$. The calcium ions are 8-coordinated, and the axes of the Si_2O_7 groups lie in two directions in the ab—plane.

These results indicate that suolunite is quite different from any other calcium silicate hydrate, natural or synthetic; it does not even appear to be closely related to any of the other compounds. The occurrence of a new phase of this composition and the fact that it does not appear to have been obtained in any of the numerous synthetic studies are of the greatest interest. The results are also of considerable crystal chemical interest, in that they appear to demand the presence of pyrosilicate ions containing Si–OH groups ($Si_2O_5(OH)_2^{4-}$ or, less probably, $Si_2O_3(OH)_4^{2-}$), which have not hitherto been reported. Further information, including especially the complete X-ray powder pattern, would be of great interest.

Rosenhahnite

This phase was originally reported as a synthetic product by Pistorius (37) and has subsequently been found to occur in California as a natural mineral by Pabst, Gross and Alfors (38). It has the composition $3CaO \cdot 3SiO_2 \cdot H_2O$ and forms only at high pressures. Pistorius obtained it at pressures of about 25–50 kilobars and temperatures around 400°C; at lower pressures, it was prelaced by xonotlite and at higher temperatures by wollastonite. Pabst, Gross and Alfors (38) determined the unit cell and the optical properties, and also studied the morphology and behaviour on heating. They found that it was slowly converted to wollastonite at 400–500°C in air, the latter being formed in an unusually perfect topotactic relation.

The unit cell does not indicate any close relation to other calcium silicate hydrates. The phase is thus of considerable general crystal chemical interest, although it does not appear to be of direct importance to cement chemistry.

Gyrolite and Related Phases

Suggestions have been made that the formula of gyrolite is $C_3S_4H_3$ (39) or CS_2H_2 (40), but a careful synthetic study, together with an appraisal of the analyses of natural specimens, led Harker (41) to conclude that the generally accepted formula $C_2S_3H_2$ agrees better with the evidence. More recently, Cann (42) concluded from a study of a newly discovered natural specimen from Scotland that the idealized

formula is $Ca_{16}Si_{24}O_{60}(OH)_8 \cdot 14H_2O$, or $C_8S_{12}H_9$. This is perhaps the most satisfactory formula yet proposed. Harker (41) found that molecular water lost on static heating at 215°C was resorbed on treatment with boiling water. The ready loss and regain of molecular water, which recalls the behaviour of zeolites, may explain the difficulty in assigning an exact H/S ratio to this phase.

Gyrolite has been shown to exhibit polytypism, two- (39), three- (42) and six- (43) layer modifications all having been reported. Stacking mistakes are frequent (40, 41, 43). These effects may be expected to cause slight variability in the X-ray powder pattern.

There has been some uncertainty over the use of the names reyerite and truscottite. Strunz and Micheelsen (39) and Meyer and Jaunarajs (40) concluded that the natural minerals originally described by these names were identical, and if this is accepted, the name reyerite has priority. However, subsequent work by Chalmers, Farmer, Harker, Kelly and Taylor (44) showed that small but distinct differences exist in the layer thickness, which is about 19.0 Å for reyerite and 18.7 Å for truscottite, and in infrared spectrum. The minerals from Greenland (44) and from Scotland (42, 44) were shown on these criteria to be reyerite, while those from Sumatra and from Japan were shown to be truscottite. Chemical analysis of the Greenland mineral indicated the idealized formula $KCa_{14}Si_{24}O_{60}(OH)_5 \cdot 5H_2O$ and it was concluded that potassium was probably an essential constituent of reyerite, as opposed to truscottite. Cann (42) concluded from a chemical analysis of the Scottish mineral that the latter had a similar composition, but with considerable isomorphous replacement, including some Na^+ for K^+, $4OH^-$ for SiO_4^{4-} and possibly $(Al^{3+} + OH^-)$ for $(Si^{4+} + O^{2-})$.

Truscottite appears to contain no essential components other than CaO, SiO_2 and H_2O; synthetic preparations containing only these components have been shown to resemble truscottite rather than reyerite (44). The exact composition of truscottite has been a matter of some controversy. Analyses of the Sumatra mineral are difficult to interpret, mainly because the mineral is closely admixed with quartz. They have been held to support formulas ranging from C_2S_4H (45, 46) to C_3S_4H (39). Meyer and Jaunarajs (40) concluded from work on synthetic preparations that the composition was C_2S_4H, but their evidence appears to show only that the Ca:Si ratio is between 0.5 and 0.67. There appears to be no evidence for a Ca:Si ratio above 0.67. Funk (47) also concluded from work on synthetic preparations, which included determinations of unreacted silica by a chemical extraction method, that the composition was C_2S_4H. In contrast, Harker (41, 48) found that, in equilibrium preparations of bulk Ca:Si ratio 0.5, truscottite was always accompanied by significant amounts of silica; he obtained it pure, in sealed systems, only at bulk Ca:Si ratios of 0.57–0.60. He also reported thermal weight-loss curves, and concluded that the idealized formula was $C_6S_{10}H_3$.

Neither of these formulas is easily reconciled with crystallographic data. By analogy with gyrolite and reyerite, the presence of the $Si_{24}O_{60}$ grouping in the unit cell might be assumed. To yield this, Harker's formula must be written $Ca_{14.4}(Si_{24}O_{60})(OH)_{4.8}(H_2O)_{4.8}$. It is tempting to approximate this to $Ca_{14}(Si_{24}O_{60})(OH)_5(H_2O)_5$, which would be in accordance with the very close resemblance to reyerite; however, this gives an X-ray density of 2.57 g cm^{-3}, which is well above the range (2.36–2.48) of observed values. The formula C_2S_4H, on the other hand, appears to indicate the cell contents and constitution $Ca_{12}(Si_{24}O_{60}) \cdot 6H_2O$. This gives a more satisfactory X-ray density of 2.41 g cm^{-3} (the value of 2.47 g cm^{-3} given by Heller and Taylor (31) is wrongly calculated), but the implied absence of hydroxyl water does not agree with the infrared (44) or thermal weight-loss (41, 46) evidence. The position is further complicated by the possibility of appreciable substitution of 4H for Si, as was postulated for the Scottish reyerite (42). The idealized formula must therefore still be regarded as uncertain, though it would appear definitely to lie within the range C_2S_4H–$C_6S_{10}H_3$. A variable composition does not seem to be ruled out.

Harker (41) reported the formation of mixed-layer crystals of gyrolite and truscottite in some of his preparations. Gyrolite, truscottite, and reyerite all yield pseudowollastonite on heating at 800°C; (44, 47) an earlier observation (46) that truscottite behaves differently is incorrect.

Assarsson (49) described a product of approximate composition CS_2H_2 (or CS_2H_3) which he called Z-phase, this appears (25) to be essentially similar to one which Funk and Thilo (50) considered to be $CaH_4Si_2O_7(CS_2H_2)$. This product, which is especially characterized by an X-ray powder spacing of about 15 Å, has been further studied by Funk (47), Harker (41) and Wieker (51). Harker concluded that the composition was uncertain but that the phase was richer than gyrolite in both SiO_2 and H_2O. Funk (47) recorded new X-ray powder data, electron micrographs, and DTA curves, and concluded that material dried over silica gel had the composition $C_2S_4H_3$. Some loosely held, molecular water may well have been lost

by this drying technique. Electron micrographs showed crumpled foils resembling those of C–S–H (I), but the powder pattern was distinct from that of the latter and it appears likely to the present author that the phase belongs structurally to the gyrolite group. Wieker (51) concluded from application of the chemical method mentioned earlier (13, 14) that layer silicate anions were present; this supports the above conclusion.

Kilchoanite and Related Phases

A phase substantially identical with the "Phase Z" of Roy (52, 53) has been found to occur as a natural mineral and named kilchoanite (54). This phase is entirely different from the Z-phase mentioned previously and, to avoid confusion, the mineral name is to be preferred. The crystal data reported at the Washington Symposium for the synthetic material (25) have since been reported more fully (55, 56) and closely similar data have been given for the natural mineral (54). The preparations originally described by Roy had the composition C_9S_6H (53), but the natural mineral, as well as synthetic preparations made at about 700°C (55), are anhydrous. The anhydrous phase thus appears able to accommodate a little water in its structure. Some further data bearing on this problem have been published (56), but the explanation of the effect must await determination of the crystal structure.

At the Washington Symposium it was suggested that the material generally known as γ-dicalcium silicate hydrate of $C_2SH(C)$ was probably a mixture of calciochondrodite with a lime-rich, hydrous variety of kilchoanite (25). Further work (56, 57) has confirmed that the material is a mixture having calciochondrodite as one major constituent. The other major constituent is a previously unrecognized phase which has the idealized composition C_8S_5; in addition, xonotlite seems usually also to be present as a minor constituent.

C_8S_5 has not yet been obtained pure, but can be obtained mixed with other phases by hydrothermal treatment of γ-C_2S-quartz mixtures over a wide range of conditions (56, 57). In its ordered form, it appears to have a crystal structure consisting of alternate slabs of γ-C_2S and kilchoanite; this gives the composition C_8S_5. When it is formed in "γ-dicalcium silicate hydrate" (e.g. by treatment of γ-C_2S with water under saturated steam pressures at 180°C), the layer sequence appears to be somewhat disturbed, the proportion of γ-C_2S layers being increased. This raises the Ca:Si ratio from 8:5 in the direction of a limiting value of 2:1.

Thilo, Wieker and Stade (13) and Wieker and Stade (14) showed by a chemical extraction method that the products which Funk (58) named C_2SH (CI) and C_2SH (CII) both contained a mixture of ortho- and pyrosilicate ions. C_2SH (CI) has been shown to be identical with "γ-dicalcium silicate hydrate", i.e. to be essentially calciochondrodite and C_8S_5, while C_2SH(CII) is a mixture of calciochondrodite and kilchoanite (56). The chemical extraction results are thus readily explained, since calciochondrodite and γ-C_2S are orthosilicates, while the formula of kilchoanite suggests that it is almost certainly a pyrosilicate.

No new data of significance have been reported for calciochondrodite, but the fluoride analogue, $Ca_5(SiO_4)_2F_2$, has been prepared (59).

Other Calcium Silicate Hydrates

Since the Washington Symposium, the compound described by Roy as "Phase Y" (52, 53) has been found as a natural mineral and named dellaite (2). New X-ray and other data have been reported for this phase, for which the composition C_6S_3H originally proposed by Roy is confirmed (60).

A new calcium silicate hydrate phase has been reported as a natural mineral and named rustumite (2). Electron-probe analysis indicated the composition C_4S_2H; X-ray powder data, optical properties, density and the unit cell and space group (obtained from single-crystal X-ray study) were also given. The ionic constitution is possibly $Ca_4(Si_2O_7)(OH)_2$. This is analogous to cuspidine ($Ca_4(Si_2O_7)F_2$), but the unit cell parameters are somewhat more akin to those of tilleyite. As explained earlier, the tilleyite and cuspidine structures are quite closely related, and rustumite most probably belongs structurally to this group of minerals. It does not appear to be identical with any of the synthetic products described in the literature.

Thilo, Wieker and Stade (13), Wieker and Stade (14) and Lentz (10) confirmed by their respective chemical extraction methods the presence of orthosilicate anions in α-dicalcium silicate hydrate (13, 14) and afwillite (10). Mamedov and Belov (18) have modified an earlier suggestion (61) as to the crystal structure of tricalcium silicate hydrate, but there is still no crystallographic evidence other than unit cell parameters (62) whereby either of their suggested structures can be tested.

Crystalline Calcium Silicate Hydrates: Equilibria and Conditions of Formation

The Sub-System $CaSiO_3$–SiO_2–H_2O

The difficulty of reaching equilibrium in the CaO–SiO_2–H_2O system is well known. Harker (41) has recently discussed some of the problems, which are especially acute for siliceous compositions below about 150°C. At least four crystalline phases—nekoite, okenite, suolunite, and techaranite—that have been reported as natural minerals, and that might reasonably be expected to have stability fields in this part of the system, have never been synthesized, and one further phase in this category (14 Å tobermorite) has only once (63) been reported as a synthetic preparation. On the other hand semi-crystalline phases such as C–S–H (I), and poorly defined crystalline ones such as Z-phase, are readily formed. C–S–H (I) in particular is formed reproducibly from a variety of starting materials and is even known to occur as a natural mineral, plombierite. It may nevertheless be doubted whether any of these phases has a true field of stability.

A further complication arises where silica is present as a solid phase. In calcium-containing hydrothermal systems below about 450°C, this is usually formed in a hydrous, amorphous variety or as cristobalite, although quartz is the stable polymorph under these conditions. Coombs, Ellis, Fyfe and Taylor (64) have suggested that this effect may be caused by the formation on cristobalite particles of protective films of calcium silicate hydrates. The same authors have shown that this variation in the polymorphic form of the silica is likely to influence the equilibria profoundly. This has two practical consequences. First, it may help to explain the differences which are known to exist between the behaviour of quartz and that of other forms of silica, such as diatomite, in industrial processes. Second, hydrous silica is not a precisely defined phase; this may be epxected to contribute to the difficulty of obtaining reproducible equilibria, even of a metastable nature.

Equilibria in the $CaSiO_3$–SiO_2–H_2O subsystem have recently been comprehensively studied and reviewed by Harker (41) and by Roy and Johnson (3). Harker's main results are shown in Fig. 2. He assumed the solid phases in the subsystem at low temperatures to be C–S–H (I) and silica (Field 1), although he recognized that C–S–H(I) was probably metastable relative to other and more crystalline phases; he regarded the reactions occurring at progressively higher temperatures as a series of dehydration processes. Above about 110°C for saturated steam pressures, gyrolite and 11 Å tobermorite appear (Field 2). Two aspects only of Harker's results will be discussed: the stability fields of gyrolite and truscottite, and the conditions under which 11 Å tobermorite gives place to xonotlite.

Tr = Truscottite	Wo = Wollastonite

Curves I–IV and curve VI (Fig. 2) define the stability fields of gyrolite and truscottite. They imply that for saturated steam pressures and appropriate bulk compositions, gyrolite is stable at about 110–220°C and truscottite at 160–350°C. For high pressures (around 30,000 p.s.i.) these temperature ranges are about 140–230°C and 180–320°C respectively. These lower limits for the formation of truscottite are difficult to determine. In the presence of a mineralizer (2% of NaF) truscottite can be formed above about 160°C under saturated steam pressures, but in its absence, gyrolite-truscottite intergrowth are formed around 160–220°C and pure truscottite crystals only appear to be obtainable above about 220°C (47, 65).

Harker concluded from his own results and those of earlier workers that the C/S ratio of crystalline, 11 Å tobermorite could vary between 0.8 and 1.0. He regarded the replacement of 11 Å tobermorite by xonotlite as a dehydration reaction in which no other solid phase was involved. If this is accepted, 11 Å tobermorite and xonotlite can coexist stably only along a univarient P-T curve (Fig. 2, curve V). He concluded that the dehydration temperature at saturated steam pressures was 170 ± 20°C, and, in accordance with the earlier results of Buckner, Roy and Roy (66), that it rose sharply with pressure to about 300°C at 25,000 p.s.i. This marked dependence on pressure is unusual in this system; Harker suggested that it might be explained by assuming that slightly different forms of 11 Å tobermorite were involved at different points on the curve. The occurrence of such different forms was discussed at the Washington Symposium (25), and earlier in the present review.

Roy and Johnson (3) considered that the C/S ratio of 11 Å tobermorite in its most stable form could vary only slightly from the ideal value of 5-6, and represented the decomposition of this phase under high pressures as yielding xonotlite, truscottite and water. If this is accepted, 11 Å tobermorite and xonotlite can coexist over a field of pressure and temperature and not merely at points on a P-T curve. Roy and Johnson concluded that, for pressures of 30,000–45,000 p.s.i., the two phases coexisted stably from 285°C down to at least as low as 175°C, which was the lowest temperature studied.

There appear to be good experimental grounds for accepting Roy and Johnson's view, at least for high pressure conditions (15,000–45,000 p.s.i.). In this case, the upper part of Harker's curve V (Fig. 2) must be taken to represent the decomposition of 11 Å tobermorite to give xonotlite, truscottite, and water, and xonotlite must be added to the phase assemblages existing at temperatures below this curve. A need for further experimental work to establish the temperatures below which xonotlite becomes unstable is indicated.

The significance of these considerations for equilibria at saturated steam pressures may now be discussed. If 11 Å tobermorite is assumed to have a fixed C/S ratio of 5:6, it could coexist with xonotlite at temperatures below the value of 170°C proposed by Harker (41). It is suggested that the available data could be largely explained if the stable calcium silicate hydrate phases in the $CaSiO_3$–SiO_2–H_2O pseudo-system at saturated steam pressures are as follows (all temperatures are ±10 deg. C):

100–130°C: Gyrolite, 11 Å tobermorite, afwillite
130–160°C: Gyrolite, 11 Å tobermorite, xonotlite
160–170°C: Truscottite, gyrolite, 11 Å tobermorite, xonotlite.
170–220°C: Truscottite, gyrolite, xonotlite
>220°C: Truscottite, xonotlite

The lower limit of 130°C for the stability of xonotlite is supported by recent observations of Funk (12). The situation is complicated by the strong tendency for tobermorite of high C/S ratio (around 1.0) to persist metastably in place of xonotlite. Two conclusions of possible practical importance emerge. Firstly, at bulk C/S 5:6, 11 Å tobermorite may be stable relative to xonotlite up to 170°C; this may explain why it is formed in preference to xonotlite in many commercial products. Secondly, if formation of xonotlite is desired, there might be a possibility of achieving this in practicable times at temperatures as low as 130° if a way could be found to de-stabilize the 11 Å tobermorite of 1:1 Ca:Si ratio.

Equilibria in the $CaSiO_3$–H_2O system at very high pressures (5–53 k bars) were studied by Pistorius (37). His results define the stability fields of xonotlite, wollastonite and rosenhahnite in this region. His P-T curve for the dehydration of xonotlite to give wollastonite connectes smoothly with those obtained by Buckner, Roy and Roy (66) and by Harker (41) (Fig. 2, curve VII) at lower pressures.

The Sub-System $CaSiO_3$–CaO–H_2O at High Pressures

Roy and Johnson (3) reported the results of a study dealing with equilibria at high pressures (20,000–45,000 p.s.i.). Their results largely confirm and partly modify those presented at the Washington Symposium by Roy and Harker (65). The conclusions resulting from these two investigations, as regards the stable anhydrous or hydrated calcium silicate phases in this pressure region, where as follows (TSH = tricalcium silicate hydrate):

160–235°C Xonotlite—afwillite—hillebrandite—TSH
250–290°C Xonotlite—hillebrandite—calciochondrodite—TSH
290–355°C Xonotlite—foshagite—hillebrandite—calciochondrodite—TSH
355–430°C Xonotlite—foshagite—dellaite—calciochondrodite—TSH
430–520°C Wollastonite—foshagite—dellaite—calciochondrodite—TSH

520–650°C Wollastonite—foshagite—dellaite—calciochondrodite
650–810°C Wollastonite—dellaite—calciochondrodite

In the range 810–840°C, dellaite is replaced by α'–C_2S and rankinite appears. Subsequent work on the high temperature part of the system was reported by Harker, Roy and Tuttle (67), who showed that metling begins in the ternary system $Ca(OH)_2$–Ca_2SiO_4–CaO at 820°C. At 15,000 p.s.i., calciochondrodite melts incongruently at 955°C, giving Ca_2SiO_4 and liquid.

The role of kilchoanite in the system has presented much difficulty. Roy and Johnson (3) noted that this phase forms readily at about 15,000 p.s.i. over the approximate range 250–820°C and did not wholly exclude the possibility that it might form stably in part of this range. On balance, however, they considered that, at least at high pressures, it was probably metastable at all temperatures up to that of the foshagite decomposition (~650°C); above this temperature it possibly had a stable existence. In general agreement with this view, Agrell (2) considered that at 5000 p.s.i. foshagite was a stable phase below about 550°C, above which temperature it was replaced by kilchoanite.

Several values have been reported for the kilchoanite-rankinite inversion temperature, which because of the smallness of the volume change must be almost independent of pressure. Roy (53) placed it at 800–850°C, Agrell (2), quoting unpublished work by McConnell, at 700°C, and Speakman, Taylor, Bennett and Gard (56) at about 625°C. The latter investigators obtained evidence consistent with the view that, at high pressures, kilchoanite had a narrow temperature range of stability around 600°C. They considered that at lower temperatures, it was possibly replaced by wollastonite plus dellaite at 500–550°C, and by foshagite plus dellatie below 500°C.

The considerations of the last two paragraphs suggest that the stable phases at 430–810°C at high pressures are possibly:

430–500°C Wollastonite—foshagite—dellaite—calciochondrodite—TSH
500–520°C Wollastonite—dellaite—calciochondrodite—TSH
520–550°C Wollastonite—dellaite—calcio calciochondrodite
550–625°C Wollastonite—kilchoanite—dellaite—calciochondrodite
625–810°C Wollastonite—rankinite—dellaite—calciochondrodite

The Sub-System $CaSiO_3$–CaO–H_2O at Saturated Steam Pressures

The semicrystalline or near-amorphous calcium silicate hydrates that are formed at room temperature on hydration of portland cement or in other ways appear to be indefinitely persistent, but they are probably metastable relative to afwillite and $Ca(OH)_2$ (68). This probably accounts for the formation of afwillite when C_3S is ball-milled with water at room temperature (69).

The stability relations of kilchoanite relative to xonotlite, foshagite and hillebrandite at saturated steam pressures present some difficulty. Kilchoanite, or related phases or mixtures such as "γ-dicalcium silicate hydrate", are readily formed from mixtures of β- or γ–C_2S with silica at temperatures around 200°C and saturated steam pressure, and appear under these conditions to persist indefinitely. Lime-silica mixtures under similar conditions sometimes yield kilchoanite or related phases (70), but more often give xonotlite, foshagite, hillebrandite, or combinations of these phases, and these latter three phases then appear to be indefinitely persistent. Roy and Johnson (3) suggested that kilchoanite might have a stability field at low pressures, and Speakman, Taylor, Bennett and Gard (56) observed that this would be compatible with their results obtained in runs using γ-C_2S as the principal starting material. In contrast, workers who used other starting materials, such as Peppler (71) and Assarsson (49), concluded that xonotlite and hillebrandite coexist stably at temperatures around 180°C.

The problem probably cannot be resolved by runs using simple starting materials, and Ahmed and Taylor (72) therefore adopted a different approach, which is illustrated by the following example. A mixture of γ-C_2S and quartz of bulk Ca/Si ratio 1.5 was autoclaved at 180°C and gave a product consisting largely of kilchoanite. A mixture of lime and quartz was similarly treated and gave a product consisting mainly of xonotlite, hillebrandite, and foshagite. The two products were then mixed to yield a mixture which will be called (I). Portions of (I) were re-autoclaved at 180°C for various times to yield a series of products. The X-ray patterns of these products were compared with that of the mixture (I) in order to see which phases were increasing, and which decreasing in relative amount. The results indicated clearly that xonotlite and hillebrandite were stable relative to kilchoanite and foshagite. A similar group of experiments showed that at 250°C the stable phases at bulk Ca/Si ratio 1.5 were foshagite and hillebran-

dite. There were indications that calciochondrodite was unstable at both 180° and 260°C, but the results in this respect were not conclusive.

Evidence regarding the stability fields of other phases in the $CaSiO_3$–CaO–H_2O subsystem at saturated steam pressures was largely summarized at the Washington Symposium (25, 65). From this and the newer results presented here the stable calcium silicate hydrate phases in this subsystem at saturated steam pressure appear to be as follows:

<100°C	14 Å tobermorite—afwillite
100–130°C	11 Å tobermorrite—afwillite
130–140°C	Xonotlite—afwillite
140–150°C	Xonotlite—afwillite—hillebrandite
150–180°C	Xonotlite—hillebrandite
180–250°C	Xonotlite—hillebrandite—TSH
250–320°C	Xonotlite—foshagite—hillebrandite—calciochondrodite—TSH
>320°C	Xonotlite—foshagite—dellaite—calciochondrodite—TSH

Further work is needed to clarify a number of points, including the following:

(i) Does a crystalline phase related structurally to either C–S–H (II) or jennite (both of which are discussed later) have a stability field in the system?

(ii) Does rustumite have a stability field, and under what conditions can it be synthesized?

(iii) What are the lower temperature limits of stability of calciochondrodite and of tricalcium silicate hydrate? The values given above rest on slender evidence.

(iv) Does α-dicalcium silicate hydrate have any true stability field? This phase is formed very readily from a variety of starting materials at 100–180°C. It appears always to be metastable relative to hillebrandite or to afwillite plus $Ca(OH)_2$, but this cannot be considered certain.

(v) Under what conditions are kilchoanite or structurally related phases formed from lime-quartz mixtures? Kalousek, Logiudice and Dodson (70) obtained some results bearing on this question, but further work is needed.

(vi) What is the nature of the material that Aitken and Taylor (73) called "Phase F", ($C_5S_3H_2$ approx.)? This, or a similar material, has again been obtained from lime-quartz mixtures (72), but its nature is still obscure.

Crystalline Calcium Silicate Hydrates with Additional Ions

Of the various compounds in this category, we shall consider only those that appear especially important for cement hydration chemistry and for which significant work has been reported since the Washington Symposium. Substitution of additional ions in structures already described (e.g. of Al^{3+} in 11 Å tobermorite) is considered later.

Scawtite

This is identical with the phase which has been called CSH (A). Harker (74) has discussed the conditions of formation and stability of this phase, for which he assumes the general formula $Ca_{14}(OH)_4(Si_{16-x-y}C_xH_{4y})O_{44}$. He noted that scawtite has frequently been observed to form in runs in the CaO–SiO_2–H_2O system in which slight CO_2 contamination had occurred, and found that it could be synthesized at low partial pressures of CO_2 in the presence of excess water; its stability range appeared to extend from 140° to 300°C and to be independent of water pressure from saturated steam pressures up to at least 50,000 p.s.i. Harker obtained scawtite pure by using as starting material a mixture of $Ca(OH)_2$ and silicic acid, together with excess water containing the calculated amount of dissolved CO_2, so as to give the molar ratios Ca:Si:C = 14:12:1 or 14:12:2. Below 140°C, scawtite was unstable relative to 11 Å tobermorite and calcite, while above 300°C it was unstable relative to xonotlite and calcite; it was thus formed largely at the expense of xonotlite in the CaO–SiO_2–H_2O system. At 21°C, it was decomposed by stirring with CO_2-saturated water at 1 atmosphere for 16 hours.

Jennite

Jennite is a sodium calcium silicate hydrate of approximate composition $Na_2Ca_8Si_5O_{30}H_{22}$.* As will be shown later in this review, it is possibly more nearly related in structure to the predominant calcium silicate hydrate of cement pastes than is any other crystalline phase, including tobermorite. The available information about it will therefore be considered in some detail.

Jennite has so far been found as a crystalline phase only as a natural mineral. The formula given above is

*Subsequent analytical work (107) does not confirm the presence of appreciable sodium into in this mineral.

based on the analysis of the first specimen to be discovered which was found at Crestmore, California, and studied by Carpenter, Chalmers, Gard, Speakman and Taylor (75). A second specimen has since been discovered in Israel and shown by Heller (76) to give X-ray single crystal patterns identical with those of the Crestmore mineral, but no chemical analysis or other data for this second specimen have yet been reported.

Jennite forms small, blade-shaped crystals or fibrous aggregates. The unit cell was determined and indexed X-ray powder data obtained, together with infra-red, thermal decomposition, density, and electron microscope and diffraction data. There is a repeat distance of 7.25 Å parallel to the *b* or needle axis, with very marked pseudohalving; reflections corresponding to the 7.25 (as opposed to 3.625) Å repeat were invisible on X-ray rotation photographs, and only a few extremely weak ones were detectable on oscillation photographs. The triclinic cell has a thickness (d_{001}) of 10.42 Å in the direction perpendicular to the cleavage. The cell parameters (*a* 10.56, *b* 7.25, *c* 10.81 Å, α 99°42′, β 97°40′, γ 110°04′) somewhat resemble those of cuspidine, but the cell contents are distinctly different ($Na_2Ca_8Si_5O_{30}H_{22}$ for jennite, $Ca_{16}Si_8O_{28}F_8$ for cuspidine). From infrared and thermal decomposition evidence, it was suggested that the ionic constitution was possibly $Na_2Ca_8(SiO_3)_3$-$(Si_2O_7)(OH)_6 \cdot 8H_2O$, wollastonite-like chains and pyrosilicate groups thus both being present.

If jennite is heated in air at 70–90°C, four molecules of water are lost from the above formula unit, and the unit cell shrinks in the *c*-direction to give a layer thickness of 8.66 Å. The product thus formed is called metajennite. It closely resembles jennite as regards the *ab*-face of the unit cell, the general distribution of intensity in reciprocal space, as shown in single-crystal X-ray patterns, and the infrared absorption spectrum. Metajennite is therefore presumably derived from jennite by loss of water molecules from between layers which themselves undergo little or no change.

Meta-jennite loses water gradually at 90–750°C; with increasing temperature within this range the product becomes progressively less crystalline. By 450°C, X-ray diffraction shows only diffuse powder rings with spacings of about 3.0, 2.8, 2.0, and 1.8 Å. At 900–1060°C, wollastonite forms, and at 1100°C the main product is β-C_2S.

Subsequent to the publication of the above results, the present author has derived a tentative crystal structure from X-ray fibre rotation data; more certain results will be difficult to obtain because the crystals are poor. Fig. 3 shows the essential features. The structure is based on corrugated Ca–O sheets lying parallel to the (001) plane. On both faces of these, some of the oxygen atoms are shared with Si–O chains, which run parallel to the *b*-direction. These chains are probably highly disordered and contain frequent gaps: they are not of uniform length, and probably have a minimum chain length of two, and a mean chain length of five tetrahedra. In configuration they resemble portions of wollastonite chains. Of the oxygen atoms of the Ca–O sheets that are not linked to silicon, some must occur in water molecules, and others in hydroxyl groups. The structure is completed by the addition of interlayer sodium ions and water molecules. The sodium ions may not be essential; calcium might possibly replace them, especially in poorly crystallized material, if some appropriate balancing replacement also occurred.

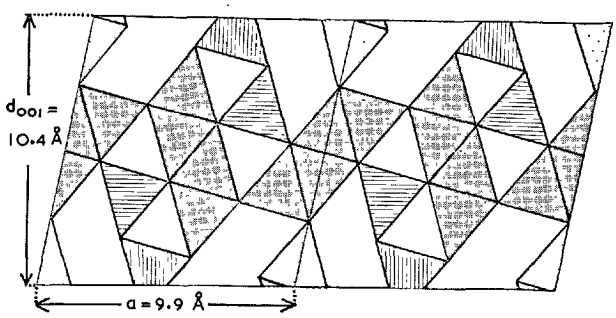

Fig. 3. *Suggested crystal structure for jennite (idealized and tentative), viewed along the* b*-direction. Axes relate to the monoclinic pseudocell with* a *9.9,* b *3.6,* c *10.6* Å, β *102°. Diamonds with dense point-shading represent* Ca(O, OH, $H_2O)_6$ *octahedra, which are linked to form a corrugated sheet that is seen edge-on and runs horizontally across the figure. Diamonds with light point-shading represent interlayer* $Na(H_2O)_6$ *octahedra, Triangles with horizontal line-shading represent* Si_2O_7 *groups, seen end-on. Triangles with vertical line—shading represent oxygen tetrahedra of which about one-half, statistically distributed, contain silicon atoms, which link the* Si_2O_7 *groups into short chains of various lengths. For clarity, tetrahedra of this type belonging to the two adjacent layers are omitted. The chains are seen end-on.*

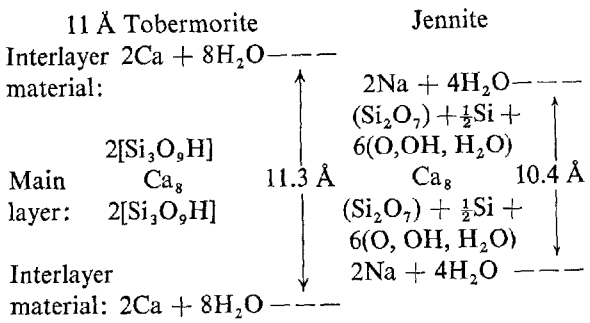
The suggested structure, of which the tentative nature is emphasized, has features in common with those of tilleyite, cuspidine, and one of the structures suggested for tricalcium silicate hydrate (18). It has some broad similarities to that of tobermorite (77), but also some important differences. The most important of these are the very different configurations of the Ca–O sheets, which lower the repeat distance in the tobermorite a-direction from 11.2 Å in tobermorite to 9.9 Å in jennite, and the presence in jennite of hydroxyl ions and water molecules within these sheets. The two structures are compared schematically below:



they considered to have the constitution $NaCaHSiO_4$, by hydrothermal treatment of Na_2CaSiO_4 in saturated steam (not liquid water) at 180°C.

Sazhin and co-workers (82, 83) reported studies on the N–C–A–S–H system at 240–280°C. They obtained in additions to $Ca(OH)_2$ and a hydrogarnet phase, two compounds which they considered to be $NC_2S_2H_n$ and $N_4C_2A_3S_6H_3$. In a similar study at 280°C, Ni and co-workers (84–86) reported the formation of $NC_2S_2N_n$ and $N_{1.25}C_{0.5}AS_2H$. Similarities of crystal morphology and refractive indices suggest that these phases may have been identical with the corresponding ones of Sazhin and co-workers. The X-ray powder data and refractive indices reported by the latter for $NC_2S_2H_n$ are, in turn, near to those of pectolite, but the formulae differ and the resemblances could be accidental. The relation between the $NC_2S_2H_n$ phases reported in these investigations and the $NaCaHSiO_4$ of Thilo, Funk and Wichmann (81) requires investigation. None of the synthetic products mentioned above appears to resemble jennite. Further work is needed to correlate the results of the various investigators.

Several other studies on the C–S–H system in the presence of alkalis have been reported recently (87–91) but most are mainly concerned with the influence of alkalis on the reactivity of anhydrous calcium silicates, and none with the formation of hydrated phases containing alkalis as essential constituents. A number of other calcium silicate hydrates with essential sodium or potassium are known as natural minerals, but apart from reyerite, which has already been mentioned, the only one whose composition appears to be in a range of apparent significance for cement hydration chemistry is miserite ($KCa_4Si_5O_{13}(OH)_3$) (92).

Synthetic Studies on Alkali-Containing Systems

Several studies have recently been reported on aspects of the N–C–A–S–H system relevant to cement chemistry. This system is of interest for several reasons. Firstly, as already mentioned in the case of jennite, some of the sodium-containing compounds may be structurally related to pure calcium silicate hydrates. secondly, raw materials containing alkalis and Al_2O_3, such as felspars, are used in some autoclave processes. Thirdly, in probably all processes of cement hydration the alkali present in the cement, though small in absolute amount, appears to go into solution rapidly, so that in the early stages of hydration the effective ratios of alkali oxides to other constituents may be quite high.

The early work of Clark and Bunn (78) and Thilo and Funk (79) showed that pectolite ($NaCa_2HSi_3O_9$) can readily be synthesized from a variety of starting materials of appropriate composition by hydrothermal treatment at 180–200°C under saturated steam pressures. This phase is structurally closely related to wollastonite (80). Thilo, Funk and Wichmann (81) described also the synthesis of a compound which

Poorly Crystalline Calcium Silicate Hydrates

This term will be used to denote all calcium silicate hydrates giving X-ray powder patterns significantly poorer than those of typical crystalline phases. It is convenient to divide them arbitrarily into semi-crystalline and near-amorphous phases. We shall use the term "near-amorphous" for phases or materials giving not more than three X-ray powder lines, which in general will usually be more or less broadened. The calcium silicate hydrate present in normally cured cement pastes (so-called "tobermorite gel") is typical of this group. In such materials only short-range order would seem to occur. The term "semi-crystalline" will be used for phases or materials whose X-ray powder patterns contain more than three lines, but give clear indication of absence of full three-dimensional order either because too few lines are present, or because of marked broadening or some other reason. The phase known as "C–S–H (I)" is typical of this group. It is, of course, assumed that fewness of lines is not due solely to use of an inadequate X-ray technique or to the fact that the phase is present as a minor constituent of a mixture. In the author's experience X-ray goniometers designed for single-crystal work are considerably more satisfactory for studies on poorly crystallized calcium silicate hydrates than are diffractometers, Guinier cameras,

or conventional Debye-Scherrer powder cameras.

Many workers in this field, including the present writer, have regarded all poorly-crystalline calcium silicate hydrates as structurally degenerate varieties of tobermorite and have called them tobermorites or tobermorite-like phases. While in some cases this view is probably correct, in others the evidence is weak, and in yet others there are positive grounds for postulating a closer relation to crystalline phases other than tobermorite. We shall use the term C–S–H to denote any poorly-crystalline calcium silicate hydrate, whether semicrystalline or near-amorphous. The letters C–S–H stand for "calcium silicate hydrate", and hyphens are inserted to show that no particular composition is implied.**

The classification of C–S–H varieties is rendered difficult by the indefinite nature of these materials, which probably comprise, not a finite number of phases each of definite composition and structure, but a largely continuous range with a number of variable parameters which are only partly correlated. It will be convenient to consider them in sequence of increasing C/S ratio.

Materials of Low C/S Ratio

In 1955, Funk and Thilo (50) described a virtually amorphous preparation which they obtained by mixing $Na(H_3SiO_4)$ and $CaCl_2$ solutions at 0°C. After drying over silica gel, it had the composition CS_2H_3 and they considered it to have the constitution $Ca(H_3SiO_4)_2$. On being autoclaved at 180°C, it yielded a product described as $CaH_4Si_2O_7$, and which appears to have been identical with Assarsson's "Z-phase" (25, 49). Funk (47) later repeated the preparations of CS_2H_3 and Z-phase, and described additional poorly crystalline products obtained by autoclaving CS_2H_3 at 120°C, for which he gave X-ray powder, DTA, TGA and electron microscope data. He considered that these products might be mixtures. The X-ray data do not agree with those of C–S–H (I) or other known phases. The nature of these products is still not clear, but it is at least possible that they are structurally related to gyrolite rather than to tobermorite. There appears to be little evidence for the ionic constitution $Ca(H_3SiO_4)_2$ assigned by Funk and Thilo (50); indeed, Wieker (93) showed by the chemical method described earlier (13, 14) that layer silicate anions were present. This is consistent with the hypothesis of a gyrolite-like structure.

The occurrence of a poorly-crystalline calcium silicate hydrate of low C/S ratio as an initial product in hydrothermal reactions employing lime and silica glass or gel is suggested by the results of Buckner, Roy and Roy (66), Assarsson (49) and Kondo (94). Such a product, if formed, could possibly be similar in structure to the poorly-crystalline materials discussed above.

C–S–H (I)

This term will be used to denote the product which has a C/S mole ratio of 0.8–1.5, appears as crumpled foils under the electron microscope, and gives an X-ray powder pattern consisting mainly of reflections corresponding to a two-dimensional, centred, orthogonal lattice with *a* 5.6, *b* 3.6 Å approx. There may or may not also be a strong basal reflection with a spacing of 9–14 Å, this value depending on the H/S and C/S ratios. C–S–H (I) is formed from a wide range of starting materials, most characteristically in aqueous suspensions at room temperature, but also hydrothermally as an intermediate reaction product. Natural plombierite of low C/S ratio (34) is substantially identical with C–S–H (I).

The X-ray powder pattern of C–S–H(I), and the changes in basal spacing that occur on dehydration (32), suggest strongly that the phase is a structurally degenerate form of tobermorite. This implies some degree of condensation in the silicate anions. Chemical studies of this problem have led to divergent conclusions. Brunauer and Greenberg (17), reporting unpublished work by Greenberg and Pressler, concluded that increasing depolymerization occurred with increasing C/S ratio. They gave no quantitative conclusions, but for a preparation with C/S 0.8 made at 85°C, the rates of dissolution in 0.5 M aqueous HCl and of reaction of the extract with an aqueous molybdic acid reagent suggested a substantial degree of condensation. Greenberg and Chang (95), reporting further unpublished results of Greenberg, Pressler and Chang, however concluded that "products of the reaction of calcium oxide, silica and water mixtures begin to dissolve completely in HCl at a CaO/SiO_2 mole ratio of 1. Therefore, in the $CaO–SiO_2–H_2O$ system, silica is completely depolymerized at this mole ratio." From this and other evidence, they concluded that preparations having C/S $\geqslant$ 1 contained a substance of formula CaH_2SiO_4.

The formula CaH_2SiO_4 was earlier assigned by

**Several prominent workers in the field, e.g. Assarsson (49), appear never to have accepted the hypothesis that all poorly-crystalline calcium silicate hydrates are tobermorite-like in structure. The writer thanks Professor H. Funk, for pointing out to him the weakness of this hypothesis, and Miss A. E. Moore, M. Sc., for suggesting the term C-S-H.

Thilo, Funk and Wichmann (81) to a product that was almost certainly C–S–H (I); these authors, too, considered that orthosilicate ions were present. However, Wieker (93) concluded from his chemical method that this product in fact contained chain-type silicate anions.

Funk (12) studied the degrees of condensation in C–S–H (I) preparations by his method based on dissolution in methanolic HCl and subsequent reaction with a molybdic acid solution. He concluded that, in all preparations studied, a distribution of anion sizes occurred. He considered that reliable information could be obtained regarding trends, but that absolute degrees of condensation could only be roughly estimated. The degree of condensation decreased with increasing C/S ratio over the range 0.81–1.1, and increased on raising the temperature of preparation from room temperature to 110°C. Funk made the following estimates for the anion size distributions of two preparations (apparently made at room temperature):

	Approx. percentages of SiO_2 present as anions of:			
C/S ratio	3–4 tetrahedra	4–6 tetrahedra	6–10 tetrahedra	>10 tetrahedra
1.01	—	10	80	10
1.1	20	40	40	—

He reported parallel results for preparations autoclaved at 130–170°C. These were shown by X-rays to contain tobermorite or xonotlite or both; the extent of condensation was found to increase further with increased temperature of preparation or decrease in C/S ratio. Funk's and Wieker's conclusions, unlike those reported by Greenberg and Chang, can readily be reconciled with the X-ray evidence.

New studies on the equilibria involving C–S–H (I) have been reported by Greenberg and his colleagues. Greenberg, Chang and Anderson (96) prepared solids at 85°C that appear to have been essentially C–S–H (I). They equilibrated these with aqueous solutions at 25°C, and from determinations of pH and Ca^{++} and silicic acid concentrations in solution derived values for two solubility products which were formulated as

$$K_{SP_1} = {}^{a}Ca^{++} \times {}^{a}H_2SiO_4^{2-}$$

and

$$K_{SP_2} = {}^{a}Ca^{++} \times {}^{a^2}H_3SiO_4^{-}.$$

They found $pK_{SP_1} = 7.0 \pm 0.1$ and $pK_{SP_2} = 8.5 \pm 0.1$. K_{SP_1} was assigned to an equilibrium between CaH_2SiO_4 and solution, and K_{SP_2} to an equilibrium involving $Ca(H_3SiO_4)_2$.

Greenberg and Chang (95) later reported a study of the pH values and Ca^{++} and silicic acid concentrations in solutions coexisting with solids of a range of C/S ratios. Their results were similar to those reported by numerous earlier workers. They concluded that at C/S 0.14–1 the solid consisted of CaH_2SiO_4 plus silica; the evidence for $Ca(H_3SiO_4)_2$ was not conclusive. At C/S 1–1.75, the solid was regarded as a solid solution of composition $CaH_2SiO_4 \cdot nCa(OH)_2$, and a distribution coefficient was derived relating the activity of the $Ca(OH)_2$ dissolved in this solid to its value in solution. The lack of positive evidence for $Ca(H_3SiO_4)_2$ in these results does not necessarily conflict with the observations of Funk and Thilo (50) metnioned earlier, as these workers used different preparative conditions.

Lawrence (97) has studied the dehydration of C–S–H (I) preparations of varying C/S ratios. Preparations with C/S 0.5–0.9 showed only minor changes in X-ray pattern up to 700°C; the 12.5 and 5.5 Å reflections disappeared and the remaining spacings were slightly shortened. At 770°C, there was a sharp transition to wollastonite. He showed that formation of β–C_2S, reported earlier by Gard, Howison and Taylor (98) occurred only if contamination by CO_2 had occurred. He considered that (uncarbonated) C–S–H (I) with C/S 0.5–0.9 could lose most or all of its water without serious disruption of the structure; the rapid increase in velocity of transformation to β–CS at 770°C suggested that some form of nucleation process controlled the reaction. Preparations with C/S 1.0–1.5 behaved differently, a near-amorphous intermediate material being formed at 550–770°C. At C/S 1.0–1.2 this yielded β–CS at 770°C; at C/S 1.2–1.5 it gave β–CS and β–C_2S. Wollastonite was also formed at 550–770°C if heating was prolonged. These results can perhaps be correlated with the DTA results of Kalousek (99), who showed that the sharp exotherm at about 800°C was depressed to lower temperatures with increase in C/S ratio. The cocurrence of this exotherm with C–S–H (I), which contrasts with its absence for crystalline Al-free tobermorite (63), suggests that the mechanism of wollastonite formation differs in the two cases.

The similarity of the X-ray powder patterns and compositions of C–S–H (I) and tacharanite has already been mentioned; it may, however, be fortuitous.

Grudemo (100) has published new electron micrographs and diffraction patterns for C–S–H (I) and other calcium silicate hydrates; these substantially confirm and augment those reported earlier (30, 101).

The balance of the existing evidence regarding C–S–H (I) seems clearly to support the view that material with C/S ~ 0.8 is a structurally degenerate tobermorite. There is little evidence that C/S can fall below 0.8 without silica occurring as a separate phase. Increase in C/S above 0.8 seems definitely to be associated with lower average degrees of condensation (12, 17) and with decrease in layer thickness (30). The only explanations that appear consistent with both these facts are ones in which the structure is modified by omission of tetrahedra from the chains, as suggested originally by Taylor and Howison (16), and supported in modified form by Brunauer and Greenberg (17). At the higher C/S ratios, omission of entire chains and their replacement by hydroxyl groups possibly also occurs; this could happen in a variety of ways, such as the incorporation of regions of jennite-like structure, or the replacement of the whole of one side of a layer as suggested by Gard, Howison and Taylor (98) and Grudemo (101). This matter has been further discussed elsewhere (102). The variable characteristics and generally indefinite nature of C–S–H (I) of high C/S ratio suggest strongly that several different causes of variable C/S ratio may operate.

C–S–H (II)

This term will be used to denote any semi-crystalline calcium silicate hydrate with a C/S ratio of 1.5 or above. Such products are more varied in character, and almost always less crystalline, than C–S–H (I), and the term may therefore cover a number of phases of different structural affiliations.

The most crystalline variety of C–S–H (II) that has been described is probably that which forms under certain conditions from C_3S (103) or β–C_2S (17) in aqueous solutions at room temperature, appears as characteristic fibre bundles in the electron microscope (17, 100, 101, 104), and gives an X-ray powder pattern somewhat similar to that of C–S–H (I) and having a longest spacing of 9.8 Å (31). In recent studies, Grudemo (100) and Gard (104) were unable to obtain selected area electron diffraction patterns from this material, but Copeland and Schultz (105) found that it gave a distorted hexagonal pattern with reflections having d-spacings of 3.07, 2.80 and 1.83 Å; this would appear to indicate a tobermorite-like structure. Some support for this hypothesis is provided by the X-ray powder pattern (31), which is relatively close to that of 10 Å tobermorite (31), especially if the effect of the slightly differing basal spacings is allowed for. If the C–S–H (II) preparations discussed above are structurally related to tobermorite, their high C/S ratios must presumably be explained in one or more of the ways already mentioned in relation to C–S–H (I).

Glasser and Taylor (107) studied the thermal decomposition of C–S–H (II) preparation D-69 of Brunauer and Greenberg (17), which is of the variety discussed above. On being heated at 10 deg C min^{-1}, this shows no significant change in X-ray pattern up to 250°C. Above about 300°C the 9.8 Å reflection disappears and some other minor changes occur, and at somewhat higher temperatures the material becomes almost amorphous. Neither these results, nor the DTA curve or the infrared absorption spectrum which were also obtained, provide any definite indications as to the structure.

Kurczyk and Schwiete (106) described hydration products of C_3S and β–C_2S that were possibly identical with the fibrous C–S–H (II) preparations discussed above. Like the preparation studied by Copeland and Schulz (105), these appear to have given tobermorite-like electron diffraction patterns.

Funk and Fahlke (108) found that two different hydration mechanisms operate with β–C_2S. If the solution was supersaturated with $Ca(OH)_2$, reaction proceeded by dissolution and represipitation, and yielded a product having C/S 1.86, showing as foils in the electron microscope, and giving broad X-ray powder spacings of 1.83, 3.05 and 11–14 Å. If the $Ca(OH)_2$ concentration was kept below saturation, the reaction appeared to proceed by a conversion of the crystals *in situ*. The intensities of the β–C_2S powder reflections changed relative to each other, and eventually needle-shaped crystals of a hydration product with C/S 1.54 were formed. These were possibly identical with the relatively crystalline form of C–S–H (II) discussed above. Funk and Fahlke (108) concluded that the second of these mechanisms was topotactic. In-situ conversion of dicalcium silicate to C–S–H has also been reported to occur in nature (68).

The other poorly crystallized calcium silicate hydrates with C/S $\geqslant$ 1.5 that have been described are of so low a degree of crystallinity that they might be considered to show only short range order and some are discussed later in connection with calcium silicate pastes. Several new electron microscope and diffraction studies have been made (100, 105, 109), but otherwise there has been little progress since the Washington Symposium. The electron microscope studies confirm that a range of morphologies occurs. Some forms, like that described previously, appear to give tobermorite-like electron diffraction patterns, but others give only a single, broad powder ring of

spacing 2.8–3.1 Å, together sometimes with either a second powder ring or a pair of relatively sharp reflections corresponding to a fibre repeat distance of about 1.8 Å. Such patterns could be taken as indicating a structural resemblance to any one of a number of crystalline phases. The application of new experimental methods, such as those mentioned earlier in this review, is probably essentiall if significant further progress is to be made in elucidating the structures of these materials.

Paste Hydration of C_3S and β-C_2S

It is well known that the products of hydration of C_3S or β-C_2S in pastes at room temperature are $Ca(OH)_2$ and a near-amorphous C–S–H. The latter is frequently called "tobermorite gel", but this name may be criticized on two grounds. First, the evidence relating it structurally to the crystalline tobermorites is weak; it amounts largely to a correspondance of the two or three broad X-ray powder reflections of the C–S–H constituent of the gel with strong *hko* reflections of the tobermorites, together with indirect support from what is known or suspected concerning the structures of the semi-crystalline products, C–S–H (I) and C–S–H (II). As will be shown, the hydration products formed in pastes probably comprise a range of phases of differing compositions, depending on such factors as time, temperature, and water: cement ratio. Some of them may be structurally related to tobermorite, but others probably are not; electron diffraction evidence suggests that some, at least, of the fibrous particles that have been observed may be more nearly related to jennite. The second objection to "tobermorite gel" is that a gel is, by definition, a heterogeneous material of a particular type, and to apply the name to a single phase in such a material is incorrect and may well lead to confusion of thought. We shall therefore refer to the calcium silicate hydrate formed in these pastes as C–S–H, particularizing further when necessary, on the basis of composition, morphology, or other characteristics.

Chemical Composition and Specific Surface

Since the Washington Symposium, Brunauer and his colleagues have extended the studies which they reported there (17) on the chemical composition and specific surface area of the C–S–H in calcium silicate pastes (110, 111, 112). Their results for C/S ratios are based on the use of extraction methods (112, 113), which enabled a distinction to be made between Ca^{2+} present in the C–S–H and that present as crystalline or amorphous $Ca(OH)_2$. The C/S ratio appears to depend on the degree of hydration, temperature, and water: cement ratio, but not on the fineness of grinding, assuming that pastes with the same degree of hydration are compared.

In 1962, Kantro, Brunauer and Weise (110, 111) reported results for C_3S and β-C_2S pastes at water: cement ratio 0.7. Their results were summarized by Brunauer (114) and Brunauer and Kantro (115). Specific surface areas and C/S and H/S ratios for the C–S–H were plotted against percentages of the anhydrous compound reacted, which in turn were plotted against time, for temperatures of 5°, 25° and 50°C. The main results were as follows:

(i) With both C_3S and β-C_2S, the C/S ratios are high initially possibly equalling those of the anhydrous phases themselves, and the specific surfaces are relatively low. With β-C_2S, the C/S ratio passes through a minimum at the same degree of hydration as the specific surface passes through a maximum; this stage is reached in about 12 hr at 25°C. With C_3S, the C/S ratio does not show a minimum, but the specfic surface does show a maximum, which is reached in 6 hr at 25°C. The lowest C/S ratios observed (for β-C_2S pastes at 5°C) are around 1.1, and the final C/S ratios are 1.4–1.7.

(ii) Temperature affects the percentages of hydration corresponding to maximum specific surface, and (for β-C_2S pastes) minimum C/S ratio, in a complex way. For β-C_2S pastes the final C/S ratios rise slightly with temperature, but for C_3S pastes there is no clear trend.

(iii) For the end products of the reaction, the H/S ratios are related to the C/S ratios; for materials dried over ice at −78°C, the compositions can be written approximately as $C_{(0.5+n)}SH_r$.

Kantro, Brunauer and Weise (111) interpreted these results to indicate the occurrence of three stages in the reaction. Firstly, a product of high C/S ratio and low specific surface was formed. They considered this to be a skin adhering to the particles of the anhydrous compounds and calculated that it grew to some tens of molecular layers in thickness. The second stage was the splitting-off of particles of a low C/S, high surface area intermediate, which were calculated to be either one or two layers thick, together with $Ca(OH)_2$. The final stage was the growth of these particles to a thickness of three layers. It was suggested

that the two- and three-layer products had C/S ratios of 1.39 and 1.73 respectively. The observed kinetics could be explained by assuming that the rate-determining step was, in the early stages, the reaction between the anhydrous silicate and water, and later the diffusion of ions through the gel layer. The second and third stages were distinct with β–C_2S, but not with C_3S.

In 1966, Kantro, Weise and Brunauer (112) extended their observations by studying the effects of varying the fineness and the water: cement ratio. The fineness was found to have no effect other than on the rate; i.e., if C/S ratio or other parameters were plotted against degree of hydration, fineness had no effect. The water: cement ratio, in contrast, had an important effect; values of 0.45–0.70 were studied. The general trends found in the earlier work were confirmed for all the water: cement ratios studied. The most important effect of water: cement ratio was that the C/S ratios of the final products increased as the water: cement ratios decreased; thus for C_3S at 25°C, the final C/S ratio was 1.42 for W/C = 0.7 and 1.61 for W/C = 0.45. Corresponding values for β–C_2S were 1.66 for W/C = 0.7 and 1.80 for W/C = 0.45. This effect was explained by assuming that the smaller amount of space available at low water: cement ratios favoured the formation of the denser three-layer product which, as already seen, was considered to be of higher C/S ratio.

Locher (116) has reported results for C_3S pastes at 20°C which agree in many respects with those of Brunauer and his colleagues. He worked with pastes of water: cement ratios 0.25–2 (those above 0.8 did not harden); $Ca(OH)_2$ was determined by a chemical extraction method and by TGA. Water contents were determined after drying over ice at −79°C. No results were reported for degrees of hydration below about 28%. For water: cement ratios $\geqslant$0.6 Locher found little variation in C/S with the percentage of hydration over the range studied; the chemical extraction method gave 1.4–1.6, and TGA 1.6–1.9. At lower water: cement ratios (especially at 0.25–0.35), the C/S ratios were higher, and rose not only with decreasing water: cement ratio, but also with increasing time. For W/C = 0.45, the final value was about 1.75 (by chemical extraction) or 2.05 (by TGA). Corresponding values for W/C = 0.25 (about 80% hydration) were around 2.15 and 2.37 respectively. Water contents were found to be correlated with C/S ratios, the general formula of the C–S–H being given as $C_{(0.34+n)}SH_n$. Locher concluded that the phase had a tobermorite-like structure in which the high C/S ratio was caused by the presence of attached $Ca(OH)_2$ layers, together possibly with replacement of silicate by hydroxyl ions on one side of the tobermorite sheet as suggested previously (98, 101).

Stein and Stevels (117) and de Jong, Stein and Stevels (117a) reported some studies on the kinetics and mechanism of the C_3S—water reaction in suspensions which led them to conclude that three successive reaction products are formed. They considered that the initial product had a rather high C/S ratio and that it adhered strongly to the C_3S from which it was formed; it was replaced by a product which had a lower C/S ratio and adhered less strongly. Electron microscopic studies (discussed later) gave some indications that this second product might initially be C–S–H (I), which later gave place to fibrous C–S–H (II). These conclusions seem to agree well with those of Kantro, Brunauer and Weise (111). Greenberg and Chang (118) concluded from a somewhat similar study that reaction proceeded by the reaction of Ca^{2+} and $H_2SiO_4^{2-}$ ions in solution to give a hydration product that crystallized initially on the C_3S surface; Stein and Stevels (119) considered that these results could be reinterpreted in a manner compatible with their own hypothesis.

Degree of Anion Condensation

Lentz (10) has studied the changes in the degree of condensation of the silicate anions in C_3S and portland cement pastes by his method based on formation of trimethylsilyl derivatives. The C_3S paste was 2.7 years old and had a W/C ratio of 0.7, and the C_3S had presumably largely or completely reacted. Lentz reported the following distribution of anion types expressed as percentages of the total acid-soluble silica present in each form):

SiO_4^{4-}	$Si_2O_7^{6-}$	$Si_3O_{10}^{8-}$	$Si_4O_{12}^{8-}$	Highly condensed
9.5	22.4	3.8	1.9	50.8

The $Si_4O_{12}^{8-}$ was considered to be a cyclic anion. A 14.7 year old portland cement paste gave closely similar results but showed a higher proportion (17.0 %) of silica present as SiO_4^{4-}. A study of cement pastes of differing ages showed a progressive trend to higher degrees of condensation with increase in curing time (Fig. 4). It was not established to what extent the orthosilicate contents could be attributed to unreacted C_3S and β–C_2S.

Lentz obtained evidence that the highly condensed material contained a variety of anion sizes. A later study (10a) indicated a mean anion size of 15.8 tetrahedra in a 15-year old paste. The rapid develop-

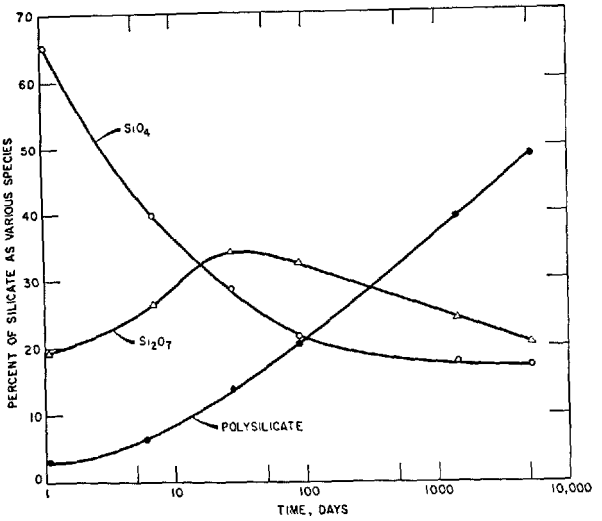


Fig. 4. *Variation with time in the distribution of anion sizes in a portland cement paste (W/C = 0.7; Lentz* (101)).

ment of $Si_2O_7^{6-}$ anions (19.8% of the soluble silica at 1 day, rising to a maximum of 34.3% at 28 days) is especially noteworthy. It would be of great interest to make a similar study on C_3S pastes of different ages and to carry out X-ray determinations of the unreacted C_3S at each stage so that the contributions of this constituent to the SiO_4^{4-} content could be assessed. Lentz's results suggest that (i) an orthosilicate may or may not be formed as the immediate product of reaction, (ii) if it is, it is quickly replaced by a pyrosilicate, which is relatively persistent, and (iii) the subsequent condensation of the silicate anions into larger units continues to advance for at least 15 years.

Electron Microscopy and Diffraction

Electron optical studies on C_3S, β–C_2S and alite pastes have been reported since the Washington Symposium by Copeland and Schulz (105), Copeland, Bodor, Chang and Weise (120), Grudemo (100), Stein and Stevels (117) and others. Grudemo (100, 101) reported that fully hydrated C_3S pastes with water: cement ratio 0.7 contained two types of C–S–H particles, in comparable amounts. One type appeares as small, thin particles, which showed at most in electron diffraction patterns a single, very diffuse ring at 2.8–3.1 Å. The other appeared as needles or rods, which seemed to be made of bundles of fibres or rolled sheets. The same two forms were observed in β–C_2S pastes.

The acicular particles have also been described by Copeland and Schulz (105) and Copeland, Bodor, Chang and Weise (120). They give a characteristic

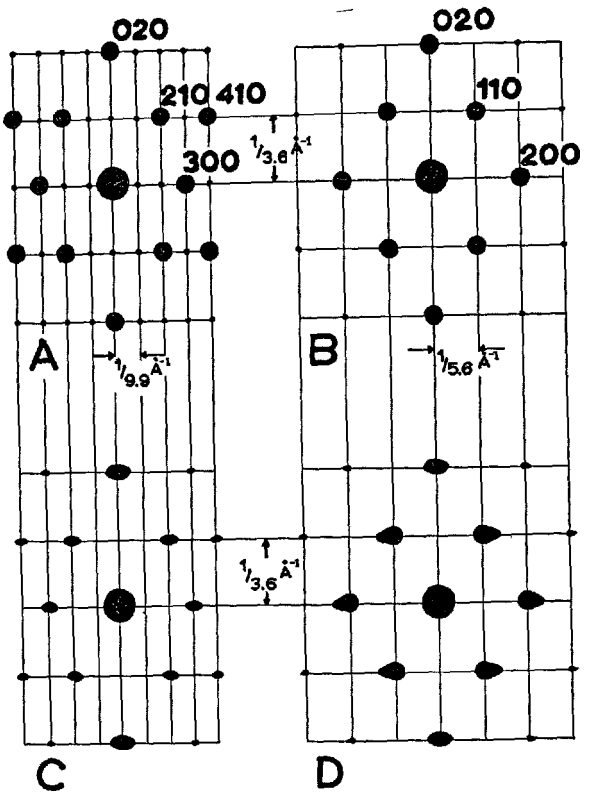

Fig. 5. *Idealized representations of some real or hypothetical electron-diffraction patterns.*

electron diffraction pattern (100, 101, 120) which was recorded particularly clearly by Copeland, Bodor, Chang and Weise, and is shown diagramatically in Fig. 5c. It differs markedly from the tobermorite-type of pattern (Fig. 5b) which is given by certain C–S–H (II) preparations mentioned earlier. The difference cannot be attributed to rolling of a thin tobermorite sheet, which would be expected to elongate the 110 and 200 reflections as shown in Fig. 5d; a tobermorite-like structure thus seems to be ruled out. The pattern in Fig, 5c does, however, show some similarity to the weighted reciprocal lattices of jennite and metajennite, which have groups of especially strong reflections with 30° and 21° indices, as well as a strong 020 reflection (Fig. 5a). Rolling of a thin crystal of jennite-like structure might be expected to change the pattern to something resembling that shown in Fig. 5c. The acicular particles in C_3S and β–C_2S pastes may therefore have a structure related to that of jennite.

Stein and Stevels (117) recorded some electron micrographs for C_3S pastes with water:cement ratio 1.0. For ages up to 2 hours, crinkly foils were observed, but after 4 hours these seemed to split into needle-like fragments, some of which appeared to be combined into cigar-shaped agglomerates. Copeland and Schulz (105) observed similar changes in the early hydration of cement pastes.

No systematic attempts seem to have been made to see whether the intensities of the C–S–H peaks or bands in the X-ray powder patterns of C_3S or β–C_2S pastes are always the same relative to each other, or not. It would be of interest to see whether any such variation occurs, and if so, whether it can be correlated with such factors as degree of hydration, temperature, or water: cement ratio, or with the relative proportions of acicular and flaky or foil-like particles revealed by electron microscopy. One might expect acicular particles to be associated with increased intensity of the 1.82 Å reflection, and flaky particles with increased intensity of the band or bands in the 2.8–3.1 Å region.

Calcium Silicate Pastes: Discussion

Lentz's (10) observation that the mean anion size rises continuously with time of hydration is readily correlated with the initial fall in C/S ratio postulated by Kantro, Brunauer and Weise (110) and by Stein and Stevels (117), as increased condensation must, in the absence of other changes, be associated with expulsion of Ca^{2+} from the structure. The subsequent rise in C/S ratio found by Kantro, Brunauer and Weise (110) can be attributed to incorporation of the elements of $Ca(OH)_2$ into the structure in amounts sufficient to outweigh the effect of increased condensation. The hypothesis that particles of jennite-like structure occur in fully hydrated pastes agrees with this explanation.

It is tentatively suggested that the following forms of C–S–H and sequence of changes occur in C_3S and β–C_2S pastes. Initially, a high C/S product is formed as a surface coating. It is probably composed initially of Ca^{2+}, $H_2SiO_4^{2-}$ and OH^- ions and H_2O molecules, and has a C/S ratio close to that of the starting material. Nothing is known of its structure; it may be amorphous. Anion condensation to, or perhaps beyond, the pyrosilicate stage may occur in this material. The second product is formed from the first by dissolution and reprecipitation. It probably has a C/S ratio of 1.0–1.5 and forms foils or platelets some 10–20 Å thick; it may be a very poorly crystallized C–S–H (I), with a tobermorite-like structure. How this low-lime phase coexists with free $Ca(OH)_2$ does not seem to have been explained; perhaps a high concentration gradient exists. Further anion condensation may occur within this material, either by *in situ* transformation or by repeated dissolution and reprecipitation. The third product has, in its most developed form, a fibrous morphology and a jennite-like structure, with a C/S ratio of 1.5–2.0. The distinctions between the second and third products, and calcium hydroxide particles, are probably not sharp; the small, thin particles which Grudemo (101) observed in fully hydrated C_3S pastes could have structures based on more-or-less continuous Ca–O layers, both surfaces of which are coated with a highly disordered mixture of hydroxyl ions and silicate anions of various sizes. Within any one such layer, the structure might in some places approximate to that of tobermorite or C–S–H (I), in others to that of jennite, and in yet others to that of $Ca(OH)_2$; this would explain the very poor electron diffraction pattern. Still greater disorder probably occurs in the presence of other ions, such as aluminate or sulphate; this is discussed in the next section.

Isomorphous Substitution

Substitution in Crystalline Tobermorite

In 1957, Kalousek (121) showed that Al^{3+} could enter the structure of 11 Å tobermorite. His results have recently been confirmed and extended by Diamond, White, and Dolch (122) who studied the synthesis of this phase in the presence of Al^{3+}, Mg^{2+}, and Fe^{3+}. Al^{3+} was added as kaolinite or as $Al(OH)_3$. In approximate agreement with Kalousek's results, it was shown that Al^{3+} could be present in amounts corresponding to replacement of about 15% of the Si^{4+} in the structure before a hydrogarnet appeared as an additional phase, and that this replacement caused the basal spacing to increase. Diamond, white and Dolch reported that the 002 spacing increased from 11.18 Å in the Al-free compound to 11.45 Å for maximum substitution. X-ray spectroscopy indicated that the Al^{3+} was in fourfold coordination, thus supporting the view that it replaced Si^{4+} in the structure.

Diamond, White and Dolch (122) found that entry of Al^{3+} into the structure caused only minor changes in the infrared spectrum, peaks at 1207 and 745 cm^{-1} being shifted to 1175 and 700 cm^{-1} respectively. Electron microscopy also showed no marked changes in morphology with Al-substitution, all the specimens examined consisting of platey crystals with sometimes a slight tendency to elongation. Specific surface areas (78 m^2/g for the Al-free preparation) showed no systematic trend with substitution. D.T.A. curves gave results broadly similar to those reported by Kalousek; the unsubstituted preparation showed a broad endotherm at about 275°C and a weak exotherm at 815°C, and the main effect of maximum Al-replacement was greatly to increase the size of the exotherm and to shift it to 835°C. X-ray results showed that both unsubstituted and substituted specimens had changed to the 9 Å hydrate by 350°C. Al-rich specimens appeared partly fused when cooled from 775°C or over. It was suggested that both this and the increased size of the exotherm might be caused by the formation of some quasi-amorphous phase, such as an Al–Si spinel.

As Diamond, White and Dolch pointed out, Farmer (123) has suggested that the infrared peak at about 1200 cm^{-1} in preparations such as those under discussion could be attributed to xonotlite. The conditions of preparation used by Diamond, White and Dolch (19 hour treatment of a lime-quartz slurry at 175°C under saturated steam pressure) might have caused partial conversion to xonotlite. The presence of a little xonotlite in the preparations would not invalidate the main conclusions reached by these authors.

Diamond, White and Dolch also studied the preparation of 11 Å tobermorite in the presence of Fe^{3+}, added as hematite or as goethite, and in the presence of Mg^{2+}, added as MgO. The hematite did not react. The results obtained using goethite and MgO suggested that both Fe^{3+} and Mg^{2+} could enter the structure, but reproducible results were not obtained and no detailed conslusions were reached.

Roy and Johnson (3) reported equilibrium studies on the hydrothermal treatment of mixes of compositions C_5S_6A and $C_{10}S_{12}A$ at 20,000–45,000 p.s.i. They expressed their results in terms of compatibility volumes within the C–A–S–H tetrahedron, which were shown projected on the C–S–H face for four temperature ranges. At 175–255°C, an Al-rich tobermorite coexisted with a hydrogarnet of approximate composition C_3ASH_4; at 260–275°C, a range of substituted tobermorites coexisted with xonotlite, and a particular one with xonotlite and a hydrogarnet. At 280–330°C the only stable tobermorite was an Al-substituted one, which above 330°C became unstable relative to a hydrogarnet and xonotlite. Roy (124) considered that the presence of Al^{3+} accelerated the crystallization of tobermorite, that it raised the upper temperature limit of its stability and that there was little evidence that it accelerated the change from tobermorite to xonotlite.

Substitution in C–S–H Preparations

It has long been recognized that ill-crystallized forms of C–S–H such as those produced in cement pastes may well contain ions other than those of the pure $CaO–SiO_2–H_2O$ system. At the London Symposium in 1952, Kalousek (99) suggested that all of the Al^{3+}, Fe^{3+} and SO_4^{2-} ions present in the cement tend eventually to enter the C–S–H. Although subsequent work has not supported this extreme view, at any rate for normally cured cement pastes, it still appears likely that these ions are partly present in the C–S–H. In the case of the sulphate ion, Kalousek (125) has recently placed this suspicion on a firmer basis by determining the amounts of crystalline SO_4–containing phases, which he showed to be inadequate to account for all the SO_4^{2-} ion present.

Copeland, Bodor, Chang and Weise (120) have studied the preparation of lime-rich C–S–H in the presence of Al^{3+}, Fe^{3+} and SO_4^{2-}, and the reactions with these ions of C–S–H gel preparations already made. Two types of evidence showed that Al^{3+} can enter the structure of the lime-rich C–S–H formed in C_3S and β–C_2S pastes. Firstly, experiments were carried out in which a hardened C_3S paste was ground and then treated with water and a reactant such as C_4AH_{13}. The only phases detected in the product were $Ca(OH)_2$ and a C–S–H gel phase. Essentially the same products were obtained on paste hydration of alite, or by ball-milling of mixtures of C_3S and C_3A. Secondly, it was shown that the morphology of the C–S–H gel particles changed if sufficient Al^{3+} was present. Thus a C_3S paste that had been ground and then shaken with water for 3 months was shown by electron microscopy to contain rolled sheets or fibres. If the experiment was repeated with C_4AH_{13} present during the shaking, the particles observed were ribbed sheets or laths similar to those formed during the early stages of hydration of cement. Evidence was obtained that the maximum amount of Al^{3+} that could be incorporated in the C–S–H was around 1 atom of Al per 6 atoms of Si. The variations in C/S and H/S ratios with Al-substitution were studied. They suggested that Al^{3+} could enter the structure in two ways: in the first,

$Al^{3+} + H^+$ replaced Si^{4+}, and in the second, $2Al^{3+}$ replaced $3Ca^{2+}$. In support of this conclusion, X-ray spectroscopy suggested that both octahedral and tetrahedral Al^{3+} were present.

These results may be compared with those of Diamond, White and Dolch (122) for crystalline tobermorite. The upper limits of Al/Si ratio in the structure are comparable in the two cases, but in the crystalline tobermorite, Al^{3+} seems to replace only Si^{4+} and not also Ca^{2+}.

Copeland, Bodor, Chang and Weise (120) prepared iron-substituted C–S–H gels by milling hardened pastes of C_3S with different proportions of C_2F. From studies of C/S and H/S ratios, they concluded that $2Fe^{3+}$ replaced $Ca^{2+} + Si^{4+}$. The upper limit of substitution was one atom of Fe^{3+} to six atoms of silicon.

Sulphate substitution was studied in several ways. In one, mixtures of C_3S and gypsum were hydrated in the ball-mill. X-ray and electron optical studies showed no phases in the product except C–S–H and $Ca(OH)_2$. The compositions of the products suggested that S^{6+} replaced $Si^{4+} + 2H^+$. X-ray spectra showed the sulphur K_α peak to be nearer that found with $K_2S_2O_7$ than that found with gypsum. It was concluded that sulphur replaced silicon in a chain anion. The upper limit of sulphur substitution was one atom of S per six atoms of Si.

Some additional experiments were carried out to show that C–S–H in hardened pastes reacts with sulphate solutions even when the pastes are not first ground and re-dispersed: replica studies with the electron microscope showed that changes in morphology occur on treatment with a SO_4^{2-} solution.

The results described above suggest clearly that Al^{3+} Fe^{3+} and SO_4^{2-} ions can all enter the structure of C–S–H formed in calcium silicate pastes. Their presence is likely to render the C–S–H formed as the final product in paste hydration of cement even less definite in structure than that given by the calcium silicates.

Written Discussion

Jerzy R. Dyczek

Introduction

The information contained in your report about the influence of the concentration of $Ca(OH)_2$ on the reaction of the hydration of calcium silicates are in a good agreement with the results of my latest work concerning the dependence of the texture of the products of hydration of cement on the type and amount of calcium sulphate added to the cement.

It is known, that the presence of more or less soluble calcium sulphate ($CaSO_4 \cdot 2H_2O$ or $CaSO_4 \cdot \frac{1}{2}H_2O$) has an important influence on the solubility of $Ca(OH)_2$.

Procedure

The cements used in the following tests were prepared in the following way: two industrial clinkers of the chemical compositions given in Table 1 were ground and then mixed in a laboratory ball mill with the addition of ground calcium sulphate. Calcium sulphate was added in such quantities as always to ensure 2% content of SO_4^{2-} in the cements. Thus six cements were obtained of which two had no calcium sulphate addition and were pure ground A and B clinkers, the two next were A and B clinkers with 2% addition of SO_4^{2-} introduced in the form of $CaSO_4 \cdot 2H_2O$ and designated in abbrevation as A_2 and B_2, and finally the two cements with 2% addition of SO_4^{2-} introduced in the form of $CaSO_4 \cdot 0.5H_2O$ and designated as $A_{0.5}$ and $B_{0.5}$.

The compression, bending strengths and the setting time were determined and the degree of grinding was checked for the cements tested by screen analysis and by determining their specific surfaces by the Blaine method (results given in Table 2).

To make possible a comparison of the specific surfaces of the hardened cement pastes (determined by the BET method) prepared from the above mentioned cements, a knowledge of the degree of hydration was indispensable. Therefore for corresponding hardening times the evaporable water was determined by the method described by Copeland, the results being given in Table 3.

The cement pastes intended for determination of the specific surfaces were prepared with such a quantity of water as to obtain a water-cement ratio of 0.4.

The paste samples were stored in a thermostatic bath (20°C ± 2°) in hermetically sealed glass test tubes.

After the elapse of 3, 7, 14, 21 and 28 days the test tubes with corresponding pastes were broken, the paste crushed and, after the evaporable water in it was determined, approximately 2 g of the hardened paste was transferred to the BET apparatus in order to determine the specific surface. Nitrogen was used as the absorbed gas.

The results of determination of the specific surfaces are presented in Fig. 1.

Considerable differences observed in the specific surfaces for the same hardening times of the cements tested and differing only in the form of calcium sul-

phate added were the reason for taking a series of photographs by means of an electron microscope.

The microscope preparations were made by the extraction replica technique, spraying the carbon and platinum at a 30° angle onto a triofal foil taking a fresh fracture of a hardened cement paste.

The Results and Their Discussion

From a comparison of the results of the determinations of the evaporable water in the pastes from cements produced from A and B clinkers respectively it appears that slightly more uncombined water was removed from the cements containing calcium sulphate dihydrate than from those of cement with calcium sulphate semihydrate. The greatest quantity of evaporable water (identified with that chemically uncombined) was removed from the hardened pastes made from the clinkers without a calcium sulphate addition (Table 3). The pastes that had undergone the reaction with water to a smallar degree did not always displayed a small specific surface. After three days hardening the pastes made from clinkers without a calcium sulphate addition had rather big specific surfaces (Fig. 1), while after longer hardening times (7, 14, 21 and 28 day respectively) the specific surfaces were smallest.

The greatest specific surfaces were measured in the pastes made from cements with calcium sulphate dihydrate and these cements had also the highest mechanical properties after hardening. A maximum may be observed occurring after about 14 days on the curves illustrating the specific surfaces depending on the hardening time. The later reduction of the surface may be explained by the recrystallization of the hydration and hydrolysis products with a simultaneous hindering of the reaction of that part of the cement grains which have not undergone reaction with water caused by the products of these reactions surrounding them (coatings hindering the access of water to the cement grains). A similar decrease in the specific surface of the reaction products of the alite and belite with water was observed by Copeland who explained this by the formation of a two and then of a three layer tobermorite. The differences in the specific surfaces of the investigated hardened pastes which clearly depended on the presence of calcium sulphate dihydrate and calcium sulphate semihydrate may be explained as follows: during the first moment after mixing the cement with water the better soluble $CaSO_4 \cdot 0.5H_2O$ passing into the solution reduces considerably the solubility of $Ca(OH)_2$ causing its precipitation in a spherical shape. The low concentration of $Ca(OH)_2$ may favour the formation of the lime poor habits of tobermorite (CSH I).

After mixing the cement with water in the presence of the less soluble $CaSO_4 \cdot 2H_2O$ more $Ca(OH)_2$ will be able to pass into the solution and the crystallization of the tobermorite-similar phase will occur in conditions favouring the formation of the lime rich fibrous CHS II variety. The differences in the crystal habit of these two varieties of tobermorite-like phase (CSH I—lamellae; CSH II—fibres of tubular structure) may be explained by the differences in the observed specific surfaces of the pastes tested.

In spite of the fact that after several minutes after mixing with water the calcium sulphate semihydrate initially present in the cement will become hydrate, the further course of crystallization will follow the already existing model.

Microscopic examinations support the interpretation of the results given above:

A total of about 150 photographs were taken. Only chosen examples are presented here. The single crystals designated on the photographs were identified by the electron diffraction method. Photographs No. 1–4 illustrate the cement pastes from A series with calcium sulphate dihydrate, No 5–8 with calcium sulphate semihydrate, No. 9–10 from pure clinker without calcium sulphate addition.

A better crystallization of the fibrous habits of CSH II and the presence of elongated aggregates of this variety (Photo 1–4) which are longer than those in the cement pastes with $CaSO_4 \cdot 0.5H_2O$ may explain the better strength properties after hardening of the cement pastes with calcium sulphate dihydrate and the tubular structure of the CSH II the large specific surface of these pastes.

In the pastes produced from the cements with calcium sulphate semihydrate the lamellar shapes of

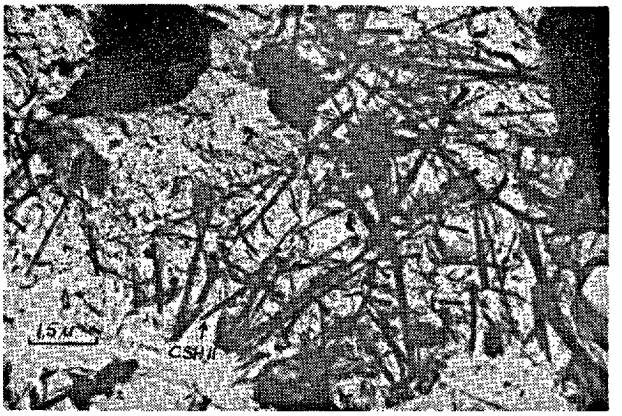

Photo 1.

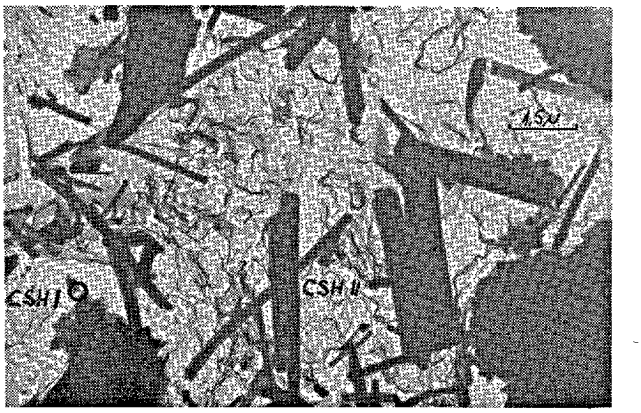

Photo 2.

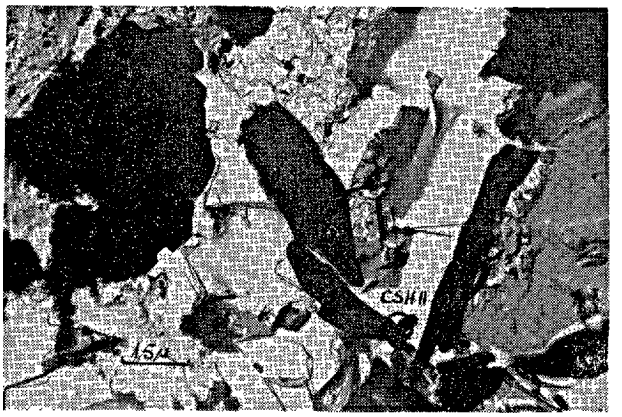

Photo 3.

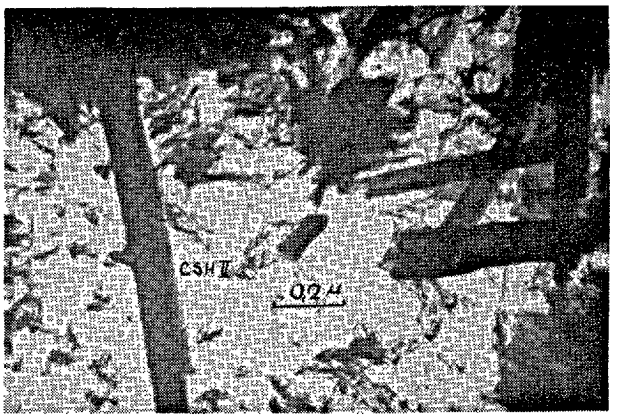

Photo 4.

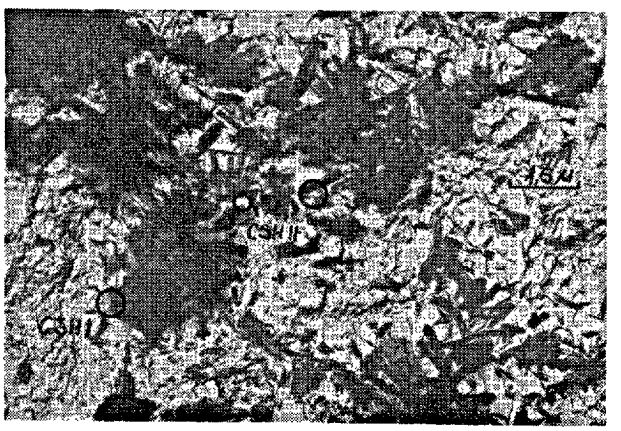

Photo 5.

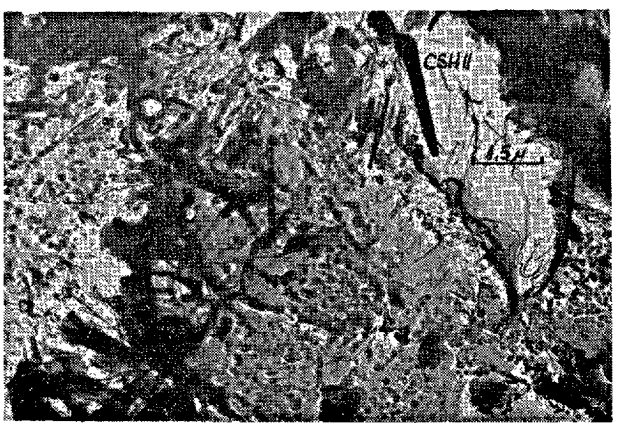

Photo 6.

the CSH I may be observed more often as irregular aggregates.

In all the preparations both varieties of the calcium hydroxide were observed. However, the portlandite occurred most often in the preparations taken from pastes made of cements with calcium sulphate dihy-

drate.

Conclusions

From the results presented above it may be concluded that the disadvantageous effects of false setting (decrease in mechanical strength, surface hardness, etc) are caused by the changes in the texture of the products of the reaction of the cement with water, and in particular of the tobermorite-similar phase. When the cement contains $CaSO_4 \cdot 0.5H_2O$ less fibrous habits of CSH II form in the paste made of it than in the paste with the calcium sulphate dihydrate where CSH II will form moreover elongated and better crystallized habits.

Additional Note

I think, that the results of my work given above may contribute to the better understanding of the phenomena of false setting and its influence on some properties of cement in use.

Written Discussion

Paul Longuet

The works which have been done for some years upon the paste hydration of pure tricalcium silicate seem to be able to bring some complements to the calorimetric studies mentioned in the principal paper. Specially the use of the isothermal calorimeter on the first stage of hydration allowed new observations. We reproduce here the communication of B. Courtault (1) on this subject.

"D. L. Kantro, S. Brunauer and C. H. Weise (2, 3), A. Van Bemst (4) and H. N. Stein and J. M. Stevels (5) deduce from their works, the formation of several hydrated phases during the hydration in paste of the tricalcium silicate. Those authors found as a rule their speculations on the analytic results of the hydrated products and their characterizations by means of electronmicroscopy.

Calorimetry and more specially the often used isothermal calorimetry (5, 6, 7, 8) seems to be the ideal mean to show the real evolution of the different hydrated forms but in practice this prospect has not yet been confirmed. Two reasons seem responsible for this seeming failure: the usual conditions in the technical employment which lead to the mixing of solid-liquid outside the calorimeter and the lack of exact definitions of the heterogeneous system studied.

For the first point, we suggested a calorimetric device allowing the recording of the thermal phenomena at the initial stage of hydration (8). For the second one, we studied the influence of the tricalcium silicate grading, of the experiment temperature, of the hydrated state of the solid phase, of the composition of the liquid phase in touch with the solid, of initial additions to the solid or liquid phase.

Grading conditions affect the saturation rate of the liquid phase and the formation rate of the hydrated phase. The conclusions are summarized on the Fig. 1. A large and fairly coarse grading gives a simple thermogram of the type usually mentioned in literature (5, 6) while a granulometric portion, fine and well definite allows to specify the different phases of the thermal reaction.

The rate of the different reactions is conditioned by the temperature (Fig. 2). The slowing down due to the temperature drop permits to make a peak obvious in the first stage, on the thermograms at 6°C and 15°C.

The relations between the thermal effects and the equilibrium state of the system have been established point by point upon the solution in touch, after pressing out and upon the solid after hardening and elimination of free water by cryosublimation (this process used at the CERILH since 1955 consists in freezing suddenly the sample and to sublimate the produced ice under high vacuum).

The extracted solution allows to determinate the lime content of the solution at a definite time. The thermogravimetric measurements of the cryosublimated solid give the amount of $Ca(OH)_2$ released during the hydration and the amount of water bound to the hydrated portion.

The whole determinations made upon the same sample are shown on the Fig. 3. Their examination

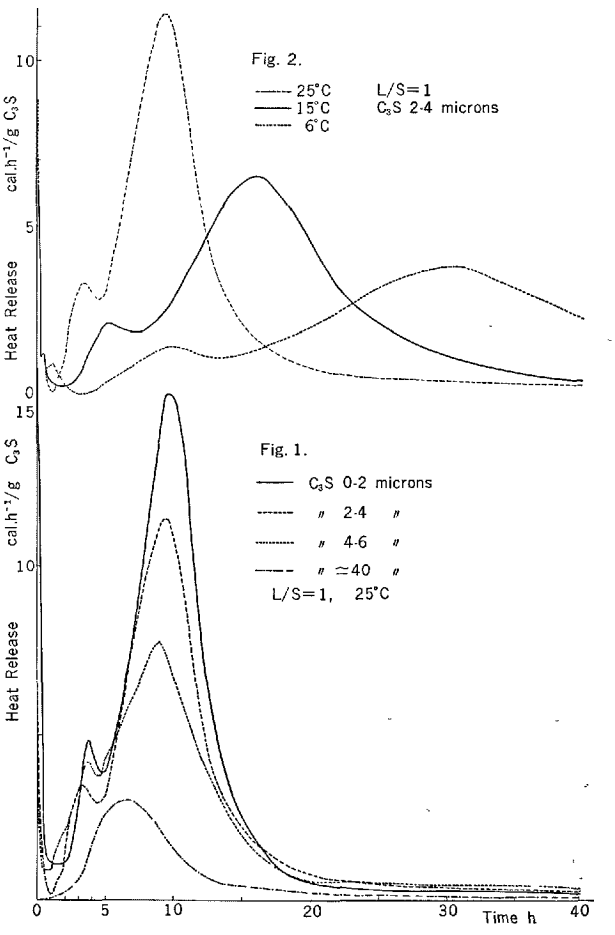

Fig. 1. *Grading influence*
Fig. 2. *Temperature influence*

brings the following remarks:

—The biginning of the endothermic effect is bound to a definite concentration of lime in solution.

—The development of the endothermic effect corresponds to a temporary increase of the lime concentration in the solution in touch.

Those two effects characterize a hydrolysis reaction (transition for a definite concentration of the solution, to a less saturated salt with release of base).

—The formation rate of $Ca(OH)_2$ released by hydration, increases before the endothermic effect while the formation rate of the hydrated phase grows only after the end of this effect.

To sustain the supposition of the hydrolysis reaction, the effects due to changes of lime concentration in solution in touch must be verified (Fig. 4). The addition of amorphous silica, already studied by Stein and Stevels (5) accelerates the hydration, inducing a decrease of the lime concentration in the liquid phase.

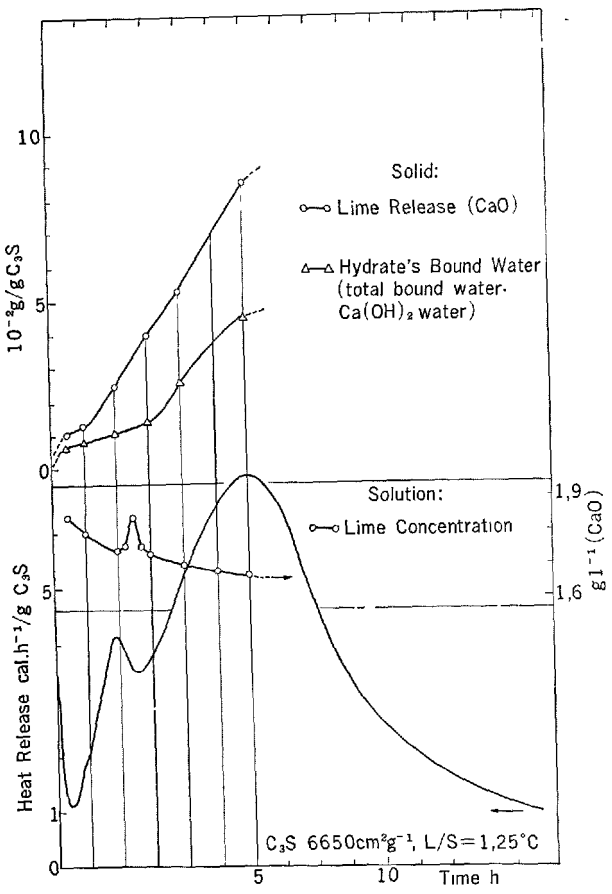

Fig. 3. *Solid, solution and heat release modifications*

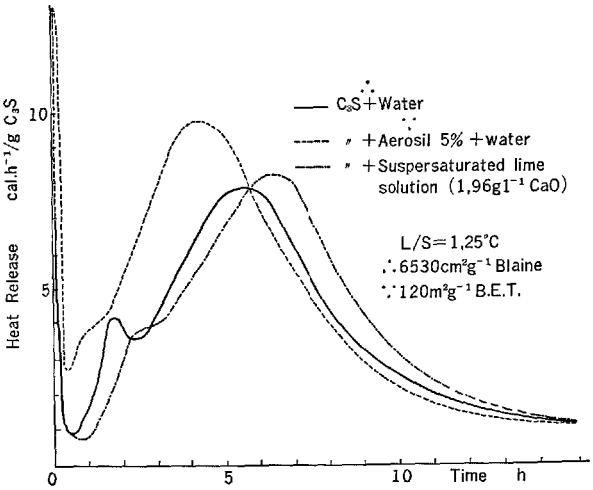

Fig. 4. *Hydration's medium influence*

On the other hand, when the initial water is substituted by a super-saturated lime solution, prepared according to Longuet and Zelwer (9), the hydrolysis equilibrium is displaced and the hydration is delayed. The study of the anomaly in the thermograms obtained by isothermal calorimetric measurements, gives an experimental confirmation of the supposed transformation of an hydrate with high C/S ratio, formed in the first stage of the reaction between water and C_3S (Kantro, first hydrate of Stein) in a hydrate with lower C/S ratio of CSH I type (second hydrate of Stein).

Written Discussion

O. P. Mchedlov-Petrosyan, I. P. Vyrodov and L. P. Papkova.

D. I. Mendelejev (1) a prior noted that interaction between lime and aggregate is inevitable in durable mortars, while V. N. Young (2) has found by the use of chromatic reactions the presence of calcium hydrosilicates in the mortars of ancient buildings. Some reliable investigators denied the possibility of active interaction between binder and aggregate (3) and considered the formation of calcium carbonate to be

the only cause of the durability of ancient lime mortars (4).

Even the present time literature still uses the term "inert aggregates".

Our numerous attempts to explain experimentally the processes of prolonged hardening of lime mortars aged up to 2000 years (5–9) were conducted with the use of a complex of various physico-chemical and biochemical methods and allow us to picture a certain supposed course and nature of interaction between the components of durable mortars.

However we consider the results of X-ray examination of ancient lime-mortars as a decisive factor in solving the problem.

We used the method of X-ray ionization recording. This method is used widely in the investigation of mortars.

The apparatus used are: USR-50-IM and USR-50-I.

Some of the specimens of ancient mortars were examined by means of Deby's method (powder-method) with X-ray apparatus URS-55-A.

To determine reliable data of the phase-contents of ancient mortars we conducted X-ray investigation on specimens aged from 200 to 2000 years by means of three different apparatus in three different laboratories because we could not find the data of X-ray examination of ancient mortars in the modern Russian and foreign literature (12 and others).

The Table 1 displays the results of X-ray examination of these mortars; their study show that after centuries hardening the following products are observed:

1. The main component is calcite, increasing with the age of mortars;
2. The content of calcium hydrosilicate is much lower than of calcite; though all the specimens contain the hydrosilicates of following types: C_2SH(A, B, C); CSH(B); C_2S_2H; $C_3S_2H_3$; tobermorite etc. These calcium hydrosilicate are hydration products of portland-cement in which they are however presented in great quantity (10);
3. The investigation of the majority of examined specimens (11 of 12) has shown the presence of hillebrandite (C_2SH(B)), which is known as a product of hydro-thermal treatment of portland-cement paste; most of specimens contain, besides it, the hydrosilicates of the tobermorite group;
4. Several specimens showed the presence of amorphous silica; the hollow galls (eroded gall) in X-ray data indicate it's presence.
5. The content of hydrosilicates of calcium as well as that of calcite increases with the age of lime mortars.

The X-ray investigation has shown in all specimens of ancient mortars similar phase content according to nomenclature of products of hardening in the specimens of various climate zones.

The results of X-ray examination of all ancient mortars agree with the data obtained through other experimental methods, thermo-analysis, chemical-petrographical, luminescentical analysis and electron-microscopical analysis etc. and confirm the presence of calcium hydroscilicates (6–9). The content of calcium hydrosilicates confirms the presence of the hydrosilicate-type of hardening in ancient lime mortars similar to the hardening of portland-cement.

The presence of hillebrandite (C_2SH(B)), afwillite ($C_3S_2H_3$), gyrolite ($C_2S_3H_3$), riversidite (C_2S_2H) and others in ancient lime-mortars, which are formed under hydrothermal conditions in portland-cement, allows to assume, that the replacement of thermal treatment by long-time hardening (and vice versa) may give qualitatively the same results (11).

Table 1. *Results of X-ray analysis of ancient mortars.*

Number ordinal	Specimen number	Century of building	Phase composition
1	2	3	4
1	53[x)]	I	calcite; C_2SH(C); C_2SH(A); tobermorite; C_2SH(B); CSH(B)
2	72	IV	calcite; C_2SH(C); C_2SH(A); C_2SH(B); tobermorite; CSH(B).
3	59[x)]	XII	calcite; C_2SH(C); tobermorite; C_2SH(A); CSH(B).
4	80	XII	calcite; C_2SH(B); C_2SH(A); tobermorite; C_2SH(C); CSH(B).
5	85	XIII	calcite; C_2SH(C); C_2SH(A); C_2SH(B); tobermorite.
6	25	XV	calcite; C_2SH(B); C_2SH(A); tobermorite; C_2SH(C); CSH(B).
7	33	XVII	calcite; C_2SH(B); C_2SH(A); tobermorite; C_2SH(C); CSH(B).
8	54	I	calcite; C_3SH_2; hillebrandite.
9	87	VII	calcite; hillebrandite.
10	1	XI	calcite; hyrolite; hillebrandite. calcite; C_2S_2H-macro-crystallic.[xx)]
11	24	XIV	calcite; hyrolite; afwillite.
12	46	XVIII	calcite; hillebrandite; C_3SH_2; C_2SH.

Notes: Specimens 1-7 were analysed by means of the X-ray apparatus URS-50-IM; specimens 8-12—by means of the apparatus URS-50-I; specimen 10[xx)]—by means of the apparatus URS-55-3I (Deby-method). In specimens I and 3 there were observed "hollow galls" proving the presence of amorphous silica.

In spite of the essential differencies in phase-content of hardened lime and portalnd-cement stones they contain qualitatively the same products of hardening. This fact apparently allows, to a certain extent, to suppose the considerable durability of artificial stone made of portland-cement under unaggressive conditions of service. The age of portland-cement stone is only about 150 years, while the age of lime mortars is several thousands of years.

Oral Discussion

Udo Ludwig and Hans E. Schwiete

1. During hydration of glasses of the chemical composition of melilites in lime saturated water we found out together with Würth and Grieshammer that the glasses rich in MgO are leading to a formation of a foil-like C_2MS_2 aq.

The 12.6 Å interference was absent when we added anhydrite to the starting mixtures (Fig. 3). The formation of gehlenite-hydrate, ettringite and monosulphate-hydrate and hydrogarnet should be in this case out of discussion.

2. Together with Seiler we found out, that the C/S-ratio of the calcium silicate hydrates was in the range of 2.25 and 2.70 when the starting material was as follows:

The last results show a maximum C/S ratio of 3. When starting with a industrial retarder we found

Table 1. *Reaction of retarders with lime saturated solutions*

Oral Discussion

Della M. Roy

Professor Taylor has emphasized the importance of establishing equilibrium conditions when defining reactions taking place under hydrothermal conditions or at saturated steam pressures. Recently it has been suggested that C–S–H phases having a Ca: Si ratio of 3:2 are metastable with respect to afwillite. Another instance where metastable reaction products are

apparently produced is the case where high-SiO_2 phases such as gyrolite or truscottite are formed by reacting mixtures which contain a high surface area source of SiO_2. Presumably the stable equilibrium product under the given pressure-temperature-composition conditions would contain tobermorite. Does the author know of any work related to this problem? Particularly, is there any evidence that such metastable products eventually yield to the stable equilibrium phases?

SESSION II-2 CRYSTAL STRUCTURES AND PROPERTIES OF CEMENT HYDRATION PRODUCTS (HYDRATED CALCIUM ALUMINATES AND FERRITES)

Principal Paper Crystal Structures and Properties of Cement Hydration Products (Hydrated Calcium Aluminates and Ferrites)

Hans E. Schwiete and Udo Ludwig*

Introduction

In the following communication a review is given of the structures and properties of hydrated calcium aluminates and hydrated calcium ferrite aluminates together with those of the hydrates and double salts derived from them.

Following upon the knowledge that was available at previous symposia a report is presented of new results:

1. Previous data have been confirmed by new work.
2. Progress has been made particularly in investigating dehydration and in distinguishing the various hydrated tetra- and carboaluminates.
3. Numerous crystallographic data have been worked out for the double salts of general composition $3\,CaO \cdot Al_2O_3 \cdot Ca(X, Y_2) \cdot nH_2O$.
4. Two other double salts were synthesized and are described.
5. The only fully-clear structure is still that of C_3AH_6 which is derived from grossularite (C_3AS_3).

Crystal Structure and Properties of the Hydrated Calcium Aluminates and Ferrites

Amongst the calcium-rich hexagonal or pseudo-hexagonal hydrated calcium aluminate or calcium aluminate ferrites one must distinguish between those that contain three molecules of a calcium-bearing compound ($CaSO_4$, $Ca(OH)_2$, $CaCl_2$, $CaSiO_3$ and $CaCO_3$) and those which contain only one molecule of these compounds per unit of formula. Based on a suggestion of Smolczyk (1) it seems appropriate to designate the hexagonal hydration products which crystallize with three molecules of a calcium salt per unit of formula and whose prototype is ettringite ($C_3ACs_2H_{32}$) as "AFt phases". This is an abbreviation of (tricalcium)-aluminate *f*errite·*t*ri (sulphate, -hydroxide, etc.)·(hydrate)-*phase*. Consequently it is reasonable to name the corresponding phases whose prototype is C_4AH_{19} as "AFm"-phases (*m* = mono).

The distinction into these two groups is useful since the structures and properties of the AFt and AFm phases are fundamentally different.

The AFt phases are morphologically recognizable as hexagonal columns or needles in which the water of crystallization is contained in channels parallel to the *c*-axis. The AFm phases on the other hand are hexagonal or pseudo-hexagonal sheets in which the water of crystallization is bound in layers normal to the *c*-axis. These differences have an effect on the properties of dehydration.

*Institut für Gesteinshüttenkunde, Technische Hochschule Aachen, Aachen, West Germany.

One can further distinguish a group of hexagonal or pseudo-hexagonal hydrated calcium aluminates or calcium aluminate ferrites with a low calcium content which occur in high alumina cement or in slag-rich blast-furnace cements. A final group comprises the isometric hydrated calcium aluminate ferrites in which two molecules of water can be replaced by one molecule of SiO_2.

AFt Phases

In the following sections are described in more detail a phase of the composition $C_3A \cdot 3CaCl_2 \cdot 30H_2O$ and the AFt phases in which calcium hydroxide is wholly or partially replaced by calcium sulphate. For the corresponding calcium silicate and calcium carbonate phases reference is made to the original literature (2, 3).

$C_3AC_3H_{32}$

The hydrated tricalcium-aluminate-trisulphate is called ettringite after the natural mineral of the same composition. The mineral ettringite (named after Ettringen in the Eifel Mountains, Germany) was first discovered and investigated by Lehmann (4) in 1874. Michaelis (6) was probably the first to synthesize it in 1892. Bannister, Hey and Bernal (7) carried out a structural determination in 1936 and found for the lattice constants $a_0 = 11.24$ Å and $c_0 = 21.45$ Å. The space group was found to be $P6_3/mmc$. The density is 1.75 – 1.79 g/cm³. The lattice constants and the space group were confirmed by Feitknecht and Busser (12), as well as by Swanson, Gilfrich, Cook, Stindfield and Parks (13). In our own investigations (14) we found experimentally a density of 1.72, and one of 1.75 g/cm³ from X-ray data (Table 1).

In a recent publication Bezjak and Jelenic (15) determined by a Patterson synthesis the distances between the single atoms and the atomic groups and they are listed in Table 1. A final report on these investigations has not yet been published.

Bereczky (16) determined the pH value of ettringite as 10.52. From our own measurements (14) the value lies between 10.2 and 10.3. By boiling with the ester of acetic acid for one hour 4.74% CaO was dissolved from ettringite.

$C_3(A, F)C_3 \cdot H_{32}$

All the work so far carried out on ettringite in which

the Al^{3+} ions are replaced by Fe^{3+} ions is shown in Table 2. It can be seen that McIntire and Shaw (11) in 1925 were the first to prepare an iron-ettringite. Aruja and Rosaman (17) were the first to establish the a_0 value as 11.23 Å and the c_0 value as 22.14 Å. Smolczyk (1) found the a_0 value to be 11.25 Å and that of c_0, 22.02 Å.

According to our own investigations (14) the values are $a_0 = 11.25$ Å and $c_0 = 21.49$ Å, i.e. the values found by us are closer to those of the normal aluminium-ettringite. On the other hand the investigations of Malquori and Cirilli (19) and those of Cirilli (19) have shown that the solid solution series,—i.e. the replacement of aluminium by iron is incomplete. They found a maximum F/A ratio of 3:1.

We have carried out several thermo-chemical investigations (20, 14) on ettringite and also on a reaction mixture of iron-ettringite and monosulphate hydrate (Fig. 1). Both kinds of ettringite continuously give off water above 40°C and the maximum of the endothermal peak is reached at 130°C. Normal ettringite shows a second endothermal peak at 270°C which has not been found for iron-ettringite. Instead the latter has the additional characteristic peaks of monosulphate hydrate and calcium hydroxide.

$C_3A \cdot 3CaCl_2 \cdot H_{30}$

A chlorine-bearing hydrate which corresponds in composition to ettringite i.e. which contains $3CaCl_2$ instead of $3CaSO_4$, was described by Serb-Serbina (21) in 1956. He established that this hydrate is formed at low temperatures and he examined its thermal properties by means of DTA.

We have investigated (22) the formation of $3CaO \cdot Al_2O_3 \cdot 3CaCl_2 \cdot 30H_2O$ at temperatures between +20° and −10°C in the presence of various concentrations of calcium chloride. The starting materials were C_3A and $CaCl_2 \cdot H_2O$ (analyticgrade) and doubly distilled water.

Our infra-red spectroscopic investigations of ettringite ($3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O$) which was produced by hydration of C_3A in the presence of gypsum, and of $3CaO \cdot Al_2O_3 \cdot 3CaCl_2 \cdot 30H_2O$ (Fig. 2) show a structural similarity between these two hydrate phases. In both hydrates the water is present in two different forms. The absorption band at a wave length of 2.8 μm indicates the presence of hydroxyl groups whilst that at 6.2 μm represents molecular water. The bands at 7 μm suggest the formation of carbonate during the infra-red investigation; the reso-

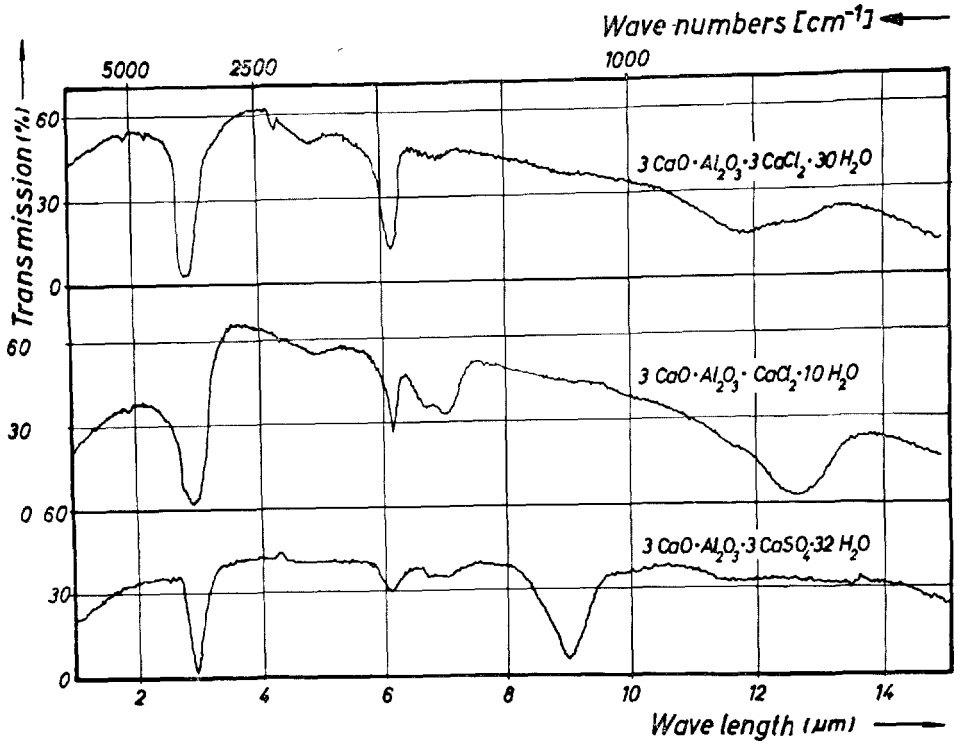

Fig. 2. *Infrared-spectroscopic investigations on calcium aluminate hydrates (Schwiete, Ludwig, Albeck 1967)*

nances at 9 μm and 15 μm of the ettringite are characteristic for the S-O-bonds of the SO_4^{2-} groups whilst in the range 11–13 μm the vibrations for the Al-O-bonding of the compound $3CaO \cdot Al_2O_3 \cdot 3CaCl_2 \cdot 30H_2O$ appear. The shapes of the DDK curves for ettringite and the corresponding calcium chloride-bearing compound (Fig. 3) also show good agreement. For ettringite the main endothermal peak begins at 70°C and has its maximum at 140°C. Release of water from the chlorine analogue begins at 50°C and reaches a maximum at 160°C.

Because of the structural relationship of $3CaO \cdot Al_2O_3 \cdot 3CaCl_2 \cdot 30H_2O$ with ettringite the equations for the hexagonal system were used for determining the (hkil)-values. In this way all the interference lines on the powder photograph could be given an (hkil)-value. Single crystal photographs were not possible because of the minute dimensions of the crystals. In Table 3 the calculated lattice constants and the density

Table 3. *Crystallographic data of hydrates with the composition* $3CaO \cdot Al_2O_3 \cdot 3Ca(X, Y_2) \cdot nH_2O$

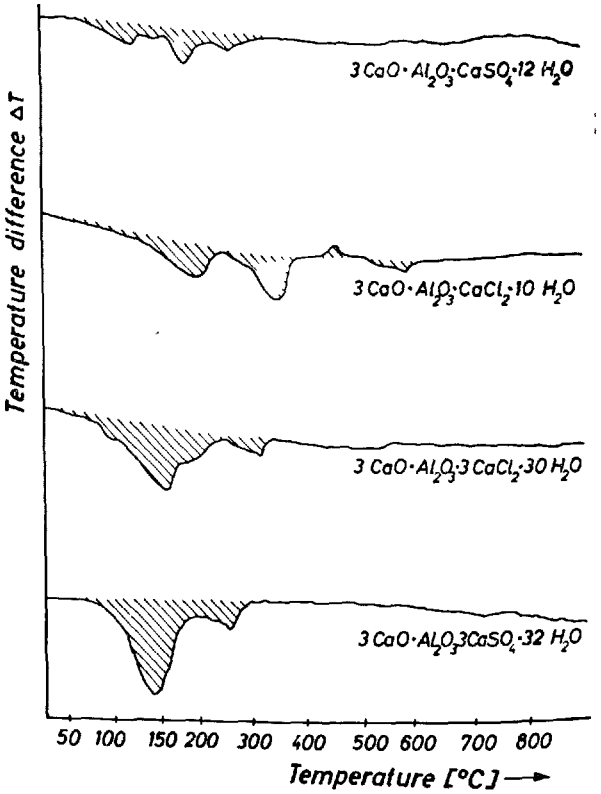

Fig. 3. *DDK—Investigation on calcium aluminate sulphate-and-chloride hydrates (Schwiete, Ludwig, Albeck 1967)*

of ettringite and those of the calcium-bearing analogue are compared.

Investigations with the scanning electron microscope show that the crystallographic habit of the chlorine-bearing compound is the same as that of ettringite, however whilst the length of the ettringite needles may reach 10 μm those of the latter are not longer than 1.5 μm.

Current attempts to prepare hydrate with the composition $3CaO \cdot Fe_2O_3 \cdot 3CaCl_2 \cdot 30H_2O$, starting from C_2F, CaO and calcium chloride, at $-10°C$ prove that a corresponding iron-bearing compound exists.

C_3A (CaS, $CaSO_4$)Hx

Furthermore we (22) succeeded in preparing an AFt-phase with CaS instead of $CaSO_4$ which shows the ettringite-like X-ray interferences and in normal and scanning electron microscope hexagonal prisms.

We are going on to find out more data of this compound that is from importance in accordance to the question of slag containing cements.

AFm Phases

The structure of the prototype of the AFm phase, C_4AH_x, has not yet been explained, although Brandenberger (23), Tilley, Megaw and Hey (24), Buttler, Dent Glasser and Taylor (25) and Grudemo (26) have attempted a clarification. They assume a layer structure and that the total oxygen is bonded as hydroxyl groups within the structural element $Ca_2Al(OH)_7$ of the compound C_4AH_7, a compound which is free of water of crystallization. There is difference of opinion about the sequence and composition of the various layers. According to Buttler, Dent Glasser and Taylor the pseudo-cell contains only one layer of octahedra which is similar in construction to portlandite. One can imagine that in a portlandite layer one of three Ca^{2+} positions is replaced by Al^{3+} (Fig. 4). To balance the charges the seventh (OH)-ion of the structural element $(Ca_2Al(OH)_6)OH$ is situated above the aluminium positions in the gaps between the (OH) belonging to the octahedra. The true cell is not known, however this hypothesis permits an explanation of the one-dimensional swelling parallel to the *c*-axis.

Assuming that the pseudo-cell of C_4AH_x is correct, Kuzel (27) derived the pseudo-cell for the analogue C_3ACsH_{12} as being three layers of the composition $1/2(Ca_4Al_2SO_4(OH)_{12} \cdot 6H_2O)$. The lattice constant, a_0, differs only slightly from that of C_4AH_{13} although two (OH) groups are replaced by one SO_4^{2-}. The thickness of the layers, however, is increased from 7.92 Å to 8.93 Å.

We see in the diagrams a relationship between the hydrates which we shall find again for the other chlorine- and sulphate-bearing compounds.

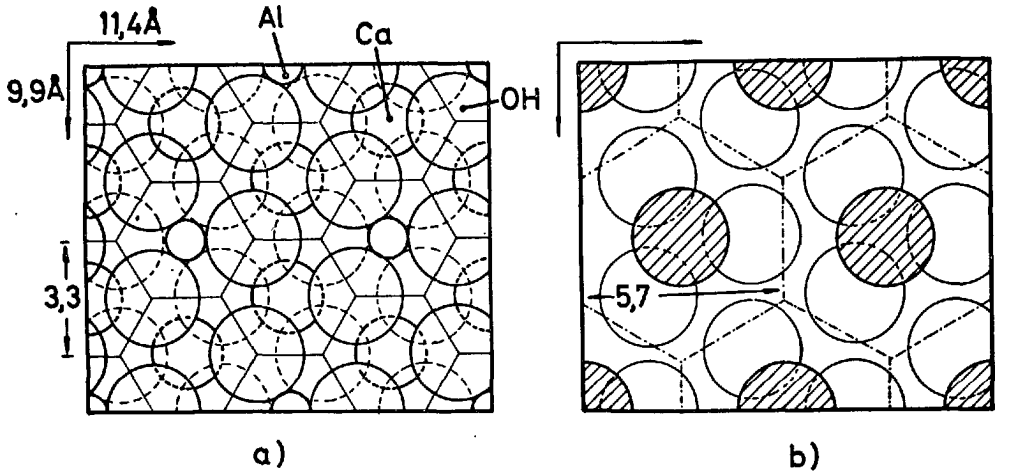

Fig. 4. *Structural element of* C_4AH_{19} *calculated by Buttler, Dent-Glaser and Taylor (in Dosch 1967)*
a) octahedra layer, b) "outer OH" (hatched) orded or statistically distributed on both sides of the octahedra layer

C_4AH_{19}

In 1957 Roberts (28) prepared and investigated C_4AH_{19}. In Table 4 the work that has so far been published on this compound is listed. It can be seen that one can distinguish between an α_1- and α_2-form of C_4AH_{19}. In his first experiments Roberts could only prove the existence of one form for which he assumed the existence of a solid solution series with C_2AH_8. Later Roberts and Jones (29) found that two tetracalcium aluminate hydrate phases exist. In 1960–1 Aruja (30) proved that the α_1 phase is trigonal and the α_2, hexagonal. In all investigations the basal interference of C_4AH_{19} was between 10.6 and 10.77 Å. Furthermore these papers have shown that the most hydrous forms of tetracalcium aluminate hydrate are stable only at a relative humidity of more than 88% at 25°C.

The unstable α_1 phase has a greater volume and a density of 1.79 g/cm³ in contrast to the stable α_2 phase with a density of 1.81 g/cm³.

In addition Aruja's work showed that a solid solution series with α_2–C_2AH_8 does not exist. This Roberts had previously assumed on the grounds of similar cell dimensions.

Analogous hydration products with 19 molecules of water, in which the aluminium oxide is wholly or partly replaced by iron oxide, have not yet been reported in the literature. It should be pointed out, however, that as early as 1883 Le Chatelier (31) found a tetracalcium aluminate hydrate with 21 molecules of water existing under humid conditions, which inverted to a 12-hydrate form at temperatures above 40°C. It is not impossible that this is the same hydrate phase which 75 years later was re-discovered.

Dehydration Products of C_4AH_{19}

Far more numerous are the authors (34-38) who, willingly or unwillingly, have found the dehydration products of C_4AH_{19} on their hands, as Table 5 shows. Here again we can recognize the existence of an α and a β phase, as in the case of C_4AH_{19}. But for C_4AH_{13} they can be distinguished on the grounds of their basal interference. Buttler, Dent Glasser and Taylor (25) proved in 1959 that the pseudo-cell of the β-modification contains only a single layer of octahedra with the composition $(Ca_2Al(OH)_6)OH$. Further structural determinations on the dehydration products of tetracalcium aluminate hydrate have not so far been published i.e. the arrangement of the structural elements in the true cell is not yet known.

At relative humidities between 84% and 12% only mixtures of α-and β–C_4AH_{13} were obtained. Dosch and zur Strassen (33) were able to show that at relative humidities of less than 80% only α–C_4AH_{13} is stable; at 22% humidity this reverts to β–C_4AH_{12}, at 11% to C_4AH_{11}, and at 8×10^{-5}% or by drying at 120°C, to C_4AH_7. Furthermore in 1962 Alégre (39) showed that the conversion to β–C_4AH_{13} is reversible. According to the latter investigations the α–C_4AH_{13} with a basal interference of 8.18 Å reverts in the presence of lithium chloride to β–C_4AH_{12} with a basal interference of 7.82 Å. With a saturated solution of calcium sulphate he managed to prepare α–C_4AH_{13} again. Thus Alégre's work showed for the first time, that β-tetracalcium aluminate hydrate contains one molecule of water less than its α-counterpart.

*d in g/cm³

No difference between the α- and β-phases has so far been found on structural grounds. Various authors (33, 39) have shown that the β-phase has a lower water content of only 12 molecules of H_2O. Thus it appears that the phases contain different amounts of water.

Whereas the density of the α_1-phase of C_4AH_{19} is 1.79 g/cm³ and that of the α_2-phase is 1.81 g/cm³, the density for α- and β-C_4AH_{13} was determined as 2.02 g/cm³. As the water content falls to 11 and 7 molecules of water the density rises to 2.08 and 2.28 g/cm³ respectively. For comparison, the density of hydrocalumite, the naturally-occurring tetracalcium aluminate hydrate with 1.8% CO_2 and 11.6–11.8 molecules of water, is 2.12 g/cm³. Fig. 5 shows the mole ratio of H_2O to Al_2O_3 in C_4AH_{13} plotted against temperature. There figures were produced by Buttler, Dent Glasser and Taylor (25) using a thermal balance or by weighing after cooling. The results agree well with the data on the dehydration products of C_4AH_{19} shown in Table 5. In addition the authors showed that at temperatures above 600°C free CaO is split off $C_4A \cdot aq$ and that between 150° and 250°C a compound of the composition $C_4A_3H_3$ is formed.

Lavanant and Barret (40, 41) investigated the stability ranges of various tetracalcium aluminate hydrates and their P-T-diagram is seen in Fig. 6. It is obvious from this diagram that C_4AH_{12} has only a very narrow stability field which is the reason for the common occurrence of mixtures of hydrate phases with various water contents.

The adsorption of organic molecules by inorganic layer-lattice minerals has long been known, particularly for the clays, and has been described by numerous authors. Recently, in Germany, Weiss (43, 44), in particular, has investigated what can be taken up by these lattices and, in this connection, has examined more than 1000 organic compounds.

Nothing was previously known about the adsorption of organic compounds within the structures of the hydration products of cement, in spite of the fact

that numerous organic materials are added to cements in order to influence their properties. Recently Dosch (42) has reported the inclusion of organic molecules within tetracalcium aluminate hydrate, and more than 500 adsorption complexes have been prepared by this author.

In contrast to the clays, which are formed of layers of macro-ions held together by exchangeable ions of a different charge, tetracalcium aluminate hydrate is composed of neutral layers. The organic molecules are, in general, attracted by van der Waals forces or held by hydrogen bonds. In some cases they form covalent bonds with the inorganic host lattice.

Dosch has prepared and X-rayed complexes with the following organic compounds:

monovalent alcohols
multivalent alcohols, sugars and oxy-acids
mercaptane
amines
aldehydes
carbonic acids

He also succeeded in alkylising tetracalcium aluminate hydrate.

Primary alcohols have well-developed basal reflections which shift to smaller angles as the number of the carbon atoms increases (Fig. 7). As one ascends the alcohol series the speed of the adsorption reaction decreases. This is also true for the branched-chain alcohols. It is apparent form the X-ray data that the chains of alcohol in C_4AH_x are arranged perpendicular to the layers of the host mineral, whereas in montmorillonite an arrangement parallel to them is favoured by the energy requirements.

Multivalent alcohols, sugars, oxy-acids, mercaptane and amines are included in a similar fashion; both the perpendicular and the parallel type of arrangement is found. Aldehydes and carbonic acids react with C_4AH_x showing strong thermal effects. The underlying chemical reaction is not yet completely clear in the case of aldehydes. The carbonic acids presumably react to form esters with the basic (OH)-groups of the C_4AH_x lattice.

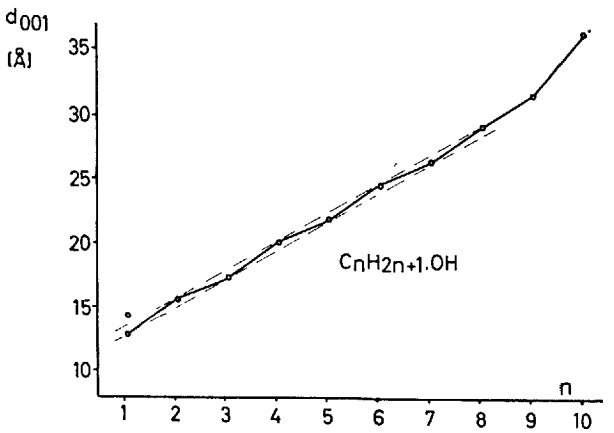

Fig. 7. C_4AH_x *adsorption complexes of* n*—alcohols (Dosch 1967)*

By means of dynamic differential calorimetry the amount of water in the hydrates and how strongly it is bonded can be determined (20, 42). Our own investigations (14) in connection with tetracalcium aluminate hydrates show four pronounced endothermal reactions (Fig. 1). The first minimum occurs at 75°C, the second at 170°C, the third at 300°C and the fourth at 500°C. The first two minima are caused by the splitting-off of water; the third is due to the release of lime and the formation of $C_{12}A_7$. The fourth minimum occurs when the liberated calcium hydroxide is finally dehydrated (14).

Our investigation shows that at about 300°C a splitting-off of $Ca(OH)_2$ with the formation of $C_{12}A_7$.* The dehydration curves of Taylor also do not show to the same extent the dehydration of calcium hydroxide at about 500°C. In Taylor's investigations there is a strong thermal effect above 600°C which does not appear in our diagram.

Bereczky (16) measured the pH value of a suspension of $C_4A \cdot aq$ in water as 12.36. The values of our own measurements (14) lie between 12.7 and 12.8. With the ester of acetic acid we dissolved 26.1 % of CaO from C_4AH_{13}. This is 65 % of the total lime content. An amount of lime remains which is roughly that stoichiometrically necessary for the formation of $C_4A_3H_3$ (14). Fig. 8 shows, amongst other things, the I-R diagram for C_4AH_{13}. Besides the characteristic vibrations for this compound at 7 μm, there is one for CO_3^{--}. This is due to the preparation of the sample with KBr and does not occur if paraffin oil is used.

$C_4F \cdot aq$ and $C_4(A, F) \cdot aq$

The corresponding tetracalcium ferrite hydrate was prepared for the first time in 1851 by Pelouze (46) in the form of white hexagonal plates and later on this was repeated by Le Chatelier (31), Hoffmann (47) and Malquori and Cirilli (Table 6). Malquori and Cirilli established, as Feitknecht (38) and Schwiete and Iwai (45) have also done, that a solid solution $C_4F_xA_{1-x}H_{13}$ $(0 \leq x \leq 1)$ exists. In 1966 Carlson (48) confirmed the earlier results of Schwiete and Iwai that at less than 16°C hexagonal tetracalcium alumi-

*takes place while Buttler, Dent-Glasser and Taylor (25) in 1959 found a formation of $C_4A_3H_3$ in this range of temperature.

nate ferrite hydrate is formed and that above 35°C cubic tricalcium aluminate ferrite hydrate occurs, whilst between 15° and 25°C a mixture of the two hydrates can be observed. According to Feitknecht (38) and Schwiete and Iwai (45) the basal interference of the iron-bearing hydrate is higher than that of the aluminium phase, although Carlson (48) finds it to be lower.

Schwiete and Iwai (45) produced C_4AH_{13}, the mixed crystal $C_4A_{0.5}F_{0.5}H_{13}$ and C_4AH_{13} by precipitation from calcium hydroxide and iron- or aluminium chloride solutions. They calculated the lattice constants from the interferences of the lattice planes (002), (110) and (112). These values are listed in Fig. 9 and it is

apparent that the a_0 value rises from 5.76 Å for C_4AH_{13} to 5.90 Å for C_4FH_{13}, whilst the c_0 values go from 7.76 to 7.90 Å. The pH value of a suspension of C_4Faq was determined by Bereczky (16) as 12.16 to 12.36.

$C_3A(CaCO_3, Ca(OH)_2)aq$

In the older literature a series of tricalcium aluminate hydrates are described which today are identified as carboaluminate hydrates. Because of this it is necessary to deal with the carboaluminate hydrates in detail. Table 7 shows the present state of knowledge. It is apparent that one can distinguish between the so-called "quarter-carbonate" the semi-carbonate and the mono-carbonate. In addition a compound is known which corresponds to ettringite but which contains $3CaCO_3$ instead of $3CaSO_4$. The latter compound was first found by Flint and Wells (49) in 1941 and later its existence was confirmed by Carlson and Berman (50) in 1960. It crystallizes in needles, as ettringite does. The carboaluminate hydrate with 1/4–1 molecules of $CaCO_3$, however, forms hexagonal plates.

By comparing the basal interferences of the tetracalcium aluminate hydrates with those of the carboaluminate hydrates one finds that it is possible to distinguish the members of the two groups by the position of the basal interference of their dehydration products, as zur Strassen and Dosch (33) have illustrated (Fig. 10). With respect to the stability of the semi-carbonate it should be pointed out that the hydrate first described by Seligmann and Greening (32) has not been confirmed by zur Strassen and Dosch (33). As dehydration product a compound with 9 molecules of

water was observed in the case of the quarter-carbonate and one with 6 molecules of water in the case of the mono-carbonate. In the former instance the basal interference decreased from 8.2 to 7.7 Å; in the latter case, the drying temperature is 150°C according to the work of Turriziani and Schippa (51) and 120°C according to zur Strassen and Dosch (33).

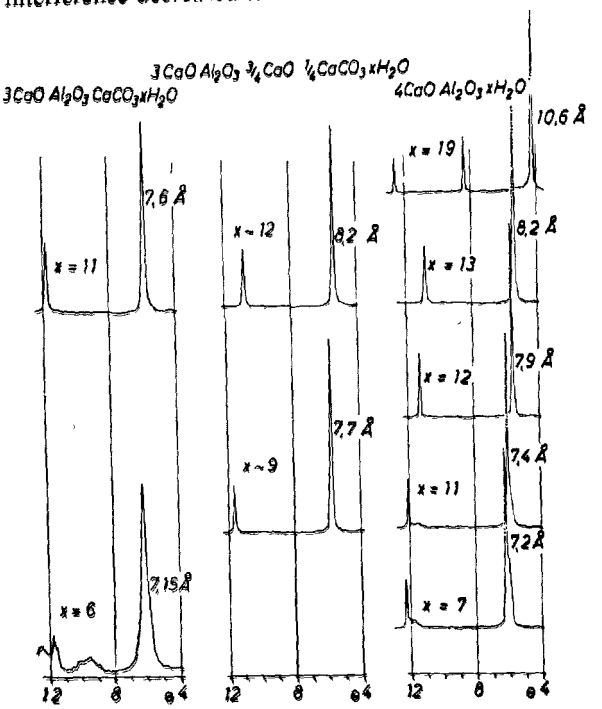

Fig. 10. *Dehydration products of calcium aluminate hydrates with and without* $CaCO_3$ (*Dosch, zur Strassen 1965*)

Spohn and Lieber found out, that test specimens of C_3A or C_4AF or portland cement with $CaCO_3$ attain higher strengths than specimens without carbonate admixture. They detected the formation of $C_3A \cdot CaCO_3 \cdot H_{10}$ formed in aqueous suspensions or in pastes.

$C_3ACs \cdot aq$

Table 8 lists the work on the calcium aluminate monosulphate hydrates. According to Turriziani and Schippa (53) the compound richest in water crystallizes with 16 molecules H_2O and is only stable at a relative humidity of more than 90 % at 20°C.

The latest structural determination on monosulphate hydrate was carried out by Kuzel (27) in 1965 and yielded the lattice constants $c_0 = 26.79$ Å and $a_0 = 5.76$ Å; the symmetry is probably trigonal. He determined the density as 1.90 g/cm³. The dehydration products have mostly been investigated by Turriziani and Schippa (53) who found a least hydrous compound with 7 molecules of water which was obtained at 110°C A number of workers have observed the formation of a solid solution between monosulphate hydrate and C_4AH_{13}. This was first recorded by Kalousek (55)

by $x = 1$ and 14–15 H_2O	8.75–9.02	—/—	$(0.6 \leq X \leq 1)$, radiogr. determined	Seligmann and Greening(1964)

in 1941 and according to D'Ans and Eick (56) the solid solution is complete. Our investigations (14), which agree with those of Seligmann and Greening (57), show a miscibility gap at the sulphate-poor end of the series. Fig. 1 shows the differential calorimetric investigations on pure C_3ACsH_{12}. Several endothermal reactions are recognizable in the range 50°–300°C. The strongest of these occurs at about 200°C.

We determined the pH value of C_3ACsH_{12} to be 12–12.1 (14). No CaO was dissolved out after boiling for one hour in ester of acetic acid.

Dosch and zur Strassen (57a) found a hitherto unknown hexagonal or pseudo-hexagonal sodium-bearing hydrate whose approximate composition is $4CaO \cdot 0.9Al_2O_3 \cdot 1.1SO_3 \cdot 0.5Na_2O 16H_2O$; the alkali content in particular is variable. Table 9 lists the basal interference and the water content in relation to relative humidity.

Fig. 11 shows a completely indexed X-ray photograph. Whereas the *c*-axis shrinks on drying, the *a*-axis remains constant at 5.75 Å which permits this hydrate to be grouped in the same family to which monosulphate hydrate and tetracalcium aluminate hydrate also belong. The authors presume that the new hydrate can be derived from monosulphate hydrate by the loss of Al^{3+} from the basal layer, which thus acquires a negative charge. The intermediate layer contains water of crystallization, sodium sulphate and Na^+ ions to balance the charges.

Table 9. *Range of Hydration of the* $4CaO \cdot 0.9Al_2O_3 \cdot 1.1SO_3 \cdot 0.5Na_2O \cdot 16H_2O$ *(Dosch and zur Strassen)*

rel. humidity	$H_2O/4CaO$	d_{001} (Å)
95	16	10.0
50	16	10.0
10	12	9.3
10–1	12	9.3
10–2	8	8.1
10–4	8	8.1

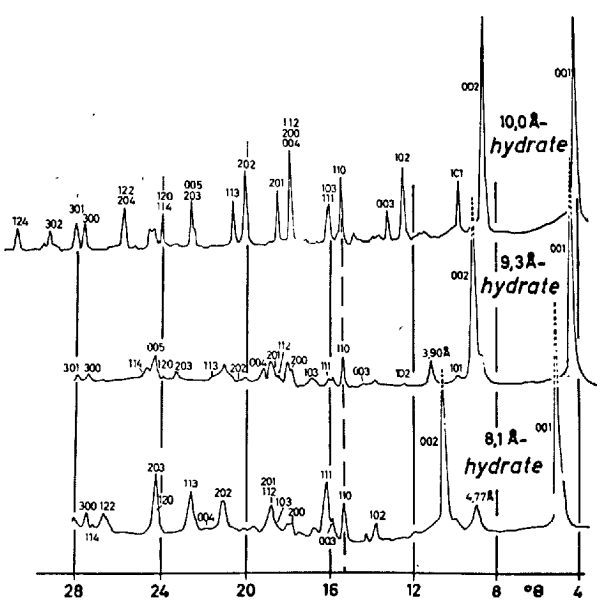

Fig. 11. *Hydrates of phase "U_s" (Dosch, zur Strassen 1967)*

The new hydrate was prepared both from monosulphate hydrate and trisulphate hydrate in the presence of an equilibrium solution of alkali aluminate, alkali sulphate and caustic soda. The content of caustic soda, aluminate and sulphate ions in the solution must be sufficiently high.

$C_3(A, F)Cs$ aq

In the monosulphate hydrates the aluminium can be completely replaced by iron. Malquori and Caruso (18) in 1938 were the first to observe C_3FCsH_x (Table 10). Together with Cirilli, Malquori (9) investigated the dehydration products of C_3FCsH_{10} and found hydrates with 10, 8, 6 and 4–5 molecules of water. Schippa (58) investigated the monosulphates and observed a water-rich iron monosulphate with 13–14 molecules of water and a basal interference of 10.45 Å. According to him the hydrate with 11–12 molecules of water has a basal interference of 8.98 Å. In addition he determined the lattice constants a_o and c_o and indicated the possibility of a solid solution between C_3FCsH_x and C_3ACsH_x.

Our experiments (14) also show a solid solution between iron and aluminium sulphate hydrates. Our starting materials were C_2F, C_4AF and C_6A_2F. Recently we have observed the formation of a solid solution in which not only is aluminium replaced by iron but also calcium sulphate by calcium hydroxide. In connection with C_2F we found only a pure monosulphate hydrate and no further solid solubility with tetracalcium ferrite hydrate. For C_4AF and C_6A_2F there are only solid solutions in the range of more than 0.4 mole calcium sulphate, i.e. as in the case of tricalcium monosulphate hydrate there is no solid solution with the corresponding tetracalcium aluminate ferrite hydrate in the calcium sulphate-poor region. A clear presentation of our values is given in Fig. 12.

$C_3(A, F)(CaSO_4, CaCl_2, Ca(OH_2))aq$

Since the description by Friedel (59) of a hydrate with composition $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ (later known as Friedel Salts) and by Malquori and Caruso (18), Turriziani and Schippa (62), Mylius (37), Lafuma

(34) and others of the corresponding compound $3CaO \cdot Fe_2O_3 \cdot CaCl_2 \cdot 10H_2O$, various authors have dealt with the effect of calcium chloride on the clinker minerals during the hydration of cement. The work of Wells (35), Lieber and Bleher (66), Roberts (67), Rosenberg (68) and the new investigations of Tenoutasse (69) are noteworthy (Table 11).

In recent hydrothermal experiments Kuzel (64) could prove that there were two polymorphs of $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ whose inversion point was found by DTA to be $28° \pm 2°C$. By reactions at normal temperature we (65) only found out the β–$C_3A \cdot CaCl_2 \cdot H_{10}$.

Single crystal X-ray photographs of the monoclinic α-phase, stable at lower temperatures, indicate a monoclinic cell with $a_o = 9.98 \pm 0.04$ Å, $b_o = 5.74 \pm 0.02$ Å, $c_0 = 16.79 \pm 0.04$ Å and $\beta = 110.2°$. The space group is C2/c or Cc. The unit cell of α–$C_3A \cdot CaCl_2 \cdot H_{10}$ probably contains two identical layers of the composition $Ca_4Al_2(OH)_{12} \cdot Cl_2 \cdot 4H_2O$. The density determined with the pycnometer shows that that of the α-form is 2.03 g/cm³.

The trigonal modification has a unit cell in which $a_o = 5.74 \pm 0.02$ Å and $c_o = 46.88 \pm 0.08$ Å. Assuming the same density of 2.03 g/cm³ the unit cell contains 2.9 units of formula and is composed of six layers with the composition $Ca_2Al(OH)_6 \cdot Cl \cdot 2H_2O$.

Kuzel (64) could not find a solid solution between α- or β–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ and $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$. However he found a new compound of the composition $6CaO \cdot 2Al_2O_3 \cdot CaSO_4 \cdot CaCl_2 \cdot 24H_2O$ with a trigonal unit cell having the lattice constants $a_0 = 5.74 \pm 0.02$ Å, $c_0 = 100.6 \pm 0.2$ Å and a space group R3c or $R\bar{3}c$. The density of this hydrate is 2.2 g/cm³. Its pseudo-cell with c = 16.76 Å is about twice as large as those of C_3ACsH_{12} and $C_3A \cdot CaCl_2 \cdot H_2O$. Kuzel assumed double layers of the composition $Ca_4Al_2(OH)_{12} \cdot Cl \cdot 1/2\ SO_4 \cdot 6H_2O$ in which SO_4^{--} and Cl^- ions alternate in planes parallel

to (0001).

The investigations of Turriziani and Schippa (62) in 1955 showed a complete miscibility between the compounds $3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot 12H_2O$ and $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$.

Furthermore we (22) succeeded in preparing at ordinary temperatures as well as Kuzel at hydrothermal conditions an AFm-phase with CaS, which is of great importance in case of the slag bearing cements.

Hexagonal Hydrates with a Low $Ca(OH)_2$ Content

The following hydrates also have a layer structure but in contrast to the previous ones they occur only in high aluminate cements or occasionally in blast furnace cements rich in slag.

C_2Aaq

It can be seen from Table 12 that Allen and Roger (70) in the year 1900 were the first to prepare and investigate dicalcium aluminate hydrate. This compound crystallizes as hexagonal plates. Schwiete, Büssem and Salmoni (71) were able to isolate a series of dicalcium aluminate hydrates with variable water contents. The maximum water content was 13 molecules; at 300°C all the water was driven off. Roberts and Jones (29) distinguished an α_1, and α_2 and a β–C_2AH_8. The α_2-form is metastable relative to the α_1-form. Lavanant proved that the dehydration of C_2AH_8 to C_2AH_6 is a reversible reaction. The basal interference of α_2- and β–C_2AH_8 lies between 10.5 and 10.8 Å. By means of diboranhydrolysis he could distinguish how the water is bonded in the dicalcium aluminate hydrates. Whereas he found only hydroxyl groups in the hydrates with 5 molecules of water, in those richer in water he found, in addition, molecular and zeolitic water.

Lavanant (41) represented the water content of the dicalcium aluminate hydrates in a P-T-diagram (Fig. 13). One can see on the graph the equilibrium curves for C_2AH_5, C_2AH_6 and finally for C_2AH_9, which

practically coincide with the curve for water vapour.

There are numerous other hydrates which have been reported by Schwiete, Büssem and Salmoni (71) and more recently by Henning (80) but their significance in terms of energy has not yet been investigated. Chatterji and Majumdar (84) found by means of X-ray studies hexagonal hydrates with the composition C_2FH_y and a = 10.8 Å (as compared with 10.7 Å for C_2AH_8) together with the corresponding mixed crystals $C_2(A, F)H_8$. Their starting materials were C_2F, $C_2F_{0.7}A_{0.3}$ and $C_2F_{0.3}A_{0.7}$ with a ratio of water/solids of 0.6.

CA · aq

Monocalcium aluminate hydrate is principally responsible for the hydraulic hardening of cement. It crystallizes as needles with a density of 1.7 g/cm³ (Table 13).

It, too, forms hydrates with a varying water content. From the present knowledge it appears that the most hydrous member contains 10 molecules H_2O. Henning

(80) found hydrates with 10 to 2 molecules of water. The basal interference of the form with 10 molecules is 14.6 Å. At 200–250°C Henning obtained a hydrate with two molecules of water whose basal interference was 8.84 Å. According to Longuet (87) the last water is expelled at temperatures above 600°C.

No descriptions have appeared so far of a monocalcium aluminate hydrate in which the aluminium is partly or wholly replaced by iron although the existence of such a hydrate is to be expected.

C_2ASH_8

C_2ASH_8 is easily obtained by the reaction of at 600–800°C calcined kaolin or glass of the composition of gehlenite with a saturated solution of lime. It is probably by this reaction that Rebuffat (88) synthesized a hydrate of the composition C_2ASH_8 for the first time.

However, Strätling and zur Strassen (89) have shown later that by starting with calcined kaolin two hydrates are formed and thus Rebuffat was unable to separate the gehlenite hydrate by means of chemical methods. Contrary to the results of Fratini and Turriziani (90) who assumed hexagonal symmetry for C_2ASH_8, Schmitt (91) found it to have a monoclinic symmetry with an *a*-axis of 9.96 Å; he used the intensity distribution in a single-crystal electron diffraction photograph. In addition he found that 0.3 molecules of Al_2O_3 can be replaced by Fe_2O_3 causing a increase in the length of the *a*-axis from 9.96 Å to 10.07 Å and a decrease in the *c*-axis form 12.56 Å to 12.52 Å; the refractive index rises from 1.512 to 1.525. By exact measurement (92) of the impulse rate at intervals of $0.1° = 2\theta$ we established the monoclinic symmetry for gehlenite hydrate with $a_o = 9.9153$ and $c_o = 12.4458$. The starting materials were glasses of the composition of melilite and others with compositions in the solid solution series gehlenite (C_2AS)-akermanite (C_2MS_2). Measurement of the values for the interferences (003), (302) and (300) indicated how the lattice constants varied in the direction of the *c*- and *a*-axis. It can be seen from Fig. 14 that at amounts of up to 5% akermanite glass in melilite glass the lattice expands strongly in the a- and c-directions. A further increase in the akermanite fraction of the glass leads to an expansion along the *c*-axis only.

Using the ionic radii of Ahrens (1952) with the values $Mg^{++} = 0.64$ Å, $Al^{+++} = 0.50$ Å and $Ca^{++} = 1.02$ Å one can calculate a contraction of the lattice by 49% if Mg^{++} replaces Ca^{++}. The exchange by Al^{+++} produces a dilation of 28%. If magnesium is taken into the lattice, therefore, it probably replaces aluminium. The re-arrangement in the lattice necessary to maintain electrostatic neutrality can only be solved by a structural analysis.

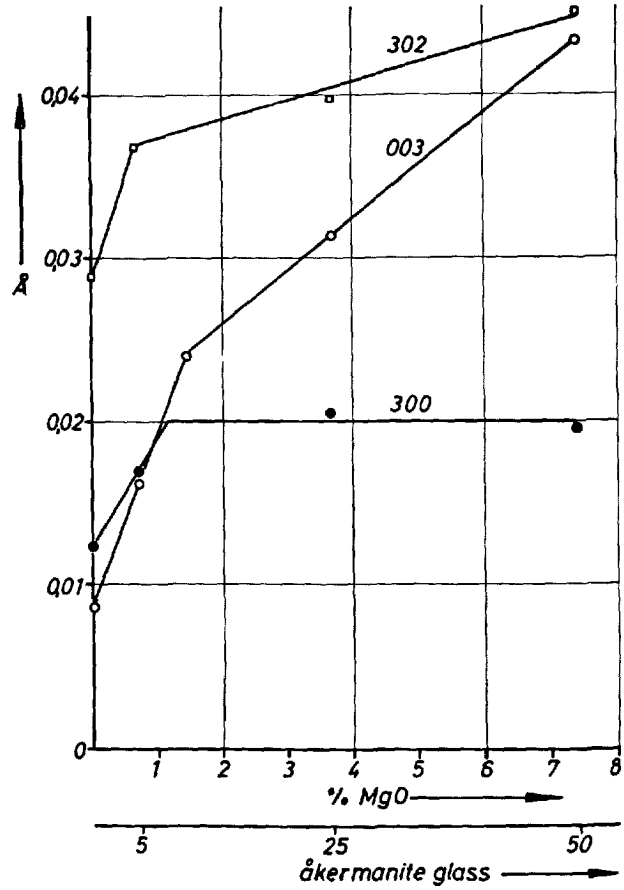

Fig. 14. *Lattice constants of gehlenite hydrate as a function of MgO content (Schwiete, ludwig, Würth, Grieshammer 1965)*

Interesting work was produced by Krönert, Schwiete and Wetzel (93) who allowed kaolin to react with an aqueous solution of calcium hydroxide at temperatures between 20° and 100°C for 8 weeks. The kaolin was either left unprepared or was treated mechanically by grinding. The untreated kaolin was not altered to gehlenite hydrate. In the case of the ground kaolin, however, at temperatures up to 60°C the formation of gehlenite hydrate was observed. Whereas at temperature of 40°C the amount of gehlenite hydrate remained constant for the 8 weeks, at 60°C it decreased rapidly and was replaced by hydro-garnet.

Cubic Hydration Products

C_3AH_6

Since the previous symposium in Washington it has been established that no pure tricalcium ferrite hydrate exists. Thus Allen and Roger (70) in 1900 were probably the first to deal with the cubic hydrate (Table 14). According to Wells, C_3AH_6 crystallizes in icositetrahedra or rhombic dodecahedra.

C_3AH_x	—		system C–A–H with variable P and T system C–A–H a) with analytic grade b) with spectroscopic grade starting points	Lavanant(1965) Crowley(1964)

Important investigations were carried out by Thorvaldson, Grace and Vigfusson (94) in 1929. They proved that the lattice of C_3AH_6 is cubic body-centred and that the space group is Ia3d. The unit cell contains 8 units of formula. The density is 2.52 g/cm³. The authors derived the structure of C_3AH_6 from that of grossularite, whereby one SiO^{4+} is replaced by $4(OH)^-$. According to Farmer (95) the Al^{3+} is in sixfold co-ordination. As a dehydration product, Majumdar and Roy (97) identified a hydrate with 1.5 molecules of water, stable at temperatures below 275°C. Above 550°C, $C_{12}A_7$ is formed together with free CaO, and at temperatures above 1050°C, C_3A. Later on the same authors observed the formation of $C_4A_3H_3$ with a basal interference of 3.58Å under conditions of increased temperature and pressures of between 5 and 20 kilobars; similar observations were made by Pistorius (82) at a pressure range reaching 50 kilobars. His product had a basal interference of 3.64 Å. Pistorius investigated C_3AH_6 under various conditions of temperature and pressure. He found equilibrium curves for C_3AH_6 and diaspore on the one hand, and $C_4A_3H_3$ on the other. His curves are for the range 5–50 kilobars and 200–370°C. At higher temperatures and lower pressures he investigated the stability of $C_4A_3H_3$ and of $C_{12}A_7$, CA_2 and H_2O. He could show that up to 800°C and 20 kilobars the hydrate of the composition $C_4A_3H_3$ occurs (Fig. 15).

There is interesting work by Kelly (102), who showed by means of radio-actively marked calcium, that $C_3AH_6 + Ca(OH)_2$ cannot be transformed into C_4AH_{13}. This confirmed the earlier observations according to which C_3AH_6 is the only stable pure calcium aluminate hydrate present, under normal conditions of temperature and pressure, in the system Al_2O_3–CaO–H_2O.

Fig. 1 shows our differential calorimetric investigations (14) of the endothermal reactions of C_3AH_6. One can see a distinct endothermal effect at about 300°C, as in the case of tetracalcium aluminate hydrate. It is due to the formation of $C_4A_3H_3$ with the release of free $Ca(OH)_2$. Once again the dehydration of calcium hydroxide occurs at about 500°C.

Bereczky found the pH value to be 12.1 (16). Our measurements give values of 12.1–12.2 which show a good agreement. No CaO was dissolved out of C_3AH_6 after one hour's boiling with the ester of acetic acid.

$C_3(A, F)S_n H_{(6-2n)}$

In the lattice of the cubic C_3AH_6, Al^{3+} can be replaced by Fe^{3+}, and two H_2O by one SiO_2 (Table 15). When one or more of these substitutions occur

the product is called hydrogarnet. A hydrogarnet in which the Al^{3+} is replaced by Fe^{3+} was first prepared by Eiger in 1937 (103). zur Strassen and Dörr (104, 105) are of the opinion that pure C_3FH_6 does not exist. According to them, and to Carlson (106) and Schwiete and Iwai (45) 0.163 molecules of Al^{3+} must be contained in hydrogarnet. Schwiete and Iwai calculated the lattice constants for the solid solution series C_3AH_6–C_3FH_6 using the Bragg equation for the cubic system with the strong reflections (321), (400), (420), (422), (431) and (521) and (532). They compared their values with those of Flint, Wells and McMurdie (96) and zur Strassen and Dörr (104, 105). The lattice constant rises from 12.55 Å for pure C_3AH_6 to 12.7 Å for $C_3A_{0.2}F_{0.8}H_6$ and there is a linear dependence. The value of Flint and co-workers for pure "C_3FH_6" lies on the extension of this line at 12.74 Å (Fig. 16).

Krönert, Schwiete and Wetzel (93) succeeded in preparing a silica-bearing hydrogarnet of the composition $C_3AS_{0.13}H_{5.74}$ at temperatures between 40° and 100°C and normal pressure, starting from uncalcined kaolin and calcium hydroxide. Further, silica-bearing garnets have been produced by Fratini and Turriziani (90) from calcined kaolin and lime water, and by zur Strassen (104) and Dörr (105) from calcium aluminate silicate glasses and lime water. Flint, McMurdie and Wells (96) allowed tricalcium aluminate ferrite hydrate and calcium silicate hydrate react under hydrothermal conditions and found a $C_3(A, F)SH_4$ with lattice constant of 12.42 Å.

Schwiete and Iwai (45) investigated reaction mixtures of C_4AF with CaO and increasing proportions of C_3S in aqueous solution under normal conditions of temperature and pressure. They observed a decrease in the lattice constant from 12.65 Å for the hydrogarnet prepared from C_4AF to 12.42 Å for the compound richest in silica, whose approximate composition is $C_3A_{0.5}F_{0.5}SH_4$. These results are in good agreement with those of Flint and Wells (49) as Fig. 17 shows. Thus in the hydrogarnets we observe an increase in the lattice constant with increasing iron content and a decrease in that with increasing silica.

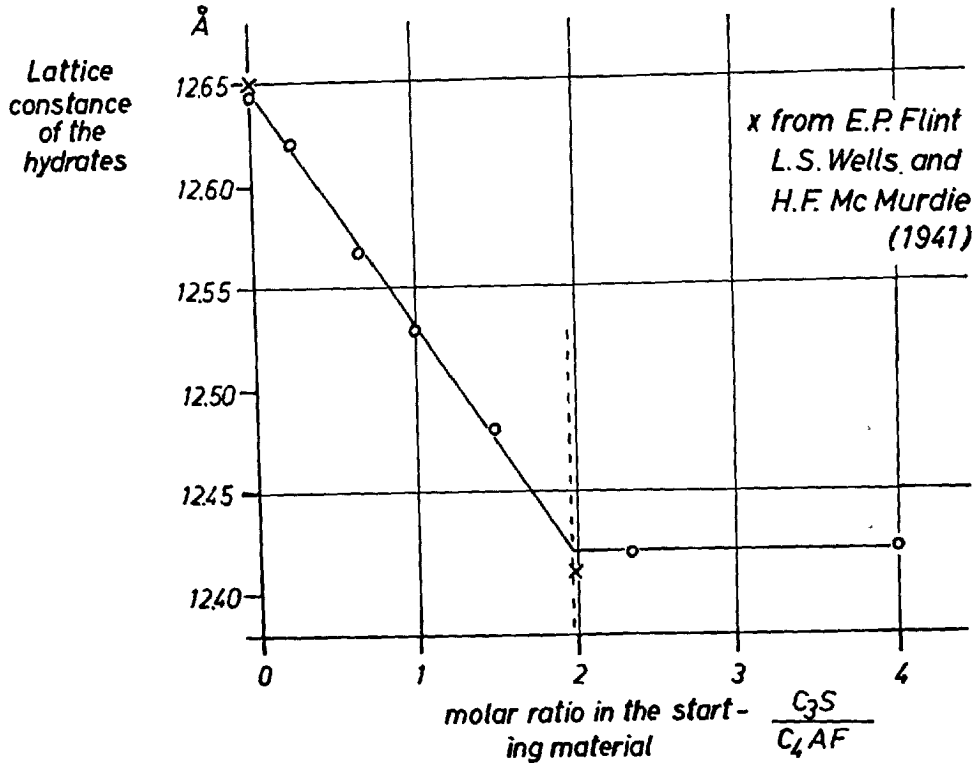

Fig. 17. *Lattice constants of Hydrogarnets in the system* C_4AF–C_3S–CaO–H_2O *(Schwiete, Iwai 1964)*

Investigations in the System CaO–Al_2O_3–H_2O at High Pressure with Varying Temperature

Crowley (81) examined the pseudo-binary system CaO–Al_2O_3–H_2O, at a pressure of 1055 kg/cm² and with increasing temperatures, firstly starting with spectrographically pure $CaCO_3$, and secondly with chemically pure $CaCO_3$.

Fig. 18 shows the diagram for spectrographically pure $CaCO_3$. In the calcium-rich region, at low temperatures, one can recognize the stability field of C_4AH_{19}, a field in which α–C_4AH_{19} co-exists with α–C_2AH_8, one with α–C_2AH_8 and CAH_{10}, and finally one in which CAH_{10} and AH_3 occur together. At temperatures above 25°C C_2AH_8 is transformed to C_3AH_6, whilst α–C_4AH_{19} and CAH_{10} remain stable. C_4AH_{19} and CAH_{10} are also altered to C_3AH_6 and gibbsite (AH_3) or C_3AH_6 and calcium hydroxide ($Ca(OH)_2$) respectively, depending on the starting material. Gibbsite inverts to diaspore above about 140°C. At temperatures of nearly 250°C C_3AH_6 is transformed into $C_4A_3H_3$ and $Ca(OH)_2$ or diaspore. It is interesting to note that, independent of the high pressures applied (1055 kg/cm²), the same reactions and phases are observed as can be found at normal temperatures e.g. by differential calorimetry or in experiments of isobaric decomposition.

In Fig. 19 a similar diagram is shown, which is obtained when chemically pure $CaCO_3$ is used as the starting material. It is interesting that here in the lime-rich region C_4AH_{13} is stable together with $Ca(OH)_2$ at temperatures up to 150°C. In the lime-poor region up to 250°C the C_2AH_6 is also partly stable, however the equilibrium temperature falls as the Al^{3+} content in the starting material increases. The use of less pure calcium carbonate thus leads to an important increase in the stability field of the tetra- and dicalcium aluminate hydrates, which according to previous work, are known to be unstable phases. Above 250°C $C_4A_3H_3$ is again observed with $Ca(OH)_2$ or aluminium hydroxide and it is remarkable that, in contrast to the experiments with spectrographically pure $CaCO_3$ the reactions of the low temperature phases are reversible if only chemically pure $CaCO_3$ is used.

Properties

The properties of calcium aluminate hydrates and calcium aluminate ferrite hydrates respectively are judged in different ways. In the following section, a distinction is to be made between the properties of the

hydration products during the formation of the cement stone and those of the hydration products in the cement stone itself.

Properties during the Formation of the Cement Stone

The calcium aluminate and aluminate ferrites respectively are characterized by their high reaction speeds in aqueous solution; the reaction speed increases as the ferrites contain a higher percentage of Al_2O_3. These reactions are accompanied by a high liberation of heat. The thermodynamic computations by V. J. Babuskin, G. M. Matveev and O. P. Mchedlov-Petrosyan (1965) have furnished us with a lot of data (Table 16). With the cements that contain much lime this quick reaction is delayed by the addition of calcium sulphates and by the resulting formation of an ettringite cover. $C_3(A, F)CsH_x$ and the mixed crystals of $C_3(A, F)CsH_x$ with $C_4(A, F)H_x$ respectively are formed only after the concentration of sulphate has fallen short of the minimum necessary for the formation of ettringite. The reaction by which ettringite is formed takes place, topochemically, at C_3A, $C_2(A, F)$ or at the granulated aluminate containing slag grain. If the percentage of sulphate is carefully harmonized with the composition and the fineness of the cement, the main formation of ettringite takes place at the early stage of setting and hardening so that it is only rarely possible to observe any expansion.

In contrast to the cements that contain much lime, the formation of ettringite in the supersulphated cements that contain less lime takes place through the phase of solution and contributes towards cementation. In the case of these cements, an expansion in the course of the formation of ettringite is observed only when this cement is produced with a too high percentage of clinker; by this circumstance, the pH-value is increased during the setting and the hardening.

In the case of the reaction of alumina and of iron from clinker and granulated blast furnace slags, when phases with very much lime are formed, one must in addition reckon with a lime combination by which, according to the law of the mass effect, the hydration of the calcium silicates must be accelerated.

Because of the quick reaction of the calcium aluminates and the calcium aluminate ferrites, one must furthermore reckon with the creation of additional surfaces on the calcium silicates so that the entire progress of the hydration will be favourably influenced by this circumstance, too.

Therefore this exposition demonstrates two facts; on the one hand, the calcium aluminates and the calcium aluminate ferrites respectively from the cements can bring about a decrease in strength at the beginning of the setting and the hardening by an eventual expansion; on the other hand, however, they can favourably influence the hydration and the hydrolysis of the cements in several ways by the high heat liberation, by their quick hydration and by the resulting creation of additional surfaces as well as by the lime combination.

In the case of the high alumina cements, the calcium aluminate hydrates CAH_{10} and C_2AH_8 are responsible for the hydraulic strength.

Table 16. *Thermodynamic data of aluminate hydrates*

Hydration product	ΔH_{298} kcal/mol	ΔG_{298}
C_4AH_{19}	−2409	−2092
C_4AH_{13}	−1983	−1749
C_3AH_6	−1317.6	−1187.6
C_2AH_8	−1291	−1142
C_3ACsH_{12}	−2082.8	−1843.6
$C_3ACs_3H_{31}$	−4110.9	−3556.4

By V. J. Babuskin, G. M. Matveev and O. P. Mchedlov-Petrosyan Thermodynamik der Silikate-VEB-Verl. Berlin 1965.

Properties in the Cement Stone

With the exception of the above-mentioned qualifications with regard to the formation of the cement stone and with the exception of the formation of ettringite which possibly has an expansion effect, the installation of the calcium aluminate ferrite hydrates in the cement stone may, to begin with, be expected to contribute in increasing its strength and its density. According to investigations by Spohn and Lieber (52) in 1965, an addition of $CaCO_3$ to C_3A or C_4AF results in an increase of the strength. This increase, however, results already from the strong increase in specific volume of solids which takes place when the anhydrous phases changes in the hydration products; the increase in specific volume is to be derived from the low densities of the calcium aluminate ferrite hydrates.

The contribution which the calcium aluminate hydrates make to strength becomes particularly obvious in the high alumina cements during the formation of the hexagonal or pseudo-hexagonal hydrates which contain little lime.

In this context, however, we must not consider without qualification the stability of these phases in dependence on temperature, pressure and relative humidity; from the above-mentioned thoughts we know that the hydrates rich in water, especially those

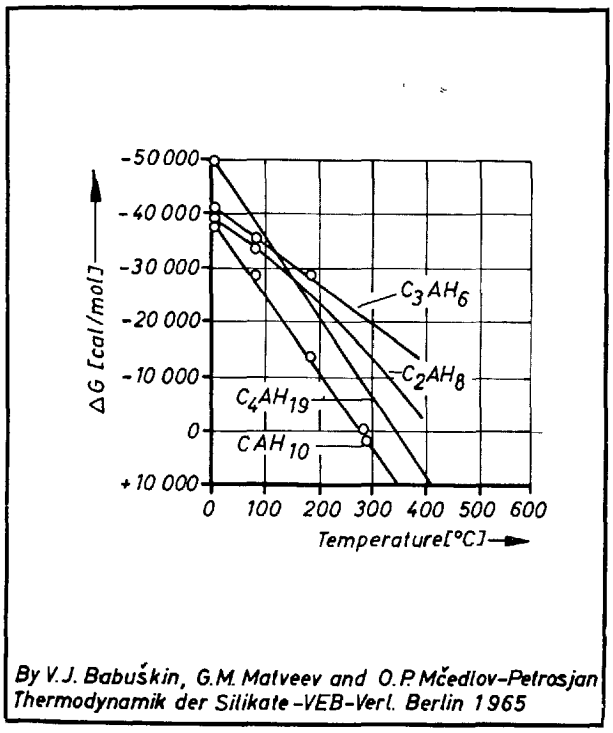

Fig. 20. $\Delta G_{react} = f(T)$ *in the system of* $3CaO \cdot Al_2O_3 - H_2O$

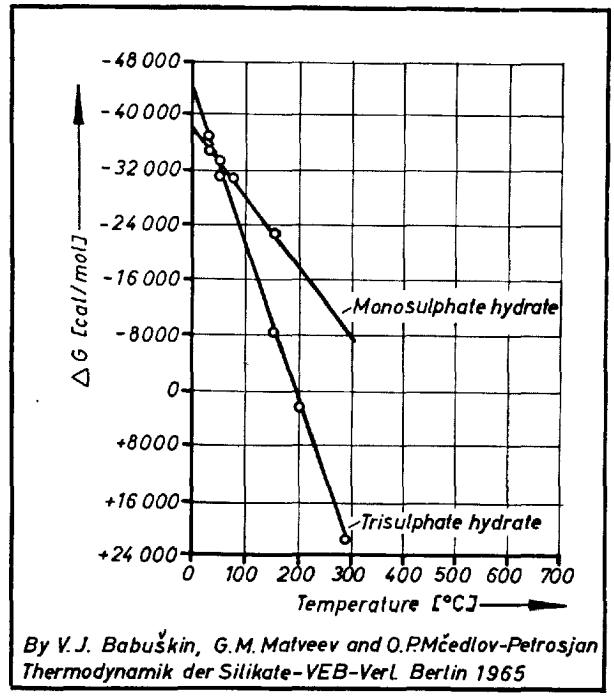

Fig. 21. *Stability of monosulphate and trisulphatehydrate*

of the AFm-phases, can only be preserved at high relative humidities. According to the present state of investigations, the AFt-phases and the hydrogarnets are more stable. The stability of some calcium aluminate hydrates, the ettringite and the monosulphate hydrate is shown in function of the temperature by Babuskin, Matveev and Mchedlov-Petrosyan in the following Figs. 20 and 21.

In the case of the high alumina cements, especially when the atmosphere is moist, temperatures >23°C have a negative accelerative effect on the conversion of the voluminous hexagonal or pseudo-hexagonal hydrates into denser cubic hydrogarnets; the reason is that the latter ones have a smaller volume where by the porosity of the cement stone is greatly increased and the strength are reduced. One tries to counteract that circumstance by making this set and harden at higher temperatures with a small water cement ratio whereby the stable phases form directly.

The stability of the AFm-Phases and the cubic tricalcium aluminate hydrates is additionally endangered by changes in concentration. When parts of cement stone contain these hydration products and can come into contact with solutions that contain sulphate, one has to reckon with the formation of ettringite which can lead to the destruction of the building. However, the intensity of the attack which must be expected depends on the density of the cement stone, on the strength of the sulphate concentration, on temperature and on the way in which the sulphate attacks, that is on the question whether the transport takes place by means of diffusion or capillarity.

When considering the stability of the phases in question one must not, however, forget to take into account that, according to investigations carried out by Copeland, Bodor, Chang and Weise (111) in 1967, a strong reaction of tobermorite geles on the aluminates, ferrites and sulphates takes place whereby these phases can most certainly be heavily reduced in dependence on time. These investigations fit in very well with our own frequent observations that often in old mortars and concretes no or only very low percentages of calcium aluminate and of aluminate ferrite hydrates are found. It is therefore probable that the entire complex of problems must be gone over and revised anew.

Summary

1. It has been possible to determine the inter-atomic distances in the compound $C_3ACs_3H_{32}$ by means

of a Patterson synthesis. Moreover, starting from C_2F, an ettringite has been repeatedly prepared in which Al^{3+} is completely replaced by Fe^{3+}.

2. The formation of $C_3A \cdot 3CaCl_2 \cdot H_{30}$ was not observed above 20°C, however, between 0° and −10°C (under conditions of increasing calcium chloride concentration, it was found in increasing quantities. From the d-spacing the (hkil)-values for the hexagonal system have been calculated. The existence of an iron-bearing analogue is to be expected. Moreover an AFt-phase of the composition $C_3A(CaS, CaSO_4)Hx$ was found.
3. Contrary to earlier results it has been shown that there is only one modification of C_4AH_{13} and that the previously assumed α- and β-phases only differ in having water contents of 13 and $12H_2O$ respectively.
4. Dehydration of C_4AH_{19} produced hydrates with 13, 12, 11 and 7 molecules H_2O. A complete solid between C_4AH_{13} and C_4FH_{13} has been reconfirmed.
5. For the carboaluminate hydrates the phases with the composition $C_3A \cdot 1/4CaO \cdot 1/4CaCO_3 \cdot H_{11-12}$, $C_3A \cdot 1/2CaO \cdot 1/2CaCO_3 \cdot H_x$ and $C_3A \cdot CaCO_3 \cdot H_{10-11}$ exist. They can be distinguished amongst themselves and from C_4AH_{13} on the grounds of their basal interference and those of their hydration products.
6. $C_4A_3H_3$ can be produced only from C_4AH_{13} and C_3AH_6 by splitting-off $Ca(OH)_2$. The solid solution between C_3AH_6 and C_3FH_6 has been confirmed. The most iron-rich member has the composition $C_3A_{0.163}F_{0.837}H_6$. The compound richest in silica has the composition $C_3A_{0.5}F_{0.5}SH_4$ under normal conditions of temperature and pressure.
7. Crystals of C_3ACsH_{12} were found to have a hexagonal pseudo-cell with $a_o = 5.76$ Å, and $c_o = 26.79$ Å; the space group is R3 or $R\bar{3}$. More recent investigations have proved a partial miscibility with C_4AH_{13}. This solid solution is also found when Al^{3+} is partly replaced by Fe^{3+} but not if pure C_2F is used as the starting material.
8. A hydrate of the composition $C_4A_{0.9} \cdot 1.1SO_3 \cdot 0.5Na_2O \cdot H_{16}$ was prepared from C_3ACsH_{12} and was examined by X-rays. It is one of three hydrates with 16, 12 and $8H_2O$ respectively.
9. According to investigations under normal and hydrothermal conditions no solid solubility exists between $C_3A \cdot CaCl_2 \cdot H_{10}$ and C_3ACsH_{12}, but there is another compound of the composition $C_6A_2 \cdot CaSO_4 \cdot CaCl_2 \cdot H_{24}$ with $a_o = 5.74$ Å and $c_o = 100.6$ Å; its space group is R3c or $R\bar{3}c$.
10. An α- and a β-form of $C_3A \cdot CaCl_2H_{10}$ can be distinguished, whose reversible inversion point is 28°C + 2°. The β-form stable above 28°C, has the lattice constants $a_o = 5.75$ Å and $c_o = 46.88$ Å, if a trigonal symmetry is assumed. According to rotation-, Weissenberg- and precession-photographs, α-$C_3A \cdot CaCl_2 \cdot H_{10}$ has a monoclinic pseudohexagonal unit cell with $a_o = 9.98$ Å, $b_o = 5.47$ Å and $c_o = 16.79$ Å; $\beta = 110.2°$.
11. A new AFm-phase with CaS is $C_3A \cdot CaS \cdot Hx$ whose formation was found as well at ordinary temperatures as at hydrothermal conditions.
12. For the di- and monocalcium aluminate hydrates the principal investigations in recent years have been on dehydration. Only partial agreement has been found with earlier results. X-ray investigations under controlled conditions of temperature and humidity are still lacking. Only substitution of Al^{3+} by Fe^{3+} was observed for C_2AH_8 and none in the case of CAH_{10}.
13. When small amounts of MgO are added to glasses of the composition melilite the lattice of C_2ASH_8 expands both in the a-and c-directions. With larger amounts an expansion along the c-axis only is observed. The dilation of the lattice is probably due to replacement of Al^{3+}.
14. The stability fields of the unstable hexagonal or pseudo-hexagonal phases are shifted towards higher temperatures if impure starting materials are used.
15. Complete data on density and pH values are given.

The writers express their appreciation to Dr. Ing. P. A. H. Otto for help with the manuscript. Our own work was supported by the Verein Deutscher Zementwerke (Düsseldorf), Arbeitsgemeinschaft Industrieller Forschungsvereinigungen (Köln) and the Deutsche Forschungsgemeinschaft (Bad Godesberg).

Written Discussion

Melville H. Roberts

Synopsis

The present note is a contribution to the written discussion of a paper by H. E. Schwiete and U Ludwig entitled 'Crystal structures and properties of cement hydration products (Hydrated calcium aluminates and ferrites), to be presented at the Fifth International Symposium on the Chemistry of Cement, Tokyo, October 1968. Available evidence for the con-

clusion that cubic $3CaO \cdot Al_2O_3 \cdot 6H_2O$ is a metastable or unstable phase in solution at temperatures slightly below 20°C is discussed. Additional results are presented which appear to confirm this conclusion, since this cubic hydrate is partially transformed into the hexagonal-plate hydrates $2CaO \cdot Al_2O_3 \cdot 8H_2O$ and $4CaO \cdot Al_2O_3 \cdot 19H_2O$ in water and lime solutions at 1°C. Slight carbonation and the formation of quaternary carbonate hydrates also occurred, and to elucidate the influence of carbonate contamination the effects of carbon dioxide on $3CaO \cdot Al_2O_3 \cdot 6H_2O$ in aqueous suspensions at 25°C are briefly described.

Schwiete and Ludwig in their principal paper state that "C_3AH_6 is the only stable pure calcium aluminate hydrate present, under normal conditions of temperature and pressure, in the system Al_2O_3–CaO–H_2O". While this statement is also very probably true, even at high pressures, at temperatures up to about 225°C, there is some evidence pointing to the conclusion that cubic C_3AH_6 is a metastable or unstable phase with respect to the hexagonal-plate hydrates C_2AH_8 and C_4AH_{19} in solution at temperatures slightly below 20°C. In the following, the available data are discussed and some additional results are presented which appear to confirm this conclusion.

Buttler and Taylor (1) treated samples of C_3AH_6 with water and lime solutions at 5°C for various periods up to about 8 months, and they observed that the C_3AH_6 apparently dissolves congruently to give solution compositions near to the solubility curve for C_3AH_6 previously obtained at 20–21°C by other investigators (2, 3). On the other hand, in similar experiments at 1°C over periods from 9 to 16 months with intermittent shaking Carlson (4) found that partial transformation into C_2AH_8 or "C_4AH_{13}" occurred in some reaction mixtures, though not in all. some carbonation also took place in these tests, as shown by the presence of $C_3A \cdot CaCO_3 \cdot 11H_2O$ in all final solids, and this may possibly account for the erratic results. Nevertheless, Carlson concluded on the basis of these experiments that C_3AH_6 is less stable than C_2AH_8 or "C_4AH_{13}" at 1°C. While the difference in temperature might account for the different results at 1°C and 5°C, Jones (5) later inferred in his comprehensive review of the equilibria in the CaO–Al_2O_3–H_2O system that C_3AH_6 is still the only stable ternary phase at 1°–5°C. However, van Aardt and Visser (6) carried out further investigations in which C_3AH_6, with and without solid $Ca(OH)_2$, was treated with water for 7 days, and X-ray examination of moist solids showed the formation of C_4AH_{19} or C_2AH_8 at 5°C but not at 25°C. The X-ray powder patterns also indicated the presence of basal spacings at 8.2 Å and 7.6 Å, and though not recognized as such by these authors these spacings evidently arise from the quaternary carbonate hydrates $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ and $C_3A \cdot CaCO_3 \cdot 11H_2O$, respectively. In this case, contamination by atmospheric CO_2 may have mainly occurred during the X-ray diffractometer examination, whereas to account for previous work (1, 4) where little or no conversion of the C_3AH_6 apparently occurred after many months, it is conceivable that the results were also influenced by inadvertent carbonation in that the quaternary carbonate hydrates possibly formed a protective coating on the C_3AH_6 crystals in the aqueous suspensions.

Additional evidence for the instability of C_3AH_6 at 5°C is provided by the X-ray diffraction investigation of Seligmann and Greening (7). These authors studied the behaviour at different temperatures of a sample consisting initially of a mixture of C_4AH_{19}, $Ca(OH)_2$ and $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ and contained in a special X-ray diffractometer sample holder with an atmosphere of moist nitrogen. It was found that the C_4AH_{19} converted into C_3AH_6 and $Ca(OH)_2$ after 2 hours at 80°C, but subsequent storage over water for 17 hours at 5°C resulted in the disappearance of the X-ray pattern of C_3AH_6 and the restoration of that of C_4AH_{19}. A reversible transformation between C_3AH_6 and C_4AH_{19} has also been observed in later work by Carlson (8), who used a technique involving the microscopical observation of crystals in aqueous suspensions. By this means, it was shown that surface alteration of the C_3AH_6 crystals, evidently through the formation of C_4AH_{19}, occurred after 1 day at 10°C, and was removed after 2 days at 30°C. This surface alteration also took place at 15°C, but 14 days at 20°C produced no change in the C_3AH_6 crystals. Furthermore, a reversible transformation between the hexagonal and cubic phases was also observed to occur with various closely related calcium aluminoferrite hydrates over similar temperature ranges.

In contrast to these results, which indicate that C_3AH_6 is unstable in solution even at temperatures up to 15°C, Feldman and Ramachandran (9) studied the hydration of C_3A compacts at various tempera-

tures and concluded from DTA investigations that there is immediate formation of the hexagonal-plate hydrates at 2°, 12° and 23°C, followed subsequently after some time at these temperatures by conversion into cubic C_3AH_6. In view of the very different crystal structures of C_3AH_6 and the hexagonal-plate hydrates, together with the general observation that the conversion only takes place in the presence of water, it is probable that the transformation into C_3AH_6 occurs by a "through-solution mechanism" involving the crystallization of C_3AH_6 from solution and the dissolution of C_2AH_8 and/or C_4AH_{19} to maintain the solution composition. The DTA thermograms obtained by Feldman and Ramachandran, showing the presence of small amounts of C_3AH_6 in hydrated solids after 10 days at 2°C, after 6 hours at 12°C and after 30 minutes at 23°C, would thus seem to indicate that C_2AH_8 and C_4AH_{19} are unstable with respect to C_3AH_6 at these temperatures. While this conclusion is very probably true at 23°C, an alternative interpretation can be suggested for the results at 2° and 12°C. Thus, it should be noted that the hydrated samples were dried superficially, presumably at room temperature, before examination and that water will also be liberated by dehydration of the hexagonal-plate hydrates during the initial heating period in the DTA apparatus. It seems possible therefore that sufficient water may be present so that some C_3AH_6 could form during the course of the preparation and DTA examination of the hydrated samples, and all the C_3AH_6 may be formed in this way in the samples hydrated at 2°C, and possibly also at 12°C, and not actually be present in the samples at low temperature. A similar explanation may also account for the apparent formation of C_3AH_6 at 2° and 12°C in later work by Feldman and Ramachandran (10) with C_3A + $CaSO_4 \cdot 2H_2O$ compacts. There may therefore really be no conflict between the data of these authors for C_3A compacts and the view that C_3AH_6 is unstable with respect to C_2AH_8 and C_4AH_{19} at low temperature.

In order to examine further the stability of C_3AH_6 at low temperature, some additional tests have recently been made in which 1 g samples of C_3AH_6 were added to 100 ml water, or various lime solutions, at 1°C. After continuous shaking at 1°C for different periods, the reaction mixtures were filtered in the absence of atmospheric CO_2, the filtrates analysed for CaO and Al_2O_3, and an X-ray examination made on the solid phases while still moist with mother-liquor. The results are summarised in Table 1, and the final solution compositions are plotted in Fig. 1, superimposed upon the solubility curves at 1°C given by Jones (5) on the basis of a re-interpretation of the data of Carlson (4).

The C_3AH_6 remained essentially unchanged after shaking for 7 days in water (mixes 1 and 2), and the solution compositions were near to the CaO/Al_2O_3 = 3 composition line, indicating practically congruent solubility. However, at longer times of shaking up to 35 days (mixes 3 and 4) there was partial transformation of C_3AH_6 into C_2AH_8 (or possibly a "C_2AH_8–C_4AH_{19}" solid-solution composition) and the solution concentration changed to that of the solubility curve TY for the "hexagonal-plate" solid solution. Conversion of C_3AH_6 into C_2AH_8 or C_4AH_{19} also could not be detected at 7 days when C_3AH_6 was added to lime solutions of concentration up to about 1.2 g CaO per litre (mixes 5–8), but the formation of C_4AH_{19} was observed in saturated lime solution with excess crystalline $Ca(OH)_2$ at 7 days (mix 9), though

some C_3AH_6 still remained after 39 days (mix 10). With these reaction mixtures of C_3AH_6 in lime solutions, all the final solution compositions were near to the solubility curves TY and YV, the latter being for C_4AH_{19}. Even at 7 days in mixes 5–8, it is possible therefore that the hexagonal-plate hydrates were present in small quantities, insufficient for detection by X-rays, and these may determine the solution compositions, though the quaternary carbonate hydrates present may also play some part. Small amounts of $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$, and usually traces of $C_3A\cdot CaCO_3\cdot 11H_2O$, were detected in all final solids, except for mixes 2 and 3 where a freshly prepared sample of C_3AH_6 was used. This carbonation may have mainly arisen from the use in most reaction mixtures of an old C_3AH_6 preparation, since the X-ray pattern of this preparation showed the presence of additional weak spacings at 7.9 Å and 7.6 Å, presumably from quaternary carbonate hydrates. In as much as similar results were obtained with mixes 2 and 3 in comparison with mixes 1 and 4, it does not appear that the carbonate contamination has affected the rate of conversion of C_3AH_6 in the continuously shaken suspensions. The transformation of C_3AH_6 into C_2AH_8 or C_4AH_{19} apparently does not occur very readily at 1°C, possibly because the latter hydrates precipitate as a protective coating on the C_3AH_6 crystals.

The above results are broadly similar to those obtained by Carlson (4) in his experiments on the solubility of C_3AH_6 in water and lime solutions at 1°C, and the solution compositions are included for comparison in Fig. 1. It is seen that some of these solution compositions are near to the plotted solubility curves, especially when the presence of "C_2AH_8" or "C_4AH_{13}" is indicated, but others differ markedly from these curves. In the latter cases, and perhaps aggravated by the intermittent shaking procedure, it is possible that the quaternary carbonate hydrates which are also present may be dominant, as a protective coating, in determing the solution compositions.

In connection with the effects of carbonate contamination, it has been observed in other experiments that C_3AH_6 is decomposed in the presence of CO_2 or $CaCO_3$ in aqueous suspensions at 25°C and marked changes in solution composition then occurred. On the basis of an X-ray examination of moist solid phases, it was indicated that treatment of C_3AH_6 suspensions in mother-liquor with increasing amounts of CO_2 at 25°C resulted initially in the formation of $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$, then increasing amounts of $C_3A\cdot CaCO_3\cdot 11H_2O$ and $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$ (or a similar solid-solution composition) were formed until the C_3AH_6 eventually disappeared, and subsequently hydrated alumina as well as calcite were precipitated. At the same time, the solution composition changed, and starting from a composition of about 0.56 g CaO per litre, 0.07 g Al_2O_3 per litre in the presence of a little $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$, the CaO concentration decreased slightly while the Al_2O_3 concentration increased appreciably, reaching values of 0.39 g CaO per litre and 0.32 g Al_2O_3 per litre. The solution compositions in the presence of $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$ (or a similar solid-solution composition) thus followed a path approximately parallel to the solubility curve TY for "C_2AH_8–C_4AH_{19}" solid solutions obtained at 25° by Jones and Roberts (11), and displaced to sligh-

tly lower CaO and Al_2O_3 concentrations. It may be noted that these solution compositions are very similar to those observed by Stein (12, 13) during the hydration of C_3A, with and without quartz, in aqueous suspensions at 25°C when increasing amounts of C_3AH_6 were being formed from the initially precipitated hexagonal-plate hydrates. It can therefore be suggested that, in spite of the precautions taken to obtain CO_2-free conditions, these results may have been influenced by inadvertent carbonation and the resulting formation of $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$, rather than by a mechanism involving the alleged slower transformation of "C_4AH_n" then C_2AH_8 and the supposed precipitation of hydrous alumina, as indicated by Stein.

With the larger additions of CO_2 to C_3AH_6 suspensions, when hydrated alumina and calcite were present together with $C_3A \cdot CaCO_3 \cdot 11H_2O$ and $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$, the solution concentration decreased to about 0.2 g CaO per litre, 0.08–0.10 g Al_2O_3 per litre. A similar solution composition was also obtained when $C_3A \cdot CaCO_3 \cdot 11H_2O$ was treated with water at 25°C, while in lime solutions of increasing concentration the Al_2O_3 concentration decreased rapidly to practically nil at about 0.3 g CaO per litre and remained barely detectable at higher lime concentrations up to saturation. The solubility curve of $C_3A \cdot CaCO_3 \cdot 11H_2O$ at 25°C appears to be very similar to that reported (11) for $C_3A \cdot 6H_2O$, but the latter hydrate should be more soluble than $C_3A \cdot CaCO_3 \cdot 11H_2O$.

Similar effects of carbonation on the solution composition to those described above at 25°C are to be expected at 1°C, and since small amounts of the quaternary carbonate hydrates were present in most of the reaction mixtures, some of the solution compositions reported may have been influenced by carbonation. However, although the results are not completely satisfactory in this respect, they support the conclusion that cubic C_3AH_6 is a metastable or unstable phase with respect to the hexagonal-plate hydrates C_2AH_8 and C_4AH_{19} at 1–5°C. The C_3AH_6 may also be unstable in solution at temperatures up to about 15°C, as observed by Carlson (8), but further work seems to be needed to check this observation.

Synopsis

A low-temperature phase of C_4AH_{19} was found below $-15°C$.

In solid solutions $Ca_2Al(OH)_6[(1-y)OH \cdot yX] \cdot aq$ the substitution rate y ranges in the complexes with carbonate from $y = 0.25$ to 0.5, with halides from 0.25 to 1 and with sulphate from 0.5 to 1, the basal distances being constant or nearly constant (CO_3, Cl, Br) or with a slight shift of ~ 0.2 Å (I. SO_4). In reaction mixtures low in iodide, a phase built up by regularly interstratified layers of C_4AH_{19} and the iodide-poorest solid solution was found, besides the separate phases. The halide complexes show a steeply increasing solubility of the halide ion in the solid solution range, among the carbonate complexes the quarter carbonate has an extremely low solubility.

The highest hydration stage of monosulphate (10.3 Å $16H_2O$) is formed only when the crystals are well ordered.

C_2AH_x is formed like quaternary complexes by replacing the exchangeable OH in $Ca_2Al(OH)_6OH \cdot aq$ by the anion $Al(OH)_4^-$.

The presence of the exchangeable OH is essential for the sorption capacity of C_4AH_x for organic molecules.

This contribution deals with a new modification of C_4AH_x and with various aspects of the solid solutions $Ca_2Al(OH)_6$ (OH, X)·aq, where X means a monovalent anion or an equivalent part of a polyvalent anion. Numerous anions, chosen after crystallochemical or geometrical features, were embedded into the C_4AH_x—lattice, only the main results will be reported here. Furthermore, new results on hydration stages of monosulphate, on C_2AH_8 and organo-complexes will be presented.

Low Temperature Modification of C_4AH_{19}

At room temperature, C_4AH_{19} exists in two polytypes, α_1– and α_2–C_4AH_{19} (1). Both modifications are built up by the same pseudocell, differing only in the stacking sequence of the elementary layers. By means of DTA and X-ray analysis, we found at low temperatures a modification of C_4AH_{19}, which has different dimensions of the pseudocell (2). The transformation

$$\alpha_2\text{–}C_4AH_{19} \xleftrightarrow{-15 \pm 2°C} \beta\text{–}C_4AH_{19}$$

is reversible at $-15 \pm 2°C$ and was observed only with exceptionally well crystallized C_4AH_{19}. The longest basal spacing of this "β–C_4AH_{19}" is 10.42 Å, the (110)—parameter enlarges from 2.88 Å (α_2–C_4AH_{19}) to 2.90 Å. Further work will be undertaken to get more complete X-ray data and to establish the symmetry of the new phase. With lower hydration stages of C_4AH_x there was no corresponding thermal transformation observed which originated in dimensional changes of the pseudocell.

Solid Solutions $Ca_2Al(OH)_6(OH, X) \cdot aq$

Preparation

Quaternary derivatives of C_4AH_x were prepared with reaction mixtures of CaO, $NaAlO_2$, H_2O and the calcium or alkali salt of the wanted anion. These mixtures were shaken at room temperature for at least one week. The same results are obtained by exchange of the outer OH's in preformed C_4AH_x against the wanted anions (added as salts) using aqueous or nonaqueous suspensions (exchange reactions). It is possible to produce the quaternary complexes also by neutralization: $Ca_2Al(OH)_6OH \cdot aq + HX \rightarrow Ca_2Al(OH)_6X \cdot aq + H_2O$, provided that the addition of the acid is extremely slow. This interlamellar sorption process preferably is done in C_4AH_x-benzene suspensions.

X-ray Characteristics

Regarding a certain hydration state, quaternary complexes derived from C_4AH_x are characterized by distinct basal spacings. Generally the same basal spacings are observed with members of the solid solution series $Ca_2Al(OH)_6(OH, X)\cdot aq$, however, some exceptions are noteworthy.

Constant Basal Distances

The CO_2-containing phases are of special interest with regard to cement hydration. Repeating an older work (3), we investigated once more the system C_4AH_x $-CO_2$, the CO_2-increments being this time more closer. We obtained the following results (Fig. 1):

The low carbonate phase (8.2 Å) is the only reaction product when the substitution rate y has reached values between 0.25 and 0.3. The basal distance keeps constant (8.2 Å) until $y = 0.5$. Exceeding amounts of CO_2 produce monocarbonate (7.6 Å) as a second phase and the 8.2 Å-phase disappears gradually until at $y = 1$ monocarbonate alone is present. Our investigations show, that the low carbonate phase (8.2 Å) has a varying composition: $Ca_2Al(OH)_6\left[(1-y)OH\cdot y\frac{CO_3}{2}\right]\cdot aq$ $(y = 0.25 - 0.5)$. Within this tolerance both statements of Dosch and zur Strassen (3) (1/4-carbonate) and Seligmann and Greening (4) (1/2-carbonate) are reconciled.

A continuous range of solid solution formation was also observed with halogenes and other anions. In the case of Cl- and Br- complexes, a single phase $Ca_2Al(OH)_6[(1-y)OH\cdot y\,Hal]\cdot aq$ was obtained, when y reached 0.25. The basal distance is almost the same as for the corresponding saturated complexes ($y = 1$) and does not shift significantly during further embedding of halogenes (Table 1).

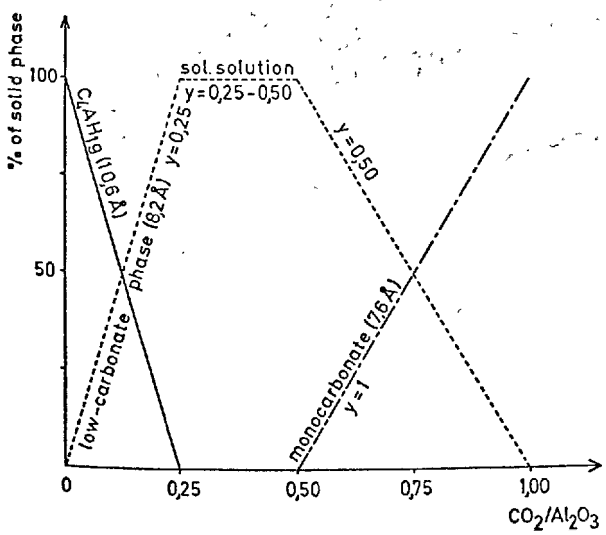

Fig. 1. *Sequence of carbonate complexes* $Ca_2Al(OH)_6\left[(1-y)OH\cdot y\frac{CO_3}{2}\right]\cdot aq$

Shift of Basal Distances

Examples for a distinct shift of the basal spacing with increasing replacement of OH by anions are the solid solution series with monoiodide (Table 1) or with monosulphate (Fig. 2).

When in the latter solid solution series the substitution rate y is below $0.5C_4AH_{19}$ and a sulphate bearing C_4AH_x ($c' = 8.78$ Å) coexist. Above 0.5, there are only mixed crystals. With increasing sulphate content the basal spacings get longer. The rate of increase is at first great, then becomes smaller. The end member, monosulphate-12-hydrate, is characterized by the longest basal distance of 8.94 Å, the total shift of the basal distances thus being about 0.2 Å.

The slope of the first part of the curve, where basal spacings of specimens with molar ratios SO_4^{2-}/Al_2O_3 below 0.5 are plotted, is reliable. But since the basal reflections of these specimens are weak and broad, they are measurable less accurately than those of compounds rich in sulphate. It is assumed that randomly interstratified layers of C_4AH_x and 1/2-monosulphate are formed when the molar ratios SO_4^{2-}/Al_2O_3 of the reaction mixtures are below 0.5. Since in these reaction products C_4AH_{19} is present as a second phase, the ratio of C_4AH_x to sulphate containing layers cannot be determined.

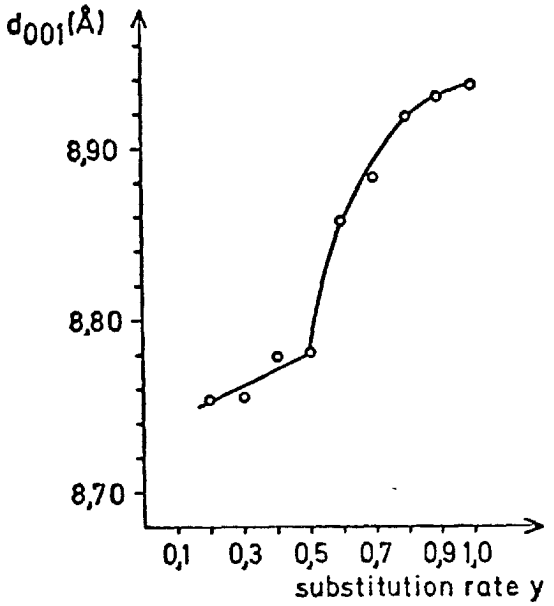

Fig. 2. *Basal distances of solid solutions* $Ca_2Al(OH)_6\left[(1-y)OH \cdot y\frac{SO_4}{2}\right] \cdot aq$

Regularly Interstratified Layers

Another type of solid solution formation was observed in mixed crystals $Ca_2Al(OH)_6[(1-y)OH \cdot yI] \cdot aq$ ($y = 0 - 0.25$). The reaction products, when still moist with mother liquor, showed among other basal reflections (Table 1) weak, but sharp integral 001—reflections, the longest basal spacing being 19.2 Å. This value originates from regularly interstratified sheets of C_4AH_{19} (10.6 Å) and sheets of monoiodide (8.62 Å): 10.6 + 8.6 = 19.2. This regularly stratified structure is destroyed on drying or when more iodide —ions are added to the starting reaction mixture. Exceeding the substitution rate y = 0.25, only mixed crystals are present, the basal spacing of which shifts from 8.5 to 8.6 Å, when half of the exchangeable OH is replaced by I.

Conclusions

We conclude, that in most cases of solid solution formation a certain low amount of embedded anions is sufficient to produce the basal spacing which is characteristic for a certain hydration stage of the corresponding saturated complex. Since under equal humidity and temperature conditions the basal distances of the quaternary compounds are in most cases widely separated from those of C_4AH_x and since there are always integral series of 001—reflections observed, it is concluded, that the solid solutions are not composed of randomly interstratified layers of $Ca_2Al(OH)_6OH \cdot aq$ and $Ca_2Al(OH)_6X \cdot aq$, or

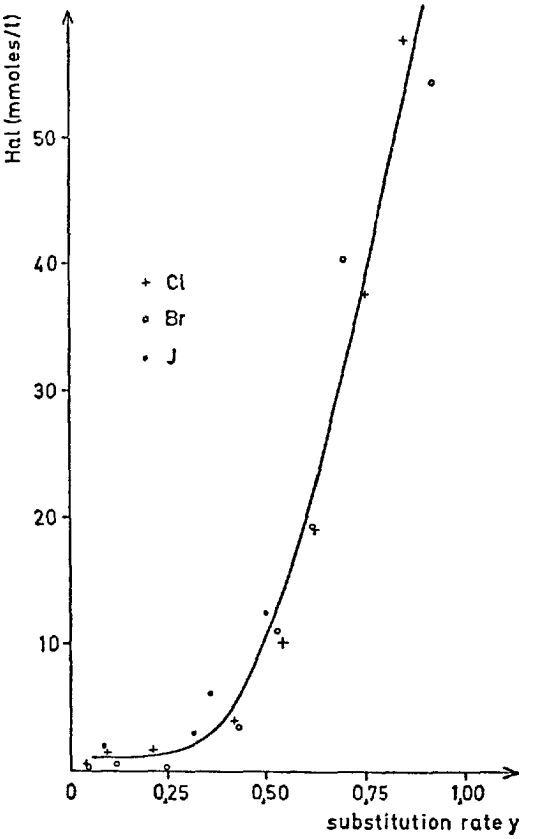

Fig. 3. *Solubility curves of solid solutions* $Ca_2Al(OH)_6[(1-y)OH \cdot yHal] \cdot aq$

intergrowths of larger stacks of ternary and quaternary compounds. The replacement of OH—ions by anions X takes place statistically on the surfaces of all $Ca_2Al(OH)_6$—principal layers. The resulting basal distance depends on the effective thickness of the anion X, but not on the total amount of exchanged anions. A minimum quantity, which is different for different anions, suffices to widen the elementary layers to the characteristic basal spacing of the quaternary complex. Further exchange of anions probably only has an influence on the crystal symmetry. But this picture is only a rough one, because it does not take into consideration the variation of the interlayer water during the sorption of anions by C_4AH_x.

The solid solution crystals are not very stable. Long storage or de- and rehydration cycles result in products giving rather complex X-ray patterns. Part of them indicate irregular interstratified layers, others show separation into ternary and quaternary phases.

Sorption Equilibria

The solubilities with regard to the sorbed anions

of the various complexes are very different. Extremely low solubilities have for instance the complexes with carbonate, sulphate, molybdate and uranate. C_4AH_x is, therefore, suitable for quantitative determinations of these anions or for the disintegration of salts and minerals, for example, calcite, coelestine and the like. Other quaternary complexes (for instance those of chromate, permanganate, chlorate, nitrate, halides) are strongly dissociated in aqueous solutions.

In Fig. 3. there is the halide content in solution plotted against the substitution rate. The solid consists (Table 1) of one single phase when y reaches 0.25. At lower contents of halide, there are two phases, C_4AH_{19} and the halide-poorest member ($y = 0.25$) of the solid solution series.

In agreement with this the first part in Fig. 3 indicates a very low and nearly constant solubility of the anion. The slope of the solubility curve begins at $y = 0.25$, when the solid consists of one phase. Very high solubilities have the saturated compounds ($y = 1$).

It was shown that an equimolecular mixture of calcite and tricalcium aluminate when shaken in aqueous suspension reacts by forming monocarbonate hydrate (5). The same decomposition of calcite is obtained when shaken with tetracalcium aluminate hydrate (Table 2, reaction 1). This shows that the solubility of calcite is higher than that of the carbonate complex. In the same way it can be demonstrated that the solubility with respect to the CO_3—anion is still lower in the low carbonate solid solution phase. Monocarbonate hydrate is decomposed by tetraclacium aluminate hydrate to semicarbonate (reaction 2), the later by additional CO_2—free phase to quarter carbonate (reaction 3). Monocarbonate and quarter carbonate react to semicarbonate (reaction 4). It is noteworthy that these transformations take place in spite of the extremely low solubility of the phases.

Table 2. *Reactions in aqueous suspension demonstrating the decreasing solubility of the carbonate complexes with decreasing carbonate content.*

1. $\frac{1}{2}CaCO_3 + Ca_2Al(OH)_6OH \cdot aq \longrightarrow Ca_2Al(OH)_6\left[\frac{CO_3}{2}\right] \cdot aq + \frac{1}{2}Ca(OH)_2$
   calcite — C_4AH_x — monocarbonate
2. $Ca_2Al(OH)_6\left[\frac{CO_3}{2}\right] \cdot aq + Ca_2Al(OH)_6OH \cdot aq \longrightarrow 2Ca_2Al(OH)_6\left[\frac{1}{2}OH \cdot \frac{1}{2}\frac{CO_3}{2}\right] \cdot aq$
   monocarbonate — C_4AH_x — semicarbonate
3. $Ca_2Al(OH)_6\left[\frac{1}{2}OH \cdot \frac{1}{2}\frac{CO_3}{2}\right] \cdot aq + Ca_2Al(OH)_6OH \cdot aq \longrightarrow 2Ca_2Al(OH)_6\left[\frac{3}{4}OH \cdot \frac{1}{4}\frac{CO_3}{2}\right] \cdot aq$
   semicarbonate — C_4AH_x — quarter carbonate
4. $Ca_2Al(OH)_6\left[\frac{CO_3}{2}\right] \cdot aq + 2Ca_2Al(OH)_6\left[\frac{3}{4}OH \cdot \frac{1}{4}\frac{CO_3}{2}\right] \cdot aq \longrightarrow 3Ca_2Al(OH)_6\left[\frac{1}{2}OH \cdot \frac{1}{2}\frac{CO_3}{2}\right] \cdot aq$
   monocarbonate — quarter carbonate — semicarbonate

Hydration Stages of Monosulphate Hydrate

Much uncertainty still seems to exist about the hydration stages of monosulphate. The following results (6) were obtained:

All de- and rehydration processes were followed stepwise by X-ray analysis, using a humidity and temperature controlled specimen cell. From reaction mixtures prepared above 10°C, 9.5 Å—monosulphate ($14H_2O$) is obtained. At room temperature and 95% r.h. this phase dehydrates to the 12—hydrate (8.9 Å), which exists within the range of 95% r.h. to 20% r.h.. Below 20% r.h. monosulphate-10-hydrate (8.15 Å) is formed. Over P_2O_5 and at temperatures between 30 and 50°C two more molecules of interlayer water are splitt off. This phase has a basal spacing of 7.95 Å. At room temperature it rehydrates rapidly at relative humidities below 1% to the 10—hydrate (8.15 Å). The latter phase rehydrates to the 8.9 Å—monosulphate at 30% r.h., 25°C. Further rehydration to the 9.5 Å—phase is possible in 100% r.h. at temperatures above 55°C. This phase converts to the 10.3 Å—phase, when the sample is cooled to below 8°C. Rising the temperature, 9.5 Å—monosulphate again is obtained. Not all preparations of monosulphate showed the re- and dehydration process forming the 9.5 Å and 10.3 Å—product. However, this conversion was always found with monosulphate which was prepared at temperatures around 0°C and which was X-rayed when still moist with mother liquor. Apparently only well ordered crystals—slowly grown at low temperatures—are able to de- and rehydrate at 8°C. We estimate the water content of the 10.3 Å—phase to be 16.

There is another example which indicates that some quaternary complexes of C_4AH_x must be of high crystalline orderliness to get their highest possible hydration stage: Foret (7) described the compound

$C_3A \cdot Ca(NO_3)_2 \cdot 16H_2O$, no X-ray data were given. Examining the solid solution series $Ca_2Al(OH)_6(OH, NO_3) \cdot aq$ we obtained the 16—hydrate ($c' = 10.39$ Å) only when the substitution rate y in the solid exceeded 0.75.

Since the H_2O dipoles are oriented not only to the octahedral OH's of the principal layer $Ca_2Al(OH)_6$ but also to the embedded anions, we conclude, that a high order of the anion arrangement is necessary to admit the formation of additional H_2O—layers, especially double layers of H_2O with or without participation of anionic oxygens. Lower hydration stages are far more tolerant of disordered crystals.

C_2AH_8, a Derivative of C_4AH_x

Among the numerous anions which are sorbed by C_4AH_x, there is also $Al(OH)_4^-$. This anion is of special interest since the interlamellar exchange of OH by $Al(OH)_4^-$ in C_4AH_x results in a compound which has the chemical composition of C_2AH_x:

$$Ca_2Al(OH)_6OH \cdot aq + Al(OH)_4^- \longrightarrow Ca_2Al(OH)_6Al(OH)_4 \cdot aq + OH^-$$

Indeed, our expectation to get C_2AH_x by this reaction was realized. According to that, C_2AH_x could be nominated "tetracalcium aluminate monoaluminate hydrate".

Our experiments were carried out using well crystalline C_4AH_x (average diameter 70μ) which was suspended in a concentrated alkaline $NaAl(OH)_4$ solution. Since in a strongly alkaline medium at room temperature the conversion of C_4AH_x to C_3AH_6 takes place readily, temperatures around 0°C had to be employed. The innercrystalline sorption of $Al(OH)_4^-$ is performed within 12 hours. One could argue that C_4AH_x disintegrates to form with $Al(OH)_4^-$ new crystals of C_2AH_x. But samples, which were examined at intermediate times during the sorption process did not exhibit any signs of decay. The C_2AH_8 ($c' = 10.7$ Å) formed this way is distinguishable from C_4AH_{19} ($c' = 10.7$ Å) by X-ray analysis only by its behaviour on dehydration.

Sorption of Organic Material by C_4AH_x

Until recently, we were not informed that Lavanant and Barret (8) were the first who found an organic sorption compound of C_4AH_x. However, the authors succeeded only to prepare a complex with methanol. Having no success with gaseous ethanol and benzene, they did not pursue such experiments.

Among cement hydration products, only C_4AH_x seems to possess the capability of innercrystalline swelling on the addition of organic substances, although the other hydration products partly form various hydration stages (9).

Esters, fatty acids and other acids are generally rapidly saponified by C_4AH_x. Recent IR-examinations have shown, that fatty acids are bonded as anions, there is no ester—like bond to the C_4AH_x—layers as was formerly supposed (10).

Free lime in cements is determined by the Franke method, using acetoacetic ester. At room temperature, this reagent violently disintegrates C_4AH_x, Ca-enolate and aluminium hydroxide being the reaction products. Therefore it is obvious that the Franke method is not applicable in the presence of C_4AH_x. Except calcium silicate hydrates, other products of cement do not react with acetoacetic ester.

Inorganic derivatives of C_4AH_x like monosulphate, Friedel's salt do not interlamellarly adsorb organic molecules. But solid solutions with C_4AH_x in which the exchangeable OH is only partially replaced by inorganic anions are capable to absorb organic molecules, though this process is rather complicated because partial decompositions into inorganic and organic derivatives of C_4AH_x take place. From this follows, that the sorption of organics is based on the existence of the exchangeable OH in $Ca_2Al(OH)_6 \cdot aq$ (9).

It must be pointed out, that there are two types of derivatives of C_4AH_x, which are capable to swell one-dimensionally with organic substances:

a) Inorganic derivatives of C_4AH_x containing anions which due to a certain electron configuration are able to fix organics. An example for this case is the quaternary complex $Ca_2Al(OH)_6Ni(CN)_4 \cdot aq$. Because of steric hindrances, only small molecules like methanol, formamide, acetone, pyridine are absorbed (2).

b) Alkali-monosulphate, though more widely differing from C_4AH_x, is the other compound showing sorption properties for organic molecules. In this compound, alkali cations which are situated between

negatively charged elementary layers are replaceable by alkylammonium cations, analogous to mica-like layer silicates (9).

Oral Discussion

Alice E. Moore and Harry F. W. Taylor

We have determined the crystal structure of ettringite by single-crystal X-ray methods, and our results do not support the structure of Bezjak and Jelenić

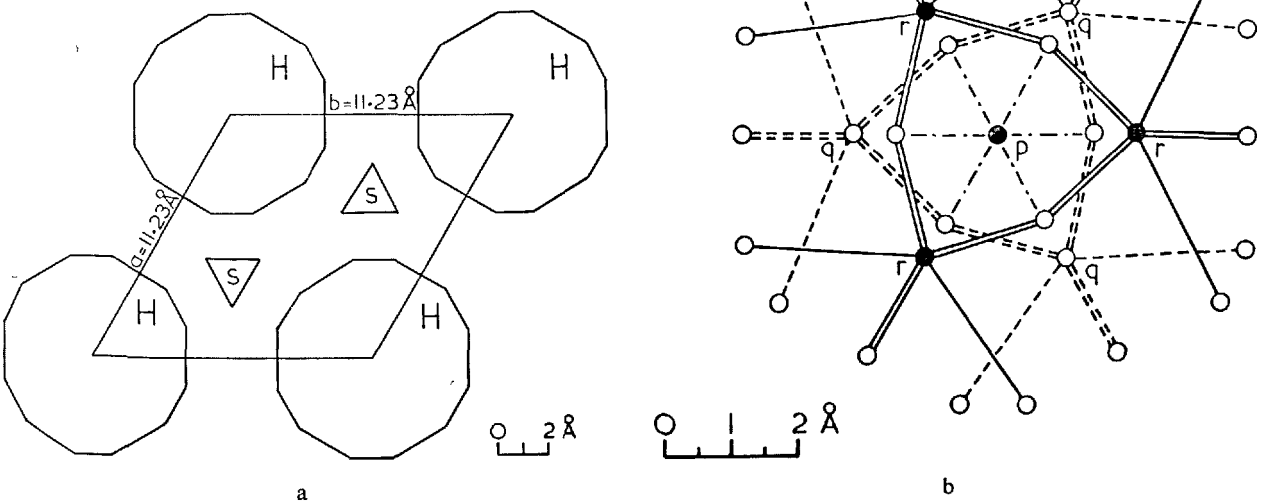

Fig. 1. *General features of the structure.* A, *Projection along* c, *showing the outlines of the columns* (*H*) *and of the sulphate groups* (*S*). B, *One of the columns in greater detail, also projected along* c. p, Al^{3+} *ions at* $z = 0$ *and* $\frac{1}{2}$ *(coincident in projection);* q *and* r, Ca^{2+} *ions at* $z = \frac{1}{4}$ and $\frac{3}{4}$, *respectively. (1) which is mentioned in the Principal Paper. We have reported preliminary results elsewhere (2), and have since refined the structure further using three-dimensional methods to give an R-factor of 0.11 for about 700 independent reflections.

The true space group is $\underline{P}31\underline{c}$ and the apparently hexagonal symmetry of some crystals must be attributed to disorder. The structure (Fig. 1a) is based on columns, of empirical composition $[Ca_3 \cdot Al(OH)_6 \cdot 12H_2O]^{3+}$, running parallel to the $\underline{c}$- or needle axis. In the channels between these columns occur the sulphate ions and remaining water molecules. Fig. 1b shows the structure of an individual column. Each Al^{3+} ion is octahedrally coordinated by hydroxyl ions, and each Ca^{2+} ion is 8-coordinated, by 4 hydroxyl ions and 4 water molecules. The Ca^{2+} and Al^{3+} polyhedra share edges. The surface of the column is formed by the H_2O molecules, and it is reasonable to suppose that the net positive charge of the column is distributed, more or less uniformly, among the hydrogen atoms of these water molecules.

Considering now the material in the channels, refinement of site-occupancies suggests that there are $1.5H_2O$ molecules per $3SO_4^{2-}$ ions, thus indicating the composition $Ca_6[Al(OH)_6]_2(SO_4)_3 \cdot 25\frac{1}{2}H_2O$, or $C_3A \cdot 3CaSO_4 \cdot 31\frac{1}{2}H_2O$, for ettringite. The contents of each channel follow the sequence SO_4–SO_4–SO_4–$1.5H_2O$, where the latter term represents a mean of $1.5H_2O$ molecules distributed statistically among 3 sites disposed symmetrically around the axis of the channel.

Further refinement is in progress and is beginning to show the positions of the hydrogen atoms.

Authors' Closure

Hans E. Schwiete and U. Ludwig

Roberts states in his paper that there is some evidence that C_3AH_6 is not the only stable pure calcium aluminate hydrate under normal conditions of temperature and pressure in the system Al_2O_3–CaO–H_2O at temperatures below 20°C.

We are in the opinion that it is very difficult in time to give a clear answer on this question. There is a lot of work stating the stability of C_3AH_6 at low temperatures and there are too experimental data from which we can derive instability and formation of C_2AH_8 and C_4AH_{19}. But when instability was found mostly there was found some impurity of CO_2 and in this case we have not the pure ternary system. From our own work we know, that it is not very easy to produce pure C_3AH_6 without any unhydrated C_3A, that could form afterwards C_4AH_{19} together with $Ca(OH)_2$. Together with Roberts we think that this is still a problem and further experimental work seems to be needed.

Dosch, Keller and zur Strassen gave in their paper some new data of the tetracalcium aluminate hydrate and the complex salts which can derived from it. We took care of this results already in our oral presentation of principal paper and appreciated the authors to their new data, specially the conversion of C_4AH_{19} at −15°C, and the explanation of the formation of complex salts by replacing exchangeable OH in $Ca_2Al(OH)_6OH \cdot aq$ and given boundary of the substitution rate of complex salts with CO_3, halides and SO_4.

A. E. Moore and H. F. W. Taylor gave a new space group for the crystal structure of the ettringite with $P31c$. This new space group is not only in contrast to the work of Bezjak and Jelenić but is also a correction of the former work of Bannister, Hey and Bernal.

The given composition of the ettringite with $Ca_6(Al(OH)_6)_2(SO_4)_3 \cdot 25\frac{1}{2}H_2O$ is in good agreement with our measurement of dehydration of ettringite that shows two endotherm peaks at about 60° to 200°C and 200° to 300°C with minima at 130° and 260°C.

The R-factor of 0.11 for about 700 reflections shows the accuracy of the given work. We are very much interested in the last details of the new structure of ettringite the authors announced.

Supplementary Paper II-14 Quaternary Calcium Aluminate Hydrates: Crystal Structure of Calcium Aluminate Monobromide Hydrate

François Le Bel and Guy Grasland*

Synopsis

Quaternary calcium aluminate hydrates, belonging to one or other of two series of compounds with formulae:

$$Ca_2Al(OH)_6\,X\cdot nH_2O \text{ or } [Ca_2Al(OH)_6]_2Y\cdot nH_2O$$

(X and Y being respectively mono and divalent anions), are discussed. Synthesis methods used for monocrystal preparations are described.

The structural data concerning the calcium aluminate monobromide hydrate are given; the compound is trigonal (R3), the triple hexagonal cell includes three $Ca_2Al(OH)_6\,Br\cdot 2H_2O$ units, its parameters are:

$$a = b = 5.76\ \text{Å} \qquad c = 24.45\ \text{Å}$$

A structure determination obtained from 145 independent reflexions leads to a R index of 0.20. New intensity measurements associated with absorption corrections are being made to obtain a more precise determination of the structure.

The structure can be described as follows: Ca^{2+} and Al^{3+} ions, located in octahedral sites existing between two hydroxyl group layers are surrounded by six OH^-, polyhedrons of coordination having a common edge. Water molecules layers are found on both sides of the hydroxy-layers, the neighbouring of each Ca^{2+} ion is so completed with one water molecule. The Br^- ions are surrounded by six water molecules belonging to two successive layers.

A comparison is made with structure hypothesis formerly given.

Introduction

Present knowledge concerning the structure of hydrated calcium aluminates is very limited. This blank arises from the fact that it is very difficult to obtain single crystals of proper size, making possible direct analysis by X-ray diffraction.

At present, the only well-known structure is that of C_3AH_6. It was assessed by analogy with that of the glossularite C_3AS_3, by Flint, Wells and MacMurdie (1), and recently further specified by Weiss, Grandjean and Pavin (2).

The hydrocalumite, a natural mineral close to C_4AH_{13}, was the subject of a research on single crystals by Tilley, Megaw and Hey (3): however, the structure is still poorly understood.

Bezjac and Jelenic (4) recently presented a description of the structure of the ettringite, the work being carried out on powder photographies.

Studies on single crystals permitted Kuzel (5) to give crystal space groups and the unit cell of several calcium chloro and sulfoaluminates.

Lastly, many theories were proposed concerning the structure of the various hydrated calcium aluminates, in particular: Brandenberger (6); Tilley, Megaw and Hey (3); Bessey (7); Buttler, Dent Glasser and Taylor (8); Grudemo (9); Feitknecht and Buser (10).

The present work concerns the direct assessement of the structure of hydrated calcium monobromoaluminate, by X-ray analysis on single crystals.

*Ciments Lafarge, Paris, France.

Foreword

The hydrated calcium bromoaluminate $C_3A \cdot CaBr_2 \cdot 10H_2O$, belongs to the series of hydrated quaternary calcium aluminates. These compounds conform to the general formula $C_3A \cdot CaX_2 \cdot nH_2O$ or $C_3A \cdot CaY \cdot nH_2O$, X being a monovalent anion and Y a divalent anion. The series of these bodies was mainly studied by Buser (11). Chloroaluminates ($X = Cl^-$) sulfoaluminates ($Y = SO_4^{2-}$), carboaluminates ($Y = CO_3^{2-}$), compounds encountered in the hydration of cements, were particularly studied, as well as "hexagonal" aluminates to this series, with respective anions $Al(OH)_4^-$ and OH^-.

All these compounds present strong analogies, both by their crystallography (hexagonal facies of crystals, hexagonal parameter close to 5.7 Å..) and by their physical properties (easy cleavage parallel to 001, behaviour on dehydration, phyllitous nature . . .).

The choice of the calcium bromoaluminate within the series of these compounds was guided on one hand by the presence of the "heavy" bromine atom, on the other hand by the possibility of producing single crystals.

Preparation of Single Crystals

The hydrated calcium bromoaluminate $C_3A \cdot CaBr_2 \cdot 10H_2O$ can be produced as single crystals using the method described by H. W. Buser (11). This method uses the slow diffusion of a solution A, containing $Al(OH)_4^-$ and OH^- ions, and of a solution B, containing Br^- ions, into a third solution C, which may be either water, or a solution containing Br^- ions. According to the strengths of the three solutions A, B and C, the quality of crystals varies. The best conditions were obtained with:

Solution A(250 cm³)
$Al(OH)_4$: 0.05M; OH^- 0.1M; NaBr 0.6M
Solution B(250 cm³)
$CaBr_2$: 0.1M; NaBr 0.4M
Solution C(500 cm³)
NaBr: 0.6M

Crystals produced in this way appear as hexagonal plates 40 microns thick and 400 microns wide.

We also obtained single crystals by hydrothermal synthesis from lime, alumina and calcium bromide. A similar method was used by Friedel (12), who obtained crystals of calcium chloroaluminate; similarly, H. J. Kuzel (13) used this method to produce single crystals of chloro and sulfoaluminates. However synthesis remained smaller than that of diffusion crystals.

Structure of the Hydrated Calcium Bromoaluminate

This structural study was carried out in cooperation with Prof. Weiss's laboratory, of the Strasbourg University.

The X-ray diffraction study (powder diagram, rotating crystal, Weissenberg camera) indicates that the hydrated calcium bromoaluminate is rhombohedral. The parameters of the triple cell are $a = b = 5.76$ Å, $c = 24.45$ Å; it contains $1.5C_3A \cdot CaBr_2 \cdot 10H_2O$ units or, more precisely, three $Ca_2Al(OH)_3Br, 2H_2O$ units.

The only symmetry element is a ternary axis; the condition for the existence of reflections is $-h + k + l = 3n$.

Thus, possible space groups are R3 and $R\bar{3}$. The structure leads to the assumption of the R3 group.

The intensities of 145 independent reflections were recorded on Weissenberg camera, using CuKα-radiation. A first determination of the structure was made, leading to a quality factor R of about 0.20.

With such value, it is not possible to assert the accuracy of the structure; it can be explained by the high radiation absorption. At present, the intensities of about 500 independent reflections were measured with a Philips automatic diffractometer, using MoKα-radiation. Moreover, absorption corrections are now in progress, which will allow a greater accuracy.

In the present state of our knowledge, the structure can be described in the following way. (see Figs. 1, 2 and 3.)

Br, Ca, H_2O atoms are in special positions 00z of the R3 group, hydroxyl groups being in general xyz position. Ca^{2+} and Al^{3+} ions are located in octahedral cavities between two layers of hydroxyl groups. Each aluminium atom is thus surrounded by six hydroxyl groups, the same holding for each calcium

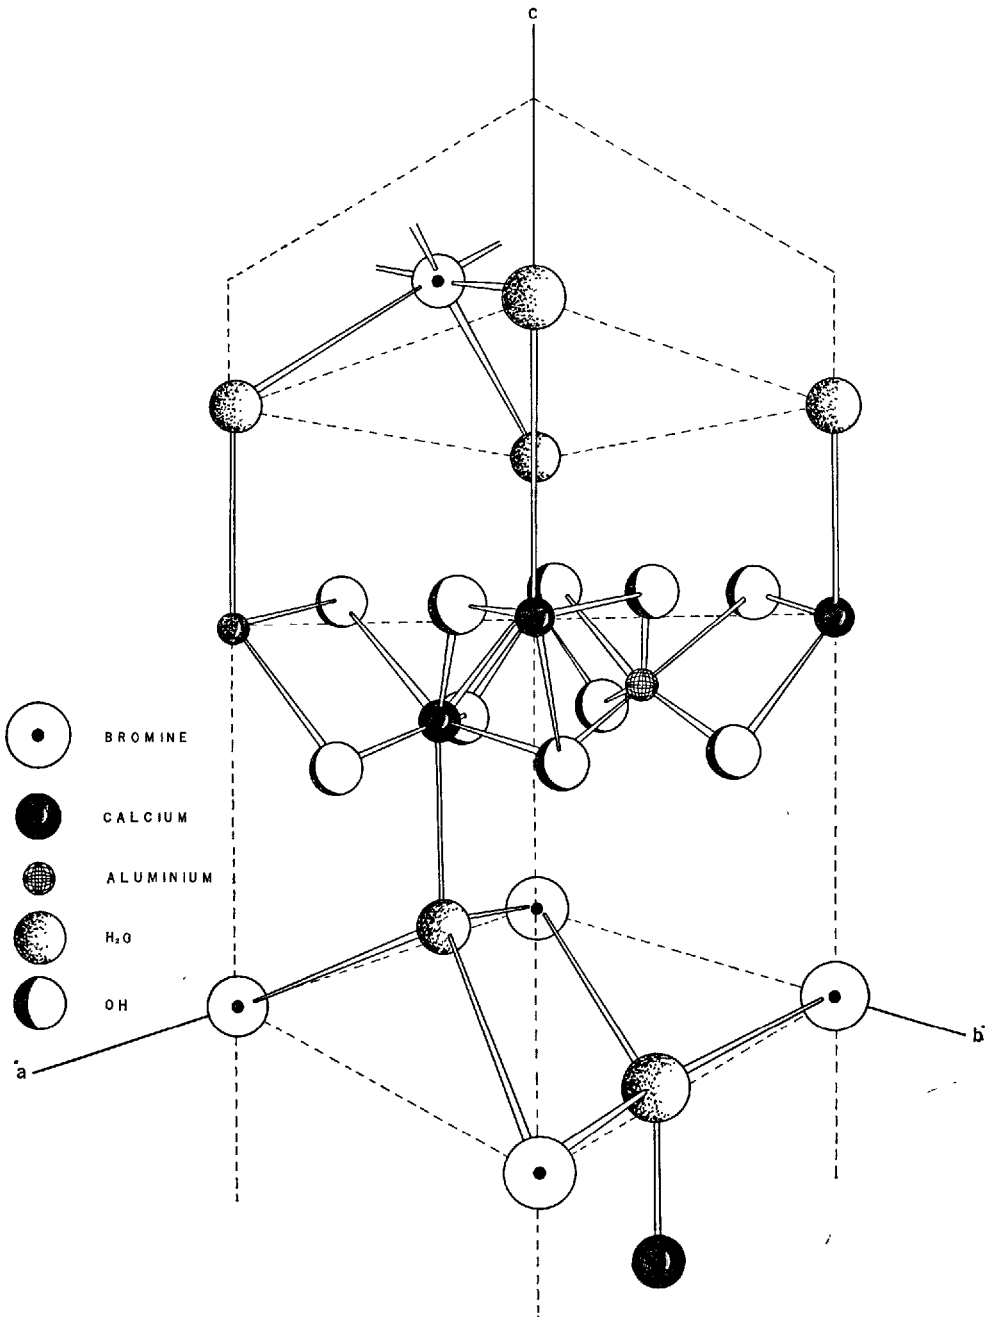

Fig. 1. $Ca_2Al(OH)_6Br \cdot 2H_2O$ *General view of the structure* ($\frac{1}{3}$ *of the cell*)

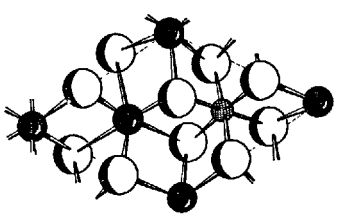

Fig. 2. $Ca_2Al(OH)_6$ *Layer: (001) projection*

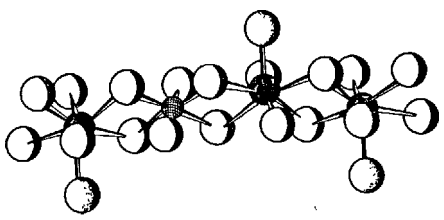

Fig. 3. $Ca_2Al(OH)_6$ *Layer: (110) projection*

atom. Coordinating polyhedrons have a common edge. Between hydroxyl layers there are two calcium atoms for one aluminium atom. Water molecules are located on both sides of these layers. The surrounding of each Ca^{2+} ion is thus completed by one water molecule.

Water molecules form layers parallel to hydroxyl layers. Bromine atoms are located between these layers, each Br^- being thus surrounded by six water molecules.

The structure is of the ionic type, and it can be easily shown to follow Pauling's rules.

Discussion of the Structure

Owing to the structure, we think it better to write the formula of the bromoaluminate as $Ca_2Al(OH)_6Br \cdot 2H_2O$. More generally, hydrated quaternary calcium aluminates should then be written:

$$Ca_2Al(OH)_6X \cdot nH_2O \text{ or } [Ca_2Al(OH)_6]_2Y \cdot nH_2O$$

Such writing is more representative of the properties of these compounds, as it lays stress on the hexacoordinance of aluminium and marks hydration water molecules.

The octahedral surrounding of aluminium is corroborated by the work of Fripiat (14) who showed an hexacoordinance of aluminium in $Ca_2Al(OH)_6 \cdot 3H_2O (C_4AH_{13})$ and in $[Ca_2Al(OH)_6]_2CO_3 \cdot 5H_2O$ $(C_3ACaCO_3H_{11})$ by measurements of X-ray emission wave length. Similarly, in C_2AH_8, half of the aluminium is hexacoordinated and the other half tetracoordinated, which is properly expressed by the formula: $Ca_2Al(OH)_6Al(OH)_4 3H_2O$.

The dehydration of the bromoaluminate conduces to the loss of two water molecules at approximately 180°C. This, in turn, produces a shortening of the *c*-axis which, according to Buser, changes from 8.1 to 7.15 Å.

The layer arrangement of water molecules and the relative weakness of the linking with the anion are in accordance with the easiness of cleavage parallel to 001.

The presence of the anion between layers explains the variations of the c-parameter in connection with the anion size (H. W. Buser) (11).

The works of Michel (15) and Buser (11), as well as our own experiences, indicated that it was very easy to carry out anion exchanges in quaternary aluminates; likely, this feature can be explained by the comparatively weak linking with the anion.

Previously Proposed Structures (Assumptions)

A review of previous theories about the structure can be found in Taylor's work (16).

We shall not go into the details of these assumptions, the only one close to that established by us for the calcium monobromoaluminate being that of Buttler, Dent Glasser and Taylor (8).

However, we can say that:

The structures proposed by Tilley (3) and Bessey (7) consider the substitution of H_2O to some Ca^{2+} ions in octahedral layers, and are inconsistent with a parameter remaining unchanged during dehydration.

The structure proposed by Grudemo (9) contradicts the hexacoordinance of aluminium.

The structure proposed by Buser (10–11) differs by the position of Al^{3+} ions, outside octahedral layers.

As to Buttler's assumption (8), recently modified by Dosh (17), it is very similar to that established for the bromoaluminate, owing to the existence of the octahedral layer $Ca_2Al(OH)_6$; the difference is mainly due to the fact that OH^- anion is assumed directly linked to the octahedral layer while, as we already saw, the Br^- anion is located between water molecule layers. Possibly, this difference may be explained by the size difference between Br^- and OH^- anions.

Conclusion

The production of single crystals permitted the direct assessment of the structure of the hydrated calcium monobromoaluminate $Ca_2Al(OH)_6B_2 \cdot 2H_2O$.

This structure is in accordance with several characteristics common to this compound and to the group of quaternary aluminates. It is essentially characterized by the existence of a double layer of hydroxyl

ions, containing calcium and aluminium atoms; anions are located between the layers of water molecules linked to the calcium.

Among previous theoreis, the structure proposed by Buttler, Dent Glasser and Taylor (8) is the nearest to our interpretation.

Addendum

It is only after completing the writting of this publication, that the work by Ahmed and Taylor (18), concerning the structure of a compound offering similitudes with $4CaO \cdot Al_2O_3 \cdot 13H_2O$, was known to us.

There is a very strong analogy between the structure of the said compound and that of bromoaluminate. Indeed, one may observe an octahedric layer $Ca_2Al(OH)_6$ and the presence of anions between two layers of water molecules. Calcium environment is actually completed to 7 by those water molecules.

A thorough comparison will be interesting when both of said structures will be definitely settled.

Supplementary Paper II-15 Contribution to the Study of Complex Aluminates: Hydrated Calcium and Magnesium Monocarboaluminates

Gérard Sadran and Bernard Cottin*

Synopsis

The authors have pointed out the existence of a series of calcium and magnesium aluminate monocarbonate hydrates derived from calcium aluminate monocarbonate hydrate by substitution from 0 to 95% of calcium by magnesium.

The analysis of these compounds conforms to the following formula:

$$[Mg_xCa_{2-x}Al(OH)_6]_2CO_3 \cdot 5H_2O$$

x varying from 0 (calcium aluminate monocarbonate hydrate) to 1.90.

These products have been prepared synthetically. Their X-ray patterns closely resemble the calcium aluminate monocarbonate pattern, except for high degrees of substitution in which case the principal lines only remain and are very much broadened.

The authors have ascertained that calcium and magnesium aluminate monocarbonate hydrates appear during the hydration of mixtures of aluminous cement and magnesium hydroxycarbonate. Their formation is effected from the hydrates usually precipitated during the set of aluminous cement: $CaO \cdot Al_2O_3 \cdot 10H_2O$ and $2CaO \cdot Al_2O_3 \cdot 8H_2O$. This formation is the result of a topochemical reaction, since no previous dissolution of the magnesium carbonate is observed. The reaction is easier using a carbonate with a large surface area.

The initial aim of this work was to state the particular conditions liable to promote the abundant crystallization of hydrated monocarboaluminate, both in the conditions of crystal synthesis and in pure pastes, mortars or concretes of aluminous cements. In fact, it is well known that, in usual conditions, this phase is very often present, but in limited amount, and that it is very difficult to increase its importance.

Further we were led to extend this research to the possibilities of isomorphic substitution between calcium and magnesium within the monocarboaluminate.

The existence of calcium and magnesium monocarboaluminate according to the formula $3CaO \cdot Al_2O_3 \cdot CaCO_3 \cdot 11H_2O$ was considered as likely by G. E. Bessey (1) as early as 1938. This body was further synthetically produced by R. Turriziani and G. Schippa (2) and its properties were studied by many authors using X-ray diagrams, differential and gravimetric thermal analysis crystal parameters, ...

The formation of hydrated calcium monocarboaluminate was observed during the air-carbonation of alumina and lime solutions (R. Turriziani and G. Schippa (2)—E. T. Carlson and H. A. Berman (3)) and of specimens of pure aluminous cement paste (G. Schippa (4)).

It was also observed during the hydration of anhydrous calcium aluminates and of portland or aluminous cement, in the presence of finely ground calcite: J. Farran (5)—T. Manabe, N. Kawada and M. Nishiyama (6)—Budnikov, Kolbasov and Panteleev (7).

These authors, as well as J. Farran (8) noted the coming out of an hydrate similar to the calcium monocarboaluminate by hydration of portland cement and of anhydrous calcium aluminates in the presence of dolomite or of magnesium carbonate.

In the presence of anhydrous carbonates such as $CaCO_3$ or $CaMg(CO_3)_2$, the formation of monocarboaluminates is a real fact, but this mineral appears only in small amounts and always accompanied by the other types of hydrated calcium aluminates: $CaO \cdot Al_2O_3 \cdot 10H_2O$–$2CaO \cdot Al_2O_3 \cdot 8H_2O$–$3CaO \cdot Al_2O_3 \cdot 6H_2O$—and $4CaO \cdot Al_2O_3 \cdot nH_2O$.

On the other hand, we observed that the reaction of anhydrous calcium aluminates or of their solutions, with hydromagnesite according to the formula $3MgCO_3 \cdot Mg(OH)_2 \cdot 3H_2O$ permitted the formation of very large amounts of monocarboaluminate, and even a complete reaction, the monocarboaluminate in such conditions becoming the only hydrated calcium aluminate present in the medium.

*Centre de Recherches de la Jonchère-Côte de la Jonchère, Ciments Lafarge, Paris, France.

Synthesis Conditions

We realized the production of hydrated monocarboaluminate by stirring a solution of lime and alumina, of molecular ratio $CaO/Al_2O_3 = 3$ in the presence of hydromagnesite. We selected this ratio because we hoped to obtain a monocarboaluminate by fixation of lime and alumina on the magnesium carbonate.

This solution (2.7 liters at 1130 mg/l of CaO and 690 mg/l of Al_2O_3) was obtained by adding 1.7 liter of a saturated lime solution to one liter of aluminous cement filtrate.

Stirring was carried out at room temperature, in 5-liter flasks, in the presence of increasing amounts of hydromagnesite, from 0.5 to 6 grams. In order to simplify, we shall denote by A_n the result of the stirring operation in the presence of n grams of hydromagnesite. $A_{1.5}$ corresponds to the amount of hydromagnesite just required for total combination with the lime and the alumina of the solution, resulting in an hydrated calcium and magnesium monocarboaluminate of assumed formula:

$$3CaO \cdot Al_2O_3 \cdot MgCO_3 \cdot xH_2O$$

After one week of stirring, the precipitate was filtered on sintered glass, dried by acetone washing followed by ether-washing, analysed and X-ray tested.

Simultaneously, we made a reference preparation of hydrated calcium monocarboaluminate, according to the method developed by R. Turriziani and G. Schippa (2). We shall denote by T. S. the result of this preparation.

Study of Resulting Products

X-ray Analysis

The study of obtained diffractograms indicates that for $A_{1.5}$ stirring, resulting spectra are that of pure hydrated calcium monocarboaluminate. The only impurity, unnoticeable by this method, appears by differential thermal analysis: a small amount of $Mg(OH)_2$ brought by the hydromagnesite.

For lower amounts of hydromagnesite, the monocarboaluminate is mixed with hydrated dicalcium aluminate, the A_0 stirring giving practically pure $2CaO \cdot Al_2O_3 \cdot 8H_2O$. $A_{0.5}$ stirring moreover indicates the presence of a body at 8.2 Å and 4.1 Å, corresponding to a solid solution of $3CaO \cdot Al_2O_3 \cdot Ca(OH)_2aq$ (or $4CaO \cdot Al_2O_3aq$) and of $3CaO \cdot Al_2O_3 \cdot CaCO_3aq$, according to W. Dosch and H. zur Strassen (9).

For higher hydromagnesite amounts, the monocarboaluminate is in the presence of $CaCO_3$, the proportion being the higher as the hydromagnesite at the onset is more important. However A_6 stirring, except for calcite lines, only gives highly broadened lines, corresponding to the strongest lines of the hydrated calcium monocarboaluminate.

Table 1 gives a summary of our results. Figures are proportional to the heights of the lines of the various bodies obtained, being understood that these heights are not rigorously proportional to concentrations, owing to preferring orientation. Nothing in the position of lines, or in their relative intensities, permits a discrimination between obtained calcium-magnesium products and purely calcium monocarboaluminate, the diagram of which was given by various authors.

Thermal Analysis

The dosing by ponderance thermal analysis of the various constituents was not possible because water, hydroxyl and CO_2 losses are not enough differentiated and take place continuously.

On the other hand, the differential thermal analysis, in an air atmosphere, enabled us to corroborate and complete X-ray tests, as shown in Table 2. According to the stirring type, one notes the presence of endothermic peaks characteristic of hydrated dicalcium aluminate, of hydrated magnesia $Mg(OH)_2$, of calcium carbonate and of hydrate monocarboaluminate. This latter presents the same endothermic peak at 200°C as the hydrated calcium monocarboaluminate and is

Table 1. *Synthesis of hydrated monocarboaluminates X-ray diffraction lines intensities*

	Monocarbo-aluminate	2 CaO Al_2O_3 8 H_2O	Compound	Calcite	Aragonite	$Mg(OH)_2$
	7.6 Å	10.8 Å	8.2 Å	3.035 Å	3.396 Å	2.365 Å
A_0		450				
$A_{0.5}$	110	370	115			
A_1	360	45				
$A_{1.5}$	450			ε		
A_2	360			35		
$A_{2.5}$	330			40	15	
A_3	400			60	55	
A_6	50 broadened			400		ε 30

mixed with $2CaO \cdot Al_2O_3 \cdot 8H_2O$ or $CaCO_3$ according to the amount of hydromagnesite at the onset.

The endothermic peak at 380°C, corresponding to the dehydration of $Mg(OH)_2$, is proportional to the weight of hydromagnesite used in the various stirring conditions. The magnesium hydroxide, present in the hydromagnesite at the onset did not react and is found unchanged in precipitates.

Chemical Analysis

The chemical analysis of precipitates, after acetone-ether washing, are reported in Table 3.

The knowledge of the phases present in these precipitates, determined by X-ray tests and by differential thermal analysis, permits the computation of the relative proportions of these phases and an approximate analysis of obtained hydrated monocarboaluminates, with the use of following assumptions:

—the molecular ratio CO_2/Al_2O_3 of these monocarboaluminates is 1.

—the basic portion $Mg(OH)_2$ of the hydromagnesite did not react, and is found unchanged in precipitates.

The results of these computations are presented in Table 4; they do not present any incompatibility with X-ray tests and differential thermal analysis. The various molecular ratios of monocarboaluminates are shown in Table 5. $(CaO + MgO)/Al_2O_3$ and MgO/Al_2O_3 are respectively about 4 and 11–12, except for $A_{0.5}$ stirring, for which we already indicated that X-rays showed the formation of an hydrate at 8.2 Å, for which we did not make allowance in our computations.

Conclusions

Our results permit us to say that a substitution is possible between MgO and CaO in the monocarboaluminate formula, and to assume, for all these products, a general formula

$$[Ca_{2-x}Mg_xAl(OH)_6]_2CO_3 \cdot 5\text{–}6H_2O$$

where x varies from 2 to 0, showing that this substitution can take place in any proportions.

Thus we have a continuous series of hydrated calcium and magnesium monocarboaluminates, one pole of which is the calcium monocarboaluminate (for which $x = 0$).

X-ray spectra of these hydrated calcium and magnesium monocarboaluminate are identical with that of hydrated calcium monocarboaluminate, at least up to 50% of substitution of MgO to CaO. For higher degrees of substitution, the product is not so well crystallized and shows only the highly broadened main lines of the monocarboaluminate.

The formation of calcite or aragonite, on stirring in the presence of more than 1.5 gram of hydroma-

*Substitution rate of CaO by MgO

gnesite, may be explained by the fact that the total molecular ratio CO_2/Al_2O_3 is higher than unity, which would corroborate the assumption used for the computations of formula. The excess of CO_2, precipitates as $CaCO_3$, less soluble than $MgCO_3$, and the corresponding lime is replaced by magnesia, in the lattice of the hydrated monocarboaluminate.

Other Conditions of Formation

In view of applications, various experimentations were carried out to check the possibility of an abundant formation of this phase in other conditions, and, in particular, in the conditions of "pastes" in the presence of limited water amounts.

Formation during the Hydration of Anhydrous Aluminates

These tests were carried out on aluminous cement pure pastes, mortars or concrete, with the addition of 10 and 20% of hydromagnesite, percentages corresponding either to the amount required to hydrate the $CaO \cdot Al_2O_3$ present in the cement as monocarboaluminate, either to an excess amount; i.e. in conditions similar to $A_{1.5}$ and A_3 stirring conditions of the above paragraph.

Results were studied by X-ray diffraction on pure paste, in the case of the 10% mixture, in order to study reaction kinetics. In the case of 20% additions, phenomena were similar, except for the additional coming out of calcium carbonate, according to the results obtained in the cases of synthesis.

Hydration in the Presence of Excess Water

The mixture aluminous cement*-hydromagnesite is stirred at room temperature in ten times its weight of water: ponderance ratio water/solid = 10. At predetermined times, a residue is obtained by filtration and tested by X-ray diffraction.

The Fig. 1 gives the peak intensities for the various bodies observed, in relation with time. After 4 hours of stirring, the hydrated monocalcium aluminate appears, increasing up to about 25 hours. At approximately 15 hours, an hydrate is formed, the main peak of which, at 9.4 Å, also reaches a maximum after about 25 hours, possibly the hydrated tricarboaluminate according to E. T. Carlson and H. A. Berman (3). These two hydrates gradually disappear and are replaced by the hydrated monocarboaluminate.

Note that we never observed magnesia in solution in obtained filtrates.

3. Compound: 9.5 Å
4. Hydrated monocarboaluminate: 7.6 Å

Normal Paste Hydration

The mixture of aluminous cement* and hydromagnesite is mixed with a water/solid ratio of 0.5. The resulting paste hydrates in the sample holder of an X-ray diffractometer. The sample-holder is enclosed in a sealed chamber, the temperature of which is controlled. Figs. 2, 3 and 4 present the variation with time of the peak intensities of the various hydrates obtained at 20°C, 50°C and 70°C.

At 20°C, after a latency time of 20 hours or so, the anhydrous monocalcium aluminate hydrates, giving an hydrated monocalcium aluminate and a body with a broadened main line corresponding to a reticular distance of 8–8.5 Å. According to P. Seligmann and N. R. Greening (11) and to W. Dosch and H. zur Strassen (9), this line may correspond either to the hydrated hydroxyaluminate $4CaO \cdot Al_2O_3 \cdot 13H_2O$ or $3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot 12H_2O$, either to a solid solution between the hydrated hydroxyaluminate and the hydrated monocarboaluminate $3CaO \cdot Al_2O_3 \cdot xCa(OH)_2 \cdot (1 - x)CaCO_3 \cdot yH_2O$. In our experience, the hydrated monocarboaluminate appears only after about 40 hours.

At 50°C, hydration reactions are much more rapid. The hydrated dicalcium aluminate appears after some

4. Hydrated monocarboaluminate: 7.6 Å
5. Gibbsite: 4.34 Å
6. $3CaO \cdot Al_2O_3 \cdot 6H_2O$: 5.14 Å

hour, then rapidly increases. Lastly some gibbsite, then some hydrated cubic aluminate are formed after about one hour and half.

Whatever the hydration temperature of the aluminous cement* hydromagnesite mixture may be, hydrated calcium and magnesium monocarboaluminate is obtained. But this hydrate is not the first produced: it appears, according to the hydration temperature, after monocalcium, dicalcium or tetracalcium—more or less carbonated—hydrated aluminates, and to their detriment. Thus, we thought interesting to study the conditions of production of the monocarboaluminate from synthetic hydrated aluminates, in the presence of hydromagnesite.

Formation from Hydrated Calcium Aluminates

We mixed synthetic hydrated calcium aluminates $CaO \cdot Al_2O_3 \cdot 10H_2O$–$2CaO \cdot Al_2O_3 \cdot 8H_2O$–$3CaO \cdot Al_2O_3 \cdot 6H_2O$ and $4CaO \cdot Al_2O_3 \cdot 12H_2O$ with hydromagnesite and with the required water in order to get a fluid and well-homogenized paste. The proportions of hydromagnesite were computed in order to realize following theoretical reactions

$$3(CaO \cdot Al_2O_3 \cdot 10H_2O) + MgCO_3 = 3CaO \cdot Al_2O_3 \cdot MgCO_3 \cdot xH_2O + 2(Al_2O_3 \cdot 3H_2O)$$

*Trade mark "Ciment Fondu"

i.e. about 10% of hydromagnesite

$$\tfrac{3}{2}(2CaO \cdot Al_2O_3 \cdot 8H_2O) + MgCO_3 = 3CaO \cdot Al_2O_3 \cdot MgCO_3 \cdot xH_2O + \tfrac{1}{2}(Al_2O_3 \cdot 3H_2O)$$

i.e. about 17% of hydromagnesite

$$3CaO \cdot Al_2O_3 \cdot 6H_2O + MgCO_3 = 3CaO \cdot Al_2O_3 \cdot MgCO_3 \cdot xH_2O$$

i.e. about 23% of hydromagnesite

$$4CaO \cdot Al_2O_3 \cdot 12H_2O + MgCO_3 = 3CaO \cdot Al_2O_3 \cdot MgCO_3 \cdot xH_2O + CaO \cdot H_2O$$

i.e. about 17% of hydromagnesite.

These pastes, stored at room temperature in sealed bottles, were tested by X-ray diffraction after various times, after washing and drying with acetone-ether.

Figs. 5 to 8 show the variations of peak intensities with time. The identification of hydrates was made

according to the data of W. Dosch (10).

In every case, calcite is rapidly formed. The advent of the spectrum of the calcium and magnesium monocarboaluminate coincides with the decrease of the amount of calcite. In the presence of lime, which is dissolved, the magnesium is completely or partially transformed into less soluble calcium carbonate, then the calcium and magnesium monocarboaluminate seems to be formed, at least partially, from the calcite precipitated in this way.

Hydrated Monocalcium Aluminate

Its incongruent solubility promotes the precipitation of hydrated alumina. The hydrated monocarboaluminate appears only after more than 48 hours. After 50 days, $CaO \cdot Al_2O_3 \cdot 10H_2O$ has completely disappeared, but calcite still remains.

Hydrated Dicalcium Aluminate

The hydrated monocarboaluminate appears only between 24 and 48 hours. But there is intermediary formation of $4CaO \cdot Al_2O_3 \cdot 12H_2O$ and of a solid solution between $4CaO \cdot Al_2O_3 \cdot 12H_2O$ and the hydrated monocarboaluminate. After 50 days, $2CaO \cdot Al_2O_3 \cdot 8H_2O$ and $CaCO_3$ have disappeared, togeher with $4CaO \cdot Al_2O_3 \cdot 12H_2O$.

Hydrated Tricalcium Aluminate

The monocarboaluminate forms after only 5 hours. After 14 days, the reaction seems completed, but some cubic remains in the presence of the monocarboaluminate.

Hydrated Tetracalcium Aluminate

The advent of the monocarboaluminate is also very rapid. But reactions are more complex, owing to the more or less transient formation of $4CaO \cdot Al_2O_3 \cdot 19H_2O$, $4CaO \cdot Al_2O_3 \cdot 13H_3O$ and a solid solution between $4CaO \cdot Al_2O_3 \cdot xH_2O$ and the hydrated monocarboaluminate. The hydrated lime begins to crystallise after less than 7 days.

Note that, in our experimental conditions, the hydrated cubic aluminate, well-known for its stability, is, among hydrated calcium aluminates, the one most rapidly transformed into monocarboaluminate. The following assumption can be made.

The solubility of $3CaO \cdot Al_2O_3 \cdot 6H_2O$ is congruent. The molecular ratio CaO/Al_2O_3 of the solution is then favourable to the rapid formation of a complex aluminate, according to the formula $3CaO \cdot Al_2O_3 \cdot MgCO_3 \cdot 11H_2O$. The same is true of the solution in contact with $4CaO \cdot Al_2O_3 \cdot xH_2O$, the molecular ratio CaO/Al_2O_3 is still higher, the excess lime precipitating as hydrated lime. On the other hand, the solubility of $CaO \cdot Al_2O_3 \cdot 10H_2O$ is incongruent. The hydrated alumina slowly precipitates and the molecular ratio CaO/Al_2O_3 of the solution gradually increases and reaches a value of 3 which favours the precipitation of the hydrated monocarboaluminate. The case of $2CaO \cdot Al_2O_3 \cdot 8H_2O$ appears more complex, but the intermediary formation of an hydrated tetracalcium aluminate shows that the molecular ratio CaO/Al_2O_3 of the solution is high and permits the precipitation of the monocarboaluminate.

Conclusions

Experiences already described show that the hydrated monocarboaluminate in fact corresponds to a series of formula:

$$[Ca_{2-x}Mg_x \cdot Al(OH)_6]_2CO_3 \cdot 5\text{–}6H_2O$$

where the substitution of magnesium to calcium can take place in any proportions; the calcium monocarboaluminate, the best known at present, is only the calcium pole of this series. The magnesium pole $[Mg \cdot 2Al(OH)_6]_2CO_3 \cdot xH_2O$ was practically reached in our A_6 conditions of stirring.

These hydrates were not isolated, but their analysis can be deduced from chemical analysis, X-ray diffraction spectra and differential thermal analysis.

This series is remarkable for the steadiness of positions and intensity ratios of X-ray diffraction lines: even in the extreme magnesian case, there is no noticeable change of the position of strongly weakened lines.

In the presence of hydromagnesite, the formation of these monocarboaluminates may be very abundant, and may even lead to the crystallization of this only phase as hydrate.

The hydrated calcium and magnesium monocarboaluminate seems to form directly from CaO and Al_2O_3 solutions, but the study of other production conditions indicated that, in the presence of small amounts of water, its cristallization took place after the formation of conventional hydrated aluminates.

In particular, this is the case for the hydration of aluminous cement in the presence of hydromagnesite; the calcium and magnesium monocarboaluminate is formed after preliminary precipitation of hydrated

mono-, bi- or tetracalcium aluminates.

In the presence of hydromagnesite, the formation of monocarboaluminate is very easy, even from aluminates known as stables; the reaction is the simplest and the most rapid with the hydrated cubic aluminate. With hydrated mono- and dicalcium aluminates, it is preceded by the formation of other hydrates (gibbsite and tetracalcium aluminate), which seems to corroborate the possibility of direct precipitation from solutions with a molecular ratio $CaO/Al_2O_3 = 3$, and would in particular explain the rapidity of the reaction with the cubic aluminate, for which the congruent solubility permits to directly reach this value of the molecular ratio in the solution.

Supplementary Paper II-19 X-ray Investigations of Some Complex Calcium Aluminate Hydrates and Related Compounds

Hans J. Kuzel*

Synopsis

Single crystals of several calcium aluminate hydrates of the type $3CaO \cdot Al_2O_3 \cdot CaX \cdot nH_2O$ and $3CaO \cdot Al_2O_3 \cdot CaY_2 \cdot nH_2O$ with $Y = Cl^-$, Br^-, J^-, NO_3^-, BrO_3^- and $X = SO_4^{2-}$, CrO_4^{2-} were prepared by hydrothermal methods. Rotation, Weissenberg and precession photographs showed that the structures are usually completely ordered containing only one polytypic modification. The true unit cells have monoclinic, trigonal or rhombohedral symmetry. Ordered structures containing one, two, three or six layers have been observed. Space groups and unit cells of the compounds are given. Results of powder and single crystal investigations of $3CaO \cdot Ga_2O_3 \cdot CaBr_2 \cdot 10H_2O$, $3CaO \cdot Cr_2O_3 \cdot CaCl_2 \cdot 10H_2O$, $3CaO \cdot Cr_2O_3 \cdot CaSO_4 \cdot 12H_2O$, $3CaO \cdot Fe_2O_3 \cdot CaCl_2 \cdot 10H_2O$ and $3CaO \cdot Fe_2O_3 \cdot CaSO_4 \cdot 12H_2O$ are presented. A structure proposed by F. G. Buttler, L. S. Dent Glasser and H. F. W. Taylor (12) was confirmed by the determination of z-coordinates of the atoms in some compounds of this type.

Introduction

The composition of the complex calcium aluminate hydrates with layer structures may be represented by the general formula $3CaO \cdot Al_2O_3 \cdot CaY_2 \cdot nH_2O$ and $3CaO \cdot Al_2O_3 \cdot CaX \cdot nH_2O$ where Y is an univalent and X a divalent anion. At relative humidities of 35–45 percent the water content is $n = 10$–$12H_2O$. Many synthetic complex salts of this type were prepared and described by W. Lerch, F. W. Ashton and R. H. Bogue (1), J. Foret (2), W. Mylius (3), W. Feitknecht and M. Gerber (4), W. Feitknecht and H. Buser (5) and many other authors. Early work in this field was reviewed by F. E. Jones (6) and more recent contributions are mentioned by H. F. W. Taylor (7), R. Turriziani (8) and F. E. Jones (9).

The exact crystal structures of the complex calcium aluminate hydrates are not known. Since all compounds of this type crystallize in hexagonal or pseudohexagonal plates with perfect (0001) cleavage, E. Brandenberger (10) concluded that they have layer structures. C. E. Tilley, H. D. Megaw and M. H. Hey (11) proposed a crystal structure for hydrocalumite, a natural mineral which resembles the synthetic compound $3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot 12H_2O$ in morphology and composition. The structure contained $Ca(OH)_2$ layers in which one Ca^{2+} out of three was replaced by H_2O alternating with layers of Al^{3+} ions, the remaining H_2O molecules and OH^- groups. This structure gave good agreement between observed and calculated 001 intensities.

A somewhat different crystal structure was suggested by F. G. Buttler, L. S. Dent Glasser and H. F. W. Taylor (12) based on packing considerations and single crystal X-ray examination of hydrocalumite and synthetic $3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot 12H_2O$. The structure of these authors contains layers of the composition $[Ca_2Al(OH)_6]^+$ in which the octahedral sites are occupied by $2Ca^{2+}$ and one Al^{3+} in ordered positions. The seventh OH^- ion is placed between the layers where it is associated with the remaining water.

The OH group outside the octahedral layer may be completely replaced by other anions. The number of water molecules between the layers depends on relative humidity. F. G. Buttler, L. S. Dent Glasser and H. F. W. Taylor reported that even thin crystals of synthetic $3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot 12H_2O$ contained two or more polytypes and perhaps stacking faults "so that the true structure only repeats after a large number of layers".

Of nearly all complex calcium aluminate hydrates with layer lattice only the pseudocells are known. The lattice constant a_0 appears to be about 5.7 Å. The thickness of the pseudocell depends on the size of the anions X and Y and the number of water molecules between the octahedral layers. More detailed data on the unit cells and space groups of the

*Institut für Kristallographie der Universität Frankfurt, Frankfurt, West Germany.

compounds $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$, $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$ and $3CaO \cdot Al_2O_3 \cdot 1/2CaSO_4 \cdot 1/2CaCl_2 \cdot 12H_2O$ based on single crystal X-ray investigations were reported by H.-J. Kuzel (13, 14). The structures of these complex salts were completely ordered. The true cells contained 2, 3 and 6 layers.

Other compounds are derived from these hydrated calcium aluminates by substitution of the larger cations Ga^{3+}, Cr^{3+} and Fe^{3+} for Al^{3+}. Several calcium ferrite hydrates of the type $3CaO \cdot Fe_2O_3 \cdot Ca(X, Y_2) \cdot nH_2O$ are already known. Preparations of the compounds $3CaO \cdot Fe_2O_3 \cdot Ca(OH)_2aq$, $3CaO \cdot Fe_2O_3 \cdot CaSO_4 \cdot 12H_2O$, $3CaO \cdot Fe_2O_3 \cdot CaCl_2 \cdot 10H_2O$ and $3CaO \cdot Fe_2O_3 \cdot Ca(NO_3)_2 \cdot 10H_2O$ were reported by G. Malquori and V. Cirilli (15). These authors summarized evidence for the close analogy between hydrated calcium ferrites and aluminates containing the same anion. The replacement of Al^{3+} by Fe^{3+} seems to be nearly isomorphous in that the essential features of the layer structures are not affected.

In the present work the unit cells, space groups and crystal structures of several compounds of the type $3CaO \cdot R_2O_3 \cdot Ca(X, Y_2) \cdot nH_2O$ have been investigated using X-ray single crystal and powder methods.

Experimental Procedure

Methods of Preparation

The determination of unit cells and space groups of compounds with large lattice constants is usually possible only with the aid of single crystal methods.

Since many complex calcium aluminate hydrates of the layer lattice type are stable at temperatures above 100°C under saturated steam hydrothermal methods have been used in preparing single crystals suitable for X-ray work. Crystals up to 0.1–0.2 mm across were made by heating calculated amounts of CaO and $Al(OH)_3$ (bayerite) with calcium salt solutions in simple Morey bombs at temperatures between 100°C and 200°C for several weeks.

Larger crystals could be often made by treating synthetic $3CaO \cdot Al_2O_3 \cdot 6H_2O$ with calcium salt solutions at 150°C. Hexagonal plates of $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$ and $3CaO \cdot Al_2O_3 \cdot CaCrO_4 \cdot 12H_2O$ up to 1 cm across were obtained by this method. Details of the experimental procedure were given in preceeding papers (13, 14).

Bulk preparations of all compounds were made by the usual method mixing solutions of calcium salts and lime water with a metastable calcium aluminate solution. The crystals from each method were hexagonal flakes with perfect (0001) cleavage. Faces of rhombohedrons were observed on crystals of $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$, $3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$ and $3CaO \cdot Al_2O_3 \cdot Ca(NO_3)_2 \cdot 10H_2O$.

Except α–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ and α–$3CaO \cdot Ga_2O_3 \cdot CaCl_2 \cdot 10H_2O$ all compounds were uniaxial negative.

No single crystals of compounds $3CaO \cdot R_2O_3 \cdot CaY_2 \cdot nH_2O$ and $3CaO \cdot R_2O_3 \cdot CaX \cdot nH_2O$ where $R = Cr^{3+}$ and Fe^{3+} could be produced. Powders were made by mixing freshly precipitated Cr^{3+}-and Fe^{3+}-hydroxides with solutions of the desired calcium salt and lime water. The mixtures were shaken for several weeks at temperatures below 100°C. All products were filtered in a glove box under CO_2-free conditions and dried over saturated $CaCl_2$ at about 37 percent relative humidity.

The water contents of the various compounds were determined by heating the powder in a vacuum thermobalance and recording the loss of molecular water. At heating rates of 4°C/h the dehydration curves showed definite steps corresponding to the loss of the molecular water between the octahedral layers. At about 37 percent relative humidity the composition of the layers may be given by the general formulas $Ca_2Al(OH)_6 \cdot Y \cdot 2H_2O$ and $Ca_2Al(OH)_6 \cdot 1/2X \cdot 3H_2O$.

X-ray Investigations

In case single crystals were available lattice constants and space groups were determined using rotation, Weissenberg and precession cameras with filtered copper and iron radiation. The water contents of complex salts which contain tetrahedral anions are very sensitive towards alterations to relative humidity. These compounds were exposed to X-rays under controlled atmospheric conditions.

Powder diffraction patterns were taken with a Philips Norelco diffractometer using Si (Schuchardt 99.999%, $a_0 = 5.4308$ Å) as an internal standard. The powder patterns were indexed by aid of single crystal data. The lattice constants were refined by least squares methods.

Results

Unit Cells and Space Groups of Compounds $3CaO \cdot Al_2O_3 \cdot Ca(X, Y_2) \cdot nH_2O$

The results of X-ray examinations of some calcium aluminate hydrates containing other anions are listed in Table 1.

Crystals made under hydrothermal conditions were usually completely ordered if dried with caution and handled carefully. Compounds prepared by precipitation from metastable calcium aluminate solutions often showed considerable disorder.

On heating the monoclinic low temperature form α–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ changes to the rhombohedral β-phase, the transformation taking place readily and reversibly at 28 ± 2°C. The unit cell of α–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ contains two identical layers of the composition $Ca_4Al_2(OH)_{12} \cdot 2Cl \cdot 4H_2O$. The β-phase was investigated with the help of a little furnace attached to a precession camera. The observed reflections of β–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ agree with the space groups R3c and R$\bar{3}$c. Fig. 1 illustrates the relations between the unit cells of $Ca(OH)_2$, α–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ and β–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ in the ab plane. The structure of the β-phase is based on a 6R polytypic modification as well as that of $3CaO \cdot Al_2O_3 \cdot CaBr_2 \cdot 10H_2O$.

The unit cells of $3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$, $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$ and $3CaO \cdot Al_2O_3 \cdot CaCrO_4 \cdot 12H_2O$ contain three layers in regular stacking sequences. Other polytypic modifications were not observed. Large crystals of the compounds with tetrahedral anions are considerably disordered when the freshly prepared specimens were dried quickly at 37 percent relative humidity, probably due to the loss of a part of the molecular water between the octahedral layers. The precession photographs showed diffuse streaks along the reciprocal lattice rows parallel c.

The only known complex calcium aluminate hydrate with a one-layer-structure appears to be $3CaO \cdot Al_2O_3 \cdot Ca(NO_3)_2 \cdot 10H_2O$. For the compounds $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 16H_2O$ and $3CaO \cdot Al_2O_3 \cdot Ca(BrO_3)_2 \cdot 10H_2O$ only powder diffraction data were available. The condition for hexagonal indexing of a rhombohedral lattice $-h + k + l = 3n$ ($n = 0, 1, 2, \ldots$) was clearly satisfied in both cases. Reflections h0hl with $h \neq 3n$ occur only with $l \neq 3n$, reflections hh$\bar{2}$hl were observed only for $l = 3n$. The space groups would therefore probably be R3, R$\bar{3}$, R32, R3m and R$\bar{3}$m. Which one of these is the correct space group cannot be decided from powder data and a further subdivision is impossible without knowledge of the Laue symmetries.

Single crystals of another compound similar to $3CaO \cdot Al_2O_3 \cdot 1/2CaSO_4 \cdot 1/2CaCl_2 \cdot 12H_2O$ with the composition $3CaO \cdot Al_2O_3 \cdot 1/2Ca(NO_3)_2 \cdot 1/2CaCl_2 \cdot 10H_2O$ were prepared with hydrothermal methods. The unit cell contains 6 double layers $Ca_4Al_2(OH)_{12} \cdot NO_3 \cdot Cl \cdot 4H_2O$. The Cl^- ions as well as NO_3^- probably occupy positions in alternating layers parallel (0001). Even the layers of these long period compounds were

completely ordered. Both compounds contained traces of other unknown polytypic modifications.

A c-axis rotation photograph of $3CaO \cdot Al_2O_3 \cdot 1/2CaSO_4 \cdot 1/2CaCl_2 \cdot 12H_2O$ is shown in Fig. 2.

Numerous experiments showed that intermediate compounds of this type should be expected in systems of complex calcium aluminate hydrates which contain anions of considerably different sizes.

Several other complex salts of this type with the anions S, NO_2, WO_4, and MoO_4 were prepared but not yet investigated.

Unit Cells and Space Groups of Compounds $3CaO \cdot R_2O_3Ca(X, Y_2) \cdot nH_2O$

Several complex hydrates $3CaO \cdot R_2O_3 \cdot Ca(X, Y_2) \cdot nH_2O$ with R = Fe^{3+}, Cr^{3+} and Ga^{3+} were prepared and investigated with X-ray methods. The results are listed in Table 2. The X-ray powder diagrams showed that the compounds containing Cr^{3+} and Fe^{3+} have ordered three-layer-structures independant of the method of preparation. The crystal structures are closely related to those of the complex aluminate hydrates.

The lattice constants a_0 increase with increasing radius of the cation R^{3+}. The basal spacings decrease in the same direction. This evidence agrees with the structural model proposed by F. G. Buttler, L. S. Dent Glasser and H. F. W. Taylor (12) the cations R^{3+} occupying octahedral sites. Increasing the radius of the cation R^{3+} causes probably higher OH–OH distances within the octahedral layer in directions perpendicular to c, the anions and water molecules between the layers being able to glide into the space between the OH-ions. The compound $3CaO \cdot Ga_2O_3 \cdot CaCl_2 \cdot 10H_2O$ seems to be closely related to the corresponding aluminate showing the same polymorphic transition at about 30°C.

Crystal Structures

The now available data from X-ray investigations on complex calcium aluminate hydrates of the type $3CaO \cdot R_2O_3 \cdot Ca(X, Y_2) \cdot nH_2O$ support the view of F. G. Buttler, L. S. Dent Glasser and H. F. W. Taylor (12) of the crystal structures of these compounds. To clear the question whether their structural model is correct or the one proposed by C. E. Tilley, H. D. Megaw and M. H. Hey (11) the z-coordinates of the atoms in some compounds which contain simple anions between the octahedral layers were determined from the intensities of 001 reflections.

The intensities of about 20 001 reflections of α–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$, $3CaO \cdot Al_2O_3 \cdot CaBr_2 \cdot 10H_2O$, $3CaO \cdot Ga_2O_3 \cdot CaBr_2 \cdot 10H_2O$ and $3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$ were measured with the aid of a single crystal counter diffractometer using MoK_α-radiation. The rhombohedral crystals were mounted along the a-axis, the monoclinic α–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ along b. From the intensity data relative structure factors were computed.

Since there existed a set of isomorphous crystals, the light and heavy atoms of which should be in the same positions, the replaceable atom method was applicable to determine the phases of high intensity reflections. A preliminary Fourier synthesis of $3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$ calculated with 13 structure

Table 3. *Z-coordinates of the atoms of some complex calcium aluminate hydrates referred to the pseudocells*

$3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$			$3CaO \cdot Al_2O_3 \cdot CaBr_2 \cdot 10H_2O$		
Atom	z(c′)	B	Atom	z(c′)	B
Al	0		Al	0	
2Ca	0.0647 ± 5	1.3	2Ca	0.077 ± 1	1.2
6OH	0.1127 ± 5		6OH	0.112 ± 1	
$2H_2O$	0.339 ± 2		$2H_2O$	0.369 ± 3	
J	1/2	2.1	Br	1/2	1.4
$3CaO \cdot Ga_2O_3 \cdot CaBr_2 \cdot 10H_2O$			α-$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$		
Ga	0		Al	0	
2Ca	0.0679 ± 5	1.4	2Ca	0.080 ± 1	0.7
6OH	0.1227 ± 1		6OH	0.126 ± 1	
$2H_2O$	0.379 ± 2	2.5	$2H_2O$	0.386 ± 3	2.1
Br	1/2		Cl	1/2	

factors indicated the z-coordinates (referred to the pseudocell with $c' = 8.857$ Å) to be about $z_{Al} = 0$, $z_{OH} = 0.11$, $z_{H_2O} = 0.35$, $z_J = 1/2$, the Ca^{2+} ions being displaced by about 0.5 Å out of their ideal position at $z = 0$. When these data and separate isotropic temperature factors for the octahedral layer and the layer containing the anion and the water molecules were refined by least squares methods on the basis of 22 001-intensities, the R-factor dropped to 3.2 percent.

With the data obtained for $3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$ the z-coordinates of the other compounds were refined.

The results listed in Table 3 are compatible with the centrosymmetric space groups $R\bar{3}$ for $3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$ and $3CaO \cdot Ga_2O_3 \cdot CaBr_2 \cdot 10H_2O$, $R\bar{3}c$ for $3CaO \cdot Al_2O_3 \cdot CaBr_2 \cdot 10H_2O$ and C2/c for α–$3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$. Particularly the refinement of the z-parameters of the compound $3CaO \cdot Ga_2O_3 \cdot CaBr_2 \cdot 10H_2O$, the light cation Al^{3+} being replaced by the heavy Ga^{3+}, shows that the structural model proposed by F. G. Buttler, L. S. Dent Glasser and H. F. W. Taylor is correct.

Thus, in the case of the rhombohedral compounds, the x- and y-coordinates of all atoms, with the exception of the OH^- ions of the octahedral layers, are special coordinates. The octahedral layer contains both Ca^{2+} and the cation R^{3+} in ordered positions. These results are confirmed by the X-ray work of R. Allmann (personal communication) on the compound $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$. The resulting positive charge of the octahedral layers is balanced by the anion situated in $z = 1/2$ of the pseudocell. The constitution of these compounds at about 37 percent relative humidity may be given by the formulas

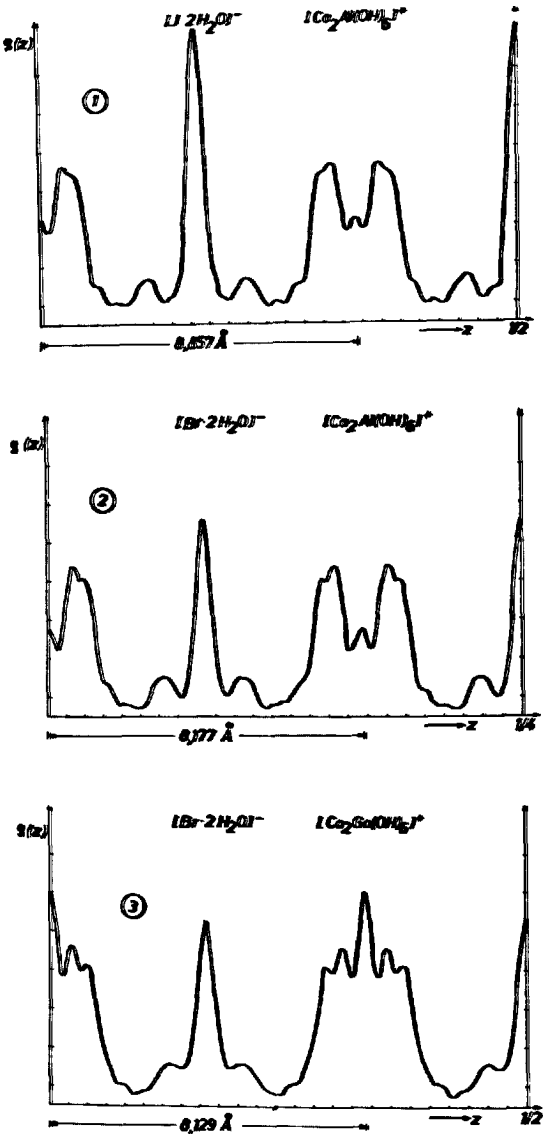

Fig. 3. *One dimensional Fourier projections $p(z)$ of* $3CaO \cdot Al_2O_3 \cdot CaJ_2 \cdot 10H_2O$ (1), $3CaO \cdot Al_2O_3 \cdot CaBr_2 \cdot 10H_2O$ (2) and $3CaO \cdot Ga_2O_3 \cdot CaBr_2 \cdot 10H_2O$ (3)

$$[Ca_2R(OH)_6]^+[Y \cdot 2H_2O]^-$$

and

$$[Ca_2Al(OH)_6]^+[1/2X \cdot 3H_2O]^-$$

In the case of the anions Cl^-, Br^- and J^- situated between the octahedral layers, there is not enough space left for the remaining water molecules at $z = 1/2$. These are, therefore, shifted off the position $z = 1/2$ along the c-axis. This is clearly indicated by the Fourier projections $p(z)$ shown in Fig. 3.

Supplementary Paper II-27 Proton Magnetic Resonance Studies of C_3AH_6

Ryôiti Kiriyama, Hideko Kiriyama and Masanori Takagawa*

Synopsis

The proton magnetic resonance studies on crystal powders of synthetic $Ca_3Al(OH)_{12}$, abbreviated as C_3AH_6 in cement chemistry, were carried out over the temperature range between −186° and 110°C. The experimental values obtained for the second moment are 22.7 ± 0.3 and 19.6 ± 0.5 gauss^2 at liquid nitrogen and room temperatures, respectively. The samller value of the second moment found at room temperature is due to the increased amplitudes of the proton motions. The lattice constant is 12.536 Å at −170° and 12.566 Å at 24°C. Many structural models are tested by calculating the second moments for them and comparing the results with the experimental value. Thus, the positions of protons are located in a restricted region within the lattice of C_3AH_6: the representative parameters are given as $x_H = 0.093$, $y_H = 0.074$, and $z_H = 0.681$. This most probable sites of hydrogen atoms in the $Al(OH)_6$ group are not found on the production of the Al–O lines. There is no distinct tendency to form a H_4-cluster inside the oxygen tetrahedron which corresponds to the SiO_4 tetrahedron in the isomorphous silicate, grossular $Ca_3Al_2(SiO_4)_3$.

Introduction

Among many calcium aluminate hydrates, the isotropic structure of C_3AH_6, the abbreviation of the garnet type hydroxide $Ca_3Al_2(OH)_{12}$, presents a striking contrast to predominant layer structures of many others. The knowledge of chemical constitution of the hydroxyl groups in these compounds should be important to discuss the mechanism of hydration or dehydration process in cement chemistry. The determination of the hydrogen positions in the crystal lattice by X-ray diffraction technique is very difficult owing to the low scattering power of hydrogen atoms. The broad line proton magnetic resonance (PMR) is useful for the locating of the hydrogen positions and consequently it has been recommended as a supplementaty method for structure analysis. For this purpose, the knowledge about the atomic positions other than hydrogen's is required, which has been obtained by precise X-ray structure analysis. However, PMR gives an accurate information about the mutual interaction among the nearest protons as compared with the result obtained by any method of diffraction crystallography.

There has been another structural interest remaining in C_3AH_6. That is the possibility of a wide sense isomorphism between $Ca_3Al_2(SiO_4)_3$ and $Ca_3Al_2(OH)_{12}$ which implies the substitution of Si^{4+} by $4H^+$ for the charge balance requirement. The question whether a H_4-cluster is formed inside the oxygen tetrahedron or not is one of the important problems of the current crystal chemistry, and is a good problem for study by PMR.

Materials

Synthesis

C_3AH_6 was synthesized by adding aluminium powders slowly into a saturated aqueous solution of $Ca(OH)_2$ in the atmosphere free from carbon dioxide under a moderately warm condition. All reagents used were of extra-pure grade. The white precipitate was filtered quickly to avoid carbonate formation in air, and then was dried at 150°C. The samples were put into a glass tube and sealed off in vacuum. This glass sample tube was fitted in the PMR probe.

*The Institute of Scientific and Industrial Research, Osaka University, Osaka, Japan.

Identification

Chemical Analysis

Quantitative analyses of CaO and Al_2O_3 by ordinary wet gravimetric methods and the weight loss by ignition were as follows:

	obs.	calc.
CaO	45.27%	44.48%
Al_2O_3	27.45	26.95
H_2O	27.29	28.57
	100.01	100.00

The weight loss by ignition should be attributed to the water content for the chemical formula, $3CaO \cdot Al_2O_3 \cdot 6H_2O$. Thus the analysis agreed closely with the value calculated from the chemical formula. The slightly less value of the water content of the synthetic sample than that of the calculated one means that the dried powder contains no detectable water adsorbed.

X-ray Diffractometry.

All the diffraction patterns of the C_3AH_6 powder obtained by a X-ray diffractometer using filtered Cu K radiations were well indexed as the cubic, garnet type lattice and the line profiles were sharp. No diffraction lines other than those of the garnet type lattice were observed. Therefore, the synthetic C_3AH_6 was identified with pure, well-crystallized powder.

The lattice constants at 24°C and also at −170°C were determined by an inner-standard method using silicon powder.

a_o	12.566 Å	at 24°C
a_o	12.536 Å	at −170°C

The mean linear expansion coefficient between −170° and 24°C was calculated from these data: $\alpha = 1.25 \times 10^{-5}$ degree^{-1}.

Partial dehydration occurred between 270° and 350°C and amorphous diffraction patterns were observed in this temperature range. Above 370°C, the crystalline phase of $12CaO \cdot 7Al_2O_3$ appeared. The ignition product of C_3AH_6 at 900°C was well crystal lized $12CaO \cdot 7Al_2O_3$ powder.

Infra-red Absorption

In the O-H stretching vibration region a sharp absorption peak at 3600 cm^{-1} and a rather broad band with a shoulder at about 3500 cm^{-1} were observed, indicating the hydroxyl group to be free from any hydrogen bond. No peak was found in the neighbourhood of 1600 cm^{-1}, the H-O-H bending region. The lack of the absorption at 1600 cm^{-1} suggests that the sample contains no detectable adsorbed water.

Experimental Procedure

A PKW type broad line nuclear magnetic resonance spectrometer was used throughout the PMR measurements. The first derivative of the absorption line was recorded by keeping r.f. frequencies at 12 and 20 Mc/sec and sweeping the magnetic field. The amplitude of the magnetic field modulation was set less than 1/12 of the line width. Because the precise measurement of the second moment was required, the value of time varying applied field was continuously calibrated by a field tracking nuclear resonance gaussmeter. In our experiments on C_3AH_6, more than fifteen such curves were obtained at 25°C and −190°C. The experiments at low temperatures were performed to minimize line narrowing by thermal motion of the protons. Also it was found that spectra of better S/N ratios were obtained at liquid nitrogen temperatures.

The experimental value of the second moment was corrected for the modulation broadening according to the Andrew's formula (1).

$$\Delta H_2^2(\text{exp}) = \Delta H_2^2(\text{obs}) - \tfrac{1}{4}H_m^2 \qquad (1)$$

where H_m is the modulation amplitude in gauss.

The samples of about 3 g of C_3AH_6 powders sealed in a glass tube of 40 mm length and of 20 mm diameter were used in the PMR measurement.

Some of the experimental curves obtained at 12.000 Mc/sec are reproduced in Fig. 1.

The absorption was a broad, bell-shaped curve without resolved structure. The narrow component observed at room temperatures is due to the free water molecules, possibly included at the time of sealing off the glass sample tube. In the temperature range measured, the absorption lines showed only a slight motional narrowing. The line widths, taken as the separation in gauss of the maximum and minimum of the derivatives, were 15.1 and 14.1 gauss at −186°C and 25°C, respectively. A mean value of the second moment obtained from twenty low-temperature curves and that obtained from fifteen room-temperature curves were as follows:

ΔH_2^2(exp) at −186°C	22.7 ± 0.3 gauss^2
at 25°C	19.6 ± 0.5 〃

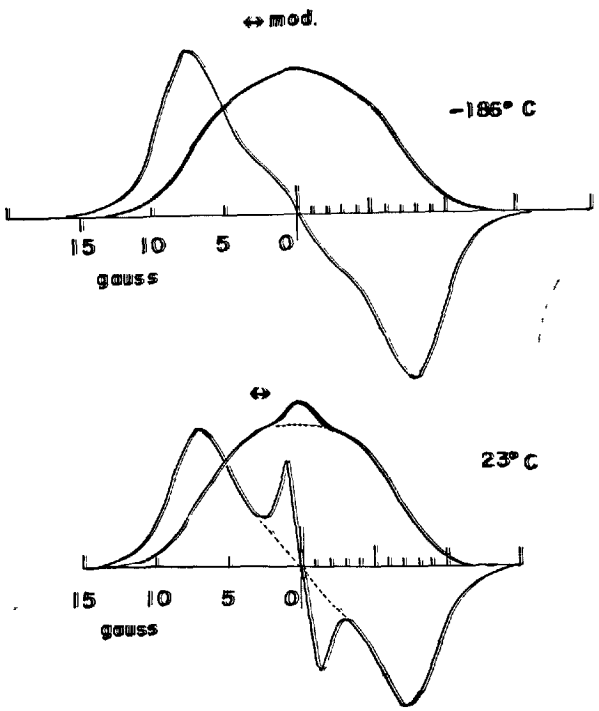

Fig. 1. *PMR absorption curves and those derivatives for C_3AH_6 powder.*

These values of the second moment of PMR are the main results obtained experimentally for the determination of the hydrogen positions.

Result

The crystal structure of C_3AH_6 was refined by Weiss (2) using X-ray diffraction. The space group is Ia3d and the lattice constant at a room temperature is 12.573 Å. The positions of heavy atoms are as follows:

16	Al	in	(a)	(0, 0, 0)
24	Ca	in	(c)	$(\frac{1}{8}, 0, \frac{1}{4})$
96	O	in	(h)	(x_0, y_0, z_0)

where x_0 is 0.030, y_0 is 0.052 and z_0 is 0.640.

From the symmetrical consideration, the hydrogen atoms must take the equivalent positions of 96(h), that is, the positional parameters are x_H, y_H and z_H. From the PMR experiment for C_3AH_6 powder, only one value of the second moment is available, so that the three structural parameters of the hydrogen positions in the crystal lattice can not be determined independently. However, some electrostatic and chemical considerations have often bring a useful and reasonable prediction of the arrangement of hydrogen atoms. Thus the possible structure would be considerably restricted.

In order to obtain the structural information from the PMR spectra, the theoretical second moment must be calculated by the method of Van Vleck (3) for various model structures.

Firstly, it is assumed that the hydrogen atom, or the proton in PMR phenomena, lies on the Al–O–H straight line and locates with an O-H distance changed between 0.96 and 1.12 Å.

In the case of C_3AH_6 the magnetic nuclei occupy structurally equivalent sites, so the second moment is expressed by the simple form

$$\Delta H_2^2(\text{calc}) = 358.1\sum_k r_{jk}^{-6} + 126.0\sum_m r_{jm}^{-6} \qquad (2)$$

where the first term is due to the magnetic dipole interaction between the protons and the second term is the interaction between the proton and aluminium nucleus. Because the second moment depends upon inverse sixth power of the inter-nuclear distance, the summation $\sum r_{jk}^{-6}$ in equation (2) converges rapidly as r_{jk} becomes large. Therefore, in calculating theoretical second moment for comparison with the experimental one, the terms in $\sum r^{-6}$ were obtained explicitly only for the neighbouring magnetic nuclei, hydrogen and aluminium, within a radius of 6 Å. The residual contributions by more distant nuclei were approximated by integration assuming the magnetic

moments of nuclei to be distributed uniformly. In this calculation, the cell dimension of 12.536 Å for −170°C was used and the coordinate parameter for oxygen was assumed to be the same as for room temperatures.

As shown in Fig. 2, the O–H distance fitted to the experimental second moment of 22.7 gauss² is given as 1.10 Å. This bond distance, however, seems to conflict with the result of the infrared absorption. On the other hand, O–O distance in the oxygen tetrahedron in C_3AH_6 lattice are 3.06 Å and 3.22 Å. It is, therefore, expected that the OH group in C_3AH_6 is free from any hydrogen bonding and the O–H distance of 0.98 Å is the most reasonable one. Moreover, in the above model, the nearest H–H separation is calculated to be 1.74 Å. This value is much shorter than the extreme value of 1.9 Å found in brucite, $Mg(OH)_2$, or an ordinary interhydrogen van der Waals separation of 2.0 ~ 2.4 Å. From such considerations, the model of the linear Al–O–H arrangement must be abandoned, and the hydrogen atom should be located deviating from the Al–O straight line having an apparent oxygen bond angle less than 180°.

Secondly, the location of the hydrogen nucleus was searched out by trial and error on assumptions: (i) the O–H distance is 0.98 Å and (ii) the hydrogen atom keeps the neighbouring calcium ions at a distance. If the O–H distance is fixed, unknown positional parameters should be diminished from three to two. Instead of three parameters, x_H, y_H and z_H, two new parameters α_H and β_H were taken. Angle α_H is defined as the azimuthal angle of the vector joined the origin of the unit cell to one selected hydrogen site $H_{68}(\frac{1}{2} + z_H, \bar{x}_H, y_H)$, which is measured from the X-axis in the XY-plane, and β_H is the polar angle of this vector. In the same manner, the oxygen parameters of $\alpha_O = -12°$ and $\beta_O = 20°$ were calculated for $O_{68}(\frac{1}{2} + z_O, \bar{x}_O, y_O)$ using the oxygen parameters found by Weiss. (2)

The value of β_H was fixed to some selected values of 20°, 18°, 16° and 14° and for each of β_H the parameter α_H was varied from −12° to −36° at 1° or 2° intervals. Fig. 3 shows the dependence of ΔH_2^2(calc) upon the parameters α_H and β_H. By comparing these results with the experiment, it was found that a locus for the points A, B and C in the Fig. 3 was the acceptable region for the actual location of the proton. The interatomic distances for each model are tabulated in Table 1.

Table 1. *Interatomic distances* (Å) *in* C_3AH_6

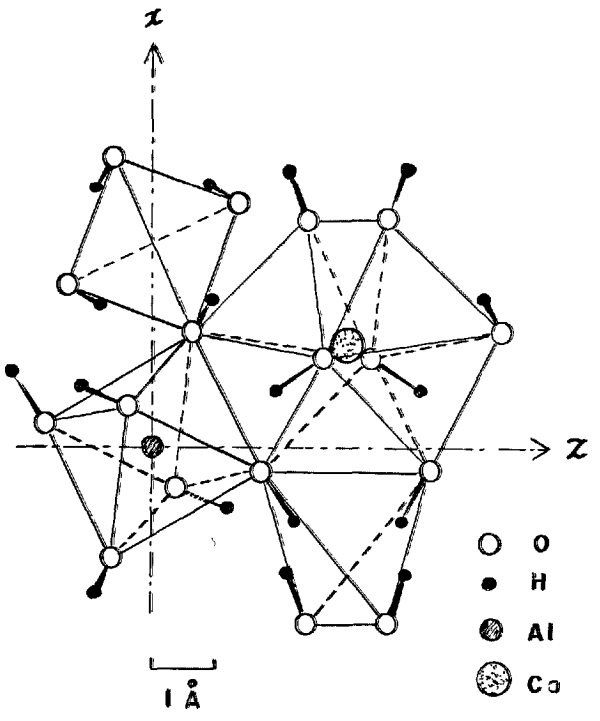

Fig. 4. *Projection of the crystal structure of* C_3AH_6 *on (010). Only the octahedron* $Al(OH)_6$ *at (000) and the neighbouring atoms around* H_{68} *are included.*

It seems that the location A of the hydrogen position is more preferable than the others in view of electrostatic energy. The atomic coordinates for the selected point A can be obtained from α_H, β_H and the assumed O–H distance of 0.98 Å:

$$x_H = 0.093,\ y_H = 0.074,\ z_H = 0.681.$$

The projection for the model A on (010) is shown in Fig. 4 with respect to H_{68} (hydrogen atom at $\frac{1}{2} + z_H, \bar{x}_H, y_H$) and its neighbours. It is noted that the hydrogen atoms occur outside of the oxygen tetrahedron (apart from the face less than about 0.2 Å) and consequently any discrete H_4-cluster is not formed. Thus, the H-H distances are 1.96 and 2.56 Å in the same $(OH)_4$ tetrahedron, while the shortest distance between adjacent tetrahedrons is 2.02 Å. In table 1 some results obtained by Cohen-Addad, Ducros, and Bertaut (6) are also included in comparison with ours.

Discussions

One of us, H. K., (4) reported a preliminary determination of the hydrogen position in C_3AH_6 by PMR experiments. In this earlier study the second moments measured were 17.6 gauss^2 at 105°C and 18.5 gauss^2 at −170°C. Cohen-Addad et al. (5) investigated independently the structure of C_3AH_6 by PMR and neutron diffraction and reported that the location of hydrogen position by neutron diffraction was confirmed by PMR. However, their measurement of the second moment was made at a room temperature only and effects of motional line narrowing were neglected. Their value of the second moment of 28 ± 3 gauss^2 was far larger than the value of 18 gauss^2 obtained by us. Such a disagreement led us to make a more precise measurement of the second moment at liquid nitrogen temperatures.

Recently, Cohen-Addad, Ducros and Bertaut (6) have refined the hydrogen coordinates by neutron diffraction at 4°K: $x_H = 0.101$, $y_H = 0.049$ and $z_H = 0.662$. From these values and the lattice constant found by us at −170°C, the theoretical second moment for the static model is estimated to be 26.9 gauss^2. This value is also appreciably larger than the experimental values of 22.7 gauss^2 at liquid nitrogen temperatures. The fact that the line narrowing between −186° and 25°C is relatively small indicates that the hydrogen atoms are bound to their structural sites by relatively strong forces. This, in turn, implies that thermal motion of the hydrogen is so reduced that a static model is applicable at the lower temperature. Therefore, in the present study the value of the experimental second moment at −186°C is used to locate the hydrogen positions in C_3AH_6.

One would not expect from the PMR data only to obtain accurate values of proton coordinates but an acceptable region for them. Nevertheless, the proton positions located by Cohen-Addad, Ducros and Bertaut (6) are not included in the allowed region. Thus, an ambiguity about the proton positions arises from the somewhat different results by different methods.

However, essential features of the hydroxyl radical in C_3AH_6 are similar as regards the fact that there is no discrete H_4-cluster inside the oxygen tetrahedron of the garnet lattice and also no definite hydroxyl bonds as like as proposed in $Al(OH)_3$. As may be seen in Table 1 and Fig. 4, some of the H-H distances between the neighbouring hydroxyl tetrahedra i.e. in the dodecahedron are close to twice the van der

Waals radius as occurred in the same tetrahedron.

Consequently, it is concluded from a viewpoint of crystal chemistry that the hydroxyl groups in C_3AH_6 are closely connected with the Al^{3+} ion forming a hydrogen-aluminate ion or hexahydroxoaluminate anion $[Al(OH)_6]^{3-}$, and these aluminate ions construct the ionic lattice of a garnet type with Ca^{2+} cations. If the anion $[Al(OH)_6]^{3-}$ is free, the Al-O-H bond should be linear owing to electrostatic interactions. Within the crystal lattice, however, the approach of the ions causes the O-H bond direction to have an appreciable deflection from the Al-O line. The position of the hydrogen deduced from the present PMR experiment will be favourable from these considerations. Namely, the hydrogen atom locates in 2.61 and 3.04 Å apart from two neighbouring Ca^{2+} ions and the separation of Al-H and the apparent bond angle of Al-O-H in its ion $[Al(OH)_6]^{3-}$ are 2.72 Å and 138°, respectively. The nearest inter-anionic hydrogen separation is 1.96 Å, suggesting a van der Waals contact with each other. In contrast to ours, the values found by neutron diffraction are 2.47 Å for Al-H distance and 117° for the bond angle of oxygen atom. The significance of their values may be difficult to assess at present.

Supplementary Paper II-29 Calcium Aluminate Hydrates and Related Basic Salt Solid Solutions

Melville H. Roberts*

Synopsis

The composition and identity of different tetracalcium aluminate hydrates are studied in order to elucidate conflicting views in the literature. It is shown that two polytypes of $4CaO \cdot Al_2O_3 \cdot 19H_2O$ normally occur in contact with the liquid phase, and three lower hydrates with $13H_2O$, $11H_2O$ and $7H_2O$ are produced by dehydration under different drying conditions. Previous claims for the existence of $4CaO \cdot Al_2O_3 \cdot 13H_2O$ and $4CaO \cdot Al_2O_3 \cdot 12H_2O$ giving X-ray patterns with respective longest basal spacings of 8.2 Å and 7.9 Å are therefore not supported by the present study, and it is suggested instead that the 7.9 Å basal spacing originates from $4CaO \cdot Al_2O_3 \cdot 13H_2O$ and the 8.2 Å spacing from a related quaternary carbonate hydrate of composition $4CaO \cdot Al_2O_3 \cdot \frac{1}{2}CO_2 \cdot 12H_2O$.

The possibilities for the replacement of hydroxyl ions in the crystal lattice of calcium aluminate hydrates by other anions to give solid-solution series are examined. The previously reported replacement of sulphate ion by hydroxyl ion in $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O$ is not confirmed, but solid solutions involving $4CaO \cdot Al_2O_3 \cdot 13H_2O$ are obtained under suitable conditions. Direct X-ray evidence is presented for the formation of a partial solid-solution series with compositions varying from $3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$ to $3CaO \cdot Al_2O_3 \cdot \frac{1}{2}Ca(OH)_2 \cdot \frac{1}{2}CaSO_4 \cdot 12H_2O$ and a longest basal spacing decreasing within this range from 8.96 Å to 8.77 Å. A quaternary carbonate hydrate of composition $4CaO \cdot Al_2O_3 \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ is readily formed by the action of CO_2 on $4CaO \cdot Al_2O_3 \cdot 19H_2O$ suspensions. The probable formation of a partial solid-solution series $4CaO \cdot Al_2O_3 \cdot \frac{1}{2}CO_2 \cdot 12H_2O$–$3CaO \cdot Al_2O_3 \cdot CaCO_3 \cdot 11H_2O$ giving basal spacings in the range 8.2–7.6 Å is also indicated. Preliminary results for chloride-containing solid solutions suggested the formation of similar partial solid-solution series with values for the basal spacings slightly higher than those for $4CaO \cdot Al_2O_3 \cdot 13H_2O$ and $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$. It is also indicated that related quinary solid solutions containing chloride and sulphate, or carbonate and sulphate may be formed in some circumstances.

Introduction

A comprehensive review of the then available knowledge of calcium aluminate hydrates in relation to the hydration of cement was made by Jones (1) at the Fourth International Symposium on the Chemistry of Cement. These hydrates have subsequently been the subject of many other studies (2–9), but some uncertainties still remain and conflicting views occur in the literature. In this connection, it may be noted that there are many difficulties in carrying out experimental work on calcium aluminate hydrates and related compounds, and two considerations are of particular importance. In the first place, many of the compounds exist in different hydration states, depending on the conditions of drying, and it is therefore necessary to maintain precise control over "H_2O" content and to prevent any interconversion between different hydrates, either by dehydration or rehydration, which may arise during subsequent treatment and examination of solid phases. Secondly, the hydrates are very susceptible to attack both by any carbonate in the reaction mixtures and by atmospheric CO_2, and all possible care must be taken to prevent such carbonation at every stage of preparation, treatment and examination, or if need be to make allowance for the effects of any carbonation that may occur unavoidably.

Carbonation is responsible for some erroneous interpretation in the past, as for example in the case of the so-called "C_3AH_{12}", which on the basis of many investigations (2, 10–13) is now accepted to be really the quaternary carbonate hydrate $C_3A \cdot CaCO_3 \cdot 11H_2O$. The opportunity for similar confusion and misinterpretation in identification still exists especially

*Building Research Station, Herts, United Kingdom.

with the tetracalcium aluminate hydrates, because of their close similarity to the related quaternary basic salt hydrates and particularly to the carbonate-containing hydrates which may occur with varying composition. The possibility of the formation of quaternary carbonate hydrates has therefore been given careful consideration in the first part of this study dealing with the tetracalcium aluminate hydrates. In addition, an attempt has been made to resolve the difficulties with regard to identification, and some experiments have been made to further investigate previous findings on these hydrates with the aim of elucidating the existing controversy on the composition and identity of different tetracalcium aluminate hydrates.

The existence of quaternary basic salt hydrates of the hexagonal-plate type, such as calcium monosulphoaluminate, monocarboaluminate, and monochloroaluminate, is well established (5). In view of the close structural relationship that evidently exists between these quaternary hydrates and C_4Aaq, there is therefore the possibility of the formation of "solid solutions" of varying degree of complexity involving the replacement of hydroxyl ions in the crystal lattice of calcium aluminate hydrates by any or all of such anions as sulphate, carbonate and chloride. The existence of these solid solutions has indeed been generally accepted, but little direct X-ray evidence of their formation appears to be available. The purpose of the remaining part of the present investigation is to examine the possibilities for the formation of such complex solid-solution series, particularly taking into account the more recent findings on calcium aluminate hydrates. An attempt has also been made to obtain data on the composition ranges and X-ray properties of the solid solutions, and some preliminary, though rather incomplete, results are given for basic salt solid solutions containing sulphate, carbonate or chloride.

Experimental

Materials and Procedures

The procedures for the preparation, filtration, analysis, and examination of different phases were very similar to those described by Jones and Roberts (13). In all cases, precautions were taken against contamination arising from carbonation by avoiding as much as possible any contact with atmospheric CO_2 at every stage of the preparation and subsequent treatment and examination, but attack by atmospheric CO_2 was not always completely prevented though the effects were probably minimised.

The basic ingredients of the reaction mixtures were a supersaturated monocalcium aluminate solution and freshly-ignited CaO, the former being prepared by treating a calcium aluminate cement ("Secar 250") with CO_2-free water and the latter by igniting "Analar" $CaCO_3$ at 1000°C. Quaternary compositions were obtained by adding to the calcium aluminate hydrate suspension either weighed quantities of the calcium salt ($CaCO_3$, $CaSO_4 \cdot 2H_2O$, or $CaCl_2 \cdot 2H_2O$), or, where appropriate, known volumes of the salt solution; all the salts were "Analar" chemicals. In the case of the quaternary carbonate compositions, incomplete reaction of the added $CaCO_3$ often occurred, and it was found to be preferable to introduce the carbonate by means of a method based on an adaptation of the barium hydroxide vacuum method for the determination of carbonate as described by Jones (14). This procedure involved the decomposition of a weighed amount of $CaCO_3$ with acid, and absorption at reduced pressure of the liberated CO_2 in a continuously stirred suspension of the calcium aluminate hydrate in mother-liquor contained in a conical filter flask.

The different reaction mixtures, contained in sealed "polythene" bottles, were shaken continuously at 25°C, for various periods, usually at least 7 days, before filtration either on a sintered-glass or a sintered stainless steel funnel in the absence of atmospheric CO_2. The solid phases obtained in the earlier stages of the investigation were dried to constant weight at room temperature and reduced pressure in a vacuum desiccator containing either a saturated salt solution to give the required relative humidity (usually 81% R. H.) or another drying agent, but since this procedure almost invariably resulted in some slight carbonation a different drying technique was later used. A sintered-glass funnel assembly fitted with ground glass joints and taps was used; the solid collected on the funnel after filtration being first washed with acetone, followed by ether, and evacuated for several minutes to remove the ether. The funnel was then disconnected from the filter flask, and, after closing at the top and bottom with ground glass joints fitted with small taps, was placed in an air thermostat at 25°C and connected to a supply of nitrogen which had previously been conditioned to

the required relative humidity by passing it through a saturated salt solution, or other drying agent as appropriate. The stream of nitrogen was continuously passed through the sintered-glass disc and the solid, and the funnel and contents weighed at 24 hour intervals until constant weight (± 1 mg) was obtained.

X-ray Examination

X-ray powder photographs were taken of a thin-layer specimen of solid using CuK_α radiation in a Guinier-type focusing camera with a diameter of 115 mm. To avoid both carbonation and possible changes in state of hydration, the specimens were prepared in a glove-box containing CO_2-free air at an appropriate relative humidity, and in general were exposed to X-rays in a sealed envelope formed by sealing each side of the power layer with self-adhesive "polythene" tape. Furthermore, to establish the hydrates actually present in contact with the liquid phase the X-ray examination was always, first of all, made on solid phases immediately after filtration and while still moist with mother-liquor. Subsequently, the solid phases were usually dried in a desiccator before X-ray examination, but difficulties often then arose from changes in the water content of the solid during preparation and from inadvertent carbonation of samples. To overcome these difficulties, some X-ray examinations were also made using a humidity-controlled specimen cell, as described by Aruja (15), whereby nitrogen at various relative humidities was passed over the X-ray powder specimen and the formation of different hydrates during drying or rehydrating cycles could be rapidly surveyed by X-ray examination with minimum risk of contamination by atmospheric CO_2 and of changes in state of hydration. Complete X-ray powder data for many of the hydrates considered have been published elsewhere (13, 16).

Results and Discussion

Tetracalcium Aluminate Hydrates

Results of the present investigation relating to the different states of hydration of hydrated tetracalcium aluminate are summarised in Table 1, which also includes results for some closely related quaternary carbonate hydrates. In the following discussion, the difficulties with regard to identification of different tetracalcium aluminate hydrates are examined, and the data of Table 1 are used to interpret and explain results previously obtained by other investigators.

Table 1. *Characteristics of tetracalcium aluminate hydrates and some related quaternary carbonate hydrates*

C_4AH_{19}

In agreement with previous work by the present author (11, 13, 17), the tetracalcium aluminate hydrate in metastable equilibrium with mother-liquor at 25°C was found to be C_4AH_{19} (α_1 and α_2) with a longest basal spacing of 10.7 Å. This result has also been confirmed by many other investigators (3, 8, 9, 18–21), and on the basis of this work it is indicated that when hydrated tetracalcium aluminate is formed at temperatures in the range 1° to 50°C and at atmospheric pressure it is present as a $19H_2O$ hydrate in contact with the liquid phase. It has also been shown that this fully-hydrated C_4AH_{19} occurs in two polytypes, designated α_1 and α_2, which give X-ray patterns showing the same basal spacings and only differing slightly in the positions of non-basal reflections (13, 22).

Dehydration of C_4AH_{19} takes place very readily at room temperature at relative humidities below about 88%, and depending on the actual drying conditions, various lower hydrates not relevant to the aqueous system are formed. Consequently, in order to establish the presence of C_4AH_{19} in a hydrated product, it is generally advisable to undertake an X-ray examination of the moist solid in contact with mother-liquor with precautions to prevent loss of water from the specimen. This procedure may, however, result in some difficulty if C_2AH_8 is also present in the solid, because this hydrate gives basal spacings practically

identical to those of C_4AH_{19}. In this case, the often-used procedure of drying the moist solid phase in some way before X-ray examination may be helpful in distinguishing between the dicalcium and tetracalcium hydrates, but the utmost care most then be taken to prevent any carbonation both before and during the X-ray examination. If carbonation occurs, the X-ray examination of dried solids presents the opportunity of confusion of the X-ray patterns of quaternary carbonate hydrates with those of dehydrated C_4Aaq, as will be shown later. Furthermore, since these carbonate compounds may also be formed other than by carbonation of C_4Aaq, some uncertainty may then arise as to whether C_4AH_{19} was ever present in the original solid phase, as appears to be the case with some solid phases in many previous investigations (23–27).

C_4AH_{13}

As shown in Table 1, the present study has indicated the existence of a single C_4AH_{13} with a longest basal spacing of 7.9 Å. In contrast to this result, it was thought in earlier work by the present author (11, 13) that dehydration of C_4AH_{19} at 81% R.H. resulted in the formation of two polymorphs of C_4AH_{13}, designated α– and β–C_4AH_{13} and characterised in the X-ray patterns by longest basal spacings of 8.2 Å and 7.9 Å, respectively. However, Jones and Roberts (13) later suggested in an addendum to their paper that β–C_4AH_{13} was a true ternary hydrate, and that α–C_4AH_{13} contained carbonate in its structure. This conclusion was based on observations made on "C_4Aaq" preparations both with the deliberate introduction of CO_2 and with the rigid exclusion of atmospheric CO_2. Exposure of β–C_4AH_{13} to atmospheric CO_2 and treatment of suspensions of C_4AH_{19} in mother-liquor with $CaCO_3$, Na_2CO_3, or CO_2 resulted in the formation of "α–C_4AH_{13}" with a longest basal spacing of 8.2 Å. On the other hand, when X-ray examinations were made in a CO_2-free atmosphere using a humidity-controlled specimen cell (15), the passage of nitrogen at 81% R. H. over samples of α_1– and α_2–C_4AH_{19}, and C_4AH_{11} produced a single hydrate corresponding to β–C_4AH_{13} with a longest basal spacing of 7.9 Å. These observations have been confirmed by additional experiments on many other C_4Aaq preparations, and some typical results for a few preparations subjected to successive dehydration and rehydration cycles are given in Table 2. These results show that a basal spacing of 7.9 Å is obtained alone at relative humidities in the range 81 to 11%, provided that adequate precautions are taken

Table 2. *X-ray examination of* C_4Aaq *and* $C_4A\cdot\frac{1}{2}CO_2\cdot aq$ *during successive dehydration and rehydration cycles in X-ray specimen cell at room temperature.*

to exclude atmospheric CO_2. In some of the tests, particularly at the later stages of the cycling treatment, a basal spacing of 8.2 Å with a weak or very weak intensity was also present, but this spacing was observed with greater intensity in samples dried in desiccators or deliberately exposed to the atmosphere. This 8.2 Å spacing evidently arises by carbonation and the resulting formation of the so-called "α–C_4AH_{13}", or really $C_4A\cdot\frac{1}{2}CO_2\cdot12H_2O$ as established by other work involving deliberate carbonation (see later). With regard to the water content of the 7.9 Å hydrate, results from loss on ignition (1000°C) tests on several different C_4Aaq samples dried by N_2 at relative humidities in the range 81–33% at room temperature, or dried at 25% R. H. at 40°C, and only containing traces, if any, of the 8.2 Å hydrate, gave values in the range 41.2–42.5%, as compared with theoretical values of 41.8% H_2O for C_4AH_{13} and 39.9% H_2O for C_4AH_{12}. It is indicated, therefore, that the 7.9 Å hydrate (or "β–C_4AH_{13}") corresponds to a true ternary C_4AH_{13} hydrate, while the 8.2 Å hydrate (or "α–C_4AH_{13}") is actually a closely related quaternary carbonate hydrate.

In agreement with the above results Seligmann and Greening (3, 20) have also concluded that "α–C_4AH_{13}" was not a ternary phase, but really a "hemicarboaluminate" with a composition $C_3A\cdot\frac{1}{2}Ca(OH)_2\cdot\frac{1}{2}CaCO_3\cdot XH_2O$. However, in contrast with these views on "α– and β–C_4AH_{13}", Alègre (4) and Lavanant (7) have suggested instead that there existed a

C_4AH_{13} (8.2 Å) and a C_4AH_{12} (7.9 Å). This conclusion is not supported by the present study, particularly in that samples dried at room temperature over a range of relative humidities from 81% to about 22% showed a composition very near to C_4AH_{13} (7.9 Å) and this changed to C_4AH_{11} (7.4 Å) on further dehydration, together with the fact that the X-ray powder data given by Alègre and Lavanant for C_4AH_{13} (or "α–C_4AH_{13}") and C_4AH_{12} (or "β–C_4AH_{13}") are practically identical to those now obtained for $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$ and C_4AH_{13}, respectively.

It should also be noted that the question of contamination by atmospheric CO_2 was only considered by Alègre and Lavanant in so far as it might result in the formation of $C_3A\cdot CaCO_3\cdot aq$, since other quaternary carbonate hydrates were not recognised at that time. Although strict precautions were taken against contact with atmospheric CO_2, there is nevertheless still some doubt as to whether these precautions were completely successful in excluding CO_2 from the samples. This doubt arises from the use of techniques involving very small samples with consequent greater risks of carbonation effects, and in addition X-ray diffraction work on a Geiger-counter diffractometer which is vulnerable with regard to carbonation because the diffracting surface is only a very thin layer of the surface of the sample, particularly liable to be affected by any atmospheric CO_2 with magnified effects. It would appear to be very probable, therefore, that the results of these two previous studies were affected in some degree by carbonation and consequent formation of $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$ and $C_4A\cdot\frac{1}{2}CO_2\cdot 10H_2O$ (see Table 1) and indeed it is possible to interpret the results on this basis. For example, it could be suggested that the results obtained by Alègre for the alleged conversion of "C_4AH_{12}" (7.9 Å) into "C_4AH_{13}" (8.2 Å) at high relative humidity (Figs. 2 and 3 of original paper) are actually caused by carbonation during the course of X-ray examination with the resulting formation of $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$ (8.2 Å). Furthermore, this suggestion is then supported by the results at low relative humidity (Figs. 4 and 5, and Table 4 of original paper) which contrary to the opinion of Alègre do not appear to show conversion of "C_4AH_{13}" (8.2 Å) into "C_4AH_{12}" (7.9 Å), but rather that first of all $C_4A\cdot\frac{1}{2}CO_2\cdot 12H_2O$ (8.2 Å) dehydrates to the lower $10H_2O$ hydrate (7.7 Å), and at longer times the true C_4AH_{13} (7.9 Å) also dehydrates to C_4AH_{11} (7.4 Å). Alègre interpreted the final X-ray results at this low relative humidity (about 10% R. H.) as indicating the presence of C_4AH_{11} and C_4AH_7, but the formation of C_4AH_7 under this drying condition is extremely unlikely since the results given in Table 1 and 2 show that C_4AH_{11} is still stable at a lower relative humidity over anhydrous $CaCl_2$ or solid NaOH and that much more rigourous drying conditions are necessary to form C_4AH_7.

Similar alternative interpretations can also be suggested for the results on C_4Aaq obtained by Lavanant(7). In this investigation, it is noteworthy that the results for the immediate X-ray examination of compositions near to C_4AH_{13} at relative humidities of 80% and 50% do, in fact, indicate that a longest basal apacing of 7.9 Å is predominant. Lavanant preferred, however, to place greater reliance on results from samples "aged" in desiccators at these humidities, and it is not surprising that the longest basal spacing of 8.2 Å then predominated because it is very difficult, if not impossible, to prevent some carbonation of the samples under these conditions.

The question of the composition of "α– and β–C_4AH_{13}" together with the effect of carbonation on C_4Aaq have also recently been considered by Dosch and zur Strassen (8), and based on X-ray diffractometer studies it was concluded that the 7.9 Å basal spacing arose from a C_4AH_{12}, while the 8.2 Å spacing was derived both from a C_4AH_{13} and from a "quarter-carbonate" compound of composition $C_3A\cdot\frac{3}{4}CaO\cdot\frac{1}{4}CaCO_3\cdot 12H_2O$. Leaving aside the question of the composition of the quaternary carbonate hydrate, which is discussed again later, this work would appear to reconcile the two opposing points of view on "α– and β–C_4AH_{13}" which have already been considered above. However, the evidence presented by Dosch and zur Strassen for the existence of the two hydrates C_4AH_{13} (8.2 Å) and C_4AH_{12} (7.9 Å) is inconclusive and also inconsistent in some respects. In particular, very little data for the actual water content of preparations of the alleged "$13H_2O$" and "$12H_2O$" hydrates were given by these authors. A $12H_2O$ composition was said to be obtained after drying at 22% R. H. at 25°C, but the $13H_2O$ composition was only assumed on the basis of an incorrect interpretation of previous work. This single water content determination is not in agreement with the results for the water content of the 7.9 Å hydrate now obtained in the present investigation, which as shown above gave a composition nearer to C_4AH_{13} than to C_4AH_{12}.

Dosch and zur Strassen have also indicated that the "$12H_2O$" hydrate (7.9 Å) and the lower hydrates are converted into the "$13H_2O$" hydrate (8.2 Å) on storage at 81% R. H., but unfortunately detailed results for these transformations based on X-ray examination of pure C_4Aaq during dehydration and rehydration cycles were not given. The results of such an examina-

tion were only elaborated (Fig. 5 of original paper) in the case of a deliberately carbonated sample, consisting initially of a mixture of C_4AH_{19} (10.7 Å) and the related 8.2 Å carbonate hydrate, and consequently the position with regard to the possible existence of a C_4AH_{13} hydrate with a longest basal spacing of 8.2 Å was not clearly established. The authors interpreted these results as showing that C_4AH_{19} (10.7 Å) is dehydrated at 81% R. H. to a "$13H_2O$" hydrate with a longest basal spacing of 8.2 Å coincident with the 8.2 Å spacing of the quaternary carbonate hydrate, but against this interpretation no increase in intensity of the 8.2 Å spacing was shown in the diffractometer traces. It is, therefore, possible that difficulty may have occurred initially in resolving the 8.2 Å spacing of the carbonate hydrate from the 7.9 Å spacing which present results have indicated to be obtained from C_4AH_{13} under these conditions. Furthermore, these particular results given by Dosch and zur Strassen also appear to show the formation of a 7.9 Å spacing, together with a 8.2 Å spacing, when C_4AH_{11} (7.4 Å) and the dehydrated quaternary carbonate compound (7.7 Å) are rehydrated at 81% R. H., and this indication agrees with the present study but not with the conclusion of Dosch and zur Strassen that C_4AH_{13} with a longest basal spacing of 8.2 Å is formed at 81% R. H. It is also noteworthy that complete X-ray powder data for the quaternary carbonate hydrate and the alleged "C_4AH_{13}" with the same basal spacing of 8.2 Å were not given by Dosch and zur Strassen. Such data would appear to be necessary to confirm their separate existence, since some differences would be expected in other spacings in the X-ray patterns, but such differences have not so far been demonstrated. Finally, despite the elaborate precautions that were taken against atmospheric CO_2, it is likely, for reasons given above, that storage of solids in desiccators and X-ray examination by means of a diffractometer still offer the possibility of inadvertent carbonation having some effect on the results obtained by Dosch and zur Strassen.

C_4AH_{11}

Tables 1 and 2 show that the tetracalcium aluminate hydrate formed in samples dried over anhydrous $CaCl_2$ or solid NaOH is a $11H_2O$ hydrate with a longest basal spacing of 7.4 Å. This result is in agreement with similar previous results of many other investigators (3, 8, 11, 13, 28), though it has also been claimed by Alègre (4) and Lavanant (7) that C_4AH_{11} gave an X-ray pattern with characteristic spacings at 7.6 Å and 3.79 Å. However, pure C_4AH_{11} was not obtained in the latter two studies and, as already indicated above, some confusion and misinterpretation in identification of the mixture of hydrates appears to have arisen. Thus, it is likely that the spacings of 7.6 Å and 3.79 Å really originated from a dehydrated quaternary carbonate hydrate, while the other spacings of 7.4 Å and 3.70 Å were actually those of C_4AH_{11} and not C_4AH_7 as concluded by Alègre and Lavanant.

With regard to the range of drying conditions under which C_4AH_{11} is formed, some previous work (4, 7, 8) has indicated that this hydrate is obtained at 11% R. H. at 25°C (saturated LiCl solution), whereas the results in Tables 1 and 2 show the presence of C_4AH_{13} (7.9 Å) at this relative humidity. This minor point of difference may possibly be attributed to this drying condition giving a water vapour pressure near to the limiting value for the transition between the $13H_2O$ and $11H_2O$ hydrates, coupled with the fact that there may be some lack of precise control of the actual water vapour pressure obtained with saturated LiCl solution in different circumstances.

C_4AH_7

The results of the X-ray examination of C_4Aaq dried at room temperature over P_2O_5 were a little uncertain in that the preparations examined gave very poor X-ray patterns with a few weak and diffuse reflections. The water content obtained by loss on ignition (1000°C) tests on such samples was in the range $7–8H_2O$ indicating that only "hydroxyl" water is retained over P_2O_5, and it is possible that the almost complete removal of "inter-layer" water may have resulted in some deterioration of the crystallinity affecting the X-ray pattern. These patterns showed a weak basal spacing at about 5.5 Å, and this value is in approximate agreement with data for C_4AH_7 given by Feitknecht (29) and Buttler, Dent-Glasser, and Taylor (28).

In contrast to the above results, other investigators (4, 7, 8, 11) have claimed that C_4AH_7 gave an X-ray pattern with a longest basal spacing of about 7.4 Å. Such a spacing was obtained in earlier work by the present author (7), but this result was probably influenced by the effects of rehydration and/or carbonation under the conditions of examination used at that time. Alègre (4) and Lavanant (7) have also given a basal spacing of 7.4 Å for C_4AH_7, though as discussed above the X-ray patterns with sharp reflections which were attributed by these authors to C_4AH_7 actually correspond very closely to the X-ray pattern

of C_4AH_{11}. An X-ray pattern with sharp basal reflections, the longest being at 7.2 Å was obtained by Dosch and zur Strassen (8) when C_4Aaq was dried over P_2O_5 at 25°C. This finding is difficult to reconcile with present results, but two possible explanations may be suggested. In the first place, there is the possibility of rehydration of C_4AH_7 to C_4AH_{11}, which occurs very readily, causing some confusion in the X-ray patterns, and secondly inadvertent carbonation may have affected the results. Some support for the latter suggestion seems to be provided by the results now obtained for one quaternary carbonate preparation dried over P_2O_5, since as shown in Table 1 this preparation gave a reasonably sharp X-ray pattern with a longest basal spacing of about 7.3 Å very near to the value of 7.2 Å given by Dosch and zur Strassen for C_4AH_7.

Prossible Influence of Other Trace Impurities

The above discussion has clearly shown that control of water content of solid phases and prevention of carbonate contamination are two important factors in studies of hydrated calcium aluminates. Another possible complicating factor arises from the conclusion of Crowley (6) that trace impurities of foreign metal ions in the starting materials may have a pronounced influence on the phase relations in the system $CaO–Al_2O_3–H_2O$. Since stringent precautions as to the purity of the initial reactants were not taken in the present study, it appears to be necessary to examine the basis for this conclusion.

Crowley studied the phase relations at temperatures from 4° to about 300°C under high pressure, and reported that the phase diagram of the $CaO–Al_2O_3–H_2O$ system obtained from starting materials prepared from "reagent-grade" $CaCO_3$ was markedly different from that observed using an allegedly purer "luminescent-grade" $CaCO_3$. However, it is noteworthy that the phase diagram in the latter case (Fig. 1 of original paper) appears to agree reasonably well with other published work (13, 30–32) on the system $CaO–Al_2O_3–H_2O$, even though strict precautions as to the purity of the starting materials were not taken in these other investigations. Furthermore, when the initial reactants consisted of impure calcium aluminate cements or contained admixtures of different clays and various salts and bases the results were mainly in agreement with this diagram, suggesting that some factor other than the presence of trace impurities was operative in the case of different results obtained with "reagent-grade" $CaCO_3$.

The main differences in the diagram obtained using "reagent-grade" $CaCO_3$ (Fig. 5, of original paper) were that the compounds C_2AH_8 and CAH_{10} were not included, and instead a large field of stability, even up to about 240°C, for a "C_2AH_6" hydrate was obtained. This so-called "C_2AH_6" was not characterised clearly by Crowley, but it was implied that it was a dehydrated form of C_2AH_8, and presumably it was therefore identified in the X-ray powder patterns by a longest basal spacing in the region 8.7 Å to 8.8 Å on the basis of previous work (11, 13, 33). However, in these other investigations at atmospheric pressure, it was shown that the dehydrated from of C_2AH_8 was only obtained under fairly rigorous drying conditions and that rehydration to C_2AH_8 occurred very readily. In view of these results, together with the fact that Crowley also indicated the simultaneous presence of "C_2AH_6" and $Ca(OH)_2$ in some hydration products, it would appear that the true identity of the so-called "C_2AH_6" obtained by Crowley is far form clear. It may be conjectured that in some instances the preparation of the reaction mixtures was defective in that the initial reactants were contaminated with the nitrate ion involved in their preparation. If this were the case, the quaternary hydrate $C_3A \cdot Ca(NO_3)_2 \cdot aq$ would be formed, and since the X-ray pattern of this hydrate, as given by Van Aardt (34), shows a longest basal spacing of about 8.8 Å which is practically identical to that reported for the dehydrated form of C_2AH_8, it is possible that some confusion may have arisen.

In addition, the carbonate compounds "α–C_4AH_{13}" and $C_3A \cdot CaCO_3 \cdot 11H_2O$ were identified in many of the hydration products, and it is clear therefore that the effects of contamination by atmospheric CO_2 must also have played some part in the results reported by Crowley. The occurrence of such contamination is indeed to be expected when it is considered that little care was taken to exclude atmospheric CO_2 and that the techniques which were used involved the treatment of very small samples (20 mg of initial solid) and air-drying of the hydrated products before X-ray examination. The many inconsistencies in the detailed results reported, suggesting that some uncontrolled factor is operating, may therefore be attributed, at least partly, to the effects of variable carbonation of samples.

On the basis of the above remarks, it appears to the present author that Crowley's conclusion with regard to the marked influence of trace impurities of foreign metal ions in studies of hydrated calcium aluminates has not been substantiated, but rather that the effects of contamination by atmospheric CO_2 and lack of precise control of water content of solid phases are the principal factors to be guarded

against in such studies.

Quaternary Solid Solutions Containing Sulphate

Several possibilities exist for the replacement of OH^- in the crystal lattice of calcium aluminate hydrates by SO_4^{--}. The probable formation of five interconnected solid-solution series has been suggested by Kalousek (5, 35), but some of these can now be dismissed on the basis of more recent evidence. The supposed solid solution between C_3AH_{12} and $C_3A \cdot CaSO_4 \cdot 12H_2O$ can no longer be accepted, since it has been shown that the allged "C_3AH_{12}" is actually $C_3A \cdot CaCO_3 \cdot 11H_2O$ (2, 10–13). In addition, the suggested formation of the two solid-solution series $C_3A \cdot CaSO_4 \cdot 12H_2O$–$C_3A \cdot 3CaSO_4 \cdot 31H_2O$ and C_4AH_{13}–"$C_6A \cdot aq$" would appear to be ruled out by the different crystal lattice structures involved, and indeed the experimental evidence obtained by several investigators (36–38) has shown that the two aluminate sulphates do not form solid solutions.

The existence of the supposed solid solution between $C_3A \cdot 3CaSO_4 \cdot 31H_2O$ and "$C_6A \cdot aq$" is also rather doubtful, because no satisfactory evidence for the formation of "$C_6A \cdot aq$" has so far been obtained, despite many attempts by the writer and others (39, 40) to prepare this compound. Nevertheless, Midgley and Rosaman (40) still considered that limited replacement of SO_4^{--} by OH^- could occur in $C_3A \cdot 3CaSO_4 \cdot 31H_2O$, though the X-ray evidence obtained for this limited solid-solution formation was based solely on very slight apparent differences in the 100 reflection at about 9.7 Å, which is liable to appreciable error in measurement. In an attempt to obtain more conclusive evidence for this reported solid solution, some additional solid samples, prepared by the same methods as used by Midgley and Rosaman, were examined in the present study. It was found that the X-ray powder patterns of the various moist solids were practically identical to that shown by pure $C_3A \cdot 3CaSO_4 \cdot 31H_2O$, even in the case of the high angle reflections, and the alleged solid-solution formation was therefore not confirmed. Chemical analysis of the preparations gave values for the $CaSO_4/Al_2O_3$ molar ratio in the range 2.83–3.14, but difficulties occurred in the analytical determinations because of the presence of sugar, as may also well have been the case in the work of Midgley and Rosaman. It seems therefore that the evidence available at present for the replacement of SO_4^{--} by OH^- in $C_3A \cdot 3CaSO_4 \cdot 31H_2O$ is inconclusive, and further work is needed before its occurrence can be accepted.

The remaining possibility for solid-solution formation is that involving $C_4A \cdot aq$ and $C_3A \cdot CaSO_4 \cdot aq$, and several investigators (35–37) have indicated the existence of a solid-solution series between these two hydrates on the basis of variations in the refractive indices observed with dried solids of varying composition. However, in view of the difficulties arising in microscopical examination of finely divided solids, as well as possible changes produced during drying of the solids, this evidence cannot be regarded as completely satisfactory. Moreover, it has also been questioned (5, 38) whether such optical data provide evidence of the existence of a true solid solution, and it was suggested instead that the phenomenon might be caused by the formation of intergrowths of a particular kind. This situation arises from the investigation made by Turriziani and Schippa (38), in which it was observed that quaternary solids with $CaSO_4/Al_2O_3$ molar ratios of 0–1, dried over $CaCl_2$, gave X-ray patterns with reflections due to both "α–C_4AH_{13}" and $C_3A \cdot CaSO_4 \cdot 12H_2O$, whereas a single solid phase with varying refractive indices was obtained optically. The significance of these results is however not clear, since the formation of C_4AH_{11} (7.4 Å) and $C_3A \cdot CaSO_4 \cdot 10H_2O$ (8.2 Å) is to be expected on drying over $CaCl_2$ if $C_4A \cdot aq$ and $C_3A \cdot CaSO_4 \cdot aq$ were present, and complications due to changes produced by drying the moist solids, as well as by carbonation, may well have had some influence. Yet another possible complicating factor arises from the occurrence in the aqueous system of three different modifications of $C_3A \cdot CaSO_4 \cdot aq$, characterised in the X-ray powder patterns by respective longest basal spacings of 10.3 Å, 9.6 Å and 9.0 Å. While it is widely accepted that the 9.0 Å hydrate corresponds to $C_3A \cdot CaSO_4 \cdot 12H_2O$, the problem of the composition of the other two modifications has not yet been conclusively resolved, because their formation appears to depend both on the temperature and on the initial composition of the reaction mixture in relation to the final position in the quaternary CaO–Al_2O_3–$CaSO_4$–H_2O system. On the basis of some work by the present author, it has been indicated (41) that the 10.3 Å hydrate is a $15H_2O$ hydrate which is more stable at temperatures below 25°C, and that the 9.6 Å and 9.0 Å hydrates are polymorphs of a $12H_2O$ hydrate, the 9.6 Å hydrate being formed especially in solutions of low lime content. However, water contents of $16H_2O$ and $18H_2O$ for the 9.6 Å hydrate have also been reported (5, 42), and further work is needed to elucidate the problem of the composition and behaviour of the 9.6 Å and 10.3 Å hydrates.

In order to further investigate the possibility of the formation of a solid-solution series between $C_4A \cdot aq$ and $C_3A \cdot CaSO_4 \cdot aq$, some reaction mixtures in the $CaO–Al_2O_3–CaSO_4–H_2O$ were prepared, involving the treatment of a suspension of C_4AH_{19} in mother-liquor with increasing additions of $CaSO_4 \cdot 2H_2O$. The initial compositions of these mixtures were so arranged as to leave some $Ca(OH)_2$ in the final solid phases, so that the reflections due to $Ca(OH)_2$ in the X-ray powder patterns could be used as an internal standard to calibrate the measurements on other reflections. Furthermore, it was also found that in the presence of excess lime only one modification of $C_3A \cdot CaSO_4 \cdot 12H_2O$, the 9.0 Å hydrate, was formed, and complications due to the presence of the other two forms of this compound did not arise. X-ray powder photographs were taken of moist solid phases immediately after filtration, and the results from measurements on certain selected interplanar spacings from each of the various preparations are given in Figs. 1 and 2. The indexing of these particular reflections was based on the hexagonal pseudocell with $a = 5.76$ Å and $c = 26.79$ Å determined by Kuzel (43) for $C_3A \cdot CaSO_4 \cdot 12H_2O$, and the measurements for 006 were corrected against the $Ca(OH)_2$ reflection at 4.91 Å the 110 against the $Ca(OH)_2$ reflection at 3.110 Å, the 119 and 208 against the $Ca(OH)_2$ reflection at 1.927 Å, and the 300 against the $Ca(OH)_2$ reflection at 1.687 Å. Such internal calibration of the measurements was found to be necessary because small variations in the location of the specimen in the focusing camera caused the position of the reflections to change slightly from one photograph to the next.

The X-ray examination results (Figs. 1 and 2) showed that the 110 and 300 reflections remained practically constant for all solid phases, but the 006, 119 and 208 reflections only remained constant with the mixed solid phases giving $CaSO_4/Al_2O_3$ molar ratios of 0.09–0.50 and 1.0–1.25, and at intermediate values there was a gradual shift of these reflections. The same changes are apparent in Fig. 2, which gives mean values for $\frac{1}{3}c$ (corresponding to the longest basal spacing, 003) and mean values of a calculated from measurements on the particular reflections examined. These results indicated that solids of $CaSO_4/Al_2O_3$ molar ratio of 1 or higher consisted of mixtures of $C_3A \cdot 3CaSO_4 \cdot aq$ and a $C_3A \cdot CaSO_4 \cdot aq$ hydrate with $a = 5.75$ Å and $\frac{1}{3}c = 8.96$ Å, while a solid-solution series was formed with solids of $CaSO_4/Al_2O_3$ ratio varying from 1 to 0.50, the longest basal spacing decreasing gradually in this composition range from 8.96 Å to 8.77 Å but a remaining constant at 5.75 Å. Solids of $CaSO_4/Al_2O_3$ ratio below 0.50 consisted of mixtures of C_4AH_{19} and the limiting solid solution $C_4A \cdot \frac{1}{2}SO_3 \cdot aq$ with $a = 5.75$ Å and $\frac{1}{3}c = 8.77$ Å, the amount of C_4AH_{19} increasing with decreasing $CaSO_4/Al_2O_3$ ratio. In general agreement with these

results, Seligmann and Greening (20) have given brief indications of the formation of similar solid-solutions in solid phases obtained from the hydration of C_3A with $Ca(OH)_2$ and $CaSO_4 \cdot 2H_2O$, but the limiting solid solution composition was reported as $C_4A \cdot \frac{3}{5}SO_3 \cdot aq$.

A few tests were made in the X-ray specimen cell to examine the stability of the solid solutions under different drying conditions. The X-ray pattern of the solid solution was found to remain unchanged after drying with N_2 at 81% R. H., but with N_2 dried by solid NaOH the X-ray pattern deteriorated markedly and a weak and diffuse basal spacing was observed at about 8 Å, which may be compared with the value of 8.2 Å for $C_3A \cdot CaSO_4 \cdot 10H_2O$ under the same drying conditions. The original X-ray pattern with a spacing at about 8.8 Å returned on rehydration at 81% R. H.. Only a few water-content determinations were made on the solid-solution compositions. Three preparations with $CaSO_4/Al_2O_3$ molar ratios of 0.56, 0.39 and 0.55 gave water contents corresponding to $12.6H_2O$, $12.3H_2O$ and $12.1H_2O$ after drying at 81% R. H. at room temperature. It is, therefore, indicated that this solid solution is formed between $C_3A \cdot CaSO_4 \cdot 12H_2O$ and C_4AH_{13}, and the replacement of OH^- by SO_4^{--} evidently results in the loss of "interlayer" water from C_4AH_{19}.

Very little information is available on the effect of slight carbonation on $C_3A \cdot CaSO_4 \cdot aq$ and the quaternary sulphate solid solutions, and on the possible formation of a complex solid solution containing sulphate and carbonate. This problem was encountered by Seligmann and Greening (20), but it was not resolved and it was only possible to indicate in the X-ray patterns that the basal spacing of the sulphate-containing hydrates fell within the limits of 9.6 Å for one form of $C_3A \cdot CaSO_4 \cdot aq$ to 7.6 Å for $C_3A \cdot CaCO_3 \cdot 11H_2O$. It has also been shown (12) that in contact with solution the presence of carbonate can result in some circumstances in the formation of $C_3A \cdot CaCO_3 \cdot 11H_2O$ and $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ coexisting with $C_3A \cdot CaSO_4 \cdot 12H_2O$ and $C_3A \cdot 3CaSO_4 \cdot 31H_2O$. However, a weak basal spacing in the region 8.3–8.5 Å was frequently observed in the X-ray patterns of some of the above solid-solution compositions after drying in desiccators at 81% R. H., and this spacing may possibly arise from carbonation with the consequent formation of a quinary solid solution containing carbonate and sulphate.

Quaternary Solid Solutions Containing Carbonate

Similar considerations to those already discussed for quaternary sulphate solid solutions would seem to apply to the possibilities of solid-solution formation between calcium aluminate hydrates and the quaternary carbonate hydrates, and only the solid-solution series $C_4A \cdot aq–C_3A \cdot CaCO_3 \cdot aq$ was therefore studied. A series of reaction mixtures in the $CaO–Al_2O_3–CaCO_3–H_2O$ system were prepared by treating suspensions of C_4AH_{19} in mother-liquor, sometimes together with $Ca(OH)_2$ with increasing amounts of CO_2 and the compositions of the final solid phases are given in Table 3. These results showed that with small additions of CO_2 mixtures of C_4AH_{19} and a quaternary carbonate hydrate with a longest basal spacing of 8.2 Å were formed. This 8.2 Å hydrate increased in amount with increasing additions of CO_2 until at a CO_2/Al_2O_3 molar ratio near to 0.5 only this carbonate compound was obtained. With still larger additions of CO_2, $C_3A \cdot CaCO_3 \cdot 11H_2O$ was also formed and this monocarbonate increased in amount, while the 8.2 Å hydrate diminished, until the solid consisted mainly of $C_3A \cdot CaCO_3 \cdot 11H_2O$ at CO_2/Al_2O_3 ratios near to 1. At higher CO_2/Al_2O_3 ratios mixtures of $CaCO_3$ and $C_3A \cdot CaCO_3 \cdot 11H_2O$ were present.

Although the behaviour with CO_2 additions to C_4AH_{19} was similar in some respects to that already described for additions of $CaSO_4 \cdot 2H_2O$, an important difference was the formation of a mixture of the 8.2 Å carbonate-containing hydrate and $C_3A \cdot CaCO_3 \cdot 11H_2O$ at CO_2/Al_2O_3 ratios above 0.5. Furthermore, with all the preparations given in Table 3 it was not possible to detect any differences in the X-ray patterns

indicative of the formation of a solid-solution series. These results, therefore, appeared to suggest the formation of an unique quaternary carbonate hydrate of composition approximating to $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$, and giving an X-ray pattern identical to that previously reported (13, 16) for "α-$C_4A \cdot H_{13}$". However, other results obtained with reaction mixtures of different compositions indicated the existence of other C_4AH_{13}–$C_3A \cdot CaCO_3 \cdot 11H_2O$ solid-solution compositions. When $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ was treated with lime solutions of varying concentrations, the X-ray patterns of the moist solids were unchanged with final lime concentrations in solution down to about 0.6 g CaO/litre, but at final concentrations of 0.52 g CaO/litre, 0.49 g CaO/litre, 0.42 g CaO/litre and 0.28 g CaO/litre the moist solid phases gave X-ray patterns with basal spacings of 8.15 Å, 8.10 Å, 8.05 Å, and 7.8 Å, respectively. At the same time, the Al_2O_3 concentration of the solution increased with decreasing lime concentration and the CO_2/Al_2O_3 molar ratio of the solid solution phase also gradually increased. Similar changes in the X-ray patterns, with a decrease in the basal spacings, were also frequently observed when samples containing the quaternary carbonate solid-solution were dried in a desiccator at 81% R. H., or subjected to lengthy cycling treatment in the X-ray specimen cell, and thus were vulnerable to further attack by atmospheric CO_2. Longest basal spacings in the range 8.2–7.6 Å may, therefore, be obtained for a solid-solution series with compositions probably varying from $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ to $C_3A \cdot CaCO_3 \cdot 11H_2O$.

The value of 8.2 Å for the longest basal spacing obtained from the carbonate-containing solid solution appears to be anomalous in that it is higher than the corresponding values for C_4AH_{13} (7.9 Å) and $C_3A \cdot CaCO_3 \cdot 11H_2O$ (7.6 Å). This situation may possibly arise from variations in the amount of H_2O displaced by the introduction of CO_3^{--} since full replacement of $2OH^-$ in C_4AH_{13} by CO_3^{--} to give $C_3A \cdot CaCO_3 \cdot 11H_2O$ also results in the loss of $1H_2O$. Unlike $C_3A \cdot CaCO_3 \cdot 11H_2O$, all the solid-solution compositions behaved in a similar manner to C_4AH_{13} and lost water when dried over anhydrous $CaCl_2$, and then gave X-ray patterns with basal spacings at about 7.7 Å. The results obtained with a sample of $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ subjected to successive dehydration and rehydration cycles are included in Table 2, and it is shown that dehydration occurred more readily than with C_4AH_{13} since it began at 33% R. H. and the longest basal spacing of 7.7 Å was obtained alone at 1–11% R. H.. As shown in Table 1, samples of $C_4A \cdot \frac{1}{2}CO_2 \cdot$ aq dried over anhydrous $CaCl_2$ gave a water content approximating to $10H_2O$, and the X-ray pattern of this hydrate showed low-angle spacings of medium or strong intensity at 7.7 Å, 4.57 Å, 3.85 Å, 3.78 Å and 2.87 Å. Further loss of water occurred on drying over P_2O_5 and the basal spacing decreased to about 7.3 Å.

Similar results to those given in Table 3 have also been obtained by Dosch and zur Strassen (8) for reaction mixtures consisting of CaO, $CaCO_3$ and sodium aluminate solution, but the 8.2 Å quaternary carbonate hydrate was given a composition $C_4A \cdot \frac{1}{4}CO_2 \cdot 12H_2O$ and the 7.7 Å hydrate obtained by dehydration at 11% R. H. had a composition $C_4A \cdot \frac{1}{4}CO_2 \cdot 9H_2O$. These compositions differ appreciably from those obtained in the present study, and it can only be suggested that this discrepancy may possibly arise from the results obtained by Dosch and zur Strassen being affected by additional carbonation from atmospheric CO_2 during the X-ray diffractometer examination of the various solids.

Quaternary Solid Solutions Containing Chloride

A limited number of experiments were made to study the solid solutions which have been reported (5) to be formed between C_4A·aq and $C_3A \cdot CaCl_2 \cdot 10H_2O$. Table 4 gives the results of the X-ray examination of moist solid phases prepared by treating C_4AH_{19} suspensions with increasing additions of $CaCl_2$, together with the molar compositions, the latter being obtained by calculation and thus perhaps subject to some error. Solids of calculated $CaCl_2/Al_2O_3$ molar ratios from 0.96 to 0.88 gave X-ray patterns with low-angle spacings at 7.8 Å (strong), 4.87 Å

(very weak), 3.91 Å (medium), 3.80 Å (medium), 3.41 Å (weak) and 2.87 Å (strong), and these patterns appeared to be identical to that of a pure preparation of $C_3A \cdot CaCl_2 \cdot 10H_2O$ (analysed composition 2.99 $CaO \cdot 1Al_2O_3 \cdot 0.97CaCl_2 \cdot 10.4H_2O$) obtained by reaction of a mixed $CaCl_2$–$AlCl_3$ solution with NaOH solution. These patterns also corresponded to that of β–$C_3A \cdot CaCl_2 \cdot 10H_2O$ as given by Kuzel (44). A quaternary chloride compound was also obtained alone with solids of $CaCl_2/Al_2O_3$ ratio in the range 0.72–0.58, but visual comparison of the X-ray patterns now showed slight differences from one preparation to the next and the basal spacings had also increased somewhat as compared with those of $C_3A/CaCl_2 \cdot 10H_2O$. With solids of still lower $CaCl_2 \cdot Al_2O_3$ ratio in the range 0.40–0.13, mixtures of C_4AH_{19} and apparently the same quaternary chloride hydrate with a basal spacing of about 8.0 Å were formed. This behaviour with $CaCl_2$ additions to C_4AH_{19} resembles that already described for the formation of quaternary sulphate solid solutions, and it is therefore indicated that C_4AH_{13} and $C_3A \cdot CaCl_2 \cdot 10H_2O$ form a limited solid-solution series over a restricted range of compositions. Further work is, however, needed to establish the changes in the X-ray patterns more precisely, and to correlate these changes with varying $CaCl_2/Al_2O_3$ ratio in the solids.

No information seems to be available on the effect of slight carbonation on the quaternary chloride hydrates, and on the possible formation of quinary solid solution containing chloride and carbonate, but some evidence was obtained for such a solid solution containing chloride and sulphate. Treatment of $C_3A \cdot CaCl_2 \cdot 10H_2O$ (1.00 g) with 150 ml $CaSO_4$ solution (0.66 g $CaSO_4$/litre), both without added $Ca(OH)_2$ and in the presence of excess $Ca(OH)_2$, was found to result in the complete removal of sulphate from solution and in the displacement of chloride from the original solid. X-ray examination of the moist solid phases showed the presence in each case of a single compound giving a longest basal spacing of 8.4 Å. The solid obtained in the absence of excess $Ca(OH)_2$ gave a composition $3.09CaO \cdot 1Al_2O_3 \cdot 0.39CaCl_2 \cdot 0.49CaSO_4 \cdot 12.3H_2O$ after drying at 81% R. H., and it is therefore indicated to be a quinary solid solution. This composition is very near to that of the compound $C_3A \cdot \frac{1}{2}CaCl_2 \cdot \frac{1}{2}CaSO_4 \cdot 12H_2O$ with a basal spacing of 8.3 Å which was prepared under hydrothermal conditions by Kuzel (44), but it is possible that a range of compositions exist for these quinary hydrates containing chloride and sulphate.

Conclusions

The results obtained in the present investigation, together with a critical examination of previous studies, give a substantial clarification of the existing uncertainties with regard to the composition and identity of different tetracalcium aluminate hydrates. The available data lead to the conclusion that there are five modifications of this compound, and these are characterised in the X-ray powder patterns by longest basal spacings of 10.7 Å (α_1– and α_2–C_4AH_{19}), 7.9 Å (C_4AH_{13}), 7.4 Å (C_4AH_{11}) and approximately 5.5 Å (C_4AH_7).

It is widely accepted that C_4AH_{19} is the only hydrate present in contact with the liquid phase at temperatures in the range 1° to 50°C and at atmospheric pressure, but some controversy exists with regard to the lower hydrates produced by dehydrating C_4AH_{19} under different drying conditions. It is suggested that some confusion and misinterpretation in identification of the various hydrates examined in previous studies has arisen from lack of precise control of water content of solid phases and especially from the effects of contamination by atmospheric CO_2. In this connection, it may be noted that X-ray diffraction work carried on a Geiger-counter diffractometer is particularly likely to be subjected to the influence of these two factors, because a very thin layer of the sample is the diffracting surface and this is where the effects of carbonation, dehydration or rehydration are very liable to occur unless extensive precautions are taken. Even when extreme care is exercised by the use of specially designed sample holders with a surrounding controlled atmosphere, it may be virtually impossible to completely exclude atmospheric CO_2 from the samples, and some caution must therefore be exercised in the interpretation of X-ray diffractometer data obtained with calcium aluminate hydrates, and related basic salt hydrates.

Inadvertent carbonation by atmospheric CO_2, and the resulting unrecognised presence of closely related quaternary carbonate hydrates are probably mainly responsible for the conflicting views in the literature on the lower hydrates of $C_4A \cdot aq$, especially with regard to the composition of the hydrates heretofore called α– and β–C_4AH_{13}, giving longest basal spacings of 8.2 Å and 7.9 Å, respectively. On present evidence, it is considered that the existence of a

C_4AH_{13} with a basal spacing of 8.2 Å and a C_4AH_{12} with a basal spacing of 7.9 Å has not been conclusively established, and it is concluded instead that a single 13 H_2O hydrate (corresponding to "β–C_4AH_{13}") with a basal spacing of 7.9 Å exists, while "α–C_4AH_{13}" with a basal spacing of 8.2 Å is actually a related quaternary carbonate hydrate of composition $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$. The latter compound is dehydrated to a $10H_2O$ hydrate with a basal spacing of 7.7 Å and this spacing has occasionally in the past been incorrectly attributed to C_4AH_{11} which actually gives a basal spacing of 7.4 Å. In addition, provided that adequate precautions are taken to prevent both rehydration to C_4AH_{11} and carbonation, it is shown that the lowest hydrate C_4AH_7 gives a longest basal spacing of approximately 5.5 Å, and not 7.2–7.4 Å as indicated in some previous investigations.

With regard to the formation of solid-solution series between ternary calcium aluminate hydrates and related quaternary basic salts, the previously reported existence of solid solutions involving the hypothetical hexacalcium aluminate hydrate is not confirmed and only those involving tetracalcium aluminate hydrate are shown to be formed. Although the latter compound normally occurs only as the $19H_2O$ hydrate in contact with the liquid phase, it appears that replacement of hydroxyl ions in the crystal lattice by other anions results in the loss of "inter-layer" water so that effectively C_4AH_{13} is concerned in the solid-solution formation. Furthermore, complete solid-solution series are not formed but only partial series over restricted composition ranges, at any rate with basic salt solid solutions containing sulphate, or carbonate or chloride. With these anions, the behaviour when added to C_4AH_{19} suspensions is similar though not identical. The existence of a partial solid-solution series between C_4AH_{13} and $C_3A \cdot CaSO_4 \cdot 12H_2O$ is established over the range of compositions from $C_3A \cdot CaSO_4 \cdot 12H_2O$ to $C_3A \cdot \frac{1}{2}Ca(OH)_2 \cdot \frac{1}{2}CaSO_4 \cdot 12H_2O$, the longest basal spacing in the X-ray powder patterns decreasing within this range from 8.96 Å to 8.77 Å. The possible existence of solid solutions involving the 9.6 Å and 10.3 Å modifications of $C_3A \cdot CaSO_4 \cdot aq$ which also occur in the aqueous system still remains to be examined. A quaternary carbonate hydrate $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$ is readily obtained, and, although variations in its composition and X-ray pattern are not observed in preparations obtained from C_4AH_{19} suspensions, it is probable that under other conditions a solid-solution series $C_4A \cdot \frac{1}{2}CO_2 \cdot 12H_2O$–$C_3A \cdot CaCO_3 \cdot 11H_2O$ is formed giving basal spacings in the range 8.2–7.6 Å. Some preliminary results obtained for the quaternary chloride solid solutions suggest that the behaviour is almost the same as with the sulphate-containing solid solutions, though the change in basal spacing with solid-solution formation to give higher values than those of C_4AH_{13}, and $C_3A \cdot CaCl_2 \cdot 10H_2O$ resembles that observed with the carbonate-containing solid solutions. It is suggested that the latter effect arises from variations in the amount of H_2O displaced by the incorporation of Cl^- or CO_3^{--} in the crystal lattice. Brief indications are also obtained that related quinary solid solutions containing chloride and sulphate, or carbonate and sulphate, may exist under suitable conditions. Further investigations are needed to establish more precisely the compositions and X-ray properties of these quinary solid solutions and the quaternary chloride-containing solid solutions, as also appear necessary to map out the various solid-solution fields in the equilibria of the relevant aqueous systems.

Supplementary Paper II-77 Crystal Structures and Reactions of C_4AH_{12} and Derived Basic Salts

S. J. Ahmed, L. S. Dent Glasser and Harry F. W. Taylor*

Synopsis

The crystal structure of a phase approximating in composition to C_4AH_{12}, with some structural CO_3^{2-}, has been determined. It is based on considerably distorted brucite-like layers of composition $[Ca_2Al(OH)_6]^+$, with interlayer H_2O, OH^- and CO_3^{2-}. Some of the interlayer water molecules occupy well-defined sites adjacent to Ca^{2+} ions, the coordination numbers of which are thereby raised to seven. The remaining H_2O molecules and OH^- and CO_3^{2-} ions occupy cavities and are only semi-ordered.

The thermal dehydration reactions of $Ca_2Al(OH)_6Cl\cdot 2H_2O$, $Ca_2Al(OH)_6Br\cdot 2H_2O$, and $Ca_2Al(OH)_6(NO_3)\cdot 1\frac{1}{2}H_2O$ have been studied by static and dynamic weight-loss curves, differential thermal analysis, and X-ray, infrared, and chemical examinations of heated material. In each case, the molecular water is lost below 100°C (static) or 200°C (dynamic). The dehydration products thus formed decompose at 200–500°C, with loss of part of the hydroxyl water, to give amorphous products. Dehydroxylation is only completed when CaO and $C_{12}A_7$ or related phases crystallize at 500–1000°C. The position is complicated by loss of chloride (or bromide) in the case of the halides, and by the successive decompositions to nitrite and eventually to oxide in that of the nitrate.

C_4AH_{12} and C_4AH_{19} readily undergo anion exchange reactions when placed in 2M solutions of $NaNO_3$, Na_2SO_4, or $NaO_2C\cdot CH_3$. This provides a possible method for growing crystals for X-ray structure determinations.

The crystal structures of the entire group of lamellar double hydroxides and basic salts related to C_4AH_{12} are almost certainly essentially similar to that of the latter phase, the only important differences lying in the composition of the interlayer material and the stacking sequences of the $[Ca_2Al(OH)_6]^+$ layers. Known or probable features of the structures of the hydroxide, halide, sulphate, carbonate and hydroxoaluminate (C_2AH_8) members of the group are discussed.

Introduction

Some of the lamellar calcium aluminate hydrates and related basic salts, such as C_4AH_{12} and $C_3A\cdot CaSO_4\cdot 12H_2O$ respectively, play important roles in the chemistry of cement hydration. We have recently determined the crystal structure of one of these phases (1). In the present paper, these results are summarized, some additional observations on thermal decomposition and anion exchange reactions described, and some conclusions reached as to the structures of these compounds in general.

Studies by Alègre (2) and Dosch and zur Strassen (3) have shown that the hydroxide phase having a layer thickness of 7.9 Å is C_4AH_{12} and not C_4AH_{13}, as has widely been supposed. This conclusion is compatible with the data for natural hydrocalumite, (4, 5) which has a layer thickness of 7.86 Å and a composition approximating to $Ca_{16}Al_8(OH)_{54}(CO_3)\cdot 20$–$21H_2O$. This composition, if the formula with 20 H_2O is assumed, is equivalent to C_4AH_{12} with minor replacement of $2OH^-$ by CO_3^{2-}.

Crystal Structure Determination

The crystals studied were selected from a preparation approximating in composition to C_4AH_{12-13} with some structural CO_3^{2-}. Because of the small amount available, exact chemical analysis was not possible, but the available chemical and optical evidence, toghther with the crystallographic results to be described, suggested that the probable composition was the same as that of hydrocalumite, of which the material was possibly a polytype.

X-ray single crystal studies showed the crystals to be trigonal, with space group $R\bar{3}c$. The unit cell, with $\underline{a} = 5.73$, $\underline{c} = 47.16$ Å (referred to trigonal axes), contains six formula units of mean composition $Ca_2Al(OH)_{6(3/4)}(CO_3)_{1/8} \cdot 2\frac{1}{2}H_2O$. The crystal structure was determined using three-dimensional data. Within the unit cell, there are six layers of composition $[Ca_2Al(OH)_6]^+$, which lie perpendicular to $\underline{c}$ and will be called "principal layers". They are 7.86 Å apart in the $\underline{c}$-direction. Between the principal layers lie regions of interlayer material. Each principal layer, with the interlayer material on one side of it, contains a single formula unit, each interlayer region thus having the mean composition $(OH^-)_{3/4}(CO_3^{2-})_{1/8} \cdot 2\frac{1}{2}H_2O$.

Fig. 1 shows the main features of the structure. The principal layers (Fig. 1 A and C) are completely ordered, and might be described either as distorted, brucite-like layers in which Ca^{2+} and Al^{3+} are regularly arranged, or as agglomerates of Ca^{2+} and $Al(OH)_6^{3-}$ ions. Comparison of Fig. 1 A and C indicates the stacking relation between adjacent layers.

The interlayer material (Fig. 1 B) is only partly ordered. Water molecules occur on the sites marked P and raise the Ca-coordination to seven; probably all of these P-sites are occupied. The remaining H_2O molecules and OH^- and CO_3^{2-} ions occur in cavities of the type centred on X, and must necessarily be statistically distributed. The composition may now be re-written as $[Ca_2Al(OH)_6 \cdot 2H_2O](OH)_{3/4}(CO_3)_{1/8}(H_2O)_{1/2}$, the contents of the cavities being represented by the material outside the square brackets.

The experimental data gave only an approximate indication of the arrangement of the material within the cavities, but were consistent with the following interpretation. One-half of the cavities contain a single OH^- group at X. One-eighth contain a CO_3^{2-} ion, with the carbon atom at or near X and the oxygen atoms at or near sites of the type marked Q. One-eighth contain two H_2O molecules, and the remainder (one-quarter) an OH^- ion and an H_2O molecule. In the two last-mentioned cases, the oxygen atoms occur at, or more probably near to two of the Q-sites. Space considerations make it unlikely that they actually occur on the Q-sites, or that more than two oxygen atoms can occur in the same cavity unless they form part of a CO_3^{2-} ion; this is discussed more fully later. The results gave no indication of any ordering among the various types of occupancy of the cavities, though the weak X-ray reflections by which this could have been detected might well have been unobserved with the small crystal used. They also did not show whether or not a continuous solid solution series exists between the hydrocalumite composition and C_4AH_{12}.

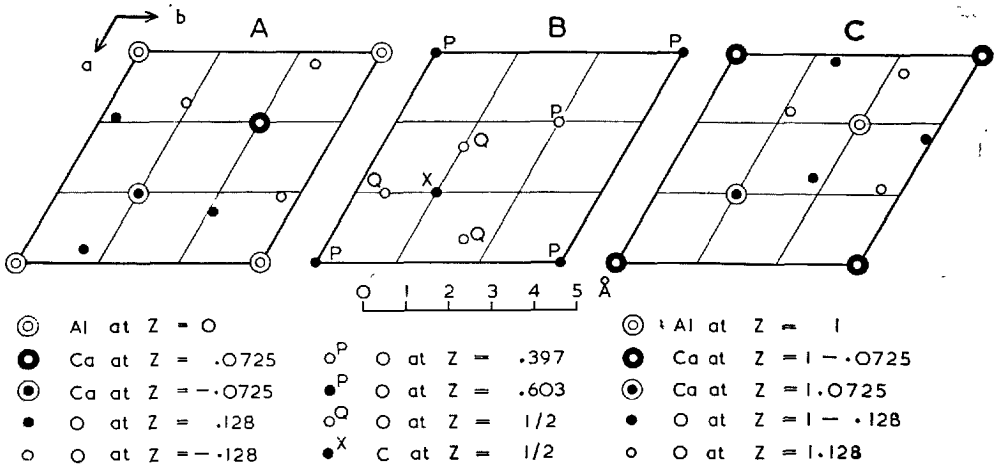

Fig. 1. *Diagram of parts of the structure, seen in projection along the $\underline{c}$-axis; $\underline{z}$-coordinates are given as fractions of the single layer thickness of 7.86 Å. A, principal layer with Al at $\underline{z} = 0$; B, interlayer region around $\underline{z} = \frac{1}{2}$; C, principal layer with Al at $\underline{z} = 1$. The full coordinates of one of the hydroxyl groups of the principal layers are (0.310, 0.057, 0.128).*

Tarte (6) concluded independently that these structures contain isolated AlO_6 (or $Al(OH)_6^{3-}$) octahedra on the basis of the infrared spectra. From an X-ray crystal structure determination, Allmann (7) independently found a closely similar structure for $C_3A \cdot CaSO_4 \cdot 12H_2O$; the two structures are virtually identical as regards the principal layers and the H_2O molecules in the P-sites. In the sulphate derivative, one-half the cavities contain an SO_4^{2-} ion, and the rest two H_2O molecules. The very close crystallographic similarities between all the members of this group of phases make it appear highly probable that the same principal layers occur in all of them. The H_2O molecules in the P-sites seem usually also to be present, except in dehydration products such as C_4AH_7-$(Ca_2Al(OH)_7)$. The phases differ essentially in the composition and structure of the interlayer material and in the stacking sequences of the principal layers.

Comparative single-crystal X-ray studies showed that natural hydrocalumite must have a structure differing only in minor respects from that of the synthetic material discussed above. The structure which Tilley, Megaw, and Hey (4) proposed for this phase is incorrect.

Thermal Decomposition Reactions

Previous workers have reported on the thermal decompositions of C_4AH_{13} and hydrocalumite (5), and of $C_3A \cdot CaCO_3 \cdot 11H_2O$ (8). We have now studied the decomposition of $C_3A \cdot CaCl_2 \cdot 10H_2O$, $C_3A \cdot CaBr_2 \cdot 10H_2O$ and $C_3A \cdot Ca(NO_3)_2 \cdot 9H_2O$ using static and dynamic weight-loss curves, differential thermal analysis, and X-ray, infrared and chemical examination of heated material.

Experimental

The starting materials were prepared as described by Mylius (9). Static weight-loss curves were obtained by heating a sample to constant weight in N_2 at successively higher temperatures. Dynamic weight-loss (TGA) curves were obtained in air, using a Stanton thermobalance, with a heating rate of 10 deg C min^{-1}. DTA curves were obtained on a Dupont instrument, in a N_2 atmosphere, also at 10 deg C min^{-1}. X-ray powder patterns were recorded using film techniques; for high-temperature work (up to 200°C) a nickel-foil heating element (10) was used. Infrared absorption spectra were recorded using a double-beam instrument and the KBr disk technique.

$C_3A \cdot CaCl_2 \cdot 10H_2O$

The specimen, which contained about 10% of C_4AH_{12} as impurity, gave an X-ray powder pattern and optical data agreeing with those reported by Kuzel (11) for β-$C_3A \cdot CaCl_2 \cdot 10\,H_2O$. The data were inadequate to show whether the C_4AH_{12} was present in solid solution or as a separate phase, but the apparent stabilization at room temperature of a stacking modification otherwise stable only above 28°C (10) possibly favours the former explanation. The infrared absorption spectrum was compatible with that found by Tarte (7), the main bands in the 650–4000 cm^{-1} region being at 785 cm^{-1} (Al–O–H bending), 1130 cm^{-1} (?), 1620 cm^{-1} (H–O–H bending), and 3450 and 3600 cm^{-1} (O–H stretching). In subsequent discussion, we shall consider the material as if it were pure $C_3A \cdot CaCl_2 \cdot 10H_2O$.

Interpretation of the weight-loss curves is rendered complicated by the loss of Cl^- at the higher temperatures. Chemical analyses showed that no loss of Cl^- occurs on static heating up to 640°C, but some loss occurs by 800°C, and a sample heated to constant weight at 1000°C retained only 15% of the Cl^- initially present. Loss of the Cl^- was slow, and was negligible on dynamic heating at 10 deg C min^{-1} up to 880°C, the highest temperature studied. Separate experiments showed that $CaCl_2$ begins to yield HCl at 850°C when heated in air of ordinary humidity.

Both static and dynamic weight-loss curves (Fig. 2) show distinct steps. The first occurs mainly at 40–100°C (static) or 90–170°C (dynamic) and is in either case complete by 200°C. The product at 200°C has the composition $C_3A \cdot CaCl_2 \cdot 6H_2O$, or $Ca_2Al(OH)_6Cl$. High-temperature X-ray photographs taken at 100–200°C broadly resembled that of the initial material, but indicated a layer thickness of 6.8 Å. X-ray patterns of samples cooled from these temperatures were closely similar to that of the initial material, but with some deterioration of crystallinity in the case of the 200°C sample; rehydration had occurred within a few hours on cooling. The infrared absorption spectra of samples cooled from 100–200°C resembled that of the initial material, but all bands were more diffuse, the 1620 cm^{-1} band was weakned, and the two O-H stretching bands were replaced by a single, broad band peaking at 3400 cm^{-1}. These results are

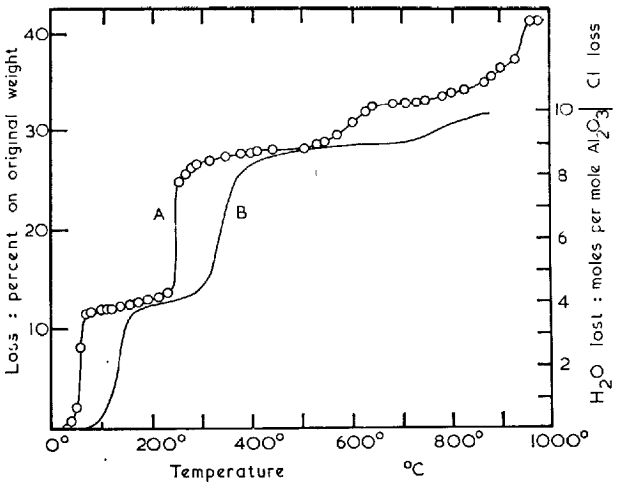

Fig. 2. *Weight-loss curves for* $Ca_2Al(OH)_6Cl \cdot 2H_2O$: *A, static; B, dynamic.*

compatible with loss of the molecular water, if it is assumed that partial rehydration occurred before the spectrum could be recorded.

The second step in the weight-loss curves occurs mainly at 240–270°C (static) or 290–380°C (dynamic) and is complete in either case by 500°C. The 500°C product has the approximate composition $C_3A \cdot CaCl_2 \cdot H_2O$, or $Ca_2Al(OH)O_{2(1/2)}Cl$. X-ray patterns of samples cooled from 300–500°C showed these to be almost amorphous, apart from some calcite which probably formed during the exposure. The infrared spectra of these samples somewhat resembled that of the 200°C product, but became progressively more diffuse with increase in temperature.

The third step in the weight-loss curve occurs mainly at 550–650°C (static) or 740–880°C (dynamic). It corresponds to loss of the remaining hydroxyl, so that the product has the bulk composition $C_3A \cdot CaCl_2$. X-ray powder photographs of samples cooled from these temperatures showed only amorphous material, but the infrared spectrum of a sample cooled from 650°C was consistent with formation of either $C_{12}A_7$ or $C_{11}A_7 \cdot CaCl_2$, and DTA evidence, described shortly, confirmed that crystallization of new phases from the amorphous material begins well before 750°C under dynamic heating conditions. The arrest in the loss of water around 500°C which separates the second and third steps in both static and dynamic curves may be explained by assuming that the amorphous dehydroxylation product tenaciously retains a proportion of the hydroxyl groups initially present, and that these are only lost when the temperature is high enough to bring about the crystallization of new phases. It is most unlikely to be associated with any structural feature of the initial material.

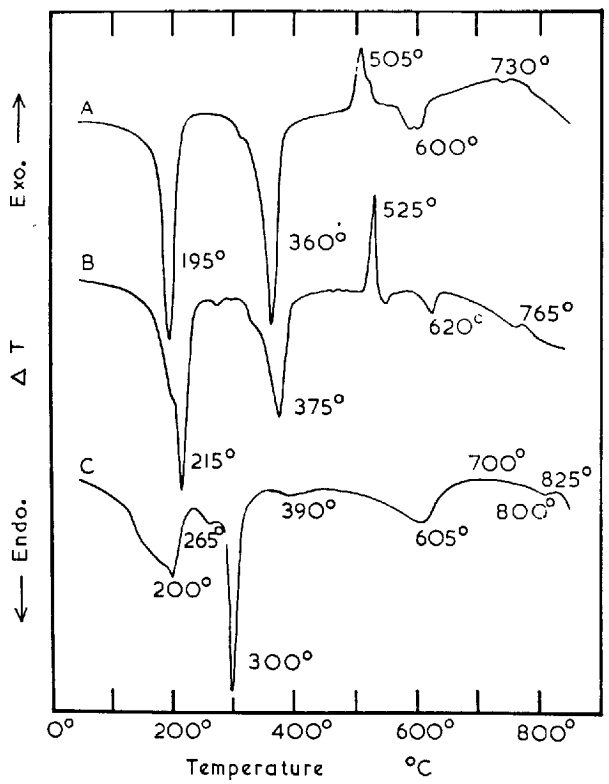

Fig. 3. *Differential thermal analysis curves for A,* $Ca_2Al(OH)_6Cl \cdot 2H_2O$; *B,* $Ca_2Al(OH)_6Br \cdot 2H_2O$; *C,* $Ca_2Al(OH)_6(NO)_3 \cdot 1\frac{1}{2}H_2O$.

The dynamic curve was not continued beyond 880°C, but the static curve showed a further weight loss at 650–1000°C. Comparison of the Cl^- contents of samples cooled from 640° and 1000°C showed that this loss could be attributed to the replacement of $2Cl^-$ by O^{2-}. The necessary oxygen for this reaction may have come from water or oxygen impurities in the nitrogen atmosphere. X-ray photographs and infrared spectra of samples cooled from 700–1000°C together showed that progressive crystallization of $C_{11}A_7 \cdot CaCl_2$ and CaO occurs over this range. The former product was shown to be $C_{11}A_7 \cdot CaCl_2$ rather that $C_{12}A_7$ or $C_{12}A_7H$ by its $\underline{a}$-axial length, which was found using an X-ray powder diffractometer to be 12.010 Å; a specimen of $C_{12}A_7$ for comparison, gave $\underline{a} = 11.991$ Å. Jeevaratnam, Glasser, and Dent Glasser (12) reported 12.004 Å for $C_{11}A_7 \cdot CaCl_2$, 11.983 Å for $C_{12}A_7H$, and 11.977 Å for $C_{12}A_7$. The amount of Cl^- remaining in the product at 1000°C agrees with that expected assuming stoichoimetric formation of $C_{11}A_7 \cdot CaCl_2$ and CaO.

The infrared spectrum of a sample cooled from 1200°C showed that C_3A had been formed.

On the DTA curve (Fig. 3A), the first two endo-

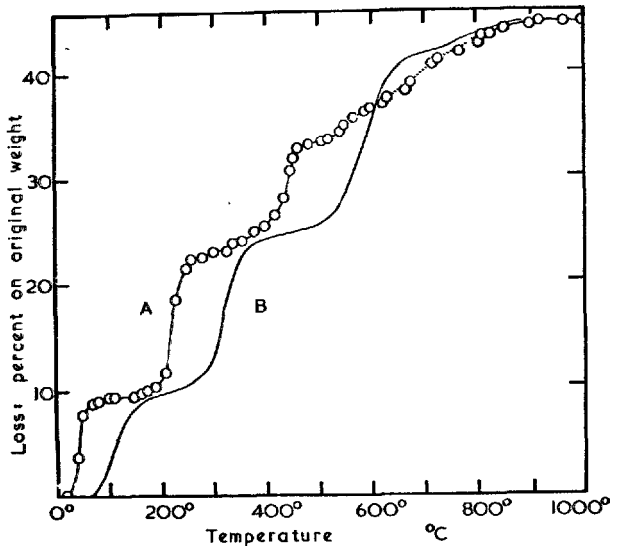

Fig. 5. *Weight-loss curves for* $Ca_2Al(OH)_6(NO_3) \cdot 1\frac{1}{2}H_2O$: *A, static; B. dynamic. The part of the static curve at 450–850°C is possibly in error due to absorption of water vapour or* CO_2 *during cooling.*

therms (195° and 360°C) correspond to the first and second steps respectively of the weight-loss curves. The exotherm at 505°C is attributed to the beginning of crystallization; evidently DTA is more sensitive than X-ray diffraction for detecting this process. The broad endotherm around 600°C is attributed to the final stage of dehydroxylation and the very broad, exothermic bulge around 730°C to continued development of crystallization.

$C_3A \cdot CaBr_2 \cdot 10H_2O$

This was studied by the same methods as the chloride derivative and gave closely similar results, which will therefore not be reported in detail. The X-ray pattern of the initial material indicated a layer thickness of 8.16 Å; this agrees with the value (8.1 Å) earlier reported by Feitknecht and Buser (13). The first two steps in the weight-loss curves (Fig. 4) correspond to formation of $Ca_2Al(OH)_6Br$ and $Ca_2Al(OH)O_{2(1/2)}Br$ respectively. The first of these products gave an X-ray pattern broadly similar to that of the initial material but indicating a layer thickness of 7.1 Å; it readily rehydrated in moist air. The second, like the corresponding product obtained from the chloride, was substantially amorphous. Loss of Br^- began at 600°C on static heating in N_2, and by 660°C much of the Br^- initially present had been lost. There was no arrest in the curve corresponding to that at about 700°C for the chloride. About 50% of the Br^- initially present was lost by 850°C on dynamic heating in air, and 85% by 950°C on static heating in N_2. X-ray and infrared studies indicated the progressive crystallization of CaO and either $C_{12}A_7$ or $C_{12}A_7H$ at 600–1000°C. In agreement with the findings of Jeevaratnam, Glasser and Dent Glasser (12), no evidence was obtained of the formation of a compound $C_{11}A_7 \cdot CaBr_2$ analogous to $C_{11}A_7 \cdot CaCl_2$, and the manner in which the residual Br^- is held at 1000°C was not established. The DTA curve (Fig. 3B) resembles that of the chloride and its features can be interpreted in the same way.

$C_3A \cdot Ca(NO_3)_2 \cdot 9H_2O$

Chemical analysis indicated this composition for a preparation dried over $CaCl_2$ at room temperature; Mylius (9) reported H_2O: Al_2O_3 ratios of 8.54–9.34 for similarly dried material. X-ray powder photographs indicated a layer thickness of 8.66 Å, which agrees with the value (8.6 Å) reported by Feitknecht and Buser (13). In agreement with Mylius's observation, the crystals were optically positive. The infrared absorption spectrum in the 650–2000 cm^{-1} region showed strong or moderate peaks at 785 cm^{-1} (Al–O–H bending), 1385 cm^{-1} (N–O stretching) and 1620 cm^{-1} (H–O–H bending).

Interpretation of the weight-loss data (Fig. 5) is complicated by the effects of the decompositions of NO_3^- to NO_2^- and of NO_2^- to O^{2-}. Chemical analyses

of cooled samples showed that the NO_3^- content is unaffected by static heating at 100°C. By 300°C, the NO_3^- has been completely converted to NO_2^-. Conversion of NO_2^- to O^{2-} is negligible at 300°C, but has reached 90% by 500°C and is virtually complete by 1000°C. No nitride (N^{3-}) was detected at any stage.

Both static and dynamic weight-loss curves show well-defined steps. The first, which occurs at 30–100°C (static) or 50–200°C (dynamic), yields $Ca_2Al(OH)_6(NO_3)$. High-temperature X-ray powder photographs of this product broadly resembled the pattern of the initial material but indicated a layer thickness of 7.9 Å. The material readily rehydrated on cooling. The infrared spectrum of the 100°C product confirmed that the molecular water had been lost and that the NO_3^- remained.

The second step occurs at 200–350°C (static) or 250–450°C (dynamic). As shown above, the NO_3^- is converted to NO_2^- in this range. Allowing for this, the composition of the product formed on completion of this step is thus found to be $Ca_2Al(OH)_3O_{1(1/2)}(NO_2)$. X-ray photographs of samples cooled from around 300°C showed these to be virtually amorphous, apart from some calcite which had probably formed during the exposure. Infrared spectra showed that some NO_3^- was still present at 300°C, but not at 400°C; this is compatible with the analytical results, if the higher sensitivity of the spectroscopic method is allowed for. The reason for the ending of the second step probably lies in the completion of the NO_3^- decomposition, rather than in any structural feature. Some OH^- ion remains, but is relatively firmly bound in the amorphous product at these temperatures (350–450°C).

The third step begins at 350°C (static) or 450°C (dynamic). The initial sharp rise in each case is caused largely by the decomposition of NO_2^- to O^{2-}, which is almost complete by 500°C under static heating conditions; the subsequent slower rise is due, partly to completion of the NO_2^- decomposition, but mainly to loss of residual hydroxyl. As with the halides, this process occurs mainly above 700°C, and was shown from X-ray photographs to be associated with the crystallization of CaO and $C_{12}A_7$ or $C_{12}A_7H$.

The DTA curve (Fig. 3C) shows an initial, broad endotherm peaking at 200°C, which can be attributed to loss of molecular water. The subsequent endotherms at 265°C (weak), 300°C (strong), and 390°C (weak) can be associated with the second step of the weight-loss curves, and thus with decomposition of the NO_3^- and partial dehydroxylation. The broad endotherm at 605°C is associated mainly with decomposition of the NO_2^-, and the exothermic bulge around 700°C with recrystallization. A sharp exotherm corresponding to the one near 500°C observed with the chloride and bromide is not seen, perhaps because it is swamped by the 605°C endotherm. The effects at 800 and 825°C possibly represent the completion of dehydroxylation and crystallization respectively.

Anion Exchange Reactions

Dosch (14) has shown that C_4AH_{13} reacts with solutions of many different organic substances, the molecules of which penetrate between the layers, causing major changes in layer thickness. These results suggested that exchange of interlayer anions could possibly be effected by placing crystals in appropriate aqueous salt solutions. Preliminary experiments have shown that this is indeed the case. Crystals of either C_4AH_{12} or C_4AH_{19} were placed in 2M-solutions of either Na_2SO_4, $NaNO_3$, or $NaO_2C\cdot CH_3$, the C_4AH_{19} being introduced as a concentrated suspension in its own mother-liquor. After a few hours, the crystals were removed and examined microscopically and by X-ray single-crystal methods. Some crystals had partly dissolved but all gave diffraction patterns. The layer thicknesses thus found showed that either partial or total replacement of the interlayer anion had occurred. These results are of interest because of their bearing on possible mechanisms of sulphate attack on concrete, and also because they provide a possible method of obtaining single crystals suitable for X-ray structure determination of phases for which these are otherwise difficult to prepare.

Discussion

Hydroxides

As a result of the work of Alègre (2) and Dosch and zur Strassen, (3) five C_4A hydrates now appear well-established; these are listed, with their layer thicknesses, below:

$C_4AH_{19} = [Ca_2Al(OH)_6 \cdot 2H_2O]OH \cdot 4H_2O$ (10.6 Å)
$C_4AH_{13} = [Ca_2Al(OH)_6 \cdot 2H_2O]OH \cdot H_2O$ (8.2 Å)
$C_4AH_{12} = [Ca_2Al(OH)_6 \cdot 2H_2O]OH \cdot \frac{1}{2}H_2O$ (7.9 Å)
$C_4AH_{11} = [Ca_2Al(OH)_6 \cdot 2H_2O]OH$ (7.4 Å)
$C_4AH_7 = [Ca_2Al(OH)_6]OH$ (5.8–7.4 Å)

The layer thickness of C_4AH_7 depends on how the phase is formed, values of 7.2–7.4 Å being recorded for preparations made by dehydrating the higher hydrates at room temperatures over powerful dehydrating agents (3, 15), while lower ones of 5.8–6.5 Å result from heating at 100–150°C (5).

The layer thickness of C_4AH_{11} could be explained by assuming the interlayer OH^- ion to lie on the X-site; this would place it about 3.3 Å away from both the water molecules and the OH^- ions of the $Al(OH)_6^{3-}$ groups, a distance which is comparable with the OH–OH separation in $Ca(OH)_2$. The retention of a 7.4 Å layer thickness in C_4AH_7 can be explained by supposing the water molecules to be lost without further change occuring. A reduction in layer thickness to a minimum of about 6 Å can be explained if it is assumed that the $Al(OH)_6^{3-}$ octahedra rotate about axes parallel to $\underline{c}$ and the Ca^{2+} ions undergo small displacements parallel to this axis; these changes are made possible by the loss of the H_2O molecules, and permit the OH^- ion to replace the latter in the coordination spheres of the Ca^{2+} ions. The final result of this process, though not the intermediate stages, could also be described in terms of migration of the OH^- ion to a new site of the type $(\frac{1}{3}, \frac{2}{3}, \underline{z})$ or $(0, 0, \underline{z})$, together with a change in stacking. The former mechanism is perhaps more probable, as it explains the apparently gradual nature of the decrease in layer thickness. The process presumably occurs when dehydration is effected by heating because this supplies some necessary energy which is not made available when dehydration occurs at room temperature.

In C_4AH_{13}, two oxygen atoms (one present as H_2O and one as OH^-) must be accommodated within the cavity centred on the X-site. As mentioned earlier, it seems most unlikely that these occur exactly on the Q-sites (Fig. 1B), although the X-ray evidence strongly suggests that they are not far away from them. Fig. 6 gives a possible interpretation of the results. Within each cavity, there are six possible sites; these occur in paris, and each is about 0.7 Å away from one of the Q-sites. For steric reasons, only two out of the six sites in a given cavity can be occupied, of which one must be of higher, and the other of lower z-coordinate than the X- and Q-sites. This arrangement gives each OH^- ion or H_2O molecule a tetrahedral environment, with 4(OH, H_2O) at 2.6–2.7 Å.

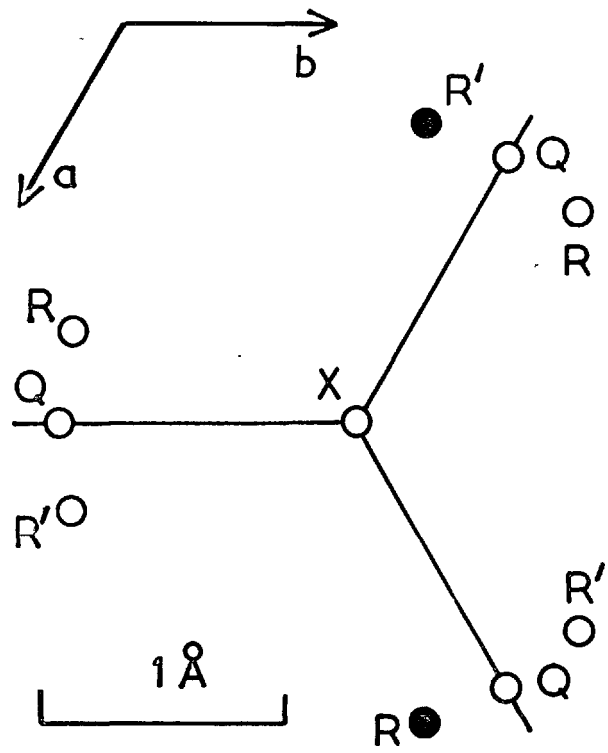

Fig. 6. C_4AH_{13}: *part of the interlayer region showing a possible arrangement of material in the cavities centred on the X-sites. Sites X and Q have the same significance as in Fig. 1B. Sites R and R' lie at* $\underline{z}$*-coordinates about 0.6Å respectively above and below that of the X- and Q- sites. In a given cavity, any one R- site, and the R'—site furthest away from it, can be occupied by* (H_2O, OH^-). *The full circles indicate one of the three ways in which this can occur.*

Dosch (14) suggested that C_4AH_{12} might be a randomly interstratified compound composed of layers of C_4AH_{11} and C_4AH_{13}. This is a possible explanation, and is consistent with the X-ray structure evidence described earlier in this paper. However, it does not appear to explain the apparently constant composition and layer thickness of this phase and more detailed study is required.

C_4AH_{19} can readily be explained as being derived from C_4AH_{13} by interpolation of an additional layer of water molecules between each $Ca_2Al(OH)_6$ layer and the next.

Nitrates

The positive optic sign and relatively great layer thickness (8.66 Å) of $C_3A \cdot Ca(NO_3)_2 \cdot 9H_2O(Ca_2Al(OH)_6 \cdot (NO_3) \cdot 1\frac{1}{2}H_2O)$ strongly suggest that the NO_3^- groups lie with their planes perpendicular to (0001). It may also be assumed that the NO_3^- groups occur in

the cavities centred on X. To satisfy the symmetry of the cavities, it is necessary to assume, either that the NO_3^- ions rotate freely about axes normal to (0001), or that they are statistically distributed as regards orientation. In the latter case at least three orientations are required, for which the planes of the NO_3^- ions are 120° apart. There does not appear to be sufficient room to permit free rotation of the ion, but several ways can be found of placing the ion in three or more equivalent orientations which would give reasonable distances between its oxygen atoms and the surrounding hydroxyl ions and water molecules. It does not appear profitable to discuss the matter further on the basis of the present evidence. No certain explanation can be offered for the apparent absence of H_2O molecules from some of the P-sites, though the ease with which the molecular water is lost (Fig. 5) suggests that the amount present may depend critically on the atmospheric temperature and humidity.

For the dehydration product, $Ca_2Al(OH)_6 \cdot (NO_3)$, the relatively high layer thickness (7.9 Å) suggests that the NO_3^- groups remain oriented perpendicular to the layers, but further investigation is needed before this can be considered certain.

Carbonates

The results obtained in the present investigation indicate that, in the material studied, the CO_3^{2-} ions lie with their planes parallel to (0001), with the carbon atom approximately at X and the oxygen atoms on Q-sites (Fig. 1B). The possibility of slight shifts from this situation, to bring the oxygen atoms onto sites similar to those proposed for C_4AH_{13} (Fig. 6) cannot be excluded. Packing considerations make it appear highly probable that the CO_3^{2-} ion occurs in this situation in all phases having a layer thickness under about 7.9 Å, such as $C_3A \cdot CaCO_3 \cdot 11H_2O$ (7.6 Å) and hydrocalumite. In the 8.2 Å phase, to which compositions $C_3A \cdot \frac{1}{2}CaCO_3 \cdot \frac{1}{2}Ca(OH)_2 \cdot \underline{x}H_2O$ (16) and $C_3A \cdot \frac{1}{4}CaCO_3 \cdot \frac{3}{4}CaO \cdot 12H_2O$ (3) have variously been assigned, the CO_3^{2-} groups may also occur in the same situation, but the possibility is not excluded that they are packed with their planes normal to (0001), similarly to the NO_3^- groups in $C_3A \cdot Ca(NO_3)_2 \cdot 9H_2O$.

Halides

It is tempting to assume that the halide ions, because of their spherical shape, lie in the centres of the cavities, on the X-sites. For $Ca_2Al(OH)_6I \cdot 2H_2O$, this assumption taken in conjunction with the observed cell parameters (19) gives I-OH_2 distances in reasonable agreement with the sum of the ionic radii, and is furthermore in accordance with evidence from the intensities of the 0001 X-ray reflections. (17) For $Ca_2Al(OH)_6Br \cdot 2H_2O$ ($C_3A \cdot CaBr_2 \cdot 10H_2O$), and especially for $Ca_2Al(OH)_6Cl \cdot 2H_2O$, in contrast, the halogen-water distances considerably exceed the sums of the ionic radii, and it is possible that the ions do not lie in the centres of the cavities.

The layer thicknesses of the dehydration products $Ca_2Al(OH)_6Cl$ and $Ca_2Al(OH)_6Br$ found in the present investigation can be satisfactorily explained if it is assumed that displacements within the principal layers or migration of the interlayer anions occurs, as was suggested for C_4AH_7.

Hydroxoaluminates

The compound C_2AH_8 and its various lower hydrates are closely related in structure to the group of phases under discussion. It is here suggested that they may be hydroxoaluminate members of the group; if this is so, the constitution of C_2AH_8 may be represented as $[Ca_2Al(OH)_6 \cdot 2H_2O]Al(OH)_4 \cdot 3H_2O$. The layer thickness is close to that of C_4AH_{19}; this is compatible with the above hypothesis.

Sulphates

As mentioned earlier, Allmann (7) has determined the crystal structure of $C_3A \cdot CaSO_4 \cdot 12H_2O$. The SO_4^{2-} groups, which occur in one-half of the cavities, are randomly distributed between two orientations. For both of these, the sulphur atoms lie at the X-sites, and one S–O bond is perpendicular to (0001), the other three oxygen atoms occupying sites similar to three of those shown in Fig. 6. The two orientations are related by inversion through a centre of symmetry at the X-sites, which occurs in this phase by virtue of the stacking sequence of the principal layers.

General

The ions discussed above are only a few of the many that can serve as interlayer anions in these phases (9, 13, 14); it is clear that anions of widely differing shapes and sizes can be accommodated, and also that the interlayer content frequently varies from point to point within a single crystal. In some respects, the interlayer regions resemble the channels in zeolites, but they differ in being extensible in one dimension and in that they are required to have a negative, and not a positive charge. Several especially important

and mutually related questions require clarification. First, the scale on which variation in composition occurs in individual cases is, in general, not known; there is a continuous range of possibilities extending from mixtures of physically separate crystals of different compositions, through intergrowths and randomly or regularly interstratified structures, to solid solutions or intermediate phases with random or regular variation in the composition within each individual layer. For a given bulk composition, more than one scale of mixing may be possible, depending on the conditions of formation. Secondly, many problems of the degree of order or disorder require to the studied. Lastly, the occurrence of continuously variable ranges of composition and, conversely, of miscibility gaps or of intermediate phases of apparently definite composition (e.g. C_4AH_{12}) need to be explained in the light of such considerations as those mentioned above.

Acknowledgments

We thank Dr. R. Allmann and Dr. P. Tarte for making available typescripts of papers in advance of publication, Dr. R. A. Chalmers for the nitrogen analyses, Mrs. L. Ingram M. Sc. and Miss W. Bissett for assistance with experimental work, and the editor, and publishers of "Nature" for permission to reproduce Fig. 1.

Oral Discussion

Shigeaki Koide

It is of much interest that all the compounds have ionized layers of composition $[Ca_2Al(OH)_6]^+$. Concerning the minute structure of the layer, however, we hope the authors to present their comment. It seems difficult to consider the layer to be of the above mentioned composition so long as Ca^{++} and Al^{3+} played the roles of octahedral and tetrahedral cations, respectively. Comparing the ionic radii of both cations, they might not be surrounded with the same number of hudroxyl ions.

What coordination numbers are considered for Ca^{++} and Al^{3+} in the layer, and whether the hydrates are analogous to clay minerals in their layer structure or not?

Authors' Closure

S. J. Armed, L. S. D. Glasser and H. F. W. Taylor

In reply to Dr. Koide, the Al^{3+} ions are octahedrally, and the Ca^{2+} ions seven-coordinated. The structures resemble certain clay minerals in their ability to accommodate varying amounts of interlayer water, with corresponding changes in layer thickness, and in some other ways. However, the layers are positively charged, whereas those of the clay minerals are negatively charged, and the structures of the layers themselves are only distantly related to those of the clay minerals.

Supplementary Paper II-137 The Alteration of Silicate Anions in Tobermorite Gels

Herbert Funk*

Synopsis

All tobermorite gels studied were found, by standing or drying condensation proceeds, to contain several silicate anions of different condensation degrees. The extent of condensation is influenced by the CaO/SiO_2 ratio.

Introduction

The calcium silicate hydrates which are formed in hardening portland cement are not uniform substances. Their composition and the form of their smallest particles differ. X-ray diffraction patterns of these substances are not always identical, yet have certain similarities with those of the mineral tobermorite, $5CaO \cdot 6SiO_2 \cdot 5H_2O$, and are therefore called "tobermorite like calcium silicate hydrates" or "tobermorite gels". The symbols C–S–H (I) or (II) are also commonly used for the hardening silicate. In the present paper these substances will be abbreviated as CSH.

About the Estimation of the Degrees of Condensation of Dissolved Silicic Acids. The Dissolving of Silicates and Formation of Corresponding Silicic Acids.

By an earlier described method (1) it can be determined, whether an acid-soluble silicate contains uniform silicate anions or different degrees of condensation. Changes in the degree of condensation by the reaction of the SiOH-groups of the anions to form SiOSi bonds can also be estimated. This method is not applicable to all silicates, but it can be used for tobermorite-like CSH.

For the determination of silicate anions of low degree of condensation, the CSH is dissolved in methanolic HCl. This yields primarily the free silicic acids, which corresponds to the silicate anions in the dissolved silicate. In order to get them into solution unchanged, certain rules of caution have to be obeyed (1, 2). The error that occurs during the dissolving of CSH due to condensation can be kept down to about 5%. To the silicic acid solution in methanol paramolybdate solution is added as soon as the weight sample has dissolved. By mixing the two solutions the complexing reaction proceeds under standardized conditions with a rate depending only on the degree of condensation of the dissolved silicic acid.

*Institut für Anorganische Chemie, Freie Universität Berlin, Berlin, West Germany.

The rates of molybdato silicic acid $H_4SiMo_{12}O_{40}$ formed after certain complexing times—calculated as % SiO_2 of the silicic acid in solution—are plotted against the complexing times on a logarithmic scale, thus producing the reaction or complexing curve (3, 4).

Fig. 1 represents the reaction curves of various silicic acids that are straight lines if there is only one type of silicic acid in solution. The complexing rates of uniform silicic acids, therefore, follow a first order reaction. In order to obtain only one type of silicic acid in solution crystallized test silicates of known structure, that had been finely powdered, were dissolved in methanolic HCl (10 mg SiO_2 in 10 ml methanol). Fig. 1 shows that the not highly condensed silicic acids are well to distinguish. The particular lines represents the complexing rates of

Curve 1: H_4SiO_4, monosilicic acid, from β–Ca_2SiO_4,
Curve 2: $H_6Si_2O_7$, disilicic acid, from $Na_6Si_2O_7$,
Curve 3: $H_6Si_3O_9$, tricyclosilicic acid, from α–$CaSiO_3$ (5) (Pseudowollastonite)
Curve 4: $H_8Si_4O_{12}$, tetracyclosilicic acid, from $K_4H_4Si_4O_{12}$ (6, 7),

Curve 5: $H_{12}Si_6O_{18}$, hexacyclosilicic acid, from $Cu_6Si_6O_{18} \cdot 6H_2O$ (8) (Dioptase)

If—e.g.— monosilicic acid solution is allowed to stand at normal temperature for 10 minutes, the reaction rates leave the straight line received for pure monocilicic acid and then proceeds with increasing curvature. After a standing time of one hour —e.g.— only less than 30% monosilicic acid remains and the curvature of the complexing curve increases.

Curve 6 (Fig. 1) shows the complexing curve of a two component solution, mixed of 4 moles mono— and 1 mole tetracyclosilicate. The first part of the curve has the slope of curve 1 (monosilicic acid), the remainder agrees with curve 4 (tetracyclosilicic acid). Extrapolation of the last part of the curve to the ordinate shows that both silicic acids are present with 50% (calculated as SiO_2). In this manner the type and amount of components of only simple mixtures can be determined. Curve 6 would not end as a straight line—as can be extrapolated—if further, higher silicic acids were present. Such complexing curves had, as already mentioned, not only been observed for dissolved silicic acids after standing, but for all dissolved CSH examined until now.

The Examination of Tobermorite Gels (CSH)

Different degrees of condensation are present in the anions of CSH formed by hydration of C_3S or β–C_2S: Fig. 2, Curve 1 represents the complexing rates of a C_3S hydration product (composition: $2CaO \cdot SiO_2 \cdot 2H_2O$). Curve 2 shows the complexing rates of a corresponding CSH (composition: 1.65 $CaO \cdot SiO_2 \cdot 1.9H_2O$) formed by hydration of β–C_2S at 25°C. In both cases the starting material is a monosilicate, yet both hydration products contain no noticeable monosilicate. Disilicate is present only to 20–30%, the greater part of CSH has higher condensed anions. Silicates with more than $6SiO_4$-tetrahedra are produced by C_3S (Curve 1) to less than 40%, by β–C_2S (Curve 2) about 50%.

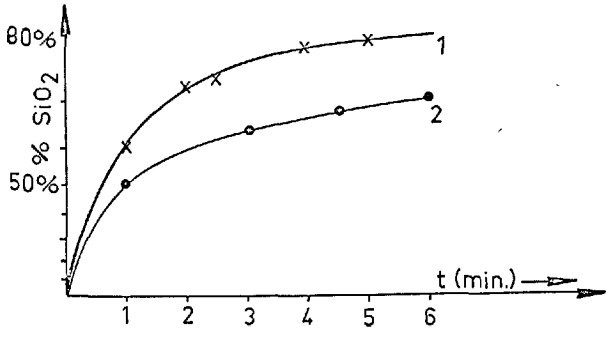

Fig. 2. *Complexing curves of* CSH *indicating condensation of silicate anions,*

1. C_3S hydration product
2. β-C_2S hydration product

The different condensation degrees in both hydration products of Fig. 2 are not characteristic to CSH produced from C_3S and β–C_2S, respectively. This is indicated by the differences of complexing rates in Fig. 3. Three CSH samples, that had been formed by hydration of C_3S, are represented by the Curves 1, 2 and 3 and differ to a greater extent than do the curves in Fig. 2.

Curve 1: C_3S, 90 days (25°C) with supersaturated $Ca(OH)_2$ solution (2:20 g):
$1.76CaO \cdot SiO_2 \cdot 2.5H_2O$.

Curve 2: C_3S, 90 days (25°C) with water (2:20 g):
$1.54CaO \cdot SiO_2 \cdot 2.0H_2O$.

Curve 3: C_3S, 5 years (paste):
$1.51CaO \cdot SiO_2 \cdot 1.09H_2O$.

Curve 1: The highest condensation degree in this CSH is a tetrasilicate, the sum of mono—, di—, tri—and tetrasilicate is therefore about 100%. In the CSH, used for Curve 2, not more than 50% di-, tri-

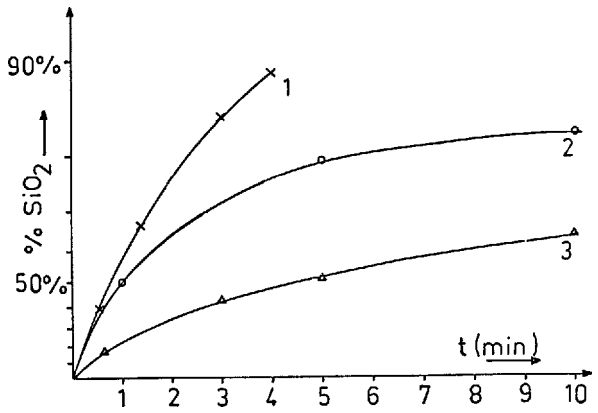

Fig. 3. C_3S *hydration under different conditions yielding different degrees of condensation*

and tetrasilicates are present, while more than 40% of the SiO_2 have a condensation degree of six or more. The differing degrees of condensation expressed by Curves 1 and 2 may be caused by the different CaO/SiO_2 ratios of the CSH products. The higher condensation in the CSH represented by Curve 3 is mainly due to a 5 years' standing as paste. The CaO/SiO_2 ratio does not change appreciable in this time, but the water content is lower, as can be expected for higher condensed silicates. The free $Ca(OH)_2$ that is always formed in considerable excess by the action of water on C_3S does not hinder the condensation of the primarily monomeric silicate anions.

The relationship between the degrees of condensation in CSH and its CaO/SiO_2 ratio was studied in further experiments.

CSH Gels of Different CaO/SiO_2 Ratio

Tobermorite gels having different CaO/SiO_2 ratios are easily obtained by precipitation from $Ca(ClO_4)_2$ solution with 0.1 molar $Na_2H_2SiO_4 \cdot 8H_2O$ in solution. An addition of NaOH to the silicate solution yields CSH higher in lime content. After rinsing the precipitated gels, voluminous water rich gels (95–97% H_2O) are obtained. Neither do the lines characteristic for $Ca(OH)_2$ appear on the X-ray diffraction pattern nor is more than 0.5% of the CaO soluble when the dried substance is extracted with a mixture of acetoacetic ester and isobutanol (9). This both facts indicate that all CaO contained in the CSH is bonded to the silicate. The X-ray patterns show merely some broad hko interferences which are typical of ill-crystallized CSH (10).

In the following descriptions about factors influencing the condensation of anions in CSH, the results are illustrated not only with the help of curves but also with tabulations. These tables contain complexing values obtained after 1, 5 and 10 minutes and make a general picture possible. From Table 1 and Fig. 1 it can be seen that all monosilicate and most of di- and trisilicate have been complexed after one minute.

The complexing curves of four precipitated CSH gels are presented in Fig. 4.

1.18	44	65	71
1.41	65	90	95

lime content produces a decreased complexing rate. The degrees of condensation of the silicate anions, therefore, are influenced by the CaO/SiO_2 ratio in CSH. This dependance is also clearly indicated by further examples shown in Table 4.

The difference in Fig. 4 between Curve 1 A and Curve 1 (3 days and 14 months after preparation) shows that by standing of the CSH, the condensation degree is increased. Further examples in Table 2. show that wet tobermorite gels have changed already after 14 days. In a freshly prepared CSH gel condensation also occurs by drying, as can be seen from the complexing values shown in Table 3.

These changes by drying are mainly observed for water containing CSH gels obtained by precipitation from aqueous silicate solutions. Drying causes condensation to a similar extent as does month-long storage at 25°C under wet conditions. Storage of a dried CSH does not cause any further condensation while standing of CSH with water showed noticeable condensation after 5 years (Fig. 3, Curve 3).

Discussion of the Results

The studied tobermorite-like CSH were found to contain always silicate anions of different degree of condensation. With regard to the anion mixtures obtained in the CSH, the way of preparation and—if the starting materials are identically—the details of reaction conditions for the CSH are of influence.

It can be assumed, that the tobermorite gels contain anions of SiOH-groups that are able to react one with another increasing the number of SiOSi-bonds. This reaction is analogous to the condensation of SiOH-groups of free silicic acids.

The extent of anion condensation depends—with in certain limits—upon the CaO/SiO_2 ratio in the respective CSH. This may be explained by the fact that the tendency to form higher condensed units increases with the number of SiOH-groups. Moreover, there is a relationship between calcium ions bonded to silicate and SiOH groups on the other hand, since calcium ions—leaving the silicate by hydrolysis to form $Ca(OH)_2$—yield simultaneously and necessarily SiOH groups.

Crystallized CSH have—in comparison with tobermorite gels—only one type of anion. The mixture of different silicate anions occurring in tobermorite gels may well be the reason for the always ill-crystallized state of the CSH. The crystal quality does not improve upon standing for months or even for years at room temperature. Only under hydrothermal conditions may condensation yield long-chain anions that are able to crystallize within certain limits of the CaO/SiO_2 ratio. This way the "actual" tobermorite is formed at about 160°C. This CSH is very similar in X-ray diagramm to one form of tobermorite found as mineral in Scotland. This tridimensional and crystalline ordered "actual" tobermorite has a definite composition and is a terminal member of a great number of possible tobermorite-like CSH. It is not to include into the group of tobermorite like CSH.

The nearly amorphous tobermorite gels are much more reactive than any form of crystallized CSH, which—e.g.—do not yield higher condensed silicates at ordinary temperature. Therefore, the behaviour of

the well crystallized tobermorite is much more similar to other crystallized CSH than to a tobermorite gel. Some important properties, characteristic of tobermorite gels—in comparision with crystallized CSH including "actual" tobermorite—are

1. ill-crystallized or nearly amorphous state in the CSH with typically hko-interferences,
2. several silicates of different condensation degrees are present in the CSH, probably causing the ill-crystallized state,
3. the higher reactivity of tobermorite gels
   a) of SiOH groups in silicate anions to form higher condensation degrees,
   b) of calcium ions toward hydrolysis.

(B) Papers regarding Properties

Supplementary Paper II-6 Stability of Hydrogarnet Series Terms to Sulphate Attack

Bernardo Marchese and Riccardo Sersale*

Synopsis

Resistance to sulphate ions of terms belonging to "tricalcium aluminate-grossularite" (hydrogarnets) series, has been investigated.

Low silica hydrogarnets have been prepared by hydrothermal treatment of suitable glasses, and tested for crystallinity by thermogravimetric analysis and electron microscopy. Successively, they have been treated with saturated lime solutions containing different amounts of calcium sulphate. The ettringite produced has been identified by differential thermal analysis, X-ray diffraction, and electron microscopy.

Rate and degree of completeness of the reaction have been measured with good accuracy by means of differential calorimetry and X-ray diffraction. Minimum amount of silica required for hydrogarnet stability toward sulphate attack has been evaluated around 0.3 mols SiO_2 per mol of compound.

Resistance to sulphate ions of terms in the series "tricalcium aluminate hexahydrate-grossularite" (hydrogarnets), besides theoretical considerations, is of considerable importance on technical ground because the resistance of certain cement works, for instance steam-cured concrete (1), to sulphate containing solutions, can be ascribed to it.

Foundamental contributions to the study of hydrogarnet stability in presence of sulphate ions have been given by Flint and Wells, zur Strassen and, more recently, by Schwiete and Iwai, Richartz, Yang (2). It has been pointed out that tricalcium aluminate hexahydrate (extreme term in the already mentioned series) as well as tricalcium aluminate, are rapidly transformed into ettringite after contact with calcium sulphate solutions. The substitution of silica in place of water, as far as the cubic aluminate turns into grossularite, bears a lattice shrinkage (3) which corresponds to an increased sulphate resistance, as will be shown later.

The minimum amount of silica which gives resistance towards sulphate to hydrogarnets, seem thus to be of great importance. It has been evaluated by zur Strassen around 0.3 mols.

We have studied reactivity of hydrogarnets of suitable composition in contact with sulphate solutions, measuring rate and degree of completeness of reaction. This has led to the necessity of measuring with good accuracy the amount of ettringite formed in each run. The two different techniques used, which will be described later, have allowed also the evaluation of silica amount capable of transforming hydrogarnet series terms into virtually resisting compounds. In this note an account will be given of the experimental work done and of the corresponding conclusions.

Preparation of Specimens

Four intermediate terms in the hydrogarnet series have been prepared. Their composition resulted from chemical analysis were:

1) $C_3AS_{0.225}H_{5.56}$
2) $C_3AS_{0.28}H_{5.44}$
3) $C_3AS_{0.35}H_{5.30}$
4) $C_3AS_{0.43}H_{5.10}$

They have been prepared, according to literature

*Istituto di Chimica Industriale, Università di Napoli, Napoli, Italy.

(4), by long hydrothermal treatment (around 350 hrs), at 150°C, of glasses obtained by quenching melts of appropriate composition.

Soon after, the completeness of glass → crystal transformation has been tested. In fact, glasses with composition falling in the interval explored by us, are rapidly attacked by sulphate contact solution, with formation of ettringite. A small amount of residual glass in the hydrothermally crystallized product would thus invalidate the measurement of rate of fixation, especially at shorter times.

Control of "Crystallinity" by TGA and by EM

Weight losses of each specimen, before and after hydrothermal treatment, have been measured with methods of thermogravimetric analysis with a "Mass-flow thermobalance" of Stanton Instr. Inc. For example, curves relative to specimen No. 2 (0.28 mol SiO_2), before (a) and after (b) hydrothermal crystallization, have been reported in Fig. 1. The weight loss of the glass specimen is practically negligible (~1%), while that of the crystallized specimen amounts to 25.28% (stoichiometric value is 25.40%). Electron microscope observations are in good agreement with this result. The same specimen, observed after hydrothermal treatment, shows micrograph a) in Photo 1, only monometric crystals without glass particles. Crystals appear to be well formed even if edges are rounded by continuous shaking.

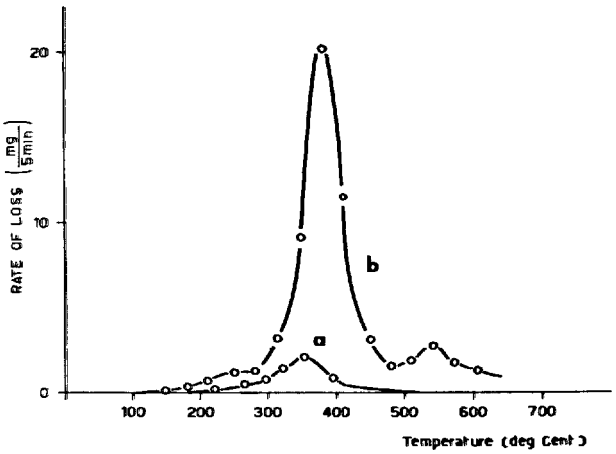

Fig. 1. TGA *of* $C_3AS_{0.28}H_{5.44}$:
a) *before hydrothermal crystallization*
b) *after* " "

Sulphate Fixation Rate Measurement

After evaluation of "crystallinity", for each specimen has been measured the rate of calcium sulphate fixation in continuous saturated lime solution. Experimental procedure has been described in a previous work (5). Rate curves, i.e. amount of sulphate fixed at room temperature against time of fixation, have been reported in Fig. 2.

Plots show a decrease in the amount of sulphate fixed in compounds with higher silica content. An abrupt decrease is shown passing from the 0.225 mols SiO_2 to the 0.28 mols term. It corresponds to the diminished reactivity toward attack solution already mentioned by zur Strassen (2).

X-ray Diffraction

Only diffraction data concerning the 0.28 mol terms have been reported.

Patterns in Fig. 3 (symbols as in Fig. 2) show, as time increases, transformation of reactant in contact with a constantly lime saturated and initially sulphate saturated solution, and point out progressive formation of ettrinigite (reflections at 9.73, 5.61, 3.88 Å). For reference purposes patterns of initial hydrogarnet of ettringite and of $Ca(OH)_2$ have been reported.

Unit-cell sizes of four hydrogarnet series terms with increasing SiO_2 content, have been measured. Values, reported in Fig. 4, show a cell shrinkage, which corresponds to an increase of lattice stability.

Differential Thermal Analysis

Differential thermal analysis curves in Fig. 5 are limited to products obtained from the 0.28 mol term

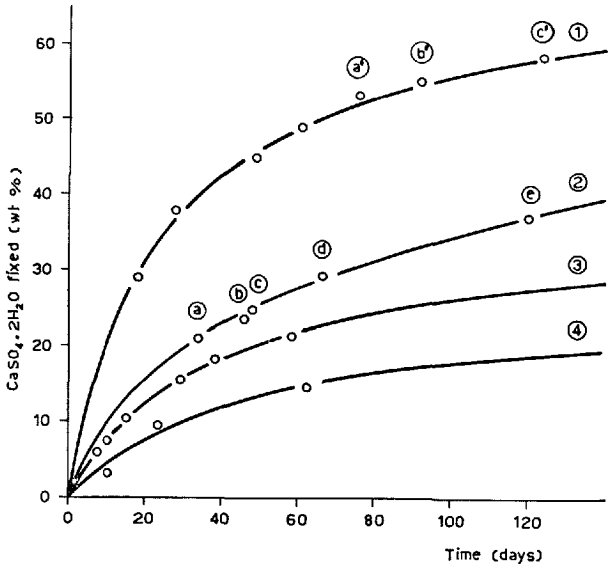

Fig. 2. *Fixation of* $CaSO_4 \cdot 2H_2O$ *by four hydrogarnet series terms*

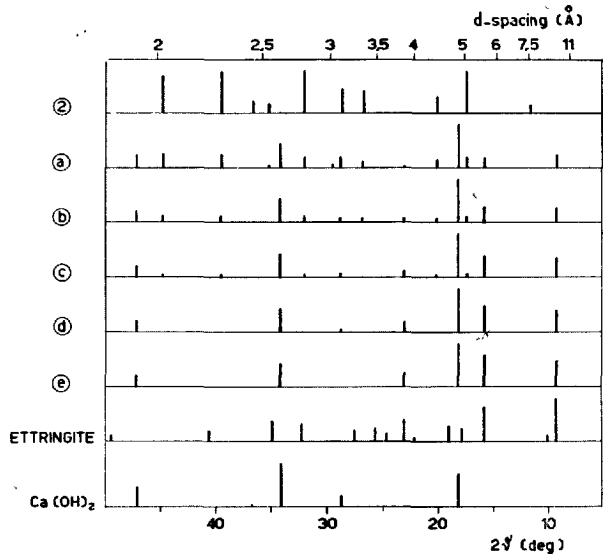

Fig. 3. *X-ray powder diffraction patterns of* $C_3AS_{0.28}H_{5.44}$, *in five successive stages of ettringite formation (symbols as in Fig. 2.)*

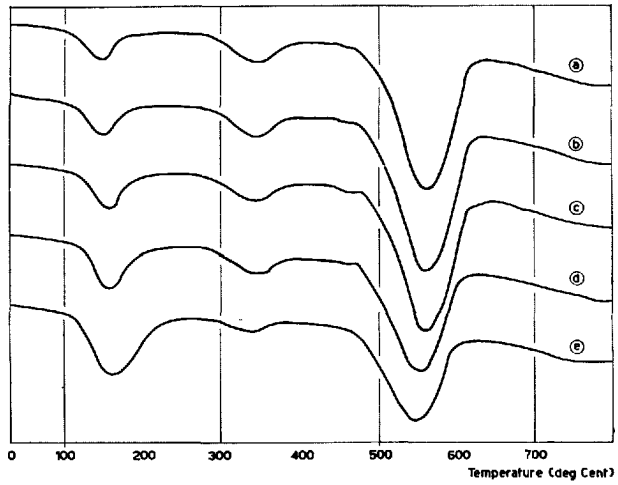

Fig. 5. DTA *of reaction products (symbols as in Fig. 2 and 3)*

only: all other terms show similar behaviour.

While the endothermic peak of hydrogarnet series term at 350°C decreases, the endothermic peak at 150°C corresponding to ettringite increases and the thermal effect with maximum at 550°C, corresponding to the dehydration of free calcium hydroxide, decreases.

Microscope Examination

Nucleation and successive growth of ettringite needles, during sulphate attack of hydrogarnet series terms studied, have been systematically followed with both optical (phase contrast) and electron (carbon replica method) microscopes.

Micrograph b) in Photo 1 corresponds to an intermediate stage of the attack: fragments of hexagonal plates on which sites of successive evolution into ettringite crystals can be recognized, are shown.

Micrograph c) in Photo 2 shows a more advanced stage in which the recently formed ettringite can be observed.

Micrograph d), corresponding to a standard specimen of ettringite prepared according to the literature (6), has been reported for comparison purposes.

Differential Calorimetry

A Perkin-Elmer DSC-1B apparatus has been used. Uniform drying of products has been necessary before examination. After passing a stream of cold dry air on them, powders have been kept for 24 hours on $CaCl_2$. Even if great care should be used during this treatment otherwise, a small amount of dehydration could lead to a defective determination of hydrogarnet and ettringite, the calorimetric determination resulted simple and rapid, thanks to the straightforward relation between mass and enthalpy. In the system being investigated, the degree of completeness of reaction has been evaluated measur-

c′	57.3	0	0	128	59.2	54
Ettringite	—	0	0	216	100	100

ing, on the same thermogram, both the decrease of reactant hydrogarnet and the increase of ettringite produced.

Calorimetric measurements on products corresponding to 0.225 and 0.28 mols terms have been reported in Table 1. Percentage of each chemical species has been evaluated on the basis of heats of transformation of pure products (hydrogarnet and ettringite) which also have been reported in Table 1. These percentages are in good agreement with those calculated on the basis of peak intensity of X-ray diffraction.

Conclusions

The whole of experimental results corroborates the statement according to which in the series tricalcium aluminate (cubic)-grossularite, substitution of H_2O with SiO_2 causes resistance to sulphate attack. Small amounts of silica are sufficient to induce resistance; the term with 0.28 mols SiO_2 is much more stable than term with 0.225 mol, so that a term with 0.30 mol SiO_2 can be considered practically sulphate resistant.

The product originated after reaction of initial hydrogarnet with sulphates, is a calcium sulphoaluminate (with high sulphate content) formed with a mechanism of dissolution and successive precipitation from calcium hydroxide and calcium sulphate solution.

Differential calorimetry has made possible precise and rapid determination of the degree of attack suffered by reactant hydrogarnet; the determination is comparable, as it concerns accuracy, with the results of X-ray diffraction analysis.

Supplementary Paper II-40 Formation of Hydrated Gehlenite through the Reaction of Clay Minerals and Lime

Akira Ariizumi*

Synopsis

Hydrated gehlenite was firstly found by Strätling (1940) as the reaction product of metakaolin and lime. Later the properties of the hydrate were investigated by Turriziani (1954). It was observed by various authors, zur Strassen (1958), Locher (1960) and Goto (1962) that the hydrate can be formed also through the reaction of slag (or generally C-S-A glass) and lime. The crystal structure of the hydrate was discussed by zur Strassen.

The present author, on investigating the pozzolanic reaction of clay minerals, found out that allophane, hydrated halloysite or finely ground kaolinite results hydrated gehlenite as the product of lime reaction. Further an almost pure sample of the hydrate was obtained through the reaction of coprecipitated Al_2O_3–SiO_2 gel and lime, and some properties of the hydrate were examined.

It was demonstrated that the reactivity of the hydrate, which forms easily ettringite on the presence of gypsum, can be utilized for the soil stabilization in the Kanto-loam zone around Tokyo, of which dominant clay minerals are allophane and hydrated halloysite.

Introduction

Soils of volcanic origin are widely distributed in Japan. "Kanto loam" around Tokyo vicinity is the most typical of them. Dominant clay minerals contained in this loam are allophane and hydrated halloysite, which cause unfavorable soil mechanical properties. Investigation into soil stabilization is to be done for highway construction works in order to ensure a good trafficability. Conventional soil-cement method which needs a great quantity of cement to achieve a desired effect is not economical, and lime admixing method possesses such defect that development of strength is slow. It was found that admixing of lime and gypsum is effective and economical for soil stabilization.

The present author carried out a basic study on the mechanism of soil stabilization by means of the reaction of soil-lime and soil-lime-gypsum. It was confirmed that hydrated gehlenite (1) is formed in the mixture of allophane-lime at the room temperature and cement bacillus is formed by admixing lime and gypsum. It was further found that hydrated halloysite reacts easily with lime to result hydrated gehlenite. As these studies belong to an applied field of cement chemistry, here is reported the result of investigation which has been made in the Public Works Research Institute, Ministry of Construction, during the last ten years.

Materials Resulting from Reaction of Allophane-Lime and Allophane-Lime-Gypsum

Allophane was separated from various volcanic soils of Japan, and treated with lime solution or lime-gypsum solution under various reaction conditions. The resulting materials were examined through X-ray diffraction, DTA, infra-red absorption and chemical analysis. The following are the summary of the study.

The present author (2) (3) reported that lime can be absorbed by allophane when placed in lime solution, forming hydrated gehlenite C_2ASH_n. The nature of C_2ASH_n was examined. The reaction was found to be common for allophanes of various localities. The reactivity could be improved through heat treatment of allophane, eliminating the formation of C_4AH_{13}. The reaction mechanism was not disturbed with Truog's deferration processing or EDTA processing, but was disturbed with deferration processing of Tamm's reagent or alternative processing

*Kajima Construction Co., Ltd., Tokyo Japan.

of Na_2CO_3–HCl which removes free oxides. It was also confirmed that three layer clay minerals and their heat-treated materials do not result in C_2ASH_n.

The present author and Ohba (4) studied on the relationship of such reaction conditions to the resulting materials as lime concentration, lime-allophane ratio, temperature involved and reaction time. Thereby the decrease of lime during reaction process was examined. As the resultants, the following materials were identified as C_2ASH_n, C_3AH_6 (C_3ASH_4 after long reaction time), C_4AH_{13}, 7.6 Å hydrate (seems to be carboaluminate) and X-ray amorphous lime-absorbed allophane. C-S-H phase was not identified.

The reaction started with lime absorption, then C_4AH_{13} and 7.6 Å hydrate were formed, finally C_2ASH_n appeared and simultaneously 7.6～8.2 Å lines disappeared after lime concentration had dropped. Within 35 days of reaction time, C_2ASH_n was obtainable at the reaction temperature below 50°C, C_3AH_6 at 80°C. At 60°C, C_2ASH_n appeared with low lime concentration, C_3AH_6 with high lime concentration.

When lime concentration was too low, C_2ASH_n could not exist. Amount of lime absorbed should be more than 20% of allophane in order to bring about C_2ASH_n. Reaction of C_2ASH_n formation was observed to be slow when it was proceeded in a paste form.

Under an excess amount of lime, C_4AH_{13} was obtained instead of C_2ASH_n.

The present author and Wada (5) investigated the reaction between coprecipitated SiO_2–Al_2O_3 gel and lime solution. Various SiO_2–Al_2O_3 gels with mol ratio of 0.18～10.1 were prepared, among which the gels with mol ratio of 0.23～5.1 were found to have properties similar to those of natural allophane.

With a high mol ratio Al_2O_3/SiO_2, gibbsite, boehmite and bayerite were identified in the prepared materials.

1 g of gel and 1*l* of saturated lime solution brought out C_2ASH_n at 20°C when Al_2O_3/SiO_2 was 0.3～8.5, they resulted also C_3AH_6 when gel contained gibbsite or other minerals. When Al_2O_3/SiO_2 was very small, C-S-H phase was presumably formed.

X-ray diffraction pattern of C_2ASH_n was best-defined when Al_2O_3/SiO_2 was 1. At 80°C, C_3AH_6 was obtainable when a large amount of lime was absorbed. The reaction mechanism of C_2ASH_n formation was favored by heat treatment, intensifying the X-ray diffraction pattern of resultant. Heat treated gel with large Al_2O_3/SiO_2 ratio gave 11.1 Å and 5.5 Å lines which were not identified. Coprecipitated Fe_2O_3–SiO_2 gel($Fe_2O_3/SiO_2 = 0.4$) and lime brought out X-ray amorphous material at 20°C, but well-defined lines of C_3FH_6 at 80°C.

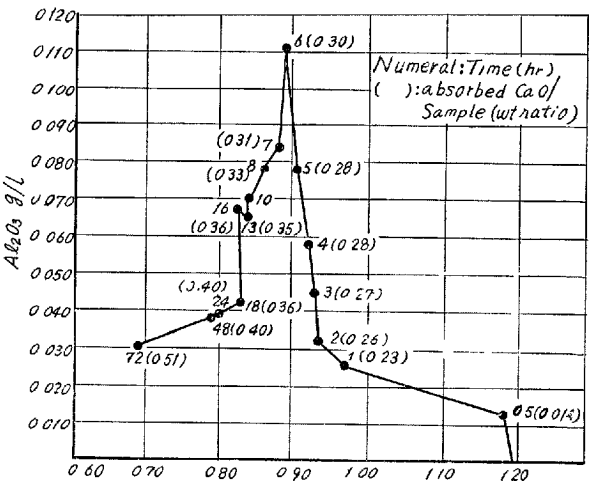

Fig. 1. *Composition of liquid phase during the reaction of coprecipitated* Al_2O_3–SiO_2 *gel with lime solution*

A further investigation into this reaction was made by the present author (6). Coprecipitated gel ($Al_2O_3/SiO_2 = 1$) was prepared as the starting material.

0.1 g of the gel was treated with 100 cc of saturated lime solution at 20°C. The resulting material was identified through X-ray diffraction, and the liquid phase examined by chemical analysis. The concentration of Al_2O_3 and CaO in the liquid phase is shown in Fig. 1.

According to the X-ray analysis, 7.6 Å line, 8.2 Å line and very weak lines of C_2ASH_n could be identified within 30 minutes of reaction time. The lines of C_2ASH_n became stronger after 1 hr, they were quite well-defined after 2 hrs. The main resultant, C_2ASH_n, became dominant, while the by-product with 7.6 Å line tended to disappear. It can be assumed that the natural allophane behaves similarly to the coprecipitated gel, although the reaction speed is slow. As was described by Strätling (1), the reaction of allophane with lime solution proceeds topochemically, and there is pseudo equilibrium between absorbed lime and liquid phase concentration, or between the resulting crystal material and liquid concentration. To investigate this mechanism, the next experiment was made. Coprecipitated Al_2O_3–SiO_2 gel ($Al_2O_3/SiO_2 = 1.00$) was heated at 600°C for 1 hr, added to lime solutions of various concentration, aged at 20°C for 35 days. As Fig. 2 shows, the amount of absorbed lime and the concentration of lime in liquid phase after the reaction were examined.

The relationship presented in Fig. 2 gives no straight line, but a line with three-steps gradient. This relationship was observed in air-dried allophane, but sometimes AC was straight line in the case of heat-treated

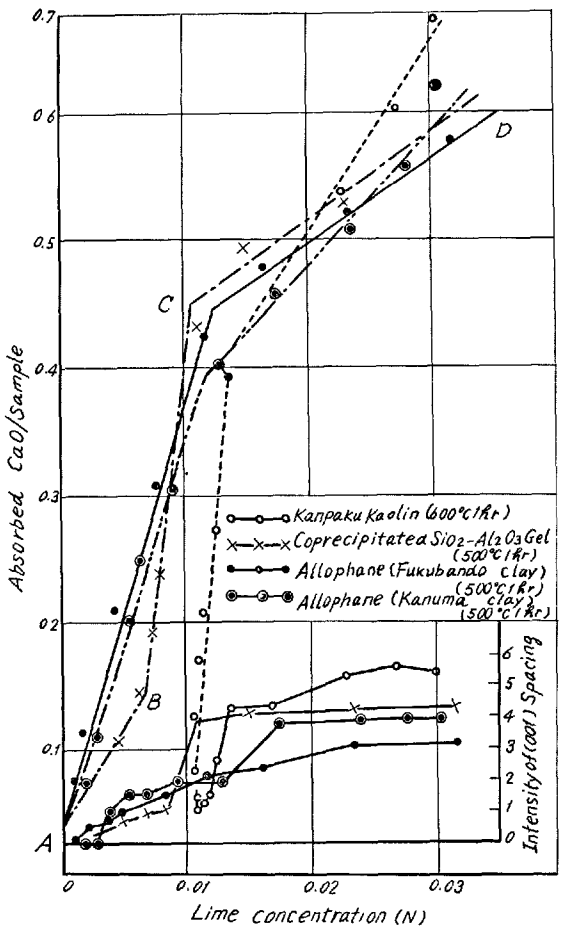

Fig. 2. *Relationship between lime absorbed and lime in liquid phase after reaction (Also intensity of basal reflexion of resulted material is plotted against lime concentration.)*

allophane. Between A and B no resulting crystal phase was identified, between B and C the intensity of the basal reflexion of C_2ASH_n was observed to increase gradually, and between C and D the intensity stayed unchanged. This characteristics was common with other experiments using allophanes from "Kanuma clay" and "Fukubando clay" or metakaolin from "Kanpaku kaolin". Points B and C correspond to 0.008 N and 0.013 N respectively.

Although the behavior of SiO_2 was not clarified with the above examination, the behavior of CaO could be summarized as the following. In the lime-poor region allophane exists together with lime-absorbed allophane, in the next region up to 0.013 N C_2ASH_n co-exists, in which the formation of C_2ASH_n from absorbed body proceeds. In the further lime-rich region, the reaction speed for the C_2ASH_n formation slows down, lime absorption continues gradually. In the region near to lime-saturation it is assumed that C_2ASH_n changes to C_4AH_{13}. The absorption reaction, C_2ASH_n formation through topochemical reaction or other possible reaction takes place simultaneously, and true equilibrium is not to be established.

The present author and Ohba (7) investigated the reaction of allophane with lime-gypsum solution.

0.15 g of allophane was treated with 100 cc of the solution of various components, varying the reaction time and temperature. With 5% gypsum added to allophane, low sulphate bacillus was obtained within a few hours. At 20°C C_4AH_{13} coexisted, the resulting bacillus re-dissolves as the lime in liquid phase was consumed by the absorbing reaction. At 60°C the resulting bacillus and C_4AH_{13} disappeared when original lime amount was more than 65% to allophane, C_3AH_6 appeared instead as a stable phase. With less than about 50% lime, C_3AH_6 could not be formed, and resulting bacillus tended to decrease while C_4AH_{13} increased.

With more than 15% gypsum added to allophane, high sulphate bacillus was formed as a stable phase at room temperature. Lime in liquid phase was consumed through both of bacillus formation and C_2ASH_n formation. During high sulphate bacillus redissolved as the results of lime consumption, it behaved approximately along the dissolving curve of bacillus to lime. The existence of gypsum disturbed the C_2ASH_n formation.

The present author and Maki (8) made laboratory experiment as well as field experiment on the soil stabilization, using "Kanto loam" treated with lime and gypsum. It was established that bacillus formation is attributable to the strength development in soil-lime-gypsum mixture, and the existence of gypsum gives the initial strength. When lime-gypsum was added to allophane clay with high sensibility as well as with high moisture content (more than liquid limit), it was observed that the strength and the bearing power were not sensitive to the moisture content, the resulting soil had enough strength to bear pedestrian's weight one hour after mixing, bringing out a sufficient initial trafficability.

Materials Resulting from Reaction of Hydrated Halloysite and Lime

As was described, allophane reacts with lime at room temperature to result in C_2ASH_n. Behavior of hydrated halloysite was not established. To clarify this point, the present author and Fujisaki (9) carried

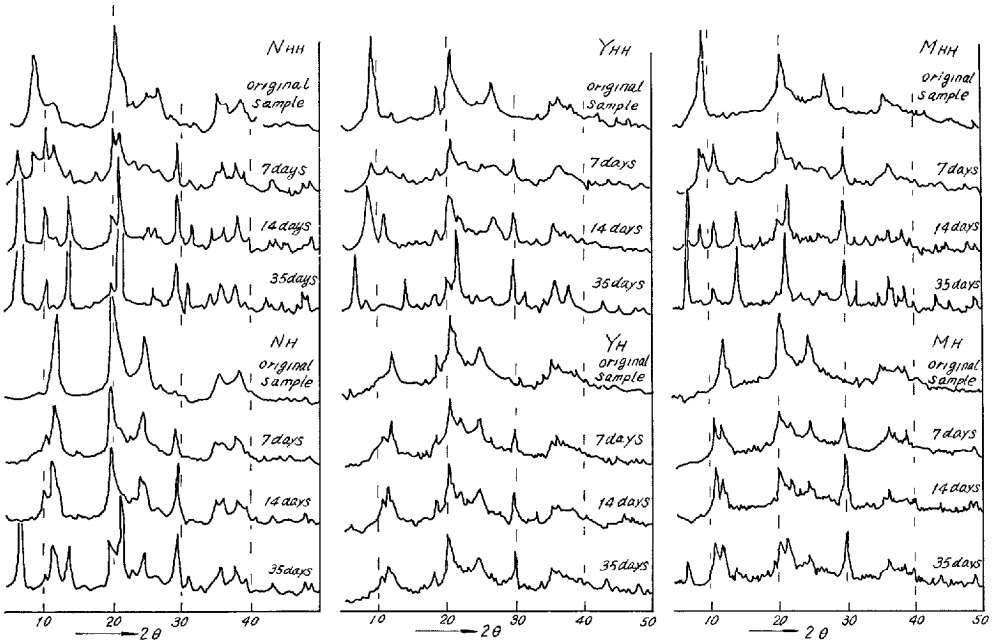

Fig. 3. *X-ray diffraction diagrams of reaction products 0.100 g sample to 100 cc lime saturated solution*

out an investigation similar to that in the case of allophane using three kinds of specimen of hydrated halloysite. It was confirmed that C_2ASH_n could be easily formed through the reaction and the reactivity decreased through dehydration of the starting material.

Specimens and Experimental Method

Naegihakudo clay, Yame clay and Musashino loam were treated with Kelley's method (10) to bring out Ca-clay specimen of less than 1μ. The specimens were kept in a desiccator with 60% moisture. Each specimen was named N_{HH}, Y_{HH} and M_{HH}. The specimens were heated at 150°C for 20 minutes to give N_H, Y_H and M_H. Besides N_{HH} was heated at 350°C for 2 hours to give 7.3 Å spacing. Hong Kong kaolin was named H_H. Also, well-crystallized Kanpaku kaolin was used for grinding experiment.

0.100 g of specimen was treated with 100 cc of lime saturated solution at room temperature for various reaction times (3, 7, 14, 21 and 35 days). Reaction vessel was of polyethylene, and care was taken to avoid CO_2 contamination. After the reaction was completed, lime concentration in liquid phase was measured and the amount of absorbed lime was determined. The reacted specimens were washed and kept in a desiccator with 60% moisture to give constant weight. X-ray diffraction, self-recording DTA and electron microscope were applied to examine the resultants. Care was taken to prevent dehydration of hydrated halloysite.

Experimental Results

Clay minerals were identified through X-ray diffraction and DTA, as shown in Figs. 3 and 4. All specimens could be identified as hydrated halloysite. Y_{HH} contained a small amount of gibbsite, M_{HH} a small amount of allophane. The order of structural perfectness was found to be $N_{HH} > M_{HH} > Y_{HH}$. On heating at 150°C, (001) spacing of all specimens shifted to 7.5 Å. The relationship between absorbed lime and reaction time is shown in Fig. 5.

The better crystallized specimens absorbed more lime. As is similar to the case of allophane, the C_2ASH_n formation started after the amount of absorbed lime had attained a limited value. The reactivity decreased through the dehydration of specimens when it was heat-treated.
